Effect of Heating Time. The thermal equilibrium is not always attained even when the exchanger is thermally treated until no weight loss is observed. To make clear this point, the effect of the heating time on the properties of the material was investigated at 200 °C and 400 °C. Table 2 shows that the composition of the exchangers (both immediately after the heat treatment and after the humidifying operation) is independent of the length of the heating period. There existed no difference in the uptake curves for Na^+, the thermal analysis curves, and the X-ray diffraction patterns between the samples heated for 12 h and those for 72 h. The materials, therefore, reach to thermal eqilibrium within 12 h.

Thermal Stability of the Exchanger. The thermal stability of hydrous niobium(V) oxide can be summarized as follows. The amount of water contained in the exchanger immediately after the heat treatment decreases with increasing temperature and becomes zero at 400 °C. The structure of the samples heated up to 400 °C, however, remains essentially unchanged, and the stabilized matrix can accomodate an approximately constant amount of a zeolitic water and some bound water when humidified. This brings about the recovery of a large part of the exchange sites; less acidic sites are more stable to thermal decomposition than more acidic sites. The ion-exchange capacity is halved when the exchanger is heat-treated at 400 °C. When the exchanger is heat-treated at temperatures above 500 °C, the crystallization of the matrix proceeds to an extreme and the structure changes completely. In this case, almost all the water is not recovered by the humidifying operation and, thereby, the sample has no ion-exchange capacity for Na^+ even in strong alkaline solution.

If the thermal stability of the exchangers is compared with hydrous titanium(IV) oxide[9] and hydrous tin(IV) oxide,[10] which have previously been investigated by the present authors, niobium(V) oxide is superior to these two hydrous oxides; hydrous titanium(IV) oxide, hydrous tin(IV) oxide, and niobium(V) oxide, respectively, keep 25, 29 and 57% of the original ion-exchange capacities for Na^+ when they are heat-treated at 300 °C.

Simultaneous Multielement Determination of Trace Metals in Seawater by Inductively Coupled Plasma Atomic Emission Spectrometry Using Chelating Resin Column Preconcentration

CHU Jia Cheng,† Tasuku AKAGI, and Hiroki HARAGUCHI*
Department of Chemistry, Faculty of Science, The University of Tokyo, 7-3-1, Hongo, Bunkyo-ku, Tokyo 113
(Received April 20, 1985)

Preconcentration of trace metals in seawater using a Chelex-100 resin column was investigated for simultaneous determination by inductively coupled plasma atomic emission spectrometry (ICP-AES). The optimum preconcentration conditions were examined in detail. With 100 ml of 1 M ammonium acetate buffer solution (1 M=1 mol dm^{-3}), the matrix elements in seawater could be removed sufficiently without loss of analytes. The concentration factor of 200 times could be achieved by dissolving the dried HNO_3 eluent of the column. The blanks of the method were negligibly small for most elements investigated. The detection limits were in the range of several ng/l to 100 ng/l for Al, Cd, Co, Cr, Cu, Fe, Mn, Mo, Ni, Pb, Ti, V, and Zn. The present technique was applied to the determination of trace metals in coastal and ocean seawater.

In recent years various methods for the determination of trace elements in seawater have been developed. Since the concentration levels of trace elements in seawater are very low, sensitive analytical techniques such as spectrophotometry,[1] atomic absorption spectrometry,[2-4] anodic stripping voltammetry,[5] isotope dilution mass spectrometry,[6] neutron activation analysis,[7] and X-ray fluorescence spectrometry[8] have been applied to seawater analysis.

Inductively coupled plasma atomic emission spectrometry (ICP-AES) which has the capability of simultaneous multielement detection has been often employed for determination of trace metals in seawater samples.[9-14] Adequate preconcentration techniques are, however, required prior to ICP-AES measurement because of insufficient sensitivity for the trace metal level in seawater and serious interferences caused by salts at high concentration. Therefore, preconcentration techniques such as solvent extraction,[9,10] coprecipitation,[11,12] and chelating exchange,[13,14] have been employed for seawater analysis with ICP-AES.

It has been shown that Chelex-100 chelating resin is an efficient exchanger of many trace metals and provides low analytical blank.[15] Further, as it is a strong chelator, it can remove metal ions from natural chelators existing in seawater.[15-17] Therefore, Chelex-100 resin may be useful for preconcentration of analytes prior to the ICP-AES measurement. Even so, it should be noted that Chelex-100 chelating resin often collects a part of Mg and Ca as well as trace metals in seawater.[18]

Berman *et al.* tried preconcentration of trace metals from seawater by Chelex-100 chelating resin followed by ICP-AES measurement.[13] They avoided the physical interference caused by salts using an ultrasonic nebulizer. Ammonium acetate buffer solution was known to remove the Mg and Ca cations from the resin,[19] but it also has the disadvantage to elute partly some of analytes such as Mn, Fe, and Cu.[20] Although an ICP-AES spectrometer equipped with a conventional cross flow nebulizer is widely prevailed, the preconcentration method using the Chelex-100 resin column and ICP-AES with a conventional cross flow nebulizer has not been reported. The Chelex-100 resin preconcentration procedure which allows minimum loss of analytes and efficient removal of matrix salts should be established in order to utilize ICP-AES effectively as a monitoring method of trace metals in seawater.

In this study, Chelex-100 resin column treatment is evaluated for preconcentration followed by ICP-AES measurement. Recoveries of trace metals and concentration of matrix elements in concentrated analysis solution are examined in detail for optimization of preconcentration conditions in ICP-AES analysis.

Experimental

Apparatus. An ICP instrument (Model Plasma Atomcomp Mk II from Jarrell-Ash Co., USA) was used with a conventional crossflow type nebulizer. The instrumental components and operating conditions for ICP-AES are summarized in Table 1. The emission lines used are shown in Table 2 along with the detection limit of each element. A pH meter (Model F-7, Horiba Seisakusho Ltd.) was used for the pH measurement. A class-100 clean booth (Model KCR-2D) was made by San-ei Seisakusho, and all column performance and preconcentration procedures were carried out in there.

Chemicals. All chemicals used were of analytical reagent grade or of better grade. The standard solutions for Al, Cd, Co, Cr^{3+}, Cu, Fe, Mg, Ni, Pb, Ti, and Zn were prepared from pure metals, and those for As, Cr^{6+}, Mo, V, Y, Na, K, and Ca from corresponding salts or oxides. HCl, HNO_3, acetic acid, and ammonium solution were of extra pure grade purchased from Wako Chemical Co., Ltd. HCl

and HNO_3 used for resin purification and column conditioning were prepared by sub-boiling the acids of extra pure grade. Pure water for ordinary use was deionized/distilled water, and it was further purified by sub-boiling distillation when necessary. Ammonium acetate was prepared by mixing ammonium solution and acetic acid, and was purified by passing 2 times through the Chelex-100 column. Chelex-100 resin (200—400 mesh) was purchased from Bio Rad Laboratories, U.S.A. Before packing the resin in the column, the resin was kept for cleaning in 5 M HCl five times for 5 d, and then with pure water, 2 M HNO_3, and finally pure water. The HCl solution used for the resin cleaning was changed with new one everyday. The artificial seawater used for the recovery test was prepared after the prescription reported by Kester *et al.*[21] It contained 13 constituents whose concentrations

are higher than 1 mg/l, and its salinity was adjusted at 35‰.

Column Preparation. The column system used is shown schematically in Fig. 1. The inner diameter of the column was 14 mm. A polyethylene bottle for the sample reservoir was connected with the column through the polyethylene tube. To avoid contamination the column system was designed as a closed one from the atmosphere, just being open to the air *via* a pin hole in the sample reservoir and a column outlet. Sample flow rate was controlled by the stopcock. All parts of the column were well precleaned with 1:1 HNO_3 and pure water. The Chelex-100 resin (dry weight 2.5 g) was packed in the column. The packed column was preconditioned with 10 ml of 2 M ammonium solution, 30 ml of sub-boiled pure water, and 20 ml of 1 M ammonium acetate buffer solution (pH 6) prior to each use. The length of the preconditioned resin in the column was about 40 mm.

Preconcentration Procedure. One liter of a seawater sample was filtered with Nuclepore filter (pore size 0.4 μm) and the pH of the solution was adjusted to pH 5.5—6 with 10 ml of 1 M ammonium acetate solution. The seawater sample was then taken into the sample reservoir and eluted at a flow rate of 2 ml/min through the preconditioned column. For removal of matrix salts the column was treated with 100 ml of 1 M ammonium acetate buffer (pH 6) and 50 ml of sub-boiled pure water after each seawater elution. Trace metals collected on the resin were then eluted with 25 ml of 2 M HNO_3 solution into a PTFE

beaker. The eluent in the beaker was heated to dryness on a hot plate, and then the residue was dissolved with 5 ml of 0.2 M HNO_3. Thus a 200-fold concentrated solution (hereafter called "analysis solution") was prepared for ICP-AES measurement. In case of the recovery test, the eluent was filled up to 50 ml with pure water.

Results and Discussion

pH Dependence of Calcium and Magnesium Concentrations in the Analysis Solution. In ICP-AES measurement, high concentrations of matrix elements in the analysis solution are sometimes prone to spectral and physical interferences.[22,23] Since parts of Ca and Mg in seawater were collected on the Chelex-100 resin,[18] the effects of Ca and Mg on the emission intensities of analytes were investigated by aspirating the test solutions which contained Ca and Mg at various concentrations. The emission intensities observed for the test solutions included both spectral and physical interferences. The emission intensities due to spectral interference were first corrected by using the correction coefficients for spectral interference,[11,12] which were estimated by introducing pure Ca or Mg solution (lower than 200 mg/l) into the ICP. Then physical interference was estimated. When the total concentration of the two elements was 1600 mg/l, the intensities were reduced by 10%. When their total concentration was smaller than 200 mg/l, the intensity changes due to the influences of nebulization process were negligibly small. Therefore, it was desirable that the total concentration of matrix elements was less than 200 mg/l.

The concentrations of Ca and Mg collected on 1 g resin are shown as a function of pH in Fig. 2. These values were obtained with artificial seawater which contained matrix elements at the same concentration levels as natural seawater, *i.e.*, 1350 mg of Mg/l and 400 mg of Ca/l. The concentrations of Ca and Mg on the resin increased at higher pH. The results agreed well with those reported previously.[24] When 2.5 g resin was used and the 200-times preconcentration was made even at pH 3, the concentrations of Mg and Ca in the final analysis solution were 2500 mg/l and 1200 mg/l, respectively. Matrix elements at such high concentration levels may seriously influence the analytical results in ICP-AES due to their spectral and physical interferences. Therefore, a proper procedure to remove matrix elements on the resin was necessary prior to elution of analyte elements.

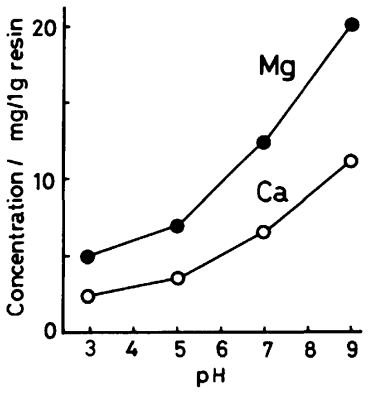

Fig. 2. pH Dependence of concentrations of Ca and Mg in 1 g resin after column preconcentration. The original concentrations of Ca and Mg were 400 mg/l and 1350 mg/l, respectively, which were the same as those in seawater.

Removal of Matrix Elements with Ammonium Acetate Buffer Solution. Kingston *et al.* reported that Mg and Ca retained on the resin could be removed by ammonium acetate solution.[19] However, excess amounts of ammonium acetate solution may cause loss of analytes.[20] In Table 3, the effect of ammonium acetate solution (pH 6) on removal of matrix elements are summarized. The values in the table are the concentrations in 50 ml of the eluent, when 1 l of artificial seawater was treated with the chelating resin column. As can be seen in Table 3, the concentrations of matrix elements were lowered remarkably when the volume of the buffer solution for washing was increased. In the analysis of natural seawater, the volume of the final analysis solution was 5 ml. Thus the concentration values should be multiplied by ten. Therefore, at least 100 ml of 1 M ammonium acetate buffer solution (pH 6) is required in treatment of natural seawater samples. Fortunately, the recoveries of all the elements were not affected by using the ammonium acetate buffer solution up to 100 ml. Thus 100 ml of the ammonium acetate solution was used for removal of matrix elements in natural seawater samples.

pH Dependence of Recoveries of Analytes. In Fig. 3, pH dependences of recoveries of Cu and Mn are shown. Since Cu has the largest stability constant and Mn has the smallest one with Chelex-100 resin, these two elements among fifteen elements were chosen as representative examples. In Fig. 3 the values indicated by black and white circles show the

Table 3. Concentrations (mg/l) of matrix elements in the 50 ml eluent after washing with various volumes of ammonium acetate buffer

Element	Volume of buffer[a] (ml)				
	0	50	100	200	300

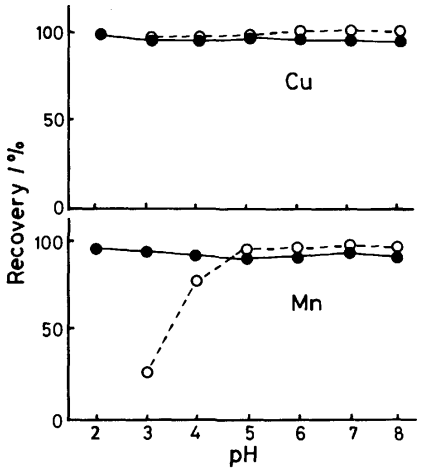

Fig. 3. pH Dependence of recoveries for Cu and Mn.
Black circles (●) indicate the values for pure water sample without washing with buffer solution.
White circles (○) indicate the values for artificial seawater after washing with 100 ml of 1 M ammonium acetate buffer solution.
The original concentrations of Cu and Mn were 100 μg/l.

experimental results for acidified water and artificial seawater used as the samples, respectively. Both solutions contained all the analytes at a concentration of 0.1 mg/l. In the case of artificial seawater the resin was treated with ammonium acetate buffer in order to remove the matrix elements. The pH dependences of recoveries for Al, Cd, Co, Fe, Mo, Ni, Pb, Ti, V, and Zn in acidified water was similar to those for Cu and Mn, *i.e.*, constant recoveries more than 90% in the pH range of 2—8. The pH dependences of the recoveries for As and Cr, however, were greatly different from those for the other elements, being less than 90% at any pH.

On the other hand, Mn in artificial seawater showed poor recovery at pH lower than 5 (see Fig. 3). The same deterioration in recovery from artificial seawater was also observed for Cd. Other elements such as Al, Co, Fe, Mo, Ni, Pb, Ti, V, and Zn showed constant recoveries similar to Cu (see Fig. 3). As mentioned previously, the concentrations of Ca and Mg in the analysis solution increased with pH, and so treatment with a large volume of ammonium acetate solution was needed for the removal of salts in the higher pH region. Thus pH 5.5—6 was chosen for preconcentration of the natural sample, which allowed efficient preconcentration of 12 elements including Mn and Cd on the chelating resin.

Recovery, Blank, and Detection Limits. The recovery and standard deviation obtained by the present method are summarized in Table 4. As can be seen in the table, the reproducibility in preconcentration is good for almost all elements except As and Cr. The poor reproducibilities of As and Cr may be caused by their poor recoveries in the column concentration, while other elements were quantitatively collected on the Chelex-100 resin with recoveries greater than 90%.

When natural seawater sample was analysed, the HNO_3 eluent from the column was heated to dryness. The recovery values including the drying process were examined by using artificial seawater which

contained the analytes at the same levels as those in Table 4. The results are shown in the last column of Table 4. It can be seen that the recoveries of the analytes did not significantly deteriorate through drying.

Blank and detection limits in the present method were summarized in Table 5. The blank values were obtained by performing the same preconcentration procedure using 100 ml of sub-boiled pure water and were converted to the concentration corresponding to 1 l of an original sample. The analytical detection limits were calculated by dividing the detection limits (Table 2) for analytes by the concentration factor (200). As for Cd, Co, Cr, Cu, Ni, Pb, Ti, and V, the blank values were lower than the analytical detection limits. This may have resulted from the use of the well-closed column system, purification of chemicals, and a class-100 clean air system. The blank values for Al, Fe, and Zn were larger than the analytical detection limits. For these elements corrections of the blank values were carried out in the actual seawater analysis.

Application to Natural Seawaters. In Table 6 the analytical results for natural seawaters which were sampled on the cruises of the Tansei-Maru research vessel (the Ocean Research Institute, University of Tokyo) and the Toyoshio-Maru research vessel (Faculty of Applied Biological Science, Hiroshima University) are summarized. The analytical results for most elements except Mo in the ocean seawater sample were lower than those in the coastal seawater samples. The concentration levels in the ocean seawater were similar to those reported by Turekian *et al.*[25] The concentrations of Al, Fe, and Ti in the Seto Inland Sea water were much larger than those in the Tokyo Bay water.

The analytical results for several elements in seawater from the Tokyo Bay were compared with those obtained by the gallium coprecipitation method.[11] The concentrations of Al, Ni, Fe, Mn, and Zn obtained by the two analytical methods were consistent with each other. This indicates that the present method is accurate enough to apply to the multielement determination of trace metals in seawater.

TABLE 6. ANALYTICAL RESULTS FOR TRACE METALS IN NATURAL SEAWATERS[a]

Element	Concentration/μg/l

a) The seawater samples were stored after acidifying at pH 2 with HNO_3. b) The values in parenthesis were obtained by ICP-AES using gallium coprecipitation (Ref. 11).

Conclusion

The present Chelex-100 resin column method is convenient and effective for multielement preconcentration of trace metals in seawater. Ammonium acetate buffer solution reduced the concentration of remaining salts on the resin low enough so as to obtain a large concentration factor of 200 for the ICP-AES determination. Therefore, the present method can be successfully applied to determine trace metals such as Al, Cd, Co, Cu, Fe, Mn, Mo, Ni, Pb, Ti, V, Y, and Zn in coastal and open seawater. However, it does take about 9 h for one sample treatment by the column method, which may not be useful in routine analysis of seawater. A more efficient treatment system using the chelating resin, for example, a flow or batch preconcentration system is therefore required in such ICP-AES analysis.

The authors thank Prof. Keiichiro Fuwa in the University of Tokyo for his kind encouragement and valuable discussion. We also express our thanks to Prof. Hitoshi Sakai and his staff at the Ocean Research Institute in the University of Tokyo, and also to Prof. Hiroyuki Tsubota in the University of Hiroshima for their help in seawater sampling and valuable discussion. We are owed to Ms. J. E. Teague in preparation of the manuscript.

X-Ray scattering, Raman, and ^{13}C- and ^{14}N-NMR measurements were performed on aqueous solutions containing tetrathiocyanato complex ions of Zn(II), Cd(II), and Hg(II). The radial distribution functions revealed that four thiocyanate ions tetrahedrally coordinated to Zn(II) and to Hg(II) ions through the N and S atoms, respectively, while Cd(II) ion was bound to two sulfur and two nitrogen atoms within the coordinated four SCN^- ions. The bond distances and bond angles are as follows: Zn-N 204 pm, Cd-N and Cd-S 225 and 265 pm, respectively, and Hg-S 254 pm, and Zn-N-C 145°, Cd-N-C and Cd-S-C 149° and 106°, respectively, and Hg-S-C 102°. The Raman bands of the C-S vibration within the tetrathiocyanato complexes of Zn(II), Cd(II), and Hg(II) ions in aqueous solutions appeared at 821 and 710 cm^{-1} for the Zn(II) and Hg(II) complexes, respectively, consistent with the values in the literature. The C-S stretching Raman bands of tetrathiocyanatocadmate(II) complex were resolved into two components at 779 and 732 cm^{-1}. The C-S frequency shifted toward the higher frequency side than that (747 cm^{-1}) of the free SCN^- ion in the case of the binding of SCN^- to metal ion *via* the N atom in the Zn(II) and Cd(II) cases, while the C-S bands influenced by the M-S bonding appeared on the lower frequency side in the Cd(II) and Hg(II) complexes. The ^{13}C chemical shifts of the tetrathiocyanato complexes in aqueous solutions showed the downfield and upfield shifts for Zn(II) and Hg(II), respectively, and the intermediate for Cd(II). The nitrogen-14 resonance in $[M(SCN)_4]^{2-}$ in aqueous solutions shifted upfield (−30.8 ppm) for Zn(II), downfield (30.3 ppm) for Hg(II), and in between for Cd(II) (−1.3 ppm). The trend of the ^{13}C- and ^{14}N-chemical shifts supported the different types of binding of ambient SCN^- ion deduced from the X-ray and Raman measurements.

Complex formation between thiocyanate ions and different metal ions has widely been investigated from interesting ambient nature of SCN^- ion, which can bind with metal ions through either the nitrogen or the sulfur atom depending on the central cation involved. Among these studies, thiocyanato complexes of the Group IIb metals are of particular interest,[1-21] since Hg(II) and Zn(II) ions behave as soft and hard acids, respectively, and Cd(II) ion has an intermediate character. From recent X-ray diffraction and Raman spectral studies[21] on the thiocyanate complexes of Zn(II), Cd(II), and Hg(II) ions in combination with the thermodynamic data[7] in dimethyl sulfoxide (DMSO), it has been established that thiocyanate ions coordinate to both Hg(II) and Cd(II) ions through the sulfur atom, but to Zn(II) ion through the nitrogen atom.

Formation of the thiocyanato complexes of Zn(II), Cd(II), and Hg(II) ions in aqueous solution has also been studied by thermodynamic,[1-5] Raman and infrared methods.[8-14] The results obtained from these studies are consistent with the conclusion that thiocyanate ions bind with Hg(II) ion through the sulfur atom, but to Zn(II) ion through the nitrogen atom, giving in both cases mononuclear species up to the tetra-complex. However, the coordination site of thiocyanato groups to Cd(II) ion in aqueous solution is still not conclusive.

Fronaeus and Larsson[9] interpreted two C-N absorption bands at 2098 and 2132 cm^{-1} in terms of the presence of mononuclear and bridged polymer species, respectively, in aqueous solutions having lower molar ratios of thiocyanate to cadmium ions. Taylor *et al.*[11] measured Raman spectra of the tetrathiocyanatocadmate(II) complex in aqueous solutions, suggesting that some SCN^- ions bound to Cd(II) through the N and some through the S atoms in the Cd(II) complex. In a recent Raman spectral measurement of thiocyanato complexes of Cd(II) ion in aqueous solutions, Antić-Jovanović *et al.*[14] assigned the band at 2132 cm^{-1} to the $[Cd(SCN)]^+$ complex, while the bands appearing at 2102 and 784 cm^{-1} were attributed to higher members of the stepwise $[Cd(NCS)_n]^{2-n}$ series. Their conclusion for the binding type of SCN^- to Cd(II) ions is consistent with that by Taylor *et al.*[11]

In crystal of $Cd(SCN)_2$,[18] a cadmium(II) ion is octahedrally surrounded by four sulfur and by two *trans*-nitrogen atoms with a slightly distorted geometry. In β-$Zn(NCS)_2$ crystal,[19] there are two crystallographically different Zn(II) ions, the one surrounded tetrahedrally by four N atoms and the other by four S atoms.

In the present study, we aimed at determining the structure of the tetrathiocyanato complex of Cd(II) ion in aqueous solution to clarify the type of binding of SCN^- ion by the X-ray diffraction, Raman, and NMR methods. The structure of tetrathiocyanato complexes of Zn(II) and Hg(II) ions in aqueous solution has also been determined for comparison.

Experimental

Preparation of Sample Solutions. If not otherwise

TABLE 1. THE COMPOSITION (mol/dm³), DENSITY d (g/cm³) AND STOICHIOMETRIC VOLUME V (10^6 pm³) PER SCN OF THE SAMPLE SOLUTIONS INVESTIGATED

	A	B	C	D
	Hg(II)	Cd(II)	Zn(II)	NH_4^+
M^{2+}	0.979	1.04	1.00	—
NH_4^+	5.02	5.04	5.03	7.12
SCN^-	6.98	7.12	7.03	7.12

d	1.30	1.23	1.17	1.11
V	2.38	2.33	2.36	2.33

stated, all chemicals used were of analytical reagent grade purchased from Wako Pure Chemical Industries, Ltd.

Zinc(II) thiocyanate was prepared by reacting zinc(II) sulfate with a stoichiometric amount of barium(II) thiocyanate which had been recrystallized twice from water. Zinc(II) thiocyanate thus prepared was then recrystallized from water.

Cadmium(II) thiocyanate was prepared from cadmium(II) perchlorate and ammonium thiocyanate, the former reagent having been prepared by dissolving cadmium(II) oxide in an aqueous perchloric acid solution and then recrystallized twice from water. Cadmium(II) thiocyanate thus obtained was recrystallized twice from water.

Mercury(II) thiocyanate commercially available was recrystallized twice from water.

Ammonium thiocyanate purchased was used without further purification.

The sample solutions investigated were prepared by dissolving required amounts of zinc(II), cadmium(II), mercury(II), and ammonium thiocyanates in water so that the tetrathiocyanato species was predominantly formed according to thermodynamic data[1-5] in the literature which were assumed to be valid in relatively concentrated sample solutions. Density of the solutions was determined pycnometrically.

The composition of the solutions used for X-ray diffraction measurements is given in Table 1. The same samples were used for Raman and NMR studies.

X-Ray Data Collection. X-Ray scattering measurements were carried out at 23 °C with a JEOL θ-θ diffractometer by using Mo$K\alpha$ radiation (λ=71.07 pm). The scanning range of the scattering angle (2θ) was 2—140°, corresponding to the scattering vector $3\times10^{-3}< s/\mathrm{pm}^{-1}<0.16$ ($s=4\pi\sin\theta/\lambda$). Different slit combinations and step angles were used and a total amount of 80000 counts was collected at each angle. Details of the diffractometer and the method of measurements have been described elsewhere.[22,23]

Raman Measurements. Raman spectra of the sample solutions used in the X-ray measurements were recorded at room temperature on a JEOL JRS-SI spectrometer using the 514.5 nm line of NEC GLG3200 argon ion laser.

NMR Measurements. ^{13}C-NMR spectra of the sample solutions were obtained at room temperature in the pulsed Fourier transform mode at 25.00 MHz on a JEOL FX-100 spectrometer. ^{14}N-NMR spectra were measured at 7.14 MHz. Small amounts of deuterium oxide as the internal lock and DDS (sodium 2,2-dimethyl-2-silapentane-5-sulfonate) as the internal standard were added to the sample solutions.

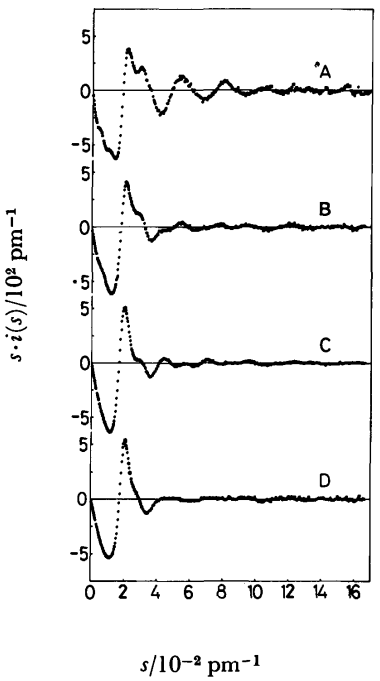

Fig. 1. Experimental structure functions $i(s)$ multiplied by s of aqueous solutions of mercury(II) thiocyanate (A), cadmium(II) thiocyanate (B), zinc(II) thiocyanate (C), and ammonium thiocyanate (D).

X-Ray Data Treatment. Experimental intensities were corrected for background, absorption, polarization, double scattering and Compton scattering and were scaled to absolute units in the usual manners described elsewhere.[22-26] The scattering factors of neutral atoms and the values for the Compton scattering and the anomalous dispersion effect were taken from the same sources previously described.[26]

The structure function $i(s)$ was obtained by

$$i(s) = I(s) - \Sigma x_j f_j^2(s), \quad (1)$$

where $I(s)$ is the scaled observed intensities, f_j the scattering factor of the jth atom corrected for anomalous dispersion and x_j the number of the jth atom in the stoichiometric volume containing one SCN^- ion. The structure functions of the sample solutions multiplied by s are shown in Fig. 1.

The radial distribution function was calculated by the Fourier transform of the $s\cdot i(s)$ values using the equation,

$$D(r) = 4\pi r^2\rho_0 + (2r/\pi)\int_{s_{min}}^{s_{max}} s\cdot i(s)M(s)\sin(rs)\mathrm{d}s. \quad (2)$$

Here, $M(s)$ is the modification function $[\Sigma x_j f_j(0)^2/\Sigma x_j f_j(s)^2]\exp(-0.01\ s^2)$, s_{min} and s_{max} denote, respectively, the lower and upper limits of the s values available in the experiments. The resulting $D(r)$ values are plotted in Fig. 2. All the calculations were performed by program KURVLR.[27]

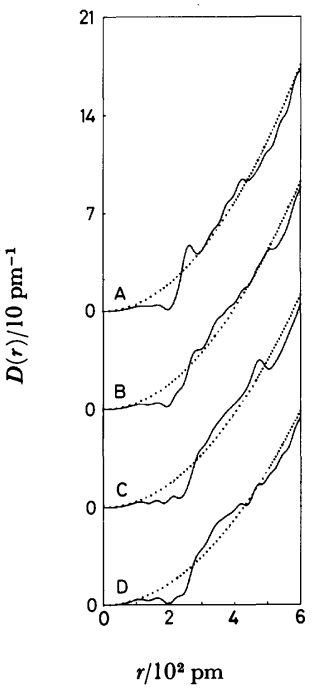

Fig. 2. Radial distribution functions $D(r)$ (solid lines) derived from the curves shown in Fig. 1. Dots show the values of $4\pi r^2\rho_0$.

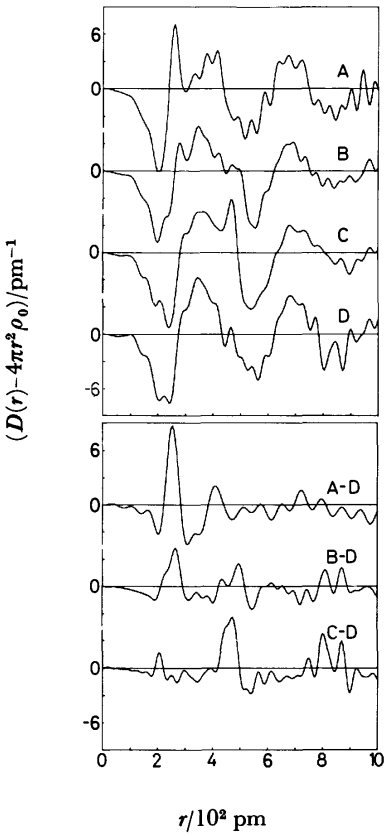

Fig. 3. Radial distribution functions of the form $D(r) - 4\pi r^2\rho_0$ derived from the curves in Fig. 1 (above). The figures below are the difference RDFs obtained by subtraction of curve (D) from curves (A), (B), and (C).

Results

X-Ray Radial Distribution Functions (RDFs). The total RDFs in the form of $D(r)-4\pi r^2\rho_0$ of Hg(II), Cd(II), Zn(II), and ammonium thiocyanate aqueous solutions of the stoichiometric volume per SCN ion are shown in Fig. 3 (upper figure). The peaks arising from the structure of SCN^- ion should appear at 120 pm (C-N), 165 pm (C-S), and 280 pm (S···N)[18-21] in all the RDFs. As is seen in Fig. 3 A through D, however, the large broad peak at 250—550 pm due to the hydration of SCN^- ion and the bulk water structure is dominant in the RDFs with distinct peaks at 255, 260, and 490 pm, respectively, in the RDFs of Hg(II), Cd(II), and Zn(II) thiocyanate solutions.

In order to extract the peaks originating from Hg(II), Cd(II), and Zn(II) thiocyanato complexes in the solutions, the RDF of NH_4SCN solution (Fig. 3 D) was subtracted from those of the metal thiocyanate solutions. Since an ammonium ion has a similar size as a water molecule and all the sample solutions contain an almost equal amount of SCN^- ions as well as the sum of $[NH_4^+]+[H_2O]$ (see Table 1), the bulk structure and the hydration structure of SCN^- ion may be similar in all the solutions at the first approximation. Thus, in the differences between the total RDFs A, B, or C and D (Fig. 3 lower figures, abbreviated as A-D, B-D, and C-D), the contribution of the bulk water and the SCN^- hydration structure is mostly eliminated and hence the peaks due to the metal thiocyanato complexes in the solutions are emphasized.

In the difference RDF of Hg(II) thiocyanate solution there are two peaks centered at 254 and 415 pm (Fig. 3 A-D). From the sum of the covalent radii of Hg and S (148 and 104 pm,[28] respectively) and the mean Hg-S bond length of 255 pm reported in a structure determination of $[Hg(SCN)_4][Cu(en)_2]$ crystal,[20] the first peak at 254 pm can be assigned to the Hg-S bonds within $[Hg(SCN)_4]^{2-}$. In the crystal structure of $[Hg(SCN)_4][Cu(en)_2]$, nonbonding Hg···N and interligand S···S interactions appear around 400 and 420 pm, respectively, and hence they are possibly responsible for the peak at 415 pm in the difference RDF of the Hg(II) thiocyanate solution.

In the case of Zn(II) thiocyanate solution, the difference RDF shows the distinct peaks at 204 and 462 pm. On the basis of the effective ionic radii of Zn and N atoms (60 and 146 pm[29], respectively) and the knowledge of the mean Zn-N (200 pm) and nonbonding Zn···S lengths (470 pm) within the $[Zn(NCS)_4]^{2-}$ moiety in β-$Zn(SCN)_2$ crystal,[19] the peaks around 204 and 462 pm are assignable to the Zn-N and Zn···S interactions within $[Zn(NCS)_4]^{2-}$, respectively.

The difference RDF of Cd(II) thiocyanate solution is more complex with peaks at 265, 435, and 490 pm with a shoulder at 225 pm. The values of 225 and 265 pm coincide well, respectively, with the sum of the effective ionic radii of Cd and N, and of Cd and S (Cd: 78 pm, N: 146 pm, S: 184 pm[29]). In the crystal structure of $Cd(SCN)_2$ having two Cd-N and four Cd-S bonds,[18] the Cd-N and Cd-S distances have been reported to be 224—225 and 271—280 pm, respectively. On the basis of these facts, it can be concluded that the peak at 265 pm with the shoulder at 225 pm consists of both Cd-S and Cd-N bonds within $[Cd(SCN)_4]^{2-}$ in the aqueous solution.

Model Calculations. A quantitative analysis of the X-ray scattering data was performed by comparing experimental values with theoretical ones calculated by a model both in the difference RDFs and in the difference structure functions.

A theoretical structure function of atom pair "i—j" was calculated by the Debye equation,

$$i(s)_{\text{calcd}} = n_{ij}f_i(s)f_j(s)\sin(sr_{ij})/(sr_{ij})\exp(-b_{ij}s^2), \quad (3)$$

where r_{ij}, b_{ij}, and n_{ij} represent the interatomic distance, the temperature factor and the number of interactions, respectively. The corresponding peak shape is obtained by the Fourier transform of the $s \cdot i(s)_{\text{calcd}}$ values using Eq. 2.

Firstly, the difference RDFs of Zn(II), Cd(II), and Hg(II) thiocyanate solutions were analyzed. In the difference RDF of the Hg(II) system (Fig. 3 A-D), the peak shape calculated for four Hg-S interactions was compared reasonably with the contour of the first peak at 254 pm, suggesting the tetrahedral coordination of four SCN^- ions to Hg(II). On the basis of the tetrahedral geometry of the $[Hg(SCN)_4]^{2-}$ complex, the interligand S···S interaction was estimated to be 415 pm, a corresponding peak appearing at 417 pm in the difference RDF. The nonbonding Hg···N interaction should also appear around 417 pm according to the crystal structure of $[Hg(SCN)_4]$-$[Cu(en)_2]$.[20] The distance of the Hg···C interactions within the $[Hg(SCN)_4]^{2-}$ complex in the solution was also estimated to be 330 pm from the crystal structure data.[20] The peak shapes calculated for these atom pairs are shown in Fig. 4. Subtraction of the sums of the peak shapes from the difference RDF gave the residue shown by dots in Fig. 4. Thus, the difference RDF of the Hg(II) thiocyanate solution was satisfactorily explained by the tetrahedral coordination model of four SCN^- ions to Hg(II) through the S atom.

A similar analysis applied to the difference RDF of the Zn(II) thiocyanate solution resulted in four Zn-N bonds from the area of the first peak at 204 pm. Four Zn···S interactions also explained satisfactorily the distinct peak at 460 pm. On the basis of the Zn-N and Zn···S distances with a linear SCN^- ion, the Zn···C interaction was expected to appear 310 pm, consistent well with the peak at 310 pm in the difference RDF (Fig. 5). The theoretical peak shapes due to the Zn-N, Zn···C, Zn···S, and interligand N···N interactions were calculated for the tetrahedral model of the $[Zn(NCS)_4]^{2-}$ complex and subtracted from the difference RDF. In the resulting residue shown by dots in Fig. 5, a small and broad peak still remains at 350—500 pm, which may be attributable to other interligand interactions such as N···C, N···S, C···S, and S···S. Small ripples left at 200—300 pm may be physically insignificant features judging from uncertainties in the difference RDF.

In the case of the Cd(II) thiocyanato complex, the first peak at 200—300 pm was analyzed by a trial-and-error method assuming various combinations of Cd-N and Cd-S interactions, and the most likely

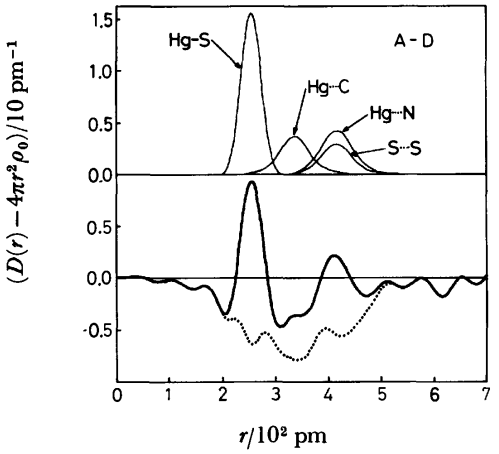

Fig. 4. Difference RDF of aqueous mercury(II) thiocyanate solution (solid line, below) obtained in Fig. 3A, and the residue (dots, below) obtained after subtraction of the peak shapes (solid line, above).

model attained was the one with two Cd–N and two Cd–S bonds per Cd(II). Nonbonding Cd···N and Cd···S interactions were assigned to the peaks at 440 and 490 pm, respectively, from the structural data of $Cd(SCN)_2$ crystal.[18] Cd···C and interligand N···N, S···S, and N···S distances were calculated from the tetrahedral geometry of the $[Cd(SCN)_4]^{2-}$ complex with the linear SCN^- ion coordinated and their peak shapes are shown in Fig. 6. Small peaks at 380—500 pm left after subtraction of the sum of the peak shapes from the difference RDF are probably related to other interligand interactions which were not taken into consideration. Since the X-ray scattering data can give the time- and space-averaged structure of a species, the present X-ray data for the Cd(II) thiocyanate solution could also be explained in terms of an equivalent mixture of $[Cd(SCN)_4]^{2-}$ having four Cd–S bonds and $[Cd(NCS)_4]^{2-}$ having four Cd–N bonds or a statistic mixture of $[Cd(NCS)_{4-n}(SCN)_n]^{2-}$ with the n value of 0 to 4. This problem will be discussed in more detail in a later section.

A direct comparison between experimental and theoretical difference structure functions was also performed by the least-squares method of minimizing the error square sum,

$$U = \sum_{s_{min}}^{s_{max}} s^2[\Delta i(s)_{obsd} - \Delta i(s)_{calcd}]^2. \quad (4)$$

Here, $\Delta i(s)_{obsd}$ denotes the difference structure functions experimentally obtained by subtraction of the total $i(s)$ values of NH_4SCN solution from those of metal thiocyanate solutions, s_{min} and s_{max} the lower and upper values of the s-range used in the calculations. Program NLPLSQ[30] was used for the calculations.

The model considered had the following characteristics.

(a) Four SCN^- ions coordinate to Zn(II) ion through the N atom, and to Hg(II) ion through the S atom. Cd(II) ion is bound with two SCN^- through the N atom, and the other two through the S atom.

(b) The interactions between atoms directly bonded to metal ion were taken into account by assuming the tetrahedral coordination of the atoms around the metal ion.

(c) The interactions between metal ion and the N or S atoms in SCN^- groups were defined by their interatomic distances, temperature factors, and number of interactions (=4), and the corresponding parameters r_{ij} and b_{ij} were allowed to vary independently with the coordination number fixed to the value of four. Parameters (r and b) due to the nonbonding M···C interactions were also allowed to vary in order to examine the deviation from the linearity of the SCN^- ions.

The final results of important parameters are summarized in Table 2. As shown in Fig. 7, the difference structure functions experimentally obtained are satisfactorily reproduced by the models, except for the data in the s-range less than 0.02 pm^{-1}, to which much longer interactions than those considered in the present models may contribute. On the basis of the M–N, M–C, and M–S distances within $[M(SCN)_4]^{2-}$, we see that the SCN^- ion within the complex has an almost linear structure.

Raman Spectra. Raman bands of the C–N and C–S stretching vibrations in the Zn(II), Cd(II), Hg(II), and ammonium thiocyanate solutions are shown by dots in Figs. 8 and 9, respectively.

A quantitative analysis of the Raman bands was performed by a nonlinear least-squares method by assuming the Lorentzian-Gaussian function expressed by

$$I(\nu) = I(\nu_0)[\exp\{-4\ln 2((\nu-\nu_0)/\sigma)^2\}\{1+(\nu-\nu_0)/\sigma\}^{-1}]^{1/2}, \quad (5)$$

where $I(\nu_0)$ denotes the peak height at the peak position ν_0, σ the half width. Parameters $I(\nu_0)$, ν_0, and σ were allowed to vary independently in the optimizing procedure.

Resolved peak components are shown by broken lines in Figs. 8 and 9, respectively, for the C-N and C-S bands. The sum of the components thus calculated is given by solid lines in the figures, which agrees well with the experimental values. The C-S and C-N frequencies thus determined are summarized in Table 3, together with those reported previously by other groups.[11,13,14]

As seen in Fig. 8, the C-N band at 2068 cm^{-1} observed in all the thiocyanate solutions is due to free SCN^- ion on the basis of the spectrum of the NH_4SCN solution. The higher C-N frequencies around 2100 cm^{-1} appearing in the metal thiocyanate solutions, the values of which agree well with those reported previously (Table 3),[11,14] are ascribed to SCN^- ions bound to a metal ion. As seen in Table 3, in the case of the bonding between SCN^- ion and a metal ion through the S atom, the C-N band appears at the higher frequency side than that of free SCN^- ion. The C-N frequency also increases when the

nitrogen atom within SCN^- binds to a metal ion. Tramer[10] and Taylor *et al.*[11] have commented that the increasing C-N frequency on binding of SCN^- ion to a metal ion through the N atom is caused by the removal of repulsive interactions between the lone-pair electrons on the N atom. The shift of the C-N frequency thus is not applicable to specify the end atom of SCN^- bound to a metal ion.

On the other hand, the influence of complex formation between SCN^- and metal ions on the C-S frequency is more distinct (see Fig. 9 and Table 3). As seen in Fig. 9, the C-S frequency of SCN^- ions bound to a metal ion increases for the Zn(II) thiocyanate solution, but decreases for the Hg(II) system, relative to that of free SCN^- ion observed in the NH_4SCN solution. The C-S frequencies determined for the Zn(II) and Hg(II) thiocyanate solutions in the present analysis are in accordance with the previous values[11,13,14] and suggest that SCN^- ions are bound to Zn(II) ion through the N atom, and to Hg(II) ion through the S atom.

In the case of the Cd(II) thiocyanate solution, two C-S bands were observed at around 745 and 780 cm^{-1} (Fig. 9). These C-S frequencies have been reported in Refs. 11 and 14. However, a preliminary analysis of the C-S bands assuming two Lorentzian-Gaussian components failed, but the error square sum decreased significantly in the case of the calculation with three peaks and the whole contour of the C-S bands was satisfactorily reproduced. The final C-S frequencies obtained are given in Table 3 and the corresponding peaks are shown in Fig. 9. The lower and higher C-S frequencies (732 and 779 cm^{-1}) correspond well, respectively, to the presence of both N- and S-bindings to Cd(II) ion, which has been revealed by the X-ray diffraction study of the Cd(II) thiocyanate solution as described in a previous section.

NMR Spectra. The chemical shifts δ of ^{13}C- and ^{14}N-NMR spectra were measured as the internal standards DDS and NH_4^+ ion, respectively, in the Zn(II), Cd(II), Hg(II), and ammonium thiocyanate solutions and are summarized in Table 4. The differences between the chemical shifts for the metal thiocyanate solutions and that for the NH_4SCN solution are also given as $\Delta\delta(SCN^-)$ in Table 4.

Table 4. Chemical shifts (ppm) of Hg(II), Cd(II), Zn(II), and ammonium thiocyanate solutions

	^{13}C-NMR		^{14}N-NMR	
	δ(DSS)	$\Delta\delta(SCN^-)$	$\delta(NH_4^+)$	$\Delta\delta(SCN^-)$
$[Hg(SCN)_4]^{2-}$	130.1	−4.9	215.0	30.8
$[Cd(SCN)_4]^{2-}$	134.3	−0.7	182.9	−1.3
$[Zn(NCS)_4]^{2-}$	136.4	1.4	153.9	−30.3
NH_4SCN	135.0	0.0	184.2	0.0

The $\Delta\delta(SCN^-)$ of the nitrogen-14 resonance shifted downfield in the Zn(II) thiocyanate solution, but upfield in the Hg(II) thiocyanate solution. Howarth *et al.*[15] measured the ^{14}N-chemical shifts of many S- and N-bonding metal thiocyanato complexes in various solvents and have reported that the ^{14}N-resonance shifts downfield in the N-bonding complexes, but upfield in the S-bonding complexes, from that of the free thiocyanate ion. Thus, the present ^{14}N-chemical shifts of the Zn(II) and Hg(II) thiocyanate solutions suggest the coordination of SCN^- ions to Zn(II) ion *via* the N atom, and to Hg(II) ion *via* the S atom. In the Cd(II) thiocyanate solution, the $\Delta\delta(SCN^-)$ value is in between those for Zn(II) and Hg(II) cases. This can be interpreted in terms of the convolution of peaks of downfield and upfield shifts due, respectively, to both N- and S-bonding SCN^- ions for Cd(II) ion, together with the peak of free SCN^- ion.

The $\Delta\delta(SCN^-)$ values of the ^{13}C-resonance of Zn(II), Cd(II), and Hg(II) thiocyanate solutions have shown the downfield shift for Zn(II), the upfield for Hg(II), and the intermediate for Cd(II) (Table 4), the same trend but reverse order of the $\Delta\delta(SCN^-)$ values being found in the ^{14}N-chemical shifts. Thus, ^{13}C-chemical shifts of these solutions also indicate the different types of bonding of SCN^- ions to Zn(II), Cd(II), and Hg(II) ions in the thiocyanate solutions.

Discussion

The structural parameters of Zn(II), Cd(II), and Hg(II) thiocyanato complexes both in aqueous solution and in DMSO are compared in Table 5. The SCN^- ions are bound to Hg(II) through the S atom within the $[Hg(SCN)_4]^{2-}$ complex in both aqueous solution and in DMSO and the Hg-S bond length and the bond angle Hg-S-C are similar in the two solvents within experimental uncertainties.

The Zn-N distance within $[Zn(NCS)_4]^{2-}$ in H_2O is

TABLE 5. COMPARISON OF INTERATOMIC DISTANCES (pm) AND BOND ANGLES (ϕ/°) WITHIN THE TETRATHIOCYANATO COMPLEXES OF Hg(II), Cd(II), AND Zn(II) IONS IN H_2O AND IN DMSO

	Hg		Cd			Zn

∠M-S-C	102	108		106	106[a]		

a) The values determined for complex species in a DMSO solution of $\bar{n}=2.3$ in Ref. 21 where $\bar{n}$ denotes the average number of thiocyanato ions bound to the central metal ion.

somewhat longer than the corresponding distance in DMSO. In the analysis of the X-ray scattering data of a DMSO solution of Zn(II) thiocyanate,[21] the Zn-N distance within $[Zn(NCS)_4]^{2-}$ has not been directly determined because of a low Zn(II) concentration and fixed at the value (194 pm) found in β-$Zn(NCS)_2$ crystal, although the structure of the crystal has not been solved with a high precision (the R-value= 0.09[19]). The Zn-N distance obtained in the present study is in good agreement with the value estimated from the effective ionic radii (206 pm[29]). The Zn-N-C bond angle may also be affected from the errors of the same source.

Thus, a relatively hard acceptor Zn(II) ion prefers to bind with the nitrogen atom and a soft acceptor Hg(II) ion combines with the soft sulfur atom within an SCN^- ion in both aqueous and DMSO solutions.

The structural parameters of Cd(II) thiocyanate complex determined in DMSO were those of a mixture of $[Cd(SCN)_2]$ and $[Cd(SCN)_3]^-$ because the structure determination of cadmium(II) thiocyanato complexes in DMSO has been carried out in a solution of $\bar{n}=2.3$ ($\bar{n}$ is the average coordination number of SCN^- ion within the complexes). However, as far as Persson *et al.*[21] have examined, cadmium(II) ion combines with SCN^- ions through the S atoms in DMSO (see Table 5).

On the other hand, cadmium(II) ion binds with both nitrogen and sulfur atoms within SCN^- ions in the $[Cd(SCN)_4]^{2-}$ complex in water. This fact may be related to different donicities of H_2O and DMSO, the latter has a larger donor number than the former (H_2O: 18.0, DMSO: 29.8[31]). The larger electron donation from ligand solvent molecules toward the central metal ion may decrease the fractional charge of the metal ion and thus the metal ion becomes softer. Therefore the metal ion may prefer a soft ligand atom than a hard one in a solvent with a larger donicity. Water molecule having a larger acceptor number than DMSO (H_2O: 54.8, DMSO: 19.3[30]) may preferentially solvate to the sulfur atom than the nitrogen site and thus the N-end within SCN^- tends to bind to Cd(II) ion in H_2O, while the S-end may not be strongly solvated in DMSO. These two factors of different solvating properties of H_2O and DMSO may affect the bonding of SCN^- to Cd(II) ion. The Cd-S bond length and the bond angle Cd-S-C do not differ significantly in the two solutions.

The present X-ray scattering data of the Cd(II) thiocyanate solution have demonstrated the presence of two Cd-N and two Cd-S bonds per Cd(II) on the average within the tetrathiocyanatocadmate(II) ion in aqueous solution. By the X-ray diffraction experiment, however, the result is not distinguishable between the formation of the $[Cd(SCN)_2(NCS)_2]^{2-}$ complex and the statistic mixture of $[Cd(NCS)_{4-n}(SCN)_n]^{2-}$ with n=0—4. Thermodynamic quantities (ΔG°_n, ΔH°_n, and ΔS°_n for the stepwise formation of $[Cd(NCS)_n]^{(2-n)+}$ complexes) and Raman spectra of solutions containing the thiocyanato complexes with low $\bar{n}$ values in aqueous solution, details of which will be described elsewhere,[32] indicated that the first SCN^- ion coordinates to Cd(II) ion through the N atom and the second and third SCN^- ions combine with Cd(II) ion through the S and N atoms, respectively, and then, at the fourth step, the Cd-S bond forms. These results indicate that the X-ray diffraction data obtained for the tetrathiocyanatocadmate(II) solution should be interpreted in terms of the formation of the $[Cd(NCS)_2(SCN)_2]^{2-}$ with two Cd-N and two Cd-S bonds, but not the statistical mixture of $[Cd(NCS)_{4-n}(SCN)_n]^{2-}$ complexes.

The covalency of the metal-ligand bonds within thiocyanato complexes of Zn(II), Cd(II), and Hg(II) may be reflected on their bond lengths. The Zn-N distance (204 pm) is close to the value estimated from the effective ionic radii (206 pm) (*cf.* 201 pm for the sum of the covalent radii of the atoms[28]), while the Hg-S distance (254 pm) agrees well with the sum (252 pm) of covalent radii of the relevant atoms (*cf.* 280 pm for the sum of the ionic radii of Hg^{2+} and S^{2-}). Both Cd-N (225 pm) and Cd-S (265 pm) distances are close to those (224 and 264 pm, respectively) calculated using the effective ionic radii (*cf.* 218 and 252 pm, respectively, for the sum of the covalent radii of the atoms).

The authors thank Dr. Yoshiyuki Nakamura for ^{13}C-NMR measurements, and Dr. Masayoshi Harada for ^{14}N-NMR measurements. A part of the calculations was carried out by using M-200H computers at the Institute for Molecular Science. The present work has been financially supported, in

part, by a Grant-in-Aid for Scientific Research No. 57470054 of the Ministry of Education, Science and Culture.

Ion-exclusion Chromatography of Weak Acids Using a Carbonic Acid Solution as Eluent

Hisaaki ITOH* and Yoshio SHINBORI
Faculty of Pharmaceutical Sciences, Josai University, Sakado, Saitama 350-02
(Received June 5, 1985)

Ion-exclusion chromatographic separation of organic acids using a carbonic acid solution as eluent is presented. This permits conductivity detection of ionic species without a suppressor as a post-column reactor. It was found that the proposed method was applicable to the separation of organic acids having pK_a over *ca* 3.5. This technique was applied to the determination of acetic acid in pharmaceuticals without tedious sample preparation.

In recent years, ion-exclusion technique, first reported by Wheaton and Bauman[1] for the separation of nonionic from ionic materials, has become of wider interest because of its ability to separate strong acids as a class from weak acids and also from each other.

Tanaka *et al.*[2] have indicated that ion-exclusion chromatography (IEC) using a hydrogen-type cation-exchange resin and flow-coulometric detection could be used for the separation of many weak acids from each other and for their determination. They[3] also have recently described the ion-exclusion behavior of a large number of strong and weak acids using water as eluent. Furthermore, Turkelson and Richards[4] have reported the use of IEC to separate most of the Krebs cycle acids, demonstrating that ion-exclusion can also separate weak acids from each other by the use of dilute hydrochloric acid solution as eluent.

Ion chromatography exclusion (ICE) technique, one of the modes of ion chromatography,[5] has also been successfully applied to the separation and analysis of many organic acids in various samples having complex matrices, *i.e.* brine,[6] foods,[7] and biologicals.[8] In this technique, using a dilute hydrochloric acid solution as eluent and conductivity detection, the separator column is connected with a so-called halide suppressor, which permits a sensitive detection of the ionic species in a sample solution with the reduction of the background conductivity. Although it has been proven that the ICE technique was a useful one for the analysis of organic acids, unfortunately, it has some disadvantages because of the use of the halide suppressor. In the suppression reaction procedure, the formation of silver chloride precipitation in the suppressor column causes an increase of back pressure in the system. Consequently, the retention time of the analyte will change and the detector response of the analyte will be diminished. Thus, the identification of unknown species will be somewhat difficult and the analytical precision in the quantification of the species will be poor, even though these problems may be improved by replacement with a different suppressor and/or by cutting off the consumed part of the suppressor.

In the previous communication,[9] we have briefly reported a new ion-exclusion technique using a carbonic acid solution as eluent and conductivity detection without a suppressor as a post column reactor. The present paper describes the elution behavior of several organic acids and the application to the acetate analysis to some pharmaceuticals.

Experimental

Materials. All reagents used were of reagent grade. All standard solutions, except for the solution of lithium lactate, valeric and hexanoic acid, were prepared by dissolving the acid and/or the corresponding sodium salt in distilled and deionized water (DI water). Valeric and hexanoic acid standard solutions were prepared by dissolving the acid in aliquots of 1 mol dm^{-3} NaOH solution and diluting with DI water. In addition, acetic acid standard solution for calibration was prepared by dissolving the potassium salt in DI water. The salt was dried in an electric drier oven at 110 °C for 24 h. Klinisalz® B Ringer's solution (Eisai) and Celtol® Intramuscular 1Gm (Takeda) were obtained from commercial sources. The aqueous solution of Celtol® injections was prepared by dissolving 0.5325 g of it (500 mg as Potency) in 5.0 cm^3 of the distilled water for injection and held in water bath at 25 °C.

1: Eluent reservoir, 2: Pump, 3: Dionex Anion Suppressor (P/N 30828), 4: Injection valve, 5: Sample loop, 6: Dionex Anion Suppressor (P/N 38029), 7: Dionex ICE Separator (9 mm i.d. × 250 mm, P/N 30888), 8: Conductivity detector, 9: Recorder.

Chromatographic System. The Dionex Model 10 Ion Chromatograph equipped with conductivity detector was modified. The flow diagram of the modified system is shown in Fig. 1. Two Dionex anion suppressors[10] were used: One (9 mm i.d.×100 mm) between the pump and the injection valve and another (6 mm i.d.×60 mm) between the injection valve and the ICE Separator.[11] There are two reasons for introducing a suppressor before the ICE Separator. First, this column plays a role of a so-called guard column for the ICE Separator. Second, it neutralizes the sample solution and converts the sample ions into the corresponding acid forms. Thus, the system can be continually operated for 20 to 30 h depending upon the sample matrix and the flow rate without column regeneration. In addition, with a view to faster analysis, both the separator valve and the suppressor valve were bypassed by connecting the top of the suppressor column directly to the injection valve and the bottom of the ICE Separator directly to the conductivity cell inlet using a short length of tubings (0.5 mm i.d). The eluent reservoir contains a sodium carbonate solution and/or a standard sodium hydrogencarbonate/sodium carbonate solution which is commonly used for the anion analysis in ion chromatography. This solution is converted into a definite concentration of carbonic acid solution by passing it through the suppressor column. The injection volume was 50 mm^3. The strip chart recorder was operated at 1 mV full scale range and a chart speed of 30 cm h^{-1}. A 0.5 mol dm^{-3} sulfuric acid solution was used for column regeneration at flow rate of 1.0 cm^3 min^{-1}.

Results and Discussion

Elution Behavior of Organic Acids. In the previous paper,[9] it was shown that the presence of carbonic acid in the eluent dramatically improves the separation of organic acids such as formic, acetic, propionic, and butyric. Figure 2 typically shows the variation of the chromatographic capacity factor (k') of four organic acids with the concentration of carbonic acid in the eluent. The increase of each k' value was observed with the increase of the concentration of carbonic acid, that is, the decrease of pH of the eluent (pH 5.0 to 4.3). This is a characteristic effect of the pH of the eluent in ion-exclusion chromatographic separation.[4,12]

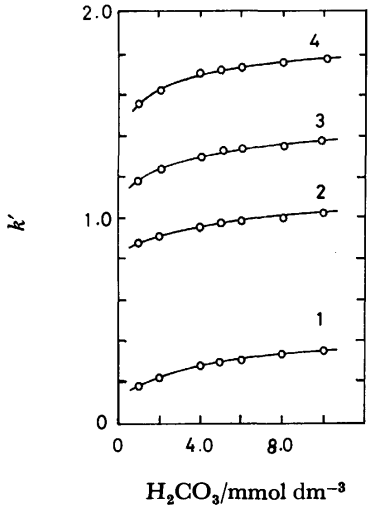

Fig. 2. Variation of the chromatographic capacity factor (k') with the concentration of carbonic acid solution.
Notations: 1 Formic acid, 2 acetic acid, 3 propionic acid, 4 butyric acid.

The factors which affect the separation characteristics in IEC are pK_a, structure and concentration of solute, temperature, eluent pH, nature of the resin, such as degree of cross linkage, and eluent flow rate *etc.*[1,6] Among these factors, generally, the pK_a of the solute can be used to predict its elution behavior. Because of a Donnan membrane effect, at a given eluent pH, the distribution of the solute between the occluded liquid inside the resin pores and the interstitial liquid of the resin particles depends upon its pK_a. The lower the pK_a, the smaller the distribution, that is, the lower the pK_a, the faster the elution. Indeed, Tanaka *et al.* have shown that this general rule holds for a large number of inorganic acids and also for some organic acids such as formic and acetic.[3]

Table 1 lists k' values of mono- and dicarboxylic acids and some substituted derivatives of these acids obtained by using carbonic acid solution (5.0 mmol dm^{-3}) as eluent together with their pK_a values. These k' data show that the general rule mentioned above holds only for acids of low molecular weight such as formic, acetic, succinic and glutaric *etc.*

Table 1. Chromatographic k' data

Acids	pK_a[a]	k'
Oxalic	1.19 (4.28)[b]	0
Pyruvic	2.49	0
Malonic	2.85 (5.69)	0
(*S*,*S*)-Tartaric	3.03 (4.36)	0
L-Malic	3.4 (5.1)	0.08
Formic	3.752	0.28
Lactic	3.862	0.28
Succinic	4.20 (5.64)	0.40
Glutaric	4.343 (5.42)	0.64
Adipic	4.430 (5.41)	0.97
Acetic	4.756	1.02
4-Oxovaleric	4.59	1.15
Propionic	4.874	1.33
Pimelic	4.509 (5.4)	1.64
Butyric	4.820	1.75
Valeric	4.86	2.85
Suberic	4.5 (4.7)	3.1
Hexanoic	4.88	5.0

a) Landolt-Börnstein, "Zahlenwerte und Funktionen," II B., 7 Teil, Springer (1960). b) Parenthesis: pK_2 value.

However, as the solutes become more aliphatic in nature, that is, with increase of the hydrophobic moiety, Van der Waals forces and/or the hydrophobic interactions between the hydrophobic moiety of the solute and the hydrocarbon portion of the resin become more dominant. Thus, the elution sequences differ from that predicted from the pK_a of solutes only. The k' values obtained show a tendency to increase with that of the hydrophobic moiety, that is, the molecular weight of solute regardless of its pK_a. In addition, hydroxy and keto carboxylic acids show smaller k' values than those of the corresponding normal acids because the introduction of such a hydrophilic group makes the acid stronger and increases the hydrophilicity of the solute.

In summary, although the definite correlation between k' value and pK_a of the solute was not observed from the results shown in Table 1, it can be seen that this technique is applicable for the separation of organic acids having pK_a over *ca* 3.5.

Application to the Determination of Acetic Acid in Pharmaceuticals. In order to evaluate the applicability of the present system, the determination of acetic acid in pharmaceutical samples, Klinisalz® B Ringer's solution and Celtol® injections, was undertaken. Klinisalz® B Ringer's solution contains NaCl, KCl, CH_3COONa, KH_2PO_4, $MgCl_2$, and xylitol as components. Celtol® injections contains cephacetrile sodium (CEC), which is one of the 3-(acetoxymethyl)-cephalosporins, and it is known that it partially decomposes to liberate acetic acid in aqueous solution and that the resulting desacetyl derivative has only a low potency. Thus, from the standpoint of quality control for both pharmaceuticals, it is required to analyze the acetic acid content.

The calibration curves constructed by using the peak height of standard acetate solution were linear over the range of 0.1—10 μg cm^{-3} and 0.5—30 μg cm^{-3} (as CH_3COO^-) at 3 μS and 10 μS, respectively. A relative standard deviation of 1.3% was obtained for five replicate injections of 1.0 μg cm^{-3} level at 10 μS. In addition, the detection limit established using 50 mm^3 standard injection was 40 ng cm^{-3}.

Both samples were directly injected without sample preparation except for diluting with DI water. The CEC solution was held in a cooling bath at 10 °C after dilution since CEC was stable in aqueous solution at low temperature.[13)]

The analytical results based on peak height measurements and chromatograms are shown in Table 2 and Fig. 3, respectively. For Klinisalz® B Ringer's solution, 11.81 μg cm^{-3} and 11.85±0.08 μg cm^{-3} are values calculated from the appended component table as taken and obtained from five replicate determinations, respectively. These data show that the method we describe is simple, precise and sensitive, which is applicable for routine analysis of the acetate of these pharmaceutical samples.

Thermal Reactions of the Nickel(II) Complexes Containing 1-Phenyl-1,2-ethanediamine in the Solid Phase

Yoshinori IHARA
Laboratory of Chemistry, Faculty of Education, Kanazawa University, Kanazawa 920
(Received June 20, 1985)

Nickel(II) complexes $[Ni(phenen)_2](ClO_4)_2$ and $[Ni(H_2O)_2(phenen)_2]X_2$ (phenen=1-phenyl-1,2-ethanediamine, X=Cl, Br, or NO_3) were prepared, and their thermal behavior was investigated in the solid phase. The nitrate showed a thermochromism consisting of two steps, violet→yellow→violet, which corresponds to a structural change from an octahedral diaqua complex to a square planar anhydride, and then to the octahedral dinitrato complex, respectively. Both the chloride and bromide were converted into the octahedral dianiono complexes by thermal deaquation-anation, retaining their octahedral configuration. However, no change was observed in the perchlorate, which is invariably square planar.

When two molecules of a *N*- and/or *C*-substituted ethylenediamine are coordinated to a nickel(II) ion, the resulting bis(diamine) complex is generally either square planar ($[Ni(diamine)_2]X_2$) or octahedral ($[NiX_2(diamine)_2]$ or $[NiA_2(diamine)_2]X_2$: X=a univalent anion, A=a solvent molecule). Two main factors for deciding whether X or A are coordinated or not can be distinguished: (i) the coordinating ability of these ligands, and (ii) the steric hindrance resulting from *N*- or *C*-substituents of the diamine.

Tsuchiya *et al.* have studied the relative stabilities of these two structures, and the ease of their interconversions, using many complexes containing different types of diamines, on the basis of their thermal reactions in the solid phase.[1-3] Recently, the author found more interesting examples of such a thermal transformation, including some octahedral→square planar→octahedral changes which are peculiarly thermochromic (violet→yellow→violet or blue), in the nickel(II) complexes with butanediamines[4] or 1,2-diphenyl-1,2-ethanediamines[5] in the solid phase. Such transformations were found to occur most easily in the case of the complex chloride or nitrate of *dl*-form diamines.

In a continuation of these studies, thermal reactions of the nickel(II) complexes of 1-phenyl-1,2-ethanediamine (phenen) were studied. The obtained results are reported in this paper. It is interesting to note that it was just these complexes, and those of 1,2-diphenyl-1,2-ethanediamines, that Lifschitz *et al.* studied and discussed in their historical paper on the structure of the nickel(II) complexes.[6]

Experimental

Preparation. Methyl 2-amino-2-phenylacetate[7] was converted into 2-amino-2-phenylacetamide by the method of Arpesella.[8] 1-Phenyl-1,2-ethanediamine was obtained by reducing the amide with $LiAlH_4$ according to the procedure described by Yano *et al.*[9]

The complexes were prepared following the method of Lifschitz *et al.*[6] with slight modifications.

(i) Complex chloride, nitrate, and perchlorate: To an aqueous solution of nickel(II) chloride or nitrate, an ethanolic solution of phenen was added in the molar ratio of 1:2. The violet crystals which separate out on standing were recrystallized from boiling water. The same procedure with nickel(II) perchlorate gave orange crystals of the complex perchlorate.

(ii) Complex bromide: When nickel(II) bromide was used in the method (i), a mixture of violet blue and violet crystals was almost always obtained irrespective of the organic solvent used (methanol or ethanol) and its concentration. The mixture was dissolved in boiling water, and the resulting solution was cooled rapidly on ice to yield pure violet crystals.

Measurements. Simultaneous TG and DSC measurements were carried out with a Rigaku Denki standard TG-DSC apparatus under a constant flow of nitrogen (20 ml/min). The heating rates and amounts of samples used are given in the figures.

The electronic spectra in the solid phase were measured by the diffuse reflectance method on a JASCO UVIDEC-410 spectrophotometer. The effective magnetic moments were evaluated from the susceptibilities measured by Gouy's method at room temperature.

Results and Discussion

Structures of the Original Complexes. The reflectance spectra of the chloride and perchlorate are shown in Fig. 1. The bromide and nitrate revealed

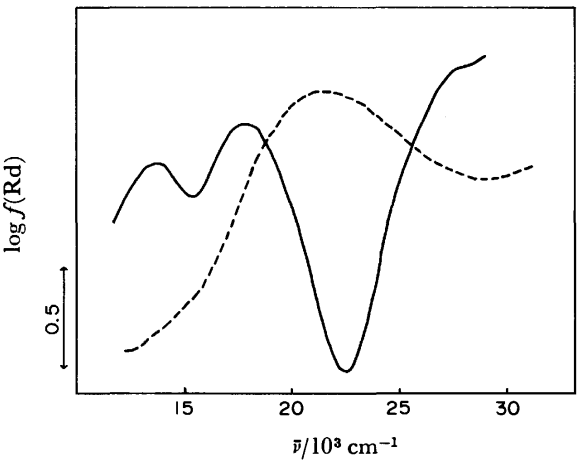

Fig. 1. Electronic spectra of $[Ni(H_2O)_2(phenen)_2]Cl_2$ (——) and $[Ni(phenen)_2](ClO_4)_2$ (----).

Table 1. Data on the elemental analyses, electronic spectra and magnetic moments of the original complexes

Complexes	Color	Analytical data[a]			Absorption maxima			μ_{eff}

similar spectral patterns to that of the chloride. The spectral data of all the complexes are summarized in Table 1, together with their magnetic moments and analytical data. It is well understood from Fig. 1 and Table 1 that the violet complexes have an octahedral geometry and the orange perchlorate has a square planar one, leading to the formulas of the complexes given in Table 1.

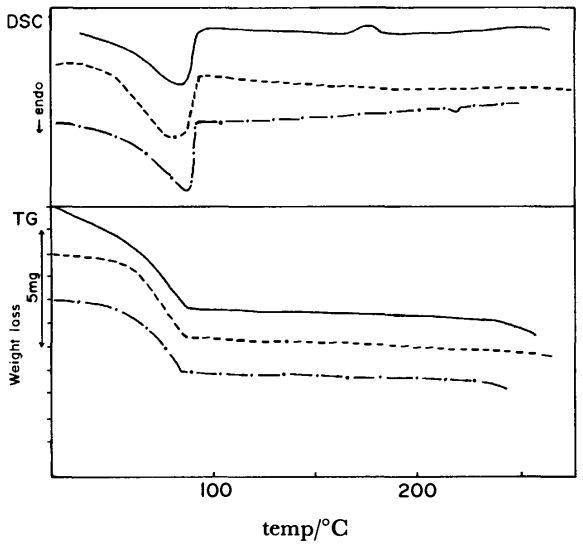

Fig. 2. TG–DSC patterns of $[Ni(H_2O)_2(phenen)_2]X_2$, where X=Cl (——), Br (----), and NO_3 (—·—). Heating rate: 1.25 °C min^{-1} for all complexes. Amount of sample used: 28.5 mg (chloride), 25.5 mg (bromide), and 20.1 mg (nitrate).

Thermal Analyses. The results of simultaneous TG–DSC measurements of the complexes are shown in Fig. 2. The results of the perchlorate are not shown, because it did scarcely show any change on TG and DSC curves before its decomposition. The weight losses observed below 100 °C correspond to the liberation of two moles of the coordinated water in the respective complexes (obsd. 8.07%, calcd. 8.23% for chloride; 6.86%, 6.84% for bromide; 7.46%, 7.34% for nitrate, respectively). The colors of the chloride and bromide were changed to violet blue and that of nitrate to yellow, after the dehydration.

On the DSC curves, a small exothermic peak is observed at 175 °C in the case of the chloride and an endothermic one at 215 °C in the case of the nitrate, after the peak caused by the dehydration. It is likely that these changes are not so drastic to bring about a distinct structural transformation, because no appreciable change was observed in the reflectance spectra of the complexes before and after the peak temperature.

On the other hand, the nitrate is strongly thermochromic, changing from yellow to violet at about 130 °C, after the color change by dehydration (violet→yellow) is over. This change indicates that, upon heating the yellow anhydrous complex a square planar-octahedral transformation takes place. But, the DSC curve remains nearly linear in this range irrespective of the obvious color change. Thus,

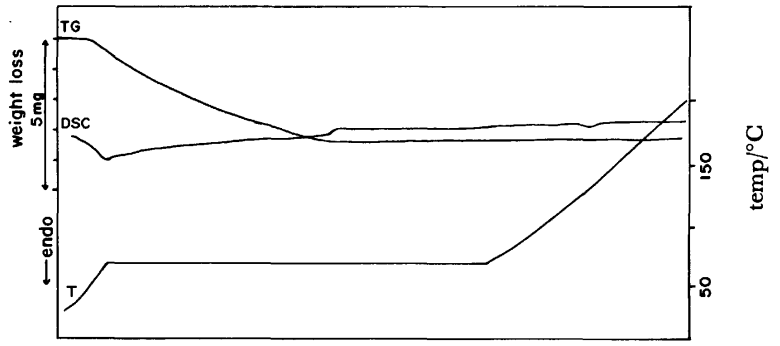

Fig. 3. TG–DSC pattern of $[Ni(H_2O)_2(phenen)_2](NO_3)_2$. Heating rate: 2.5 °C min^{-1} until 70 °C. After the dehydration was completed at 70 °C, heating was continued at the same rate. The sensitibity of DSC was the same as that of Fig. 2.

a more detailed measurement regarding this thermal reaction was tried, with the result is shown in Fig. 3. Avoiding an overlap with the dehydration peak, a measurement was performed by using an isothermal technique at 70 °C, under the conditions given in the caption of the figure.

The new small peak observed at about 130 °C revealed the existence of an endothermic reaction, which seems to correspond to the color change (yellow→violet). The peak is, however, too weak for estimating the amount of heat absorbed in the reaction.

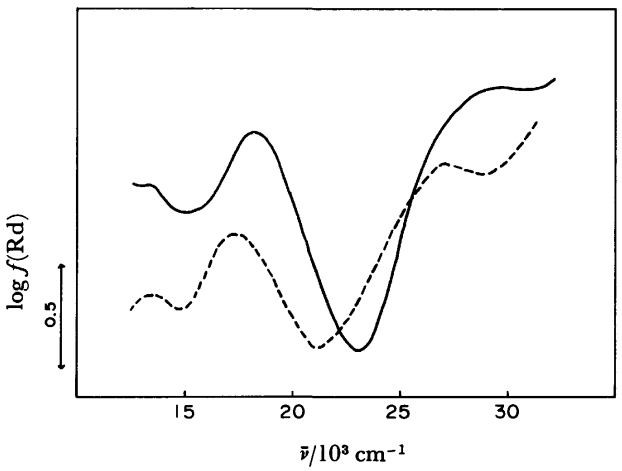

Fig. 4. Electronic spectra of $[Ni(H_2O)_2(phenen)_2]Br_2$ before heating (——) and after heating (----).

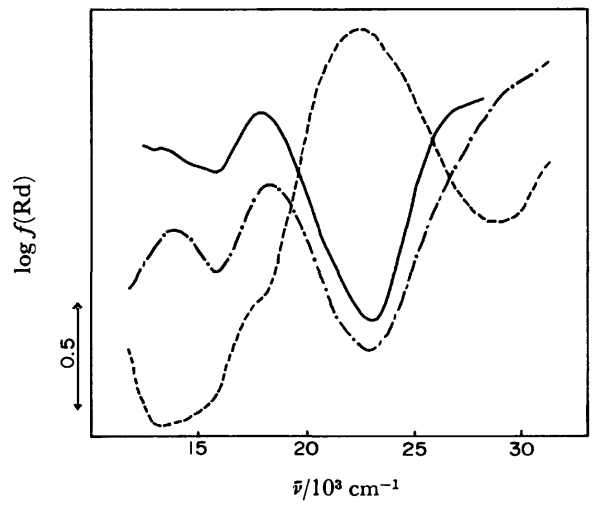

Fig. 5. Electronic spectra of $[Ni(H_2O)_2(phenen)_2](NO_3)_2$ before heating (——) and after heating at 70 °C (----) and at 150 °C (—·—).

Structures of the Complexes Obtained by Heating. The products of the thermal reactions were obtained by isothermal heating at the temperatures of the respective DSC peaks using an electric furnace in static air.

The reflectance spectra of the complex bromide and nitrate before and after heating are compared in Figs. 4 and 5, respectively. As shown in Fig. 4, the spectrum of the anhydrous complex bromide obtained upon heating is almost identical with that of the mother complex, except for a slight shift of the maximum peaks to longer wavelengths. The shifts can be attributed to an exchange of the coordinated species, *i.e.*, that of water molecules by bromide ions. A similar spectral change is also observed in the case of the chloride (Table 2). Consequently, both the chloride and bromide are found to undergo thermal deaquation-anation (Eq. 1; see below).

On the other hand, the spectrum of the yellow product of the nitrate is very similar to that of the complex perchlorate, but is completely different from those of the two violet species (Fig. 5). The violet product obtained by heating at 150 °C shows a spectral pattern nearly identical with that of the original octahedral dihydrate, while the pattern of the yellow product is that of a square planar nickel(II) complex, which have a broad and strong absorption band in the blue part of the spectrum. The data of the magnetic moments in Table 2 support these discussions.

The thermochemical changes observed can thus be represented by the following equations (as to the notations Oh, Oh′, and Sp, see below):

$$\underset{\text{Oh}}{[Ni(H_2O)_2(phenen)_2]X_2} \xrightarrow[\Delta]{-2H_2O} \underset{\text{Oh}'}{[NiX_2(phenen)_2]} \quad (X=Cl \text{ or } Br), \tag{1}$$

$$\underset{\text{Oh}}{[Ni(H_2O)_2(phenen)_2](NO_3)_2} \xrightarrow[\Delta]{-2H_2O} \underset{\text{Sp}}{[Ni(phenen)_2](NO_3)_2} \xrightarrow{\Delta} \underset{\text{Oh}'}{[Ni(NO_3)_2(phenen)_2]}. \tag{2}$$

Table 3. Classification of thermal reactions of nickel(II) complexes containing *C*-substituted ethylenediamines

	Cl	Br	I	NO_3	ClO_4
pn[10]	Oh→Oh′	Oh→Oh′		Oh→Oh′	Oh→Sp
phenen	Oh→Oh′	Oh→Oh′		Oh→Sp→Oh′	Sp
i-bn[4]	Sp→Oh′	Sp	Sp	Sp	Sp
m-bn[4]	Sp	Sp	Sp	Sp→Oh′	Sp
dl-bn[4]	Oh→Sp→Oh′	Oh→Sp→Oh′		Oh→Sp	Oh→Sp
m-stien[5]	Sp	Sp	Sp	Sp	Sp
dl-stien[5]	Oh→Sp→Oh′	Oh→Sp→Oh′	Sp	Oh→Sp→Oh′	Sp

Abbreviations pn, phenen, *i*-bn, *m*-bn, *dl*-bn, *m*-stien, and *dl*-stien are 1,2-propanediamine, 1-phenyl-1,2-ethanediamine, 2-methyl-1,2-propanediamine, *meso*- and *dl*-2,3-butanediamine, and *meso*- and *dl*-1,2-diphenyl-1,2-ethanediamine, respectively. Oh and Sp denote an octahedral and a square planar structure. As to Oh→Oh′, Oh→Sp, Oh→Sp→Oh′, and Sp→Oh′, see text.

Only in the case of the nitrate, a square planar structure is observed as a stable product of the thermal reaction. The reason for the peculiarity of the nitrate showing such a transformation had been discussed in the preceding paper.[4,5]

Effects of Structures of Diamines upon Thermal Reactions. Table 3 summarizes the results of the thermal reactions of phenen complexes and those of the nickel(II) complexes with other *C*-substituted ethylenediamines already studied.

When the original species are octahedral, *i.e.* the diaqua bis(diamine)nickel(II) complexes, they are denoted by Oh in this Table. They contain monosubstituted, or *m*- or *dl*-disubstituted ethylenediamines, as shown below the table. When heated, they change in one of the three ways, *i.e.*: (i) simple deaquation leading to a square planar (Sp) species: Oh→Sp; (ii) single-step deaquation-anation leading to an octahedral dianiono species (Oh′): Oh→Oh′ (*cf.* Eq. 1); and (iii) two-step deaquation-anation: Oh→Sp→Oh′ (*cf.* Eq. 2). On the other hand, when the original species are square planar, they may remain unchanged upon heating, or may be converted into the octahedral dianiono species (simple anation, Sp→Oh′).

It can be seen that the phenen complexes easily undergo deaquation-anation either in one step or in two, producing dianiono complexes, retaining (or restoring) their octahedral configuration. An important reason for this easy anation can be found in the structure of the planar complex, $[Ni(phenen)_2]^{2+}$. It is clear that there is enough space above and below it to permit the anation of counter ions since the bulky phenyl groups can occupy the equatorial positions on the plane containing two diamines. On the other hand, in the complexes with *i*-bn, *m*-bn, or *m*-stien, at least two of their substituents are forced to occupy the axial positions. Such a conformation generates a large steric hindrance, preventing the approach of the other ligands and stabilizing the Sp structure.

The data in Table 3 (especially the comparison of phenen with bn and stien) lead, finally, to an impression that, for the square planar-to-octahedral transformation to occur, the steric hindrance of the ligands should be intermediate; it can be neither too large, nor too small. Diamines satisfying the following two conditions seemingly favor the transformation: (i) The substituent groups in the diamine protruding on the equatorial plane should be so bulky that they can influence the strength of axial coordination to some extent. (ii) The substituent groups protruding toward the axial directions are unnecessary for the reaction; if they exist, they should be as small as possible (*e.g.* methyl).

Use of Alternating Current Impedance Method in Diagnosing Electrode Kinetics of $[Fe(CN)_6]^{4-/3-}$ Complex Confined to Protonated Poly(4-vinylpyridine) Film on Graphite Surfaces

Takeo OHSAKA, Toru USHIROGOUCHI, and Noboru OYAMA*

Department of Applied Chemistry for Resources, Tokyo University of Agriculture and Technology, Koganei, Tokyo 184

(Received June 26, 1985)

A "heterogeneous" electron-transfer process of $[Fe(CN)_6]^{4-/3-}$ redox couple, which was confined electrostatically to the protonated poly(4-vinylpyridine) (PVP) film, at basal-plane pyrolytic graphite (BPG) electrode/PVP film interfaces and a "homogeneous" charge-transport process within the PVP film were examined by alternating current (ac) impedance method. The obtained impedance loci were found to correspond to those expected for the electrochemical impedance expressed by "Randles's equivalent circuit." The relevant kinetic parameters (*i.e.*, the standard rate constant, k° and the cathodic transfer coefficient, α) of the electrode reaction, the apparent diffusion coefficients, D_{app}, for the "homogeneous" charge-transport within the film, the double-layer capacity, C_{dl} and the solution resistance, R_{soln} were determined at various concentrations of $[Fe(CN)]^{3-}$ in PVP coatings. The obtained D_{app}, k°, and α values were compared with those recently obtained by normal pulse voltammetry. In addition, an equivalent circuit model is given for the impedance obtained for the redox reaction on a BPG electrode coated with a protonated PVP confining $[Fe(CN)_6]^{4-/3-}$ couple.

Recently, there has been much attention focused on the physical, electrochemical, photoelectrochemical, and other kinds of behavior of "polymer-coated electrode."[1] A key question concerning the behavior involves the kinetics of two distinct charge (ion or electron)-transfer processes: One is the "homogeneous" charge-transfer process within polymer coatings and another is the "heterogeneous" electron-transfer process between electrode and redox species (or sites) confined to polymeric domains. In a series of recent papers,[2-9] we have reported the kinetic study of these both charge-transfer processes for various polymer-coated electrode systems by means of a normal pulse voltammetry (NPV). They involve the $[Mo(CN)_8]^{4-/3-}$, $[Fe(CN)_6]^{4-/3-}$, $[W(CN)_8]^{4-/3-}$, and $[IrCl_6]^{3-/2-}$-protonated poly(4-vinylpyridine) (PVP) systems,[2-5] the $[Fe(CN)_5]^{3-/2-}$–PVP system,[4] the $[Fe(CN)_6]^{4-/3-}$–poly(*N*,*N*-dimethylaniline) system,[8] the $MV^{2+/+}$-Nafion® system (MV^{2+}: *N*,*N*′-dimethyl-4,4′-bipyridinium)[6] the poly(xylylviologen)-poly(*p*-styrenesulfonate) (PSS) system,[6] and the poly(methylviologen) (PMV), PMV–Nafion and PMV–PSS systems.[6,7,9] Some interesting results were obtained: (i) the values of the standard rate constant (k°) of the heterogeneous electron-transfer process and the apparent diffusion coefficient (D_{app}) for the diffusion-like charge-transport process within the polymer films are smaller than those for the corresponding solution-phase redox species, (ii) the k° and D_{app} depend on the concentration (c_p) of the redox species (or site) confined to the polymer, (iii) the k° and D_{app} change with the polymers confining the redox species (or site) and/or the supporting electrolytes, (iv) the transfer coefficient (α) of the heterogeneous electron-transfer process changes with c_p in some cases, and (v) there are linear relationships between $\log k^\circ$ and $\log D_{app}$. These results, which have not been completely explained yet, are of specific interest to this work.

In the present study, in order to obtain further information about the above-mentioned points, we examine the kinetics of the heterogeneous electron-transfer process of the $[Fe(CN)_6]^{4-/3-}$ couple confined to the protonated PVP coating on a pyrolytic graphite electrode as well as the homogeneous charge-transport process within the coating by means of ac impedance method, which has been recently increasingly gaining interest for characterization of the polymer films deposited on electrode surfaces (*e.g.*, glow-discharge polymer films prepared on Pt electrode from 4-vinylpyridine,[10] electropolymerized polypyrrole film,[11-13] polyacetylene film[14]). The data obtained are compared with those previously obtained by NPV. In addition, an equivalent circuit model for the impedance obtained with the redox reaction on a BPG electrode which is coated with a protonated PVP confining $[Fe(CN)_6]^{4-/3-}$ couple is represented.

Experimental

Materials. The basal-plane pyrolytic graphite (BPG) (Union Carbide Co.) disk electrodes (area: 0.17 cm^2) were prepared and mounted into glass tube with heat-shrinkable polyolefin tube as previously described.[15] Poly(4-vinylpyridine) (PVP) (Borden Inc., Philadelphia, Pa) was recrystallized from methanol–diethyl ether. Its average molecular weight was 7.4×10^5. Potassium hexacyanoferrate(III), $K_3[Fe(CN)_6]$, was of reagent grade (Merck). Aqueous solutions were prepared from doubly distilled water. The supporting electrolyte solution was 0.2 M (1 M=1 mol dm^{-3}) CF_3COONa (Aldrich) adjusted to pH 1.5 with CF_3COOH. Other chemicals were reagent grade and were used as received.

Apparatus and Procedures. The electrochemical measurement was made with a conventional potentiostatic device with three electrodes. The working electrodes were BPG disk electrodes coated with PVP films to which

$[Fe(CN)_6]^{3-}$ ions were confined electrostatically at various concentrations.[2-8, 15] The counter electrode was a spiral platinum wire with a surface area of *ca.* 20 cm^2. The reference electrode was a sodium chloride saturated calomel electrode (SSCE). All potentials were measured and are reported with respect to SSCE. The working electrode was potentiostated at a given dc potential and then a sinusoidal perturbation signal with an amplitude (ΔE) of 5.0 mV was superimposed onto the dc potential.

The ac impedance measurements were performed with a Frequency Response Analyzer (Solartron Model 1250) and a Potentiostat/Galvanostat 2000 (Toho Technical Research, Tokyo) equipped with GPIB interface. Measurements were carried out in the potentiostatic mode. The impedance diagrams were plotted in the frequency range from 1 Hz to 65 kHz at 10 points per frequency decade. The impedance data were transferred to the laboratory's minicomputer (NEC, PC-9801E) where calculation and tabulation were performed, and then graphically presented on a plotter (Hewlett Packard 7470A) in the form of complex impedance plane plots of Z'' *vs.* Z' and/or in the form of complex admittance plane plots of Y''/ω *vs.* Y'/ω, where Z and Y are the complex impedance and the complex admittance, respectively and superscripts $'$ and $''$ on Z and Y denote in-phase and quadrature (*i.e.*, 90° out-of-phase) components, and ω is the angular frequency. The tabulated data were stored on a computer disk file ready for further analysis.

Coatings of PVP were prepared by micropipetting 1 to 10 μl aliquots of a methanolic stock solution of PVP (0.5%) onto freshly cleaved BPG electrodes and allowing the solvent to evaporate.[2-5, 15, 16] Electrostatic binding of $[Fe(CN)_6]^{3-}$ ions to the protonated PVP coatings resulted from exposure of the coated electrodes to 0.2—10 mM solutions of $K_3[Fe(CN)_6]$ in a 0.2 M CF_3COONa solution (pH 1.5) for periods of 1 to 30 min depending on the desired quantity of incorporated $[Fe(CN)_6]^{3-}$. The quantities (coverage values) of $[Fe(CN)_6]^{3-}$ incorporated into the protonated PVP coatings were determined by transferring the electrodes into solutions containing only supporting electrolyte (0.2 M CF_3COONa-CF_3COOH (pH 1.5)) and integrating the current-time curves obtained when the potential was stepped to a value well beyond the voltammetric peak potential and held there until the rate of charge accumulation decreased to background levels. The coverage value was obtained in units of mol cm^{-2} and then the molar concentration (in units of mol cm^{-3}) was calculated by using the thickness of the PVP film estimated by assuming that the density of the wet PVP is 0.65 g cm^{-3}.[16]

Nitrogen gas was passed through the solutions to remove the dissolved oxygen before the measurements and over the solutions during the measurements. Experiments were conducted at 25 °C.

Results and Discussion

Impedance Measurements of the $[Fe(CN)_6]^{4-/3-}$-protonated PVP System. Figure 1 shows the typical cyclic voltammogram for the $[Fe(CN)_6]^{4-/3-}$ couple confined to the protonated PVP coating on a BPG electrode in a 0.2 M CF_3COONa solution (pH 1.5). The wave shape is similar to that for the solution-phase $[Fe(CN)_6]^{4-/3-}$ couple at a bare electrode, that is, the wave is diffusion-like, with broad peaks and a diffusion tail. The peak height and wave shape of the cyclic voltammogram remained substantially unchanged after 30 min when the electrode potential was scanned between −0.2 and 0.8 V *vs.* SSCE at 100 mV s^{-1}. The survival of the electrostatically bound $[Fe(CN)_6]^{4-/3-}$ couple for such long periods allowed us to carry out ac impedance measurements of this system.

In Fig. 2 are shown typical Cole-Cole plots (*i.e.*, plots of the quadrature component of the ac impedance *vs.* its real component) for the redox reaction of the $[Fe(CN)_6]^{4-/3-}$ couple confined to the protonated PVP film on BPG electrodes. The data in Fig. 2 show the complex plane impedance plots for the redox reaction of the $[Fe(CN)_6]^{4-/3-}$ couple at each formal redox potential. The formal redox potential for the $[Fe(CN)_6]^{4-/3-}$ confined to the protonated PVP film, which was estimated as the average of the anodic and cathodic peak potentials of the cyclic voltammograms (such as those shown in Fig. 1) for the redox reaction of the $[Fe(CN)_6]^{4-/3-}$ couple confined to the protonated PVP film, changed with the $[Fe(CN)_6]^{3-}$ concentration. Both of these curves were obtained at each formal redox potential, curve A taken at 0.275 V *vs.* SSCE and curve B at 0.265 V *vs.* SSCE. It can be seen that the impedance loci of these curves correspond to those expected for the electrochemical impedance represented by the well-known "Randles's equivalent circuit" (shown in Fig. 3).[17] The double-layer capacity C_{dl}, in parallel with the electron-transfer resistance R_{et}, gives rise to the circular part of the diagram (line I in Fig. 2). A straight line of unity slope (line II) corresponds to

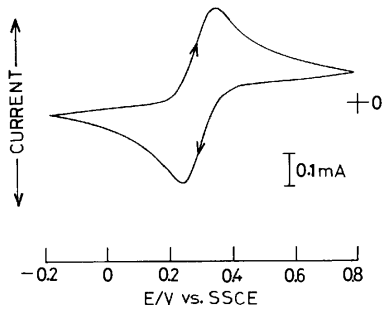

Fig. 1. A typical cyclic voltammogram for the oxidation-reduction of the $[Fe(CN)_6]^{4-/3-}$ redox couple confined to the protonated PVP film on a BPG electrode in a 0.2 M CF_3COONa solution (pH 1.5). Surface concentration of pyridine as PVP, Γ_{PVP}: 4.6×10^{-7} mol cm^{-2}. The concentration of $[Fe(CN)_6]^{3-}$ confined to protonated PVP film (thickness: 7.1×10^{-5} cm): 5.5×10^{-4} mol cm^{-3}. Scan rate: 100 mVs^{-1}.

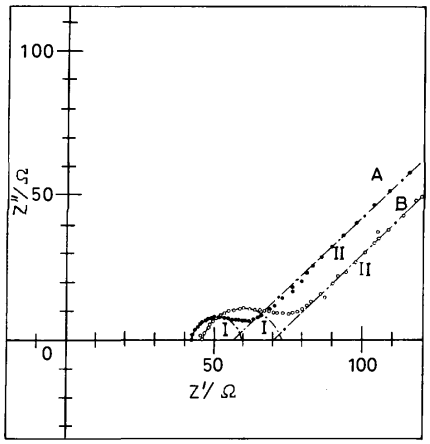

Fig. 2. Typical Cole-Cole plots for the redox reaction of the $[Fe(CN)_6]^{4-/3-}$ couple confined to the protonated PVP film on BPG electrodes in a 0.2 M CF_3COONa solution (pH 1.5). In both cases (A and B), the thicknesses of the PVP films were 8.7×10^{-5} cm and the surface concentration (Γ_{PVP}) of the pyridine site of PVP was 5.6×10^{-7} mol cm^{-2}. The concentrations (c_p) of $[Fe(CN)_6]^{3-}$ in PVP films were (A) 1.1×10^{-3} and (B) 4.1×10^{-4} mol cm^{-3}. The molar ratios of incorporated $[Fe(CN)_6]^{3-}$ to protonated pyridine site of PVP ($\Gamma_{[Fe(CN)_6]^{3-}}/\Gamma_{PVP}$) were (A) 0.17 and (B) 0.069. The dc potentails were set at (A) 0.275 and (B) 0.265 V *vs.* SSCE which were formal redox potentials in cases A and B. The amplitude of an imposed ac voltage was 5.0 mV.

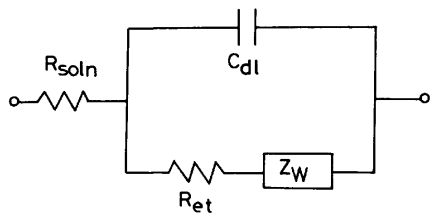

Fig. 3. Randles's equivalent circuit.
R_{soln} denotes solution resistance, R_{et} electron-transfer resistance, C_{dl} double-layer capacity, and Z_w Warburg diffusional impedance.

the Warburg diffusional impedance Z_w which arises as a consequence of diffusional polarization resulting from an imposed ac voltage.[18] Strictly speaking, the impedance plots shown in Fig. 2 are not perfectly semicircles. The center of the semicircle lies slightly below the real axis. This problem will be in detail discussed in the next section. As a first approximation, the impedance loci obtained may be expressed by the Randles's equivalent circuit. Thus, the kinetic parameters concerning the heterogeneous electron-transfer process and homogeneous charge-transport process (*i.e.*, the standard rate constant k° and the transfer coefficient α of heterogeneous electron-transfer and the apparent diffusion coefficient D_{app} for the charge-transport within polymer coatings) are estimated on the basis of the conventional analysis[18,19] of the complex impedance plane plots such as those shown in Fig. 2. According to the Randles's equivalent circuit shown in Fig. 3, the diameter of the semicircle equals the heterogeneous electron-transfer resistance R_{et}, while the double-layer capacity C_{dl} can be calculated from the angular frequency ω_{max} which corresponds to the maximum of the semicircle by using the relation $\omega_{max}R_{et}C_{dl}=1$ with $\omega=2\pi f$. From the R_{et} obtained, the k° can be calculated. The solution resistance R_{soln} is obtained from the high-frequency intercept with the real axis. Further, the diffusion coefficient can be obtained from the intercept of the line II with the real axis by knowing R_{soln} and C_{dl} and assuming that the diffusion coefficients for $[Fe(CN)_6]^{4-}$ and $[Fe(CN)_6]^{3-}$ are the same. It is apparent from curves A and B that the R_{soln} and R_{et} vary with the concentration of $[Fe(CN)_6]^{3-}$ in the PVP coatings. The values of R_{soln}, D_{app}, k°, and C_{dl} were estimated by the above-mentioned procedures and the data obtained are summarized below. The values of α were estimated from the analysis of the phase angle ϕ as mentioned below. By the similar analysis of ϕ, the k° values were also obtained.

The phase angle ϕ for the simple electrode process, $Ox+ne\rightleftarrows Red$, which is of great interest as a source of kinetic information about the heterogeneous electron-transfer reaction, can be expressed as follows:[18,19]

$$\cot\phi = 1 + \frac{(2D_{Ox}^{1-\alpha}D_{Red}^{\alpha}\omega)^{1/2}}{k^\circ}\cdot\left[\frac{1}{e^{(1-\alpha)\xi}(1+e^{-\xi})}\right] \quad (1)$$

with

$$\xi = \frac{nF}{RT}(E_{dc}-E_{1/2}), \quad (2)$$

where D_{Ox} and D_{Red} are the diffusion coefficients of Ox and Red, respectively, α is the cathodic transfer coefficient, E_{dc} is the applied dc potential, $E_{1/2}$ is the reversible half-wave potential of the Ox/Red couple, n is the number of electrons involved in the heterogeneous electron-transfer reaction, F is the Faraday constant, R is the gas constant, and T is the absolute temperature. The bracketed factor indicates that cot ϕ depends on the dc potential. That is, at large negative value of ξ, cot ϕ is close to 1 (*i.e.*, when $\xi\rightarrow-\infty$, cot $\phi\rightarrow1$). As ξ increases, cot ϕ increases and passes the maximum point. With further increase in ξ, cot ϕ decreases and at large positive value of ξ cot ϕ approaches to 1 (*i.e.*, when $\xi\rightarrow+\infty$, cot $\phi\rightarrow1$). The dc potential at which cot ϕ is a maximum is given by

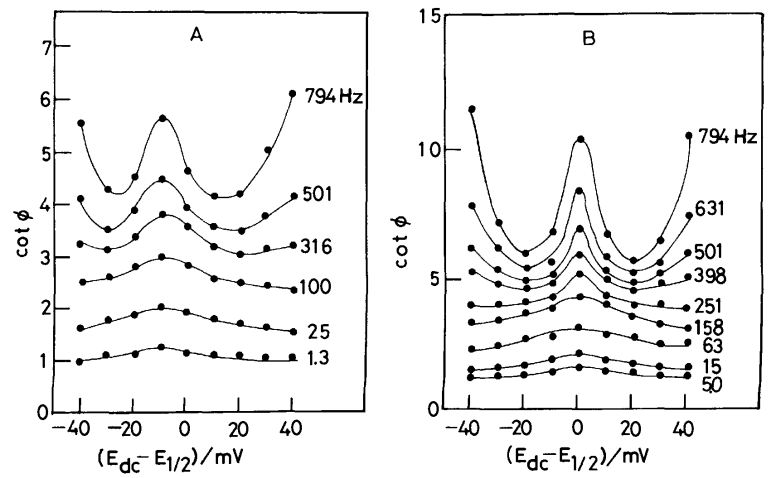

Fig. 4. Dependence of cot ϕ on E_{dc}.
The plots A and B correspond to cases A and B, respectively, shown in Fig. 2. The experimental conditions are the same as in Fig. 2. The numbers on respective plots indicate angular frequencies.

$$E_{dc} = E_{1/2} + \frac{RT}{nF} \ln \frac{\alpha}{1-\alpha}. \quad (3)$$

Thus, this maximum point is independent of nearly all experimental variables, for example, the amplitude of the applied ac voltage ΔE, the electrode area A and the angular frequency ω. The difference between $E_{1/2}$ and the potential of maximum cot ϕ provides transfer coefficient α. A typical example of such behavior is shown in Fig. 4. Note that the potential of maximum cot ϕ is independent of frequency, as predicted above. In the case of Fig. 4B (corresponding to curve B (c_p: 4.1×10^{-4} mol cm^{-3}) in Fig. 2), the maximum point is at $E_{dc}-E_{1/2}=0$ and thus α is 0.5. Similarly, in the case of Fig. 4A which corresponds to curve A (c_p: 1.1×10^{-3} mol cm^{-3}) in Fig. 2, the α value is estimated as 0.41. The dependence of α on c_p has been previously observed for the same redox system[4] as that examined here and for the other redox polymer-coated electrode systems.[2,3,5-9] The previous studies were conducted by NPV. The present data of α were in fair agreement with those obtained by NPV.

Further, it is also apparent from Fig. 4 that at higher frequencies, cot ϕ tends to increase as the value of $E_{dc}-E_{1/2}$ becomes larger. The reason for this behavior is not clear, but this may be probably due to the variation of C_{dl} in the dc potential region examined (see Fig. 7).

As can be seen from Eq. 1, plots of cot ϕ *vs.* $\omega^{1/2}$ yield k°, once α is known from the potential of maximum cot ϕ and the diffusion coefficients are known from the intercept of line II with the real axis or other measurements. Especially, at $E_{dc}=E_{1/2}$, $\xi=0$, and thus Eq. 1 can be reduced to Eq. 4

Typical examples of $[\cot\phi]_{E_{1/2}}$ *vs.* $\omega^{1/2}$ plots are shown in Fig. 5. As expected from Eq. 4, the straight

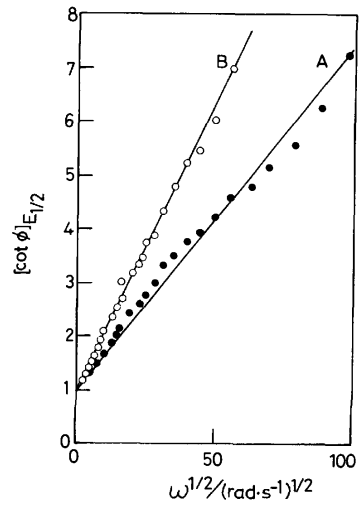

Fig. 5. Plots of $[\cot\phi]_{E_{1/2}}$ *vs.* $\omega^{1/2}$.
The plots A and B correspond to cases A and B, respectively, shown in Fig. 2. The experimental conditions and the symbols are the same as in Fig. 2. [cot $\phi]_{E_{1/2}}$ indicates cot ϕ at $E=E_{1/2}$.

$$[\cot\phi]_{E_{1/2}} = 1 + \left(\frac{D_{Ox}^{1-\alpha} D_{Red}^{\alpha}}{2}\right)^{1/2} \cdot \frac{\omega^{1/2}}{k^\circ}. \quad (4)$$

lines with the intercept of 1 on the ordinate can be obtained. The different slopes of these straight lines are ascribable to the different k°'s and/or D_{app}'s.

The data obtained for k° and D_{app} at the different concentrations of $[Fe(CN)_6]^{3-}$ in PVP coating are summarized in Fig. 6, where the data obtained by NPV are also shown for comparison. It can be seen from this figure that the k° values obtained from the R_{et} values by ac impedance method are almost equal to those obtained by NPV, while the D_{app} values are by about 1 to 2 orders of magnitude smaller than those obtained by NPV. The observed differences

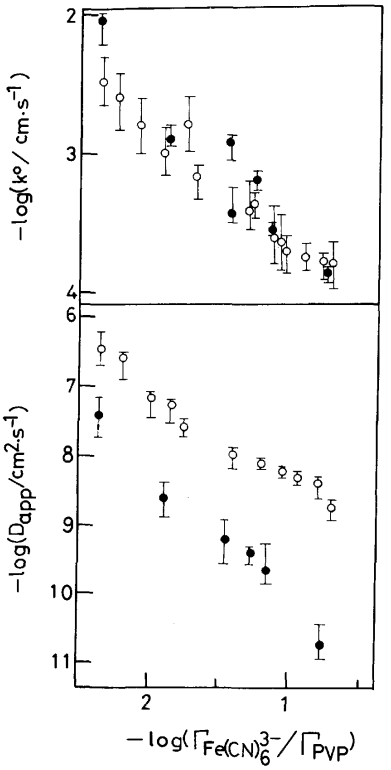

Fig. 6. Plots of the logarithms of D_{app} and k° *vs.* the logarithm of the molar ratio of incorporated $[Fe(CN)_6]^{3-}$ to the protonated pyridine site of PVP, $\Gamma_{[Fe(CN)_6]^{3-}}/\Gamma_{PVP}$. The thicknesses of the PVP films were 8.7×10^{-5} cm. Γ_{PVP}: 5.6×10^{-7} mol cm^{-2}. Supporting electrolyte: 0.2 M CF_3COONa–CF_3COOH (pH 1.5). The closed and open circles indicate the data obtained by ac impedance method and normal pulse voltammetry, respectively.

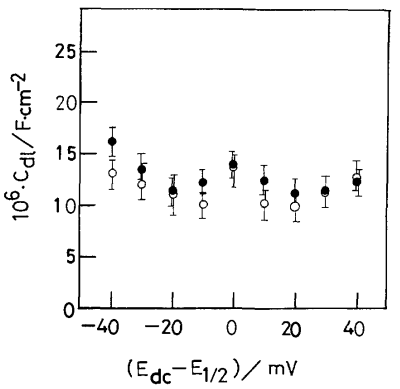

Fig. 7. Dependence of C_{dl} on $(E_{dc}-E_{1/2})$. c_p: (●) 1.1×10^{-3} and (○) 4.1×10^{-4} mol cm^{-3}. Other experimental conditions are the same as in Fig. 6.

between the D_{app} values obtained by the two methods seem not to be due to only the errors in the D_{app} estimation by ac impedance method, although the determination of D_{app} by ac impedance method is less accurate than the k° estimation. At the present stage,

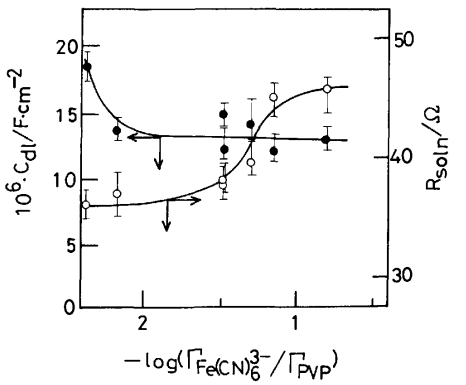

Fig. 8. Dependences of C_{dl} and R_{soln} on $-\log(\Gamma_{[Fe(CN)_6]^{3-}}/\Gamma_{PVP})$. The experimental conditions are the same as in Fig. 6. The values of C_{dl} and R_{soln} were obtained from the complex impedance loci such as those shown in Fig. 2 which were measured at the respective formal redox potentials, depending on $\Gamma_{[Fe(CN)_6]^{3-}}/\Gamma_{PVP}$.

we have no reasonable explanation for such differences in D_{app}'s, but this may be considered to be ascribed to the different time windows of these two methods in the D_{app} estimation, *i.e.*, the time window of ac impedance method is *ca.* one order of magnitude shorter than that of NPV. It is also apparent that the k° and D_{app} depend on the concentration (c_p) of $[Fe(CN)_6]^{3-}$ in polymer coatings, irrespective of the methods used. Such concentration dependences of k° and D_{app} may be understood by the same idea as that used previously:[2-6] As c_p increases, the extent of electrostatic cross-linking of PVP polymer by electrostatic force between multiply-charged anion (*i.e.*, $[Fe(CN)_6]^{3-}$) and positively charged protonated pyridine sites of PVP becomes higher and as a result the physical motion of $[Fe(CN)_6]^{3-}$ and/or supporting electrolytic ions through the film becomes more difficult.

Figure 7 shows the dependence of the double-layer capacity C_{dl} on the dc potential E_{dc}. It is obvious that C_{dl} depends on E_{dc} in the examined range of the potential. Such dependence of C_{dl} on E_{dc} seems to be almost the same irrespective of c_p. The values of C_{dl} are almost the same as those obtained with a bare BPG electrode in the same supporting electrolytic solution as that used here. Figure 8 shows the dependence of C_{dl} and the solution resistance (R_{soln}) upon c_p. The C_{dl} tends to decrease with an increase in c_p, while the R_{soln} increases with increasing c_p.

Equivalent Circuit Model for the Redox Reaction of $[Fe(CN)_6]^{4-/3-}$ Couple Confined to the Protonated PVP Coatings on BPG Electrodes. In the previous section, the impedance loci for the redox reaction of $[Fe(CN)_6]^{4-/3-}$ couple confined to the PVP coating on BPG electrodes were analyzed by assuming that the equivalent circuit for this redox reaction system can be expressed by the Randles's equivalent circuit (Fig.

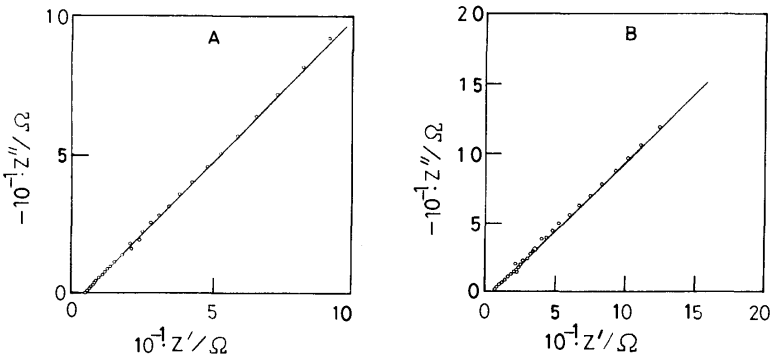

Fig. 9. The complex impedance plane plots finally obtained according to the procedure of De Levie *et al.*
The plots A and B correspond to cases A and B, respectively, shown in Fig. 2.

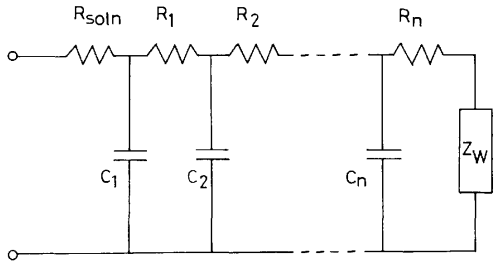

Fig. 10. The transmission line equivalent circuit obtained for the redox reaction of the $[Fe(CN)_6]^{4-/3-}$ couple confined to the protonated PVP film on BPG electrodes.
For the case A in Fig. 2, $R_{soln}=42\,\Omega$, $R_1=10\,\Omega$, $R_2=3\,\Omega$, $R_3=2\,\Omega$, $R_4=3\,\Omega$, $C_1=1.25\,\mu F$, $C_2=2\,\mu F$, $C_3=3\,\mu F$, and $C_4=6\,\mu F$, and for the case B in Fig. 2, $R_{soln}=45\,\Omega$, $R_1=14\,\Omega$, $R_2=7\,\Omega$, $R_3=5\,\Omega$, $C_1=1\,\mu F$, $C_2=1.7\,\mu F$, and $C_3=6\,\mu F$.

3). To elucidate equivalent circuit model expressing more exactly the actual redox reaction, the following procedure, originally suggested by De Levie *et al.*[20,21] for the analysis of ac impedance data, was used. The complex impedance representation such as that shown in Fig. 2 is first made and the frequency-independent resistance component R (in this case, solution resistance R_{soln}) can be obtained as an intercept on the abscissa by extrapolation of the impedance locus to infinite frequency. After subtraction of R_{soln}, the remaining impedance is transformed into an admittance, devided by ω, and the frequency-independent capacitance component C was determined as an intercept on the ordinate (*i.e.*, Y''/ω axis) by extrapolating the admittance locus to infinite frequency. A series of such procedures are repeated until the 45° straight line representing the Warburg impedance in the complex impedance plane can be obtained. The finally obtained complex plane impedance plots are shown in Fig. 9, and the equivalent circuit so obtained is shown in Fig. 10. The obtained equivalent circuit is well known as the so-called "transmission line equivalent circuit (TL equivalent circuit)."[22] The TL equivalent circuit of this type has been previously presented for the impedance for a porous electrode.[22-24] The similar equivalent circuit has been presented for electrodes where homogeneous or heterogeneous chemical processes are coupled to the heterogeneous electron-transfer step and also where adsorption of reactants or products or both occurs.[22] The obtainment of TL equivalent circuit can be considered to be due to a result of an "impedance dispersion."[25-28] This phenomenon, which is explained by the distribution of the time constants of the electrode processes, has been believed to be caused by (i) the influence of the microscopic roughness of the electrode surface, (ii) the selective adsorption phenomena, (iii) the non-uniform distribution of the current density on the surface, and so on. The same idea seems to be applicable to the present system. In order to obtain further information concerning this point, the kinetic study of electrode processes by ac impedance method is now extended to other polymer-coated electrode systems.

(Received July 13, 1985)

In the electrically-heated carbon-furnace atomic-absorption spectrometry of selenium and mercury, inter-elemental interference is present between the two elements. Mercury has no effect on selenium sensitivity in a simple inorganic selenium solution. When, however, the solution contains organic materials such as 0.5% albumin, the selenium sensitivity is decreased. The presence of mercury in addition to the organic material further decreases the sensitivity to about a half of that of a solution containing only selenium and albumin. The addition of 0.94 mmol dm^{-3} palladium ion completely removes the negative interferences due to organic materials and mercury. On the other hand, in mercury determination the presence of organic materials also decreases the mercury sensitivity. The addition of palladium, in contrast to selenium determination, enhances the mercury sensitivity about 50 times, independent of whether or not the solution contains organic materials.

It is known that some dolphins accumulate mercury and selenium in their livers at concentrations as high as 1.27 mmol dm^{-3}.[1,2] The chemical forms and the roles of these elements in livers are, however, still unknown. The concentration of the elements range from as low as 0.01 mmol dm^{-3} to more than 1.27 mmol dm^{-3}. As for the concentrations of these elements, it has been reported that the mercury concentration increases with the increase in the selenium concentration. However, there is no definite conclusion as to the cause of the accumulation of the two elements. This accumulation phenomenon is especially interesting from the viewpoints of the biochemical role of selenium in mammals, the toxicological effect of mercury, and the biochemical relation between the two elements.[3,4] Although the importance of selenium as an essential trace element is widely recognized today, no intensive study seems to have been carried out concerning the chemical forms and functions of these elements in dolphin livers. This is probably a result of the lack of a highly sensitive analytical method for these elements. Recently, the present authors have reported that the addition of palladium greatly enhances the sensitivities of both selenium and mercury, while removing interference due to organic materials in electrically-heated carbon-furnace atomic-absorption spectrometry.[5,6] In the present paper, inter-elemental interference between the two elements and the effects of organic materials on the sensitivities of the two elements in the palladium-addition method were studied. Although interference due to organic materials was investigated in previous studies[5,6] for both elements when they exist independently, it was found in the present study that the interference is completely different when the two elements co-exist in a solution. The correct estimation of such interference is indispensable to an accurate analysis of such samples as dolphin livers.

As for the palladium-addition method for selenium determination, Taga *et al.*[7] and S. X.-Quan *et al.*[8] have reported that palladium slightly enhances the sensitivity. However, our results show that the effect is remarkable and by far larger than has been reported previously. Moreover, there has been no report concerning the inter-elemental interference between selenium and mercury.

Experimental

Equipment and Measurement Conditions. A Shimadzu AA-640-13 atomic-absorption spectrometer equipped with a Shimadzu GFA-4 graphite-furnace atomizer was used. A selenium wavelength of 196.0 nm and a mercury wavelength of 253.7 nm were used. The measurement conditions were as follows; Se: dry 150 °C, 40 s, ramp mode; ash 500 °C, 60 s, ramp mode; atomize 2100 °C, 6 s, step mode; Hg: dry 150 °C, 40 s, ramp mode; ash 400 °C, 60 s, ramp mode; atomize 2000 °C, 6 s, step mode.

Reagents and Samples. Standard solutions of mercury ($HgCl_2$), selenium (Na_2SeO_3), and palladium ($PdCl_2$) were prepared by diluting a commercial 1000 mg dm^{-3} solution obtained from the Wako Co. Bovine albumin and methionine and selenomethionine from the Sigma Co. were used.

An extract solution of dolphin livers was prepared by extracting a homogenate of the livers with a 0.2 M ammonium acetate buffer (pH 7). The solution was then submitted to ultrafiltration with a YM-2 filter, Amicon Co.; the filtrate (M. W. less than 1000) was used for analysis. When comparing selenium results for undecomposed and acid-decomposed extract solutions, the filtrate was decomposed by adding HNO_3, H_2O_2, and $HClO_4$.

Procedure. A palladium solution of 9.4 mmol dm^{-3} was added to a sample solution before measurement so that the solution contained palladium at 0.94 mmol dm^{-3}.

Thirty mm^3 of the solution was then injected into a carbon furnace with an Eppendorf micropipette.

Results and Discussion

Effect of Palladium Addition for Sensitivity Enhancements of Selenium and Mercury in Biological Samples. The effect of palladium addition on selenium sensitivity was investigated; the results are shown in Fig. 1(A). Palladium neither enhances nor decreases the sensitivity for selenium when selenium exists in a solution as inorganic selenite. When selenium is added to an extract solution of dolphin livers, however, the selenium sensitivity is reduced to less than a twentieth; this negative interference is due to organic materials in the solution. However, the sensitivity is completely recovered to that of a simple inorganic selenium solution when 0.94 mmol dm^{-3} of palladium is added to the extract solution. The effect is remarkable, and it should be noted that the intercept of the calibration curve for the Pd-added extract solution corresponds to the selenium originally contained in the solution. In other words, selenium in such biological samples can be determined by the standard addition method with the aid of palladium addition.

On the other hand, in the mercury determination shown in Fig. 1 (B), palladium addition enhances the sensitivity about 50 times, even in a simple inorganic solution. Mercury sensitivity in an extract solution is so much decreased that no signal is observed. However, with the addition of palladium, mercury sensitivity is recovered to about a half of that of a simple inorganic mercury solution with palladium added.

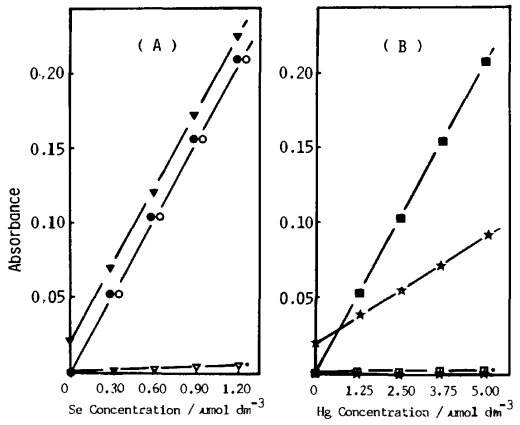

Fig. 1. Effect of palladium addition on selenium and mercury sensitivities.
(A) ○: An aqueous solution, ●: ○+Pd 0.94 mmol dm^{-3}, ▽: an extract solution of dolphin's livers, ▼: ▽+Pd 0.94 mmol dm^{-3}, (B) □: An aqueous solution, ■: □+Pd 0.94 mmol dm^{-3}, ☆: an extract solution of dolphin's livers, ★: ☆+Pd 0.94 mmol dm^{-3}.

Effect of Organic Materials on the Palladium-enhancement Effect. In order to study the effect of organic materials in the palladium-addition method, albumin was added to a selenium (1.27 μmol dm^{-3}) or mercury (9.97 μmol dm^{-3}) solution at various concentrations and the sensitivities were compared. Figure 2 clearly exhibits the effect. The existence of organic material, even at concentrations of less than 1%, drastically decreases the sensitivities of both selenium and mercury. The addition of palladium, however, completely restores the sensitivity to that of a solution without organic materials, even when albumin is present at concentrations of up to 2.0% during selenium determination. On the other hand, mercury sensitivity is increased by palladium addition at any albumin concentration, as is shown in Fig. 2.

Effect of Mercury in the Palladium-addition Method of Selenium. For the accurate determinations of mercury and selenium in extract solutions of dolphin's livers, inter-elemental effects between the two elements must be studied, especially with regard to the present palladium-addition method. The effect of palladium addition in the selenium analysis of a solution containing mercury is shown in Fig. 3. As Fig. 3 shows, the existence of mercury or the addition of palladium has no effect on the selenium sensitivity in a simple inorganic selenium solution. However, when the solution contains albumin (0.5%), the selenium sensitivity is decreased to about one-fifth of that of a simple inorganic selenium solution. The addition of palladium to a solution containing both selenium and organic materials restores the selenium sensitivity to that of a simple inorganic solution. Figure 3 also shows that the presence of mercury in addition to albumin further decreases the selenium sensitivity to about a half of that of a selenium solution containing only albumin.

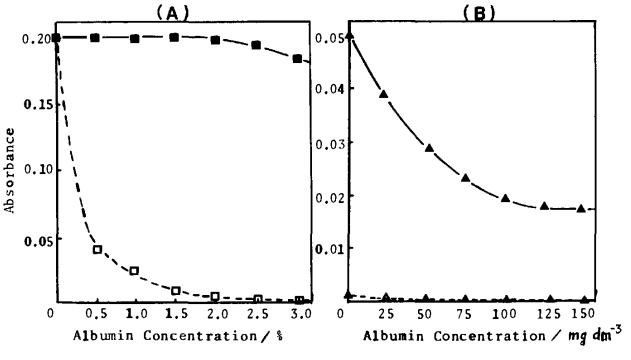

Fig. 2. Interference due to albumin in selenium and mercury determinations and effect of palladium addition for removal of the interference and enhancement of the sensitivity.

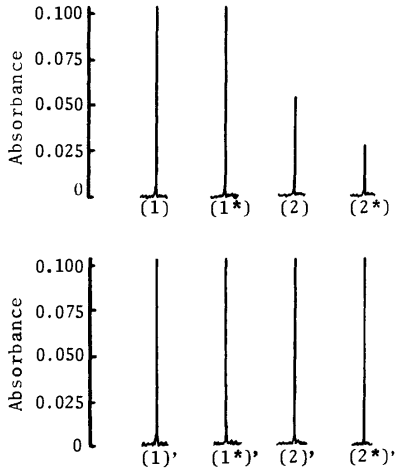

Fig. 4. Selenium sensitivity dependence on the chemical form and effect of palladium addition.
(1): Selenite (Se 0.63 μmol dm^{-3}), (1*): (1)+Hg 0.63 μmol dm^{-3}, (2): selenomethionine (Se 0.64 μmol dm^{-3}), (2*): (2)+Hg 0.63 μmol dm^{-3}, (1)': (1)+Pd 0.94 mmol dm^{-3}, (1*)': (1*)+Pd 0.94 mmol dm^{-3}, (2)': (2)+Pd 0.94 mmol dm^{-3}, (2*)': (2*)+Pd 0.94 mmol dm^{-3}.

The addition of palladium to such a solution completely restores the sensitivity. All the severe negative interferences due to organic materials and/or mercury can be completely removed by palladium addition, as is shown in (B) of Fig. 3.

In order to examine whether or not the selenium sensitivity is dependent on the chemical form, the sensitivities of selenite and selenomethionine solutions were compared. The effects of palladium addition were also compared for the two solutions; the results are shown in Fig. 4. It should be noted that the selenium sensitivity of selenomethionine is less than a half of that of a selenite solution. The presence of 0.63 μmol dm^{-3} of mercury does not affect the selenium sensitivity in a selenite solution. However, the sensitivity is decreased to nearly a half when selenium exists as selenomethionine. Considering the results of Figs. 3 and 4 together, it can be inferred that mercury decreases the selenium sensitivity only in organic-matrix solutions. "Organic matrix" means that either the solution contains organic substances in addition to inorganic selenium or selenium is contained as organic selenium molecules. The addition of palladium completely restores the sensitivity in any organic-matrix solution with or without mercury.

Effect of Selenium in the Palladium-addition Method of Mercury. It was found that selenium additionally enhances mercury sensitivity when added together with palladium. Figure 5 shows the dependence of the mercury sensitivity on the selenium concentration in a solution to which

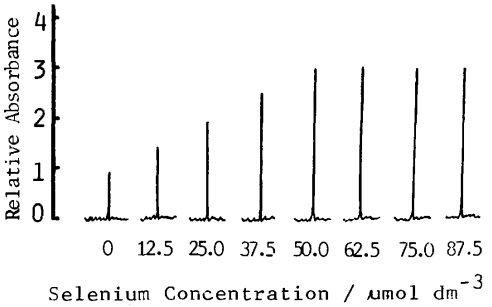

Fig. 5. Enhancement effect of selenium in palladium addition method of mercury. The solution contains Hg 0.05 mmol dm^{-3} and Pd 0.94 mmol dm^{-3}.

0.94 mmol dm^{-3} of palladium has already been added. The mercury sensitivity is linearly increased with an increase in the selenium concentration until it reaches 50 μmol dm^{-3}. At selenium concentrations higher than 50 μmol dm^{-3}, however, no more sensitivity enhancement is observed. It should be noted that 50 μmol dm^{-3} of selenium corresponds to a 1:1 molar ratio of Se and Hg; this suggests that the sensitivity enhancement may result from a 1:1 complex formation between Se and Hg, a complex which is retained in a carbon furnace up to higher temperatures than when only mercury is present. A similar enhancement effect for mercury by sulphur addition has been reported by Ediger.[9] The effect is believed to be due to the formation of mercury sulphide.

Effect of Palladium Addition for Mercury Determination in Solutions of Various Matrices. The effects

Table 1. Comparison of selenium determinations for undecomposed and acid-decomposed extract solutions of dolphin livers (mmol dm^{-3})

Sample[a)]	Undecomposed solution	Acid-decomposed solution
1	26.8	24.1
2	14.1	17.1
3	16.4	15.2
4	9.5	10.3

a) One g of liver was extracted with a 10 cm^3 solution. The Extract solutions were as follows: 1, 1 mol dm^{-3} phosphate buffer (pH 7); 2, 1 mol dm^{-3}, phosphate buffer (pH 7) +1% SDS; 3, 1% NaCl; 4, 1 mol dm^{-3} phosphate buffer (pH 7) +2% Triton.

of selenium compounds, organic materials, and palladium on the mercury sensitivity are summarized in Fig. 6. Figure 6 (A) shows that the mercury sensitivity is reduced to almost a half of that of a simple mercury solution when methionine or albumin is present. On the contrary, the presence of selenomethionine increases the sensitivity about 1.5 times. When inorganic selenium is added to the solution of (A) in Fig. 6, the sensitivity is increased about 3 times. The fact that the sensitivities of (2) and (3) in Fig. 6 (B) are almost equal to that of (2*) suggests that the enhancement effect of selenium is independent of its chemical form. Although selenium enhances the mercury sensitivity in organic-matrix solutions, it cannot completely remove the negative interference due to organic materials, as is shown in Fig. 6 (B). Figure 6 (C) shows the effect of palladium. The addition of palladium enhances the mercury sensitivity about 50 times. This enhancement ratio is independent of whether the solution contains organic materials or selenium. The addition of both selenium and palladium enhances the mercury sensitivity about 150 times. This enhancement ratio is equal to the sum of the enhancement ratios of the two elements. Table 1 compares the selenium determinations obtained for undecomposed and acid-decomposed extract solutions of dolphin livers. All the measurements were done by means of the palladium-addition method; the results show that the present palladium-addition method makes possible the direct determination of selenium in an undecomposed solution containing organic materials.

The inter-elemental effects of selenium and mercury may be summarized as follows. Mercury decreases the selenium sensitivity, whereas selenium enhances the mercury sensitivity. The presence of organic materials decreases the sensitivities for both elements. The addition of palladium to a selenium solution

with an organic matrix completely removes the negative interferences caused by organic materials and mercury, whereas the addition of palladium enhances the mercury sensitivity in solutions with both inorganic and organic matrices.

A Synthesis of a Versatile Intermediate Leading to Thienamycin Analogs[1)]

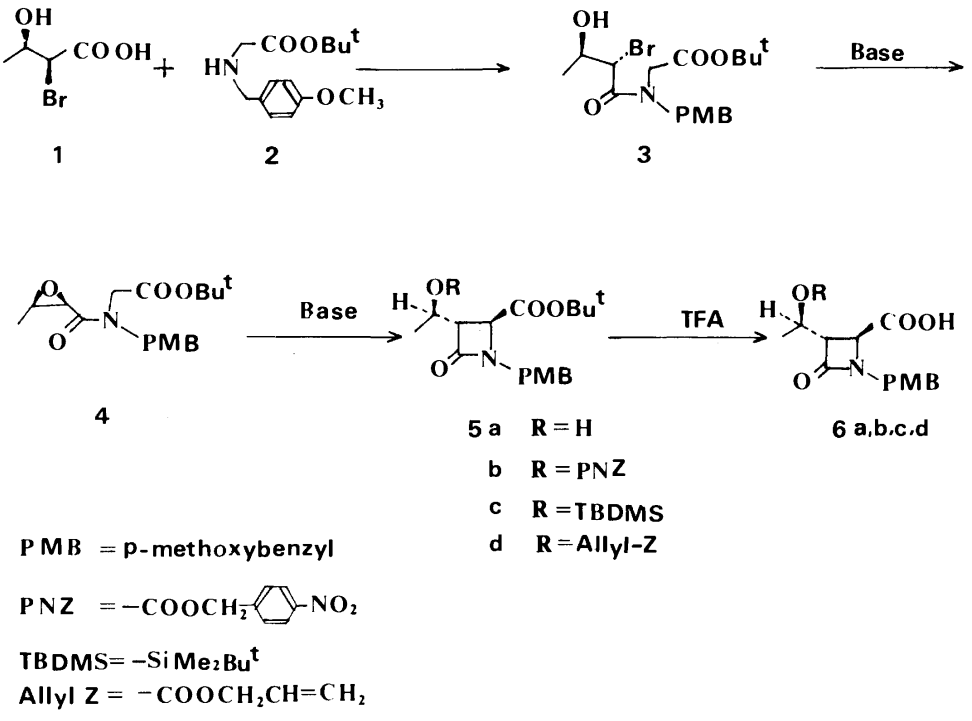
Hiroshi MARUYAMA,*,† Masao SHIOZAKI, and Tetsuo HIRAOKA
Process Development Laboratories† and Chemical Research Laboratories, Sankyo Co., Ltd., Hiromachi, Shinagawa-ku, Tokyo 140
(Received May 8, 1985)

L-Threonine was converted to a versatile azetidinone derivative stereospecifically in 3 steps. This azetidinone was further transformed to (3*S*,4*R*)-3-[(*R*)-1-hydroxyethyl]-1-(4-methoxybenzyl)-4-[(phenylthio)-carbonylmethyl]-2-azetidinone (*S*-Phenyl thioester), a key intermediate for the synthesis of thienamycin and it's biologically active analogs. Since the thiol part of this *S*-phenyl thioester can be exchanged easily with other complex or useful thiols under mild conditions, important *S*-thioester precursors for the production of carbapenem analogs were obtained in high yield.

After the discovery of thienamycin,[2)] various analogs of 1-carbapenem antibiotics have been found and attracted many organic chemists to synthesize these compounds, as a result of which several synthetic methods have been reported.[3)] Recently the cyclization reaction for the formation of the carbapenem nucleus has been disclosed utilizing the trialkoxyphosphoranylidene-substituted *S*-thioester reaction,[4)] which is one of a number of versatile methods for the synthesis of carbapenem analogs. Thus the *S*-thioester of 4-carboxymethyl-2-azetidinone became an important intermediate in this route.

We have reported stereocontrolled syntheses of chiral and racemic intermediates (2-azetidinones) for thienamycin from D-*allo*-threonine,[5b)] *trans*-crotonic acid and L-threonine.[5)] This report describes the stereoselective synthesis of a precursor for thienamycin analogs (*S*-thioesters) from L-threonine by a stereocontrolled method.

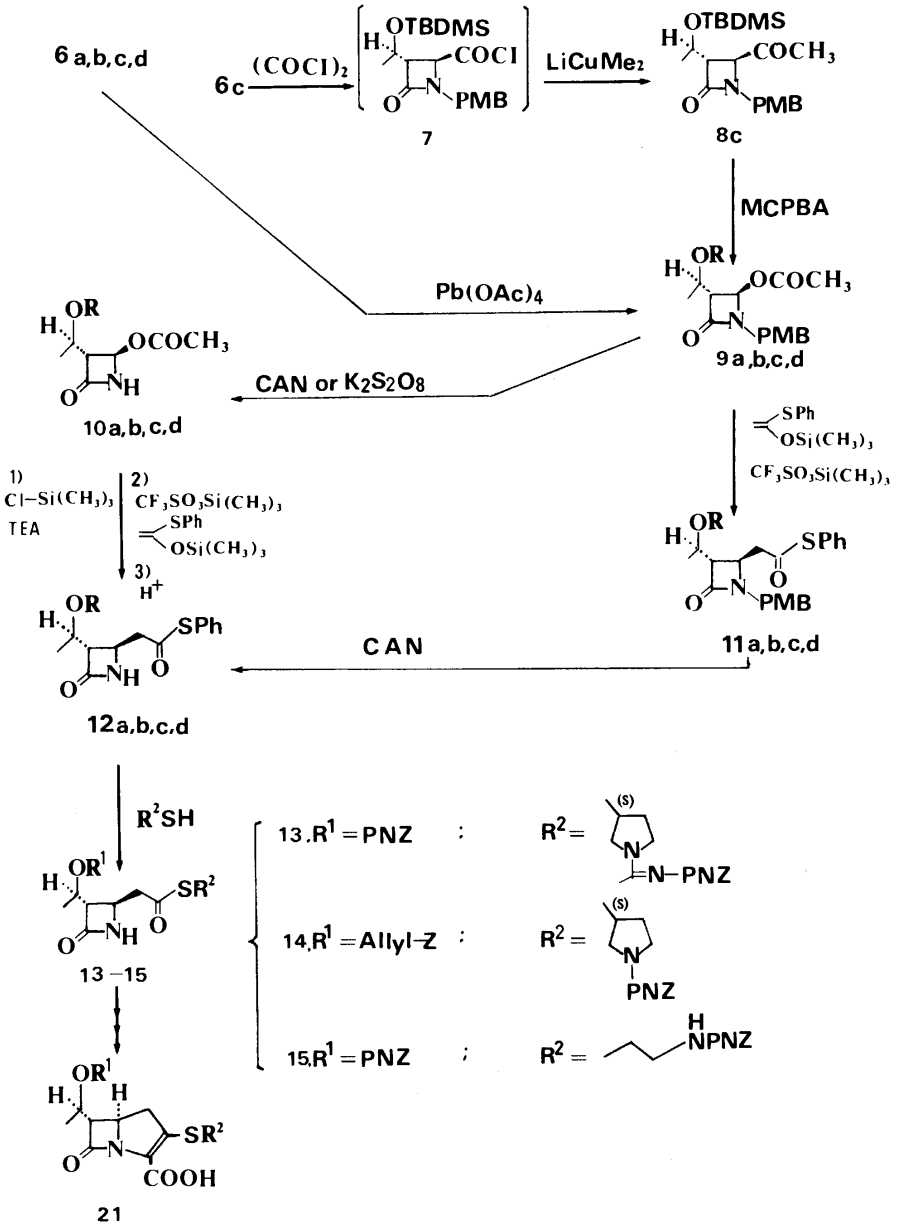
(2*S*,3*R*)-2-Bromo-3-hydroxybutyric acid (**1**) was derived in high yield from L-threonine according to a known method.[6)] The butyric acid **1** was condensed with *N*-(4-methoxybenzyl)glycine *t*-butyl ester (**2**) to give the amide **3**. The amine **2** was synthesized from *t*-butyl bromoacetate and 4-methoxybenzylamine. The compound **3** was purified by silica-gel chromatography and then converted in good yield to the *cis*-epoxy amide **4** by treating with 1.05 equiv of lithium hexamethyldisilazide in tetrahydrofuran (THF). Without isolation, this epoxy amide **4** was cyclized



Scheme 1.

with lithium hexamethyldisilazide (1.05 equiv) in THF to give *t*-Butyl (2*S*,3*S*)-3-[(*R*)-1-hydroxyethyl]-1-(4-methoxybenzyl)-4-oxo-2-azetidinecarboxylate (**5a**) in 63.9% yield from the amide **3**. If necessary, this epoxy amide can be isolated as a stable intermediate.

As mentioned in the previous paper,[5b] when cyclization reaction was carried out at −78 °C, the reaction products contained cis-isomer as a minor product. But when the same reaction was run at 20—23 °C only one product of *trans*-**5a** was obtained without containing the cis-isomer, suggesting a kinetic control is operating. Thus in the compound **5a** the stereochemistry at the 3 and 4 position of the β-lactam and the side chain is exactly correct for thienamycin. These exact configurations were only attained through the epoxide **4** by the double inversion at the compound **3**. The hydroxyl function of **5a** was protected by appropriate groups such as *p*-nitrobenzyloxycarbonyl, *t*-butyldimethylsilyl, and allyloxycarbonyl group. The de-esterification of **5a**, **b**, **d** was carried out by treating with trifluoroacetic acid (TFA) at 0 °C, to give the corresponding free acid **6a**, **b**, **d** in quantitative yield. However the *t*-butyldimethylsilyl group of **5c** was not stable to TFA due to partial desilylation, so **5c** was de-esterified with sodium hydroxide (1.0 equiv) in ethanol. These



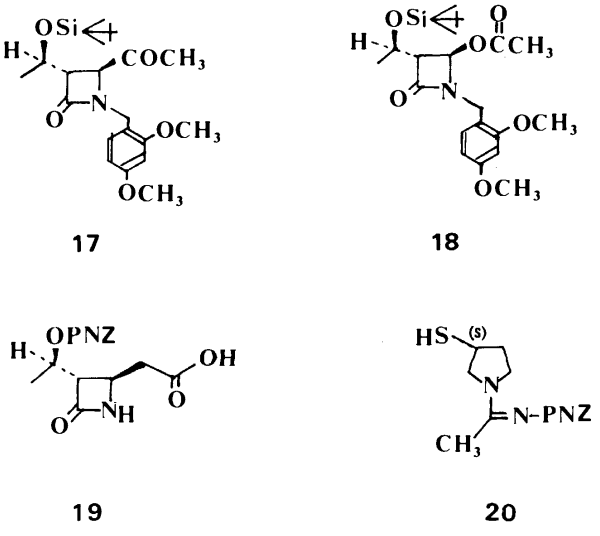
Scheme 2.

carboxylic acids were converted to 4-acetoxy-2-azetidinone derivatives by two methods: (i) The Baeyer-Villiger method[7] after conversion of the carboxylic acid to the acetyl group and (ii) the lead tetraacetate method.[8]

The carboxylic acid **6c** was converted with oxalyl di-chloride to the acid chloride **7** which was transformed into 4-acetyl derivative **8c** by reaction with lithium dimethylcuprate (I). By the Baeyer-Villiger reaction of **8c** with *m*-chloroperbenzoic acid (MCPBA), 4-acetoxy-2-azetidinone **9c** was obtained quantitatively. In this reaction the 3,4-*trans*-2-azetidinone derivative **9c** was formed selectively with retention of configuration as reported by Mislow and Brenner.[9] When this Baeyer-Villiger reaction was carried out starting from *N*-(2,4-dimethoxybenzyl) derivative **17**, no desired product **18** was obtained due to oxidation of the 2,4-dimethoxybenzene moiety. The same compound **9c** was also produced by treatment of **6c** with lead tetraacetate in *N,N*-dimethylformamide (DMF)–acetic acid.[10] Similarly, the carboxylic acids **6a**, **6b**, and **6d** gave the acetoxy derivatives **9a**, **9b**, and **9d**, respectively, by the same reaction in good yields. When starting from **6a**, a trace amount of the 3,4-cis isomer of **9a** was isolated. Removal of the *N*-protecting group of **9b,c,d** was achieved by treatment with cerium (IV) ammonium nitrate (CAN) or potassium peroxodisulfate ($K_2S_2O_8$) in good yield to afford **10b,c,d** respectively, which were identified by comparison with authentic samples. The same deprotection reaction by electrolysis seemed to be possible but tried without success (Pt or graphite as electrodes). The acetate **10b**, **c**, **d** were converted to the *S*-thioesters **12b**, **c**, **d** in quantitative yield by reaction with 1-phenylthio-1-trimethylsiloxyethylene in dichloromethane in the presence of trimethylsilyl trifluoromethanesulfonate as catalyst after trimethylsilylation of the N-atom.[11] The compound **9b—d** were also transformed to the 4-[(phenylthio)carbonylmethyl]-2-azetidinone derivatives **11b—d** in high yields by the same procedure. The *p*-methoxybenzyl group of **11b—d** was also removed with CAN in the same way to give the deprotected *S*-thioesters **12b—d**, respectively.

Generally *S*-thioesters such as **15** were synthesized by the condensation of thiol (**20**) and carboxylic acid (**19**) which was obtained, for example by reaction of the 4-acetoxy derivative **10b** with 1,1-bis(trimethylsiloxy)ethylene in the presence of a catalytic amount of trimethylsilyl trifluoromethanesulfonate. However, the yield of this condensation was unsatisfactory due to interaction of the triflate with the nitrogen part of the thiol **20**. Thus *S*-thioester exchange of **12** was tried and found to proceed under mild conditions to furnish many kind of useful *S*-thioesters, which were difficult to synthesize by the usual condensation reaction of an acid and thiol using dicyclohexylcarbodiimide. For example, in the case of the thiol **20** the reaction with **12b** proceeded smoothly in dichloromethane at room temperature in the presence of triethylamine to give the *S*-thioester **13**. This exchange reaction may be controlled by the acidity and nucleophilicity of the thiols, which is closely connected with the equilibrium constant. The compound **13** was already transformed to the carbapenem **21** by the cyclization using trialkyl phosphite.[4]

Thus we succeeded in finding a very simple method for the synthesis of the useful *S*-thioester derivatives. It seems that by this method several problems for the total synthesis of the trienamycin analogs were resolved. This *S*-thioester exchange method is useful and versatile together with an application of the previously reported cyclization by a new Wittig reaction.[4]



Scheme 3.

Experimental

All melting points were uncorrected. Optical rotation were obtained using a Perkin-Elmer 241 Polarimeter. ^{1}H NMR spectra were determined at 60 MHz with a Varian T-60 spectrometer using tetramethylsilane as internal standard. The IR absorption spectra were determined on a Jasco IR A-2 spectrophotometer. Preparative TLC was performed on silica-gel plate (Merk 60 PF254). Elemental analyses were performed by the Analytical Center of the Analytical and Metabolic Research Laboratories, Sankyo Company, Limited.

(2S,3R)-N-(4-Methoxybenzyl)-N-(t-butoxycarbonylmethyl)-2-bromo-3-hydroxybutyramide (3). To a stirred solution of (2*S*,3*R*)-2-bromo-3-hydroxybutyric acid **1** (50.96 g, 0.278 mol) were added amine **2** (70.14 g, 0.278 mol) in THF (1L), and *N,N'*-dicyclohexylcarbodiimide (57.3 g, 0.278 mol) at 20—30 °C with stirring. After 30 min, the precipitated urea

was filtered off and washed with a small amount of THF. The combined filtrate was evaporated, and chromatographed on silica-gel (900 g) with cyclohexane-EtOAc (2:1) to give amide **3** (81.9 g, 71.5%) as an oil; IR (Liquid) 1750, 1660 cm^{-1}; ^1H NMR ($CDCl_3$) δ=1.25 (3H, d, J=6.5 Hz), 1.40 (9H, s), 3.75 (3H, s), 3.90 (1H, d, J=3.5 Hz), 3.90—4.30 (1H, m), 4.20 and 4.75 (2H, ABq, J=12.5 Hz), 4.30 and 4.65 (2H, ABq, J=25.0 Hz), 6.70—7.30 (4H, m). MS m/z 336 (−79, Br).

*t-Butyl (2S,3S)-3-[(R)-1-Hydroxyethyl]-1-(4-methoxybenzyl)-4-oxo-2-azetidinecarboxylate (**5a**).* To a stirred solution of amide **3** (51.7 g, 0.124 mol) in THF (200 mL) was added lithium hexamethyldisilazide [$LiN(SiMe_3)_2$] solution [prepared by addition of n-BuLi solution (81.5 mL of 1.6 M[†] hexane solution, 0.13 mol) into a solution of hexamethyldisilazane (27 mL, 0.128 mol) in THF (75 mL) under nitrogen over a period of 15 min at 2—3 °C]. After 5 min the temperature was elevated to 20—23 °C and the same amount of [$LiN(SiMe_3)_2$] solution was further added to this solution at 20—23 °C and stirring was continued for 30 min. The reaction mixture was quenched with 10% HCl and evaporated to give an oily residue which was dissolved in ethyl acetate (EtOAc). This solution was washed with 5% $NaHCO_3$ and brine, dried ($MgSO_4$) and evaporated to give a crude oil which was chromatographed on silica-gel (1.5 Kg). Elution with cyclohexane-EtOAc (1:1) gave **5a** (26.6 g, 63.9%) as crystals; mp 75—76 °C; IR (KBr) 1760 cm^{-1}; ^1H NMR ($CDCl_3$) δ=1.25 (3H, d, J=6.5 Hz), 1.40 (9H, s), 2.50 (1H, d, J=4.0 Hz), 3.15 (1H, dd, J=3.0, 4.5 Hz), 3.75 (3H, s), 3.90 (1H, d, J=3.0 Hz), 4.00—4.40 (1H, m), 4.05 and 4.75 (2H, ABq, J=14.5 Hz), 6.80 (2H, d), 7.10 (2H, d). Found: C, 64.7; H, 7.47; N, 4.18%. Calcd for $C_{18}H_{25}NO_5$: C, 64.5; H, 7.51; N, 4.18%.

*t-Butyl (2S,3S)-3-[(R)-1-(t-Butyldimethylsiloxy)ethyl]-1-(4-methoxybenzyl)-4-oxo-2-azetidinecarboxylate (**5c**).* A mixture of **5a** (1.15 g, 3.43 mmol), t-butyldimethylsilyl chloride (1.48 g, 6.86 mmol) and 4-dimethylaminopyridine (837 mg, 6.86 mmol) in DMF (5 mL) was stirred for 16 h at room temperature. The reaction mixture was diluted with EtOAc, washed with dil HCl, water, 5% $NaHCO_3$, saturated NaCl, and dried ($MgSO_4$). After evaporation, the oily residue was chromatographed on silica-gel. Elution with cyclohexane-EtOAc (1:1) gave a crude **5c** (2.08 g) as an oil which was employed for the next reaction without further purification.

*t-Butyl (2S,3S)-1-(4-Methoxybenzyl)-3-[(R)-1-(p-nitrobenzyloxycarbonyloxy)ethyl]-4-oxo-2-azetidinecarboxylate (**5b**)* and *t-Butyl (2S,3S)-3-[(R)-1-(allyloxycarbonyloxy)ethyl]-1-(4-methoxybenzyl)-4-oxo-2-azetidinecarboxylate (**5d**).* 2-Azetidinone **5a** was converted to **5b** and **5d** by the similar reaction as in the case of **5c**.

Physical data **5b**: mp 75—76 °C; IR (KBr) 1770, 1760 cm^{-1}; ^1H NMR ($CDCl_3$) δ=1.35 (3H, d, J=6.5 Hz), 1.43 (9H, s), 3.40 (1H, dd, J=3.0, 7.0 Hz), 3.70 (3H, s), 3.85 (1H, d, J=3.0 Hz), 4.00 and 4.75 (2H, ABq, J=14.5 Hz), 4.90—5.31 (1H, m), 5.2 (2H, s), 6.50 (2H, d), 7.10 (2H, d), 7.81 (2H, d), 8.15 (2H, d). Found: C, 60.5; H, 5.82; N, 5.48%. Calcd for $C_{26}H_{30}N_2O_9$: C, 60.7; H, 5.88; N, 5.45%. **5d**: IR (Liquid) 1760 cm^{-1}; ^1H NMR ($CDCl_3$) δ=1.35 (3H, d, J=6.5 Hz), 1.40 (9H, s), 3.25 (1H, dd, J=3.0, 4.5 Hz), 3.75 (3H, s), 3.85 (1H, d, J=3.0 Hz), 4.00 and 4.75 (2H, ABq, J=14.5 Hz), 4.56 (2H, d, J=6.0 Hz), 4.92—5.20 (1H, m), 5.11—5.50 (2H, m), 5.70—6.10 (1H, m), 6.80 (2H, d), 7.15 (2H, d). MS m/z 419 (M^+).

*(2S,3S)-1-(4-Methoxybenzyl)-3-[(R)-1-(p-nitrobenzyloxycarbonyloxy)ethyl]-4-oxo-2-azetidinecarboxylic Acid (**6b**) and (2S,3S)-3-[(R)-1-(Allyloxycarbonyloxy)ethyl]-1-(4-methoxybenzyl)-4-oxo-2-azetidinecarboxylic Acid (**6d**).* 2-Azetidinone **6b** and **6d** were obtained from **5b** and **5d** with TFA as an oil in 99.2, 79.2% yield, respectively. Physical data: **6b**; IR (Liquid) 1760 cm^{-1}; ^1H NMR ($CDCl_3$) δ=1.25 (3H, d, J=6.5 Hz), 3.25 (1H, dd, J=3.0, 4.5 Hz), 3.75 (3H, s), 4.10 and 4.70 (2H, ABq, J=16 Hz), 4.11 (1H, d, J=3.0 Hz), 4.90—5.20 (1H, m), 5.10 (2H, s), 6.75 (2H, d), 7.10 (2H, d), 7.35 (2H, d), 8.15 (2H, d). MS m/z 456 (M^+). **6d**: ^1H NMR ($CDCl_3$) δ=1.40 (3H, d, J=6.5 Hz), 3.45 (1H, dd, J=3.0, 5.0 Hz), 3.79 (3H, s), 4.02 (1H, d, J=3.0 Hz), 4.00 and 4.85 (2H, ABq, J=14.0 Hz), 4.60 (2H, d, J=5.5 Hz), 5.00—5.31 (1H, m), 5.10—5.61 (2H, m), 5.70—6.20 (1H, m), 6.80 (2H, d), 7.15 (2H, d). MS m/z 363 (M^+).

*(2S,3S)-3-[(R)-1-(t-Butyldimethylsiloxy)ethyl]-1-(4-methoxybenzyl)-4-oxo-2-azetidinecarboxylic Acid (**6c**).* To a stirred solution of crude **5c** (230 mg) in EtOH (1.3 mL), was added 1 M NaOH (0.9 mL) and stirring continued at 60—70 °C for 2 h. The reaction mixture was diluted with water (10 mL) and acidified to pH 2 with dil HCl. The mixture was extracted with EtOAc and washed with water, saturated NaCl and dried ($MgSO_4$). After evaporation **6c** was obtained as crystals (201 mg, 100%): mp 107—109 °C; IR (KBr) 1758, 1720 cm^{-1}; ^1H NMR ($CDCl_3$) δ=0.30 (6H, s), 0.72 (9H, s), 1.10 (3H, d, J=6.0 Hz), 3.71 (3H, s), 3.72 (1H, t, J=2.5 Hz), 4.05 (1H, d, J=2.5 Hz), 4.07 and 4.70 (2H, ABq, J=15.0 Hz), 4.20 (1H, m), 6.81 (2H, d), 7.20 (2H, d), 7.91 (1H, s). Found: C, 60.8; H, 7.99; N, 3.51%. Calcd for $C_{20}H_{31}O_5NSi$: C, 61.1; H, 7.89; N, 3.56%.

*(2S,3S)-3-[(R)-1-(t-Butyldimethylsiloxy)ethyl]-1-(4-methoxybenzyl)-4-oxo-2-azetidinecarbonyl Chloride (**7**).* To a solution of **6c** (197 mg, 0.5 mmol) in THF (2 mL) and DMF (1 mL) was added oxalyl dichloride (0.5 mL) at 0 °C, and kept at 0 °C overnight. After evaporation, the resulted oily residue was used in the next reaction without purification.

*(3S,4S)-4-Acetyl-3-[(R)-1-(t-butyldimethylsiloxy)ethyl]-1-(4-methoxybenzyl)-2-azetidinone (**8c**).* To a stirred suspension of CuI (477 mg, 2.5 mmol) in ether (5 mL) was added a solution of MeLi (1.6 M solution in ether, 3.5 mmol) at 0 °C under nitrogen. After 5 min stirring at 0 °C, the solution was cooled to −78 °C, and a solution of acid chloride **7** (0.5 mmol) in ether (2 mL) and THF (0.5 mL) was added. After 15 min stirring at −78 °C, the reaction mixture was quenched with MeOH (1 mL), diluted with EtOAc, washed with water, saturated NaCl and dried ($MgSO_4$). After evaporation, the oily residue was chromatographed on silica gel. Elution with cyclohexane-EtOAc (3:1) gave **8c** (141 mg, 72% yield). Physical data of **8c**: IR (Liquid) 1758, 1710 cm^{-1}; ^1H NMR ($CDCl_3$) δ=0.04 (3H, s), 0.06 (3H, s), 0.85 (9H, s), 1.33 (3H, d, J=6.0 Hz), 2.00 (3H, s), 2.99 (1H, dd, J=2.5, 4.5 Hz), 3.74 (3H, s), 3.98 (1H, d, J=2.5 Hz), 4.11 and 4.59 (2H, ABq, J=14.0 Hz), 4.18 (1H, m, 6.83 (2H, d), 7.13 (2H, d). MS m/z 337 (M^+ −t-Bu).

*(3S,4S)-4-Acetoxy-3-[(R)-1-(t-butyldimethylsiloxy)ethyl]-1-(4-methoxybenzyl)-2-azetidinone (**9c**).* To a stirred solution

[†] 1 M=1 mol dm^{-3}.

of **8c** (412 mg, 1.05 mmol) in chloroform (5 mL) was added *m*-chloroperbenzoic acid (340 mg, 1.58 mmol) and the resulting solution was kept at room temperature overnight. The reaction mixture was diluted with EtOAc, washed with 5% $NaHCO_3$ (three times), saturated NaCl and dried ($MgSO_4$). After evaporation the oily residue was chromatographed on silica gel. Elution with cyclohexane–EtOAc (1:1) gave **9c** (369 mg, 86%) yield. Physical data **9c**: ^1H NMR ($CDCl_3$) δ=0.30 (3H, s), 0.80 (3H, s), 0.85 (9H, s), 1.20 (3H, d, J=6.0 Hz), 1.85 (3H, s), 3.08 (1H, dd, J=0.5, 3.0 Hz), 3.76 (3H, s), 3.90—4.20 (1H, m), 4.25 (2H, Bs), 6.01 (1H, d, J=0.5 Hz), 6.75 (2H, d), 7.15 (2H, d).

(2S,3S)-3-[(R)-1-Hydroxyethyl]-1-(4-methoxybenzyl)-4-oxo-2-azetidinecarboxylic Acid (6a). Azetidinone **5a** (20.0 g, 0.06 mol) was dissolved in trifluoroacetic acid (TFA, 50 mL) at 0 °C and stirred at the same temperature for 3 h. After evaporation of TFA, the residue was dissolved in benzene (100 mL) and evaporated again to remove the remaining TFA. The oily residue was dissolved in EtOAc (200 mL), which was washed with water, saturated $NaHCO_3$, saturated NaCl and dried ($MgSO_4$), and evaporated to give **6a** as crystals in quantitative yield; mp 100—102 °C; IR (KBr) 1740 cm^{-1}; ^1H NMR ($CDCl_3$) δ=1.30 (3H, d, J=6.5 Hz), 3.30 (1H, dd, J=3.5, 4.0 Hz), 3.75 (3H, s), 4.05 (1H, d, J=3.5 Hz), 4.00—4.40 (1H, m), 4.05 and 4.08 (2H, ABq, J=16.0 Hz), 6.45 (1H, Bs), 6.80 (2H, d), 7.15 (2H, d). Found: C, 60.2; H, 6.16; N, 4.93%. Calcd for $C_{14}H_{17}NO_5$: C, 60.2; H, 6.14; N, 5.02%.

(3S,4R)-4-Acetoxy-3-[(R)-1-hydroxyethyl]-1-(4-methoxybenzyl)-2-azetidinone (9a). To a solution of **6a** (2.80 g, 10 mmol) in DMF–AcOH (5:1, 10 mL) was added $Pb(OAc)_4$ (4.43 g, 10 mmol) with stirring under nitrogen. The mixture was stirred at 50—55 °C for 15 min, then the mixture was diluted with EtOAc (300 mL), washed with water (twice), 5% $NaHCO_3$, saturated NaCl and dried ($MgSO_4$). After evaporation of the solvent, the oily residue was chromatographed on silica gel (50 g). Elution with cyclohexane–EtOAc (1:2) gave **9a** (1.63 g, 51.3%) as crystals; mp 84—85 °C; IR (KBr) 1755 cm^{-1}; ^1H NMR ($CDCl_3$) δ=1.30 (3H, d, J=6.5 Hz), 2.5 (1H, dd, J=1.0, 4.0 Hz), 2.00 (3H, s), 3.10 (1H, Bd, J=7.0 Hz), 3.90—4.30 (1H, m), 3.80 (3H, s), 4.10 and 4.50 (2H, ABq, J=15.0 Hz), 5.75 (1H, d, J=1.0 Hz), 6.80 (2H, d), 7.15 (2H, d). Found: C, 61.32; H, 6.43; N, 4.81%. Calcd for $C_{15}H_{19}NO_5$: C, 61.4; H, 6.53; N, 4.78%.

By the lead tetraacetate method **6b** and **6d** were converted to corresponding **9b** and **9d** in 71.9 and 63% yield, respectively, as in the case of **9a**.

Physical data **9b**: IR (Liquid) 1770 cm^{-1}; ^1H NMR ($CDCl_3$) δ=1.43 (3H, d, J=6.5 Hz), 1.95 (3H, s), 3.35 (1H, dd, J=1.0, 6.5 Hz), 3.75 (3H, s), 4.10 and 4.50 (2H, ABq, J=14.5 Hz), 4.90—5.20 (1H, m), 5.23 (2H, s), 5.98 (1H, d, J=1.0 Hz), 6.78 (2H, d), 7.20 (2H, d), 7.52 (2H, d), 8.23 (2H, d). Found: C, 58.4; H, 5.31; N, 5.75%. Calcd for $C_{23}H_{24}N_2O_9$: C, 58.4; H, 5.08; N, 5.93%. MS m/z 472 (M^+). **9d**: IR (Liquid) 1765 cm^{-1}; ^1H NMR ($CDCl_3$) δ=1.40 (3H, d, J=6.5 Hz), 1.92 (3H, s), 3.28 (1H, dd, J=1.0, 6.5 Hz), 3.75 (3H, s), 4.10 and 4.50 (2H, ABq, J=15.0 Hz), 4.80—5.20 (1H, m), 4.40—4.70 (2H, m), 5.10—5.50 (2H, m), 5.70—6.20 (1H, m), 5.90 (1H, d, J=1.0 Hz), 6.75 (2H, d), 7.16 (2H, d). Found: C, 59.8; H, 6.03; N, 3.67%. Calcd for $C_{19}H_{23}NO_7$: C, 60.4; H, 6.14; N, 3.71%. MS m/z 377 (M^+).

(3S,4R)-4-Acetoxy-3-[(R)-1-(t-butyldimethylsiloxy)ethyl]-2-azetidinone (10c). To a solution of **9c** (408 mg, 1.0 mmol) in acetonitrile water (1:1, 32 mL) were added K_2HPO_4 (1.50 g) and $K_2S_2O_8$ (3.0 g). The mixture was stirred at 75 °C for 1 h under nitrogen, and concentrated *in vacuo* to half volume, and extracted with EtOAc. The extracts were washed with saturated $NaHCO_3$, saturated NaCl, dried ($MgSO_4$) and concentrated to an oily residue which was purified by preparative TLC plate on silica gel (20×20×0.2 cm). Development with cyclohexane–EtOAc (2:1) gave **10c** (115 mg, 41%) as crystals; mp 101—102 °C; IR (Nujol) 3200, 1785, 1745 cm^{-1}; ^1H NMR ($CDCl_3$) δ=0.07 (6H, s), 0.85 (9H, s), 1.24 (3H, d, J=6.5 Hz), 2.12 (3H, s), 3.20 (1H, dd, J=1.0, 3.0 Hz), 4.24 (1H, dq, J=3.0, 6.5 Hz), 5.89 (1H, d, J=1.0 Hz), 6.85 (1H, Bs); MS m/z 577 (M^+), 230, 188, 144; $[\alpha]_D^{24}$ +47.2 (c=1.0, $CHCl_3$).

(3S,4R)-4-Acetoxy-3-[(R)-1-(p-nitrobenzyloxycarbonyloxy)ethyl]-2-azetidinone (10b). To a stirred solution of **9b** (410 mg, 0.89 mmol) in acetone (3 mL) was added cerium(IV) ammonium nitrate (CAN) (910 mg, 1.75 mmol) at room temperature and stirring was continued for 1 h. The reaction mixture was diluted with EtOAc (30 mL) which was washed with water, saturated $NaHCO_3$, saturated NaCl and dried ($MgSO_4$). After evaporation an oily residue was purified by preparative TLC (20×20×0.2 cm) on silica gel with cyclohexane–EtOAc (1:1) to give deprotected **10b** (150 mg, 49% yield) as an oil; IR (Liquid) 3250, 1770 cm^{-1}; ^1H NMR ($CDCl_3$) δ=1.45 (3H, d, J=6.5 Hz), 2.10 (3H, s), 3.35 (1H, dd, J=2.5, 6.5 Hz), 4.90—5.51 (1H, m), 5.24 (2H, s), 5.81 (1H, d, J=2.5 Hz), 7.23 (1H, Bs), 7.50 (2H, d), 8.16 (2H, d).

(3S,4R)-4-Acetoxy-3-[(R)-1-(p-nitrobenzyloxycarbonyloxy)ethyl]-1-(4-methoxybenzyl)-2-azetidinone (9b). To a solution of **9a** (2.93 g, 10 mmol) in dichloromethane (20 mL) were added *p*-nitrobenzyloxycarbonyl chloride (6.45 g, 30 mmol) and 4-dimethylaminopyridine (3.66 g, 30 mmol) under ice cooling. After stirring for 1 h the reaction mixture was diluted with EtOAc and washed with dil HCl, water, saturated $NaHCO_3$, saturated NaCl and dried ($MgSO_4$). The solution was evaporated to afford an oily residue which was chromatographed on silica gel (50 g). Elution with cyclohexane–EtOAc (1:1) gave **9b** (300 mg, 74%) as an oil. The physical data was identical with that of an authentic sample obtained by the lead tetraacetate method.

(3S,4R)-4-Acetoxy-3-[(R)-1-(t-butyldimethylsiloxy)ethyl]-1-(4-methoxybenzyl)-2-azetidinone (9c) and *(3S,4R)-4-Acetoxy-3-[(R)-1-(allyloxycarbonyloxy)ethyl]-1-(4-methoxybenzyl)-2-azetidinone (9d).* Compound **9a** was converted to **9c** and **9d** by the similar reaction as in the case of **9b**, with *t*-butyldimethylsilyl chloride and imidazole, and allyloxycarbonyl chloride and 4-dimethylaminopyridine. The physical data were identical with that of authentic samples obtained in another route.

(3S,4R)-1-(4-Methoxybenzyl)-4-[(phenylthiocarbonyl)methyl]-3-[(R)-1-(p-nitrobenzyloxycarbonyloxy)ethyl]-2-azetidinone (11b). To a stirred solution of azetidinone **9b** (1.18 g, 2.5 mmol) in dichloromethane (10 mL) were added 1-phenylthio-1-trimethylsilyloxyethylene (2.74 g, 10 mmol) and trimethylsilyl trifluoromethanesulfonate (1.11 g, 1.25 mmol) at room temperature. The reaction mixture was kept at room temperature overnight, and diluted with EtOAc (100 mL),

washed with water, 5% $NaHCO_3$, saturated NaCl, and dried ($MgSO_4$). After evaporation, an oily residue was chromatographed on silica-gel (60 g). Elution with cyclohexane–EtOAc (1:1) gave **11b** (1.34 g, 94.9%); IR (Liquid) 1765 cm^{-1}; ^1H NMR ($CDCl_3$) δ=1.35 (3H, d, 6.5 Hz), 2.70—2.90 (2H, m), 3.15 (1H, dd, J=3.0, 7.0 Hz), 3.75 (3H, s), 3.80—4.10 (2H, m), 4.10 and 4.50 (2H, ABq, J=14.5 Hz), 4.90—5.30 (1H, m), 5.15 (2H, s), 6.75 (2H, d), 7.15 (2H, d), 7.35 (5H, s), 7.50 (2H, d), 8.15 (2H, d); MS m/z 564 (M^+).

(3S,4R)-3-[(R)-1-(t-Butyldimethylsiloxy)ethyl-1-(4-methoxybenzyl)-4-[(phenylthiocarbonyl)methyl]-2-azetidinone (11c) and (3S,4R)-3-[(R)-1-(Allyloxycarbonyloxy)ethyl]-1-(4-methoxybenzyl)-4-[(phenylthiocarbonyl)methyl]-2-azetidinone (11d). 2-Azetidinone **9c** and **9d** gave **11c** and **11d** respectively by the same reaction as in the case of **11b**.

Physical data **11c**: ^1H NMR ($CDCl_3$) δ=0.03 (6H, s), 0.83 (9H, s), 1.14 (3H, d, J=6.0 Hz), 2.76 (2H, d, J=6.0 Hz), 2.88 (1H, dd, J=2.0, 4.5 Hz), 3.75 (3H, s), 3.97 (1H, dt, J=2.0, 6.0 Hz), 4.16 (1H, dq, J=2.0, 6.0 Hz), 4.26 (2H, s), 6.77 (2H, d), 7.13 (2H, d), 7.35 (5H, Bs). **11d**: IR (Liquid) 1760 cm^{-1}; ^1H NMR ($CDCl_3$) δ=1.40 (3H, d, J=6.5 Hz), 2.84 (2H, d, J=5.5 Hz), 3.10 (1H, dd, J=2.0, 7.0 Hz), 3.76 (3H, s), 3.80—4.60 (1H, m), 4.10 and 4.50 (2H, ABq, J=14.0 Hz), 4.50—4.60 (2H, m), 4.80—5.20 (1H, m), 5.10—5.40 (2H, m), 5.60—6.10 (1H, m), 6.80 (2H, d), 7.12 (2H, d), 7.30—7.50 (5H, m). MS m/z 496 (M^+).

(3S,4R)-3-[(R)-1-(p-Nitrobenzyloxycarbonyloxy)ethyl]-4-[(phenylthiocarbonyl)methyl]-2-azetidinone (12b). To a stirred solution of cerium (IV) ammonium nitrate (3.0 g, 5.47 mmol) in water (2 mL) was added a solution of **11b** (203 mg, 0.36 mmol) in acetone (10 mL) and stirred for 2 h. The reaction mixture was diluted with EtOAc (200 mL), washed with water, 5% $NaHCO_3$, saturated NaCl and dried ($MgSO_4$). After evaporation an oily residue was chromatographed on silica-gel. Elution with cyclohexane–EtOAc (2:1) gave **12b** (111 mg, 69.5%) as an oil; IR (Liquid) 1770 cm^{-1}; ^1H NMR ($CDCl_3$) δ=1.44 (3H, d, J=6.5 Hz), 2.90—3.20 (3H, m), 3.86—4.10 (1H, m), 4.90—5.30 (1H, m), 5.15 (2H, s), 6.40 (1H, Bs), 7.45 (5H, s), 7.50 (2H, d), 8.15 (2H, d); MS m/z 444 (M^+).

(3S,4R)-3-[(R)-1-(t-Butyldimethylsiloxy)ethyl]-4-[(phenylthiocarbonyl)methyl]-2-azetidinone (12c) and *(3S,4R)-3-[(R)-1-Allyloxycarbonyloxy)ethyl]-4-[(phenylthiocarbonyl)methyl]-2-azetidinone (12d).* 2-Azetidinones **11c**, **11d** were converted to the corresponding **12c** and **12d** by the same reaction as in the case of **11b**.

Physical data **12c**: mp 95—96 °C; IR (Nujol) 1765, 1725 cm^{-1}; ^1H NMR ($CDCl_3$) δ=0.08 (6H, s), 0.87 (9H, s), 1.19 (3H, d, J=6.0 Hz), 2.55—3.25 (3H, m), 3.70—4.33 (2H, m), 6.20 (1H, Bs), 7.35 (5H, s); $[\alpha]_D^{24}$ +41.7 °C (C=1.64, $CHCl_3$). **12d**: IR (Liquid) 1770 cm^{-1}; ^1H NMR ($CDCl_3$) δ=1.40 (3H, d, J=6.5 Hz), 2.80—3.20 (3H, m), 3.80—4.20 (1H, m), 4.42—4.71 (2H, m), 4.80—5.20 (1H, m), 5.10—5.40 (2H, m), 5.60—6.10 (1H, m), 6.20 (1H, Bs), 7.32 (5H, s). Found: C, 5.81; H, 5.49; N, 3.89; S, 9.35%. Calcd for $C_{17}H_{19}NO_5S$: C, 58.4; H, 5.47; N, 4.00; S, 9.15%.

(3S,4R)-4-[(S)-[[1-[N-(p-Nitrobenzyloxycarbonyl)acetimidoyl]-3-pyrrolidinylthio]carbonylmethyl]]-3-[(R)-1-(p-nitrobenzyloxycarbonyloxy)ethyl]-2-azetidinone (13). To a stirred solution of 2-azetidinone **12b** (115 mg, 0.26 mmol) in dichloromethane (5 mL) were added 3-pyrrolidinethiol **20** (125 mg, 0.89 mmol) in dichloromethane (5 mL) and triethylamine (26 mg, 0.26 mmol) with stirring at room temperature and the resulting solution was kept at room temperature overnight. After evaporation, the oily residue was chromatographed on silica-gel. Elution with EtOAc gave **13** (168 mg, 98%) as an oil; IR (Liquid) 1770 cm^{-1}; ^1H NMR ($CDCl_3$) δ=1.22 (3H, d, J=6.0 Hz), 2.30 (3H, s), 1.60—2.60 (2H, m), 2.90 (2H, d, J=6.5 Hz), 3.04 (1H, Bd, J=7.0 Hz), 3.20—4.20 (6H, m), 4.90—5.20 (1H, m), 5.18 (2H, s), 5.13 (2H, s), 6.70 (1H, Bs), 7.25 (4H, d), 8.10—8.30 (4H, m).

(3S,4R)-3-[(R)-1-(Allyloxycarbonyloxy)ethyl]-4-[(S)-[[1-(p-nitrobenzyloxycarbonyl)-3-pyrrolidinylthio]carbonylmethyl]]-2-azetidinone (14). *S*-Phenyl thioester **12d** was converted to the corresponding exchanged *S*-thioester **14** by the same reaction as in the case of **13**; IR (Liquid) 1770 cm^{-1}; ^1H NMR ($CDCl_3$) δ=1.40 (3H, d, J=6.5 Hz), 1.60—2.70 (2H, m), 2.70—3.00 (3H, m), 3.20—4.21 (6H, m), 4.60 (2H, d, J=7.0 Hz), 4.80—5.21 (1H, m), 5.20—5.50 (2H, m), 5.20 (2H, s), 5.62—6.21 (1H, m), 6.40 (1H, Bs), 7.48 (2H, d), 8.15 (2H, d).

(3S,4R)-4-[[2-(p-Nitrobenzyloxycarbonylamino)ethylthio]carbonylmethyl]-3-[(R)-1-(p-nitrobenzyloxycarbonyloxy)ethyl]-2-azetidinone (15). To a stirred solution of 2-azetidinone **12b** (444 mg, 10 mmol) in dichloromethane (10 mL) were added 2-(*p*-nitrobenzyloxycarbonylamino)ethanethiol (512 mg, 20 mmol) and triethylamine (202 mg, 20 mmol) at room temperature and the solution was kept at the same temperature for 5 h. The mixture was diluted with EtOAc (50 mL) and washed with water, saturated $NaHCO_3$, saturated NaCl and dried ($MgSO_4$). After evaporation the oily residue was purified by column chromatography on silica-gel. Elution with cyclohexane–EtOAc gave **15** (431 mg, 73%) as an oil; IR (Liquid) 3260, 1760, 1740 cm^{-1}; ^1H NMR ($CDCl_3$) δ=1.42 (3H, d, J=6.5 Hz), 2.60—3.20 (4H, m), 3.20—3.50 (2H, m), 3.90—4.25 (2H, m), 4.80—5.30 (1H, m), 5.18 (2H, s), 5.26 (2H, s), 5.65 (1H, m), 6.90 (1H, Bs), 7.35—8.50 (8H, m).

Catalytic Epoxidation of Olefins with *t*-Butyl Hydroperoxide in the Presence of Polymer-supported Vanadium(V) and Molybdenum(VI) Complexes

Toshiro YOKOYAMA, Masato NISHIZAWA, Tetsuo KIMURA, and Toshishige M. SUZUKI*
Government Industrial Research Institute, Tohoku, 4-2-1 Nigatake, Sendai 983
(Received May 13, 1985)

Oxovanadium(V) and oxomolybdenum(VI) ions have been incorporated into cross-linked polystyrene resins functionalized with iminodiacetic acid or diethylenetriamine derivatives. The polymer complexes have been used as catalysts in the epoxidation of olefins with *t*-butyl hydroperoxide. Vanadium(V) complexes promote epoxidation of allylic alcohols in a highly regioselective manner, *e.g.*, 2,3-epoxide has been preferentially obtained in 98% selectivity from (*E*)-geraniol at 80 °C. The catalytic activity of the vanadium(V) complexes is generally higher than that of the molybdenum(VI) complexes in the epoxidation of allylic alcohols whereas an opposed trend holds for the epoxidation of cyclohexene. Life time of catalysts have been examined by repeated use of the complexes in the epoxidation of (*E*)-geraniol at 80 °C in benzene. Approximately 15—25% of vanadium has been leaked out of the polymer beads on five time recycles leading to the decrease in the yield of 2,3-epoxide from initial value of 98% to 95—93%. Neither appreciable loss of metal nor reduction of catalytic activity has been observed in the molybdenum complex systems over five runs.

It is widely known that complexes of oxometal ions such as vanadium, molybdenum, and tungsten catalyze the epoxidation of olefins with alkyl hydroperoxides.[1-7] Recently anchoring of catalytically active transition metal complexes onto a polymer matrix received considerable attention[8,9] due to their potential advantages in practical synthesis, *i.e.*, i) the catalyst is easily separated from the reaction solution by filtration or centrifugation, ii) the recovered catalyst can be used repeatedly.

Several studies have been carried out on the catalytic epoxidation of olefins by polymer-anchored metal complexes.[10-13] However the functional groups so far used as metal-ion-binding unit were mostly monodentate and bidentate ligands, which often suffer from the disadvantage of the metal ion leaking from the polymer support. Accordingly a more stable metal-polymer linkage is required to avoid such leaking of metal ion into the reaction solution.

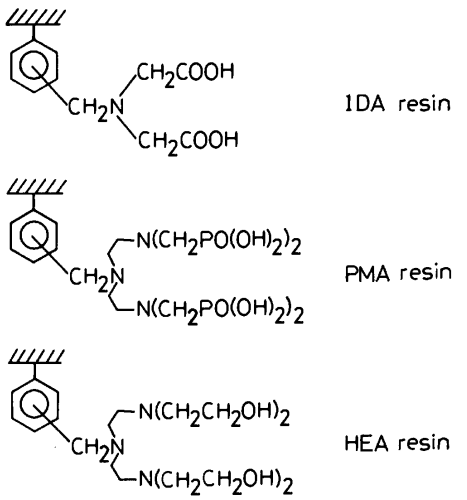

Fig. 1. Polymer chelating resins containing multidentate functional group.

Recently we have reported that the cross-linked polystyrene resins with a functional group having bis(phosphonomethyl)amino (PMA) and bis(2-hydroxyethyl)amino (HEA) moieties (Fig. 1) readily form metal complexes with oxovanadium(V) and oxomolybdenum(VI) ions in aqueous solution.[14] These polymer complexes were found to catalyze the epoxidation of (*E*)-geraniol with *t*-butyl hydroperoxide (*t*-BuOOH) without significant loss of the metal ion.[15] This is the full detailed description of the work including the preparation of the polymer complex catalysts, and the epoxidation of allylic alcohols and cyclohexene.

Experimental

Materials. Microreticular (Gel) and macroreticular (MR) types of polystyrene resins containing iminodiacetic acid (IDA) moieties are commercial products, *i.e.*, Dowex A-1 (Gel type, 25—50 mesh) and Lewatit-OC-1048 (MR-type, 25—50 mesh). The polymer matrices used for the preparation of PMA and HEA resins were Gel-type styrene-2%-divinylbenzene copolymer (from Kodac Co, 200—400 mesh) and MR-type styrene-10%-divinylbenzene copolymer (from Mitsubishi Chemical Co., 60—100 mesh). The surface area and mean pore radius of the MR-type resin were 7.3 $m^2 g^{-1}$ and 720 Å, respectively.

Preparation of the Chelating Resins. Both Gel- and MR-types of polystyrene beads were chloromethylated,[16] and then functionalized with diethylenetriamine (dien) to give a dien-resin in which diethylenetriamine is linked to the polymer uniquely through the secondary amino nitrogen.[17] The dien-resin was used as the starting material for the preparation of the PMA and HEA resins.

PMA Resin: To a refluxed mixture of dien-resin (Gel-type, 15 g), phosphorous acid (33 g) and 6 M HCl (80 cm^3, M=mol dm^{-3}) was added dropwise 37% of aqueous

formaldehyde solution (64 cm^3) in the course of 2 h. The reaction mixture was kept at refluxing temperature for an additional 3 h. The resin was filtered, washed with water, ethanol and then diethyl ether, and dried *in vacuo* at 50 °C. Yield: 25.3 g.

HEA Resin: The Gel-type of dien-resin (11 g) was stirred with aqueous ethylene oxide (9.6 g in 100 cm^3) for 3 h under ice cooling. After standing overnight at room temperature, the resin was filtered, washed throughly with water, ethanol and diethyl ether, and then dried *in vacuo* at 50 °C. Yield: 19.5 g.

Functionalization of the MR-type polystyrene resin was performed under similar conditions to those for the Gel-type of PMA and HEA resins.

Preparation of Polymer Complexes: Polymer complexes were generally prepared by the following procedures: One gram of dry resin was shaken with 10 mM of aqueous $NaVO_3$ or K_2MoO_4 solution (1000 cm^3) at pH about 4 for 24 h. The concentration of the remaining metal ion in the solution was analyzed by atomic absorption spectrometry to determine the amount of metal adsorbed on the resin. The polymer beads were filtered, washed throughly with distilled water, ethanol, diethyl ether, and then dried *in vacuo* at 50 °C.

Epoxidation of Olefins: A typical procedure for the epoxidation of allylic alcohols is as follows: In a 50 cm^3 round-bottomed flask equipped with a reflux condenser was placed a polymer complex containing 0.2—0.3 mmol of metal, 30 cm^3 of benzene, (*E*)-geraniol (4.0 g, 26 mmol) and 70% of aqueous *t*-BuOOH (4.0 g, 31 mmol). The reaction mixture was heated at 80 °C with stirring. The reaction was monitored by TLC. After the reaction was completed, the polymer beads were filtered off, and the filtrate acetylated by the published method[3] prior to the product analysis. The reaction conversion of allylic alcohol and the distribution of the products were analyzed on a GLC (2% OV-17 on Uniport HP, 80—100 mesh: 16 ft×1/8 in.) using methyl stearate as an internal standard. The geometry of the epoxide isomers was confirmed by ^1H NMR spectroscopy. Epoxidation of cyclohexene was carried out under conditions similar to those for the epoxidation of the allylic alcohols. The reaction solution was analyzed on a GLC (15% PEG-20M on Uniport S, 60—80 mesh, 16 ft×1/8 in.) using toluene as an internal standard.

Lifetime of the Catalysts: The polymer complexes were recovered by filtration at the end of the epoxidation of (*E*)-geraniol. After washing with benzene, the complexes were used in successive runs under identical conditions. The conversion and the selectivity were determined after each run as described above. In order to determine the amount of metal ion which leaked into the reaction solution, the polymer catalyst was removed by filtration. The filtrate was evaporated and extracted twice with 0.5 M HCl. The metal ion in the extract was determined by atomic absorption.

Catalytic Decomposition of t-BuOOH: Decomposition of *t*-BuOOH was monitored by iodometry in the absence of a substrate. To a mixture of the polymer complex (100 mg) and benzene (30 cm^3) was added 70% of aqueous *t*-BuOOH (4.0 g) and the whole heated at 80 °C with stirring. Small portions of the sample (1 cm^3) were withdrawn at appropriate intervals and titrated iodometrically according to the published method.[18]

Measurements: ^1H NMR spectra were measured with a JEOL FX-100 spectrometer in chloroform-*d* with TMS as an internal standard. The metal ion concentration was determined with a Shimadzu atomic absorption/flame photometer Model AA-610S. GLC-analysis was performed on a Varian Model 3700 gas-chromatograph equipped with an electron digital integrator Varian Model CDS-111.

Results

Polymer Catalysts. Analytical data and the amounts of the functional group contained in one gram of dry resin are shown in Table 1. The ligand contents of Gel- and MR-type resins (PMA and HEA) do not differ much from each other, indicating that the functionalization proceeds to a similar extent, irrespective of the type of polymer support. However the physical form of the Gel-type resin is affected by the solvent while the MR-type resin has only minor shrinking and swelling properties. Metal ions were incorporated into the polymer ligands by treating the

Table 1. Analytical data of polymer chelating resins and the maximum adsorption capacity for V(V) and Mo(VI)

Chelating Resin	Analytical Data	Ligand Capacity[a]	Ads. Capacity/(mmol/g-resin)[b]	
	N(%)	mmol/g-resin	V	Mo
Gel-IDA	6.27	4.46	1.7	1.1
MR-IDA	3.64	2.60	1.4	2.0
Gel-PMA	6.53	1.55	3.2	3.3
MR-PMA	5.54	1.32	3.3	4.0
Gel-HEA	7.32	1.74	3.1	3.2
MR-HEA	7.43	1.77	4.0	4.0

a) Calculated from the actual nitrogen content: Ligand capacity (mmol/g-resin) is estimated by $\frac{\%N}{14n}$, where %N=nitrogen in product, and n=number of nitrogen atoms in the ligand.[29] b) The amount of metal adsorbed on one gram of dry resin.

resins with aqueous Mo(VI) or V(V) solution at pH *ca.* 4.0, conditions under which the amounts of metal adsorbed are maximal. The maximum adsorption capacities of the present resins for Mo(VI) and V(V) are also given in Table 1. The amounts of metal adsorbed on one gram of PMA and HEA resins always exceed the ligand contents while those on IDA resins do not.

Epoxidation of Allylic Alcohols. The results of epoxidation of allylic alcohols are summarized in Table 2. (*E*)-Geraniol was epoxidized preferentially at the olefinic site close to the hydroxyl group regardless of the metal ion, the functional group or the type of polymer matrix. The following general features were observed in the present reactions: i) The conversion of (*E*)-geraniol and the selectivity toward the formation of 2,3-epoxide by vanadium catalysts are generally higher than those by the molybdenum complex systems. ii) Apparently complexes with the MR-type polymer matrix undergo epoxidation at a much faster rate than the corresponding complexes of the Gel-type polymer. iii) The catalytic activities are almost independent of the type of functional group. iv) The epoxidation rate is retarded by addition of an excess amount of *t*-butyl alcohol (*t*-BuOH). Vanadium complexes epoxidize (*E*)-geraniol almost quantitatively and the selectivity is remarkably high (≈98%). The reaction conversion and the selectivity are comparable to those observed with homogeneous $VO(acac)_2$ (acac=acetylacetonato) when MR–vanadium complexes were employed. The epoxidation of 2-cyclohexen-1-ol and linalool was carried out in a similar manner to that of (*E*)-geraniol in the presence of vanadium complexes of MR-type resin. The reaction of these secondary and tertiary alcohols required much longer reaction times and resulted in lower conversion.

The time-course plots of the epoxidation of (*E*)-geraniol by vanadium catalysts are illustrated in Fig. 2. The reaction at 80 °C is facile in the initial stage and in most of the cases 80% conversion was attained within 30 min. Although it takes longer reaction time, the epoxidation proceeds under moderate temperature (20 °C) by use of MR-vanadium catalysts. The vanadium complexes of IDA and PMA resins accomplished 80—90% conversion in 8 h whereas HEA resin required much longer induction periods.

Epoxidation of Cyclohexene. Epoxidation of cyclohexene with *t*-BuOOH (cyclohexene/*t*-BuOOH= 1) was carried out using vanadium(V) and molybdenum(VI) complexes of MR-type resins. Table 3 shows the conversion of cyclohexene and the selectivity toward the formation of cyclohexene oxide after a 24 h reaction period. In contrast to allylic alcohols, the epoxidation of a simple olefin catalyzed

	Mo	≫15,000
MR-HEA	V	90
	Mo	≫15,000

by molybdenum gave a higher conversion and better selectivity than the reaction by vanadium complexes. The vanadium catalyzed reactions generally gave several by-products involving polymerized compounds.

Lifetime of Catalysts. The lifetimes of the catalysts (MR-resins) were examined by their repeated use in the epoxidation of (*E*)-geraniol. The amount of metal ion leaked into the solution was determined for each run. Approximately 75% of the vanadium remained on MR-IDA and MR-HEA resins while more than 85% of the metal was still retained on the MR-PMA resin after five runs. The yield of 2,3-epoxide decreased only slightly, *i.e.*, the initial value of 98% decreased to 95—93% after fivefold recycling. In most cases notable change in selectivity has not been observed. Leakage of the metal ion does not take place in the absence of substrate and *t*-BuOOH. Neither appreciable loss of metal nor reduction of catalytic activity was observed in the molybdenum complex systems after five runs.

Catalytic Decomposition of t-BuOOH. The rates of consumption of *t*-BuOOH by the polymer complexes in the absence of substrate have been monitored by iodometry. Half-lives ($t_{1/2}$) of the reactions are given in Table 4. Obviously vanadium complexes remarkably facilitate the decomposition of *t*-BuOOH while those by molybdenum complexes are very slow.

Discussion

The major advantage of polymer-anchored catalysts over their homogeneous counterparts is the ease of recovering and recycling of the catalysts. So far bidentate ligands such as ethylenediamine,[10] acetylacetonato,[10,12] and dithiocarbamato[13] have been used as the polymer-metal (M=V(IV), Mo(V)) binding unit and the catalytic epoxidation of olefins has been carried out using the polymer complexes. However significant leakage of metal ion from the polymers inevitably took place during epoxidation, leading to a rapid lowering of the catalytic activity upon repeated use. Our catalyst systems, by contrast, are relatively long-lived. The catalytic activities after five

runs are essentially the same as those of the first run irrespective of the catalysts used. The polymer–metal bond in these complexes appears to be very durable toward the dissociation of the metal ion under the given catalytic conditions. It has been pointed out that the rate of dissociation of a chelated complex decreases significantly as the dentate number of the ligand increases.[19] This trend was exemplified by the studies on acid hydrolysis of a number of Mo(V) complexes.[20,21] The enhanced stability of the present complexes may be attributed to the increasing dentate number of the immobilized ligands.

Iminodiacetic acid (IDA) which is the functional group of the IDA resin acts as a tridentate ligand and is known to form 1:1 (ligand:metal) complexes with Mo(VI) and V(V).[22–24] The facial tridentate coordination of IDA group to the trioxomolybdenum(VI) was proposed on the basis of the ^{1}H-NMR study of the IDA–Mo(VI) complex[23] and confirmed in the solid state for a 2:1 complex $Na_4(MoO_3)_2(edta)\cdot 8H_2O$ (H_4edta=ethylenediaminetetraacetic acid).[25] The PMA and HEA resins formally contain two sets of tridentate ligands, bis(phosphonomethyl)amino and bis(2-hydroxyethyl)amino moieties, respectively. The maximum amount of metal ion adsorbed on PMA and HEA resins is much higher than the estimated amount of ligand contained in one gram of dry resin. It seems that each of the tridentate ligand having one nitrogen and two oxygens as the donating atoms forms 1:1 complexes with Mo(VI) and V(V) in a similar fashion to those for IDA and EDTA complexes. The coordination of the hydroxyl arms onto Mo(VI) has been demonstrated by ^{13}C-NMR study of the Mo(VI) complex with *N,N,N',N'*-tetrakis(2-hydroxyethyl)ethylenediamine.[14] The remaining coordination sites in the octahedral complexes are generally occupied with oxo ligands (or water) which can be replaced by the substrate or oxidizing agent in the epoxidation reaction. The higher durability of the PMA–V(V) complex toward metal dissociation suggests stronger coordination of the phosphonomethyl groups than that of the acetate or hydroxyl group.

As has been claimed earlier in the homogeneous catalyst systems[2,26] the high regioselectivity in the epoxidation of allylic alcohols can be interpreted by a mechanism in which coordination of the hydroxyl group of the substrate and *t*-BuOOH to the metal ion at neighbouring position is involved as the key intermediate. The fixed geometry of the allylic alcohols by the formation of such ternary complex results in preferential transfer of oxygen to an olefinic site close to the hydroxyl group. This may be supported by the observation that the rate of epoxidation is retarded in the presence of a large amount of *t*-BuOH which can compete with the substrate for coordination to the active center. With allylic alcohols vanadium complexes always gave a faster rate and better selectivity than the molybdenum complexes. A similar trend has been observed in the homogeneous catalyst system and has been attributed to the stronger coordination of hydroxyl group to vanadium.[2] In practice, the retardation by *t*-BuOH is more serious with vanadium complexes than with molybdenum complexes under similar reaction conditions.

Catalysts anchored on an MR-type resin always showed kinetic properties superior to those supported on a Gel-type resin. The MR-type resin has actual pores forming numerous channels which allow facile diffusion of the substrate into the polymer matrix.[27,28] On the other hand, the tight polymer network of the Gel-type resin may interfere with a smooth transfer of substrate to the active center.

Both vanadium and molybdenum complexes catalyze the decomposition of *t*-BuOOH to give peroxyl radicals.[4,6] Therefore the epoxidation of olefins catalyzed by these metal complexes involves competing with the metal-catalyzed decomposition of *t*-BuOOH. The vanadium-catalyzed decomposition of *t*-BuOOH is remarkably facile in the absence of a substrate, while in the presence of allylic alcohols, the epoxidation proceeds preferentially. An intramolecular oxygen transfer from peroxovanadium(V) complex to allylic alcohol seems to take place at a much faster rate than the decomposition of the peroxide when the olefins is fixed to metal through a functional group. On the contrary, the epoxidation of cyclohexene gave an extremely poor yield of epoxides indicating that the decomposition reaction takes place prior to the efficient oxygen transfer to the substrate. For the nonfunctionalized olefin the opportunity to form the stable ternary complex might be limited. Radicals produced by the homolytic decomposition of peroxide must be responsible for the formation of many kinds of by-products. Reactions involving such peroxyl radicals would be less remarkable in the molybdenum-catalyzed epoxidation since the rate of decomposition of *t*-BuOOH is significantly slow.

A Kinetic Study on the Reaction of (Arylthio)trimethylgermane with Benzoyl Chloride Giving *S*-Aryl Thiobenzoate and Chlorotrimethylgermane

Seizi KOZUKA,* Shoji TAMURA, Tetsuya YAMAZAKI, Shigeru YAMAGUCHI, and Waichiro TAGAKI

(Received June 1, 1985)

A kinetic study has been conducted on the reactions of (substituted arylthio)trimethylgermanes with aroyl chlorides giving *S*-aryl thioaroates and chlorotrimethylgermane. The rates of the reactions were distinctly accelerated in polar solvents. Both of the effects due to the substituents of the arylthio and the aroyl moieties gave positive ρ values especially in a polar solvent. A mechanism involving initial 5-coordination, ionic cleavage of the Ge–S bond giving arenethiolate ion, and followed by rate-determining addition of the thiolate to the carbonyl carbon, was suggested for the reaction.

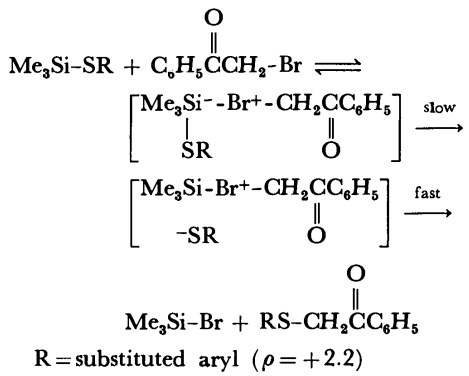
Previously, we have reported kinetic and stereochemical studies on the reactions of methylthio- and (substituted arylthio)trimethylstannanes with haloalkanes.[1] Nucleophilic attacks of the sulfur atom on the haloalkanes have been suggested for the reactions based on the negative ρ value together with other kinetic and stereochemical results.

$$Me_3Sn\text{-}SR + R'\text{-}X \longrightarrow [Me_3Sn\text{-}S^+RR'\,X^-] \longrightarrow R\text{-}S\text{-}R' + Me_3Sn\text{-}X$$

R = substituted aryl ($\rho = -1.4$), Me
R′ = Me, Et, $C_6H_5CH_2$, 1-Me-heptyl (inversion)
X = I, Br, Cl.

Scheme 1.

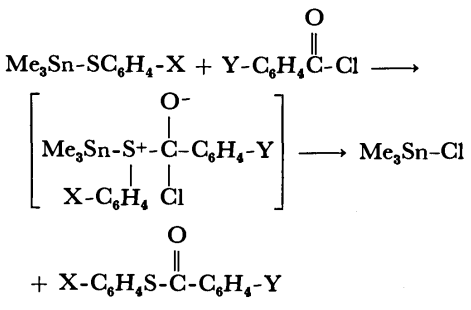
On the other hand, quite different kinetic aspects were observed for the analogous reactions of arylthiosilanes. Namely, the reactions of (substituted arylthio)trimethylsilanes with a haloalkane were found to give the products in a similar way but with quite different kinetic results.[2] Phenacyl bromide was chosen as the haloalkane for the kinetic study because of the low reactivity of the arylthiosilanes towards common haloalkanes. A large positive ρ value (+2.2) was observed. The result was well recognized in terms of initial 5-coordination of the silicon atom and followed by the rate-determining Si–S bond cleavage (Scheme 2).



R = substituted aryl ($\rho = +2.2$)

Scheme 2.

A comparable difference was also observed between the analogous reactions of the arylthiostannanes and the arylthiosilanes with aroyl chlorides. The reactions of the (arylthio)trimethylstannanes with aroyl chlorides were found to give *S*-aryl thioaroates. The kinetic study on the reactions revealed opposite substituent effects due to the arylthio ($\rho_X = -1.6$) and the aroyl ($\rho_Y = +1.1$) moieties. Hereafter, the substituents on the arylthio and the aroyl groups are abbreviated as X and Y, respectively. Accordingly, the reaction was considered to involve a nucleophilic addition of the sulfur atom to the carbonyl carbon (Scheme 3).[3]

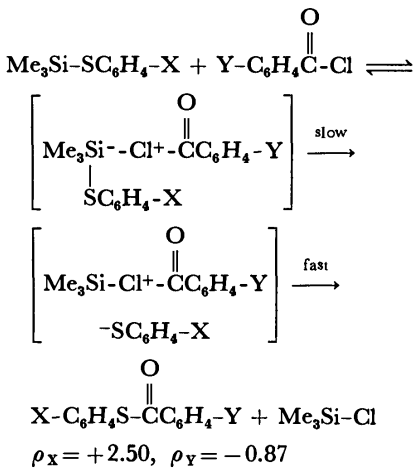


$\rho_X = -1.6$, $\rho_Y = +1.1$

Scheme 3.

Contrary to these results, the reactions of the (arylthio)trimethylsilanes with aroyl chlorides were found to give the same thioaroates but with quite different kinetic aspects. A large positive ρ value due to X ($\rho_X = +2.50$) was observed while that of Y was small negative ($\rho_Y = -0.87$). These results suggested initial 5-coordination followed by rate-determining formation of arenethiolate ion for the reaction (Scheme 4).[4]

A kinetic study on the reactions of the arylthiogermane analogs would be of interest since quite different kinetic aspects were observed for the reactions of the arylthiosilanes and the arylthio-



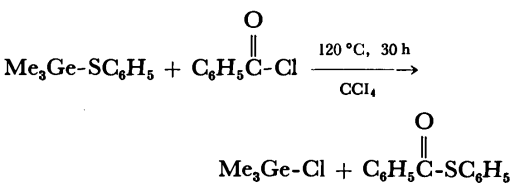
Scheme 4.

stannanes as far described. Substituted aroyl chlorides were chosen as the reactants because the reactions of these reagents have well been studied kinetically.[3,4]

Results and Discussion

The reaction of trimethyl(phenylthio)germane with benzoyl chloride was found to give chlorotrimethylgermane and *S*-phenyl thiobenzoate. No other product was found in the reaction solution by ^{1}H NMR analysis. The chlorogermane and the thiobenzoate were isolated and characterized.

The rate of the reaction of the phenylthiogermane with a small excess of benzoyl chloride was measured by monitoring the decrease in the ^{1}H NMR trimethyl signal of the starting phenylthiogermane (δ=0.47) and the increase in that of the chlorogermane



Scheme 5.

(δ=0.72). The reaction was found to obey a second order rate equation. The kinetic experiments were performed in various solvents at different temperatures. The results are given in Table 1 together with the activation parameters and the observed solvent effects. The possible reactions of the arylthiogermanes with the solvents were examined in control experiments. Small amounts of the solvolysis products were found on prolonged heating of the arylthiogermanes in some solvents. The rates (pseudo-first-order: k_1), however, were found much smaller and negligible comparing with those of the reactions with aroyl chlorides.

The activation parameters appeared in similar magnitudes with those of the analogous reactions which proceed by ionic processes.[1-3] Distinct solvent effects were observed as shown in Table 1. The results also suggest an ionic process for the reaction.

The effect of the substituents of the arylthio group (ρ_X) was examined to clarify the reaction mechanism. The results are shown in Table 2.

Clearly positive ρ_X values were observed for both the reactions carried out in carbon tetrachloride and in benzonitrile as the solvents. The positive ρ_X values would suggest 5-coordination of the germanium atom as was suggested for the reactions of the

arylthiosilanes.[2,4,5] The enhanced ρ_X value observed in benzonitrile solution also suggests the rate-determining cleavage of the Ge–S linkage giving arenethiolate ion since the value is comparable with that of the dissociation of arenethiols.[6] The present reaction, thus once, appeared to be similar in the mechanism to that of the reactions of the arylthiosilanes with phenacyl bromide[2] and with aroyl chlorides[4] which involve initial 5-coordinations followed by rate-determining formations of arenethiolate ions. The effect of the substituent Y, (ρ_Y), however, strongly suggests that the rate-determining step of the present reaction is quite different from those of the reactions of the arylthiosilanes.[2,4]

As shown in Table 3, the effects of Y observed for the reactions in carbon tetrachloride were obscure, or rather U-shape plot was observed. On the other hand, the observed ρ_Y value is clearly positive for the reactions in benzonitrile as the solvent. The positive ρ_Y value strongly suggests an alternative mechanism for the reaction since a similar mechanism to that of the reactions of the arylthiosilanes demands a negative ρ_Y value (Scheme 4).[4]

The most appropriate mechanism for the reaction based on the kinetic results can be depicted as follows (Scheme 6).

The positive ρ_Y value observed in benzonitrile can be rationalized in terms of a rate-determining addition of the thiolate ion to carbonyl carbon giving the intermediate III. The positive ρ_X value would be originated from the both steps, the initial 5-coordination giving the intermediate I and the ionic fission of the Ge–S bond giving the ion pair II. Energetically disfavored equilibrium giving I and II might well account for the observed positive ρ_X values since favorable formations of I and II would disappear the effect of X or bring small negative ρ_X values.

It is uncertain, why the effects of Y in carbon tetrachloride gave a U-shaped Hammett plot. The electron-donating substituents Y may stabilize both the intermediates I and II. The stabilizations may slightly accelerate the reactions. Another process to rationalize the abnormal effects of Y is a charge-separated 4-center transition state which has been suggested for the reactions of the (aryloxy)trimethylstannanes with methanesulfonyl chloride.[7] The 4-center process may be favorable for the ionic reactions forced to proceed in nonpolar solvents. However, the observed solvent effects ($k_{C_6H_5CN}/k_{CCl_4}$= 280) are too large in comparison with that of the 4-center reaction which showed small and abnormal solvent effects.[8] Different mechanisms in individual solvents are not plausible in view of a clear isokinetic relationship in all the solvents examined as shown in Fig. 1.

The mechanism of the reactions of (substituted arylthio)trimethylgermanes with the aroyl chlorides has thus been found to be similar to that of the analogous reactions of the arylthiosilanes at the initial step and the following heterolysis of the metal-sulfur bond, but differ in the rate-determining step. The reactions of the arylthiosilanes involve rate-

determining heterolyses of the metal-sulfur bonds while the heterolysis is the second equilibrium step in the present reaction as shown in Scheme 6. The mechanism presently suggested is also different from that of the analogous reactions of the arylthiostannanes.[3] Thus, the reactions of the arylthiosilanes, -germanes, and -stannanes with aroyl chlorides have been found to proceed by individually different mechanisms.

Experimental

Materials. Solvents were dried and distilled. Substituted aroyl chlorides were purified by distillation or recrystallization before use.

Preparation of Tetramethylgermane. The germane was prepared by modified procedure of the literature.[9] In a 3-necked flask equipped with a stirrer, a refluxing condenser, and dropping funnel, 20 g of magnesium was placed and dry nitrogen gas was passed for 30 min. Dibutyl ether (300 cm^3) was added. Methyl iodide (114 g) diluted with dibutyl ether (*ca.* 70 cm^3) was added dropwise with cooling (ice bath) and stirring. After the addition, the Grignard solution was allowed to stand for 30 min with stirring. Tetrachlorogermane (25 g) dissolved in dibutyl ether (*ca.* 20 cm^3) was added dropwise with cooling (ice-salt bath, −15 °C) and vigorous stirring. The solution was gently heated up to 70 °C after the addition. Water was carefully added dropwise with cooling (ice bath) to consume the remaining Grignard reagent. The resulting mixture was distilled and low-boiling fraction containing tetramethylgermane, water, and dibutyl ether was collected (bp 42—89 °C). Water was separated from the distillate and the organic layer was dried (Na_2SO_4). Centrifugation of the reaction mixture to separate the precipitated magnesium salt and water, and followed by rough distillation was also effective to obtain crude tetramethylgermane. Fractional distillation gave tetramethylgermane, 4.92 g, bp 42—43 °C, ^{1}H NMR δ=0.15.

Preparation of Bromotrimethylgermane. Bromine (5.94 g) was added to tetramethylgermane (4.92 g) containing catalytic amount of aluminium trichloride (*ca.* 30 mg) with stirring. The mixture was allowed to stand overnight with stirring. Excess bromine was decolorized by addition of small amount of mercury. Bromotrimethylgermane was obtained by distillation, bp 113—114 °C, 5.94 g (81%), ^{1}H NMR δ=0.85.

Trimethyl(phenylthio)germane. The phenylthiogermane was prepared as follows: To chloroform (50 ml) solution of bromotrimethylgermane (1.0 g) and triethylamine (0.77 g), benzenethiol (0.56 g) was added and the mixture was refluxed for 2 h. The solvent was evaporated and hexane (30 ml) was added to precipitate the amine salt. Trimethyl(phenylthio)germane was obtained by distillation after evaporation of hexane, bp 62 °C/1 mmHg (133.332 Pa.), ^{1}H NMR δ=0.47. Other (arylthio)trimethylgermanes were prepared similarly. Substituents, bp at 1 mmHg, and ^{1}H NMR signals other than aryl protons are as follows: *p*-Methoxy-, 85 °C, δ=0.48 and 3.83; *p*-Methyl-, 83 °C, δ=0.47 and 2.37; *p*-Chloro-, 76 °C, δ=0.44; *m*-Chloro-, 87 °C, δ=0.42; *m*-Bromo-, 106 °C, δ=0.42.

Product Analysis. Trimethyl(phenylthio)germane (1.00 g, 5.1×10^{-3} mol) was heated with an equimolar amount of benzoyl chloride (0.71 g) in carbon tetrachloride (10 cm^3) in a sealed tube at 120 °C for 30 h. ^{1}H NMR Analysis of the solution showed signals only due to chlorotrimethylgermane and *S*-phenyl thiobenzoate. Chlorotrimethylgermane was isolated by distillation (bp 108—110 °C, 68%). *S*-Phenyl thiobenzoate was obtained from the residue and purified by recrystallization, mp 55 °C (from chloroform-hexane, 70%, lit,[10] 56 °C).

Kinetics. (Arylthio)trimethylgermanes (6.55×10^{-4} mol) and aroyl chlorides (7.55×10^{-4} mol) were dissolved in the solvent using 5 ml volumetric flask. The solutions were devided into 10 portions and sealed in glass tubes of *ca.* 0.7 cm^3 volume. The tubes were heated in a constant temperature bath (±0.1 °C) and samples were taken at appropriate time intervals and cooled (ice bath). Each sample of the solution was subjected to NMR analysis. Conversion at the time was measured by the relative intensities of the starting trimethyl (δ=0.42—0.48) and that of the product (chlorotrimethylgermane: δ=0.72) which were determined by 8 to 10 repeated scannings. The rate constant k was obtained by least squares calculation of second order rate equation.

The Reactions of the Arylthiogermanes with the Solvents Used for the Kinetics. Carbon tetrachloride solution of (*m*-chlolophenylthio)trimethylgermane (0.13 mol dm^{-3}) was heated at 130 °C for 22 h. The reaction conditions correspond to more than 80% completion of the reaction of the germane with the least reactive *p*-methoxybenzoyl chloride. The amount of chlorotrimethylgermane (δ=0.72)

was measured by ^{1}H NMR analysis. Pseudo-first-order rate constant (k_1) was estimated from the conversion. Similarly, other arylthiogermanes were heated in carbon tetrachloride or in dibromomethane and the amounts of the chlorogermane (in CCl_4) and the bromogermane (in CH_2Br_2) were measured. The arylthiogermanes, solvent, and k_1 at 130 °C were as follows: $Me_3GeSC_6H_4Cl$-*m*, CCl_4, 7×10^{-7} s^{-1}; $Me_3GeSC_6H_4OMe$-*p*, CCl_4, 1×10^{-6} s^{-1}; $Me_3GeSC_6H_5$, CH_2Br_2, 3×10^{-5} s^{-1}. No reaction was found with benzonitrile under the kinetic conditions (50 °C, 24 h). The solvolyses rates were thus found much smaller than those of the reactions with aroyl chlorides and can be neglected for the kinetic studies with aroyl chlorides.

cis-Oxypalladation Complexes Derived from (1*R*,5*R*)-2(10),3-Pinadiene and Their Utilization in Pd(II)-catalyzed Enantioselective Cyclization of 2-(*trans*-2-Butenyl)phenols

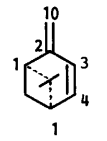
Takahiro Hosokawa,* Yasushi Imada, and Shun-Ichi Murahashi*
Department of Chemistry, Faculty of Engineering Science, Osaka University, Machikaneyama, Toyonaka, Osaka 560
(Received June 19, 1985)

(1*R*,5*R*)-2(10),3-Pinadiene, when treated with either Na_2PdCl_4 in MeOH or $Pd(OAc)_2$ in AcOH and NaCl, gives di-μ-chloro-bis[(3,2,10-η-*cis*-4-methoxy or acetoxypinene)palladium(II)] (**4a**) or (**4b**), respectively. These complexes represent the firstly isolated *cis*-oxypalladation adduct. The ligand exchange of **4b** with AgOAc affords di-μ-acetato-bis[(3,2,10-η-*cis*-4-acetoxypinene)palladium(II)] (**5b**) which serves as the catalyst for the asymmetric cyclization of 2-(*trans*-2-butenyl)phenols leading to 2-vinyl-2,3-dihydrobenzofurans (**13**). Although the enantioselectivities induced in this asymmetric cyclization are not high (1—29% ee), noteworthy is that the *cis*-complex **5b** affords (*R*)-(−)-enantiomer of **13** while the parent di-μ-acetato-bis[(3,2,10-η-pinene)palladium(II)] give the (*S*)-isomer. As an application of the present asymmetric cyclization, attempts to synthesize (*S*)-(+)-tremetone have been made.

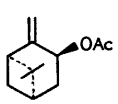
During the course of our study on the asymmetric cyclization of 2-allylphenols using (η^3-pinene)palladium(II) catalyst,[1,2] our interest has been extended to prepare η^3-allylpalladium(II) complexes bearing functionalized pinanyl ligands. For this purpose, (1*R*,5*R*)-2(10), 3-pinadiene (**1**) (verbenene) has been chosen as a precursor of the pinanyl ligand, since the reactions of 1,3-dienes with Pd(II) compounds in the presence of nucleophiles gives functionalized η^3-allylpalladium(II) complexes.[3] This type of reactions with oxygen nucleophiles such as alcohol[4] has been known to proceed by *trans*-addition; however, η^3-allylpalladium(II) complexes **4** obtained from **1** were the products derived from *cis*-addition. Although the stereochemistry of oxypalladation of alkenes has been extensively studied,[5] there has been no unambiguous examples of *cis*-oxypalladation complexes.[6] Described herein are the preparation and structural elucidation of the *cis*-oxypalladium complexes **4a**—**c**,[7] and their utilization as the catalyst for the asymmetric cyclization of 2-(*trans*-2-butenyl)-phenols.

Results and Discussion

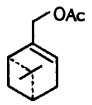
Preparation of Di-μ-chloro-bis[3,2,10-η-cis-4-methoxy or Acetoxypinene)palladium(II)] (4). The synthesis of pinadiene **1** has been previously performed by bromination of α- or β-pinene with NBS followed by dehydrobromination.[8] Although this procedure seems to be a reasonable manipulation, the diene **1** was synthesized by utilizing palladium-catalyzed elimination of allylic acetates to dienes.[9] Thus, when a mixture of allylic acetates **2** and **3** (**2**/**3**=2/1), prepared from (−)-β-pinene and $Pb(OAc)_4$,[10] was treated with $Pd(OAc)_2$ (5 mol%) in the presence of PPh_3 (0.5 equiv), diene **1** was obtained in 72% yield {$[\alpha]_D$ +106° (CCl_4)}. The overall yield of **1** (32%) from β-pinene in this procedure is comparable to that in the previous method.[8]



1

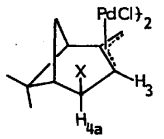


2

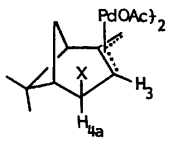


3

When the diene **1** thus obtained was allowed to react with an equimolar amount of Na_2PdCl_4 in MeOH, the *cis*-complex **4a** was formed as a single product in 66% isolated yield. The reaction of **1** with $Pd(OAc)_2$ in AcOH followed by addition of NaCl gave the complex **4b** (71%). The use of $Pd(OAc)_2$ in MeOH under otherwise the same conditions afforded two complexes **4a** (12%) and **4b** (14%). Also, the reaction of **1** with $Pd(OCOCF_3)(OOBu^t)$ in acetone and subsequent addition of NaCl gave the complex **4c** (85%).



4a; X=OMe
4b; X=OAc
4c; X=OBu^t



5a; X=OMe
5b; X=OAc
5c; X=H

The chloride ligand of complexes **4a** and **4b** is readily exchanged to acetate upon treatment with an equimolar amount of AgOAc. The complexes **5a** and **5b** thus obtained serve as the catalyst for the asymmetric cyclization of 2-(*trans*-2-butenyl)phenols (**12**). The results will be compared to those obtained by using the parent complex **5c** (X=H) (*vide infra*).

Structural Characterization. The structural elucidation of **4a**—**c** was undertaken by comparing the spectral data of **4a** and **4b** with those of the corresponding *trans*-isomers **7a** and **7b**. The authentic complexes **7a** and **7b** were prepared as

follows. The β-pinenes **6a** and **6b** bearing the substituent (X=OMe or OAc) at the C(4),*endo*-position were prepared from (−)-α-pinene by the reported method.[11,12] The reaction of **6a** with an equimolar amount of $Pd(OAc)_2$ in MeOH followed by addition of NaCl gave a 58% yield of complex **7a** (Eq. 1). Likewise, the *trans*-complex **7b** was obtained from **6b** in 52% yield. The reaction of β-pinene (**6c**) with $PdCl_2$ has been shown to proceed by the *exo*-attack of palladium at sterically less-hindered site of C(2)=C(10) olefin to give the complex **7c**.[13] The β-pinenes **6a** and **6b** react similarly with Pd(II) to afford the *trans*-complexes **7a** and **7b** as depicted in Eq. 1.

Comparison of the ^1H NMR spectral data shown in Table 1 unambiguously indicates the configurational difference between **4a** and **7a** or **4b** and **7b** (Entries 1, 2, 5, and 6), respectively. The following data in Table 1 support that the palladium is situated at the *exo*-position of all these complexes. Thus, the difference in chemical shifts between *gem*-dimethyl groups ($\Delta\delta$Me-8,9) of the *exo*-α-pinenes **4a**, **4b**, **8**, and **9** (group i) fall into the region of 0.36—0.48, whereas those of the *endo*-isomers **7a**, **7b**, **10**, and **11** (group ii) are in 0.26—0.36. Although these values tend to be lowered upon complexation, no significant difference was observed between the value of η^3-allyl complex and the corresponding α-pinene (*e.g.*, **4a** and **8**). If palladium in these complexes occupies the site opposite to that depicted, the relative chemical shift must differ greatly owing to the proximity of palladium to one of the Me group.[14] These considerations allow us to assign the *cis*-configuration of **4a** and **4b**.

The ^1H NMR spectrum of *trans*-complex **7a**

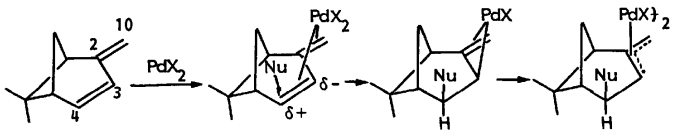
a) ^1H NMR spectra of complexes were obtained on a JEOL FX-100 ($CDCl_3$), and those of α-pinenes on a JEOL MH-100 (CCl_4) spectrometer. b) Not ascertainable.

showed no coupling between H-3 and H-4b (Table 1, Entry 5), while the coupling constant of 4.5 Hz was observed between H-3 and H-4a in the *cis*-complex **4a** (Entry 1). Similar observation was also made between the complexes **7b** and **4b**. The dihedral angle between H-3 and H-4b protons estimated by using a stereochemical model is roughly 80—90°, while that between H-3 and H-4a is around 30—40° because of the structural distortion of the pinanyl ligand. These angles, when applied to the Karplus equation, are in good agreement with the observed coupling constants. This also supports the configurational assignment of the complexes.

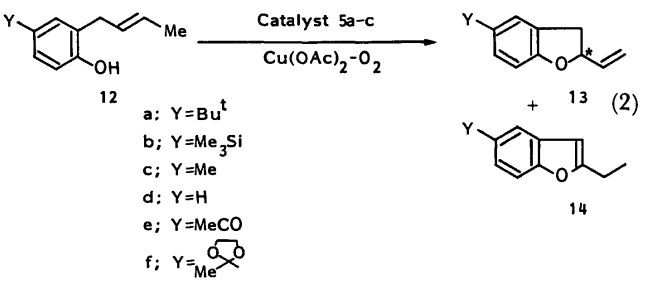
The present oxypalladation proceeds *via* π-coordination of Pd(II) to the C(3)=C(4) olefin (Scheme 1). The coordination is probably "slipped" away from the symmetrical position because of the steric factors. This allows the C(4) carbon to be more positive.[15] The *cis*-, *exo*-attack of nucleophiles on this carbon could be favorable,[16] similarly to the *cis*-oxymercuration of strained olefins such as norbornenes.[17]

*Asymmetric Cyclization of 2-(*trans*-2-Butenyl)phenols.* The results of the asymmetric cyclization of 2-(*trans*-2-butenyl)phenols (**12**) using the *cis*-complex **5b** (X=OAc) as the catalyst are shown in Table 2,



Scheme 1.

together with those obtained by using the parent complex **5c** (Eq. 2). Although the induced enantioselectivities (% ee) of product **13** are not much high in either case, the following two points are of noteworthy. 1) The acetoxy complex **5b** leads to the predominant formation of (*R*)-enantiomer of **13**, opposite to that with the complex **5c**. 2) The electron-withdrawing substituent (Y) of phenoxyl group provides a relatively higher enantiomer excess in either case, as has been observed previously,[2] and the enantioselectivity is not much affected by the steric factor of substituent Y.



The mechanistic implication of these results may deserve comments. The internal chelation of the *cis*-OAc group in **5b** to palladium(II) blocks the front side corner of the pinanyl ligands. Accordingly, the bulky phenoxyl substituent of olefin **12** prefers to be far apart from the OAc group in the stage where the substrate approaches palladium. The π-complexation A shown in Scheme 2 is thus attained at the expence of steric interference between the Me substituent of

Scheme 3.

olefin and the blocking OAc group. In the parent complex **5c**, the least steric hindrance is achieved if the Me group is situated in the "pocket" existing over the C(1) bridgehead hydrogen[2] (B in Scheme 2). *trans*-Oxypalladation from these arrangements followed by Pd–H elimination results in the formation of (*R*)- or (*S*)-enantiomer of **13**, respectively, as shown in Scheme 2.[18] The observed substituent (Y) effect common to both of the complexes suggests that the OAc group of pinanyl ligand does not alter the reaction pathways themselves.

In the case of complex **5a** (X=OMe), the two types of π-complexation (A and B) will be involved because the front-side corner must be less effectively blocked by the OMe group. In fact, the use of complex **5a** gives rise to poor enantioselectivity (1—4% ee) in the cyclization of **12a** and **12d** (Table 2, Entries 12 and 13).

As an application of the present asymmetric cyclization, the synthesis of optically active tremetone (**18**) was attempted. The oxidation of (+)-**13d** {$[\alpha]_D$ +4.11°, 16% ee} with Bu^tOOH in the presence of $Pd(OCOCF_3)(OOBu^t)$ as the catalyst gave (−)-2-acetyl-2,3-dihydrobenzofuran (**15**) {48%, $[\alpha]_D$ −9.30°} which was transformed into (*S*)-(+)-tremetone (**18**) by the following sequences (Scheme 3). Conversion of (−)-**15** into tertiary alcohol **16** with MeMgBr followed by acetylation ($SnCl_4$, Ac_2O) afforded 1-(5-acetyl-2,3-dihydro-2-benzofuranyl)-1-methylethyl acetate (**17**) (82%). Pyrolysis of the acetate **17** (330 °C, 1.5 min) gave (*S*)-(+)-tremetone (**18**) {$[\alpha]_D$ +10.4°, 17% ee[19,20]} in 76% yield. Alternatively, the Wittig reaction of (+)-**15** ($Ph_3P=CH_2$, 40 °C, 19 h, 33%) followed by acetylation ($SnCl_4$, Ac_2O, 89%) led to the formation of (*S*)-(+)-**18** {$[\alpha]_D$ +10.5°, 17% ee}.

The asymmetric cyclization of acetal **12f** (Y= ) using *cis*-complex **5b** gave (*R*)-(−)-**13f** in 29% ee. Thus, the natural (*R*)-(−)-tremetone (**18**), one of biologically active components in the white snakeroot and others, which induces "tremble" in cattle and "milksickness" in higher animals and humans,[19,20] can be derived from either (*R*)-acetals **13f** or (*R*)-(−)-**13d** (Y=H).

Experimental

Optical rotation were measured with JASCO DIP-4 polarimeter with 1 dm-long cell at room temperature. ^1H NMR spectra were recorded on JMN-MH-60 (JEOL) and JMN FX-100 (JEOL) spectrometers. GLC analysis was performed on a JEOL Model JGC-20KFP flame ionization chromatograph using a 1 m×4 mm, 10% PEG 20 M on 80—100 mesh Celite column under the conditions of injection temperature (200 °C) and column temperature (100—230 °C). Preparative GLC was carried out on a JEOL Model JGC-20KT thermal conductive chromatograph using a 2 m×4 mm or 1 m×4 mm, 10% PEG 20 M on Celite column. Preparative thin-layer chromatography plates were made of silica gel 60 PF254 (Merck).

Palladium(II) acetate $[Pd(OAc)_2]$,[21] sodium tetrachloropalladate(II) (Na_2PdCl_4),[22] and (*t*-butyldioxy) (trifluoroacetato)palladium(II) $[Pd(OCOCF_3)(OOBu^t)]$[23] were prepared as the reported method. *t*-Butyl hydroperoxide (80%) is commercially avairable [Maruwaka Chemical Ind., Ltd. (Osaka)].

Preparation of (1R,5R)-2(10),3-Pinadiene (Verbenene) (1): A mixture of 2(10)-pinen-3-yl acetate (**2**) and 2-pinen-10-yl acetate (**3**) (**2**/**3**=2/1) (12.0 g, 61.8 mmol) prepared from (−)-β-pinene {$[\alpha]_D$ −20°, Tokyo Kasei} and $Pb(OAc)_4$,[10] was added to a stirred solution of $Pd(OAc)_2$ (0.690 g, 3.08 mmol) and PPh_3 (8.10 g, 30.8 mmol) in dry dioxane (72 mL) under argon. After the mixture was refluxed for 24 h, pentane (200 mL) was added to the reaction mixture. The resulting precipitate was removed by filtration, and the filtrate was washed with water (50 mL×2), 5% aqueous $NaHCO_3$ solution (50 mL), and brine (50 mL), and dried over Na_2SO_4. Evaporation followed by distillation gave pinadiene **1** (6.00 g, 72%): bp 60—65 °C (20 mmHg) (1 mmHg=133.322 Pa); $[\alpha]_D^{22}$ +106° (*c* 0.47, CCl_4); IR (neat) 3050, 2945, 1632, 1582, 1370, and 878 (C=CH_2) cm^{-1};

^{1}H NMR (100 MHz, CCl_4) δ=0.87 (3H, s, *gem*-Me), 1.36 (3H, s, *gem*-Me), 1.46 (1H, d, J=8.0 Hz), 2.25—2.65 (3H, m), 4.66 (2H, s, H-10), 6.02 (1H, d, J=8.0 Hz, H-3), and 6.32 (1H, dd, J=8.0 and 6.5 Hz, H-4).

Found: C, 89.17; H, 10.66%. Calcd for $C_{10}H_{14}$: C, 89.49; H, 10.51%. This compound has been reported to be prepared by dehydrobromination of 10-bromo-2-pinene with γ-collidine in 46—64% yields.[8]

Reaction of Pinadiene 1 with Na_2PdCl_4 in MeOH: Into a 0.1 M (1 M=1 mol dm^{-3}) solution of Na_2PdCl_4 in MeOH (10.0 mL, 1.00 mmol) was added pinadiene **1** (0.134 g, 1.00 mmol), and the solution was stirred for 1 h at room temperature. After removal of the solvent, the residue was extracted with CH_2Cl_2 (20 mL), and the extract was washed with brine (10 mL) and dried over Na_2SO_4. Evaporation followed by Al_2O_3 column chromatography (eluent CH_2Cl_2) afforded di-μ-chloro-bis[(3,2,10-η-*cis*-4-methoxypinene)palladium(II)] (**4a**) (0.204 g, 66%): mp 145—158 °C (decomp); IR (Nujol) 1356, 1250, 1104 (C-O), 982, and 788 cm^{-1}; The ^{1}H NMR spectral data of this compound **4a** are listed in Table 1, together with those of **4b**, **7a**, **7b**, **8**, **9**, **10**, and **11** described below.

Found: C, 43.69; H, 5.62; Cl, 11.32%. Calcd for $C_{11}H_{17}ClOPd$: C, 43.02; H, 5.58; Cl, 11.54%.

Reaction of Pinadiene 1 with $Pd(OAc)_2$ in AcOH: Into a suspended solution of $Pd(OAc)_2$ (0.449 g, 2.00 mmol) in AcOH (10 mL) was added pinadiene **1** (0.268 g, 2.00 mmol). After the solution was stirred for 1 h at room temperature, NaCl (0.350 g, 6.00 mmol) was added into the solution, and stirring was further continued for 30 min. The reaction mixture was extracted with CH_2Cl_2 (50 mL), washed with 5% aqueous $NaHCO_3$ solution (20 mL×2), and brine (20 mL) and dried over Na_2SO_4. Evaporation followed by Al_2O_3 column chromatography (eluent CH_2Cl_2) to give di-μ-chloro-bis[(3,2,10-η-*cis*-4-acetoxypinene)palladium(II)] (**4b**) (0.476 g, 71%): mp 117 °C; $[\alpha]_D^{22}$ −237° (*c* 0.22, MeOH); IR (Nujol) 1737 (C=O), 1241 (C-O), 1030, and 781 cm^{-1}.

Found: C, 43.36; H, 5.26; Cl, 10.72%. Calcd for $C_{12}H_{17}ClO_2Pd$: C, 43.01; H, 5.11; Cl, 10.58%.

Reaction of Pinadiene 1 with $Pd(OAc)_2$ in MeOH: The reaction of pinadiene **1** (0.460 g, 3.43 mmol) with $Pd(OAc)_2$ (0.770 g, 3.43 mmol) in MeOH (15 mL) was carried out according to the procedure described above. After usual workup, the crude oil was purified by preparative TLC [SiO_2, benzene-acetone (9:1)] to give **4a** (0.130 g, 12%, R_f 0.49) and **4b** (0.163 g, 14%, R_f 0.57).

Preparation of Di-μ-chloro-bis[(3,2,10-η-cis-4-t-butoxypinene)palladium(II)] (4c): The reaction of pinadiene **1** (0.067 g, 0.50 mmol) with $Pd(OCOCF_3)(OOBu^t)$ (0.154 g, 0.50 mmol) in acetone (2.5 mL) was carried out according to the procedure described above. After usual workup, Al_2O_3 column chromatography (eluent CH_2Cl_2) afforded complex **4c** (0.149 g, 85%): ^{1}H NMR (60 MHz, $CDCl_3$) δ=1.03 (3H, s, *gem*-Me), 1.25 (9H, s, Bu^t), 1.41 (3H, s, *gem*-Me), 2.00—2.75 (4H, m), 3.13 (1H, br), 3.75 (1H, br), 3.85—3.95 (1H, m), and 4.16—4.25 (1H, m).

Found: C, 48.29; H, 6.47%. Calcd for $C_{14}H_{23}ClOPd$: C, 48.15; H, 6.64%.

Ligand Exchange of Complex 4a and 4b with AgOAc: The reaction of chloride complex **4a** and **4b** with AgOAc in $CHCl_3$ was carried out according to the procedure described previously.[1]

Di-μ-acetato-bis[(3,2,10-η-cis-4-methoxypinene)palladium(II)] (5a): Yield 64%; IR (KBr) 1570, 1412, 1342, 1096, 976, 920, and 780 cm^{-1}; ^{1}H NMR (60 MHz, $CDCl_3$) δ=1.00 (3H, s, *gem*-Me), 1.41 (3H, s, *gem*-Me), 1.87—2.73 (4H, m), 2.01 (3H, s, OAc), 2.83 (1H, s, *syn*-H-10), 3.30 (3H, s, OMe), 3.47 (1H, dd, J=5 and 2 Hz, H-4), 3.66 (1H, s, *anti*-H-10), and 3.98 (1H, d, J=5 Hz, H-3).

Found: C, 47.17; H, 6.19%. Calcd for $C_{13}H_{20}O_3Pd$: C, 47.22; H, 6.10%.

Di-μ-acetato-bis[(3,2,10-η-cis-4-acetoxypinene)palladium(II)] (5b): Yield 84%; $[\alpha]_D^{27}$ −75° (*c* 0.25, MeOH); IR (KBr) 1730, 1570, 1416, 1240, and 1024 cm^{-1}; ^{1}H NMR (60 MHz, $CDCl_3$) δ=1.05 (3H, s, *gem*-Me), 1.43 (3H, s, *gem*-Me), 1.80—2.03 (1H, m), 1.96 (6H, s, OAc), 2.23—2.80 (3H, m), 3.35 (1H, s, *syn*-H-10), 3.52 (1H, d, J=2 Hz, *anti*-H-10), 3.85 (1H, d, J=5 Hz, H-3), and 4.72 (1H, dd, J=5 and 3 Hz, H-4).

Found: C, 47.29; H, 5.78%. Calcd for $C_{14}H_{20}O_4Pd$: C, 46.88; H, 5.62%.

Preparation of (1S,4S,5S)-2(10)-Pinen-4-yl Methyl Ether (6a): According to the sequence of G. Ohloff *et. al.*,[12] (−)-(1S,4S,5S)-2(10)-pinen-4-ol (**20**) was firstly prepared starting from (−)-α-pinene {$[\alpha]_D$ −29° (neat), Tokyo Kasei}. In this procedure, isomerization of (1S,5S)-2-pinen-4-one (verbenone) to (1S,5S)-2(10)-pinen-4-one was performed by Herrmann's method.[24] The alcohol **20** obtained in this way was transformed into the methyl ether **6a** by the following procedure.

Sodium hydride (0.068 g, 2.83 mmol) was added to a solution of alcohol **20** (0.400 g, 2.63 mmol) and MeI (0.436 g, 3.07 mmol) in dry DME (1.5 mL) over a period of 10 min with stirring at room temperature. After stirring for 10 min, a further quantity of MeI (0.100 g, 0.705 mmol) was added, and stirring was continued for additional 2 h. The DME and excess MeI were then removed by distillation at atmospheric pressure. To the remaining mixture was added ether (5 mL), and the resulting NaI was filtered off and washed with additional ether (10 mL). Evaporation of ether followed by distillation gave 2(10)-pinen-4-yl methyl ether (**6a**) (0.357 g, 82%): bp 90—95 °C (35 mmHg); IR (neat) 2935 (C-H), 1648, 1468, 1372, 1092, 874, and 846 cm^{-1}; ^{1}H NMR (60 MHz, CCl_4) δ=0.93 (3H, s, *gem*-Me), 1.25 (3H, s, *gem*-Me), 1.63—1.75 (1H, m), 2.18—2.93 (5H, m), 3.28 (3H, s, OMe), 3.63—3.98 (1H, m, H-4), and 4.63 (2H, d, J=2 Hz, H-10).

Preparation of (1S,4S,5S)-2(10)-Pinen-4-yl Acetate (6b): The alcohol **20** (0.584 g, 3.84 mmol) was acetylated by using Ac_2O (0.431 g, 4.22 mmol) in the presence of pyridine (0.455 g, 5.76 mmol). Usual workup followed by distillation gave 2(10)-pinen-4-yl acetate (**6b**) (0.653 g, 88%): bp 70—75 °C (2 mmHg); IR (neat) 2940 (C-H), 1738 (C=O), 1648, 1472, 1372, 1242, 1042, 1024, 880, and 852 cm^{-1}; ^{1}H NMR (60 MHz, CCl_4) δ=0.93 (3H, s, *gem*-Me), 1.30 (3H, s, *gem*-Me), 1.73—2.60 (6H, m), 1.96 (3H, s, OAc), 4.66 (2H, t, J=2 Hz, H-10), and 5.05—5.50 (1H, m, H-4).

Preparation of Di-μ-chloro-bis[(3,2,10-η-trans-4-methoxypinene)palladium(II)] (7a): Into a suspended solution of $Pd(OAc)_2$ (0.225 g, 1.00 mmol) in anhydrous MeOH (5 mL) was added methyl ether **6a** (0.166 g, 1.00 mmol). After the mixture was stirred for 30 min, NaCl (0.174 g, 3.00 mmol) was added to the solution, and stirring was continued for further 30 min. The solvent was then removed under reduced pressure, and the residue was extracted with

CH_2Cl_2 (50 mL×2), washed with brine (20 mL×2), and dried over Na_2SO_4. After evaporation of the solvent, the residual yellow oil was chromatographed on Al_2O_3 (15 g). Elution with $CHCl_3$ (100 mL) gave oily material which was purified by preparative TLC [benzene–EtOAc (4:1)] to give complex **7a** (0.179 g, 58%): R_f 0.75; mp 147—151 °C (decomp); IR ($CHCl_3$) 1470, 1252, 1086, 948, and 822 cm^{-1}.

Found: C, 43.02; H, 5.58; Cl, 11.54%. Calcd for $C_{11}H_{17}ClOPd$: C, 43.39; H, 5.69; Cl, 11.03%.

Preparation of Di-μ-chloro-bis[(3,2,10-η-trans-4-acetoxypinene)palladium(II)] (7b): The reaction of acetate **6b** (0.194 g, 1.00 mmol) and $Pd(OAc)_2$ (0.225 g, 1.00 mmol) was carried out according to the procedure described above. Chromatographic purification of the resulting oil followed by preparative TLC [benzene–EtOAc (4:1)] gave complex **7b** (0.174 g, 51%): R_f 0.70; mp 145 °C (decomp); $[\alpha]_D$ −94° (*c* 0.19, MeOH); IR ($CHCl_3$) 1740 (C=O), 1045, 1023, and 980 cm^{-1}.

Found: C, 43.65; H, 5.21; Cl, 10.32%. Calcd for $C_{12}H_{17}ClO_2Pd$: C, 43.00; H, 5.11; Cl, 10.58%.

(1S,4R,5S)-2-Pinen-4-yl Acetate (9): The pinene **9** bearing OAc group at the C(4),*exo*-position was prepared by the reaction of α-pinene with $Pb(OAc)_4$ followed by isomerization in AcOH[11] in 47% yield from α-pinene; bp 96—98 °C (8 mmHg); IR (neat) 2930, 1730 (C=O), 1372, 1240 (C–O), 1018, 970, and 773 cm^{-1}.

(1S,4R,5S)-2-Pinen-4-yl Methyl Ether (8): The pinene **8** bearing OMe group at the C(4),*exo*-position was synthesized by the hydrolysis of the acetate **9** followed by treatment with MeI in 61% yield from **9**; bp 83—85 °C (23 mmHg); IR (neat) 2920, 2815, 1468, 1445, 1192, 1138, 1086, and 959 cm^{-1}.

(1S,4S,5S)-2-Pinen-4-yl Methyl Ether (10): The pinene **10** bearing OMe group at the C(4),*endo*-position was prepared by treatment of (1*S*,4*S*,5*S*)-2-pinen-4-ol (**21**) with MeI in 84% yield. The alcohol **21** was obtained by MnO_2 oxidation of (1*S*,4*R*,5*S*)-2-pinen-4-ol followed by $LiAlH_4$ reduction;[12] bp 80—83 °C (20 mmHg); IR (neat) 2930, 2810, 1446, 1368, 1354, 1190, 1088, and 952 cm^{-1}.

(1S,4S,5S)-2-Pinen-4-yl Acetate (11): The esterification of alcohol **21** with Ac_2O gave the pinene **11** bearing OAc group at the C(4),*endo*-position in 89% yield: bp 90—95 °C (8 mmHg); IR (neat) 2940, 1740 (C=O), 1662, 1450, 1375, 1242, 1022, 976, and 810 cm^{-1}.

Found: C, 74.15; H, 9.40%. Calcd for $C_{12}H_{18}O_2$: C, 74.19; H, 9.34%.

