(Received March 31, 1984)

From analyses of Langmuir-type isotherms and α_s-plots for nitrogen adsorption, both the micropore volume and the external surface area have been determined for pillar interlayered montmorillonite (abbreviated as PILM) prepared by intercalating the polynuclear Al cation into the montmorillonite interlayer. The applicability of the Gurvitsch rule to microporous PILM samples was confirmed for adsorption of heptane, whereas the adsorbed amounts of polar adsorbates were dependent on dehydrated states of the alumina pillar. High density of benzene in the micropore independent of calcination temperature suggests some peculiar orientation of benzene in the adsorbed state due to its molecular shape. The interaction of a water molecule with the adsorption site is weak and dependent on the calcination temperature of PILM samples. On this basis, the inhibition of rehydration of the alumina pillar has been discussed.

The pore structure of a solid is essentially important for its adsorption properties. For example, the diffusion characteristics of benzene molecules adsorbed on pillar interlayered montmorillonite (abbreviated as PILM) are in contrast with those on faujasite-type zeolite, although both the adsorbents are similar in micropore size;[1] irreversible dehydration of the alumina pillar has been correlated with surface chemical properties of PILM.[2]

Since Langmuir-type isotherms for nitrogen adsorption on hydroxy-zirconium,[3] hydroxy-chromium,[4] and hydroxy-bismuth[5] montmorillonites were attributed to steric hindrance to the multilayer formation in micropores, elucidation has been expected of the adsorption behavior inside PILM micropores of various adsorbates including nitrogen. Moreover, some new clue to the characterization of surface chemical properties of PILM is necessary, since the generally adopted method of measuring heat of immersion[6] is inapplicable to microporous solids. In this study, we attempt to clarify surface chemical properties by measuring the adsorption enthalpy of water, because the small and polar molecule of water may penetrate with ease through pores of a solid during the adsorption process. An additional purpose is to examine whether or not surface hydroxyl groups can be regenerated, as it is important for the acidic nature of PILM catalysts.

Experimental

Montmorillonite. Otay montmorillonite, supplied from Ward's Natural Science Establishment, Inc., was separated by gravity sedimentation in water dispersion to obtain the fraction less than 2 μm in diameter, and was treated with NaCl (1.0 mol dm^{-3}) to obtain the mother material for PILMs in the Na ion exchanged form (hereafter the material is referred to as Na-Mont).

Preparation of Intercalation Compounds. Preparation of the polynuclear cation $[Al_{13}O_4(OH)_{24}(OH_2)_{12}]^{+7}$[7–9] and its intercalation into montmorillonite were done in the same manner as in previous studies.[1,2] The sample dried in an oven overnight at 393 K is referred to as PILM 120. This sample was calcined in air for 2 h at 473, 673, 873, or 1073 K (hereafter the calcined sample is referred to as PILM 200, PILM 400, PILM 600, or PILM 800, respectively). All these samples were kept in a vessel containing saturated aqueous solution of NH_4Cl to provide a constant humidity. A perspective view of PILM 120 is shown in Fig. 1.

Adsorption Analysis. Both volumetrical adsorption measurements with nitrogen at 77 K using an Orr surface-area

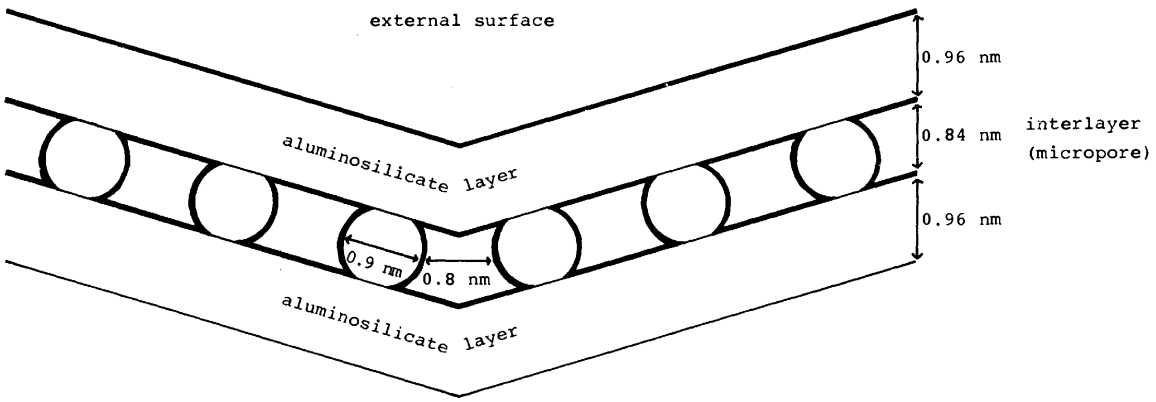

Fig. 1. Perspective view of the pillar interlayered montmorillonite, with the interdistance minimized for the homogeneous arrangement.

pore-volume analyzer (2100 D, Micromeritics Instrument Corp.) and gravimetrical measurements at 298 K using a spring balance for heptane, benzene, 1-chlorobutane, and 1-nitropropane were conducted after a standard pretreatment of overnight evacuation ($<10^{-3}$ Pa) at 393 K.

Calorimetric Measurements of Water Adsorption. A twin conduction type calorimeter (Tokyo Riko Co., Ltd.) equipped with a vacuum system was used to detect the heat evolved during the adsorption process. Before measurement at 298 K, all samples were heat-treated at 393 K for 6 h under vacuum ($<10^{-3}$ Pa).

Results and Discussion

Estimation of the External Surface Area of Montmorillonite Samples with and without Interlayered Pillar. Figure 2 shows adsorption and desorption isotherms for nitrogen. The Langmuir-type adsorption, observed for all the samples except PILM 800, indicates the predominance of adsorption to fill up the micropore. The adsorption behavior in the middle pressure region will correspond to the adsorption on external surface, which may be ignored in the case of zeolite.[10] Abrupt change is noticed with the desorption isotherms at $p/p_0 \simeq 0.5$, resulting from the tensile strength effect.[11]

The α_s-method is useful for discriminating the monolayer capacity of external surface from the micropore capacity.[12,13] As for nonporous adsorbents, the external surface area, S_{ex}, is deduced from the slope of its α_s-plot, a straight line passing through the origin. In the case of microporous adsorbents, however, both the external surface and the micropore provide adsorption sites as far as the micropore is unfilled with adsorbate. Adsorption behavior different from that of nonporous solids would be expected; the α_s-plot provides a linear portion in the region of high coverage, whose slope gives the S_{ex} value for microporous solids.

Representative α_s-plots are shown in Fig. 3. Table 1 summarizes the S_{ex} values thus obtained from the slope of linear portion. The coincidence of the S_{ex} values among all the PILM samples except PILM 800 in Table 1 is remarkable. The α_s-plot for PILM 800 gives a straight line passing through the origin; thermal collapse of montmorillonite layer structure was previously observed in an X-ray diffraction pattern.[2]

Surface Areas of Montmorillonite Samples with and without Interlayered Pillar. The surface area, S, of adsorbent is generally evaluated by

$$S = v_a s N/M, \quad (1)$$

where v_a is the apparent monolayer capacity, s the cross-sectional area of adsorbate,[14] N Avogadro's number, and M the molar weight of adsorbate. Table 2 summarizes physical properties of adsorptives necessary for the adsorption analysis described later.

The v_a values of PILMs 120—600 were obtained from their Langmuir plots (for nitrogen $0.05<p/p_0<0.30$ and for the other adsorbates $0.10<p/p_0<0.35$). Since the adsorption isotherms of PILM 800 obeyed the BET equation, its S values were determined from BET

PILM 800[b)]	37.9	43.4	—[c)]	30.7	32.1

a) Nitrogen was adsorbed at 77 K and the other adsorbates at 298 K. Unless otherwise noted, adsorption obeyed the Langmuir equation. b) Adsorption obeyed the BET equation. c) Adsorption obeyed neither the BET nor the Langmuir equation.

plots (the p/p_0 range was the same as above) except the case of benzene. Table 3 shows surface area values of PILM samples thus derived from Eq. 1 with various adsorbates. The coincidence between the BET surface area, S (37.9 m^2 g^{-1}), and the α_s-plot external surface, S_{ex} (38.7 m^2 g^{-1}), for PILM 800 strongly supports the applicability of the α_s-method to the present system.

Applicability of the Gurvitsch Rule to Pillar Interlayered Montmorillonite. According to Breck and Grose,[15] the Gurvitsch rule on the amount of adsorbate taken up at saturation holds good for various types of zeolites, *i.e.*, a given adsorbent adsorbs different adsorbates up to the same amount as expressed in volume of liquid. This rule was applied to obtain the micropore volume of PILM samples as follows.

From the monolayer capacity, v_{ex}, of external surface obtainable from

$$S_{ex} = v_{ex}sN/M, \tag{2}$$

micropore capacity, v_{in}, is obtained as

$$v_{in} = v_a - v_{ex} \tag{3}$$

and is used to evaluate micropore volume, v, according to

$$v = v_{in}/\rho, \tag{4}$$

where ρ is the density of liquid.

Comparison of micropore volumes obtained with various adsorbates is useful for elucidating adsorption properties of PILM micropore. Figure 4 shows the relationship between the micropore volume for a polar or nonpolar adsorbate relative to that of nitrogen, v_{N_2}, and the calcination temperature. The dipole moment of each adsorbate is given in parentheses.

As far as the Gurvitsch rule is valid for the PILM micropore, all the values of v must be equal to v_{N_2}. Actually, the nonpolar adsorbate heptane gives a value of unity irrespective of calcination temperature, suggesting that the adsorption state in the micropore corresponds closely to liquid nitrogen.

The values for the polar adsorbates, 1-chlorobutane and 1-nitropropane, on the other hand, are larger than unity, especially with the samples for low calcination temperatures. Moreover, the deviation from unity is larger for 1-nitropropane (3.57 D) than for 1-chlorobutane (2.05 D). Since the irreversible dehydration of the alumina pillar proceeds in the calcination pretreatment on PILM samples,[2] water molecules and/or hydroxyl groups on the pillar surface should be responsible for the extraordinarily high density of these

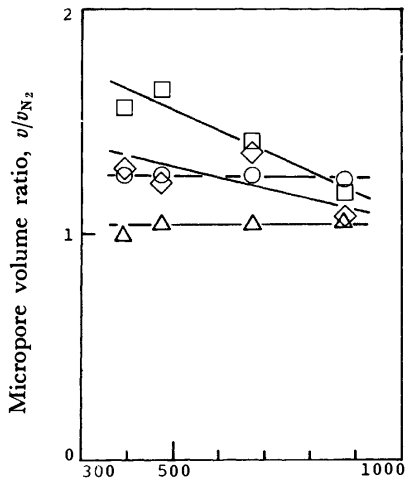

Fig. 4. Micropore volume ratio of PILM samples obtained with polar and nonpolar adsorbates as a function of calcination temperature.

polar adsorbates. In addition, it is to be noted that the gradual decrease in the v/v_{N_2} values down to unity with elevating calcination temperature indicates the decisive influence of the alumina pillar on the adsorbate density. The assumption of homogeneous arrangement of the alumina pillars in the montmorillonite interlayer, therefore, is most likely.

The adsorbate density of benzene is high and independent of calcination temperature, which suggests a highly oriented adsorption of benzene due to its molecular shape under restriction of the slit width of PILM micropore.

Derivative Enthalpy of Water Adsorption on Pillar Interlayered Montmorillonite. Derivative enthalpies of water adsorption on PILM samples obtained by calorimetry are given in Fig. 5. In the range of sufficiently large amounts of water adsorbed, all the samples give almost the same values equal to the liquefaction enthalpy of water. The interaction of a water molecule with an adsorption site on a PILM sample is weaker than on zeolite[16] and decreases in degree with elevating calcination temperature.

The heat of immersion of α- and γ-alumina in water was reported to decrease with elevating pretreatment temperature in the relatively high temperature region; this phenomenon was ascribed to irreversible stabilization of dehydrated alumina surface.[17] Inhibition of the rehydration process would as well be responsible in the present PILM system.

Sodium Sulfate Mixed with Rare Earth Sulfates(Ln=Y and Gd) and Silicon Dioxide as a Solid Electrolyte for a Sulfur Dioxide Detector

Nobuhito IMANAKA, Yasuo YAMAGUCHI, Gin-ya ADACHI,* and Jiro SHIOKAWA
Department of Applied Chemistry, Faculty of Engineering, Osaka University, Yamadaoka, Suita, Osaka 565
(Received May 14, 1984)

Sodium sulfate mixed with rare earth sulfates(Ln=Y and Gd) and silicon dioxide exhibits a Na_2SO_4-I-like phase as well as a small amount of silicon dioxide phase. The former phase is excellent in Na^+ ion conduction. The electrical conductivity of the Na_2SO_4–$Ln_2(SO_4)_3$–SiO_2(Ln=Y and Gd) systems is considerably higher than that of pure sodium sulfate. When the Na_2SO_4–$Ln_2(SO_4)_3$–SiO_2(Ln=Y and Gd) sample is applied as a solid electrolyte for a SO_2 gas concentration cell, the measured EMF is in good agreement with the calculated EMF for a SO_2 gas concentration range from 0.1% (1000 ppm) to 23%, and 0.32% (3200 ppm) to 10%, respectively.

Acid rain produced from the absorbtion of SO_2 and NO_2 in air is deteriorating the environment considerably in recent years. The control of the SO_2 and NO_2 in the exhausted gas and in the atmosphere is becoming a serious problem.

Alkali metal sulfates,[1-9] which are cation conductors at elevated temperature, have been applied as solid electrolytes for the SO_2 gas detector. Sodium sulfate holds the phase transformation from Na_2SO_4-III to Na_2SO_4-I.[10-26] The phase transformation, however, results in cracks in the electrolyte. The sulfate becomes soft at a temperature higher than approximately 1073 K. In addition, the electrical conductivity of Na_2SO_4 is appreciably lower than other Na^+ ion conductors such as NASICON.[27-32] Therefore, several attempts[33-37] to dope mono-, di-, or trivalent cations into sodium sulfate have been made to obtain higher electrical conductivity.

In our previous papers,[7-9,38] sodium vanadate and rare earth sulfates(Ln=Eu, Pr, and Y) have been doped in order to promote the oxidation from SO_2 to SO_3 and maintain the hig h conductive Na_2SO_4-I phase, and to increase the electrical conductivity.

In this investigation, silicon dioxide was added so as to obtain an effective network structure for Na^+ ion migration and in addition, to suppress the electrolyte becoming soft. Rare earth sulfates(Ln=Y and Gd) were also mixed to enhance the electrical conductivity. The suppression of the phase transformation from Na_2SO_4-I to Na_2SO_4-III was also attempted by mixing SiO_2 and $Ln_2(SO_4)_3$(Ln=Y and Gd) simultaneously with Na_2SO_4.

Experimental

Materials. Sodium sulfate(purity 99.99%) and silicon dioxide(purity 99.9%) were purchased from Wako Pure Chemical Industries Ltd. Yttrium(purity 99.9%) and gadlinium oxide(purity 99.99%) were bought from Shiga Rare Metal Industries Ltd. Yttrium and gadlinium sulfate were prepared by adding concd sulfuric acid into Y_2O_3 and Gd_2O_3, respectively. Sodium sulfate which is hygroscopic, and silicon dioxide were preheated before weighing. $Ln_2(SO_4)_3$ (Ln=Y and Gd) were also heated to eliminate the included water. Since $Ln_2(SO_4)_3$(Ln=Y and Gd) easily absorbs water, the real concentration of lanthanoid cation in the mixture was determined by the EDTA titration. Preheated materials were cooled in a desiccator, weighed, and mixed thoroughly in an agate mortar. Mixtures of Na_2SO_4–SiO_2 and Na_2SO_4–$Ln_2(SO_4)_3$–SiO_2(Ln=Y and Gd) were melted at 1473 K in air, then quenched in air. The resulting sample was pulverized in an agate ball, made into pellets under hydrostatic pressure (2.65×10^8 Pa) and then heated at 1073 K for 1 h in air.

Measurements. X-ray and thermal analyses were performed for the Na_2SO_4–SiO_2 and Na_2SO_4–$Ln_2(SO_4)_3$–SiO_2(Ln=Y and Gd) systems in order to investigate their phases and phase transformations using a Rigaku Rotaflex diffractometer equipped with a Cu target and a Rigaku Thermoflex, respectively. Electrical conductivities were measured by the complex impedance method[39] with a Hewlett Packard vector impedance meter 4800A. Electromotive force(EMF) measurements were carried out with a Takeda Riken Digital Multimeter TR-6841 by constructing the SO_2 gas concentration cell depicted in Fig. 1. Mixture gases of SO_2 ranging from 6% to 23% were prepared by controlling the SO_2 and the O_2

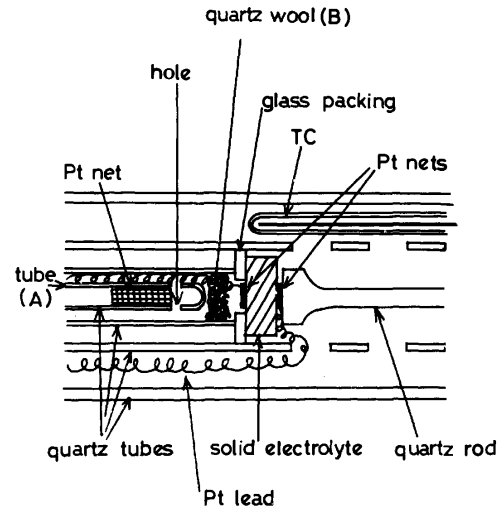

Fig. 1. The apparatus for the electromotive force (EMF) measurements.

gas flow volumes with self-made glass flow meters. The SO_2 gas concentration between 40 ppm and 11100 ppm was regulated by Standard Gas Generator(SGGU-711SD) from Standard Technology Co. The test SO_2 and O_2 gas mixture is introduced from the tube A depicted in Fig. 1. A Pt net is inserted so as to accelerate the oxidation of SO_2 to SO_3. The gas is led to the outer tube compartment through two small holes, and then reaches the electrolyte. The quartz wool is sacked in the place indicated by B shown in Fig. 1 in order to help to diffuse the gas uniformly and to avoid the occurrence of temperature gradient on the electrolyte surface. The ringed glass packing is fixed between the outer quartz tube of the test gas and the solid electrolyte by a spring loading a quartz rod so as to assure the separation of the test gas from the reference gas. The volume of the compartment for the reference SO_2 and O_2 gas mixture has been designed considerably larger compared with that for the test gas so that the SO_2–SO_3 equilibrium can be easily achieved.

Results and Discussion

Electrical Conductivity, Phases, and Thermal Properties. *Na_2SO_4–SiO_2 Systems*: Na_2SO_4–SiO_2 systems prepared are listed in Table 1 together with the results of X-ray and thermal analyses. All samples show the Na_2SO_4-III phase along with SiO_2. DTA curves also indicate a typical peak of the phase transformation from Na_2SO_4-III to Na_2SO_4-I at 513 K. Addition of silicon dioxide to sodium sulfate does not contribute to obtaining the Na_2SO_4-I-like phase which is excellent in the Na^+ ion conduction.

Electrical conductivity measurements for Na_2SO_4–SiO_2 systems are shown in Fig. 2. Mixing SiO_2 with Na_2SO_4 does not enhance the electrical conductivity. The discontinuity in the $\log(\sigma T)$-$1/T$ curve which is attributed to the III to I phase transformation, also exists for the Na_2SO_4–SiO_2 systems. The temperature at the break is about 513 K, which exactly coincides with the temperature obtained by the DTA measurements.

TABLE 1. THE PHASES AND THERMAL PROPERTIES OF Na_2SO_4–SiO_2

Sample No.	Na_2SO_4 (mol%)	SiO_2 (mol%)	Phases	DTA peak T/K
1	90	10	Na_2SO_4-III + SiO_2	513
2	70	30	Na_2SO_4-III + SiO_2	513
3	50	50	Na_2SO_4-III + SiO_2	513

The Na_2SO_4–SiO_2 systems, therefore, do not seem to be suitable for solid electrolytes because of their low electrical conductivities and because of the existence of the phase transformation from III to I.

Na_2SO_4–$Y_2(SO_4)_3$–SiO_2 Systems: The results of phase analyses and DTA measurements are presented in Table 2. X-Ray measurements indicate that a new phase, A, in which the peaks of Na_2SO_4-I-like phase are included, and a small amount of SiO_2 coexist. In sample No.1, some peaks of phase A split. Therefore, a symbol A′ is given to this phase instead of A. This sample(No.1) exhibits an endothermal peak with no gravimetric change at 593 K, showing that a phase transformation occurs. On the other hand, samples from No. 2 to 5 exhibit no phase transition.

Figure 3 illustrates the electrical conductivities results for Na_2SO_4–$Y_2(SO_4)_3$–SiO_2 systems. Sample No.1 exhibits relatively high conductivity. However, the discontinuity lies in the $\log(\sigma T)$ *vs.* $1/T$ curve approximately at 593 K. This temperature is identical with the result from DTA measurement. Similar $\log(\sigma T)$-$1/T$ curves were obtained for the samples of No, 2, 3, and 4. Their curves are nearly straight lines and their conductivities are about 20 times larger than that of Na_2SO_4 at 873 K. In the case of 14.8 mol% $Y_2(SO_4)_3$(No. 5), the electrical conductivity decreased. The cation vacancies are apt to form clusters which do not contribute to the cation conduction.

In the systems of Na_2SO_4–$Y_2(SO_4)_3$–SiO_2, the samples from No. 2 to 4 can be applied as solid electrolytes for a

5	45.1	14.8	40.1	A + (small SiO_2)	—

A and A′: the phase which includes the peaks of Na_2SO_4-I-like phase.

SO_2 gas detector.

Na_2SO_4-$Gd_2(SO_4)_3$-SiO_2 Systems: The phases and thermal properties of Na_2SO_4-$Gd_2(SO_4)_3$-SiO_2 systems are tabulated in Table 3. The samples No. 1 to No. 4 exhibit a new phase α with a small amount of SiO_2. This phase is the phase where some peaks of phase A, are disappearing. The peaks of phase α' are slightly deviated from those of phase α toward low degree side except a peak at 31.6 degree. From thermal analyses, every sample exhibits no endo or exothermal peak on its DTA curve. The results of electrical conductivities for Na_2SO_4-$Gd_2(SO_4)_3$-SiO_2 systems are presented in Fig. 4. The electrical conductivities for the sample No. 1—3 show the highest values in the systems (at temperature higher than 781 K). In the case of 11.6mol% $Gd_2(SO_4)_3$, its conductivity decreased. This is because of the formation of cation vacancy clusters. When 17.2 mol% of $Gd_2(SO_4)_3$ is added(No. 5), the electrical conductivities becomes higher even at low temperatures. However, the bend in $\log(\sigma T)$ *vs.* $1/T$ curve appears at approximately 543 K.

-■-: $Na_2SO_4 : Y_2(SO_4)_3 : SiO_2 = 55.1 : 4.9 : 40.0$,
-○-: $Na_2SO_4 : Y_2(SO_4)_3 : SiO_2 = 52.2 : 7.7 : 40.1$,
-●-: $Na_2SO_4 : Y_2(SO_4)_3 : SiO_2 = 50.1 : 9.9 : 40.0$,
-△-: $Na_2SO_4 : Y_2(SO_4)_3 : SiO_2 = 48.1 : 11.8 : 40.1$,
-▲-: $Na_2SO_4 : Y_2(SO_4)_3 : SiO_2 = 45.1 : 14.8 : 40.1$,
——: Na_2SO_4.

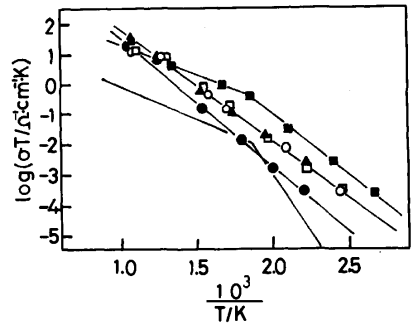

Fig. 4. Temperature dependences of electrical conductivities for the Na_2SO_4-$Gd_2(SO_4)_3$-SiO_2.
-□-: $Na_2SO_4 : Gd_2(SO_4)_3 : SiO_2 = 55.2 : 4.7 : 40.1$,
-○-: $Na_2SO_4 : Gd_2(SO_4)_3 : SiO_2 = 52.0 : 8.0 : 40.0$,
-▲-: $Na_2SO_4 : Gd_2(SO_4)_3 : SiO_2 = 51.0 : 8.2 : 40.8$,
-●-: $Na_2SO_4 : Gd_2(SO_4)_3 : SiO_2 = 48.2 : 11.6 : 40.2$,
-■-: $Na_2SO_4 : Gd_2(SO_4)_3 : SiO_2 = 43.8 : 17.2 : 39.0$,
——: Na_2SO_4.

In the Na_2SO_4-$Gd_2(SO_4)_3$-SiO_2 systems, the samples No. 1—3 are good candidates for solid electrolytes.

EMF Measurements: EMF measurements with the appropriate sample of Na_2SO_4-$Y_2(SO_4)_3$-SiO_2 (50.1 : 9.9 : 40.0) are shown in Fig. 5. The measured EMF was in good agreement with the calculated EMF, with the initial SO_2 gas concentration between 0.1% (1000 ppm) and 23%. When the initial SO_2 gas concentration was less than 0.1%, the measured EMF becomes lower than the calculated EMF. Figure 6 presents the variation of the EMF with the pertinent sample of Na_2SO_4-$Gd_2(SO_4)_3$-SiO_2 (51.0:8.2:40.8). The measured EMF coincided with calculated EMF, with the initial SO_2 gas range from 0.32% (3200 ppm) to 10%. When the initial SO_2 gas content was smaller than 0.32%, the difference between the measured and the calculated EMF became larger. The reason that the measured

—— is calculated EMF.[5)]

and the calculated EMF does not coincide at relatively lower SO_2 gas concentration, may be predominantly accounted to the inadequate oxidation of SO_2 to SO_3.

In conclusion, sodium sulfate mixed with $Ln_2(SO_4)_3$(Ln=Y and Gd) and SiO_2 maintains relatively high electrical conductivities. When Na_2SO_4-$Ln_2(SO_4)_3$-SiO_2 (Ln=Y and Gd) are applied as solid electrolytes for a sulfur dioxide gas sensor, they can detect the SO_2 gas in the initial SO_2 gas concentration range from 0.1% to 23%, and 0.32% to 10%, respectively.

The Short Range Structure of Ion-polar Solvent Mixtures. Calculations by the RISM Integral Equations

Masaharu OHBA and Kiyoshi ARAKAWA*
Research Institute of Applied Electricity, Hokkaido University, Sapporo 060
(Received May 14, 1984)

The reference hypernetted chain like integral equation of the interaction site model is solved numerically for a solution of ions in a polar solvent. In our model, the ions and the solvent molecules are taken to be charged hard spheres and polar hard dumb-bells, respectively. Calculated pair correlation functions contain a great deal of interesting information on the short range structure of the ionic solutions: a solvated structure around ions and an effect of ionic charges upon the structure of the solvent. It is found that various types of associated structures of constituent species, such as simple ion pairs, ion triplets, and ion pairs separated by one solvent molecule exist in ionic solutions.

One of today's central problems of the physical chemistry of ionic solutions is to develop the theory based on the more realistic model for ionic solutions than the so called primitive model.[1] In the primitive model of ionic solutions, a solvent is considered as a continuum medium, in which ions are immersed, with the same dielectric constant as that of the pure solvent. For the last one decade, several authors proposed theories of ionic solutions in which microscopic structures of solvents were explicitly taken into account.[2-12] Many of these theories were concerned with a mixture of charged hard spheres and dipolar hard spheres.

Taking account of a structure of ions and solvent molecules, we proposed a theory[10] on the static dielectric function and site-site pair correlation functions of ionic solutions composed of polyatomic ions and polar polyatomic molecules based on the interaction site model. In the present paper, we obtain site-site radial distribution functions of ionic solutions composed of charged hard spheres and polar hard dumb-bells using the RISM integral equations.[13,14]

Recently, we proposed an RHNC-like integral equation of RISM-1[15] and solved the equation in the case of fluids composed of dipolar hard dumb-bells. Morriss and Cummings[16,17] presented Monte Carlo simulation results for site-site radial distribution functions and the dielectric constant of the polar hard dumb-bell fluids. A comparison of our results with their simulation results is also made in this paper. An agreement of these two results is fairly good, which encourages us to apply the RHNC-like integral equation of RISM-1 to ionic solutions.

In this paper, we extend the RHNC-like integral equation of RISM-1 to multi-component systems and solved it for ionic solutions composed of charged hard spheres and dipolar hard dumb-bells in order to investigate a short range structure of ionic solutions.

The RHNC-like Integral Equation for Fluid Mixtures

An extension of the RHNC-like integral equation of RISM-1[15] to the case of multi-component systems is made in this section.

We assume here that the molecule of type M has n_M interaction sites and a charge $q_{\alpha M}$ is sited on the α-th site of the molecule of type M. The total potential energy of the fluid mixture is assumed to be the sum over all pairs of the intermolecular potentials. The intermolecular potential between the i-th molecule of type M and the j-th molecule of type M', $U_{MM'}(i_M, j_{M'})$, is given as

$$U_{MM'}(i_M,j_{M'}) = \sum_{\alpha=1}^{n_M}\sum_{\gamma=1}^{n_{M'}} u_{\alpha M\gamma M'}(|\boldsymbol{r}_{iM}^{\alpha}-\boldsymbol{r}_{jM'}^{\gamma}|), \quad (1)$$

where $u_{\alpha M\gamma M'}(|\boldsymbol{r}_{iM}^{\alpha}-\boldsymbol{r}_{jM'}^{\gamma}|)$ is a site-site interaction between the pair of site αM and γM' and $\boldsymbol{r}_{iM}^{\alpha}$ the position of the α-th site of the i-th molecule of type M. The site-site interaction can be divided into two parts,

$$u_{\alpha M\gamma M'}(r) = u^{(0)}_{\alpha M\gamma M'}(r) + u^{(1)}_{\alpha M\gamma M'}(r). \quad (2)$$

Here, $u^{(0)}_{\alpha M\gamma M'}(r)$ is a short range part of the site-site interaction, which is treated as a reference potential, and the perturbation potential $u^{(1)}_{\alpha M\gamma M'}(r)$ is a long range Coulomb potential, that is,

$$u^{(1)}_{\alpha M\gamma M'}(r) = \frac{q_{\alpha M}q_{\gamma M'}}{4\pi\varepsilon_0 r}, \quad (3)$$

where ε_0 is the dielectric constant of vacuum.

The Ornstein-Zernike type equation for a multi-component system is

$$\tilde{\boldsymbol{h}}' = \tilde{\boldsymbol{\omega}}\tilde{\boldsymbol{c}}'\tilde{\boldsymbol{\omega}} + \tilde{\boldsymbol{\omega}}\tilde{\boldsymbol{c}}'\tilde{\boldsymbol{h}}', \quad (4)$$

where $\tilde{\boldsymbol{h}}'$, $\tilde{\boldsymbol{c}}'$, and $\tilde{\boldsymbol{w}}$ are matrices with elements $\sqrt{\rho_M\rho_{M'}}\tilde{h}_{\alpha M\gamma M'}(k)$, $\sqrt{\rho_M\rho_{M'}}\tilde{c}_{\alpha M\gamma M'}(k)$, and $\tilde{\omega}_{\alpha M\gamma M'}(k)$, respectively. ρ_M is the number density of molecules of type M. Hereafter, $\tilde{\boldsymbol{A}}'$ denotes a matrix with the element $\sqrt{\rho_M\rho_{M'}}\tilde{A}_{\alpha M\gamma M'}(k)$ and $\tilde{A}_{\alpha M\gamma M'}(k)$ is the Fourier transform of $A_{\alpha M\gamma M'}(r)$,

$$\tilde{A}_{\alpha M\gamma M'}(k) = \int d\boldsymbol{r} A_{\alpha M\gamma M'}(r)e^{-i\boldsymbol{k}\cdot\boldsymbol{r}}$$

$h_{\alpha M\gamma M'}(r)$ is the site-site total correlation function, and $c_{\alpha M\gamma M'}(r)$ is the site-site direct correlation function. $\omega_{\alpha M\gamma M'}(r)$ is the intramolecular pair correlation function

and the Fourier transform of $\omega_{\alpha M\gamma M'}(r)$ for rigid molecule is

$$\tilde{\omega}_{\alpha M\gamma M'}(k) = \delta_{MM'}\left\{\delta_{\alpha\gamma} + (1-\delta_{\alpha\gamma})\frac{\sin kl_{\alpha\gamma M}}{kl_{\alpha\gamma M}}\right\}, \quad (5)$$

where δ_{ab} is the Kronecker delta and $l_{\alpha\gamma M}=|r^{\alpha}_{iM}-r^{\gamma}_{iM}|$ the distance between the α-th site and the γ-th site of the same molecule of type M.

The Ornstein-Zernike type equation for a reference system is

$$\tilde{h}^{(0)\prime} = \tilde{\omega}\tilde{c}^{(0)\prime}\tilde{\omega} + \tilde{\omega}\tilde{c}^{(0)\prime}\tilde{h}^{(0)\prime}, \quad (6)$$

where a superscript (0) denotes the reference system quantity. From Eqs. 4 and 6, we obtain

$$\delta\tilde{h}' = \tilde{\chi}\{\boldsymbol{1}-\delta\tilde{c}'\tilde{\chi}\}^{-1}\delta\tilde{c}'\tilde{\chi}, \quad (7)$$

where $\tilde{\chi}=\tilde{\omega}+\tilde{h}^{(0)\prime}$, $\delta\tilde{h}'=\tilde{h}'-\tilde{h}^{(0)\prime}$, and $\delta\tilde{c}'=\tilde{c}'-\tilde{c}^{(0)\prime}$. $\boldsymbol{1}$ is the unit matrix and $\boldsymbol{A}^{-1}$ is the inverse matrix of $\boldsymbol{A}$.

An RHNC-like approximation of RISM-1 for the multi-component system is expressed as

$$\delta c_{\alpha M\gamma M'}(r) = \delta h_{\alpha M\gamma M'}(r) - \ln\frac{g_{\alpha M\gamma M'}(r)}{g^{(0)}_{\alpha M\gamma M'}(r)}e^{\beta u^{(1)}_{\alpha M\gamma M'}(r)}, \quad (8)$$

where $g_{\alpha M\gamma M'}(r)=h_{\alpha M\gamma M'}(r)+1$ is the site-site radial distribution functiion, $\beta=1/k_BT$, k_B the Boltzmann constant and T the absolute temperature. Combining Eq. 7 with Eq. 8, we can solve the integral equation when the reference system quantities are given.

As is shown in the appendix, $h_{\alpha M\gamma M'}(r)$ is a short range function in the case of ionic solutions as well as the case of polar fluids.[18] Then, the RHNC-like approximation, Eq. 8, implies the following asymptotic form of $c_{\alpha M\gamma M'}(r)$ at large r

$$c_{\alpha M\gamma M'}(r) \simeq -\beta q_{\alpha M}q_{\gamma M'}/4\pi\varepsilon_0 r. \quad (9)$$

However, Cummings and Stell[19] showed that Eq. 9 is not correct and the exact asymptotic forms of $c_{\alpha M\gamma M'}(r)$, for example, of a fluid composed of polar diatomic molecules is

$$c_{\alpha M\gamma M'}(r) \simeq -A\beta q_{\alpha M}q_{\gamma M'}/4\pi\varepsilon_0 r, \quad (10)$$

where A is the state dependent constant. All the closure relations of RISM-1 have the same asymptotic form Eq. 9. Thus, it seems that pair correlation functions calculated by the RISM-1 type integral equation have an incorrect long range nature. Nevertheless, the previous calculations showed that the RISM-1 equation gives good results for a short range structure of liquids.[14,20-22] Rossky *et al.*[23] showed that a modification of the asymptotic form of the closure relations produces only very small deviations in the site-site pair correlation functions at a short range region. Since we are interested in a short range structure of ionic solutions, we solve the Ornstein-Zernike type equation with the closure relation Eq. 8.

Applications to Ion-solvent Mixtures.

Model. A system considered is an 1:1 electrolyte solution. Cations(i+) and anions(i−) are charged hard spheres with the same diameter σ_{ii} and have charges $+q_i$ and $-q_i$, respectively. Solvent molecules(s) are fused hard spheres with the same diameter σ_{ss}, on whose center charges $+q_s$ and $-q_s$ are sited. The bond length of solvent molecules is l. An illustration of molecules is shown in Fig. 1. The reference potential is given as

$$u^{(0)}_{\alpha M\gamma M'}(r) = \begin{cases}\infty, & r<\sigma_{MM'}\\ 0, & r>\sigma_{MM'}\end{cases}, \quad (11)$$

where we assume that $\sigma_{is}=(\sigma_{ii}+\sigma_{ss})/2$. The system is electrically neutral, that is, $\rho_{i+}=\rho_{i-}\equiv\rho_i$. Because of the symmetry, we have $g_{i+i+}(r)=g_{i-i-}(r)$, $g_{i+i-}(r)=g_{i-i+}(r)$, $g_{s+s+}(r)=g_{s-s-}(r)$, $g_{s+s-}(r)=g_{s-s+}(r)$, $g_{i+s+}(r)=g_{s+i+}(r)=g_{i-s-}(r)=g_{s-i-}(r)$, $g_{i+s-}(r)=g_{s-i+}(r)=g_{i-s+}(r)=g_{s+i-}(r)$.

Computational Procedures. The function $\delta h_{\alpha M\gamma M'}(r)$ and $\delta c_{\alpha M\gamma M'}(r)$ have a discontinuity at $r=\sigma_{MM'}$, but $H_{\alpha M\gamma M'}(r)=\delta h_{\alpha M\gamma M'}(r)-\delta c_{\alpha M\gamma M'}(r)$ is a continuus function of r.[14,15,20] As is shown in the appendix, $h_{\alpha M\gamma M'}(r)$ for ionic solutions is a short range function. Thus, similar considerations in the previous paper[15] give us the following equations from Eqs. 7 and 8

$$\tilde{H}^{S\prime} = \tilde{\chi}\{\boldsymbol{1}-(\delta\tilde{c}^{S\prime}-\tilde{H}^{L\prime})\tilde{\chi}\}^{-1}(\delta\tilde{c}^{S\prime}-\tilde{H}^{L\prime})\tilde{\chi}-\delta\tilde{c}^{S\prime} \quad (12)$$

and

$$\delta c^{S}_{\alpha M\gamma M'}(r) = g^{(0)}_{\alpha M\gamma M'}(r)[\exp\{H^{S}_{\alpha M\gamma M'}(r)-\psi^{S}_{\alpha M\gamma M'}(r)\}-1] - H^{S}_{\alpha M\gamma M'}(r). \quad (13)$$

Here,

$$\delta c^{S}_{\alpha M\gamma M'}(r) = \delta c_{\alpha M\gamma M'}(r) + H^{L}_{\alpha M\gamma M'}(r),$$

$$H^{S}_{\alpha M\gamma M'}(r) = H_{\alpha M\gamma M'}(r) - H^{L}_{\alpha M\gamma M'}(r),$$

$$H^{L}_{\alpha M\gamma M'}(r) = \frac{\beta q_{\alpha M}q_{\gamma M'}}{4\pi\varepsilon_0 r}(1-e^{-\alpha r}),$$

$$\psi^{S}_{\alpha M\gamma M'}(r) = \frac{\beta q_{\alpha M}q_{\gamma M'}}{4\pi\varepsilon_0 r}e^{-\alpha r},$$

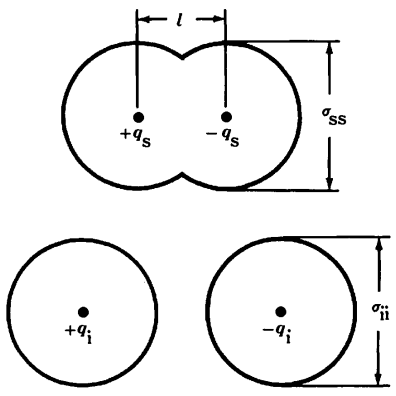

Fig. 1. The shapes of ions and a solvent molecule.

where a is a disposable parameter chosen so as to make the function $\psi^{S}_{\alpha M\gamma M'}(r)$ negligibly small at the termination of the finite range of r. Equations 12 and 13 involve only short range functions that can be numerically handled in the usual way. An iteration calculation is carried out by the use of Eqs. 12 and 13 with an initial guess $H^{S}_{\alpha M\gamma M'}(r)=0$, and is continued until the self consistency of

$$\left|\frac{\exp\{H^{S}_{\alpha M\gamma M'}(r)_{out}\}-\exp\{H^{S}_{\alpha M\gamma M'}(r)_{in}\}}{\exp\{H^{S}_{\alpha M\gamma M'}(r)_{in}\}}\right| < 10^{-6} \quad (14)$$

is satisfied. The site-site radial distribution function is finally obtained as

$$g_{\alpha M\gamma M'}(r) = g^{(0)}_{\alpha M\gamma M'}(r)\exp\{H^{S}_{\alpha M\gamma M'}(r) - \psi^{S}_{\alpha M\gamma M'}(r)\}. \quad (15)$$

Reference System Quantities. Reference system quantities are indispensable for solving the RHNC-like integral equation. It was shown that the PY-like approximation of RISM-1 gives good description of a structure of liquids with short range forces.[14,20] Therefore, a solution of the PY-like integral equation of RISM-1 is used as a reference system quantity. The PY-like approximation of RISM-1 is expressed as[14]

$$c^{(0)}_{\alpha M\gamma M'}(r) = g^{(0)}_{\alpha M\gamma M'}(r)\{1-e^{\beta u^{(0)}_{\alpha M\gamma M'}(r)}\}. \quad (16)$$

We transform Eqs. 6 and 16 into the following equations

$$\tilde{\boldsymbol{H}}^{(0)\prime} = \tilde{\boldsymbol{\omega}}(\boldsymbol{I}-\tilde{\boldsymbol{c}}^{(0)\prime}\tilde{\boldsymbol{\omega}})^{-1}\tilde{\boldsymbol{c}}^{(0)\prime}\tilde{\boldsymbol{\omega}}-\tilde{\boldsymbol{c}}^{(0)\prime}, \quad (17)$$

and

$$c^{(0)}_{\alpha M\gamma M'}(r) = y^{(0)}_{\alpha M\gamma M'}(r)\{e^{-\beta u^{(0)}_{\alpha M\gamma M'}(r)}-1\}, \quad (18)$$

where $y^{(0)}_{\alpha M\gamma M'}(r)=1+H^{(0)}_{\alpha M\gamma M'}(r)$ and $H^{(0)}_{\alpha M\gamma M'}(r)=h^{(0)}_{\alpha M\gamma M'}(r)-c^{(0)}_{\alpha M\gamma M'}(r)$. An interation calculation is carried out by the use of Eqs. 17 and 18 with an initial guess $H^{(0)}_{\alpha M\gamma M'}(r)=0$, and is continued until the self consistency of

$$\left|\frac{y^{(0)}_{\alpha M\gamma M'}(r)_{out}-y^{(0)}_{\alpha M\gamma M'}(r)_{in}}{y^{(0)}_{\alpha M\gamma M'}(r)_{in}}\right| < 10^{-6} \quad (19)$$

is satisfied. The reference system quantities are finally obtained as

$$g^{(0)}_{\alpha M\gamma M'}(r) = y^{(0)}_{\alpha M\gamma M'}(r)e^{-\beta u^{(0)}_{\alpha M\gamma M'}(r)} \quad (20)$$

and

$$\tilde{\boldsymbol{\chi}} = (\boldsymbol{I}-\tilde{\boldsymbol{\omega}}\tilde{\boldsymbol{c}}^{(0)\prime})^{-1}\tilde{\boldsymbol{\omega}}. \quad (21)$$

Results and Discussion

The system considered is characterized by six parameters as follows: the reduced number densities of ions and solvent molecules $\rho_i^*=\rho_i\sigma^3_{ii}$ and $\rho_s^*=\rho_s d^3$, the reduced charge of ions $q_i^*=(\beta q_i^2/4\pi\varepsilon_0\sigma_{ii})^{1/2}$, the reduced dipole moment of solvent molecules $\mu_s^*=(\beta\mu_s^2/4\pi\varepsilon_0 d^3)^{1/2}$, the reduced bond length of solvent molecules $L^*=l/\sigma_{ss}$, and the ratio of σ_{ii} to σ_{ss} $\sigma^*_{ii}=\sigma_{ii}/\sigma_{ss}$. Here, $\mu_s=q_s l$ is the magnitude of the dipole moment of solvent molecules and d, the diameter of the hard sphere whose volume is the same as the solvent molecule, is given by the following equation

$$d^3 = \sigma^3_{ss}(1+3L^*/2-L^{*3}/2). \quad (22)$$

The numerical calculations were carried out with a grid width $\Delta r=0.01\sigma_{ss}$ and the integrals were truncated at $r\approx 10\sigma_{ss}$. Calculations were checked by doubling the cutoff distance, and no meaningfull difference between the two calculations was found.

Comparisons with Monte Carlo Simulation Results for Polar Fluids. Recently, Monte Carlo calculations were carried out for dipolar hard dumb-bell fluids.[16,17] In this subsection, our results are compared with the

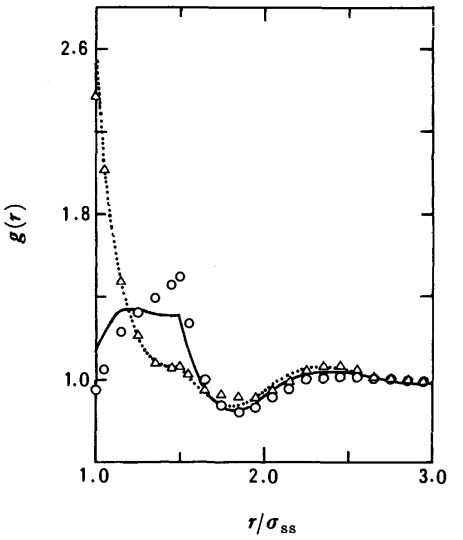

Fig. 2. The site-site radial distribution functions for the polar hard dumb-bell fluid at $\rho_s^*=0.78$, $\mu_s^*=1.17$ and $L^*=0.5$, ——: $g_{++}(r)$ by the RHNC-like equation, ·····: $g_{+-}(r)$ by the RHNC-like equation, ○: $g_{++}(r)$ by the Monte Carlo simulation, △: $g_{+-}(r)$ by the Monte Carlo simulation.

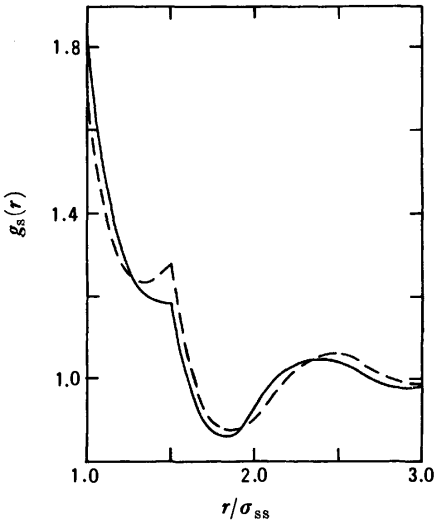

Fig. 3. The radial distribution functions of the centers of atoms. Parameters are the same as Fig. 2. ——: RHNC-like, ·····: Monte Carlo.

simulation results[16] of the polar hard dumb-bell fluid at $L^*=0.5$. $\rho_s^*=0.78$, and $\mu_s^*=1.17$.

Site-site radial distribution functions $g_{++}(r)$ and $g_{+-}(r)$ are shown in Fig. 2. An agreement between the simulation results and ours is good on the whole. Especially, the agreement of $g_{+-}(r)$ is very good except near a contact distance. The radial distribution function of the center of atoms $g_s(r)$ and the radial distribution function of charges $g_d(r)$ are shown in Figs. 3 and 4, respectively. Here, $g_s(r)$ and $g_d(r)$ are defined as

$$g_s(r) = \{g_{++}(r)+g_{+-}(r)\}/2$$

and

$$g_d(r) = \{g_{++}(r)-g_{+-}(r)\}/2.$$

$g_d(r)$ calculated using the interaction site approximation (ISA)[24] is also shown in Fig. 4. The ISA is defined as

$$h_{\alpha M\gamma M'}(r) = -1, \qquad r<\sigma_{\alpha M\gamma M'}$$

and

$$c_{\alpha M\gamma M'}(r) = -\beta u_{\alpha M\gamma M'}(r). \qquad r>\sigma_{\alpha M\gamma M'}$$

This is the molecular fluid analogue of the mean spherical approximation for simple fluids. Though our $g_s(r)$ is qualitatively correct, a small systematic difference between RHNC and Monte Calro results is found from Fig. 3. On the other hand, the agreement of $g_d(r)$ is good. It is said from Fig. 4 that the RHNC-like approximation is superior to the ISA. $\delta g(r)=g_s(r)-g^{(0)}(r)$ are plotted in Fig. 5, where $g^{(0)}(r)$ is the site-site radial distribution function of a nonpolar hard dumb-bell fluid with the same values of L^* and ρ_s^*. It is noted that $g_s(r)$ by ISA is equal to $g^{(0)}(r)$ calculated by the use of the PY-like approximation of RISM-1. Both the $\delta g(r)$ of RHNC and Monte Calro results are nearly equal to zero except at $r/\sigma_{ss}\approx 1-1.7$ where the RHNC result is qualitatively correct. This result shows that most of the disagreement of $g_s(r)$ of RHNC-like results with simulation ones comes from the use of approximate results as the reference system quantities. Thus, it is reasonable to expect that the use of the exact pair correlation functions obtained by computer simulations as reference system quantities gives an excellent result for short range structure of fluids.

Distribution Functions of Ionic Solutions. The figures 6a—6c show the site-site radial distribution functions of an ionic solution. Broken curves in Fig. 6a are ion-ion radial distribution functions by the primitive model for the same state, which are calculated from the RHNC integral equation. The dielectric constant ε of a solvent used in calculations of the primitive model is given by $\varepsilon/\varepsilon_0=1+3y$, where $y=4\pi\beta\rho_s\mu_s^2/9$. This is consistent with the use of the RHNC-like approximation, because the asymptotic form Eq. 9 is obtained from Eq. 10 with $A=1$ and the approximation $A=1$ implies $\varepsilon/\varepsilon_0=1+3y$.[19] It is found from Fig. 6a that the primitive model gives an incorrect description on the short range nature of ion-ion radial distribution functions. The contact value of $g_{i+i-}(r)$ shown in Fig. 6a is large, which indicates that the degree of association of ionic specics is considerably large in this system. $g_{i+i+}(r)$

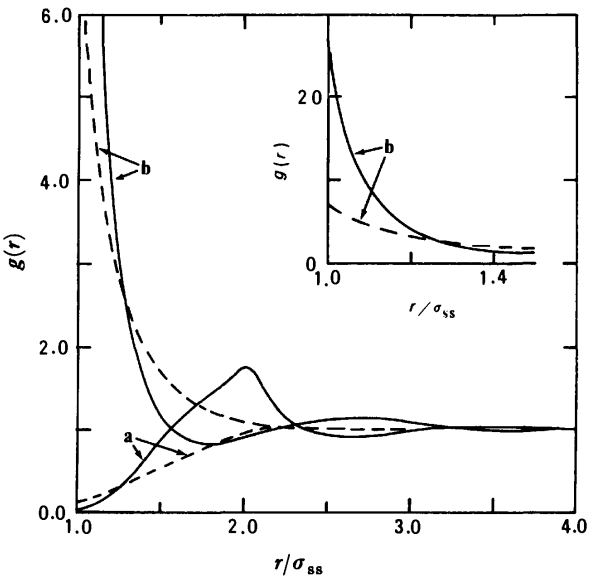

Fig. 6a. The ion-ion radial distribution functions for the ionic solution at $\rho_i^*=0.03$, $\rho_s^*=0.6$, $q_i^*=4.5$, $\mu_s^*=1.0$, $L^*=0.6$ and $\sigma_{ii}^*=1.0$. a: $g_{i+i+}(r)$, b: $g_{i+i-}(r)$. ——: the ion-solvent mixture, ----: the primitive model.

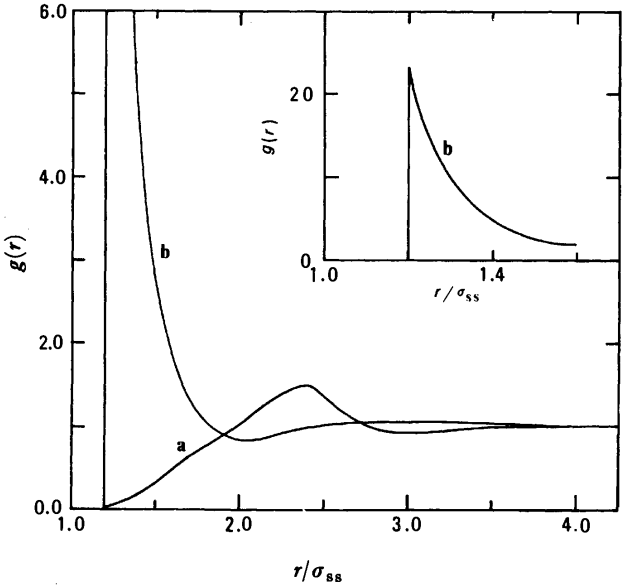

Fig. 7. The ion-ion radial distribution functions for the ionic solution whose parameters are the same as Fig. 6a except $\sigma_{ii}^*=1.2$. a: $g_{i+i+}(r)$, b: $g_{i+i-}(r)$.

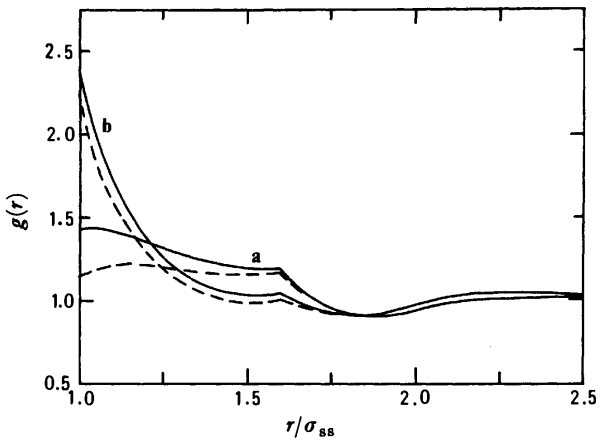

Fig. 8. The solvent-solvent radial distribution functions of the ionic solution at $\rho_i^*=0.05$, $\rho_s^*=0.6$, $\mu_s^*=1.0$, $L^*=0.6$ and $\sigma_{ii}^*=1.0$. a: $g_{s+s+}(r)$, b: $g_{s+s-}(r)$. ——: $q_i^*=4.5$, ----: $q_i^*=0.0$.

has a maximum at $r=2\sigma_{ss}=2\sigma_{ii}$. This maximum suggests the existence of ion triplets shown in Fig. 10a. In order to ascertain this consideration, an effect of the variation of the diameter of ions was investigated. Figure 7 shows the ion-ion radial distribution functions at the same parameters as that of Fig. 6 except $\sigma_{ii}^*=1.2$. The maximum of $g_{i+i+}(r)$ shifts to $r=2.4\sigma_{ss}=2\sigma_{ii}$, which supports the idea that the maximum at $r=2\sigma_{ii}$ comes from ion triplets.

Solvent-solvent radial distribution functions shown in Fig. 6b are similar to those of pure solvents whose details are described in Ref. 15. An effect of ionic charges on the solvent structure is found in Fig. 8. A system with $q_i^*=0$ is the mixture of polar hard dumbbells and neutral hard spheres. The values of solvent-solvent radial distribution functions at $q_i^*=4.5$ are larger than those at $q_i^*=0$ in a small r region. The behavior is explained as follows: ionic charges promote the association of ionic species, and resultantly, a probability that solvent molecules approach each other is enlarged. This effect is small in the case at $\rho_i^*=0.03$.

Ion-solvent radial distribution functions shown in Fig. 6c have cusps at $r/\sigma_{ss}=1+L^*$, which is the same as solvent-solvent radial distribution functions. These cusps come from the structure of solvent molecules and will be rounded off for the system with continuous potentials. The curves of $g_{i+s+}(r)$ and $g_{i+s-}(r)$ intersect each other, and $g_{i+s+}(r)<g_{i+s-}(r)$ at $r/\sigma_{ss}\approx 1$ and $g_{i+s+}(r)>g_{i+s-}(r)$ at $r/\sigma_{ss}\approx 1+L^*$, which is explained in a similar manner to the case of solvent-solvent radial distribution functions for pure solvent. These results imply that an atom of the solvent molecule with an opposite charge to an ion tends to orient toward the ion, that is, a solvated structure is formed around the ion.

It was found that a variation of the polarity of solvent molecules caused an interesting effect upon the short range structure of ionic solutions. $g_{i+i+}(r)$ and $g_{i+s+}(r)$ are shown in Fig. 9, and the contact values of $g_{i+i-}(r)$ and $g_{i+s-}(r)$ are shown in Table 1. With increasing μ_s^*, the maximum at $r/\sigma_{ss}=2$ of $g_{i+i+}(r)$ becomes small and a new maximum arises at $r/\sigma_{ss}\approx 1.5$. Further, a shoulder of $g_{i+s+}(r)$ near $r/\sigma_{ss}=1.4$ grows up to a maximum for $\mu_s^*=3$. Simultaneously, the contact value of $g_{i+i-}(r)$ decreases and the contact value of $g_{i+s-}(r)$ increases. These behaviors can be explained as follows. The ion-solvent interaction increases with increasing μ_s^*. As the result, the degree of association of ions themselves will decrease, and so the ion triplets will also decrease. Thus, the contact value of $g_{i+i-}(r)$ and the maximum at $r/\sigma_{ss}=2$ of $g_{i+i+}(r)$ will decrease with increasing μ_s^*. Further, because of the increment of ion-solvent interactions, a new type of ion pairs which, we suppose, has a structure shown in Fig. 10b will be formed, and thus the new maximum of $g_{i+i+}(r)$ and $g_{i+s+}(r)$ will arise near $r/\sigma_{ss}=1.5$. In order to ascertain the consideration, we calculated the Coulombic energy of an associated group of two cations and one solvent molecule which contact each other with an arrangement shown in Fig. 10b in vaccum, and determined the most stable structure of the group energitically. The results are shown in Table 2, where x is the distance between two cations, y the distance between the cation and the positive atom of the solvent molecule, u the electrostatic energy of the group. Parameters used in this calculation are the same as those in the case of Fig. 9, that is, $q_i^*=4.5$, $L^*=0.6$ and $\sigma^*_{ii}=1.0$. The distance x and y is roughly consistent with the position of the maximum of $g_{i+i+}(r)$ and $g_{i+s+}(r)$ at $\mu_s^*=3.0$, respectively. This result supports the consideration that the new maximums of $g_{i+i+}(r)$ and $g_{i+s+}(r)$ come from the ion pairs separated by one solvent molecule as shown in Fig. 10b. In a recent report, Levesque *et al.*[8] expected the existence of ion pairs separated by one solvent molecule as shown in Fig. 10c based on their LHNC and QHNC calculations of mixtures of

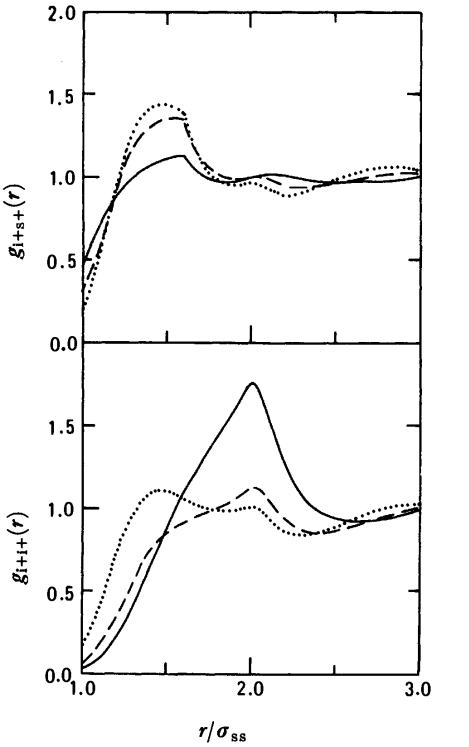

Fig. 9. $g_{i+i+}(r)$ and $g_{i+s+}(r)$ for the ionic solutions at $\rho_i^*=0.03$, $\rho_s^*=0.6$, $q_i^*=4.5$, $L^*=0.6$ and $\sigma^*_{ii}=1.0$. ——: $\mu_s^*=1.0$, ----: $\mu_s^*=2.0$, ·····: $\mu_s^*=3.0$.

charged hard spheres and dipolar hard spheres. The ion pairs expected by Levesque *et al.* have a different structure from ours, which shows that the details of molecular structures must be considered when the short range structures of ionic solutions are investigated.

Concluding Remarks

Site-site radial distribution functions of pure polar fluids calculated with the RHNC-like integral equation of RISM-1 were compared with those of the Monte Carlo calculation. It was found from the comparison that the RHNC-like integral equation gives a fairly good result for the short range structure in polar fluids.

The short range structure in ionic solutions was also investigated by means of the RHNC-like integral equation. It was shown from the calculated site-site radial distribution functions that not only simple ion pairs but also ion triplets (Fig. 10a) and ion pairs separated by one solvent molecule (Fig. 10b) exist in ionic solutions and a solvated structure is formed around ions. The effect of a polarity of solvent molecules on the degree of association of ions and a change of the solvent structure caused by ionic charges have been investigated by the use of the RHNC-like integral equation.

Appendix

It is shown in this appendix that the total correlation functions of ionic solutions are short range functions. Here, we use the same notations as in Ref. 10, hereafter refered to as I.

From Eq. I. 2. 14, we obtain

$$\tilde{\boldsymbol{\chi}} = \tilde{\boldsymbol{\Omega}} + \tilde{\boldsymbol{\Omega}}\tilde{\boldsymbol{\phi}}^{(re)}\tilde{\boldsymbol{\Omega}}, \tag{A. 1}$$

where

$$\chi_{\alpha M \gamma M'}(r) = \rho_M \delta_{MM'}\omega_{\alpha\gamma M}(r) + \rho_M\rho_{M'}h_{\alpha M\gamma M'}(r) \tag{A. 2}$$

Eq. I. 4. 1 is expressed as

$$\tilde{\boldsymbol{\phi}}^{(re)} = -\frac{4\pi\beta}{\varepsilon(k)k^2}\boldsymbol{Z}. \tag{A. 3}$$

Combining Eq. A3 with Eq. A1, we have

$$\tilde{\boldsymbol{\chi}} = \tilde{\boldsymbol{\Omega}} - \frac{4\pi\beta}{\varepsilon(k)k^2}\tilde{\boldsymbol{\Omega}}\boldsymbol{Z}\tilde{\boldsymbol{\Omega}}. \tag{A. 4}$$

By inserting Eqs. I. 3. 11 and I. A. 1 into Eq. A. 4, and by expanding the right hand side of Eq. A4 in power series of k, we find the following equation for ionic solutions at small k

$$\tilde{\boldsymbol{\chi}} = \boldsymbol{\chi}^{(0)} + k^2\boldsymbol{\chi}^{(2)} + \cdots, \tag{A. 5}$$

where

$$\boldsymbol{\chi}^{(0)} = \boldsymbol{\Omega}^{(0)} - \frac{4\pi\beta}{K^2}\boldsymbol{\Omega}^{(0)}\boldsymbol{Z}\boldsymbol{\Omega}^{(0)}, \tag{A. 6}$$

and

$$\boldsymbol{\chi}^{(2)} = \boldsymbol{\Omega}^{(2)} - \frac{4\pi\beta}{K^2}(\boldsymbol{\Omega}^{(0)}\boldsymbol{Z}\boldsymbol{\Omega}^{(2)} + \boldsymbol{\Omega}^{(2)}\boldsymbol{Z}\boldsymbol{\Omega}^{(0)} - \frac{E}{K^2}\boldsymbol{\Omega}^{(0)}\boldsymbol{Z}\boldsymbol{\Omega}^{(0)}). \tag{A. 7}$$

Thus, the existence of $\boldsymbol{\chi}^{(2)}$ is verified, which means that $\chi(r)$ decays faster than r^{-5} at large r. $\omega_{\alpha\gamma M}(r)$ is intrinsically short range. Thus, we find from Eq. A2 that $h_{\alpha M\gamma M'}(r)$ of ionic solutions will decay faster than r^{-5} at large r.

Selective Hydrogenation of Conjugated Dienes Catalyzed by Thiocyanatotris(triphenylphosphine)cobalt(I)

Taisei NAKAYAMA and Hiroyoshi KANAI*
Division of Molecular Engineering, Graduate School of Engineering, Kyoto University, Sakyo-ku, Kyoto 606
(Received June 7, 1984)

Thiocyanatotris(triphenylphosphine)cobalt(I) prepared *in situ* from bis(thiocyanato)bis(triphenylphosphine)cobalt(II), triphenylphosphine, zinc bromide, selectively hydrogenated conjugated dienes to the corresponding cis-monomenes. The C_2-or/and C_3-methyl substituted 1,3-butadienes enhance the reactivity by a factor of 2.3 per one methyl group, while C_1- or/and C_4-methyl substituted 1,3-butadienes lower the reactivity by a factor of 1/23 per one methyl group. In the hydrogenation of cyclic conjugated dienes α-angle ($\angle$C–C=C) is closely related to the hydrogenation rate. The rates of hydrogenation in cyclic ethers are greater than those in acyclic ethers, but the cis-selectivity in acyclic ethers is much higher. Deuterium selectively adds to 1,3-butadiene and 2,5-norbornadiene (bicyclo[2.2.1]hepta-2,5-diene) to give 3,4-dideuterio-1-butene and *cis*-1,4-dideuterio-2-butene, and *endo,endo*-5,6-dideuterionorbornene and *endo,endo*-3,5-dideuterionortricyclene, respectively. A mechanism is proposed which derives from *anti*-π-allylcobalt hydride or delocalized nortricyclenylcobalt hydride as an intermediate.

Univalent cobalt complexes with halogen and pseudohalogen ligands were limited until recently.[1] The principal difficulties in the synthesis of Co(I) complexes are due to the capacity of Co(I) complexes for oxidation, reduction and disproportionation. The interest in Co(I) complex has been stimulated by studies in the field of stereochemistry[2] and catalysis.[3]

In the hydrogenation of 1,3-butadiene a cationic cobalt(I) complex, $[Co(PPh_3)_3]BF_3X$ (X=halogen),[3d] selectively gave 1-butene, while $CoX(bpy)_2$/zinc system (bpy=2,2′-bipyridyl) mainly gave *cis*-2-butene.[3h]

We reported here the selective hydrogenation of conjugated dienes with a cobalt(I) thiocyanate complex.

Experimental

Materials. 1,3-Butadiene was obtained from Takachiho Chemical Co. and distilled under vacuum. *trans*-1,3-Pentadiene, *trans*-2-methyl-1,3-pentadiene, *trans,trans*-2,4-hexadiene, 4-methyl-1,3-pentadiene and 2,3-dimethyl-1,3-butadiene were obtained from Aldrich Chemical Co. and distilled under vacuum. Isoprene and 1,3-cyclohexadiene were from Nakarai Chemical Co. and distilled under vacuum. Cyclopentadiene was prepared from the pyrolysis of dicyclopentadiene.[4] 1,3,5-Cycloheptatriene, 1,3-cyclooctadiene, 1,5-cyclooctadiene, β-myrcene and 2,5-norbornadiene were obtained from Nakarai Chemical Co. and used without further purification. 1,2-Butadiene was obtained from Tokyo Kasei Co. and distilled under vacuum.

Solvents were refluxed over lithium aluminium tetrahydride, distilled, and stored in a nitrogen atmosphere.

Preparation of Bis(thiocyanato)bis(triphenylphosphine)cobalt(II).[5] Cobalt(II) thiocyanate was prepared from cobalt(II) sulfate (Hayashi Junyaku Co.) and barium thiocyanate (Mitsuwa Kagaku Co.) by the literature method.[6] After $Co(SCN)_2$ (28 g, 98 mmol) was dissolved in acetone (300 ml) and the insoluble residue was filtered off, triphenylphosphine (48 g, 200 mmol) were added to the filtrate and the green solution was concentrated to *ca.* 100 ml by using an evaporator. Petroleum ether was added to the concentrated solution. The precipitate of $[Co(SCN)_2(PPh_3)_2]$ was collected, washed with petroleum ether for several times and dried: yield 32 g (67% based on $Co(SCN)_2$).

Hydrogenation Procedure. The catalyst was prepared *in situ* from the reduction of $[Co(SCN)_2(PPh_3)_2]$ 0.21 g (0.3 mmol) with Zn (3.0 mmol) and $ZnBr_2$ (1.0 mmol) in the presence of PPh_3 (0.3 mmol) in glyme (1,2-dimethoxyethane) (10 ml) under nitrogen. The solution, which was initially purple, turned brown after 2—3 h. Then substrates (2 mmol) were added and nitrogen was replaced by hydrogen. Hydrogenation was conducted at 17 °C with stirring under the constant pressure of hydrogen using the gas buret. The rate of hydrogenation was determined by hydrogen uptake and products were analyzed by gas chromatography (30% 2,4-dimethylsulfolane on C-22, 5.6 m, r.t.).

Isotopic exchange of H_2–D_2 and D_2–olefin were carried out by the analogous procedure. The deuterated products of 1,3-butadiene in H_2–D_2 mixed gas were analyzed by a gas chromatography–mass spectrometer (NEVA TE600, porapak Q, 110 °C, ionization voltage 10 V). Deuterated products of 1,3-butadiene and 2,5-norbornadiene were identified by ^{13}C and ^1H NMR spectra obtained on a JEOL FX-100 spectrometer.

Results and Discussion

Preparation of Co(I) Complex and Active Species. Sodium tetrahydroborate was ineffective to decompose the complex. Zinc can reduce $[Co(SCN)_2(PPh_3)_2]$ to the Co(I) complex, but it takes too much time. The activated zinc prepared from zinc halides and potassium,[7] or from zinc bromide, lithium and naphthalene[8] was not appropriate because they gave complexed compounds to lose reproducibility. We found that $[Co(SCN)_2(PPh_3)_2]$ was smoothly reduced by zinc in the presence of zinc bromide.[9] The effect of zinc bromide on the hydrogenation of 1,3-butadiene indicates that the highest activity was observed above the ratio of $ZnBr_2/Co=3.3$ (Fig. 1). Other Lewis acids, $AlCl_3$ and $FeCl_3$ were ineffective. Zinc bromide was the most effective among zinc halides.

The addition of triphenylphosphine increased the

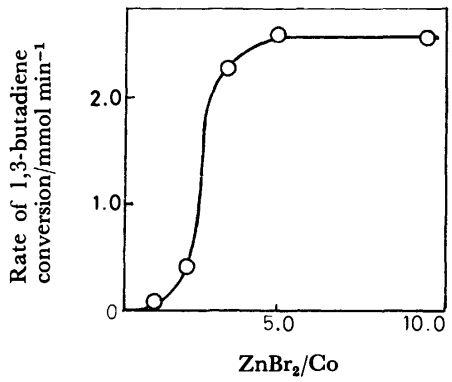

Fig. 1. Effect of zinc bromide on the hydrogenation of 1,3-butadiene.

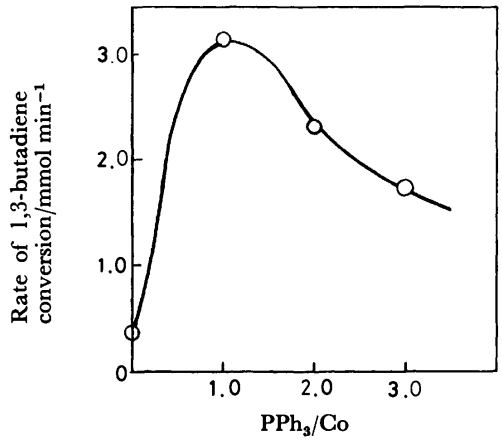

Fig. 2. Effect of triphenylphosphine on the hydrogenation of 1,3-butadiene.

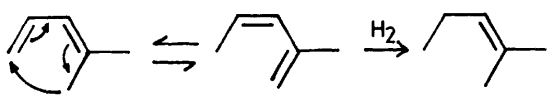
yield of hydrogenation, but the excess inhibited (Fig. 2). The maximum yield at the 1:1 ratio of triphenylphosphine to the cobalt complex indicated that the precursor of the active species is [Co(SCN)(PPh3)3]. After the reduction of [Co(SCN)2(PPh3)2] in the presence of PPh3, ZnBr2, and Zn, the red-brown solution was separated from zinc by filtration. When 1,3-butadiene was introduced into the filtrate in an atmosphere of hydrogen, no reaction was observed. When butadiene was treated with another filtrate in contact with fresh zinc, hydrogenation began to occur. Zinc plays a role to keep the cobalt complex a univalent state. No anion exchange between [CoBr(PPh3)3] and NaSCN was observed in glyme at r.t. The red-brown solution where [CoBr(PPh3)3] was treated with Zn(SCN)2 caused hydrogenation of 1,3-butadiene, but hydrogen uptake stopped after 60 min by giving catalytically inactive green complex. Consequently, anion exchange method was not suitable to prepare the Co(I) complex.



Scheme 1.

We have not isolated the Co(I)-thiocyanate complex. Putting all accounts together catalytic species must be [Co(SCN)(PPh3)3]. The presence of zinc is required as a reductant to keep the unstable complex active.

Hydrogenation of Unsaturated Hydrocarbons. Hydrogenation of unsaturated compounds were summarized in Table 1. Conjugated acyclic dienes were selectively hydrogenated to the corresponding cis-monoenes. No alkanes were observed. The rates of hydrogenation decreased in the following order; 2,3-dimethyl-1,3-butadiene>*trans*-2-methyl-1,3-butadiene-(Isoprene)>1,3-butadiene>*trans*-2-methyl-1,3-pentadiene>*trans*-1,3-pentadiene. *trans,trans*-2,4-Hexadiene was not hydrogenated. 4-Methyl-1,3-pentadiene was concluded to be hydroganated *via* 2-methyl-1,3-pentadiene, since hydrogenation products were the same as those of 2-methyl-1,3-pentadiene which had been formed in the course of hydrogenation. This reaction is similar to the 1,5-hydrogen shift explained by Frankel and Butterfield (Scheme 1).[10]

To investigate the coordination and reactivity sequences of conjugated dienes, the competitive hydrogenation of 1,3-butadiene and 2,3-dimethyl-1,3-butadiene was conducted. Since the hydrogenation of each dienes occurred at its own rate, the coordinating strength of dienes did not determine the reactivity sequence.

Among conjugated cyclic dienes, cyclopentadiene and 1,3-cyclohexadiene were selectively hydrogenated to the corresponding cyclomonoenes. 1,3,5-Cycloheptatriene was also hydrogenated to cycloheptene *via* 1,3- or 1,4-cycloheptadiene. No hydrogenation of 1,3- and 1,5-cyclooctadiene occurred. 1,5-Cyclooctadiene was isomerized to 1,3- and 1,4-cyclooctadienes. The composition of cyclooctadienes after 24 h were 1,3-cyclooctadiene: 1,4-cyclooctadiene: 1,5-cyclooctadiene= 4:29:67. 1,2-Butadiene was hydrogenated to butenes without selectivity but polymer was obtained as a by-product.

Although 2,5-norbornadiene is classified as a non-conjugated diene, Hoffmann *et al.* showed that its π-electron systems have direct through-space overlap interaction.[11] So it should be treated as one of conjugated dienes when it is coordinated to cobalt complex.

2,5-Norbornadiene was hydroganeted to bicyclo-[2.2.1]hept-2-ene (norbornene) and tricyclo[2.2.1.$0^{2,5}$]-heptane (nortricyclene). It is notable that nortricyclene is produced in the hydrogenation of norbornadiene by a cobalt catalyst, while it is barely produced by transition-metal complexes.[12] Parallel to the hydrogenation, dimerization occurred.[13] No dimerization of any other conjugated dienes in Table 1 was observed.

No hydrogenation occurred for following unsaturated compounds; 1-hexyne, styrene, *trans*-1-phenyl-1,3-butadiene, phenylacetylene, furan, and methyl acrylate.

Effect of Hydrogen Pressure, and the Concentrations of

TABLE 1. HYDROGENATION OF CONJUGATED DIENES CATALYZED BY $[Co(SCN)(PPh_3)_3]$ PREPARED *in situ* FROM $[Co(SCN)_2(PPh_3)_2]$, Zn AND $ZnBr_2$[a)]

a) Reactions were carried out as following conditions: diene 2 mmol, $[Co(SCN)_2(PPh_3)_2]$ 0.3 mmol, Zn 3.0 mmol, $ZnBr_2$ 1.0 mmol, glyme 10 ml, total pressure 1 atm at 17 °C.
b) β-Myrcene (1.2 mmol) was used.

Cobalt Complex and Dienes. Figure 3 illustrates the first order dependence upon hydrogen pressure. The first order dependence upon the concentration of the complex is observed up to a cobalt complex charge of 0.03 mol dm^{-3} which is the saturated concentration (Fig. 4). The hydrogenation is independent of the concentration of dienes except for β-myrcene. The lowering of the rate in the hydrogenation of β-myrcene with the elapse of time is attributed to the coordination of the diene products. Hydrogen uptake increases linearly with time, and products were not isomerized until dienes were almost consumed.

Solvent Effects. The nature of solvents has a significant effect on both the selectivity and the hydrogenation rate (Table 2). No reduction of [Co(SCN)$_2$-(PPh$_3$)$_2$] occurred in the following solvents; diethyl ether, dibutyl ether, and toluene. Methanol, ethanol, and acetonitrile were inadequate to make the complex dissociate into Co(SCN)$_2$ and PPh$_3$. The UV spectra of [Co(SCN)$_2$(PPh$_3$)$_2$]-Zn-ZnBr$_2$ in these solutions showed the same absorption bands as those of Co(SCN)$_2$ in the solutions except for the absorption bands attributed to triphenylphosphine.

Ethers can be typed into two groups, one is cyclic ethers and the other is acyclic polyethers. Acyclic ethers gave higher cis-selectivity than cyclic ones. The increase of n in $CH_3O(CH_2CH_2O)_nCH_3$ leads to the increase of cis-selectivity and the decrease of hydrogenation rate (Fig. 5). In a mixture of THF and glyme (ratio 1:1), THF controlled the hydrogenation rate and selectivity. The coordination strength of cyclic ethers toward the cobalt complex is larger than that of acyclic ethers. When crown ether (18-crown-6) was added to glyme (crown:Co=1:1 and 10:1) the hydrogenation rates were a little slower than that in glyme alone without change of selectivity. The high cis-selectivity in acyclic ethers seems to be attributed to the weak chelate coordination of free movable oxyetylene units.

Deuteration. Deuteration of 1,3-butadiene gave 3,4-dideuterio-1-butene **1** and *cis*-1,4-dideuterio-2-butene **2** which were identified by their ^{13}C NMR spectra. Hydrogen was selectively introduced into 1,3-butadiene *via* 1,2- and 1,4-addition. The isotopic effect is calculated as r_H/r_D=1.4. Hydrogenation products of 1,3-butadiene in H_2-D_2 mixed gas (ratio of H_2/

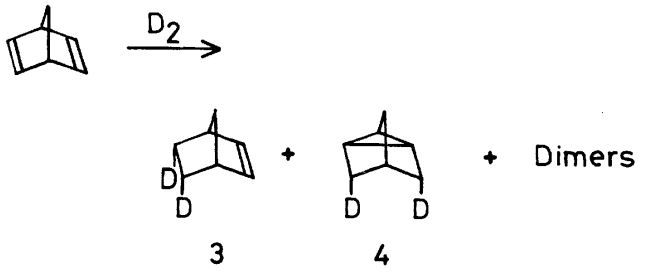
D_2=1.08) were **1**, **2**, 1-butene and *cis*-2-butene. Mono- and polydeuterated products were not observed, so molecular identity was maintained.