*Preparation of 4-Substituted 2-(*trans*-2-Butenyl)phenols 12*: 4-*t*-Butyl-2-(*trans*-2-butenyl)phenol (**12a**) was prepared by *C*-alkylation of *p*-*t*-butylphenol with *trans*-1-chloro-2-butene (Tokyo Kasei). 4-Trimethylsilyl-2-(*trans*-2-butenyl)-phenol (**12b**) was synthesized by the silylation of 4-bromo-2-(*trans*-2-butenyl)phenol prepared by *O*-alkylation of *p*-bromophenol with 3-chloro-2-butene followed by the Claisen rearrangemet (200 °C, *N*,*N*-diethylaniline). The silylation procedure is as follows. Into a solution of 4-bromo-2-(*trans*-2-butenyl)phenol (3.40 g, 15.0 mmol) in dry THF (20 mL) was dropwise added Bu^nLi (1.6 M in hexane, 31 mL, 50 mmol) at −78 °C, and then chlorotrimethylsilane (5.7 mL, 45 mmol) was added to the solution at −78 °C. The mixture was warmed up to room temperature, stirred overnight, quenched with 2 M HCl (30 mL), and extracted with ether. Usual workup followed by distillation gave **12b** (2.56 g, 78%); bp 95—102 °C (1 mmHg); IR (neat) 3460 (OH) and 960 (C=C) cm^{-1}; ^1H NMR (60 MHz, CCl_4) δ=0.00 (9H, s, $SiMe_3$), 1.35—1.55 (3H, m, Me), 2.90—3.23 (2H, m, CH_2), 5.10 (1H, br s, OH), and 5.18—5.50 (2H, m, CH=CH). The acetal **12f** was synthesized as follows. A mixture of 4-acetyl-2-(*trans*-2-butenyl)phenol (**12e**) (1.14 g, 6.0 mmol), ethylene glycol (18.6 g, 300 mmol), and fumaric acid (0.06 g, 0.5 mmol) in dry benzene (20 mL) was refluxed with stirring. The water formed during the reaction was removed azeotropically (Dean-Stark trap) for 72 h. After the mixture was cooled to room temperature, benzene (200 mL) and K_2CO_3 was added until drying agent was coagulated. The solid was filtered off by suction. The filtrate was washed with 5% aqueous $NaHCO_3$ solution (20 mL) and brine (20 mL), and dried over Na_2SO_4. Evaporation of the solvent and addition of pentane induced crystallization to give ethylene acetal **12f** (1.07 g, 76%): IR (Nujol) 3370, 2930, 1611 (C=C), 1504, 1377, 1275, 1204, 1097, 1036, 971, 860, and 820 cm^{-1}; ^1H NMR (60 MHz, $CDCl_3$) δ=1.65 (3H, s, Me), 1.68—1.78 (3H, m, Me), 3.38 (2H, br s), 3.75—4.10 (4H, m, OCH_2CH_2O), 4.20—5.10 (1H, m, OH), 5.60—5.78 (2H, m, CH=CH), 6.81 (1H, d, *J*=9 Hz, ArH), and 7.20—7.40 (2H, m, ArH). Preparation of other phenols **12c—e** was described previously.[1,2]

Asymmetric Cyclization of 12: The cyclization of **12** (2.5 mmol) was performed by using di-μ-acetato-bis[(3,2,10-η-pinene)palladium(II) **5a—c** (0.125 mmol as a dimer) and $Cu(OAc)_2$ (0.0454 g, 0.25 mmol) in anhydrous MeOH (5 mL) under an atmosphere of O_2 (1 atm) at 35 °C according to the general procedure described previously.[1,2] The cyclized products **13** and **14** were isolated by Kugelrohr distillation and purified by either preparative GLC (20% PEG 20 M, 2 m) or TLC. The spectral and analytical data of newly obtained products are listed below.

2-Vinyl-5-t-butyl-2,3-dihydrobenzofuran (13a): Kugelrohr distillation, bp 120—129 °C (6 mmHg); IR (neat) 2970, 1500, 1240, 930, and 810 cm^{-1}; ^1H NMR (60 MHz, CCl_4) δ=1.15 (9H, s, Bu^t), 2.69 (1H, dd, *J*=15 and 8 Hz, H-3), 3.13 (1H, dd, *J*=15 and 9 Hz, H-3), 4.75—5.35 (3H, m, H-2 and CH_2=C), 5.57—6.12 (1H, m, CH=C), 6.35 (1H, d, *J*=9 Hz, ArH), and 6.78—7.02 (2H, m, ArH).

Found: C, 83.16; H, 8.87%. Calcd for $C_{14}H_{18}O$: C, 83.12; H, 8.97%.

5-t-Butyl-2-ethylbenzofuran (14a): Kugelrohr distillation, bp 135 °C (6 mmHg); IR (neat) 2970, 1480, 1370, 1270, and 800 cm^{-1}; ^1H NMR (60 MHz, CCl_4) δ=1.32 (9H, s, Bu^t), 1.35 (3H, t, *J*=8 Hz, Me), 2.73 (2H, q, *J*=8 Hz, CH_2), 6.20 (1H, br s, H-3), and 7.12—7.41 (3H, m, ArH).

Found: C, 83.03; H, 8.84%. Calcd for $C_{14}H_{18}O$: C, 83.12; H, 8.97%.

5-Trimethylsilyl-2-vinyl-2,3-dihydrobenzofuran (13b): TLC [SiO_2, hexane–$CHCl_3$ (4:1)], R_f 0.51; IR (neat) 2950, 1600, 1480, 1250, 1240, and 815 cm^{-1}; ^1H NMR (60 MHz, CCl_4) δ=0.00 (9H, s, $SiMe_3$), 2.88 (1H, dd, *J*=18 and 8 Hz, H-3), 3.40 (1H, dd, *J*=18 and 10 Hz, H-3), 5.05—5.83 (3H, m, H-2 and CH_2=C), 7.11 (1H, d, *J*=9 Hz, ArH), and 7.37—8.07 (2H, m, ArH).

5-Trimethylsilyl-2-ethylbenzofuran (14b): TLC (the same conditions as above), R_f 0.64; IR (neat) 2950, 1598, 1250, and 820 cm^{-1}; ^1H NMR (60 MHz, CCl_4) δ=0.00 (9H, s, $SiMe_3$), 1.15 (3H, t, *J*=8 Hz, Me), 2.80 (2H, q, *J*=8Hz, CH_2), 6.60 (1H, br s, CH=C), and 7.68—8.10 (3H, m, ArH).

5-Acetyl-2-vinyl-2,3-dihydrobenzofuran Ethylene Acetal (13f): TLC [SiO_2, hexane–EtOAc (5:1)], R_f 0.70; bp 122—124 °C (1 mmHg); $[\alpha]_D$ −9.40° (*c* 4.31, CCl_4); ^1H NMR (60 MHz, CCl_4) δ=1.48 (3H, s, Me), 2.83 (1H, dd, *J*=13 and 7 Hz, H-3), 3.28 (1H, dd, *J*=13 and 8 Hz, H-3), 3.53—3.91 (4H, m, OCH_2CH_2O), 4.78—5.39 (3H, m, H-2 and CH_2=), 5.92 (1H, ddd, *J*=15, 9, and 5 Hz, -CH=), 6.50 (1H, d, *J*=9 Hz, ArH), and 6.91—7.16 (2H, m, ArH).

Found: C, 72.39; H, 6.88%. Calcd for $C_{14}H_{16}O_3$: C, 72.40; H, 6.94%.

5-Acetyl-2-ethylbenzofuran Ethylene Acetal (14f): TLC (the same conditions as above), R_f 0.80; ^1H NMR (60 MHz, CCl_4) δ=1.31 (3H, t, *J*=8 Hz, Me), 1.61 (3H, s, Me), 2.78 (2H, q, *J*=8 Hz, CH_2), 3.64—4.05 (4H, m, OCH_2CH_2O), 6.30 (1H, s, H-3), and 7.23—7.34 (3H, m, ArH).

Determination of Enantiomer Excess of 13a (Y=Bu^t): The % ee determination of **13a** (Y=Bu^t) was attempted by using Eu(tfc)$_3$ through the NMR spectrum of methyl ester derived from $KMnO_4$ oxidation of **13a** followed by esterification.[2] However, during the workup process of $KMnO_4$ oxidation performed in MeCN–glyme solution, unreproducible results were obtained for this compound, because of the difference in solubility of the resulting enantiomeric potassium 5-*t*-butyl-2,3-dihydrobenzofuran-2-carboxylate into aqueous NaOH solution.[25] Hence, the enantiomer excess of **13a** was determined through the NMR spectrum of 2-(5-*t*-butyl-2,3-dihydro-2-benzofuranyl)-2-propanol (**22**) prepared by the same manner as that of **16** (see Scheme 3).

a) Transformation of 13a (Y=Bu^t) into Tertiary Alcohol 22: A solution of 2-vinyl-5-*t*-butyl-2,3-dihydrobenzofuran (**13a**) {0.270 g, 1.3 mmol, $[\alpha]_D^{21}$ −4.54° (*c* 8.58, CCl_4)}, $Pd(OCOCF_3)(OOBu^t)$ (0.040 g, 0.13 mmol), and Bu^{t}OOH (0.30 mL, 1.3 mmol) in benzene (6 mL) was stirred at 50 °C for 65 h. Evaporation of the solvent followed by addition of pentane afforded brown precipitate which was removed by filtration. Concentration of the filtrate followed by Kugelrohr distillation gave a 60:40 mixture (0.155 g) of 2-acetyl-5-*t*-butyl-2,3-dihydrobenzofuran (**23**) and unreacted **13a**. The compound **23** purified by preparative TLC [SiO_2, hexane–EtOAc (7:3)] showed the following characteristics: R_f 0.40; IR (neat) 2952, 2860, 1812, 1756, 1720, 1494, 1362, 1239, 1216, 1160, 1064, 962, and 829 cm^{-1}; ^1H NMR (60 MHz, $CDCl_3$) δ=1.29 (9H, s, Bu^t), 2.23 (3H, s, COMe), 3.29 (1H, d, *J*=8 Hz, H-3), 3.31 (1H, d, *J*=10 Hz, H-3), 4.95 (1H, dd, *J*=10 and 8 Hz, H-2), and 6.63—7.30 (3H, m, ArH). The acetylbenzofuran **23** (0.090 g, 0.41 mmol) was treated with MeMgBr (0.50 mmol) in dry ether (4 mL) at 0 °C. Usual workup followed by preparative TLC [SiO_2, benzene–EtOAc (4:1)] gave tertiary alcohol **22** (0.040 g, 42%): R_f 0.45; ^1H NMR (60 MHz, $CDCl_3$) δ=1.23 (3H, s, Me), 1.34 (3H, s, Me), 1.31 (9H, s, Bu^t), 2.03 (1H, br, OH), 3.18 (2H, d, *J*=9 Hz, H-3), 4.67 (1H, t, *J*=9 Hz, H-2), and 6.73—7.49 (3H, m, ArH).

b) Determination of Enantiomer Excess of 13a through tert-Alcohol 22: The ^1H NMR spectra ($CDCl_3$) of tertiary alcohol **22** (0.013 g) obtained above showed a triplet signal due to the C(2) proton at δ=4.67 (*J*=9 Hz). The proton was separated clearly into two sets of triplets (*J*=9 Hz) by addition of Eu(tfc)$_3$ (0.004 g). The relative peak areas of the three sets of splitting signals led to 18% ee for this compound. Thus, the maximum rotation of **13a** is estimated to be 25.4° (CCl_4). Using **13a** with different $[\alpha]_D$ values, the experiment was repeated three times, and the results were shown to be reproducible.

Application of this procedure to **13c** (Y=Me) led to the % ee in good agreement with that obtained by the previous method.[2]

Determination of Enantiomer Excess of 13b (Y=SiMe$_3$): Optically active **13b** (0.209 g, 0.96 mmol) of $[\alpha]_D^{23}$ −5.04° (*c* 16.3, CCl_4) was dissolved in CCl_4 (3 mL), into which was added trifluoroacetic acid (5 mL) at room temperature. After stirring for 24 h, the mixture was diluted with ether, poured into saturated $NaHCO_3$ solution (20 mL), and extracted with ether. Preparative TLC [SiO_2, hexane–EtOAc (4:1), R_f 0.80] followed by Kugelrohr distillation [bp 80—82 °C (1 mmHg)] gave **13d** (Y=H) (0.023 g, 17%), the $[\alpha]_D$ of which was −4.32° (*c* 1.16, CCl_4). This value corresponds to 17% ee based on the previously reported maximum rotation.[1] The maximum rotation of **13b** is thus estimated to be −30.3° (CCl_4).

Determination of Enantiomer Excess of 13f: Into a solution of **13f** {0.182 g, 0.78 mmol, $[\alpha]_D$ −9.40°} in ether (20 mL) was added 2 M HCl solution (20 mL). After the mixture was stirred at room temperature overnight, the ether layer was washed with water and brine, and dried over Na_2SO_4. Evaporation followed by preparative TLC [SiO_2, hexane–EtOAc (4:1), R_f 0.45] gave 4-acetyl-2-vinyl-2,3-dihydrobenzofuran (**13e**) (0.085 g, 58%), the $[\alpha]_D$ of which was −25.0° (CCl_4). This value corresponds to 29% ee.[2]

Preparation of 2-Acetyl-2,3-dihydrobenzofuran (15): A solution of 2-vinyl-2,3-dihydrobenzofuran **13d** {1.00 g, 6.84 mmol, $[\alpha]_D^{23}$ +4.11° (*c* 5.55, CCl_4)}, $Pd(OCOCF_3)(OOBu^t)$ (0.210 g, 0.68 mmol), and Bu^{t}OOH (1.76 mL, 14.7 mmol) in benzene (30 mL) was stirred at 50 °C for 16 h. The mixture was extracted with CH_2Cl_2, washed with a 10% aqueous Na_2SO_3 and brine, and dried over Na_2SO_4. Evaporation of the solvent gave oily material, which was dissolved into a small amount of ether. Addition of pentane to this solution afforded brown precipitate which was removed by filtration. Evaporation followed by Kugelrohr distillation gave 2-acetyl-2,3-dihydrobenzofuran **15** (0.532 g, 48%). Analytically-pure **15** was obtained by preparative GLC; bp 100—110 °C (2 mmHg); $[\alpha]_D^{24}$ −9.30° (*c* 1.52, CCl_4); IR (neat) 1720 (C=O) cm^{-1}; ^1H NMR (60 MHz, CCl_4) δ=2.27 (3H, s, COMe), 3.37 (2H, br d, *J*=9 Hz, H-3), 4.93 (1H, t, *J*=9 Hz, H-2), and 6.53—7.26 (4H, m, ArH).

Found: C, 73.58; H, 6.18%; M^+, 162. Calcd for $C_{10}H_{10}O_2$: C, 74.05; H, 6.22%; M, 162.

Preparation of 2-(2,3-Dihydro-2-benzofuranyl)-2-propanol (16): Into a solution of MeMgBr (11.6 mmol) in ether (30 mL) was slowly added a solution of **15** (0.754 g, 4.6 mmol) in ether (10 mL). The mixture was stirred for 1 h at room temperature and then acidified by 2 M HCl. Extraction with ether followed by Kugelrohr distillation gave tertiary alcohol **16** (0.580 g, 70%) which was purified by preparative GLC: bp 78—80 °C (0.1 mmHg); $[\alpha]_D^{24}$ +5.87° (*c* 1.02, EtOH); IR (neat) 3400 (OH) cm^{-1}; ^1H MNR (60 MHz, $CDCl_3$) δ=1.12 (3H, s, Me), 1.25 (3H, s, Me), 3.05 (2H, br d, *J*=9 Hz, H-3), 3.17—3.83 (1H, m, OH), 4.51 (1H, dd, *J*=10 and 9 Hz, H-2), and 6.60—7.25 (4H, m, ArH).

Preparation of 1-(5-Acetyl-2,3-dihydro-2-benzofuranyl)-1-methylethyl Acetate (17): A mixture of tertiary alcohol **16** (0.514 g, 2.88 mmol) and Ac_2O (0.894 g, 8.76 mmol) in

benzene (20 mL) was stirred at 0 °C while a solution of $SnCl_4$ (2.25 g, 8.64 mmol) in benzene (10 mL) was added dropwise over a period of 20 min. After stirring for further 30 min, the solution was poured into ice-water, extracted with ether until neutral, and dried over Na_2SO_4. Evaporation of the solvent gave acetate **17** (0.623 g, 82%) as solid which was recrystallized from pentane; mp 95.5—97.0 °C; IR (Nujol) 1730, 1664, 1610, 1270, 1250, 966, and 820 cm^{-1}; ^1H NMR (60 MHz, CCl_4) δ=1.48 (3H, s, Me), 1.55 (3H, s, Me), 1.94 (3H, s, OAc), 2.51 (3H, s, COMe), 3.17 (2H, d, J=9 Hz, H-3), 5.02 (1H, t, J=9 Hz, H-2), 6.73 (1H, d, J=9 Hz, ArH), and 7.57—7.92 (2H, m, ArH).

Found: 68.58; H, 6.83%. Calcd for $C_{15}H_{18}O_4$: C, 68.69; H, 6.92%.

Preparation of Tremetone (18): The acetate **17** (0.117 g, 0.45 mmol) was pyrolyzed at 330 °C for 1.5 min according to the procedure of Bonner *et al.*[20] The crude tremetone (**18**) formed in 76% yield (0.091 g, 75% pure) was purified by preparative GLC: $[\alpha]_D^{21}$ +10.4° (*c* 0.87, EtOH); IR (neat) 1678, 1608, and 1264 cm^{-1}; ^1H NMR (60 MHz, $CDCl_3$) δ=1.73 (3H, s, Me), 2.40 (3H, s, COMe), 2.95 (1H, dd, J=16 and 9 Hz, H-3), 3.35 (1H, dd, J=16 and 9 Hz, H-3), 4.85 (1H, br s, $=CH_2$), 5.03 (1H, br s, $=CH_2$), 5.15 (1H, t, J=9 Hz, H-2), 6.68 (1H, d, J=9 Hz, ArH), and 7.57—7.83 (2H, m, ArH). The spectral data agrees well with that reported previously.[26] The $[\alpha]_D$ value of +10.4° corresponding to 17% ee based on the reported maximum rotation.[19]

Found C, 76.80; H, 7.07%. Calcd for $C_{13}H_{14}O$: C, 77.20; H, 6.98%.

Tremetone (18) Prepared via *Wittig Reaction*: Into a solution of Bu^nLi (1.6 M in hexane, 2.10 mL, 3.36 mmol) in ether (8 mL) was added $[Ph_3PMe]^+Br^-$ (1.32 g, 3.70 mmol) by portions, and the mixture was stirred for 4 h at room temperature under argon. Into this mixture was added dropwise a solution of 2-acetyl-2,3-dihydrobenzofuran (**15**) {0.600 g, 3.70 mmol, $[\alpha]_D$ −9.30°} in ether (2 mL). The whole mixture was then heated at 40 °C for 19 h under argon, and the resulting solid was removed by filtration. The ether layer was washed with water until neutral, and dried over $CaCl_2$. Evaporation followed by Kugelrohr distillation gave 2-isopropenyl-2,3-dihydrobenzofuran (**19**) (0.180 g, 33%): bp 105—120 °C (2 mmHg); ^1H NMR (60 MHz, $CDCl_3$) δ=1.74 (3H, d, J=1 Hz, Me), 2.96 (1H, dd, J=16 and 9 Hz, H-3), 3.34 (1H, dd, J=16 and 9 Hz, H-3), 4.83—5.33 (3H, m, $C=CH_2$ and H-2), and 6.67—7.42 (4H, m, ArH). The dihydrobenzofuran **19** (0.174 g, 1.17 mmol) was converted into tremetone (**18**) (0.223 g, 94% pure) in 89% yield by the procedure using Ac_2O (0.364 g, 3.57 mmol) and $SnCl_4$ (0.917 g, 3.52 mmol) in benzene (15 mL). Preparative TLC (SiO_2, $CHCl_3$, R_f 0.27) followed by Kugelrohr distillation [bp 170 °C (2 mmHg)], gave pure **18** of $[\alpha]_D^{24}$ +10.5° (*c* 2.64, EtOH) in 17% ee.[19]

We wish to thank Mr. Satoru Yamamoto for the experimental assistance, and Mr. Yoshio Terawaki for measureing ^1H NMR spectra.

3,3′-(Phenylphosphinylidene)bis[2(3*H*)-benzoxazolone] and 3,3′-(Phenylphosphinylidene)bis[2(3*H*)-benzothiazolone]. New Activating Agents

Mitsuru UEDA,* Amane MOCHIZUKI, Ichirō HIRATSUKA, and Hideaki OIKAWA
Department of Polymer Chemistry, Faculty of Engineering, Yamagata University, Yonezawa, Yamagata 992
(Received June 24, 1985)

New activating agents, 3,3′-(phenylphosphinylidene)bis[2(3*H*)-benzoxazolone] (**4**) and 3,3′-(phenylphosphinylidene)bis[2(3*H*)-benzothiazolone] (**5**), were readily prepared by the reaction of phenylphosphonic dichloride (**3**) with 2(3*H*)-benzoxazolone (**1**) and 2(3*H*)-benzothiazolone (**2**) respectively in the presence of triethylamine at room temperature. The new activating agents **4** and **5** were found to be useful for the preparation of amides, esters, and dipeptides under mild conditions. Furthermore, the direct polycondensation of isophthalic acid with aromatic diamines using the activating agent **4** in the presence of pyridine proceeded fast at room temperature to produce polyamides with inherent viscosities up to 0.80 dL/g.

As a part of our continuing research program on the synthesis of amides, esters and polyamides under mild conditions, our group has been studying the synthesis of new activating agents. In particular, our previous studies have resulted in a series of good leaving groups for use in the synthesis of active esters and amides.[1] Based on those studies, we showed that 3-substituted 1,2-benzisothiazole 1,1-dioxides,[2] active carbonate,[3] carbonamide,[4] and 1,2-benzisoxazol-3-yl diphenyl phosphate[5] species are new reactive activating agents for the synthesis of amides, esters and polyamides.

In the previous papers,[6,7] we showed that *N*-acyl derivatives of 2(3*H*)-benzoxazolone (**1**) or 2(3*H*)-benzothiazolone (**2**) are reactive acylating agents for the synthesis of amides and polyamides. This finding prompted us to develop further new activating agents. Recently, diphenyl 2,3-dihydro-2-oxo-3-oxazolylphosphonate has been shown to serve as a carbonyl activating agent to permit a direct preparation of versatile intermediate, 3-acyl-2(3*H*)-oxazolone or a one-step formation of amides from carboxylic acids.[8]

We now report that amides, esters, dipeptides and polyamides can be easily obtained from carboxylic acids and nucleophiles by the direct procedure using the new activating agents, 3,3′-(phenylphosphinylidene)bis[2(3*H*)-benzoxazolone] (**4**) and 3,3′-(phenylphosphinylidene)bis[2(3*H*)-benzothiazolone] (**5**).

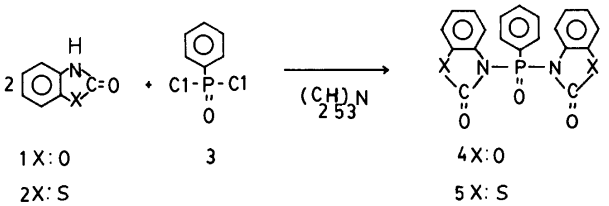
Results and Discussion

Synthesis of Activating Agents 4 and 5. The new activating agent **4** was readily prepared by reacting **1** with phenylphosphonic dichloride (**3**) in the presence of triethylamine (TEA) in benzene at room temperature. Similarly, the reagent **5** was prepared by the reaction of **2** with **3** in acetonitrile (Scheme 1).

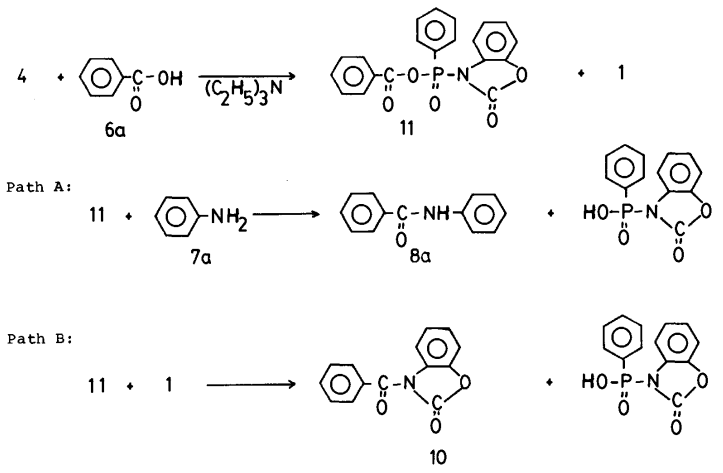
Recrystallization of these compounds from benzene gave white crystals. The structures of **4** and **5** were characterized by elemental analyses, MS, and IR spectroscopies. The IR spectrum of **4** showed carbonyl absorptions at 1780 and 1800 cm^{-1}, and P=O bond absorption at 1300 cm^{-1} On the other hand, the IR spectrum of **5** had carbonyl absorptions at 1690 and 1720 cm^{-1}, and the P=O bond absorption at 1240 cm^{-1}

Synthesis of Amides (8) and Esters (9). In order to clarify the reactivity of the activating agent **4**, we first studied the synthesis of benzanilide (**8a**) from benzoic acid (**6a**) and aniline (**7a**) in the presence of the reagent **4** by the direct procedure. This procedure consists of adding the reagent **4** to a solution of **6a** and **7a** in *N*-methyl-2-pyrrolidone (NMP) that contains a tertiary base to form benzoate ion. TEA as a tertiary base was used. The condensation proceeded rapidly at room temperature and gave **8a** in 90% yield, together with a small amount of 3-benzoyl-2(3*H*)-benzoxazolone (**10**). The most probable reaction pathway is as follows (Scheme 2).

The activating agent **4** first reacts with benzoate ion to form the mixed carboxylic-phosphoric anhydride (**11**), highly activated acylating agent. The activated intermediate **11** is less stable and its enhanced reactivity causes it to react rapidly with available nucleophiles, that is **7a** (Path A) and **1** (Path B) liberated in the first step. These reactions yield **8a** and **10**, respectively. To prevent the nucleophilic attack on the activated intermediate **11**



Scheme 1.



Scheme 2.

TABLE 1. YIELDS OF BENZANILIDE UNDER VARIOUS CONDITIONS[a)]

Ratio of 4/benzoic acid	Reaction time/h	Yield %
0.5	12	48
0.75	12	63
1.0	12	86
1.1	12	90
1.2	12	91
1.3	12	88
1.5	12	80
1.2	0.5	61
1.2	1.0	86
1.2	2.0	91
1.2	8.0	92
1.2	12	92

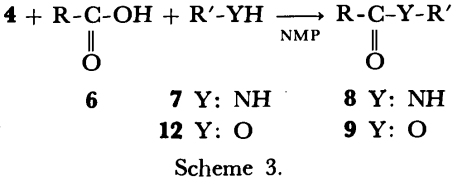
a) Reaction was carried out with 1 mmol of each monomer in the presence of TEA in NMP (2 ml) at room temperature.

by leaving group anion, pyridine (pK_a=4), less basic base than TEA (pK_a=11), was used because the acidity of **1** is about 8. Use of base TEA fully converts **1** to its anion. As would be expected, the formation of **10** was suppressed and the desired product **8a** was obtained in 98% yield.

Table 1 lists the effect of amount of the activating agent **4** and reaction time in the presence of TEA on the synthesis of **8a**. The best yield was obtained where 1.1—1.2 molar equivalent of **4** relative to **6a** was employed, and the reaction was completed in 2 h at room temperature.

On the bases of these results, the condensation of carboxylic acids (**6**) with amines (**7**) or phenols (**12**) was carried out using the activating agent **4** in the presence of TEA or pyridine in NMP (Scheme 3).

The reactions proceeded smoothly to give the corresponding amides (**8**) and esters (**9**) in good yields. Esterification required a 2 molar equivalent



Scheme 3.

of base relative to **6**. Pyridine as a base was more favorable than TEA in the synthesis of amides, but was not effective for the synthesis of esters due to the formation of active amide **10** in fairly large quantities.

Amines reacted more rapidly with the activated intermediate **11** than did phenols. With this different reactivity, next the selective *N*-acylation and *N,O*-diacylation of *p*-aminophenol (**13**) were performed either in the presence of equivalent of **4** and **6a** or 2 molar equivalent of these to **13**, respectively. The corresponding amide, 4′-hydroxybenzanilide (**14**) or amide ester, 4′-(benzoyloxy)benzanilide (**15**) was obtained in good yield (Scheme 4). (Table 2).

Similarly, the conversions of carboxylic acids **6** into amides **8** using the new activating agent **5** were carried out by the direct procedure at room temperature in the presence of TEA. In this case, pyridine did not work well, and the reagent **5** was almost recovered unchanged from the reaction solution. Synthesis of amides using the reagent **4** accompanied the formation of **10** in the presence of TEA. However, when the reagent **5** was used, the formation of 3-benzoyl-2(3*H*)-benzothiazolone was not observed. The reactions of **6** with **7** in the presence of the reagent **5** proceeded smoothly to give the corresponding amides **8** in good yields. Subsequently, selective *N*-benzoylation of **13** and glucosamine hydrochloride (**16**) were performed in the presence of TEA at room temperature to give desired amides **14** and (**17**) having free hydroxyl groups in excellent yields (Scheme 5).

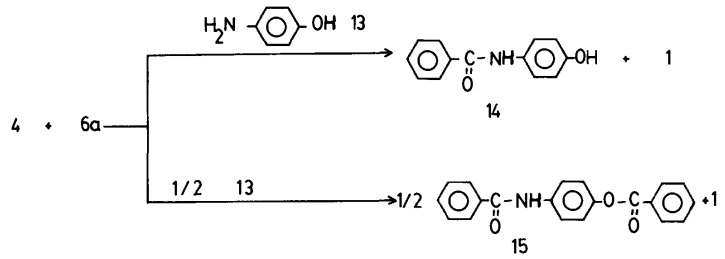
a) Reaction was carried out with 1 mmol of the reactants in NMP(2 ml). b) Solvent: Sulfolane, Reaction time: 24 h.



Scheme 4.

These results are summarized in Table 3.

Synthesis of Dipeptides (18). Peptide synthesis is essentially concerned with the formation of the amide bond. Therefore, the present reaction was applied to the preparation of dipeptides **18** (Scheme 6).

The *N*-protected α-amino acid (**19**), the α-amino acid ester hydrochloride (**20**), and the activating agent **4** or **5** were mixed in dichloromethane in the presence of 2 molar equivalent of TEA for 2 h at room temperature. The *N*-protected dipeptide **18** was isolated in the ordinary manner. The optical purity of the dipeptides was estimated by comparison of the specific rotation with the reported value. The *N*-protected dipeptide esters were obtained in the excellent yields with little racemization. These results are summarized in Tables 4 and 5.

Synthesis of Polyamides (21). In order to further demonstrate the preparative utility of our method, it was applied to the synthesis of aromatic polyamides **21**. Recent intensive investigations in the field of the synthesis of polyamides under mild conditions have resulted in the development of new methods including direct polycondensation by phosphorylation reactions and active esters. The direct polycondensation of dicarboxylic acid (**22**) with aromatic diamines (**23**) was carried out using the activating agent **4** in the presence of pyridine in polar aprotic solvents at room temperature (Scheme 7).

The effect of amount of the reagent **4** on the polycondensation of isophthalic acid (**22**) and 4,4′-oxydianiline (**23a**) is shown in Fig. 1. The inherent viscosity of the polymer reached its highest value with 30 mol% excess of the reagent **4** based on each

a) Polymerization was carried out with 1 mmol of each monomer using the activating agent **4** (2.6 mmol) in the solvent at room temperature. b) Measured at a concentration of 0.5 g/dl in concentrated sulfuric acid at 30 °C.

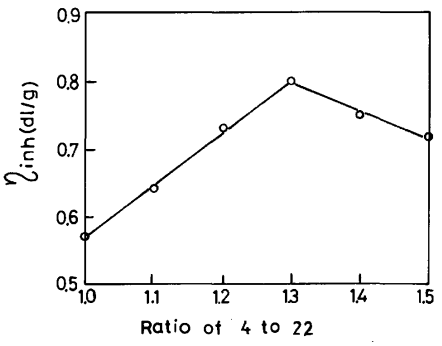

Fig. 1. Effect of amount of activating agent **4** on polycondensation.

monomer. Figure 2 shows the course of the polymerization in terms of inherent viscosity of the resulting polymer. Polycondensation took place rapidly and was almost completed within 2 h at room temperature. Table 6 shows the results of polycondensations of **22** with **23** in the presence of the reagent **4**. High-molecular-weight polyamides could be formed quite readily in polar aprotic solvents in which the polymers remained dissolved.

The polymers obtained were identified as polyamides by comparing their IR spectra with those of the authentic polyamides.

In summary, our studies indicate that the new activating agents **4** and **5** are very useful for the synthesis of amides, esters, dipeptides, and polyamides. These reagents are crystalline solids having excellent hydrolytic stability. Furthermore, 2(3*H*)-benzoxazolone **1** and 2(3*H*)-benzothiazolone **2**, leaving groups, are readily removed from the reaction products by washing the reaction mixture with 5% aqueous sodium carbonate.

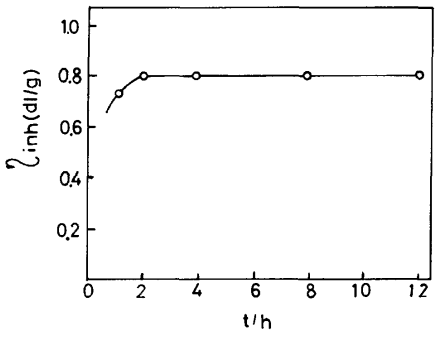

Fig. 2. Polycondensation of isophthalic acid **22** with 4,4′-oxydianiline **23a** using activating agent **4** in NMP at room temperature.

Experimental

Melting points were uncorrected. Infrared spectra were obtained using potassium bromide pellets with a JASCO IRA-1 spectrophotometer. 4,4′-Oxydianiline(**23a**) and 4,4′-methylenedianiline (**23b**) were recrystallized from tetrahydrofuran and benzene, respectively. *N*-Methyl-2-pyrrolidone (NMP), hexamethylphosphoric triamide (HMPA), and *N*,*N*-dimethylacetamide (DMAc) were purified by vacuum distillation and stored over 4 Å Molecular Sieves. *N*-Protected α-amino acids and α-amino acid ester hydrochlorides were prepared by usual procedures. The other reagents were used without further purification.

2(3H)-Benzoxazolone (1). This compound was prepared by the modified method reported by Böshagen.[9] To a ice-cold suspension of salicylohydroxamic acid (21 g, 0.14 mol) in tetrahydrofuran (45 ml), thionyl chloride (11 ml) was added dropwise over 30 min. Then excess thionyl chloride and the solvent were removed *in vacuo* to give a white paste, which was dissolved in toluene (300 ml). This solution was heated slowly to 80 °C and stirred at this temperature for 1 h, then at 120 °C for 2 h. The solvent was removed *in vacuo* to yield a white solid, which was dissolved in methanol. This solution was poured into water (500 ml). The product was collected by filtration, washed with water, and dried to give 13.5 g (73%). Recrystallization from water produced white needles. Mp 138—139 °C(lit,[9] 138 °C).

3,3′-(Phenylphosphinylidene)bis[2(3H)-benzoxazolone] (4). A solution of **1** (6.8 g, 0.05 mol) and TEA (7 ml, 0.05 mol) in dry benzene (40 ml) was cooled in an ice-water bath. To this solution was added dropwise with stirring a solution of **3** (4.9 g, 0.025 mol) in benzene (20 ml) under nitrogen. The addition was completed in 20 min, and stirring was continued at room temperature for an additional 1 h. The precipitate was separated by filtration and dried. To remove TEA·hydrochloride, the product was poured into water (100 ml). The precipitate was collected by filtration and dried *in vacuo*. Purification by recrystallization from benzene gave white needles; yield 6.3 g (64%). Mp 136 °C(by DTA); IR (KBr), 1800, 1780 (C=O), and 1300 cm^{-1} (P=O); MS, *m/z*, 392.3 (M^+). Found: C, 61.2; H, 3.5; N, 6.9%. Calcd for $C_{20}H_{13}N_2O_5P$: C, 61.23; H, 3.34; N, 7.14%.

3,3′-(Phenylphosphinylidene)bis[2(3H)-benzothiazolone] (5). 2(3*H*)-Benzothiazolone **2** was synthesized according to the method of Hunter[10] in 88% yield by the acid hydrolysis of 2-chlorobenzothiazole, which was prepared readily from 2-benzothiazolethiol and sulfuryl chloride;[11] mp 136—137 °C(lit,[10] 138 °C). A solution of **2** (5.53 g, 30 mmol) and TEA (8.4 ml, 60 mmol) in acetonitrile (12 ml) was cooled in an ice-water bath. To this solution was added dropwise with stirring a solution of **3** (2.98 g, 15 mmol) in acetonitrile (12 ml). The addition was completed in 5 min, and stirring was continued at room temperature for an additional 30 min. The solution was poured into water (100 ml). A precipitate formed and it was collected by filtration, washed with water, and dried *in vacuo*; yield 5.40 g (85%). Recrystallization from benzene produced white needles, mp 193 °C. IR(KBr), 1690, 1720 cm^{-1} (C=O), and 1240 cm^{-1} (P=O); MS, *m/z*, 424.4 (M^+). Found: C, 56.4; H, 3.2; N, 6.8%. Calcd for $C_{20}H_{13}N_2O_3PS_2$: C, 56.60; H, 3.08; N, 6.60%.

Amides (8). General Procedure: The activating agent **4** or **5** (1.1 mmol) was added to a solution of carboxylic acid **6** (1.0 mmol), amine **7** (1.1 mmol) and base (1.0 mmol) in NMP (2 ml). The solution was stirred at room temperature for 2 h, and then was poured into 5% aqueous sodium carbonate (50 ml). The precipitate was collected and dried. When TEA as a base was used, a small amount of **10** was formed (when **4** was used). But, it was removed by stirring in 5% aqueous sodium carbonate for 10 h.

Ester (9). General Procedure: A mixture of **4** (1.1 mmol), benzoic acid **6a** (1.0 mmol), phenol **12** (1.1 mmol) and TEA (2.2 mmol) was stirred at room temperature for 3 h. The reaction mixture was worked up as described above.

Protected Dipeptide Ester (18). General Procedure: To a solution of the *N*-protected α-amino acid **19** (1 mmol), the α-amino acid ester hydrochloride **20** (1 mmol) and TEA (2.0 mmol) in dichloromethane (2 ml), the reagent **4** or **5** (1.1 mmol) was added under nitrogen. The solution was stirred for 2 h at room temperature. After removal of the solvent *in vacuo*, the residue was dissolved in ethyl acetate and the organic solution was washed successively with 1 mol dm^{-3} hydrochloric acid, 5% aqueous sodium carbonate and saturated brine, and then dried with anhydrous sodium sulfate. After evaporation of ethyl acetate, the dipeptide was purified by recrystallization.

The crude products obtained (amides, esters, and dipeptide esters) were virtually pure (IR, ^{1}H-NMR spectra).

Polyamide (21). General Procedure: To a solution of isophthalic acid **22** (1.0 mmol), diamine **23** (1.0 mmol) and pyridine (2.2 mmol) in solvent was added the activating agent **4** (2.6 mmol). The mixture was stirred at room temperature for 2 h. The resulting viscous solution was diluted with solvent, and poured into methanol (200 ml). The polymer that precipitated was filtered, and was refluxed in methanol for 2 h. The fibrous polymer was collected and dried *in vacuo* at 100 °C. The yield was essentially quantitative. The inherent viscosity was measured at a concentration of 0.5 g/dl in concentrated sulfuric acid at 30 °C.

We are indebted to Mr. Sadao Kato for the performance of the elemental analyses.

Synthetic Studies of Pyridomycin. IV.[1] Syntheses of Some Twelve-membered Ring Compounds Designed for Construction of Intact Ring System with Exocyclic (*Z*)-*s*-Butylidene Side Chain in Pyridomycin

Mitsuhiro KINOSHITA* and Yasuharu MORI
Department of Applied Chemistry, Fuculty of Science and Technology, Keio University, Hiyoshi, Kohoku-ku, Yokohama 223
(Received July 1, 1985)

(2*R*,5*R*,6*S*,9*S*,10*S*,11*R*)-10-Hydroxy-2-[(1′*S*)-1′-hydroxy-1′-methylpropyl]-5,11-dimethyl-9-(3-pyridylmethyl)-6-(benzyloxycarbonylamino)-8-aza-1,4-dioxacyclododecane-3,7,12-trione and its 1′-*O*-methyl derivative, and (2*S*,1′*R*)-diastereomer of the latter have been enantiospecifically synthesized from sugar and L-threonine derivatives. The attempts to convert them into a pyridomycin precursor with the 2-(*Z*)-*s*-butylidene side chain were unsuccessful.

Pyridomycin(**1**) is an antimycobacterial antibiotic[2] produced by *Streptomyces pyridomyceticus*.[3] The most striking characteristic in its structure[4] is a novel heterocyclododecane system with unique exocyclic *s*-butylidene and 3-pyridylmethyl side chains. In the studies directed towerd the total synthesis of pyridomycin, it was first considered[1] that the cyclic compound **14** could serve as a synthetic precursor of **2** which was an intermediate of **1**, if the regiospecific dehydration[5] from **14** proceeded through an *anti*-elimination mechanism to generate the corresponding exocyclic (*Z*)-*s*-butylidene side chain in **2**. The synthetic segments, **3**[6] and **4** (or **5**),[1] utilizable to construct **14** together with L-threonine derivatives have already been enantiospecifically synthesized from D-glucose in our laboratories. Recently, an open chain model compound **8** prepared from **4** was treated with thionyl chloride in pyridine at −30 °C for 1 h to yield, in a 40% yield, a mixture[7] consisting of 16% methyl (*Z*)-2-benzyloxy-3-methyl-2-pentenoate **9** and each 42% of its regioisomers, **10** and **11** (Eq. 1). This fact indicated that the dehydration of **8** procceded through a concerted *anti*-elimination

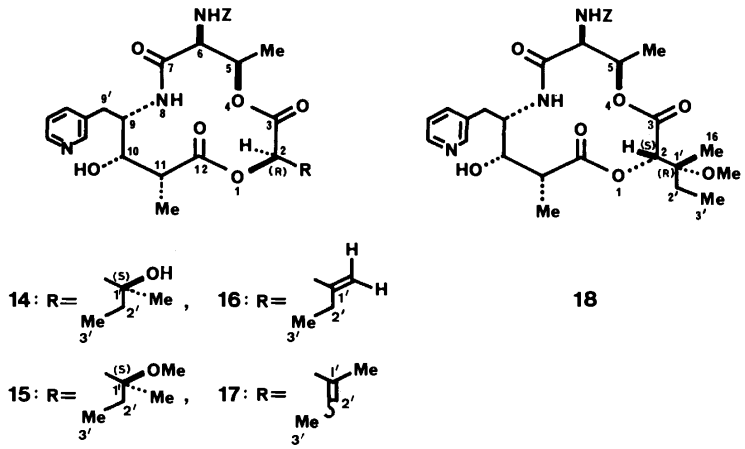
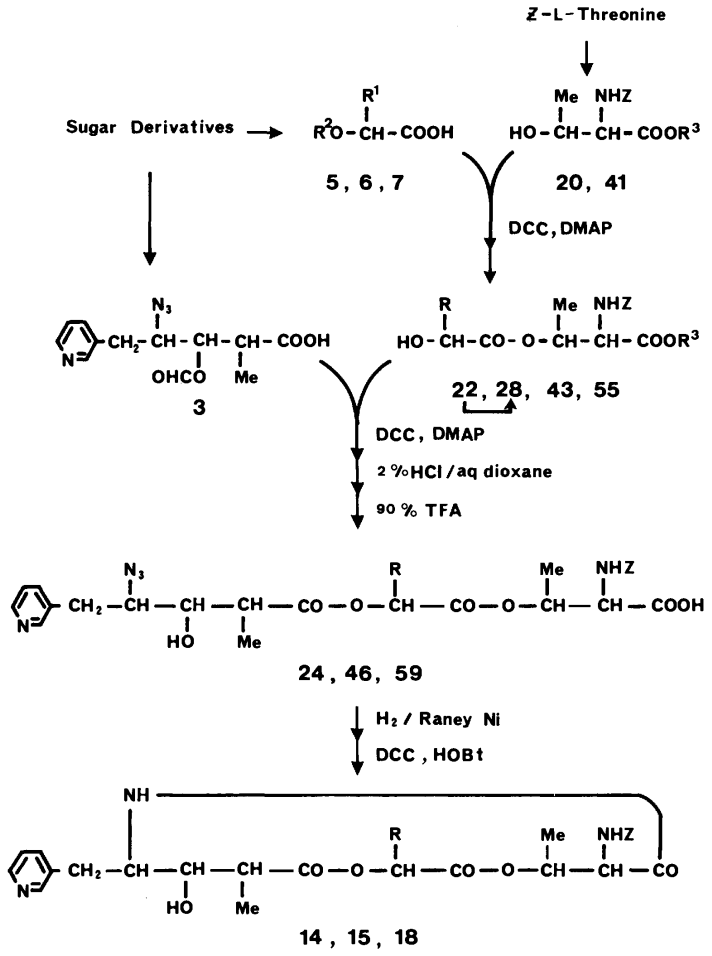
12 **9** **13** **10** (2)



mechanism[5] to yield exclusively the *Z*-isomer **9**. In order to improve the regioselectivity in the formation of **9**, the treatment of **12** derived from **8** with 1.2 equivalents of lithium diisopropylamide (LDA) in THF at −78 °C for 30 min gave a 1:1:1 mixture[7] of **9**, **13**, and **10** in a 40% yield (Eq. 2). This reaction appeared to proceed by an ElcB like mechanism where competitive abstractions of the H-2 proton and the 3-methyl proton are followed by expulsion of the 3-methoxymethoxyl group. These observations suggested that the 12-membered cyclic substrates, **14** and **15** (or **18**) would be a key intermediate for the total synthesis of pyridomycin **1**. Herein we describe the enantiospecific syntheses of **14**, **15**, and its diastereomer **18**, along with the attempts made to convert them into **2** by β-elimination.



Scheme 1.

The synthetic routes are summarized in Scheme 1 accompanied by Charts 1, 2, and 3. *O-t*-Butyl-*N*-benzyloxycarbonyl-L-threonine[8] was converted, in a 92% yield, into the 2,2,2-trichloroethyl ester **19** by treatment with 2,2,2-trichloroethanol, dicyclohexylcarbodiimide (DCC), and 4-dimethylaminopyridine (DMAP)[9] in ethyl acetate. De-*O-t*-butylation of **19** with trifluoroacetic acid (TFA) afforded a 95% yield of **20**, which was condensed with **5**[1] in the presence of DCC and DMAP to give **21** in an 85% yield. Deisopropylidenation of **21** with 80% TFA followed by condensation of the resulting **22** with **3**[5] in the presence of DCC and DMAP afforded a 73% yield of **23**. One-step conversion of **23** into the seco amino acid **26** of the lactam **14** by treatment with Zn-dust in acetic acid was unsuccessful because of formation of many complex products. Treatment of **23** with Zn-dust in 1 M† aqueous ammonium acetate gave the azido acid **24** (53% yield) and the 5-membered lactam **25** (17.6% yield). De-*O*-formylation of **23** with 2% hydrogen chloride in 50% aqueous dioxane followed by treatment with Zn-dust in 1 M† aqueous ammonium acetate afforded a crude product, whose TLC showed the presence of **26** and **25**, indicating the absence of **24**. However, only the lactam **25** was isolated on the preparative TLC [silica-gel(Merck 5715), 3:1:1 *n*-BuOH–AcOH–H_2O] of the crude product.

On the other hand, treatment of **22** with Zn-dust in acetic acid provided a 98% yield of **27**, which was converted into the benzhydryl ester **28** in an 89% yield by treatment with diphenyldiazomethane in ethyl acetate. Coupling reaction of **28** and **3** with DCC and DMAP proceeded smoothly to afford **29** in an 86% yield. De-*O*-formylation of **29** with 2% hydrogen chloride in 50% aqueous dioxane followed by treatment with 90% TFA gave **24** in an 84% yield. The azido acid **24** was selectively hydrogenolized with Raney Ni in methanol to provide the seco amino acid **26** in good yield. Cyclization of **26** was performed according to the modified Okawa's method in 10^{-3} M DMF solution with DCC (20 equiv) and 1-hydroxybenzotriazole (HOBt, 5 equiv)[10] at 5 °C for 60 h to afford the intramolecular cyclization product **14** in a 37% yield. The cyclization of **26** which was carried out with Woodward's reagent *K* according to the procedure described in the previous paper,[11] gave a 1.5% yield of **14**.

Another route to **14** from **27** was also investigated. Treatment of **27** with *t*-butyl carbazate and DCC in ethyl acetate afforded the *N*-Boc-hydrazide **30** in an 82% yield. Condensation of **30** and **3** with DCC and DMAP gave a 91% yield of product **31**. De-*O*-formylation of **31** by treatment with 2 equivalents of hydrazine hydrate in ethanol afforded a 63% yield of **32**. Hydrogenolysis of **32** with Raney Ni in 50% acetic acid followed by exposure of the resulting amino acid *N*-Boc-hydrazide to 90% TFA gave the crude seco amino acid hydrazide trifluoroacetate, which was then cyclized by the azide method using HOBt as a catalyst according to the procedure described by Veber *et al.*[12] to yield a 2.9% yield of **14**. The structure of **14** thus obtained was confirmed by 250 MHz ^{1}H-NMR and MS.

Dehydration of **14** with thionyl chloride in pyridine was carried out in the same way as in the case of the model compound **8** to give a 79% yield of dehydration product (EIMS, *m/z* 553 (M^+)) after silica-gel column chromatography. The 250 MHz ^{1}H-NMR spectrum of this product revealed that it consisted mostly of a *ca.* 1:1 mixture of the undesired regioisomers, **16** and **17** (a mixture of geometrical isomers), being contaminated by a trace amount of **2** (see Expl.). Moreover, all attempts to separate these isomers on TLC were unsuccessful. Furthermore, though attempts to isomerize the mixture of **16** and

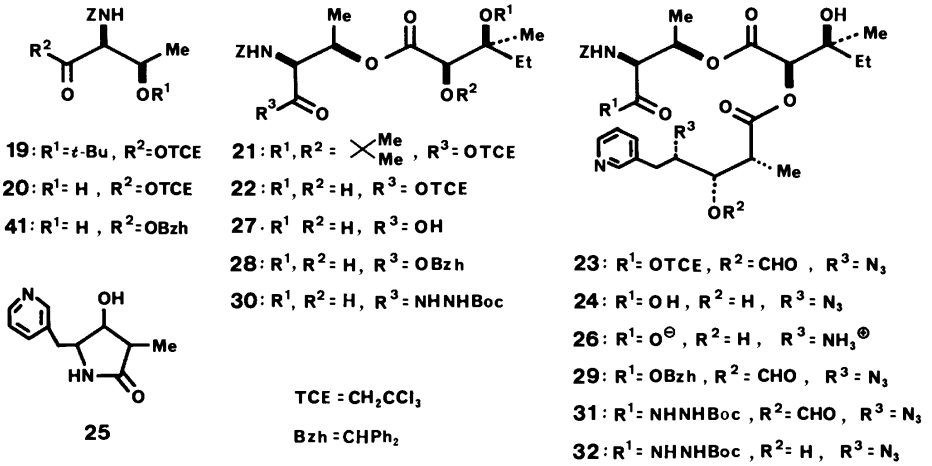


Chart 1.

† 1 M=1 mol dm^{-3}.

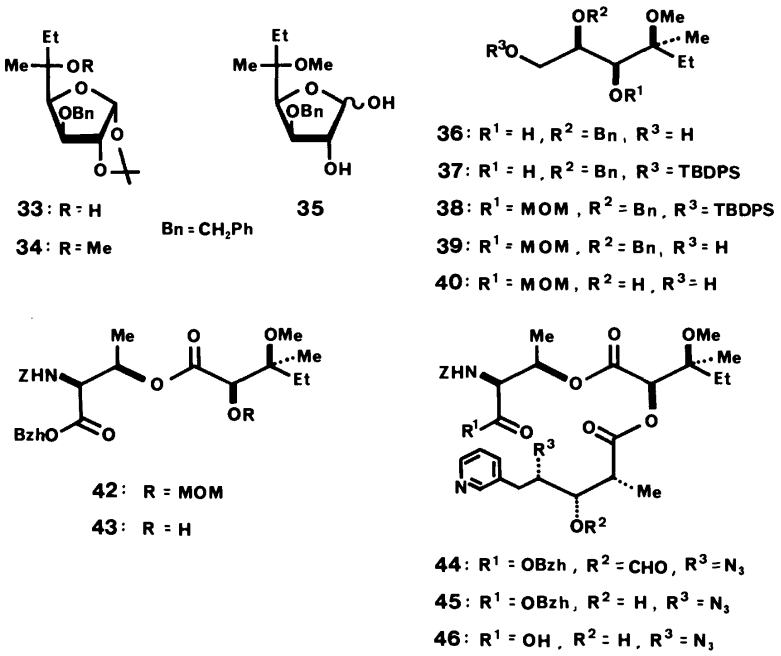

Chart 2.

17 to **2** were made under the following conditions; (a) triethylamine, DMF, 11—15 °C, 20 h, (b) LDA, THF, −75 °C, 1 h, (c) [RhCl(Ph$_3$P)$_3$],[13] ethanol, 100 °C, 3 h, (d) DBU, dioxane, 35 °C, 1.5 h, no appreciable change in the constitutional ratio of the starting olefins could be observed, with the exception of the condition (d) in which **16** was completely isomerized to **17**.

The second key intermediate **15** was next synthesized. The starting material **6** was derived from **33** which was previously prepared from D-glucose.[6] *O*-Methylation of **33** with sodium hydride and methyl iodide in DMF afforded a 77% yield of **34**, which was deisopropylidenated with boiling 50% aqueous acetic acid to give the lactol **35** in a 65% yield. Periodate oxidation of **35** followed by lithium aluminium hydride reduction afforded the diol **36** in a 67% yield. Selective *t*-butyldiphenylsilylation of **36** followed by methoxymethylation of the resulting silyl derivative **37** yielded **38**, which was then desilylated with tetrabutylammonium fluoride in THF to afford **39** in a 42% yield from **36**. Hydrogenolysis of **39** on Pd-black, followed by periodate oxidation of the resulting diol **40** gave the crude aldehyde, which was immediately oxidized with pyridine dichromate (PDC) in DMF to provide the carboxylic acid **6** in a 74% overall yield from **39**. *N*-Benzyloxycarbonyl-L-threonine was treated with diphenyldiazomethane to afford the benzhydryl ester **41** in an 80% yield. Condensation of **6** and **41** with DCC and DMAP followed by the sequential treatments of the resulting linear ester **42** with 90% TFA and with diphenyldiazomethane gave **43** in a 42% overall yield from **6**. Condensation of **43** and **3** with DCC and DMAP followed by the sequential treatments of the resulting linear ester **44** with 2% hydrogen chloride in 50% aqueous dioxane and with 90% TFA gave the azido acid **46** in a 57% overall yield from **43**. Selective hydrogenolysis of the azide group of **46** with Raney Ni in methanol followed by cyclization of the resulting seco amino acid with DCC (20 equiv) and HOBt (5 equiv) in 10^{-3} M DMF solution afforded the intramolecular cyclization product **15** in a 15% yield after sillica-gel column chromatography. The structure of **15** was also confirmed by ^{1}H-NMR and MS.

The elimination reaction of **15** was carried out with 2.2 equivalents of LDA in THF at −78 °C for 1 h. However, from the resulting light yellow solution, only the starting **15** was recovered in *ca.* 70% yield after silica-gel chromatography. This result showed that there occurred no base-promoted elimination from **15** through an ElcB like mechanism in contrast to the case of the acyclic model substrate **12**. This might be explained as follows. The ^{1}H-NMR spectrum of **15** revealed that **15** had a preferred rigid conformation. Unfortunately, because of this conformation, the base catalized enolization of the C-3 carbonyl group of **15** may be hardly stereoelectronically[14,15] or stereochemically assisted. In this respect, we were interested in the base-promoted elimination from the third cyclic substrate **18** which was the (2*S*, 1′*R*)-diastereomer of **15** and therefore might exist in a conformation different from **15**.

The preparation of **18** was started from **7**, the

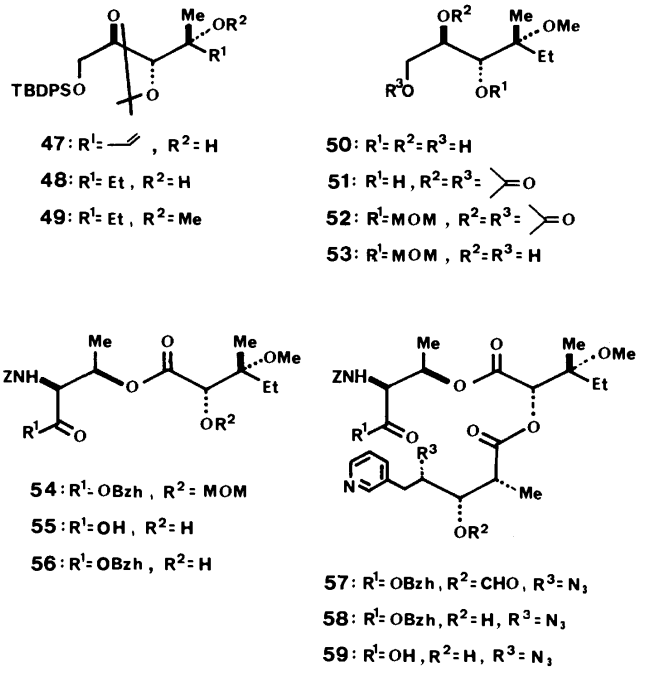

Chart 3.

enantiomer of **6**, in the same manner as that described in the preparation of **15**. The vinyl compound **47**[16] whose stereochemistry had been well confirmed, was hydrogenated on Pd–carbon to yield **48** in a 99% yield. *O*-Methylation of **48** with sodium hydride and methyl iodide in DMF afforded **49** in a 76% yield. The successive treatments with tetrabutylammonium fluoride and with 80% TFA gave **50** in a 67% yield. Reaction of **50** with *N,N'*-carbonyldiimidazole in benzene afforded the cyclic carbonate **51** as a sole product in a 61% yield. The *O*-methoxymethylated product **52** derived from **51** was decarbonated with sodium hydroxide in methanol to afford the crude diol **53**, which was subjected to the two-stage oxidation with sodium periodate in aqueous acetone and with PDC in DMF to provide **7** in a 51% overall yield from **52**. Condensation of **7** and **41** afforded an 85% yield of **54**, which was transformed, in a 65% yield, into the hydroxy benzhydryl ester **56** *via* **55** by the procedure described in the preparation of the diastereomer **43**. Condensation of **56** and **3** gave the linear ester **57** in a 72% yield, which was converted into the azido acid **59** *via* **58** in an 80% yield. Hydrogenolysis of **59** followed by cyclization with DCC and HOBt to afford **18** in a 15% yield after silica-gel column chromatography. The structure of **18** was confirmed by ^{1}H-NMR and MS. The elimination reaction of **18** was carried out in the same condition as in the case of **15** and no elimination reaction occurred. The starting **18** was recovered from the reaction mixture in *ca.* 60% yield.

Experimental

The melting points were determined on a micro hot-stage Yanaco MP-S3 and are uncorrected. The optical rotations were measured with a Carl Zeiss photoelectric polarimeter and a JASCO DIP-360 photoelectric polarimeter in chloroform unless stated otherwise. The ^{1}H-NMR spectra were recorded with either a Varian EM-390 or a Bruker WM 250 spectrometer in $CDCl_3$ using TMS as the internal standard. The IR spectra, EIMS, and SIMS were measured with a Hitachi Perkin-Elmer 225 spectrophotometer, a Hitach RMU-6M mass spectrometer, and Hitachi M-80 mass spectrometer, respectively. The TLC was carried out on Merck TLC plates (60F-254, 0.25 mm). The column chromatography was performed on silica-gel, Wakogel C-200. In general, the evaporation and concentration were carried out under reduced pressure below 30 °C unless otherwise noted.

N-Benzyloxycarbonyl-O-t-butyl-L-threonine 2,2,2-Trichloroethyl Ester (19). DCC (1.56 g, 7.573 mmol) was added at a time to an ice-cooled solution of *N*-benzyloxycarbonyl-*O*-*t*-butyl-L-threonine (2.23 g, 7.212 mmol), 2,2,2-trichloroethanol (0.696 ml, 7.212 mmol), and DMAP (59 mg, 0.48 mmol) in dry ethyl acetate (36 ml) and the mixture was stirred at 0 °C for 1.5 h. After the *N,N'*-dicyclohexylurea (DCU) had been filtered off, a small amount of acetic acid was added to the filtrate and the mixture (pH 3—4) was stirred under ice-cooling until unchanged DCC was destroyed. The DCU formed was filtered and the filtrate was evaporated to a white solid (3.41 g), which was chromatographed on silica-gel (200 g) with 12:2:1 benzene–hexane–ethyl acetate to afford **19** (2.91 g, 92%) as colorless needles. Recrystallization from pentane gave a pure sample: Mp 89—90 °C; $[\alpha]_D^{19}$ −5° (*c* 1.00); ^{1}H-NMR (90 MHz) δ=1.15 (9H, s), 1.28 (3H, d, J=6.5 Hz), 4.62 and 4.82 (2H, each d), 5.17 (2H, s), and 7.39 (5H, s).

Found: C, 48.76; H, 5.50; N, 3.01; Cl, 23.86%. Calcd for $C_{18}H_{24}NO_5Cl_3$: C, 49.05; H, 5.49; N, 3.18; Cl, 24.13%.

N-Benzyloxycarbonyl-L-threonine 2,2,2-Trichloroethyl Ester (20). A solution of **19** (1.89 g) in TFA (6.0 ml) was kept at room temperature for 5 min and then evaporated. The residue was repeatedly co-evaporated with ether and then dried over NaOH pellets under reduced pressure to give a crystalline solid (1.66 g), which was recrystallized from ether–pentane to afford **20** (1.56 g, 95%) as colorless needles: Mp 90—91 °C; $[\alpha]_D^{23}$ −21° (*c* 0.79); ^{1}H-NMR (90 MHz) δ=1.31 (3H, d, J=6.4 Hz); 4.77 and 4.88 (2H, each d), 5.17 (2H, s), and 7.40 (5H, s).

Found: C, 43.43; H, 4.13; N, 3.60; Cl, 27.58%. Calcd for $C_{14}H_{16}NO_5Cl_3$: C, 43.71; H, 4.19; N, 3.64; Cl, 27.58%.

N-Benzyloxycarbonyl-O-[(2R,3S)-2,3-dihydroxy-2,3-O-isopropylidene-3-methylpentanoyl]-L-threonine 2,2,2-Trichloroethyl Ester (21). To an ice-cooled solution of **5** (445 mg, 2.36 mmol), **20** (909 mg, 2.363 mmol), and DMAP (29 mg, 0.236 mmol) in dry ethyl acetate (8.4 ml) was added DCC (488 mg, 2.385 mmol) at a time and the mixture was stirred at 0 °C for 2 h. The DCU resulted was filtered off and the filtrate was evaporated to a pale yellow solid (1.43 g), which was chromatographed on silica-gel (100 g) with 10:1 benzene–ethyl acetate to afford **21** (1.12 g, 85%) as colorless needles. Recrystallization from ethyl acetate–

pentane gave a pure sample: Mp 108—109 °C; $[\alpha]_D^{23}$ +16° (*c* 0.55); IR (CCl_4) 3390 and 1720 cm^{-1}; ^{1}H-NMR (90 MHz) δ=0.99 (3H, t, *J*=6.5, 8.0 Hz), 1.12 (3H, s), 1.39 and 1.56 (each 3H, each s), 1.45 (3H, d, *J*=6.5 Hz), 1.5—2.0 (2H, m), 4.33 (1H, s), 4.67 (1H, dd, *J*=4.0, 11.0 Hz), 4.75 and 4.81 (2H, each *d*), 5.21 (2H, s), 5.53 (1H, dq), 5.3—5.7 (1H, br), and 7.43 (5H, s).

Found: C, 50.03; H, 5.55; N, 2.45; Cl, 19.37%. Calcd for $C_{23}H_{30}NO_8Cl_3$: C, 49.78; H, 5.45; N, 2.52; Cl, 19.17%.

N-*Benzyloxycarbonyl*-O-*[(2*R,*3*S)-*2,3-dihydroxy-3-methylpentanoyl]*-L-*threonine 2,2,2-Trichloroethyl Ester (22).* A solution of **21** (856 mg) in 80% aqueous TFA (10 ml) was allowed to stand at room temperature for 1 h and then evaporated. The residue (792 mg) was chromatographed on silica-gel (30 g) with 3:1 benzene–ethyl acetate to afford **22** (743 mg, 94%) as colorless needles: Mp 76—77 °C, $[\alpha]_D^{21}$ −41° (*c* 0.97); IR (CCl_4) 3440 and 1725 cm^{-1}; ^{1}H-NMR (90 MHz) δ=0.91 (3H, t, *J*=6.9, 7.9 Hz), 1.17 (3H, s), 1.42 (3H, d, *J*=6.5 Hz), 1.3—1.8 (2H, m), 2.78 (2H, br-s), 3.97 (1H, s), 4.5—4.8 (1H, m), 4.76 (2H, s), 5.18 (2H, s), 5.52 (1H, dq, *J*=3.5 Hz), 5.3—4.9 (1H, br), and 7.39 (5H, s).

Found: C, 46.82; H, 5.14; N, 2.52; Cl, 20.32%. Calcd for $C_{20}H_{26}NO_8Cl_3$: C, 46.66; H, 5.09; N, 2.72; Cl, 20.66%.

N-*Benzyloxycarbonyl*-O-*[(2*R,*3*S)-*2-((2*R,*3*S,*4*S)-*4-azido-3-formyloxy-2-methyl-5-(3-pyridyl)pentanoyloxy)-3-hydroxy-3-methylpentanoyl]*-L-*threonine 2,2,2-Trichloroethyl Ester (23).* To an ice-cooled solution of **22** (213 mg, 0.414 mmol), **3** (115 mg, 0.414 mmol), and DMAP (5.1 mg, 0.041 mmol) in dry ethyl acetate (2.9 ml) was added DCC (89.7 mg, 0.435 mmol) and the mixture was stirred at 0 °C for about 24 h. After the DCU had been filtered off, a small amount of acetic acid was added to the filtrate and the mixture was stirred at room temperature for 1 h. The DCU was removed by filtration and the filtrate was evaporated to a yellow syrup (447 mg), which was chromatographed on silica-gel (30 g) with 2:1 benzene–ethyl acetate to afford **23** (235 mg, 73%) as colorless syrup: $[\alpha]_D^{26}$ −8° (*c* 1.0); IR (CCl_4) 3440, 2110, and 1735 cm^{-1}; ^{1}H-NMR (90 MHz) δ=0.93 (3H, t, *J*=7.5 Hz), 1.23 (3H, s), 1.28 (3H, d, *J*=4.0 Hz), 1.40 (3H, d, *J*=9.0 Hz), 1.5—1.7 (2H, m), 2.5—3.3 (3H, m), 3.5—3.8 (1H, m), 4.0—4.3 (1H, br), 4.5—4.7 (1H, m), 4.76 (3H, s), 5.16 (2H, s), 5.2—6.0 (3H, m), 7.06 (5H, s), 7.2—7.4 (1H, m), 7.5—7.7 (2H, m), 8.20 (1H, s), and 8.4—8.6 (2H, m).

Found: C, 49.77; H, 5.06; N, 8.81%. Calcd for $C_{32}H_{38}N_5O_{11}Cl_3$: C, 49.59; H, 4.94; N, 9.04%.

N-*Benzyloxycarbonyl*-O-*[(2*R,*3*S)-*2-((2*R,*3*S,*4*S)-*4-azido-3-hydroxy-2-methyl-5-(3-pyridyl)pentanoyloxy)-3-hydroxy-3-methylpentanoyl]*-L-*threonine (24).* *(a) Preparation from 23.* To a stirred solution of **23** (25.5 mg, 0.033 mmol) in dry THF (0.25 ml) was added an aqueous 1 M ammonium acetate solution (0.022 ml) and then Zn-dust (21.5 mg, 3.3 mmol) at room temperature. After being stirred for 20 h at room temperature, the reaction mixture was filtered through a Celite and the filter cake was washed with chloroform. The filtrate and washings were evaporated and the residue was chromatographed on silica-gel (5 g) with 80:15:1 chloroform–methanol–acetic acid to give **24** (10.8 mg, 53%) and **25** (1.2 mg, 18%), whose R_f-values in the same solvent system were 0.37 and 0.13, respectively. **24**: Colorless syrup; IR ($CHCl_3$) 2100 cm^{-1}; ^{1}H-NMR (250 MHz) δ=0.88 (3H, t, *J*=8.0 Hz), 1.03 (3H, d, *J*=6.0 Hz), 1.24 (3H, s), 1.26 (3H, d, *J*=7.5 Hz), 1.53 (1H, dq, *J*=8.0 Hz), 1.66 (1H, dq), 2.9—3.2 (3H, m), 3.35 (1H, m), 3.68 (1H, d-like), 4.32 (1H, d, *J*=7.0 Hz), 4.73 (1H, s), 5.14 (2H, s), 5.4—5.8 (3H, m), 6.08 (1H, d, 10.0 Hz), 7.14—7.21 (1H, m), 7.2—7.4 (5H, m), 7.56—7.64 (1H, m), 8.47 (1H, m), and 8.56 (1H, d-like); SIMS, *m/z* 616 (M^+ +1). **25**: Colorless crystal, IR (KBr) 3300, 3180, 1700, and 1660 cm^{-1}; ^{1}H-NMR (250 MHz) δ=1.12 (3H, d, *J*=8.0 Hz), 2.54 (1H, dq, *J*=5.0 Hz), 2.91 (1H, dd, *J*=15.0, 8.0 Hz), 3.08 (1H, dd, *J*=10.0 Hz), 3.88 (1H, m), 4.07 (1H, m), 4.70 (1H, m), 7.85 (1H, d, *J*=8.0 Hz), 8.41 (1H, d, *J*=4.0 Hz), and 8.52 (1H, s).

(b) Preparation from 29. A solution of **29** (246 mg) in 25 ml of 2% HCl [in 50% (v/v) aqueous dioxane] was kept at 20 °C for 8 h and was concentrated to a syrup (250 mg), which was dissolved in 90% TFA (2.5 ml). The solution was kept at 20 °C for 0.5 h and then evaporated. The residue was co-evaporated with ether repeatedly to remove TFA and the final residue was chromatographed on silica-gel (20 g) with 90:10:1 chloroform–methanol–acetic acid to afford **24** (169 mg, 84% yield from **28**). This product was proved to be identical with the sample of **24** obtained in (a) by TLC and ^{1}H-NMR.

N-*Benzyloxycarbonyl*-O-*[(2*R,*3*S)-*2,3-dihydroxy-3-methylpentanoyl]*-L-*threonine (27).* To a solution of **22** (494 mg, 0.96 mmol) in acetic acid (5 ml) was added Zn-dust (2.2 g, 33.6 mmol) portionwise over a period of 1 h. After being stirred at 20 °C for 4 h, the reaction mixture was filtered through a Celite and the filter cake was washed with chloroform. The filtrate and washings were evaporated to a syrup (450 mg), which was chromatographed on silica-gel (25 g) with 80:5:1 chloroform–methanol–acetic acid to give **27** as a colorless glass (365 mg, 98%): ^{1}H-NMR (90 MHz, $CDCl_3$+D_2O) δ=0.88 (3H, t, *J*=7.5 Hz), 1.13 (3H, s), 1.33 (3H, d, *J*=6.0 Hz), 1.4—1.7 (2H, m) 3.90 (1H, s), 4.3—4.6 (1H, m), 5.08 (2H, s), 5.3—5.6 (1H, m), and 7.38 (5H, s).

N-*Benzyloxycarbonyl*-O-*[(2*R,*3*S)-*2,3-dihydroxy-3-methylpentanoyl]*-L-*threonine Benzhydryl Ester (28).* A mixture of benzophenone hydrazone (214 mg, 1.09 mmol), HgO (yellow) (239 mg, 1.10 mmol) and petroleum ether (0.3 ml) were stirred at room temperature for 5 h. The reaction mixture was filtered and the filtrate was evaporated to give a red-purple colored syrup of diphenyldiazomethane, which was dissolved in ethyl acetate (1.6 ml). To a solution of **27** (167 mg, 0.53 mmol) in ethyl acetate (1.6 ml) was added dropwise the above prepared solution of diphenyldiazomethane. After violent foaming had been settled, the reaction mixture was stirred at room temperature for 2 h, and then the excess diphenyldiazomethane was decomposed by addition of concd HCl under ice-cooling. The resulting mixture was washed with cold saturated aqueous $NaHCO_3$ and NaCl solutions, dried, and evaporated to a yellow syrup (359 mg), which was chromatographed on silica-gel (15 g) with 5:1 toluene–ethyl acetate to afford **28** (250 mg, 89%) as a syrup: $[\alpha]_D^{19}$ −4°, $[\alpha]_{365}^{19}$ −8° (*c* 1.81); ^{1}H-NMR (90 MHz) δ=0.83 (3H, t, *J*=6.0 Hz), 0.95 (3H, s), 1.33 (3H, d, *J*=6.0 Hz), 1.0—1.5 (2H, m), 1.6—2.0 (1H, br), 2.9—3.2 (1H, br), 3.81 (1H, br-d, *J*=10 Hz), 4.5—4.8 (1H, m), 5.13 (2H, s), 5.4—5.9 (2H, m), 6.80 (1H, s), and 7.2—7.6 (15H, m).

Found: C, 67.57; H, 6.46; N, 2.45%. Calcd for $C_{31}H_{35}NO_8$: C, 67.75; H, 6.41; N, 2.55%.

N-*Benzyloxycarbonyl*-O-*[(2*R,*3*S)-*2-((2*R,*3*S,*4*S)-*4-azido-3-formyloxy-2-methyl-5-(3-pyridyl)pentanoyloxy)-3-hydroxy-3-

methylpentanoyl]-L-threonine Benzhydryl Ester (29). To a solution of **28** (952 mg, 1.79 mmol), **3** (497 mg, 1.79 mmol), and DMAP (20 mg, 0.16 mmol) in dry ethyl acetate (15 ml) was added DCC (442 mg, 3.14 mmol) at a time and the mixture was stirred at room temperature for 48 h. The formed DCU was filtered off and the filtrate was concentrated and chromatographed on silica-gel (100 g) with 1:1 toluene–ethyl acetate to give **29** (1.23 g, 86%) as a glassy solid: ^{1}H-NMR (90 MHz) δ=0.85 (3H, t, J=7.5 Hz), 1.06 (3H, s), 1.20 (3H, d, J=9.0 Hz), 1.36 (3H, d, J=6.0 Hz), 1.2—1.5 (2H, m), 2.6—3.3 (3H, m), 3.5—3.8 (1H, m), 4.0—4.3 (1H, br), 4.5—4.8 (1H, m), 4.70 (1H, s), 5.3—5.8 (3H, m), 6.86 (1H, s), 7.1—7.4 (15H, m), 7.5—7.7 (1H, m), 8.16 (1H, s, CHO), and 8.4—8.6 (2H, m).

N-Benzyloxycarbonyl-O-[(2R,3S)-2,3-dihydroxy-3-methylpentanoyl]-L-threonine t-Butoxycarbonylhydrazide (30). To a solution of **27** (253 mg, 0.66 mmol) and Boc-NHNH$_2$ (105 mg, 0.79 mmol) in dry ethyl acetate (2.6 ml) was added DCC (143 mg, 0.69 mmol) and the mixture was stirred at room temperature for 2 h. The formed DCU was filtered off and the filtrate was concentrated and chromatographed on silica-gel (50 g) with 1:1 chloroform–ethyl acetate to give a glassy solid, which was again chromatographed on silica-gel (50 g) with 5:1 toluene-acetone to afford pure sample of **30** (286 mg, 82%) as a colorless glassy solid: $[\alpha]_D^{20}$ +50° (c 1.00); IR ($CHCl_3$) 3425, 3340, 1765, 1720, and 1685 cm^{-1}; ^{1}H-NMR (250 MHz) δ=0.86 (3H, t, J=7.0 Hz), 1.16 (3H, s), 1.24 (3H, d, J=6.0 Hz), 1.44 (9H, s), 1.40—1.60 (2H, m), 4.06 (1H, d, J=4.0 Hz), 4.50 (1H, dd, J=3.0, 10 Hz), 4.91 (1H, br-s), 5.10 (2H, s), 5.30—5.45 (2H, m), 6.45 (1H, d, J=2.0 Hz), 6.84 (1H, d, J=10 Hz), 7.36 (5H, s), and 8.80 (1H, d, J=2.0 Hz).

Found: C, 55.49, H, 7.10; N, 8.54%. Calcd for $C_{23}H_{35}N_3O_9$: C, 55.52; H, 7.09; N, 8.45%.

N-Benzyloxycarbonyl-O-[(2R,3S)-2-((2R,3S,4S)-4-azido-3-formyloxy-2-methyl-5-(3-pyridyl)pentanoyloxy)-3-hydroxy-3-methylpentanoyl]-L-threonine t-Butoxycarbonylhydrazide (31). To an ice-cooled solution of **30** (72.9 mg, 0.146 mmol), **3** (40.7 mg, 0.146 mmol), and DMAP (1.8 mg, 0.015 mmol) in dry ethyl acetate (0.8 ml) was added DCC (31.8 mg, 0.154 mmol) and the mixture was stirred at room temperature for 5 h. The DCU formed was filtered off and the filtrate was concentrated and chromatographed on silica-gel (10 g) with 1:3 chloroform–ethyl acetate to give **31** (100 mg, 91%) as a glassy solid: IR ($CHCl_3$) 2100 cm^{-1}; $[\alpha]_D^{17}$ 0°, $[\alpha]_{436}^{17}$ −39°, $[\alpha]_{365}^{17}$ −71° (c 0.84); ^{1}H-NMR (250 MHz) δ=0.93 (3H, t, J=7.0 Hz), 1.28 (3H, s), 1.29 (3H, d, J=8.0 Hz), 1.33 (3H, d, J=7.0 Hz), 1.5—1.65 (2H, m), 2.84 (1H, dd, J=11.0, 15 Hz), 3.04 (1H, dd, J=6.0 Hz), 3.16 (1H, dq, J=7.0 Hz), 3.65 (1H, br), 3.83 (1H, ddd, J=4.0 Hz), 4.48 (1H, d, J=10 Hz), 4.78 (1H, s), 5.12 (2H, ABq), 5.39 (1H, dd), 5.48 (1H, dq), 5.86 (1H, d, J=10 Hz), 7.2—7.35 (1H, m), 7.35 (5H, s), 7.63 (1H, d, J=10 Hz), 8.22 (1H, s), 8.53 (1H, d, J=4.0 Hz), 8.60 (1H, d, 2.0 Hz), and 8.74 (1H, br).

Found: C, 55.65; H, 6.35; N, 12.80%. Calcd for $C_{35}H_{47}N_7O_{12}$: C, 55.47; H, 6.25; N, 12.94%.

N-Benzyloxycarbonyl-O-[(2R,3S)-2-((2R,3S,4S)-4-azido-3-hydroxy-2-methyl-5-(3-pyridyl)pentanoyloxy)-3-hydroxy-3-methylpentanoyl]-L-threonine t-Butoxycarbonylhydrazide (32). A mixture of **31** (208 mg, 0.274 mmol), hydrazine hydrate (0.027 ml, 0.56 mmol), and ethanol (2 ml) was stirred at room temperature for 5 h. The reaction mixture was then concentrated and chromatographed on silica-gel (20 g) with 20:1 chloroform–methanol to afford a syrup of **32**. This syrup was again chromatographed on silica-gel (15 g) with 1:3 chloroform–ethyl acetate to give a pure sample of **32** (125 mg, 62.5%): IR ($CHCl_3$) 2100 cm^{-1}; $[\alpha]_D^{17}$ +9° (c 1.66).

(2R,5R,6S,9S,10S,11R)-10-Hydroxy-2-[(1'S)-1'-hydroxy-1'-methylpropyl]-5,11-dimethyl-9-(3-pyridylmethyl)-6-(benzyloxycarbonylamino)-8-aza-1,4-dioxacyclododecane-3,7,12-trione (14).

(a) *By HOBt-DCC Method:*[11] A solution of **24** (336 mg, 0.546 mmol) in methanol (30 ml) was stirred with a catalytic amount of Raney Ni (Nikko R-100) for 1 h under bubbling with hydrogen gas. The reaction mixture was filtered through a Celite and the catalyst was washed with a 1:1 methanol–dioxane. The combined filtrate and washings were evaporated to a glassy solid of crude **26**, To a solution of this residue in dry DMF (540 ml) was added HOBt (370 mg, 2.73 mmol) and then DCC (2.27 g, 11 mmol) portionwise at 0 °C with stirring. The mixture was kept at 5 °C for 60 h, after which time acetic acid (2 ml) was added to the mixture to decompose the unchanged DCC. The resulting mixture was then evaporated and the residue was taken with chloroform. The DCU undissolved was filtered and washed with chloroform twice. The combined filtrate and washings were washed with saturated aqueous $NaHCO_3$ and NaCl solutions successively, dried, and evaporated. The residue was chromatographed on silica-gel (20 g) with 15:1 chloroform–methanol to afford **14** (118 mg, 37%) as an amorphous powder: $[\alpha]_D^{18}$ −21° (c 0.96); EIMS, m/z 571 (M$^+$); ^{1}H-NMR (250 MHz) δ=0.93 (3H, t, J=7.5 Hz), 1.25 (3H, s), 1.31 (3H, d, J=6.5 Hz), 1.42 (3H, d, J=7.5 Hz), 1.52 and 1.65 (each 1H, each dq, J_{gem}=7.5 Hz), 2.55 (1H, q, J=0, 7.5 Hz), 2.6—2.8 (2H, m), 3.59 (1H, br-s), 4.03 (1H, q-like), 4.25—4.45 (2H, m), 4.96 (1H, s, H-2), 5.14 (2H, s), 5.34 (1H, dq, J=6.5, 7.0 Hz), 5.49 (1H, d, J=9 Hz), 6.26 (1H, d, J=9 Hz), 7.17 (1H, dd, J=5.0, 8.0 Hz), 7.37 (5H, s), 7.61 (1H, ddd, J=1.5, 1.8, 8.0 Hz), 8.46 (1H, dd, J=1.5, 5.0 Hz), and 8.54 (1H, d, J=1.8 Hz).

Found: C, 60.22; H, 6.69; N, 7,13%. Calcd for $C_{29}H_{37}N_3O_9$: C, 60.93; H, 6.52; N, 7.35%.

(b) *By Azide Method Using HOBt:*[12] A solution of **32** (87 mg, 0.119 mmol) in 50% aqueous acetic acid (8.7 ml) was stirred with Raney Ni for 3 h under bubbling with hydrogen gas. The mixture was filtered through a Celite and the filter cake was washed with methanol. The combined filtrate and washings were concentrated to a green syrup (250 mg), which was dissolved in 90% aqueous TFA (3 ml). The resulting solution was kept at room temperature for 1 h and then evaporated. The residue was co-evaporated with ether repeatedly to afford amorphous powder. A solution of this powder (250 mg) in dry DMF (3 ml) was acidified by addition of 6.53 M HCl in THF (0.109 ml, 0.715 mmol) at −25 °C. Isopentyl nitrite (0.020 ml, 0.145 mmol) was added and the solution stirred at −25 °C for 2 h. The resulting solution of the acyl azide was added to 100 ml of cold (−40 °C) DMF containing HOBt (81.1 mg, 0.6 mmol). The solution was neutralized by addition of triethylamine (0.150 ml, 1.062 mmol) and stored at −30 °C for 18 h and −5 °C for 24 h. The solvent was evaporated and the residue was partitioned between ethyl acetate (10 ml) and water (10 ml). The aqueous layer

separated was extracted with ethyl acetate (10 ml×5). The combined organic layers were washed with saturated aqueous $NaHCO_3$ and NaCl solutions, dried, and evaporated. The residue was chromatographed on silica-gel (20 g) with 10:1 chloroform–methanol to afford a syrup (3.5 mg). It was preparatively thin-layer chromatographed on PLC plate (Merck 5715) with 10:1 chloroform–methanol to give a pure sample of **14** (2 mg, 2.9%).

Dehydration Product (16+17) from 14. To a cold (−30 °C) solution of **14** (9 mg, 0.016 mmol) in dry pyridine (0.2 ml) was added freshly distilled $SOCl_2$ (0.012 ml, 0.16 mmol) under stirring. After being stirred at −20—−30 °C for 45 min, cold water was added and the mixture was extracted with chloroform (5×1 ml). The combined extracts were washed with saturated aqueous NaCl, dried, and evaporated to give a brown syrup (10 mg). It was chromatographed on silica-gel (2 g) with 30:1 chloroform–methanol to afford a colorless syrup of dehydration product (7 mg, 79%): EIMS, *m/z* 553 (M^+); ^{1}H-NMR (250 MHz) δ=1.08 (t, 3×H-3′ (**16**, **2**)), 1.31 (d, 5-Me, J=7.0 Hz), 1.38 (d, 11-Me (**16**, **17**), J=7.0 Hz), 1.39(d, H-5 (**2**), J=7.0 Hz), 1.50 (d, 11-Me (**2**), J=7.5 Hz), 1.63 (s, 1′-Me (**17**)), 1.67 (d, 3×H-3′ (**17**), J=7.0 Hz), 1.9—2.2 (2H, m, H-2′ (**16**, **2**)), 2.28 (*ca.* 0.5H, s, 1′-Me (**2**)), 2.50 (1H, dq, H-11, $J_{10,11}$=1.0 Hz), 2.60 (0.2H, dq, H-11 (**2**)), 2.90—3.05 (2H, m, 2×H-9′), 3.50—3.60 (1H, m, H-10), 4.02 (1H, q-like, H-9, $J\fallingdotseq$8 Hz), 4.29 (1H, t-like, H-6, $J\fallingdotseq$7 Hz), 4.35—4.50 (1H, br, OH), 5.14 (2H, s, $OC\underline{H}_2Ph$), 5.18 and 5.38 (each 0.5H, each s, H-2 (**16**, **17**)), 5.26 and 5.32 (each *ca.* 0.5H, each s, $\underline{H}_2C$=(**16**)), 5.38 (1H, dq, H-5, $J_{5,6}$=7.0 Hz), 5.40—5.50 (1H, br, 6-NH), 5.77 (*ca.* 0.5H, m, H-2′ (**17**)), 6.04 (1H, br-d, H—N(8), J=8 Hz), 7.18 (1H, dd, J=8.0, 4.5 Hz), 7.38 (5H, s, Ph), 7.62 (1H, ddd, J=2.0, 2.0 Hz), 8.46 (1H, dd), and 8.54 (1H, d).

Isomerization of Dehydration Products with DBU (16→17). A sample of the dehydration product (**16**+**17**) (7.9 mg) was dissolved in DBU (0.006 ml) and dry dioxane (0.01 ml), and then dioxane was removed by evaporation under reduced pressure. The residue was stored at 35 °C for 1.5 h. The reaction mixture was neutralized with aqueous 0.5 M HCl and then extracted thoroughly with chloroform. The combined extracts were washed with saturated aqueous NaCl, dried, and evaporated to give a yellow syrup, which was chromatographed on silica-gel (2 g) with 15:1 chloroform–methanol to afford a colorless syrup (2.7 mg) of **17** whose R_f-value was identical with the starting dehydration product: ^{1}H-NMR (250 MHz) δ=1.30 (3H, d, 5-Me, J=7.0 Hz), 1.39 (3H, 11-Me, J=7.5 Hz), 1.63 (3H, s, 1′-Me), 1.67 and 1.68 (each 1.5H, each d, 3×H-3′, J=7.0 Hz), 2.50 (1H, dq, H-11, $J_{10,11}$=1.0 Hz), 2.90—3.05 (2H, m, 2×H-9′), 3.50—3.60 (1H, m, H-10), 4.02 (1H, q-like, H-9, $J\fallingdotseq$8 Hz), 4.29 (1H, t-like, H-6, $J\fallingdotseq$7 Hz), 4.35—4.50 (1H, br, OH), 5.15 (2H, s, $OC\underline{H}_2Ph$), 5.18 and 5.38 (each 0.5H, each s, H-2), 5.38 (1H, dq, H-5, $J_{5,6}$=7.0 Hz), 5.40—5.50 (1H, br, 6-NH), 5.77 (1H, m, H-2′), 6.04 (1H, br-d, H-N(8), $J\fallingdotseq$8 Hz), 7.18 (1H, dd, J=8.0, 4.5 Hz), 7.38 (5H, s, Ph), 7.62 (1H, ddd, J=2.0, 2.0 Hz), 8.46 (1H, dd), and 8.54 (1H, d).

3-O-Benzyl-6-deoxy-5-C-ethyl-1,2-O-isopropylidene-5-O-methyl-α-D-glucofuranose (34). To a solution of **33** (5.37 g, 0.017 mol) in dry DMF (26 ml) was added 55% NaH (2.27 g, 0.052 mol) under ice-cooling. After the mixture had been stirred at room temperature for 0.5 h, methyl iodide (2.12 ml, 0.034 mol) was added to the mixture and stirring was continued for 1 h. The resulting mixture was poured into cold water and extracted with ethyl acetate. The extract was dried and evaporated to a brown syrup (8 g), which was chromatographed on silica-gel (200 g) with 5:1 toluene–ethyl acetate to afford **34** (4.38 g, 77%): A colorless syrup, $[\alpha]_D^{31}$ −68° (*c* 1.44); ^{1}H-NMR (90 MHz) δ=0.86 (3H, t, J=6.0 Hz), 1.30 (3H, s), 1.35 and 1.51 (each 3H, each s), 3.30 (3H, s), 3.90 and 4.15 (each 1H, each d, J=0, 3.0 Hz), 4.55 (1H, d, J=4.5 Hz), and 5.96 (1H, d).

Found: C, 67.55; H, 8.30%. Calcd for $C_{19}H_{28}O_5$: C, 67.83; H, 8.39%.

3-O-Benzyl-6-deoxy-5-C-ethyl-5-O-methyl-D-glucofuranose (35). A mixture of **34** (4.3 g) and 50% aqueous acetic acid (40 ml) was boiled under reflux for 5 h, and evaporated to a brown syrup, which was chromatographed on silica-gel (200 g) with 1:2 toluene-ethyl acetate to afford **35** (2.45 g, 65%).

Found: C, 64.73; H, 8.10%. Calcd for $C_{16}H_{24}O_5$: C, 64.84; H, 8.16%.

2-O-Benzyl-5-deoxy-4-C-ethyl-4-O-methyl-D-arabinitol (36). To a solution of **35** (2.35 g) in acetone (60 ml) was added a solution of sodium periodate (3.4 g) in water (40 ml). After the mixture had been stirred at room temperature for 3 h, a solution of the periodate (1.7 g) in water (20 ml) was added to the reaction mixture. The mixture was stirred in a dark place at room temperature for 1 h and filtered. Acetone was removed from the filtrate by concentration and the aqueous residue was extracted with chloroform. The extract was washed with saturated aqueous NaCl, dried, and evaporated. The residual syrup (1.74 g) was dissolved in dry THF (34 ml) and cooled in an ice-bath. Powdered $LiAlH_4$ (0.6 g, 155 mmol) was added slowly to the stirred solution and then stirred at room temperature for 2 h. Wet ether was added to the ice-cold reaction mixture to decompose the excess $LiAlH_4$. The mixture was filtered and the filter cake was washed with chloroform. The filtrate and washings were combined and evaporated to a yellow syrup (2 g), which was chromatographed on silica-gel (50 g) with 2:1 benzene–ethyl acetate to give **36** (1.4 g, 67%): a colorless syrup, $[\alpha]_D^{34}$ −25° (*c*, 1.00); ^{1}H-NMR (90 MHz) δ=0.88 (3H, t, J=7.5 Hz), 1.23 (3H, s), and 3.25 (3H, s).

Found: C, 67.06; H, 8.74%. Calcd for $C_{15}H_{24}O_4$: C, 67.13; H, 9.02%.

2-O-Benzyl-5-deoxy-4-C-ethyl-3-O-methoxymethyl-4-O-methyl-D-arabinitol (39). To a solution of **36** (1.43 g, 8.1 mmol) in dry DMF (14 ml) was added imidazole (817 mg, 12 mmol) and *t*-butyldiphenylsilyl chloride (TBDPSCl) (3.12 ml, 12 mmol), and the mixture was stirred at room temperature for 2 h. The resulting mixture was poured into cold water, and extracted with ethyl acetate. The extract was washed with a saturated aqueous NaCl solution, dried, and evaporated to a syrup, which was chromatographed on silica-gel (100 g) with 10:1 toluene–ethyl acetate to give a practically pure sample of **37** (a yellow syrup, 4.0 g, 97%). To an ice-cooled solution of this sample of **37** (4.0 g) in dry DMF (40 ml) was added methoxymethyl chloride (0.9 ml, 11.9 mmol) and diisopropylamine (2 ml, 11.5 mmol), and then the mixture was stirred at 60 °C for 2 h. The reaction mixture was poured into a cold water and extracted with ethyl acetate. The extract was washed with a saturated aqueous NaCl

solution, dried and evaporated to a crude syrup of **38** (4.0 g). To a solution of this syrup (4.0 g) in dry THF (20 ml) was added tetrabutylammonium, fluoride (1 M THF solution, 10 ml) dropwise under ice-cooling. After being stand at 0 °C for 2 h, the mixture was poured into an icewater and extracted with chloroform. The extract was washed with a saturated NaCl solution, dried, and evaporated to a syrup (4 g), which was chromatographed on silica-gel with 1:1 toluene–ethyl acetate to afford **39** (1.03 g, 42% from **36**): A colorless syrup; $[\alpha]_D^{33}$ −15° (*c* 1.00); ^{1}H-NMR (90 MHz) δ=0.87 (3H, t, *J*=7.2 Hz), 1.29 (3H, s), 1.57 (2H, q), 3.22 and 3.46 (each 3H, each s), 4.62 and 4.79 (each 2H, each s), and 7.38 (5H, s).

Found: C, 65.58; H, 8.87%. Calcd for $C_{17}H_{28}O_5$: C, 65.36; H, 9.03%.

(2R,3S)-(+)-3-Methoxy-2-(methoxymetoxy)-3-methylpentanoic Acid (6). A solution of **39** (740 mg) in methanol (7 ml) was stirred with Pd-black for 1 h under bubbling with hydrogen gas. The filtered solution was evaporated to a colorless syrup of **40** (700 mg), which was dissolved in acetone (7 ml) and to the solution a solution of sodium periodate (1.5 g, 7 mmol) in water (15 ml) was added dropwise under ice-cooling. After being stirred in a dark place at room temperature for 4 h, the reaction mixture was filtered, and acetone was removed by concentration. The resulting aqueous residue was extracted with chloroform. The extract was washed with saturated aqueous NaCl, dried, and evaporated to give 4-deoxy-3-*C*-ethyl-2-*O*-(methoxymethyl)-3-*O*-methyl-D-erythrose (colorless liquid, 780 mg). The crude aldehyde was dissolved in DME (1.8 ml) and to the solution PDC (5.4 g) was added. After being stirred at room temperature for 2 d, the mixture was filtered through silica-gel (10 g) with ether to remove the chromate. The filtrate was then evaporated to a syrup, which was chromatographed on silica-gel (30 g) with 80:5:1 chloroform–methanol–acetic acid to afford **6** (a colorless syrup, 480 mg, 74%): $bp_{0.1}$ 130 °C (bath temp); IR ($CHCl_3$) 1723 cm^{-1}; $[\alpha]_D^{29}$ +64° (*c* 1.09); ^{1}H-NMR (90 MHz) δ=0.92 (3H, t, *J*=7.5 Hz), 1.30 (3H, s), 1.73 (2H, q), 3.35 and 3.44 (each 3H, each s), 4.11 (1H, s) 4.60 and 4.85 (2H, m), and 7.79 (1H, br-s, COOH).

Found: C, 52.70; H, 8.69%. Calcd for $C_9H_{18}O_5$: C, 52.41; H, 8.80%.

N-Benzyloxycarbonyl-L-threonine Benzhydryl Ester (41). To a solution of *N*-benzyloxycarbonyl-L-threonine (500 mg, 1.97 mmol) in ethyl acetate (5 ml) was added dropwise a solution of diphenyldiazomethane in petroleum ether prepared from benzophenone hydrazone (580 mg, 2.95 mmol) and HgO (yellow) (640 mg, 2.95 mmol) in petroleum ether (0.3 ml) at room temperature for 5 h. After violent foaming had been settled, the reaction mixture was stirred at room temperature for 2 h and then excess diphenyldiazomethane was decomposed by addition of concd HCl. Water was added to the reaction mixture and extracted with ethyl acetate four times. The combined extracts were evaporated to a yellow syrup, which was chromatographed on silica-gel with 3:1 toluene–ethyl acetate to afford a pale yellow crystalline solid (662 mg, 80%). Recrystallization from hexane–ethyl acetate gave a pure sample of **41**: Colorless needles, mp 94—95 °C; $[\alpha]_D^{29}$ −19° (*c* 1,03); ^{1}H-NMR (90 MHz) δ=1.20 (3H, d, *J*=6.0 Hz), 1.8—2.1 (1H, br-s), 4.2—4.5 (2H, m), 5.10 (2H, s), 5.61 (1H, br-d, *J*=10 Hz), 6.90 (1H, s), and 7.36 (15H, s).

Found: C, 70.90; H, 6.07; N, 3.40%. Calcd for $C_{25}H_{25}NO_5$: C, 71.58; H, 6.01; N, 3.34%.

N-Benzyloxycarbonyl-O-[(2R,3S)-2-(methoxymethoxy)-3-methoxy-3-methylpentanoyl]-L-threonine Benzhydryl Ester (42). By the procedure described in the preparation of **21**, the mixture of **41** (712 mg, 1.7 mmol), **6** (350 mg, 1.69 mmol), ethyl acetate (8 ml), DMAP (20 mg, 0.16 mmol), and DCC (520 mg, 2.55 mmol) afforded **42** (650 mg, 65%) after silica-gel chromatography with 5:1 benzene–ethyl acetate: A colorless syrup, ^{1}H-NMR (90 MHz) δ=0.83 (3H, t, *J*=7.5 Hz), 1.12 (3H, s), 1.32 (3H, d, *J*=6.6 Hz), 1.53 (2H, q,), 3.18 and 3.28 (each 3H, each s), 4.00 (1H, s), 4.3—4.65 (1H, m), 4.39 and 4.48 (each 1H, ABq, J_{gem}=7.5 Hz), 5.13 (2H, s), 5.3—5.8 (2H, m), 6.86 (1H, s), and 7.10—7.50 (15H, m).

N-Benzyloxycarbonyl-O-[(2R,3S)-2-hydroxy-3-methoxy-3-methylpentanoyl]-L-threonine Benzhydryl Ester (43). A solution of **42** (650 mg) in 90% aqueous TFA (6 ml) was kept at room temperature for 1 h. Evaporation of the reaction mixture followed by co-evaporation with ether yielded a brown syrup (750 mg), which was chromatographed on silica-gel (30 g) with 80:5:1 chloroform–methanol–acetic acid to afford a colorless syrup (370 mg, 89%) of the hydroxy acid. By the same procedure as described in the preparation of **41**, the syrup (113 mg) was treated with diphenyldiazomethane to give a crude syrup (300 mg) of **43**, which was chromatographed on silica-gel (10 g) with 5:1 benzene–ethyl acetate to afford a pure sample of **43** (115 mg, 72%): A colorless syrup; $[\alpha]_D^{30}$ −2°, $[\alpha]_{365}^{30}$ −5° (*c* 2.24); ^{1}H-NMR (90 MHz) δ=0.86 (3H, t, *J*=7.5 Hz), 1.00 (3H, s), 1.31 (3H, d, *J*=7.5 Hz), 1.50 (2H, q), 2,83 (1H, br-s), 3.03 (3H, s), 3.96 (1H, s), 4.60 (1H, dd, *J*=3.0, 9.0 Hz), 5.10 (2H, s), 5.53 (1H, dq), 5.73 (1H, br-s), 6.86 (1H, s), and 7.07—7.47 (15H, m).

Found: C, 68.28; H, 6.62; N, 2.70%. Calcd for $C_{32}H_{37}NO_8$: C, 68.19; H, 6.62; N, 2.49%.

N-Benzyloxycarbonyl-O-[(2R,3S)-2-((2R,3S,4S)-4-azido-3-hydroxy-2-methyl-5-(3-pyridyl)pentanoyloxy)-3-methoxy-3-methylpentanoyl]-L-threonine (46). By the procedure described in the preparation of **29**, a mixture of **43** (117 mg, 0.207 mmol), ethyl acetate (2 ml), DMAP (2.5 mg, 0.02 mmol), and DCC (105 mg, 0.5 mmol) afforded **44** (105 mg, 63%) after purification through silica-gel (20 g) column with 3:1 toluene–ethyl acetate. A solution of **44** (105 mg) in 22 ml of a 2% HCl (in 50% (v/v) aqueous dioxane) was stirred at 35 °C for 10 h, and then evaporated to afford a syrup of **45**, which was dissolved in a 90% TFA (1 ml) and kept at room temperature for 30 min. The reaction mixture was evaporated and co-evaporated with ether. The final residue was chromatographed on silica-gel (10 g) with 80:5:1 chloroform–methanol–acetic acid to give **46** (70 mg, 57% from **43**) as a colorless glassy solid.

(2R,5R,6S,9S,10S,11R)-10-Hydroxy-2-[(1'S)-1'-methoxy-1'-methylpropyl]-5,11-dimethyl-9-(3-pyridylmethyl)-6-(benzyloxycarbonylamino)-8-aza-1,4-dioxacyclododecane-3,7,12-trione (15). By the procedure described in the preparation (a) of **14**, the azido acid **46** (110 mg) afforded a crude syrup of **15** which was purified through silica-gel column chromatography with 30:1 chloroform–methanol to provide a pure sample of **15** (16 mg, 15%) as a colorless glass: $[\alpha]_D^{27}$ −17° (*c* 0.53); ^{1}H-NMR (250 MHz) δ=0.85 (3H, t, *J*=6.2 Hz), 1.29 (3H, s), 1.30 (3H, d, *J*=7.5 Hz), 1.41 (3H, d, *J*=6.3 Hz), 1.71 (2H, q,

J=6.2 Hz), 2.59 (1H, q, J=6.3 Hz), 2.86—3.05 (2H, m), 3.21 (1H, s), 3.58 (1H, s-like), 3.93—4.10 (1H, m), 4.1—4.5 (2H, m), 5.00 (1H, s, H-2), 5.15 (2H, s), 5.40 (1H, dq, J=5.4, 7.5 Hz), 5.3—5.5 (1H, br), 6.25 (1H, br-d), 7.17 (1H, dd, J=5.0, 8.0 Hz), 7.38 (5H, s), 7.61 (1H, ddd, J=1.5, 1.8, 8.0 Hz), 8.46 (1H, dd, J=1.5, 5.0 Hz), and 8.53 (1H, d, J=1.8 Hz).

Found: m/z 585.2692. Calcd for $C_{30}H_{39}N_3O_9$: M, 585.2684.

5-O-(t-Butyldiphenylsilyl)-1-deoxy-2-C-ethyl-3,4-O-isopropylidene-D-ribitol (48). A solution of **47**[16] (3.0 g, 6.8 mmol) in methanol (30 ml) was stirred with 5% Pd-carbon (*ca.* 0.5 g) for 0.5 h under bubbling with hydrogen gas. The filtered solution was evaporated to a syrup of **48** (3.0 g, 99%). An analytical sample was obtained by silica-gel column chromatography with 10:1 toluene-ethyl acetate; colorless syrup, $[\alpha]_D^{31}$ +28° (c 1.09).

Found: C, 70.65; H, 8.40%. Calcd for $C_{26}H_{37}O_4Si$: C, 70.55; H, 8.64%.

5-O-(t-Butyldiphenylsilyl)-1-deoxy-2-C-ethyl-3,4-O-isopropylidene-2-O-methyl-D-ribitol (49). By the procedure described in the *O*-methylation of **33**, the sample of **48** (2.85 g) was *O*-methylated to afford a crude syrup of **49** (5 g), which was chromatographed on silica-gel (100 g) with 20:1 toluene-ethyl acetate to give a pure sample of **49** (2.24 g, 76%); a colorless syrup, $[\alpha]_D^{30}$ +35° (c 1.16); ^{1}H-NMR δ=0.86 (3H, t, J=7.5 Hz), 1.08 (9H, s), 1.12 (3H, s), 1.33 and 1.38 (each 3H, each s), 1.5—1.8 (2H, m), 3.15 (3H, s), and 3.5—3.8 (2H, m).

Found: C, 71.29; H, 8.62%. Calcd for $C_{27}H_{40}O_4Si$: C, 71.02; H, 8.82%.

1-Deoxy-2-C-ethyl-2-O-methyl-D-ribitol (50). To a cold solution of **49** (2.24 g) in dry THF (12 ml) was added (n-Bu)$_4$NF (7.75 ml of 1 M THF solution) dropwise. After being stirred at 5 °C for 3 h, the mixture was poured into a cold water and extracted with ethyl acetate. The extract was washed with saturated aqueous NaCl, dried, and evaporated to afford a syrup, which was dissolved in an 80% aqueous TFA (25 ml). After being kept at room temperature for 1 h, the mixture was evaporated. The residue (2.5 g) was chromatographed on silica-gel (100 g) with 15:1 chloroform–methanol to give a pure sample of **50** (5.8 g, 67%); a colorless syrup, $[\alpha]_D^{31}$ +9° (c 1.00); ^{1}H-NMR (90 MHz) δ=0.91 (3H, t, J=6.0 Hz), 1.21 (3H, s), 1.73 (2H, q), 2.7—3.1 (3H, br), and 3.23 (3H, s).

Found: C, 53.81; H, 9.90%. Calcd for $C_8H_{18}O_4$: C, 53.91; H, 10.18%.

1-Deoxy-2-C-ethyl-2-O-methyl-D-ribitol 4,5-carbonate (51). A solution of **50** (65 mg, 0.37 mmol) and *N,N'*-carbonyldiimidazole (72 mg, 0.444 mmol) in dry benzene (1.3 ml) was stirred at room temperature for 2 h, and the reaction mixture was then poured into a cold water and extracted with ethyl acetate. The extract was washed with saturated aqueous NaCl, dried, and evaporated. The residual syrup (80 mg) was chromatographed with 3:1 benzene–ethyl acetate to afford **17** (46 mg, 61%) as colorless crystals; mp 77—79 °C (hexane–ethyl acetate); $[\alpha]_D^{33}$ +17° (c 1.00); ^{1}H-NMR (90 MHz) δ=0.93 (3H, t, J=7.0 Hz), 1.18 (3H, s), 1.6—1.85 (2H, m), 2.9—3.1 (1H, br-s), 3.25 (3H, s), 3.88 (1H, d, J=4.5 Hz), and 4.4—5.0 (3H, m).

Found: C, 52.85; H, 7.75%. Calcd for $C_9H_{16}O_5$: C, 52.93; H, 7.90%.

1-Deoxy-2-C-ethyl-3-O-methoxymethyl-2-O-methyl-D-ribitol 4,5-carbonate (52). By the procedure described in the *O*-methoxymethylation of **47**, the sample of **51** (251 mg) was *O*-methyoxymethylated to afford a crude syrup of **52** (251 mg), which was chromatographed on silica-gel (25 g) with 5:1 benzene–ethyl acetate to give a pure sample of **52** (252 mg, 93%); a colorless syrup, $[\alpha]_D^{33}$ +30° (c 1.00); IR ($CHCl_3$) 1803 cm^{-1}: ^{1}H-NMR (90 MHz) δ=0.91 (3H, t, J=7.5 Hz), 1.20 (3H, s), 1.5—1.7 (2H, m), 3.23 and 3.43 (each 3H, each s), 3.91 (1H, d, J=1.0 Hz), and 4.3—5.1 (5H, m).

Found: C, 53.28; H, 7.97%. Calcd for $C_{11}H_{20}O_6$: C, 53.21; H, 8.12%.

(2S,3R)-(−)-3-Methoxy-2-(methoxymethoxy)3-methylpentanoic Acid (7). To a solution of **52** (251 mg, 1.08 mmol) in methanol (3 ml) was added an aqueous 1 M NaOH solution (2.2 ml). After being stirred at room temperature for 20 min, the reaction mixture was neutralized with CG-50 resin (H^+ type) to pH 6—8 under ice-cooling, and filtered. The filtrate and methanolic washings were combined and evaporated to give a crude syrup of **53**. The two-stage oxidation of the crude **53** was carried out by the same procedure described in the preparation of **6** from **40** to afford the enantiomeric **7** (114 mg, 51% yield from **52**). This sample of **7** was purified by bulb to bulb distillation; colorless syrup, $bp_{0.1}$ 130 °C (bath temp.); IR ($CHCl_3$) 1723 cm^{-1}; $[\alpha]_D^{28}$ −61° (c 0.96); the ^{1}H-NMR (90 MHz) and IR spectra were identical with those of **6**.

Found: C, 52.52; H, 8.61%. Calcd for $C_9H_{18}O_5$: C, 52.41; H, 8.80%.

N-Benzyloxycarbonyl-O-[(2S,3R)-2-(methoxymethoxy)-3-methoxy-3-methylpentanoyl]-L-threonine Benzhydryl Ester (54). The title compound **54** was prepared from **7** and **41** by the procedure described in the preparation of **42**. **54**: A colorless syrup, ^{1}H-NMR (90 MHz) δ=0.81 (3H, t, J=7.5 Hz), 1.13 (3H, s), 1.36 (3H, d, J=6.6 Hz), 1.2—1.5 (2H, m), 3.18 (3H, s), 3.31 (3H, s), 4.00 (1H, s), 4.36 and 4.53 (each 1H, ABq, J=7.5 Hz), 4.63 (1H, dd, J=2.5, 12 Hz), 5.15 (2H, s), 5.61 (1H, dq), 5.78 (1H, br-d), 6.90 (1H, s), and 7.13—7.58 (15H, m).

N-Benzyloxycarbonyl-O-[(2S,3R)-2-hydroxy-3-methoxy-3-methylpentanoyl]-L-threonine (55). **55**: Colorless needles, mp 120—121 °C; $[\alpha]_D^{28}$ +39° (c 1.25); ^{1}H-NMR (90 MHz) δ=0.83 (3H, t, J=7.5 Hz), 1.10 (3H, s), 1.30 (3H, d, J=6.0 Hz), 1.60 (2H, q), 3.15 (3H, s), 3.88 (1H, br), 4.08 (1H, s), 4.56 (2H, dd, J=1.0, 10 Hz), 5.08 (2H, s), 5.53 (1H, dq), 5.5—6.2 (2H, br), and 7.40 (5H, s).

N-Benzyloxycarbonyl-O-[(2S,3R)-2-hydroxy-3-methoxy-3-methylpentanoyl]-L-threonine Benzhydryl Ester (56). **56**: A colorless syrup, $[\alpha]_D^{30}$ +3°, $[\alpha]_{365}^{30}$ +16° (c 1.49); ^{1}H-NMR (90 MHz) δ=0.81 (3H, t, 7.5 Hz), 1.00 (3H, s), 1.33 (3H, d, J=6.6 Hz), 1.26—1.70 (2H, m), 2.8—3.0 (1H, m), 3.16 (3H, s), 3.73 (1H, s), 4.50—4.76 (1H, m), 5.15 (2H, s), 5.4—5.8 (2H, m), 6.83 (1H, s), and 7.13—7.58 (15H, m).

Found: C, 68.17; H, 6.61; N, 2.48%. Calcd for $C_{32}H_{37}NO_8$: C, 68.19; H, 6.62; N, 2.49%.

N-Benzyloxycarbonyl-O-[(2S,3R)-2-((2R,3S,4S)-4-azido-3-formyloxy-2-methyl-5-(3-pyridyl)pentanoyloxy)-3-methoxy-3-methylpentanoyl]-L-threonine Benzhydryl Ester (57). The compound **57** was prepard from **3** (118 mg) and **56** (232 mg) by the same procedure as described in the preparation of **44**. A practically pure sample of **57** (281 mg, 72%) was obtained

by silica-gel (25 g) column chromatography of the crude product with 1:1 toluene–ethyl acetate.

N-Benzyloxycarbonyl-O-[(2S,3R)-2-((2R,3S,4S)-4-azido-3-hydroxy-2-methyl-5-(3-pyridyl)pentanoyloxy)-3-methyoxy-3-methylpentanoyl]-L-threonine Benzhydryl Ester (58). A practically pure sample of **57** (281 mg) was dissolved in a 2% HCl solution in 50% aqueous dioxane (5 ml). After being stirred at 35 °C for 7 h, the reaction mixture was evaporated to a syrup of **58** which was used for the next preparation without further purification. A pure sample of **58** was obtained by silica-gel column chromatography with 40:1 chloroform–methanol; a colorless syrup, $[\alpha]_D^{31}$ +8°, $[\alpha]_{365}^{31}$ +17° (*c* 0.90).

Found: C, 64.91; H, 6.35; N, 8.75%. Calcd for $C_{43}H_{49}N_5O_{10}$: C, 64.90; H, 6.20; N, 8.80%.

(2S,5R,6S,9S,10S,11R)-10-Hydroxy-2-[(1'R)-1'-methoxy-1'-methylpropyl]-5,11-dimethyl-9-(3-pyridylmethyl)-6-(benzyloxycarbonylamino)-8-aza-1,4-dioxacyclododecane-3,7,12-trione (18). By the procedure described in the preparation of **15**, the title compound **18** was obtained in a 12% yield from **58** *via* the azido acid **59** as a colorless syrup: $[\alpha]_D^{29}$ −48° (*c* 0.89); ^{1}H-NMR (250 MHz) δ=0.88 (3H, t, *J*=8.3 Hz), 1.17 (3H, d, *J*=5.0 Hz), 1.33 (3H, d, *J*=8.0 Hz), 1.43 (3H, s), 1.65—1.90 (2H, m), 2.44 (2H, dq, *J*=1.5, 8.0 Hz), 2.9—3.2 (2H, m), 3.26 (3H, s), 3.60 (1H, br), 4.00—4.13 (1H, m), 4.0—4.5 (1H, br), 4.45 (1H, dd, *J*=5.0 Hz), 4.71 (1H, s, H-2), 5.00 (1H, dq), 5.13 (2H, s), 5.86 (1H, br-d), 6.76 (1H, br-d), 7.25 (1H, dd, *J*=5.0, 8.0 Hz), 7.36 (5H, s), 7.69 (1H, ddd, *J*=1.5, 1.8, 8.0 Hz), 8.51 (1H, dd, *J*=1.5, 5.0 Hz), and 8.59 (1H, d, *J*=1.8 Hz).

Found: *m/z* 585.2678. Calcd for $C_{30}H_{39}N_3O_9$: M, 585.2683.

We are grateful to Prof. Sumio Umezawa, Institute of Bioorganic Chemistry, and Prof. Hamao Umezawa, Institute of Microbial Chemistry, for the generous support of our program. We also thank Mr. Masaki Awamura and Mr. Noriyoshi Igami for their early contributions to this project, Mr. Saburo Nakada for elemental analyses, and Miss Yukiko Suzuki for 250 MHz ^{1}H-NMR analyses.

Stereoselective Oxylactonization. Preparation of 2-Deoxy-DL-ribono-1,4-lactone Derivatives from 3-Silyloxy-4-alkenamides

Yuh-ichiro ICHIKAWA, Tetsuo MIWA, and Koichi NARASAKA*
Department of Chemistry, Faculty of Science, The University of Tokyo, Hongo, Bunkyo-ku, Tokyo 113
(Received July 6, 1985)

The oxylactonization of 3-silyloxy-4-alkenamides proceeds stereoselectively by treatment with *m*-chloroperbenzoic acid to give the corresponding 2-deoxy-DL-ribono-1,4-lactone derivatives.

Halolactonization reaction of acyclic alkenoic acids or their derivatives has been used to functionalize double bonds in a stereoselective manner,[1] and widely applied to the synthesis of natural products.[2] It was expected that the development of oxylactonization in which alkenoic acid derivatives are converted to the corresponding hydroxy lactones in a one-pot manner would provide an effective method for the preparation of polyhydroxy compounds. Hence, the oxylactonization of 4-alkenoic acid derivatives was undertaken using *m*-chloroperbenzoic acid (MCPBA) as an oxidant.

When 4-pentenoic acid (**1a**) and the corresponding 3-phenylpropyl ester **1b** were treated with MCPBA at room temperature, the generation of the epoxides was observed. The successive lactonization to 5-hydroxy-4-pentanolide (**2**), however, proceeded very slowly.[3] On the other hand, the reaction of *N,N*-dimethyl-4-pentenamide (**1c**) with MCPBA was found to afford 5-hydroxy-4-pentanolide (**2**), however, even at room temperature.[4]

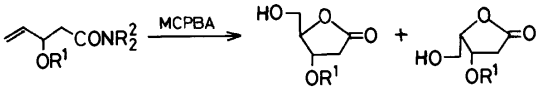
1a X=OH
b X=O(CH$_2$)$_3$Ph
c X=NMe$_2$

2

As an alkenamide is susceptible to the oxylactonization with MCPBA, we next investigated the stereochemical course of the oxylactonization of 3-hydroxy-4-pentenamide **3a**. The treatment of *N,N*-diisopropyl-3-hydroxy-4-pentenamide (**3a**) with a 4-molar amount of MCPBA in benzene at room temperature generated 3,4-*trans*(*erythro*)-3,5-dihydroxy-4-pentanolide (**4a**) predominantly along with the 3,4-*cis*(*threo*)-isomer **5a** (**4a**:**5a**=2.6:1).

Particularly interesting was that the oxylactonization of **3a** with MCPBA shows the opposite stereoselectivity to the halolactonization of 3-hydroxy-(or silyloxy)-4-alkenoic acids, which are generally converted to the 3,4-cis-substituted butanolides.[1c] Therefore, the stereoselectivity of this oxylactonization was examined in detail by introducing various protecting groups to the 3-hydroxyl group of the amide **3a**. When acyl groups such as acetyl, benzoyl, pivaloyl, and ethoxycarbonyl groups were employed for the protection of the 3-hydroxyl group, the yields of oxylactones **4** and **5** were very low because of the elimination of acyloxyl groups occurred under the reaction conditions. The reaction of the benzyl (Bn) ether **3b** and the methoxymethyl (MOM) ether **3c** with MCPBA proceeded smoothly, however, the stereoselectivity toward the *trans*(*erythro*)-lactone **4** was not improved (**4**:**5**=*ca.* 2:1).

The high selectivity was observed when the *t*-butyldimethylsilyl (TBS) ether **3d** was employed. The reaction of **3d** with MCPBA in benzene afforded the trans-substituted isomer **4d** in favorable selectivity. The structure of **4d** was confirmed by the transformation to 2-deoxy-DL-ribono-1,4-lactone[5] by removal of the TBS group with aqueous acetic acid in tetrahydrofuran at 80 °C.

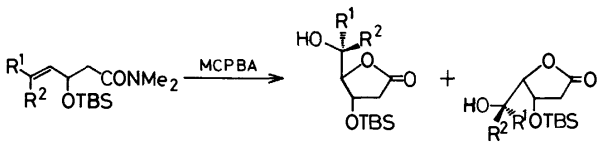


3 4 5

Table 1. Oxylactonization of the 3-hydroxy-4-pentenamide derivatives **3**

	R^1	R^2	Yield/%	(**4** : **5**)
3a	H	*i*-Pr	88	(2.6 : 1)
3b	Bn	Me	70	(2.1 : 1)
3c	MOM	Me	54	(1.9 : 1)
3d	TBS	*i*-Pr	90	(4.3 : 1)

Furthermore, (*E*) and (*Z*)-isomers of 3-silyloxy-4-hexenamide (**6a** and **6b**) were prepared and submitted to the reaction with MCPBA. In the oxylactonization of the (*Z*)-amide **6a**, the both stereoisomers **7a** and **8a** were formed in comparable amounts. On the other hand, it was noted that the 3,4-*trans*-substituted lactone **7b** was generated in good selectivity (**7b**:**8b**=3.9:1) from the (*E*)-hexenamide **6b**.

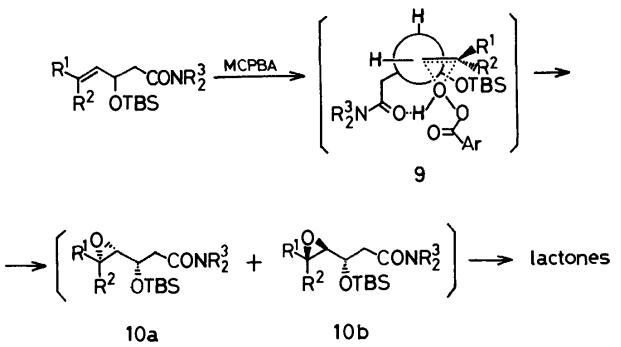


6 7 8

Table 2. Oxylactonization of the 3-silyloxy-4-hexenamides **6**

	R^1	R^2	Yield/%	(**7** : **8**)
6a	H	Me	63	(1.1 : 1)
6b	Me	H	79	(3.9 : 1)

From these results, the following speculation might be suggested for the *trans* stereoselection in the present oxylactonization. The lactonization is considered to proceed *via* unstable epoxy amides **10**, which are successively converted to hydroxy lactones by the intramolecular attack of the amide oxygen. The stereoselectivity is consequently directed in the epoxidation step. The epoxidation maybe proceeds through "the inside alkoxy transition state **9**"[6] in which MCPBA forms a hydrogen bond with the amide group[7] to result in the predominant formation of the *threo*-epoxide **10a**. The remarkable decrease of the selectivity in the case of the (*Z*)-amide **6a** is well explained by the steric interaction between the (*Z*)-methyl group and the TBS group in the preferred transition state **9**.



9

10a 10b

In conclusion, the oxylactonization of 3-silyloxy-4-alkenamides was found to proceed by the simple treatment with MCPBA to yield 2-deoxy-DL-ribono-1,4-lactone derivatives in good stereoselectivity. In contrast to *cis*-selective halolactonization, the present oxylactonization provides a useful method for the preparation of polyoxygenated 3,4-*trans*-substituted butyrolactones.

Experimental

All the melting and boiling points are uncorrected. The IR spectra were determined on a Hitachi Model 260-30 spectrometer. The ^{1}H NMR spectra were recorded with Hitachi R-24B and Varian EM-390 spectrometers in $CDCl_3$ with tetramethylsilane as an internal standard. Benzene was distilled and dried over sodium wire. Tetrahydrofuran (THF) was freshly distilled from sodium benzophenone ketyl. *N,N*-Dimethylformamide (DMF) was distilled from CaH_2 and stored over Molecular Sieve. Purification of products was performed by column chromatography on silica gel (Wakogel C-200 or Merck, Art. 9385 Kieselgel 60, 230—400 mesh).

Preparation of N,N-*Diisopropyl-3-hydroxyl-4-pentenamide (3a).* To a solution of lithium diisopropylamide (55 mmol) in THF (100 mL) was added a solution of *N,N*-diisopropylacetamide (7.16 g, 50 mmol) in THF (10 mL) at −78 °C, and the mixture was stirred for 1 h at −78 °C.[8] A THF (5 mL) solution of acrylaldehyde (3.36 g, 60 mmol) was added and then stirred for 15 min at −78 °C. To the mixture was added sat. aqueous NH_4Cl and the organic layer was extracted with dichloromethane. The separated organic layer was dried over Na_2SO_4 and was condensed under reduced pressure. Purification by column chromatography (hexane:ethyl acetate=3:1, v/v) and distillation gave the amide **3a** (8.21 g, 82%): Bp 101—102 °C/0.8 mmHg (1 mmHg=133.322 Pa). IR (neat) 3420, 1625 cm^{-1}. ^{1}H NMR δ=1.22 (6H, d, J=6.8 Hz), 1.38 (6H, d, J=6.8 Hz), 2.33 (1H, dd, J=8.3, 16.0 Hz), 2.55 (1H, dd, J=3.3, 12.0 Hz), 3.22—4.17 (2H, m), 4.32—4.70 (2H, m), 5.00—5.42 (2H, m), 5.88 (1H, ddd, J=5.4, 10.0, 17.0 Hz).

By the same procedure, the corresponding *N,N*-dimethyl amide (**3**, R^1=H, R^2=Me) was prepared in 82% yield: Bp 84—88 °C/0.35 mmHg. IR (neat) 3400, 1615 cm^{-1}. ^{1}H NMR δ=2.37 (1H, dd, J=7.8, 16.2 Hz), 2.59 (1H, dd, J=4.0, 16.2 Hz), 2.98 (3H, s), 3.03 (3H, s), 4.25—4.70 (2H, m), 5.02—5.43 (2H, m), 5.90 (1H, ddd, J=5.5, 10.0, 16.5 Hz).

Preparation of N,N-*Diisopropyl-3-t-butyldimethylsilyloxy-4-pentenamide (3d).* A mixture of **3a** (1.99 g, 10 mmol), triethylamine (1.52 g, 15 mmol), *t*-butyldimethylsilyl chloride (1.81 g, 12 mmol) and a catalytic amount of 4-dimethylaminopyridine in DMF (30 mL) was stirred for 3 h at room temperature.[9] Then pH 7 phosphate buffer (100 mL) was added, and the mixture was extracted with ether. The ether extract was washed with water and sat. aqueous NaCl and dried over Na_2SO_4. The ether solution was concentrated and the residue was purified by column chromatography on silica gel (hexane:ethyl acetate=10:1, v/v) and distillation to give the silylated amide **3d** (3.02 g, 96%): Bp 122 °C/0.4 mmHg. IR (neat) 1640 cm^{-1}. ^{1}H NMR δ=0.07 (6H, s), 0.88 (9H, s), 1.19 (6H, d, J=6.5 Hz), 1.34 (6H, d, J=6.5 Hz), 2.32 (1H, dd, J=6.0, 14.5 Hz), 2.62 (1H, dd, J=6.8, 14.5 Hz), 3.37—4.20 (2H, m), 4.73 (1H, br, q, J=6.5 Hz), 4.91—5.34 (2H, m), 5.90 (1H, ddd, J=5.5, 10.0, 16.5 Hz). Found: C, 64.59; H, 11.52; N, 4.52%. Calcd for $C_{17}H_{35}NO_2Si$: C, 65.12; H, 11.25; N, 4.47%.

Preparation of (Z)-N,N-*Dimethyl-3-t-butyldimethylsilyloxy-4-hexenamide (6a).* The reaction of lithiated *N,N*-dimethylacetamide with 2-butynal according to the procedure described above yielded *N,N*-dimethyl-3-hydroxy-4-hexynamide in 85% yield: Bp 125—126 °C/0.7 mmHg. The acetylenic amide was hydrogenated over 5% Pd/$BaSO_4$-quinoline catalyst[10] in methanol under usual pressure, and the hydroxyl group was silylated to give **6a** in 86% overall yield: Bp 120 °C (bath temp)/0.1 mmHg. IR (neat) 1650 cm^{-1}. ^{1}H NMR δ=0.02 (6H, s), 0.81 (9H, s), 1.60 (3H, d, J=5.5 Hz), 2.15 (1H, dd, J=4.8, 14.0 Hz), 2.63 (1H, dd, J=8.0, 14.0 Hz), 2.86 (3H, s), 2.98 (3H, s), 4.76—5.04 (1H, m), 5.10—5.55 (1H, m). Found: C, 61.77; H, 11.07; N, 5.20%. Calcd for $C_{14}H_{29}NO_2Si$: C, 61.93; H, 10.77; N, 5.16%.

Preparation of (E)-N,N-*Dimethyl-3-t-butyldimethylsilyloxy-4-hexenamide (6b).* As mentioned above, (*E*)-*N,N*-dimethyl-3-hydroxy-4-hexenamide was prepared by the reaction of lithiated *N,N*-dimethylacetamide with crotonaldehyde in 86% yield: Bp 99—100 °C/0.5 mmHg. The hydroxy amide was then silylated to give **6b** in 82% yield:

Bp 125—130 °C (bath temp)/0.3 mmHg. IR (neat) 1650 cm^{-1}. ^1H NMR δ=0.02 (6H, s), 0.87 (9H, s), 1.64 (3H, d, J=5.0 Hz), 2.22 (1H, dd, J=5.0, 13.5 Hz), 2.63 (1H, dd, J=8.0, 13.5 Hz), 2.88 (3H, s), 2.98 (3H, s), 4.33—4.73 (1H, m), 5.13—5.82 (2H, m). Found: C, 61.61; H, 11.00; N, 5.01%. Calcd for $C_{14}H_{29}NO_2Si$: C, 61.93; H, 10.77; N, 5.16%.

Oxylactonization of ***3d***. A benzene (2 mL) solution of the amide **3d** (152 mg, 0.48 mmol) was added to a suspension of MCPBA (70% pure, 478 mg, 1.94 mmol) in benzene (2 mL), and the mixture was stirred at 20—30 °C overnight. A mixture of sat. aqueous Na_2SO_3 and 10% aqueous K_2CO_3 was added and the mixture was extracted with ether. The ether extract was washed successively with 10% aqueous K_2CO_3 and sat. aqueous NaCl. After being dried over Na_2SO_4, the ether solution was condensed *in vacuo*. The residue was purified by column chromatography (hexane:ethyl acetate=3:1—1:1, v/v) to give the less polar **4d** (87.6 mg, 73%) and the more polar **5d** (20.7 mg, 17%).

*3-O-t-Butyldimethylsilyl-2-deoxy-*DL*-erythro-pentono-1,4-lactone (**4d**)*: Mp 54—55 °C (hexane). IR (CH_2Cl_2) 3620, 1785 cm^{-1}. ^1H NMR δ=0.09 (6H, s), 0.78 (9H, s), 2.28 (1H, dd, J=4.0, 16.5 Hz), 2.57 (1H, br s), 2.78 (1H, dd, J=6.5, 16.5 Hz), 3.53—3.82 (2H, m), 4.07—4.56 (2H, m). Found: C, 53.46; H, 9.23%. Calcd for $C_{11}H_{22}O_4Si$: C, 53.62; H, 9.00%. Hydrolysis of **4d** (49 mg, 0.20 mmol) in THF (0.5 mL), H_2O (0.5 mL), and acetic acid (1.5 mL) at 80 °C gave 2-deoxy-DL-ribono-1,4-lactone.[5]

*3-O-t-Butyldimethylsilyl-2-deoxy-*DL*-threo-pentono-1,4-lactone (**5d**)*: Mp 99—100 °C (cyclohexane). IR (CH_2Cl_2) 3620, 1785 cm^{-1}. ^1H NMR δ=0.09 (6H, s), 0.89 (9H, s), 2.37 (1H, br s), 2.40 (1H, dd, J=3.0, 17.5 Hz), 2.74 (1H, dd, J=5.7, 17.5 Hz), 3.58—4.07 (2H, m), 4.34—4.70 (2H, m). Found: C, 53.37; H, 8.93%. Calcd for $C_{11}H_{22}O_4Si$: C, 53.62; H, 9.00%.

The Oxylactonization of ***6a*** *and* ***6b*** *was Carried out by the Same Procedure.* *3-O-t-Butydimethylsilyl-2,6-dideoxy-*DL*-lyxo-hexono-1,4-lactone (**7a**)*: Bp 180—185 °C (bath temp)/2.5 mmHg. IR (CH_2Cl_2) 3480, 1775 cm^{-1}. ^1H NMR δ=0.09 (6H, s), 0.77 (9H, s), 1.19 (3H, d, J=6.0 Hz), 2.22 (1H, dd, J=4.0, 17.5 Hz), 2.37 (1H, br s), 2.78 (1H, dd, J=7.0, 17.5 Hz), 3.43—4.13 (2H, m), 4.22—4.60 (1H, m). Found: C, 55.26; H, 9.56%. Calcd for $C_{12}H_{24}O_4Si$: C, 55.34; H, 9.29%.

*3-O-t-Butyldimethylsilyl-2,6-dideoxy-*DL*-xylo-hexono-1,4-lactone (**8a**).* Mp 82—83.5 °C (cyclohexane). IR (CH_2Cl_2) 3580, 1785 cm^{-1}. ^1H NMR δ=0.12 (6H, s), 0.89 (9H, s), 1.25 (3H, d, J=6.2 Hz), 2.47 (1H, dd, J=3.3, 17.5 Hz), 2.65 (1H, br s), 2.77 (1H, dd, J=6.2, 17.5 Hz), 3.97—4.32 (2H, m), 4.42—4.69 (1H, m). Found: C, 55.24; H, 9.53%. Calcd for $C_{12}H_{24}O_4Si$: C, 55.34; H, 9.29%.

*3-O-t-Butyldimethylsilyl-2,6-dideoxy-*DL*-ribo-hexono-1,4-lactone (**7b**)*: Bp 150—160 °C (bath temp)/2 mmHg. IR (CH_2Cl_2) 3610, 1780 cm^{-1}. ^1H NMR δ=0.10 (6H, s), 0.76 (9H, s), 1.10 (3H, d, J=6.0 Hz), 2.18 (1H, dd, J=3.0, 17.5 Hz), 2.77 (1H, dd, J=6.5, 17.5 Hz), 2.80 (1H, br s), 3.57—4.13 (2H, m), 4.30—4.58 (1H, m). Found: C, 55.04; H, 9.51%. Calcd for $C_{12}H_{24}O_4Si$: C, 55.34; H, 9.29%.

*3-O-t-Butyldimethylsilyl-2,6-dideoxy-*DL*-arabino-hexono-1,4-lactone (**8b**)*: Mp 88.5—90.5 °C (cyclohexane). IR (CH_2Cl_2) 3610, 1780 cm^{-1}. ^1H NMR δ=0.13 (6H, s), 0.93 (9H, s), 1.35 (3H, d, J=6.0 Hz), 2.23 (1H, br d, J=4.5 Hz), 2.45 (1H, dd, J=3.0, 17.5 Hz), 2.75 (1H, dd, J=5.7, 17.5 Hz), 3.93—4.19 (2H, m), 4.57—4.80 (1H, m). Found: C, 55.04; H, 9.23%. Calcd for $C_{12}H_{24}O_4Si$: C, 55.34; H, 9.29%.

The authors are grateful to Professor Teruaki Mukaiyama for valuable discussion during this work.

Diene-transmissive Diels-Alder Reaction Using 2-Ethoxy-3-methylene-1,4-pentadiene and 2-(2-Bromo-1-ethoxyethyl)-1,3-butadiene

Shuji KANEMASA, Hirohiko SAKOH, Eiji WADA, and Otohiko TSUGE*

Research Institute of Industrial Science, and Department of Molecular Science and Technology, Interdisciplinary Graduate School of Engineering Sciences, Kyushu University, Kasugakoen, Kasuga 816

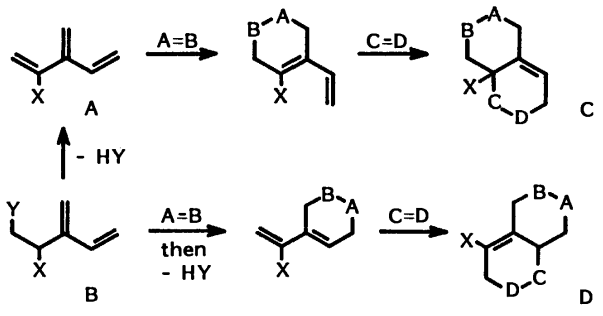
(Received June 19, 1985)

A new cross-conjugated triene, 2-ethoxy-3-methylene-1,4-pentadiene, and a triene equivalent, 2-(2-bromo-1-ethoxyethyl)-1,3-butadiene, have been synthesized and their diene-transmissive Diels-Alder cycloadditions are investigated. The initial Diels-Alder reaction selectively occurs not across the diene part substituted with the alkoxyl moiety but the monosubstituted diene. Some cross types of diene-transmissive Diels-Alder reaction are demonstrated using the triene equivalent and two different dienophiles.

Recently, polyconjugated molecules of cross type called dendralene have received increasing attention in synthetic and theoretical field of chemistry.[1] Of special interest in organic synthesis is cross-conjugated triene because its reiterative Diels-Alder cycloadditions offer a useful process leading to substituted hydrocarbons of fused [6.6] ring systems.[2] We have reported a simple synthesis of bis(silyloxy) cross-conjugated trienes as functionalized dendralenes[3] and their multiple Diels-Alder reaction process termed diene-transmissive Diels-Alder reaction.[3,4] Stepwise sequence of this reaction using cross-conjugated triene equivalents is useful as a process for the cross type of reiterative Diels-Alder cycloaddition.[5]

The diene-transmissive Diels-Alder reaction starts with the first Diels-Alder cycloaddition across one of the two diene units of cross-conjugated triene and the second reaction is followed across the diene part which has been constructed in the first cycloaddition step. An attractive extension of this process is cross type of reaction in which two different dienophiles are used separatedly in each step.

We have planned to synthesize 2-ethoxy-3-methylene-1,4-pentadiene **1** from its precursor 2-(2-bromo-1-ethoxyethyl)-1,3-butadiene **2** with an aim of establishing a finely controlled diene-transmissive Diels-Alder reaction system of cross type.



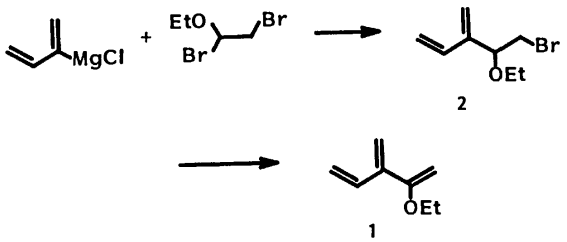
Scheme 1.

Scheme 1 shows a possible reaction mode of a cross-conjugated triene **A** with a diene-activating group X and its precursor **B**. As the diene-activating group X not only activates the diene as its carrier but also directs the regiochemistry of cycloaddition, it would be possible that the initial Diels-Alder reaction occurs across the diene part substituted with X under a regioselective control. The second cycloaddition with another dienophile, which is presumed also regioselective, gives a cross bis-cycloadduct **C**. On the other hand, the stepwise sequence of double cycloaddition of the precursor **B** using the same combination of dienophiles will lead to another bis-cycloadduct **D** which corresponds to an isomer of **C**.

Results and Discussion

The cross-conjugated triene **1** was synthesized in two steps starting from (1-methylene-2-propenyl)-magnesium chloride which is readily available from chloroprene. The cross-coupling reaction of (1-methylene-2-propenyl)magnesium chloride with 1-ethoxy-1,2-dibromoethane at 0 °C gave, after chromatography over silica gel and then distillation under vacuum, pure 2-(2-bromo-1-ethoxyethyl)-1,3-butadiene **2** in only 14% yield (Scheme 2). Although **2** was obtained in a better yield (40%, purity 68% (GLC)) in the same reaction using a catalyst Li_2CuCl_4[6] under milder conditions (−40 to −50 °C), the separation of **2** from one of the side products ended in failure.[7]

The dehydrobromination of **2** is a trouble-making



Scheme 2.

process. In order to avoid the polymerization of **1** as a labile product, **1** was separated from the reaction mixture by a vacuum distillation as soon as it was formed by the reaction of **2** with 1,8-diazabicyclo-[5.4.0]undec-7-ene (DBU) at 100—110 °C. Consequently, the cross-conjugated triene **1** isolated in 82% yield was contaminated with the unreacted **2** (18% (GLC)). As repeated distillation was found helpless, the triene of this purity (82%) was used for the following reactions.

A smooth cycloaddition took place between the triene **1** and *N*-methylmaleimide **3** under mild conditions (at room temperature for 24 h) to give 66% yield of a bis-cycloadduct **4** as the only isolated product, indicating that the initial Diels-Alder reaction was highly chemoselective. To our surprise, however, **4** was assigned as the bis-cycloadduct derived from the mono-cycloadduct **E** as shown in Scheme 3. Consequently the initial Diels-Alder reaction has favored the mono-substituted diene part which we assumed less reactive (See Scheme 1). As the stereostructure of **4** could not be determined only on the basis of the spectral data, the electronically and sterically most favorable approach in the second cycloaddition stage was taken into account.[8]

A similar reaction of **1** with dimethyl acetylenedicarboxylate **5** also produced the unexpected bis-cycloadduct **6** in 63% yield, which was readily dehydrogenated into tetramethyl 4-ethoxynaphthalene-1,2,6,7-tetracarboxylate **7** (81%) by the action of chloranil.

These unexpected diene reactivity is explained from a conformational point of view as shown in Fig. 1. There are two diene parts involved in the triene **1**, the monosubstituted "a" diene and the disubstituted "b" diene. The diene "b" can hardly occupy a planar s-cis conformation because of the steric hindrance between the two adjacent substituents (OEt and vinyl), while no such serious hindrance exists in the monosubstituted diene "a". Accordingly the initial Diels-Alder cycloaddition has occurred selectively across the diene "a".

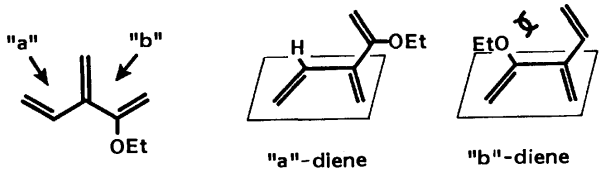


Fig. 1. s-cis Conformation for each diene part contained in the cross-conjugated triene **1**.

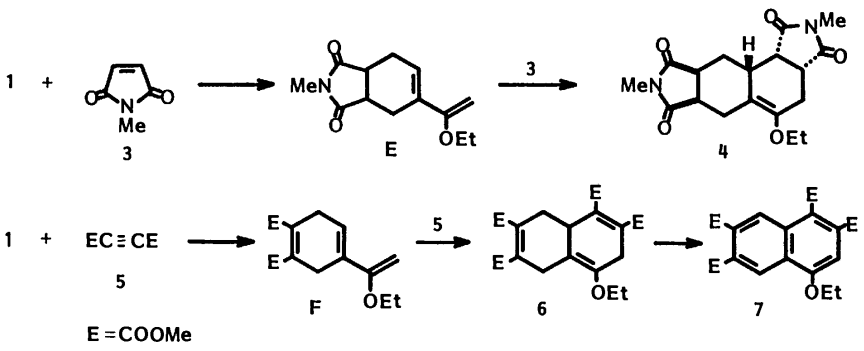
The use of two different dienophiles at each step of the above reaction, a cross type of cycloaddition, looks quite hard. Even though it is possible, a cross cycloadduct from this process can be obtained more easily by the stepwise sequence of double cycloaddition using the triene equivalent **2**. With this reason and because of the thermal instability of **1**, the stepwise cycloadditions of **2** were investigated.

The Diels-Alder cycloadditions of diene **2** with a variety of dienophiles **3**, **5**, **8**—**10** proceeded smoothly giving almost quantitative yields of cycloadducts **11**—**15** (Scheme 4). The results and reaction conditions are listed in Table 1. In the reactions with **3**, **8**, and **9**, each two diastereoisomeric cycloadducts were formed, but their ratios being slightly different (**11**, **12**: 1/2 and **14**: 1/1). The ratio of two regioisomeric cycloadducts of **15** was found to be 68/32 (para/meta) based on the GLC analysis, and about the same to that observed in the reaction of isoprene with **10** at 120 °C (para/meta=7/3).[9]

The diene functionality was revealed by dehydrobromination of the cycloadducts obtained above. Although **11** as an example resisted the dehydrobromination either when heated in benzene with triethylamine or refluxed in toluene with pyridine, successful dehydrobromination occurred by use of DBU. Thus, **12**, **14**, and **15** were converted into the corresponding dienes **16**, **18**, and **20**, respectively (Scheme 5 and Table 1). As these dienes are subject to the ready hydrolysis leading to enones, some of them were lost during the purification by column chromatography over silica gel.

The enones **17**, **19**, and **21** correspond to the Diels-Alder adducts of 2-acetyl-1,3-butadiene which can not be isolated because of its too easy dimerization.[10]

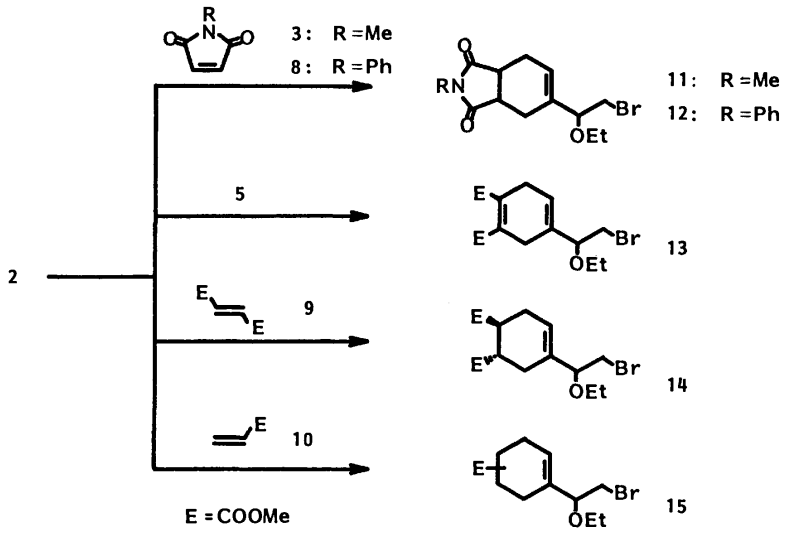


Scheme 3.

Accordingly, the diene **2** is a useful synthetic equivalent of 2-acetyl-1,3-butadiene.[11] An attempt of the second Diels-Alder reaction of the above dienes will be described later.

Dehydrobromination of the acetylene cycloadduct **13** with DBU gave no expected diene **F**, but instead the 4-(1-ethoxyethyl)- **22** and 4-vinylphthalate **23** in 95% of combined yield. The ready formation of **22**, presumably through a hydrogen migration of **F**, may have been driven by the aromatization on the six-membered ring. An attempt to trap the diene **F** with methyl propiolate **26** ended in failure, the same result being obtained.

The second Diels-Alder reactions were carried out using acetylenic dienophiles **5** and **26** (Scheme 6 and Table 1). The reaction of **16** with **5** gave a stereoselective cross bis-cycloadduct **24** along with its dehydrogenated derivative **25** in 78% of combined



Scheme 4.

TABLE 1. STEPWISE SEQUENCE OF DIENE-TRANSMISSIVE DIELS-ALDER REACTIONS OF A CROSS-CONJUGATED TRIENE EQUIVALENT **2**

First cycloaddition		Reaction conditions			Product (yield/%)[a]
Diene	Dienophile	Solvent	Temperature	Time/h	
2	**3**	benzene	reflux	6	**11** (96)

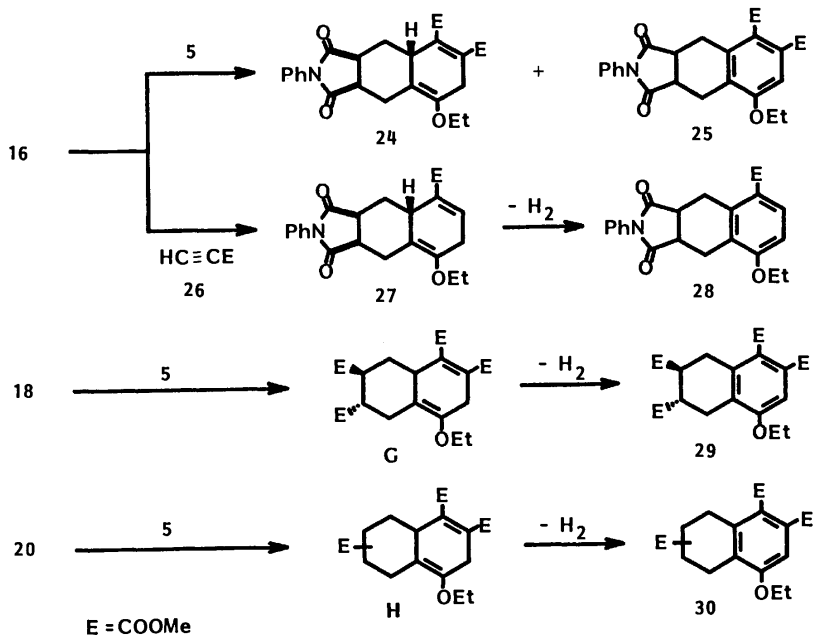
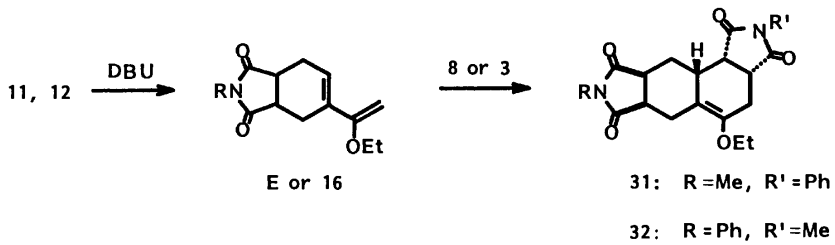


Scheme 6.

yield. As anticipated, an unsymmetrical acetylene **26** cycloadded to **16** under high regioselection, the stereo- and regioselective cross bis-cycloadduct **27** being isolated as the single product. The structures of **24** and **27** were hardly determined only on the basis of the spectral data, therefore based on the steric consideration in the approaches. These cycloadducts **24** and **27** were easily dehydrogenated with chloranil into the aromatic derivatives **25** and **28**, respectively, in high yields. A one-pot procedure for the second cycloaddition and dehydrogenation could be performed between **18** and **5** (similarly **20** and **5**) under the conditions shown in Table 1. This procedure gave the tetrahydronaphthalene derivatives **29** and **30** in good yields.

The both procedures of the diene formation by dehydrobromination and the second cycloaddition could be achieved in the same flask. First, the maleimide cycloadduct **11** or **12** was allowed to react with DBU under reflux in toluene and the excess or unreacted DBU was completely consumed by the action with methyl iodide (Scheme 7). Then, the diene **E** or **16** formed in solution was subjected to the second cycloaddition with **8** or **3**. Thus, a



Scheme 7.

stereoselective cross bis-cycloadduct **31** (56%) or **32** (65%) was isolated through a column chromatography of the crude mixture.

Experimental

General and Materials. Melting points were measured on a Yanagimoto micro melting point apparatus and uncorrected. IR spectra were recorded on a JASCO A-702 and JEOL JIR-100 FT-IR spectrometers. ^{1}H-NMR spectra were taken at either 90 MHz (Hitachi R-40) or 100 MHz (JEOL FX-100), and ^{13}C-NMR at 25.05 MHz (JEOL FX-100). ^{1}H- and ^{13}C-NMR chemical shifts are recorded in δ values (ppm) relative to internal Me_4Si. Mass spectra were measured with a JEOL JMS-01SG-2 spectrometer at 75 eV of ionization energy. Elementary analyses were performed on a Hitachi 026 CHN micro analyzer. Analytical gas-liquid chromatography (GLC) was accomplished on a Yanaco G-2800 gas chromatograph equipped with a flame ionization detector (column: SE-30, 3.5×300 mm). Wakogel C300 and Florisil (100—200 mesh) were used for preparative column chromatography. Thin-layer chromatography (TLC) was accomplished on 0.2 mm precoated plates of silica gel 60 F-254 (Merck) and of aluminum oxide 60 F-254 type-E (Merck). Visualization was with ultraviolet light (254 and 365 nm) and iodine. Micro vacuum distillation was carried out with a Sibata GTO-250R Kugelrohr distilling apparatus. Solvents were evaporated with a Tokyo Rikakikai rotary evaporator type V.

Tetrahydrofuran (THF), benzene, and toluene were distilled over sodium wire immediately prior to their use. 1-Ethoxy-1,2-dibromoethane was prepared by the bromination of ethyl vinyl ether.[12] Methyl propiolate **26** was obtained by the esterification of commercial propiolic acid in the presence of *p*-toluenesulfonic acid.[13] Li_2CuCl_4 was prepared by mixing LiCl and $CuCl_2$ in 2:1 ratio.

2-(2-Bromo-1-ethoxyethyl)-1,3-butadiene **2** *and 2-Ethoxy-3-methylene-1,4-pentadiene* **1**. To a 0.1 M solution of (1-methylene-2-propenyl)magnesium chloride (20 ml, 20 mmol) was added dropwise a solution of 1-ethoxy-1,2-dibromoethane (2.7 ml, 20 mmol) in dry THF (20 ml) at 0 °C. The mixture was stirred at 0 °C for 6 h under nitrogen and then treated with water. Products were extracted in ether, the ether washed with 5% sodium hydrogencarbonate solution and with brine, dried over $MgSO_4$, and finally evaporated *in vacuo*. The residue was chromatographed over silica gel. An elution with hexane–benzene (2:1) gave 1.66 g (40%, purity 52% by GLC) of **2** which was purified by a vacuum distillation on Kugelrohr to afford pure **2** (0.58 g, 14%).

This compound **2** was also available by the following procedure: To a mixture of 1-ethoxy-1,2-dibromoethane (1.4 ml, 10 mmol) and Li_2CuCl_4 (220 mg, 1 mmol) in dry THF (10 ml) was added slowly a 0.1 M solution of (1-methylene-2-propenyl)magnesium chloride in THF (12 ml, 12 mmol) at −40 to −50 °C. The mixture was stirred at the same temperature for 4 h and treated with water. The same work up described above and a vacuum distillation gave 0.81 g of **2** (40%, purity 68% by GLC).

2: Colorless liquid; bp 80 °C (267 Pa) (bulb-to-bulb); IR (neat) 1580, 1120, and 1100 cm^{-1}; ^{1}H-NMR ($CDCl_3$) δ=1.20 (3H, t, $C\underline{H}_3CH_2$), 3.22—3.66 (4H, m, CH_2Br and $C\underline{H}_2Me$), 4.21 (1H, dd, J=4.3 and 7.8 Hz, $C\underline{H}OEt$), 5.10 (1H, d, J_{4-3}=11.0 Hz, one of 4-H), 5.26, 5.28 (each 1H, s, 1-H), 5.35 (1H, d, J_{4-3}=18.0 Hz, the other of 4-H), 6.32 (1H, dd, J_{3-4}=11.0 and 18.0 Hz, 3-H); ^{13}C-NMR ($CDCl_3$) δ=15.21 (q, Me), 35.21 (t), 64.82 (t), 79.79 (d, $\underline{C}HOEt$), 114.66, 117.24 (each t, 1- and 4-C), 135.56 (d, 3-C), and 143.66 (s, 2-C); MS *m/z* 206 and 204 (M^+).

Found: *m/z* 204.0125. Calcd for $C_8H_{13}OBr$: M, 204.0150.

A mixture of **2** (266 mg, 1.3 mmol) and DBU (395 mg, 2.6 mmol) was heated in a micro distilling flask at 100—110 °C under a reduced pressure (2666 Pa) while being distilled. The distillate collected in 30 min was purified by distillation on Kugelrohr to give **1** (132 mg, 82%, purity 82% by GLC).

1: Colorless liquid; GC/FT-IR (gas) 1585 and 980 cm^{-1}; ^{1}H-NMR ($CDCl_3$) δ=1.33, 3.78 (5H, $OC\underline{H}_2C\underline{H}_3$), 4.14, 4.26 (each 1H, d, J_{gem}=2.0 Hz, 1-H), 5.14 (1H, dd, J_{5-4}=10.5 and J_{gem}=2.0 Hz, one of 5-H), 5.22, 5.43 (each 1H, d, J_{gem}=2.0 Hz, 3-CH_2=), 5.43 (1H, dd, J_{5-4}=17.5 and J_{gem}=2.0 Hz, the other of 5-H), and 6.40 (1H, dd, J_{4-5}=17.5 and 10.5 Hz, 4-H); ^{13}C-NMR ($CDCl_3$) δ=14.47 (q, Me), 62.96 (t), 84.74 (t, 1-C), 114.47, 116.42 (each t, 5-C and 3-CH_2=), 135.56 (d, 4-C), 143.31 (s, 3-C), and 159.35 (s, 2-C); GC-MS *m/z* 124 (M^+).

Found: *m/z* 124.0872. Calcd for $C_8H_{12}O$: M, 124.0888.

Reaction of **1** *with* **3** *Leading to* **4**. A mixture of **1** (108 mg, purity 84%, 0.73 mmol) and **3** (193 mg, 1.74 mmol) in dry benzene (3 ml) was stirred at room temperature for 2 h. The residue which was obtained by evaporation of the solvent was chromatographed over silica gel using hexane–ethyl acetate (1:3) as an eluent to give 167 mg (66%) of **4**: Colorless solid; mp 113—116 °C; IR (KBr) 1770 and 1700 cm^{-1} (CO); ^{1}H-NMR ($CDCl_3$) δ=1.12 (3H, t, $CH_2C\underline{H}_3$), 1.84—3.32 (11H, m, 3×CH_2 and 5×CH), 2.88, 2.92 (each 3H, s, NMe), and 3.63 (2H, q, $C\underline{H}_2Me$); ^{13}C-NMR ($CDCl_3$) δ=15.01 (q, Me), 21.00, 23.54 (each t), 24.85 (d),

† 1 M=1 mol dm^{-3}.

25.68 (t), 32.75, 39.03, 40.15, 43.22 (each d), 64.76 (t), 113.25, 147.80 (each s), 177.47, 179.03, 179.77, and 180.11 (each s, CON); MS *m/z* 346 (M^+).

Found: *m/z* 346.1562. Calcd for $C_{18}H_{22}O_5N_2$: M, 346.1527.

Reaction of 1 with 5 Leading to 6 and Its Dehydrogenation into 7. A solution of **1** (103 mg, purity 82%, 0.68 mmol) and **5** (236 mg, 1.7 mmol) in dry benzene (2 ml) was refluxed for 6 h. The solvent was removed off *in vacuo* and the residue was chromatographed over silica gel. An elution with hexane-ethyl acetate (1:1) gave 176 mg (63%) of **6**: Colorless viscous liquid; IR (neat) 1725 cm^{-1} (CO); ^{1}H-NMR ($CDCl_3$) δ=1.26 (3H, t, $CH_2C\underline{H}_3$) 2.00—2.40 (1H, m), 2.60—3.98 (8H, m), 3.73, 3.86, and 3.90 (12H, s, COOMe); ^{13}C-NMR ($CDCl_3$) δ=15.40 (q, Me), 26.80, 27.24, 32.89 (each t), 36.60 (d), 52.29, 52.39 (each q, each 2×C, COO<u>Me</u>), 63.89 (t), 109.16, 129.28, 133.23, 134.98, 137.03, 142.58 (each s), 166.71, 167.77 (each s, <u>C</u>OOMe), and 168.07 (s, 2×C, <u>C</u>OOMe); MS *m/z* 408 (M^+).

Found: *m/z* 408.1373. Calcd for $C_{20}H_{24}O_9$: M, 408.1419.

A mixture of **6** (276 mg, 0.68 mmol) and chloranil (665 mg, 2.7 mmol) in toluene (6 ml) was refluxed for 72 h. Evaporation of the solvent and the chromatography over silica gel (hexane-ethyl acetate 1:1) gave 222 mg (81%) of **7**: Colorless prisms from hexane-ethyl acetate; mp 157—158 °C; IR (KBr) 1720 cm^{-1} (CO) ^{1}H-NMR ($CDCl_3$) δ=1.56, 4.26 ($OC\underline{H}_2C\underline{H}_3$), 3.92 (9H, s, COOMe), 4.01 (3H, s, COOMe), 7.28 (1H, s, 3-H), 8.14 (1H, s, 5-H), and 8.64 (1H, s, 8-H); ^{13}C-NMR ($CDCl_3$) δ=14.53 (q, Me), 52.95 (q, 4×C, COO<u>Me</u>), 64.89 (t), 105.83, 124.89 (each d), 126.60, 127.19 (each s), 127.83 (d), 129.66, 129.89, 131.01, 156.25 (each s), 166.37, 168.72 (each s, <u>C</u>OOMe), and 167.83 (s, 2×C, <u>C</u>OOMe); MS *m/z* 404 (M^+).

Found: C, 59.25; H, 4.97%. Calcd for $C_{20}H_{20}O_9$: C, 59.41; H, 4.99%.

Cycloadditions of 2 to Dienophiles 3, 5, and 8—10. General procedure is as follows: A mixture of **2** and dienophiles (1.2—2 equivalents) in dry benzene (2—3 ml per 1 mmol of **2**) was refluxed for the time shown in Table 1. The solvent was evaporated *in vacuo* and the residue was chromatographed over silica gel. The yields of cycloadducts are given in Table 1.

11: The reaction between **2** (308 mg, purity 85%, 1.28 mmol) and **3** (167 mg, 1.50 mmol) was followed by the chromatography with hexane-ethyl acetate (1:1) to give 389 mg (96%) of **11** in 2:1 ratio of diastereomers whose separation failed: Colorless viscous liquid; IR (neat) 1775 and 1710 cm^{-1} (CO); ^{1}H-NMR ($CDCl_3$) δ=1.12 (3H, t, $CH_2C\underline{H}_3$), 1.90—3.48 (10H, m), 2.88 (3H, s, NMe), 3.78 (1H, t, J=6.0 Hz, C<u>H</u>OEt), and 5.86 (1H, m, 6-H); ^{13}C-NMR ($CDCl_3$) the major: δ=14.91 (q, Me), 22.54, 23.66 (each t), 24.89 (q, NMe), 32.11 (t), 38.92, 39.22 (each d), 64.23 (t), 81.96 (d, <u>C</u>HOEt), 126.46 (d, 6-C), 136.68 (s, 5-C), and 179.42 (s, 2×C, CON); the minor: δ=14.68 (q, Me), 23.48 (t), 24.66 (q, NMe), 32.76 (t), 81.08 (d, <u>C</u>HOEt), 125.81 (d, 6-C), and 179.12 (s, CON); MS *m/z* 222 (M^+-CH_2Br).

Found: C, 49.36; H, 5.73; N, 4.43%. Calcd for $C_{13}H_{18}O_3NBr$: C, 49.38; H, 5.74; N, 4.43%.

12: The reaction between **2** (512 mg, purity 74%, 1.85 mmol) and **8** (539 mg, 3.11 mmol) and the followed chromatography using hexane-ethyl acetate (2:1) gave 685 mg (98%) of **12** as a mixture of two diastereomers in a ratio of 2:1, which could not be separated: Colorless viscous liquid; IR (neat) 1780 and 1720 cm^{-1} (CO); ^{1}H-NMR ($CDCl_3$) δ=1.07, 1.17 (3H, each t, $CH_2C\underline{H}_3$), 2.00—2.96 (4H, m), 3.08—3.52 (6H, m), 3.85 (1H, t, J=6.5 Hz, C<u>H</u>OEt), 5.98 (1H, m, 6-H), and 7.08—7.60 (5H, m, Ph); ^{13}C-NMR ($CDCl_3$) the major: δ=15.15 (q, Me), 23.20, 24.02, 33.04 (each t), 39.03, 39.42 (each d), 64.71 (t), 82.21 (d, <u>C</u>HOEt), 125.97 (d, 6-C), 126.16, 128.35, 128.89 (each d), 131.96 (s), 137.32 (s, 5-C), 178.60, and 178.74 (each s, CON); the minor: δ=14.86 (q, Me), 22.95, 23.88 (each t), 81.62 (d, <u>C</u>HOEt), 137.17 (s, 5-C), and 178.35 (s, CON); MS *m/z* 379 and 377 (M^+).

*Dehydrobromination of **14** Leading to **18** and **19**.* A mixture of **14** (253 mg, 0.72 mmol) and DBU (165 mg, 1.08 mmol) in dry toluene (3 ml) was refluxed for 20 h and the solvent was removed *in vacuo*. The residue was chromatographed over Florisil with hexane–ethyl acetate (9:1) to give 115 mg (59%) of **18** as unstable material. Further elution with hexane–ethyl acetate (1:1) afforded 34 mg (20%) of **19**.

18: Colorless liquid; ^{1}H-NMR (C_6D_6) δ=1.13, 3.52 (OCH_2CH_3), 2.10—3.02 (6H, m), 3.38, 3.40 (each 3H, s, COOMe), 3.92, 4.10 (each 1H, d, J_{gem}=2.5 Hz, $=CH_2$), and 6.07 (1H, m, 2-H); ^{13}C-NMR (C_6D_6) δ= 14.57 (q, Me), 28.17, 28.36 (each t), 41.32, 41.96 (each d), 51.51 (q, 2×C, COOMe), 62.81 (t), 122.41 (d, 2-C), 130.84 (s, 1-C), 159.59 (s), and 174.70 (s, 2×C, COOMe).

19: Colorless liquid; IR (neat) 1740 and 1670 cm^{-1} (CO); ^{1}H-NMR ($CDCl_3$) δ=2.29 (3H, s, MeCO), 2.10—3.00 (6H, m), 3.67, 3.68 (each 3H, s, COOMe), and 6.84 (1H, m, 2-H); MS *m/z* 240 (M^+) and 43.

Found: C, 59.97; H, 6.76%. Calcd for $C_{12}H_{16}O_5$: C, 59.99; H, 6.71%.

*Dehydrobromination of **15** Leading to **20** and **21**.* A solution of **15** (228 mg, 0.78 mmol) and DBU (179 mg, 1.18 mmol) in dry toluene (3 ml) was refluxed for 20 h. The residue obtained by the evaporation of solvent was chromatographed over Florisil with hexane–ethyl acetate (9:1) gave 66 mg (40%) of unstable diene **20**. Further elution with hexane–ethyl acetate (2:1) afforded **21** (59 mg, 40%).

20: Colorless liquid as a mixture of two regioisomers (2:1); ^{1}H-NMR (C_6D_6) δ=1.10, 3.50 (OCH_2CH_3), 1.40—2.60 (7H, m), 3.30, 3.34 (3H, each s, COOMe), 3.94 (1H, d, J_{gem}=2.0 Hz, $=CH_2$), 4.17, 4.23 (1H, each d, J_{gem}=2.0 Hz, $=CH_2$), and 6.43 (1H, m, 2-H).

21: Colorless liquid as a 2:1 mixture of regioisomers; IR (neat) 1735 and 1685 cm^{-1} (CO); ^{1}H-NMR ($CDCl_3$) δ=1.50—2.68 (7H, m), 2.28 (3H, s, MeCO), 3.68, and 3.69 (3H, each s, COOMe); MS *m/z* 182 (M^+).

Found: *m/z* 182.0994. Calcd for $C_{10}H_{14}O_3$: M, 182.0942.

*Dehydrobromination of **13** Leading to **22** and **23**.* A mixture of **13** (236 mg, 0.68 mmol) and DBU (193 mg, 1.27 mmol) in dry toluene (4 ml) was refluxed for 3 h and the solvent was evaporated *in vacuo*. The residue was chromatographed over silica gel using hexane–ethyl acetate (3:1) to give **23** (41 mg, 27%) and then **22** (122 mg, 67%).

22: Colorless viscous liquid; IR (neat) 1725 cm^{-1} (CO); ^{1}H-NMR ($CDCl_3$) δ=1.19, 3.36 (OCH_2CH_3), 1.42 (3H, d, *J*=6.5 Hz, Me), 3.87, 3.89 (each 3H, s, COOMe), 4.46 (1H, q, *J*=6.5 Hz, CH(Me)OEt), 7.48 (1H, dd, *J*=1.5 and 8.0 Hz, 5-H), 7.63 (1H, d, *J*=1.5 Hz, 3-H), and 7.72 (1H, d, *J*=8.0 Hz, 6-H); ^{13}C-NMR ($CDCl_3$) δ=15.03, 23.66 (each q, Me), 52.19 (q, 2×C, COOMe), 63.99 (t), 76.62 (d, CH(Me)OEt), 126.11, 128.16, 128.98 (each d), 130.22, 132.22 (each s), 148.01 (s, 4-C), 167.32, and 167.79 (each s, COOMe); MS *m/z* 266 (M^+) and 251 (M^+—Me, base peak).

Found: C, 63.08; H, 6.69%. Calcd for $C_{14}H_{18}O_5$: C, 63.15; H, 6.81%.

23: Colorless liquid; IR (neat) 1725 cm^{-1}; ^{1}H-NMR ($CDCl_3$) δ=3.88, 3.89 (each 3H, s, COOMe), 5.39 (1H, dd, J_{gem}=0.5 and J_{vic}=11.0 Hz, one of $=CH_2$), 5.84 (1H, dd, J_{gem}=0.5 and J_{vic}=17.5 Hz, the other of $=CH_2$), 6.71 (1H, dd, *J*=11.0 and 17.5 Hz, CH=), 7.49 (1H, dd, *J*=2.0 and 8.0 Hz, 5-H), 7.66 (1H, d, *J*=2.0 Hz, 3-H), and 7.70 (1H, d, *J*=8.0 Hz, 6-H); MS *m/z* 220 (M^+) and 189 (M^+—OMe, base peak).

*Cycloaddition of **16** to **5** Leading to **24** and **25**.* A mixture of **16** (248 mg, 0.83 mmol) and **5** (237 mg, 1.67 mmol) in toluene (4 ml) was refluxed for 20 h and the solvent was evaporated *in vacuo*. The residue was chromatographed over silica gel with hexane–ethyl acetate (1:1) gave 227 mg (62%) of **24** and then 63 mg (17%) of **25**. A mixture of **24** (68 mg, 0.15 mmol) and chloranil (42 mg, 0.17 mmol) in toluene (3 ml) was refluxed for 36 h. Column chromatography of the crude mixture over silica gel (hexane–ethyl acetate (1:1)) afforded 53 mg (78%) of **25**.

24: Colorless solid; mp 85—87 °C; IR (KBr) 1775 and 1720 cm^{-1} (CO); ^{1}H-NMR ($CDCl_3$) δ=1.25 (3H, t, CH_2CH_3), 1.40—2.10 (2H, m), 2.50—3.92 (9H, m), 3.73, 3.79 (each 3H, s, COOMe), and 7.10—7.56 (5H, m, Ph); ^{13}C-NMR ($CDCl_3$) δ=15.30 (q, Me), 25.78, 27.34, 29.04 (each t), 37.33, 40.20, 40.30 (each d), 52.34 (q, 2×C, COOMe), 64.03 (t), 110.81 (s), 126.16 (d, 2×C), 128.35 (d), 129.04 (d, 2×C), 129.13, 131.86, 137.86, 143.12 (each s), 166.60, 167.77 (each s, COOMe), 177.04, and 177.91 (each s, CON); MS *m/z* 439 (M^+).

Found: C, 65.47; H, 5.80; N, 3.56%. Calcd for $C_{24}H_{25}O_7N$: C, 65.59; H, 5.73; N, 3.19%.

25: Colorless prisms from ethanol; mp 159—160 °C; IR (KBr) 1775 and 1720 cm^{-1} (CO); ^{1}H-NMR ($CDCl_3$) δ=1.42, 4.05 (OCH_2CH_3), 2.60—3.80 (6H, m), 3.84, 3.90 (each 3H, s, COOMe), 6.90—7.08, and 7.14—7.48 (each 3H, m, Ph and Ar); MS *m/z* 437 (M^+).

Found: C, 65.71; H, 5.37; N, 3.23%. Calcd for $C_{24}H_{23}O_7N$: C, 65.90; H, 5.30; N, 3.20%.

*Cycloaddition of **16** to **26** Leading to **27** and Dehydrogenation of **27** into **28**.* A solution of **16** (180 mg, 0.61 mmol) and **26** (255 mg, 3.03mmol) in dry toluene (6 ml) was heated in a sealed glass tube at 110 °C for 68 h. The solvent was evaporated *in vacuo* and the residue was chromatographed over silica gel using hexane–ethyl acetate (1:1) to give 113 mg (49%) of **27**. This product **27** (43 mg, 0.11 mmol) and chloranil (42 mg, 0.17 mmol) were refluxed in toluene (2 ml) for 48 h and the crude mixture was chromatographed, after evaporation of the solvent, over silica gel with hexane–ethyl acetate (1:1) to afford 33 mg (77%) of **28**.

27: Colorless prisms from ether; mp 140—141 °C; IR (KBr) 1775 and 1710 cm^{-1} (CO); ^{1}H-NMR ($CDCl_3$) δ=1.24

(3H, t, $CH_2C\underline{H}_3$), 1.20—1.60 (1H, m), 1.70—2.04 (1H, m), 2.72—3.90 (9H, m), 3.72 (3H, s, COOMe), 6.87 (1H, t, J=3.0 Hz, =CH), and 7.16—7.56 (5H, m, Ph); ^{13}C-NMR ($CDCl_3$) δ=15.15 (q, Me), 26.42, 27.01, 30.41 (each t), 35.05, 40.28, 40.57 (each d), 51.49 (q, COO<u>Me</u>), 63.58 (t), 112.72 (s), 125.99 (d, 2×C), 128.05 (d), 128.75 (d, 2×C), 130.63, 131.86 (each s), 135.21 (d), 142.72 (s), 166.09 (s, <u>C</u>OOMe), 177.07, and 178.07 (each s, CON); MS m/z 381 (M^+).

Found: C, 69.28; H, 6.08; N, 3.67%. Calcd for $C_{22}H_{23}O_5N$: C, 69.12; H, 6.04; N, 3.62%.

28: Colorless prisms from ethanol; mp 200—202 °C; IR (KBr) 1775 and 1705 cm^{-1} (CO); ^{1}H-NMR ($CDCl_3$) δ=1.42, 4.05 ($OC\underline{H}_2C\underline{H}_3$), 2.60—3.74 (6H, m), 3.84 (3H, s, COOMe), 6.74 (1H, d, J=9.0 Hz, 6-H), 6.84—7.00 (2H, m), 7.24—7.50 (3H, m), and 7.80 (1H, d, J=9.0 Hz, 7-H); MS m/z 379 (M^+).

Found: C, 69.44; H, 5.67; N, 3.66%. Calcd for $C_{22}H_{21}O_5N$: C, 69.65; H, 5.58; N, 3.69%.

*Cycloaddition of **18** to **5** and Subsequent Dehydrogenation Leading to **29**.* A solution of **18** (97 mg, 0.36 mmol) and **5** (77 mg, 0.54 mmol) in dry toluene (2 ml) was refluxed for 6 h. Chloranil (133 mg, 0.54 mmol) was added and the resulting mixture was further refluxed for 15 h. Column chromatography of the crude product over silica gel with hexane–ethyl acetate (2:1) gave 97 mg (66%) of **29**: Colorless needles from ethanol; mp 128—129 °C; IR (KBr) 1725 cm^{-1} (CO); ^{1}H-NMR ($CDCl_3$) δ=1.43, 4.08 ($OC\underline{H}_2C\underline{H}_3$), 2.40—3.40 (6H, m), 3.70, 3.72, 3.84, 3.87 (each 3H, s, COOMe), and 7.22 (1H, s, 3-H); MS m/z 408 (M^+).

Found: C, 59.03; H, 6.00%. Calcd for $C_{20}H_{24}O_9$: C, 58.82; H, 5.92%.

*Cycloaddition of **20** to **5** and Subsequent Dehydrogenation Leading to **30**.* A mixture of **20** (43 mg, 0.2 mmol) and **5** (44 mg, 0.31 mmol) in toluene (1.5 ml) was first refluxed for 6 h and further 15 h after chloranil (75 mg, 0.31 mmol) was added. The crude product was chromatographed over silica gel with hexane–ethyl acetate (3:1) to give **30** (48 mg, 67%) as a 2:1 mixture of regioisomers: Colorless solid; mp 117—123 °C; IR (KBr) 1725 cm^{-1} (CO); ^{1}H-NMR ($CDCl_3$) δ=1.43, 4.07 ($OC\underline{H}_2C\underline{H}_3$), 1.60—3.20 (7H, m), 3.69, 3.72, 3.84, 3.88, 3.89 (9H, each s, COOMe for the major and minor regioisomers), and 7.21 (1H, s, 3-H); MS m/z 350 (M^+).

Found: C, 61.77; H, 6.41. Calcd for $C_{18}H_{22}O_7$: C, 61.71; H, 6.33%.

*Cycloaddition of **11** to **8** Leading to **31**.* A mixture of **11** (167 mg, 0.53 mmol) and DBU (88 mg, 0.58 mmol) in dry toluene (4 ml) was refluxed for 6 h and then cooled to room temperature. After iodomethane (a few drops) and **8** (205 mg, 1.18 mmol) were added, the mixture was stirred at room temperature for 12 h. The crude product was chromatographed over silica gel with hexane–ethyl acetate (1:1) to afford **11** (34 mg, 20% recovered) and then **31** (121 mg, 56%): Colorless solid; mp 188—191 °C; IR (KBr) 1770 and 1700 cm^{-1} (CO); ^{1}H-NMR ($CDCl_3$) δ=1.16, 3.66 ($OC\underline{H}_2C\underline{H}_3$), 1.90—3.40 (11H, m), 2.93 (3H, s, NMe), and 7.00—7.56 (5H, m, Ph); MS m/z 408 (M^+).

Found: C, 67.46; H, 5.96; N, 6.86%. Calcd for $C_{23}H_{24}O_5N_2$: C, 67.63; H, 5.92; N, 6.86%.

*Cycloaddition of **12** to **3** Leading to **32**.* A mixture of **12** (160 mg, 0.42 mmol) and DBU (71 mg, 0.47 mmol) in toluene (4 ml) was refluxed for 6 h and cooled to room temperature. After iodomethane (a few drops) and **3** (94 mg, 0.85 mmol) were added, the mixture was stirred at room temperature for 24 h. The crude product was chromatographed over silica gel. An elution with hexane–ethyl acetate (2:1) gave **12** (18 mg, 11% recovered) and with hexane–ethyl acetate (1:2) **32** (112 mg, 65%): Colorless needles from ethanol; mp 105—107 °C; IR (KBr) 1770 and 1700 cm^{-1} (CO); ^{1}H-NMR ($CDCl_3$) δ=1.16, 3.64 ($OC\underline{H}_2C\underline{H}_3$), 2.00—3.40 (11H, m), 2.91 (3H, s. NMe), and 7.04—7.56 (5H, m, Ph); MS m/z 408 (M^+).

Found: m/z 408.1696. Calcd for $C_{23}H_{24}O_5N_2$: M, 408.1684.

We are grateful to Toyo Soda Manufactural Company for a generous sample of chloroprene.

Stereochemical Study on 1,3-Dipolar Cycloaddition Reactions of Heteroaromatic *N*-Ylides with Unsymmetrically Substituted Olefinic Dipolarophiles

Otohiko Tsuge,* Shuji Kanemasa, and Shigeori Takenaka
Research Institute of Industrial Science, and Department of Molecular Science and Technology, Interdisciplinary Graduate School of Engineering Sciences, Kyushu University, Kasugakoen, Kasuga 816
(Received July 8, 1985)

Regioselectivity and stereoselectivity of the cycloadditions of heteroaromatic *N*-ylides with unsymmetrically-substituted olefins such as methyl-substituted cis olefins, an acrylate, the related olefins, trans nitro olefins, and other trans olefins have been investigated. These cycloadditions are highly regioselective, while the stereoselectivity depends upon both the electronic and steric nature of substituents of the ylide and olefin. The 1-endo-2-exo cycloadducts of the anti form of ylides which have been formed as kinetically controlled products undergo the isomerization into either the 1-endo-2-exo cycloadducts of the syn ylides through a retro cycloaddition process or the 1-exo-2-endo cycloadducts of the syn ylides *via* betaine intermediates.

The preceding paper has dealt with the stereochemical study on the 1,3-dipolar cycloaddition reactions of heteroaromatic *N*-ylides to symmetrically substituted cis and trans olefins,[1] and some important stereochemical features in such cycloadditions have been figured out:

1) The anti form of ylides exclusively participates in the cycloadditions if the ylides are stabilized by a substituent of carbonyl type.

2) The reactions with cis olefins are highly stereoselective, the endo approach of olefins to the anti ylides being the only favored pathway.

3) If the cycloadducts formed are substituted by strongly electron-withdrawing groups, they suffer from the ready stereospecific dissociation into the starting ylides and olefins which then recombine in a stereospecific manner giving the thermodynamically more favored isomers.

4) After all, the stereochemical course of cycloadditions of heteroaromatic *N*-ylides depends upon the electronic nature and steric size of substituents on the olefins and ylides. The attractive secondary orbital interaction working between the olefin substituents and the heteroaromatic plane leads to the kinetically favored cycloadducts, and the steric repulsion working among the olefin substituents and the ylide ring and substituent favors the formation of thermodynamically controlled cycloadducts. The stereochemistry of the reactions is revealed as a result from the counter-balance of the above two interactions.

In the present paper, the cycloaddition reactions of heteroaromatic *N*-ylides to unsymmetrically substituted cis and trans olefins are investigated with the aim of knowing the generality and limitation of our rules which were outlined in the preceding paper and abstracted above. In the reactions with unsymmetrical olefins, of special interest are the regioselectivity, the stereoselectivity of ylide substituent (or the periselectivity), the stereoselectivity of olefin substituents (the endo and exo selectivity), and the thermodynamical stability of cycloadducts. For wide applications of the 1,3-dipolar cycloadditions to organic synthesis, it is necessary to discriminate among the factors which control the stereochemistry of cycloaddition and to understand which certain factor predominates over the other.

So far examples for the cycloadditions of heteroaromatic *N*-ylides to unsymmetrically substituted olefinic dipolarophiles are quite limited. In the most reported cases, the cycloadducts could not be isolated because of their instability[2] or, if isolated, their stereostructures remained unsolved.[3,4] It is only in recent year that the regio- and stereoselective cycloadducts of triazolium or dihydroisoquinolinium methylides to acrylic olefins have been reported to be the endo cycloadducts to the anti form of the ylides.[5,6] Some other unsymmetrical olefins have been employed in the cycloadditions to dihydroisoquinolinium methylides giving the regio- and stereoselective cycloadducts with a cis-trans-cis geometry as to the newly formed five-membered rings.

Results and Discussion

Thirteen heteroaromatic *N*-ylides **1**—**5** including five different types of heterocyclic systems were employed in the present work as shown in Scheme 1: Several pyridinium methylides **1a**—**e**, isoquinolinium methylides **2a**—**e**, pyridazinium **3**, thiazolium **4**, and benzothiazolium phenacylides **5**. These ylides are labile, so they were all generated *in situ* from the corresponding quaternary bromides and triethylamine in the presence of an olefinic dipolarophile.

After the cycloaddition was completed, triethylamine hydrobromide quantitatively formed was removed off by washing the reaction mixture with water. The crude mixture was submitted, in every case, to the ^{1}H-NMR measurement to get informations on the regio- and stereoselectivity of the

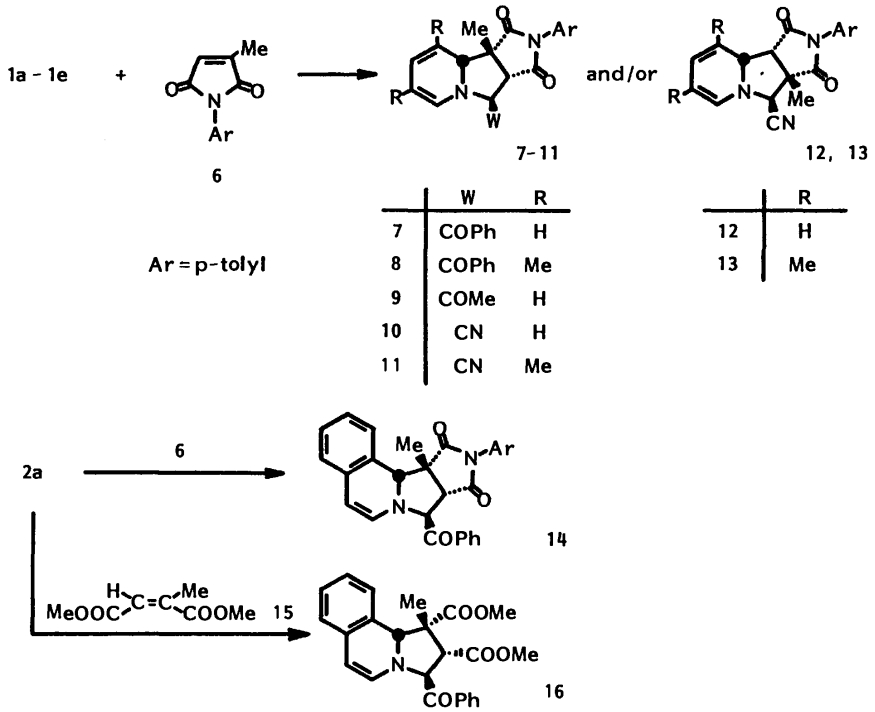
cycloaddition, and then subjected to the isolation and purification procedure of products. Figure 1 shows the numberings for the ring systems of cycloadducts formed from the cycloadditions.

Cycloadditions to Methyl-substituted cis Olefins. We have recently found that such cis olefins as maleimides and maleates undergo the stereospecific and stereoselective cycloadditions to heteroaromatic *N*-ylides providing the endo 3+2 cycloadducts to the anti form of ylides.[1] When a methyl substituent is introduced at the olefin part of cis olefins, one of two possible endo approaches between the ylide and the methyl-substituted cis olefin may be disfavored because of the steric repulsion between the methyl moiety and a ylide-stabilizing substituent. Therefore, it is easily expected that the regioselectivity of cycloadditions to methyl-substituted cis olefins should be excellent in favor for the formation of cycloadducts with the methyl and ylide-stabilizing substituents in a 1,3-relationship.

The reaction of pyridinium phenacylide **1a** with *N*-(*p*-tolyl)citraconimide **6** in chloroform at room temperature produced a single isomer of the 3+2 cycloadduct **7** in a quantitative yield as shown in Scheme 2 and Table 1. Similarly 3,5-dimethylpyridinium phenacylide **1b** and pyridinium acetonylide **1c** gave almost quantitative yields of stereospecific, regio-, and stereoselective cycloadducts **8** and **9**, respectively, both as single isomers.

Although these cycloadducts **7**—**9** are all too unstable to be purified by recrystallization or column chromatography as is usual with the cycloadducts of heteroaromatic *N*-ylides to maleimides,[1] their structures were successfully determined as the 9b-methyl derivatives of the endo 3+2 cycloadducts of **6** to the anti form of **1** on the basis of the spectral data shown in Table 2. With the cycloadduct **7** as an example, the small coupling constant of 0.8 Hz between 3a-H and 4-H as well as the low field shift of 9-H compared with 7-H (5.49 and 4.82 ppm, respectively) is consistent with the endo cycloadduct to the anti ylide. It is clear that the methyl substituent is sitting at the 9b-position on the basis of the splitting patterns of methine hydrogens on the newly formed five-membered ring.

On the other hand, the reactions of pyridinium methylides **1d** and **1e** with a cyano moiety as a sterically small ylide-stabilizing substituent furnished each two regioisomeric cycloadducts **10**+**12** and **11**+**13**, respectively, whose separation was unsuccessful. The major products **12** and **13** were assigned as the 3a-methyl-substituted cycloadducts and the minor ones **10** and **11** the 9b-methyl derivatives by the careful reading of the ^{1}H-NMR spectral data. Such reversal of regioselectivity which should be deeply related with the steric size of the cyano moiety will be discussed later. The cycloadditions of isoquinolinium phenacylide **2a** to **6** and of **2a** to dimethyl citraconate



Scheme 2.

15 took place, quite readily under milder conditions than the others, giving quantitative yields of regio- and stereoselective cycloadducts **14** and **15**, respectively.

The regioselectivity in the cycloadditions with such methyl-substituted cis olefins as **6** and **15** can be satisfactorily explained by the steric repulsion during the approach of the both reagents (Fig. 2). As has been demonstrated in the preceding work,[1] the cycloadditions of heteroaromatic *N*-ylides to a variety of cis olefins proceed through the endo approach to the anti form of ylides due to both the high stabilization of anti ylide and the minimization of steric repulsion from the ylide-stabilizing substituent. The same mode of approach may be applied to the present cases. Simple combination of the polarized structures of **1** and **6** leads to the approach **A** in

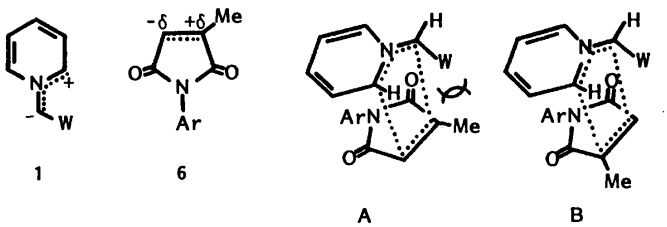

Fig. 2. Two regioisomeric endo approaches between **1** and **6**.

which some steric repulsion exists between the ylide-stabilizing substituent W and the methyl moiety. When W is small in size such as cyano group, the approach **A** is more favored providing **12** and **13** as major products. When the steric repulsion of W to the methyl is critical, the approach **A** becomes

disfavored and instead the other approach **B** is the only allowed pathway.

Cycloadditions to Acrylic and Related Olefins. The cycloadditions of **2a** with acrylonitrile **17a** and methyl acrylate **17b** as monosubstituted olefinic dipolarophiles were found to occur readily, at room temperature for 10 min, furnishing quantitaive yields of regioselective and stereochemically pure 3+2 cycloadducts **18** and **19**, respectively (Scheme 3 and Table 3). On the other hand, the isoquinolinium ylide **2d** having *p*-nitrophenyl moiety as a ylide-stabilizing substituent showed very poor stereoselectivity in the reaction with **17a**, a mixture of two stereoisomers **20** and **21** being obtained in 100% yield. They were tentatively assigned as the endo 3+2 cycloadducts to the anti and syn forms of the ylide **2d** on the ground of the mechanistic discussion described later. Unfortunately the similar reaction of **2d** with **17b** gave no 3+2 cycloadduct but the only obtained product **22** was the dehydrogenated cycloadduct, 1-methoxycarbonyl-3-(*p*-nitrophenyl)-2,3-dihydropyrrolo[2,1-*a*]isoquinoline.

Although quite sluggish, the cycloaddition of benzothiazolium *N*-pnenacylide **5** to **17a** gave 74% of the regio- and stereoselective cycloadduct **23** as a single product.

The structures of these cycloadducts were confirmed mainly on the basis of the ^{1}H-NMR spectral data listed in Table 4. The cycloadduct **19** which was obtained from **2a** and **17b** offers the most clear ^{1}H-NMR spectrum supporting the proposed stereostructure as shown in Fig. 3.

The ester methyl at the 1-position, appeared at 3.28 ppm, should be sitting in the midst of shielding zone of the fused benzene ring, and hence the relationship between 1-H and 10b-H is cis. The 1-H couples with one (Ha) of two adjacent methylene hydrogens with a small coupling constant of 2.3 Hz and the other (Hb) with a medium coupling of 8.0 Hz, indicating that Ha and Hb are trans and cis to 1-H, respectively. The molecular model for **19** with a confirmed stereochemistry at the 10b-, 1-, and 2-

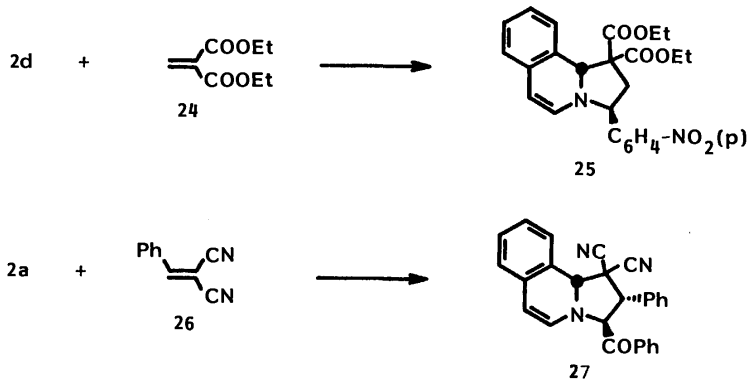
positions and with an undetermined configuration at the 3-position was built up and the coupling constants between 2-Hs and 3-H were estimated. As the result, the structure of **19** was determined as the endo 3+2 cycloadduct to the anti form of **2a**, whose formation was mostly predictable from our rule founded in the preceding paper.[1]

Contrary to the poor stereoselectivity of the cycloaddition between **2d** and **17a** mentioned above, a similar reaction of **2d** with diethyl 2-methylenemalonate **24** which carries two electron-withdrawing substituents at the same carbon was highly selective giving the single 3+2 cycloadduct **25** in a quantitative yield (Scheme 4 and Table 3).

The purification of **25** ended in failure because of its instability, but the ^{1}H-NMR spectrum as well as mass spectrum (Table 4) confirms the tetrahydropyrrolo[2,1-*a*]isoquinoline structure of **25**. The only ambiguousness is the configuration at the point of fusion (10b-H), which was tentatively assigned as shown in Scheme 4 (10b-H is trans to 3-H) on the basis of the mechanistic consideration discussed using Fig. 4 in the following section.

The stereo- and regioselective cycloadduct **27** was similarly obtained in the cycloaddition of **2a** to 2-benzylidenemalononitrile **26**.

The stereochemical features revealed in the cycloadditions to acrylic and related olefins are summarized in Fig. 4. It is quite understandable that the reactions of **2a** and **5** with acrylic olefins **17** have proceeded in a highly regio- and stereoselective fashion through the endo approach **C** (W=COPh, the case of isoquinolinium ylide) of **17** to the anti form of the ylides, because it is now known from our previous work[1] that the ylide **2a** as well as **5**, each of carbonyl-stabilized type, is more stabilized in the anti form than the syn form. On the other hand, the nonstereoselective cycloaddition of **2d** was also predictable. The ylide **2d** carrying a ylide-stabilizing substituent of noncarbonyl type has a similar stability in the anti and syn forms and hence the both endo approaches **C** and **D** (W=*p*-$NO_2C_6H_4$) seem



Scheme 4.

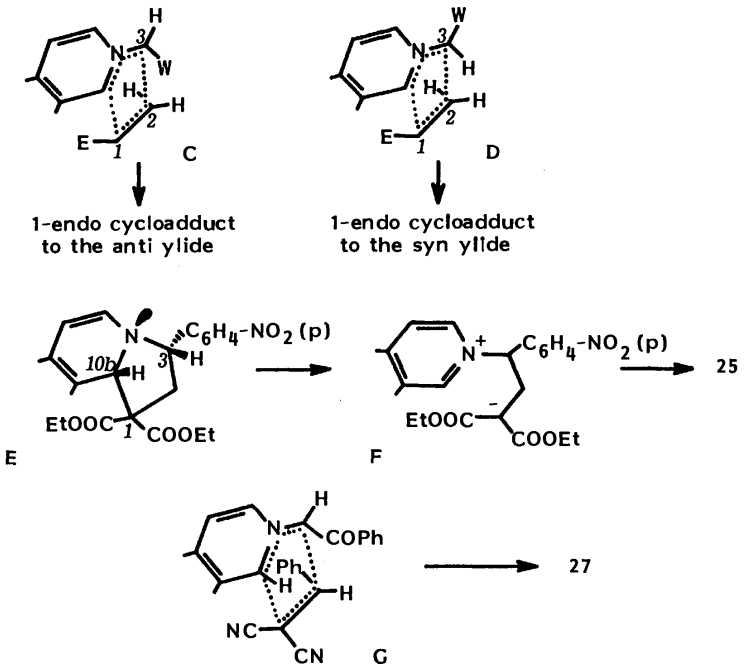


Fig. 4. Stereochemistry in the cycloadditions of **2** to acrylic **17** and related olefins **24, 26.**

likely to compete with the comparable easiness.

Surprising is the formation of single cycloadduct **25** in the reaction of **2d** with the 2-methylenemalonate **24.** We anticipated a kinetically nonstereoselective cycloaddition in this case because all the situation looked about the same to the cycloaddition to **17a.** This can be explained as follows: In this reaction also two isomeric cycloadducts **25** and **E** should have been formed through the energetically almost equal two endo approaches. As the both cycloadducts carry two electron-withdrawing ester groups at the 1-position, the 1—10b bond is readily cleaved into the stable betaine intermediate **F.** The recyclization of **F** must occur in a direction of producing the thermodynamically more stable cycloadduct **25** of the two. Such bond cleavage forming a betaine intermediate has been observed in the hydroalkylidenation reaction using pyridinium methylides[7] and will be discussed later.

In the cycloaddition between **2a** and 2-benzylidenemalononitrile **26** are possible two endo approaches to the anti form of **2a.** However, the reaction has trod the approach **G** leading to **27.** This high selectivity may be the result from either of the attractive interaction between the phenyl plane of **26** and the heteroaromatic plane of **2a** or the steric repulsion between the phenyl group and the benzoyl moiety of the anti form of **2a** as shown in Fig. 4.[8]

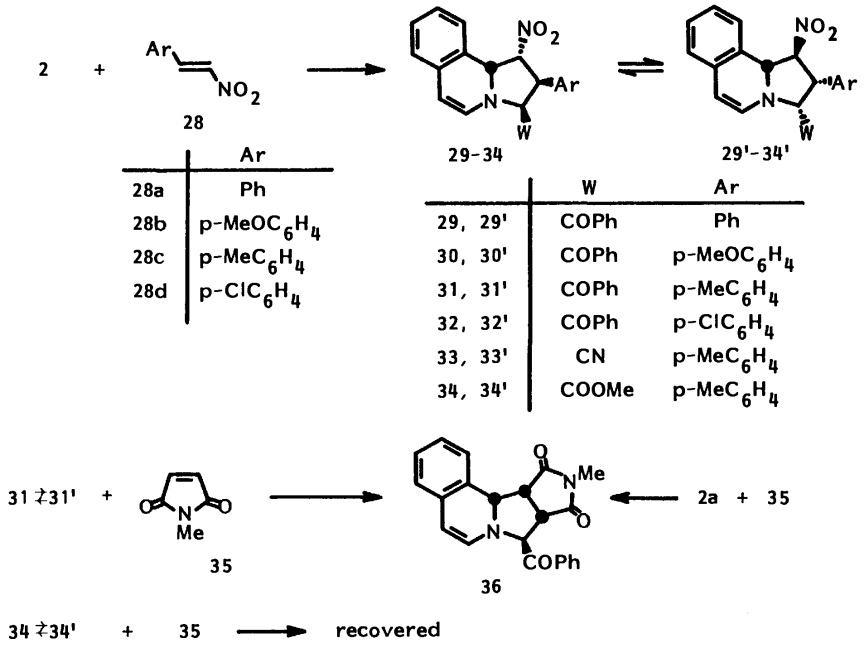
Cycloadditions to Nitro Olefins. The reactions of isoquinolinum ylides **2** with β-nitrostyrenes **28** proceeded at room temperature affording quantitative yields of 1 : 1 adducts in all cases (Scheme 5). The ^{1}H-NMR measurement of crude products showed that the product was, more or less in each case, composed of two stereoisomers of 3+2 cycloadduct and that the isomer ratio was dependent upon the solvent used for the ^{1}H-NMR measurement and also the time after the ^{1}H-NMR sample was prepared.

Although one isomer of the two or the both could be often separated in an almost pure form through crystallization or precipitation, it was unsuccessful to tell which of the two was the initial cycloadduct (kinetical product) because of the poor solubility and too rapid equilibration of the cycloadducts.

After all, it was concluded that the cycloadducts to **28** were under an equilibrium control (or thermodynamical control) and the energy barrier for the equilibrium was quite small. Their structures were assigned on the basis of the ^{1}H-NMR spectra, the chemical conversions, the molecular model inspection, and the proposed mechanism for the isomerization, all of which will be discussed soon later: **29**—**34**: the 1-endo-2-exo cycloadducts of the anti form of the ylides **2** as kinetically controlled products; **29′**—**34′**: the 1-exo-2-endo cycloadducts of the syn form of **2** as thermodynamically controlled products (Scheme 5).

Table 5 summarizes all the results obtained in the reactions of **2a**—**c** with several β-nitrostyrenes **28a**—**d**. The melting points are given only for the cycloadducts isolated in a pure form through crystallization or precipitation. The structural assignment for the cycloadducts formed from **2a**+**28a** and **2a**+**28d** was impossible because the only solvent in which they are satisfactorily soluble is DMSO, and in this solvent the equilibration between **29** and **29′** (also **32** and **32′**) is finished in a short time.

As shown in Scheme 5, the cycloadducts **31**+**31′** underwent the retro cycloaddition, in DMSO at room temperature, going back to the nitrostyrene **28c** and the ylide **2a** which was quantitatively captured with *N*-methylmaleimide **35** as the maleimide cycloadduct **36**. However, it is not likely that this retro reaction is deeply related with the isomerization between **31** and **31′** since the retro reaction is too slow compared with the isomerization (50 and 100% of **36** were formed after 4 and 48 h, respectively, at room temperature in



Scheme 5.

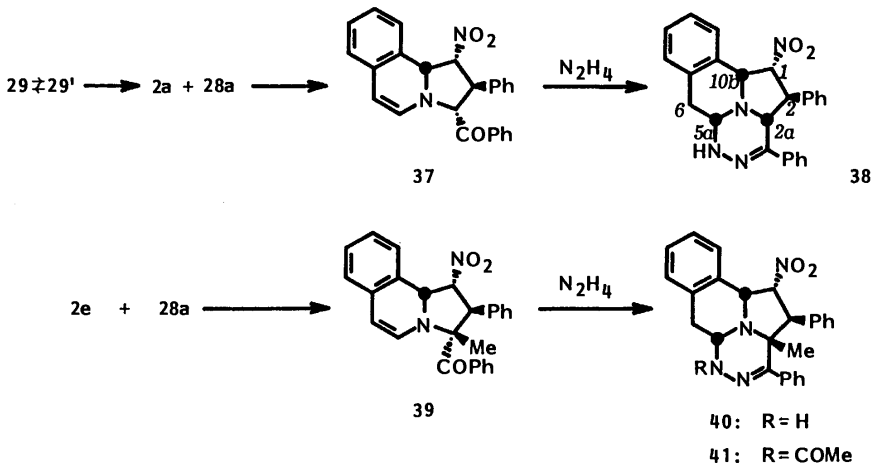
a) Carried out in chloroform. b) All yellow solid. c) Isolated yields. d) One isomer was less soluble than the other, being separated in a pure form. e) Very rapid equilibration was observed in DMSO. The ratio was based on the ^{1}H-NMR spectrum.



Scheme 6.

DMSO while the equilibration is completed in less than a few minutes under the same conditions). In fact, in spite of the ready isomerization between **34** and **34'**, the cycloadducts from the ylide **2c** bearing an ester substituent, at room temperature in DMSO, they never undergo the retro reaction with **35** even under harder conditions. As a conclusion, this rapid equilibration takes place *via* a betaine intermediate formed by the 1—10b bond cleavage of the cycloadduct. This will be discussed in detail in the following section.

The rapid equilibration is partly attributable to the high stability of the intermediary betaine compound (**J** in Fig. 6). If the 5—6 double bond of cycloadducts is reduced, such bond cleavage may be suppressed. In order to consume the 5—6 double bond and also to make the conformation of the pyrrolidine ring rigid, the equilibrating mixture of **29** and **29'** was allowed to react with hydrazine hydrate under reflux in ethanol producing a single isomer of the expected diazacyclazine derivative **38** (Scheme 6).

The structure of **38** was determined on the basis of the ^{1}H-NMR spectrum (Fig. 5) and the molecular model inspection: The 2-H is trans both to the 2a-H and 1-H (J_{2-2a}=3.5 and J_{2-1}=6.0 Hz) and the 1-H is cis to the 10b-H (from the molecular model analysis and J_{1-10b}=9.5 Hz). To our surprise, this coupling pattern around the pyrrolidine ring was found completely different from those of **29** (J_{3-2}=8.5, J_{2-1}=4.0, and J_{1-10b} could be about 7 Hz) and **29'** (J_{3-2}=J_{2-1}=J_{1-10b}=8.0 Hz), showing that **38** was derived from an isomeric cycloadduct **37** which was formed by the isomerization of **29** or **29'** under the reaction conditions. The coupling pattern of **31** with a medium-small-medium coupling was once observed in the 1-endo-2-exo cycloadducts of symmetrical trans olefins to the anti form of **2** as the kinetical products.[1]

Now, it is clear that **29** is the 1-endo-2-exo cycloadduct to the anti form of **2** as a kinetically

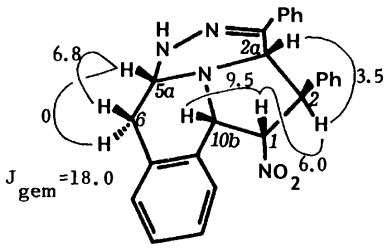


Fig. 5. Stereostructure and ^{1}H-NMR spectral data of **38**.

controlled product, **29'** is the 1-exo-2-endo cycloadduct to the syn form of **2** as a thermodynamically controlled product formed through the isomerization of **29** *via* a betaine intermediate, and that **38** was derived from another thermodynamical cycloadduct **37**, the 1-endo-2-exo 3+2 cycloadduct to the syn form of **2a**. This second thermodynamic cycloadduct **37** may have been formed, under forced conditions, through the retro cycloaddition of **29** (Scheme 6).

The similar reaction of isoquinolinium 1-benzoylethylide **2e** with **28a** and the subsequent cyclization with hydrazine gave **40** also as a single isomer in 21% of total yield. The structural inspection using the ^{1}H-NMR spectra of **40** and its *N*-acetylated derivative **41** confirmed the 1-endo-2-exo skeleton of the noniso-lated cycloadduct **39** as shown in Scheme 6.

The IR and ^{1}H-NMR spectra of the cycloadducts **29**—**34** and **29'**—**34'** are listed in Table 6. These spectra are consistent with the proposed structures for each isomers. The both ester methyls at the 3-position of **34** and **34'** are strongly shielded by the fused benzene ring and/or the adjacent phenyl ring.

The stereochemical variety in the cycloadditions of isoquinolinium ylides **2** to nitrostyrenes **28** is summarized in Fig. 6 with an exemplified reaction of **2a** with **28a**. This cycloaddition proceeds through the 1-endo-2-exo approach **H** of **28a** to the anti form of **2a**, just like the cycloadditions of heteroaromatic

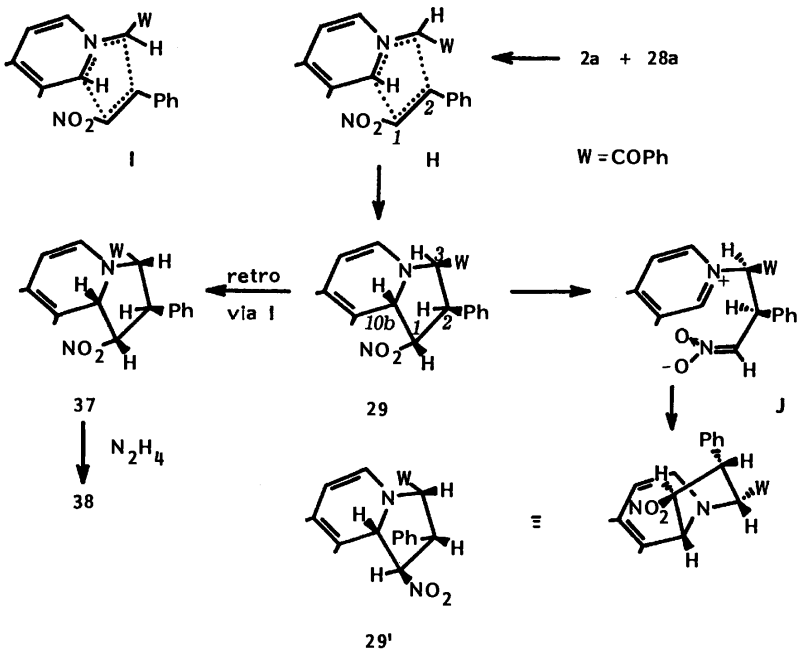

Fig. 6. Stereochemical course of the cycloaddition of **2a** to **28a**.

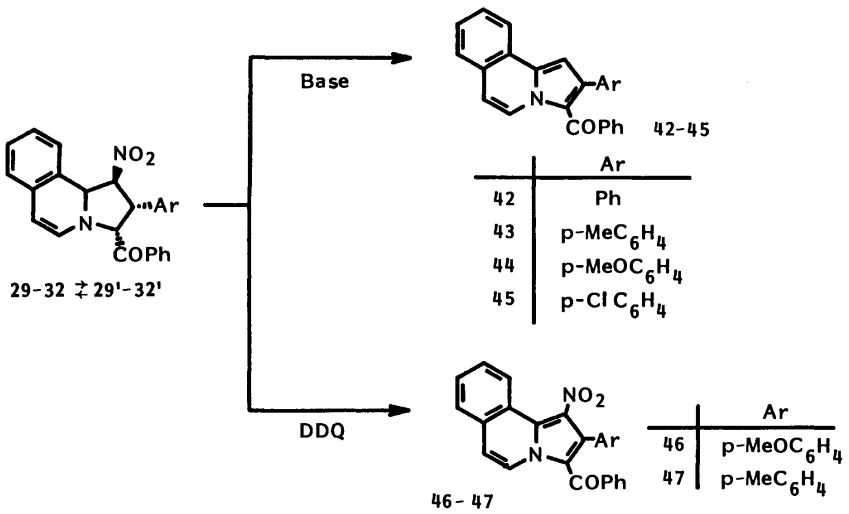
N-ylides to symmetrical trans olefins,[1] giving **29** as a kinetically controlled cycloadduct. This product **29** undergoes a rapid bond cleavage at the 1—10b bond leading to a betaine intermediate **J**. This easy betaine formation must have been induced by the anion stabilization with the nitro group and also by the cation stabilization in the isoquinolinium ring. The recyclization at the other side of the isoquinoline ring gives **29′** as a thermodynamically controlled cycloadduct. As the thermodynamical stability between **29** and **29′** looks about the same and the energy barrier between **29** and **J** and between **J** and **29′** might be small, they come into a rapid equilibration with the comparable isomer ratio. On the other hand, the kinetical cycloadduct **29** can undergo a slow retro cycloaddition providing **2a** and **28a** which recombine through the 1-endo-2-exo approach **I** to the syn form of **2a** giving the second thermodynamic cycloadduct **37**. Similar isomerization of the kinetical cycloadduct into two isomeric cycloadducts through a betaine intermediate or a retro cycloaddition path will be again discussed in the following section.

When the cycloadducts **29**—**32** and **29′**—**32′** were treated with bases, they were found to aromatize into the corresponding pyrrolo[2,1-*a*]isoquinoline derivatives **42**—**45** with the elimination of the nitro moiety (Scheme 7 and Table 7). Although the yields were not so high, such nitrous acid elimination is important as a method of synthesizing the indolizine derivatives carrying no electron-withdrawing substituent at the 1-position. It was also found that triphenylphosphine was even more effective, but the reaction mechanism is not clear so far.

The aromatization into the indolizines **46**—**47** carrying a nitro group at the 1-position was achieved by the usual dehydrogenation using DDQ (Scheme 7 and Table 7).

Cycloadditions to Unsymmetrical trans Olefins. Isoquinolinum methylides **2**, which belong to the most reactive heteroaromatic *N*-ylide, were found to react with unsymmetrically substituted trans olefins such as (*E*)-1-(*p*-methylbenzoyl)-2-phenylethene **48a**, cinnamaldehyde **48b**, crotonaldehyde **48c**, and (*E*)-1-benzoylpropene **48d** at room temperature, but rather slowly compared with the cycloadditions to other dipolarophiles previously employed. As the reactions under heating generally lead to the contamination of cycloadduct by some secondary products formed through the isomerization, dehydrogenation, or decomposition of the initially formed cycloadduct



Scheme 7.

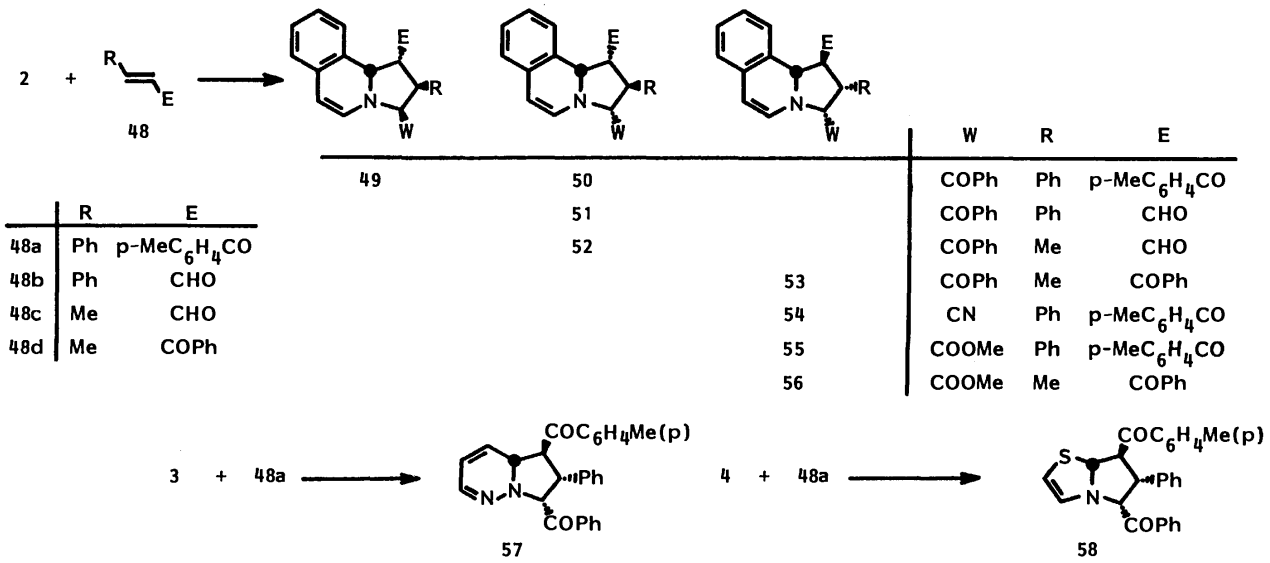
and since such cycloadducts are usually not so stable enough to be separated or purified safely, only limited numbers of dipolarophiles were used. No clear result was given in the reactions with such unreactive olefins as crotonates, cinnamates, (*E*)-4-phenyl-3-propen-2-one, and (*E*)-3-penten-2-one which required harder reaction conditions and therefore resulted in the complex mixture of products. The results are summarized in Scheme 8 and Table 8.

Three different types of 3+2 cycloadducts were isolated in the reactions with **48**, depending upon the nature of substituents of the ylide **2** and olefin **48** and also upon the reaction conditions. The reaction of **2a** with **48a** in acetonitrile precipitated a labile cycloadduct **49** in a pure form. This cycloadduct **49** was found to readily isomerize into **50** in DMSO even at room temperature. When the same reaction was carried out in chloroform, no precipitate appeared and only **50** was obtained in a quantitative yield. These facts indicate that **49** and **50** are the kinetic and thermodynamic cycloadducts, respectively. The third type of cycloadducts are **53**—**58** which were formed from either the alkyl-substituted vinyl ketone **48d**, the ylides **2b** and **2c** carrying a cyano or ester ylide-stabilizing substituent, or the other types of ylides **3** and **4**.

Each type of these cycloadducts showed a characteristic coupling pattern among the methine hydrogens on the newly formed five-membered ring as shown in Table 9. The product **49** showed similar couplings to the kinetically controlled cycloadduct between **2** and symmetrical trans olefins,[1] being assigned to be the 1-endo-2-exo cycloadduct to the anti form of **2a** as a kinetical product. Its isomer **50** exhibited a coupling pattern similar to both **38** (hence **37**) and the thermodynamically controlled cycloadduct of **2** to symmetrical trans olefins (1-exo-2-endo cycloadduct to the anti ylide). Based on this fact and also its chemical conversion into a diazacyclazine derivative which will be described



Scheme 8.

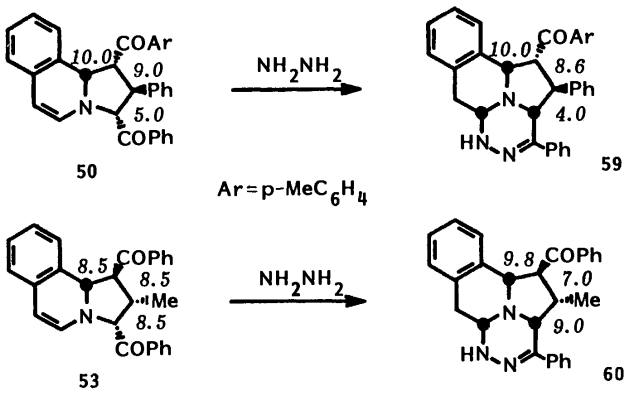
a) Contaminated by 20% of an isomer which shows 0.92^d (2-Me). b) Contaminated by 14% of an isomer which shows 1.03^d (2-Me). c) Contaminated by 30% of an isomer which shows 1.37^d (2-Me) and 3.77^s (COOMe). d) No parent ion peak was observed.

later, **50** was determined to be the 1-endo-2-exo cycloadduct to the syn form of **2a** as a thermodynamically controlled product, and the same to the others **51—52**.

The coupling pattern of the third type of cycloadducts **53—58** is close to the 1-exo-2-endo cycloadducts **29′—34′** of nitro olefins to the syn form of **2** (see Scheme 5 and Table 6). Thus, they were assigned to be the 1-exo-2-endo cycloadducts to the syn form of **2** as the cycloadducts isomerized through betaine intermediates.

To confirm the structures of the above cycloadducts, rather stable two cycloadducts **50** and **53** were subjected to the cyclization using hydrazine hydrate. As shown in Scheme 9, two types of diazacyclazine derivatives **59** and **60** were obtained. It is clear that the stereochemistry has not changed, in both cases, before and after the cyclization, because the starting materials **50** and **53** showed very similar couplings to those of the products **59** and **60**, respectively. Not only the coupling pattern but also the mode of cyclization supports the proposed



Scheme 9.

structures of **50** and **53**, and hence of **50—52** and **53—58**. Molecular model inspection shows that such hydrazine cyclization is possible only when the 3-benzoyl moiety is endo, and both **50** and **53** were assigned as the cycloadducts of syn ylide.

The stereochemical features observed in the cycloadditions of the ylides **2—4** with unsymmetrically substituted trans olefins **48** are symmarized in Fig. 7 with the cycloaddition example using **2**. In this case also, the kinetically favored approach is the 1-endo-2-exo approach **K** to the anti form of **2** forming the kinetical product **N**. The cycloadduct **49** is an example belonging to this kind. When W is strongly ylide-stabilizing and also the both olefin substituents R and COR′ are highly activating the olefin, the kinetical cycloadduct **N** suffers from a ready retro cycloaddition giving back to the ylide **2** and olefin **48**. They again undego a cycloaddition, but through a different approach **L**, the 1-endo-2-exo approach to the syn form of **2**, producing the thermodynamic cycloadduct **O**. The cycloadducts **50—52** are the examples. When the retro cycloaddition path is forbidden (W is cyano or ester, or the olefin substituents are not highly activating), the kinetical cycloadduct **N** takes another isomerization pathway. As have been observed for the nitrostyrene cycloadducts, the isomerization through a betaine intermediate **M** occurs leading to the 1-exo-2-endo cycloadduct **P** to the syn form of **2**. The cycloadducts **53—56** are the cases.

Experimental

Materials. *N*-Phenacyl-3,5-dimethylpyridinium bromide (mp 200—203 °C, Found: C, 58.56; H, 5.33; N, 4.54%. Calcd for $C_{15}H_{16}ONBr$: C, 58.82; H, 5.23; N, 4.58%) and *N*-cyanomethyl-3,5-dimethylpyridinium bromide (mp 143—145 °C, Found: C, 47.36; H, 4.84; N, 12.15%. Calcd for $C_9H_{11}N_2Br$: C, 47.58; H, 4.85; N, 12.33%) were prepared by

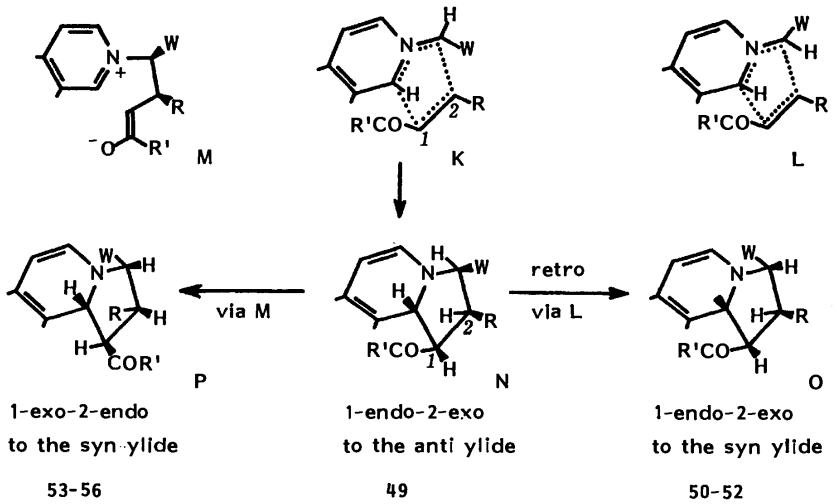


Fig. 7. Stereochemical course of the cycloaddition between **2** and **48**.

the reactions of 3,5-dimethylpyridine with α-bromoacetophenone and α-bromoacetonitrile, respectively. *N*-(*p*-Tolyl)citraconimide **6** was obtained by the reaction between citraconic anhydride and *p*-methylaniline followed by the treatment with acetic anhydride in the presence of sodium acetate.[9] Diethyl methylenemalonate **24** and benzylidenemalononitrile **26** were synthesized by the condensation of diethyl malonate with paraformaldehyde[10] and of malononitrile with benzaldehyde,[11] respectively. β-Nitrostyrenes **28a—d** were all prepared from the condensations between nitromethane and *p*-substituted benzaldehydes:[12] **28a**: Pale yellow prisms ($CHCl_3$), mp 58 °C; **28b**: Yellow prisms (EtOH), mp 81—82 °C; **28c**: Yellow needles ($CHCl_3$), mp 92—94 °C; **28d**: Pale yellow prisms ($CHCl_3$). (*E*)-1-(*p*-Methylbenzoyl)-2-phenylethene **48a** and (*E*)-1-benzoylpropene **48d** were obtained by the condensations between *p*-methylacetophenone and benzaldehyde[13] and between triphenylphosphonium phenacylide and acetaldehyde,[14] respectively. Other olefinic dipolarophiles **15—17**, **35**, and **48b—c** were all commercially available.

General Procedure for the Cycloadditions of 1a—e and 2a to Methyl-substituted Olefins 6 and 15. To the equivalent suspension of a ylide precursor and an olefin in dry chloroform (30 ml for the 1 mmol-scaled reaction), was slowly added an equivalent amount of triethylamine at room temperature. The mixture was allowed to stir at room temperature (one exception: The reaction between **2a** with **15** was carried out under reflux in chloroform) until all the precursor salts dissolved into a clear solution. After the completion of cycloaddition, the mixture was poured into ice water and extracted with chloroform twice (20 ml×2). The combined extracts were dried over $MgSO_4$ and evaporated *in vacuo* below room temperature. The crude oily material was weighed and subjected to the ^{1}H-NMR measurement. Often it solidified when triturated with petr. ether and/or ether. The reaction conditions, the melting points and yields of products are listed in Table 1. In every case the purification of cycloadduct was unsuccessful because of their lability. Therefore, the solidified products, or oily product itself, were submitted for the spectral measurement. Table 2 shows all the spectral data of cycloadducts **7—14** and **16**.

General Procedure for the Cycloadditions of 2 and 5 to Acrylic 17 and Related Olefins 24 and 26. The cycloadditions were performed by the similar procedures described above under the reaction conditions listed in Table 3. The melting points and yields of products are shown in Table 3 and the spectral data in Table 4. Other data are given as follows: **18**: Yellow prisms ($CHCl_3$–ether); ^{1}H-NMR ($CDCl_3$) δ=2.20—2.70 (2H, m, 2-H), 3.30—3.60 (1H, m, 1-H), 4.96 (1H, d, J_{10b-1}=5.2 Hz, 10b-H), 5.23 (1H, dd, J_{3-2}=9.0 and 6.0 Hz, 3-H), 5.37 (1H, d, J_{6-5}=7.5 Hz, 6-H), 6.16 (1H, d, J_{5-6}=7.5 Hz, 5-H), 6.90—7.70, and 7.80—8.10 ppm (9H, each m, ArH); Found: C, 80.06; H, 5.16; N, 9.04%. Calcd for $C_{20}H_{16}ON_2$: C, 79.98; H, 5.37; N, 9.33%. **19**: Yellow prisms (ether); Found: C, 75.42; H, 5.73; N, 4.28%. Calcd for $C_{21}H_{19}O_3N$: C, 75.65; H, 5.74; N, 4.20%. **20+21**: ^{13}C-NMR ($CDCl_3$) the major: δ=37.40 (t, 2-C), 38.57 (d, 1-C), 63.28, and 64.65 (each d, 3- and 10b-C); the minor: δ=35.20 (t, 2-C), 36.33 (d, 1-C), 63.57, and 65.92 ppm (each d, 3- and 10b-C). The intensity ratio was 2/1. **23**: colorless needles (EtOH); ^{13}C-NMR ($CDCl_3$) δ=33.3 (t, 2-C), 36.7 (d, 1-C), 68.0, 72.4 (each d, 3- and 9a-C), and 196.9 ppm (s, PhCO); Found: C, 70.44; H, 4.45; N, 9.07%. Calcd for $C_{18}H_{14}ON_2S$: C, 70.56; H, 4.61; N, 9.14%.

General Procedure for the Cycloadditions of 2 to Nitro Olefins 28. These cycloadditions were carried out using each equivalent amount of **2** and **28** according to the procedure mentioned above under the reaction conditions shown in Table 5. The results and the spectral data of cycloadducts are summarized in Table 5 and 6, respectively. The methods for separation of the isomeric cycloadducts and other data are given as follows:

29+29′: Either of **29** or **29′** was precipitated when the reaction mixture was condensed *in vacuo*. **29** or **29′**: Yellow needles ($CHCl_3$); MS *m/z* (rel intensity, %) 347 (M^+−49, 4), 105 (76), and 77 (base peak); Found: C, 75.85; H, 5.11; N, 7.16%. Calcd for $C_{25}H_{20}O_3N_2$: C, 75.74; H, 5.09; N, 7.07%.

30+30′: **30** was separated as precipitate during the cycloaddition in $CHCl_3$ and the evaporation of the filtrate gave a mixture of **30** and **30′**. **30**: Yellow needles ($CHCl_3$); MS *m/z* (rel intensity, %) 377 (M^+−49, 10), 348 (6), 228 (42), 105 (66), and 77 (base peak); Found: C, 72.75; H, 5.16; N, 6.79%. Calcd for $C_{26}H_{22}O_4N_2$: C, 73.22; H, 5.20; N, 6.57%. **30+30′**: Yellow solid; Found: C, 73.27; H, 5.10; N, 6.49%. Calcd for $C_{26}H_{22}O_4N_2$: C, 73.22; H, 5.10; N, 6.49%.

31+31′: **31′** was precipitated when the reaction mixture was condensed *in vacuo* at room temperature, and **31** was obtained as precipitate from the solution of **31′** in acetone. **31**: Yellow prisms (Me_2CO). **31′**: Yellow needles ($CHCl_3$); MS *m/z* (rel intensity, %) 377 (M^+−23, 17) and 361 (base peak); Found: C, 75.36; H, 5.28; N, 6.85%. Calcd for $C_{26}H_{22}O_3N_2$: C, 76.08; H, 5.40; N, 6.83%.

32+32′: Either of **32** or **32′** was isolated when the reaction mixture was evaporated *in vacuo* and the residue was triturated with ether. **32** or **32′**: Yellow needles ($CHCl_3$); MS *m/z* (rel intensity, %) 431 (M^+, 1) and 278 (base peak); Found: C, 69.78; H, 4.37; N, 6.18%. Calcd for $C_{25}H_{19}O_3N_2Cl$: C, 69.52, H, 4.40; N, 6.49%.

33+33′: **33′** was obtained as yellow viscous oil when the reaction solvent was removed *in vacuo*, and the solution of **33′** in $CHCl_3$ precipitated **33** after a long period of time at room temperature. **33**: Yellow needles ($CHCl_3$); MS *m/z* 315 (M^+−16), 290, and 282 (M^+−49, base peak); Found: C, 72.61; H, 5.22; N, 12.41%. Calcd for $C_{20}H_{17}O_2N_3$: C, 72.49; H, 5.17; N, 12.68%.

34+34′: **34′** was obtained when the oily crude product was treated with ether and isomerized in $CHCl_3$ at room temperature into a mixture of **34** and **34′**. **34′**: Yellow prisms (ether); MS *m/z* (rel intensity, %) 364 (M^+, 26), 317 (M^+−47, 72), and 258 (base peak); Found: C, 68.91; H, 5.63; N, 7.90%. Calcd for $C_{21}H_{20}O_4N_2$: C, 69.21; H, 5.53; N, 7.60%.

Retro Cycloadditions of 31+31′ and 34+34′ in the Presence of N-Methylmaleimide 35. A mixture of **31** and **31′** (1:1) in DMSO-d_6 was placed in an NMR sample tube and an equivalent amount of **35** was added. The resulting mixture was observed by ^{1}H-NMR spectroscopy. After 4 h at room temperature, each 50% of **31+31′** and **35** was consumed and the endo cycloadduct **36** was formed. And after 48 h at the same temperature, none of **31**, **31′**, and **35** was in the solution and the only compounds contained were **36** and **28c**. The similar procedure using a mixture of **34**, **34′**, and **35** in DMSO-d_6 showed no formation of the

cycloadduct between **28c** and **35**.

Reaction of 29+29′ with Hydrazine Hydrate Leading to 38. To a mixture of **29** and **29′** (396 mg, 1 mmol) in EtOH (20 ml), was added hydrazine hydrate (4 ml) and the resulting mixture was heated under reflux for 6 h. The residue, obtained by evaporation of the solvent *in vacuo*, was treated with ice water (20 ml) and then extracted with ether (20 ml×2). The ether was dried over $MgSO_4$ and evaporated *in vacuo*. The residue was chromatographed over silica gel (C-300) with chloroform giving 127 mg of **38** (31%): Colorless prisms (ether-petr. ether); mp 188 °C; IR (KBr) 3350, 1540, and 1360 cm^{-1}; ^{1}H-NMR ($CDCl_3$) δ=2.65 (1H, d, J_{gem}=18.0 Hz, 6-*endo*-H), 3.25 (1H, dd, J_{gem}=18.0 and J_{6-5a}=6.8 Hz, 6-*exo*-H), 3.53 (1H, dd, J_{2-1}=6.0 and J_{2-2a}=3.5 Hz, 2-H), 4.68 (1H, d, J_{5a-6}=6.8 Hz, 5a-H), 4.79 (1H, br.d, J_{2a-2}=3.5 Hz, 2a-H), 4.98 (1H, d, J_{10b-1}=9.5 Hz, 10b-H), 5.03 (1H, dd, J_{1-10b}=9.5 and J_{1-2}=6.0 Hz, 1-H), 5.96 (1H, br.s, NH, D_2O exchangable), and 6.90—7.50 ppm (14H, m, ArH); ^{13}C-NMR ($CDCl_3$) δ=31.77 (t, 6-C), 55.21, 58.67, 63.74, 64.42 (each d, 2-, 2a-, 5a-, and 10b-C), 95.27 (d, 1-C), 123.29, 125.67, 126.31, 127.53, 128.01, 128.31, 128.45, 128.89, 129.18, 131.91 (s), 134.20 (s), 135.76 (s), 141.12 (s), and 145.46 ppm (s, 3-C); MS *m/z* (rel intensity, %) 410 (M^+, 12), 364 (70), and 244 (base peak).

Found: C, 73.29; H, 5.36; N, 13.39%. Calcd for $C_{25}H_{22}O_2N_4$: C, 73.15; H, 5.40; N, 13.65%.

Cycloaddition between 2e and 28a Followed by Hydrazine Cyclization Leading to 40. A mixture of *N*-(1-benzoylethyl)isoquinolinium bromide (684 mg, 2 mmol) and **28a** (298 mg, 2 mmol) in dry chloroform (30 ml) was refluxed for 30 min in the presence of NEt_3 (0.28 ml, 2 mmol). The solvent was evaporated *in vacuo*, the residue treated with water (30 ml), extracted with ether (20 ml×2), the ether dried over $MgSO_4$, and then evaporated *in vacuo*. The residue was dissolved in EtOH (30 ml). After hydrazine hydrate (4 ml) was added, the mixture was heated under reflux for 22 h. The ethanol was evaporated *in vacuo*, the residue treated with water (10 ml), extracted with ether (20 ml×2), the ether dried over $MgSO_4$, and evaporated *in vacuo*. The residue was chromatographed over silica gel using chloroform as an eluent to give **40** (264 mg, 31%): Colorless solid; mp 109 °C; IR (KBr) 1550 cm^{-1}; ^{1}H-NMR ($CDCl_3$) δ=1.34 (3H, s, Me), 2.73 (1H, d, J_{gem}=18.0 Hz, 6-*endo*-H), 3.30 (1H, dd, J_{gem}=18.0 and J_{6-5a}=6.0 Hz, 6-*exo*-H), 3.92 (1H, d, J_{2-1}=6.8 Hz, 2-H), 4.78 (1H, d, J_{10b-1}=9.5 Hz, 10b-H), 4.90 (1H, d, J_{5a-6}=6.0 Hz, 5a-H), 5.27 (1H, dd, J_{1-10b}=9.5 and J_{1-2}=6.8 Hz, 1-H), 6.04 (1H, br.s, NH, D_2O exchangable), and 6.80—7.28 ppm (14H, m, ArH); MS *m/z* (rel intensity, %) 424 (M^+, 2), 275 (60), and 258 (base peak).

This product **40** was acetylated with acetic anhydride in the presence of a catalytic amount of pyridine at room temperature for 2 d to afford 43% of **41**: Colorless prisms (ether-hexane); mp 161 °C; IR (KBr) 1690 cm^{-1}; ^{1}H-NMR ($CDCl_3$) δ=1.33 (3H, s, Me), 2.37 (3H, s, COMe), 3.70 (1H, dd, J_{gem}=18.5 and J_{6-5a}=6.0 Hz, 6-*exo*-H), 3.90 (1H, dd, J_{gem}=18.5 and J_{6-5a}=3.7 Hz, 6-*endo*-H), 4.23 (1H, d, J_{2-1}=4.5 Hz, 2-H), 4.58 (1H, d, J_{10b-1}=8.0 Hz, 10b-H), 5.24 (1H, dd, J_{1-10b}=8.0 and J_{1-2}=4.5 Hz, 1-H), 5.47 (1H, dd, J_{5a-6}=6.0 and 3.7 Hz, 5a-H), and 6.90—7.70 ppm (14H, m, ArH); MS *m/z* (rel intensity, %) 466 (M^+, 1) and 258 (base peak).

Found: C, 72.27; H, 5.77; N, 12.14%. Calcd for $C_{28}H_{26}O_3N$: C, 72.08; H, 5.62; N, 12.01%.

General Procedure for the Aromatization of 29—32 and 29′—32′ Leading to 42—47. To the solution of **29—32** and **29′—32′** (1 mmol in 10 ml of solvent), was added an equivalent amount of PPh_3, NEt_3, DBU, or DDQ. The resulting mixture was allowed to react until all the cycloadduct was consumed (checked on TLC). The base, oxidant, solvent, temperature, and time are listed in Table 7. After the reaction was completed, the solvent was evaporated *in vacuo*. The residue was chromatographed over silica gel using benzene as an eluent to give the aromatized cycloadduct. The melting points and yields of products are summarized in Table 7. Other date are given as follows:

42: Yellow prisms (ether); IR (KBr) 1600 cm^{-1}; ^{1}H-NMR ($CDCl_3$) δ=6.82—7.78 (14H, m, ArH), 8.00—8.23 (1H, m, ArH), and 9.23 ppm (1H, d, J=8.0 Hz, 10-H); MS *m/z* (rel intensity, %) 347 (M^+, 8) and 380 (base peak).

Found: C, 86.24; H, 4.97; N, 4.35%. Calcd for $C_{25}H_{17}ON$: C, 86.43; H, 4.93; N, 4.03%.

43: Yellow prisms (ether); IR (KBr) 1610 and 1590 cm^{-1}; ^{1}H-NMR ($CDCl_3$) δ=2.20 (3H, s, *p*-Me), 6.70—7.20 (8H, m, ArH), 7.30—7.80 (5H, m, ArH), 8.00—8.20 (1H, m, ArH), and 9.25 ppm (1H, d, J=7.5 Hz, 10-H); MS *m/z* 361 (M^+).

Found: C, 77.11; H, 4.63; N, 6.73%. Calcd for $C_{26}H_{18}O_3N_2$: C, 76.83; H, 4.46; N, 6.87%.

General Procedure for the Cycloadditions of 2—4 to Unsymmetrical trans Olefins 48. To the mixture of 1 mmol each of the ylide precursor and **48** in 30 ml of solvent, was added an equivalent amount of NEt_3. The resulting mixture was stirred at room temperature until all the suspension dissapeared. The reaction solvent and time are listed in Table 8. After the completion of cycloaddition, the mixture was poured into ice water and extracted twice (each 20 ml) with dichloromethane. The combined extracts were dried over $MgSO_4$ and evaporated

in vacuo giving crude cycloadduct. As the cycloadducts **49**—**58** are all too labile to be purified through a chromatography or from crystallization, they were subjected to the spectral measurement. The yields and spectral data of cycloadducts are shown in Table 8 and 9, respectively. Other data are given as follows:

49: Yellow needles (CH_3CN); mp 165—167 °C; **50**: Yellow solid; mp 94—96 °C; Found: C, 84.26; H, 5.83; N, 2.84%. Calcd for $C_{33}H_{27}O_2N$: C, 84.40; H, 5.80; N, 2.98%. **51**: Yellow needles (ether); mp 182—185 °C (dec). **52**: Yellow solid; mp 102—104 °C. **53**: Orange solid; mp 61—65 °C. **54**: Orange solid; mp 105—107 °C. **55**: Yellow solid; mp 79—82 °C. **56**: Orange solid; mp 64—70 °C.

*Hydrazine Cyclization of **50** Leading to **59**.* A mixture of **50** (928 mg, 2 mmol) and hydrazine hydrate (4 ml) in EtOH (50 ml) was refluxed for 14 h and the solvent was evaporated *in vacuo*. The residue was treated with ice water, extracted with ether (20 ml×2), the ether dried over $MgSO_4$, and evaporated *in vacuo*. The residue was chromatographed over silica gel (Merck C-200) with ethyl acetate–hexane (1:4) to give **59** (347 mg, 36%): Colorless prisms (Me_2CO); mp 132—133 °C; IR (KBr) 3350, 1700, 1660, and 1600 cm^{-1}; ^1H-NMR ($CDCl_3$) δ=2.28 (3H, s, *p*-Me), 2.77 (1H, br.d, J_{gem}=18.0 Hz, 6-*endo*-H), 3.11 (1H, dd, J_{2-1}=8.6 and J_{2-2a}=4.0 Hz, 2-H), 3.43 (1H, br.dd, J_{gem}=18.0 and J_{6-5a}=6.7 Hz, 6-*exo*-H), 4.09 (1H, dd, J_{1-10a}=10.0 and J_{1-2}=8.6 Hz, 1-H), 4.87 (1H, br.d, J_{5a-6}=6.7 Hz, 5a-H), 4.88 (1H, d, J_{2a-2}=4.0 Hz, 2a-H), 5.04 (1H, d, J_{10b-1}=10.0 Hz, 10b-H), 5.76 (1H, br.s, NH, D_2O exchangable), 6.56 (1H, br.d, J=8.0 Hz, ArH), and 6.64—7.46 ppm (17H, m, ArH); MS *m/z* (rel intensity, %) 483 (M^+, 7), 482 (9), and 244 (base peak).

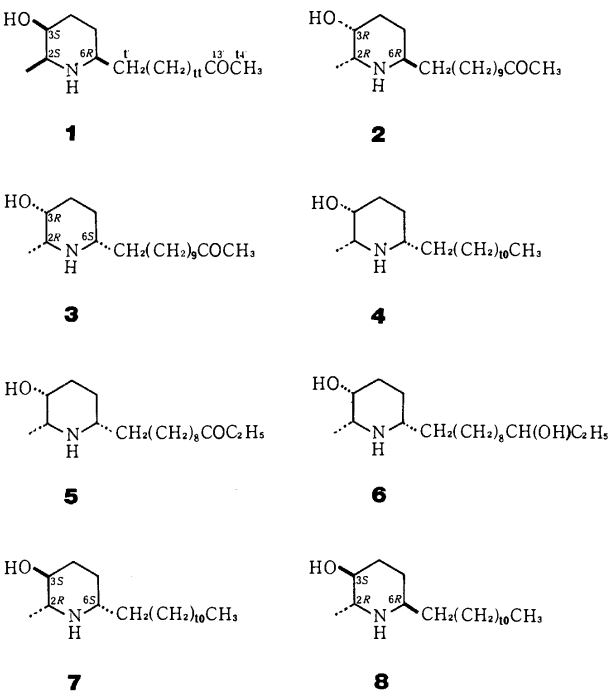
(Received July 12, 1985)

(−)-Deoxocassine [(2*R*,3*R*,6*S*)-6-dodecyl-2-methyl-3-piperidinol] and its diastereomers with 2*R*-configuration were synthesized starting from D-alanine by a route involving the intramolecular aminomercuration of an ε,ζ-unsaturated amine.

A number of piperidine alkaloids were isolated from plants of *Prosopis*,[1a] *Cassia*,[1b,c] *Azima*,[1d] and *Bathiorhamnus*[1c] species and from venoms of fire ants, *Solenopsis* species[1f] and their structures were elucidated. In these alkaloids, three substituents generally exist on the piperidine ring; a methyl or hydroxymethyl group at C-2, a hydroxyl or acyloxyl group at C-3, and a long alkyl side chain at C-6. Frequently there occur congeners from the same plant, and stereochemical investigation on the substituents between the congeners reveals that the same or homologous substituents on the same carbon atoms of the piperidine rings often possess the opposite configurations each other. For example, Christofidis *et al.*[1b] obtained three piperidine alkaloids, (+)-spectaline (**1**), (+)-iso-6-cassine (**2**), and (−)-cassine (**3**) from leaves of *Cassia spectablis* DC (Leguminosae). The absolute configurations of 2-methyl, 3-hydroxyl, and 6-alkyl side chain in these compounds were found to be (2*S*,3*S*,6*R*), (2*R*,3*R*,6*R*), and (2*R*,3*R*,6*S*) for **1**, **2**, and **3**, respectively.

Many synthetic investigations of the piperidine alkaloids have been reported.[2] Recently we reported a total synthesis of (−)-deoxoprosopinine and (−)-deoxoprosophylline[3] using an intramolecular aminomercuration.[4] From an interest in the occurrence of diastereomeric compounds such as **2** and **3** from the same origin, a total synthesis of (−)-deoxocassine (**4**)[5] and its diastereomers was planned. Although (−)-deoxocassine (**4**) is corresponding to a deoxo derivative of (−)-cassine (**3**), the compound (**4**) was also registered as desoxoprosafrinine and desoxoprosafrinone in Ratle's dissertation.[5] The original piperidine alkaloids, (−)-prosafrinine (**5**) and (−)-prosafrine (**6**) were isolated from *Prosopis africana* (GUILL and PERR.) TAUB.[1a] This paper describes a total synthesis of (−)-deoxocassine (**4**) and two diastereomers (**7** and **8**) with 2*R*-configuration starting from D-alanine by a route utilizing the intramolecular aminomercuration.[4]



1 **2** **3** **4** **5** **6** **7** **8**

N-Phthaloylation[6] and the Rosenmund reduction[7] of D-alanine afforded (2*R*)-2-phthalimidopropanal (**9**), the aldehydic proton of which appeared as a sharp singlet at δ 9.68 in the ^{1}H NMR spectrum. The aldehyde (**9**) was treated with diallylzinc[8] in tetrahydrofuran (THF) at −30 to −10 °C to afford diastereomeric alcohols (**10** and **11**) in 51 and 10% yields, respectively. The major alcohol (**10**) showed double quartet signals due to $C_{(2)}$-H at δ 4.37 ($J_{2,3}$=4 Hz), while the corresponding signal of the minor alcohol (**11**) appeared at δ 4.42 as a quintet (J=7 Hz). The stereostructure of the major alcohol (**10**) was inferred to be an *erythro* isomer [(2*R*,3*S*)-2-phthalimido-5-hexen-3-ol] and the minor one (**11**) (2*R*,3*R*)-*threo* isomer by the Cram's rule, and these assignments were further confirmed by Horeau's method.[9] The *erythro* and *threo* isomers (**10** and **11**) were treated with racemic 2-phenylbutyric anhydride

† Present address: Institute of Chemistry, Kyoto Prefectural University of Medicine, Taishogun, Kita-ku, Kyoto 603.

and the reaction mixtures were worked up as usual, respectively. The 2-phenylbutyric acid obtained from the reaction with **10** showed $[\alpha]_D$ −0.015° (*c* 0.2, optical yield 10%) and the 2-phenylbutyric acid from **11** $[\alpha]_D$ +0.031° (*c* 0.2, optical yield 21%) showing that the asymmetric centers (C-3) of the secondary alcohols (**10** and **11**) possess *S* and *R* configurations, respectively.

Since the minor alcohol (**11**) with (3*R*)-configuration should be required for a preparation of (−)-deoxocassine (**4**), a direct conversion of the configuration at C-3 of the major alcohol (**10**) was attempted first using an adoptation of Mitsunobu's method.[10] However, treatment of **10** with an acid such as benzoic acid or formic acid in the presence of triphenylphosphine and diethyl azodicarboxylate did not afford any desired ester. When the reaction was conducted in the presence of *N*,*N*-dimethylformamide dineopentylacetal[10c,11] and bis(diethylamino)chlorophosphine,[10d,12] only a complex mixture was produced, respectively.

On oxidation with pyridinium chlorochromate, the main alcohol (**10**) gave a ketone (**12**) in 88% yield, which was subjected to reduction with zinc borohydride to afford two alcohols (**10** and **11**) in 25 and 53% yields, respectively. The main reduction product was completely identical, including the optical purity, with the alcohol (**11**) obtained as the minor product by the reaction of aldehyde (**9**) with diallylzinc.

The (2*R*,3*R*)-alcohol (**11**) was treated with methoxymethyl chloride in triethylamine and acetonitrile to afford (2*R*,3*R*)-*N*,*N*-phthaloyl-3-methoxymethoxy-5-hexen-2-amine (**13**) quantitatively. The methoxymethyl derivative (**13**) was subjected to hydroboration to give (4*R*,5*R*)-4-methoxymethoxy-5-phthalimido-1-hexanol (**14**) in 83% yield, which was oxidized with pyridinium chlorochromate. (4*R*,5*R*)-4-Methoxymethoxy-5-phthalimidohexanal (**15**), susceptible to air-oxidation, was obtained in 85% yield. The Wittig reagent which was generated from dodecyltriphenylphosphonium bromide (prepared by Chasin's procedure[13]) and butyllithium in hexane, was quickly treated with the aldehyde (**15**) in THF at −78 °C. The usual work-up gave (2*R*,3*R*)-3-methoxymethoxy-2-phthalimido-6-octadecene (**16**) in 60% yield. The olefin (**16**) is inferred to mainly consist of a (*Z*)-isomer, because no band due to *trans*-olefin was observed in the IR spectrum. This conclusion was confirmed by the separate synthetic route (*vide infra*).

The *N*-phthaloyl group of **16** was removed by treatment with an excess of hydrazine monohydrate to give (2*R*,3*R*,6*Z*)-3-methoxymethoxy-6-octadecen-2-amine (**17**), which, without purification, was subjected to the aminomercuration with mercury(II) acetate in methanol and successively to the demercuration with sodium borohydride. Since the reaction product was shown to be a complex mixture of several reaction products, the chromatographic separation was attempted, but the desired piperidine derivatives (**18** and/or **19**) could not be isolated. Then separation of the mixture was attempted after *N*-protection. However, neither *N*-*t*-butoxycarbonyl,[14] *N*-trityl, nor *N*-methoxycarbonyl derivative[15] could be prepared, while *N*-tosyl and *N*-acetyl derivatives could not be successfully deprotected. Then the mixture was treated with benzyloxycarbonyl chloride[16] and the reaction mixture was separated by silica-gel column chromatography to afford the sole product. The *N*-protected product was obtained only in a 15% isolation yield from **16** through three steps. The poor yield may be due to the facts that both dephthaloylation and aminomercuration yielded complex reaction mixtures. Any other diasteromeric isomer could not be isolated from the reaction mixture. The reaction product showed the molecular ion peak at *m/z* 461 and prominent fragment peaks at *m/z* 292 and *m/z* 91, indicating that the reaction product is one of the diastereoisomers of *N*-benzyloxycarbonylpiperidines (**20** and **21**).

The *N*-benzyloxycarbonylpiperidine was subjected to hydrogenolysis in the presence of 5% palladium on carbon to give the *N*-deprotected product (**18**) in 36% yield, which was successively treated with 1 M (1 M=1 mol dm^{-3}) hydrochloric acid in methanol at reflux temperature for 2 h. The reaction product, after alkalification, was extracted with ether and purified by column chromatography on alumina to give one diastereomer of (2*R*,3*R*)-6-dodecyl-2-methyl-3-piperidinols as white crystals, mp 47.5—48.5 °C, $[\alpha]_D^{18}$ −12.3°, in 44% yield. The physical and spectral data being identical with those of deoxocassine, and also desoxoprosafrinine and desoxoprosafrinone described in the Ratle's dissertation[5] (Table 1), the compound obtained by this preparation was determined to be (−)-deoxocassine (**4**) with a (2*R*,3*R*,6*S*)-configuration.

Stereochemistries of the synthetic (−)-deoxocassine (**4**) were further confirmed by ^{13}C and ^1H NMR and IR spectral measurements. The absolute configurations of (+)-spectaline (**1**) and (+)-iso-6-cassine (**2**) are (2*S*,3*S*,6*R*) and (2*R*,3*R*,6*R*), respectively and ^{13}C NMR shift values of C-2, C-3, C-6, and C-1′ are reported as shown in Table 2. The shift values observed in the synthetic (−)-deoxocassine (**4**) are nearly the same as those of the all-*cis*-substituted piperidine derivative, (+)-spectaline (**1**), indicating that two compounds possess the same relative configurations. Since the synthetic **4** possesses the (2*R*,3*R*) configuration, the stereochemistry of **4** was established to be (2*R*,3*R*,6*S*).

In ^1H NMR spectrum of the synthetic **4**, a methine proton at C-3 resonated at δ 3.56 as a multiplet signal, whose half-width was 4.8 Hz and a methine proton at C-2 was observed at δ 2.76 as double quartet

Table 1. Comparison of physical and spectral data of **4** with those of literature[5]

Table 2. ^{13}C NMR Spectra and $W_{1/2}$ and $J_{2,3}$ values of ^{1}H NMR spectra of **4**, **1**[1b], and **2**[1b]

	Synthetic-**4**	**1**	**2**
^{13}C NMR spectra (δ)			
C-3	68.02	67.6	68.9
C-2	57.27	57.0	50.4
C-6	55.85	55.7	49.5
C-1′	36.97	37.1	34.0
^{1}H NMR spectra (δ)			
$C_{(2)}$-H	2.76 (dq, $J_{2,3}$=1.4 Hz)	2.90 (br m, $J_{2,3}$=1.5 Hz)	3.06 (oct, $J_{2,3}$=3 Hz)
$C_{(3)}$-H	3.56 (m, $W_{1/2}$=4.8 Hz)	3.55 (br s, $W_{1/2}$=6 Hz)	3.66 (quint, J=6.5, 3.2, and 3 Hz)

signals with $J_{2,3}$=1.4 Hz, indicating that the $C_{(3)}$-H and $C_{(2)}$-H are in β-(equatorial) and β-(axial) orientations, respectively. These values are similar to those observed in (+)-spectaline (**1**), but apparently different from those of (+)-iso-6-cassine (**2**)[1b] (see Table 2).

In 2,6-dialkyl-3-piperidinols with all *cis*-configurations, two possible conformers (**A** and **B**) would exist in equilibrium and **A** is expected to be much more preferable, because of a formation of an intramolecular hydrogen bonding between the axial-OH and a lone pair of the nitrogen atom[17] and also a conformation with two alkyl side chain at C-2 and C-6 in equatorial orientations (Fig. 1). In a dilute solution of the synthetic **4** in carbon tetrachloride, the hydrogen-bonded OH absorption (E_b) was observed at 3523 cm^{-1} in the IR spectrum, while the free OH absorption (E_f) at 3629 cm^{-1} and their intensity ratio (E_b/E_f) was 14. These findings observed in ^{13}C and ^{1}H NMR and IR spectral measurements lead to the conclusion that the synthetic **4** is formulated as (2*R*,3*R*,6*S*)-6-dodecyl-2-methyl-3-piperidinol, identical with the natural (−)-deoxocassine.

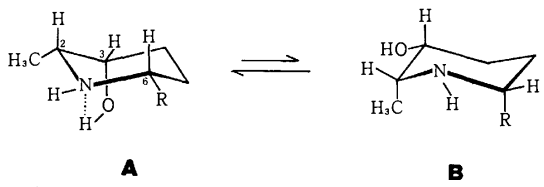

Fig. 1.

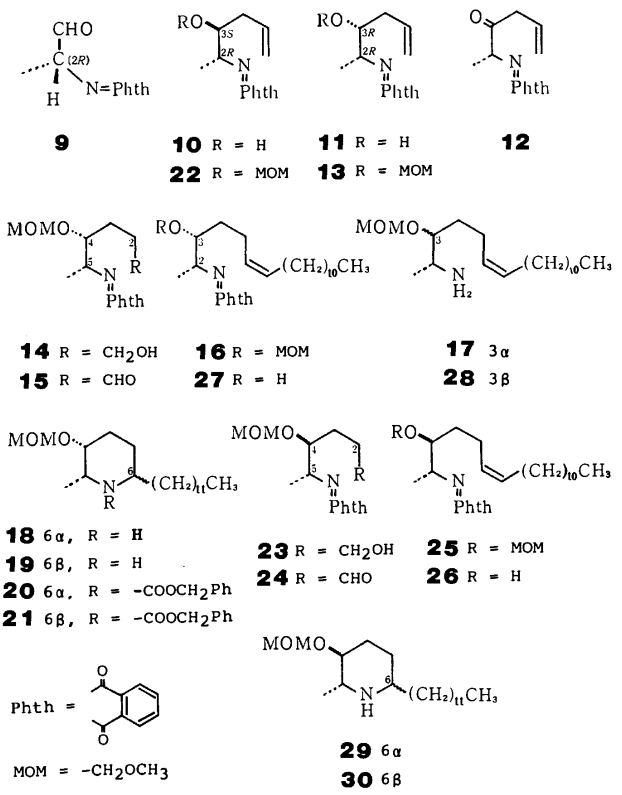
The *erythro*-alcohol (**10**) was treated with methoxymethyl chloride to afford a methoxymethyl derivative (**22**) in 98% yield, which was converted into (4*S*,5*R*)-4-methoxymethoxy-5-phthalimidohexanal (**24**) in 71% yield from **22** through **23**. The Wittig reaction gave (2*R*,3*S*)-3-methoxymethoxy-2-phthalimido-6-octadecene (**25**) in 62% yield, which was shown to contain a small amount of (*E*)-isomer; a very weak band at 964 cm^{-1} due to *trans*-olefin was observed together



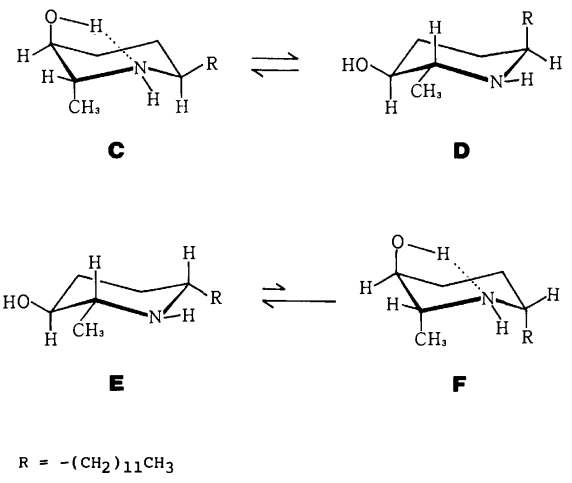


Fig. 2.

with an absorption at 765 cm^{-1} with medium intensity in the IR spectrum.

The olefin (**25**) was also prepared by the Grignard reaction. The *N*-phthaloyl aldehyde (**9**) was treated with a Grignard reagent prepared from (*Z*)-3-pentadecenyl bromide[3] and magnesium to give a diastereomeric mixture (3:1) of (2*R*,6*Z*)-2-phthalimido-6-octadecen-3-ols (**26** and **27**). Since the Grignard reagent reacted with also the phthaloyl group to yield a complex mixture, the isolation yield of the mixture of **26** and **27** was 23%. The configurations at C-3 were determined by the ^1H NMR spectral measurement. The major alcohol (**26**) showed double quartet signals ($J_{2,3}$=4 Hz) due to $C_{(2)}$-H at δ 4.35, while the minor alcohol (**27**) afforded a quintet signal (J=6.5 Hz) due to $C_{(2)}$-H at δ 4.43. These shift values and coupling constants are almost the same as those of the (3*S*)-alcohol (**10**) and (3*R*)-alcohol (**11**), respectively (*vide supra*). Methoxymethylation of the (2*R*,3*S*,6*Z*)-isomer (**26**) gave a methoxymethyl derivative in 54% yield, which was completely identical with **25**. Although this synthetic route containing the Grignard reaction consisted of only 2 steps, the overall yield was less than 10%. On the contrary, the route through the Wittig reaction comprised 5 steps and gave **25** in 12% overall yield. Both routes gave **25** in nearly the same yields, but the latter was much preferable to the former in respect of separation procedure of the reaction products.

On hydrazinolysis, the phthaloyl derivative (**25**) yielded (2*R*,3*S*,6*Z*)-3-methoxymethoxy-6-octadecen-2-amine (**28**) in 82% yield. The ε,ζ-unsaturated amine (**28**) was subjected to the aminomercuration and demercuration as before and separation by column chromatography on alumina gave two piperidine derivatives (**29** and **30**) in 17 and 43% yields, respectively. The piperidine derivatives (**29** and **30**) were heated under reflux in 4 M acetic acid overnight to give 6-dodecyl-2-methyl-3-piperidinols (**7**) and (**8**), respectively.

The stereochemistry of C-6 in **7** and **8** was determined by examining intensities of the IR absorption bands due to the intramolecular OH····N bonded (E_b) and free OH forms (E_f) in the dilute solution of **7** and **8** in carbon tetrachloride.[17] The piperidine derivative (**8**) obtained from the major product (**30**) exhibits free OH band at 3631 and 3626 cm^{-1} and hydrogen-bonded OH bands at 3531 cm^{-1} with approximately equal intensities (E_b/E_f=1), while the minor one (**7**) shows only free OH band at 3631 cm^{-1}. In 2α-methyl-3β-piperidinols with 6β-alkyl side chain, the conformation-determining effects of the *trans*-placed methyl and the alkyl side chain likely canceled out and two conformers (**C** and **D**) with the "OH-axial" and "OH-equatorial" conformations could exist in equilibrium. This is the case of **8**. On the other hand, the piperidine derivative (**7**) would exist exclucively in a triequatorial conformation (**E**) and, therefore, the IR spectrum of **7** measured in the dilute solution would exhibit no hydrogen-bonded OH band (Fig. 2). Thus the structures of two diastereomers **7** and **8** were determined to be (2*R*,3*S*,6*S*)- and (2*R*,3*S*,6*R*)-6-dodecyl-2-methyl-3-piperidinols, respectively.

Experimental

General Procedures. Melting points were measured on a Mel-temp capillary melting-point apparatus (Laboratory Devices) and uncorrected. IR spectra were measured

with a Hitachi 260-30, a Hitachi EPI-G2, a JEOL JIR-103 (FT), or a JEOL JIR-100 (FT) spectrometer. ^{1}H NMR spectra were taken with a Hitachi R-20B (60 MHz), a Hitachi R-24B (60 MHz), a Varian EM-390 (90 MHz), a JEOL FX-90Q (90 MHz), a JEOL JNM-PS100 (100 MHz), or a JEOL GX-270 (270 MHz) spectrometer and ^{13}C NMR spectra with a JEOL FX-90Q (22.5 MHz) or a JEOL GX-270 (67.8 MHz) spectrometer in $CDCl_3$ solution containing TMS as an internal standard. High and low resolution mass spectra were taken on a JEOL JMS-D300 mass spectrometer at 70 eV. Measurements of optical rotations were carried out with a JASCO DIP-181 polarimeter. Thin-layer chromatography (TLC) was carried out on Kieselgel GF_{254} (E. Merck) and Alumina B-10F (Wako) in 0.25mm-thickness for analytical use and 0.5 mm-thickness for preparative use. Wakogel C-200 (Wako), Aluminium Oxide W-200 neutral (ICN Pharmaceuticals), and Florisil 100-200 mesh (Wako) were used for column chromatography.

(2R)-2-Phthalimidopropanal (9). *N*-Phthaloyl-D-alanine (mp 144.5—145.0 °C, $[\alpha]_D^{22}$ +22.4°; 15 g) was dissolved in benzene (40 ml) and thionyl chloride (15 ml) was added. The mixture was refluxed for 1 h and then an excess of thionyl chloride was removed *in vacuo* completely, and the residue was allowed to stand overnight under reduced pressure.

A mixture of the acid chloride and 10% palladium on carbon (4 g) in benzene (150 ml) was refluxed with stirring, while hydrogen was bubbled continuously. The reaction was monitored by titration of evolved hydrogen chloride with alkali. After the usual work-up, crystallization from benzene gave (2*R*)-2-phthalimidopropanal (**9**; 10.4 g) as white crystals, mp 109.0—110.5 °C; $[\alpha]_D^{22}$ −32.5° (*c* 1.04, EtOH); ^{1}H NMR δ=1.62 (3H, d, *J*=7 Hz, C*H*$_3$-CH-(N=phth)-), 4.75 (1H, q, *J*=7 Hz; CH_3-C*H*(N=phth)-), 7.83 (4H, m; aromatic H's), and 9.68 (1H, s; -CHO); IR (KBr) 1768, 1730, 1710, 1385, 1032, 872, and 721 cm^{-1}; MS (EI) *m/z* (%) 174 (100); CI-MS (methane) *m/z* (%) 204 ([M+1]$^+$; 100) and 174 (14); Found: C, 64.90; H, 4.33; N, 6.99%. Calcd for $C_{11}H_9NO_3$: C, 65.02; H, 4.46; N, 6.89%.

(2R,3S)- and (2R,3R)-2-Phthalimido-5-hexen-3-ols (10 and 11). Allyl bromide (12.1 g) was added dropwise to THF (35 ml) containing zinc turnings (6.54 g) at room temperature under a nitrogen atmosphere, and then the mixture was heated at 50 °C for 1 h. After cooling, a small amount of unchanged zinc (0.84 g) was filtered off to give a yellow solution (50 ml; 1.74 mmol/ml) of diallylzinc, concentration of which was estimated from the amount of consumed zinc.

The solution (47 ml; 81.8 mmol) of diallylzinc was added dropwise to a solution of the aldehyde (**9**; 11 g, 54.5 mmol) in THF (120 ml) at −40 °C under a nitrogen atmosphere. After stirring for 1 h at −30 to −10 °C, THF-water (1:1, 30 ml) and 1 M hydrochloric acid (20 ml) were added, and the reaction product was extracted with ether (400 ml). The extract was washed with a saturated sodium hydrogencarbonate solution (30 ml) and a saturated sodium chloride solution (40 ml), dried over magnesium sulfate, and evaporated under reduced pressure to give a residue. The residue was chromatographed on a column of silica gel (250 g) using hexane–ethyl acetate (7:1) as eluent to give alcohol (**10**; 6.8 g) and alcohol (**11**; 1.34 g). **10**: mp 84.0—84.5 °C (from hexane-ethyl acetate); $[\alpha]_D^{28}$ −7.7° (*c* 0.31, EtOH); ^{1}H NMR δ=1.48 (3H, d, *J*=7 Hz; C*H*$_3$-CH-(N=phth)-), 2.29 (2H, t-like, *J*=6 Hz; -C*H*$_2$-CH=CH$_2$), 3.50 (1H, d, *J*=3 Hz; -OH), 4.07 (1H, m; -C*H*(OH)-), 4.37 (1H, dq, *J*=4 and 7 Hz; CH_3-C*H*(N=phth)-), 5.13 (2H, m, -CH=C*H*$_2$), 5.89 (1H, ddt, *J*=18, 9, and 6 Hz; -C*H*=CH$_2$), and 7.78 (4H, m; aromatic H's); IR (KBr) 3450, 1705, 1390, 1020, and 722 cm^{-1}; MS (EI) *m/z* (%) 227 (2), 204 (29), and 174 (56); CI-MS (methane) *m/z* (%) 246 ([M+1]$^+$; 100), 228 (91), 204 (30), and 174 (34); Found: C, 68.70; H, 6.23; N, 5.65%. Calcd for $C_{14}H_{15}NO_3$: C, 68.55; H, 6.16; N, 5.71%. **11**: mp 107.5—108.5 °C (from hexane-ethyl acetate); $[\alpha]_D^{30}$ −35.1° (*c* 0.30, EtOH); ^{1}H NMR δ=1.49 (3H, d, *J*=7 Hz; C*H*$_3$-CH(N=phth)-), 2.23 (2H, t-like, *J*=7 Hz; -C*H*$_2$-CH=CH$_2$), 3.17 (1H, d, *J*=8.5 Hz; -OH), 4.02 (1H, q, *J*=7 Hz; -C*H*(OH)-), 4.42 (1H, quint, *J*=7 Hz; CH_3-C*H*(N=phth)-), 5.05 (1H, d, *J*=18 Hz; $^{H}\!>\!C\!=\!C\!<^{H}_{H}$), 5.07 (1H, d, *J*=9 Hz, $^{H}\!>\!C\!=\!C\!<^{H}_{H}$), 5.90 (1H, ddt, *J*=18, 9, and 7 Hz; -C*H*=CH$_2$), and 7.80 (4H, m; aromatic H's); IR (KBr) 3510, 3260, 2940, 2920, 1690, 1640, 1560, 1395, 1392, 1168, 1022, and 722 cm^{-1}; MS (EI) *m/z* (%) 227 (9), 204 (82), and 174 (75); CI-MS (methane) *m/z* (%) 246 ([M+1]$^+$; 100), 228 (59), 204 (25), and 174 (16): Found: C, 68.82; H, 6.13; N, 5.97%. Calcd for $C_{14}H_{15}NO_3$: C, 68.55; H, 6.16 N, 5.71%.

(2R)-2-Phthalimido-5-hexen-3-one (12). A solution of (2*R*,3*S*)-2-phthalimido-5-hexen-3-ol (**10**; 10.1 g) in dichloromethane (60 ml) was added to a suspension of pyridinium chlorochromate (26.3 g) in dichloromethane (120 ml) and the mixture was stirred for 17 h at room temperature. The reaction mixture was decanted to afford a supernatant liquid and a black residue. The supernatant liquid was passed through a column of Florisil (45 g). The black residue was dissolved in a saturated sodium hydrogencarbonate solution and extracted with ether. The ethereal extract was washed with brine, dried over magnesium sulfate, and combined with the eluate from the Florisil column. The combined solution was evaporated and purified by column chromatography on silica gel (180 g). Elution with a mixture of hexane-acetone (4:1) afforded (2*R*)-2-phthalimido-5-hexen-3-one (**12**; 8.8 g) in 88% yield, mp 56.0—57.0 °C; $[\alpha]_D^{18}$ +23.0° (*c* 2.6 EtOH); ^{1}H NMR δ=1.67 (3H, d, *J*=7 Hz; C*H*$_3$-CH(N=phth)-), 3.27 (2H, d, *J*=7 Hz; -C*H*$_2$-CH=CH$_2$), 4.85 (1H, q, *J*=7 Hz; CH_3-C*H*(N=phth)-), 5.07 (1H, d, *J*=18 Hz; $^{H}\!>\!C\!=\!C\!<^{H}_{H}$), 5.11 (1H, d, *J*=9 Hz; $^{H}\!>\!C\!=\!C\!<^{H}_{H}$), 5.90 (1H, ddt, *J*=18, 9, and 7 Hz: -C*H*=CH$_2$), and 7.80 (4H, m; aromatic H's); IR (KBr) 1780, 1720, 1395, 1020, and 720 cm^{-1}; MS (EI) *m/z* (%) 243 (M$^+$; 3), 202 (42), and 174 (100); Found: C, 69.02; H, 5.12; N, 5.84%; MW 243.0881. Calcd for $C_{14}H_{13}NO_3$: C, 69.12; H, 5.39; N, 5.76%; M, 243.0894.

Reduction of Ketone (12) with Zinc Borohydride. Anhydrous zinc chloride (4.0 g) was added in ether (50 ml) and the mixture was refluxed for 1 h in a nitrogen atmosphere to yield an ethereal solution of zinc chloride, which was added dropwise to a suspension of sodium borohydride (2.7 g) in ether (150 ml). The mixture was stirred for 2 d at room temperature and decanted to afford a zinc borohydride solution (200 ml).

To an ice-cooled solution of (2*R*)-2-phthalimido-5-

hexen-3-one (**12**; 9.05 g) in ether (400 ml) the zinc borohydride solution (64 ml) above prepared was added in a nitrogen atmosphere and stirring was continued for 5 h at 0 °C. After addition of a solution (200 ml) of ammonium chloride, the organic layer was separated and evaporated to give a residue, which was chromatographed on silica gel. Elution with a mixture of hexane–ethyl acetate (5:1) afforded alcohol (**10**; 2.26 g) and alcohol (**11**; 4.87 g) in 25 and 53% yields, respectively. **10**: Mp 80.5—81.5 °C; $[\alpha]_D^{21}$ −10.4° (*c* 0.70, EtOH). **11**: Mp 107.5—108.5 °C; $[\alpha]_D^{22}$ −36.0° (*c* 3.0, EtOH).

*(2*R*,3*R*)-*N*,*N*-Phthaloyl-3-methoxymethoxy-5-hexen-2-amine (13).* Methoxymethyl chloride (12.7 g) was added to a mixture of alcohol (**11**; 4.86 g) and triethylamine (16.2 g) in acetonitrile (40 ml). The mixture was refluxed for 2.5 h in a flask equipped with a calcium chloride tube. After cooling to room temperature, water (30 ml) and a saturated solution (50 ml) of sodium hydrogencarbonate were added and the reaction product was extracted with ether. Evaporation and separation by column chromatography on silica gel (150 g) eluted with hexane–ethyl acetate (6:1) afforded (2*R*,3*R*)-*N*,*N*-phthaloyl-3-methoxymethoxy-5-hexen-2-amine (**13**; 5.71 g) quantitatively as a colorless oil, $[\alpha]_D^{23}$ −119° (*c* 0.36, $CHCl_3$); ^{1}H NMR δ=1.49 (3H, d, *J*=7 Hz; CH_3–CH(N=phth)–), 2.51 (2H, m; –CH_2–CH=CH_2), 3.00 (3H, s; CH_3O–), 4.28 (2H, m; –CH(N=phth)–CH(OMOM)–), 4.50 (2H, s; –OCH_2O–), *ca.* 5.16 (2H, m, –CH=CH_2), 6.00 (1H, ddt, *J*=17, 9, and 7 Hz; –CH=CH_2), and 7.80 (4H, m; aromatic H's); IR (neat) 2940, 1770, 1710, 1385, 1145, 1090, 1038, 920, 881, and 722 cm^{-1}; MS *m/z* (%) 248 (15) and 174 (100); CI-MS (methane) *m/z* (%) 290 ($[M+1]^+$; 13), 259 (18), 258 (100), 228 (13), and 174 (5); Found: C, 66.21; H, 6.81; N, 4.73%. Calcd for $C_{16}H_{19}NO_4$: C, 66.42; H, 6.62; N, 4.84%.

*(4*R*,5*R*)-4-Methoxymethoxy-5-phthalimido-1-hexanol (14).* A diborane solution (6 ml, *ca.* 12 mmol) in THF was added to a solution of the MOM-olefin (**13**; 922 mg) in THF (15 ml) in a nitrogen atmosphere at 0 °C and the reaction mixture was stirred at room temperature for 2 h. After an excess of diborane was destroyed by addition of water (1 ml), 2 M sodium hydroxide solution (4.5 ml) and 30% hydrogen peroxide (7 ml) were added at 0 °C, and the mixture was stirred at 50 °C for 1.5 h followed by extraction with ether (40 ml). The usual work-up afforded an oily residue, which was subjected to separation by column chromatography on silica gel (15 g). Elution with hexane-ethyl acetate (1:1) gave (4*R*,5*R*)-4-methoxymethoxy-5-phthalimido-1-hexanol (**14**; 815 mg) as an oil in 83% yield, $[\alpha]_D^{22}$ −58.9° (*c* 0.48, $CHCl_3$) ^{1}H NMR δ=1.49 (3H, d, *J*=6.5 Hz; CH_3–CH(N=phth)–), 1.77 (2H, m; –CH_2–CH_2OH), 2.65 (1H, m; –OH), 3.00 (3H, s; CH_3O–), 3.71 (2H, m; –CH_2–OH), 4.32 (2H, m; –CH(N=phth)–CH(OMOM)–), 4.53 (2H, s; –OCH_2O–), and 7.80 (4H, m; aromatic H's).

*(4*R*,5*R*)-4-Methoxymethoxy-5-phthalimidohexanal (15).* The MOM-alcohol (**14**; 603 mg) in dichloromethane (4 ml) was added to a suspension of pyridinium chlorochromate (1.5 g) in dichloromethane (7 ml) at room temperature. After stirring for 2.5 h, the reaction mixture was decanted to afford a supernatant liquid and a dark-brown residue. The supernatant liquid was diluted with ether, passed through a column of Florisil (6 g), and eluted with ether. The dark-brown residue was dissolved in a sodium hydrogencarbonate solution and extracted with ether. The ethereal extract was combined with the eluate from the Florisil column and chromatographed on a short column of silica gel. Elution with hexane–ethyl acetate gave MOM–aldehyde (**15**; 508 mg) in 85% yield, ^{1}H NMR δ=1.48 (3H, d, *J*=6.5 Hz CH_3–CH(N=phth)–), 1.90 (2H, m; –CH_2–CH_2–CHO), 2.64 (2H, td, *J*=9 and 1.5 Hz; –CH_2–CHO), 3.00 (3H, s; CH_3O–), 4.26 (2H, m; –CH(N=phth)–CH(OMOM)–), 4.46 (2H, s; –OCH_2O–), 7.89 (4H, m; aromatic H's), and 9.86 (1H, t, *J*=1.5 Hz; –CHO); IR (neat) 2935, 1770, 1710, 1381, 1140, 1030, 920, 881, and 721 cm^{-1}; MS (EI) *m/z* (%) 244 (5) and 174 (100); CI-MS (methane) *m/z* (%) 306 ($[M+1]^+$; 3), 275 (4), 274 (22), 260 (2), 245 (16), 244 (100), and 174 (4).

*(2*R*,3*R*,6*Z*)-3-Methoxymethoxy-2-phthalimido-6-octadecene (16).* Butyllithium (6.5 ml; 11.3 mmol) in hexane was added dropwise to a solution of dodecyltriphenylphosphonium bromide (7.5 g; 14.6 mmol) in dry THF at 0 °C under a nitrogen atmosphere. The red solution was stirred for 20 min at room temperature and 40 min at 40 °C, and then cooled to −78 °C. To the solution was added a solution of the MOM-aldehyde (**15**; 3.45 g) in THF (60 ml), and the mixture was stirred for 20 min at −78 °C and 20 min at 0 °C, and then allowed to stand overnight at room temperature. Ether (200 ml) and water (150 ml) were added and the ethereal layer was separated. The aqueous layer was extracted with ether and the extract was combined with the ethereal layer. The usual work-up gave an oily mixture, which was subjected to separation by column chromatography on silica gel (70 g). Elution was performed with hexane-ethyl acetate (6:1) to afford (2*R*,3*R*,6*Z*)-3-methoxymethoxy-2-phthalimido-6-octadecene (**16**; 3.12 g) as an oil, $[\alpha]_D^{21}$ −49.2° (*c* 0.62, $CHCl_3$); ^{1}H NMR δ=0.87 (3H, t-like, *J*=6 Hz; terminal CH_3), 1.27 (20H, br s; methylenes), 1.48 (3H, d, *J*=6.5 Hz; CH_3–CH(N=phth)–), 2.05 (4H, m –CH_2–CH=CH–CH_2–), 2.97 (3H, s; CH_3O–), 4.30 (2H, m; –CH(N=phth)–CH(OMOM)–), 4.51 (2H, s; –OCH_2O–), 5.39 (2H, t, *J*=5 Hz; –CH=CH–), and 7.77 (4H, m; aromatic H's); IR (neat) 2925, 1773, 1712, 1382, 1148, 1038, 922, 884, and 721 cm^{-1}; MS (EI) *m/z* (%) 457 (M^+; 0.1), 426 (1), 425 (3), and 174 (100); CI-MS (methane) *m/z* (%) 458 ($[M+1]^+$; 13), 427 (30), 426 (100), 397 (2), 396 (6), and 174 (4); Found: C, 73.53; H, 9.33; N, 3.03%. Calcd for $C_{28}H_{43}NO_4$: C, 73.48; H, 9.47; N, 3.06%.

*(2*R*,3*R*,6*Z*)-3-Methoxymethoxy-6-octadecen-2-amine (17).* 100% Hydrazine hydrate (0.2 ml) was added to a solution of phthalimido-olefin (**16**; 425 mg) in ethanol (4 ml) at room temperature and the mixture was stirred for 1 h. To the reaction mixture, ether (200 ml) and 2 M sodium hydroxide (10 ml) were added and the ethereal layer was separated. The aqueous layer was extracted with ether repeatedly and the extracts were combined with the ethereal layer. The usual work-up afforded crude ε,ζ-unsaturated amine (**17**; 512 mg) as a pale yellow oil, which was used for next synthetic step without any purification. **17** (crude): ^{1}H NMR δ=0.87 (3H, t-like, *J*=6 Hz; terminal CH_3); 1.07 (3H, d, *J*=7 Hz $C_{(2)}$–CH_3), 1.31 (22H, br s; methylenes), 1.4—2.2 (4H, m; –CH_2–CH=CH–CH_2–), 2.47 (2H, m; –NH_2), 3.37 (3H, s; CH_3O–), 4.65 (2H, s; –OCH_2O–), and 5.33 (2H, t-like, *J*=6 Hz; –CH=CH–); MS (EI) *m/z* (%) 327 (M^+; 3), 296 (4), 282 (6), 266 (3), and 44 (100); Found: *m/z* 327.3119. Calcd for $C_{20}H_{41}NO_2$: M, 327.3139.

*Crude (2*R*,3*R*,6*S*)-3-O-Methoxymethyldeoxocassine (18).*

Mercury(II) acetate (618 mg) was added to a solution of the ε,ζ-unsaturated amine (**17**; 512 mg) in methanol (4 ml) at room temperature, and the mixture was stirred for 2 d. To the reaction mixture, was added a solution of sodium borohydride (60 mg) in 2 M sodium hydroxide solution (6 ml). The reaction mixture was filtered and the filtrate was extracted with ether. The ethereal layer was worked up as usual to give crude (2*R*,3*R*,6*S*)-3-*O*-methoxymethyldeoxocassine (**18**; 249 mg) as a yellow oil.

*(2*R*,3*R*,6*S*)-N-Benzyloxycarbonyl-3-O-methoxymethyldeoxocassine (20).* Benzyloxycarbonyl chloride (180 mg) was added to an ice-cooled solution of the crude MOM-deoxocassine (**18**; 106 mg) and potassium carbonate (113 mg) in acetone (4 ml). The reaction mixture was stirred at 0 °C for 1.5 h and then for 1 d at room temperature, and filtered. The precipitates were washed with ether and the washings and the filtrate were combined. The usual work-up yielded an oily residue, which was subjected to separation by column chromatography on silica gel (7 g) eluted with hexane–ether (4:1) to afford a benzyloxycarbonyl derivative (**20**; 27.5 mg) as an oil, $[\alpha]_D^{17}$ −2.0° (*c* 1.8, EtOH); ^{1}H NMR δ=0.87 (3H, t-like, *J*=6 Hz; terminal CH_3), 1.28 (25H, br s; $C_{(2)}$–CH_3 and methylenes), 1.4—2.3 (4H, m; $-CH_2-CH_2-$), 3.38 (3H, s; CH_3O–), 3.4—5.3 (3H, m; $C_{(2)}$–H, $C_{(3)}$–H, and $C_{(6)}$–H), 4.63 (2H, s; $-OCH_2O-$), 5.12 (2H, s; $-CH_2-C_6H_5$), and 7.33 (5H, m; aromatic H's); IR (neat) 2925, 2850, 1700, 1300, and 1150 cm^{-1}; MS (EI) *m/z* 461 (M^+; 1), 429 (1), 292 (42), and 91 (100); Found: *m/z* 461.3544. Calcd for $C_{28}H_{47}NO_4$: M, 461.3504.

*Pure (2*R*,3*R*,6*S*)-3-O-Methoxymethyldeoxocassine (18).* The benzyloxycarbonyl derivative (**20**; 59 mg) in ethanol (5 ml) was subjected to hydrogenolysis in the presence of 5% palladium on carbon (146 mg) for 1 d. The usual work-up and separation by column chromatography on alumina (2 g) eluted with hexane–ether (1:1) affoded pure (2*R*,3*R*,6*S*)-3-*O*-methoxymethyldeoxocassine (**18**; 15 mg) as an oil, $[\alpha]_D^{16}$ −20° (*c* 0.57, $CHCl_3$); ^{1}H NMR δ=0.87 (3H, t-like, *J*=6 Hz; terminal CH_3), 1.14 (3H, d, *J*=7 Hz; $C_{(2)}$–CH_3), 1.27 (22H, br s; methylenes), 1.4—1.8 (4H, m; $-CH_2-CH_2-$), 1.8—3.7 (3H, m; $C_{(2)}$–H, $C_{(3)}$–H, and $C_{(6)}$–H), 3.37 (3H, s; CH_3O–), and 4.65 (2H, *AB*q, *J*=7 Hz; $-OCH_2O-$); MS (EI) *m/z* (%) 327 (M^+; 3), 312 (2), 296 (4), 282 (10), 266 (6), and 158 (100); Found: *m/z* 327.3098. Calcd for $C_{20}H_{41}NO_2$: M, 327.3145.

(−)-Deoxocassine (4). A solution of the methoxymethyl derivative (**20**; 13 mg) in 1 M hydrochloric acid–methanol was heated under reflux for 2 h. After cooling, 2 M sodium hydroxide solution (1.5 ml) was added and the reaction product was extracted with ether and worked up as usual to give a residue, which was subjected to column chromatographic separation on alumina (1 g). Elution with ether–methanol (9:1) gave (−)-deoxocassine (**4**; 5 mg) as white crystals, mp 47.5—48.5 °C (from methanol); $[\alpha]_D^{18}$ −12.3° (*c* 0.19; $CHCl_3$); ^{1}H NMR δ=0.88 (3H, t-like, *J*=6.0 Hz; terminal CH_3), 1.11 (3H, d, *J*=6.4 Hz $C_{(2)}$-CH_3), 1.26 (22H, br s; methylenes), 1.3—1.4 (2H, m; $C_{(5)}$–H_2), 1.4—1.5 (2H, m; $C_{(4)}$–H_2), 1.8—2.0 (1H, m; –NH), 2.4—2.7 (2H, m; $C_{(6)}$–H and –OH), 2.76 (1H, qd, *J*=6.5 and 1.4 Hz; $C_{(2)}$–H), and 3.56 (1H, m, $W_{1/2}$ 4.8 Hz; $C_{(3)}$–H); ^{13}C NMR δ=14.12, 18.66, 22.69, 25.83, 26.10, 29.35, 29.61, 29.66, 29.80, 31.92, 32.05, 36.97, 55.85, 57.27, and 68.02; MS (EI) *m/z* (%) 283 (M^+; 0.4), 282 (0.2), 268 (0.3), 114 (100), and 96 (5); Found: *m/z* 283.2875. Calcd for $C_{18}H_{37}NO$: M, 283.2875.

*(2*R*,3*S*,6*S*)- and (2*R*,3*S*,6*R*)-Deoxocassines (7 and 8).* (3*S*)-Diastereomers (**7** and **8**) of (−)-deoxocassine (**4**) were prepared from (2*R*,3*S*)-2-phthalimido-5-hexen-3-ol (**10**) according to the same procedures as described for preparation of **4**. (2*R*,3*S*)-*N*,*N*-phthaloyl-3-methoxymethoxy-5-hexen-2-amine (**22**): An oil, $[\alpha]_D^{19}$ +30.2° (*c* 0.26, $CHCl_3$); ^{1}H NMR δ=1.54 (3H, d, *J*=6.5 Hz; CH_3–CH(N=phth)–), 2.33 (2H, m; $-CH_2-CH=CH_2$), 3.40 (3H, s; CH_3O–), 4.40 (2H, m; $-CH$(N=phth)–CH(OMOM)–), 4.73 (2H, s; $-OCH_2O-$), 5.04 (2H, m; CH_2=CH–), 5.86 (1H, ddt, *J*=17, 9, and 7 Hz; $-CH=CH_2$), and 7.79 (4H, m; aromatic H's); IR (neat) 2925, 1772, 1710, 1385, 1142, 1095, 1035, 915, 876, and 715 cm^{-1}: MS (EI) *m/z* (%) 248 (52), 228 (20), and 174 (100); CI-MS (methane) *m/z* (%) 290 ($[M+1]^+$; 6), 259 (16), 258 (100), 228 (18), and 174 (13); Found: C, 66.49; H, 6.76; N, 5.06%. (2*R*,3*S*,6*R*)-Deoxocassine (**8**): (2*R*,3*S*,6*R*)-3-*O*-Methoxymethyldeoxocassine (**30**; 34.7 mg) was deprotected as before to afford **8** (16.6 mg) as an amorphous solid, $[\alpha]_D^{24}$ −3.1° (*c* 0.15, $CHCl_3$); ^1H NMR δ=0.85 (3H, t-like, *J*=6 Hz; terminal CH_3), 1.13 (3H, d, *J*=7 Hz; $C_{(2)}$-CH_3), 1.25 (22H, br s; methylenes), 1.40—2.20 (6H, m; -CH_2-CH_2-, -$\dot{N}H$, and -OH), 2.87 (2H, m), and 3.35 (1H, m); MS (EI) *m/z* (%) 283 (M^+; 1), 282 (2), 268 (4), 265 (4), 250 (10), 114 (100), and 96 (39); Found: *m/z* 283.2873. Calcd for $C_{18}H_{37}NO$: M, 283.2877.

(2R,3S,6Z)-3-Methoxymethoxy-2-phthalimido-6-octadecene (25) (by Grignard reaction). A Grignard reagent[3] (0.68 mmol), prepared from (*Z*)-3-pentadecenyl bromide and magnesium, was added to a solution of *N*-phthaloyl aldehyde (**9**; 100 mg) in THF (1.5 ml) at −45 °C under a nitrogen atmosphere, and the reaction mixture was stirred at −30 °C for 6 h. The usual treatment gave a crude oil (320 mg), which was chromatographed on silica gel (6 g). Fractions containing diastereomeric alcohols (**26** and **27**), eluted with benzene–ether (19:1), were combined and further purified by preparative TLC (silica gel in 1 mm thickness, developed with benzene–ether (7:2) twice) to give a mixture (48 mg) of **26** and **27**. The separation of **26** and **27** was achieved by preparative TLC (silica gel in 0.3 mm thickness, developed with hexane–ethyl acetate (3:1) three times) to afford (2*R*,3*S*,6*Z*)- and (2*R*,3*R*,6*Z*)-2-phthalimido-6-octadecen-3-ols (**26** and **27**; in a ratio of *ca.* 3:1). **26**: mp 34.0—34.5 °C; $[\alpha]_D^{30}$ +9° (*c* 0.23, $CHCl_3$); ^1H NMR δ=0.87 (3H, t-like; terminal CH_3), 1.27 (18H, br s; methylenes), 1.43 (3H, d, *J*=7 Hz; CH_3-CH(N=phth)-), 1.50 (2H, m; -O-$\dot{C}H$-CH_2-), 2.10 (4H, m; -CH_2-CH=CH-CH_2-), 3.70 (1H, d, *J*=3 Hz; -OH), 4.00 (1H, m; -$\dot{C}H$-OH), 4.35 (1H, qd, *J*=7 and 4 Hz CH_3-CH(N=phth)-), 5.37 (2H, m; -CH=CH-), and 7.80 (4H, m; aromatic H's); IR (neat) 3400, 3300, 2920, 1775, 1710, 1390, 1020, 880, and 720 cm^{-1}; Found: C, 75.40; H, 9.80; N, 3.21%. Calcd for $C_{26}H_{39}NO_3$: C, 75.50; H, 9.51; N, 3.39%. **27**: mp 34.5—35.0 °C; $[\alpha]_D^{19}$ −9° (*c* 0.23, $CHCl_3$); ^1H NMR δ=0.89 (3H, t-like; terminal CH_3), 1.27 (18H, br s; methylenes), 1.40 (2H, m; -O-$\dot{C}H$-CH_2-), 1.46 (3H, d, *J*=6.5 Hz; CH_3-CH(N=phth)-), 2.10 (4H, m; -CH_2-CH=CH-CH_2-), 3.24 (1H, d, *J*=9 Hz; -OH), 3.92 (1H, m; -$\dot{C}H$-OH), 4.43 (1H, quint, *J*=6.5 Hz; CH_3-CH(N=phth)-), 6.37 (2H, m; -CH=CH-), and 7.80 (4H, m; aromatic H's); IR (neat) 3450, 2920, 1775, 1710, 1040, 880, and 720 cm^{-1}. Found: C, 76.64; H, 10.08; N, 3.19%. Calcd for $C_{26}H_{39}NO_3$: C, 75.50; H, 9.51; N, 3.39%.

The (2*R*,3*S*)-alcohol (**26**; 10 mg) was methoxymethylated with methoxymethyl chloride (82 mg) in acetonitrile (1 ml) containing triethylamine (91 mg) by the same procedure as before. A methoxymethyl derivative (**25**; 6 mg) was obtained as an oil, whose spectral data were completely identical with those of the specimen (**25**) obtained by the Wittig reaction.

The authors wish to express their thanks to Professor Takaharu Ohnishi, Tokyo Institute of Technology, for FT-IR measurement, Dr. Hajime Nagano, Ochanomizu University, for NMR measurement at 270 MHz, and Miss Toshiko Seki and Mrs. Kimiyo Saeki, The University of Tokyo, for micro analyses.

Reactivities of Stable Rotamers. XVI. Tributylstannane Reduction and Electron-impact Mass Spectra of Rotamers of 1,2,3,4-Tetrachloro-9-(2-chloro-1,1-dimethylethyl)triptycene and 1,2,3,4-Tetrachloro-9-(2-chloro-1-chloromethyl-1-methylethyl)triptycene[1)]

Katsumi YONEMOTO, Fumihiko KAKIZAKI, Gaku YAMAMOTO, Nobuo NAKAMURA, and Michinori ŌKI*

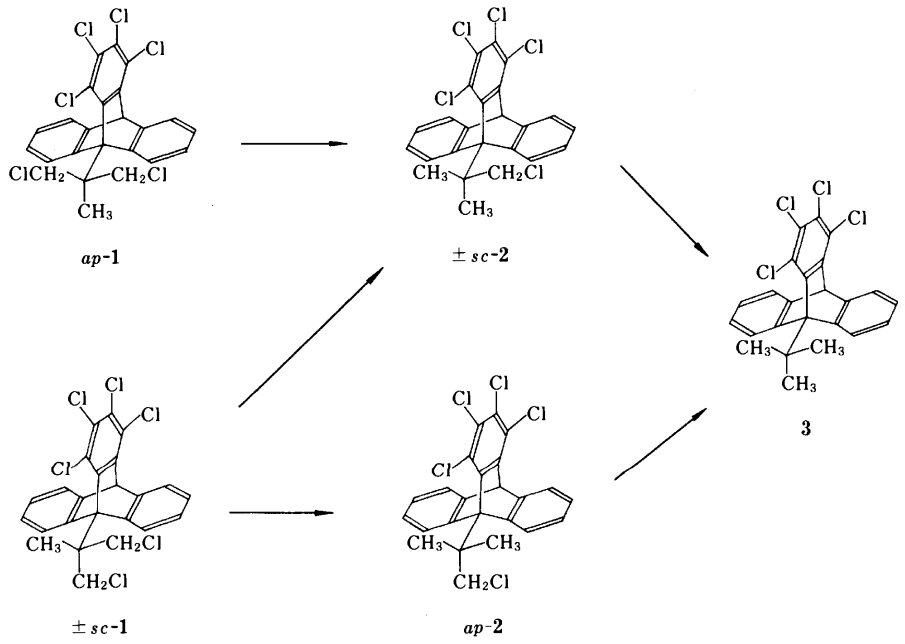
Department of Chemistry, Faculty of Science, The University of Tokyo, Bunkyo-ku, Tokyo 113

(Received July 26, 1985)

1,2,3,4-Tetrachloro-9-(2-chloro-1-chloromethyl-1-methylethyl)triptycene (**1**) and 1,2,3,4-tetrachloro-9-(2-chloro-1,1-dimethylethyl)triptycene (**2**) were reduced with tributylstannane in the presence of azobisisobutyronitrile in benzene. **1** was reduced to **2** which was further converted to a 9-*t*-butyltriptycene under the conditions. The chloromethyl group *sc* to the *peri*-chloro substituent was found to be *ca.* 7 times more reactive than the *ap* in *sc*-**1**. *sc*-**2** was consumed 1.7 times more rapidly than *ap*-**2**. The results are attributed to the participation of the *peri*-chloro substituent in the chlorine abstraction. Electron impact mass spectra of these compounds reveal that they give different intensities at a number of peaks. The difference is again attributed to the chloro participation in stabilizing the cation formed.

In one of the previous papers of this series, we pointed out that a radical reaction, chlorination of the methyl groups of the *t*-butyl group in 9-*t*-butyl-1,2,3,4-tetrachlorotriptycene (**3**), can be accelerated by the participation of the 1-chloro substituent.[2)] Since there are varieties of radical reactions known, the transition states of which should vary from the product-like to substrate-like, the degree of enhancement by the participation of the chloro substituent must be different from reaction to reaction. Alternatively, the degree of the chloro participation could tell the earliness or the lateness of the transition state of a reaction, if a common radical intermediate is to be formed by a variety of reactions.

The rotational barriers in 1,2,3,4-tetrachloro-9-(2-chloro-1-chloromethyl-1-methylethyl)triptycene (**1**) and 1,2,3,4-tetrachloro-9-(2-chloro-1,1-dimethylethyl)-triptycene (**2**) are known to be high enough so that any mixing of rotational isomers can be neglected during the course of reactions.[2)] The barrier to rotation of the radicals produced in the reaction may be assumed to be high as well from the results in the radical halogenations.[2)] To support this assumption, we may cite a fact that 9-*t*-alkyltriptycenes which possess the 9-substituent of a *t*-butyl type, one of the methyls of which is replaced by an sp^2 group, show high barriers as well.[3)] Therefore, any contamination by the contribution of other rotamer(s) during the



Scheme 1.

reaction may be neglected in this system, if the reaction is run in the vicinity of 100 °C for a week or so.

At an outset of investigations of other radical reactions, we chose reduction of rotamers of **1** and **2** with tributylstannane. The tributylstannane reduction of organic halides, which can be initiated by azobisisobutyronitrile, is known to proceed with radical intermediates: the rate-determining step is the abstraction of a halogen from the organic halides by tributylstannyl radicals.[4]

Compound **1** was prepared according to the method described before and separated into rotational isomers, *ap*-**1** and ±*sc*-**1**, by chromatography.[2] Although separation of *ap*-**2** and ±*sc*-**2** from the mixture of the two was reported to be tedious, as is shown in Scheme 1, if the tributylstannane reduction is successful for *ap*-**1**, it should give mixtures of ±*sc*-**2** and 9-*t*-butyl-1,2,3,4-tetrachlorotriptycene (**3**) in addition to the unreacted starting material, if any, of which separation by chromatography is not too difficult. Indeed, by this method, we could obtain sufficient quantity of ±*sc*-**2** for chracterization and some reactions.

The reaction of the halogen compounds with tributylstannane was generally carried out in benzene solutions, unless otherwise stated. The competitive reactions and determination of the relative rates of reactions were carried out as follows. Nearly equimolar mixtures of *ap*-**2** and ±*sc*-**2** or *ap*-**1** and ±sc-**1** were dissolved in benzene together with a reference compound, either 4-methoxytoluene or 1-methoxy-3,5-dimethylbenzene. Azobisisobutyronitrile was added to the mixture and then tributylstannane (equimolar with the mixture of the substrate) under a nitrogen atmosphere, and the mixture was heated at three temperatures. The decrease in the substrate was monitored by ^{1}H NMR spectroscopy and/or high pressure liquid chromatography (HPLC).

Although we wished to be quantitative, the reactions of **1** were not clean by any means: we found a number of peaks, though small, in HPLC charts in addition to the starting materials and the desired products, **2** and **3**. Especially the peak due to **3** was often in the midst of many small peaks which prevented us from obtaining reliable data of **2**. The yields of compound **2** (±*sc* and *ap*) from compound **1** were *ca.* 50% based on the consumed substrates. These results may be attributed to the strain of the molecules, which could make the aromatic chlorine substituents susceptible to the attack of the tributylstannyl radicals, and force us to be semiquantitative in discussion. The results of the reductions of *ap*-**1** and ±*sc*-**1** are compiled in Tables 1 and 2.

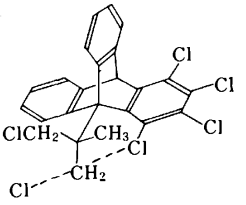
Though the reaction is not clean, we may take the ratio *ap*-**2**/*sc*-**2** in the reaction of ±*sc*-**1** as indicating the reactivity of the *sc* and the *ap*-chloromethyl groups in ±*sc*-**1**. Examination of the data in Table 1 reveals that the chloromethyl group *sc* to the *peri*-substituent is about 7 times more reactive than the *ap* group. By reducing the conversion ratio of ±*sc*-**1**, we should be able to expect that the consumption of ±*sc*-**2** is negligible. Yet the ratio *ap*-**2**/*sc*-**2** is almost constant. Thus the reactivity of the *sc*-chloromethyl group is indeed higher than that of the *ap*. This should be attributed to the participation of the *peri*-chloro substituent (**4**), which stabilizes the transition state of the reaction. This type of participation of a chlorine atom in stabilizing radicals has been reported.[5]

Table 1. Competitive reduction of the *sc* and *ap* chloromethyl groups in ±*sc*-**1**

Temperature/ °C	Conversion/ %	*ap*-**2**/ *sc*-**2**	Reaction time/ h
80	53	6.7	3
69	21	5.8	3
69	13	8	1.5
69	7	6	0.5

Table 2. Results of competitive reactions of ±*sc*-**1** and *ap*-**1** with tributylstannane after 3 h

Temperature/°C	Conversion/%		Product ratio
	±*sc*-**1**	*ap*-**1**	(*sc*-**2**/*ap*-**2**)
100	57	63	2.8
80	57	63	2.4
69	28	31	2.3



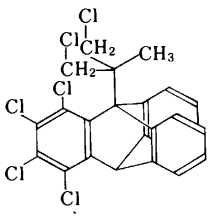
4

It is also noted that the relative reactivity of the *sc* chloromethyl group to that of the *ap* found in ±*sc*-**1** is much larger than that (1.6) in the radical chlorination of **3** with sulfuryl chloride.[2] The results will mean that the bond lengthening (C–Cl and C–H, respectively) in the transition states in these reactions are different to a considerable extent.

The data for the competitive reduction of *ap*-**1** and ±*sc*-**1**, shown in Table 2, indicate that the *ap*-form is a little more reactive than the *sc* and the product ratio (*ap*-**2**/*sc*-**2**) is larger than 2. If the two chloromethyl groups in *ap*-**1** had the same reactivity with the *sc*-chloromethyl group in ±*sc*-**1**, the followings could be

expected. Since there are two *sc*-chloromethyl groups in *ap*-**1**, the overall rates of reduction of either one of the groups are twice of that of the *sc*-chloromethyl group in ±*sc*-**1**. That means that ±*sc*-**2** is produced from *ap*-**1** with a factor of *ca.* 14 relative to the reduction of the *ap*-chloromethyl group in ±*sc*-**1**. Since the relative rate of formation of ±*sc*-**2** from ±*sc*-**1** is small, the formation of *sc*-**2** *via* this route may be neglected. Then the formation ratio (*ap*-**2**/*sc*-**2**) in the competitive reaction should be 2, if the reactivities of the *sc*-chloromethyl groups in *ap*-**1** and ±*sc*-**1** were the same. The observed ratios are significantly larger than 2 to indicate that the chloromethyl group in *ap*-**1** is more reactive than that in ±*sc*-**1** which is *sc* to the 1-chloro substituent for some reasons. The enhanced rates of decreasing in *ap*-**1** relative to those in *sc*-**1** may be also taken as supporting evidence for the above conclusion.

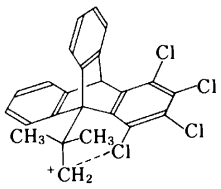
In the ground state, there are two Cl···CH_2Cl interactions[6] in *ap*-**1**, whereas there is only one such interaction in ±*sc*-**1**. This will necessarily make the Cl···CH_2Cl interactions in *ap*-**1** weaker than that in ±*sc*-**1**. The results then may show that this less stabilization in the ground state in *ap*-**1** is important. It may also be pointed out that three C–Cl dipoles are parallel in *ap*-**1** in close proximity (**5**) but one of them is more distant in ±*sc*-**1**: this should result in higher ground state energy of *ap*-**1** than that in ±*sc*-**1**. In addition, probably the steric congestion in *ap*-**1** is more effectively relieved than that in ±*sc*-**1** by the formation of transition state, because the congestedness in this molecule is expected to be greater than that in ±*sc*-**1**. Diagnosis of contributions of these factors awaits further investigations.



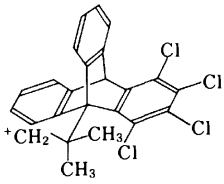
5

The reduction of ±*sc*-**2** and *ap*-**2** were not clean as well. The competitive reactions of ±*sc*-**2** and *ap*-**2** indicated that the *sc*-form was consumed 1.5, 1.6, and 2.0 times faster than *ap*-**2** at 100, 80, and 61 °C, respectively, after 3 h heating. We cannot postulate directly from the results that ±*sc*-**2** is more vulnerable to the attack of the tributylstannyl radicals than *ap*-**2** because of the complex nature of the reaction, but nonetheless it is tempting to consider so from the results with ±*sc*-**1** and *ap*-**1**. The interesting point here is that the difference in reactivities between the *sc*-chloromethyl group and the *ap* in **2** seems to be diminished considerably from the values observed in ±*sc*-**1**. We do not have good explanations for this finding but it could be postulated that the stabilization due to the Cl···CH_2Cl interaction, the congestedness, Coulombic interactions, and the enhanced electronegativity of the chloromethyl group in *ap*-**1** relative to that in ±*sc*-**2** are responsible.

Having had two rotamers of compound **2** in hand, we can now compare some properties of the rotamers of **2**, which cannot be examined as a mixture. As one of such examples we have taken the electron-impact mass spectra of the rotamers. Although there are ample reports which describe different fragment patterns of diastereomeric isomers,[7] those of rotational isomers are limited.[8] Therefore, it will be worthwhile to acquire mass spectral data of rotational isomers of **2** as well as **1**, because the mass spectra are usually obtained as a mixture of possible rotamers of a compound. We also expected that, from the results of ionization reactions of these isomers that showed significant stabilization of the *sc*-carbocation by the participation of the 1-chloro substituent in **2**,[9] the fragment species **6** should be more abundant than the fragment **7** in which no special stabilization is expected.



6



7

Sets of typical results are shown in Table 3. Since vaporization of the samples took place at 180—210 °C, we can assume that internal rotation is negligibly slow during the measurement. The intesities of the peaks varied from one measurement to another but the trends in intensities discussed below were reproducible. As expected, we observed a number of peaks in the mass spectra of which relative intensities were different from a rotamer to another. We will discuss the peaks corresponding to species which bear ^{35}Cl atoms only for the sake of simplicity and the absence of ambiguity in the discussion.

Base peaks in both ±*sc*-**2** and *ap*-**2** were mostly at *m/z* 356 which correspond to the loss of the 9-substituent and a chlorine atom with the gain of two hydrogen atoms. The loss is reasonable since removal of the 9-substituent and/or the chlorine atom at the 1-position relieves the strong steric strain. The features noticed in comparison of the two spectra due to ±*sc*-**2** and *ap*-**2** are that the relatively large molecular ion peak for the *ap*, the relatively large peak corresponding to $[M-35]^+$ for the *sc*, and

Table 3. Typical sets of mass spectral data of compounds **1** and **2**[a)]

Assignment	Compound **1**			Compound **2**		
	m/z	±*sc*	*ap*	*m/z*	±*sc*	*ap*
M^+	514	8.5	10.0	480	14.5	20.0
$[M-Cl]^+$	479	10.5	10.0	445	20.5	8.0
$[M-HCl]^+$	478	4.5	10.5	444	38.0	2.5
$[M-(Cl+HCl)]^+$	443	12.7	38.0			
$[M-2HCl]^+$	442	7.0	27.0			

a) Relative intensities to the base peaks which were at *m/z* 356 in all the cases shown here.

the relatively large peak corresponding to $[M-36]^+$ in the *sc*. The first two features both speak for the stabilization of $[M-35]^+$ species in the *sc* form which can be assigned to structure **6**. A part of the reasons for the less abundance of the M^+ peak for the ±*sc*-isomer must be attributed to the more intense peaks corresponding to $[M-35]^+$ and $[M-36]^+$. Since it is known that, if once the cationic species **6** is formed, it undergoes reactions, cyclization and olefin-formation,[9] this peak may be assigned to the cationic species formed after these reactions. Therefore, the abundance of $[M-36]^+$ peak in the mass spectra of the ±*sc*-form is also evidence for the stabilization of **6**.

In Table 3, are also included the electron impact mass spectra of ±*sc*-**1** and *ap*-**1**. Here again the base peaks were generally *m/z* 356. The features of the mass spectra of *ap*-**2** and ±*sc*-**2** are reproduced here again. Since both rotamers of **1** bear at least one *sc*-chloromethyl group to the *peri*-chloro, it may be fair to compare the results which correspond to the loss of the second chlorine atom. Although we could not observe a $[M-2Cl]^+$ peak, the peaks corresponding to $[M-(Cl+HCl)]^+$ and $[M-2HCl]^+$ are more abundant in the *ap* form than in the *sc*.[10] The anchimeric assistance in the fragmentation in mass spectra is again important.

Experimental

Substrates were prepared as reported previously,[2] except for ±*sc*-1,2,3,4-tetrachloro-9-(2-chloro-1,1-dimethylethyl)-triptycene (**2**), of which method of preparation is given below. The products were identified by comparison of their ^1H NMR spectra and retention times in HPLC.

Competitive Reactions. A nearly equimolar amount (*ca.* 5 mg or *ca.* 0.01 mmol) each of *ap* and ±*sc* isomers of **1** was weighed and dissolved in 1.3 mL of benzene. A small amount of azobisisobutyronitrile was added to the solution together with 60 µL of 1-methoxy-3,5-dimethylbenzene or 4-methoxytoluene. After purging of the air by nitrogen, 5.4 µL (0.02 mmol) of tributylstannane was added and the solution was sealed in a tube. The tube was heated at 100, 80, or 69 °C for 3 h by immersing the tube into a boiling bath of water, benzene, or hexane. Averages of 3 runs are given in Table 1. Competitive reactions between *ap*-**2** and ±*sc*-**2** were carried out similarly. A small amount of products which were derived by reduction of the aromatic chlorine atom(s) was detected but these were neglected in analyses.

Analysis of the Unreacted Materials and Products. Analysis was carried out with the use of a Waters HPLC apparatus equipped with a UV detecter at 254 nm, a microporasil column being used. Typical retention times for these compounds were as follows, when the flow rate of hexane was 1.5 mL min^{-1}: **3** 8.4 min, *ap*-**2** 11.5 min, ±*sc*-**2** 11.9 min, *ap*-**1** 14.7 min, ±*sc*-**1** 21.3 min. Intensities were measured by the weight method except for compound **2**, for which special care was taken because of the overlap of the corresponding peaks in HPLC. A calibration curve was drawn by comparing the intensities of the peaks due to the substrates and the products in HPLC with those of ^1H NMR spectra in the former case. The peak heights were used in the case of **2** and a calibration curve was drawn as well.

Mass Spectrometry. The electron-impact mass spectra were recorded on a JEOL-JMS-D300 mass spectrometer with 70 eV electrons. The temperature required for obtaining high enough vapor pressure for the measurement ranged from 180 to 210 °C. The intensities of peaks of interest changed from a measurement to another. Those data given in Table 3 are sets of typical values of which trends were reproducible.

±sc-*1,2,3,4-Tetrachloro-9-(2-chloro-1,1-dimethylethyl)-triptycene (2).* A solution of 110 mg (0.22 mmol) of *ap*-**1** in 12 mL of toluene was heated with 59 µL (0.22 mmol) of tributylstannane and a small amount of azobisisobutyronitrile under reflux for 6 h. The solvent was evaporated and the residue was chromatographed on a silica-gel plate with hexane-dichloromethane as an eluent. The desired product was obtained as crystals, mp 185.0—186.0 °C, in 16% yield. Found: C, 59.38; H, 3.71; Cl, 37.34%. Calcd for $C_{24}H_{17}Cl_5$: C, 59.72; H, 3.55; Cl, 36.73%. ^1H NMR ($CDCl_3$), δ=2.13 (3H, s), 2.32 (3H, s), 4.87 and 4.95 (2H, ABq, J=11.6 Hz), 6.06 (1H s), 6.9—7.2 (4H, m), 7.3—7.5 (2H, m), 7.8—8.0 (2H, m).

Although it was possible to increase the amount of ±*sc*-**2** in this reaction by increasing the reducing reagent, products derived by the reduction of aromatic chlorine atom(s) increase in its amount as well. Thus the above procedure is the optimum so far we have achieved. *ap*-**1** could be recovered in *ca.* 80% yield on an average.

10) In one measurement, the peak at m/z 444 appeared as a very strong one. This peak involves contributions of the fragment $[M-2^{35}Cl]^+$ from $C_{24}H_{17}{}^{35}Cl_5$ and that $[M-2H^{35}Cl]^+$ from $C_{24}H_{17}{}^{35}Cl_4{}^{37}Cl$. However, this peak is omitted from the discussion for the following reasons. Firstly, the cause for the stabilization of $[M-2Cl]^+$ is difficult to find and, secondly, division of the contributions by the two kinds of fragments is not tried in this work.

Kinetic Studies of Fast Equilibrium by Means of High-performance Liquid Chromatography. XII.[1] Rate Constants and Energy Barriers of Intramolecular Carbonyl-Nitrogen Bond Rotation of *o*-Substituted Acetanilides

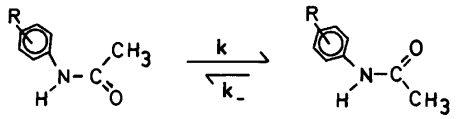
Masataka Moriyasu,* Kazuko Kawanishi, Atsushi Kato, Yohei Hashimoto, Makiko Sugiura, and Torei Sai

Kobe Women's College of Pharmacy, Motoyamakita-machi Higashinada-ku, Kobe 658

(Received April 24, 1985)

A novel high-performance liquid chromatographic(HPLC) method has been proposed to determine the rate constants and activation energies of the interconversion between two labile species existing in equilibrium in solution. The rotational energy barriers to intramolecular bond rotation about the carbonyl-nitrogen bonds of several *o*-substituted acetanilides have been determined by this method. These energy barriers have been found to increase when bulkier groups are attached at the *o*-position on the benzene ring. These have also been determined by a dynamic nuclear magnetic resonance spectroscopic(DNMR) method, which gives good agreement with the HPLC results.

In our previous reports,[2,3] dynamic equilibria between two rotamers (*E*- and *Z*-form) of several anilides including formanilide and acetanilide derivatives have been investigated by means of high-performance liquid chromatography(HPLC). HPLC



E-form Z-form

of several anilides at low temperatures have led to the successful separation of two labile rotamers. We have called the HPLC method dynamic high-performance liquid chromatography(DHPLC) in imitation of dynamic NMR. When the interconversion is relatively slow even at room temperature, either of the equilibrated species can be enriched by HPLC. In this case the rate constants and energy barriers to the interconversion can be easily determined.[4] On the other hand, when the interconversion is faster, as is the case for formanilide[2] and metal dithiocarbamates,[5] this treatment failed at room temperature, but was found possible under cooled conditions. This treatment was found to be inapplicable to acetanilides as the interconversion between the two rotamers of acetanilides are much faster than in the case of formanilide. Thus, when each of the portions collected were rechromatographed, howsoever carefully and quickly the experiments were carried out, almost equilibrated chromatograms were always obtained even at low temperatures. The difficulty has forced us to devise another method to determine the rate constants and energy barriers to the bond rotation. In this report, an approximate HPLC method is proposed to determine the energy barriers from the change in the HPLC chromatograms. We have determined the rate constants and energy barriers of intramolecular bond rotation of several *o*-substituted acetanilides. We have also determined the energy barriers by DNMR and compared both results. The attempt to determine the energy barriers in other acetanilides such as *m*- or *p*-substituted ones by means of HPLC was unsuccessful because the content of the *E*-form is low for these acetanilides.

Experimental

2-Methylacetanilide, 2-ethylacetanilide, 2-isopropylacetanilide, and 2,4-dimethylacetanilide were prepared by usual procedures from the corresponding aromatic amines and acetic anhydride.[6] The samples were twice recrystallized from hexane-acetone. The HPLC apparatus for use in low-temperature measurements was described in our previous communications.[3,5] The column effluent was passed through a narrow stainless steel tube (0.5 mm in internal diameter and 10—20 m in length) which was thermostated at 50—100 °C in an air bath prior to detection by means of a UV detector.[3] This treatment, however, was found not always to be necessary in this case because the ratios of the two rotamers were found to be unchanged in the presence and absence of heating. This suggests that either the absorption coefficients of the two rotamers are almost the same or the re-equilibrium is attained promptly before the column effluent reaches the cell of the UV detector even in the absence of the heating. The NMR instrument (Varian XL-200) was also similar to the one described previously.[3] In order to determine the energy barriers to bond rotation, the DNMR method was applied as follows: Total line shape analysis was carried out according to the DNMR3-IT$_2$[7] program after modifying the input and output modes partially. The calculation was made on an NEC ACOS series 77 system 1000 type computer at the Computation Center of Osaka University.

Theoretical

When the system composed of dynamic equilibria in solution is chromatographed, the separation and the interconversion will compete and complicated chromatograms may be obtained. This phenomenon

is sometimes observed in TLC,[8] GC,[9,10] and HPLC[11] included in our previous study.[2,5] In our series of measurements, we demonstrated the use of the HPLC method to investigate fast equilibria in solution. Two equilibrated species ($X \underset{k_-}{\overset{k}{\rightleftharpoons}} Y$) exist in solution, interconversion between two labile isomers being an example. The interconversion is assumed not to be rapid as compared with the separation speed by HPLC. Thus, when HPLC is carried out at low temperature, the two labile rotamers will be separated completely and interconversion between two isomers will not occur during chromatography (Fig. 1(a)). When the column temperature is slightly raised, interconversion between two labile species will occur to some extent. In this case, as shown in Fig. 1(b), the base line separation of the two species is no longer attained. When the interconversion X→Y (or Y→X) partially occurs during chromatography, the formed species Y (or X) will be eliminated from X (or Y) promptly, provided that the intrinsic retention time of X and Y differ markedly from one another. Thus, the peak area of X ($=S_X$) indicates the residual amount of X at a definite time t. The value t is approximated from the retention time of X ($=t_r$) as follows: When a sample composed of X and Y is introduced to HPLC from an injector, it reaches the column head after the lapse of a slight interval, t_1, and the separation process then begins with the slight interconversion between the two rotamers being attained during chromatography. After the lapse of time, t, X reaches the column end and the separation stops. It will still take some more time, t_2, before X reaches the cell of the detector. Assuming that the peak shape is symmetrical and that the separation is attained promptly near the column head, the following equation will apply: $t_r=t_1+t_2+t$. The residual amount of X at a time t is proportional to the product S_X in Fig. 1(b) and the flow rate v. When the flow rate is decreased with the column temperature being kept constant, a larger part of X should transform into Y during the chromatographic process. Thus, from the plot $S_X v$ *vs.* t, the rate constant of the bond rotation can be calculated. It is noteworthy here that in this method the transformed species is promptly eliminated from the peak and thus the effect of the reverse reaction can be approximately neglected, which differs from other kinetic methods. When the rate constants are measured at a variety of column temperatures, the rotational energy barrier can be calculated from the Arrhenius' plot.

Results and Discussion

HPLC of 2-Methylacetanilide. As shown in the theoretical section, it is necessary to determine the void volume from the injector to the column head and from the column end to the cell of the UV detector. This was determined to be 0.25 cm^3 for the present HPLC apparatus by connecting a voidless 2-way union instead of the column and then injecting a sample to be detected. Thus, t_1+t_2 was calculated by dividing the dead volume by each flow rate.

Then, 2-methylacetanilide was chromatographed at low temperatures. The two rotamers of 2-methylacetanilide were separated under the HPLC conditions described previously;[3] solvent system: hexane:1-propanol:acetic acid=100:10:3; column: Polygosil 60—5 (4.6 mm×15 cm); flow rate: 2.0 cm^3 min^{-1}; detection: UV 254 nm. Under these conditions and the column temperature at −50 °C, base line separation of the two rotamers was achieved, and the equilibrium constants prior to HPLC could be determined. On the other hand, when the column temperature was higher than −20 °C, the two peaks coalesced, and consequently only one broad peak appeared on the chromatograms. Between these two extremes, two peaks, the larger one corresponding to the *E*-rotamer and the smaller one to *Z*-rotamer, appeared on the chromatograms with slight interconversion being attained during chromatography.[3] Then, the column temperature was adjusted from −40 to −25 °C, at various flow rates (0.3—4.0 cm^3 min^{-1}). The change of chromatograms at −35 °C is depicted in Fig. 2. With increasing flow rate, the interconversion is suppressed. The product of the peak area and the flow rate $S_X v$ is plotted against the residence time t and the results is shown in Fig. 3. From the slope of these linear lines, the rate constant k corresponding to the conversion from *E*-to *Z*-form at each temperature was determined. The results were 5.2×10^{-3}, 1.0×10^{-2}, 2.0×10^{-2}, and 3.7×10^{-2} s^{-1} at −40, −35, −30, and −25 °C, respectively. In Fig. 3, it is noteworthy that when the same amount of the sample was injected the extraporated values of $S_X v$ at $t=0$ were similar at different temperatures. This can reasonably be attributed to the fact that the initial content of the *E*-form before chromatography is similar for each sample.

With similar procedures, the reverse rate constant k from *Z*- to *E*-form at each temperature was deter-

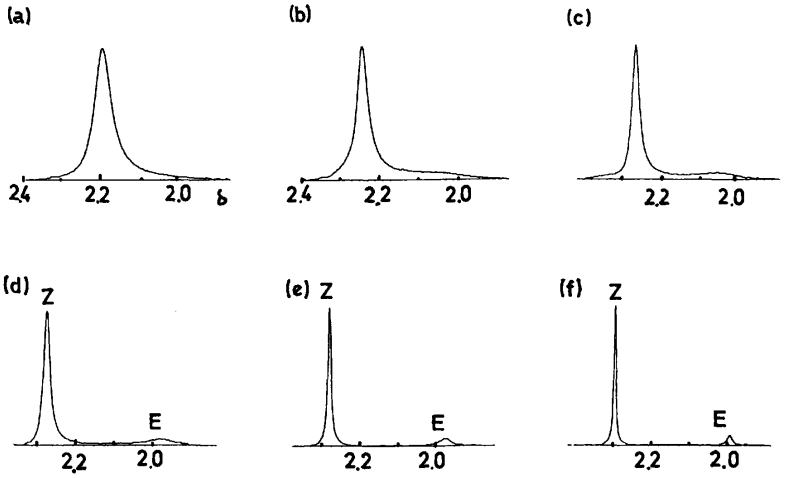

Fig. 5. ^{1}H-NMR spectra of 2-ethylacetanilide in $CDCl_3$ at different temperatures.
(a): 50 °C, $k = 6.7 \times 10^1$ s^{-1}, (b): 40 °C, $k = 2.7 \times 10^1$ s^{-1}, (c): 35 °C, $k = 1.6 \times 10^1$ s^{-1}, (d): 30 °C, $k = 9.8 \times 10^0$ s^{-1}, (e): 20 °C, $k = 3.4 \times 10^0$ s^{-1}, (f): 10 °C.

mined to be 6.1×10^{-4}, 1.0×10^{-3}, 1.6×10^{-3}, and 3.2×10^{-3} s^{-1} at −40, −35, −30, and −25 °C, respectively. Thus, the equilibrium constant K (=[*Z*-form]/[*E*-form]) should be from 8 to 12 over this temperature range. The equilibrium constant K can be directly determined by means of HPLC by dissolving 2-methylacetanilide in an HPLC eluent and then letting it stand for enough time to attain equilibrium between the two rotamers, followed by HPLC analysis at −50 °C.[3] The equilibrium constant at 25, 0, and −50 °C was thus determined and was found to be almost the same(K=4.5). Both results agree relatively well.

HPLC of Other o-Substituted Acetanilides. Using the procedure described above, the rate constants for the bond rotation were determined for other *o*-substituted acetanilides at low temperatures(−40 to −25 °C). The rate constants k and k_- at −40 °C are summarized in Table 1. These results suggest that when bulkier groups are attached at the *o*-position of the phenyl ring, intramolecular bond rotation becomes slow.

Energy Barriers to the Bond Rotation. Figure 4 indicates Arrhenius' plots (k *vs.* $1/T$) for *o*-substituted acetanilides. From the slope of these linear lines, the energy barriers to the bond rotation from the *E*- to the *Z*-form were calculated; they were found to increase slightly when bulkier groups were substituted. Using similar procedures, the energy

1: 2-Methylacetanilide, 2: 2-Ethylacetanilide, 3: 2-Isopropylacetanilide.

barriers of the reverse reaction (from *Z*- to *E*-form) were determined. These results are summarized in Table 2. The energy barriers of the bond rotation of forward and backward reactions were found to be closely similar.

DNMR Measurements. Previous NMR study have also demonstrated the presence of both *E*- and *Z*-forms for *o*-substituted acetanilides[12] but evaluation of the energy barriers by the DNMR method was not carried out as the percentages of the *E*-form are low, and consequently, total line shape analysis was difficult using relatively low field NMR instruments with low sensitivity. Figure 5 indicates 200 MHz ^{1}H-NMR spectra of 2-ethylacetanilide for the acetyl protons from 10 to 50 °C. Two sharp signals (δ=2.28 and 1.98 for *Z*- and *E*-form, respectively) at 10 °C are broadened with the rise of temperature and at 50 °C the two peaks coalesce. It is interesting to note that the change in the NMR spectra (Fig. 5) resembles that of the HPLC chromatograms (Fig. 2). The rate constants for the bond rotation at each temperature were determined by total line shape analysis (Fig. 5). The energy barrier corresponding to the conversion from the *Z*- to the *E*-form was calculated to be 78.8 kJ mol^{-1} from the Arrhenius' plots (Fig. 6). Similar experiments were carried out for 2-methylacetanilide and 2-isopropylacetanilide. The rate constants k_- at −30 °C were determined to be 1.1×10^1, 9.8×10^0, and 9.4×10^0 s^{-1}, for 2-methylacetanilide, 2-ethylacetanilide, and 2-isopropylacetanilide, respectively. The energy barriers were also calculated and the results are shown in Table. 1. In both NMR and HPLC the energy barriers are found to increase when bulkier substituents are introduced at the *o*-position. The energy barriers obtained by HPLC are somewhat smaller than those by NMR, which may be interpreted at least partially in terms of the difference in the polarity of the solvents and the temperature range. If these conditions are taken into consideration, both results agree fairly well. The energy barriers obtained by the present HPLC method are not always accurate because it may sometimes occur that the bond rotation is catalytically accelerated or suppressed on the surface of the adsorbent silica-gel. The authors, however, consider that the HPLC method will be a useful method for approximately estimating the energy barriers of fast equilibria.

The authors wish to express their gratitude to Dr. Usha Shome, National Botanical Research Institute, Lucknow, India, who kindly corrected the English of this paper.

(Received June 5, 1985)

An improved synthetic method gives pure 7*H*-dibenz[*a*,*kl*]anthracen-7-one, $C_{21}H_{12}O$, in a higher yield than those reported so far. The crystal structure has been determined by X-ray analysis. The space group is $Pn2_1a$, with unit cell dimensions of a=23.325(5), b=14.149(3), c=3.986(1) Å, and Z=4. The structure was solved by the direct method and refined by the block-diagonal least-squares method to an R value of 0.044. The molecule is greatly distorted from the planar conformation because of an intramolecular steric repulsion between the hydrogen atoms.

Bradley *et al.* reported[1] that the condensation of benz[*a*]anthracene-7,12-dione (**1**) with glycerol and concentrated sulfuric acid gave two products; 7*H*-benzo[*hi*]chrysen-7-one (8,9-BzBT, **2**) and 13*H*-dibenz-[*a*,*de*]anthracen-13-one (5,6-BzBT, **3**). In this case, the cyclization in the 11 and 12 positions of **1** should occur to produce 7*H*-dibenz[*a*,*kl*]anthracen-7-one (10,11-BzBT, **4**), although they did not mention it. Clar *et al.* reported[2] that 10,11-BzBT was prepared by decarboxylating its 13-carboxylic acid, which had itself been produced by the partial cyclization of 1,1′-binaphthyl-8,8′-dicarboxylic acid. However, this method requires many steps and gives only a poor yield. We reexamined the method reported by Bradley *et al.* and obtained 10,11-BzBT in a satisfactory yield.

Previously, we determined the crystal structures of 8,9-BzBT[3] and 5,6-BzBT.[4] These compounds are distorted from the planar conformation because of a steric repulsion between O and H, which are indicated by *. In 10,11-BzBT, the distortion from the planar structure is expected to be caused by the repulsion between the hydrogen atoms with *. The present paper deals with the crystal structure of **4** in comparison of the distortion modes with those of 8,9-BzBT and 5,6-BzBT.

Experimental

Synthesis of o-(1-Naphthoyl)benzoic Acid. A mixture containing naphthalene (25.0 g) and finely powdered anhydrous aluminum chloride (50.0 g) was dissolved in 120 ml of 1,1,2,2-tetrachloroethane, into which phthalic anhydride (25.0 g) was added with stirring, the temperature being kept below 10 °C for 2 h. Then the mixture was kept at 20 °C for 8 h. The contents were poured into water (300 ml) containing a small amount of hydrochloric acid, and the whole was steam-distilled. The cold residue was extracted with a small amount of 4% aqueous sodium hydroxide, and then concentrated hydrochloric acid was added until the solution was made acidic. After the solution had stood overnight, the precipitated *o*-(1-naphthoyl)benzoic acid was collected and washed with water. Recrystallization from glacial acetic acid gave the *o*-(1-naphthoyl)benzoic acid as white plates; mp 175—176 °C (uncorrected). Yield, 42.7 g.

Synthesis of Benz[a]anthracene-7,12-dione. *o*-(1-Naphthoyl)benzoic acid (21.0 g) was mixed with concentrated sulfuric acid (210 ml), and the mixture was heated to 65 °C for 4 h. After cooling, the contents were poured into water (1 l). The precipitate was collected and washed thoroughly with water. The crude product (7.2 g) was then boiled for 2 h with glacial acetic acid. Yield, 6.0 g; green yellow needles; mp 167—168 °C.

Glycerol Condensation of Benz[a]anthracene-7,12-dione. To a mixture of benz[*a*]anthracene-7,12-dione (5.0 g), aniline (5.0 g), and 80% sulfuric acid (140 g), glycerol (14.0 g) was added, drop by drop, at 50 °C. The mixture was then heated at 100 °C for 8 h. After cooling, the contents were poured into a large amount of water, collected, and washed with hot water. The crude product (3.2 g), a brown mass with a mp of 123—153 °C, was extracted with acetone (50 ml). The extraction was carried

†† Present address: Department of Chemistry, Faculty of Science, Ochanomizu University, Otsuka, Bunkyo-ku, Tokyo 112.

out by means of hot filtration. The filtrate, on evaporation to dryness, gave a dark brown mass (1.4 g). A chlorobenzene solution of this product was passed through a column of silica-gel (300 mesh) and eluted with chlorobenzene. The products was developed into three bands. The red band was separated and concentrated, giving red needles. Yield 0.2 g; mp 197—198 °C. The intense yellow band, overlapping with a pale yellow band, was eluted with chlorobenzene and concentrated to give a yellow mass (1.1 g); mp 162—168 °C. This product was dissolved in a large amount of ethanol, and the solution was put into a column of alumina. The absorbed layer was developed into two bands; the lower layer, an intense yellow band, was separated and concentrated to give intense yellow needles. Yield, 0.3 g; mp 183—184 °C. The upper layer, a pale yellow band, gave pale yellow needles. Yield 0.7 g; mp 188—189 °C. The red needles (mp 197—8 °C) and the intense yellow needles (mp 183—4 °C) were proved to be 5,6-BzBT[4] and 8,9-BzBT[3], respectively. Thus, the pale yellow needles (mp 188—9 °C) were assumed to be 10,11-BzBT.

X-Ray Data Collection of 10,11-BzBT. The crystals (mp 188—9 °C) were grown from an ethanol solution. Crystals; $C_{21}H_{12}O$, M.W. 280.3, orthorhombic, a=23.325(5), b=14.149(3), c=3.986(1) Å, and U=1315.4(5) Å^3, D_X=1.415 g cm^{-3}; Z=4; space group, Pn2$_1$a; μ(Mo $K\alpha$)=0.90 cm^{-1}. The intensity data were collected on a Rigaku automated four-circle diffractometer, using the $\omega/2\theta$ scan technique with a scanning rate of 4° (2θ) min^{-1}. The crystal size was 0.5×0.3×0.1 mm. A total of 1220 independent reflections were measured (up to 2θ=55°) using graphite monochromated Mo $K\alpha$ radiation, of which 656 reflections with $|F_o|>3\sigma$ ($|F_o|$) were used for the analysis. Correction was made for the Lorentz and polarization factors, but not for absorption.

Structure Determination

The systematic absences of $0kl$ ($k+l=2n+1$) and $hk0$ ($h=2n+1$) indicated the space group to be Pnma or Pn2$_1$a. The packing consideration suggested a non-centrosymmetric arrangement, and the structure was successfully refined on the basis of the space group Pn2$_1$a. The structure was determined by the direct method, with the MULTAN78 program[5], and was refined by the block-diagonal least-squares method. The coordinates of the hydrogen atoms were derived from an idealized geometry and refined with the isotropic temperature factor. The final R became 0.044. No peaks higher than 0.3 eÅ^{-3} were found on the final difference map. The atomic-scattering factors were taken from Ref. 6. The final atomic parameters, with their standard deviations, are listed in Table 1. Lists of the observed and calculated structure factors, the anisotropic thermal parameters for the non-H atoms, and the positional parameters for the H atoms are deposited as Document No. 8547 at the office of the Chemical Society of Japan.

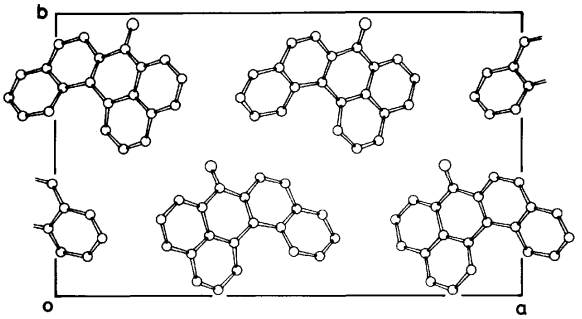

Fig. 1. Projection of the crystal structure along the c axis.

Results and Discussion

The present study has established the structure of **4**. This method is convenient for preparing not only 5,6-BzBT and 8,9-BzBT, but also 10,11-BzBT, since it gives pure 10,11-BzBT more easily and in a higher yield than the method described in Ref. 2.

Figure 1 illustrates the crystal structure of 10,11-BzBT viewed along the c axis. Molecules are stacked face-to-face along the c axis. The overlapping mode

is shown in Fig. 2. The stacking disorder found in the crystals of 8,9-BzBT and 5,6-BzBT is not observed here. There are two dimer pairs of molecules with different populations in the crystals of 8,9-BzBT and 5,6-BzBT. The mean interplanar distance is 3.582 Å, which is larger than that of 3.47 Å between the molecules with larger populations in 8,9-BzBT and 5,6-BzBT. There are no unusually short contacts between the molecules.

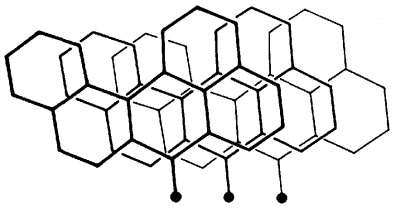

Fig. 2. Overlapping mode.

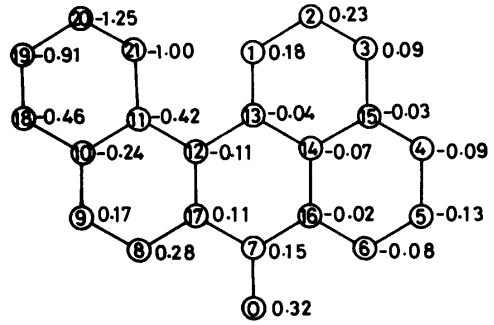

Fig. 3. Deviations of the atoms (l/Å) from the mean molecular plane.

The deviations of the atoms from the mean molecular plane are shown in Fig. 3. The bond distances and angles are listed in Tables 2 and 3 respectively. The molecules are greatly distorted from a planar conformation because of the steric repulsion, which is known as 1,7 interaction. The repulsion is released mainly by the enlargement of the C(1)–C(13)–C(12), C(11)–C(12)–C(13), and C(12)–C(11)–C(21) angles and the distortion from the planar conformation. The degree of the distortion was defined as the twisting angle around the pseudo bond of C(11)···C(13).[7] The angle of C(1)–C(13)···C(11)–C(21) is 33.4°. The corresponding angles (O–C···C–C) in 8,9-BzBT and 5,6-BzBT are 8.2° (Molecule A) and 6.3° (Molecule B) in the former, and 6.0° in the latter. These values are considerably smaller than that of

Optical Absorption and Conductimetric Studies on Ionic Dissociation of Metallotetraphenylporphyrins in Ethanol Solutions

Mikio HOSHINO,* Shunzo KATAYAMA, and Kiyoko YAMAMOTO
The Institute of Physical and Chemical Research, Wako, Saitama 351-01
(Received June 17, 1985)

Optical absorption spectra of chloro[tetraphenylporphyrinato(2-)]metals, $M^{III}Cl(tpp)$ (M=Mn, Fe, Co, and In), and diacetato[tetraphenylporphyrinato(2-)]tin(IV), $Sn^{IV}(CH_3COO)_2(tpp)$, in ethanol and benzene solutions were measured. A marked difference in the absorption spectra between the ethanol and benzene solutions was observed for $Mn^{III}Cl(tpp)$, $Fe^{III}Cl(tpp)$, and $Co^{III}Cl(tpp)$, while a small difference for $In^{III}Cl(tpp)$ and $Sn^{IV}(CH_3COO)_2(tpp)$. The electric conductivity measurements demonstrated that $M^{III}Cl(tpp)$ (M=Mn, Fe, Co, and In) undergoes ionic dissociation in ethanol, whereas $Sn^{IV}(CH_3COO)_2(tpp)$ does not. Solvent effects on the optical absorption spectra observed for ethanol and benzene solutions of the metallotetraphenylporphyrins are discussed on the basis of (1) the ionic dissociation revealed from the conductivity measurements and (2) charge-transfer (from porphyrin ligand to the central metal) character of the electronic absorption bands.

Synthetic metalloporphyrins have received much attention because of their importance as a model compound of natural metalloporphyrins that dominate electron-transport phenomena occurring in life.[1,2] Furthermore, the chemical and physical properties of these porphyrins strikingly depend on the nature of the central metal. For these reasons, studies of synthetic metalloporphyrins have been carried out by many researchers in diversed fields.[3-6]

Recently, the study of solar energy conversion and storage has been increasingly important subject of photochemistry.[7-9] Since metalloporphyrins efficiently absorb visible light from the sun, the photochemistry of them has been subjected to numerous studies, in particular, on electron transfer reactions between the excited states of porphyrins and electron-acceptor molecules.[10-16]

Despite of the importance of metalloporphyrins as mentioned above, conductivity measurements of them in solutions have not yet been carried out. The conductivity measurements have been proved of great use for the study of the ionic dissociation of solute molecules in solutions.

In the present study we have measured optical absorption spectra and conductivity of metalloporphyrins in ethanol and benzene solutions. The metalloporphyrins used are chloro[tetraphenylporphyrinato(2-)]metals, $M^{III}Cl(tpp)$ (M=Mn, Fe, Co, and In), and diacetato[tetraphenylporphyrinato(2-)]-tin(IV). The optical absorption spectra of the former three porphyrins in ethanol solutions were found to differ markedly from those in benzene solutions. On the other hand, the spectra of the latter two porphyrins showed slight difference between the ethanol and benzene solutions. We consider that this result is interpreted in terms of either (1) ligation of an ethanol molecule in the vacant axial position of metalloporphyrins or (2) ionic dissociation of metalloporphyrins. The conductivity measurements give a clear solution for this problem. On the basis of the optical absorption spectroscopic and conductivity measurements, the dissolved states of these metalloporphyrins are discussed in detail.

Experimental

Chloro[tetraphenylporphyrinato(2-)]metals, $M^{III}Cl(tpp)$ (M=Mn, Fe, Co, and In), and diacetate[tetraphenylporphyrinato(2-)]tin(IV) (these are abbreviated, respectively, as $Mn^{III}Cl(tpp)$, $Fe^{III}Cl(tpp)$, $Co^{III}Cl(tpp)$, $In^{III}Cl(tpp)$, and $Sn^{IV}(CH_3COO)_2(tpp)$ hereafter), were synthesized and purified according to the literature.[17-20] Reagent grade ethanol and benzene were fractionally distilled after being dried over molecular sieves to remove traces of water: conductivity of dry ethanol was obtained to be 2×10^{-8} S cm^{-1} and that of dry benzene, 1.0×10^{-9} S cm^{-1} at 25 °C.

Optical absorption spectra were recorded on a Hitachi 330 spectrophotometer.

The electric conductivity of solutions was measured at 1000 Hz by the conductance-linear-bridge method as described in the previous paper.[21] The resistance readings of the linear-bridge were calibrated by substitution method with a precision decade resistance box (Dekastat RS-624 from Electro Scientific Industries: the accuracy is ±0.005%). A conductivity cell which is specially designed for solutions of low conductivity was used throughout this study. The cell constant was determined to be 0.1348 cm^{-1} with the use of standard potassium chloride solutions. The experimental error of the conductivity measurements was less than 0.1%. All the measurements were carried out at 25.00±0.01 °C by using a water bath equipped with a thermostat.

The thermodynamic ion-association constants, K_A, for the reactions

$$Cl^- + [M^{III}(tpp)]^+ \rightleftarrows M^{III}Cl(tpp)$$
(M: Mn, Fe, Co, and In)

and

$$[Sn^{IV}(CH_3COO)(tpp)]^+ + CH_3COO^- \rightleftarrows Sn^{IV}(CH_3COO)_2(tpp) \quad (1)$$

can be calculated from the conductivity data on the basis of the Fuoss-Hsia conductance theory.[22-24] The revised

Fuoss-Hsia equation for the molar conductivity, Λ, of an associated symmetrical electrolyte is given by

$$\Lambda = \Lambda^{\infty} - S\cdot c^{1/2}\cdot\gamma^{1/2} + E\cdot c\cdot\gamma\log(c\cdot\gamma) + J_1\cdot c\cdot\gamma - J_2^{3/2}(c\cdot\gamma)^{3/2} - K_A\cdot c\cdot\gamma\cdot f_{\pm}^2\cdot\Lambda \quad (2)$$

with

$$K_A = (1-\gamma)/c\cdot\gamma^2\cdot f_{\pm}^2 \quad (3)$$

where Λ^{∞} is the limiting molar conductivity; c, the molar concentration; γ, the degree of dissociation; S, the Onsager limiting slope; $f_{\pm}$, the mean ionic activity coefficient, and E, J_1, and J_2 are the theoretical coefficients, respectively. The coefficients, J_1 and J_2, are formulated as a function of the mean distance (a) of closest approach of positive and negative ions. These coefficients were used for the evaluation of a.

The mean activity coefficient $f_{\pm}$, was estimated by means of Debye-Hückel equation:

$$\log f_{\pm} = -A|z_+z_-|\sqrt{I}/(1+B\cdot a\cdot\sqrt{I}) \quad (4)$$

where z_+ and z_- are the charge numbers of the positive and negative ions, respectively, I is the ionic strength, and A and B are the theoretical coefficients. The values of permitivity and viscosity of ethanol used in the present calculation were taken from literature.[25] A set of Λ^{∞}, K_A, and a values was obtained in such a way that the theoretical equation gives the best fit to the conductivity data obtained experimentally. All the calculations were performed on a FACOM computer using a FORTRAN program (JCCOND) which was kindly supplied from Professor J. C. Justice in Université de Paris.

Results and Discussion

Optical Absorption Spectra. Figure 1 shows the optical absorption spectra of $Mn^{III}Cl(tpp)$ in benzene and ethanol solutions at room temperature. The spectrum observed in ethanol is found to differ considerably from that in benzene. When the solvent is changed from benzene to ethanol, the absorption bands located around 1.3 and 2.7×10^4 cm^{-1} are red-shifted and those around 1.7 and 2.1×10^4 cm^{-1}, to the contrary, are blue-shifted. The solvent effects on the optical absorption spectra are closely related to the nature of each electronic band.

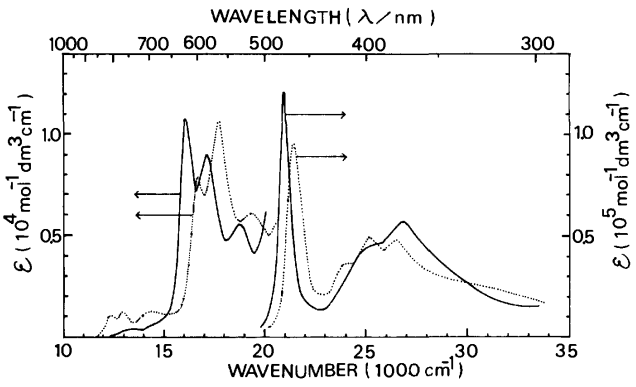

Fig. 1. Optical absorption spectra of $Mn^{III}Cl(tpp)$ in benzene (——) and in ethanol (----) solution.

The theoretical calculation has been carried out in order to elucidate the significant difference in the optical absorption spectra between manganese(III) porphyrin and usual metalloporphyrin such as zinc(II) porphyrin.[26-27] For manganese(III) porphyrin, d levels of the central manganese atom are very close to the porphyrin π levels, resulting in strong mixing of the d and π levels. As a consequence of the strong mixing, porphyrin has a number of charge-transfer bands in the UV-visible region of the absorption spectrum.[28] On the other hand, d levels of zinc(II) porphyrin are too low to make a strong mixing with the porphyrin π levels.

The location of the electronic bands having charge-transfer character in the spectra of manganese porphyrin is known to vary depending on the nature of the axial ligands as well as the negative ion in the axial position.[27] Boucher[28] has studied the absorption spectra of manganese(III) protoporphyrin IX dimethyl ester complexes in coordinating and non-coordinating solvents. The spectra observed in benzene solutions are characteristically different for each of the halide ion complexes of the manganese(III) porphyrin. However, the spectra observed in methanol solutions are independent of the axial halide ions. These results are well interpreted in terms of the ionic dissociation of the manganese(III) porphyrin in methanol solutions:[28]

$$[Mn^{III}X\ \text{porphyrin}]\ (X\text{: halogen atom}) \longrightarrow X^- + [Mn^{III}\ \text{porphyrin}]^+$$

No ionic dissociation is observed for the benzene solutions.

The above discussion is also acceptable for the interpretation of the absorption spectra of $Mn^{III}Cl(tpp)$: $Mn^{III}Cl(tpp)$ undergoes ionic dissociation in ethanol, while it does not in benzene. The previous studies on one-electron reduction induced by γ-rays at 77 K have strongly suggested that $Mn^{III}Cl(tpp)$ in ethanol dissociated into Cl^- and $[Mn^{III}(tpp)]^+$.[29] Furthermore, the conductivity measurements, as will be described later, confirmed the ionic dissociation of $Mn^{III}Cl(tpp)$ in ethanol solutions.

Figure 2 shows the optical absorption spectra of $Fe^{III}Cl(tpp)$ in benzene and ethanol solutions. The spectrum observed in ethanol differs markedly from that in benzene. In comparison with the spectrum measured in benzene, four major features are recognized for the spectrum in ethanol: (1) The 1.5×10^4 cm^{-1} band loses its intensity without shift, (2) The 1.95×10^4 cm^{-1} band is red-shifted, (3) The 2.4×10^4 cm^{-1} band is slightly blue-shifted, and (4) The 2.7×10^4 cm^{-1} band is largely blue-shifted.

The situation of the metal d levels and porphyrin π levels in iron(III) porphyrins is very similar to that in manganese(III) porphyrins.[27] Thus, we can expect

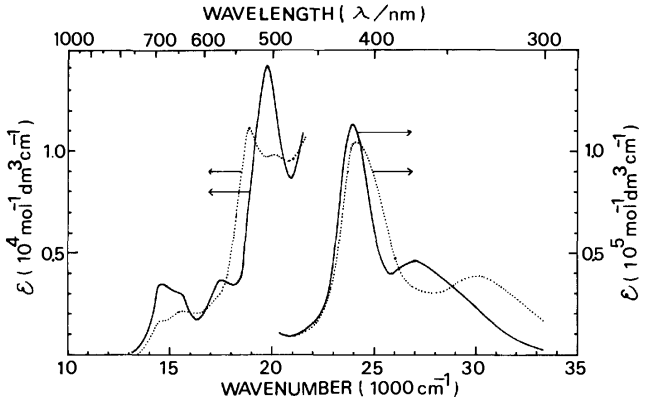

Fig. 2. Optical absorption spectra of $Fe^{III}Cl(tpp)$ in benzene (——) and in ethanol (----) solution.

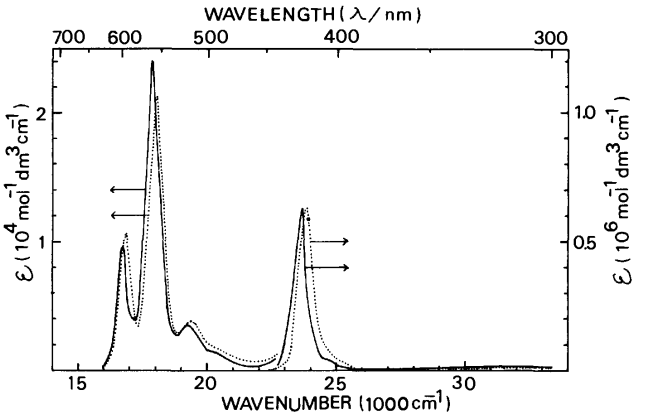

Fig. 3. Optical absorption spectra of $In^{III}Cl(tpp)$ in benzene (——) and in ethanol (----) solution.

that the electronic bands of $Fe^{III}Cl(tpp)$ have a charge-transfer character as in the case of $Mn^{III}Cl(tpp)$.[27] In fact, the theoretical calculation involving the configuration interaction between the porphyrin π states and the charge-transfer (from porphyrin to iron(III)) states gives a consistent interpretation for the optical absorption spectra of $Fe^{III}Cl(tpp)$.[30] Since the charge-transfer character of the electronic bands depends on the d levels of the central metal and the porphyrin π levels, the absorption spectrum of $Fe^{III}Cl(tpp)$ is regarded to vary by the coordinating nature of the solvents. Therefore, the absorption spectrum of $Fe^{III}Cl(tpp)$ as well as $Mn^{III}Cl(tpp)$ observed in non-coordinating solvent, benzene, is considered to differ from that in coordinating solvent, ethanol.

A significant change in the absorption spectra of $Fe^{III}Cl(tpp)$ between ethanol and benzene solutions suggests that ionic dissociation of $Fe^{III}Cl(tpp)$ occurs in ethanol solutions.

The absorption spectra of $Co^{III}Cl(tpp)$ in benzene and ethanol solutions exhibit two distinct features: (1) the Soret (*ca.* 2.3×10^4 cm^{-1}) and Q (*ca.* 1.8×10^4 cm^{-1}) bands in an ethanol solution become narrower than those in a benzene solution and (2) although the peak maximum of the Soret band observed for an ethanol solution is remarkably red-shifted by *ca.* 1.1×10^4 cm^{-1}, the Q band is slightly blued-shifted by *ca.* 0.2×10^4 cm^{-1} in comparison with each band observed for a benzene solution.

The absorption spectrum in the ethanol solution is in good agreement with that observed for the six-coordinated $Co^{III}(tpp)$.[31] Therefore, the species in the ethanol solution is presumed to be $Co^{III}Cl(tpp)(C_2H_5OH)$ or $[Co^{III}(tpp)(C_2H_5OH)_2]^+$ in which ethanol molecule(s) are located in the axial position(s). The spectrum observed for the benzene solution is ascribed to the five-coordinated species, $Co^{III}Cl(tpp)$.[32]

It is suggested that cobalt porphyrins have a number of charge-transfer transitions as in the case of nickel porphyrins.[27] A significant difference in the spectra between ethanol and benzene solutions is interpreted by assuming that the absorption bands, in particular the Soret band, have a charge-transfer character.

As to the ionic dissociation of $Co^{III}Cl(tpp)$, paper electrophoresis study has revealed that $Co^{III}Cl(tpp)$ in ethanol is dissociated as[32]

$$Co^{III}Cl(tpp) + 2C_2H_5OH \longrightarrow Cl^- + [Co^{III}(tpp)(C_2H_5OH)_2]^+$$

Here, C_2H_5OH molecules in $[Co^{III}(tpp)(C_2H_5OH)_2]^+$ are assumed to be located in the axial positions. The ionic dissociation of $Co^{III}Cl(tpp)$ in ethanol was also suggested on the basis of the optical and ESR studies of one-electron reduced species of $Co^{III}Cl(tpp)$ produced by γ-radiolysis of the ethanol solution at 77 K.[29]

Figure 3 shows the optical absorption spectra of $In^{III}Cl(tpp)$ in benzene and ethanol solutions. The spectra differ remarkably from those of $Mn^{III}Cl(tpp)$, $Fe^{III}Cl(tpp)$, and $Co^{III}Cl(tpp)$ but are very similar to those of usual metallotetraphenylporphyrins such as tetraphenylporphyrinato(2-)zinc(II). This fact suggests that the absorption bands scarcely have a charge-transfer character. In fact, only small difference in the spectra between ethanol and benzene solutions is observed. Both the Q and Soret bands are found to be slightly blue-shifted on going from benzene to ethanol solutions as shown in Fig. 3. This result may be interpreted in terms of general solvent effects on the optical absorption bands.

There have been no reports on the ionic dissociation of $In^{III}Cl(tpp)$ in ethanol solutions. However, we assumed the dissociation of $In^{III}Cl(tpp)$ in ethanol solutions in order to elucidate the electron-transfer reaction from the photoexcited triplet state of $In^{III}Cl(tpp)$ to methylviologen.[16] The electiric conductivity measurements, as will be shown later, confirmed the ionic dissociation:

$$In^{III}Cl(tpp) + 2C_2H_5OH \longrightarrow Cl^- + [In^{III}(tpp)(C_2H_5OH)_2]^+$$

Table 1. Molar conductivities Λ of $Mn^{III}Cl(tpp)$, $Fe^{III}Cl(tpp)$, $Co^{III}Cl(tpp)$, $In^{III}Cl(tpp)$, and $Sn^{IV}(CH_3COO)_2(tpp)$ in ethanol solutions at 25 °C

$Co^{III}Cl(tpp)$	31.64±0.01	82±2	1.42±0.2
$In^{III}Cl(tpp)$	30.71±0.01	282±4	1.14±0.1

where C_2H_5OH molecules in $[In^{III}(tpp)(C_2H_5OH)_2]^+$ are assumed to occupy the axial positions.

The optical absorption spectra of $Sn^{IV}(CH_3COO)_2$-(tpp) in benzene and ethanol solutions are very similar to those of $In^{III}Cl(tpp)$. The peak maxima observed for a benzene solution are located at 1.66×10^4, 1.78×10^4, and 1.93×10^4 cm^{-1} in the Q band region and at 2.34×10^4 cm^{-1} in the Soret band region. When the solution is changed from benzene to ethanol, the Q band peaks are slightly blue-shifted by *ca.* 0.1×10^4 cm^{-1} and the Soret band peak, by *ca.* 0.3×10^4 cm^{-1}. No significant differences in the spectra between the two solutions are observed, indicating that the charge-transfer character in the optical absorption is very weak. The small blue shift of the Q and Soret band observed in ethanol solutions is regarded as being due to the general solvent effects similar to the case of $In^{III}Cl(tpp)$.

Electric Conductivity Measurements. The molar conductivities, Λ, for $Mn^{III}Cl(tpp)$, $Fe^{III}Cl(tpp)$, $Co^{III}Cl(tpp)$, $In^{III}Cl(tpp)$, and $Sn^{IV}(CH_3COO)_2(tpp)$ in ethanol solutions at 25 °C are summarized in Table 1. The Λ values of the former four porphyrins are obtained to be 24—31 S cm^2 mol^{-1} in their concentration range 5×10^{-5}—2×10^{-3} mol dm^{-3}. However, the Λ value of $Sn^{IV}(CH_3COO)_2(tpp)$ is extremely small in comparison with those of the former four porphyrins. Taking account of the limiting molar conductivity of acetate ion in ethanol (λ^∞=17.9 S cm^2 mol^{-1}),[33] we conclude that $Sn^{IV}(CH_3COO)_2(tpp)$ is hardly dissociated in ethanol solutions.

In Table 2 are listed the values of Λ^∞, K_A, and a determined for $Mn^{III}Cl(tpp)$, $Fe^{III}Cl(tpp)$, $Co^{III}Cl$-(tpp), and $In^{III}Cl(tpp)$ in ethanol solutions at 25 °C. The values of Λ^∞ are calculated to be 30—33 S cm^2 mol^{-1}. Since λ^∞_- of Cl^- in ethanol is reported to be 24.3 S cm^2 mol^{-1},[34] the limiting molar conductivities of $[M^{III}(tpp)]^+$ ions (λ^∞_+) are determined to be 8.45, 5.80, 7.34, and 6.41 S cm^2 mol^{-1} for M=Mn, Fe, Co, and In, respectively. The fact that $[M^{III}(tpp)]^+$ gives the λ^∞_+ values smaller than the λ^∞_- value of Cl^- is ascribed to the ion size in solutions: $[M^{III}(tpp)]^+$ has a larger size than Cl^-.

The K_A values obtained for the four metallotetraphenylporphyrins are found to decrease in the sequence $In^{III}Cl(tpp) \gg Fe^{III}Cl(tpp) \cong Co^{III}Cl(tpp) > Mn^{III}Cl(tpp)$. By using K_A values, we can calculate the degree of ionic dissociation, γ, from the equation 3. When $c=10^{-4}$ mol dm^{-3}, the values of γ are obtained to be 0.998, 0.992, 0.993, and 0.970 for $Mn^{III}Cl(tpp)$, $Fe^{III}Cl(tpp)$, $Co^{III}Cl(tpp)$, and $In^{III}Cl$-(tpp) in ethanol solutions, respectively. Since the absorption spectroscopic measurements in the present study were carried out in the concentration range 10^{-5}—10^{-4} mol dm^{-3}, the major species (>90%) in the ethanol solutions of $M^{III}Cl(tpp)$ (M=Mn, Fe, Co, and In) are ascribed to $[M^{III}(tpp)]^+$ produced by the ionic dissociation of $M^{III}Cl(tpp)$. Presumably, $[M^{III}(tpp)]^+$ in ethanol solution has two axial ethanol molecules to be formulated as $[M^{III}(tpp)(C_2H_5OH)_2]^+$.

The mean distance (a_{J_2}) of the closest approach of $[M^{III}(tpp)]^+$ and Cl^- is calculated from J_2 to be 1.1—1.4 nm. These values of the distance are found to be in good agreement with those estimated from the Stokes' law.[38] In comparison with the distance-(0.22—0.24 nm) between the central metal and Cl atom in $M^{III}Cl(tpp)$,[18,35-37] the distance of the closest approach in ethanol solution is very large. It is likely that the solvent sphere around Cl^- and the axial ethanol molecules in $[M^{III}(tpp)(C_2H_5OH)_2]^+$ afford the large value of the distance of the closest approach.

Conclusion

The optical absorption spectra of $M^{III}Cl(tpp)$ (M=Mn, Fe, and Co) in ethanol solutions markedly differ from those in benzene solutions, whereas the spectra of $In^{III}Cl(tpp)$ and $Sn^{IV}(CH_3COO)_2(tpp)$ in ethanol solutions are rather similar to those in benzene solutions. The electric conductivity measurements carried out for the ethanol solutions revealed that $M^{III}Cl(tpp)$ (M=Mn, Fe, Co, and In) undergo ionic dissociation, while $Sn^{IV}(CH_3COO)_2$-(tpp) does not. A marked difference in the absorption spectra between the ethanol and benzene solutions of $M^{III}Cl(tpp)$ (M=Mn, Fe, and Co) is concluded to be caused not only from the ionic dissociation but also from the charge-transfer character of the absorption bands. This conclusion is further supported by the facts that (1) $In^{III}Cl(tpp)$ undergoes ionic dissociation in ethanol without giving rise to substantial difference in the absorption spectra between ethanol and benzene solutions and (2) the absorption spectra of $In^{III}Cl(tpp)$ in ethanol and benzene solutions are very similar to those of $Sn^{IV}(CH_3COO)_2(tpp)$ which is demonstrated to be nondissociative in an ethanol solution.

We thank Professor Reita Tamamushi of Fukushima University for critical reading of the manuscript.

Magnetic-field Effect on the Thermal Decomposition of Dilauroyl Peroxide

Yoshifumi TANIMOTO,* Masato NISHINO, and Michiya ITOH
Faculty of Pharmaceutical Sciences, Kanazawa University, Takara-machi, Kanazawa 920
(Received April 24, 1985)

Synopsis. In the thermal decomposition of dilauroyl peroxide in octane, the yield of docosane increases by 3—6% in the presence of magnetic fields (0.15—1 T). The results are interpreted in terms of a radical-pair model.

Magnetic-field effects on photochemical reactions have been extensively and successfully studied in the last decade.[1,5] On the other hand, there have been few reports on the thermal reactions, since the first observation of the effect on the reaction of pentafluorophenylmethyl chloride with C_4H_9Li in hexane.[2] Recently, though, Imoto and Nomoto[3] studied the magnetic-field effect on the radical polymerization of methyl methacrylate initiated with poly(2-hydroxyethyl methacrylate). In the present paper, we have studied the magnetic-field effect on the thermal decomposition of dilauroyl peroxide in octane. In the presence of magnetic fields (0.15—1 T), the yield of docosane, a cage product, increases by 3—6%. The results are interpreted in terms of a radical-pair model.

Experimental

The octane solution (0.2 ml) of dilauroyl peroxide (0.05 mol dm^{-3}) in a NMR tube was placed in a home-made heat bath at the center of an electromagnet (JASCO, MCD-1BS). The temperature of the bath was kept at 97 °C by circurating ethylene glycol from a thermostat.

The decrease in dilauroyl peroxide was monitored by means of iodometric titration. Its half-lifetime was about 20 min. The reaction time was set at 90 min in order to decompose 96% of the peroxide.

The yields of the three products, docosane, undecane, and 1-undecene, were determined by means of vapor-phase chromatography VPC, using hexadecane as the external standard. Since undecane and 1-undecene showed the same retention time under our VPC conditions, the sum of the yields was measured.

Results and Discussion

In the thermal decomposition of dilauroyl peroxide, the yields of docosane, undecane, and 1-undecene have been reported to be 56, 36, and 9% in octane, and 58, 16, and 4% in *o*-dichlorobenzene, respectively.[4] Since *o*-dichlorobenzene is a radical scavenger, these facts imply that docosane is a cage product, while the larger amounts of undecane and 1-undecene are mainly formed *via* free-radical reactions. Figure 1 shows the magnetic-field dependence of the product yields in the decomposition of dilauroyl peroxide. The yield of docosane increases by 3—6% in the presence of magnetic fields. On the other hand, the yield of the undecane/1-undecene mixture is almost magnetic-field-independent, though the data points are rather scattered. This scattering is because the

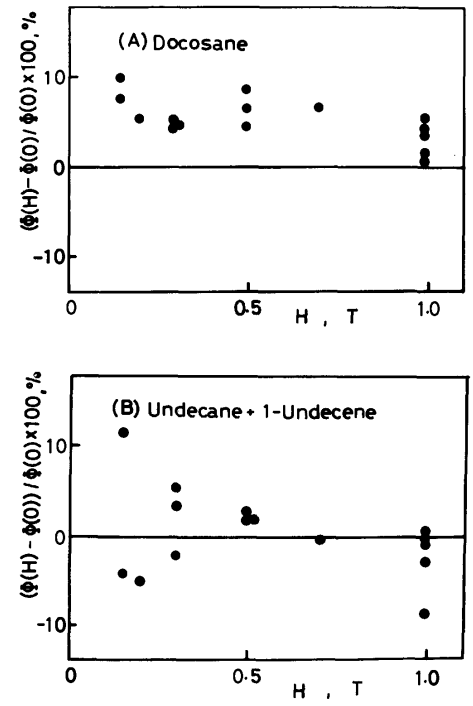

Fig. 1. Magnetic field dependence of the relative yields of (A) docosane and (B) the undecane/1-undecene mixture. Here, $\Phi(0)$ and $\Phi(H)$ represent the yields in the absence and presence of a magnetic field H, respectively.

TABLE 1. MAGETIC-FIELD EFFECT ON THE RELATIVE PRODUCT YIELDS (%) FOR THE THERMAL DECOMPOSITION OF DILAUROYL PEROXIDE AT 1 T

	Isopropyl iodide (mol dm^{-3})	
	0	1.5
Docosane	3.0±2.0	2.9±1.3
Undecane/ 1-undecene	−2.7±2.9	−0.7±3.5
No. of runs	5	11

VPC peak of the mixture appears just after the intense peak of the solvent under our VPC conditions.

To check the influence of a radical scavenger, isopropyl iodide is added into the solution. The VPC peak of the mixture remarkably decreases in intensity, while that of docosane is insensitive to the scavenger. This also implies that docosane and undecane/1-undecene are mostly a cage product and free-radical products respectively. The magnetic-field effects on the product yields in the absence and in the presence of the scavenger are shown in Table 1. The

lack of any significant change in the magnetic-field effect by the scavenger supports the assignment of products presented above.

A proposed mechanism for the present thermal decomposition of dilauroyl peroxide is as follows:

$$C_{11}H_{23}COO_2COC_{11}H_{23} \xrightarrow{\Delta} {}^1(C_{11}H_{23}COO\cdot \cdot OCOC_{11}H_{23}) \quad (1)$$

$${}^1(C_{11}H_{23}COO\cdot \cdot OCOC_{11}H_{23}) \longrightarrow {}^1(C_{11}H_{23}\cdot \cdot C_{11}H_{23}) + 2CO_2 \quad (2)$$

$${}^1(C_{11}H_{23}\cdot \cdot C_{11}H_{23}) \longrightarrow C_{22}H_{46} \quad (3)$$

$${}^1(C_{11}H_{23}\cdot \cdot C_{11}H_{23}) \longrightarrow {}^3(C_{11}H_{23}\cdot \cdot C_{11}H_{23}) \quad (4)$$

$${}^{1,3}(C_{11}H_{23}\cdot \cdot C_{11}H_{23}) \longrightarrow 2C_{11}H_{23}\cdot \quad (5)$$

$$2C_{11}H_{23}\cdot \longrightarrow C_{11}H_{24} + CH_2{=}CH(CH_2)_8CH_3 \quad (6)$$

The initial step in the reaction is the homolysis of the oxygen–oxygen bond to generate a singlet radical pair of the lauroyloxyl radicals, (1). The decarboxylation of the lauroyloxyl radical, (2), is probably a very rapid process, since no appreciable amount of undecyl laurate, the product to be expected from the reaction of the radical, is detected.[4] The decarboxylation of lauroyloxyl radicals generates a singlet pair of the undecyl radicals. From the singlet radical pair, there are three processes; *i.e.*, a recombination into docosane, a cage product (3), an intersystem crossing to the triplet radical pair (4), and a diffusive separation into free radicals (5). The singlet-triplet intersystem crossing of the undecyl radical pair occurs *via* electron-nuclear hyperfine interaction. The rate is reduced in the presence of an external magnetic field because of the Zeeman splitting of the triplet sublevels (hfc mechanism). Therefore, this reduction in the intersystem-crossing rate leads to an increase in the yield of docosane, the cage product, in magnetic fields. Although an external magnetic field is also expected to decrease the yield of the free-radical products, the undecane/1-undecene mixture, this decrease is not so clear as that of the cage product because of the experimental error.

In the singlet-sensitized photolysis of dibenzoyl peroxide,[5] phenyl benzoate is detected as a cage product, and its magnetic-field effect (an 8% decrease at 4.3 T) is interpreted in terms of the Δg mechanism, in which the singlet-triplet intersystem crossing of the benzoyloxyl-phenyl radical pair is enhanced because of the difference in the g values of the component radicals. In the present reaction, the yield of docosane increases in the presence of relatively weak magnetic fields (0.15—1 T). Therefore, the magnetic-field effect observed here is mostly attributable to that on the undecyl radical pair by the hfc mechanism. The difference between dibenzoyl peroxide and dilauroyl peroxide reactions might be attributable to that in the decarboxylation rate of the intermediate radicals.

Viscosity *B* Coefficients for Polymethylenebis(trimethylammonium) Dibromides in Aqueous Solutions

Kunio TAMAKI* and Akifumi FUJIWARA
Department of Chemistry, Yokohama City University, Kanazawa-ku, Yokohama 236
(Received May 16, 1985)

Synopsis. The viscosity *B* coefficients of the Jones-Dole equation for *N,N'*-polymethylenebis(trimethylammonium) dibromides $[(CH_3)_3N(CH_2)_nN(CH_3)_3]Br_2$ (n=3—8, 10, and 12) and for comparison for alkyltrimethylammonium bromides $C_nH_{2n+1}N(CH_3)_3Br$ (n=2—6) in aqueous solutions at 25 and 35 ° have been determined, and the effect of structural changes in the solvent water upon the dissolution of both series of electrolytes is discussed.

In a previous paper,[1] the balance of ionic hydration and hydrophobic hydration in aqueous solutions of *N,N'*-polymethylenebis(trimethylammonium) dibromides ($[(CH_3)_3N(CH_2)_nN(CH_3)_3]Br_2$, which will be abbreviated as, MeC_nMe) were discussed on the basis of the changes in the heat capacity upon dissolution in water. In this paper, an experimental study of the viscosity *B* coefficients for a series of MeC_nMe and, for comparison, for a series of alkyltrimethylammonium bromides ($C_nH_{2n+1}N(CH_3)_3Br$, which will be abbreviated as C_nMe) in aqueous solutions will be reported.

Experimental

MeC_nMe except for MeC_7Me and C_nMe were the same samples as those described in a previous paper.[1] MeC_7Me was prepared by the reaction of 1,7-dibromoheptane with an excess of trimethylamine in ethanol, and was purified several times by recrytallization from ethanol. Water was triply distilled.

The viscosities were measured at 25 and 35 °C with an automatic viscometer of the Shibayama Scientific Co., Ltd. The densities were measured using a vibrating-tube densimeter, twin-type SS-D-200 of the Shibayama Scientific Co., Ltd. The detailed procedure was described in a previous paper.[2] The electrical conductivities were measured with a Yokogawa audio-frequency bridge using a frequency of 1000 Hz.

Results and Discussion

The Viscosity B *Coefficients of Electrolytes.* The viscosity of an aqueous solution of an electrolyte, η, can be represented by the Jones-Dole equation:

$$\eta=\eta_0(1+Ac^{1/2}+Bc) \quad (1)$$

where η_0 is the viscosity of water, c is the molar concentration, A is a constant related to the ion-ion interaction, and B is the viscosity *B* coefficient. The constant A was interpreted theoretically by Falkenhagen and Vernon,[3] and can be calculated using the data of the limiting equivalent conductivities of the salt, cation, and anion. Equation 1 may be converted to,

$$\eta/\eta_0-1-Ac^{1/2}=Bc \quad (2)$$

When the left-hand side of Eq. 1, using the calculated values of A, is plotted against c, the viscosity *B* coefficient is obtained as the slope of a linear line. Figures 1 and 2 show the results of plotting Eq. 2 for MeC_nMe and C_nMe respectively. The values of A and B for both series of compounds are summarized in Table 1. The *B* values for C_2Me, C_4Me, and C_6Me are in reasonable agreement with the values reported by Tanaka *et al.*[4] The *B* values for both series of compounds increase approximately linearly with the number of carbon atoms in the polymethylene or alkyl group, n.

The temperature dependence of the *B* values is a factor of the solute-solvent interaction; the *B* values increase with the temperature for a solvent-structure-breaking salt, and decrease with temperature for a solvent-structure-making solute.[5] For the MeC_nMe series, it may be seen in Table 1 that the *B* values for MeC_3Me and MeC_4Me increase as the temperature is

raised from 25 to 35 °C, and these salts may therefore be considered to behave as structure-breaking salts in the water phase. The B values of MeC_6Me are insensitive to the temperature. With MeC_7Me and higher homologs, the B values decrease with an increase in the temperature, therefore these salts exhibit a water-structure-making-effect. It was noted in previous work[1] on the change of heat capacity upon dissolution that MeC_6Me exhibited a slight tendency to behave as a structure-making solute. The classification of the behavior of a salt in water is somewhat dependent on the experimental method adopted.

With the C_nMe series, viscometric studies of tetramethylammonium bromide $(CH_3)_4NBr$, abbreviated as C_1Me in this paper, have been reported by several investigators, and the results by Out and Los[6] are included in Table 1. The B values for C_1Me increase with the temperature; this salt may be considered to act as a structure-breaking salt. The B values of C_2Me are insensitive to the temperature, and it seems to be a borderline salt. The B values for C_3Me and the higher homologs decrease with the temperature, and they are to be classified as hydrophobic structure-makers.

Figure 3 shows the changes in the viscosity B coefficients which occur as the temperature is raised from 25 to 35 °C, ΔB, as a function of n for MeC_nMe and C_nMe. If we take one-half the values of ΔB for

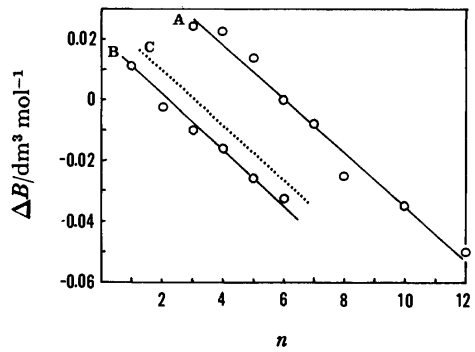

Fig. 3. Plots of ΔB aganist n. A, MeC_nMe; B, C_nMe; C, $-(CH_2)_nN(CH_3)_3Br$.

MeC_nMe, the values of ΔB for a series of $-(CH_2)_nN\cdot(CH_3)_3Br$ can be estimated. The ΔB *vs.* n relation thus obtained is plotted as a dotted line in Fig. 3. It is found that, for the same number of n, the values of ΔB for $-(CH_2)_nN(CH_3)_3Br$ are higher than those of ΔB for C_nMe. This fact indicates that the hydrophobic character of the polymethylene chain in MeC_nMe is considerably diminished as compared with that of the alkyl chain in C_nMe with the same number of n.

The Viscosity B Coefficients of Ions. The B values of electrolytes are determined by adding the individual contributions of the ions. Out and Los[6] reported the ionic B values of the Br^- ion as a function of temperature according to the convention of Gurney[7] that the ionic B values for K^+ and Cl^- ions are equal. The ionic B values of Br^- ion[6] are -0.040 and $-0.026\ dm^3\ mol^{-1}$ at 25 and 35 °C, respectively. The B values of organic ions obtained are included in Table 1. With the MeC_nMe^{2+} series, the ionic B values of MeC_3Me^{2+} and MeC_4Me^{2+} ions vary little with temperature. The ionic B values of MeC_5Me^{2+} and the higher homologous ions decrease with the temperature, so they are classified as structure-making ions. With the C_nMe series, the ionic B values of C_1Me^+ are practically constant between 25 and 35 °C. The B values of C_2Me^+ and the higher homologous ions decrease with the temperature, so they are classified as structure-making ions.

Formation of α-Methylstyrene Dimer Radical Cations *via* Molecular Aggregates Studied by Pulse Radiolysis

Yukio YAMAMOTO,* Yukio CHIKAI, and Koichiro HAYASHI
The Institute of Scientific and Industrial Research, Osaka University, 8-1 Mihogaoka, Ibaraki, Osaka 567
(Received May 30, 1985)

Synopsis. Pulse radiolysis of α-methylstyrene was carried out in 1,2-dichloroethane, and the effect of additives on the formation of the dimer radical cations was investigated. In the presence of excess amounts of hexenes and biphenyl, the dimer radical cations are suggested to be formed *via* molecular aggregates by charge-transfer reactions.

The initiation processes of the radiation-induced cationic polymerization of styrene derivatives have been studied by pulse radiolysis methods.[1-4] Monomer and dimer radical cations and propagating cations have been detected as transient species responsible for the cationic polymerization. The monomer radical cations are quite short-lived, and the mechanistic details have been obtained by the pulse radiolysis at low temperature, −165 °C, in a mixture of isopentane and butyl chloride.[3] The following reaction scheme has been proposed for styrene and α-methylstyrene (MS):

$$\text{S(solvent)} \rightsquigarrow S^+ + e \quad (1)$$

$$S^+ + \text{M(monomer)} \longrightarrow S + M^+ \quad (2)$$

$$S^+ + M_2 \longrightarrow S + (M_2)^+ \quad (3)$$

$$S^+ + M_2 \longrightarrow S + M\text{-}M^+ \quad (4)$$

$$M^+ + M \rightleftharpoons (M_2)^+ \quad (5)$$

$$M^+ + M \longrightarrow M\text{-}M^+ \quad (6)$$

$$(M_2)^+ \longrightarrow M\text{-}M^+ \quad (7)$$

$$M\text{-}M^+ + M \longrightarrow \cdot M\text{-}M\text{-}M^+ \quad (8)$$

where $M\text{-}M^+$ and $(M_2)^+$ are the bonded and associated dimer radical cations, respectively. The formation of the dimer radical cations *via* molecular aggregates, M_2, has been proposed to account for their rapid formation during pulse irradiation.[2,3] The existence of the molecular aggregates, however, has been ruled out by another research group.[4] In the present study, the pulse radiolysis of MS was carried out in 1,2-dichloroethane at room temperature (*ca.* 22 °C) by using 8 ns electron pulses. The effect of additives on the formation of the dimer radical cations was examined in order to investigate the contribution of such neutral molecular aggregates.

Experimental

MS and 1,2-dichloroethane (Wako Chemicals) were successively washed three times with an aqueous solution of NaOH and with distilled water and then distilled over CaH_2. The middle fractions were stored under vacuum over CaH_2. Cyclohexene and 1-hexene (Wako Chemicals) were distilled over CaH_2 and stored under vacuum. Zone-refined biphenyl (BP) (Tokyo Kasei) was used without further purification. Bu_4NPF_6 (Bu, butyl) was prepared from Bu_4NBr and KPF_6 and twice recrystallized from a water-methanol mixture. The samples for the pulse radiolysis were prepared in a high vacuum operation and sealed into Suprasil cells of 10-mm optical path length. The pulse radiolysis techniques employed in this laboratory have been described elsewhere.[5]

Results and Discussion

The transient absorption spectra of MS in 1,2-dichloroethane are shown in Fig. 1. According to the literature,[3] the absorption band at 470 nm is assigned to the bonded dimer radical cations, although the possibility of a contribution of another type of dimer radical cations, associated ones, to the absorption still remains.[2] In this paper, the dimer radical cations having the 470-nm band are tentatively represented by $M\text{-}M^+$, and their formation processes are discussed.

At the higher concentration, 0.1 mol dm^{-3} (Fig. 1 (A)), the formation of $M\text{-}M^+$ seems to be almost completed within the pulse duration, 8 ns, and the 470-nm band decreases as a function of time. The absorption bands at 350 and 690 nm assigned to the monomer radical cations, M^+, are negligible even at the end of the pulse. The absorption below 400 nm with a relatively slow decay rate is attributed to

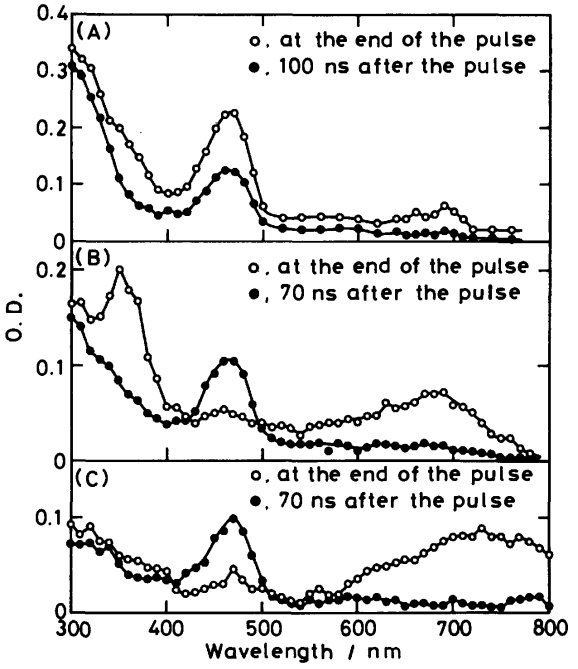

Fig. 1. Transient absorption spectra of MS solutions: (A) [MS]=0.1 mol dm^{-3}; (B) [MS]=0.01 mol dm^{-3}; and (C) [MS]=0.01 mol dm^{-3} in the presence of 0.5 mol dm^{-3} cyclohexene.

radical species such as benzyl-type radicals. The formation of the associated dimer radical cations having absorption bands at 620 and 1600 nm seems to be less important at room temperature than at −165 °C.[3]

At the low MS concentration, 0.01 mol dm^{-3} (Fig. 1 (B)), a rapid decay of the absorption due to M^+ can be seen, and the 470-nm band increases after the pulse. The absorption of M-M^+ attained a maximum at 70 ns. The effect of Bu_4NPF_6 was examined in order to establish the formation of M-M^+ from M^+. As has been reported,[6,7] the addition of Bu_4NPF_6 results in the stabilization of radical cations toward neutralization through ion-pair formation. When 5×10^{-3} mol dm^{-3} Bu_4NPF_6 was added to the 0.01 mol dm^{-3} MS solution, the formation of M-M^+ was enhanced, and the decay of M^+ became slightly slower. Therefore, the enhancement of the M-M^+ formation is attributable to the stabilization of M^+ toward neutralization with Cl^-, the product of dissociative electron capture by the solvent. That is to say, the growth of the 470-nm band is a result of the reaction of M^+ taking place in competition with the neutralization.

In the 0.01 mol dm^{-3} MS solution containing 0.5 mol dm^{-3} cyclohexene (Fig. 1 (C)), the 470-nm band increases after the pulse similarly to that in the solution not containing cyclohexene. However, no absorption peak is observed at 350 nm. The result can be explained by assuming that M-M^+ is formed *via* the MS molecular aggregates by the charge-transfer reaction probably from the cyclohexene dimer radical cations.[8] A similar result was obtained for the 0.01 mol dm^{-3} MS solution containing 0.5 mol dm^{-3} 1-hexene.

When 0.1 mol dm^{-3} BP was added to the 0.01 mol dm^{-3} MS solution, the transient absorption spectrum obtained at the end of the pulse was similar to that of the BP solution not containing MS. The absorption bands at 370 and 680 nm are assigned to BP^+, although the former band includes the absorption by the triplet excited state of BP. As the absorption of BP^+ decayed, the 470-nm band appeared, whereas no absorption peak due to M^+ was observed at any stage after the pulse. It was demonstrated that the decay of BP^+ is accelerated in the presence of added MS resulting in the direct formation of M-M^+. The result may be explained by the occurrence of the charge-transfer from BP^+ to the MS molecular aggregates.

From the results presented above, it seems likely that the MS molecular aggregates exist and contribute to the formation of M-M^+. Clearly further investigation is required to reveal the nature of the molecular aggregates.

(Received May 30, 1985)

Synopsis. Olefin hydrogenation was carried out over ZSM-5 type zeolite catalysts modified with various alkaline earth metals. It was found that the catalytic activity of H-ZSM-5 for the olefin hydrogenation decreases upon such a modification.

Several papers have claimed that alumina, silica-alumina gels, and crystalline aluminosilicates (mordenite) are effective for the hydrogenation of ethylenic double bonds.[1-5] Recently, our previous communications have dealt with the conversion of the synthesis gas to hydrocarbons in a two-stage system consisting of a methanol synthesis reactor, followed by a hydrocarbon-forming reactor containing H-ZSM-5 zeolite. It has also been shown that the H-ZSM-5 zeolite catalyst is active for olefin hydrogenation.[6,7]

In this paper, it will be shown that the activity of the H- ZSM-5 zeolite catalyst in the olefin hydrogenation decreases when it is modified with alkaline earth metals.

Experimental

The H-ZSM-5 catalysts modified with alkaline earth metals were synthesized hydrothermally from ZSM-5 zeolite in the presence of alkaline earth metal acetates. Crystallization was carried out in a 300 ml stainless steel autoclave at 150—160 °C for 15—24 h. The precipitate was filtered off, washed thoroughly with distilled water, and calcined at 500 °C for 15 h in order to remove an organic base. It was then protonated in a hydrochloric acid solution of 1 M (1 M=1 mol dm^{-3}) and calcined in air at 500 °C for 6 h. Some analytical data are given in Table 1. The synthetic alkaline earth metal-modified ZSM-5 catalyst had a well defined ZSM-5 type structure, as demonstrated by the X-ray powder diffraction pattern.

The silicalite and silica gel used were prepared as follows. The silicalite was synthesized from tetraethoxysilane in the method described above. The silica gel was obtained by the hydrolysis of tetraethoxysilane. The precipitate was filtered off, dried at 100 °C, and then calcined at 500 °C for 10 h.

TABLE 1. PREPARATION OF VARIOUS ALKALINE EARTH METAL-MODIFIED H-ZSM-5 TYPE ZEOLITE CATALYSTS

Hydrogenation was carried out at 400 °C and at a space velocity (SV) of 5000 h^{-1} under 40 kg cm^{-2}, using a high-pressure fixed-bed system. The reaction gas was composed of 2.5 mol% C_2H_4 (or C_3H_6), 50 mol% H_2, and 47.5 mol% Ar. The catalyst was packed into a quartz tube reactor, which was set in the pressure vessel. The effluent gas was led directly to sampling valves of a Yanaco AG-1000TFH auto gas chromatograph for analysis. The ethylene (or propylene)-based yields of the products were calculated by using argon as the internal standard.

The temperature programmed desorption (TPD) spectra of NH_3 over various catalysts were measured using a conventional TPD apparatus. The measurement was done from 100 °C to 600 °C with a heating rate of 5 °C min^{-1} and with nitrogen as the carrier gas (flow rate, 100 ml min^{-1}). The catalyst charged was 0.30 g.

Results and Discussion

Figure 1 shows some typical results for the hydrogenation of ethylene or propylene over various alkaline earth metal-modified ZSM-5 catalysts. The shaded parts in Fig. 1 indicate C_2 to C_5 olefins. Products both lower and higher in molecular weight were formed through a variety of reactions, such as polymerization, isomerization, cracking, and hydrogenation. The yields of light olefins and higher-carbon-number hydrocarbons (C_6^+) increased in the following order: H-ZSM-5≈Mg-H-ZSM-5<Ca-H-ZSM-5<Sr-H-ZSM-5<Ba-H-ZSM-5. In the case of the C_2H_4 (or C_3H_6)-H_2 system over these catalysts, hardly no aromatic hydrocarbons(BTX) were obtained as compared with those obtained in the C_2H_4 (or C_3H_6)-He system over the H-ZSM-5 catalyst (self-hydrogenation). In addition, the hydrogenation of these olefins was carried out over silicalite and silica gel of a very high purity. However, these olefins were hardly hydrogenated at all over these catalysts.

The TPD spectra of H-ZSM-5 zeolite exhibited two peaks, whose temperatures at the peak maximum were about 170 and 450 °C. By the addition of alkaline earth metals, the amount of desorbed NH_3 above 350 °C, which corresponded to that of the second peak, of various catalysts decreased in the following order: H-ZSM-5>Ca-H-ZSM-5>Mg-H-ZSM-5>Sr-H-ZSM-5>Ba-H-ZSM-5. In Fig. 2 are plotted the molar ratios of the C_2 to C_5 paraffins (C_2^-—C_5^-) to the C_2 to C_5 olefins ($C_2^=$—$C_5^=$) over these catalysts (given in Fig. 1) against the normalized amount of desorbed NH_3 [based on that of H-ZSM-5]. Except for Mg-H-ZSM-5, the (C_2^-—C_5^-)/($C_2^=$—$C_5^=$) molar ratio decreased as the amount of

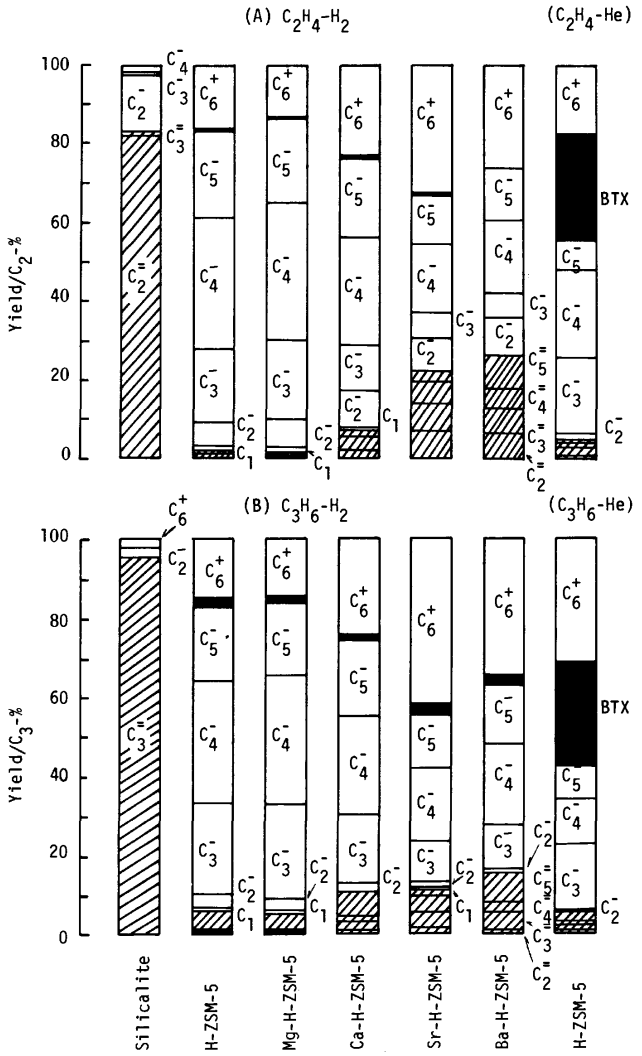

Fig. 1. Olefin hydrogenation over ZSM-5 type zeolite catalysts modified with various alkaline earth metals. Reaction conditions: $P=40$ kg cm^{-2}, $T=400$ °C, SV $=5000$ h^{-1}
Shaded parts indicate C_2 to C_5 olefins.

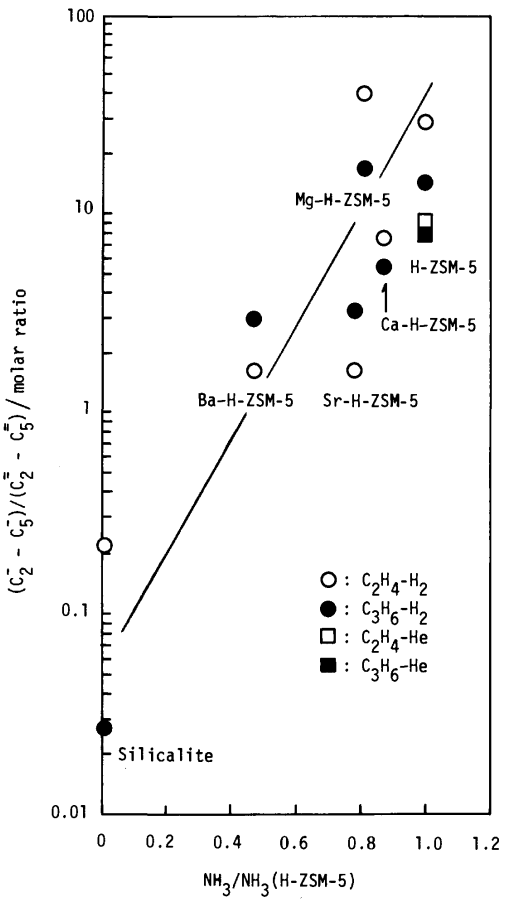

Fig. 2. Relation between the $(C_2^-—C_5^-)/(C_2^=—C_5^=)$ molar ratio and the amount of desorbed NH_3 of various catalysts. $(C_2^-—C_5^-)$:C_2 to C_5 paraffins, $(C_2^=—C_5^=)$: C_2 to C_5 olefins.

desorbed NH_3 decreased, namely, the basicity of alkaline earth metal increased. The temperature at the peak maximum of the second peak of the Mg-H-ZSM-5 catalyst hardly differed from that of H-ZSM-5.

Moreover, the impurities presented in the H-ZSM-5 zeolite were carefully analyzed by means of X-ray fluoresence spectrometry and inductively coupled argon plasma emission spectrometry. Only a trace amount of Fe (0.0065 wt%) was detected. The other metals were far below the detection limit of the inductively coupled argon plasma emission spectroscope (Shimadzu ICPS-50).

From these results, it can be concluded that the olefins are hydrogenated on the acidic sites of the H-ZSM-5 zeolite catalyst and that this hydrogenation activity decreases upon modification with alkaline earth metals.

The increase in the C_6^+ yield over the catalyst modified with alkaline earth metals may be attributed to the occurrence of the other reactions, such as polymerization, isomerization, and cracking, which take place in preference to the hydrogenation.

The limited data of the present work can not serve to clarify the detailed mechanism of this alternation of the acid property in zeolites.

This work is a part of the "C_1 Chemistry Project," a National Research and Development Program of the Agency of Industrial Science and Technology, Ministry of International Trade and Industry (M.I.T.I.), Japan.

Preparation of (L-Cysteinato)(L- or D-histidinato)chromium(III) Complex

Yoshio ODAKA, Yuichi HASEGAWA, and Masatoshi WATABE*
General Education Department, Kogakuin University, Hachioji, Tokyo 192
(Received March 29, 1985)

Synopsis. Mixed-ligand chromium(III) complexes of the form [Cr(L-cys)(L-or D-his)] (L-cys=L-cysteinate and L-his=L-histidinate anions) were prepared. Isolated isomers of each complex were assigned structures on the basis of their high-speed liquid chromatograms and the distribution of the isomers.

Recently we have reported the preparation and stereochemistry of L- or D-aspartato(L-histidinato)-chromium(III) and bis(aspartato)chromate(III) complexes.[1] Hoggard prepared two of three isomers of the bis(L-histidinato)chromium(III) complex,[2] and Meester *et al.* prepared only one of three isomers of the bis(L-cysteinato)chromate(III) complex, the structure of which was determined as a trans sulfur isomer by X-ray crystallography.[3] Here, we report the preparation, chromatography, and absorption spectra of the chromium(III) complexes containing D- or L-his and L-cys.

Experimental

Preparations of [Cr(L-cys)(L- or D-his)] L-histidine (0.01 mol) and L-cysteine(0.01 mol) were dissolved in 80 cm^3 of water heated on a steam bath. The solution was added to an aqueous solution (60 cm^3) containing $Cr(NO_3)_3 \cdot 9H_2O$ (0.01 mol 4.00 g). After the mixture was heated for 10 min on the steam bath, the pH of the solution was adjusted to 7 with a 1-mol dm^{-3} NaOH solution. The solution was heated for 30 min, evaporated to 30—40 cm^3 and then loaded onto a column (50×500 mm) of QAE Sephadex A-25 anion resin in a chloride form. The column was kept at about 0 °C by circulating ethylene glycol-water. Three bands descended, the first was cations and the second and the third were neutral species corresponding to two isomers of the desired complex which were called A1 and A2, respecively. These two eluates were frozen as quickly as possible and evaporated at 0 °C. Two isomers of [Cr(L-cys)(D-his)] were obtaind by a similar method using D-histidine instead of L-histidine and were called B1 and B2 in the order of the elution in chromatography. As the two isomers in each D- and L-his complex easily isomerize to each other, they should be dissolved in ice-water. Anal. Calcd for $CrC_9H_{13}N_4O_4S \cdot H_2O$: C, 31.52; H, 4.40; N, 16.33%. Found (A1): C,31.01 H,3.95; N, 15.99%. Found (B1): C,31.32; H, 4.21; N, 16.15%. Calcd for $CrC_9H_{13}N_4O_4S \cdot 2H_2O$: C, 29.94; H, 4.74; N, 15.52%. Found (A2): C, 29.44; H, 4.94; N, 14.93%. Found (B2): C, 29.84; H, 5.12; N, 15.21%.

Measurements. The electronic absorption spectra were measured with a JASCO 505 spectrophotometer. The complexes were dissolved in water at 0 °C. The cell was treated with ethyleneglycol to prevent it from becoming wet with dew. The chromium content was determined with an atomic absorption photometer(Nippon Jarrel-Ash AA-845). Chromatographic separation was carried out with a JASCO-LCP-350. A 300×4 mm column containing a QAE Sephadex A-25 anion resin in a chloride form was used. The complexes were eluted with water at a flow rate of 0.1 cm^3 min^{-1} at a pressure of 40 kg cm^{-2}.

Results and Discussion

Figure 1 shows the six possible isomers of [Cr(L-cys)(L- or D-his)]. These isomers are denoted as L- or D-series with respect to the his ligand used and called L(or D)-*trans*(NNi), L(or D)-*trans*(NN), and L(or D)-*trans*(NO), where the left side N in parenthesis indicates that the nitrogen of cysteine and the following Ni, N, and O stand for the imidazole nitrogen, the nitrogen, and the oxygen atoms of coordinated histidine. Figure 2 shows high-speed liquid chromatograms of A1 and A2 together with that for [Cr(L-asp)(L-his)][1a](isomers CL1 and CL2) since the tridentate cysteinate coordinates with N,O,S atoms and the aspartate with N,O,O atoms so that the geometry and spectral behavior are expected to be similar in both complexes. The "a" in Fig. 2 represents a marker. Since all isomers of [Cr(L-cys)(L- or D-his)] isomerize in water at room temperature, the chromatograms in Fig. 2 show two peaks. Peak b corresponds to isomer A1 and peak c to isomer A2. These were determined by observing the time dependence of the peak heights. The same situation occurs in the chromatogram of [Cr(L-cys)(D-his)]. The peak of A1 appears a little later than that of CL1 and A2 elutes a little faster than CL3 of [Cr(L-asp)-(L-his)].

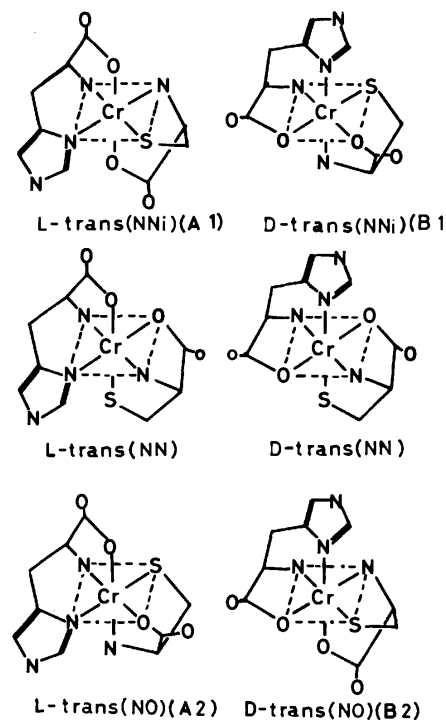

Fig. 1. The six possible isomers of [Cr(L-cys)(L- or D-his)], The isomers obtained are shown in parenthesis.

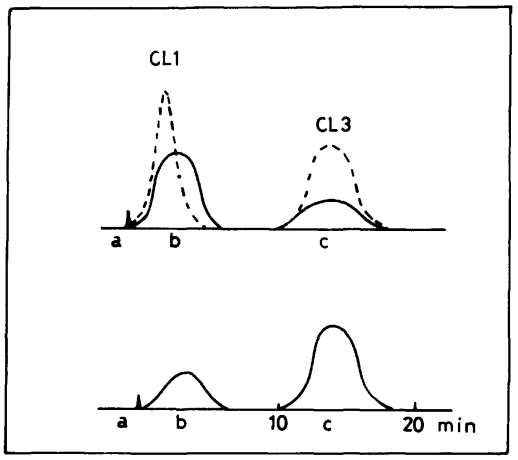

Fig. 2. High-speed liquid chromatograms indicating a mixture of [Cr(L-cys)(L- or D-his)] together with that of [Cr(L-asp)(L-his)]. Upper; from Al, lower; from A2. CL1 (*trans* (NNi)), CL2 (*trans* (NN)), and CL3 (*trans* (NO)) are the prepared isomers of [Cr (L-asp) (L-his)] in the order of elution.

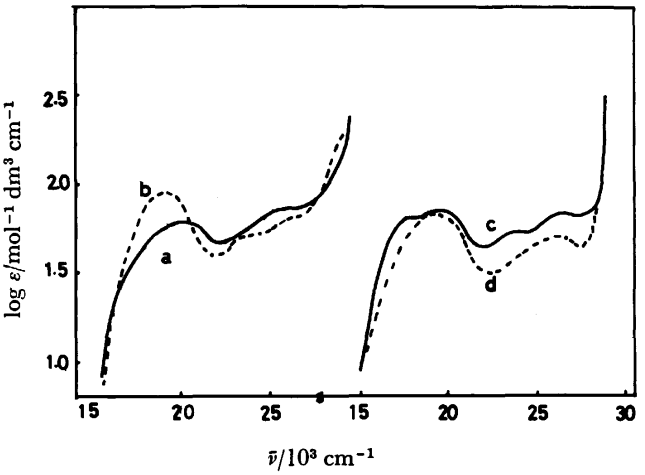

Fig. 3. Visible absorption spectra of [Cr(L-cys)(L- or D-his)]: Left a: Al and b: A2; right c: Bl and d: B2.

Though there are small differences in the peak positions, isomer Al can be assigned as L-*trans*(NNi) or L-*trans*(NN) and isomer A2 as L-*trans*(NO) by taking into consideration that the value of the dipole moment of the [Cr(L-cys)(L-his)] complex may be similar to that of [Cr(L- or D-asp)(L-his)]. In the same way, isomer Bl can be assigned as D-*trans*(NNi) or D-*trans*(NN) and isomer B2 as D-*trans*(NO). Figure 3 shows the visible absorption spectra of [Cr(L-cys)(L-or D-his)]. There are some peaks in the visible absorption spectra of [Cr(L-cys)(L-or D-his)] in both the first and second absorption band regions. Thioether complexes did not show any charge-transfer absorption[4] in the first and second absorption band regions. We tried to change the thiolate complex to a thioether complex by adding dimethyl sulfate. However, it was uncertain whether they were due to a d-d transition or a sulfite charge transfer since the thiolate complex could not be changed quantitatively to a thioether complex by adding dimethyl sulfate. Some infomation was, nevertheless, obtained; the band widths of isomers A2 and B2 in the first absorption band region were narrower than those of isomers Al and Bl, which indicates that A2 and B2 have a *trans*(NO) configuration (facial geometry when CrN_3O_3 type).

It is necessary to assign the first eluted isomers (Al and Bl). We have prepared mixed-ligand type, $[Co(N)_3(O)_3]$ and $[Cr(N)_3(O)_3]$, complexes containing two different tridentate ligands, such as [Co(L- or D-asp)(L-his)] and [Cr(L- or D-asp)(L-his)]. In all cases, the yields of the *trans*(NN) isomers were the lowest of all the possible isomers. In general, yields of isomers are dependent on the steric repulsion between ligands and on the electronic effect, such as the trans effect of a sulfur atom in chromium(III) complexes. We tentatively assigned Al as L-*trans*(NNi), A2 L-*trans*(NO), Bl D-*trans*(NNi) and B2 D-*trans*(NO). Though the isomerization of the complexes in solution could not be studied, it is interesting to note that the isomers of [Cr(L-cys)(L-or D-his)] isomerize in water at temperatures greater than 5 °C, when we consider the role of chromium(III) complexes containing cysteine in biological reactions.[6,7]

The Electrochemical Cleavage of Carbon-Halogen Bonds of Haloferrocenes

Tetsuo SAJI* and Naoyuki ITO
Department of Chemical Engineering, Tokyo Institute of Technology, Ohokayama, Meguro-ku, Tokyo 152
(Received June 8, 1985)

Synopsis. The cyclic voltammetric studies for haloferrocenes, FcX (X=Cl, Br, and I), in etylene glycol dimethyl ether at −45 °C have been reported. The cyclic voltammogram and the absorption spectrum of the solution after the exhaustive controlled-potential reduction for the reduction step of haloferrocene show a quantitative formation of ferrocene and a cleavage of the carbon-halogen bond of haloferrocene.

A vast amount of information regarding the organic chemistry of ferrocene (FcH) has been reported since its discovery.[1] The chemistry of ferrocene is similar to that of aromatic hydrocarbons. For example, ferrocene very readily undergoes Fridel-Craft acylation, alkylation, metalation by butyllithium.

It is known that FcH and its derivatives can be oxidized to ferrocenium cation (FcH^+) electrochemically as well as chemically.[2] On the other hand, Mugnier *et al.* and we ourselves have reported that ferrocene can be reduced quasireversibly in etylene glycol dimethyl ether (DMeE) at −45 °C, and that a stable ferrocene anion (FcH^-) exists for a few minutes.[3,4] Only a few cases of the electrochemical reduction of ferrocene dirivatives have been reported.[5] Such electron-rich anions are interesting in their reactivity.[6] The present note will deal with voltammetric and controlled-potential electrolytic studies of haloferrocenes undertaken in order to examine the mechanism of the reduction process.

Experimental

Iodoferrocene (FcI) was prepared by the reaction of (chloromercurio) ferrocene with iodine.[6] Chloroferrocene (FcCl) and bromoferrocene (FcBr) were prepared by the halogen-exchange reaction of FcI with copper(I) salts.[7] These complexes were purified by sublimation and identified on the basis of their melting points and elemental analyses on C, H, N, and halogen. The preparation of the test solutions and the procedures for the electrochemical measurements has been described previously.[4] Chloroferrocene: mp 56—56.5 °C (lit,[7] 56—56.5 °C). Found: C, 53.85; H, 4.04; N, 0.00, Cl, 16.78%. Calcd for $C_{10}H_9ClFe$: C, 54.47; H, 4.11; N, 0.00; Cl, 16.08%. Bromoferrocene: mp 30.5—31 °C (lit,[9] 30—31 °C). Found: C, 44.84; H, 3.32; N, 0.00; Br, 31.78%. Calcd for $C_{10}H_9BrFe$: C, 45.33; H, 3.42; N, 0.00; Br, 30.16%. Iodoferrocene: mp 48—49 °C (lit,[10] 49—49.5 °C). Found: C, 38.40; H, 2.84; N, 0.00; I, 41.23. Calcd for $C_{10}H_9IFe$:C, 38.50; H, 2.91; N, 0.00; I, 40.68%.

Results and Discussion

Figure 1 shows a cyclic voltammogram for 0.6 mM (mmol dm^{-3}) of FcCl in 0.2 M tetrabutylammonium perchlorate (TBAP) in DMeE, recorded at −45 °C with a scan rate of 0.2 V s^{-1}. It exhibits one reversible one-electron step at +0.04 V *vs.* Ag/$AgNO_3$(sat.), and two reduction steps at −3.35 V (reduction peak potential, E_{pc}) and −3.56 V, where potentials are indicated in terms of the potential at the midpoint between the cathodic peak potential (E_{pc}) and the anodic one (E_{pa}), $(E_{pa}+E_{pc})/2$, except for the case of the first reduction step. The reversal current peak of the step at −3.35 V can not be observed, even with a scan rate of 2 V s^{-1}. The step at −3.56 V was quasireversible. After the cathodic sweep was reversed at a potential less than the first reduction step, a small reversible one-electron oxidation step appeared at −0.13 V (Fig. 1-b). The half-wave potentials and the reversibilities of the second reduction and small oxidation steps were the same as those for the reduction and oxidation steps of FcH under the same conditions (Table 1). At room temperature, the first reduction step was observed at −3.28 V (E_{pc}), but the second reduction step was masked by the ultimate current rise. Similar voltammograms were obtained for FcBr and FcI. Table 1 lists the voltammetric results of these compounds. The first reduction peak potentials become more positive in the order of substituents, I>Br>Cl. This order agrees with that of the reactivities of haloferrocenes for photosubstitution.[11]

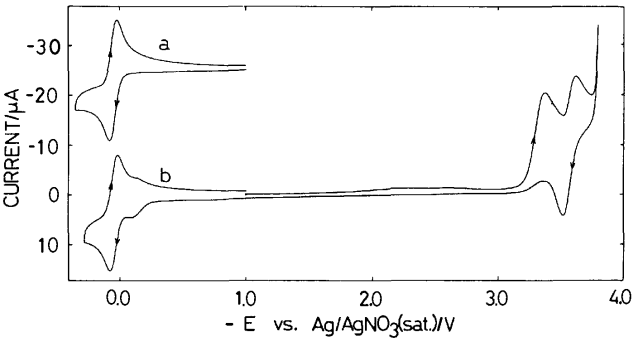

Fig. 1. Cyclic voltammogram of 0.6 mM chloroferrocene in 0.2 M TBAP-DMeE at −45 °C. Scan rate 0.2 V s^{-1}.

TABLE 1. THE VOLTAMMETRIC DATA OF CHLORO-, BROMO-, AND IODO- FERROCENES IN 0.2 M TBAP-DMeE AT −45 °C. SCAN RATE: 0.2 V s^{-1}

Compound	$E_{1/2}^{ox}$ a,b	$E_{1/2}^{ox}$ a,c	E_p^{red} a,d	$E_{1/2}^{red}$ a,e
Chloroferrocene	+0.04	−0.13	−3.35	−3.56
Bromoferrocene	+0.03	−0.13	−3.29	−3.57
Iodoferrocene	+0.01	−0.13	−3.23	−3.57
Ferrocene		−0.13		−3.58

a) *Vs.* Ag/$AgNO_3$(sat.) in V. b) Half-wave potential of the oxidation step in V. c) Half-wave potential of the small oxidation step after cathodic sweep in V. d) Peak potential of the first reduction step in V. e) Half-wave potential of the second reduction step in V.

An exhaustive controlled potential reduction of 2.0 mM FcCl in 0.5 M TBAP-DMeE with a Pt electrode held at −3.4 V at room temperature was undertaken in order to study the product for the reduction of FcCl. The solution of the reduced product was yellow. A cyclic voltammogram of this solution agreed with that of ferrocene under the same conditions. The peak current of this oxidation step showed that FcCl is quantitatively converted into ferrocene. The absorption spectrum of this solution also agreed with that of ferrocene.

Consequently, the electrochemical reduction of haloferrocene (FcX) may be said to result in the cleavage of the carbon-halogen bond and may proceed through the following process in the same manner as aromatic hydrocarbons:[12]

$$\mathrm{FcX} \overset{+e}{\rightleftharpoons} \mathrm{FcX^-}$$
$$\longrightarrow \mathrm{Fc\cdot} + \mathrm{X^-}$$
$$\mathrm{Fc\cdot} \overset{+e}{\longrightarrow} \mathrm{Fc^-}$$
$$\overset{+H^+}{\longrightarrow} \mathrm{FcH}$$

Such a quantitative formation of the ferrocenyl radical can be used in the preparation of ferrocene derivatives in place of the photolytic method.[11,13]

Substituent Effect on Stereoselectivity for Cobalt(III), Chromium(III), and Manganese(III) Complexes of Ring-substituted 1-*l*-Menthyloxy-3-benzoylacetones[1)]

Michio NAKAMURA, Hisashi ŌKAWA,* and Sigeo KIDA
Department of Chemistry, Faculty of Science, Kyushu University 33, Hakozaki, Higashi-ku, Fukuoka 812
(Received June 14, 1985)

Synopsis. Stereoselectivities of tris(1-*l*-menthyloxy-3-benzoylacetonato)M(III) ([M(*l*-moba)$_3$] (M=Co^{III}, Cr^{III}, Mn^{III})) and its homologs [M(*l*-moba-Br)$_3$] and [M(*l*-moba-Me)$_3$] (possessing bromo and methyl substituents at the 4-position of the aromatic ring, respectively) were examined by CD spectra. The stereoselectivity increased in the order [Co(*l*-moba-Br)$_3$]<[Co(*l*-moba)$_3$]<[Co(*l*-moba-Me)$_3$], and this trend was explained in terms of the electronic effect of the substituents on the interligand CH/π-interaction.

In the previous paper we showed that tris(1-*l*-menthyloxy-3-benzoylacetonato)M(III) complexes, [M(*l*-moba)$_3$] (M=Co^{III}, Cr^{III}, Mn^{III}), were obtained predominantly in one isomer, *cis-Δ*, probably because of the intramolecular, interligand CH/π-interactions operating between the phenyl and the *l*-menthyl groups (Fig. 1, R=H).[2)] The interligand CH/π-interaction was supported by the enhanced selectivities in tris{1-*l*-menthyloxy-3-(2-naphthoyl)acetonato}M(III) complexes[3)], [M(*l*-mona)$_3$], compared with those in [M(*l*-moba)$_3$] because the π-system of the naphthyl group which is larger than the phenyl group give rise to a more efficient interaction with the *l*-menthyl group.

In order to obtain further evidences for the CH/π-interaction, we prepared in this study H(*l*-moba) homologs with bromo and methyl substituents at the 4-position of the aromatic ring (abbreviated as H(*l*-moba-Br) and H(*l*-moba-Me), respectively), and the stereoselectivities of their cobalt(III), chromium(III), and manganese(III) complexes were examined in comparison with those of [M(*l*-moba)$_3$].

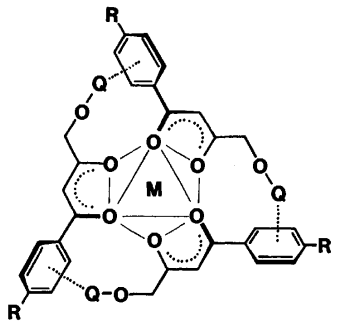

Fig. 1. Schematical representation of interligand CH/π-interaction supposed for [M(*l*-moba-R)$_3$] (Q=*l*-menthyl)

TABLE 1. ELEMENTAL ANALYSES OF THE COMPLEXES

Complex	Found(%)		Calcd(%)	
	C	H	C	H
Co(*l*-moba-Br)$_3$·H$_2$O	57.63	6.37	57.20	6.40
Cr(*l*-moba-Br)$_3$·3H$_2$O	55.79	6.50	55.91	6.51
Co(*l*-moba-Me)$_3$	72.28	8.50	72.25	8.37
Cr(*l*-moba-Me)$_3$	72.60	8.51	72.73	8.45
Mn(*l*-moba-Me)$_3$	71.37	8.38	71.29	8.45

Experimental

H(*l*-moba-Br) and H(*l*-moba-Me) were synthesized in a way similar to that for H(*l*-moba), using *p*-bromoacetophenone and *p*-methylacetophenone instead of acetophenone, respectively.[2)]

The metal complexes, [M(*l*-moba-Br)$_3$] and [M(*l*-moba-Me)$_3$] (M=Co^{III}, Cr^{III}, Mn^{III}), were prepared in the same way as that of [M(*l*-moba)$_3$].[2)] The elemental analyses for the complexes are given in Table 1.

The electronic and circular dichroism (CD) spectra were measured in carbon tetrachloride on a Shimadzu Multipurpose Spectrophotometer Model MPS-5000 and a JASCO J-500C Spectropolarimeter, respectively.

Results and Discussion

The spectral data are listed in Table 2. The electronic spectra of the cobalt complexes closely resemble those of previously reported tris(1,3-diketonato)cobalt(III) complexes.[2-5)] In Fig. 2 the spectrum of [Co(*l*-moba-Me)$_3$] is shown with the CD spectrum as an example. [Co(*l*-moba-Me)$_3$] exhibits intense circular dichroism in the d-d band region, a positive CD at 15.2×10^3 cm^{-1}($\Delta\varepsilon$=+2.27) and a negative CD at 17.3×10^3 cm^{-1}($\Delta\varepsilon$=−10.00), demonstrating that the chirality is configurational in

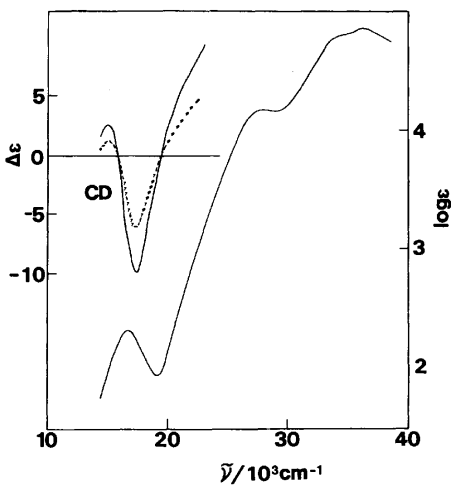

Fig. 2. Electronic and CD spectra of [Co(*l*-moba-Me)$_3$] (——) and [Co(*l*-moba)$_3$] (----) in carbon tetrachloride.

Table 2. Electronic and CD spectral data in carbon tetrachloride

	CD[a] $\Delta\varepsilon$/dm^3 mol^{-1} cm^{-1} ($\tilde{\nu}$/10^3 cm^{-1})		Absorption $\tilde{\nu}$/10^3 cm^{-1} (log ε)
[Co(*l*-moba-Br)$_3$]	+0.32(15.1)	− 1.73(17.3)	16.6(2.24), 27.4(sh), 35.1(sh), 36.8(4.80)
[Co(*l*-moba-Me)$_3$]	+2.36(15.2)	−10.00(17.3)	16.6(2.28), 27.5(4.16), 35.4(sh), 36.8(4.82)
[Cr(*l*-moba-Br)$_3$]	+0.17(15.9)	− 0.74(18.3)	17.1(2.03), 21.7(4.41), 32.0(4.42) 37.3(4.57)
[Cr(*l*-moba-Me)$_3$]	+0.79(16.2)	− 3.90(18.4)	17.6(2.02), 27.5(4.46), 32.3 (sh) 34.7(sh), 37.0(4.51)
[Mn(*l*-moba-Me)$_3$]	+0.15(18.2)	− 0.33(21.9)	8.0(2.18), 16.7(sh), 22.2(sh), 26.3(sh), 32.3(4.63), 38.5(4.42)

a) CD spectral data for [M(*l*-moba)$_3$]: +1.6(15.2) −6.1(17.4) for [Co(*l*-moba)$_3$], +0.56(15.9) −1.60(18.5) for [Cr-(*l*-moba)$_3$], and +0.10(18.0) −0.24(22.0) for [Mn(*l*-moba)$_3$].

origin. The CD pattern is the same as that of [Co(*l*-moba)$_3$], but the intensity is much higher than that of [Co(*l*-moba)$_3$] as seen in Fig. 2. In comparison with the CD spectra of *Λ*-[Co(acac)$_3$][5] and [Co(*l*-moba)$_3$],[2] the preferred configuration of [Co(*l*-moba-Me)$_3$] was shown to be of *cis*-*Δ*. Similarly, the circular dichroism of [Co(*l*-moba-Br)$_3$] exhibited the same pattern as that of [Co(*l*-moba)$_3$][2] and [Co(*l*-mona)$_3$][3] in the d-d band region. However, its CD intensity was weaker than that of [Co(*l*-moba)$_3$] (See Table 2).

The electronic spectra of [Cr(*l*-moba-Br)$_3$] and [Cr(*l*-moba-Me)$_3$] resemble those of tris(1,3-diketonato)chromium(III) complexes previously reported.[2,6,7] Their CD spectral pattern in the visible region indicated the predominant formation of the *cis*-*Δ* isomer.[2]

The manganese complex [Mn(*l*-moba-Me)$_3$] also showed fairly intense CD at 18.2×10^3 and 21.9×10^3 cm^{-1}. It is presumed that the *cis*-*Δ* isomer also predominates in this case by analogy with the case of the cobalt(III) and chromium(III) complexes.

Thus, all the complexes showed a stereoselectivity which led to the formation of the *cis*-*Δ* isomer. From Table 2, it is seen that the CD intensity induced at the d-d band region increases generally in the order, [M(*l*-moba-Br)$_3$]<[M(*l*-moba)$_3$]<[M(*l*-moba-Me)$_3$], for each metal ion, suggesting the stereoselectivity enhanced in this order provided that the CD intensity of the *cis*-*Δ* isomer is not significantly affected by the substituents on the ring. The trend can be reasonably explained in terms of the electronic effect of the substituents on the ring. That is, the π-electron density of the ring should increase in the order 4-BrC$_6$H$_4$<C$_6$H$_5$<4-CH$_3$C$_6$H$_5$, and thence the interligand CH/π-interaction (Fig. 1) becomes more effective in this order.

The authors are grateful to Mr. Y. Hisaeda for measuring CD spectra.

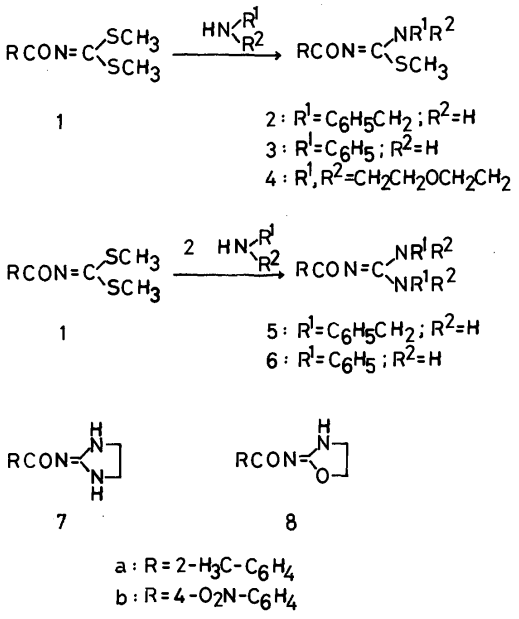
The Reaction of Dimethyl *N*-Benzoylcarbonimidodithioates with Amines

Naoaki FUKADA,* Masahiro HAYASHI, and Yukari SUZUKI
Department of Chemistry, Faculty of Science, Chiba University, Yayoicho, Chiba 260
(Received May 16, 1985)

Synopsis. 1-Substituted 3-benzoyl-2-methylisothioureas and 1,3-disubstituted 2-benzoylguanidines were synthesized from dimethyl *N*-benzoylcarbonimidodithioates and amines. From ethylenediamine and 2-aminoethanol, imidazolidine and oxazolidine derivatives were obtained respectively.

In recent years, α-oxoketene dithioacetals have been widely used for the preparation of heterocycles and intermediates in organic synthesis. However, relatively few studies have been reported on the reactions of the corresponding aza-analog *N*-acylcarbonimidodithioic acid dithioesters. In our continuing study of the reactions of amides with carbon disulfide,[1,2] we have previously reported the general synthesis of dimethyl *N*-aroylcarbonimidodithioates from aromatic amide, carbon disulfide, and sodium hydride.[3] The dithioesters reacted with hydrazine hydrate to give 3-aryl-5-methylthio-1*H*-1,2,4-triazoles in good yields.[3] Augustin *et al.* reported the syntheses of dimethyl *N*-cinnamoyl- and *N*-aroylcarbonimidodithioates, and their reactions with nucleophilic compounds.[4–7] Recently Potts *et al.* used diethyl *N*-benzoylcarbonimidodithioates and the potassium enolates of methyl ketones to prepare *N*-acyl-β-enamino ketones.[8]

In this note, we wish to report the reactions of dimethyl *N*-benzoylcarbonimidodithioates **1** obtained from 2-methyl- and 4-nitrobenzamides with several amines. When equimolar mixtures of **1** and amines



(benzylamine, aniline, and morpholine) were heated in ethanol, 1-substituted 3-benzoyl-2-methylisothioureas **2**—**4** were obtained in good yields. Two moles of the amines (benzylamine and aniline) gave 1,3-disubstituted 2-benzoylguanidines **5** and **6**. For the latter reactions it was necessary to heat in boiling xylene. Although early reports[9,10] described the preparation of compounds of these types (**2**—**6**), the method reported here is more convenient. From ethylenediamine and 2-aminoethanol, the cyclized compounds, 2-(benzoylimino)imidazolidines **7** and 2-(benzoylimino)oxazolidine **8** respectively, were obtained.

These results are similar to those of the reaction of α-oxoketene dithioacetals with amines[11] and offer new possibilities in preparing heterocycles.

Experimental

*1-Substituted 3-Benzoyl-2-methylisothioureas (**2**—**4**).*
General Procedure. A mixture of dimethyl *N*-benzoylcarbonimidodithioate (**1**, 0.002 mol),[3] amine (benzylamine, aniline, or morpholine; 0.0022 mol), and ethanol (30—40 ml) was refluxed for 1—3 h. The solvent was then removed, and the residual solid was recrystallized.

*1-Benzyl-2-methyl-3-(2-methylbenzoyl)isothiourea (**2a**)*: Recrystallized from ethanol; IR (KBr) 3160 m (NH) and 1590 *vs.* cm^{-1} (C=O); UV (EtOH) λ_{max} 244sh (log ε 4.13), 249 (4.15), 255 (4.15), 262sh (4.22), and 282 nm (4.47); ^{1}H NMR (CCl_4) δ=2.55 (s, 3H, CH_3), 2.58 (s, 3H, CH_3), 4.55 (d, 2H, CH_2), 7.2—8.5 (m, 9H, C_6H_4 and C_6H_5), and 11.77 (br s, 1H, NH); MS *m/z* 298 (M^+).

*1-Benzyl-3-(4-nitrobenzoyl)-2-methylisothiourea (**2b**)*: Recrystallized from ethanol; IR (KBr) 3250 w (NH) and 1580 *vs.* cm^{-1} (C=O); MS *m/z* 329 (M^+).

*2-Methyl-3-(2-methylbenzoyl)-1-phenylisothiourea (**3a**)*: Recrystallized from hexane–ethanol; IR (KBr) 1605 *vs.* cm^{-1} (C=O); MS *m/z* 284 (M^+).

*2-Methyl-3-(4-nitrobenzoyl)-1-phenylisothiourea (**3b**)*: Recrystallized from ethanol; IR (KBr) 1615 m cm^{-1} (C=O); MS *m/z* 315 (M^+).

*4-[2-Methylbenzoylimino(methylthio)methyl]morpholine (**4a**)*: Recrystallized from ethanol; IR (KBr) 1604 s cm^{-1} (C=O); UV (EtOH) λ_{max} 240 (log ε 4.27) and 281 nm (4.23); MS *m/z* 278 (M^+).

*4-[Methylthio(4-nitrobenzoylimino)methyl]morpholine (**4b**)*: Recrystallized from ethanol; IR (KBr) 1630 s cm^{-1} (C=O); MS *m/z* 309 (M^+).

*1,3-Disubstituted 2-Benzoylguanidines (**5** and **6**).*
General Procedure. A mixture of **1** (0.002 mol), amine (benzylamine or aniline; 0.0044 mol), and xylene (30—40 ml) was refluxed for 5 h. In the case of **6a**, ethanol was used as the solvent. The solvent was removed, and the residual solid was recrystallized.

*1,3-Dibenzyl-2-(2-methylbenzoyl)guanidine (**5a**)*: Recrystallized from ethanol; IR (KBr) 3295 *vs.* (NH) and 1615 *vs.* cm^{-1} (C=O); MS *m/z* 357 (M^+).

*1,3-Dibenzyl-2-(4-nitrobenzoyl)guanidine (**5b**)*: Recrystallized from hexane–ethanol; IR (KBr) 3398 s (NH) and 1612 s cm^{-1} (C=O); MS *m/z* 388 (M^+).

*1,3-Diphenyl-2-(2-methylbenzoyl)guanidine (**6a**)*: Recrystallized from ethanol; IR (KBr) 3380 m, 3250 s (NH), and 1680 *vs.* cm^{-1} (C=O); UV (EtOH) λ_{max} 234sh (log ε 4.33) and 278 nm (4.42); MS *m/z* 329 (M^+).

Reactions of Trimethylsilylmethyl Azide with Aromatic Acid Derivatives Catalyzed by Fluoride Ion

Kozaburo NISHIYAMA,* Hiroyuki MIKUNI, and Mari HARADA
Department of Chemistry, Tokyo Metropolitan University, 2-1-1, Fukasawa, Setagaya-ku, Tokyo 158
(Received May 28, 1985)

Synopsis. The treatment of an aromatic acid halide with trimethylsilylmethyl azide (TMSMA) in the presence of potassium fluoride and crown ether gave triazine, methanediamine, and benzamide derivatives, while the reaction of acid anhydride with TMSMA gave tertiary amine together with methanediamine and benzamide under similar conditions.

We are currently interested in the reactivities and the synthetic utilities of azide compounds containing silicon atoms.[1] Trimethylsilylmethyl azide (TMSMA) has various reaction sites and a synthetic applicability as a synthon for the amination of aromatic halides,[1b] 1,3-dipolar cycloaddition,[2] or heterocumulenes.[3] In this paper, we describe unexpected reactions involving TMSMA with acid derivatives to give triazine, methanediamine, tertiary amine, and benzamide derivatives.

Results and Discussion

A mixture of benzoyl chloride and TMSMA in the presence of potassium fluoride and a catalytic amount of 18-crown-6 in benzene was heated to reflux for 50 h. Surprisingly, the extract with dichloromethane gave 30% of 1,3,5-tribenzoylhexahydro-1,3,5-triazine (**1a**) and 34% of *N,N'*-dibenzoylmethanediamine (**2a**) together with 16% of benzamide.

2

a, $Ar=C_6H_5$
b, $Ar=p\text{-}NO_2C_6H_4$
c, $Ar=p\text{-}MeC_6H_4$

Without either potassium fluoride or crown ether, no products were formed. Other aroyl chlorides were treated in a similar manner and the results are listed in the Table. With *p*-nitrobenzoyl chloride, both triazine **1b** and methanediamine **2b** along with *p*-nitrobenzamide were isolated, though the product distribution was different from that of benzoyl chloride itself. When *p*-methylbenzoyl chloride was employed, only triazine **1c** was obtained in a much higher yield (73%) as the sole product. As for the formation of these compounds, it has been reported that benzonitrile, 1,3,5-trioxane, and a catalytic amount of concd sulfuric acid gave either triazine **1a**[4] or methanediamine **2a**,[5] depending on the conditions.

As a reaction pathway, we assumed that the

Scheme

desilylation of TMSMA induced by fluoride ions gave $K^+[CH_2N_3]^-$, followed by an evolution of nitrogen to form $K^+[CH_2{=}N]^-$ at the temperature, which afforded *N*-benzoylmethanimine ($ArCON{=}CH_2$) *via* a nuclereophilic attack on acid chloride. The triazine derivative **1** would be obtained by a trimerization of the species. Such a trimerization of methanimine has been reported;[6] 1,3,5-tris(benzylsulfonyl)hexahydro-1,3,5-triazine was transformed from phenylmethanesulfonamide and 1,3,5-trioxane *via* *N*-(benzylsufonyl)methanimine ($PhCH_2SO_2N{=}CH_2$), in which 3,4-dihydro-1*H*-2,3-benzothiazine 2,2-dioxide was also obtained as a thermodynamically controled product. In our case, however, the intramolecular cyclization product, 1-isoindolinone, was not detected even when the reaction time was prolonged.

When benzoic anhydride was employed, 28% of methanediamine **2a**, 3% of tris(benzoylaminomethyl)-amine (**3a**), and 4% of benzamide, along with the

$(RCONHCH_2)_3N$ **3**, a, R=Ph; b, R=Me

starting material, were obtained. With a three-fold excess of potassium fluoride to benzoic anhydride, the yield of **2a** was decreased to 10%, while that of amine **3a** was increased to 22%. Ethyl benzoate and acetic anhydride gave neither **1**, **2**, nor **3**.

From reported investigations[4,5,6] and these results, the reaction pathway to **1** and **2** might be competitive (as shown in the Scheme) and the formation of **3** would be rationalized by a nucleophilic attack of benzoyloxy anions towards **2**. However, it was not easy to confirm the reaction course.

Experimental

Melting points are uncorrected. ^{1}H NMR spectra were determined with a Hitachi R-600 or a JEOL PS-100 spectrometer using tetramethylsilane as an internal standard. IR spectra were taken on a Hitachi 260-10 infrared spectrometer and mass spectra were measured with a JEOL DX-300 spectrometer. Aroyl chlorides, potassium fluoride, and 18-crown-6 were commercial products and were purified when necessary. Trimethylsilylmethyl azide was prepared from trimethylsilylmethyl chloride and sodium azide according to a reported method.[1d]

Reaction of Aroyl Chloride with TMSMA. A mixture of benzoyl chloride (1.40 g, 10 mmol), TMSMA (1.94 g, 15 mmol), KF (0.58 g, 10 mmol), and 18-crown-6 (26 mg, 0.1 mmol) in benzene (10 cm^3) was heated to reflux for 50 h with stirring. To the reaction mixture was added a 10% sodium carbonate solution (30 cm^3). Stirring was continued for 24 h. The reaction mixture was extracted with dichlromethane. After drying over magnesium sulfate and evaporating the solvent *in vacuo*, the residual solid was chromatographed on alumina. Rapid elution with benzene/chloroform gave 405 mg (30%) of 1,3,5-tribenzoylhexahydro-1,3,5-triazine (**1a**), recrystallized from ethanol, colorless prisms, mp 216—218 °C (lit,[4] 220—222 °C), mass spectrum *m/z* 399 (M^+), and 435 mg (34%) of *N,N'*-dibenzoylmethanediamine (**2a**), recrystallized from methanol, colorless needles, mp 215—216 °C (lit,[5] 216—218 °C), *m/z* 254 (M^+). Further elution with methanol afforded 197 mg (16%) of benzamide. ^{1}H NMR spectra of **1a** and **2a**: **1a** ($CDCl_3$) δ=5.41 (6H, s) and 7.48 (15H, m); **2a** (DMSO-d_6) δ=5.08 (2H, t, J=6 Hz), 7.5—8.1 (10H, m) and 9.15 (2H, t, J=6 Hz).

Other aroyl chlorides were similarly treated unless otherwise mentioned. With *p*-nitrobenzoyl chloride (1.85 g, 10 mmol), the reaction time was prolonged to 120 h. To the reaction mixture was added chloroform and water. A precipitated solid was filtered and then washed with hot acetonitrile, giving 160 mg of a colorless solid, which was found to be 1,3,5-tris(*p*-nitrobenzoyl)hexahydro-1,3,5-triazine (**1b**, 9%), mp >260 °C, ν_{max} 1650 and 1530 cm^{-1}. The ^{1}H NMR spectrum in DMSO-d_6 showed at δ=5.38 (6H, s) and 7.76, 8.26 (12H, AA'BB'q, J=8 Hz). Found: C, 53.46; H, 3.33; N, 15.60%. Calcd for $C_{24}H_{18}N_6O_9$: C, 53.93; H, 3.39; N, 15.73%. Column chromatography on alumina of the combined filtrate gave 650 mg (38%) of *N,N'*-bis(*p*-nitrobenzoyl)methanediamine (**2b**), recrystallized from acetonitrile, colorless needles, mp 245—246 °C, *m/z* 344 (M^+), ^{1}H NMR (DMSO-d_6) δ=5.08 (2H, t, J=6 Hz), 8.35, 8.54 (12H, AA'BB'q, J=9 Hz), and 9.65 (2H, t, J=6 Hz), ν_{max} 3290, 1630, and 1510 cm^{-1}. Found: C, 51.97; H, 3.42; N, 16.27%. Calcd for $C_{15}H_{12}N_4O_6$: C, 52.33; H, 3.51; N, 16.27%. *p*-Nitrobenzamide along with unidentified products was also obtained.

When *p*-methylbenzoyl chloride (1.55 g, 10 mmol) was employed, 1,3,5-tris(*p*-methylbenzoyl)hexahydro-1,3,5-triazine (**1c**) was obtained in 73% (1.07 g) yield. The compound was recrystallized from ethanol to give colorless needles, mp 211—212 °C, *m/z* 441 (M^+). The IR spectrum showed at 1660 and 1640 cm^{-1} and the ^{1}H NMR spectrum in $CDCl_3$ showed signals at δ=2.40 (9H, s), 5.40 (6H, s), and 7.28 (12H, m). Found: C, 73.23; H, 6.07; N, 9.48%. Calcd for $C_{27}H_{27}N_3O_3$: C, 73.45; H, 6.17; N, 9.52%.

Reaction of Acid Anhydride with TMSMA. The reaction of benzoic anhydride (2.26 g, 10 mmol) with TMSMA (1.94 g, 15 mmol) was carried out as metioned above. Extraction with CH_2Cl_2 and column chromatography eluted by benzene/chloroform gave 350 mg (28%) of **2a** and 41 mg (3%) of tris(benzoylaminomethyl)amine (**3a**), recrystallized from ethanol, colorless plates, mp 188—189 °C, *m/z* 416 (M^+), ν_{max} 3320 and 1645 cm^{-1}. ^{1}H NMR ($CDCl_3$) δ=4.73 (6H, d, J=7 Hz), 7.0—7.7 (15H, m), and 8.10 (3H, t, J=7 Hz). Found: C, 69.05; H, 5.71; N, 13.28%. Calcd for $C_{24}H_{24}N_4O_3$: C, 69.21; H, 5.80; N, 13.45%. Benzamide (48 mg, 4%) was also obtained by elution with methanol on alumina. With 3 equiv of KF, yields of **2a**, **3a**, and benzamide were 127 mg (10%), 305 mg (22%), and 48 mg (4%), respectively.

Palladium-catalyzed Displacement of Aryl Halide by Tin Analogue of Reformatsky Reagent

Masanori KOSUGI, Yoshikazu NEGISHI, Masayuki KAMEYAMA, and Toshihiko MIGITA*
Department of Chemistry, Faculty of Technology, Gunma University, Kiryu, Gunma 376
(Received May 28, 1985)

Synopsis. Reaction of ethyl α-(tributylstannyl)acetate with aryl bromides in the presence of zinc bromide or chloride and a catalytic amount of dichlorobis(tri-*o*-tolylphosphine)palladium was found to give ethyl arylacetates in good yields except with the aryl bromide having *p*-acetyl or *p*-nitro group.

Transition metal-catalyzed displacement of aryl halides by an enolate-like reagent giving a carbon–carbon bond is of recent interest.[1,2] We have reported the aromatic displacement by enolate-like tin reagents (α-stannyl ketone and/or stannyl enol ether) catalyzed by dichlorobis(tri-*o*-tolylphosphine)-palladium.[3] The nickel or palladium-catalyzed arylation[4] and alkenylation[5] of Reformatsky reagent have also been reported, but these reactions seem to have disadvantage in the low catalytic efficiencies and the limitation in a functional group exsisting in the aryl halide.

In this note, we report the displacement of aryl halides by organotin analogue of Reformatsky reagent in the presence of palladium complex.

$$n\text{-}Bu_3SnCH_2CO_2Et + ArX \xrightarrow{[Pd]} ArCH_2CO_2Et + n\text{-}Bu_3SnX$$

The reaction gave aryl acetate in moderate yields together with 1-arylbutane and biaryl which were formed through butyl transfer from the tin compound and homocoupling of the aryl bromides, respectively. Results are shown in Table 1. Similarly to the reaction of tin enolate, dichlorobis(tri-*o*-tolylphosphine)palladium was the best catalyst among the palladium complexes examined here. However, in contrast with the reaction of tin enolate,[3] proper solvents were polar aprotic ones, such as hexamethylphosphoric triamide (HMPA), *N*-methyl-2-pyrolidone (NMP), *N*,*N*-dimethylformamide (DMF), or dimethyl sulfoxide (DMSO). We chose DMF as a solvent, with which a relatively short reaction time was required.

As can be seen in Table 1, however, the yield was not particularly good, and sometimes was not reproducible. This is probably due to instability of α-stannyl acetate as well as α-stannyl ketone or stannyl enol ether under the reaction conditions. After many trials to overcome the difficulty, the addition of an equimolar amount of zinc bromide or chloride to the reaction system was found to enhance the yield of the product to almost quantitative, as shown in Table 2.

As Table 2 shows, zinc bromide or chloride was an especially effective additive, while other Lewis acids seem to deactivate the catalyst. Based on these results, the best reaction conditions were found to be as follows; a mixture of ethyl α-stannylacetate (1.3 mmol), bromobenzene (1.0 mmol), zinc bromide (1.3 mmol), $PdCl_2[P(o\text{-tolyl})_3]_2$ (0.01 mmol), and DMF (2 cm^3) was heated under argon at 80 °C for 5 h. Usual workup gave ethyl phenylacetate in 71% isolated yield. Table 3 shows the results with various aryl bromides.

The yield was greatly improved compared with

* GLC yield based on the halide.

that with Reformatsky reagent. In our case, the best substrate was bromide, and iodide which was a better substrate in Reformatsky reaction gave poor results, and chloride did not react at all. The reaction with aryl bromides having *p*-acetyl or *p*-nito group gave the product in low yields. These tendencies were also observed in other cross-coupling reactions, where the palladium catalyst having tri-*o*-tolylphosphine as a ligand was used.[3,6,7]

The mechanistic role of zinc salts which enhance the yields of the reaction products is not yet clear. The metal exchange between zinc salts and organotin producing Reformatsky reagent seems unlikely, considering the above difference in behaviors of iodobenzene and bromobenzene.

Experimental

IR spectra were recorded on Jasco A-100 spectrophotometer. ^1H NMR spectra were recorded on a Varian EM-360 instrument. GLC analyses were carried out with Ohkura 802 instrument, using columns (1.5 m) packed with 10% Silicone SF-96 and SE-30 on Celite 545.

Materials. Ethyl α-(tributylstannyl)acetate was prepared by the reaction of tributyltin ethoxide with ketene.[8] bp 117—119 °C/0.2 mmHg. (lit,[8] 150—152 °C/1.6 mmHg (1 mmHg=133.322 Pa)). Aryl bromides and palladium catalyst have already reported.[3]

Reaction Procedure. Zinc bromide (1.3 mmol) was placed in 10 cm^3 flask, and heated at 140 °C for 1 h under reduced pressure. Then, a mixture of ethyl α-(tributylstannyl)acetate (1.3 mmol), aryl bromide (1.0 mmol), $PdCl_2[P(o\text{-tolyl})_3]_2$ (0.01 mmol), and DMF (2 cm^3) was added into the flask, and heated under argon at 80 °C for 5 h. The reaction mixture was washed with water to remove the solvent, extracted with ether, and dried with anhydrous sodium sulfate. After column chromatography on silica gel, the product was isolated by distillation or crystallization.

Products. All the products were known and their structures were identified with IR and ^1H NMR spectra. Ethyl phenylacetate,[9,10a] ethyl *p*-methylphenylacetate,[10b] ethyl *m*-methylphenylacetate,[10c] ethyl *o*-methylphenylacetate,[10d] ethyl *p*-chlorophenylacetate,[10e] ethyl *o*-chlorophenylacetate,[10f] ethyl *p*-methoxyphenylacetate,[4,10g] ethyl *o*-methoxyphenylacetate,[10h] ethyl *p*-acetylphenylacetate,[4] ethyl *p*-cyanophenylacetate,[4] and ethyl *p*-nitrophenylacetate.[4]

The gift of tributyltin oxide by Kohriyama Kasei Co. is gratefully acknowledged.

Peterson Olefination of (α-Methoxybenzyl)silane with Aldehydes and Ketones Leading to Vinyl Ethers

Shuji KANEMASA, Junji TANAKA, Hideki NAGAHAMA, and Otohiko TSUGE*

Reserach Institute of Industrial Science, and Department of Molecular Science and Technology, Interdisciplinary Graduate School of Engineering Sciences, Kyushu University, Kasugakoen, Kasuga 816

(Received June 6, 1985)

Synopsis. (α-Methoxybenzyl)trimethylsilane is deprotonated with butyllithium and then allowed to react with a variety of carbonyl compounds giving vinyl ethers which are convertible into methyl ketones under mild conditions.

Although a variety of α-hetero-substituted organosilanes have been utilized in organic synthesis as an attracting member of isolable α-hetero organometallics, only limited applications of α-hydroxy or α-alkoxy alkylsilanes are known.[1] The present paper describes the vinyl ether synthesis using (α-methoxybenzyl)trimethylsilane **1** which is readily available through the 1,2-anionic rearrangement of silyl moiety of benzyl silyl ether.[2]

When the silane **1** was treated with a mixture of butyllithium and *N,N,N′,N′*-tetramethyl-1,2-ethanediamine (TMEDA) in dry THF at 0 °C, the solution immediately began to color and became deep red in 5 min. In this solution, the silyl-stabilized carbanion **2** was found to form in an excellent yield. Benzaldehyde **3a** was added and the mixture was allowed to stir at 0 °C and then at room temperature until all the silane **1** was consumed (checked on TLC). From the above procedure, 83% yield of **4a** was given as 7:2 mixture of E and Z isomers.

As shown in Scheme 1 and Table 1, the silyl-stabilized carbanion **2** was allowed to react with several carbonyl compounds. The reactions with aromatic aldehydes **3b—f**, heteroaromatic aldehydes **3g—h**, an α,β-unsaturated aldehyde **3i**, aliphatic aldehydes **3j—k**, and ketones **5a—d** gave the corresponding vinyl ethers in good yields as mixtures of E and Z isomers. Their structures were determined on the basis of the spectral data and elementary analyses.

Some of the vinyl ethers thus obtained were readily hydrolyzed under mild conditions. When the vinyl ethers **4** were heated in methanol in the presence of a catalytic amount of hydrochloric acid the correspond-

a) All the reactions were performed by using each 1.5 equivalent amounts of butyllithium, carbonyl compounds, and TMEDA in dry THF under nitrogen. In the beginning the reaction mixture was stirred at 0 °C for 1 h and then at room temperature for the time shown in Table. b) All isolated yields as mixtures of E and Z isomers. c) Determined by ^{1}H-NMR spectra. d) Measured in deuteriochloroform. All the signals appear as singlets otherwise cited. d: doublet; t: triplet.

Table 2. Hydrolysis of the vinyl ethers

Vinyl ether	Conditions[a]	Product	R	Yield/%[b]
4a	reflux in MeOH 3 h	**7a**	Ph	86
4f	reflux in MeOH 6 h	**7b**	*m*-ClC_6H_4	91
4i	reflux in MeOH 5 h	**7c**	PhCH=CH (t)	86[c]
	rt in HCOOH 5 h	**7c**		35
4l	reflux in MeOH 3 h	**7d**	*t*-Bu	78

a) The reaction in MeOH was carried out in the presence of a catalytic amount of HCl. b) All isolated yields. c) Containing 42% of 3-methoxy-1,4-diphenyl-1-butanone.

ing methyl ketones **7a—d** were given as shown in Scheme 1 and Table 2. A part of **7c** underwent the double bond migration into a conjugated ketone and the subsequent methanol addition gave 3-methoxy-1,4-diphenyl-1-butanone (42%).

Experimental

General Procedure for the Reaction of 1 with Carbonyl Compounds 3 and 5. To the solution of TMEDA (2.3 ml, 1.5 mmol) in dry THF (distilled over lithium aluminum hydride immediately before use, 2 ml) was added at 0 °C under nitrogen butyllithium (15% content in hexane, 0.94 ml, 1.5 mmol). After 5 min, the silane **1** (0.194 g, 1.5 mmol in 0.5 ml of THF) was added slowly by the use of a syringe, the color of solution turning deep red. After an additional 5 min at the same temperature, carbonyl compounds **3** or **5** (1.5 mmol for **3a—f, 3i, 5a—d**, and 2.0 mmol for **3g—h, 3j—l** in 1 ml of THF) were added dropwise. The resulting mixture was stirred at 0 °C under nitrogen for 1 h and then at room temperature for the time shown in Table 1. Aqueous ammonium chloride solution (**3—5** ml) was added and the mixture was extracted with ether (20 ml×2). The ether extracts were combined and washed with saturated sodium chloride three times, and finally dried over anhydrous magnesium sulfate. The residue obtained by evaporation of the ether *in vacuo* was chromatographed over silica gel using hexane-benzene (5:1) as an eluent giving viscous oil of vinyl ethers **4** and **6**. The yields, E/Z ratios, ^{1}H-NMR, IR, and mass spectral data are listed in Table 1. As the separation of the E and Z isomers by repeated column chromatography were unsuccessful, purified E/Z mixtures were submitted to elementary analyses.

Other data for the vinyl ethers **4** and **6** are as follows: **4a**: colorless oil (E/Z=7/2), Found: C, 85.49; H, 6.64%. Calcd for $C_{15}H_{14}O$: C, 85.68; H, 6.71%. **4b**: colorless oil (E/Z=7/2), Found: C, 85.83; H, 7.13%. Calcd for $C_{16}H_{16}O$: C, 85.68; H, 7.19%. **4c**: colorless oil (E/Z=7/2), Found: C, 85.62; H, 7.27%. Calcd for $C_{16}H_{16}O$: C, 85.68; H, 7.19%. **4d**: pale yellow oil (E/Z=7/2), Found: C, 85.55; H, 7.10%. Calcd for $C_{16}H_{16}O$: C, 85.68; H, 7.19%. **4e**: colorless oil (E/Z=1/1), Found: C, 73.75; H, 5.55%. Calcd for $C_{15}H_{13}OCl$: C, 73.62; H, 5.35%. **4f**: colorless oil (E/Z=7/2), Found: C, 73.82; H, 5.55%. Calcd for $C_{15}H_{13}OCl$: C, 73.62; H, 5.35%. **4g**: pale yellow oil (E/Z=3/1), ^{1}H-NMR ($CDCl_3$) δ=5.53, 6.72 (1H, 3:1, d, J=3.0 Hz, 3-H of furyl), 6.15, 6.43 ppm (1H, 3:1, m, 4-H of furyl), Found: *m/z* 200.0840. Calcd for $C_{13}H_{12}O_2$: M, 200.0837. **4h**: pale yellow oil (E/Z=6/1), Found: C, 72.06; H, 5.57%. Calcd for $C_{13}H_{12}OS$: C, 72.19; H, 5.59%. **4i**: pale yellow oil (E/Z=3/1), ^{1}H-NMR ($CDCl_3$) δ=5.65 (3/4H, d, J=9.0 Hz, C<u>H</u>=C(OMe)Ph of E isomer), 6.06 (1/4H, d, J=9.5 Hz, C<u>H</u>=C(OMe)Ph of Z isomer), 6.37 (3/4H, d, J=17.0 Hz, PhC<u>H</u>=CHCH= of E isomer), 6.50 (1/4H, d, J=17.5 Hz, PhC<u>H</u>=CHCH= of Z isomer), and 6.84 ppm (3/4H, dd, J=9.0 and 17.0 Hz, PhCH=C<u>H</u>CH= of E isomer). **4j**: colorless oil (E/Z=1/1), ^{1}H-NMR ($CDCl_3$) δ=0.89, 0.98 (each 3/2H, t, CH_3), 1.28—1.70 (2H, m, $CH_2C\underline{H}_2CH_3$), 2.07, 2.26 (each 2/2H, q, =CHC<u>H</u>$_2$-), 4.71 (1/2H, t, J=7.5 Hz, =C<u>H</u>CH_2 of E isomer), and 5.29 ppm (1/2H, t, J=8.0 Hz, =C<u>H</u>CH_2 of Z isomer), Found: *m/z* 176.1200. Calcd for $C_{12}H_{16}O$: M, 176.1207. **4k**: colorless oil (E/Z=1/1), ^{1}H-NMR ($CDCl_3$) δ=0.97, 1.06 (each 3/2H, d, $\underline{Me}_2CH$), 2.26 (1/2H, m, $Me_2C\underline{H}$ of E isomer), 3.20 (1/2H, m, $Me_2C\underline{H}$ of Z isomer), 4.52 (1/2H, d, J=9.5 Hz, =CH- of E isomer), and 5.12 ppm (1/2H, d, J=9.5 Hz, of Z isomer), Found: *m/z* 176.1202. Calcd for $C_{12}H_{16}O$: M, 176.1202. **4l**: the E and Z isomers were separated through the column chromatography over silica gel using hexane-benzene (5:1). *E*-**4l**: colorless oil, Found: *m/z* 190.1307. Calcd for $C_{13}H_{18}O$: M, 190.1357; *Z*-**4l**: colorless oil, Found: *m/z* 190.1352. Calcd for $C_{13}H_{18}O$: M, 190.1357. **6a**: colorless prisms from benzene-hexane, mp 110—111 °C, Found: C, 88.08; H, 6.34%. Calcd for $C_{12}H_{18}O$: C, 87.92; H, 6.31%. **6b**: colorless oil (E/Z=2/1), Found: C, 85.51; H, 7.11%. Calcd for $C_{16}H_{16}O$: C, 85.68; H, 7.19%. **6c**: colorless oil, ^{1}H-NMR ($CDCl_3$) δ=0.92, 1.03 (each 3H, t, $C\underline{H}_3CH_2$), 1.93, 2.23 (each 2H, q, $CH_3C\underline{H}_2$), and 7.18 ppm (5H, br.s, ArH), Found: *m/z* 190.1295. Calcd for $C_{13}H_{18}O$: M, 190.1357. **6d**: colorless oil, ^{1}H-NMR ($CDCl_3$) δ=1.55—1.90 and 2.20—2.70 ppm (each 4H, m, CH_2), Found: *m/z* 188.0830. Calcd for $C_{13}H_{16}O$: M, 188.1119.

General Procedure for the Hydrolysis of 4. The vinyl ether **4** was heated under reflux in methanol containing a catalytic amount of hydrochloric acid until **4** was completely consumed (checked on TLC). The methanol was evaporated *in vacuo*, the residue was treated with water, extracted with ether (twice), the ether was washed with aqueous sodium hydrogencarbonate, and dried over magnesium sulfate. The residue obtained by the removal of the ether *in vacuo* was chromatographed over silica gel using hexane-benzene (2:1) as an eluent. The reaction conditions and yields are listed in Table 2. All the methyl ketones **7** are known compounds, therefore their structures were confirmed by the comparison of melting points and/or spectral data with those of authentic samples. **7b**: colorless prisms; mp 43 °C;[3] IR (neat) 1690 cm^{-1}; ^{1}H-NMR ($CDCl_3$) δ=4.13 (2H, s, CH_2) and 6.98—7.55 ppm (9H, m, ArH); MS *m/z* 230, 232 (M^+) and 105 (base peak). **7c**: colorless prisms (benzene-hexane), mp 88—89 °C,[4] IR (KBr) 1660 cm^{-1}, ^{1}H-NMR ($CDCl_3$) δ=3.79 (2H, m, CH_2), 6.35 (2H, m, C<u>H</u>=C<u>H</u>), and 7.00—8.00 ppm (10H, m, ArH), MS *m/z* 222 (M^+) and 105 (base peak). **7d**: colorless oil,[5] IR (neat) 1660 cm^{-1}; ^{1}H-NMR ($CDCl_3$) δ=1.03 (9H, s, *t*-Bu), 2.79 (2H, s, CH_2), and 7.20—7.88 ppm (5H, m, ArH), MS *m/z* 176 (M^+) and 77 (base peak).

Synthetic Studies on the Validamycins. XII. Synthesis of Optically Active Valienamine and Validatol

Seiichiro OGAWA,* Yasushi SHIBATA, Taisuke NOSE, and Tetsuo SUAMI
Department of Applied Chemistry, Faculty of Science and Technology, Keio University, Hiyoshi, Yokohama 223
(Received June 6, 1985)

Synopsis. (+)-Valienamine and (+)-validatol have been totally synthesized as the peracetyl derivatives starting from a common synthetic intermediate, (1*S*)-(1,3/2)-4-methylene-5-cyclohexene-1,2,3-triol.

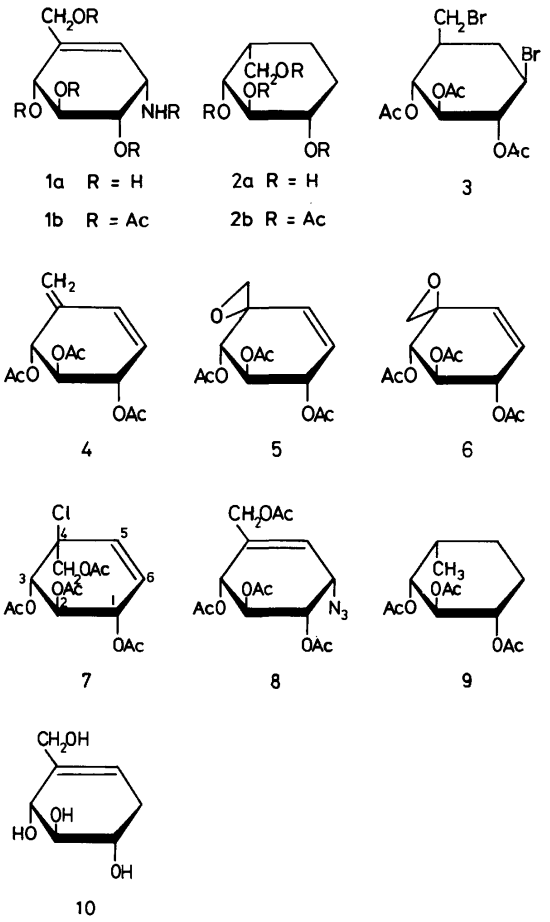
Valienamine (**1a**) is an unsaturated branched-chain aminocyclitol found in the structural unit of the antibiotic validamycins[1] and several pseudo-oligosaccharidic α-glucosidase inhibitors.[2] Later, **1a** itself was shown to be an α-glucosidase inhibitor.[3] Hydrogenolysis of validamycin A produced validatol (**2a**), resulting from a reductive elimination of the imino group of the aminocyclitol part.[4]

We have reported the synthesis of the racemic forms of **1a**[5–7] and **2a**,[8] and Paulsen and Heiker have first synthesized the optically active **1a** starting from quebrachitol (L-2-*O*-methyl-*chiro*-inositol).[9]

We now describe a facile synthesis of the penta-*N*,*O*-acetyl derivative (**1b**) of **1a** from the optically active diene intermediate (**4**), following the route previously used for preparation of its racemate.[6,7] In addition, a new synthesis of the tetra-*O*-acetyl derivative (**2b**) of **2a** is reported.

Dehydrobromination of (1*R*)-(−)-1,2,3-tri-*O*-acetyl-(1,3/2,4,6)-4-bromo-6-bromomethyl-1,2,3-cyclohexanetriol (**3**)[10] with 1,8-diazabicyclo[5.4.0]undec-7-ene (DBU) in toluene afforded exclusively the diene (**4**), which was, without purification, treated with equimolar amount of *m*-chloroperbenzoic acid (MCPBA) in dichloromethane to oxidize the exomethylene group. A mixture of the products was fractionated by a silica-gel column to give the spiro oxiranes **5** (27%) and **6** (12%). Their structures were confirmed by comparison of the ^{1}H NMR spectra with those of the respective racemates.[6,7] Chlorination of **5** with concd hydrochloric acid in tetrahydrofuran (THF) followed by acetylation gave the chloride (**7**) in 92% yield. Treatment of **7** with sodium azide in *N*,*N*-dimethylformamide (DMF) at 60 °C gave selectively the azide (**8**) in a quantitative yield. Reduction of **8** with hydrogen sulfide followed by the conventional acetylation gave **1b**, mp 92.5—95 °C, $[\alpha]_D$ +20° ($CHCl_3$), in 94% yield. The ^{1}H NMR spectrum was superposable on that of an authentic sample.[1,5]

On the other hand, a new synthesis of **2b** was attempted by reduction of **7**. Direct hydrogenolysis of **7** in the presence of Raney nickel and a basic resin gave a complex mixture of products. Therefore, dechlorination was first carried out by treatment of **7** with lithium aluminum hydride (LAH) in THF, and then the product was hydrogenated in the presence of Raney nickel and successively acetylated to give **2b**, $[\alpha]_D$ −16° ($CHCl_3$), in 19% yield, together with tri-*O*-acetyldeoxyvalidatol[4,8] (**9**) (17%). Formation of **9** suggested that the initial dechlorination involved an attack of a hydride ion at C-6 giving an allyl alcohol (**10**). Hydrogenation of **4** with platinum oxide gave only **9** in 56% yield.



Experimental

Melting points were determined on a Büchi 510 capillary melting-point apparatus and are uncorrected. Optical rotations were measured on a Jasco DIP-4 polarimeter. The ^{1}H NMR spectra were recorded on a Varian EM-390 (90 MHz) spectrometer for solutions of chloroform-*d*. The silica gel used for column chromatography was Wakogel C-300 (Wako Co., Osaka). The structures of the optically active compounds synthesized were confirmed by comparison of the ^{1}H NMR spectra with those of the corresponding racemic modifications.

(2R)-(+)-2,3,4-Tri-O-acetyl-1,7-anhydro-(1,2,4/3)- (5) and (1,3/2,4)-1-C-Hydroxymethyl-5-cyclohexene-1,2,3,4-tetrol (6). Treatment of (1*R*)-(−)-1,2,3-tri-*O*-acetyl-(1,3/2,4,6)-4-bromo-6-bromomethyl-1,2,3-cyclohexanetriol[9] (**3**) (1.0 g, 2.3 mmol) with DBU in toluene similarly as described in the preparation of the racemate[8] gave a diene (**4**) (574 mg), which was, without isolation, subjected to an oxidation

with MCPBA in dichloromethane.[6,7] A crystalline mixture of the products (540 mg) was fractionated by a silica-gel column (18 g) with 1:10 2-butanone–toluene as an eluant to give 82 mg (12%) of **6** as plates (from ethanol): mp 114—115 °C; $[\alpha]_D^{24}$ +147° (*c* 1.03, $CHCl_3$). The second fraction gave 179 mg (27%) of **5** as plates (from ethanol): mp 102—103 °C; $[\alpha]_D^{22}$ +65° (*c* 1.0, $CHCl_3$).

Found for **5**: C, 54.78; H, 5.46%, and for **6**: C, 54.64; H, 5.73%. Calcd for $C_{13}H_{16}O_7$: C, 54.93; H, 5.67%.

(2S)-(+)-1,2,3-Tri-O-acetyl-(1,3/2,4)-4-C-acetoxymethyl-4-chloro-5-cyclohexene-1,2,3-triol (7). Treatment of **5** (119 mg, 0.42 mmol) with concd hydrochloric acid (0.044 ml) in THF (4.8 ml) similarly as described in the preparation of the racemate.[6,7] The product was crystallized from ethanol to give 141 mg (92%) of **7** as thin needles: mp 103.5—105 °C; $[\alpha]_D^{18}$ +60° (*c* 1.02, $CHCl_3$).

Found: C, 49.71; H, 5.48%. Calcd for $C_{15}H_{19}ClO_8$: C, 49.66; H, 5.28%.

(1S)-1,2,3-Tri-O-acetyl-(1,3,6/2)-4-acetoxymethyl-6-azido-4-cyclohexene-1,2,3-triol (8). The chloride (**7**) (67 mg, 0.18 mmol) was treated with sodium azide in DMF similarly as described in the preparation of the racemate[6,7] to give 68 mg (99%) of **8** as a syrup: $[\alpha]_D^{20}$ +40° (*c* 1.0, $CHCl_3$).

Found: C, 48.79: H, 5.25; N, 11.44%. Calcd for $C_{15}H_{19}N_3O_8$: C, 48.78; H, 5.19; N, 11.38%.

(1S)-1,2,3-Tri-O-acetyl-(1,3,6/2)-6-acetamido-4-acetoxymethyl-4-cyclohexene-1,2,3-triol [penta-N,O-acetyl-(+)-valienamine] (1b). The azide (**8**) (90 mg, 0.24 mmol) was reduced with hydrogen sulfide and then acetylated similarly as described in the preparation of the racemate[6,7] to give 88 mg (94%) of **1b** as needles (from ethanol–toluene): mp 92.5—95 °C; $[\alpha]_D^{21}$ +20° (*c* 1.04, $CHCl_3$) [lit.[1] mp 95 °C, $[\alpha]_D^{23}$ +30.2° ($CHCl_3$)].

Found: C, 53.27; H, 6.01; N, 3.42%. Calcd for $C_{17}H_{23}NO_9$: C, 52.98; H, 6.02; N, 3.63%.

(3R)-1,2,3-Tri-O-acetyl-(1,3,4/2)-4-acetoxymethyl-1,2,3-cyclohexanetriol [tetra-O-acetyl-(−)-validatol] (2b) and (3R)-1,2,3-Tri-O-acetyl-(1,3,4/2)-4-methyl-1,2,3-cyclohexanetriol [tri-O-acetyl-(−)-deoxyvalidatol] (9). A mixture of **7** (66 mg, 0.18 mmol), lithium aluminum hydride (42 mg), and THF (7.5 ml) was refluxed for 9 h. To a cooled mixture was added water (1.5 ml), and an insoluble material was removed by filtration and the filtrate was concentrated. The residue was treated with acetic anhydride (0.6 ml) and pyridine (0.6 ml) at room temperature overnight. The product was then hydrogenated in ethyl acetate (10 ml) in the presence of Raney nickel T-4[11] (0.5 ml) at room temperature overnight (initial hydrogen pressure of 3.4 kg cm^{-2}). The products were separated by a silica-gel column with 1:8 2-butanone-toluene to give first 8.7 mg (17%) of **9** as a syrup: $[\alpha]_D^{23}$ −7.9° (*c* 0.37, $CHCl_3$).

Found: C, 57.38; H, 7.13%. Calcd for $C_{13}H_{20}O_6$: C, 57.34; H, 7.40%.

The second fraction gave 12 mg (19%) of **2b** as a syrup: $[\alpha]_D^{25}$ −16° (*c* 0.52, $CHCl_3$).

Found: C, 54.84; H, 6.79%. Calcd for $C_{15}H_{22}O_8$: C, 54.54; H, 6.71%.

Catalytic Hydrogenation of 4. The crude **4** (139 mg) was hydrogenated in ethyl acetate (10 ml) in the presence of platinum oxide (10 mg) at room temperature overnight (initial hydrogen presure of 3.4 kg cm^{-2}). The product was purified by a silica-gel column with 1:10 2-butanone-toluene to give 91 mg (56%) of **9** as a syrup: $[\alpha]_D^{21}$ −8.6° (*c* 1.0, $CHCl_3$).

The authors wish to thank Mr. Saburo Nakada for his elemental analyses.

(Received June 7, 1985)

Synopsis. The low-energy photoelectron spectra (PES) of twelve peralkylated catenates of group 4B elements (silicon, germanium, and tin) were recorded. The trends in the energies and the nature of the metal-metal and metal-carbon bonds are discussed.

In connection with predicting rates of the reactions and the products for processes involving electron transfer, UV photoelectron spectra (PES) of the organometals, particularly of group 4B metals, have received considerable attention.[1] These PES studies have mainly focussed on the metal-carbon,[2-8] metal-hydrogen,[9-15] and metal-halogen bonds[16-24] of the group 4B metals. However, there are a few reports on PES of the metal-metal bonds of the group 4B metals.[25-29] Compounds which contain metal-metal bonds have attracted increasing interest in comparison with those of carbon-carbon double bonds.[30,31] The carbon-carbon double bonds have, of course, already been very extensively studied by PES.[32] Here we present the PES of twelve peralkylated catenates of group 4B elements, $R_3M\text{-}M'R_3$ (R=Me, Et; M, M'=Si, Ge, Sn) to explain trends in the energies and the nature of metal-metal and metal-carbon bonds.

Results and Discussion

Although the PES of permethylated and perethylated catenates of group 4B elements (silicon, germanium, and tin) are slightly different from the spectrum of carbon analogue, 2,2,4-trimethylpentane,[28] these spectra show similar patterns, each exhibiting three bands of increasing intensity. The vertical ionization potentials corresponding to the highest three occupied orbitals are summarized in Table 1, together with the designated symmetry and the principal contributions to MO's.[28] The highest occupied molecular orbital (HOMO), which is of principal concern to us, is associated with ionization from M-M' σ bonding orbital (a_1), while the next two bands correspond to M-C and/or M'-C bonding orbitals (e).

Table 1. Ionization potentials (eV) of group 4B dimetals

Compound	M-M' (a_1)	C-M (e)	C-M' (e)
$Me_3SiSiMe_3$	8.68	10.23, 10.67	
$Me_3SiGeMe_3$	8.62	9.91	10.50
$Me_3GeGeMe_3$	8.60	9.87, 10.40	
$Me_3SiSnMe_3$	8.39	9.71	10.41
$Me_3GeSnMe_3$	8.36	9.65	10.09
$Me_3SnSnMe_3$	8.20	9.26, 9.62	
$Et_3SiSiEt_3$	8.39	9.40, 9.78	
$Et_3SiGeEt_3$[a]	8.24	b)	9.75
$Et_3GeGeEt_3$	8.33	9.14, 9.53	
$Et_3SiSnEt_3$	8.10	8.90	9.70
$Et_3GeSnEt_3$	8.05	8.79	9.29
$Et_3SnSnEt_3$	7.82	8.49, 8.87	

a) The PES resolution was rather poor due to the complexity of the compounds under study. b) This band was not resolved from leading edge of the 9.75 eV band.

The bands corresponding to M-M' σ bonding orbital ionization of a series of kindred catenates of group 4B elements will appear at lower ionization potentials than the bands corresponding to the interaction of this 4B atom with the methyl or ethyl group, since each group 4B atom studied has an ionization potential much lower than carbon. The first ionization potentials of a series of kindred catenates of group 4B elements shown in Table 1 are essentially the same as those of the parent metal (C, 11.26; Si, 8.15; Ge, 7.88; Sn, 7.34 eV),[33] indicating that electrons ionized are localized relatively at the M-M' bonds. The first ionization potential of a series of peralkylated catenates of group 4B elements decreases generally in order: Si-Si>Si-Ge>Ge-Ge>Si-Sn>Sn-Sn in accord with the M-M' ionic bond dissociation energy. The internal consistency of the data is illustrated in Fig. 1 by a comparison of the ionization potentials of the permethylated derivatives with the perethylated analogues.

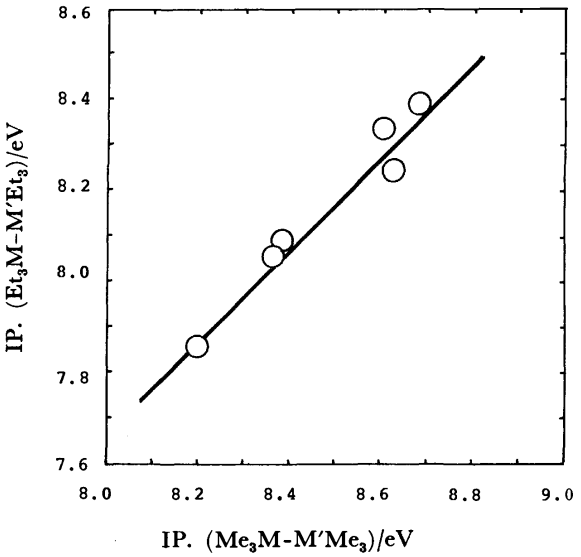

Fig. 1. First ionization potential of $Me_3M\text{-}M'Me_3$ *vs.* the first ionization potential of $Et_3M\text{-}M'Et_3$ (M, M' =Si, Ge, Sn).

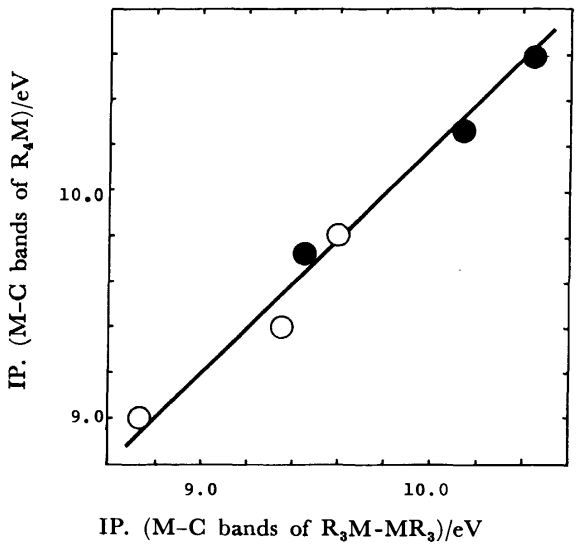

Fig. 2. The mean value of two bands of M-C bonding orbitals of R_3M–MR_3 *vs.* the first ionization potential of R_4M (M=Si, Ge, Sn); ●; permethylated derivatives, ○; perethylated derivatives.

Furthermore, the average of the next two bands corresponding to M-C bonding orbitals of kindred catenates of group 4B elements is close in energy and linearly related to the M-C σ bonding orbital (the HOMO) of R_4M (Si, 10.57, 9.8; Ge, 10.23, 9.4; Sn, 9.70, 9.0 eV for R=Me, Et).[2,15] The correlation of the average of bands corresponding to M-C bonding orbitals of kindred catenates of group 4B elements with M-C σ bonding orbitals (the HOMO) of R_4M is illustrated in Fig. 2. Figure 2 shows that interaction between the M-M bond and the M-C bond is weak.[25]

The ionization potentials of peralkylated catenates of group 4B elements in this study should provide interesting criteria for evaluating electron transfer processes involving catenates of group 4B elements.

Experimental

Peralkylated catenates of group 4B elements (silicon, germanium, and tin) and the photoelectron spectrometer used in these studies have been described previously.[34]

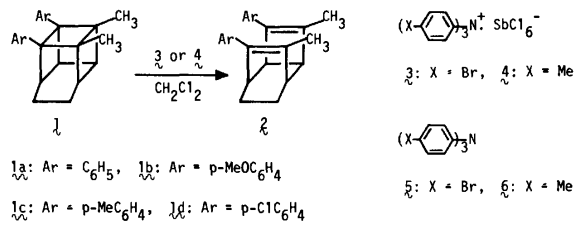
Cycloreversion Reaction of Cage Compounds Initiated by Aminium Cation Radical Salts[1)]

Eietsu HASEGAWA and Toshio MUKAI*
Department of Chemistry, Faculty of Science, Tohoku University, Sendai 980
(Received June 18, 1985)

Synopsis. Treating cage compounds **1** with triarylaminium cation radical salts, **3** and **4**, resulted in the effective conversion of **1** to dienes **2**. The cation radical isomerization induced by electron-transfer from **1** to aminium salt was suggested by the effect of substituent of **1** as well as by the effect of addition of electron donors as quenchers.

Since it was suggested that certain aminium cation radicals play a role of useful one-electron oxidation reagents, [2)] much attention has centered on the cation radical reactions initiated by the aminium cation radical salts.[3)] For instance, Bauld recently reported noticeable aspects of the cation radical pericyclic reactions induced by tris(*p*-bromophenyl)aminium cation radical salt.[4)] On the other hand, Gassman claimed that the aminium salt-catalyzed Diels-Alder reaction proceeds not only by the simple cation radical mechanism but involves the protic acid generation mechanism.[5)] This controversy has prompted us to examine the catalytic character of aminium cation radical salts. For this purpose, we chose cage compounds **1** as reaction substrates, because the cation radicals of **1** cleanly isomerize to those of dienes **2** without any side reactions, and because the electron-donating ability of **1** can be controlled by changing the substituent on the phenyl group.[6)]

Upon stirring a dichloromethane solution of bisphenylated cage compound **1a** and tris(*p*-bromophenyl)aminium hexachloroantimonate **3**[2)] for 1 min at room temperature, quantitative conversion of **1a** to the corresponding diene **2a** was observed, whereas a similar treatment with tris(*p*-methylphenyl)aminium hexachloroantimonate **4**[3i)] gave a lower conversion (22%). This finding can be rationalized in terms of the electron-donating property of neutral amines, **5** and **6**. Since the oxidation potential of **5** ($E_{1/2}^{ox}$=1.05 V)[7,8)] is higher than that of **6** ($E_{1/2}^{ox}$=0.75 V),[7,8)] the electron-transfer from **1a** to aminium cation radical salt **3** is certainly more favorable than that to **4**. The involvement of electron-transfer was furthermore confirmed by the substituent effect of **1** on the reaction with **4** (Table 1). The reactivity of **1a** was lower than those of **1b** and **1c** (see No. 1,2, and 4 in Table 1), while no isomerization was observed for **1d** under similar reaction conditions (No. 6). More facile transformation was observed for **1b** than for **1c** (No. 3 and 5). A correlation of the reactivities with the electron-donating abilities of cage compounds **1** (**1b**>**1c**>**1a**>**1d**) suggests that the reaction efficiency depends on an electron-transfer process from **1** to aminium salt in the first step of the reaction.



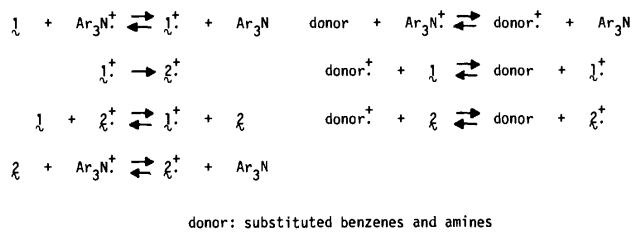
Scheme 1.