Deuteration of norbornadiene was tried to investigate the stereochemistry of the addition of hydrogen. *endo, endo*-5,6-Dideuteriotricyclo[2.2.1]hept-2-one **3** and *endo,endo*-3,5-dideuteriotricyclo[2.2.1.$0^{2,5}$]heptane **4**, which were identified by their ^{1}H NMR spectra by comparison of those of authentic samples,[13] were obtained to ensure that hydrogen was added selectively via cis-endo-addition.



3 4

Methyl-substituted Effect on Acyclic Conjugated Dienes. We compared the rates of hydrogenation of methyl-substituted 1,3-butadienes (Table 3). The hydrogenation of C_1- or/and C_4-substituted 1,3-butadienes was faster than that of 1,3-butadiene, while the hydrogenation of C_1 or/and C_4-substitued 1,3-butadienes was slower. The substitution of methyl group at C_2 as seen in isoprene accelerates the hydrogenation rate 2.3 times as fast as that of 1,3-butadiene. 2,3-Dimethyl-1,3-butadiene can be estimated to be hydrogenated faster than 1,3-butadiene by a factor of 2.3^2=5.3 which is in fair agreement with the experimental value.

On the other hand, C_1- or C_4-subtituted methyl group lowers the hydrogenation rate by 1/23 time. The hydrogenation rate of *trans,trans*-2,4-hexadiene can be estimated to be $1/23^2$=0.002 time of that of 1,3-butadiene. The value is regarded as nearly zero. No hydrogenation of *trans,trans*-2,4-hexadiene occurred in practice. The hydrogenation rate of *trans*-2-methyl-1,3-pentadiene can be estimated to be 2.3×1/23=0.1 time of that of 1,3-butadiene. The value almost agrees with the experimental one on the basis of the order.

α-Angle Effect on the Hydrogenation of Cyclic Conjugated Dienes. The reason why cyclopentadiene, 1,3-cyclohexadiene and 1,3-cycloheptadiene were hydrogenated but 1,3-cyclooctadiene not, may be related to α-angles of cyclic dienes (Table 4). The hydrogenation rate is almost independent of β-angles. Strohmeier

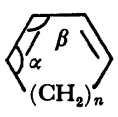
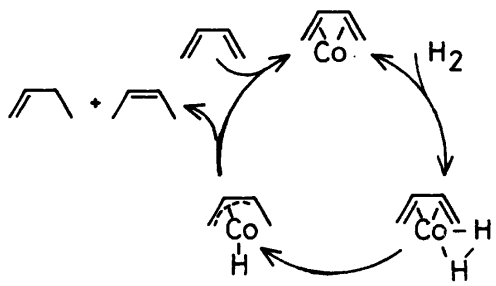
a) By Strohmeier and Iglauer.[15] b) Angle of cyclooctatetraene.



and Iglauer explained the ease of the hydrogenation of cyclic dienes by $[Co(CN)_5]^{3-}$ in terms of the strain energy of carbon-carbon bonding.[15]

Although no hydrogenation of 1,3- and 1,5- cyclooctadiene occurred, 1,5-cyclooctadiene was isomerized even in the absence of hydrogen. Hydrogen is not required for the isomerization of cyclooctadiene. The isomerization may occur *via* a 1,3-hydrogen shift with a π-allylcobalt hydride intermediate. The hydrogenation rates decrease in the order cyclopentadiene>1,3-cyclohexadiene>1,3-cycloheptadiene$\gg$1,3-cyclooctadiene. The smaller α-angle is, the more reactive the cyclic diene is. The ease of hydrogenation of cyclic dienes with small α-angle is related to the facile approach of hydrogen coordinated with cobalt toward coordinated dienes. Because α-angles are related to the distances between the C_1 and C_4 carbons of conjugated dienes and cobalt. On the crystallographic studies the distances between cobalt and C_1-carbon of π-cyclopentadienyl-1-phenylcyclopentadiene cobalt was 1.97 Å,[16] while that of *cis*-di-μ-carbonyl-bis[carbonyl-(π-cyclohexa-1,3-diene)cobalt] was 2.13 Å.[17]

Mechanism of Hydrogenation. A monomeric cobalt complex is an active species due to the first dependence of the cobalt concentration. The catalytic species must be $[Co(SCN)(PPh_3)_3]$. Zero-order dependence of butadiene indicates that the reaction between Co(I) complex and butadiene gives cobalt(I)-butadiene π-complex (Scheme 2). Hydrogen adds to the complex to form *anti*-1-methyl-π-allylcobalt hydride complex. Since *trans*-2-butene was not formed at all, no scrambling of the anti-complex to the syn-isomer occurred.[18] *anti*-π-Allylcobalt hydride complex produces *cis*-2-butene and 1-butene to regenerate the initial cobalt(I) complex.



Co ≡ [Co(SCN)(PPh3)n]

Scheme 2.

In the case of norbornadiene, cobalt(I)-norbornadiene complex **5** is formed (Scheme 3). Then hydrogen reacts with the complex to form the delocalized nortricyclenylcobalt hydride complex **6**. When the hydride reacts *via* path I, norbornene is produced, and *via* path II, nortricyclene is produced.

(Received June 13, 1984)

A tight-binding MO-sum-over-state theory has been used to calculate the ^{13}C NMR chemical shift of polyglycine having the forms I and II and that of poly(L-alanine) having the α-helix and β-sheet forms, in order to justify the origin of the conformation-dependent ^{13}C NMR chemical shift previously determined by the cross polarization-magic angle spinning technique. The calculated results on the carbonyl, C_α and C_β carbons were found to exhibit the conformation-dependent ^{13}C NMR chemical shifts comparable with the experimental data.

A recent development of the cross polarization-magic angle spinning (CP-MAS) NMR technique has provided useful information about the conformation of polypeptides in the solid state.[1-12] It has been demonstrated that the ^{13}C chemical shifts of the C_α, C_β, and carbonyl carbons are displaced up to 7 ppm, depending on the particular conformations such as the α-helix, β-sheet and ω-helix forms.

In a previous work,[7] we have justified by using a dipeptide fragment of poly(L-alanine), *N*-acetylalanine methylamide, and the finite perturbation theory(FPT) within the INDO MO framework[13-17] that the conformation-dependent ^{13}C chemical shift arises from changes of electronic structure varying with the dihedral angles (ϕ and ψ) of the skeletal bond. (On the other hand, Tonelli[33] has suggested that ^{13}C NMR chemical shifts of backbone carbonyl and side chain carbons in polypeptides provide information about their structure by means of the γ-gauche effect.) Such approaches are useful to obtain appropriate knowledge regarding the conformation of polypeptides. However, it may be necessary to clarify the following points: The specification of the long finite interaction length for the electronic structure, and the hydrogen bond's involved in the α-helix or β-sheet form are not always included sufficiently in the dipeptide.

Such a situation leads to the application of the tight-binding (TB) MO theory to the NMR chemical shift calculation for polypeptides without using the model compounds.[18] It is emphasized that the intrachain hydrogen bonds of the α-helix conformation are easily taken into account by this approximation. So far, the TB MO approximation has been used for describing the electronic structure of polymers with a periodic structure.[19-25] Thus, in this work we attempt to calculate the conformation-dependent ^{13}C chemical shift for polyglycine and poly(L-alanine) which was previously measured, on the basis of the TB MO approximation in order to gain an insight into the ^{13}C chemical shift in polypeptides.

Theory and Calculation

With the aid of the LCAO approximation and Bloch's theorem, the wave function for electrons in a polymer chain in which N-1 cells (or amino acid residues) interact with the original cell is expressed by[19-21]

$$\Psi_n(k,r) = \frac{1}{N}\sum_\nu \sum_j \exp(ikj) C_{\nu n}(k)\phi_\nu(r-ja), \quad (1)$$

where n is the band index; ν the atomic orbital in the j-th cell; N the total number of cells; l the number of atomic orbital in the cell; a the unit vector of translational symmetry and k the wave number. The parameters j and k vary from $-(N-1)/2$ to $(N-1)/2$ and from $-\pi/2$ to $\pi/2$, respectively, within the first Brillouin zone. The symbol i denotes the imaginary number. $\phi_p(r-ja)$ represents the p-th atomic orbital in the j-th cell and $C_{\nu n}(k)$ its expansion coefficient. Using Eq. 1, the Schrödinger equation for a polymer chain is given by

$$H(k) = \varepsilon(k)S(k), \quad (2)$$

where

$$H_{\mu\nu}(k) = \sum_j \exp(ikj)H^{0j}_{\mu\nu},$$
$$S_{\mu\nu}(k) = \sum_j \exp(ikj)S^{0j}_{\mu\nu}, \quad (3)$$

in which $H^{0j}_{\mu\nu}$ is the interaction between the μ-th atomic orbital in the original cell and the ν-th atomic orbital in the j-th cell. $S^{0j}_{\mu\nu}$ is the overlap integral between the μ-th atomic orbital in the original cell and the ν-th atomic orbital in the j-th cell. Thus, we can directly treat a polymer chain which has infinite length without model compounds such as a dimer,

trimer, *etc.* Previously, the electronic structure of polymers (including polyglycine and poly(L-alanine)) were calculated by means of the extended Hückel and CNDO MO theories and conformational energies were compared.[22-25]

Hence, we perform calculations within the framework of the extended Hückel approximation. It is said that the extended Hückel calculation should be compared among molecules with a similar structure, because, generally, such a calculation for polar molecules has a tendency to overestimate the electronic polarization. Therefore, it is considered that the extended Hückel method is significantly applicable to the conformation-dependent ^{13}C chemical shift calculation as done in this work. In the extended Hückel approximation, the diagonal and off-diagonal elements of the Hamiltonian are estimated as follows:

$$H^{00}_{\mu\mu} = -I_\mu$$
$$H^{0J}_{\mu\nu} = \frac{1}{2}KS^{0J}_{\mu\nu}(H^{00}_{\mu\mu}+H^{00}_{\nu\nu}), \quad (4)$$

where I_μ is the ionization potential energy of the μ-th orbital and K is taken to be 1.75. The valence-state ionization potential energy for the paticular atomic orbital used here is as follows:[26] I_{1s}=13.6 eV for hydrogen atom; I_{2s}=21.43 eV and I_{2p}=11.42 eV for carbon atom; I_{2s}=27.5 eV and I_{2p}=14.49 eV for nitrogen atom; I_{2s}=35.3 eV and I_{2p}=17.76 eV for oxygen atom. The Slater's effective nuclear charges used for hydrogen, carbon, nitrogen and oxygen atoms are 1.00, 3.25, 3.90, and 4.55, respectively.[26] Thus, we can directly obtain the expansion coefficients, $C_{\nu n}(k)$, and the electronic structure of an infinite regular polymer.

Using $C_{\nu n}(k)$, we estimate the ^{13}C NMR chemical shift of polyglycine and poly(L-alanine). In general, an NMR chemical shift can be written as

$$\sigma_A = \sigma^d_A + \sigma^p_A + \sigma', \quad (5)$$

where σ^d_A and σ^p_A are the diamagnetic and paramagnetic contributions, respectively. σ' is the contribution from neighbouring atoms. For the carbon atom, σ' is much smaller than 1 ppm and can be considered negligible. Thus, the ^{13}C NMR chemical shift can be estimated by the sum of σ^d and σ^p which are expressed by[18]

$$\sigma^d_A(k) = \frac{\mu_0}{4\pi}\frac{2e^2}{3m_e^2}\sum_\nu^A\sum_{\nu'}^A P_{\nu\nu'}(k)\langle\phi_\nu(r)|r^{-1}|\phi_{\nu'}(r)\rangle \quad (6)$$

$$\sigma^p_{A,\alpha\beta}(k) = -\frac{\mu_0}{4\pi}\frac{\hbar^2e^2}{m_e^2}\sum_m^{occ}\sum_n^{unocc}\sum_j^A\langle r^{-3}\rangle_{2p}({}^1E^n_m-{}^1E_0)^{-1} \quad (7)$$
$$\times\sum_B\sum_I^B (X(j,m,n,\beta,\gamma)X(l,n,m,\gamma,\alpha)$$
$$- Y(j,m,n,\beta,\gamma)Y(l,n,m,\gamma,\alpha)$$
$$+ X(j,m,n,\gamma,\alpha)X(l,n,m,\beta,\gamma)$$
$$- Y(j,m,n,\gamma,\alpha)Y(l,n,m,\beta,\gamma)),$$

where

$$P_{\nu\nu'}(k) = \sum_m^{occ} C^*_{\nu n}(k)C_{\nu' m}(k)$$
$$X(j,m,n,\beta,\gamma) = C^{R\beta}_{jm}C^{I\gamma}_{jn} + C^{R\beta}_{jn}C^{I\gamma}_{jm} - C^{R\gamma}_{jn}C^{I\beta}_{jm} - C^{R\gamma}_{jm}C^{I\beta}_{jn} \quad (8)$$
$$Y(j,m,n,\beta,\gamma) = C^{R\beta}_{jm}C^{R\gamma}_{jn} - C^{R\gamma}_{jm}C^{R\beta}_{jn} + C^{I\beta}_{jm}C^{I\gamma}_{jn} - C^{I\gamma}_{jm}C^{I\beta}_{jn}$$

in which j and l are orbitals on atoms A and B, respectively; $\sum_m^{occ}$ and $\sum_n^{unocc}$ are the summations over the occupied and unoccupied orbitals, respectively; α, β, γ=x, y, z in cyclic order; and R and I represent the real and imaginary parts of coefficient $C_{\nu n}(k)$, respectively.

The geometry data on polyglycine and poly(L-alanine) obtained from an X-ray diffraction analysis are used, and the dihedral angles (ϕ and ψ) are listed in Table 1. The structure of the hydrogen-bonded two polypeptide chains is shown in Fig. 1. The calculation for the two chains is carried out as a function of the hydrogen-bond length, R.

In the tight-binding MO calculation, it is important to determine the number of divisions for the wave vector, k. In a previous paper[18] on the ^{13}C chemical shift for polyethylene, we obtained the results that the ^{13}C chemical shift of polyethylene converges to a definite value as the number of the divisions increases. The magnitude of the variation of ^{13}C chemical shift is smaller than 0.1 ppm if the number of divisions exceeds 20. For this reason, we chose 60 and 30 points as the number of divisions for polyglycine and poly(L-alanine), respectively.

The calculations were performed on a HITAC M200H computer in the Computer Center of Tokyo Institute of Technology and a HITAC M200H computer in the Computer Center of Institute for Molecular Science, Okazaki.

Results and Discussion

Polyglycine. First, we are dealing with an isolated polymer chain. In Table 2 are shown the calculated and observed ^{13}C chemical shifts of a polyglycine chain with forms I and II. The calculated chemical

shift (σ) is a nuclear shielding constant and so the negative sign means deshielding. On the other hand, the negative sign of the observed chemical shift means shielding. Therefore, the relative difference in the calculated chemical shift (σ) should be compared with the observed chemical shifts (δ). The observed carbonyl ^{13}C chemical shift for form I appears at higher field by about 4 ppm than that for form II. The calculated ^{13}C chemical shift for form I appears at higher field by about 11 ppm than that in form II, which is in parallel with the experimental finding. There is no significant difference between the methylene ^{13}C chemical shifts for forms I and II within the experimental error. In this stage, we cannot determine whether the chemical shift for form I or II appears at higher field. On the other hand, the calculated ^{13}C chemical shift for form I appears at lower field by about 3 ppm than that for form II, so the calculation predicts the existence of a chemical shift difference (about 3 ppm) between forms I and II. It appears that the calculated shifts are somewhat exaggerated as compared with the observed values. Nevertheless, the observed trend that the ^{13}C chemical shift difference for the methylene carbon is considerably small compared with that for the carbonyl carbon, is reproduced qualitatively by the calculation. Accordingly, the overall trend in the observed conformation-dependent ^{13}C chemical shift of polyglycine can be qualitatively explained by the present calculation.[34]

Up to now we have dealt with an isolated polymer chain. However, real polymer chains in the solid state interact with each other. Especially, polyglycine has the hydrogen bond in both of forms I and II.[29-30] Form I has an antiparallel β-sheet structure and each chain has a hydrogen bond with both sides of the chains in the sheet. Form II has 3_1-helix structure and each chain is intermolecularly hydrogen-bonded to six surrounding chains. Therefore, it is important to investigate the effect of the hydrogen bond on the ^{13}C chemical shift. Then, we carried out a TB MO calculation on the ^{13}C chemical shift of polyglycine for forms I and II considering the effect of the hydrogen bond. In the TB MO

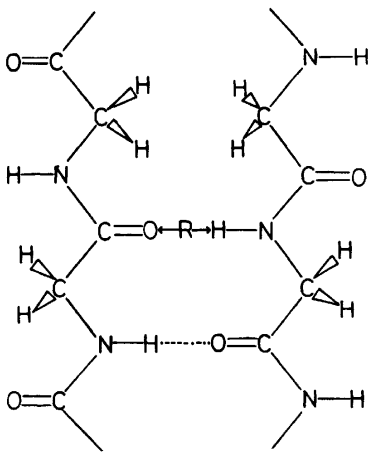

Fig. 1. The structure of two hydrogen-bonded β-sheet chains. R is the distance between oxygen and hydrogen atoms.

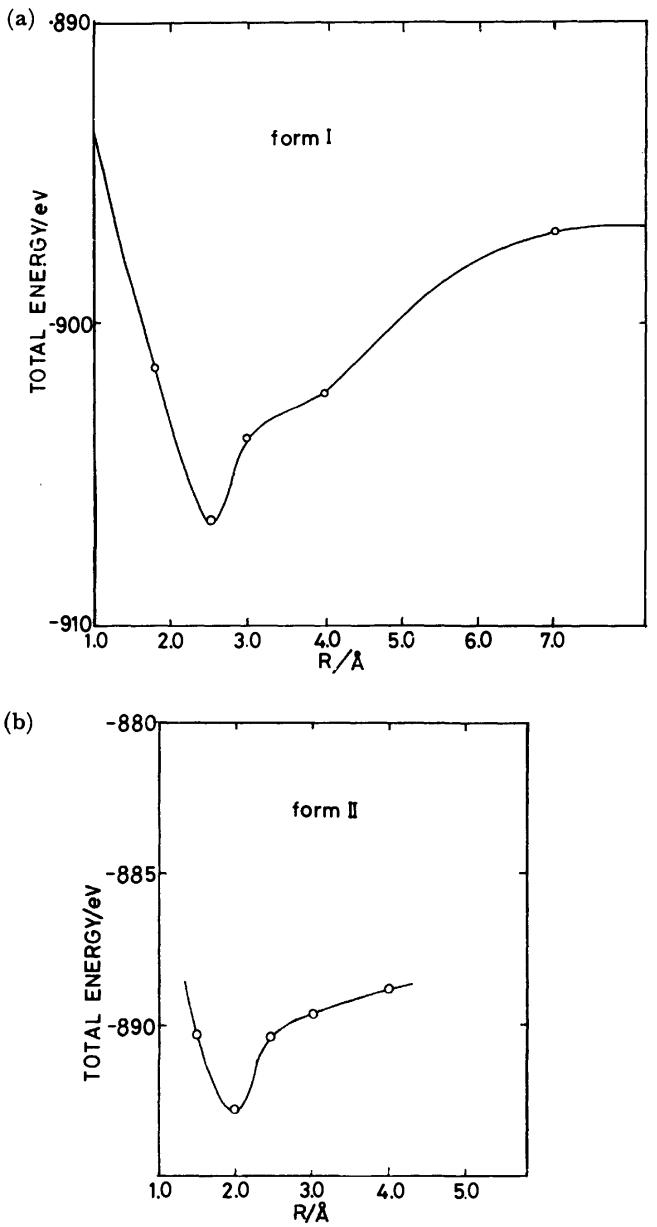

Fig. 2. The R dependence of the total electronic energy of polyglycine.
(a): form I, (b): form II.

calculation, it is not practical in this stage to treat the complete molecular structure of polyglycine in the solid state, which was determined from X-ray diffraction, because the TB MO calculation requires a very long calculation time and a large memory in the computer. Thus, instead of a real molecular structure, we will treat the two polyglycine chains which are hydrogen-bonded to each other (Fig. 1). In Fig. 1, R stands for the distance between the oxygen atom and the hydrogen atom bonded to the nitrogen atom. The TB MO calculation on the ^{13}C chemical shift was carried out as a function of R, in order to evaluate the influence of the hydrogen bond on the chemical shift. The calculation on form II was carried out in a similar manner. In Figs. 2 (a) and (b) is shown the R dependence of the total electronic energy of polyglycine in forms I and II, respectively. Obviously, form I has the energy minimum at about 2.5 A, and form II at 2.0 A. In the former the distance between the nitrogen and the oxygen atoms involved in the hydrogen bond for form I is longer than that for form II. It is known from an X-ray diffraction study that the distances between the nitrogen and oxygen atoms in forms I and II are 2.95 and 2.73 A, respectively.[30,31] Taking into account that the length of the N-H bond is 1.0 A, the above-calculated results are in parallel with the results found by X-ray diffraction: The length in form I is longer than that in form II.

Next, we will discuss the R dependence of the ^{13}C chemical shift for forms I and II. In Fig. 3(a) is shown the R dependence of the ^{13}C chemical shift of the carbonyl carbons for forms I and II. In the case of form I, for the carbonyl ^{13}C chemical shift moves downfield as R increases from 2 to 3.2 A, and upfield as R increases further from 3.2 A. In the case of form II, the carbonyl ^{13}C chemical shift moves downfield as R increases. Comparing this with the results for an isolated polymer chain, the carbonyl ^{13}C chemical shifts for both forms I and II appear largely downfield. This means that the carbonyl ^{13}C chemical shift moves largely downfield caused by the hydrogen bonding. At the minimum energy position (R=2.5 and 2.0 A for forms I and II, respectively), the carbonyl ^{13}C chemical shift for forms I and II are −274.9 and −286.2 ppm, respectively (Figs. 2 and 3). Thus, the carbonyl ^{13}C chemical shift for form I appears upperfield than that for form II, again consistent with the experimental finding. In Fig. 3(b) is shown the R dependence of the methylene ^{13}C chemical shift. The R dependence of the ^{13}C chemical shift of the methylene carbon is much smaller than that of the carbonyl carbon. Especially, the R dependence of the methylene ^{13}C chemical shift for form II is very small. This may be due to a fact that the carbonyl carbon is directly involved in the hydrogen bond, but the methylene carbon is not. In the case of form I, the methylene ^{13}C chemical shift moves to

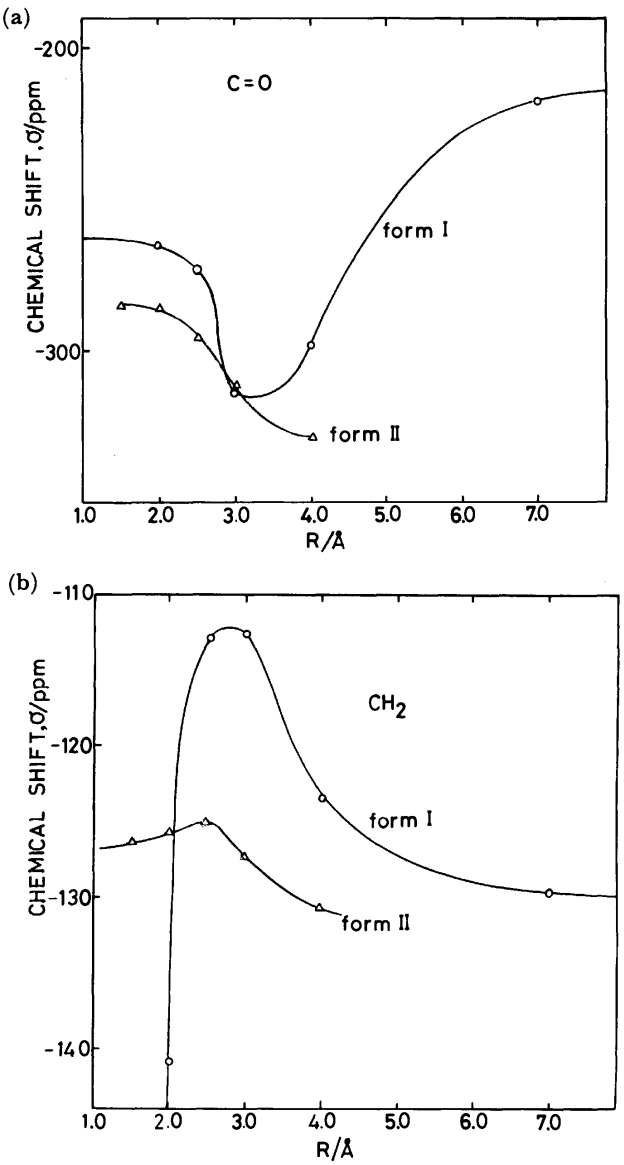

Fig. 3. The R dependence of the calculated ^{13}C NMR chemical shift of the carbonyl carbon (a) and methylene carbon (b) in polyglycine.
○: form I, △: form II.

upfield, as R increases from 2 to 2.8 A, and to downfield as R increases further from 2.8 A. In the case of form II, the ^{13}C chemical shift is similar to that of form I, but the magnitude of the change is much smaller compared with that for form I. At the minimum energy position the ^{13}C chemical shift of the methylene carbon for forms I and II are −112.9 and −126.0 ppm, respectively. Therefore it appears that the difference in ^{13}C chemical shift of the methylene carbon between forms I and II is much overemphasized. Experimentally, the ^{13}C chemical shift of the methylene carbon for form I is almost the same as that in form II. The ^{13}C chemical shift of the methylene carbon for form I changes largely in the vicinity of the energy minimum position, especially in the range of R between at 2.0

and 2.5 A. Therefore, this shows that the electronic structure of form I changes considerably in this region. As shown in Fig. 3(b), the ^{13}C chemical shift of the methylene carbon for form I moves to downfield as R decreases from the value at the energy minimum, and at the value of about 2.3 A it becomes almost equal to the ^{13}C chemical shift of the methylene carbon in form II. At this value of R, the ^{13}C chemical shift of the carbonyl carbon for form I appear at higher field than that for form II, and this result coincides with the observation. It is plausible that the R value obtained by the energy minimization of the two chains might be slightly modified by taking into account many chains in the solid state. Thus, by considering the hydrogen bond, we can reasonably explain the behavior of the ^{13}C chemical shift for forms I and II.

Poly(L-alanine) In Table 3 are shown the calculated and observed ^{13}C chemical shifts of poly(L-alanine). First, we consider the ^{13}C chemical shift of poly(L-alanine) taking the α-helix form. It is known that poly(L-alanine) has an right-handed α-helix(α_R-helix) form, but that the L-alanine residues are incorporated into the left-handed α-helix (α_L-helix) in D-alanine sequence in the random copolymers consisting of L- and D-alanines.[23] Therefore, we consider the ^{13}C chemical shifts of poly(L-alanine) in the α_R- and α_L-helix forms. We have already reported that the observed C_α and carbonyl ^{13}C chemical shifts of L-alanine residues incorporated into the α_L-helix form in the D-alanine sequence are between those in the β-sheet and α_R-forms and appears near that in the β-sheet form, while the C_β shift of the α_L-helix is close to that of the α_R-helix.[3-7] As seen from Table 3, the calculated ^{13}C chemical shifts of the C_α, C_β, and carbonyl carbons move to upfield (6.7 ppm), downfield (−1.3 ppm) and upfield(10.3 ppm), respectively, when the conformation changes from the α_R-helix to α_L-helix form. Experimentally, displacements of signals are 3.3, 0.0, 3.5, ppm for C_α, C_β, and carbonyl carbons, respectively. Therefore, the present calculation reproduces the experimental data.[34]

Next, we discuss the ^{13}C chemical shift for the β-sheet form. In the above calculation of α_R- and α_L-helix forms, we were able to include the O(=C) and H(-N)

Table 3. The observed and the calculated ^{13}C chemical shifts of an isolated poly(L-alanine) chain (in ppm)

	$\delta^{a)}_{obsd}$			$\sigma^{b)}_{calcd}$		
	α_R	α_L	β	α_R	α_L	β
$CH_3(C_\beta)$	14.9	14.9	19.9	−94.8	−96.1	−98.3
$CH(C_\alpha)$	52.4	49.1	48.2	−151.5	−144.8	−143.0

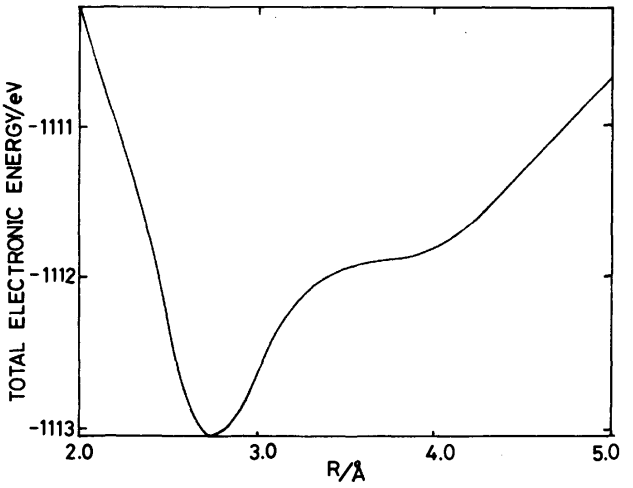

Fig. 4. The R dependence of the total electronic energy of poly(L-alanine) in the β-sheet form.

atoms making hydrogen bond without any difficulty. In the β-sheet form, where the hydrogen bonds are formed between chains, we calculated the ^{13}C chemical shift for the β-sheet form by taking into account the hydrogen bonds as a similar manner as that of polyglycine (Fig. 1). In Fig. 4 is shown the R dependence of the total electronic energy of poly(L-alanine). As seen from this figure, the energy minimum exists at R=2.75 A. From the results of an X-ray diffraction study, it is known that the distance between the nitrogen and oxygen atoms in the β-sheet form is 2.83 A.[29] If the distance between the nitrogen and hydrogen atoms is about 1.0 A, the distance between the oxygen and hydrogen atoms determined from the X-ray diffraction study is 1.83 A. The calculated results are longer than those from the X-ray diffraction, as also encountered in the calculation of forms I and II of polyglycine taking into account intermolecular hydrogen bonds. This may be due to the fact that the extended Hückel MO method is often apt to overestimate the polarity of a molecule. In Figs. 5 (a), (b), and (c) are shown the R dependences of the ^{13}C chemical shift of the C_α, C_β, and carbonyl carbons, respectively. It is shown that the ^{13}C chemical shifts of the C_α and C_β carbons moves to upfield from 2.0 to 3.6 A and downfield further from 3.6 A as R increases. On the other hand, in the case of the carbonyl carbon, the ^{13}C chemical shift moves to downfield from 2 to 3.7 A and then upfield above 3.7 A as R increases. The carbonyl carbon shows the largest R-dependence. This result agrees with the result for polyglycine. The carbonyl carbon is bonded directly to the oxygen atom by a double bond and a transfer of electrons from the carbon to the more electronegative oxygen occurs. At the energy minimum (R=2.75 A), the ^{13}C chemical shifts of the C_α, C_β, and carbonyl carbon are −144.5, −99.3, and −287.0 ppm, respectively, as seen from Fig. 5. These values of the C_α, C_β, and carbonyl carbon for the β-sheet form appear upperfield (7.0 ppm), lowerfield

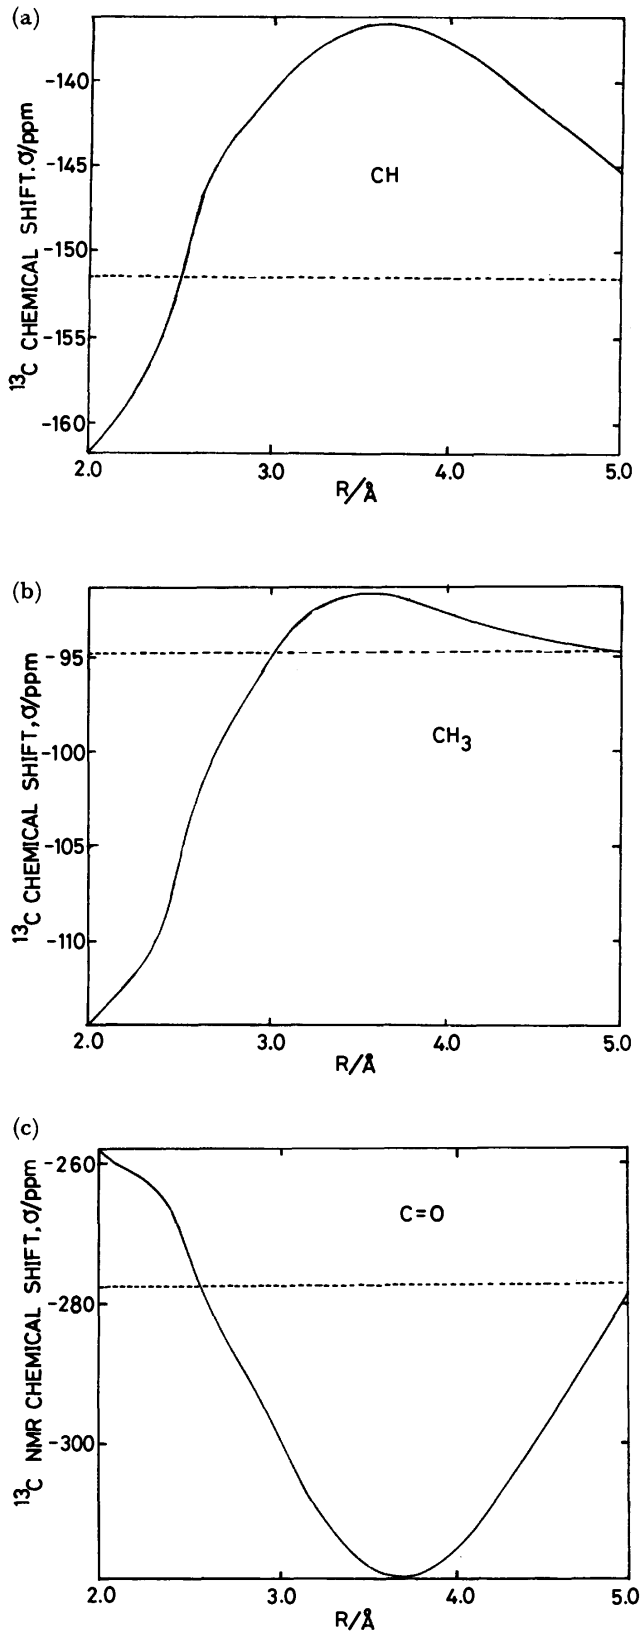

Fig. 5. The R dependence of the calculated ^{13}C NMR chemical shift of poly (L-alanine) in the β-sheet. The solid line is for two hydrogen-bonded β-sheet chains. The dashed line indicates the ^{13}C chemical shift value for an isolated α-helix chain.
(a): C_α, (b): C_β, (c): C=O.

(−4.5 ppm) and lowerfield (−8.9 ppm), respectively as compared with the shielding values of the α_R-helix form (Table 3). Experimentally, however, the ^{13}C NMR chemical shifts of the C_α, C_β, and carbonyl carbon for the β-sheet form appear upperfield (4.2 ppm), lowerfield (−5.0 ppm) and upperfield (4.6 ppm), respectively, compared with those for the α_R-helix. Therefore, it is shown that the calculated shielding constant for the carbonyl carbon at the minimum energy is not consistent with the experimental results, although the C_α and C_β chemical shifts are well reproduced. This is caused by that the carbonyl ^{13}C chemical shift is extremely sensitive to the hydrogen bond distance R. Another possibility is that the R value determined by the energy minimum should be slightly modified when many chains more than two chains are hydrogen-bonding in the real β-sheet form. Therefore, it is worthwhile to examine the "R" value which reproduces the experimental data instead of the R value at the energy minimum. For this, the ^{13}C chemical shift value for the α_R-form is indicated by the dashed line in Fig. 5. (The solid line indicates the ^{13}C chemical shift for the β-sheet form.) For the C_α, C_β, and carbonyl carbons both the lines intersect with each other at R=2.5 A, 3.0 A, and 2.56 A, respectively. Accordingly, the approximate value of R at which the calculated results are in parallel with the experimental result falls on the range of 2.5 to 2.56 A. This range is still longer than the length for the hydrogen bond determined from X-ray diffraction. Such an argument, however, arose from the use of an inadequate wavefunction such as the extended Hückel MO approximation. It is probable that this sort of problem might easily be resolved when more accurate wavefunctions such as CNDO, INDO or non-empirical theory are employed.

Nevertheless, the present calculation is very useful because the conformation-dependent ^{13}C chemical shifts in polypeptides are reproduced with some limitation. A more refined calculation using the tight-binding CNDO MO is in progress.

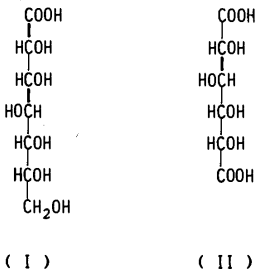
Interactions of Calcium Ions with Carbohydrates. The Crystal Structure of Calcium D-Glycero-D-gulo-heptonate Tetrahydrate

Tooru TAGA,* Taneno KAJI, and Kenji OSAKI
Faculty of Pharmaceutical Sciences, Kyoto University, Sakyo-ku, Kyoto 606
(Received June 30, 1984)

The crystal structure of the calcium salt of D-glycero-D-gulo-heptonic acid has been determined by the X-ray method. The crystal is monoclinic of space group $P2_1$ with unit-cell dimensions of a=10.064(1), b=10.540 (2), c=11.340(2) Å, and β=108.92(1)°. The intensity data for 1754 unique reflections were measured with an automatic diffractometer. A trial structure, obtained by the direct method, was refined by the full-matrix least-squares method to R=0.030. The two independent heptonate anions have different conformations, and they chelate a calcium ion in different ways. The calcium ion is surrounded by eight oxygen atoms in a deformed dodecahedral form, the Ca···O distances ranging from 2.40 Å to 2.48 Å. The distortion of the moleular strcuture of the heptonate anions due to the calcium chelation was discussed in relation to the calcium-binding sites on a linear carbohydrate chain.

The previous X-ray and NMR studies of interactions of calcium ions with carbohydrates in the solid and solution states have shown that the calcium ion is stereospecifically bound with a carbohydrate molecule and that the three-dimensional arrangement of the oxygen atoms of the carbohydrate chain is an important factor in forming a stable calcium-carbohydrate complex.[1] The geometry of the calcium-carbohydrate interactions in many crystalline complexes have been studied to date.[2] It has been reported that the C(6) carboxyl group of D-glucaric acid (II) is unlikely to interact with the calcium ion.[3-5] The carbohydrate chain of D-glycero-D-gulo-heptonic acid (I) has a relatively similar sequence to that of D-glucaric acid (II); the configurations around C(2), C(3), C(4), and C(5) in (I) correspond to the antipodal configurations around C(5), C(4), C(3), and C(2) respectively in (II). Thus the interactions of the calcium ions with the carboxylate (I) is of interest, and the X-ray analysis of the crystal structure of the title complex was undertaken. Since two crystallographically independent anions exist in the crystal structure, their molecular structures were compared in order to make clear the effect of the calcium chelation on the carbohydrate-chain structure.



(I) (II)

Scheme 1.

Experimental

Transparent needle-like crystals were grown by evapolating an aqueous 2-propanol solution of the calcium salt of D-glycero-D-gulo-heptonic acid. The crystal data are: $Ca^{2+}[C_7H_{13}O_8^-]_2 \cdot 4H_2O$, MW=564.5, monoclinic, $P2_1$, Z=2, a=10.064(1), b=10.540(2), c=11.340(2) Å, β=108.92(1)°, and D_x=1.647 g/cm³. The space group $P2_1$ was indicated by the systematic absence of $0k0$ reflections with k odd. The unit-cell parameters were determined by a least-squares analysis of the angular settings of 22 high-angle reflections, measured on a Rigaku AFC-5 diffractometer using a graphite-monochromated Cu $K\alpha$ radiation (λ=1.54178 Å).

The intensity data were collected with the AFC-5 diffractometer operating with a RU-200 X-ray generator (40 KV, 150 mA), using a crystal with dimensions of 0.10×0.14×0.33 mm. A total of 1894 reflections were recorded in the range of $2\theta<120°$ in the $\omega-2\theta$ scanning mode with a scan speed of 4° min^{-1} in ω. The scan width was $\Delta(\omega)=0.8°+0.5\tan\theta$. The data were corrected for Lorentz and polarization factors, and then converted to the F_o structure factors. No absorption correction was applied.

The structure was solved with MULTAN78[6] using 445 reflections for phase-generation. The first E-map revealed one calcium ion and eight oxygen atoms surrounding the calcium ion. Subsequent E-map synthesized with the phases including the contributions of these atoms produced a complete non-hydrogen-atom structure. The trial structure was refined by the full-matrix least-squares method using a modified version of the ORFLS program.[7] The minimized quantity was $\sum w(|F_o|-k|F_c|)^2$, where k was the scale factor, and the weight w was equal to $1/[\sigma^2(F_o)+0.0023F_o)^2]$. All the hydrogen atoms were located from the difference Fourier maps synthesized after several cycles of the least-squares refinement optimizing the positional and anisotropic thermal parameters of the non-hydrogen atoms. The refinements including the positional and isotropic thermal parameters of the hydrogen atoms converged to R=0.030 and R_w=0.041 [$R_w=(\sum w|F_o-kF_c|^2/\sum|F_o|^2)^{1/2}$] for 1754 reflections [$F_o>3\sigma(F_o)$]. Scattering factors for Ca^{2+}, C, O, and H were obtained from the International Tables for X-ray Crystallography (1974).[8] All the computations were performed on a FACOM M-382 in the Data-processing Center of Kyoto University.

Results and Discussion

Table 1 lists the non-hydrogen-atom parameters and their estimated standard deviations. Table 2 lists the hydrogen-atom parameters and their estimated standard deviations. The bond distances and the bond

angles, and the torsion angles, for the non-hydrogen atoms are listed in Table 3 and Table 4 respectively. The anisotropic thermal parameters of the non-hydrogen atoms and the observed and calculated structure factors are preserved at the Chemical Society of Japan (Document No. 8503).

The crystal structure, stereographically illustrated in Fig. 1, is stabilized by the hydrogen bonds and the calcium-oxygen interactions. All the hydrogen atoms of the hydroxyl groups and of the water molecules participate in the hydrogen-bond network. The distances and angles for the hydrogen bonds are listed in Table 5. As is shown in Fig. 2, one calcium ion binds four heptonate anions and one water molecule. One heptonate anion chelates the calcium ion through the carboxyl oxygen O(1A) atom, together with the α-hydroxyl O(2) atom, a second anion through the O(4′) and O(5′) pair of hydroxyl groups, a third anion through the O(6) and O(7) pair of hydroxyl groups, and a fourth anion through the single carboxyl O(1B) atom. Consequently, the calcium ion is surrounded by eight oxygen atoms in a deformed dodecahedron arrangement, as is shown in Fig. 3. The Ca···O distances range from 2.40 Å to 2.48 Å. These distances are the usual distances observed in the other calcium-carbohydrate complex crystals.[9] As has been described in the Introduction, the carboxyl group of the heptonate anion was assumed to be unfavorable to the calcium binding. Actually, in the present crystal structure, the carboxyl oxygen atoms of the primed anion have no direct interactions with the calcium ion, although those of the unprimed anion are bound to the calcium ion.

A perspective drawing of the structures of the two independent heptonate anions with thermal ellipsoids of 50% probability is shown in Fig. 4. The backbone conformations of the two moieties differ from each other mainly in the torsion angles around the C(2)-C(3) bonds: the C(1)-C(2)-C(3)-C(4) torsion angle is −77.4(4)°, while the corresponding angle for the primed anion is 82.1(4)°. The conformational difference may be caused by the different intermolecular interactions around the carboxyl groups, since the calcium-oxygen interactions about the carboxyl groups differ remarkably, as has been described above. Apart from the large conformational difference about the C(2)-C(3) bonds, the bond distortions due to the calcium chelation became apparent upon comparing the corresponding bond distances and angles of the two anions (see Table 3). In particular, the C-C-O valence angles are greatly changed by the calcium chelation, and the internal C-C-O angles of the five-membered ring formed by the O-C-C-O linkage with the calcium ion are smaller than those in the absence of the calcium ion. The change in the torsion angles due to the calcium chelation is also remarkable (see Table 4). The calcium chelation tends to decrease the absolute values of the O-C-C-O torsion angles, and the O···O nonbonding distances between the adjacent hydroxyl groups are significantly shorter than the corresponding distances without calcium chelation: O(4′)···O(5′) 2.585(4) Å and O(6)···O(7) 2.636(3) Å for calcium chelation, while O(4)···O(5) 2.753(3) Å and O(6′)··· O(7′) 2.776(4) Å without calcium chelation. These O···O distances in the case of the calcium chelation are smaller than the sum of van der Waals radii (3.04 Å) and also of the ionic radii (2.80 Å) of oxygen atoms. Concerning a calcium chelation by the two hydroxyl oxygen atoms of a linear carbohydrate

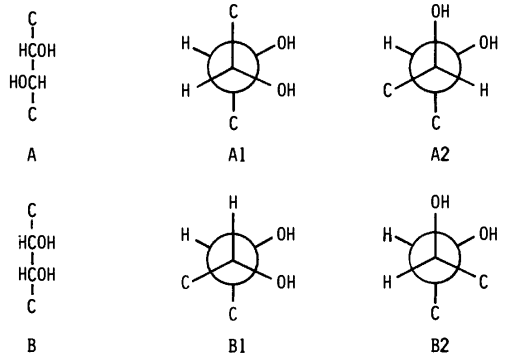
chain, it seems possible for four stable gauche conformations, represented as A1, A2, B1, and B2, to chelate a calcium ion. From a consideration of the bond distortions due to the calcium chelation described above, the B conformations are, however, unfavorable to the calcium chelation, because the calcium binding to B1 and B2 will decrease the absolute values of the O-C-C-O and C-C-C-C torsion angles and result in energetically unfavorable backbone conformations. On the other hand, the effects



Scheme 2.

of such bond distortions on the A conformers are small. For A2, a decrease in the absolute O-C-C-O torsion angle accompanies the increase in the absolute C-C-C-C torsion angle. The calcium chelation through the O(4′) and O(5′) atoms in the present crystal corresponds to Al. To our knowlege, there are no calcium chelation by the B conformations in the reported crystal structures of the calcium linear-carbohydrate complexes.[10-12] In conclusion, the calcium chelation by the two hydroxyl oxygen atoms decreases the absolute value of the O-C-C-O torsion angle; this fact indicates that, in general, the calcium chelation by the linear carbohydrate chain occurs selectively at the site of the configuration A in which the two hydoxyl groups are located on opposite sides of the carbon chain in the Fischer notation.

Excess Volume of Mixing of Quaternary Phosphonium Chlorides with Potassium Chloride in Water

Katsuko TAKAIZUMI* and Toshiki WAKABAYASHI
The College of General Education, Tohoku University, Kawauchi, Sendai 980
(Received July 2, 1984)

Volume changes upon mixing aqueous solutions of potassium chloride and the quaternary phosphonium chloride, n-$Bu_{4-n}Ph_nPCl$, (n=0—4), have been measured at various constant total ionic strengths (I=0.25, 0.5, 1.0) at 25 °C. Based on Friedman's theory for a mixed electrolyte solution, volume-interaction parameters, v_o, were determined at each ionic strength. The dependence of v_o on I shows that contributions to the excess volume due to structural effects of a pairwise interaction between the cations and triplet interactions including a single anion are most significant for the Bu_4P^+ ion and decrease with increasing n. A comparison of the v_o's with the excess-volume properties of the salts in each pure solution shows that the interaction between the phosphonium cations and the potassium ion results in negative contributions to the excess volume of mixing, which also decreases as n increases.

Measurements regarding the excess thermodynamic properties of aqueous mixed-electrolyte solutions have provided useful information on specific interactions between ions in solution.[1] Information on pairwise interactions between like-charged ions can be obtained by examining the mixing process of two kinds of electrolyte solutions containing a common counterion at constant ionic strength. Effects due to both the ionic atmosphere and oppositely charged ions are kept constant during the mixing process.

Wen and his associates[2,3] studied the excess volumes of mixing Δ_mV^E in the systems, tetraalkylammonium halides (R_4NX) and potassium halides, applying Friedman's theory[4] for mixed-electrolyte solutions. They found that the hydrophobic interactions between tetraalkylammonium ions are the major factors regarding the nonideal behavior of the mixtures in the case of R=propyl and butyl. They confirmed this conclusion by means of a more complete characterization of the hydrophobically induced cation-cation interaction.[5] They also suggested that cationic interactions between these R_4N^+ and K^+ ions gave positive contributions to Δ_mV^E.

In previous papers,[6,7] we determined the volume B-coefficients(B_v) for the quaternary phosphonium salts, n-$Bu_{4-n}Ph_nPX$, and concluded that the B_v's, which are all negative, reflect mainly the effects resulting from the cation-cation interactions. The time-averaged clathratelike hydration model seemed to be plausible for the butyl groups but not for the phenyl groups. Further, the B_v's were decomposed into contributions arising from the butyl-butyl, phenyl-phenyl, and butyl-phenyl interactions.

In this study, we carried out measurements to determine the excess volumes upon mixing quaternary phosphonium chloride with potassium chloride at constant ionic strength.

Experimental

Materials and Apparatus. The five quaternary phosphonium salts(n=0—4) were obtained and purified as previously reported.[8] The potassium chloride delivered from Merck(Suprapur) was used without further purification.

Volume changes upon mixing were measured using Hashitani's cells,[9] with some modification (Fig. 1). The cells(quartz) have a total capacity of *ca.* 60 cm^3. Each cell is divided into two rooms by a disk with a mirror surface. The room capacities were calibrated five times using conductivity water with a standard deviation of 0.004 cm^3. The capillary tubing attached at the top of the cap(Pyrex glass) had an inner diameter of *ca.* 0.6 mm with a minimum graduation of 0.0005 cm^3. This was calibrated using mercury. The inside of the capillary was coated with sillicon grease as previously reported.[10] Leakage of the solution through the disk separator was checked spectrophotometrically using a set of solutions, pure water(upper room) and a dye solution (lower room). No leakage was found.

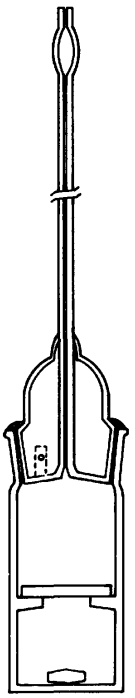

Fig. 1. The cell for measurering Δ_mV^E.

Measurements of $\Delta_m V^E$. Throughout the following procedures, the cells were kept in a water bath (25±0.003 °C). The two solutions, which had been degassed and equilibrated to the bath temperature, were introduced stepwise into each separated room. The cap was fixed with Decotinsky cement after adjusting the meniscus height in the capillary. The cell was thoroughly immersed in the bath and the equilibrium meniscus-height(initial volume) was read with a precision of 1×10^{-4} cm^3. Then, the disk separator was shifted by turning the cell upside down, the contents were thoroughly mixed by a magnetic stirrer, and the final meniscus-height(final volume) was measured.

Generally, for every mixing system, the measurements were carried out for more than ten of volume ratios and at ionic strengths of 0.25, 0.5, and 1.0 (mol kg^{-1}). The volume changes of mixing ranged from 0.002 to 0.03 cm^3.

Results and Discussion

The Friedman's theory for mixed electrolytes[4] leads to an expression for the excess volume of mixing two electrolyte solutions of identical ionic strength I as;

$$\Delta_m V^E/W = I^2 y(1-y)[v_o + (2y-1)v_1], \quad (1)$$

where W is the weight(kg) of the solvent water and y the mole ratio of one electrolyte to the total electrolytes and $v_0, v_1, ..$, are the volume-interaction parameters. The quantity of lhs. of Eq. 1 is the excess volume of mixing per kg of solvent and is related to the experimental data through the equation

$$\Delta_m V^E/W = mV_\phi(\text{mixture}) - ymV_\phi(\text{AX}) - (1-y)mV_\phi(\text{BX}) \quad (2)$$

where V_ϕ(MX) is apparent molar volume of MX in its pure solution, m the molality(equal to I in the present systems) and X, a common anion. The interaction parameters may be expressed as[11]

$$v_o = v_{\text{pairs}} + Iv_{\text{triplets}},\ v_1 = Iv^1_{\text{triplets}} \quad (3)$$

$$v_{\text{pairs}} = 2v^*_{AB} - v^*_{AA} - v^*_{BB}\cdots, \quad (4)$$

where v_{pairs} is the contribution to the excess volume of mixing from pairwise interactions between cations and v_{triplets} is the contribution from the triplet interactions of the cation-cation-anion type and; v^1_{triplets} is the contribution from the other types of triplet interactions. The v^*_{ij}'s are functions of ionic strength. In this paper, subscripts A and B stand for the phosphonium cation and the potassium ion, respectively. As employed by Wen and Nara,[3] the difference of excess volumes of two separate solutions, v^*, at an identical ionic strength I can be expressed by,

$$v^* = [V^E(\text{BX}) - V^E(\text{AX})]/I^2 = v^*_{BB} + 2v^*_{BX} - v^*_{AA} - 2v^*_{AX}\cdots \quad (5)$$

The excess volume can be written in the form,

$$V^E(\text{MX}) = m(V_\phi - \overline{V}^\circ) = m(A_v m^{1/2} + B_v m + C_v m^2 + \cdots) \quad (6)$$

where $\overline{V}^\circ$ is the standard partial molar volume of MX, and A_v is the Debye-Hückel limiting slope and; B_v, C_v,.. are empirical parameters. Combining Eq. 6 with Eq. 5, we obtain the relation,

$$v^* = B_v(\text{BX}) - B_v(\text{AX}) + I[C_v(\text{BX}) - C_v(\text{AX})]\cdots \quad (7)$$

In Fig. 2, the volume changes of mixing per kg of solvent water are plotted against the mole ratio of the phosphonium salt, y, at three ionic strengths and 25 °C. The height of a curve at y=0.5 gives v_o and the skewness is governed by v_1 (Eq. 1). As the ionic strength decreases, the skewness becomes less, and almost disappears at the lowest ionic strength, 0.25 mol kg^{-1}, for all systems examined. The values for the volume-interaction parameter v_o (Eq. 1) were determined from $\Delta_m V^E$ by a least-squares method based on Eq. 1 and are tabulated in Table 1, along with the B_v's.[6,7] Figure 3 is a plot of the v_o against the ionic strength, where the systems Me_4NBr/KBr and Bu_4NCl/KCl[2] are also shown, for comparison.

In general, two effects may be accompanied by the mixing process. One is the dilution effect for ions, which will result in a decrease in cosphere overlapping between the phosphonium cations as well as other ions. This effect for the salt AX at low concentrations is approximately expressed by the volume B-coefficient with a negative sign, $-B_v$(AX). Another is the effect due to the occurrence of a new type of cationic interaction pair, that is, the phosphonium cation and the K^+ ion, which is expressed by v^*_{AB} (Eq. 4).

As seen from Eqs. 3 and 4, the v_o value at I=0 reflects cationic pairwise interactions only. However, to experimentally determine $v_o(I=0)$ is very difficult because

Table 1. Volume interaction parameter v_o(Eq. 3) and v^*(Eq. 5)[a]

	Bu_4PCl		Bu_3PhPCl		Bu_2Ph_2PCl		$BuPh_3PCl$		Ph_4PCl

B_v[b]	−16.71		−10.52		−7.87		−5.81		−5.77	

a) Units; v_o and v^*/cm^3 kg mol^{-2}, B_v/cm^3 dm^3 mol^{-2}. b) Ref. 6 and 7.

$\Delta_m V^E$ is proportional to the square of the ionic strength (Eq. 1). The curves in Fig. 3 suggest large positive values for $v_o(I=0)$, showing that the pairwise interactions are large for all the systems ($n=0$—4). If the assumption is made that the activity coefficients of the ions are constant independent of ionic strength, then we can expect a linear relation between v_o and I, as discussed by Wen[11] (*cf.* Eq. 3). Since the dependence of the activity coefficient of ions on ionic strength decreases with increasing I, we can conclude that the successive substitution of phenyl groups of the Ph_4P^+

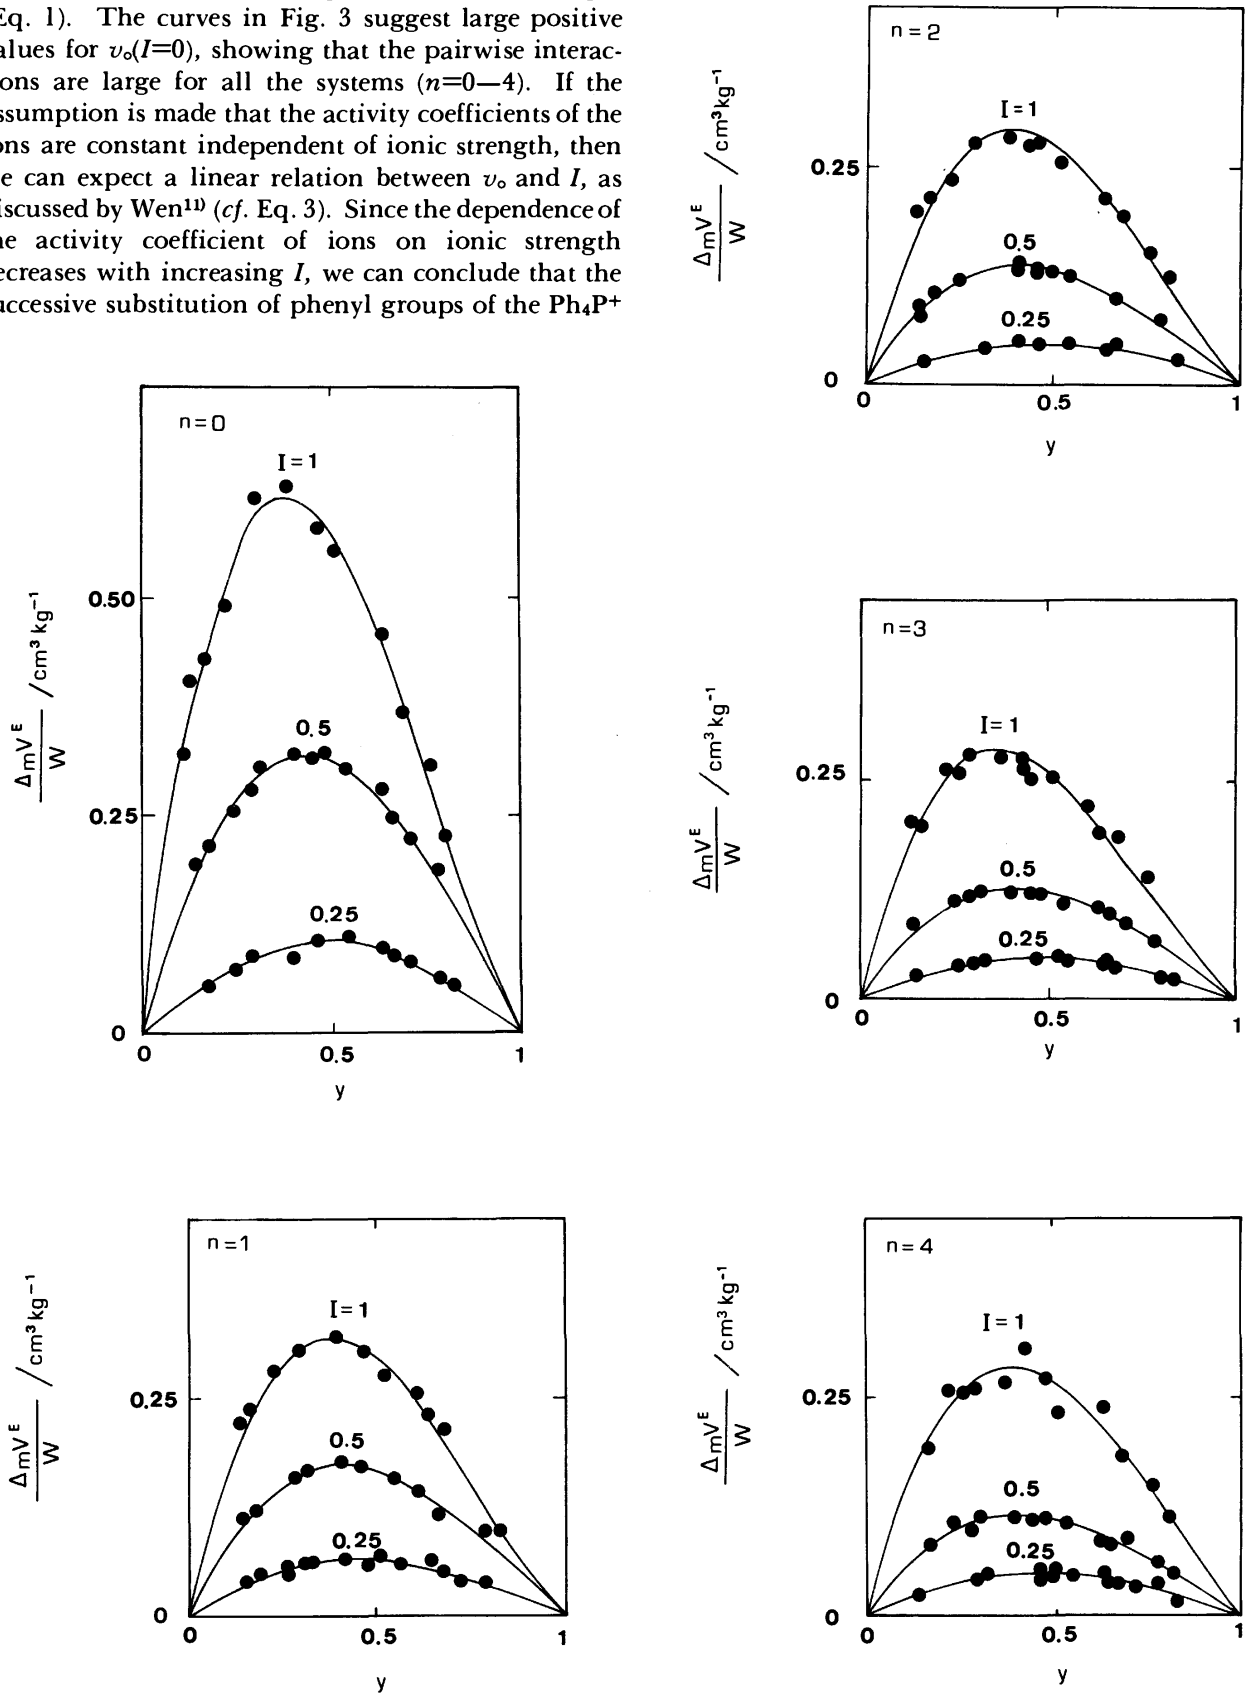

Fig. 2. The volume changes on mixing per kg of solvent water as functions of the mole ratio (y) of phosphonium chloride in the system, n-$Bu_{4-n}Ph_nPCl$/KCl ($n=0$—4), at 25 °C.

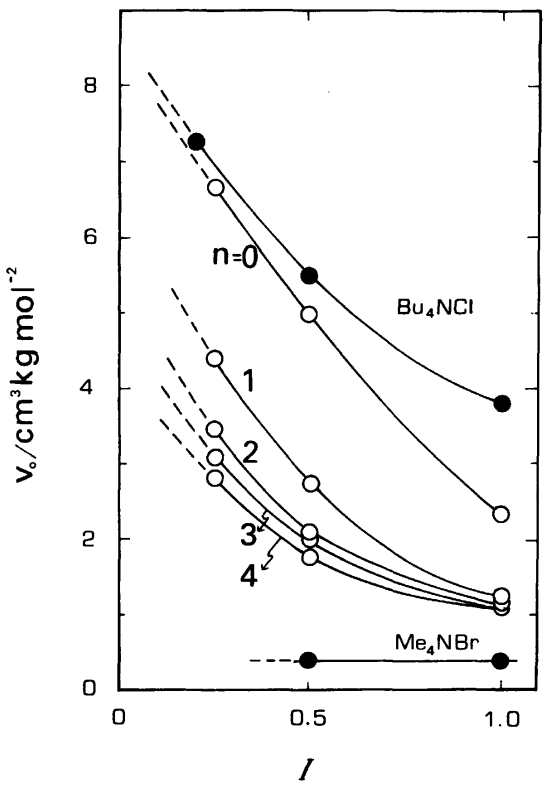

Fig. 3. The volume interaction paramenters v_o(-○-) in the systems, $Bu_{4-n}Ph_nPCl/KCl$ (n=0—4), as functions of ionic strength I, at 25 °C. The data for the systems Bu_4NCl/KCl and Me_4NBr/KBr, (-●-), were taken from Ref.2.

ion by butyl groups results in elevating the triplet and higher order interactions. This is illustrated in Fig. 3 and seems to be consistent with the clathrate-like hydration model for a butyl group assumed in previous studies.[6,7] The remarkable decrease in $V_o(Bu_4PX)$ with concentration was attributed to pairwise interaction between the cations in low concentrations and higher order interactions including the anions at high concentrations in which water-separated pairing of the cations was regarded as essential to reduce the solution volume.

It was shown in previous papers that the B_v's are negative for all the phosphonium halides (n=0—4) and mainly reflect contributions from the cation-cation interactions, that is, v_{AX}* in Eq. 5 would be relatively much smaller in magnitude than v_{AA}*. The small B_v value for KCl, 0.08 cm^3 mol^{-2} dm^3 [12], suggests that v_{BB}*+2v_{BX}* (Eq. 5) would be negligible in comparison with the large magnitudes of v_{AA}* for the phosphonium cations. A comparison of v_o's with v*'s (Table 1) reveals that all the v_o values are considerably smaller than the v* values, about halves of v*'s, even at the ionic strength of 0.25 where the v* values for all the systems are close to the magnitudes of B_v(AX)'s (*cf.* Eq. 7). Thus, it follows that the interactions between unlike cations (v_{AB}*) are mostly responsible for the differences between the magnitudes of v_{pairs} and v*. This difference is largest for a system with n=0 and decreases with n, indicating that the butyl cosphere-K^+ interaction results in decrease in solution volume.

This conclusion is contradictory to a suggestion made by Wen,[11] who attributed the difference found for the n-Bu_4NCl-KCl system to the Bu_4N^+-Cl^- interaction.

The second hydration layer, the B-zone in the Frank and Wen's hydration model, of the Bu_4P^+ ion would be more structured and, hence, more bulky than bulk water, as illustrated by a Monte Carlo simulation for a methane molecule in water.[13] Thus, the negative change in volume accompanied by the butyl-K^+ interaction is explicable if the assumption is made that the K^+ ion breaks the second layer structure of the butyl cosphere but not the first layer; if the K^+ ion breaks also the first layer a volume increase should be accompanied owing to disappearence of the caging effect,[11] which is assumed for clathrate-like hydration.

It is of interest to note that the interaction between the Ph_4P^+ and K^+ ions also contributes negatively to the solution volume, *i.e.*, v_{AB}*<0, even though the Ph_4P^+ ion behaves not always as a structure maker for solvent water[10] and its hydration dissimilar to clathrate-like one is assigned. In this regard, the Geiger's hydration model is of interest. Geiger[14] has simulated the effect of charges on the hydration of a nonpolar spherical solute with the size of a Xenon atom by the molecular dynamic technique. He obtained the result that the originally rigid hydrophobic hydration shell (zero charge) is "softened" from its inner sphere and its outer sphere remains more or less unchanged when electric charges below unit are given. If the delocalized charges on the phenyl groups[15,16] play a role in a way similar to this model, the water molecules in the B-zone of the groups would be more structured than bulk water and, hence, the interaction between the B-zone and the K^+ ion could result in a negative contribution to the solution volume due to a relaxing of the structured water in the B-zone to the bulk water.

For intermediate systems with n=1—3, the behavior found in v_{AB}* can be understood qualitatively as the sum of the effects found in the systems with n=0 and 4.

Delayed Fluorescence in Mixed Crystals Due to the Direct Resonance Interaction, as Revealed by Excitation Duration and Intensity Effects on the Decay Behavior

Shoji TAEN* and Yasuhiko GONDO

Department of Chemistry, Faculty of Science, Kyushu University 33, Hakozaki, Higashiku, Fukuoka 812

(Received July 6, 1984)

The decay of the temperature-independent delayed fluorescence observed in the mixed crystals of phenanthrene in the biphenyl host has been studied at 77 K. That triplet molecules are involved in the mechanism for the emission of temperature-independent delayed fluorescence has been shown by observing the intensities at the instances of the short-pulse excitations effected with different dark periods after the steady-state excitation. It has been found that both the excitation duration and the excitation light intensity affect the decay behavior of the temperature-independent delayed fluorescence. The decay after short-pulse excitation has been observed to be more rapid than the decay after prolonged excitation with the same intensity. When the excitation light intensity is increased with a fixed duration, the delayed fluorescence is observed to decay more rapidly. It is concluded that the decay behavior of the temperature-independent delayed fluorescence can be accounted for in terms of the direct-resonance-interaction mechanism.

The delayed fluorescence (DF) of organic compounds has attracted the attention of many investigators,[1] and different aspects of it, such as the temperature dependence,[2-6] the magnetic-field effect,[7-10] and the caging effect,[11] have been studied. Accordingly, the nature of DF is fairly well understood, and DF is now an important probe for studying excited states. For example, the singlet-triplet (S-T) absorption spectrum can be determined by measuring the DF excitation spectrum,[12] and the Davydov splitting in a certain CT molecular crystal was measured from the doublet DF-ODMR (optically detected magnetic resonance) signals.[13] However, some aspects of DF are still not understood. The existence of temperature-independent delayed fluorescence (TIDF) in organic mixed crystals, in addition to the usual temperature-dependent delayed fluorescence (TDDF), has been reported by several investigators.[3b,5,14,15] The mechanism for TDDF is ascribed to the triplet-triplet (T-T) annihilation between a thermally produced triplet exciton and a guest triplet state.[2-6] As for the mechanism for TIDF, though several possible mechanisms have been suggested thus far,[3,15] no definite one has been proposed. Because of the lack of sufficient experimental data on the TIDF, the discussion of the mechanism for TIDF has reached a dead end, and a breakthrough has been longed for.

Decay characteristics provide further knowledge about the mechanism for DF. In view of the nonexponential decay behavior of TIDF,[3,4] it was felt by the present authors that a careful study of the form of the decay curves would yield some information about the nature of TIDF. In a previous brief report on the benzo[*f*]quinoline-biphenyl mixed-crystal system, we have shown for the first time that the excitation duration markedly affects the decay behavior of TIDF at 77 K.[16] In this study, it has also been found that the excitation-light intensity affects the decay behavior of TIDF. We wish here to report these new effects and to discuss the mechanism for TIDF. Technically, the measurement of the excitation-light-intensity effect has been made possible as a result of the recent advent of data-processing instruments such as microcomputers and digital memories, which enable us to measure the decay curves of intrinsically weak TIDF easily and accurately.

Experimental

Chemicals and Samples. Phenanthrene (Tokyo Kasei, EP) was subjected to the chemical treatment described previously.[17] Biphenyl (Wako, EP) was twice recrystallized from ethanol and zone-refined over 200 passes. Then, a central portion of the ingot, the purest portion, was subjected to an additional 200 passes of zone refining. The polycrystalline samples were prepared between two fused-silica disks as has been described previously.[14] The guest concentration has been chosen to be fairly high, that is, 1.0×10^{-2} mol/mol, since the TIDF intensity is generally low.

Apparatus. Optical measurements were made on the apparatus illustrated in Fig. 1. The analyzing system consisted of a 220-mm grating monochromator (Spex, Doublemate 1672) equipped with a photomultiplier (HTV, R106), a DC preamplifier incorporating an operational amplifier (Teledyne Philbrick, 1009), a transient converter (Riken Denshi, TCB1000S-11), and a microcomputer (Fujitsu, MB25020). As a square-wave excitation source, mechanically-chopped radiation from a 250-W high-pressure mercury lamp (Ushio Electric, USH-250D) was used, in combination with a 5-cm optical-path aqueous filter. The mechanical chopping was effected by means of an electromagnetic shutter (shutter E in Fig. 1, Vincent Associates, 26LOAOX5), operated by means of a home-made control system incorporating multivibrators (Toshiba, TC4528BP) and Darlington configurations of transistors. When the excitation-light-intensity dependence was measured, calibrated neutral filters made of brass-wire gauze were used to modify the excitation-light intensity. Another shutter of the same model (shutter A in Fig. 1) was used in order to exclude the prompt fluorescence. Shutter A was opened with a delay time of about 5 ms after the cessation of excitation. The delay time is mainly determined by the operation of the control system. The intrinsic response time of the

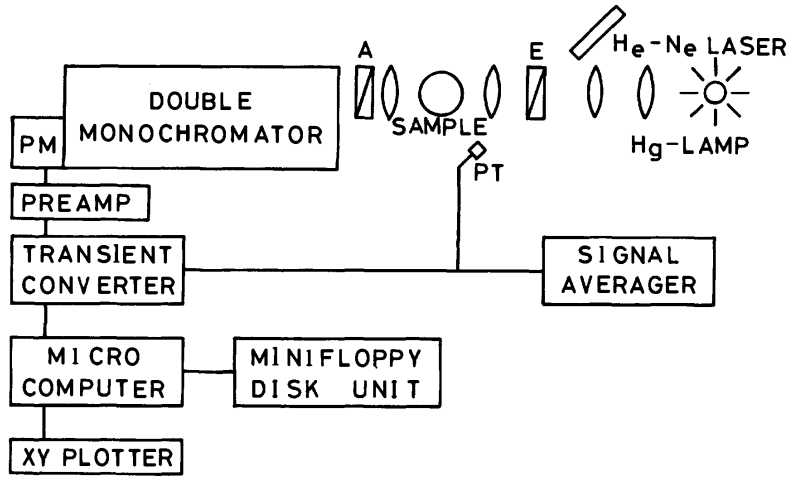

Fig. 1. A block diagram of the apparatus. A and E are electromagnetic shutters. PM and PT stand for photomultiplier and phototransistor, respectively.

shutters is claimed to be of the order of 1 ms. The delayed luminescence decay signals were memorized on the transient converter. After a measurement run, the data were transmitted from the transient converter to the microcomputer, utilizing an RS-232C interface with 9600 bauds. This interface circuit was a home-made one incorporating a UART (Intersil 6402). The transmitted data were stored on a minifloppy disk (Epson, F100A). The analyzed results were displayed on an XY plotter (Graphtec, MP1000). The operation of the shutter E was monitored on a digital memory device (Nicolet 1170 signal averager), displaying the output of a phototransistor illuminated by a He–Ne laser (NEC, GLG5000). The output signal in turn triggered the transient converter. The delayed luminescence spectra were measured in the square-wave excitation.

Results and Discussion

General Remarks on the Spectra and the Temperature Dependence of the Spectral Intensities. Figure 2 shows the delayed luminescence spectra obtained at 77 K with a train of square-wave excitations. For comparison, the prompt fluorescence spectrum is also shown in Fig. 2, comfirming that the observed DF is genuine. As the shortest wavelength fluorescence band tends to be affected by reabsorption, the excitation-duration effect and the excitation-light-intensity effect have been studied with the f band for DF. The phosphorescence decay curve has been observed on the p band, where the T–T absorption spectrum does not overlap the phosphorescence spectrum.[18] In this paper, t signifies the time elapsed after the cessation of excitation.

As has been reported by Misra,[15] the DF and phosphorescence intensities show characteristic temperature-dependences. As the temperature is raised from 6 K, the DF intensity is constant up to about 80 K. TIDF is observed throughout this temperature range. Then it increases to reach a maximum at about 160 K and decreases thereafter. The phosphorescence intensity decreases monotonically as the temperature is raised from 6 K to 180 K, and the DF observed at 77 K consists essentially of TIDF alone.

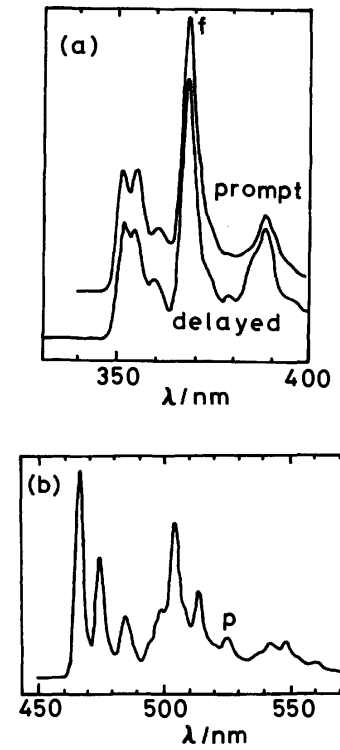

Fig. 2. Delayed luminescence and prompt fluorescence spectra. (a) Delayed and prompt fluorescence and (b) phosphorescence.

Energy Reservoir. As the spectrum of TIDF coincides with that of the prompt fluorescence, the final process of TIDF is a transition from the lowest excited singlet state to the ground state. However, TIDF emission continues for about 2.5 s after excitation is

removed. Therefore, the mechanism for TIDF must involve long-lived excited states. The most probable candidate for this energy reservoir is a triplet state. In this section, we will present experimental evidence that the guest triplet-state molecule is a constituent of the TIDF mechanism.

The phosphorescence decay is nearly exponential, with a lifetime of 3.8 s, and the TIDF intensity becomes negligible 2.5 s after the excitation light is extinguished. Consequently, that triplet molecules are involved can be shown by comparing the TIDF intensities at the instances of the short-pulse excitations effected with different dark periods after a steady-state excitation. The actual experimental procedure is as follows. The steady-state excitation is performed from −5 to 0 s, and then a 20-ms excitation is performed after a certain dark period in the course of the phosphorescence decay. The next set of 5-s and 20-ms excitations are performed after a period of darkness long enough for the triplet concentration, as estimated by monitoring the phosphorescence, to have fallen to a negligible value. The dark periods between the 5-s and 20-ms excitations have been chosen to be 0, 0.284, 0.549, 1.101, 1.616, 2.226, 2.750, 3.188, 3.750, 3.938, 4.490, 4.918, 9.740, and 60 s. The observed results are shown in Fig. 3, where, for comparison, the decay curve of phosphorescence is also shown. It may be noted that the intensities for the dark periods of 2.750 through 9.740 s are greater than that with the prolonged dark period of 60 s. Thus, it is proved that the guest triplet state is necessary for TIDF, since the excited state persisting for 10 s and disappearing at 60 s after excitation is the triplet state, as can be seen from the phosphorescence decay in Fig. 3.

The next problem to be solved is the number of triplet-state molecules which are required to produce one excited singlet state. Attempts were made to ascertain the dependence of the TIDF intensity, I_{TIDF}, on the phosphorescence intensity, I_P, when the excitation-light intensity, I_{exc}, was altered. The TIDF and phosphorescence intensities were measured as the integrated output obtained by the repetition of 20-ms excitations and 20-ms observations, with intervals of 10 ms between excitations and observations. The interdependence of $I_{TIDF} \propto I_P^{1.7}$ has thus been confirmed. The deviation from the square law may be brought about by the dead time of 10 ms in the operation of the two electromagnetic shutters, since the difference between the rates of disappearance of TIDF and of the phosphorescence is considerable. There are two alternative interpretations of this; *i.e.*, the above experimental facts indicate that two triplet-state molecules or one triplet-state molecule and one photon of excitation light produce one excited-singlet-state molecule, which is then responsible for TIDF. In phenanthrene, twice the energy of the lowest excited triplet state is larger than the value of the energy of the lowest excited singlet state. Consequently, both interpretations of the biphotonic nature are conceivable.

Possible Mechanisms. Here, in an effort to pick possible mechanisms for TIDF, we will list the mecha-

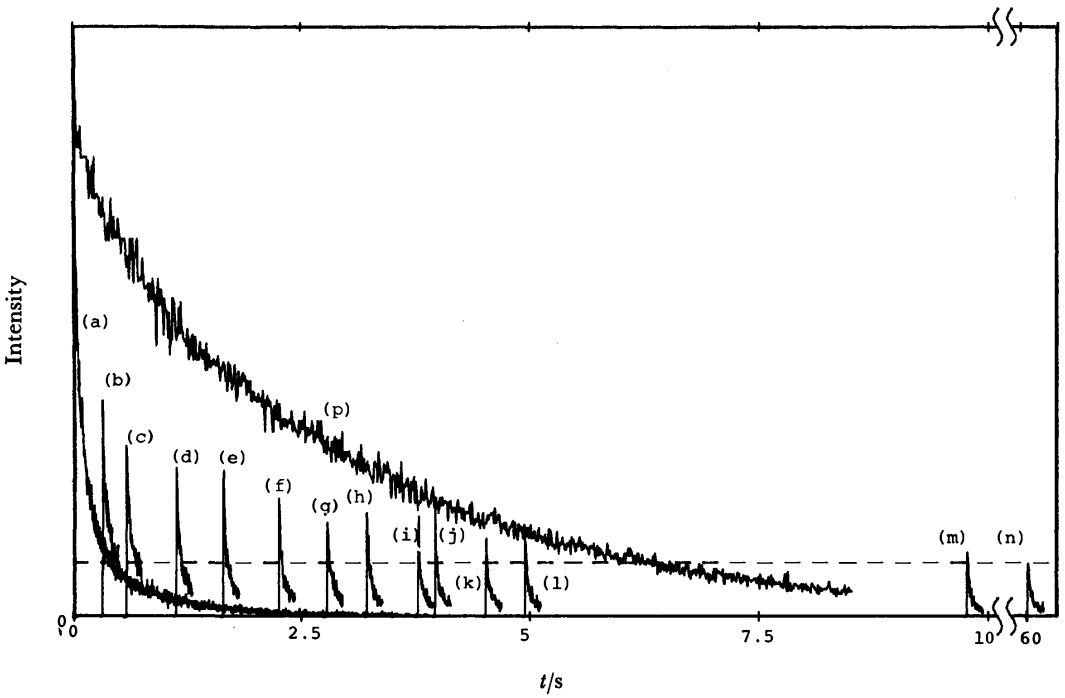

Fig. 3. Decay curves of delayed fluorescence and phosphorescence. (p) Phosphorescence decay after 5 s excitation. (a—n) TIDF decays by successive double pulse excitations. The excitation durations of the first and second pulses are chosen to be 5 s and 20 ms, respectively. The dark periods between the first and the second pulses are (a) 0, (b) 0.284, (c) 0.549, (d) 1.101, (e) 1.616, (f) 2.226, (g) 2.750, (h) 3.188, (i) 3.750, (j) 3.938, (k) 4.490, (l) 4.918, (m) 9.740, and (n) 60 s, respectively.

nisms proposed thus far for DF. The E-type,[1a] Williams-Stevens,[1a] exciton-splitting,[19] recombination,[20] trap,[4] P-type,[1a] exciton-migration,[2-6] direct-resonance-interaction,[3,4,19] double-excitation,[1a] and reabsorption mechanisms[1a-3,19] have all been proposed in the literature. According to the preceding discussion, the mechanism for TIDF must involve two triplet-state molecules or one triplet-state molecule and one photon of excitation. Then, the possible mechanisms for TIDF are the direct-resonance interaction, double-excitation, and reabsorption mechanisms.

In the case of the direct-resonance-interaction mechanism, two separately produced guest triplet molecules interact with each other and energy transfer occurs from one triplet-state molecule to the other. A highly excited state will eventually be produced, and once produced it will revert to the lowest excited singlet state or the triplet state with a significantly higher probability than excitation back to the initial state. The excited singlet state thus produced emits TIDF.

In the case of the double-excitation mechanism, a guest molecule is first excited to a triplet state, and then this triplet-state molecule is excited to a higher excited state X by a second quantum of light. The excited state X thereafter reverts partially to the lowest excited singlet state.

In the case of the reabsorption mechanism, one triplet molecule reaches a higher triplet/singlet state by reabsorbing the energy that another triplet radiates as phosphorescence.

Of these three mechanisms, the first, the direct-resonance interaction mechanism, is the most probable, because this is simply a special case of the mechanism for TDDF, as will be detailed below. The mechanism for TDDF may be summarized as follows:[4]

$$S_0 + h\nu \rightarrow S_1 \quad \text{(absorption)} \quad (1)$$
$$S_1 \rightarrow S_0 + h\nu \quad \text{(fluorescence)} \quad (2)$$
$$S_1 \rightarrow S_0 \quad \text{(relaxation)} \quad (3)$$
$$S_1 \rightarrow T_1 \quad \text{(intersystem crossing)} \quad (4)$$
$$T_1 \rightarrow S_0 + h\nu \quad \text{(phosphorescence)} \quad (5)$$
$$T_1 \rightarrow S_0 \quad \text{(relaxation)} \quad (6)$$
$$T_1 + T_1 \rightarrow S_1 + S_0 \quad \text{(annihilation)} \quad (7)$$
$$T_1 + T_1 \rightarrow T_1 + S_0. \quad \text{(annihilation)} \quad (8)$$

TDDF is ascribed to the fluorescence emitted by the S_1 state produced in the process of Eq. 7. Equation 7 is an abbreviated representation of thermal excitation, exciton migration, and annihilation and is realized as follows;

$$T_1 \rightleftarrows T_1^* \quad \text{(thermal excitation)} \quad (9)$$
$$T_1^* + S'_{0H} \rightleftarrows S_0 + T'_{1H} \quad \text{(energy transfer from guest to exciton)} \quad (10)$$
$$T'_{1H} + S_{0H} \rightleftarrows S'_{0H} + T_{1H} \quad \text{(exciton migration)} \quad (11)$$
$$T_{1H} + S_{0H} \rightleftarrows S_{0H} + T_{1H} \quad \text{(exciton migration)} \quad (12)$$
$$T_{1H} + S''_{0H} \rightleftarrows S_{0H} + T''_{1H} \quad \text{(exciton migration)} \quad (13)$$
$$T''_{1H} + T_1 \rightarrow S''_{0H} + S_1, \quad \text{(annihilation)} \quad (14)$$

where the subscript H identifies the host species; the primed symbols identify host molecules which are adjacent to guest molecules, and T_1^* is a vibrationally excited triplet state of the guest with an energy comparable to the host triplet-exciton band. (For more detailed information, Ref. 4 can be referred to.) Equation 9 represents a thermal excitation of the guest triplet state. As the mechanism for TDDF involves the thermal excitation of Eq. 9, TDDF can be said to depend on the temperature. Equation 12 stands for one-step migration or many-step migration, as the case may be. Equation 14 represents the process of energy transfer from a host triplet-state molecule to a guest triplet-state molecule. Kinoshita and McGlynn[4] assumed that the energy transfer of Eq. 14 was operative between adjacent molecules and explained the behavior of TDDF satisfactorily. However, we assume that energy transfer by long-range interaction can also be operative with a relatively small probability. This process may be rendered undetectable by competing fast exciton diffusion and process of Eq. 14 at high temperatures where TDDF is intense. At low temperatures where the process of Eq. 9 is ineffective, long-range direct-resonance interaction between guest molecules is predominant to give rise to DF, which is here called TIDF, because the fast, competing process favoring TDDF is absent. Therefore, Eqs. 9 through 13 do not apply at low temperatures; now, Eq. 7 represents not a sequence of processes, but really a one-step process. This mechanism does not need thermal excitation and is compatible with the experimental results described thus far. This mechanism for TIDF is the same as that proposed by Azumi and McGlynn in rigid glass.[19] The validity of their proposal has partly been proved by the experimental results of Nakashima *et al.*[21] According to Kellogg,[22] the necessary conditions for this type of energy transfer to occur are satisfied in phenanthrene.

Excitation-duration and Excitation-light-intensity Effects. In this section, we will show the experimental results of excitation-duration and excitation-light-intensity effects on TIDF decay. These two effects have been observed under exactly the same conditions except for the excitation duration and the excitation light intensity.

Figure 4 shows the observed TIDF decay curves. The excitation durations are chosen to be (a) 4.25, (b) 0.257, (c) 0.102, (d) 0.050, and (e) 0.021 s. It can easily be seen that shortening the excitation duration makes not only the TIDF intensity weak, but also the decay steep. The TIDF decay curves with excitations of more than 5 s are essentially the same as that with the excitation of 4.25 s.

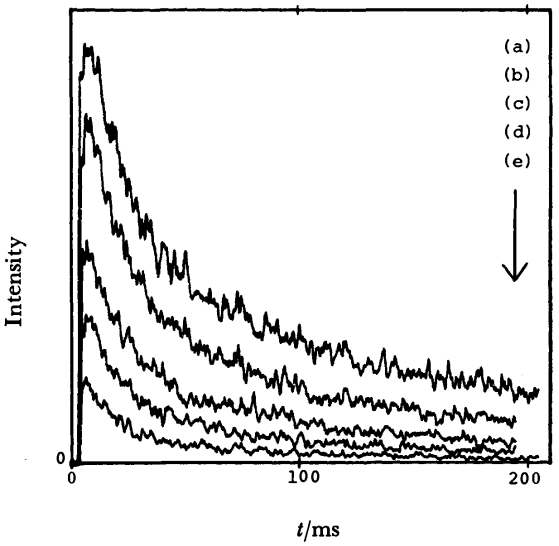

Fig. 4. Excitation duration effect on the delayed fluorescence decay at 77 K. Excitation durations are (a) 4.25 s, (b) 257 ms, (c) 102 ms, (d) 50 ms, and (e) 21 ms, respectively.

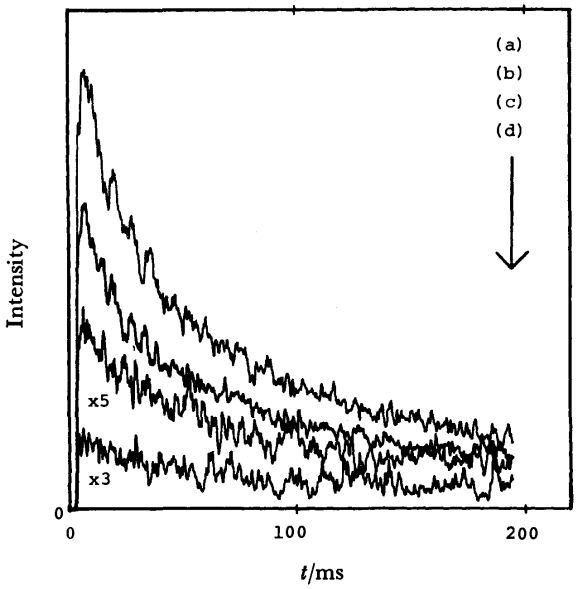

Fig. 5. Excitation light intensity effect on the delayed fluorescence decay observed at 77 K with a fixed excitation duration of 8.6 s. Relative excitation light intensities are (a) 1, (b) 0.6, (c) 0.1, and (d) 0.02, respectively.

Figure 5 shows the results of the observation of the excitation-light-intensity effect. The relative excitation light intensities are chosen to be 1, 0.6, 0.1, and 0.02.

When the excitation duration or excitation-light intensity are altered, the amount of light energy which is stored in the guests is changed. The TIDF intensities thus observed are greatly different from each other, as is shown in Figs. 4 and 5; in consequence, it is desirable to normalize the TIDF decay curves for the convenience of comparison. Figure 6 shows the normalized TIDF decay curves. The experimental conditions are as follows: (a) The excitation duration is 8.62 s; the relative excitation-light intensity is 1. (b) The excitation duration is 8.62 s; the relative excitation-light intensity is 0.02. (c) The excitation duration is 21 ms; the relative excitation-light intensity is 1. We can clearly see from this figure that (b) and (c) show opposite tendencies when we choose (a) as a reference.

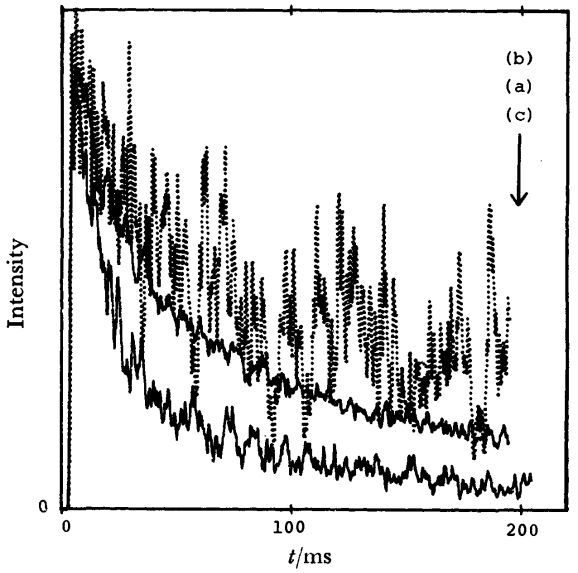

Fig. 6. Comparison between the excitation duration and excitation light intensity effects. Excitation durations are (a) 8.62 s, (b) 8.62 s, (c) 21 ms, respectively. Relative excitation light intensities are (a) 1, (b) 0.02, (c) 1, respectively.

The Mechanism for TIDF. In the foregoing sections, we have discussed the mechanism for TIDF and shown that the possible mechanisms for TIDF are the direct-resonance-interaction, double-excitation, and reabsorption mechanisms. In this section, we will consider the types of TIDF decay to be expected for the three possible mechanisms when the excitation duration and the excitation-light intensity are altered and will compare them with the experimental results shown in the preceding section.

If TIDF is caused by the direct-resonance-interaction mechanism, the energies from the two seperate guest triplet molecules are concentrated in a single guest molecule by the long-range direct interaction. Part of the resultant highly excited guest molecules are degraded into the lowest excited singlet state and then emit TIDF. We can now postulate that this interaction depends on the distance between the two interacting triplet molecules; the closer these two molecules, the higher the transfer probability. A triplet-state molecule far apart from other triplet-state molecules obeys the exponential decay law with the intrinsic transition probability. If another triplet-state molecule lies near the triplet-state molecule, this molecule obeys an exponential decay with an enhanced transition probability.

Therefore, the spatial distribution of the triplet-state molecules is important in this mechanism. In the case of the delta-pulse excitation, the distribution of the triplet-state molecules may be random at the moment of excitation. Consequently, the distances between triplet-state molecules are various and the decay laws to be obeyed are different for triplet-state molecules in different environments. As we observe the total TIDF intensity, the observed decay is a sum of the TIDF decays with different transition probabilities. In the case of the steady-state excitation, the situation is different from the case of the delta-pulse excitation. The distribution of the triplet-state molecules may be random at the initial stage of excitation, while interaction between triplet-state molecules is occurring. As pairs with shorter distances are annihilated with higher probabilities, pairs with longer distances survive with relatively higher probabilities. Therefore, the observed TIDF decay is a sum of the TIDF decays weighting slower components; *i.e.*, the TIDF decay after steady-state excitation contains more of the slowly decaying components than that after a delta-pulse excitation. In other words, a short excitation duration increases the relative number of pairs of triplet-state molecules with short distances. Contrary to this, decreasing the excitation-light intensity reduces the relative number of pairs of triplet-state molecules with short distances. Therefore, shortening the excitation duration quickens the TIDF decay, while decreasing the excitation light intensity makes it slower.

If the double-excitation mechanism is valid, the interaction between the excited states X is negligible. If X is confined within a molecule, the decay law is exponential. As a nonexponential decay is a necessary condition to observe the effect of excitation duration, the effect of excitation duration is not expected to appear in this case. If X is associated with more than one molecule, like an excimer and an exciplex, or with an electron-cation pair, TIDF will decay nonexponentially, and the effect of excitation duration may appear. When the excitation-light intensity is decreased, the total intensity of TIDF decreases, but the form of the decay curve does not change.

If the reabsorption mechanism is operative, a triplet-state molecule absorbs a photon of phosphorescence emitted by another triplet-state molecule and then undergoes the same processes as those in the direct-resonance-interaction mechanism. The effects of excitation duration and excitation-light intensity can be detected easily, judging from the fact that the triplet-state concentration is the major factor in the reabsorption and is affected both by the excitation duration and by the excitation-light intensity. Either shortening the excitation duration or decreasing the excitation-light intensity should have the same effect on TIDF decay.

Figure 6 shows the observed decay type, which is in accord with the prediction by the direct-resonance-interaction mechanism. Consequently, the observed effects of the excitation duration and excitation-light intensity can be reconciled only by adopting the direct-resonance-interaction mechanism for TIDF.

Solvent Effects on Chemical Reactivities of Conjugated Molecules

Takayuki OHMAE
Department of Chemistry, Faculty of Science, Tohoku University, Sendai 980
(Received July 11, 1984)

The propagator method is applied to the study of solvent effects on chemical reactivities of conjugated molecules. It is shoen that the number of π-electrons of a solute molecule (a conjugated molecule) controls the solvent effects on chemical reactivities. The obtained theory is applied to the study of solvent effects on selectivities of pericyclic reactions.

In recent years, a number of theoretical investigations of the solvent effects on electronic spectra and molecular structures have been made.[1-10] They can be classified in two different approaches: (1) The solvent effects are approximately described by explicitly considering one or numerous solvent molecules around the solute molecule;[1-3] (2) The virtual charge model in which the effects of solvent molecules are replaced by electrostatic continua and this allows the incorporation of the environmental effect into the Hamiltonian.[4-10]

On the other hand, there have been few theoretical studies of the solvent effects on chemical reactivities. Although reactions in the gas phase are simpler to deal with theoretically, the fact remains that most reactions occur actually in solutions. It is well known that the variation of solvent can change the rate and/or the reaction product.[11]

In this investigation it is shown that on the basis of the virtual charge model, the number of π-electrons of the solute molecule (the conjugated molecule) controls the solvent effects on the reactivities of pericyclic reactions.[12]

Hamiltonian

The reaction system in question is assumed to be well described by the following Hamiltonian[13,14] in the second quantized representation:

$$H_0 = \sum_s \alpha_s a_s^\dagger a_s + \sum_{s,t} \beta_{st} a_s^\dagger a_t + \sum_q h\omega b_q^\dagger b_q + \sum_q \sum_{s,t} (g_{st}^{q*} b_q^\dagger + g_{st}^q b_q) a_s^\dagger a_t, \quad (1)$$

where $a_s^\dagger$ and a_s are respectively the creation and annihilation operators for the π-electron at the s-th atom of the solute molecule, $b_g^\dagger$ and b_g are the creation and annihilation operators for the phonon with mode q, respectively, α_s is the coulomb integral, β_{st} the resonance integral, ω the phonon energy and g_{st}^q the electron-phonon interaction constant. In this model, the solvent is replaced by a phonon gas and the solvent-solute interaction by the electron-phonon interaction.[13]

The electron-photon interaction constant in Eq. 1 is defined by

$$g_{st}^q \equiv 4\pi i \frac{e^2 h}{2\gamma\omega} \frac{1}{q} \langle s | e^{iqx} | t \rangle, \quad (2)$$

where γ is given by the following formula;

$$\gamma \equiv \frac{4\pi}{\omega^2} \left(\frac{1}{\varepsilon_\infty} - \frac{1}{\varepsilon} \right)^{-1}, \quad (3)$$

where ε_∞ is the dielectric constant (ε) measured at the optical mode. The Hamiltonian is popular in the solid state phisics, and is successfully applied to a problem of electric resistance and so on.[14]

In this paper we neglect the mode dependence of the phonon energy. It is well known that the assumption is valid for polar media.

Propagator

In this chapter, we treat the propagator defined by

$$G_{rs}^0(t) \equiv -i\langle T[a_r(t) a_s^\dagger(0)] \rangle, \quad (4)$$

where $\langle \cdots \rangle$ denotes the ground state average, and T is the Wick time-ordering operator. Once the propagator is known, we can obtain the information about the eigenvalues and eigenvectors.[15,16]

We now introduce the Fourier transform of the propagator defined by

$$G_{rs}^0(z) \equiv \ll a_r;\ a_s^\dagger \gg = \int_{-\infty}^{+\infty} dt\, e^{izt} G_{rs}^0(t). \quad (5)$$

The Fourier transform satisfies the following equation of motion;

$$zG_{rs}^0(z) = \delta_{rs} + \ll [a_r,\ H_0];\ a_s^\dagger \gg, \quad (6)$$

where brackets [,] indicate a commutator. The commutation relation in Eq. 6 can be written as

$$[a_r,\ H_0] = \alpha_r a_r + \sum_u \beta_{ru} a_u + \sum_q \sum_u (g_{ru}^{q*} b_q + g_{ru}^q b_u) a_u. \quad (7)$$

The substitution Eq. 17 into Eq. 6 yields

$$zG_{rs}^0(z) = \delta_{rs} + \alpha_r G_{rs}^0(z) + \sum_u \beta_{ru} G_{us}^0(z) + \sum_q \sum_u g_{ru}^{q*} \ll b_q^\dagger a_u;\ a_s^\dagger \gg + \sum_q \sum_u g_{ru}^q \ll b_q a_u;\ a_s^\dagger \gg. \quad (8)$$

In evaluating $G^0_{rs}(z)$ by using this equation, we have to consider the higer order propagators:

$$M^{q\dagger}_{us}(z) \equiv \ll b^\dagger_q a_u;\ a_s \gg,$$
$$M^{q}_{us}(z) \equiv \ll b_q a_u;\ a_s \gg. \tag{9}$$

These propagators also satisfy the following equation of motion,

$$\begin{aligned} zM^{q\dagger}_{us}(z) &= (a_u-\omega)M^{q\dagger}_{us}(z) + \sum_v \beta_{uv}M^{q\dagger}_{vs}(z) \\ &+ \sum_l\sum_v g^{l*}_{uv}\ll b^\dagger_q b^\dagger_l a_v;\ a^\dagger_s\gg \\ &+ \sum_l\sum_v g^{l}_{uv}\ll b^\dagger_q b_l a_v;\ a^\dagger_s\gg \\ &- \sum_{v,t} g^{q}_{vt}\ll a^\dagger_v a_t a_u;\ a^\dagger_s\gg. \end{aligned} \tag{10}$$

To solve the above equation we assume as follows;[16]

$$\begin{aligned} \ll b^\dagger_q b_l a_v;\ a^\dagger_s\gg &= \langle b^\dagger_q b_l\rangle \ll a_v;\ a^\dagger_s\gg \\ &= \delta_{ql} n_q G^0_{vs}(z). \end{aligned} \tag{11}$$

Moreover we can assume that

$$\ll b^\dagger_q b^\dagger_l a_v;\ a^\dagger_s\gg = 0, \tag{12}$$

since the many phonon processes described by this propagator should be negligible. Further, we neglect higher order corrections to the electronic processes, that is,

$$\ll a^\dagger_v a_t a_u;\ a^\dagger_s\gg = 0. \tag{13}$$

Substituting the above approximations into Eq. 10, we obtain the following equation in the matrix notation,

$$z\mathbf{M}^{q\dagger}(z) = (\mathbf{h}-\omega)\mathbf{M}^{q\dagger}(z) + n_q\mathbf{g}^q\mathbf{G}^0(z), \tag{14}$$

or

$$\mathbf{M}^{q\dagger}(z) = n_q(z+\omega-\mathbf{h})^{-1}\mathbf{g}^q\mathbf{G}^0(z), \tag{15}$$

where

$$\mathbf{h} = \boldsymbol{\alpha} + \boldsymbol{\beta}. \tag{16}$$

Similarly $\mathbf{M}^q(z)$ is obtained as

$$\mathbf{M}^q(z) = (n_q+1)(z-\omega-\mathbf{h})^{-1}\mathbf{g}^{q*}\mathbf{G}^0(z). \tag{17}$$

Substituting Eqs. 15 and 17 into Eq. 8, we have the propagator, $\mathbf{G}^0(z)$, of the π-electron system in a solvent.

$$\begin{aligned} \mathbf{G}^0(z) = [&z-\mathbf{h}-\sum_q \mathbf{g}^{q*}n_q(z+\omega-\mathbf{h})^{-1}\mathbf{g}^q \\ &- \sum_q \mathbf{g}^q(n_q+1)(z-\omega-\mathbf{h})^{-1}\mathbf{g}^{q*}]^{-1}. \end{aligned} \tag{18}$$

Stabilization Energy

Let us consider a reagent, R, approaching atom r of a solvent molecule (see Fig. 1). The coulomb integral, α_s, and the resonance integral, β_{rs}, will undergo changes on approach of R. Assuming these changes or the perturbations, $\mathbf{v}$, to be small, the change of the total π-electron energy or the stabilization energy, ΔE, can be calculated by use of perturbation theory. ΔE is an energy change at the very beginning of the reaction and the reaction is expected to occur at the position where ΔE is smallest.[17]

The total π-electron energy is,

$$E_0 = \mathrm{Tr}\frac{1}{2\pi i}\int_c \mathrm{d}z\, z\mathbf{G}^0(z), \tag{19}$$

where $\mathbf{G}^0(z)$ is the matrix of the propagator, z the energy parameter and Tr the trace with respect to the arbitrary representation.[15,18] Integration contour, c, in Eq. 20 is the so-called Coulson contour shown in Fig. 2. Note that the integration includes the spin sum hereafter.

The stabilization energy[19-20] caused by the perturbation, $\mathbf{v}$, is

$$\begin{aligned} \Delta E &\equiv E - E_0 \\ &= \mathrm{Tr}\frac{1}{2\pi i}\int_c \mathrm{d}z\, z\mathbf{G}(z) - \mathrm{Tr}\frac{1}{2\pi i}\int_c \mathrm{d}z\, z\mathbf{G}^0(z) \\ &= \sum_n \frac{1}{n}\mathrm{Tr}\frac{1}{2\pi i}\int_c \mathrm{d}z\{\mathbf{G}^0(z)\mathbf{v}\}^n, \qquad (20) \\ &= -\frac{1}{2\pi i}\int_c \mathrm{d}z\, ln\ \mathrm{det}\{1-\mathbf{G}^0(z)\mathbf{v}\}, \qquad (21) \end{aligned}$$

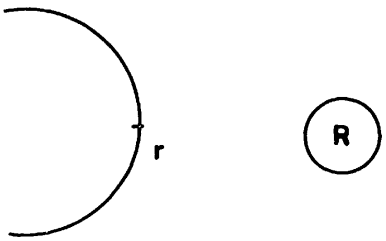

Fig. 1. R is reagent approaching a conjugated molecule.

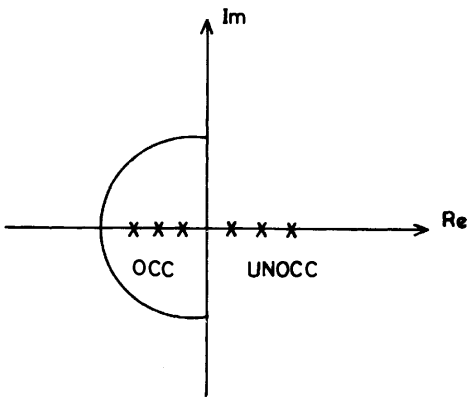

Fig. 2. Coulson contour.

where E and $\mathbf{G}(z)$ are the total π-electron energy and the propagator of the perturbed conjugated system, respectively.

It should be noted that Eqs. 20 and 21 are the straightforward generalization of the famous Coulson-Longuet-Higgins' perturbation formula.[19,21]

The substitution Eq. 18 into Eq. 20 yields

$$\Delta E = \sum_n \frac{1}{n} \mathrm{Tr} \frac{1}{2\pi i} \int_c dz [\{z-\mathbf{h}-\sum_q \mathbf{g}^{q*} n_q (z+\omega-\mathbf{h})^{-1} \mathbf{g}^q - \sum_q \mathbf{g}^q (n_q+1)(z-\omega-\mathbf{h})^{-1} \mathbf{g}^{q*}\}^{-1} \mathbf{v}]^n. \quad (22)$$

The reactivity of a chemical reaction is mainly determined by the first order term with respect to $\mathbf{v}$.[19] Accordingly, it is sufficient for us to study the first-order energy change

$$\Delta E^{(1)} \equiv \mathrm{Tr} \frac{1}{2\pi i} \int_c dz \{z-\mathbf{h}-\sum_q \mathbf{g}^{q*} n_q (z+\omega-\mathbf{h})^{-1} \mathbf{g}^q - \sum_q \mathbf{g}^q (n_q+1)(z-\omega-\mathbf{h})^{-1} \mathbf{g}^{q*}\}^{-1} \mathbf{v}. \quad (23)$$

Equation 23 is the general formula in our theory of the solvent effects on chemical reactivities.

Pericyclic Reaction

Let us consider ring closure reactions of conjugated chains. It is well known that selection rules of ring closure reactions can be generalized to those of pericyclic reactions.[12,19] Figure 3 shows the model of the ring closure reaction. The arrows stand for the basis functions, together with the phases.

For the sake of simplicity, let us now consider the case in which the chain is composed of n atoms and n π-electrons. If the ring closure reaction begins, the extra interaction, v, occurs between 0th and $(n-1)$th atoms:

$$v_{0,n-1} = v_{n-1,0} = v \begin{cases} >0, & \text{for the conrotatory mode} \\ <0, & \text{for the disrotatory mode.} \end{cases} \quad (24)$$

If a mode works to stabilize the solute molecule, *i.e*, $\Delta E^{(1)}<0$, we can choose this mode as the desired reaction path.

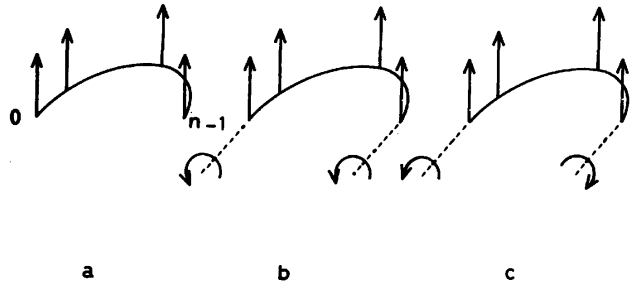

Fig. 3. Ring closure reaction, a: transition state, b: conrotatory mode, c: disrotatory mode.

The stabilization energy, $\Delta E^{(1)}$, in Eq. 23 can be expanded with respect to the electron-phonon interaction constant, $\mathbf{g}^q$,

$$\Delta E^{(1)} = \mathrm{Tr} \frac{1}{2\pi i} \int_c dz (z-\mathbf{h})^{-1} \mathbf{v} + \mathrm{Tr} \frac{1}{2\pi i} \times \int_c dz (z-\mathbf{h})^{-1} \sum_q \mathbf{g}^{q*} n_q (z+\omega-\mathbf{h})^{-1} \mathbf{g}^q (z-\mathbf{h})^{-1} \mathbf{v} + \mathrm{Tr} \frac{1}{2\pi i} \int_c dz (z-\mathbf{h})^{-1} \sum_q \mathbf{g}^q (n_q+1) \times (z-\omega-\mathbf{h})^{-1} \mathbf{g}^{q*} (z-\mathbf{h})^{-1} \mathbf{v} + \cdots. \quad (25)$$

The first term of Eq. 25 determines the selection rules of electrocyclic reactions.[12] This term has already been studied by Ohmae *et al.*[19] The second and third terms are responsible for the solvent effects on the selection rules of electrocyclic reactions in the lowest order. Equation 25 can be rewritten as

$$\Delta E^{(1)} \cong \Delta E_{\mathrm{rule}} + \Delta E_{\mathrm{solv}}, \quad (26)$$

where

$$\Delta E_{\mathrm{rule}} \equiv \mathrm{Tr} \frac{1}{2\pi i} \int_c dz (z-\mathbf{h})^{-1} \mathbf{v}, \quad (27a)$$

and

$$\Delta E_{\mathrm{solv}} \equiv \mathrm{Tr} \frac{1}{2\pi i} \int_c dz (z-\mathbf{h})^{-1} \sum_q \mathbf{g}^{q*} n_q (z+\omega-\mathbf{h})^{-1} \times \mathbf{g}^q (z-\mathbf{h})^{-1} \mathbf{v} + \mathrm{Tr} \frac{1}{2\pi i} \int_c dz (z-\mathbf{h})^{-1} \times \sum_q \mathbf{g}^q (n_q+1)(z-\omega-\mathbf{h})^{-1} \mathbf{g}^{q*} (z-\mathbf{h})^{-1} \mathbf{v}. \quad (27b)$$

First, we study the first term of Eq. 27b. We can treat this term by the representation in which the propagators are diagonal. Thus we have

$$\mathrm{Tr} \frac{1}{2\pi i} \int_c dz (z-\mathbf{h})^{-1} \sum_q \mathbf{g}^{q*} n_q (z+\omega-\mathbf{h})^{-1} (z-\mathbf{h})^{-1} \mathbf{v} = \sum_q n_q \sum_{i,j,k} \frac{1}{2\pi i} \int_c dz \frac{1}{z-\varepsilon_i} \mathbf{g}^{q*}_{ij} \frac{1}{z+\omega-\varepsilon_j} \mathbf{g}^q_{jk} \frac{1}{z-\varepsilon_k} \mathbf{v}_{kj}, \quad (28)$$

where ε_i is the orbital energy or the eigenvalue of $\mathbf{h}$. Now we suppose that the electron-phonon interaction constant, g^q_{ij}, has a dominant value between the highest occupied molecular orbital, HOMO, and the lowest unoccupied molecular orbital, LUMO. Equation 28 then reduces to

$$\sum_q n_q \sum_{i,j,k} \frac{1}{2\pi i} \int_c dz \frac{1}{z-\varepsilon_i} \mathbf{g}^{q*}_{ij} \frac{1}{z+\omega-\varepsilon_j} \mathbf{g}^q_{jk} \frac{1}{z-\varepsilon_k} \mathbf{v}_{kj} \cong \sum_q n_q v_{\mathrm{HH}} |g^q_{\mathrm{HL}}|^2 \frac{1}{2\pi i} \int_c dz \frac{1}{(z-\varepsilon_{\mathrm{H}})^2 (z+\varepsilon-\varepsilon_{\mathrm{L}})}$$

$$+\sum_q n_q v_{LL}|g^q_{HL}|^2\frac{1}{2\pi i}\int_c dz\frac{1}{(z-\varepsilon_L)^2(z+\omega-\varepsilon_H)}$$
$$=\sum_q n_q v_{HH}|g^q_{HL}|^2\frac{-1}{(\varepsilon_H-\varepsilon_L+\omega)^2}$$
$$+\sum_q n_q v_{LL}|g^q_{HL}|^2\frac{1}{(\varepsilon_H-\varepsilon_L-\omega)^2}$$
$$\cong -\sum_q n_q v_{HH}|g^q_{HL}|^2\frac{1}{(\varepsilon_H-\varepsilon_L+\omega)^2}, \quad (29)$$

where we have assumed that $(\varepsilon_H-\varepsilon_L-\omega)>(\varepsilon_H-\varepsilon_L+\omega)$, and HOMO and LUMO are given by the symbol H and L, respectively.

If we deal with the second term of Eq. 27b, the similar treatment gives

$$\sum_q(1+n_q)v_{LL}|g^q_{HL}|^2\frac{1}{(\varepsilon_H-\varepsilon_L+\omega)^2}. \quad (30)$$

Therefore, we have

$$\Delta E_{solv}=\sum_q|g^q_{HL}|^2\frac{-n_q v_{HH}+(1+n_q)v_{LL}}{(\varepsilon_H-\varepsilon_L+\omega)^2}. \quad (31)$$

In order to study the solvent effects on selection rules of electrocyclic reactions, it is necessary to examine v_{HH} and v_{LL}. As is shown in Eq. 24, the non-vanishing matrix elements of $\mathbf{v}$ are only $v_{0,n-1}$ and $v_{n-1,0}$ in the atomic orbital representation. We can decompose v_{AA} as follows:

$$v_{AA}=\sum_{s,t}\langle A|s\rangle\langle s|\mathbf{v}|t\rangle\langle t|A\rangle=2v_{0,n-1}p^A_{0,n-1}, \quad (32)$$

where $p^A_{0,n-1}$ is a partial bond order relating to the A th molecular orbital alone. The partial bond order is defined by using the propagator

$$p^A_{st}\equiv\frac{1}{2\pi i}\int_A dz g(s,t), \quad (33)$$
$$g(s,t)=\frac{\sin(n-t)\theta\sin(s+1)\theta}{\sin(n+1)\theta\sin\theta}, \quad (34)$$
$$z=2\cos\theta, \quad (35)$$

where $g(s,t)$ is the propagator between the s th and t th atoms of the conjugated chain molecule.[22] The contour A encloses only the pole at ε_A. From these equations we get

$$v_{AA}=(-1)^A\frac{4v}{n+1}\sin^2\frac{\pi A}{n+1}, \quad (36)$$

where

$$A=\frac{n+1}{\pi}\cos^{-1}\frac{\varepsilon_A}{2}. \quad (37)$$

The substitution Eq. 36 into Eq. 31 yields

$$\Delta E_{solv}\cong(-1)^H v\sum_q\frac{4}{n+1}\frac{|g^q_{HL}|^2}{(\varepsilon_H-\varepsilon_L+\omega)^2}$$
$$\times\left\{n_q\sin^2\frac{\pi H}{n+1}+(1+n_q)\sin^2\frac{\pi(H+1)}{n+1}\right\}$$
$$\propto(-1)^H v, \quad (38)$$

where H is a half of the number of the π-electrons. From this equation, we can calculate the solvent effects on the selection rules of electrocyclic reactions. The results obtained are summarized in Table 1.

Table 1. Solvent effects on the selectivity of the pericyclic reactions

Number of electron	sign of $(-1)^H$	sign of v[a]	sign of ΔE_{solv}	solvent effect[b]	selection rule
4m	+	+	+	unfavor	allowed
	+	−	−	favor	forbidden
4m+2	−	+	−	favor	forbidden
	−	−	+	unfavor	allowed

a) $v=\begin{cases}+ & \text{for conrotatory mode}\\ - & \text{for conrotatory mode}\end{cases}$

b) favor: The solvent effects accelerate the reaction
unfavor: The solvent effects disturb the reaction.

It has thus been shown that solvent effects depend on the number of π-electrons of the solute molecule only. The nature of the solvent reflects only on the magnitude of the solvent effects;

$$|g^q_{ij}|^2\propto\left(\frac{1}{\varepsilon_\infty}-\frac{1}{\varepsilon}\right). \quad (39)$$

It should be noted that allowed reactions are always disturbed by the solvent, but forbidden reactions are not. If we use the solvent which has the property of $|\varepsilon_\infty-\varepsilon|\gg 0$, we can expect to obtain the thermal reaction products which are the same as the photo chemical reaction ones.

We would like to thank Professor Takeshi Nakajima for helpful discussions.

High Resolution ^{29}Si Nuclear Magnetic Resonance Study on Gallosilicates with Zeolitic Structures

Shigenobu HAYASHI,* Kunio SUZUKI, Shigemitsu SHIN, Kikuko HAYAMIZU, and Osamu YAMAMOTO
National Chemical Laboratory for Industry, Tsukuba, Ibaraki 305
(Received July 14, 1984)

High resolution ^{29}Si nuclear magnetic resonance spectra have been measured using magic angle sample spinning technique for several gallosilicates and aluminosilicates with zeolitic structures. The number of gallium atoms coordinating to the SiO_4 tetrahedron was determined by the technique in the same manner as established for aluminium in aluminosilicates. The resonance lines were observed to shift to lower field by the substitution of silicon atoms with gallium as well as aluminium. The magnitudes of lower-field shifts were larger for the substitution by gallium than aluminium. The chemical shift ranges of ^{29}Si nuclei are discussed for gallosilicates with the values for aluminosilicates compared.

High resolution ^{29}Si nuclear magnetic resonance (NMR) spectroscopy in solids has recently become a powerful tool to study the structure of various silicates[1] and aluminosilicates.[2] In silicates the chemical shift of ^{29}Si nuclei depends on the degree of condensation of silicon-oxygen tetrahedra. On the other hand, aluminosilicates are composed of two kinds of tetrahedra, SiO_4 and AlO_4, and the ^{29}Si chemical shift correlates well with the degree of substitution of silicon by aluminium.

A zeolite is a crystalline aluminosilicate with many pores inside it. The pore size is an important factor in determining the selectivity of the catalytic reaction and of the molecular sieving. Various modifications have been carried out to change the pore size: for example, the substitution of silicon and aluminium by other elements, cation exchange, and modification of the surface. In some zeolites aluminium atoms can be replaced by gallium atoms, resulting in zeolitic gallosilicates.[3-6]

Vaughan *et al.*[7] have recently measured high resolution ^{29}Si NMR spectra of gallium faujasites and sodalite to study the effect of gallium substitution for aluminium on the ^{29}Si spectra, but no other works have been reported so far on gallosilicates. In the present work we have carried out an extensive study of high resolution ^{29}Si NMR spectra of various gallosilicates. The ^{29}Si chemical shift has been observed to change depending on the number of gallium atoms coordinating to the silicon-oxygen tetrahedron in the same manner as established for aluminosilicates. In addition to the one caused by the gallium atom, the ^{29}Si resonance line shifts by a crystallographical inequivalence. The range of the chemical shift in ^{29}Si spectra has been discussed, taking into consideration the effects of the substitution by gallium and of the crystallographical inequivalence, and the values for gallosilicates have been compared with those for aluminosilicates.

Experimental

Several gallosilicates were synthesized by the procedures described in Refs. 3—6. Aluminosilicates which have similar compositions and structures were synthesized for comparison. The structures of the synthesized zeolitic materials were checked by measuring powder X-ray diffraction patterns, and the compositions were determined by X-ray fluorescence (XRF) method.

High resolution ^{29}Si NMR spectra were measured by a Bruker CXP-100 pulsed spectrometer which was equipped with a probe for magic angle spinning of the sample and was operated at a resonance frequency of 17.9 MHz. An Andrew-type rotor[8] made of Delrin (polyoxymethylene) was spun at a rate of about 3.5 kHz. The angle of the rotation axis was determined by optimizing the ^{127}I spectrum of KI, using a procedure similar to that described in Ref. 9. Free induction decay signals observed after single pulse excitations were accumulated before Fourier transformation. The repetition times of the pulse excitations were between 2 and 10 s. Silicone rubber was used as an internal second reference, whose chemical shift is −22.0 ppm with respect to tetramethylsilane (TMS).[10] All the chemical shifts in this paper are referred to TMS.

The spectra were deconvoluted into several components with Lorentzian or Gaussian line shapes by a nonlinear least squares method using a FACOM M-380 computer.

Results and Discussion

NMR measurements have been performed for four kinds of zeolitic materials which were reported that aluminium can be substituted by gallium. Figures 1—4 show high resolution ^{29}Si spectra of gallosilicates as well as aluminosilicates in the increasing order of the Si/M ratio (M=Ga or Al). All the silicon atoms are equivalent crystallographically in the frameworks of hydroxysodalite and faujasite, while inequivalencies are present in offretite and ZSM-5.[11] The assignment of each peak observed in gallosilicates has been performed by analogy with aluminosilicates having similar composition and structure, as described below. Si(nM) used in this work means the silicon atom in an SiO_4 tetrahedron coordinated by n Al atoms.

Hydroxysodalite. The spectra for hydroxysodalites are shown in Fig. 1, and the results are summarized in Table 1. Spectra have been measured for three gallosilicates with different Si/Ga ratios,

and for one aluminosilicate. The observed peaks can be assigned to silicon atoms in Si(nM) configurations as shown in Table 1. The spectrum of the aluminosilicate has a line shape with a large asymmetry, which might be due to two overlapping lines attributed to Si(4Al) and Si(3Al). The chemical shifts of the two lines are determined to be −84 and −88 ppm. In gallosilicates the spectra are composed of two lines with chemical shifts, −75 and −83 ppm. By comparing the spectra with that of the aluminosilicate, the lines in the gallosilicates can be assigned to Si(4Ga) (−75 ppm) and Si(3Ga) (−83 ppm). The observed line shapes have been well fitted by using Lorentzian line shapes. The Si(nGa) line in gallosilicates shifts to lower field compared with the corresponding Si(nAl) line in aluminosilicate. The chemical shift values in Ref. 7 are also listed in Table 1, and the values obtained in the present work are in good agreement to the reported values.

The ratio of the number of silicon atoms to that of gallium or aluminium atoms (Si/M ratio) has been determined by the XRF method as well as the NMR method. The Si/M ratio from the NMR spectra was calculated assuming Loewenstein's rule,[12] that is, by using the following equation:

$$(\mathrm{Si/M}) = (\sum_{n=1}^{4} nI_n/4)^{-1}, \quad (1)$$

where I_n is a normalized intensity of the Si(nM) resonance line. Good agreements between the ratios obtained from the XRF and NMR methods are found in the cases of gallium-containing hydroxysodalite A and B within the experimental errors of the two methods. However, the discrepancy observed in gallium-containing hydroxysodalite C is too large to be explained by the experimental errors. Since the sample was found to be too rich in gallium atoms, it was considered to violate the Loewenstein's rule, as reported in Ref. 4, and hence Eq. 1 cannot be applied to this sample.

Faujasite. Figure 2 shows the spectra of faujasites containing Na ions. Four resonance lines are clearly observed in the aluminium-containing compound. Their chemical shifts are determined to be −83.6, −88.4, −93.8, and −99.2 ppm, which can be attributed to Si(4Al), Si(3Al), Si(2Al), and Si(1Al), respectively. A peak around −102 ppm is not clearly resolved but observed as a shoulder, which can be assigned to Si(0Al). The gallium-containing faujasite has also four clearly resolved lines. Their chemical shifts are −76.7, −83.3, −90.8, and −98.8 ppm, which can be assigned to Si(4Ga), Si(3Ga), Si(2Ga), and Si(1Ga), respectively, by analogy with the aluminium-containing compound. In both faujasites the spectra can be simulated well when a Lorentzian line shape is assumed for each line. The results are summarized in Table 2, together with the values in Ref. 7. The differences in the chemical shift between the neighboring

lines are 6—8 ppm for gallosilicates and 5—6 ppm for aluminosilicates. In gallosilicates the shift differences are a little larger in the present work than in Ref. 7. It can be concluded that a gallium atom deshields the silicon nucleus more than an aluminium atom.

Offretite. Figure 3 shows the spectra of offretites containing tetramethylammonium ion. Four lines are observed in the aluminum-containing compound, whose chemical shifts are −96.5, −101.7, −107.0, and −110.9 ppm. Nagy *et al.*[13] have measured the spectra of offretite with an Si/Al ratio of 3.8, and have made assignment as follows; −92 ppm to Si(3Al), −97 ppm to Si(2Al), −102 ppm to Si(1Al), and −107 and −112 ppm to Si(0Al). Two inequivalent sites however are present with the ratio of 2:1 in the framework of offretite, in contrast to hydroxysodalite and faujasite. Fyfe *et al.*[14] have reassigned the spectra of offretite by taking into consideration the effect of crystallographical inequivalence on the ^{29}Si chemical shift. The chemical shift dispersion for the two structurally inequivalent sites was reported to be about 5 ppm,[14] which is comparable in magnitude to the effect of the first nearest neighboring aluminium. According to the assignment of Fyfe *et al.*,[14] the lines observed in the present work are assigned as follows; −96.5 ppm to Si(2Al), −101.7 ppm to a mixture of Si(2Al) and Si(1Al), −107.0 ppm to a mixture of Si(1Al) and Si(0Al), and −110.9 ppm to Si(0Al). The fraction of each component is estimated as shown in Table 3, assuming that each Si(nAl) line consists of two lines with the intensity ratio of 2:1. Excellent agreement is obtained between the observed and estimated fractions, and the Si/M ratios obtained from the two methods are considered to agree within the experimental error.

In the spectra of gallium-containing offretite four resonance lines can be clearly observed, whose chemical shifts are −88.2, −94.6, −101.4, and −110.7 ppm. In addition to the four lines, there seems to exist at least one line between −101.4 and −110.7 ppm, whose chemical shift is calculated to be −104.5 ppm. They are tentatively assigned as shown in Table 3 by analogy with the aluminium-containing offretite, taking into

consideration the effects of the first nearest neighboring gallium and the crystallographical inequivalence. The agreement between the observed and estimated fractions is not very good for the lines at −104.5 and −110.7 ppm. The discrepancy is considered to have its origin in the procedure of the deconvolution of the spectra. Since the three lines between −101 and −111 ppm overlap markedly, the observed fractions are considered to include appreciable errors. Furthermore, the line shape in the higher field appears to be different from a Lorentzian line shape, as shown in Fig. 3a, although Lorentzian line shapes are assumed for all lines. If the line shape can be assumed differently for each line based on a theoretical consideration, the observed spectra should be simulated very well, which is impossible at the present stage.

ZSM-5. ZSM-5 has a very high Si/M ratio compared with the materials described above, and has several sites which are inequivalent crystallographically. Figure 4 shows the spectra of H-type ZSM-5 with different Si/M ratios, and Table 4 summarizes the results. The observed spectra can be well simulated by assuming a Gaussian line shape for each component.

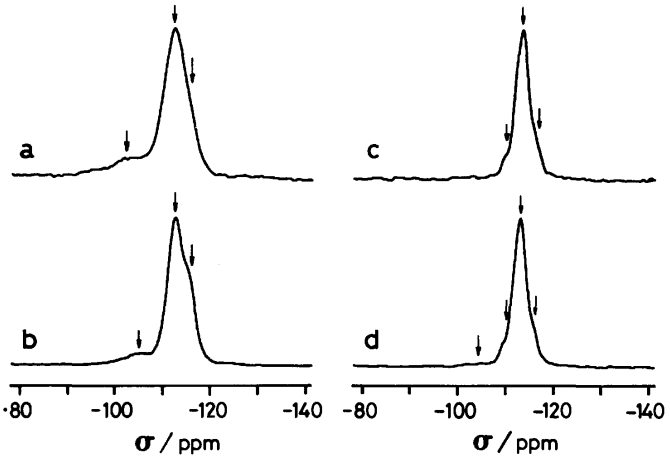

Fig. 4. High resolution ^{29}Si spectra of H-type ZSM-5. Gallium-containing A (a) and B (c), and aluminium-containing A (b) and B (d).

In aluminium-containing compounds with a lower Si/Al ratio, three lines are observed, whose chemical shifts are −105.6, −112.3, and −115.6 ppm. For the

ZSM-5 with a higher Si/Al ratio four lines are observed, whose chemical shifts are −104.5, −110.3, −113.2, and −116.2 ppm. The lines at about −105 ppm are attributed to Si(1Al), from the consideration of the Si/Al ratio obtained by the XRF method. The other lines are all assigned to Si(0Al), whose chemical shifts are dispersed because of the crystallographical inequivalence, as pointed out by Fyfe *et al.*[15]

The spectral shapes of the gallium-containing ZSM-5 are similar to those of the aluminium-containing ones with similar Si/M ratios. Three lines are observed in the sample with a lower Si/Ga ratio whose chemical shifts are −103.7, −112.3, and −115.7 ppm, while the sample with a higher Si/Ga ratio has three lines with chemical shifts of −110.6, −113.7, and −116.9 ppm. The line around −104 ppm is attributed to Si(1Ga), and the other lines are all attributed to Si(0Ga). It is reasonable that the Si(0Al) and Si(0Ga) lines have almost the same chemical shift.

Chemical Shift. The ranges of the chemical shift of Si(nM) lines in gallosilicates are summarized in Table 5, together with the values in aluminosilicates. The ranges of the chemical shifts of Si(nGa) lines cover lower field than the corresponding Si(nAl). In other words, gallium deshields ^{29}Si nucleus more than aluminium. The deshielding effects are 6—8 ppm per gallium atom and 5—6 ppm per aluminium atom when a nearest neighboring silicon atom is substituted by gallium or aluminium. In addition to the deshielding effect, the crystallographical inequivalence affects the chemical shift, which broadens the range of the chemical shift of each Si(nM) line.

Line Shape. In the procedure of the deconvolution a Lorentzian line shape was used for hydroxysodalite, faujasite, and offretite, while a Gaussian line shape was used for ZSM-5. In offretite, a Loretzian line shape is not suitable for the higher-field line. In other words, a Lorentzian line shape is suitable for the Si(nM) lines with n between 1 and 4, while a Gaussian line shape for Si(0M) line. There are two mechanisms of the line broadening: dipolar interaction between ^{29}Si and ^{27}Al or between ^{29}Si and ^{69,71}Ga, and distribution of aluminium and gallium in second and further nearest coordination spheres. The origin of the linewidth in aluminosilicates at high magnetic fields has been discussed by Fyfe *et al,*[17] and they concluded that the aluminium atoms in the second and further nearest coordination spheres produce the chemical shift dispersion of silicon nuclei. At the magnetic field used in the present work the dipolar interaction works in addition to the above mechanism, since the quadrupole interactions in ^{27}Al nuclei becomes larger at lower magnetic fields.[18] The mechanisms of the line broadening in gallosilicates are considered to be the same as those in aluminosilicates. The shape and width of each Si(nM) line reflect the contribution of the two mechanisms. In this work the linewidths of the ^{29}Si lines are found to be broader for gallosilicates than those for aluminosilicates. The gallium atoms in the second and further nearest coordination spheres may be one of the causes of the broader linewidth in gallosilicates, since the deshielding character is stronger in a gallium atom than in an aluminium atom.

In addition to the above mechanisms of the line broadening the site inequivalence makes the spectra very complex, sometimes producing the overlap of the resonance lines, as shown in offretite. The deconvolution of the ^{29}Si NMR spectrum is difficult when lines are heavily overlapped. The error in the fraction of each line produces a larger error in the calculated Si/Al ratio as the ratio becomes higher. The value obtained from the XRF method may have the experimental error of ±10%. Consequently, the Si/M ratios obtained from NMR and XRF methods are considered to agree well within the experimental errors in most cases.

Spin-lattice Relaxation Time. Spin-lattice relaxation times (T_1) of ^{29}Si nuclei in gallosilicates studied in this work range between 1 and 3 s at a resonance frequency of 17.9 MHz, which are the same order of magnitude as the T_1 values in aluminosilicates with similar structures. These results indicate that either a gallium atom as well as an aluminium atom have little contribution to the ^{29}Si spin-lattice relaxation, or the two atoms have the similar contribution to it if exists. Barron *et al.*[19] and Watanabe *et al.*[20] have measured the T_1 values of ^{29}Si nuclei in several layer aluminosilicates, and have correlated the T_1 value with paramagnetic impurities. In the case of the relaxation due to paramagnetic impurities all of the ^{29}Si nuclei should have the same T_1 value. independent of the number of coordinating aluminium atoms. In the present work however differences in the T_1 values are found among the peaks in the two NaX samples studied. There is a trend that the T_1 value of the Si(nM) line with higher n value becomes shorter. From the dependence of the T_1 value on the n value it can be concluded that aluminium and gallium nuclei contribute to the spin-lattice relaxation of ^{29}Si nuclei in gallosilicates and aluminosilicates.

Fluorescence Emissions of Cycloalkanes and Mono-olefin by Controlled Electron Impact

Hirofumi KAWAZUMI, Tsuneaki UCHIDA, and Teiichiro OGAWA*
Department of Molecular Science and Technology, Kyushu University, Kasuga-shi, Fukuoka 816
(Received July 26, 1984)

Emission spectra of cyclohexane, methylcyclohexane, *trans*-decalin and tetramethylethylene were measured under the controlled electron-impact (5—100 eV) excitation. A broad band was observed in the ultraviolet region in addition to lines and bands from such fragments as H, CH, and C_2. This broad band was assigned to the fluorescence emission from the excited parent molecule, since its peak and lineshape resemble the fluorescence measured for liquid and since the threshold energy agrees with the absorption onset. The emission cross sections for these emissions were determined at an electron energy of 50 eV.

The intense absorption band of the saturated and mono-olefinic hydrocarbons lies in the far ultraviolet region.[1-2] A very weak broad fluorescence appears upon excitation by VUV photon,[3-8] UV two-photon,[9-10] X-ray[11] or β-ray.[12] Lipsky *et al.*[3-5] systematically investigated this fluorescence for a variety of normal and cyclic alkanes, and their alkyl derivatives; the fluorescence quantum yield increases almost linearly with number of carbon atoms for normal alkanes and depends on the molecular structure for cyclic and branched alkanes. The fluorescence lifetimes of these compounds are of the order of 10^{-9} s as measured by the excitation of the hydrogen flashlamp,[7] the synchrotron radiation,[8] the nitrogen laser[10] and the pulsed X-ray.[11]

The electron is a powerful excitation source, and it can induce not only an electric-dipole allowed but also an optically-forbidden transition.[13] Aromatic molecules show their characteristic emission which is apparently similar to optical fluorescence;[14-17] however, optically-forbidden levels are preferentially excited in the case of benzene.[18] Some of the amino compounds also show an excited molecular emission.[19] However, most organic molecules do not give their own fluorescence emission, mainly because nonradiative processes are fast.

We have recently obtained the fluorescence emission of such hydrocarbons as cyclohexane, methylcyclohexane, *trans*-decalin and tetramethylethylene upon the controlled electron-impact excitation, and discussed the dynamics of molecular excitation.

Experimental

The apparatus consists of a stainless steel collision chamber and a highly sensitive photodetection system. The collision chamber was evacuated with a 4″ oil-diffusion pump with a liquid nitrogen trap. The base pressure was of the order 10^{-5} Pa and the operating pressure was 2.7×10^{-2} Pa (uncorrected ionization gauge reading). Electrons from a tungsten filament were accelerated and collimated with electrostatic lenses, and were monitored with a Faraday cup. The sample was jetted into the collision region through a multichannel nozzle and was crossed to collide with the electron beam.

The optical emission produced in the collision region was observed through a quartz window and a quartz lens at an angle of 60° with respect to the electron beam. The spectrum in the entire region was recorded with a SPEX 1670 monochromator equipped with a 1200 grooves/mm grating blazed at 300 nm and with an HTV R585 photomultiplier. The spectrum in the 190—300 nm region was recorded with the same monochromator equipped with a 1200 grooves/mm grating blazed at 500 nm and used in the second order and with an HTV R166UH solar blind photomultiplier; this system offers a higher sensitivity in the above region. Photons were counted with an ORTEC 9315 photoncounter, and data were stored and analyzed with an NEC PC8800 microcomputer.

The instrumental response of the optical system was calibrated as a function of wavelength with a standard deuterium lamp. Corrected spectra were obtained in units of relative number of photons per wavenumber.

The excitation function and the threshold energy were measured with the latter optical system. The electron energy was calibrated with the threshold of N_2^+ (391.4 nm) at 18.75 eV and its energy resolution was ±0.8 eV.

Cyclohexane (Dojindo, luminasol grade), methylcyclohexane (Nakarai, spectroscopic grade), *trans*-decalin (Nakarai, guaranteed grade), tetramethylethylene (Tokyo Kasei, guaranteed grade), ethylene (Seitetsukagaku, research grade) and carbon monoxide (Takachiho, research grade) were used as supplied. The purity of cyclohexane was >99.98% from gas chromatographic analysis.

Results and Discussion

The emission spectrum of cyclohexane by controlled electron impact at an electron energy of 80 eV shows the Balmer lines of the excited hydrogen atom and bands of the CH (the A-X and B-X transitions) and C_2 (the d-a transition) radicals, as shown in Fig. 1. No molecular emission of cyclohexane was clear in this figure because of low sensitivity.

By using the more sensitive photodetection system for the 190—300 nm region as mentioned in the Experimental, a broad band could be observed for cyclohexane at an electron energy of 50 eV, as shown in Fig. 2. This spectrum was not corrected for the instrumental response. No vibrational structure was clear and the spectral feature did not vary with the bandpass width of 1—10 nm. In addition, atomic lines of C (247.9 nm), C^+

(283.7 nm) and C^{++} (229.7, 269.8, and 272.5 nm) could be observed at 100 eV.

This broad band resembles the equilibrated fluorescence[3,5] excited optically for neat liquid. Thus, the observed band of cyclohexane is assigned to the fluorescence transition from the lowest excited singlet state (S_1) to the ground state (S_0). The intensity of the fluorescence emission was proportional to both the electron beam current (0—80 μA) and the gas pressure ((0.7—4.0)$\times 10^{-2}$ Pa); so the excited cyclohexane should be produced in a one-electron primary collision process.

The lifetime of the excited cyclohexane is 1.2—1.3 ns.[7] Therefore, no collisional relaxation of the S_1 state occurs in the pressure used. The peak and the band shape of the observed emission did not change for incident electron energies of 30—100 eV and agree with those of the equilibrated fluorescence. Thus, the major emitting state should be the S_1 state for all incident energies. The electron-impact excitation is a nonresonant process and is equivalent to the one by white light, whose maximum energy is that of the incident electron;[20] electrons can excite many vibronic levels simultaneously. Cyclohexane has a number of vibrational modes, and fluorescence from highly excited vibronic levels would lack any structural features. The fluorescence emission of aromatic hydrocarbons except benzene excited by electrons resembles the equilibrated fluorescence.[17] The trapped electron spectra for saturated hydrocarbons indicated excitation to the lowest triplet state as a result of electron exchange processes;[21] however, the transition from a triplet state should not give an intense emission as observed here.

The excitation function for the fluorescence emission of cyclohexane is shown in Fig. 3. The excitation function increased from threshold rapidly to 12 eV, and then decreased gradually to higher energies. The threshold energy was 6.9±1.0 eV, and agrees with the onset of the absorption spectrum (7.1 eV)[1] within experimental uncertainties. This finding supports that the observed emission is due to the S_1—S_0 transition. The highly excited states produced directly by electrons should decay nonradiatively or result in photodissociation.

Methylcyclohexane, *trans*-decalin and tetramethylethylene also show the broad fluorescence emission. Figure 4 shows their spectra taken at an electron energy of 50 eV; these spectra were smoothed and corrected for the wavelength response of the instrument. Each spectrum well resembles the fluorescence band measured for liquid,[3-6] as shown in Table 1; the vapor spectrum by photoexcitation was shown to be almost identical to the one for liquid. Therefore, they were assigned to the fluorescence emission from the excited parent molecules. No fluorescence, however, could be observed from ethylene with the present instrument. Its fluorescence quantum yield is extreme-

ly small ($\phi_f < 4\times10^{-7}$) for neat liquid.[6]

The emission cross sections (σ_{em}) of these bands were measured with reference to the CO^+ emission (the B-($v'=0$)—X($v''=0$) transition, 219.0 nm,[22] by comparing the area of the corrected emission spectrum; the sensitivity of the ionization gauge (S)[23] was corrected. The results obtained at an electron energy of 50 eV are summarized in Table 2 together with the optical oscillator strength (f) of the corresponding absorption band[1,28] and the fluorescence quantum yield (ϕ_f).[5,6] The error would be about 50%; its major source is uncertainties in the pressure measurements. The emitting species do not escape from the viewing region during their lifetimes[6-8,24] of 10^{-8}—10^{-9} s.

When the energy of the incident electrons substantially exceeds the excitation energy of the molecule, the Born approximation is applicable; the excitation cross section into the level i ($\sigma_{exc}(i)$) is expressed by the optical oscillator strength ($f(i)$) and the transition energy ($E(i)$). The probability of optical emission from this level is proportional to the fluorescence quantum yield ($\phi_f(i)$). Thus, the emission cross section ($\sigma_{em}(i)$) is given as follows:[17,25]

$$\sigma_{em}(i) = \phi_f(i)\sigma_{exc}(i) = b\phi_f(i)f(i)/E(i)$$

where b is a proportionality constant. This equation can be used for an order of magnitude estimation of the excitation process by the controlled electron impact.

The emission cross sections of the hydrocarbons are

much larger than that of benzene ($\sigma_{em}=4.8\times10^{-19}$ cm^2)[16] although the fluorescence quantum yields are contrary ($\phi_f=0.22$ for the zero point level of benzene),[26] because the excitation to the S_1 state of benzene is synmetry forbidden and less efficient ($f=0.0013$).[27]

The optical oscillator strength increases gradually with the number of C-C and C-H bonds for alkanes.[1] Therefore, the emission cross section shows a close correlation to the product of the optical oscillator strength and the fluorescence quantum yield for cycloalkanes. For tetramethylethylene, however, the fluorescence maximum is blue-shifted compared to that for neat liquid and for vapor (1.66×10^4 Pa with 8.47×10^4 Pa of N_2),[6] and the emission cross section is larger than expected from the optical oscillator strength and the fluorescence quantum yield. The observed emission originates from the S_1-S_0 transition for cycloalkanes. In contrast, the valence state (π^*) and the 3 s Rydberg state lie in the equivalent energy region for mono-olefins.[28] Hirayama *et al.* suggested that the emitting state is probably the Rydberg state and an internal conversion from the Rydberg state to the valence state is very efficient.[6] Since a collisional nonradiative decay may be suppressed under low-pressure conditions, the emission cross section of tetramethylethylene is large and its fluorescence band is shifted to blue.

The authors thank Professor Yukio Nishimura for his loan of the standard deuterium lamp.

Delayed Fluorescence of Zinc Porphyrin in Poly(vinyl alcohol) Film

Osamu OHNO, Youkoh KAIZU, and Hiroshi KOBAYASHI*
Department of Chemistry, Tokyo Institute of Technology, O-okayama, Meguro-ku, Tokyo 152
(Received July 27, 1984)

The delayed fluorescence was observed at room temperature with tetrakis(4-sulfophenyl)porphinatozinc ($ZnTPPS_4$) dyed on poly(vinyl alcohol) (PVA) film. In the film, the T-T annihilation is prohibited since any two molecules in the excited triplet can not encounter during their lifetime. Three types of luminescence emission were observed; fluorescence ($S_1 \rightarrow S_0$), phosphorescence ($T_1 \rightarrow S_0$) and delayed fluorescence ($T_1 \rightsquigarrow S_1 \rightarrow S_0$). The delayed fluorescence can be detected only at elevated temperatures where thermal activation from the lowest excited triplet can repopulate the lowest excited singlet.

The lifetimes of phosphorescence of (2,3,7,8,12,13, 17,18-octaethylporphinato)zinc (10 ms)[1] and (5,10,15, 20-tetraphenylporphinato)zinc (0.3 ms)[2] have been measured in toluene solution at ambient temperature. Upon low density excitation by a laser, encounters of the long-lived excited metalloporphyrin molecule in the lowest triplet state with another molecule in the ground state result in the formation of an ion-pair in solution ($^3P^* + P \rightarrow P^+ + P^-$). Upon high density excitation, however, the triplet-triplet annihilation is the path of the ion-pair formation.[1-4]

Since the initial population of the excited singlet state is dissipated in a short period after excitation, a delayed fluorescence is observed only when the lowest excited singlet state is repopulated. The triplet-triplet annihilation results in a population of the lowest singlet state. However, competitive to the bimolecular processes, the lowest excited singlet can be repopulated by a thermal activation of the long-lived excited molecule in the lowest triplet state at elevated temperatures. The delayed fluorescence by this mechanism has been reported on Pd porphyrins in liquid methyl methacrylate.[5] In the present work, the delayed fluorescence was studied with water-soluble zinc porphyrin dyed on the poly(vinyl alcohol) (PVA) film, in which any two excited porphyrin molecules can not encounter during their lifetime.

Experimental

Water-soluble tetrakis(4-sulfophenyl)porphin (H_2TPPS_4) was prepared by the method given elsewhere.[6] The sulfonation of all four phenyls of H_2TPP was confirmed by thin-layer chromatography using silica gel. Tetrasodium[tetrakis(4-sulfonatophenyl)porphinato]zinc ($ZnTPPS_4$) was prepared by refluxing H_2TPPS_4 and zinc perchlorate in an aqueous solution. $ZnTPPS_4$ thus obtained was purified by recrystallization from methanol and acetone. The counter ion of the sulfonates was converted to sodium by use of a cation-exchange resin column. Anal. Calcd for $ZnTPPS_4Na_4(H_2O)_3$: C, 46.35; H, 2.65; N, 4.91. Found: C, 46.24; H, 2.66; N, 4.78. $CuTPPS_4$ was also prepared by the similar method.

PVA films of 0.2 mm thickness were prepared by spontaneous evaporation of an aqueous solution of PVA (degree of polymerization: 1400) on a glass plate at ambient temperature during 10 days and then the films were heated at 80—90 °C for 1 h. The PVA film was sufficiently swelled in water before use and then dipped in an aqueous solution of the water-soluble porphyrin at 45 °C. After dried under dry nitrogen at ambient temperature, the film was used for measurements.

Luminescence emission and excitation spectra were recorded on a Hitachi fluorescence spectrophotometer model MPF-2A, equipped with a Hamamatsu Photonics photomultiplier R928. A component of the emission with a decay lifetime longer than 1 ms was detected through a rotating chopper which can cut the short-lived fluorescence. The decay lifetime of phosphorescence was measured on the Hitachi MPF-2A spectrophotometer equipped with its phosphorescence measuring attachment. The output from the instrument was AD converted and accumulated on a Kawasaki Electronica M-50E transient memory with its averager model TMC-400. The decay profile obtained from the data accumulated for 512 or 1024 times was analyzed on a Commodore CBM3032 microcomputer interfaced to the transient memory.

The sample film in a quartz tube was placed in a quartz Dewar vessel for emission measurements. Measurements were carried out at several temperatures obtained during elevation of the temperature in the vessel after the Dry Ice disappeared in Dry Ice-methanol mixture. The temperature of the film was measured by a thermocouple placed in the sample tube and regulated within an error less than 2 °C. Similar measurements were achieved also at temperatures obtained during cooling of hot water in the vessel.

Absorption spectra were measured on a Shimadzu recording spectrophotometer model MPS-50 and ESR spectra were taken on a JEOL-ME-3X spectrometer.

Results and Discussion

Absorption spectra of $ZnTPPS_4$ in PVA films conform to those observed with $ZnTPPS_4$ in methanol. A typical concentration of $ZnTPPS_4$ in the films used for the measurements was 10^{-4} M. ESR measurements were carried out on the PVA films dyed with $CuTPPS_4$ in the similar concentrations. The ESR spectra indicate that no appreciable interaction is present between copper porphyrin molecules in the film. In the medium, the molecules are isolated and in random orientation without forming dye aggregates such as dimer.

The ESR spectra of $CuTPPS_4$ in PVA film are in good agreement with those of magnetically diluted CuTPP in polycrystalline. Thus the effect of rotational and diffusional Brownian motions of the molecules in the

PVA film can be disregarded.[6]

$ZnTPPS_4$ in PVA film exhibits both phosphorescence (13000 cm^{-1}) and fluorescence (15000—16500 cm^{-1}) emission at ambient temperature, while only fluorescence is observed with $ZnTPPS_4$ in degassed water or methanol media. In the film, the rate of nonradiative process of the excited porphyrin in the lowest triplet state is decreased since the diffusional encounter processes are prohibited. In fact, paramagnetic metalloporphyrins $CuTPPS_4$ as well as $VOTPPS_4$ in the PVA film exhibit a strong phosphorescence even at room temperature.

The emission spectra were observed as shown in Fig. 1, where the component luminescence of decay lifetime shorter than 1 ms was cut by use of the phosphoroscope. Not only the phosphorescence at 13000 cm^{-1} but also the luminescence at 15000—16500 cm^{-1} were observed. The latter showed an identical spectral profile to that of the fluorescence but decayed with a lifetime which comformed to that of the phosphorescence.

Since the migration of molecules is prohibited in the film, the emission should be ascribed to the E(eosin)-type delayed fluorescence.[7] Repopulation of the lowest excited singlet is attributed to the thermal activation of the long-lived excited porphyrin in its lowest triplet. The thermal activation is possible only at elevated temperatures. In fact, the intensity of the delayed fluorescence decreases with lowering of temperature and is actually not detectable at temperatures below −20 °C.

The rate constants of intramolecular processes between three levels including the ground state (S_0), the lowest excited singlet and triplet (S_1, T_1) are defined as in Fig. 2. The ratio of the yields of delayed fluorescence and phosphorescence is given by

$$\phi_{df}/\phi_p = k_{-3} \times \frac{1}{k_p} \times \phi_f, \tag{1}$$

where ϕ_f stands for the yield of fluorescence. Since an equilibrium is established between S_1 and T_1 and thus

$$k_{-3}/k_3 = \frac{1}{3} \exp\{-\Delta E_{ST}/kT\}, \tag{2}$$

the Eq. 1 is rewritten as follows:

$$\phi_{df}/\phi_p = \frac{1}{3}\phi_f \frac{k_3}{k_p} \exp\{-\Delta E_{ST}/kT\} \tag{3}$$

where ΔE_{ST} is an energy gap between S_1 and T_1, 1/3, the ratio of the degeneracies of S_1 and T_1, k, Boltzmann constant and T, temperature. Provided that the ratio of the observed emission intensities is proportional to ϕ_{df}/ϕ_p,

$$\ln[I_{df}(660\text{ nm})/I_p(780\text{ nm})] = -\Delta E_{ST}/kT + \ln\left(\text{const} \times \frac{1}{3}\frac{k_3}{k_p}\right). \tag{4}$$

If k_p, k_3, and ϕ_f are temperature independent, a linear relation between $\ln[I_{df}(660\text{ nm})/I_p(780\text{ nm})]$ and $1/T$ is expected. The plots of $\ln[I_{df}(660\text{ nm})/I_p(780\text{ nm})]$ against $1/T$ result in a straight line as shown in Fig. 3. From the slope of the straight line, ΔE_{ST} was estimated as 3.5×10^3 cm^{-1} which was in good ageement with a gap between the observed fluorescence and phosphorescence maxima (3.9×10^3 cm^{-1}). If the minima of the excited singlet and triplet surfaces are shifted, the observed gap of phosphorescence and fluorescence peaks must be greater than the actual gap between S_1 and T_1. If k_{-3} is thermal in origin, rather than bimolecular, the excited states S_1 and T_1 will decay as

$$S_1 = c_1 \exp(-\alpha t) + c_2 \exp(-\beta t)$$
$$T_1 = c_3 \exp(-\alpha t) + c_4 \exp(-\beta t) \tag{5}$$

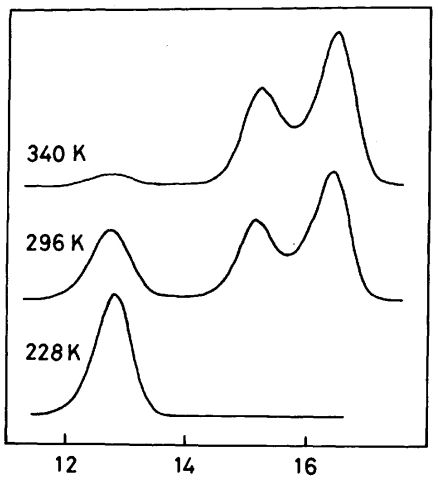

Fig. 1. Phosphorescence and delayed fluorescence of $ZnTPPS_4$ in PVA film at various temperatures.

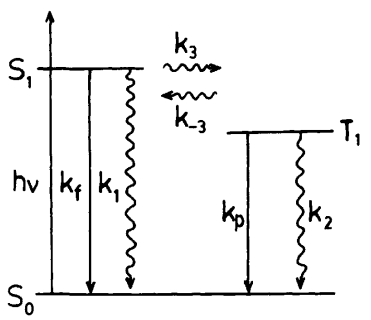

Fig. 2. Energy level diagram and the rate constants of intramolecular processes.
S_1 and T_1 stand for the lowest excited singlet and triplet states and S_0, the ground state.
⟶: radiative and ⇝: nonradiative processes.

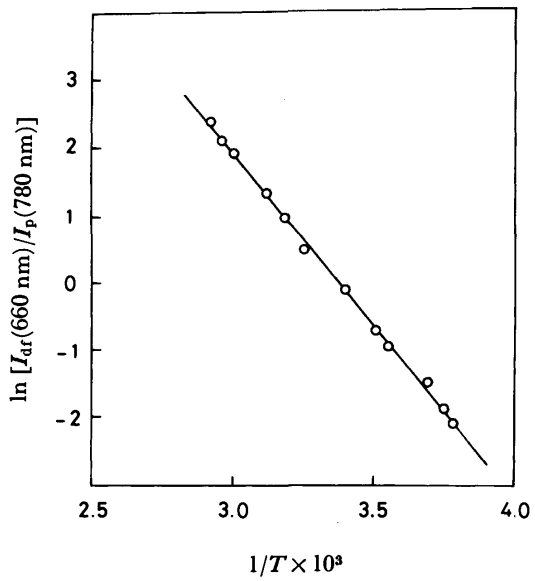

Fig. 3. Temperature dependence of ln [I_{df}(660 nm)/I_p(780 nm)].
I_{df}(660 nm) is the intensity of delayed fluorescence at 660 nm and I_p(780 nm), the intensity of phosphorescence at 780 nm.

where

$$\binom{\alpha}{\beta} = \frac{1}{2}\{(A+B) \pm \sqrt{(A-B)^2+4k_3k_{-3}}\} \quad (6)$$

and

$$A \equiv k_f + k_1 + k_3,$$
$$B \equiv k_2 + k_p + k_{-3}. \quad (7)$$

The faster component of decay ($\alpha > A = k_f + k_1 + k_3$) determines the lifetime of fluorescence. On the other hand, the slower component of decay determines the lifetimes of delayed fluorescence and phosphorescence which are approximated as

$$\beta = 1/\tau_p = 1/\tau_{df} = k_2 + k_p + k_{-3}(1-\phi_t) \quad (8)$$

where it is assumed that $k_{-3} \ll k_3$, $k_2 + k_f$, and ϕ_t stands for the yield of T_1 state. In fact, the observed decay curves in the ms time scale were of single exponential and yielded an identical lifetime regardless of the monitoring wavelengths, delayed fluorescence at 660 nm and phosphorescence at 780 nm, respectively. However the lifetime varies with temperature. Figure 4 shows the plots of the inverse lifetime of phosphorescence $1/\tau_p$ against temperature. It is noted that the lifetime is almost constant from liquid nitrogen temperature up to −20 °C but it decreases with elevation of temperature only above −10 °C. The delayed fluorescence can be detected above −10 °C where the lifetime of phosphorescence decreases. This indicates that $k_p + k_2$ of

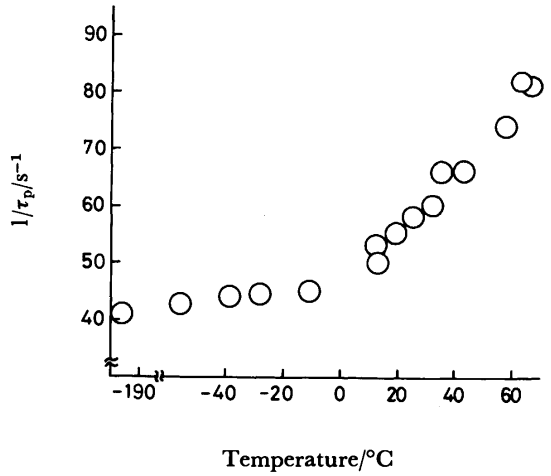

Fig. 4. Plots of the inverse phosphorescence lifetime versus temperature.

$ZnTPPS_4$ in PVA film increases only to a lesser extent with temperature but k_{-3}, the rate constant of activation in the thermal equilibrium between S_1 and T_1, is sufficiently increased with temperature only at elevated temperatures.

In fluid solution, the radiationless transition of the long-lived excited molecules is accelerated by a variety of diffusion-controlled bimolecular processes and thus the rate constant of nonradiative deactivation is sizable and heavily temperature dependent. Since the excited molecules cannot appreciably migrate during their lifetime in the polymer, the diffusion-controlled bimolecular mechanisms cannot play an important role in the relaxation of excited molecules.

In the present work, the metalloporphyrins fixed in the polymer film are isolated from the counterparts and this made it possible to study the intramolecular relaxation processes of excited metalloporphyrin in its lowest triplet by analysis of the temperature dependence of phosphorescence and delayed fluorescence.

Infrared Intensities in Methyl Chloride. III. Improvement of the Anharmonic Force Field and the Analysis of the Overtone and Combination Band Intensities

Shigeo KONDO,* Yoshinori KOGA, and Taisuke NAKANAGA
National Chemical Laboratory for Industry, Tsukuba Research Center, Yatabe, Ibaraki 305
(Received August 3, 1984)

A recently obtained anharmonic *ab initio* force field of methyl chloride has been improved by the method of "predicate observations" using the observed values of the spectroscopic constants. The newly obtained force field was used to make re-analysis of the absorption intensities of the binary overtone and combination bands for CH_3Cl and CD_3Cl. Contribution from the electrical anharmonicity to the band intensities was estimated and compared with the *ab initio* result.