Quenching by electron donors is a useful technique for exploring electron-transfer reactions. Substituted benzenes such as 1,4-dimethoxybenzene ($E_{1/2}^{ox}$=1.34 V),[7,9)] 1,3,5-trimethoxybenzene ($E_{1/2}^{ox}$=1.49 V),[7,9)] and toluene ($E_{1/2}^{ox}$=1,98 V),[7,9)] which have oxidation potentials similar to or higher than **1a**, apparently did not quench the reaction of **1a** with **3**. However, 1,2,4,5-tetramethoxybenzene (TMB) effectively quenched the isomerization of **1a** to **2a** (conversion of **1a**=31%). When **3** was added to a dichloromethane solution of **1a** and TMB, the deep blue color of the solution immediately turned to yellow. On the other hand, **2a** was obtained in a similar yield (26%) when **1a** was added to a yellow solution of TMB and **3**. Since electron-transfer from TMB ($E_{1/2}^{ox}$=0.81 V)[7,9)] to **3** is more favorable than that from **1a**, the concentration of TMB cation radical must be even higher than that of the cation radical of **1a** at the initial reaction step. Therefore, **2a** would be mainely formed by an interaction of **1a** with initially formed TMB cation radical. The proposed reaction mechanism is summarized in Scheme 2.

TABLE 1. CYCLOREVERSION REACTION OF CAGE COMPOUNDS **1** BY tris(*p*-METHYLPHENYL)AMINIUM HEXACHLOROANTIMONATE **4**[a)]

No.	Cage(Ar)	$E_{1/2}^{ox}$ / V *vs.* SCE	10⁴×[**4**] / mol dm⁻³	Reac. time / min	Conversion[b)] / %
1	**1a**(C_6H_5)	1.41	2.80	1.0	22
2	**1b**(p-$MeOC_6H_4$)	1.09	2.80	1.0	100
3	**1b**	1.09	0.56	0.5	100
4	**1c**(p-MeC_6H_4)	1.28	2.80	1.0	100
5	**1c**	1.28	0.56	0.5	55
6	**1d**(p-ClC_6H_4)	1.49	2.80	1.0	0

a) [**1**]=2.37—2.42×10⁻² mol dm⁻³ in dichloromethane. b) Determined by ¹H NMR.



Scheme 2.

The aminium salt-catalyzed cycloreversion reaction of **1a** was relatively sensitive to addition of amine derivatives. For instance, addition of alkylamines such as 1,4-diazabicyclo[2.2.2]octane ($E_{1/2}^{ox}$=0.68 V),[7,9] triethylamine ($E_{1/2}^{ox}\simeq$1.0 V),[10] or diethylamine ($E_{1/2}^{ox}\simeq$1.3 V)[10] completely quenched the trans formation of **1a** to **2a**. By contrast, triphenylamine ($E_{1/2}^{ox}$=0.92 V)[7,8] did not quench the cycloreversion reaction of **1a**. These observations are consistent with the fact that alkylamine cation radicals are less stable than arylamine cation radicals.[11] In fact, although the deep blue color of **3** immediately disappeared upon adding the alkylamines to a dichloromethane solution of **3**, triphenylamine did not affect the color of the reaction solution. Therefore, triphenylamine cation radical possessing a relatively long lifetime would interact with **1a**,[3a] resulting in the formation of **2a** *via* cation radicals of **1a** and **2a**. Interestingly the reaction was quenched by pyridine (conversion of **1a**=21%), even though the electron-donating ability of pyridine ($E_{1/2}^{ox}\simeq$2.1 V)[10] is lower than that of toluene which did not quench the reaction. Since **3** was rapidly decolorlized by pyridine in the presence of **1a** but not in its absence, it appears that a direct interaction between **3** and pyridine is not important. A possible interpretation might be provided by assuming that pyridine interacts with the cation radicals of **1a** and **2a**, which are formed by reversible electron-transfer with **3**, to promote the conversion of amine cation radical to neutral amine.

On the other hand, although a protic acid-catalyzed the isomerization of **1a** to **2a**, the reaction efficiency was even lower than that of aminium salt initiated reaction ([**1a**]=2.11×10^{-2} mol dm^{-3}, [HBF_4]$\simeq$ 4×10^{-2} mol dm^{-3}, stirred for 15 min in mixed solvent: CH_2Cl_2/CH_3CN=3/1, conversion of **1a**=17%).

All these findings suggest that the electron-transfer of cage compounds **1** to the aminium cation radical salt initiates the cation-radical isomerization of **1** to dienes **2** which proceeds *via* a cation-radical chain mechanism.[6,12]

Experimental

Measurements and Materials. ^{1}H NMR (60 MHz) were measured on a Varian EM-360A Spectrometer, where CCl_4 containing TMS as an internal standard was used as a solvent. Cage compounds **1** were synthesized according to the literature.[13] Aminium salts were prepared by the reported method.[2,3i]

Aminium Salt-catalyzed Reaction of Cage Compounds 1. The following is a general procedure. To a dichloromethane solution of cage compound **1** (3 ml), aminium salt dissolved in dichloromethane (1 ml) was added ([**1**]=2.32—2.45×10^{-2} mol dm^{-3}, [aminium salt]= 2.80×10^{-4} mol dm^{-3}). After stirring at room temperature, the reaction was quenched by addition of CH_3ONa (28% in methanol: commercial grade). To the reaction solution, 4 ml of dichloromethane and 10 ml of water were added, and then the organic layer was washed with water. Solvent was evaporated after drying (Na_2SO_4). The conversion of **1** was measured by ^{1}H NMR.

The experiments for the effects of additives were carried out under the same conditions as above ([additive]= 2.26—2.47×10^{-2} mol dm^{-3}).

Synthesis of Alkyl Dihydrogenphosphate by the Reaction of Alcohols and Silyl Polyphosphate

Yoshiki OKAMOTO

The Institute of Scientific and Industrial Research, Osaka University, 8-1, Mihogaoka, Ibaraki, Osaka 567

(Received June 27, 1985)

Synopsis. Alkyl dihydrogenphosphates were readily prepared by phosphorylation of alcohols with trimethylsilyl polyphosphate or polyphosphorylated silica-gel.

Various methods have been reported for phosphorylation of alcohols.[1] However, there are a few methods which are well suited to preparation of alkyl dihydrogenphosphate (**1**) for industrial use.[2] The cheapest and convenient method is the phosphorylation with powdery diphosphorus pentaoxide (Eq. 1),

$$3ROH + 1/2P_4O_{10} \longrightarrow \underset{\mathbf{1}}{(RO)P(O)(OH)_2} + \underset{\mathbf{2}}{(RO)_2P(O)OH} \quad (1)$$

which has been widely used for industrial production of surfactants of **1**.[3] But, this reaction was always accompanied by the formation of considerable amounts (16—20%) of dialkyl hydrogenphosphate (**2**). Furthermore, vigorous stirring and careful control of the temperature are required, because the reaction is heterogeneous and much exothermic.

In this report, a new selective synthetic method of **1** by phosphorylation of alcohols with trimethylsilyl polyphosphate (**3**) is described. Trimethylsily polyphosphate (**3**) is readily prepared by refluxing the benzene solution of diphosphorus pentaoxide and hexamethyldisiloxane.[4,5] Alcohol reacts smoothly with **3** to give alkyl trimethylsilyl hydrogenphosphate (**4**), which is easily hydrolyzed with water into **1** (Eq. 2). For the purpose of synthesis of **1**, the trimethylsilyl polyphosphate (**3**),

$$n\mathrm{ROH} + \underset{\mathbf{3}}{\left[\begin{array}{c}O\\ \|\\ -O-P-O-\\ |\\ OSiMe_3\end{array}\right]_n} \longrightarrow \underset{\mathbf{4}}{n\mathrm{RO}-\overset{O}{\overset{\|}{P}}-OH} \xrightarrow{H_2O} \underset{\mathbf{1}}{n\mathrm{RO}-\overset{O}{\overset{\|}{P}}-OH} + n/2Me_3SiOSiMe_3 \quad (2)$$
$$\quad\quad\quad

Table 3. Results of phosphorylation of 1-decanol with polyphosphorylated silica-gel (**5**)[a]

Polyphosphorylated silica-gel (**5**) Reagent ratio (weight ratio) P_4O_{10}/Silica-gel	Yields of phosphates/%	
	$C_{12}H_{21}OP(O)(OH)_2$(**1b**)	$(C_{12}H_{21}O)_2P(O)OH$(**2b**)
1/8	52	2
1/5	58	4.5
1/2	64	9
Without silica-gel	69	18

a) With polyphosphorylated silica-gel (**5**) prepared from P_2O_{10} 7.1 g (25 mmol) and prescribed amounts of silica-gel, 1-decanol 15.8 g (100 mmol) was phosphorylated in benzene (100 ml) at the refluxing temperature for 4 h.

combined alkaline extacts were acidified with 60 ml of 10% hydrochloric acid solution, and again extacted three times with 100 ml of ether. The ethereal solution was dried (Na_2SO_4), and evaporation of the ether gave 17.0 g of colorless crystalline product (76% yield) in an almost pure state. However, the product **1a**, **f**, and **g**, which did not crystalize, were characterized as anilinium salts. The **1/2** ratios of these products were determined by elemental analysis or alkalimetry.[10]

Typical Procedure 2: Reaction With Polyphosphorylated Silica-gel (5). The mixture of dry silica-gel (20 g, Kieselgel 60, 70—230 mesh, Merck for chromatography, calcinated at 900 °C for 4 h), diphosphorus pentaoxide (7.1 g, 25 mmol), and 100 ml of benzene was stirred at refluxing temperature for 3 h. 1-Decanol (15.8 g, 100 mmol) was added to the mixture and it was stirred at the same temperature for 4 h. After the reaction, the solvent was removed off, and 100 ml of water was added into the residue to hydrolyze the silyl phosphate. The mixture was filtered, and the silica-gel was washed twice with 100 ml of ether. The combined ether solutions were extracted three times with 20 ml of 5% sodium hydroxide solution. The combined alkaline extracts were acidified with 60 ml of 1 mol dm^3 hydrochloric acid solution, and again extracted three times with 100 ml of ether. The ethereal solution was dried and evaporation of the ether gave a mixture of decyl dihydrogenphosphate (**1b**) and didecyl hydrogenphosphate (**2b**) in 58% and 4.5% yields, respectively.

Chemistry of *N*-Nitrososulfonamides. Substitution Reaction by the Acetyl Group

Masaaki IWATA* and Hiroyoshi KUZUHARA
Riken (The Institute of Physical and Chemical Research), Wako, Saitama 351-01
(Received April 1, 1985)

Synopsis. The *N*-nitroso group on *N*-nitrososulfonamides was substituted for the acetyl group in chloroform to give *N*-acetylsulfonamides in moderate yields.

We started the present research in order to understand fundamental chemical properties of sulfonamides. From attempts to survey the reactivity of the sulfonamide group, we found a new substitution reaction of the *N*-nitroso derivatives for an acetyl group without a base.

Nitrosation of sulfonamide was performed in quantitative yield by use of a modified procedure using a sodium nitrite-acetic anhydride-acetic acid mixture.[1-3] Thus, α,ω-bis(*N*-nitrososulfonamide)s, **2a—c**, were prepared from the corresponding sulfonamides **1a—c**. The nitroso group could be removed by either light, protic solvents, radical initiator such as AIBN, or L-ascorbic acid to regenerate the corresponding sulfonamides.

It was predicted that acid anhydride and *N*-nitrososulfonamide can be disposed to take a six-membered cyclic transition state advantageous for the lowered activation energy upon a substitution reaction through an intermediate (**5**). When a suspended mixture of **2a**, acetic anhydride, and chloroform was refluxed, **3a** (diacetyl sulfonamide) and **4a** (monoacetyl sulfonamide) were obtained in 54 and 13% yields, respectively. In the same way, **2b** and **2c** gave the corresponding diacetyl sulfonamides, **3b** and **3c**, in 38 and 29% yields, respectively. Usual acetylation of **1a** employing acetic anhydride and pyridine afforded neither mono- nor diacetyl sulfonamide. In addition, more drastic acetylation using acetyl chloride unsatisfactorily gave **3c** and **4c**. These results indicate that the acetyl substitution reaction of *N*-nitrososulfonamides effectively proceeds through such a transition state **5** as predicted.

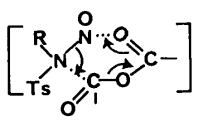
b R = $-(CH_2)_6-$

c R = $-(CH_2)_2-$



5

IR and ^{1}H-NMR spectral data suggested the stronger electrophilic nature of the acetyl group on *N*-acetylsulfonamides than those in usual acetates and acetamides. When a mixture of **3a** and anhydrous potassium carbonate in a mixed solvent of methanol-water was refluxed,[4] **1a** was obtained in quantitative yield.

The net cycle of introduction-removal of the *N*-acetyl group regarding sulfonamides will become a possible route to utilize the *N*-acetyl group as a protecting group for a variety of synthetic purpose.

Experimental

^{1}H-NMR spectra were recorded on a JEOL JNM GX-400 (400 MHz) spectrometer with Me_4Si as the internal standard in $CDCl_3$; chemical shifts (δ) and coupling constants (J) are in parts per million and Herz, respectively. Infrared spectra (IR) was obtained on a Shimadzu IR-27G spectrophotometer. Electronic absorption spectra (UV) were recorded on a Hitachi 124 spectrophotometer. Mass spectra (MS; rel. intensity) were recorded with a Hitachi RMU-6MG spectrometer by using an ionizing potential at 20 eV. Merck silica-gel 60 (Art. 7734, 0.063—0.20) was used for column chromatography and Merck precoated silica-gel 60 F_{254} plates (Art. 5715, 20×20) were used for thin-layer chromatography (TLC). The solvent system employed for column chromatography and TLC was benzene-ethyl acetate (10:1 v/v) and R_f values are referred to this solvent system, unless otherwise noted. α,ω-Disulfonamides (**1**) were prepared by the previously described method.[5] Elemental analyses were performed at Riken. The uncorrected melting points were measured with a micro melting-point apparatus (Yanagimoto Seisakusho).

N-Nitrosation of Sulfonamides. Optimal *N*-nitrosation was achieved by the following modified method of that described by de Boer *et al.*[2b] To a suspended mixture of sulfonamide (**1**) (1 g), acetic anhydride (10 ml), and acetic acid (2 ml), was added sodium nitrite (2 mol eq to **1**) portion by portion at *ca.* 10 °C, while rapidly stirred. After stirring for 30 min at room temperature, water (30 ml) was added to quench the reaction. The mixture was stirred for 30 min at *ca.* 10 °C. Crystalline α,ω-bis(*N*-nitrososulfonamide)s (**2**) were collected by filtration and washed well with water. This pale-yellow crystalline solid was pure enough.

2a: (90% yield) mp 131—133 °C. Calcd for $C_{22}H_{22}N_4S_2O_6$: C, 52.58; H, 4.41; N, 11.15; S, 12.76%. Found: C, 52.36; H, 4.40; N, 10.91; S, 12.72%. IR (KBr) 1510(N=O), and 1380 and 1170(SO_2) cm^{-1}. R_f 0.75.

2b: (99% yield) mp 86—88 °C. Calcd for $C_{20}H_{26}N_4S_2O_6$: C, 49.78; H, 5.43; N, 11.61; S, 13.29%. Found: C, 50.26; H,

5.49; N, 10.77; S, 13.33%. IR (KBr) 1510(N=O), and 1375 and 1169(SO_2) cm^{-1}. R_f 0.75.

2c: (99% yield) mp 120 °C (decomp). Calcd for $C_{16}H_{18}N_4S_2O_6$: C, 45.06; H, 4.25; N, 13.14; S, 15.04%. Found: C, 45.34; H, 4.26; N, 12.96; S, 14.88%. IR (KBr) 1516(N=O), and 1384, 1188, 1174, and 1155(SO_2) cm^{-1}. R_f 0.75.

Reaction of N-Nitrososulfonamides with Acetic Anhydride in Chloroform. When a suspended mixture of *N*-nitrososulfonamide (**2**) (1 g), acetic anhydride (1 ml) and chloroform (20 ml) was refluxed, the suspension disappeared in 10 min. The reaction was monitored by tlc till no more change was observed (15—30 h). After cooling, the reaction mixture was evaporated and the residue was chromatographed on a silica-gel column. Thus **2a** gave *N,N'*-diacetyl-*N,N'*-ditosyl-α,α'-*p*-xylenediamine (**3a**) in 54% yield and *N*-acetyl-*N,N'*-ditosyl-α,α'-*p*-xylenediamine (**4a**) in 13% yield.

Recrystallization of **3a** from diethyl ether gave colorless crystals; mp 178—180 °C. Calcd for $C_{26}H_{28}N_2S_2O_6$: C, 59.07; H, 5.34; N, 5.30; S, 12.13%. Found: C, 59.06; H, 5.36; N, 5.10; S, 12.10%. IR (KBr) 1700(C=O), and 1350 and 1160(SO_2) cm^{-1}. ^{1}H-NMR; 2.31 ($COCH_3$), 2.43 (CH_3), and 5.07 (CH_2). MS; *m/z* 444 (0.4%), 374 (100%), and 332 (38%).

Recrystallization of **4a** from diethyl ether gave colorless crystals; mp 142—143 °C. Calcd for $C_{24}H_{26}N_2S_2O_5$: C, 59.24; H, 5.39; N, 5.76; S, 13.18%. Found: C, 59.27; H, 5.45; N, 5.58; S, 12.96%. IR (KBr) 3280(NH), 1700(C=O), and 1358, 1318, 1163, and 1148(SO_2) cm^{-1}. ^{1}H-NMR; 2.28 ($COCH_3$), 2.44 and 2.45 (CH_3), 4.11 (J=6.11, CH_2), 4.62 (J=6.11, NH), and 5.02 (CH_2). MS; *m/z* 445 (0.9%), 332 (87%), 290 (100%).

N,N'-Diacetyl-*N,N'*-ditosyl-1,6-hexanediamine (**3b**) was obtained from **2b** in 29% yield (R_f 0.5, benzene-ethyl acetate 4:1 v/v), accompanied by two other unidentified products at R_f 0.8 and 0.66. Recrystallization of **3b** from acetone-diethyl ether gave colorless crystals; mp 155—157 °C. Calcd for $C_{24}H_{32}N_2S_2O_6$: C, 56.67; H, 6.34; N, 5.51; S, 12.61%. Found: C, 56.70; H, 6.36; N, 5.33; S, 12.50%. IR (KBr) 1700(C=O), and 1360 and 1158(SO_2) cm^{-1}. ^{1}H-NMR; 1.37 (CH_2), 1.71 (CH_2), 2.32 ($COCH_3$), 2.45 (CH_3), 3.76 (J=7.56, NCH_2). MS; *m/z* 337 (100%), 296 (30%), and 254 (42%).

N,N'-Diacetyl-*N,N'*-ditosyl-1,2-ethanediamine (**3c**) was obtained from **2c** in 38% yield (R_f 0.58, benzene-ethyl acetate 4:1 v/v), accompanied by an unidentified product at R_f 0.77. Recrystallization of **3c** from benzene gave colorless fine needles; mp 215—216 °C. Calcd for $C_{20}H_{24}N_2S_2O_6$: C, 53.08; H, 5.35; N, 6.19; S, 14.17%. Found: C, 53.02; H, 5.33; N, 6.16; S, 14.02%. IR (KBr) 1700(C=O), and 1340 and 1170(SO_2) cm^{-1}. ^{1}H-NMR; 2.43 ($COCH_3$), 2.45 (CH_3), and 4.01 (NCH_2). MS; *m/z* 240 (27%), 226 (4.2%), and 184 (100%).

Reaction of Sulfonamide (1c) with Acetyl Chloride. To a suspended mixture of 0.5 g of **1c** in 20 ml of chloroform, 1 ml of acetyl chloride was added all at once. To the mixture, 1 ml of triethylamine was added at 0—5 °C. After 15 min, the reaction was found to be almost completed on TLC. After evaporation of solvents, the residue was chromatographed on a silica-gel column eluted with chloroform-acetone (93:7 v/v), to give 49 mg (8% yield) of **3c** and 152 mg (27%) of *N*-acetyl-*N,N'*-ditosyl-1,2-ethanediamine (**4c**). The rest was the unchanged starting **1c**. **4c** was obtained as colorless viscous liquid (spontaneous cryst.). Calcd for $C_{18}H_{22}N_2S_2O_5$: C, 52.66; H, 5.40; N, 6.83; S, 15.62%. Found: C, 52.59; H, 5.39; N, 6.74; S, 15.43%. IR (KBr) 3250(NH), 1700(C=O), and 1360, 1328, and 1158(SO_2) cm^{-1}. ^{1}H-NMR; 2.31 ($COCH_3$), 2.44 and 2.46 (CH_3), 3.24 (J=6.10, NCH_2), 3.88 (J=6.10, NCH_2), 4.95 (J=6.10, NH). MS; *m/z* 255 (18%), 213 (3.2%), 197 (19%), and 184 (100%).

Spontaneous Decomposition of N-Nitrososulfonamide (2a) in Ethanol. When an ethanolic solution of **2a** (0.315 mg/20 ml) was allowed to stand on a bench top, the reaction induced by ambient room light was monitored by repetitive measurements of the UV spectra (every day in the range 210—350 nm). The original shoulder band at 250 nm revealed hypochromism and a band at 290 nm, hyperchromism, having an isosbestic point at 271 nm. After 47 d, the decomposition of **2a** became less significant. The eventual UV spectrum was superimposable to that of **1a**.

Removal of the N-Nitroso Group in N-Nitrososulfonamide (2c) with L-Ascorbic Acid. When a mixture of 0.43 g (1 mmol) of **2c** and 0.178 g (1 mmol) of L-ascorbic acid in 20 ml of ethanol was heated at *ca.* 70 °C overnight, **1c** was the only isolable product in quantitative yield. At the lowered temperature, the reactioin was markedly retarded.

Removal of N-Acetyl Group in N-Acetylsulfonamide (3a) with Potassium Carbonate. When a mixture of 90 mg of **3a** and 0.188 g (8 mmol eq) of anhydrous potassium carbonate in a mixed solvent of methanol-water (20 ml:1 ml) was refluxed for 1 h, **1a** was obtained in quantitative yield (76 mg) after silica-gel chromatography eluted with chloroform–methanol (17:3 v/v).

We are grateful to Dr. Haruo Homma and his staff at Riken for performing elemental analyses and Dr. Jun Uzawa and Mrs. Tamiko Chijimatsu at Riken for recording ^{1}H-NMR spectra.

Stereoselective Synthesis of (*E*)-Alkylidenesuccinates by Palladium-catalyzed Carbonylation

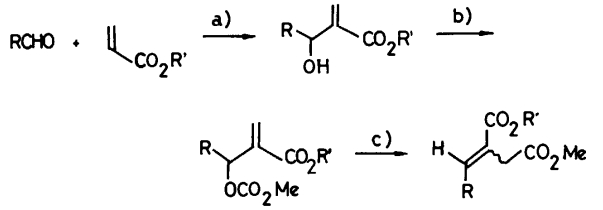
Keiji YAMAMOTO,* Ryoji DEGUCHI, and Jiro TSUJI
Department of Chemical Engineering, Tokyo Institute of Technology, Meguro-ku, Tokyo 152
(Received May 30, 1985)

Synopsis. (*E*)-Alkylidenesuccinates have been prepared stereoselectively starting with acrylates by a three-step procedure involving a palladium-catalyzed carbonylation of allylic carbonates.

The well-known Stobbe condensation of aldehydes with an ester of succinic acid is rather limited to the use of aromatic aldehydes, because in the case of aliphatic ones possible isomerization of the produced alkylidenesuccinic acids often yields positional as well as geometrical isomers.[1]

We report here that (*E*)-alkylidenesuccinic acid esters can readily be prepared by a three-step procedure which consists of a base-catalyzed addition of acrylates to aliphatic aldehydes,[2] carbonate formation of the resulting allylic alcohols, and facile palladium-catalyzed carbonylation of the allylic carbonates reported recently by one of us.[3] Scheme 1 shows the procedure.

Although the addition of acrylates to common aldehydes was found to take place slowly but in moderate yields, the yield in carbonate formation was rather inconsistent with recovery of the starting allylic alcohols (40—85% yield).



a) 1,4-Diazabicyclo[2.2.2]octane (DABCO) (20 mol%). b) $ClCO_2Me$/pyridine/benzene. c) $Pd(OAc)_2+2PPh_3$ (2 mol%)/CO (20 kg/cm²).

Scheme 1.

The decarboxylation-carbonylation was carried out by using allyl methyl carbonates thus obtained in the presence of a catalytic amount (2 mol%) of a palladium(0)-phosphine complex generated *in situ* under carbon monoxide pressure at 50 °C.[3]

It should be mentioned that the palladium-catalyzed carbonylation is very characteristic of allylic carbonates, other allylic derivatives, such as halides or acetates, being hardly applicable to the catalytic process.

In Table 1 are summarized the results of the preparation of alkylidenesuccinates (**2**).

Three points may be worth commenting: 1) CO pressure affects significantly both the yield of **2** and the selectivity for *E*/*Z* isomers (Table 1, entries 1—3). 2) Satisfactorily high *E*-selectivity (entries 3—5) must be a direct consequence of the carbonylation from *anti*-η^3-allylpalladium intermediate which contains an alkoxycarbonyl group at 2-position. 3) While an isopropyl ester in **1b** has no effect in favor of forming (*E*)-**2b**, an isopropyl substituent of R in **1c** enhances *E*-selectivity of **2c**.

In addition to these results, it was found that the carbonylation of the corresponding cyano analogue of **1**, which was obtained similarly starting with acrylonitrile, afforded mainly (*Z*)-alkylidenesuccinic acid mononitrile (**3**) (*E*/*Z*=1/6), reflecting *syn*-η^3-allylpalladium intermediate to be carbonylated preferably. It follows, therefore, that effect of an alkoxycarbonyl group at 2-position of *anti*-1,2-disubstituted η^3-allylpalladium is steric rather than electronic.

Experimental

Preparation of 3-(Methoxycarbonyloxy)-2-methylenealkanoate (1). A typical procedure is as follows: A mixture of isovaleraldehyde (40 mmol), methyl acrylate (40 mmol), and DABCO (8 mmol) was stirred at room temperature for several days.[2] Remaining acrylate was removed *in vacuo*, the residue was taken up in dichloromethane, washed with 1M HCl(1 M=1 mol dm^{-3}), and dried ($MgSO_4$). The concentrated material was distilled under reduced pressure to give methyl 3-hydroxy-5-methyl-2-methylenehexanoate, bp 48—50 °C/2 Torr (52% yield) (1 Torr=133.322 Pa). The latter (10 mmol) was treated with methyl chloroformate (30 mmol) and pyridine (30 mmol) in dry benzene (50 mL) in a usual manner giving methyl 3-(methoxycarbonyloxy)-5-methyl-2-methylenehexanoate (**1a**), bp 62—64 °C/2 Torr (85%).

Similarly, from isopropyl 3-hydroxy-5-methyl-2-methylenehexanoate (bp 65—67 °C/3 Torr, 62%), isopropyl 3-(methyoxycarbonyloxy)-5-methyl-2-methylenehexanoate (**1b**) was obtained and purified by column chromatography (70% yield with 43% recovery of the starting alcohol). From methyl 3-hydroxy-4-methyl 2-methylenepentanoate (bp 78—80 °C/4 Torr, 51%), methyl 3-(methoxycarbonyloxy)-4-methyl-2-methylenepentanoate (**1c**) was prepared and purified similarly as above (40% yield with 26% recovery of the starting material).

Proton NMR data of **1a—c** are given below: ^{1}H NMR (90 MHz, $CDCl_3$, TMS) **1a**: δ=0.93 (d, J=5.9 Hz, 3H), 0.96 (d, J=5.7 Hz, 3H), 1.54—1.68 (m, 3H), 3.78 (s, 3H), 3.79 (s, 3H), 5.47—5.61 (m, 1H), 5.84 (br s, 1H), and 6.30 ppm (br s, 1H). **1b**: 0.94 (d, J=6.4 Hz, 3H), 0.95 (d, J=6.2 Hz, 3H), 1.29 (d, J=6.4 Hz, 6H), 1.35—1.58 (m, 2H), 1.60—2.04 (m, 1H), 3.77 (s, 3H), 5.10 (sept, J=6.3 Hz, 1H), 5.45 (br t, J=7.2 Hz, 1H), 5.77 (t, J=1.2 Hz, 1H), and 6.18 (d, J=0.7 Hz, 1H). **1c**: 0.92 (d, J=6.6 Hz, 3H), 0.96 (d, J=6.8 Hz, 3H), 1.82—2.26 (m, 1H), 3.78 (s, 3H), 3.79 (s, 3H), 5.34 (dd, J=0.9 and 5.5 Hz, 1H), 5.80 (t, J=1.0 Hz, 1H), and 6.37 (d, J=0.9 Hz, 1H).

General Procedure for the Palladium-catalyzed Carbonylation. In a 50 mL micro-autoclave with glass lining were placed under a nitrogen atmosphere an allylic carbonate (**1**) (5 mmol), $Pd(OAc)_2$ (2 mol%) and PPh_3 (4 mol%). Carbon monoxide was introduced (20 kg/cm^2) and the mixture was heated at 50 °C overnight with stirring. The red-brown solution was filtered through a short Florisil column to remove the catalyst, the latter being rinsed with little ether. The filtrate was condensed *in vacuo*, and the residue was purified by distillation under reduced pressure (Kugelrohr) to give the corresponding alkylidenesuccinate (**2**). (*Z*)-Isomer as a minor component was isolated by preparative GLC and identified by ^{1}H and/or ^{13}C NMR. Yields and the ratios of *E*- and *Z*-isomers of **2** are summarized in Table 1, and spectral and analytical data of **2a—c** and **3** are given below:

Dimethyl (E)-(3-Methylbutylidene)succinate (2a): ^{1}H NMR 0.94 (d, J=6.4 Hz, 6H), 1.32—1.92 (m, 1H), 2.09 (dd, J=6.4 and 7.5 Hz, 2H), 3.36 (s, 2H), 3.68 (s, 3H), 3.75 (s, 3H), and 7.00 (t, J=7.5 Hz, 1H). ^{13}C NMR (22.5 MHz) δ=22.4 (MeX2), 28.2, 32.2, 38.0, 51.9 (OMeX2), 125.9, 144.9, 167.4, and 171.2 ppm. IR (neat) 1263, 1715, and 1745 cm^{-1}. Anal. Calcd for $C_{11}H_{18}O_4$: C, 61.82; H, 8.47%. Found: C, 61.82; H, 8.37%. (*Z*)-**2a**: ^{1}H NMR 0.92 (d, J=6.2 Hz, 6H), 1.20—1.90 (m, 1H), 2.47 (dd, J=6.8 and 7.5 Hz, 2H), 3.28 (s, 2H), 3.68 (s, 3H), 3.74 (s, 3H), and 6.09 (t, J=7.5 Hz, 1H).

1-Isopropyl 4-Methyl (E)-2-(3-Methylbutylidene)succinate (2b): ^{1}H NMR 0.94 (d, J=6.4 Hz, 6H), 1.26 (d, J=6.4 Hz, 6H), 1.60—2.00 (m, 1H), 2.08 (t, J=7.3 Hz, 2H), 3.34 (s, 2H), 3.67 (s, 3H), 5.06 (sept, J=6.3 Hz, 1H), and 7.04 (t, J=7.6 Hz, 1H). ^{13}C NMR 21.8 (MeX2), 22.5 (MeX2), 28.3 32.4, 37.9, 51.9, 68.1, 126.6, 144.1, 166.4, and 171.4. IR (neat) 1260, 1710, snf 1740 cm^{-1}. Anal. Calcd for $C_{13}H_{22}O_4$: C, 64.44; H, 9.15%. Found: C, 64.18; H, 9.07%. (*Z*)-**2b**: ^{1}H NMR 0.93 (d, J=6.6 Hz, 6H), 1.25 (d, J=6.4 Hz, 6H), 1.44—1.85 (m, 1H), 2.47 (t, J=7.2 Hz, 2H), 3.26 (s, 2H), 3.67 (s, 3H), 5.07 (sept, J=6.3 Hz, 1H), and 6.05 (t, J=7.5 Hz 1H). ^{13}C NMR 21.8 (MeX2), 22.4 (MeX2), 28.8, 38.4, 40.4, 51.8, 67.8, 126.0, 145.9, 166.8, and 172.0.

Dimethyl (E)-(2-Methylpropylidene)succinate (2c): ^{1}H NMR 1.04 (d, J=6.6 Hz, 6H), 2.24—2.95 (m, 1H), 3.36 (s, 2H), 3.68 (s, 3H), 3.74 (s, 3H), and 6.77 (d, J=10.1 Hz, 1H). ^{13}C NMR 21.9 (MeX2), 28.5, 32.2, 52.0 (OMeX2), 123.2, 152.1, 167.6, and 171.3. IR (neat) 1265, 1710, and 1740 cm^{-1}. Anal. Calcd for $C_{10}H_{16}O_4$: C, 59.98; H, 8.05%. Found: C, 60.33; H, 8.07%. (*Z*)-**2c**: ^{1}H NMR 1.02 (d, J=6.6 Hz, 6H), 3.12—3.48 centered at 3.37 (decoupled) (m, 1H), 3.24 (s, 2H), 3.68 (s, 3H), 3.74 (s, 3H), and 5.84 (d, J=9.9 Hz, 1H).

Methyl (Z)-3-Cyano-6-methyl-3-heptenoate (3): ^{1}H NMR 0.96 (d, J=6.4 Hz, 6H), 1.56—2.12 (m, 1H), 2.32 (dd, J=7.0 and 7.3 Hz, 2H), 3.24 (s, 2H), 3.75 (s, 3H), and 6.33 (t, J=7.7 Hz, 1H). ^{13}C NMR 22.2 (MeX2), 28.2, 39.0, 40.6, 52.4, 108.0, 116.9, 151.1, and 169.5. IR (neat) 1260, 1740, and 2200 cm^{-1}. Anal. Calcd for $C_{10}H_{15}NO_2$: C, 66.27; H, 8.34;, N, 7.73%. Found: C, 66.16; H, 8.40; N, 7.58%. (*E*)-**3**: ^{1}H NMR 0.93 (d, J=6.4 Hz, 6H), 1.56—1.96 (m, 1H), 2.10 (dd, J=6.6 and 7.3 Hz, 2H), 3.26 (s, 2H), 3.75 (s, 3H), and 6.58 (t, J=7.6 Hz, 1H). ^{13}C NMR 22.2 (MeX2), 28.1, 34.1, 37.7, 52.4, 107.8, 116.7, 150.8, and 168.9.

Convenient Synthesis of β-Truxinic Acid *via* Photodimerization of *p*-Nitrophenyl Cinnamate in the Crystalline State

Tadatomi NISHIKUBO,* Eiji TAKAHASHI, Takatoshi MIYAJI, and Takashi IIZAWA
Department of Applied Chemistry, Faculty of Engineering, Kanagawa University, Rokkakubashi, Kanagawa-ku, Yokohama 221
(Received June 13, 1985)

Synopsis. β-Truxinic acid was synthesized in extremely high yield *via* a topochemical photodimerization of *p*-nitrophenyl cinnamate crystals, followed by the hydrolysis of the obtained dimer.

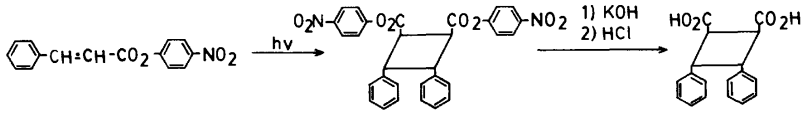
Since topochemical photodimerizations of cinnamic acid derivatives have been investigated extensively by Schmidt and his co-workers,[1] the photodimerizations of cinnamic acids and other olefinic compounds in the crystalline state, which is very interesting as crystal engineering, have been reported. The stable α-form of (*E*)-cinnamic acid gives α-truxillic acid selectively whereas the metastable β-form of (*E*)-cinnamic acid yields pure β-truxinic acid at low temperature. However, the metastable form of (*E*)-cinnamic acid is transformed to the stable form at temperatures higher than 50 °C in the crystalline state. Recently, although many substituted α-truxillic acids or β-truxinic acids were prepared[2-5] by the topochemical photodimerizations of the corresponding forms of substituted (*E*)-cinnamic acids, the unsubstituted β-truxinic acid has not been obtaind by topochemical photodimerization on a preparative scale so far due to the above transformation.

This article reports on the successful photodimerization of *p*-nitrophenyl cinnamate (NPC) in a crystalline state at various temperatures to give β-truxinic acid in high yield per reaction. As shown in Fig. 1, the rate of photochemical reaction of NPC embeded in KBr pellet was much faster than those of cinnamic acid (CA) and phenyl cinnamate (PC). This means that NPC has a high photochemical reactivity in the crystalline state.

Therefore, the photochemical reaction of NPC has been carried out under various conditions. The results are summarized in Table 1. The yield of bis(*p*-nitrophenyl) β-truxinate (BNPT) was not affected by the reaction temperature, the solvent and air. However, the yield was dependent on the irradiation time. The yield of BNPT was also affected by the amounts of NPC suspended in hexane, because a small amount of the suspended NPC was soluble in hexane. (*E*)-NPC in a hexane solution changed to the (*Z*)-isomer (confirmed by HPLC) upon irradiation by UV light.

According to the intensity of the X-ray diffraction patterns, the crystallinity of NPC decreased extremely along with the progress of the reaction. Then, new weak peaks, which seem to be peaks of the dimer crystal, appeared. However, the diffraction pattern of as-prepared BNPT was quite different from that of the recrystallized BNPT. This is good evidence that the reaction of NPC proceeded topochemically.

Recently, we have found[6] that the pendant 4-nitrophenoxide moiety acts as an excellent photosensitizer for a pendant cinnamic ester in a polymer film and a diluted solution of the polymer. From these results, it seems that 4-nitrophenoxide on NPC



(NPC) (BNPT)

Table 1. Photochemical reaction of NPC in the crystalline state

Run No.	Cinnamic ester/g/l	Dispersant	Irradiation conditions		Yield
			Temp/°C	Time/h	%
1	NPC (4.0)	Hexane	30	3	67.3
2	NPC (12.0)	Hexane	30	3	80.2
3	NPC (20.0)	Hexane	30	3	88.9
4	NPC (40.0)	Hexane	30	3	84.4
5	NPC (40.0)	Hexane	30	3	85.2[a]
6	NPC (40.0)	Hexane	−10	3	89.9

also acted as a photosensitizer in the crystalline state.

The BNPT obtained by a photodimerization reaction in a crystalline state was successfully hydrolyzed in high yield to give β-truxinic acid using excess potassium hydroxide in methanol.

From these results, we reveal here that NPC is an excellent starting compound for obtaining an unsubstituted β-truxinic acid by crystal engineering.

Experimental

NPC (mp 144—145 °C)[7] was prepared through a reaction of cinnamoyl chloride with 4-nitrophenol. Then it was recrystallized twice from methanol.

Measurement of the Rate of Photochemical Reaction of NPC in KBr Pellet. NPC (10^{-6} mol) with KBr (0.089 g) was ground and molded into pellet form. The pellet fastened to a plate was irradiated using 250-W high-pressure mercury lamp (Ushio Electric Co., USH-250D) at a distance of 30 cm. The rate of the disappearance of the absorption peak due to a C=C group at 1640 cm^{-1} was measured by IR spectrometry (JASCO model A-202).

Synthesis of BNPT by Photodimerization of NPC in the Crystalline State. NPC crystals (1.6—80 g) were dispersed in hexane (400 ml) in a Pyrex flask. The flask was then irradiated with a 100-W high-pressure mercury lamp (Ushio Electric Co., UM-102) at various temperatures. Then the progress of the reaction was monitored by measuring the decrease of NPC and the increase of BNPT by HPLC [JASCO model; Twincl, detecter; uvidec-100-III, column (4.6 mm×250 mm) packed with a silicagel-ODS-10, elutant; water-acetonitrile (ratio; 4/6)] and/or from UV spectrum of NPC (absroption maximum; 271 nm in THF) by the spectrometry (Shimazu model; UV-240). The final product was filtered off, washed with hot methanol, and recrystallized twice from 2-butanone. Mp 192—193 °C. IR (KBr) 1750 (C=O), 1520 and 1350 ($-NO_2$), 1150 cm^{-1} (C-O-C). NMR ($CDCl_3$) δ=4.6 (s, 2H, C-CH-C), and 7.1—8.5 (m, 9H, aromatic protons). Found: C, 66.51; H, 4.10; N, 5.10%. Calcd for $C_{30}H_{22}N_2O_8$: C, 66.91; H, 4.12; N, 5.20%.

Synthesis of β-truxinic acid by Hydrolysis of BNPT. BNPT (53.8 g; 0.1 mol) and potassium hydroxide (28.1 g; 0.5 mol) were dissolved in methanol (250 ml). Then, the solution was refluxed for 5 h. The reaction mixture was poured into water (750 ml) the PH of the solution was adjusted to 3 with concd HCl solution. The precipitated β-truxinic acid was filtered off, washed with water, and dried. Yield: 28.6 g (96.7%). The crude β-truxinic acid was recrystallized twice from acetic acid. Mp 209—210 °C (Lit,[8] 209—210 °C).

The authors thank professor M. Hasegawa of the University of Tokyo for his helpful advice.

The 1-Octanol/Water Partition Coefficient of Mercury

Shoichi OKOUCHI* and Sokichi SASAKI
Chemical Laboratory, College of Engineering, Hosei University, Koganei, Tokyo 184
(Received February 8, 1985)

Synopsis. The 1-octanol/water partition coefficient of metallic mercury was measured as a useful parameter for predicting the environmental behavior or fate of mercury. The partition coefficient obtained was 4.15±0.20 at 298 K; it slightly decreased from 4.80 to 3.80 as the temperature rose from 278 to 308 K. The partition coefficient of metallic mercury is very low in comparison with those of such nonpolar organic compounds as benzene and tetrachloromethane. Therefore, it was found that metallic mercury has a tendency to be further concentrated in the atmosphere.

It is well known that mercury has been released to the environment[1] by the combustion of fossil fuels. It has been increasingly important to predict how contaminants will behave upon their release to the environment in order to assess the potential hazards of contaminants. Several models[2,3] have been developed which predict environmental behavior or fate from accessible physico-chemical properties, such as vapor pressure, aqueous solubilities, Henry's constant, the soil-sorption constant, and the bioconcentration factor. The soil-sorption constant based on the organic carbon content[4,5] and, in particular, the bioconcentration factor[6,7] are complicated to measure experimentally, therefore, they have been correlated to the 1-octanol/water partition coefficient,[16] which is relatively measurable. The partition coefficient is, then, very useful parameter in predicting the environmental behavior of a contaminant.

In this work, the partition coefficient of metallic mercury is experimentally determined; no information on this has previously been reported.

Experimental

All the chemicals used were of an analytical-reagent grade. The metallic mercury was further purified in the usual manner.[8] The 1-octanol/water was distilled twice to remove trace amounts of impurities, which tended to produce emulsions.[9] Doubly distilled water was used throughout this work.

By shaking an octanol solution containing a few drops of the purified metallic mercury and 0.001 mol dm^{-3} of hydrazine used as a reducing agent to prevent the mercury oxidation,[8] the mercury was dissolved into the 1-octanol (approximately 0.8 mg-mercury/cm^3). A 2-cm^3 aliquot of the 1-octanol solution and 20 cm^3 of the distilled water were then shaken for 24 h at a constant temperature in a closed 25-cm^3 centrifuge tube. After equilibrium and then centrifugation, the two phases were separated and analyzed by means of the cold-vapor atomic-absorption method.[10] The mercury concentrations in the two phases were constant after 24 h of shaking and thereafter remained constant over a period of several days. The 1-octanol/water partition coefficient was determined in the temperature range from 278 to 308 K.

Results and Discussion

Figure 1 shows the effect of the temperature on the 1-octanol/water partition coefficient, K_{OW}. The partition coefficient was 4.15±0.20 at 298 K, but it slightly decreased from 4.80 to 3.80 as the temperature rose from 278 to 308 K. The K_{OW} value of metallic mercury thus obtained is very low in comparison with those of nonpolar organic compounds, for example, 1.34×10^2 [11] for benzene and 4.37×10^2 [11] for tetrachloromethane, and with that of 1.66×10^6 [16]for PCB (aroclor 1242).

Table 1 shows the soil-sorption constant, based on the organic carbon content, K_{OC}, and the bioconcentration factor, K_B, of metallic mercury and organic compounds calculated using the correlation equations of Karickhoff *et al.*[6] and Veith *et al.*[5] from the partition coefficient. The sorption by a soild phase, such as soil, a suspended solid, and sediment, and the

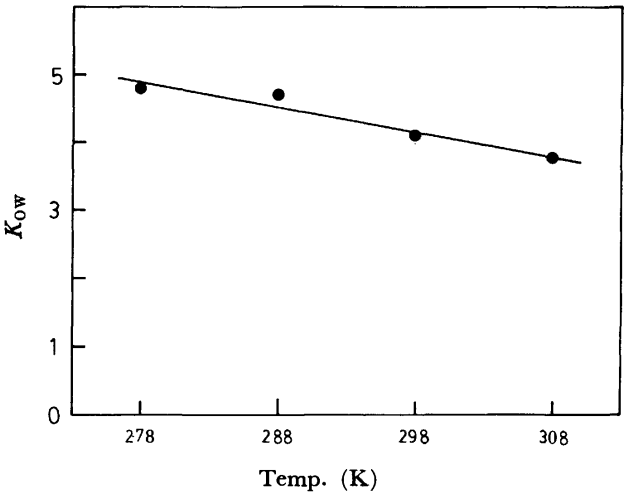

Fig. 1. Effect of temperature on the 1-octanol/water partition coefficient of metallic mercury, K_{OW}.

TABLE 1. THE VALUES OF K_{OW}, K_{OC}, K_B, AND $K_V^{(i)}/K_V^{(O_2)}$.

Contaminant	K_{ow}	K_{OC}[6]	K_B[5]	$K_V^{(i)}/K_V^{(O_2)}$
Mercury	4.15	2.6	6.7×10^{-1}	0.94[12]
Benzene	1.34×10^2 [11]	8.3×10^1	1.3×10^1	0.56[13]
Tetrachloromethane	4.37×10^2 [11]	3.0×10^2	$3.5\times10_1$	0.62[14]
PCB (aroclor 1242)	1.66×10^6 [16]	1.0×10^6	3.9×10^4	0.22[15]

uptake by the aquatic-biota phase for mercury are much less than those for nonpolar organic compounds such as benzene and tetrachloromethane, and for PCB (aroclor 1242). In addition, Okouchi *et al.*[12] has reported that the volatilization rate of metallic mercury from water to the atmosphere is more rapid than those of benzene,[13] tetrachloromethane,[14] and PCB (aroclor 1242)[15] by factors of about 1.7, 1.5, and 4.3 respectively, judging from the volatility coefficient ($K_v^{(i)}/K_v^{(O_2)}$) as is shown in Table 1. The volatility coefficient represents the comparative volatilization rate of a volatile contaminant $K_v^{(i)}$ with oxygen $K_v^{(O_2)}$.

Therefore, from the 1-octanol/water partition coefficient of mercury measured in this work, it was found that metallic mercury has a tendency to be further concentrated in the atmosphere because of very low sorption by the particulate soild phase and uptake by the aquatic-biota phase.

Temperature Dependence of Walden Product of 18-Crown-6-K^+ Complex in Water

Yasuyuki TAKEDA* and Osamu ARIMA
Department of Chemistry, Faculty of Science, Chiba University, Yayoi-chō, Chiba 260
(Received March 19, 1985)

Synopsis. Limiting ionic molar conductivities of the 18-crown-6-K^+ complex in water were determined at 15 and 35 °C. Walden product values of the complex at 15, 25, and 35 °C are nearly identical within experimental errors of conductance measurements. Solvation properties of the complex in water were discussed in detail.

From a viewpoint of solution chemistry, it is interesting to study solvation properties of crown ether-alkali metal ion complexes as well as medium effects on stabilities of the complexes. It has been carried out by various methods and the information on solute-solvent interactions regarding the crown ether complexes has been reported. For example, density and speed-of-sound measurements suggested that hydration number of K^+ in 18-crown-6 (18C6) is zero.[1] The data for entropies of transfer from water to methanol of the 18C6-K^+ complex indicate that the complex in water undergoes hydrophobic hydration.[2] It was concluded from the results of viscosity measurements that the dragging resistance of the 18C6-K^+ complex is nearly the same as that of the free 18C6 in water.[3] It was reported from conductance study that the 18C6-K^+ complex acts as a structure breaker in water.[4,5] In a series of our conductance studies,[4-7] limiting ionic molar conductivity at 25 °C of the 18C6-K^+ complex in a given solvent was compared with that of $(n\text{-}C_4H_9)_4N^+$ since they have almost the same size, and Walden products of the complex at 25 °C in various solvents were discussed.

In this work, in order to obtain more detailed information about solvation behavior of the 18C6-K^+ complex in water, limiting ionic molar conductivities of the complex in water were determined at 15 and 35 °C, and temperature dependence of Walden products for the complex was investigated.

Experimental

18-Crown-6 and extremely pure potassium chloride were obtained from Nisso Co., Ltd. and Merck Japan Ltd., respectively. The 18C6 was recrystallized three times from acetonitrile and, prior to use, dried at 70 °C in a vacuum oven. The potassium chloride was used without further purification. Conductivity of water was less than $2\times10^{-7}\ \Omega^{-1}\ cm^{-1}$. Conductance measurements were made on a Fuso conductivity apparatus, model 362 A, in a water bath thermostated at 10, 15, 20, 25, 35, 45±0.01 °C. Two cells were used with cell constants of 0.059707 and 0.093938 cm^{-1}.

The experimental procedures to obtain formation constants and limiting ionic molar conductivities of the 18C6-K^+ complex were described in the previous paper.[7] For each conductance measurement system, total concentrations of KCl and 18C6 were kept below 5×10^{-3} and 3×10^{-2} mol dm^{-3}, respectively.

Table 1. $\log K_{ML^+}$ values of the 18C6-K^+ complex and Λ° values of the 18C6 complex with potassium chloride in water at various temperatures

Temp/°C	$\log(K_{ML^+}/mol^{-1}\ dm^3)$	$\Lambda^\circ/\Omega^{-1}\ cm^2\ mol^{-1}$
10	2.288±0.008	—
15	2.253±0.012	81.2±0.5
20	2.135±0.011	—
25	2.034±0.004	101.7±0.3[4]
35	1.940±0.004	124.2±0.5
45	1.790±0.020	—

Results and Discussion

Formation constant (K_{ML^+}) and limiting ionic molar conductivity (λ°) of the 18C6-K^+ complex were obtained in the same manner described in the previous study.[7] M^+ and L designate an alkali metal ion and a crown ether, respectively. It is assumed that the association between a cation and an anion is negligible and that 18C6 forms a 1:1 complex with K^+. Corrections for viscosity changes due to solute were neglected. The $\log K_{ML^+}$ values of the 18C6-K^+ complex and the limiting molar conductivity (Λ°) values of the 18C6 complex with potassium chloride in water at various temperatures are listed in Table 1.

The $\log K_{ML^+}$ value at 25 °C determined in this study is in good agreement with those by Izatt *et al.*[8] (2.03±0.10, by calorimetric titration) and Stover[9] (2.029±0.028, by isotachophoresis); however, it is slightly lower than those by Frensdorff[10] (2.06±0.04, using cation-selective electrode by potentiometry) and Høiland *et al.*[1] (2.0476±0.0015, using cation-exchange membrane by potentiometry). The $\log K_{ML^+}$ *vs.* T^{-1} plots in Fig. 1 show a linear relationship. Enthalpy change (ΔH) and entropy change (ΔS) were calculated from these data by using equations, $\Delta G = -RT\ln K_{ML^+}$ and $\Delta G = \Delta H - T\Delta S$, ΔG being free energy change. The ΔH and ΔS values are

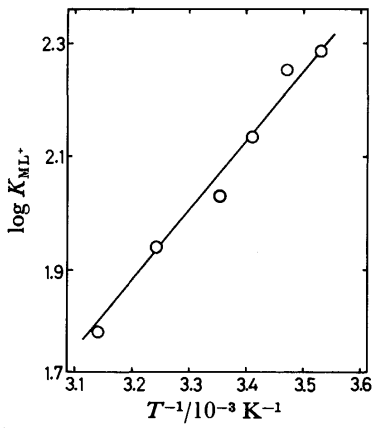

Fig. 1. $\log K_{ML^+}$ *vs.* T^{-1} plots for the 18C6-K^+ complex in water.

TABLE 2. $\lambda^\circ/\Omega^{-1}\,cm^2\,mol^{-1}$ AND WALDEN PRODUCTS IN WATER AT VARIOUS TEMPERATURES

Temp/°C	η_o/cP* [12]	18C6-K^+		$(n\text{-}C_4H_9)_4N^+$		Cl^-
		λ°	$\lambda^\circ\eta_o$	λ° [13]	$\lambda^\circ\eta_o$	λ°
10	1.306	—	—	12.56	0.1640	—
15	1.138	19.8	0.22_5	—	—	61.4_1 [12]
25	0.8903	25.3 [4]	0.22_5	19.31	0.1719	76.39 [13]
35	0.7194	32.0	0.23_0	—	—	92.2_1 [12]
45	0.5963	—	—	30.40	0.1813	—

* η_o denotes viscosity of water, 1 P=0.1 Pa s.

-25.01 kJ mol^{-1} and -44.34 J K^{-1} mol^{-1}, respectively; they agree well with those by Izatt *et al.*[8] ($\Delta H=-25.9$ kJ mol^{-1}, $\Delta S=-47.6$ J K^{-1} mol^{-1}). Values of log K_{ML^+} at 25 °C (2.140 ± 0.022), ΔH (-23.43 ± 0.83 kJ mol^{-1}), and ΔS (-37.60 ± 3.22 J K^{-1} mol^{-1}) determined by Michaux and Reisse[11] (log K_{ML^+}: using electrode by potentiometric titration, ΔH and ΔS: by calorimetric measurement) are relatively larger than those by us.

Thus, conductometry is a very accurate and reliable method for obtaining formation constants and thermodynamic parameters of crown ether-metal ion complexes.

As can be seen from Table 2, λ° values at 15 and 35 °C of the 18C6-K^+ complex are nearly equal to and larger than those at 25 and 45 °C of $(n\text{-}C_4H_9)_4N^+$, respectively; both mobilities of the 18C6-K^+ complex and $(n\text{-}C_4H_9)_4N^+$ gradually increase with an increase in temperature. This indicates that the 18C6-K^+ complex is more mobile than $(n\text{-}C_4H_9)_4N^+$ in water as reported previously.[4] The explanation for the results was offered in the preceding paper.[4] Walden product values of the 18C6-K^+ complex in water at 15, 25, and 35 °C are nearly identical within experimental errors of conductance measurements (Table 2). This may reflect the effects caused by the following two factors. (1) There exist possible interactions between the central potassium ion and water molecules on two axial sides of the 18C6 plane, and between ether oxygen atoms of the 18C6 and water molecules *via* hydrogen bonding. The interactions may be weakened with an increase in temperature. Thus, the 18C6-K^+ complex is more mobile than expected at a higher temperature. This would cause a positive temperature coefficient of Walden product of the 18C6-K^+ complex in water. (2) The 18C6-K^+ complex acts as a structure breaker in an aqueous solution.[4,5] Since hydrogen-bonded structure of water gradually disappears at a higher temperature, the 18C6-K^+ complex is less mobile than expected. This would cause a negative temperature coefficient of Walden product. These two factors compensate each other, resulting in no temperature dependence of Walden product of the 18C6-K^+ complex.

Values of $\lambda^\circ(K^+)/\lambda^\circ$(18C6-$K^+$) for CH_3OH, CH_3CN, DMF, DMSO, propylene carbonate, and water are 1.31, 1.41, 1.24, 1.46, 1.34, and 2.90, respectively. These were calculated from the data in Ref. 4. If the radii of moving entities of K^+ and 18C6-K^+ complex in the nonaqueous solvents (*i.e.*, effective radii) are considered to be 2.9 and 4.9 Å, respectively, the $\lambda^\circ(K^+)/\lambda^\circ$(18C6-$K^+$) value is about 1.6 ($\lambda^\circ=0.819/\eta_o r$, r being radius). The former was evaluated from Stokes' radii of K^+ in the nonaqueous solvents, and the latter is the crystal ionic radius itself evaluated from the crystal ionic radius of K^+ and the 18C6 volume. Experimental $\lambda^\circ(K^+)/\lambda^\circ$(18C6-$K^+$) values of the nonaqueous solvents are very much closer to the calculated value (1.6) compared to that of water (2.90). This indicates that the 18C6-K^+ complex is not so much strongly solvated in the nonaqueous solvents as K^+. From the fact that there is no large difference in Walden products of the 18C6-K^+ complex among these solvents (including water)[4] and that the Walden product value of K^+ for water is very much larger than those for the other solvents,[4] the considerably high $\lambda^\circ(K^+)/\lambda^\circ$(18C6-$K^+$) value of water is attributed completely to the role of K^+ as a structure breaker in water. This is supported by the data that the $\lambda^\circ(K^+)/\lambda^\circ$(18C6-$K^+$) value of water decreases with an increase in temperature ($\lambda^\circ(K^+)$ [12]$=59.6_6$ at 15 °C and 88.2_1 at 35 °C). From the fact that the 18C6-K^+ complex in water shows no temperature dependence of Walden product, whereas Walden product of K^+ in water decreases with an increase in temperature, the negative temperature coefficient of the $\lambda^\circ(K^+)/\lambda^\circ$(18C6-$K^+$) value for water may be caused entirely by the decrease of iceberg structure in water at a higher temperature.

A Molecular Mechanical Calculation along the Intrinsic Reaction Coordinate

Seikichi Cho
Department of Chemistry, Faculty of Education, Gunma University, 4-2 Aramakicho, Maebashi, Gunma 371
(Received June 14, 1985)

Synopsis. A normal coordinate analysis was applied to nonequilibrium states composed of atoms. A normal coordinate, Q_k, can be the intrinsic reaction coordinate if, and only if, all the first-order differentials have vanished except the k-th one. The HNC-to-HCN isomerization reaction was treated with the *ab initio* STO-3G potential surface: we thus observed several interesting features.

Molecular mechanical calculations usually utilize empirical expressions of the potential energy, which approximate near the equilibrium state of atoms in the system. The adiabatic potential energy surface can now be calculated at the *ab initio* SCF or a more elaborate level over a wide range of nonequilibrium states. The extension of the molecular mechanical calculation to nonequilibrium states or to the "reaction coordinates" is desirable. This paper concerns this extension by means of *ab initio* STO-3G SCF calculations with standard parameters.[1]

The relative kinetic energy[2] of an N atomic system can be calculated from the total kinetic energy minus the translational energy of, and the rotational energy around, the center of gravity:

$$T = T^{\mathrm{tot}} - T^{\mathrm{trans}} - T^{\mathrm{rot}} = \frac{1}{2}\sum_{i,j=1}^{3N} T_{ij}\dot{q}_i\dot{q}_j, \tag{1}$$

and the potential energy is approximated by the Taylor expansion to the second order:

$$V = V_0 + \sum_{i=1}^{3N} d_i q_i + \frac{1}{2}\sum_{i,j=1}^{3N} F_{ij}q_iq_j, \tag{2}$$

$$d_i = \frac{\partial V}{\partial q_i}, \qquad F_{ij} = \frac{\partial^2 V}{\partial q_i \partial q_j}.$$

As is well-known, Eqs. 1 and 2 can be transformed simply, by the introduction of a normal coordinate,[3] Q, to:

$$T = \frac{1}{2}\sum_{i=1}^{f} \dot{Q}_i^2, \tag{3}$$

$$V = V_0 + \sum_{i=1}^{f} g_i q_i + \frac{1}{2}\sum_{i=1}^{f} \lambda_i Q_i^2, \tag{4}$$

so that the Lagrange equations of motion are given by:

$$\frac{d^2Q}{dt^2} + g_i + \lambda_i Q_i = 0, \quad i = 1,2,\cdots\cdots,f. \tag{5}$$

The ordinary solution of Eq. 5 involves the simple harmonic motion around the center, $-g_i/\lambda_i$, and ν_i, the frequency:

$$Q_i = A\sin(2\pi\nu_i t+\alpha) - g_i/\lambda_i, \ \nu_i = \frac{1}{2\pi}\sqrt{\lambda_i}, \tag{6}$$

where A and α are determined from the initial conditions. The simple harmonic motion is generally thought to be a very fast motion of the nuclei. However, if we assume an infinitely slow motion[4] of the nuclei as the initial condition, the solutions are quite different from Eq. 6:

$$\frac{Q_i}{(g_i+\lambda_i Q_i)} = -\tau^2 = const.,$$

or:

$$Q_i = \frac{-\tau^2 g_i}{(1+\tau^2\lambda_i)}. \tag{7}$$

Thus, the normal coordinates are the solutions of the infinitely slow motion, *i.e.*, the "trajectories." If, and only if, all the gradients, g_i's, except one, say g_k, are zero, the nonvanishing trajectory is given by Q_k. This is the necessary and sufficient condition of the so-called "intrinsic reaction coordinate," previously defined by Fukui.[5]

The present normal coordinate analysis was applied to the HNC-to-HCN isomerization reaction using the *ab initio* STO-3G potential surface. The intrinsic reaction coordinate of this system was previously determined by Ishida *et al.*[6] by means of the gradient method: it was also treated by Cerjan and Miller[7] by making explicit use of the second-order derivatives of the potential energy surface. The equilibrium state of HNC has three vibrational modes, a NH-stretching vibration (4224 cm^{-1}), a CH-stretching vibration (2410 cm^{-1}), and a doubly-degenerate HNC bending vibration (758 cm^{-1}). All the reaction coordinates are, of course, zero. If the curvature of the potential energy surface is small enough for nuclei to reach far from the equilibrium position at a small excess vibrational energy, a chemical reaction will take place. Therefore, the initial step was taken along the lowest frequency vibration, the HNC bending. The step size was 0.2 Å. Departing from the equilibrium state, none of the gradients vanish, and no unique reaction coordinate is found. The distance to the bottom of a valley of the potential energy surface is found to be:

$$d_i = -g_i/\lambda_i, \tag{8}$$

d_3, corresponding to ν_3, being the largest in absolute value. Moving towards the bottom of valleys along ν_1 and ν_2, g_1 and g_2 become zero and the nonvanishing reaction coordinate remains Q_3.

The second step is to "walk uphill" along the reaction coordinate Q_3, taking care of the sign of the gradient. The process was repeated until the saddle point was reached, where the gradient along the reaction coordinate was zero. Then the reaction coordinate turned to "walk downhill" to the point of the HCN equilibrium. The whole process is

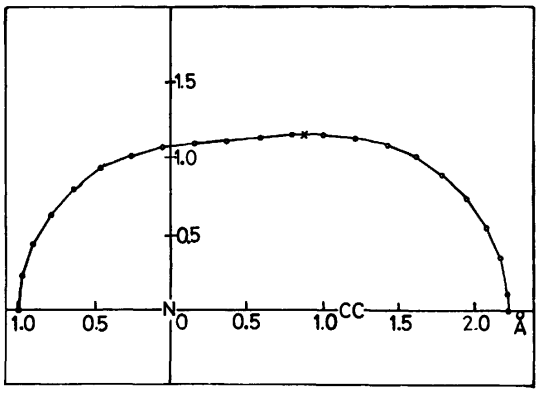

Fig. 1. The intrinsic reaction coordinate of H atom in the HNC-HCN isomerization reaction. The points denoted by —○— were calculated at the *ab initio* STO-3G potential surface and the solid lines connected these points. The symbol —⨯— is the saddle point. The N atom, denoted by N, is fixed at the origin and the C atom, denoted by C, moves slightly on the abscissa.

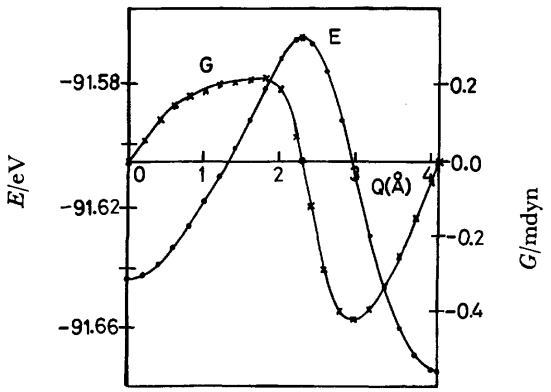

Fig. 2. The potential energy and the gradient curve along the intrinsic reaction coordinate of HNC-HCN reaction. The points denoted by —●— and —⨯— were calculated on the STO-3G potential surface. The point where the gradient is vanishing corresponds to the saddle point.

demonstrated graphically in Figs. 1 and 2, which completely reproduce those given by Ishida *et al.*[6]

More interesting features are seen in the variations of vibrational frequencies with the progress of the chemical reaction (Fig. 3). The frequency along the reaction coordinate is imaginary over a rather wide range. (The scattering of points is probably due to

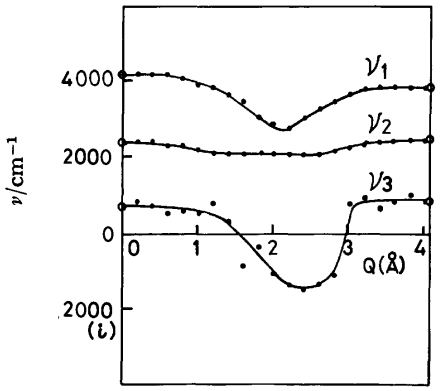

Fig. 3. The variation of the vibrational frequencies along the intrinsic reaction coordinate of HNC-HCN reaction. ν_1 corresponds to the NH or the CH stretching, ν_2 to the CN stretching, and ν_3 to the HNC bending vibrations. The points were calculated on the STO-3G potential surface.

errors in the numerical differentiation, as revealed by the lowest eigenvalue.) The CN stretching frequency is fairly constant throughout the whole process, while the NH stretching vibration transforms to the CH stretching vibration in the region of the transition state. These facts seem reasonable from the standpoint of chemistry.

The whole calculation, including the numerical differentiation to the second order, was carried out on the HITAC M-240H computer located at Gunma University. A more efficient program[8] and a more faster computer may facilitate the molecular mechanical analysis of chemical reactions.

^{15}N NMR Spectra of Cobalt(III) Complexes Containing $^{15}NO_2^-$

Yoshio ODAKA, Akira YAMASAKI, and Masatoshi WATABE*
General Education Department, Kogakuin University, Hachioji, Tokyo 192
(Received April 25, 1985)

Synopsis. The nitrogen-15 nuclear magnetic resonance spectra of the cobalt(III) complexes containing $^{15}NO_2^-$ were first measured; the coordination chemical shifts, $\Delta\delta$ ($=\delta_{complex}-\delta_{free}$), were found to be from 135.0 to 161.5 ppm. The relationship between $\Delta\delta$ and the geometrical configuration was discussed in terms of the paramagnetic anisotropy of the cobalt(III) ion.

The nuclear magnetic resonance spectroscopy of nitrogen in coordination compounds is an area of considerable potential interest. Only a few ^{15}N chemical shift data of the cobalt(III) complexes have, however, been reported.[1-4] In our previous paper,[5] we reported the ^{15}N-NMR data for the bis (L-aspartato)cobaltate(III) and discussed the main factor which affects the ^{15}N chemical shift by using the magnetic anisotropy[6,7] of the central cobalt ion. This method could explain the trend of the ^{15}N chemical shifts of $[Co(L\text{-}asp)_2]^-$ to a certain extent. However, it is necessary to collect a great many ^{15}N chemical-shift information concerning metal complexes. Herein we report on the ^{15}N NMR spectroscopy of the cobalt(III) complexes containing the $^{15}NO_2^-$ ion.

Experimental

Cis-$[Co(^{15}NO_2)_2(en)_2]Cl$[8] is prepared from $[Co(CO_3)(en)_2]$-Cl, and *trans*-$[Co(^{15}NO_2)_2(en)_2]Cl$,[9] from $Co(NO_3)_2\cdot 6H_2O$. These cis and trans complexes are too insoluble in water for the ^{15}N NMR spectra to be measured. In order to change the counter anion, a solution of these complexes was placed in a Sephadex C-25 cation-exchange column (Cl^- form). After the column had then been swept with water, the adsorbed material was eluted with 1 mol dm^{-3} sodium aspartate. The eluate was concentrated with a rotary evaporator at about 5 °C. The resulting complexes, $[Co(NO_2)_2(en)_2]$ aspNa, were very soluble in water. *Cis*-$[CoCl(^{15}NO_2)(en)_2]Cl$[10] and *trans*-$[CoCl(^{15}NO_2)(en)_2]NO_3$[11] were prepared from *trans*-$[Co(^{15}NO_2)_2(en)_2]NO_3$. These two complexes are soluble enough in water for the ^{15}N NMR spectra to be measured. The ^{15}N NMR spectra were measured in the Fourier transform mode with a Varian FT-80A spectrometer. The chemical shifts at 8.104 MHz were determined by the use of a 2-kHz range and a 16-K memory and were measured with respect to external ^{15}N ammonium chloride or ^{15}N sodium nitrite in D_2O. About 200 mg of material was dissolved in 1.5 cm^3 of H_2O in a 10-mm tube, and the spectra were accumulated 50000-70000 times at 37 °C.

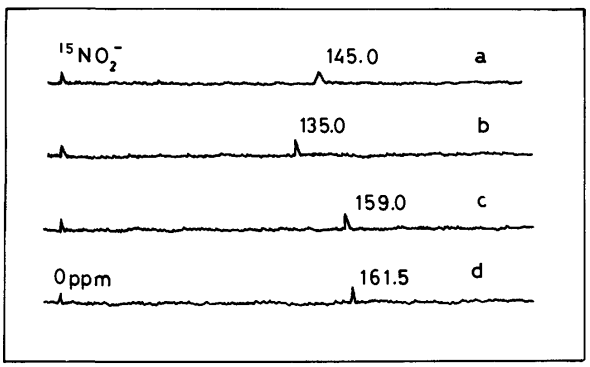

Fig. 1. ^{15}N NMR spectra in H_2O; a; *cis*-$[Co(NO_2)_2(en)_2]^+$, b; *trans*-$[Co(NO_2)_2(en)_2]^+$, c; *cis*-$[CoClNO_2(en)_2]^+$, d; *trans*-$[CoClNO_2(en)_2]^+$.

Results and Discussion

Figure 1 shows the ^{15}N NMR spectra of *trans*- and *cis*-$[Co(^{15}NO_2)_2(en)_2]$aspNa (asp=aspartate), *trans*-$[CoCl(^{15}NO_2)(en)_2]Cl$, and *cis*-$[CoCl(^{15}NO_2)(en)_2]NO_3$. The chemical shifts of the nitrogen-15 of the NO_2^- type coordinating to the cobalt(III) ion, were first obtained. The sharp singlet peaks on the left side of all the spectra are the peaks of the ^{15}N-enriched sodium nitrite. The chemical shifts are interpreted by means of Ramsey equations[12] as

$$\delta = \delta_p + \delta_d + \delta_i, \quad (1)$$

where the δ_p term is the paramagnetic component, the δ_d term is the diamagnetic term, and the δ_i term is the anisotropy term, which arises from the effects of neighboring atoms. Since the metal ion was the same in all cases, the paramagnetic and the diamagnetic contribution should be fairly constant, as was suggested by Bose and Abott[3]. Nakashima *et al.*[4] stated that the chemical shift, δ_i, induced by the paramagnetic anisotropy of cobalt(III) ion is of minor importance to the ^{15}N chemical shifts; this is in contrast with the finding that they are of dominant importance to the ^1H chemical shift. However, we reported in our previous paper that the

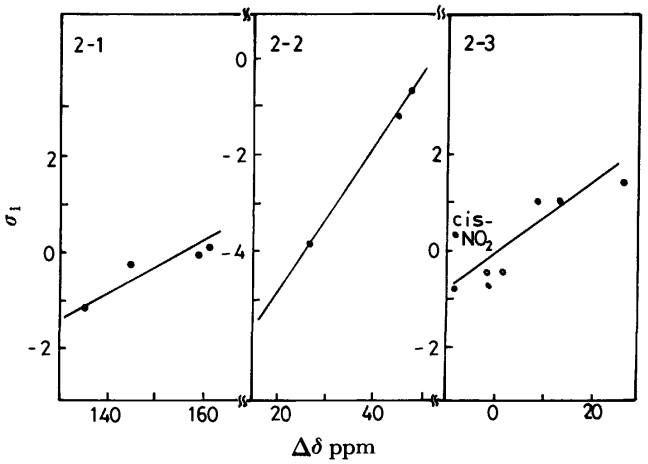

Fig. 2. The correlation between $\Delta\delta$obsd and σ_1, NO_2^- complex (from NO_2^-)(Fig. 2-1), ^{15}N-aspartate complex (from ^{15}N-asp)(Fig. 2-2), and the $^{15}NH_3$ complex (from $[Co(^{15}NH_3)_6]^{3+}$(Fig. 2-3), In Fig. 2-3, ○: Denotes the cis complex, ●: The trans complex.

calculated anisotropy shift could be correlated with the observed ^{15}N chemical shift if the former values are multiplied about 10 or 20 times. We tried again to calculate the δ_i term by using the method demonstrated by Yoneda.[7] For the complexes dealt with here, we postulate the following values $\delta(^1H) \propto \delta(^{15}N)$; $\langle r^{-3} \rangle = 5.77$ a.u, which is the value for $[Co(NH_3)_6]^{3+}$; the distance between nitrogen-15 and metal is 1.95 Å (=3.68 a.u.); $\delta(NO_2) = -4073$ ppm; $\delta(Cl) = -5910$ ppm, and $\delta(en/2) = -4603$ ppm. If the coordinated NO_2^- is placed in the Z axis, then $\theta = 0$, $\varphi = 0$, and the chemical shifts ($[Co(NH_3)_6]^{3+}$ is taken as a standard) can easily be evaluated to be as follows; −1.13 for *trans*-$[Co(NO_2)_2(en)_2]^+$, −0.28 for *cis*-$[Co(NO_2)_2(en)_2]^+$, 0.08 for *trans*-$[CoClNO_2(en)_2]^+$, and −0.21 for *cis*-$[CoClNO_2(en)_2]^+$. The correlation between the calculated and the experimental values is shown in Fig. 2-1. The slope is 0.040, and the standard deviation, R, is 0.925. This value is smaller than those for $[Co(L\text{-asp})_2]^-$ (0.154) and R(0.996)(Fig. 2-2). In Fig. 2-3, the correlation between the calculated chemical shift and the ^{15}N chemical shift of $[CoX(NH_3)_5]^{n+}$ is shown. The slope for the trans complex is 0.068, and R, 0.929. These good standard deviations of the three series confirm that paramagnetic anisotropy is one of the factors influencing the ^{15}N chemical shift of the cobalt(III) complexes. The ^{15}N chemical shift of the cis NH_3 of $[CoNO_2(NH_3)_5]^{2+}$ is not in line with those of the other $[CoX(NH_3)_5]^{n+}$-type complexes. We considered that hydrogen bonding exists in *cis*-$[CoNO_2(NH_3)_5]^{2+}$ between the NH_3 hydrogen and NO_2^- and that this hydrogen-bonding ^1H atom may influence the magnetic field around the ^{15}N atom. Fung *et al.*[13] reported that the chemical shifts of ^{15}N directly bound to cobalt are hardly affected at all by the solvents. This implies intramolecular hydrogen bonding. The difference in the slopes among the three series is natural because the atoms around the cobalt are different. Though, in every series, the experimental values are ten times those calculated, the calculated chemical shifts are useful in predicting which complex among similar complexes shows the chemical shift at a higher magnetic field.

Behavior of Polyacrylamide-Acyclic Poly(oxyethylene)-coated Ion-selective Electrodes in Nonaqueous Solvents

Toshio NAKAMURA,* Kazuyuki OGIWARA, Kosuke IZUTSU, and G. A. RECHNITZ†
Department of Chemistry, Faculty of Science, Shinshu University, Asahi, Matsumoto 390
†*Department of Chemistry, University of Delaware, Newark, Delaware 19716, U.S.A.*
(Received June 1, 1985)

Synopsis. Ion-selective electrodes constructed with polyacrylamide(PAA) coupled to acyclic poly(oxyethylene) neutral carriers, tetraethylene glycol monododecyl ether (POE4) or hexaethylene glycol monododecyl ether (POE6), were reported. Nernstian responses were obtained to magnesium and barium ions in AN with the PAA-POE4 membrane and to copper(II) and silver(I) ions in DMSO with the PAA-POE6 membrane.

Ion-selective electrodes have been shown to be useful for analytical and physicochemical studies in nonaqueous and mixed solvents[1] and their applications are steadily increasing. Ion-selective electrodes applicable in nonaqueous solutions, however, have mainly been limited to those with glass- or crystalline- sensing elements because of possible damage to or dissolution of the electrode components by organic solvents. Development of other types of ion-selective electrodes for use in nonaqueous solutions is desirable.

Recently we showed that a gelatine membrane electrode coated on a copper disk was durable in dimethyl sulfoxide(DMSO) and could respond in a Nernstian way to the activities of the magnesium and calcium ions in DMSO.[2] We also showed that a platinum disk electrode coated with polyacrylamide (PAA) polymer coupled to macrocyclic polyether neutral carrier (dibenzo-18-crown-6) could serve as a barium ion sensor durable for at least twenty days in acetonitrile(AN).[3] In the present report, we will report the behavior of electrodes which have been prepared by coating a platinum disk with a membrane of PAA coupled to acyclic poly(oxyethylene) neutral carriers. As the acyclic poly(oxyethylene), tetraethylene glycol monododecyl ether (POE4) and hexaethylene glycol monododecyl ether (POE6) were used. The PAA-POE4 electrode showed a Nernstian response to the activities of the magnesium and barium ions in AN and the PAA-POE6 electrode showed a Nernstian response to those of the copper(II) and silver(I) ions in DMSO.

Experimental

Apparatus. Potentiometric measurements were carried out at 25 °C with a Beckman Φ71 digital pH/mV meter and a Yokogawa Denki type 3056 strip chart recorder. Construction of the indicator electrode is similar to that reported before.[3] The silver/silver ion reference electrode and the salt bridge were as shown below in Cell I.

Reagents. The POE4 and POE6 were obtained from Tokyo Kasei Kogyo Co. Ltd. All other chemicals were the same as those used in the previous reports.[2,3]

Preparation of PAA-POE4 and PAA-POE6 Conjugates. The acyclic neutral carriers, POE4 and POE6, were conjugated at the carboxyl group of the carboxyl-modified polyacrylamide by esterification in benzene under the coexistence of *p*-toluenesulfonic acid as a catalysis.[4] The products were washed with tetrahydrofuran and dried under high vacuum.

Construction and Preparation of the Indicator Electrode. The indicator electrodes were constructed using either PAA-POE4 or PAA-POE6. Small amounts of the respective materials were dissolved in 5 μl of water and spread on the end surface of a 3 mm platinum disk. After flushing with nitrogen gas to volatile water, it was placed in a desiccator with silica gel for a few hours. The electrode was then conditioned in 0.01 M Et_4NClO_4–AN (1 M=1 mol dm^{-3}) or 0.01 M Et_4NClO_4–DMSO for 1 d. The electrodes should be stored in the same solution for repeated use.

Measurements of the Electrode Potential. The response of the electrodes was tested in the following cell,

$$\mathrm{Ag}\,|\,0.005\ \mathrm{M}\ \mathrm{AgNO_3} + 0.01\ \mathrm{M}\ \mathrm{Et_4NClO_4(D)}\,\|$$
$$0.05\ \mathrm{M}\ \mathrm{Et_4NClO_4(D)}\,\|\,C\ \mathrm{M(ClO_4)}_x + 0.01\ \mathrm{M}$$
$$\mathrm{Et_4NClO_4(D)}\,|\,\mathrm{Polymer\ Membrane}\,|\,\mathrm{Pt}\cdots\ \mathrm{Cell\ I}$$

where D denotes AN or DMSO. $M(ClO_4)_x$ is the perchlorate of the cation to be tested (sodium, potassium, silver(I), magnesium, barium, copper(II) or zinc(II) ion). All the solutions were freshly prepared daily. The concentration, C in mol dm^{-3}, of the metal perchlorate was usually increased by the standard addition method to obtain calibration curves. Steady state potentials were read to ±0.1 mV. The electrode potentials were not significantly affected by a change in stirring rate.

Results and Discussion

The membrane electrodes, PAA-POE4 and PAA-POE6, constructed in this experiment were durable in AN and DMSO for at least about a week. The responses of these electrodes to the magnesium, barium, copper(II), and silver(I) ions in AN or DMSO are summarized in Table 1. Some typical calibration curves are also shown in Fig. 1. The activity of the metal ion, $a_{M^{n+}}$, was calculated by using the Debye-Hückel equation as previously described.[2] The results in Table 1 have not been corrected for the change of the liquid junction potential between the sample solution and the salt bridge of Cell I, but its effect seems to be small. In AN, the PAA-POE4 membrane electrode could respond in a Nernstian way to the activities of the magnesium and barium ions between the concentration ranges 5.0×10^{-7} M—5.0×10^{-3} M and 6.8×10^{-6} M—1.5×10^{-3} M, respectively. In DMSO, the PAA-POE6 electrode could respond in a Nernstian way to the activities of copper(II) and silver(I) ions between the concentration ranges 1.5×10^{-5} M—1.6×10^{-3} M and 6.2×10^{-5} M—1.1×10^{-2} M, respectively. The response of the PAA-POE4 electrode to the activity of the silver(I)

Table 1. The responses of the polymer membrane electrodes to some metal ions in nonaqueous solvents at 25 °C[a)]

Ion	$2r_c$,Å	Solvent	Slope (mV/$pa_{M^{n+}}$)	Range of the linear response ($pa_{M^{n+}}$)

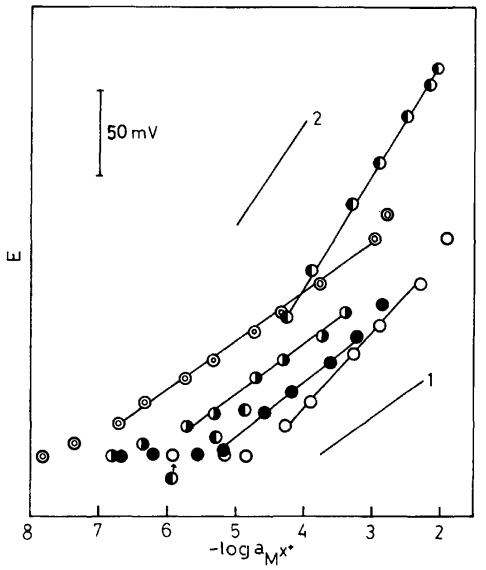

Fig. 1. Calibration curves in nonaqueous solvents at 25 °C. Lines 1 and 2, theoretical slope for divalent cations (29.6 mV/$pa_{M^{2+}}$) and for univalent cations (59.2 mV/$pa_{M^{+}}$), respectively. ◎, Mg^{2+} in AN with PAA-POE4; ◑, Ba^{2+} in AN with PAA-POE4; ○, Ag^{+} in DMSO with PAA-POE4; ◐, Ag^{+} in DMSO with PAA-POE6; ●, Cu^{2+} in DMSO with PAA-POE6.

ion in DMSO was sub-Nernstian between the concentration of 6.2×10^{-5} M and 6.5×10^{-3} M. In all cases, the steady state potential was reached within ten minutes after each increase of the ionic concentration. Both electrodes of PAA-POE4 and PAA-POE6, however, showed poor responses to sodium and potassium ions in AN. These electrodes also showed poor responses to sodium, potassium, and zinc(II) ions in DMSO. The approximate selectivity coefficient obtained for the magnesium ion *vs.* barium ion, $\log k_{Mg^{2+},Ba^{2+}}$, was 1.2 by the mixed solution method in AN in the case of PAA-POE4 electrode.

Yanagida *et al.*[5)] showed a specific interaction of the magnesium ion with POE4 in acetone and suggested that the so called "hole-size rule" in the complexation of metal ions with crown ethers could be applicable to complexation with such acyclic polyethers as POE4 and POE6. If we consider that the magnesium ion in AN reacts with POE4 to form a stable complex, the response of the PAA-POE4 electrode to a wide concentration range of the magnesium ion in AN may be reasonable. But the electrode could also respond, though in a narrower concentration range, to the barium ion with a larger ionic size. The fact that the response to the silver(I) ion in DMSO was Nernstian with the PAA-POE6 electrode but was sub-Nernstian with the PAA-POE4 electrode may also be related to the hole sizes of POE4 and POE6. It seems reasonable to assume that complexation of the metal ions with POE4 or POE6 is essential for the electrode response. For correlation between the electrode response and the hole size concept, however, more detailed data will need to be obtained. In connection with this, solvents may play important roles on the electrode behavior through their solvation to the metal ions and also to the electrode materials. The extremely slow and poor response behavior of the electrode constructed of polyacrylamide polymer alone in AN has been reported before.[3)] The present experiment confirms that the presence of the neutral carrier, POE4 or POE6, in the membrane serves to stabilize the electrode potential and to improve the reproducibility and dynamic response behavior. Further experiments concerning the response behavior of these electrodes in other aprotic organic solvents and the application of these electrodes to obtain information about the solvent effect on the cations used in this experiment are now under investigation in this laboratory.

Induced Circular Dichroism of Bis(tropolonato)copper(II) with Optically Active Amines

Tasuku MURAKAMI
Faculty of Education, Iwate University, Ueda, Morioka 020
(Received June 18, 1985)

Synopsis. Bis(tropolonato)copper(II) forms adducts with chiral aromatic amines and exhibits circular dichroism(CD) induced for d-d and intra-ligand transitions. The applicability of the dispersion-induced CD theory to this complex system is discussed.

In a previous paper, we reported the CD spectra of some copper(II) β-diketonates in optically active bases such as (+)-1-phenylethylamine.[1] The chiral base coordinates at the axial position of the complexes to form mono base-adducts, gives a dissymmetric influence to the parent achiral complexes, and induces optical activities to their electronic transitions.

Dispersion-induced circular dichroism(DICD) treatment has been developed by Schipper for the interaction between achiral and chiral species with no specific orientation; for example, an achiral solute/chiral solvent system.[2,3] He applied this theory to the above system of copper(II) β-diketonates with optically active amines and his results supported most of our discussion.[2]

However, the examined achiral complex/chiral amine couples were so limited that the observations and theoretical applications could not be generalized. Thus, we have studied more systems including a tropolonate complex and (+)-1-(1-naphthyl)ethyl- and (+)-1-(2-naphthyl)ethylamine.

Experimental

Bis(tropolonato)copper(II), $Cu(trop)_2$, was prepared according to the literature.[4] (+)-1-(1-Naphthyl)ethylamine was commercially available and distilled before use. $[\alpha]_D^{20}=+58.2°$ (c=2, methanol). 1-(2-Naphthyl)ethylamine was prepared from 2′-acetonaphthone according to literature[5] and resolved by the use of (+)-tartric acid. For its (+)-antipode, $[\alpha]_D^{20}=+19.6°$ (c=3.5, methanol). Chloroform of spectro-grade was used as solvent without further purification.

TABLE 1. THE VALUES OF $\Delta\varepsilon$ AND STABILITY CONSTANT(K_b) FOR THE 1:1 BASE-ADDUCTS OF $Cu(trop)_2$ IN CHLOROFORM

(+)-Amine	K_b, M^{-1} (25 °C)	$\Delta\varepsilon$, $cm^{-1}M^{-1}$ ($\tilde{\nu}/10^3\,cm^{-1}$)
1-Phenylethylamine	2.3	+0.009(12.7), −0.002(16.7) −0.32(25.6), +0.55(30.0)
1-(1-Naphthyl)-ethylamine	3.1	+0.027(12.4) −1.01(24.8), +0.64(30.4)
1-(2-Naphthyl)-ethylamine	2.6	−0.65(25.6), +0.66(29.8)

Upon the addition of bases, the visible absorption band shifts to a longer wavelength with a much-increased intensity (Fig. 1). From this spectral change, the formation of mono base-adducts is obvious.[6] The formation constant (K_b) of the adducts was determined by the ordinary spectrophotometric method.[7] The values of K_b are listed in Table 1.

The spectra of the chiral amine-adducts were obtained for the chloroform solutions containing 5×10^{-3} M of complex and 1—1.5 M of amines(1 M=1 mol dm^{-3}). Under this condition, approximately 70% of the parent complex transforms to the adduct, in spite of the low K_b values. The values of $\Delta\varepsilon$ summarized in Table 1 are based on the adduct concentration, whereas the vertical scales of Fig. 1 refer to 1 mol of the copper ion. Since tropolone seems to undergo no corbonyl reactions,[4] the chelated tropolonate appeared stable even in the presence of primary amines.

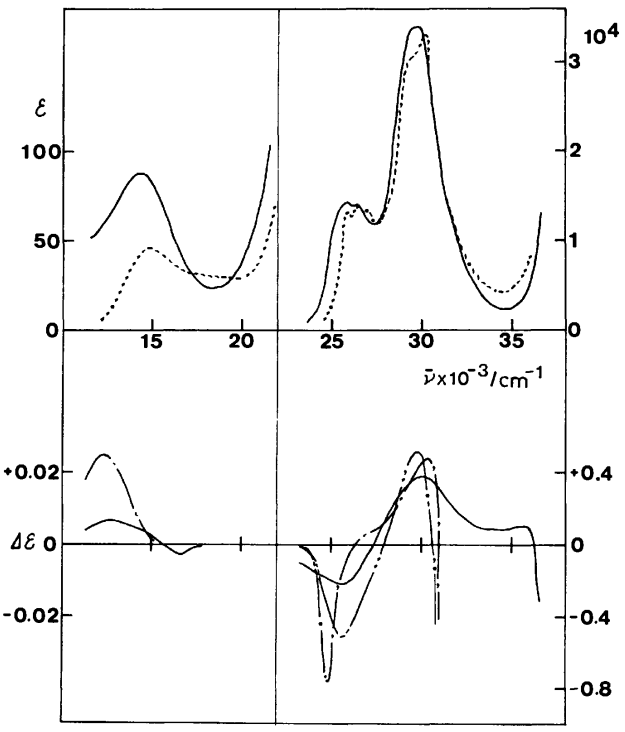

Fig. 1. Absorption and CD spectra of $Cu(trop)_2$ with the addition of (+)-amines in chloroform; the concentration of complex is about 5×10^{-3} M and the numbers in parentheses represent mole ratios in amine/complex. ----, no amine added; ——, (+)-1-phenylethylamine (200); — — —, (+)-1-(1-naphthyl)ethylamine (190); — — — —, (+)-1-(2-naphthyl)ethylamine (240).

Results and Discussion

Figure 1 shows the absorption and CD spectra of $Cu(trop)_2$ in chloroform containing (+)-amines. The main CD band in the visible region appears at the lower wavenumber side of the broad d-d absorption band. This is the same result as those for the β-diketonate complexes as previously reported.[1] Therefore, this CD band originates from the two low-energy transitions, $d_{z^2} \rightarrow d_{x^2-y^2}$ and $d_{xy} \rightarrow d_{x^2-y^2}$. As suggested by Schipper,[2] only the latter, which is *z*-polarized magnetic dipole-allowed in a parent molecular symmetry D_{4h}, mainly contributes the optical activity.

Two intense absorption bands are observed at around 26000 and 30000 cm^{-1} as shown in Fig. 1, and at a higher wavenumber another more intense band is expected to appear.[4] Free tropolone also exhibits three bands, each located at a slightly higher wavenumber compared with the corresponding three bands of $Cu(trop)_2$.[4,8,9] Such a red shift of the intra-ligand band due to the complex formation has been also observed for other ligands, acetylacetone, salicyl-aldehyde, and so on.[10,11] Thus, from the positions and intensities, the two bands at 26000 and 30000 cm^{-1} are supposedly associated with the intra-ligand transitions, although their more detailed nature is not clear so far.

Upon the addition of amine, the tropolone bands shift slightly to lower wavenumbers. Any of three (+)-amines used induces similar optical activities; a negative band at 26000 and a positive one at 30000 cm^{-1}. These (+)-amines show an intrinsic negative CD band at the lowest energy transition which corresponds to the L_b band of phenyl or naphthyl ring.[12,13] On the basis of these findings, the induced CD of this region is discussed as follows.

(1) Schipper has suggested that DICD bands for the electric dipole-allowed transitions of achiral species have the same sign as that of the intrinsic CD of the inducing transition of chiral species.[2] However, the induced optical activity observed possesses different signs as mentioned above. This discrepancy between the DICD theory and the observation would be caused by the assumption that the achiral and chiral species have no orientational correlation. In the amine-adducts, the amine molecule acts as ligand rather than as mere solvent and coordinates to the copper ion. Therefore, the chiral amine and the achiral tropolonate will have a fairly fixed orientation, although the aromatic chromophore of the amine will rotate, to some extent, around the tetragonal axis in the solution. The two tropolone transitions in question possess different polarizations along the tropolone plane,[9] which may be responsible for their opposite-signed CD bands.

(2) The exciton coupling between the transitions of the tropolonate rings cannot constitute the inducing mechanism, since only one CD component appears under the lobe of each absorption band, as previously mentioned.[1]

(3) The inherent CD intensity associated with the L_b band of (+)-1-(1-naphthyl)ethylamine is much different from that of (+)-1-(2-naphthyl)ethylamine; the value of $\Delta\varepsilon$ at 320 nm is -0.03 for the former and -0.27 for the latter in chloroform.[14] This comes from the polarization of the L_b transition which is along the long axis of the naphthalene plane. In spite of such a different electric inducing power,[2] these two (+)-amines induce comparable optical activities for each of the two tropolonate transitions. This also suggests that the orientation between the chromophores of the chiral amine and the achiral tropolonate ring is significant as mentioned above.

The author thanks Prof. Masahiro Hatano for his permission of use of Jasco J-500c spectropolarimeter.

Chlorination of Poly(vinyltoluene) by Electrolysis in an Organic/Water Suspension System

Yoshiharu MATSUDA, Masayuki MORITA,* Hiroshi YAMAMOTO, Hiroyuki WATANABE,† Tooru SEITA,† and Akira AKIMOTO†

Department of Industrial Chemistry, Faculty of Engineering, Yamaguchi University, Tokiwa-dai 2557, Ube 755

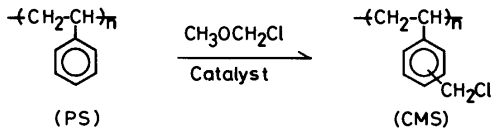
(Received April 20, 1985)

Synopsis. Chlorinated poly(vinyltoluene) was synthesized by controlled-current electrolysis of poly(vinyltoluene) in a suspension system consisting of aqueous and organic solutions. A high Cl-content polymer, in which Cl was introduced to the methyl group and the main chain, was obtained without changes in the molecular-weight distribution of the polymer.

Chlorinated poly(vinyltoluene) (C-PVT) and its derivatives are promising materials as sensitive nega-type microresists which cross-link under electron beam or X-ray irradiation.[1-3] Among them, poly[(chloromethyl)styrene] (CMS) has been synthesized by the chloromethylation of polystyrene (PS)[4] (Scheme 1). This method, however, involves a rather



Scheme 1.

complicated procedure and tends to change the molecular-weight (MW) distribution of the product polymer.[3] On the other hand, a direct chlorination of poly(vinyltoluene) (PVT) by Cl_2 gas or thionyl chloride with some catalysts also yields C-PVT.[5] However, with this method it is difficult to control the Cl content and the substitution position in the polymer. We have found a simple process for introducing Cl to the methyl group as well as to the main chain of PVT which involves electrolysis.

There has been much work concerning the electro-halogenation of aromatic compounds with low molecular weights,[6] but little is known about the electro-halogenation of macromolecular compounds.[7] The principal reason for this is the difficulty in choosing a homogeneous electrolyte system. In this work, we have employed a suspended system consisting of an organic solution and an aqueous electrolytic solution.

Experimental

The starting PVT was prepared at Toyo Soda Manufacturing Co. Two kinds of polymers were used; one was a mixture of *m*- and *p*-isomers ($\overline{Mn}\simeq40000$: PVT-I), and the other consisted of *p*-isomer only ($\overline{Mn}\simeq170000$: PVT-II). The polydispersivity ($\overline{Mw}/\overline{Mn}$) was about 1.1 for both polymers. An electrolytic synthesis was conducted in a suspension system consisting of aqueous and organic solutions. The aqueous phase contained an acid, HCl, which acted as both a supporting electrolyte and a Cl source. The organic solvent was dichloromethane (CH_2Cl_2), chloroform ($CHCl_3$), or benzene (C_6H_6), which dissolved the substrate PVT. The electrolytic cell was a normal beaker-type, one-compartment cell (volume: $\simeq$50 cm^3). The anode was a platinum wire (surface area: 3.5 cm^2), and the cathode was a platinum sheet (surface area: 6.5 cm^2). Controlled-current electrolysis was carried out with vigorous stirring of the solution using a magnetic stirrer while water-cooling the cell (16°—20 °C). The electric charge was normally 2.41×10^5 C (2.5 F) per mol of monomer. Such a charge ideally enables 1.25 atoms of Cl per monomer unit to be introduced to PVT.

The product polymer, separated from the organic phase, was purified by reprecipitation. No attempt was made to exclude light during the electrolysis, but the isolated products were stored under an Ar atmosphere while shielding the container from light. The Cl content in the product was determined by an elemental analysis, and the MW distribution of the polymer was estimated by gel permiation chromatography (GPC). The chlorinated position in the product polymer was determined by ^{1}H NMR spectroscopy (solvent: $CDCl_3$, standard reference: TMS).

Results and Discussion

Table 1 shows the results of the electro-chlorination of PVT in organic/water suspension systems. An estimation of the MW distribution of the products was based on the shape of the GPC curves, and is qualitatively described in the last column of Table 1 (symbols A, B, and C). The values of $\overline{Mw}/\overline{Mn}$ were determined from the calibration curve of the standard PS, and were $\simeq$1.1 for the products labeled "A", $\simeq$1.3 for "B", and $\simeq$2.1 (or above) for "C". As shown in the table, PVT-I was highly chlorinated, and the MW distribution was little changed by the chlorination. It was assumed that the electro-chlorination of PVT proceeds with a two-electron transfer, like the anodic halogenation of usual organic substances.[6,8] Thus, a Cl content of 1.14 in the product (Run 2) is equivalent to a 91% current efficiency. During the chlorination of PVT-II, the MW distribution of the product tended to spread, though Cl was introduced into PVT with 0.9 atoms or more per monomer unit (Runs 3—5). The product labeled "C" in the table was not satisfactory as a microresist.[3] A change in the MW distribution was not observed upon decreasing the PVT-II concentration (Runs 6 and 7), but the Cl content in the product was also lowered ($<$0.1).

The effective chlorination of PVT-II without any change in the MW distribution became feasible upon

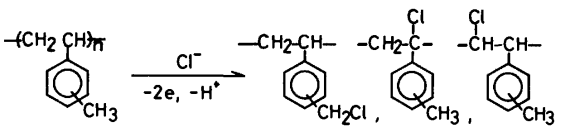
choosing an appropriate solvent for the organic phase. Regarding electrolysis in a $CHCl_3/H_2O$ suspension (Run 8), the MW distribution was little spread, but the Cl content was relatively low. The use of C_6H_6 as a solvent brought about an improvement in the Cl content without broadning of the MW distribution (Runs 9—11). The Cl content increased upon increasing the PVT concentration, but the influence of the current density on the Cl content was rather small. An increase in the electric charge lead to a high Cl content in the product (Run 12). In this case, however, the current efficiency fell to 30% or less, and the MW distribution of the polymer tended to spread. This is probably due to the electrochemical reduction of the product C-PVT at the counter electrode (cathode), where a subtraction of the Cl from the C-PVT and/or a reductive cross-linking of the polymer might occur.

The differences in the results regarding electro-chlorination between PVT-I and PVT-II are probably responsible for the differences in the mean molecular weight and/or the isomer ratio of the starting PVT. On the other hand, solvent properties, such as the donor- and acceptor numbers[9], apparently affected the results of the PVT-II chlorination. It is supposed that the molecular Cl_2 formed by a side reaction is more polarized in CH_2Cl_2 than in C_6H_6. The activated Cl_2 in CH_2Cl_2 would promote the polymer chains to cross-link with each other.

The ^{1}H NMR spectra of the product polymer suggested that chlorination occurred at the methyl group of toluene as well as at the α- and β-positions of the chain (Scheme 2). A variation in the



Scheme 2.

experimental conditions (such as the PVT concentration and the current density) did not seem to affect the chlorinated positions. In the electro-halogenation of low molecular-weight aromatics such as alkylbenzenes[6,10] and alkoxybenzenes,[11–13] nuclear-substituted compounds have been main products. During the present electro-chlorination of PVT, however, nuclear substitution was not detected. The differences in the substitution position might originate from the difference in the solvent that was used. That is, homogeneous organic solutions containing polar solvents were used in previous work for the chlorination of alkyl- or alkoxybenzenes.[6,10–13] However, a suspension of C_6H_6 (or CH_2Cl_2)/H_2O was employed in the present work. These solvent effects, which relate to the details of the reaction mechanism, are now under investigation.

Comparison of the Excited-state Dipole Moments and Polarizabilities Estimated from Solvent Spectral Shifts with Those from Electrooptical Measurements

Takehiro ABE* and Idowu IWEIBO†
College of General Education, Tohoku University, Kawauchi, Sendai 980
(Received June 3, 1985)

On the assumption that the average energy for all transitions from a low-lying excited state to all other states was approximately the same as that for all transitions from the ground state to all excited states, Abe's improved expression for the solvent spectral frequency shift (*Bull. Chem. Soc. Jpn.*, **54**, 327 (1981)) was applied to spectral data for some neutral organic molecules in solution in order to estimate their excited-state dipole moments and polarizabilities. The changes in the dipole moments and/or polarizabilities of these molecules upon excitation were compared with those obtained from electrooptical measurements. Both methods give results that are consistent.

Many theories[1-11] have hitherto been proposed regarding solvent spectral frequency shifts of organic molecules. On the basis of some of these, dipole moments and polarizabilities have been estimated for the excited states of organic molecules. Such detailed information, which essentially leads to knowledge regarding excited-state structures of organic molecules, may help in the understanding of the photophysics and photochemistry of such molecules. Alternatively, changes in the dipole moments and/or polarizabilities upon excitation have been obtained for many organic molecules in the vapor phase, in solution, or in a crystalline host from electrooptical measurements. In particular, the magnitudes of the changes in the dipole moments of some substituted benzenes, directly determined by a technique involving the optical Stark effect[12] in the gas phase, seem to be very reliable. On the basis of a few assumptions, the values of the excited-state dipole moments and/or polarizabilities of molecules in solution or in a crystalline host have been obtained using electric-field perturbation techniques. Recently, Morales,[13] Prabhumirashi *et al.*,[14,15] and Koutek[16] have tried to compare their results, which were obtained from solvent spectral shifts, with those obtained from electrooptical measurements. Their comparisons appear, however, to be insufficient as will be shown below.

Until now, there has been no detailed and systematic study comparing the excited-state dipole moments and/or polarizabilities estimated from the solvent spectral shifts with those determined from electrooptical measurements. Such comparisons are necessary, in part, to justify the theoretical expressions for the solvent spectral frequency shifts and, in part, to confirm the reliability of the electrooptical measurements or to reveal any inadequacies leading to discrepancies in both methods of measurement and in their variants. Electrooptical measurements are, in general, difficult. In particular, the most reliable technique regarding the optical Stark effect in the gas phase is confined to vaporizable substances, while measurements of solvent spectral shifts are easy and widely applied. It is, therefore, desirable to find a solvent spectral shift theory that gives excited-state dipole moment and polarizability values that are comparable to those of electrooptical measurements. This paper applies Abe's generalized equation,[4] which includes all interaction modes, to data for a representative group of compounds. There is, generally, reasonable agreement between the results of the present type analysis and those for electrooptical measurements. This shows that the use of a multiple linear regression analysis to compute the excited-state dipole moment and polarizability without introducing solvent macroscopic parameters, such as the relative permittivity and the refractive index, is certainly an advantage.

Theory

According to Abe's improved theory,[4] the wave number (σ_{i0}) of a transition from the ground state to the ith-excited state of a neutral solute molecule in solution is given by:

$$\sigma_{i0} = \sigma_{i0}^{\circ} + A \times \frac{(d^s/M_r^s)^{2/3}(p_{00}^s)^2}{(r_A+r_s)^4} + B \times \frac{(d^s/M_r^s)^{2/3}\alpha_{00}^s}{(r_A+r_s)^4}, \quad (1)$$

where

$$r_A = (3M_r^A/4\pi L d^A)^{1/3}, \quad (2)$$

$$r_S = (3M_r^s/4\pi L d^s)^{1/3}, \quad (3)$$

$$A = \frac{\pi}{hc}\left(\frac{4\pi L}{3}\right)^{2/3} \times \left[\frac{2\{(p_{00}^A)^2 - p_{00}^A p_{ii}^A \cos\theta\}}{3(4\pi\varepsilon_0)^2 kT} + \frac{(\alpha_{00}^A - \alpha_{ii}^A)}{4\pi\varepsilon_0}\right], \quad (4)$$

and

$$B = \frac{\pi}{hc}\left(\frac{4\pi L}{3}\right)^{2/3} \frac{1}{4\pi\varepsilon_0} \times \left[\{(p_{00}^A)^2 - (p_{ii}^A)^2\} + \frac{3}{2} \times \left(\frac{\Delta E_0^A \alpha_{00}^A}{1+\Delta E_0^A/\Delta E_0^s} - \frac{\Delta E_i^A \alpha_{ii}^A}{1+\Delta E_i^A/\Delta E_0^s}\right)\right]. \quad (5)$$

†Present address: Department of Chemistry, University of Ibadan, Ibadan, Nigeria.

The corresponding transition energy (in cm^{-1}) of the molecule in a vapor state is denoted by σ_{i0}°. For example, the superscripts/subscripts (A and s) denote the solute and solvent molecules, respectively. The symbol c is the speed of light in vacuum, h the Planck constant, L the Avogadro constant, ε_0 the permittivity of a vacuum, M_r the relative molecular mass, and d the density. Moreover, p_{00} and α_{00} denote the electric dipole moment and the electric isotropic polarizability, respectively, for the ground state. The corresponding values for the ith-excited state are p_{ii} and α_{ii}. The angle between $\boldsymbol{p}_{00}^{A}$ and $\boldsymbol{p}_{ii}^{A}$ is denoted by θ. In addition, ΔE_0 and ΔE_i denote the average transition energies for all transitions from the ground state and the ith-excited state, respectively, to all other excited states. The average transition energy (ΔE_0) is usually replaced by the ionization potential (I_0) of the ground state. Similarly ΔE_i is replaced by the ionization potential of the excited state as given by $\Delta E_i^{A}=I_0^{A}-hc\sigma_{i0}^{\circ}$.[4,17] However, Amos and Burrows[1a,18] stated that the average transition energies in Abe's previous expression[17] should be approximately the same for transitions from a ground state and an excited one. In applying Eq. 1, therefore, we have adopted this assumption of Amos and Burrows:

$$\Delta E_i^{A} = \Delta E_0^{A} = I_0^{A}. \tag{6}$$

As is described in a previous paper,[4] Eq. 1 has been derived on the assumption that a spherical solute molecule exhibits no effective hydrogen bonds or complexes with spherical solvent molecules.

Explicitly, we can rewrite Eq. 1 with the use of Eq. 6 as

$$C \times (p_{00}^{A}\cos\theta)p_{ii}^{A} + D \times (p_{ii}^{A})^2 + E \times \alpha_{ii}^{A} = \sigma_{i0}^{\circ} - \sigma_{i0} + F, \tag{7}$$

where

$$G = \frac{(d^s/M_r^s)^{2/3}}{(r_A+r_s)^4} \times \frac{\pi}{hc}\left(\frac{4\pi L}{3}\right)^{2/3}, \tag{8}$$

$$C = G \times \frac{2(p_{00}^{s})^2}{3(4\pi\varepsilon_0)^2kT}, \tag{9}$$

$$D = G \times \frac{\alpha_{00}^{s}}{4\pi\varepsilon_0}, \tag{10}$$

$$E = G \times \left\{\frac{(p_{00}^{s})^2}{4\pi\varepsilon_0} + \frac{3}{2} \times \frac{I_0^{s}I_0^{A}\alpha_{00}^{s}}{I_0^{s}+I_0^{A}}\right\}, \tag{11}$$

and

$$F = G \times \left[\frac{2(p_{00}^{s})^2(p_{00}^{A})^2}{3(4\pi\varepsilon_0)^2kT} + \frac{1}{4\pi\varepsilon_0} \times \{(p_{00}^{s})^2\alpha_{00}^{A} + \alpha_{00}^{s}(p_{00}^{A})^2\} + \frac{3}{2} \times \frac{I_0^{s}I_0^{A}\alpha_{00}^{s}\alpha_{00}^{A}}{I_0^{s}+I_0^{A}}\right]. \tag{12}$$

Unfortunately, except for nonpolar solute molecules, we can not obtain directly reliable values for p_{ii}^{A} and α_{ii}^{A} by means of a least-squares analysis of data regarding solvent spectral shifts by means of Eq. 7. This is because a cubic equation with respect to p_{ii}^{A} must be solved in the case of polar solute molecules. Solving the equation is not practicable. We, therefore, proceed to obtain values of p_{ii}^{A} and α_{ii}^{A} by the following method for a polar solute molecule.

Calculation 1. At first we assumed $(p_{00}^{A}\cos\theta)p_{ii}^{A}(1)=\{(p_{ii}^{A}(1)\}^2$ in Eq. 7 and obtained the first approximate values of $p_{ii}^{A}(1)$ and $\alpha_{ii}^{A}(1)$ by the least-squares method. Next, we wrote the second approximate values as $p_{ii}^{A}(2)=p_{ii}^{A}(1)+\Delta(p)$ and $\alpha_{ii}^{A}(2)=\alpha_{ii}^{A}(1)+\Delta(\alpha)$ in Eq. 7. On the assumption that $2p_{ii}^{A}(1) \gg \Delta(p)$, values of $\Delta(\alpha)$ and $\Delta(p)$ were then obtained by the least-squares method as well as those of $p_{ii}^{A}(2)$ and $\alpha_{ii}^{A}(2)$. The same calculation was repeated until both values for $\Delta(p)$ and $\Delta(\alpha)$ became smaller than 10^{-4} of a unit of measurement of the electric dipole moment or the polarizability.

On the other hand, we adopted the following (Calculations 2 and 3) for a nonpolar solute molecule having no dipole moments in either the ground or the excited states.

Calculation 2. When the value of σ_{i0}° was known, we obtained a value for α_{ii}^{A} by averaging the values of α_{ii}^{A} for all solvents by means of Eq. 7.

Calculation 3. When the σ_{i0}° value was unknown, at first we arbitrarily assumed the first appropriate approximate value of $\sigma_{i0}^{\circ}(1)$ for σ_{i0}° in Eq. 7 and obtained a first approximate value of $\alpha_{ii}^{A}(1)$ by the least-squares method. The second approximate values for σ_{i0}° and α_{ii}^{A} were then given as $\sigma_{i0}^{\circ}(2)=\sigma_{i0}^{\circ}(1)+\Delta(\sigma)$ and $\alpha_{ii}^{A}(2)=\alpha_{ii}^{A}(1)+\Delta(\alpha)$ and the final values for σ_{i0}° and α_{ii}^{A} were obtained by repeating the iterative procedure adopted in Calculation 1.

In applying Eq. 7, we always assumed the temperature to be 20 °C and, unless it is otherwise stated, that all the electric dipole moments and ionization potentials for molecules in the vapor phase were taken from Refs. 19 and 20. Values for α_{00} were calculated from sums of bond refractions. Moreover, we excluded data for solvents lacking information regarding their dipole moments and ionization potentials and of solvents which are capable of forming hydrogen bonds and complexes with solutes. We used the spectral data reported by the same authors for solutes.

Results and Discussion

Benzene, Naphthalene, and Anthracene. The solvent effects on the position of the ^1L_b transition of benzene were investigated by Macovei.[21] We have assumed Macovei's value of 39539 cm^{-1} for σ_{i0}° and have chosen data for 13 solvents (out of his reported total of 27 solvents) by excluding hydrogen bonding solvents. This is because benzene is low in the scale regarding hydrogen-bond acceptor strength determined by Kamlet and Taft.[22] Similarly, we chose data for only 10 and 9 solvents for the ^1L_b and ^1L_a transitions, respectively, in naphthalene from the data of Weigang and Wild.[23,24] For calculations regarding anthracene, data for 25 solvents were taken from the report of Nicol *et al.*[25] The values of α_{ii}^{A} (estimated by Calculation 2) are listed in Table 1, where $\Delta\alpha=\alpha_{ii}^{A}-\alpha_{00}^{A}$.

Except for the expression for the dipole–dipole interaction term between the solute and solvent molecules in Eq. 1, the latter is essentially the same as Abe's previous expression.[17] Accordingly, the application of Eq. 7 to a nonpolar solute gives the same correlation between the experimental frequencies and

TABLE 1. THE $\Delta\alpha$ VALUES FOR NONPOLAR SOLUTE MOLECULES

Molecule	Method	α_{00}^{A}	r_A	α_{ii}^{A}	$\Delta\alpha$

the frequencies calculated by Eq. 7 as was found using Abe's previous expression. The latter correlation was discussed in detail by Nicol *et al.*[25]

The observed $\Delta\alpha$ values for the aromatic hydrocarbon molecules in Table 1 are those measured by Mathies and Albrecht[26] for molecules dissolved in a rigid solution of 3-methylpentane at 77 K and by Liptay *et al.*[27] for anthracene in cyclohexane at 25 °C by means of electric field techniques.

Table 1 shows that the large $\Delta\alpha$ values estimated using Eq. 7 for the ^1L_a transitions of naphthalene and anthracene roughly approach those determined by electrooptical measurements. The difference was a maximum of 16%, and the small $\Delta\alpha$ values estimated using Eq. 7 for the ^1L_b transitions of benzene and naphthalene were higher by a factor of *ca.* 3 than those of the electrooptical measurements. The significantly large differences in the $\Delta\alpha$ values for the ^1L_b transitions obtained by using the two different methods may be due to a number of causes: (1) The present theoretical model for the solvent shift assumes spherical shapes for the solute and solvent molecules. The estimation of r_A using Eq. 2 may, therefore, be inappropriate for plane hydrocarbon molecules whose shapes considerably deviate from the spherical model. This is why we consider it inappropriate to extend the application of Eq. 7 to largely plane polynuclear hydrocarbons such as tetracene and perylene, although the $\Delta\alpha$ values for these molecules have been obtained from electrooptical measurements.[27] An arbitrary choice of smaller r_A values for benzene and naphthalene in our calculations minimized the differences in the $\Delta\alpha$ values obtained from both methods. (2) It has been reported that some excited-state polarizabilities vary with solvents to some extent.[27,28] The $\Delta\alpha$ values of Mathies and Albrecht are those for the hydrocarbons in 3-methylpentane at 77 K, while the $\Delta\alpha$ values in our present estimation correspond to those for the hydrocarbons in a vapor phase at 20 °C. Moreover, the electrooptical measurements of Mathies and Albrecht contain a few assumptions. Accordingly, some difference in the $\Delta\alpha$ values obtained by both methods may be unavoidable. (3) The differences may also result, in part, from the present assumption regarding Eq. 6.

In Table 1, the application of Eq. 7 gives $\Delta\alpha$ values which are larger than those determined by Mathies and Albrecht by less than 3×10^{-24} cm^3. This means that the excited-state polarizabilities estimated using Eq. 7 may be larger than those of Mathies and Albrecht by less than 3×10^{-24} cm^3. Compared to the polarizability values, the difference of *ca.* 3×10^{-24} cm^3 is small. Thus, we may conclude that our present application of Eq. 7 gives a reasonable estimation of the excited-state polarizabilities for the aromatic hydrocarbon molecules and that the estimation is better with a larger $\Delta\alpha$ value.

Lycopene. The r_A value of lycopene was taken to be 0.7 nm, the value that Myers and Birge[29] estimated for β-carotene from crystallographic data, as both lycopene and β-carotene have the same molecular formula ($C_{40}H_{56}$) and are similar in shape. The ionization potential of the ground state of a lycopene molecule having 11 conjugated double bonds was extrapolated to be 7.48 eV (1 eV=1.602×10^{-19} J) from the linear relationship[30] between the observed ionization potentials and the Hückel HOMO energy levels for ethylene, *s-trans*-1,3-butadiene and hexatriene. We used the reported spectral data[31] for the first transition in lycopene. The σ_{i0}° value of 23050 cm^{-1} and the $\Delta\alpha$ value in Table 1 were estimated according to Calculation 3. Obviously, the $\Delta\alpha$ value so estimated from solvent frequency shifts closely agrees with that obtained from the electric field-induced spectral change of lycopene in 3-methylpentane at 25 °C by Seibold *et al.*[28] (Table 1).

Chlorobenzene. Macovei[32] has investigated in detail the effects of a solvent on the 0-0 vibrational component[33] of the 37052-cm^{-1} π-π^* band of chloro-

benzene in the vapor phase. We chose data for 13 solvents from his spectral data involving 27 solvents. The data for carbon tetrachloride as a solvent were excluded since this molecule forms weak donor-acceptor complexes with benzene and substituted benzenes.[34] The values of p^A_{ii} and α^A_{ii} estimated by means of Calculation 1 are shown in Table 2. Even if a value of −1.0 was used for cosθ, we still obtained the same excited-state values recorded in Table 2, where $\Delta p=|p^A_{ii}|-|p^A_{00}|$. By using the p^A_{ii} and α^A_{ii} values so estimated, one can calculate the frequencies according to Eq. 1. We show in Fig. 1 the correlation between the experimental frequencies (σ_{i0} (obsd)) and the calculated ones (σ_{i0} (calcd)) for the ^1L_b band of chlorobenzene, as a representative example for the polar solutes. On the whole, the correlation is good.

The observed $|\Delta p|$ values (Table 2) determined by Lombardi *et al.*[12] by means of the optical Stark effect in the vapor phase are very reliable. As Lombardi[12a,c] clearly described, however, the sign of Δp cannot be determined using their experimental method. In the case of chlorobenzene, therefore, the two possible values of 2.03 and 1.55 D (1 D=3.333×10^{-30} Cm) are consistent with each measured splitting.[12e] By comparing the changes in rotational constants upon excitation, Wu and Lombardi[12e] expected the larger value for p^A_{ii}=2.03 D to be correct one. Their choice of 2.03 D, however, is not consistent with the theoretical results predicted by Kimura and Nagakura[35] by means of an MO calculation. Their theoretical results showed that the electron density on the chlorine atom in the first excited state of chlorobenzene should be slightly less than that of the chlorine atom in the ground state. This means that the value of p^A_{ii} is slightly less than that of p^A_{00}, since the substituent is the negative end of the dipole in both the ground and the excited states. Accordingly, the smaller value of p^A_{ii}=1.55 D should be the preferred experimental value of Wu and Lombardi. Our estimation of p^A_{ii}=1.47 D closely agrees with their reliable experimental value. By applying McRae's equation[36] to the solvent spectral frequency data for chlorobenzene, Macovei[32] also obtained a good result of p^A_{ii}=1.526 D. Thus, the comparable results on chlorobenzene, as determined by the electrooptical measurement and our present analysis, show that upon the assumption of Eq. 6, Eq. 1 can be applied for estimating the excited-state dipole moment of a polar solute molecule.

Fluorobenzene. There is a limited amount of data regarding polar solvents which do not form hydrogen bonds with fluorobenzene. Unfortunately, no desirable data regarding solvent effects for the 0-0 band (37829 cm^{-1})[37] of the first $\pi\cdot\pi^*$ transition in fluorobenzene in a vapor state are available. We were, therefore, restricted to using the undesirable data of Bowden and Braude[38] who reported that fluorobenzene in both cyclohexane and ethanol showed the 0-0 band to be at the same position (37590 cm^{-1}).

We wrote an equation for each solvent (cyclohexane or ethanol) according to Eq. 7. By solving the two equations simultaneously, we first obtained the two possible p^A_{ii} values, 1.42 and 242.70 D. For probabilistic reasons, however, the smaller value (1.42 D) was adopted as p^A_{ii} and the α^A_{ii} value was obtained as shown in Table 2. Huang and Lombardi[12d] determined the two possible excited-state dipole moments to be 1.37 and 1.96 D. They selected the larger value of 1.96 D as they did for chlorobenzene. According to Kimura and Nagakura,[35] the theoretical results regarding fluorobenzene are similar to those for chlorobenzene. If, by the same reasoning as we adopted in the case of chlorobenzene, we select their smaller value of 1.37 D as the experimental excited-state dipole moment of fluorobenzene, the p^A_{ii} value of 1.42 D estimated by the present method agrees well with the experimental value of 1.37 D.

Aniline. We chose the solvent spectral data of Mataga[39] for the first absorption band (35490 cm^{-1})[37] of aniline in vapor: 34800 (cyclohexane), 34700 (1,2-dichloroethane) and 34600 cm^{-1} (acetonitrile). In the present case, the angle θ between $\boldsymbol{p}^A_{00}$ and $\boldsymbol{p}^A_{ii}$ was

Table 3. Changes in the dipole moment and polarizability on excitation in aniline[a)]

cos θ	P_{ii}^{A}/D	Δp/D	$\Delta\alpha/10^{-24}$ cm^3
1.0	1.35	−0.13	9.56
0.8	1.69	0.21	9.46
0.5845	2.33	0.85	9.22
0.4	3.48	2.00	8.60
0.2	8.19	6.71	3.50

−0.2	−8.07	6.59	3.98
−0.4	−3.48	2.00	8.61
−0.5845	−2.33	0.85	9.22
−0.8	−1.69	0.21	9.46
−1.0	−1.35	−0.13	9.56

a) r_A=0.331 nm, P_{00}^{A}=1.48 D, and α_{00}^{A}=11.73×10^{-24} cm^3.

unknown. Consequently, we calculated the excited-state values for the possible values of cosθ according to Calculation 1 and give examples of the results in Table 3. By varying r_A in steps over a range from 0.2 to 0.4 nm, we found that Δp varies little with our choice for r_A. However, Δα depends on r_A considerably. According to Lombardi's experimental result of $|\Delta p|_{obsd}$= 0.85±0.15 D,[12a)] the value for p_{ii}^{A} should be either 0.63 or 2.33 D. In Table 3, the larger value (2.33 D) was reproducible by the present method to give cosθ=±0.5845. The angle of p_{ii}^{A} when the value of the moment is 2.33 D and cosθ=0.5845 is the same as when the p_{ii}^{A} moment is −2.33 D and cosθ=−0.5845=cos(180°− 54.23°). However, the direction of the former moment is different from that of the latter moment, as are shown in Fig. 2. Table 3 shows that the application of Eq. 7 gives no excited-state dipole moment smaller than 1.35 D in absolute value. Accordingly, the smaller (0.63 D) of the two possible experimental values proposed by Lombardi may be discarded on the basis of disagreement with the results of the solvent spectral-shift method. Lombardi[12a)] also explained his preference for the larger value of the excited-state dipole moment. Thus, the angle between $\boldsymbol{p}_{00}^{A}$ and $\boldsymbol{p}_{ii}^{A}$ is expected to be 54.23°. There is, therefore, two possible directions for the excited-state dipole moment as are shown by p_{ii}^{A}=±2.33 D in Fig. 2. The frequencies calculated using estimated values of p_{ii}^{A} and α_{ii}^{A} for cosθ=±0.5845 were 34820 (obsd, 34800), 34680 (obsd, 34700) and 34600 cm^{-1} (obsd, 34600 cm^{-1}) for the solvents of cyclohexane, 1,2-dichloroethane, and acetonitrile, respectively.

The ground-state dipole moment of aniline was calculated by Hehre *et al.*[40)] to be 1.44 D by means of *ab initio* MO theory. Their calculated components for the dipole moment and the direction of the ground-state dipole moment (p_{00}^{A}) are shown in Fig. 2. All the MO calculations of Baba,[41)] Mataga,[39)] and Hirota and Nagakura[42)] show a decrease in the π-electron density at the nitrogen atom in the excited state of aniline. This decrease only increases the magnitude of the excited-state dipole moment component parallel to the plane containing both the benzene ring and the nitrogen atom in the same direction as that of the corresponding ground-state dipole moment component. Accordingly, the positive and negative terminals of the dipole moment component in question will not change sign upon excitation. In Fig. 2, only the positive moment (p_{ii}^{A}=2.33 D) of the two possible moments of ±2.33 D for p_{ii}^{A} does clearly not change the sign of the dipole moment component. Thus, the direction of the excited-state dipole moment may be predicted as shown by p_{ii}^{A}=2.33 D in Fig. 2.

The p_{ii}^{A} value for aniline has been estimated by Mataga (2—2.5 D),[39)] Murrell (5 D),[43)] Iweibo *et al.* (a value nearly equal to p_{00}^{A}),[44)] Suppan (5.2 D),[5)] and Prabhumirashi *et al.* (2.12 D)[14,15)] from solvent shifts of absorption and/or fluorescence spectra. Mataga and Murrell used an equation for solvent shifts of absorption and fluorescence spectra.[45,46)] Suppan used a similar equation. Iweibo *et al.* and Prabhumirashi *et al.* used an approximation (Eq. 46 of Ref. 1a) of McRae's general expression.[36)] Since such an ap-

proximation obviously neglects the dispersion effect, the excited-state dipole moments estimated from such measurements will, for less polarized molecules, show sufficient departure from those of the electrooptical measurements. The fortuitously good estimate of Prabhumirashi *et al.* seems to be due to their choice of a rather small value of 0.146 nm for r_A. Except for Suppan, all of the above authors assumed collinear ground- and excited-state dipole moments. In view of the molecular structure[47] and the *ab initio* calculation[40] of the ground-state dipole moment for aniline, it seems difficult to assume such collinear dipole moments.

Retinal. Recently, Ponder and Mathies[48] have obtained the excited-state dipole moment and polarizability of *all-trans*-retinal from measurements of electric-field-induced changes in its optical absorption spectrum. We attempt to estimate the values of p^{A}_{ii} and α^{A}_{ii} for retinal by applying Eq. 7 to the available spectral data of Corsetti *et al.*[49] We chose 9 data points including those of 5 polar solvents from a total of 16 data points. From an extrapolation of a good linear relationship between absorption maxima (in cm^{-1}) of retinal in various nonpolar solvents and refractive indices of the solvents, we estimated the σ°_{i0} value of retinal to be 29210 cm^{-1}. The ionization potential of the retinal was estimated to be 8.31 eV as in the case of lycopene where parameters of the coulomb and resonance integrals for an oxygen atom were those referred to in Ref. 30. We used values of 4.55 D for p^{A}_{00} and 0.458 nm for r_A. These values were obtained by Myers and Birge[50] upon assuming a spherical model. Following Ponder and Mathies,[48] we assumed that both p^{A}_{00} and p^{A}_{ii} were parallel. Listed in Table 4 are the values of p^{A}_{ii} and $\Delta\alpha$ estimated by means of Calculation 1, in addition to the experimental results of Ponder and Mathies. The former values which were estimated by the present analysis agree well with the latter ones which were obtained from electrooptical measurements in a gas phase.

Azulene. The excited-state dipole moments and/or polarizabilities of azulene were obained from electrooptical measurements[51–55] as listed in Table 5. Hochstrasser and Noe,[51] Barker *et al*,[52] and Clark and Small[55] applied the Stark spectroscopy of mixed molecular crystals to the absorption systems of azulene. Mathies and Albrecht[52] adopted electric field broadening experiments for the absorption spectrum of azulene in 3-methylpentane at 77 K. Using reaction fields, Baumann[54] analyzed data obtained from electrooptical absorption and dielectric measurements for azulene in cyclohexane at 298 K.

We estimated the first and second excited-state dipole moments and polarizabilities of azulene by applying Calculation 1 to the available spectral data[23,24] as shown in Table 5. We chose 11 data points including 6 for nonpolar solvents and 5 for polar ones. For r_A we used the value of 0.308 nm, whose cube was already estimated by Baumann[54] for the spherical model of the azulene molecule. In the case of azulene, $\cos\theta$ obviously takes a value of either 1 or −1. Setting $\cos\theta=1$, yielded negative excited-state dipole moments. We, therefore, assumed that $\cos\theta=-1$.

As shown in Table 5, the present analysis gives the first and second excited-state dipole moments that are opposite in direction to that of the ground state. This result agrees with that obtained from the electrooptical measurements. The present analysis gives a far smaller decrease in the polarizability of the first excitation than do the measurements of Baumann. The first excited-state dipole moment estimated in the present analysis agrees roughly with those obtained from the electrooptical measurements. However, the present analysis shows that the magnitude of the second excited-state dipole moment is larger than that of the first excited state; electrooptical measurements show a reverse situation. The above differences between the present solvent shift method and the electrooptical

measurements may be ascribed to the same reasons preferred for the aromatic hydrocarbons above. More reliable excited-state dipole moments for azulene must wait for determinations regarding the optical Stark effect in the gas phase.

p-Nitroaniline. From the electrooptical absorption measurements, Czekalla and Wick[56] and Liptay *et al.*[57] obtained the p_{ii}^{A} values listed in Table 6. In order to make a comparison with their values, we applied Eq. 7 to the solvent spectral shift data of Kamlet and Taft[22] for the observed 34210 cm^{-1} absorption maximum[58] of *p*-nitroaniline in a vapor phase. We chose 7 data points relative to their 9 non-hydrogen-bonding solvents. The value of 6.29 D[59] was used for p_{00}^{A}. The direction of the ground-state dipole moment may obviously not lie in the plane of the benzene ring of *p*-nitroaniline for the same reason as described in the case of aniline. In using Calculation 1, therefore, we changed the value of cosθ to be within the range of 0.5—1.0. The results of the calculation are shown in Table 6.

The electrooptical measurements made by both Czekalla and Wick[56] and Liptay *et al.*[57] assumed that the ground- and excited-state dipole moments were parallel to each other. With this assumption, the results of their measurements can be compared with our present calculation only when cosθ=1. Their values are considerably higher than that estimated by the present analysis. Czekalla and Wick completely neglected the effects of the ground- and excited-state polarizabilities of *p*-nitroaniline, while Liptay *et al.* neglected only the contribution of its excited-state polarizability. The large difference in the p_{ii}^{A} value using the two methods seems to be mainly due to their neglect of the contributions due to these polarizabilities. Thus, at the present stage, we have no reliable value for an electrooptically determined excited-state dipole moment in the case of *p*-nitroaniline.

The p_{ii}^{A} value has been estimated by Abe (10.26 D),[60] Suppan (16.3 D),[61] Millefiori *et al.* (10.13—10.50 D),[58,62] and Koutek (15.5 D)[16] from solvent spectral-shift theories. Koutek has applied the local reaction fields of Block and Walker[63] and Wertheim[64] to the already presented equations based on McRae's theory.[36] The expressions used by Suppan and Millefiori *et al.* lack any consideration of the polarizabilities and are based on the assumption that the ground- and excited-state dipole moments were parallel to each other. Koutek's treatments are also insufficient regarding these points. Thus, much weight cannot be credited to results from such computations.

Photochemical Magnetic Field Effects of 4-Methyl-2-quinolinecarbonitrile

Norisuke HATA* and Naoya NISHIDA
Department of Chemistry, College of Science and Engineering, Aoyama Gakuin University, Chitosedai, Setagaya-ku, Tokyo 157
(Received July 10, 1985)

The irradiation of 4-methyl-2-quinolinecarbonitrile **1** in ethanol or cyclohexane resulted in the formation of 2-(1-hydroxyethyl)-4-methylquinoline **2** or 2-cyclohexyl-4-methylquinoline **3** in the yield of *ca.* 48 or 65%. The effects of an external magnetic field upon the photosubstitution reaction were investigated in either the absence or presence of 1,3-pentadiene (triplet quencher). In the case of the photosubstitution reaction (**1**→**2**) in ethanol, the chemical yield of **2** increased quadratically with an increase in the field strength (magnetic field effect due to Δg mechanism) and it also showed a minimum at approximately 1.1T (magnetic field effect due to HFI-J mechanism). The addition of 1,3-pentadiene caused a complete disappearance of the Δg magnetic field effect. Thus, the formation of **2** at a zero field was concluded to occur from the S_1-state *via* the singlet hydrogen-bonded radical pair. In the case of the photosubstitution reaction (**1**→**3**) in cyclohexane, the chemical yield of **3** decreased steeply upon the application of a magnetic field of 40mT (magnetic field effect due to HFI mechanism) and a further increase in the field strength resulted in a quadratic increase in the yield (magnetic field effect due to Δg mechanism). Neither an HFI nor a Δg magnetic field effect was observed in the presence of 1,3-pentadiene. The reaction was thus concluded to proceed from the S_1 and T_1 states *via* the singlet and triplet radical pairs. Reaction mechanisms deduced from the external magnetic field effects were consistent with the results of Stern-Volmer analyses.

Photochemical reactions proceeding *via* a radical-pair intermediate in solution can generally be expected to show an external magnetic field effect which arises from an electronic Zeeman interaction (Δg mechanism), electron-nuclear hyperfine interaction (HFI mechanism), or hyperfine-interaction mechanism including an electron-exchange interaction (HFI-J mechanism) in a radical-pair intermediate (*cf.* Appendix).[1] The magnetic field effect due to the HFI-J mechanism is considered to be particularly interesting and important from the viewpoint of mechanistic photochemistry, becuase it is expected when hydrogen- or electron-transfer between a photoexcited molecule and the hydrogen-bonded species occurs to form an appropriate hydrogen-bonded radical pair or radical ion-pair intermediate in a solvent cage.[2] In 1976 this type of magnetic field effect was found for the first time by one (N.H.) of the authors in the case of the photochemical isomerization of isoquinoline *N*-oxide in ethanol.[2] In order to find a second example of the magnetic field effect due to the HFI-J mechanism, in the present investigation, the photoinduced substitution reaction of 4-methyl-2-quinolinecarbonitrile in ethanol and in cyclohexane were studied in both the absence and presence of a magnetic field.[3]

Experimental

Materials. The 4-methyl-2-quinolinecarbonitrile **1** used as a sample was prepared from 4-methylquinoline *N*-oxide according to a method (Reissert reaction) given in the literature;[4] it was then purified by recrystallization from methanol several times; mp 97—98°C. 1,3-Pentadiene used as a triplet quencher was a Chemical-pure product of Tokyo Kasei Kogyo Co., which was further purified by distillation; bp 42—43.5°C. The ethanol and cyclohexane used as the photoreaction medium were Reagent-grade products of Wako Pure Chemical Industries; the former was used without further purification, while the latter was purified by silica-gel chromatography.

Isolation and Identification of Photoproducts. 4-Methyl-2-quinolinecarbonitrile **1** (50 mg) dissolved in 50-cm³ of ethanol (or cyclohexane) in a Pyrex vessel was irradiated with a 100 W high-pressure immersion mercury lamp (Riko Kagaku Sangyo Co.) for 5 h (or 8 h) in an atmosphere of nitrogen at room temperature. After the removal of the solvent under reduced pressure, unreacted **1** and product **2** (or **3**) were separated by means of silica-gel TLC (Merck TLC silica-gel plate $60F_{254}$; layer thickness, 2 mm; the eluent, hexane–diethyl ether (1:2) for the separation of **1** and **2**, and hexane–ethyl acetate (5:1) for the separation of **1** and **3**). The product **2** was 2-(1-hydroxyethyl)-4-methylquinoline, which has been identified previously;[5] mp 82—82.5°C; the yield, *ca.* 48%. The product **3** was a colorless liquid; bp 121°C/2 mm, mp (the picrate) 182°C; the yield, *ca.* 65%. It was identified as 2-cyclohexyl-4-methylquinoline by the following analytical data. NMR($CDCl_3$) δ(ppm): 8.2—7.3 (m, 5H, aromatic), 2.70 (s, 3H, $-CH_3$), 2.2—1.1 (m, 11H, $-C_6H_{11}$). MS: 225(M^+). Found (the picrate): C, 58.46; H, 4.86; N, 12.05%. Calcd for $C_{22}H_{22}N_4O_7$ (the picrate): C, 58.15; H, 4.85; N, 12.33%.

Stern-Volmer Experiments. A determination of the quantum yields (the disappearance of **1** and the formation of **2** or **3**) was performed in a quartz cell (4.5-cm in diameter and 1-cm in length) containing the ethanolic solution (or cyclohexane solution) of **1** (1.62×10^{-3} mol dm^{-3}) and 1,3-pentadiene (0—10.0×10^{-3} mol dm^{-3}) under a nitrogen atmosphere at room temperature. The light source employed was a Ushio Super-high-pressure Mercury Lamp (USH-500D) equipped, for the 313-nm irradiation, with a filter combination of a nickel sulfate solution with Toshiba filters UV-29 and UV-D33S. The light intensity was determined by means of a potassium tris-(oxalato)ferrate (III) actinometer. The amounts of unreacted **1** and product **2** (or **3**) were determined by means of a silica-gel chromatographic separation, using the same eluent as that described before, combined with a spectrophotometric determination.

Magnetic Perturbation Experiments. A 50-cm³ of ethanolic solution (or cyclohexane solution) containing 4-

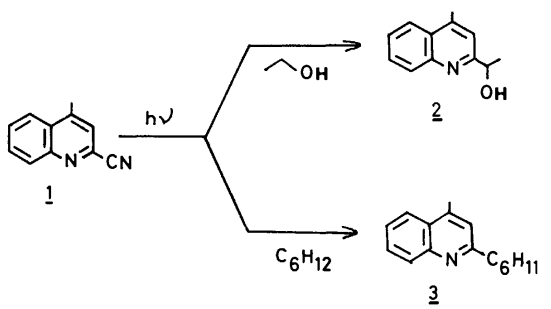
methyl-2-quinolinecarbonitrile **1** (35 mg) and 1,3-pentadiene (0 or 3.0×10^{-1} mol dm^{-3}) in a quartz vessel (44×45×25 mm) was placed in an electromagnet (EEO-1815) supplied by the Maezumi Electric Company and subsequently, irradiated with two 500 W Super-high-pressure Mercury Lamps (USH-500D) equipped with a Toshiba filter UV-31 for 40 min at room temperature while nitrogen was bubbled. The unreacted **1** and product **2** (or **3**) were separated by means of silca-gel TLC in the same manner as that described before and the amounts were determined spectrophotometrically.

Spectroscopic Measurements. UV absorption spectra were taken with a Shimadzu recording spectrophotometer, UV-220. Fluorescence and phosphorescence spectra were determined with a Hitachi recording fluorescence spectrophotometer, MPF-2A. Reagent-grade ethanol (Wako Pure Chemical Industries) and Spectro-grade methylcyclohexane (Dotite Spectrosol) were used as the solvent. NMR spectra were taken in $CDCl_3$ with a Hitachi-Perkin Elmer NMR spectrometer R-20 at 60 MHz, using TMS as the internal standard. Mass spectra were measured with a Hitachi mass spectrometer, RMU-6M.

Results and Discussion

Photochemical Reactions and the Stern-Volmer Analyses. It has been already reported in previous papers[5] that the irradiation of 2-quinolinecarbonitriles in alcoholic solvents generally results in the replacement of the cyano group at the 2-position of a quinoline nucleus by hydroxyalkyl group. As has been described in the Experimental section, when 4-methyl-2-quinolinecarbonitrile **1** in ethanol was irradiated in an atmosphere of nitrogen, 2-(1-hydroxyethyl)-4-methylquinoline **2** was obtained in a *ca.* 48% yield (Eq. 1). In the case of a cyclohexane solution, there also occurred a similar photosubstitution reaction to give rise to 2-cyclohexyl-4-methylquinoline **3** in a yield of *ca.* 65% (Eq. 2).



(1)

(2)

In order to characterize the excited states responsible for the photosubstitution reaction of 4-methyl-2-quinolinecarbonitrile **1** in ethanol or cyclohexane, the effects of 1,3-pentadiene upon the quantum yield (Φ_{-1}) of the disappearance of **1** and that (Φ_2 or Φ_3) of the formation of **2** or **3** were examined. The excitation energy of the lowest triplet state of 4-methyl-2-quinolinecarbonitrile was estimated, from the first maximum of the phosphorescence spectrum (Table 1), to be *ca.* 247 kJ mol^{-1}; hence 1,3-pentadiene was used as a triplet quencher for the photochemical reaction of **1**.

Figure 1 shows a plot of $\Phi^{\circ}_{-1}/\Phi_{-1}$ or Φ°_{2}/Φ_2 against the concentration of 1,3-pentadiene ([C_5H_8]) for the photosubstitution reaction (**1**→**2**) in ethanol (Stern-Volmer plot), where the quantum yield (Φ°_{-1}) of the disappearance of **1** and that (Φ°_{2}) of the formation of **2** at [C_5H_8]=0 were 0.0825 and 0.0461, respectively. As can be seen from Fig. 1, Φ_2 was independent of the concentration of 1,3-pentadiene, whereas Φ_{-1} decreased with an increase in the concentration of 1,3-pentadiene until it became constant above a concentration of 7.0×10^{-3} mol dm^{-3} 1,3-pentadiene. The results clearly indicate that the photosubstitution reaction (**1**→**2**) proceeds from the S_1 state and that some complicating reactions occur from the T_1 state.

Figure 2 shows Stern-Volmer plots for a photosubstitution reaction (**1**→**3**) in cyclohexane, where the quantum yield (Φ°_{-1}) of the disappearance of **1** and that (Φ°_{3}) of the formation of **3** at [C_5H_8]=0 were 0.0374 and 0.0271, respectively. Both quantum yields, Φ_{-1} and Φ_3, decreased with an increase in the concentration of 1,3-pentadiene until no further quenching occurred above a concentration of 1.7×10^{-3} mol dm^{-3} 1,3-pentadiene. This means that, unlike the case of the photosubstitution reaction **1**→**2**, both S_1 and T_1 states are responsible for the photosubstitution reaction **1**→**3**.

The chemical yield, Y_S or Y_T, of the S_1- or T_1-born product **3** was estimated from the Stern-Volmer plot (curve (a) in Fig. 2) in the following manner. The chemical yield (Y) of **3** at [C_5H_8]=0 is given by the sum of Y_S and Y_T (Eq. 3). The chemical yield (Y_S) of the S_1-born product **3** is given by Eq. 4, where $(\Phi^{\circ}_{3}/\Phi_3)_0$ and $(\Phi^{\circ}_{3}/\Phi_3)_s$ represent, respectively, Φ°_{3}/Φ_3 at [C_5H_8]=0 and [C_5H_8]>1.7×10^{-3} mol dm^{-3}. Y_S and Y_T were thus

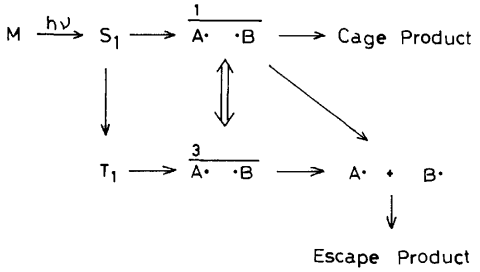
evaluated by substituting $(\Phi^{\circ}_{3}/\Phi_{3})_s$=1.41 and Y=65% into Eqs. 3 and 4 to be 46 and 19% respectively.

Magnetic Field Effects. In the case where the photochemical reactions in solution proceed *via* a radical-pair intermediate (as is shown in Scheme 1), the chemical yield of the cage product or escape product shows a magnetic field dependence provided that the rate of the intersystem crossing of a radical pair is influenced by an external magnetic field.[1] As will be briefly described in Appendix, such a field dependence of chemical yield has been currently classified into six patterns (Figs. 5 and 6), depending on whether the product is a cage- or escape-product and an S_1- or T_1-born product and also whether the magnetic perturbation is due to Δg, HFI, or HFI-J mechanism. Consequently, an examination of the field dependence of chemical yield is supposed to furnish quite significant information regarding photochemical reaction mechanism.[6]

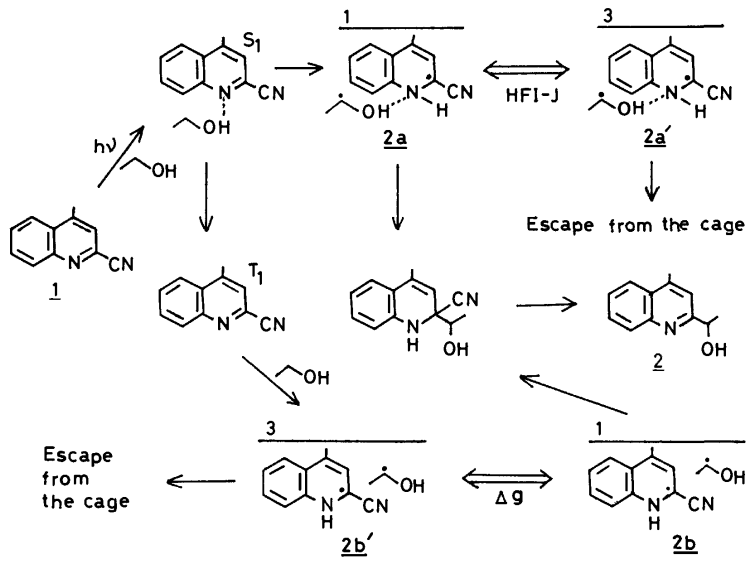


Scheme 1.

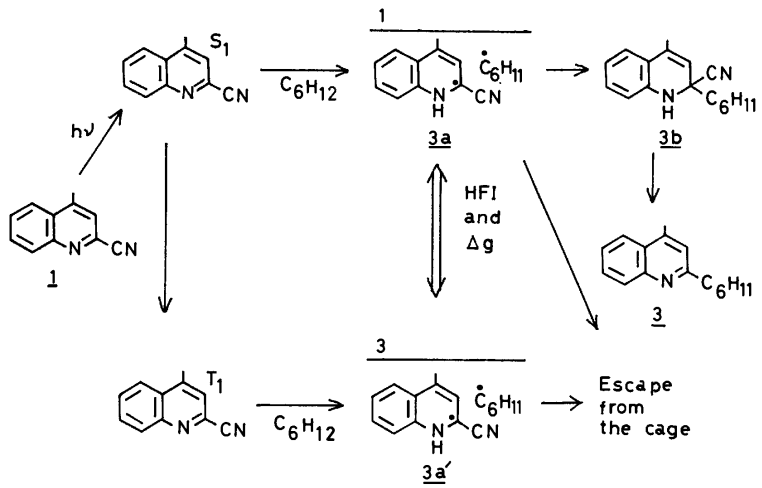
As mentioned before, the Stern-Volmer plots (Fig. 1) of the photoinduced substitution reaction (**1**→**2**) in ethanol revealed the S_1 state to be responsible for this reaction. Previously,[7,8] it had also been demonstrated from the solvent dependence of the absortpion and fluorescence spectra of 2-quinolinecarbonitriles (*cf.* Table 1) that a hydrogen-bonding interaction between the ring nitrogen and an ethanol does exist in the S_1 state, although there is no appreciable interaction in the S_0 state.[9] Furthermore, the photoreaction has been reasonably assumed to proceed *via* the S_1 state through hydrogen abstraction by the ring nitrogen from the

hydrogen-bonded ethanol.[7] Hence, as is shown in Scheme 2, it seems quite reasonable to assume that the S_1-born singlet hydrogen-bonded radical pair **2a** is formed as a transient intermediate of this reaction. If this assumption is valid, the magnetic field effect due to the HFI-J mechanism (curve (3) in Fig. 5) may be expected for the photosubstitution reaction **1**→**2**, just as the case of the photoisomerization of isoquinoline *N*-oxide in ethanol;[2] it is because the radical centers in the radical pair **2a** are in close proximity as a result of hydrogen-bonding interaction between the two radicals (consequently, the electron-exchange interaction is much greater than the electron-nuclear hyperfine energy). On the other hand, the photosubstitution reaction (**1**→**3**) in cyclohexane was demonstrated from Stern-Volmer plots (Fig. 2) to occur from both the S_1 and T_1 states. Therefore, as is shown in Scheme 3, if the reaction proceeds *via* the S_1-born singlet and T_1-born triplet radical pairs, **3a** and **3a'**, as the reactive intermediate, then it may be subject to a magnetic field effect due to Δg or HFI mechanism (curve (1) or (2) in Fig. 5 and curve (1') or (2') in Fig. 6), because either the radical pair **3a** or **3a'** is not a hydrogen-bonding pair of radicals in close proximity and therefore the electron-exchange interaction is disregarded. For these reasons, the effects of an external magnetic field on the photoinduced substitution reactions of 4-methyl-2-quinolinecarbonitrile **1** in ethanol and in cyclohexane were investigated in either the absence or presence of 1,3-pentadiene (triplet quencher).

First we will describe the magnetic field effect upon the photosubstitution reaction (**1**→**2**) in ethanol. Figure 3 shows the results when the chemical yield of **2** is plotted as a function of the field strength in the absence and presence of 1,3-pentadiene, where the conversion remained almost constant (20—22%). In the absence of 1,3-pentadiene, as is shown by curve (a) in Fig. 3, the chemical yield of **2** was *ca.* 48% at the zero field, but it increased quadratically with an increase in the field strength to be *ca.*58% at about 1.5 T (the



Scheme 2.



Scheme 3.

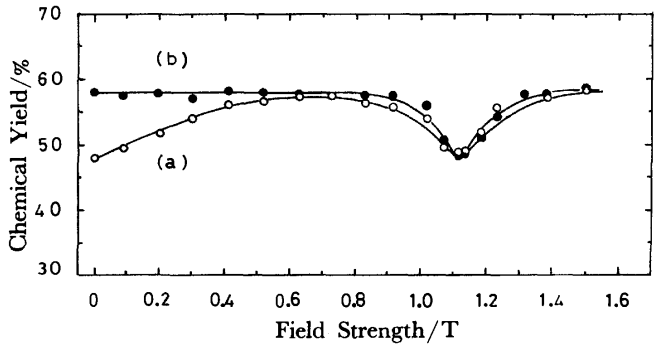


Fig. 3. External magnetic field effect upon the photosubstitution reaction (**1**→**2**) in ethanol. Chemical yield of **2** *vs.* magnetic field strength. [**1**]= 4.01×10^{-3} mol dm^{-3}.
(a) —○—: $[C_5H_8]=0$, (b) —●—: $[C_5H_8]=3.0\times10^{-1}$ mol dm^{-3}.

magnetic field effect due to Δg mechanism); this is the same pattern as for the field dependence of the chemical yield of the S_1-born escape product or the T_1-born cage product (curve (1′) in Fig. 6). The chemical yield of **2** also showed a minimum (*ca.* 49%) at approximately 1.1 T (the magnetic field effect due to HFI-J mechanism); this is the same pattern as for the field dependence of the chemical yield of the S_1-born cage product or the T_1-born escape product (curve (3) in Fig. 5). The Δg magnetic field effect, as is shown by curve (b) in Fig. 3, disappeared completely upon the addition of 1,3-pentadiene, although the magnetic field effect due to the HFI-J mechanism was still observed. Thus, the chemical yield of **2** was *ca.* 58% at a magnetic field below 0.8 T, but it decreased steeply with an increase in the field strength to become *ca.* 48% at about 1.1 T. A further increase in the magnetic field resulted in a steep increase in the chemical yield until it became approximately constant (*ca.* 58%). The results explicitly indicate that the Δg or the HFI-J magnetic field effect observed in a photochemical reaction can be assigned to the field dependence of the chemical yield of the T_1- or S_1-born cage product.

Such an examination of the magnetic field effects leads to the conclusion that a photosubstitution reaction of 4-methyl-2-quinolinecarbonitrile **1** in ethanol (Eq. 1) proceeds according to the mechanism shown in Scheme 2. Thus, the photoexcitation of **1** into the S_1 state results in the formation of a hydrogen bond between the ring nitrogen and an ethanol. This is followed by hydrogen abstraction by the ring nitrogen from the hydrogen-bonded ethanol, which gives rise to the singlet hydrogen-bonded radical pair **2a** that is responsible for the formation of **2** (S_1-born cage product). The S_1-born singlet hydrogen-bonded radical pair **2a** undergoes a magnetic perturbation due to the HFI-J mechanism. As a result, the chemical yield of the S_1-born cage product **2** comes to show a minimum at approximately 1.1 T. In addition, an observation of the magnetic field effect due to the Δg mechanism (which disappears upon the addition of 1,3-pentadiene) indicates, unambiguously, that in the T_1 state there also occurs hydrogen abstraction by the ring nitrogen from an ethanol to yield the triplet radical pair **2b′**. The T_1-born triplet radical pair **2b′**, because of its triplet character, undergoes a diffusive separation into the solvent bulk to cause some complicating radical reactions. It should also be noted that a magnetic field effect due to the HFI mechanism, ascribed to the T_1-born triplet radical pair **2b′** (curve (2′) in Fig. 6), was not observed in this reaction system. This implies that, unless a magnetic field is applied to this system, the triplet radical pair **2b′** does not undergo an intersystem crossing to the singlet radical pair **2b** responsible for the formation of **2** (T_1-born cage product). This agrees well with the conclusion from Stern-Volmer analyses (Fig. 1) that the photosubstitution reaction **1**→**2** proceeds from the S_1 state, while some complicating reactions occur from the T_1 state.

As a general rule (*cf.* Appendix), a magnetic field effect due to the Δg or the HFI mechanism should be expected when the two components of a field-sensitive radical pair in a solvent cage is sufficiently far apart that the electron-exchange interaction can be neglected. On the other hand, a magnetic field effect due to the HFI-J mechanism should be expected when the two component radicals are in close proximity as a result of a hydrogen-bonding interaction (the electron-exchange interaction can not be disregarded). Thus, it may be considered that the S_1-born singlet radical pair **2a** which undergoes a magnetic perturbation due to HFI-J mechanism is a hydrogen-bonding pair, whereas the T_1-born triplet radical pair **2b′** which is subject to a magnetic perturbation due to the Δg mechanism is a nonhydrogen-bonding pair. This in turn leads to the conclusion that hydrogen-bonding interaction between the ring nitrogen and an ethanol does exist in the S_1 state, but that it is negligibly small in the T_1 state. This agrees well with the previously obtained conclusion from solvent-effect studies on the fluorescence and phosphorescence spectra of 2-quinolinecarbonitriles (*cf.* Table 1).[9]

Next, we describe the effect of an external magnetic field on a photosubstitution reaction (**1**→**3**) in cyclohexane. Figure 4 shows the results when the chemical yield of **3** is plotted against the field strength in either the absence or presence of 1,3-pentadiene. In either case the conversion was almost independent of the field strength (19—21%). In the absence of 1,3-pentadiene, as can be seen from curve (a) in Fig. 4, the chemical yield of **3** was *ca.* 65% at a zero field. However, it steeply decreased upon the application of a magnetic field of 40 mT to be *ca.* 54% (the magnetic field effect due to HFI mechanism). This is the same pattern as that for the field dependence of the chemical yield of the S_1-born escape product or the T_1-born cage product (curve (2′) in Fig. 6). A further increase in the field strength resulted in a quadratic increase in the chemical yield (the

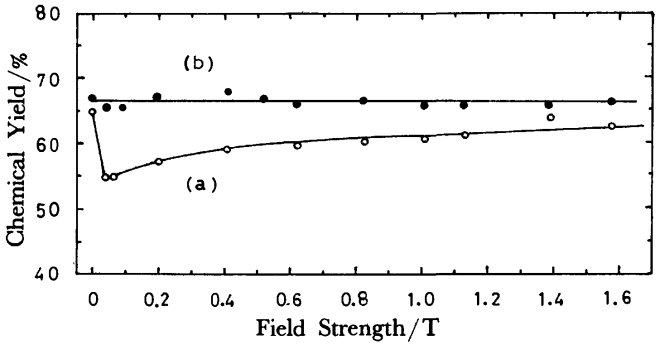

Fig. 4. External magnetic field effect upon the photosubstitution reaction (**1**→**3**) in cyclohexane. Chemical yield of **3** *vs.* magnetic field strength. [**1**]=4.01 ×10^{-3} mol dm^{-3}.
(a) —○—: [C_5H_8]=0, (b) —●—: [C_5H_8]=3.0×10^{-3} mol dm^{-3}.

magnetic field effect due to Δg mechanism). This is the same pattern as the field dependence of chemical yield of the S_1-born escape product or the T_1-born cage product (curve (1′) in Fig. 6). The addition of 1,3-pentadiene, however, caused a complete disappearance of these magnetic field effects; as a result, the chemical yield of **3** became independent of the field strength to show *ca.* 67%. This means that both the HFI and Δg magnetic field effects observed in this reaction can be assigned to the field dependence of chemical yield of the T_1-born cage product. Also, the fact that the product **3** was obtained in a high yield (*ca.* 67%), even in the presence of 1,3-pentadiene, suggests strongly that the photosubstitution reaction proceeds from the S_1 state as well as the T_1 state. This is consistent with a conclusion from Stern-Volmer analyses (Fig. 2).

The external magnetic field effects described above lead to the conclusion that the photosubstitution reaction of 4-methyl-2-quinolinecarbonitrile **1** in cyclohexane (Eq. 2) proceeds according to the mechanism shown in Scheme 3. Thus, the photochemical reaction is initiated by a hydrogen abstraction from cyclohexane by the ring nitrogen, which occurs from both the S_1 and T_1 states, to yield the S_1-born singlet radical pair **3a** and T_1-born triplet radical pair **3a′** as transient intermediates. The S_1-born singlet radical pair **3a** undergoes mostly efficient cage recombination to generate the product **3** (S_1-born cage product). On the other hand, the T_1-born triplet radical pair **3a′** undergoes partly hyperfine-induced intersystem crossing to the singlet radical pair **3a** responsible for the formation of **3** (T_1-born cage product) and partly diffusive separation into the solvent bulk.

As can be seen from Fig. 4, a magnetic field effect which could be ascribed to the S_1-born singlet radical pair **3a** was not observed at all, although the formation of the product **3** undoubtedly occurs from the S_1 state, probably, *via* the intermediate **3a**. This may be interpreted as follows. As is shown in Scheme 3, the S_1-born singlet radical pair **3a** undergoes mainly the following two processes; one of them is a cage recombination (**3a**→**3b**) or diffusive separation of the component radicals, while the other is a magneto-sensitive intersystem crossing (**3a**→**3a′**) which occurs with a rate of the order of 10^7—10^8 s^{-1} *via* electron-nuclear hyperfine interaction. Therefore, if the cage recombination takes place in competition with the intersystem crossing, the singlet radical pair **3a** is supposed to be subject to a magnetic perturbation due to the Δg or HFI mechanism. However, the fact that such a magnetic field effect as shown in curve (1) or (2) in Fig. 5 is not observed at all implies that the cage recombination is much faster than an intersystem crossing. A similar interpretation has been made regarding the photochemical magnetic field effect of 1-isoquinolinecarbonitriles in ethanol.[6]

The chemical yield, Y_S or Y_T, of the S_1-born or T_1-born cage product **3** was estimated from data regarding the magnetic field effects in the absence of 1,3-pentadiene (curve (a) in Fig. 4) in the following way. The chemical yield ($Y°$) of **3** at a zero field is equal to the sum of Y_S and Y_T (Eq. 5). The chemical yield (Y^H) of **3** at a magnetic field of 40 mT is given by Eq. 6, where the chemical yield of the T_1-born cage product **3** at a magnetic field of 40 mT is assumed to be $(1/3)Y_T$ because the number of effective working channels for the hyperfine-induced intersystem crossing of a radical pair reduces by the application of a magnetic field from three ($T_{0,\pm}$↔S) to one (T_0↔S). Thus, Y_S and Y_T were evaluated by substituting $Y°$=65% and Y^H=54% into

$$Y° = Y_S + Y_T \quad (5)$$

$$Y^H = Y_S + (1/3)Y_T \quad (6)$$

Eqs. 5 and 6 to be 48.5 and 16.5% respectively. These values approximately agree with those (Y_S=46% and Y_T=19%) obtained by Stern-Volmer analyses (Fig. 2).

Conclusion

The second example of a magnetic field effect due to the HFI-J mechanism (ascribed to the S_1-born singlet radical pair) was found for the case of a photoinduced substitution reaction of 4-methyl-2-quinolinecarbonitrile in ethanol (Eq. 1). This reaction also showed the magnetic field effect due to the Δg mechanism which can be ascribed to the T_1-born triplet radical pair. In the case of a photosubstitution reaction in cyclohexane (Eq. 2), the formation of a T_1-born triplet radical pair intermediate was concluded by the observation of magnetic field effects due to the HFI and Δg mechanisms. However, a magnetic field effect which could be ascribed to an S_1-born singlet radical pair was not observed. From the experimental results, the photosubstitution reaction of 4-methyl-2-quinolinecarbonitrile in ethanol or cyclohexane was unambiguously deter-

mined to proceed according to the mechanism shown in Scheme 2 or 3. This is consistent with the results of Stern-Volmer analyses. The present studies explicitly demonstrate that magnetic-perturbation experiments are quite useful for the mechanistic elucidation of photochemical reactions in solutions.

Appendix

Magnetic Field Dependence of the Chemical Yield of Photoproduct. Scheme 1 shows the case of a compound M in a solution absorbing light and, thus, being excited into S_1 and T_1 states. It thus forms singlet and triplet radical-pair intermediates. The S_1-born singlet radical pair, because of its singlet character, mostly undergoes recombination or disproportionation within a solvent cage to give rise to the S_1-born cage product. On the other hand, the T_1-born triplet radical pair, because of its triplet character, undergoes a diffusive separation into a solvent bulk to give the T_1-born escape product. Also, the intersystem crossing of the radical-pair intermediates results in the formation of the S_1-born escape product or T_1-born cage product. If such an intersystem crossing is subject to a magnetic perturbation, the chemical yield of the cage- or escape-product comes to show a magnetic-field dependence (external magnetic field effect upon photochmical reactions in solution).[1]

If the exchange interaction between the unpaired electrons in a radical pair is neglected, the singlet (S) and triplet ($T_{0,\pm}$) levels being degenerate, the rate of the intersystem crossing may be affected by an external magnetic field in the following ways. (1) Electronic Zeeman interaction (Δg mechanism); the external magnetic field causes the intersystem crossing ($S \leftrightarrow T_0$) of a radical pair by virtue of the different g-values of the component radicals. (2) Electron-nuclear hyperfine interaction (HFI mechanism); the external magnetic field causes the number of effective working channels for the hyperfine-induced intersystem crossing of a radical pair to reduce from three ($S \leftrightarrow T_{0,\pm}$) to one ($S \leftrightarrow T_0$).

On the other hand, when the unpaired electrons in a radical pair is in close proximity as a result of a hydrogen-bonding interaction between the two component radicals, the electron-exchange interaction may be greater than the electron-nuclear hyperfine energy; the singlet (S) and triplet ($T_{0,\pm}$) levels of the pair are nondegenerate, having an energy gap of $2|J|$, where J denotes the electron-exchange integral. In this case, the intersystem crossing $S \leftrightarrow T_+$ or $S \leftrightarrow T_-$ may be induced by an electron-nuclear hyperfine interaction mechanism at the magnetic field in which the S level is in resonance with the T_+ or T_- level (HFI-J mechanism).

Figure 5 shows the field dependence of chemical yield of the S_1-born cage product (CP-S_1) or the T_1-born escape product (EP-T_1). In Fig. 6 the field dependence of chemical yield of the S_1-born escape product (EP-S_1) or T_1-born cage product (CP-T_1) is also shown. In the case of a magnetic field effect due to the Δg mechanism, the chemical yields of CP-S_1 and EP-T_1 (or EP-S_1 and CP-T_1) decrease (or increase) quadratically with an increase in the field strength (curve (1) in Fig.5 or curve (1′) in Fig. 6). In the case of a magnetic field effect due to the HFI mechanism, the chemical yields of CP-S_1 and EP-T_1 (or EP-S_1 and CP-T_1) increase (or decrease) steeply at a very low field (curve (2) in Fig. 5 or curve (2′) in Fig. 6). Also, in the case of a magnetic field effect due to the HFI-J mechanism, the chemical yields of CP-S_1 and EP-T_1 (or EP-S_1 and CP-T_1) show a minimum (or a maximum) at a particualr magnetic field (curve (3) in Fig.5 or curve (3′) in Fig. 6).

It has been reported that examination of the magnetic-field and heavy-atom effects on the photosubstitution reaction of 1-isoquinolinecarbonitrile or photochemical substitution and decyanation reactions of 3-methyl-1-isoquinolinecarbonitrile in ethanol were quite useful for the mechanistic elucidation of the reactions. From the experimental results, the photosubstitution reaction was revealed to proceed *via* the S_1 and/or T_1 states through hydrogen abstraction by the ring

nitrogen from ethanol, whereas the photodecyanation reaction was concluded to occur from the S_1 state through hydrogen abstraction by the ring nitrogen from the methyl group at the 3-position of an isoquinoline nucleus.

9) In previous papers,[6-8] hydrogen-bonding interaction of the ring nitrogen of some azaaromatic nitriles in the S_0, S_1, or T_1 state with an ethanol has been discussed on the basis of the solvent effect of absorption and emission spectra (*cf.* Table 1). The absorption spectrum, both the spectral shape and maximum wavelength (the extinction coefficient), was essentially unchanged in either methylcyclohexane (MCH) or ethanol (EtOH). This means that there is no appreciable hydrogen-bonding interaction between the ring nitrogen and an ethanol in the S_0 state. On the other hand, the fluorescence spectrum showed a remarkable dependence on the solvent. The non-fluorescence (or very weak fluorescence) in MCH was interpreted in terms of a mixing of the S_1 (π,π^*) state with a closely lying ^1n, π^* state through the vibronic coupling, and the fluorescence activation in ethanol was attributable to a great decrease in such a vibronic mixing owing to the formation of hydrogen bond between the ring nitrogen and an ethanol in the S_1 state. The phosphorescence spectrum, which was observed only in the case of 2-quinolinecarbonitriles, was not affected significantly by changing the solvent from MCH to EtOH, indicating that hydrogen-bonding interaction of the ring nitrogen with an ethanol is negligibly small in the T_1 state as well as in the S_0 state.

Reaction of Malonaldehyde with Nucleic Acid. II. Formation of Fluorescent Pyrimido[1,2-*a*]purin-10(3*H*)-one Mononucleotide

Hiroshi SETO,* Tomoyuki TAKESUE,† and Tadashi IKEMURA†
Tokyo Metropolitan Research Laboratory of Public Health, Sinjuku-ku, Tokyo 160
†*College of Science and Technology, Nihon University, Chiyoda-ku, Tokyo 101*
(Received April 10, 1985)

The reaction of malonaldehyde under acidic conditions (pH 4.5) with guanosine 5′-monophosphate resulted in the formation of fluorescent 3-(β-D-ribofuranosyl)pyrimido[1,2-*a*]purin-10(3*H*)-one 5′-phosphate (**3a**). This adduct was also isolated from malonaldehyde-reacted RNA. The amount of **3a** in the modified RNA was estimated to be 0.4 per cent by weight. The fluorescence spectrum of **3a** (E_x max. 360 nm, E_m max. 500 nm) was similar to that of guanine- and guanosine-malonaldehyde adducts which have the same type base structure. On the other hand, another type of fluorophore (E_x max. 390 nm, E_m max. 460 nm) was also formed in the reaction of malonaldehyde with a nucleic acid polymer. Thus, at least two different types of fluorophores are present in malonaldehyde-reacted nucleic acid.

Malonaldehyde (1), an end product of lipid peroxidation and a side product of prostagrandin and thromboxane biosynthesis in animal tissues,[1] is mutagenic[2–4] and carcinogenic.[4–6] These toxicological data suggest chemical interactions between 1 and various biological macromolecules. Therefore, the presence of 1 in foods[7] and in living organs[8,9] in which the lipid fraction has undergone oxidation may be of physiolosical significance. Malonaldehyde is reactive toward DNA to form fluorescent products which are accounted for by cross-linking of DNA between amino groups of the bases of DNA.[10] Recently, Nair *et al.*[11] reported novel adducts from the modification of adenine and cytosine by 1. As previously reported,[12] the adducts formed by the reaction of 1 with guanosines are fluorescent pyrimido[1,2-*a*]-purin-10(3*H*)-one nucleosides. Malonaldehyde also reacts with DNA or RNA (presumably with guanine base), as we previously reported.[12] However, a difference was apparent between the fluorescence spectra of the modified DNA and that of the modified guanosines. An investigation regarding the reactions of 1 with guanosine 5′-monophosphate (5′-GMP) and polyguanylic acid (poly[G]) is of interest in connection with an elucidation of the effect of the phosphate group on the fluorescence (FL) spectrum.

The present paper describes the isolation and characterization of 5′-GMP-malonaldehyde and guanine-malonaldehyde adducts and the formation of a pyrimido[1,2-*a*]purine-10(3*H*)-one base by the reaction of 1 with RNA. We also describe the formation of another fluorophore which is resistant to enzymic digestion.

Results and Discussion

5′-GMP-malonaldehyde Adduct. Figure 1 shows an HPLC chromatogram of a reaction mixture of 5′-GMP (**2a**) with 1. The fluorescence peak pl (estimated yield, 2.2%) appeared after the reaction. The

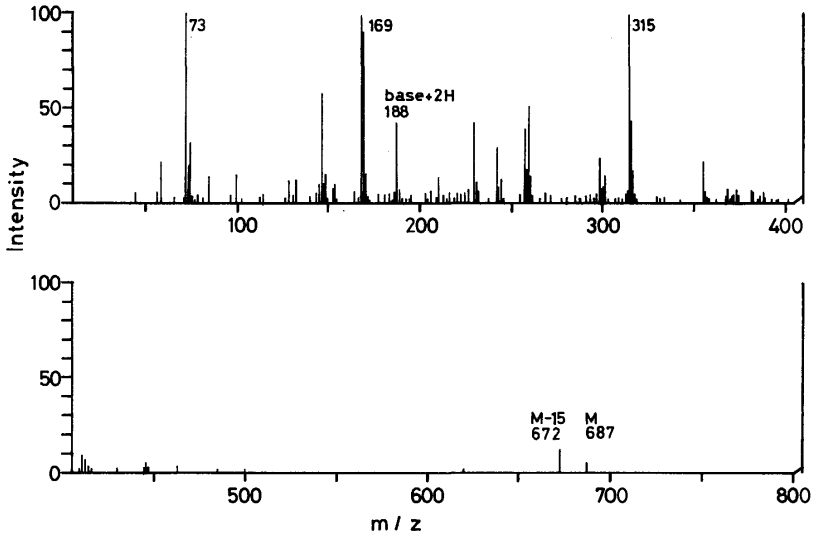

Fig. 3. EI mass spectrum of the TMS derivative of **3a**.

product, a labile light-brown solid (purity 99% as determined by HPLC analysis), was deduced to be 3-(β-D-ribofuranosyl)pyrimido[1,2-*a*]purin-10(3*H*)-one 5′-phosphate (**3a**) from the following chemical and spectroscopic evidence.

TBA (2-thiobarbituric acid)[13] and Molish tests[14] were positive. No carbonyl group (ketone or aldehyde) was detected in the 2,4-dinitrophenylhydrazine test.[14] The pH profile of the UV absorption of compound **3a** is shown in Fig. 2. The pK_a value was calculated spectrophotometrically as 1.23.

The EI mass spectrum of trimethylsilylated **3a** (TMS-**3a**) showed M^+ at *m/z* 687 and an $(M-15)^+$ peak at *m/z* 672 (intensity ratio: *m/z* 687/ *m/z* 672=0.35)(Fig. 3). An important peak of the base was observed at *m/z* 188 $(base+2H)^+$. In the mass spectra of nucleotide-TMS, the base ion is usually accompanied by ions b+H and b+2H.[15] The ions of characteristically high abundance in the spectrum are *m/z* 315 ($HOP(OTMS)_3$) and *m/z* 169 ($C_8H_{13}O_2Si$) from ribotide. The molecular weight of TMS-**3a** was confirmed by the CI mass spectrum, which showed an MH at *m/z* 688. The molecular formula of **3a**, $C_{13}H_{14}N_5O_8P$, was established by high-resolution mass spectrometry (found: *m/z* 687.2186. Calcd for $C_{13}H_{10}N_5O_8P(TMS)_4$: M, 687.2161).

The IR (KBr) spectrum showed absorption bands at 3280 (O–H) and 1725 (C=O) cm^{-1}. The UV spectrum of **3a** was similar to that of pyrimido[1,2-*a*]purin-10(3*H*)-one nucleosides.[12]

A part of the proton NMR spectrum of **3a** is shown in Fig. 4. The characteristic double doublet peaks are typical AMX-type signals due to the -CH=CH-CH= group. The ^{13}C-NMR spectrum showed the existence of 3 carbons (δ 112.3, 142.5, and 163.4 (each d)) in addition to those of **2a** (Fig. 5).

Guanine-malonaldehyde Adduct. The adduct was deduced to be pyrimido[1,2-*a*]purin-10(3*H*)-one (**3b**) from spectroscopic evidence (UV, IR, NMR, and MS).

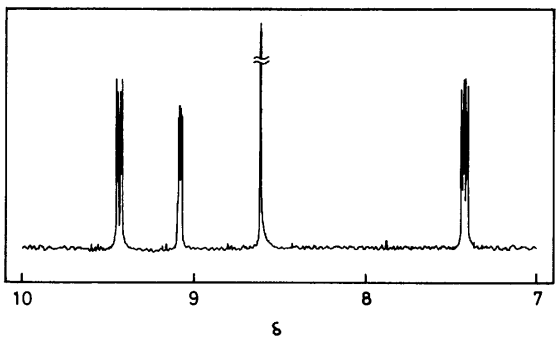

Fig. 4. ^1H-NMR spectrum of **3a**.

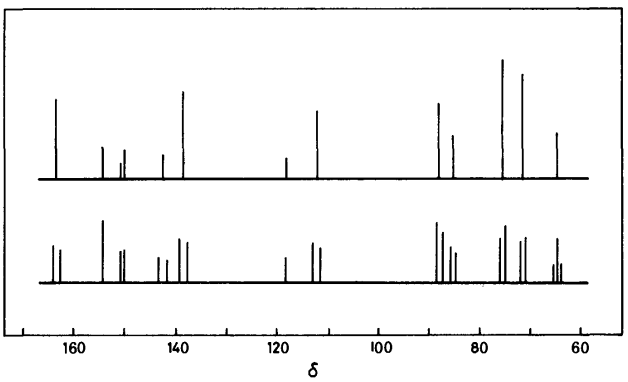

Fig. 5. ^{13}C-NMR spectra of **3a**. Upper: Complete decoupling, Lower: Off-resonance decoupling.

Figure 6 shows an HPLC chromatogram of the extract containing **3b** (peak p2) from the precipitate. The fluorescent product, a yellow amorphous solid, was obtained in 8.4% yield after purification (purity 97% as determined by HPLC analysis). Compound **3b** showed chemical properties similar to those of **3a** in TBA[13] and the 2,4-dinitrophenylhydrazine tests.[14] The UV absorption of **3b** at various pH values is illustrated in Fig. 7. The pK_a value was calculated to be 1.89.

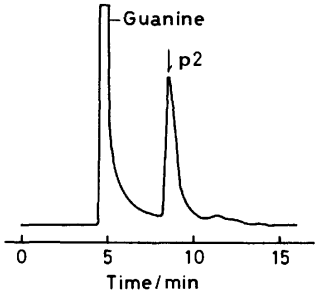

Fig. 6. HPLC chromatogram of the hot water extract from guanine-malonaldehyde reaction mixture. Column: Partisil 10 SCX (4.6φ×250 mm), UV 254 nm, range 16, 10 μl inj.

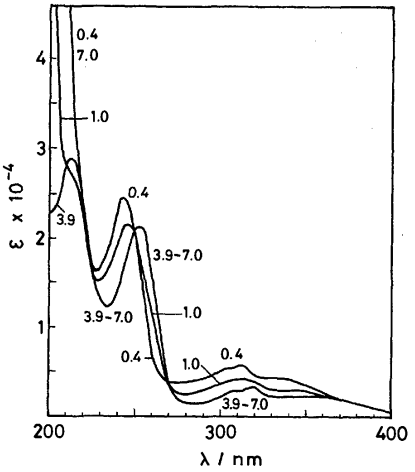

Fig. 7. UV absorption spectra of **3b** at various pH values.

Comparison with the Fluorescence Spectra The Fluorescence(FL) spectra of nucleic acid- and the analog-malonaldehyde adducts are summarized in Fig. 8. The FL spectra of **3a** and **3b** coincided with those of pyrimido[1,2-*a*]purin-10(3*H*)-one nucleosides. It seems that the effect of the phosphate moiety on the FL spectrum is negligible. However, the FL spectra (named Type I) of polymer-malonaldehyde adducts can be distinguished from those (named Type II) of the monomeric compounds which contain a pyrimido[1,2-*a*]purin 10(3*H*)-one base. The spectral difference between the two groups can presumably be attributed to their different structures.

*Isolation of **3a** from the Modified RNA.* Figure 9 shows an HPLC chromatogram of digested RNA which had been modified by 1. The product in peak p3 was separated and characterized. Peak p3 gave UV and FL spectra essentially identical with those of **3a**. The absorbance ratio (A 319 nm/ A 251 nm) of the compound (0.24) was in fair agreement with that of **3a** (0.22), and the retention time of p3 on HPLC coincided with that of **3a**. TMS-treated p3 gave an EI mass spectrum similar to that of **3a**. The molecular ion M^+ at *m/z* 687, $(M-15)^+$ at *m/z* 672 and $(base+2H)^+$ at *m/z* 188 were observed. The product at p3 was therefore identified as compound **3a**.

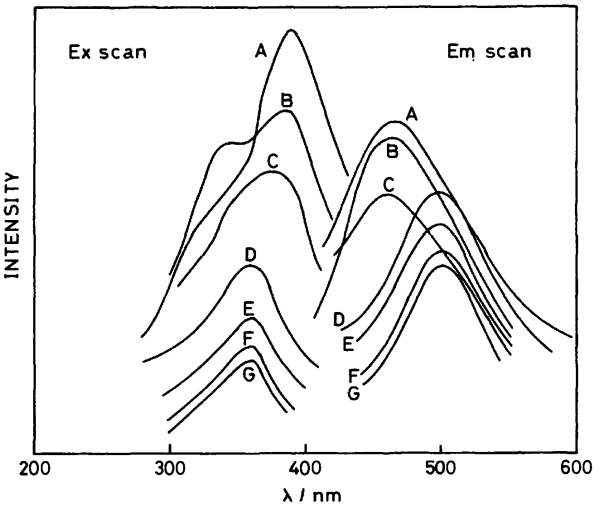

Fig. 8. Fluorescence spectra of malonaldehyde-reacted nucleic acid and analogs. Solvent: water. Substrate (E_x max./nm, E_m max./nm) A: DNA (390,460), B: RNA (390, 460), C: poly[G] (380, 460), D: 5′-GMP (358, 500), E: guanine (363, 500), F: guanosine (360, 500), G: 2′-deoxyguanosine (360, 500). Fluorescence emission spectra were measured by holding fluorescence excitation at 365 nm. Fluorescence excitation spectra were measured by holding fluorescence emission at 460 nm. Concentration of the solution was not normalized.

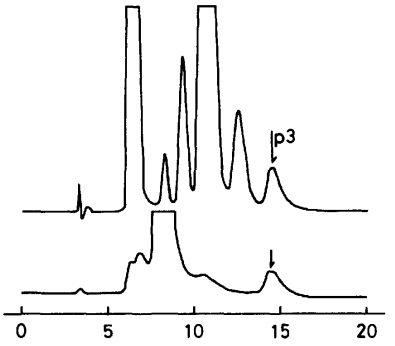

Fig. 9. HPLC chromatograms of the digested RNA solution. The sample for injection was cleaned-up on a DEAE Sephadex column. Column: Partisil 10 SAX (4.6φ×250 mm). Upper: UV 254 nm, range 8, 10 μl inj., Lower: FL 365—460 nm, 50 μl inj.

The amount of **3a** formed in RNA (20 mg) modified by 1 was estimated to be 85 μg (210 nmol, 0.4 wt%) by an HPLC determination. The total amount of 1 incorporated into the RNA was at least 420 nmol as determined by the TBA method.[13] Thus, the modified RNA contains significant amounts of 1 incorporated by some other types of reaction. When the digested RNA solution was applied to a DEAE Sephadex column, a yellow fluorescent band, which contained the major fluorophore, was observed on top of the column bed. This fluorescent substance become strongly bound to the gel.

Tappel *et al.* suggested that the reaction of 1 with DNA produces interstrand crosslinking (N=CH-CH=CH-N)[10] and determined the crosslinks by a fluorescence measurement.[13] However, our result shows that at least two types of FL products (corresponding to Type I and Type II) are formed in the reaction of 1 with nucleic acid. It is necessary to elucidate the structure and properties of Type-I fluorophore.

Experimental

Apparatus. Melting points are uncorrected. IR, UV, and FL spectra were recorded on Hitachi EPI-G3, Shimadzu UV 240, and Shimadzu RF-500 spectrophotometers, respectively. NMR spectra were obtained on a JEOL FX-270 spectrometer with 1,4-dioxane as an internal standard in D_2O at room temperature. Mass spectra were recorded on a JEOL D-300 mass spectrometer. TLC analyses were carried out with Wako polyamide FM plates (5×10 cm). Analytical HPLC was carried out with a Shimadzu LC-2 equipped with UV (254 and 330 nm) and FL (E_x 365 nm, E_m 460 nm) detectors, on a Partisil 10 SAX (4.6ϕ×250 mm) column (the mobile phase was 0.05 M KH_2PO_4 (1M=1 mol dm^{-3}) pH 3.5) and a Partisil 10 SCX (4.6ϕ×250 mm) column (the mobile phase was 0.05 M $NH_4H_2PO_4$). The inlet of the FL detector was connected to the outlet of the UV detector.

Determination of Malonaldehyde Incorporated into Nucleic Acid Polymers. A 0.5 ml aliquot of the solution to be analyzed was taken, and 2 ml of 0.6% 2-thiobarbituric acid and 0.5 ml of glacial acetic acid were then added. The mixture was kept in boiling water for 30 min, and the absorbance was measured at 532 nm.

Reaction of Malonaldehyde with 5'-GMP. 5'-GMP·2Na (**2a**) was purchased from Yamasa Shoyu Co. Ltd., Tokyo. Malonaldehyde (1) was prepared by the hydrolysis of 1,1,3,3-tetraethoxypropane (4.4 g, 0.02 mol) with 0.1 M HCl (200 ml). The mixture was stirred at 40 °C for 40 min, then adjusted to pH 4.5. A solution of 1 (0.02 mol), **2a** (4.1 g, 0.01 mol) and KH_2PO_4 (27.2 g, 0.2 mol) in two liters of water was kept at 37 °C for 7 d, then concentrated to about 400 ml at 40 °C. Acetonitrile was then added, and the whole was kept overnight in a refrigerator (4 °C). The precipitate was collected by filtration, washed with acetonitrile and redissolved in a small amount of water. It was then subjected to DEAE Sephadex A-25 chromatography (5ϕ×70 cm, 0.01 M KH_2PO_4, pH 3.5). The fluorescent fractions were collected, concentrated, and purified by Partisil 10 SAX chromatography (8ϕ×250 mm, 0.1 M KH_2PO_4, pH 3.5). The fraction containing **3a** was applied to a Unisil C-18 column (8ϕ×250 mm, water) for desalting. The product solution was evaporated to dryness *in vacuo*.

Reaction of Malonaldehyde with Guanine. A solution of 1,1,3,3-tetraethoxypropane (5.5 g, 25 mmol) in 25 ml of 1 M HCl was kept at 40 °C for 40 min. Subsequently, guanine (0.75 g, 5 mmol, Yamasa Shoyu Co. Ltd.) and 25 ml of 1 M HCl were added. The mixture was stirred at 40 °C for 1 h. The precipitate was collected by centrifugation (2500 min^{-1}, 10 min), washed with ethyl alcohol, and then centrifuged again. The guanine-malonaldehyde adduct was extracted from the precipitate with hot water (60 °C). The extract was cleaned on a polyamide column (5ϕ×30 cm, water). The fluorescent fractions were collected and concentrated to remove sedimenting guanine. The solution was purified by Partisil 10 SCX chromatography (8ϕ×250 mm, 0.1 M $NH_4H_2PO_4$). Finally, the eluate containing guanine-malonaldehyde adduct (**3b**) was evaporated *in vacuo*.

Reaction of Malonaldehyde with DNA, RNA, or Poly [G]. Calf thymus DNA, baker's yeast RNA, and poly [G] were purchased from Sigma Chemical Co., St. Louis, MO. A mixture containing 10 mg of nucleic acid and 136 mg of KH_2PO_4 (1 mmol) in 10 ml of 1 (0.01 M) solution was maintained at 37 °C for 10 d. The solution was dialyzed against distilled water for 5 d, then evaporated *in vacuo* to give a modified nucleic acid.

Isolation of 5'-GMP-malonaldehyde Adduct (3a) from the Modified RNA. The malonaldehyde-reacted RNA (20 mg) was hydrolyzed in 10 ml of buffer solution (1 mM KH_2PO_4, 0.1 mM $ZnCl_2$, pH 5.3) with 1 mg of Nuclease P_1 from *Penicillium citrinum* (Yamasa Shoyu Co. Ltd.) at 37 °C for 2 d. The digested RNA solution was cleaned on a DEAE Sephadex A-25 column (10ϕ×150 mm, 0.01 M KH_2PO_4, pH 3.5). The eluate was concentrated to 2 ml, then chromatographed on a Partisil 10 SAX column (4.6ϕ× 250 mm, 0.05 M KH_2PO_4, pH 3.5). The fractions of 5'-GMP-malonaldehyde adduct (**3a**) were collected, desalted and evaporated *in vacuo*.

Cation-binding Properties of Ionophorous Cyclic Octapeptide in Acetonitrile Solution

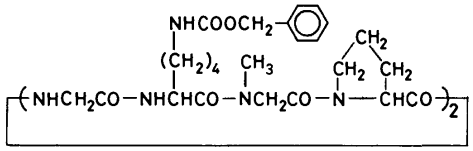
Toshimi SHIMIZU,* Yoshio TANAKA, and Keishiro TSUDA
Research Institute for Polymers and Textiles, Yatabe-Higashi 1-1-4, Tsukuba, Ibaraki 305
(Received June 7, 1985)

Complex formation of synthetic cyclic octapeptide, cyclo[Gly-L-Lys(Z)-Sar-L-Pro]$_2$, with alkali and alkaline earth metal ion was investigated by CD and NMR spectroscopy. Titration curves obtained from CD data revealed three kinds of CGLSP2(P)/cation(C) complexes. P_2C ("peptide sandwich"), PC ("1 : 1"), and PC_2 ("cation sandwich") complexes occurred in the complexation between CGLSP2 and Ba^{2+}. In the presence of Li^+, Mg^{2+}, or Ca^{2+}, the existence of PC and PC_2 was assumed. K^+ and Na^+ form only a PC species with CGLSP2. By analyzing the titration curves, 1 : 1 complex-formation constants (K_1) were evaluated. The K_1 values decrease in the order $Ba^{2+}>Ca^{2+}>Mg^{2+}>Li^+\gg Na^+$, K^+. ^{1}H- and ^{13}C-NMR data showed that CGLSP2 in acetonitrile exists in at least five different conformational states in a free state. A predominant conformer had a C_2-symmetric structure containing two cis Lys-Sar peptide bonds. After the addition of equimolar amounts of $Ba(ClO_4)_2$, these conformations converged into a single C_2-symmetric one with all-trans peptide bonds. This corresponds to a PC species. On further addition of the salt, CGLSP2 changed the conformation into an asymmetric structure with one cis Lys-Sar peptide bond. This corresponds to a PC_2 species.

Ionophores form stable and lipophilic complexes with Na^+, K^+, and Ca^{2+} *etc.*, and are able to transport them across artificial and biological membranes. Some cyclic oligopeptides have an interesting feature to bind a specific alkali and alkaline earth metal ion.[1-4] In the light of this characteristic, cation extraction,[5] cation transport through a liquid membrane,[6,7] and liquid membrane electrode[8] have been examined by using cyclic peptides. We also reported behavior of cyclic octapeptide, cyclo[Gly-L-Lys(Z)-Sar-L-Pro]$_2$ (CGLSP2) as an ionophorous agent.[9] CGLSP2 could transport or extract Ba^{2+} and Ca^{2+} preferably over Mg^{2+}, K^+, Rb^+, and Na^+. Among physiological cations, Ca^{2+}/Mg^{2+} selectivity in the cation extraction reached 1.5×10^2. Thus, CGLSP2 can compete in this high discrimination ability with naturally occurring antibiotics.[10]

Valinomycin is a macrocyclic dodecadepsipeptide, displaying an exceptionally high selectivity for K^+ over Na^+. The feature can be interpreted in terms of a limited structure of the cyclic backbone in the complexed state.[11] On the other hand, a variety of conformations have been detected for the uncomplexed form in solution.[12] They are found to be highly dependent on solvent polarity. In this way, the cation-binding specificity of valinomycin is based on a conformational rearrangement accompanying complex formation. In particular, CGLSP2 contains four N-substituted peptide bonds (Lys–Sar and Sar–Pro bonds) which are able to take cis as well as trans geometry.[13,14] Therefore, a number of conformations are allowed by random distribution of the cis and trans peptide bonds.

From this point of view, we have studied a cation binding of CGLSP2 with alkali and alkaline earth metal ions in an acetonitrile solution by CD and NMR spectroscopy. Acetonitrile was chosen as a suitable aprotic medium. Its resolution of cation complexes is better than that of protic solvents such as water or methanol. Since CD spectra are very sensitive to peptide conformation upon complexation, they serve to follow a change of complexed species. In addition, it takes the advantage that complex-formation constants can be determined for a certain binding species.[15,16] On the other hand, NMR spectra give information about the structure of that species. Since cis-trans isomerism is slow on the NMR time scale, the conformations can be detected individually by NMR. This paper focused on resolutions and identifications of several complexed species.



cyclo[Gly-L-Lys(Z)-Sar-L-Pro]$_2$ (CGLSP2)

Experimental

The preparation and physical characteristic of the cyclic octapeptide, cyclo[Gly-L-Lys(Z)-Sar-L-Pro]$_2$ (CGLSP2) are reported in our preceding paper.[9]

^{1}H-NMR spectra were obtained at 360 MHz on a NICOLET NT-360 spectrometer with a NIC 1180 Computer Data System, operating in the Fourier transform mode with quadrature detection. ^{13}C-NMR spectra were recorded on a Varian CFT-20 spectrometer at 20 MHz, in the Fourier transform mode with proton-noise decoupling. All the chemical shifts are given in parts per million (ppm) relative to the internal tetramethylsilane.

Circular dichroism spectra were recorded on a JASCO J-40A automatic recording spectropolarimeter equipped with a J-DPY data processor at 20 °C. Measurements were carried out using a quartz cell with 0.1-cm path length over 250 nm to 200 nm. Data are represented as molar ellipticities. Unless otherwise noted, spectrophotometric-grade acetonitrile was used as the solvent.

Alkali metal cations used for binding studies were Li^+ (1.20

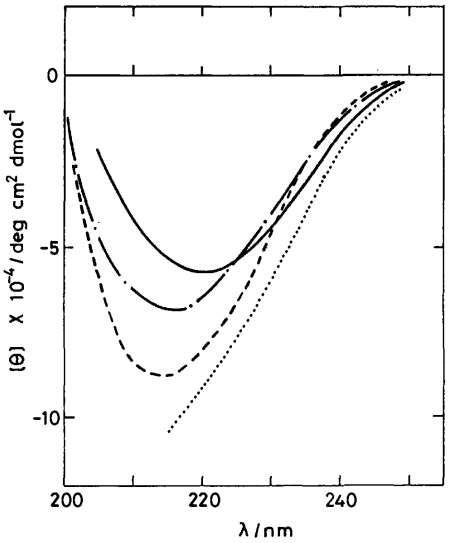


Fig. 1. CD spectra of CGLSP2 in various solvents. Acetonitrile (——), methanol (— — —), 2,2,2-trifluoroethanol (– – – – –), and 1,4-dioxane (·····). Peptide concentration; 6.23×10^{-4} mol dm^{-3}.

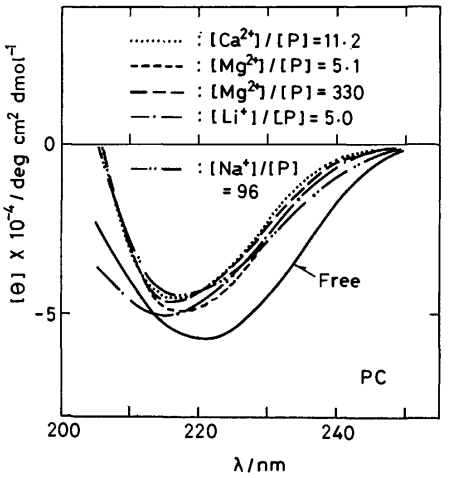

Fig. 2. CD spectra of CGLSP2 in acetonitrile in the presence of lithium, sodium, magnesium, and calcium perchlorate. Molar ratios of a salt to CGLSP2 are shown in the figure. Peptide concentration; 2.47×10^{-4} mol dm^{-3}.

Å), Na^+ (1.90 Å), and K^+ (2.66 Å), and alkaline earth metal cations Mg^{2+} (1.30 Å), Ca^{2+} (1.98Å), and Ba^{2+} (2.70 Å). The value in parentheses indicates each ionic diameter. The cations were dissociated from the corresponding perchlorates. In the case of K^+, acetonitrile/water (95/5, by volume) mixture was used to dissolve the salt. Both CD and NMR measurements were performed after the complexation equilibrium was completely established on addition of each salt.

Results and Discussion

CD Spectra of Cyclic Octapeptide in a Free and a Complexed State. CD spectra of CGLSP2 in various solvents (acetonitrile, methanol, 2,2,2-trifluoroethanol, and 1,4-dioxane) are shown in Fig. 1. Dielectric constant of each solvent is 37.5, 32.7, 26.7, and 2.2, respectively. A large negative Cotton effect appeared at 214—221 nm, which is mainly attributed to an $n\rightarrow\pi^*$ transition of the amide bond. The extremum is shifted to longer wavelength when dielectric constant of the solvent increased. At the same time ellipticity of the negative band decreased. There seems to be no remarkable differences in conformation in these solvents.

When cations smaller than 2.00 Å (Li^+, Na^+, Mg^{2+}, and Ca^{2+}) were added stepwise to a solution of CGLSP2 in acetonitrile, a small spectral change was observed, as shown in Fig. 2. There was a slight decrease of the negative ellipticity. The extremum was shifted 216—218 nm from 221 nm for the free peptide. These spectra are designated type I.

In the presence of cations larger than 2.00 Å [Ba^{2+} (small amounts) and K^+ (large amounts)], the 221-nm negative band decreased in intensity and the extremum was shifted to longer wavelength. In addition,

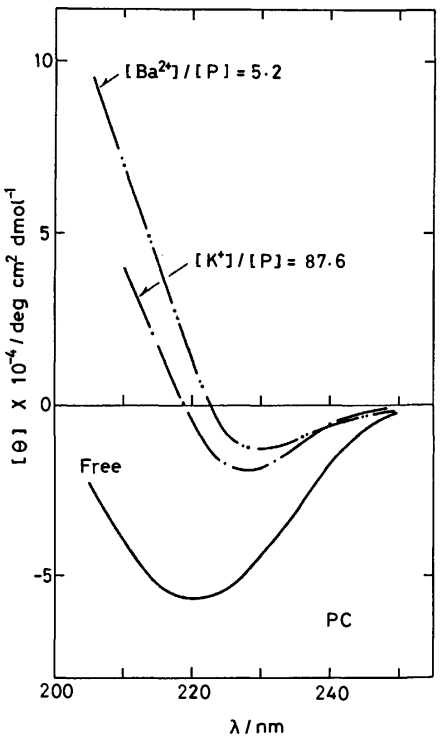

Fig. 3. CD spectra of CGLSP2 in acetonitrile in the presence of potassium and barium perchlorate. Unless otherwise noted, the conditions are the same as those described in Fig. 2.

appearance of a strong positive band around 200—210 nm could be observed (Fig. 3). These are referred to type II. Besides these two types of spectra, a group of spectra designated as type III were found. They were characterized by a small negative ellipticity at 235—250 nm and a relatively sharp negative band at 210—220 nm (Fig. 4). These spectra appeared in the presence of large amounts of Ba^{2+}, Ca^{2+}, and Li^+. The above

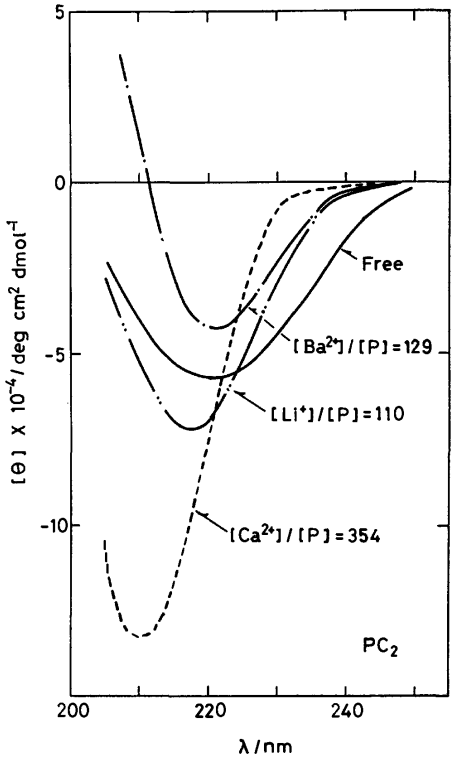

Fig. 4. CD spectra of CGLSP2 in acetonitrile in the presence of lithium, calcium, and barium perchlorate. Unless otherwise noted, the conditions are the same as those described in Fig. 2.

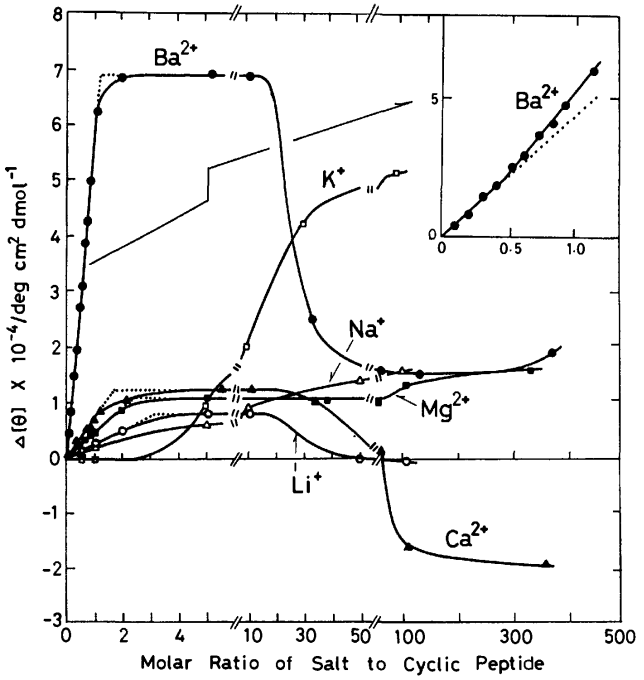

Fig. 5. Titration curves of CGLSP2 for various metal perchlorates in acetonitrile. $\Delta[\theta]$ indicates the difference between the molar ellipticity of a complexed peptide and that of a free peptide.

results suggest that several complexed species exist with different stoichiometries. Moreover, they vary with peptide/cation sets. To clarify these features, we obtained titration curves for each cation from CD spectra.

Titration Curves. Titration curves were depicted, in which the changes in molar ellipticities at a certain wavelength were plotted against the molar ratio of metal salt to cyclic peptide. Titration curves generated from several wavelength (210—230 nm) showed no remarkable differences. Figure 5 indicates the titration curves at 220 nm for Li^+, Na^+, K^+, Mg^{2+}, Ca^{2+}, and Ba^{2+}. Three representative curves were depicted according to cations. The first is a titration curve for Ba^{2+}. After adding less than half equivalent of Ba^{2+}, the increase of the ellipticity was linear with the amount of the salt. As the molar ratio further increased (0.5—1.1 equiv), the straight line became another one with a slightly larger slope than that at the early part of titration. After the addition of more than two equivalents of Ba^{2+}, two plateaus that correspond to type II and type III were observed. This finding suggests that CGLSP2 forms at least three types of complexes with Ba^{2+}. At the peptide concentration over the range of 10^{-5}—10^{-3} mol dm^{-3} we have studied, the first species of the complexation may be expressed as P_2C, where P is the cyclic peptide and C is a metal cation. The second and the third step can be interpreted in terms of the formation of a 1:1 PC species and a 1:2 PC_2 species, respectively. The above feature of binding is similar to those found for other cyclic peptides.[16-18]

In the case of Li^+-, Mg^{2+}-, and Ca^{2+}-titration curves, a clear folding could not be observed around the molar ratio of 0.5. Only one plateau is observed within the addition of less than 400 equiv of the cation. It would be associated with the formation of a 1:1 complex. At the late part of titration, the decrease of ellipticity for Li^+ and Ca^{2+}, or the increase of ellipticity for Mg^{2+} indicates an appearance of PC_2 species in place of PC.

K^+- and Na^+-titration curves showed a gradual increase of the ellipticity when the molar ratio increased. The last part of titration with K^+ corresponds to type II which is similar to the case of the first plateau in Ba^{2+} titration (Fig. 3). CD spectrum of CGLSP2 in the presence of 96 equiv of Na^+ resembles closely to that of a 1:1 complex between CGLSP2 and Ca^{2+} (Fig. 2). The above results support that a single complexation step in K^+- and Na^+-titration curve is associated with the formation of a 1:1 complex.

Complex-formation Constants. The data obtained from CD spectra and CD-titration curves revealed the following. (1) P_2C ("peptide sandwich"), PC ("1:1"), and PC_2 ("cation sandwich") complexes occur in the complexation between CGLSP2 and Ba^{2+}. (2) In the Li^+, Mg^{2+}, and Ca^{2+} systems, the existence of PC and PC_2 is assumed. (3) K^+ and Na^+ form only a PC species with CGLSP2. Of course, one can not exclude an existence of alternate complexed species in the presence of larger amount of cations than that we have

Table 1. Complex-formation constants (K_1) of CGLSP2 with various metal perchlorates in acetonitrile at 20°C

Cation	Charge density$\times10^{-10}$/s A m^{-3}	K_1/mol^{-1} dm^3
Li^+	12.1	$(2.4\pm0.2)\times10^3$
Na^+	4.46	Very low
K^+	1.62	Very low
Mg^{2+}	26.8	$(5.6\pm0.9)\times10^3$
Ca^{2+}	7.90	$(7.6\pm1.9)\times10^3$
Ba^{2+}	3.17	$(2.7\pm0.7)\times10^4$

studied. From the region of a 1:1 complex formation in the titration curves, complex-formation constants (K_1) were determined so as to satisfy a normalized α-ϕ curves calculated by Prestegard and Chan.[19] The obtained values are given in Table 1. The affinity of Ba^{2+} for CGLSP2 in acetonitrile ($K_1\approx2.7\times10^4$ mol^{-1} dm^3) is *ca.* 10-fold smaller than that of K^+ for valinomycin ($K_1\approx3\times10^5$ mol^{-1} dm^3 in CH_3CN).[20] In addition, CGLSP2 binds Ca^{2+} favorably ($K_1\approx7.6\times10^3$ mol^{-1} dm^3). This affinity is *ca.* 10-fold smaller than that of a naturally occurring cyclic decapeptide, antamanide which forms a very stable complex with Ca^{2+} ($K_1=1\times10^5$ mol^{-1} dm^3 in CH_3CN).[21] The K_1 sequences were $Ba^{2+}>Ca^{2+}>Mg^{2+}>Li^+\gg Na^+$, K^+. It can be clearly seen that doubly charged cations are bound preferentially over monovalent cations. Between cations having similar ionic diameter (Ba^{2+} and K^+), the ratio of the binding constants, $K_1(Ba^{2+}):K_1(K^+)$, is approximate 10^4. Similar trend could be seen between Ca^{2+} and Na^+ [$K_1(Ca^{2+}):K_1(Na^+)\approx10^3$]. The binding of both Na^+ and K^+ is much lower than that of the other cations, even the smaller cations, Li^+ or Mg^{2+}. As observed with the complex formation between cyclo-(L-Val-Gly-Gly-L-Pro)$_3$ and Li^+, or Mg^{2+},[16] high charge density of the cations may serve to form a stable 1:1 complex.

Rate of Complex Formation. Kinetics of a 1:1 complex formation between CGLSP2 and $Ba(ClO_4)_2$ was investigated in acetonitrile by CD spectroscopy. The complexing reaction was started by combining solutions of the salt (1.14 equiv) and the cyclic peptide. Immediately after mixing, the ellipticity at 220 nm was measured at 1-min intervals. Under these conditions, formation of a 1:1 complex is clearly demonstrated by the titration curves shown in Fig. 5. Consequently, equilibrium was already reached even after 1 min. This result indicates that the rate of complex formation between CGLSP2 and Ba^{2+} is fairly rapid. Formation and dissociation of the complex can be expressed by the following scheme;

$$P + C \underset{k_d}{\overset{k_f}{\rightleftharpoons}} PC$$

where k_f and k_d is rate constants of the complex formation and dissociation, respectively. Assuming the half-life of free cyclic peptide (P) is 1 min, we can

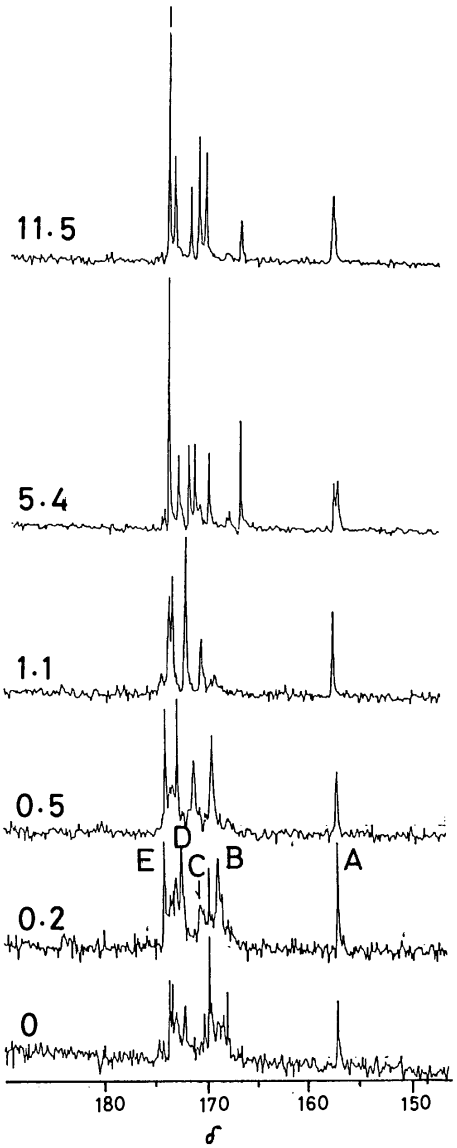

Fig. 6. ^{13}C-NMR spectra of C=O region of CGLSP2 in acetonitrile-d_3 when barium perchlorate was added. Numbers represent the molar ratio of salt to peptide. Peptide concentration; 54.2 g dm^{-3}. Temperature; 25°C.

evaluate the rate constant (k_f) roughly in the same manner as described by Kimura and Imanishi.[4] The k_f value obtained was larger than 66 (mol^{-1} dm^3 s^{-1}) at 20°C. This value appears to be lower than that reported for valinomycin/K^+ complex (3.5×10^7 mol^{-1} dm^3 s^{-1} in methanol).[22] However, it is at least 300-fold larger than that reported for complex formation between cyclo[L-Lys(Z)-L-Pro]$_4$ and Ba^{2+} [0.2 mol^{-1} dm^3 s^{-1} in ethanol/ water (95/5, v/v) mixture].[4]

NMR Investigation. Titration of CGLSP2 with $Ba(ClO_4)_2$ was investigated in acetonitrile-d_3 by NMR spectroscopy (^{1}H and ^{13}C). The number of both C=O carbon resonances and N-CH_3 proton resonances serves to clarify the symmetry of the ring. In addition, the chemical shifts of Pro C^β and C^γ carbon are indica-

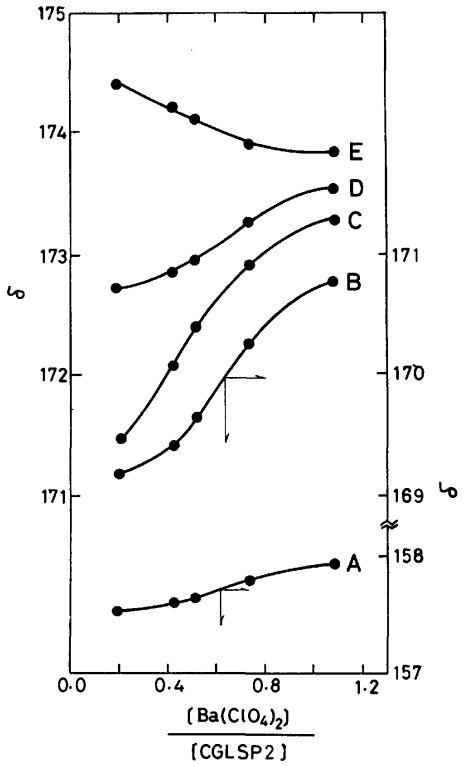

Fig. 7. Shift of carbonyl resonances of CGLSP2 in acetonitrile-d_3 when barium perchlorate was added.

tive of a cis-trans isomerism around Sar–Pro peptide bonds.[13,23] The chemical shifts of Sar N–CH_3 protons reflect a cis-trans isomerism around Lys–Sar peptide bonds.[23,24] In Fig. 6, spectral change of carbonyl resonance region in ^{13}C-NMR is presented. A large number of resonances appeared in the absence of barium salt. When the salt was added stepwise to the solution (<1.1 equiv of Ba^{2+}), five signals became pronounced with increasing in concentration of the salt. This finding indicates that CGLSP2 converged into a single C_2-symmetric conformation from multiple conformations in a free state by the complex formation with Ba^{2+}. That species in a complexed state corresponds to PC that is responsible for type I spectrum in CD. Figure 7 indicates the shift of the five carbonyl carbon resonances caused by the addition of $Ba(ClO_4)_2$. A downfield shift was observed for the signals A, B, C, and D except the signal E. This downfield shift is considered to be caused by ion-dipole interactions between Ba^{2+} and carbonyl groups.[4,17,25] Accordingly, differences in their chemical shifts ($\Delta\delta$) between the cases containing 0.2 and 1.1 equiv of Ba^{2+} were determined. The difference ($\Delta\delta$) of the signals B and C is at least two times larger than that of the other signals A, D, and E. Assignment of the signals were carried out by comparison with the signals of a precursory linear peptides and related compounds,[9] and on the basis of literature information.[26] The Pro C=O, Lys(Z) C=O, Gly or Sar C=O, and Lys(Z) NHCOO carbon resonances must be located in this order from the lowfield. Thus,

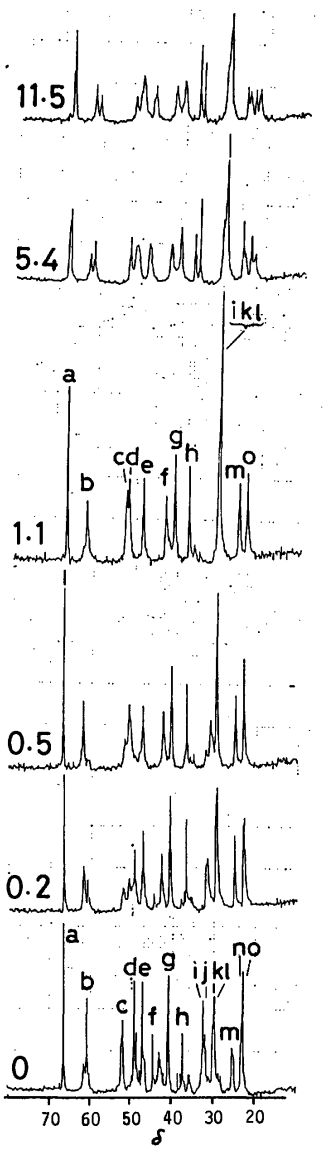

Fig. 8. ^{13}C-NMR spectra of upfield regions of CGLSP2 in acetonitrile-d_3 when barium perchlorate was added. Numbers represent the molar ratio of salt to peptide. Tentative resonance assignments were indicated; (a) $\underline{C}H_2$–C_6H_5, (b) Pro C^{α}, (c) Pro C^{δ}, (d) Lys C^{α}, (e) Sar C^{α}, (f) Gly C^{α}, (g) Lys C^{ε}, (h) Sar N–CH_3, (i) Lys C^{δ}, (j) Pro C^{β}(cis), (k) Pro C^{β}(trans), (l) Lys C^{β}, (m) Pro C^{γ}(trans), (n) Pro C^{γ}(cis), and (o) Lys C^{γ}.

the signals B and C can be attributed to Gly C=O and Sar C=O carbon. Therefore, four carbonyl oxygens of Gly and Sar residues are considered to participate to bind Ba^{2+} cooperatively in the C_2-symmetric conformer. At this time, the side-chain carbonyl groups of Lys residue do not involve in complexation, since the signal A can be assigned to carbonyl carbon of benzyloxycarbonyl group of Lys.

Further addition of more than 1.1 equiv of the salt produced another pattern of signals which was ascribable to a new complexed species. As judged from the number and peak area of resonances in the pres-

ence of 5.4 equiv of the salt, the new species possesses an asymmetric conformation. This conformer corresponds to PC_2 that is responsible for type III spectrum in CD.

Upfield regions of the ^{13}C-NMR spectra of CGLSP2 are given in Fig. 8. Remarkable spectral changes were observed in Pro C^{β} and C^{γ} resonance regions (δ 20—35). As the molar ratio of salt to peptide increases, the Pro C^{β} and Pro C^{γ} carbon signals (j and n) involving in a cis Sar-Pro peptide bond in free peptide diminished and alternatively signals (k and m) arising from the trans peptide bond became predominant. In the presence of 1.1 equiv of the salt, only one signal attributed to the trans Sar-Pro peptide bond appeared at δ 30.31 for Pro C^{β} carbon and δ 25.31 for Pro C^{γ} carbon.[13,24] Even when the salt was further added, the resonances of Pro C^{β} and Pro C^{γ} carbon remained within the region associated with trans Sar-Pro bond.

Similarly, ^1H-NMR spectra were investigated while $Ba(ClO_4)_2$ was added stepwise to CGLSP2 in acetonitrile-d_3. They also suggested a conformational convergence into the single C_2-symmetric conformation. In Fig. 9 , spectral change of N-CH_3 resonance region is shown. In the absence of the salt, a strong signal appears at δ 2.87, in addition to a single resonance at δ 2.92 and three pairs of six signals at δ 2.83, 2.90, 2.96, 2.98, 3.17, and 3.20. Therefore, free CGLSP2 exists in at least five different conformational states (two C_2-symmetric conformers and three asymmetric ones) in acetonitrile. As previously reported,[9] conformational distribution of these conformers is similar to that in chloroform. Moreover, a predominant C_2-symmetric conformer includes two cis Lys-Sar peptide bonds that are the same in chloroform. The temperature dependences of predominant NH proton resonances (not shown) were found to be $\approx$0 ppm deg^{-1} for Lys NH protons and $\approx 7\times10^{-3}$ ppm deg^{-1} for Gly NH protons in acetonitrile-d_3. This result suggests that Lys NH protons of the predominant conformer are shielded from the solvent. ^{13}C-NMR measurement showed that Pro C=O carbon resonance (the signal E) is shifted to upfield upon complexation (Fig. 7). Together with these results, Lys NH protons could be intramolecularly hydrogen-bonded to Pro C=O oxygens in (some) conformers of the free peptide. Consequently, the upfield shift of Pro C=O carbon resonance may be attributed to the destruction of hydrogen bonds in the complex formation.[6]

With increasing in Ba^{2+} concentration (<1.0 equiv of Ba^{2+}), a strong N-CH_3 signal (○) at δ 2.87 disappeared gradually. At the same time, a new N-CH_3 signal (▲) appeared at δ 3.10 upon the addition of 0.25 equiv of Ba^{2+}, and its intensity increased. In the presence of 0.5—1.0 equiv of Ba^{2+}, one major signal was observed at δ 3.09. Further addition of the salt (>1.0 equiv of Ba^{2+}) produced a new pair of signals (●) at δ 3.03 and 2.84. In the presence of more than 5.6 equiv of Ba^{2+}, only this

Fig. 10. Scheme for the complexation of CGLSP2 with $Ba(ClO_4)_2$ or $Ca(ClO_4)_2$, which was deduced from ^1H- and ^{13}C-NMR spectroscopy. C_2 and C_2' represent distinct C_2-symmetric conformers. A, A', A'', and A''' represent asymmetric conformers. M^{2+} means Ba^{2+} or Ca^{2+}. Peptide-bond sequences in parentheses are given for the linkage of Lys(Z)-Sar-Pro-Gly-Lys(Z)-Sar-Pro-Gly-Lys(Z) on the ring.

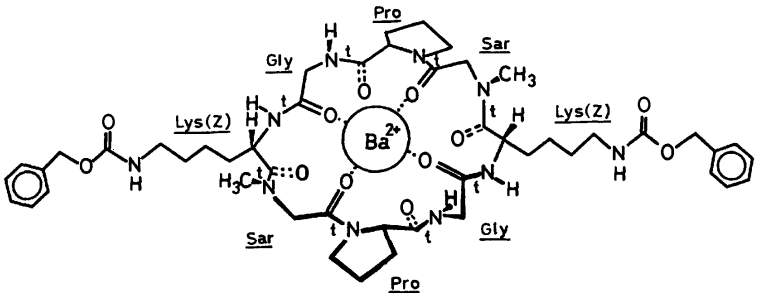

Fig. 11. Schematic representation of a proposed conformation of the 1:1 complex between CGLSP2 and barium cation.

pair of signals exist. These features are consistent with those observed in ^{13}C-NMR measurement, which demonstrates the existence of two complexation steps. However, in ^{1}H- and ^{13}C-NMR spectra, we could not resolve and identify the P_2C species that was detected in a CD spectrum. It has been reported that a resonance for N–CH_3 protons involved in a trans peptide bond occurs in a lower field region than that involved in a cis peptide bond.[24,27] Thus, the N–CH_3 signal marked with (▲) could be associated with trans Lys–Sar peptide bond. In a similar way, the lowfield signal of the two marked with (●) is ascribed to N–CH_3 protons associated with the trans Lys–Sar bond, and the highfield signal is ascribed to those of the cis Lys–Sar bond.

By the combination of the above ^{1}H- and ^{13}C-NMR data, the cis-trans arrangements of peptide bonds in CGLSP2 can be deduced for each complexed species in Ba^{2+} binding. A PC (1:1) complex has an all-trans peptide bonds. In contrast to this, a P_2C (2:1) complex contains one cis Lys–Sar peptide bond. Both conformations are absent in a free state. Moreover, it is of interest that the structure of CGLSP2/Ba^{2+} (1:1) complex in acetonitrile is different from that of CGLSP2/Ca^{2+} (1:1) complex in chloroform/acetonitrile (5/3, v/v) mixture.[9] In order to obtain further details, we measured ^{13}C- and ^{1}H-NMR spectra of the 1:1 Ca^{2+} complex with CGLSP2 in acetonitrile. As a result, the chemical shifts of Sar N–CH_3, Pro C^{β}, and Pro C^{γ} resonances are indicative of the occurrence of all-trans peptide bond arrangement. This fact indicates that the structural difference between Ca^{2+}- and Ba^{2+} -complex is not affected by the nature of cation but by that of solvent. From the above, the following scheme may be proposed for the Ba^{2+} binding and the Ca^{2+} binding by CGLSP2 in acetonitrile. It is shown in Fig. 10.

Inspection of a CPK molecular model having all-trans peptide bonds revealed that four coplanar carbonyl groups form a cavity for binding a cation. The barium or calcium ion may be bound favorably by the carbonyl groups of the two Sar and two Gly residues. This is supported by the chemical shift change of each carbonyl resonances upon complexation (Fig. 7). Figure 11 indicates a proposed conformation of 1:1 complex between CGLSP2 and Ba^{2+}, in which the divalent charge of the cations enhances the stability of 1:1 complex more effectively than the fitness of the cation size to cavity. Actually, CGLSP2 had poor affinity for K^{+} that is suitable for the cavity size.

Cyclo(L-Pro–Sar)$_4$ showed a conformational multiplicity that is based on cis/trans isomerism of all N-substituted peptide bonds.[14,28,29] In this respect, CGLSP2 has a localized distribution of N-substituted peptide bonds,[9] when compared with other cyclic octapeptides.[7,29] Therefore, this approach might provide CGLSP2 with a relatively limited structure of the cyclic backbone similarly to that of valinomycin. However, the ratio of the complex-formation constants, $K_1(Ca^{2+}):K_1(Mg^{2+})$, was very low ($\approx$1.4) in acetonitrile (Table 1). We have reported that the Ca^{2+} transport and extraction by CGLSP2 is much higher than Mg^{2+}.[9] Particularly, the ratio of the extraction equilibrium constants, $K_{ex}(Ca^{2+}):K_{ex}(Mg^{2+})$, was about 150. This high Ca^{2+}/Mg^{2+} selectivity disagrees with that of complex formation. It can be interpreted in terms of three constituent equilibria of the extraction process;[30] (1) distribution of CGLSP2 between the two phases, (2) complex formation of CGLSP2 with the metal cation in the aqueous phase, and (3) ion-pair extraction of CGLSP2/metal cation/picrate-anion species. The Ca^{2+}/Mg^{2+} selectivity of CGLSP2 has no relation with equilibrium (1). Therefore, the Ca^{2+} -selective transport and extraction by CGLSP2 may be closely related to the equilibria (2) and/or (3). With regard to the equilibrium (2), it could be owing to the high Ca^{2+}/Mg^{2+} selectivity of complex formation in the aqueous solution. This could not be confirmed experimentally because CGLSP2 was insoluble in water. With regard to the equilibrium (3), it could be attributed to the fairly poor solubility of the CGLSP2/Mg^{2+}/picrate-anion species into the chloroform phase in comparison with the corresponding Ca^{2+}-complexed ion pair.

Preparation of Pyrido- and Azepino-fused Cycl[3.2.2]azines[1)]

Michihiko NOGUCHI,* Noriyuki TANIGAWA, and Shoji KAJIGAESHI
Department of Industrial Chemistry, Faculty of Engineering, Yamaguchi University, Tokiwadai, Ube 755
(Received June 17, 1985)

Pyrido- and azepino-fused cycl[3.2.2]azines were obtained by the reaction of the corresponding pyrido- and azepino[*hi*]indolizines with electron-deficient acetylenes in the presence of appropriate oxidants. The reaction pathway of their preparation was proposed to be a sequence of Michael addition of indolizine to acetylene, 10π-electrocyclic reaction of Michael adduct, and dehydrogenation by means of the chemical conversions of the isolated intermediates.

Much attention has been paid for the synthesis of the heterocyclic compounds with new ring systems because of their chemical and physicochemical as well as biological interests.

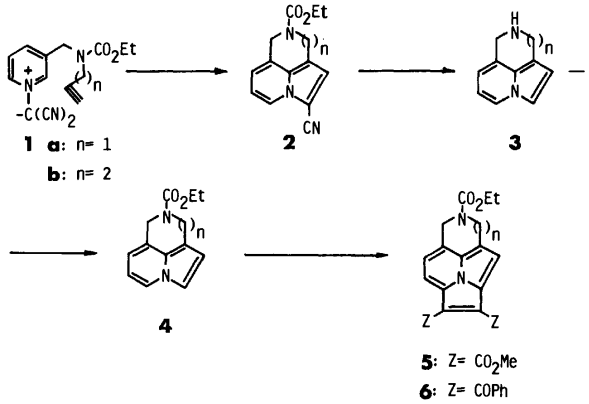
Recently, we reported the interesting physical properties of 4*H*-benzo[*hi*]pyrrolo[2,1,5-*cd*]indolizin-4-ones[2)] and cyclohepta[*hi*]pyrrolo[2,1,5-*cd*]indolizines,[3)] which were prepared by the oxidation of 5,6-dihydro-4*H*-benzo- and 4,5,6,7-tetrahydrocyclohepta[*hi*]pyrrolo [2,1,5-*cd*]indolizines,[4)] respectively. In the continuation of our studies on [*ef*]fused cycl[3.2.2]azine systems, our attention was focused on the synthesis of pyrido- and azepino-fused cycl[3.2.2]azines as aza-analogs of the above two systems.

We wish to report here the synthesis of 2,3-dihydro-1*H*-pyrido- and 1,2,3,4-tetrahydro[3,4,5-*hi*]pyrrolo[2, 1,5-*cd*]indolizines from the corresponding [*hi*]fused indolizines. A mechanistic aspect for the cyclazine synthesis was also described.

Results and Discussion

5-Cyano-2-ethoxycarbonyl-2,3-dihydro-1*H*-pyrido- (**2a**) and 6-cyano-2-ethoxycarbonyl-1,2,3,4-tetrahydroazepino [3,4,5-*hi*]pyrrolo[2,1,5-*cd*]indolizine (**2b**) were prepared by the intramolecular 1,3-dipolar addition of pyridinium-1-dicyanomethylides **1** according to the procedure developed by us.[5)] It was proved that the cyano group at 5 or 6-position of **2** hindered the reaction with acetylenes, so **2a** and **2b** were converted to 2,3-dihydro-1*H*-pyrido- (**3a**) and 1,2,3,4-tetrahydroazepino[3,4,5-*hi*]pyrrolo[2,1,5-*cd*]indolizine (**3b**), respectively, with alkaline hydrolysis followed by decarboxylation. In order to protect the amine moiety, **3a** was again converted to carbamate **4a**, which was allowed to react with dimethyl acetylenedicarboxylate (DMAD) in toluene under reflux for 20 h in the presence of palladium-charcoal (Pd/C) to give 2-ethoxycarbonyl-2,3-dihydro-5,6-bis(methoxycarbonyl)-1*H*-pyrido[3,4,5-*hi*]pyrrolo [2,1,5-*cd*]indolizine (**5a**) in 59% yield. The azepinopyrroloindolizine **5b** was also obtained from **4b** and DMAD in 68% yield.

The reactions of **4a** and **4b** with dibenzoylacetylene (DBZA) were carried out in tetrahydrofuran (THF) at 0°C in the presence of 2,3-dichloro-5,6-dicyano-1,4-benzoquinone (DDQ) to afford the expected pyrido- and azepinopyrroloindolizines, **6a** and **6b**, in 57 and 49% yields, respectively (Scheme 1).



Scheme 1.

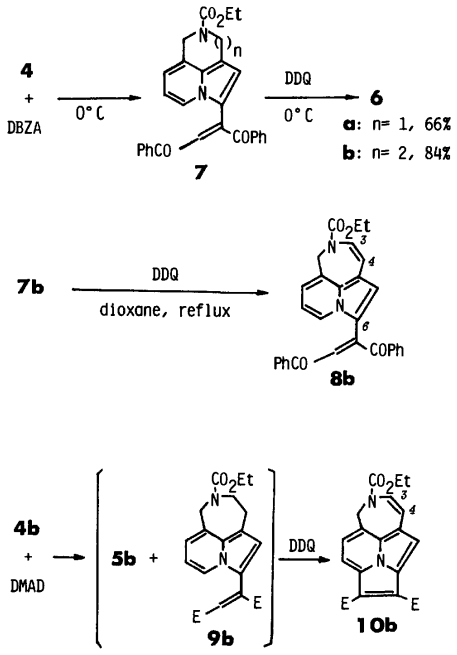
The analytical data and spectroscopic properties of **5** and **6** were consistent with the proposed structures. Especially, in ^{1}H NMR spectrum of **6a** or **6b**, one pair of the signals assignable to ethyl, methylene, and olefin protons were observed. The spectra of **6a** in deuteriochloroform at elevated temperatures revealed that the signals corresponding to two isomers were coalesced at *ca.* 50°C and sharpened again with an increase of the temperature. From these findings, we concluded that **6** in the solution was consisted of two conformational isomers concerning to the azepine ring.

In recent investigations of the mechanism on the cyclazine synthesis from indolizine, the isolation of intermediary products under the conditions without dehydrogenating reagents and their chemical conversions revealed considerably reliable reaction profiles.[6,7)] A proposed mechanism[7)] for the reaction with electron-deficient acetylene is as follows: Indolizine **A** attacks nucleophilically on acetylene to give the zwitterionic intermediate **B**, which leads to Michael adduct **C** and [8+2] cycloadduct **D**. The cycloadduct **D** is converted to more stable isomer(s) by the migration of hydrogen atom and finally dehydrogenated to the cyclazine.

In the synthesis of the benzo- and cyclohepta-fused cyclazines,[4)] some, at least more than two, intermediary products leading to cyclazines were also detected by ^{1}H NMR spectra and thin-layer chromatographies (TLC) of the reaction mixtures and, however, had not been identified owing to their thermodynamically

liablities. The 6-vinylindolizine derivative **7b**, the initially-formed product, was isolated in 62% yield as a pure form at the first time in the reaction of **4b** with DBZA in THF at 0°C without DDQ. The structural elucidation of **7b** was accomplished on the basis of its spectral data and elemental analysis. Particularly, its ^{1}H NMR spectrum showed a broad doublet at δ 8.46 assignable to the proton at 8-position. The similar reaction of **4a** with DBZA gave the 5-vinylindolizine **7a**, whose structure was confirmed by its ^{1}H NMR spectral data compared with those of **7b**.

While the treatment of **7b** with an equimolar DDQ in THF at 0°C gave the cyclazine **6b** in 84% yield, the similar treatment in dioxane under reflux afforded 6-(1,2-dibenzoylvinyl)-2-ethoxycarbonyl-1,2-dihydroazepino[3,4,5-*hi*]indolizine (**8b**) in 73% yield, which was formed by the oxidation of cyclic methylene moiety of **7b**. On the other hand, the reaction of **4b** with DMAD in dioxane without Pd/C gave a (1:4) mixture of **5b** and an intermediate **9b** similar to **7b**. The mixture was treated with an equimolar DDQ under reflux to give a mixture of **5b**, **9b**, and 2-ethoxycarbonyl-1,2-dihydroazepino[3,4,5-*hi*]pyrrolo[2,1,5-*cd*]indolizine (**10b**), then, with two equimolar DDQ to give **10b** in 66% yield as a sole product (Scheme 2).

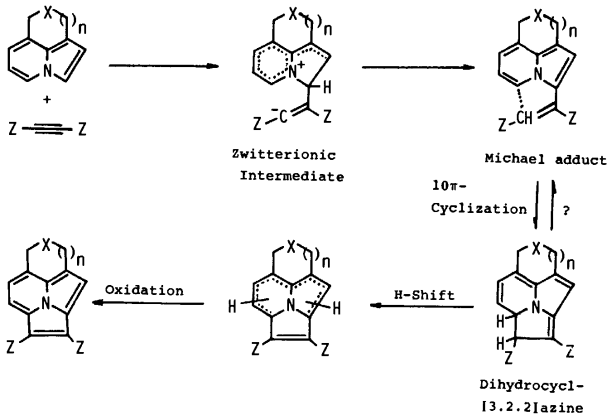


Scheme 2.

These results implied the possibility of the conversion of Michael adduct **C** to cyclazine system in the above-mentioned pathway or, circumstantially, of the interconversion between these two systems, which had been overlooked by preceding investigators.

In the actual synthesis of **6b** from **4b** and DBZA in the presence of DDQ, the examination by TLC revealed that the 6-vinylindolizine **7b** was converted to another intermediate, which was oxidized to the cyclazine **6b** finally.

From these results, we believe that the cyclazine synthsis from [*hi*]fused indolizines and acetylenes proceeds in a stepwise manner than in a concerted one.[8] Also, we suggest that vinylindolizines such as **7** or **9**, the Michael type adducts, would undergo 10π-electrocyclic reaction to give 1,2,3,4,7,7a-hexahydroazepino- or 2,3,6,6a-tetrahydro-1*H*-pyrido[3,4,5-*hi*]pyrrolo[2,1,5-*cd*]indolizines, which are converted to more stable isomer(s) and oxidized to the cyclazines (Scheme 3).



Scheme 3.

Experimental

All melting points are uncorrected. The IR spectra were measured on a JASCO IRA-1 spectrometer as potassium bromide pellets. ^{1}H NMR spectra were obtained on a JEOL JMN-MH-100 spectrometer with tetramethylsilane as an internal standard. Mass spectra were determined with a JEOL JMS-D mass spectrometer equipped with a direct inlet and at an ionization energy of 75 eV. Elemental analyses were performed on a Hitachi 026 CHN analyzer. The TLC was accomplished on 0.2 mm precoated plates of silica gel 60 F-254 (Merck) or on 0.2 mm precoated plates of aluminium oxide 60 F-254 type E (Merck). Visualization was made with ultraviolet light (254 and 365 nm). For the preparative column chromatography, Wakogel C-300 was used.

Preparations of Cyanoindolizines **2**: The pyridinium-1-dicyanomethylides **1** were prepared from the corresponding 3-(aminomethyl)pyridines and tetracyanooxirane and converted to cyanoindolizines **2** by the heating in toluene similarly to the reported method.[5]

*3-[N-(Ethoxycarbonyl)propargylaminomethyl]pyridinium-1-dicyanomethylide (**1a**)*: Yield 58%; yellow prisms; mp 81—84°C.

Found: C, 64.05; H, 5.16; N, 19.56%. Calcd for $C_{15}H_{14}N_4O_2$: C, 63.82; H, 5.00; N, 19.85%; M, 282.

*3-[N-(Ethoxycarbonyl)-3-butynylaminomethyl]pyridinium-1-dicyanomethylide (**1b**)*: Yield 55%; yellow prisms; mp 119—120°C.

Found: C, 65.09; H, 5.48; N, 18.96%. Calcd for $C_{16}H_{16}N_4O_2$: C, 64.85; H, 5.44; N, 18.91; M, 296.

*5-Cyano-2-ethoxycarbonyl-2,3-dihydro-1H-pyrido[3,4,5-hi]-indolizine (**2a**)*: Yield 75%; colorless needles; mp 104—105°C; IR (KBr) 2200 (CN) and 1700 cm^{-1} (CO); ^{1}H NMR ($CDCl_3$) δ=1.30 (3H, t, $-CH_3$, J=7 Hz), 4.20 (2H, q, $-CH_2-$, J=7 Hz),

4.8 (4H, m, 1 and 3-H), 6.7—6.9(2H, m, 8 and 9-H), 7.09 (1H, s, 4-H), and 8.06 (1H, br d, 7-H, J=6 Hz).

Found: C, 65.96; H, 5.12; N, 16.23%. Calcd for $C_{14}H_{13}N_3O_2$: C, 65.87; H, 5.13; N, 16.46%; M, 255.

*6-Cyano-2-ethoxycarbonyl-1,2,3,4-tetrahydroazepino[3,4,5-hi]indolizine (**2b**)*: Yield 87%; colorless prisms; mp 126—127 °C; IR (KBr) 2200 (CN) and 1960 cm^{-1} (CO); ^{1}H NMR ($CDCl_3$) δ=1.2—1.4 (3H total, m, $-CH_3$), 3.1—3.2 (2H, m, 4-H), 3.8 (2H, t, 3-H, J=6 Hz), 4.0—4.2 (2H, m, $-CH_2-$), 4.74 (2H, br s, 1-H), 6.7 (2H, m, 9 and 10-H), and 8.04 (1H, br d, 8-H, J=6 Hz).

Found: C, 67.05; H, 5.65; N, 15.34%. Calcd for $C_{15}H_{15}N_3O_2$: C, 66.90; H, 5.61; N, 15.61%; M, 269.

*Conversion of Cyanoindolizines **2** to Indolizines **3** (Typical Procedure)*: **2a** (3.9 mmol) was refluxed in 15% ethanolic potassium hydroxide (100 ml) for 10 h and ethanol was removed to give a residue. The residue was made acidic with concd hydrochloric acid (150 ml) and refluxed for 3 h. The solution was concentrated *in vacuo* and made basic with sodium hydroxide and extracted with ether (50 ml×5). The ethereal layer was collected, dried, and evaporated to give the indolizine **3a** (0.56 g, 91%).

*2,3-Dihydro-1H-pyrido[3,4,5-hi]indolizine (**3a**)*: Colorless prisms; mp 97—99 °C; IR (KBr) 3200 cm^{-1} (NH); ^{1}H NMR ($CDCl_3$) δ=2.3 (1H, s, NH), 3.96, 4.12 (2H each, 2s, 1 and 3-H), 6.15 (1H, d, 9-H, J=6 Hz), 6.34 (1H, t, 8-H, J=6 Hz), 6.50 (1H, d, 4-H, J=2 Hz), 7.12 (1H, d, 5-H, J=2 Hz), and 7.62 (1H, d, J=6 Hz); MS m/z 158(M^+).