In Part II of the present series, we have analyzed the binary overtone and combination band intensities of CH_3Cl and CD_3Cl attempting to determine the values of the second derivatives of the dipole moment with respect to the normal coordinates ($\partial^2 P/\partial q_r \partial q_s$).[1] However, for some of the observed bands the predicted intensities were markedly different from the observed ones, where *ab initio* values were used for the second derivatives of the dipole moment. It seemed that some of the cubic force constants then available[2] contained relatively large errors. Therefore, we did not show the values of the second derivatives of the dipole moment derived therefrom.

Recently, the present authors have calculated the anharmonic potential function for methyl chloride as well as for methyl fluoride by *ab initio* MO method. Certainly, these theoretical force fields were obtained without any procedure of fitting to the observed values of the spectroscopic constants. Still, their values have been shown to remarkably well reproduce the observed values of the molecular constants such as the vibration-rotation constants, l-doubling constants, and the vibrational anharmonicity constants.[3] This means that if the calculations are made with well selected basis functions, the individual values of the theoretical (cubic) force constants are really close to the true values.

Furthermore, in a separate paper[4] we have shown for methyl fluoride that thus obtained anharmonic *ab initio* force field can be further refined by fitting the calculated values of the molecular constants still better to the observed values. In this manner, we have obtained a set of anharmonic force constants for methyl fluoride, which are able to estimate the mechanical contribution to the effective dipole moment in the excited vibrational states to an accuracy of at least a few thousandths of a Debye unit.[4]

Therefore, also in the case of methyl chloride since we have full cubic terms of the anharmonic force field derived from *ab initio* MO method, we expect that an improved set of anharmonic force constants be obtained through a similar analysis as adopted in methyl fluoride. And then, it will be possible to make a quantitative estimation of the values of the second derivatives of dipole moment from the analysis of the absorption band intensities of the two quantum transitions of this molecule.

Results

(1) Refinement of the Cubic Force Constants. In a previous paper,[3] the anharmonic force field of methyl chloride has been derived *ab initio* with Pople's 4-31G* basis set[5,6] and also Dunning's double zeta basis set augmented with the polarization functions for H, C, and Cl atoms (DZP).[7] The effect of the configuration interaction was also examined by using the Mφller-Plesset second-order perturbation theory (abbreviated as MP2).[8] The anharmonic force field was also calculated by adopting the MP2/DZP geometry as the reference geometry for the SCF calculations with 4-31G* and DZP basis sets. The five sets in total of the anharmonic force field thus obtained were found to be very similar to each other.

Furthermore, in order to moderate a systematic trend observed among these anharmonic force fields that the diagonal force constants for the bond stretching modes become smaller on going from lower levels of theoretical calculation to higher levels, and become closer to the observed values,[3] each set of the theoretical force constants was scaled by the observed quadratic force constants. For the scaling, the harmonic force field derived by Duncan *et al.*[9] was utilized. The scaled values of the force constants are summarized in Table 1.

In order to refine further the theoretical force constants thus obtained the method of "predicate observations" was utilized.[10] In this method, a parameter is tied to a "predicate" value by a spring whose strength can be adjusted arbitrarily. It was emphasized that the fitting procedure to the observed values of the molecular constants should not be too strict particularly when the concerned vibrational levels are involved in intramolecular resonances.[4]

In the actual calculation, the least-squares method was used, where in stead of the usual residual value the following quantity was minimized;

a) Calculated values for I, II, III, IV, and V are obtained from the force fields I, II, III. IV, and V in Table 4, respectively. b) Ref. 1. c) Ref. 2. d) Ref. 20. e) Ref. 21. f) Ref. 22. g) Ref. 23. h) Ref. 24. i) Ref. 25. j) Ref. 19.

$$\chi_0 = \chi_1 + \chi_2, \tag{1a}$$

where

$$\chi_1 = \sum_i W_i(E_i^{obsd} - E_i^{calcd})^2, \tag{1b}$$

and

$$\chi_2 = \sum_j w_j(p_j^{pred} - p_j)^2. \tag{1c}$$

Here, p_j^{pred} is the "predicate" value and p_j the current value of the jth force constant, and w_j is a weight factor.

As usual, the weight W_i for the ith observed constant E_i was determined as $1/(\Delta E_i)^2$, where ΔE_i is the estimated "error" in E_i.[2] It is to be noted, however, that the values ΔE_i employed here are in general much larger than the experimental uncertainties reported in the literature,[11-25] for they should also include uncertainties due to approximations used for the theoretical expressions of the constants.[26] The actual values for ΔE_i were rather arbitrarily chosen as listed in Tables 2 and 3.

On the other hand, in order to choose appropriate values for w_j, trial calculations were carried out a number of times, in each of which different values were adopted for w_j as in the case of methyl fluoride. Eventually, the value of 0.1 in the respective units, which are given in the footnote to Table 1, in general and the value of 0.3 for the diagonal stretching force constants were adopted for Δp_j, where $w_j=1/(\Delta p_j)^2$. These values are the same as those used in Ref. 4.

Once the values of ΔE_i and Δp_j are determined, the procedure for refining the force constants is straightforward. The calculation was carried out for the above mentioned five sets of anharmonic force field (Table 1). For example, in the case of 4-31G* with the consistent geometry, the original value of residual was χ_1=3270. Through the refinement, the value has been altered to be χ_1=11.0 (χ_2=25.7). Thus, the degree of agreement between the observed and calculated constants became better by more than two orders of magnitude in the residual value. Similarly, for the MP2/DZP case, through the refinement calculation, the residual value changed from χ_1=3860 to χ_1=10.2 (χ_2=28.2).

Table 4 shows the result of the refinement calculations. Comparison of the numbers listed in Tables 1 and 4 reveals that the changes in the individual cubic force constants are by no means large. Apart from the

a) For the units, see footnote a) to Table 1. b) The results for I, II, III, IV, and V have been derived by adopting I, II, III, IV, and V in Table 1, respectively, as the "predicate" values. See text.

diagonal stretching force constants, most of them show changes less than 0.1 of the respective units. The numbers in the parentheses are one standard deviation resulting from the least-squares calculation under the present condition. It is to be noted that they can not simply be considered as the errors involved in their values.[4] The calculated values of the spectroscopic constants from these force constants are listed in Tables 2 and 3. Certainly, a very good agreement is obtained between the calculated and observed constants.

The obtained values of the force constants for the five cases are all very similar to each other; they actually agree with each other within the "standard errors" resulting from the present calculations.

(2) Binary Overtone and Combination Band Intensities. It is well known that the integrated intensity of a binary combination band is expressed by the following equation:[1,27]

$$A_{ss'} = 2.5066 \times (\omega_s + \omega_{s'}) d_f |Q_{ss'}|^2 Z_s Z_{s'} \{1 - e^{-\beta(\omega_s + \omega_{s'})}\}. \quad (2)$$

Similarly, for a binary overtone band,

$$A_{ss} = 2.5066 \times (2\omega_s) d_f |Q_{ss}|^2 Z_s^2 (1 - e^{-2\beta\omega_s}). \quad (3)$$

Here, ω_s is the sth normal frequency, d_f is the degeneracy of the upper vibrational state, β is $1/kT$, Z_s is the partition function for the sth normal vibration, $Z_s=1/\{1-\exp(-\beta\omega_s)\}$, and Q_{ss} and $Q_{ss'}$ are the transition moments calculated from the contact transformed dipole moment operator.[27] The numerical coefficient used in these equations is for the case where ω_s and φ_{rst} are given in cm^{-1}, P_r and P_{rs} in Debye units, and A_{ss} and $A_{ss'}$ in km mol^{-1}.

The actual expressions for the transition moments, Q_{ss} and $Q_{ss'}$, are given in Ref. 1 for different kinds of two quantum transitions of symmetric top molecules. They are given by the effective values of the second derivatives of the transformed dipole moment $\Omega_{ss'}^{\alpha}$ multiplied by different numerical factors as follows:[1] $Q_{ss}^{z}=\Omega_{ss}^{z}/2\sqrt{2}$, $Q_{ss'}^{z}=\Omega_{ss'}^{z}/2$, $Q_{st}^{x}=\Omega_{st}^{x}/2$, $Q_{tt}^{z}=\Omega_{tt}^{z}/2$, $Q_{tt}^{x}=\Omega_{tt}^{x}/2$, $Q_{tt'}^{z}=\Omega_{tt'}^{z}/\sqrt{2}$, and $Q_{tt'}^{x}=\Omega_{tt'}^{x}/\sqrt{2}$, where the index s denotes a nondegenerate mode and t denotes a degenerate mode.

The intensities of binary overtone and combination bands contain contributions both from electrical and mechanical anharmonicities. The mechanical contribution to the intensities may be obtainable if the normal coordinate cubic force constants and the values for $(\partial P/\partial q_r)$ are known. The former can be calculated from the anharmonic symmetry force field determined in the present study. They were calculated from the force field in Table 4 (case V) and are shown in Table 5. The phases of the normal coordinates used here is the same as in Part I of the present series.[11] On the other hand, the P_r values have also been determined in Part I and the actual values expressed in Debye units are summarized in Table 6.

a) Observed values of $\Omega_{rs}{}^{\alpha}$. Numbers in parentheses are the estimated errors. Their signs were so chosen that the resulting value of P_{rs} (see III) may agree better with the *ab initio* value (see IV). b) Mechanical anharmonicity obtained from set V of Table 4. c) Estimated values of P_{rs}; I—II. The numbers in parentheses are for the alternative signs of $\Omega_{rs}{}^{\alpha}$ in column I. d) *Ab initio* values of P_{rs} (Ref. 1).

the cubic force field in Ref. 2, the second from the scaled force field initially obtained with the MP2/DZP calculation (case V in Table 1), and the third one from the final force field (case V in Table 4). In all these calculations, the P_{rs} values obtained in Ref. 1 from *ab initio* MO calculation with 4-31G* basis set were utilized. Marked differences are observed between the first case and the other two cases, particularly in the values for $2\nu_2$, $\nu_5+\nu_6$, and $\nu_3+\nu_6$ of CH_3Cl, and $2\nu_2$ and $\nu_5+\nu_6$ of CD_3Cl. Certainly, this is due to the difference in the employed anharmonic force fields. If the values of the normal coordinate force constants listed in Table 5 are compared with those in Table 3 of Ref. 1, those concerned mainly with ν_2, ν_5, and ν_6 are markedly different between the two results. In fact, the values for the cubic force constants such as φ_{122}, φ_{222}, φ_{166}, φ_{256}, φ_{266}, φ_{356}, φ_{555}, φ_{556}, and φ_{666} have been improved very much.

On the other hand, the difference between the second and third cases is not so large. This is expected because the actual changes in the individual force constants were not large, although there was remarkable improvement on the agreement between the observed and calculated molecular constants. Also the latter improvement of the force field has yielded considerable changes in the calculated intensities of $2\nu_5$, $\nu_5+\nu_6$, and $\nu_2+\nu_6$ of both CH_3Cl and CD_3Cl molecules.

Tables 9 and 10 show the results of the analysis of the observed values of the transition dipole moment. In these tables, the column I shows the observed values of $\Omega_{rs}{}^{\alpha}$. These numbers are given with the signs. They were chosen as follows; at first, the contribution from the mechanical anharmonicity to $\Omega_{rs}{}^{\alpha}$ has been obtained by using the force constants for case V in Table 4 and is shown in column II. Then, the values of P_{rs} have been obtained by subtracting the numbers listed in column II from those in column I (and are shown in column III).

Table 10. Analysis of the transition dipole moment for CD_3Cl (in $10^{-4}\times$D)

66 (x)	0 (72)	12	−12	−8

a) Observed values of $\Omega_{rs}{}^{\alpha}$. Numbers in parentheses are the estimated errors. Their signs were so chosen that the resulting value of P_{rs} (see III) may agree better with the *ab initio* value (see IV). b) Mechanical anharmonicity obtained from set V of Table 4. c) Estimated values of P_{rs}; I—II. The numbers in parentheses are for the alternative signs of $\Omega_{rs}{}^{\alpha}$ in column I. d) *Ab initio* values of P_{rs} (Ref. 1).

The resulting values of P_{rs} for the two possible signs of $\Omega_{rs}{}^{\alpha}$ were compared with the theoretical values in column IV, the latter being obtained with Pople's 4-31G* basis set.[1] The signs given to the numbers in column I were so chosen that the resulting values of P_{rs} may agree better with the theoretical ones. In fact, if they are chosen in this manner, agreement between the observed and calculated values of P_{rs} is very good, *i.e.*, there is almost no doubt about the correctness of the present sign choice of $\Omega_{rs}{}^{\alpha}$. The numbers in parentheses in column III are those for the alternative signs of the transition moment.

Discussion

We did not show actual values of the errors involved in P_{rs} in Tables 9 and 10. This is because the errors involved in the force constants themselves are, as stated above, not well known. However, from comparison of the observed values of P_{rs} with the *ab initio* values listed in the same tables, the magnitudes of the errors may be on the average a few thousandths of a Debye unit.

On the other hand, it is well known that information on P_{rs} is also obtainable through observation of the dipole moment in the excited vibrational states.[28] By vibrationally averaging the transformed dipole moment operator[27] with a harmonic oscillator wave function, we obtain the expression for the dipole moment in each vibrational state;

$$\langle P\rangle_v = P_0 + \sum_a \delta P_a(v_a + d_a/2), \tag{4a}$$

where

$$\delta P_a = (1/2)\{P_{aa} - \sum_m P_m \varphi_{aam}/\omega_m\}. \tag{4b}$$

For CD_3Cl, Yamada and Hirota have measured the dipole moment in the ν_2 and ν_5 states; they obtained $\langle P\rangle_2$=1.90741(33), $\langle P\rangle_5$=1.90607(36), and $\langle P\rangle_0$= 1.90597(33) D.[21] Eq. (6) shows that from comparison of the dipole moment in the ν_2 and ν_5 states, respectively, with that of the ground state, we obtain the following quantities;

$$\delta P_2 = (1/2)\{P_{22} - P_1\varphi_{122}/\omega_1 - P_2\varphi_{222}/\omega_2 - P_3\phi_{223}/\omega_3\}, \tag{5}$$

and

$$\delta P_5{}^z = (1/2)\{P_{55}{}^z - P_1\varphi_{155}/\omega_1 - P_2\varphi_{255}/\omega_2 - P_3\varphi_{355}/\omega_3\}. \tag{6}$$

By substituting in these equations the above data for the dipole moment,[21] the observed values for the first derivatives (Table 6),[1] and the cubic force constants in Table 5, we obtain the values of P_{22}=−0.0243 D and $P_{55}{}^z$=−0.0034 D. If these values are compared with those resulting from the band intensities, *i.e.* P_{22}=−0.0165 D and $P_{55}{}^z$=0.0002 D (Table 10), the agreement between the two sets of data is about the magnitude we expected in the above for the errors in P_{rs}.

In this concern, it should be remembered that the expressions used for the intensity analysis has been derived through the contact transformation method.[1-27] The contribution of the mechanical anharmonicity calculated by using these equations may, therefore, contain large errors when there are close resonances. In the case of CD_3Cl, the values of P_{22} and $P_{55}{}^z$ derived from the intensity analysis may have suffered from the effect of this approximation. Considering this, the above discrepancy of the two sets of data could indicate the upper limit of the errors involved in the values of P_{rs} obtained in the present

analysis.

Now a study on the infrared intensities of binary overtone and combination bands of methyl fluoride is in progress in our laboratory. Also we are planning to extend similar studies on various molecules, *e.g.*, methyl bromide, formaldehyde, ethylene, and so forth.

The Phosphorescence Spectra of 9,10-Anthraquinone β- and β,β'-Sulfonates in an Aqueous Solution at 77 K

Akira KUBOYAMA* and Sanae Y. MATSUZAKI
National Chemical Laboratory for Industry, Tsukuba Research Center, Yatabe, Ibaraki 305
(Received March 8, 1984)

The nπ* phosphorescence spectra, and their excitation spectra and lifetimes of 9,10-anthraquinone-2-sulfonate, and -2,6- and -2,7-disulfonates in water–ethylene glycol 1:1 mixture at 77 K have been obtained. These phosphorescence spectra shift to the red with increases in the concentration of the solutions, and show an excitation-wavelength dependence. From the results obtained it is concluded that in the glassy solutions at 77 K an association of these quinones occurs, and that the phosphorescence state of the associates corresponds to the nπ* triplet excimer state, similar to that of the *p*-quinone aggregates in polycrystalline solutions at 77 K, previously studied.

Heretofore, we have studied the nπ* phosphorescence spectra of quinones in organic solvents at 77 K.[1] In this work, we examine the phosphorescence spectra of 9,10-anthraquinone β- and β,β'-sulfonates (9,10-anthraquinone is abbreviated as AQ in the following) in a glassy aqueous solution at 77 K. Investigations of the complex formation of these quinones with enzymes and cyclodextrins using these spectra are now in progress. These quinones have the following features favorable to the above studies. They are water-soluble and stable in the dark, have a large hydrophobic quinone moiety, and their phosphorescence spectra in a glassy aqueous solution at 77 K are relatively strong. Sodium AQ-2-sulfonate has been used in many photochemical[2] and biochemical[3] studies. However, few studies of the emission spectra of these quinones have been reported.

Experimental

Measurements. The phosphorescence spectra, and their excitation spectra and lifetimes in solutions were obtained at 77 K using an Aminco SPF-500 spectrofluorometer equipped with a photon counter (PM tube 1P28).[1] The energy distribution of the exciting radiation (a 250 W xenon arc lamp) and the spectral transmittance of the monochromator have not been taken into account. In the measurements, the sample solutions were rapidly cooled to 77 K. In some cases the results obtained using fast and slow cooling-speeds were compared. Water–ethylene glycol 1:1 mixture (H_2O–EG) which forms a glassy solution at 77 K was mainly used as a solvent. The pH value of this solvent was 6.8 at 26.0 °C. Methanol–ethanol 1:4 mixture which forms a glassy solution at 77 K was also used. The electronic absorption spectra in solution were obtained at room temperature using a Cary 17D self-recording spectrophotometer. In the measurements of high concentration solutions of the quinones, a 0.1 mm quartz cell of Gaskuro Kogyo Co. was used. Since the quinones are easily reduced in aqueous solutions by irradiation, especially at room temperature, care was taken to shield the sample solutions of the quinones from light.

Materials. Sodium AQ-2-sulfonate (AQ-2S) and disodium AQ-2,6-disulfonate (AQ-26S) of Tokyo Kasei Kogyo Co. were purified by recrystallization from water. Disodium AQ-2,7-disulfonate (AQ-27S) was purified by alumina column chromatography (eluent H_2O–EG). Their purity was checked by TLC (silica gel, developer water–propanol (3:7) mixture). Non-fluorescent water from Wako Junyaku Kogyo Co. was used. Ethylene glycol of Nakarai Kagaku Yakuhin Co. specially prepared for chromatography was used. No fluorescent impurity was detected in H_2O–EG. Spectrograde methanol and analytical-grade ethanol from Wako Junyaku Kogyo Co. were used without further purification.

Results and Discussion

In Fig. 1, the phosphorescence spectrum of AQ-2S in H_2O–EG shows a red-shift with increase in the concentration of the solutions, and an excitation-wavelength dependence, especially in the two medium concentrations (those in the spectra b and c). The spectra obtained with the 365 nm excitation are at longer wavelengths than those obtained with the 330 nm excitation. This excitation-wavelength dependence is very small in the low and high concentrations (those in the spectra a and d). These results suggest that the quinone molecules associate. The spectra in the low concentration (6.6×10^{-5} mol dm^{-3}) at the 330 nm excitation and in the high concentration (2.0×10^{-2} mol dm^{-3}) at the 365 nm excitation may be thought to be close to those of the quinone monomer and associate, respectively. The distance between these two spectra is *ca.* 600 cm^{-1}. Similar results were also observed in AQ-26S and -27S, as is seen in Figs. 2 and 3, but in these two quinones such a high concentration where the same spectra were obtained at the 330 and 365 nm excitations in the case of AQ-2S (the spectra d in Fig. 1) can not be realized because of the low solubility of these quinones in H_2O–EG.

The shapes of the spectra b and c of AQ-2S in the medium concentrations in Fig. 1 are similar to those of the spectra a and d in the low and high concentrations in Fig. 1. They are different from those of the simulation spectra in Fig. 4. The latter are composed of the two above-mentioned spectra which are thought to be close to those of the monomer and the associate. In Fig.

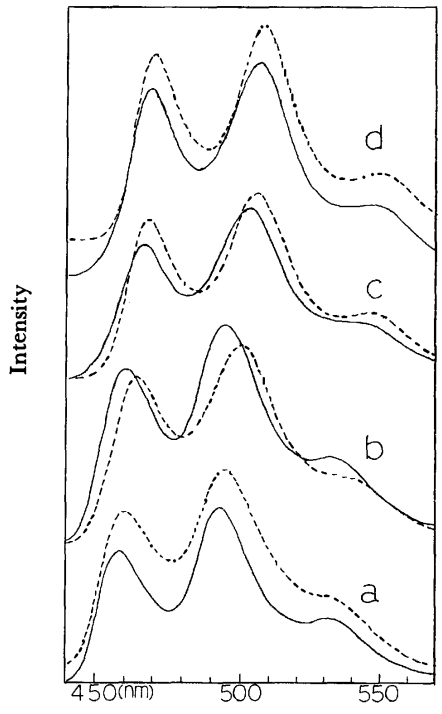

Fig. 1. Phosphorescence spectra of sodium 9,10-anthraquinone-2-sulfonate in the water–ethylene glycol mixture solution at 77 K, obtained without the rotating sector.

a: 6.5×10^{-5} M, b: 3.6×10^{-4} M, c: 7.9×10^{-3} M, ——: 330 nm ex., ----: 365 nm ex.

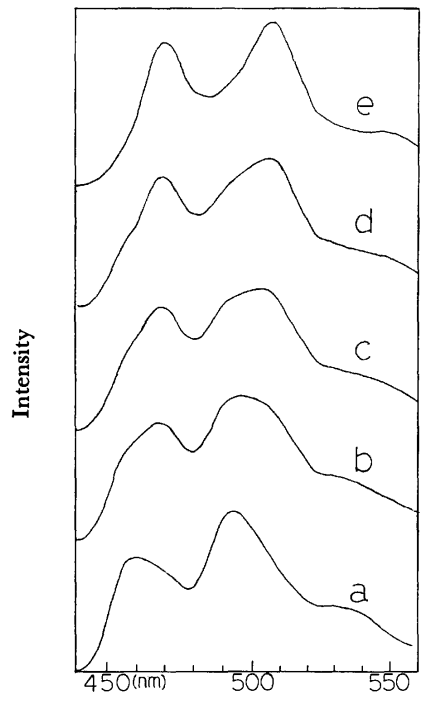

Fig. 4. Simulation spectra of sodium 9,10-anthraquinone-2-sulfonate composed of the spectra a (330 nm ex.) and d (365 nm ex.) in Fig. 1. The ratios of these two spectra in the spectra a—e are 4 : 1, 3 : 2, 1 : 1, 2 : 3, and 1 : 4, respectively.

l the peaks in the observed spectra are symmetrical, while in Fig. 4 most peaks in the simulation spectra are asymmetrical. Therefore, it is thought that there are more than one species in the number of the component molecules of the quinone associates, and consequently that in the high concentration solution the number of component molecules of the main part of the associates is greater than two, though its estimation is difficult at this stage. The spectra in the medium concentrations may be composed of the monomer and associates having various number of component molecules.

As is seen in AQ-2S (Fig. 5), the low-energy $\pi\pi^*$ absorption spectra[4] of these quinones in H_2O-EG at room temperature are broad and show only a small red-shift with increases in the concentration of the solutions. In Fig. 5, the peak wavelengths of the spectra 1 and 2 are 330 and 331 nm, respectively. The λ_{max} and molar absorption coefficients of the solutions of the concentrations lower than 1.8×10^{-3} mol dm^{-3} are almost constant.

These phosphorescence spectra show a clear CO stretching vibrational structure and the phosphorescence lifetimes are around 2 ms, as is seen in Table 2. Since the phosphorescence spectra are similar to the $n\pi^*$ phosphorescence spectra of AQ[1b-1g] in organic solvents in position, vibrational structure, and lifetime, they also may be safely assigned to the $n\pi^*$ phosphorescence spectrum. As the electronic transition in the $n\pi^*$ phosphorescence spectra of AQ is orbitally forbidden,[5,6] the relative height of the shortest wavelength peak, 0-0 peak, in the phosphorescence spectrum of AQ-2S is also low in organic solvents, as is seen in Fig. 6,[7] while those in H_2O-EG in Fig. 1 are considerably larger. This may result from the symmetry-degradation of the quinone π-electronic system due to the strong, random hydrogen-bond formation between AQ-2S and water.

As is seen in Fig. 7, the phosphorescence spectrum obtained with the slow rotating sector is far broader than that obtained with the fast rotating sector. In the spectra of the methanol-ethanol mixture solution of AQ-2S in Fig. 6, no such a sector-speed dependence of the phosphorescence spectra can be observed. In our previous work[1g] on methyl-substituted AQ's, results similar to the above sector-speed dependence of the phosphorescence spectra were obtained in non-saturated-hydrocarbon solutions. This may be due to there being a T_1 $n\pi^*$ level and a close-lying T_2 $\pi\pi^*$ level in AQ-2S in H_2O-EG, resulting from the strong hydrogen-bond formation between AQ-2S and water. There is a T_1 $\pi\pi^*$ level in the strongly solvated species. Consequently, in the spectra obtained with the slow rotating sector the sharp $n\pi^*$ and broad $\pi\pi^*$ spectra with different lifetimes overlap, as in the case of methyl-substituted AQ's.[1g] Since above-mentioned broad spectrum is observed only weakly, the phosphorescence spectrum obtained with the fast rotating sector contains the $\pi\pi^*$ spectrum as a very small contribution. The results similar to the above results are also observed in AQ-26S and -27S.

The phosphorescence excitation spectra of the low and high concentration solutions of AQ-2S are shown with that of a low-concentration solution of AQ-27S in Fig. 8. In these spectra, the weak long-wavelength part with a structure,[8] and the strong, broad short-wavelength part correspond to the S-S $n\pi^*$ and $\pi\pi^*$ absorption spectra, respectively.[9] In Fig. 8, the short-wavelength part of the excitation spectrum b of the high-concentration solution of AQ-2S is omitted, because the absorption in this wavelength region is very strong. The long-wavelength part of the excitation spectra in AQ-2S is almost the same in position and shape in the low- and high-concentration solutions. Similar results were obtained for AQ-26S and -27S. Therefore, the $n\pi^*$ absorption spectra of the monomer and associates of these quinones are at almost the same position. However, as mentioned before, the $n\pi^*$ phosphorescence spectra of these quinones shift considerably to the red with increases in the concentration. These circumstances are similar to those in the $n\pi^*$ phosphorescence spectra of the aggregates of the *p*-quinones, 1,4-naphthoquinone and 5,14:7,12-pentacenediquinone, in polycrystalline solutions at 77 K, previously studied.[1h] According to our previous work,[1h] the phosphorescence states of the quinone associates discussed here are also thought to correspond to the $n\pi^*$ excimer state. In these quinones, the $n\pi^*$ absorption spectra of the quinone monomer and associates are at almost the same position, as is mentioned above, while in the polycrystalline solutions the $n\pi^*$ absorption spectra of the aggregates are at shorter wavelengths than those of the corresponding quinone monomer, though the $n\pi^*$ phosphorescence spectra of these *p*-quinone aggregates appear at considerably longer wavelengths than those of the corresponding monomers.[10] This may indicate that the interaction between the quinone molecules in these associates is weaker than those in the *p*-quinone aggregates in the polycrystalline solutions.

With regards to the phosphorescence lifetimes shown in Table 2, the phosphorescence lifetimes of AQ-2S and -26S[11] in the methanol-ethanol mixture solution are considerably shorter than that of AQ

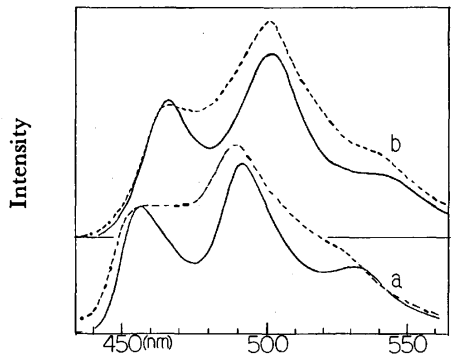

Fig. 7. Effect of the sector-speed on the phosphorescence spectra of sodium 9,10-anthraquinone-2-sulfonate in the water–ethylene glycol mixture solution at 77 K. a: 6.6×10^{-5} M, 330 nm ex., b: 6.6×10^{-3} M, 330 nm ex., —— with the fast-rotating sector (11500 min^{-1}), ---- with the slow-rotating sector (2070 min^{-1}).

a: 6.6×10^{-5} M, b: 6.6×10^{-3} M, c: 3.3×10^{-5} M.

and only slightly longer than the corresponding ones in H_2O-EG, in spite of the relative height of the 0-0 peak in the phosphorescence spectrum of AQ-2S in these two solutions being considerably different, as is seen in Figs. 1 and 6. In AQ also, the phosphorescence lifetimes of the methylcyclohexane and methanol-ethanol mixture solutions are both 3.3 ms, in spite of the relative height of the 0-0 peak in the latter solution being considerably larger than that in the former solution.[1g] In AQ-2S, the phosphorescence lifetime in the high-concentration solution is slightly longer than that in the low-concentration solution.

The association of these quinones is thought to be due to their having both a large hydrophobic quinone moiety and hydrophilic sulfonato anion groups. In the associates, the quinone molecules are thought to orient themselves, avoiding the strong steric hindrance of the sulfonato anion groups and overlapping their planar quinone moiety. The detailed structures of the associates can not be discussed at this stage.[1h]

Adsorption of Hydrophobic Anions onto Phospholipid Membranes. The Effect of Membrane Surface Charge

Hideo MATSUMURA,* Hiroyuki KAKOKI,† and Kunio FURUSAWA†
Electrotechnical Laboratory, Sakura-mura, Ibaraki 305
†*Department of Chemistry, The University of Tsukuba, Sakura-mura, Ibaraki 305*
(Received April 16, 1984)

Hydrophobic adsorption of tetraphenylborate ions (TPB) onto lipid membranes were studied at different pH's of aqueous phase by using lipid vesicles and monolayers. The amount of adsorbed TPB is much higher at pH 2 than at pH 7.4. This result indicates that the adsorption of hydrophobic ions is affected by the ionization state of surface polar groups of lipids, *i.e.*, that the membrane surface potential plays a role in the adsorption of hydrophobic ions.

Interactions of ions with phospholipid membranes have been intensively studied, especially, the binding of metal cations to negatively charged phospholipid membranes, which is now fairly well understood.[1-4] Interactions of organic ions with phospholipid membranes, however, have not yet been explored. Hydrophobic ions may be permeable through lipid bilayers *via* their hydrophobic interaction with lipid hydrocarbon chains. Therefore, hydrophobic anions and cations have been used as tracers to estimate the barrier height of membrane's electrical potential. The transport mechanism for hydrophobic ions passing through a lipid bilayer membrane has been studied by Ketterer *et al.*[5] They measured the conductance of tetraphenylborate ions through a black bilayer membrane of dioleoyllecithin, and proposed the "three-step model" that consists of adsorption, translocation, and desorption steps. In this model, the adsorption sites are considered to be located near the membrane-aqueous solution interface on the membrane side. Therefore, it is possible to determine the membrane potential by measuring the amount of these ions adsorbed from the aqueous phase. Further, it is significant to elucidate exactly the feature of adsorption of these ions from the aqueous phase.[6]

Andersen *et al.*[7] measured surface potential change of bacterial phosphatidylethanolamine monolayer on aqueous solution as a function of aqueous TPB concentration and proposed the discrete charge effect for the boundary potential model with a limiting number of adsorbed ions. In this sense, electrical charges near the membrane surface have a remarkable influence on the adsorption behavior of charged molecules toward the membrane. It is believed that charges on the membrane surface play a role in the binding of charged molecules such as metal ions and ionic detergents to the membrane.[8] In this work, the effect of the ionization state of surface polar groups on the adsorption of TPB onto a phospholipid membrane has been studied systematically by using phospholipid vesicles and monolayers as membrane samples.

Experimental

Bovin brain phosphatidylethanolamine (BPE), dipalmitoylphosphatidylethanolamine (DPPE), and dimyristoylphosphatidic acid (DMPA) were purchased from Sigma Chemical Co. (USA) to be used as phospholipids. Sodium tetraphenylborate was purchased from DOJINDO Laboratories (Japan). These were employed without further purification. The other reagents used were of analytical grade. All solutions of these substances were made with deionized and doubly distilled water.

BPE vesicles were prepared by sonication without using any buffer to eliminate the spurious effect of included buffer ions.[9] The amount of TPB adsorbed on these vesicles was measured as follows: 2 ml of a vesicle suspension was added to 2 ml of a TPB solution of known concentration in a glass-stoppered vial (5 ml). After the mixture had been left standing overnight at room temperature, the vesicle particles were separated from the medium liquid by ultrafiltration (MILLIPORE, PTGC). The concentration of TPB in the filtrate as well as in the original solution was measured by the inductively coupled Argon plasma method (Jarrell-Ash 975). From these measurements, the amount of adsorbed TPB per gram of vesicles was calculated by using a calibration curve.

Electrophoretic mobilities of large vesicles were determined at various pH values in an aqueous solution of 1×10^{-3} mol dm^{-3} KCl at 25 °C. The measurments were performed in a Rank Brother microelectrophoresis apparatus (MK-2) using a rectangular glass cell.

Monolayers of phospholipids were prepared by spreading a chloroform/ethanol (3:1) solution of DPPE or hexane/ethanol (9:1) solution of DMPA on the surface of a subphase solution containing 0.1 mol dm^{-3} NaCl and 0.01 mol dm^{-3} *Tris*-HCl buffer at pH 7.4 or HCl at pH 2 in an 80 ml Teflon trough. The subphase solution was continuously stirred with a glass-sealed 5 mm needle by a magnetic stirrer, except while the surface potential change being measured. A concentrated TPB solution was added to the solution, and this mixed solution was stirred for more than 30 min. Surface potentials of the monolayer were measured with a vibrating electrode against an Ag/AgCl reference electrode as a function of TPB concentration.

Results and Discussion

The degree of ionization of phospholipid polar groups depends on the pH of solution. It has been reported that a phosphatidylethanolamine (PE) membrane has net negative charges at neutral pH due to the deprotonating effect of the lower amino group on the vesicle surface[3] or due to hydrolytic degradation of PE molecules.[4] To confirm the state of ionization of our PE vesicles, electrophoretic mobility was measured in 0.001 mol dm^{-3} KCl aqueous solution. Figure 1 indicates that the PE vesicles have net negative surface charges at neutral pH and that the value decreases with decrease in pH value. This trend agrees qualitatively with the result of Papahadjopoulos[4] shown in Fig. 1, which was obtained with 0.145 mol dm^{-3} NaCl aqueous solution. Both data exhibit that electrophoretic mobilities converge to zero at pH 2. The membrane surface potential (or more exactly, the potential at the Stern layer) at pH 7.4 can be calculated, on the assumption of a Boltzmann distribution for the counter ions from our data and that of Papahadjopoulos, according to

$$\zeta = \phi_0 e^{-\kappa d}, \quad (1)$$

where ζ is the zeta potential, κ Debye's reciprocal length, d the distance from membrane surface to slipping plane, and ψ_0 the membrane surface potential. By this analysis using the ζ value at pH 7.4, the result of d=11 Å and ψ_0=−60 mV is obtained. Considering the value of d=10 Å for silica particles in 0.01 mol dm^{-3} NaCl solution, the value of d=11 Å is not so unrealistic as the distance in 0.1—0.001 mol dm^{-3} salt solution. Furthermore, as shown later, the estimated ψ_0 value (ψ_0=−60 mV) is in close agreement with the value derived from adsorption experiments.

In Fig. 2, adsorption isotherms for TPB on PE vesicles are shown in the form of semi-log plot, which were obtained at pH's 7.4 and 2 in 0.001 mol dm^{-3} KCl solution. From these data, it is possible to examine the surface potential effect on the adsorption by using the following relation:

$$[\mathrm{TPB}]_m = K[\mathrm{TPB}]_b e^{\psi_0 F/RT}, \quad (2)$$

where $[\mathrm{TPB}]_m$ is the concentration of TPB adsorbed on the membrane, $[\mathrm{TPB}]_b$ the residual concentration of TPB in the bulk solution, ψ_0 the membrane surface potential, K a constant independent of the surface potential term (K can be expressed by $K_{ad}e^{\Phi F/RT}$, where K_{ad} is the adsorption coefficient and Φ the electrostatic potential difference between membrane surface and adsorbing site), and the other symbols have the usual meanings. The solid lines in Fig. 2 are the curves obtained by calculation from Eq. 2 for two $Ke^{\psi_0 F/RT}$ values, which are different from each other by a factor of

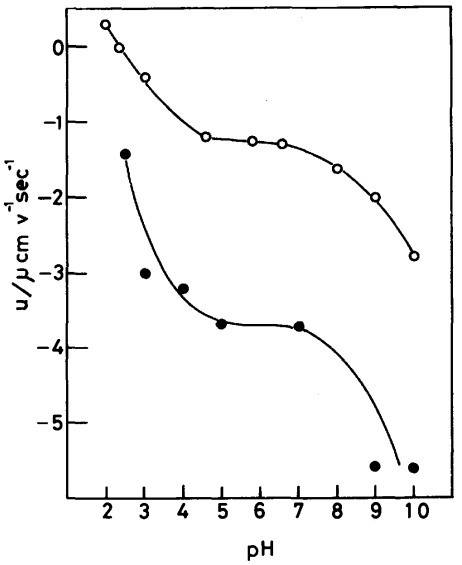

Fig. 1. Electrophoretic mobility-pH curves for PE vesicles.
(●): 0.001 mol dm^{-3} KCl, (○): Papahadjopoulos' data: 0.145 mol dm^{-3} NaCl.

10, indicating that between the two cases there is a difference of about 60 mV in surface potential. As seen from Fig. 2, the two analytical curves fit the respective data very well, suggesting that the membrane surface potential at pH 7.4 is nearly −60 mV since the potential at pH 2 will become zero (see Fig. 1). An analogous discussion can be developed by using the data from the potential measurements on monolayer membranes. Potential change owing to TPB adsorption onto the monolayer can be given as follows on the simple capacitor model:

$$\Delta\Delta V = [\mathrm{TPB}]_m(F/C) = K_{ad}[\mathrm{TPB}]_b e^{\psi_0 F/RT} e^{\Phi F/RT}(F/C), \quad (3)$$

where Φ is the potential difference between membrane surface and adsorbing site, C the specific capacitance of the outer region of monolayer, K_{ad} the adsorption

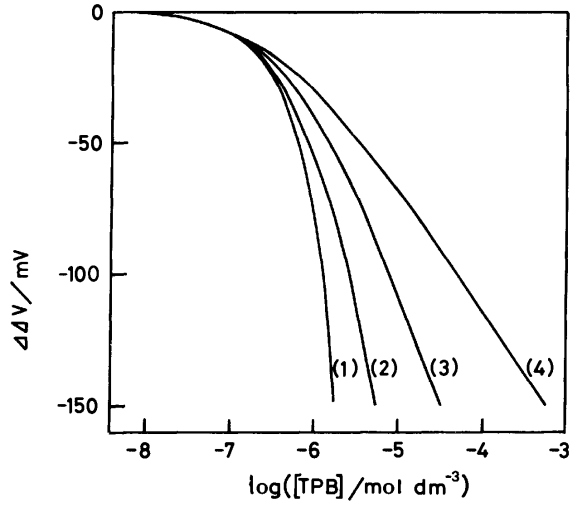

Fig. 3. Calculated curves from Eq. 3 for surface potential change of monolayer membrane. (1): $\Phi=0$, (2): $\Phi=0.2\Delta\Delta V$, (3): $\Phi=0.5\Delta\Delta V$, (4): $\Phi=\Delta\Delta V$.

coefficient, ψ_0 the surface potential, and the other symbols have the usual meanings.

Figure 3 shows several calculated curves obtained from Eq. 3 by assuming ψ_0 is constant. In this case, Φ, is the electrostatic potential produced by adsorption of TPB on the membrane and expressed by the equation $\Phi=a\cdot\Delta\Delta V$. In the case if $a=1$, the full electrostatic potential produced by the adsorption of TPB molecules affects the adsorption of the next TPB molecule onto the membrane. In the case of $a=0$, the adsorption is affected by the chemical potential difference between solution and membrane and by the surface potential. In the experiments, intermediate cases with $0<a<1$ were observed. In Fig. 4, data of $\Delta\Delta V$ are plotted against the solution concentration of TPB (not against the residual concentration, though actually both are equal to each other) for the two values of pH. In these experiments, DPPE monolayers which have a packing density of

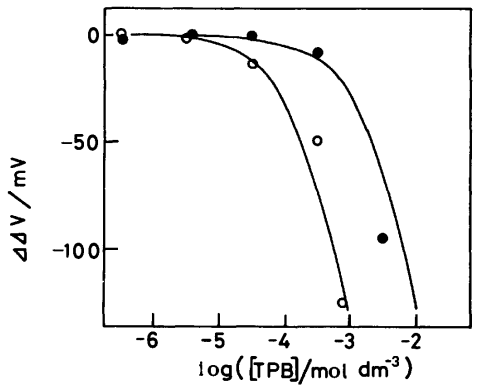

Fig. 4. Surface potential change of DPPE monolayer membrane *vs.* concentration of TPB. (●): pH 7.4, (○): pH 2.

1/80 molecule/Å^2 were used as the membrane sample. The solid lines in the figure are calculated curves from Eq. 3 in the case of $\Phi=0.2\Delta\Delta V$ for the two $K_{ad}(F/C)e^{\psi_0 F/RT}$ values differing from each other by a factor of 10. The agreement between the observed and calculated values is excellent if we take the experimental errors in consideration. If the capacitance value (C) in the boundary region is kept constant, there is expected to be about 60 mV difference in the surface potential of DPPE monolayer membrane between pH's 7.4 and 2. This value is in close agreement with the result estimated by the zeta potential analysis.

Similar behavior has been observed with DMPA monolayer membranes which have a packing density of 1/60 molecule/Å^2. In this case, calculated curves for $\Phi=0.5\Delta\Delta V$ were in close agreement with experimental data as shown in Fig. 5. These data suggest that there is a difference of about 60 mV in the surface potential of DMPA monolayer membrane between pH's 7.4 and 2.

The present analysis indicates that the adsorption equilibrium of TPB may be reasonably expressed by Eq. 3. This means that adsorption equilibrium exists between the concentration of TPB in the membrane, $[TPB]_m$, and the concentration of TPB at the membrane surface, $[TPB]_0$, which is represented by $[TPB]_b e^{\psi_0 F/RT}$. This is in good agreement with observations made on other charged molecules.

Study of Chemisorption and Hydrogenation of 2-Butenes on Platinum by Temperature-programmed Desorption

Shinji TOKITAKA,† Hayao IMAMURA, and Susumu TSUCHIYA*
Department of Industrial Chemistry, Faculty of Engineering, Yamaguchi University, Tokiwadai, Ube 755
(Received May 10, 1984)

The temperature-programmed desorption (TPD) chromatograms of *cis*- and *trans*-2-butene from platinum black comprised three peaks (A, B, and C) with peak maxima at about 253, 373, and 573 K, respectively. Peak A was identified to be *cis*- or *trans*-2-butene and butane. Peaks B and C were from mixtures of *cis*- or *trans*-2-butene and butane with a trace amount of propylene. The propylene may have been formed from chemisorbed *cis*- or *trans*-2-butene by decomposition as the temperature was raised during the subsequent TPD. The reactivities of various types of chemisorbed hydrogen previously detected by TPD were also investigated with regard to the hydrogenation of 2-butenes. Two types of chemisorbed hydrogen, presumed to be present on the surface in the form of hydrogen atoms, chemisorbed on top of platinum atoms and in the bridge form of molecular hydrogen, were found to react with 2-butenes.

The existence of four different chemisorbed species of hydrogen (α, β, γ, and δ) on platinum surfaces has previously been detected by a temperature-programmed desorption (TPD) with peak maxima at about 170, 250, 360, and 570 K, respectively.[1] The TPD chromatogram with four peak maxima has been confirmed by Verbeeks and Sachtler.[2] These chemisorbed species were tentatively assumed to correspond to two types of molecularly chemisorbed hydrogen (one in a linear form (α) and the other in a bridge form (β)) and two types of hydrogen atoms (one adsorbed right on top of metal atoms (γ) and the other in the interstices between the metal atoms(δ)). The differences in their reactivities have been investigated for the H_2–D_2 exchange reaction[3] and for the hydrogenation of ethylene,[4] and of propylene.[5] The reactivity, however, was not necessary the same: β-hydrogen not involved in the H_2–D_2 exchange reaction did react with ethylene and propylene to form ethane and propane, respectively.[4,5] It is, therefore, important to investigate this matter more deeply.

In the present study, 2-butenes were employed as the reactants to investigate differences in the reactivity of various forms of chemisorbed hydrogen since it is the lowest olefin that can be hydrogenated and isomerized.

The isotope exchange involving reactant olefins during the hydrogenation in the presence of deuterium has been of interest to many investigators.[6] Information related to this matter can contribute to the understanding of the mechanism regarding the hydrogenation of olefins. If the reactant olefin molecules are more rapidly exchanged than hydrogenated, the deuterated olefin molecules may be stably chemisorbed on the surface. In previous cases (ethylene[4] and propylene[5]) deuterated olefin molecules which were chemisorbed could not be measured. Since the chemisorbed state is an intermediate state, related information on this species is of importance.

In the present study, the chemisorbed species were removed by the TPD technique and collected for further analysis in order to obtain information on the reaction mechanism.

Experimental

Apparatus and Materials. The apparatus used was the same as that used previously[4] and consisted, basically, of two parts. The first part consisted of an adsorption and a reaction system in which adsorption and reaction were measured in conventional manners. The second part consisted of a TPD system, in which adsorbed gas was later desorbed into a carrier-gas stream (N_2 or He) by means of the programmed heating of a catalyst. The concentration of the desorbed gas was measured and recorded by means of a thermal conductivity detector. The catalyst was platinum black from the same lot previously employed.[4] Its surface area was 3.2×10^3 cm^2/g and the amount used was 2.18 g. The initial reduction and the treatment of the catalyst between experiments have also been described previously.[4]

Cylinder hydrogen (99.975%) supplied by the Osaka hydrogen Co. was stored in a reservoir for use as a reactant after having been passed over platinized silica at 720 K and then through a liquid-nitrogen trap. The same cylinder hydrogen could also be fed through to the reactor for the reduction of the catalyst. Matheson's deuterium (99.5%) passed through a liquid-nitrogen trap was also used as a reactant. *cis*- and *trans*-2-butene obtained from Tokyo Kasei Kogyo Co., Ltd., were purified by repeated distillation *in vacuo*; the purity was confirmed by means of gas chromatography to be more than 99%. High-purity helium (99.995%) and high-purity nitrogen (99.999%), obtained from the Seitetsu Kagaku Co., Ltd., were used as carrier gases for TPD after being passed through a molecular sieve trap.

Procedure. In a typical experiment with *cis*-2-butene, for example, a known amount of *cis*-2-butene was adsorbed for 15 min at the experimental temperature. The reactor was then cooled to 238 K with the *cis*-2-butene present in the gas phase, and kept for 90 min. Following this, the carrier gas, helium, was diverted from the bypass into the reactor in order to remove the *cis*-2-butene in its gas phase. After 5 min the catalyst was heated in a programmed manner. The heating was stopped at about 800 K, after which the catalyst was

† Present address: Toyo Soda Co., ltd., Tokuyama, 746.

kept in a helium stream for 20 min at the same temperature as before cooling. A more detailed description of the TPD method has been given elsewhere.[7] Reproducible results were usually obtained by this procedure. When the results were not reproducible, however, the catalyst was treated with oxygen to oxidize any organic contamination, and was then reduced by hydrogen. This treatment improved the reproducibility considerably.

In the hydrogenation of *cis*- and *trans*-2-butene, various types of chemisorbed hydrogen were first prepared by the TPD technique described previously,[1,3,8] and then olefin was admitted to the reaction system to start the reaction. Helium was added to dilute the olefin when the circulating pump in the reaction system was operated. After the reaction, all the system except for the reactor was evacuated through a liquid-nitrogen trap to collect any condensable hydrocarbons, which were transferred to a sampler for analysis. The carrier gas was then diverted into the reactor, and any materials adsorbed on the catalyst were removed by TPD.

The reactants, the reaction mixtures, and the desorption products were identified by gas chromatography. The deuterated hydrocarbons obtained after the reaction were analyzed by means of a JEOL JMS D-100 mass spectrometer. Before subjecting the reaction mixtures to mass-spectrometric analysis, if possible, they were separated gas chromatographically to avoid any mutual interference of the mass spectra.

Results and Discussion

Temperature-programmed Desorption. Figure 1 shows some typical TPD chromatograms taken after the *cis*-2-butene had been adsorbed on platium black in the absence, or presence, of hydrogen with helium used as the carrier gas. The pressure of the *cis*-2-butene or hydrogen admitted was *ca.* 5×10^2 Pa, and the reaction temperature was 238 K. These four TPD chromatograms resemble each other, characteristically being composed of three peaks with peak maxima at about 253, 373, and 573 K. These peaks are referred to as A, B, and C in the order of appearance with an increase in the temperature. By gas-chromatographic analysis, peak A was indentified to be *cis*-2-butene and butane. Peaks B and C were identified to be mixtures of *cis*-2-butene and butane with a trace amount of propylene. It is suggested that the butane was formed by the self-hydrogenation of chemisorbed *cis*-2-butene when hydrogen was absent. The propylene may have been formed by decomposition from the chemisorbed *cis*-2-butene heated by TPD.

Similar results were obtained for *trans*-2-butene. The description mentioned above is applicable if the word "*cis*-2-butene" is replaced by "*trans*-2-butene".

Reactivity of Chemisorbed Hydrogen. Table 1 shows the results of the surface-hydrogenation experiments with hydrogen preadsorbed on platinum black in various forms (the surface reactant) and with gaseous *cis*- or *trans*-2-butene subsequently admitted into the reaction system (the gas-phase reactant). No gaseous hydrocarbon other than 2-butenes and *n*-butane was observed under the present experimental conditions. The double-bond migration and the *cis-trans* isomerization of butenes and the skeletal isomerization of butane could not be detected. The amounts of butane formed in Series C-2 and T-2 with δ-hydrogen agreed well with that in Series C-1 and T-1 in which *n*-butane was formed by a self-hydrogenation reaction. Apparently, δ-hydrogen hardly reacts with the gas-phase reactant under the present experimental conditions.

In Series C-3 and T-3 with δ- and γ-hydrogen preadsorbed on the surface, however, relatively larger amounts of butane were produced than for Series C-2 and T-2. In the TPD chromatogram obtained after one of 2-butenes was admitted to the preadsorbed hydrogen, where nitrogen was used as the carrier

gas, the γ-hydrogen disappeared, while δ-hydrogen was still present in almost the same amount. It is, therefore, clear that γ-hydrogen is involved in the hydrogenation.

In Series C-4 and T-4 in which β-, γ, and α-hydrogen were preadsorbed, the formation of butane was again observed. The contribution of β-hydrogen to the hydrogenation, however, was not clear at this stage, because the amounts of butane formed were not much different from those of γ-hydrogen. Since the amounts of butane formed in C-4 and T-4 were not very much different from those in C-3 and T-3, the results may suggest that β-hydrogen makes a minor contribution, if at all.

To elucidate the point, the preadsorbed hydrogen was partially displaced by deuterium before *cis*- or *trans*-2-butene was introduced, and the deuteriobutanes formed by hydrogenation were then analyzed. The participation of the different types of chemisorbed hydrogen was consequently elucidated. For the sake of simplicity, the word "hydrogen" in the present paper will hereafter stand for both isotopes, protium and deuterium, and, where necessary, the individual isotopes will be designated as H and D. The types of surfaces used were as follows: 1) δ-Hydrogen was displaced by deuterium, and γ- and β-hydrogen were displaced by protium (βH-γH-δD); 2) δ- and β-hydrogen were displaced by deuterium, and γ-hydrogen was displaced by protium (βD-γH-δD); 3) δ-Hydrogen was displaced by protium, and β- and γ-hydrogen were displaced by deuterium (βD-γD-δH). The method of preparation was described previously;[8)] the isolation of different types of chemisorbed hydrogen was confirmed by separate TPD experiments.

Table 2 shows the results of hydrogenation: The type of surface employed, the amounts of hydrogen preadsorbed and those of the individual deuteriobutanes formed by the hydrogenation are shown. The reactions were carried out at 238 K for 90 min. In the mass spectra of *cis*- or *trans*-2-butene, the reactant, the $m/e>56$ could not be observed, the ^{13}C contribution having been corrected; the H-D exchange between surface deuterium and gaseous *cis*- or *trans*-2-butene could not be detected.

Obviously, *cis*- and *trans*-2-butene were deuterated to deuteriobutanes over the βD-γH-δD, βD-γH-δH, and βH-γD-δH surfaces, but not over the βH-γH-δD surface. These results agree quite well with the above suggestions that δ-hydrogen does not, and γ-hydrogen does, participate in the hydrogenation. The results also suggest the participation of β-hydrogen, which was not clearly detected before.

It is natural that two possibilities for the participation of β-hydrogen be considered: 1) β-Hydrogen directly reacts with 2-butenes. 2) β-Hydrogen first converts to the γ-form and then reacts with 2-butenes. The very slow conversion of β-hydrogen to γ- and/or δ-hydrogen has previously been reported.[1)] In this case, olefin was absent and only hydrogen was present in the system. Therefore, if such conversion takes place during the hydrogenation, the conversion must proceed very fast and the 2-butenes also act as accelerators for the conversion. Since the conversion is actually the dissociation of a hydrogen molecule and the accelerator compound generally contacts with a reactant, 2-butenes must come into contact with β-hydrogen. The step is, namely, a direct reaction. Accordingly, these two types are essentially the same.

After the reaction, the reactant, *cis*- or *trans*-2-butene adsorbed and the product, butane, adsorbed on the surface were removed by TPD technique, and then analyzed by means of the mass spectrometer. The mass spectrometric analysis of reactant olefins chemisorbed and removed by TPD could not be succeeded in the previous cases with ethylene and propylene,[4,5)] because

the amounts of olefins desorbed were too small to be transferred to the sampler for analysis. The results of *cis*- and *trans*-2-butene are shown in Table 3; deuterio-2-butenes and deuteriobutanes were observed. Since any deuteriobutene was not observed in the gase phase, the results suggest that the hydrogenation of chemisorbed *cis*- or *trans*-2-butene is easier than the desorption.

In peak A, any deuterio-2-butene was not observed in the case with βH-γH-δD surface. The result suggests that δ-deuterium does not react with *cis*- and *trans*-2-butene to form deuterio-2-butenes below 273 K. The formation of deuterio-2-butenes observed in the case of the βD-γH-δD and of the βD-γH-δH surfaces was therefore due to the participation of β-deuterium. In the case of the βH-γD-δH surface, the deuterio-2-butenes observed may have been formed by a reaction with γ-deuterium at 238 K.

In peak B, no deuterio-2-butenes was observed in the case of the βH-γH-δD surface. Since peak B appeared

between 290—490 K, and since δ-hydrogen, peak δ, appeared between 470—670 K, δ-deuterium does not suggestively participate in the H-D exchange reaction with 2-butenes. The result with βH-γD-δH surface is reasonably explained by the participation of γ-deuterium.

Small amounts of deuterio-2-butenes were observed in the case of the βD-γH-δD and of the βD-γH-δH surfaces, where the γ-hydrogen was protium. The results can be explained in such a way that the deuterio-2-butenes were formed from β-deuterium and 2-butenes at a lower temperature and, subsequently, desorbed by the rise of temperature.

Peak C appeared between 510—650 K, where δ-hydrogen mostly desorbed. In the case of the βH-γH-δD surface, therefore, the deuterium atoms in deuterio-2-butenes observed obviously came from δ-deuterium, which is only deuterium source.

In the case of the βD-γH-δH surface, some amounts of deuterio-2-butenes were observed. The result suggests that the deuterium atoms in the deuterio-2-butenes came from β-deuterium, and that deuterio-2-butenes formed at a lower temperature subsequently desorbed by the rise of temperature during TPD. In the case of the βH-γD-δH surface, deuterio-2-butenes observed may also be formed during TPD. The results with βD-γH-δD surface are qualitatively consistent with the explanation mentioned above.

The results of the mass spectrometric analysis of deuteriobutanes in peak A, B, and C shown in Table 3 agree quite well with the above suggestions that β- and γ-hydrogen do, and δ-hydrogen does not, participate in the hydrogenation.

In peak B, small amounts of deuteriobutanes were observed in the case of the βD-γH-δD and of the βD-γH-δH surface, where the γ-hydrogen was protium, but the β-hydrogen was deuterium. The results can be explained in such a way that the deuteriobutanes were formed from β-deuterium and 2-butene at a lower temperature and subsequently desorbed by the rise of temperature.

Peak C appeared between 510—650 K, where δ-hydrogen was mostly desorbed. In the case of the βH-γH-δD surface, therefore, the deuterium atoms in deuteriobutanes observed obviously came from δ-deuterium, which was the only deuterium source.

For the βD-γH-δH surface, some amounts of deuteriobutanes were observed. The result suggests that the deuterium atoms in the deuteriobutanes may have come from β-deuterium, and that deuteriobutanes formed at a lower temperature was subsequently desorbed by the rise of temperature during TPD. In the case of the βH-γD-δH surface, deuteriobutanes observed may also be formed during TPD. The results regarding the βD-γH-δD surface are qualitatively consistent with the explanation mentioned above.

A mass spectrometric analysis of propylene with regard to peaks B and C, was not carried out since the amount of propylene was too small to be separated from other components and from the carrier gas by condensation in the gas chromatograph stream. If any deuteriopropylene is observed, they are reasonably considered to have been formed from the chemisorbed deuteriobutenes by decomposition during TPD. The deuteriobutenes, however, do not necessary give the deuteriopropylenes which may depend on the degree of deuteration and the mechanism of decomposition of the chemisorbed deuteriobutanes.

Regarding the mechanism of the hydrogenation of olefins, extensive studies have been reported.[6,9,10] In the hydrogenation of ethylene over platinum catalyst, Bond-Wells mechanism may be accepted. According to the IR study by Soma (Soma-Noto),[10] π-adsorbed ethylene was easily hydrogenated at such low temperature as 195 K, and no hydrogenated species remained on the surface. The obsevation is consistent with the present result that the hydrogenation of *cis*- or *trans*-2-butene was more rapid than the desorption. Accordingly, the following scheme of the hydrogenation of *cis*- or *trans*-2-butene may be suggested. *cis*- or *trans*-2-butene is first chemisorbed on the surface and rapidly exchanged with the surface deuterium, without desorbing from the surface. The deuterio-2-butenes formed are stably chemisorbed on the surface with π-bond. Then, the deuterio-2-butenes are hydrogenated to deuteriobutanes and desorbed from the surface.

The four types of chemisorbed hydrogen were tentatively assigned on the basis of the previous results[1] and the postulates of other workers.[11-16] The γ- and δ-hydrogen were assigned to the weakly and strongly chemisorbed hydrogen atoms so far proposed. The α-hydrogen was assigned to the linearly chemisorbed hydrogen molecules. The β-hydrogen was the intermediate between α- and γ-hydrogen. Later, Primet *et al.*[17] and Dixon *et al.*[18,19] independently proposed their assignment on the basis of the IR studies. Dixon *et al.* deduced the existence of five kinds of hydrogen adsorption. Type I is physisorption, and the other four types, II—V, were corresponded to α—δ hydrogen.

It has previously been presumed that γ-hydrogen is present on the surface in the form of hydrogen atoms chemisorbed on top of platinum atoms, and that β-hydrogen is molecular hydrogen chemisorbed in a bridge form.[1] The difference in the reactivity may, accordingly, be due to the chemisorbed state, whether or not the H-H bond has been split. In the H_2-D_2 exchange reaction, β-hydrogen is not reactive, but it is reactive in the hydrogenation of olefins, and in the H-D exchange between the surface deuterium and 2-butenes. It is, accordingly, probable that a different tendency would be shown depending upon the sort of reaction; the explication of the other reactions awaits further investigations.

Conclusion

While some of the information could perhaps be obtained otherwise, the TPD technique in many cases can be used with unique advantage. Although the information that 2-butenes are more strongly chemisorbed than hydrogen on a catalyst had already been suggested on the basis of kinetic data,[9] it was more clearly shown by TPD, and in addition, the amounts of chemisorbed species could be estimated. Using isotopes, the individual chemisorbed species can be differently labeled, and the reactivity of each is separately measurable. The participation of various types of chemisorbed hydrogen in the 2-butenes hydrogenation were similar to that in the hydrogenation of ethylene and of propylene. γ-Hydrogen, presumed to be present on the surface in the form of hydrogen atoms chemisorbed on top of platinum atoms and β-hydrogen, presumed to be molecular hydrogen chemisorbed in a bridge form, were found to be involved in the 2-butenes hydrogenation. The information on the chemisorbed deuterio-2-butenes during the reaction revealed by the labeled TPD technique, suggests the following scheme of hydrogenation: *cis*- or *trans*-2-butene chemisorbed was first exchanged with deuterium to form deuterio-2-butenes, and before desorbing from the surface, the deuterio-2-butenes were hydrogenated to form deuteriobutanes.

The authors are grateful to Dr. Shizuo Fujisaki of this faculty for obtaining the mass spectra. This work was supported by a Grant-in-Aid for Scientific Research from the Ministry of Education, and by Watanabe foundation for which the authors' thanks are due.

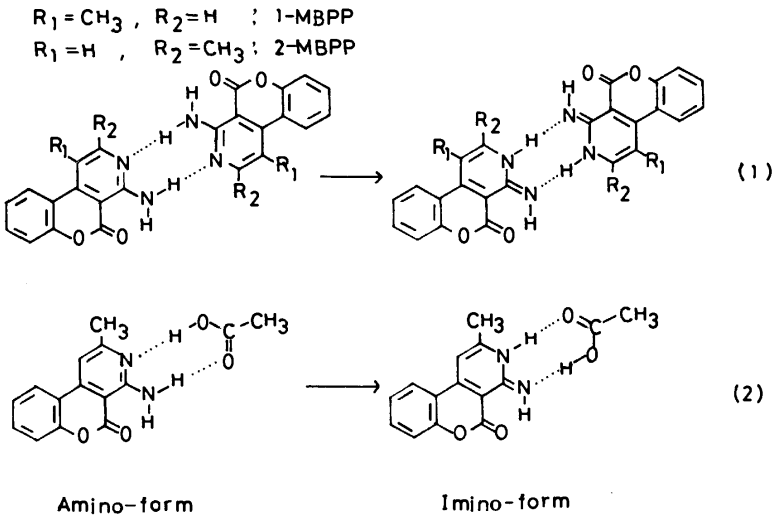
(Received June 29, 1984)

The fluorescence rise and decay times and UV absorption spectra of 1-methyl-4-amino-5*H*-[1]benzopyrano-[3,4-*c*]pyridin-5-one (1-MBPP), 2-methyl-4-amino-5*H*-[1]benzopyrano[3,4-*c*]pyridin-5-one (2-MBPP), and the 1-MBPP/acetic acid and 2-MBPP/acetic acid systems have been measured in hydrocarbon and hydroxylic solvents at room temperature and 77 K. From these data, a rapid formation of proton-transferred species (tautomers) was found to occur in an excited state for 1-MBPP (or 2-MBPP) hydrogen-bonded dimers in hydrocarbon at 77 K, and for 1-MBPP (or 2-MBPP) hydrogen-bonded complexes with acetic acid in hydrocarbon at room temperature and 77 K. The rise times of the tautomer fluorescence for the dimers and complexes were less than 65 ps. The observed fluorescence lifetimes of the 1-MBPP and 2-MBPP monomers agreed well with the lifetimes calculated using the integrated absorption intensity and fluorescence quantum yield.

El-Bayoumi *et al.*[1] have presented the results of a time-resolved fluorescence study of an excited-state double proton transfer. The observed value of the rate constant for a deuterium transfer in a deuterated 7-azaindole dimer at 77 K was $1.9\times10^{8}\ s^{-1}$. Recently, Hetherington III *et al.*[2] have suggested that photo-excited dimers of 7-azaindole undergo a double proton transfer in less than 5 ps at room temperature and 77 K. The proton-transfer rate in an excited state is generally as fast as reported by them[1,2] and other workers.[3-5]

In a previous paper[6] we presented the emission spectra and polarization spectra of 1-methyl-4-amino-5*H*-[1]benzopyrano-[3,4-*c*]pyridin-5-one (1-MBPP), 2-methyl-4-amino-5*H*-[1]benzopyrano-[3,4-*c*]pyridin-5-one (2-MBPP), and the 2-MBPP acetic acid system (2-MBPP/AcOH) in glassy solvents at 77 K. In the course of this investigation, an anomalous fluorescence was observed with a maximum near 450 nm for 1-MBPP, near 436 nm for 2-MBPP, and near 460 nm for 2-MBPP/AcOH in hydrocarbon glassy solvents at 77 K. The anomalous fluorescence band was thought to have originated from the tautomer (imino-form) of the 1-MBPP and 2-MBPP formed by an intermolecular double proton transfer in the excited state of the doubly hydrogen-bonded dimer and complex of amino-form as shown in Schemes 1 and 2. In addition, the fluorescence spectra of the monomer, dimer (or complex) and tautomer, and the phosphorescence spectra of the monomer and dimer have been separately observed on the basis of concentration and tempera-



Schemes 1 and 2.

ture effects on these emissions.[6] 7-Azaindole is known to show the double proton transfer in the excited state, where the phosphorescence spectrum greatly overlaps the tautomer fluorescence band.[7] 1-MBPP and 2-MBPP are, therefore, suitable for studying the dynamics of proton transfer in excited states.

In the present study, the fluorescence rise and decay times and the UV absorption spectra of 1-MBPP, 2-MBPP, 1-MBPP/AcOH, and 2-MBPP/AcOH in hydrocarbon and hydroxylic solvents at ambient temperature and 77 K were investigated in order to elucidate the proton-transfer mechanism in an excited state.

Experimental

Materials. 1-MBPP, 2-MBPP, acetic acid, and solvents were the same as in a previous paper.[6] Solvents used were as follows: (1) a mixed solvent of isopentane and methylcyclohexane (volume ratio 5:1) (IM), (2) a mixed solvent of ethanol and methanol (volume ratio 5:1) (EM), and (3) diethyl ether-isopentane-ethanol (volume ratio 5:5:2) (EPA). Concentrations of 1- and 2-MBPP were 1×10^{-4} mol dm^{-3} and that of the acetic acid was 5×10^{-4} mol dm^{-3}.

UV Absorption Measurements. The UV absorption spectra were obtained at room temperature and at 77 K with an Hitachi model 323 spectrophotometer. The UV absorption measurements at 77 K were carried out on rigid glass samples in a quartz cell of 5 mm path length placed in a glass Dewar vessel with quartz windows.

Fluorescence Time Profile Measurements. A nitrogen laser (Molectron UV24), a pumped dye laser (DL14), and a second-harmonic generator (a KDP crystal) were used for the nanosecond excitation.[8] The excitation wavelength was 305 nm (Rhodamine B/KDP, pulse duration 5 ns). A single-photon counting system (ORTEC) connected to a Spex 14 (0.75 m) monochromator and a HTV R1332 photomultiplier was used for the fluorescence lifetime measurements. More precise measurement with picosecond excitation was performed using a synchronously pumped, cavity-dumped dye laser (Spectra Physics 375 and 3445), operated with a mode-locked Ar^+ laser (Spectra Physics 171—18). The laser was operated with a repetition rate of 800 kHz and a pulse duration of 6 ps. The dye used was Na-fluorescein and its second harmonic (280 nm) was generated with a KDP crystal. Through a modification of the detecting systems, the apparent pulse width (fwhm) was found to be about 70 ps, and the rise and decay times were analyzed by a convolution-simulation method using the time profile of scattered laser light as a reference. Details of the experimental setup and single-photon counting systems for picosecond regions have been reported elsewhere.[9]

Results and Discussion

The UV absorption spectra of 1-MBPP in hydrocarbon[10] and hydroxylic[11] solvents at room temperature are shown elsewhere. The UV absorption spectra of 1-MBPP and 2-MBPP in IM and EM at 77 K are illustrated in Fig. 1 with those of 1-MBPP/AcOH and 2-MBPP/AcOH in IM at 77 K. The UV spectra of 1- and 2-MBPP in EPA at 77 K were similar to those in EM at 77 K. 1-MBPP and 2-MBPP in alcoholic solvents at room temperature as well as at 77 K exist as monomers, though they form hydrogen-bonded complexes with alcohols.[11] These molecules in IM at room temperature exist as monomers,[10] but at 77 K they are considered to form molecular complexes since the UV absorption spectra of 1- and 2-MBPP in IM are similar to those of hydrogen-bonded complexes of 1-MBPP/AcOH and 2-MBPP/AcOH in the same solvent at 77 K, respectively (Fig. 1). From the similarity of these UV absorption spectra, the model of the molecular complex for 1- and 2-MBPP is assumed to be the doubly hydrogen-bonded dimer of the amino-form as shown in Scheme 1.

The fluorescence lifetimes ($\tau_{f\,obsd}$) were measured at fluorescence band maxima ($\lambda_{f\,max}$) in various solvents at room temperature (Table 1) and 77 K (Table 2). An example of fluorescence decay curves observed by means of the single-photon counting method is presented in Fig. 2 for 1-MBPP at ambient temperature.

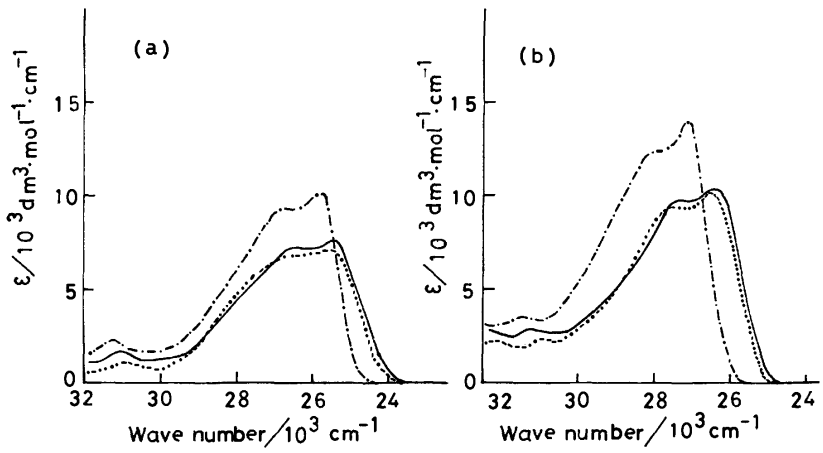

Fig. 1. UV absorption spectra of 1-MBPP (a) and 2-MBPP (b) in IM (——) and EM (—·—) at 77 K, with those of 1-MBPP/AcOH and 2-MBPP/AcOH (·····) in IM at 77 K.

a) See Ref. 6.

The decay curve was found to be single exponential and the lifetime was 0.95 ns (Table 1). In Tables 1 and 2, the fluorescence quantum yields (ϕ_f) and the calculated fluorescence lifetimes ($\tau_{f\,calcd}$), deduced from the integrated UV absorption intensity and ϕ_f, are also shown together with the radiative (k_r) and nonradiative (k_{nr}) rate constants calculated from the fluorescence characteristics in several solvents at room temperature and 77 K, respectively.

The values of $\lambda_{f\,max}$ for 1- and 2-MBPP in IM glassy matrices and those for 1-MBPP/AcOH and 2-MBPP/AcOH are appreciably longer wavelengths than those in an alcoholic glass.[6] The values of $\tau_{f\,obsd}$ of 1-MBPP/AcOH and 2-MBPP/AcOH in nonpolar glass were greater than those of $\tau_{f\,calcd}$ estimated from the integrated absorption intensity of the hydrogen-bonded complex of amino-form and the fluorescence quantum yields observed at the band maxima (473 nm for 1-MBPP and 460 nm for 2-MBPP). This tendency was also seen for the cases of 1- and 2-MBPP in IM at 77 K. The results described above and the resemblance of the fluorescence characteristics of 1-MBPP and 2-MBPP in IM at 77 K indicate that the tautomer (imino-form) formation from the 1-MBPP and 2-MBPP hydrogen-bonded dimers (amino-form) occurs in the excited state, as given in Scheme 1, just as in the case of acid complexes in Scheme 2.[6] On the other hand, the values of $\tau_{f\,obsd}$ in alcoholic matrices at 77 K agreed with those of $\tau_{f\,calcd}$. This result is compatible with the assumption that 1-MBPP and 2-MBPP in an alcoholic solvent at 77 K (as well as at room temperature) behave like monomers, though they make hydrogen-bonded complexes with alcohol.

The tautomerization from benzopyranopyridine hydrogen-bonded dimers (amino-form) to imino-form was investigated with the picosecond laser induced fluorescence technique. The fluorescence rise times were observed at the tautomer fluorescence band at room temperature and 77 K. It is noted that there are fast and slow rise components in the tautomer fluorescence for 1-MBPP and 2-MBPP at 77 K, and for 1-MBPP/AcOH and 2-MBPP/AcOH at room temperature and 77 K, as summarized in Table 3. As described by Hetherington III *et al.* in the study on the proton

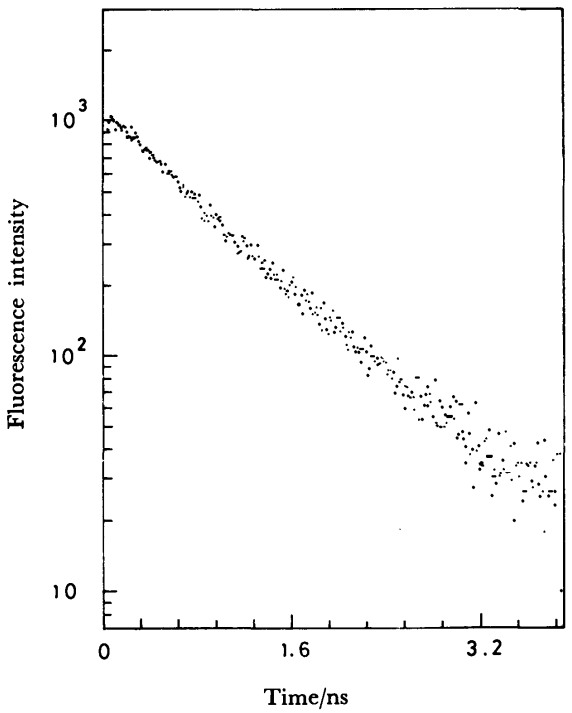

Fig. 2. Logarithmic plot of a fluorescence decay of 1-MBPP in IM at room temperature.
Excitation wavelength; 280 nm, Emission wavelength; 403 nm.

Table 3. Rise times of tautomer fluorescence for different systems in IM at room temperature and 77 K

System	Fast component	Slow component
	ps	ps
1-MBPP at 77 K	<20	~40
1-MBPP/AcOH at room temp	<20	~45
1-MBPP/AcOH at 77 K	<20	~65
2-MBPP at 77 K	<20	~35
2-MBPP/AcOH at room temp	<20	~45
2-MBPP/AcOH at 77 K	<20	~65

transfer of the 7-azaindole dimer,[2] the presence of fast and slow rise components in the tautomer fluorescence for 1- and 2-MBPP and their acetic acid complex systems suggests that there are two different pathways for the formation of the tautomer in an excited state: (a) the rapid proton transfer from the excited Franck-Condon state and (b) the relatively slow proton transfer from the excited state generated by energy relaxation from the excited Franck-Condon state.

The slow fluorescence rise times for 1-MBPP/AcOH and 2-MBPP/AcOH at room temperature were shorter than those for the same systems at 77 K. This result indicates that tautomer formation *via* pathway (b) at room temperature is more favored than at 77 K because proton transfer at room temperature occurs effectively across the barrier by thermal activation. In addition, the rise time of the dimer was shorter than that of heterogeneous systems such as 1-MBPP/AcOH. This result means that the barrier height in proton transfer in the excited state for homogeneous complexes is lower than that for heterogeneous complexes.

The intensity ratio of the fast and slow rise components in the tautomer fluorescence is thought to depend on the excitation wavelength. In the present case the excitation wavelength was 280 nm, about 9500—11700 cm^{-1} above the absorption edge of the complexes. A red edge excitation and time profile observation will give further information on the energy and proton transfer in an excited state.

The Preparation and Spectral Properties of *trans(CN)*-$[Co(CN)_2(tmdda)]^-$ and -$[Co(CN)_2(L\text{-}ala)_2]^-$ Complexes

Kan KANAMORI,* Yoko NUNOMURA, Masumi TAKASHIMA, Kiyonori NAGATA, Kiyoyasu KAWAI, and Jinsai HIDAKA†

(Received May 23, 1984)

All-*trans*- and *trans(CN),cis(N)*-$[Co(CN)_2(L\text{-}ala)_2]^-$ and *trans(CN)*-$[Co(CN)_2(tmdda)]^-$ were newly prepared; here, tmdda denotes trimethylenediamine-*N,N'*-diacetate. These complexes were characterized from their electronic absorption, NMR, and Raman spectra. The CD spectra of two *trans(CN)* isomers of the bis(L-alaninato)-complex are also presented.

There have been few reports on the preparation of *trans(CN)*-$[Co(CN)_2(N)_2(O)_2]$-type complexes, though many reports have appeared on *trans(CN)*-$[Co(CN)_2(N)_4]$-type complexes, where $(N)_2(O)_2$ denotes diamine-*N,N'*-diacetate or bis(amino carboxylate) and $(N)_4$ tetraammine[1] or bis(diamine).[2] For instance, three *cis(CN)*-$[Co(CN)_2(am)_2]^-$ isomers (am=amino carboxylate) have been reported for the glycinato complexes,[3,4] but the *trans(CN)* isomer has not yet appeared. Recently, work on synthesizing cobalt(III) complexes with a linear quadridentate O-N-N-O ligand, tmdda, have been reported, and it was suggested that tmdda prefers the *unsym-cis* to the *sym-cis* geometry, when the ligand coordinates to the Co^{III} ion.[5,6] This fact seems to reveal that the *trans(CN)* coordination is possibly formed in the preparation of the dicyano Co^{III} complex with tmdda.

The present work is concerned with the preparation of all-*trans*- and *trans(CN),cis(N)*-$[Co(CN)_2(L\text{-}ala)_2]^-$ and *trans(CN)*-$[Co(CN)_2(tmdda)]^-$, which are characterized by their electronic absorption, Raman, and NMR spectra. The CD spectra of the two isomers of $[Co(CN)_2(L\text{-}ala)_2]^-$ are also presented.

Experimental

Preparation. *1) Lithium* trans(CN)-*Dicyano(trimethylenediamine*-N,N'-*diacetato)cobaltate(III),* trans(CN)-*Li[Co(CN)$_2$(tmdda)].* To a solution of trimethylenediamine-*N,N'*-diacetic acid dihydrochloride[7] (5.2 g; 0.02 mol) in 200 cm^3 of water we added 4.5 g (0.02 mol) of $[CoCl(CN)(NH_3)_4]Cl$.[8] The mixture was adjusted to pH=8 with an aqueous NaOH solution, and then a small amount of activated charcoal was added. The mixture was stirred at 60 °C for 30 h. After removing the activated charcoal, the filtrate was adjusted to pH=7 with dilute acetic acid and diluted to 1 dm^3 with water. Then the charged compound was removed by passing it through a cation-exchange (Dowex 50W×8, Li^+ form) column and an anion-exchange (Dowex 1×8, Cl^- form) column. The eluate was concentrated to dryness with a rotary evaporator. The residue was washed with ethanol and dried. This dark-red intermediate product, which was presumed to be $[Co(CN)(tmdda)(NH_3)]$, was used in the next step without any purification. The intermediate product (4.5 g) and KCN (0.98 g; 0.015 mol) were kept at 60 °C in 200 cm^3 of dimethyl sulfoxide for 30 h. After the reaction solution has then been diluted to 2 dm^3 with water, a small amount of an insoluble material was filtered off. The filtrate was applied to an anion-exchange column (Dowex 1×8, 200-400 mesh, Cl^- form, 4×60 cm), and the adsorbed band was eluted with an aqueous LiCl solution (0.5 g/dm^3), separating into orange and orange-red bands. It was found from the spectral properties that the first, orange eluate contained the all-*cis*-$[Co(CN)_2(tmdda)]^-$ complex, with the second, orange red one contained the desired *trans(CN)*-$[Co(CN)_2(tmdda)]^-$ complex. The orange-red eluate was evaporated to dryness with a rotary evaporator, and the residue was washed with ethanol to remove the LiCl. The crude product was recrystallized from a small amount of water by adding methanol. Yield, 0.4 g. Found: C, 32.09; H, 4.52; N, 16.53%. Calcd for $Li[Co(CN)_2(tmdda)]\cdot 1.75H_2O = LiCoC_7H_{12}N_4O_4\cdot 1.75H_2O$: C, 32.05; H, 4.63; N, 16.61%.

2) Lithium trans(CN)-*Dicyanobis(L-alaninato)cobaltate(III),* trans(CN)-*Li[Co(CN)$_2$(L-ala)$_2$].* The two isomers of *trans(CN)*-$[Co(CN)_2(L\text{-}ala)_2]^-$ were obtained by a method similar to that in 1). That is, $[CoCl(CN)(NH_3)_4]Cl$ (9.0 g; 0.04 mol), L-alanine (7.2 g; 0.08 mol), and NaOH (3.2 g; 0.08 mol) were dissolved in a mixture of 100 cm^3 of dimethyl sulfoxide and 100 cm^3 of water; then the solution was stirred at 60 °C for 30 h. The intermediate product, which was supposed to be $[Co(CN)(L\text{-}ala)_2(NH_3)]$, was isolated by a manner similar to that used for $[Co(CN)(tmdda)(NH_3)]$. The intermediate product (5.6 g) and KCN (1.3 g; 0.02 mol) were kept at 60 °C in 200 cm^3 of dimethyl sulfoxide for 30 h. The reaction mixture was then diluted to 2 dm^3 with water and poured onto an anion-exchange column (Dowex 1×8, 200—400 mesh, Cl^- form; 4×60 cm). Four colored bands, yellow, pinkish red, orange-red, and orange, were obtained, in this order, by eluting with an aqueous NH_4Cl solution (1 g/dm^3). The first two bands (yellow and pinkish red) partially overlapped, so the eluates were combined and evaporated to dryness under reduced pressure. The yellow isomer and NH_4Cl were extracted from the residue with ethanol, leaving the pinkish red isomer, which was insoluble in ethanol. The yellow isomer was found to be the *cis(CN), trans(N)* isomer by comparing its electronic absorption spectrum with that of *cis(CN),trans(N)*-$[Co(CN)_2(gly)_2]^-$.[4] The pinkish red isomer was converted to lithium salt by rechromatography. The crude product was recrystallized by dissolving it in a small amount of water, and then adding methanol. It was found by

spectral measurements to be described later that this isomer has the all-*trans* configuration. After these two bands were removed, the eluent was changed from an aqueous NH_4Cl solution to an aqueous LiCl solution (1 g/dm^3). The orange isomer was found to be the all-*cis* isomer by comparing its electronic absorption spectrum with that of all-*cis*-[Co(CN)$_2$(gly)$_2$]$^-$.[4] The orange-red fraction was concentrated to dryness with a rotary evaporator, and the residue was washed with ethanol and recrystallized from a small amount of water by adding methanol. The orange-red isomer was assigned to have the *trans(CN)*, *cis(N)* configuration on the basis of the spectral properties to be described below. Yields, 0.5 g for the pinkish red isomer and 0.2 g for the orange-red isomer. Found for the pinkish red isomer: C, 28.62; H, 5.51; N, 15.56%. Calcd for Li[Co(CN)$_2$(L-ala)$_2$]·2.5H_2O·0.5CH_3OH=$LiCoC_8H_{12}N_4O_4$·2.5H_2O·0.5CH_3OH: C, 28.74; H, 5.39; N, 15.78%. The solvation of methanol was confirmed by the ^1H and ^{13}C NMR spectra. Found for the orange-red isomer: C, 27.82; H, 5.12; N, 16.10%. Calcd for Li[Co(CN)$_2$(L-ala)$_2$]·3H_2O=$LiCoC_8H_{12}N_4O_4$·3H_2O: C, 27.63; H, 5.22; N, 16.11%.

Measurements. The electronic absorption spectra were recorded with a Hitachi 220 spectrophotometer and the CD spectra, with JASCO J-20 and J-500 spectrophotometers. Raman spectra were recorded on a JASCO R-800 Laser Raman spectrophotometer with an excitation of the He–Ne laser (632.8 nm, 50 mW) in water and a disk. The IR spectra were recorded on a JASCO IRA-3 spectrophotometer, and the samples were provided as nujol mulls. The NMR spectra were recorded on JEOL FX-100 and FX-90Q spectrometers in D_2O. Sodium 2,2-dimethyl-2-silapentane-5-sulfonate (DSS) was used as the internal reference.

Results and Discussion

Structural Assignment. Figure 1 shows five geometrical isomers of [Co(CN)$_2$(N)$_2$(O)$_2$]-type complexes. All of them are possible for [Co(CN)$_2$(L-ala)$_2$]$^-$, while the possible isomers for [Co(CN)$_2$(tmdda)]$^-$ are reduced to three, *trans(CN)*, *cis(N)*, *cis(CN)*, *trans(O)*, and all-*cis*. Poznjac and Pawlowski[3] reported the preparations and spectroscopic properties of three *cis(CN)* isomers of [Co(CN)$_2$(gly)$_2$]$^-$ and two *cis(CN)* isomers of [Co(CN)$_2$(edda)]$^-$. Figure 2 shows the absorption spectra of the orange-red isomer of [Co(CN)$_2$(tmdda)]$^-$ and the pinkish red and orange-red isomers of [Co(CN)$_2$(L-ala)$_2$]$^-$; their data are summarized in Table 1. As the absorption spectrum of the orange isomer of [Co(CN)$_2$(tmdda)]$^-$ is quite similar to that of all-*cis*-[Co(CN)$_2$(edda)]$^-$,[5] it can be assigned to the all-*cis* one. On the other hand, the orange-red isomer of [Co(CN)$_2$(tmdda)]$^-$ can be assigned to the *trans(CN)* one, since the absorption spectrum differs distinctly from that of the *cis(CN)*,*trans(O)*-[Co(CN)$_2$(edda)]$^-$ (Table 1).

The orange-red isomer of [Co(CN)$_2$(L-ala)$_2$]$^-$ is also assignable to the *trans(CN)*,*cis(N)* one, since the d-d spectrum is quite similar to that of *trans(CN)*-[Co(CN)$_2$(tmdda)]$^-$, as may be seen in Fig. 2. The d-d spectrum of the pinkish red isomer differs remarkably from that of *trans(CN)*,*cis(N)*-[Co(CN)$_2$(L-ala)$_2$]$^-$ and those of the three *cis(CN)* isomers of [Co(CN)$_2$(gly)$_2$]$^-$[4] (Fig. 2 and Table 1). Consequently, the pinkish red isomer of [Co(CN)$_2$(L-ala)$_2$]$^-$ can be assigned to the all-*trans* one.

The ^{1}H and ^{13}C NMR spectra of the cobalt(III) complexes with tmdda have also been investigated.[5,6] The ^{13}C NMR spectrum of *trans(CN)*-[Co(CN)$_2$(tmdda)]$^-$ exhibits four resonance lines (at δ 28.88, 53.09, 60.08, and 183.60), corresponding to the four different carbon atoms; these lines are assignable to the resonances of -$CH_2\underline{C}H_2CH_2$-, -$NH\underline{C}H_2CH_2$-, -$NH\underline{C}H_2COO$-, and -$CH_2\underline{C}OO$- respectively, following the assignment of Gailey *et al.*[5] This observation indicates that the two glycinate moieties of the coordinated tmdda are equivalent, being consistent with the *trans(CN)* configuration. The six-membered backbone chelate ring of *trans(CN)*-[Co(CN)$_2$(tmdda)]$^-$ would take either the skew-boat or chair form. The middle methylene protons of the backbone trimethylenediamine ring would be in different magnetic environments to each other in the chair form, whereas they would be equivalent in the skew-boat form. In order to determine the conformation of the backbone chelate ring, the ^{1}H NMR spectra of *trans(CN)*-[Co(CN)$_2$(tmdda)]$^-$ were measured. Figure 3-A shows its ^{1}H NMR spectrum in D_2O acidified with D_2SO_4 (pD≈2), and Figure 3-B, that in D_2O. The proton-exchange rate of imino groups would be slow enough to give the observable signals in an acidified solution. In contrast, imino protons are expected to be quickly exchanged with deuterons in D_2O. From a comparison of Fig. 3-A with Fig. 3-B, the broad band at δ 5.8, which was observed only in the acidified D_2O, can be assigned to the imino protons. The doublet (at δ 3.35 and 3.27) and the multiplet (at *ca.* δ 2.5) in Fig. 3-A, which are transformed into a singlet and a simpler multiplet in D_2O (Fig. 3-B), can be assigned to the methylene protons adjacent to the imino groups. Two multiplets (at *ca.* δ 2.1 and

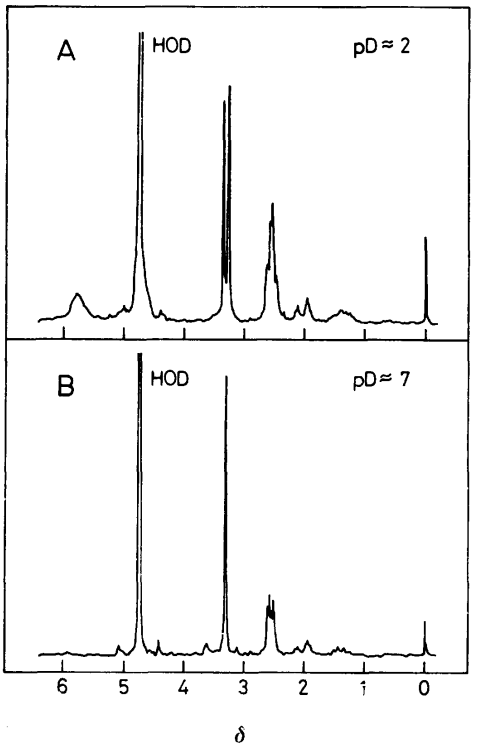

Fig. 3. ^{1}H NMR spectra of *trans(CN)*-[Co(CN)$_2$(tmdda)]$^-$ in D_2O acidified with D_2SO_4 (A) and D_2O (B). (Resonance lines around δ 1.4 are due to a contaminant in DSS.)

ca. 1.9), which remained unchanged by the deuteration of the imino groups, can be assigned to the middle methylene protons, though the integrated intensity was somewhat weaker than expected (the overall intensity of the two multiplets was about three-tenths of that of the multiplet at δ 2.5). This assignment is consistent with that of the middle methylene protons of a series of Co^{III}-tn complexes,[9] for which the middle methylene protons were assigned to the resonance lines near δ 2. The spacing of the two multiplets (δ 0.15) can not be explained on the basis of the spin-spin coupling between the middle methylene and the terminal methylene protons, since the spacing of the resonance lines due to the terminal methylene protons is much narrower than δ 0.15. Therefore, these two multiplets can be regarded as resonances of different protons in different magnetic environments. This fact suggests that the six-membered backbone chelate ring in the complex takes the chair form; in other words, the complex takes the *meso* form with respect to the coordinated nitrogen atoms.

The Raman spectrum gives useful information concerning the structural elucidation of Co^{III} complexes;[10,11] for instance, the Raman spectra in the skeletal stretching region were successfully applied to the differentiation of the isomers of [Co(gly)$_2$(AA)]-type complexes, where AA denotes en or ox.[11] The all-*trans* isomer can be regarded as having a C_{2h} symmetry, and then the Co-N and Co-O stretching vibrations are reduced to $2A_g+2B_u$, of which the A_g modes are Raman-active. On the other hand, the *trans(CN),cis(N)* isomer can be regarded as having a C_{2v} symmetry and the Co-N and Co-O stretching vibrations are reduced to $2A_1+2B_1$, of which all modes are Raman-active. The aqueous Raman spectra of the all-*trans*- and *trans(CN),cis(N)*-[Co(CN)$_2$(L-ala)$_2$]$^-$ complexes in the 650—450 cm^{-1} region are shown in Fig. 4 and correspond to those in the solid state well. The all-*trans* isomer exhibits two bands (581 and 537 cm^{-1}) in the Co-N and Co-O stretching vibration region, as expected from the symmetry. In contrast to the all-*trans* isomer, the *trans(CN),cis(N)* isomer exhibits three bands (595, 537, and 495 cm^{-1}) in the corresponding region. The fourth Raman-active band would be weak and concealed by the strong band at 595 cm^{-1}. The IR band at 577 cm^{-1} may be the counterpart of the concealed Raman band. These results confirm the assignment of the two isomers of [Co(CN)$_2$(L-ala)$_2$]$^-$ based on the absorption spectral behavior.

Absorption and CD Spectra. It has been suggested that, in the first absorption band of the *trans(CN)*-[Co(CN)$_2$(N)$_4$]-type complex ((N)$_4$=tetraammine or bis(diamine)), the position of the lower-energy component agrees with the one predicted from the semiempirical calculation,[12] whereas the position of the absorption component at a higher energy deviates from the one predicted.[1] This behavior in the first-absorption-band region is also realized in the present *trans(CN),cis(N)* isomer. The short vertical lines in Fig. 2 show the positions of the absorption components of the first absorption band, estimated in terms of the parameters, δ^1(CN)=32050 from [Co(CN)$_6$]$^{3-}$, δ^1(N)=21300 from [Co(en)$_3$]$^{3+}$, and δ^1(O)=16600 cm^{-1} from [Co(ox)$_3$]$^{3-}$. The splitting pattern of the first absorption band for the *trans(CN),cis(N)*-[Co(CN)$_2$(L-ala)$_2$]$^-$ isomer is similar to that of *trans(CN)*-[Co(CN)$_2$(NH$_3$)$_4$]$^+$;[1] namely, the higher energy component deviates remarkably from the one predicted. In the first absorption band of the all-*trans*-[Co(CN)$_2$(L-ala)$_2$]$^-$ isomer, however, the observed components agree fairly well with the predicted ones. This fact seems to deny that only *trans(CN)* arrangement is responsible for the deviation.

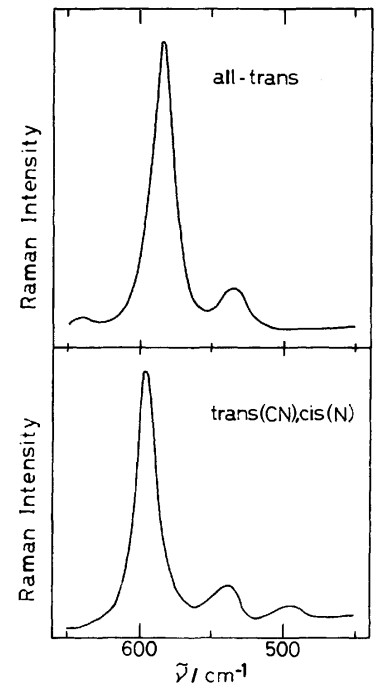

Fig. 4. Aqueous Raman spectra of the two isomers of *trans(CN)*-[Co(CN)$_2$(L-ala)$_2$]$^-$.

The CD spectra of *trans(CN),cis(N)*- and all-*trans*-[Co(CN)$_2$(L-ala)$_2$]$^-$ are mainly contributed by the *S*(C)-configuration of the L-alaninate ligand. In the d-d absorption-band region, the two isomers show similar CD patterns, though the CD spectrum of the all-*trans* isomer is somewhat stronger in intensity than that of the *trans(CN),cis(N)* isomer. Their CD bands in the second-absorption-band region are comparatively intense (Fig. 2 and Table 1). In contrast to the d-d absorption-band region, their CD spectra in the charge-transfer region (*ca.* 35—42×10^3 cm^{-1}) differ significantly from one another. It is apparent that the positive CD band (at 37.9×10^3 cm^{-1}) of the all-*trans* isomer corresponds to the absorption shoulder at *ca.* 37×10^3 cm^{-1}, and the negative CD band (at 39.5×10^3 cm^{-1}) of the *trans(CN),cis(N)* one, to the absorption

shoulder at *ca.* $37\times10^3\,cm^{-1}$. However, more data will be needed in order to discuss this CD spectral behavior in relation to the structural difference between the two geometrical isomers.

The authors wish to express their thanks to Professor Yoichi Shimura of Osaka University for his fruitful discussion.

Synthetic Inorganic Ion-exchange Materials. XXXVII. Ion-exchange Behaviors of Alkylammonium Ions on Hydrous Titanium Dioxide

Masamichi Tsuji,* Mitsuo Abe, and Minoru Orimo†
Department of Chemistry, Faculty of Science, Tokyo Institute of Technology, 2-12-1, Ookayama, Meguro-ku, Tokyo 152
(Received June 11, 1984)

Ion-exchange behavior of alkali hydroxide and alkylamines having different sizes and forms on hydrous titanium dioxide ion exchanger (HTDO) were studied. The uptakes of all the cations by HTDO indicated the ion-exchange stoichiometry at a pH range studied. The pH titration curves vary, depending on the cation species and the strength of the bases used: amorphous HTDO(Am-HTDO) behaves as a bifunctional acid towards strong bases and as a monofunctional acid towards weak bases. Am-HTDO shows an affinity series in the increasing order: large ions($(C_2H_5)_3NH^+$, $(CH_3)_4N^+$, and $(n\text{-}C_4H_9)_4N^+$)<ions in medium size ($CH_3NH_3^+$, $n\text{-}C_3H_7NH_3^+$, $n\text{-}C_4H_9NH_3^+$ *etc.*)<small ions(Na^+, K^+, and NH_4^+). The large ions suffer from a strong steric effect, because of the limited space of the ion-exchange site available. The results correlate with the pore size distribution: the pore radius ranged from 4 to 7 Å in Am-HTDO degassed at 40 °C by a rotary pump. The maximum volume occupied by the alkylammonium ions exchanged (0.2—0.3 cm^3/g), calculated by assuming cations to be unhydrated, is in good agreement with the value determined by N_2 gas adsorption (0.16 cm^3/g). An anatase-type HTDO showed a larger steric effect for uptake of the alkylammonium ions than that by the Am-HTDO, due to a decrease in the ion-exchange cavity.

Recently, ion-exchange selectivities on synthetic inorganic ion exchange materials have been studied.[1-4] Hydrous oxides and hydroxides of multivalent metals are reported to behave as selective ion exchangers towards a few metal ions. Hydrous titanium(IV) oxide showed selectivity for uranium(VI) in sea water.[5-7] Hydrous tin(IV) antimonate exhibited a unique selectivity sequence of $Na^+<K^+<Rb^+<Cs^+ \ll Li^+$ in an increasing order.[8] Hydrous manganese(IV) oxide in cryptomelane-type showed an unusual selectivity sequence towards alkali metal ions: $Li^+<Na^+<Cs^+ \ll K^+$, Rb^+. This exchanger shows a high selectilvity for the ions having the effective ionic radius[9] of 1.4 Å.[10,11] Crystalline antimonic(V) acid cation exchanger shows an excellent selectivity towards metal ions having an effective ionic radius of about 1 Å.[3] Cations larger than 6 Å in diameter cannot enter the cavity of crystalline antimonic acid.[12] Adsorption of Alkyl Orange dyes on silica gel indicated that a correlation exists with the molecular size of the dye.[13] It has been known that clinoptilolite cannot exchange alkylammonium ions larger than 6 Å.[14] These behaviors are well known as the ion-sieve action. No ion-sieve effect was observed on γ-zirconium phosphate ion exchanger, because of expansion along the c-axis by exchanging the large organic ions.[15] A steric effect can be expected for large spherical cations and long cations exchanged by HTDO, if it has a rigid framework and a small ion-exchange cavity.

The present paper describes the ion-exchange behaviors of univalent cations having different van der Waals dimensions on HTDO.

Experimental

Ion-exchange Material. Am-HTDO was prepared by hydrolysis of $TiCl_4$ solution with NaOH solution.[16] Am-HTDO in H^+ form was obtained by removing Na^+ ions by percolation of 0.1 M HCl (1 M=1 mol dm^{-3}) solution into a column of Am-HTDO containing Na^+ ions (1 cmϕ×10 cm).

X-Ray and Thermal Analyses. X-Ray analysis with the powder method was carried out using Ni-filtered Cu-$K\alpha$ radiation with a JEOL diffractometer, Model JDX-7E. Thermogravimetry(TG) and differential thermal analysis (DTA) were undertaken with a Rigaku Denki thermoflex type thermal analyzer, Model 8001, at a heating rate of 10 °C min^{-1}.

Pore Size Distribution. The nitrogen gas adsorption isotherm of Am-HTDO was determined at 77 K by using N_2 gas adsorption equipment (Calro Erba, Co., Model Sorptomatic 1800). Prior to the measurement, degassing with a rotary pump was carried out until about 0.5 g of Am-HTDO in 50—100 mesh size became constant at 40 °C. A cross section of 16.2 $Å^2$ for N_2 molecule was employed.

pH Titration Curves. A 0.125 g portion of Am-HTDO in H^+ form was added into 12.5 cm^3 of (MCl+HCl) or (MCl+MOH) mixed solution of the ionic strength 0.1 at 30±0.5 °C in a thermostated bath, where M=Na, NH_4, and alkylammonium. It was shaken intermittently and allowed to stand until the concentration of M^+ ions became constant within the experimental error. Thereafter, pH values and the concentration of M^+ and Cl^- in the supernatant solution were determined. The pH measurement was carried out using a Toa Dempa pH meter, Model HM-5A. The concentrations of M^+ and Cl^- ions in the solution were determined by an "ion-exchange and titration" method: After neutralizing a 10 cm^3 aliquot with a standardized 0.1 M HNO_3 or 0.05 M NaOH solutions, the solution was percolated through Dowex 50W-X8 ion-exchanger column in H^+ form (1.0 cmϕ×10 cm) and then washed with water. The effluent was collected and titrated with standardized 0.05 M NaOH solution. The amount of M^+ ions in the solution was determined by sub-

tracting the amount of NaOH used for neutralization from the amount of the titrant. Cl^- ions in the equilibrated solution were determined by titrating with 0.03 M $AgNO_3$ solution using fluorescein as indicator after neutralization. Thus, the uptakes of M^+ and Cl^- ions by the Am-HTDO were calculated from the difference relative to the initial concentration.

Chemicals. $(n\text{-}C_4H_9)_4NOH$ was supplied as a 10% aqueous solution by Tokyo Kasei Ind. and other chemicals were supplied by Wako Pure Chemical Ind., Ltd. All chemicals were of analytical grade and used without further purification. Alkylammonium chloride solutions were prepared by neutralizing with dilute HCl solution.

Results and Discussion

Am-HTDO as an Ion-exchange Material. The Am-HTDO was characterized by X-ray diffraction and thermal studies. The X-ray powder pattern showed almost no distinct peak, indicating the product to be nearly amorphous. The crystallite sizes were estimated to be smaller than 20 Å in diameter. DTA curve showed an endothermic peak based on dehydration up to 200 °C and a sharp exothermic peak due to the transformation from nearly amorphous to the anatase modification at 400 °C. These features are in good agreement with those reported in our previous paper.[17] The composition of Am-HTDO obtained from the weight loss was $TiO_2 \cdot 1.84H_2O$ by assuming that the ignition product is TiO_2. The same composition was obtained in Am-HTDO kept in air at RT for 8 months, but it showed a weak anatase-type diffraction pattern, yielding a crystallite of about 30 Å.

Pore Size Distribution. The adsorption-desorption isotherm of N_2 gas on Am-HTDO was measured; this gives important informations about the pore structures of the solid. It shows the Langmuir-type[18] (Fig. 1). There was almost complete reversibility through the entire pressure range studied. A straight line was obtained on the BET plot,[19] giving S_{BET}= 345 m^2/g and C_{BET}=194. As long as the constant C_{BET} is lower than 200, a surface area, S_t, obtained by V_l-t plot based on the "MP method" by Brunauer, Mikhail and Bodor[20] shows good agreement with S_{BET}. In the present sample, S_t was 356 m^2/g, showing a discrepancy of 3.2%. This is a reasonable agreement, which permits use of V_l-t plot.

The pore volume distribution curve of Am-HTDO is shown in Fig. 2. The degassed Am-HTDO consists largely of micropores of 4—7 Å in hydraulic radius. The total pore volume was 0.16 cm^3/g. A sample degassed with a rotary pump until a constant weight was achieved showed a composition of $TiO_2 \cdot 1.2H_2O$. Hence, the skeleton of the Am-HTDO is still covered with hydrated and interstitial water. If the water could be removed more extensively without destruction of the ion-exchange sites or crystallization, a wider dis-

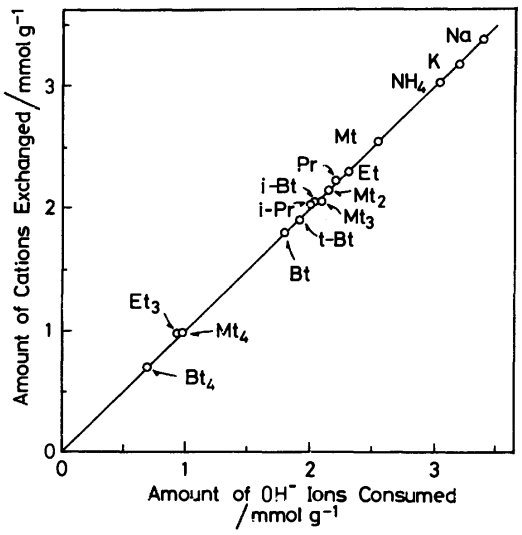

Fig. 3. Stoichiometry of ion-exchange reaction of alkylamines on Am-HTDO.
HTDO: 0.125 g, Soln: 0.1 M Amine or mixture of amine and the chloride, Total vol: 12.5 cm^3, Temp: 30 °C. Marks: Mt=$CH_3NH_3^+$, Et=$C_2H_5NH_3^+$, Pr=$C_3H_7NH_3^+$, Bt=$C_4H_9NH_3^+$, Mt_2=$(CH_3)_2NH_2^+$, Mt_3=$(CH_3)_3NH^+$, Mt_4=$(CH_3)_4N^+$, Et_2=$(C_2H_5)_2NH_2^+$, Et_3=$(C_2H_5)_3NH^+$, Bt_4=$(n\text{-}C_4H_9)_4N^+$.

tribution of pores accessible to nitrogen molecules would be obtained. However, degassing at elevated temperatures destroys the exchange sites.

Ion-exchange Stoichiometry for Various Alkylammonium Ions. The uptake of cations with different dimensions was studied in alkaline media(Fig. 3). The amount of hydroxide ions consumed was in good agreement with the amount of cation exchanged. This indicates the stoichiometry of the exchange reaction for all the cations used. Accordingly, almost all protons in Am-HTDO behave as a Brönsted acid. The uptake occurs through two possible schemes: One includes an exchange process with a replaceable proton,

$$-\overset{|}{\underset{|}{\text{Ti}}}\text{-OH} = -\overset{|}{\underset{|}{\text{Ti}}}\text{-O}^- + \text{H}^+ \qquad \text{(first step)}$$

$$-\overset{|}{\underset{|}{\text{Ti}}}\text{-O}^- + \text{R}_m\text{NH}^+_{n+1} = -\overset{|}{\underset{|}{\text{Ti}}}\text{-O-R}_m\text{NH}^+_{n+1} \qquad \text{(second step)}$$

and the other occurs through hydrogen bonding,

$$-\overset{|}{\underset{|}{\text{Ti}}}\text{-OH} + \text{R}_m\text{NH}_n = -\overset{|}{\underset{|}{\text{Ti}}}\text{-O-R}_m\text{NH}_{n+1}$$

where m and n are integer, and R denotes alkyl groups. However, the titration method cannot distinguish between the dissociation step and the adsorption step, because of the difficulty of the measurement of the H^+ ion concentration in the solid phase.

pH Titration Curve. It has been known that the Am-HTDO ion exchanger has an amphoteric character in aqueous solutions. The ion-exchange capacity towards Na^+ and Cl^- ions depends upon the pH of the solution used. The pH titration of the Am-HTDO ion exchanger was carried out in a pH range from 2 to 12, by using bases with different strengths, and geometrical forms and sizes in order to investigate the details of the change in the exchange capacity with pH values. A distinct break point can be found on each titration curve with strong bases at pH 7.5—8 irrespective of the geometrical dimensions of the cations (Fig. 4), while no break point is observed on the titration curves with weak bases over a wide range of pH studied (Fig. 5). Therefore the Am-HTDO acts as an apparent bifunctional acid towards strong bases and as an apparent monofunctional acid towards weak bases.

In the titration of a soluble weak acid with a strong base, generally the pH discontinuity at the end point is more obscure with decreasing strength of the base. Moreover, a steric effect also occurs in the case of the titration of inorganic ion-exchange materials having a rigid three-dimensional structure, as described below. The titration curves in Figs. 4 and 5 suggest these effects.

The uptakes for these cations were determined (Figs. 6 and 7). These results correspond well to each pH

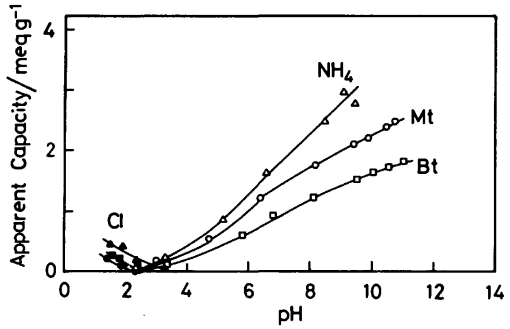

Fig. 7. Apparent capacities of NH_4^+ and nonspherical alkylammonium ions having different size parameters as a function of pH. Conditions are the same as in Fig. 5. Open marks are for cations and closed marks are for coexisting Cl^- ions.

titration curve in Figs. 4 and 5, indicating that the ion-exchange reaction is predominant over the whole range of pH studied. The apparent capacities for Na^+, K^+, $(CH_3)_4N^+$, and $(n$-$C_4H_9)_4N^+$ ions increase monotonically up to pH 7.5—8. At higher pH, the uptakes for Na^+ and K^+ ions having a small size show further increase, but those for large $(CH_3)_4N^+$ and $(n$-$C_4H_9)_4N^+$ ions constant up to pH 12. These suggest that smaller cations (Na^+, K^+) among strong bases can easily approach the ion-exchange sites present in micro-pores, while larger cations ($(n$-$C_4H_9)_4N^+$, $(CH_3)_4N^+$) are difficult of access to the micro-pores. At lower pH than 2, anion uptakes are predominant and a small uptake of Cl^- ions can be observed.

On the contrary, the apparent capacity for NH_4^+, $CH_3NH_3^+$, and n-$C_4H_9NH_3^+$ ions monotonically increases up to pH 10—11. With increasing dimensions, the apparent capacity decreased, when it was compared at pH>4.

A replaceable proton responsible for the ion-exchange reaction on various hydrous oxides and composite oxides has been determined by the butylamine titration method.[21,22] Johnson used butylamine as the titrating base for the reasons that it does not disturb the coloration at the end point using Hammet indicators and is not volatile. Many other authors have employed this base to determine the surface acid-sites.[23,24] The present results show that all the ion-exchange sites of Am-HTDO cannot be determined by the technique using this amine because of the steric hindrance. An alkali hydroxide or NH_3 aq. should be employed for the determination of the total protons responsible for the ion-exchange reaction of hydrous oxides of multivalent metals. However, an objection to the use of KOH can be found in the literature:[25] A silicate bond, $-\overset{|}{\underset{|}{Si}}-O-\overset{|}{\underset{|}{Si}}-$, is broken by the uptake of K^+ ions and the simultaneous consumption of OH^- ions on silica gel and the structure is rearranged. An uptake of Na^+ ions on hydrous tin(IV) oxide obeys a reversible ion-exchange reaction.[26] Hence, the breaking reaction of an $-\overset{|}{\underset{|}{Sn}}-O-\overset{|}{\underset{|}{Sn}}-$ bond will not be probable. Whether such a reaction including a break of $-\overset{|}{\underset{|}{Ti}}-O-\overset{|}{\underset{|}{Ti}}-$ occurs or not cannot be decided by the forward pH titration technique only.

Exchanged amounts of the alkylammonium ions having different van der Waals dimensions are compared in Table 1. Small spherical cations (NH_4^+, Na^+,

and K^+) of diameter<3 Å and ellipsoidally-shaped cations (n-$C_4H_9NH_3^+$ ions, *etc.*) can be exchanged to a greater extent. However, large ions>6 Å in dimension cannot fully replace a proton in the ion-exchange sites. Pore sizes of Am-HTDO vary over a range of 4—7 Å in radius (Fig. 2). These large organic ions are known to behave as a breaker of water structure in inorganic ion exchangers and exclude water molecules within the exchangers.[12] Water molecules in the Am-HTDO will be excluded more effectively than the degassing with a rotary pump when these large cations approach the ion-exchange sites. Thus, these alkylammonium ions can be exchanged.

The cross-section and volume of unhydrated cations were calculated, assuming the cations to be spheres (Na^+, NH_4^+) or prisms of elliptical cross-section (Table 2). The amounts of cations exchanged were plotted against the cross-section and the volume of the alkylammonium ion (Fig. 8 top and bottom, respectively). Uptakes of alkylammonium ions showed weak dependence on the cross-section, except n-$C_4H_9NH_3^+$, $(C_2H_5)_3NH^+$, and $(CH_3)_4N^+$ ions. These latter ions are very long or else very large spheres. The geometrical hindrance dose not permit these cations to be exchanged completely.

The uptakes decrease approximately linearly with increasing volumes of the unhydrated cations. The extent of the decrease is large for long (n-$C_4H_9NH_3^+$), wide ($(C_2H_5)_3NH^+$) or large spherical cations ($(CH_3)_4N^+$, $(n$-$C_4H_9)_4N^+$). It is due to the steric effect by these cations.

The maximum volume available for the ingoing ions can be estimated to be 0.2—0.3 cm^3/g. This value is comparable with that determined by N_2 adsorption (0.16 cm^3/g). It may be due to the effect of exclusion of water molecules by large cations exchanged that the former value is slightly large.

It has been known that an Am-HTDO in H^+ form is crystallized to an anatase-type while it is kept in the atmosphere at room temperature for a long period.[29]

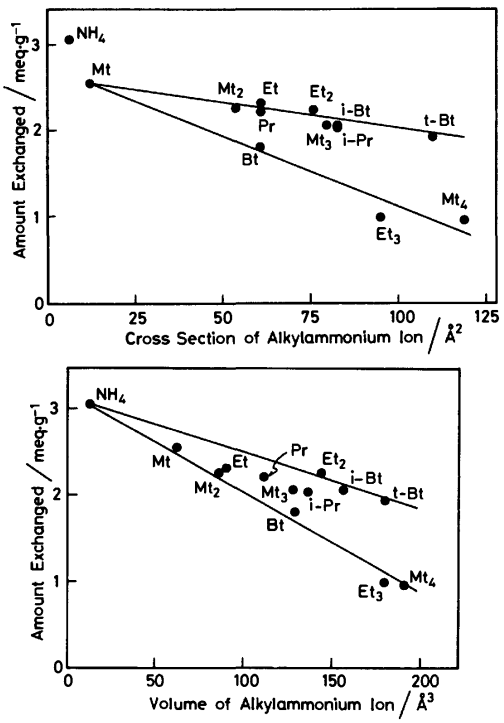

Fig. 8. Effect of the cross-section (top) and the volume (bottom) of unhydrated alkylammonium ions on the amount exchanged by Am-HTDO in H^+ form. Marks are the same as in Fig. 3.

Table 2. Total area and pore volume occupied by alkylammonium ions exchanged by Am-HTDO

Cations	Volume/Å³ of Unhydrated Cations	Cross-Section/Å² of Unhydrated Cations	Total Area m^2/g	Pore Volume cm^3/g

K^+	11.0	6.0	36	0.021

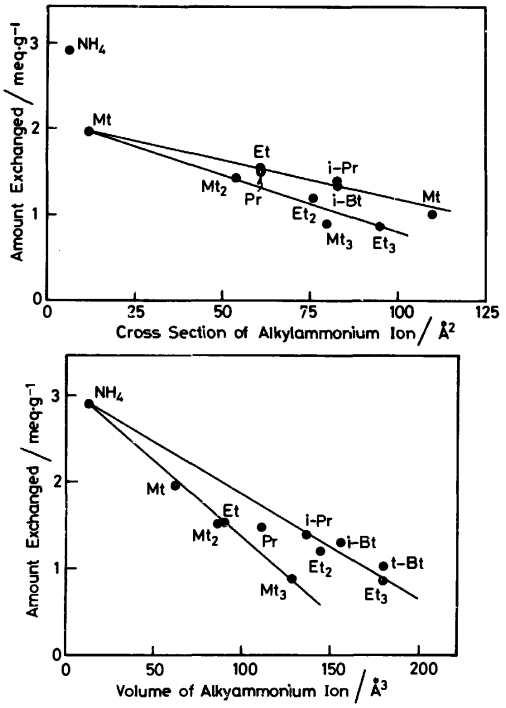

Fig. 9. Effect of the cross-section (top) and the volume (bottom) of unhydrated alkylammonium ions on the amount exchanged by An-HTDO in H^+ form. Marks are the same as in Fig. 3.

The Am-HTDO in H^+ form changed to An-HTDO having a crystallite size of about 30 Å after keeping it in the atmosphere for 8 months at room temperature. The An-HTDO showed about the same values as the Am-HTDO for the uptakes of NH_4^+ and $(C_2H_5)_3NH^+$ ions, while it showed a substantially decreased uptake for other alkylammonium ions (Fig. 9, top). This may be due to a decrease in the size of the cavity to accommodate the ingoing cations of medium size (5—7 Å). It suggests that the crystallization to the anatase-type causes shrinking of the Am-HTDO structure, followed by a decrease in the volume of the cavity necessary for the access to the ion-exchange sites. Consequently, the amounts exchanged more rapidly decreased with increasing volume of alkylammonium ions than Am-HTDO (Fig. 9, bottom). Thus, An-HTDO showed a larger steric effect than Am-HTDO.

The present authors are grateful to Mr. Kenta Ooi at the Government Industrial Research Institute, Shikoku, for the measurement of the pore size distribution.

Electronic Spectra of the Aluminum(III) Complexes of 5,10,15,20-Tetraphenylporphin and 2,3,7,8,12,13,17,18-Octaethylporphin

Youkoh KAIZU, Naoaki MISU, Katsuhisa TSUJI,
Yoshiaki KANEKO, and Hiroshi KOBAYASHI*
Department of Chemistry, Tokyo Institute of Technology, O-okayama, Meguro-ku, Tokyo 152
(Received August 2, 1984)

Absorption, magnetic circular dichroism (MCD) and emission spectra as well as preparations of the aluminum(III) complexes of 5,10,15,20-tetraphenylporphin (TPP) and 2,3,7,8,12,13,17,18-octaethylporphin (OEP) are presented. On the basis of the spectral observations, the molecular parameters to describe the lowest (π,π^*) excited states of a typical metal porphyrin with only minor perturbation by the incorporated tervalent metal ion were determined. The orbital angular momenta in the excited states were evaluated from the MCD spectra as follows: TPPAlCl, $A_z=\pm3.0\,\hbar$ in Q_{00} band, $A_z=\pm0.61\,\hbar$ in B band and OEPAlCl, $A_z=\pm3.4\,\hbar$ in Q_{00} band, $A_z=\pm0.55\,\hbar$ in B band. A Davydov splitting of the Soret band observed for the μ-oxo dimer was interpreted in terms of the exciton coupling between two parallel porphyrin chromophores.

Aluminum(III) porphyrin is a typical porphyrin incorporated with a tervalent metal ion; characteristic Q and B bands in the visible and near-ultraviolet region, respectively, arise from the (π,π^*) excitations in the porphyrin ring with only minor perturbation from the outer-shell electrons of the central metal ion. On the other hand, the iron(III) porphyrins found in the heme proteins exhibit rather complicated spectral profiles attributable to the configuration-interaction admixtures of the porphyrin (π,π^*) excited states and the "porphyrin-to-iron" charge-transfer excited states.[1-4] Preparations of some aluminum(III) porphyrins have been reported,[5,6] however, the spectra of aluminum(III) porphyrins have received little attention until very recently.[7] A recent notable finding is that aluminum(III) porphyrin alkoxide behaves as the propagating end of the living polymerization of epoxide.[8]

In this paper, absorption and emission spectra as well as preparations of the aluminum(III) complexes of 5,10,15,20-tetraphenylporphin(TPP) and 2,3,7,8,12,13,17,18-octaethylporphin(OEP) are presented, since the spectra measured on the well-characterized samples of this particular reference porphyrin have never been reported. The spectra of the μ-oxo dimer, $(TPPAl)_2O$, which was prepared first in the present work, are also reported. The spectral character of the dimer is interpreted in terms of the exciton coupling model.

Experimental

Synthesis of Chloro(tetraphenylporphinato)aluminum(III) (TPPAlCl). The metal-free base ($TPPH_2$) was prepared from pyrrole and benzaldehyde by the method of Adler, *et al.*[9] A contamination of tetraphenylchlorin was oxidized by use of 2,3-dichloro-5,6-dicyano-*p*-benzoquinone.[10] $TPPH_2$(0.5 g) was vigorously refluxed for 1—2 h with anhydrous aluminum chloride(0.5 g) in dry benzonitrile (80 ml). The reflux was continued until no further change of the absorption spectrum was detected. If the metal insertion was incomplete, the mixture was refluxed again after addition of some anhydrous aluminum chloride. After cooled, the mixture was filtered and then excess hexane was added to the filtrate for completion of precipitation. (A trace of methanol facilitated precipitation of TPPAlCl from oily solutions which often appeared upon addition of hexane). The precipitates were collected by filtration, washed with hexane, and then dissolved in methanol (30—40 ml). After filtration of the methanol solution, 3 M HCl (1 M=1 mol dm^{-3}) was added for precipitation of the complex. The precipitates were collected on a filter, washed with 3 M HCl, dissolved in a smallest amount of acetone, and then recrystallized from the solution by addition of hexane. Reddish purple crystals thus obtained were $TPPAlCl\cdot4H_2O$. More reddish crystals of $TPPAlCl\cdot H_2O$ were obtained by drying $TPPAlCl\cdot4H_2O$ at 110—120 °C for 2 h.

Found: C, 76.12; H, 4.28; N, 7.98; Cl, 5.03%. Calcd for $C_{44}H_{30}N_4OAlCl$($TPPAlCl\cdot H_2O$): C, 76.24; H, 4.36; N, 8.08; Cl, 5.12%.

An effective metal insertion could not be achieved in pyridine, although the metal insertion in refluxing pyridine was reported in the case of meso- and etioporphin.[11]

Synthesis of Chloro(octaethylporphinato)aluminum(III) (OEPAlCl). The metal-free base ($OEPH_2$) was prepared by the method of Paine, *et al.*[12] from 3,4-diethyl-2-ethoxycarbonyl-5-methyl-pyrrole.[13]

Found: C, 80.87; H, 8.55; N, 10.38%. Calcd for $C_{36}H_{46}N_4$: C, 80.85; H, 8.67; N, 10.48%.

OEPAlCl was prepared in the similar way as described for preparation of TPPAlCl.

Found: C, 72.14; H, 7.52; N, 9.28; Cl, 5.42%. Calcd for $C_{36}H_{44}N_4AlCl$(OEPAlCl): C, 72.65; H, 7.45; N, 9.41; Cl, 5.96%.

The reaction of $OEPH_2$ and tris(acetylacetonato)aluminum(III) in phenol was reported.[5,6] However, $OEPH_2$ as well as $TPPH_2$ showed no significant reaction with tris(acetylacetonato)aluminum(III) in boiling benzonitrile.

Synthesis of Hydroxo(tetraphenylporphinato)aluminum(III) (TPPAlOH). By shaking of porphinatoaluminum(III)-chloride dissolved in a mixture of chloroform and methanol with an aqueous solution of $AgNO_3$, porphinatoaluminum(III) hydroxide was obtained in the chloroform layer. The reaction of conc H_2SO_4, which had been applied to the preparation of phthalocyaninatoaluminum-(III)hydroxide,[14,15] resulted in elimination of the central

metal ion.

TPPAlCl·H_2O (300 mg) was dissolved in a mixture of chloroform (300 ml) and methanol (30 ml). The solution was shaken with 100 ml of 0.1% aqueous solution of $AgNO_3$ and the chloroform layer was separated. To the chloroform layer, 20 ml methanol and 30 ml chloroform were added. The mixture was again shaken with 100 ml of 0.1% aqueous solution of $AgNO_3$. This procedure was repeated until no AgCl precipitated. The chloroform layer was thoroughly washed with water, being added an amount of chloroform and methanol to keep solubility of the complex. The chloroform solution thus obtained was concentrated up to a volume of 150 ml, and then 300 ml hexane was added for precipitation of the complex. The precipitate was dissolved in a smallest amount of methanol, concentrated by distillation of methanol and recrystallized by adding water. The crystals were thoroughly washed with 0.5 M aqueous ammonia and then water and recrystallized from a mixture of methanol and water. Purple crystals thus obtained were dried at 110—120 °C for 3 h.

Found: C, 78.29; H, 4.44; N, 8.37; Cl, 0.00%. Calcd for $C_{44}H_{31}N_4O_2Al$(TPPAlOH·H_2O): C, 78.33; H, 4.63; N, 8.30; Cl, 0.00%.

Synthesis of Hydroxo(octaethylporphinato)aluminum(III) (OEPAlOH). OEPAlOH was prepared by reaction of aqueous $AgNO_3$ with OEPAlCl in a similar way as described for preparation of TPPAlOH.

Found: C, 72.05; H, 7.83; N, 9.45%. Calcd for $C_{36}H_{47}N_4O_2Al$(OEPAlOH·H_2O): C, 72.70; H, 7.97; N, 9.42%.

Synthesis of μ-Oxo-bis[(tetraphenylporphinato)aluminum-(III)]. (TPPAl)$_2$O was obtained by heating TPPAlOH·H_2O at 300—340 °C for 10 h under reduced pressure (10^{-2}—10^{-3} mmHg).

Found: C, 81.65; H, 4.29; N, 7.98%. Calcd for $C_{88}H_{58}N_8OAl_2$ ((TPPAl)$_2$O): C, 81.59; H, 4.36; N, 8.65%.

A trace of TPPAlOH contamination in (TPPAl)$_2$O could not be eliminated by further purification because (TPPAl)$_2$O was not so stable in solution and not sublimable. The μ-oxo dimer exhibits a characteristic IR band of Al-O-Al at 1050 cm^{-1} (Fig. 1), which conforms to the band found in the μ-oxo dimer of aluminum phthalocyanine.[15]

The corresponding band of (OEPAl)$_2$O, however, could not be detected after heating OEPAlOH for several hours under reduced pressure in a variety of temperatures around the melting point of OEPAlOH. Preparation of (OEPAl)$_2$O by heating under reduced pressure has been reported, however, the reported IR spectrum lacks the characteristic Al-O-Al band.[16]

All other reagents and solvents used for preparations and measurements were commercially available. Benzonitrile was distilled under reduced pressure after dried over anhydrous sodium sulfate more than one night. Dichloromethane(CH_2Cl_2), chloroform($CHCl_3$) and carbon tetrachloride(CCl_4) were shaken with conc H_2SO_4 and then aqueous sodium hydrogencarbonate, washed with water, dried over anhydrous calcium chloride more than one night and then distilled. For further dehydration, CCl_4 was refluxed over phosphorus pentaoxide, distilled and then kept over sodium hydroxide. Methanol was purified by distillation after dried over $CaSO_4$.

Measurements. Electronic absorption spectra were taken on a Hitachi 220 A spectrophotometer. Since (TPPAl)$_2$O was stable only in concentrated solution, the intense absorption band was measured using a cell of 0.3 mm path length. On the other hand, the routine spectral measurements were carried out with solutions in quartz cuvetts of 1 cm path length. Emission and excitation spectra were recorded on a Hitachi MPF-2A fluorescence spectrophotometer equipped with a Hamamatsu Photonics photomultiplier R-928. Fluorescence intensity was corrected by the method of Lippert, *et al.*[17] Phosphorescence was detected on the fluorescence spectrophotometer attached with its phosphorescence device.

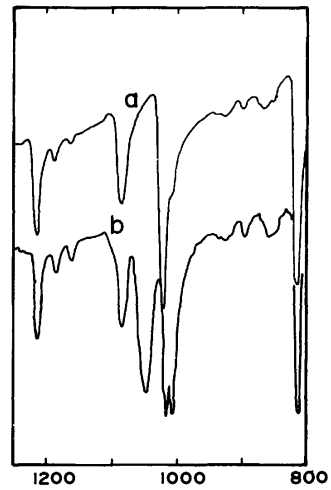

Fig. 1. IR spectra of TPPAlCl and (TPPAl)$_2$O in KBr disks.
a: TPPAlCl, b: (TPPAl)$_2$O.

Magnetic circular dichroism was measured on a JASCO J-500C spectropolarimeter with an electromagnet. The magnetic field was set at 1T.

Infrared spectra of TPPAlCl and (TPPAl)$_2$O in KBr disks were taken on a Hitachi 260-10 infrared spectrophotometer.

Results and Discussion

Absorption and fluorescence spectra of TPPAlCl and OEPAlCl in CCl_4 containing 2.5% methanol are shown in Fig. 2. The spectra of TPPAlOH and OEPAlOH were actually coincident with the spectra of the corresponding chloro complexes. In polar solvents such as methanol, ethanol, acetone, and acetonitrile, the complexes were stable. In non-polar solvents such as benzene and toluene, however, the complexes usually displayed a spectral drift for a period of time. A small amount of methanol added to the non-polar solvents stabilized the spectra and an increase in the concentration of methanol gives rise to a slight blue shift of each band. TPPAlOH and OEPAlOH in CH_2Cl_2 were rather stable and exhibited the spectral profiles given in Fig. 3. Absorption and fluorescence spectra of (TPPAl)$_2$O in CCl_4 are illustrated in Fig. 4. The spectra were rather stable only when the dimer was dissolved in CCl_4 which was treated with NaOH just before use.

The fluorescence spectra given in Figs. 2, 3, and 4 are

in a mirror image of the corresponding absorption spectra. The excitation spectra of fluorescence as well as phosphorescence were in good agreement with the absorption spectra. Figure 5 shows the phosphorescence spectra of the chloro complexes in ethanol at 77 K. Figure 6 shows the MCD spectra of TPPAlCl and OEPAlCl in methanol. The MCD spectra display a positive A term dispersion in each band. The ob-

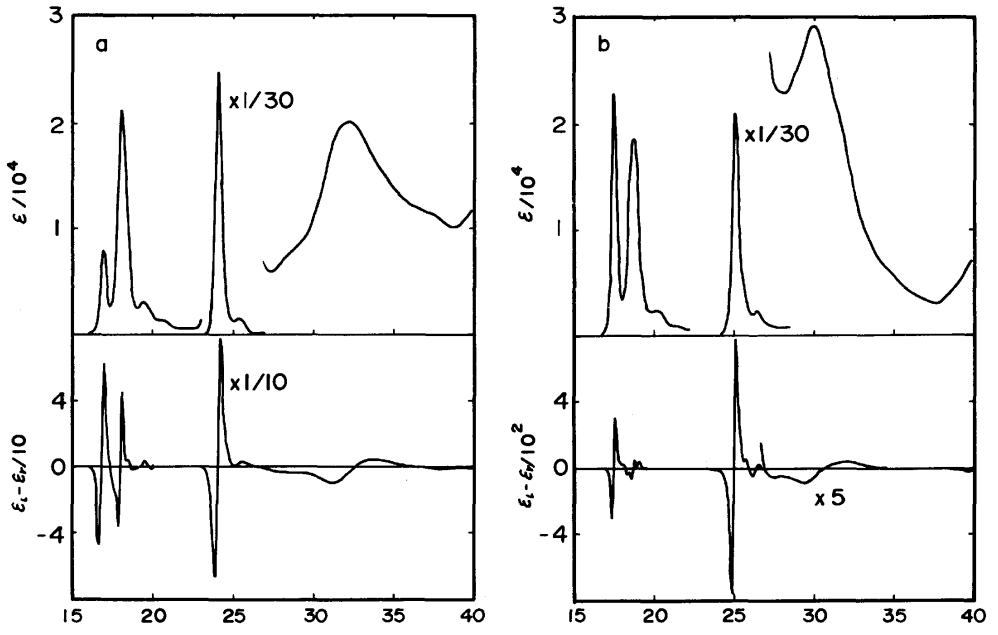

Fig. 6. MCD spectra of TPPAlCl (a) and OEPAlCl (b) in methanol.

served spectral characters are very similar to those of the typical (π,π^*) transition observed for the D_{4h} metalloporphins incorporated with a divalent metal ion such as Mg^{2+} and Zn^{2+}.

The lowest (π,π^*) excited states of metalloporphins are well described as a 50-50 admixture of the lowest excited configurations $(a_2)^2a_1e$ and $(a_1)^2a_2e$, where a_2 and a_1 are the highest filled orbital pair and e are the lowest vacant degenerate orbitals. Since the top filled orbitals are accidentally degenerate, their 50-50 admixtures $(a_2\pm ia_1)/\sqrt{2}$ are taken instead of individual a_2 and a_1 orbitals. The highest occupied orbital pair correspond to the degenerate orbital pair of the circular box model

$$|\pm 4) = f(\mathbf{r}) \exp[\pm 4i\theta], \tag{1}$$

where ± 4 denote the z components of orbital angular momentum $\lambda=4\hbar$, while the lowest vacant degenerate e orbitals are denoted as

$$|\pm 5) = f(\mathbf{r}) \exp[\pm 5i\theta]. \tag{2}$$

The one-electron excitations $|\pm 4)\rightarrow|\pm 5)$ and $|\mp 4)\rightarrow|\pm 5)$ give rise to two degenerate excited states with different total angular momenta $M_z=\pm 1\,\hbar$ and $M_z=\pm 9\,\hbar$, respectively. The ground state has zero angular momentum $M_z=0\,\hbar$. Thus the selection rule allows a pair of transitions of $\Delta M_z=\pm 1\,\hbar$, in which the angular momentum of the photons is conserved. The intense near-ultraviolet B(Soret) band is identified with the allowed transition pair $\Delta M_z=\pm 1\,\hbar$, whereas the weak Q band is characterized with the forbidden but vibronically allowed transition pair $\Delta M_z=\pm 9\,\hbar$. Table 1 shows the diagonal energies of the lowest excited states in terms of the exchange integrals

$$K_1 \equiv (4^*5|5^*4) = e^2\iint \frac{f^2(\mathbf{r}_1)f^2(\mathbf{r}_2)}{r_{12}} \exp[i(\theta_1-\theta_2)]d\tau_1 d\tau_2, \tag{3}$$

$$K_9 \equiv (-4^*5|5^*-4) = e^2\iint \frac{f^2(\mathbf{r}_1)f^2(\mathbf{r}_2)}{r_{12}} \exp[9i(\theta_1-\theta_2)]d\tau_1 d\tau_2, \tag{4}$$

and the off-diagonal one-electron term

$$\varepsilon \equiv -(4^*|\hat{\mathbf{h}}|-4) = \frac{1}{2}\{(a_1|\hat{\mathbf{h}}|a_1)-(a_2|\hat{\mathbf{h}}|a_2)\} \tag{5}$$

which arises from the fact that the a_2 and a_1 orbitals are not exactly degenerate in metalloporphins.

In the case of TPPAlCl in methanol, the Q band is observed at 16900 cm^{-1}($\varepsilon_{Q_{0,0}}$(max)=0.765×10⁴ M^{-1} cm^{-1}), and the B band at 24100 cm^{-1}(ε_B(max)=73.3×10⁴ M^{-1} cm^{-1}); the phosphorescence appears at 12900 cm^{-1}. The transitions to $^1(\pm 4\rightarrow\pm 5)$ are exclusively allowed. However, the off-diagonal element ε carries the spectral intensity from the allowed B transition to the forbidden Q counterpart. Assuming a Gaussian shape function with half-width $\tilde{\Gamma}$, the transition moment is evaluated from the observed absorption intensity,

$$|\mathbf{m}|^2 = 1.514\times 10^{-3}\{(\tilde{\Gamma}/\bar{\nu})\varepsilon(\max)/g\} \text{ (a.u.}^2\text{)}, \tag{6}$$

TABLE 1. THE LOWEST (π,π^*) EXCITED SINGLET AND TRIPLET STATES OF THE METALLOPORPHIN

$\|^{1,3}(-4\rightarrow+5)>$	$\|^{1,3}(+4\rightarrow-5)>$	$\|^{1,3}(+4\rightarrow+5)>$	$\|^{1,3}(-4\rightarrow-5)>$
$\Delta(4,5)+\binom{2}{0}K_9$	0	ε	0
	$\Delta(4,5)+\binom{2}{0}K_9$	0	ε
		$\Delta(4,5)+\binom{2}{0}K_1$	0
			$\Delta(4,5)+\binom{2}{0}K_1$

The top integer in ( ) stands for the excited singlet, while the bottom, for the excited triplet.
The excited states $|Q>$ and $|B>$ are described by

$$|Q> = -\sin\nu\,|^1(\pm4\rightarrow\pm5)> + \cos\nu\,|^1(\mp4\rightarrow\pm5)>$$
$$|B> = \cos\nu\,|^1(\pm4\rightarrow\pm5)> + \sin\nu\,|^1(\mp4\rightarrow\pm5)>,$$

where $\nu = \frac{1}{2}\tan^{-1}(\varepsilon/K_1 - K_9)$.

where g is the degeneracy of excited state, $g=2$ in this particular case, ε(max), and $\tilde{\nu}$ are molar absorption coefficient and wavenumber at the absorption maximum, respectively. The observed intensity ratio yields $|m(Q)|^2/|m(B)|^2=0.016$, where the values of $\tilde{f}(Q)$ and $\tilde{f}(B)$ are 520 cm^{-1} and 490 cm^{-1} respectively. Provided that $\Delta(4,5)=13800\ cm^{-1}$, $K_1=5100\ cm^{-1}$, $K_9=1600\ cm^{-1}$, and $\varepsilon=-900\ cm^{-1}$, not only the observed transition energies of the lowest triplet and singlet excited states but also the ratio $|m(Q)|^2/|m(B)|^2$ are well reproduced.

The corresponding values of OEPAlCl in methanol are as follows:

$$\Delta(4,5) = 15800\ cm^{-1},\ K_1 = 4400\ cm^{-1},\ K_9 = 1000\ cm^{-1}$$
$$\varepsilon = 1600\ cm^{-1}.$$

Here it is assumed that the a_1 orbital is higher than the a_2 orbital in OEPAlCl while it is reversed in TPPAlCl.[18]

The *ab initio* molecular orbital calculations even at the recent stage provide only poor predictions on the electronic excited states. However the screened potential molecular orbital approach yields a reasonable picture of the porphin excited states.[19,20] Theoretically evaluated values for metalloporphin are as follows;[20]

$$\Delta(4,5) = 13400\ cm^{-1},\ K_1 = 6600\ cm^{-1},\ K_9 = 1600\ cm^{-1}$$
$$\varepsilon = 1200\ cm^{-1}.$$

These results seem reasonable but still far from the observation.

The orbital angular momenta in the excited states were determined by computer simulations of the positive A term dispersions observed in the MCD spectra assuming Gaussian shape functions for the corresponding absorption bands.[21] The orbital angular momenta of TPPAlCl were obtained as $A_z=\pm3.0$ $\hbar$ and $A_z=\pm0.61\,\hbar$ in the excited states of Q_{00} and B band, respectively. This implies that the angular momenta of the highest occupied and the lowest vacant orbitals are $\lambda_4=1.2\,\hbar$ and $\lambda_5=1.8\,\hbar$, respectively. The corresponding values of OEPAlCl are as follows; $A_z=\pm3.4\,\hbar$ in Q_{00} band, $A_z=\pm0.55\,\hbar$ in B band, $\lambda_4=1.6\,\hbar$ and $\lambda_5=2.0\,\hbar$.

The absorption spectrum of the μ-oxo dimer as seen in Fig. 4 exhibits a remarkable blue shift of the B band with lower wavenumber tail extending to about 22000 cm^{-1} which is attributable to an exciton coupling in the B band. The dimer Q band is also blue-shifted but to a lesser extent. A similar spectral behavior has been found with the μ-oxo dimer $(TPPSc)_2O$, while the red shift of the dimer Q band was observed in the case of $(OEPSc)_2O$.[22]

The geometry of the μ-oxo dimer is assumed in D_{4d} symmetry. As revealed by X-ray analysis, the interplanar distance is greater than anticipated by the intermetal distance.[23,24] An extreme short intermetal distance has been found for the linear Al-O-Al bridge between two trigonal-bipyramidal pentacoordinated aluminum atoms.[25] In the case of $(TPPAl)_2O$, Al^{3+} ion can not displace much more than 0.5 Å out of the porphin plane, however, a doming distortion in two porphin skeletons results in an interplanar distance as high as 4.8 Å. Because of the small overlap between the π orbitals of two component porphins in such a distance, K_{AB}, an electrostatic interaction between the overlap charges (j_Aj_B) and (a_Aa_B), can be ignored. The exciton coupling arises only from the Coulomb interaction J_{AB} between two transition charges (j_Aa_A) and (j_Ba_B), which are often approximated by the interaction between two transition dipoles $\mathbf{m}_A$ and $\mathbf{m}_B$ on the counterparts A and B.

The basis sets of the exciton states are given by 50-50 admixtures of the local excited states; $|Q^+>=(|Q_A>+|Q_B>)/\sqrt{2}$, $|Q^->=(|Q_A>-|Q_B>)/\sqrt{2}$, $|B^+>=(|B_A>+|B_B>)/\sqrt{2}$, $|B^->=(|B_A>-|B_B>)/\sqrt{2}$. The interactions between these states are shown in Table 2, where

TABLE 2. THE INTERACTION BETWEEN THE LOWEST (π,π^*) EXCITED SINGLETS OF THE μ-OXO METALLOPORPHIIN DIMER

$\|Q^+>$	$\|Q^->$	$\|B^+>$	$\|B^->$
$E(Q)+\sin^2\nu J$	0	$-\sin\nu\cos\nu J$	
	$E(Q)-\sin^2\nu J$		$\sin\nu\cos\nu J$
		$E(B)+\cos^2\nu J$	
			$E(B)-\cos^2\nu J$

The exciton states are given by

$$|Q>=-\sin\phi\,|B^\pm>+\cos\phi\,|Q^\pm>$$
$$|B>=\cos\phi\,|B^\pm>+\sin\phi\,|Q^\pm>$$

where $\phi=\frac{1}{2}\tan^{-1}\{\mp\sin 2\nu/[E(B)-E(Q)\pm\cos 2\nu J]\}$.

$E(Q)$ and $E(B)$ are the energies of the component Q and B states in the μ-oxo dimer, which might be different from the monomer values and the interaction terms are given in units of $J=2(4_A{}^*5_A|5_B{}^*4_B)$.

Absorption spectrum of $(TPPAl)_2O$ exhibits the $Q_{0,0}$ band at 16900 cm^{-1} ($\varepsilon_{Q_{0,0}}(max)=0.650\times10^4$ M^{-1} cm^{-1}, $\tilde{\nu}=700$ cm^{-1}) and the B band at 24800 cm^{-1} ($\varepsilon_B(max)=100\times10^4$ M^{-1} cm^{-1}, $\tilde{\nu}=550$ cm^{-1}), respectively. Assuming the monomer values for $E(B)$ and $E(Q)$, the absorption spectrum of the μ-oxo dimer was reproduced for $J=1000$ cm^{-1}. The theory predicts that the allowed B state is in 25100 cm^{-1} and the forbidden one in 23100 cm^{-1} and thus the Davydov splitting is 2000 cm^{-1} in the B band while that of the Q band is less than 50 cm^{-1}. Conserving the monomer values only for two-electron terms K_1 and K_9, $E(Q)=16900$ cm^{-1}, $E(B)=24100$ cm^{-1} and $J=700$ cm^{-1} are evaluated from the transition energies and the intensity ratio observed for the μ-oxo dimer spectrum. On the other hand, the values, $E(Q)=16800$ cm^{-1}, $E(B)=23300$ cm^{-1} and $J=1500$ cm^{-1}, yield the forbidden and allowed B states in 21800 cm^{-1} and 24800 cm^{-1} respectively, and the corresponding Q states in 16800 cm^{-1} and 16900 cm^{-1}. The observed Davydov splitting in the B band is less than 3000 cm^{-1}.

The transition dipole $m\equiv\sqrt{2}(5|m|4)$ is estimated as 3.4 a.u. from the parameter values determined for TPPAlCl in methanol and thus J is evaluated as 3400 cm^{-1} for the parallel stacking by the approximation of dipole-dipole interaction $m^2/r_{AB}{}^3$ in a distance $r_{AB}=4.8$ Å. The diagonalization of the interactions using the parameters for TPPAlCl predicts a rather big splitting ($\approx$6800 cm^{-1}) in the B band. The value of J can be calculated by use of the wavefunctions obtained by molecular orbital calculations.[20] For $r_{AB}=4.8$ Å is obtained $J=4400$ cm^{-1}, which predicts a much greater splitting.

The Determination of a Small Amount of Biological Constituent by the Use of Chemiluminescence. IV. A Highly Sensitive Detector for the HPLC of Protein

Tadashi HARA,* Motohiro TORIYAMA, and Takashi EBUCHI
Department of Chemical Engineering, Faculty of Engineering, Doshisha University, Karasuma Imadegawa, Kamigyo-ku, Kyoto 602
(Received August 23, 1984)

A highly sensitive detector for the HPLC of protein has been manufactured by making use of the phenomenon that the catalytic activity of copper(II) against the chemiluminescence between luminol and hydrogen peroxide is lowered in the presence of protein. According to the present detector, 2×10^{-4}—1×10^{-1} g/dm^3 protein could be determined, with the detection limit of 10 ng. By combining the present detector with a TSK-GEL G3000SW column, 2×10^{-3}—1×10^{-1} g/dm^3 ovalbumin could be determined, with the detection limit of 50 ng. The ovalbumin in 2×10^{-2} g/dm^3 could be determined by the internal-standard method with a coefficient of variation of 8.65% (n=5). Care had to be taken in the detection of the protein acting as a chemiluminescent catalyst.

As detectors for the high-performance liquid chromatography(HPLC) of protein, the following apparatus are now being used: a ultraviolet spectrophotometer(UV), a differential refractometer(RI), a light-scattering spectrophotometer, and so on. The detection limit of RI is inferior to that of UV.[1] A precise determination of protein by the use of a light-scattering spectrophotometer alone is difficult because the signal obtained with it is given by the product of the molecular weight of protein and its concentration.[2] UV is also unsuitable for application to an unknown sample because a measured value varies depending on the kind of protein, and the detection limit of 20 μg/cm^3 protein is still unsatisfactory for the determination of a small amount of protein in a clinical laboratory. To improve the detector sensitivity, a fluorometer has been applied to the determination of peptides after separation by means of HPLC.[3] On the other hand, a method for the flow-injection analysis of protein has been established by the present authors on the basis of the fact that the catalytic activity of copper(II) against the chemiluminescence (CL) between 5-amino-2,3-dihydro-1,4-phthalazinedione(luminol) and hydrogen peroxide(H_2O_2) is lowered in the presence of protein.[4] This method is applicable to the detection of 2×10^{-4}—1×10^{-1} g/dm^3 protein and is more sensitive than any others thus far reported. Moreover, this method shows a similar sensitivity for various kinds of proteins and makes a continuous determination of protein possible. Since this method was expected to be a promising post-column detector for the protein separated in an aqueous HPLC system without losing the inherent property of protein, the analytical conditions, detection limit, and so on were investigated.

Experimental

Reagents. All the reagents used were of a commercially available special grade. A 2.0×10^{-6} mol/dm^3 copper(II) solution was prepared by diluting a 2.0×10^{-2} mol/dm^3 copper(II) stock solution with a buffer solution(Buff-I)(pH 10.2) consisting of 0.1 mol/dm^3 boric acid and 0.1 mol/dm^3 potassium hydroxide. A 1.0×10^{-4} mol/dm^3 luminol solution was prepared by the use of the same buffer solution as above. A 5.0×10^{-4} mol/dm^3 H_2O_2 solution was prepared by diluting a 0.3 wt% H_2O_2 solution with distilled water. A 3.33×10^{-3} mol/dm^3 phosphate buffer solution(Buff-II; pH 6.19), consisting of a 2.67×10^{-3} mol/dm^3 potassium dihydrogenphosphate(KH_2PO_4) solution, a 6.67×10^{-4} mol/dm^3 disodium hydrogenphosphate(Na_2HPO_4) solution, and a 0.15 mol/dm^3 potassium chloride(KCl) solution, was prepared; it was also used as an eluent later on. The sample solutions of bovine serum albumin(BSA) (Sigma Chemical Co.), lysozyme (from chicken egg white) (Sigma Chemical Co.), ovalbumin (Sigma Chemical Co.), and the Gel Filtration Standard(Bio. Rad) were prepared by dissolving them in Buff-II and by diluting them with Buff-II.

Apparatus and Procedure. A HPLC system equipped with a CL detector was set up for the separation and determination of protein (Fig. 1). All the tubes (0.5 mm i.d.) and connectors(n) used were made of Teflon. Each solution of luminol(a) and H_2O_2(b), held at 25 °C by means of a thermostat(q) (Netsudenshi kogyo Co., Ltd.), and of copper(II)(c), held at room temperature, was fed by means of nitrogen gas of 3.3×10^5 Pa pressure gauge, the flow rate was adjusted to 1.0 cm^3/min by the use of a flow-meter equipped with a needle valve(h)(GILMONT). An eluent(buffer solution)(d) was fed at the flow rate of 1.0 cm^3/min by means of a pump(i) (Pharmacia High-precision Pump P-500). A 50-mm^3 portion of a mixed protein solution was injected into the eluent line through the sampling loop(k_1) and the seven-way cock(j_1) (Pharmacia Fine Chemicals, Valve-7), after which the protein was separated on the column(m) (TSK-GEL G3000SW column: 600×7.5 mm i.d.+TSK-GEL G3000SW guard column: 75×7.5 mm i.d.). The protein in an eluate was first mixed with a copper(II) solution, and then the resulting solution was further mixed with a H_2O_2 solution at the position W and with a luminol solution at the position X after having passed through a reaction tube(o) (0.64 m), held at 95 °C and a cooling tube(p) (0.40 m), held at 0 °C, in that order. Finally, the mixed solution was introduced into the same flow cell(r) as in the previous paper. The CL intensity

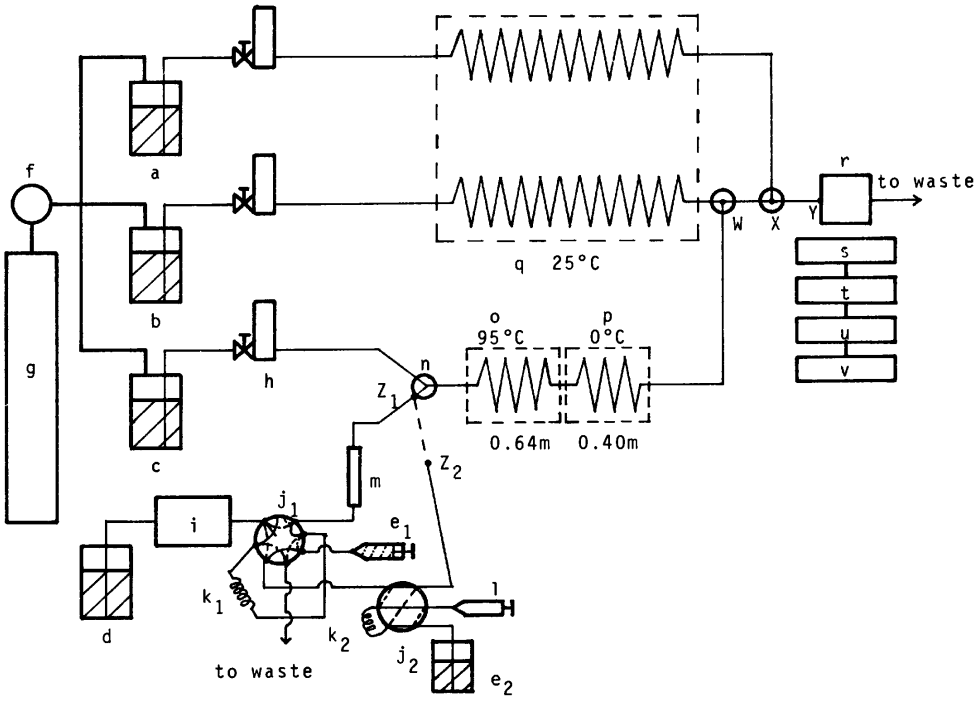

Fig. 1. Schematic diagram of the system equipped with CL detector.
a: Luminol solution, b: H_2O_2 solution, c: copper (II) catalyst solution, d: eluent (buffer solution), e_1 and e_2: sample solution, f: regulator, g: N_2 cylinder, h: flow-meter equipped with a needle valve, i: pump, j_1: seven-way cock, j_2: six-way cock, k_1 and k_2: sampling loop, l: syringe, m: cloumn, n: connector, o: reaction tube, p: cooling tube, q: thermostat, r: flow cell, s: photomultiplier, t: amplifier, u: recorder, and v: integrator.

was measured by means of a photomultiplier(s) (Hamamatsu TV Co., Ltd., R928), amplified with an amplifier(t) (Horiba Ltd., OPE-402), and recorded on a recorder(u) (Yokogawa Electric Works, Ltd., 3046), followed by the measurement of the peak area by the use of an integrator(v) (Shimadzu Chromatopac C-R2A). The distances between X and W or Y were 30 cm and 10 cm respectively.

The flow-injection analysis of protein by a direct-injection method was carried out by injecting a sample solution into the eluent line by operating a seven-way cock (j_1) and a six-way cock(j_2) equipped with a sampling loop(k_2) after connecting Z_1 with Z_2. Though a ghost peak appeared periodically owing to the exchange between the two cylinders in the pump(i), it did not interfere with the determination of the protein.

Results and Discussion

Characteristics of the Detector. The stability of a base line is generally indispensable for the exact determination of protein by means of HPLC. Though the CL intensity was significantly influenced by the temperature, no care was taken about the temperature except for a copper(II) solution in the previous paper. Therefore, no stable base line was obtained over a long period. In the present study, both the luminol solution and the H_2O_2 solution were held at 25 °C so as to give a stable base line. Since the flow rate of eluent in HPLC was generally less than 1.0 cm^3/min, a BSA sample solution was directly estimated by flow-injection analysis under the same conditions as were used in the previous paper except for the use of 1.0 cm^3/min instead of 10 cm^3/min for the flow rate of the buffer solution(Buff-I) (Fig. 1(d)). The detection limit of BSA was 40 ng in the previous paper, while it was 400 ng in this case. This was assumed to be due to the dilution of a sample solution, for the flow rate of each solution of copper(II), luminol, and H_2O_2 was 10 cm^3/min in the previous paper, while that of the buffer solution containing BSA in the present study was 1.0 cm^3/min. Therefore, the flow rate of each solution was selected as 1.0 cm^3/min. The diameter of the tubing was also changed from 1 mm to 0.5 mm so as to reduce the diffusion of a sample. Furthermore, the length of the reaction tube and the cooling tube were changed from 1.0 m to 0.64 m and from 1.6 m to 0.40 m respectively so as to provide the same residence time as in the previous paper. Under these conditions, the maximum diminution in the CL intensity based on the injection of protein was observed at a 1.0×10^{-4} mol/dm^3 luminol, a 5.0×10^{-4} mol/dm^3 H_2O_2, and a 2.0×10^{-6} mol/dm^3 copper(II) solution.

The calibration curve obtained by the flow-injection analysis of BSA, using the direct-injection technique at the above-mentioned flow rate and reagent concentra-

tion, is shown in Fig. 2, together with that obtained in the previous paper. According to the present detector, 2×10^{-4}—1×10^{-1} g/dm^3 BSA could be determined; its detection limit(S/N=2) was the same as in the previous paper. The coefficients of variation for ten measurements of 1×10^{-3} and 1×10^{-2} g/dm^3 BSA were 11.2% and 6.9% respectively. As can be seen from Fig. 2, the slope of the present calibration curve was about one, while that in the previous paper was about one-half. The difference between these two slopes may be supposed to be based on (1) the difference in the reaction conditions for the chelate formation between copper(II) and protein and/or (2) the difference between the residence times in the flow cell in the previous paper(about 0.3 s) and in the present paper(about 3.4 s).

Conditions for the Separation of Protein. A combination of the present detector and gel-permeation chromatography, in which proteins could be separated by the use of an aqueous eluent without changing the higher-order structure of protein, was devised for the separation of proteins. For this combination, care had to be taken in the use of an eluent with a pH value of around 7 against a TSK-GEL G3000SW column and of the alkaline solution for the chelate formation between copper(II) and protein and in the CL reaction.

The effects of the concentration of a phosphate buffer solution and a salt solution on the present detector in the gel-permeation chromatography of ovalbumin and lysozyme were also examined. The effect of the phosphate solution on the chelate formation between copper(II) and protein and the subsequent CL reaction is shown in Fig. 3. The results in Fig. 3 can be understood from the following experimental data.

The pH of the solution in a flow cell was inferred by measuring the pH value of the mixed solution consisting of distilled water, a Buff-I solution, and a phosphate buffer solution (3.33×10^{-2}, 3.33×10^{-3}, 3.33×10^{-4} mol/dm^3) containing a KH_2PO_4 solution and a Na_2HPO_4 solution in a volume ratio of 1:2:1; pH values of 9.8, 10.0, and 10.0 were found, in that order. This shows that the pH value of the solution in a flow cell is around the pH value desired for the measurements of the CL intensity.

On the other hand, the pH value of the mixed solution consisting of a Buff-I solution and a phosphate buffer solution (3.33×10^{-2}, 3.33×10^{-3}, 3.33×10^{-4} mol/dm^3), containing a KH_2PO_4 solution and a Na_2HPO_4 solution in a volume ratio of 1:1, was measured to ascertain the pH value in a reaction tube containing copper(II) and protein; the pH values 9.4, 9.9, and 9.9 were thus obtained.

In other words, the difference in the results of Fig. 3 may be concluded to be primarily due to the difference in the chelate formation by pH. Since the detection limits for A and B in Fig. 3 did not differ much from

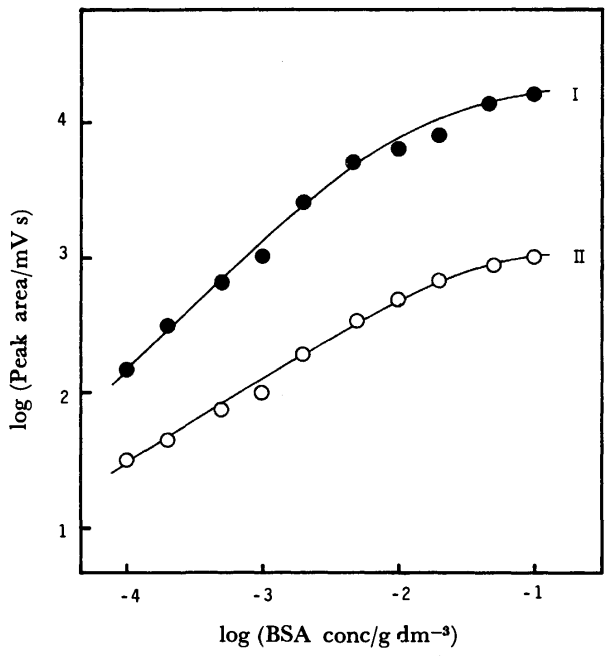

Fig. 2. Calibration curves of BSA by the present method and the previous method.
I: present paper and II: previous paper.
Conditions: previous paper; 5.0×10^{-4} mol/dm^3 luminol, 5.0×10^{-4} mol/dm^3 H_2O_2, 2.0×10^{-6} mol/dm^3 copper(II), and Buff-I(pH 10.15) as a buffer solution and present paper; 1.0×10^{-4} mol/dm^3 luminol, 5.0×10^{-4} mol/dm^3 H_2O_2, 2.0×10^{-6} mol/dm^3 copper(II), and Buff-II(pH 6.19) as a buffer solution.