Found: C, 75.93; H, 6.42; N, 17.57%. Calcd for $C_{10}H_{10}N_2$: C, 75.92; H, 6.37; N, 17.71%; M, 158.

*1,2,3,4-Tetrahydroazepino[3,4,5-hi]indolizine (**3b**)*: Yield 98%; colorless needles; mp 87—89 °C; IR (KBr) 3260 cm^{-1} (NH); ^{1}H NMR($CDCl_3$) δ=2.0 (1H, s, NH), 3.0—3.2 (4H, m, 3 and 4-H), 4.06 (2H, s, 1-H), 6.3 (2H, m, 9 and 10-H), 6.52 (1H, d, 5-H, J=2 Hz), 7.18 (1H, d, 6-H, J=2 Hz), and 7.62 (1H, dd, 8-H, J=5 and 3 Hz); MS m/z 172 (M^+).

Found: C, 76.54; H, 7.18; N, 16.24%. Calcd for $C_{11}H_{12}N_2$: C, 76.71; H, 7.02; N, 16.27%; M, 172.

Reaction of [hi]Fused Indolizines with DMAD (Typical Procedure): To a solution of **3a** (4.65 mmol) and triethylamine (6 mmol) in THF (20 ml), ethyl chloroformate (5 mmol) was added and the mixture was allowed to stand at room temperature overnight. After being filtrated the precipitates, the filtrate was concentrated to give a residue, which was treated with a short column chromatography (silica gel-chloroform) to afford **4a** quantitatively. Without further purification, **4a** was reacted with DMAD (5 mmol) in toluene (30 ml) under reflux in the presence of 0.5 g of 5% Pd/C overnight and the reaction mixture was worked up usually to give the cyclazine **5a**.

*2-Ethoxycarbonyl-2,3-dihydro-1H-pyrido[3,4,5-hi]indolizine (**4a**)*: Pale yellow oil; ^{1}H NMR ($CDCl_3$) δ=1.20 (3H, t, $-CH_3$, J=7 Hz), 4.12 (2H, q, $-CH_2-$, J=7 Hz), 4.62, 4.72 (2H each, 2s, 1 and 3-H), 6.1—6.3 (2H, m, 8 and 9-H), 6.46 (1H, d, 4-H, J=2 Hz), 7.03 (1H, d, 5-H, J=2 Hz), and 7.46 (1H, br d, 7-H, J=6 Hz).

*2-Ethoxycarbonyl-2,3-dihydro-5,6-bis(methoxycarbonyl)-1H-pyrido[3,4,5-hi]pyrrolo[2,1,5-cd]indolizine (**5a**)*: Yellow prisms; mp 95—96 °C; IR (KBr) 1725 and 1675 cm^{-1} (CO); ^{1}H NMR ($CDCl_3$) δ=1.34 (3H, t, $-CH_3$, J=7 Hz), 4.01, 4.05 (3H each, 2s, $-CH_3$), 4.23 (2H, q, $-CH_2-$, J=7 Hz), 5.2—5.3 (4H, br, 1 and 3-H), 7.36 (1H, br s, 4-H), 7.68 (1H, d, 8-H, J=8 Hz), and 8.35 (1H, d, J=8 Hz); MS m/z 370 (M^+).

Found: C, 61.65; H, 4.98; N, 7.89%. Calcd for $C_{19}H_{18}N_2O_6$: C, 61.61; H, 4.90; N, 7.56%; M, 370.

*2-Ethoxycarbonyl-1,2,3,4-tetrahydroazepino[3,4,5-hi]indolizine (**4b**)*: Pale yellow oil; ^{1}H NMR ($CDCl_3$) δ=1.1—1.3 (3H total, m, $-CH_3$), 3.1—3.3 (2H total, m, 4-H), 3.7—3.9 (2H total, m, 3-H), 4.0—4.2 (2H total, m, $-CH_2-$), 4.64, 4.68 (2H total, 2s, 1-H), 6.4 (2H, m, 9 and 10-H), 6.58 (1H, br s, 5-H), 7.24 (1H, br s, 6-H), and 7.70 (1H, br d, 8-H, J=6 Hz).

*2-Ethoxycarbonyl-1,2,3,4-tetrahydro-6,7-bis(methoxycarbonyl)-azepino[3,4,5-hi]pyrrolo[2,1,5-cd]indolizine (**5b**)*: Yellow prisms; mp 133—135 °C; IR (KBr) 1730, 1690, and 1665 cm^{-1} (CO); ^{1}H NMR ($CDCl_3$) δ=1.2—1.3 (3H total, m, $-CH_3$), 3.4—3.5 (2H total, m, 4-H), 3.94 (2H total, m, $-CH_2-$), 5.15, 5.20 (2H total, 2s, 1-H), 7.4 (1H, br s, 5-H), 7,60, 7.63 (1H total, 2d, 9-H, J=8 Hz each), 8.30, and 8.32 (1H total, 2d, 8-H, J=8 Hz each); MS m/z 384 (M^+).

Found: C, 62.51; H, 5.23; N, 7.31%. Calcd for $C_{20}H_{20}N_2O_6$: C, 62.49; H, 5.24; N, 7.29%; M, 384.

Reaction of [hi]Fused Indolizines with DBZA (Typical Procedure): To a cooled at 0 °C and stirred solution of **4a** (1 mmol) in THF (10 ml), DBZA (1 mmol) in THF (5 ml) was added dropwise for 10 min. After the consumption of the starting materials being confirmed by TLC, DDQ (1.1 mmol) in THF (5 ml) was added to the mixture, which was allowed to stir for additional 10 min at the same temperature. The resultant hydroquinone was filtered off and the filtrate was evaporated to dryness. Chromatography on silica gel with chloroform as an eluent gave **6a** (264 mg, 57%).

*5,6-Dibenzoyl-2-ethoxycarbonyl-2,3-dihydro-1H-pyrido[3,4,5-hi]pyrrolo[2,1,5-cd]indolizine (**6a**)*: Yellow prisms; mp 69—71 °C; IR (KBr) 1690 and 1655 cm^{-1}(CO); ^{1}H NMR ($CDCl_3$) δ=1.35 (3H, t, $-CH_3$, J=7 Hz), 4.30 (2H, q, $-CH_2-$, J=7 Hz), 5.3(4H, br, 1 and 3-H), 7.3—7.6 (7H, m, 8-H and phenyl protons), 7.6—7.9 (5H, m, 4-H and phenyl protons), and 8.14 (1H, d, 7-H, J=8 Hz); MS m/z 462 (M^+).

Found: C, 75.49; H, 5.10; N, 5.87%. Calcd for $C_{29}H_{22}N_2O_4$: C, 75.31; H, 4.80; N, 6.06%; M, 462.

*6,7-Dibenzoyl-2-ethoxycarbonyl-1,2,3,4-tetrahydroazepino[3,4,5-hi]pyrrolo[2,1,5-cd]indolizine (**6b**)*: Yellow prisms; mp 147—150 °C; IR (KBr) 1700 and 1650 cm^{-1} (CO); ^{1}H NMR ($CDCl_3$) δ=1.2—1.4 (3H total, m, $-CH_3$), 3.4—3.5 (2H total, m, 4-H), 3.95 (2H, br t, 3-H, J=7 Hz), 4.1—4.3 (2H total, m, $-CH_2-$), 5.22, 5.27 (2H total, 2s, 1-H), 7.2—7.5 (7H, m, 5-H and phenyl protons), 8.15, and 8.19 (1H total, 2d, 8-H, J=8 Hz each); MS m/z 476 (M^+).

Found: C, 75.50; H, 5.10; N, 5.67%. Calcd for $C_{30}H_{24}N_2O_4$: C, 75.61; N, 5.08; N, 5.88%; M, 476.

*Identification of Primarily-formed Intermediates in the Reaction of [hi]Fused Indolizines **4** with DBZA or DMAD (Typical Procedure)*: DBZA (1 mmol) in THF (5 ml) was added to a solution of **4b** (1 mmol) in THF (10 ml) for 10 min at 0 °C under nitrogen atmosphere. The reaction mixture was stirred for additional 10 min at the same conditions, evaporated to dryness, and a reddish crystalline **7b** (296 mg, 62%) was obtained from ether.

*6-(1,2-Dibenzoylvinyl)-2-ethoxycarbonyl-1,2,3,4-tetrahydroazepino[3,4,5-hi]indolizine (**7b**)*: Red prisms, mp 170—171 °C; IR (KBr) 1690 and 1650 cm^{-1} (CO);^{1}H NMR ($CDCl_3$) δ=1.99 (3H, t, $-CH_3$, J=7 Hz), 2.9—3.1 (2H, m, 4-H), 3.72 (2H, br t, 3-H, J=6 Hz), 4.07 (2H, q, $-CH_2-$, J=7 Hz), 4.6—4.8 (2H, br s, 1-H), 6.6—6.8 (3H, m, 5, 9, and 10-H), 7.3—7.6 (7H, m, vinyl and phenyl protons), 7.8—8.0 (4H, m, phenyl protons), and 8.46 (1H, br d, 8-H, J=6 Hz); MS m/z 478 (M^+).

Found: C, 75.13; H, 5.60; N, 6.02%. Calcd for $C_{30}H_{26}N_2O_4$: C, 75.29; H, 5.48; N, 5.85%; M, 478.

The reaction of **4a** with DBZA gave a reddish amorphous **7a** (62%), whose structure was confirmed by ^{1}H NMR spectral data without satisfactory analytical data.

*5-(1,2-Dibenzoylvinyl)-2-ethoxycarbonyl-2,3-dihydro-1H-pyrido[3,4,5-hi]indolizine (**7a**)*: ^{1}H NMR ($CDCl_3$) δ=1.90 (3H, t, $-CH_3$, J=7 Hz), 4.32 (2H, q, $-CH_2-$, J=7 Hz), 4.70, 4.75 (2H each, 2s, 1 and 3-H), 6.6—6.8 (3H, m, 4, 8, and 9-H), 7.2—7.6 (7H, m, vinyl and phenyl protons), 7.7—8.0 (4H, m, phenyl protons), and 8.33 (1H, br d, 7-H, J=6 Hz).

The formation of 6-vinylindolizine **9b** from **4b** and DMAD was elucidated by the ^{1}H NMR spectrum of the reaction mixture in octadeuteriodioxane. It showed three singlets at δ 3.78 and 3.92 (methyl protons), 6.04 (vinyl proton), and a doublet at δ 8.00 (8-H, J=6 Hz) besides the other protons overlapped with those of **5b**.

*Reactions of 6-Vinylindolizines **7** with DDQ (Typical Procedure)*: A mixture of **7b** (0.21 mmol) and DDQ (0.22 mmol) in THF (5 ml) was stirred at 0 °C for 30 min and evaporated *in vacuo* to give a residue. The residue was treated with a short column chromatography (silica gel-chloroform) to give **6b** (84 mg, 84%).

A mixture of **7b** (0.42 mmol) and DDQ (0.44 mmol) in dioxane (10 ml) was refluxed for 10 min. After the usual working-up, 145 mg(73%) of **8b** was obtained.

*6-(1,2-Dibenzoylvinyl)-2-ethoxycarbonyl-1,2-dihydroazepino[3,4,5-hi]indolizine (**8b**)*: Red prisms; mp 132—134 °C; IR (KBr) 1690 and 1655 cm^{-1} (CO); ^{1}H NMR ($CDCl_3$) δ=1.26 (3H, t, $-CH_3$, J=7 Hz), 4.18 (2H, q, $-CH_2-$, J=7 Hz), 4.61 (2H, br s, 1-H), 5.90 (1H, d, 4-H, J=8 Hz), 6.60 (1H, d, 3-H, J=8 Hz), 6.7—6.8 (3H, m, 5, 9, and 10-H), 7.3—7.6 (7H, m, vinyl and phenyl protons), 7.8—8.0 (4H, m, phenyl protons), and 8.51 (1H, dd, 8-H, J=6 and 4 Hz); MS m/z 476 (M^+).

Found: C, 75.52; H, 5.14; N, 5.82%. Calcd for $C_{30}H_{24}N_2O_4$: C, 75.61; H, 5.08; N, 5.88%; M, 476.

*Reactions of 6-Vinylindolizine **9b** with DDQ (Typical Procedure)*: DDQ (3.5 mmol) was added to a (1:4) mixture of **5b** and **9b**, from indolizine **4b** (1.64 mmol) and DMAD (1.76 mmol), in dioxane (20 ml) and the reaction mixture was refluxed for 30 h. The resultant hydroquinone was removed by filtration and the filtrate was worked up usually to give **10b** (412 mg, 66%).

*2-Ethoxycarbonyl-6,7-bis(methoxycarbonyl)-1,2-dihydroazepino[3,4,5-hi]pyrrolo[2,1,5-cd]indolizine (**10b**)*: Orange prisms; mp 118—120 °C, IR (KBr) 1720 and 1700 cm^{-1} (CO); ^{1}H NMR ($CDCl_3$) δ=1.28 (3H, t, $-CH_3$, J=7 Hz), 4.04, 4.07 (3H each, 2s, $-CH_3$), 4.24 (2H, q, $-CH_2-$, J=7 Hz), 5.21 (2H, s, 1-H), 6.43 (1H, d, 4-H, J=8 Hz), 6.84 (1H, br d, 3-H, J=8 Hz), 7.42 (1H, s, 5-H), 7.70 (1H, d, 9-H, J=8 Hz), and 8.34 (1H, d, 8-H, J=8 Hz); MS m/z 476 (M^+).

Found: C, 75.50; H, 5.10; N. 5.67%. Calcd for $C_{30}H_{24}N_2O_4$: C, 75.61; H, 5.08; N, 5.88%; M, 476.

(Received June 26, 1985)

Kinetical studies and products analyses of the thermal decomposition of *t*-butyl heptafluoroperoxybutyrate (TBH) in benzene, octane, nitrobenzene, pyridine, and methoxybenzene have been carried out. In benzene and octane, the decomposition appears to be entirely a radical process. In nitrobenzene and pyridine, the reactions are found to give ionic decomposition products exclusively. On the other hand, the decomposition of TBH in methoxybenzene is characteristic of mixed ionic and radical cleavages.

Although the mechanisms for the thermolysis of a series of peroxy esters have been extensively investigated,[1] studies on fluorinated peroxy esters are very limited. Fluorinated peroxy esters are expected to show a different decomposition behavior from corresponding aliphatic peroxy esters due to the strong electron-withdrawing properties of fluoroalkyl groups. Strong electron-withdrawing groups in peroxide weaken the O–O bond and lower the energy level of an antibonding (σ^*) O–O bond.[2] Bartlett and Traylor reported that the *t*-butyl peroxy esters derived from a strong organic acid might well undergo an ionic cleavage with a Criegee rearrangement.[3] Recently, we also reported that *t*-butyl heptafluoroperoxybutyrate (TBH) decomposes in methanol to give methyl heptafluorobutyrate and *t*-butyl hydroperoxide in good yields according to the following transesterification.[4]

$$C_3F_7CO_2OC(CH_3)_3 \xrightarrow[CH_3OH]{} C_3F_7CO_2CH_3 + (CH_3)_3COOH$$

However, we found that the thermal decomposition of TBH suffered extreme solvent effects. In this paper, we wish to report on studies regarding the reaction mechanism for the thermal decomposition of TBH in benzene, octane, nitrobenzene, pyridine, and methoxybenzene.

Results and Discussion

The thermal decomposition of TBH in benzene was monitored by iodometry at various temperatures from 60.0 to 80.0 °C; the rate of decomposition deviated upwards remarkably from a first-order rate plot after about 30% of the reaction. However, the rate of decomposition of TBH was found to follow very well a first-order equation when pyridine was added in order to suppress the autocatalyzed decomposition by produced heptafluorobutyric acid. The anomalous behavior regarding the thermal decomposition of highly acid-sensitive peroxy esters is well-known and in order to prevent autocatalysis, pyridine has usually been used.[5,6] The decomposition of 0.02 M†† TBH in benzene was carried out at 75.0 °C in the presence of various (0.005—0.025 M) amounts of pyridine. It was found that as the amount of pyridine was increased, the decomposition rates of TBH decreased and the apparent rate constants leveled off at about 0.015 M pyridine as shown in Fig. 1. Products attributable to a reaction between TBH and pyridine were not obtained except for pyridinium heptafluorobutyrate. In the

$(CH_3)_3COC(CH_3)_3$	0.04		

a) 1.0 M pyridine was used. b) Heptafluoropropane could be detected by GC–MS, however, the exact yield could not be determined. c) Isolated yield of pyridinium heptafluorobutyrate recrystallized from toluene.

absence of pyridine, the decomposition of TBH gave a considerable amount of 2-methoxy-1-propene (**1**: $CH_3OC(CH_3)=CH_2$, 0.15 mol/mol peroxide) in addition to the products listed in Table 2. The production of propene shows the acid-catalyzed decomposition of TBH.

$$C_3F_7\overset{\overset{O}{\|}}{C}OOC(CH_3)_3 \xrightarrow{H^+} C_3F_7\overset{\overset{+O-H}{\|}}{C}OOC(CH_3)_3 \longrightarrow$$

$$C_3F_7CO_2H + CH_3O-\overset{\overset{CH_3}{|}}{\overset{+}{C}}-CH_3 \xrightarrow{-H^+} CH_3O-\overset{\overset{CH_3}{|}}{C}=CH_2$$

(**1**)

The rates of decomposition of TBH in benzene in the presence of an equimolar amount of 2,6-lutidine, which is known to play the role of a proton acceptor and not a nucleophile, gave similar values as those for TBH, using pyridine as a suppresser. These results indicate that pyridine or lutidine played the role of the suppresser of the heptafluorobutyric acid-catalyzed decomposition.

The rate constants and activation parameters for the thermal decomposition of TBH in several solvents are summarized in Table 3. The decomposition was extremely solvent-dependent as shown in Table 3, while the thermal decomposition of nonfluorinated peroxy esters, for example, *t*-butyl peroxyacetate in aliphatic and aromatic solvents showed a weak solvent dependence.[7]

As shown in Tables 1 and 3, the activation parameters for the thermal decomposition of TBH in benzene and octane have similar values as those for the homolytic decomposition of non-fluorinated peroxy esters; *t*-butyl peroxybenzoate in chlorobenzene, ΔH^*=140.2 KJ mol^{-1}, ΔS^*=32.6 JK^{-1} mol^{-1};[5] *t*-butyl phenylperoxyacetate in chlorobenzene, ΔH^*=116.7 kJmol^{-1}, ΔS^*=8.4 JK^{-1} mol^{-1}.[8] The products obtained from the thermal decomposition of TBH in benzene and in octane are shown in Table 2. The decomposition of TBH in benzene gave no ionic Criegee rearrangement products such as 2-methoxy-1-propene, but heptafluorobutyric acid, toluene, biphenyl, *t*-butyl heptafluorobutyrate, acetone, and condensation products of acetone such as mesityl oxide and 1,3,5-trimethylbenzene. The production of toluene, biphenyl, *t*-butyl heptafluorobutyrate, acetone, and acetone derivatives indicates that TBH decomposes homolytically in benzene. The generation of the radical species was also confirmed by ESR studies. In studies on the decomposition of TBH using nitrosodurene as a spin-trapping reagent, the ESR signal of some nitroxide radicals were observed: one signal was assigned to the adduct of methyl radical to nitrosodurene from the following h.f.s.c.; a_N=14.0 G, $a_{\beta\text{-H}}$=12.2 G, g=2.0068, (lit, a_N=13.70 G, $a_{\beta\text{-H}}$=12.17 G, g=2.0060).[9] Formation

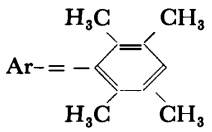
Table 3. Rate constants and activation parameters for the thermal decomposition of 0.10 M TBH & 0.10 M pyridine in various solvents

Solvent	Temp/°C	$k_d(s^{-1})\times10^5$	ΔH^*/kJ mol^{-1}	ΔS^*/JK^{-1} mol^{-1}
Octane	85.0	0.51±0.01		
	90.0	0.95±0.01	136.8	34.7
	95.0	1.75±0.04		
	100.0	3.41±0.06		
$PhNO_2$	40.0	3.26±0.04		
	45.0	6.36±0.03	85.8	−56.9
	50.0	9.31±0.23		
Pyridine	30.0	2.74±0.03		
	40.0	7.66±0.11	75.3	−82.8
	50.0	18.68±0.18		
$PhOCH_3$	55.0	5.01±0.05		
	60.2	8.56±0.11	95.4	−37.2
	65.0	13.78±0.22		
	70.0	24.44±0.45		

of this nitroxide is explained by the decomposition of a cage-escaped *t*-butoxyl radical to acetone and methyl radical.

$$\cdot OC(CH_3)_3 \longrightarrow \cdot CH_3 + (CH_3)_2CO$$

$$\cdot CH_3 + ArNO \longrightarrow ArNO\cdot \quad (CH_3 \text{ on } \cdot)$$



No adduct radical due to $C_3F_7\cdot$ and nitrosodurene was observed.[10]

In the decomposition of TBH in octane, the heptafluoropropane (**2**), and methyl heptafluorobutyrate (**3**) were produced, and their production can be attributed to homolytic cleavages of TBH. Thus, the decomposition of TBH in octane may also be proceeded by a homolytic cleavage, according to Scheme 1. The homolysis of TBH in octane was further confirmed by ESR studies using nitrosodurene as a spin-trapping reagent. When TBH was decomposed in the presence of nitrosodurene, ESR signals of more than three nitroxide radicals were observed; the main signal was a triplet of doublet with coupling to nitrogen and hydrogen. This signal is probably due to the adduct radical of the secondary alkyl radicals to nitrosodurene. Also, the adduct radical of $C_3F_7\cdot$ to nitrosodurene could not be observed in this case. The radicals generated by the homolysis of TBH did not attack nitrosodurene but abstracted a hydrogen atom from solvent octane to give a mixture of secondary alkyl radicals ($C_8H_{17}\cdot$) which could be trapped by nitrosodurene. In order to confirm this, an ESR study of TBH in cyclohexane was also carried out. In this case, the spin adduct of the produced single radical (cyclohexyl radical) to nitrosodurene was observed; a_N=13.4 G, a_H=6.7 G, g=2.0059, (lit, a_N=13.57 G, a_H=6.93 G, g=2.0060).[9]

$$C_3F_7C(=O)\text{-}OOC(CH_3)_3 \longrightarrow \overline{C_3F_7C(=O)\text{-}O\cdot \quad \cdot OC(CH_3)_3} \longrightarrow$$

$$(CH_3)_2CO + C_3F_7C(=O)\text{-}O\cdot + \cdot CH_3 \longrightarrow C_3F_7CO_2CH_3 \quad (\mathbf{3})$$

Fate of the cage-escaped radical:

$$C_3F_7\cdot + RH(\text{solvent}) \longrightarrow C_3F_7H + R\cdot \quad (\mathbf{2})$$

$$\cdot OC(CH_3)_3 \longrightarrow \cdot CH_3 + (CH_3)_2CO$$

$$\cdot CH_3 + RH \longrightarrow CH_4 + R\cdot$$

Scheme 1.

As mentioned before, it was considered that TBH decomposes homolytically in octane and in benzene. However, the activation parameters for the thermal decomposition of TBH in benzene have smaller values compared with those in octane, and heptafluorobutyric acid was obtained in much higher (63%) yield than that in octane. These results suggest that the induced decomposition of TBH by the cyclohexadienyl radicals, which were formed by the attack of radicals to benzene, may occur, in part, in benzene.

On the other hand, the activation parameters for the thermal decomposition of TBH in nitrobenzene and pyridine have similar values as those for the ionic decomposition of other *t*-butyl peroxy esters accompanied by a Criegee rearrangement; for instance, *t*-butyl peroxytosylate in methanol, $\Delta H^{\ddagger}$=90.0 kJmol^{-1}, $\Delta S^{\ddagger}$=3.8 JK^{-1}mol^{-1}.[3] It was also found that TBH decomposed in nitrobenzene and pyridine to give one molar equivalent of heptafluorobutyric acid and several Criegee rearrangement products such as 2-methoxy-1-propene (**1**), 2,2-dimethoxypropene (**4**), and 1-methoxy-1-methylethyl heptafluorobutyrate (**5**) as shown in Table 4. 2,2-Dimethoxypropane is probably produced by the reaction of a 1-methoxy-1-methylethylium ion with water (giving acetone and methanol) followed by a reaction involving the evolved methanol with another 1-methoxy-1-methylethylium ion. These results indicate that the decomposition of TBH in nitrobenzene and pyridine is principally an ionic decomposition accompanied by a Criegee rearrangement, according to the following scheme. However, nonfluorinated *t*-butyl peroxy esters are reported to decompose homolytically even in a polar solvent such as nitrobenzene.[11]

$$C_3F_7C(=O)\text{-}OOC(CH_3)_3 \xrightarrow{\text{ionic cleavage}}$$

$$[C_3F_7C(=O)\text{-}O^- \ {}^+O\text{-}C(CH_3)_2\text{-}CH_3] \xrightarrow{\text{Criegee rearrangement}}$$

$$[C_3F_7C(=O)\text{-}O^- \ {}^+C(OCH_3)(CH_3)\text{-}CH_3] \rightarrow C_3F_7C(=O)\text{-}O\text{-}C(OCH_3)(CH_3)\text{-}CH_3 \quad (\mathbf{5})$$

$$[C_3F_7C(=O)\text{-}O^- \ {}^+C(OCH_3)(CH_3)\text{-}CH_3] \rightarrow CH_3\text{-}C(OCH_3)=CH_2 + C_3F_7CO_2H \quad (\mathbf{1})$$

Scheme 2.

In the decomposition of TBH in pyridine, 2-*t*-butoxy-2-methoxypropane (**6**) was obtained in 21% yield. The formation of this product may be explained by a nucleophilic attack of the N-lone pair of pyridine on a peroxidic α-oxygen of peroxy ester to give *t*-butoxide ion which reacted with 1-methoxy-1-methylethylium ion. It was reported that a reaction of *t*-butyl perbenzoate with dimethyl sulfide occurred at the peroxidic α-oxygen of the benzoyloxyl group to form a dimethylbenzoyloxysulfonium ion, not at the *t*-butoxyl

Table 4. Products from the thermal decomposition of 0.10 M TBA in nitrobenzene[a] at 70 °C for 7 h, in pyridine at 50 °C for 12 h and in methoxybenzene[a] at 70 °C for 7 h

Product	$PhNO_2$ mol/mol	C_5H_5N mol/mol	$PhOCH_3$ mol/mol
$(CH_3O)C(CH_3)=CH_2$	0.19	0.46	0.14

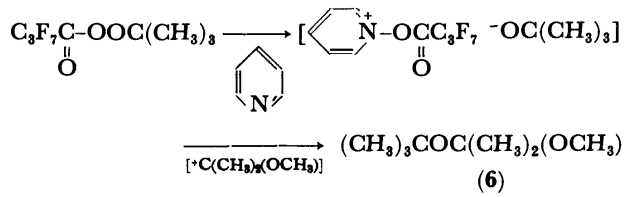
oxygen to form dimethyl-*t*-butoxysulfonium ion.[12] The peroxidic α-oxygen of a heptafluorobutyryloxyl group should be more electropositive than the *t*-butoxyl oxygen. α-Oxygen in a peroxy ester O–O bond is estimated to be more electropositive than α-oxygen according to a MO calculation.[13] Therefore, a nucleophilic attack of pyridine on the heptafluorobutyryloxyl peroxidic oxygen rather than on the *t*-butoxyl oxygen is expected to be favored.



(6)

In a thermal decomposition of TBH in methoxybenzene, the values of the activation enthalpy and entropy for the thermal decomposition of TBH were $\Delta H^{\ddagger}=95.4\,kJmol^{-1}$, $\Delta S^{\ddagger}=-37.2\ JK^{-1}mol^{-1}$. These values are larger than those for a thermal decomposition of TBH in nitrobenzene. Ionic Criegee type rearrangement products such as 2-methoxy-1-propene (**1**), 2,2-dimethoxypropane (**4**), and 1-methoxy-1-methylethyl heptafluorobutyrate (**5**) were obtained as the decomposition products in methoxybenzene. Furthermore, acetone (**7**), *t*-butyl heptafluorobutyrate (**8**), and methoxymethylbenzene (**9**), which would result from a homolytic cleavage, were also obtained as shown in Table 4. From these results, it may be concluded that the thermal decomposition of TBH in methoxybenzene is characteristic of mixed ionic and radical cleavages.

Thus, the decomposition of TBH was affected by the polarity of the solvents; the rate of decomposition increased with the dielectric constant of a solvent (ε). In a nonpolar solvent such as octane (ε=1.90) and benzene (ε=2.27), the decomposition proceeds homolytically and the ionic decomposition becomes dominant in a polar solvent such as nitrobenzene (ε=34.6), and pyridine (ε=12.3). In methoxybenzene (ε=4.30), the decomposition is characteristic of mixed ionic and radical cleavages. Although the dielectric constant of nitrobenzene is larger than that of pyridine, the decomposition in pyridine is faster than that in nitrobenzene. This may be due to a nucleophilic attack of pyridine to the O–O bond of TBH.

Experimental

The ^{1}H-NMR spectra were taken with a JEOL JNM-MH-100 spectrometer. The mass spectra were measured with a JEOL JMS-D300 spectrometer. ESR signals were taken with a JES-PE-3X spectrometer. GLC analyses were performed on a Shimadzu GC-4APTF gas chromatograph. IR spectra were recorded on a JASCO A-3 spectrophotometer. Benzene, octane, nitrobenzene, pyridine, and methoxybenzene were purified according to conventional methods. Heptafluorobutyryl chloride was prepared by a reaction of heptafluorobutyric acid and phosphorus pentachloride. The pure acid chloride had a bp of 39—40 °C/760 mmHg (1 mmHg=133.322 Pa), (38—39 °C/740 mmHg[14]) and $\nu_{C=O}$ 1795 cm^{-1}. *t*-Butyl hydroperoxide (commercial grade of Nippon Oil & Fats Co.) was distilled prior to use, bp 32—35 °C/15 mmHg.

Preparation of t-Butyl Heptafluoroperoxybutyrate (TBH). Heptafluorobutyryl chloride (77 g, 0.33 mol) was added to *t*-butyl hydroperoxide (35 g, 0.39 mol) in pentane (55 g) at −2 °C and the mixture was cooled to −10 °C. Dry pyridine (31 g, 0.39 mol) was added dropwise with stirring over a period of 20 min while the temperature was maintained below 0 °C. The reaction mixture was then kept at −5 °C—−10 °C for an additional 40 min. The resulting mixture containing a white precipitate was poured into 100 mL of cold aqueous 10% hydrochloric acid and was thoroughly stirred. The pentane layer was separated, washed twice with 100 mL of cold aqueous 5% sodium hydroxide, and finally with 100 mL of cold water. After being dried over anhydrous magnesium sulfate, the solution was concentrated to give 42 g of a crude colorless peroxy ester. This was carefully distilled to give a pure colorless peroxy ester, bp 39.5—40.0 °C/17 mmHg. The infrared spectra exhibited the characteristic peroxy ester carbonyl band at 1815 cm^{-1}. ^{1}H-NMR ($CF_2ClCFCl_2$) δ=1.36 (9H, s). MS *m/z* 286 (M^+), 271, 197, 169, 150, 119, 100, 73, 69, 58, 57 (base), 55, 45, 43, 42, 39, 31, 29, 27, and 15; Anal. Calcd for $C_8H_9O_3F_7$: C, 33.58; H, 3.17%. Found: C, 32.50; H, 2.99%.

Kinetic Measurement. A solution of TBH in a degassed sealed tubes were immersed in a constant-temperature bath. Each sample tube was taken out after appropriate time intervals and immersed in a Dry Ice–acetone bath to quench the reaction; the amount of the residual TBH was estimated by iodometric titration.

Decomposition Products of TBH. The products of the decomposition of TBH were identified by GC–MS and by their retention times of GLC compared with those of authentic samples. The yield of heptafluorobutyric acid was determined by titration after hydrolysis of the reactants. Yields of the other products were determined by GLC using internal standards.

The authors wish to express their thanks to Mr. Shigehiko Yamaguchi at the Tsukuba Central Research Laboratory of Nippon Oil & Fats Co., Ltd. for GC–MS spectrometric measurement.

Total Syntheses of (±)-Aerothionin, (±)-Homoaerothionin, and (±)-Aerophobin-1

Shigeru NISHIYAMA and Shosuke YAMAMURA*
Department of Chemistry, Faculty of Science and Technology, Keio University, Hiyoshi, Kohoku-ku, Yokohama 223
(Received July 17, 1985)

(±)-Aerothionin, (±)-homoaerothionin, and (±)-aerophobin-1 have been successfully synthesized using phenolic oxidation of the methyl pyruvate oxime derivative with thallium(III) trifluoroacetate as a key step. The stereostructure of aerophobin-2 has been also established by comparison of the ^{1}H NMR spectrum with those of related compounds.

Recently, enlarged synthetic attention has been focused on marine natural products having physiological activities.[1] Among them, several sponges have served attractive bromine-containing metabolites derived from tyrosine, which in biosynthetic pathway seem to involve phenolic oxidation affording dimerization, cyclization and so on.

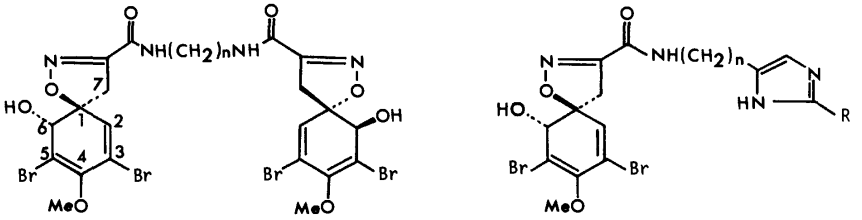
As a part of our approach directed toward total syntheses of these natural products using thallium(III) salt-induced phenolic oxidation as a key step,[2] we have already accomplished total synthesis of bastadins isolated from the sponge *Ianthella basta*.[3] Along this line, our attention turned to aerothionin (**1**),[4] homoaerothionin (**2**),[4] aerophobin-1 (**3**),[5] and -2 (**4**)[5] which are also metabolites of such sponges as *Aplysia fistularis, Verongia thiona* and *V. aerophoba*. Especially, the absolute stereostructure of **1** was established by an X-ray crystallographic analysis coupled with circular dichroism,[6] and its synthetic effort was also made by Thomson *et al.*,[7] wherein sodium borohydride reduction of tetradehydroaerothionin did not yield natural *trans, trans*-aerothionin, but *cis, cis*-aerothionin.

Configurations of the hydroxyl group at C^6-position in aerophobin-1 (**3**) and its congener (**4**) possessing 2-aminohomoistamine moiety instead of histamine in **3** remained unsettled. From a biogenetic point of view, however, they should have the same stereostructures as that of **1**. Accordingly, it was expected that the spiroisoxazoline derivative (**14a**) would be a potent intermediate for syntheses of aerothionin (**1**), homoaerothionin (**2**) and aerophobin-1 (**3**), respectively, and the ketone (**11**) conceivable as a precursor of **14a** might be obtained by the two-electron oxidation process (*i.e.* **9**→**11**) involving attack of a hydroxyimino group to a carbonium ion generated on phenolic oxidation. We describe herein total syntheses of **1**, **2**, and **3** as well as determination of aerophobin-2 (**4**).

When a readily accessible azulactone (**5**)[4] was submitted to alkaline hydrolysis followed by oximation and benzylation, the tribenzyl derivative (**6**) was obtained in 31% yield, together with the enamine (**7**) in 14% yield, from which on treatment with the same reaction sequence **6** was further obtained. The structure of **6** could be confirmed by its successful conversion to a known alkaline degradation product of **1**,[4] *N,N'*-bis[3-(3,5-dibromo-2-hydroxy-4-methoxyphenyl)-2-hydroxyiminopropionyl]-1,4-butanediamine (**8**) by treatment with 1,4-butanediamine followed by hydrgenolysis. Furthermore, transesterification of **6** in methanol containing K_2CO_3 afforded the corresponding methyl ester, which on hydrogenolysis led to the desired dihydroxy derivative (**9**) in moderate yield.

The methyl ester (**9**) so far obtained was oxidized with thallium(III) trifluoroacetate (TTFA) in trifluoroacetic acid (room temp, 4 h) to afford **10**, **11** and **12** as isolable products in 21, 27, and 3% yields, respectively. The aspect of the TTFA oxidation is compatible, except for the dimer (**12**), with the results reported by Forrester *et al.*,[8] in which they examined several oxidation reactions of phenols [A] using MTA, $Pb(OAc)_4$, Ag_2O, Br_2, and TBCO as oxidant to afford [B] and [C].

As seen in the case of *cis,cis*-aerothionin formation,[7] on treatment of **11** with $NaBH_4$, the undesired **13a** was also obtained in high yield together with trace amount of **14a**. However, evaluation of several reaction conditions provided an improvement to pro-



1 n = 4
2 n = 5
3 n = 2, R = H
4 n = 3, R = NH_2

Fig. 1. Some novel spiroisoxazolines from marine sponges.

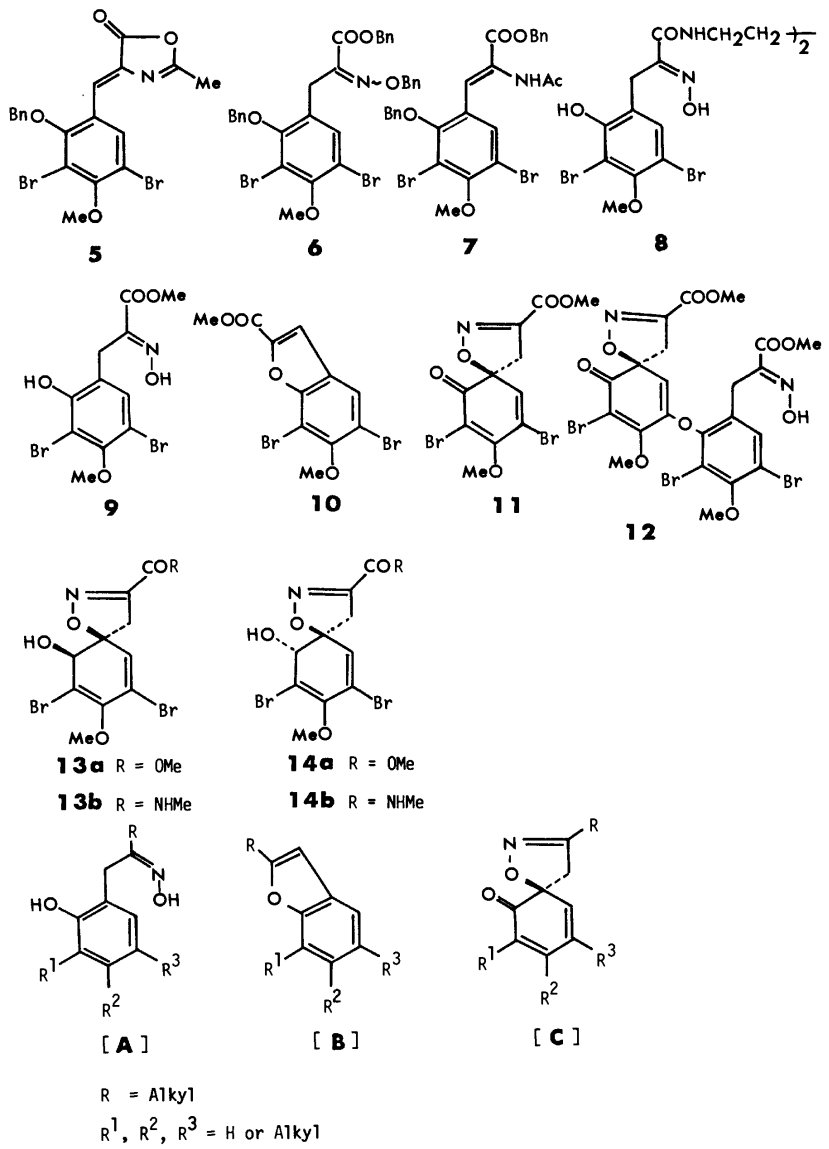


Fig. 2.

duce **14a** in preparative scale. Namely, reduction of **11** was carried out with excess $Zn(BH_4)_2$ in ether (room temp, 7 min) to afford a 1.3:1 mixture of **13a** and **14a**, in 70% yield, which were easily separable on preparative TLC. The stereostructures of **13a** and **14a** could be established on the basis of exhaustive comparison of both ^1H NMR spectra with those of **1** and *cis,cis*-aerothionin which has a cis vicinal relationship between a hydroxyl group and an oxygen atom in the spiroisoxazoline unit, as seen in Table 1.

Finally, amidation of **14a** with 1,4-butanediamine, 1,5-pentanediamine and histamine (room temp, overnight) successfully afforded aerothionin (**1**), homoaerothionin (**2**) and aerophobin-1 (**3**), in 18, 4.4 and 82% yields, respectively. Interestingly, on the other hand, the ester (**13a**), which has the trans relationship between the hydrogen atom attached to the carbon atom bearing the hydroxyl group and the oxygen atom in a spiroisoxazoline ring, was quite unstable to amines. The amides (**1**), (**2**), and (**3**) thus obtained were indistinguishable with authentic samples under the full range of spectral (IR, ^1H NMR, and mass) and chromatographical (TLC and HPLC) means. However, in the cases of **1** and **2**, a possibility that each product consists of a mixture of the natural product and its concomitant diastereomer, could not be ruled out. Unfortunately, up to date we have no reliable solution for it.

The stereostructure of aerophobin-2 could be established as depicted in **4** on the basis of exhaustive comparison of the ^1H NMR spectrum with those of **13b** and **14b**: particularly, the resonances of δ 4.14 and 6.35 ascribed to C^6-H and C^2-H are rather agreeable with those of δ 4.08 and 6.40 in **14b** than those of δ 4.40 and 6.55 in **13b**. Furthermore, while *cis,cis*-aerothionin, **13a** and **13b** have the broad signals attributable to the two geminal protons at C^7-position in their ^1H NMR spectra, the NMR signals due to the corresponding

protons in **1**, **2**, **3**, **14a**, and **14b** are observed as two doublets because of an interaction of the hydroxyl group with one of the geminal protons. Accordingly, it is reasonable that aerophobin-2 (**4**) exhibiting two doublets at δ 3.20 and 3.85 should possess the same structure unit as those of the latter compounds.

Experimental

All the melting points were obtained on a Mitamura Riken melting point apparatus and uncorrected. IR spectra were recorded on a JASCO Model A-202 spectrophotometer. ^{1}H NMR spectra were obtained on a Varian EM-390 NMR spectrometer (90 MHz) using tetramethylsilane as an internal standard. High resolution mass spectra were obtained on a Hitachi M-80 GC-MS spectrometer operating with an ionization energy (70 eV). Preparative and analytical TLC were carried out on silica-gel plates (Kieselgel 60 F_{254}, E. Merck A.G. Germany) using UV light and/or 5% molybdophosphoric acid in ethanol for detection, unless otherwise stated. HPLC were performed on a JASCO Trirotar-II apparatus using a 4.6×250 mm Develosil 60-3 column with hexane–AcOEt (v/v 1:1) at 1 ml/min flow rate.

Benzyl 2-Benzyloxyimino-3-(2-benzyloxy-3,5-dibromo-4-methoxyphenyl)propionate (6). The azulactone (**5**)[4] (8.22 g) was hydrolyzed at 100 °C for 9 h with KOH (11 g) in dioxane (50 ml)–H_2O (50 ml). After addition of hydroxylamine hydrochloride (3.7 g), the reaction mixture was allowed to stand at room temperature overnight, and then acidified with 2M HCl(1M=1 mol dm^{-3}) and extracted with AcOEt. The AcOEt layer was washed with brine, dried over anhydrous Na_2SO_4, and then evaporated. The residue was treated with benzyl chloride (6 ml) and K_2CO_3 (6 g) in DMF (50 ml) at room temperature overnight. The mixture was partitioned between AcOEt and H_2O, and then the AcOEt layer was washed with brine, dried over anhydrous Na_2SO_4, and then evaporated under reduced pressure to leave a crude syrup, which was submitted to silica-gel column chromatography (250 g) using benzene as eluant to give **6** (3.42 g) and **7** (1.4 g). **6**: mp 83—85 °C from hexane–AcOEt; IR (film) 1720, 1600, and 1580 cm^{-1}: ^{1}H NMR ($CDCl_3$) δ=3.85(3H, s), 3.88(2H, s), 4.88(2H, s), 5.12(2H, s), 5.22(2H, s), and 7.2—7.5(16H, complex); Found: *m/z* 651.0244. Calcd for $C_{31}H_{27}NO_5{}^{79}Br_2$: M, 651.0254. **7**: mp 159—160 °C from hexane–AcOEt; IR (film) 3250, 1730, 1660, 1575, and 1520 cm^{-1}; ^{1}H NMR ($CDCl_3$) δ=1.93(3H, s), 3.90(3H, s), 4.90(2H, s), 5.25(2H, s), 7.2—7.5(10H, complex), and 7.55 (1H, s); Found: *m/z* 586.9952. Calcd for $C_{26}H_{23}NO_5{}^{79}Br_2$: M, 586.9943.

Methyl 2-Hydroxyimino-3-(3,5-dibromo-2-hydroxy-4-methoxyphenyl)propionate (9). A mixture of the tribenzyl derivative (2.16 g) and K_2CO_3 (0.91 g, 2 equiv mol) in dioxane (10 ml)–MeOH (10 ml) was stirred at room temperature for 40 min. The mixture was partitioned between AcOEt and H_2O, and the organic layer was washed with 2M HCl and then dried over anhydrous Na_2SO_4. After evaporation of the solvent, the residue was hydrogenated at room temperature overnight in the presence of catalytic Pd–C (10%) in dioxane (20 ml)–AcOH (20 ml) to afford the methyl ester (**9**) (0.97 g): mp 148—149 °C from hexane–AcOEt; IR (film) 3300, 1730, 1700 sh., 1650, 1590, and 1550 cm^{-1}; ^{1}H NMR ($CDCl_3$) δ=3.85 (3H, s), 3.88(3H, s), 3.92(2H, s), and 7.42(1H, s); Found: *m/z* 396.8984. Calcd for $C_{11}H_{11}NO_5{}^{79}Br^{81}Br$: M, 396.9005.

N,N'-Bis[3-(3,5-dibromo-2-hydroxy-4-methoxyphenyl)-2-hydroxyiminopropionyl]-1,4-butanediamine (8). A mixture of **6** (2.76 g, 4 mmol) and 1,4-butanediamine (0.16 ml, 1.6 mmol) was kept at room temperature for 6 d, and then heated at 60 °C for 6 h. The resulted syrup was passed through a silica-gel column (20 g) using hexane–AcOEt (2:1) as eluant to afford the desired amide (1.63 g): mp 108—110 °C from hexane–AcOEt. A 857 mg portion of the product was submitted to hydrogenolysis in the presence of catalytic Pd–C (10%) in dioxane (40 ml)–AcOH (40 ml) at room temperature for 3 d to yield **8** (564 mg): mp 189—190 °C from ether–acetone [lit,[4] mp 188.5—189.5 °C].

TTFA Oxidation of 9. To a solution of TTFA (1.33 g, 2.4 mmol) in TFA (30 ml) was added the ester (**9**) (0.43 g, 1.1 mmol) in TFA (10 ml). The mixture was stirred at room temperature for 4 h, and then partitioned between $CHCl_3$ and H_2O. The organic layer was dried over anhydrous Na_2SO_4 and evaporated under reduced pressure to give a brownish residue, which was further separated by preparative TLC using hexane–AcOEt (2:1) to afford **10** (81 mg), **11** (114 mg), and **12** (12 mg), respectively. The physical data of these products are as follows: **10**: mp 141.5—143 °C from hexane–AcOEt; IR (film) 1720 sh., 1600, 1575, and 1550 cm^{-1};

^{1}H NMR (acetone-d_6) δ=3.97(6H, s), 7.70(1H, s), and 8.07(1H, s); Found: m/z 363.8763. Calcd for $C_{11}H_8O_4{}^{79}Br^{81}Br$: M, 363.8768. **11** as a colorless oil: IR (film) 1710, 1670, 1585, and 1530 cm^{-1}; ^{1}H NMR ($CDCl_3$) δ=3.27(1H, d, J=18Hz), 3.65(1H, d, J=18Hz), 3.93(3H, s), 4.20(3H, s), and 6.78(1H, s); Found: m/z 394.8809. Calcd for $C_{11}H_9NO_5{}^{79}Br^{81}Br$: M, 394.8826. **12** as a colorless oil: IR (film) 3300, 1725, 1680, 1650 sh., 1595, and 1555 cm^{-1}: ^{1}H NMR ($CDCl_3$) δ=3.10(1H, d, J=18Hz), 3.57(1H, d, J=18Hz), 3.80(3H, s), 3.83(3H, s), 3.90(3H, s), 3.8—3.9(2H, overlapped with MeO signals), 4.32(3H, s), 4.92(1H, s), and 7.50(1H, s); Found: m/z 712. Calcd for $C_{22}H_{19}N_2O_{10}{}^{79}Br^{81}Br$: M, 712. The molecular ion peak at m/z 712 has not been detected by high resolution mass spectrum, but observed in quite low intensity on measurement of its normal mass spectrum.

Reduction of 11 with Zinc Borohydride. The dienone (**11**) (103 mg) in CH_2Cl_2 (3 ml) was treated, at room temperature for 7 min, with excess $Zn(BH_4)_2$ in ether (2 ml), and then the mixture was quenched as usual to give a crude product, which was separated by preparative TLC using hexane–AcOEt (5:1) to afford **13a** (41 mg) and **14a** (30 mg). Their physical data are as follows: **13a** as a syrup: IR (film) 3470, 1730, 1620, 1595, and 1575 cm^{-1}; Found: m/z 394.8987. Calcd for $C_{11}H_{11}NO_5{}^{79}Br_2$: M, 394.9002. **14a** as a syrup: IR (film) 3450, 1725, 1630, 1590, and 1580 cm^{-1}; Found: m/z 396.8979. Calcd for $C_{11}H_{11}NO_5{}^{79}Br^{81}Br$: M 396.8983.

Synthesis of Aerothionin (1). A mixture of **14a** (19 mg, 0.05 mmol) and 1,4-butanediamine (2 µl, 0.02 mmol) was allowed to stand at room temperature overnight. Direct separation of the mixture by preparative TLC [benzene–acetone (5:1)] afforded aerothionin (**1**) (3 mg, 18% yield based on 1,4-butanediamine) and unreacted **14a** (7.2 mg). The IR and ^{1}H NMR spectra of the synthetic compound (**1**) were completely identical with those of an authentic sample, and the both aspects in HPLC (retention time, 7 min) were indistinguishable.

Synthesis of Homoaerothionin (2). The ester (**14a**) (8 mg, 0.02 mmol) was treated with 1,5-pentanediamine (1 µl, 0.009 mmol) according to essentially the same procedure as described above to yield homoaerothionin (**2**) (0.3 mg, 4.4%) and unreacted **14a** (7.5 mg). The IR, ^{1}H NMR, and HPLC (retention time, 6.5 min) of the product were identical with those of an authentic sample.

Synthesis of Aerophobin-1 (3). A mixture of **14a** (4.5 mg, 0.01 mmol) and histamine (12.5 mg, 0.1 mmol) in MeOH (0.1 ml)–dioxane (0.1 ml) was kept at room temperature overnight, and then directly purified by preparative TLC using $CHCl_3$–MeOH (3:1) to afford aerophobin-1 (**3**) (4.4 mg, 82%) (IR and ^{1}H NMR spectra).[5] Further acetylation of the synthetic compound (**3**) was carried out using Ac_2O–pyridine (1:1) as usual to afford the corresponding *O*-acetyl derivative, whose spectral data were superimposable with those of an authentic sample.

Syntheses of 13b and 14b. A mixture of **6** (1.06 g) and methylamine (40% aq solution, 1.5 ml) in THF (10 ml) was kept at room temperature for 13 h. The resulted mixture was acidified with 2M HCl, and then partitioned between AcOEt and H_2O. The organic layer was washed with aq $NaHCO_3$ and dried over anhydrous Na_2SO_4. After removal of the solvent under reduced pressure, the crystalline residue was recrystallized from hexane–AcOEt to give the corresponding amide (0.6 g, 65%): mp 112—113 °C. In the next step, a 544 mg portion of the amide was hydrogenated at room temperature for 8 h in dioxane (15 ml)–AcOH (15 ml) in the presence of catalytic Pd–C (10%) to afford the hydroxy derivative (272 mg, 73%): mp 143—145 °C from hexane–AcOEt. According to essentially the same procedure as described in **9** the hydroxy amide (450 mg, 1.1 mmol) was oxidized with TTFA (1.26 g, 2.3 mmol) in TFA to give the spiroisoxazoline derivative [41 mg, 9.2% (mp (dec)<170 °C)] as well as the benzofuran (14 mg, 3.4%) and the dimer (98 mg, 24%).

To a solution of the spiroisoxazoline derivative (16 mg) in CH_2Cl_2 was added excess $Zn(BH_4)_2$. After stirring at room temperature for 1.5 h, the reaction mixture was quenched by usual manner. The crude product was separated by preparative TLC using hexane–AcOEt (1:1) to give **13b** (4.6 mg, 29%) and **14b** (4.2 mg, 27%), the physical data of which were shown below: **13b**: mp 182—185 °C (dec.) from hexane–AcOEt; IR (film) 3350, 1640, 1600, 1565, and 1545 cm^{-1}; Found: m/z 393.9172. Calcd for $C_{11}H_{12}N_2O_4{}^{79}Br_2$: M, 393.9164. **14b** as a syrup: IR (film) 3360, 1660, 1630 sh., 1595, 1580, and 1550 cm^{-1}; Found: m/z 395.9141. Calcd for $C_{11}H_{12}N_2O_4{}^{79}Br^{81}Br$: M, 395.9142.

The authors wish to thank Prof. Forrester (University of Aberdeen) for providing them with authentic samples of aerothionin, homoaerothionin and *cis-cis* aerothionin, and also Dr. G. Sodano (Instituto per la Chimica di Molecole di Intersse Biologico del C.N.R.) for providing them with the ^{1}H NMR spectra of aerophobin-1 and its acetate in addition to an authentic sample of the latter. This research has been supported in part by grants from the Takeda Science Foundation as well as from the Kawakami Memorial Foundation, to which grateful acknowledgment is made.

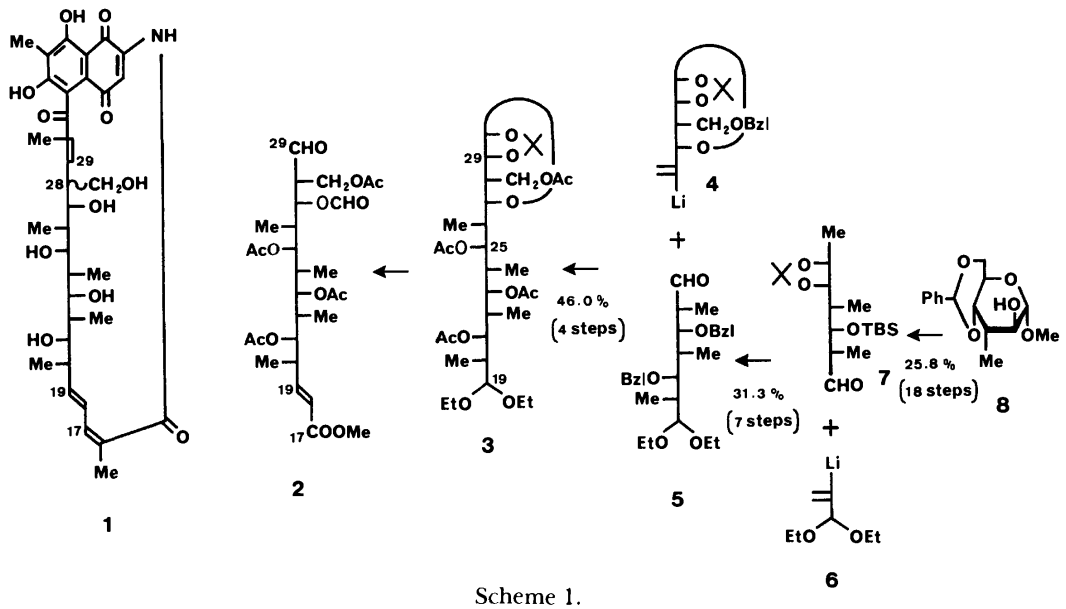
Synthetic Studies of Rifamycins. VIII.[1] An Improved Practical Synthesis of the Ansa-chain Compounds for the Rifamycin W Synthesis

Masaya NAKATA, Kazunobu TOSHIMA, Toshiyuki KAI, and Mitsuhiro KINOSHITA*
Department of Applied Chemistry, Faculty of Science and Technology, Keio University, Hiyoshi, Kohoku-ku, Yokohama 223
(Received July 10, 1985)

The improved practical synthesis of 6,8,10-tri-*O*-acetyl-3-*C*-(acetoxymethyl)-3,5,7,9,11-pentadeoxy-1,2-*O*-isopropylidene-5,7,9,11-tetra-*C*-methyl-L-*erythro*-D-*altro*-β-L-*talo*-dodecodialdofuranose-(1,4) 12-(diethyl acetal) (**3**), a useful synthetic segment for the rifamycin W ansa-chain, is described. The key intermediate, 3-*O*-benzyl-2,4,7-trideoxy-5,6-*O*-isopropylidene-2,4-di-*C*-methyl-*aldehydo*-D-*glycero*-D-*allo*-heptose (**22**), was synthesized in a 29.4% yield from methyl 4,6-*O*-benzylidene-3-deoxy-3-*C*-methyl-α-D-altropyranoside (**8**) in 15 steps. The coupling of **22** with the lithium reagent prepared from butyllithium and 3-*C*-(benzyloxymethyl)-3,5,6-trideoxy-5-iodo-1,2-*O*-isopropylidene-α-D-ribo-5-hexenofuranose afforded only the "Cram" product **24** in a 61% yield. The homogeneous hydrogenation of **24** with [$RhCl(Ph_3P)_3$] gave 8-*O*-benzyl-3-*C*-(benzyloxymethyl)-3,5,7,9,12-pentadeoxy-1,2:5,6-di-*O*-isopropylidene-5,7,9-tri-*C*-methyl-D-*erythro*-D-*altro*-L-*talo*-dodecofuranose-(1,4) (**25**) and its C-5 epimer in 95 and 3.8% yields respectively. 6,8-Di-*O*-benzyl-3-*C*-(benzyloxymethyl)-3,5,7,9-tetradeoxy-1,2-*O*-isopropylidene-5,7,9-tri-*C*-methyl-D-*altro*-β-L-*talo*-decodialdofuranose-(1,4), derived from **25** in a 91% yield, was subjected to coupling with 3,3-diethoxy-2-lithio-1-propene to afford about 1.7:1 excess of the "Cram" product (**30**, 59% yield). The conversion of **30** into **3** was accomplished by the sequence of reactions involving homogeneous hydrogenation, debenzylation, and acetylation in a 75% yield. The 24-step synthesis of **3** from **8** was achieved in a 7% overall yield.

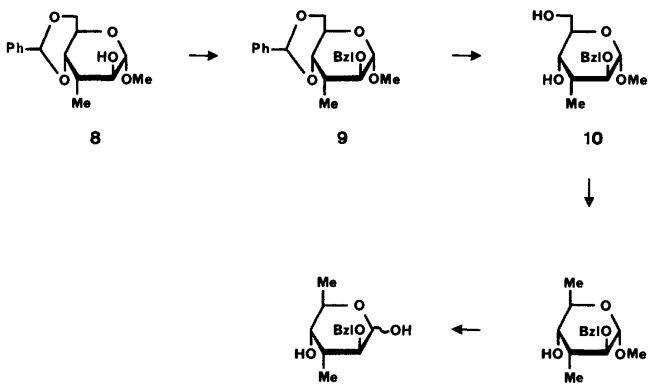
For the purpose of synthesizing practically the optically active natural macrolides such as rifamycins and erythronolides which contain a long chain consisting of many consecutive chiral carbon atoms, it is indispensable to realize the highly diastereoselective connections between the selected chiral carbon chain segments which can be effectively synthesized from appropriate chiral compounds, but on the other hand each resulting coupling product must naturally be transformed into each target compound as effectively as possible. In the studies directed toward the total synthesis of rifamycin W (**1**), the selected ansa-chain compound **2**[2] corresponding to the C-17 – C-29 portion of **1** was first synthesized from the sugar derivative **8** in our laboratories. In this synthesis, the precursor **3** of **2** was prepared in good yield from **5** by the sequence of reactions involving the highly diastereoselective coupling of **4** and **5** followed by the stereospesific homogeneous hydrogenation of the major "Cram" product and two successive transformations. However, the 7-steps synthesis of **5** from **7**, involving the coupling of **6** with **7** followed by the stereospecific homogeneous hydrogenation of the desilylated compound of the major "Cram" product and four successive transformations, was not satisfactory because of the low overall yield caused by the requirement of many steps of transformation not directly neccessary for the connection of carbon chains in the synthetic route. Moreover, the long way (18 steps) to **7** from **8** was also undesirable for the large scale preparation of **7**. In our recent synthetic studies of **3** directed at the total synthesis of rifamycin W, it was found that a modified synthetic route which was shorter by five steps than the old route effected a 2-fold improvement in the overall



Scheme 1.

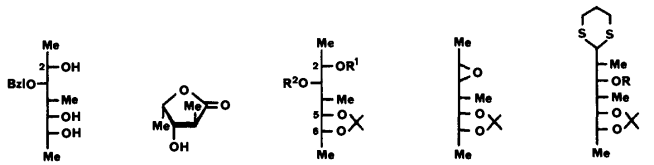
yield of **3** from the starting material **8** with no sacrifice in the stereoselectivities of the peculiar carbon chain connections which we have termed a "two stage coupling," and were effectively used in the old route. In this paper, we wish to report the improved practical synthesis of **3**, the most important key intermediate for the rifamycin W ansa-chain synthesis.

The starting material, methyl 4,6-*O*-benzylidene-3-deoxy-3-*C*-methyl-α-D-altropyranoside (**8**)[3,4] was *O*-benzylated and the resulting **9** was treated with 75% dichloroacetic acid (DCA) to afford the crystalline derivative **10**. The selective 6-*O*-mesylation of **10** followed by reduction with lithium aluminium hydride gave **11**. The acetolysis of **11** followed by the hydrolysis yielded **12** in a 71% overall yield from **8**.



Scheme 2.

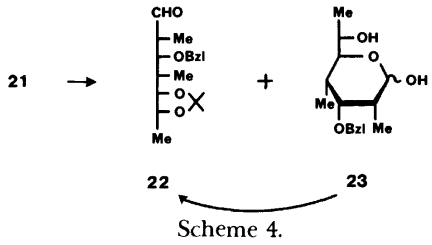
The Grignard reaction of **12** with 10 equimolar amounts of methylmagnesium iodide in ether gave **13** in an 86% yield as a sole product. The (2S)-configuration of **13** was confirmed by conversion to the known 1,4-lactone **14**[5] by the sequence of reactions involving periodate-oxidation, debenzylation, and bromine-oxidation. The isopropylidenation of **13** with 2,2-dimethoxypropane (DMP) in acetone containing a catalytic amounts of concd sulfuric acid gave the 5,6-isopropylidene derivative **15** without the



Scheme 3.

formation of the undesired 2,5-isopropylidene derivative.[2] Subsequent acetylation of **15** gave the crystalline derivative **16** in an 89% yield from **13**. The hydrogenolysis of **16** was reproducibly carried out with an atmospheric pressure of hydrogen and a freshly prepared palladium black in a 9:1 mixture of ethyl acetate–methanol. The resulting debenzylated product was immediately mesylated to afford **17** in a 95% yield. The mesylate **17** was then treated with sodium methoxide in chloroform to afford the epoxide **18** in an 81% yield after distillation. The nucleophilic addition of 2-lithio-1,3-dithiane to the *cis*-epoxide **18** gave regiospecifically only the desired C-6-adduct **19** in a 93% yield. The structure of **19** could be determined by the coupling feature (double doublet) of the acetoxymethine proton in the ^{1}H-NMR spectrum of its acetate **20**. The reason for this high regioselectivity in ring-opening of the *cis*-epoxide has been reasonably explained in the preceding paper.[2]

The benzylation of **19** provided, in a 91% yield, the benzyl ether **21**, whose dithioacetal group was cleaved with a 1:1 mixture of mercury(II) chloride and red mercury(II) oxide to generate the aldehyde **22** in a 65% yield together with the 27% yield of the deisopropylidenation heptopyranose **23**. The latter could

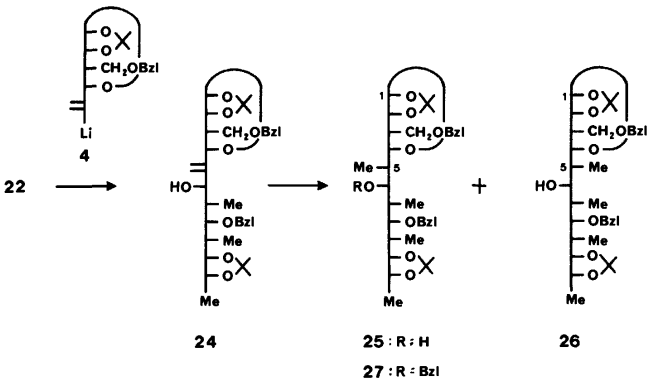


Scheme 4.

be converted to the former, in a 67% yield, by a sequence of reactions involving sodium borohydride reduction, isopropylidenation, and Swern oxidation, therefore the yield of **22** from **21** amounted to an 83% (or to a 29.4% overall yield from**8**).

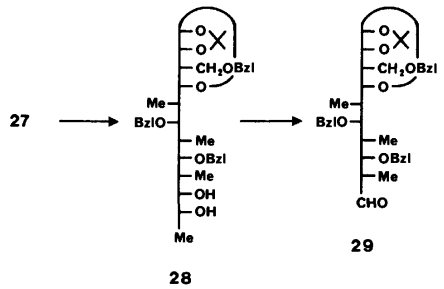
With the aldehyde **22** corresponding to the central portion of the rifamycin W ansa-chain now in hand, the next stage was elaboration of it to the key intermediate **3** using our "two stage coupling." The coupling of **22** with the lithium reagent **4**, prepared from the corresponding iodide[2] (3 equiv) and butyllithium (2.8 equiv) in ether at −95—−90 °C, was carried out in ether at −95—−90 °C to afford a sole coupling product **24** in a 61% yield based on **22**. The homogeneous hydrogenation of **24** with 0.25 equimolar amounts of chlorotris(triphenylphosphine)rhodium(I) in benzene under an atmospheric pressure of hydrogen gave the hydrogenated products **25** and **26** in 95 and 3.8% yields respectively. We could confidently predict the structures of **24**, **25**, and **26** as depicted in Scheme 5 by the fact that in the old synthetic route (Scheme 1)[2] the "two stage coupling" of **4** and **5** gave predominantly the precursor of **3**. This prediction was confirmed in the later stage of this ansa-chain synthesis.

The benzylation of **25** followed by the selective deisopropylidenation of the resulting benzyl ether **27** afforded **28**, which was subjected to the periodate-oxidation to give the aldehyde **29** in a 91% yield from



Scheme 5.

25. The coupling of **29** with the lithium reagent **6**, prepared from 3 equiv of 2-bromo-3,3-diethoxy-1-propene[2,6] and 2.5 equiv of butyllithium in THF at −110—−108°C, was performed in THF at −110—−108°C to afford, after column-chromatographic separation, **30** and **31** in 59 and 35% yields respectively based on **29**. The homogeneous hydrogenation of the



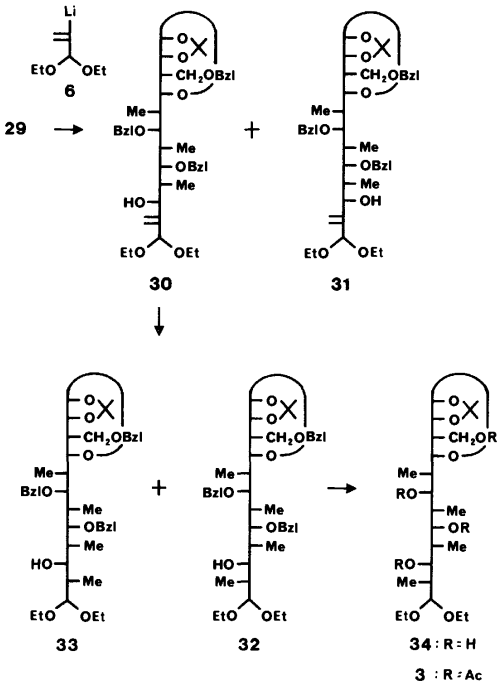
Scheme 6.

major product **30** with 0.25 equimolar amounts of rhodium catalyst gave **32** and its C-11 epimer **33** in 83 and 3.6% yields respectively. The major product **32** was debenzylated with lithium in liquid ammonia to afford **34**, which was acetylated with acetic anhydride and 4-dimethylaminopyridine (DMAP) in ethyl acetate to give the target key intermediate **3** in a 90% yield from **32**. The ^{1}H-NMR spectrum, R_f-value on TLC, and mp of **3** were identical with those of the authentic sample.[2] This result established the structures of **30—33**, together with those of the first "two stage coupling" products **24—26**. The overall yield of **3** from **8** (24 steps) thus amounted to a 7%, whereas the 29 steps overall yield of **3** from **8** in the old route was 3.5%.

Having achieved improved practical synthesis of **3**, we now undertake the total synthesis of rifamycin W.

Experimental

Melting points were determined on a micro hot-stage Yanaco MP-S3 and were uncorrected. The specific rotations were measured with a Carl Zeiss or JASCO DIP-360 photoelectric polarimeter in chloroform unless stated otherwise. IR spectra were recorded on a Hitachi Perkin-



Scheme 7.

Elmer 225 spectrometer and ^{1}H-NMR spectra on either a Varian EM-390 or a Bruker WM 250 spectrometer in $CDCl_3$ using TMS as internal standard. Mass spectra were recorded on Hitachi M-80 mass spectrometer. Silica-gel TLC and column chromatography were performed on Merck TLC 60F-254 and Wakogel C-200, respectively. In general, evaporation of solvents was carried out under reduced pressure below 35°C.

Methyl 2-O-Benzyl-4,6-O-benzylidene-3-deoxy-3-C-methyl-α-D-altropyranoside (9). To an ice-cold stirred solution of **8** (31.1 g, 111 mmol) in dry DMF (218 ml), sodium hydride (5.30 g, 221 mmol) was added portionwise. The mixture was stirred at room temperature for 1 h and then ice-cooled. Benzyl bromide (26.4 ml, 221 mmol) was added dropwise and the resulting mixture was stirred at room temperature for 2 h. The reaction mixture was poured into ice water (600 ml) and the resulting mixture was extracted with ethyl acetate (300 ml×3). The extracts were washed with a saturated aqueous NaCl solution, dried, and evaporated. The residue was chromatographed on silica gel (1.5 kg) with 40:1 benzene–ethyl acetate to afford **9** (40.1 g, 98%) as a colorless syrup: R_f=0.72 (5:1 benzene–ethyl acetate); $[\alpha]_D^{27}$ −24° (*c* 2.10); ^{1}H-NMR δ=1.17 (3H, d, 3-Me, J=7.0 Hz), 2.30—2.70 (1H, m, H-3), 3.33 (3H, s, OMe), 3.60—4.30 (5H, m, H-2, 4, 5,6, and 6′), 4.54 (2H, s, $OC\underline{H}_2Ph$), 4.62 (1H, s, H-1), 5.55 (1H, s, $C\underline{H}Ph$), and 7.38 (10H, s, 2×Ph).

Found: C, 71.38; H, 7.05%. Calcd for $C_{22}H_{26}O_5$: C, 71.33; H, 7.07%.

Methyl 2-O-Benzyl-3-deoxy-3-C-methyl-α-D-altropyranoside (10). To an ice-cold sample of **9** (35.0 g, 94.5 mmol) was added ice-cold 75% aqueous dichloroacetic acid (350 ml). After being stirred at 0°C for 0.5 h, the reaction mixture was poured into a cold saturated aqueous $NaHCO_3$ solution (3 l). The mixture was extracted with chloroform (1 l×3) and the extracts were washed with a saturated aqueous NaCl solution (1 l), dried, and evaporated. The crystalline residue was washed with cold hexane to remove benzalde-

hyde and a practically pure sample of **10** (22.1 g, 83%) was obtained: mp 68.0—69.0 °C (colorless plates from acetone); R_f=0.09 (3:1 benzene–ethyl acetate); $[\alpha]_D^{23}$ +42° (*c* 1.38); ^{1}H-NMR δ=1.09 (3H, d, 3-Me, J=7.0 Hz), 1.20—2.40 (3H, m, H-3 and 2×OH), 3.33 (3H, s, OMe), 3.45—4.30 (5H, m, H-2, 4, 5, 6, and 6′), 4.51 (2H, s, OC$\underline{H}_2$Ph), 4.61 (1H, s, H-1), and 7.35 (5H, s, Ph).

Found: C, 63.76; H, 7.99%. Calcd for $C_{15}H_{22}O_5$: C, 63.81; H, 7.85%.

Méthyl 2-O-Benzyl-3,6-dideoxy-3-C-methyl-α-D-altropyranoside (11). To an ice-cold solution of **10** (48.6 g, 172 mmol) in dry pyridine (486 ml) was added mesyl chloride (14.6 ml, 189 mmol) over a period of 5 min. After being stirred at 0 °C for 1 h, the reaction mixture was poured into cold water (450 ml) and the resulting mixture was extracted with ethyl acetate (400 ml×3). The extracts were evaporated and the residue was resolved in ethyl acetate (250 ml). The solution was washed successively with saturated aqueous $KHSO_4$ (100 ml), $NaHCO_3$ (100 ml), and NaCl (100 ml) solutions, dried, and evaporated. To an ice-cold stirred solution of this crude syrup (62.0 g) of the 6-mesylate in dry ether (930 ml), $LiAlH_4$ (14.4 g, 379 mmol) was added portionwise over a period of 10 min. After being stirred at room temperature for 2 h, $Na_2SO_4 \cdot 10H_2O$ (122 g, 379 mmol) was added to the reaction mixture, and the resulting insoluble matter was filtered and the filter cake was washed thoroughly with chloroform. The combined filtrate and washings were evaporated and the residue was chromatographed on silica gel (1.5 kg) with 3:1 benzene–ethyl acetate to afford **11** (41.9 g, 91%) as a colorless syrup: R_f=0.42 (2:1 benzene–ethyl acetate); $[\alpha]_D^{30}$ +15° (*c* 1.37); ^{1}H-NMR δ=1.10 (3H, d, 3-Me, J=7.5 Hz), 1.27 (3H, d, 5-Me, $J_{5,6}$=6.3 Hz), 1.91 (1H, d, OH, J=7.5 Hz), 1.90—2.30 (1H, m, H-3), 3.31 (1H, dd, H-2, $J_{1,2}$=3.0 Hz, $J_{2,3}$=6.5 Hz), 3.40 (3H, s, OMe), 3.59 (1H, dd after addition of D_2O, H-4, $J_{3,4}$=3.8 Hz, $J_{4,5}$=6.3 Hz), 3.89 (1H, dq, H-5, $J_{4,5}$=6.3 Hz), 4.55 and 4.67 (each 1H, ABq, OC$\underline{H}_2$Ph, J_{gem}=12.0 Hz), 4.58 (1H, d, H-1, $J_{1,2}$=3.0 Hz), and 7.34 (5H, s, Ph).

Found: C, 67.65; H, 8.22%. Calcd for $C_{15}H_{22}O_4$: C, 67.64; H, 8.33%.

2-O-Benzyl-3,6-dideoxy-3-C-methyl-D-altropyranose (12). To an ice-cold stirred solution of **11** (10.0 g, 37.5 mmol) in acetic anhydride (300 ml), concd H_2SO_4 (0.30 ml) was added. After being stirred at 0 °C for 10 min, the reaction mixture was poured into a cold saturated aqueous $NaHCO_3$ solution (250 ml) and the resulting mixture was extracted with ethyl acetate (200 ml×1+100 ml×1). The extracts were washed with a saturated aqueous NaCl solution (150 ml), dried, and evaporated to give a yellow syrup (11.4 g). To a solution of this syrup in methanol (113 ml) was added dropwise 1 M† aqueous NaOH solution (113 ml) and the mixture was kept at room temperature for 3.5 h. The reaction mixture was then neutralized (pH 7) with CO_2 gas and evaporated. The residue was triturated with acetone and the insoluble matter was removed by filtration and the filter cake was washed with acetone. The combined filtrate and washings were evaporated and the residue was chromatographed on silica gel (260 g) with 1:2 toluene–ethyl acetate to afford **12** (9.06 g, 96%) as a colorless syrup: R_f=0.41 (1:2 toluene–ethyl acetate); $[\alpha]_D^{18}$ −29° (*c* 1.19, MeOH, after 2d); ^{1}H-NMR δ=1.10—1.30 (6H, m, 2×Me), 2.15—2.55 (1H, m, H-3), 2.60 (0.6H, d, α-OH, J=3.0 Hz), 3.19 (0.4H, br, β-OH-4), 3.44 (0.6H, d. α-OH, J=3.0 Hz), 3.55—4.20 (3H, m, H-2, 4, and 5), 4.04 (0.4H, d, β-OH-1, J=6.0 Hz), 4.55 and 4.65 (ABq, OC$\underline{H}_2$Ph, J_{gem}=12.0 Hz), 4.56 (s, OC$\underline{H}_2$Ph), 5.22 (0.4H, dd, β-H-1, $J_{1,2}$=4.5 Hz), 5.41 (0.6H, d, α-H-1, $J_{1,2}$=0 Hz), and 7.34 and 7.37 (each s, Ph).

3-O-Benzyl-1,4,7-trideoxy-4-C-methyl-D-glycero-D-glucoheptitol (13). A solution of **12** (8.70 g, 34.5 mmol) in dry ether (25 ml) was added dropwise to an ice-cold stirred ether solution of methylmagnesium iodide [prepared from magnesium turnings (8.39 g, 345 mmol) and methyl iodide (21.5 ml, 345 mmol) in dry ether (84 ml)]. After being stirred at 35 °C for 20 h, a saturated aqueous NH_4Cl solution was carefully added to the ice-cold reaction mixture. The organic layer was separated and the aqueous layer was extracted with chloroform (300 ml×3). The combined organic layers were dried and evaporated to a syrup (9.52 g), which was chromatographed on silica gel (463 g) with 1:5 toluene–ethyl acetate to afford **13** (8.00 g, 86%) as a colorless syrup and unchanged **12** (0.72 g, 8.3%). **13**: R_f=0.33 (1:5 toluene–ethyl acetate); $[\alpha]_D^{17}$ +3°, $[\alpha]_{365}^{17}$ +18° (*c* 3.81); ^{1}H-NMR δ=0.90 (3H, d, Me, J=7.5 Hz), 1.14 (3H, d, Me, J=6.0 Hz), 1.21 (3H, d, Me, J=6.0 Hz), 1.70—2.00 (1H, m, H-4), 2.10—2.40, 2.40—2.70, and 2.90—3.15 (each 1H, each br, 3×OH), 3.55—4.15 (4H, m, H-2, 3, 5, and 6), 4.70 and 4.79 (each 1H, ABq, OC$\underline{H}_2$Ph, J_{gem}=12.0 Hz), and 7.40 (5H, s, Ph).

(2S,3S,4S)-3-Hydroxy-2-methyl-4-pentanolide (14). A solution of $NaIO_4$ (82 mg, 0.38 mmol) in water (0.8 ml) was added to a solution of **13** (68.6 mg, 0.256 mmol) in acetone (0.69 ml) under ice-cooling. After being stirred for 20 min, the mixture was diluted with water and extracted with ether. The extracts were washed with a saturated aqueous NaCl solution, dried, and evaporated. The residual syrup (49.4 mg) was hydrogenolyzed in *t*-BuOH (0.98 ml) with palladium black at 28 °C for 40 min under bubbling with H_2 gas. The filtered solution was evaporated to a colorless syrup (29.2 mg), which was then oxidized with bromide (0.0148 ml, 0.287 mmol) in 50% aqueous dioxane (0.29 ml) at room temperature for 7.5 h. The reaction mixture was extracted with ethyl acetate, and the extracts were washed with saturated aqueous $Na_2S_2O_3$ and NaCl solutions, dried, and evaporated. The residue was chromatographed on silica gel (2 g) with 1:5 toluene–ethyl acetate to give **14** (13.8 mg, 46% from **13**) as a colorless oil. The ^{1}H-NMR spectrum of **14** was identical with that of the authentic sample.[5]

3-O-Benzyl-1,4,7-trideoxy-5,6-O-isopropylidene-4-C-methyl-D-glycero-D-gluco-heptitol (15). To an ice-cold stirred solution of **13** (8.00 g, 29.8 mmol) and DMP (7.30 ml, 59.6 mmol) in dry acetone (160 ml) was added dropwise concd H_2SO_4 (0.008 ml). After being stirred at 0 °C for 0.5 h, the reaction mixture was neutralized with solid Na_2CO_3. The insoluble matter was filtered and washed with acetone. The combined filtrate and washings were evaporated to afford a crude sample of **15** (8.30 g, 90%) as colorless needles. This sample was pure enough for the next step without further purification. An analytical sample was obtained after silica-gel column chromatography with 20:1 chloroform–acetone: mp 53—54 °C; R_f=0.88 (1:5 toluene–ethyl acetate); $[\alpha]_D^{15}$ +28° (*c* 0.79); ^{1}H-NMR δ=0.86 (3H, d, Me, J=6.6 Hz), 1.11 (3H, d,

†1 M=1 mol dm^{-3}.

Me, J=6.0 Hz), 1.16 (3H, d, Me, J=6.0 Hz), 1.30 and 1.45 (each 3H, each s, CMe_2), 1.60—2.00 (1H, m, H-4), 2.47 (1H, d, OH, J=3.0 Hz), 3.61 (1H, dd, H-3, $J_{3,4}$=2.0 Hz, $J_{2,3}$=7.5 Hz), 3.77 (1H, ddd, H-2, $J_{1,2}$=6.0 Hz), 4.06 (1H, dd, H-5, $J_{5,6}$=6.0 Hz, $J_{4,5}$=10.5 Hz), 4.25 (1H, dq, H-6, $J_{6,7}$=6.0 Hz), 4.71 and 4.79 (each 1H, ABq, $OC\underline{H}_2Ph$, J_{gem}=11.7 Hz), and 7.37 (5H, s, Ph).

2-O-*Acetyl-1,4,7-trideoxy-5,6*-O-*isopropylidene-3*-O-*mesyl-4*-C-*methyl*-D-glycero-D-gluco-*heptitol* (**17**). A mixture of **16** (998 mg, 2.85 mmol), palladium black (freshly prepared from 1 g of palladium(II) chloride), ethyl acetate (9 ml), and methanol (1 ml) was vigorously stirred at 25 °C for 3.5 h under bubbling with H_2 gas, and the suspension was filtered. The filtrate was evaporated to a colorless syrup (741 mg, 100%), which was mesylated with mesyl chloride (0.661 ml, 8.54 mmol) in dry pyridine (7.4 ml) at room temperature for 2 h. The reaction mixture was poured into cold water (7.4 ml) and the resulting mixture was extracted with ethyl acetate (10 ml×3). The extracts were washed successively with saturated aqueous $KHSO_4$ (6 ml×5), $NaHCO_3$ (6 ml), and NaCl (6 ml) solutions, dried, and evaporated. The residue was chromatographed on silica gel (50 g) with 3:1 toluene-ethyl acetate to afford **17** (918 mg, 95%) as colorless crystals: mp 88—90 °C (needles from hexane); R_f=0.51 (3:2 toluene-ethyl acetate); $[\alpha]_D^{16}$ 0°, $[\alpha]_{365}^{16}$ −32° (c 1.48); IR (KBr) 1738 cm^{-1}; ^{1}H-NMR δ=0.93 (3H, d, Me, J=7.2 Hz), 1.14 (3H, d, Me, J=6.0 Hz), 1.27 (3H, d, Me, J=6.0 Hz), 1.33 and 1.44 (each 3H, each s, CMe_2), 1.75—2.10 (1H, m, H-4), 2.09 (3H, s, OAc), 3.04 (3H, s, OMs), 3.94 (1H, dd, H-5, $J_{5,6}$=6.0 Hz, $J_{4,5}$=10.5 Hz), 4.26 (1H, dq, H-6, $J_{6,7}$=6.0 Hz), and 5.00—5.40 (2H, m, H-2 and 3).

3-O-*Benzyl-2,4,7-trideoxy-5,6*-O-*isopropylidene-2,4-di*-C-*methyl*-D-glycero-D-allo-*heptose Trimethylene Dithioacetal* (**21**). By the procedure described in the preparation of **9**, a sample of **19** (305 mg, 0.952 mmol) afforded, after silica-gel (19.5 g) column chromatography with 50:1 toluene-ethyl acetate, **21** (357 mg, 91%) as a pale yellow syrup. An analytical sample was obtained after silica-gel column chromatography with 50:1 toluene-ethyl acetate: R_f=0.70 (5:1 toluene-ethyl acetate); $[\alpha]_D^{15}$ −20° (c 1.02); ^{1}H-NMR δ=0.96, 1.09, and 1.12 (each 3H, each s, 3×Me, J=7.2, 6.0, and 7.5 Hz), 1.30 and 1.43 (each 3H, each s, CMe_2), 1.55—3.00 (8H, m, H-2, 4, and $SCH_2CH_2CH_2S$), 3.70 (1H, dd, H-3, J=2.1 and 10.2 Hz), 4.00—4.30 (2H, m, H-5 and 6), 4.60 (1H, d, H-1, $J_{1,2}$=2.7 Hz), 4.74 (2H, s, $OC\underline{H}_2Ph$), and 7.20—7.45 (5H, m, Ph).

Found: C, 64.19; H, 8.18; S, 15.26%. Calcd for $C_{22}H_{34}O_3S_2$: C, 64.35; H, 8.35; S, 15.62%.

3-O-*Benzyl-2,4-7-trideoxy-5,6*-O-*isopropylidene-2,4-di*-C-*methyl-aldehydo*-D-glycero-D-allo-*heptose* (**22**) *and Deisopropylidenation Heptopyranose* **23**. To a mixture of **21** (233 mg, 0.567 mmol) and mercury(II) oxide (540 mg, 2.49 mmol) in

aqueous 80% acetone (16.3 ml) was added mercury(II) chloride (677 mg, 2.49 mmol) at room temperature with efficient stirring. The mixture was stirred at 60 °C for 10 min, cooled, and filtered with a Celite. The filter cake was washed with acetone, and then the filtrate and washings were combined. After the subsequent removal of the acetone by concentration, the aqueous residue was extracted with chloroform (10 ml×3) and the extracts were washed with an aqueous 10% KI solution (8 ml×2) and a saturated aqueous NaCl solution (8 ml), dried, and evaporated. The residue was chromatographed on silica gel (9.1 g) with 20:1 toluene–ethyl acetate to afford **22** (118 mg, 65%) as a colorless syrup: R_f= 0.48 (20:1 toluene–ethyl acetate); ^{1}H-NMR δ=0.91, 1.11, and 1.14 (each 3H, each d, 3×Me, J=6.6, 6.0, and 7.0 Hz), 1.28 and 1.42 (each 3H, each s, CMe_2), 2.00—2.40 (1H, m, H-4), 2.60—3.00 (1H, m, H-2), 3.90—4.20 (2H, m, H-3 and 5), 4.23 (1H, dq, H-6, $J_{5,6}$=$J_{6,7}$=6.0 Hz), 4.53 and 4.63 (each 1H, ABq, $OC\underline{H}_2Ph$, J=12.0 Hz), 7.34 (5H, s, Ph), and 9.83 (1H, d, H-1, $J_{1,2}$=3.0 Hz). The elution of the silica-gel column with ethyl acetate gave **23** (42.6 mg, 27%) as a colorless syrup: R_f=0.37 and 0.46 (10:1 chloroform–methanol); ^{1}H-NMR δ=0.90—1.30 (9H, m, 3×Me), 1.40—2.00 (2H, m, H-2 and 4), 2.40—2.80 and 3.30—3.60 (each 1H, each br, 2×OH), 3.50—4.20 (3H, m, H-3, 5, and 6), 4.64 (2H, s, $OC\underline{H}_2Ph$), 4.80—5.20 (1H, m, H-1), and 7.36 (5H, s, Ph).

*Transformation of **23** into **22**.* To a solution of **23** (50 mg, 0.18 mmol) in 95% ethanol (0.5 ml) was added $NaBH_4$ (13.5 mg, 0.357 mmol) and the mixture was stirred at room temperature for 24 h. The reaction mixture was neutralized with CO_2 gas and then evaporated. The residue was taken up with chroloform and an insoluble matter was filtered off. The filter cake was washed with chroloform and the combined filtrate and washings were evaporated. The residue (50.4 mg, 100%) was dissolved in dry DMF (0.5 ml) and to this were added DMP (0.044 ml, 0.36 mmol) and *dl*-10-camphorsulfonic acid (4.1 mg, 0.018 mmol). The mixture was stirred at room temperature for 3 h and poured into a cold solution of 0.1 M aqueous NaOH. The mixture was extracted with ethyl acetate and the extracts were washed with a saturated aqueous NaCl solution, dried, and evaporated. The residue was chromatographed on silica gel (3 g) with 3:1 toluene–ethyl acetate to afford an alcohol. DMSO (0.0271 ml) was added to a solution of oxalyl dichloride (0.0164 ml, 0.191 mmol) in dry dichloromethane (0.83 ml) cooled to −60 °C. After being stirred at −60 °C for 15 min, a solution of the above alcohol (41 mg) in dry dichloromethane (0.32 ml) was added to the mixture and the new mixture was stirred at −60 °C for 15 min. After being added triethylamine (0.0881 ml, 0.636 mmol), the mixture was stirred at −25 °C for 15 min. Ether (2 ml) and water (2 ml) were added and the two layers were separated. The aqueous layer was extracted with ether and the combined organic layers were washed with a saturated aqueous NaCl solution, dried, and evaporated. The residue was chromatographed on silica gel (2 g) with 20:1 toluene–ethyl acetate to afford a syrup (37 mg, 67% from **23**). The ^{1}H-NMR spectrum and TLC of this sample were identical of them of **22**.

*8-O-Benzyl-3-C-(benzyloxymethyl)-3,5,7,9,12-pentadeoxy-1,2:10,11-di-O-isopropylidene-7,9-di-C-methyl-5-methylene-*D-glycero-D-allo-L-talo-*dodecofuranose-(1,4) (**24**).* To a cooled (−90—−95 °C) solution of 3-*C*-(benzyloxymethyl)-3,5,6-trideoxy-5-iodo-1,2-*O*-isopropylidene-α-D-ribo-5-hexenofuranose[2] (0.451 g, 1.08 mmol) in dry ether (10 ml) was added 1.48 M butyllithium in hexane (0.68 ml, 1.01 mmol) over a period of 5 min under argon. After being stirred at the same temperature for 0.5 h, a solution of **22** (0.116 g, 0.361 mmol) in dry ether (0.23 ml) was added to the mixture over a period of 2 min, and stirring was continued at the same temperature for 20 min. To the reaction mixture was added a saturated aqueous NH_4Cl solution, and the separated aqueous layer was extracted with ether. The organic layers were combined, washed with a saturated aqueous NaCl solution, dried, and evaporated. The residual yellow syrup (0.553 g) was chromatographed on silica gel (83 g) with 5:1 toluene–ethyl acetate to afford **24** (0.170 g) contaminated with a small amount of impurity. This was again chromatographed on silica gel (17 g) with 2.5:1 hexane–ethyl acetate to afford a pure sample of **24** (0.134 g, 61%) as a colorless syrup: R_f=0.19 (5:1 toluene–ethyl acetate); $[\alpha]_D^{18}$ +36° (*c* 0.69); ^{1}H-NMR δ= 0.91, 0.97, and 1.11 (each 3H, each d, 3×CMe, J=6.5, 7.5, and 6.0 Hz), 1.28, 1.32, 1.41, and 1.47 (each 3H, each s, 2×CMe_2), 2.00—2.55 (3H, m, H-3, 7, and 9), 2.88 (1H, br s, OH), 3.40—4.90 (12H, m, H-2,4,6,8,10,11, $C\underline{H}_2OBzl$, and 2×$OC\underline{H}_2Ph$), 5.30 and 5.37 (each 1H, each br s, C=CH_2), 5.81 (1H, d, H-1, $J_{1,2}$=3.3 Hz), 7.33 and 7.36 (each 5H, each s, 2×Ph).

Found: C, 70.81; H, 8.15%. Calcd for $C_{36}H_{50}O_8$: C, 70.79; H, 8.25%.

*8-O-Benzyl-3-C-(benzyloxymethyl)-3,5,7,9,12-pentadeoxy-1,2:10,11-di-O-isopropylidene-5,7,9-tri-C-methyl-*D-erythro-D-altro-L-talo-*dodecofuranose-(1,4) (**25**) and* D-allo *Epimer (**26**).* A solution of **24** (0.123 g, 0.201 mmol) and chlorotris(triphenylphosphine)rhodium(I) (0.0465 g, 0.0502 mmol) in benzene (6.1 ml) was stirred under an atmospheric pressure of hydrogen at room temperature for 4.5 h. The reaction mixture was then evaporated and the residue was passed through Florisil (100—200 mesh, 2.5 g) with ether and again evaporated. The residue was chromatographed on silica gel (16 g) with 4:1 toluene–ethyl acetate to afford **25** (0.117 g, 95%) and **26** (0.0047 g, 3.8%) as colorless syrups: **25**, R_f=0.29 (4:1 hexane–acetone); $[\alpha]_D^{26}$ +38° (*c* 0.75); ^{1}H-NMR (250 MHz) δ=0.78 (3H, d, 5-Me, J=6.5 Hz), 0.97 (3H, d, 9-Me, J=6.8 Hz), 0.99 (3H, d, 7-Me, J=6.8 Hz), 1.14 (3H, d, 3×H-12, J=6.5 Hz), 1.28, 1.32, 1.43, and 1.49 (each 3H, each s, 2×CMe_2), 1.70—1.80 (1H, m, H-5), 2.00—2.15 (1H, m, H-7), 2.15—2.30 (2H, m, H-3 and 9), 3.26 (1H, d, OH, J=2.3 Hz), 3.46 (1H, dd, one of $C\underline{H}_2$OBzl, J=5.3 Hz, J_{gem}=9.8 Hz), 3.71 (1H, dd, H-8, $J_{7,8}$=3.8 Hz, $J_{8,9}$=5.0 Hz), 3.79 (1H, dd, one of $C\underline{H}_2OBzl$, J=7.8 Hz, J_{gem}=9.8 Hz), 3.94 (1H, dd, H-10, $J_{9,10}$=10.5 Hz, $J_{10,11}$=5.0 Hz), 3.99 (1H, d, H-6, $J_{5,6}$=9.0 Hz, $J_{6,7}$=0 Hz), 4.22 (1H, dq, H-11), 4.37 (1H, dd, H-4, $J_{3,4}$=11.3 Hz, $J_{4,5}$=1.3 Hz), 4.46 and 4.67 (each 1H, ABq, $OC\underline{H}_2Ph$, J=12.0 Hz), 4.52 (2H, s, $OC\underline{H}_2Ph$), 4.70 (dd, H-2, $J_{1,2}$=$J_{2,3}$=3.5 Hz), 5.76 (1H, d, H-1), and 7.20—7.40 (10 H, m, 2×Ph).

Found: C, 70.05; H, 8.42%. Calcd for $C_{36}H_{52}O_8$: C, 70.56; H, 8.55%.

26, R_f=0.20 (4:1 hexane–acetone); ^{1}H-NMR (250 MHz) δ=0.94 and 1.00 (each 3H, each d, 7- and 9-Me, J=7.3 and 7.5 Hz), 1.08 (3H, d, 5-Me, J=7.3 Hz), 1.12 (3H, d, 3×H-12, J=6.5 Hz), 1.28, 1.32, 1.42, and 1.47 (each 3H, each s, 2×CMe_2), 1.90—2.05 (1H, m, H-5), 2.05—2.30 (3H, m, H-3, 7, and 9), 2.55 (1H, d, OH, J=3.8 Hz), 3.51 (1H, dd, one of $C\underline{H}_2$ OBzl, J=5.3 Hz, J_{gem}=10.0 Hz), 3.62 (1H, dd, H-8, J=3.5 and 6.5 Hz), 3.68 (1H, dd, one of $C\underline{H}_2OBzl$, J=10.0 Hz, J_{gem}=10.0 Hz), 3.84 (1H, dd, H-4, $J_{3,4}$=10.0 Hz, $J_{4,5}$=3.8 Hz), 3.94 (1H, ddd, H-6, $J_{5,6}$=6.3 Hz, $J_{6,7}$=2.5 Hz), 4.03 (1H, dd, H-10, $J_{9,10}$=10.0 Hz, $J_{10,11}$=5.0 Hz), 4.17 (1H, dq, H-11), 4.39 (2H,

s, OCH$_2$Ph), 4.56 and 4.67 (each 1H, ABq, OCH$_2$Ph, J=11.3 Hz), 4.66 (1H, dd, H-2, $J_{1,2}$=$J_{2,3}$=4.0 Hz), 5.68 (1H, d, H-1), and 7.20—7.40 (10H, m, 2×Ph).

*6,8-Di-O-Benzyl-3-C-(benzyloxymethyl)-3,5,7,9,12-pentadeoxy-1,2:10,11-di-O-isopropylidene-5,7,9-tri-C-methyl-*D-erythro-D-altro-L-talo-*dodecofuranose-(1,4) (27).* By the procedure described in the preparation of **9**, a sample of **25** (1.05 g, 1.71 mmol) afforded, after silica-gel column chromatography with 15:1 toluene–ethyl acetate, **27** (1.16 g, 97%) as a colorless syrup: R_f=0.26 (15:1 toluene–ethyl acetate); $[\alpha]_D^{30}$ −10° (*c* 1.86); ^{1}H-NMR δ=0.85, 0.93, 0.98, and 1.07 (each 3H, each d, 4×CMe, J=7.5, 7.5, 7.0, and 6.0 Hz), 1.29, 1.33, and 1.45 (3H, 6H, and 3H, each s, 2×CMe$_2$), 1.70—2.40 (4H, m, H-3, 5, 7, and 9), 3.30—4.40 [7H, m, H-4, 6, 8, 10, 11, and CH$_2$OBzl, including dd of 3.42 (1H, J=6.0 and 9.0 Hz)], 4.51 (4H, s, 2×OCH$_2$Ph), 4.50 and 4.77 (each 1H, ABq, OCH$_2$Ph, J_{gem}=12.0 Hz), 4.69 (1H, dd, H-2, $J_{1,2}$=$J_{2,3}$=3.9 Hz), 5.80 (1H, d, H-1), and 7.31 (15H, s, 3×Ph).

*6,8-Di-O-Benzyl-3-C-(benzyloxymethyl)-3,5,7,9,12-pentadeoxy-1,2-O-isopropylidene-5,7,9-tri-C-methyl-*D-erythro-D-altro-L-talo-*dodecofuranose-(1,4) (28).* A solution of **27** (1.21 g, 1.72 mmol) in 75 (v/v)% aqueous acetic acid (24 ml) was stirred at 50°C for 1.5 h, then evaporated. The residue was chromatographed on silica gel (36 g) with 2:1 toluene–ethyl acetate to afford **28** (1.11 g, 97%) as a colorless syrup: R_f=0.31 (2:1 toluene–ethyl acetate); $[\alpha]_D^{30}$ −27° (*c* 1.50); ^{1}H-NMR δ=0.85, 0.97, 1.04, and 1.16 (each 3H, each d, 4×CMe, J=7.5, 7.5, 6.0, and 6.0 Hz), 1.27 (6H, s, CMe$_2$), 1.60—2.35 (4H, m, H-3, 5, 7, and 9), 3.35—4.90 (10H, m, H-2, 4, 6, 8, 10, 11, CH$_2$ OBzl, and OCH$_2$Ph), 4.53 and 4.58 (each 2H, each s, 2×OCH$_2$ Ph), 5.78 (1H, d, H-1, $J_{1,2}$=3.0 Hz), 7.30 (10H, s, 2×Ph), and 7.33 (5H, s, Ph).

Found: C, 72.20; H, 7.92%. Calcd for $C_{40}H_{54}O_8$: C, 72.48; H, 8.21%.

*6,8-Di-O-Benzyl-3-C-(benzyloxymethyl)-3,5,7,9-tetradeoxy-1,2-O-isopropylidene-5,7,9-tri-C-methyl-*D-altro-β-L-talo-*decodialdofuranose-(1,4) (29).* To an ice-cold solution of **28** (0.933 g, 1.41 mmol) in acetone (9.3 ml) was slowly added a solution of $NaIO_4$ (0.904 g, 4.23 mmol) in water (9.0 ml). After being stirred at room temperature for 5 h, the mixture was diluted with water (9.0 ml) and saturated with NaCl. The mixture was extracted with ethyl acetate (15 ml×3) and the extracts were washed with a saturated aqueous NaCl solution, dried, and evaporated. The residue was chromatographed on silica gel (15 g) with 10:1 toluene–ethyl acetate to afford **29** (0.840 g, 97%) as a colorless syrup: R_f=0.51 (5:1 toluene–ethyl acetate); ^{1}H-NMR δ=0.80, 0.83, and 1.15 (each 3H, each d, 3×CMe, J=7.5, 7.2, and 6.3 Hz), 1.25 and 1.26 (each 3H, each s, CMe$_2$), 1.70—2.45 (3H, m, H-3, 5, and 7), 2.70—2.95 (1H, m, H-9), 3.35—4.35 [5H, m, H-4, 6, 8, and CH$_2$OBzl, including dd of 3.46 (1H, J=6.6 and 9.6 Hz) and d of 4.28 (1H, J=0 and 10.2 Hz)], 4.46 and 4.50 (each 1H, two center peaks of ABq, OCH$_2$Ph), 4.53 (2H, s, OCH$_2$Ph), 4.55 and 4.85 (each 1H, ABq, OCH$_2$Ph, J=12.0 Hz), 4.69 (1H, dd, H-2, $J_{1,2}$= $J_{2,3}$=3.3 Hz), 5.82 (1H, d, H-1), 7.35 (15H, s, 3×Ph), and 9.83 (1H, s, CHO).

*6,8-Di-O-benzyl-3-C-(benzyloxymethyl)-3,5,7,9,11-pentadeoxy-1,2-O-isopropylidene-5,7,9-tri-C-methyl-11-methylene-*L-glycero-D-altro-β-L-talo-*dodecodialdofuranose-(1,4) 12-(Diethyl Acetal) (30) and* D-glycero-D-altro-β-L-talo *Epimer (31).* To a solution of 2-bromo-3,3-diethoxy-1-propene (846 mg, 4.05 mmol) in dry THF (5.7 ml) cooled at −108—−110°C was added 1.40 M butyllithium in hexane (2.41 ml, 3.37 mmol) under argon. After being stirred at the same temperature for 15 min, a solution of **29** (832 mg, 1.35 mmol) in dry THF (2.5 ml) was added to the mixture and stirring was continued at the same temperature for 0.5 h. The reaction was quenched by adding a saturated aqueous NH_4Cl solution (5 ml) and the mixture was then extracted with ether (10 ml×3) at room temperature. The organic layer were washed with a saturated aqueous NaCl solution, dried, and evaporated. The residue was chromatographed on silica gel (150 g) with 9:1 toluene–ethyl acetate to afford **30** (592 mg, 58.8%) and **31** (351 mg, 34.8%) as colorless syrups: **30**, R_f=0.32 (9:1 toluene–ethyl acetate); ^{1}H-NMR δ=0.87, 0.99, and 1.02 (each 3H, each s, 3×CMe, J=6.6, 7.5, and 7.5 Hz), 1.15—1.30 (12H, m, 2×OCH$_2$Me and CMe$_2$), 1.80—2.40 (4H, m, H-3, 5, 7, and 9), 3.30—4.40 (10H, m, H-4, 6, 8, 10, 2×OCH$_2$Me, and CH$_2$ OBzl), 4.50—5.00 (8H, m, H-2, 12, and 3×OCH$_2$Ph), 5.30—5.50 (2H, m, C=CH$_2$), 5.80 (1H, d, H-1, $J_{1,2}$=4.5 Hz), and 7.32 (15H, s, 3×Ph).

31, R_f=0.23 (9:1 toluene–ethyl acetate); ^{1}H-NMR δ=0.84, 0.92, and 1.04 (each 3H, each s, 3×CMe, J=6.6, 7.0, and 7.0 Hz), 1.10—1.30 (12H, m, 2×OCH$_2$Me and CMe$_2$), 1.75—2.40 (4H, m, H-3, 5, 7, and 9), 3.30—4.40 (10H, m, H-4, 6, 8, 10, 2×OCH$_2$Me, and CH$_2$OBzl), 4.50—5.00 (8H, m, H-2, 12, and 3×OCH$_2$Ph), 5.35—5.50 (2H, m, C=CH$_2$), 5.80 (1H, d, H-1, $J_{1,2}$=4.5 Hz), and 7.30 and 7.34 (10H and 5H, each s, 3×Ph).

*6,8-Di-O-benzyl-3-C-(benzyloxymethyl)-3,5,7,9,11-pentadeoxy-1,2-O-isopropylidene-5,7,9,11-tetra-C-methyl-*L-erythro-D-altro-β-L-talo-*dodecodialdofuranose-(1,4) 12-(Diethyl Acetal) (32) and* D-threo-D-altro-β-L-talo *Epimer (33).* A solution of **30** (256 mg, 0.343 mmol) and chlorotris(triphenylphosphine)-rhodium(I) (79.4 mg, 0.0858 mmol) in benzene (13 ml) was stirred under an atmospheric pressure of hydrogen at room temperature for 1 d. The reaction mixture was then evaporated and the residue was passed through Florisil (100—200 mesh, 20 g) with ether and again evaporated. The residue was chromatographed on silica gel (45 g) with 4:1 hexane–acetone to afford **32** (212 mg, 82.7%), **32**+**33** (21.7 mg, 8.4%), and **33** (9.3 mg, 3.6%) as colorless syrups: **32**, R_f=0.28 (4:1 hexane–acetone); $[\alpha]_D^{29}$ −35° (*c* 0.97); ^{1}H-NMR δ=0.82, 0.85, 0.92, and 1.05 (each 3H, each d, 4×CMe, J=7.5 Hz), 1.20 (6H, t, 2×OCH$_2$Me, J=7.5 Hz), 1.27 (6H, s, CMe$_2$), 1.60—2.40 (5H, m, H-3, 5, 7, 9, and 11), 3.35—4.40 (10H, m, H-4, 6, 8, 10, 2×OCH$_2$Me, and CH$_2$OBzl), 4.50—5.00 (8H, m, H-2, 12, and 3×OCH$_2$Ph), 5.80 (1H, d, H-1, $J_{1,2}$=4.2 Hz), and 7.30 and 7.33 (10H and 5H, each s, 3×Ph).

Found: C, 72.20; H, 8.43%. Calcd for $C_{45}H_{64}O_9$: C, 72.16; H, 8.61%.

33, R_f=0.19 (4:1 hexane–acetone); ^{1}H-NMR δ=0.80—1.30 (24H, m, 8×CMe), 1.70—2.40 (5H, m, H-3, 5, 7, 9, and 11), 3.25—4.40 (10H, m, H-4, 6, 8, 10, 2×OCH$_2$Me, and CH$_2$-OBzl), 4.45—4.90 (8H, m, H-2, 12, and 3×OCH$_2$Ph), 5.82 (1H, d, H-1, $J_{1,2}$=3.6 Hz), and 7.32 and 7.37 (10H and 5H, each s, 3×Ph).

*6,8,10-Tri-O-acetyl-3-C-(acetoxymethyl)-3,5,7,9,11-pentadeoxy-1,2-O-isopropylidene-5,7,9,11-tetra-C-methyl-*L-erythro-D-altro-β-L-talo-*dodecodialdofuranose-(1,4) 12-(Diethyl Acetal) (3).* To a solution of **32** (362 mg, 0.484 mmol) in dry ether (7.25 ml) was added liquid ammonia (36 ml), and then lithium (270 mg, 39 mmol) was added under cooling (−78°C). After the mixture was stirred at the same temperature for 4 h, the excess lithium was destroyed by adding of solid NH_4Cl. The mixture was then diluted with ether and allowed to concentrate spontaneously. The residue was taken with ether

and the solution was washed with a saturated aqueous NaCl solution, dried, and evaporated. The residual colorless syrup (231 mg, 100%) of **34** was dissolved in ethyl acetate (2.3 ml) and to this were added acetic anhydride (0.365 ml, 3.86 mmol) and DMAP (354 mg, 2.90 mmol). After being stirred at room temperature for 4 h, the reaction mixture was diluted with ethyl acetate (5 ml) and washed with a saturated aqueous NaCl solution (3 ml), dried, and evaporated. The residue was chromatographed on silica gel (30 g) with 3:2 toluene–ethyl acetate to afford **3** (280 mg, 90%) as colorless needles. The ^{1}H-NMR spectrum, R_f-value on TLC, and mp of this sample were identical with those of the authentic sample.[2]

We are grateful to Prof. Sumio Umezawa, Institute of Bioorganic Chemistry, and Prof. Hamao Umezawa, Institute of Microbial Chemistry, for the generous support of our program. The authors wish to thank Mr. Saburo Nakada for carrying out the microanalyses, and Mr. Seiichi Sato for his early contribution to this project. Supports by the Ministry of Education, Science and Culture (Grant-in-Aid for special research) and the Asahi Glass Foundation for Contribution to Industrial Technology are deeply acknowledged.

Brillouin Scattering of Supercooled Liquids. II. Diisobutyl Phthalate

Shinobu KODA, Ryuki HASHITANI, and Hiroyasu NOMURA*
Department of Chemical Engineering, School of Engineering, Nagoya University, Chikusa-ku, Nagoya 464
(Received April 3, 1985)

The Brillouin scattering spectra of diisobutyl phthalate were measured over a wide range of temperatures. The sound velocity dispersion was observed in the GHz region in a temperature range between 240 and 340 K. We concluded that the sound dispersion of the sample was attributed to the structural relaxation of a supercooled liquid. The relaxation curve of the longitudinal modulus was obtained by a superposition method and could be analyzed using a generalized B.E.L. model with a parameter of $K=0.3$—0.5. The viscoelastic relaxation in the GHz region was found to have a narrower distribution of relaxation times than in the MHz region.

It is well known that molecules in a liquid state are in an ordered structure at local and very short separations. However, at the greater separations, this ordered structure becomes indistinct. Therefore, when a mechanical force is suddenly applied to liquids, they at first respond elastically, just as if they were solid bodies, but relax as viscoelastic bodies. In order to better understand local structures of liquids and solutions regarding molecular interaction forces, it is very important to know the relaxation mechanism of liquids and solutions under such external forces as mechanical and electrical. However, it has been roughly estimated that the structural relaxation times of ordinary liquids are of an order of 10^{-13} s. Because of their low viscosities, we can not measure the relaxation times directly by means of relaxation spectroscopy. In order to study the dynamic properties of liquids, supercooled liquids are suitable materials, since such liquids have a large viscosity coefficient and their characteristic relaxation times are so long that they fall within measurable frequency ranges. Our final goal is to determine the dynamic properties of liquids and solutions. Supercooled materials will present useful information.

Most investigations regarding the dynamic properties of supercooled liquids were carried out in the megahertz regions and relaxation curves were obtained by superimposing data at different temperatures on the basis of a reduced procedure. The Brillouin scattering method is also a very useful technique for studying the viscoelastic properties of liquids. It provides information about the dynamic properties of liquids in the GHz range. Scattering is due to local thermal density fluctuations in the liquid phase.

In our previous paper,[1] the sound velocities of tri-*o*-tolyl phosphate in the GHz region were measured using the Brillouin scattering method with wide scattering angles and temperature ranges. The relaxation curves of the obtained longitudinal modulus were expressed by the B. E. L. model. However, the K parameter, which involves a distribution of the relaxation times, was somewhat different from those obtained in the MHz region.

In this paper, we report on the experimental results of Brillouin scattering in diisobutyl phthalate for a wide range of temperatures. The molecular dimension and symmetry of diisobutyl phthalate are quite different from those of tri-*o*-tolyl phosphate which was previously investigated. Viscoelastic relaxation, obtained from sound dispersion curves in the GHz region, are discussed on the basis of a generalized B. E. L. equation for bulk and shear moduli and is compared with the results from the MHz region.[2] The temperature dependence of the K parameter in the generalized B. E. L. equation is also discussed.

Experimental

Diisobutyl phthalate, guaranteed grade, was obtained from Nakarai Chemicals Co., Ltd. The sample was distilled under reduced pressure at 4 mmHg†, and poured into a scattering cell by filtration using a millipore filter with a pore size of 1.0 μm.

The Rayleigh-Brillouin spectra were obtained with a pressure-scanning Fabry-Perot interferometer, using a He-Ne laser (NEC., GLG 5800, output 50 mW). Detailed descriptions of the apparatus and experimental procedures are given in previous papers.[1,3] Measurements were performed over a temperature range between 197 and 348 K for various scattering angles (30 to 150°). The accuracy of the sound velocity was within ±1.0%.

Velocities at 5 MHz were measured using an ultrasonic interferometer over a temperature range between 273 and 333 K. Ultrasonic absorption coefficients were also measured at a frequency of 5 MHz by the usual pulse method. The refractive indexes of the samples were measured using an Abbe refractometer between 258 and 318 K. Values at the lower and higher temperatures were estimated by extrapolating the temperature dependences of the velocity and the refractive index.

Results

Figure 1 shows the typical Rayleigh-Brillouin spectra of diisobutyl phthalate at a constant scattering angle, $\theta=90°$, as a function of temperature. The sound velocity, V, can be calculated from the values of the Brillouin frequency shift, $\Delta\omega$, and the scattering angle, θ, by the following relation;

$$V=\left(\frac{\Delta\omega}{\omega_0}\right)\frac{c}{2n\sin(\theta/2)}, \quad (1)$$

† 1 mmHg=133.322 Pa.

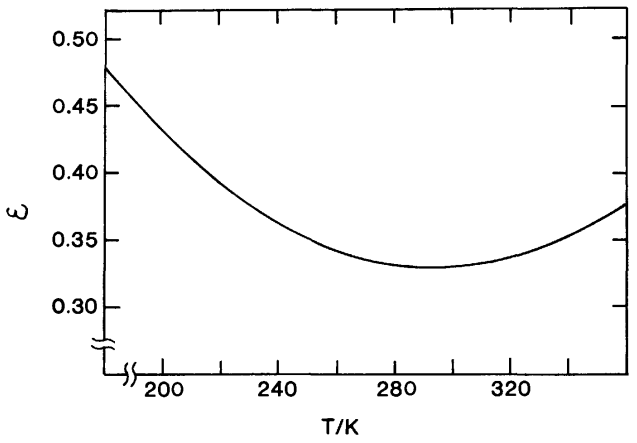

Fig. 4. Temperature dependence of the relaxation strength, ε.

where ω_0 is the frequency of the incident light, c the velocity of light, and n the refractive index of the sample.

Figure 2 shows a plot of the sound velocities against the frequencies at 298 K. The sound velocity dispersion was observed in the GHz region. The temperature dependence of the sound velocities, which were obtained at various scattering angles, is shown in Fig. 3. As can be seen, a clear sound velocity dispersion was obtained in the mid temperature range. In the low temperature region, below 238 K, although velocities were measured for various scattering angles, these velocities were independent of the scattering angles, that is, were independent of the frequencies. These velocities can be considered as those at the high frequency limit for various temperatures. The temperature dependence of the velocities at the high frequency limit, V_∞, can be represented by the following equation by analogy with the temperature dependence of the shear modulus.[2)]

$$V_\infty = \frac{a}{T(\mathrm{K})} + b. \quad (2)$$

The numerical values of a and b are 3.59×10^5 m s^{-1}·K and 479 m s^{-1}, respectively. Those were determined by a curve fitting method, using data from the lower temperature regions. For the low frequency limit of the sound velocity, V_0, values measured by an ultrasonic interferometer operating at 5 MHz were employed. The temperature dependence of V_0 can be expressed as V_0=−3.43 T(K)+2400.[2)]

Discussion

Generally, the origin of sound velocity dispersion in the GHz region is mainly ascribed to the following two relaxation processes. One is vibrational relaxation, which is due to an energy transfer from vibrational modes of a molecule to translational motion. The other is a viscoelastic relaxation, that is, structural relaxation.

The temperature dependence of the relaxation

strength, $\varepsilon=(V_\infty^2-V_0^2)/V_\infty^2$, is shown in Fig. 4. As can be seen, ε decreases with increasing temperature. If the velocity dispersion were due to vibrational relaxation, ε would increase with increasing temperature.[4] It might be, therefore, concluded that the observed sound velocity dispersion is not mainly due to vibrational relaxation, but to the viscoelastic relaxation. This is also true for tri-*o*-tolyl phosphate in the GHz region. This conclusion can be supported by taking into consideration the fact that observed value of $\varepsilon=0.331$ (at 298 K) is one order of magnitude larger than $\varepsilon=0.0315$ (at 298 K) estimated using the Planck-Einstein relation with frequencies of the vibrational modes.

At this stage, shear modulus data in the GHz region are not available by any method. Thus, longitudinal data cannot be divided into that related to the bulk and shear modulus, respectively, through the relation $M^*=K^*+4/3\,G^*$ (where K^* and G^* refer to the bulk and shear modulus respectively, and the superscript* refers to the complex modulus). Therefore, our data analysis was constrained to only longitudinal data, that is, M' (hereafter the real and imaginary parts of the complex are distinguished by ′ and ″, respectively).

The storage modulus, which is the real part of the complex longitudinal modulus M^*, can be estimated by $M'=\rho V^2$, where ρ is the density. According to a data analysis which was proposed by Lamb's school, a reduced plot of $(M'-M_0)/(M_\infty-M_0)$ against $\omega\eta_s/G_\infty$ was carried out and is shown in Fig. 5, where ω is the angular frequency ($\omega=2\pi f$). η_s/G_∞ ($=\tau_s$) corresponds to the relaxation time of the Maxwell element for a single relaxation, where η_s is the shear viscosity and G_∞ is the complex shear modulus at the high frequency limit. The temperature dependences of the viscosity and the density of the sample investigated here can be found in the literature.[5] The values of G_∞ at each temperature that were used were determined at an ultrasonic frequency at low temperatures.[5] As can be seen in Fig. 5, a master curve has been found in spite of the wide temperature and frequency ranges within the experimental error.

Assuming the generalized B. E. L. equation for K^* and G^*,[2] respectively, the expression for M^* is given as

$$\frac{M^*-M_0}{M_\infty-M_0}=C\left[1+\frac{1}{i\zeta\omega\tau_s}+2K\left(\frac{1}{i\zeta\omega\tau_s}\right)^{1/2}\right]^{-1}+(1-C)\left[1+\frac{1}{i\omega\tau_s}+2K\left(\frac{1}{i\omega\tau_s}\right)^{1/2}\right]^{-1}$$

$$C=\frac{K_\infty-K_0}{M_\infty-M_0}=1-\frac{4}{3}\frac{G_\infty}{M_\infty-M_0}$$

$$\zeta=\frac{\tau_v}{\tau_s}=\frac{\eta_v}{\eta_s}\frac{G_\infty}{M_\infty-M_0}=\frac{3}{4}\frac{\eta_v}{\eta_s}(1-C), \quad (3)$$

where K is an adjustable parameter for the broadness of the relaxation region. The K parameter is assumed to be the same for both shear and bulk relaxation processes.[2]

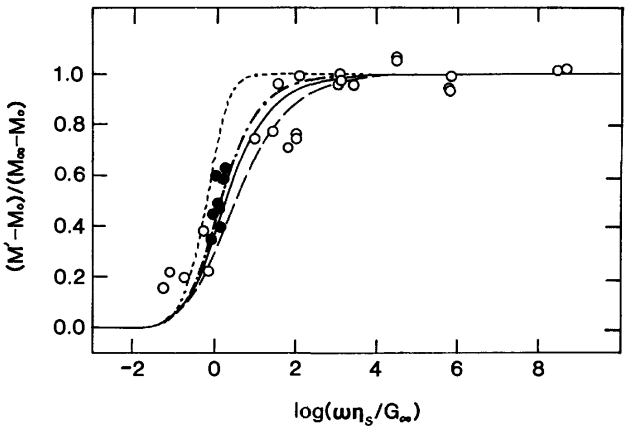

Fig. 5. Values of the normarized longitudinal modulus, $(M'-M_0)/(M_\infty-M_0)$ plotted as a function of $\log(\omega\eta_s/G_\infty)$.
(------); K=0, (—·—·-); K=0.3, (——); K=0.5, (— — —); K=1.0.
(●): Data at 25℃.

The value of C was estimated from data regarding the temperature dependence of the relaxation strength (Fig. 4) and G_∞'s which are also found in the literature.[5] C has a constant value of 0.35 in the low temperature range (from 197 to 300 K) but at higher temperatures, C increases slightly (C=0.40 at 320 K). The values of ζ can be estimated from data regarding η_v/η_s, which can be determined by measurements of the ultrasonic absorption coefficient at the low frequency limit, using the following equation.[2]

$$\lim_{\omega\to 0}\frac{\alpha}{\omega^2}=\frac{1}{2\rho v_0^3}(\eta_v+4/3\,\eta_s). \quad (4)$$

The obtained value of η_v/η_s is 2.64.

Calculated curves of $(M'-M_0)/(M_\infty-M_0)$ are drawn in Fig. 5 for K=0, 0.3, 0.5, and 1.0, by lines using Eq. 3 with the observed values of C and ζ. The curve with K=0 corresponds to that of the Maxwell model for a single relaxation. The curve with K=1.0 corresponds to the original B. E. L. equation and is in good agreement with those obtained in the MHz region for many supercooled liquids (as reported by Barlow *et al.*).[6-11] As can be seen in Fig. 5, the curve for K=1.0 is considerably broader than that obtained experimentally. The curve for K=0.3 and/or 0.5 reproduces the experimental values within experimental error. In the higher temperature region, that is, in the low frequency region, a deviation from the B. E. L. model was appeared. This deviation may be due to the rotational molecular motion of molecules in the liquid.

Previously,[1] we suggest that the relaxation curves of the longitudinal modulus for tri-*o*-tolyl phosphate in the GHz region could be reproduced by the B. E. L. model with a parameter of K=0.5. Therefore, both results for tri-*o*-tolyl phosphate and diisobutyl phthalate indicate the same tendency; that is, the longitudinal modulus obtained from the measure-

ments in the GHz region at various temperatures can be apparently composed with a master curve using the B. E. L. method, like that for the MHz region. However, the K parameter obtained from data in the GHz region was somewhat different from that in the MHz region. If the superposition procedure were to hold completely, the values of K which were obtained from data in the GHz and MHz regions should coincide with each other.

The solid circles in Fig. 5 represent the data obtained at a constant temperature of 298 K as a function of the frequency. According to the superposition procedure, these data for the GHz region at log $(\omega\eta_s/G_\infty)\simeq 0$ correspond to that around a frequency of 50 MHz at about 250 K. The data in the MHz region should correspond to the spectrum for $K=1.0$. On the other hand, as shown in Fig. 5, the data in the GHz region at 298 K do not coincide with the spectrum for $K=1.0$ and the data in the GHz region give a narrower relaxation spectrum than the spectrum for $K=1.0$. This fact clearly suggests that the distribution of the relaxation times at 298 K is different from that at 250 K.

At this stage, we would like to limit ourselves to pointing out that the distribution of the relaxation times of the longitudinal modulus of supercooled liquids may depend on the temperature. In order to confirm this fact more clearly, measurements over a frequency range between 300 and 700 MHz are needed. Work along this line is in progress and will be reported elsewhere.

Kinetic Study of the Thermal Decomposition of Isocyanic Acid in Shock Waves

Okitsugu KAJIMOTO,† Osamu KONDO, Kazuo OKADA, Jiro FUJIKANE, and Takayuki FUENO*
Department of Chemistry, Faculty of Engineering Science, Osaka University, Toyonaka, Osaka 560
(Received May 25, 1985)

Thermal decomposition of isocyanic acid HNCO diluted to less than 2.0 mol% in argon was studied behind incident shock waves over the temperature range 2100—2500 K. The decomposition course was followed by monitoring the light absorption of HNCO and NH($^3\Sigma^-$) at 206 and 336 nm, respectively. It is confirmed that the primary step of the decomposition is a bimolecular process HNCO+Ar→NH($^3\Sigma^-$)+CO+Ar, ΔH°_0=337 kJ mol^{-1}, with the low-pressure limit rate constants $k=10^{17.23\pm0.36}\exp[-(402\pm17)\text{ kJ mol}^{-1}/RT]$ cm^3 mol^{-1} s^{-1}. The siglet-to-triplet crossing point is estimated on the basis of the RRKM low-pressure-limit rate constant calculations. The overall decomposition mechanism is suggested and its validity is confirmed by computer simulation of the time-concentration profiles of NH($^3\Sigma^-$) at varying temperature.

Decomposition of isocyanic acid (HNCO) as a possible source of the imino radical (NH) has already been investigated by several groups of workers. Holland *et al.*[1] first photolyzed HNCO to observe a strong absorption by NH. Wooley and Back[2] found that the primary process of the HNCO photolysis at 206.2 nm involves the following two branches with nearly equal probabilities:

$$\text{HNCO} + h\nu \longrightarrow \begin{cases} \text{NH} + \text{CO} \\ \text{H} + \text{NCO} \end{cases}$$

Pyrolysis of HNCO was also studied by Back and Childs[3] at the temperature range 550—770 °C. Unfortunately, however, the overall decomposition process was so complex because of the secondary reactions as well as the surface effects that the kinetic features of even the primary step remained to be disclosed.

In the present investigation, isocyanic acid diluted in argon has been decomposed in incident shock waves over the temperature range 2100—2500 K. Time-resolved measurements of the light absorptions of both reactant and product radicals at elevated temperatures greatly facilitated kinetic studies of the decomposition. Of the following three conceivable initial steps of decomposition:

		ΔH°_0(kJ mol^{-1})[5,6]	
HNCO + Ar	→ NH($^1\Delta$) + CO + Ar	488	(1a)
	→ NH($^3\Sigma^-$) + CO + Ar	337	(1b)
	→ H + NCO + Ar	474	(1c)

the spin-forbidden reaction 1b has been concluded to be the most dominant, just as in the case of the hydrazoic acid (HN_3) decomposition studied previously.[4] The overall decomposition mechanism was inferred on this basis, and its validity was confirmed from the computer tracing of the time histories of the NH($^3\Sigma^-$) concentrations at varying temperature.

Experimental

(A) Materials. Isocyanic acid was synthesized by heating a mixture of potassium cyanate and stearic acid for 8 h on an oil bath at 95 °C. All the volatile substances were collected in a trap maintained at −196 °C. Impurities that remained were carbon dioxide and water, which were removed by successive trap-to-trap distillations at −60 °C and −20 °C. Purity of the resulting isocyanic acid was checked by the mass,[9] IR,[10] and UV[11] spectrometries.

Sample gases of various concentrations (0.1—2.0 mol%) were prepared by diluting isocyanic acid with high purity (99.999%) argon. They were allowed to stand in 10-l Pyrex bulbs for at least 10 h before use. No trace of polymerization of HNCO was perceived in these diluted gas samples.

(B) Kinetic Measurements. A stainless-steel shock tube of 10.4 cm diameter was used. The driver and driven sections were 2.0 and 3.0 m in length, respectively. A 25-l dump tank was attached to the end wall of the driven section in order to prevent the driven gas from being heated further by reflected shock waves. An involatile substance was found to be formed near the end of the driven section unless such a tank was used. The two sections were separated by a Mylar diaphragm of 0.10, 0.18, or 0.25 mm thickness. The bursting pressures of these Mylar sheets were *ca.* 4, 7, and 10 atm,[12] respectively. The driven section was evacuated to less than 2×10^{-5} Torr[12] before charging it with a gas sample. A diaphragm of selected thickness was used in combination with a driver gas, H_2 or He, of given driven pressures, so that the net pressure of the reaction zone could vary from 500 to 1500 Torr. The temperature, pressure, and density of shocked gas were calculated from the measured shock velocity by assuming an ideal shock behavior. Both the boundary layer effects and the effects of reaction heat were estimated to be unimportant under our experimental conditions.

The light absorption at 206.2±2.8 nm was utilized to follow the concentration of HNCO. A home-made microwave-operated I_2 lamp, together with a Bausch-Lomb MC-20 grating monochromator, was used to isolate the 206.2 nm atomic line. The NH($A^3\Pi$–$X^3\Sigma^-$) absorption was also followed at the wavelength 335.96±0.14 nm.[13] A 400-W Ushio high-pressure mercury lamp and a Rikotsusho MC-50 grating monochromator were used for this purpose. The wavelength scale of the monochromator was calibrated by using an NH lamp[14] which was microwave-operated on a flowing mixture of 1 Torr of ammonia and 4 Torr of argon.

The light which passed an appropriate optical path was collected on an EMI-9634Q photomultiplier. Its time-dependent output signal was amplified with a Keithley 102B amplifier and stored in a Kawasaki Electronica TM-1450

†Present address: Faculty of General Education, The University of Tokyo, Meguro-ku, Tokyo 153.

transient memory. The stored signal was displayed on an oscilloscope for photographing or on a pen recorder.

Results

(A) Kinetics of the HNCO Decay. In all experiments, the HNCO absorption increased abruptly upon the arrival of incident shock wave, and then decreased gradually with elapsing time. At the shock wave temperatures above 2500 K, the effects of unidentified emission were found to be inevitable. Below 2200 K, on the other hand, the absorption often showed an irregular increase, especially when the pressure of the reaction zone exceeded 1000 Torr. Observations of the HNCO decay were thus limited to the temperature range between 2200 and 2500 K.

At temperatures between 2200 and 2500 K, the observed HNCO decay signals were smooth enough and well reproducible. It is believed that the initial decays of HNCO observed in this temperature region are entirely due to its decomposition effected by the shock heating. This point was corroborated from the observations of the concurrent increase in concentration of the NH radicals as the primary decomposition product, as will be demonstrated shortly below.

The absorption coefficient of HNCO at each experimental temperature was evaluated from the absorbance extrapolated to time zero and the calculated initial post-shock concentration of HNCO. The absorption coefficients thus obtained were essentially constant at $(1.37\pm0.20)\times10^5$ $cm^2 mol^{-1}$ over the temperature range studied.

By use of the average absorption coefficient $\varepsilon = 1.37\times10^5$ $cm^2 mol^{-1}$, the absorbance-time records were converted into concentration-time curves. First-order plots of the HNCO concentration against the particle time t were satisfactorily linear during the initial 100 μs. The first-order rate constants k_{1st} obtained from such plots for several typical runs are listed in Table 1, together with the relevant shock parameters.

Plots of log k_{1st} against $1/T$ gave three separate straight lines which were parallel-shifted upward as the total pressure P_2 was increased stepwise (500, 900, and 1300 Torr). The second-order rate constants k_{2nd} were obtained by dividing k_{1st} by the post-shock argon concentration. The values of k_{2nd} obtained for typical runs are given in the final column of Table 1.

The Arrhenius plots of k_{2nd} were found to give a single straight line. Figure 1 shows such plots for a total of 22 runs. Evidently, the HNCO decay is in the low-pressure region under our experimental conditions. The least-squares treatment of all the data given in Fig. 1 resulted in the following Arrhenius expression:

$$k_{2nd} = 10^{17.23\pm0.36} \exp[-(402\pm17)\text{kJ mol}^{-1}/RT] \quad \text{cm}^3\,\text{mol}^{-1}\,\text{s}^{-1}. \quad (1)$$

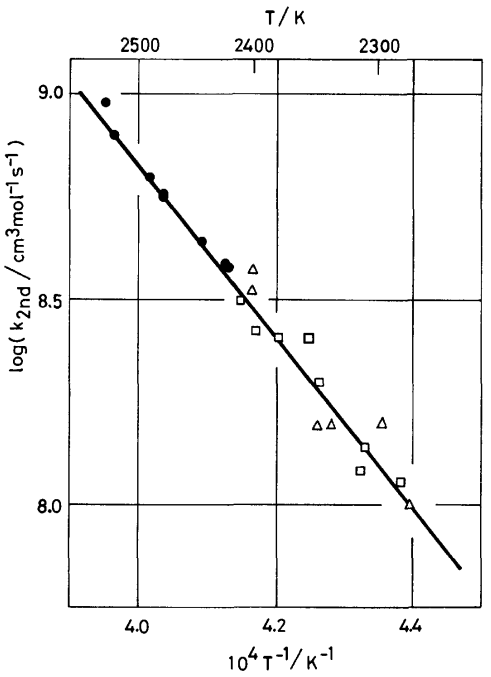

Fig. 1. Arrhenius plots of the second-order rate constants (k_{2nd}) for the decay of HNCO. The approximate Total pressures and the concentrations of HNCO in Ar were as follows: ●, 500 Torr, 2.0 mol%; □, 900 Torr, 0.5 mol%; △, 1350 Torr, 0.5 mol%.

(B) Rate Constants for the $NH(^3\Sigma^-)$ Formation. Observation of the $NH(^3\Sigma^-)$ absorption at 336 nm was feasible at reaction temperatures down to 2100 K. At any temperature between 2100 and 2500 K, the absorption started up sharply upon the arrival of the incident shock. It increased monotonously until it reached a maximum, beyond which it decreased gradually. As the reaction temperature was raised, the absorption increased more abruptly, thus reaching its maximum in a shorter time interval and then decreasing faster. The maximum absorption became larger correspondingly. These qualitative features of absorption suffice to indicate an initial production of $NH(^3\Sigma^-)$ by the shock heating, followed by its decay due to subsequent reactions with coexistent species.[15]

The rates of the $NH(^3\Sigma^-)$ formation were evaluated from the initial slope of the absorption-time profile, assuming the average absorption coefficient $\varepsilon=1.0\times10^7$ cm^{2}mol^{-1} for $NH(^3\Sigma^-)$.[4] The resulting rates were divided by the concentration product of Ar and HNCO, to obtain the second-order rate constant k_{1b}. The values of k_{1b} thus obtained for some representative runs are given in Table 2, together with the shock parameters.

Figure 2 shows the Arrhenius plots of k_{1b} obtained for a total of 31 runs. Irrespective of the total pressure ranging from 500 to 1500 Torr, all the experimental points are seen to be fitted by a single straight line. The results indicate that the unimolecular decomposition of HNCO into $NH(^3\Sigma^-)$+CO is in the low-pressure limit. The least-squares treatment of the data gave the following Arrhenius expression:

$$k_{1b} = 10^{17.38\pm0.29}\exp[-(412\pm13)\text{kJ mol}^{-1}/RT]\ \text{cm}^3\,\text{mol}^{-1}\,\text{s}^{-1}. \quad (2)$$

Shown with a dotted line in Fig. 2 is the k_{2nd}, Eq. 1. The essential agreement between these two lines can be taken as a strong indication that HNCO decomposes mostly into $NH(^3\Sigma^-)$+CO.

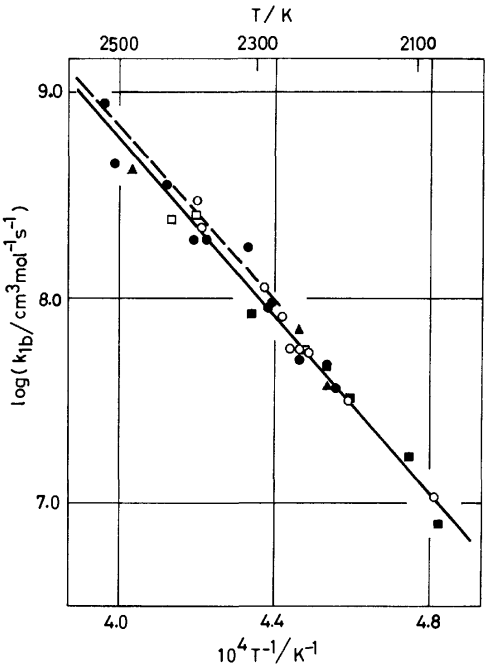

Fig. 2. Arrhenius plots of the second-order rate constants (k_{1b}) for HNCO+Ar→$NH(^3\Sigma^-)$+CO+Ar determined from the initial slope of the $NH(^3\Sigma^-)$ absorption. The approximate total pressures and the concentrations of HNCO in Ar were as follows: ○, 550 Torr, 0.5 mol%; ●, 550 Torr, 0.2 mol%; ■, 1000 Torr, 0.2 mol%; □, 1000 Torr, 0.1 mol%; △, 1500 Torr, 0.1 mol%. The rate constant of HNCO disappearance, k_{2nd}, is also shown with a dotted line.

Discussion

(A) Primary Decomposition Step. The close agreement between k_{2nd} and k_{1b} strongly suggests that HNCO is decomposed into $NH(^3\Sigma^-)$ and CO. The decomposition step is evidently bimolecular in type at least under our experimental conditions. The low-pressure limit behavior in the ordinary pressure regime has also been reported for other four-atomic molecules such as HN_3,[4] NH_3,[16] C_2N_2,[17,18] H_2O_2,[19] and SO_3,[20] diluted in inert gas.

The activation energy of k_{2nd}, E_a=402 kJ mol^{-1}, is noticeably greater than the heat of reaction ΔH°_0=337 kJ mol^{-1} for the triplet path 1b but is clearly smaller than the heat of reaction ΔH°_0=488 kJ mol^{-1} for the singlet path 1a. Similar situations have been noted in the thermal decompositions of HN_3[4] and N_2O,[21]

where the observed activation energies are in between the heats of reaction for the lowest triplet path and the higher singlet path.

In order to estimate the threshold energy for reaction 1b, we have undertaken RRKM calculations of the low-pressure limit rate constants:

$$k^{\mathrm{RRKM}} = (\lambda Z/Q_{\mathrm{v}})\exp(-E_0/RT)\int_0^{\infty} N(\varepsilon+E_0)\exp(-\varepsilon/RT)\mathrm{d}\varepsilon. \quad (3)$$

The various symbols appearing in Eq. 3 have their usual meanings.[22]

In calculating k^{RRKM}, we adopted the Whitten-Rabinovitch approximation[23] to $N(\varepsilon+E_0)$. The collision diameter between HNCO and Ar was assumed to be 0.39 nm. The six vibrational normal-mode frequencies of HNCO were all taken from the literature:[8] 3535, 2274, 1327, 808.0, 672.5, and 563.5 cm^{-1}.

We first calculated the k^{RRKM} as the functions of E_0 and T. Then we searched for a value of E_0 such that the observed temperature dependence of $k_{2\mathrm{nd}}$ (Eq. 1) was best reproduced. For the sake of simplicity, we neglected possible minor temperature dependence of the collisional efficiency λ. The best fit was achieved when we chose E_0=439 kJ mol^{-1}. The resulting RRKM rate constant was

$$k^{\mathrm{RRKM}} = \lambda 10^{17.76}\exp(-402\mathrm{kJ\ mol^{-1}}/RT)\ \mathrm{cm^3\ mol^{-1}s^{-1}}. \quad (4)$$

Comparison of Eq. 4 with Eq. 1 leads to the collisional efficiency λ=0.30. The λ value thus obtained does not seem to be unreasonable in view of the fact that the decompositions of most four-atomic molecules take on λ of the order of 0.1.[24] In addition, the critical energy E_0=439 kJ mol^{-1} of our choice suggests that the singlet and triplet potential energy curves cross each other at 102 kJ mol^{-1} *above* the zero point energy level of $NH(^3\Sigma^-)$+CO. The situation is very similar to the case of HN_3.[4] The schematic potential energy diagrams for both cases are compared in Fig. 3.[25]

The critical energy E_0 for reaction 1b is smaller than the heats of reaction for paths 1a and 1c by 49 and 35 kJ mol^{-1}, respectively. Because reaction 1b of our major concern is found to be in the low-pressure limit region, the contributions of 1a and 1c to the decomposition are likely to be negligible under the experimental conditions adopted in this work.[26]

(B) Overall Decomposition Mechanism. On the basis of the previously reported results on the photolysis of HNCO[27,28] as well as the mechanism proposed for the pyrolysis of HN_3,[4] we here assume the overall mechanism of the HNCO thermal decomposition to be such as follows:

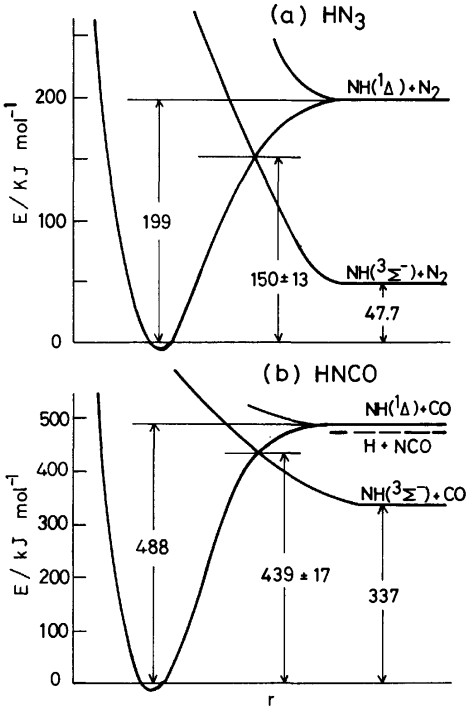

Fig. 3. Schematic potential energy curves of HN_3 (a) and HNCO(b).

		ΔH°_0(kJ mol^{-1})[5,6]
$HNCO+Ar$	$\xrightarrow{1b}$ $NH(^3\Sigma^-)+CO+Ar$	337
$NH(^3\Sigma^-)+HNCO$	$\xrightarrow{2}$ NH_2+NCO	99
$H+HNCO$	$\xrightarrow{3}$ NH_2+CO	−38
NH_2+HNCO	$\xrightarrow{4}$ NH_3+NCO	26
$2NH(^3\Sigma^-)$	$\xrightarrow{5}$ N_2+2H	−272
$2NH_2(+Ar)$	$\xrightarrow{6}$ $H_2NNH_2(+Ar)$	−277
$H+NH_2+Ar$	$\xrightarrow{7}$ NH_3+Ar	−448
$2H+Ar$	$\xrightarrow{8}$ H_2+Ar	−432
$NH(^3\Sigma^-)+NH_2(+Ar)$	$\xrightarrow{9}$ $HNNH_2(+Ar)$	−361
$H+HNNH_2$	$\xrightarrow{10}$ $2NH_2$	−34
$2NCO$	$\xrightarrow{11}$ N_2+2CO	−546

In order to examine the validity of this mechanism, the simultaneous kinetic equations for the various species involved were solved numerically (GEAR method) on a computer. Specifically, we aimed at comparing the calculated time-concentration profiles of $NH(^3\Sigma^-)$ with the observed ones at varying temperature. The rate constants used for computations are summarized in Table 3. Most of these data were either taken directly from the literature[29-31] or estimated judiciously by the procedures analogous to those delineated previously for the case of HN_3.[4]

The time-concentration profiles of $NH(^3\Sigma^-)$ were

a) Estimated, b) Adjusted.

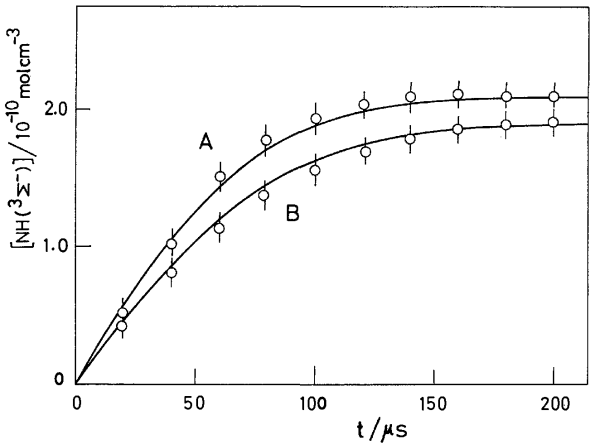

Fig. 4. Comparisons of the computed NH($^3\Sigma^-$) concentration profiles (——) with the observed (O): (A)NHCO=0.20 mol%, T_2=2281 K, P_2=532 Torr; (B) HNCO=0.20 mol%, T_2=2108 K, P_2=1052 Torr. The vertical lines indicate the range of uncertainty due to the low S/N ratio.

found to be governed by the rates of the initial process 1b and the NH "recombination" reaction 5. The rate constants for reactions 6—8, 10, and 11 had virtually no effects on the calculated profiles. In practice, we adopted k_{2nd} (Eq. 1) rather than k_{1b} (Eq. 2) as the rate constant for reaction 1b since there may well exist some uncertainty in the absorption coefficient of NH($^3\Sigma^-$). The rate constant of reaction 5 was most influential in the determination of the position as well as the height of the peak of the calculated profiles. We thus adjusted the value of k_5 so as to best reproduce the observed profiles of NH($^3\Sigma^-$) at various temperatures studied. The best fit was obtained when k_5 was taken to be constant at 2×10^{13} $cm^3\,mol^{-1}\,s^{-1}$ within the temperature range studied. This value agrees well with 2.5×10^{13} $cm^3\,mol^{-1}\,s^{-1}$ adopted previously.[4]

Figure 4 shows examples of the calculated time histories of the NH($^3\Sigma^-$) concentration. Circles shown in Fig. 4 are the concentrations calculated from the observed absorption profiles of NH($^3\Sigma^-$) by using $\varepsilon=1.0\times10^7$ $cm^2\,mol^{-1}$ as the absorption coefficient of NH($^3\Sigma^-$). Agreements between the calculated curves and the observed are satisfactory. The results lend strong support not only to the overall decomposition mechanism assumed but also to the various assumptions invoked as well as the experimental techniques adopted in the present work.

In conclusion, the primary process of the shock-wave decomposition of HNCO in argon at the total pressure range 550—1500 Torr is a bimolecular reaction, giving rise exclusively to NH($^3\Sigma^-$). The activation energy E_a=402 kJ mol^{-1} for this "triplet" process is evidently higher than its heat of reaction $\Delta H°_0$=337 kJ mol^{-1}, indicating that the singlet-triplet potential-energy curve crossing occurs at a level above the dissociation limit. The kinetic behavior is found to conform to the RRKM theory in the low-pressure limit.

15) These features alone can by no means rule out the possibility that HNCO is first decomposed to give rise to $NH(^1\Delta)$, which is then rapidly quenched to $NH(^3\Sigma^-)$ on collisions with the reactant HNCO. In our previous investigation of the HN_3 decomposition,[4] we considered such a process beside the process giving $NH(^3\Sigma^-)$ directly. However, the conclusion was that the triplet path was evidently preponderant over the singlet path under the experimental conditions adopted there. Whether or not the triplet path is the major step of the initial decomposition in the present HNCO case also, is to be judged cautiously from the magnitudes as well as the temperature dependences of the rate constants observed for both the HNCO decay and the $NH(^3\Sigma^-)$ production.

Photoionization Study of the Sulfur Monoxide Radical Produced by Pyrolysis of Ethylene Sulfoxide

Eisuke NISHITANI, Kenichi FUKUDA, and Ikuzo TANAKA*
Department of Chemistry, Tokyo Institute of Technology Ohokayama, Meguro-ku, Tokyo 152
(Received June 10, 1985)

Sulfur monoxide (SO) radical has been produced in the gas phase by pyrolysis of ethylene sulfoxide (C_2H_4=SO) at 510 °C. The vacuum ultraviolet photoionization efficiency curve between 915 and 1220 Å has been obtained for the first time. Several thermodynamic data about C_2H_4=SO have also been obtained from direct photoionization. The values of the bond energies of $D_0(C_2H_4$=SO) and $D_0(C_2H_4$=SO^+) are 4640±30 and 5160±30 cm^{-1} respectively. Ionization potentials (IP) of the SO($X^3\Sigma^-$) radical and C_2H_4=SO, and the appearance potential (AP) of SO^+ fragment ion from C_2H_4=SO are 10.28±0.01, 9.49±0.02, and 10.13±0.01 eV. In the system of C_2H_4=SO, the AP is lower than the IP and this phenomenon has only been found in this system.

The sulfur monoxide (SO) radical has been studied as an important intermediate in reactions involving oxygen atoms and molecules containing sulfur. It has also been found in interstellar space by radio telescopes.[1] In addition, the SO radical is a very interesting radical from the point of electronic structure because of the isoelectronic species of diatomic sulfur (S_2) and molecular oxygen (O_2). In contrast to the large amount of spectroscopic data obtained for O_2, SO, and S_2 in several low-lying electronic states,[2] our current knowledge concerning the SO radical in the vacuum ultraviolet region is very limited. Though autoionization in radicals has been rarely observed in this region so far, it is expected that the autoionization peaks might appear in the SO radical because of the similarity to O_2.

Since the far ultraviolet absorption spectrum of O_2 was observed by Price and Collins in 1935,[3] absorption spectra, the photoionization efficiency curves and photoelectron spectra of O_2 have been intensively studied. A high resolution (FWHM 0.07 Å) photoionization study of O_2 has been carried out by Dehmer and Chupka.[4] For the S_2 radical, the relative photoionization efficiency curve has been observed by Berkowitz *et al.*[5] in the gas phase by thermal vaporization of HgS. They found that an autoionization structure emerged, but the peak shapes were not clear enough to allow spectroscopic studies.

Compared to the study of these species, at the present stage, very few works have been carried out on the SO radical in the vacuum ultraviolet region. Donovan *et al.*[6] have obtained the absorption spectrum of the SO radical and studied the Rydberg series (The $D^3\Pi$ and $E^3\Pi$ states) converging to the $X^2\Pi$ state of SO^+. The photoelectron spectrum of the SO radical produced by discharge of CS_2 and O_2 was also observed by Jonathan *et al.* in 1974.[7]

The present work reports the first mass spectrometric analysis of the relative photoionization efficiency curve of the SO radical produced by pyrolysis of ethylene sulfoxide (C_2H_4=SO). The synthesis of C_2H_4=SO[8] and production of the SO radical by its pyrolysis has been reported.[9] Also the $a^1\Delta$ state of the SO radical produced by pyrolysis of C_2H_4=SO was analyzed from the microwave spectrum by Saito in 1970.[10]

The pyrolysis and photoionization in the present system are described below:

$$C_2H_4{=}SO \xrightarrow{\Delta} C_2H_4(X^1A_{1g}) + SO(a^1\Delta)$$

$$SO(a^1\Delta) + M \longrightarrow SO(X^3\textstyle\sum^-) + M$$

$$SO(X^3\textstyle\sum^-) + h\nu \longrightarrow SO^+(X^2\Pi) + e \quad \text{(IP)} \quad (1)$$

$$C_2H_4{=}SO + h\nu \longrightarrow C_2H_4{=}SO^+ + e \quad \text{(IP)} \quad (2)$$

$$C_2H_4{=}SO + h\nu \longrightarrow C_2H_4(X^1A_{1g}) + SO^+(X^2\Pi) + e \quad \text{(AP)} \quad (3)$$

From the threshold energies for above processes, the bond energies of $D_0(C_2H_4$=SO) and $D_0(C_2H_4$=SO^+) were determined. The IP of the SO radical in process (1) obtained from mass spectrometric photoionization is in excellent agreement with the results of photoelectron studies[7] and photofragmentation studies of sulfur dioxide.[11] The IP of C_2H_4=SO in process (2) and the AP of SO^+ from C_2H_4=SO in process (3) were obtained. Thus, these threshold energies indicate that the AP of SO^+ from C_2H_4=SO should be lower than the IP of the SO radical. This unique phenomenon was first observed in the system of C_2H_4=SO.

On the other hand, in process (1) the relative photoionization efficiency curve of the SO radical was obtained by scanning the excitation wavelength. Rather strong autoionization peaks were observed on this curve. But these peaks could not be assigned due to the lack of strong vibrational progressions such as are found for O_2^+.

Experimental

The experimental arrangement is shown in Fig. 1. The apparatus consisted of a hydrogen discharge light source operated at 0.4 A dc with about 700 V across the tube, a 50 cm Seya-Namioka type vacuum monochromator with a resolution of 2.3 Å (FWHM) which dispersed and refocused the monochromatic light into the ionization chamber, a set of

ion extraction and focusing lenses, and a quadrupole mass spectrometer (NEVA NAG-520) for ion detection.

Ion counts were measured by an electronmultiplier (Murata EMS-6081B), and photon counts were measured by the scintillation counter of a photomultiplier (HTV R-268) coated with sodium salicylate. After each signal had been amplified and identified by a fast pre-amplifier (ORTEC 9301) and an amplifier-discriminator (ORTEC 9302), it was integrated by the counter (ORTEC 9315). The accumulation of signals and control of the experimental apparatus were regulated by a microcomputer (NEC PC-9801). The relative photoionization efficiency was derived by the normalization method, dividing the ion counts by the photon counts.

In order to obtain radicals by pyrolysis, a tape-heater wrapped around a 10 mm diameter quartz tube was used at about 20 cm upstream from the ionization chamber. The temperature was varied in the region between room temperature and 580 °C. The total pressure was measured by a capacitance manometer (MKS-Baratoron). The sample pressure was typically about 0.6 m Torr in the ionization chamber.

In order to investigate the temperature dependence of pyrolysis of C_2H_4=SO, ion counts for several species were measured in the range, room temperature to 580 °C. The sample was irradiated by light at 1160.3 Å, whose energy is higher than either of the IPs of the parent molecule or ethylene produced by pyrolysis, but it was lower than the AP of the fragment ethylene ion from the parent molecules. The SO^+ radical ion could not be used for monitoring the pyrolysis because its IP is higher than the AP of the SO^+ fragment ion from the parent molecules. The temperature dependence of ion counts produced by irradiation at 1160.3 Å is shown in Fig. 2. At 300 °C, the ion counts of C_2H_4=SO^+ were reduced to one-half of those at room temperature. With a further rise in the temperature, they were rarely observed. On the other hand, ion counts of ethylene increased up to 500 °C, and above 500 °C they remained stationary. Thus, the temperature of the pyrolysis was maintained at 510 °C throughout this experiment.

Results and Discussion

The relative photoionization efficiency curve of SO^+ from the SO radical for the wavelength region 915—1220 Å, is shown in Fig. 3, where the hydrogen discharge lamp was used as a source at a wavelength resolution (FWHM) of 2.3 Å. In the present experiment, the accuracy of the wavelength was determined to be within about 0.5 Å from H Lyman-α and H Lyman-β in the light source. For excited $O_2(a^1\Delta_g)$, Jonathan *et al.*[13] examined the photoelectron spectrum of the ($^2\Delta_g \leftarrow {}^1\Delta_g$ and $^2\Phi_u \leftarrow {}^1\Delta_g$) ionization transition using phase-sensitive detection. These transitions from the $a^1\Delta$ state could not be being observed in the present photoionization efficiency curve, the reason that the excited $SO(a^1\Delta)$ may have almost completely been deactivated. The photoionization efficiency rises sharply at 1206.3±0.5 Å (=10.28±0.01 eV), and above this threshold there is a gradual increase in ionization cross section. Somewhat strong peaks, assigned to autoionization structures, have been detected between 1010 and 920 Å from which the autoionization structures have been determined. But along the SO^+ photoionization curve there are no very strong vibrational progressions like O_2^+ between 1005 Å (the threshold of IP) and 850 Å.[4] Therefore, spectroscopic studies could not be done as successfully of the autoionization peaks in SO^+ as those of the broad ones S_2^+.[5]

Furthermore, to obtain various thermodynamic data

Table 1. Summary of photoionization data for the system of ethylene sulfoxide

Ion	Threshold eV[a)]	Process	Temperature °C
SO^+	10.28±0.01	$SO(X^3\Sigma^-)+h\nu\rightarrow SO^+(X^2\Pi)+e$	510
SO^+	10.13±0.01	C_2H_4=SO+$h\nu\rightarrow C_2H_4(X^1A_{1g})+SO^+(X^2\Pi)+e$	26
C_2H_4=SO^+	9.49±0.02	C_2H_4=SO+$h\nu\rightarrow C_2H_4$=SO^++e	26

a) Estimated uncertainties.

relating to C_2H_4=SO, the threshold energies were measured. Figure 4 shows the relative photoionization cross section of (a) C_2H_4=SO at room temperature, (b) SO^+ fragment ion from C_2H_4=SO at room temperature, (c) SO^+ ionized directly from the SO radical at 510°C. $C_2H_4^+$ fragment ions at room temperature were not observed. These threshold energies are summarized in Table 1.

The IP of SO in the present work is in excellent agreement with the value of 10.29±0.02 eV obtained from photoelectron spectra by Jonathan *et al.*[7] and that of 10.21 eV obtained from the photofragmentation method by Dibeler and Liston.[11] Though, it was assumed that SO^+ ions might appear from $SO(a^1\Delta)$

produced by pyrolysis of C_2H_4=SO in the region longer than 1206.3 Å (=10.28 eV) by means of an allowed $SO^+(X^2\Pi)\leftarrow SO(a^1\Delta)$ ionization transition, in fact, SO^+ ions were not observed in this region as can be seen in Fig. 4(c). This results from the fact that the excited $SO(a^1\Delta)$ was almost completely deactivated to the ground state before it reached to the ionization chamber.

The AP of SO^+ fragment ion from C_2H_4=SO and the IP of C_2H_4=SO were determined. It is worth noting that the IP of the SO radical is about 0.15 eV higher than the AP of SO^+ from C_2H_4=SO. In the pyrolysis of C_2H_4=SO described in process (1), C_2H_4=SO must correlate to $SO(a^1\Delta)$ from spin conservation, thus decomposition to $C_2H_4+SO(a^1\Delta)$ is an endothermic reaction. The values of ΔH_f in the following reactions are derived by using the transition energy of $SO(a^1\Delta\leftarrow X^3\Sigma^-)$ from chemiluminescence studies of Barnes *et al.*[12]

$$C_2H_4{=}SO \begin{cases} \rightarrow C_2H_4+SO(a^1\Delta) \\ \qquad\qquad \Delta H_f = 13.3\pm0.1 \text{ kcal/mol}^\dagger \\ \rightarrow C_2H_4+SO(X^3\Sigma^-) \\ \qquad\qquad \Delta H_f = -3.5\pm0.1 \text{ kcal/mol} \end{cases}$$

The transitions to $SO^+(X^2\Pi)$ from both $SO(a^1\Delta)$ and $SO(X^3\Sigma^-)$ are allowed. It seems that the exothermicity of the reaction in pyrolysis contributes to the ionization of SO from parent molecule. Therefore, it stands to reason that the AP of SO^+ from C_2H_4=SO is lower than the IP of the SO radical. From these results and the IP of C_2H_4=SO, the following bond energies of $D_0(C_2H_4{=}SO)$ and $D_0(C_2H_4{=}SO^+)$ were obtained;

$$D_0(C_2H_4{=}SO) = 4640\pm30 \text{ cm}^{-1}$$

$$D_0(C_2H_4{=}SO^+) = 5160\pm30 \text{ cm}^{-1}$$

Furthermore, from a consideration of the temperature dependence of C_2H_4=SO, the activation energy in the system of C_2H_4=SO has been estimated.

This reaction is regarded as a first-order irreversible unimolecular decomposition reaction of the plug type, and, so, the following equation in logarithmic form is obtained;

$$\ln(C_0/C) = (k/v)l, \tag{4}$$

where C_0 and C are sample concentrations of the entrance and exit regions of the pyrolysis tube, respectively, and k is the rate constant, v is the flow rate, and l is the length of the pyrolysis tube. From the expressions for the rate constant, k expressed in terms of the frequency factor A, and the activation energy E, we obtain the following equation;

$$\ln(\ln(C_0/C)) = -E/RT + \ln Al/v. \tag{5}$$

†1 cal_{th}=4.184 J.

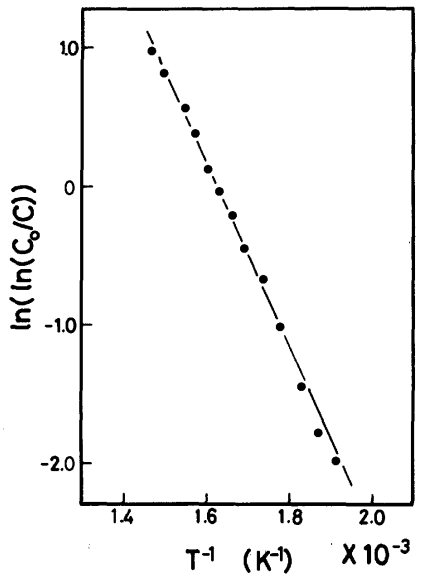

Fig. 5. Arrhenius plot of $\ln(\ln(C_0/C))$ versus T^{-1} obtained from the ion counts of C_2H_4=SO^+ in Fig. 2.

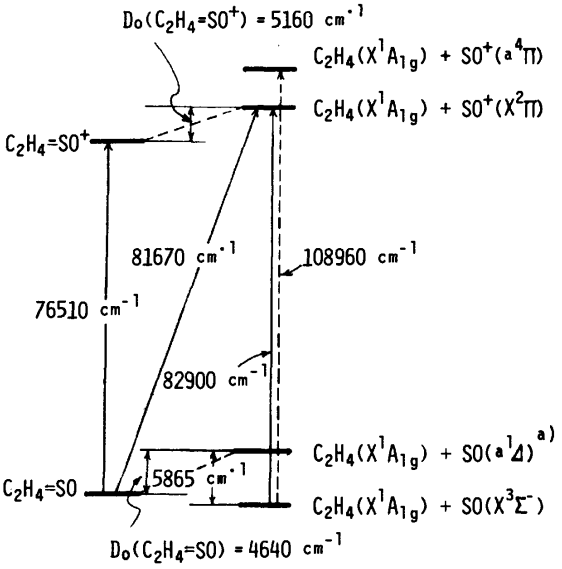

Fig. 6. The energy diagram of C_2H_4=SO and SO.
a) The energy difference between $a^1\Delta$ and $X^3\Sigma^-$ from Ref. 12.

Then the plot of $\ln(\ln(C_0/C))$ versus T^{-1} will yield the activation energy E from slope of the curve.

The plot of $\ln(\ln(C_0/C))$ versus T^{-1} which was obtained from the ion counts of C_2H_4=SO^+ in Fig. 2 is shown in Fig. 5. The activation energy was estimated to be 13.6 kcal/mol and was in excellent agreement with the value of $D_0(C_2H_4{=}SO)$ obtained from the above discussion.

The energy diagram of C_2H_4=SO and SO is summarized in Fig. 6.

Although the electronic state of C_2H_4=SO has not yet been studied, it is presumed that the electron in the highest occupied molecular orbital is an antibonding electron because the bond energy of the neutral state is

less than that of the ionic state.

The authors would like to thank Dr. S. Saito of Institute for Molecular Science for preparing ethylene sulfoxide.

Internal Energy Distributions of NH($A^3\Pi$). An Application of Phase Space Theory to the Electron-impact Dissociation

Ikuo Tokue* and Yoshio Ito
Department of Chemistry, Faculty of Science, Niigata University, Niigata 950-21
(Received June 27, 1985)

Internal energy distributions of NH(A) produced by electron impact on NH_3, HN_3, and HNCO are compared with those predicted by use of the phase space theory based on the method of Light and Pechukas. The values predicted under conservation of energy and total angular momentum are found to be inconsistent with the experimental results. The observed values are well simulated *via* the introduction of a nonstatistical bias by representing the selective coupling between the reaction coordinate and the rotational modes of the products. The dynamics for formation of NH(A) is discussed.

The decomposition of polyatomic molecules is a typical example of unimolecular reactions. Unimolecular processes only proceed at an appreciable rate when the reacting molecule posseses an internal energy greater than a certain threshold value corresponding to the activation energy. These active molecules arise in the process of chemical reaction as a result of inelastic molecular collisions, or on electron, or photon, impact. The basic idea of the statistical theory of unimolecular reactions[1] is that an active molecule is considered as a closed system whose states are distributed with equal probability over hypersurfaces of constant total energy.

The transition state theory[2] of chemical reactions identifies the transition complex having activation energy along the reaction coordinate. In the reactions such as bond dissociations, however, there is little or no potential-energy barrier along the reaction coordinates. Light and Pechukas[3] treated atom-molecule reactions which proceed without activation energy under the requirement that the reaction complex can dissociate over the orbital angular momentum barrier in the final state. Their method was successfully applied to the photodissociation $NH_3 \rightarrow NH(c^1\Pi)+H_2$.[4] Mies[5] pointed out that their space theory is a special microcanonical version of the transition state theory for the "loose complex," where the activated complex is the rotational barrier in the asymptotic channel. Horie and Kasuga[6] proposed another statistical model including the law of angular momentum conservation and discussed the decomposition $H_2O \rightarrow H+OH(A^2\Sigma^+)$ through electron or photon impact.

We previously reported formation and internal energy distributions of NH($A^3\Pi$) by electron impact on NH_3,[7] HN_3,[8] and HNCO.[9] The basic idea of Light and Pechukas[3] can be applied to these electron-impact dissociations. In the present paper, the observed distributions of NH(A) from NH_3, HN_3, and HNCO are compared with those predicted by a statistical calculation based on the method of Light and Pechukas.[3] In order to give an account of the observed values, we have introduced a nonstatistical bias by representing the selective coupling between the reaction coordinate and the rotational mode of the products. On comparison between the observed distributions and the predicted by the statistical calculations, the dynamics for formation of NH(A) is discussed.

Method of Calculation

Outline of Calculation. The main requirements imposed on the system[1] are that the reaction proceeds *via* an intermediate complex with a long lifetime and that the coupling between different degrees of freedom must ensure a sufficiently intensive energy exchange between them. This statistical theory assumes that the size of the phase volume accesible to the active and activated molecules is limited only by the condition that the energy is constant. Furthermore, conservation of the total angular momentum of the system imposes an additional restriction on the size of the phase volume of the active and activated molecules. This restriction is especially important for "loose" activated molecules. Moreover, the conservation of angular momentum is important when the active molecule arises as a result of excitation by electron impact. This is connected with the fact that, due to electron impact, a large amount of electronic-vibrational excitation energy is usually transferred to the molecule, but the rotational angular momentum of the molecule is very little changed.

To evaluate the energy distribution, we introduce the available energy (E_{av}) defined by the difference between the vertical and the adiabatic energy required for decomposition. The probability of decomposition of the parent molecule to a given state is the same to all the states to be accessible under conservation of energy and total angular momentum. Thus, for this system, the validity of the microcanonical distribution is assumed. Accordingly, after decomposition, E_{av} is allowed to be distributed among all the degrees of freedom in the products. The initial angular momentum $\boldsymbol{J}$ (momentums are written throughout in units of $\hbar$) possessed by the parent molecule as molecular rotation must be equal to the sum of those of the molecular rotations of the fragments and the orbital angular momentum between them.

Theoretical Energy Distributions of the NH(A) Product.

We treat here a direct dissociation into final fragments such as Reactions 1 and 2, and do not consider an indirect process such as Reaction 3, where one of the products are quasibound in an intermediate state.

$$NH_3 \longrightarrow NH(A)+H_2(X), \quad (1)$$

$$NH_3 \longrightarrow NH(A)+H(ls)+H(ls), \quad (2)$$

$$NH_3 \longrightarrow NH_2^*+H(ls), \quad (3a)$$

$$NH_2^* \longrightarrow NH(A)+H(ls), \quad (3b)$$

$$HN_3 \longrightarrow NH(A)+N_2(X), \quad (4)$$

$$HNCO \longrightarrow NH(A)+CO(X). \quad (5)$$

The calculation of the internal energy distributions was carried out on the basis of the following methods: Method 1 is a simple statistical calculation under the requirement of conservation of energy. Method 2 is the statistical calculation based on the method of Light and Pechukas.[3] In Method 3, a nonstatistical bias is introduced into the population distribution.

In the case of a reaction such as M→NH+B, where B is a diatomic molecule, $\boldsymbol{J}_N$, $\boldsymbol{J}_B$, $\boldsymbol{J}$, $\boldsymbol{l}$, $\boldsymbol{k}$, their space-fixed z components, v_N, and v_B can be used to specify the quantum states of all the products. The v_N and v_B are the vibrational quantum numbers of NH and B, respectively. The $\boldsymbol{J}_N$ and $\boldsymbol{J}_B$ are the rotational angular momenta of NH and B, respectively, $\boldsymbol{l}$ is the orbital angular momentum among the fragments, $\boldsymbol{k}$ is an intermediate angular momentum associated with a vector sum $\boldsymbol{J}_N+\boldsymbol{J}_B$, and $\boldsymbol{J}$ corresponds to the total angular momentum $\boldsymbol{J}=\boldsymbol{k}+\boldsymbol{l}$. The angular momenta are restricted by energy conservation and by the triangle inequalities:[10] namely, the corresponding quantum numbers k and J can have the values $|J_N-J_B|\leq k\leq J_N+J_B$ and $|k-l|\leq J\leq k+l$.

On the assumption of a Boltzmann temperature of 298 K for the ground state of parent molecules, the distribution of J, $P(J)$, was evaluated by use of the rotational constants.[11] The total number of the J state among various product states with E_{av} is given by

$$N(J,E_{av})=\sum_{v_N}\sum_{v_B}\sum_{J_N}\sum_{J_B}\sum_{l=0}^{l_{max}} 1, \quad (6)$$

under conservation of total energy that $E_{av}=E_{tr}+E_{rot}+E_{vib}$, where E_{tr} denotes the translational energy, and E_{rot} and E_{vib} are the rotational and the vibrational energies of all the fragments,[12] respectively. Light and Pechukas[3] derived the quantum number of the maximum orbital angular momentum, l_{max}, from the interaction potential between the products. However, no information is found about the interaction potential among the fragments from parent molecules. In this study, the interaction constant (spherically averaged sum of dipole-induced dipole and dispersion contributions) denoted by C are estimated on the basis of the method of Hirschfelder *et al.*[13] by use of data on the polarizabilities, dipole moments, ionization potentials for H[14] and diatomic fragments.[12,13] Dipole moment and polarizabiliy of NH(A) are assumed to be 3.34×10^{-30} Cm (1 D) and 1×10^{-30} m^3, respectively. The interaction constants thus obtained are listed in Table 1. In preliminary analysis, the internal energy distributions evaluated are found to be rather insensitive to l_{max}.

The probability of dissociation into each accessible final state having J is $P(J)/N(J,E_{av})$. Thus, the rotational distribution in the v_N level of NH(A) can be reperesented with collection of all the states having J_N and v_N as follows:

$$P(J_N,v_N,E_{av})=\sum_{v_B}\sum_{J_B}\sum_{l}\sum_{J}P(J)/N(J,E_{av}), \quad (7)$$

under the conservation of energy and the restriction based on the two triangle inequalities on angular momenta. In Reaction 2, we must exclude summation over v_B and J_B from Eqs. 6 and 7. Equation 7 is summed to give the vibrational distribution of NH(A),

$$P(v_N,E_{av})=\sum_{J_N}P(J_N,v_N,E_{av}). \quad (8)$$

In calculation of the rotational distribution of NH(A) by Method 1, Eq. 7 is replaced by

$$P(J_N,v_N,E_{av})=\sum_{v_B}\sum_{J_B} 1, \quad (9)$$

where the sum includes, of course, the accessible states under conservation of energy.

In electron-impact dissociation at energies over the onset for formation of NH(A), an available energy (E_{av}) converting into the translational and internal energies of products cannot be given very clearly because collisions with electrons are essentially an energy-loss process. Thus, E_{av} was treated as an adjustable parameter.

Following a series of diagnostic calculation for Reactions 1, 2, 4, and 5, a nonstatistical bias is introduced into the rotational distribution (Method 3) with the view of agreement with the observed values: namely, Eq. 7 is multiplied by a factor of $\exp(-\beta|E_{av}-E_{rot}|)$, where β is a parameter representing the strength of coupling between the reaction coordinate and the rotation of the fragments. This factor realizes the resonance feature in energy transfer of the available energy into the rotation of the fragments. Thus, in Method 3, the validity of the microcanonical distribution no longer holds good. The parameter β represents insufficientness in energy exchange among various degrees of freedom at the energy partitioning process.[15] When β decreases to zero, Method 3 apparently results in Method 2.

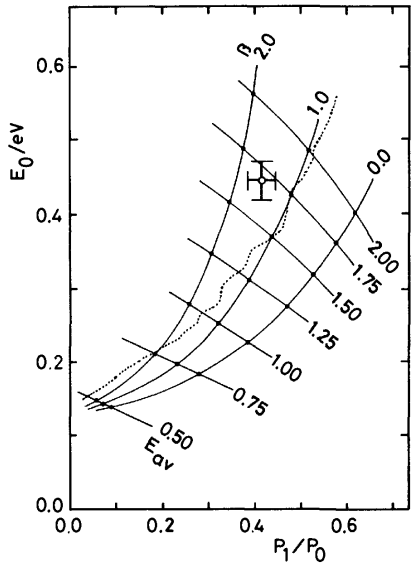

Fig. 1. Rotational energy (E_0) *versus* vibrational population ratio (P_1/P_0) predicted for Reaction 1: the open circle with error bars shows the observed values at electron energy of 17 eV. The dotted line shows the results by Method 1. The solid line with β=0 shows those by Method 2 and the others with β=1.0 and 2.0 show those by Method 3.

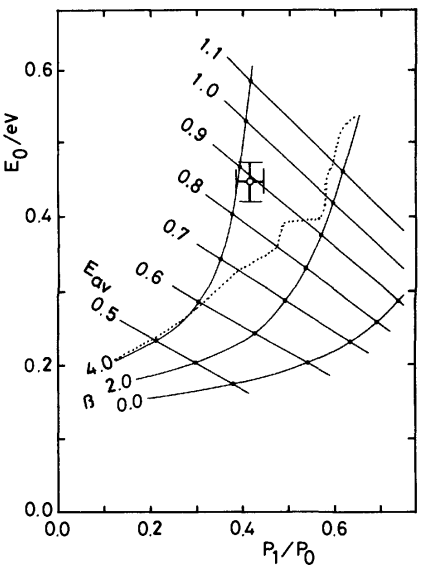

Fig. 2. The same as Fig. 1 but for Reaction 2.

Results and Discussion

Vibrational Population Ratio versus *Rotational Energy of NH(A).* In the analysis of the emission intensities of the NH(A-X) spectrum, we used the relative vibrational population ($P_v/P_{v=0}$) and the rotational temperature (T_v) of the v=0 and 1 levels of the NH(A) state. Although the rotational distribution evaluated by use of the statistical methods can be approximated by a Boltzmann temperature, the population decreases more rapidly with increasing J_N and

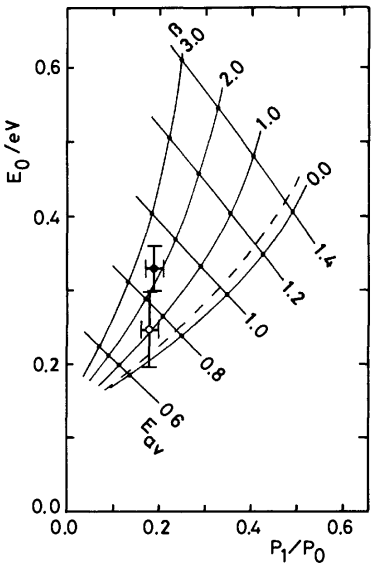

Fig. 3. The same as Fig. 1 but for Reaction 4. The open and the closed circles with error bars show the results at electron energies of 7 and 10 eV, respectively.

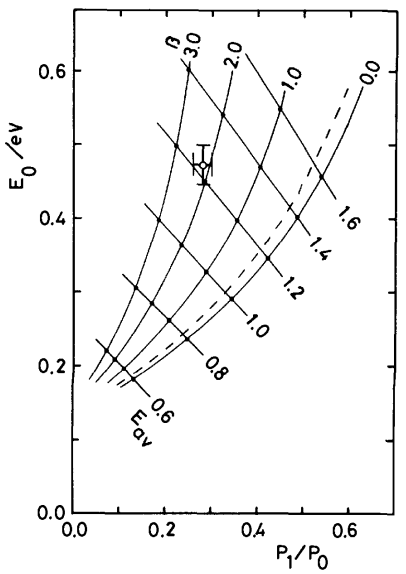

Fig. 4. The same as Fig. 1 but for Reaction 5.

disappears suddenly. Henthforce, the observed rotational distributions were compared with those predicted in the form of E_v being the rotational energy concerning with the v level.

In Figs. 1—4, E_0 is plotted *versus* P_1/P_0 comparing the observed values with the predicted by three methods. The observed results from NH_3 and HN_3 are nearly consistent with the predicted by Method 1 for Reactions 1 and 4, respectively, but are inconsistent with those by Method 2. On the contrary, the results predicted for Reactions 2 and 5 by both Methods 1 and 2 cannot explain the observed values from NH_3 and HNCO, respectively. These imply that the agreement between the observed and the predicted for

Reactions 1 and 4 by Method 1 is specious because Method 2 is more accurate than Method 1. Accordingly, in order to explain the observed results, we have introduced a nonstatistical bias and have adjusted not only E_{av} but the coupling parameter β. Table 1 lists the predicted E_0 and P_1/P_0 by use of best fit E_{av} and β comparing with the observed.

Recently, Kajimoto[15] has treated the rotational distributions of NH($c^1\Pi$) through photolysis of NH_3 by use of a nonstatistical bias representing the coupling between the bending motion of NH_3 precursor and the rotation of NH(c). On the assumption of vibrational energy of 21 kJ/mol (0.22 eV) for bending motion of NH_3, the observed distributions has been well simulated by use of β=0.024 mol/kJ (2.3 eV^{-1}). On the contrary, the best-fit E_{av} and β for formation of NH(A) through electron impact on NH_3, HN_3, and HNCO are 0.8—1.7 eV and 1.0—3.7 eV^{-1}, respectively. This implies that many vibrational motions of precursor are strongly coupled with the rotation of NH(A).

Formation of NH(A) from NH_3. In electron-impact dissociation of NH_3, NH(A) is produced *via* two different channels.[7] One corresponds to Reaction 1 *via* a triplet precursor with the onset energy of 8.0 eV and the other corresponds to Reaction 2 with the onset energy of 12.3 eV. Reactions 1 and 2 similarly contribute to the formation of NH(A) at the lowest impact energy of 17 eV, to which the population analysis could be applied, while Reaction 2 is main contributors of the formation of NH(A) above 17 eV. The rotational distributions of the v=0 and 1 levels of NH(A) are found to vary only moderately from 17 up to 92 eV. This indicates that the rotational distribution of NH(A) produced *via* Reaction 1 is nearly equal to those *via* Reaction 2.

The observed values are shown in Fig. 5 comparing with the results predicted for Reactions 1 and 2. The distributions predicted for Reaction 1 is in fairly good agreement with the observed, while those for Reaction 2 is inconsistent with the observed. The results for Reaction 1 by Method 3, however, rather overestimate

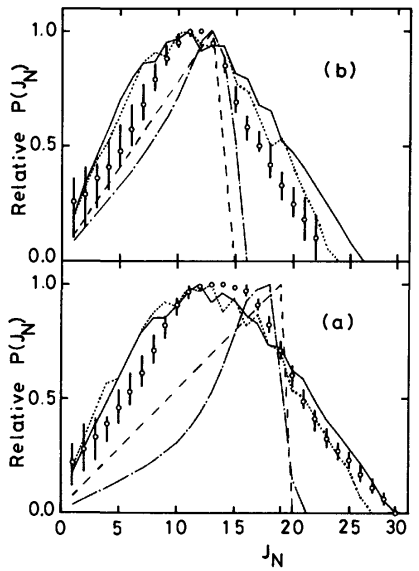

Fig. 5. The relative rotational distributions of NH(A) from NH_3 for (a) the v=0 level and (b) the v=1 level: ------, Method 1 for Reaction 1; ——, Method 3 for Reaction 1; ———, Method 1 for Reaction 2; —·—·—, Method 3 for Reaction 3. The open circles with error bars show the observed values.

the distributions of the v=1 level above J_N=15. This is due to the application of single coupling constant β to the distributions of both the v=0 and 1 levels. The difference between the observed distributions and the predicted for Reaction 2 seems to originate in the application of the method of Light and Pechukas.[3]

In unimolecular reactions into an atom(s)+diatomic product such as Reaction 2, the predicted distribution is extremely nonthermal and strongly depends on E_{av}. In case of electron-impact excitation, the electron energy for impinging electron is not so monoenergetic, contrary to photon excitation. On the basis of the Franck-Condon principle, the distribution of E_{av} may be determined by reflecting the position probability function associated with the normal vibrations of the ground state of parent molecule onto the potential

energy surface of the precursor state. Accordingly, E_{av} is expected to have a rather broad distribution. In such a case, it is necessary to take the weighted mean of the population distributions obtained for a wide range of values of E_{av}. On the assumption of a Gaussian distribution for E_{av}, Horie and Kasuga[6] reproduced the rotational distribution of OH(A) produced by electron impact on H_2O. When both the ground and the precursor states of NH_3 are well informed, we expect to give an account of the observed rotational distribution of NH(A) for Reaction 2 by Method 3 using a suitable distribution of E_{av}. On the contrary, in unimolecular reactions into two diatomic products such as Reactions 1, 4, and 5, the predicted distribution is nearly thermal and only moderately depends on E_{av}. In this case, even if we do not consider the distribution of E_{av}, we can reproduce the observed distribution by use of the best fit E_{av} and β. The value of E_{av} thus obtained means rather an averaged value. Incidentally, for Reaction 3b, calculation of the internal energy distributions of NH(A) by Method 2 by use of a variety of Boltzmann temperatures for NH_2* failed in agreement with the observed.

Runau *et al.*[16] reported in their *ab initio* study that the SCF potential curve calculated for Reaction 1 correlates with the $^3A_2''$ state (point group D_{3h}), which corresponds to excitation out of the $3a_1$ (C_{3v}) MO into the $4a_1$ (Rydberg 3s+H 1s) orbital. This $^3A_2''$ precursor (the lowest triplet state) belongs to the Rydberg state having a planar geometry since one of the lone pair electrons is mainly excited into the atomic orbital of the N atom. Thus, the excitation from the non-planar ground state into the planar triplet precursor causes the strong excitation of the umbrella inversion of NH_3. The rotational distributions of the departing fragments are selectively enhanced during subsequent bond-dissociation process. This gives rise to the breakdown of the assumption of the microcanonical distribution.

Formation of NH(A) from HN_3 and HNCO. The molecular structures of the ground state of HN_3[17] and HNCO[18] are trans bent in equilibrium (point group C_s). On the basis of CNDO/S study, we reported[8,9] that the precursor forming NH(A) from HN_3 and HNCO is presumably the $2^3A''$ state corresponding to excitation out of the 9a′ MO into the 3a″ MO. This result for HN_3 is supported by *ab initio* study.[19]

The observed rotational distributions of the $v=0$ level of NH(A) from HN_3 depend on the impact energy, while those from HNCO is independent of the impact energy. In HN_3, the values near the onset are compared with those predicted since the foregoing energy dependence is due to two different channels for formation of NH(A).

In the previous report for HNCO,[9] T_0 and P_1/P_0 are compared with those predicted by a simple statistical calculation based on the information theory.[20] This method assumes complete randomization of the available energy among all degrees of freedom in the products under the requirement of conservation of energy. The results predicted by use of E_{av}=0.7 eV show that the internal energy of NH(A) is selectively enhanced in the dissociation of the precursor state of HNCO. The present results show that the rotational distributions of NH(A) from HN_3 and HNCO are selectively enhanced much more than predicted by Method 2. Thus, the assumption of the microcanonical distribution cannot apply to Reactions 4 and 5. It can be concluded that the molecular structure of the $2^3A''$ precursor state of HN_3 and HNCO in equilibrium is fairly different from each ground state. For HN_3, Moore and Rosengren[21] found that the HN-NN stretch is strongly mixed with the H-N-N bend on the ground state. This suggests that the HN-NN stretching motion enhances the angular momentum of the separating NH+N_2 products when HN_3 dissociates.

Conclusion

On comparison of the observed and predicted internal energy distributions of NH(A), the assumption of the microcanonical distribution is found to be inapplicable to formation of NH(A) from NH_3, HN_3, and HNCO. The good agreement with the observed results is obtained by introduction of a coupling parameter, which represents the resonance feature in energy transfer process of the available energy. This result leads to selective excitation of the rotation of the fragments during bond-dissociation process.

Even if the phase space theory cannot be applied to the dissociation of such a small molecule, the internal energy distribution predicted can be used to estimate the mean available energy in electron-impact dissociation. Furthermore, this method including a nonstatistical bias can be used as a convenient criterion for prediction of whether the available energy is completely randomized among all the degrees of freedom in the products or a specific mode is enhanced.

Preparation, Crystal Structure, and Stereochemical Properties of {*N,N'*-Ethylenebis(1,1,1-trifluoro-4-imino-2-pentanonato)} (L-methioninato)cobalt(III)

Ken-ichi OKAMOTO,* Katsuhiro MATSUTANI, and Yuki FUJII†

†*Department of Chemistry, Ibaraki University, Mito, Ibaraki 310*
(Received July 9, 1985)

The $(-)_{435}$ isomer of the {*N,N'*-ethylenebis(1,1,1-trifluoro-4-imino-2-pentanonato)}(L-methioninato)cobalt(III) complex, $(-)_{435}$-[Co(tfac$_2$en)(L-met)], was preferentially crystallized from an equilibrium mixture of the $(-)_{435}$ and $(+)_{435}$ isomers in methanol. The crystal structure of the $(-)_{435}$ isomer was determined by X-ray diffraction. The $(-)_{435}$ isomer is of a Λ-cis-β_2 type in which the quadridentate tfac$_2$en takes a nonplanar configuration, and the L-methioninate is bound to the cobalt atom by nitrogen and oxygen atoms as a bidentate ligand. The electronic absorption, CD, and ^{1}H NMR spectral behaviors of both $(-)_{435}$ and $(+)_{435}$ isomers are discussed in relation to their geometrical and absolute configurations.

Mixed cobalt(III) complexes with quadridentate Schiff base and bidentate ligands (such as amino carboxylates and β-diketonates) have been investigated regarding their kinetic and thermodynamic stereoselectivities.[1-6] Some of these have been determined by X-ray crystal structure analyses.[7-10] Concerning these cobalt(III) complexes, it has been known that a quadridentate Schiff base, which usually contains salicylideneaminate moieties, selectively takes a nonplanar cis-β configuration[11a] by coordination.[1-10] Further, complexes with amino carboxylate as a bidentate ligand preferentially take a mer(N)[11b] configuration.[1-5] In order to elucidate the source of a regioselective effect due to the quadridentate Schiff base, we employed in this work *N,N'*-ethylenebis(1,1,1-trifluoro-4-imino-2-pentanonate), tfac$_2$en, which has flexible β-imino ketone moieties instead of salicylideneaminate ones. Also, its cobalt(III) complex with L-methioninate was prepared.

The present paper deals with the crystal structure of $(-)_{435}$-[Co(tfac$_2$en)(L-met)], which was preferentially crystallized from an equilibrium mixture of the $(-)_{435}$ and $(+)_{435}$ isomers in methanol. The absorption and CD spectra of the $(-)_{435}$ and $(+)_{435}$ isomers are discussed in comparison with those of corresponding cobalt(III) complexes with a quadridentate Schiff base, together with their stereochemical properties.

Experimental

1) Preparation of [Co(tfac$_2$en)(L-met)]. A warm solution (*ca.* 40 °C) containing 0.57 g of L-methionine in 15 cm^3 of water was added to a hot solution (*ca.* 40 °C) containing 1.5 g of [Co(tfac$_2$en)] (prepared by a procedure similar to that described in the literature[16,17]) in 80 cm^3 of methanol. The solution was vigorously stirred in the open for about 4 h at room temperature. The color of the solution changed from orange-brown to green. After filtration, the green filtrate was concentrated to about 10 cm^3 and appeared as a green crude product. The product (collected by filtration) was dissolved in a small amount of methanol and then slowly recrystallized by evaporating the solvent at room temperature to form the $(-)_{435}$ isomer as massive crystals in about 80% yield. A piece of crystal, thus obtained, was used for an X-ray diffraction study. Found: C, 37.84; H, 4.08; N, 7.83%. Calcd for [Co(tfac$_2$en)(L-met)]=$CoC_{17}H_{22}N_3O_4SF_6$: C, 38.00; H, 4.13; N, 7.82%. $[M]^{25}_{435}=-52900°$ / mol dm^{-3} m (mixed solvent of *N,N*-dimethylformamide (DMF)–$CHCl_3$ (1:4 in volume); concentration, 1.0×10^{-3} mol dm^{-3}).

When the green crude product or the pure $(-)_{435}$ isomer obtained above was recrystallized from a methanol–water (4:1) mixture, the complex consisted of two kinds of crystalline forms, a large amount of massive crystals ($(-)_{435}$ isomer) and a small amount of needle-shaped crystals ($(+)_{435}$ isomer). The needle-shaped crystals could be sorted by hand. Yield; about 15%. Found: C, 38.04; H, 4.13; N, 8.08%. Calcd for [Co(tfac$_2$en)(L-met)]: C, 38.00; H. 4.13; N, 7.82%. $[M]^{25}_{435}=+50100°$ / mol dm^{-3} m (mixed solvent of DMF–$CHCl_3$ (1:4); concentration, 1.0×10^{-3} mol dm^{-3}).

2) General Data. The electronic absorption spectra were recorded with JASCO UVIDEC-1 and UVIDEC-610 spectrophotometers and the CD spectra with a JASCO J-20 spectropolarimeter. All measurements were carried out at room temperature. Rotations at 435 nm were measured with a JASCO DIP-140 polarimeter at 25 °C. The ^{1}H NMR spectra were recorded with a Hitachi R-20 spectrometer at 35 °C, using tetramethylsilane (TMS) as an internal reference. X-Ray analysis calculations were carried out on a FACOM M-380 computer at the Uviversity of Tsukuba.

3) X-Ray Characterization. Unit cell parameters and intensity data for the single crystal (*ca.* $0.1\times0.12\times0.5$ mm^3) were measured on a Rigaku-denki four-circle diffractometer (AFC-5) with graphite-monochromatized Mo$K\alpha$ radiation. The unit-cell parameters were determined by a least-squares refinement based on 44 reflections. Systematic absences led to an assignment of the space group $P2_12_12_1$. The crystal data are summarized in Table 1.

Intensity data were collected by a ω—2θ scan technique up to $2\theta=60°$ with a scan rate of 3 °/min. The intensity data were converted to F_o data in the usual manner. Absorption corrections were not applied. A total of 2059 independent reflections with $F_o>3\sigma(|F_o|)$ were considered as 'observed' and used for the structure analysis.

4) Determination of the Crystal Structure. The position of the cobalt atom was obtained from a three-dimentional Patterson function. Difference Fourier maps, based on the cobalt position, revealed all the non-hydrogen atoms. The

structure was refined by a full-matrix least-squares refinement of the positional and anisotropic thermal parameters of all the non-hydrogen atoms (program RFINE by L. W. Finger was used). The neutral atomic scattering factors for all the non-hydrogen atoms were taken from the literature.[18] The final R and R_w values converged to 0.086 and 0.098, respectively. The absolute configuration was determined on the basis of the known configuration of L-methioninate.[19] The final atomic parameters are given in Table 2. A list of structure factors (Table A), anisotropic thermal parameters of non-hydrogen atoms (Table B), and the projected figure of the crystal structure (Fig. A) are kept at the Chemical Society of Japan as Document No. 8551.

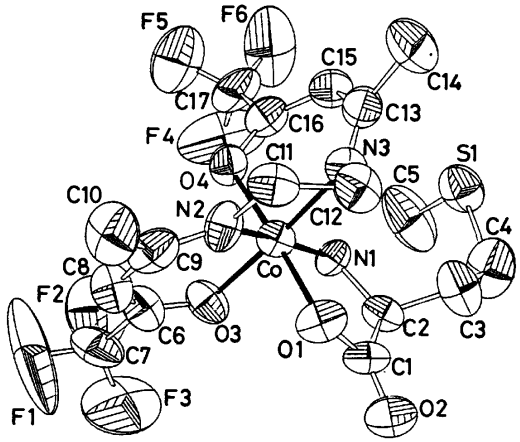

Fig. 1. A perspective drawing of (−)$_{435}$-Λ-cis-β_2-[Co(tfac$_2$en) (L-met)] with the numbering scheme of atoms.

Results and Discussion

Description of the Structure. A perspective drawing of (−)$_{435}$-[Co(tfac$_2$en)(L-met)] is given in Fig. 1, together with a numbering scheme. The bond lengths and angles (with their standard deviations) for the (−)$_{435}$ isomer are listed in Table 3. The L-methioninate ligand coordinates to a cobalt atom with nitrogen and oxygen atoms serving as a bidentate ligand. The tfac$_2$en Schiff base, which coordinates as a quadridentate ligand, takes the cis-β_2 configuration by coordination.[11] Namely, the cobalt atom is surrounded by a meridional N_3O_3 structure and the nitrogen atom in the L-met (N1) is located on the trans position of the nitrogen atom (N2) of the tfac(1) moiety (tfac; 1,1,1-trifluoro-4-imino-2-pentanonate). The absolute configuration of (−)$_{435}$-[Co(tfac$_2$en)(L-met)] was determined to be Λ on the basis of the known absolute configuration, $S(C)$, of the asymmetric carbon atom of the L-methioninate.[19] Thus, the structure of the (−)$_{435}$ isomer is denoted as the Λ-cis-β_2 type (Fig. 1). This has a similar structure to those of [Co(α-Me-sal$_2$en)(L-isoleu)][9] and [Co(α-Me-sal$_2$en)(N-Bz-L-ala)][10] (α-Me-sal$_2$en; N,N'-ethylenebis(*o*-hydroxy-α-methylbenzylideneaminate, L-isoleu; L-isoleucine, and N-Bz-L-ala; N-benzyl-L-alanine). These results coincide with the fact that the cis-α structure of the cobalt(III) Schiff base complexes is unstable and such a complex has not been found yet.[1-5,9,10]

The bond lengths and angles of (−)$_{435}$-[Co(tfac$_2$en)(L-met)] are similar to those of cobalt(III) complexes with amino carboxylate and quadridentate Schiff bases such as salen and α-Me-sal$_2$en (Table 3).[9,10] The Co–O and Co–N bond lengths of the tfac$_2$en ligand are somewhat longer than those of [Co(α-Me-sal$_2$en)(L-isoleu)][9] and [Co(α-Me-sal$_2$en)(N-Bz-L-ala)],[10] while the distances of the L-methioninate, Co–O1 1.849(9) Å and Co–N1 1.968(9) Å, are significantly shorter than those of the N-Bz-L-ala and L-isoleu in the α-Me-sal$_2$en complexes.[9,10] On the contrary, the chelate angles for the L-met,

plane(1)-tfac(2)	62.0°	plane(3)-met	8.1°
plane(1)-met	81.7°	plane(3)-tfac(1)	80.6°
plane(2)-tfac(2)	34.5°	plane(3)-tfac(2)	75.7°

N1-Co-O1 85.5(4)°, and for the tfac$_2$en, N2-Co-N3 83.4(5)° and N3-Co-O4 90.4(4)°, are approximately in agreement with those of the cobalt(III) complexes with α-Me-sal$_2$en and amino carboxylate.[9,10]

The angles among the planes of the three equatorial planes, plane(1)-plane(3), of the octahedron around the cobalt atom and the planes passing through tfac(1), tfac(2), and the L-met moieties are summarized in Table 4. These dihedral angles are affected by the highly strained conformational state about the coordinated ethylene ring, N2-C11-C12-N3, and the coordination geometry around the azomethine nitrogens, N2 and N3, as in the case of the cobalt(III) complexes with a quadridentate Schiff base.[7-10] In the present complex, however, the dihedral angle between plane(1) and tfac(1) is 10.4° and is smaller than the corresponding angles of [Co(salen)(acac)] (17.9°)[7] and [Co(α-Me-sal$_2$en)(*N*-Bz-L-ala)](29.3°).[10] This seems to reflect the difference in the rigidity between the 1,1,1-trifluoro-4-imino-2-pentanonate and salicylideneaminate moieties.

Absorption and CD Spectra. The electronic absorption and CD spectra of $(-)_{435}$-Λ-cis-β_2-and $(+)_{435}$-[Co(tfac$_2$en)(L-met)] are shown in Fig. 2 and their data are summarized in Table 5. The absorption spectral behaviors of the $(-)_{435}$-Λ-cis-β_2 and $(+)_{435}$ isomers closely resemble each other, showing identical peaks at 17.24, 29.76, and 38.17×10^3 cm^{-1}. The $(-)_{435}$-Λ-cis-β_2 isomer exhibits four CD bands in the region of 14—35×10^3 cm^{-1}, corresponding to absorption peaks and shoulders as shown in Fig. 2. The $(+)_{435}$ isomer exhibits CD patterns that are almost enantiomeric relative to that of the $(-)_{435}$-Λ-cis-β_2 one. These facts indicate that the $(+)_{435}$ isomer can safely be assigned a Δ-cis-β_2 structure.

The configurational CD curve (Λ) and the vicinal CD curve (L) due to a coordinated L-met of the $(-)_{435}$-Λ-cis-β_2 isomer are shown in Fig. 2. These were calculated using the following equations:

$$(\text{L}) = 1/2 \times \{\Delta\varepsilon(-) + \Delta\varepsilon(+)\}$$

$$(\Lambda) = 1/2 \times \{\Delta\varepsilon(-) - \Delta\varepsilon(+)\}$$

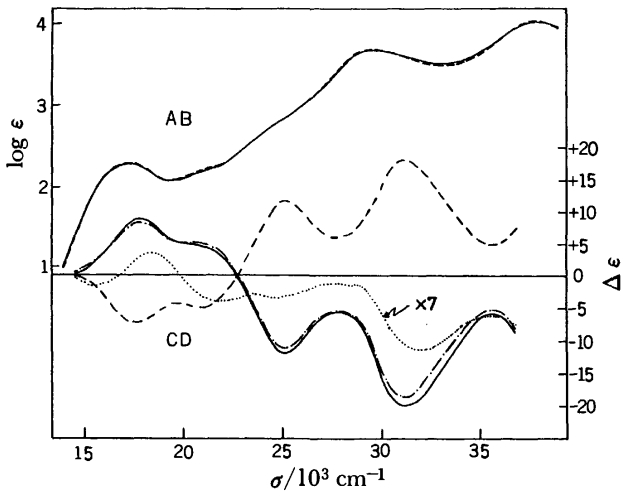

Fig. 2. Absorption and CD spectra of *cis*-β_2-[Co(tfac$_2$en)(L-met)] in DMF-$CHCl_3$ (1:4) mixture: $(-)_{435}$-*Λ-cis*-β_2 (——) and $(+)_{435}$-*Δ-cis*-β_2 (------). Two calculated CD curves of the vicinal (·····) and configurational (—·—·—·—) effects are also shown.

where $\Delta\varepsilon(-)$ and $\Delta\varepsilon(+)$ denote the CD curves of the $(-)_{435}$ and $(+)_{435}$ isomers, respectively. The calculated configurational curve (Λ) shows almost the same pattern as the $(-)_{435}$-Λ-cis-β_2 isomer over the whole region and the positive CD sign in the first d-d absorption band region (Fig. 2). A similar configurational CD behavior has also been observed for the Λ-cis-β_2 isomers of cobalt(III) complexes with a sal$_2$en-type Schiff base and amino carboxylate.[5] The vicinal CD contribution (L) in the first d-d absorption band region is quite similar to those of sal$_2$en and α-Me-sal$_2$en cobalt(III) complexes with L-amino carboxylates chelated by their nitrogen and oxygen atoms (Fig. 2).[5] This fact coincides with the results of the present X-ray crystal analysis: (1) the coordinated atoms of L-met in [Co(tfac$_2$en)(L-met)] are nitrogen and oxygen and (2) the conformation of the N-O chelate ring of the coordinated L-met is quite similar to those of the L-amino carboxylates in α-Me-sal$_2$en complexes.[9,10]

It is interesting to note that the CD intensities in the d-d absorption band regions of Λ- or Δ-cis-β_2-[Co(tfac$_2$en)(L-met)](Fig. 2 and Table 5) are stronger than those of optically active cobalt(III) complexes with the linear quadridentate ligands such as ethylenediamine-*N,N'*-diacetate (edda) and its derivatives.[20] The absorption shoulder at 24.50×10^3 cm^{-1} and the CD band at 24.69×10^3 cm^{-1} seem to correspond to the second d-d absorption band due to their position and the absorption intensity (log ε=2.75). Also, the CD intensity is quite strong compared with that of cobalt(III) complexes with an edda-type ligand.[20] This intense CD band in the second d-d absorption band region seems to arise from a coordination of the alcoholic oxygen atoms of the Schiff base ligand to the cobalt(III) ion.[21] Such an increase of CD intensity has also been observed in the case of sal$_2$en-type complexes.[1,2,4,5]

The Λ- or Δ-cis-β_2 isomer of [Co(tfac$_2$en)(L-met)] exhibit an absorption band at 29.76×10^3 cm^{-1} and the CD band at *ca.* 30×10^3 cm^{-1} (Fig. 2). It has been known that the sal$_2$en-type complexes of Cu(II), Ni(II), Co(II), Co(III), and so on exhibit broad absorption bands and CD bands at *ca.* 30×10^3 cm^{-1} due to ligand π-π* transitions. This is mostly associated with an azomethine chromophore.[12-15] This suggests that the absorption and CD bands at *ca.* 30×10^3 cm^{-1} are assignable to the ligand π-π* transition due to azomethine moieties in the tfac$_2$en ligand. In the simple sal$_2$en-type complexes of Cu(II), Ni(II), Co(II), and Co(III), π-π* transitions split into two CD components with different signs due to the exciton interaction.[12-15] However, *Λ-* or *Δ-cis*-β_2-[Co(tfac$_2$en)(L-met)] exhibits only one CD band for this transition region and no exciton couplet was observed (Fig. 2). A similar trend was also observed for cis-β_2 type cobalt(III) complexes with a sal$_2$en-type Schiff base and bidentate ligands.[1-5] These facts suggest that the two azomethine moieties in *Λ-* or *Δ-cis*-β_2-[Co(tfac$_2$en)(L-met)] form a negligible dihedral angle which gives rise to non-zero components regarding the exciton interaction between them.

Properties. The $(-)_{435}$-Λ- and $(+)_{435}$-Δ-cis-β_2 isomers of [Co(tfac$_2$en)(L-met)] showed no mutarotation in *N,N*-dimethylformamide, dimethyl sulfoxide, and chloroform. However, they did exhibit mutarotation in methanol and showed the same optical rotation under equilibrium conditions (Fig. 3). The absorption spectral change during mutarotation was very small for each of the $(-)_{435}$-Λ- and $(+)_{435}$-Δ-cis-β_2 isomers and plots of ln $\alpha_\infty-\alpha_t$ *vs.* time for each mutarotation gave a straight line with the same slope ($k_{obsd}=9.50\times10^{-5}$ s^{-1}) up to at least 90% completion,[22] where α_t and α_∞ denote the optical rotation at 435 nm at time t and at equilibrium, respectively. Accordingly, it is obvious that the two isomers of *cis*-β_2-[Co(tfac$_2$en)(L-met)] isomerize in methanol to give a mixture of both isomers under equilibrium conditions. As shown in Fig. 4, the ^{1}H NMR spectra of the $(-)_{435}$

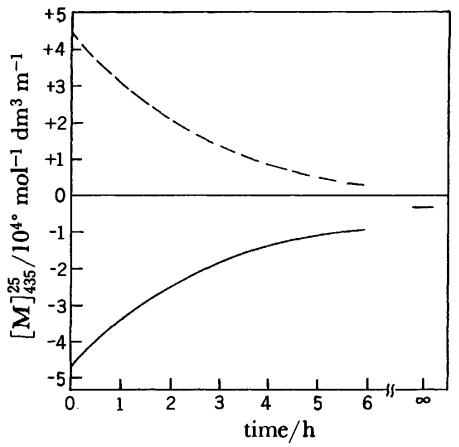

Fig. 3. Mutarotation of *cis*-β_2-[Co(tfac$_2$en)(L-met)] in CH_3OH at 25 °C: $(-)_{435}$-*Λ-cis*-β_2 (——) and $(+)_{435}$-Δ-*cis*-β_2 (------).

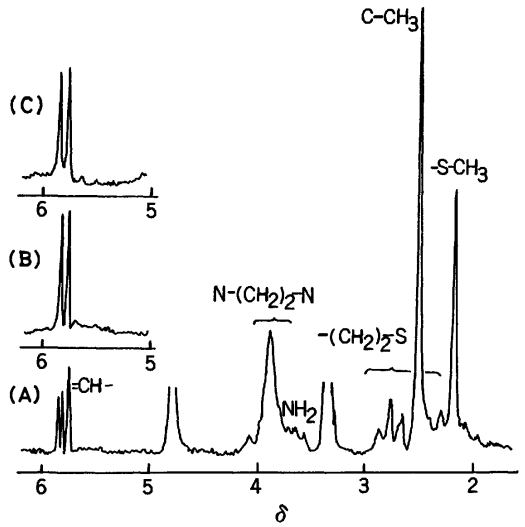

Fig. 4. ^{1}H NMR spectrum of *cis*-β_2-[Co(tfac$_2$en)(L-met)] in CD_3OD under equilibrium condition (A), and the C=CH signals of the $(-)_{435}$ (B) and $(+)_{435}$ (C) isomers soon after dissolution.

and $(+)_{435}$ isomers closely resemble each other except for the C=CH signal, supporting a similar geometrical structure to each other. From the intensity of the ^{1}H NMR signal for C=CH, the isomeric ratio in the equilibrium mixture, Λ-cis-β_2: Δ-cis-β_2, was estimated to be about 1:1. This ratio differs significantly from those in *cis*-β_2-[Co(sal$_2$en)(L-met)] (1.5:1) and *cis*-β_2-[Co(α-Me-sal$_2$en)(L-met)](2:1). This difference of diastereomeric stereoselectivity may be partly due to the flexibility of the β-imino ketone moieties as compared with those of salicylideneaminate. The $(-)_{435}$-Λ-cis-β_2 isomer was crystallized in high yield (*ca.* 80% for the total complex) from the solution, regardless of a 1:1 formation of the $(-)_{435}$-Λ- and $(+)_{435}$-Δ-cis-β_2 isomers under equilibrium conditions. Since the complex was labile in isomerization, the preferential crystallization of the $(-)_{435}$-Λ-cis-β_2 isomer could be safely ascribed to a thermodynamic origin. That is, a second-order asymmetric transformation from the Δ-cis-β_2 isomer to the Λ-cis-β_2 isomer due to the lower solubility of the latter. This kind of preferential crystallization is quite rare in cobalt(III) complexes.

In the case of [Co(tfac$_2$en)(L-met)], a cis-β_2 isomer was formed in the 100% regioselectivity as observed for the sal$_2$en-type Schiff base complexes.[1-5,9,10] Therefore, the regioselective behavior seems to be common in mixed cobalt(III) complexes with various kinds of quadridentate Schiff bases and amino carboxylate. It is fairly difficult, however, to explain the stereochemical reason for the high regioselectivity toward the cis-β_2 structure, *mer*(N_3O_3), as the corresponding cis-β_1 isomer, *fac*(N_3O_3), has not been found yet. It is probable that an electrostatic repulsion among three negatively charged oxygen atoms is much weaker in the *mer*(N_3O_3) configuration than in the *fac*(N_3O_3) configuration. Thus, the cis-β_2 isomer is thermodynamically more stable than the cis-β_1 isomer.[10]

(Received July 16, 1985)

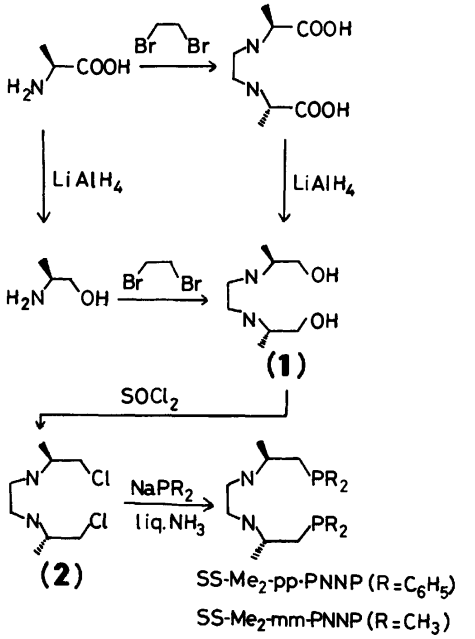
Two new optically active quadridentate phosphine ligands, (3*S*,8*S*)-3,8-dimethyl-1,1,10,10-tetraphenyl-4,7-diaza-1,10-diphosphadecane(*SS*-Me$_2$-pp-PNNP) and (4*S*,9*S*)-2,4,9,11-tetramethyl-5,8-diaza-2,11-diphosphadodecane-(*SS*-Me$_2$-mm-PNNP) and their cobalt(III) complexes, *trans*-[CoCl$_2$(*SS*-Me$_2$-pp- or *SS*-Me$_2$-mm-PNNP)]$^+$, *Λ*-*cis*-*β*-[Co(acac)(*SS*-Me$_2$-pp-PNNP)]$^{2+}$ (acac=2,4-pentanedionate ion), *Λ*-*cis*-*β*-[Co(CO$_3$)(*SS*-Me$_2$-pp-PNNP)]$^+$, and *Δ*- and *Λ*-*cis*-*β*-[Co(acac)(*SS*-Me$_2$-mm-PNNP)]$^{2+}$ were prepared and characterized. The molecular structure and the absolute configuration of (+)$_{589}$-*Λ*-*cis*-*β*-[Co(acac)(*SS*-Me$_2$-mm-PNNP)](ClO$_4$)$_2$·H$_2$O were determined by X-ray analysis. Crystal data; monoclinic, C2, *a*=28.274(4)Å, *b*=9.266(1)Å, *c*=11.0901(9)Å, *β*=92.97(1)°, *V*=2901.6(5)Å^3, and *Z*=4. Three five-membered chelate rings in the complex form distorted gauche (*δλλ*) conformations, and the methyl group on carbon of the apically linked chelate ring takes an axial disposition. Stereochemistry of all the complexes was discussed on the basis of the NMR, absorption and CD spectra.

In a previous paper,[1] cobalt(III) complexes containing 1,1,10,10-tetraphenyl-4,7-diaza-1,10-diphosphadecane (pp-PNNP) or 2,11-dimethyl-5,8-diaza-2,11-diphosphadodecane (mm-PNNP) were prepared, and the absorption spectra and stereochemistry were compared with those of the corresponding (2-aminoethyl)-diphenylphosphine (edpp) complexes. All of these quadridentate phosphine complexes formed stereoselectively a particular geometrical isomer. Introduction of asymmetric carbon atoms into a chelate ligand often brings about remarkable stereoselectivity in the formation of a particular optical isomer.[2] In this paper, we have prepared two optically active quadridentate phosphine ligands, (3*S*,8*S*)-3,8-dimethyl-1,1,10,10-tetraphenyl-4,7-diaza-1,10-diphosphadecane (*SS*-Me$_2$-pp-PNNP) and (4*S*,9*S*)-2,4,9,11-tetramethyl-5,8-diaza-2,11-diphosphadodecane (*SS*-Me$_2$-mm-PNNP), and their cobalt(III) complexes. The structure and absolute configuration of (+)$_{589}$-[Co(acac)(*SS*-Me$_2$-mm-PNNP)](ClO$_4$)$_2$·H$_2$O (acac=2,4-pentanedionate ion) have been determined by the X-ray diffraction method. Stereochemistry of other complexes was discussed by comparing the NMR, absorption, and circular dichroism spectra with those of the structurally known (+)$_{589}$-complex.

Experimental

Phosphine ligands, *SS*-Me$_2$-pp- and *SS*-*Me*$_2$-mm-PNNP, were prepared and handled under an atmosphere of nitrogen until they formed cobalt(III) complexes. All solvents used for preparing the ligands and complexes are deoxygenated by bubbling nitrogen for 20 min immediately before use. ^{1}H NMR, absorption and circular dichroism spectra were recorded on a Jeol JNM GX-400 spectrometer, a Hitachi 323 spectrophotometer and a Jasco J-40CS spectropolarimeter, respectively.

Preparation of Ligands. The optically active quadridentate phosphine ligands were prepared according to the synthetic route given in Scheme 1.



Scheme 1.

(2*S*,7*S*)-2,7-Dimethyl-3,6-diaza-1,8-octanediol (**1**) was prepared from (*S*)-alaninol (2-amino-1-propanol)[3] by a modified method of Holdiness *et al.*[4] (method **a**), or from (2*S*,7*S*)-2,7-dimethyl-3,6-diaza-octanedionic acid (EDDP)[5] (method **b**). Method **a**: To (*S*)-alaninol (63.8 g, 0.85 mol) in a 1 dm^3 three-necked round bottom flask was added dropwise 1,2-dibromoethane (25.3 g, 0.125 mol) over 1 h at 100 °C with stirring. Stirring was continued for 4 h at 100 °C, and then the solution was cooled to 0 °C and mixed with KOH (19.6 g, 0.35 mol) in ethanol (200 cm^3). After 1 h KBr precipitated was filtered, and the filtrate was evaporated under reduced pressure to remove ethanol, yielding an oily liquid. The liquid was distilled at *ca.* 130 Pa, giving unreacted (*S*)-alaninol at *ca.* 50 °C and the desired **1** at *ca.* 160 °C. Yield: 15.1 g, mp 99 °C, [*α*]$_D$=+28 °(H$_2$O, 25 °C). Elemental analysis

was performed on the hydrochloride salt of **1** (*vide infra*). Method **b**: To $LiAlH_4$ (15 g) in THF (400 cm^3) at 0 °C was added EDDP (14.8 g, 72.5 mmol) in small portions with stirring. The mixture foamed violently. The resulting solution was stirred at 0 °C for 30 min and then refluxed for 10 h. After cooling an aqueous solution (*ca.* 100 cm^3) saturated with KNa[*d*-tartrate]·$4H_2O$ was added dropwise to the solution. A white precipitate was filtered and washed twice with ethanol (50 cm^3×2). The filtrate and washings were combined, and the solvent was evaporated under reduced pressure. An oily liquid obtained was vacuum-distilled under the same conditions as in Method **a** to yield **1**. Yield: 6.05 g.

(2*S*,7*S*)-2,7-Dimethyl-1,8-dichloro-3,6-diazaoctane dihydrochloride (**2**) was prepared from **1**. HCl gas was bubbled under cooling into a chloroform solution (150 cm^3) of **1** (6.0 g, 34 mmol) in a 1 dm^3 three-necked round bottom flask, yielding white crystals (Found: C, 38.39; H, 8.93; N, 11.04%. Calcd for $C_8H_{22}N_2Cl_2O_2$=**1**·2HCl: C, 38.56; H, 8.93; N, 11.24%.). To the mixture was added $SOCl_2$ (12.5 g, 0.121 mol) dropwise over 15 min under cooling. The resulting solution was refluxed for 4 h in a water bath (60 °C), and then cooled in an ice bath. White crystals formed were filtered and recrystallized from hot isopropyl alcohol (200 cm^3). Yield: 4.5 g. Found: C, 33.72; H, 7.04; N, 9.84%. Calcd for $C_8H_{20}N_2Cl_4$(**2**): C, 33.59; H, 7.05; N, 9.79%.

(3S,8S)-3,8-Dimethyl-1,1,10,10-tetraphenyl-4,7-diaza-1,10-diphosphadecane (SS-Me$_2$*-pp-PNNP).* To liquid ammonia (250 cm^3) containing metallic sodium (1.33 g, 57.8 mmol) in a 500 cm^3 three-necked round bottom flask was added dropwise diphenylphosphine[6] (11.0 g, 59.1 mmol) over 5 min with stirring at −78 °C. After stirring for 1 h, the color of the solution changed from deep blue to orange. To the orange solution was added compound **2** (4.15 g, 14.5 mmol) in small portions with stirring. Stirring was continued for 1 h, giving a colorless solution. After liquid ammonia had been evaporated, water (100 cm^3) and then diethyl ether (80 cm^3) were added to the residue with stirring. The ethereal layer was separated from the aqueous layer and dried over $MgSO_4$ (*ca.* 3 g) overnight. A viscous liquid was obtained by removing the solvent and unreacted diphenylphosphine under vacuum. The product (*ca.* 6.0 g) was used for preparing cobalt(III) complexes without further purification.

(4S,9S)-2,4,9,11-Tetramethyl-5,8-diaza-2,11-diphosphadodecane (SS-Me$_2$*-mm-PNNP).* To liquid ammonia (100 cm^3) containing metallic sodium (0.6 g, 26 mmol) in a 300 cm^3 three-necked round bottom flask was added dropwise tetramethyldiphosphine[7] (1.5 g, 12.3 mmol) with stirring at −78 °C. After stirring for 1 h, compound **2** (1.8 g, 6.3 mmol) was added to the resulting orange solution in small portions with stirring. After 1 h liquid ammonia was evaporated, and then water (50 cm^3) and diethyl ether (50 cm^3) were added successively to the residue with stirring. The ethereal layer was separated from the aqueous layer, dried over $MgSO_4$ (*ca.* 2 g) overnight, and then distilled under reduced pressure to remove the solvent and unreacted dimethylphosphine. The colorless oily product thus obtained (*ca.* 1.3 g) was used for preparing cobalt(III) complexes without further purification.

Preparation of Complexes. trans-*[CoCl*$_2$*(SS-Me*$_2$*-pp-PNNP)]ClO*$_4$·*0.5H*$_2$*O*: To a methanol solution (50 cm^3) of $Co(ClO_4)_2·6H_2O$ (1.30 g, 3.55 mmol) was added *SS*-Me_2-pp-PNNP (1.75 g, 3.99 mmol) with stirring. An orange solution was obtained. Methanol was removed under reduced pressure, and the residue was dissolved in dichloromethane (250 cm^3). Chlorine gas was bubbled into the dichloromethane solution for 10 min, and then nitrogen gas for 20 min to remove excess Cl_2. To the resulting green solution was added methanol (20 cm^3), and the solution was evaporated to a small volume under reduced pressure, yielding a green precipitate (the solution should not be evaporated to dryness since perchlorates of complexes are potentially explosive in a solid state). The precipitate was dissolved in hot methanol (150 cm^3). Solid $NaClO_4·H_2O$ (22 g) was dissolved in the solution, which was stored in a refrigerator overnight. Green crystals yielded were filtered, washed with water and then diethyl ether, and air-dried. Yield: 627 mg. Additional crystals (234 mg) were obtained by concentrating the filtrate. Total yield: 34%. Found: C, 51.24; H, 5.00; N, 3.67%. Calcd for $C_{32}H_{39}N_2Cl_3CoO_{4.5}P_2$: C, 51.18; H, 5.23; N, 3.73%. The complex is soluble in methanol, dichloromethane, chloroform and acetone, but not in water, diethyl ether and benzene.

trans-*[CoCl*$_2$*(SS-Me*$_2$*-mm-PNNP)]ClO*$_4$·*0.5H*$_2$*O*. To *cis*-$[CoCl_2(en)_2]Cl$[8] (en=ethylenediamine) (2.5 g, 8.76 mmol) in a mixture of water (10 cm^3) and methanol (40 cm^3) was added *SS*-Me_2-mm-PNNP (0.871 g, 3.30 mmol) with stirring. After 1 h the solution was mixed with concd HCl(10 cm^3) and stirred for 4 h, the temperature of the solution being gradually raised from room temperature to 45 °C. The solution was cooled, filtered to remove $[Co(en)_3]Cl_3$ precipitated, and the filtrate was evaporated to dryness. Methanol (100 cm^3) was added to the residure, and the solution was filtered to remove insoluble $[Co(en)_3]Cl_3$. The filtrate was diluted with water (500 cm^3), and the solution was applied on a column (ϕ 8 cm×5 cm) of SP-Sephadex C-25 (Na^+ form). By elution with 0.05 mol dm^{-3} HCl, a blue eluate was collected, and evaporated to dryness under reduced pressure. The blue complex was extracted from the residue with ethanol, and the extract was evaporated again to dryness under reduced pressure. The residue was mixed with $LiClO_4·3H_2O$ (2 g) in water (15 cm^3), and the solution was stored in a refrigerator overnight, yielding blue crystals, which were filtered, washed with water and air-dried. Yield: 267 mg. Found: C, 28.73; H, 6.57; N, 5.06%. Calcd for $C_{12}H_{31}N_2Cl_3CoO_{4.5}P_2$: C, 28.68; H, 6.02; N, 5.57%. The complex is soluble in water, methanol and acetone, but not in dichloromethane, chloroform, diethyl ether and benzene.

Λ-cis*β*-*[Co(acac)(SS-Me*$_2$*-pp-PNNP)](ClO*$_4$*)*$_2$·*H*$_2$*O*. A methanol solution (75 cm^3) containing *trans*-$[CoCl_2(SS$-Me_2-pp-PNNP)]ClO_4·0.5H_2O$ (200 mg, 0.266 mmol) and Li(acac) (30 mg, 0.28 mmol) was stirred at room temperature for 7 h. The resulting orange-red solution was diluted with water (700 cm^3), and the solution was applied on a column (ϕ 3.5 cm×100 cm) of SP-Sephadex C-25. By elution with 0.2 mol dm^{-3} NaBr, a very small red band, a large red one, and a brown one were eluted successively. The eluate of the second red band was collected and concentrated to a small volume under reduced pressure. The red complex was extracted with chloroform, and the extract was evaporated to dryness. The residue was dissolved in water (10 cm^3), and the solution was mixed with $NaClO_4·H_2O$ (0.2 g) in water (1 cm^3). Red crystals formed were filtered, washed with a very small amount of water and then diethyl ether, and air-dried. Yield: *ca.* 50 mg. Found: C, 50.29; H, 5.19; N, 3.28%. Calcd for $C_{37}H_{47}N_2Cl_2CoO_{11}P_2$: C, 50.07; H, 5.34; N, 3.16%. The complex is soluble in water, methanol, dichloromethane and acetone, but not in diethyl ether and benzene.

(−)$_{589}$-Δ-cisβ-[Co(acac)(SS-Me$_2$-mm-PNNP)](ClO$_4$)$_2$·0.5NaClO$_4$·H$_2$O and (+)$_{589}$-Λ-cisβ-[Co(acac)(SS-Me$_2$-mm-PNNP)](ClO$_4$)$_2$·H$_2$O. A mixture of [Co(acac)$_3$][9] (380 mg, 1.08 mmol), *SS*-Me$_2$-mm-PNNP (200 mg, 0.320 mmol) and active charcoal (*ca.* 50 mg) in methanol (100 cm^3) was stirred at room temperature for 10 h, and filtered. The filtrate was diluted with water (1 dm^3) and applied on a column (φ3.5 cm×10 cm) of SP-Sephadex C-25. After complexes with the +1 charge contained in the adsorbed product had been eluted with 0.05 mol dm^{-3} NaCl, those with the +2 charge were eluted with 0.2 mol dm^{-3} NaCl. The orange eluate obtained was diluted with water (3 dm^3) and applied on a column (φ 3 cm×30 cm) of SE-Toyopearl.[10] Yellow-orange and orange bands (F-1 and F-2) were eluted successively with 0.3 mol dm^{-3} NaCl. Each eluate of F-1 and F-2 was mixed with excess NaClO$_4$·H$_2$O (*ca.* 2 g), and concentrated to a small volume under reduced pressure, yielding orange crystals which were filtered, washed with cold water, and air-dried. Yield (F-1): 10 mg. Found: C, 29.43; H, 5.72; N, 3.99%. Calcd for $C_{17}H_{39}N_2Cl_{2.5}CoNa_{0.5}O_{13}P_2$: C, 29.15; H, 5.61; N, 4.00%. Yield (F-2): 80 mg. Found: C, 32.04; H, 5.96; N, 4.52%. Calcd for $C_{17}H_{39}N_2CoCl_2O_{11}P_2$: C, 31.94; H, 6.15; N, 4.38%. Both complexes are soluble in water, methanol and acetone, but not in chloroform, dichloromethane, diethyl ether and benzene. Complexes F-1 and F-2 were assigned as the *Δ-cisβ* and *Λ-cisβ* isomers, respectively (*vide post*).

Λ-cisβ-[Co(CO$_3$)(SS-Me$_2$-pp-PNNP)]ClO$_4$·1.5(NaClO$_4$)·H$_2$O. To a methanol solution (100 cm^3) of *trans*-[CoCl$_2$(*SS*-Me$_2$-pp-PNNP)]ClO$_4$·0.5H$_2$O (300 mg, 0.40 mmol) were added (NH$_4$)$_2$CO$_3$ (100 mg, 1.04 mmol) and active charcoal (50 mg). The mixture was stirred for 2 h at room temperature and filtered. The filtrate was diluted with water (2 dm^3), and the solution applied on a column (φ 3.5 cm×90 cm) of SP-Sephadex C-25. The adsorbed product was eluted with 0.05 mol dm^{-3} NaCl, and the eluate of the first main red band was concentrated to a small volume under reduced pressure. The concentrate was mixed with chloroform to extract the red complex into the chloroform layer. The chloroform was evaporated under reduced pressure, and the residue was dissolved in water (25 cm^3). The solution was mixed with NaClO$_4$·H$_2$O (3.0 g) in water (5 cm^3), and stored in a refrigerator overnight, yielding a pink precipitate, which was filtered, washed with a small amount of water, and air-dried. Yield: 205 mg. Found: C, 42.74; H, 4.12; N, 2.85%. Calcd for $C_{33}H_{40}N_2CoCl_{2.5}Na_{1.5}O_{14}P_2$: C, 42.50; H, 4.32; N, 3.00%. The complex is soluble in water, methanol, acetone, dichloromethane and chloroform, but not in diethyl ether and benzene.

Optical Resolution of cisβ-[Co(acac)(pp-PNNP)](ClO$_4$)$_2$·H$_2$O. The complex was prepared by the method reported[1] and resolved by the follwing method. An aqueous solution of *cisβ*-[Co(acac)(pp-PNNP)](ClO$_4$)$_2$·H$_2$O (*ca.* 100 mg) was applied on a column (φ 3.5 cm×100 cm) of SP-Sephadex C-25. On elution with 0.1 mol dm^{-3} Na$_2$[Sb$_2$(*d*-tartrate)$_2$], two bands appeared. The eluate of the fast-moving band was collected, diluted ten times with water, and the solution was applied on a column (φ 3.5 cm×5 cm) of SP-Sephadex C-25. The adsorbed complex was eluted with 0.2 mol dm^{-3} NaCl. On addition of excess NaClO$_4$·H$_2$O the eluate gave crystalline (+)$_{589}$-*cisβ*-[Co(acac)(pp-PNNP)](ClO$_4$)$_2$·NaCl. From the slow-moving band the antipode was obtained. Found: C, 46.93; H, 4.74; N, 2.99%. Calcd for $C_{35}H_{41}N_2Cl_3CoNaO_{10}P_2$: C, 46.71; H, 4.51; N, 3.11%.

X-Ray Analysis. Single crystals of (+)$_{589}$-[Co(acac)(*SS*-Me$_2$-mm-PNNP)](ClO$_4$)$_2$·H$_2$O were obtained by recrystallizing the complex from methanol-water (3:2). Crystal data are as follows; Formula: $C_{17}H_{39}N_2Cl_2CoO_{11}P_2$, FW=639.3, Crystal system: monoclinic, Space group: C2, a=28.274(4) Å, b=9.266(1) Å, c=11.0901(9) Å, β=92.97(1)°, V=2901.6(5) Å^3, D_m=1.45 g cm^{-3}, D_x=1.46 g cm^{-3}, Z=4, μ(Mo $K\alpha$)=0.962 mm^{-1}. A specimen with dimensions 0.30×0.40×0.76 mm^3 was used for the X-ray work. Diffraction data were collected on a Rigaku AFC-5 four-circle diffractometer with graphite monochromatized Mo $K\alpha$ radiation at 298 K. Within the range $2\theta<60°$, 3229 independent reflections ($|F_o| \geqq 3\sigma(|F_o|)$) were obtained. In order to determine the absolute configuration, intensity data for Bijvoet pair reflections were also collected up to $2\theta=40°$. The intensity data were corrected for Lorentz-polarization effects, and for absorption. The calculations of the structure analysis were performed on a HITAC M-200H computer at the Computer Center of the Institute for Molecular Science with the Universal Crystallographic Computation Program System UNICS III[11]. The coordinate of the cobalt atom was deduced from a three dimensional Patterson function, and those of other atoms except hydrogens were determined by successive Fourier syntheses. The positions of all the hydrogen atoms were identified in subsequent difference-Fourier maps. The structure was refined by the block-diagonal least-squares method with anisotropic thermal parameters for non-hydrogen atoms and isotropic for hydrogens. The weighting scheme $\sigma_w=[\sigma_{count}^2+(0.015|F_o|)^2]^{-1}$ was employed. At the final stage, refinements were carried out on two enantiomeric models, *Δ* and *Λ*, using 4503 intensities including the Bijvoet pair reflections. The R and R_w values were reduced to 0.053 and 0.078, respectively for the *Λ*-configuration, whereas the values were 0.062 and 0.086 for the *Δ*-configuration, respectively. Thus application of the R-factor ratio test[12] showed that the *Δ*-model can be rejected at the 99.5% confidence level. This result confirms that two asymmetric carbon atoms in the *SS*-Me$_2$-mm-PNNP ligand have the *S*-configuration. Table 1 lists the atomic parameters for non-hydrogen atoms. Complete lists of observed and calculated structure factors, hydrogen atomic parameters, and thermal parameters for non-hydrogen atoms are preserved by the Chemical Society of Japan (Document No. 8552).

Results and Discussion

The optically active quadridentate phosphine ligands, *SS*-Me$_2$-pp- and *SS*-Me$_2$-mm-PNNP were prepared from (*S*)-alanine according to the same route as that for achiral pp- and mm-PNNP ligands.[1] The cobalt(III) complexes with these chiral ligands were also prepared by methods similar to those for the corresponding achiral PNNP complexes.[1] Chemical properties such as stability or solubility in various solvents of the new complexes are similar to those of the corresponding PNNP complexes.

The absorption spectra of [CoCl$_2$(*SS*-Me$_2$-pp- or *SS*-Me$_2$-mm-PNNP)]$^+$ shown in Fig. 1 are very similar to those of *trans*-[CoCl$_2$(pp- or mm-PNNP)]$^+$,[1] respectively, indicating the trans (Cl,Cl) isomer. The spectral data are listed in Table 2. On the other hand,

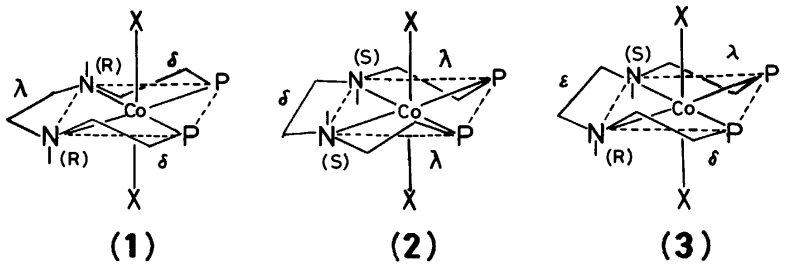

Fig. 2. Three possible diastereomers of *trans*-[$CoCl_2$(*SS*-Me_2-pp-PNNP)]$^+$.

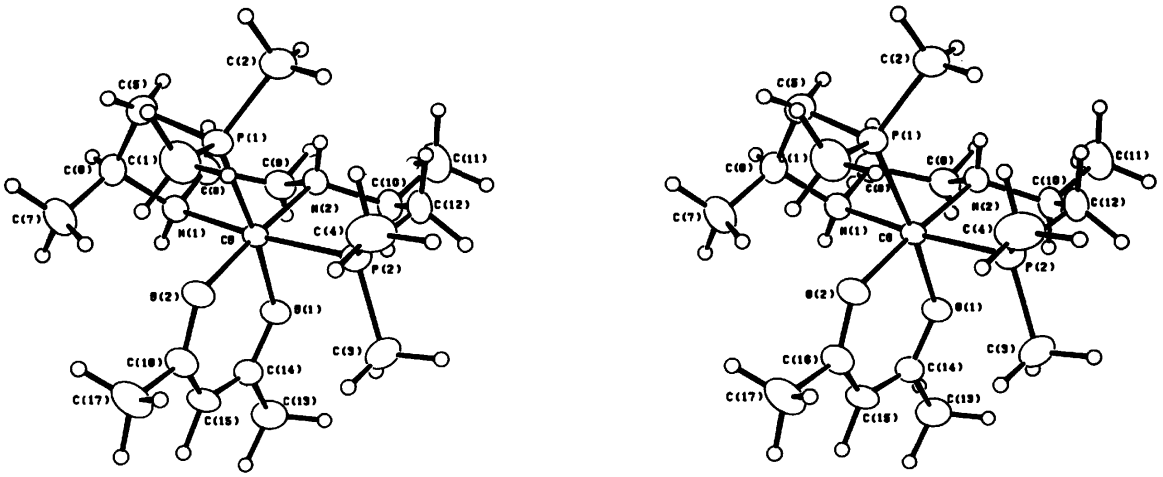

Fig. 3. ORTEP stereoview of $(+)_{589}$-*Λ*-*cisβ*-[Co(acac)(*SS*-Me_2-mm-PNNP)]$^{2+}$.

the CD spectrum of [$CoCl_2$(*SS*-Me_2-pp-PNNP)]$^+$ is nearly enantiomeric to that of *trans*(Cl,Cl),*cis*(P,P)-[$CoCl_2$(*S*-pdpp)$_2$]$^+$ (*S*-pdpp=(*S*)-$NH_2CH(CH_3)CH_2P(C_6H_5)_2$)[13] over the whole region as shown in Fig. 1, although the structures of the two complexes are similar, and all the chiral carbon atoms are the same *S* configuration. For the *SS*-Me_2-pp-PNNP complex, there are two more chiral sources, the chiral nitrogen atoms and the chiral conformation of the N–N chelate ring. In a previous paper,[13] we reported that the vicinal effect of the chiral nitrogen atom in the *trans*(Cl,Cl),*cis*(P,P)-[$CoCl_2$(N–P)$_2$]$^+$-type complex is very small, since the CD spectra of *S*-pdpp and *S*-prdpp (*S*(C),*S*(N)-$CH_2CH_2CH_2NHCHCH_2P(C_6H_5)_2$) complexes of this type are very similar. The latter complex has a chiral nitrogen donor atom of the *S*-configuration. Thus the effect of chiral conformation of the N–N chelate ring may be responsible for the big difference in CD spectra between the *SS*-Me_2-pp-PNNP and the *S*-pdpp complexes. The *trans*-[$CoCl_2$(*SS*-Me_2-pp-PNNP)]$^+$ complex has three possible diastereomers as shown in Fig. 2. The methyl groups of the *δ* and *λ* N–P chelate conformations have equatorial and axial dispositions, respectively, to the chelate ring. Since the complex shows only one kind of methyl signal in the ^{1}H NMR spectrum (-CH_3: 1.83 ppm), isomer **3** in Fig. 2 which has an equatorial and an axial methyl group can be excluded. Isomer **2** will be the least stable among the three isomers because of two axially disposed methyl groups. Thus the complex can be assigned as isomer **1**, where both methyl groups take an equatorial disposition, and the N–P and N–N chelate rings have the *δ* and *λ* conformations, respectively. In this isomer both nitrogen donor atoms become necessarily the *R* configuration. A structurally related tetraammine complex, $(-)_{589}$-*trans*-[$Co(NO_2)_2$(*SS*-3,8-Me_2-trien)]ClO_4 (*S,S*-3,8-Me_2-trien=(*SS*)-$NH_2CH_2CH(CH_3)NHCH_2CH_2NHCH(CH_3)CH_2NH_2$) forms three chelate rings of *δ*, *λ*, and *δ* conformations, and has two equatorial methyl groups and two *R*-nitrogen donor atoms.[14] The *trans*(Cl,Cl),*cis*(P,P)-[$CoCl_2$(*S*-pdpp)$_2$]$^+$ complex has no N–N chelate ring, and the N–P chelate rings will be stabilized in the *δ* conformation with an equatorial methyl group.[13] Thus the enantiomeric CD pattern of the *SS*-Me_2-pp-PNNP complex to that of the *S*-pdpp complex may be attributable to the extremely strong vicinal effect of the *λ*-(N–N) chelate ring compared with that of *δ*-(N–P) chelate one. Five-membered N–P chelate rings in cobalt(III) complexes often form a distorted gauche (nearly envelope) conformation,[15] and the vicinal effect of such a chelate ring would be smaller than that of a chelate ring with the typical gauche conformation.

The CD spectrum of the *SS*-Me_2-mm-PNNP complex resembles that of the *SS*-Me_2-pp-PNNP complex in the Ia absorption band region (14000—19000 cm^{-1}),

indicating similar chiral skeletal structures for both complexes. In the higher energy region, however, the CD spectra are quite different from each other. These differences may be attributable to the difference in substitutent on the phosphorus atom, methyl and phenyl groups.

For the [Co(O–O)(*SS*-Me_2-pp- or *SS*-Me_2-mm-PNNP)]$^{n+}$-type complexes (O–O=acac, CO_3^{2-}), two geometrical isomers cisα and cisβ are possible, and each geometrical isomer can form diastereomers arising from the chiral carbon and nitrogen atoms. The structure of $(+)_{589}$-[Co(acac)(*SS*-Me_2-mm-PNNP)]$(ClO_4)_2\cdot H_2O$, which was formed in much larger amounts than the other $(-)_{589}$-isomer, was determined by X-ray analysis. Figure 3 shows a stereoview of the complex cation with the numbering scheme of the atoms. The selected bond distances and angles are listed in Table 3. The complex ion has the *Λ*-cisβ configuration. The three chelate rings form distorted gauche ($\delta\lambda\lambda$) or envelope conformations as shown in Fig. 4. One methyl group (C(7)) at C(6) lies in an axial disposition to the chelate ring, while the other methyl group (C(11)) is in an equatorial disposition to the chelate ring. Such an axial methyl group has been found in *Λ*-cisβ-[Co(CO_3)(*SS*-3,8-Me_2-trien)]ClO_4.[16,17]

The Co–P distances (2.208(2), 2.196(2) Å) are slightly shorter than those found in [Co(edmp)$_2$(dmpe)]$Br_3\cdot 2H_2O$ (Co–edmp=2.294(3), 2.245(4); Co–dmpe=2.273(4), 2.295(3) Å),[18] $(+)_{589}$-*Λ*-[Co(en)$_2$(dmpe)]$Br_3\cdot 1.5H_2O$ (2.264(3), 2.248(3) Å),[19] and $(+)_{589}$-*Λ*-*fac*-[Co(edmp)$_3$]$Br_3\cdot 3H_2O$ (2.231(5), 2.239(4), 2.242(5) Å,[20] where edmp and dmpe denote $NH_2CH_2CH_2P(CH_3)_2$ and $(CH_3)_2PCH_2CH_2P(CH_3)_2$, respectively. The bond distances of Co–N(1) and Co–O(1) (trans to the P atom) are longer by 0.057 and 0.043 Å, respectively, than those of Co–N(2) and Co–O(2) (cis to the P atom), indicating trans influence of the P donor atom.[15] The average Co–N distance (2.015 Å) is fairly longer than that of the corresponding central two Co–N bonds in $(+)_{589}$-*Λ*-cisβ-[Co(CO_3)(*SS*-3,8-Me_2-trien)]ClO_4 (1.949 Å),[17] whereas the N–Co–N angles of these phosphine and trien complexes are similar (85.2(2) and 86.7(2)°, respectively). The chelate angles of P(1)–Co–N(1) (84.7(1)°) and P(2)–Co–N(2) (86.6(1)°) are nearly the same as those (84—86°) found in the edpp ($NH_2CH_2CH_2P(C_6H_5)_2$)[13,15] and edmp[18,20] complexes of cobalt(III).

The geometrical structure of the other isomer $(-)_{589}$-[Co(acac)(*SS*-Me_2-mm-PNNP)]$^{2+}$ can be assigned as the cisβ form, since it shows two kinds of –CH_3(acac) signals at 2.50 and 2.68 ppm in the ^{1}H NMR spectrum. Figure 5 compares the absorption and CD spectra with those of $(+)_{589}$-*Λ*-cisβ-[Co(acac)(*SS*-Me_2-mm-PNNP)]$^{2+}$. The CD spectrum of the $(-)_{589}$-isomer is nearly enantiomeric to that of the $(+)_{589}$-*Λ*-cisβ-isomer over the whole region. Thus the $(-)_{589}$-isomer is assigned as the *Λ*-cisβ-isomer. This isomer has further two possible

Table 3. Selected bond lengths(l/Å) and bond angles(ϕ/°) for $(+)_{589}$-*Λ*-cisβ-[Co(acac)(*SS*-Me_2-mm-PNNP)]$(ClO_4)_2\cdot H_2O$.

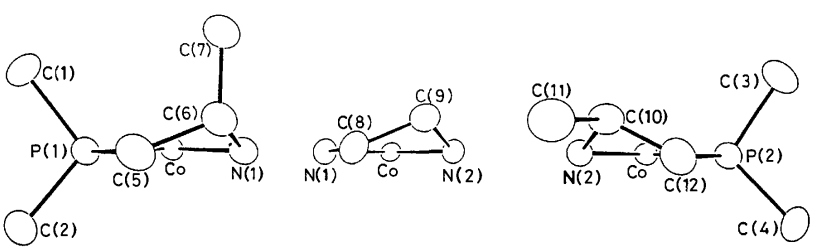

Fig. 4. Three chelate rings of $(+)_{589}$-*Λ*-cisβ-[Co(acac)(*SS*-Me_2-mm-PNNP)]$^{2+}$.

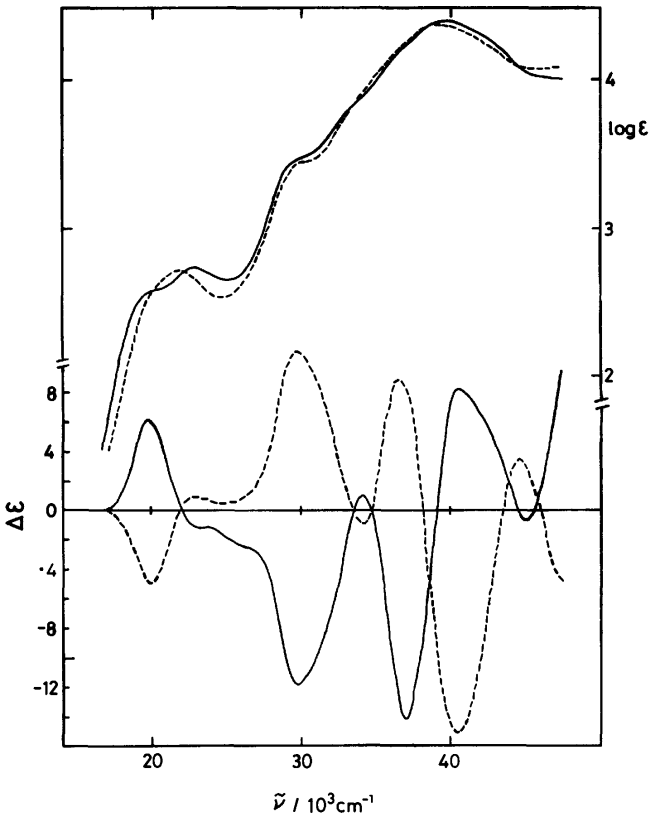

Fig. 5. Absorption and CD spectra of $(+)_{589}$-Λ-*cis*β-[Co(acac)(*SS*-Me$_2$-mm-PNNP)]$^{2+}$ (——) and $(-)_{589}$-Λ-*cis*β-[Co(acac)(*SS*-Me$_2$-mm-PNNP)]$^{2+}$ (------).

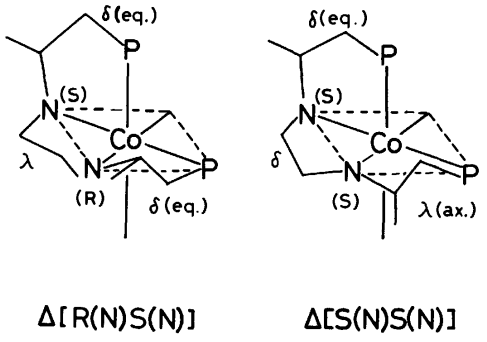

Fig. 6. Two possible diastereomers of Λ-*cis*β-[Co(acac)(*SS*-Me$_2$-mm-PNNP)]$^{2+}$.

diastereomers arising from the absolute configuration of the nitrogen donor atom as shown in Fig. 6. In the Λ[*R*(N)*S*(N)]-isomer, both methyl groups on carbon take an equatorial disposition, while in the Λ[*S*(N)*S*(N)]-isomer, the methyl group on carbon of the meridional-(PNN) coordination moiety (in-plane) becomes axial. No *cis*β complex having such an axial "in-plane" methyl group has been reported probably because of large intra- and interligand steric interactions with this methyl group. Thus the $(-)_{589}$-isomer can be assigned as the Λ[*R*(N)*S*(N)]-*cis*β-isomer shown in Fig. 6. This isomer was obtained by reaction of [Co(acac)$_3$] with the ligand in methanol in poor yield, the formation ratio of it to the other $(+)_{589}$-Λ-*cis*β-isomer being *ca.* 1/8. The

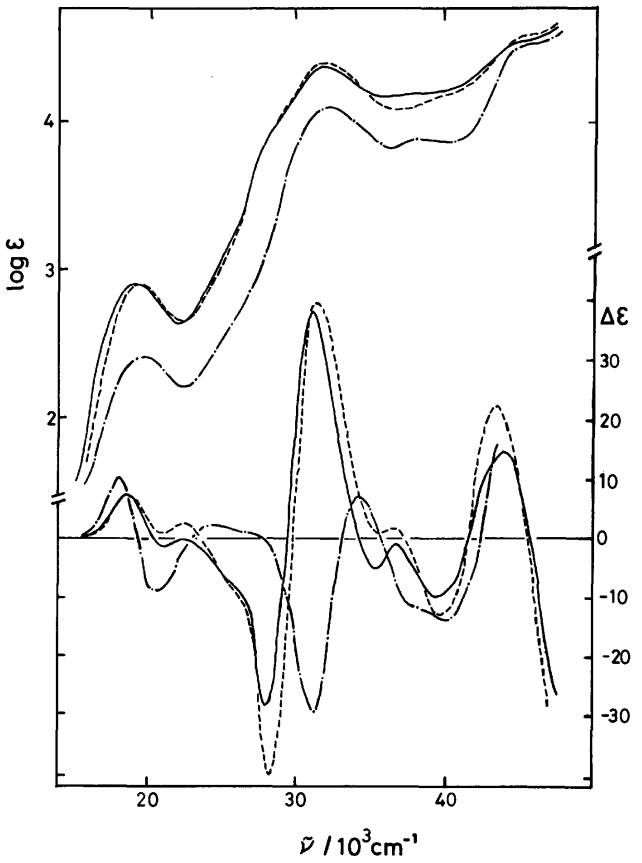

Fig. 7. Absorption and CD spectra of $(+)_{589}$-Λ-*cis*β-[Co(acac)(*SS*-Me$_2$-pp-PNNP)]$^{2+}$ (——), $(+)_{589}$-Λ-*cis*β-[Co(acac)(pp-PNNP)]$^{2+}$ (------) and $(+)_{589}$-Λ-*cis*β-[Co(CO$_3$)(*SS*-Me$_2$-pp-PNNP)]$^+$ (-·—·-).

reaction of *trans*-[CoCl$_2$(*SS*-Me$_2$-mm-PNNP)]$^+$ with Li(acac) in methanol afforded only the Λ-*cis*β-isomer, no other isomer being formed. In either experiment no *cis*α-isomer was yielded. These experimental results indicate that [Co(acac)(*SS*-Me$_2$-mm-PNNP)]$^{2+}$ is the most stable in the Λ[*R*(N)*R*(N)]-*cis*β structure, although this structure has an axially disposed methyl group on carbon of the apically linked N–P chelate ring. The reason for such selectivity is not clear at present. Saburi *et al.*[16] reported that structurally related [Co(CO$_3$)(*SS*-3,8-Me$_2$-trien)]$^+$ is more stable in the Λ-*cis*β form than in other forms. Complexes of such a (3*S*,8*S*)-dimethyl-substituted quadridentate ligand seem to be stabilized in the Λ-*cis*β form, irrespective of the kind of terminal donor atoms.

Both [Co(acac)(*SS*-Me$_2$-pp-PNNP)]$^{2+}$ and [Co(CO$_3$)(*SS*-Me$_2$-pp-PNNP)]$^+$ yielded only the $(+)_{589}$-isomer by reactions of *trans*-[CoCl$_2$(*SS*-Me$_2$-pp-PNNP)]$^+$ with Li(acac) and $(NH_4)_2CO_3$, respectively. For the acac complex, the reaction of [Co(acac)$_3$] with the ligand also formed only the same isomer. The ^{1}H NMR spectra of these acac and carbonato complexes clearly indicate that both of them are the *cis*β isomer. Figure 7 shows absorption and CD spectra of these complexes together with those of $(+)_{589}$-*cis*β-[Co(acac)(pp-PNNP)]$^{2+}$.

The CD spectral patterns of both *SS*-Me_2-pp-PNNP complexes resemble that of $(+)_{589}$-*Λ-cisβ*-[Co(acac)(*SS*-Me_2-mm-PNNP)]$^{2+}$ in the first absorption band region, a positive and a negative CD band from the low energy side. Thus the complexes can be assigned as the *Λ-cisβ*-isomer. All the nitrogen donor atoms in these isomers will have the same *R* configuration as those in *Λ-cisβ*-[Co(acac)(*SS*-Me_2-mm-PNNP)]$^{2+}$, since the *R*(N)*S*(N) isomer has two methyl groups in an axial disposition, and the *S*(N)*S*(N) isomer can not form the *Λ* configuration. As stated above, the *SS*-Me_2-pp-PNNP complexes formed only the *Λ-cisβ*-isomer. Neither the *cisα*- nor the *Δ-cisβ*-isomer which corresponds to the minor product ($(-)_{589}$-isomer) of [Co(acac)(*SS*-Me_2-mm-PNNP)]$^{2+}$ was detected.

The *cisβ*-[Co(acac)(pp-PNNP)]$^{2+}$ complex, which was only isomer obtained from *trans*-[$CoCl_2$(pp-PNNP)]$^+$ and Li(acac) in methanol,[1] shows an absorption spectrum nearly the same as that of the corresponding *SS*-Me_2-pp-PNNP complex. The CD spectrum of the resolved $(+)_{589}$-isomer is also very similar to that of the *SS*-Me_2-pp-PNNP complex which was assigned to the *Λ* configuration. Thus $(+)_{589}$-*cisβ*-[Co(acac)(pp-PNNP)]$^{2+}$ is assigned as the *Λ*-isomer,[21] and the two nitrogen donor atoms will have the same *R* configuration as those in the *SS*-Me_2-pp-PNNP complex. The presence of two chiral carbon atoms in the *SS*-Me_2-pp-PNNP complex seems to little affect both absorption and CD spectra.

The authors wish to thank the Ministry of Education for Scientific Research Grant-in-Aid No. 58470032 and 60470046, and the Institute for Molecular Science for the use of a diffractometer and a HITAC M-200H computer.

Na^+/H^+ Ion-exchange Process on Layered Hydrous Titanium Dioxide

Takayoshi SASAKI,* Mamoru WATANABE, Yū KOMATSU, and Yoshinori FUJIKI
National Institute for Research in Inorganic Materials, 1-1 Namiki, Sakura-mura, Niihari-gun, Ibaraki 305
(Received July 3, 1985)

The Na^+/H^+ ion-exchange on layered hydrous titanium dioxide, $H_2Ti_4O_9 \cdot 1.2—1.3H_2O$, has been studied from chemical and structural aspects. The ion-exchange reaction proceeded stepwise through two stages [0—50%, 50—72% conversion]. In stage I a discontinuous change in interlayer distance took place and the 1/2-exchanged phase with a widened interlayer distance appeared. The exchange in stage II proceeded *via* a solid solution and resulted in the 3/4-exchanged phase. The variation in unit cell dimensions indicates that these partially exchanged phases were formed by swelling the spacing of adjacent $[Ti_4O_9^{2-}]_n$ sheets. The structural and the thermoanalytical data can be interpreted on the basis of the structural model in which sodium ions and water molecules are arranged in a double row in the interlayer region.

Layered hydrous titanium dioxide, $H_2Ti_4O_9 \cdot 1.2—1.3H_2O$, has recently been prepared from potassium tetratitanate ($K_2Ti_4O_9$) by extracting interlayered potassium ions.[1-3] This material is attractive since it is one of the first hydrous metal oxides with a layer structure which act as inorganic ion exchangers. The material has a layer structure which consists of the host macroanion, $[Ti_4O_9^{2-}]_n$ sheets, and exchangeable protons (see Fig. 1).[4] Two types of exchangeable protons exist in the interlayer region; one oxonium ion and one hydroxylated proton per chemical formula. The unit cell has two equivalent interlayer spaces which are shifted by $b/2$ along the b axis. Each space contains two oxonium ions and two hydroxylated protons. This means that the material has four independent exchange sites. The authors have studied the K^+/H^+ ion-exchange process and obtained the satisfactory interpretation on the reaction mechanism which is consistent with the structural model described above:[4] Potassium ions replace the four exchange sites one by one. It is interesting and important to examine the exchange behavior of another ion to investigate whether the analogous explanation can be applied or not.

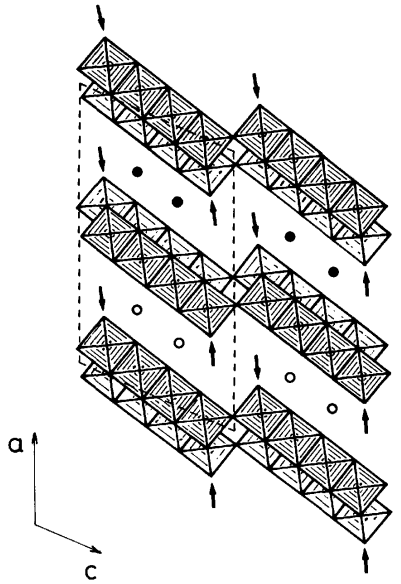

Fig. 1. Idealized representation of the crystal structure of layered hydrous titanium dioxide projected along (010). Arrows and circles show the possible positions of hydroxyl bonds and hydronium ions, respectively.

The ion-exchanged phases of layered hydrous titanium dioxide can be regarded as hydrated phases of alkali metal tetratitanate. Since these hydrated phases are chemically active, they are promising as catalyst carriers and starting or intermediate materials for further syntheses. There have been several reports on the hydrated phases which are obtained by hydrolyzing potassium tetratitanate.[1-3,5,6] This field is, however, in a state of confusion because the studies were not done systematically and they do not agree with each other. Moreover, no study has yet appeared on the hydrated phases of sodium tetratitanate. Thus it is significant to characterize the Na^+-exchanged phases from the viewpoint of clarifying the system of the hydrated phases of alkali metal tetratitanate.

This paper describes the Na^+/H^+ ion-exchange behavior on layered hydrous titanium dioxide and characterization of the Na^+-exchanged phases. The ion-exchange mechanism is discussed from chemical and structural aspects.

Experimental

Reagents. The titanium dioxide used was of 99.98% purity. All the other chemicals were of reagent grade. Distilled, deionized water was used throughout the experiments.

Preparation of Layered Hydrous Titanium Dioxide. Potassium tetratitanate ($K_2Ti_4O_9$) was grown in a fibrous form by slowly cooling a mixture of K_2O–$3TiO_2$ in a K_2MoO_4 flux melt from 1150 °C to 950 °C.[7] Layered hydrous titanium dioxide was obtained by extracting interlayered potassium ions from potassium tetratitanate:

$$K_2Ti_4O_9(s) + 2H^+(aq) + 1.2—1.3H_2O(aq) \longrightarrow H_2Ti_4O_9 \cdot 1.2—1.3H_2O(s) + 2K^+(aq)$$

The potassium ion extraction was performed by a column technique; about 15 g of potassium tetratitanate in a column (2.5 cm i.d.) was treated with a 1 mol dm^{-3} HCl solution until

the potassium ion concentration in the effluent decreased to be negligible. The resulting product was washed with water and was dried over a saturated NaCl solution (relative humidity: 70%) to a constant weight. The material used in this experiment had a composition of $H_2Ti_4O_9 \cdot 1.2H_2O$ (theoretical ion-exchange capacity: 5.57 mequiv g^{-1}) because the weight loss at 800 °C was 10.9%.

Titration Experiment. The titration experiment was carried out batchwise by shaking a weighed amount of the material with a 0.1 mol dm^{-3} (NaCl+NaOH) solution at 25±0.5 °C. The solution to solid ratio was 0.1 dm^3 g^{-1} and the ratio of NaCl/NaOH varied from 0.1 M/0.0 M to 0.0 M/0.1 M (1 M=1 mol dm^{-3}). After shaking for 4 d, an aliquat of the supernatant solution was pipetted and its sodium ion content as well as pH value was measured. The sodium ion uptake was calculated from the difference between initial and equilibrium concentrations of the solution. The solid was filtered off, washed with water and then dried over a saturated NaCl solution to a constant weight. The solid was characterized by chemical analysis, thermal analysis and powder X-ray diffractometry.

Apparatus. A TOA HM-20E digital pH meter was used to measure pH values of the solution. Sodium ion contents in the solution were determined by a Hitachi 180-80 atomic absorption spectrophotometer. X-Ray powder diffraction patterns were recorded by using a Philips PW-1130 type diffractometer with Ni-filtered Cu $K\alpha$ radiation (λ=1.5405 Å). Silicon or titanium dioxide (rutile) was used as an internal standard. The lattice constants were refined by the least-squares method.[8] The DTA-TG measurement was performed by using a Rigaku Denki M 8075 thermal analyzer at a heating rate of 10 °C min^{-1}.

Results and Discussion

Ion-exchange Process. Figure 2 shows the sodium ion titration curve. After an initial rising portion, the pH value increased rather gradually up to approximately 40% conversion. A pH jump was observed at 40—50% conversion and then the curve had a mild slope region again. At the uptake of 4.0 mequiv g^{-1}, the pH value increased steeply, indicating that the apparent capacity was approximately 3/4 of the theoretical limit.

Figure 3 shows the X-ray powder diffraction patterns of the ion-exchanged solids at various loading levels which were obtained in the titration experiment. The X-ray patterns changed continuously up to the loading level of 0.5 mequiv g^{-1}. This means that layered hydrous titanium dioxide (designated as phase HH) can accommodate sodium ions by forming a solid solution in this region. This region corresponded to the initial rising portion of the titration curve. Beyond this loading level, two immiscible solid phases were present; one was the resulting phase of the solid solution and the other was the exchanged phase with a widened interlayer distance of 11.2 Å. The latter phase increased as the exchange proceeded, and was observed alone near 50% conversion. This phase was verified as the 1/2-exchanged phase since the chemical composition was determined to be $Na_{0.98}H_{1.02}Ti_4O_9 \cdot 3.3H_2O$

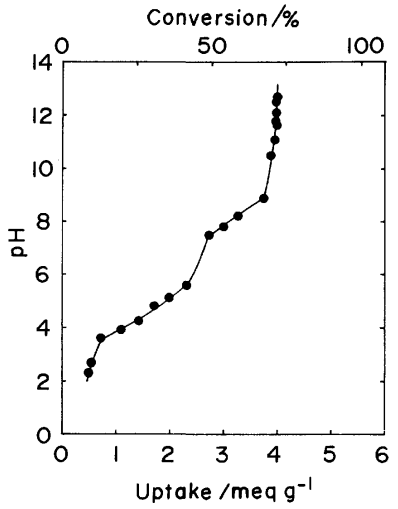

Fig. 2. Sodium ion titration curve. Exchanger: 0.2 g, Titrant: 20 cm^3 of 0.1 mol dm^{-3} (NaCl+NaOH) solution.

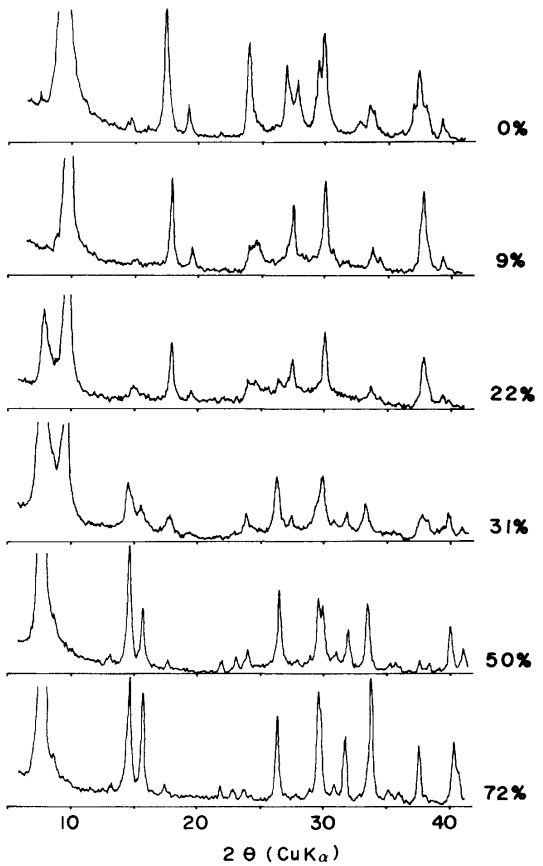

Fig. 3. X-Ray powder diffraction patterns of the sodium ion-exchanged solids at various loading levels. Numerals represent the percent uptake of sodium ion.

(termed phase Na1). Further exchange took place without an appreciable change in interlayer distance and water content. This indicates that sodium ions were taken into phase Na1 *via* a solid solution. The 3/4-exchanged phase (phase Na2) was formed at a result of this solid solution.

From the above results, the Na^+/H^+ ion-exchange process can be divided into two stages; stage I [0—50% conversion] and stage II [50—72%]. The ion-exchange reaction in each stage can be formulated as follows: stage I:

$$H_2Ti_4O_9 \cdot 1.2H_2O(s) + Na^+(aq) + 2.1H_2O(aq) \quad [9.1\ Å] \longrightarrow NaHTi_4O_9 \cdot 3.3H_2O(s) + H^+(aq) \quad [11.2\ Å]$$

stage II:

$$NaHTi_4O_9 \cdot 3.3H_2O(s) + 0.4Na^+(aq) \quad [11.2\ Å] \longrightarrow Na_{1.4}H_{0.6}Ti_4O_9 \cdot 3.3H_2O(s) + 0.4H^+(aq) \quad [11.2\ Å]$$

where numerals in brackets give the interlayer distance (d_{200}), and the subscripts "s" and "aq" represent solid and aqueous phases, respectively.

Figure 4 gives the approximate ratios of the above mentioned phases as a function of sodium ion uptake, which were estimated from the relative intensities of the (200) reflection.

Interpretation of the Ion-exchange Process. Analogously to the K^+/H^+ exchange process,[4] the Na^+/H^+ exchange proceeded in a stepwise fashion *via* several partially exchanged phases with different interlayer distances. Table 1 summarizes the salt forms of the solid phases that appeared in both processes. The two processes tended to be divided at $n/4$ of the theoretical ion-exchange capacity (n=1,2,3,4). This phenomenon is consistent with the structural model of phase HH in which four independent exchange sites exist. The Na^+/H^+ exchange process can be interpretted as follows: Two of the four sites are replaced simultaneously to form the 1/2-exchanged phase (stage I). The third site is occupied in stage II, which results in the 3/4-exchanged phase.

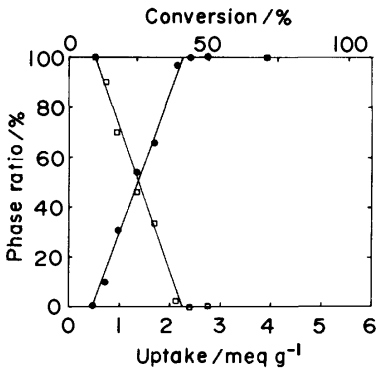

Fig. 4. Approximate ratios of the sodium ion-exchanged phases as a function of uptake.
□: Phase HH, ●: phase Na1, ■: phase Na2.

On the other hand, there are several differences between the Na^+/H^+ and K^+/H^+ exchange processes.

i) A complete exchange was not achieved for the Na^+/H^+ exchange.

ii) A 1/4-exchanged phase as well as a fully-exchanged one did not appear in the Na^+/H^+ exchange process.

iii) Phases Na1 and Na2 have larger interlayer distances than the corresponding K^+-exchanged phases.

Item i) may be due to the higher hydration energy of sodium ion than potassium ion:[9] A cation must give up a part or all of hydrated water when it enters into a host lattice. Therefore, a cation with a higher hydration energy is more difficult to be ion-exchanged.

Fact ii) may be explained by the idea that the ion-exchange behavior is rather dependent on the relative stability of the solid phases formed than the acidities of exchangeable protons.

Item iii) will be discussed in the next section.

Characterization of the Ion-exchanged Phases. The X-ray powder patterns of phases Na1 and Na2 could be indexed as a *C* base-centered monoclinic lattice. The X-ray data of phase Na1 is given in Table 2. The refined lattice constants are listed in Table 3 together with the values for phase HH.

Phase Na1 has the largely expanded *a* axis while the other three parameters were almost equal to those of phase HH. This means that phase Na1 was formed by swelling the interlayer spacing while the host framework of $[Ti_4O_9^{2-}]_n$ was remained unchanged.

Phase Na1 contains 1 mol of sodium ion and ≈3 mol of water per formula weight in the interlayer region. In contrast sodium tetratitanate ($Na_2Ti_4O_9$) accommodates 2 mol of interlayered sodium ion per formula weight. This means that phase Na1 accom-

modates a double number of interlayered species compared with the case of sodium tetratitanate. Phase NaI has a larger interlayer distance than sodium tetratitanate (d_{200}=8.38 Å)[10] by 2.8 Å, which is equal to the diameter of a water molecule. We can propose the structural model to explain the above facts: Interlayered sodium ions and water molecules are arranged in a double row which lies on the levels at y=0 and 1/2, as shown in Fig. 5. Although there may be other possible structural models for phase NaI, the model in Fig. 5 is appropriate to explain the ion-exchange behavior and thermoanalytical data described later. For example, this model gives a good explanation for the fact iii). (The corresponding K^+-

(a) Fully K^+-exchanged phase, (b) Phase NaI.
In the fully K^+-exchanged phase each circle is occupied evenly by potassium ion and water molecule, and in phase NaI at 25 and 75% by sodium ion and water molecule, respectively.

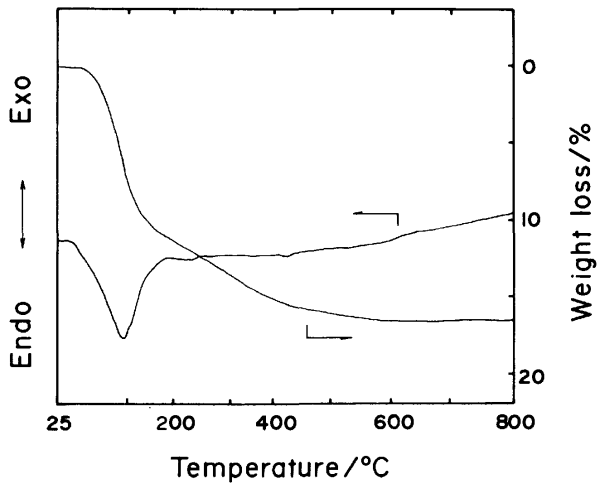

Fig. 7. DTA-TG curve of phase Na1. Heating rate: 10°C min^{-1}.

exchanged phase has a single row arrangement.)[4]

The similar double row arrangement of interlayered species has been reported for the fully K^+-exchanged phase.[4] The double row is tilted with respect to the (010) plane in this case: Potassium ions and water molecules occupy the sites which are shifted above and below the levels at $y=0$ and 1/2 (see Fig. 6). This tilt is considered to be due to the accommodation of relatively large interlayered species; potassium ions (ionic radius: 1.51 Å) and water molecules (1.40 Å).[11] On the contrary, phase Na1 can accommodate the interlayered species at the same y level since sodium ion is much smaller in size (1.16 Å)[11] than potassium ion.

The dehydration of phase Na1 took place apparently in two steps as shown in Fig. 7. The weight losses in each step were 10.0 and 6.5% and corresponded to the loss of 2.3 mol of hydrated water up to 100°C and then 1.5 mol in the temperature range of 100—600°C. When phase Na1 was heated at 100°C, the interlayer spacing decreased to 8.4 Å. The resulting material easily rehydrated to restore the original state by being exposed to moisture in the air. Being heat-treated up to 600°C, the material was decomposed into sodium hexatitanate ($Na_2Ti_6O_{13}$) and anatase (TiO_2).

In summary, the dehydration process can be written in the following scheme:

$$\begin{array}{lll} & NaHTi_4O_9\cdot 3.3H_2O & [11.2\ \text{Å}] \\ \text{step I} & 100°C \downarrow \quad \uparrow \text{in the air} & \\ & NaHTi_4O_9\cdot H_2O & [8.4\ \text{Å}] \\ \text{step II} & 100\text{—}600°C \downarrow & \\ & 1/2Na_2Ti_6O_{13}+TiO_2 & \end{array}$$

The process can be understood on the basis of the structural model described above (see Fig. 8). In step I the double row arrangement of interlayered species is destroyed by evaporating 8 water molecules per unit cell (2 mol/formula weight). The resulting phase has a single row arrangement of sodium ions and water molecules. This inference is consistent with the shrinkage of interlayer distance, 2.8 Å, which is in good agreement with the size of a water molecule. The weight loss in step II corresponds to the removal of remaining interlayered water molecules and the condensation of the host framework. The layer structure cannot be maintained by such a dehydration.

The water content and interlayer distance of phase Na2 were almost equal to those of phase Na1. This fact implies that phase Na1 has some space in the interlayer region which can accommodate additional sodium ions.

The authors would like to express their gratitude to

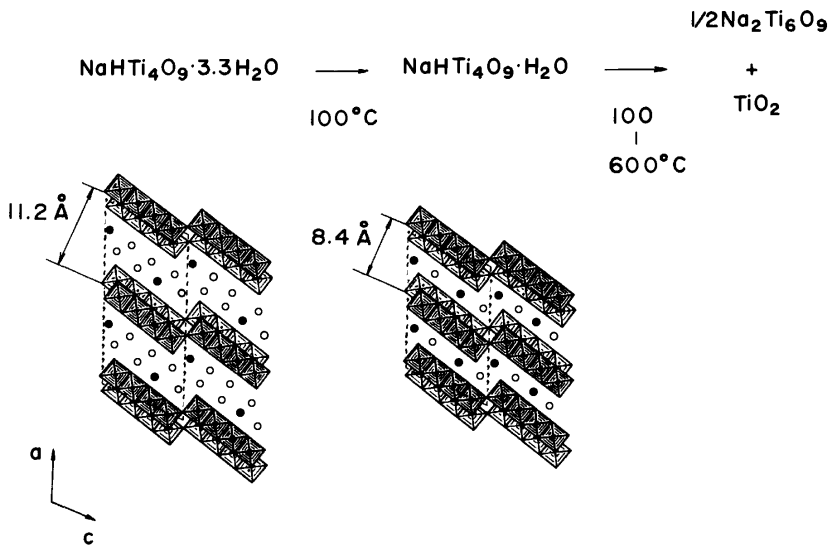

Fig. 8. Schematic explanation of the dehydration process of phase Na1. The closed circles and open ones denote sodium ions and water molecules, respectively. The configurations of the interlayered species are tentative.

Dr. Takefumi Mitsuhashi, National Institute for Research in Inorganic Materials, for his valuable discussion on the thermal analysis.

(Received July 3, 1985)

Crystal and molecular structures of NH_4[Co(NCS)(hedtra)]·H_2O and K[Co(SCN)(edtra)]·1.5H_2O have been determined by single-crystal X-ray analyses, where $hedtra^{3-}$ and $edtra^{3-}$ denote *N*-(2-hydroxyethyl)ethylenediamine-*N,N',N'*-triacetate and ethylenediamine-*N,N,N'*-triacetate ions, respectively. Crystal data are as follows: For the former species, triclinic, space group P1, a=7.477(2)Å, b=9.135(2)Å, c=6.899(1)Å; α=84.37(2)°, β=107.31(2)°, γ=108.35(2)°, V=427.0(2)Å^3, Z=1; for the latter species, monoclinic, space group $P2_1/a$, a=15.288(2)Å, b=7.059(1)Å, c=14.373(2)Å, β=107.55(1)°, V=1479.0(4)Å^3, Z=4. It has been proved unequivocally that the former species contains N-bonded SCN^- ligand and the latter species, the S-bonded ligand. Coordination geometry around the cobalt atom in each species deviates considerably from the regular octahedron, so that a very open space is created around the Co-NCS or Co-SCN moiety. This structural feature may be associated with the facile formation of the novel S-bonded species.

Quite recently, a pair of linkage isomers, $[Co(NCS)L]^{n-}$ and $[Co(SCN)L]^{n-}$, were prepared, where L denotes ethylenediamine-*N,N,N',N'*-tetraacetate ion ($edta^{4-}$) and *N*-(2-hydroxyethyl)ethylenediamine-*N,N',N'*-triacetate ion ($hedtra^{3-}$); *n* is 2 for $edta^{4-}$ and 1 for $hedtra^{3-}$.[1] When [Co(hedtra)(H_2O)] is allowed to react with SCN^-, comparable amounts of both $[Co(SCN)(hedtra)]^-$ and $[Co(NCS)(hedtra)]^-$ are formed simultaneously in an early stage of the reaction. Then, the thiocyanato (S-bonded) isomer changes to the isothiocyanato (N-bonded) isomer, because the N-bonded isomer is thermodynamically more stable than the S-bonded isomer. Therefore, the novel S-bonded isomer can be obtained in a good yield by controlling the reaction time.

Although the simultaneous formation of both $[Co(SCN)(NH_3)_5]^{2+}$ and $[Co(NCS)(NH_3)_5]^{2+}$ was also observed by the direct reaction of $[Co(NH_3)_5(H_2O)]^{3+}$ with SCN^-, the yield of the S-bonded isomer was much lower than that of the N-bonded isomer.[1] In the reaction of $[Co(CN)_5(H_2O)]^{2-}$ with SCN^-, the initial product has been found to be the N-bonded isomer $[Co(CN)_5(NCS)]^{3-}$.[2] Therefore, in the systems of $[Co(NH_3)_5(H_2O)]^{3+}$ and $[Co(CN)_5(H_2O)]^{2-}$, the N-bonded isomers are formed more easily than the S-bonded isomers. In order to elucidate the reason why $[Co(SCN)(hedtra)]^-$ is formed in a good yield, X-ray structural studies were undertaken for single crystals of K[Co(SCN)(edtra)]·1.5H_2O and NH_4[Co(NCS)(hedtra)]·H_2O, where $edta^{3-}$ denotes ethylenediamine-*N,N,N'*-triacetate ion.

Experimental

Materials. Ammonium salt of the complex, NH_4[Co(NCS)(hedtra)]·H_2O, was prepared from the corresponding potassium salt K[Co(NCS)(hedtra)]·2.5H_2O[1] by use of ion-exchange resin (QAE Sephadex). Slow evaporation of an aqueous solution saturated with the ammonium salt gave reddish violet needle crystals of NH_4[Co(NCS)(hedtra)]·H_2O. Found: C, 30.74; H, 4.90; N, 13.10%. Calcd for NH_4[Co(NCS)(hedtra)]·H_2O: C, 30.85; H, 4.94; N, 13.08%.

Potassium salt of the complex, K[Co(SCN)(edtra)]·1.5H_2O, was prepared by a method similar to NH_4[Co(SCN)(hedtra)]·0.3H_2O.[1] Found: C, 26.09; H, 3.41; N, 10.29%. Calcd for K[Co(SCN)(edtra)]·1.5H_2O: C, 26.74; H, 3.71; N, 10.14%. Blue plate crystals of K[Co(SCN)(edtra)]·1.5H_2O were obtained by dropwise addition of 0.3 ml of methanol to an aqueous solution of the complex (10 mg of complex in 6 ml of water) and by leaving the solution in a refrigerator for two weeks.

X-Ray Analyses. Diffraction data were obtained on a Rigaku automated four circle diffractometer AFC-5 with graphite monochromatized Mo$K\alpha$ radiation (λ=0.71073 Å). Intensity data were corrected for the Lorentz-polarization effects and for absorption. The lattice parameters were obtained from the least-squares fit of 50 (for NH_4[Co(NCS)(hedtra)]·H_2O) and 35 (for K[Co(SCN)(edtra)]·1.5H_2O) 2θ values with $25° < 2\theta < 30°$.

The structures of both complexes were solved by standard heavy-atom techniques and refined by block-diagonal least square methods. The weight (w) was taken as $w=[\sigma_c^2+(0.015|F_o|)^2]^{-1}$. The scattering factors for non-hydrogen atoms were taken from the literatures.[3] For hydrogen, the values given by Stewart *et al.* were used.[4] All the hydrogen atoms were located by difference syntheses and included in the refinement with isotropic temperature factors. Absolute configuration of the NH_4[Co(NCS)(hedtra)]·H_2O was determined by using anomalous scattering technique. Least-squares calculation including the anomalous scattering corrections for non-hydrogen atoms gave R and R_w values of 0.023 and 0.029. The enantiomeric structure was refined under identical conditions to give R and R_w values of 0.032 and 0.045, respectively. The crystal specimen of NH_4[Co(NCS)(hedtra)]·H_2O used in the X-ray work has the absolute configuration illustrated in Fig. 1 ($\Lambda(R,R)\Delta(R,G)$ form, *vide infra*). When the *R*-factor ratio test[5] was applied to the R_w values, the alternative model was rejected at the less than 0.005 significant level. Crystallographic data and the final R indices are summarized in Table 1. The final fractional atomic coordinates and equivalent isotropic thermal parameters for non-hydrogen atoms of NH_4[Co-

(NCS)(hedtra)]·H_2O and K[Co(SCN)(edtra)]·1.5H_2O are given in Tables 2 and 3.

All calculations were carried out on the HITAC M-200H computer at the Computer Center of the Institute for Molecular Science using the Universal Crystallographic Computation Program System UNICS III.[6] The lists of structure factors and anisotropic thermal parameters are deposited at the Office of the Chemical Society of Japan (Document No. 8553).

Results and Discussion

Description of the Molecular Structures of [Co(NCS)(hedtra)]$^-$ and [Co(SCN)(edtra)]$^-$. Figures 1 and 2 show, respectively, stereoscopic views of the complex anions, [Co(NCS)(hedtra)]$^-$ and [Co(SCN)(edtra)]$^-$.

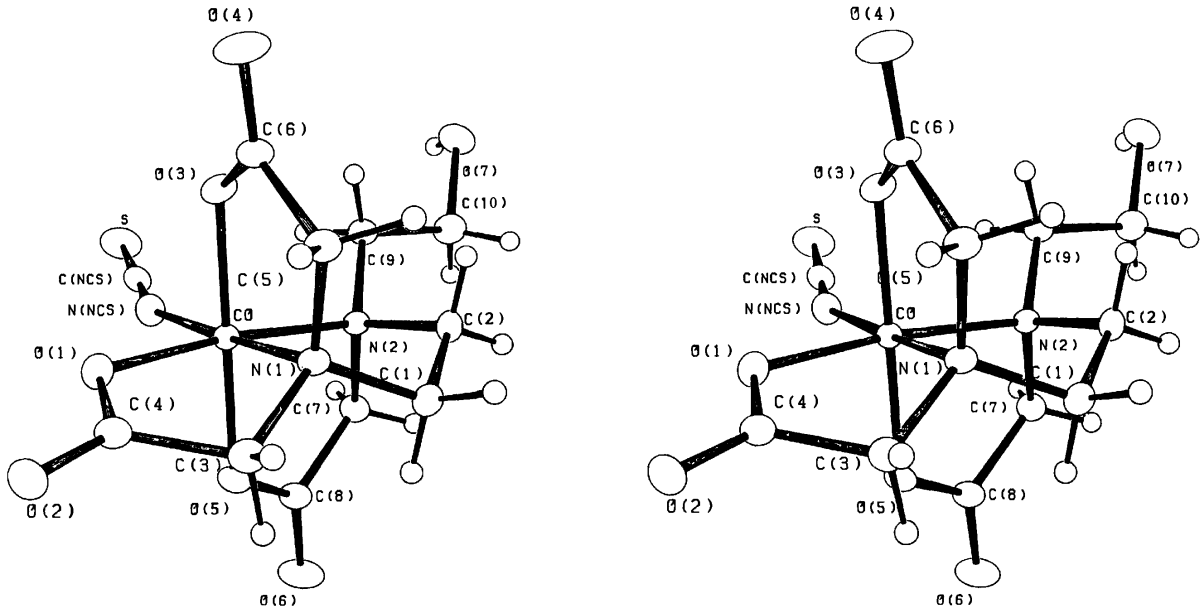

Fig. 1. Stereoscopic view of $[Co(NCS)(hedtra)]^-$.

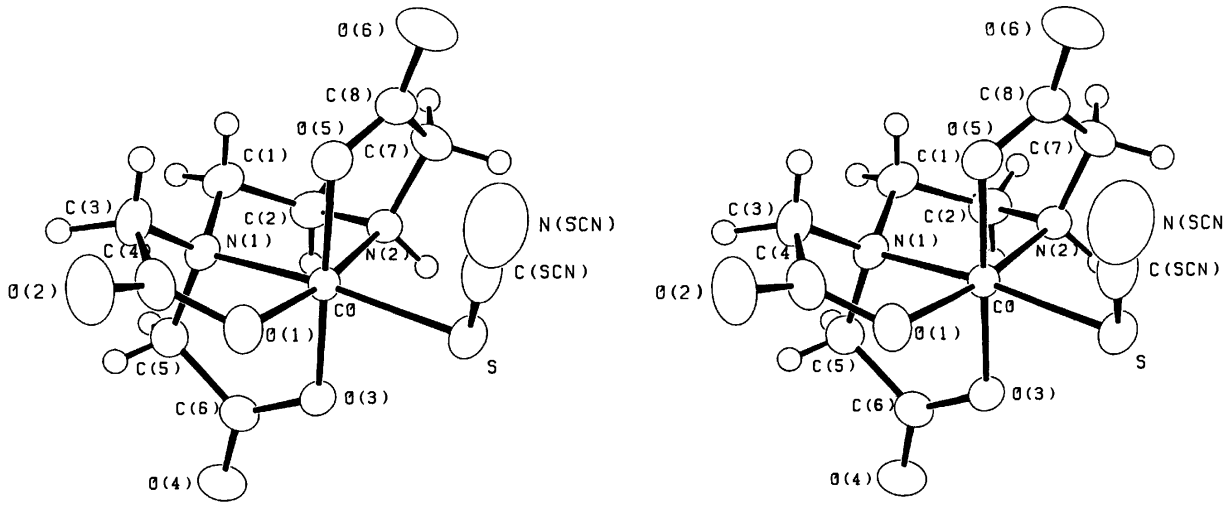

Fig. 2. Stereoscopic view of $[Co(SCN)(edtra)]^-$.

The relevant bond lengths and bond angles based on the atomic numbering scheme in these figures are listed in Tables 4—7. The present structural determinations prove unequivocally that $[Co(NCS)(hedtra)]^-$ contains isothiocyanato ligand and $[Co(SCN)(edtra)]^-$, thiocyanato ligand. The diamine-*N*,*N*′-polycarboxylate ions, $hedtra^{3-}$ and $edtra^{3-}$, act as pentadentate ligands. In each complex, isothiocyanato or thiocyanato ligand exists in the plane containing cobalt atom and two amino nitrogen atoms. Wiekliem and Hoard have pointed out for $[Co(edta)]^-$ that the strain in the complex can be expressed by the deviation from planarity of acetate (N–C–C–O–Co) rings.[7] The out-of-plane acetate rings (*R* rings) of the complexes studied here are less strained than the in-plane acetate rings (*G* rings), because the deviation from the planality of the *R* rings is smaller than that of the *G* rings. Similar trends have been observed for other related complexes, $[Co(Hedta)(H_2O)]$[8] and $[Co(NO_2)(edtra)]^-$.[9] The strains existing in the complexes are also disclosed in the Co–O bond lengths: The Co–O bond lengths of the *G* rings are longer than those of the *R* rings.

The bond angle of Co–N(NCS)–C(NCS) in $[Co(NCS)(hedtra)]^-$ is 157.1(3)°. This value deviates significantly from the values commonly found for various N-bonded complexes. The reported values lie in the range of 163.5—177.6°.[10–14] The deviation may come from a packing effect, because any specific group which can interact with the Co–NCS group is absent. The value of the bond angle of Co–S(SCN)–C(SCN) in $[Co(SCN)(edtra)]^-$ (102.9(1)°) is within the range of

those reported for various S-bonded complexes (90—109°).[12,15]

The C-N (SCN) bond length of [Co(NCS)(hedtra)]$^-$ (1.156(4) Å) is essentially identical with those of [Co(SCN)(edtra)]$^-$ (1.150(5) Å), other cobalt(III) complexes containing thiocyanate ion such as [Co(SCN)$(NH_3)_5]^{2+}$ (1.14(4) Å)[15] and [$(CN)_5$Co(SCN)Co$(NH_3)_5$] (1.145(7) Å)[12] and uncoordinated thiocyanate ion (1.158(5) Å and 1.149(7) Å).[16] Therefore, the C-N bond lengths of thiocyanate ion are hardly influenced by the bonding mode of thiocyanate ion. The C-S bond lengths, however, are influenced by the bonding mode: 1.664(3) Å for [Co(SCN)(edtra)]$^-$, 1.627(4) Å for [Co(NCS)(hedtra)]$^-$, 1.645(5) Å for [$(CN)_5$Co(SCN)Co$(NH_3)_5$],[12] and 1.644(4) and 1.646(5) Å for free thiocyanate ion.[16] The C-S bond lengths change in the following order: Co-NCS<SCN$^-$≃Co-SCN-Co<Co-SCN.

Infrared spectroscopy has been used for the determination of the bonding mode of thiocyanate ion.[17] The C-S stretching frequencies change in the order M-SCN<SCN$^-$<M-NCS and provide a good diagnostic test for the bonding mode.[18] The order is consistent with the change in the bond lengths shown above. Although it has been stated that the C-N stretching frequencies are generally higher for M-SCN than for M-NCS, the reverse is also sometimes true.[19] This comes from the fact that the C-N bond length is almost constant regardless of the bonding mode.

Description of the Crystal Structures of NH_4[Co(NCS)-(hedtra)]·H_2O and K[Co(SCN)(edtra)]·1.5H_2O. The stereoscopic view of the crystal structure for NH_4[Co(NCS)(hedtra)]·H_2O is given in Fig. 3. The crystals of the compound belong to the space group P1 with one molecule in a unit cell as shown in Table 1. This necessitates the occurrence of a spontaneous resolution. This was confirmed by the measurement of the CD spectrum of the solution which was prepared by dissolving a single crystal in water. The absolute

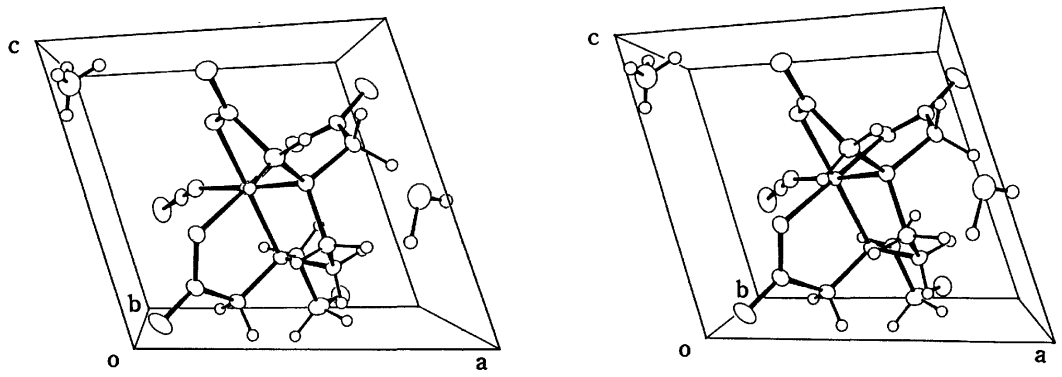

Fig. 3. Stereoscopic view of $NH_4[Co(NCS)(hedtra)]\cdot H_2O$.

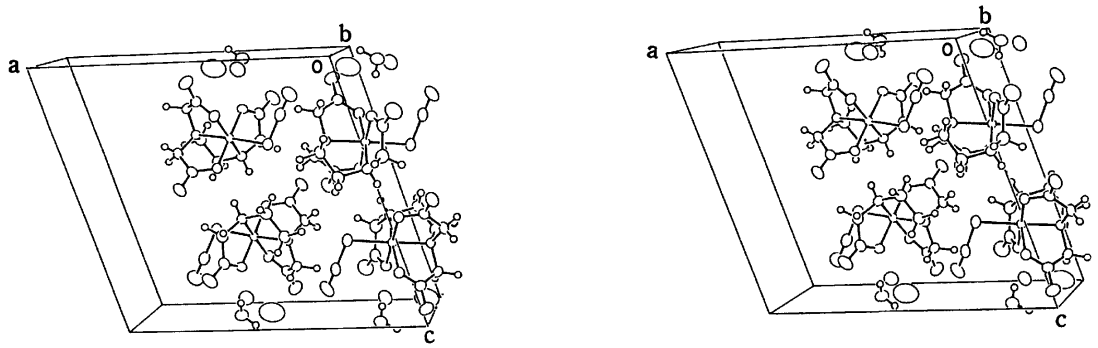

Fig. 4. Stereoscopic view of $K[Co(SCN)(edtra)]\cdot 1.5H_2O$.

configuration of the complex in the crystal used for X-ray analysis was $\Lambda(R,R)\Delta(R,G)$, showing that two R rings take Λ configuration and that one R ring (N2–C7–C8–O5–Co) and G ring take Δ configuration.

The stereoscopic view of the crystal structure for $K[Co(SCN)(edtra)]\cdot 1.5H_2O$ is given in Fig. 4. A unit cell of the complex is composed of four molecules which are two pairs of enantiomers, thus forming a racemic crystal.

Steric Circumstances around Cobalt(III) Centers in Thiocyanato and Isothiocyanato Cobalt(III) Complexes. The complexes, $[Co(NCS)(hedtra)]^-$ and $[Co(SCN)(edtra)]^-$, are so distorted that large open spaces are created around the coordination sites of N-bonded and S-bonded thiocyanate ions. This is evidenced by the fact that an angle of O(1)–Co–N(2) at the same side as NCS^- (or SCN^-) is opened to 189.0(1)° in $[Co(NCS)(hedtra)]^-$ and to 189.3(1)° in $[Co(SCN)(edtra)]^-$. We have attempted to evaluate the magnitude of the open spaces of these and the related complexes: The R_v value defined in Eq. 1 was calculated.

$$R_v = \sum_{cis} V_{do} / \sum_{cis} V_{ro} \qquad (1)$$

For a thiocyanato or an isothiocyanato complex, let us consider the plane which is perpendicular to the Co–SCN (or NCS) bond axis and involves the center of the cobalt atom (Fig. 5). The plane will hereafter be

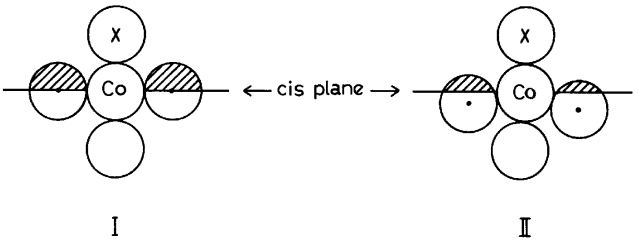

Fig. 5. Schematic expression of V_{do} (shaded part) of thiocyanato or isothiocyanato complex ($[CoXA_5]$). X denotes sulfur or nitrogen atom in thiocyanate. When $[CoXA_5]$ is a regular octahedron in geometry, V_{do} corresponds to V_{ro}. I: Regular octahedral $[CoXA_5]$. II: Distorted octahedral $[CoXA_5]$.

referred to as the cis plane. If the geometry of the complex is a regular octahedron, the centers of four donor atoms in cis position (A_1, A_2, A_3, and A_4) must be involved in the cis plane. In an actual complex, however, the four donor atoms deviate more or less from the cis plane. The space occupied by a cis donor atom is divided into two parts by the cis plane. The quantity given in Eq. 1, V_{do}, denotes the volume of the part of the side containing the thiocyanato ligand. Hence the term $\sum_{cis} V_{do}$ denotes the sum of the V_{do} values of the four atoms in the cis plane. The V_{ro} value is defined as the V_{do} value obtained when the geometry of the complex is assumed to be a regular octahedron. According to the definition, $\sum_{cis} V_{ro}$ can be expressed as follows:

TABLE 8. THE V_{do} AND R_v VALUES OF THE THIOCYANATO AND ISOTHIOCYANATO COMPLEXES AND RELATED COMPLEXES

Complex	Co-X bond	V_{do}/Å^3	R_v	Ref
$[Co(NCS)(hedtra)]^-$	Co-N(NCS)	1.84	0.73	This work
$[Co(SCN)(edtra)]^-$	Co-S	2.14	0.85	This work
$[Co(Hedta)(H_2O)]$	Co-O(H_2O)	2.22	0.88	8
$[Co(NO_2)(edtra)]^-$	Co-N(NO_2)	2.12	0.84	9
$[Co(SCN)(NH_3)_5]^{2+}$	Co-S	2.91	1.01	15
$[Co(NH_3)_5(NCS)$- in dimer[a]	Co-N(NCS)	3.00	1.04	12
$[Co(CN)_5(SCN)$- in dimer[a]	Co-S	3.83	1.00	12

a) Dimer means $[(NH_3)_5Co(NCS)Co(CN)_5]$.

$$\sum_{cis} V_{ro} = \frac{1}{2}(\text{the sum of the volume occupied by the donor atoms } A_1, A_2, A_3, \text{ and } A_4) \quad (2)$$

Therefore, if the complex in question takes the geometry of a regular octahedron, the R_v value must be unity. When there is a large open space around the coordination site of the thiocyanato ligand, the R_v value becomes smaller than unity. In the calculation of the R_v values, all donor atoms are assumed to be spherical and have covalent radii (C, 0.77; N, 0.70; O, 0.66).[20] The R_v and V_{do} values thus obtained are summarized in Table 8. For the $[Co(NO_2)(edtra)]^-$ and $[Co(Hedta)(H_2O)]$ complexes, the Co-NO_2 and Co-OH_2 bonds are regarded as Co-SCN (or NCS) bond.

There is a remarkable difference between the R_v values of the complexes containing diamine-*N*,*N*′-polycarboxylate and the other complexes: The former complexes show smaller R_v values (<0.9) than the latter complexes (≈1). This means that the pentaammine and pentacyano complexes are almost regular octahedral in geometry, while the complexes containing diamine-*N*,*N*′-polycarboxylates are considerably distorted octahedral molecules so that very open spaces are created around the Co-X bond (X=SCN^-, NCS^-, H_2O, or NO_2^-). Therefore, the sixth coordination sites of the pentaammine and pentacyano complexes which accommodate thiocyanato ligand are more crowded than those of the diamine-*N*,*N*′-polycarboxylato complexes.

Steric Factor Controlling the Formation of the Thiocyanato and Isothiocyanato Linkage Isomers. The reactions of $[Co(NH_3)_5(H_2O)]^{3+}$ and $[Co(CN)_5(H_2O)]^{2-}$ with SCN^- lead to the almost exclusive formation of N-bonded isomers.[1,2] In the system of $[CoL(H_2O)]^{n-}$ containing diamine-*N*,*N*′-polycarboxylate ion, however, spontaneous formation of both N-bonded and S-bonded isomers was observed. This may be due to the difference in the steric circumstances around the coordination sites which accommodate thiocyanate ions.

The substitution reactions of $[Co(NH_3)_5(H_2O)]^{3+}$, $[Co(CN)_5(H_2O)]^{2-}$, and $[CoL(H_2O)]^{n-}$ will proceed through *D* or I_d mechanism to produce five coordinate intermediate, because substitution reactions of most cobalt(III) complexes have been believed to proceed through the mechanism.[21] The vacant coordination site of the intermediate yielded from $[CoL(H_2O)]^{n-}$ would be much less crowded than those from $[Co(NH_3)_5(H_2O)]^{3+}$ and $[Co(CN)_5(H_2O)]^{2-}$.

The size of a sulfur atom is larger than that of a nitrogen atom. The Co-SCN bond in S-bonded isomers is bent (<CoSC=≈100°), while the Co-NCS bond is approximately linear. Therefore, the coordination of the sulfur end in thiocyanate ion requires a larger open space around the coordination site than that of the nitrogen end. The smaller open space in $[Co(NH_3)_5]^{3+}$ and $[Co(CN)_5]^{2-}$ intermediates cannot accept the sulfur end favorably, but the larger open space in $[CoL]^{n-}$ intermediate can accept not only the nitrogen end but also the bulky sulfur end.

The Synthesis and Thermal Behavior of Barium Bis(hydrogenphosphoramidate) and Barium Phosphoramidate

Shoji SATO and Makoto WATANABE*
Department of Industrial Chemistry, Chubu University, Matsumoto-cho, Kasugai, Aichi 487
(Received July 9, 1985)

Barium bis(hydrogenphosphoramidate) monohydrate and barium phosphoramidate monohydrate were made by mixing a solution of potassium hydrogenphosphoramidate and a solution of barium chloride at pH 6.1—6.4 and 10.0—10.5 respectively. Both products were stable at room temperature. Barium bis(hydrogenphosphoramidate) monohydrate was decomposed by water to produce the orthophosphate. This was condensed to make polyphosphates above 100 °C and finally formed barium metaphosphate above 500 °C. The thermal products of the hydrogenphosphoramidate did not produce any phosphate with imino groups. Barium phosphoramidate produced ortho-, di-, imidodi-, and triphosphates when it was heated above 200 °C. These thermal products were converted to dibarium diphosphate in air above 500 °C.

Among many phosphorus–nitrogen compounds, phosphazenes are probably the best-known and the most intensively investigated compounds. Some of them are already used as industrial materials and products. There are a series of phosphorus–nitrogen compounds which have amino groups on a P atom. These compounds can be used as a new type of chemical fertilizer with a P–N covalent bond and as flameproof materials because they produce polyphosphates having imino and amino groups when they are heated. They can also be used as starting materials for the preparation of many organic and inorganic phosphorus compounds.

In our previous papers,[1-4] the synthesis and the thermal behavior of magnesium and calcium phosphoramidates and hydrogenphosphoramidates were reported. Both the hydrogenphosphoramidates were unstable even at room temperature and decomposed to polyphosphates, while the phosphoramidates were stable at room temperature. These phosphoramidates and hydrogenphosphoramidates were decomposed to polyphosphates above room temperature in air. This paper will describe the synthesis and the thermal behavior of barium bis(hydrogenphosphoramidate) and phosphoramidate.

Experimental

Preparation of Barium Bis(hydrogenphosphoramidate). Potassium hydrogenphosphoramidate was made by the method described in a previous paper;[5] 0.08 mol of the phosphoramidate was dissolved in 85 cm^3 of water. The aqueous solution of barium chloride, which was made by dissolving 0.04 mol of barium chloride dihydrate in 40 cm^3 of water, was added to the phosphoramidate solution below 5 °C to prevent the hydrolysis of the phosphoramidate. The pH of the solution was 6.1—6.4 during the treatment. A white precipitate was filtered off and washed with cold water, ethanol, and then acetone. The product was dried at 50 °C for 1 d under reduced pressure.

Preparation of Barium Phosphoramidate. Potassium hydrogenphosphoramidate(0.04 mol) was dissolved in 400 cm^3 of water. Barium chloride dihydrate (0.04 mol) was dissolved in 120 cm^3 of water. The solution was poured into the phosphoramidate solution and the resulting solution was stirred for 5—10 min. During the treatment, the temperature of the phosphoramidate solution was kept below 5 °C to prevent the hydrolysis of the phosphoramidate; the pH of the solution was kept at 10.0—10.5 with aqueous ammonia. The white precipitate thus obtained was removed by filtration. Acetone was added to the mother liquor and the white product was filtered off, washed with 50-V% aqueous ethanol, ethanol, and then acetone. The product was dried at 25 °C for 1 d under reduced pressure.

Chemical Analysis. Phosphorus in a sample was determined colorimetrically by dissolving about 0.2 g of the sample in 100 cm^3 of a 6%-EDTA (disodium dihydrogen ethylenediaminetetraacetate dihydrate) aqueous solution. Barium and nitrogen in a sample were estimated by the gravimetric technique and the Kjeldahl method respectively.

Paper Chromatography and Colorimetry of Phosphates. The thermal products of barium hydrogenphosphoramidate were dissolved in a 6%-EDTA aqueous solution and those of barium phosphoramidate were dissolved in the EDTA solution of pH 9—10 controlled with aqueous ammonia. The one-demensional paper-chromatographic separation and the colorimetric determination of the phsophate species in the EDTA solutions were made by the method described in our previous paper.[1]

X-Ray Diffractometry. An X-ray diffraction diagram of a powder sample was taken with nickel-filtered Cu $K\alpha$ radiation using a Toshiba X-ray diffractometer, ADG-102.

IR Spectrophotometry. An IR spectrum of a sample was recorded on a JASCO IR spectrophotometer, A-3, using the KBr disc method.

^{31}P NMR Measurement. The nuclear magnetic resonance data were taken with a JNM-GX270 spectrograph on the aqueous solutions of the thermal products located by paper chromatography. As is customary, the NMR chemical shifts are reported relative to external 85%-orthophosphoric acid with positive shifts being downfield.

DTA and TG. A sample was heated at a rate of 5 °C min^{-1} in air by means of a Cho Balance TRDA$_1$-H apparatus.

Results and Discussion

Barium Bis(hydrogenphosphoramidate). The yield of the product was about 10.2 g. Found: P, 18.4; N, 7.9; Ba, 38.5%. Calcd for $Ba(HPO_3NH_2)_2 \cdot H_2O$: P, 17.8; N, 8.1; Ba, 39.5%. In this manner, the product was

a) $Ba(HPO_3NH_2)_2 \cdot H_2O$. b) Amorphous.

found to be barium bis(hydrogenphosphoramidate) monohydrate. The X-ray diffraction diagram of the product was the same as that of $Ba_{1/2}HPO_3NH_2 \cdot H_2O$ (JCPDS card, No. 18—170), but the careful measurement of the heating weight loss of the product, as will be shown later, also supported the above conclusion. Magnesium and calcium bis(hydrogenphosphoramidate) slowly decomposed to polyphosphates at room temperature,[1,2] while the product obtained in this work was very stable and did not decompose at room temperature. To study the thermal behavior of the product, DTA and TG curves of the product were taken with the result shown in Fig. 1. The samples as numbered on Fig. 1 were removed from a furnace, cooled in a silica-gel desiccator, and subjected to further analysis. The results are shown in Table 1, and Figs. 2 and 3. The hydrogenphosphoramidate showed two endothermic peaks accompanying weight loss below 200°C. The following dehydration reaction may be written for the endothermic process:

$$Ba(HPO_3NH_2)_2 \cdot H_2O \longrightarrow Ba(HPO_3NH_2)_2 + H_2O. \quad (1)$$

As Table 1 shows, the thermal product 1 exhibited less N content than that of $Ba(HPO_3NH_2)_2$ and contained ammonium ions. The N content of the product 2 was less than that of the product 1. Almost all the nitrogen of the product 2 was present as ammonium ions. The IR spectra of the thermal products 1 and 2 showed peaks

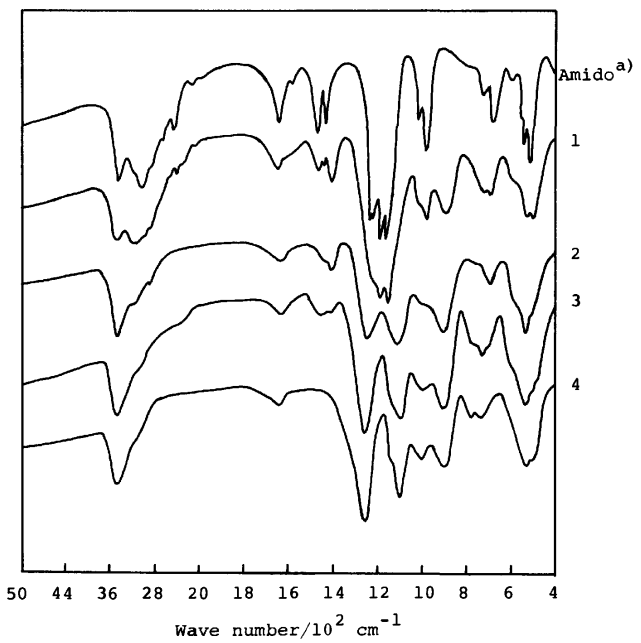

Fig. 2. IR spectra of the thermal products of $Ba(HPO_3NH_2)_2 \cdot H_2O$.
a): $Ba(HPO_3NH_2)_2 \cdot H_2O$.

of NH_4^+ at 1400 cm^{-1}, P-O-P and/or P-N(H)-P at 900 cm^{-1}, and $(PO_2)^-$ at 1220—1250 cm^{-1}. The paper-chromatographic analysis of the thermal products 1 and 2 agreed well with these results. Since the thermal

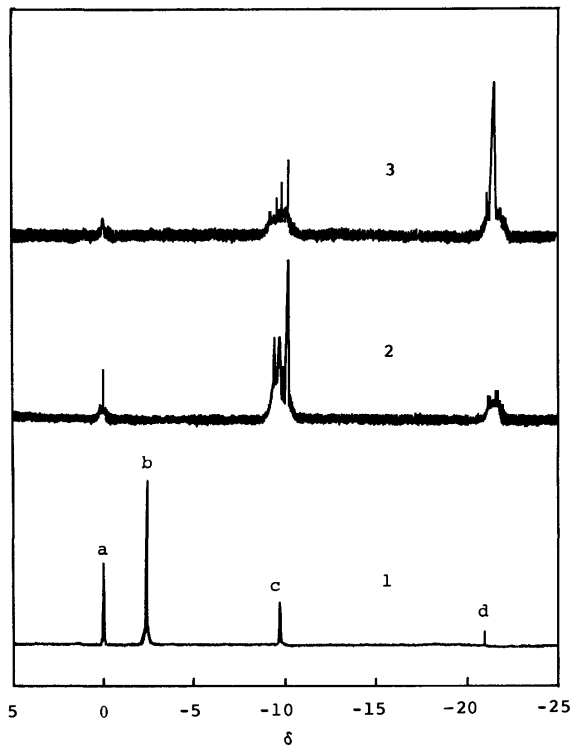

Fig. .3 ^{31}P NMR spectra of the thermal products of $Ba(HPO_3NH_2)_2 \cdot H_2O$ in air.
a: Orthophosphate, b: phosphoramidate, c: end-PO_4 group, d: middle-PO_4 group.

products other than 1 and 2 contained insoluble material and the separation of the phosphate species was poor, the paper-chromatographic analysis of the products was not possible. The above results do not indicate clearly that P-NH_2 linkages thermally decompose to form P-N(H)-P linkages with the elimination of ammonia as follows:

$$-\overset{|}{\underset{|}{P}}-NH_2 + NH_2-\overset{|}{\underset{|}{P}}- \longrightarrow -\overset{|}{\underset{|}{P}}-N(H)-\overset{|}{\underset{|}{P}}- + NH_3. \quad (2)$$

Accordingly, a ^{31}P NMR study of the thermal products was made. The ^{31}P NMR spectrum of the thermal product 1 showed peaks due to orthophosphate (0 ppm), phosphoramidate (−2.4 ppm), an end-PO_4 group (−9.8 ppm), and a middle-PO_4 group (−20.9 ppm). The thermal product 2 showed the NMR peaks of orthophosphate, an end-PO_4 group, and a middle-PO_4 group. Accordingly, these thermal products did not contain any substance with P-N(H)-P linkages. The hydrogenphosphoramidate did not form thermal products with imino groups. According to the above results, one can write the following reactions for the thermal decomposition of the hydrogenphosphoramidate to orthophosphate and condensation of the orthophosphate to polyphosphates:

$$Ba_{1/2}HPO_3NH_2 + H_2O \longrightarrow Ba_{1/2}NH_4HPO_4, \quad (3)$$

$$2Ba_{1/2}NH_4HPO_4 \begin{cases} \nearrow Ba(HO_3POPO_3H) + 2NH_3 + H_2O, & (4) \\ \searrow Ba(HO_3POPO_3NH_4) + NH_3 + H_2O, & (5) \end{cases}$$

$$Ba(HO_3POPO_3H) + Ba_{1/2}NH_4HPO_4 \longrightarrow Ba_{3/2}[HO_3POP(O_2)OPO_3H] + NH_3 + H_2O. \quad (6)$$

The thermal product 3 contained only a small amount of nitrogen and the product 4 contained no nitrogen. The IR spectra of these products were similar to that of polyphosphate with a meta composition. The ^{31}P NMR spectrum of the product 3 showed a small orthophosphate peak and peaks of end- and middle-PO_4 groups. Therefore, the successive broad endothermic peaks were found to be caused by the condensation of ortho- and polyphosphates to polyphosphate with a meta composition. The thermal products 1-3 showed weak unknown X-ray diffraction peaks and the product 4 was amorphous by X-ray diffractor. The product 5 showed X-ray diffraction peaks of barium metaphosphate(JCPDS card, No. 20—141). The large exothermic peak at about 510 °C is responsible for the conversion of amorphous barium metaphosphate into the crystalline form. The measured weight losses of the products 5 and 6 were close to the calculated one according to the following reaction:

$$Ba(HPO_3NH_2)_2 \cdot H_2O \longrightarrow Ba(PO_3)_2 + 2NH_3 + H_2O. \quad (7)$$

The last endothermic peak at about 870 °C was found to be caused by the melting of the barium metaphos-

phate.

Barium Phosphoramidate. The yield of the product was about 8.5 g. Found: P, 12.3; N, 5.4; Ba, 54.7%. Calcd for $BaPO_3NH_2 \cdot H_2O$: P, 12.4; N, 5.6; Ba, 54.2%. Accordingly, the product is barium phosphoramidate monohydrate. As will be described in the later part of this section, the study of the heating weight loss of the product supported this conclusion. The phosphoramidate was stable and did not decompose at room temperature. To study the thermal behavior of the product, DTA and TG curves of the product were taken with the result in Fig. 4. The chemical analysis data, the IR spectra, and the ^{31}P NMR spectra of the thermal products are shown in Table 2, and Figs. 5 and 6 respectively. The first large endothermic reaction accompanied by rapid weight loss seemed to be caused mainly by removal of the bound water because the measured weight loss was close to the calculated one according to the reaction:

$$BaPO_3NH_2 \cdot H_2O \longrightarrow BaPO_3NH_2 + H_2O. \quad (8)$$

As Table 2 shows, the nitrogen content of the thermal

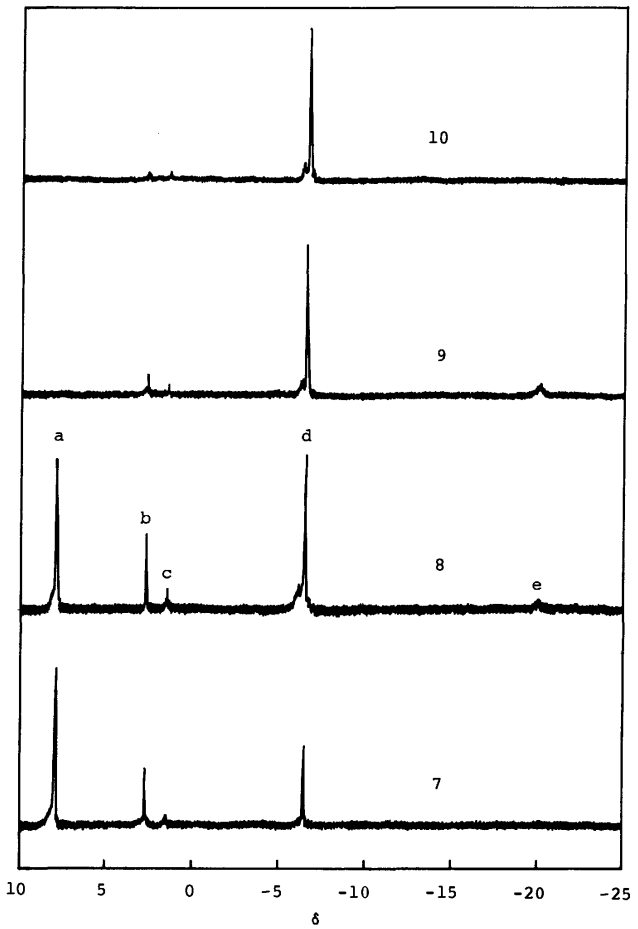

Fig. 6. ^{31}P NMR spectra of the thermal products of $BaPO_3NH_2 \cdot H_2O$ in air.
a: Phosphoramidate, b: orthophosphate, c: imidodiphosphate,[6] d: end-PO_4 group, e: middle-PO_4 group.

product 7 was less than that of $BaPO_3NH_2$. The product contained ammonium ions and ortho-, and diphosphate and/or imidodiphosphate other than the phosphoramidate. The IR spectrum of the product 7 exhibited absorptions of NH_4^+ at 1400 cm^{-1} and P–O–P and/or P–N(H)–P linkages at 900 and 720 cm^{-1}. These results indicate that barium phosphoramidate monohydrate reacts at this stage according to the following processes other than reaction 8:

$$BaPO_3NH_2 + H_2O \longrightarrow BaNH_4PO_4, \quad (9)$$

$$BaNH_4PO_4 \longrightarrow BaHPO_4 + NH_3, \quad (10)$$

$$2BaHPO_4 \longrightarrow BaO_3POPO_3Ba + H_2O, \quad (11)$$

$$2BaPO_3NH_2 \longrightarrow BaO_3PN(H)PO_3Ba + NH_3. \quad (12)$$

As Fig. 6 shows, the product 7 contained phosphoramidate, orthophosphate, imidodiphosphate, and diphosphate. (Barium phosphoramidate, tribarium bis(phosphate), and dibarium diphosphate showed ^{31}P NMR peaks at about 7.8—8.0, 2.8, and −5.6—−6.3 ppm respectively in a 6%-EDTA solution of pH 9—10 controlled with aqueous ammonia). So all the above reactions 9—12 take place at this stage. The intensity of the imidodiphosphate peak was weak and the rate of the Reaction 12 seemed to be much slower than those of the other reactions. According to Table 2, successive slow weight loss was due to the elimination of ammonia. Since the NMR spectrum of the product 8 exhibited peaks with stronger intensity than that of the product 7 at the same δ, the above reactions 9—12 may take place rapidly over the temperature range of 400—500 °C. The total energy of the reactions was considered to be exothermal. As Table 2 and Fig. 6 show, the thermal products 8 and 9 contained triphosphate. It is not probable that orthophosphate with Ba/P ratio of 1.0 would form triphosphate over this low temperature range. The problem can be solved by taking into account the following reorganization or disproportionation reaction in this system:

$$2BaNH_4PO_4 \longrightarrow Ba_{3/2}PO_4 + Ba_{1/2}(NH_4)_2PO_4. \quad (13)$$

The chemical species, $Ba_{1/2}(NH_4)_2PO_4$, can form triphosphate according to the reaction as follows:

$$Ba_{1/2}(NH_4)_2PO_4 + 2BaNH_4PO_4 \longrightarrow Ba_{5/2}[O_3POP(O_2)OPO_3] + 4NH_3 + 2H_2O. \quad (14)$$

The product 10 contained small amounts of ortho- and imidodiphosphates other than diphosphate and did not contain higher polyphosphates, so the reorganization or the decomposition of the triphosphate to diphosphate may occur according to the reaction:

$$Ba_{5/2}[O_3POP(O_2)OPO_3] + Ba_{3/2}PO_4 \longrightarrow 2Ba_2(O_3POPO_3). \quad (15)$$

The NMR data also showed that imidodiphosphate gradually converted to diphosphate. The reaction written below can be responsible for the conversion:

$$BaO_3PN(H)PO_3Ba + H_2O \longrightarrow BaO_3POPO_3Ba + NH_3. \quad (16)$$

We thank Dr. S. Motojima and Dr. H. Ishihara, Department of Industrial Chemistry, Gifu University, for providing the ^{31}P NMR spectral data of many samples.

Studies on Mixed Chelates. XIV. Influences of Solvent Polarity, and of Substituent Groups in β-Diketonate Ligands, on the Electronic Spectra of 5-Coordinated Mixed Copper(II) Chelates in Organic Solutions[1)]

Yutaka FUKUDA,* Mayumi YASUHIRA, and Kozo SONE
Department of Chemistry, Faculty of Science, Ochanomizu University, Otsuka, Bunkyo-ku, Tokyo 112
(Received July 22, 1985)

Several chelates of copper(II), Cu(tmen)(dike)X, were newly obtained where tmen=*N,N,N′,N′*-tetramethylethylenediamine, dike= a β-diketonate ion, and X^-= a halide or pseudohalide anion. These complexes exist as 5-coordinated species, with axially coordinated X^-, in nonpolar solvents. In more polar solvents, they are ionized according to the solvent polarity, and form the following equilibrium mixtures:

$$[Cu(tmen)(dike)X] \rightleftharpoons [Cu(tmen)(dike)]^+ + X^-$$

5-coordinated 4-coordinated (solvated, tetragonal)

This equilibrium is controlled by (a) the strengths of acceptor and donor properties of the solvent, which can be expressed by its polarity factor (Pf), *i.e.*, a linear combination of the donor number and acceptor number of the solvent, and (b) the changes of the ligand field strength of dike caused by the electron-withdrawing and -releasing properties of its α-substituent groups.

In the previous papers,[1-3)] we reported the properties of mixed Cu(II) chelates of the general formula Cu(diam)(dike)X in solid state and in various solvents.*[1)]

All these chelates are easily soluble in various organic solvents, and characteristic solvatochromism (color change caused by the nature of the solvent) is observed in their solutions. Moreover, in the same solvent, the spectral and conductivity behaviors of the chelates with different anions show drastic changes according to the coordination power of the anion (anion effect).

When X^-=ClO_4^-, or NO_3^-, *e.g.* with [Cu(tmen)(acac)]ClO_4, the solvatochromism observed is mainly due to the solute-solvent interaction between the chelate cation and the solvent molecules. On the other hand, when X^-= a halide or pseudohalide anion, *e.g.* with [Cu(tmen)(acac)Cl], the chelate exists as 5-coordinated green species in solid crystals and in nonpolar solvents. Here the solvatochromism observed in polar solvents is due to the competition of X^- and solvent molecules for the axial site(s) of the chelate cation, which leads to complicated solute-solute-solvent interactions.

In these former studies, a large number of chelates with various diamines and β-diketonates were prepared and studied, with ClO_4^- or NO_3^- as X^-, but only the chelates with tmen and acac were reported so far with a halide or pseudohalide anion as X^-.[4)] In continuation of these studies, therefore, we have prepared the latter type of chelates with tmen and various β-diketonates such as tfac, hfac and dipm. The effects of α-substituents in them, the anion (X^-), and solvent polarity on the formation of the 5-coordinated complexes in their solutions will be discussed in this paper.

Experimental

Materials. The ligands used (tmen and dike) and metal salts were "Guaranteed Grade" or "Extra Pure," and the solvents used for physical measurements were "Dotite Spectrosol" of Dojindo Laboratories, or "Guaranteed Grade" of Wako Pure Chemical Industry Co. Ltd. They were used without further purification.

Preparation of New Chelates. 1) Cu(tmen)(dike)X(dike =dipm, tfac, or hfac, X^-=Cl^- or Br^-): These complexes could be obtained by concentrating methanol solutions of the mixtures of CuX_2($CuCl_2 \cdot 2H_2O$ or $CuBr_2$), tmen, and dike of which molar ratio was 1:1:1. The hfac-Cl-chelate was rather difficult to prepare, because the deep green crystals of the mixed chelate [Cu(tmen)(hfac)Cl] contained small amounts of its disproportionation products, *i.e.*, blue plates of [$Cu(tmen)Cl_2$] and light green crystals of [$Cu(tmen)(hfac)_2$]. The compositions of these by-products were ascertained by elemental analyses. To remove them, the crude deep green products were recrystallized from $CHCl_3$ or DCE, and washed with cold DCE and ether. Among these complexes, the tfac- and hfac-chelates are all green and stable in atmospheric moisture but the dipm-chelates absorb water to form the monohydrates, showing the color change from green to bluish-violet(Cu(tmen)(dipm)X·H_2O, see Table 1).

2) Cu(tmen)(dike)X(dike=dipm or tfac, X^-=NCS^-; dike=tfac, X^-=I^-). These compounds could be obtained by the anion exchange of [Cu(tmen)(dike)]NO_3 with NaX in acetone, which is very similar to the method described before.[3)] As the iodide complexes were very difficult to crystallize, we could obtain only one of them, Cu(tmen)(tfac)I. The green crystals obtained were recrystallized from DCE.

*[1)] Abbreviations used in this article are as follows: diam= *N*-alkylated ethylenediamine, tmen=*N,N,N′,N′*-tetramethylethylenediamine, dike= a β-diketonate ligand ($R_1COCHCOR_2^-$), acac=acetylacetonate (R_1=R_2=CH_3), hfac=hexafluoroacetylacetonate (R_1=R_2=CF_3), tfac=trifluoroacetylacetonate (R_1=CH_3, R_2=CF_3), dipm=dipivaloylmethanate (R_1=R_2=$C(CH_3)_3$); DCE=1,2-dichloroethane, NM=nitromethane, DMF=*N,N*-Dimethylformamide, DMSO=dimethyl sulfoxide.

TABLE 1. ANALYTIAL DATA, COLOR, AND MAGNETIC MOMENTS OF THE COMPLEXES OBTAINED[a)]

Complex	C(%)	H(%)	N(%)	Color	μ_{eff}/BM
Cu(tmen)(tfac)Cl	35.76(35.87)	5.60(5.47)	7.61(7.61)	light green	1.87
Cu(tmen)(tfac)Br	31.90(32.01)	5.00(4.88)	6.77(6.79)	deep green	1.85
Cu(tmen)(tfac)I	28.39(28.74)	4.33(4.39)	6.09(6.09)	deep green	1.81
Cu(tmen)(tfac)NCS	36.57(36.87)	5.24(5.16)	10.79(10.75)	green	1.86
Cu(tmen)(dipm)Cl·H_2O	48.86(49.02)	8.81(8.95)	6.86(6.73)	bluish violet	1.84
Cu(tmen)(dipm)Br·H_2O	43.73(44.30)	6.01(6.08)	8.05(8.09)	bluish violet	1.80
Cu(tmen)(dipm)NCS	51.26(51.34)	8.38(8.38)	9.99(9.98)	bluish green	1.90
Cu(tmen)(hfac)Cl	31.25(31.29)	4.13(4.06)	6.79(6.63)	green	1.88
Cu(tmen)(hfac)Br	28.36(28.31)	3.69(3.67)	6.00(6.00)	green	1.87

a) Calculated values are shown in parentheses.

Elemental analyses of the prepared chelates were performed at the Laboratory of Organic Microanalysis of the Institute of Physical and Chemical Research.

Physical Measurements. The electronic spectra of the complex solutions (5×10^{-3} mol dm^{-3}) in visible region were measured with a Hitachi 340 Recording Spectrophotometer at room temperature (20—25 °C) in 10 mm quartz cells. Infrared spectra (400—5000 cm^{-1}) were measured as Nujol mulls with a JASCO IR-A3 Grating Spectrophotometer. Magnetic susceptibility measurements were performed with a Shimadzu Torsion Magnetometer MB-100 at room temperature. Electric conductivities of the solutions (1×10^{-3} mol dm^{-3}) were measured with a Conductivity Outfit Model AOC-10 (Denki-Kagaku-Keiki Co. Ltd.) at 25±0.2 °C. TG-DTA measurements were performed with a Differential Thermal Analyser TGD-3000 M (Sinku-Riko) under static air with the heating rate of 3 °C/min.

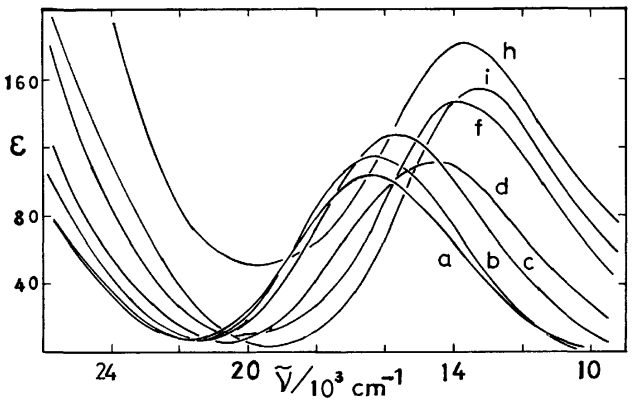

Fig. 1. Absorption spectra of [Cu(tmen)(tfac)Cl] in various solvents. The alphabetic notations a to i, on each curve are those for the solvents, and are the same as those in Table 2.

Results and Discussion

Properties of the Solid Complexes. In Table 1, the analytical data, magnetic moments at room temperature and colors of the mixed chelates obtained in this study are summarized. All of the analytical data agree fairly well with the proposed formulas. The dipm-halide complexes are monohydrates. When they were dried under reduced pressure, their colors turned from bluish violet to green. The loss of one H_2O in this process was confirmed by TG-DTA method. The magnetic moments of all these chelates were normal, showing that they are mononuclear Cu(II) chelates. Solid reflectance spectra of these chelates were very similar to those in nonpolar solvents (see Table 2). The bands of $\tilde{\nu}_{C\equiv N}$ of NCS^- in the IR spectra of the thiocyanate chelates with dipm, acac, and tfac appeared at 2070—2075 cm^{-1}, and those of $\tilde{\nu}_{C\text{-}S}$ of these three chelates at 770—780 cm^{-1}, indicating that the NCS^- ions in them are N-bonded monodentate.[5)] All these results, and comparison with the previous data,[3,4)] support that the green solid chelates with the general formula [Cu(tmen)(dike)X] (X^-: halide or pseudohalide ion; dike: dipm, acac, tfac, or hfac) are all 5-coordinated. Their structure, therefore, is quite different from the planar one expected for the nitrates or perchlorates, [Cu(tmen)(dike)]X ($X^-=NO_3^-$ or ClO_4^-).

Electronic Spectra of the Chelates in Various Solvents. The characteristic properties of the chelates obtained are (1) their high solubility in various solvents, and (2) the drastic change in the color of the solution observed in going from one solvent to another, that is, strong solvatochromism of their solutions. In Fig. 1, the spectral changes of [Cu(tmen)(tfac)Cl] in various solvents are shown as an example of this solvatochromism. There are, in addition, (3) notable anion effect and (4) substituent effect of dike on the colors (or absorption spectra) of such solutions. All the spectral data ($\tilde{\nu}_{max}$ and ε_{max} values of the d-d band) obtained are summarized in Table 2, including the previous data on Cu(tmen)(acac)X. A plot of $\tilde{\nu}_{max}$ values of the tfac-chelates is given in Fig. 2, which indicates the effects (2) and (3) more clearly.

At first, comparing the spectral and conductivity data (Table 3) of the chelates reported before, it can be seen that ClO_4^- acts only as a counter ion of the chelate cation, and does not interact in any solvent with the latter. Consequently, the structure of [Cu(tmen)(tfac)]-ClO_4 in solution depends only on the donor properties of the solvent used (Gutmann's donor number=DN), as was reported previously in similar systems.[4)] In other words, there exist only solute-solvent interactions in these systems: the spectral changes observed in such a

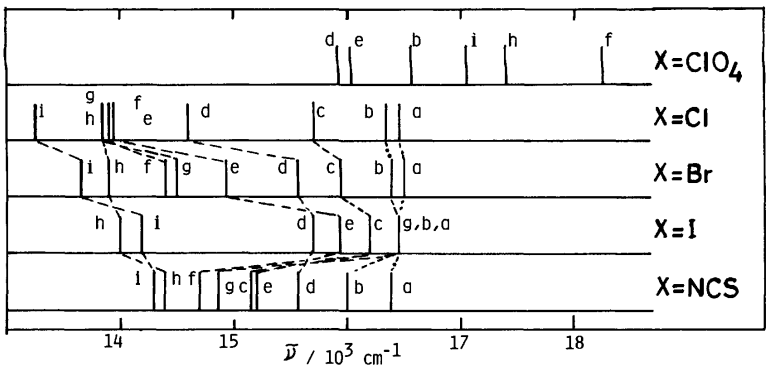

Fig. 2. The $\tilde{\nu}_{max}$ values of the complexes Cu(tmen)(tfac)X in various organic solvents. As to the notations a to i, *cf.* Fig. 1. The data for X=ClO_4 were taken from Ref. 2.

system will be called "Type A Solvatochromism." The characteristics of this solvatochromism are summarized schematically below, taking [Cu(tmen)(tfac)]ClO_4 as an example.

$[Cu(tmen)(tfac)]^+ \longrightarrow [Cu(tmen)(tfac)(Solv)_2]^+$

Structure: More planar $\longrightarrow$ Tetragonal

$\longrightarrow$ More octahedral

$\tilde{\nu}_{max}$ of the solution: Higher $\longrightarrow$ Lower

Solvent Polarity (DN): Small $\longrightarrow$ Large

Color of the Complex: Violet $\longrightarrow$ Blue

(Type A Solvatochromism)

The behaviors of halide- and NCS-chelates in various solvents are now very different. Here the anion in the complex can be coordinated to the chelate cation as well as the solvent molecules, so that the competition of these two types of ligands for the axial site(s) of the chelate cation takes place. These situations are so-called "solute-solute-solvent interaction," and are schematically shown in Fig. 3.

In a polar solvent, the negative center of the 5-coordinated complex, *i.e.*, the X^- anion, attracts the positive ends of the solvent molecules (hydrogen bond will be formed when the solvent is amphiprotic). The

a) Standard values for a 1:1 electrolyte are 140, 85, and 20 in CH_3CN, NM, and DCE, respectively.[10] b) The values in parentheses are the degree of the dissociation (%) of the anion based on the standard values given in a).

Cu–X bond is weakened by this interaction, and finally dissociates off the X^- anion. In the previous paper,[4] we emphasized this effect, and stated that the main driving force to dissociate the anion X^- from such a complex is the anion solvation power of the solvent used, which is expressed as the acceptor number (AN),[6,7] the E_T value,[8] or the Z value.[9]

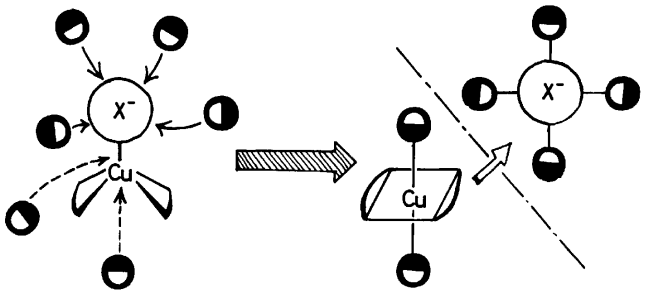

Fig. 3. Schematic representation of the dissociation process of the 5-coordinated complex in a polar organic solvent. The solvent molecules are shown here by half-shadowed balls; their white and dark halves, respectively, correspond to the positive and negative ends of the molecules.

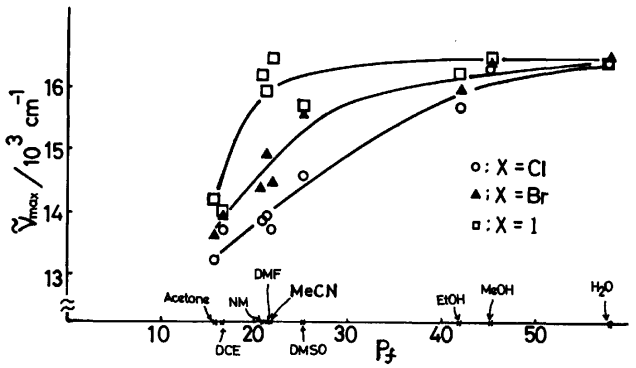

Fig. 4. The correlation between the $\tilde{\nu}_{max}$ values of the complexes Cu(tmen)(tfac)X in various solvents and the solvent parameter P_f.

A look at Fig. 3 suggests, however, that there is another cooperative factor, *i.e.*, the coordination power of the solvent to the metal ion which corresponds to the donor number (DN) of the solvent. In fact, although there is a general correlation between the $\tilde{\nu}_{max}$ of the solutions of these types of chelates and AN of their solvents,*2) there are certain deviations which indicate that, when two solvents have similar AN values, the one with the larger DN favors the change shown in Fig. 3.

Taking this into account, we have newly introduced a new polarity parameter of the solvent, polarity factor (P_f), which is a linear combination of AN and DN. Figure 4 shows the relation between the $\tilde{\nu}_{max}$ of the tfac-halide-chelates and P_f values of the solvents which, in this paticular case, were taken to be equal to

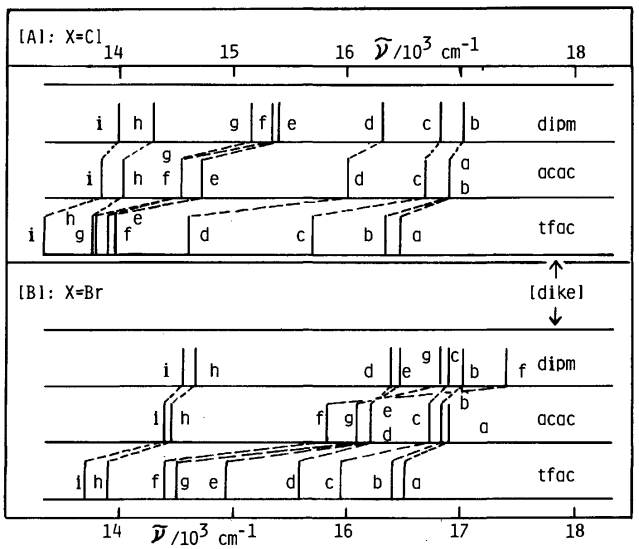

Fig. 5. The $\tilde{\nu}_{max}$ values of the complexes Cu(tmen)(dike)X in various solvents, [A]=[Cu(tmen)(dike)Cl] and [B]=[Cu(tmen)(dike)Br]. As to the notations a to i, *cf.* Fig. 1.

(AN+0.2DN). The fact that the change in Fig. 3 is favored with the increase of this P_f, and in the order of $I^->Br^->Cl^-$, is clearly seen from these curves. Similar curves can also be obtained for the Cl- or Br-acac-chelates, although the points for the I-acac-complex tend to scatter.[1)]

Previous results showed that, in general, increasing strength of the Cu^{2+}–X^- bond brings about the stabilization of 5-coordinate species which, in its turn, is reflected on the decrease of its $\tilde{\nu}_{max}$. Comparing the $\tilde{\nu}_{max}$ values in solvents of very low P_f (DCE or acetone) where the 5-coordinate species predominate, it can be seen that they change in the order of $Cl^-<Br^-<I^-$, indicating that the stabilities of the 5-coordinated species are in the opposite order. The conductivity data (see below) also show that the Cl-complex is more stable than the Br-complex, and the I-complex is the most unstable, as the 5-coordinate species in the same solvent. Thus it is evident that the stability order of the 5-coordinate complexes, [Cu(tmen)(dike)X], in solution is $Cl^->Br^->I^-$. Comparison with the data of the NCS-complex shows that it comes between Cl^- and Br^-, or sometimes near Cl^- or Br^- in this series, although its exact position seems to depend markedly on the solvent used.

Figure 5 shows the $\tilde{\nu}_{max}$ diagram of the Cl- and Br-complexes with different kinds of dike in various solvents, including the data of the corresponding acac-complexes reported previously. The $\tilde{\nu}_{max}$ of a chelate containing Cl^- or Br^- changes, in general, in the order of MeOH>EtOH>DMSO>DMF>NM>CH_3CN>DCE≃ acetone in various solvents (*i.e.*, nearly in the order of P_f), with some ambiguity at hfac-chelates. And, in the same solvent, for example in MeOH, EtOH, or DMSO, it changes as dipm>acac>tfac>hfac, with

*2) This correlation of $\tilde{\nu}_{max}$ with AN (and that with Pf) can be understood with the view that the $\tilde{\nu}_{max}$ of a solution is determined by the position of the equilibrium (1) in it (see later). In fact, the absorption band observed is a superposition of the band of [Cu(tmen)(dike)X] and that of [Cu(tmen)-(dike)(Solv)$_2$]$^+$, and the latter is susceptible to type A solvatochromism, changing somewhat from one solvent to another. Nevertheless, examination of the data indicates, in most cases, that the above view can be taken as a reasonable approximation.

the change of the α-substituent groups in dike. This is the same as the order of the ligand field strengths of the dike ligands, although the degree of the shift of the $\tilde{\nu}_{max}$ from one another is different in each solvent; *e.g.*, in MeOH and EtOH the shifts of the $\tilde{\nu}_{max}$ of the hfac-chelate from that of the dipm-chelate are rather large, but that in DCE is very small.*3) The conductivity data (see below), on the other hand, reveal that the degree of dissociation of the dipm-chelate (for example, Cu(tmen)(dipm)Cl: 45 % in CH_3CN) is, in most cases, larger than those of the corresponding chelates of acac, tfac, or hfac, which decreases in this order (33, 11, and 3%, respectively, in CH_3CN). All these data mean that, as the equatorial ligand field of the chelate is weakened by the α-substituents, the coordination of the axial ligand X^- is strengthened, and the equilibrium leading to the tetragonal, solvated [Cu(tmen)(dike)] cation (see below) is thus shifted to the left hand side.

The characteristics of the spectral changes in the present systems, which will be called "Type B Solvatochromism," can thus be summarized as follows:

$$[Cu(tmen)(dike)X] + n(Solv) \rightleftharpoons [Cu(tmen)(dike)(Solv)_2]^+ + X^-(Solvated) \quad (1)$$

Structure: 5-Coordinated $\rightleftharpoons$ Tetragonal

$\tilde{\nu}_{max}$ of the solution : Lower ⟶ Higher

Solvent Polarity (Pf) : Small ⟶ Large

Anion Effect(X^-): Cl^- ⟶ (NCS^-) ⟶ Br^- ⟶ I^-

Substituent Effect(dike): hfac ⟶ tfac ⟶ acac ⟶ dipm

Color of Solution: Green ⟶ Bluish violet

(Type B Solvatochromism)

The anion effect and substituent effect may be called, respectively, the "Axial Ligand Field Variation Effect" and "Equatorial Ligand Field Variation Effect" on the Type B solvatochromism. Owing to the latter effect, the tetragonal structure is stabilized especially in the case of the dipm chelates. This may be reflected in the easy formation of monohydrates of these chelates, Cu(tmen)(dipm)X·H_2O (see experimental).

Electric Conductivities of the Chelates. Electric conductivity data (molar conductance) of the chelates in three solvents(CH_3CN, NM, and DCE) are summarized in Table 3. These and similar results obtained in other solvents in Table 2 can be explained as follows, supporting the conclusions of the spectral observations.

1) In alcohols and H_2O, almost all of the complexes dissociate strongly into $[Cu(tmen)(dike)(Solv)_2]^+$ and X^-, except the hfac-Cl-complex which decomposes into [Cu(tmem)(hfac)$_2$] and [Cu(tmen)Cl_2] in water (see next section). This is quite natural because the solvents have large DN and AN, so that their P_f are high, and the equilibrium (1) is shifted strongly to the right hand side.

2) In a solvent with a lower P_f, such as CH_3CN or NM, there is a smaller ionization of the complexes, *i.e.*, the equilibrium (1) is shifted to the right to a limited extent.

3) In the case of 2), there is a characteristic anion effect on the equilibrium. For example, the equilibrium of [Cu(tmen)(tfac)X] is shifted to the left hand side in the order of $Cl^- > NCS^- > Br^- > I^-$ in most solvents, as pointed out in last section.

4) In the case of 2), there is also a notable substituent effect on the equilibrium, as stated in the last section. The stability of the 5-coordinate species is found to increase as follows:

$$\text{dipm} < \text{acac} < \text{tfac} < \text{hfac},$$

although an apparent reversal of dipm and acac is observed at times (*cf.* the data in NM).

5) In a solvent with very low P_f such as DCE or acetone, most of the chelates studied here exist as the stable 5-coordinate green species. In this case, notable anion effects and substituent effect cannot be observed.

Ligand Rearrangement Reaction of Cu(tmen)(hfac)Cl. As mentioned above, the tfac- or hfac-chelates containing electron-withdrawing CF_3 groups have a weak equatorial ligand field and favor axial coordination of the anion X^-. In the extreme case of the hfac-Cl-chelate, these effects make the 5-coordinate species unstable, so that a ligand rearrengment reaction (or disproportionation) occurs in water:

$$2[Cu(tmen)(hfac)Cl] \rightleftharpoons [Cu(tmen)(hfac)_2] + [Cu(tmen)Cl_2].$$

The identity of each of the two disproportionation products was checked by their elementary analyses and spectral properties reported in the literature.[11] A very similar disproportionation was formerly observed with analogous Ni(II) chelates,[12] where the reaction could occur also in solid state and with other dike, *e.g.*, acac:

$$2[Ni(tmen)(acac)X(OH_2)] \xrightarrow{\Delta}$$

greenish blue

$$[Ni(tmen)(acac)_2] + [Ni(tmen)X_2]$$

green violet

The non-charged stable chelate, [Ni(tmen)(acac)$_2$], formed by this thermal reaction was very volatile, so it was easy to separate the two disproportionation products from each other.[12]

In the copper system, at present, we could not observe such a thermal reaction. Any drastic weight loss, or release or absorption of heat, could not be observed by TG-DTA technique, until a complicated decomposition begins to take place. This difference

*3) In the case of the bromide-dipm complex, the $\tilde{\nu}_{max}$ of most complexes tend to flock together, showing type A solvatochromism to some extent, and only those in DCE and acetone are left apart from them. This is similar to the result observed with the iodide-tfac complex (*cf.* Fig. 2), and indicates that the stronger ligand field of dipm hinders the coordination of Br^- quite remarkably, while the weaker tfac can do so only toward I^-.

between the Cu(II)- and the Ni(II)-chelates may be explained by the crystal field stabilization energies and the complex-forming powers of these metal ions (Irving-William's rule) and the Jahn-Teller effect in the copper(II) system. More precise work along this line is now in progress.

The present work was partially supported by a Grant-in-Aid for Scientific Research (No. 59430009) from the Ministry of Education, Science and Culture.

Solvent Effect on Adsorption of TCNQ onto Metal Oxides

Kunio Esumi,* Kazuaki Miyata, and Kenjiro Meguro
Department of Applied Chemistry, Institute of Colloid and Interface Science, Science University of Tokyo, Kagurazaka, Shinjuku-ku, Tokyo 162
(Received April 22, 1985)

7,7,8,8-Tetracyanoquinodimethan (TCNQ) was adsorbed on the surfaces of alumina and titania from three basic solvents. The amount of TCNQ adsorbed decreased with an increase in the acid-base interaction between TCNQ and the basic solvent for both metal oxides. The TCNQ anion radicals were formed as a result of electron transfer from the metal oxide surfaces to adsorbed TCNQ. Further, the concentration of TCNQ anion radicals formed on the oxides after the TCNQ adsorption decreased also with an increase in the acid-base interaction between TCNQ and the basic solvent.

It is well known[1,2] that, when strong electron acceptors or donors are adsorbed on metal oxides, the corresponding radicals are formed as a result of electron transfer. By measuring the concentrations of the radicals formed, the electron-donor-acceptor properties of metal oxides have been evaluated.[3–5] Furthermore, Esumi *et al.*[6,7] attempted to determine the distribution of Lewis sites with different strengths of metal oxides; they found that the distribution of Lewis sites with different strengths on alumina was much wider than that on titania.

Recently, the acid-base theory has been applied to colloidal systems. Fowkes *et al.*[8] studied the interactions between polymers and inorganic solids by using the Drago correlation[9] of the heats of acid-base interaction and reported that strong polymer adsorption is observed only from solvents more neutral than the adsorbate polymer or the adsorbent surface sites. Thus, the acid-base interaction is a very important factor at interfaces.

In this work, electron-donor-acceptor interactions on metal oxides were examined by means of 7,7,8,8-tetracyanoquinodimethan(TCNQ) adsorption from various solvents.

Experimental

Materials. Two kinds of metal oxides, alumina and titania, were used. These metal oxides were prepared as follows: excess aqueous methanol (water: methanol,4:1 in weight) was vigorously added into a butanolic solution of each alkoxide. Stirring was continued for 5 h at about 90 °C. The precipitate was then separated by centrifuging, washed with methanol, finely ground, and then evacuated at 100 °C. The dried products were calcined for 2 h at 500 °C.

The TCNQ was obtained from Wako Chemicals and purified by repeated recrystallization. The solvents used in this study were dried by the use of molecular sieves.

Procedure. The metal oxide was placed in a L-type test tube, and a solution of TCNQ in an organic solvent was then poured in. After the tube had subsequently been shaken for 2 h at 25 °C, the dispersion thus obtained was used for the zeta potential measurement. The metal oxide was collected by centrifuging and dried at room temperature *in vacuo*. The dried sample was then used for the ESR measurement.

The ESR spectra were measured by means of a Japan Electrons Optics Laboratory ESR spectrometer (JES-FE3X) operating with an X-band microwave 100 kHz field modulation. The radical concentrations were estimated by comparing the area under the absorption curves for the sample and for standard solutions of 2,2-diphenyl-1-picrylhydrazyl in benzene.

The zeta potential of metal oxide after the adsorption was measured by means of an electrophoresis apparatus (Laser Zee 500, Pen Kem).

The amount of TCNQ adsorbed was determined from the difference in concentrations before and after the adsorption. The absorbance of TCNQ was measured by means of an UV spectrophotometer (Hitachi 220A). The maximum absorption wavelengths of the absorption band of TCNQ in the three basic solvents were 393 nm in acetonitrile, 395 nm in ethyl acetate, and 403 nm in 1,4-dioxane.

The specific surface areas of the samples were determined with a Sorptograph, Model ADS-1B (Shimadzu Seisakusho Co., Ltd.).

Results and Discussion

The amount of TCNQ in solutions adsorbed on the surfaces of alumina and titania was determined using three basic solvents: acetonitrile, a very weak base; ethyl acetate, a weak base, and 1,4-dioxane, a moderately weak base. The adsorption isotherms of TCNQ from these basic solvents are given in Fig. 1; it is apparent that their isotherms may be classified as the Langmuir type for both metal oxides. From the Langmuir plots of these isotherms, the saturated amounts of TCNQ were obtained; their values are listed in Table 1. It may be seen that the amount of TCNQ adsorbed decreases very appreciably with an increase in the basicity of the solvent for both metal oxides. To interpret this result in terms of the acid-base theory, the Drago equation[9] was employed:

$$-\Delta H^{ab} = C_A C_B + E_A E_B$$

where E and C are the Drago constants for the acidic compound(A) and the basic compound(B). Drago determined many E and C values for organic solvents from measurements of the heat of acid-base interaction made by his group and by others using calorimetric and spectroscopic methods.[9,10] These studies demonstrated that the Drago equation usually predicted ΔH^{ab} values within 3%. A very useful approach for relating the

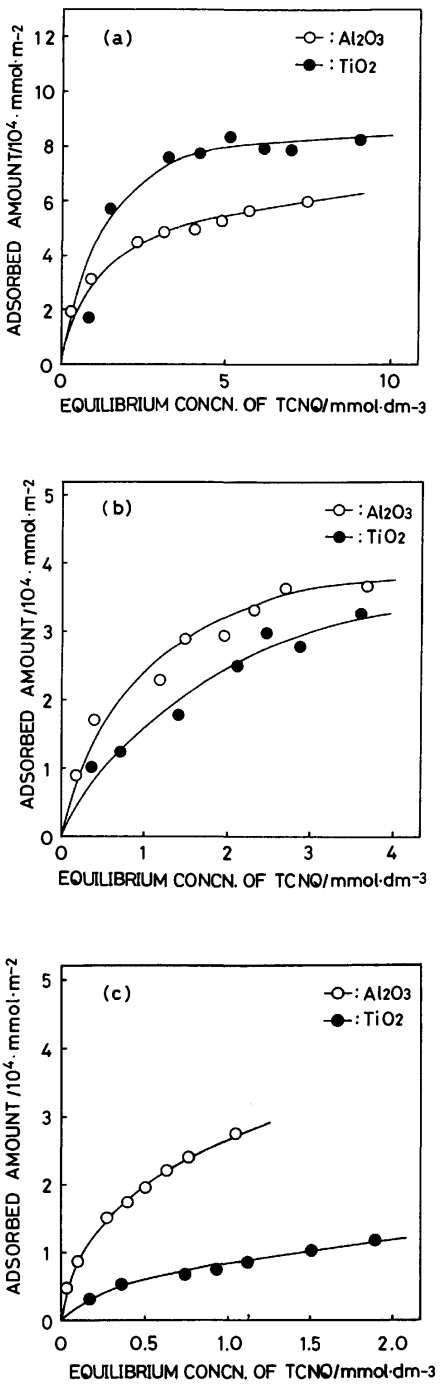

Fig. 1. Adsorption isotherms for TCNQ adsorbing from basic solvents onto metal oxides: (a) Acetonitrile, (b) Ethyl acetate, (c) 1,4-Dioxane.

Table 1. Data of TCNQ adsorption

Sample	Color of oxide surfaces		
	Acetonitrile	Ethyl acetate	1,4-Dioxane
Alumina	Blue green	Yellowish green	Yellowish white
Titania	Violet	Pale violet	—
	Amount adsorbed ($\times 10^4$ mmol/m^2)		
Alumina	6.2	4.4	2.9
Titania	7.7	5.7	1.7

Table 2. Acid-base parameters

Solvent	C_B	E_B	$-\Delta H^{ab}$ with TCNE[a] (kcal/mol)
Acetonitrile	1.34	0.889	3.51
Ethyl acetate	1.74	0.975	4.27
1,4-Dioxane	2.38	1.09	5.23

a) TCNE (C_A=1.51, E_A=1.68). (1 cal$_b$=4.184 J).

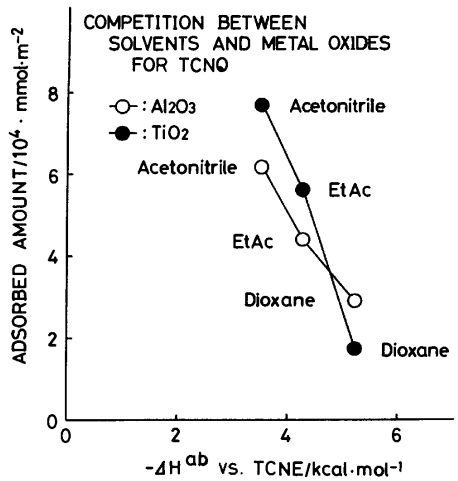

Fig. 2. Saturated amount of TCNQ adsorbing onto metal oxides *vs.* acid-base interaction enthalpy.

interfacial interactions quantitatively has been the Drago equation of enthalpy changes in acid-base complexation. When the Drago equation is applied to this work, the basic compounds correspond to the solvents, such as acetonitrile, ethyl acetate, and 1,4-dioxane, and the acidic compound, to TCNQ. The E and C values for three basic solvents are available,[9] but not for TCNQ. Therefore, in this study, the E and C values[9] of tetracyanoethylene(TCNE), which is similar to TCNQ, are employed insteads of these of TCNQ. These acid-base parameters are listed in Table 2.

Figure 2 shows the amount of TCNQ saturated on alumina and titania as a function of ΔH^{ab}; the amount of TCNQ saturated decreases with an increase in the acid-base interaction (ΔH^{ab}) between the basic solvent and TCNQ.

When TCNQ was adsorbed from the solutions on alumina and titania, the surfaces of the metal oxides developed a remarkable coloration. The color was dependent on the kind of solvent; the results are shown in Table 1. It has previously been reported[4,5] that the adsorption of electron acceptors on metal oxides produces a surface coloration and gives unresolved ESR spectra. The samples colored by the TCNQ adsorption gave unresolved ESR spectra with a g-value of 2.003. These spectra have been identified[4,5] as being those of TCNQ anion radicals.

The above results support the idea that the TCNQ anion radicals are formed as a result of electron transfer from the metal oxide surface to the TCNQ adsorbed.

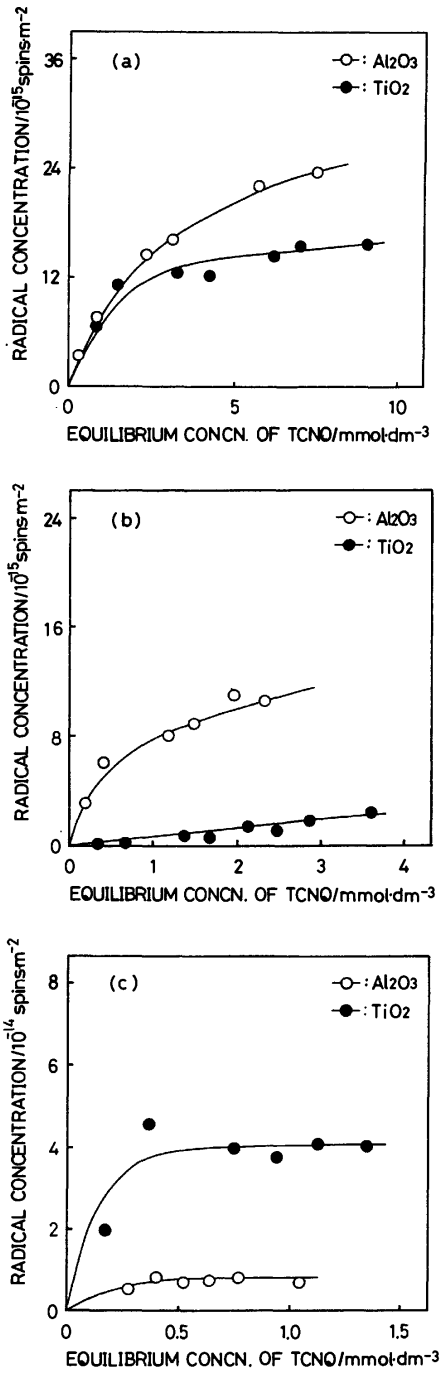

Fig. 3. TCNQ radical concentration onto metal oxides *vs.* equilibrium concentration of TCNQ into basic solvent:
(a) Acetonitrile, (b) Ethyl acetate; (c) 1,4-Dioxane.

The TCNQ-radical concentrations formed on the surface of metal oxides are plotted against the equilibrium concentration of TCNQ in Fig. 3. The TCNQ-radical concentration decreased with an increase in the basicity of the basic solvents. Furthermore, in order to compare the TCNQ-radical concentration on the surface of metal oxide as a function of ΔH^{ab}, the TCNQ-radical concentration corresponding to the half-value of the saturated amount of TCNQ was obtained; the results are illustrated in Fig. 4. The TCNQ-radical concentrations of alumina decreased gradually in the weak acid-base interaction and steeply in the moderate acid-base interaction. On the other hand, in the case of titania, they decreased steeply in the weak acid-base interaction and gradually in the moderate acid-base interaction. The TCNQ-radical concentrations on alumina were larger than those on titania for two of the three basic solvents, but not 1,4-dioxane, indicating that the concentration of electron-donor sites having relatively weak strengths on alumina is larger than that on titania. Furthermore, in the case of 1,4-dioxane, the TCNQ-radical concentration on titania was larger than that on alumina. This result suggests that the concentration of electron-donor sites having relatively strong strengths on titania is larger than that on alumina. These results agreed fairly well with similar measurements previously reported by us.[6]

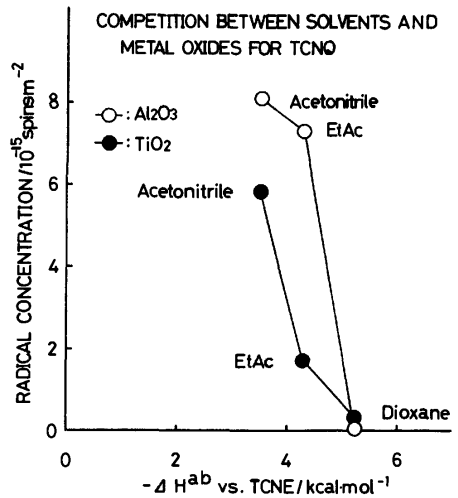

Fig. 4. TCNQ radical concentration corresponding to half-value of saturated amount of TCNQ onto metal oxides *vs.* acid-base interaction enthalpy.

The zeta potentials of metal oxides before and after TCNQ adsorption were also measured. The zeta potential of alumina and titania in the basic solvent alone decreased with an increase in the basicity of the solvents. In this case, the acid sites of alumina and titania interacted with the basic solvent. After the TCNQ adsorption, the zeta potentials of alumina and titania decreased with an increase in the concentration of TCNQ for the three basic solvents. Further, the magnitude of the decrease in the zeta potential of both metal oxides was dependent on the acid-base interaction between TCNQ and the basic solvent; the order of magnitude of the decrease was acetonitrile>ethyl acetate>1,4-dioxane. Labib *et al.*[11] measured the zeta-potential for several solids in a series of organic liquids chosen to cover a wide range of electron-donor properties; they reported that, for most of the solids, the zeta potential changes its sign for

some value of the liquid donicity because of the acid-base interaction between solids and organic liquids.

The electron-donor sites of metal oxides for the electron transfer are considered as follows: two possible electron-donor sources exist on the alumina surface. One of these has electrons trapped at intrinsic defects, while the other has hydroxide ions. Free electrons derived from the intrinsic defects on the surface of the alumina would normally be expected to participate in the electron-transfer adsorption. However, since it has been reported[1] that the electron-donor defect site on the surface of alumina was created at an activation temperature above 500 °C, it may be suggested that the electron-donor defect site does not play an important role in this study. The other site is the surface hydroxide ions which have been confirmed to exist on the surface of alumina. The ionization potentials of the hydroxide ions are comparatively small[12] (≈2.6 eV in the gas phase). It seems likely that the surface hydroxide ions on alumina as an electron-donor site can be attributed to the electron-transfer adsorption. Indeed, Fomin *et al.*[13] have reported that electron transfer from the hydroxide ion can occur in certain solvent systems, provided a suitable acceptor molecule is present. The electron-donor sites of titania have been associated with surface hydroxide ions and Ti^{3+} ions.[14] The latter site has been reported[14] to be formed at high temperatures *in vacuo*. In the present study, the hydroxide ions on the titania surface have been found to operate mainly as an electron-donor site.

The authors are indebted to Mr. Shizuo Sugimoto for obtaining the ESR spectra.

CO_2 Laser-induced Decomposition of 1,1,2-Trichloroethane

Hiroo OGURA
The Institute of Space and Astronautical Science, Komaba, Meguro-ku, Tokyo 153
(Received June 15, 1985)

$CH_2ClCHCl_2$ was photolyzed with a focusing geometry using the P(24) line of the 10.6 μm CO_2 band (940.6 cm^{-1}). The final products of neat photolysis were *cis*- and *trans*-CHCl=CHCl, $CH_2=CCl_2$, $CH_2=CHCl$, CH≡CCl, CH≡CH, and C_4H_2. The relative yield of $CH_2=CCl_2$ in particular was strongly dependent on $CH_2ClCHCl_2$ pressure and sensitive to the addition of H atom containing molecules. A series of diagnostic experiments shows that the dichloroethene isomers are formed by three different processes, *i.e.*, infrared multiphoton decomposition, collision-induced decomposition, and radical chain reaction. Infrared mulitiphoton decomposition and collision-induced decomposition give rise to *cis*- and *trans*-CHCl=CHCl predominantly, while the radical chain reaction generates the dichloroethene isomers in comparable amounts at high reactant pressures, the most probable initiation step being the C-Cl bond-scission reaction of the parent molecule. Formation mechanisms for other minor products are also discussed.

Infrared multiphoton decomposition (IRMPD) of halogenated ethanes has been extensively studied.[1-12] In these studies it has been shown that molecular elimination of hydrogen halide is the predominant dissociation channel. Among the partially chlorofluorinated ethanes, CH_2XCHXY (X,Y=Cl,F) is unique in that it undergoes molecular elimination of HX (X=Cl,F) giving more than one haloethene. This was confirmed in chemical activation studies,[13,14] in a shock tube study,[15] and in flow tube studies[16,17] on $CH_2ClCHCl_2$ and CH_2FCHF_2, which decompose to three isomeric dichloro- and difluoroethenes, respectively.

In a previous study[9] we showed that $CH_2ClCHFCl$ is also decomposed upon an infrared multiphoton excitation (IRMPE) to $CH_2=CFCl$, *trans*- and *cis*-CHF=CHCl in the primary step and that the branching ratio of $CH_2=CFCl$ is remarkably increased with respect to those of *trans*- and *cis*-CHF=CHCl as the reactant pressure is increased up to 3 Torr (1 Torr=133.322 Pa). These results suggest a mechanistic change in the formation of $CH_2=CFCl$ at higher reactant pressures. We have extended the study on CH_2XCHXY to $CH_2ClCHCl_2$ and CH_2FCHF_2[18] and report in this paper the results of $CH_2ClCHCl_2$. A series of diagnostic experiments such as product yield dependence on reactant and buffer gas pressure was carried out and the results were interpreted on the basis of the simple extended threshold model presented by Hackett *et al.*[4]

Experimental

The experimental apparatus and analytical procedure used are essentially the same as those in a previous study and have been fully described.[9] Only a brief description will be given here. The pulse beam from a Lumonics 103-2 TEA CO_2 laser with N_2 added was passed through an aperture (14 mm in diameter) and focused in an irradiation cell (46-mm diameter, 22-cm long, NaCl windows) by means of Ge lens (12.7-cm focal length). The principal line used in these experiments was the P(24) line of the 10.6 μm band at 940.6 cm^{-1}. The output pulse was attenuated by CaF_2 flats and the incident pulse energy was measured with a calibrated pyroelectric detector, the repetition rate being 1 Hz for all runs. MKS Baratron transducers were used for the pressure measurements.

All photolysis products were identified by comparative GC retention times with known samples, in particular, with the IRMPD products of $CH_2ClCHFCl$.[9] For quantitative determination of the photolysis products, temperature programmed gas chromatographic analyses were carried out using Porapak N column (flame ionization detector). The reactant (Tokyo Kasei Co. Ltd.) was purified by gas chromatography using octane/Porasil C (Durapak) column, and then further distilled under vacuum at low temperature.

Results

Upon the photolysis at 940.6 cm^{-1}, which falls within a band of $CH_2ClCHCl_2$ corresponding to a CH_2 wagging vibration,[19] several products were observed by gas chromatography. The final products detected were

Table 1. Pressure dependence of relative yields[a)]

P/Torr	0.20	0.40	0.60	1.0	3.0	5.0
CH≡CH	1.16	1.14	0.95	0.87	0.54	0.48
CH≡CCl	8.38	8.17	9.01	8.24	8.46	8.56
CH_2=CHCl	0.93	1.08	1.38	1.66	1.68	1.78
CH_2=CCl_2	3.32	3.04	4.44	7.27	27.2	46.7
trans-CHCl=CHCl	53.8	53.5	57.0	60.1	62.6	66.6
cis-CHCl=CHCl	100	100	100	100	100	100
	(0.495)	(0.524)	(0.587)	(0.742)	(1.71)	(2.52)

a) Relative yields at E_0=0.136 J/pulse and 500 shots. The yield of *cis*-CHCl=CHCl in % conversion per 500 shots (in parenthesis) is taken as 100.

CH_2=CCl_2, *trans*- and *cis*-CHCl=CHCl, CH_2=CHCl, CH≡CCl, CH≡CH, and C_4H_2. C_4H_2, which was formed in trace amounts at high substrate pressures and high laser fluences, was identified by comparing the rentention time with that of the C_4H_2 prepared from C_6H_6: C_6H_6 of about 30 Torr was irradiated by the CO_2 laser at 1043.1 cm^{-1}, C_4H_2 being trapped from the effluent of the gas chromatograph and identified by mass spectrometry. CHCl=CCl_2, CH_2ClCH_2Cl, and $CHCl_2CHCl_2$ were sought by using octane/Porasil C column at 110 °C, but were found in trace amounts or not found at all, no quantitative determination of CHCl=CCl_2 being made.

A series of diagnostic experiments was performed to establish the unimolecular dissociation and subsequent reaction mechanism of $CH_2ClCHCl_2$ subjected to the intense CO_2 laser irradiation. In each diagnostic experiment the relevant photolysis parameter was varied, the other parameters being kept constant or same.

Dependence on Reactant Pressure. Product yields as a function of $CH_2ClCHCl_2$ pressure were investigated at the pulse energy of 0.136 J/pulse, product yields and relative yields being shown in Fig. 1 and Table 1, respectively. Figure 1 shows that all product yields increase as the substrate pressure is increased, in particular, the increase in the yield of CH_2=CCl_2 with higher reactant pressure is most significant: The yield of CH_2=CCl_2 at 5.0 Torr is more than 70 times greater than that at 0.2 Torr, while those of *trans*- and *cis*-CHCl=CHCl are increased by a factor of 5—6 of their yields at 0.2 Torr. From the viewpoint of relative yields, the yield of *cis*-CHCl=CHCl being arbitrarily taken as 100, those for *trans*-CHCl=CHCl, CH_2=CCl_2, and CH_2=CHCl show an increase with higher reactant pressure, in particular, that of CH_2=CCl_2 increases much more rapidly than that of *trans*-CHCl≡CHCl, while that of CH=CH shows an opposite trend. In the case of CH≡CCl there appears to be no discernible pressure dependence. Major products are *cis*- and *trans*-CHCl=CHCl at lower pressures, CH_2=CCl_2 being less important than CH≡CCl, whereas CH_2=CCl_2 becomes major product at higher pressures together with *cis*- and *trans*-CHCl=CHCl.

Dependence on Pulse Number. The effects of pulse number on product yields were examined at 0.2 and 5.0 Torr reactant pressure and pulse energy of 0.202 J/pulse. All product yields, even those for minor products, are proportional to pulse number n up to 500, which affirms that all the products are formed upon each pulse irradiation, *viz.*, within the time interval between pulses.

Table 2. Pulse energy dependence of relative yields[a)]

E_0/(J/pulse)	0.311	0.202	0.136	0.0916
CH≡CH	4.46	2.58	1.16	0.35
CH≡CCl	12.4	9.94	8.38	5.49
CH_2≡CHCl	1.41	1.04	0.93	0.23
C_4H_2	1.22	0.61	b)	b)
CH_2=CCl_2	5.00	4.19	3.32	2.49
trans-CHCl=CHCl	50.0	49.2	53.8	60.5
cis-CHCl=CHCl	100	100	100	100
$d\times10^5$/(pulse)$^{-1}$	8.24	3.97	1.68	0.754

a) Relative yields at 0.20 Torr $CH_2ClCHCl_2$ pressure as compared to the yield of *cis*-CHCl=CHCl. b) Yield is too small to be quantitatively determined.

Dependence on Pulse Energy. Product yields as a function of pulse energy were investigated at 0.2 Torr substrate pressure. All yield, as mentioned above, is propertional to pulse number, indicating pseudo-first order decay of the parent molecule over a fairly wide range of conversion. The dissociation rate constant(d) could be defined by $d=-(1/n)\ln(1-X)$, where X is the dissociated fraction of $CH_2ClCHCl_2$ after irradiation of n pulses. Log d is correlated linearly with log E_0 in the pulse energy (E_0) range of 0.311—0.0916 J/pulse with a slope of 1.98. The slope value obtained is somewhat larger than the standard 3/2 power dependence of d on E_0 for a "tightly" focused geometry. It has been recognized that at relatively low pulse energy and local fluence below the critical fluence, the power dependence of d is higher than the standard value, and approaches 1.5 as E_0 increases.[20] At higher fluences where the 3/2 power law holds, main contribution of the irradiated volume to the dissociation yield comes from the reaction zone where the laser fluence exceeds the critical fluence for $CH_2ClCHCl_2$ decomposition and all molecules contained dissociate with unit probability. Since the observed power dependence of d

cis-CHCl=CHCl	100	100	100	100	100	100	100
	(2.52)	(1.48)	(1.31)	(0.906)	(0.863)	(0.610)	(0.549)

a) Relative yields at E_0=0.136 J/pulse as compared to the yield of *cis*-CHCl=CHCl in % conversion per 500 shots (in parenthesis). Reactant pressure is 5.0 Torr, those of additives being 5.0 Torr. b)The GC peak was masked by an impurity contained in the C_2H_6.

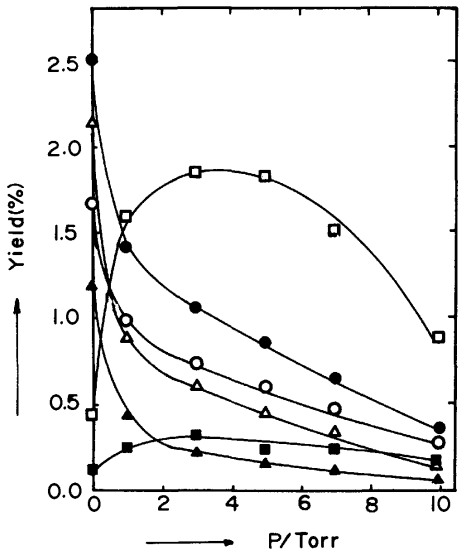

Fig. 2. Product yields as a function of H_2 pressure. (Reactant pressure=5.0 Torr, E_0=0.136 J/pulse, n=500, =940.6 cm^{-1}).
●: *cis*-CHCl=CHCl, ○: *trans*-CHCl=CHCl, ▲: CH_2=CCl_2, △: CH≡CCl(×10), □: CH_2=CHCl(×10), ■: CH≡CH(×10).

is not so far from 1.5, the relative yields with respect to the yield of *cis*-CHCl=CHCl, as predicted from the simple extended threshold model, change slightly with increasing E_0, at most 10 for that of *trans*-CHCl=CHCl (Table 2). However, the increase in the relative yields of minor products and the decrease in that of *trans*-CHCl=CHCl with increasing pulse energy are worthy of note to discuss the photolysis mechanism.

Effects of Additives on Product Yields. The product yields as a function of several additive pressure up to 5—10 Torr were examined at 5.0 reactant pressure and 0.136 J/pulse laser energy. Upon the addition of N_2, NO, and CF_4, all the product yields decrease monotonically as the pressure is increased. The yield-pressure behaviors for these molecules are similar to one another, the relative yields being little affected by the presence of these additives and by increasing the additive pressure. On the other hand, by the addition of H_2, CH_4, and C_2H_6 , the yield of CH_2=CCl_2 together with its relative yield is decreased more rapidly and significantly than those of *cis*- and *trans*-CHCl=CHCl. The yield of CH_2=CHCl increased markedly upon the addition of H_2 and C_2H_6 at lower additive pressures and then decreases slowly with higher additive gas pressure. The yield-pressure behaviors for H_2 and C_2H_6 are similar to each other, the increase in the yield of CH_2=CHCl being more significant upon the addition of H_2. While the relative yield of CH_2=CHCl is increased by the addition of CH_4 as in the case of H_2 and C_2H_6 addition, its yield is decreased slightly by the presence of CH_4. At the same time the yield of CH≡CH is increased to small extent at lower H_2 pressures and then decreased slowly with increasing H_2 pressure. Similarly, at lower CH_4 pressures it is increased by a factor of 2 greater than that by the same amount of H_2 addition. The relative yields at the additive gas pressure of 5.0 Torr are summarized in Table 3. The yield-pressure plot in the presence of H_2 is shown in Fig. 2, the relative yields being summarized in Table 4.

Discussion

Primary Photolysis. The final product dis-

Table 4. Dependence of relative yields[a)] on H_2 pressure

a) Relative yields at E_0=0.136 J/pulse as compared to the yield of *cis*-CHCl=CHCl in % conversion per 500 shots(in parenthesis). Reactant pressure was 5.0 Torr for these runs.

tribution obtained in the neat photolysis of $CH_2ClCHCl_2$ in the pressure range up to 5 Torr (Table 1) suggests that $CH_2=CCl_2$, *trans*- and *cis*-CHCl=CHCl are important products, *trans*- and *cis*-CHCl=CHCl being the major products over the whole pressure range examined and $CH_2=CCl_2$ formation being significant only at higher pressures. As can be seen from Table 1, all the products as well as their relative yields are relatively constant at reactant pressures below 0.4 Torr. At these pressures the effects of collisions would not be important, since all product yields increase linearly with the substrate pressure. The principal mode of dissociation at lower pressures would be the direct elimination of HCl upon the infrared multiphoton absorption. Molecular elimination of HCl is in line with the IRMPD studies on related systems[7-9] and with a chemical activation study on this system:[13]

$$CH_2ClCHCl_2 + nh\nu \longrightarrow CH_2=CCl_2 + HCl, \quad (1)$$

$$\longrightarrow trans\text{-}CHCl=CHCl + HCl, \quad (2)$$

$$\longrightarrow cis\text{-}CHCl=CHCl + HCl. \quad (3)$$

By analogy with the chemically activated $CH_2ClCHCl_2$, the reactant molecule upon the IRMPE would eliminate HCl *via* three-center reaction together with more common four-center reaction mentioned above:

$$CH_2ClCHCl_2 + nh\nu \longrightarrow CH_2ClCCl: + HCl, \quad (4)$$

$$CH_2ClCCl: \longrightarrow trans\text{-}CHCl=CHCl, \quad (5)$$

$$\longrightarrow cis\text{-}CHCl=CHCl. \quad (6)$$

There is now sufficient evidence for the vibrational excitation of HCl eliminated by the IRMPD of halogenated ethanes. It has been shown that the *trans*- and *cis*- CHCl=CHCl produced from the chemically activated $CH_2ClCHCl_2$, in particular those formed *via* three-center reaction, have enough internal energy to undergo isomerization. The threshold energies for $CH_2=CCl_2$, CHCl=CHCl *via* four-center reaction, and CHCl=CHCl *via* three-center reaction have been estimated to be 57.1, 58.8, and 60.0 kcal/mol(1 cal_{th}= 4.184 J), respectively. Formation of *cis*-form is favored channel in both four- and three-center eliminations, *cis*-form being thermodynamically more stable than *trans*-form by 0.650 kcal/mol.[21] Activation energy for the isomerization of *cis*-CHCl=CHCl is reported to be 56.9 kcal/mol.[22] In the case of CHCl=CHCl isomers it is not possible to distinguish between three- and four-center eliminations, $CH_2=CCl_2$ being attributed to four-center reaction. The contribution of three-center elimination is estimated to be 25% for chemically activated $CH_2ClCHCl_2$.[13] Similarly, three-center elimination would not predominate over four-center reaction in the IRMPD of $CH_2ClCHCl_2$. The relative yield of $CH_2=CCl_2$ at reactant pressures below 0.4 Torr is about 50 times smaller than that of *trans*- plus *cis*-CHCl=CHCl, which can be partly ascribed to the 7 times smaller statistical weight of $CH_2ClCHCl_2$ activated complexes leading to $CH_2=CCl_2$.[13] Dai *et al.* also observed the very small relative yield of $CH_2=CCl_2$ with respect to those of *trans*- and *cis*-CHCl=CHCl in their SiF_4 sensitized IR laser pyrolysis of $CH_2ClCHCl_2$, and suggested that the activation energy of $CH_2=CCl_2$ formation should be higher than those of *trans*- and *cis*-CHCl=CHCl by more than 5 kcal/mol, the activation energies for *cis*- and *trans*-CHCl=CHCl obtained being 58.5 and 59.5 kcal/mol, respectively.[23] This higher activation energy for $CH_2=CCl_2$ is not consistent with the lower threshold estimated from the chemical activation study, a good agreement being seen between the laser pyrolysis and chemical activation results for the activation energies of 1,2-dichloroethene production.

According to the simple extended threshold model for multiple dissociation channels,[4] the reaction zone with a "tightly" focused laser beam is divided by individual critical fluence and all molecules contained in the volume defined by the threshold fluence contours decompose *via* individual channel with unit probability. At low pressures the relative yields from various channels are the ratios of the individual reaction volume. This model would be applicable approximately to our system, although a slight deviation of d at 0.2 Torr from the standard 3/2 power law is observed in the present experiments. The very small relative yield of $CH_2=CCl_2$ indicates that the critical fluence for $CH_2=CCl_2$ formation locate spacially inside those of *trans*- and *cis*-CHCl=CHCl channels in the photolysis cell: In terms of threshold energy $CH_2=CCl_2$ formation channel has higher threshold energy than those of CHCl=CHCl channels.

The activation energy for the C–Cl bond rupture was estimated to be 64 kcal/mol from the laser pyrolysis results.[23] This energy threshold is very close to those for the HCl elimination channels and the C–Cl bond fission would take place in the primary photolysis:

$$CH_2ClCHCl_2 + nh\nu \longrightarrow CH_2ClCHCl\cdot + Cl \quad (7)$$

Since the threshold energy of C–C bond scission is about 85 kcal/mol,[13] the C–C bond rupture channel might contribute to IRMPD to very minor extent. Actually no CH_3Cl, CH_2Cl_2, CH_2ClCH_2Cl, and $CHCl_2$-$CHCl_2$ were found in the product analysis.

Secondary Photolysis. The formation of the minor products by one step from the parent molecule is unlikely from the viewpoint of threshold energy and from mechanistic considerations. Nagai and Katayama reported that the major product of TEA CO_2 laser-induced reaction of *trans*-CHCl=CHCl is the *cis*-form, minor products being CH≡CH and CH≡CCl with a ratio of 1:3.[24] $CH_2=CCl_2$ was also reported to dissociate

to CH≡CCl upon an intense CO_2 laser irradiation.[25] The IR laser photolysis of *trans*-CHCl=CHCl and CH_2=CCl_2 in their ground vibrational states using the same excitation line as that for $CH_2ClCHCl_2$ did not give any appreciable amounts of the dissociation products. It is now recognized that polyatomic products formed in the primary photolysis are in their vibrationally excited states where they can absorb the laser photons efficiently and suffer from secondary photolysis.[9,10]

In the IRMPD of the dichloroethenes HCl elimination and C–Cl bond scission need 60—70 and 80—90 kcal/mol, respectively, isomerization channel being the lowest in *trans*- and *cis*-CHCl=CHCl:

$$cis(trans)\text{-}CHCl{=}CHCl^{\dagger} + mh\nu \longrightarrow trans(cis)\text{-}CHCl{=}CHCl \quad (8)$$

$$\longrightarrow CH{\equiv}CCl + HCl, \quad (9)$$

$$\longrightarrow CHCl{=}CH\cdot + Cl, \quad (10)$$

where CHCl=CHCl† denotes the CHCl=CHCl molecule excited to its quasicontinuum region or very close to it by the primary photolysis. As shown in Table 2, the relative yields of CH≡CCl and CH≡CH are increased with an increase in the laser energy, while that of *trans*-CHCl=CHCl with respect to *cis*-CHCl=CHCl is decreased with higher pulse energy. This strongly suggests that CH≡CCl is derived from *trans*- and *cis*-CHCl=CHCl predominantly. The relative yield of CH_2=CCl_2, however, shows a similar behavior to those of minor products, indicating that its dissociation is not so significant in the secondary photolysis as those of CHCl=CHCl isomers.

Similarly, the radicals primarily formed by the C–Cl bond scission would be decomposed by the secondary photolysis:

$$\cdot CHClCH_2Cl^{\dagger} + mh\nu \longrightarrow CH_2{=}CHCl + Cl \quad (11)$$

CH≡CH might be formed by the sequential elimination of Cl atom from CHCl=CHCl in a similar manner to CH_2=CHCl.[26] Under the present conditions, however, it seems more likely that CH≡CH is derived by the H-atom abstraction reaction of CH≡C· radical, since C_4H_2 is observed at higher laser energies. Thus CH≡CCl rather than CHCl=CH· radical would be further dissociated:

$$CH{\equiv}CCl^{\dagger} + m'h\nu \longrightarrow CH{\equiv}C\cdot + Cl, \quad (12)$$

$$CH{\equiv}C\cdot + CH_2ClCHCl_2 \longrightarrow CH{\equiv}CH + CH_2ClCCl_2\cdot, \quad (13)$$

$$2CH{\equiv}C\cdot \xrightarrow{M} C_4H_2\cdot \quad (14)$$

Effects of Pressure on Mechanism. The increase in the product yields in % conversion (Table 1) indicates that the collisional effects outside the reaction zone become significant at higher pressures, since the volume of reaction zone in which the fluence exceeds the lowest critical value and the fluence distribution are unaltered with increasing the reactant pressure at a given pulse energy, the absorption along the laser beam being neglected. As the substtrate pressure is increased, collisional energy transfer between the reactant molecules excited by the laser outside the reaction zone can drive them to higher energy levels than those excited upon the laser irradiation:

$$2CH_2ClCHCl_2^{\dagger} \longrightarrow CH_2ClCHCl_2^{*} + CH_2ClCHCl_2, \quad (15)$$

where $CH_2ClCHCl_2^{\dagger}$ and $CH_2ClCHCl_2$* stand for the $CH_2ClCHCl_2$ molecules excited below and above the dissociation threshold, respectively. The difference of critical energies between the HCl elimination and the C–Cl bond rupture is so small that the $CH_2ClCHCl_2$* molecule excited above the critical energy by the energy-pooling process would exit *via* both channels.

Since the yields of secondary products as well as those of primary products are increased with higher reactant pressure, other process of collisional energy transfer at higher pressures must be operative. At higher pressures many collisions are avialable to establish higher energy distribution of the reactant molecule, Reaction 15 being merely a simplified form of this process. Collisional energy transfer from energized parent molecule to other species occurs with a time scale comparable to the pulse duration.[23] This is the basis of IR laser pyrolysis experiment, except that IR sensitizers are in general much stronger absorbers of the laser photons and have higher energy threshold for their decomposition than $CH_2ClCHCl_2$. Thus the products formed by the collision-induced decomposition would be further dissociated as a result of intermolecular energy transfer:

$$CHCl{=}CHCl + CH_2ClCHCl_2^{\dagger} \longrightarrow CHCl{=}CHCl^{*} + CH_2ClCHCl_2, \quad (16)$$

$$CH{\equiv}CCl + CH_2ClCHCl_2^{\dagger} \longrightarrow CH{\equiv}CCl^{*} + CH_2ClCHCl_2, \quad (17)$$

$$\cdot CHClCH_2Cl + CH_2ClCHCl_2^{\dagger} \longrightarrow \cdot CHClCH_2Cl^{*} + CH_2ClCHCl_2. \quad (18)$$

Collisionally excited $CH_2ClCHCl_2$*, CHCl=CHCl*, ·$CHClCH_2Cl$*, and CH≡CCl* above the dissociation thresholds undergo decomposition analogous to Reactions 1—12.

In the presence of additives, the energy-pooling process 15 is suppressed by collisional deactivation of $CH_2ClCHCl_2^{\dagger}$ with the additive gases, and, as a reslut, the dissociation yields decrease monotonically. As mentioned earlier (Table 3), all the products yields at 5.0 Torr reactant pressure are decreased and their relative yields are little affected by the addition of N_2,

NO, and CF_4. These observations indicate that $CH_2ClCHCl_2$ is free from rotational bottlenecking due to its high density of rotational-vibrational states and these molecules are serving to quench the highly vibrationally excited parent molecules. The efficiency of collisional deactivation appears to be dependent on the molecular size of quenchers, since Table 3 shows that CF_4 quenches more efficiently than N_2 and NO. On the other hand, H_2, CH_4, and C_2H_6 decrease the yields of primary products more significantly and influence the relative yields remarkably, in particulr, those of $CH_2=CCl_2$, $CH_2=CHCl$, and $CH\equiv CH$. Therefore, other interaction than collisional quenching must be sought in the case of H_2, CH_4, and C_2H_6 addition.

$CH_2ClCHCl_2$ is found to react primarily by radical chain propagation in thermal reactor, molecular elimination of HCl being operative at the same time.[16,17] Radical chain reactions give the same dichloroethene isomers as those by unimolecular HCl elimination:

$$Cl + CH_2ClCHCl_2 \longrightarrow CH_2ClCCl_2\cdot + HCl, \quad (19)$$

$$\longrightarrow \cdot CHClCHCl_2 + HCl, \quad (20)$$

$$CH_2ClCCl_2\cdot \longrightarrow CH_2=CCl_2 + Cl, \quad (21)$$

$$\cdot CHClCHCl_2 \longrightarrow cis\text{-}CHCl=CHCl + Cl, \quad (22)$$

$$\longrightarrow trans\text{-}CHCl=CHCl + Cl, \quad (23)$$

The radical chain terminates by[17]

$$Cl + CH_2ClCCl_2\cdot \longrightarrow CHCl=CCl_2 + HCl,$$

$$Cl + \cdot CHClCHCl_2 \longrightarrow CHCl=CCl_2 + HCl.$$

In the presence of H_2, CH_4, and C_2H_6, Cl atom can abstract H atom from these molecules and inhibit the radical chain, depending on their rates of H-atom abstraction reactions:

$$Cl + RH \longrightarrow HCl + R\cdot, \ R=H, CH_3, \text{ and } C_2H_5 \quad (24)$$

The yield of $CH_2=CCl_2$ and those of *trans*- and *cis*-CHCl=CHCl formed by the radical chain reactions would be comparable, since the rate constants for Reactions 19 and 20 were found to be similar to each other.[27] The significant decrease in the relative yield of $CH_2=CCl_2$ upon the addition of the H atom containing molecules could be ascribed to Reaction 24, which inhibits the radical chain. The decrease also provides an evidence that the relative yield of $CH_2=CCl_2$ derived from the radical chain reaction is much greater than those by IRMPD and collision-induced decomposition (Table 3). The rate constant of Reaction 24 becomes greater in the order of H_2, CH_4, and C_2H_6.[28] In the case of H_2 the rate constant of Reaction 24 is about 25 times smaller than that of Reaction 19 plus 20 at 300 K. As shown in Table 4, the relative yield of $CH_2=CCl_2$ is appreciably decreased by the addition of only 1.0 Torr H_2, which implies that Reaction 24 is competitive with Reactions 19 and 20 at this pressure. Its rate constant becomes comparable to those of Reactions 19 and 20 at higher temperature, since its activation energy is greater than those of Reactions 19 and 20. Therefore, as a result of the collisional energy transfer the system is effectively at higher temperatures. The relative yield of $CH_2=CCl_2$ in the presence of H_2 up to 10 Torr is greater than those upon the addition of 5.0 Torr CH_4 and C_2H_6, indicating that inhibition of the radical chain by H_2 is imcomplete over the pressure range examined.

Table 5. Dependence of relative yields[a] on C_2H_6 pressure

P/Torr	1.0	2.0	3.0	5.0
$CH\equiv CCl$	7.89	6.20	4.82	3.73
$CH_2=CHCl$	5.82	6.44	6.09	6.25
$CH_2=CCl_2$	5.38	4.63	4.41	4.31
trans-CHCl=CHCl	75.4	74.1	73.1	71.7
cis-CHCl=CHCl	100 (1.26)	100 (0.897)	100 (0.798)	100 (0.549)

a) Relative yields at 5.0 Torr reactant pressure and E_0=0.136 J/pulse as compared to the yield of *cis*-HCl=CHCl in % conversion per 500 shots(in parenthesis). C_2H_2 was not measured by the same reason as in Table 3.

As the rate of the reaction of Cl atom with C_2H_6 is much faster than that with $CH_2ClCHCl_2$, C_2H_6 would inhibit the radical chain completely. The relative yields of the dichloroethene isomers change very slightly with increasing C_2H_6 pressure (Table 5), showing the radical chain is completely stopped by the addition of C_2H_6. The slight decrease in the relative yields would result from the decrease in the effective temperature with higher C_2H_6 pressure. In a tightly focused geometry and at a given pulse energy, as mentioned earlier, the volume of reaction zone where the fluence exceeds the lowest critical value and IRMPD takes place would remain rather constant with increasing reactant pressure. Thus the increase in the product yields (in % conversion) with increasing pressure could be attributed to the contribution from the collision-induced decomposition outside the reaction zone. With reference to Tables 1 and 5, at 5.0 Torr $CH_2ClCHCl_2$ with 1.0 Torr C_2H_6 added, where the radical chain reactions are negligible, the yield of *cis*-CHCl=CHCl is seen to be about 2.5 times greater than that *via* the neat IRMPD at 0.2 Torr. Since at 0.2 Torr $CH_2ClCHCl_2$ pressure collisional effects can be considered to be very small, the relative yields of the dichloroethene isomers obtained in the presence of 1.0 Torr C_2H_6 would reflect the product distribution in the collision-induced decomposition to a considerable extent. The relative yield of $CH_2=CCl_2$ observed at 1.0 Torr C_2H_6 and pulse energy of 0.136 J/pulse is roughly similar to that in the neat photolysis at 0.2 Torr reactant pressure. This may suggest that the energy

distribution of the dissociating $CH_2ClCHCl_2$ molecules by IRMPE is not so different from that excited by energy-pooling process. A considerably higher *trans/cis* ratio in the collision-induced decomposition than that in the neat IRMPD at the low reactant pressure, may result from the more significant thermarization of the *trans/cis* ratio due to higher substrate pressure in the former.

Upon the addition of H_2 (Fig. 2), the yields of CH_2=CHCl and CH≡CH are increased markedly. It is tempting to ascribe their formation to the H-atom abstractions of CHCl=CH· and CH≡C· radicals, which are generated by the C–Cl bond rupture of CHCl=CHCl and CH≡CCl, respectively. Table 4 shows that the relative yield of CH_2=CHCl upon the addition of H_2 is greater than that of CH≡CCl. However, it is unlikely that the branching ratio of C–Cl bond-scission channel with higher energy threshold is greater than that of lower HCl elimination channel. In addition, the yield-pressure behavior of CH_2=CHCl in presence of C_2H_6 is similar to that of H_2 addition, while upon the addition of CH_4 its yield is decreased slightly. Therefore, H atom generated by Reaction 24 and that emitted by the decomposition of C_2H_5· radical would be participated in the formation of CH_2=CHCl in the presence of H_2 and C_2H_6· CH_3· radical requires much higher energy than C_2H_5· radical:

$$C_2H_5\cdot \xrightarrow{(M)} C_2H_4 + H, \qquad (25)$$

$$H + CHCl{=}CHCl \longrightarrow \cdot CHClCH_2Cl^* \longrightarrow CH_2{=}CHCl + H. \qquad (26)$$

In a similar manner, the following reaction is possible:

$$H + CH{\equiv}CCl \longrightarrow CH{\equiv}CH + Cl$$

In contrast to CH_2=CHCl, the yield of CH≡CH upon the addition of CH_4 is greater than that upon the addition of H_2, indicating that H-atom arstraction is more important for the fromation of CH≡CH and, as a result, that the C–Cl bond scission of CH≡CCl is an important source of Cl atom. The relative yield of CH≡CH in the neat photolysis becomes smaller than that of CH_2=CHCl with increasing reactant pressure. Most probable initiation reaction of the radical chain would be the C–Cl bond rupture of $CH_2ClCHCl_2$.

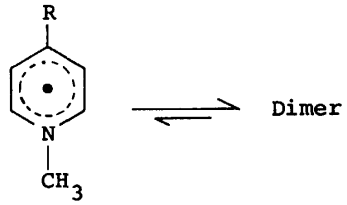
Photolytic Generation and the Subsequent Dimerization of 4-Alkyl-1-methylpyridinyl Radicals in Solution as Studied by Steady-state and Kinetic ESR Spectroscopy

Kimio Akiyama, Toru Ishii, Shozo Tero-Kubota,† and Yusaku Ikegami*
Chemical Research Institute of Non-Aqueous Solutions, Tohoku University, Katahira 2-1-1, Sendai 980
†*Institute for Molecular Science, Myodaiji, Okazaki 444*
(Received July 18, 1985)

1-Methylpyridinyl and 4-alkyl-1-methylpyridinyl (alkyl=methyl, ethyl, isopropyl, and *t*-butyl) radicals were generated photolytically from their dimers in solution. Hyperfine splitting constants for these radicals were assigned and the temperature dependence was discussed. Absolute dimerization rates of these radicals in the range of −50—−100 °C were determined by analyzing the ESR signal decay during the dark period. A nearly constant activation energy of dimerization was observed for five radicals, while the frequency factor decreased with the bulkiness of 4-substituent, which are discussed in terms of the steric hindrance for the dimerization.

Electron spin resonance (ESR) spectra of the neutral pyridinyl radicals prepared by one-electron reduction of the corresponding pyridinium salts have been successfully analyzed.[1] However, the isolable radicals in solution are restricted to those having electron-withdrawing and delocalizing group at 2- or 4-position of the pyridine ring. In our recent studies,[2] it was established that some pyridinyl radicals are equilibrated with the dimers and the interconversion between the radical and the dimer is completely reversible for an intermittent photolysis or a temperature change. A kinetic ESR method was applied to such equilibrium systems and elucidated the dimerization mechanism showing a two-step decay of the ESR signal due to the radical generated photolytically. Further, the time-resolved ESR studies revealed that the precursor of the radical generated upon light irradiation was singlet radical pair for the reason that the A/E polarized transient ESR spectra were observed in solution.[3,4]

Based upon these results, we attempted the generation of simple 4-alkyl-substituted pyridinyl radicals which might be produced by photoirradiation of the corresponding dimers. In spite of the radical formation from the singlet radical pair, the pair has relatively long lifetime enough to cause ST_0-mixing and to escape from the primary cage. The ESR spectra



1 R=H
2 R=CH_3
3 R=CH_2CH_3
4 R=$CH(CH_3)_2$
5 R=$C(CH_3)_3$

of five pyridinyl radicals, **1**—**5**, were then observed during the continuous irradiation and analyzed to obtain the hyperfine splitting (hfs) constants. The kinetic ESR study was also carried out to determine the activation parameters of the second-order dimerization.

Experimental

Vacuum line technique was standard in the preparation and purification of the radicals and solvents. Each pyridinyl radical was prepared from the corresponding pyridinium iodide by the reduction with 3% sodium-amalgam in degassed acetonitrile at about −30 °C and extracted with a nonpolar solvent such as methylcyclohexane. All pyridinium iodides were obtained by treating the pyridines with methyl iodide without solvent, and recrystallized from ethanol. Solvents for the measurements were transferred by the trap-to-trap method using a vacuum system. Steady-state ESR measurements were carried out with a Varian E-109E EPR spectrometer. A high pressure Hg-lamp (Ushio 500 W) as a light source was equipped with a UV-31 glass filter to prevent undesirable decomposition of radicals. Spectral simulation and McLachlan calculation were performed by using a Sharp MZ-80C microcomputer. Kinetic ESR technique was described previously.[2]

Results and Discussion

Hfs Constants of 4-Alkyl-1-methylpyridinyl Radicals. The 4-alkyl-1-methylpyridinyl radicals dimerize in solution at room temperature forming covalently-bonded dimers, which show a broad absorption band in the near UV region. As the radical-dimer equilibrium is in favor of the dimer side, no ESR signal was observed at room temperature for all radicals examined. Either photolysis or rise in temperature of a dimer solution led to exhibit the ESR spectrum. The interconversion between the radical and the dimer was completely reversible at temperatures below 80 °C. Figure 1a shows the ESR spectrum observed during a continuous irradiation to the dimer of 1-methylpyridinyl radical (**1**) in 2-methyltetrahydrofuran (MTHF) at −40 °C. Hyperfine structure of the spectrum was reasonably analyzed on the computer simulation (Fig. 1b). The hfs constants were assigned tentatively according to the types of splitting and by comparing them with the spin density calculations by the McLachlan procedure. The constants and assignments are given in Table 1 together with those of the other alkyl-substituted pyridinyl radicals. As seen in Table 1, changes in the constants with the substitution of 4-alkyl group are negligibly small compared with the substitution of electron-withdrawing or delocalizing groups.[5] Relatively large

a) Measured in toluene. b) Unresolved.

hfs constants were observed at 4-, 2-, and 6-positions, where would apt to couple in the dimerization.

The hfs constants of β-protons of 4-alkyl groups, ring nitrogen, and N-methyl protons showed dependence on temperature, while the other constants were almost independent. Temperature dependence of the hfs constants of pyridinyl radicals having polarizable groups has been discussed in terms of polarity change of the solvent and the restricted rotation of substituents.[5,6] On the other hand, the temperature dependent hfs constants of 1-hydropyridinyls have been analyzed using the model of localized out-of-plane vibration of the protons.[7] For the present radicals, the comparatively large dependence was found with temperature coefficients of 5.4×10^{-4} and 8.3×10^{-4} mT/°C for the β-protons in **3** and **4**, respectively. These values can be interpreted by the existence of restricted rotation of the alkyl groups. This is supported by the small hfs constants, 0.871 mT for **3** and 0.566 mT for **4**, compared with 1.168 mT for **2** in which the methyl group rotates freely in temperature range examined (−80—+40 °C). After the usual manner to interprete the internal rotation of alkyl groups by ESR spectroscopy, we found that the conformation of the alkyl groups is similar to those of 1-alkyl-4-methoxycarbonylpyridinyl radicals reported previously.[6]

The hfs constant of the N-methyl protons reflects the spin density on the bonded nitrogen atom and the conformational change around this atom. The nitrogen spin density also correlates with the spin densities on the adjacent atoms with the Karplus-

a) Observed value at −80°C.

Fraenkel relation.[8] In the present radicals, since the spin densities at 2- and 6-positions were independent of temperature, the latter contribution to the change of the nitrogen spin density with temperature can be ignored, though the overlapping between the $p\pi$-orbital of the nitrogen and the 1s orbital of the bonded methyl protons may vary with the structural change. It is rather indicative of the presence of the out-of-plane vibration of the *N*-methyl group that the temperature coefficients for a^N and $a^H_{N\text{-}CH_3}$ showed the opposite signs each other. With a lowering of temperature, $a^H_{N\text{-}CH_3}$ would decrease and a_N increases, because the out-of-plane vibrational amplitude decreases. Sander and Dohrmann[7] reported the temperature dependent hfs constants of protons and nitrogen for 1-hydropyridinyl radicals and estimated the frequencies of the out-of-plane vibrations of the protons. Das and Fraenkel[9] suggested that the out-of-plane vibration of the N-H proton probably contributes to the temperature dependent hfs constants of the dihydropyrazine cation radical. In our case, the observed temperature coefficient of 1.3×10^{-4} mT/°C for nitrogen is small for the conformational change with temperature, compared with those of 1-hydropyridinyl radicals. This may be due to the low vibrational frequency and the small displacement of N-CH_3 group from the π-plane.

Kinetic Treatment of the Dimerization. The dimers of the 4-alkyl-substituted pyridinyl radicals have a dihydropyridine type structure and show each a broad absorption band in the near UV region. Light irradiation to this band causes a homocentric C-C bond cleavage, resulting the appearance of ESR signal of the monomeric radical. After the pulse irradiation, the radical dimerizes and then the signal decays in the intermittent dark period. Figure 2 shows a growth and decay of the ESR signal measured during the photolysis of the dimer of 1-methylpyridinyl in MTHF at −76°C. The signal was accumulated 2000 transient times. Although the signal-to-noise ratio is rather poor, the decay curve could be analyzed in terms of a second-order kinetics. The straight line inserted in Fig. 2 represents a least squares fit to the points according to the equation:

$$1/[R] = k_{exp}t + 1/[R]_0 \quad (1)$$

where $[R]_0$ is the concentration of the radical at time t=0 after an onset of the dark period. This equation is best explained by the C-C bond formation of two radicals. The dimerization rate constants (k_{exp}) were estimated by obtaining values from three independent measurements at −80°C. The constants are listed in Table 2.

The rates were also measured in the temperature range −50—−100°C. Figure 3 presents the Arrhenius plots for the dimerization of **1**—**5**. The activation

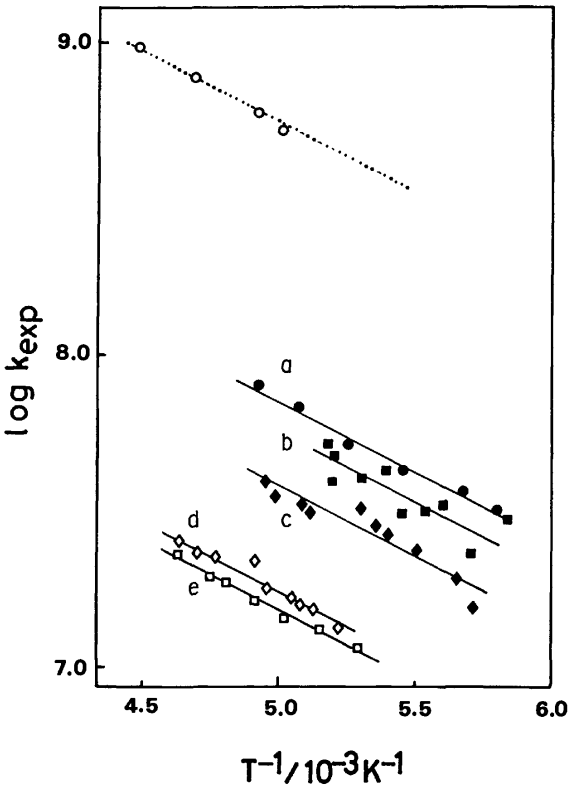

Fig. 3. Dimerization rate constants *vs.* $1/T$ for a: **1**, b: **2**, c: **3**, d: **4**, and e: **5**. A dotted line represents the diffusion-controlled rate constants (see text).

energies (E_a) and frequency factors (A) were each estimated by the least squares method from the plots, as summarized in Table 2. Because of the low yield of **2** from the dimer, the integrated signal intensities of ESR showed a poor reproducibility, leading to a significant deviation of the plot. The rates observed for **5** were slightly larger than those reported reviously.[4] This is caused by that, in the previous study, the concentration ($\approx 10^{-4}$ mol dm^{-3}) of the standard 2,2-diphenyl-1-picrylhydrazyl (DPPH) solution used to evaluate the initial concentration of radical was far different from the radical concentration ($\approx 10^{-6}$ mol dm^{-3}) produced by light irradiation.[10] In the present work, a standard DPPH solution of *ca.* 10^{-6} mol dm^{-3} was used.

A dotted line in Fig. 3 represents the diffusion-controlled second-order rate constants estimated by use of the Smoluchowsky-Stoles-Einstein relation:[11]

$$k_{diff} = 8RT/3 \times 10^3 \eta(T) \quad (2)$$

where $\eta(T)$ denotes the temperature-dependent viscosity of solvent MTHF.[12] From the slope of the line, we obtain the activation energy of 8.98 kJ mol^{-1} for a diffusion in MTHF and the frequency factor of log A=11.1 mol^{-1} dm^{-3} s^{-1}. It is implied from Eq. 2 that the diffusion-controlled rate constants for a bimolecular reaction are independent of the size of the reactants. This may be true to the radicals in which the electron is completely delocalized so that the reaction is equally probable at any direction, but it would be unadaptable to saturated or σ-type radicals, in which the unpaired electron is localized and the reaction therefore occurs at a particular site on the radical.

The radical **5** forms only the 2,2′-dimer composed of its diastereoisomers.[4] On the other hand, **1** forms the 4,4′-dimer at the temperature range 30—−70 °C.[11] Since the highest spin density is located at 4-position, as discussed on the basis of the steady-state ESR experiments, this position would be the most active site for dimerization. However, when a sterically large group such as *t*-butyl is substituted at this position, the dimerization occurs at the position having next higher spin density, *i.e.* 2- or 6-position, forming 2,2′-dimer. In spite of the delocalized unpaired electron, the coupling reaction of pyridinyls proceeds in a site-selective manner like σ-type radical. Even if the above factor shifts the diffusion rates for the present radicals from that expressed by Eq. 2, the observed rates are two or three orders of magnitude smaller than that of diffusion encounter. The slow rate is ascribed to the small frequency factor. The activation energies in Table 2 agree well with that of diffusion in the MTHF solution within experimental error limit. Although the frequency factors are small compared with that of diffusion, the values of 10^{9-10} mol^{-1} dm^3 s^{-1} are larger than those in the dimerizations of spin-delocalized π-radicals such as triphenylmethyl and triphenylimidazolyl.[14,15] The values for the present radicals are rather comparable to those of spin-localized alkyl radicals.[16]

Although the activation energy is nearly constant for the dimerizations of **1**—**5**, the rate constant and the frequency factor are significantly affected by the size of 4-substituent. Since the bulky substituent prevents the bond formation at 4-position, the dimerization occurs at 2-position. Thus, with a decrease in the probability of 4,4′-dimer formation, the frequency factor and the rate decreased. In order to extend further discussion, the thermodynamic parameters of the monomer-dimer equilibria for **1**—**5** should be obtained. Determination of the parameters, however, has been unsuccessful, because the radical concentrations could not be determined by reason of that each equilibrium inclines overwhelmingly toward the dimer side even at 70 °C.

Preparation of Polyoxa- and Dioxapolythia[*n*](1,1′)-ruthenocenophanes and Their Metal Complexes

Yoichi HABATA, Sadatoshi AKABORI,* and Masaru SATO†
Department of Chemistry, Faculty of Science, Toho University, Funabashi, Chiba 274
†*Chemical Analysis Center, Saitama University, Urawa, Saitama 338*
(Received July 25, 1985)

Polyoxa- and dioxapolythia[*n*]ruthenocenophanes were prepared by the reaction of 1,1′-diacetoxyruthenocene with α-(2-bromoethyl)-ω-bromopoly(oxyethylene) in the presence of alkali metal hydroxides and by the reaction of 1,1′-bis(2-chloroethoxy)ruthenocene with dithiolate in the presence of sodium hydroxide, respectively. The extraction ability of their compounds was excellent for mercury(II) and thallium(I) ions. The ruthenocenophanes with oxygen atoms attached to the ruthenocene nucleus showed excellent extraction ability for a silver(I) ion, although the corresponding ferrocenophane analogs decomposed in similar reaction conditions. The ruthenocenophanes formed 1 : 1 complexes with mercury(II) and silver(I) ions. ^{1}H-NMR, electronic, and IR spectral data of their complexes showed the presence of direct electronic interaction between the mercury-(II) or silver(I) ion and the ruthenium atom of ruthenocenophanes.

For the purpose of syntheses of crown compounds possessing specific properties, several research groups to date have reported on the syntheses and complexing ability of crown ether typed compounds containing a ferrocene nucleus in their macrocyclic skeleton.[1-5] Morrison *et al.* reported on the Ru–Hg and the Fe–Hg interaction in the mercury adducts of ruthenocene and ferrocene.[6] However, Biernat *et al.* suggested that the interaction between the iron atom of the ferrocene nucleus and the complexed rubidium ion was not present from their electronic spectral data.[1b] Our X-ray analysis elucidated no interaction between the iron atom of 1,4,7,10,13-pentaoxa[13](1,1′)ferrocenophane and the complexed sodium cation in the solid state.[5b] The above results suggest that the soft mercury(II) and silver(I) ions which were incorporated by the crown site of the ferroceno-crown ethers might cause the strong interaction with the iron atom of the ferrocene nucleus. Although the compound **2** with sulfur atoms at the 1,*n*-position of the ferrocenophane was not decomposed by treating with silver(I) and mercury(II) ions, the compound **1** with oxygen atoms at the 1,*n*-position of the ferrocene nucleus, decomposed by their metal ions.

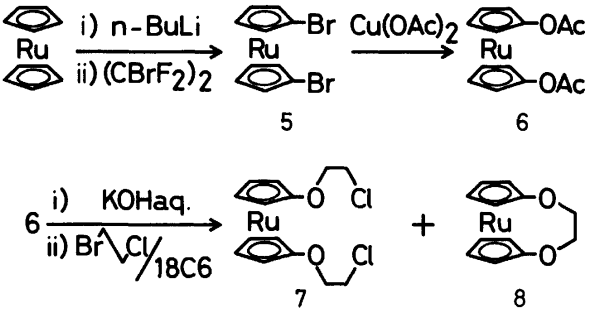
1 : X=Y=O
2 : X=S, Y=O or S
3 : X=S, Y=O
4 : X=Y=S

a : n=1, b : n=2, c : n=3, d : n=4

The enhanced stability of the silver complexes of **2** may be attributed to the pπ-dπ interaction of sulfur and iron atoms of the ferrocene nucleus of **2**.[2d] It is well-known[7] that ruthenocene is more stable for oxidation compared with ferrocene as seen by the reduction potential of both metallocene. Therefore, in this paper, we wish to report on the synthesis of polyoxa- and dioxapolythia[*n*]-(1,1′)ruthenocenophanes and their complexing ability with transition metal ions, along with alkali and alkaline earth metal ions.[8]

Results and Discussion

Syntheses of Polyoxa[n](1,1′)- (10) and Oxathia[n]-(1,1′)ruthenocenophanes (11). In order to obtain the starting material of **10**, 1,1′-diacetoxyruthenocene **6** was prepared according to the method of the synthesis of 1,1′-diacetoxyferrocene.[5b] 1,1′-Dilithioruthenocene which was prepared by the reaction of ruthenocene with butyllithium in the presence of *N,N,N′,N′*-tetramethylethylenediamine (TMEDA), was reacted with 1,2-dibromo-1,1,2,2-tetrafluoroethane to give 1,1′-dibromoruthenocene **5** in 53% yield. Compound **5** was reacted with copper(II) acetate to give **6** in 53% yield. After **6** had been hydrolyzed by alkali metal hydroxide, α-(2-bromoethyl)-ω-bromopoly(oxyethylene) (**9**) was immediately added to the hydrolyzate. The stirring was



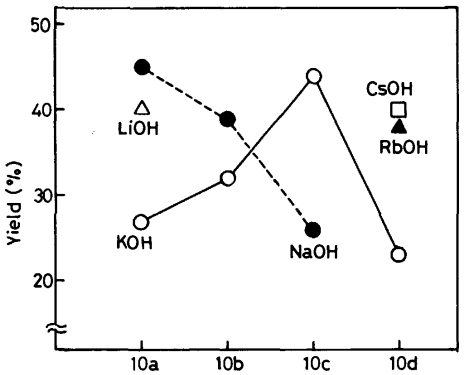


Fig. 1. The relationship between yields and alkali metal hydroxids on the syntheses of **10a—d**.

continued for 5 h at reflux temperature under nitrogen. The reaction mixture was treated by the usual method and subsequently separated by Silica-gel TLC to give 10. In the above reactions several kinds of alkali metal hydroxide were used for hydrolysis. As shown in Fig. 1, the use of sodium and potassium hydroxides resulted maximum yield of **10a** and **10c**, respectively. In the synthesis of **10d**, the use of cesium hydroxide was most favorable. This result is correlated to the cavity size of metallocenophanes.[9,10] Compound **7**, the starting material for dioxapolythia[n](1,1′)ruthenocenophanes, was synthesized by the reaction of **6** with 1-bromo-2-chloroethane in the presence of a catalytic amount of 18-crown-6. To prepare **11a**, a mixture of **7** and sodium sulfide in *N*,*N*-dimethylformamide (DMF) was stirred at reflux temperature for 9 h. The reaction mixture was treated by the usual method and separated by silica-gel TLC to give **11a** in 11% yield. The compound **7** was reacted with disodium 1,2-ethanedithiolate in ethanolic tetrahydrofuran (THF) to give **11b** and **11c** in 25 and 5% yields, respectively. The possible mechanism of the formation of **11c** in the above reaction may be the same as that for ferrocene analogues.[5f] Similarly, **7** was reacted with disodium 2,2′-thiobis(ethanethiolate) in ethanolic THF to give only **11c** in 63% yield.

The ^{1}H-NMR and ^{13}C-NMR spectra of **10**—**11** are summarized in Table 1. The structures of the new compounds were determined on the basis of ^{1}H-NMR, ^{13}C-NMR, mass spectra and elemental analyses. For example, the molecular formula of **10c** was deduced to be $C_{18}H_{24}O_5Ru$ by the elemental analysis and mass spectroscopy (M^+ 422). As the ^{1}H-NMR spectrum of **10c** showed α- and β-protons of the ruthenocene nucleus appeared as two triplets (J=1.8 Hz) at δ 4.63 and 4.24, respectively and the methylene protons appeared as a multiplet of the A_2B_2 type at δ 3.89—3.49 and a singlet at δ 3.58. In the completely decoupled ^{13}C-NMR spectrum of **10c**, bridge-head, α-, and β-carbons of the ruthenocene nucleus appeared at δ 128.3, 60.2, and 64.8 ppm, respectively. Furthermore, eight methylene carbons appeared as four signals at δ 71.2, 70.4, 69.8, and 69.1 ppm. The structures of the new other compounds were also determined by a similar method described above.

The Extraction Ability. The measurement of extraction ability was carried out by the method

a) in CH_3CN. b) CsI disk.

described in a previous paper.[5f] Their results are summarized in Table 2. The extraction ability of their compounds toward alkali and alkaline earth metal ions was very low and/or negligible in value and this tendency was the same for the ferrocene analogues.[5b,f] However, the extraction ability of **10** and **11** toward silver(I), mercury(II), and thallium(I) ions was excellent and showed ionic selectivity. Although ferrocenophanes bearing oxygen atoms at the 1,1′-positions were decomposed by the attack of silver(I) ion, **10** and **11** showed excellent extraction ability without decomposition. This result is explicable by means of the higher stability of ruthenocene nucleus than that of the ferrocene nucleus for oxidation by silver(I) nitrate, because the oxidation potential of ruthenocene (0.693 eV) is higher than that of ferrocene (0.307 eV).[7] The compounds **10c** and **11b** showed the highest extraction ability toward silver(I) ion due to the fitness of the diameter of the guest ion on the hole size of the host molecule. Furthermore, the extraction ability of the ruthenocenophanes containing soft sulfur atoms for silver(I) ions as shown in **3**, **4**, and **11** was higher than that of polyoxa[*n*]ruthenocenophanes **10** containing no sulfur atoms. This result is in accord with the HSAB rule.[11] However, the extraction ability of the ruthenocenophanes containing sulfur atoms except **3** toward mercury(II) and thallium(I) ions was lower than that of **10**. These results show that the extraction ability also depends on the hetero-atom (Y); *i.e.* compounds **3** and **10** (Y=O) showed the good extraction ability toward mercury(II) and thallium(I) ions, while compounds **4** and **11** (Y=S) showed low or negligible extraction ability. Consequently, in the ruthenoceno crown ethers, the selectivity toward a metal cation can be controlled not only by the kind and number of heteroatoms and cavity size, but also the position of the heteroatoms.

*Isolation of Silver(I) and Mercury(II) Complexes of **10** and **11**.* A solution of ruthenoceno-crown ethers (**10** and **11**) in ether was reacted with an equimolar of silver(I) nitrate or mercury(II) chloride in acetonitrile solution to give 1:1 complexes in good yield. The melting or decomposition points of their silver and mercury complexes were higher than those of the metal free ligands, respectively.

*Electronic, Infrared, and ^{1}H-NMR Spectral Change of Compounds **10** and **11** to Their Mercury(II) and Silver(I) Complexes.* The electronic and infrared spectral data of the title compounds are summarized in Table 3. In the electronic spectra of mercury(II) complexes (**12** and **13**), the wavelength of maximum absorption showed a blue shift about 8—34 nm and their molecular coefficient increased when compared with those of the free ligands (**10** and **11**). Only the **12b** showed red shift about 11 nm, but ε increased to the same extent as the other mercury(II) complexes. Derisovich *et al.*[12] described the electronic spectra of ruthenocene–$HgCl_2$ adduct as showing an intense band at 280 nm, which is absence in ruthenocene itself. This fact suggests that mercury(II) complexes (**12** and **13**) have the interaction between the ruthenium atom of ruthenoceno-crown

Table 4. ^{1}H-NMR spectral data of compounds **12**—**15**

a) Compound **14** was measured in CD_3CN. Compounds **12**, **13**, and **15** were measured in DMSO-d_6. A downfield shift is denoted as a positive value. Shift changes are presented in parentheses.

ethers and mercury(II) chloride. The maximum absorption of **13**, containing sulfur atoms, was in a longer wavelength range than that of **12** containing no sulfur atom. This result may be explained by a difference in the coordination ability between the sulfur and oxygen atoms toward the mercury(II) ion.[11] That is, the sulfur atoms of **11** are so strongly coordinated to the mercury(II) ion that the interaction between Ru and Hg(II) is weakend.

On comparison of the IR spectra of mercury(II) complexes with their free ligands, slight differences were observed at the C–H and C–C streching bands and Cp–Ru–Cp ring tilting band of the ruthenocene nucleus. Morrison *et al.*[6] reported that the antisymmetric C–C streching band at 1400 cm^{-1} region of the mercury(II) adduct of ruthenocene was split into two absorption bands because of ring tilting derived from the $HgCl_2$ interaction. However, the absorption band at 1400 cm^{-1} of the mercury(II) complexes (**12** and **13**) did not show the spliting in the IR spectra. Therefore, the bridging between the two Cp rings by the crown moiety of the ruthenocenophanes may be inhibit the tilting of the Cp rings. As the ^{1}H-NMR spectral changes showed the β-protons of the ruthenocene nucleus of all mercury complexes (**12** and **13**) were more shifted downfield than the α-protons, whereas the ethylene protons were only little downfield shifted by 0.01—0.05 ppm. From their spectral data of the mercury complexes (as shown in Table 4), two types of complexing form are anticipated as follows: (i) the mercury ion incorporated into the crown cavity has an interaction with the ruthenium atom of the ruthenocene nucleus. (ii) the mercury(II) ion is coordinated to the ruthenium atom from the opposite site of the macrocyclic ring. On the other hand, **14d** showed characteristic spectral data in contrast to other silver complexes. For example, in the electronic spectra of **14d**, new and very intense absorption appeared at 299 (ε 7700), 357 (sh), and 459 nm (310), whereas **15** showed merely a little increase of ε (+60—+70) and a slight shifting of the d-d transition band of the ruthenocene nucleus. As early as 1952, Wilkinson reported[13] that the electronic spectra of the ruthenicinium cation which was prepared from ruthenocene and perchloric acid employing controlled potential anodes showed characteristic bands at 320 (ε *ca.* 10000), 400(sh), and 450 nm (sh). This tendency was very similar to that of **14d**. In the complex **14d** the silver(I) cation is incorporated into the cavity of macrocyclic polyether and coordinated weakly toward the six oxygen atoms although the complexed silver(I) cation in the complex **15** is coordinated more strongly toward the sulfur atoms. Therefore, the distance between the silver(I) cation and the ruthenium atom in the complex **14d** is shorter than that in the complex **15**. So, it is suggested that the electron transfer from the ruthenium atom to the complexed silver(I) ion in **14d** leads to the change of the ruthenocene nucleus to the ruthenicinium cation form. A similar phenomenon was also observed in the mercury complex **13b** and **13c**. Some remarkable differences were also observed in the IR spectrum of **14d**. Apparently, the C–H stretching band at the 3080 cm^{-1} region shifted to low frequency by about 50 cm^{-1} and the Cp–Ru–Cp ring tilting band at 430 cm^{-1} was split into three bands at 450, 460, and 470 cm^{-1}. Complexes **15b** and **15a** showed no characteristic change in the IR spectrum as **14d** did. Furtheremore, the ^{1}H-NMR spectrum of **14d** changed dramatically as shown in Fig. 2. The α- and β-protons of the Cp rings were shifted downfield by 1.43 and 1.47 ppm, respectively. The methylene protons near the ruthenocene nucleus were more shifted downfield (0.85—0.10 ppm) than other methylene protons. However, in **15c** carrying sulfur atoms as donor atoms, only the methylene protons attached to sulfur atoms were shifted (+0.22 ppm), and the Cp ring protons and the methylene protons attached to oxygen atoms were shifted slightly. This result suggests that the silver(I) ion of **14d** is coordinated with the crown site near the ruthenocene nucleus and then interacts with the ruthenium atom, while **15b** and **15c** has no interaction between ruthenium atom of ruthenocene and the incapsulated silver(I) ion.

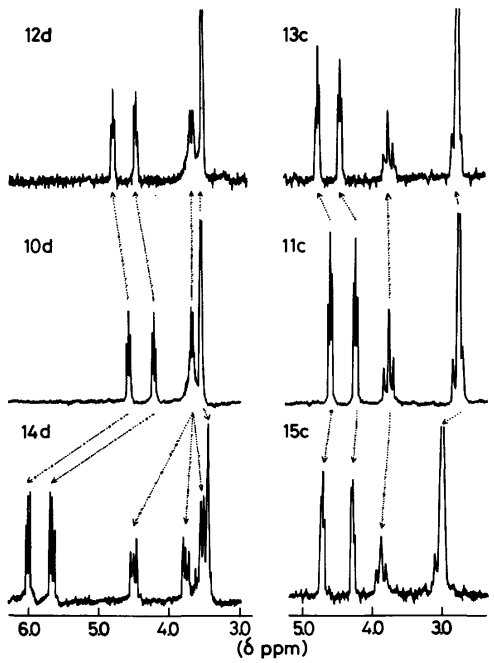

Fig. 2. ^{1}H-NMR Spectra of **10d**, **11c**, **12d**, **13c**, **14d**, and **15c**.

Experimental

The melting points are uncorrected. The mass spectra were taken on a Hitachi M 80 mass spectrometer. The ^{1}H-NMR (90 MHz) and the ^{13}C-NMR (22.5 MHz) were obtained on a JEOL-FX-90Q spectrometer, with TMS as an internal standard. The electronic spectra were obtained on a Hitachi Model 330 spectrometer. The IR spectra were measured on a JASCO DS-701G Diffraction Grating Infrared Spectrometer.

Materials. The silica-gel used for thin-layer chromatography was Wako gel B-5F. Ruthenocene,[13] 1,5-dibromo-3-oxapentane (**9a**),[14] and 1,8-dibromo-3,6-dioxaoctane (**9b**)[15] were prepared according to the procedure described in the literature. Compounds **9c** and **9d** were prepared by the same manner as described for **9a**.

1,1'-Dibromoruthenocene (5). To a solution of butyllithium in hexane (100 cm^3, 144 mmol) and TMEDA (30 cm^3, 199 mmol) in hexane (15 cm^3) was added ruthenocene in hexane (300 cm^3) under nitrogen. After mixture had been stirred for 5 h at room temperature, 1,2-dibromo-1,1,2,2-tetrafluoroethane (26.8 cm^3, 103 mmol) was added dropwise for 1 h at −60 °C. The stirring was continued overnight at −60 °C. After the solution had been warmed to room temperature, water (15 cm^3) was added to the reaction mixture. The aqueous solution was extracted with three 300 cm^3 portions of hexane. The hexane extracts were combined, washed with water, and concentrated *in vacuo*. The yellow solid was sublimed at 130 °C/0.3 mmHg. The pure product was obtained as pale yellow needles by recrystallization from hexane in 53% yield. Mp 117—118 °C, ^{1}H-NMR ($CDCl_3$) δ= 4.51 (t, J=1.8 Hz, 4H), 4.86 (t, J=1.8 Hz, 4H). Found: C, 30.87; H, 2.22%. Calcd for $C_{10}H_8Br_2Ru$: C, 30.87; H, 2.08%. MS (60 eV): m/z 389 (M^+).

1,1'-Diacetoxyruthenocene (6). Compound **5** (16.7 g, 83 mmol) and copper(II) acetate (92 g, 460 mmol) in 50% aqueous ethanol (600 cm^3) were refluxed for 1.5 h under nitrogen. After the mixture had been cooled to room temperature, the resulting solid was removed by filtration. The solid was washed with ether (20 cm^3) three times. The ethereal layer combined was dried over anhydrous magnesium sulfate and the ether was removed *in vacuo*. The residue was chromatographed on silica-gel (benzene–ethyl acetate as eluent). The pure product was obtained as pale yellow needles by recrystallization from hexane in 53% yield. Mp 74.5—75 °C. ^{1}H-NMR ($CDCl_3$) δ=4.94 (t, J=1.8 Hz, 4H), 4.42 (t, J=1.8 Hz, 4H), 2.12 (s, 6H). Found: C, 48.69; H, 4.07%. Calcd for $C_{14}H_{14}O_4Ru$: C, 48.41; H, 4.06%. MS (60 eV): m/z 348 (M^+).

Polyoxa[n](1,1')ruthenocenophanes (10a—d). As a typical example, preparation of 1,4,7,10,13-pentaoxa[13](1,1')ruthenocenophane (**10c**) is described here. After a mixture of **6** (452 mg, 1.30 mmol) and potassium hydroxide (423 mg, 7.55 mmol) in water (15 cm^3) was stirred for 30 min under nitrogen, 1,11-dibromo-3,6,9-trioxaundecane (**9c**) (510 mg, 1.59 mmol) in 60% aqueous ethanol (60 cm^3) was added to the mixture at once. The stirring was continued for 5 h. The reaction mixture was cooled and extracted with three 30 cm^3 portions of ether. The ethereal extract was washed with water (30 cm^3), and was evaporated. The resulting solid was chromatographed on silca-gel TLC (hexane–acetone as eluent). The main fraction was extracted with acetone and the solution was evaporated *in vacuo*. Recrystallization of the resulting solid from hexane (10 cm^3) gave **10c** as pale yellow crystals in 44% yield. Mp 94.5—95 °C. Found: C, 51.42; H, 5.54%. Calcd for $C_{18}H_{24}O_5Ru$: C, 51.29; H, 5.75%. MS (60 eV): m/z 422 (M^+).

1,4,7-Trioxa[7](1,1')ruthenocenophane (10a). Mp 97.5—98 °C. Found: C, 50.26; H, 4.80%. Calcd for $C_{14}H_{16}O_3Ru$: C, 50.44; H, 4.85%. MS (60 eV): m/z 334 (M^+).

1,4,7,10-Tetraoxa[10](1,1')ruthenocenophane (10b). Mp 70—70.5 °C. Found: C, 50.71; H, 5.40%. Calcd for $C_{16}H_{20}O_4Ru$: C, 50.89; H, 5.35%. MS (60 eV): m/z 378 (M^+).

1,4,7,10,13,16-Hexaoxa[16](1,1')ruthenocenophane (10d). Mp 29—30 °C. Found: C, 51.37; H, 5.80%. Calcd for $C_{20}H_{28}O_6Ru$: C, 51.59; H, 6.07%. MS (60 eV): m/z 465 (M^+).

1,1'-Bis(2-chloroethoxy)(1,1')ruthenocene (7). After **6** (2.164 g, 6.21 mmol) had been reacted with sodium hydroxide (1.558 g, 38.9 mmol) in water (10 cm^3) for 30 min in the presence of 18-crown-6 (438 mg, 1.83 mmol) under nitrogen, 1-bromo-2-chloroethane (28.4 g, 198 mmol) was added to the mixture at once. The stirring was continued for 5 h at a reflux temperature. The reaction mixture was cooled, and extracted with three 300 cm^3 portions of ether. The extracts were combined, washed with water, and concentrated *in vacuo*. The residual solid was chromatographed on silica gel (benzene as eluent). The first fraction was extracted with acetone and the solution was evaporated *in vacuo*. Recrystallization of the residue from hexane gave **8** as white needles in 1% yield, mp 120—121.0 °C. ^{1}H-NMR ($CDCl_3$) δ=4.84 (t, J=1.8 Hz, 4H), 4.31 (t, J=1.8 Hz, 4H), 4.00 (s, 4H). MS (60 eV): m/z 289 (M^+). Found: C, 49.53; H, 4.14%. Calcd for $C_{12}H_{12}O_2Ru$: C, 49.81; H, 4.18%. The second fraction was extracted with acetone and the product was recrystallized from hexane to gave **7** as a white amorphous solid in 40% yield, mp 78.5—79.0 °C. MS (60 eV): m/z 388 (M^+). Found: C, 43.16; H, 4.14%. Calcd for $C_{14}H_{16}O_2Cl_2Ru$: C, 43.30%; H, 4.16%.

1,7-Dioxa-4-thia[7](1,1')ruthenocenophane (11a). To sodium sulfide nonahydrate (328 mg, 1.37 mmol) in reflux-

ing DMF (30 cm³) was added **7** (251 mg, 0.65 mmol) in DMF (30 cm³). After the mixture had been cooled to room temperature, water (60 cm³) was added and the resulting mixture was extracted with three 30 cm³ portions of chloroform. The extracts were combined and concentrated *in vacuo*. The residue was chromatographed on silica-gel TLC (benzene as eluent). The main fraction was extracted with acetone and the solvent was removed. Recrystallization of the crude product from hexane gave **11a** as white needles in 17% yield, mp 117—117.5 °C. Found: C, 48.14; H, 4.68%. Calcd for $C_{14}H_{16}O_2SRu$: C, 48.12; H, 4.62%. MS (60 eV): *m/z* 350 (M^+).

1,10-Dioxa-4,7-dithia[10](1,1')ruthenocenophane (11b). A solution of **7** (282 mg, 0.73 mmol) in THF (50 cm³) and a mixture of 1,2-ethanedithiol (300 mg, 3.19 mmol) and sodium hydroxide (230 mg, 5.95 mmol) in ethanol (50 cm³) were added dropwise to ethanolic THF (ethanol:THF=1:1) (240 cm³) over a 2.5 h under reflux. The refluxing was continued for 14 h with stirring and then the reaction mixture was cooled and concentrated *in vacuo*. The residual oil was separated by alumina column chromatography (benzene as eluent) and then TLC (silica gel, benzene as eluent). The first fraction in TLC was extracted with acetone and recrystallized from hexane to give **11b** as white needles in 25% yield, mp 116.5—117.0 °C. MS (60 eV): *m/z* 409 (M^+). Found: C, 46.94; H, 4.86%. Calcd for $C_{16}H_{20}O_2S_2Ru$: C, 46.92; H, 4.93%. The second fraction in TLC was extracted with acetone and recrystallized from hexane to give **11c** as white needles in 5% yield, mp 113—113.5 °C. MS (60 eV): *m/z* 469 (M^+). Found: C, 46.03; H, 5.05%. Calcd for $C_{18}H_{24}O_2S_3Ru$: C, 46.03; H, 5.15%.

1,13-Dioxa-4,7,10-trithia[13](1,1')ruthenocenophane (11c). A solution of **7** (314 mg, 0.91 mmol) in THF (50 cm³) and a solution of bis(2-mercaptoethyl) sulfide (640 mg, 4.16 mmol) and sodium hydroxide (330 mg, 8.25 mmol) in ethanol (50 cm³) were added dropwise to refluxing ethanolic THF (ethanol:THF=1:1) (300 cm³) at the same rate for 2.5 h. The stirring was continued for 14 h at a refluxing temperature. The reaction mixture was cooled and concentrated *in vacuo*. The residual oil was chromatographed on alumina column (benzene as eluent). The main fraction was combined and concentrated. Recrystallization of the crude product from hexane gave **11c** as white needles in 63% yield. The pure **11c** obtained by this reaction was identified by comparison with the melting point, R_f value of TLC and the special data of the authentic sample.

Method of Solvent Extraction. Extraction ability of ruthenoceno-crown ethers toward alkali, alkaline earth, and some non-transition and transition metal ions was examined by the extraction method described in the previous paper.[5f] All metals used were metal nitrates, except for mercury(II) chloride.

Mercury(II) Chloride Complexes (12 and 13). A solution of ruthenoceno-crown ether (**10** or **11**, 0.06 mmol) in ether (5 cm³) was added to a solution (15 cm³) containing mercury(II) chloride (0.06 mmol) in ether (15 cm³). As the ethereal solution was concentrated to 10 cm³ *in vacuo*, a yellow solid was precipitated. Recrystallization of the solid from acetonitrile (2 cm³) gave pure mercury complexes in 80—90% yiled as yellow needles.

12a: Mp 210 °C (decomp). Found: C, 27.77; H, 2.65%. Calcd for $C_{14}H_{16}O_3Ru\ HgCl_2$: C, 27.80; H, 2.67%.

12b: Mp 200 °C (decomp). Found: C, 29.59; H, 3.08%. Calcd for $C_{16}H_{20}O_4Ru\ HgCl_2$: C, 29.61; H, 3.11%.

12c: Mp 160 °C. Found: C, 31.23; H, 3.44%. Calcd for $C_{18}H_{24}O_5Ru\ HgCl_2$: C, 31.20; H, 3.40%.

12d: Mp 150 °C (decomp). Found: C, 32.29; H, 3.67%. Calcd for $C_{20}H_{28}O_6Ru\ HgCl_2$: C, 32.58; H, 3.84%.

13b: Mp 184—185.5 °C. Found: C, 28.11; H, 2.91%. Calcd for $C_{16}H_{20}O_2S_2Ru\ HgCl_2$: C, 28.22; H, 2.97%.

13c: Mp 166—167 °C. Found: C, 28.97; H, 3.27%. Calcd for $C_{18}H_{24}O_2S_3Ru\ HgCl_2$: C, 29.17; H, 3.27%.

Silver(I) Nitrate Complex (14d). A solution of **10d** (129 mg, 0.28 mmol) in acetonitrile (2 cm³) was added to a solution of silver(I) nitrate (55 mg, 0.32 mmol) in acetonitrile (2 cm³) at one time. After 1.5 h, the resulting precipitate was filtered and then a small amount of ether was added dropwise to the filtrate to give orange crystals in 19% yield. Mp 113—115 °C. Found: C, 40.54; H, 4.64; N, 6.71%. Calcd for $C_{25.5}H_{35.5}N_{3.5}RuAg$: C, 40.67; H, 4.86; N, 6.64%.

Silver(I) Nitrate Complexes (15). A solution of ruthenoceno-crown ether (0.06 mmol) in acetonitrile (2 cm³) was added to silver(I) nitrate (0.06 mmol) in acetonitrile (2 cm³). The resulting crystals were collected by filtration and washed with small portions of acetonitrile to give **15** in 76% yield as white needles.

15b: Mp 170 °C (decomp). Found: C, 33.02; H, 3.48; N, 2.50%. Calcd for $C_{16}H_{20}NO_5S_2RuAg$: C, 33.16; H, 3.49; N, 2.42%.

15c: Mp 167—169 °C (decomp). Found: C, 33.64 ; H, 3.66; N, 2.13%. Calcd for $C_{18}H_{24}NO_5S_3RuAg$: C, 33.80; H, 3.79; N, 2.19%.

We wish to thank the Nukada Scholarship of Toho University for financial support.

(Received August 2, 1985)

Pyrido[2,1-*a*]isoindole cycloadds to olefinic dipolarophiles in a highly *exo*-selective fashion giving the kinetically controlled cycloadducts which gradually isomerize into the Michael adducts. With acetylenic dipolarophiles, the hydrogen-migrated cycloadducts are the only products. The mechanism of cycloadditions is discussed.

Some time ago the first example of stereochemical study on the peripheral cycloaddition reactions of indolizines to olefins was reported.[1] These cycloadditions are stereospecific and highly *exo*-selective. Nevertheless the stepwise mechanism through zwitterionic intermediates was proposed since Michael type adducts were formed in some cases.

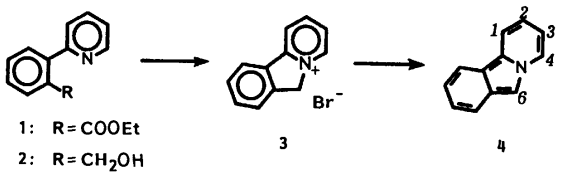
Thereafter a great number of cycloadditions of a variety of heteroaromatic *N*-ylides[2] and peripheral azomethine ylides[3–5] have been investigated, and these ylides were found to react with olefinic dipolarophiles in an exclusively *endo*-selective fashion. The high selectivity might be due to the positive interaction between the heteroaromatic plane and the unsaturated substituents of dipolarophiles.

We came to wonder why the indolizine cycloaddition showed such an exceptional *exo*-selectivety. Is it due to the stepwise reaction pathway?. If so, how? More informations on the stereoselectivity of the analogous cycloadditions are needed.

In the present paper, the cycloadditions of pyrido[2,1-*a*]isoindole with olefinic dipolarophiles were investigated and it was found that these reactions proceeded not *via* the zwitterionic intermediates but through synchronous cyclization pathway. The *exo*-selection might be a result from the $8\pi+2\pi$ concerted cycloaddition.

Results and Discussion

Pyrido[2,1-*a*]isoindole **4** is a known compound which was synthesized by the photoreaction between 2-bromopyridine and benzyl bromide.[6] Our approach to **4** starts with the reduction of ethyl 2-(2-pyridyl) benzoate **1** into 2-(2-pyridyl)benzyl alcohol **2** with lithium aluminum hydride, bromination of **2** into 6*H*-pyrido[2,1-*a*]isoindolium bromide **3** with hydrobromic acid, and the final step of dehydrobromination of **3** with aqueous sodium carbonate (Scheme 1).



Scheme 1.

An advantage of this preparation is that the starting ester **1** is readily available in large quantities through the reaction of pyridine with 2-lithiotoluene and the subsequent several steps can be all performed in large scales. Furthermore, the salt **3** as the precursor of air-sensitive **4** can be safely stored without any serious decomposition.

Rapid cycloadditions were found to occur when **4** was allowed to react with electron-deficient olefins at 0 °C, but the cycloadducts formed were too labile to be isolated. They gradually changed into the corresponding Michael adducts. Accordingly, the structural analyses of the cycloadducts were based only on the ^{1}H-NMR spectra.

Equivalent amounts of **4** and dimethyl maleate **5**

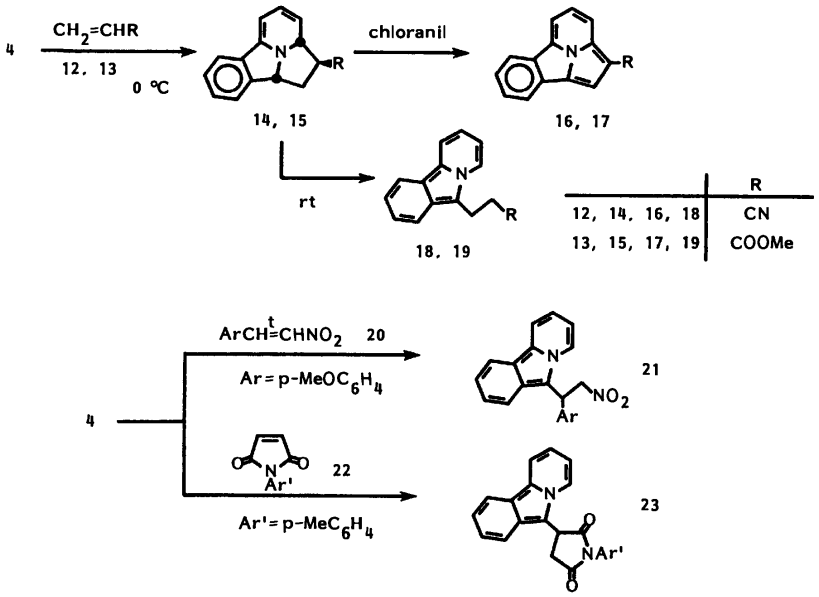

Scheme 3.

were dissolved in $CDCl_3$ at 0°C in an NMR sample tube and immediately subjected to the ^{1}H-NMR measurement. Only observed were the signals for the *exo*-selective and *cis*-specific cycloadduct **6**, indicating the quantitative formation of **6** (Scheme 2). On the other hand, the reaction of **4** with dimethyl fumarate **7** at 0°C formed the 7:3 mixture of two isomeric cycloadducts **8** and **9**. On standing at room temperature, these cycloadducts **6**, **8**, and **9** gradually isomerized into the same compound **11** which was isolated by the evaporation of the solvent and identified as the Michael adduct shown in Scheme 2.

The structural assignment of **6**, **8**, and **9** was based on the coupling constants among the methine hydrogens on the newly formed five-membered rings and the chemical shifts of ester methyls (Table 1). The stereochemistry of the starting olefins **5** and **7** must be retained in the cycloadducts and a molecular model inspection indicates that the only configuration for the points of fusion is cis (the methine hydrogens at the 2a- and 9b-positions are cis to each other). The 1—9b couplings of **6** and **9** are small to medium and the ester methyls at the 1-position of **8** and the 2-position of **9** are shielded. These informations are enough to determine the stereostructures of cycloadducts: **6**: 1-*exo*-2-*exo*-; **8**: 1-*endo*-2-*exo*-; **9**: 1-*exo*-2-*endo*-cycloadducts.

The cyclic structures of **6**, **8**, and **9** were confirmed by their dehydrogenation with chloranil at 0°C into dimethyl indolizino[3,4,5-*ab*]isoindole-1,2-dicarboxylate **10** which was no longer labile.

The regioselective and stereoselective cycloadducts **14** and **15** were formed also as unstable products in similar reactions of **4** with acrylonitrile **12** and methyl acrylate **13** (Scheme 3). They again isomerized into the

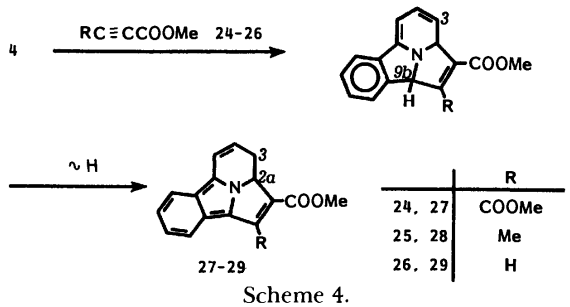
a) IR and ^{1}H-NMR spectra were measured as KBr disks and in $CDCl_3$, respectively.

Michael adducts **18** and **19** at room temperature and were dehydrogenated into the aromatized heterocycles **16** and **17** on treatment with chloranil at 0°C.

On the other hand, the reactions of **4** with (*E*)-1-(*p*-methoxyphenyl)-2-nitroethene **20** and *N*-(*p*-methylphenyl)maleimide **22** at 0°C provided no trace of the corresponding cycloadducts, only the Michael adducts **21** and **23** being observed in the reaction mixtures. By the evaporation of the reaction solvent, they were isolated as the sole products.

The spectral data of the Michael adducts **11**, **18**, **19**, **21**, and **23** as well as the indolizino[3,4,5-*ab*]isoindoles **10**, **16**, and **17** are summarized in Table 2. All the indolizino[3,4,5-*ab*]isoindoles show intense fluorescence in solution.

With acetylenic dipolarophiles such as dimethyl acetylenedicarboxylate **24**, methyl 2-butynoate **25**, and methyl propynoate **26** readily reacted **4** at room temperature giving the stable 1:1 adducts **27—29** all as yellow fluorescent materials (Scheme 4).



Scheme 4.

These regioselective products **27—29** were assigned as the hydrogen-migrated cycloadducts, from the 9b- to the 3-position, on the basis of the ^{1}H-NMR spectra shown in Table 3.

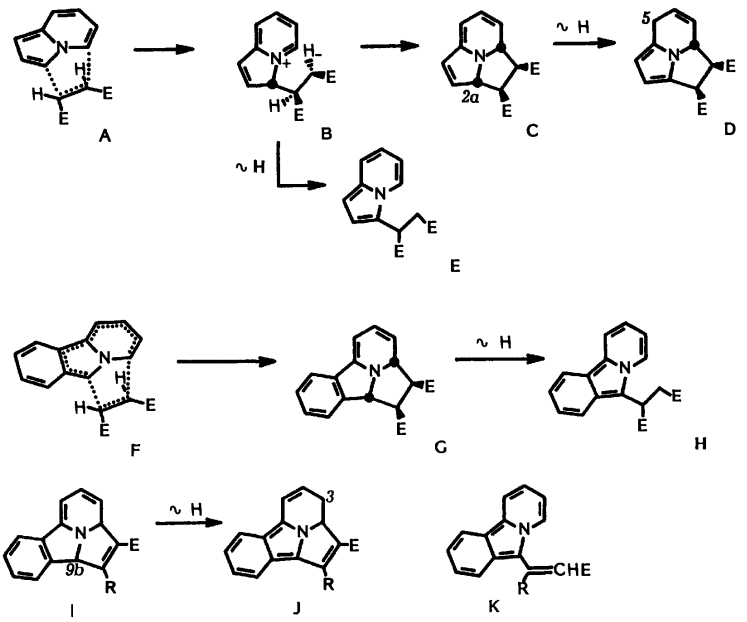
In the previous paper on the *exo*-selective cycloadditions of indolizines to olefinic dipolarophiles,[1] we proposed the stepwise mechanism *via* a zwitterionic intermediate **B**. This mechanism was based upon the formation of either the cycloadduct **D** or the Michael adduct **E** depending on the nature of dipolarophile and upon no interconversion between **D** and **E**. However, we would have to amend the reaction path because we now know that the Michael adduct **H** is the secondary product formed from the cycloadduct **G** (Scheme 5). The revised pathway is **A**→**C**→**D** or **A**→**C**→**E**.

In the cases of indolizines, two isomerization paths from **C**, the hydrogen migration from the 2a- to the 5-position leading to **D** and the bond cleavage into **B** (and hence **E**), presumably happened to compete. Once **D** and **E** are formed, there should be little chance of their interconversion. In the present cases, the similar hydrogen migration of **G** is suppressed by the influence of the additional fused benzo moiety, the cycloadduct **G** getting a chance of bond cleavage into **H**.

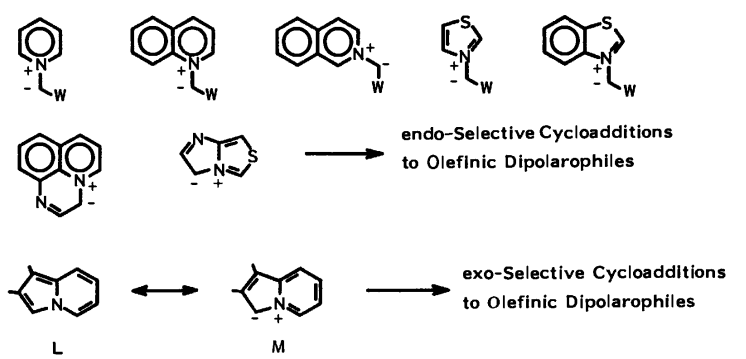
The acetylene cycloadduct **I** lies in a quite different situation. To accomplish the maximum extension of conjugation, the methine hydrogen at the 9b-position migrates long way to the 3-position giving **J** which was the isolated product. Since this migration may quickly occur, no Michael adduct **K** was obtained.

According to our study on the stereoselectivity of the cycloadditions of azomethine ylides involved as a part of heterocycles, all tested cases have shown the exclusive endo selectivity in the reactions with olefinic dipolarophiles[2-5] (Scheme 6); pyridinium, quinolinium, isoquinolinium, thiazolium, benzothiazolium methylides, anhydro-3*H*-pyrido[1,2,3-*de*]quinoxalinium hydroxide, thiazolo[4,3-*a*]isoindole, and imidazo[1,2-*c*]-thiazole.

Indolizine and pyrido[2,1-*a*]isoindole can be also regarded as the peripheral azomethine ylide 1,3-dipoles as illustrated with the charge-separated form **M** in Scheme 6. If the azomethine ylides participated in the $4\pi+2\pi$ cycloadditions, no satisfactory explanation for the high *exo*-selection would be available. We so far believe that the cycloadditions of indolizine and pyrido[2,1-*a*]isoindole to olefins belong to an $8\pi+2\pi$ synchronous cycloaddition.



Scheme 5.



Scheme 6.

Experimental

Melting and boiling points are all uncorrected. Spectral characterization was carried out with the following instruments: IR: JASCO IRA-1 spectrometer; ^{1}H-NMR: JEOL JNM-MH 100 spectrometer using tetramethylsilane as an internal standard; MS: JEOL JMS-100 mass spectrometer using a direct insertion probe at 70 eV of ionization energy. Elementary analyses were obtained on Shimadzu CHN-1A micro analyzer. Melting points were taken in capillaries on Mitamura Riken melting point measurement apparatus. Solvents were evaporated *in vacuo* using a rotary evaporator.

2-(2-Pyridyl)benzyl Alcohol **2**. To a suspension of lithium aluminum hydride (2.66 g, 0.07 mol) in dry ether (250 ml), was added slowly ethyl 2-(2-pyridyl)benzoate **1**[7] (10.59 g, 0.047 mol) in ether (200 ml) in 10 min. The mixture was stirred at room temperature for 1 h and poured into ice water. The ether separated was dried over $MgSO_4$, evaporated *in vacuo*, and the residual oil was distilled under vacuum to give **2** (8.13 g, 94%) as colorless liquid: Bp 159—164 °C/266 Pa; IR (Nujol) 3280 cm^{-1} (OH); ^{1}H-NMR ($CDCl_3$) δ= 4.46 (2H, s, CH_2), 6.10 (1H, br. s, OH), 7.14—7.86, and 8.52 (8H, m, ArH); MS *m/z* 185(M^+, base peak). Found: C, 77.7; H, 6.1; N, 7.4%. Calcd for $C_{12}H_{11}NO$: C, 77.8; H, 6.0; N, 7.6%.

6H-Pyrido[2,1-a]isoindolium Bromide **3**. A mixture of **2** (0.65 g, 3.5 mmol) and concd hydrobromic acid (48% content, d=1.48, 0.4 ml, 3.5 mmol) was warmed at 90 °C for 1.5 h. All the voratile materials were removed by evaporation *in vacuo* and the residue was treated with methanol to give **3** (0.77 g, 89%) which was purified by crystallization from ethanol: Colorless plates; mp 203—205 °C (lit,[6] mp 207.5—209.5 °C); ^{1}H-NMR (CF_3COOH) δ=5.53 (2H, s, CH_2), 7.30—8.32, and 8.70 (8H, m, ArH).

Pyrido[2,1-a]isoindole **4**. To a saturated aqueous solution of **3**, was added saturated aqueous solution of sodium carbonate at room temperature to give yellow precipitate of **4** in a quntitative yield: Yellow needles from ethanol; mp 221—223 °C (lit,[6] 225 °C).

General Procedure for the Cycloadditions of 4 to Olefins. Freshly prepared **4** (84 mg, 0.5 mmol) was added to a solution of olefins (0.5 mmol) in 1 ml of $CDCl_3$ at 0 °C. This mixture was transferred into an NMR sample tube and subjected to the ^{1}H-NMR measurement at 0 °C. In about 5 min, all the starting materials disappeared and instead very clean spectrum of the cycloadduct was observed. All the operations of integration, expansion, and decoupling were carried out at 0 °C. The ^{1}H-NMR spectra of **6**, **8**, **9**, **14**, and **15** are listed in Table 1.

General Procedure for the Michael Adduct Formation. The Michael adduct was obtained according to either of the following two procedures: 1) The solution of cycloadduct prepared above was allowed to stand at room temperature for 1 d and the solvent was evaporated *in vacuo* to give the Michael adduct. 2) An equivalent mixture of **3** (0.75 g, 3.0 mmol) and olefin in methanol (5 ml) was treated with triethylamine (5 mmol). The mixture was stirred at room temperature for 1 h and the solvent was evaporated *in vacuo*. The residue was triturated with cold 2-propanol or chromatographed over silica gel with chloroform to give the Michael adduct. The spectral data as well as melting points are summarized in Table 2. Other data are given below:

11: Yellow needles from methanol, Found: C, 69.6; H, 5.5; N, 4.3%. Calcd for $C_{18}H_{17}NO_4$: C, 69.4; H, 5.5; N, 4.5%.

18: Yellow needles from methanol. Found: C, 81.7; H, 5.6; N, 12.4%. Calcd for $C_{15}H_{12}N_2$: C, 81.8; H, 5.5; N, 12.7%.

21: Yellow prisms from methanol. Found: C, 72.7; H, 5.1; N, 8.2%. Calcd for $C_{21}H_{18}N_2O_3$: C, 72.8; H, 5.2; N, 8.1%.

23: Pale yellow prisms from acetone-methanol. Found: C, 77.5; H, 5.1; N, 8.2%. Calcd for $C_{23}H_{18}N_2O_2$: C, 77.9; H, 5.1; N, 7.9%.

General Procedure for the Indolizino[3,4,5-ab]isoindole Formation. A mixture of freshly prepared **4** (0.17 g, 1.0 mmol) and 1.2 equiv of olefin in dichloromethane (5 ml) was stirred at 0 °C for 15 min and chloranil (0.5 g, 2.0 mmol) was introduced. The resulting mixture was stirred at 0 °C for 1 h. The precipitate was removed by filteration and washed with boiling chloroform (15 ml×2). The combined filtrates were evaporated *in vacuo* and the residue was chromatographed over silica gel using chloroform as the eluent. The intensely fluorescent fraction gave the indolizino[3,4,5-*ab*]isoindoles, whose spectral data and melting points are given in Table 2. Other data are as follows:

10: Yellow plates from acetone. Found: C, 70.6; H, 4.3; N, 4.5%. Calcd for $C_{18}H_{13}NO_4$: C, 70.4; H, 4.3; N, 4.6%.

16: Yellow needles from methanol. Found: C, 83.3; H, 3.9; N; 13.0%. Calcd for $C_{15}H_8N_2$: C, 83.3; H, 3.7; N, 13.0%.

17: Yellow needles from petr. ether. Found: C, 77.0; H, 4.3; N, 5.8%. Calcd for $C_{16}H_{11}NO_2$: C, 77.1; H, 4.4; N, 5.6%.

General Procedure for the Cycloadditions of 4 to Acetylenes. An equimolar mixture of freshly prepared **4** and acetylene was allowed to react under the conditions shown in Table 3. After the solvent was evaporated *in vacuo*, the residue was chromatographed over silica gel with chloroform. The data of the product are listed in Table 3. Other data are as follows:

27: Yellow prisms from acetone. Found: C, 70.2; H, 4.8; N, 4.2%. Calcd for $C_{18}H_{15}NO_4$: C, 69.9; H, 4.9; N, 4.5%.

28: Yellow needles from petr. ether. Found: C, 77.1; H, 5.7; N, 5.5%. Calcd for $C_{17}H_{15}NO_2$: C, 77.0; H, 5.7; N, 5.3%.

Extraction-spectrophotometric Study of the System Technetium-Chromotropic Acid-Long Chain Quaternary Ammonium Salt

Feliçiá Grases,* Juan Gabriel March, Félix Mata,† and Alberto Peñafiel†
Department of Analytical Chemistry, Faculty of Sciences, University of Palma de Mallorca, 07071-Palma de Mallorca, Spain
†*Nuclear Medicine Section, Residencia Sanitaria "Virgen de Lluch," Palma de Mallorca, Spain*
(Received July 30, 1984)

A simple and highly selective extraction-spectrophotometric determination of technetium is described. The ion-associate formed between the technetium-chromotropic acid (CA) anion and trioctylmethylammonium (TOMA) is extracted with toluene in acidic media. The absorption maximum of the extracted species occurs at 630 nm, the molar absorptivity being 3.1×10^3 dm^3 mol^{-1} cm^{-1}. The composition of the ion-associate is estimated to be $[Tc(CA)_2(TOMA)_3]$.

Radiochemical methods are the most widely used procedures so far for technetium determination. These methods, however, require extensive chemical separation and purification to remove interferences and this can be difficult and laborious. The recent increase in technetium production has aroused interest in the development of methods of analysis that could be used to supplement the radiochemical ones. Methods described so far for technetium determination by means of nonradiochemical processes are however very scarce.[1] On the other hand, the recent production of appreciable quantities of technetium has allowed initiation of the study of its chemical behavior,[2] that has been restricted for a long time due to available quantities of this element being very small. In this aspect it can be pointed out that, although some complexes of the element were isolated for its different states of oxidation and even in some cases its structure was determined, knowledge of the behavior of this element in solution is still unknown in many aspects.

The present paper is concerned with the spectrophotometric determination of traces of technetium by extracting its complex with chromotropic acid in the presence of Adogen 464. The absorbance of the organic phase is very stable and is thus suitable for routine work. This system seems worthwhile because of the simplicity and high selectivity of the procedure.

Experimental

Reagents and Apparatus. Stock solution of chromotropic acid (CA) (supplied by Panreac) included a 7.5 g dm^{-3} aqueous solution of the compound ($C_{10}H_8O_8S_2\cdot 2H_2O$). Trioctylmethylammonium chloride (TOMA), better known as Adogen 464 (supplied by Serva) included a 2.5 g dm^{-3} solution in toluene.

Technetium-99 in solution form, as ammonium pertechnetate, was obtained from Amersham/Searle Co., Arlington Heights, Ill. A technetium solution of 119 ppm was prepared by dilution of the primary standard with water.

A Perkin-Elmer 552 spectrophotometer with 1.0-cm cells was used.

Extraction Procedure. To a series of 100 cm^3 separatory funnels, add 5 cm^3 of chromotropic acid (7.5 g dm^{-3}), 2 cm^3 of 18% L-ascorbic acid, 2.5 cm^3 of concentrated HCl (11.8 mol dm^{-3}), and the volume of technetium solution necessary for the final concentration to be between 0.5—6 ppm, and dilute to 25 ml with water. Mix well, and warm in a steam bath for 10 min. Add 5 ml of Adogen 464 (2.5 g dm^{-3}) and shake on a mechanical shaking apparatus for 30 min. Allow to stand for adequate time to separate the layers and discard the aqueous layer. Measure the absorbance of the organic layer at 630 nm using toluene as a reference.

Results and Discussion

Absorption Spectra. Maximum absorption of the

Thiocyanate	585	16500	Fe(III), Mo(VI)	8
Thiocyanate	510	50000	Fe(III), Mo(VI)	8

Tc-CA complex in aqueous media occurs at 740 nm ($\varepsilon=2.0\times10^3$ dm^3 mol^{-1}cm^{-1}), as can be seen in Fig. 1. The absorption spectrum (Fig. 1) of the extracted ternary system shows important changes of absorptivity and the maximum position ($\lambda_{max}=630$ nm, $\varepsilon=3.1\times10^3$ dm^3 mol^{-1}cm^{-1}) as a result of the ion-associate formation and extraction (the band shift involved is about 110 nm).

Effect of the Variables. The effect of pH on the formation of the Tc-CA complex was investigated. It was deduced from this study that complex formation is detected only when the assay takes place in acid medium as can be seen in Fig. 2. Maximal absorbance corresponds to hydrochloric acid interval concentrations of 0.6—1.4 mol dm^{-3}. At higher concentration, the absorbance decreases slightly, probably as a consequence of complex destruction. At lower hydrochloric acid concentrations, the absorbance decreases markedly. Formation of the Tc-CA complex only in strong acid medium can be explained admitting that the reduction process of Tc(VII) is more favored in this medium and not as a consequence of instability of complex species formed at lower hydrochloric acid concentrations. Thus, it has been proved that once having obtained the colored species in 1.2 mol dm^{-3} hydrochloric acid, they are not destroyed until pH=5 when basifying.

Ascorbic acid is used to reduce Tc(VII), the most stable species of the element in aqueous solution, to Tc(V), the probable oxidation state required for the CA color development. Other reductants produced either no color, or not as much color as ascorbic acid. Thus, tin(II) chloride seems. to be too strong and in the presence of a little excess of this reductant, absorbance decreases notably. The color does not develop in the absence of this special reductant because the CA is unable to act as a reductant by itself. The color appearance is not instantaneous and is favored by means of calefaction. It has been proved that for maximum color development, 10 min calefaction in a steam bath is necessary. A final concentration of 0.5% ascorbic acid is sufficient for maximum color development.

The effects of changing the CA and TOMA concentrations on the absorbance of the ternary complex were examined. The absorbance was found to increase rapidly on addition of CA up to a technetium:CA mole ratio of 1:12, when higher than this value it was practically independent of reagent concentration. For TOMA, this ratio was 1:8. It should be remembered that a very large excess of surfactant can retard the rate at which the phases separate and remain clear.[3] The stability of the ternary complex was studied. The absorbance of the extracted phase was stable at least for 24 h.

Nature of the Ion-associate. To determine the composition of the formed species, the Yoe-Jones method was used. Thus, stoichiometries of 1:2 (Tc:CA) and 1:2:3 (Tc:CA:TOMA) were found, suggesting that the extracted species is an ion-associate with formula $Tc(CA)_2(TOMA)_3$. This is in good agreement with the hypothesis that suggests the V oxidation state for technetium.

Characteristics of the Analytical Method. When the recommended procedure was used, Beer's law was followed in the range 0.5—6 μg Tc cm^{-3}. The molar absorptivity and precision of the method were established by carrying out ten parallel experiments. The molar absorptivity thus obtained is 3.1×10^3 dm^3 mol^{-1} cm^{-1}, which corresponds to a Sandell sensitivity of 31.9 ng Tc cm^{-2} for A=0.001. The relative standard deviation was 1.3% (95% confidence).

The selectivity of the method was tested by application of the recommended procedure in the presence of several foreign ions. A 100-fold amount of each of Ca, Sr, Ba, Mg, Ag, Ni, Co(II), Zn, Mn(II), Pb, Al, Cr(III), Fe(III), Mo(VI), W(VI), U(VI), Re(VII), V(V), NO_3^-, and SO_4^{2-} did not interfere. Only Cu(II) causes some serious interference. Thus, the presence of Cu(II) in large amounts prevents complex formation. Only 0.5 ppm of Cu(II) is tolerated. It is important to point out that U(VI), Re(VII), W(VI), and Mo(VI) which frequently accompany technetium and cause important disturbances in most of nonradiochemical procedures for technetium determination, do not cause any interference. This selectivity compares favorably with those obtained for other technetium complexes used spectrophotometrically (Table 1).

Finantial support by the CAICYT (Grand No. 2060-83) is gratefully acknowledged.

Electrodeposition of Catalytically Active Cobalt Powder from Aqueous Sulfate Electrolytes

A. M. Abd El-Halim*,† and Reda Mohamed Khalil
Department of Chemistry, Faculty of Science, King Abdulaziz University, Jeddah, Saudi Arabia
(Received July 23, 1984)

The electrodeposition of cobalt powder was investigated from aqueous sulfate solutions containing 0.0125—0.0500 $CoSO_4 \cdot 7H_2O$ (I), 0.23—1.00 $(NH_4)_2SO_4$ (II), 0.1 H_3BO_3 and 0.07 mol dm^{-3} $Na_2SO_4 \cdot 10H_2O$. The effects of the bath composition, the pH, the deposition current density and the duration of electrolysis on the cathodic polarization and the efficiency of cobalt electrodeposition, as well as on the morphology and the catalytic activity (towards the decomposition of 0.4% H_2O_2 solution) of the as-deposited cobalt powders were discussed. X-Ray diffraction studies proved that cobalt powders were very pure and deposited in the hexagonal close-packed structure with the orientations (100), (002), and (101). Cobalt powder deposited with an efficiency of 32% and had a catalytic activity approaching 100% could be obtained from the above-mentioned bath formula containing 0.05 mol dm^{-3} (I) and 0.46 mol dm^{-3}(II). The optimum operation conditions to achieve these characteristics were: pH 4.78, $j=10\,A\,dm^{-2}$ and $t=15$ min.

Little use has been made of pure cobalt deposits and this seems to be due to commercial and technical reasons.[1] However, cobalt powder is important in metalloceramics industry[2] and in manufacture of alloys characterized by a desired protective, decorative, and magnetic properties.[3,4]

The electrochemistry of cobalt is not well established, the number of contributions on the subject is low, and the data on this process is incomplete.[2] However, the electrodeposition of cobalt powder was investigated from sulfate[5] and tetrafluoroborate[6] aqueous solutions. On the other hand, the deposition of cobalt powder is favored by nonaqueous media and has been investigated in a two-layer bath.[7] The electrolyte was an aqueous solution of $CoCl_2 \cdot 6H_2O$ and the organic medium was 0.5% solution of oleic acid in toluene. The process was further developed to yield cobalt powder proper for use in the production of magnets.[8]

The present study was undertaken to investigate the electrodeposition of cobalt powder in dilute aqueous sulfate solutions. The process may be suitable for recovery of Co^{2+} ions from industrial effluents in form of fine grained powder of beneficial use as a catalyst.

Experimental

The baths used for electrodeposition of cobalt were prepared in distilled water using AnalaR grade chemicals (BDH). The symbol, composition, pH, and specific conductance of each of these baths are given in Table 1. The experimental arrangement for electrodeposition consisted of a Perspex cell with a copper cathode positioned midway between two plane parallel platinum anodes; all electrodes were of the same geometrical area. The anodes were surrounded by asbestose diaphragms to preclude oxidation of Co^{2+} ions and errors in the measured potentials caused by the oxygen evolved at the anodes.

The cathodic polarization curves were measured relative to the saturated calomel electrode (SCE) by means of a Wenking potentioscan model POS 73 and recorded automatically with a Philips x-y recorder model PM 8132. The cathodic efficiencies (f%) were determined by the use of a standard copper coulometer. The morphology of the as-formed cobalt powders was examined with a scanning electron microscope (JEOL model JSM 35). X-Ray diffraction studies were carried out by a Philips X-ray diffractometer PW 1390 with a nickel filter and copper radiation. The percentage decomposition (D%) of 0.4% H_2O_2 solution (at 40 °C) on the surface of the electrodeposited powders was considered as a measure for their catalytic activity. Therefore, a definite volume (50 ml) of the H_2O_2 solution was passed (single-pass) over a fixed bed (0.15 g) of the test powder with a constant flow-through rate (150 ml h^{-1}) by the aid of a MICROPERPEX peristaltic pump (LKB Bromma model 2132). D% was calculated by measuring the exact concentrations of H_2O_2 spectrophotometrically before and after its passage over the powder.

The electrodeposition experiments were carried out (in a selected bath) at various pH values; current densities, j (A dm^{-2}) and durations, t (min) using stationary electrodes. The pH of the bath was adjusted by additions of concentrated H_2SO_4 (98%) or NaOH solutions. One variable was changed

while the other two were held constant. Unless otherwise stated, all types of measurements were carried out at 25 °C.

Results and Discussion

Polarization Curves. The cathodic polarization curves for cobalt electrodeposition from Baths Co. 1—3 are shown in Fig. 1(A). The curves are characterized by an initial rapid potential-shift to the more negative values followed by a gradual increase with rise of current density and then the potential remains almost constant. This indicates that the electrodeposition of cobalt is attended by a high activation polarization.[9] This can be seen more clearly in Fig. 1(B) which shows that the Tafel relation holds good within the current density range 0—1 A dm^{-2}. Furthermore, the Tafel lines and the polarization curves shift to less negative potentials with increase in the concentration of Co^{2+} ion in the bath. This could be attributed to the corresponding decrease in the activation and the concentration polarizations.[10] However, regardless of the concentration of Co^{2+} ion in the bath, codeposition and vigorous evolution of hydrogen could be easily seen.

Decreasing the concentration of $(NH_4)_2SO_4$ in Baths Co. 3—5 which was expected to decrease the cathodic polarization *via* decreasing the stability constants of the Co^{2+}-ammonium complex ions,[11] is in practice found to has the opposite effect, *viz.* increasing the polarization (Figs. 2(A) and (B)). In addition, a corresponding decrease in the specific conductance of these baths is observed (Table 1).

As can be seen in Fig. 3(A), the cathodic polarization increases with increase in the pH of Bath Co. 4 over the range 2.1—9.6. This feature could be ascribed to the corresponding increase in the hydrogen overvoltage[12]

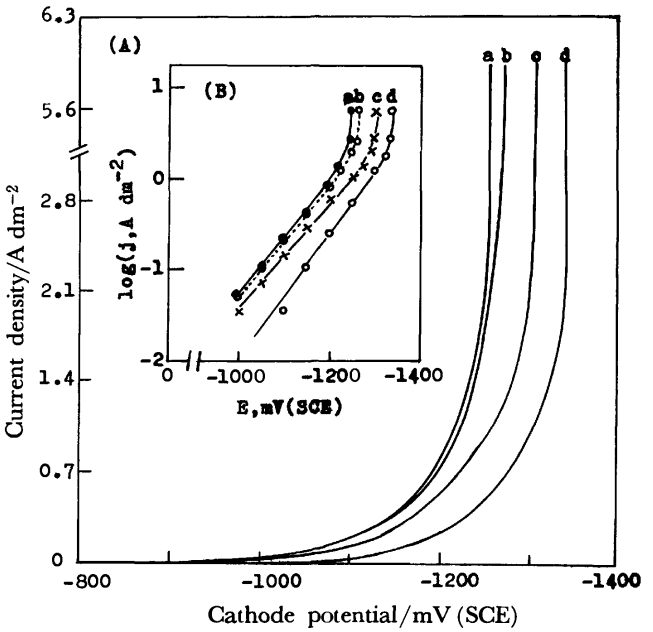

Fig. 3. (A) Polarization curves and (B) Tafel lines for cobalt electrodeposition from Bath Co. 4 at pH 2.1 (Curve a), pH 4.78 (Curve b), pH 7.7 (Curve c), and pH 9.6 (Curve d).

and the observed increase in the activation polarization of the cobalt deposition reaction (see Fig. 3(B)). In addition, at a low pH the rate of hydrogen evolution is so high that most of the gas formed escapes as bubbles. Increase in pH produces a state at which bubble formation is not fast enough for the gas to escape and consequently hydrogen adsorption occurs giving rise to an increase in the cathode potential.[6]

Current Efficiency. The percentage current efficiency (f%) of cobalt deposition increases with increase in the concentration of Co^{2+} ion in Baths Co. 1—3

Table 2. Effect of the bath composition on the efficiency and the catalytic activity of cobalt deposits

Property	Bath Co.

a) j=6.6 A dm^{-2}, t=10 min. b) j=10 A dm^{-2}, t=30 min.

Table 3. Effect of pH in bath Co. 4 on the efficiency and the catalytic activity of cobalt deposits

Property	pH			
	2.1	4.78	7.7	9.6
f %[a]	31.33	32.22	29.70	21.56
D %[b]	94.50	97.62	95.35	96.20

(a) and (b) are the same as in Table 2.

(Table 2). This effect could be due to the corresponding decrease of the concentration and the activation polarizations of cobalt deposition (Figs. 1(A) and (B)) and the simultaneous inhibition of discharge of H^+ ions. However, a general increase in the efficiency with concentration of the depositable metal ion in the bath was reported in previous studies.[10,13]

As the concentration of ammonium sulfate decreases in Baths Co. 3—5, there is a regular trend of increase in the efficiency of cobalt deposition (Table 2). This could be attributed to the expected decrease in the stability constant of Co^{2+}-ammonium complex ions[11] and the consequent increase in the concentration of the free Co^{2+} ions in the cathode layer. A similar increase in the efficiency with decrease in the concentration of the complexing agent has been observed during the electrodeposition of other metal powders.[13]

Bath Co. 4 is distinguished by a comparatively high current efficiency and the produced powder is characterized by the highest catalytic activity. Therefore, this bath was selected to explore the effect of the variables pH, j, and t on the electrodeposition of cobalt powder.

The data of Table 3 show that the efficiency from the as-prepared Bath Co. 4, of pH 4.78, decreases slightly with lowering of the pH to 2.1. This could be due to the competition between Co^{2+} ions and H^+ ions for discharge. This result is in good agreement with that obtained for the electrodeposition of cobalt from an acidic chloride bath.[14] On the other hand, the efficiency decreases considerably with rise of the pH over the range 4.78—9.60. This could be explained by the observed increase in the cathodic polarization with pH (Fig. 3).

The efficiency of cobalt deposition from Bath Co. 4 decreases gradually with increase in the current density (Table 4). This feature may be ascribed to the depletion of Co^{2+} ions in the cathode layer, arising from the increased rate of deposition, and the preferential discharge of hydrogen at high current densities. Similar results have been observed in several acidic plating electrolytes.[15,16]

Table 4. Effect of current density on the efficiency and the catalytic activity of cobalt deposits from bath Co. 4

Property	j/A dm^{-2}			
	2.0	6.6	10.0	13.2
f %[a]	43.65	32.22	30.35	28.26
D %[b]	98.15	97.90	97.62	94.32

a) pH=4.78, t=10 min. b) pH=4.78, t=30 min.

Table 5. Effect of deposition time on the efficiency and the catalytic activity of cobalt deposits from bath Co. 4

Property	t/min			
	10	15	20	30
f %[a]	32.22	32.18	28.41	11.04
D %[b]	100.00	99.00	98.10	97.62

a) pH=4.78, j=6.6 A dm^{-2}. b) pH=4.78, j=10 A dm^{-2}.

A regular trend of decrease in efficiency with increase in deposition time is represented in Table 5. Actually, this is an unfavourable feature and could be avoided by using soluble cobalt anodes or replenishing the Co^{2+} ions in the bath.

Surface Morphology. The powder obtained from Bath Co. 1 consists of fine crystals which have a characteristic fern-like shape (Fig. 4(A)). On increasing the concentration of Co^{2+} ions in Baths Co. 2 and 3, there is a growth habit modification towards the formation of coarser leaf-like dendritic deposit (Fig. (4B)). This change could be due to the decrease in the concentration and the activation polarizations (Figs. 1(A) and (B)) and the increase in diffusion of Co^{2+} ions which enable preferential growth on certain crystallographic planes and directions.[17]

The inclusion of lower concentrations of ammonium sulfate in Baths Co. 4 and 5 results in the formation of dispersed nodular deposit and better coverage of the cathode surface (Fig. 4(C)). This result is in agreement with the observed increase in the cathodic polarization (Fig. 2) and the correspondingly expected increase in the nucleation sites.[10]

On lowering the pH of Bath Co.4 from 4.78 to 2.10, there is no remarkable change in the growth morphology of the deposit other than refinement of the crystal size. In contrast, increase in pH of Bath Co. 4 over the range 4.78—9.60 leads to passivation of the cathode and formation of isolated dendritic clusters (Fig. 4(D)). This could be due to the polarization increasing effect with pH (Fig. 3) resulting from the increase in adsorption of hydrogen onto the cathode surface[6] and the consequent inhibition of Co^{2+} ions deposition.