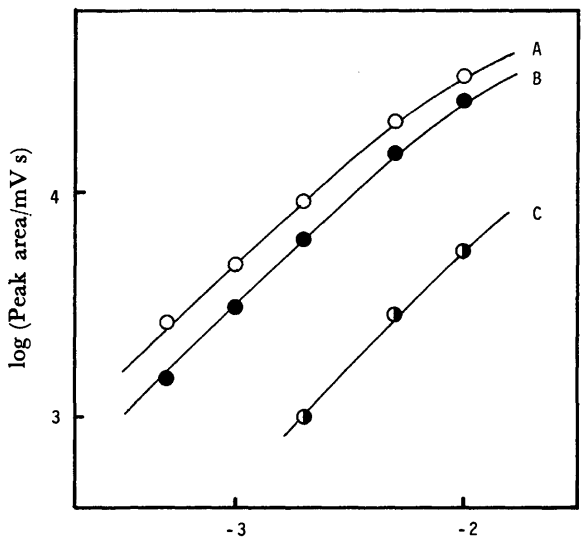

Fig. 3. Effect of concentration of phosphate buffer solution on the present detector.
A: 3.33×10^{-4} mol/dm^3-, B: 3.33×10^{-3} mol/dm^3-, and C: 3.33×10^{-2} mol/dm^3-phosphate buffer solution consisting of KH_2PO_4 solution and Na_2HPO_4 solution.
Conditions: 1.0×10^{-4} mol/dm^3 luminol, 5.0×10^{-4} mol/dm^3 H_2O_2, 2.0×10^{-6} mol/dm^3 copper (II), and ovalbumin as sample.

each other, and since a larger buffer capacity was desired for an eluent, a 3.33×10^{-3} mol/dm^3 phosphate buffer solution was chosen as the eluent for the HPLC.

The ionic strength of an eluent was enhanced by the addition of a salt to suppress the ionic adsorption of protein on the column. The effect of the added salt(KCl) on the present detector is shown in Fig. 4. The base line was lowered with an increase in the concentration of KCl, and then the CL intensity was influenced by the addition of KCl. The peak area in Fig. 4 is shown against the base line in a KCl-free ovalbumin solution. As can be seen from Fig. 4, the peak area was almost definite independent of the concentration of KCl, and the addition of KCl did not affect the reaction between copper(II) and ovalbumin. Since more than 0.2 mol/dm^3 of KCl reduced the CL intensity, and since the detection limits in the 0, 0.05, 0.10, and 0.15 mol/dm^3 KCl solutions were all approximately the same, a 0.15 mol/dm^3 KCl solution was selected as the optimum concentration.

Separation by Means of a Column. The number of theoretical plates was calculated from the peak width and the elution time recorded on recorder chart paper by injecting 1 μg of ovalbumin; the value of 1840 was thus obtained. According to the UV method, the number of theoretical plates 2488 was reported[5] to be obtained under the following conditions: a 0.1 mol/dm^3 phosphate buffer solution as an eluent, a flow rate of 0.875 cm^3/min, 100 μg of ovalbumin, and a 30.5-cm TSK-GEL G3000SW column. This value was calculated to be 5890 at the flow rate and the column length used in the present study.

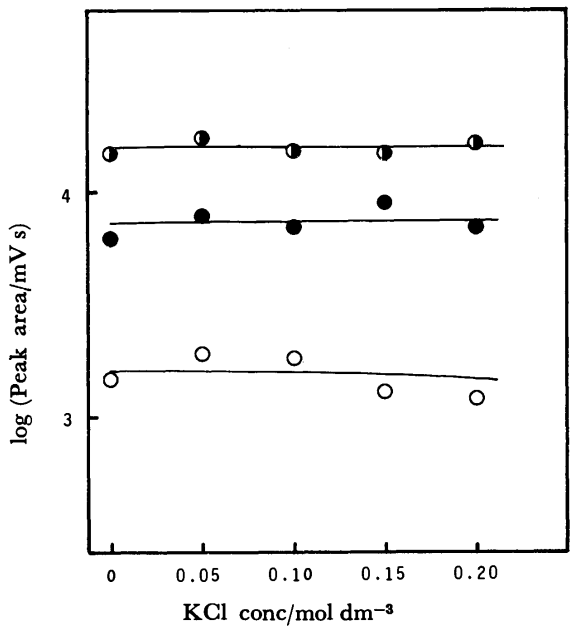

Fig. 4. Effect of added KCl on the present detector.
○: 5.0×10^{-4} g/dm^3-, ●: 2.0×10^{-3} g/dm^3-, and ◑: 5.0×10^{-3} g/dm^3-ovalbumin.
Conditions: 1.0×10^{-4} mol/dm^3 luminol, 5.0×10^{-4} mol/dm^3 H_2O_2, 2.0×10^{-6} mol/dm^3 copper (II), and 3.33×10^{-3} mol/dm^3 phosphate buffer solution consisting of 2.67×10^{-3} mol/dm^3 KH_2PO_4 solution and 6.67×10^{-4} mol/dm^3 Na_2HPO_4 solution.

It has usually been accepted in flow-injection analysis that the band broadening of a sample based on the diffusion in a tube can be neglected at a tube diameter of less than 0.5 mm. Since a tube 0.5 mm i.d. was used in the present study, the diffusion of a sample in the eluate seems not to lower the number of theoretical plates. Therefore, the lowering of the number of theoretical plates may be supposed to be attributed to the residence time in the flow cell, the amount of the sample, and so on.

A 18-mg sample(Gel Filtration Standard) of a mixture consisting of protein aggregates, thyroglobulin-(bovine), γ-globulin(bovine), ovalbumin(chicken), myoglobin(horse), and vitamin B-12 was dissolved in a 0.5-cm^3 Buff-II solution, and from the solution(Sample I) a 50-mm^3 fraction was taken, after which analysis was done by means of HPLC using a UV detector(Hitachi, Ltd., wavelength-tunable effluent monitor, 634). On the other hand, Sample I was diluted to 1:667 with Buff-II, and from the solution(Sample II) a 50-mm^3 fraction was taken, followed by analysis by means of HPLC using the present detector. The chromatograms thus obtained are shown in Fig. 5.

As can be seen from both chromatograms in Fig. 5, the D and E peaks in the chromatogram obtained by the present detector were relatively small in comparison with the A, B, and C. Furthermore, the D and E peaks appeared on the side opposite those in II of Fig. 5 when Sample I was diluted to 1 :200 and a 50-mm^3 fraction was similarly analysed.

Hemoglobin, catalase, and peroxidase, which are all hemoproteins containing an iron-porphine complex structure, have been well known to act as catalysts in the CL reaction. Since myoglobin is also a hemoprotein, it was expected to act more or less as a catalyst in the CL reaction.

The peak D of myoglobin in II of Fig. 5 was obtained by subtracting the inverse response based on the catalytic activity of myoglobin as a catalyst against the CL reaction from the response based on myoglobin as a protein. Vitamin B-12, containing a cobalt(II)-porphine complex structure in its central position, was experimentally confirmed by the authors to act as a weak catalyst against the CL reaction; then, the E peak was obtained by reasoning similar to that in case of the D peak.

To sum up, the present detector was shown to be a useful one for the sensitive detection of protein in an eluate from the HPLC column, though care had to be taken in the detection of protein acting as a catalyst against the CL reaction.

Determination by Means of a Column. Two calibration curves were obtained as follows: (I) each 50-

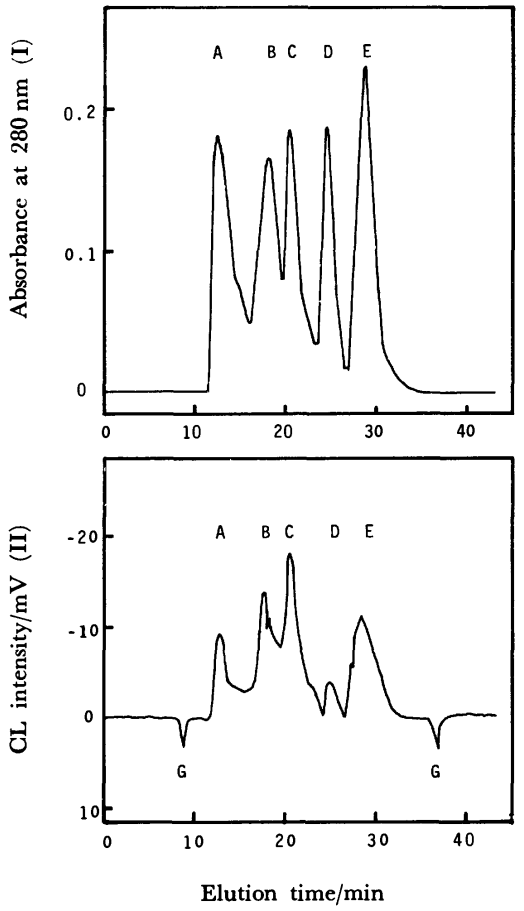

Fig. 5. Chromatograms of Gel Filtration Standard obtained by the present detector and the UV detector.
A: protein aggregates+thyroglobulin(bovine), B: γ-globulin(bovine), C: ovalbumin(chicken), D: myoglobin, E: vitamin B-12, and G: ghost peak.
Conditions: 3.33×10^{-3} mol/dm³ phosphate buffer solution(Buff-II)(pH 6.19) as eluent, load volume 50 mm³, I(UV detector); Range 1.28 and Sample-I: Gel Filtration Standard (18 mg mixture sample)/0.5 cm³ Buff-II, and II(present detector); Sample-II: Sample-I diluted to 1 : 667 with Buff-II.

mm³ portion in the concentration range of 2×10^{-3}—1×10^{-1} g/dm³ ovalbumin was injected into a separation column, and the ovalbumin in the eluate was monitored by means of the present CL detector, and (II) each 50-mm³ portion in the concentration range of 2×10^{-4}—1×10^{-1} g/dm³ ovalbumin was directly subjected to flow-injection analysis without using a separation column. The results obtained are shown in Fig. 6.

The coefficient of variation for five measurements of 2×10^{-2} g/dm³ ovalbumin in the former (I) was 12.7%. The deviation of the calibration curve II from a straight line can be understood in terms of the shortage of copper(II) in the reaction with ovalbumin; the shift of the calibration curve I to the higher side of ovalbumin concentration can also be understood by the dilution of the sample in a column. Here, the average recovery of 2×10^{-3}—2×10^{-2} g/dm³ ovalbumin

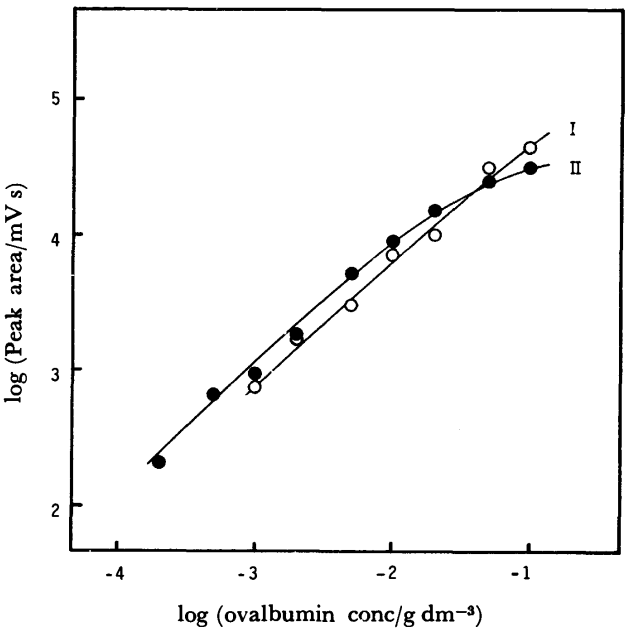

Fig. 6. Calibration curves of ovalbumin obtained by HPLC and flow-injection analysis.
I: through a column and II: column-free.
Conditions: injection volume 50 mm³, 1.0×10^{-4} mol/dm³ luminol, 5.0×10^{-4} mol/dm³ H_2O_2, 2.0×10^{-6} mol/dm³ copper(II), and Buff-II (pH 6.19) as buffer solution.

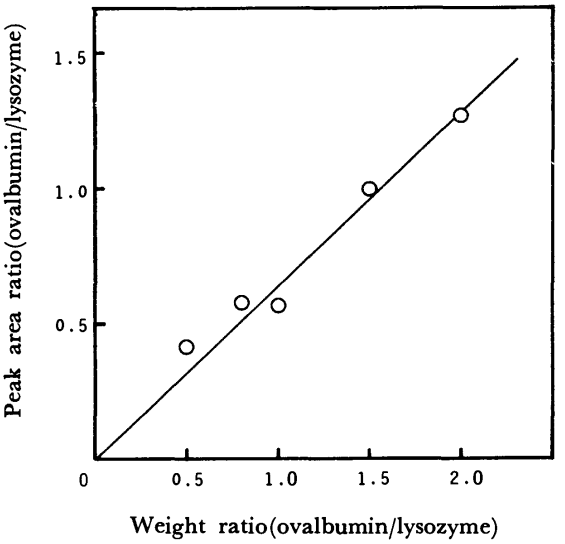

Fig. 7. Calibration curve of ovalbumin by use of lysozyme as internal standard.
Conditions: load volume 50 mm³, Buff-II (pH 6.19) as eluent, and 2.0×10^{-2} g/dm³ lysozyme as internal standard.

was 77.3%. Thus, the detection limit of the flow-injection analysis was 10 ng, while that of the column procedure was 50 ng.

Ovalbumin solutions of 1.0×10^{-2}, 1.6×10^{-2}, 2.0×10^{-2}, 3.0×10^{-2}, and 4.0×10^{-2} g/dm³ were determined by the use of a 2.0×10^{-2} g/dm³ lysozyme solution as the internal standard (Fig. 7). A linear relationship

was obtained between the weight ratio of ovalbumin to lysozyme and the ratio of the corresponding peak area. The coefficient of variation for five measurements of 2.0×10^{-2} g/dm^3 ovalbumin was 8.65%, and the internal standard method was shown to be superior to the absolute calibration method using the calibration curve I in Fig. 6.

To sum up, it has been found by the present authors that the catalytic activity of copper(II) against the CL between luminol and H_2O_2 is lowered in the presence of protein, and a sensitive and new detector for the HPLC of protein has been developed, 2×10^{-3}—1×10^{-1} g/dm^3 ovalbumin being determined within the detection limit of 50 ng. Since, however, the detection limit of the present detector was damaged by dilution and the low recovery which occurred when the present detector and HPLC were combined, some improvements overcoming these problems have to be done in future studies.

Benzylphenol Derivatives as Antioxidants for Autoxidation of Tetralin

Fukiko YAMADA,* Tomihiro NISHIYAMA, Yasuki SUZUURA, and Tatsuo YAMAMURA
Department of Applied Chemistry, Faculty of Engineering, Kansai University, Yamatecho, Suita, Osaka 564
(Received November 24, 1983)

A series of 4-benzylphenols, 2-methyl-4-benzylphenols, 4-methyl-2-benzylphenols and 4-methoxy-2-benzylphenols have been prepared and evaluated as antioxidants for tetralin at 60 °C by means of an oxygen-absorption method. Very good activities have been observed with a series of 4-methoxy-2-benzylphenols. The electrochemical oxidation potentials of these compounds were determined using linear-sweep voltammetry. The antioxidative activities were found to correlate with both the ^{13}C NMR chemical shifts (δ) of the *ipso*-carbon of the OH substituent and their peak potentials (E_p).

During the course of our studies of phenol derivatives as antioxidants,[1-5] compounds containing a diarylmethyl group with a phenolic hydroxyl group showed high activities as antioxidants for paraffin wax,[1,2] lard,[3] vitamin A,[4] mineral oils,[5] and greases.[5] In a recent study of benzylphenols,[6] we found that the introduction of a benzyl group to the *para*- and/or *ortho*-positions of the hydroxyl group on the benzene ring improved the antioxidative activities of phenols. Furthermore, the antioxidative activities of the benzylphenols increased with a decrease of the ^{13}C NMR chemical shifts (δ) of the *ipso*-carbon of the OH substituent.[6]

In this paper, the antioxidative activities of twenty compounds of four series of benzylphenols were evaluated by means of an oxygen-absorption method and are discussed in connection with their ^{13}C NMR chemical shifts and electrochemical oxidation data.

Experimental

Measurements. All the boiling and melting points were uncorrected. ^{13}C NMR spectra were recorded on a JNM-PS-100/EC-100 FT spectrometer operating at 25.15 MHz with complete proton decoupling. The pulse width and repetition time were 10.2 μs (for a 45° pulse) and 6 s, respectively. The spectra were observed as 2 mmol cm^{-3} solutions in $(CD_3)_2CO$ with a spectral width of 6250 Hz. Chemical shifts were referred to internal standard TMS. Mass spectra were obtained with a JEOL JMS-01SG Mattauch-Herzog double-focusing mass spectrometer at an ionizing voltage of 75 eV. GLC analyses were carried out on a Yanagimoto gas chromatograph(model GCG-550-T) using a 1.50-m column packed with Silicone SE-30 (10% wt).

Antioxidants. The benzylphenol derivatives studied in this work were as follows; 4-benzylphenol (**1**), 4-(α-methylbenzyl)phenol (**2**), 4-(α-ethylbenzyl)phenol (**3**), 4-(α-isopropylbenzyl)phenol (**4**), 4-benzhydrylphenol (**5**), 2-methyl-4-benzylphenol (**6**), 2-methyl-4-(α-methylbenzyl)-phenol (**7**), 2-methyl-4-(α-ethylbenzyl)phenol (**8**), 2-methyl-4-benzhydrylphenol (**9**), 2-methyl-4-(α, α-dimethylbenzyl)-phenol (**10**), 4-methyl-2-benzylphenol (**11**), 4-methyl-2-(α-methylbenzyl)phenol (**12**), 4-methyl-2-(α-ethylbenzyl)phenol (**13**), 4-methyl-2-(α-isopropylbenzyl)phenol (**14**), 4-methyl-2-benzhydrylphenol (**15**), 4-methoxy-2-benzylphenol (**16**), 4-methoxy-2-(α-methylbenzyl)phenol (**17**), 4-methoxy-2-(α-ethylbenzyl)phenol (**18**), 4-methoxy-2-(α-isopropylbenzyl)-phenol (**19**), and 4-methoxy-2-benzhydrylphenol (**20**).

Compounds **1**—**20** were prepared by Friedel-Crafts benzylations of the corresponding phenols in nitromethane using a catalyst for the desired time at a suitable temperature.[7,8] The reaction conditions for benzylations were as follows: (1) The reactions of the corresponding phenols with benzyl chloride or α-methylbenzyl chloride using $AlCl_3$ as the catalyst (1.0/1.0/0.1 molar ratio) at 60—70 °C gave the corresponding products, **1**, **7**, and **16**, respectively, (2) the reactions of the corresponding phenols with benzyl chloride using $ZnCl_2$ (1.0/1.0/0.1) at 25—45 °C gave products **6** and **11**, (3) the reactions of the phenols with α-ethylbenzyl alcohol, α-isopropylbenzyl alcohol, or benzhydrol using $ZnCl_2$ (1.0/1.0/1.0) at 25—45 °C gave products **3**, **4**, **5**, **8**, **9**, **13**, **14**, **15**, **18**, **19**, and **20**, respectively, and (4) the reactions of the phenols with styrene or α-methylstyrene using concd H_2SO_4 (1.0/1.0/1.0) at 30—60 °C gave products **2**, **10**, **12**, and **17**.

Each reaction was monitored using GLC analysis. The compound obtained was characterized by chemical shifts in the ^{13}C NMR spectrum. The physical properties and the results of elemental analyses of compounds **1**—**20** (prepared here) are summarized in Table 1.

Determination of Antioxidative Activity. Measurements of oxygen-absorption rates were performed with an isobaric gas-absorption apparatus under a closed-flow system (2.0±0.1 L oxygen/h) provided with an electrolyser using 50 cm^3 of tetralin containing an antioxidant (0.001 mol dm^{-3}) and azobis(isobutyronitrile) as the initiator (0.01 mol dm^{-3}). The oxidation temperature was kept at 60 ±0.1 °C and oxygen absorption was periodically measured in a constant-pressure closed system. Satisfactory and reproducible data were obtained.

The induction period (IP) and the oxidation rates both during and after the induction period were determined in the usual way.[9]

Tetralin used for the test was purified by shaking with concd sulfuric acid, dried with sodium, and distilled under an inert atmosphere.

Electrochemical Determination. Linear-sweep voltammograms were recorded for each compound (0.001 mol dm^{-3}) in acetonitrile with $LiClO_4$ (0.1 mol dm^{-3}) as a supporting electrolyte. The counter and working electrodes were made of platinum and the working electrode potential was referred to Ag/AgCl. Potential sweeps were generated by a Hokuto Denko HB-107A function generator in connection with a potentionstat Hokuto Denko HA-

104. All the measurements at the scan rate of 200 mV s^{-1} were carried out at 25 ±0.1 °C using a constant-temperature bath under a nitrogen atmosphere.

The acetonitrile was of optically pure grade and was free from water.

Results and Discussion

Activities of Antioxidants. Data regarding the activities of compounds **1—20** (denoted by the induction period, the stoichiometric factor, and the rates of the oxygen absorption) are listed in Table 2.

The autoxidation of tetralin at 60 °C was initiated by azobis(isobutyronitrile) (AIBN) and the inhibition by phenol derivatives can be described by the following chain-reaction schemes;[13,14]

Initiation: $\text{AIBN; RH} \xrightarrow{O_2} \text{RO}_2\cdot$ (1)

Propergation: $\text{RO}_2\cdot + \text{RH} \xrightarrow{k_p} \text{ROOH} + \text{R}\cdot$ (2)

$\text{R}\cdot + \text{O}_2 \longrightarrow \text{RO}_2\cdot$ (3)

Termination: $2\text{RO}_2\cdot \xrightarrow{k_t} \text{non-radical products}$ (4)

$\text{RO}_2\cdot + \text{ArOH} \xrightarrow{k_{inh}} \text{ROOH} + \text{ArO}\cdot$ (5)

a) The stoichiometries were determined at 60 °C by the induction-period method,[9,10] by using the values, the activity factor of the initiator, 0.6,[11] and the rate constant of decomposition of the initiator, 6.0×10^{-4} min^{-1} (the mean from the data in Ref. 12). b) The rates of oxygen absorption; (I) for an inhibited autoxidation during IP and (II) for an uninhibited oxidation after IP.

$$(n-1)RO_2\cdot + ArO\cdot \longrightarrow \text{non-radical products}, \quad (6)$$

where RH denotes the organic substrate (tetralin) and $RO_2\cdot$ is the peroxyl radical. In the presence of an antioxidant, ArOH, the oxidation chains become shortened, termination 4 is suppressed, and reactions 5 and 6 occur instead of 4. The induction period and the rates of inhibited and uninhibited oxidations can be represented by Eqs. I, II, and III, respectively;

$$IP = n[ArOH]/R_i \quad (I)$$

$$-d[O_2]/dt = k_p R_i[RH]/nk_{inh}[ArOH] \quad (II)$$

$$-d[O_2]/dt = k_p(R_i/2k_t)^{1/2}[RH] \quad (III)$$

where R_i is the rate of the chain initiation.

As can be seen from Table 2, the characterizations of the antioxidative activities can be expressed by three values: IP, n, and $-d[O_2]/dt$. These values are thought to be dependent on the structures of the phenol nuclei with various substituents at different positions. The length of IP increased in the order of **16—20** (4-methoxyphenols)> **11—15** (4-methylphenols)> **6—10** (2-methylphenols)> **1—5** (phenols). In each series, the compounds with an α-alkyl substituent possessed a longer IP than that of the α-phenyl substituent. Compounds **16—20** with a 4-methoxyl group exhibit much longer IP and, thus, higher stoichiometric factors (around n=3) in comparison with those of **1—15**.

For oxygen absorption during IP, much lower rates were found in compounds **16—20**, while higher rates were observed for **1—15**, (particularly **1—5**). According to Eq. II, the rate is proportional to the reciprocal of n. This relation is clearly illustrated in Fig. 1. On the other hand, the rates after IP are quite complicated. When all ArOH are consumed by reactions 5 and 6 (up to IP), the rate of autoxidation obeys Eq. III and is equal to that of the control test. In fact, the rates of **10** and **16—20** are close to 8.6. However, **1—15** (except for **10**) show much lower rates. This means that the retardation ability persists even after IP is over due to some products of the antioxidant. Figure 2 shows the tendency of IP values to increase with decreasing rates of **1—15** (except for **10**). Particularly, both groups **1**, **6** and **11** and **5**, **9** and **15** (with an α-phenyl substituent) show linear relations. This indicates the influence of a 2-methyl or 4-methyl substituent.

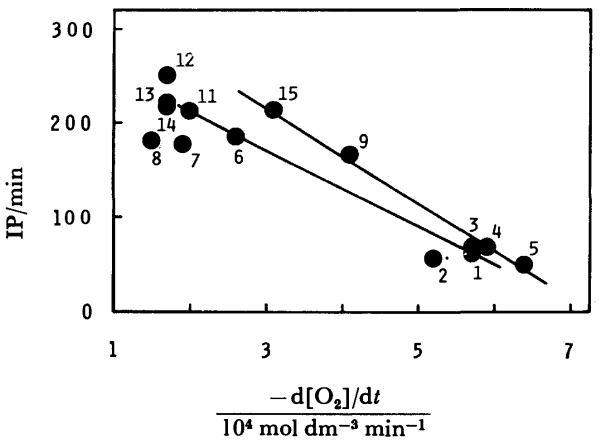

Fig. 2. Plot of IP *vs.* the rate of oxygen absorption.

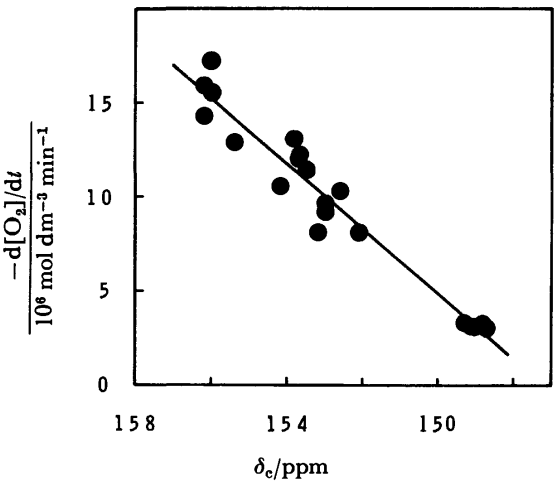

Fig. 4. Plot of the rate of oxygen absorption *vs.* ^{13}C chemical shift of the *ipso*-carbon of OH; $r=0.972$.

Correlations of Antioxidative Activities with ^{13}C Chemical Shifts and Oxidation Potentials. In order to understand the factors and mechanisms govering antioxidative activities of compounds **1—20**, several attempts were made to plot their IP values and the rates of oxygen absorption against the *ipso*-carbon chemical shifts of the OH substituents and the electrochemical oxidation potentials, respectively. The data used in this attempt are listed in Table 2.

Figure 3 shows the relation between the IP values and the *ipso*-carbon chemical shifts of the OH substituents. The plotted points fall on a straight line. This fact indicates that the IP values increase with the decreasing of the chemical shifts, and that the electron density on the *ipso*-carbon of the OH substituent governs antioxidative activity. In a previous paper,[15] we proved that the electron transmission through the *ipso*-carbon to the oxygen atom in phenols depends mostly upon the resonance contribution. Consequently, the total π-electron density of the oxygen atom may be increased by increasing the electron density of the *ipso*-carbon atom. According to a proposal by Morokuma *et al.*,[16] this will necessarily decrease the electronegativity of the oxygen atom and make the Coulomb integral of the σ orbital on the oxygen more positive. In the inhibition processes (reactions 5 and 6) the reactivities of phenolic hydrogen and the phenoxyl radical are the controlling factors. The reactivity of phenolic hydrogen for an attack on a peroxyl radical (electronegative radical) is greatly elevated by an increased π-electron density on the oxygen. Consequently, the reactivity of the phenoxyl radical produced can be elevated by an increased π-electron density.

Figure 4 also shows a linear relation between the rates of oxygen absorption during IP and the *ipso*-carbon chemical shifts of the OH substituents. The rates increase with increasing chemical shifts. From Eq. II, it is seen that the rate is proportional to

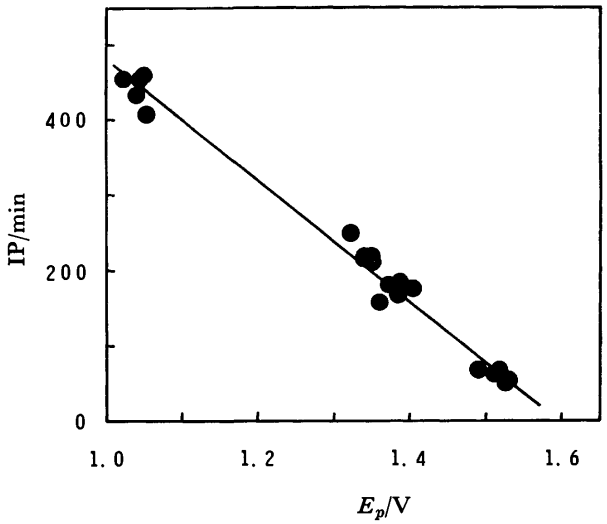

Fig. 5. Plot of IP *vs.* E_p; $r=0.993$.

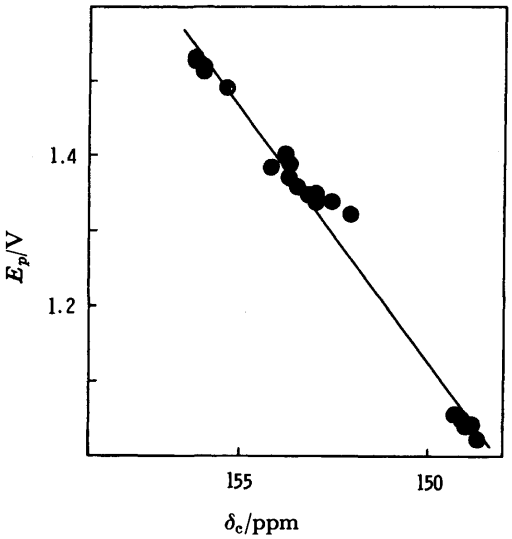

Fig. 6. Plot of E_p *vs.* ^{13}C chemical shift of the *ipso*-carbon of OH; $r=0.993$.

the reciprocal of n and k_{inh}. As was mentioned above, the activity of an antioxidant (which can be expressed by both n and k_{inh} values) is greatly elevated by an increased π-electron density on the phenolic oxygen.

The IP values show a linear relationship with the E_p values, as can be seen in Fig. 5. The IP values increase with a decreasing value of the oxidation potentials. In general, when the oxidation of a molecule is carried out at some potential, the reaction involves an initial electron loss, followed by proton migration. It is, therefore, thought that the simplicity of one-electron and one-proton transfers can be displayed by lower E_p values. In addition, there is the linear relationship between the *ipso*-carbon chemical shifts of the OH substituents and the E_p values, as can be seen in Fig. 6. This indicates that the easiness of one-electron and one-proton transfers is greatly increased by an increased electron density at the *ipso*-carbon of the OH substituent. The IP values were determined under an oxygen atmosphere while the electrochemical oxidations were performed in a solvent. The IP and E_p values were obtained for the different systems. Although the mechanism of the initial step of the inhibition is still unsettled, the above facts indicate that the oxidation of the phenol derivatives in these different systems proceed by a similar mechanism.

In conclusion, the ^{13}C chemical shift of the *ipso*-carbon of the OH substituent and the E_p value made it possible to estimate the antioxidative activity of a series of benzylphenol derivatives.

Synthesis of O-β-D-Glucopyranosyl-(1→2)-O-β-D-glucopyranosyl-(1→6)-D-glucopyranose; Dehydrative β-D-Glucosylation Using 2-O-Acetyl-3,4,6-tri-O-benzyl-D-glucopyranose

Shinkiti KOTO,* Naohiko MORISHIMA, Hiroko SATO, Yuko SATO, and Shonosuke ZEN
School of Pharmaceutical Sciences, Kitasato University, Shirokane, Minato-ku, Tokyo 108
(Received April 12, 1984)

A step-by-step synthesis of O-β-D-glucopyranosyl-(1→2)-O-β-D-glucopyranosyl-(1→6)-D-glucopyranose through the dehydrative β-D-glucosylation using 2-O-acetyl-3,4,6-tri-O-benzyl-D-glucopyranose and the ternary system of *p*-nitrobenzenesulfonyl chloride, silver trifluoromethanesulfonate, and triethylamine is described.

Our continuing study of glycosylation[1] has shown that the ternary system of *p*-nitrobenzenesulfonyl chloride (NsCl, Ns=$-SO_2C_6H_4NO_2(p-)$, silver trifluoromethanesulfonate (AgOTf, Tf=$-SO_2CF_3$), and triethylamine (Et_3N) induces selective β-D-glucosylation of glycosyl acceptors with the D-glucosyl donor having a free OH group at *C*-1 such as 2,3,4,6-tetra-*O*-benzyl-α-D-glucopyranose (**1**).[2] However, in any reaction with less reactive acceptors it almost always loses its selectivity.[3] To improve such an undesirable aspect, the benzyloxyl group at *C*-2 of **1** was replaced with an acetoxyl group, since an acyloxyl group at *C*-2 plays an important role in β-D-glycosylation using the 1-*O*-sulfonates.[4] Expectedly, the D-glucosylation with 2-*O*-acetyl-3,4,6-tri-*O*-benzyl-D-glucopyranose (**3**) yielded β-D-glucosides with excellent selectivity, while that with 6-*O*-acetyl-2,3,4-tri-*O*-benzyl-D-glucopyranose preferred to form α-D-glucosides.[5]

1,2,3,4,6-Penta-*O*-acetyl-β-D-glucopyranose (**2**) was readily converted into a D-glucosyl donor **3**[6] (α:β≈85:15) *via* a continuous four-stage through process.

D-Glucosylation of the primary OH group of methyl 2,3,4-tri-*O*-benzyl-α-D-glucopyranoside **4**[7] with **3** through the ternary system at 0 °C for 20 h gave the corresponding β-D-glucoside **5** in a 62% yield (Table 1). The β-selectivity was retained even in the D-glucosylation of the less reactive secondary OH group of methyl 2,3,6-tri-*O*-benzyl-β-D-glucopyranoside **6**[8] though the yield of the reaction was lowered. Thus, the β(1→4)-linked disaccharide **7** was selectively obtained at a 46% yield. The selectivity was also maintained in the D-glucosylation of the axial OH group of the galactose derivative **8**.[9] Therefore, it is, concluded that the acetoxyl group at *C*-2 controls the selectivity in dehydrative D-glucosylation irrespective of the type of OH group of D-glucosyl acceptor to produce β-D-glucoside in comparison with the previous experiments using **1**.[3]

Using the β-D-glucosylation described above, a linear trisaccharide **10** was synthesized as illustrated in Fig. 1. The first D-glucosylation of the acceptor **11**[10,11] with **3** was carried out using the ternary system; the gentiobiose derivative **12** was obtained selectively at a 61% yield. After deacetylation, the second glucosylation was performed by the ternary system to give the β-D-glucoside **14** at a 34% yield; an appreciable amount of the α-D-glucoside was isolated. In contrast to this, the use of **1** instead of **3** yielded the α-D-glucoside **15** as a significant by-product. A mixture of methanesulfonic acid ($MeSO_3H$) and $CoBr_2$[12] was useful for the first D-glucosylation to give **12** at a 41% yield. However, it was not at all useful for a second glucosylation of **13** with **3**. Deacetylation and successive hydrogenolysis of **14** afforded the trisaccharide **10**, whose ^{13}C NMR spectrum in D_2O was consistent with its proposed structure—6-*O*-β-sophorosyl-D-glucose.[13]

Experimental

Instrumentation for measuring the physical characteristics of the products was described in previous papers.[2,3,12] The D-glucosylation with the ternary system and the following processes were carried out in a manner which was detailed before.[2,3,5] The results of D-glucosylation are summarized in Table 1. The analytical and physical data of the products are listed in Table 2.

2-O-Acetyl-3,4,6-tri-O-benzyl-D-glucopyranose (3). 1,2,3,4,6-Penta-*O*-acetyl-β-D-glucopyranose (**2**, Kyowa, 1.0 g, 2.56 mmol) was treated in $CHCl_3$ (3.0 ml) containing AcBr (1.05 ml) and H_2O (0.23 ml) at room temperature for 2 h.[11] Evaporation and coevaporation with toluene gave a syrup which was dissolved in $MeNO_2$ (2.5 ml). 2,6-Dimethylpyridine (0.95 ml) and EtOH (1.15 ml) were added to the solution, which was then kept at room temperature overnight. The mixture was diluted with chloroform and washed with aq $NaHCO_3$ (5%). An organic layer was evaporated to dryness to give a syrup which was then heated in $PhCH_2Cl$ (14 ml) containing powdered KOH (7 g) for 2 h at 110 °C. Filtration and evaporation gave a syrup which was then stirred in aq AcOH (80%, 70 ml) for 2 h at room temperature. The mixture was diluted with toluene and an organic layer was washed with aq $NaHCO_3$ (5%) and water. After an evaporation, chromatography on a silica gel using a toluene–2-butanone system (gradient) gave a homogeneous syrup (R_f 0.18, toluene:2-butanone=6:1). This was crystallized from diisopropyl ether to afford **3** (0.37 g, 29%); ^1H NMR ($CDCl_3$, TMS): δ=2.00 (s, 3H, $C\underline{H}_3CO$), 3.44 (d, 1H, *J* 4.0 Hz, O<u>H</u>), 5.38 (dd, 1H, *J*=3.8 and 4.0 Hz, H-1).

Alternative Synthesis of Benzyl 6-O-(2-O-Acetyl-3,4,6-tri-O-benzyl-β-D-glucopyranosyl)-2,3,4-tri-O-benzyl-α-D-glucopyranoside (12). To a stirring mixture of **11**[10,11] (82 mg, 0.17 mmol), **3** (90 mg, 0.17 mmol), and $CoBr_2$ (36.5 mg, 0.17 mmol) in CH_2Cl_2 (0.45 ml), $MeSO_3H$ (3.3 μl, 0.05 mmol) was added at 20 °C and stirring was continued for 2 h. After processing[12] and chromatography the product was shown to be **12** (69 mg, 41%).

Benzyl 2,3,4-Tri-O-benzyl-6-O-(3,4,6-tri-O-benzyl-β-D-glucopyranosyl)-α-D-glucopyranoside (13). Compound **12** (127.6 mg, 0.126 mmol) was treated with a mixture of methanolic NaOMe (0.3%, 4.3 ml) and 1,4-dioxane (4 ml) at 20 °C overnight. Chromatography on a silica gel with toluene–2-butanone system gave **13** (112.3 mg, 92%).

Benzyl O-(2,3,4,6-Tetra-O-benzyl-α- and -β-D-glucopyranosyl)-(1→2)-O-(3,4,6-tri-O-benzyl-β-D-glucopyranosyl)-(1→6)-2,3,4-tri-O-benzyl-α-D-glucopyranoside (15 and 16). Triethylamine (22 μl, 0.158 mmol) was added into a stirred mixture of **I**[14] (84 mg, 0.156 mmol, $\alpha:\beta \approx 95:5$), **13** (116.2 mg, 0.12 mmol), NsCl (35 mg, 0.158 mmol), and AgOTf (40 mg, 0.156 mmol) in CH_2Cl_2 (0.65 ml) at −40 °C. The bath temperature was gradually raised to 0 °C, at which temperature the reaction was continued overnight. After processing, chromatography on a silica gel with toluene–2-butanone (gradient) gave a syrup (46.6 mg, 39%) consisting of **15** and **16**. Rechromatography of this syrup on silica gel using $(CH_2Cl)_2$–AcOEt (gradient) gave pure **16** (25.1 mg, 21%) and then **15** (19.2 mg, 16%).

Benzyl O-(3,4,6-Tri-O-benzyl-β-D-glucopyranosyl)-(1→2)-O-(3,4,6-tri-O-benzyl-β-D-glucopyranosyl)-(1→6)-2,3,4-tri-O-benzyl-α-D-glucopyranoside (17). The trisaccharide derivative **14** (79.5 mg, 0.055 mmol) was treated in a mixture of methanolic NaOMe (0.4%, 2 ml) and 1,4-dioxane (4 ml) at 20 °C overnight. After chromatography on silica gel with toluene-2-butanone system gave **17** (73.8 mg, 96%).

Compound **17** (47 mg, 0.033 mmol) was heated in $PhCH_2Cl$ (0.8 ml) containing NaH (60%, 40 mg) at 135 °C for 16 h to give the aforementioned fully benzylated trisaccharide **16** (25 mg, 50%).

O-β-D-Glucopyranosyl-(1→2)-O-β-D-glucopyranosyl-(1→6)-D-glucopyranose (10). Two hydrogenolyses of **17** (47.4 mg, 0.034 mmol) in AcOH (6 ml) containing Pd–C (10%, 40 mg) under H_2 (340 kPa) and subsequent chromatography on silica gel with $CHCl_3$–MeOH (1:1) gave glassy **10** (10.0 mg, 59%); ^{13}C NMR (D_2O, ext. TMS): δ=62.0 (C-6′), 62.2 (C-6″), 69.9 (C-6α), 70.0 (C-6β), 70.8 (C-4′ and -4″), 70.9 (C-4α and -4β), 71.7 (C-5α), 72.8 (C-2α), 74.0 (C-3α), 75.0 (C-2″), 75.4 (C-2β), 76.2 (C-3β), 77.0 (C-5β, -3′, and -3″), 77.5 (C-5′ and -5″), 81.2 (C-2′), 93.5 (C-1α), 97.4 (C-1β), 102.6 (C-1′), and 103.8 (C-1″).

Similar hydrogenolysis of **16** (25 mg, 0.017 mmol) gave **10** (4 mg, 48%).

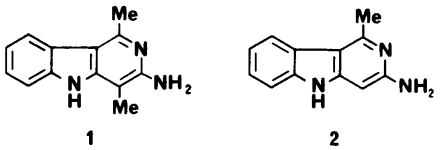
Synthesis of 3-Amino-5*H*-pyrido[4,3-*b*]indoles, Carcinogenic γ-Carbolines

Hiroshi AKIMOTO,* Akiyoshi KAWAI, and Hiroaki NOMURA
Central Research Division, Takeda Chemical Ind., Ltd., Juso, Yodogawa-ku, Osaka 532
(Received May 23, 1984)

The carcinogenic γ-carbolines 3-amino-1,4-dimethyl-5*H*-pyrido[4,3-*b*]indole (**1**) and 3-amino-1-methyl-5*H*-pyrido[4,3-*b*]indole (**2**) were synthesized efficiently by the following procedures. The key method involved the acid-catalyzed cyclization of 2-acetamido-3-(2-indolyl)alkanoic acids to 1,2-dihydro-γ-carbolines. This was followed by dehydrogenation to the γ-carbolinecarboxylates and conversion of the ester group to the carboxyl and finally to the amino one by Curtius rearrangement. Alternative methods involved the thermolysis of 4-(1-benzotriazolyl)-3,6-dimethyl-2-pyridinamine to synthesize **1** and the condensation of 3-acetylindole-2- acetonitrile with ammonia to synthesize **2**. The structures of γ-carbolines **1** and **2** were unambiguously established by comparing samples of each synthesized by the two different routes. A selective and one-step synthesis of ethyl 2-acetamido-3-(2-indolyl)alkanoates was newly exploited starting from diethyl acetamidomalonate and quaternary ammonium salts of 2-[1-(dimethylamino)alkyl]indoles.

In a preliminary communication,[1] we reported on the total synthesis of the carcinogenic γ-carboline derivatives, 3-amino-1,4-dimethyl-5*H*-pyrido[4,3-*b*]indole (named Trp-P-1, **1**) and 3-amino-1-methyl-5*H*-pyrido-[4,3-*b*]indole (named Trp-P-2, **2**).[2] This study was initiated in order to obtain sufficient amounts of samples to allow extensive biological studies, including carcinogenesis tests of **1** and **2**,[3] and has contributed to the development of new routes for the large-scale preparation of these γ-carbolines.

Massive research on environmental mutagenes and carcinogens over the last decade has led to the identification of many of these substances which occur in food, water and air.[3a] One series of such environmental agents, heterocyclic amines formed by pyrolysis of various amino acids and proteins, was identified as being mutagenic and has been intensively investigated by Sugimura and his co-workers.[3] The first isolated and highly potent mutagens among these compounds are the γ-carboline derivatives Trp-P-1 (**1**) and Trp-P-2 (**2**) isolated from protein pyrolysates[4] and more favorably tryptophan pyrolysates.[5] The structures of these carbolines have been determined from spectral data and, in the case of **1**, also from X-ray analysis.[5] These mutagens were suspected to be carcinogenic, based on their ability to induce morphological transformation of cultured mammalian embryo cells.[6,7] However, sufficient quantities of these compounds were needed for carcinogenicity tests in animals. Their preparation by tryptophan pyrolysis gave extremely low yields.[5] Thus, we developed new procedures for the large-scale synthesis of **1** and **2**.[1]



1 2

Fig. 1. Structures of Trp-P-1 (**1**) and Trp-P-2 (**2**).

Results and Discussion

Only a few reports have appeared regarding the synthesis of γ-carboline and its derivatives. They include 1) cyclization to the γ-carboline pyrrole ring by thermal decomposition of azidobenzenes or benzotriazoles containing a pyridine ring (Graebe-Ullmann type reaction),[8] 2) building the γ-carboline pyridine ring by cyclization of azomethines derived from 3-formylindole and amino acetal,[9] and 3) cyclization to 1,2,3,4-tetrahydro-γ-carbolines by thermal reaction of 4-piperidone phenylhydrazones (Fischer indole synthesis).[10] We tried three approaches to the synthesis of γ-carbolines **1** and **2**: A) Thermolysis of 4-(1-benzotriazolyl)-3,6-dimethyl-2-pyridinamine (**6**) in polyphosphoric acid, B) ring closure from 2-acetamido-3-(2-indolyl)alkanoic acids (**14a,b**) to 1,2-dihydro-γ-carbolines, followed by dehydrogenation, and C) building the γ-carboline pyridine ring by cyclization of the 2,3-disubstituted indole **19** with ammonia.

*Synthesis of 3-Amino-1,4-dimethyl-5*H*-pyrido[4,3-b]indole (1) by Route A.* A key intermediate for the synthesis of **1**, 3,6-dimethyl-4-nitro-2-pyridinecarboxylic acid (**3**), was prepared from 2,5-dimethylpyridine[11] and the nitro group was readily replaced by *o*-phenylenediamine to yield the *N*-phenyl-4-pyridinamine compound (**4**). Upon treatment with nitrous acid, this was converted to the 4-(benzotriazolyl)-pyridine derivative **5** in excellent yield. The carboxyl group of **5** was easily converted to the amino group by Curtius rearrangement using diphenylphosphoryl azide(DPPA)[12] to yield the 2-amino derivative **6**. Heating a sample of **6** in polyphosphoric acid gave the desired product **1**, which was isolated as colorless prisms of the acetic acid salt in moderate yield (46%) (Chart 1). Elemental analysis and mass spectroscopy supported the molecular formula of $C_{13}H_{13}N_3 \cdot CH_3COOH$. The UV spectrum of **1** showed several absorption maxima at 226,

244, 265, 267, 307, and 319 nm in an acidic solution, the pattern being comparable to that of γ-carboline.[13] The IR spectrum showed absorption bands at 1650 (CH_3COOH salt) and 1610 (γ-carboline) cm^{-1}. The ^1H NMR spectrum had signals for three methyl groups, acetic acid and those at the C-1 and C-4 positions at δ 2.08 (3H, s), 2.36 and 2.96 (each 3H, s), respectively, together with the four aromatic protons at δ 7.20—7.42 (3H, m) and 8.03 (1H, m).

Synthesis of 3-Amino-1,4-dimethyl-5H-pyrido[4,3-b]indole (1) by Route B. 2-Acetamido-3-(2-indolyl)-butyric acid (**14a**) was synthesized by subjecting the intermediary 2-[1-(dimethylamino)ethyl]indole (**11**), which was prepared from 2-indolecarboxylic acid (**7**) *via* 2-acetylindole (**8**), the dialkylamine **9** and *N,N*-dialkylformamide **10**, to malonic ester synthesis.[14] Quaternarization of **11** and subsequent reaction with diethyl acetamidomalonate gave 2-acetamido-3-(2-indolyl)butyrate (**13a**) in 81% yield from **11**. This ester was subjected to alkaline hydrolysis to yield 2-acetamido-3-(2-indolyl)butyric acid (**14a**) in quantitative yield. Treatment of **14a** with thionyl chloride in ethanol resulted in intramolecular cyclization and a simultaneous esterification to yield the dihydro-γ-carboline ester **15a**.[15] Dehydrogenation with sulfur quantitatively gave γ-carboline-3-carboxylate **16a**, and subsequent alkaline hydrolysis provided the γ-carbolinecarboxylic acid **17a** in high yield (68% yield from **13a**). The final step was Curtius rearrangement of **17a** using DPPA which gave **1** in 41% yield (Chart 2). Elemental analysis, UV, IR, and mass spectra gave results identical to those of the product obtained by route A.

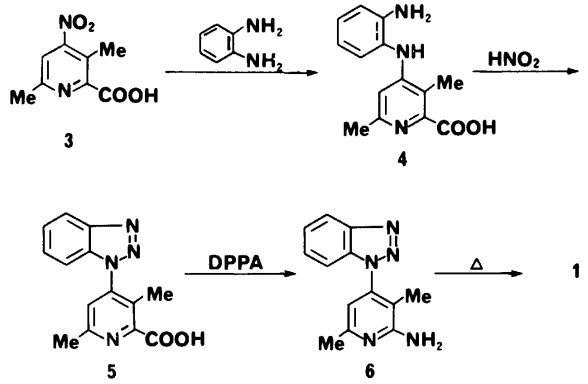


Chart 1. Synthesis of Trp-P-1 by Route A.

Synthesis of 3-Amino-1-methyl-5H-pyrido[4,3-b]indole (2) by Route B. Since route B was very efficient for the synthesis of **1**, we applied it to the synthesis of **2**. As described above, the trimethylammonium salt derived from 2-(dimethylaminomethyl)indole (**12**) was subjected to a malonic ester synthesis using diethyl acetamidomalonate, which yielded 2-acetamido-3-(2-indolyl)propionate (**13b**) in high yield (82%). This compound was cyclized to the dihydro-γ-carboline ester **15b** by treatment with thionyl chloride in ethanol. Dehydrogenation and alkaline hydrolysis, as in the synthesis of **17a** from **11**, gave γ-carbolinecarboxylic acid **17b** in good yield (77.8% from **13b**). Conversion of the carboxyl group to the amino function using DPPA yielded the desired γ-carboline **2** (Chart 2). The physical properties were determined with the crystalline acetic acid salt. The molecular for-

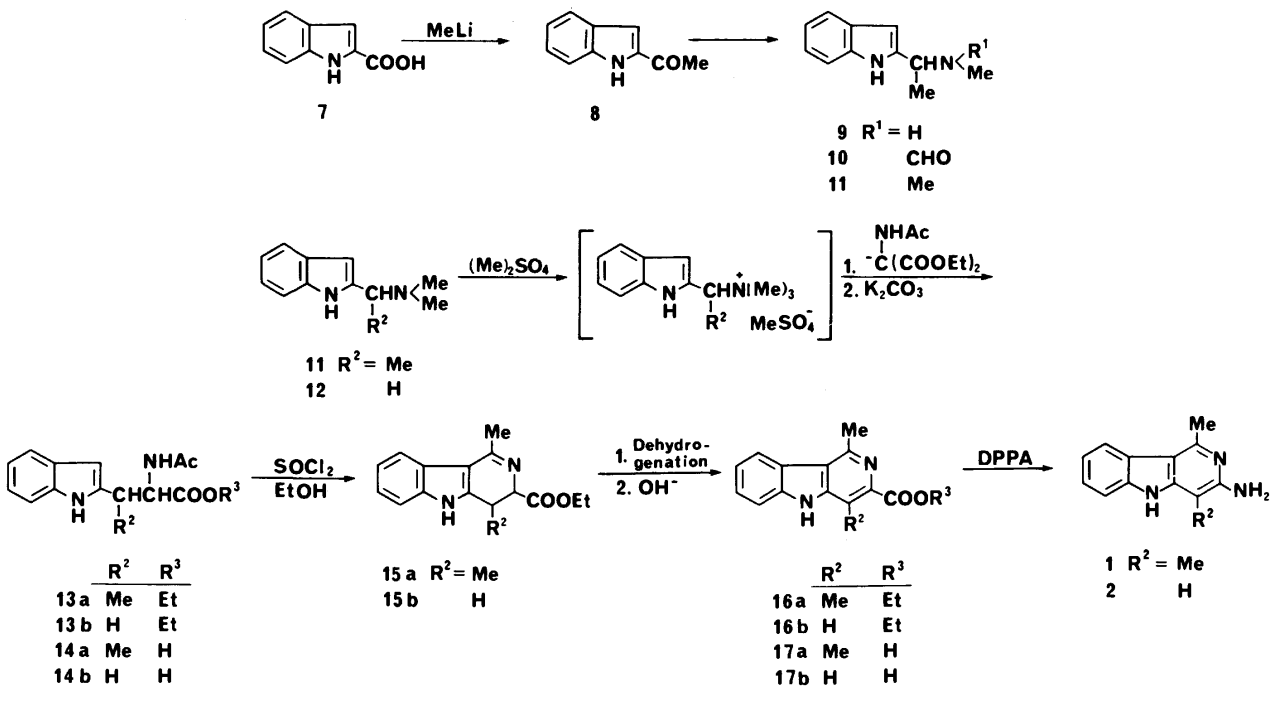

Chart 2. Synthesis of Trp-P-1 and Trp-P-2 by Route B.

mula agreed with $C_{12}H_{11}N_3 \cdot CH_3COOH$ on elemental analysis and mass spectroscopy. Its IR and UV spectra showed the absorption bands characteristic to γ-carboline and were very similar to those of **1** (the acetic acid salt). The structure was further supported by the ^1H NMR spectrum, which showed the signals at δ 1.93 (3H, s) due to acetic acid methyl protons, at δ 2.74 (3H, s) due to C-1 methyl protons, at δ 6.37 (1H, s) due to C-4 proton and at δ 7.07—7.53 (3H, m) and 7.97 (1H, d) due to four aromatic protons.

Synthesis of 3-Amino-1-methyl-5H-pyrido[4,3-b]indole (2) by Route C. In order to confirm the structure of **1**, the alternative, more short-cut method was exploited. Chart 3 shows the synthetic route of **2**, *via* indole-2-acetonitrile (**18**)[16] which was readily available from 2-(dimethylaminomethyl)indole (**12**). Compound **18** was converted to 2-acetylindole-2-acetonitrile (**19**) by the Vilsmeier-Haack reaction[17] with *N,N*-dimethylacetamide (DMA) and phosphoryl chloride. This key intermediate **19**, when treated with methanolic ammonia, underwent spontaneous condensation and aromatization to give the desired product **2** in 58% yield (Chart 3). The physical data regarding the product agreed with those of the sample obtained by route B.

Malonic Ester Synthesis Starting from 1-(2-Indolyl)alkylamines, 11 and 12. When quaternary ammonium salt derived from **11** and **12** were allowed to react with excess sodioacetamidomalonate in ethanol at room temperature, the corresponding monocarboxylates **13a,b** were obtained selectively and quantitatively without hydrolytic decarboxylation procedure (Table 1, runs 3 and 6). In each case, an equimolar quantity of diethyl carbonate was formed in the reaction mixture, offering some suggestion for the reaction mechanism.

In the present reaction, the composition and yields of the products were markedly influenced by changes in the reaction conditions, particularly, the molar ratio of 1-(2-indolyl)alkylamines **11** and **12** and sodioacetamidomalonate. In fact, an entirely different mode of reaction was encountered when the reaction was carried out using sodioacetamidomalonate in amounts less than equimolar to that of the quaternary salts derived from **11** and **12**. The reaction products were the indolylmethyl derivatives of 2-acetamidomalonates **20a,b** (Table 1, runs 1 and 4). When the sodiomalonate was used in slight excess of the equimolar quantity of **11**, the dihydropyrrolo[1,2-*a*]indole **21a** was produced selectively (Table 1, run 2).

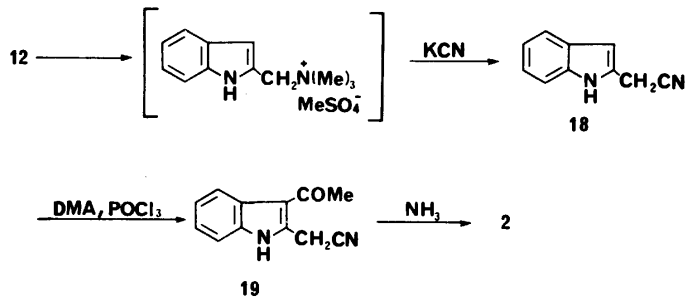

Chart 3. Synthesis of Trp-P-2 by Route C.

These substituted carboxylates, **20a,b**, **21a** and **13a,b**, when treated with alkali, gave the identical 2-acetamidoalkanoic acids **14a,b** in quantitative yields. Thus, this tricyclic hetero system **21** is assumed to be a precursor which can be readily converted to **13a,b**. Several attempts to isolate the tricyclic compound **21b** were unsuccessful under a range of reaction conditions, presumably due to the higher lability of **21b**, because the less hindered ring-carbonyl is considered to be more susceptible to nucleophile attack than that of the sterically more crowed pyrrolidone **21a** during the reaction. These results suggest that, under conditions using excess sodioacetamidomalonate, the reaction proceeds from 1-(2-indolyl)alkylamines **11** and **12** to the monocarboxylates **13a,b** *via* **20** and **21** (Chart 4). An intramolecular attack by the indole anionic nitrogen of **20** upon one of the malonic ester carbonyls results in the formation of the tricyclic pyrrolidone **21**, which, on attack by ethoxide, affords the corresponding monocarboxylates **13a,b**, through C–C bond cleavage of the pyrrolidone ring and another attack by ethoxide ion on the resulting ethoxycarbonyl group of the presumed intermediate (Chart 4). Thus, the present malonic ester-type reaction opens an efficient one-step synthesis of the 3-(2-indolyl)alkanoates, extending a two-carbon chain at the methyl position of the 2-indolylmethyl group

Table 1. Malonic ester synthesis starting from quaternary salts of **11** and **12**[a]

Run	Molar ratio: Sodiomalonate[b] / Quaternary salt of **11**[c]	Product ratio/%[d]: **20a**	**21a**	**13a**
1	0.98	82 (67)	16	2[e]
2	1.10	1	88 (71)	11
3	1.25	—	6	94 (81)[f]
	Sodiomalonate[b] / Quaternary salt of **12**[c]	**20b**	**21b**	**13b**
4	0.98	94 (76)	—	6[e]
5	1.10	42	—	58
6	1.25	3	—	97 (82)[f]

a) See text for reaction conditions. b) Calculated as sodium ethoxide which was employed in the reaction with the equimolar quantity of diethyl acetamidomalonate. c) Prepared from equimolar amounts of the corresponding amine **11** or **12** and dimethyl sulfate. d) For evaluation of the product ratios (%), each sample was analyzed by HPLC (Waters Associates; μ-Porasil, 3.9 mm × 30 cm, $CHCl_3$: AcOEt = 4 : 1; detection at 254 nm). Figures in parentheses express the isolated yields. e) Diethyl carbonate was not detected. f) A nearly quantitative yield of diethyl carbonate was detected by HPLC analysis.

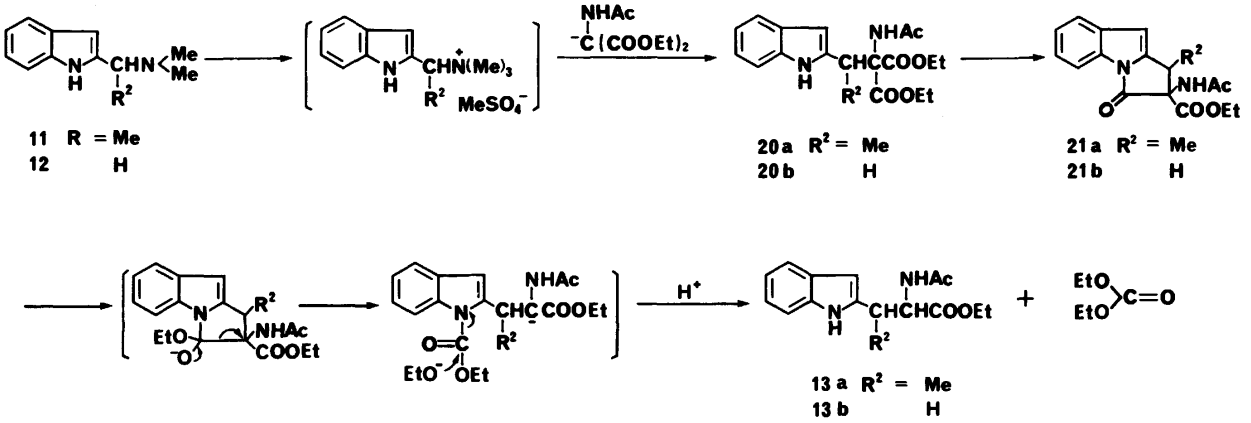

Chart 4. Reaction Mechanism of Monocarboxylic Ester Formation.

under mild reaction conditions.

Our new routes for synthesizing mutagenic γ-carbolines **1** and **2** are efficient and useful for preparing large quantities of these compounds. These methods enabled the synthesis of sufficient amounts of **1** and **2** for carginogenesis testing, including an almost one-year administration of **1** and **2** to mice, by Sugimura and his groups.[3,7] The results have proven that these γ-carbolines are carcinogenic.[3a,18]

Experimental

Melting points were measured on a Yanagimoto MP-S3 hot-plate apparatus and are uncorrected. Infrared spectra were recorded on a Hitachi 215 spectrometer. UV spectra were taken on a Hitachi EPS-3T spectrometer. Mass spectra were determined with a Hitachi RMU-6D spectrometer equipped with a direct-inlet system. ^{1}H NMR spectra were obtained using a Varian XL-100-12 instrument: Chemical shifts (δ) are expressed in ppm downfield from internal TMS. Preparative column chromatography was carried out on a Kieselgel 60 (E. Merck, Art. 7743).

3,6-Dimethyl-4-nitro-2-pyridinecarboxylic Acid (3). This compound was prepared from 2,5-dimethylpyridine according to a method[12] described in the synthesis of 6-ethyl-3-methyl-4-nitro-2-pyridinecarboxylic acid. Recrystallization from acetonitrile gave **3** as colorless needles: Mp 145—146 °C; IR (KBr) 3420, 3100, 1720, 1610, 1540, 1520, 1440, 1390, 1295, 1220, 1190, 1120, 960, 890, 800, and 780 cm^{-1}; ^{1}H NMR (CD_3OD) δ=2.46 (3H, s), 2.60 (3H, s), 7.67 (1H, s). Found: C, 48.99; H, 4.03; N, 14.38%. Calcd for $C_8H_8N_2O_4$: C, 48.98; H, 4.11; N, 14.28%.

3,6-Dimethyl-4-(2-aminophenylamino)-2-pyridinecarboxylic Acid (4). A solution of **3** (3.6 g) and *o*-phenylenediamine (5.4 g) in water (100 cm^3) was heated under reflux for 1 h, and evaporated *in vacuo*. The residue was charged on Amberlite XAD-II (500 cm^3) column which was then washed with water (1000 cm^3) and eluted with 20% aqueous MeOH. The combined fractions containing the desired product were evaporated *in vacuo* and gave a pale-yellow solid. Recrystallization from water provided colorless needles (4.4 g, 93%): Mp 241—242 °C; IR (KBr) 2700—2400, and 1600 cm^{-1}; ^{1}H NMR (CD_3OD) δ=2.03 (3H, s), 2.16 (3H, s), 5.80 (1H, s), 6.33—6.68 (3H, m). Found: C, 65.30; H, 5.79; N, 16.28%. Calcd for $C_{14}H_{15}N_3O_2$: C, 65.36; H, 5.88; N, 16.33%.

4-(1-Benzotriazolyl)-3,6-dimethyl-2-pyridinecarboxylic Acid (5). A 10% hydrochloric acid solution (30 cm^3) of **4** (2.0 g) was cooled in an ice bath and then sodium nitrite (1.1 g) in water (30 cm^3) was added. This mixture was left stainding at 0 °C for 2 h. The precipitated solid was collected, washed with 10% hydrochloric acid and dissolved in 2 mol dm^{-3} NaOH. The solution was filtered to remove any insoluble material and then hydrochloric acid was slowly added. Filtration and drying of the resulting crystalline precipitate gave the hydrochloride of **5** (2.25 g, 93%) as colorless needles: Mp 187—188 °C; IR (KBr) 2850—2300, and 1700 cm^{-1}; ^{1}H NMR (CD_3OD) δ=2.60 (3H, s), 2.93 (3H, s), 7.73 (3H, m), 8.13 (1H, m), 8.26 (1H, s). Found: C, 54.89; H, 4.36; N, 18.33; Cl, 11.69%. Calcd for $C_{14}H_{12}N_4O_2 \cdot HCl$: C, 55.18; H, 4.38; N, 18.39; Cl, 11.63%.

4-(1-Benzotriazolyl)-3,6-dimethyl-2-pyridinamine (6). A mixture of **5** (10 g), diphenylphosphoryl azide (DPPA; 10.8 g), and triethylamine (8.3 g) in *t*-BuOH (200 cm^3) was heated under reflux for 1.5 h and gave a residue when evaporated *in vacuo*. This was dissolved in ethyl acetate (200 cm^3), washed successively with saturated aqueous NaCl and saturated aqueous $NaHCO_3$, dried over $MgSO_4$ and evaporated. The resulting solid was dissolved in 25% HBr-acetic acid (140 cm^3) and the solution was kept standing at 0 °C for 30 min, then diethyl ether (140 cm^3) was added. When the mixed solution was left standing for another 1 h, a white precipitate separated. This was collected by filtration, washed with diethyl ether, and dried to give an amorphous powder (the hydrobromide of **6**). This material was suspended in 15% aqueous ammonia (140 cm^3) and extracted with ethyl acetate. The extract was washed with saturated aqueous NaCl, dried over $MgSO_4$, and evaporated *in vacuo*. Recrystallization of the residue from diethyl ether gave the free amino compound **6** (6.1 g, 78%) as pale yellow needles: Mp 139—140 °C; IR (KBr) 3320, 3200, 1620, and 1590 cm^{-1}; ^{1}H NMR ($CDCl_3$) δ=1.83 (3H, s), 2.34 (3H, s), 4.80 (2H, bs), 6.54 (1H, s), 7.40 (3H, m), 8.06 (1H, m). Found: C, 65.28; H, 5.34; N, 29.34%. Calcd for $C_{13}H_{13}N_5$: C, 65.26; H, 5.48; N, 29.27%.

2-Acetylindole (8). A solution of 2-indolecarboxylic acid (**7**; 14.2 g, Fluka AG, Switzerland) and methyl lithium, prepared from lithium (7.2 g) and methyl iodide (29 g), in

diethyl ether (300 cm^3) was refluxed for 1 h. The reaction mixture was poured into ice water and extracted with diethyl ether. The extract was washed with saturated aqueous NaCl, dried over $MgSO_4$ and evaporated to dryness *in vacuo*. Recrystallization of the residue from ethyl acetate gave 11.7 g (84%) of **8** as colorless needles: Mp 154—155 °C; IR (KBr) 3300, 1640, and 1610 cm^{-1}; ^1H NMR ($CDCl_3$) δ=2.57 (3H, s), 7.12 (2H, m), 7.40 (2H, m), 7.67 (1H, d). Found: C, 75.31; H, 5.62; N, 8.78%. Calcd for $C_{10}H_9NO$: C, 75.45; H, 5.70; N, 8.80%.

2-[1-(Methylamino)ethyl]indole (9). A solution of **8** (11.8 g) in 40% methanolic methylamine (350 cm^3) was heated under reflux for 5 h and left overnight at room temperature. After evaporation, the residue was dissolved in MeOH (200 cm^3) and treated with $NaBH_4$ (4.5 g) under stirring at room temperature for 1 h. Evaporation of the reaction mixture *in vacuo* gave a residue which was suspended in 4% aqueous NaOH (100 cm^3) and extracted with ethyl acetate. The extract was washed with saturated aqueous NaCl, dried over $MgSO_4$ and evaporated *in vacuo* to yield the desired product as colorless needles (11.0 g, 89%): Mp 95—95.5 °C; IR (KBr) 3170, 1450, 1430, and 1290 cm^{-1}; ^1H NMR ($CDCl_3$) δ=1.46 (3H, s), 2.33 (3H, s), 3.93 (1H, q), 6.30 (1H, s), 6.97-7.33 (3H, m), 7.50 (1H, m). Found: C, 75.88; H, 8.16; N, 16.01%. Calcd for $C_{11}H_{14}N_2$: C, 75.82; H, 8.10; N, 16.08%.

2-[1-(N-Formylmethylamino)ethyl]indole (10). A solution of **9** (25 g) and 4-nitrophenyl formate (28.8 g) in ethyl acetate (500 cm^3) was stirred at room temperature for 1 h. The reaction mixture was washed successively with 1 mol dm^{-3} NaOH and saturated aqueous NaCl, dried and evaporated *in vacuo*. Recrystallization of the residue from diethyl ether yielded the desired product as colorless needles (23.6 g, 91%): Mp 129—130 °C; IR (KBr) 3230, 3200, 1660, and 1300 cm^{-1}; ^1H NMR ($CDCl_3$) δ=1.67, 1.70 (3H, d, ratio 45:55), 2.67, 2.70 (3H, s, ratio 55:45), 4.96, 5.83 (1H, q, ratio 55:45), 6.46 (1H, s), 7.00—7.70 (4H, m), 8.13, 8.33 (1H, s, ratio 45:55). Found: C, 71.39; H, 6.98; N, 13.68%. Calcd for $C_{10}H_{14}N_2O$: C, 71.26; H, 6.98; N, 13.85%.

2-[1-(Dimethylamino)ethyl]indole (11). A mixture of **10** (45 g) and $LiAlH_4$ (10.6 g) in dry tetrahydrofuran (1000 cm^3) was placed in a flask equipped with a calcium chloride drying tube and stirred at room temperature for 1 h. After evaporation *in vacuo*, the residue was decomposed by the addition of water (100 cm^3) and extracted with diethyl ether. The extract was dried over $MgSO_4$ and evaporated *in vacuo*. The residual oil was distilled under reduced pressure to yield the desired product as a colorless oil (36 g, 86%): Bp 111—112 °C/1 mmHg (1 mmHg≈133.322 Pa), mp 48—49 °C (solidified on standing); IR (KBr) 3400, 2970, 1460, and 1300 cm^{-1}; ^1H NMR ($CDCl_3$) δ=1.35 (3H, d), 2.22 (6H, s), 3.75 (1H, q), 6.22 (1H, s), 6.95—7.30 (3H, m), 7.47 (1H, m), 8.53 (1H, bs). Found: C, 76.55; H, 8.69; N, 14.90%. Calcd for $C_{12}H_{16}N_2$: C, 76.56; H, 8.57; N, 14.88%.

Diethyl 2-Acetamido-2-[1-(2-indolyl)ethyl]malonate (20a). To a solution of **11** (500 mg, 2.65 mmol) in abs EtOH(5 cm^3), dimethyl sulfate (332 mg, 2.65 mmol) was added dropwise at a temperature below 35 °C. The solution was kept standing at room temperature for 1 h and was then added to an ice-cooled, stirred solution prepared from sodium (59.7 mg, 2.60 mmol) and diethyl acetamidomalonate (564 mg, 2.60 mmol) in abs EtOH (10 cm^3). The mixture was allowed to react at room temperature for 2 d and evaporated *in vacuo*. The resulting residue was dissolved in $CHCl_3$ and washed successively with water, aqueous Na_2CO_3, and dil HCl. Evaporation followed by recrystallization from benzene gave the desired product as an amorphous powder (641 mg, 67%): IR (KBr) 3380, 1735, 1720, 1690, 1670, and 1500 cm^{-1}; ^1H NMR ($CDCl_3$) δ=0.90 (3H, t), 1.26 (3H, t), 1.47 (3H, d), 1.96 (3H, s), 3.96 (1H, m), 4.30 (2H×2, q), 6.23 (1H, s), 7.00—7.67 (4H, m). Found: C, 63.17; H, 6.68; N, 7.81%. Calcd for $C_{19}H_{24}N_2O_5$: C, 63.32; H, 6.71; N, 7.77%.

Ethyl 2-Acetamido-1-methyl-3-oxo-1H-2,3-dihydropyrolo[1,2-a]indole-2-carboxylate (21a). This compound (2.35 g, 71%) was synthesized from the dimethylamino compound **11** (2.0 g) by a procedure similar to that described in the preceding section except that 1.1 equivalents of sodioacetamidomalonate were used. IR (KBr) 3360, 1750, 1740, 1680, and 1610 cm^{-1}; MS *m/z* 314 (M^+); ^1H NMR ($CDCl_3$) δ=1.07, 1.20 (3H, t, ratio 6:4) 1.30, 1.34 (3H, d, ratio 4:6), 2.06, 2.08 (3H, s, ratio 4:6), 3.87, 4.03 (1H, m, ratio 4:6), 4.14, 4.21 (2H, q, ratio 6:4), 6.25, 6.26 (1H, m, ratio 6:4), 7.20—7.50 (3H, m), 8.00 (1H, m). Found: C, 65.11; H, 5.80; N, 8.90%. Calcd for $C_{17}H_{18}N_2O_4$: C, 64.96; H, 5.77; N, 8.91%.

Ethyl 2-Acetamido-3-(2-indolyl)butyrate (13a). To a stirred solution of **11** (9.17 g, 48.8 mmol) in abs EtOH (50 cm^3), dimethyl sulfate (6.3 g, 48.8 mmol) was added dropwise at a temperature below 35 °C. The mixture, after being left standing at room temperature for 1 h, was added to an ice-cooled, stirred solution prepared from sodium (1.4 g, 61 mmol) and diethyl acetamidomalonate (10.6 g, 61 mmol) in abs EtOH (100 cm^3). The combined mixture was allowed to stand at room temperature for 3 d and then evaporated *in vacuo*. After work-up, the desired product was obtained as an amorphous powder (11.3 g, 81%): IR (KBr) 3370, 3360, 3300, 3260, 1730, 1650, 1550, and 1530 cm^{-1}; ^1H NMR (CD_3OD) δ=0.93, 1.16 (3H, t, ratio 1:9), 1.43 (3H, d), 1.90, 1.96 (3H, s, ratio 9:1), 3.56 (1H, q), 4.00, 4.16 (2H, q, ratio 1:9), 4.87, 4.89 (1H, d, ratio 1:9), 6.16, 6.26 (1H, s, ratio 1:9), 6.83—7.60 (4H, m). Found: C, 66.79; H, 6.98; N, 9.16%. Calcd for $C_{16}H_{20}N_2O_3$: C, 66.54; H, 6.99; N, 9.71%.

Ethyl 2-Acetamido-3-(2-indolyl)propionate (13b). From the dimethylamino compound[14] **12** (8.5 g), the desired product **13b** (11.0 g, 82%) was obtained as colorless needles by a procedure similar to that described in the preceding section: Mp 134—135 °C (from benzene); IR (KBr) 3420, 3300, 1740, 1620, 1220, 1200, 1175, and 1020 cm^{-1}; ^1H NMR ($CDCl_3$) δ=1.18 (3H, t), 1.93 (3H, s), 3.23 (2H, d), 4.17 (2H, q), 4.90 (1H, m), 6.23 (1H, s), 6.98—7.67 (4H, m). Found: C, 65.59; H, 6.73; N, 10.01%. Calcd for $C_{15}H_{18}N_2O_3$: C, 65.68; H, 6.61; N, 10.21%.

Malonic Ester Synthesis starting from 2-[1-(Dimethylamino)-alkyl]indoles (11 and 12). A solution of **11** or **12** (0.5 mmol) in abs EtOH (0.5 cm^3) was treated with dimethyl sulfate (0.5 mmol) at a temperature below 35 °C. After the mixture had stood at 20 °C for 1 h, it was added to an ethanolic solution (1.0 cm^3) prepared from equimolar quantities of 0.49, 0.55, or 0.63 mmol of sodium and diethyl acetamidomalonate (Table 1). The mixture was allowed to react at 20 °C for 3 d while being isolated from moisture. The product composition was analyzed by HPLC (μ-Porasil, 3.9 mm×30, $CHCl_3$:AcOEt=4:1). The results are summarized in Table 1.

2-Acetamido-3-(2-indolyl)butyric Acid (14a). *a)* A mixture of **20a** (185 mg) and Na_2CO_3 (180 mg) in water (2.0 cm^3) was refluxed for 15 h and then cooled. This was acidified with concd HCl (0.3 cm^3) and extracted with ethyl acetate. The extract was washed with saturated aqueous

NaCl, dried over $MgSO_4$ and evaporated to dryness *in vacuo*. Precipitation from aqueous EtOH gave the desired product as an amorphous powder (122 mg, 91%): IR (KBr) 3450, 3340, 1740, 1720, and 1600 cm^{-1}; ^1H NMR ($CDCl_3$) δ=1.41, 1.56 (3H, d, ratio 3:7), 2.03, 2.06 (3H, s, ratio 3:7), 3.56 (1H, m), 4.98 (1H, m), 6.36 (1H, m), 6.92—7.66 (4H, m). Found: C, 64.55; H, 6.36; N, 10.73%. Calcd for $C_{14}H_{16}N_2O_3$: C, 64.60; H, 6.20; N, 10.76%.

b) In a similar manner, the tricyclic carboxylate **21a** (288 mg) was subjected to alkaline hydrolysis and gave **14a** (239 mg, 92%).

c) The 2-acetamidobutyrate **13a** (2.15 g) similarly gave **14a** (1.71 g, 97%).

2-Acetamido-3-(2-indolyl)propionic Acid (14a). *a)* In a manner similar to that described in the preceding section, the 2-acetamidomalonate **20b** (3.46 g), on being refluxed in alkaline solution for 15 h, gave **14b** (2.41 g, 98%) as pale yellow needles: Mp 187—188 °C (lit,[14] 190—191 °C); IR (KBr) 3390, 3340, 1695, 1605, and 1535 cm^{-1}; ^1H NMR ($CDCl_3$) δ=1.92 (3H, s), 3.27 (2H, d), 4.80 (1H, m), 6.03 (1H, s), 6.77—7.57 (4H, m). Found: C, 63.57; H, 5.82; N, 11.46%. Calcd for $C_{13}H_{14}N_2O_3$: C, 63.40; H, 5.73; N, 11.38%.

b) The 2-acetamidopropionate **13b** (2.74 g) similarly gave **14b** (2.34 g, 95%).