The effects of the deposition current density (1.3—13.2 A dm^{-2}) and duration of electrolysis (3—30 min) on the morphology of cobalt powder from Bath Co. 4 (pH=4.78) were also examined. At a low current density (j=1.3 A dm^{-2}) small dihedral grains randomly oriented at the cathode are obtained (Fig. 5(A)). A regular trend of increasing grain size and transformation to

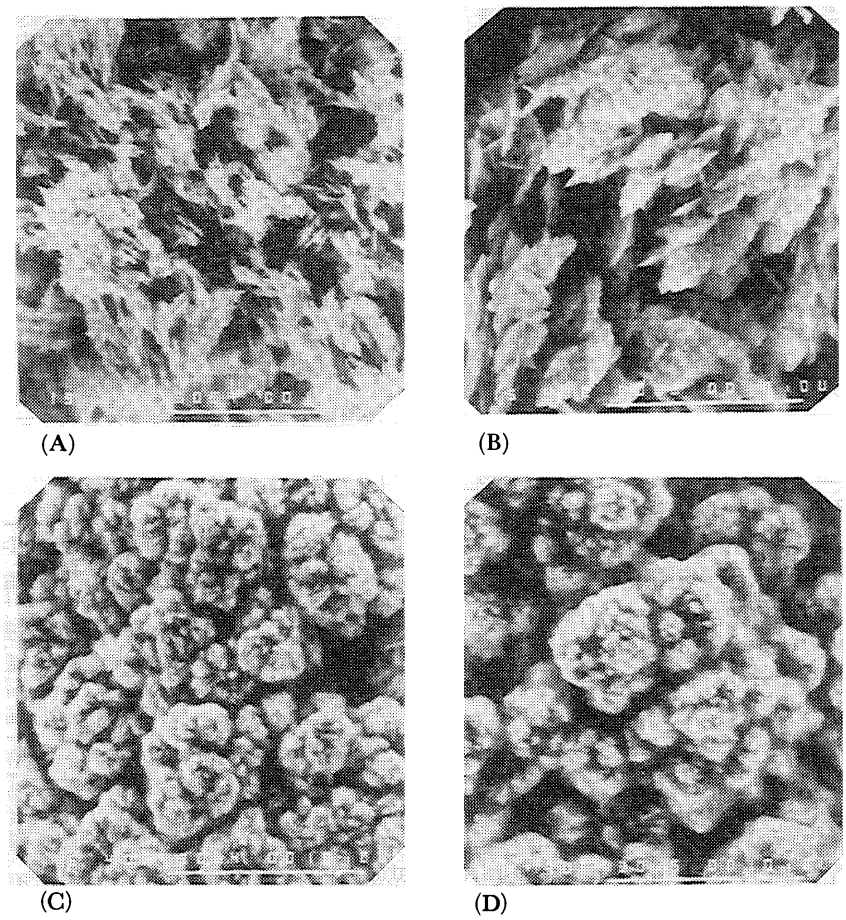

Fig. 4. Electron micrographs of cobalt powders from Baths Co. 1 (A), Co. 3 (B), Co. 4 at pH 4.78 (C), and Co. 4 at pH 7.7 (D); j=6.6 A dm^{-2}, t=10 min and magnification (×4000).

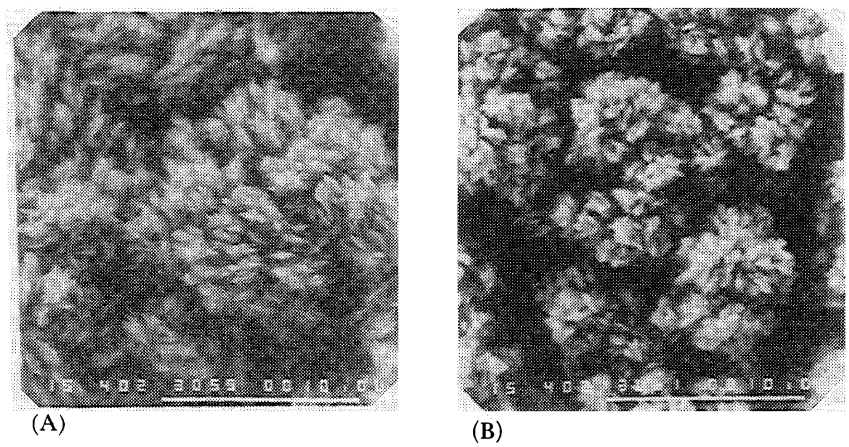

Fig. 5. Electromicrographs of cobalt powders from Bath Co. 4 at j=1.3 A dm^{-2} and t=10 min (A) and at j=6.6 A dm^{-2} and t=3 min (B); pH=4.78 and magnifications (×4000).

nodular dendrites is observed with increase in current density, as can be seen in Fig. 4(C). This feature could be attributed to the increase in the rate of discharge of Co^{2+} ions with current density; whereas, the cathodic polarization remains constant (Fig. 2(A)). Such conditions favour enlargement of the crystal size without considerably affecting the nucleation density.[15,18]

For short deposition times (t=3 min), isolated clusters of fine crystals are formed (Fig. 5(B)). On increasing the deposition time, there is a corresponding increase in the grain size of the cobalt deposit and better coverage of the cathode as shown in Fig. 4(C). These results could be ascribed to the fact that bigger grains are more stable thermodynamically, and if the system has enough time it will reach its most stable state.[19] This phenomenon would result from redissolution and recrystallization of the deposits, through the formation of local cells between them.[18] However, similar results and ex-

Table 6. X-Ray diffraction patterns of cobalt deposit from bath Co. 4

Line	2θ	d/Å	I/I_o	hkl	Observed parameters		Standard parameters	
					a/Å	c/Å	a/Å	c/Å
1	41.60	2.1690	20	100	2.505	4.065	2.507	4.070
2	44.50	2.0342	60	002				
3	47.50	1.9120	100	101				

planations were reported for the electrodeposition of cadmium.[15]

X-Ray Diffractometry. X-Ray structural studies were carried out on the electrodeposited cobalt powders from the under test baths at a current density of 10 A dm^{-2} and duration for 30 min. Table 6 shows as for example the data for the deposit formed in Bath Co. 4. Regardless of the composition or the pH of the examined baths, the obtained data reveal that cobalt powders are deposited in the hexagonal close-packed structure and exhibit the orientations (100), (002), and (101). Moreover, the powders are deposited in a very pure form as could be find out from the good agreement between the values of the calculated and the standard lattice parameters.

Catalytic Activity. In general the catalytic activity (D%) of the electrodeposited cobalt powder, towards the decomposition of 0.4% H_2O_2 solution, is relatively high (82—100%) and this seems to be a specific property. However, the catalytic activity increases with increase of Co^{2+} ions concentration in Baths Co. 1—3 and decrease of ammonium sulfate concentration in Baths Co. 3—5 (Table 2). These effects may be due to the corresponding morphological transformations (Figs. 4A—C) which would result in an increased surface area of the deposit and accordingly increase its catalytic activity.[20]

The effects of the variables, pH, current density, and deposition time on the catalytic activity of cobalt powders formed in Bath Co. 4 were also examined. A negligible change in the catalytic activity is observed with altering the pH over the range 2.1—9.6 (Table 3). This may be referred to the slight effect of pH on the surface morphology of the deposit (Figs. 4(C) and (D)).

The catalytic activity of the deposited powder at the lowest current density (2.0 A dm^{-2}) and the shortest deposition time (10 min) is almost 100%. However, the catalytic activity decreases gradually with increasing current density (Table 4) and increasing deposition time (Table 5). These results may be due to the corresponding enlargement of the cobalt grain size and formation of clusters rather than disperse deposit as mentioned above in the discussion of the surface morphology. However, it seems probable that the catalytic activity of the cobalt powder is, in general, a morphological-sensitive property.

Conclusions

The electrodeposition of cobalt powder from sulfate electrolytes can be controlled by the bath composition, the pH, the current density, and the duration. The obtained data show that the effects of these variables on the cathodic polarization influence to a great extent the surface morphology of the electrodeposited cobalt powder. In addition, the catalytic activity seems to be a morphological-sensitive property. Accordingly, the optimum bath is found to contain 0.05 $CoSO_4 \cdot 7H_2O$, 0.46 $(NH_4)_2SO_4$, 0.1 H_3BO_3, and 0.07 mol dm^{-3} $Na_2SO_4 \cdot 10H_2O$. This bath yields the best depoit, characterized by a catalytic activity of 99%, with an efficiency of 32% at the most suitable operating conditions: pH=4.78, j=10 A dm^{-1} and t=15 min.

Spectrophotometric Determination of Rhodium(III) and Iridium(III) with 3-Hydroxy-2-methyl-1,4-naphthoquinone 4-Oxime

Kamini SHRAVAH and S. K. SINDHWANI*
Department of Chemistry, University of Delhi, Delhi-7, India
(Received August 15, 1984)

Rhodium(III) and iridium(III) form 1:3 and 1:2 (metal:ligand) complex, respectively with 3-hydroxy-2-methyl-1,4-naphthoquinone 4-oxime (HMNQM). The complexes are soluble in 20% ethanol. The reagent has been used for the spectrophotometric determination of Rh(III) and Ir(III). The optimum ranges of concentration for the determination of Rh(III) and Ir(III) are 0.27—5.24 and 1.51—15.85 over the pH range 5.0—7.5 and 5.3—8.0, respectively. The Sandell sensitivities for the determination of Rh(III) and Ir(III) are 0.0042 and 0.015 $\mu g\,cm^{-2}$, respectively. The determinations have also been carried out in the presence of foreign ions.

When ethanolic solution of 3-hydroxy-2-methyl-1,4-naphthoquinone 4-oxime was added to Rh(III) or Ir(III) solution, a yellow or orange brown colored complex was formed. The present study was undertaken to investigate the possibility of the use of HMNQM as a reagent for spectrophotometric determination of rhodium or iridium. Optimum conditions for the determination of rhodium(III) or iridium(III) alone or in presence of diverse ions have also been investigated.

Experimental

Reagents and Apparatus. Preparation of 3-hydroxy-2-methyl-1,4-naphthoquinone 4-oxime (HMNQM) has been reported earlier.[1] The 1×10^{-2} M (1 M=1 mol dm^{-3}) solution of HMNQM was prepared in ethanol (95%).

Buffer solutions were prepared by mixing 0.2 M sodium acetate and 0.2 M acetic acid in the required proportions. For higher pH, sodium hydroxide was added.

Rhodium(III) Solution. A standard solution of rhodium(III) was prepared by dissolving rhodium trichloride (Johnson Matthey) in double distilled water containing 1 M hydrochloric acid. The solution was standardized gravimetrically by precipitating rhodium as the sulfide, followed by ignition to the oxide and then reduction to the metal in an atmosphere of hydrogen and cooling in carbon dioxide. Subsequent dilutions were made by diluting the stock solution, maintaining acidity at 1 M.

Iridium(III) Solution. A standard solution of iridium was prepared by dissolving iridium(III) chloride (Johnson Matthey) in double distilled water containing 1 M hydrochloric acid. The iridium solution was standardized gravimetrically by precipitating iridium as the hydrated oxide, followed by careful ignition in air and then reduction to the metal in presence of hydrogen gas and cooling in an atmosphere of carbon dioxide. Subsequent dilutions were made by diluting the stock solution and keeping the acidity at 1 M.

Reagent grade chemicals were used in the study of interferences. Double distilled water was used throughout the work.

A Unicam SP 600 spectrophotometer was used for measuring absorbance and an ECIL expanded scale pH meter PH821A was used for pH measurements.

Absorption Spectra and Effect of pH. Both rhodium and iridium complexes show the maximum absorption at 470 and 480 nm respectively (Fig. 1). Subsequent studies have been carried out at this wavelength. A plot of absorbance *vs.* pH shows that the absorbances remain constant in the pH range 5.0—7.5 and 5.3—8.0 for Rh(III) and Ir(III), respectively. Further studies have been carried out at pH 6.0 and 6.5 for rhodium and iridium, respectively.

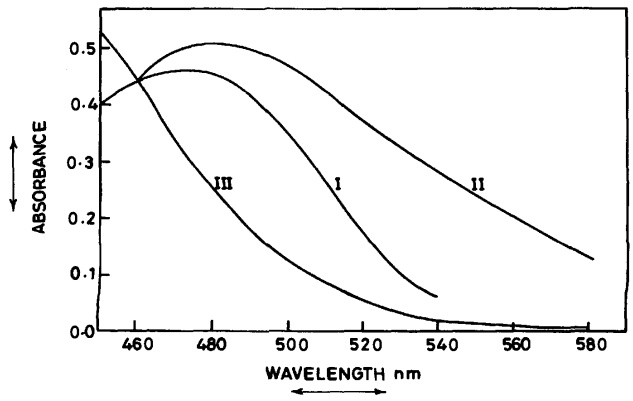

Fig. 1. Absorption spectra of I rhodium(III) complex *vs.* reagent, rhodium 2×10^{-5} M; II iridium(III) complex *vs.* reagent, iridium 4×10^{-5} M; III reagent *vs.* water, HMNQM 2×10^{-4} M.

Rate of Color Development and Stability of the Complexes. The rate of reaction between metal and HMNQM is slow at room temperature. The color intensity was found to increase when the solutions containing a fixed amount of Rh(III) or Ir(III) and excess of reagent were heated on a water bath for various intervals of time and absorbances were measured at 470 or 480 nm for Rh or Ir, respectively. Results of this study show that complete complex formation takes place on heating the contents for about 50 min and 3 h for rhodium and iridium, respectively.

The Rh-HMNQM and Ir-HMNQM complexes were found to be quite stable and absorbances were found to remain constant up to 48 and 24 h, respectively.

Effect of Ethanol Concentration. The precipitated complexes were found to be soluble in ethanol. It has been found that 20% (v/v) ethanol is sufficient to dissolve the precipitate completely. Subsequent studies for rhodium and iridium have been carried out in 20% ethanol medium.

Effect of Reagent Concentration. A plot of absorbance *vs.* moles of ligand shows that at least eight and five times molar excess of the reagent is required for maximum complex formation for rhodium and iridium, respectively (Fig. 2). In further studies ten times molar excess of the reagent was used for both metal.

Adherence to Beer's law, Optimum Range and Sensitivity. Beer's law is obeyed up to 5.97 and 17.68 ppm (1 ppm=1 $\mu g\,cm^{-1}$) while the optimum concentration ranges for accurate determination, as determined from Ringbom plot

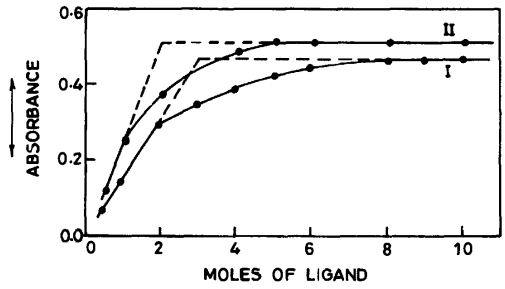

Fig. 2. Effect of reagent concentration, I: Rh(III)-complex Rh=2×10^{-5}M, II: Ir(III)-complex Ir=4×10^{-5}M.

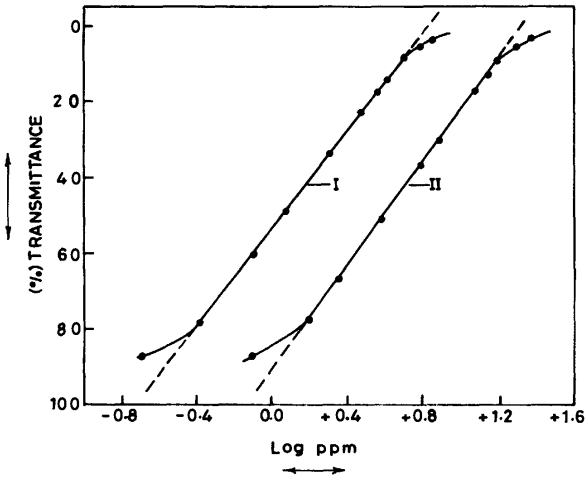

Fig. 3. Ringbom plot for I Rh(III)-HMNQM complex; II Ir(III)-HMNQM complex.

(Fig. 3), are 0.27—5.24 and 1.51—15.85 ppm for rhodium and iridium respectively. The sensitivity in terms of Sandell's definition, is 0.0044 μg Rh/cm^2 and 0.015 μg Ir/cm^2 for log I_o/I=0.001 with molar absorptivity 2.32×10^4 and 1.27×10^4 l mol^{-1} cm^{-1}, respectively.

Recommended Procedure. To a suitable aliquot containing 6.7—131.0 μg of Rh(III) or 37.7—396.2 μg of Ir(III) is added ten times molar excess of reagent. The pH is adjusted between 5.0—7.5 for rhodium and 5.3—8.0 for iridium with acetate buffer and dilute solution of sodium hydroxide. The contents are heated on a boiling water bath for 1 and 3 h, respectively for rhodium and iridium, cooled to room temperature (30±5 °C). The total volume is raised to 25 cm^3 with double distilled water, keeping 20% ethanol concentration. The absorbance of the solution is measured at 470 nm for rhodium and 480 nm for iridium against reagent blank prepared under similar conditions. Knowing the absorbance, the amount of rhodium or iridium is deduced from the calibration graph.

Molar Composition of the Complexes. The composition of the complexes were determined by Job's method of continuous variations[2,3] (Fig. 4) and mole ratio method[4] (Fig. 2). Both of these methods show that the stoichiometric ratio of metal to HMNQM in the complex is 1:3 (Rh:HNMQM) and 1:2 (Ir:HMNQM).

Absorbance Deviations. Measured under experimental conditions, absorbance of six solutions, each containing 2.06 ppm of rhodium, gave mean absorbance of 0.465 with average relative deviation of ±0.32% and maximum relative

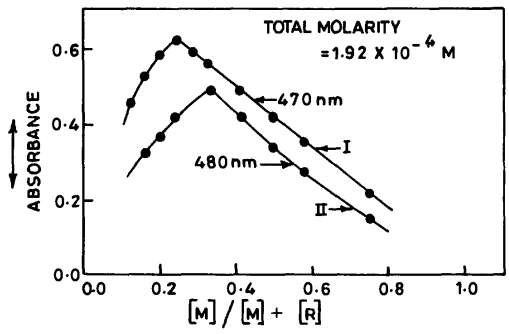

Fig. 4. Composition by Job's method, I: Rh(III)-complex, II: Ir(III)-complex.

deviation of ±0.64% with standard deviation of 0.002. Seven solutions each containing 7.68 ppm of iridium gave an average absorbance of 0.51 with standard deviation of 0.0026. The average relative deviation was found to be ±0.39% and average maximum deviation was ±0.78%.

Effect of Diverse Ions. The effect of diverse ions was studied in the determination of rhodium and iridium following the recommended procedure. The amounts (in ppm) of ions which do not cause any interference with 2.06 ppm of rhodium are given below in parentheses. Masking agents, wherever used, have been mentioned against each:

Chloride (700), bromide (300), iodide or nitrate or sulfate (200), fluoride (600), nitrite or phosphate (150), sulfite or oxalate or EDTA (100), tartrate (50), thiocyanate (80), Ca(II) (100), Ba(II) or Hg(II) (80), Mg(II) or Zn(II) or Cd(II) or Pb(II) (40), Al(III) (20), Mn(II) (30), Fe(II) or Co(II) or Ni(II) or Cu(II) (10, EDTA), Sn(II) (40, F^-), As(III) (50), Ag^I(I) (20, Cl^-), Sb(III) (25), Pd(II) (2, I^-), Os(VIII) (2, SCN^-), V(IV) or Th(IV) (20, F^-), U(VI) (10, PO_4^{3-}). Thiourea, thiosulfate, citrate, Ru(III), Ir(III), and Pt(IV) interfere and attempts to mask the cations were unsuccessful.

For 7.68 ppm of iridium(III), the limits of tolerance are; chloride (100), bromide or nitrate (300), iodide or fluoride (400), nitrite (50), citrate (70), tartrate or oxalate or thiocyanate (100), phosphate, sulfite (150), EDTA (80), sulfate (200), Ca(II) (80), Ba(II) or Cd(II) or Cr(III) (70), Mg(II) or Zn(II) (50), Al(III) (10), Hg(II) or Mn(II) (100), Fe(II) or Co(II) or Ni(II) or Cu(II) (15, EDTA), Sn(II) (20, F^-), As(III) (20), Ag^I(I) (40, Cl^-), Pd(II) (10, I^-), Os(VIII) (4, SCN^-), V(IV) (10, F^-), U(VI) (70, PO_4^{3-}). However, interference due to thiosulfate, thiourea and Ru(III), Rh(III), and Pt(IV) could not be avoided.

Discussion

Quite a few satisfactory reagents are known for the spectrophotometric determination of rhodium. Several methods for the spectrophotometric determination of Rh have been reviewed by Beamish.[5] Tin bromide[5] is a sensitive reagent for rhodium, though the method is not selective and stability of the complex is also low (3 h). The HMNQM method is more sensitive than *N,N'*-bis(3-dimethylaminopropyl)dithiooxamide,[5] *o*-mercaptobenzamide[6] and oximidobenzotetronic acid or α-isonitrosobenzotetronic acid.[7] Most of the associated metals interfere in the case of these reagents.

†Removed by centrifugation.

Table 1. Sensitivities of reagents for Rh and Ir

Reagent	Sensitivity μg Rh/cm²	Reagent	Sensitivity μg Ir/cm²
Tin(II) bromide	0.0035/427 nm	Leucocrystal Violet	0.004/590 nm
N,N-Dimethyl-*p*-nitrosoaniline	0.0015/510 nm	*o*-Dianisidine[a]	0.016/530 nm
Oximidobenzotetronic acid or α-isonitrosobenzotetronic acid	0.07/475 nm	*N,N*-Dimethyl-*p*-nitrosoaniline	0.010/530 nm
N,N'-bis(3-dimethylaminopropyl) dithiooxamide	0.012/420 nm	Oximidobenzotetronic acid or α-isonitrosobenzotetronic acid	0.020/480 nm
o-Mercaptobenzamide	0.014/377 nm	Cerium(IV) sulfate sulfuric acid	0.12/510 nm
Acenaphthenequinone monoxime	0.0036/390 nm	Acenaphthenequinone monoxime	0.021/385 nm
3-Hydroxy-2-methyl-1,4-naphthoquinone 4-oxime (Present method)	0.0044/470 nm	3-Hydroxy-2-methyl-1,4-naphthoquinone 4-oxime (Present method)	0.015/480 nm

a) 3,3'-Dimethoxybiphenyl-4,4'-diamine.

In *N,N*-dimethyl-*p*-nitrosoaniline[5] full color development takes place within 10 min of heating, but after 20 min absorbance begins to decrease and also the volume of the buffer solution used has a pronounced effect on the absorbance of the complex. In acenaphthenequinone monoxime[8] EDTA, NTA, SCN^-, $S_2O_3^{2-}$, Ir, Pt, Cu, Fe, and cerium(IV) cause serious interference. Recently 1-phenyl-3-(2-pyridyl)thiourea[9] has been successfully used for the determination of rhodium. The disadvantage is that the absorption maximum lies in UV region.

For the determination of iridium with Leucocrystal Violet,[10] Rh and Fe(III) interfere seriously. This method depends upon a specific composition of the dissolved iridium salt and aged iridium solutions give green solutions of lower absorbance than those which are freshly prepared. Tin bromide method[11,12] is not selective. This method is sensitive to certain variation in the procedure such as time of contact, temperature, quantity of reagent, and hydrobromic acid. In *o*-dianisidine[13] method, there is interference from associated metals and from oxidants and sulfuric acid solution cannot be used. The absorbance is sensitive to the amount of reagent and to the acidity of the medium. In *N,N*-dimethyl-*p*-nitrosoaniline[14] method, the composition of the complex is not known and the method offers no specificity among platinum metals and there is interference from nonvolatile acids. The method is sensitive to changes in the conditions. In acenaphthenequinone monoxime[15] method, most of the platinum metals interfere and prior separation of iridium is necessary and sensitivity is also low.

The present method, using 3-hydroxy-2-methyl-1,4-naphthoquinone 4-oxime involves simple technique. The method is quite sensitive and the complexes are stable for a long time. Other factors such as effect of buffer, pH, heating time, amount of reagent do not have any effect on the absorbance. Most of the associated metals do not interfere. The sensitivity is comparable (Table 1) with other methods known for the purpose.

X-Ray Fluorescence Study of Manganese Compounds at Stoichiometric Compositions

M. Ghodsi,* P. H. Duvigneaud, and G. Glade
Service de Chimie Industrielle et Chimie des Solides, Université Libre de Bruxelles, Belgium
(Received August 17, 1984)

Manganese oxides and other inorganic compounds were studied by electron induced X-ray fluorescence. Mn $L\alpha$ energy shifts were measured with respect to pure manganese $L\alpha$ maximum. Those shifts were shown to be a smooth function of manganese partial charge if the latter is calculated from Sanderson's electronegativity scale. The results are in good agreement with Yokokawa's previous work on oxides.

Increasing interest in X-ray analysis methods in such field as industry and research is duly justified by numerous advantages they offer. For example, X-ray fluorescence allows the study of amorphous substances and detection limits of heavy elements can be reduced to a very low level (*ca.* 100 ppm) by use of an ultrathin counter window (polypropylene 1 μm). The cold cathod tube (windowless tube) appears as a very efficient tool for the electronic excitation of K bands of light elements (boron included) and of L bands of heavier elements ($Z>20$). On the other hand, electronic excitation permits the surface analysis of samples in connection with the low penetration depth of the rays.[1]

Furthermore, this method gives access to the stoichiometric composition of samples owing to the energy shift of the characteristic bands (the so-called chemical shift) and can be successfully applied to the study of transition metal oxides[2] the importance of which is well known. Particulary, Mn $L\alpha$ energy shifts (corresponding to the transition L_{III} $M_{IV,\ V}$) can be linked with partial charge of manganese in its compounds.

Experimental

The spectrometer is an "INEL-Alpha 2020" model allowing the study of light elements owing to the use of an electron tube ("Elent 20"). This device, working under a primary vacuum, has been described elsewhere.[3] Table 1 gives the conditions of use of the spectrometer for the Mn $L\alpha$ measurements.

Materials. Each of the synthesized systems has been duly characterized by X-ray diffraction analysis. Results are summarized in Table 2. Manganosite[4] is prepared by a careful decarbonation of precipitated $MnCO_3$. Precipitation is obtained under pure N_2 atmosphere by the reaction

$$Mn(NO_3)_2 + (NH_4)_2CO_3 \longrightarrow MnCO_3 + 2NH_4^+ + 2NO_3^-. \quad (1)$$

After Reaction 1 has been completed, $MnCO_3$ is washed and decomposed at 500 °C in presence of N_2 96%–H_2 4%. Operation is complete after 48 h. Manganese(II) oxide (Riedel-De Haen-high grade purity) has also been investigated. X-Ray diffraction analysis gives a composition of 90% manganosite and 10% MnO_2 (pyrolusite). Dimanganese trioxide has been synthesized by modifying a method initially proposed by Krull.[5] $Mn(OH)_2$ is precipitated from manganese(II) acetate according to the reaction

Table 1. Experimental conditions for the study of Mn $L\alpha$

Excitation source	Electron tube
Voltage	3kV
Intensity	800μA
Analyzing crystal	RbAP(2d=26.12Å)
Detection	Flow proportional counter (90% Argon–10% methane)

Table 2. X-Ray diffraction analysis of the samples

Chemical species	Name	Lattice
MnO synth.	Manganosite	Cubic
MnO (RDH)	MnO 90% manganosite MnO_2 10% pyrolusite	
$Mn(OH)_2$	Pyrochroite	Hexagonal
Mn_2O_3	Partridgeite	Orthorhombic
Mn_3O_4	Hausmannite	Tetragonal
MnO_2	Pyrolusite	Tetragonal

$$Mn(CH_3COO)_2 + 2OH^- \longrightarrow Mn(OH)_2 + 2CH_3COO^-. \quad (2)$$

Initial reactives concentration is chosen as high as possible in order to obtain very small particles[6] and hence to improve the oxidation kinetics. The oxidation step has been performed for 6 h under pure oxygen. The system consists of Partridgeite, as shown by X-ray analysis. Mn_3O_4 is prepared by a prolonged heating of MnO_2 in presence of air (1050 °C) and characterized as Hausmannite.[7] $Mn(OH)_2$ is precipitated in an oxygen-free dilute aqueous ammonia, starting from $MnCl_2$. The hydroxide is vacuum dehydrated in presence of P_2O_5 for 48 h. Electrolytic manganese (99.99%) is polished up to complete disappearance of superficial oxide. Evolution of the surface state is measured by the intensity of the O $K\alpha$ peak. Other samples ($MnSO_4$, $MnCl_2$) though of high purity grade, have been recrystallized. In order to avoid granulometry effects,[8] a mixture of oxides (MnO 50%–MnO_2 50% and MnO 80%–MnO_2 20%) has been prepared from sieved powders (size less than 30 μm).

Energy Shifts. One of the most interesting characteristics of low energy X-ray emission bands is the change occurring in spectra when the valence state of the element under study is modified.[9,10] Since emitted soft X-rays are connected with transitions finding their origin in external levels of an atom, corresponding photon energy must be sensitive to the oxidation state of the element. Hence, significant changes in energy position of the intensity maxima can occur. Furthermore, new transitions unobserved in pure elements, can

TABLE 3. Mn L_α ENERGY SHIFTS IN MANGANESE COMPOUNDS

Compound	E/eV	ΔE Mn L_α/eV
Mn	634.7	—
MnO	635.4	+0.7
MnO(RDH)	635.4	+0.7
$Mn(OH)_2$	635.7	+1.0
Mn_3O_4	635.6	+0.9
Mn_2O_3	636.0	+1.3
MnO_2	636.1	+1.4
MnO 50%-MnO_2 50%	636.0	+1.3
MnO_2 20%-MnO 80%	635.7	+1.0
$MnCl_2$	636.0	+1.3
$MnSO_4$	636.3	+1.6

appear in their compounds.[11] If ΔE represent the energy shift of the element band maximum in a compound compared with that of the pure element, one generally finds:

$$\Delta E(K\alpha) < \Delta E(K\beta) < \Delta E(L). \quad (3)$$

If the element's oxidation state increases. As a rule, the higher the formal positive change, the more energetic the electronic transition. In the opposite case (element negatively charged), ΔE will be negative. This is only in case of light elements compounds (sulfides[12] oxides[13]) that K shifts can easily be observed. For heavier elements, only the L energy shifts can provide the required information.

Results and Discussion

Mn $L\alpha$ maxima positions (transitions between L_{III} and $M_{IV,V}$ levels) have been measured. Each point of the curve intensity *versus* angle is provided by a hundred seconds counting time, angular increment being equal to 0.01°.[2] ΔE (eV) is obtained by comparison with pure manganese $L\alpha$. Table 3 shows the observed energy shifts. All ΔE's correspond to an energy increase of the transition and appear to be directly linked with the manganese oxidation state. It is worthwhile to remark that MnO (Riedel-De Haen) behaves in the same way as pure manganosite despite the high MnO_2 concentration revealed by X-ray diffraction. This can be explained by the relatively low excitation depth. As shown by Feldman,[14] the penetration depth of the electrons in the sample is given by:

$$R(\text{Å}) = \frac{250<A>}{\rho<Z>^{n/2}} E^{n/2} \quad (4)$$

where n=1.2 (1−0.29 log<Z>), <A> is the mean atomic weight and ρ the specific mass gr/cm³) of the sample. <Z> is the mean atomic number and E (keV) is the electrons kinetic energy. Accordingly, excitation depth is *ca.* 800 Å in case of MnO. It seems obvious to assume that the particle nucleus consists of undetected MnO_2 as a result of uncompleted particle reduction. It can be pointed out that the mixture (MnO 50%-MnO_2 50%) exhibits the same overall chemical shift as Mn_2O_3.

Figure 1 represents the observed energy shift as a function of manganese partial charge calculated from Sanderson electronegativities scale[15] which appears to give a better correlation with experimental evidence than Pauling's scale.[16,17] As a matter of fact, one observes a smooth variation of ΔE as a function of q_{Mn}. Those results are in good agreement with those of Yokokawa *et al.*[18] on Si $K\alpha$ and Al $K\alpha$ chemical shifts in oxide glasses.

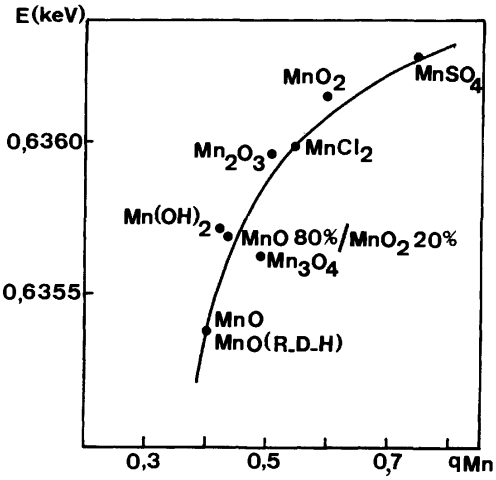

Fig. 1. MnL_α Energy shifts *versus* manganese partial charge in its compouds.
As an example, the solid line is a fifth order polynomial approximation (correlation coefficient: 0.94).

Conclusions

Soft X-ray fluorescence is an useful tool in the study of transition metal compounds. Particularly, L energy shifts give a rapid estimate of the mean stoichiometry of a compound or mixtures of compounds. Furthermore, the use of the electrons tube gives access, in contrast with Auger spectroscopy, to a relatively important analysis depth (*ca.* 1000 Å); accordingly, the contribution of possible superficial impurities is highly reduced. Finally, in view of the industrial importance of manganese and transition compounds, study of the L energy shifts provides a useful method for the rapid determination of mineral ores and metallurgy products.

The authors are indebted to the "Fonds National de la Recherche Scientifique" (FNRS-Belgium) for part of the financial support for the investigation.

Photoredox Chemistry of Chloro and Bromo Complexes of Copper(II) in Methanolic Medium

Pazhayirayyathu Geeverghese DAVID* and Paulo Augusto Correa DA SILVA
Departamento de Química, Universidade de Brasília, Brasília, Brazil
(Received August 20, 1984)

Investigation of the photoreduction of copper(II) to copper(I) in methanolic solutions of copper(II) chloride and copper(II) bromide indicates the halide-to-copper(II) charge-transfer (CT) responsible for the photoreduction. Quantum yields for the formation of copper(I) as a function of irradiating wavelength and copper(II) halide concentration show that $[Cu(CH_3OH)_5Cl]^+$ and $[Cu(CH_3OH)_4Cl_2]$ have identical photoreaction efficiency, while $[Cu(CH_3OH)_4Br_2]$ is more photoreactive than $[Cu(CH_3OH)_5Br]^+$. In the copper(II) chloride system the chloride-to-copper(II) CT band centered around 272 nm appears to be responsible for the photoreaction, while the bromide-to-copper(II) CT band centered around 245 nm effects the photoreaction in copper(II) bromide system.

Qualitative aspects of the photochemistry of copper(II) salts in organic solvents have been investigated[1] since 1804. We have reported recently the quantitative aspects of the photoredox chemistry of copper(II) perchlorate in methanolic medium;[2] the primary photoprocess is the homolytic cleavage of copper(II)–methanol bond caused by the broad methanol-to-copper(II) charge-transfer absorption with λ_{max} at 235±2 nm. Kochi[3] employed copper(II) chloride in the chlorination of organic compounds. The primary photoprocess was proposed to be the redox reaction of chloro complexes of copper(II), forming copper(I) and Cl atoms. The present work deals with the quantitative aspects of the photoredox chemistry of chloro and bromo complexes of copper(II) in methanolic medium.

Experimental

Copper(II) perchlorate (Alfa Inorganics) was purified by recrystallization from hot water and dried under vacuum. Copper(II) chloride, copper(II) bromide, lithium chloride, and lithium bromide were reagent grade chemicals (BDH) and were dried under vacuum before use. Methanol and methyl methacrylate were purified by published procedures.[4]

Gross irradiations, from which no quantum yield data were desired, were carried out in a Rayonet photochemical reactor fitted with RPR 3500 Å lamps. Photochemical irradiations, from which quantum yields were to be determined, were performed with a Hanovia 901C-1 150 W xenon lamp dispersed through a Bausch and Lomb 33-86-40 monochromator. Intensity reductions were accomplished by Baird-Atomic neutral density filters. Samples were irradiated in a 1-cm rectangular cell (volume 4.5 cm^3) fitted with ground joint and teflon stopper. The cell was thermostated at 25±0.1 °C by circulating water through the cell holder from a constant-temperature water bath. All methanolic copper(II) solutions were deaerated by bubbling oxygen-free dry nitrogen. Manipulations of methanol and methanolic solutions were carried out in a dry box in an oxygen-free dry-nitrogen atmosphere.

Source intensities were measured by potassium trioxalatoferrate(III) actinometry.[5] Copper(I) was determined spectrophotometrically as the $[Cu(dmp)_2]^+$ complex (dmp=2,9-dimethyl-1,10-phenanthroline) which has a characteristic absorption maximum at 450 nm (ε=7530 $dm^3\ mol^{-1}\ cm^{-1}$ in methanol). A large excess of dmp was always employed. Absorption due to $[Cu(dmp)_2]^{2+}$ at 450 nm (ε=150 $dm^3\ mol^{-1}\ cm^{-1}$ in methanol) was taken into consideration in computing the concentration of copper(I). Formaldehyde formed during the photolysis was determined by the published procedure.[2] Techniques utilized in chemical scavenging experiments with methyl methacrylate have been described.[6]

Results and Discussion

Irradiation of methanolic solutions of copper(II) chloride and copper(II) bromide at 350 nm resulted in the formation of copper(I) and formaldehyde as the products, the concentration of formaldehyde being always half of that of copper(I). At this wavelength the predominant light absorbing species are the halo complexes of copper(II). The results obtained are shown in Table 1. These results are identical to those reported earlier by us for the photolysis of methanolic solution of copper(II) perchlorate[2] in which the photoactive species is $[Cu(CH_3OH)_6]^{2+}$. However, the photopolymer obtained in the radical scavenging experiments using methyl methacrylate yielded positive tests for both the hydroxyl and halogen end

All the concentrations are in mol dm^{-3}. Wavelength of irradiation 350 nm. Time of irradiation was adjusted to maintain the photolysis between 5—10% of the initial copper(II) concentration. Copper(II) halide concentrations before the photolysis are indicated. Asterisks indicate copper(II) chloride solutions and the others copper(II) bromide.

groups for the chloride and bromide salts.[7] As the concentration of methyl methacrylate was increased (at constant initial concentration of 0.001 mol dm^{-3} for the copper(II) halides) the concentration of OH end group decreased, while the concentration of halogen end group increased. At [methyl methacrylate]> 0.1 mol dm^{-3}, the concentration of halogen end groups was large and unaffected by further increases in the concentration of methyl methacrylate, while the concentration of OH end group was virtually zero. These results indicate that the halogen atoms are produced in the primary photoreaction and the $\cdot CH_2OH$ radicals[8] are formed as product of secondary reactions of halogen atoms with methanol. If $\cdot CH_2OH$ were a primary product, with X$\cdot$ being formed *via* scavenging of $\cdot CH_2OH$ by X^-, the opposite result would be expected. The observation suggests instead that methyl methacrylate and methanol are competitive scavengers of halogen atoms. Hence, we suggest the homolytic cleavage of Cu(II)-X producing Cu(I) and X$\cdot$ as the primary photoprocess. The halogen atom may reoxidize copper(I) to copper(II) or may be scavenged by CH_3OH yielding $\cdot CH_2OH$ and HX. It has been reported that the principal reaction of the radical $\cdot CH_2OH$ is reduction of copper(II) leading to copper(I) and formaldehyde.[2] This is in agreement with the present result $[Cu^+]/[CH_2O]=2.0$ (Table 1). The following Eqs. may summarize the above observations.

$$CuX^+(\text{or } CuX_2) \xrightarrow{h\nu} [Cu^+\cdot X] \quad (\text{or } [CuX\cdot X]) \quad (1)$$

$$[Cu^+\cdot X](\text{or } [CuX\cdot X]) \longrightarrow Cu^+ + \cdot X \quad (\text{or } Cu^+ + X^- + \cdot X) \quad (2)$$

$$\cdot X + CH_3OH \longrightarrow \cdot CH_2OH + HX \quad (3)$$

$$\cdot CH_2OH + Cu^{2+} \longrightarrow Cu^+ + HCHO + H^+ \quad (4)$$

Quantum yields for the formation of copper(I) in the photoreduction of copper(II) chloride as a function of initial copper(II) chloride concentration are presented in Table 2. For [copper(II) chloride]<0.002 mol dm^{-3} the light absorption was incomplete (pathlength 1.0 cm) and was taken into account in calculating the quantum yields. Manahan and Iwamoto have shown that in methanol $[Cu(CH_3OH)_5Cl]^+$ and $[Cu(CH_3OH)_4Cl_2]$ are the predominant species.[9] The absorption spectra of these species in methanol are not known. However, the work of Baaz *et al.* has proved that in acetonitrile medium the mono- and dichlorocopper(II) complexes have nearly identical absorption spectra with absorption maximum at 310 nm.[10] We repeated the work of Baaz *et al.* in methanol medium using $Cu(ClO_4)_2$ and LiCl. Addition of LiCl to methanolic solution of $Cu(ClO_4)_2$ (5.0×10^{-4} mol dm^{-3}) gave rise to an absorption with maximum at 272 nm. This absorption centered around 272 nm increased until the ratio $[Cu(ClO_4)_2]/[LiCl]=1.0$. Further increase in LiCl concentration produced a slow and steady decrease in the absorption. This agrees with the findings of Baaz *et al.* that the mono- and dichlorocopper(II) complexes have nearly identical absorption spectra. Also the present results indicate that the molar absorptivity of the dichlorocopper(II) complex is less than that of the monochloro complex. The spectra of copper(II) chloride obtained as a function of concentration corroborate the above observations. An increase in ε for the band centered around 272 nm is observed upto a copper(II) chloride concentration 3.0×10^{-4} mol dm^{-3}. Further increase in concentration showed a decrease in these ε values. This indicates that $[Cu(CH_3OH)_6]^{2+}$ and $[Cu(CH_3OH)_5Cl]^+$ are at equilibrium at concentrations of copper(II) chloride $\leq3.0\times10^{-4}$ mol dm^{-3}, while $[Cu(CH_3OH)_5Cl]^+$ and $[Cu(CH_3OH)_4Cl_2]$ are at equilibrium for higher concentrations of copper(II) chloride. The constancy of the quantum yields for the concentration range $1.0\times10^{-4}-2.0\times10^{-3}$ mol dm^{-3} (Table 2) indicates that the monochloro and the dichlorocopper(II) complexes have nearly identical photoreduction efficiency. This behavior is different from that observed for the photoreduction of copper(II) bromide (see below). The decrease in quantum yields for concentrations higher than 2.0×10^{-3} mol dm^{-3} (Table 2) is probably a consequence of depth effect,[2] or reoxidation of copper(I) by Cl_2^- radicals. Increase in the concentration of copper(II) chloride increases the concentration of free Cl^- which may compete with methanol in scavenging Cl atoms. The Cl_2^- species may reoxidize copper(I) with consequent reduction in quantum yield, or may be scavenged by methanol producing $\cdot CH_2OH$ and HCl. However, the final products and the ratio $[Cu^+]/[CH_2O]$ will be unaffected by these reactions. Quantum yield for the formation of copper(I) as a function of irradiating wavelength (Fig. 1) indicate that a charge-transfer band centered around 272 nm is, in fact, responsible for the photoreduction of copper(II) in methanolic solution of copper(II) chloride.

Photoredox chemistry of copper(II) bromide does not parallel that of copper(II) chloride. Quantum yields as a function of initial concentration of copper(II) bromide (Table 3) show that higher concentrations are more effective. The quantum yield values in the concentration range 5.0×10^{-5} to 5.0×10^{-4} mol dm^{-3} are similar to those reported for the photoreduction of copper(II) perchlorate in methanol.[2] A substantial

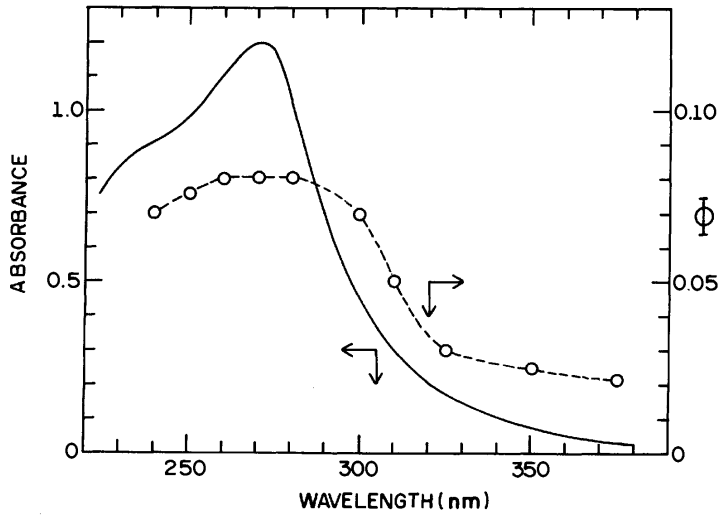

Fig. 1. Electronic absorption spectrum of 5.0×10^{-4} mol dm^{-3} copper(II) chloride in methanol (continuous line), and the variation of quantum yield for the formation of copper(I) as a function of irradiating wavelength (broken line). Initial copper(II) chloride concentration employed for the irradiations was 5.0×10^{-4} mol dm^{-3}.

increase in the quantum yields occurs for [copper(II) bromide]>8.0×10^{-4} mol dm^{-3}. We have reported recently[11] that only $[Cu(CH_3OH)_6]^{2+}$, $[Cu(CH_3OH)_5Br]^+$, and $[Cu(CH_3OH)_4Br_2]$ are important in methanolic medium at low concentrations of copper(II) (3.0×10^{-4} mol dm^{-3}) and [LiBr] up to 0.1 mol dm^{-3}. In methanol the monobromo and dibromo complexes of copper(II) have distinctly different spectra and, hence, their formation can be identified.[11] Spectral identification of the monobromo- and dibromocopper(II) complexes in methanolic solutions of copper(II) bromide was carried out in the concentration range 5.0×10^{-5}—8.0×10^{-3} mol dm^{-3}. A graph of molar absorptivity *vs.* wavelength showed an increase in molar absorptivity for $\lambda>235$ nm and a decrease for $\lambda<235$ nm with an isosbestic point at 235 nm in the concentration range 5.0×10^{-5}—5.0×10^{-4} mol dm^{-3}. In agreement with our earlier work[11] this result shows an equilibrium involving $[Cu(CH_3OH)_6]^{2+}$ and $[Cu(CH_3OH)_5Br]^+$. For concentrations higher than 5.0×10^{-4} mol dm^{-3} a general increase in molar absorptivity was observed for all wavelengths in the range 400—220 nm, the increases being larger for $\lambda<290$ nm. These results indicate the increasing formation of $[Cu(CH_3OH)_4Br_2]$ at the expense of the other two species when the [copper(II) bromide]>5.0×10^{-4} mol dm^{-3}. The increase in quantum yields for [copper(II) bromide]>8.0×10^{-4} mol dm^{-3} shows that $[Cu(CH_3OH)_4Br_2]$ is more photoactive than the other two species. Also a quantum yield which exceeds unity indicates that the deactivation reactions are less efficient in the photolysis of $[Cu(CH_3OH)_4Br_2]$ in comparison to that of $[Cu(CH_3OH)_5Br]^+$. The principal deactivation processes may be represented by the reverse of Eq. 1 (primary cage recombination) and the reoxidation of copper(I) by ·X (secondary recombination) represented by Eq. 5.

$$Cu^+ + \cdot X \xrightarrow{X^-} CuX^+(\text{or } CuX_2) \qquad (5)$$

Since for every copper(I) ion formed photochemically (Eq. 1) another copper(I) is formed thermally (Eq. 4), a quantum yield of 2.0 is attainable if Eqs. 1—4 represent entirely the photoreaction and the ensuing thermal reactions. However, the fact that this value is not attained experimentally indicates the importance of deactivation processes.

The nearly identical quantum yield values for the photoreduction of copper(II) perchlorate and copper(II) bromide in the concentration range 5.0×10^{-5}—5.0×10^{-4} mol dm^{-3} (compare this work with the results of Ref. 2) may indicate either that $[Cu(CH_3OH)_6]^{2+}$ and $[Cu(CH_3OH)_5Br]^+$ have nearly identical photoreduction efficiency or $[Cu(CH_3OH)_5Br]^+$ is photochemically inactive. The former seems more plausible. Since $[Cu(CH_3OH)_5Br]^+$, which is in equilibrium with $[Cu(CH_3OH)_6]^{2+}$ at this concentration range, is respon-

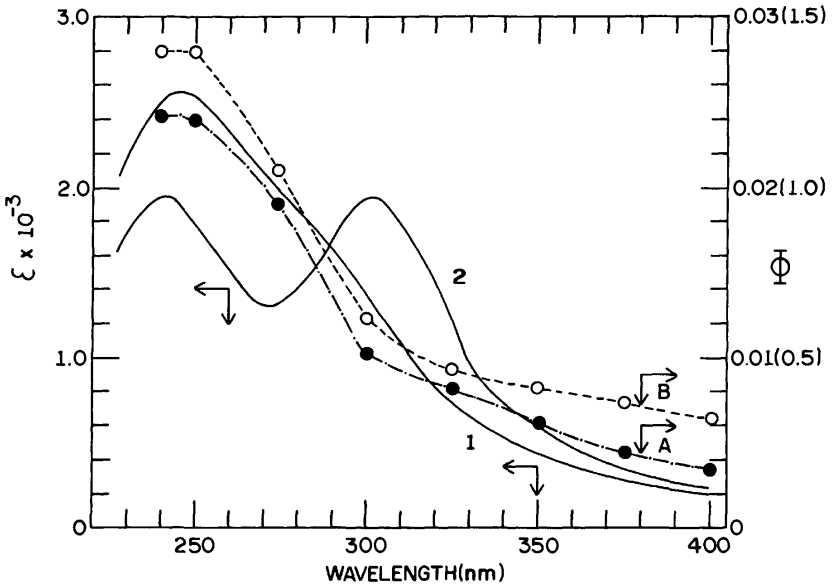

Fig. 2 Electronic absorption, spectra of $[Cu(CH_3OH)_5Br]^+$ and $[Cu(CH_3OH)_4Br_2]$ (1 and 2, respectively) in methanol, and variation of quantum yields as a function of irradiating wavelength (A and B). Curve A is for an initial concentration of copper(II) bromide 8.0×10^{-4} mol dm^{-3} and curve B for 5.0×10^{-2} mol dm^{-3}. The numbers in parentheses (right ordinate scale) are for curve B.

sible for the absorption of a significant part of the incident light its photoinertness could signify a reduction in quantum yield in comparison to that of copper(II) perchlorate solution in which the only light absorbing species is $[Cu(CH_3OH)_6]^{2+}$. Hence, the nearly identical quantum yields in the two solutions signify, quite probably, that the two species, $[Cu(CH_3OH)_6]^{2+}$ and $[Cu(CH_3OH)_5Br]^+$, have nearly identical photoreduction efficiency. The decrease in quantum yield for copper(II) bromide concentrations higher than 5.0×10^{-2} mol dm^{-3} is similar to that observed for copper(II) chloride solutions and, hence, could be the consequence of depth-effect,[2] or reoxidation of copper(I) by Br_2^- radicals.[2,12] Quantum yields as a function of irradiating wavelength (Fig. 2) shows that charge-transfer transitions occurring at wavelengths below 300 nm is in fact responsible for the photoreduction. This points to $[Cu(CH_3OH)_4Br_2]$ as the photoactive species which has the CT band centered around 245 nm.

A plausible explanation for the difference in the photoreactivities of $[Cu(CH_3OH)_5Br]^+$ and $[Cu(CH_3OH)_4Br_2]$ is that the Cu–Br distances are different in the two species. Barnes and Day[13] have showed that an increase in the internuclear distance increases the energy of the charge-transfer transition. Hence, the high energy charge-transfer transition in the dibromo complex (Fig. 2) may signify a longer Cu–Br bond in this compound in comparison to that of the monobromo complex.[14] This could mean a larger distance between Cu(I) and ·Br in the excited state of the dibromo complex and, hence, could render their separation more efficient (and cage-recombination less probable) leading to an increase in the product quantum yield.

14) The bromide-to-copper(II) CT transition is centered around 300 nm in the monobromo complex; the band centered around 240 nm could be methanol-to-copper(II) CT band. The absorption centered around 245 nm in the dibromo complex represents, quite probably, two CT bands (bromide-to-copper and methanol-to-copper) superimposed one over the other.

New Amino-protective Reagents for *t*-Butoxycarbonylation and Benzyloxycarbonylation of Amines and Amino Acids

Sunggak Kim,* Jae In Lee, and Kyu Yang Yi
Department of Chemistry, Korea Advanced Institute of Science and Technology, Seoul 131, Korea
(Received September 11, 1984)

New amino-protective reagents for *t*-butoxycarbonylation and benzyloxycarbonylation of amines and amino acids have been developed. *t*-Butyl 2-pyridyl carbonate and *t*-butyl *S*-(2-pyridyl) thiocarbonate react cleanly with various amines and amino acids to afford *N*-Boc amines and *N*-Boc amino acids in high yields. Benzyl 2-pyridyl carbonate and *O*-benzyl *S*-(2-pyridyl) thiocarbonate are also found to be very effective in the benzyloxycarbonylation of amino acids.

The *t*-butoxycarbonyl (Boc) group is one of the most important amino-protective groups along with benzyloxycarbonyl (Cbz) group in peptide synthesis because the *t*-butoxycarbonyl group is cleanly cleaved by cold trifluoroacetic acid, hot formic acid, or hydrochloric acid and *N*-Boc amino acids are resistant to racemization during peptide synthesis.[1] Since *t*-butyl chloroformate is only fairly stable below 10 °C,[2] considerable efforts have been devoted to the development of a variety of useful and reliable reagents for the preparation of *N*-Boc amino acids during last 30 years.[3] In view of the great importance of the *t*-butoxycarbonyl group in peptide synthesis, a great need still exists for an efficient and stable reagent for the *t*-butoxycarbonylation of amines and amino acids.

Since it has been found that *S*-(2-pyridyl) thioates and 2-pyridyl esters are very useful active esters as acylating agents in the synthesis of peptides,[4] ketones,[5] and carboxylic esters,[6] we have been interested in the utilization of 2-pyridyl ester moieties for the *t*-butoxycarbonylation and the benzyloxycarbonylation of amino acids. Recently, we have communicated that *t*-butyl 2-pyridyl carbonate (BPC) is very effective in the *t*-butoxycarbonylation of amino acids.[7] The present paper describes a full detail of (i) the preparation of BPC, *O*-*t*-butyl *S*-(2-pyridyl) thiocarbonate (BPT), benzyl 2-pyridyl carbonate (BZBC), and *O*-benzyl *S*-(2-pyridyl) thiocarbonate (BZPT) and (ii) their use for the *t*-butoxycarbonylation and the benzyloxycarbonylation of amines and amino acids.

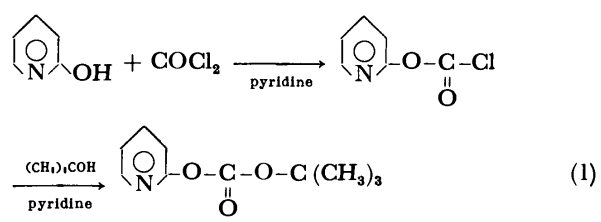
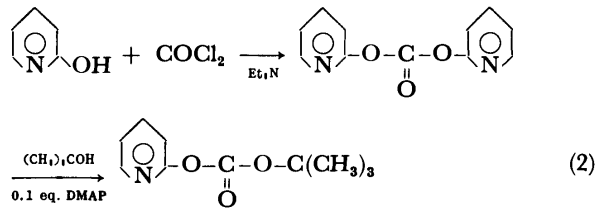
Results and Discussion

t-Butyl 2-Pyridyl Carbonate (BPC). BPC was originally prepared by the reaction of 2-pyridyl chloroformate, generated from an excess amount of phosgene and 2-pyridinol in the presence of pyridine, with equimolar amounts of *t*-butyl alcohol and pyridine in dichloromethane at room temperature and obtained in 65—70% yield along with a small amount of di-2-pyridyl carbonate (Eq. 1). In order to avoid the formation of di-2-pyridyl carbonate, we attempted to isolate 2-pyridyl chloroformate but it decomposed rapidly during usual workup, yielding 2-pyridinol as a major product. Thus, di-2-pyridyl carbonate was removed by filtration through a short column of silica gel with dichloromethane as an eluant. Recently, we have found that BPC can be prepared by the reaction of di-2-pyridyl carbonate[8] with an equimolar amount of *t*-butyl alcohol in the presence of 0.1 equiv of 4-dimethylaminopyridine[9] in dichloromethane at room temperature for 24 h in 80% yield. Di-2-pyridyl carbonate was conveniently prepared in 90% yield by treatment of phosgene with 2 equiv of 2-pyridinol in the presence of 2 equiv of triethylamine in dichloromethane (Eq. 2).



(1)

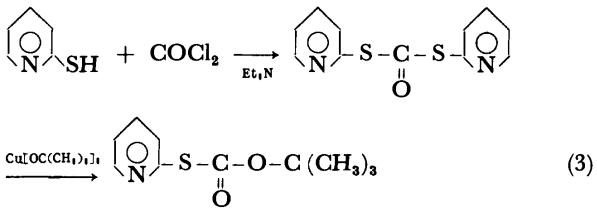


(2)

O-t-Butyl S-(2-Pyridyl) Thiocarbonate (BPT). The preparation of BPT was turned out to be very difficult. First, we adopted a similar scheme utilized in the preparation of BPC. (2-Pyridylthio)carbonyl chloride was prepared by a known procedure.[10] Unexpectedly, reaction of (2-pyridylthio)carbonyl chloride with equimolar amounts of *t*-butyl alcohol and triethylamine did not give the desired product. Instead *S*,*S*-di(2-pyridyl) dithiocarbonate was isolated in an essentially quantitative yield. Furthermore, the reaction of (2-pyridylthio)carbonyl chloride with equimolar amounts of *t*-butyl alcohol and pyridine did not occur to an observable extent, though the similar type of a reagent, *O*-*t*-butyl *S*-(4,6-dimethyl-2-pyrimidinyl) thiocarbonate, has been prepared in a high yield by use of pyridine as a base in a similar manner.[11]

Recently, we have found that *S*-(2-pyridyl) thioates are rapidly and cleanly esterified with alcohols in the presence of copper(II) bromide in acetonitrile.[6c] Thus, reaction of *S,S*-di(2-pyridyl) dithiocarbonate, which was prepared in 91% yield by the reaction of phosgene with 2 equiv of 2-pyridinethiol in the presence of 2 equiv of triethylamine in dichloromethane, with *t*-butyl alcohol in the presence of 1 equiv of copper(II) bromide in acetonitrile at room temperature was attempted. However, a desired product was not obtained. Furthermore, on the basis of a previous result obtained with BPC, we attempted the reaction of *S,S*-di(2-pyridyl) dithiocarbonate with equimolar amounts of *t*-butyl alcohol and 4-dimethylaminopyridine. However, the reaction did not proceed to an observable extent in dichloromethane, tetrahydrofuran, or *N,N*-dimethylformamide (DMF) at room temperature for 5 h.

Finally, we were able to prepare BPT by treatment of *S,S*-di(2-pyridyl) dithiocarbonate with 0.5 equiv of copper(II) *t*-butoxide in tetrahydrofuran at room temperature for 2 h (Eq. 3). BPT was obtained in 79%



(3)

yield as a relatively stable oily compound. Attempts to crystallize the product were failed.

Benzyl 2-Pyridyl Carbonate (BZPC) and O-Benzyl S-(2-Pyridyl) Thiocarbonate (BZPT). BZPC was easily prepared in 80% yield as an oil by the reaction of benzyl chloroformate with equimolar amounts of 2-pyridinol and triethylamine in dichloromethane (Eq. 4). Similarly, BZPT was prepared in a high yield from equimolar amounts of benzyl chloroformate and 2-pyridinethiol in the presence of triethylamine in dichloromethane and obtained as an oil (Eq. 4).

X = O or S

t-*Butoxycarbonylation of Amines and Amino Acids.* First, reaction of BPC with a variety of structurally different amines was examined. Simple amines such as propylamine, benzylamine, and piperidine were rapidly and quantitatively converted into the corresponding *t*-butyl carbamates in dichloromethane at room temperature within 2 h. However, the *t*-butoxycarbonylation of sterically hindered secondary amines such as diisopropylamine and 2,6-dimethylpiperidine, and relatively unreactive amines like aniline did not occur in dichloromethane to an observable extent, even after forcing conditions such as prolonged stirring at elevated temperatures. Thus, proper conditions to effect the *t*-butoxycarbonylation of sterically hindered amines were studied. Among the solvents employed, acetonitrile and DMF gave the best results in terms of the rapidity and the yield of the reaction and are generally recommended, though DMF is considered to be slightly better than acetonitrile. Reaction of diisopropylamine with BPC in DMF at 80 °C for 48 h afforded *N*-(*t*-butoxycarbonyl)diisopropylamine in 83% yield, whereas the reaction in acetonitrile at 80 °C required 60 h for completion of the reaction. Similarly, aniline was converted into *N*-(*t*-butoxycarbonyl)-aniline in high yields in DMF or acetonitrile at 80 °C. The *t*-butoxycarbonylation of imidazole and benzimidazole with BPC in DMF or acetonitrile did not occur under forcing conditions. The results obtained with several amines are summarized in Table 1.

In order to find out optimum conditions for the *t*-butoxycarbonylation of amino acids with BPC, we briefly examined the effects of bases, solvents, and reaction time by use of L-phenylalanine as a model compound. With aqueous DMF as the solvent, the effect of four bases was briefly examined at room temperature and it was found that the yield of Boc–Phe was the highest using 1.5 equiv of triethylamine (96% isolated yield): Sodium hydrogencarbonate (75%), sodium carbonate (72%), and sodium hydroxide (70%), though the reason for these results are unclear. However, the *t*-butoxycarbonylation proceeded much more rapidly with sodium hydroxide (1 h for complection of the reaction): sodium carbonate (5 h), sodium hydrogencarbonae (16 h), and triethylamine (12 h). Although aqueous DMF and aqueous dioxane were found to be equally effective in the *t*-butoxycarbonylation of amino acids, the reaction occurred more rapidly in aqueous DMF than in aqueous dioxane. For example, the reaction of L-phenylalanine with equimolar amounts of BPC in the presence of 1.5 equiv of triethylamine in aqueous DMF at room temperature afforded *N*-Boc–Phe in 96% yield in 12 h, whereas the reaction in aqueous dioxane required 16 h. The pronounced difference in the reaction rate was observed in L-leucine. The reaction in aqueous DMF required 4 h for completion of the reaction, whereas the reaction in aqueous dioxane required 16 h.

On the basis of these results obtained, the standard conditions employed for the *t*-butoxycarbonylation of amino acids with BPC involved the use of 1.5 equiv of triethylamine and aqueous DMF at room temperature. As shown in Table 2, the *t*-butoxycarbonylation of various amino acids used in this study was normally complete within 12 h at room temperature and the corresponding *N*-Boc amino acids were isolated in high yields. The identities of

a) Mp and $[\alpha]_D$ values of the known compounds were within the limit of error in comparison with the reported data and $[\alpha]_D$ values were measured at room temperature (15—25 °C). See Refs. 3, 11, and 12 for the reported data. b) Dicyclohexylammonium salt. c) Monohydrate.

N-Boc amino acids were confirmed by comparison of mp, NMR, and IR data and $[\alpha]_D$ values with reported data.[12] Furthermore, it is noteworthy that a by-product, water-soluble 2-pyridinol, can be easily removed from the reaction mixture by simple aqueous workup.

The *t*-butoxycarbonylation using BPT was performed on several amino acids under the similar conditions employed in the *t*-butoxycarbonylation of amino acids using BPC. In general, the reaction occurred smoothly but somewhat slowly in aqueous DMF at room temperature, when compared with reaction using BPC. Some experimental results are summarized in Table 2. It is noteworthy that 2-pyridinethiol, generated from the reaction, can be easily removed from the reaction mixture by washing with aqueous $CuSO_4$ solution. However, di-2-pyridyl disulfide was sometimes formed to some extent due to oxidation of 2-pyridinethiol during the reaction and it was removed by column chromatographic separation in such cases. In comparison with BPC, BPT has several disadvantages over BPC with respects to the difficulty of its preparation, an oily nature of BPT, and workup procedures.

Benzyloxycarbonylation of Amino Acids. Although benzyl chloroformate has been widely used for the preparation of *N*-Cbz amino acids, it is thermally unstable and decomposes to yield carbon dioxide and benzyl chloride when it is stored at room temperature over a long period of time. In view of

a) Mp and $[\alpha]_D$ values of the known compounds were within the limit of error in comparison with the reported data and $[\alpha]_D$ values were measured at room temperature (15—25 °C). See Refs. 3c and 13 for the reported data. b) Dicyclohexylammonium salt.

encouraging results obtained with BPC, we turned our attention to BZPC and BZPT for the introduction of benzyloxycarbonyl group in amino acids under mild conditions. Thus, the reaction of BZPC and BZPT with several amino acids was briefly examined under similar conditions employed for the *t*-butoxycarbonylation of amino acids with BPC and the results are summarized in Table 3.[13]

It was found that the benzyloxycarbonylation with BZPC and BZPT proceeded much faster than the *t*-butoxycarbonylation with BPC. The reaction was normally complete within 0.5 h in aqueous DMF at room temperature and the corresponding *N*-Cbz amino acids were isolated in excellent yields.

Experimental

NMR spectra were recorded with a Varian T-60A spectrometer, and chemical shifts are expressed as δ units relative to tetramethylsilane. Infrared spectra were recorded on a Perkin-Elmer 267 and the frequences are given in reciprocal centimeters. Melting points were determined on an Electrothermal melting point apparatus and are uncorrected. Reported boiling points are those observed during distillation with a Kugelrohr apparatus and uncorrected. Optical rotations were measured with an automatic polarimeter AUTOPOL III. Elemental analysis were performed by Korea Research Institute of Chemical Technology and Lucky Central Research Institute.

Commercially available amines and amino acids were used without further purification and all amino acids used in this study were L-configuration.

Since the reactions performed are all similar in many respects, typical reactions will be described as specific examples.

Di-2-pyridyl Carbonate. To a diluted solution of phosgene (2.5 M† in toluene, 2 ml, 5.0 mmol) with dichloromethane (8 ml) at 0 °C was added a solution of 2-pyridinol (950 mg, 10 mmol) and triethylamine (1.214 g, 10.2 mmol) in dichloromethane (20 ml). The reaction mixture was stirred at 0 °C for 1 h, washed with cold 5% $NaHCO_3$ (20 ml), cold saturated NaCl (20 ml), dried over $MgSO_4$ and filtered. The filtrate was concentrated to dryness to give di-2-pyridyl carbonate (972 mg) in 90% yield. Di-2-pyridyl carbonate could be recrystallized from dichloromethane–petrolem ether (811 mg, 75%). Mp 84—86 °C. NMR($CDCl_3$) δ=7.10—7.46 (m, 4H), 7.64—8.00 (m, 2H), 8.36—8.52 (m, 2H); IR(KBr) 1770 cm^{-1}. Found: C, 61.03; H, 3.45; N, 13.15%. Calcd for $C_{11}H_8O_3N_2$: C, 61.11; H, 3.73; N, 12.96%.

t-Butyl 2-Pyridyl Carbonate (BPC). *A*: The procedure using 2-pyridyl chloroformate is as follows. To a diluted solution of phosgene (2.5 M in toluene, 20 ml, 50 mmol) with dichloromethane (20 ml) at −10—0 °C was slowly added a solution of 2-pyridinol (951 mg, 10 mmol) and pyridine (870 mg, 11 mmol) in dichloromethane (40 ml). After being stirred at −10—0 °C for 15 min, excess phosgene and solvents were evaporated under reduced pressure and then the residue was dissolved with dichloromethane (30 ml). A solution of *t*-butyl alcohol (815 mg, 11 mmol) and pyridine (830 mg, 10.5 mmol) in dichloromethane (20 ml) was added to the flask at room temperature. The reaction mixture was stirred at room temperature for 5 h and diluted with dichloromethane (30 ml). The resulting solution was washed with saturated $NaHCO_3$ (30 ml) and brine (30 ml), dried over $MgSO_4$, and evaporated to dryness under reduced pressure. The crude product was purified by filtration through a short column of silica gel using dichloromethane as an eluant to afford *t*-butyl 2-pyridyl carbonate (1.37 g, 70%). The product could be recrystallized from hexane. Mp 48—49 °C. NMR($CDCl_3$) δ=1.60 (s, 9H), 7.00—7.39 (m, 2H), 7.62—7.97 (m, 1H), 8.30—8.50 (m, 1H); IR(KBr) 1755 cm^{-1}. Found: C, 62.13; H, 6.86; N, 6.98%. Calcd for $C_{10}H_{13}O_3N$: C, 61.53; H, 6.71; N, 7.17%.

B: The procedure using di-2-pyridyl carbonate is as follows. To a stirred solution of di-2-pyridyl carbonate (1.08 g, 5.0 mmol) in dichloromethane (15 ml) at room temperature were added *t*-butyl alcohol (370 mg, 5.0 mmol) and 4-dimethylaminopyridine (61 mg, 0.5 mmol) and stirring was continued at room temperature for 24 h. The reaction mixture was diluted with dichloromethane (30 ml), washed with saturated NH_4Cl (30 ml) and brine (20 ml), dried over $MgSO_4$, and concentrated to dryness. The crude product was purified by filtration through a short column of silica gel using dichloromethane as an eluant to afford *t*-butyl 2-pyridyl carbonate (780 mg, 80%).

S,S-Di(2-pyridyl) Dithiocarbonate. To a solution of 2-pyridinethiol (1.112 g, 10 mmol) and triethylamine (1.02 g, 10 mmol) in dichloromethane (40 ml) at 0 °C was slowly added a solution of phosgene (2.5 M in toluene, 2 ml, 5 mmol). After being stirred at 0 °C for 1 h, the reaction mixture was washed with saturated $NaHCO_3$ (30 ml) and brine (30 ml), dried over $MgSO_4$, and evaporated to

† 1 M=1 mol dm^{-3}.

dryness to afford the desired product (1.13 g) in 91% yield as an oil. The crude product was pure enough using for further reactions. NMR($CDCl_3$) δ=6.66—6.97 (m, 2H), 7.10—7.33 (m, 4H), 8.03—8.30 (m, 2H); IR(film) 1715 cm^{-1}. Found: C, 53.31; H, 3.13; N, 11.42%. Calcd for $C_{11}H_8ON_2S_2$: C, 53.21; H, 3.25; N, 11.28%.

O-t-Butyl S-(2-Pyridyl) Thiocarbonate (BPT). To a solution of *t*-butyl alcohol (371 mg, 5 mmol) in tetrahydrofuran (7 ml) at 0°C under nitrogen was added butyllithium (1.6 M in hexane, 3.2 ml, 5 mmol). After being stirred at 0°C for 10 min, the solution was added to the suspended solution of copper(II) bromide (560 mg, 2.5 mmol) in tetrahydrofuran (4 ml) and the resulting mixture was stirred at room temperature for 0.5 h. To a solution of *S,S*-di(2-pyridyl) dithiocarbonate (1.24 g, 5 mmol) in tetrahydrofuran (4 ml) at 0°C was added a solution of copper(II) *t*-butoxide and the resulting solution was allowed to warm to room temperature with stirring for 2 h. After the reaction mixture was evaporated to dryness, the residue was dissolved in dichloromethane (40 ml). The dichloromethane solution was washed with saturated NH_4Cl (30 ml) and brine (30 ml), dried over $MgSO_4$, and concentrated. The residue was subjected to silica-gel column chromatography with hexane-ethyl acetate (2:1) as an eluent to affors *O-t*-butyl *S*-(2-pyridyl) thiocarbonate (834 mg) in 79% yield as an oil. NMR ($CDCl_3$) δ=1.66 (s, 9H), 7.13—7.40 (m, 1H), 7.64—7.81 (m, 2H), 8.47—8.64 (m, 1H); IR(film) 1730 cm^{-1}. Found: C, 56.29; H, 6.43; N, 6.53%. Calcd for $C_{10}H_{13}O_2NS$: C, 56.85; 6.20; N, 6.63%.

Benzyl 2-Pyridyl Carbonate (BZPC). To a solution of benzyl chloroformate (1.71 g, 10 mmol) in dichloromethane (10 ml) at 0°C was added a solution of 2-pyridinol (1.00 g, 10.5 mmol) and triethylamine (1.06 g, 10.5 mmol) in dichloromethane (20 ml). After being stirred at room temperature for 1 h, the reaction mixture was diluted with dichloromethane (30 ml) and washed with saturated NH_4Cl (20 ml) and brine (20 ml). The dichloromethane solution was dried over $MgSO_4$ and evaporated to give benzyl 2-pyridyl carbonate (2.20 g, 96%). The crude product was purified by filtration through a short column of silica gel with ethyl acetate-hexane (1:3) as an eluant to give benzyl 2-pyridyl carbonate (1.83 g) in 80% yield as an oil. NMR($CDCl_3$) δ=5.32 (s, 2H), 7.00—7.39 (m, 2H), 7.41 (b.s, 5H), 7.61—7.96 (m, 1H), 8.30—8.50 (m, 1H); IR(film) 1750 cm^{-1}. Found: C, 68.40; H, 4.89; N, 5.69%. Calcd for $C_{13}H_{11}O_3N$: C, 68.12; H, 4.84; N, 6.11%.

O-Benzyl S-(2-Pyridyl) Thiocarbonate (BZPT). To a solution of benzyl chloroformate (1.71 g, 10 mmol) in dichloromethane (10 ml) at 0°C was added a solution of 2-pyridinethiol (1.17 g, 10.5 mmol) and triethylamine (1.06 g, 10.5 mmol) in dichloromethane (20 ml). After being stirred at room temperature for 1 h, the reaction mixture was diluted with dichloromethane (30 ml) and washed with saturated NH_4Cl (20 ml) and brine (20 ml). The dichloromethane solution was dried over $MgSO_4$ and evaporated to dryness. The residue was purified by filtration through a short column of silica gel with ethyl acetate-hexane (1:3) as an eluant to afford *O*-benzyl *S*-(2-pyridyl) thiocarbonate (2.06 g) in 84% yield as an oil. NMR($CDCl_3$) δ=5.29 (s, 2H), 7.09—7.32 (m, 1H), 7.34 (b.s, 5H), 7.57—7.82 (m, 2H), 8.42—8.63 (m, 1H); IR(film) 1720 cm^{-1}. Found: C, 63.93; H, 4.38; N, 6.04%. Calcd for $C_{13}H_{11}O_2NS$: C, 63.66; H, 4.52; N, 5.71%.

Preparation of N-Boc-Benzylamine. To a stirred solution of benzylamine (215 mg, 2.0 mmol) in dichloromethane (6 ml) at room temperature was added BPC (391 mg, 2.0 mmol). The reaction mixture was stirred at room temperature for 2 h, diluted with dichloromethane (30 ml), and washed with saturated $NaHCO_3$ (20 ml). The dichloromethane solution was dried over $MgSO_4$ and evaporated to dryness. The residue was recrystallized from dichloromethane-petroleum ether to give *N*-Boc-benzylamine (390 mg) in 95% yield. Mp 53—54°C (lit,[3a] 53—54°C); NMR($CDCl_3$) δ=1.50 (s, 9H), 4.30 (d, 2H, *J*=6 Hz), 4.64—5.31 (m, 1H), 7.28 (b.s, 5H); IR (KBr) 1680 cm^{-1}.

Preparation of N-Boc-2,6-Dimethylpiperidine. To a stirred solution of 2,6-dimethylpiperidine (115 mg, 1.0 mmol) in DMF (4 ml) at room temperature was added BPC (200 mg, 1.0 mmol). The reaction mixture was stirred at 80°C for 36 h, diluted with diethyl ether (30 ml), and washed with saturated $NaHCO_3$ (20 ml) and water (20 ml). The aqueous layer was extracted with diethyl ether (30 ml×2). The combined ether extracts were dried over $MgSO_4$ and evaporated to dryness. The curde product was distilled to give *N*-Boc-2,6-dimethylpiperidine (173 mg, 81%): Bp 102—108°C/38.5 mm Hg[†]); NMR ($CDCl_3$) δ=1.25 (d, 2H, *J*=7 Hz), 1.54 (s, 9H), 1.38—2.00 (m, 6H), 4.04—4.63 (m, 2H); IR(film) 1690 cm^{-1}. Found: C, 67.35; H, 10.62; N, 6.40%. Calcd for $C_{12}H_{12}O_2N$: C, 67.57; H, 10.87; N, 6.57%.

Preparation of N-Boc-Proline. *(A) BPC Method:* To a solution of L-proline (230 mg, 2.0 mmol) in DMF-water (2:1, 12 ml) was added triethylamine (303 mg, 3.0 mmol). After the reaction mixture was stirred at room temperature for 10 min, BPC (392 mg, 2.0 mmol) was added and the resulting mixture was stirred at room temperature for 6 h. The reaction mixture was adjusted to pH 3.5 by addition of 0.025 M oxalic acid and extracted with dichloromethane (30 ml×3). The dichloromethane solution was washed with water (20 ml) and brine (20 ml), dried over $MgSO_4$, and evaported to dryness *in vacuo* to give *N*-Boc-proline (424 mg, 98%) as a syrup, which can be crystallized from ethyl acetate-petroleum ether. Mp 133—135°C (lit,[3c] 136—137°C); $[\alpha]]_D$ −60.7° (0.9, AcOH, 20°C) [lit,[3c] $[\alpha]_D$ −60.57° (0.974, AcOH, 25°C)].

(B) BZPC Method: To a solution of L-proline (232 mg, 2.0 mmol) and triethylamine (303 mg, 3.0 mmol) in DMF-water (1:1, 8 ml) was added a solution of BZPC (423 mg, 2.0 mmol) in DMF (2 ml). The reaction mixture was stirred at room temperature for 4 h, acidified with 0.025 M oxalic acid (pH 3.5), and extracted with ethyl acetate (30 ml×3). The extracts were washed with saturated $CuSO_4$ (20 ml×2) and brine (30 ml), dried over $MgSO_4$, and evaporated to dryness *in vacuo*. The residue was crystallized from ethyl acetate-petroleum ether to give *N*-Boc-proline (408 mg, 95%). Mp 134—135°C; $[\alpha]_D$ −61.0° (0.7, AcOH, 18°C).

Preparation of N-Cbz-Phenylalanine. To a solution of L-phenylalanine (330 mg, 2.0 mmol) and triethylamine (301 mg, 3.0 mmol) in DMF-water (1:1, 8 ml) was added a solution of BZPT (492 mg, 2.0 mmol) in DMF (2 ml). The reaction mixture was stirred at room temperature for 0.5 h, acidified with 0.025 M oxalic acid (pH 3.5) and extracted with ethyl acetate (30 ml×3). The combined extracts were washed with saturated $CuSO_4$ (20 ml×2) and brine (20 ml), dried over $MgSO_4$, and evaporated to dryness. The crude product was crystallized from dichloromethane-petroleum ether to give *N*-Cbz-phenylalanine (534 mg, 89%). Mp 86—88°C (lit,[3c] 86—87°C); $[\alpha]_D$ +5.4° (0.4, AcOH, 20°C) [lit, [3c] $[\alpha]_D$ +5.54° (0.361, AcOH, 18°C)]. In the case of using BZPC, the com-

[†]1 mmHg=133.322 Pa.

bined extracts were washed with water and brine. Otherwise, the experimental procedure is almost same as described above.

Spectral Data of N-*Boc Amines.* *N*-Boc-propylamine: Bp 65—70 °C/38 mmHg; NMR ($CDCl_3$) δ=1.00 (t, 3H, J=6 Hz), 1.56 (s, 9H), 1.25—1.94 (m, 2H), 3.06 (q, 2H, J=6 Hz), 4.50—5.07 (m, 1H); IR (film) 1700 cm^{-1}. *N*-Boc-diethylamine: Bp 74—76 °C/38 mmHg; NMR ($CDCl_3$) δ=1.25 (t, 6H, J=7 Hz), 1.57 (s, 9H), 3.26 (q, 4H, J=7 Hz); IR (film) 1690 cm^{-1}. *N*-Boc-piperidine: Bp 92—95 °C/38 mmHg; NMR ($CDCl_3$) δ=1.50 (s, 9H), 1.40—1.76 (m, 6H), 3.12—3.58 (m, 4H); IR (film) 1685 cm^{-1}. *N*-Boc-di-*s*-butylamine: Bp 92—95 °C/38 mmHg; NMR ($CDCl_3$) δ=0.85 (t, 3H, J=7 Hz), 1.28 (s, 6H), 1.50 (s, 9H), 1.53 (q, 2H, J=7 Hz), 4.19—4.63 (m, 1H); IR (film) 1705 cm^{-1}. *N*-Boc-aniline: Mp 133—135 °C (lit,[14] 135.5—138 °C); NMR ($CDCl_3$) δ=1.60 (s, 9H), 6.49—7.40 (m, 6H); IR (KBr) 1685 cm^{-1}. *N*-Boc-4-aminopyridine: Mp 139—142 °C; NMR ($CDCl_3$) δ=1.56 (s, 9H), 7.25—7.50 (m, 2H), 8.06—8.80 (m, 3H); IR (KBr) 1715 cm^{-1}. Found: C, 61.88; H, 7.47; N, 14.15%. Calcd for $C_{10}H_{14}O_2N_2$: C, 61.84; H, 7.27; N, 14.42%. *N*-Boc-diisopropylamine: Bp 70—75 °C/26 mmHg; NMR ($CDCl_3$) δ=1.20 (d, 12H, J=7 Hz), 1.51 (s, 9H), 3.40—4.10 (m, 2H); IR(film) 1685 cm^{-1}. *N*-Boc-*N*-isopropylcyclohexylamine: Bp 95—100 °C/48 mmHg; NMR ($CDCl_3$) δ=1.22 (d, 6H, J=6 Hz), 1.54 (s, 9H), 1.60—2.14 (m, 10H), 3.33—4.02 (m, 2H); IR (film) 1680 cm^{-1}. Found: C, 69.65; H, 11.87; N, 5.60%. Calcd for $C_{14}H_{27}O_2N$: C, 69.67; H, 11.27; N, 5.80%.

Refractive Indices, Dielectric Constants, and Order Parameter of Four Alkyl/Alkoxyphenylcyclohexanecarboxylate Liquid Crystals in the Nematic Phase

Krishnakali KALI, Sushmita SEN, and Subir Kumar ROY*
Optics Department, Indian Association for the Cultivation of Science, Jadavpur, Calcutta-700032, India
(Received October 2, 1984)

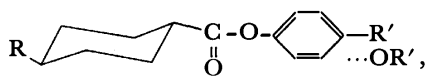
The extraordinary and ordinary refractive indices, n_e and n_o, and the densities of four liquid crystals 4-pentylphenyl *trans*-4′-pentylcyclohexanecarboxylate, 4-ethoxyphenyl *trans*-4′-propylcyclohexanecarboxylate, 4-ethoxyphenyl *trans*-4′-butylcyclohexanecarboxylate, and 4-methoxyphenyl *trans*-4′-pentylcyclohexanecarboxylate have been reported at different temperatures. The effective polarizabilities α_e and α_o in the nematic phase have been calculated using 1) Neugebauer and 2) Vuks methods. The order parameter S calculated from the two methods were comparable. The dielectric constants $\varepsilon_\parallel$ and $\varepsilon_\perp$, parallel and perpendicular to the long axis of the molecules have been measured at 1 kHz at different temperatures. The order parameters for the liquid crystals were then evaluated from dielectric anisotropy $\Delta\varepsilon(=\varepsilon_\parallel-\varepsilon_\perp)$, polarizability anisotropy $\Delta\alpha(=\alpha_e-\alpha_o)$ and dipole moment μ, using Maier and Meier equation and were found only slightly less than those obtained from refractive indices method. It was concluded that Maier and Meier equation also could be used to evaluate the order parameter of liquid crystals of molecules having dipole moments 2 Debye or less.

The knowledge of dielectric constants $\varepsilon_\parallel$ and $\varepsilon_\perp$, parallel and perpendicular to the long molecular axis helps us to select a liquid crystal for a specific electrooptical display device. The values of dielectric anisotropy $\Delta\varepsilon(=\varepsilon_\parallel-\varepsilon_\perp)$ and polarizability anisotropy $\Delta\alpha(=\alpha_e-\alpha_o)$ where α_e and α_o are the effective polarizabilities of the nematic medium and the dipole moment μ may be useful for the evaluation of order parameter of liquid crystals using Maier and Meier equation.[1] de Jeu and Lathouwers[2,3] observed that in the case of liquid crystals with zero or small dipole moment, the average dielectric constant $\bar{\varepsilon}=1/3\,(\varepsilon_\parallel+2\varepsilon_\perp)$ practically coincides with the dielectric constant ε_{iso} in the isotropic phase. They pointed out that these results indicate that the Maier and Meier equation gives qualitatively the correct picture of dielectric properties of liquid crystals. But for the lack of information on molecular polarizabilities, dipole moments, and their angle with the long molecular axis, the model could not be tested for quantitative measurements. Recently Sen *et al.*[4] observed that in the case of liquid crystals of strongly polar molecules having dipole moments of 4—5 Debye,† the order parameter S obtained from Maier and Meier equation using dielectric anisotropy and polarizability anisotropy are much less than the values obtained from other methods. Sen *et al.*[4] pointed out that the short range antiferroelectric dipole correlation of permament dipole moment μ in strongly polar nematics as proposed by Madhusudana and Chandrasekhar[5] might cause a large decrease in $\varepsilon_\parallel$ thus decreasing the order parameter. The object of the present investigation is to evaluate the order parameter S of liquid crystals with dipole moments about 2 Debye from the measurements of refractive indices and densities, and to compare these S values with those obtained from dielectric anisotropy $\Delta\varepsilon$ and polarizability anisotropy $\Delta\alpha$, using the Maier and Meier equation.[1]

†1D=3.3×10^{-30}cm.

Experimental

The structural formulae and nematic-isotropic transition temperatures of four liquid crystals which were obtained from Merck are given below. The general formula for these compounds is



where R and R′=Alkyl and OR′=Alkoxy.

1) 4-Pentylphenyl *trans*-4′-pentylcyclohexanecarboxylate (D-55)

$$C \xrightarrow{37^\circ C} N \xrightarrow{47^\circ C} I$$

2) 4-Ethoxyphenyl *trans*-4′-propylcyclohexanecarboxylate (D-302)

$$C \xrightarrow{48^\circ C} N \xrightarrow{78^\circ C} I$$

3) 4-Ethoxyphenyl *trans*-4′-butylcyclohexanecarboxylate (D-402)

$$C \xrightarrow{37^\circ C} N \xrightarrow{75^\circ C} I$$

4) 4-Methoxyphenyl *trans*-4′-pentylcyclohexanecarboxylate (D-501)

$$C \xrightarrow{40^\circ C} N \xrightarrow{71^\circ C} I$$

The liquid crystals were used in the investigations without further purification.

Measurement of Refractive Indices. The refractive indices n_o and n_e for the ordinary and extraordinary refracted rays in the nematic phase and the refractive index n in the isotropic phase at different temperatures were measured by means of an Abbe refractometer. The glass prisms of the refractometer were first treated with an aqueous solution of 3% poly (vinyl alcohol) and dried. The prism was then rubbed with a lens paper along the length of prism several times. A little of the liquid crystal was dropped on the lower prism

and was spread with a spatula. These operations helped to align the liquid crystal along the length of the prism surface. The arrangement was complete when the upper prism was clamped in place.

Two positions of a nicol placed over the eyepiece allow distinct separation of bright and dark space corresponding to n_e and n_o (in the nematic $n_e > n_o$). The temperature was maintained constant within ±0.2°C by means of a thermostat.

The densities of the liquid crystal in the nematic and isotropic phases were determined by introducing a weighed sample of the liquid crystal into a capillary tube placed in a thermostat. The length of the column in the capillary was measured at different temperatures with a travelling microscope. The density was calculated after correcting for the expansion of the glass tube.

Measurements of Dielectric Constants $\varepsilon_{\parallel}$ and $\varepsilon_{\perp}$. The static dielectric constants were measured at a frequency of 1 kHz using a GR-1620 capacitance bridge reading to an accuracy of 0.01%. A parallel plate capacitor with stainless steel electrodes of 2 cm×1 cm separated by a 1 mm teflon spacer, served as the sample holder. The temperature of the sample was measured with a thermocouple mounted directly on one of the electrodes. A magnetic field 1.0 T was used to align the liquid crystal molecules parallel and perpendicular to the electrode surfaces. The temperature of the sample holder was maintained constant within ±0.2°C by means of a thermostat. The cell was calibrated with freshly distilled toluene and chlorobenzene and the values agree to 0.1% of the standard value.[6]

Results

Refractive Indices and Polarizabilities. The experimental values of refractive indices n_e, n_o, and n and the densities of the liquid crystals are given in Tables 1 (a, b, c, d) and Fig 1. The effective polarizabilities α_e and α_o in the nematic state were calculated using two methods. 1) Neugebauer's[7] method of anisotropic internal field given by

$$n_{e,c}^2 - 1 = 4\pi N\alpha_{e,c}/(1 - N\alpha_{e,c}\gamma_{e,o}), \quad (1)$$

where N is the number of molecules per 1 cm³ and $\gamma_{e,o}$ are internal field constants. The relevant equations for calculating the polarizabilities are

$$\frac{1}{\alpha_e} + \frac{2}{\alpha_o} = \frac{4\pi N}{3}\left[\frac{n_e^2+2}{n_e^2-1} + \frac{2(n_o^2+2)}{(n_o^2-1)}\right], \quad (2)$$

$$\alpha_e + 2\alpha_o = \alpha_{//} + 2\alpha_{\perp} = \frac{9}{4\pi N}\left(\frac{n^2-1}{n^2+2}\right). \quad (3)$$

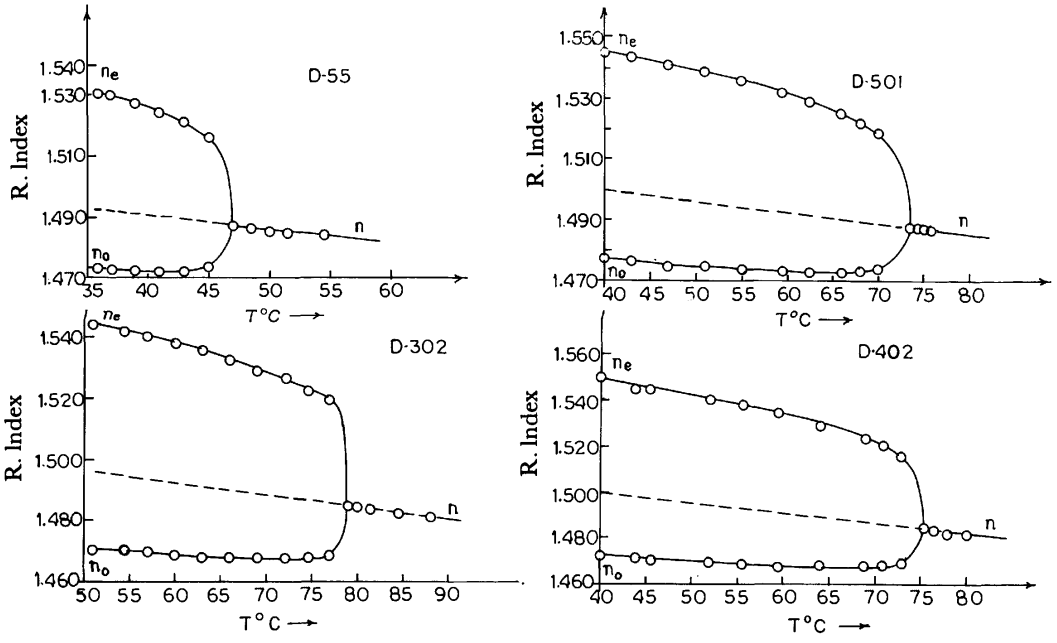

Fig. 1. Refractive index anisotropy plots for D-55, D-501, D-302, and D-402.

2) Vuks'method[8] of isotropic internal field given by

$$\frac{n_{e,o}^2-1}{\overline{n^2}+2}=\frac{4\pi N\alpha_{e,o}}{3}, \quad (4)$$

where $\overline{n^2}=1/3\ (n_e^2+2n_o^2)$.

The values of effective polarizabilities α_e and α_o obtained from the two methods are included in Tables 1 (a, b, c, d). Since the principal polarizabilities $\alpha_\parallel$ and $\alpha_\perp$, parallel and perpendicular to the long axis of the molecules in the crystalline state, were not available, the method of Haller *et al.*[9] was adopted. Graphs were plotted with $\log \alpha_e/\alpha_o$ *vs.* $\log (T_c-T)$ where T_c is the nematic-isotropic transition temperature. These plots are straight lines at lower temperatures and intersect the $\log \alpha_e/\alpha_o$ axis at 0 K assumed to correspond to $\log \alpha_\parallel/\alpha_\perp$ in the crystalline state. From Eq. 3 the values of $\alpha_\parallel$ and $\alpha_\perp$ are obtained. The order parameter S was then calculated from the relation $S=\alpha_e-\alpha_o/\alpha_\parallel-\alpha_\perp$.

Dielectric Constants $\varepsilon_\parallel$ and $\varepsilon_\perp$ and the Order Parameter. The experimental values of dielectric constants $\varepsilon_\parallel$ and $\varepsilon_\perp$ of the liquid crystals in nematic state and that in the isotropic phase ε_{iso} are given in Table 2. The dielectric anisotropy is shown in Fig. 2. The order parameter was calculated using the Maier and Meier equation,[1]

$$\Delta\varepsilon=4\pi NhF\left[\Delta\alpha-\frac{F\mu^2}{2kT}(1-3\cos^2\beta)\right]S, \quad (5)$$

where N is the number of molecules per 1 cm^3, $h=3\overline{\varepsilon}/(2\overline{\varepsilon}+1)$, the cavity field factor, $F=1/(1-\overline{\alpha}f)$, the reaction field factor, and $f=4\pi N(2\overline{\varepsilon}-2)/3(2\overline{\varepsilon}+1)$, μ the dipole moment of the molecule, $\Delta\alpha$=polarizability anisotropy $=\alpha_e-\alpha_o$, and $\Delta\varepsilon=\varepsilon_\parallel-\varepsilon_\perp$ dielectric anisotropy.

The dipole moments μ of the liquid crystal molecules were determined in dilute solutions in benzene and included in Table 2. The angle between the resultant moment and the long axis of the molecules of the liquid crystals (β) was calculated from the alkoxyl

group moment and ester group moment reported in the literature.[10] The angle β for the different samples is given in Table 2.

Discussion

It can be seen from Tables 1 (a, b, c, d) that the order parameters S for the liquid crystals under study, obtained from the refractive indices using 1) Neugebauer and 2) Vuks methods are comparable. The S value decreases with increase of temperature till it suddenly vanishes at the clearing temperature. The order parameters for these liquid crystals have not been reported so far.

From Fig. 2, it can be seen that the average dielectric constants $\bar{\varepsilon}=(\varepsilon_{\parallel}+2\varepsilon_{\perp})/3$ in the nematic phase practically coincide with the dielectric constants ε_{iso} in the isotropic phase. These results are similar to those reported by de Jeu[3] in the case of liquid crystals of very small or zero dipole moment but unlike to the case of liquid crystals having large dipole moment (μ=4—5 Debye) of which the average dielectric constant ε_{iso} in the isotropic phase reported by different workers.[11,12]

From Table 2, it can be seen that the values of the order parameter S, calculated from the values of the dielectric anisotropy $\Delta\varepsilon$, polarizability anisotropy $\Delta\alpha$ and dipole moment μ using the Maier and Meier equation for the alkoxyphenyl *trans*-4′-alkylcyclohexanecarboxylates, compare very well at all temperatures with those obtained from refractive index methods. Similarly for alkylphenyl *trans*-4′-alkylcyclohexanecarboxylates, the order parameters S from the Maier and Meier equation also agree well with those obtained from the refractive index methods, though the former values are only slightly less than the latter. The slight discrepancy may be due to the estimation of the angle β made by the resultant moment with the long axis of the molecule. So, it appears that for liquid crystals having dipole moment of about 2D, or so, the Maier and Meier equation with dielectric anisotropy $\Delta\varepsilon$, provides another method for the determination of the order parameter.

The inapplicability of the Maier and Meier theory[1] for dielectric constants in strongly polar nematics might be due to short range antiferroelectric dipole correlation of the permament dipole moment as proposed by Madhusudana and Chandrasekhar,[5] which might cause a large decrease in $\varepsilon_{\parallel}$ in strongly polar nematics (μ>4 D); Such a decrease in $\varepsilon_{\parallel}$ in less polar nematics ($\mu\approx$2D) might not affect the dielectric anisotropy and hence the order parameter very effectively.

Of course some more liquid crystals having moments of more or less 2D should be studied before drawing definite conclutions.

Our sincere thanks to Dr. S. B. Roy for his guidance.

Studies on Double Malonates. II.† Potassium Rare Earth Malonates, $K_5Ln(C_3H_2O_4)_4$ (Ln=Gd–Ho or Y)

Mahadeo Anant NABAR* and Bharat Nilkanth JUKAR

Department of Chemistry, University of Bombay, Vidyanagari, Bombay-400 098, India

(Received May 4, 1984)

Double malonates of some of the rare earths with potassium having formula $K_5Ln(C_3H_2O_4)_4$ were synthesized. The lattice parameters of the compounds were determined by X-ray powder diffractometry. Infrared absorption spectroscopy was employed to throw some light on the nature of Ln–O bonding, while the thermoanalytical techniques were made use of in proposing the thermal decomposition mechanism of some of the double malonates.

Davitashvili and his coworkers have carried out a systematic study of the double oxalates of rare earth elements with alkali metals.[1–5] However, practically no attention has been paid to the corresponding double compounds of malonic acid — the next higher homologue of oxalic acid; the only report available in the literature being on the cerium(III) double malonates.[6] Thus, it was thought worthwhile to carry out systematic work on such type of double malonates, taking rare earths and different alkali or pseudo alkali metals.[7] The present paper, which is a part of this investigation, deals with the potassium double malonates, $K_5Ln(C_3H_2O_4)_4$, where Ln=Gd–Ho or Y.

Experimental

Synthesis. The normal rare earth malonates were precipitated by adding slowly about 14 cm^3 of aqueous potassium malonate solution (134 mg $(C_3H_2O_4)^{2-}$ cm^{-3}), to the aqueous *ca.* 0.011 M rare earth nitrate solution, with constant stirring. The precipitate obtained was filtered, washed free of nitrate ions and excess of potassium malonate, and dried over silica gel under vacuum till constant weight.

The normal rare earth malonates were dissolved in the aqueous potassium malonate solution in Ln^{3+}: $(C_3H_2O_4)^{2-}$ molar proportion of 1 : 5 since it was observed that for the molar proportions equal to 1 : 2, 1 : 3, and 1 : 4, a syrupy product was obtained on evaporation. The turbid mixture was warmed to get a clear solution, which gave the desired product when allowed to crystallize slowly over silica gel. The crystals formed were picked up from the mother liquor and were washed with 50 cm^3 of 90% methanol; dried over silica gel under vacuum and stored in a desiccator because of its hygroscopic nature. All the chemicals used were of reagent grade quality.

It is interesting to note here that although the normal rare earth malonates and potassium malonate were mixed in the Ln^{3+}: $(C_3H_2O_4)^{2-}$ mole ratio as 1 : 5, the synthesized compounds were in the mole ratio 1 : 4.

Chemical Analysis. The rare earth contents of the double malonates were determined complexometrically. The potassium percentage was determined flame photometrically.

The malonate contents were determined using ion-exchange technique. Since the compounds tend to hydrolyse on dissolving in water, known volume of dilute hydrochloric acid was used for dissolution. The sample solution was passed through a cation exchanger (Seralite SRC 120) in hydrogen form (washed free of excess acid used for regeneration) at a rate of 2—3 cm^3min^{-1}. As the malonate ion gets adsorped on the strongly acidic sulphonated resin,[8] the column was eluted with 100—150 cm^3 of hot deionised water (363—373 K), to facilitate the complete desorption of the anion. The rate of flow of the effluent was 6—7 cm^3min^{-1} while washing the column with hot water so as to keep the resin warm throughout. The eluate thus obtained contains the malonic acid (equivalent to the malonate ion in the compound) plus the hydrochloric acid used for dissolution. This eluate was titrated with standard sodium hydroxide solution. The hydrochloric acid used for the dissolution was determined by following the same procedure as used for the sample solution so as to compensate for procedural errors. The reading corresponding to malonic acid was obtained by subtracting the reading corresponding to hydrochloric acid from the total reading for the eluate. The analytical results are given in Table 1.

Table 1. Results of chemical analysis of $K_5Ln(C_3H_2O_4)_4$

Ln	K/%		Ln/%		$C_3H_2O_4$/%

Instrumentation. Nickel filtered Cu $K\alpha$ radiation (mean λ=154.18 pm), operated on Philips X-ray diffractometer model No. PW 1009/30-NRD 1023, was used for the X-ray powder diffraction study. The relative intensities of the reflexions were calculated by taking that of the highest peak as 100.

The densities of the double malonates were determined by floatation method, using bromoform–hexane mixture as the working medium.

The densities of the double malonates were determined by malonates, were made in the frequency range 4000—400 cm^{-1} with a Perkin-Elmer model 377, by CsBr disc method; while the spectra of some of the intermediates obtained by isothermally heating the original compound, were scanned on Beckman IR-4250 spectrophotometer in the frequency range 4000—200 cm^{-1} using KBr pellet technique.

The TG and DTG curves of the gadolinium and holmium double malonates were scanned on a sophisticated Mettler Recording Vacuum Thermoanalyser (No. 84), in dry air, with a flow rate of 100 cm^3min^{-1}. A Pt/Pt–Rh thermocouple

was used for temperature detection. The samples were heated in an alumina crucible of volume 0.5 cm^3, at a rate of 10 K min^{-1}. The DTA curves were obtained with the help of an instrument fabricated in this laboratory.[7]

Results and Discussion

X-Ray Diffraction Study. The X-ray powder patterns for the present compounds show that the compounds are isomorphous. On analyzing with Ito's method,[9] the double malonates were found to possess a monoclinic symmetry, with two molecules per unit cell. The systematic absence of reflexes ($0k0 : k=2n+1$), suggests that the probable space group is $P2_1/m$ or $P2_1$. The lattice parameters were refined by least squares method. The unit cell dimensions and the other relevant data are given in Table 2. The decrease in unit cell volumes is not regular as is normally expected. The cell dimension "c" decreases from gadolinium to holmium linearly with decrease in ionic radii, but such regular decrease in "a" and "b" is not observed. The complete indexed data of dysprosium double malonate are given in Table 3, as a representative.

Infrared Spectroscopic Studies. The double malonates are isomorphous and hence expectedly their infrared spectra exhibit similar patterns (Fig. 1). The assignments for the various bands are based on the earlier reports.[6,10,11]

A very strong band at ≈1585 cm^{-1} and a strong one at ≈1380 cm^{-1} have quite easily been assigned to the

asymmetric and symmetric stretching vibrations of OCO group, respectively. It can be seen that these frequencies in case of the double malonates have shifted to higher and lower values, respectively, as against the corresponding frequencies in potassium malonate[10] (1563 and 1405 cm^{-1}), suggesting an increase in the covalent nature of Ln–O bond. A band with medium intensity at $\approx$780 cm^{-1} and the one with a strong intensity at $\approx$710 cm^{-1}, are probably due to OCO deformation vibrations.

The C–H stretching vibrations are observed as two very weak bands in the region 3000—2900 cm^{-1}. Strong bands at $\approx$1440 and $\approx$1260 cm^{-1} are attributed to CH_2 bending and wagging modes, respectively.

A weak broad absorption is observed in the OH stretching region, probably due to the moisture absorbed by these hygroscopic compounds.

Thermoanalytical Investigation. In order to get the insight of the thermal decomposition mechanism, the double malonates of gadolinium and holmium were subjected to the thermoanalytical investigation as representatives of the series. The corresponding thermal curves are reproduced in Figs. 2 and 3. The thermoanalytical data are given in Table 4.

The anhydrous nature of the double malonates is reflected in non observance of the dehydration stage on the thermal curves; and the decomposition of both the compounds commences at 543 K. The breaks corresponding to the formation of an intermediate of probable composition $K_{10}Ln_2O(CO_3)_3(OCOCHOCO)_4$ are observed on the TG curves at 613 and 623 K for gadolinium and holmium compounds, respectively. Formation of such a type of intermediate has also been reported in the thermal decomposition of lanthanum malonate pentahydrate.[12] It is apparent from the TG and DTG curves of both the double malonates that the decomposition of holmium compound to $K_{10}Ho_2O(CO_3)_3(OCOCHOCO)_4$ is a two stage process, the first one involving formation of $K_{10}Ho_2O(CO_3)_{1.5}(OCOCHOCO)_{5.5}$, whereas the corresponding two stages in case of gadolinium double malonate are probably overlapped. The non observance of the first stage on the TG and DTG curves of gadolinium compound can probably be due to the comparatively larger amount of the sample taken in this case (57.77 mg as against 25.9 mg of holmium double malonate). A very sharp exotherm observed at 578 K on the DTA curve of holmium double malonate can be attributed to the formation of the first stage intermediate, $K_{10}Ho_2O(CO_3)_{1.5}(OCOCHOCO)_{5.5}$. From the analogy with

the holmium compound, a similar sharp exotherm at 588 K in case of gadolinium compound can be accounted for the formation of a similar intermediate.

The intermediate $K_{10}Ln_2O(CO_3)_3(OCOCHOCO)_4$, decompose exothermically to give $K_{10}Ln_2O_2(CO_3)_{2.5}$-$(OCOCHOCO)_{3.5}$ in the temperature range 613—743 and 623—723 K, in case of gadolinium and holmium compounds, which in turn decompose to give mixture of respective rare earth oxide and potassium carbonate, at temperatures 1023 and 983 K, respectively. The endothermic effect observed at 873 K on the DTA curve of gadolinium compound is probably due to the final decomposition; however, the corresponding effect in case of holmium double malonate is not easily discernible. The endothermic activities observed at about 1153 K in case of both the compounds are probably due to the melting of potassium carbonate formed (mp of K_2CO_3 is 1174 K[13]).

The following mechanism can thus be proposed for the decomposition of the double malonates:

$$2K_5Ln(C_3H_2O_4)_4 \longrightarrow K_{10}Ln_2O(CO_3)_{1.5}(OCOCHOCO)_{5.5} \longrightarrow K_{10}Ln_2O(CO_3)_3(OCOCHOCO)_4 \longrightarrow K_{10}Ln_2O_2(CO_3)_{2.5}(OCOCHOCO)_{3.5} \longrightarrow 5K_2CO_3 + Ln_2O_3$$

The holmium double malonate heated isothermally at 550 K (21 % loss), on qualitative analysis indicated the presence of carbonate. The infrared spectra of the

intermediate (Fig. 4a) exhibits no bands ascribable to CH_2 wagging mode, indicating the absence of malonate group. A very weak band, however, is detected at $\approx 3000\ cm^{-1}$, suggesting the presence of CH group. These observations support the assumption that the (OCOCHOCO) group is present in the intermediate. The intermediate obtained was contaminated with free carbon which might have formed due to the disproportionation of liberated CO, as has been suggested earlier in the study of lanthanum oxalate.[14]

The spectrum of the final decomposition product exhibits the bands characteristic of potassium carbonate and holmium sesquioxide (Fig. 4b).

The authors are indebted to Mr. P. V. Adarkar for extending the spectral facility and to the Director, Tata Institute of Fundamental Research, Bombay, for the X-ray facility. We are also thankful to Mr. Chakraborty, Radiochemistry Division, B.A.R.C., for the facility of Mettler Thermo Analyser. One of the authors (B.N.J.) is grateful to the University of Bombay for financial assistance.

Effects of Solvents and pH on the Spectral Behavior of 2-(*p*-Aminophenyl)benzimidazole

Ashok Kumar MISHRA and Sneh Kumar DOGRA*

Department of Chemistry, Indian Institute of Technology, Kanpur-208016, U.P., India

(Received May 4, 1984)

The absorption and fluorescence spectra in different solvents and at various pH have indicated that monocation and dication of 2-(*p*-aminophenyl)benzimidazole ($PBNH_2$) are formed by protonating first the tertiary amine nitrogen atom and then the amino group, both in S_0 and S_1, whereas the monoanion in S_0 is obtained by deprotonating the imino group but in S_1, it is formed by deprotonating the amino group. Dianion at H_15 in S_1 is obtained by deprotonating the amino and then imino group.

The spectral shift, shape of the spectral band, Stokes' shift *etc.* depend upon the geometry of the molecule in the ground and excited states, the nature and the position of functional group in the molecule and nature of solvents.[1] In case of biphenyl,[2] S_1 state is relatively more planar than S_0 and large Stokes' shift has been attributed to this change in the geometry on excitation and broad absorption band involving overlapping of two transitions. The presence of groups, like alkyl, amino, vinyl, and phenyl, at the para position shift the long wavelength band towards red and make the molecule a little more planar.[3,4] The presence of these groups at the ortho position shift the spectra towards blue unless the biphenyl molecule along with the substituents form a rigid planar molecule. Similarly in case of 2-phenylnaphthalene,[5] the Stokes' shift of 1770 cm^{-1} is attributed both to the phenyl group rotation and solvent stabilization.

Recently our study on 2-phenylbenzimidazole (PBI)[6] has shown that the Stokes' shift is quite small ($\approx$324 cm^{-1}), indicating that this molecule is planar or nearly planar in S_0 and S_1 states. The presence of amino group in the ortho position of 2-phenyl-substituted benzimidazole leads to a rigid molecule, formed through the intramolecular hydrogen bonding, thus leading to two four-membered ring systems.[7a] The present study of 2-(*p*-aminophenyl)benzimidazole ($PBNH_2$) was carried out to study the above-mentioned effects and the changes observed in the absorption and fluorescence spectra in different solvents and at various pH. The equilibrium constants of various prototropic reactions are calculated both in S_0 and S_1 states.

Experimental

$PBNH_2$ was prepared by heating an equimolar mixture of *o*-phenylenediamine and *p*-aminobenzoic acid at 250 °C, as described in literature[8] and purified further by recrystallization from ethanol. The purity was checked by getting similar fluorescence maxima when excited with different excitation wavelengths. BDH spectrograde methanol, analytical grade sulfuric acid and sodium hydroxide were used as such. Analytical grade acetonitrile (E. Merck), cyclohexane, ether, dioxane, heptane (BDH), and ethanol were further purified by methods described in literature.[9] Triply distilled water was used for the preparation of aqueous solutions. A modified Hammett's acidity scale[10] (H_0) for H_2SO_4–H_2O mixture and Yagil's[11] basicity scale (H_-) for NaOH-H_2O mixture were used for the solutions below pH 1 and above pH 13 respectively.

Absorption spectra were recorded in a Cary 17-D spectrophotometer. Fluorescence spectral measurements were carried out on a recording spectrofluorometer, fabricated in our laboratory and details are described elsewhere.[12] The band width of excitation radiation is 8 mn and both the monochromators are calibrated, from time to time with low pressure mercury lamp. pH in the range 1—13 were measured on a Toshniwal pH meter, model CL-44A. The concentrations of the solutions were of the order of 10^{-5} to 10^{-4} M†. Quinine sulfate in 0.1 M H_2SO_4[13] was taken as the standard for measuring quantum yields, and wavelength used for excitation was 315 nm. The solutions for absorptiometric and fluorimetric titrations were prepared just before the measurements. In fluorimetric titrations, isosbestic wavelengths were used for excitation of different species. The values for dication–monocation, monocation–neutral and neutral–monoanion are 295, 320, and 315 nm respectively.

Results and Discussion

Effect of Solvents on Absorption and Fluorescence Spectra. The absorption and fluorescence spectra of $PBNH_2$ were observed in solvents of different polarity and of hydrogen bond formation tendency. The former is shown in Fig. 1 and the latter in Fig. 2. The absorption maxima, log ε_{max} (except in heptane where the saturated solution was used) are listed in Table 1, whereas the fluorescence maxima and fluorescence quantum yields are listed in Table 2. The two normal band systems of benzimidazole molecule (278, 272 nm, L_b; 243 nm, L_a) are kept intact except that both are red shifted (333, 318 nm, L_b; 277, 268, 258 nm, L_a) and the third band system, λ_{max} (abs) $\approx$207 nm is also observed. The L_b band system is similar to that of benzimidazole, but the structure is lost and is also red shifted as the polarity of the solvent increases except in water, where the broad band is red shifted with respect to heptane but blue shifted with respect to methanol and acetonitrile, the latter being a weakly hydrogen accepting solvent. The behavior of the 207 nm band system is similar to that of L_b one under the similar environments. Whereas the structure of L_a band system also undergoes the similar changes as the L_b one, the band maxima is regularly blue shifted.

The data of Table 2 indicate that the fluorescence spectrum of $PBNH_2$ is nicely structured in less polar solvents and can be explained by the vibrational frequency of $\approx$1450 cm^{-1} in S_0 state. The fluorescence

† 1 M = 1 mol dm^{-3}.

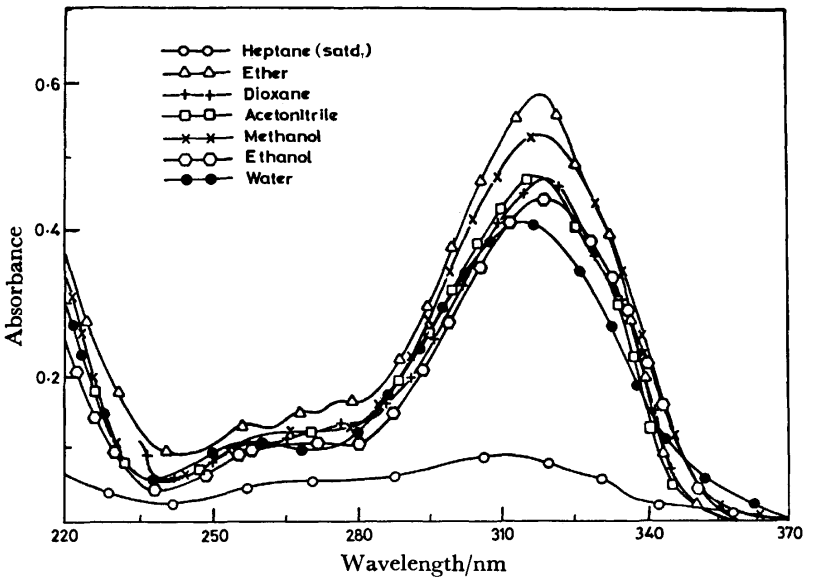

Fig. 1. Absorption spectra of $PBNH_2$ in various solvents at 298 K. (concn 2.5×10^{-5} M)

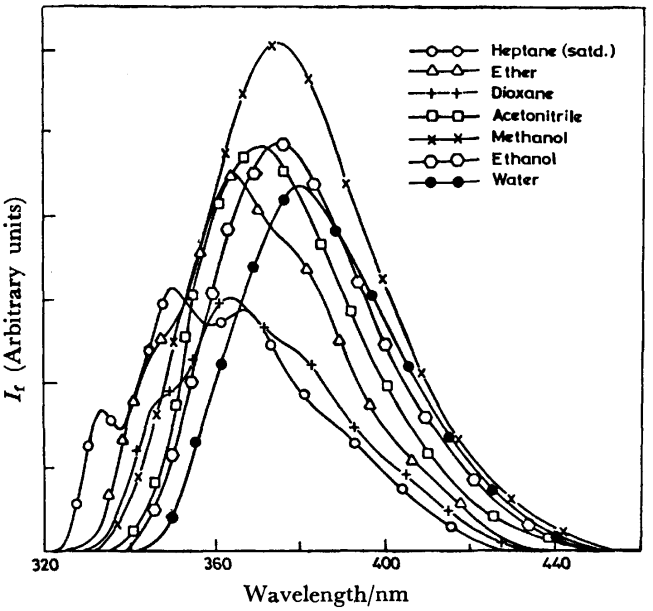

Fig. 2. Fluorescence spectra of $PBNH_2$ in various solvents at 298 K. (concn 2.5×10^{-5} M)

spectrum of $PBNH_2$ is similar to that of 2-phenylbenzimidazole (PB)[6] and the vibrational frequency in $PBNH_2$ is nearly equal to that observed in PB ($\approx$1500 cm^{-1}). The 0-0 band in the fluorescence spectrum of $PBNH_2$ in heptane can be assigned to the shortest wavelength band of 334 nm. Structure of the band is lost and the band is regularly red-shifted with the increase in the polarity and hydrogen bond formation tendency of solvents, but this effect was not as large as observed for 2-(*m*-aminophenyl)benzimidazole.[7b] The fluorescence quantum yield of $PBNH_2$ increases under the similar conditions in contrast to PB[6] (for this compound the quantum yield remains nearly constant *i.e.* 0.12+0.01 for these solvents), 2-(*m*-aminophenyl)benzimidazole ($MBNH_2$, in this case the quantum yield decreases from 0.146 to 0.08 for solvents ranging from heptane to water) and is even slightly larger than that of benzimidazole in ethanol[14] (0.7). Another fluorescence band is observed at long-wavelength (maximum at 500 nm) and its intensity is much smaller than that of short-wavelength fluorescence band, however the ratio (I_{382}/I_{500}) remains unchanged with the change in the concentration (10^{-5} to 10^{-3} M) of solute, change of solvent and pH of the solution.

It has been shown by Tway and Love[15] that the longwavelength transition in benzimidazole and 2-(4-thiazolyl)benzimidazole is of π-π^* character in non-aqueous polar solvents. Further, the absorption and fluorescence spectra of these compounds are affected by the nature of solvents although the effect is small. Similarly to other amino substituted benzimidazoles or indazoles, $PBNH_2$ also possesses two positions which can accept protons and two sites which can donate protons to the solvents. Thus the spectral shifts observed depend upon the preferential interactions of the solvents with the solute molecule. The high extinction coefficient, red shift in λ_{max} (abs) with increase in the polarity of solvents and high fluorescence yield, all confirm the π—π^* nature of the transition. The small blue shift noticed in water relative to methanol or acetonitrile tells that water is acting as better hydrogen donor solvent to the lone pair of the amino group rather hydrogen acceptor one.

Fluorescence results can also be explained exactly on the same lines. Stokes' shift [ν_{max}(abs)$-\nu_{max}$(fluo)], thought it is large, does not increase significantly with the increase in the polarity of solvents. This indicates that there is no significant change in dipole moment of $PBNH_2$ in S_1 state from that in S_0 and this could be due to the charge migration from carbocyclic ring to the heterocyclic ring, leaving some positive charge

on the carbocyclic ring, as shown below. The presence of long-wavelength fluorescence band could not be explained from this study and is still under investigation.

Effect of pH. The absorption (Fig. 3) and fluorescence spectra (Fig. 4) of $PBNH_2$ have been studied in the H_0/pH/H_- range of −9 to 16. The absorption and fluorescence maxima of various forms are reported in Tables 1 and 2 respectively. Starting with H_0 = −9, the absorption spectrum shows a long wavelength band at 295 nm. With decreasing hydrogen ion concentration, a red shifted band appears at pH 5 with λ_{max} (abs) at ≈330 nm; at pH ≈8 the absorption band appears at 310 nm; at pH 12 a structured absorption spectrum with λ_{max}(abs) at 317 nm is observed and no further change is noted in absorption spectrum after pH 13. Under the similar conditions upto pH 8, the fluorescence bands observed were at 380, 394, and 382 nm respectively and follows the same trend as observed in absorption. No extra fluorescence band is observed in the pH/H_- range of 8 to 14 besides that at 382 nm. This band is quenched at H_-=14. A new red shifted and broad fluorescence band (430 nm) starts appearing at H_-=−15 and its formation is not complete even at H_-=16, the highest basic concentration used.

Comparing the absorption and fluorescence spectra with the solvent study, 310 and 382 nm (pH 8), 340 and 394 nm (pH≈5), 295 and 380 nm (H_0≈−9) and 317 nm (pH≈12) bands could be assigned to the respective spectra of neutral, monocation, dication, and monoanion species respectively. Since the energy difference between the two observed band maxima corresponding to L_a and L_b of different species either remain nearly the same or increases with the change in hydrogen ion concentration, it can be concluded that no crossing of L_a and L_b occurs, *i.e.* the long-wavelength absorption and fluorescence bands for all of these species belong to the same electronic state (L_b).

The following trend in the absorption and fluorescence spectra is generally observed during protonation or deprotonation of heterocyclic molecules if π-π^* is the lowest energy transition: i) A blue shift in absorption and fluorescence spectra is observed on protonation of amino group and the spectra resembles with the parent molecule.[16] ii) A broad red shifted absorption and fluorescence band is noticed if the tertiary nitrogen atom is protonated[17] and iii) red shift is observed in the spectral behavior if imino or amino group is deprotonated.[18] Further, pK_a for the deprotonation of imino group in benzimidazoles is ≈12±2 whereas that for amino group is >14 and amino group becomes relatively much more acidic in S_1 state as compared to imino group.[16,19,20] The anion formed in the former case is generally fluorescent but that formed in the latter case is nonfluorescent,[19] with the exception of 2-naphtylamine,[21] iv) lastly, proton induced quenching of the fluorescence of neutral amines are generally observed at moderate hydrogen ion concentration before forming ammonium ion in S_1.[22]

With the above points in mind and the spectral behavior as shown in Figs. 3 and 4, it is clear that the monocation is formed by protonating the tertiary nitrogen atom and the dication by protonating both

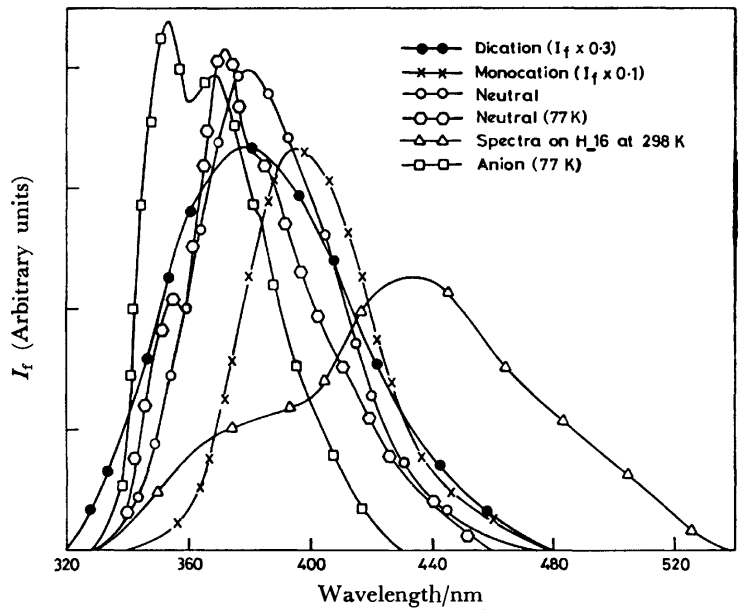

Fig. 4. Fluorescence spectra of various prototropic forms of $PBNH_2$ at 298 K and 77 K.

tertiary and primary amine nitrogen atoms, both in S_0 and S_1 states. This also agrees with the results that the pK_a value for benzimidazole molecule is nearly 5.3 and that for amino group is $\approx$4.0. Further, the λ_{max} (abs), 295 nm, of dication of $PBNH_2$ agrees nicely with the monocation of 2-phenylbenzimidazole.[6] The exact agreement may be accidental but it clearly tells that the effect of anilinium ion is similar to that of phenyl group. The ground state pK_a value for the deprotonation of imino group in benzimidazole is 13.2 and is decreased or increased further if an electron removing or electron donating group, respectively, is substituted in the parent molecule. Similar pK_a value for the deprotonation of aromatic amine is more than 14. The pK_a value of 13.0, observed for above kind of reaction in $PBNH_2$ clearly indicates that monoanion formed in S_0 state is from the deprotonation of the imino group. Further, as mentioned earlier, it has been noticed that increase in the acidity of amino group upon excitation to S_1 state is larger than that of imino group,[16,19,20] the imino anion formed by the deprotonation of amino group is nonfluorescent[19] with the exception of 2-naphthylamine,[21] whereas anion formed by the deprotonation of imino group is generally fluorescent.[18,26,27] With the above results and from our results it is clear that monoanion in S_1 state is formed by the deprotonation of amino group and not imino group as no new fluorescence spectrum was observed with the depletion of neutral $PBNH_2$ in the pH range 8—14. To substantiate this point further, the fluorescence spectrum of $PBNH_2$ at pH 12 is taken at 77 K and is shown in Fig. 4, with the data in Table 2. At

such a low temperature and in frozen state, the geometry of the species and the nature of the environments in S_1 state corresponds to that of ground state *i.e.* the species present in S_1 is the monoanion formed by the deprotonation of imino group. Though the absorption spectra of the monoanion at 77 K is not observed but the nature of vibrational mode interacting with the electronic mode obtained from the absorption spectrum at 298 K seems to be the smae as observed from the fluorescence spectrum of monoanion of $PBNH_2$ at 77 K. This will give a support to our assignment of monoanion species in S_0 and S_1 states.

The 430 nm fluorescence band, observed at 298 K and at H_15 and 16, could be assigned to the formation of dianion. This species is formed by the deprotonation of imino nitrogen atom, and is consistent with the above-mentioned conclusions. The dianion could have also been obtained by the second deprotonation of amino group but this has been rejected on the ground that the fluorescence observed from the dianion, formed by the double deprotonation of amino group in case of 9-phenanthrylamine,[23] 1- and 2-naphthylamines[28] is blue shifted, both in comparison to neutral and monoanion species whereas this one is red shifted with respect to neutral one.

The values of pK_a for various equilibria calculated spectrophotometrically are listed in Table 3. The values of pK_a^* obtained by fluorimetric titration curves (Fig. 5) as well as by Förster cycle method,[25] wherever applicable, are also listed in Table 3. These values depict the general behavior of the benzimidazoles and prove the assignment of the various species as mentioned earlier. pK^* values for monocation–neutral and neutral–monoanion equilibria are nearly equal to that for benzimidazole molecule, indicating that the presence of electron-donating amino group at the proper position of the phenyl group does not allow the phenyl group to behave as electron-withdrawing group. The results of fluorimetric titration curves (Fig. 5) are also consistent with the earlier findings *i.e.* arylammonium ions are stronger acids in S_1 state, the value of dissociation constant obtained for monocation–neutral equilibrium agrees with that of ground state value (this behavior is common for the protonation of tertiary nitrogen atom[26,27] and the relative increase in the acidity of amino group upon excitation to S_1 state is more than that of imino group. The large difference between the pK_a^* values obtained by Förster cycle

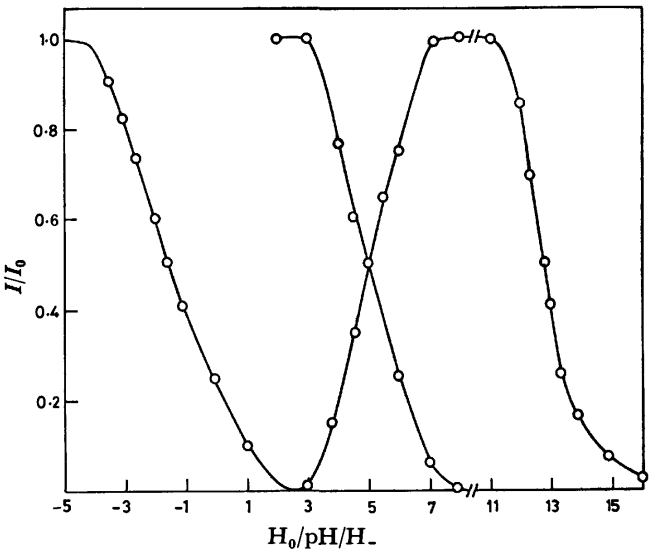

Fig. 5. Plot of relative fluorescence intesity(I/I_0) of different species as a function of H_0/pH/H_.
I/I_0 of dication in the range $H_0 = -9$ to pH=3; I/I_0 of monocation or neutral molecule in the pH range of 3 to 9; I/I_0 of neutral molecule in the pH range 11 to $H_- = 16$.

method, using absorption or fluorescence data, for the dication–monocation equilibrium (7.50 pK_a units) and monocation–neutral equilibrium (4.45 pK_a units) could be due to the unequal solvent relaxation or it may however, be due to use of band maxima in stead of 0-0 band.

Kinetics and Mechanism of the Interaction of Iminodiacetate with *cis*-Tetraamminediaquacobalt(III) Ion in Acidic Media

Prabir BHATTACHARYA and Pradyot BANERJEE*

Department of Inorganic Chemistry, Indian Association for the Cultivation of Science, Jadavpur, Calcutta 700 032, India

(Received July 5, 1984)

Kinetics of the reaction of iminodiacetate ($Hida^-$) with *cis*-tetraamminediaquacobalt(III) have been studied spectrophotometrically at pH 3.0—4.15, $[\text{iminodiacetate}]_T = 0.03$—0.4 mol dm^{-3}, $I = 0.5$ mol dm^{-3} ($NaClO_4$), in the temperature range 30—50 °C. The reaction is governed by the rate law:

$$\text{rate} = \{k_{-1} + k_1[\text{iminodiacetate}]_T\}[\text{complex}],$$

where k_{-1} and k_1 denote the reverse aquation and anation rate constants respectively. At 40 °C the k_{-1} values increase with pH and show a limiting tendency at pH≈4. The pH-anation rate profile indicates no reaction at pH<1.5 and in the range 3.5—3.9, k_1 remains constant. The pH dependence on rate is expressed as $k_1 = k_A K_{AH}/([H^+] + K_{AH})$, where k_A is the anation rate arising from the aqua complex ion and $Hida^-$ species and K_{AH}, the dissociation constant for the iminodiacetic acid. The value of k_A at 40 °C = $(5 \pm 0.02) \times 10^{-5}$ mol^{-1} dm^3 s^{-1}. The activation parameters, ΔH^* and ΔS^* for the anation step are 170 ± 2 kJ mol^{-1} and 239 ± 3 JK^{-1}mol^{-1}. The reaction is believed to operate through the initial complexation at the carboxylate end followed by a fast intramolecular proton transfer with simultaneous ring closure to form a chelated product. The complexation probably takes place through a dissociative interchange (I_d) mechanism.

Mixed-ligand complex formation has several important biological implications because of the enhanced probability of bringing two different ligands together or of facilitating enzyme-substrate interaction through a bridging metal ion. Bulky ligands, especially those which form multimembered chelate rings, inhibit substitution reactions and usually tend to mask out the influence of bonding and charge on the substitution rates.[1] Unfortunately anation reactions involving such multidentate ligands and an inert metal centre are not explored much. Herein we report the kinetics of interaction of *cis*-tetraamminediaquacobalt(III) ion with iminodiacetate ($Hida^-$).

Experimental

Reagents. The *cis*-tetraamminediaquacobalt(III) perchlorate is prepared following literature method[2] and its purity is checked by spectral and elemental analyses.

The tetraammine(iminodiacetato)cobalt(III) perchlorate has been prepared for the first time by us using the following procedure.

0.44 g (0.15 mole) disodium iminodiacetate monohydrate is dissolved in miniumm volume of water. pH of the solution is adjusted with dilute $HClO_4$ (0.1 mol dm^{-3}) to ≈4.0 and the solution is heated on water bath. To this hot solution is added with stirring an aqueous hot solution of 0.86 g (0.125 mole) *cis*-$[Co(NH_3)_4(H_2O)_2](ClO_4)_3$. Total volume of the solution is kept at ≈15 cm^3. The mixture is heated on the water bath for about 30 min. Pink colored solid product separates out from the solution. It is then cooled. The solution is filtered, the solid is washed with a little cold water followed by cold ethanol and finally dried over fused $CaCl_2$. The purity of the complex is ascertained by elemental analyses: Calcd for $[Co(NH_3)_4(Hida)](ClO_4)_2$: Co, 12.87; C, 10.48; H, 3.93; N, 15.29%. Found: Co, 12.73; C, 10.25; H, 3.79; N, 15.32%. Molar conductance (Λ_M at 25° (in water)) = 240 cm^2 Ω^{-1} mol^{-1}.

Disodium iminodiacetate monohydrate (Fluka AG) is used as received. Recrystallized sodium perchlorate (E. Merck) is used for ionic strength adjustments. pH of the reacting solutions is maintained with dilute perchloric acid prepared from 70% $HClO_4$ (E. Merck).

In addition to the elemental analysis and conductance data, spectral measurements of the synthesized complex furnish further evidence regarding the mode of binding of the acid in the complex. It is well known that amino acids form chelated species with metal ions binding through carboxylato (O^-) and amino (N) groups. The position and intensities of the first and second bands of a freshly prepared solution (at pH=4.0, I=0.5 mol dm^{-3} ($NaClO_4$)) of the isolated complex (λ_{max}, 508 nm; $\varepsilon = 90 \pm 1$ dm^3 mol^{-1} cm^{-1} and λ_{max}, 354 nm; $\varepsilon = 60 \pm 1$ dm^{3}mol^{-1}cm^{-1}) corresponding to $^1A_{1g} \rightarrow {}^1T_{1g}$ and $^1A_{1g} \rightarrow {}^1T_{2g}$ transitions match very well with those of tetraammine(amino acidato)cobalt(III) species.[3] For a tridentate ligand like *N*-methyliminodiacetate ($mida^{2-}$), Bailey *et al.*[4] have isolated an intermediate $[Cr(mida)(Hmida)(H_2O)]$ during the anation studies of $[Cr(mida)(H_2O)_3]^+$ with $Hmida^-$. In this intermediate $Hmida^-$ is coordinated as a bidentate ligand through nitrogen and one CO_2^- group and one carboxyl group (protonated) remains uncoordinated. The mode of bonding of $Hida^-$ in our complex follows the same fashion resulting in a 1 : 2 electrolyte. IR spectrum in KBr discs shows a strong absorption at 1630 cm^{-1} assignable to $[\nu_{COOM} + \delta_{d(NH_3)}]$. Free carboxyl stretching frequency generally encountered at ≈1700 cm^{-1} is probably masked by the presence of this strong band and does not appear. The presence of a sharp band at 555 cm^{-1} strongly indicates the occurance of ν(M–N(amino acid)) bonding.[5]

Measurements. The kinetics of the reaction have been followed with a Pye-Unicam SP8-150 spectrophotometer equipped with a thermostated cell compartment. pH of all the solutions has been measured with a Beckman pH meter (4500). The kinetic spectra has been recorded with a Hitachi 330 spectrophotometer. The spectral change observed during the reaction of *cis*-$[Co(NH_3)_4(H_2O)_2]^{3+}$ with iminodiacetate at pH 3.0—4.15 leads to an increase in the absorption maxima at 354 ± 2 and 508 ± 1 nm, and the rates of the reaction were followed by product absorption at 508 nm. Kinetics of the reaction were measured under pseudo-first-order conditions having $[\text{complex}] = 2 \times 10^{-3}$ mol dm^{-3} and $[\text{iminodiacetate}]_T = 0.03$—0.4 mol dm^{-3} in the pH region 3.0—4.15 at temperatures 30—50 °C. Examination of the

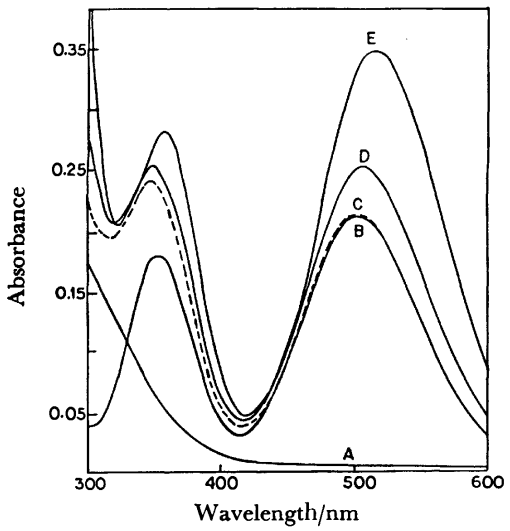

Fig. 1. Absorption spectra: (A) [iminodiacetate] = 0.4 mol dm^{-3}, pH = 4.00±0.01, I = 0.5 mol dm^{-3}; (B) [Co(NH$_3$)$_4$(H$_2$O)$_2^{3+}$] = 4×10^{-3} mol dm^{-3}, pH = 4.00±0.01; (C) [Co(NH$_3$)$_4$(H$_2$O)$_2^{3+}$] = 4×10^{-3} mol dm^{-3}, [iminodiacetate] = 0.4 mol dm^{-3}, pH = 4.00±0.01, I = 0.5 mol dm^{-3} and temperature ≈15 °C (spectrum recorded within 2 min. of mixing); (D)→(E) Change in absorbance with time during the reaction in solution (C) by gradually raising the temperature to 40 °C; curve (E) actually denotes the infinite time spectrum of the reacting solution.

absorbances at infinite time (A_∞) for reacting solutions indicates an equilibrium for the anation process.[6] The approach to equilibrium first-order rate constants (k_{app}) are evaluated from the plots of $\log(A_\infty - A_t)$ *vs.* time (t). These plots are good straight lines for more than three half-lives of the reaction, free from any kinetic complications.

Results and Discussion

A close perusal of the kinetic spectra (Fig. 1) shows that curve (C) departs largely in the range 300—400 nm, though the visible region logically shows no progress in the reaction. The origin of the departure in the region mentioned is due to the absorbance of excess iminodiacetate (curve A) and if we subtract it from that in curve(C), there is practically no difference. This result suggests that no complex of significant stability is formed by association of the diaquacobalt(III) species and iminodiacetate at the time of mixing. The curve(E) shows that the absorbance maximum value at 354 nm is also little higher (*ca.* 15%) than that of the corresponding value of the isolated product under the same conditions (*vide supra*). This also originates from the residual absorbance of iminodiacetate.

At a constant pH, the rate of reaction is shown to be linearly dependent on total iminodiacetate concentration, [iminodiacetate]$_T$. Plots of k_{app} *vs.* [iminodiacetate]$_T$ are straight lines having appreciable intercepts (Fig. 2). The intercept should correspond to the reverse aquation path which has earlier been predicted from the inconcurrence of A_∞ values. With [iminodiacetate]$_T$ present in > ten fold excess over the complex, the rate law (1) is found to apply.

$$\text{Rate} = \{k_{-1} + k_1[\text{iminodiacetate}]_T\}[\text{complex}], \quad (1)$$

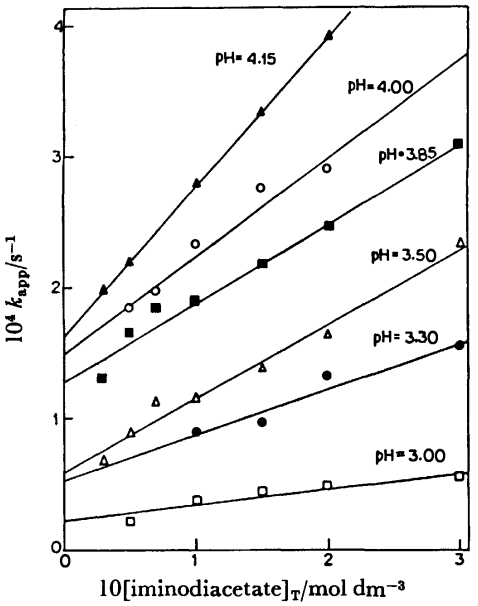

Fig. 2. Plots of k_{app} *vs.* [iminodiacetate]$_T$ at 40 °C, [complex] = 2×10^{-3} mol dm^{-3}, I = 0.5 mol dm^{-3} and pH = 3.0—4.15.

	4.15	1.62±0.02	11.46±0.06

a) Activation parameters obtained from the data corresponding to k_{-1} are ΔH^*_{-1} = 100±4 kJ mol^{-1}, ΔS^*_{-1} = −1±0.5 JK^{-1} mol^{-1}.

where k_{-1} denotes the rate constant for the aquation path and k_1, the second order anation rate constant. The least-squares values of k_{-1} and k_1 obtained at different pH and temperatures are shown in Table 1. The k_{-1} values increase with pH and show a limiting tendency at pH ≃4. The pH-anation rate profile (Fig. 3) clearly indicates three important generalisations; (i) in the high acid region where pH <1.5, there is no reaction, (ii) at pH >3.5, Hida$^-$ is the only species in solution, (iii) at pH >3.9, the reaction rate starts to increase. All three observations can be rationalized into the following derivations.

$$H_2ida \overset{K_{AH}}{\rightleftharpoons} Hida^- + H^+, \quad (2)$$

$$[Co(III)]_T + Hida^- \underset{k_{-1}}{\overset{k_A}{\rightleftharpoons}} \text{products}, \quad (3)$$

$$k_1 = \frac{k_A K_{AH}}{[H^+] + K_{AH}}. \quad (4)$$

The expression (4) is justified by the pH-anation rate

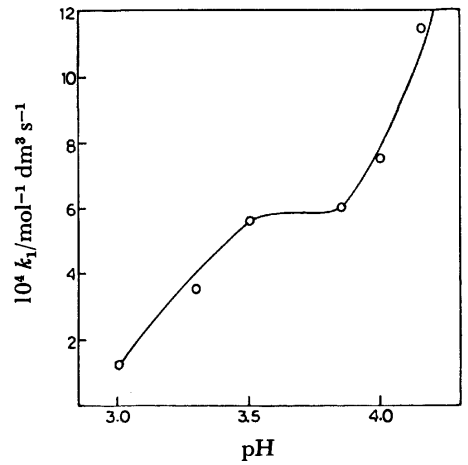

Fig. 3. pH-anation rate profile at 40 °C and I=0.5 mol dm^{-3}.

profile. At relatively high pH, $[H^+] \ll K_{AH}$ ($=3.55\times 10^{-3}$ mol dm^{-3} at 40 °C[7]), the rate becomes acid-independent since $k_1=k_A$. At very low pH when $[H^+] \gg K_{AH}$, $k_1=k_AK_{AH}[H^+]^{-1}$. Thus a plot of k_1 *vs.* $[H^+]^{-1}$ should produce strict linearity in the region of pH<2 having slope ($=k_AK_{AH}$) and $k_A=(5.0\pm0.2)\times 10^{-5}$ mol^{-1} dm^3 s^{-1} at 40 °C obtained by extrapolation of the data to $[H^+]^{-1}=0$, as we were unable to carry out experiments at pH <2 (the reaction rate becoming increasingly slow at lower pH). At pH >3.9 the increase in rate may be ascribed to the onset of protic equilibrium of the diaqua complex. The *cis*-labilisation phenomenon of coordinated-OH group is well documented in literature.[8-10]

The activation parameters obtained by analysing the kinetic data according to the Eyring equation are shown in Table 2. This also includes the comparable kinetic parameters for analogous systems. There is however not a large difference in the anation rates (k_1^x) of *cis*-$[Co(NH_3)_4(H_2O)_2]^{3+}$ with NCS$^-$, Hsal$^-$, Hphthal$^-$, and Hida$^-$. If it is assumed that the mechanism is a dissociative interchange (I_d) type (Eqs. 5 and 6), the rate constant k_1 is a measure of $K_{IP}k_i$.

$$[Co(NH_3)_4(H_2O)_2]^{3+} + \text{Hida}^- \overset{K_{IP}}{\rightleftharpoons} [Co(NH_3)_4(H_2O)_2{}^{3+}\text{Hida}^-], \quad (5)$$

$$[Co(NH_3)_4(H_2O)_2{}^{3+}\text{Hida}^-] \xrightarrow{k_i} [Co(NH_3)_4(\text{Hida})]^{2+} + 2H_2O. \quad (6)$$

The relative small difference in the values of k_1^x (x= NCS$^-$, Hsal$^-$, Hphthal$^-$, and Hida$^-$) is thus indicative of a dissociative activation since the value of $K_{IP}k_i$ are likely to remain fairly constant for similarly charged ligands. The activation parameters also support this mechanism. Assuming an I_d mechanism for any reaction, the activation parameters for the anation step imply more bond breaking than bond making in the transition state. If, however, the entering group is forming a bond in the transition state (associative in nature), stringent steric requirements have to be met and the entropy of activation would be relatively negative. The activation parameters obtained for the aquation step (Table 1) are in excellent agreement with those obtained for the aquation reaction of $[Co(NH_3)_4(NCS)(H_2O)]^{2+}$ ($\Delta H^*=102\pm7$ kJ mol^{-1}, $\Delta S^*=3\pm5$ JK^{-1} mol) and of $[Co(NH_3)_5Cl]^{2+}$ ($\Delta H^*=99.2$ kJ mol^{-1}, $\Delta S^*=-6.7$ JK^{-1}mol^{-1}).[12]

From a detailed analysis of kinetic data, Jordan[13] has suggested that the initial complexing of a metal

Table 2. Anation rate constants[a] and activation parameters

Nucleophile	$10^4 k_1^x$/mol^{-1} dm^3 s^{-1}	ΔH^*/kJ mol^{-1}	ΔS^*/JK^{-1} mol^{-1}	Ref.
NCS$^-$	2.44±0.07[b]	143±2	141±5	8

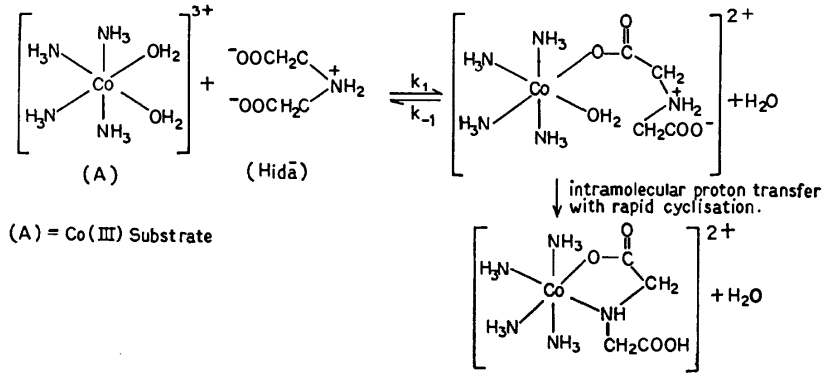
a) All at temp 40 °C and ionic strength=0.5 mol dm^{-3}. b) Represents k_1 value at pH=2.0 where no contribution from aquahydroxocobalt(III) is present, since an unusual *cis*-labilisation for the hydroxo group even at pH> 2.4 has been encountered in this reaction. c) At pH 3.5 no contribution for phthal^{2-} is observed and the rate-law is fully described by an equation analogous to (1).



Scheme 1.

ion by a simple amino acid (⁻O–N) occurs at the carboxylato group and chelate ring closure is an important kinetic factor specially for those amino acids with $pK_1 > 8$ even in a less labile system like nickel(II). With an inert metal centre, it is generally believed[14] that the initial complexing is the rate determining step followed by a rapid cyclization to form the chelated species. All these considerations lead us to the postulation of a total reaction as in Scheme 1.

Kinetics and Mechanism of Ce(IV) Oxidation of Free and Coordinated Glyoxylic Acid

Nirod Kumar MOHANTY* and Rabindra Kumar NANDA†

Post-graduate Department of Chemistry, Sambalpur University, Sambalpur, Orissa, India

†*Department of Chemistry, Utkal University, Bhubaneswar-4, Orissa, India*

(Received October 30, 1984)

The kinetics and mechanism of Ce(IV) oxidation of glyoxylic acid and pentaammineglyoxylatocobalt(III) perchlorate have been investigated in acidic sulfate media in the temperature range 35 to 50 °C and at ionic strength 0.95 M. The rate of decrease of [Ce(IV)] was found to be first order in [substrate] and [Ce(IV)]. The observed second order rate constant, k_{obsd}, for the disappearance of [Ce(IV)] is satisfactorily given by,

$$k_{obsd} = \frac{k_1 + k_2K_3[HSO_4^-]/[H^+]}{1 + K_3[HSO_4^-]/[H^+]} \quad \text{(for glyoxylato complex)}$$

and

$$k_{obsd} = \frac{k_1}{1 + K_3[HSO_4^-]/[H^+]} \quad \text{(for glyoxylic acid)}$$

Both $Ce(SO_4)_2$ and $[Ce(SO_4)_3]^{2-}$ appear to be the oxidant species for coordinated glyoxylate while for free glyoxylic acid $Ce(SO_4)_2$ seems to be the only oxidant species. The values of k_1 and k_2 and the associated activation parameters have been computed. A suitable mechanism has been suggested for the reaction.

The mechanism of Ce(IV) oxidation of carboxylic acids has been extensively investigated.[1,2] Literature survey indicates that Ce(IV) oxidation of carboxylates coordinated to inert metal ion centres has been very sparsely investigated.[3–10] Ce(IV) in $HClO_4$ and H_2SO_4 media exists as different species.[11,12] So far attempt has not been made to establish the mechanism and the nature of reactive cerium species for the oxidation of carboxylates coordinated to metal centers. In the present investigation Ce(IV) oxidation of pentaammineglyoxylatocobalt(III) ion and glyoxylic acid in H_2SO_4–$HClO_4$ media has been undertaken to explore the mechanism, to determine the nature of active cerium species and to establish the complex formation, if any, between the substrate and the oxidant. The products of oxidation have been characterised. For comparison, Ce(IV) oxidation of free glyoxylic acid has also been studied.

Experimental

Pentaammineglyoxylatocobalt(III) perchlorate was prepared by the method of Price and Taube[13] and the purity of the complex was checked by estimating cobalt as described in literature.[14] Cerium(IV) sulfate solution was prepared by dissolving cerium(IV) sulfate (A.R., B.D.H.) in calculated amount of standard sulfuric acid and was standardized against standard ammoniumiron(II) sulfate using *N*-phenylanthranilic acid as indicator.[15] Sodium hydrogensulfate solution of known concentration was prepared by partial neutralisation of standard sulfuric acid with calculated amount of standard sodium hydroxide solution. Glyoxylic acid (A.R., E. Merck) was used as such for oxidation studies. All other chemicals were of reagent grade. All the solutions were prepared from double distilled water, the second distillation being from alkaline $KMnO_4$ in an all-glass distillation set.

Kinetics

To follow the kinetics of the reaction, known amounts of sulfuric acid, perchloric acid, sodium hydrogensulfate and cerium(IV) solutions were transferred into a 50 ml reaction flask and allowed to equilibrate at the reaction temperature. In another flask solution of the substrate (to be oxidized) of known concentration was equilibrated at the same temperature. After thermal equilibrium was attained a known volume of the substrate was transferred to the reaction flask and the volume was made up to the mark with distilled water previously equilibrated at the same temperature. Aliquots of the reaction mixture were drawn out at known time intervals and the reaction was quenched in ice–cold water. The optical density of the quenched solutions was measured at preset wavelengths (410 and 430 nm for glyoxylato complex and 340 and 390 nm for glyoxylic acid). One cm matched quartz cells were used for all measurements, distilled water being taken as 100 precent transmission standard. The oxidations were carried out under second-order conditions.

Stoichiometry

Stoichiometry of the Ce(IV) oxidation of pentaammineglyoxylatocobalt(III) ion was determined as follows: Oxidation of this compound produced Co^{2+} as one of the products which was detected by the formation of the usual blue $[Co(SCN)_4]^{2-}$ species with NH_4-SCN solution. To determine the stoichiometry of the reaction, to a known amount of complex solution was added cerium(IV) sulfate in 4 to 5 fold excess in presence of excess sulfuric acid and allowed to react at 35 °C. Two aliquots of the reaction mixture were withdrawn. One aliquot was added to a calculated volume of ice–cold sulfuric acid to quench the reaction.[9,10] The solution was diluted to a known volume and the optical density of this solution was measured at the wavelength mentioned earlier at which the molar extinction coefficient of Ce(IV) had been determined previously in a separate experiment. From the knowledge of the extinction coefficient and the optical density of the reaction mixture at any time t, unreacted

[Ce(IV)] at that time was calculated. In the second aliquot (after quenching the reaction under ice-cold conditions) [Co(II)] was determined spectrophotometrically using the method of Kitson.[16] In this context it may be noted that the parent cobalt(III) complex was found not to absorb at these wavelengths under the experimental conditions. The stoichiometry for glyoxylato complex was found to be one. To determine the stoichiometry of oxidation of glyoxylic acid, 4—5 fold excess of a known amount of cerium(IV) sulfate was added to a known amount of glyoxylic acid at room temperature. Aliquots of the reaction mixture were withdrawn from time to time and cooled to ice-temperature and the optical density of the mixture was measured at the wavelength mentioned earlier. After about 24 h the absorbance of the reaction mixture was found to be unchanged indicating complete oxidation of glyoxylic acid. The stoichiometry calculated as the ratio of [Ce(IV)] consumed to the total [glyoxylic acid] was found to be 2.

Second Order Rate Expression

In the concentration range studied, preliminary experiments showed that Co(II) and Ce(III) did not absorb in the wavelength range 340—430 nm (at which all optical density measurements were made), the only absorbing species being the cobalt(III) substrate and Ce(IV). Let (i) D_0 and D_t be the optical densities of the reaction mixture at "zero" time and at time "t" respectively, (ii) "x" moles of substrate (henceforward will be known as "sub") react with "y" moles of Ce (IV) at time "t" (iii) E_1 and E_2 be the extinction coefficients of the substrate and Ce(IV) respectively, it is possible to derive the relationship

$$x = (D_0 - D_t)/(E_1 + SE_2) \quad (1)$$

Where "S" is the stoichiometry of the reaction given by

$$y = Sx \quad (2)$$

Thus from the knowledge of S, D_0, D_t, E_1, and E_2 it was possible to calculate x and y from Eqs. 1 and 2 respectively and the observed second order rate constant, "k_{obsd}" from the second order rate expression (3)

$$\ln\frac{([\mathrm{Sub}]_0 - x)}{([\mathrm{Ce(IV)}]_0 - y)} = \ln\frac{[\mathrm{Sub}]_0}{[\mathrm{Ce(IV)}]_0} + (b[\mathrm{Sub}]_0 - a[\mathrm{Ce(IV)}]_0)k_{obsd}\cdot t \quad (3)$$

for the stoichiometric reaction: a Sub + b Ce(IV) → products ($a=b=1$ for glyoxylato complex; $a=1$ and $b=2$ for glyoxylic acid) The experimental results were found to fit best to the above second order rate expression (Eq. 3). The k_{obsd} values were calculated from this expression using the method of least squares with the IBM 1130 computer of Utkal University. The k_{obsd} values and the least squares deviation are collected in Tables 1 and 2. The rate was found not to vary with ionic strength in the range 1 to 2 M†.

Product Analysis

Both glyoxylic acid and glyoxylato complex were found to produce formic acid on oxidation. Following the method of Sengupta and Aditya,[17] formic acid was separated by distillation from the reaction mixture. It was detected by the usual tests and estimated by titrating it with standard potassium permanganate

k_{calcd} stands for the rate calculated from Eq. 12 using the best value of k_1.

solution.[18] It was found that 1 mole of formic acid was produced per mole of the substrate, *i.e.*, glyoxylic acid and glyoxylato complex. The stoichiometry of the reactions can be represented as

$$CHOCOOH + 2\,Ce(IV) + H_2O = 2Ce(III) + HCOOH + 2H^+ + CO_2$$

$$[(NH_3)_5CoOCOCHO]^{2+} + Ce(IV) + H_2O + 4H^+ = Ce(III) + HCOOH + Co^{2+} + CO_2 + 5NH_4^+$$

Results and Discussion

In acidic sulfate media Ce(IV) exists mainly in form of three ionic species, namely, $[CeSO_4]^{2+}$, $Ce(SO_4)_2$, and $[Ce(SO_4)_3]^{2-}$ according to the following equilibria[12]:

$$Ce^{4+} + HSO_4^- \overset{K_2}{\rightleftharpoons} [CeSO_4]^{2+} + H^+ \quad (4)$$

$$[CeSO_4]^{2+} + HSO_4^- \overset{K_2}{\rightleftharpoons} Ce(SO_4)_2 + H^+ \quad (5)$$

$$Ce(SO_4)_2 + HSO_4^- \overset{K_3}{\rightleftharpoons} [Ce(SO_4)_3]^{2-} + H^+ \quad (6)$$

It is obvious from the above three equilibria that the proportions of Ce^{4+} and the three sulfatocerate species in solution are determined by the amounts of free HSO_4^- and H^+ ions. It is possible to express the concentrations of the various Ce(IV) species in terms of the total cerium(IV) ion concentration and the stability constants K_1, K_2, and K_3 as under:

$$[Ce^{4+}] = [Co(IV)]_T/K_1K_2R^2(1+RK_3) \quad (7)$$

$$[CeSO_4^{2+}] = [Ce(IV)]_T/K_2R(1+RK_3) \quad (8)$$

$$[Ce(SO_4)_2] = [Ce(IV)]_T/(1+RK_3) \quad (9)$$

$$[Ce(SO_4)_3^{2-}] = RK_3[Ce(IV)]_T/(1+RK_3) \quad (10)$$

where $R = [HSO_4^-]/[H^+]$

The values of K_1, K_2, and K_3 at 25 °C and ionic strength 2.0 M have been reported to be 3500, 200, and 20 respectively.[12] The ratio $[HSO_4^-]/[H^+](=R)$ maintained throughout the present investigation is in the range 0.1 to 2.0. Eq. 7 indicates that $[Ce^{4+}]$ is negligibly small compared to $[Ce(IV)]_T$ (for example, when $R=1$, $[Ce^{4+}]$ is one in 14×10^6 and was not considered to be one of the reactive species). To determine the active cerium species the concentrations of the various sulfatocerate species were varied by varying $[HSO^-]_4/[H^+]$ ratio. Such a variation resulted in a change in the rate of oxidation indicating that one or more of the sulfatocerate species acted as the oxidizing species. $[HSO_4^-]/[H^+]$ could be varied by adding different amounts of $NaHSO_4$, H_2SO_4, and $HClO_4$ to the reaction medium such that

$$[HSO_4^-] = [H_2SO_4] + [NaHSO_4]$$

and

$$[H^+] = [H_2SO_4] + [HClO_4],$$

the dissociation of HSO_4^- was assumed to be negligible under the present experimental conditions.

In Ce(IV)-oxidation of substrates, in aqueous H_2SO_4 media, usually the formation of precursor complex[17,20,21] between the substrate and sulfatocerate species has been visualized. The formation of such complexes has been established spectrophotometrically:[9,10] Two solutions, one containing Ce(IV) and the other containing the substrate, both having the same amount of HSO_4^- and H^+, on mixing had optical density less than the sum of the optical densities of the two individual solutions. This method could be applied to systems where the rate of oxidation was slow enough such that there was no change in optical density due to oixdation during the spectral measurements. Unfortunately, the oxidation of glyoxylic acid and glyoxylato complex were too fast to establish the precursor complex formation by the above method though we have been successful in establishing this fact in the case of pentaamminebis(oxalato)cobalt(III) ions.[22] Therefore, we presume the complex formation between Ce(IV) and the substrates (glyoxylic acid and glyoxylato complex).

To establish the nature of the active cerium species, one and more than one species at a time were considered and the corresponding rate expression was deduced. The experimental data fitted best to the rate expression 11 in case of glyoxylato complex and 12 in case of glyoxylic acid.

$$k_{obsd} = (k_1+k_2K_3R)/(1+K_3R) \quad (11)$$

and

$$k_{obsd} = k_1/(1+K_3R) \quad (12)$$

TABLE 3. RATE AND ACTIVATION PARAMETERS OF THE Ce(IV)-OXIDATION OF PENTAAMMINEGLYOXYLATOCOBALT(III) ION AND GLYOXYLIC ACID

$k_1/M^{-1}\,s^{-1}$	6.01±0.07	12.45±0.05	21.75±0.7	457.5±3.0	673.5±3.0	1023±7.5
$k_2/M^{-1}\,s^{-1}$	0.19±0.01	0.24±0.01	0.33±0.03	—	—	—
ΔH^*(kcal/mol), k_1-path		25.4±0.6			15.5±0.2	
ΔH^*(kcal/mol), k_2-path		9.5±2.0			—	—
ΔS^*(e.u.), k_1-path		27.5±0.2			3.0±0.1	
ΔS^*(e.u.), k_2-path		−31.0±0.6			—	

The known values of k_{obsd}, K_3, and R were used as the inputs and the parameters k_1 and k_2 were calculated by the method already indicated.[14] Value of K_3 has been reported by Hardwick and Robertson[12] to be 20 at μ=2.0 M and temperature 25 °C while in the present investigation the reactions have been studied at μ=0.95 M and at temperature range 35—50 °C. To examine the change, if any, of K_3 with the change of ionic strength and temperature we have measured K_3 values, following the method of Hardwick and Robertson, in the temperature range 30—40 °C and ionic strength 1.0 to 2.0 M and found K_3 to be temperature and ionic strength independent in this range. Therefore, the value of K_3 reported by these authors[12] has been used for the iteration process. The best values of k_1 and k_2 have been presented in Table 3. The activation parameters for the k_1 and k_2 paths, calculated from transition state equation, have been collected in Table 3.

The form of the rate laws 11 and 12 indicates that for glyoxylato complex the oxidation proceeds *via* two kinetic paths (k_1 and k_2) while for glyoxylic acid *via* k_1 path only. Assuming that oxidation proceeds *via* precursor complex formation between the substrate and the oxidant, $Ce(SO_4)_2$ and $[Ce(SO_4)_3]^{2-}$ are the oxidant species for glyoxylato complex, and only $Ce(SO_4)_2$ is the oxidant for glyoxylic acid the following general reaction scheme may be written down:

$$\text{Substrate} + Ce(SO_4)_2 \overset{K_1'}{\rightleftharpoons} (\text{Complex})_1 \xrightarrow{k_1'} \text{Products}$$

$$\text{Substrate} + [Ce(SO_4)_3]^{2-} \overset{K_2'}{\rightleftharpoons} (\text{Complex})_2 \xrightarrow{k_2'} \text{Products}$$

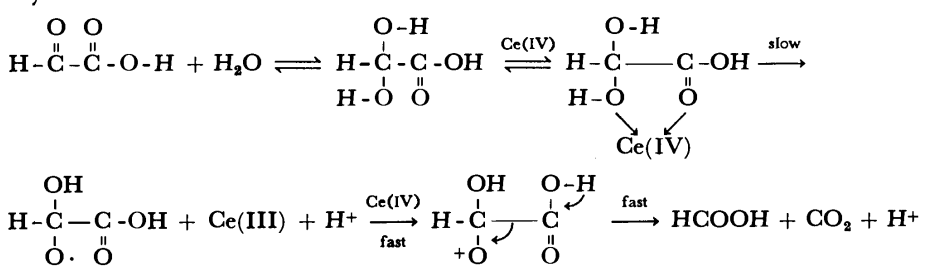
The rate of Ce(IV) loss, $-d[Ce(IV)]_T/dt$, is given by

$$-\frac{1}{b}\left(\frac{d[Ce(IV)]_{Total}}{dt}\right) = [\text{Substrate}]_{Total}\{k_1[Ce(SO_4)_2] + k_2[Ce(SO_4)_3^{2-}]\}$$

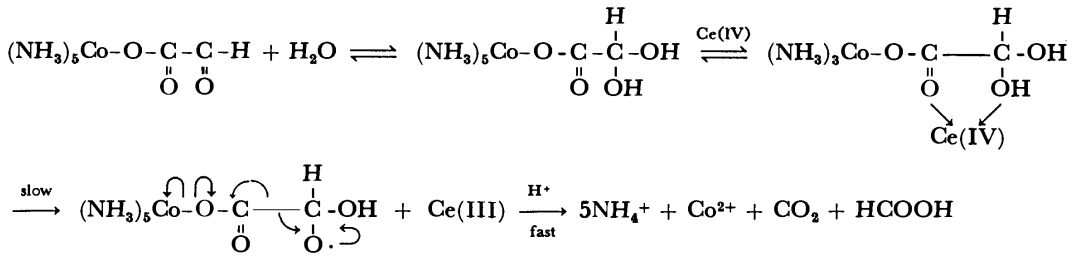
(where $k_1=k_1'K_1'$ and $k_2=k_2'K_2'$)

Substituting for $[Ce(SO_4)_2]$ and $[Ce(SO_4)_3^{2-}]$ from Eqs. 9 and 10 respectively, it is possible to show that the observed second order rate constant k_{obsd} is given by the expression 11. In the absence of k_2 path Eq. 11 reduces to Eq. 12. Thus kinetic results support that when glyoxylic acid is coordinated to positively charged $(NH_3)_5Co(III)$ moiety, $[Ce(SO_4)_3]^{2-}$, in addition to $Ce(SO_4)_2$, acts as the oxidant species. This may be attributed to the fact that the substrate and the oxidant being oppositely charged, complex formation and subsequent electron transfer between them becomes favorable. The specific rate constants for the $Ce(SO_4)_2$-path are greater than those for the $[Ce(SO_4)_3]^{2-}$-path in case of the glyoxylato complex. This is again probably due to the greater complex forming ability of $Ce(SO_4)_2$ with the substrate compared to $[Ce(SO_4)_3]^{2-}$, *i.e.*, the precursor complex of $Ce(SO_4)_2$ is considered to be innersphere type. Higher reactivity of glyoxylic acid compared to glyoxylato complex in $Ce(SO_4)_2$-path is worth noting. This implies that when glyoxylate is coordinated to a positively charged center, electron transfer becomes difficult from electrostatic considerations. The lower reactivity of $[(NH_3)_5CoC_2O_4H]^{2+}$ towards Ce(IV), compared to oxalic acid, has been similarly accounted for by Saffir and Taube.[3] The present kinetic results further indicate that $[CeSO_4]^{2+}$ is not a reactive species for both the substrates which may be due to very low concentration of $[CeSO_4]^{2+}$ under the present experimental conditions (R=0.1 to 2.0). For example, when R=2, Eqs. 8, 9, and 10 indicate that percentages of $[CeSO_4]^{2+}$, $Ce(SO_4)_2$, and $Ce(SO_4)_3]^{2-}$ respectively are 0.002, 4.76, and 95.2. A possible mechanism consistent with our observations is delineated below:

1. Glyoxylic Acid



2. Glyoxylatopentaamminecobalt(III) Ion



The mechanism presented above invokes that the formation of a radical is rate limiting. Formation of such radicals in the oxidation of carboxylic acids by Ce(IV) has long since been suggested.[3,19,23] The reaction can also proceed *via* the formation of the radical at other donor atoms. Further, the reaction products can also be explained by a concerted mechanism suggested by Gould and Srinivasan.[24] However, with the kinetic results at hand it is not possible to answer all these questions.

Extraction Chromatographic Separation of Uranium (VI) with Amberlite LA-1 from Malonic Acid

Prakash NARAYANAN and S. M. KHOPKAR*

Department of Chemistry, Indian Institute of Technology, Bombay-400 076, India

(Received November 26, 1984)

Uranium(VI) was extracted between pH 2.5 to 6.0 from 0.01 mol dm^{-3} malonic acid on a column of silica gel with Amberlite LA-1 as the extractant. It was stripped from the column with 1—2 mol dm^{-3} of hydrochloric, sulfuric, and nitric acids. Uranium(VI) was separated from alkali, alkaline earths, manganese, iron, cobalt, nickel, zinc, yttrium, lanthanum, cerium in binary mixtures by exploiting the difference in the pH of formation of malonato complexes. Uranium was separated from zirconium, hafnium, thorium, scandium, and titanium by taking its advantage of stability of chloro or sulfato complexes. The method was tested for the standard reference rock samples.

Solvent extraction separations of uranium(VI) from mineral acid media using liquid anion exchanger has been studied, but such studies from the organic acid media are lacking. The separation of uranium by extraction chromatography using sulfate media was carried out with Alamine-336[1] or Amberlite LA-2.[2] The studies from nitrate media[3–5] made use of tridodecylamine or trioctylamine as extractants. However, maximum work has been carried out from chloride media,[6–9] where Teflon was used as the stationary support with normal trioctylamine as the stationary phase. Such methods permitted the separation of uranium from actinide elements. In continuation of our work[10] with dicarboxylic acids, such as malonic acid, as the complexing media, extraction chromatographic studies were extended for the separation of uranium (VI) on silica-gel column coated with Amberlite LA-1 as the stationary phase. This paper describes some novel methods for the separation of uranium(VI) from associated elements. The method was tested for the analysis of uranium(VI) from rock samples.

Experimental

Apparatus and Chemicals. The apparatus used was similar to one described earlier.[11] The stock solution of uranium(VI) was prepared by dissolving 1.055 g of uranyl (VI) nitrate (BDH, England) in 100 cm^3 of demineralized water containing 1% of nitric acid. The solution was standardized gravimetrically.[12] It was found to contain 4.9 mg cm^{-3} of uranium(VI). A solution containing 98 μg cm^{-3} was prepared by appropriate dilution. Silica gel (100—200 mesh) was made hydrophobic by procedure described earlier.[11] The column (10×0.7 cm) was packed with silica gel coated with Amberlite LA-1.

General Procedure. An aliquot of solution containing 98 μg of uranium(VI) was mixed with 5 cm^3 of 0.01 mol dm^{-3} malonic acid, and the pH of the solution was adjusted between 2.5—6.0 with 0.01 mol dm^{-3} malonic acid or sodium hydroxide. Then the solution was passed on the column when uranium(VI) was extracted in the stationary phase containing Amberlite LA-1. It was then stripped with various mineral acids and alkalies. Ten fractions each of 5 cm^3 were collected and uranium(VI) from each fraction was determined spectrophotometrically at 530 nm as its complex with 4-(2-pyridylazo)resorcinol (PAR).

Results and Discussion

The study of extraction of uranium(VI) as a function of pH was carried out in the pH range 1.0—8.0. The extraction commenced at pH 1.0 (45.2 %) and it was quantitative in the range 2.5 to 6.0. On further increase of the pH the extraction decreased. The optimum pH for the quantitative extraction of uranium (VI) was therefore 2.5 to 6.0 (Fig. 1).

The extraction of uranium(VI) was carried out by varying the concentration of malonic acid from 1×10^{-4} mol dm^{-3} to 5×10^{-1} mol dm^{-3}. The extraction was quantitative from 1×10^{-3} mol dm^{-3} to 2.5×10^{-1} mol dm^{-3}. At higher concentration of malonic acid there was a decrease in the extraction, probably due to the setting up of a competitive equilibrium between the anionic metal malonato complex and the simple malonate anion for Amberlite LA-1. All the extractions were carried out with 1×10^{-2} mol dm^{-3} malonic acid as it was adequate for complex formation (Fig. 2).

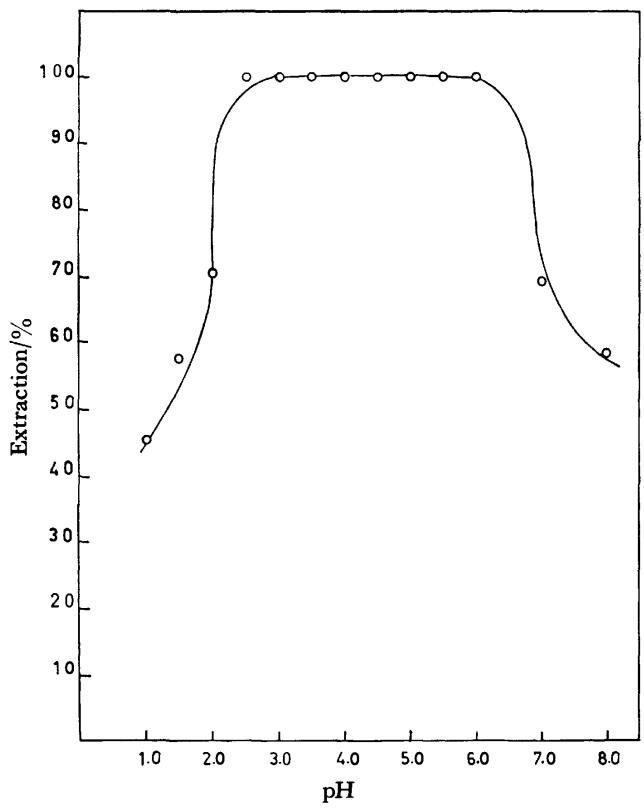

Fig. 1. Effect of pH on extraction of uranium(VI) from malonic acid.

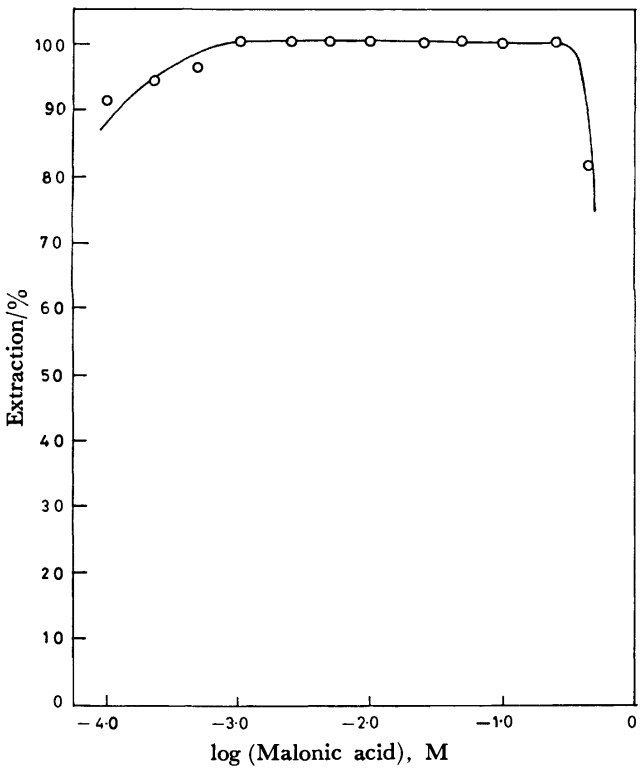

Fig. 2. Effect of malonic acid concentration. (1 M=1 mol dm^{-3}).

On the basis of batch extraction,[13] the probable mechanism of extraction involves the following transformations:

$$UO_2(NO_3)_2 + 2(\text{malonic acid}) \longrightarrow UO_2(\text{malonate})_2^{2-} + 2HNO_3 + 2H^+ \quad (1)$$

$$[(R_2NH_2)_2(\text{malonate})]_o + [UO_2(\text{malonate})_2]_w^{2-} \longrightarrow [(R_2NH_2)_2 \cdot UO_2(\text{malonate})_2]_o + (\text{malonate})_w^{2-} \quad (2)$$

where subscript o and w refer to organic and aqueous phase respectively.

The uranium(VI) was stripped after its extraction from the stationary phase with hydrochloric, sulfuric, and nitric acids and aqueous ammonia. The stripping was quantitative with 1.0 to 2.0 mol dm^{-3} for all acids, or with 0.5 to 1.0 mol dm^{-3} of aqueous ammonia. Since uranium(VI) formed anionic sulfato complex at lower concentration of sulfuric acid, hence could not strip uranium (*i.e.* <0.25 mol dm^{-3}). At high concentration of hydrochloric acid (>6.0 mol dm^{-3}), uranium(VI) formed negatively charged chloro complex, which in turn was reextracted in the extractant. These facts formed the basis for its separation from several metal ions (Fig. 3).

Separation of Uranium(VI) from Binary Mixtures. Uranium(VI) was separated from several elements in binary mixtures by utilizing the differences in their capacity to form anionic complexes. Thus, since alkali, alkaline earths, iron(II), yttrium, zinc, cadmium, lead, nickel, cobalt, aluminium, manganesee(II), lanthanum, and cerium(III) could not form anionic malonato complexes they were not extracted and hence were separated from uranium(VI). Uranium(VI) was then subsequently stripped from the column with 2 mol dm^{-3} nitric acid. Further, since uranium formed anionic sulfato complex at lower concentration of sulfuric acid, it was possible to separate it from scandium, titanium(IV), vanadium(V), iron(III), bismuth(III) as they could not form such complexes and were stripped out with 0.1 mol dm^{-3} sulfuric acid. Uranium which was retained in the form of anionic sulfato complex in the liquid anion exchanger and was subsequently stripped with 2 mol dm^{-3} nitric acid. Uranium(VI) also formed negatively charged chloro complex at 6 mol dm^{-3} hydrochloric acid but zirconium, hafnium, and thorium could not form such chloro complex and hence were stripped out first with 6 mol dm^{-3} hydrochloric acid and then uranium(VI) was stripped with 2 mol dm^{-3} nitric acid.

Separation of Uranium(VI) from Multicomponent Mixtures. The differences in acidity at which various metals formed mineral acid complexes or inability of few to form malonato complexes was exploited to develop new separations. A mixture of lead, bismuth, and uranium (VI) were passed on the column at pH 5.0, when malonato complexes of bismuth and uranium(VI) were extracted, while lead passed through the column as the uncomplexed species. Then bismuth was stripped with 0.1 mol dm^{-3} sulfuric acid and finally uranium (VI) was stripped with 2.0 mol dm^{-3} nitric acid.

The separation of yttrium, scandium and uranium (VI) was carried out by passing the mixture through the column, when yttrium passed through as it could not form extractable malonato complex, while scandium was stripped with 0.1 mol dm^{-3} sulfuric acid fol-

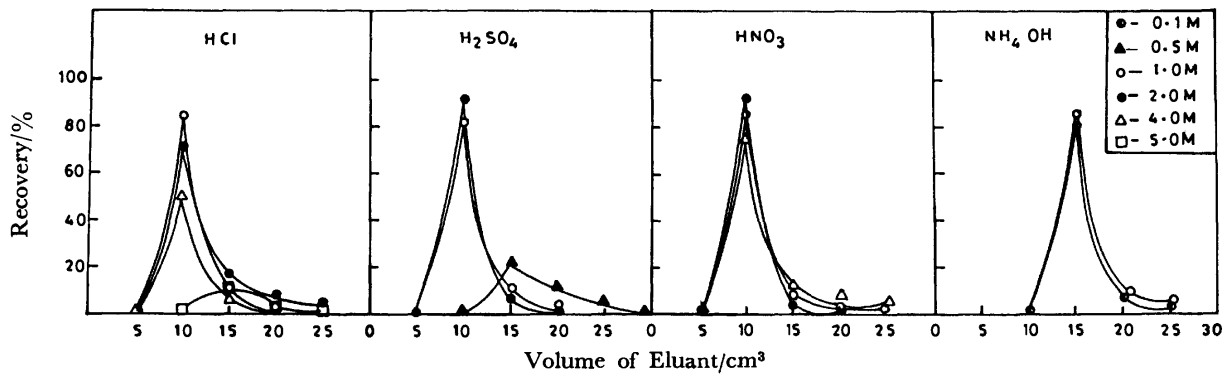

Fig. 3. Elution behavior of uranium(VI) in malonate media with various eluants.

lowed by stripping of uranium(VI) with 2 mol dm^{-3} nitric acid.

The separation of chromium(III), vanadium(V), and uranium(VI) was achieved by washing out chromium (III) with water followed by stripping of vanadium(V) with 0.1 mol dm^{-3} sulfuric acid and uranium(VI) finally with 2 mol dm^{-3} nitric acid.

The separation of uranium(VI) from aluminium, iron(III) or titanium(IV) was effected by passing the mixture through the column. Aluminium was washed with water as it did not form extractable malonato complex. Iron(III) or titanium(IV) was stripped with 0.1 mol dm^{-3} sulfuric acid and finally uranium (VI) was stripped from the column with 2 mol dm^{-3} nitric acid.

The separation of cerium(III), zirconium(IV) or hafnium(IV) was effected by washing cerium(III) with water, zirconium(IV) or hafnium(IV) was stripped latter with 6 mol dm^{-3} hydrochloric acid and finally uranium with 2 mol dm^{-3} nitric acid.

An interesting separation of uranium from lanthanum, thorium, and zirconium was achieved by passing the mixture through the column. When lanthanum was washed with water, thorium was stripped with 0.25 mol dm^{-3} sulfuric acid when zirconium and uranium (VI) were retained on the column as their sulfato complexes. Zirconium was stripped with 6 mol dm^{-3} hydrochloric acid when uranium(VI) was retained on the column as its chloro complex which was finally stripped with 2 mol dm^{-3} nitric acid (Table 1)(Fig. 4).

In all the separation it was interesting to note that uranium could be separated from other elements in the presence of various mineral acids. At 0.1 mol dm^{-3} sulfuric acid uranium(VI) forms anionic sulfato[14] complex, and thus it was possible to separate it from scandium, titanium, vanadium, iron(III), and bismuth. Similarly uranium(VI) forms chloro complex[15] with 6 mol dm^{-3} hydrochloric acid and gets reextracted where other elements like zirconium, hafnium, and thorium could be stripped with 6 mol dm^{-3} hydrochloric acid. Since uranium(VI) did not form nitrato complex at lower concentration of nitric acid, it was possible to strip uranium(VI) with 2 mol dm^{-3} nitric acid in all such cases.

Separation of Uranium(VI) from Rock Sample. About 0.5 g of the sample was heated with a mixture of hydrofluoric and nitric acid in a platinum crucible. It was then diluted to 100 cm^3 with 0.1 mol dm^{-3} nitric acid. To an aliquot of the solution 5 cm^3 of 0.01 mol dm^{-3} malonic acid was added and the pH was adjusted to 5.0. It was then passed through the

† 1 M = 1 mol dm^{-3}.

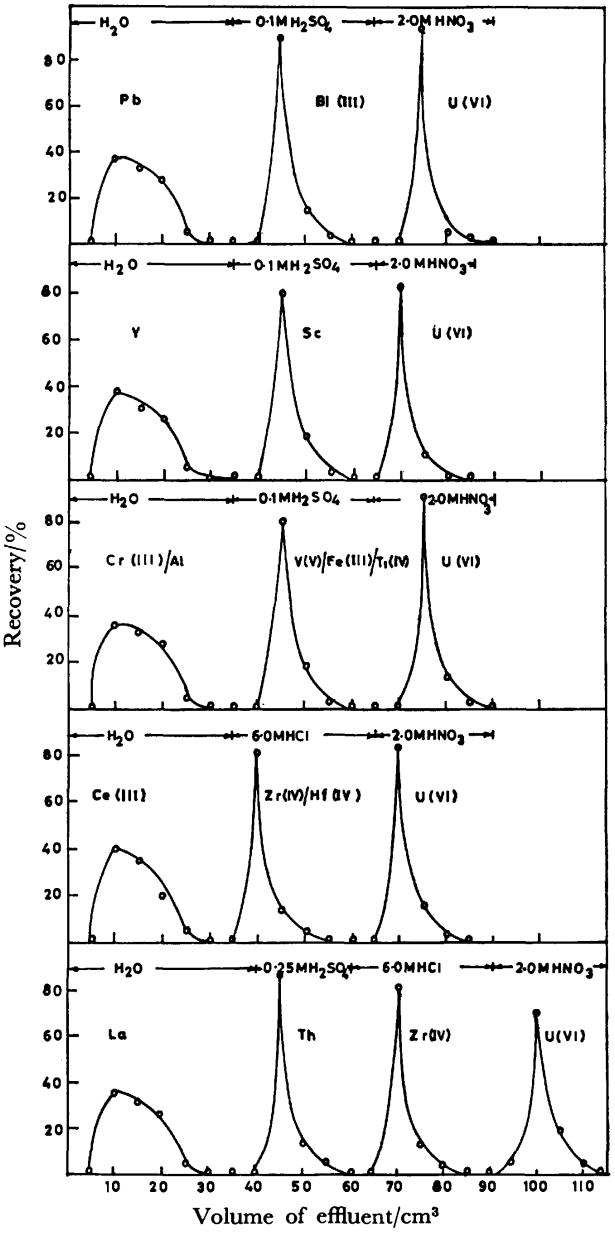

Fig. 4. Separation of uranium(VI) from multicomponent mixtures.

column when elements such as sodium, potassium, calcium, magnesium, manganese, pass through the column. The elements zirconium, thorium, and iron were coextracted with uranium. Thorium and iron (III) were stripped with 0.25 mol dm^{-3} sulfuric acid, while zirconium was stripped with 6 mol dm^{-3} hydrochloric acid under this circumstances uranium(VI) remained on the column either as sulfato complex or chloro complex. Finally uranium was stripped with 2 mol dm^{-3} nitric acid and was determined as usual. The results showed amount of uranium as a mixed oxide as 0.029% against 0.03% in the first sample and 0.079% against 0.08% in the second sample.

The separation of uranium(VI) from lead, bismuth, thorium, zirconium, and hafnium is of significance in the analysis of fission products. Also separation from aluminium, cadmium, iron, titanium, scandium, and cerium is of great importance. The proposed method is simple and rapid.

We are thankful to Council of Scientific and Industrial Research for sponsoring this project and awarding Senior Research Fellowship to one of us (PN).

Thermal Studies of 1,2-Propanediamine Complexes of Zinc(II) and Cadmium(II) in the Solid Phase

Ashutosh GHOSH, Goutam DE, and Nirmalendu RAY CHAUDHURI*

Department of Inorganic Chemistry, Indian Association for the Cultivation of Science, Jadavpur, Calcutta-700 032, India

(Received January 28, 1985)

$[ML_3]X_2 \cdot nH_2O$, where M = Zn^{II} and Cd^{II}; L = 1,2-propanediamine; X = Cl^-, Br^-, $0.5SO_4^{2-}$, and $0.5SeO_4^{2-}$ and n = 1, 1.5, and 2, have been synthesized and their thermal investigations carried out. $ZnL_{1.5}Cl_2$, $CdL_{1.5}X_2$ (X = Cl^- and Br^-), and $CdLX_2$ (X = Cl^-, $0.5SO_4^{2-}$, and $0.5SeO_4^{2-}$) have been synthesized pyrolytically in solid state from their parent diamine complexes. These $ML_{1.5}X_2$ complexes are expected to exist as $[ML_3][MX_4]$. Only $[CdL_3][CdBr_4]$ species has been synthesized from solution. Syntheses of $ZnLCl_2$, $CdLCl_2$, and $CdLBr_2$ from solution have also been reported. IR spectra suggest that symmetry of the chelate ring in mono(diamine) complexes is lowered in comparison to the other complexes. $ML_{1.5}Cl_2$ show isomorphism with each other. Thermal stability sequence of $[ML_3]X_2$ (X = Br^-, $0.5SO_4^{2-}$ and $0.5SeO_4^{2-}$) is $SO_4^{2-} < SeO_4^{2-} \leqslant Br^-$. $[ZnL_3]X_2$ and $ZnLX_2$ appear thermally more stable than those of cadmium complexes. All these complexes are thermally less stable than those of 1,2-ethanediamine complexes reported by us earlier.

We carried out thermal investigations of a good number of diamine complexes, synthesized several novel diamine complexes pyrolytically in solid state from the parent diamine complexes[1-7] and noticed, several interesting observations relating to the structures of diamine complexes derived in solid state with respect to the parent diamine complexes. Recently, we reported the thermal behavior of 1,2-propanediamine complexes of nickel(II)[8] and observed some noticeable difference in the thermal behavior from those of 1,2-ethanediamine and 1,3-propanediamine complexes of nickel(II) due to the methyl substitution in the methylene group of the diamine.

The coordination chemistry of d^{10} metal(II) is interesting. They show a variety of coordination numbers and geometries. The chemistry of diamine complexes of d^{10} metal(II) halides are now well established. Although the chemistries of zinc and cadmium are very similar, it is found that the effect of size is to make Cd^{II} more likely than Zn^{II} to assume a coordination number six.[9] In this context thermal studies on 1,2-propanediamine complexes of MX_2 (M = Zn^{II} and Cd^{II}; X = Cl^-, Br^-, $0.5SO_4^{2-}$, and $0.5SeO_4^{2-}$) are relevent.

Experimental

Preparation of the Complexes. $[ZnL_3]Cl_2 \cdot 2H_2O$ (**1**), $[ZnL_3]Br_2 \cdot 1.5H_2O$ (**2**), $[CdL_3]Cl_2 \cdot 2H_2O$ (**5**), and $[CdL_3]Br_2 \cdot 2H_2O$ (**6**): 1,2-propanediamine (4 mmol) was added dropwise with vigorous stirring to MX_2 (M = Zn^{II} or Cd^{II}; X = Cl^- or Br^-) (1 mmol) dissolved in ethanol. The desired complexes were separated out and purified by washing with ethanol.

*$CdLCl_2$ (**5b**) and $CdLBr_2$ (**6b**).* These complexes were prepared by stoichiometric addition of the ligand to the metal salts adopting similar procedure as described above.

*$[ZnL_3]SO_4 \cdot H_2O$ (**3**), $[ZnL_3]SeO_4 \cdot 1.5H_2O$ (**4**), $[CdL_3]SO_4$ (**7**), and $[CdL_3]SeO_4 \cdot 1.5H_2O$ (**8**).* 1,2-Propanediamine (4 mmol) was added dropwise with vigorous stirring to MX_2 [M = Zn^{II} or Cd^{II}; X = $0.5SO_4^{2-}$ or $0.5SeO_4^{2-}$] (1 mmol) dissolved in minimum quantity of water. The derived com-

a) Figures in parentheses are the required percentages. b) Synthesized in the solid state. c) Analyzed in anhydrous form.

plexes were separated out on evaporating the mixture on a constant temperature bath (50±2 °C). The zinc and cadmium complexes were purified by washing with ethanol and isopropanol, respectively.

$[CdL_3][CdBr_4]$ (6a). To the aqueous solution (2 ml) of 1 mmol, $[CdL_3]Br_2\cdot 1.5H_2O$, 1 mmol $[Et_4N]_2[CdBr_4]$ (dissolved in 10 ml acetonitrile) was added with stirring. To the resulting solution ether was added till the desired product was separated out. It was purified by washing with ether. All the complexes were dried in $CaCl_2$ desiccator.

$ZnL_{1.5}Cl_2$ (1a), $CdL_{1.5}Cl_2$ (5a), and $CdL_{1.5}Br_2$ (6a). These complexes were synthesized by keeping the complexes **1**, **5**, and **6** at 170, 145, and 165 °C, respectively, following the method reported earlier.[4,5,7] Similarly $CdLCl_2$ (**5b**), $CdLSO_4$ (**7b**), and $CdLSeO_4$ (**8b**) were prepared from complexes **5**, **7**, and **8** at 210, 235, and 235 °C, respectively. Thermal curves do not tally the temperatures at which thermolytic syntheses were carried out. The respective temperatures are very much optimum for isolation of the complexes in pure form.

Analytical data for the above complexes are presented in Table 1.

The apparatus employed for carrying out thermal analysis is same as reported earlier.[1-8] Tables 2a and 2b list the thermal data.

Results and Discussion

Diamine Complexes of Zinc Chloride. IR spectra (Table 3a) of $[ZnL_3]Cl_2\cdot 2H_2O$ (**1**) show that the diamines are chelated in it.[10] This tris species starts deaquation at 65 °C and transforms to $ZnL_{1.5}Cl_2$ (**1a**) at 175 °C showing three endothermic peaks in the DTA curve overlapping to each other (Fig. 1). Isolation of deaquated species is not feasible here like the

Table 2a. Thermal parameters of 1,2-propanediamine(L) complexes of zinc(II)

Decomposition reaction	Temperature range/°C	DTA peak temperature/°C
$[ZnL_3]Cl_2\cdot 2H_2O$ (**1**) → $ZnL_{1.5}Cl_2$ (**1a**)	65—175	105, 135, 165

corresponding 1,2-ethanediamine complex.[4] The synthesis of $ZnL_{1.5}Cl_2$ in solid state appears very interesting as such type of zinc diamine complex species is not known in literature although we reported[7] the synthesis of $NiL_{1.5}Cl_2$ (L=1,4-butanediamine), where diamine behaves as chelating as well as bridging bidentate ligand. The complex **1a** may be presumed to exist in dimeric form. But dimerization of the complex **1a** becomes possible if one ligand (L) acts here as bridging bidentate. Interesting observation is that IR spectra of complex **1** and **1a** show practically no difference with respect to diamine bands (Table 3a). This observation does not support the bridging behavior of diamine in $ZnL_{1.5}Cl_2$.† So it may be thought that all the diamine present in complex **1a** are chelated which is possible if the species exists as $[ZnL_3][ZnCl_4]$. The far-infrared spectrum (Table 3b) of **1a** shows a very strong band at $\approx$279 cm^{-1} and a weak band at $\approx$126 cm^{-1} which supports the existence of $[ZnCl_4]^{2-}$ [13] anion in complex. We tried to prepare this species from the equimolecular mixture of $[ZnL_3]Cl_2\cdot 2H_2O$ and $[Et_4N]_2[ZnCl_4]$, but we always obtained $ZnLCl_2$. On the other hand, synthesis of $[Fe(bpy)_3][FeBr_4]$[14] from the pyrolysis of $[Fe(bpy)_3]Br_2$ in solid state does not rule out the above possibility. On further heating $ZnL_{1.5}Cl_2$ starts decomposition at 185 °C and transforms to $ZnCl_2$ through nonisolable intermediate $ZnLCl_2$ as supported from the TG curve (Fig. 1, Table 2a). Three broad overlapping endotherms in the DTA profile account the elimination of 0.5 molecule diamine per zinc atom from $ZnL_{1.5}Cl_2$. Endothermic peak appearing at 365 °C is due to the elimination of last molecule of diamine.

Diamine Complexes of Zinc Bromide. IR spectrum (Table 3a) of $[ZnL_3]Br_2\cdot 1.5H_2O$ (**2**) with respect to the diamine bands is similar to $[ZnL_3]Cl_2\cdot 2H_2O$ suggesting practically no difference in the nature of bonding between the two complex species. Complex **2** upon heating becomes anhydrous at 125 °C in two steps (Fig. 2, Table 2a). The anhydrous compound is isolable by temperature arrest technique. It decomposes at 140 °C and transforms to $ZnBr_2$ at 405 °C through the formation of unstable intermediates ZnL_2Br_2 and $ZnLBr_2$ as is evident from the TG curve. Three overlapping endotherms account for the elimination of two molecules of diamine per zinc atom. Last two overlapping endotherms account for the elimination of residual diamine (Fig. 2). None of the inter-

† It is well established fact that different IR active vibrations will be allowed for chelated and bridged diamine in the respective metal complexes.[10-12] If there is any real evidence for bridging as well as chelating behavior of diamine in complex (**1a**), then it should show some distinguishable difference in IR spectrum from that of (1).

mediate species is isolable in solid state by arresting temperature.

Diamine Complexes of Zinc Sulfate. $[ZnL_3]SO_4 \cdot H_2O$ (**3**) shows almost similar IR spectra with that of complex **1**. It becomes anhydrous at 85 °C showing an endothermic peak at 82 °C in DTA curve. On further heating the dehydrated complex starts to lose diamine and transforms to ZnL_2SO_4 (**3a**) at 130 °C (Fig. 3) showing an endothermic peak at 120 °C in DTA curve. We could not characterize the derived bis species owing to its extreme hygroscopic nature. So the prediction about the role of the SO_4^{2-} in the complex ZnL_2SO_4 is not possible here. But from our previous study[4] and the preference of tetracoordination of zinc(II) enables us to conclude that probably SO_4^{2-} is not coordinated here. On further heating the complex ZnL_2SO_4 decomposes in a complicated way. However, the TG curve indicates the decomposition taking place through the formation of an unstable intermediate $ZnLSO_4$.

Diamine Complexes of Zinc Selenate. IR spectra of $[ZnL_3]SeO_4 \cdot 1.5H_2O$ (**4**) show very close similarity with those of the complexes **1**, **2**, and **3**. It becomes anhydrous at 105 °C through the formation of monohydrate at 75 °C (Fig. 4). The anhydrous species starts decomposition at 120 °C and transforms to ZnL_2SeO_4 (**4a**) at 165 °C. Characterization of this bis species in solid state in anhydrous form is also not possible owing to the similar reason stated in the corresponding sulfate. The TG curve shows that it decomposes to $ZnSeO_4$ in single step. But the corresponding DTA curve shows an endotherm followed by an exotherm. The exothermic peak appearing at 280 °C might be due to the decomposition of ligand. This is very much likely as the residue obtained at 292 °C is $ZnSeO_4$+carbon.

Diamine Complexes of Cadmium Chloride. IR spectrum of $[CdL_3]Cl_2 \cdot 2H_2O$ (**5**) (Table 3a) is similar to its zinc analogue. It starts deaquation at 75 °C and transforms to an isolable intermediate, $CdL_{1.5}Cl_2$ (**5a**) at 150 °C like that of complex (**1**) (Fig. 1). Here also, the later compound gives identical IR spectrum with that of its parent tris complex. Far-infrared spectrum (Table 3b) of $CdL_{1.5}Cl_2$ shows bands at 280(w), 260(s), and 245 cm^{-1} (s). These bands suggest here also the presence of $[CdCl_4]^{2-}$ anion in it[13,14] like that of zinc complex. It is noticed that the derived $[CdL_3][CdCl_4]$ appears to be isomorphous with $[ZnL_3][ZnCl_4]$ as is evident from their similar X-ray diffraction patterns (Table 4). Here also for comparative study we tried to prepare $[CdL_3][CdCl_4]$ by mixing $[CdL_3]Cl_2$ and $[Et_4N]_2[CdCl_4]$ in 1 : 1 proportion but failed to prepare it in pure form owing to the presence of $CdLCl_2$ in appreciable amount which could not be separated by

any means. The complex **5a** on further heating transforms to an isolable intermediate having composition $CdLCl_2$ (**5b**) unlike the corresponding zinc complex. IR spectra of this mono(diamine) species shows chelating bidentate character of the diamine whereas, $CdenCl_2$ synthesized by us earlier[5] possesses bridged en. $CdLCl_2$ synthesized from solution also shows similar physicochemical property with that of **5b**. Far-infrared spectral data of $CdLCl_2$ (**5b**) and $CdLBr_2$†† (**6b**) are presented in Table 3b. Compariosn of the spectrum shows the presence of ν_t(Cd–Cl) at 268 cm^{-1} and ν_b (Cd–Cl) at 178 and 184 cm^{-1} in $CdLCl_2$ and ν_t(Cd–Br) at 207 cm^{-1} and ν_b(Cd–Br) at 154 and 163 cm^{-1} in $CdLBr_2$. These data clearly indicate the presence of bridging and terminal coordination of the halogen in the mono(diamine) complex. Reported crystal structure of analogous compound $[Cd(dmpd)X_2]$[17] (dmpd =2,2-dimethyl-1,3-propanediamine) also corroborates our proposed bonding character of halogens and diamines to the metal ion. Again the splitting of the IR bands of the complex **5b** (Table 3a and b) in the region ≈3300, ≈1000, and 500 cm^{-1} which are due to ν_{NH_2}, ν_{CN}, and ν_{MN} indicate that the symmetry of the chelate ring is lowered in the complex. The decomposition of $CdLCl_2$ appears very complicated (Fig. 1). It initially melts showing an endothermic peak at 265 °C, then it decomposes and transforms to $CdCl_2$ at 355 °C. DTA curve shows overlapping endotherms as well as exotherm for the elimination of residual diamine from $CdLCl_2$.

Diamine Complexes of Cadmium Bromide. $[CdL_3]Br_2 \cdot 2H_2O$ (**6**) starts decomposition at 50 °C and becomes anhydrous at 100 °C through the formation of monohydrate at 80 °C (Fig. 2, Table 2b). The derived anhydrous compound immediately starts decomposition and transforms to an isolable intermediate $CdL_{1.5}Br_2$ (**6a**) at 170 °C. This on further heating transforms to $CdBr_2$ at 355 °C. The DTA curve shows initially two overlapping endotherms for the elimination of water, then a prominent endotherm for the elimination of 1.5 molecule of diamine. The elimination of residual diamine occurs showing two overlapping broad endotherms and then an endotherm followed by one exotherm and endotherm (Fig. 2). IR spectra of $CdL_{1.5}Br_2$, $[CdL_3]Br_2$, and $CdL_{1.5}Cl_2$ are very similar. The far-infrared spectral data of **6a** show bands at 170 and 188 cm^{-1} which are also found in $[Et_4N]_2[CdBr_4]$[15] supporting the presence of $[CdBr_4]^{2-}$ anion in **6a**. Again we prepared $[CdL_3][CdBr_4]$ from solution and observed similar thermal behavior, IR spectral data like $CdL_{1.5}Br_2$ (**6a**) isolated pyrolytically in solid state. X-ray powder patterns (Table 4) of two $CdL_{1.5}Br_2$ also appear same. The above observations suggest that the complex $CdL_{1.5}Br_2$ exists actually in $[CdL_3][CdBr_4]$ form.

Diamine Complexes of Cadmium Sulfate. $[CdL_3]SO_4$ (**7**) is hygroscopic in character. This complex starts decomposition at 82 °C and becomes CdL_2SO_4 (**7a**) at 123 °C (Fig. 3, Table 2b). Initial loss in TG curve and its corresponding endotherm in DTA curve (Fig. 3) is due to the elimination of water adsorbed while exposing the complex **7** in air. The derived bis species on further heating generates $CdSO_4$ at 322 °C through two intermediates, $CdLSO_4$ (**7b**) and $CdL_{0.66}SO_4$ at 239 and 272 °C, respectively. The mono(diamine) species is isolable in solid state. The corresponding DTA curve shows altogether six endothermic peaks. The first three endotherms are due to water elimination and the first and second molecules of diamine, respectively. Fourth endotherm is due to elimination of 0.33 mole of diamine. The last two overlapping endotherms (Fig. 3) are due to elimination of 0.66 mole of diamine. Although we could not separate $CdL_{0.66}SO_4$ in pure form, but formation of this type of complex is not unlikely as literature show examples of this type of complex.[18,19] CdL_2SO_4 is also hygroscopic in nature like the corresponding zinc salts. As Cd^{II} prefers O_h coordination and complex like $[Cd(tn)_2SO_4]$ (tn=1,3-propanediamine)[5] is known, SO_4^{2-} coordination is expected in this bis(diamine) species. IR spectrum of $CdLSO_4$ is almost identical to that of $CdLCl_2$ (Table 3a). The far-infrared spectra of these two complexes are also similar (Table 3b), though one could expect some M–O stretching vibration along with M–N stretching vibrations in the far-infrared region (500—200 cm^{-1}) owing to the coordination of SO_4^{2-} to the metal atom. So it is clear that M–O stretching force constants are much smaller than the M–N stretching force constants here.[20]

Diamine Complexes of Cadmium Selenate. $[CdL_3]SeO_4 \cdot 1.5H_2O$ (**8**) becomes anhydrous at 100 °C through the formation of monohydrate at 66 °C (Fig. 5). The derived anhydrous species immediately starts deamination and transforms to CdL_2SeO_4 (**8a**) at 135 °C. This on further heating decomposes at 190 °C and transforms to $CdSeO_4$ through the formation of an isolable intermediate, $CdLSeO_4$ (**8b**) at 240 °C. The corresponding DTA curve shows first an endotherm for the elimination of 0.5 mole of water, then an endotherm overlapping with another prominent endotherm for the elimination of residual water and one diamine molecule. The fourth endotherm accounts for the second molecule of diamine. The residual diamine elimination is associated with first an endotherm immediately followed by an exotherm. Appearance of exotherm might be due to the same reason as stated in the corresponding zinc complex. Here also, bis(diamine) species shows hygroscopic character. $CdLSeO_4$ appears to be isomorphous with $CdLSO_4$. It is interesting to note that $[ZnL_3]SeO_4$ does not yield any $ZnLSeO_4$ while pyrolysis. This type of anomaly occurs probably due to the size factor of the two metal ions.

It is noticed that the decomposition temperature of $[ML_3]X_2$ (M=zinc(II) and cadmium(II); X=Br^-, $0.5SO_4^{2-}$, and $0.5SeO_4^{2-}$) follows the sequence $SO_4^{2-} < SeO_4^{2-} \leqslant Br^-$. $[ZnL_3]X_2$ and $ZnLX_2$ appear thermally more stable than those of cadmium complexes (Tables 2a and b). Our earlier investigation shows that zinc and cadmium complexes of 1,2-ethanediamine are thermally more stable than the corresponding 1,2-propanediamine complexes. $[ML_3]SO_4$ [M=zinc(II) or cadmium(II)] complexes particularly show surprisingly less stability than the corresponding 1,2-ethanediamine

†† Synthesized from solution for characterizing ν_t and ν_b (M–X) band from far-infrared spectra.

complexes.

Über die Reaktion von Harnstoff mit Ammoniumhydrogenamidophosphat unter dem Atmosphärendruck

Choichiro SHIMASAKI* und Mitsunari HARA
Fakultät für Ingenieurwissenschaften, Universität Toyama, Nakagawasonomachi, Takaoka, Toyama 933
(Eingangsdatum: 22. Juni 1985)

Die Reaktion von Harnstoff mit Ammoniumhydrogenamidophosphat ($NH_4HPO_3NH_2$) im Schmelzzustand unter dem Atmosphärendruck ergibt, daß die Bildung des Guanidinumions (GH^+) zusammen mit dem Phosphation bei *ca.* 160 °C die maximale Hitze, und nach 7 Stunden die maximale Ausbeute erreicht. Aus IR Spektren und ^{31}P NMR-Spektren von Reaktionsgemischen und der Entwicklungsbetrag des Ammoniakgases wurde keine Zwischenprodukte, wie Ammoniumureidophosphat, aufgestellt. Die frühere Hauptreaktion der Bildung von GH^+ ist das Deamidieren von $NH_4HPO_3NH_2$. Die gebildete GH^+ und das Phosphation bilden mit zunehmender Reaktionstemperatur jeweils die Ringverbindungen wie Triazinverbindungen und die Polmerisaten wie Pyro-, Tripoly-, und Metaphosphat. Das aus $NH_4HPO_3NH_2$ isolierende Ammoniak unterdrückt die Zersetzung von Harnstoff zu Cyansäure und befördert die Transition zu Cyanamid. Die Bildung von GH^+ ist von der Reaktion von Cyanamid mit NH_4^+ abhängig.

Außer Dicyandiamid als Rohstoff sind die meisten Herstellungsmethoden der Guanidiniumsalze bekannt. Als eine durchführbare Methode für die Industrieherstellung des Guanidiniumsalzes wurde an den Gebrauch des Harnstoffs als Rohstoff gedacht. Unter dem Atmosphärendruck wurden die Reaktionen von Harnstoff mit Ammoniumsalz unter dem Silikagel-Katalysator[1] und von Harnstoff mit Ammoniumamidosulfat,[2] Ammoniummetaphosphat,[3] oder Phosphorpentaoxyd[4] unter dem Nichtkatalysator festgestellt.

Bis jetzt ist die Reaktion von Harnstoff mit $NH_4HPO_3NH_2$ nicht sehr bekannt. Auf der anderen Seite wurden in bezug auf Ammoniumamidosulfat die Literaturen von Boivin und Lovecy,[5] und von Tanihara[6] erkannt. In der jetzigen Abhandlung wird der Mechanismus der Reaktion von Harnstoff mit $NH_4HPO_3NH_2$ untersucht und die Veränderung der physikochemischen Eigenschaften von Guanidiniumsalz diskutiert.

Durchführung der Experimente

Materialien. $NH_4HPO_3NH_2$ wurde nach der Methode[7] zusammengesetzt, die in der früheren Abhandlung beschrieben ist. Das Produkt wurde unter 3333 Pa bei Raumtemperatur für zwei Tage getrocknet und mit Daten von IR Spektren,[8] Röntgenbeugungsbildern,[9] und Elementaranalysen identifiziert.

Apparate und Verfahren. Eine bestimmte Quantität von Harnstoff und $NH_4HPO_3NH_2$ (Molenverhältnis=1.0, Gesamtsumme=3.0 g) wurde in einen Dreihalskolben mit einem Rührwerk hineingetan. Die Reaktion unter dem Atmosphärendruck wurde durchgeführt. Bevor das Reaktionsgemisch erwärmt wurde, wurde das System mit Stickstoffgas durchgefüllt. Die Erwärmung wurde mit dem Thermoregler des Ölbad durchgeführt. Während die Wärme konstant gehalten wurde, wurde die Temperature mit einer Aufheizgeschwindigkeit von 5 °C/min zur gewünschten Temperatur gebracht. Nach der vorgeschriebenen Reaktionszeit wurde das Reaktiongefäß vom Ölbad, während der Einleitung des Stickstoffgases, genommen und für eine Stunde liegengelassen wie es war. Das Reaktionsgemisch wurde anschließend im Vakuumexsikkator mittels P_2O_5 getrocknet. Auch die Abtrennung des entstehenden Ammoniakgases vom Reaktionsgemisch konnte durch dauerndes Durchleiten des trockenden Stickstoffgases ins Reaktionsgefäß erfolgen. Das Ammoniakgas wurde durch rasches Durchleiten des Gasgemisches durch eiskaltes 1 M H_2SO_4 (1 M=1 mol dm^{-3}) restlos absorbiert.

Der Ammoniakgehalt wurde mit Lösung der Schwefelsäure nach der Kjeldahl Methode bestimmt. Der Phosphorgehalt wurde mittels einer gravimetrischen Methode[10] analysiert und mittels Papierchromatographie[11] mit sauren und basischen Lösungsmitteln getrennt. Der Guanidiniumiongehalt wurde mittels der kalorimetrischen Analyse bestimmt. Die DTA, DSC, und TG Kurven wurden in der Luft mit einer Aufheizgeschwindigkeit von 5 °C/min mit einem Rigaku TG-DTA Thermoflex aufgenommen. Für DTA und DSC wurde α-Al_2O_3 als Bezugsmittel gebraucht. Die Röntgenbeugungsbilder wurden mit einem Shimadzu-Beugungsmesser (Cu $K\alpha$-Strahlung, Ni-gefiltert) erhalten. Die IR Spektren wurden mittels Präparation von KBr-Presslingen mit einem Beugungsgitter IR Spektrometer der JASCO aufgenommen. Die ^{31}P NMR Spektren wurden mit einem JEOL JNM-FX 90 QFT Spektrometer aufgenommen. Als Lösungsmittel wurde schweres Wasser verwendet.

Ergebnisse und Diskussionen

Thermische Reaktion. Die DSC und TG Kurven der Probe sind in Abb. 1 dargestellt. Die DSC Kurve ergibt komplizierte endotherme Spitzen zwischen 130 und 220 °C, unter denen die erste Spitze (zwischen 130 und 145 °C) aus dem eutektischen Punkt von $NH_4HPO_3NH_2$ und Harnstoff ist. Die folgenden Spitzen zwischen 160 und 220 °C werden komplizierter, da in diesem Temperaturgebiet die Schmelzreaktion zu entstehen beginnen. Im Temperaturgebiet über 220 °C werden die endotherme und exotherme Spitzen nicht beobachtet. In dieser Temperatur hat sich herausgestellt, daß die Reaktion zum Abschluß kommt. Die TG Kurve zeigt, daß der Prozeß der Gewichtsverluste von der Probe in der Nähe der Temperatur 130 °C anfängt und mit zunehmender Temperatur der Prozentsatz der Gewichtsverluste abnimmt.

IR Spektren. Abbildung 2 zeigt den Effekt der Heiztemperatur auf IR Spektren von der Probe. Die Absorption infolge eines Guanidiniumions zeigt sich bei 160°C, was mit den Ergebnissen der Papierchromatographie (Tabelle 1) übereinstimmt. Die Absorption infolge einer P-O-P Bindung sich zeigt und die Intensität der Absorption wird mit zunehmender Temperatur vergrößert, was mittels Papierchromatographie bei aller Reaktionsgemischen beobachtet wurde. Die Absorption eines Ammoniumions wird mit zunehmender Temperatur vergrößert, andererseits nehmen die entsprechenden Absorptionen von P-O-H und P-N-H Bindungen mit zunehmender Temperatur ab. Dies bedeutet, daß eine Amido Gruppe ein Ammoniumion umwandelt und als Ammoniakgas langsam in die Luft freigegeben wird.

Röntgenbeugungsbild. Abbildung 3 zeigt das Röntgenbeugungsbild des thermischen Zerfallprodukts von der Probe. Die Intensitäten der Beugungslinien von $NH_4HPO_3NH_2$ und Harnstoff nehmen mit zunehmender Temperatur ab. Die erstere geht bei 160°C und die letztere bei 170°C vollstandig verloren. Bei 120°C werden neue Spitzen erreicht, dann werden die Intensitäten vergrößert. Diese neuen Spitzen entspre-

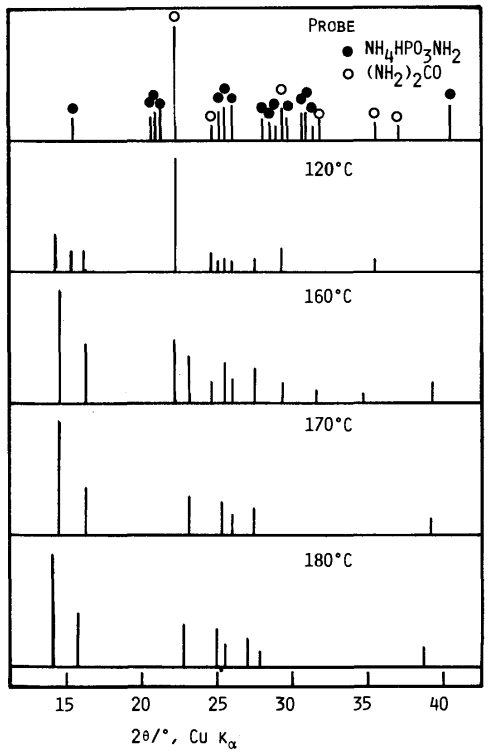

Abb. 3. Röntgenbeugungsbilder des äquimolekularen Gemisches von $NH_4HPO_4NH_2$-$(NH_2)_2CO$ in verschiedenen Temperaturen.

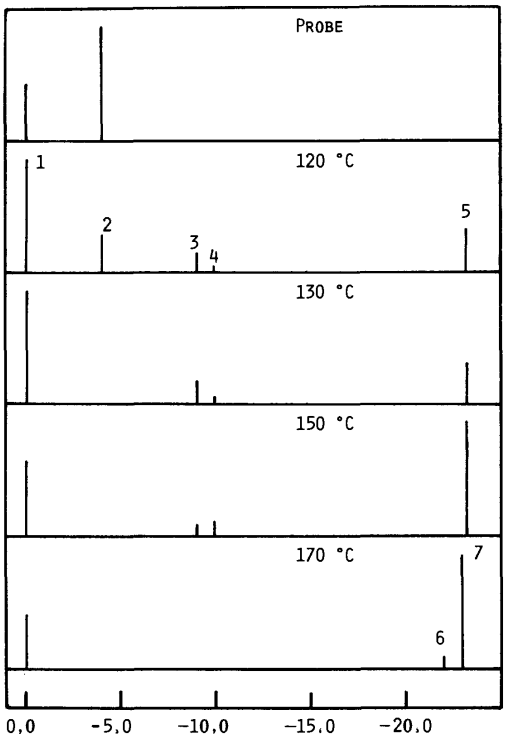

Abb. 4. ^{31}P NMR-Spektren des äquimolekularen Gemisches von $NH_4HPO_3NH_2$-$(NH_2)_2CO$ in verschiedenen Temperaturen.
1: Orthophosphat, 2: Amidophosphat, 3: Diphosphat, 4: Endgruppe des PO_4 von Triphosphat, 5: Mittegruppe des PO_4 von Triphosphat, 6: Endgruppe des PO_4 von Polyphosphat, 7: Mittegruppe des PO_4 von Polyphosphat.

chen Guanidiniumsalz. Die bei 130—150 °C gebildeten Heizprodukte sind hygroskopisch und adhäsiv, und noch dazu amorph. Die Resultate der Papierchromatographie deuten an, daß bei diesen Temperaturen $NH_4HPO_3NH_2$ festgestellt wird und als eutektisches Gemisch existiert. Aus den Resultaten der Röntgenbeugungsbilder und Papierchromatographie wurde die Existenz von Biuret nicht festgestellt. Aus diesem Grunde wird der Schluß gezogen, daß die Reaktion der Kondensationspolymerisation nicht aus Harnstoff entstehen, sondern aus der Bildungsreaktion des Guanidiniumsalzes.

^{31}P NMR-Spektren. Die ^{31}P NMR-Spektren in Abb. 4 zeigen, daß die Heizprodukte Orthophosphat, Diphosphat, und Triphosphat auch noch bei 120 °C $NH_4HPO_3NH_2$ enthalten. Bei allen Heizprodukten wird die Spitze der P-NH-P Bindung in den Spektren nicht festgestellt. Man kommt zu dem Schluß gezogen, daß Imidophosphat weder stabil noch aktiv ist. Der Bildungsprozeß von Ortho-, Di-, und Triphosphat wurde auf die gleiche Weise ausgeführt, die in der vorliegenden Abhandlung[12] erwähnt ist. Das Polyphosphat entstand nach

$$NH_4O\text{-}\underset{\underset{O}{\|}}{P}\text{-}OH \rightleftharpoons NH_4O\text{-}\overset{\overset{O}{\|}}{P}\text{-}O^- \longrightarrow$$

$$NH_4O\text{-}\overset{\overset{O}{\|}}{\overset{+}{P}}\text{-}\overset{-}{O} + NH_3 \longrightarrow \overset{ONH_4}{\overset{+}{P}}\text{-}O\text{-}\left[\begin{array}{c}ONH_4\\ P\text{-}O\\ \|\\ O\end{array}\right]_n\begin{array}{c}ONH_4\\ P\text{-}O^-\\ \|\\ O\end{array} \quad (1)$$

Reaktionsmechanismus von Harnstoff mit $NH_4HPO_3NH_2$. Watt und Post[13] gehen vermutlich über den Bildungsprozeß von Harnstoff zu Guanidiniumsalz, daß zuerst durch die Dehydrierung des Harnstoffes Cyanamid gebildet wird und bei der Reaktion mit Ammoniumsalz Guanidiniumsalz ergibt. Trotzdem in unserem Experiment konnte Cyanamid als Zwischenprodukt nicht nachgewiesen werden. Aus der thermodynamischen Betrachtung über die Reaktionstemperatur unter 300 °C ist es unmöglich, daß nach Dehydrierung und Ammoniakentzug aus Harnstoff Cyanamid und Cyansäure entstehen.[14] Aber man kann für möglich halten, daß Cyanamid sowohl gegen das System $NH_4HPO_3NH_2$-Harnstoff als auch gegen das System Ammoniumamidosulfat-Harnstoff[2] in der konjugierten Reaktion entsteht. Bei der thermischen Zersetzung von $NH_4HPO_3NH_2$ ist zuerst durch Ammoniakentzug die Bildung von Imidodiphosphat möglich:

$$2NH_4HPO_3NH_2 \rightleftharpoons NH(NH_4HPO_3)_2 + NH_3. \quad (2)$$

Es wird geschlossen, daß das Gebilde Imidodiphosphat ebenso leicht die Hydrolyse wie die Diammoniumimidobisulfat[15] beginnt. Der Effekt der Reaktionstemperatur und Reaktionszeit auf die Bildung von Guanidiniumsalz ist in Abb. 5 gezeigt. Bis 120 °C der

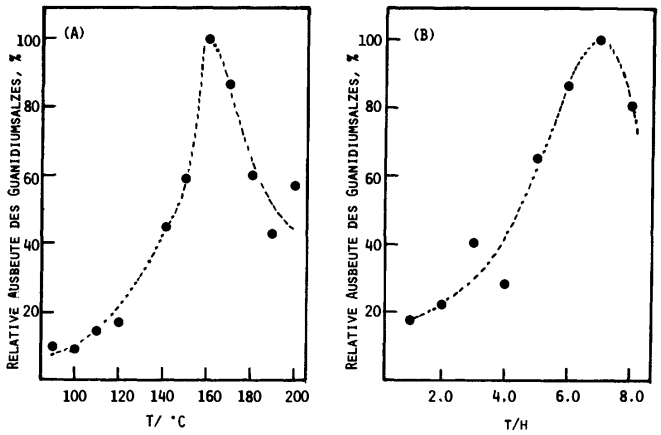

Abb. 5. Relative Ausbeute des Guanidiniumsalzes in Abhängigkeit von der Reaktionstemperatur (A) und dem Reaktionszeit (B).
(A) Reaktionszeit bei der Durchführung aller Experimente: 5 h.
(B) Reaktionstemperatur bei der Durchführung aller Experimente: 160°C.

Reaktionstemperatur wird die Bildung des Guanidiniumsalzes nicht festgestellt. Dieses Resultat stimmt mit den Resultaten von Röntgenbeugungsbilder und IR und ^{31}P NMR Spektren überein. Die Reaktion des Ammoniakentzuges bei 120°C stammt nicht aus dem Harnstoff, sondern $NH_4HPO_3NH_2$. Bei der Reaktionstemperatur über 130°C nimmt die Bildung des Guanidiniumsalzes bedeutend zu und bei 160°C erreicht die maximale Ausbeute des Guanidiniumsalzes. Zudem bei 170°C zeigt sich eine abnehmende Tendenz der Ausbeute des Guanidiniumsalzes. Aus den obigen Resultaten wird geschlossen, daß Ammoniakentzug besser ist als Dehydrierung aus Harnstoff und die Bildungsreaktion von Cyansäure vorwärtskommt. Außerdem wurde der Effekt der Reaktionszeit bei der Reaktionstemperatur 160°C untersucht. Es hat sich herausgestellt, daß in sieben Stunden die maximale Ausbeute von Guanidiniumsalz erreicht wird. Weitere Versuche haben gezeigt, daß die Entwickelungsmenge des Ammoniakgases bei einer Laufzeit der Reaktion bei 160°C bis zu sieben Stunden eine gleichmäßig steigende Kurve ergibt. Diese gefundene Ammoniakmenge entspricht gemäß Gl. 2 den berechneten Werten. In der Reaktionszeit über sieben Stunden fängt die Zersetzung des Guanidiniumsalzes an.

Der Bildungsmechanismus von Guanidiniumsalz braucht unbedingt die Dehydrierung aus Harnstoff nach

$$(NH_2)_2CO \rightleftharpoons NH_2CN + H_2O. \quad (3)$$

Die Hydrolysereaktion des Imidobiphosphates entsteht anschließend aus

$$NH(NH_4HPO_3)_2 + H_2O \longrightarrow NH_4HPO_3NH_2 + NH_4H_2PO_4. \quad (4)$$

Die Reaktion des gebildeten $NH_4H_2PO_4$ mit dem unreaktiven $NH_4HPO_3NH_2$ ergibt Imidobiphosphat und $(NH_4)_2HPO_4$ nach

$$2\,NH_4HPO_3NH_2 + NH_4H_2PO_4 \longrightarrow NH(HPO_3NH_2)_2 + (NH_4)_2HPO_4. \quad (5)$$

Diese Reaktion trägt zu der Bildung von NH_2CN mäß Gl. 3 bei, gleich wie Gl. 4. Schließlich hat es dazugeführt, daß die Reaktion von Cyanamid mit $NH_4H_2PO_4$ oder $(NH_4)_2HPO_4$ Guanidiniumphosphat gebildet wird:

$$NH_2CN + NH_4^+ \longrightarrow GH^+. \quad (6)$$

Dabei entstehen gleichzeitig als Nebenreaktion die gebildeten Phosphate wie $NH_4H_2PO_4$ und $(NH_4)_2HPO_4$ und aus dem unreaktiven Harnstoff wurden mit zunehmender Reaktionstemperatur die polymerisaten wie Pyro-, Tripoly-, und Metaphosphate und die Ringverbindungen wie Triazinverbindungen gebildet.

Aromatic Stabilization of the Dewar-Chatt-Duncanson Bonding Model

Jun-ichi AIHARA
Department of Chemistry, Faculty of Science, Shizuoka University, Oya, Shizuoka 422
(Received July 30, 1985)

Synopsis. Metal–olefin complexes can be considered as aromatics if their conjugated systems are described well by the Dewar-Chatt-Duncanson bonding model.

Stable complexes between transition metal salts and olefins have long been known,[1] but not understood until comparatively recently.[2–5] Zeise's salt is a typical example of such complexes. Ethylene in this salt occupies the fourth coordination site of the square-planar platinate ion with the C–C axis perpendicular to the platinum-ligand plane.[6] In this note, the author would like to point out that many such metal–olefin complexes are essentially aromatic, being stabilized by cyclic conjugation.

The useful bonding model for the metal–olefin complexes was presented by Dewar[7] and by Chatt and Duncanson.[8] They proposed that the bonding consists of a two-way donor-acceptor mechanism: σ donation of the π-bonding electrons of the olefin to vacant orbitals on the metal and π back donation of metal valence electrons to the π^* orbital of the olefin. The extent of back bonding varies depending upon the substituents on ethylene and other ligands on the metal. This bonding model has been referred to as a Dewar-Chatt-Duncanson model. It is noteworthy that few qualitative pictures have served us as beautifully as the Dewar-Chatt-Duncason model.[3]

This bonding model is shown graphically in Fig. 1. The basis-set orbitals for the Hückel calculation are two valence orbitals of the metal (**1** and **2**) and two carbon $2p_z$ orbitals of ethylene (**3** and **4**). In many complexes, **1** is a metal d_{xz} orbital while **2** is a metal d_{z^2} orbital or one of the dp^2- or d^2p^2-hybrid orbitals.[2–8] These two metal orbitals are represented by unconnected vertices because they are orthogonal to each other.

Such a conjugated system is depicted in terms of five resonance integrals and four Coulomb integrals. Coulomb integral parameters for **1** and **2** are denoted by h_1 and h_2, respectively. Four of the resonance integrals have a negative sign and one has a positive sign, reflecting the phase change which results from the nodal characteristic and the position of the metal d_{xz} orbital relative to the carbon $2p_z$ orbitals. Resonance integral parameters between metal and carbon valence orbitals are denoted by $\pm k_a$ and k_b, where k_a and k_b are positive in sign. The resonance integral parameter for the ethylene π bond is equal to unity. The Hückel calculation then demonstrates that the four basis-set orbitals combine to form two bonding and two antibonding molecular orbitals. Four electrons fill the two bonding molecular orbitals.

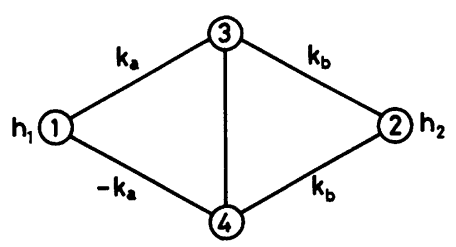

Fig. 1. Graphic representation of the Dewar-Chatt-Duncanson bondng model (k_a, k_b>0).

We then apply our graph theory of aromaticity[9] to this Dewar-Chatt-Duncanson bonding model. A characteristic polynomial for this conjugated system is obtainable by expansion of the Hückel secular determinant.[9] It is written as

$$P(X) = X^4 - (h_1+h_2)X^3 - (1+2k_a^2+2k_b^2-h_1h_2)X^2 + (h_1+h_2+2h_1k_b^2+2h_2k_a^2+2k_a^2-2k_b^2)X + (4k_a^2k_b^2-h_1h_2+2h_1k_b^2-2h_2k_a^2). \quad (1)$$

Zeros of this polynomial represent the energies of molecular orbitals for the conjugated system. The corresponding reference polynomial is derived graph-theoretically from the characteristic polynomial.[9] It is written as

$$R(X) = X^4 - (h_1+h_2)X^3 - (1+2k_a^2+2k_b^2-h_1h_2)X^2 + (h_1+h_2+2h_1k_b^2+2h_2k_a^2)X + (2k_a^2k_b^2-h_1h_2). \quad (2)$$

Zeros of this polynomial represent the energies of hypothetical molecular orbitals which the system would possess if it were totally deprived of aromaticity.[9] A conjugated system defined by this polynomial is named an olefinic reference structure.[9] Total energy for each system is given by summing energies of four electrons in the two bonding molecular orbitals.

The difference in total energy between a real conjugated system and its olefinic reference system is defined as resonance energy due to cyclic conjugation.[9] Resonance energy of the system in question is a function of h_1, h_2, k_a, and k_b. Here, h_1 must not be smaller than h_2 since **1** and **2** are electron-donating and accepting orbitals, respectively. For symplicity, h_2 is set equal to $-h_1$, and k_a equal to k_b. Here, h_1 takes a positive value. This way of choosing the parameter set satisfies the empirical fact that the metal-ethylene bond is essentially electroneutral, with donation and back-acceptance approximately balanced.[3,4] A couple of realistic values were chosen independently for h_1 and k_a. The resonance energy values thus determined for the metal–ethylene bonding system are listed in Table 1. It is worth noting that the resonance energy stays positive in sign for all parameter values. It varies in the range 0.173—0.775 β, where β is an absolute value of β. This value is comparable to the resonance energy of benzene, 0.273 β.

The nodal property of the metal d orbitals is known to aromatize the olefin–tricarbonyliron complexes.[10,11] It is now true for the present Dewar-Chatt-Duncanson

Table 1. Resonance energies of the Dewar-Chatt-Duncanson bonding model in units of β.

k_a	h_1		
	0.00	0.50	1.00
0.50	0.173	0.395	0.373
1.00	0.404	0.659	0.775

model. The presence of one phase change in the metal-olefin conjugated system makes it a Möbius system with four bonding electrons. Möbius systems are characterized by the $4n$ rule for aromaticity,[12] in contrast to the common $4n+2$ Hückel rule. The Möbius ring found along the periphery of the bonding network (Fig. 1) can, therefore, be considered to be aromatic in nature. This is the primary reason why an entire metal-ethylene conjugated system can be regarded as an aromatic species. Furthermore, it is quite likely that many other metal-olefin complexes are totally or partly stabilized by such a bonding pattern.

Bicyclo[1.1.0]butadiene has a similar bonding network, but has no phase change along the periphery. In fact, it has a large negative resonance energy of $-0.473\ \beta$. Thus, bicyclo[1.1.0]butadiene must differ in stability from the Dewar-Chatt-Duncanson bonding model. This suggests that any metal-olefin complexes whose conjugated system is analogous to bicyclo[1.1.0]-butadiene, if any, must be very unstable.

Now, several stabilizing mechanisms have been clarified for organometallic conjugated systems and polyhedral molecules. Multicenter bonds and/or a network of three-center bonds stabilize polyhedral cluster compounds.[13,14] Metallocenes and olefin-tricarbonyliron complexes are stabilized by the bonds formed between metal atoms and carbocyclic rings.[11,15] Formation of all these bonds is obviously associated with aromatization. The binding of olefins to transition metals has also occupied a central position in organometallic chemistry.[1-8] As has been seen above, the Dewar-Chatt-Duncanson model is stabilized by aromatization.

Potential Energies of Rotation of Double Bond in Ethylene Molecule and Ion

Hiroshi ICHIKAWA,* Yukiko EBISAWA, and Atsushi SHIGIHARA
Hoshi College of Pharmacy, Ebara, Shinagawa-ku, Tokyo 142
(Received July 6, 1985)

Synopsis. MP3/6-31G** calculations show that the potential barrier of a double-bond rotation in an ethylene ion is 137 kJ mol^{-1} (about half that of the molecular state) and that the orthogonally twisted ion has a C_{2v} symmetry. The geometries are discussed in relation to the total energies.

It is often said that geometrical isomers cannot be distinguished by a mass spectral observation.[1,2] This is dramatically emphasized by the fact that benzene and its linear isomer, 1,3-hexadien-5-yne, give the same mass spectra upon electron-impact ionization.[3] Unsuccessful trials for characterizing geometrical isomers have so far simply suggested that the double bond in an ionized organic molecule easily becomes twisted and changes its geometry. Using the ethylene system, we studied this problem in order to give an answer to the fundamental question regarding organic mass spectrometry. This subject has also drawn some conceptional interests regarding chemical bonding as an example of an isovalent hyperconjugation.[4]

The method for evaluating such rotational energy is straightforward: Simply obtain the energetic difference between the lowest- and highest-energy configurations of the ethylene ion. However, as care must be taken regarding the calculation for determining a twisted geometry, since in an ionic state, the D_2 or D_{2d} (at 90°) symmetry of a molecular state is possibly degraded to C_2 or C_{2v} (or even C_1 or Cs) due to a lack of one of the π electrons. There are some reports regarding Hartree-Fock[5] (HF) MO theoretical calculations for determining the rotational energy of ionized ethylene.[6–8] However, they deal with only the D_{2d} symmetry for a perpendicular structure. In addition, as is often said, a HF calculation regarding a reaction in which the number of bonds changes, is generally unreliable since the energy difference of the electron correlation between the systems becomes non-negligible. Therefore, previous results must be carefully checked. We have performed second- and third-order Møller-Plesset purterbation calculations[9] based on the HF or the UHF (unrestricted Hartree-Fock[10]) 6-31G**[11] (MP3/6-31G**) to obtain the most reliable rotational barrier values presently available.[12]

a. Geometries in an Ethylene Molecule. The various states of an ethylene molecule have been thoroughly studied through experiments[13] and theoretical calculations.[14,15] In order to check the reliability of the present method, we will compare the calculated values with experimental values and previous calculations. The geometries that are obtained by MP3/6-31G** are:

Ground state (D_{2h}):

R_{CC} = 1.333 (exptl 1.339,[13] CIPSI[16] 1.344,[14] CEPA[17] 1.336[15])

R_{CH} = 1.080 (exptl 1.086,[13] CEPA 1.074[15])

∠HCH = 116.6 (exptl 117.6,[13] CEPA 116.3[15])

Twisted triplet state (D_{2d}):

R_{CC} = 1.459 (CIPSI 1.463,[14] CEPA 1.459[15])

R_{CH} = 1.081 (CEPA 1.074[15])

∠HCH = 117.0 (CEPA 117.2[15])

The present method has been shown to be excellent for reproducing experimental values as well as previous calculations, especially regarding the CEPA results.

b. Rotational Barrier of a Ethylene Molecule and Its Ion. The rotational barrier of an ethylene molecule has been observed to be 273 kJ mol^{-1}.[13] The HF/6-31G** result gives a value that is too low (176 kJ mol^{-1}). However, the MP3/6-31G** result as well as previous CIPSI and CEPA calculations give very good experimental values (272, 263, and 280 kJ mol^{-1}, respectively). This shows the necessity for the inclusion of an electron correlation and also demonstrates the appropriateness of MP3/6-31G**.

Table 1 shows the geometries and the total energies of D_{2d} and C_{2v} ethylene ions where a C_1 atom carries an unpaired electron. Figure 1 shows plots of the total energy *vs.* the twist angle (θ). As expected, when θ is 90°, the C_{2v} structure is more stable than D_{2d}.

As can be seen in Figure 1, the rotational barrier in ionic state is found to be about half (137 kJ mol^{-1}) that of the neutral state. The PE of the twisted molecule has been reported to increase steeply as the twist angle (θ) increases.[14] However, that of the ion does not change until θ is 20°. This indicates that the double bond in an ionic state is very flexible regarding rotation in accordance with experience from organic mass spectrometry.

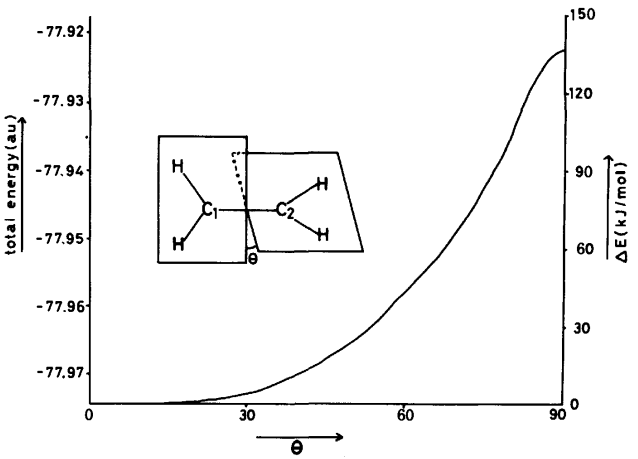

Fig. 1. Total energies *vs.* twist angle (θ) by MP3/6-31G**. All geometrical parameters except the fixed twist angle were optimized with respect to the total energy.

Table 1. Geometries and total energies of ethylene ion by MP3/6-31G**[a)]

	Planar: D_{2h} θ=0	Perpendicular: D_{2d} θ=90	Perpendicular: C_{2v} θ=90
$R(C_1-C_2)$	1.4167[b)]	1.4106	1.4118
$R(C_1-H)$	1.0824	1.0909	1.0891
$R(C_2-H)$			1.0927
HC_1H	118.8[c)]	117.6	119.7
HC_2H			116.0
Total energy	−77.974663[d)]	−77.922613	−77.922954

a) The geometry optimization was carried out by the Fletcher-Powell method.[22] b) In A. c) In degree. d) au (1 au=2625.5 kJ mol^{-1}).

c. Geometries of the Ethylene Ions. Mulliken and Roothaan proposed that the ethylene ion is an example of isovalent hyperconjugation and predicted a twist angle of 30° from a plane.[4] This is the result of a compromise between normal π bonding (planar structure) and hyperconjugative π bonding (perpendicular structure). This prediction was supported by ultraviolet studies regarding a series of Rydberg states of ethylene, which converge to the ethylene ion.[18] It has been reported that the non-plane structure can be produced by using the ab initio SCF MO CI method.[19] We have tried to reproduce this structure by optimizing all of the geometrical parameters. However, like all other reports regarding reasonably extensive SCF MO CI calculations,[20,21] a planar ion is found to be the most stable and to have a D_{2h} symmetry. It should be noted that the total energy that we have obtained is the lowest (−77.974663 au).