Ethyl 1,4-Dimethyl-5H-3,4-dihydropyrido[4,3-b]indole-3-carboxylate (15a). To an ice-cooled, stirred suspension of **14a** (1.57 g) in EtOH (30 cm^3) was added dropwise thionyl chloride (1.5 cm^3). The mixture was refluxed for 30 min and evaporated *in vacuo*, giving a dark-red residue. This was dissolved in water (30 cm^3), washed with ethyl acetate and neutralized with 1 mol dm^{-3} NaOH to give the desired product (1.40 g, 86%) as an amorphous powder: IR (KBr) 1740, 1600, 1500, and 1470 cm^{-1}; ^1H NMR (CD_3OD) δ=0.77, (3H, t, ratio 3:7), 2.53, 2.58 (3H, s, ratio 3:7), 2.85, 2.92 (3H, s, ratio 3:7), 3.20, 3.55 (1H, d, ratio 3:7), 3.87, 3.93 (2H, q, ratio 3:7), 6.80—7.53 (4H, m). Found: C, 69.70; H, 6.65; N, 10.32%. Calcd for $C_{16}H_{18}N_2O_2 \cdot 1/4H_2O$: C, 69.92; H, 6.60; N, 10.19%.

Ethyl 1-Methyl-5H-3,4-dihydropyrido[4,3-b]indo-3-carboxylate (15b). In a manner similar to that described the 3-indolylpropionic acid **14b** (49.2 g) was treated with thionyl chloride and afforded **15b** (44.5 g, 87%) as pale yellow needles: Mp 181—183 °C (from EtOH); IR (KBr) 1735, 1605, 1545, and 1465 cm^{-1}; ^1H NMR (DMSO-d_6) δ=1.22 (3H, t), 2.43 (3H, s), 3.00 (2H, m), 4.15 (2H, q), 4.43 (1H, m), 7.00—7.47 (4H, m).

Ethyl 1,4-Dimethyl-5H-pyrido[4,3-b]indole-3-carboxylate (16a). A stirred suspension of **15a** (1.2 g) and sulfur (150 mg) in dry xylene (25 cm^3) was refluxed for 5 h. The reaction mixture was evaporated *in vacuo* to yield a yellow residue. Recrystallization from EtOH gave **16a** (1.11 g, 93%) as pale yellow needles: Mp 257—258 °C; IR (KBr) 1700, 1620, and 1200 cm^{-1}; ^1H NMR (DMSO-d_6) δ=1.30 (3H, t), 2.53 (3H, s), 2.80 (3H, s), 4.26 (2H, q), 7.00—7.66 (3H, m), 8.10 (1H, m). Found: C, 71.60; H, 5.92; N, 10.30%. Calcd for $C_{16}H_{16}N_2O_2$: C, 71.62; H, 6.01; N, 10.44%.

Ethyl 1-Methyl-5H-pyridoz[4,3-b]indole-3-carboxylate (16b).

a) By Dehydrogenation of 15b with Lead Tetraacetate: Lead tetraacetate (117 g) was added in small portions to an ice-cooled, stirred solution of **15b** (51.2 g) in dry pyridine (600 cm^3). The suspension was allowed to react at room temperature for 20 min and then poured into a mixture of ethyl acetate (2000 cm^3) and water (1000 cm^3) with stirring. The organic layer was separated and the aqueous layer was extracted with ethyl acetate. The combined extract was washed successively with saturated aqueous NaCl and saturated aqueous $NaHCO_3$, dried over $MgSO_4$ and evaporated to dryness *in vacuo*. Recrystallization of the resulting reddish solid from EtOH gave pale yellow needles (39.9 g, 78%): Mp 252—254 °C; IR (KBr) 1725, 1620, 1595, 1560, and 1345 cm^{-1}; ^1H NMR ($CDCl_3$) δ=1.45 (3H, t), 3.10 (3H, s), 4.47 (2H, q), 7.10—7.67 (4H, m), 8.13 (1H, s). Found: C, 70.65; H, 5.36; N, 10.84%. Calcd for $C_{15}H_{14}N_2O_5$: C, 70.85; H, 5.55; N, 11.02%.

b) By Dehydrogenation of 15b with Sulfur: In a manner similar to that described in the preceding section, the dihydro-γ-carbolinecarboxylate **15b** (25.6 g) was dehydrogenated with sulfur (3.3 g) to give the desired γ-carbolinecarboxylate **16b** (25.1 g, 98%) as pale yellow needles. All spectral and analytical data were identical with those of the sample described above.

1,4-Dimethyl-5H-pyrido[4,3-b]indole-3-carboxylic Acid (17a). A suspension of **16a** (268 mg) in EtOH-1 mol dm^{-3} NaOH (1:1, 5.0 cm^3) was refluxed for 5 h and then concentrated *in vacuo* to half of its original volume. The concentrate, after being neutralized with 1 mol dm^{-3} HCl (2.5 cm^3), gave a pale-yellow precipitate, which was collected by filtration, washed successively with water, ethanol and diethyl ether, and dried. Recrystallization from a large amount of boiling water gave **17a** (212 mg, 88%) as pale yellow prisms: Mp 283.5—284.5 °C; IR (KBr) 1640, 1620, and 1590 cm^{-1}; ^1H NMR (CD_3OD/NaOH) δ=2.67 (3H, s), 2.95 (3H, s), 7.13—7.73 (3H, m), 8.07 (1H, d). Found: C, 69.72; H, 4.87; N, 11.43%. Calcd for $C_{14}H_{12}N_2O_2$: C, 69.99; H, 5.03; N, 11.66%.

1-Methyl-5H-pyrido[4,3-b]indole-3-carboxylic Acid (17b). In a manner similar to that described in the preceding section, the γ-carboline-3-carboxylic acid ester **16b** (63.5 g) gave the desired 3-carboxylic acid **17b** (54.5 g, 96%) as pale yellow prisms: Mp 275—277 °C; IR (KBr) 1650, 1620, 1590, 1400, and 1220 cm^{-1}; ^1H NMR (CF_3COOH) δ=3.43 (3H, s), 7.73—7.93 (3H, m), 8.30 (1H, m), 8.62 (1H, s). Found: C, 63.68; H, 4.72; N, 11.46%. Calcd for $C_{13}H_{10}N_2O_2 \cdot H_2O$: C, 63.91; H, 4.90; N, 11.46%.

3-Acetylindole-2-acetonitrile (19). Indole-2-acetonitrile[16] (**18**; 1.56 g), prepared from indole-2-carboxylic acid (**7**; Fluka Chem. Corp., Swiss), was dissolved in a mixture of phosphoryl chloride (1.16 cm^3) and *N,N*-dimethylacetamide (3.0 cm^3), and this solution was heated at 85 °C for 2 h. The reaction mixture was poured onto crushed ice (20 g) and washed with ethyl acetate. Unreacted indole-2-acetonitrile (**18**; 840 mg) was recovered from the ethyl acetate layer. The aqueous layer was neutralized with 5 mol dm^{-3} NaOH and extracted with ethyl acetate–tetrahydrofuran (1:1). The extract was washed with saturated aqueous $NaHCO_3$ and dried over $MgSO_4$. After evaporation *in vacuo*, the residue was chromatographed on a column of silica gel using EtOH–$CHCl_3$ (3:7) as an eluent. Work-up, as usual, gave **19** (479 mg, 24%) as fine yellow needles: Mp 223—225 °C; IR (KBr) 3250, 2245, 1620, 1605, 1525, 1490, 1450, and 1180 cm^{-1}; ^1H NMR (DMSO-d_6) δ=2.63 (3H, s), 4.47 (2H, s), 7.07—7.67 (4H, m), 7.83—8.13 (1H, m). Found: C, 72.58; H, 4.98; N, 13.97%. Calcd for $C_{12}H_{10}N_2O$: C, 72.71; H, 5.08; N, 14.13%.

3-Amino-1,4-dimethyl-5H-pyrido[4,3-b]indole (Trp-P-1; 1). *a) Thermal Decomposition of 4-(1-Benzotriazolyl)-3,6-*

dimethyl-2-pyridinamine (6): A mixture of **6** (2.0 g) and polyphosphoric acid (16 g) was allowed to decompose by rapid heating over a free flame until evolution of nitrogen gas ceased. After the reaction mixture had cooled to room temperature, ice-water was added and the mixture was made strongly basic with 6 mol dm^{-3} NaOH and extracted with ethyl acetate. The extract was washed with saturated aqueous NaCl, dried over $MgSO_4$ and evaporated to dryness *in vacuo*. The residue was chromatographed on silica gel using 30% MeOH in ethyl acetate as an eluent. The fractions containing **1** were combined on the basis of TLC analysis and evaporated *in vacuo*, yielding a reddish yellow solid, which upon recrystallization from ethyl acetate (20 cm^3) containing a small amount of acetic acid (0.3 cm^3), gave the desired product, the acetic acid salt of **1** (1.04 g, 46%) as colorless prisms: Mp 248—256 °C; IR (KBr) 3350, 3050, 1650, 1550, and 1400 cm^{-1}; UV (0.1 mol dm^{-3} HCl/MeOH) 227 (ε 16000), 242 (sh, 24000), 265 (67000), 267 (sh, 66000), 307 (7900),and 318 (9800); MS *m/z* 211 (M^+); ^1H NMR (pyridine-d_5) δ=2.08 (3H, s), 2.36 (3H, s), 2.96 (3H, s), 7.20—7.42 (3H, m) 8.03 (1H, m). Found: C, 66.27; H, 6.42; N, 15.20%. Calcd for $C_{13}H_{13}N_3 \cdot CH_3COOH$: C, 66.40; H, 6.32; N, 15.49%.

b) By Curtius Rearrangement of 1,4-Dimethyl-5H-pyrido[4,3-b]indole-3-carboxylic Acid (17a): A mixture of **17a** (110 mg) and triethylamine (0.15 g) in DMA (5.0 cm^3) was kept at 60 °C for 1 h with stirring and cooled to 20 °C. DPPA (0.16 g) was added and the resulting mixture was allowed to react at room temperature for 2 h, during which time the suspension became almost clear. Aqueous acetic acid (50%, 2.0 cm^3) was added dropwise and the mixed solution was heated at 90 °C for 1 h, and then poured into ice-cooled aqueous NaOH (0.75 g in 20 cm^3). The combined mixture was extracted with ethyl acetate, and the extract, after being washed with saturated aqueous NaCl and dried over $MgSO_4$, was concentrated *in vacuo* to one-fifth of its original volume. The residual ethyl acetate solution, upon the treatment with acetic acid (0.3 cm^3), afforded the desired compound (51 mg, 41%) as colorless prisms. All spectral and analytical data were identical with those of the sample obtained by the method described above. The starting material (28 mg) was recovered from the aqueous layer of the ethyl acetate extraction when the pH of the solution was adjusted to 4.5 with concd HCl.

3-Amino-1-methyl-5H-pyrido[4,3-b]indole (Trp-P-2; 2).

a) By Curtius Rearrangement of 1-Methyl-5H-pyrido[4,3-b]-indole-3-carboxylic Acid (17b): Treatment of γ-carboline-3-carboxylic acid **17b** (1.13 g) by a procedure similar to that of section **1***b)* gave the desired product (594 mg, 46%) as colorless prisms: Mp 242—247 °C; IR (KBr) 1670, 1655, 1615, 1460, and 1400 cm^{-1}; UV (0.1 mol dm^{-3} HCl/MeOH) 224 (ε 13000), 243 (sh, 24000), 265 (64000), 269 (70000), 306 (5700), and 318 nm (6400); MS *m/z* 197 (M^+); ^1H NMR (DMSO-d_6) δ= 1.93 (3H, s), 2.74 (3H, s), 6.37 (1H, s), 7.07—7.53 (3H, m), 7.97 (1H, d). Found: C, 65.13; H, 5.71; N, 16.25%. Calcd for $C_{12}H_{11}N_3 \cdot CH_3COOH$: C, 65.36; H, 5.88; N, 16.33%.

b) By Cyclization Reaction of 3-Acetylindole-2-acetonitrile (19) with Ammonia: A solution of **19** (39.6 mg) in 20% methanolic ammonia was heated in a sealed tube at 100 °C for 5 h and evaporated *in vacuo*. The drak brown residue was purified through both silica-gel and alumina (Woelm B, Akt. I) columns, using MeOH in ethyl acetate as an eluent, to give **2** (23 mg, 58%). This product was dissolved in ethyl acetate. Then, a small amount of acetic acid was added and the acetic acid salt of **2** was obtained as colorless prisms. The physicochemical data were identical with those of the sample obtained by the method described above.

We are grateful to Dr. Katsura Morita, General Manager of this Division, and to Drs. Masahiko Fujino and Masao Nishikawa for their encouragement throughout this work. We also thank Dr. Morimasa Arakawa (Nard Institute, Ltd., Osaka) for his kind cooperation.

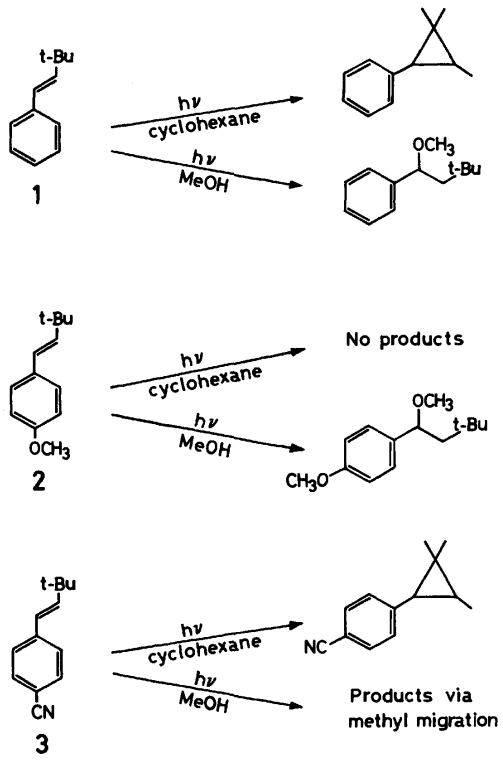
A Sudden-polarization Model to Predict Excited State Reactivity of β-*t*-Butylstyrene

Osamu KIKUCHI* and Hideki YOSHIDA
Department of Chemistry, The University of Tsukuba, Sakura-mura, Ibaraki 305
(Received June 2, 1984)

A model in which two zwitterions play a significant role was employed to account for solvent and substituent effects on photochemical reactions of β-*t*-butylstyrene. These zwitterions are formed by 90° rotation about the external C=C double bond. Semi-empirical MINDO/3 calculations showed that these zwitterions can be two channels which give the observed reacation products. The model also elucidated satisfactorily the photochemical reactions of para substituted β-*t*-butylstyrenes.

The photochemistry of β-*t*-butylstyrene has been established by Hixson.[1-6] Irradiation of β-*t*-butylstyrene in methanol solvent gave a methanol addition product, while irradiation in cyclohexane solvent gave a cyclopropane derivative which is considered to be derived by the 1,2-shift of a methyl group to the β carbon atom.[1] These reactions are singlet state processes.[1-3] The formation of the methanol addition product suggests that the excited singlet state of β-*t*-butylstyrene has a polar character. The formation of the cyclopropane derivative also suggests a polar character of the excited singlet state, since the carbon-to-carbon 1,2-shift of a methyl group occurs easily to the cationic center.[7]



Scheme 1.

From the pairing theorem of the Hückel MO framework, the electron population of the HOMO→LUMO excited state of an even-alternant hydrocarbon is identical with that of the ground state, and the polarization of the excited singlet state of the hydrocarbon should not be large, even if a more sophisticated MO theory is applied to it. Thus the photochemical reaction of β-*t*-butylstyrene, which indicates the ionic character of the excited states, is very interesting from a mechanistic point of view.

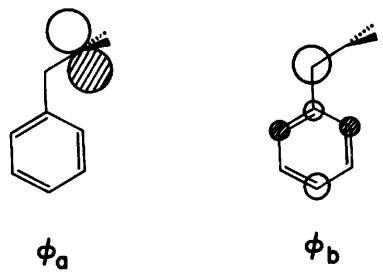
The zwitterions, which have negative and positive charges separately, are formed by a rotation about the C-C double bond of an olefin.[8] This is "sudden-polarization" appeared in the 90°-twisted olefin. The sudden-polarization model is capable of elucidating the ionic character observed in the excited states of non-polar species. Some photochemical reactions have been well elucidated on the basis of this model.[9,10] In this paper we use the sudden-polarization model to explain the excited state reactivities of β-*t*-butylstyrene and its derivatives.

The closed-shell and open-shell SCF methods as well as two-configuration SCF method were employed for the calculation of the 90°-twisted structure within the semi-empirical MINDO/3 approximation.[11] The MINDO/3 CI method was used for the potential energy curves calculation along the rotation about the double bond of styrene.

Results and Discussion

Twisted Styrene. The $\pi \rightarrow \pi^*$ singlet state of an olefin is stabilized by a double-bond rotation which gives the 90°-twisted structure. The potential energy curves along this rotation of styrene were calculated by means of MINDO/3 CI which involves 50 and 48 configuration functions for the singlet and triplet states, respectively. Three lower singlet states and the lowest triplet state are shown in Fig. 1.

The 90°-twisted styrene has two non-bonding type MO's: one is the in-plane MO localized on the terminal carbon atom, ϕ_a, and the other is a π MO of the benzyl group, ϕ_b. The lowest singlet state of the 90°-twisted styrene is the ^{1}D diradical state in which each non-



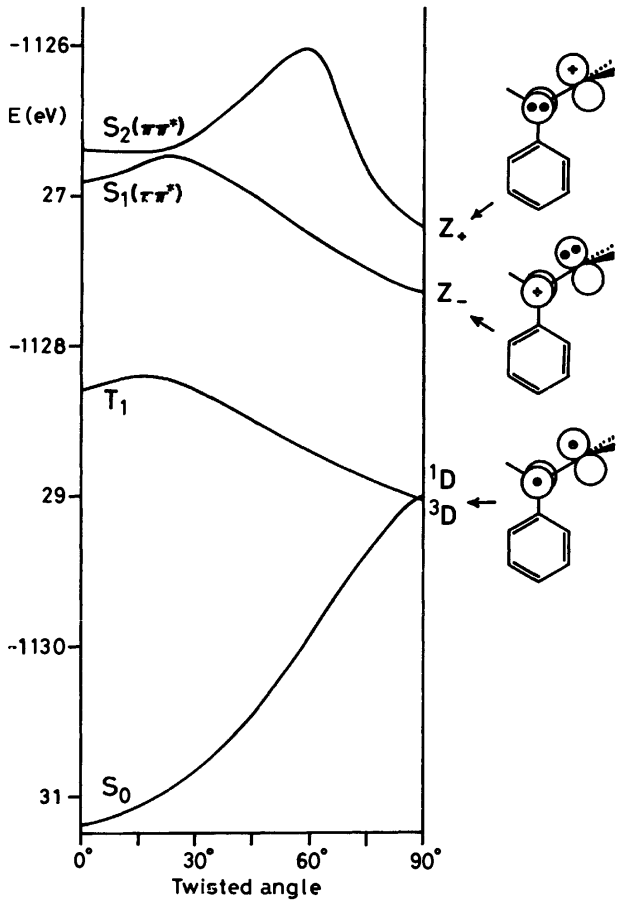


Fig. 1. Potential energy curves of styrene along the rotation about the double bond.
The structures employed were obtained by twisting the optimized ground state geometry. Three lower singlet and lowest triplet states are shown.

bonding MO is occupied by an unpaired electron. The lower excited singlet states involve the Z_- and Z_+ zwitterionic states, in which a pair of electrons occupy the ϕ_a orbital (Z_-) or ϕ_b orbital (Z_+). The electron occupations of these states are shown in Fig. 1.

As may be seen from Fig. 1, the Z_- state is lower in energy than the Z_+ state if the ground-state-twisted structure is considered. However, Bruckmann and Salem[12] pointed out that if the optimized structures corresponding to the Z_- and Z_+ zwitterions are sufficiently different from each other, both of the Z_- and Z_+ zwitterions should lie on the same lowest excited singlet energy surface at their optimized structures. This concept may rationalize the reaction processes of Scheme 1; the methanol addition product is derived from the Z_- zwitterion, while the cyclic isomerization product is from the Z_+ zwitterion *via* the 1,2-shift of a methyl group.

The electronic structure of the 90°-twisted styrene can be expressed in terms of three configurations:[13]

$$|a^2> = |\cdots\phi_a\bar{\phi}_a|$$
$$|b^2> = |\cdots\phi_b\bar{\phi}_b|$$
$$|ab> = \frac{1}{\sqrt{2}}\{|\cdots\phi_a\bar{\phi}_b| + |\cdots\phi_b\bar{\phi}_a|\}$$

The nearly degenerate orbitals of the 90°-twisted styrene, ϕ_a and ϕ_b, belong to different irreducible representations of the molecular symmetry group. The diradical ^1D state is thus expressed by the open-shell wavefunction, $|ab>$, while the zwitterionic states are expressed by two-configuration wavefunctions:

$$\Psi(Z_-) = \lambda|a^2> - \sqrt{1-\lambda^2}|b^2>$$
$$\Psi(Z_+) = \sqrt{1-\lambda^2}|a^2> + \lambda|b^2> \quad (\lambda \geqq 1/\sqrt{2})$$

For the 90°-twisted styrene, the mixing of $|a^2>$and $|b^2>$ is expected to be very small, since ϕ_a and ϕ_b have different symmetries and the value of $<a^2|H|b^2>$ is small.[14] Thus the zwitterionic states of the 90°-twisted styrene were calculated by the closed-shell SCF method, while the diradical state was calculated by the open-shell SCF method. The optimized structures of these states are shown in Fig. 2. The unpaired electron density of the ^1D state and the charge distributions of the Z_- and Z_+ states are shown in Fig. 3.

In order to understand the potential energy surface of the lowest excited singlet state of the 90°-twisted styrene, the energies of the diradical and zwitterionic states were calculated for three structures, II, III, and the ground-state twisted structure. The qualitative shapes of energy surfaces along the structural change among these three structures were obtained by simple interpolation (Fig. 4). The lowest excited singlet state has two energy minima corresponding to different polarizations, Z_- at the structure II and Z_+ at the structure III. The energy difference between these two minima was calculated to be small (22 kJ mol^{-1}).

Twisted β-t-Butylstyrene. Calculations on the 90°-twisted styrene showed two ionic channels on the energy surface of the lowest excited singlet state. This indicates two distinct photochemical pathways of styrene in which two zwitterions act as intermediates.[12]

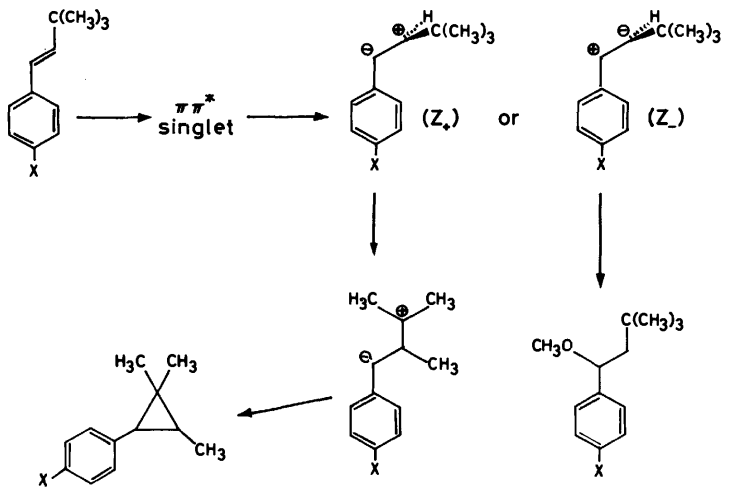

Scheme 2.

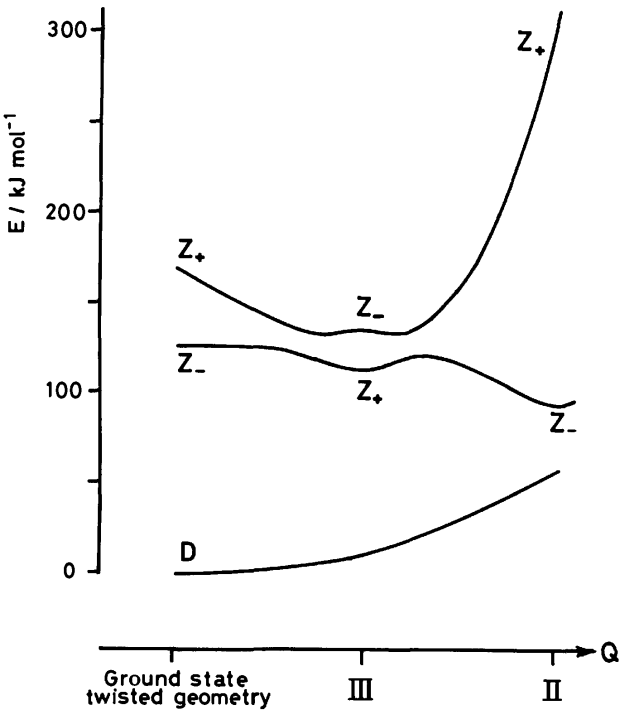

Fig. 4. Qualitative potential energy curves for the lowest singlet states of 90°-twisted styrene.
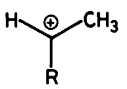
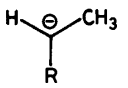
The coordinate Q indicates the structure of 90°-twisted styrene and is obtained by linear interpolation from the ground-state twisted structure to III, and from III to II; the structures II and III are shown in Fig. 2 and the ground-state twisted structure is obtained by 90° twisting of the ground state structure. The energies of the ^{1}D, Z$_-$, and Z$_+$ states were calculated for only these three structures and the energy curves were estimated by simple interpolation.

The photochemical reaction of β-*t*-butylstyrene can well be explained according to this concept (Scheme 2). The Z$_+$ zwitterion undergoes 1,2-methyl migration to the positive β carbon atom. This migration occurs very fast and is followed by cyclization to give the cyclopropane derivatives. In the Z$_-$ zwitterion, the methyl migration to the β carbon atom which has negative charge does not occur. The methanol addition product at the α carbon atom is obtained from the Z$_-$ zwitterionic state.

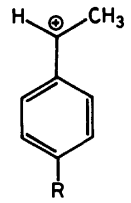
For the twisted styrene, the Z$_-$ state is more stable than the Z$_+$ one. In the case of β-*t*-butylstyrene, the Z$_+$ state may be stabilized by a *t*-butyl group. In order to estimate the relative stabilities of the Z$_-$ and Z$_+$ states of the 90°-twisted β-*t*-butylstyrene and its derivatives, the energies of ions **4**—**7** were calculated



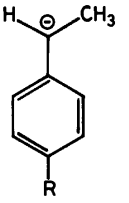
4a, R=H
b, R=C(CH$_3$)$_3$



5a, R=H
b, R=C(CH$_3$)$_3$



6a, R=H
b, R=CN
c, R=OCH$_3$



7a, R=H
b, R=CN
c, R=OCH$_3$

for their optimized geometries (Table 1). The change in the relative energy of the Z$_-$ and Z$_+$ states caused by the substitution of a *t*-butyl group at the β position was calculated by:

$$\{E(\mathbf{4a})-E(\mathbf{4b})\}-\{E(\mathbf{5a})-E(\mathbf{5b})\} = 37\ \text{kJ mol}^{-1}$$

This indicates that a *t*-butyl group at the β position stabilizes the Z$_+$ state by 37 kJ mol^{-1} in comparison with the Z$_-$ state. Since the Z$_+$ state of the unsubstituted styrene is 22 kJ mol^{-1} less stable than the Z$_-$ state, the Z$_+$ state of the 90°-twisted β-*t*-butylstyrene is expected to be 15 kJ mol^{-1} more stable than the Z$_-$ state. This energy difference is small and both of the Z$_+$ and Z$_-$ states of 90°-twisted β-*t*-butylstyrene can be the channels from which the methanol addition product and the cyclopropane derivative are formed. This agrees well with the dual pathways observed in the photochemical reaction of β-*t*-butylstyrene.[1)]

The energy differences between the Z$_+$ and Z$_-$ states of the *p*-OCH$_3$ and *p*-CN derivatives were estimated similarly. The results are shown in Table 2. The electron-withdrawing group (CN) at the para position stabilizes the Z$_+$ state, and the energy difference between the Z$_+$ and Z$_-$ states of 90°-twisted *p*-cyano-β-*t*-butylstyrene, 54 kJ mol^{-1}, is larger than that of β-*t*-butylstyrene. This indicates that in the photochemical reaction of *p*-cyano-β-*t*-butylstyrene, the Z$_+$ state may be the only channel from which the reaction product is

Table 1. MINDO/3 Energies of ions **4**—**7**

Ion	Energy/eV[a)]
4a	−318.272
4b	−944.548

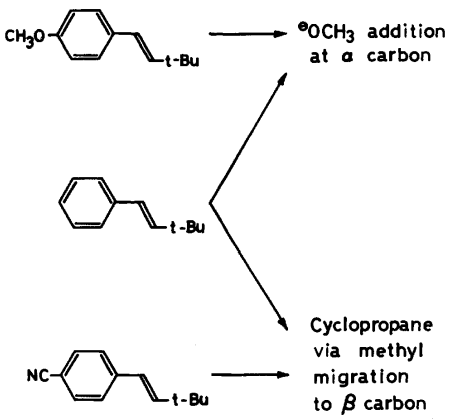
5b	−951.952
6a	−1138.774
6b	−1442.322
6c	−1607.232
7a	−1146.283
7b	−1450.229
7c	−1614.233

a) All the geometries except the benzene ring were optimized.

Table 2. Relative energies (kJ mol^{-1}) of two zwitterions of twisted β-t-butylstyrenes

β-t-Butylstyrene	Z_-	Z_+
1	0	−15
2	0	+34
3	0	−54

formed. The Z_+ state will give the cyclopropane derivative, which agrees well with experiment.[1] In the case of *p*-methoxy-β-*t*-butylstyrene, the Z_- state was calculated to be 34 kJ/mol more stable than the Z_+ state, indicating that the photochemical reaction *via* the excited singlet state of *p*-methoxy-β-*t*-butylstyrene gives the methanol addition product from the Z_- zwitterion. This also agrees well with experiment.[1]



The photochemical reactions of β-*t*-butylstyrene and its derivatives were satisfactorily elucidated on the basis of the sudden-polarization model which involves the 90°-twisted structure. Existence of the twisted structure of β-*t*-butylstyrene was supported indirectly by experiment.[2] The trans and cis forms of *p*-cyano-β-*t*-butylstyrene gave the same primary reaction product, indicating a common intermediate of the 90°-twisted structure.[2] Another fact which may support the twisted structure of styrene is the formation of carbene intermediates[2,7] in the photochemical reactions of styrene derivatives, since carbenes would be expected to be derived easily from the 90°-twisted structure of olefins.[15] It has been shown here that the present modeling is useful to understand the photochemical reactions which appear to involve polar species.

The present results indicate that the excited-state reactivity of olefins can well be described by the MINDO/3 approximation if the correct configuration functions are employed. The energy diagram along the 1,2-hydrogen shift of the 90°-twisted ethylene has been obtained by *ab initio* 4-31G calculation.[15] For this reaction, the similar diagram was obtained when the MINDO/3 CI calculation was carried out. Also, the small CI calculation with the MINDO/3 approximation reproduced well the observed excitation energies of *s-trans*-butadiene and *s-trans*-acrylaldehyde.[16] Thus we feel the MINDO/3 method can be employed for the qualitative analysis of the excited state reactivity, although its parameters were determined so as to reproduce the ground state properties of organic molecules.

(Received June 19, 1984)

2′,4′,5,7-Tetrahydroxyisoflavone was partially benzoylated with benzoyl chloride to give 7-benzoyloxy-2′,4′,5-trihydroxyisoflavone. The condensation of the 7-(benzoyloxy)isoflavone with 2-methyl-3-buten-2-ol, followed by the hydrolysis of the resultant 3′-(3-methyl-2-butenyl)isoflavone gave licoisoflavone A. Its 5′-(3-methyl-2-butenyl) isomer was also synthesized from 5-benzoyloxy-2′,4′,7-trihydroxyisoflavone in a similar manner.

Licoisoflavone A was isolated from the roots of *Glycyrrhiza* spp. (Leguminosae) along with other flavonoids.[2)] The structure has been shown to be 2′,4′,5,7-tetrahydroxy-3′-(3-methyl-2-butenyl)isoflavone (**1**) on the basis of chemical and spectroscopic studies. In the continuation of our studies on the synthesis of isoflavones having 3-methyl-2-butenyl groups on the B ring,[3)] the present paper reports in detail the unambiguous synthesis of **1** to confirm the proposed structure of the natural isoflavone and its isomer [2′,4′,5,7-tetrahydroxy-5′-(3-methyl-2-butenyl)isoflavone] (**2**).

The condensation of 2,4-bis(benzyloxy)-6-hydroxyacetophenone (**3**) with 2,4-bis(benzyloxy)benzaldehyde gave 2,4,4′,6′-tetrakis(benzyloxy)-2′-hydroxychalcone (**4**) as a major product and 2′,4′,5,7-tetrakis(benzyloxy)-flavanone (**5**) as a minor product. A mixture of **4** and **5** was easily converted into the acetate (**6**) of **4**. The oxidative rearrangement of **6** with thallium(III) nitrate trihydrate[4)] in methanol, followed by the cyclization of the resultant compound with dilute hydrochloric acid gave the tetrakis(benzyloxy)isoflavone (**7**). The partial debenzylation of **7** with concd hydrochloric acid in acetic acid at 80 °C for 10 min gave the 5-hydroxyisoflavone (**8**). In the UV spectrum of **8**, the absorption maximum showed a bathochromic shift in the presence of aluminum chloride, and the ^{1}H NMR spectrum of **8** also showed three benzyl methylene proton signals and the 5-hydroxyl proton signal. The 5-(benzoyloxy)isoflavone (**9**), which was obtained by the benzoylation of **8** with benzoyl chloride in pyridine, was converted into 5-benzoyloxy-2′,4′,7-trihydroxyisoflavone (**10**) by the hydrogenolysis over 10% palladium on charcoal in methanol–ethyl acetate. The condensation of **10** with 2-methyl-3-buten-2-ol in the presence of boron trifluoride etherate in anhydrous dioxane gave a 3-methyl-2-butenyl compound (**11**) and a bis(3-methyl-2-butenyl) compound (**12**).

† Present address: Honny chemicals CO., Ltd., 3-1-33, Hiyoshi-cho, Nagata-ku, Kobe 653.

The ^{1}H NMR spectrum of **11** showed the presence of two methyl groups as a singlet at δ 1.61, one methylene group as a doublet (J=7 Hz) centering at δ 3.06, one methine proton as a triplet (J=7 Hz) centering at δ 5.18, and two aromatic protons as each singlet at δ 6.33 (3′-H) and 6.66 (6′-H), respectively. The ^{1}H NMR spectrum of **12** showed the presence of two 3-methyl-2-butenyl groups and one aromatic proton as a singlet at δ 6.57 (6′-H). Compound **12** was hydrolyzed with dilute alkali in a nitrogen atmosphere to give 2′,4′,5,7-tetrahydroxy-3′,

Structure 1.

5′-bis(3-methyl-2-butenyl)isoflavone (**13**), which was converted into the tetraacetate (**14**). Compound **11** was hydrolyzed with dilute alkali in a nitrogen atmosphere to yield 2′,4′,5,7-tetrahydroxy-5′-(3-methyl-2-butenyl)isoflavone (**2**) (mp 232—234 °C). Compound **2** was converted into the tetraacetate (**15**) (mp 127—128 °C) and furthermore cyclized with concd hydrochloric acid in methanol to give the 3-(2,2-dimethyl-6-chromanyl)-4*H*-chromen-4-one (**16**) (mp 261—262 °C). The structure of **16** was further confirmed by the alternative unambiguous synthesis as described below.

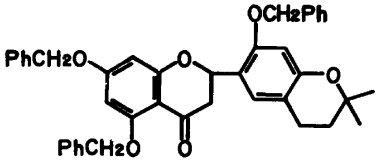
20 $R_1=R_2=R_4=PhCH_2$, $R_3=CH_3CO$



19

Structure 2.

The condensation of **3** and 7-benzyloxy-6-formyl-2,2-dimethylchroman (**17**) gave the 3-(2,2-dimethyl-6-chromanyl)-1-phenyl-2-propen-1-one (**18**) as a major product and the 2-(2,2-dimethyl-6-chromanyl)-4-chromanone (**19**) as a minor product. A mixture of **18** and **19** was converted into the acetate (**20**) of **18**. The oxidative rearrangement of **20** with thallium(III) nitrate trihydrate, followed by the cyclization of the resultant compound gave two 3-(2,2-dimethyl-6-chromanyl)-4*H*-chromen-4-ones (**21**) and (**22**). A mixture of **21** and **22** was hydrogenolyzed over 10% palladium on charcoal to give compound **16**.

From these results, the isoflavone **2** has been found to be a structural isomer of licoisoflavone A (**1**).

The hydrogenolysis of **7** over 10% palladium on charcoal, followed by the partial benzoylation of the resultant tetrahydroxyisoflavone (**23**) with benzoyl chloride in pyridine gave the 7-(benzoyloxy)isoflavone (**24**). In the UV spectrum of **24**, the absorption maximum did not show a bathochromic shift in the presence of sodium acetate. The condensation of **24** with 2-methyl-3-buten-2-ol gave two 3-methyl-2-butenyl compounds (**25**) and (**26**), and one 3′,5′-bis(3-methyl-2-butenyl)isoflavone (**27**). The ^1H NMR spectrum of **26** showed the presence of one 3-methyl-2-butenyl group and two aromatic protons as each singlet at δ 6.46 (3′-H) and 6.84 (6′-H), respectively. Both compounds **26** and **27** were also hydrolyzed to give **2** and **13**, respectively. The ^1H NMR spectrum of **25** showed the presence of one 3-methyl-2-butenyl group and two aromatic protons as each doublet (J=8 Hz) centering at δ 6.42 (5′-H) and 6.81 (6′-H), respectively. Therefore, compound **25** was shown to be 7-benzoyloxy-2′,4′,5-trihydroxy-3′-(3-methyl-2-butenyl)isoflavone, which was hydrolyzed with dilute alkali to give the desired isoflavone (licoisoflavone A) (**1**). Compound **1** was subsequently converted into the tetraacetate (**28**). In Tables 1 and 2, the UV and ^1H NMR spectral data for the synthetic isoflavone **1** and its tetraacetate **28** are shown to be identical with those for natural licoisoflavone A and its tetraacetate, respectively.[2]

On the basis of these results, the structure of licoisoflavone A was confirmed to be 2′,4′,5,7-tetrahydroxy-3′-(3-methyl-2-butenyl)isoflavone (**1**).

Experimental

All the melting points are uncorrected. The IR spectra were taken on a Hitachi 215 spectrophotometer, and the UV spectra on a Hitachi 124 spectrophotometer. The ^{1}H NMR spectra were measured with a Hitachi R-20 spectrometer (60 MHz), using tetramethylsilane as an internal standard (δ, ppm). Column chromatography and thin-layer chromatography were carried out on Kieselgel 60 (70—230 mesh) and with Kieselgel 60 F-254 (Merck).

2,4-Bis(benzyloxy)-6-hydroxyacetophenone (3). Potassium carbonate (41.4 g) was added to a solution of 2,4,6-trihydroxyacetophenone (16.8 g) and benzyl chloride (25 g) in *N,N*-dimethylformamide (DMF) (100 ml) in a nitrogen atmosphere at 150—153 °C with stirring, and the mixture was vigorously stirred at 150—153 °C for 40 min. Potassium carbonate was filtered off, and the solvent was removed under reduced pressure. The residue was crystallized from a small amount of methanol to give a mixture of two compounds, which showed R_f values of 0.39 and 0.49 on a silica-gel TLC plate [petroleum ether–1,2-dichloroethane (2:1)], respectively. The mixture was recrystallized from 1,2-dichloroethane to give the desired acetophenone **3** as colorless needles (9.1 g, 26%); mp 96—98 °C; R_f=0.39. Found: C, 75.59; H, 5.67%. Calcd for $C_{22}H_{20}O_4$: C, 75.86; H, 5.75%.

3-Benzyl-4,6-bis(benzyloxy)-2-hydroxyacetophenone was also obtained from the mother liquor by repeating recrystallization from ethyl acetate to give colorless needles (31.6 g, 31%); mp 111—112 °C; R_f=0.49. Found: C, 79.50; H, 5.88%. Calcd for $C_{29}H_{26}O_4$: C, 79.45; H, 5.94%.

2,4,4',6'-Tetrakis(benzyloxy)-2'-hydroxychalcone (4) and 2',4',5,7-Tetrakis(benzyloxy)flavanone (5). A mixture of **3** (10 g) and 2,4-bis(benzyloxy)benzaldehyde (10.2 g) was refluxed in the presence of piperidine (34 ml) in ethanol (200 ml) for 6 h to give yellow precipitates, which were collected by filtration. The precipitates were recrystallized from ethyl acetate to give **4** as yellow needles (11.5 g 68%); mp 146—147 °C. ^{1}H NMR ($CDCl_3$) δ=4.95 (2H, s, $C_6H_5C\underline{H}_2$), 5.01 (4H, s, $C_6H_5C\underline{H}_2\times2$), 5.03 (2H, s, $C_6H_5C\underline{H}_2$), 6.09 (1H, d, J=2 Hz, $C_{5'}$–H), 6.19 (2H, d, J=2 Hz, C_3–H and $C_{3'}$–H), 6.40 (1H, q, J=2 and 8 Hz, C_5–H), 6.81 (1H, d, J=8 Hz, C_6–H), 7.20—7.50 (20H, m, $C_6\underline{H}_5CH_2\times4$), 7.77 and 8.23 (each 1H, d, J=16 Hz, CH=), 12.78 (1H, s, OH). Found: C, 79.89; H, 5.63%. Calcd for $C_{43}H_{36}O_6$: C, 79.63; H, 5.56%.

The flavanone **5** was obtained from the mother liquor by repeating recrystallization from ethyl acetate as colorless needles (2.2 g, 11%); mp 159—161 °C. ^{1}H NMR ($CDCl_3$) δ=2.83—3.00 (2H, m, C_3–H), 5.04 (6H, bs, $C_6H_5C\underline{H}_2\times3$), 5.13 (2H, s, $C_6H_5C\underline{H}_2$), 5.68—5.94 (1H, m, C_2–H), 6.22 (2H, s, arom-H×2), 6.50—6.80 (2H, m, arom-H×2), 7.20—7.70 (21H, m, $C_6\underline{H}_5CH_2\times4$ and arom-H). Found: C, 79.90; H, 5.38%. Calcd for $C_{43}H_{36}O_6$: C, 79.63; H, 5.56%.

2'-Acetoxy-2,4,4',6'-tetrakis(benzyloxy)chalcone (6). Compounds **4** and **5** were converted into the acetate **6** by an acetic anhydride–sodium acetate method. Compound **6** was recrystallized from methanol–ethyl acetate to give pale yellow needles; mp 113—114 °C. ^{1}H NMR ($CDCl_3$) δ= 2.17 (3H, s, CH_3CO), 4.91 (2H, s, $C_6H_5C\underline{H}_2$), 5.00 (4H, s, $C_6H_5C\underline{H}_2\times2$), 5.02 (2H, s, $C_6H_5C\underline{H}_2$), 6.47—6.65 (4H, s, arom-H×4), 7.12—7.61 (21H, m, $C_6\underline{H}_5CH_2\times4$ and arom-H), 6.99 and 7.81 (each 1H, d, J=16 Hz, CH=). Found: C, 78.51; H, 5.54%. Calcd for $C_{45}H_{38}O_7$: C, 78.26; H, 5.51%.

2',4',5,7-Tetrakis(benzyloxy)isoflavone (7). After a mixture of **6** (10 g) and thallium(III) nitrate trihydrate (7 g) was stirred in methanol (1.6 l) at 32—35 °C for 8 h, 10% hydrochloric acid (80 ml) was added and the solution then refluxed for 3 h. After cooling, the precipitates (thallium compound) were filtered off and the solvent removed under reduced pressure. The residue was crystallized from a small amount of methanol and recrystallized from methanol to give **7** as colorless needles (7.4 g, 79%); mp 178—179 °C. ^{1}H NMR ($CDCl_3$) δ=5.00, 5.02, 5.04, and 5.17 (each 2H, s, $C_6H_5C\underline{H}_2$), 6.44—6.72 (5H, m, arom-H×5), 7.00—7.50 (20H, m, $C_6\underline{H}_5CH_2\times4$), 7.68 (1H, s, C_2–H). Found: C, 79.80: H, 5.34%. Calcd for $C_{43}H_{34}O_6$: C, 79.88; H, 5.26%.

2',4',7-Tris(benzyloxy)-5-hydroxyisoflavone (8). A mixture of concd hydrochloric acid (2 ml) and acetic acid (10 ml) was added to a solution of **7** (1 g) in acetic acid (6 ml), and the mixture heated with stirring at 80 °C for 10 min. Water was added to the reaction mixture to give pale yellow precipitates, which were recrystallized from methanol–ethyl acetate to give **8** as pale yellow needles (0.73 g, 85%); mp 117—119 °C. UV λ_{max} nm (log ε) (EtOH) 260 (4.57), 282.5 (4.20), 323i(3.65), (EtOH+NaOAc) 260.5 (4.58), 282.5 (4.22), 323i(3.68), (EtOH+$AlCl_3$) 273.5 (4.58), 309i(3.89), 375(3.65); ^{1}H NMR ($CDCl_3$) δ=5.04 (4H, s, $C_6H_5C\underline{H}_2\times2$), 5.09 (2H, s, $C_6H_5C\underline{H}_2$), 6.37—6.67 (5H, m, arom-H×5), 7.15—7.46 (15H, m, $C_6\underline{H}_5CH_2\times3$), 7.78 (1H, s, C_2–H), 12.00 (1H, s, OH). Found: C, 77.59; H, 4.94%. Calcd for $C_{36}H_{28}O_6$: C, 77.68; H, 5.07%.

5-Benzoyloxy-2',4',7-tris(benzyloxy)isoflavone (9). A mixture of **8** (2 g) and benzoyl chloride (1.67 ml) in pyridine (20 ml) was heated with stirring at 120 °C for 2 h. After cooling, the mixture was poured into ice-cold water and acidified with concd hydrochloric acid, extracted with ether, washed with aq sodium carbonate and water, and dried with sodium sulfate. The solvent was removed, and the residue recrystallized from 1,2-dichloroethane to give **9** as colorless needles (2.2 g, 90%); mp 155—157 °C. UV λ_{max} nm (log ε) (EtOH) 235.5 (4.64), 248i (4.53), 281sh (4.22), 301.5i (3.98), (EtOH+$AlCl_3$) 233.5 (4.67), 247.5i (4.53), 280sh (4.23), 301.5i (3.98); ^{1}H NMR (DMSO) δ=4.99, 5.02, and 5.27 (each 2H, s, $C_6H_5C\underline{H}_2$), 6.45—6.80 (3H, m, arom-H×3), 7.03 and 7.17 (each 1H, d, J=2 Hz, arom-H), 7.20—8.10 (20H, m, $C_6\underline{H}_5CH_2$×3 and $C_6\underline{H}_5CO$), 8.14 (1H, s, C_2–H). Found: C, 77.99; H, 4.84%. Calcd for $C_{43}H_{32}O_7$: C, 78.18; H, 4.85%.

5-Benzoylxoy-2',4',7-trihydroxyisoflavone (10). Compound **9** (2 g) was hydrogenolyzed over 10% palladium on charcoal (0.4 g) in a mixture of ethyl acetate (200 ml) and methanol (80 ml) at 30 °C until the uptake of hydrogen ceased. The catalyst was filtered off, and the solvent removed under reduced pressure. The residue was recrystallized from methanol-ethyl acetate to give **10** as colorless needles (1.1 g, 90%); mp 211—213 °C. UV λ_{max} nm (log ε) (EtOH) 237i (4.42), 250 (4.33), 260.5 (4.32), 301i (4.00), (EtOH+NaOAc) 260.5 (4.43), 297.5i (4.03), 327 (3.98), (EtOH+$AlCl_3$) 235 (4.50), 249.5i (4.33), 263 (4.22), 283 (4.14), 303i (3.88); ^{1}H NMR (DMSO) δ=6.05—6.45 (2H, m, arom-H×2), 6.60—7.40 (3H, m, arom-H×3), 7.45—8.20 (5H, m, C_6H_5CO), 8.05 (1H, s, C_2–H), 8.60—9.70 (2H, b, OH×2). Found: C, 67.69; H, 3.81%. Calcd for $C_{22}H_{14}O_7$: C, 67.69; H, 3.60%.

5-Benzoyloxy-2',4',7-trihydroxy-5'-(3-methyl-2-butenyl)isoflavone (11) and 5-Benzoyloxy-2',4',7-trihydroxy-3',5'-bis(3-methyl-2-butenyl)isoflavone (12). A solution of 2-methyl-3-buten-2-ol (0.32 ml) in anhydrous dioxane (10 ml) was gradually added to a solution of **10** (1 g) and boron trifluoride etherate (0.48 ml) in dioxane (42 ml) in a nitrogen atmosphere, and the mixture heated with stirring at 50 °C for 6 h. The reaction mixture was poured into ice-cold water and extracted with ether. The ethereal solution was washed with aq sodium hydrogencarbonate and dried with sodium sulfate. After the removal of the solvent, the residue was chromatographed over a silica-gel column with chloroform-ethyl acetate (3:1) to give two main products (R_f=0.75 and 0.24), respectively. The compound of R_f=0.24 was recrystallized from chloroform to give **11** as pale yellow prisms (261 mg, 22%); mp 180—182 °C. UV λ_{max} nm (log ε) (EtOH) 250.5i (4.33), 263 (4.34), 291sh (4.14), (EtOH+NaOAc) 261.5 (4.46), 301sh (4.07), 328 (4.02), (EtOH+$AlCl_3$) 248.5i (4.35), 266 (4.22), 285 (4.17); ^{1}H NMR (DMSO) δ=1.61 (6H, s, CH_3×2), 3.06 (2H, d, J=7 Hz, CH_2), 5.18 (1H, t, J=7 Hz, CH=), 6.33 (1H, s, $C_{3'}$–H), 6.66 (1H, s, $C_{6'}$–H), 6.74 (1H, d, J=2 Hz, C_6–H), 6.81 (1H, d, J=2 Hz, C_8–H), 7.45—8.15 (5H, m, C_6H_5CO), 8.01 (1H, s, C_2–H), 8.50—9.60 (2H, b, OH×2). Found: C, 70.57; H, 4.78%. Calcd for $C_{27}H_{22}O_7$: C, 70.73; H, 4.84%.

The compound of R_f=0.75 was a viscous pale yellow oil, compound **12** (325 mg, 26%), which did not crystallize. ^{1}H NMR (DMSO) δ=1.66 and 1.69 (each 6H, s, CH_3×2), 3.08—3.42 (4H, m, CH_2×2), 4.92—5.37 (2H, m, CH=×2), 6.57 (1H, s, $C_{6'}$–H), 6.75 (1H, d, J=2 Hz, C_6–H), 6.88 (1H, d, J=2 Hz, C_8–H), 7.50—8.20 (5H, m, C_6H_5CO), 8.10 (1H, s, C_2–H).

2',4',5,7-Tetrahydroxy-3',5'-bis(3-methyl-2-butenyl)isoflavone (13). Compound **12** (325 mg) was hydrolyzed with a 4% aq solution of sodium hydroxide (3 ml) in methanol (50 ml) in a nitrogen atmosphere at 50 °C for 1 h. The reaction mixture was acidified with dilute hydrochloric acid and extracted with ethyl acetate. The ethyl acetate solution was washed with aq sodium hydrogencarbonate, water, and dried with sodium sulfate. After the removal of the solvent, the residue was chromatographed over a silica-gel column with chloroform-acetone (10:1) to give **13** as a viscous pale yellow oil (95 mg, 36%), which did not crystallize. ^{1}H NMR ($CDCl_3$) δ=1.71 and 1.82 (each 6H, s, CH_3×2), 3.27 and 3.49 (each 2H, d, J=7 Hz, CH_2), 5.24 (2H, t, J=7 Hz, CH=×2), 5.60 (1H, bs, OH), 6.20 (1H, d, J=2 Hz, C_6–H), 6.29 (1H, d, J=2 Hz, C_8–H), 6.70 (1H, s, $C_{6'}$–H), 7.86 (1H, s, C_2–H), 12.17 (1H, s, OH).

2',4',5,7-Tetraacetoxy-3',5'-bis(3-methyl-2-butenyl)isoflavone (14). Compound **13** was converted into the tetraacetate **14** by an acetic anhydride-sodium acetate method. Compound **14** was chromatographed over a silica-gel column with chloroform-acetone (50:1) and recrystallized from ethyl acetate as colorless prisms; mp 170—171 °C. UV λ_{max} nm (log ε) (EtOH) 241 (4.46), 299 (3.89), 328 (3.37); ^{1}H NMR ($CDCl_3$) δ=1.68 (12H, s, CH_3×4), 2.09, 2.28, 2.33, and 2.40 (each 3H, s, CH_3CO), 3.18 (4H, d, J=7 Hz, CH_2×2), 4.85—5.42 (2H, m, CH=×2), 6.85 (1H, d, J=2 Hz, C_6–H), 7.00 (1H, s, $C_{6'}$–H), 7.24 (1H, d, J=2 Hz, C_8–H), 7.80 (1H, s, C_2–H). Found: C, 67.09; H, 5.74%. Calcd for $C_{33}H_{34}O_{10}$: C, 67.11; H, 5.80%.

2',4',5,7-Tetrahydroxy-5'-(3-methyl-2-butenyl)isoflavone (2). Compound **11** (83 mg) was hydrolyzed with a 4% aq solution of sodium hydroxide (3 ml) in methanol (40 ml) in a nitrogen atmosphere at 50 °C for 1 h. The reaction mixture was worked up in the same manner in the preparation of **13**. The resultant compound was chromatographed over a silica-gel column with chloroform-ethyl acetate (3:1), and recrystallized from dichloromethane-methanol to give **2** as pale yellow needles (32 mg, 50%); mp 232—234 °C. IR (KBr) 3430, 3200, 2960, 2915, 1650, 1615, 1505, 1440 cm^{-1}; UV λ_{max} nm (log ε) (EtOH) 266 (4.41), 301i (4.15), 341i (3.77), (EtOH+NaOAc) 277.5 (4.48), 301i (4.22), 334.5i (4.05), (EtOH+$AlCl_3$) 273 (4.44), 313i (3.93), 374 (3.43); ^{1}H NMR (DMSO) δ=1.67 (6H, s, CH_3×2), 3.14 (2H, d, J=7 Hz, CH_2), 5.26 (1H, t, J=7 Hz, CH=), 6.23 (1H, d, J=2 Hz, C_6–H), 6.38 (1H, d, J=2 Hz, C_8–H), 6.45 (1H, s, $C_{3'}$–H), 6.83 (1H, s, $C_{6'}$–H), 8.10 (1H, s, C_2–H), 8.70—9.64 (2H, b, OH×2), 12.96 (1H, s, OH); one OH proton was not observed. Found: C, 67.53; H, 5.05%. Calcd for $C_{20}H_{18}O_6$: C, 67.79; H, 5.12%.

2',4',5,7-Tetraacetoxy-5'-(3-methyl-2-butenyl)isoflavone (15). Compound **2** was converted into the tetraacetate **15** by an acetic anhydride-sodium acetate method. Compound **15** was recrystallized from ethyl acetate-petroleum ether to give colorless prisms; mp 127—128 °C. IR (KBr) 3070, 2970, 2940, 1785, 1650, 1630, 1500, 1435 cm^{-1}; UV λ_{max} nm (log ε) (EtOH) 244 (4.47), 300 (3.82); ^{1}H NMR ($CDCl_3$) δ=1.70 and 1.72 (each 3H, s, CH_3), 2.12, 2.28, 2.82, and 2.86 (each 3H, s, CH_3CO), 3.22 (2H, d, J=7 Hz, CH_2), 5.22 (1H, t, J=7 Hz, CH=), 6.84 (1H, d, J=2 Hz, C_6–H), 6.99 (1H, s, $C_{3'}$–H), 7.08 (1H, s, $C_{6'}$–H), 7.22 (1H, d, J=2 Hz, C_8–H), 7.78 (1H, s, C_2–H). Found: C, 64.19; H, 5.00%. Calcd for $C_{28}H_{26}O_{10}$: C, 64.38: H, 4.99%.

5,7-Dihydroxy-3-(7-hydroxy-2,2-dimethyl-6-chromanyl)-4H-chromen-4-one (16). A mixture of **2** (42 mg) and concd hydrochloric acid (1.9 ml) was refluxed in methanol (9 ml) for 4 h. The reaction mixture was poured into water to give precipitates, which were recrystallized from aq methanol to give **16** as colorless needles (37 mg, 88%); mp 261—262 °C. UV λ_{max} nm (log ε) (EtOH) 261 (4.44), 289sh (4.17), 337i (3.65), (EtOH+NaOAc) 271.5 (4.43), 302sh (4.15), 335sh (3.95), (EtOH+$AlCl_3$) 270.5 (4.47), 300i (4.10), 374 (3.64); ^{1}H NMR (DMSO) δ=1.28 (6H, s, CH_3×2), 1.72 and 2.62 (each 2H, t, J=7 Hz, CH_2), 6.18 (1H, d, J=2 Hz, C_6–H), 6.20 (1H, s, $C_{3'}$–H), 6.33 (1H, d, J=2 Hz, C_8–H), 6.82 (1H, s, $C_{6'}$–H), 8.08 (1H, s, C_2–H), 9.10 and 10.60 (each 1H, bs, OH), 12.88 (1H, s, OH). Found: C, 67.56; H, 4.98%. Calcd for $C_{20}H_{18}O_6$: C, 67.79; H , 5.12%.

7-Benzyloxy-6-formyl-2,2-dimethylchroman (17). A mixture of 6-formyl-7-hydroxy-2,2-dimethylchroman[5] (1.9 g), benzyl chloride (1.6 ml), and anhydrous potassium carbonate (4 g) in DMF (50 ml) was heated with vigorous stirring at 150 °C for 1.5 h. Potassium carbonate was filtered off, and the solvent removed under reduced pressure. The residue was extracted with ether, and the ethereal solution dried with sodium sulfate. The ethereal extract was chromatographed over a silica-gel column with chloroform–petroleum ether (1:1) to give **17** as a colorless liquid (2.1 g, 72%). ^{1}H NMR ($CDCl_3$) δ=1.33 (6H, s, CH_3×2), 1.78 and 2.71 (each 2H, t, J=7 Hz, CH_2), 5.05 (2H, s, $C_6H_5C\underline{H}_2$), 6.40 (1H, s, C_5–H), 7.36 (5H, s, $C_6\underline{H}_5CH_2$), 7.61 (1H, s, C_8–H), 10.36 (1H, s, CHO).

3-(7-Benzyloxy-2,2-dimethyl-6-chromanyl)-1-[2,4-bis(benzyloxy)-6-hydroxyphenyl]-2-propen-1-one (18) and 5,7-Bis(benzyloxy)-2-(7-benzyloxy-2,2-dimethyl-6-chromanyl)-4-chromanone (19). A mixture of **3** (4.1 g) and **17** (3.2 g) was refluxed in the presence of piperidine (15 ml) in ethanol (200 ml) for 6 h to give yellow precipitates. The precipitates were recrystallized from ethyl acetate to give **18** as yellow needles (3.5 g, 52%); mp 158—160 °C. ^{1}H NMR ($CDCl_3$) δ=1.34 (6H, s, CH_3×2), 1.72 and 2.46 (each 2H, t, J=7 Hz, CH_2), 4.97 (4H, s, $C_6H_5C\underline{H}_2$×2), 5.03 (2H, s, $C_6H_5C\underline{H}_2$), 6.07 (1H, d, J=2 Hz, $C_{5'}$–H), 6.16 (1H, d, J=7 Hz, $C_{3'}$–H), 6.30 (1H, s, C_3–H), 6.89 (1H, s, C_6–H), 7.21—7.45 (15H, m, $C_6\underline{H}_5CH_2$×3), 7.77 and 8.20 (each 1H, d, J=16 Hz, CH=). Found: C, 78.74; H, 6.16%. Calcd for $C_{41}H_{38}O_6$: C, 78.57; H, 6.11%.

The flavanone **19** was obtained from the mother liquor by silica-gel column chromatography with chloroform–hexane (5:1), and recrystallized from ethyl acetate to give colorless needles (0.15 g, 2%); mp 155—157 °C. ^{1}H NMR ($CDCl_3$) δ=1.34 (6H, s, CH_3×2), 1.79 (2H, t, J=7 Hz, CH_2), 2.60—3.10 (4H, m, C_3–H and CH_2), 5.01 (4H, s, $C_6H_5C\underline{H}_2$×2), 5.13 (2H, s, $C_6H_5C\underline{H}_2$), 5.64—5.98 (1H, m, C_2–H), 6.22 (2H, s, arom-H×2), 6.44 and 7.23 (each 1H, s, arom-H), 7.27—7.71 (15H, m, $C_6\underline{H}_5CH_2$×3). Found: C, 78.42; H, 6.04%. Calcd for $C_{41}H_{38}O_6$: C, 78.57; H, 6.11%.

3-(7-Benzyloxy-2,2-dimethyl-6-chromanyl)-1-[2-acetoxy-4,6-bis(benzyloxy)phenyl]-2-propen-1-one (20). Compound **18** and **19** were converted into the acetate **20** by an acetic anhydride–sodium acetate method. The compound **20** was recrystallized from methanol–ethyl acetate to give pale yellow needles; mp 143—144 °C. ^{1}H NMR ($CDCl_3$) δ=1.35 (6H, s, CH_3×2), 1.80 and 2.70 (each 2H, t, J=7 Hz, CH_2), 2.19 (3H, s, CH_3CO), 4.95 (2H, s, $C_6H_5C\underline{H}_2$), 5.02 (4H, s, $C_6H_5C\underline{H}_2$×2), 6.38—6.53 (3H, m, arom-H×3), 6.99 and 7.81 (each 1H, d, J=16 Hz, CH=), 7.12—7.49 (16H, m, $C_6\underline{H}_5CH_2$×3 and arom-H). Found: C, 77.16; H, 5.77%. Calcd for $C_{43}H_{40}O_7$: C, 77.22; H, 6.03%.

5,7-Bis(benzyloxy)-3-(7-benzyloxy-2,2-dimethyl-6-chromanyl)-4H-chromen-4-one (21) and 7-Benzyloxy-3-(7-benzyloxy-2,2-dimethyl-6-chromanyl)-5-hydroxy-4H-chromen-4-one (22). After a mixture of **20** (3 g) and thallium(III) nitrate trihydrate (7 g) was stirred in methanol (800 ml) at 35—37 °C for 4 h, 10% hydrochloric acid (40 ml) was added to the mixture, and the solution refluxed for 3 h. The reaction mixture was worked up in the same manner as in the preparation of **7**. The resulting compounds were chromatographed over a silica-gel column with chloroform to give two main compounds **21** (0.96 g, 33%) and **22** (1.1 g, 39%), respectively. Compound **21** was crystallized from ether–petroleum ether to give colorless prisms; mp 133—134.5 °C. ^{1}H NMR ($CDCl_3$) δ=1.31 (6H, s, CH_3×2), 1.75 and 2.70 (each 2H, t, J=7 Hz, CH_2), 4.94, 5.01, and 5.14 (each 2H, s $C_6H_5C\underline{H}_2$), 6.43 (3H, s, arom-H×3), 7.08 (1H, s, arom-H), 7.13—7.65 (15H, m, $C_6\underline{H}_5CH_2$×3), 7.68 (1H, s, C_2–H). Found: C, 78.79; H, 5.72%. Calcd for $C_{41}H_{36}O_6$: C, 78.82; H, 5.81%.

Compound **22** was crystallized from methanol to give pale yellow needles; mp 145—147 °C. ^{1}H NMR ($CDCl_3$) δ=1.34 (6H, s, CH_3×2), 1.79 and 2.75 (each 2H, t, J=7 Hz, CH_2), 5.00 and 5.10 (each 2H, s, $C_6H_5C\underline{H}_2$), 6.43 (2H, s, arom-H×2), 6.50 and 7.03 (each 1H, s, arom-H), 7.29 and 7.38 (each 5H, s, $C_6\underline{H}_5CH_2$), 7.18 (1H, s, C_2–H), 12.95 (1H, s, OH). Found: C, 76.33; H, 5.83%. Calcd for $C_{34}H_{30}O_6$: C, 76.39; H, 5.66%.

Another Synthesis of 5,7-Dihydroxy-3-(7-hydroxy-2,2-dimethyl-6-chromanyl)-4H-chromen-4-one (16). A mixture (1.66 g) of **21** and **22** was hydrogenolyzed over 10% palladium on charcoal (300 mg) in a mixture of ethyl acetate (150 ml) and methanol (150 ml) until the uptake of hydrogen ceased. After the catalyst was filtered off, the solvent was removed under reduced pressure. The residue was recrystallized from aq methanol to give **16** as colorless needles (650 mg); mp 261—262 °C [no depression in a mixed-melting-point determination with the 3-(2,2-dimethyl-6-chromanyl)-4*H*-chromen-4-one **16** synthesized above]. The ^{1}H NMR spectrum of the compound synthesized here was also identical with that of the 3-(2,2-dimethyl-6-chromanyl)-4*H*-chromen-4-one **16** synthesized above.

2',4',5,7-Tetrahydroxyisoflavone (23). Compound **7** (5 g) was hydrogenolyzed over 10% palladium on charcoal (1.7 g) in methanol (220 ml) until the uptake of hydrogen ceased. The catalyst was filtered off, and the solvent removed under reduced pressure. The residue was recrystallized from methanol to give **23** as pale yellow prisms (2.17 g, 97%); mp 255—256 °C. UV λ_{max} nm (log ε) (EtOH) 261.5 (4.38), 288i (4.15), (EtOH+NaOAc) 271.5 (4.36), 297i (4.09), 327 (3.97), (EtOH+$AlCl_3$) 271.5 (4.42), 301i (3.98), 375 (3.53); ^{1}H NMR (DMSO) δ=6.21 (1H, d, J=2 Hz, C_6–H), 6.29 (1H, q, J=2 and 8 Hz, $C_{5'}$–H), 6.37 (2H, d, J=2 Hz, $C_{3'}$–H and C_8–H), 6.96 (1H, d, J=8 Hz, $C_{6'}$–H), 8.12 (1H, s, C_2–H), 8.38—10.44 (3H, b, OH×3), 12.86 (1H, s, OH). Found: C, 62.72; H, 3.66%. Calcd for $C_{15}H_{10}O_6$: C, 62.94; H, 3.50%.

7-Benzoyloxy-2',4',5-trihydroxyisoflavone (24). Benzoyl chloride (0.88 ml) in anhydrous ether (15 ml) was gradually added to a solution of **23** (1.8 g) in pyridine (30 ml) in an ice bath, and the mixture stirred at 2—5 °C for 5.5 h. The reaction mixture was poured into ice-cold

water, acidified with concd hydrochloric acid, and allowed to stand overnight in a refrigerator to give precipitates. The precipitates were collected by filtration and recrystallized from methanol to give **24** as pale yellow prisms (914 mg, 37%); mp 212—213 °C. UV λ_{max} nm (log ε) (EtOH) 256 (4.50), 343i (3.54), (EtOH+NaOAc) 255 (4.50), 341i (3.60), (EtOH+$AlCl_3$) 264.5 (4.54), 383.5 (3.63); ^{1}H NMR (DMSO) δ=6.29 (1H, q, J=2 and 8 Hz, C$_{5'}$-H), 6.36 (1H, d, J=2 Hz, C$_{3'}$-H), 6.87 (1H, d, J=2 Hz, C$_6$-H), 7.04 (1H, d, J=8 Hz, C$_{6'}$-H), 7.19 (1H, d, J=2 Hz, C$_8$-H), 7.59—8.22 (5H, m, C_6H_5CO), 8.32 (1H, s, C$_2$-H), 8.87—10.17 (2H, b, OH×2), 12.88 (1H, bs, OH). Found: C, 67.68; H, 3.64%. Calcd for $C_{22}H_{14}O_7$: C, 67.69; H, 3.59%.

7-Benzoyloxy-2',4',5-trihydroxy-3'-(3-methyl-2-butenyl)isoflavone (25), 7-Benzoyloxy-2',4',5-trihydroxy-5'-(3-methyl-2-butenyl)isoflavone (26), and 7-Benzoyloxy-2',4',5-trihydroxy-3',5'-bis(3-methyl-2-butenyl)isoflavone (27). A solution of 2-methyl-3-buten-2-ol (0.39 ml) in anhydrous dioxane (10 ml) was gradually added to a mixture of **24** (1.2 g) and boron trifluoride etherate (0.57 ml) in dioxane (40 ml) in a nitrogen atmosphere, and the mixture heated with stirring at 51—53 °C for 6 h. The reaction mixture was worked up in the same manner as in the preparation of **11**. The resulting products were chromatographed over a silica-gel column with 1,2-dichloroethane–acetone (20:1) to give three main fractions, which showed R_f values of 0.88, 0.63, and 0.24 on a silica-gel TLC plate with 1,2-dichloroethane–acetone (20:1), respectively. The second fraction (R_f=0.63) was recrystallized from methanol to give the desired isoflavone **25** as pale yellow needles (250 mg, 18%); mp 165—167 °C. UV λ_{max} nm (log ε) (EtOH) 263.5 (4.54), (EtOH+NaOAc) 264.5 (4.51), 316sh (3.83), (EtOH+$AlCl_3$) 269 (4.55), 384 (3.41); ^{1}H NMR (DMSO) δ=1.64 and 1.73 (each 3H, s, CH_3), 3.33 (2H, d, J=7 Hz, CH_2), 5.24 (1H, t, J=7 Hz, CH=), 6.42 (1H, d, J=8 Hz, C$_{5'}$-H), 6.81 (1H, d, J=8 Hz, C$_{6'}$-H), 6.86 (1H, d, J=2 Hz, C$_6$-H, 7.13 (1H, d, J=2 Hz, C$_8$-H), 7.55—8.20 (5H, m, C_6H_5CO), 8.25 (1H, s, C$_2$-H), 8.28 and 9.38 (each 1H, s, OH), 12.86 (1H, s, OH). Found: C, 70.95; H, 4.73%. Calcd for $C_{27}H_{22}O_7$: C, 70.73; H, 4.84%.

The third fraction (R_f=0.24) was recrystallized from dichloromethane to give the 5'-(3-methyl-2-butenyl)isoflavone **26** as pale yellow needles (169 mg, 12%); mp 124—126 °C. UV λ_{max} nm (log ε) (EtOH) 255 (4.48), 317.5i (3.77), (EtOH+NaOAc) 253 (4.49), 318i (3.81), (EtOH+$AlCl_3$) 264 (4.52), 287i (4.23), 381 (3.68); ^{1}H NMR (DMSO) δ=1.68 (6H, s, CH_3×2), 3.17 (2H, d, J=7 Hz, CH_2), 5.27 (1H, t, J=7 Hz, CH=), 6.46 (1H, s, C$_{3'}$-H), 6.82 (1H, d, J=2 Hz, C$_6$-H), 6.84 (1H, s, C$_{6'}$-H), 7.12 (1H, d, J=2 Hz, C$_8$-H), 7.57—8.24 (5H, m, C_6H_5CO), 8.29 (1H, s, C$_2$-H), 9.04, 9.30, and 12.84 (each 1H, s, OH). Found: C, 70.95; H, 4.68%. Calcd for $C_{27}H_{22}O_7$: C, 70.73; H, 4.84%.

Compound **26** was hydrolyzed with dilute alkali to give the isoflavone **2**.

The first fraction (R_f=0.88) gave the 3',5'-bis(3-methyl-2-butenyl)isoflavone **27** as a viscous pale yellow oil (375 mg, 23%), which did not crystallize. ^{1}H NMR ($CDCl_3$) δ=1.77 and 1.85 (each 6H, s, CH_3×2), 3.30 and 3.54 (each 2H, d, J=7 Hz, CH_2), 5.28 (2H, d, J=7 Hz, CH=×2), 5.63 (1H, s, OH), 6.78 (1H, d, J=2 Hz, C$_6$-H), 6.97 (1H, d, J=2 Hz, C$_8$-H), 7.45—8.25 (6H, m, C_6H_5CO and C$_{6'}$-H), 8.00 (1H, s, C$_2$-H), 12.28 (1H, s, OH).

Compound **27** was hydrolyzed with dilute alkali to give the isoflavone **13**.

2',4',5,7-Tetrahydroxy-3'-(3-methyl-2-butenyl)isoflavone (Licoisoflavone A) (1). Compound **25** (180 mg) was hydrolyzed with a 4% aq solution of sodium hydroxide (3 ml) in methanol (55 ml) in a nitrogen atmosphere at 50 °C for 1.5 h. The reaction mixture was worked up in the same manner as in the preparation of **2**. The resulting compound was recrystallized from aq methanol to give the desired isoflavone **1** as pale yellow prisms (70 mg, 50%); mp 120—122 °C. IR (KBr) 3350, 2900, 1650, 1605, 1500, 1447 cm^{-1}. Found: C, 67.55; H, 5.03%. Calcd for $C_{20}H_{18}O_6$: C, 67.79; H, 5.12%.

2',4',5,7-Tetraacetoxy-3'-(3-methyl-2-butenyl)isoflavone (28). Compound **1** (licoisoflavone A) was converted into the tetraacetate **28** by an acetic anhydride–sodium acetate method. Compound **28** was recrystallized from ethanol to give colorless needles; mp 149—150 °C. IR (KBr) 2960, 2920, 1770, 1650, 1620, 1480, 1430 cm^{-1}. Found: C, 64.51; H, 4.73%. Calcd for $C_{28}H_{26}O_{10}$: C, 64.38; H, 4.99%.

The properties of this synthetic isoflavone (**1**) and its tetraacetate (**28**) were fully consistent with those of natural licoisoflavone A and its tetraacetate, respectively.

The authors are grateful to Professor Shoji Shibata, Meiji College of Pharmacy, and Dr. Takeshi Kinoshita, University of Tokyo, for supplying the sample of natural licoisoflavone A tetraacetate.

The α-Chlorination of Aryl Ketones with Manganese(III) Acetate in the Presence of Chloride Ion

Takehiko TSURUTA, Tetsuya HARADA, Hiroshi NISHINO, and Kazu KUROSAWA*
Department of Chemistry, Faculty of Science, Kumamoto University, Kurokami 2-39-1, Kumamoto 860
(Received June 21, 1984)

The reaction of 2-(4-methoxyphenyl)-4-chromanone with $Mn(OAc)_3$ in the presence of LiCl gave 3,3-dichloro-2-(4-methoxyphenyl)-4-chromanone. The reactions of 2-phenyl-4-chromanone, 1-phenyl-1-propanone, 1,2-diphenylethanone, and 1-tetralone similarly yielded α,α-dichloro derivatives in good yields. 2,2,2-Trichloroacetophenones were obtained from 2,2-dichloroacetophenones, but in the absence of LiCl, 2,2-dichloroacetophenones gave 2,2,3,3-tetrachloro-1,4-butanediones. KCl, NaCl, NH_4Cl, $AlCl_3$, and $CaCl_2$ were also employed as the Cl^- ion source. Synthetic applicability and the reaction mechanisms are discussed briefly.

In a previous publication,[1] it was reported that the reaction of 4'-methoxyacetophenone with $Mn(OAc)_3$ in AcOH containing NH_4Cl yielded 2-chloro-4'-methoxyacetophenone and 2,2-dichloro-4'-methoxyacetophenone, and the reaction of the 2-chloro-4'-methoxyacetophenone with $Mn(OAc)_3$ in AcOH alone gave several dimeric compounds. This seemed to indicate that the reaction could provide a useful method for the total α-chlorination of some aryl ketones if an excess of $Mn(OAc)_3$–Cl^- is used. Therefore, the reactions of 2-phenyl-4-chromanones (**1a** and **1b**), 1-phenyl-1-propanone (**2**), 1,2-diphenylethanones (**3a** and **3b**), 1-tetralone (**4**), and 2,2-dichloroacetophenones (**5a—5d**) with $Mn(OAc)_3$ in the presence of various chloride ion sources such as LiCl, KCl, NH_4Cl, $CaCl_2$, and $AlCl_3$ in boiling AcOH were examined. These aryl ketones were chosen for the reason that they have at least one or two hydrogens at the α-position of the carbonyl function and are all enolizable ketones.

When 2-(4-methoxyphenyl)-4-chromanone (**1a**) was heated under reflux in AcOH containing $Mn(OAc)_3$ and LiCl, the products were found to be 3,3-dichloro-2-(4-methoxyphenyl)-4-chromanone (**6a**), 3-chloro-4'-methoxyflavone (**7**), and 4'-methoxyflavone (**8a**). A similar reaction of 2-phenyl-4-chromanone (**1b**) yielded 3,3-dichloro-2-phenyl-4-chromanone (**6b**) and flavone (**8b**).

The reactions of 1-phenyl-1-propanone (**2**) and 1-tetralone (**4**) gave the corresponding α,α-dichloro derivatives as the sole product.

When 1,2-bis(4-methoxyphenyl)ethanone (**3a**) was oxidized with $Mn(OAc)_3$–LiCl, the products were 2-acetoxy-1,2-bis(4-methoxyphenyl)ethanone (**13**), 1,2-bis(4-methoxyphenyl)ethanedione (**14a**), and *p*-anisic acid (**15a**). The formation of **13** can be accounted for by assuming a substitution of the chlorine atom by acetate ion in 2-chloro-1,2-bis(4-methoxyphenyl)ethanone (**16**) which may be formed as an intermediate. In fact, **16** gave **13** when heated in AcOH. 1,2-Diphenylethanone (**3b**), on the other hand, yielded the corresponding α,α-dichloro derivative (**11**) as the major product.

When 2,2-dichloro-4'-methoxyacetophenone (**5a**) was oxidized with $Mn(OAc)_3$–LiCl, it gave 2,2,2-trichloro-4'-methoxyacetophenone (**17a**) in almost quantitative yields (Table 1, Entry 7). 2,2-Dichloro-(**5b**), 2,2,4'-trichloro-(**5c**), and 2,2-dichloro-4'-methylacetophenones (**5d**) also yielded the corresponding 2,2,2-trichloroacetophenone (**17b—17d**) in excellent yields (Entries 9, 11, and 13). The reaction of **5a** with $Mn(OAc)_3$ in AcOH alone, on the contrary, resulted in the formation of a dimeric compound (**18a**) as in the reaction of 2-chloro-4'-methoxyacetophenone.[1] It was also found that **5c** gave another dimeric compound (**19**) together with **18c**.

The formation of 3,3-dichloro-2-phenyl-4-chromanones, **6a** and **6b**, has precedence. Weber and Birkner[2] have reported that the reaction of **1a** and **1b** with $CuCl_2$ for 8 h yielded **6a** (65.5%) and **6b** (27.2%), respectively. The reaction using $Mn(OAc)_3$–LiCl is certainly better than that reported because of a shorter reaction time (130 min) and a much higher yield (73% for **6a** and 74% for **6b**). It was also reported[3] that 2,2-dichloro-1-tetralone (**12**) was obtained by a two-step reaction of **4** with $FeCl_3$ (a 53% overall yield). Again this is poor when compared with ours.

In order to examine the reaction conditions in more detail, we chose 2-(4-methoxyphenyl)-4-chromanone (**1a**) as a substrate and carried out reactions under various conditions since **1a** gave several products in a previous experiment. Also, the products could be well separated on TLC. A previous study[1] revealed that the molar ratio of a substrate to $Mn(OAc)_3$ has considerable effect on the yield of products in the reaction of 4'-methoxyacetophenone with $Mn(OAc)_3$–NH_4Cl. An increase in the yield of **6a** was observed to be at the expence of **8a**, while increasing the amount of $Mn(OAc)_3$ (they stayed constant beyond the molar ratio of 1:7). In Table 2 a summary of the molar ratios and yields is presented.