We have tried the Cs, C_{2v}, and D_{2d} structures for the perpendicular ion. The C_{2v} structure was found to be the most stable: The lowering of the order from a D_{2d} symmetry is caused by a configurational difference in which the unpaired electron occupies only one of the methylene groups. Interestingly, the C–C bondlength is maintained at almost the same independance regarding the twist angle (θ), even at 90°.

In summary, an MP3/6-31G** calculation shows that the potential barrier of a double-bond rotation in an ethylene ion is 137 kJ mol^{-1}, about half that of the molecular state. Also, an orthogonally twisted ion has a C_{2v} symmetry.

Synthesis and Characterization of a Chloro-bridged Binuclear Iron(III) Complex

Naohide MATSUMOTO,* Chikako YOSHIMURA, Yonezo MAEDA,†
Hisashi OKAWA,† and Akira OHYOSHI

Department of Synthetic Chemistry, Faculty of Engineering, Kumamoto University, Kurokami 2-39-1, Kumamoto 860
†Department of Chemistry, Faculty of Science, Kyushu University, Hakozaki, Higashi-ku, Fukuoka 812

(Received May 24, 1985)

Synopsis. A chloro-bridged binuclear iron(III) complex $[Fe_2ClL](BPh_4)$, where $[H_4L]$ and BPh_4^- denote *N,N,N′,N′*-tetrakis(3-salicylideneaminopropyl)ethylenediamine and tetraphenylborate, respectively, was prepared and characterized by elemental analysis, electrical conductivity, Mössbauer spectrum, and cryomagnetic data. The magnetic susceptibility data of the complex was analyzed by the Heisenberg model on the basis of a binuclear structure $\hat{H}=-2J\hat{S}_1\cdot\hat{S}_2$ ($S_1=S_2=5/2$), leading to an antiferromagnetic interaction parameter of $J=-3.9\,cm^{-1}$.

Chloro-bridged iron(III) complexes are rare, although a number of oxo-bridged iron(III) complexes are well known.[1] In this study, a chloro-bridged binuclear iron(III) complex $[Fe_2ClL](BPh_4)$ is reported, where $[H_4L]$ and BPh_4^- denote a decadentate binucleating ligand *N,N,N′,N′*-tetrakis(3-salicylideneaminopropyl) ethylenediamine and tetraphenylborate, respectively. The complex was characterized by elemental analysis, electrical conductivity, Mössbauer spectrum, and cryomagnetic data, and their physical properties were compared with those of the corresponding mononuclear complex chloro[*N,N*-bis(3-salicylideneaminopropyl) methylaminato] iron(III).

Experimental

Physical Measurements. Elemental analyses (C, H, N) were performed by Mr. Shinichi Miyazaki at the Technical Service Center of Kumamoto University, and an analysis of Cl was carried out by the Fajans method. Melting points were measured on a Yanagimoto micro melting point apparatus and were uncorrected. Electrical conductivity measurements were carried out on a Denki Kagaku AOC-10 type digital conductometer at *ca.* 10^{-3} mol dm^{-3} in methanol or *N,N*-dimethylformamide. The ^{1}H NMR spectrum was recorded on a JEOL MH 100 spectrometer, where the solvent used was chloroform-*d* and shift measurements were made relative to tetramethylsilane. Magnetic susceptibilities were obtained by the Faraday method in a temperature range between liquid nitrogen temperature and room temperature, according to the literature.[2] The susceptibility was corrected for the diamagnetism of the component atoms by the use of Pascal's constants. An effective magnetic moment was calculated using $\mu_{eff}=2.828\sqrt{\chi_A T}$, where χ_A is the magnetic susceptibility per iron atom. The Mössbauer spectroscopy was effected by using an instrument described elsewhere.[3] An isomer shift is reported with respect to the centroid of the spectrum of an iron foil enriched with ^{57}Fe at 295 K. This was also used as a standard material for a velocity calibration.

Syntheses. Binucleating Ligand [H4L]: N,N,N′,N′-Tetrakis(3-aminopropyl)ethylenediamine hexahydrobromide was prepared according to a method described in the literature.[4] A mixture of *N,N,N′,N′*-tetrakis(3-aminopropyl)ethylenediamine hexahydrobromide, salicylaldehyde, and triethylamine with a mole ratio of 1:4:6 in ethanol was stirred on a water bath. Yellow crystals precipitated and were collected and recrystallized from a mixture of chloroform and ethanol. Found: C, 71.58; H, 7.48; N, 11.93%. Calcd for $C_{22}H_{28}N_6O_4$: C, 71.56; H, 7.44; N, 11.92%. Mp 112 °C, ^{1}H NMR ($CDCl_3$) δ=1.7 [8H, m, $4CH_2$], 2.4 [12H, t, $6CH_2$], 3.5 [8H, t, $4CH_2$], 6.6—7.3 [16H, m, $4C_6H_4$], 8.2 [4H, s, 4CH=N].

[Fe2ClL](BPh4). The ligand $[H_4L]$ (10 mmol) and anhydrous iron(III) chloride (20 mmol) were mixed in 100 cm^3 of methanol. To the mixture was added triethylamine (40 mmol) and the resulting solution was warmed at 50 °C for 30 min and then filtered. To the filtrate was added a solution of sodium tetraphenylborate (20 mmol) in 30 cm^3 of methanol. This was warmed at 50 °C for 1 h to yield fine black crystals. These were collected, washed with methanol, and dried *in vacuo*. Found: C, 67.75; H, 6.06; N, 7.22; Cl, 3.24%. Calcd for $C_{66}H_{68}N_6BClO_4Fe_2$: C 67.91; H, 5.87; N, 7.20; Cl, 3.04%. Mp 255 °C (decomp), Λ_M 47.4 Scm^2 mol^{-1} (DMF).

Chloro[N,N-bis(3-salicylideneaminopropyl)methylaminato]-iron(III) [FeClL′]. The mononuclear chloro complex [FeClL′], used as a reference complex, was prepared according to a method described in the literature.[5] Found: C, 56.75; H, 5.80; N, 9.50%. Calcd for $C_{21}H_{25}N_3ClO_2Fe$: C, 56.97; H, 5.69; N, 9.49%. Mp 219 °C, Λ_M 0.0 Scm^2 mol^{-1}(MeOH).

Results and Discussion

The molar electrical conductance of the complex was 47.4 Scm^2 mol^{-1} in *N, N*-dimethylformamide,[6] indicating that the complex has a formula of $[Fe_2ClL]^+(BPh_4)^-$, although this value is slightly smaller than the expected value (65—90 Scm^2 mol^{-1}) of a 1:1 electrolyte in DMF.[7] The molar electrical conductance of the mononuclear complex shows that the complex is uncharged and has a formula of [FeCLL′].

The magnetic moment of the mononuclear complex [FeClL′] is independent of the temperature over the temperature range studied within the experimental error (*ca.* 5.9 BM), typical of a high spin (S=5/2) iron(III) complex. On the other hand, the magnetic moment of $[Fe_2ClL](BPh_4)$ gradually increased from 4.8 BM at 90 K to 5.6 BM at 300 K. Plots of χ_A and $1/\chi_A$ *vs.* temperature for [FeClL′] and $[Fe_2ClL](BPh_4)$ are shown in Fig. 1. The magnetism of the mononuclear chloro complex [FeClL′] obeys the Curie law, while that of the complex $[Fe_2ClL](BPh_4)$ obeys the Curie-Weiss law ($\chi_A=C/(T+\theta)$) with a Weiss constant of θ=50 K. This suggests antiferromagnetic interaction between iron (III) centers. The Mössbauer spectrum of $[Fe_2ClL](BPh_4)$ at 296 K showed a doublet with parameters of IS=0.380, QS=0.741, Γ=0.370 mms^{-1}, typical of a high-spin (S=5/2) center.

The magnetic susceptibilities of the complex $[Fe_2ClL](BPh_4)$ were analyzed by the Heisenberg model

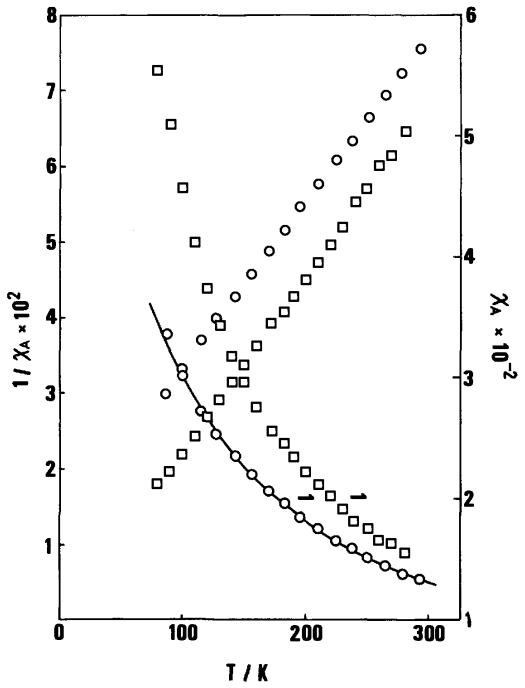

Fig. 1. Plots of χ_A and $1/\chi_A$ *vs.* temperature for [FeClL'] (□) and [Fe_2ClL](BPh_4) (○), where the solid line of χ_A *vs.* T plot for [Fe_2ClL](BPh_4) represents the theoretical curve of Eq. 1 with the parameters of $g=2.00$, $J=-3.9\,cm^{-1}$, and $p=0.015$.

on the basis of a binuclear structure. The magnetic susceptibility per iron atom of a binuclear structure ($S_1=S_2=5/2$) is given by Eq. 1,

$$\chi_A = \frac{Ng^2\beta^2}{kT}\frac{55+30x^{10}+14x^{18}+5x^{24}+x^{28}}{11+9x^{10}+7x^{18}+5x^{24}+3x^{28}+x^{30}}(1-p) + \frac{35Ng^2\beta^2}{12kT}p \quad (1)$$

where $x=\exp(-J/kT)$ and p is the amount of magnetically dilute ferric impurity which possibly coexists with the dimer. Other symbols have their usual meanings. An isotropic g value of 2.00 was assumed, and the best fit to the data gave $J=-3.9\,cm^{-1}$ and

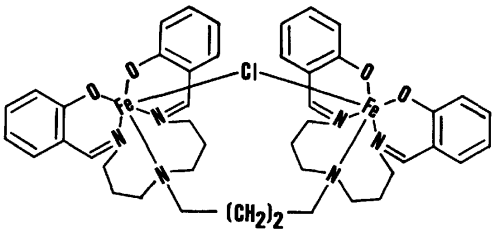

Fig. 2. A proposed structure for $[Fe_2ClL]^+$.

$p=0.015$. A theoretical χ_A *vs.* T curve using the above parameters is represented as a solid line in Fig. 1. On the basis of the electrical conductance and the magnetic property, it can be concluded that the complex [Fe_2ClL](BPh_4) assumes a binuclear structure with a chloro-bridge as shown in Fig. 2.

A number of oxo-bridged binuclear iron(III) complexes have been known and the antiferromagnetic interaction parameters vary from *ca.* $-10\,cm^{-1}$ to *ca.* $-100\,cm^{-1}$,[1] indicating that the antiferromagnetic interaction of the chloro-bridged complex is considerably smaller than those of the oxo-bridged complexes.

Preparation and Characterization of (Iminodiacetato)cobalt(III) Complexes with L-Methioninate and *S*-Methyl-L-cysteinate

Hideki UMEHARA,* Takashi ISAGO, Ken-ichi OKAMOTO, and Jinsai HIDAKA
Department of Chemistry, University of Tsukuba, Sakura, Ibaraki 305
(Received June 21, 1985)

Synopsis. The (iminodiacetato)(L-methioninato or *S*-methyl-L-cysteinato)cobalt(III) complex was prepared and separated into three geometrical isomers by ion-exchange chromatography. The isomers were characterized from the electronic absorption, ^{1}H NMR and CD spectra.

The bis or mixed type cobalt(III) complexes with branched terdentate ligands such as D- or L-aspartate (D- or L-asp), L-methioninate (L-met), and *S*-methyl-L-cysteinate (L-smc), have been investigated in concerning with the spectrochemical and stereochemical properties.[1–5] Regarding the CD spectral analysis of the complexes, however, the branched terdentate ligand such as D- or L-asp was troublesome because of the CD contribution due to *R*(*C*) or *S*(*C*) of the ligand.[3] In this work, we extended the study to the spectrochemical property of the L-met and L-smc cobalt(III) complexes with iminodiacetate (ida) which is a typical linear terdentate ligand. Each complex prepared was chromatographically separated into three possible geometrical isomers and the isomers were characterized from the absorption and ^{1}H NMR spectra.

Experimental

Preparation of Complexes. *1) [Co(ida)(L-met)]*: To a solution containing 0.89 g of iminodiacetic acid and 1.0 g of L-methionine in 30 cm^3 of water (adjusted to pH 8 by NaOH solution) was added a solution containing 1.6 g of $CoCl_2 \cdot 6H_2O$ in 30 cm^3 of water, and then 2 g of PbO_2 and 0.5 g of activated charcoal. The mixture was mechanically stirred at 70 °C for 30 min, cooled to room temperature, and then filtered. The filtrate was passed through a Dowex 1-X8 column (4.5 cm×20 cm) and then a Dowex 50W-X8 one (4.5 cm×20 cm) in order to remove the charged compounds. The eluate concentrated to *ca.* 5 cm^3 was poured onto a Dowex 50W-X8 column (Na^+ form, 200—400 mesh, 3.0 cm×100 cm), and eluted with water. Three colored bands, dark violet (A1), purple (A2), and pink-violet (A3), were eluted in this order. A1, A2, and A3 eluates contained *trans*(N_iN)-, *trans*(N_iS)-, and *trans*(N_iO)-[Co(ida)(L-met)], respectively (A1:A2:A3=*ca.* 55:40:5).[6] A1 and A2 eluates were separately concentrated to dryness. A1 isomer was recrystallized from as little water as possible by adding ethanol. A2 isomer was recrystallized from a little water. A3 eluate was concentrated to a small volume with a rotary evaporator and then kept in a refrigerator overnight. The crystals obtained were filtered and washed with ethanol and ether. Found for A1: C, 28.78; H, 4.99; N, 7.36%. Calcd for [Co(ida)(L-met)]·$2H_2O$=$CoC_9H_{15}N_2O_6S \cdot 2H_2O$: C, 28.88; H, 5.12; N, 7.49%. Found for A2: C, 31.21; H, 4.65; N, 7.93%. Calcd for [Co(ida)(L-met)]·$0.5H_2O$: C, 31.13; H, 4.64; N, 8.07%. Found for A3: C, 30.51; H, 4.77; N, 7.92%. Calcd for [Co(ida)(L-met)]·H_2O: C, 30.34; H, 4.81; N, 7.86%.

2) [Co(ida)(L-smc)]. This noncharged complex was prepared and separated by the same procedure as described in *1)*, using *S*-methyl-L-cysteine (0.91 g) instead of L-methionine, except for adjusting the solution to pH 6. Three colored eluates, dark violet (B1), purple (B2), and pink-violet (B3), contained *trans*(N_iN)-, *trans*(N_iS)-, and *trans*(N_iO)-[Co(ida)(L-smc)], respectively. B2 and B3 isomers were obtained by a procedure similar to that used for A3 in *1)*. For B1 isomer being unstable, after the fractions containing only the *trans*(N_iN) isomer were concentrated, a large amount of ethanol was immediately added to it. Gray-violet powder was filtered and washed with ethanol and ether. Found for B1: C, 26.38; H, 4.86; N, 7.70%. Found for B3: C, 26.72; H, 4.71; N, 7.89%. Calcd for [Co(ida)(L-smc)]·$2H_2O$=$CoC_8H_{13}N_2O_6S \cdot 2H_2O$: C, 26.67; H, 4.76; N, 7.78%. Found for B2: C, 27.91; H, 4.55; N, 7.94%. Calcd for [Co(ida)(L-smc)]·H_2O: C, 28.08; H, 4.42; N, 8.19%.

Measurements. The electronic absorption spectra were recorded with JASCO UVIDEC-1 and -610 spectrophotometers and the CD spectra with a JASCO J-20 spectropolarimeter. The ^{1}H NMR spectra were recorded on a JEOL JNM-FX-100 NMR spectrometer in D_2O. Sodium 2,2-dimethyl-2-silapentane-5-sulfonate was used as an internal reference.

Results and Discussion

Three geometrical isomers were isolated for each of [Co(ida)(L-met)] and [Co(ida)(L-smc)] (Fig. 1), and their absorption and CD spectra are shown in Fig. 2. Their absorption spectral behaviors are quite similar to those of the corresponding isomers of [Co(D-or L-asp)(L-met or L-smc)] over the whole region.[2] Considering the splittings of the first d-d absorption bands estimated semiempirically,[2,7] it is assigned that A1 and B1 are *trans*(N_iN), A2 and B2 *trans*(N_iS), and A3 and B3 *trans*-(N_iO) (Fig. 1).[6]

The *S*-methyl proton signals of A1 (δ 1.89), B1 (δ 1.79 and 2.02 (*ca.* 4:1 in intensity)), A3 (δ 1.89), and B3 (δ 1.96) appear in the higher field than those of A2 (δ 2.30) and B2 (δ 2.33 and 2.40 (*ca.* 7:2)).[8] These suggest that the *S*-methyl group occupies the trans position to the nitrogen atom of ida for A2 and B2, and to its oxygen atom for A1, A3, B1, and B3, because the resonance lines due to the *S*-methyl group in the trans position to the oxygen atom can be expected to shift to higher field than that to the nitrogen one, as in the case of the cobalt(III) complexes with D- or L-aspartate, L-histidinate, and L-methioninate.[2,4] Therefore, the

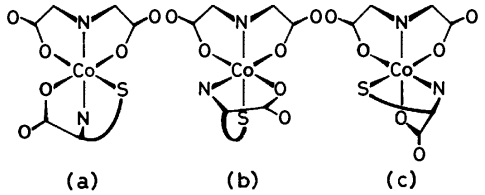

Fig. 1. Three possible isomers of [Co(ida)(L-met or L-smc)]; (a) *trans*(N_iN), (b) *trans*(N_iS), and (c) *trans*(N_iO). The N-S ring is a six-membered ring for L-met and a five-membered one for L-smc.

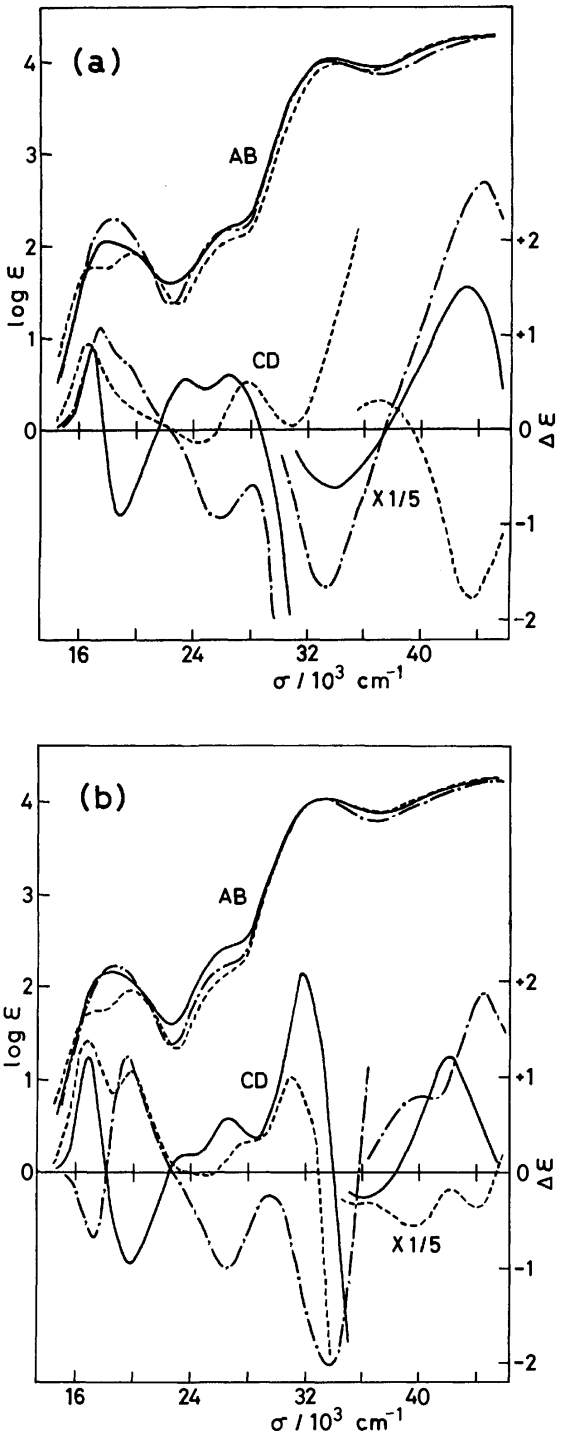

Fig. 2. Absorption and CD spectra of (a) [Co(ida)(L-met)] and (b) [Co(ida)(L-smc)]; *trans*(N_iN) (------), *trans*(N_iS) (——), and *trans*(N_iO) (—·—·—·—).

results from the ^{1}H NMR spectra of the three isomers for [Co(ida)(L-met or L-smc)] support the assignment on the basis of the absorption spectra.

Trans (N_iO)-[Co(ida)(L-met)] exhibits the CD spectrum almost enantiomeric to the *trans*(N_iS) isomer in the d-d absorption band region (Fig. 2(a)), reflecting that the two geometrical isomers have mutually quasi-enantiomeric configurations (Fig. 1). Here, it should be noted that, in the first d-d absorption band region, the enantiomeric CD spectral relation of the *trans*(N_iO) and *trans*(N_iS) isomers of [Co(ida)(L-met)] is opposite in sign to that of the corresponding isomers of [Co(D- or L-asp)(L-met)].[2] *Trans*(N_iO)- and *trans*(N_iS)-[Co(ida)(L-smc)] also exhibit enantiomeric CD patterns on the whole, but an interesting deviation is observed in the first d-d absorption band region (Fig. 2(b)). Namely, the CD band at *ca.* 17×10^3 cm^{-1} of the *trans*(N_iO) L-smc isomer exhibits the reversed sign of the corresponding CD band of the *trans*(N_iO) L-met one, though the CD pattern of the *trans*(N_iS) L-smc isomer coincides well with that of the *trans*(N_iS) L-met one (Fig. 2). This deviation is probably related to the difference of the configurations around the sulfur donor atoms or the flexibilities of the N-S rings in *trans*(N_iO)-[Co(ida)(L-met)] and -[Co(ida)(L-smc)].

A New Gas Sampler for Pyrolytic Sulfurization Gas Chromatography

Itsuro KAWAI* and Tadashi HARA†

Department of Environment and Safety Engineering, Fukui Institute of Technology, Gakuen-cho Fukui 910

†*Department of Chemical Engineering, Faculty of Engineering, Doshisha University, Karasuma Imadegawa, Kamigyo-ku, Kyoto 602*

(Received July 31, 1985)

Synopsis. A new gas sampler was designed and constructed by the use of a commercially available pyrolytic apparatus. This sampler made easier heating and crushing an ampoule, and introducing a liberated gas into a gas chromatograph than those by the conventional gas sampler.

One of the most important operations in the pyrolytic sulfurization gas chromatography[1-4] was to introduce a liberated gas into a gas chromatograph. Therefore, a new gas sampler was constructed by combining a crushing device as shown in Fig. 1 with a Shimadzu PYR-1A pyrolyzer. The sampler thus constructed has advantages in heating and crushing an ampoule and introducing the liberated gas into a gas chromatograph compared with the conventional gas sampler. The elemental analysis of polymer and carboxylic acid samples was tried by the pyrolytic sulfurization gas chromatography with the new gas sampler. The results obtained were almost satisfactory.

Experimental

Apparatus. The axial compression load method was adopted to crush an ampoule containing a sample. Figure 1 shows the crushing device of the new gas sampler. The crushing device was made of a stainless steel tube of 170 mm in length, 8 mm in outside diameter and 6 mm in inside diameter, and the device had a junction at about 45 mm from the one end. By the use of this junction, crushed pieces was able to remove easily, and the inner part of the crushing device was easily cleaned. An ampoule containing a sample was placed at position C, and crushed by pushing plunger D to the direction of the torsion. The gas sampler was heated by electric furnace F and the carrier gas was passed through A to B. The crushing device was combined with a Shimadzu PYR-1A pyrolyzer, and gas chromatograms were taken on a Shimadzu GC-4B gas chromatograph.

Reagents. Sulfur used as reagent was obtained by purifying[5] commercially available sulfur (chemical pure). Homopolymers, copolymers and terpolymers used as samples were commercially available products. Carboxylic acids and other organic compounds used as samples were of JIS special grade.

Procedure. The liberated gas was introduced into a gas chromatograph by either of the following two methods by operating a carrier gas stopcock of the pyrolytic apparatus: (a) An ampoule containing a sample was crushed while a carrier gas was passing through the crushing device. (b) An ampoule containing a sample was crushed while the carrier gas was stopped in the crushing device, and the liberated gas was introduced into the gas chromatograph with the carrier gas. In both cases, the introduced gas was analyzed under the following conditions: For polymer samples, a 2 m Silica-gel (60—80 mesh) column was used at the flow rate of 50 ml min^{-1} He carrier, and for carboxylic acid samples, a 0.25 m Chromosorb 104 (80—100 mesh) column connected with a 1.75 m Porapak Q (80—100 mesh) column in series was used at the flow rate of 30 ml min^{-1}. All the chromatograms were obtained at the programmed temperature of 20 °C min^{-1} over 80—180 °C.

Results and Discussion

Both ends of an ampoule containing a sample were conical and sharp. Figure 2 shows the crushing direction of an ampoule containing a sample. It was proved from the results of compression test (n=3) by means of a Toyo Baldwin UTM-5000-E universal testing machine of Fukui industrial laboratory that the axial compression load (A) (within 10 kg) necessary for crushing an ampoule containing a sample was smaller than the lateral compression load (B) (about 40 kg).

Fig. 2. Crushing direction of an ampoule containing a sample.
A: Axial compression, and B: lateral compression.

Therefore, the crushing method by means of the axial compression load was adopted in the following experiment. This crushing method was easily carried out by pushing the plunger in the crushing device shown in Fig. 1. The gas in an ampoule is easily liberated because the ampoule is dashed to pieces. When the liberated gas was introduced into the gas chromatograph, both the methods, (a) and (b), mentioned above gave the same gas chromatogram. The (a) method was not always applicable on account of the imperfect crushing of an ampoule, while the (b) method was always possible after confirmation of the complete crushing of an ampoule. Tables 1 and 2 show the results of elemental analyses of polymers by the (a) method, and carboxylic acids by the (b) method, respectively. Both organic halogen and organometallic compounds were also analyzed and reasonable results were obtained. This new gas sampler has the following features: (1) Connecting the gas sampler with a pyrolyzer is easier than attaching the conventional gas sampler to a gas chromatograph directly. (2) Heating and crushing an ampoule are easier than those in the conventional gas sampler. (3) The load necessary for crushing an ampoule is less than that for the conventional gas sampler. (4) Analytical operation can be continuously performed by using a carrier gas stopcock of a pyrolytic apparatus.

The Reaction of 5-Cyano- and 5-Methoxycarbonyl-7-oxabicyclo[2.2.1]hept-2-enes with Chlorotrimethylsilane/Sodium Iodide Reagent

Takao KIBAYASHI, Yasutaka ISHII,* and Masaya OGAWA
Department of Applied Chemistry, Faculty of Engineering, Kansai University, Senriyama, Suita, Osaka 564
(Received June 26, 1985)

Synopsis. Reactions of 5-cyano- and 5-methoxycarbonyl-7-oxabicyclo[2.2.1]hept-2-enes with a chlorotrimethylsilane/sodium iodide reagent in acetonitrile gave 2-furanpropanenitrile and 5-methoxycarbonyl-1,3-cyclohexadiene in good yields, respectively.

In recent years, Olah[1-4] has developed an equivalent of iodotrimethylsilane generated *in situ* from chlorotrimethysilane and sodium iodide (Me_3SiCl/NaI). Treatments of appropriate oxygen-containing compounds such as ethers, esters and lactones with this reagent afford a silicon-oxygen bonded intermediate which then can be converted to another product through a subsequent step.

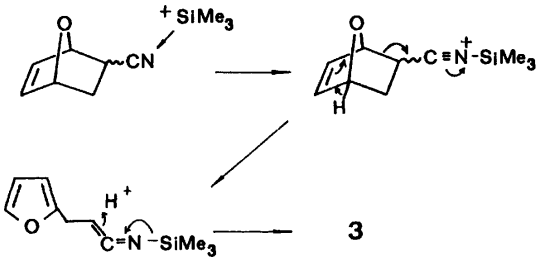
Previously, we reported the synthesis of 7-oxabicyclo-[2.2.1]hept-2-enes and their stereochemistries.[5] These compounds were allowed to react with Me_3SiCl/NaI to induce the rearrangement and deoxygenation of oxabicyclo[2.2.1]heptene ring. We describe here the rearrangement of 5-cyano-7-oxabicyclo[2.2.1]hept-2-ene (**1**) to 2-furanpropanenitrile (**3**) and the deoxgenation of 5-methoxycarbonyl-7-oxabicyclo[2.2.1]hept-2-ene (**2**) to 5-methoxycarbonyl-1,3-cyclohexadiene (**4**). (Eq. 1)

Results and Discussion

The Reaction of 1 with Me_3SiCl/NaI. An isomeric mixture of **1** (endo/exo≒1/1), derived from furan and acrylonitrile, was allowed to react with Me_3SiCl/NaI in acetonitrile at room temperature to give a rearranged product **3** in fairly good yield. (Table 1)

An approximately stoichiometric reaction of **1** with Me_3SiCl/NaI provided **3** in 91% yield. When $MeSiCl_3$ was employed instead of Me_3SiCl, **1** was rearranged slowly to **3** in 81% yield. However, the same reaction using three equiv of NaI to $MeSiCl_3$ took place rapidly giving **3** in good yield (94%). Conventionally, compound **3** has been prepared by a somewhat difficult method.[6-8] Thus, the present method seems to be favorable for preparing **3**. This rearrangement was expected to proceed catalytically, but a reaction with 0.1 equiv of Me_3SiCl/NaI merely afforded **3** at a yield of 12%. Lengthening the reaction time, however, led to an increase of **3** (46%).

The rearrangement of **1** to **3** may be illustrated by an attack by a cationic species, $[CH_3CN^+-SiMe_3]I^-$,[9] to a cyano group of **1**, followed by a cleavage of the C–C bond to form **3**. (Scheme 1)



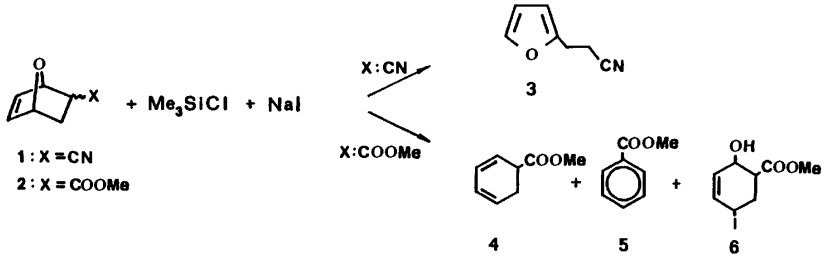
Scheme 1.

The Reaction of 2 with Me_3SiCl/NaI. A reaction of **2** with Me_3SiCl/NaI, followed by hydrolysis with water, gave deoxygenated products, **4** and **5**, as well as **6** in which the O–C bond was cleaved. However, their yields changed extremely due to the orientation of the methoxycarbonyl group of **2**. The isomeric **2** (endo/exo≒3/2), derived from furan and methylacrylate, was treated with 1.2 equiv of Me_3SiCl/NaI to form about 30% of **4** and benzoic acid **5** (3%). (Table 2) The yield of **4** increased to 43% when an excess amount of Me_3SiCl/NaI was used (Run 2).

TABLE 1. RING CLEAVAGE OF 5-CYANO-7-OXABICYCLO-[2.2.1]HEPT-2-ENE[a]

Run	**1**[b]:Me_3SiCl:NaI	Time	Yield[c] of **3**
	mmol	h	%
1	10: 12 : 12	3	91.3
2	10: 12[d]: 12	20	81.1
3	10: 10[d]: 30	3	93.6
4	10: 1 : 1	20	11.5
5	10: 1 : 1	70	46.0

a) Reactions were carried out in acetonitrile (10 ml) at room temperature. b) An isomeric mixture of *endo*-and *exo*-**1** (1:1) was used. c) Estimated by v.p.c. d) $MeSiCl_3$ was used instead of Me_3SiCl.



Equation 1.

Table 2. Ring cleavage of 5-methoxycarbonyl-7-oxabicyclo [2.2.1] hept-2-ene[a)]

Run	2 endo:exo	Time h	Yield/%[b)] 4	5	6
1	3:2	20	29.3	1.0	—
2[c)]	3:2	20	43.0	8.2	—
3[d)]	3:2	20	11.4	2.3	—
4	endo	20	42.8	11.6	27.2
5[e)]	endo	20	56.1	7.0	—
6[e)]	endo	48[f)]	67.3	13.4	—
7[e)]	endo	1[g)]	62.6	16.0	—
8[h)]	exo	20	9.2	4.0	—

a) **2** (10 mmol) was allowed to react with Me_3SiCl (12 mmol) and NaI (12 mmol) in acetonitrile (10 ml) at room temperature. b) Isolated yield c) Me_3SiCl (30 mmol) and NaI (30 mmol) were used. d) $MeSiCl_3$ was used instead of Me_3SiCl. e) Me_3SiCl (20 mmol) and NaI (20 mmol) were used. f) At 0 °C. g) At 40 °C. h) About 50% of *exo*-**2** was converted to furan and methyl acrylate.

Again, the $MeSiCl_3$/NaI reagent was milder than the Me_3SiCl/NaI one (Run 3). The reaction of *endo*-**2** with Me_3SiCl/NaI led to **4**(43%), **5**(12%), and **6**(27%). The yield of **4** increased to 67% upon using 2.0 equiv of Me_3SiCl/NaI at 0 °C for 48 h (Run 6). When the same reaction was carried out at 40 °C, the reaction was completed within 1 h to give **4** in 63% yield. **4** was prepared from 3,6-dihydrobenzoic acid by Boeckman,[10] but the procedure is somewhat difficult.

In contrast to the case of *endo*-**2**, *exo*-**2** reacted with Me_3SiCl/NaI under similar conditions yielding **4** in poor yield (9%), and most of *exo*-**2** was converted to furan and methyl acrylate, corresponding to retro-Diels-Alder products. Although the differences in the reactivity of *endo*- and *exo*-**2** with Me_3SiCl/NaI is still unclear, we believe that a cationic species, $[CH_3CN^+-SiMe_3]I^-$,[9] has difficulty in attacking the bridge-oxgen atom of *exo*-**2** in which a methoxycarbonyl group is oriented in the same direction as the bridge-oxygen atom.

Experimental

All of the starting materials were commercially available and were used without further purification except for the solvents. 7-Oxabicyclo[2.2.1]heptenes, **1** and **2**, were prepared according to procedures described in the literature.[5,11] IR spectra were taken with a JASCO-A202 spectrometer, and the ^1H- and ^{13}C-NMR spectra were recorded on a JEOL PMX-60 spectrometer and a Hitachi R-90H, respectively. GLC analyses were performed on a Yanaco-G1800 instrument.

General Method for Ring Cleavage of 7-Oxabicyclo[2.2.1]hept-2-enes. Reactions were normally conducted at a 10-mmol scale in a 25-ml flask fitted with a condenser under a nitrogen atmosphere. To a solution of chlorotrimethylsilane (12 mmol) and sodium iodide (12 mmol) in acetonitrile (10 ml) was added 7-oxabicyclo[2.2.1]hept-2-ene (10 mmol). The mixture was stirred for 20 h at room temperature and was then quenched by water. After washing with a solution of sodium thiosulfate, products were extracted with ether. The extract was washed again with water and dried over anhyd sodium sulfate. After evaporation of the ether, the products were isolated by chromatography on silica gel (hexane:ethyl acetate=10:1 eluent) and were identified by their spectral data.

2-Furanpropanenitrile (3): ^{13}C-NMR ($CDCl_3$) δ=151.4(s), 141.8(d), 118.7(s), 110.3(d), 106.6(d), 24.2(t), 16.5(t); ^1H NMR(CCl_4) δ=7.31 (d, 1H), 6.29 (t, 1H), 6.16 (d, 1H), 2.96 (t, 2H), 2.62 (t, 2H); IR (neat) 2950 cm^{-1}, 2250 cm^{-1}, 1420 cm^{-1}, 1110 cm^{-1}, 740 cm^{-1}; MS *m/z* 121.0 (M^+).

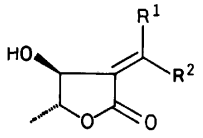
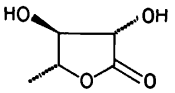
A Straightforward Access to 5-Deoxy-D-arabinono-1,4-lactone, a Versatile Intermediate in the Lauraceae Lactones Syntheses

Sigeru Torii,* Tsutomu Inokuchi, and Yoshinori Masatsugu
Department of Industrial Chemistry, School of Engineering, Okayama University, Okayama 700
(Received July 8, 1985)

Synopsis. 5-Deoxy-D-arabinono-1,4-lactone (**2**) was synthesized by a RuO_4-catalyzed oxidative cleavage of 6-deoxyglucal diacetate (**5d**), derived from D-glucal triacetate (**3**), followed by alkaline hydrolysis and acidic work-up.

Chiral γ-lactones are versatile building blocks in natural product synthesis and their syntheses from readily available carbohydrates are currently an important area of research.[1] In connection with our programs dealing with the total synthesis of the lauraceae lactones, *i.e.*, (−)-litsenolide B_1 (**1a**) and B_2 (**1b**),[2] we sought a simple method for the preparation of optically active derivatives of β-hydroxy-γ-methyl-γ-lactone. Although 5-deoxy-L-arabino-γ-lactone [(2*R*,3*S*,4*S*)-2,3-dihydroxy-4-pentanolide] is easily accessible from L-rhamnose,[3,4] the preparation of its antipode, 5-deoxy-D-arabinono-1,4-lactone (**2**) whose chirality at the C(3) and C(4) carbons coincides with asymmetric carhons of **1**, is not explored to data due to the scant availability of 6-deoxy-D-mannose. More recently, on the other hand, derivation of (3*R*,4*R*)-pentan-4-olide from D-(+)-ribonic acid by the double





1a: R^1 = H, R^2 = $(CH_2)_9C{\equiv}CH$
1b: R^1 = $(CH_2)_9C{\equiv}CH$, R^2 = H

2

deoxygenation at the C(2) and C(5) positions and its utilization in the synthesis of (−)-litsenolide C_1 and C_2 has been reported.[2d] We describe here a facile synthesis of **2** from the commercially available D-glucal triacetate (**3**)[5] *via* the oxidative cleavage of carbon–carbon double bond of the corresponding 6-deoxyglucal diacetate (**5d**).

Deoxygenation at the C(6) position of **3** to **5d** is the initially requested task in the present synthesis. According to the procedure reported preliminarily by Fraser-Reid *et al.*,[6] we first attempted to transform **3** to the *p*-toluenesulfonate **5a** by selective sulfonylation of the primary hydroxyl group of D-glucal (**4**). After alkaline hydrolysis of **3** with aqueous potassium carbonate, the liberated triol **4** was treated successively with *p*-toluenesulfonyl chloride in pyridine at range 0—50 °C for extended period and then with excess acetic anhydride. Unfortunately, no intended tosylation was observed in this reaction and the starting **3** was recovered. However, the selective sulfonylation of **4** was successfully achieved by using more reactive methanesulfonyl chloride and the desired **5b** was obtained in 52% overall yield from **3** when the reaction was followed by acetylation with acetic anhydride after mesylation. Displacement of the mesylate **5b** with lithium iodide in 2-butanone heated at reflux produced the 6-iodo derivative **5c** which was in turn reduced to the key intermediate **5d** with tributyltin hydride in 91% yield (from **5b**).

In the preceding article[7] we described a ruthenium tetroxide-catalyzed oxidative cleavage of enolic olefins of cyclic structure, giving the corresponding carboxylic acids in good yields. Taking into the advantage of this procedure, the conversion of **5d** into the carboxylic acid **6** was attempted. Thus, the treatment of **5d** with ruthenium tetroxide, generated *in situ* from a catalytic amount of ruthenium dioxide and a stoichiometric amount of sodium periodate (3 equiv) in a biphase solution of carbon tetrachloride and water (1:1 v/v), provided the tri-*O*-acyl-D-arabinonic acid **6** in 78% yield. Finally, the hydrolysis of **6** with aqueous potassium carbonate followed by acidic work-up with 10% hydrogen chloride furnished the desired **2** in 89% yield.

Experimental

Melting points are uncorrected and boiling points are indicated by an air-bath temperature without correction. IR spectra were recorded with a JASCO IRA-1 grating spectrometer. Unless otherwise noted, ^1H NMR spectra were determined with either a Hitachi R-24 (60 MHz) or a JEOL FX-100 (100 MHz). ^{13}C NMR spectra were recorded with a JEOL FX-100 (25.05 MHz) spectrometer. Optical rotations were taken on a JASCO DIP-140 digital polarimeter. Ele-

mental analyses were performed in our laboratory.

3,4-Di-O-acetyl-6-O-methylsulfonyl-1,5-anhydro-2-deoxy-D-arabino-hex-1-enitol (5b). To a solution of D-glucal triacetate (**3**, 1.0 g, 3.67 mmol) in EtOH (10 ml) was added 2M K_2CO_3 (5.5 ml) (1 M=1 mol dm^{-3}). After stirring for 19 h at room temperature, the mixture was filtered and the filtrate was concentrated *in vacuo*. The remaining solid was dried at 50—60 °C for 24 h at diminished pressure and then dissolved in pyridine (7 ml). To this solution was added methanesulfonyl chloride (0.43 ml, 5.56 mmol) at −20 °C and the resulting solution was stirred for 6.5 h at −20 °C and allowed to warm gradually to room temperature. After recooling to 0 °C, the mixture was treated with acetic anhydride (1.4 ml, 14.7 mmol) at 0 °C and stirred for 1 h at 0 °C and additional 17 h at room temperature. The mixture was poured into saturated $NaHCO_3$ and extracted several times with AcOEt. The extracts were washed with 5% $NaHCO_3$ and saturated NaCl, dried (Na_2SO_4), and concentrated. Purification of the crude products on column chromatography (SiO_2, hexane–AcOEt 5:1) gave 590 mg (52%) of **5b**: Mp 47—51 °C (from ether); $[\alpha]_D^{17}$ +15.0 °(*c* 1.6 in EtOH); IR (Nujol) 1730 (ester C=O), 1641 (C=C),1352, 1240, 1220, 1161, 1070, 1039, 963, 929 cm^{-1}; ^{1}H NMR (60 MHz, $CDCl_3$) δ=2.07, 2.11 (s, 6, CH_3CO), 3.09 (s, 3, CH_3SO_2), 4.20—4.60 (m, 1, CH-O), 4.42 (m, 2, CH_2OSO_2), 4.91 (d, d, *J*=6, 3 Hz, 1, O-C=CH), 5.13—5.50 (m, 2, CH-O), 6.51 (d, *J*=6 Hz, 1, O-CH=C). Found: C, 42.97; H, 5.35. Calcd for $C_{11}H_{16}O_8S$: C, 42.86; H, 5.23.

3,4-Di-O-acetyl-6-iodo-1,5-anhydro-2,6-dideoxy-D-arabino-hex-1-enitol (5c). A mixture of **5b** (667 mg, 2.17 mmol) and LiI (487 mg, 3.26 mmol) in 2-butanone (15 ml) was heated at reflux for 29 h. After cooling, the mixture was filtered and the filtrate was concentrated *in vacuo*. The residue was purified on column chromatography (SiO_2, hexane–AcOEt 5:1) to give 676 mg (92%) of **5c**: Bp 119—120 °C/2.5 Torr (1 Torr=133.3 Pa); $[\alpha]_D^{13}$ −3.43° (*c* 1.76 in EtOH); IR (neat) 3040, 3000, 1740, 1725 (ester C=O), 1640 (C=C), 1420, 1363, 1220, 1130, 1078, 1037, 945, 809, 745 cm^{-1}; ^{1}H NMR (60 MHz, $CDCl_3$) δ=2.06, 2.10 (s, 6, CH_3CO), 3.35 (d, *J*=1.5 Hz, 1, CH_2I), 3.44 (s, 1, CH_2I), 3.90—4.30 (m, 1, CH-O), 4.38 (m, 1, O-C=CH), 5.17—5.88 (m, 2, CH-O), 6.50 (d, *J*=6 Hz, 1, O-CH=C); ^{13}C NMR ($CDCl_3$) δ=2.0 (t), 20.8 (q), 21.0 (q), 66.6 (d), 69.7 (d), 74.8 (d), 98.8 (d), 145.3 (d), 169.3 (s), 170.1 (s). Found: C, 35.19; H, 3.73. Calcd for $C_{10}H_{13}IO_5$: C, 35.32; H, 3.86.

3,4-Di-O-acetyl-1,5-anhydro-2,6-dideoxy-D-arabino-hex-1-enitol (5d). A solution of **5c** (357 mg, 1.05 mmol) and *n*-Bu_3SnH (920 mg, 3.16 mmol) in toluene (7 ml) was stirred at room temperature for 4.5 d under nitrogen atmosphere. Evaporation of the solvent followed by column chromatography (SiO_2, hexane–AcOEt 15:1) of the residue gave 222 mg (99%) of **5d**: Bp 87—88 °C/2 Torr; $[\alpha]_D^{15}$ −47.7° (*c* 1.36 in EtOH); IR (neat) 3040, 1735 (ester C=O), 1644 (C=C), 1375, 1220, 1109, 1045, 1022, 910 cm^{-1}; ^{1}H NMR (100 MHz, $CDCl_3$) δ=1.31 (d, *J*=7 Hz, 3, CH_3), 2.04, 2.09 (s, 6, CH_3CO), 4.09 (d, q, *J*=7, 6.5 Hz, 1, CH-O), 4.75 (d, d, *J*=6.5, 3.3 Hz, 1, O-C=CH), 4.99 (d, d, *J*=8, 6 Hz, 1, CH-O), 5.32 (d, d, d, *J*=8, 3.3, 1.5 Hz, 1, CH-O), 6.40 (d, d, *J*=6.5, 1.5 Hz, O-CH=C); ^{13}C NMR ($CDCl_3$) δ=16.6 (q), 20.9 (q), 21.1 (q), 68.3 (d), 71.9 (d), 72.5 (d), 98.8 (d), 146.0 (d), 169.9 (s), 170.6 (s). Found: C, 56.23; H, 6.75. Calcd for $C_{10}H_{14}O_5$: C, 56.07; H, 6.59.

2,3-Di-O-acetyl-4-O-formyl-5-deoxy-D-arabinonic Acid (6). A solution of **5d** (71 mg, 0.33 mmol) in CCl_4 (5 ml) was mixed with a solution of $NaIO_4$ (211 mg, 0.99 mmol) in H_2O (5 ml) and to this mixture was added $RuO_2 \cdot 2H_2O$ (3 mg, 0.02 mmol). After vigorous stirring for 1 h at room temperature, the reaction was quenched with a small amount of 2-propanol. The CCl_4 layer was separated and the aqueous layer was acidified with aqueous 5% HCl and extracted several times with AcOEt. The combined extracts were filtered and the filtrate was dried (Na_2SO_4) and concentrated to give 67 mg (78%) of **6**: $[\alpha]_D^{16}$ +37° (*c* 0.75 in EtOH); IR($CHCl_3$) 3600—2400 (COOH), 1740, 1720 (C=O), 1365, 1205, 1160, 1120, 1040, 840, 930 cm^{-1}; ^{1}H NMR (60 MHz, $CDCl_3$) δ=1.30 (d, *J*=6 Hz, 3, CH_3), 2.11, 2.17 (s, 6, CH_3CO), 4.90—5.70 (m, 3, CH-O), 8.02 (s, 1, CHO), 8.50 (br, 1, COOH). Satisfactory elemental analysis for the methyl ester of **6**; Found: C, 47.70; H, 5.95. Calcd for $C_{11}H_{16}O_8$: C, 47.83; H, 5.84.

5-Deoxy-D-arabinono-1,4-lactone (2). To a solution of **6** (207 mg, 0.79 mmol) in MeOH (10 ml) was added 2 M K_2CO_3 (2 ml) at 3—5 °C. After stirring for 20 h at room temperature, the mixture was acidified to pH 2—3 with 10% HCl and concentrated *in vacuo*. The remaining solids were washed several times with hot AcOEt and the washings were filtered, dried (Na_2SO_4), and concentrated. The crude product was purified on column chromatography (SiO_2, hexane–AcOEt 2:1) to give 92.3 mg (89%) of **2**: Mp 124.5—125.5 °C (from methanol) (lit, data of L-enantiomer[3] 125 °C); $[\alpha]_D^{13}$ +37.3 °(*c* 1.01 in EtOH) (lit, data of L-enantiomer[3] −34—−39°); IR (KBr) 3400 (OH), 1758 (lactone C=O), 1390, 1363, 1330, 1230, 1195, 1144, 1095, 1055, 1019, 945, 870 cm^{-1}; ^{1}H NMR (400 MHz, CD_3OD)[8] δ=1.41 (d, *J*=6.3 Hz, 3, CH_3), 3.76 (d, d, *J*=8.8, 8.3 Hz, 1, CH-O), 4.15 (d, q, *J*=8.3, 6.3 Hz, 1, CH-O), 4.28 (d, *J*=8.8 Hz, 1, CH-O), 4.84 (s, OH); ^{13}C NMR (CD_3OD) δ=18.0 (q), 75.1 (d), 78.2 (d), 80.1 (d), 176.0 (s). Found: C, 45.32; H, 5.95. Calcd for $C_5H_8O_4$: C, 45.46; H, 6.10.

The authors are grateful to the Ministry of Education, Science, and Culture for a financial support by a Grant-in-Aid for Scientific Research (No. 60470089).

Optical Resolution of 3a,4,7,7a-Tetrahydro-4,7-methano-1*H*-indene Derivatives

Toshio Ito, Yoshio Okamoto,† and Takeshi Matsumoto*
Department of Chemistry, Faculty of Science, Hokkaido University, Sapporo, 060
†*Department of Chemistry, Faculty of Engineering Science, Osaka University, Toyonaka 560*
(Received July 10, 1985)

Synopsis. (1*RS*,3a*RS*,4*RS*,7*SR*,7a*SR*)-3a,4,7,7a-Tetrahydro-4,7-methano-1*H*-inden-1-ol was resolved kinetically and its C-1 epimer was resolved chromatographically. Absolute configurations of these resolved compounds were determined.

Optically active 3a,4,7,7a-tetrahydro-4,7-methano-1*H*-indene(dicyclopentadiene) and allied compounds seem useful chiral synthons for syntheses of optically active natural products,[1] because they contain at least four asymmetric centers and a variety of reactive sites. We report here optical resolution of (1*RS*,3a*RS*,4*RS*,7*SR*,7a*SR*)-3a,4,7,7a-tetrahydro-4,7-methano-1*H*-inden-1-ol-[(±)-**1**] and its C-1 epimer (±)-**2** (Fig. 1).[2]

Titanium(IV) tartrate-catalyzed asymmetric epoxidation developed by Sharpless *et al.*[3] was adopted for kinetic resolution of (±)-**1**. Allylic alcohol (±)-**1** (50 mmol) was treated with 0.6 mol eq of *t*-butyl hydroperoxide in the presence of diisopropyl tartrate and Ti(*i*-PrO)$_4$ as catalyst to afford epoxy compound (−)-**6** and starting material enriched in (+)-**1** in 38 and 34% isolated yields, respectively (Fig. 2). Specific rotation of the resolved **1** was +78°(*c* 1.00, $CHCl_3$). A portion of this sample was esterified with (*S*)-2-methoxy-2-trifluoromethylphenylacetyl chloride ((*S*)-MTPACl)[4] to yield (*S*)-MTPA ester **5**, which was found to be a mixture of diastereomers by the 400 MHz ^{1}H NMR spectrum. The diasteromeric excess was 68.2%. Optically pure (+)-**1** was readily obtained by recrystallization in 63% yield, from the 68.2% e. e. **1**.

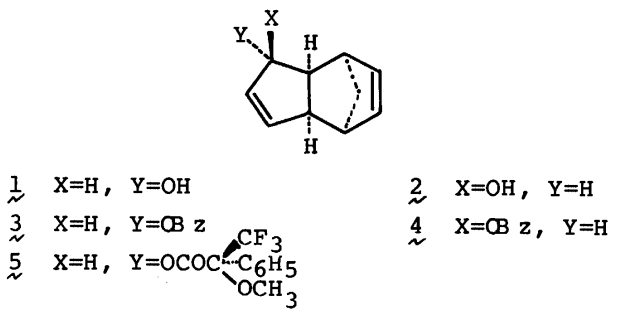

Fig. 1.

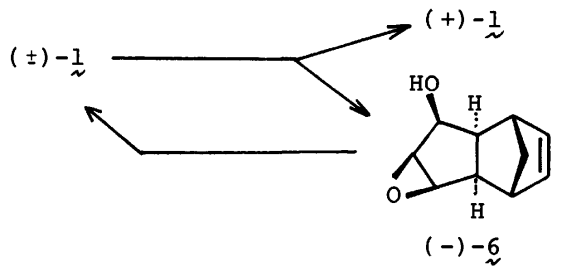

Fig. 2.

Next, the absolute configuration of the above optically active alcohol was determined by the allyl benzoate rule.[5] Alcohol (+)-**1** (68.2% e.e.) was converted to its benzoate **3**, whose CD spectrum exhibited a positive first Cotton effect peak at 222 nm. Therefore the absolute configuration of (+)-**1** was determined to be as shown in Fig. 3.

Produced epoxy alcohol (−)-**6** had low optical purity (39% e.e., by ^{1}H NMR of (*S*)-MTPA ester), and was not synthetically useful. Therefore (−)-**6** was reverted to **1**. Epoxy alcohol (−)-**6** was reduced with $TiCl_3$–$LiAlH_4$[6] to give (±)-**1** in 65% yield (Fig. 2).

The above kinetic resolution is practical for preparing a large quantity of optically active (+)-**1**. However, the method is operationally not so simple. On the other hand, the resolution by chromatography developed by one of us (Y. O.)[7] is simple. Although this method is at present not so practical for large scale preparation, resolution of dicyclopentadiene derivatives by means of the (+)-PTrMA-coated silicagel column[7] was next attempted. Dicyclopentadiene, (±)-**1** and (±)-**2**, and acetates of (±)-**1** and (±)-**2** were not resolved. Since it was reported that aryl groups strongly interacted with (+)-PTrMA,[7] (±)-**1** and (±)-**2** were

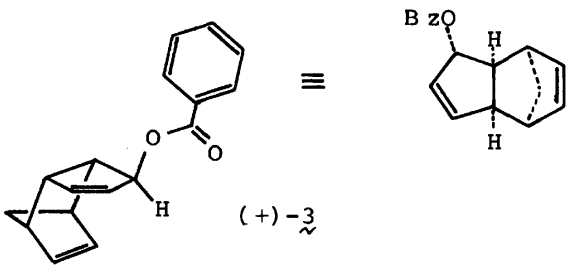

Fig. 3.

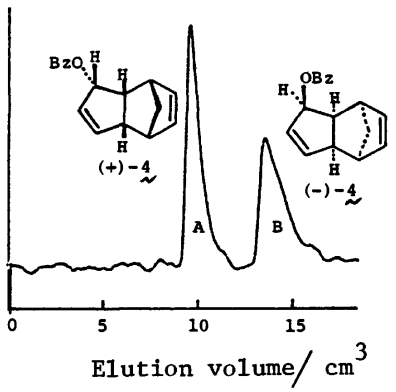

Fig. 4. Resolution of (±)-**4**(0.4 mg). (+)-PTrMA column, 25×0.46 (i.d.); eluent, MeOH; flow rate 0.76 cm^3 min^{-1}; temperature 25 °C.

benzoylated. While benzoate (±)-**3** was not separated (R_s=0.5), its C-1 epimer (±)-**4** was cleanly resolved (R_s=2.02, Fig. 4). The eluents A and B contained respectively enantiomers (+)-**4** and (−)-**4** with the absolute configuration shown in Fig. 4, which was proved as follows. Alcohol (+)-**1** (68.2% e.e.) with known configuration was converted to (−)-**2**,[2] which in turn was benzoylated and passed through the (+)-PTrMA column. The main peak coincided in retention volume with that of the eluent B (Fig. 4).

Experimental

Measurements. Melting points were uncorrected. IR spectra were measured with a JASCO model IR-S spectrophotometer. Unless otherwise noted, ^{1}H NMR spectra were recorded at 60 MHz (HITACHI R-20B). ^{1}H NMR spectra at 400 MHz were taken on a JEOL JNM FX-400. Low resolution mass spectra were obtained with a HITACHI model RMS-6U instrument. Optical rotations and CD spectra were measured by means of a JASCO model DIP-SL automatic polarimeter and a JASCO J-20 automatic recording spectropolarimeter respectively. The high-performance liquid chromatography was accomplished on a Waters associates model 6000A chromatograph equipped with a Waters associates R-401 RI detector.

Kinetic Resolution of (±)-1 and Absolute Configuration of (+)-1. A mixture of (±)-**1** (7.1 g, 50.0 mmol), diisopropyl (2*R*,3*R*)-tartrate (13.5 g, 57.7 mmol) and Ti(*i*-PrO)$_4$ (14.9 cm^3, 50.0 mmol) in dry CH_2Cl_2 (500 cm^3) was stirred at −20 °C. Anhydrous *t*-BuOOH (11.3 g, 30.0 mmol) in dry CH_2Cl_2 (about 24 w/w%) was then added, and the resulting mixture was maintained at −20 °C in a freezer. After 4 d, the cold reaction mixture was poured into a precooled (−20 °C) solution of 1000 cm^3 of acetone containing 14 cm^3 of water. The resulting mixture was stirred for 1 h at −20 °C and for 30 min at room temperature. After *ca.* 400 cm^3 of the acetone was evaporated, the residue was diluted with ether (400 cm^3) and filtered. The filtrate was concentrated and diluted again with 430 cm^3 of ether, and then 1 M NaOH soution (170 cm^3) (1 M=1 mol dm^{-3}) was added to the ether solution. The resulting homogeneous mixture was stirred for 1 h at 0 °C. After hydrolysis of the tartrate was complete, the ether layer was separated and the aqueous layer was extracted with ether (3×100 cm^3). The combined ether extracts were washed with water and NaCl solution. After drying (Na_2SO_4), the solvent was evaporated to give 5.8 g of an oily residue, which was chromatographed on silica gel (200 g) with 30% AcOEt in hexane. The elution gave 2.4 g (34%) of (+)-**1** and 3.0 g (38%) of (−)-**6**. (+)-**1**: $[\alpha]_D$=+78° (*c* 1.00, $CHCl_3$); mp 50—52 °C. (−)-**6**: $[\alpha]_D$=−32.6 (*c* 4.05, $CHCl_3$); mp 35—38 °C; IR($CHCl_3$) 3560, 1255 cm^{-1}; ^{1}H NMR ($CDCl_3$) δ=6.06 (2H, t, *J*=1.0 Hz), 3.78 (1H, t, *J*=1.5 Hz), 3.41 (1H, t, *J*=2 Hz), 3.27 (1H, d, *J*=2 Hz), 3.2—2.8 (2H, m), 1.49 and 1.30 (ABq, *J*=8 Hz); *m/z* 148 (M−H_2O). Found: C, 73.03; H, 7.39. Calcd for $C_{10}H_{12}O_2$: C, 73.14; H, 7.37%. E. e. was 68.2% for (+)-**1**; two kinds of peaks due to C-7a-H of (+)-**1** (*S*)-MTPA ester were observed at 2.70 (84%) and 2.60 (16%) in the 400 MHz ^{1}H NMR spectrum. For (−)-**6**, e. e. was 39%; two kinds of peaks due to C-6-H of (−)-**6** (*S*)-MTPA ester appeared at 4.85 (69.5%) and 4.82 (30.5%) in the 400 MHz ^{1}H NMR spectrum.

Recrystallization of (+)-**1** (68.2% e.e., 1.0 g) from petroleum ether three times afforded optically pure (+)-**1** (0.63 g, 63%) $[\alpha]_D$=+115.1 ° (*c* 1.00, $CHCl_3$); mp 69.5—72.0 °C. (*S*)-MTPA ester of (+)-**1**: $[\alpha]_D$=+138° (*c* 1.00, $CHCl_3$); IR (neat) 3120, 1750, 1625, 1460, 1225, 1170 cm^{-1}; ^{1}H NMR ($CDCl_3$, 400 MHz) δ=7.53 (2H, m), 7.39 (3H, m), 6.06 (1H, dd, *J*=6, 3 Hz), 5.91 (1H, dt, *J*=6, 2 Hz), 5.88 (1H, dd, *J*=6, 3.5 Hz), 5.57 (1H, dt, *J*=6, 2 Hz), 5.18 (1H, q, *J*=2 Hz), 3.56 (3H, q, *J*=1 Hz), 3.54 (1H, m), 3.42 (1H, br s, W_H=10 Hz), 2.84 (1H, br s, W_H=9 Hz), 2.70 (1H, qd, *J*=2, 8 Hz), 1.63 (1H, td, *J*=1.5, 8 Hz), 1.43 (1H, br d, *J*=8 Hz).

$TiCl_3$-$LiAlH_4$ Reduction of (−)-6. To an ice-cooled suspension of $TiCl_3$ (110 mg, 0.71 mmol) in dry THF (3.3 cm^3) was added $LiAlH_4$ (6.8 mg, 0.18 mmol). The resulting mixture was stirred for 20 min at 0 °C, and (−)-**6** (39% e.e., 39 mg, 0.23 mmol) in dry THF (0.5 cm^3) was added. Stirring was continued for 10 min. Celite, anhydrous Na_2SO_4 (each 500 mg), and saturated aq NH_4Cl solution (0.5 cm^3) were then added successively. The resulting mixture was filtered, and the solid material was washed with AcOEt (3×20 cm^3). The combined organic solution was washed with aq NaCl solution and dried (Na_2SO_4). The solvent was evaporated to give an oily residue, which was purified by preparative TLC to afford 22 mg (65%) of (±)-**1**.

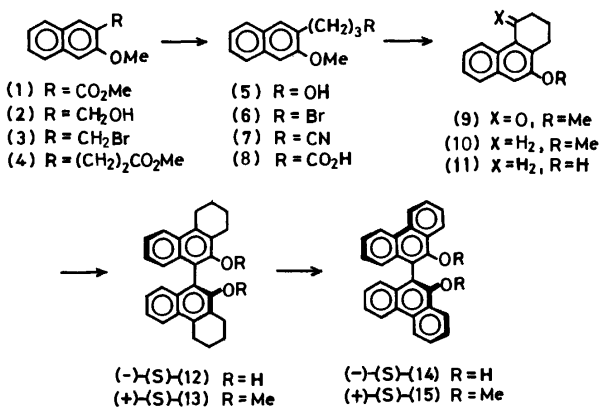
Absolute Configurations of Novel Axially Dissymmetric 10,10′-Dihydroxy-9,9′-biphenanthryl and Its Related Compounds

Koji YAMAMOTO,* Hitoshi FUKUSHIMA, Hiroya YUMIOKA, and Masao NAKAZAKI
Department of Chemistry, Faculty of Engineering Science, Osaka University, Toyonaka, Osaka 560
(Received July 13, 1985)

Synopsis. Stereoselective oxidative coupling of 10-hydroxy-1,2,3,4-tetrahydrophenanthrene derived from methyl 3-methoxy-2-naphthoate gave (−)-(*S*)-10,10′-dihydroxy-1,1′,2,2′,3,3′,4,4′-octahydro-9,9′-biphenanthryl which was converted into (+)-(*S*)-10,10′-dimethoxy-9,9′-biphenanthryl assigning the *S* configuration to (−)-10,10′-dihydroxy-9,9′-biphenanthryl.

Recently, we found that the novel axially dissymmetric molecule, 10,10′-dihydroxy-9,9′-biphenanthryl (**14**), has been used for synthesis of chiral crown ether with high enantiomer selectivity toward primary amines[1] and enantioselective reduction of ketones.[2] Here we report the determination of the absolute configuration of chiral 10,10′-dihydroxy-9,9′-biphenanthryl (**14**) and its related compounds.

Lithium aluminium hydride reduction of methyl 2-methoxy-3-naphthoate (**1**)[3] furnised the alcohol (**2**) which was converted to the bromide (**3**) with phosphorus tribromide, then submitted to the malonic ester synthesis under usual reaction conditions to afford the ester (**4**) (32.5% yield from **1**). After the side chain of **4** was extended by routine method (*via* cyanide), the resulting acid (**8**) (94% yield from **4**) was cyclized with polyphosphoric acid to yield the expected cyclic ketone (**9**) in 89% yield. Wolff-Kishner reduction of **9** followed by hydrolysis with AcOH–H_2O–concd HCl (10:5:1) gave the naphthol derivative (**11**) (69.7% yield from **9**). Stereoselective oxidative coupling of **11** was carried out using optically active amine–copper(II) complex, which prepared *in situ* by treating (−)-(*S*)-1,2-diphenylethylamine[4] and $Cu(NO_3)_2 \cdot 3H_2O$ in methanol. The coupling product was purified by recrystallization from benzene to give an optically pure specimen of the binaphthol derivative (−)-(**12**) (79% yield,$[\alpha]_D^{21}$ −29.0° ($CHCl_3$).[5] Comparison of the CD spectra of (−)-**12** with that of authentic (−)-(*S*)-2,2′-dihydroxy-3,3′-dimethyl-1,1′-binaphthyl[7] let us to conclude that these two compounds have the same configuration. Methylation of (−)-(**13**) which was dehydrogenated with 2,3-dichloro-5,6-dicyano-1,4-benzoquinone to give (+)-(*S*)-10,10′-dimethoxy-9,9′-biphenanthryl (**15**) (45% yield from **12**, $[\alpha]_D^{23}$ +26° ($CHCl_3$)). This dextrorotatory compound (**15**) could also be derived from (−)-10,10′-dihydroxy-9,9′-biphenanthryl (**14**)[2] by methylation with methyl *p*-toluenesulfonate. These correlation enable us to assign *S* configurations to (−)-**14** and its related compounds.



Experimental

Melting points are uncorrected. IR, NMR, UV, and CD spectra were recorded on a Hitachi 260-10, a JNM-MH-100, a Hitachi 220A, and a JASCO J-20 spectrometer, respectively.

3-Methoxy-2-naphthaleneethanol (2). A solution of **1** (23.6 g, 0.109 mol) in dry THF (150 ml) was added to a suspension of $LiAlH_4$ (2.5 g, 66 mmol) in dry THF (150 ml). The mixture was refluxed for 8 h with stirred and cooled in an ice-bath. To the chilled reaction mixture was added aq HCl, and extracted with ether. The ether extract was washed with water, dried ($MgSO_4$), concentrated, and recrystallized from benzene, giving 13.9 g (68% yield) of **2**: Mp 72—73 °C; IR (KBr) 3450 cm^{-1} (OH) (Found: C, 75.95; H, 5.79%).

2-Bromomethyl-3-methoxynaphthalene (3). To a stirred solution of **2** (11.9 g, 63.4 mmol) in dry ether (150 ml) was added dropwise a solution of phosphorus tribromide (8.6 g, 31.8 mmol) in dry ether (70 ml) at room temperature. The mixture was stirred for further 4 h, and quenched with water (90 ml). After a usual work-up, the crude product was recrystallized from hexane–benzene to give **3** (13 g, 81%), mp 150—151 °C (Found: C, 57.77; H, 4.50%).

Methyl 3-Methoxy-2-naphthalenepropionate (4). The alykylation of malonic ester with **3** (12.3 g, 48 mmol) was carried out according to literature[8] using sodiomalonate (prepared from sodium (1.84 g, 0.08 g-atom), ethyl malonate (21 g, 0.19 mol), and absolute ethanol (28 ml). The resulting diester was saponified by refluxing for 3 h with KOH (30 g) in 80% ethanol (280 ml). After a usual work-up, the resulting dicarboxylic acid (7 g) was decarboxylated by heating at 200 °C for 1 h. The routine esterification of the monocarboxylic acid with methanol and concd H_2SO_4 afforded **4** (6.7 g, 59%): Bp 160—162 °C (0.9 mmHg); IR (film) 1730 cm^{-1} (C=O) (Found: C, 74.01; H, 6.42%).

3-Methoxy-2-naphthalenepropanol (5). Hydride reduction of **4** was carried out followed by the same method as described of **2**, using **4** (6.7 g, 27.5 mmol) and $LiAlH_4$ (0.63 g, 16.5 mmol). The product was distilled to give **5** (5.5 g, 93%): Bp 168—169 °C (0.7 mmHg); IR (film) 3450 cm^{-1} (OH).

2-(3-Bromopropyl)-3-methoxynaphthalene (6). The alcohol (**5**) (5.2 g, 24 mmol) was converted into the bromide (**6**) following the same method as described for **3**. Recrystallization of the product from ethanol afforded **6** (4.1 g, 61%): mp 56—57 °C (Found: C, 60.22; H, 5.39%).

2-(3-Cyanopropyl)-3-methoxynaphthalene (7). A mixture of **6** (3.87 g, 13.9 mmol), KCN (2.55 g, 13.9 mmol), and 80% ethanol (30 ml) was refluxed for 6 h. After removal of the solvent, the reaction mixture was diluted with water and the product was extracted with ether. The etheral extract was dried ($MgSO_4$), concentrated, and recrystallized from methanol, giving 3.0 g (95%) of **7**: Mp 74—75 °C; IR (KBr)

2250 cm^{-1} (C≡N) (Found: C, 79.98; H, 6.78%).

3-Methoxy-2-naphthalenebutyric acid (8). A solution of **7** (2.7 g, 12.2 mmol), KOH (5.4 g, 96 mmol), and 70% ethanol (30 ml) was refluxed for 4 h, and the chilled reaction mixture was quenched with 2M HCl (200 ml) (1 M=1 mol dm^{-3}). The separated product was extracted with chloroform. The extract was dried ($MgSO_4$), concentrated, and recrystallized from methanol, giving 2.8 g (95%) of **8**: mp 93—94 °C (Found: C, 73.73; H, 6.66%).

10-Methoxy-1,2,3,4-tetrahydro-4-phenanthrenone (9). A solution of **8** (2.55 g, 10.6 mmol) and polyphosphoric acid (40 g) was stirred for 1 h at 60 °C. The hot mixture was poured onto ice-water and the product was extracted with ether. The ether solution was washed with water and dried ($MgSO_4$). After evaporation of the solvent, the residue was recrystallized from hexane to give **9** (2.13 g, 89%): Mp 83—84 °C; IR (KBr) 1660 cm^{-1} (C=O) (Found: C, 79.73; H, 6.30%).

10-Methoxy-1,2,3,4-tetrahydrophenanthrene (10). Wolff-Kishner reduction of **9** (0.9 g, 4 mmol) using KOH (0.9 g, 16 mmol), 100% hydrazine hydrate (0.8 g, 6 mmol), and diethylene glycol (20 ml) was carried out according to literature[9] to give **10** (0.64 g, 75%). Recrystallization from methanol furnished colorless needles: Mp 72—73 °C (Found: C, 84.84; H, 7.63%).

10-Hydroxy-1,2,3,4-tetrahydrophenanthrene (11). A solution of **10** (0.12 g, 0.57 mmol) in a mixture of 10:5:1 acetic acid, water, and concd HCl (16 ml) was refluxed for 15 h. The mixture poured onto ice-water and the product was extracted with ether. After a usual work-up, the crude product was recrystallized from hexane to give **11** (0.1 g, 93%): Mp 127—128 °C; IR (KBr) 3300 cm^{-1} (OH) (Found: C, 84.72; H, 7.15%).

(−)-10,10′-Dihydroxy-1,1′,2,2′,3,3′,4,4′-octahydro-9,9′-biphenanthryl (12). To a chilled solution (−5 °C) of (−)-(*S*)-diphenylethylamine ($[\alpha]_D^{23}$ −50.8° (EtOH), 99% optical purity[7]) (1.3 g, 6.6 mmol) and Cu $(NO_3)_2 \cdot 3H_2O$ (0.3 g, 1.24 mmol) in methanol (4 ml), was added a solution of **11** (0.12 g, 0.605 mmol) in methanol (1 ml). After stirring at −5 °C for 1 h under N_2, the mixture was quenched with 3% aq HCl (20 ml) and the product was extracted with ether. Work-up followed by recrystallization from benzene gave an optically pure (−)-**12**[5] (93 mg, 79%): Mp 216—218 °C; $[\alpha]_D^{21}$ −30.1° ($CHCl_3$); IR (KBr) 3520 cm^{-1} (OH); ^{1}H-NMR ($CDCl_3$) δ=1.76—2.18 (m, 8H), 2.88 (t, 4H), 3.22 (t, 4H), 5.09 (s, 2H), 7.00—7.46 (m, 6H), and 8.00 (d, 2H); UV (MeOH) 285 (log ε 4.13), 295 (4.13), 318 (3.83), and 333 nm (3.92); CD (MeOH) $[\theta] \times 10^{-3}$ (nm) +5.5 (272), −11.4 (296), −6.6 (307), −10.3 (318), −8.2 (324), −8.9 (328), and +2.0 (337); Found: C, 85.35; H, 6.70%. Calcd for $C_{28}H_{26}O_2$: C, 85.24; H, 6.64%.

(+)-10,10′-Dimethoxy-1,1′,2,2′,3,3′,4,4′-Octahydro-9,9′-biphenanthryl (13). To a boiling suspension of **12** (80 mg, 0.203 mmol), *t*-BuOK (50.2 mg, 0.447 mmol), and dry THF (4 ml) was added a solution of methyl *p*-toluenesulfonate (84 mg, 0.447 mmol) in dry THF (1 ml) under N_2. The reaction mixture was refluxed for further 5 h, cooled in an ice-bath, quenched with water, and extracted with ether. After a usual work-up, the product was recrystallized from benzene to give (+)-**13** (77 mg, 90%): Mp 170—171 °C; $[\alpha]_D^{19}$ +28.9° ($CHCl_3$); ^{1}H-NMR ($CDCl_3$) δ=1.71—2.19 (m, 8H), 2.63—3.37 (m, 8H), 3.27 (s, 6H), 7.05—7.35 (m, 6H), and 7.97 (d, 2H) (Found: C, 85.40; H, 7.23%).

(−)-10,10′-Dimethoxy-9,9′-biphenanthryl (15). a) Dehydrogenation of 13: A Solution of **13** (20.5 mg, 0.09 mmol) and 2,3-dichloro-5,6-dicyano-1,4-benzoquinone (20.5 mg, 0.09 mmol) in benzene (1 ml) was refluxed for 3 h. Evaporation of the solvent left a solid material which was recrystallized from benzene to give **15** (10 mg, 50%): Mp 251—253 °C; $[\alpha]_D^{23}$ +26.4° ($CHCl_3$); ^{1}H-NMR ($CDCl_3$) δ=3.46 (s, 6H), 7.20—7.82 (m, lOH), 8.22—8.36 (m, 2H), and 8.65—8.85 (m, 4H) (Found: C, 87.72; H, 5.67%).

b) Methylation of (−)-14: The same method as described for **13**, using (−)-**14** ($[\alpha]_D^{23}$ −71° ($CHCl_3$), 98% optical purity)[2] (0.1 g, 0.259 mmol), *t*-BuOK (60 mg, 0.52 mmol), methyl *p*-toluenesulfonate (0.1 g, 0.53 mmol) afforded **15** (70 mg, 65%): mp 251—253 °C; $[\alpha]_D^{23}$ +25.5° ($CHCl_3$).

Synopsis. Cylindrical crown ether, tridecalino-18-crown-6, shows strong embedding effect toward coordinated thallium ion.

Increasing attention has been paied to the host molecules such as cryptands,[1] spherands,[2] and cavitands,[2] which have not only high complexing ability but also high complexing selectivity. In this context, we designed a new class of cylindrical crown ether with bicycloalkane walls.[3] In this cylindrical system, it is expected that the coordinated metal ion may be embedded strongly by bicycloalkane moieties spread out above and below the crown ether ring. In this paper, we wish to report on strong embedding effect of three decalin moieties of tridecalino-18-crown-6† (**1**).

Results and Discussion

In the present cylindrical system, the embedding effect of bicycloalkane moieties constructing cylinder wall on complexation of cations can be estimated by the differences in magnitude between total stability of complexes and coordination ability of ethereal oxygen atoms. From the above concept, we selected thallium(I) and dimethylthallium(III) ions as stability and coordination probes, respectively, because it is well-known that the ionic radius of thallium(I) ion (1.40 Å)[4] and that of dimethylthallium(III) ion (1.25 Å)[5] are very close to that of potassium (1.33 Å)[4] and that the larger spin-spin coupling constants between thallium nucleus and methyl protons reflect the stronger coordination ability of ligands surrounding cation.[6]

First, spin-spin coupling constants between thallium nuclei and methyl protons of dimethylthallium (III) ion complexes were measured to estimate coordination ability of oxygens. As shown in Table 1, the cylindrical crown ethers, **1**, didecalino-18-crown-6 (**2**), and dibicyclooctano-18-crown-6† (**3**) had larger coupling constants than that of 18-crown-6 (**4**). These strong coordinations of cylindrical crown ether oxygens are ascribed to the location of oxygen atoms at the entropically favorable positions before and after complexation.

Next, complexation constants, K_c, were measured to determine total complex stabilities in chloroform according to Kimura's method.[7b,8] As is indicated in Table 1, these crown ethers showed similar complexing behavior toward potassium and thallium(I) ions.[9] Interestingly, tridecalino-18-crown-6 (**1**) having similar coordination ability to **2** gave ten-fold larger stability than that of **2** in chloroform. From these results, it may be concluded that total stability of complexes is mainly influenced by the bicycloalkane moieties of cylindrical system and, in addition, three decalin walls exhibit efficient embedding effect toward coordinated thallium ion.

Experimental

^{1}H NMR specra were taken with JEOL JMN-PS-100 (100 MHz) and HITACHI R-600S (60 MHz) spectrometers in CD_3CN solutions with Me_4Si as an internal standard.

†Ortho fused cyclic compounds are tentatively named "decalino" and "bicyclooctano" for decahydronaphtho[4*a*,8*a*,] and octahydropentaleno[3*a*,6*a*], respectively.

Electronic spectra were measured on a HITACHI 356 spectrophotometer.

Tridecalino-18-crown-6 (1). **1** was prepared from 1,2:7,8-didecalino-3,6-dioxaoctane-1,8-diol and 4,5-decalino-3,6-dioxaoctane-1,8-diol ditosylate by the method similar to that described previously[3b] and recrystallized from 1,2-dimethoxyethane (29%): mp 197—198 °C; IR (KBr) 1100, 1090 cm^{-1}, ^1H NMR ($CDCl_3$) δ=1.00—2.48 (m, 48H), 3.20—4.08 (m, 12H); ^{13}C NMR ($CDCl_3$, 60 °C) δ=21.7 (t, 6C), 23.0 (t, 6C), 30.8 (t, 6C), 61.7 (t, 6C), 78.0 (s, 6C); MS *m/z* 588 (M^+). Found: C, 73.30; H, 10.34%. Calcd for $C_{36}H_{52}O_6$: C, 73.43; H, 10.27%.

Dibicyclooctano-18-crown-6 (3). **3** was prepared from *cis*-bicyclo[3.3.0]octane-1,5-diol as described previously[3a] and recrystallized from ether: mp 73—75 °C; IR (KBr) 1150, 1120, 1090 cm^{-1}; ^1H NMR ($CDCl_3$) δ=1.12—2.20 (m, 24H), 3.65 (br s, 16H); ^{13}C NMR ($CDCl_3$) δ=21.8 (t, 4C), 36.9 (t, 8C), 64.1 (t, 4C), 71.1 (t, 4C), 91.7 (s, 4C); MS *m/z* 424 (M^+). Found: C, 67.67; H, 9.56%. Calcd for $C_{24}H_{40}O_6$: C, 67.89; H, 9.50%.

Preparation of Crown Ether Complexes with Dimethylthallium(III) Perchlorates. Complexes were prepared by the method similar to that described previously[5] in an appropriate solvent (2-propanol, acetone, or acetonitrile-d_3) and purified by recrystallization from acetone/peteroleum ether or dichloromethane/hexane.

Metal Picrates. Potassium and thallium picrates were prepared according to the described methods.[7]

Extraction. The extraction procedures were similar to those described by Kimura.[7b,8] Equal volumes (10 ml) of chloroform solution of crown ether and aqueous metal picrate solution were placed in a stoppered flask and shaken for 40 min at 25±0.1 °C. After the phase separated, aliquots varying from 0.50 to 8.00 ml of organic phase (depending on its color intensity) were very carefully removed from organic phase and evaporated to dryness. Aliquots varying from 4.00 to 20.00 ml of acetonitrile were added to the residue. Then concentration of the metal complex with crown ethers were determined spectrophotometrically. In the case of thallium picrate, a mixture of equal volumes of chloroform and acetonitrile was employed as a solvent for spectrophotometry, because a considerable amount of uncomplexed crown ether which was insoluble in acetonitrile existed. The molar absorptivities of picrates were 1.50×10^4 mol dm^{-3} cm^{-1} for potassium and thallium(I) picrates at 374 nm.

Calculations. The extraction equilibirium constant, K_e, for 1:1 crown ether/metal ion complexes is defined by

$$M^+_{aq} + Pic^-_{aq} + CE_{org} \rightleftharpoons M(CE)Pic_{org}$$

$$K_e = \frac{[M(CE)Pic]_{org}}{[M^+]_{aq}[Pic^-]_{aq}[CE]_{org}} \quad (1)$$

where M^+, Pic^-, and CE are metal ion, picrate anion, and crown ether, respectively. The existence of uncomplexed crown ether and complexed crown ether in aqueous solution is negligible, because these cylindrical crown ethers have very lipophilic bicycloalkane moieties. Therefore, the following assumption can be made:

$$D = [M(CE)A]_{org}/[M^+]_{aq} \quad (2)$$

$$[M^+]_{aq} = [Pic^-]_{aq} = M^\circ - A \quad (3)$$

$$[CE]_{org} = (CE)^\circ - A, \quad (4)$$

where M° and $(CE)^\circ$ denote the initial alkali metal ion and initial crown ether concentration, respectively, and A the concentration of picrate transferred to the chloroform solution. Then Eq. 1 is rewritten as follows:

$$D = K_e(M^\circ - A)[(CE)^\circ - A]. \quad (5)$$

The K_e values were calculated directly by Eq. 5 and checked by the slope of the plots, log D *vs.* log $(M^\circ - A)[(CE)^\circ - A]$, being unity.

The distribution and complexing constants, K_d and K_c, respectively, are defined by

$$M^+_{aq} + Pic^-_{aq} \rightleftharpoons MPic_{org}$$

$$K_d = \frac{[MPic]_{org}}{[M^+]_{aq}[Pic^-]_{aq}} \quad (6)$$

$$MPic_{org} + CE_{org} \rightleftharpoons M(CE)Pic_{org}$$

$$K_c = \frac{[M(CE)Pic]_{org}}{[MPic]_{org}[CE]_{org}} \quad (7)$$

$$K_e = K_c/K_d. \quad (8)$$

The K_c values are estimated form Eq. 8. The reported K_d values (K^+ 2.67×10^{-3} and Tl^+ 4.68×10^{-2}) were quoted for K_c calcuration.[7b,8]

Extraction conditions were listed in Table 2.

A HPLC Study of Adsorption of Organic Solutes on Cellulose Acetate

Yoshiaki Kiso
Laboratory of Sanitary Engineering, Faculty of Engineering, Toyohashi University of Technology, Tenpaku-cho, Toyohashi 440
(Received June 26, 1985)

Synopsis. The liquid chromatographic technique was useful for the measurement of adsorption of some nonionic organic solutes on cellulose acetate. It was recognized that there were linear correlations between logarithmic capacity factors measured by HPLC, log k', and logarithmic 1-octanol: water partition coefficients, log P.

In the reverse osmosis process, the adsorption of organic solutes on a cellulose acetate membrane is assumed to be important for the permeabilities of the solutes and the membrane fouling.[1-3] The interaction between cellulose acetate (CA) and some organic or inorganic solutes has been investigated with the high performance liquid chromatograhy (HPLC).[4,5] Y. Taketani *et al.*[4] estimated the distribution coefficients for solutes between the stationary phase around CA and the bulk phase, K_A'. The values of K_A' for some organic solutes were more than unity. These results rather suggested that the organic solutes were adsorbed on the CA surface. However, the factors affecting the adsorption of organic solutes on the CA surface were known little. The objects of this work are to confirm the usefulness of liquid chromatography for the measurement of adsorption characteristics and to examine the effects of molecular structures on adsorption.

Experimental

The HPLC column was prepared by packing cellulose acetate (acetyl content 39.8%, Kodak 4644, 200/325 mesh) into a stainless steal column (I. D.=4.6 mm, L=250 mm). The moving phase was water and a solvent velocity was 0.5 ml min^{-1}. The HPLC apparatus used was a Toyosoda HLC-803A connected with a RI detector. The solutes used for this study were listed in Table 1. The concentrations of organic solutes in sample solution were less than 1%. The capacity factor for each solute, k', was calculated by the following equation;

$$k' = (t_i - t_0)/t_0, \quad (1)$$

where t_i and t_0 are the retention times of solute i and D_2O, respectively.

Results and Discussion

The capacity factors of all alcohols and ketones in Table 1 were positive and these solutes seemed to be adsorbed on CA. It was also recognized that more hydrophobic solutes were adsorbed more. However, more hydrophobic compounds such as benzene, nitrobenzene or acetophenone did not elute and seemed to be adsorbed strongly on CA. These facts suggested that these HPLC conditions were useful for the measurement of relatively weak interaction between CA and organic solutes. From these results, it was attempted to correlate log k', with logarithmic 1-octanol: water partition coefficients,[6] log P, logarithmic activity coefficients at infinite dilution calculated by the UNIFAC method,[7] ln γ^∞, or the connectivity index,[8] $^1\chi^v$. These results were shown in Figs. 1, 2, and 3.

In the cases of ketones except acetyl acetone and aliphatic alcohols except 2-methyl-2-propanol, it was recognized that log k' was related linearly to log P as follows:

$$\text{1-alkanols; } \log k' = 0.675 \log P - 0.914 \quad (N = 9,\ r = 0.9961) \quad (2)$$

$$\text{2-alkanols; } \log k' = 0.699 \log P - 1.048 \quad (N = 5,\ r = 0.9986) \quad (3)$$

$$\text{ketones; } \log k' = 0.613 \log P - 0.451 \quad (N = 9,\ r = 0.9901) \quad (4)$$

Table 1. Organic solutes

15	2-Pentanol	1.29[d]	8.520	2.451	30	Acetyl acetone	0.34	1.886	1.911

a) 1-Octanol: water partition coefficient.[6] b) Logarithmic activity coefficient at infinit dilution calculated by the UNIFAC method.[7] c) Connectivity Index.[8] d) Calculated value.

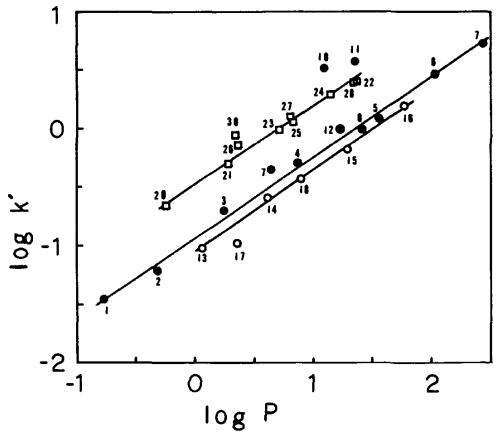

Fig. 1. The relationship between log P and log k' (numbers in figure mean the solute numbers).
●; 1-alkanol, ○; 2-alkanol, □; ketone.

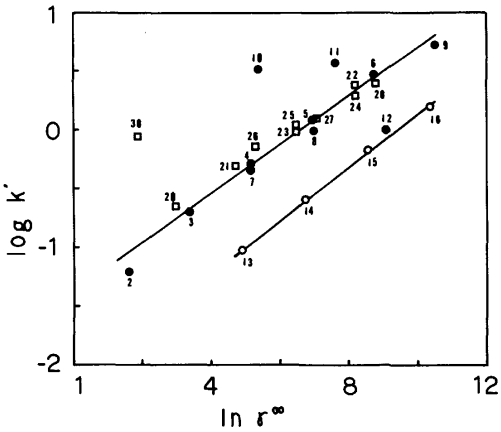

Fig. 2. The relationship between ln γ^{∞} and log k'.

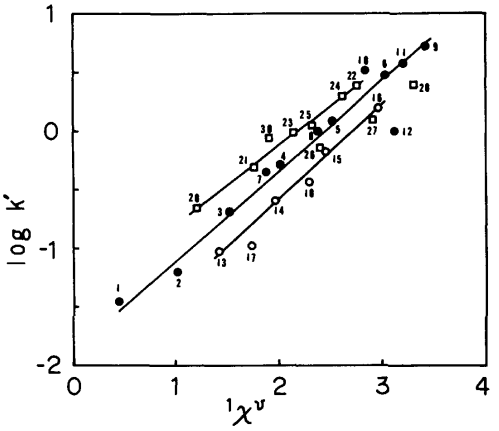

Fig. 3. The relationship between connectivity index $^1\chi^v$ and log k'.

These results indicated that the adsorption of organic solutes was controlled by the hydrophobicity of solutes and that the effect of hydrophobicity in these solutes was equivalent because the slopes in these equations were almost equal. These results showed that the functional group affected the adsorption, because the intercept of ketones was larger than that of alcohols and acetyl acetone was above the line of ketones in Fig. 1. It was assumed that the steric factors also influenced the adsorption from the following results; (a) the intercept of 2-alkanols was a little less than 1-alkanols, and (b) the log k' value of 2-methyl-2-propanol was less than the value estimated by Eq. 3.

Table 2. Solutes eluted earlier than D_2O

Solute	Retention time/min
D_2O	6.27
NaCl	5.57
Glucose	5.65
Lactose	5.57
Tween-20	5.51
PEG(#6000)	5.35
PVP(K-90))	4.35

The log k' values of benzyl alcohol and dl-1-phenylethanol were larger than those estimated by using Eq. 2. Acetophenone, nitrobenzene and benzene, whose log P values were 1.58, 1.85, and 2.15 respectively, did not elute under these conditions. These results suggested that the phenyl group was adsorbed more easily than the aliphatic group. Considering the results of aromatic compounds and ketones, it was assumed that unsaturated bonds in solutes also affected the adsorption on CA.

The relationship between log k' and ln γ^{∞} or $^1\chi^v$ was also linear as shown in Figs. 2 or 3, and these tendencies were similar to those in Fig. 1. From these results, it was assumed that the adsorption of organic solutes on CA was able to be correlated with some free energy parameters or some structure parameters.

The results for solutes whose retention time was less than that of D_2O are shown in Table 2. Glucose and lactose, the most hydrophilic solutes, were not adsorbed on CA. Polymer solutes (PEG and PVP) and Tween-20, which caused the membrane fouling,[3] were not adsorbed on CA and it seems that the retention time of these solutes decreased as molecular weight increased. Y. Taketani *et al.*[4] showed a similar tendency by using PEG. These facts seem to be caused by the size exclusion effect, because the large specific area of CA[4] suggested that there are many micro pores on the surface of cellulose acetate particles.

The author is greatly indebted to Dr. Toshio Sugita for HPLC available for this study.

Reaction of Leucomalachite Green with Chloranil

Norio NISHIMURA* and Takushi MOTOYAMA
Department of Chemistry, School of Science, Okayama University, Tsushima, Okayama 700
(Received February 25, 1985)

Synopsis. The reaction of Leucomalachite Green with chloranil to produce Malachite Green cations has been carried out in acetonitrile. Prior to the formation of the cations, a 1:1 CT complex is formed between the reactants. The equilibrium and the rate constants were estimated.

In preceding papers,[1,2] the proton/deuteron transfer reactions of Leucocrystal Violet (LCV) with tetracyanoethylene (TCNE) and chloranil (CA) under high pressures and in various solvents have been reported. It was concluded that both reactions probably proceed *via* an outer CT complex followed by a pair of radical ions. However, the electronic spectra assigned to the complex were observed only at low temperatures. This made the accurate estimation of thermodynamic quantities impossible.

This paper is concerned with the reaction of Leucomalachite Green (LMG) with CA. When the acetonitrile solutions of LMG and CA were mixed, a broad absorption spectrum ($\lambda_{max}\approx670$ nm) appeared at room temperatures. The color becomes deep upon cooling. Similar phenomena were observed in various solvents and LMG–TCNE system, too. Therefore, this blue-colored substance can be assigned to the CT complex formed between LMG and CA. The equilibrium constant K_1 for the formation of the complex was estimated by means of the Lang plot and checked by the Benesi-Hildebrand (B-H) plot modified as follows:

$$\frac{[\mathrm{LMG}]_0[\mathrm{CA}]_0}{A([\mathrm{LMG}]_0+[\mathrm{CA}]_0-A/\varepsilon)}=\frac{1}{([\mathrm{LMG}]_0+[\mathrm{CA}]_0-A/\varepsilon)}\cdot\frac{1}{K\varepsilon}+\frac{1}{\varepsilon}, \quad (1)$$

where A is the absorbance at 720 nm (1 cm cell), and ε is the molar extinction coefficient at this wavelength. In this study, the concentration ranges were: $[\mathrm{LMG}]_0=(2.5—12.8)\times10^{-3}$ mol dm^{-3}, $[\mathrm{CA}]_0=(7.9—10.4)\times10^{-3}$ mol dm^{-3}. The Lang and the modified B-H plots were repeated until an assumed pair of ε and K values became self-consistent. The results are given in Table 1.

The rate of reactions was followed by monitoring the absorbance at 620 nm which is assigned to Malachite Green cations (MG^+). Within the time interval of the kinetic measurement, the absorbance at 720 nm has not changed appreciably. This made the simultaneous estimations of the equilibrium and the rate constants possible. Figure 1 shows the time dependence of the absorption spectrum. The broad line at the bottom (500—900 nm) is due to the CT complex[3] (denoted as LMG→CA hereafter). It was found that the rate of appearance of MG^+ at the initial stage (conversion<0.5%) follows the overall second-order kinetics:

Table 1. Equilibrium constants and thermodynamic parameters for the formation of the CT complex in the LMG–CA system

Temp	$10^{-3}K_1\varepsilon$	K_1
°C	dm^6 mol^{-2} cm^{-1}	dm^3 mol^{-1}
15	3.03±0.04	6.70±0.74
20	2.67±0.06	5.90±0.69
25	2.28±0.02	5.04±0.52
30	2.02±0.01	4.46±0.45
ε/dm^3 mol^{-1} cm^{-1}=452±43		
ΔH/kJ mol^{-1}=−20.1±0.4		
ΔS(298K)/J mol^{-1} K^{-1}=−51.6±2.9		

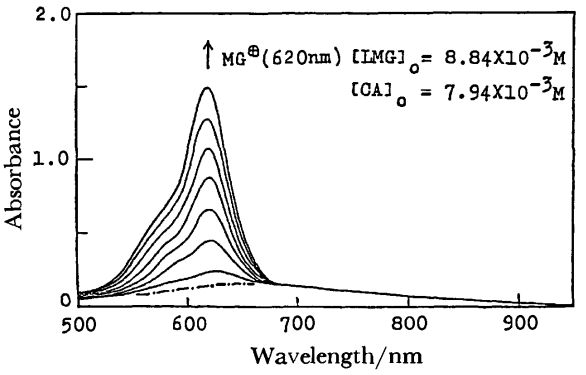

Fig. 1. Time dependence of the absorption spectrum for the reaction of LMG with CA in acetonitrile at 25 °C. Time intervals are 5 min.

$$\mathrm{d}[\mathrm{MG}^+]/\mathrm{d}t=k_{obsd}[\mathrm{LMG}]_0[\mathrm{CA}]_0 \quad (2)$$

If the proposed mechanism for the LCV–TCNE and LCV–CA systems[2] is valid for the LMG–CA system, too, the reaction route may be as follows:

$$\mathrm{LMG}+\mathrm{CA}\underset{\text{fast}}{\overset{K_1}{\rightleftharpoons}}\mathrm{LMG}\longrightarrow\mathrm{CA}\overset{K_2}{\underset{\text{fast}}{\rightleftharpoons}}$$

$$(\mathrm{LMG})^{+\cdot}(\mathrm{CA})^{-\cdot}\xrightarrow[\text{slow}]{k_1}\mathrm{MG}^+ + \cdots$$

From the above scheme, k_{obsd} can be expressed by

$$k_{obsd}=K_1K_2k_1=K_1k. \quad (3)$$

The kinetic data and the activation parameters are given in Table 2. Figure 2 shows the energy profile. The numerical value in parenthesis is the one assumed for the LCV–CA system.[2]

It is interesting to compare the above results with those for the LCV–CA system. There are two notable points. The equilibrium constant K_1 for the formation of the CT complex is considered considerably

TABLE 2. RATE CONSTANTS k_{obsd} AND k DEFINED BY Eq. 3 AND THE ACTIVATION PARAMETERS RELATED TO k

Temp	$10^4 k_{obsd}$	$10^5 k$
°C	$dm^3 mol^{-1} s^{-1}$	s^{-1}

20	0.654±0.005	1.11±0.15
25	1.02 ±0.02	2.02±0.25
30	1.54 ±0.03	3.45±0.48
$\Delta H^{\neq}$(300K)/kJ mol^{-1}=83.6±0.8		
$\Delta S^{\neq}$(300K)/J $mol^{-1} K^{-1}$=−54.7±3.0		

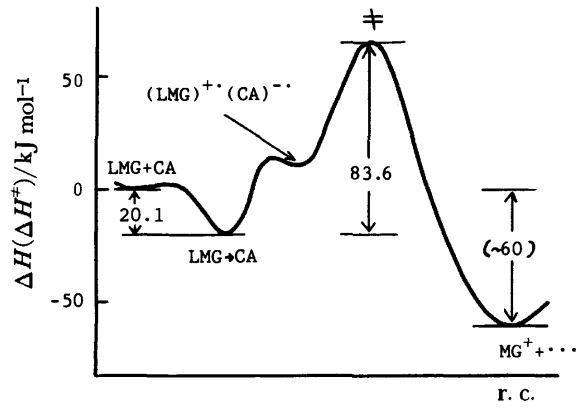

Fig. 2. Energy profile for the reaction of LMG with CA.

larger for the LMG–CA system than for the LCV–CA system, as judged from the spectral intensity observations. The second point is the k_{obsd}-value is about 10^3times smaller than that for the LCV–CA system (0.11 $dm^3 mol^{-1} s^{-1}$ at 25 °C). The $\Delta H^{\neq}$ and $\Delta S^{\neq}$ for the LCV–CA system in acetonitrile are 27.9 kJ mol^{-1} and −169 J $mol^{-1} K^{-1}$, respectively.[4] The above distinctive points are difficult to interpret in connection with the structural difference between LMG and LCV alone. We tentatively measured the ^{1}H NMR spectra and examined the chemical shift of the hydrogen being abstracted. The data are as follows: δ=2.18 in CCl_4, 2.58 in $CDCl_3$, and 3.74 in CD_3CN (s, 1H) for LMG. These values may be compared with the normal values δ=5.10—5.54 (s, 1H) for triphenylmethane, 4-diphenylmethyl-*N*,*N*-dimethylbenzenamine, and LCV, for which the solvent dependency on δ was small. The extraordinarily high-field shift and its very large solvent dependence for LMG alone in this series of compounds are very hard to interpret, and therefore require more fundamental investigations aside from this work. What we now can say is that if this high-field shift is due to the electronic effect (charge shift), it would give rise to the large K_1-value and hence the large activation energy compared with those for the LCV–CA system.

Experimental

Commercial LMG and CA were recrystallized twice from a benzene–ethanol mixture. Solvents were purified as usual manners. A Union 401 spectrophotometer was used for spectral measurements. The temperature was regulated within ±0.1 K. ^{1}H-NMR spectra were recorded on a Hitachi R-600 FT NMR spetrometer.

Laser Photolysis Study on the Duroquinone-photosensitized Isomerization of Stilbenes in Micellar Solution

Yoshifumi TANIMOTO,* Masanari TAKAYAMA, Sayaka SHIMA, and Michiya ITOH
Faculty of Pharmaceutical Sciences, Kanazawa University, Takara-machi, Kanazawa 920
(Received April 4, 1985)

Synopsis. Photoinduced electron-transfer reaction between the excited triplet duroquinone and *trans*- and *cis*-stilbenes generates *trans*-stilbene cation radical in SDS micellar solution, suggesting that the *cis-trans* isomerization of stilbene occurs *via* an electron-transfer mechanism.

Recently, an increasing interest has been paid to the photosensitized isomerization of stilbenes in electron-transfer reactions.[1-5] In the present paper, we have studied a photoinduced electron-transfer reaction between duroquinone and stilbenes in sodium dodecyl sulfate (SDS) micellar solution by nanosecond laser flash photolysis. It is shown that the electron-transfer from both *trans*- and *cis*-stilbenes to the excited triplet duroquinone generates only the *trans*-stilbene cation radical in the nanosecond timescale; the *cis-trans* photoisomerization of stilbene mostly occurs *via* an electron-transfer mechanism.

Experimental

Duroquinone (DQ) and *trans*-stilbene (TS) were purified by recrystallization. *cis*-Stilbene (CS) was purified by distillation; its purity was determined to be >95% by gas chromatography. Sodium dodecyl sulfate (for biological use, SDS) was used as supplied. Water was distilled and deionized.

The laser flash photolysis measurements were carried out in deaerated solutions at room temperature using a Molectron UV-12 N_2 laser (337 nm) as the exciting light source.[6]

Results and Discussion

Figure 1 shows transient absorption spectra of SDS micellar solutions containing DQ and stilbenes. In the absence of stilbenes, a weak triplet-triplet absorption of DQ appears in the 400—500 nm region.[7,11] In the presence of TS, a new intense band appears at ≈480 nm (the growth and decay rates are 1.1×10^6 and 1.5×10^4 s^{-1}, respectively), which is assigned to the TS cation radical (TS^+).[8] In contrast to this, no appreciable transient absorption due to TS^+ is observed in acetonitrile solution. In the aqueous micellar solution both DQ and TS are mostly solubilized in the micellar phase, since they are almost insoluble in water. This local high concentration of solute molecules in the micellar phase leads to a high efficiency of the electron transfer reaction in the micellar solution. From the plots of the growth rate *versus* the TS concentration shown in Fig. 2A, the apparent bimolecular electron-transfer rate constant was estimated to be 1.6×10^9 $mol^{-1}dm^3s^{-1}$ in the present micellar solution. The intercept in the figure deviates slightly from the origin. This is mostly due to the contamination of the T-T absorption intensity of DQ at the lower TS concentrations. Further, the absorption of the duroquinone anion radical (DQ^-), a counter radical, is expected to occur in the 400 nm region.[7] However, it is not observed clearly because of overlap with the absorption bands of the excited triplet duroquinone ($^3DQ^*$) and the TS^+ radical in this wavelength region. The TS^+ radical is mostly formed *via* the photoinduced electron-transfer reaction between $^3DQ^*$ and TS.

On the other hand, in a solution containing DQ and

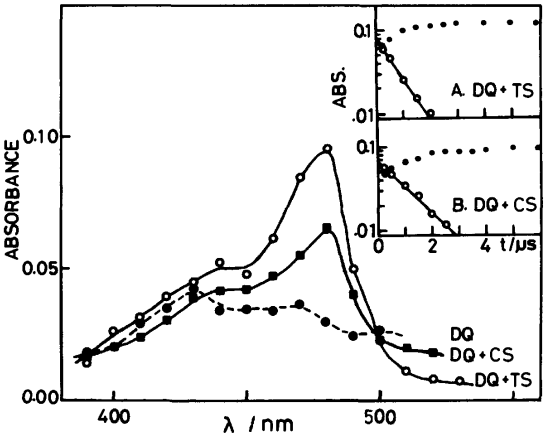

Fig. 1. Transient absorption spectra of 0.4 mol dm^{-3} SDS micellar solutions containing 6×10^{-4} mol dm^{-3} DQ (---●---), DQ and 4×10^{-4} mol dm^{-3} TS (—○—), and DQ and 3×10^{-4} mol dm^{-3} CS (—■—), at 1 μs delay after laser excitation. Inserts show typical time profiles of the absorption intensities at 480 nm for the solutions containing DQ and TS, (A), and DQ and CS, (B).

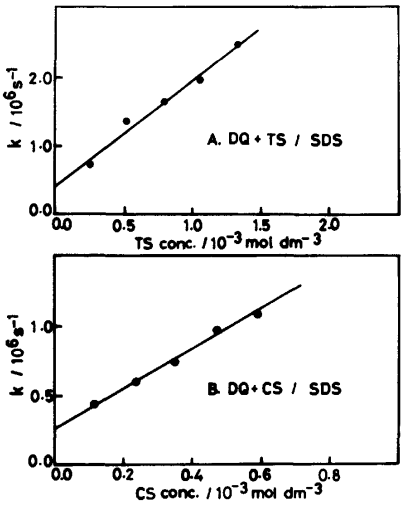

Fig. 2. Concentration dependence of the growth rate, k, of the 480 nm band for TS, (A) and CS, (B). The concentrations of SDS and DQ were 0.4 and 5×10^{-3} mol dm^{-3}, respectively.

CS, a band appears at ≈480 nm (the growth and decay rates are 0.7×10^6 and 1.5×10^4 s^{-1}, respectively) as shown in Fig. 1, though the absorption of CS^+ is reported to appear at 515 nm.[8] Since the band is similar to that of TS^+ in the figure, it is assigned to the TS^+ radical. In the photolysis of the micellar solution of DQ and CS, the $CS^+\rightarrow TS^+$ isomerization occurs rapidly, since no appreciable absorption due to CS^+ appears in the nanosecond timescale. The apparent bimolecular rate constant for CS was found to be 1.5×10^9 mol^{-1} dm^3 s^{-1} (see Fig. 2B). This is almost the same as that for TS.

The unusual $CS^+\rightarrow TS^+$ isomerization has been reported for the photobleaching of CS^+ in CCl_4 rigid glass at low temperature,[8] for the 9,10-dicyanoanthracene-sensitized oxidation of CS in acetonitrile,[2] and for the electron impact of CS.[9] The present result clearly demonstrates that the TS^+ radical is also produced by the electron transfer reaction between the excited triplet DQ and CS, whereas generation of TS^+ *via* a singlet-sensitized reaction is well known.[2]

Furthermore, the formation of CS was detected in a gas chromatograph of the photolysed solution of DQ and TS. The fact suggests that *trans-cis* isomerization of stilbene occurs *via* an electron-transfer mechanism, though triplet sensitized isomerization of stilbene *via* an energy transfer mechanism is well known.[10]

The photoreaction of DQ with TS may be interpreted in the following scheme:[1,3]

$$DQ \xrightarrow{h\nu} {}^1DQ^* \longrightarrow {}^3DQ^* \quad (1)$$

$${}^3DQ^* + TS \longrightarrow {}^3(DQ^{\cdot}TS^{+}) \quad (2)$$

$${}^3(DQ^{\cdot}TS^{+}) \rightleftharpoons {}^1(DQ^{\cdot}TS^{+}) \quad (3)$$

$${}^3(DQ^{\cdot}TS^{+}) \longrightarrow DQ + {}^3TS^* \quad (4)$$

$${}^3(DQ^{\cdot}TS^{+}) \longrightarrow DQ^{\cdot} + TS^{+} \quad (5)$$

$${}^1(DQ^{\cdot}TS^{+}) \longrightarrow DQ + TS \quad (6)$$

$${}^1(DQ^{\cdot}TS^{+}) \longrightarrow DQ^{\cdot} + TS^{+} \quad (7)$$

In the micellar solution of DQ and TS, the electron-transfer between $^3DQ^*$ and TS generates a triplet pair of DQ^- and TS^+, $^3(DQ^-\ TS^+)$. Here, we assume the radical ion pair as an intermediate by analogy with the electron-transfer reaction of DQ and diphenylamine in SDS micellar solution.[11] It is expected that there are three processes from the triplet pair; *i.e.*, intersystem crossing to the singlet pair, (3), back electron-transfer to generate the excited triplet TS, (4), and separation into free radicals, (5). *trans-cis* Isomerization may occur *via* the excited triplet TS as suggested by Leshina *et al.*[3]

On the other hand, in the micellar solution of DQ and CS, electron-transfer between $^3DQ^*$ and CS generates a triplet pair of DQ^- and CS^+, $^3(DQ^-\ CS^+)$, followed by a rapid isomerization:

$${}^3DQ^* + CS \longrightarrow {}^3(DQ^{\cdot}CS^{+}) \longrightarrow {}^3(DQ^{-}TS^{+}) \quad (8)$$

After the generation of $^3(DQ^-\ TS^+)$, the reaction processes are similar to those mentioned above. Furthermore, since the lifetime of TS^+ is relatively long (≈65 μs), an apparent *cis-trans* isomerization of TS^+ may also occur *via* an electron hole transfer from CS to TS^+ as an inter-micellar process, as proposed for the $[Ru(bpy)_3]^{2+}$ sensitized isomerization of stilbazole in SDS solution,[4] and for the singlet 9,10-dicyanoanthracene-sensitized isomerization of CS in acetonitrile:[5]

$$TS^{+} + CS \longrightarrow TS + CS^{+} \quad (9)$$

Furthermore, the observation of the magnetic field effect (1 T) on the transients was attempted in these micellar solutions. However no detectable effect was observed, suggesting that the triplet-singlet intersystem crossing of the radical ion pair is not the rate-determining step in the reaction. The magnetic field effects on the photosensitized isomerization of stilbene in organic solvents[3] and on the electron-transfer between the excited duroquinone and diphenylamine in SDS solution[11] are reported.

Finally, we believe that the present transient spectroscopic results indicate the importance of $CS^+\rightarrow TS^+$ isomerization in the triplet sensitized electron-transfer reaction of stilbenes in micellar solution.

Phase Diagrams in Binary Systems of Octafluoronaphthalene and Polynuclear Aromatic Compounds

Shigeyoshi MIYAGISHI,* Akira ISOMI, Mayumi IWATA, Tsuyoshi ASAKAWA, and Morie NISHIDA
Department of Industrial Chemistry, Faculty of Technology, Kanazawa University, Kanazawa 920
(Received July 13, 1985)

Synopsis. Solid-liquid phase diagrams were obtained for binary mixtures of octafluoronaphthalene with six polynuclear aromatic compounds, pyrene, phenanthrene, naphthalene, 1,5-naphthylenediamine, anthracene, and phenothiazine, and for mixtures of naphthalene and pyrene. The first four systems all formed well-defined 1:1 molecular complexes with congruent melting points.

In the course of our experiments on the photochemical reaction of octafluoronaphthalene (OFN) with pyrene, we observed that a solid was formed on mixing these two substances in methanol. The solid had a surprisingly high melting point compared with OFN and pyrene. Experimental evidence has indicated that hexafluorobenzene,[1-10] pentafluorobenzene,[4] pentafluorobenzonitrile,[9,11] and decafluorobiphenyl[5] form complexes with aromatic hydrocarbons. OFN has not been reported to produce complexes with the aromatic hydrocarbons except for benzene.[5] On the intermolecular force resulting in formation of such complex, opinions have differed.[5,6] Our attention is being paid to whether perfluoro-aromatic compounds always form molecular complexes with the aromatic hydrocarbons or not, and what kind of force acts between them. As the first step, the phase diagrams of binary mixtures of OFN and several polynuclear compounds were examined.

Experimental

OFN (guaranteed reagent, Tokyo Chemical Industry) was recrystallized from methanol and sublimed *in vacuo*. Pyrene (Katayama Chemicals) was of analytical grade, phenanthrene (Tokyo Chemical Industry) was zone-refined material, and anthracene (Wako Pure Chemical Industries) was a standard reagent. Naphthalene (Katayama Chemicals), 1,5-naphthylenediamine (Wako Pure Chemical Industries), and phenothiazine (Nakarai Chemicals), respectively, were reagent grade.

A mixture of a known composition of OFN and one of the other compounds was made up by weight and dissolved in diethyl ether. After the ether was evaporated at room temperature and atmospheric pressure, a part of the mixture (about 5 mg) was sealed in an aluminum vessel (15 mm^3). Calorimetric experiments were done on a differential scanning calorimeter (Daini-Seikosha DSC-560S).[12] The scanning rate was 5 $K\,min^{-1}$. Repeated heating produced lowering of the transition temperatures in the systems except for the naphthalene-pyrene system.

Results and Discussion

The phase diagrams for OFN+pyrene, OFN+phenanthrene, OFN+naphthalene, and OFN+1,5-naphthylenediamine, respectively, indicated clearly the formation of a 1:1 molecular complex between OFN and the other component (Figs. 1—4). The system

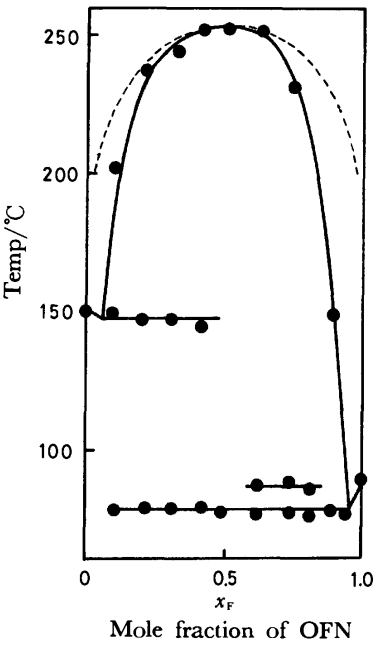

Fig. 1. Phase diagram of the OFN-pyrene system. The dotted curve is the calculated values from Eq. 2.

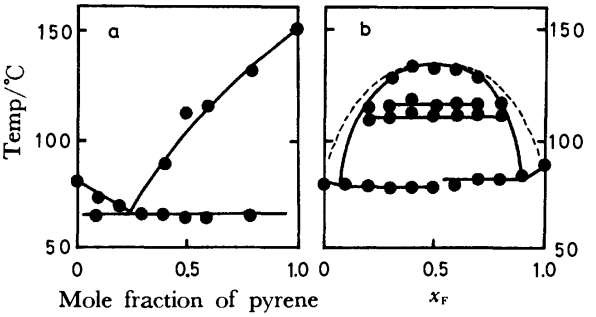

Fig. 2. Phase diagram of the naphthalene-pyrene system(a); the solid curves were calculated from Eq. 1, and that of the OFN-naphthalene system(b); the dotted curve was calculated from Eq. 2.

naphthalene+pyrene was studied in comparison with the system OFN+pyrene. It is seen from Fig. 2-a that naphtalene and pyrene form a simple eutectic. For such a binary mixture the thermodynamic equation relating the melting point of one component of the mixture to the composition of the solution is

$$\ln x = (\Delta H_1/R)(1/T_1 - 1/T), \quad (1)$$

where x is the mole fraction of the first component, and ΔH_1 and T_1 are the enthalpy of fusion and melting temperature of pure 1. The solid curve in Fig. 2-a

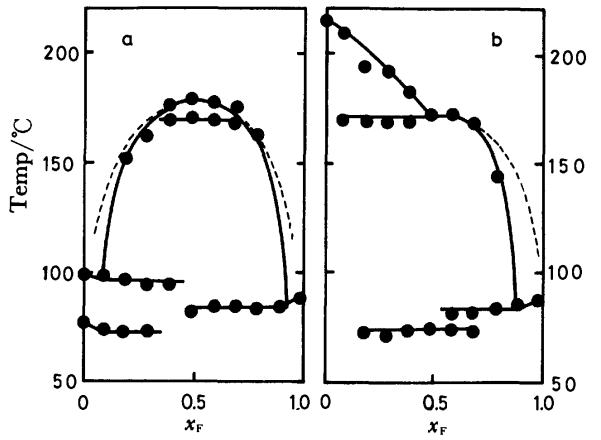

Fig. 3. Phase diagrams of the OFN-phenanthrene system(a) and the OFN-anthracene system(b). The dotted curves were calculated from Eq. 2.

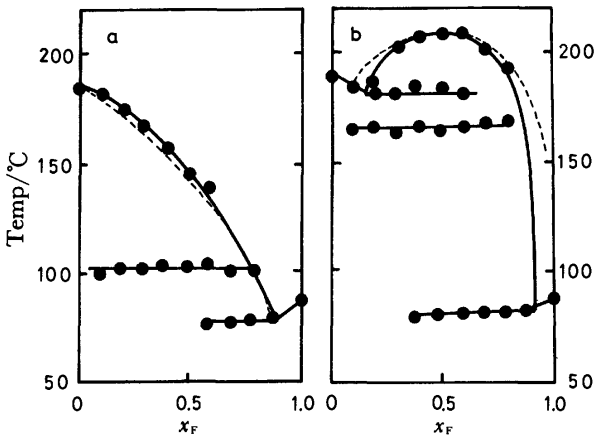

Fig. 4. Phase diagram of the OFN-phenothiazine system(a), the dotted curve was calculated from Eq. 1, and that of the OFN-1,5-naphthylenediamine system(b), the dotted curve was calculated from Eq. 2.

represents the melting temperatures calculated from Eq. 1 and is in good agreement with the experimental points. This evidence means that formation of the complex between OFN and pyrene results from the presence of fluorine atoms in OFN. Although in the system OFN+anthracene the compound molecule may be made from one OFN and one anthracene molecules, its melting temperature was lower than that of anthracene. The system OFN+phenothiazine did not give a congruent melting temperature.

The dotted curves in Figs. 1—4 represent the values calculated from Eqs. 1 or 2.[13]

$$-\ln x(1-x) + \ln 0.25 = \Delta H_c/R(1/T - 1/T_c), \quad (2)$$

here T_c is the melting temperature of the compound, and ΔH_c is its enthalpy of fusion. The equations assume ideal mixing in solution and for ΔH to be independent of temperature. The systems with congruent melting points exhibited negative deviation from Eq. 2, while the phase diagram for the system OFN+phenothiazine deviated positively from Eq. 1. The system OFN+phenothiazine seems to interact differently than the other systems. The other transition points, which were indicated in Figs. 1—4, were detected. Although some of these points may correspond to the phase transition of the molecular complexes, further investigation is required.

Thanks are given to Mrs. Kumiko Kawai for her assistance in drawing the figures.

A Common Factor Determining the Features of the Photocatalytic Hydrogenation and Isomerization of Alkenes over Ti-Si Oxides

Sukeya KODAMA,* Hiroaki NAKAYA, Masakazu ANPO, and Yutaka KUBOKAWA
Department of Applied Chemistry, University of Osaka Prefecture, Sakai, Osaka 591
(Received July 26, 1985)

Synopsis. On addition of SiO_2 to TiO_2 photocatalysts, it has been found that the yields of C_2H_6 and CH_4 in the photocatalytic hydrogenation of propylene as well as that of 1-butene in the photocatalytic isomerization of *cis*-2-butene decrease simultaneously. This gives some support for the mechanisms for both reactions where [Ti^{3+}–O^-] pairs are important.

It is well-known that in the photocatalytic reactions associated with the decomposition of water over Pt-loaded TiO_2 where charge separation takes place efficiently the reduction reactions by electrons and the oxidation reactions by holes proceed on different parts of the catalyst.[1] We have recently shown that a close association of photo-formed electrons and holes plays a significant role in some photocatalytic reactions.[2] For example, in the photocatalytic hydrogenation of propylene over TiO_2 the photo-formed trapped electron-hole pairs [Ti^{3+}–O^-] play a significant role in formation of the C=C bond fission products such as CH_4 and C_2H_6.[3] Furthermore, in the photocatalytic isomerization of 2-butene the [Ti^{3+}–O^-] pairs or Ti^{3+} (trapped electrons) are important to bring about the double bond shift in the isomerization.[4] According to such a reaction model, it would be expected that the decreases in the yields of CH_4 and C_2H_6 (hydrogenation) and 1-butene (isomerization) take place simultaneously, if removal of the trapped electrons (Ti^{3+}) is caused by in some way. Such features have been actually observed with the photocatalytic reactions over Ti–Si oxides.

Experimental

Propylene and *cis*-2-butene obtained from Takachiho Kagakukogyo Co. were purified by vacuum distillation. Ti–Si oxides with various compositions were prepared by coprecipitation of a mixed solution of $TiCl_4$ and $Si(OC_2H_5)_4$ with aqueous solution of ammonia, and by heating in air for three hours at 500 °C.[5] These catalysts were subjected to oxygen treatment for one hour at 500 °C followed by evacuation at the same temperature. *Cis*-2-butene of 4.0 kPa was introduced over the catalysts (500 mg) which had been spread on the quartz window, having a surface of *ca.* 20 cm^2. The photoisomerization was carried out by UV irradiation from a high pressure mercury lamp (Toshiba, SHL-100UV) without a filter for one hour at the ice-water temperature. The photocatalytic hydrogenation of propylene over water adsorbed catalysts was performed at room temperature in the same experimental conditions as above. Gas samples were analyzed by gas chromatography using silica gel and 2,4-dimethylsulfolane columns.

Results and Discussion

The hydrocarbon products in the photocatalytic hydrogenation of propylene by adsorbed water (reaction I) are CH_4, C_2H_6, and C_3H_8. As shown in Fig. 1, the formation rates of the products, especially those of CH_4 and C_2H_6 decrease drastically with increasing content of SiO_2 up to 60%. With the photocatalytic hydrogenations of alkenes and alkynes over TiO_2, it has recently been shown that the photo-formed [Ti^{3+}–O^-] pairs participate in formation of the products accompanied by fission of the C=C or C≡C bond.[3] It appears therefore that such a decrease in the yields of C_2H_6 and CH_4 may be explicable by the concept that the concentration of [Ti^{3+}–O^-] pairs decreases on the addition of SiO_2.

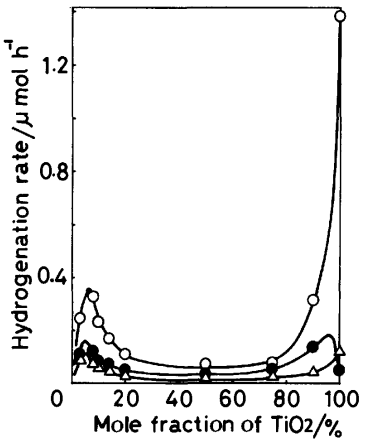

Fig. 1. Photocatalytic hydrogenation of propylene over binary Ti–Si oxides. ○: C_2H_6; ●: C_3H_8; △: CH_4.

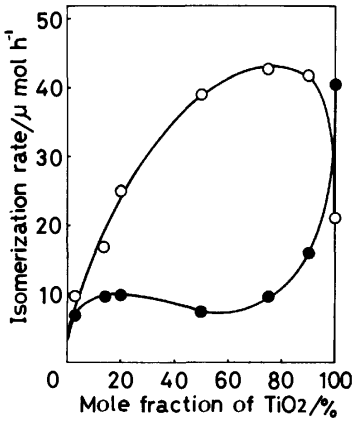

Fig. 2. Photocatalytic isomerization of *cis*-2-butene over binary Ti–Si oxides at 0 °C. ○: *trans*-2-butene; ●: 1-butene.

In the photocatalytic isomerization of *cis*-2-butene (reaction II) over Ti–Si oxides, both isomerizations to

trans-2-butene and 1-butene take place, though the isomerizations in the dark scarcely proceed at 0 °C. The rates of formation of *trans*-2-butene and 1-butene, as a function of the TiO_2 content, are shown in Fig. 2. The yield of 1-butene *i.e.* the selectivity toward 1-butene formation decreases in the range up to 60% TiO_2.

According to our recent work[4] in the photocatalytic isomerization of 2-butene the interaction of $[Ti^{3+}-O^-]$ pairs or O^- species with butene results in opening of its C=C bond, *i.e.* in formation of a radical, which participates in the photocatalytic isomerization. In the double bond shift isomerization, H atoms are removed from and added to the radical. Since H atoms are supplied from surface OH groups according to the process $OH^- \rightarrow O^{2-}+H^+$, the neutralization of protons is necessary. For this purpose the electrons trapped on Ti^{4+} ions (Ti^{3+}) are used. Accordingly, if the trapped electrons (Ti^{3+}) are removed, *i.e.* the O^- species are formed in place of the $[Ti^{3+}-O^-]$ pairs, the double bond shift isomerization would be unexpected to occur. The *cis-trans* isomerization will proceed, since it has been shown previously[4] that the interaction of the O^- species with alkene brings about the weakening of its C=C bond.[6] Replacement of the $[Ti^{3+}-O^-]$ pairs by the O^- species would result in simultaneous increase and decrease in the yields of *trans*-2-butene and 1-butene, respectively. Such feature was actually observed with the range above 90% of TiO_2. It was found that the selectivity of *trans*-2-butene formation in the photocatalytic isomerization of *cis*-2-butene is increased with Pt-loaded TiO_2 where removal of the trapped electrons (Ti^{3+}) is expected to occur. This suggests that the occurrence of the *cis-trans* isomerization is closely associated with such removal of the trapped electrons.

The considerations described above suggest that the decrease in the yields of CH_4 and C_2H_6 (reaction I) and 1-butene (reaction II) caused by the addition of SiO_2 is explicable by the same factor, *i.e.* the decrease in the concentration of $[Ti^{3+}-O^-]$ pairs brought about by removal of the trapped electrons(Ti^{3+}). Apart from the nature of such removal, which will be described later, it should be noted that such a simultaneous decrease in the yields of CH_4 and C_2H_6 and of 1-butene in both reactions would give some support for the mechanisms proposed for both reactions where the $[Ti^{3+}-O^-]$ pairs play a significant role.

In the range below 50% of TiO_2, the reversed behavior is observed, *i.e.* simultaneous increase in the yields of CH_4 and C_2H_6 and 1-butene takes place. Such feature might be explained in a similar manner, *i.e.* in the increase in the concentration of $[Ti^{3+}-O^-]$. In any events, those results will again give additional support for the proposed reaction model.

As for the removal of the trapped electrons (Ti^{3+}), the followings may be mentioned. It is well-known that trapping or recombination centers are formed by addition of a foreign material to a semiconductor. This would be the case for the present system, since formation of Lewis acid sites has been reported for Ti-Si oxides.[5] At present the depth of the traps is unknown, they appear deep enough to remove the trapped electrons (Ti^{3+}).

In the region of lower Ti contents, we have recently reported formation of a new active phase arising from a high dispersion of Ti ions.[7] In this state the radiationless transfer of photon energy absorbed by TiO_2 is suppressed because of a high coordination unsaturation. This would be expected to facilitate formation of the $[Ti^{3+}-O^-]$ pairs. Further work is necessary to clarify the nature of such phenomena.

The Microwave Spectrum of (Z)-(Acrylaldehyde Oxime)

Mariko TERASHIMA and Osamu OHASHI*

Department of Chemistry, Faculty of Science and Technology, Sophia University, Chiyoda-ku, Tokyo 102

(Received August 8, 1985)

Synopsis. The microwave spectrum of (*Z*)-(acrylaldehyde oxime) was observed in the frequency region from 10 to 40 GHz.

Several a-type R-branch transitions in the ground vibrational state were identified and the rotational constants in MHz were determined to be A=17430.7(35), B=3022.514(15), and C=2576.504(16). The conformation of (*Z*)-(acrylaldehyde oxime) has been plausibly deduced to be the s-trans Z-form from the rotational constants experimentally determined. The angle of C-C=N is discussed.

The gas chromatogram and proton magnetic resonance spectrum of acrylaldehyde oxime have suggested that this molecule has two geometrical isomers.[1] One of them is an E-form of which the microwave spectroscopic study has been reported.[2] The other one is a Z-form which has not been determined to be whether the s-trans Z-form or s-cis Z-form, or both (See Fig. 1). It is interesting to determine the molecular conformation of (*Z*)-(acrylaldehyde oxime) in gas phase. We have observed the microwave spectrum of (*Z*)-(acrylaldehyde oxime) and discussed its conformation and the angle of C-C=N.

Experimental

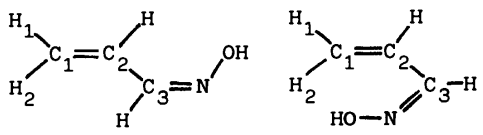
Acrylaldehyde oxime was prepared and purified by the method described elsewhere.[2] No attempt was made to separate the E- and Z-species; all measurements were made with the equilibrium mixture of the isomers at room temperature, using a flowing system in which the sample was put into a sample cell at the one end and pumped out from the other end during the measurement of the spectrum.

The spectrometer used has been described elsewhere.[2]

Results and Discussion

The first survey of the rotational spectrum was made in the frequency region of 26.5 to 40 GHz at the Stark field of 100 V/cm.

Bunches of relatively weak absorption lines that might be ascribed to the Z conformer were found with the frequency interval of about 5600 MHz, while groups of strong lines which had been assigned to the E-conformer were observed with the frequency interval of about 4600 MHz.



s-trans Z-form s-cis Z-form

Fig. 1. Two possible geometrical isomers and the numbering of carbon and hydrogen atoms of (*Z*)-(acrylaldehyde oxime).

In the first place, four transitions of J=5←4 and J=6←5 with K_{-1}=1 and six lines of J=5←4, 6←5, and 7←6 with K_{-1}=2 in the frequency region of 26.5 to 40 GHz were tentatively assigned and they led to the prelimenary rotational constants which were employed to predict the other transition lines. Then, forty a-type R-branch transition lines in the ground vibrational state were assigned in the frequency region of 10 to 40 GHz as listed in Table 1. The rotational and centrifugal distortion constants finally determined are shown in Table 2, together with the rotational

constants calculated from the molecular models (See Fig. 1 and Table 3).

From the comparison of the experimental and calculated rotational constants shown in Table 2, it is conclued that the s-trans Z conformer is attributed to the spectrum analyzed in this work.

Table 3. Structural parameters assumed for (*Z*)-(acrylaldehyde oxime)

Bond length	l/Å	Bond angle	θ/°
C=C	1.345[a]	H_1-C=C	121.45[a]
C=C	1.470[a]	H_2-C=C	119.97[a]
C_1-H	1.086[a]	C_1=C_2-H	122.83[a]
C_2-H	1.084[a]	C=C-C	119.83[a]
C=N	1.276[b]	C-C=N	121.77[b]
N-O	1.408[b]	H-C=N	115.55[b]
O-H	0.956[b]	C=N-O	110.20[b]
C_3-H	1.086[b]	N-O-H	102.68[b]

The numbering of carbon and hydrogen atoms is given in Fig. 1. a) Ref. 3, Cherniak and Costain, *J. Chem. Phys.*, **45**, 104 (1966). b) Ref. 4, Levine, *J. Chem. Phys.*, **38**, 2326 (1963).

No spectrum of any other conformer has been detected. This suggests that the population or dipole moment, or both of the other conformer is too small to be detected.

Figure 2 shows how the moments of inertia, I_a, I_b, and I_c, depend on the angle of C-C=N keeping the other structural parameters constant. According to Fig. 2, the angle of C-C=N may be plausibly determined to be 128.7°. This unexpectedly large angle is thought to be due to the steric effect between the vinyl and hydroxyl groups. However, the moments of inertia, I_a, I_b, and I_c, may largely depend on the other structural parameters, particularly the bond length of C_2–C_3 and C=N, and the angle of C=C-C and C=N-O.

The more data than we have now are needed in order to come to the final conclusion about this angle.

Extractability of Copper(II) and Zinc(II) with Crown Ethers as Picrates

Yuko HASEGAWA,* Hiroaki TANABE, and Satoshi YOSHIDA
Department of Chemistry, Science University of Tokyo, Kagurazaka, Shinjuku-ku, Tokyo 162
(Received July 2, 1985)

Synopsis. The extraction of copper(II) and zinc(II) with picrate ion and 12-crown-4(1,4,7,10-tetraoxacyclododecane) or 15-crown-5(1,4,7,10,13-pentaoxacyclopentadecane) into benzene or chloroform has been measured. The extraction of copper(II) is better than that of zinc(II), in spite of the similar ionic size, although the difference is much smaller than that in the extraction of these metal ions with β-diketones.

The study of extractions of metal ions with crown ethers has been developed in relation to the agreement between the size of the metal ion and the cavity size of the crown ether.

Since both copper and zinc ions are stable in the divalent state and have about equal size, and their size is also close to the cavity size of 12-crown-4(12C4) or 15-crown-5(15C5), a similar extraction may be expected.

On the other hand, it has been reported that the extraction of copper(II) with a given β-diketone is much better than that of zinc(II).[1]

In the present paper, the extraction of copper and zinc ions with 12C4 and 15C5 from lithium picrate solution into benzene or chloroform has been measured, in order to compare the extractability of these metal ions as ion pairs to the extractability as the chelates.

Experimental

All the procedures were performed at 25±0.5 °C. The crown ethers were obtained from the Aldrich Chemical Co., USA and Merck Inc., West Germany. The lithium picrate solution was prepared by neutralizing picric acid solution with lithium hydroxide. All other reagents were employed without purification.

An aqueous solution containing metal(II) nitrate (2.5×10^{-2} M, 1 M=1 mol dm^{-3}) and lithium picrate and the same volume of benzene or chloroform containing a certain amount of 12C4 or 15C5 were placed in a stoppered glass tube and agitated mechanically for an hour. The two phases were then centrifuged and the metal(II) in the organic phase was back extracted with 0.1 M perchloric acid. The amount of the metal(II) was measured by an atomic absorption method. The metal(II) concentration in the aqueous phase was regarded as the total concentration added initially. The distribution ratio was defined by the following equation.

$$D = [M(II)]_{o,total}/[M(II)]_{a,total}$$

The distribution constants of 12C4 and 15C5 were determined as follows: the crown ethers were distributed between water and benzene or chloroform. The concentration of each crown ether distributed between both phases was measured spectrometrically using sodium chloride and lithium dipicrylamide. The detailed procedure was reported elsewhere.[2]

Results and Discussion

Figure 1 shows the dependence of the picrate ion concentration on the extraction of copper and zinc ion with 15C5 into benzene or chloroform. The slopes of the curves are +2, except in the higher picrate concentration region. When 12C4 was used, the distribution ratio also increased in proportion to the second order of the picrate ion concentration. Since the extraction was not good, a higher concentration of

	15C5	−0.84	1.0_4	2.0_2	-0.2_6	0.6_4
$CHCl_3$	12C4	0.90	0.6_4	3.0_7	-0.1_5	1.8_0
	15C5[4]	0.88	2.0_9	4.4_4	1.0_1	3.2_8

a) Diameter (nm)[3]: 0.15 for 4 coordination, 0.18 for 6 coordination. b) cavity size (nm)[2]: 0.1—0.13 (12C4), 0.17—0.22 (15C5).

the metal ions should be employed for an accurate determination of the distribution ratio. Consequently, the nitrate concentration was as high as 0.05 M. However, the species extracted does not seem to include nitrate ions, because the value of the slope of +2 indicates that two picrate ions were present and there was no room for additional anions.

Figure 2 shows the dependence of the crown ether concentration on the extraction of these metal ions into benzene at a constant picrate concentration. The slope of the extraction curves seems to change from one to two. It suggests that the species extracted would have a 2:1 as well as a 1:1 stoichiometry of the crown ether to the metal ion.

From these results, the distribution ratio, D, can be represented as,

$$D = \frac{[MEA_2]_o + [ME_2A_2]_o}{[M^{2+}]_a} = Kex_1[A^-]_a^2[E]_a + Kex_2[A^-]_a^2[E]_a^2 \quad (1)$$

here, the subscripts "o" and "a" denote the organic and the aqueous phases, respectively, $Kex_n=[ME_nA_2]_o/[M^{2+}]_a[A^-]_a^2[E]_a^n$, and $[E]_a=[E]_{total}/(1+K_D)$ and $K_D(=[E]_o/[E]_a)$ is the distribution constant of the crown ethers. The extraction data were analyzed by a successive approximation method. The extraction constants obtained are listed in Table 1 together with the distribution constants of these crown ethers.

As seen in Table 1, the frame size of the crown ether does not seem to change the general features of the extraction of the crown ether itself. The increase of hydrocarbon segments in the frame may be more favorable to the extraction, because the segments give more hydrophobic character to the crown ether. At the same time, the increase in the hydrophobic tendency should be cancelled out by the increase in the hydrophilic tendency of the molecule, because in a series of the crown ethers such as 12C4, 15C5, and 18C6, an increase of one hydrocarbon segment, $-CH_2-CH_2-$ in the frame always causes an increase of one oxygen atom, and the oxygen atom should give hydrophilic tendency to the molecule through hydration.

On the other hand, the extraction of the metal ions with 15C5 is always better than that with 12C4 by a factor of about one order of magnitude as seen in Fig. 2. That is, the frame size seems to change the extraction of metal ions definitely. Although the reason is not clear, it may reflect that on the complexation of the metal ion with the crown ether, the oxygen atoms in the crown ether interact with metal ions, and hence the balance between the hydrophilic and hydrophobic tendency would be broken, or the stability of the complex with 12C4 would be different from that with 15C5.

The difference of organic solvents influences the extraction of the crown ethers themselves more remarkably than that of the ion pairs of the metal(II), as is seen in Table 1. This fact may also reflect that the oxygen atoms in the frame of the crown ethers may solvate more easily with chloroform, probably through a hydrogen bond, than with benzene.

Table 1 also shows that the extraction of copper ion with either 12C4 or 15C5 is better by a factor of one order than that of zinc ion, when the metal ions are extracted with the same crown ether into the same organic solvent. The extraction constant of bis(acetylacetonato) copper(II) (log $Kex=-3.47$) is larger than that of zinc chelate (log $Kex=-10.69$). The difference has been explained in terms of the different electronic structure, that is, since zinc ion forms stable octahedral chelates with the coordination number of six, the central zinc ion in the chelate may interact more with water molecules than the central copper(II) ion in the chelate.[1] On the other hand, it has been reported[4] that zinc(II) takes four coordination when the metal ion is extracted as ion pairs with trioctylphosphine oxide and perchlorate or halide ions. If the zinc ion also takes on a tetrahedral structure instead of an octahedral one on extraction with the crown ethers and picrate ions, the zinc ion in the ion pairs should not hydrate more than the ion in the chelates. Accordingly, the difference of the extraction of these metal ions would be smaller than that with β-diketones.

Without information on the thermodynamic properties such as the changes in the free energy, the enthalpy, and the entropy on the complexation or the extraction, it is impossible to discuss the extractability of these ion pairs in more detail.

The authors wish to express their gratitude to Messrs. T. Nakano, Y. Morimoto, and T. Miura for their experimental aid.

NMR Spectra of Substituted 2-(2-Nitrovinyl)thiophenes

Hajime SATONAKA* and Michio WATANABE†

Industrial Research Institute of Kanagawa Prefecture, 3173, Showa-machi, Kanazawa-ku, Yokohama 236

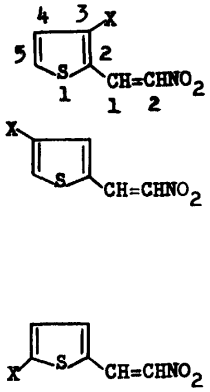
†*Permachem Asia Ltd., 2-14-5, Hiranuma, Nishi-ku, Yokohama 220*

(Received June 1, 1985)

Synopsis. ^{1}H and ^{13}CNMR spectra are reported for substituted 2-(2-nitrovinyl) thiophenes. The proton chemical shifts and coupling constants were correlated closely with those of methyl *trans*-3-(5-substituted 2-thienyl) acrylates. We have found that the additivity rule for ^{13}C chemical shifts of simple substituted thiophenes is applicable to the shifts of the ring carbons in substituted 2-(2-nitrovinyl) thiophenes.

The antibacterial property of 2-(2-nitrovinyl) thiophene has been well known.[1] Recently, we also reported some new antibacterial and fungicidal (nitrovinyl) thiophenes.[2]

We examined the substituent effect in ^{1}H and ^{13}C NMR spectra of a series of substituted 2-(2-nitrovinyl) thiophenes.



X=H	1
X=CH_3	2
X=Br	3
X=OCH_3	4
X=Cl	5
X=Br	6
X=I	7
X=OCH_3	8
X=CH_3	9
X=Cl	10
X=Br	11
X=I	12
X=CHO	13
X=$COCH_3$	14
X=COOH	15
X=$COOCH_3$	16
X=NO_2	17
X=CH=$CHNO_2$	18

^{1}H NMR spectra of substituted (2-nitrovinyl) thiophenes are very similar to those of methyl *trans*-3-(substituted 2-thienyl)acrylate.[3] Thus, assignment was made easily by comparing the spectra of two series of the compounds. The results are given in Table 1. The chemical shifts of protons in 5-substituted 2-(2-nitrovinyl)thiophenes (X=H, OCH_3, CH_3, Cl, Br, I, CHO, $COCH_3$, $COOCH_3$, and NO_2) against those of the corresponding protons in methyl *trans*-3-(5-substituted 2-thienyl)acrylates give good linear correlations [δH(3)[3] r 0.963, p 0.970, s 0.038; δH(4) r 0.992, p 0.963, s 0.062: δH(α)[4] r 0.726, p 0.726, s 0.121; and δH(β) r 0.959, p 1.05, s, 0.048], where r designates correlation coefficient, p slope, and s standard deviation.

^{13}CNMR chemical shifts (Table 2) were assigned as described below. C(β) substituted by NO_2 was unambiguously identified by its broad line width and lower intensity. The quaternary ring carbons were identified by lower intensity. C(2) and another carbon carrying the substituent were assigned on the basis of the substituent effect on substituted thiophenes.[5,6] The protonated carbons were assigned in comparison with the coupling constants between coarbons and protons. C(α) was easily identified by the smallest one bond coupling in the protonated carbons. C(3) and C(4) in 5-substituted 2-(2-nitrovinyl) thiophenes were assigned on the basis of the long-range couplings with H(α), because C(3) couples considerably with H(α), but C(4) does not.

Good linear correlations were obtained between the ^{13}C chemical shifts of the ring in substituted 2-(2-nitrovinyl) thiophenes and the corresponding chemical shifts in substituted thiophenes[6] [δC(2) r 0.988, p 0.909, s 0.793; δC(3) r 0.944, p 0.900, s 1.77; δC(4) r 0.997, p 1.01, s 1.15; and δC(5) r 0.998, p 0.945, s 1.30]. These results suggest that the additivity rule for ^{13}C chemical shifts of simple substituted thiophenes is

applicable to the shifts of the ring carbons in substituted 2-(2-nitrovinyl)thiophenes.

Chemical shifts of the ring carbons are not always correlated closely with those of hydrogen atoms attached to them. In all the compounds stuidied, $\delta H(\alpha)$ appeared at considerably lower field than $\delta H(\beta)$. In contrast, $\delta C(\alpha)$ appeared at higher field than $\delta C(\beta)$, except for **8**. The substituent effect of methoxy group may be transmitted more strongly by the contribution of resonance structures to $\delta C(\beta)$ in **8**, as to $\delta H(\beta)$ in methyl *trans*-3-(5-methoxy 2-thienyl)acrylate.[3] In 4-substituted compounds, $\delta H(3)$ appeared at lower field than $\delta H(5)$, but $\delta C(3)$ at higher field than $\delta C(5)$. These facts can be a reason for the poor correlations between δH and δC. It is exceptional that plot of $\delta H(\beta)$ *vs.* $\delta C(\beta)$ gave a good correlation (r 0.985, p 11.9, s 0.315). Besides, $\delta C(\beta)$ of 5-substituted compounds (X=H, OCH_3, CH_3, Cl, Br, I, CHO, $COCH_3$, $COOCH_3$, and NO_2) against Hammett's σ_p value[7,8] gave a good correlation (r 0.900, p 6.43, s 8.90). The effect of the substituent on the 5-position may be transmitted more regularly to $\delta H(\beta)$ and $\delta C(\beta)$ than others as observed with methyl *trans*-3-(5-substituted 2-thienyl)acrylates.[3]

Experimental

^1H and ^{13}CNMR spectra were recorded on a JEOL FX-90Q spectrometer. ^1H(±0.01 ppm) and ^{13}C(±0.1 ppm) chemical shifts were measured from internal TMS reference in $(CD_3)_2CO$ solution at probe temperature. ^1H spectra were obtained, using 45° pulse flip angle and 900 or 1100 Hz spectra width and proton decoupled ^{13}C spectra, using 30° pulse flip angle and 4500 or 5000 Hz spectra width. Proton coupled ^{13}C spectra were obtained by the normal gate decoupling technique in $(CD_3)_2SO$ solution.

Thiophenes (**1**, **2**, **3**, **6**, **9**, **10**, **11**, **13**, and **17**) were prepared according to the reported methods.[1,9-10] Melting points and analytical data of new compounds are given in Table 3.

The authors wish to thank Professor Minoru Hirota of Yokohama National University for his kind suggestions and encouragement.

A Kinetic Study of Thermal Rotational Isomerization of 5,10,15,20-Tetrakis(*o*-aminophenyl)porphyrin and 5,10,15,20-Tetrakis(*o*-pivaloylaminophenyl)porphyrin

Keiichiro HATANO,* Kazunori ANZAI, Akemi NISHINO, and Keiko FUJII

(Received June 26, 1985)

Synopsis. Rates of thermal interconversion of atropisomers of 5,10,15,20-tetrakis(*o*-aminophenyl)porphyrin and 5,10,15,20-tetrakis(*o*-pivaloylaminophenyl)porphyrin have been determined.

It is well known that four atropisomers of *ortho*-substituted tetraarylporphyrins can be thermally or photochemically interconverted by rotation about a porphyrin-aryl bond.[1-4,6] In a previous paper,[4] we reported the isomerization reactions of tetrakis-(*o*-cyanophenyl)porphyrin (ToCNPP) atropisomers. Herein we report the isomerization rates of 5,10,15,20-tetrakis(*o*-aminophenyl)porphyrin ($ToNH_2PP$) and 5,10,15,20-tetrakis(*o*-pivaloylaminophenyl)porphyrin (ToPivPP) studied at various temperatures in order to compare the effects of the *ortho* substituents on the atropisomerization.

Experimental

$ToNH_2PP$ was synthesized by methods described in the literature.[1] Calcd for $C_{44}H_{34}N_8 \cdot H_2O$; C, 76.21; H, 5.20; N, 16.16. Found: C, 76.38; H, 4.68; N, 16.01%. The separation of $ToNH_2PP$ into the four atropisomers was carried out by column chromatography on silica gel eluted with 98:2 chloroform-methanol. The preparation and purification of the four atropisomers of ToPivPP was described previously.[5]

The isomerization reactions of $ToNH_2PP$ were conducted in toluene or 1,1,2-trichloroethane solutions heated at a temperature range of 65 to 95 °C. The quantity of each isomer at appropriate reaction times was evaluated spectrometrically on the chloroform extracts of the TLC spots, or measured directly by the integrated peak area recorded on a TLC scanner.

The isomerization reactions of ToPivPP were monitored by the NMR spectral changes recorded on a JEOL FX-100 spectrometer operating in FT mode. The NMR signals due to the methyl protons of the pivaloylamino substituent allow an unambiguous assignment to each of the four conformations as described.[5] The isomerization of ToPivPP was carried out by dipping an NMR tube containing a toluene-d_8 solution of the isomers into the heated oil bath.

Results and Discussion

Thermal rotation of one substituted phenyl ring about the phenyl–porphyrin bond lead to the stereochemical isomerization reactions among the atropisomers of $ToNH_2PP$ or ToPivPP as shown schematically in Fig. 1. The R_f values on TLC eluted with 95:5 chloroform–methanol are 0.26, 0.18, 0.07, and 0.03 for $\alpha\beta\alpha\beta$-, $\alpha\alpha\beta\beta$-, $\alpha\alpha\alpha\beta$-, and $\alpha\alpha\alpha\alpha$-isomer of $ToNH_2PP$, respectively.

On permitting a toluene solution of $ToNH_2PP$ isomers to stand for 2 d at 80 °C, the four isomers were present in 0.15, 0.27, 0.49, and 0.09 ratio for the $\alpha\beta\alpha\beta$-, $\alpha\alpha\beta\beta$-, $\alpha\alpha\alpha\beta$-, and $\alpha\alpha\alpha\alpha$-isomers, respectively. The ratio was close to the statistical 1:2:4:1 ratio expected in equilibrium for the case where there is no mutual interaction between the *ortho* substituents.[4] The free energy difference corresponding to the small deviation from the ideal ratio was evaluated to be at most 0.4 kJ mol^{-1}. This value is small enough to be ignored in the rate constant determination. Therefore the rate data could be processed by assuming the idealized statistical ratio at equilibrium. Under these conditions, each isomer is considered to possess four equivalent rotational bonds. Thus, a relationship in the rate constants is deduced as follows: $k_r=k_2=k_6=k_4/2=k_1/4=k_3/4=k_5/4$, where k_r is the rate constant for the rotation about one phenyl–porphyrin bond of any isomer. The observed rate constants entered in Fig. 1 are consistent with this relationship within the experimental errors. The values of k_r were determined from several independent experiments at 65, 75, 85, 93, and 95 °C.

The equilibrium mixture of ToPivPP atropisomers produced by heating a solution of $\alpha\alpha\alpha\alpha$-

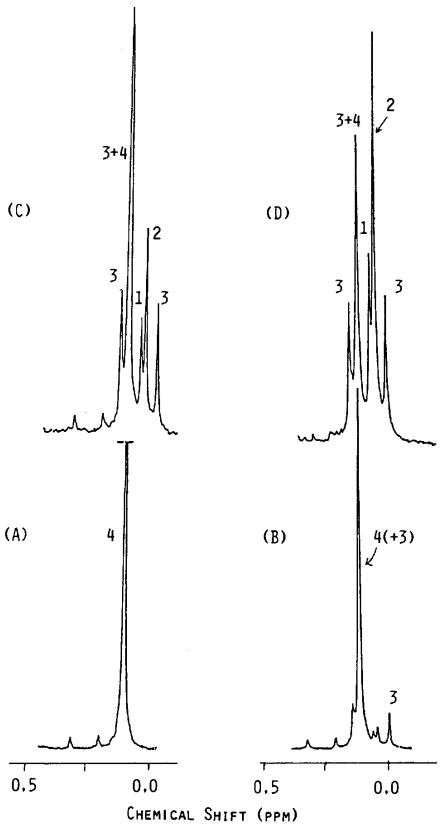

Fig. 2. NMR spectral changes during atropisomerization of ToPivPP at 90°C. Reaction time (A) 0 h (B) 30 h (C) 76 h (D) more than 720 h and the signal assignment 1.*αβαβ*; 2.*ααββ*; 3.*αααβ*; 4.*αααα* are shown.

isomer at 90°C for more than 30 d contained four isomers in a ratio of 0.14:0.28:0.47:0.11 for the respective *αβαβ*, *ααββ*, *αααβ*, and *αααα*-isomers. This ratio is surprisingly close to the statistical ratio.[6] Hence, the rate determination was carried out with the *αααα*-isomer by assuming the same relationship as in the $ToNH_2PP$ case. The outline of the NMR spectral changes during the atropisomerization reaction of ToPivPP and the signal assignment to each isomer are shown in Fig. 2. The rate constants for rotation about one axis were determined graphically. The k_r values for ToPivPP were obtained at 60, 90, and 103°C. The derived kinetic parameters are listed in Table 1.

The rotational barrier is brought about mainly by the steric hindrance of the *ortho* substituent on the phenyl ring. The bulk of the substituents is the most important factor to affect the height of the barrier. The evaluation of the barrier depending on the *ortho* substituents requires comparison of data at the same temperature. For this purpose, the extrapolation using the Arrhenius activation energy measured in a wide range of temperatures will be effective. The thermochemical activation parameters reported for some *ortho* substituents of tetraarylporphyrin free bases are summarized in Table 1 using the data of the NH_2 group as a common standard. The order of Piv>HA~NH_2>CN>CH_3O~OH with decreasing ΔG^* values was observed as the effect of substituents. The order is reasonable in view of the bulk of the *ortho* substituents, although the high barrier for the NH_2 group is remarkable. The actual friction for rotational isomerization generated by the two protons of NH_2 may be much more resistive than that expected by the simple comparison of the ionic radii.

Another remarkable feature of the kinetic parameters is the difference in the entropy of activation dependent on the substituents. All ΔS^* took negative values.[6] The order was Piv~THA>NH_2~CN with decreasing of the absolute values of ΔS^*. The order is also compatible with the bulk of the *ortho* substituents. This suggests that a bulky substituent at the *ortho* position makes a large contribution to the entropy term in the energy of activation for the rotational isomerization reaction.

It seems that there is some disagreement in the spectral observations for ToPivPP between these authors and us.[5] Their rate data obtained at two temperatures for ToPivPP were not entered in Table 1.

Bromochlorination of Conjugated Dienes with Dichlorobromate(1-) Ion

Takeshi NEGORO* and Yoshitsugu IKEDA
Department of Chemistry, Faculty of Education, Wakayama University, Sakaedani, Wakayama 640
(Received July 22, 1985)

Synopsis. The reactions of some conjugated dienes with tetrabutylammonium dichlorobromate (1-) (**1**) were found to give the bromochloroalkenes in good yields, 1,2-addition predominating. Appreciable *anti*-Markownikoff adduct was obtained from 1,3-butadiene. An $AdEC_2$-type mechanism is suggested.

The ratio of 1,2- to 1,4-addition of bromine (and bromine chloride) to conjugated dienes has been shown to be markedly dependent on the brominating (and bromochlorinating) agents employed.[1,2] The predominance of 1,2-addition was observed for the reaction with a tribromide ion.[2,3] However, no studies have been carried out on the reaction with tetrabutylammonium dichlorobromate (1-) (**1**) as a bromochlorinating agent. We have reported that the additions of **1** to alkenes are strikingly different from that of molecular bromine chloride (BrCl).[4,5] In this paper, we will report the bromochlorination of some conjugated dienes with **1**.

Results and Discussion

The reaction of **1** with 1, 3-butadiene (**2a**), 2-methyl-1, 3-butadiene (**2b**), *cis*- and *trans*-1,3-pentadienes (**2c** and **2d**), and cyclopentadiene (**2e**) in dichloromethane gave the corresponding bromochloroalkenes in good yields (Table 1). In the cases of **2b** and **2e**, a small amount of 1, 4-dichloro adducts (**6**) was isolated.

TABLE 1. REACTIONS OF DIENES WITH **1**[a]

Dienes	1,2-Adduct[b]		1,4-Adduct[b]		Yield/%[c]
	3	**4**	**5**	**6**	
2a	99.0[d]		1.0		98
2b	78.6	11.0	9.2	1.2	98
2c	66.2	29.4	4.4		99
2d	87.1	5.1	7.8		99
2e	93.2		0.9	5.9[e]	93

a) Reactions were carried out with 30 mmol of **1**, 36 mmol of diene, and 100 ml of CH_2Cl_2 at −12°C. b) The products are identified as follows: from **2a**, 4-bromo-3-chloro-1-butene (**3a**), 3-bromo-4-chloro-1-butene (**3a′**), *trans*-1-bromo-4-chloro-2-butene (**5a**); from **2b**, 4-bromo-3-chloro-3-methyl-1-butene (**3b**), 4-bromo-3-chloro-2-methyl-1-butene (**4b**), 1-bromo-4-chloro-2-methyl-2-butene (**5b**),1,4-dichloro-2-methyl-2-butene (**6b**); from **2c** and **2d**, *cis*- and *trans*-5-bromo-4-chloro-2-pentenes (**3c** and **3d**), *threo*- and *erythro*-4-bromo-3-chloro-1-pentenes (**4c** and **4d**), *trans*-1-bromo-4-chloro-2-pentene (**5c**=**5d**); from **2e**, *trans*-4-bromo-3-chlorocyclopentene (**3e**), *cis*-3-bromo-5-chlorocyclopentene (**5e′**), *cis*- and *trans*-3,5-dichlorocyclopentenes (**6e′** and **6e**). Percentages are normalized to 100%. c) Based on **1**. Total bromochloralkene yields determined by GLC using 1,2-dibromobutane as an internal standard. d) **3a**:**3a′**=84:16. e) **6e**:**6e′**=35:65.

Furthermore, in all cases, the yield of 1, 4-bromochloro adducts (**5**) decreased by the prolonged reaction time, producing **6**. It was shown that **6** is also formed upon treatment of **5** with tetrabutylammonium chloride in CH_2Cl_2. Therefore, it probably arises by the halogen-exchange reaction of 5 with generating chloride ions in the reaction system. Control experiments showed that all the 1, 2-bromochloro adducts (**3** and **4**) are stable under the reaction conditions.

A common characteristic of the present reaction is the highly selective formation of the 1, 2-bromochloro adducts. Moreover, the addition to the 3, 4-bond in **2c**, **2d**, and **2e** gave completely *anti*-stereospecific products (**4c**, **4d**, and **3e**).

In the case of **2a**, the reaction gave a mixture of 4-bromo-3-chloro-1-butene (**3a**) and 3-bromo-4-chloro-1-butene (**3a′**) as the 1, 2-adducts.

$$\underset{\textbf{2a}}{CH_2{=}CHCH{=}CH_2} + \textbf{1} \longrightarrow \underset{\textbf{3a},\ 84\%}{CH_2BrCHClCH{=}CH_2} + \underset{\textbf{3a}',\ 16\%}{CH_2ClCHBrCH{=}CH_2}$$

Fig. 1.

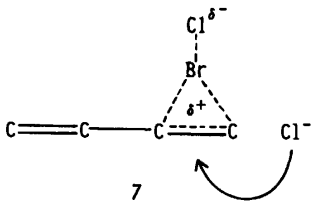
When the reaction of **2a** with **1** was carried out in the presence of a free radical inhibitor, 2,6-di-*t*-butyl-4-methylphenol or oxygen, the product composition did not change within experimental errors. This result indicates that the lack of regiospecificity cannot be ascribed to a radical process.[6]

The reaction of **2a** with **1** was investigated in a variety of solvents. The reaction in chloroform, dichloromethane, 1,2-dichloroethane, acetic anhydride, and nitromethane gave nearly the same ratio of **3a** and **3a′** (84:16) within an experimental error (±1%). The amount of the 1,4-adduct (**5a**) was less than 2% in all the solvents employed. A similar solvent independency on the regiochemistry has been previously observed for the reaction of 1-phenylpropenes with **1**.[5]

In contrast to the present results, the high preference of 1,4-addition has been observed for the reaction of BrCl (and Br_2) with conjugated dienes.[1,2,7] Furthermore, dependence of the 1,2- *vs.* 1,4-addition of Br_2 to **2a** on solvent polarity has been reported.[7] We have also found that BrCl reacted with **2a** to give a mixture of **3a** and **5a** (**3a**:**5a**=27:73). None of the *anti*-Markownikoff adduct (**3a′**) was detected by ^{13}C-NMR analysis of the product mixture.

Thus, the addition to dienes appeared to be very different in reactions with **1** and with BrCl. Therefore, the present reaction cannot be explained on the basis of any accepted mechanism involving a bromonium ion intermediate for the addition of BrCl (and Br_2).[2,3] We would like to suggest another possible mechanism

which involves the attack of chloride ions on a three-center bound π complex-type intermediate (**7**) with little delocalization of the positive charge across the allylic system: a similar mechanism has been suggested for the addition of **1** to alkenes.[4,5]



7

Experimental

The NMR and mass spectra were recorded on a JEOL JNM FX-60Q and JMS-D-300 mass spectrometer, respectively. The GLC analyses were performed on a Yanako G-180 Gas Chromatograph with a Silicone SE-30 (2.5%)-Chromosorb WAW DMCS (2 m) column at 50 °C with helium as a carrier gas (35 ml/min). All the organic starting materials were distilled before use.

*Reaction of **2a** with **1**.* Details of the reaction have been reported previousiy.[4] To a solution of **2a** (3.0 ml, 36 mmol) in CH_2Cl_2 (100 ml) was added **1** (11.8 g, 30 mmol) at −12 °C over 20 min with stirring. After the usual work-up, distillation afforded 3.83 g (75.3%) of a mixture of **3a** and **3a′**: Bp 46—48 °C/26 mmHg (1 mmHg=133.322 Pa); MS M$^+$ at *m/z*=168, 170, 172 (100:132:35); Found: *m/z* 167.9330. Calcd for C_4H_6BrCl: M, 167.9342. ^{13}C-NMR showed a 84:16 mixture of **3a** and **3a′**, respectively. ^{13}C-NMR ($CDCl_3$) (an asterisk indicates **3a′**) δ=35.0, 47.0*, 51.1*, 60.2, 119.7, 135.2, 135.5*. Although attempts to separate **3a** and **3a′** were unsuccessful, these assignments were supported for dibromo and dichloro analogs as follows: 3,4-dichloro-1-butene, ^{13}C-NMR ($CDCl_3$) δ=47.3, 60.1, 119.7, 134.8; 3,4-dibromo-1-butene, ^{13}C-NMR ($CDCl_3$) δ=34.5, 50.5, 119.8, 136.0. The structure of the minor 1,4-adduct (**5a**) was verified by comparison of the spectra of the sample prepared by the reaction of **2a** with BrCl.[2] **5a**, ^{1}H-NMR ($CDCl_3$) δ=3.90—4.10 (4H, m, CH_2Br and CH_2Cl), 5.90—6.01 (2H, m, CH=CH); ^{13}C-NMR ($CDCl_3$) δ=30.9, 43.5, 130.3 (2C).

*Reaction of **2b—e** with **1**.* The reactions were carried out similarly to those of **2a**. The relative amounts of the products were determined by the peak areas of GLC (Table 1). All the reaction products were identified by comparing GLC and NMR spectra with the authentic samples prepared by the reaction of BrCl with these dienes.[1,2] The ^{1}H-NMR spectra of the products correspond well with those reported in the literatures.[1,2]

*Reaction of **2a** with **1** Under Various Conditions.* When **2a** was treated with **1** in CH_2Cl_2 as described above, O_2 was bubbled during the reaction. ^{13}C-NMR analysis of the residue showed an 85:15 mixture of **3a** and **3a′**, respectively. The reaction was carried out with 12 mmol of **2a**, 10 mmol of **1**, and 3 mmol of 2,6-di-*t*-butyl-4-methylphenol in CH_2Cl_2 (50 ml). After the usual work-up, ^{13}C-NMR analysis of the residue showed an 86:14 mixture of **3a** and **3a′**, respectively.

To 12 mmol of **2a** in 50 ml of the solvent ($CHCl_3$, CH_2Cl_2, CH_2ClCH_2Cl, $(CH_3CO)_2O$, and CH_3NO_2) was added 10 mmol of **1** at −12 °C over 5 min with stirring. After the usual work-up, the residues were subjected to GLC and ^{13}C-NMR analyses. In all cases, GLC analysis showed over 98% of the 1, 2-adducts. ^{13}C-NMR analysis showed nearly the same ratio of **3a** and **3a′** (84:16) within an experimental error (±1%).

Halogen Exchange Reaction. To 5 mmol of **5a** in CH_2Cl_2 (25 ml) was added 10 mmol of tetrabutylammonium chloride and the mixture was allowed to stand for 24 h at 0 °C with stirring. After the usual work-up, GLC analysis showed the composition to be: **5a**, 5%; *trans*-1,4-dichloro-2-butene (**6a**), 95%. Similar treatment of **5b—e** and **5e′** with chloride ions gave over 95% of the corresponding 1,4-dichloro compounds.

Palladium-catalyzed Reaction of Stannyl Sulfide with Aryl Bromide. Preparation of Aryl Sulfide

Masanori KOSUGI,* Toshimi OGATA, Masahiro TERADA, Hiroshi SANO, and Toshihiko MIGITA*
Department of Chemistry, Faculty of Technology, Gunma University, Kiryu, Gunma 376
(Received August 5, 1985)

Synopsis. Tributylstannyl alkyl or aryl sulfide and bis(tributylstannyl) sulfide were found to be useful to prepare aryl sulfides in good yields under the usual conditions of the palladium-catalyzed reaction with aryl bromides.

Versatility of organotin reagents can be found in that organotin compounds having either carbon–tin bond[1] or heteroatom–tin bond can be utilized in palladium-catalyzed cross-coupling with organic halides. Thus, silylstannane,[2] distannane,[3] and aminostannane[4] transfer silyl, stannyl, and amino groups to aryl halides, respectively. However, palladium-catalyzed alkoxylation or acyloxylation of aryl halides by using the alkoxy or acyloxy tin compounds is not attained so far. In contrast, stannyl sulfide, an analogue of stannyl alkoxide, was found to undergo the cross-coupling with aryl bromides.[6]

In this note, we report the palladium-catalyzed reaction of stannyl sulfides with aryl bromides.

$$n\text{-Bu}_3\text{SnSR} + \text{ArBr} \xrightarrow{[\text{Pd}]} \text{ArSR} + n\text{-Bu}_3\text{SnBr}$$

Previously we reported that aryl phenyl or aryl alkyl sulfides were formed by the reaction of sodium benzenethiolate or alkanethiolate with aryl iodides or bromides, catalyzed by palladium.[5] The present method is an alternative one without any use of strong base and is applied to aryl bromides bearing wider variety of substituents. Results are summarized in Table 1.

The reaction took place with either butylthio or phenylthio tin compounds and gave the sulfides in good yields regardless of the nature of functional groups in substrates. With mesityl bromide, the yield was rather low probably due to steric hindrance. As the yield did not depend on the solvent polarity, we chose aromatic hydrocarbon for the convenience of its removal in workup processes.

The reaction of bis(tributylstannyl) sulfide was exemplified for the preparation of symmetrical sulfide as shown in Table 2, although the palladium-catalyzed reaction of aryl iodides or vinyl bromides with bis(triethylstannyl) sulfide has appeared in a recent review of Beletskaya[6] without any reference cited. The reaction was carried out under similar conditions to those shown in Table 1. The reaction gave the sulfide in moderate yields except with aryl bromides having ortho substituents. A similar situation was also observed in the reaction with vinyl bromides, showing that steric hindrance might be an important factor in these reactions. Trials for the preparation of unsymmetrical sulfides by using a mixture of two bromides were failed.

Experimental

IR spectra were recorded on a Jasko A-100 spectrophotometer. ^{1}H NMR spectra were recorded on a Varian EM-360 instrument. GLC analyses were carried out with an Ohkura 802 instrument, using columns (1.5 m) packed with 10% Silicone SF-96 and SE-30 on Celite 545.

Materials. Tributylstannyl butyl and phenyl sulfide were prepared by treating the corresponding thiols with tributyltin oxide in the presence of base (sodium ethoxide).[7] Bis(tributylstannyl) sulfide was prepared by the reaction of tributyltin oxide with thiourea.[7] Palladium complex and halide were already reported.[1b]

Reaction Procedures. A mixture of stannyl sulfide (1.3 mmol), halide (1.0 or 2.0 mmol), tetrakis(triphenylphosphine)palladium (1 mol%), and toluene or xylene (1 cm^3) was heated under argon at 120 °C for 20 h. After the reaction mixture was washed with aqueous potassium fluoride and filtered to remove tributyltin fluoride, the organic layer was extracted with ether and dried over magnesium sulfate. The product was distilled by Kugelrohr.

Products. Most of the products were known and their structures were identified by IR and ^{1}H NMR spectra.

Di-p-tolyl Sulfide: ^{1}H NMR (CCl_4) δ=2.29 (s, 6H) and 6.8—7.3 (m, 8H). Found: C, 78.05; H, 6.73%. Calcd for $C_{14}H_{14}S$: C, 78.46; H, 6.58%.

Substituent Effects on Cation-extraction and Transport Properties of a Series of 4′-Substituted Benzo-15-Crown-5 Derivatives

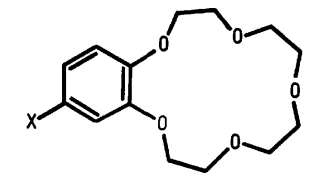
Hiroshi TSUKUBE,* Kentaro TAKAGI, Tatsuo HIGASHIYAMA, Tadashi IWACHIDO, and Naomi HAYAMA
Department of Chemistry, College of Liberal Arts and Science, Okayama University, Okayama 700
(Received August 7, 1985)

Synopsis. The substituent effects on chemical functions of benzo-15-crown-5 derivatives were found to be considerably large and often comparable to the ring-size effects. For example, 4′-aminobenzo-15-crown-5 transported K^+ ion 14-times faster than 4′-nitrobenzo-15-crown-5, while 4′-nitrobenzo-18-crown-6 showed 12-times higher transport rate than 4′-nitrobenzo-15-crown-5.

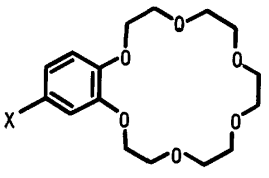
Macrocyclic crown ethers form stable and selective complexes with alkali and alkaline earth cations, and show characteristic cation-transport and related functions.[1] Since their cation-binding properties are largely changed by chemical modifications of crown ether structures,[2] a variety of functional substituents have been introduced into crown ether skeletons. Here we examined the cation-extraction and transport properties of a series of 4′-substituted benzo-15-crown-5 derivatives, and found that the substituent effects on chemical functions of crown ethers were considerably large and often comparable to the crown ring-size effects. Although several types of benzo-crown ether derivatives have been prepared as cation-binders, carriers, and catalysts,[3] this is the first report concerning substituent effects on the cation-transport phenomena.[4] Therefore, the present study may offer the further possibilities in the designing new functional benzo-crown ethers and related polymers.

Results and Discussion

1. Substituent Effects on Cation-extraction Properties of Benzo-15-Crown-5 Derivatives. The cation-extraction properties of a series of benzo-15-crown-5 derivatives **1**, **3**, **4**, and **5** were examined by equilibrating a CH_2Cl_2 solution of a crown ether with an aqueous solution of metal perchlorate.



1: X=NH_2
2: X=t-C_4H_9
3: X=H
4: X=Br
5: X=NO_2



6: X=NO_2

Fig. 1. Examined benzo-crown ethers.

The examined benzo-15-crown-5 derivatives extracted Na^+ and K^+ ions much more effectively than Li^+ and Cs^+ ions under the employed conditions (Table 1). Their extraction properties were generally controlled by guest cation-crown ring size fitness, and also largely influenced by the natures of 4′-substituents attached to benzene ring. For example, crown **1** bearing electron-donating -NH_2 group showed higher extraction abilities for Na^+ and K^+ ions than crowns **4** and **5** bearing electron-withdrawing -Br and -NO_2 substituents. Smid *et al.* have measured the stability constants for some Na^+·benzo-15-crown-5 complexes in acetone and observed somewhat similar substituent effects: $K\times10^{-3}$ (M^{-1})=8.21 for **1**; 2.05 for **4**; 0.165 for **5**.[4a] As shown before,[4] substituent groups attached to benzene rings may change basicities of two aromatic ether oxygen atoms. (1 M=1 mol dm^{-3}).

4′-Nitrobenzo-18-crown-6 (**6**) extracted K^+ ion more effectively than 4′-nitrobenzo-15-crown-5 (**5**). Since K^+ ion fits ring size of 18-membered crown ether more tightly than that of 15-membered one, crown ring size effects seemed to be a dominant factor as reported frequently.[1] However, its extraction efficiency and selectivity for K^+ ion were lower than those of benzo-15-crown-5 derivatives **1** and **3**. These observations strongly suggest that the nature of substituent is a more important factor in determining extraction ability than ring size of parent crown ether.

2. Substituent Effects on Cation-transport Properties of Benzo-15-Crown-5 Derivatives. The transport experiments were performed in the CH_2Cl_2 liquid membrane,[5] in which crown ether solubilizes guest cation salt into the membrane and facilitates transport from source aqueous phase through CH_2Cl_2 membrane to receiving aqueous phase. The measured values of initial cation-transport rates are summarized in Table 2.

The transport rates of Na^+ and K^+ ions with benzo-

Table 1. Extraction properties of benzo-crown ethers

	Li^+	Na^+	K^+	Cs^+
1	0	3.6	13.6	0.4
3	0.4	3.8	10.4	0
4	0	0.8	2.8	0
5	0.2	1.8	3.6	0
6	0	3.4	4.6	2.1

Conditions: Aqueous phase; Metal perchlorate, 0.02 mmol/H_2O, 2 ml. Organic phase; Crown, 0.15 mmol/CH_2Cl_2, 3 ml. a) [Metal salt extracted in CH_2Cl_2]/[Metal salt added initially]×100 was shown, which was calculated from the difference in the extraction percentages of crown-containing and blank (no crown) systems.

Table 2. Transport properties of benzo-crown ethers

Crown	Transport Rate ($\times 10^6$ mol/h)[a]			
	Li^+	Na^+	K^+	Cs^+
1	0.1	0.7	9.9	1.1
2	<0.1	0.6	9.1	1.2
3	<0.1	0.6	8.9	0.7
4	<0.1	0.2	2.3	0.3
5	<0.1	0.1	0.7	<0.1
6	<0.1	0.4	8.7	3.0

Conditions; Source aqueous phase; Metal perchlorate, 0.5 mmol/H_2O, 5 ml. Membrane phase; Crown, 0.05 mmol/CH_2Cl_2, 12 ml. Receiving aqueous phase; H_2O, 5 ml. a) The values indicated were calculated from the difference in the transport rates of carrier-containing and blank (no carrier) systems. Reproducibility was confirmed as ±15% or better.

15-crown-5 derivatives also showed a pronounced dependence on the natures of 4′-substituents attached to benzo-crown ring. The electron-withdrawing substituents such as -Br and -NO_2 groups largely decreased transport rates of Na^+ and K^+ ions, though electron-donating -NH_2 and -t-C_4H_9 groups offered fast transport rates. As a result, a 14-fold difference in the transport rates of K^+ ion was observed between benzo-15-crown-5 derivatives **1** and **5**. When 4′-nitrobenzo-18-crown-6 (**6**) was employed as a carrier, its transport rate of K^+ ion was 12-times higher than that of 4′-nitrobenzo-15-crown-5 (**5**), but lower than those of 4′-amino- and 4′-*t*-butylbenzo-15-crown-5 derivatives **1** and **2**. Since we confirmed that the leakages of the examined benzo-crown ethers **1**—**6** were almost negligible,[6] the present results demonstrate that transport profiles are easily modified by simple substitution of benzo-crown ether. In other words, the nature of substituent introduced into crown ether skeleton should be seriously considered in the modification and functionalization of benzo-crown ether type ligand system.

Experimental

1. Materials. 4′-Substituted benzo-crown ethers **1**, **4**, **5**, and **6** were prepared as decribed before,[4a] and showed satisfactory Mass, ^{1}H-NMR, and ir spectral data. Crowns **2** and **3** were purchased from Merck Japan and Parish Chemical, respectively. Other employed reagents were commercially available and used without further purifications.

2. Extraction Procedures. The extraction abilities of crown ethers were estimated on the basis of the partition of metal perchlorate between CH_2Cl_2 (3 ml) and aqueous solution (2 ml). After extraction experiments (3 h), the aqueous phase was separated and the concentrations of K^+, Na^+, and ClO_4^- ions were determined by means of ion-selective electrodes (Orion Model 931901, 971100, and 938100). The crown **2** was not examined here, because of its low solubility into the CH_2Cl_2.

3. Transport Procedures. The transport experiments were carried out at room temperatue in a U-tube glass cell (2.0 cm, i. d.) as reported before.[5] The crown in CH_2Cl_2 (12 ml) was placed in the base of the U-tube, and two aqueous phases (5 ml, each) were placed in the arms of the U-tube, floating on the CH_2Cl_2 membrane. The membrane phase was constantly stirred with a magnetic stirrer. The transported amounts of K^+, Na^+, and ClO_4^- ions were also determined by ion-selective electrode techniques.

Possible Interpretation of Inactivity of Novel Gramicidin S Analogs by CD Spectral Analysis of Tetrapeptide Derivatives Related to the Analogs[1)]

Kazuki SATO, Ukon NAGAI,* and Makoto TAMAKI†
Mitsubishi-Kasei Institute of Life Sciences, 11 Minamiooya, Machida, Tokyo 194
†*Department of Chemistry, Faculty of Science, Toho University, Miyama, Funabashi, Chiba 274*
(Received August 9, 1985)

Synopsis. CD spectral analysis of chromophoric derivatives of tetrapeptides related to the β-turn part of [D-Val$^{1,1'}$]- and [D-Val$^{1,1'}$, L-Phe$^{4,4'}$]-gramicidin S indicated that they had very low preference for β-turn formation. The results suggested that neither analog could take gramicidin S-like β-sheet conformation. It seems noteworthy that the side-chain bulkiness of the 4th amino acid of a tetrapeptide affects the stability of β-turn.

In the previous papers, we reported that the CD spectra of *N*-(2,4-dinitrophenyl) tetrapeptide *p*-nitroanilides reflected well the β-turn preference of the tetrapeptide sequences.[2-4)] β-Turn preferences of the tetrapeptides related to the β-turn part of gramicidin S (GS), *cyclo*(-L-Val$^{1,1'}$-L-Orn$^{2,2'}$-L-Leu$^{3,3'}$-D-Phe$^{4,4'}$-L-Pro$^{5,5'}$-)$_2$ (Fig. 1),[5)] had good correlation with antibiotic activities of the GS analogs having similar tetrapeptides sequences at their β-turn parts.[3)]

Recently, one of the authors (M. Tamaki) and his co-workers synthesized [D-Val$^{1,1'}$]- and [D-Val$^{1,1'}$, L-Phe$^{4,4'}$]-GS and found that both analogs were inactive against Gram-positive bacteria.[6)] In this paper, we attempted to explain the inactivity of the analogs by β-turn preference of their partial sequences. First, we synthesized Dnp-L-Ala-D-Ala-L-Pro-D-Ala-pNA (**2D**) and Dnp-L-Ala-L-Ala-L-Pro-D-Ala-pNA (**2L**) as models of the partial sequences of [D-Val$^{1,1'}$]- and [D-Val$^{1,1'}$, L-Phe$^{4,4'}$]-GS, respectively. Especially, **2D** was of interest due to the LDLD sequence which have never been examined yet.

Figure 2 shows the CD spectra of **2D** and **2L** together with those of Dnp-L-Leu-D-Ala-L-Pro-L-Val-pNA (**1D**)[2)] and Dnp-L-Leu-L-Ala-L-Pro-L-Val-pNA (**1L**)[2)], which are model peptides for [D-Ala$^{4,4'}$]-GS,[7,8)] and [L-Ala$^{4,4'}$]-GS,[8)] respectively. Compound **2D** sbowed strong Cotton effect above 250 nm typical for the exciton coupling between the two terminal chromophores, though it was a little weaker than that of GS-model peptide **1D**. So, β-turn preference of the sequence in **2D** seems to be high enough to allow the GS-analog containing the similar sequence to take GS-like conformation. On the other hand, **2L** did not show any particular CD patterns above 250 nm suggesting that **2L** took random conformation. The CD spectrum seems to be explained by the summation of CD of a Dnp-L-amino acid and a D-amino acid *p*-nitroanilide as in the case of **1L**. So, the inactivity of [D-Val$^{1,1'}$, L-Phe$^{4,4'}$]-GS seems to be due to the difficulty of taking GS-like β-sheet conformation as in the case of [L-Ala$^{4,4'}$]-GS.[8)]

Though CD spectra of **2D** suggested that [D-Val$^{1,1'}$]-GS had some possibility of taking GS-like β-sheet conformation, the analog was inactive and showed different CD spectra from that of GS.[6)] Based on the molecular model study, we considered that the bulky D-Val side chain might destabilize the β-turn conformation because of large steric hindrance with carbonyl oxygen of the L-Pro residue (cf. Fig. 1). So, we

synthesized Dnp-L-Leu-D-Ala-L-Pro-D-Val-pNA (**3D**) and Dnp-L-Leu-L-Ala-L-Pro-D-Val-pNA (**3L**) as closer models to the original sequences of the GS analogs. Tetrapeptide **3D** as well as **3L** showed weak CD bands above 250 nm (Fig. 2). The result suggested that **3D** did not prefer to take β-turn conformation and therefore [D-Val$^{1,1'}$]-GS did not take GS-like β-sheet conformation.

Consequently, inactivity of both [D-Val$^{1,1'}$]- and [D-Val$^{1,1'}$, L-Phe$^{4,4'}$]-GS seems to be caused by the reluctance of their partial sequences to take β-turn conformation. However, the reason of reluctance seems to be different; partial sequence of the former has some potential to take β-turn conformation except for the steric hindrance of bulky D-Val side chain, whereas, that of the latter has not such potential at all.

Present study proves that CD spectra of the chromophoric derivatives of peptides are useful for interpreting the structure-activity relationships of GS analogs, and suggests that the bulkiness of the 4th-position amino acids as well as their configurations[9] has a significant effect on β-turn formation.

Experimental

All the melting points were uncorrected. Thin-layer chromatographies were carried out on Merck silica gel 60 F_{254} plates with the following solvent systems: R_f^1, $CHCl_3$–MeOH (5:1, v/v); R_f^2, $CHCl_3$–MeOH–AcOH (95:5:1, v/v); R_f^3, *n*-BuOH–AcOH–pyridine–H_2O (4:1:1:2, v/v). Optical rotations were measured on an Union automatic polarimeter PM-201. CD spectra were recorded on a JASCO J-40A spectropolarimeter at the concentration of 0.1 mM (1 M=1 mol dm^{-3}) at 23 °C. All the peptides were synthesized according to schemes shown in Fig. 3 by similar manners as reported previously,[3] and the results are summarized in Table 1.

We thank Professors Michiaki Takimoto of Toho University and Ichiro Muramatsu of Rikkyo University for helpful discussion, Miss Rika Kato of Mitsubishi-Kasei Institute of Life Sciences for her technical assistance, and the members of Analysis Center of Mitsubishi Chemical Industries Ltd. for elemental analysis.

Further Evidence for the Regioselectivity Rules in Nucleophilic Aromatic Photosubstitution

Kiyoshi MUTAI* and Ryoichi NAKAGAKI†

†*Institute for Molecular Science, Myodaiji, Okazaki 444*

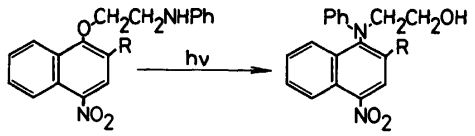
(Received May 24, 1985)

Synopsis. In order to assess the validity of our regioselectivity rules for nucleophilic aromatic photosubstitution, 4-nitronaphthyl ethers were designed and their photochemical behavior was studied by applying frontier molecular orbital theory. The results provide supporting evidence for our rules.

In a previous paper[1] we proposed two rules to rationalize the regioselectivities observed in nucleophilic aromatic photosubstitutions; namely, (rule 1) photosubstitutions accompanying direct addition of a nucleophile to an excited aromatic substrate substituted with a strongly electron-withdrawing group (s) show HOMO-controlled regioselectivity, and (rule 2) those involving photoinduced electron transfer from a nucleophile to an aromatic substrate show LUMO-controlled regioselectivity, where, HOMO and LUMO, refer to those of the aromatic substrate in the ground state.

The objectives of the present paper are to extend the scope of application of these rules to naphthalene derivatives and, thus, to provide further evidence for the rules.

By analogy with the substituted benzenes previously reported to undergo photorearrangement,[2] naphthalene derivatives **1** and **2** are designed and submitted to photoreaction.



1, R = H
2, R = OMe

3, R = H
4, R = OMe

HOMO-controlled Photosubstitution. Since 1-methoxy-4-nitro- and 1,2-dimethoxy-4-nitronaphthalenes can be regarded as simplified models for the nitroaromatic moieties of **1** and **2**, respectively, nucleophilic photosubstitutions of these model compounds were examined.

In Fig. la, the frontier electron density (FED) maps of the HOMO and LUMO of 1-alkoxy-4-nitronaphthalene are depicted. The values were calculated by the CNDO/2 approximation, assuming that the alkoxyl group can be replaced with a hydroxyl without causing any significant change in the FED distribution pattern.[1] According to frontier molecular orbital theory, photosubstitutions are expected to occur at the carbons with high FED, *i.e.* C_1–OR, C_2 or C_4–NO_2. All the reactions so far reported (with cyanide, hydride as BH_4^-, and methoxide ions)[3] have been observed at the position with the highest FED, C_4. Although the FED map in the LUMO suggests that the C_4-substitutions may also be interpreted as LUMO-controlled, electron transfer pathway cannot be expected for these

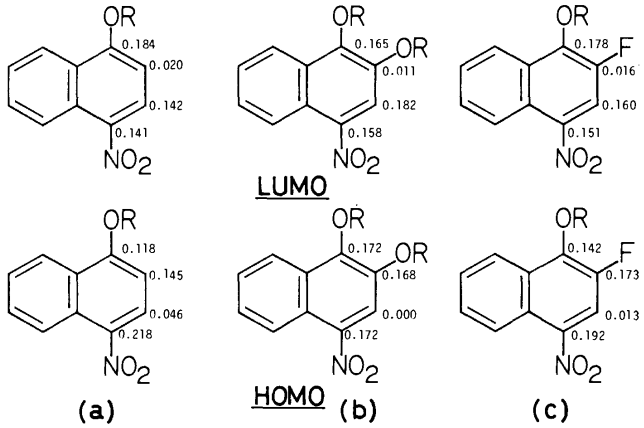


Fig. 1. Frontier electron density (FED) maps of the HOMO and LUMO of (a) 1-alkoxy-4-nitro-, (b) 1,2-dialkoxy-4-nitro-, and (c) 1-alkoxy-2-fluoro-4-nitronaphthalene.

nucleophiles, which have shown no tendency of electron release in the photosubstitutions of benzene derivatives.[1]

The photoreaction of 1,2-dimethoxy-4-nitronaphthalene has not been reported, but for the present purpose we could adopt 2-fluoro-1-methoxy-4-nitronaphthalene as a good substitute, because the FED maps of the HOMO's and LUMO's of these two models show a similar pattern (Fig. 1b and 1c). Nucleophilic photosubstitutions of 2-fluoro-1-methoxy-4-nitronaphthalene have been reported to occur[4] at C_1 with hydroxide ion, at C_2 with methoxide ion, and at C_4 with cyanide ion. A secondary reaction has been noted in the case of methoxide ion, replacing the nitro group at C_4 (an example of the photoreaction of the original model compound, 1,2-dimethoxy-4-nitronaphthalene). These three positions, C_1, C_2, and C_4, bear comparably large FED's (0.142, 0.173, and 0.192, respectively) and, therefore, the observed regioselectivity towards nucleophiles is consistent with rule 1.

LUMO-Controlled Photosubstitution. For the photoreactions accompanying electron transfer or the LUMO-controlled reactions, substitution in both **1** and **2** should occur at C_1 (intramolecular reaction at C_4 is sterically impossible) to afford rearranged products. On irradiating solutions of **1** and **2**, containing a catalytic amount of triethylamine, with a high-pressure Hg lamp, **3** and **4**, respectively, were isolated as reaction products in good yields (Eq. 1).[5] It is also noticeable that the photosubstitution observed for **2** occurred only at C_1 and not at C_2; because the C_2 carbon is bonded to a good leaving group and its FED of the HOMO is sufficiently large to accept a nucleophile, the substitution should occur, at least partly, at this position if the reaction takes

the HOMO-controlled pathway. This fact also underlines the importance of the LUMO in this photorearrangement. A marked contrast with the HOMO-controlled reactions strongly suggests that the rearrangements took place *via* electron transfer.

So far as we judge only by the structure of the product **3**, the observed regioselectivity of **1** is explicable either by rule 1 or rule 2, since its C_1 carbon has high FED's in both HOMO and LUMO. Rigorously speaking, it is difficult to rule out the HOMO-controlled mechanism. However, the LUMO-controlled pathway is more plausible, because even the nitroaromatic moiety with an additional electron-donating substituent, methoxyl group, in **2** is supposed to be able to accept an electron from the anilino moiety as discussed above and the counterpart in **1**, lacking in the methoxyl, is expected to have a larger electron affinity.

In order to obtain further supporting evidence for electron transfer process, we have tried to detect a transient species formed immediately after photoexcitation of **1** by means of nanosecond laser flash photolysis. However, it was found that the observation of transient spectra attributable to the charge-separated biradical consisting of the donor cation and acceptor anion was difficult due to strong fluorescence from the naphthalene moiety. Thus, no direct evidence for photoinduced electron transfer has been obtained.

Experimental

The details of the MO calculations have been described in a previous paper.[1] ^{1}H-NMR Spectra were recorded on a Varian EM-390 spectrometer. Melting points are uncorrected. Homogeneity of the compounds was established by HPLC on a JASCO FLC-A10 using methanol as an eluent.

1-(2-Bromoethoxy)-4-nitronaphthalene. To a mixture of 3.82 g (20 mmol) of 4-nitro-1-naphthol[6] and 9.30 g (50 mmol) of 1,2-dibromoethane in 15 ml of water containing 3 ml of dioxane was added a solution of 0.8 g (20 mmol) of sodium hydroxide in 10 ml of water under reflux with stirring during 1.5 h, and reflux was continued for 2 d. After cooling, the reaction mixture was poured into 30 ml of 5% aqueous sodium hydroxide solution and extracted with three 10-ml portions of dichloromethane. The extracts were collected and the solvent was removed by distillation. Chromatography on 80 g of active alumina eluting with benzene–dichloromethane mixture afforded 1.95 g (33%) of the bromide as yellow cyrstals: mp 77—78 °C; ^{1}H NMR ($CDCl_3$) δ= 3.76 (2H, t, J=5 Hz, CH_2Br), 4.46 (2H, t, J=5 Hz, OCH_2), 6.63 (1H, d, J=9 Hz, H-2), 7.3—7.8 (2H, m, H-6 and H-7), 8.0—8.35 (2H, m, H-5 and H-8), 8.63 (1H, d, J=9 Hz, H-3).

Found: C, 48.72; H, 3.26; N, 4.97%. Calcd for $C_{12}H_{10}NO_3Br$: C, 48.67; H, 3.40; N, 4.73%.

1-(2-Bromoethoxy)-2-methoxy-4-nitronaphthalene. This compound was prepared from 2-methoxy-4-nitro-1-naphthol[7] by a procedure similar to that described above for the bromide in a yield of 32%: mp 115—116 °C; ^{1}H NMR ($CDCl_3$) δ=3.71 (2H, t, J=6 Hz, CH_2Br), 4.02 (3H, s, OCH_3), 4.60 (2H, t, J=6 Hz, OCH_2), 7.4—7.7 (2H, m, H-6 and H-7), 8.17 (1H, s, H-3), 8.2—8.7 (2H, m, H-5 and H-8).

Found: C, 47.74; H, 3.71; N, 4.35%. Calcd for $C_{13}H_{12}NO_4Br$: C, 47.87; H, 3.71; N, 4.30%.

1-(2-Anilinoethoxy)-4-nitronaphthalene (1). This compound was prepared from aniline and the corresponding bromide by a reported procedure[2b] in a yield of 59%: mp 161—162 °C; ^{1}H NMR ($CDCl_3$–DMSO-d_6) δ=3.5—3.8 (2H, m, CH_2N), 4.37 (2H, t, J=6 Hz, OCH_2), 5.56 (1H, t, J=5 Hz, NH), 6.2—7.2 (6H, m, C_6H_5 and H-2), 7.2—7.8 (2H, m, H-6 and H-7), 8.25—8.4 (2H, m, H-3 and H-8), 8.54 (1H, dd, J=2 and 8 Hz, H-5).

Found: C, 69.88; H, 5.00; N, 9.08%. Calcd for $C_{18}H_{16}N_2O_3$: C, 70.12; H, 5.23; N, 9.08%.

1-(2-Anilinoethoxy)-2-methoxy-4-nitronaphthalene (2). This compound was prepared[2b] from aniline and the corresponding bromide in a yield of 88%: mp 110.5—112 °C; ^{1}H NMR ($CDCl_3$) δ=3.60 (2H, t, J=5 Hz, CH_2N), 3.97 (3H, s, OCH_3), *ca.* 4.3 (1H, br s, NH), 4.43 (2H, t, J=5 Hz, OCH_2), 6.6—7.3 (5H, m, C_6H_5), 7.4—7.6 (2H, m, H-6 and H-7), 8.17 (1H, s, H-3), 8.15—8.3 (1H, m, H-8), 8.5—8.7 (1H, m, H-6).

Found: C, 67.18; H, 5.33; N, 8.02%. Calcd for $C_{19}H_{18}N_2O_4$: C, 67.44; H, 5.36; N, 8.28%.

1-[N-(2-Hydroxyethyl)anilino]-4-nitronaphthalene (3). The amine **1** (370 mg, 1.2 mmol) dissolved in a mixture of methanol (800 ml), acetonitrile (150 ml), and triethylamine (10 ml) was irradiated with a 400 W high-pressure Hg lamp for 50 min. Usual workup and chromatography on 50 g of silica gel eluting with a 1:1 mixture of benzene and dichloromethane afforded **3** (293 mg, 79%) as brick-red crystals: mp 131—132 °C; ^{1}H NMR ($CDCl_3$) δ=1.70 (1H, t, J=5 Hz, OH), 3.7—4.2 (4H, m, NCH_2CH_2O), 6.7—7.25 (5H, m, C_6H_5), 7.50 (1H, d, J=9 Hz, H-2), 7.4—7.8 (2H, m, H-6 and H-7), 8.01 (1H, dd, J=*ca.* 1.5 and 9 Hz, H-8), 8.31 (1H, d, J=9 Hz, H-3), 8.65 (1H, dd, J=*ca.* 1.5 and 9 Hz, H-5).

Found: C, 70.07; H, 4.95; N, 8.81%. Calcd for $C_{18}H_{16}N_2O_3$: C, 70.12; H, 5.23; N, 9.08%.

1-[N-(2-Hydroxyethyl)anilino]-2-methoxy-4-nitronaphthalene (4). Irradiation of the amine **2** under similar conditions to those used for **3** and usual workup afforded **4** as brick-red crystals in a yield of 53%: mp 117—118 °C; ^{1}H NMR ($CDCl_3$) δ=*ca.* 2.63 (1H, br t, J=*ca.* 5 Hz, OH), 3.75 (4H, br m, NCH_2CH_2O), 3.93 (3H, s, OCH_3), 6.45—7.2 (5H, m, C_6H_5), 7.35—7.6 (2H, m, H-6 and H-7), 7.7—7.9 (1H, m, H-8), 8.11 (1H, s, H-3), 8.4—8.6 (1H, m, H-5).

Found: C, 67.69; H, 5.54; N, 8.12%. Calcd for $C_{19}H_{18}N_2O_4$: C, 67.44; H, 5.36; N, 8.28%.

We are grateful to Professor Koichi Ohno and Dr. Akinori Inoue, the University of Tokyo, for their advice and help in calculation. This work was supported by the Joint Studies Program (1984) of the Institute for Molecular Science.

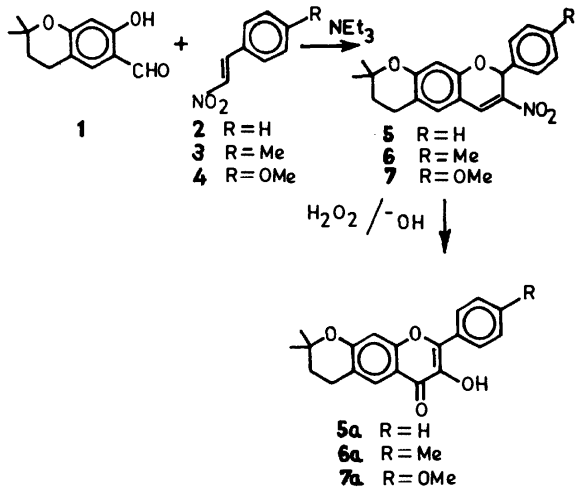
A Novel Synthesis of Dihydropyranoflavonols

Sudhakar Rao TAKKELLAPATI, Hari Har MATHUR, and Girish Kumar TRIVEDI*
Department of Chemistry, Indian Institute of Technology, Bombay-400 076, India
(Received August 9, 1984)

Synopsis. Condensation of 6-formyl-7-hydroxy-2,2-dimethylchroman with ω-nitrostyrene in the presence of triethylamine yields 3-nitro-8,8-dimethyl-2-phenyl-7,8-dihydro-2*H*,6*H*-benzo[1,2-*b*:5,4-*b'*]dipyran which on treatment with hydrogen peroxide gives 3-hydroxy-8,8-dimethyl-2-phenyl-7,8-dihydro-4*H*,6*H*-benzo[1,2-*b*:5,4-*b'*]dipyran-4-one.

The occurrence of dihydropyrano- and pyranoflavonols in nature is well known[1-5] and there are very few reports on the synthesis of the title compounds and their dehydrogenated products.[5-8] Till now most of the syntheses reported are mainly based on the well known Algar-Flynn-Oyamada reaction[6-8] wherein 6-acetyl-7-hydroxychromans have been used as the starting materials. Now here in we wish to report a new route for the synthesis of dihydropyranoflavonols, starting from 6-formyl-7-hydroxy-2,2-dimethylchroman (**1**) and ω-nitrostyrene (**2**—**4**). This method consists of the synthesis of 3-nitro-8,8-dimethyl-2-phenyl-7,8-dihydro-2*H*,6*H*-benzo[1,2-*b*:5,4-*b'*]dipyran and its conversion to 3-hydroxy-8,8-dimethyl-2-phenyl-7,8-dihydro-4*H*,6*H*-benzo[1,2-*b*:5,4-*b'*]dipyran-4-one *via* hydrogen peroxide treatment.



Experimental

Proton NMR spectra were obtained in $CDCl_3$ solution, unless otherwise stated, containing Me_4Si as reference using a Varian XL-100 spectrometer. Infrared spectra were recorded on a Perkin Elmer Model 618 instrument. UV spectra were recorded in $CHCl_3$ on a Varian Superscan-3 spectrometer. Mass spectra were determined on a MAT 112 S mass spectrometer. Melting points were taken in open capillaries and were not corrected.

*General Procedure for the Synthesis of 3-Nitro-8,8-dimethyl-2-phenyl-7,8-dihydro-2*H,6H*-benzo[1,2-*b*:5,4-*b'*]dipyran (**5**—**7**).* 4 mmol of 6-formyl-7-hydroxychroman (**1**) and 8 mmol of ω-nitrostyrene (**2**—**4**) were taken in a round bottom flask to which 5 ml of triethylamine was added and refluxed for 30 min on a water bath. Then the remaining triethylamine was evaporated off and the resulting solid mass was dissolved in dichloromethane and filtered. The solid residue after repeated washings with dichloromethane was discarded and the combined washings and filtrate on concentration and chromatography (pet. ether) yielded the trace amount of unreacted nitrostyrene, 6-formyl-7-hydroxychroman and 3-nitro-8,8-dimethyl-2-phenyl-7,8-dihydro-2*H*,6*H*-benzo[1,2-*b*:5,4-*b'*]dipyran consecutively. Crystallization was achieved from methanol. The yields of isolated compounds were varying from 30 to 35%.

*3-Nitro-8,8-dimethyl-2-phenyl-7,8-dihydro-2*H,6H*-benzo[1,2-*b*:5,4-*b'*]dipyran (**5**)*: Mp 210 °C; IR: 1320, 1560 (NO_2) cm^{-1}; NMR: δ=1.32 (3H, s), 1.34 (3H, s), 1.8 (2H, t, *J*=6 Hz), 2.72 (2H, t, *J*=7 Hz), 6.3 (1H, s), 6.34 (1H, s), 7.02 (1H, s), 7.36 (5H, s), 8.04 (1H, s); MS *m/z* (relative intensity) 55 (53), 63 (42), 69 (52), 77 (42), 115 (34), 139 (22), 178 (34), 235 (38), 291 (100), 337 (M^+, 50). Found: C, 71.10; H, 5.58; N, 4.13%. Calcd for $C_{20}H_{19}NO_4$: C, 71.22; H, 5.64; N, 4.15%.

*3-Nitro-8,8-dimethyl-2-(4-methylphenyl)-7,8-dihydro-2*H,6H*-benzo[1,2-*b*:5,4-*b'*]dipyran (**6**)*: Mp 146—148 °C; IR: 1320, 1560 (NO_2) cm^{-1}; NMR (DMSO-d_6): δ=1.23 (6H, s), 1.65 (2H, t, *J*=7 Hz), 2.2 (3H, s), 2.46 (2H, t, *J*=7 Hz), 6.13 (1H, s), 6.46 (1H, s), 7.16 (4H, s, br), 7.26 (1H, s), 8.26 (1H, s); MS *m/z* (relative intensity) 91 (9), 119 (7), 151 (11), 178 (12), 221 (8), 249 (39), 250 (25), 305 (100), 351 (M^+, 46). Found: C, 71.62; H, 5.88; N, 3.93%. Calcd for $C_{21}H_{21}NO_4$: C, 71.79; H, 5.98; N, 3.99%.

*3-Nitro-8,8-dimethyl-2-(4-methoxyphenyl)-7,8-dihydro-2*H,6H*-benzo[1,2-*b*:5,4-*b'*]dipyran (**7**)*: Mp 163—164 °C; IR: 1310, 1550 (NO_2) cm^{-1}; NMR: δ=1.32 (3H, s), 1.34 (3H, s), 1.79 (2H, t, *J*=7 Hz), 2.71 (2H, t, *J*=7 Hz), 3.78 (3H, s), 6.26 (1H, s), 6.48 (1H, s), 6.84 (2H, d, *J*=9 Hz), 7.02 (1H, s), 7.32 (2H, d, *J*=9 Hz), 8.02 (1H, s); MS *m/z* (relative intensity) 55 (21), 69 (25), 77 (19), 165 (22), 265 (39), 266 (20), 321 (100), 367 (M^+, 19). Atomic Absorption Spectrophotometric Determination of Cadmium

Mohamed A. KABIL* and Mohamed A. MOSTAFA
Department of Chemistry, Faculty of Science, Mansoura University, Mansoura, A.R. Egypt
(Received August 4, 1984)

Synopsis. In the determination of cadmium by atomic absorption spectrophotometry(AAS), the interfering effects of different species can be completely eliminated by adding excess cyanide. The mechanism by which the cyanide eliminates interference by influencing the atomization process is discussed. Also the AAS for the analysis of cadmium in complex form is elaborated. The aim of this investigation is to achieve a determinate characterization of compound formation. The way to reach this purpose is the utilization of the continuous titration technique.

The interfering effects on cadmium are rarely mentioned in the literature and what has been published are concerned with its determination.[1-3] In this work the effects of some inorganic and organic compounds have been examined and the feasibility of the compound formation is elaborated.

When solutions of cadmium complexes are examined, the absorption signals are mainly depend on the extent to which the ligands affect the atomization processes of Cd. In this respect, the work of Fujiwara[4] is important. He observed a significant difference in the absorbances in the lower part of the air–acetylene flame for the transition metal complexes. These differences were attributed to the type of complex present in solution.

Cyanide has already been successfully applied in AAS for some metals.[5-7] Since cyanide forms very stable complexes with most of transition metal ions,[8] elimination of the interfering effects by adding cyanide was examined.

Experimental

Atomic absorption spectrophotometer, Unicam SP '90 A series 2 fitted with a new HTA photomultiplier tube No. R 270 from EMI. Air was supplied through PU 9003 air compressor. Acetylene was obtained from cylinders after passing through concentrated sulfuric acid and glass wool for purification. A continuous titration device[9,10] was attached to the instrument and the results were computed using a CASIO FX-502 P type programmable pocket calculator. Absorbance values were recorded with a Philips PM 8251 single-pen recorder.

The instrumental parameters were: Lamp current, 4 mA; wavelength, 228.8 nm; slit width, 0.1 mm; observation height, 0.4 cm; air flow rate, 5 $dm^3 min^{-1}$, fuel flow rate, 1.0 $dm^3 min^{-1}$.

All solutions were prepared from B. D. H. Chemicals, Stock solutions of metals and organic compounds were prepared using twice distilled water; aliquots were suitably diluted to give the desired concentration used for the experiments. Stock solution of cadmium was prepared from $CdCl_2 \cdot H_2O$. The concentration of cadmium in the stock solution was 100 $\mu g cm^{-3}$.

The complexes, dibromobis(acetyltrimethylammonium-4-phenylthiosemicarbazide)cadmium(II) chloride [$Cd(H_2atpts)_2Br_2]Cl_2$, bis(1-anthraniloyl-4-phenylsemicarbazide) cadmium(II) [$Cd(Hapsc)_2$], bis(1-benzoyl-4-phenylthiosemicarbazide)cadmium(II) monohydrate [$Cd(Hbpts)_2] \cdot H_2O$, dibromo(acetylpyridinium-4-phenylthiosemicarbazide) cadmium(II) chloride [$Cd(H_2apts)Br_2]Cl$, acetato(1-acetyl-4-phenylthiosemicarbazide)cadmium(II) monohydrate [Cd(Hapts)(ac)]$\cdot H_2O$ and bis(1-anthraniloyl-4-phenylthiosemicarbazide)cadmium(II) [$Cd(Haptsc)_2$] were prepared as mentioned in the literature.[11,12] Other complexes; tris(1,2-propanediamine-$N,\overline{N}$)cadmium(II) dithionate [$Cd(pn)_3]S_2O_6$ and tris(1,2-ethanediamine-$N,\overline{N}$)cadmium (II) hydroxide [$Cd(en)_3](OH)_2$ were also prepared as mentioned earlier.[13] The 4.44×10^{-5} M (1 M=1 mol dm^{-3}) solutions of cadmium complexes were prepared by dissolving the appropriate weight of the solid complex in a few amount of *N,N*-dimethylformamide(DMF) and completed to the mark using twice distilled water.

Results and Discussion

Effect of potassium cyanide. Figure 1 shows the change in the absorption signal of cadmium as a function of [cyanide]/[Cd] molar ratio. There is a decrease in the signal with distinct break-point corresponding to [CN]/[Cd], 4:1 molar ratio, followed by a sharp enhancement to 130% of the recovery, giving a plateau.

The interpretation of the cyanide behaviour can be discussed on the basis of three main steps which may take place during its continuous increase in the flame, (i) Vaporization of the solid cyano complex particles followed by a decomposition giving Cd atoms which react instantaneously with the oxidizing species in the flame forming cadmium compound(s) essentially CdO, (ii) After the particular stoichiometric ratio is attained at 4:1 for CN:Cd, the excess of CN radical in the flame reacts with the cadmium compound(s) according to the following equation.

$$CdO + CN \longrightarrow Cd + N + CO$$

(iii) The continuous increase of the CN radical scavenging the excess oxidizing species, thus performing a reducing environment for increasing the Cd atom population. There is a balance between the CN

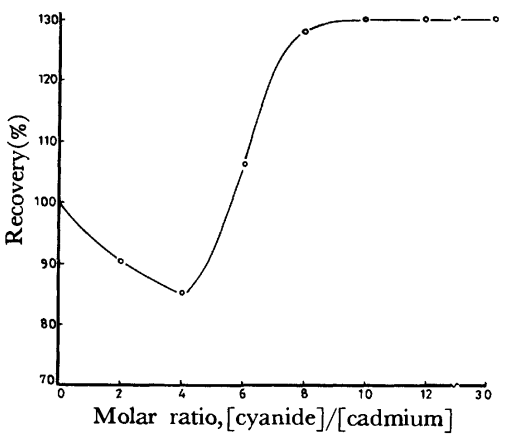

Fig. 1. Titration of 5 ppm Cd (4.44×10^{-5} mol dm^{-3}) with KCN.

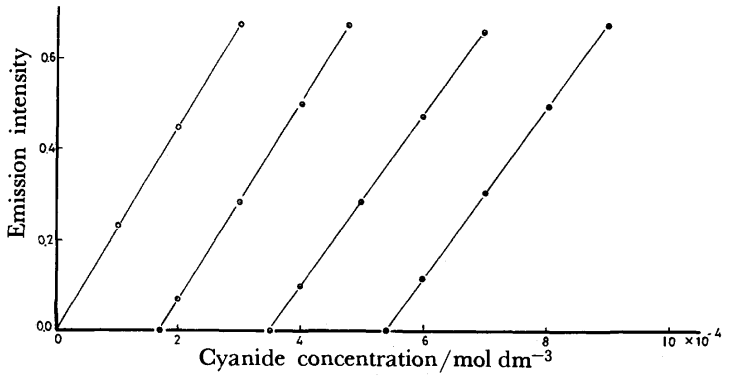

Fig. 2. Changes of cyanide band emission intensity as a function of cyanide concentration, (O) emission signal in absence of Cd, (⊙), (◒), and (●) in presence of 4.44×10^{-5}, 8.89×10^{-5}, and 1.33×10^{-4} mol dm^{-3} of Cd respectively.

radical and the excess oxidizing species in the flame at the plateau.

To assess both the formation of (4:1) molar ratio of CN:Cd and the presence of CN radical in the flame, we measured the emission intensity at 358 nm. Figure 2 curve (o) indicates the initial existence of CN radical in the flame at the starting of the titration process and in absence of the analyte (Cd). On conducting the titration in the presence of 4.44×10^{-5}, 8.89×10^{-5}, and 1.33×10^{-4} M of cadmium, the curves (⊙, ◒, and ●) of Fig. 2 are attained, respectively. These curves show, the emission intensity of CN radical, which disappears at the beginning of the titration and continued till the CN ion concentration reaches the stoichiometric ratio 4:1 for CN:Cd. Thence the emission intensity of CN radical increasing of CN ion.

Elimination of interferences. Different and diverse Cd(II) complexes are investigated. The relationship between the free Cd atom population and the height of measurement above the burner top is measured. The distribution curves in Fig. 3 clearly indicate the differences in the thermal stabilities of the tested complexes. Different times in the flame are required to achieve the same ratio of free atoms from various compounds. The general applicability of the cyanide addition to Cd(II) complexes is indicated by the data in Table 1.

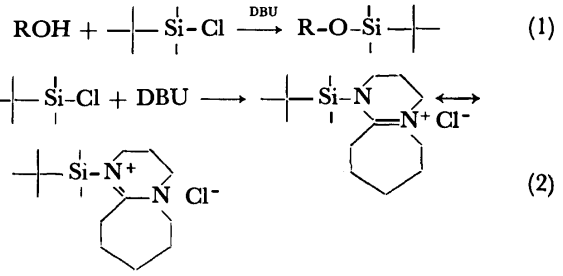
1,8-Diazabicyclo[5.4.0]undec-7-ene. An Effective and Selective Catalyst for the *t*-Butyldimethylsilylation of Alcohols

Sunggak KIM* and Heung CHANG
Department of Chemistry, Korea Advanced Institute of Science and Technology, Seoul 131, Korea
(Received October 11, 1984)

Synopsis. The use of 1,8-Diazabicyclo[5.4.0]undec-7-ene (DBU) as a catalyst has been found to be very effective and selective in the *t*-butyldimethylsilylation of primary and secondary alcohols.

In view of the great importance of the *t*-butyldimethylsilyl group in the protection of alcohols,[1] various synthetic methods have been reported in the literature after discovery by Corey.[2,3]

We have found that DBU is an effective and selective catalyst for the *t*-butyldimethylsilylation of alcohols (Eq. 1). Under the present reaction conditions, it is assumed that DBU forms a complex with *t*-butyldimethylchlorosilane (TBDCS) which subsequently reacts with alcohols to give *t*-butyldimethylsilyl ethers (Eq. 2). Furthermore, in view of large steric requirements of the complex, it is expected that high selectivity between primary alcohols and secondary alcohols can be achieved by use of DBU as a catalyst.



(1)

(2)

Table 1 includes several experimental results and shows the efficiency, the applicability, and the scope of this procedure. When primary alcohols such as phenethyl alcohol and nonyl alcohol were allowed to react with equimolar amounts of TBDCS and DBU in dichloromethane at room temperature, the reaction was complete within 20 min and the *t*-butyldimethylsilyl ethers were obtained in high yields. Application of 0.2 equiv of DBU in the presence of 1 equiv of triethylamine in dichloromethane at room temperature for 4 h resulted in clean silylation of alcohols. Furthermore, the silylation of alcohols using DBU proceeded smoothly in various solvents such as *N,N*-dimethylformamide, acetonitrile, and tetrahydrofuran. Similarly, secondary alcohols were cleanly silylated to the corresponding *t*-butyldimethylsilyl ethers in high yields at room temperature within 4 h. As we expected from large steric requirements of the complex as shown in Eq. 2, this procedure reaches a limit with tertiary alcohols. Thus, the *t*-butyldimethylsilylation of 2-phenyl-2-butanol did not occur to an observable extent, even after prolonged stirring.

TBDCS has been used in the selective protection of primary alcohols in the presence of secondary alcohols due in part to steric bulkiness of *t*-butyldimethylsilyl group.[4] It has been reported that the use of 4-dimethylaminopyridine (DMAP)[5] as a catalyst is very

a) For selective silylation of selected diols, 1.0 equiv of TBDCS was used, Otherwise, 1.1 equiv of TBDCS was employed. b) A: 1.1 equiv DBU, B: 0.2 equiv DBU/1 equiv Et_3N, C: 1.1 equiv DBN. c) The numbers in parentheses indicate the ratio of the primary silyl ether, the secondary silyl ether, and the bissilyl ether, respectively. The product ratios were determined by GLC analysis. d) Spectral data of silyl ethers were in satisfactory agreement with reported or expected values. 1 Torr=133.322 Pa.

effective in the selective *t*-butyldimethylsilylation of primary alcohols in the presence of secondary alcohols, whereas the use of imidazole does not give satisfactory results.[3b] We have found that DBU can be utilized for the selective silylation of primary alcohols in the presence of secondary alcohols. For example, reaction of 2-ethyl-1,3-hexane-diol with 1 equiv of TBDCS and 1.1 equiv of DBU gave almost exclusively the primary silyl ether with a trace amount (<1%) of the secondary silyl ether, whereas it is known that the use of imidazole gives a mixture of all the possible isomers without high selectivity. Similar results were obtained with 1,3-butanediol and 1-phenyl-1,2-ethanediol. The selectivity achieved with DBU as a catalyst is superior to imidazole and is comparable to DMAP as a catalyst in the selective silylation of primary alcohols.[3b]

It is noteworthy that 1,5-diazabicyclo[4.3.0]non-5-ene (DBN) was also found to be effective in the *t*-butyldimethylsilylation of alcohols.

In conclusion, the present procedure offers the advantages of the ready availability of DBU, the rapidity of the reaction, the wide choice of solvents, and the high selectivity between primary alcohols and secondary alcohols.

Experimental

^{1}H-NMR spectra were recorded with a Varian T-60A spectrometer and infrared spectra were recorded on a Perkin-Elmer 267. GLC analysis was performed on a Varian 2800 gas chromatograph using FID detector. All analyses were carried out on 10 ft×0.125 in. 10% Carbowax 20 M. Reported boiling points are those observed during distillation with a Kugelrohr apparatus and are uncorrected.

Since the reaction were performed are all similar in many respects, typical reactions will be described as specific examples.

t-Butyldimethylsilylation of Cinnamyl Alcohol. To a solution of cinnamyl alcohol (270 mg, 2.0 mmol), DBU (60 mg, 0.4 mmol), and triethylamine (205 mg, 2.0 mmol) in dichloromethane (5 ml) at room temperature was added *t*-butyldimethylchlorosilane (335 mg, 2.2 mmol). The reaction mixture was stirred at room temperature for 5 h, diluted with dichloromethane (40 ml), and washed with cold 5% HCl solution (20 ml), saturated $NaHCO_3$ solution (20 ml), and brine (20 ml). The organic layer was dried over anhydrous $MgSO_4$ and evaporated to dryness. The residue was distilled *in vacuo* to give *t*-butyldimethylsilyl cinnamyl ether (465 mg, 93%). Bp 93—96 °C/0.5 Torr (lit,[3c] bp 90—92 °C/0.3 Torr). ^{1}H-NMR (CCl_4) δ=0.10 (s, 6H), 1.0 (s, 9H), 4.35 (d, 2H, J=6), 6.20—6.80 (m, 2H), 7.25 (s, 5H).

Selective t-Butyldimethylsilylation of 2-Ethyl-1,3-hexanediol. To a solution of 2-ethyl-1,3-hexanediol (290 mg, 2.0 mmol), DBU (58 mg, 0.4 mmol), and triethylamine (210 mg, 2.0 mmol) in dichloromethane (6 ml) at room temperature was added *t*-butyldimethylchlorosilane (298 mg, 2.0 mmol). The reaction mixture was stirred at room temperature for 2 h, diluted with dichloromethane (30 ml), and washed with cold 5% HCl solution (20 ml), saturated $NaHCO_3$ solution (20 ml), and brine (20 ml). The organic layer was dried over anhydrous $MgSO_4$ and evaporated to dryness to afford the primary silyl ether (486 mg) in 94% yield. The product was subjected to GLC analysis, which showed 99% of the primary silyl ether and <1% of the secondary silyl ether without any contamination of the bissilyl ether. For the characterization of the products, a mixture of all the possible isomers was prepared by the known procedure, while the primary silyl ether was also prepared by use of DMAP–Et_3N.[3b]

Synopsis. The Todd reaction, involving formation of a dialkyl phosphorochloridate by reaction of a dialkyl phosphonate with tetrachloromethane under basic conditions, has been determined to involve the intermediacy of the trichloromethanide anion.

The Todd reaction, a synthetically valuable method for the preparation of dialkyl phosphoramidates[1] and dialkyl phosphorochloridates,[2] was the subject of early kinetic investigations by Steinberg.[3] On the basis of the kinetic data, several possible mechanisms for the reaction were proposed, two of these involving the intermediacy of the trichloromethanide anion. We have now obtained direct evidence for the intermediacy of this species in the Todd reaction under carefully defined conditions, giving foundation for a detailed mechanism.

The chemistry of the trichloromethanide anion has become quite well known since the postulation of its intermediacy in the Todd reaction. Hine[4] first gained positive data for the dissociation of the trichloromethanide anion into chloride ion and dichlorocarbene during the hydrolysis of chloroform. It was later noted that dichlorocarbene so produced could add to olefins.[5] Should the Todd reaction proceed through a route involving the trichloromethanide anion, it would be anticipated that dichlorocarbene would be produced which is capable of being trapped.

The formation of dialkyl (or diaryl) phosphorochloridate in the Todd reaction occurs with near violent rapidity upon addition of small amounts of base (amine) to a mixture of dialkyl (or diaryl) phosphonate and tetrachloromethane as shown in Scheme 1.

$$(RO)_2POH + CCl_4 \xrightarrow{Et_3N} (RO)_2\overset{O}{\overset{\|}{P}}Cl + HCCl_3$$
$$R = CH_3,\ C_2H_5,\ C_6H_5$$

Scheme 1.

We have confirmed and extended several earlier observations[3] regarding this reaction: 1) In the absence of base, no reaction occurs, even with prolonged heating. 2) The reaction is not influenced by the presence of free radical initiators or inhibitors. 3) The only phosphorus-containing side products are those as reported by Steinberg,[3] the hypophosphate and pyrophosphate, resulting from further reaction of the initially generated dialkyl (diaryl) phosphorochloridate; under GLC analysis using either thermal conductivity or hydrogen flame detection capable of detecting products at amounts less than 0.1 % conversion, no formation of the dialkyl trichloromethylphosphonate could be observed. This material is easily formed in an Arbuzov-type reaction with a trialkyl phosphite as shown in Scheme 2. 4) The reaction may be accomplished in the presence or absence of solvent, which simply serves to moderate the reaction.

$$(RO)_3P + CCl_4 \xrightarrow{\Delta} (RO)_2\overset{O}{\overset{\|}{P}}CCl_3 + RCl$$

Scheme 2.

The general procedure for performing and analyzing reactions involved placement of the dialkyl (diaryl) phosphonate (0.1 mol) with the solvent (if any) and a weighed amount of a suitable inert standard (for quantitative GLC analysis) in a reaction flask equipped with a dropping funnel, reflux condenser, and magnetic stirrer. If amine were used as base, an equivalent amount (0.1 mol) was then added; if the sodium salt of the dialkyl phosphonate were used, sodium or sodium hydride was added with stirring until all had reacted. Tetrachloromethane was then added dropwise at ambient temperature, and stirring continued for 2 h.

An immediate analysis was made using GLC to determine quantitatively chloroform generated, and to note the presence of the phosphorochloridate using one of the following columns: (a) 5′×1/4″ 1.5 % OV-101 on Chrom GHP, (b) 5′×1/4″ 30 % SE-30 on Chromsorb W, or (c) 5′×1/4″ 20 % Apiezon L on Chromsorb W. As the phosphorochloridates underwent significant decomposition under the analytical conditions, the reaction mixture was then treated with an excess of abs ethanol and triethylamine for conversion of the phosphorochloridate to the phosphate. A further chromatographic analysis was then made to determine the yield of the phosphate, and by inference the phosphorochloridate (*minimal* yield). The phosphate was also isolated from the reaction mixture and its structure was confirmed by ^{1}H-NMR analysis (Varian EM-360).

In all attempts using a tertiary amine to initiate the reaction and cyclohexene as solvent or cosolvent, the reaction proceeded "normally" yielding only the products found in the absence of solvent. It had been anticipated that cyclohexene would serve to trap any dichlorocarbene which would result from trichloromethanide decomposition.

Attempts using a less than one equivalent amount of preformed anion of dialkyl phosphonate produced similar results (Scheme 3). When a small amount of anion was generated by addition of sodium hydride

$$(RO)_2POH + NaH \xrightarrow{\bigcirc} (RO)_2PONa$$
$$<0.1\ \text{equiv} \qquad \downarrow CCl_4$$
$$(RO)_2\overset{O}{\overset{\|}{P}}Cl + HCCl_3$$
$$R = CH_3,\ C_2H_5$$

a) Equiv amounts of base, CCl_4, and dialkyl (diaryl) phosphonate. b) Preformed anion with 0.1 equiv Na; Yields based on 0.5 equiv CCl_4. c) Preformed anion with 0.015 equiv NaH; Yields based on CCl_4 as limiting reagent. d) Preformed anion with 1.0 equiv NaH. e) Below detectable limits.

and to this was added tetrachloromethane, rapid reaction ensued generating phosphorochloridate and chloroform with an average conversion of 60 % based on tetrachloromethane.

This result could be observed in the absence of solvent or in the presence of varying amounts of several solvent systems (tetrahydrofuran, toluene, cyclohexene). Again, with cyclohexene no trapping of dichlorocarbene could be noted using GLC techniques.

Finally the reaction was performed by the conversion of the entire amount of dialkyl phosphonate to the anion form using sodium hydride. To this system in cyclohexene was added an equivalent amount of tetrachloromethane. Analysis of the reaction mixture showed the formation of dialkyl phosphorochloridate along with 7,7-dichloronorcarane, the product of dichlorocarbene addition to cyclohexene, with an average 50 % conversion. Typical results are illustrated in Table 1.

The verification of the intermediacy of the trichloromethanide anion along with prior data regarding the phosphorus stereochemistry (retention) for this type of reaction[6,7] supports the overall mechanism as illustrated in Scheme 4. In the presence of any proton source the trichloromethanide anion accepts a proton with extreme rapidity precluding decomposition to dichlorocarbene. In the absence of any such proton source, the resultant trichloromethanide anion leads to products derived from dichlorocarbene.

Spectrophotometric Determination of Cobalt(II) with Thiocyanate. A Modification for Increasing Sensitivity and Selectivity

Ajai Kumar SINGH,* Dinesh KUMAR, and Mohan KATYAL
Department of Chemistry, Indian Institute of Technology, New Delhi 110 016, India
(Received December 18, 1984)

Synopsis. The ion association complex formed between $[Co(SCN)_4]^{2-}$ and 3,3'-(1,1'-biphenyl-4,4'-diyl)bis[2,5-diphenyl-2*H*-tetrazolium] dichloride, commercially known as neotetrazolium chloride, has been extracted into isobutyl methyl ketone and used for the photometric determination of 2.5—9.8 μg cm^{-3} cobalt at pH 3.5—5.0 (acetate buffer). Sandell's sensitivity of the method (0.02 μg cm^{-2}) is better than most of the other thiocyanate methods known so far. Interference of diverse ions has been studied. Using the higher tolerances of anions, many cations interfering in the other thiocyanate methods have been masked, thus making the present procedure more selective. The method has been applied to wire alloys.

Thiocyanate is among the most commonly used spectrophotometric reagents[1] of cobalt. The tetrathiocyanatocobaltate(II) as well as its ion associates with a variety of counter ions have been employed for the determination of the metal,[2,3] but the sensitivity exceeding 0.04 μg cm^{-2} (for 0.001 absorbance) has been rarely reported. In the course of studies on tetrazolium salts it has been observed that the ion pair formed between neotetrazolium chloride (NTC) and $[Co(SCN)_4]^{2-}$ is highly absorbing in isobutyl methyl ketone (MIBK) medium in comparision to other ion pairs of the anions investigated so far (Sandell's sensitivity 0.02 μg cm^{-2}). The detailed results of these investigations are reported in the present note.

The aqueous solution of $[Co(SCN)_4]^{2-}$ on mixing with NTC solution forms a greenish blue precipitate which is extractable into organic solvents. However the absorbance of this ion pair has been found maximum in MIBK. The tolerance of anions is more in this system than other Co–SCN systems and therefore can be utilized to create a more selective method for the determination of cobalt(II) with thiocyanate.

Experimental

Apparatus. Unicam SP 500 and 700 spectrophotometers were used for absorbance measurements and a Elico LI-10 pH meter for measuring pH.

Reagents. A stock solution 0.01 M (1 M = 1 mol dm^{-3}) of cobalt(II) was prepared by dissolving $CoSO_4 \cdot 7H_2O$ (BDH, A. R.) in doubly distilled water. It was standardized by titration with ethylenediaminetetraacetic acid (EDTA) before use. The solution of NTC, procured from Aldrich (U. S. A.), was prepared in 50% ethanol. Thiocyanate solution(10%) was prepared by dissolving the requisite amount in doubly distilled water. All other solutions of cations and anions were prepared by dissolving analytical grade chemicals in doubly distilled water.

Recommended Procedure. To a suitable aliquot containing 20 to 70 μg of cobalt add acetate buffer of pH 4.5, 10% ammonium thiocyanate and 0.4% NTC solution(4.0 cm^3 each). To this mixture add 2 cm^3 of water and 5 cm^3 (*N,N*-dimethylformamide) (DMF) to dissolve the precipitate. Extract the complex with 7 cm^3 MIBK and measure the absorbance of organic layer after centrifugation, at 620 nm against water blank. Deduce the metal content from calibration curve.

Results and Discussion

Spectral Behavior of the Complex and Effect of pH. The ion associate absorbs maximum at 620 nm. Absorbance remains maximum in the pH range 2.5 to 5.0. The variation in pH does not affect the absorbing characteristics of the complex. Reagent blank does not absorb at 620 nm. Acetate buffer is most suitable for pH adjustment .

Effect of Thiocyanate and NTC Concentration. For 1 cm^3 of 1 mM cobalt solution the maximum absorbance is attained in the presence of 3.7 cm^3 NTC solution (0.04 %). At least 3 cm^3 of 10 % thiocyanate solution should be added for full color development. The excess of either reagent does not affect the absorbance.

Effect of DMF and Stability of the Complex. At least 4.5 cm^3 of DMF should be added in the estimation of 1 cm^3 cobalt(II) to dissolve the precipitate. Excess up to 8 cm^3 does not have any effect but beyond this the extraction becomes erratic due to very slow irreproducible separation of the immiscible layers. The color does not fade even on keeping the solution for 12 h.

Characteristics of the Complex. Beer's law is obeyed up to 13 μg cm^{-3} at pH 4.5. The optimum concentration, evaluated by Ringbom method, is 2.5 to 9.8 μg cm^{-3}. The Sandell's sensitivity is 0.02 μg of cobalt cm^{-2}. The molar absorptivity is 3.0×10^3 l mol^{-1} cm^{-1}. The metal: NTC ratio, as found by Job's method of continuous variation, is 1 : 1. The species $(NTC)^{2+} \cdot [Co(SCN)_4]^{2-}$ are most probably responsible for the absorption. The standard deviation for the mean absorbance 0.345 has been found to be 0.003.

Effect of Diverse Ions. Synthetic solutions containing known amounts of diverse ions and cobalt(II) were prepared and the recommended procedure was followed for determination of the metal. An error of 2 % in the absorbance measurement was considered tolerable. In the determination of 8.4 μg cm^{-3} cobalt the anions tolerated (in μg cm^{-3} given in parentheses) are as follows: fluoride, chloride, iodide, nitrate(1000 each); phosphate (1250); oxalate(1280); nitrite (1200); bromide(625); thiosulfate (600); citrate, tartrate (480), and thiourea (150). The metal ions tolerated are: Ca(II), Sr(II), Ba(II), Ni(II), Cd(II), Mn(II), Al (III), Ti(IV) (250 μg cm^{-3} each); Zn(II) or Fe(II) (50 μg cm^{-3}); and Cu(II) (10). EDTA interferes seriously. All other metal ions which form colored complex with thiocyanate also interfere in this system. However, 100 μg cm^{-3} of iron can be masked with

Table 1. Determination of cobalt in alloys

Alloy	Cobalt/%		No. of detn.	Relative standard deviation
	Reported	Found		%
"K" Monel wire	0.51	0.50	6	3.8
Nilo "K" wire	17.4	17.6	6	2.0

fluoride. Tolerance of copper can be improved up to 60 μg cm^{-3} by using thiourea as masking agent. Similarly mixture of citrate and tartrate improves the tolerance of nickel up to 1000 μg cm^{-3}.

Determination of Cobalt in Alloys. To exhibit the advantages of higher sensitivity and selectivity of this method, the contents of cobalt in some wire alloys have been estimated using SCN and NTC as chromogenic reagent. The detailed procedure is given below.

Weighed samples of "K" Monel wire and Nilo "K" wire were dissolved in concentrated nitric acid. Excess acid was evaporated off and the residue was dissolved in doubly distilled water. By applying the recommended procedure the cobalt contents of the samples were determined. To mask copper, nickel, and iron present in these alloys requisite amounts of thiourea, citrate, tartrate, and fluoride were added. The results are reported in Table 1.

Comparision with Other Methods Based on Thiocyanate. The present method is better in sensitivity than most of the other methods based on thiocyanate. Sensitivities are compared in Table 2. The high molecular weight and conjugation of NTC^{2+} ion is responsible.

Table 2. Sensitivities of thiocyanate methods for the photometric determination of cobalt(II)

Method	Sensitivity (μg Co cm^{-2})	Reference
Thiocyanate (isopentyl alcohol)	0.055 (620 nm)	1, 4
Thiocyanate + tetraphenylarsonium ion (chloroform)	0.034 (620 nm)	1, 4
Thiocyanate + 1,1-diantipyrinylethane	0.075 (625 nm)	4
Thiocyanate + tributylammonium salt	0.045 (615 nm)	4
Thiocyanate + 2,3,5-triphenyltetrazolium salt	0.055 (625 nm)	1, 5
Thiocyanate + Neotetrazolium chloride	0.020 (620 nm)	Present method

A CIDEP Study of the Addition of Trialkylsilyl Radicals to Substituted *p*-Benzoquinones

Marjory T. CRAW, Angelo ALBERTI,† M. Catherine DEPEW, and Jeffrey K. S. WAN*
Department of Chemistry, Queen's University, Kingston, Ontario, Canada K7L 3N6
(Received January 5, 1985)

Synopsis. Evidence has been obtained through the combined ESR and CIDEP techniques for the two distinct pathways in which trialkylsilyl radicals add to substituted *p*-benzoquinones *via* the carbonyl oxygen as well as the ring carbon–carbon double bonds. The results represent the first observation of CIDEP from organic radicals containing an organosilyl group in solution.

The reaction of organosilyl radicals with carbonyl compounds has received considerable attention in the past decade.[1-4] While it is generally accepted that the most *stable* adduct formed between a trialkylsilyl radical and 2,6-di-*t*-butyl-*p*-benzoquinone (DTBQ) at room temperature is the adduct to the carbonyl oxygen, recent experiments at low temperature with 3,6-dimethylthieno[3,2-*b*]thiophen-2,5-dione[5] indicate that the faster reaction is the addition of the trialkylsilyl radicals to the ring carbon–carbon double bond. Although CIDEP has been detected previously from trialkylsilyl radicals in solution, it is possible that in a fast reaction involving a primarily polarized organosilyl radical and a quinone the secondary racical adduct may retain and exhibit the initial polarization. In an ideal case, the magnitude of the secondary polarization is a direct measure of the relative efficiencies of the different reaction pathways. We wish to report here the first observation of CIDEP of the trialkylsilyl radical adducts to DTBQ formed by two distinct mechanisms.

When *t*-butylbenzene solutions of DTBQ and triethylsilane were photolyzed in the microwave cavity of an ESR spectrometer at −50 °C a first derivative spectrum (Fig. 1a) was observed which showed *a* triplet attributable to the oxygen adduct (**1**) (a_H=1.08 G (1G ≈10^{-4})) and *a* broad doublet due to the ring adduct (**2**) (a_H=7.03 G).

The polarization spectrum of the same system obtained in the CIDEP experiment is shown in Fig. 1b. The totally emissive character of the polarization spectrum is consistent with the photochemistry of the triplet DTBQ which must lead to the formation of two primary, emissive radicals, DTBQH* and $R_3\dot{S}i$*. In the present system with excess benzoquinone, the addition reactions of $R_3\dot{S}i$* to the ground state benzoquinone molecules are so rapid (faster or comparable to the spin lattice relaxation rate of $R_3\dot{S}i$*) that only the radical adducts (**1**) and (**2**) are observed in the cw spectrum. However, in the polarization spectrum, additional emissive lines due to the semiquinone radical DTBQH* are also apparent. In order to avoid the complication of the polarization spectrum due to the overlapping semiquinone radicals, triethylsilane was replaced with hexamethyldisilane as the reactant. In such a system the overall reaction can be represented by the following steps:

[1] ^{3}DTBQ* + $Me_3SiSiMe_3$ ⟶ DTBQ-$SiMe_3$* + $Me_3\dot{S}i$*,

[2] $Me_3\dot{S}i$* + DTBQ ⟶ (**1**) and (**2**).

The cw and the polarization spectra of the DTBQ/hexamethyldisilane system at 23 °C are shown in Fig. 1c and 1d, respectively. At room temperature, the predominant radical adduct was (**1**), while a weak polarized spectrum of the ring adduct (**2**) was observable in the CIDEP experiment.

The present results clearly establish that there are two distinct pathways for the addition of trialkylsilyl radicals to *p*-benzoquinones. The variation of temperature in the reaction system further confirms that the most thermally stable adduct is the oxygen adduct. At room temperature with DTBQ most of our previous

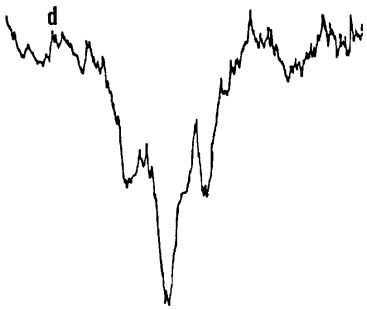

Fig. 1c. Polarization spectrum of the same system in 1c at 23 °C.

studies of the reactions of organometallic radicals, $\dot{M}R_3$, indicate the predominant formation of adducts of the type (**1**). In a more interesting study of the photochemical and thermal reactions of $Me_3Sn–\dot{M}n(CO)_5$, we have shown[6] that at room temperature the two primary radicals, $Me_3\dot{S}n$ and $\dot{M}n(CO)_5$ behaved very differently towards the addition mechanism to DTBQ: The $Me_3\dot{S}n$ radicals added to the carbonyl oxygen of DTBQ while the $\dot{M}n(CO)_5$ radicals attacked only at the carbon–carbon double bond of the ring. These results can be explained by the reversibility and endothermicity of the addition of stannyl radicals to ethylenic double bonds.[7]

Experimental

Cw ESR spectra were recorded on a Varian E-3 X-band spectrometer with 100 kHz field modulation. Irradiation in cw experiments was accomplished by using a 200 watt super pressure mercury lamp. For CIDEP experiments, a Molectron nitrogen laser (1 MW) was used as the excitation source and the ESR transients were directly detected without modulation using a Hewlett Packard wide band preamplifier and a Princeton Applied Research model 162 boxcar integrator and a Nicolet microcomputer controlled digital oscilloscope with a Hewlett Packard 7475A digital plotter.

Chemicals were supplied by Aldrich, the *p*-benzoquinone was sublimed and the tertiary butylbenzene distilled before use.

This research is supported by the operating grant and an International Scientific Collaboration award from the Natural Science and Engineering Research Council of Canada.