Changing LiCl to other salts as a chloride ion source has some effect on the yields of the products (Table 3). It is demonstrated that KCl and NaCl are better salts and gave a much higher yield of **6a** than the other. $CaCl_2$ yielded a moderate amount of **8a**. NH_4Cl and

$AlCl_3$ were intermediary and gave *r*-3-acetoxy-*t*-2-(4-methoxyphenyl)-4-chromanone (**9**) together with **6a**, **7**, and **8a**. **9** was the major product in the reaction of **1a** with $Mn(OAc)_3$ alone (Entry 6). In the case of $AlCl_3$ it was necessary to acidify the reaction mixture with 2 M (1 M=1 mol/dm^3) hydrochloric acid to free the products from $AlCl_3$. All salts other than LiCl and $AlCl_3$ were only partially soluble in AcOH and some remained at the bottom of the flask. Although KCl gave the maximum yield of **6a**, it is better to use LiCl as the chloride ion source since KCl gives a rather poor yield in the case of 1,2-diphenylethanone (**11**, 50%).

The formation of the dimeric compound (**18a—d** and **19**) seems to suggest the radical nature of the reaction. The formation of **17a** in the reaction of **5a**, even in the absence of Cl^- ions (Table 1, Entry 8), indicates that **5a**, itself, could supply Cl^- ions. It can be postulated that the α-keto radical (A) produced from a 2,2-dichloroacetophenone by the action of a Mn(III) species is the common reaction intermediate both for the α-chlorination and for the formation of dimeric compounds. The intermediate A reacts with $Mn(OAc)_3/Cl^-$ to give **17a—d**, and in the absence of Cl^- ions dimerizes by a head-to-head coupling to give **18a—d** and by a head-to-tail coupling to give **19** (Scheme 1). When **19** was heated at 180 °C under reduced pressure, it isomerized to **18c**. This indicates that the dissociation of **19** to A (Ar=4-chlorophenyl) takes place and a recombination of A gives **18c**. Hydrolysis of **19** with aqueous AcOH yielded **5c** and 4-chlorobenzoic acid (**15c**). The formation of the α,α-dichloro derivatives in the reaction of other ketones can also be accounted for by the similar α-keto radical intermediates (-CO-CH- and -Co-CCl=).

It was thus shown that the reaction of $Mn(OAc)_3$-LiCl provides a facile and extremely simple procedure for α-chlorination of aryl ketones.

Experimental

All the ^{1}H-NMR spectra were recorded with a Hitachi-Perkin-Elmer R-24 spectrometer with tetramethylsilane as the internal reference. The proton decoupled ^{13}C-FT NMR spectra were measured for deuteriochloroform solutions at 100 MHz on a JEOL FX 100 spectrometer using tetramethylsilane as the internal reference. The IR spectra were taken for chloroform solutions on a JASCO IR A-1 grating spectrometer and the UV spectra were recorded for methanol solutions with a Hitachi EPS 3T spectrophotometer. The melting points were determined with a Yanagimoto micro-melting point apparatus and were not corrected.

Materials. 2-(4-Methoxyphenyl)-4-chromanone[4] (**1a**) 2-phenyl-4-chromanone[5] (**1b**), 1,2-bis(4-methoxyphenyl)-ethanone[6] (**3a**), 1,2-diphenylethanone[7] (**3b**), 2,2-dichloro-4′-methoxyacetophenone[8] (**5a**), 2,2-dichloroacetophenone[9] (**5b**) 2,2,4′-trichloroacetophenone[10] (**5c**), and 2,2-dichloro-4′-methylacetophenone[11] (**5d**) were prepared by the method described in the literature. 1-Phenyl-1-propanone (**2**) and 1-tetralone (**4**) were commercially available (Wako Pure Chemical Industries Ltd.).

Oxidations of Aryl Ketones with $Mn(OAc)_3$-Cl^-. The general procedure for the oxidation of aryl ketones with $Mn(OAc)_3$-Cl^- was as follows. To a heated solution of $Mn(OAc)_3 2H_2O$[12] (4—9 mmol) and Cl^- (10 mmol) in AcOH (20 ml), a ketone (1 mmol) was added. The mixture was then heated under reflux until the dark color of the solution

a) Yields based on the amount of the substrate used.

2-Acetoxy-1,2-bis(4-methoxyphenyl)ethanone (13) from 2-Chloro-1,2-bis(4-methoxyphenyl)ethanone[19] (16). A solution of **16** (128 mg) in AcOH (20 ml) was heated under reflux for 90 min. Evaporation of the solvent *in vacuo* gave **13** (136 mg, 98%), identical with an authentic sample.

Dichloro-1,2-diphenylethanone (11): Mp 62.1—62.9 °C (lit,[20] 61—62 °C). *1,2-Diphenylethanedione (14b)*: Mp 94—95 °C. *Benzoic acid (15b)*: Mp 120 °C.

2,2,2-Trichloro-4'-methoxyacetophenone (17a): Bp 120—125 °C (bath temp)/0.02 mmHg (lit,[21] mp 33—35.3 °C).

2,2,2-Trichloroacetophenone (17b): Bp 105—110 °C (bath temp)/0.02 mmHg (lit,[10] 145 °C/25 mmHg).

2,2,2,4'-Tetrachloroacetophenone (17c): Bp 110—115 °C (bath temp)/0.02 mmHg (lit,[22] mp 28 °C).

2,2,2-Trichloro-4'-methylacetophenone (17d): Bp 115—120 °C (bath temp)/0.02 mmHg (lit,[23] 137 °C/10 mmHg).

Oxidation of Aryl Ketones with $Mn(OAc)_3$. The general procedure for the oxidation of aryl ketones with $Mn(OAc)_3$ was virtually identical with that for the reaction with $Mn(OAc)_3$–Cl^-.

2,2,3,3-Tetrachloro-1,4-bis(4-chlorophenyl)-1,4-butanedione (18a): Mp 145—146 °C (lit,[1] 145—146 °C).

2,2,3,3-Tetrachloro-1,4-diphenyl-1,4-butanedione (18b): Colorless Cubes; mp 94—95 °C (from light petroleum); IR 1700 cm^{-1} (–C=O): UV λ_{max} (ε) 265 nm (20900); ^{1}H-NMR ($CDCl_3$) δ=7.2—7.6 (6H, m, H-3', H-3", H-4', H-4", H-5', and H-5"), and 8.1—8.3 (4H, m, H-2', H-2", H-6', and H-6"). Found: C, 51.04; H, 2.67%. Calcd for $C_{16}H_{10}Cl_4O_2$: C, 51.07; H, 2.68%.

2,2,3,3-Tetrachloro-1,4-bis(4-chlorophenyl)-1,4-butanedione (18c): Colorless cubes; mp 167—168 °C (from light petroleum), IR 1712 cm^{-1} (>C=O); UV λ_{max} (ε) 219^{sh} (9000) and 276 nm (27700); ^{1}H-NMR ($CDCl_3$) δ=7.48 (4H, m, H-3', H-3", H-5', and H-5"), and 8.16 (4H, m, H-2', H-2", H-6', and H-6"); ^{13}C-NMR δ=183.958 (>C=O), 140.100 (=C–Cl), 132.118 (2×=C–H), 130.719 (=C–CO), 128.405 (2×=C–H), and 89.420 (–CCl_2–). Found: C, 43.09; H, 1.81%. Calcd for $C_{16}H_4Cl_6O_2$: C, 43.16; H, 1.81%.

4,β,β-Trichloro-α-[dichloro-(4-chlorobenzoyl)methoxy]styrene (19): Colorless cubes; mp 81.7—82.7 °C (from light petroleum); IR 1730 cm^{-1} (>C=O); UV λ_{max} (ε) 224^{sh} (17400) and 263 nm (15300); ^{1}H-NMR (DMSO-d_6) δ=7.64 (4H, m, H-2, H-3, H-5 and H-6), 7.69 (2H, m, H-3' and H-5'), and 8.18 (2H, m, H-2' and H-6'); ^{13}C-NMR δ=180.605 (>C=O), 144.788 (=C–O–), 140.709 (=C–Cl), 136.445 (=C–Cl), 132.547 (2×=C–H), 131.509 (2×=C–H), 129.438 (=C–CO), 128.707 (4×=C–H). 128.2 (=C–C(O)–), 120.486 (=CCl_2), and 109.765 (–CCl_2–). Found: C, 43.22; H, 1.81%. Calcd for $C_{16}H_8Cl_6O_2$: C, 43.16; H, 1.81%.

2,2,3,3-Tetrachloro-1,4-bis(4-methylphenyl)-1,4-butanedione (18d): Colorless cubes; mp 167.5—169.5 °C (from CCl_4–light petroleum); IR 1720 cm^{-1} (>C=O); UV λ_{max} (ε) 219^{sh} (7800) and 278 nm (23600); ^{1}H-NMR ($CDCl_3$) δ=2.40 (6H, s, 2×CH_3), 7.27 (4H, m, H-3', H-3", H-5', and H-5"), and 8.16 (4H, m, H-2', H-2", H-6', and H-6"). Found: C, 53.13; H, 3.44%. Calcd for $C_{18}H_{14}Cl_4O_2$: C, 53.47; H, 3.49%.

Isomerization of 4,β,β-Trichloro-α-[dichloro-(4-chlorobenzoyl)methoxy]styrene (19) to 2,2,3,3-Tetrachloro-1,4-bis(4-chlorophenyl)-1,4-butanedione (18a). **19** (33.9 mg) was heated in a glass tube at 180—190 °C under reduced pressure (15 mmHg) for 1 h. The product was recrystallized from light petroleum to give **18a** (28.9 mg, 85%), mp 167—168 °C.

Hydrolysis of 4,β,β-Trichloro-α-[dichloro-(4-chlorobenzoyl)-methoxy]styrene (19). A mixture of **19** (73.5 mg), AcOH (2 ml), water (1 ml), and concd hydrochloric acid (0.05 ml) was heated under reflux for 2 h. After the AcOH was removed *in vacuo*, the resulting substance was separated on TLC with carbon tetrachloride as the eluting solvent to give **5c** (27.5 mg, 74%), mp 61—62 °C (lit,[10] 51 °C) and 4-chlorobenzoic acid (**15c**) (6.9 mg, 26%), mp 244.5—245.5 °C (in a sealed tube) (lit,[24] 241.5 °C).

We wish to thank Professor Hitoshi Takeshita and Associate Professor Akira Mori of the Research Institute of Industrial Science, Kyushu University, for their measurements of the ^{13}C-NMR spectra.

Synthetic Studies on Germacranolides. Synthesis of Optically Active 3-Oxygenated 13-Norheliangolides[1)]

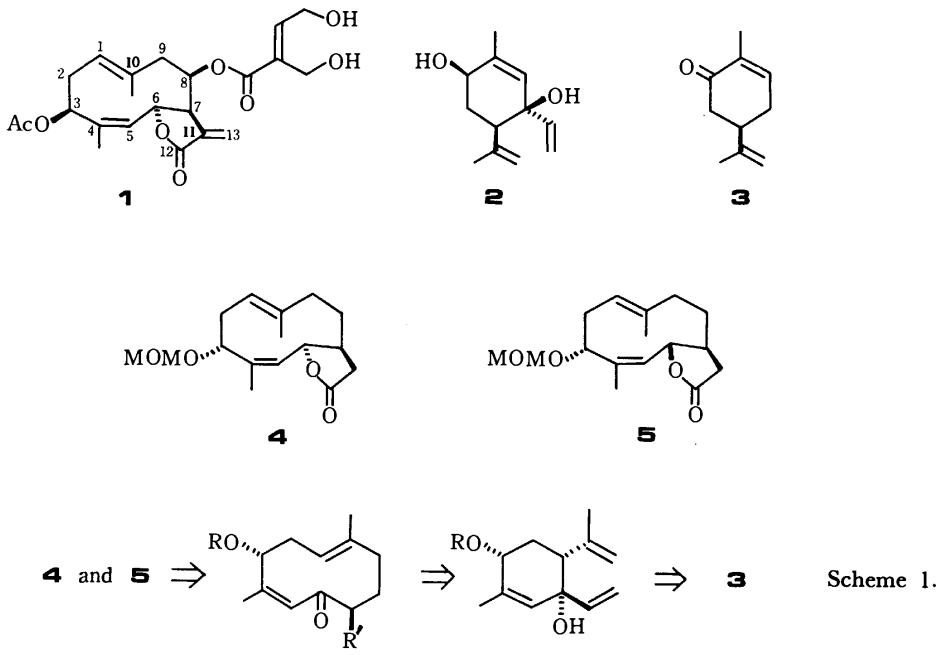
Chiaki KURODA,† Takayoshi NAKAMURA,†† Hiroshi HIROTA,* Katsumi ENOMOTO, and Takeyoshi TAKAHASHI*

Department of Chemistry, Faculty of Science, The University of Tokyo, Hongo, Bunkyo-ku, Tokyo 113

(Received June 25, 1984)

(3*R*,6*S*,7*S*,1(10)*E*,4*Z*)- and (3*R*,6*R*,7*S*,1(10)*E*,4*Z*)-3-Methoxymethoxy-13-nor-1(10),4-germacradieno-12,6-lactones were synthesized from (−)-carvone, utilizing anionic oxy-Cope rearrangement to construct a ten-membered ring compound.

A group of germacrane-type sesquiterpene lactones are known as "germacranolides," and a large number of germacranolides have been isolated from various species of plants in these years.[2)] Among them, (1(10)*E*,4*E*)- and (1(10)*E*,4*Z*)-1(10),4-germacradienolides constitute a group of "germacrolides" and that of "heliangolides," respectively.[3)] Most of germacranolides possess an α-exomethylene structure on γ-lactone ring, and some of them show significant anti-tumor activities.[4)] One of us and co-workers have isolated several kinds of germacranolides from plants of the genus *Eupatorium*.[5)] Hiyodorilactone A (**1**), a heliangolide isolated from *Eupatorium sachalinense* Makino, showed a strong inhibitory activity *in vivo* against the Ehrlich ascites carcinoma.[5a)] Synthetic studies on germacrolides have already been reported by many groups.[6)] But, those on heliangolides have been reported by only two groups, one is our preliminary report[1)] and the other is the total synthesis of **1** by Still's group,[7)] although a number of (1*E*,5*Z*)-1,5-cyclodecadiene derivatives without a lactone moiety were synthesized by the route involving oxy-Cope rearrangement,[8)] pyrolysis,[9)] or cyclization.[10)] We chose optically active C(3) oxygenated 13-norheliangolides as synthetic targets, because most of natural heliangolides have an oxygen function at C(3) position[11)] and the introduction of an α-methylene group to the γ-lactone ring in the final stage of the synthesis has been well-investigated.[12)] In this paper, we wish to report the preparation of (1*S*,4*R*,6*R*)-1-ethenyl-3-methyl-6-(1-methylethenyl)-2-cyclohexene-1,4-diol (**2**) from (−)-carvone (**3**) and the synthesis of (3*R*,6*S*,7*S*,



Scheme 1.

1(10)*E*,4*Z*)- and (3*R*,6*R*,7*S*,1(10)*E*,4*Z*)-3-methoxymethoxy-13-nor-1(10),4-germacradieno-12,6-lactones (**4** and **5**)[13] from **2** utilizing anionic oxy-Cope rearrangement as a key step, in detail.

Retro-synthetic pathway is shown in Scheme 1.

The first stage of the synthesis was a preparation of the diol (**2**) from an easily available optically active compound. We chose (−)-carvone (**3**) as a starting material. Several carvone derivatives oxygenated at allylic position have already been derived from carvone by three groups; Still's group had obtained **6** in 37% yield by 6 step reactions,[7] Miyashita and Yoshikoshi had prepared **7** in about 40% yield through eight synthetic intermediates,[14] and Noma and Nishimura had obtained **7** in 10% yield by microbial one step oxidation.[15] To obtain a large amount of **6**-type compound from carvone, we planned a direct allylic oxidation reaction of carveol derivative. The good hydroxyl-protecting group to carveol was turned out to be ester-type one (acetate or benzoate). When (−)-*cis*-carveol (**8**),[16] prepared by reduction of (−)-carvone (**3**) with lithium aluminum hydride, was acetylated and then treated with *t*-butyl chromate, a corresponding ketone (**9**) was obtained in 41% yield. When Collins reagent [chromium(VI) oxide-pyridine complex] was used instead of *t*-butyl chromate as an oxidizing agent, the reaction rate was very slow, and oxidation with selenium (IV) oxide gave no desired compound. Reaction of **9** with 1.4 equivalent moles of vinylmagnesium bromide gave trienes, **10** and **2**, in 28 and 6% yields, respectively. The acetate (**10**) was hydrolyzed by potassium carbonate in aqueous methanol to afford **2** in 85% yield. (Consequently, **2** was obtained from **9** in 30% yield.) No diastereomer of **2** was obtained. The stereochemistry at the vinyl- and hydroxyl-carrying carbon atom of **2** was deduced from the formation mechanism. When the benzoate of carveol was utilized instead of acetate in these consecutive reactions, allylic oxidation step gave a worse result and Grignard step gave a better one, and overall yield was almost the same as in the case of acetate. Anionic oxy-Cope rearrangement reaction of the diol (**2**) was examined. The secondary hydroxyl group of **2** was protected by methoxymethyl (MOM) group and then the resulting triene (**11**) was treated with potassium hydride and 18-crown-6 in tetrahydrofuran under reflux affording a cyclodecadienone (**12**) in 67% yield. When **2** was directly treated with the same conditions as above, only complex mixture was obtained. Any ten-membered ring compound could not be obtained when acetyl (compound **10**), trimethylsilyl, *t*-butyldimethylsilyl, or *t*-butyldiphenylsilyl protecting groups was used instead of MOM group. Although the geometry of olefinic double bonds of **12** could have already been expected from the reaction fashion of oxy-Cope

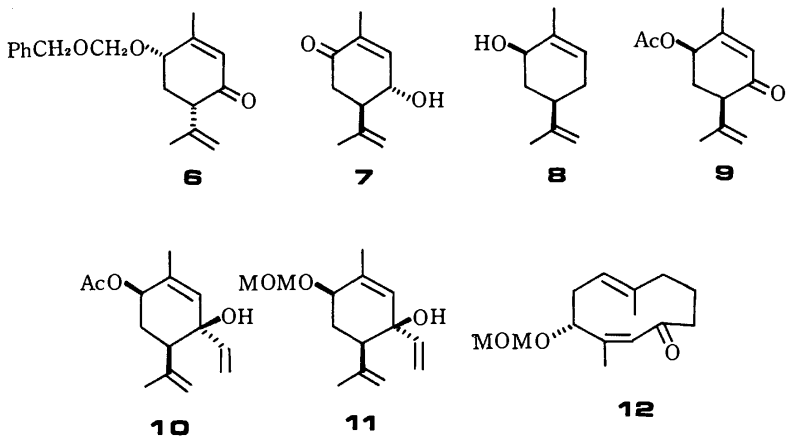

Table 1.[a] NOE data for **12**

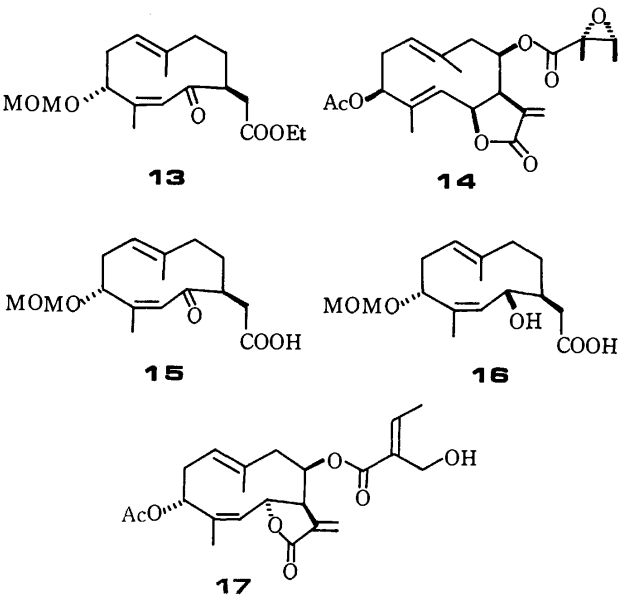
Irradiated proton(s)	Observed proton	NOE[b]
C(10)-CH_3 (δ=1.56, 3H, s)	C(1)-H (δ=5.03, 1H, t, $J_{1,2\alpha}=J_{1,2\beta}=8$ Hz)	2%
	C(2β)-H (δ=2.51, 1H, ddd, $J_{1,2\beta}=8$ Hz, $J_{2\alpha,2\beta}=13$ Hz, $J_{2\beta,3\beta}=5.5$ Hz)	7%
	C(3β)-H (δ=4.88, 1H, dd, $J_{2\alpha,3\beta}=11$ Hz, $J_{2\beta,3\beta}=5.5$ Hz)	10%
C(4)-CH_3 (δ=1.79, 3H, s)	C(1)-H	15%
	C(5)-H (δ=6.07, 1H, s)	20%
C(2β)-H	C(3β)-H	12%

a) Assignment of signals was determined by decoupling experiments. b) Accuracies are about ±2%.

rearrangement, it was confirmed by NOE experiments. The result shown in Table 1 can only be interpreted based on the (1(10)*E*,4*Z*)-structure (**A**).[8] The ketone (**12**) was treated with lithium diisopropylamide followed by ethyl bromoacetate to give a keto ester (**13**) stereoselectively as a sole product in 74% yield. The stereochemistry at C(7) of **13** would be *S*(7α-H) from the reaction pathway as the following. That is, the enolate ion generated with lithium diisopropylamide would have a more stable 6*Z*-double bond, which can conjugate with 4*Z*-double bond, while the corresponding 6*E*-enolate can not do. On the enolate ion, methoxymethoxyl group at C(3) would take an equatorial form (**B**). Then, the electrophile would attack from the less hindered outer side of the ten-membered ring to give 7α-H configuration compound. This stereochemical assignment was supported by the following transformation into *cis*-lactone (**5**).

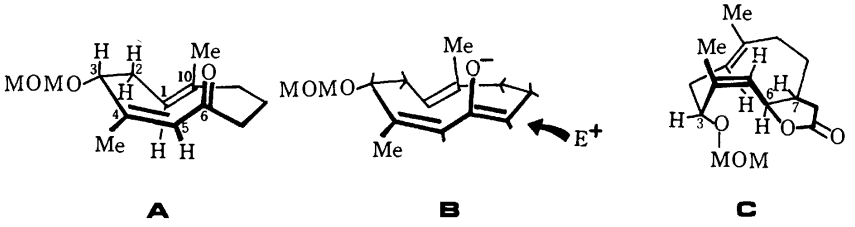
The keto ester (**13**) was reduced with sodium borohydride in ethanol to give a lactone (**5**) in 12% yield, together with more polar products which were suggested to be a keto alcohol (19%) and a diol (15%). The stereochemistry of **5** was decided to be 6*R*(6α-H) and 7*S*(7α-H) (**C**) from the NMR spectrum as follows. The methoxymethoxyl group at C(3α) is in axial conformation judging from the coupling constant of C(3β)-H (t, J=3 Hz). The chemical shift of C(6)-H (δ 6.01) is fairly low, which could be explained that C(6)-H is situated at the close position to the C(3α)-axial methoxymethoxyl oxygen, meaning that C(6)-H is α-oriented; large J values (7 and 11 Hz) observed for C(6)-H lead to a *cis*-lactone structure with C(6α)-H and C(7α)-H configuration for **5**. The *cis* lactone structure is also compatible with the formation mechanism that a hydride would attack C(6) carbonyl carbon preferentially from the less hindered outer side of the ten-membered ring. Consequently, the absolute stereostructure of **5** is established as (3*R*,6*R*,7*S*,1(10)*E*,4*Z*)-3-methoxymethoxy-13-nor-1(10),4-germacradieno-12,6-lactone.

No natural heliangolide possessing (6α-H,7α-H)-12,6-lactone has been known, even though several germacrolides of this type have been known (*e.g.* ursinolide A (**14**)).[17] In order to obtain *trans*-lactone, we planned to lactonize the hydroxy acid (**16**) with inversion at C(6) stereochemistry by activating the hydroxyl group. The keto ester (**13**) was hydrolyzed with potassium carbonate in aqueous methanol, and the resulting keto acid (**15**) was reduced with lithium borohydride to afford **16**. As the hydroxy acid (**16**) was easily lactonized into *cis*-lactone (**5**), **16** without purification was treated with *N*,*N*-dimethylformamide dineopentyl acetal in boiling toluene[18] to afford a lactone (**4**) in 15% yield from **13**.[19] The stereochemistry of the lactone (**4**), which has different physical data from those of *cis*-lactone (**5**), must have been *trans* (6*S*,7*S*), which was convincingly suggested from the formation mechanism.[18] The NMR spectral data were also compatible with the structure **4** when compared with those of natural heliangolide, eupasimplicin A (**17**).[20] Thus, the structure of **4** including the absolute stereochemistry was shown to be (3*R*,6*S*,7*S*,1(10)*E*,4*Z*)-3-methoxymethoxy-13-nor-1(10),4-germacradieno-12,6-lactone.



Experimental

General Procedures. All melting points were measured on a Mel-temp capillary melting point apparatus (Laboratory Devices) and uncorrected. Optical rotation was determined on a JASCO polarimeter DIP-SL. Ultraviolet absorption (UV) and infrared (IR) spectra were measured on a Hitachi 340 and a Hitachi 260-30 spectrometer, respectively. Mass (MS) spectra were run on a JEOL JMS-D300 mass spectrometer operating at 70 eV. Proton nuclear magnetic resonance (^{1}H NMR) spectra were taken using a Varian EM390 (90 MHz), a JEOL FX90Q (90 MHz), and a Brucker



WH270 (270 MHz). Chemical shifts were expressed in δ (ppm) downfield from tetramethylsilane as an internal standard and coupling constants in Hz. Thin-layer chromatography (TLC) was carried out on Kieselgel 60 GF_{254} coated in 0.25 mm-thickness. Wakogel C-200 (Wako) and Florisil (100—200 mesh) were used for column chromatography. Liquid Chromatograph Model ALC/GPS 202/401 (Waters Assoc.) was used for high performance liquid chromatography (HPLC).

(−)-cis-Carvyl Acetate ((3R,5R)-3-Acetoxy-2-methyl-5-(1-methylethenyl)cyclohexene). To a solution of 6.7 g of (−)-*cis*-carveol (**8**) in 100 ml of pyridine was added 20 ml of acetic anhydride and the whole was stirred for about 12 h. After addition of 30 ml of methanol and removal of solvent *in vacuo*, the reaction mixture was extracted with ether as usual. After the removal of impurities at 40 °C under reduced pressure (10 mmHg; 1 mmHg=133.322 Pa), 8.11 g of acetate was obtained: bp 82—83 °C/2 mmHg; $[\alpha]_D^{11}$ −54.4° (*c* 6.99, EtOH); IR (neat) 1740, 1645, and 1240 cm^{-1}; NMR ($CDCl_3$) δ=1.62 (3H, br s), 1.72 (3H, s), 2.07 (3H, s, $-OCOCH_3$), 4.70 (2H, s, $-\underset{|}{C}=CH_2$), 5,42 (1H, br, C(1)-H), and 5.55 (1H, br, C(3)-H); MS *m/z* (%) 194 (M^+, 0.4), 152 (39), 134 (56), and 84 (100).

Allylic Oxidation of (−)-cis-Carvyl Acetate. To a solution of 5.0 g of (−)-*cis*-carvyl acetate in 70 ml of carbon tetrachloride was added 70 ml of a carbon tetrachloride solution of *t*-butyl chromate (prepared from 13 g of chromium(VI) oxide), 20 ml of acetic anhydride, and 7 ml of acetic acid, and the whole was refluxed for 1 d. A solution of oxalic acid (16 g) in 120 ml of water and then 50 g of oxalic acid were added. After removal of precipitate, ether was added for extraction. The ether layer was washed with aqueous sodium hydrogensulfite, saturated sodium hydrogencarbonate aqueous solution, and saturated brine, successively, and dried over sodium sulfate. After evaporation of solvent, the residue was chromatographed on a column of silica gel (80 g). Elution with hexane–ether (5:1) afforded 2.35 g of the unreacted starting material, and elution with hexane–ether (2:1) gave (4*R*,6*R*)-4-acetoxy-3-methyl-6-(1-methylethenyl)-2-cyclohexen-1-one (**9**, 1.22 g): an oil, $[\alpha]_D^{14}$ −52.2° (*c* 6.50, EtOH); IR (neat) 1740, 1680, 1635, and 1235 cm^{-1}; UV (EtOH) 228 nm (ε 9800); ^1H NMR ($CDCl_3$) δ=1.72 (3H, s, $CH_2=\underset{|}{C}-CH_3$), 1.91 (3H, s, C(3)-$CH_3$), 2.13 (3H, s, $-OCOCH_3$), 3.11 (1H, dd, *J*=4.5 and 13.5 Hz, C(6)-H), 4.79 and 4.95 (each 1H, br s, $-\underset{|}{C}=CH_2$), 5.7 (1H, br, C(4)-H), and 5.92 (1H, br s, C(2)-H); MS *m/z* (%) 208 (M^+, 0.5), 166 (17), and 98 (100); Found: *m/z* 208.1090. Calcd for $C_{12}H_{16}O_3$: 208.1097.

Grignard Reaction of the Keto Acetate (9). The Grignard reagent was prepared by heating the mixture of small pieces of magnesium ribbon (110 mg), 7 ml of dry tetrahydrofuran (dry THF; freshly distilled from lithium aluminum hydride), and vinyl bromide (0.35 ml) under nitrogen atmosphere. To the Grignard reagent cooled at 0 °C with ice-bath, a solution of **9** (675 mg) in THF (3.5 ml) was added, and the mixture was stirred for 20 min at room temperature. After addition of saturated ammonium chloride solution, the mixture was extracted with ether and then subjected to separation by silica gel (20 g) column chromatography. Elution with hexane–ether (5:1) gave **10** (157.0 mg), elution with hexane–ether (4:1) gave starting material (**9**; 189.1 mg), and then elution with hexane–ether (1:1) gave **2** (35.2 mg). (1*S*,4*R*,6*R*)-4-Acetoxy-1-ethenyl-3-methyl-6-(1-methylethenyl)-2-cyclohexen-1-ol (**10**): an oil, $[\alpha]_D^{14}$ −29.9° (*c* 5.58, EtOH); IR (neat) 3500, 1735, 1635, and 1235 cm^{-1}; ^1H NMR ($CDCl_3$) δ=1.68 (3H, t, *J*=0.5 Hz, $CH_2=\underset{|}{C}-CH_3$), 1.79 (3H, s, C(3)-Me), 2.09 (3H, s, $-OCOCH_3$), 4.8—5.5 (6H, m), and 5.87 (1H, dd, *J*=10 and 17 Hz, $-\underset{|}{C}-CH=CH_2$); MS *m/z* (%) 194 [$(M-42)^+$, 3], 176 (8), and 125 (100). Fragment ion peak due to $(M-CH_2CO)^+$ was observed at *m/z* 194.1308. Calcd for $C_{12}H_{18}O_2$: $M-C_2H_2O$, 194.1307. (1*S*,4*R*,6*R*)-1-Ethenyl-3-methyl-6-(1-methylethenyl)-2-cyclohexene-1,4-diol (**2**): crystals, mp 142.5—144.5 °C, $[\alpha]_D^{16}$ −23.9° (*c* 2.80, EtOH); IR (KBr disk) 3320, 3250, and 1635 cm^{-1}; ^1H NMR ($CDCl_3$) δ=1.80 (6H, s), 4.1 (1H, br, C(4)-H), 4.8—5.3 (5H, m), and 5.86 (1H, dd, *J*=10 and 17 Hz, $-\underset{|}{C}-CH=CH_2$); MS *m/z* (%) 194 (M^+, 0.2), 176 (1), 161 (5), and 126 (100). Found: C, 73.92%; H, 9.22%. Calcd for $C_{12}H_{18}O_2$: C, 74.19%; H, 9.34%.

Hydrolysis of the Acetate (10). A mixture of **10** (1.13 g) and potassium carbonate (1.8 g) in 80% aqueous methanol (120 ml) was stirred at room temperature for 1 h. After removal of methanol *in vacuo*, ether extraction was carried out as usual, and white crystals of **2** (786.7 mg) was afforded.

Methoxymethylation of the Diol (2). To a solution of **2** (174 mg) in dry acetonitrile (35 ml) were added triethylamine (3.5 ml) and methoxymethyl chloride (1.2 ml), and the mixture was refluxed for 8 h. After addition of saturated aqueous solution of sodium hydrogencarbonate and removal of acetonitrile *in vacuo*, ether extraction was done as usual. The mixture was separated by Florisil (20 g) column chromatography. Elution with hexane–ether (9:1) afforded 90.2 mg of methoxymethyl ether (**11**) and elution with ether gave unreacted diol (**2**; 55.2 mg). (1*S*,4*R*,6*R*)-1-Ethenyl-4-methoxymethoxy-3-methyl-6-(1-methylethenyl)-2-cyclohexen-1-ol (**11**): an oil, $[\alpha]_D^{16}$ −61.2° (*c* 4.25, EtOH); IR (neat) 3480 and 1640 cm^{-1}; ^1H NMR ($CDCl_3$) δ=1.79 (6H, s), 3.40 (3H, s, $-OCH_2OCH_3$), 4.05 (1H, br t, *J*=7.5 Hz, C(4)-H), 4.65 and 4.76 (each 1H, A and B parts of an ABq, *J*=6 Hz, $-OCH_2OCH_3$), 4.7—5.1 (5H, m), and 5.84 (1H, dd, *J*=10 and 17 Hz, $-\underset{|}{C}-CH=CH_2$); MS *m/z* (%) 193 [$(M-MOM)^+$, 4], 170 (36), and 108 (100). The fragment ion peak due to $(M-MOM)^+$ was observed at *m/z* 193.1236. Calcd for $C_{12}H_{17}O_2$: $M-C_2H_5O$, 193.1228.

Cyclodecadienone (12): (3R,1(10)E,4Z)-3-Methoxymethoxy-11,12,13-trinor-1(10),4-germacradien-6-one.[8] All the reactions were carried out under argon atmosphere. To a solution of potassium hydride (17 mg) in 10 ml of dry THF were added a THF (3 ml) solution of **11** (85.8 mg) and a solution of 18-crown-6 (107 mg) in THF (1.5 ml). After the mixture was refluxed for 1 h, the whole was cooled to room temperature, and subjected to ether extraction as usual. The products were separated by Florisil (7 g) column chromatography. Elution with hexane–ether (7:1) afforded the recovered starting material (**11**; 29.6 mg), and elution with hexane–ether (2:1) gave the cyclodecadienone (**12**; 37.5 mg): crystals, mp 52—53 °C (recrystallization from hexane), $[\alpha]_D^{11}$ −110.6° (*c* 3.02, EtOH); IR (film) 1680 and 1630 cm^{-1}; UV (EtOH) 235 nm (ε 5300); ^1H NMR ($CDCl_3$) δ=3.42 (3H, s, $-OCH_2OCH_3$), 4.65 and 4.67 (each 1H, A and B parts of an ABq, *J*=6 Hz, $-OCH_2OCH_3$), and signals listed in Table 1; MS *m/z* (%) 238 (M^+, 8), 193 (19), 169 (50), 81 (95), and 45 (100). Found: C, 70.47%; H, 9.57%. Calcd for $C_{14}H_{22}O_3$: C, 70.56%; H, 9.30%.

Keto Ester (13): *Ethyl (3R,7S,1(10)E,4Z)-3-Methoxymethoxy-6-oxo-13-nor-1(10),4-germecradien-12-oate.* A mixture of 1 ml of dry THF, 0.053 ml of diisopropylamine, and 0.24 ml of butyllithium (1.56 M hexane solution; 1 M=1 mol dm^{-3}) was stirred at −70 °C under nitrogen atmosphere, and a THF (1.5 ml) solution of **12** (74.7 mg) was added and the mixture was stirred at −70 °C for 45 min. Ethyl bromoacetate (0.15 ml) was added and the mixture was stirred at −23 °C (Dry Ice in carbon tetrachloride) for 5 h. Water was added and the mixture was extracted with ether as usual. Products were separated by Florisil (6 g) column chromatography. Elution with hexane–ethyl acetate (19:1) gave starting material (**12**; 26.2 mg). Elution with hexane–ethyl acetate (9:1) afforded the keto ester (**13**; 48.4 mg): an oil, $[\alpha]_D^{12}$ −39.5° (*c* 6.45, EtOH); IR (neat) 1735, 1680, and 1630 cm^{-1}; UV (EtOH) 238 nm (ε 5800); ^1H NMR ($CDCl_3$) δ=1.24 (3H, t, *J*=7 Hz, $-COOCH_2\underline{CH_3}$), 1.52 (3H, s, C(10)-Me), 1.80 (3H, s, C(4)-Me), 3.42 (3H, s, $-OCH_2OC\underline{H_3}$), 4.11 (2H, q, *J*=7 Hz, $-COOC\underline{H_2}CH_3$), 4.65 (2H, s, $-OC\underline{H_2}OCH_3$), 4.91 (1H, dd, *J*=6 and 11.5 Hz, C(3β)-H), 5.01 (1H, t, *J*=7 Hz, C(1)-H), and 6.23 (1H, br s, C(5)-H); MS *m/z* (%) 324 (M^+, 4), 255 (40), and 45 (100). Found: *m/z* 324.1948. Calcd for $C_{18}H_{28}O_5$: M, 324.1937.

Sodium Borohydride Reduction of the Keto Ester (13). Sodium borohydride (*ca.* 70 mg) was added to an ethanol solution (15 ml) of the keto ester (**13**; 76.3 mg), and the mixture was stirred at room temperature for 2 d. After addition of acetone to decompose the excess sodium borohydride and removal of solvent *in vacuo*, the products were extracted with ether as usual. The products were separated by Florisil (7 g) column chromatography. Elution with hexane–ethyl acetate (4:1) afforded the recovered starting material (**13**; 17.8 mg), the lactone (**5**; 5.2 mg), and a keto alcohol (9.8 mg). Elution with ethyl acetate gave a diol (7.5 mg). (3*R*, 6*R*,7*S*,1(10)*E*,4*Z*)-3-Methoxymethoxy-13-nor-1(10),4-germacradieno-12,6-lactone (**5**): an oil, $[\alpha]_D^{24}$ −110° (*c* 0.70, EtOH); IR (neat) 1765 cm^{-1}; ^1H NMR ($CDCl_3$) δ=1.46 (3H, s), 1.75 (3H, s), 3.36 (3H, s, $-OCH_2OC\underline{H_3}$), 4.36 (1H, t, *J*=3 Hz, C(3β)-H), 4.51 and 4.65 (each 1H, A and B parts of an ABq, *J*=6.5 Hz, $-OC\underline{H_2}OCH_3$), 5.37 (2H, m, C(1)-H and C(5)-H), and 6.01 (1H, dd, *J*=7 and 11 Hz, C(6)-H); MS *m/z* (%) 280 (M^+, 6), 248 (10), and 159 (100). Found: *m/z* 280.1656. Calcd for $C_{16}H_{24}O_4$: M, 280.1673.

Hydrolysis of the Keto Ester (13). As it was rather hard to separate **13** from **12** by Florisil column chromatography, the hydrolysis of a mixture of **12** and **13** was examined. To the mixture of **12** and **13** (35.6 mg) was added potassium carbonate (45 mg) in 80% aqueous methanol (3 ml), and the whole was stirred at room temperature for 8 h. After addition of water and evaporation of methanol, the mixture was extracted with ether. Aqueous layer was adjusted to approximately pH 3 by addition of dil. HCl, and was extracted with dichloromethane several times. From the ether layer 14.0 mg of **12** was recovered, and from the dichloromethane layer 18.3 mg of keto acid (**15**) was obtained. (3*R*,7*S*,1(10)*E*,4*Z*)-3-Methoxymethoxy-6-oxo-13-nor-1(10),4-germacradien-12-oic acid (**15**): an oil; IR (neat) 3400—2500 (br), 1710, and 1685 cm^{-1}; ^1H NMR ($CDCl_3$) δ= 1.52 (3H, s, C(10)-Me), 1.80 (3H, s, C(4)-Me), 3.07 (3H, s, $-OCH_2OC\underline{H_3}$), 4.63 (2H, s, $-OC\underline{H_2}OCH_3$), 4.96 (2H, m, C(1)-H and C(3β)-H), 6.20 (1H, m, C(5)-H), and 7.83 (1H, br, -COOH).

(3R,6S,7S,1(10)E,4Z)-3-Methoxymethoxy-13-nor-1(10),4-germacradieno-12,6-lactone (4). A mixture of the keto acid (**15**; 23.3 mg) in dry THF (2 ml) and about 10 mg of lithium borohydride was stirred at room temperature for 20 h. After addition of water and evaporation of THF, dil.HCl was gradually added to pH 4—5, and dichloromethane extraction was carried out several times. The extract was dried over sodium sulfate, and was concentrated into *ca.* 1 ml *in vacuo*. Toluene (6 ml) was added and the solvent (mainly dichloromethane) was removed under atmospheric pressure to give toluene solution (*ca.* 4 ml). To this toluene solution was added 0.03 ml of *N,N*-dimethylformamide dineopentyl acetal in toluene (0.4 ml), and the mixture was refluxed for 2 h. After removal of solvent, the reaction mixture was charged onto silica gel (*ca.* 3 g) column chromatography. Elution with benzene–ethyl acetate (5:1) gave 3.2 mg of *trans*-lactone (**4**), which was purified through HPLC (μ-Porasil; CH_2Cl_2). **4**: an oil, $[\alpha]_D^{19}$ +61° (*c* 0.04, EtOH); IR (neat) 1770 cm^{-1}; ^1H NMR ($CDCl_3$) δ=1.59 (3H, s, C(4)-Me), 1.75 (3H, br, C(10)-Me), 3.37 (3H, s, $-OCH_2OC\underline{H_3}$), 4.20 (1H, dd, *J*=6 and 9.5 Hz, C(3β)-H), 4.48 and 4.57 (each 1H, A and B parts of an ABq, *J*=7 Hz, $-OC\underline{H_2}OCH_3$), 4.55 (1H, br, C(1)-H), and 5.12 (2H, br, C(5)-H, and C(6β)-H) [Corresponding signals of eupasimplicin A (**17**)[20]: δ=5.60 (1H, dd, *J*=5 and 11 Hz, C(3β)-H) and 5.25 (2H, br, C(5)-H and C(6β)-H]; MS m/z (%) 280 (M^+, 1), 282 (12), and 81 (100). Found: *m/z* 280.1672. Calcd for $C_{16}H_{24}O_4$: M, 280.1672.

Hexacarbonylmolybdenum-induced Reaction of Isoxazoles. Cycloaddition of Isoxazoles with Acetylenic Esters and Related Reactions[1)]

Tomoshige KOBAYASHI and Makoto NITTA*
Department of Chemistry, School of Science and Engineering, Waseda University, Shinjuku-ku, Tokyo 160
(Received June 16, 1984)

In the presence of hexacarbonylmolybdenum, substituted isoxazoles undergo a cycloaddition reaction with dimethyl acetylenedicarboxylate across the C-4–C-5 bond to give 3,4-bis(methoxycarbonyl)pyridine derivatives. In a similar cycloadition of isoxazoles with methyl propiolate, 4-(methoxycarbonyl)pyridine derivatives were also obtained. The β-carbon atom of methyl propiolate could intervene in the bonding with the C-5 position of the isoxazoles regioselectively. A mechanism involving a complexed 2-oxa-3-azabicyclo[3.2.0]hepta-3,6-diene derivative and the subsequent N–O and C-1–C-5 bond cleavage leading to a complexed (β-keto vinyl)nitrene intermediate is proposed for the formation of pyridine derivatives. In order to clarify the mechanistic aspect, the reaction of 4-phenyl-2-oxa-3-azabicyclo[3.2.0]hepta-3,6-diene and its related compounds were also studied to give pyridine derivatives.

An isoxazole ring system has been the subject of an extensive investigation for its useful synthetic transformations. Its photochemical[2)] and thermal[3] reactions have been shown to isomerize to the corresponding ketoazirine derivatives. The catalytic hydrogenation of isoxazoles to β-amino enones is widely applicable in synthesis.[4)] Previously, we showed that [$Fe(CO)_5$], [$Fe_2(CO)_9$], and [$Mo(CO)_6$] effect the reductive cleavage of the N–O bond of substituted isoxazoles to give β-amino enones under mild conditions in the presence of water.[5)]

In contrast to these ring cleavage reactions, the cycloaddition of simple isoxazoles with olefins or acetylenic esters has not been accomplished,[6)] although the heterodiene system of 2,1-benzisoxazole derivatives has been shown to undergo a Diels-Alder reaction with *N*-phenylmaleimide,[7)] benzyne,[8)] and dimethyl acetylenedicarboxylate.[9)] The Diels-Alder reaction of 2,1-benzisoxazole with maleic anhydride has been shown to give only a starting material,[10)] although in a previous paper the reaction was reported to proceed.[11)]

This paper describes a [$Mo(CO)_6$]-induced cycloaddition of 3,5-disubstituted isoxazoles (**1a—f**) with acetylenic esters across the C-4–C-5 bond and the subsequent elimination of an oxygen atom to give pyridine derivatives, albeit, in low yields. Furthermore, [$Mo(CO)_6$]-induced reactions of 4-phenyl-2-oxa-3-azabicyclo[3.2.0]hepta-3,6-diene (**17**) and its related compound, **18** and **22**, were also studied to assess the mechanistic aspect of the above-mentioned cycloaddition reaction.

Results and Discussion

A benzene solution of isoxazoles **1a—f**, dimethyl acetylenedicarboxylate (DMAD), and [$Mo(CO)_6$] was refluxed for an adequate period to give the pyridine derivatives **2a—f**, as shown in Scheme 1. The reaction conditions and the yields of the products are summarized in Table 1 (Entries 1—6). The yields of the pyridines are rather poor and each of the reactions was accompanied by the formation of hexamethyl benzenehexacarboxylate (**4**) (10—20% yield based on DMAD used) and a mixture of more than three compounds. The latter mixture seemed to contain no methoxycarbonyl group and could not be separated. Thus, the structures have not been elucidated. Compound **4** could possibly be derived from [$Mo(CO)_6$]-induced trimerization of DMAD.[12)]

A similar reaction of isoxazoles **1a,d,e** with methyl propiolate (MP) afforded the pyridine derivatives **3a,d**. No pyridine bearing a methoxycarbonyl group at the 3-position could be detected. This fact clearly indicates that the β-carbon atom of MP connects regioselectively with the C-5-carbon atom of the isoxazole ring. In this case, the trimerization of MP was not observed. Since the thermal treatment of the isoxazole **1a** with DMAD in refluxing benzene afforded no adduct and **1a** was recovered quantitatively, [$Mo(CO)_6$] is indispensable for the present reaction.

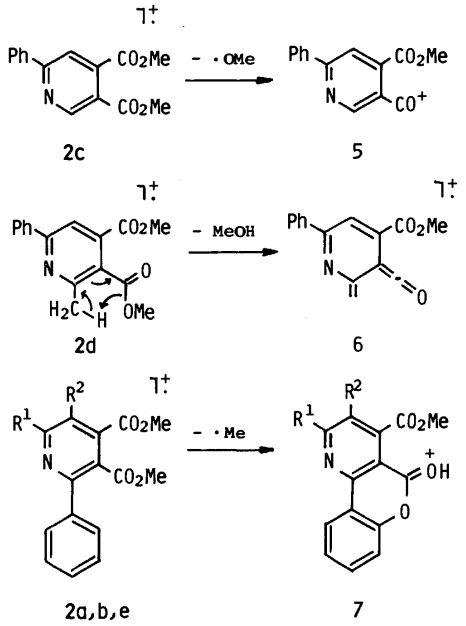
Scheme 1.

Table 1. Reaction of isoxazoles **1a—f** with acetylenic esters[a] in the presence of $[Mo(CO)_6]$[b]

Entry	Isoxazole	Acetylenic Ester	Reaction Time/h	Pyridine (Yield/%)
1	**1a**	DMAD[c]	24	**2a** (28)
2	**1b**	DMAD	24	**2b** (22)
3	**1c**	DMAD	24	**2c** (16)
4	**1d**	DMAD	24	**2d** (26)
5	**1e**	DMAD	10	**2e** (12)
6	**1f**	DMAD	20	**2f** (11)
7	**1a**	MP[c]	24	**3a** (19)
8	**1d**	MP	20	**3d** (21)
9	**1e**	MP	10	**3d** (19)

a) 2.0 Molar equivalent of acetylenic ester to **1** was used. b) 1.0 Molar equivalent of $[Mo(CO)_6]$ to **1** was used. c) DMAD: dimethyl acetylenedicarboxylate; MP: methyl propiolate.



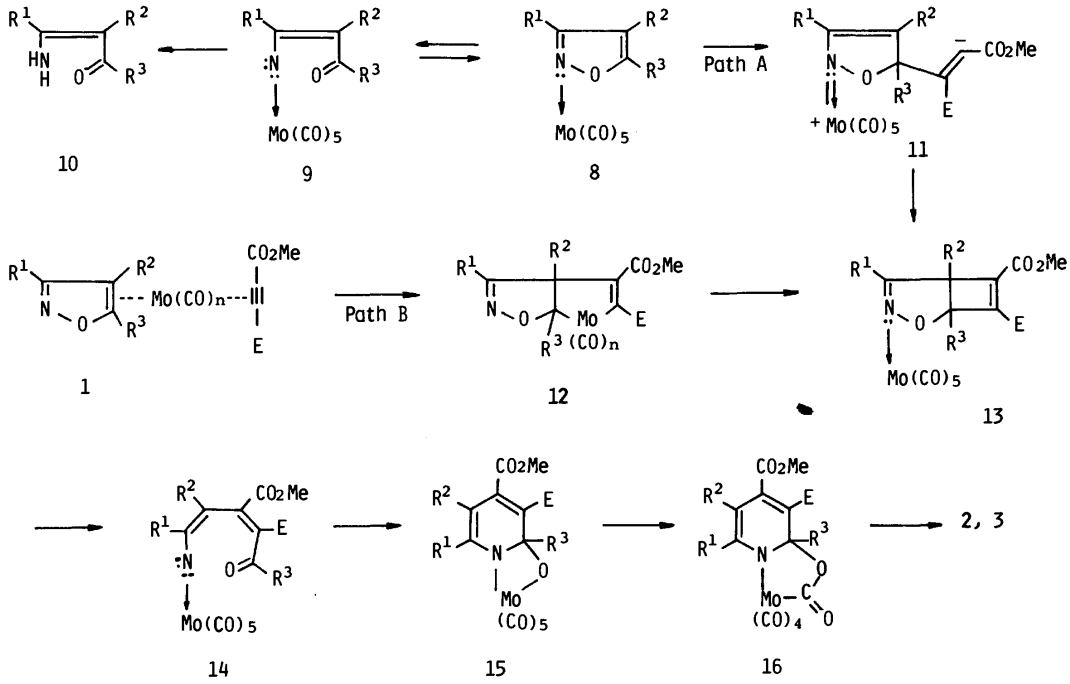
Scheme 2.

The structures of the pyridines were established by their spectral properties (NMR, IR, MS, and in part UV) and by a comparison of the physical data (mp and bp) with those of the authentic specimens. Only the pyridines, **2a** and **2f**, are new compounds. A comparison of their mass spectra revealed the position of the substituents. The main fragmentation pathways of the pyridines are illustrated in Scheme 2. The pyridine **2c** gives the ion **5** with *m/z* 240 (M^+-31), which is derived from the elimination of the MeO group. This fragmentation pattern is generally observed for compounds **2a—f** and **3a,d**. On the other hand, **2d** gives the ion **6** with *m/z* 253 (M^+-32), in addition to an ion with *m/z* 254 (M^+-31). The ion **6** indicates a loss of a methanol molecule through a general "ortho" effect. However, the spectrum of **3d**, which has a methoxycarbonyl group at the 4-position, did not exhibit the corresponding ion of M^+-32. Furthermore, **2a**, **2b**, and **2e**, all of which have a phenyl group adjacent to the methoxycarbonyl group at the 3-position, exhibit an ion of M^+-15 along with an ion of M^+-31. The former ion would be derived from a loss of a methyl group to give the ion **7**, which is stabilized by the phenyl group.[13] The mass spectrum of **3a** did not exhibit the corresponding ion of M^+-15. A comparison of the mass spectral data of the new pyridines with those typical fragmentations and the reaction sequences of the present reaction (*vide infra*) revealed the structure of **2a** and **2f** unequivacally.

Possible mechanistic pathways for the formation of the pyridines are outlined in Scheme 3. An initial complexation of the isoxazole to $[Mo(CO)_6]$ would give the n-donor complex **8**,[5] which has been shown to undergo an N-O bond cleavage to give the complexed nitrene intermediate **9**, collapsing to the corresponding β-amino enone **10** in the presence of water.[5] The factor allowing the facile N-O bond cleavage of **8** could be attributed to the delocalization of the p-d electron from molybdenum to the π* orbital of the isoxazole.[5] The addition reaction of several β-amino enones with DMAD has been shown to give no pyridines.[14] Furthermore, the β-amino enone, which is derived from the isoxazoles **1a**, did not undergo a reaction with DMAD under the present conditions. In the presence of DMAD or MP, **8** may undergo cycloaddition to give complex **13** *via* **11** (Path A). In the case of MP, the C-5-atom of the isoxazole in **8** seems to attack the more electron-deficient β-carbon atom of MP to afford **13** (E=H) (Path A). The regioselectivity affording **3a,d**, which have a methoxycarbonyl group at the 4-position, originate at this stage.

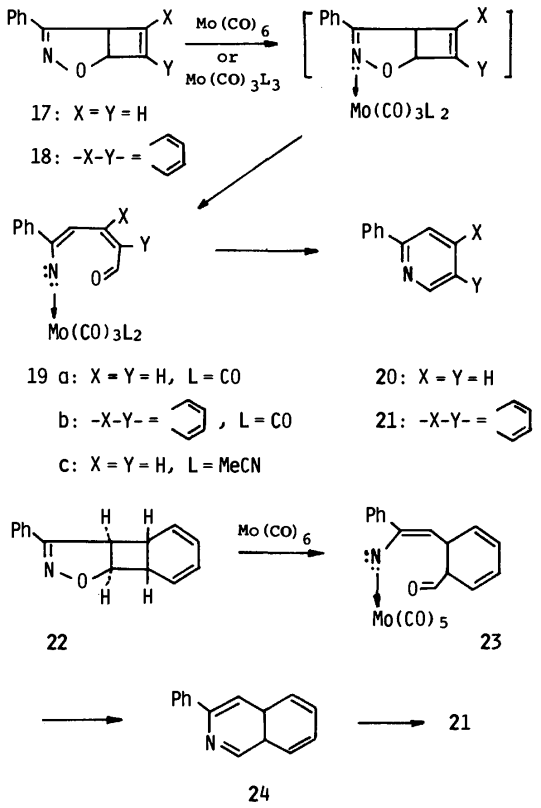
On the other hand, $[Mo(CO)_6]$-induced cyclobutane formation has been proposed for the reaction of 3-phenyl-2*H*-azirines with DMAD.[15] In some cases, $[Mo(CO)_6]$ has also been used for the metathetic reaction of acetylenes.[16] Therefore, an alternative mechanistic possibility may be a [2+2] cross-cycloaddition between **1** and an acetylenic ester to give **13** *via* a metallacycle such as **12** (Path B). Considering the facile n-donor complexation[5] of the isoxazole with $[Mo(CO)_6]$ species as well as the regioselectivity giving **3a,d**, Path A seems to be plausible over Path B.

It has been shown that the N-O and C-4-C-5 bond cleavage of 3,5-disubstituted isoxazolines afford the corresponding aldehydes and the complexed nitrene intermediate in the presence of $[Fe(CO)_5]$, $[Fe_2(CO)_9]$,[17] or $[Mo(CO)_6]$.[18] In a similar fashion, **13** would give the complexed nitrene intermediate **14**. The cyclization of **14** to produce **15** and the following ligand migration gives **16**, which collapses to afford the pyridines **2** or **3**.[19]



Scheme 3.

In order to study the possible intervention of complexes such as **13** and **14**, we investigated the reaction of 4-phenyl-2-oxa-3-azabicyclo[3.2.0]hepta-3,6-diene (**17**) and its benzoannelated compound **18** with $[Mo(CO)_6]$. As shown in Scheme 4, the reaction of **17** or **18** in refluxing benzene gave 2-phenylpyridine (**20**) or 3-phenylisoquinoline (**21**) in a 76 or 65% yield, respectively. A complexed nitrene intermediate, such as **19a,b** (cf. **14**), which could be derived from the cleavage of the N-O and C-1-C-5 bonds of an isoxazoline moiety, would also be a reasonable intermediate in the transformations. Thus, the intermediacy of **13** and **14** in Scheme 3 seems to be plausible. The $[Mo(CO)_6]$-induced cleavage of **17** is very similar to the photochemical N-O and C-1-C-5 bond-cleavage of **17** to give 3-(3-phenylazirin-2-yl)acrolein.[20] This fact also suggests the delocalization of the p-d electron from molybdenum to the π^* orbital of the C=N-O moiety of the complexed **17**.[17] The *in situ* preparation of $[Mo(CO)_3(MeCN)_3]$,[21] and the subsequent reaction with **17** at an ambient temperature gave **20** in a 76% yield. This fact may suggest that the ligand-exchange reaction of $[Mo(CO)_3(MeCN)_3]$ with **17** proceeds under mild conditions as compared to that of $[Mo(CO)_6]$ with **17**. The N-O bond cleavage of the complexed **17** and the subsequent ring-annelation occurs even at ambient temperature.

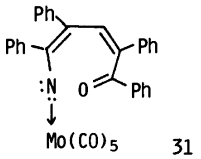


Scheme 4.

Furthermore, the reaction of **22**, which is a dihydrogenated analogue of **18**, with $[Mo(CO)_6]$ also afforded **21** in a 76% yield. The formation of **21** could be explained by an intervention of the complexed nitrene species **23**, ring-annelation giving **24**, and the subsequent dehydrogenation. Thus, the intramolecular ring-annelation of the complexed nitrene moiety with the carbonyl group, which is located in a preferable

stereochemical situation in compounds such as **14**, **19**, and **23**, seems to be general.

On the contrary, the complexed nitrene **31**, which is similar to **14** or **19a,b**, has been proposed as an intermediate of the $[Mo(CO)_6]$-induced transformation of (*Z*)-2-(3-oxo-1-phenyl)-2*H*-azirine derivative to pyrrole derivatives.[22] The yields of the products have not been mentioned, and no pyridine derivative has been obtained.[22] The steric and/or electronic effect of the benzoyl group in **31** seems to be reflected in the reaction pathway giving pyrrole derivatives. In contrast, the complex **14** or **19** bearing a benzoyl, acetyl, or formyl group could give only a pyridine ring. This fact may suggest that the electron-withdrawing property of the methoxycarbonyl group also affects the reaction pathway. A further confirmation of this point may be necessary.



31

Scheme 5.

In conclusion, the $[Mo(CO)_6]$-induced cycloaddition of isoxazoles with acetylenic esters was suggested to give a 2-oxa-3-azabicyclo[3.2.0]hepta-3,6-diene skeleton. The N-O and C-1-C-5 bond-cleavage of the ring system was indicated to give the complexed (β-keto vinyl)nitrene intermediate, which collapses to the pyridine ring. The present reaction could also serve as a convenient method for the preparation of a series of [6](2,5)pyridinophane ring system.[23]

Experimental

The IR spectra were recorded on a Shimadzu IR-400 spectrometer. The NMR spectra were recorded on a Hitachi R-24 spectrometer and the chemical shifts are given in ppm (δ) relative to an internal $SiMe_4$ standard. Mass spectral studies were conducted using Hitachi RMU-60 spectrometer. All of the $[Mo(CO)_6]$-induced reactions were carried out under a dry nitrogen atmosphere. Solvents were purified and dried by the standard methods. The isoxazoles **1a**,[24] **1b**,[25] **1c**,[26] **1e**,[27] 2-oxa-3-azabicyclo[3.2.0]hepta-3,6-diene derivatives **17**,[28] and **18**[29] were prepared by methods described in the literature. The isoxazole **1f** was prepared by a procedure similar to that for 1c and was identified on the basis of physical data.[30] All of the melting points were uncorrected.

Preparation of Isoxazole **1d**. To a solution of benzhydroximoyl chloride (1.56 g, 10 mmol) and isopropenyl acetate (3.0 g, 30 mmol) in ether (100 cm^3), triethylamine (5 cm^3) was added over 1 h at 0 °C. After the mixture was stirred for 20 h, it was extracted with ether. The ether extract was dried over $MgSO_4$ and concentrated to give a crude product. This was purified by column chromatography on silica gel to give **1d** (794 mg, 50%); mp 41—42 °C (from hexane) (lit,[31] 42—43 °C); NMR ($CDCl_3$), δ=2.25 (3H, s), 6.10 (1H, s), 7.20—7.40 (3H, m), 7.60—7.80 (2H, m).

General Procedure for the Reaction of Isoxazoles **1a—f** *with DMAD in the Presence of* $[Mo(CO)_6]$. A solution of isoxazole **1** (2 mmol), DMAD (568 mg, 4 mmol), and $[Mo(CO)_6]$ (528 mg, 2 mmol) in benzene (10 cm^3) was refluxed for an adequate period. To this reaction mixture, hexane (10 cm^3) was added and filtered through Celite to remove insoluble materials. The filtrate was concentrated and the residue was separated by TLC on silica gel using chloroform as the eluent to give the pyridine derivative **2**, along with hexamethyl benzenehexacarboxylate (**4**)[12] (10—20% yield based on DMAD used) and an unidentified mixture (30—40 mg). The reaction times and the yields of the pyridines are summarized in Table 1. The structural proof for the pyridine derivatives **2a—f** were based on the following physical data. 3,4-Bis(methoxycarbonyl)-2,6-diphenylpyridine **2a**: mp 104—105 °C; IR (CCl_4), 1733 cm^{-1}; NMR (CCl_4), δ=3.72 (3H, s), 3.96 (3H, s), 7.20—7.80 (8H, m), 8.00—8.20 (2H, m), 8.17 (1H, s); MS, *m/z* (rel intensity), 347 (M^+, 41), 332 (100), 317 (5), 316 (22). Found: C, 72.91; H, 5.19; N, 4.11%. Calcd for $C_{21}H_{17}NO_4$: C, 72.61; H, 4.93; N, 4.03%. 3,4-Bis(methoxycarbonyl)-2,5,6-triphenylpyridine **2b**: mp 221—222 °C (from benzene)(lit,[32-34] 222—223 °C, 231 °C); IR ($CHCl_3$), 1742, 1739 cm^{-1}; NMR ($CDCl_3$), δ=3.57 (3H, s), 3.67 (3H, s), 7.10—7.80 (15H, m); MS, *m/z* (rel intensity), 423 (M^+, 100), 422 (89), 408 (48), 392 (13), 390 (13), 376 (17). 3,4-Bis(methoxycarbonyl)-6-phenylpyridine **2c**: mp 72.5—73 °C (from hexane) (lit,[35] 74 °C); IR ($CHCl_3$), 1731 cm^{-1}; UV (EtOH), λ_{max} (logε), 262 (4.28), 297 (4.33); NMR ($CDCl_3$), 3.96 (3H, s) 3.98 (3H, s), 7.35—7.60 (3H, m), 7.90 (1H, s), 7.95—8.20 (2H, m), 9.13 (1H, s); MS, *m/z* (rel intensity), 271 (M^+, 91), 240 (100), 236 (11), 212 (13). 3,4-Bis(methoxycarbonyl)-2-methyl-6-phenylpyridine **2d**: bp 140—150 °C (bath temp)/13.3 Pa [lit,[36] 175—185 °C (bath temp)/26.6 Pa]; IR ($CHCl_3$), 1743 cm^{-1}; UV (EtOH), λ_{max} (logε), 252 (4.33), 305 (4.24); NMR ($CDCl_3$), δ=2.70 (3H, s), 3.97 (3H, s), 3.98 (3H, s), 7.30—7.60 (3H, m), 7.85—8.20 (2H, m), 8.05 (1H, s); MS, *m/z* (rel intensity), 285 (M^+, 79), 254 (77), 253 (100), 226 (7), 195 (72), 167 (16). 3,4-Bis(methoxycarbonyl)-6-methyl-2-phenylpyridine **2e**: mp 116—117 °C (from CCl_4) (lit,[37] 215—217 °C); IR ($CHCl_3$), 1730 cm^{-1} NMR ($CDCl_3$), δ=2.65 (3H, s), 3.68 (3H, s), 3.88 (3H, s), 7.27—7.77 (5H, m), 7.55 (1H, s); MS, *m/z* (rel intensity), 285 (M^+, 34), 270 (100), 254 (39), 242 (9), 210 (2). 3,4-Bis(methoxycarbonyl)-6-(4-chlorophenyl)pyridine **2f**: mp 118—120 °C (from EtOH); IR ($CHCl_3$), 1724 cm^{-1}: NMR ($CDCl_3$), δ=3.92 (3H, s), 3.96 (3H, s), 7.45 (2H, d, *J*=8.8 Hz), 7.80 (1H, s), 7.95 (2H, d, *J*=8.8 Hz), 9.07 (1H, s); UV (EtOH), λ_{max} (logε), 266 (4.07), 276 (4.19); MS, *m/z* (rel intensity), 307 (M^+, 31), 305 (M^+, 100), 276 (27), 274 (72), 262 (1), 260 (3). Found: C, 58.97; H, 3.86; N, 4.79%. Calcd for $C_{15}H_{12}ClNO_4$: C, 58.93; H, 3.96; N, 4.58%.

General Procedure for the Reaction of Isoxazoles **1a, d, e** *with Methyl Propiolate (MP) in the Presence of* $[Mo(CO)_6]$. A solution of isoxazole **1** (1 mmol), MP (168 mg, 2 mmol), and $[Mo(CO)_6]$ (264 mg, 1 mmol) in benzene (10 cm^3) was refluxed for an adequate period. To this reaction mixture, hexane (10 cm^3) was added and filtered through Celite. The filtrate was concentrated, and the residue was purified by TLC on silica gel using benzene as the eluent to give the pyridine derivative **3**. The reaction times and the yields of the pyridines are summarized in Table 1 (Entries 7—9). The pyridine derivatives **3a,d** are known compounds and were

identified on the basis of the following physical data. 4-Methoxycarbonyl-2,6-diphenylpyridine **3a**: mp 104—105 °C (from hexane) (lit,[38] 104—105.5 °C); IR ($CHCl_3$), 1730 cm^{-1}; NMR ($CDCl_3$), δ=4.05 (3H, s), 7.45—7.68 (3H, m), 8.15—8.40 (2H, m), 8.27 (2H, s); MS, *m/z* (rel intensity), 289 (M^+, 100), 258 (2), 231 (93). 4-Methoxycarbonyl-2-methyl-6-phenylpyridine **3d**: mp 55—57 °C (from hexane) (lit,[39] 59—60 °C); IR (CCl_4), 1733 cm^{-1}; NMR (CCl_4), δ=2.64 (3H, s), 3.89 (3H, s), 7.25—7.45 (3H, m), 7.50 (1H, d, *J*=1.2 Hz), 7.90—8.10 (2H, s), 7.97 (1H, d, *J*=1.2 Hz); MS, *m/z* (rel intensity), 227 (M^+, 100), 196 (7), 169 (19) 127 (19).

Reaction of 3-Amino-1,3-diphenyl-2-propenone ***10a*** *with DMAD in the presence of [Mo(CO)$_6$].* A solution of **10a** (223 mg, 1 mmol), DMAD (284 mg, 2 mmol), and [$Mo(CO)_6$] (268 mg, 1 mmol) in 10 cm^3 of benzene was refluxed for 24 h. After the evaporation of the solvent, the residue was purified by TLC on silica gel using chloroform as the eluent to give unreacted **10a** (211 mg, 95%).

Reaction of 17 with [Mo(CO)$_6$]. A solution of **17** (171 mg, 1 mmol) and [$Mo(CO)_6$] (264 mg, 1 mmol) in 10 cm^3 of benzene was refluxed for 18 h. To this reaction mixture, hexane (10 cm^3) was added and filtered through Celite. The filtrate was concentrated and the residue was purified by TLC on silica gel using benzene as the eluent to give 2-phenylpyridine (**20**)[40] (118 mg, 76%).

Reaction of 17 with [Mo(CO)$_3$(MeCN)$_3$]. A solution of [$Mo(CO)_3(MeCN)_3$] was prepared from [$Mo(CO)_6$] (528 mg, 2 mmol) in 3 cm^3 of acetonitrile under reflux for 4 h.[20] After this solution was cooled to the ambient temperature, **17** (171 mg, 1 mmol) was added to the solution and it was stirred for 18 h. A workup similar to the one described above gave **20** (117 mg, 76%).

Reaction of 18 with [Mo(CO)$_6$]. A solution of **18** (140 mg, 0.63 mmol) and [$Mo(CO)_6$] (167 mg, 0.63 mmol) in 10 cm^{-3} of benzene was refluxed for 6 h. To this reaction mixture, hexane (10 cm^3) was added and filtered through Celite. The filtrate was concentrated and the residue was purified by TLC on silica gel using benzene as the eluent to give 3-phenylisoquinoline (21) (85 mg, 65%); mp 103—103.5 °C (from hexane); (picrate, mp 196.5—198 °C (from methanol) (lit,[41] mp 102—103.5 °C; picrate, mp 197—199 °C).

Reaction of 22 with [Mo(CO)$_6$]. A solution of **22** (223 mg, 1 mmol) and [$Mo(CO)_6$] (264 mg, 1 mmol) in 10 cm^3 of benzene was refluxed for 22 h. A similar workup followed by TLC on silica gel gave **21** (131 mg, 64%).

Elucidation of the Origin of Substituent Effects. Theoretical Investigation of Field Effect in Aliphatic Systems by *ab initio* Molecular Orbital Calculation Using Simple Models

Naoki INAMOTO,* Shozo MASUDA, and Jun NIWA†

Department of Chemistry and Research Centre for Spectrochemistry, Faculty of Science, The University of Tokyo, Hongo, Tokyo 113

†*College of General Education, Nagoya University, Chikusa-ku, Nagoya 464*

(Received July 18, 1984)

The electronic substituent effect in the aliphatic systems was investigated using *ab initio* calculation at STO-3G and 4-31G levels. The relative energy changes, $\delta\Delta E$, in isodesmic reaction of the 4-substituted bicyclo[2.2.2]octane-1-carboxylic acids were compared with those for 1-substituted bicyclo[2.2.2]octanes(XC_8H_{13}), CH_3X, and H-X molecules perturbed with isolated pure point charges. The interaction energies between isolated dipole and point charge system, F-H···(±), were proportional to the reciprocal square of the distance between the center of dipole and the charge. Isodesmic reaction energies for the present systems at the distance longer than 5 Å can be practically explained by charge-dipole interaction. From the comparison of $\delta\Delta E$ in XCH_3···(±), XC_8H_{13}···(±), and XC_6H_5···(±) systems with those for X-H···(±), it was concluded that the pure field parameters for various substituents should be determined on the basis of the isodesmic reaction energy for X-H···(±) system. Correlations between $\delta\Delta E$ in X-H···(±) system and the field parameters recently proposed, σ_F and σ_I(gas), were generally better in the cases calculated at 4-31G level than those at STO-3G level.

The effect of a partial structural change on the chemical reactivities in organic compounds is one of long standing problems in physical organic chemistry.[1] Recently, some attempts to simplify complicated interactions in the systems have been made in order to make the physical meaning of substituent effect clear. Analyses of acidities and basicities in gas phase[2] free of solvent effect and *ab initio* molecular orbital (MO) calculations[3] of energy changes in isodesmic reactions[4] for isolated molecule systems[5] where only through-space effect is operative have deepened the understanding on the origin and mechanism of transmission of substituent effect.[1c-f]

Usually, the interactions between substituent and reaction (or probe) center have been explained in terms of four effects, namely, field effect (through-space effect),[1e,1f,6] σ-inductive effect (electronegativity or through-bonds effect),[7] resonance and hyperconjugation effects (charge transfer effect),[1,8] and polarization effect,[3a,8] although other effects have also been suggested.[1e]

We reported evidence for σ-inductive effect on spectral data at the adjacent position to substituent,[9] and established a reliable method to calculate inductive substituent parameters (ι; Gk., iota) as a measure of σ-inductive effect.[10] Reynolds, Taft, and Topsom[7] have reported that the charge densities at the hydrogen atom in the H-X molecules (at 6-31G* level) were well correlated with the group electronegativities of the substituents, because of the absence of the hyperconjugative interaction, and soon after, we also showed a similar relationship with our revised electronegativities.[11]

On the other hand, Streitwieser *et al.*[12] reported the results of *ab initio* MO calculations for the monosubstituted benzenes perturbed with positive and negative unit charges as a simple model of substituent effect, and suggested that the highly or weakly polarizable groups should not be included in the Hammett relationship on the basis same as normal substituents.

Recently, the scales of field effect (T_F,[13] σ_I(STO-3G),[10] F°,[8] and σ_F[7]) have been proposed on the basis of *ab initio* calculations of appropriate model systems at the STO-3G and 4-31G levels. However, usefulness of these scales is not so clear. Then we expected that a satisfactory interpretation for substituent effect might be obtained from a comparison of the energy changes in isodesmic reaction of 4-substituted bicyclo[2.2.2]octane-1-carboxylic acids (**1**) with those of 1-substituted bicyclo[2.2.2]octane perturbed with positive and negative point charges (**2**) as a simple model, though the acidities of **1** in gas phase have not been reported.

4

Systematic *ab initio* MO calculations for the through-space field effect in σ-bond systems **2**—**4** were

also carried out using perturbation with pure point charges to model nonbonded reaction center.

Calculation Methods

Calculations were performed on the *ab initio* STO-3G[14a] or/and 4-31G[14b] levels using the Gaussian-70[14c] and 80[14d] series of computer program, and the molecular geometries were taken from experimentally determined values.[15] The geometry of the carboxylate moiety in **1** was obtained to be $r_{C\text{-}O}$=1.27 Å and ∠OCO=130.4° from the optimized geometry of formate ion at the STO-3G level, and assumed to be constant for all substituted derivatives (**1**). The geometry of a pure dipole "substituent" having positive and negative point charges is the same as that used by Streitwieser *et al.*[12]

In other systems (**2**—**4**), perturbation of the systems was induced by both positive and negative point charges. The point charge was located at 1 Å from the 4-hydrogen atom in **2**, and at 4.7 Å from the methyl carbon and hydrogen atoms in **3** and **4**, respectively, along the X-C bond. Thus, the distances (4.7 Å) between *ipso*-carbon atom (hydrogen atom in **4**) and point charge in **2**—**4** are almost equal to that (4.67 Å) between C_4 atom and reaction center in **1**.

The following isodesmic reaction (Eq. 1) was used to evaluate the substituent effect on the above perturbed systems:

$$\underset{\mathbf{A}}{\text{X-R}} + \underset{\mathbf{B}}{\text{H-R}\cdots(\pm)} \rightleftharpoons \underset{\mathbf{C}}{\text{H-R}} + \underset{\mathbf{D}}{\text{X-R}\cdots(\pm)} \quad (1)$$

where X represents substituent and R-H is parent compound. The relative energy change ($\delta\Delta E$) in the above isodesmic reaction was obtained using Eq. 2.

$$\delta\Delta E = (E_C+E_D) - (E_A+E_B) = (E_D-E_A) - (E_B-E_C) = \Delta E_X - \Delta E_H \quad (2)$$

A negative value in $\delta\Delta E$ corresponds to a stabilizing effect compared with that of parent compound. All calculations were carried out on a FACOM M-382 computer at the Nagoya University Computation Center.

Results and Discussion

The total energies of the carboxylic acids (**1**) and the corresponding carboxylate ions, the relative energy changes ($\delta\Delta E$) in the isodesmic reaction (Eq. 3) of the series **1**,

$$XC_8H_{12}CO_2H + C_8H_{13}CO_2^- \rightleftharpoons C_8H_{13}CO_2H + XC_8H_{12}CO_2^- \quad (3)$$

and the relative charge densities (Δq_H) at the carboxyl hydrogen atom in **1** are given in Table 1.

The linear relationships between $\delta\Delta E$ and charge densities at a particular atom have been shown in the alkyl chlorides (STO-3G),[16] substituted phenols and benzoic acids (INDO[17] and STO-3G[18]), aliphatic aldehydes (STO-3G),[19] substituted anilines and toluenes (STO-3G),[20] and several isolated molecule systems.[6,13]

Correlation between the relative energy changes in the isodesmic reaction ($\delta\Delta E_{(1)}$) and Δq_H in the series **1** is as follows:

$$\delta\Delta E_{(1)} = 2135\Delta q_H - 0.056 \quad (r=0.9985,\ n=9,\ f=0.045)$$

Analogous correlation of $\delta\Delta E_{(1)}$ with $\Delta\sum q_O$(COOH) or $\Delta\sum q_O(COO^-)$, which is the sum of the relative charges on the both oxygen atoms in the carboxyl group of the series **1** or those in the corresponding carboxylate, respectively (see Table 1), shows that $\Delta\sum q_O(COO^-)$ can be used as a measure of $\delta\Delta E_{(1)}$ similarly to Δq_H, as shown in the following equations.

$$\delta\Delta E_{(1)} = -1352\Delta\Sigma q_o(\mathrm{COOH}) - 0.327 \quad (r=0.943,\ n=9)$$

$$\delta\Delta E_{(1)} = -982\Delta\Sigma q_o(\mathrm{COO^-}) + 0.220 \quad (r=0.997,\ n=9)$$

In the case of the substituted phenols,[21] it has been found that the electron-donating groups deviate considerably from the correlation between the corresponding $\delta\Delta E$ values and the relative charges on the oxygen atom in the substituted phenoxides, because of conjugation of the oxide group with the π-electrons system.

The total energies of 1-substituted bicyclo[2.2.2]octanes, monosubstituted methanes, and H-X molecules at the STO-3G and 4-31G levels are given in Table 2. Table 3 shows $\delta\Delta E$ in the series **2**—**4** at both basis sets.

It was shown for the $CH_4\cdots(-)$ system as an example that the effect of slight change in bond length on $\delta\Delta E$ can be ignored in the case of the relative energy due to substituent effect as shown below. In Table 2, the C-H bond length of 1.10 Å was used. If the length is extend to 1.11 Å, the total energies of methane itself and methane perturbed with negative point charge were calculated to be −39.72450 and −39.72448 au, respectively. Thus the difference in $\delta\Delta E$ is 1×10^{-5} au (*ca.* 0.006 kcal mol^{-1} (1 cal=4.184 J)).

The electrostatic energy due to the interaction between dipole and point charge is calculated as the sum of the energies due to charge-permanent dipole interaction,[10] W_p (Eq. 4), and those due to charge-induced dipole interaction (polarizability effect),[10] W_α (Eq. 5):

$$W_p = -ep\cos\theta/(Dr^2) \quad (4)$$

$$W_\alpha = -e^2\alpha/(2Dr^4) \quad (5)$$

where e is the unit electric charge, p permanent dipole moment of substituent, θ the angle between the axis of dipole and the line joining the center of dipole and point charge, r the distance between the center of dipole and point charge, α group polarizability, and D dielectric constant of medium.

Recently, Yoder *et al.*[22] have evaluated the substituent effects on the energies of proton-transfer equilibria in gas phase using classical electrostatic model. Therefore, it is of interest to examine whether the electrostatic model can quantitatively account for the isodesmic reaction energies calculated by *ab initio* MO method in the cases of the systems **2**—**4**.

In order to test if Eq. 4 can be applied sufficiently to our models **2**—**4**, the perturbed energy changes at various distances between F-H, in which a contribution of polarizability effect is small because of a lower polarizability, and point charges were calculated at

the 4-31G level. The results are shown in Table 4. A plot of $\log|\delta\Delta E|$ against $-\log r$ using the values (r=3.0—13.0 Å) listed in Table 4 showed a straight line having slope of nearly 2 (*i.e.*, 1.90 and 1.85 for negative and positive charges, respectively), as expected from Eq. 4.

It has been found that the polarization of the π-electron of ethylene[23] by $\overset{+}{N}H_4$ species approximately follows Eq. 4.

The effect of change of r on electrostatic field energies expressed by Eqs. 4 and 5 was also examined using the dipole moment of p=2.95 D[24] (1 D=3.333×10^{-30} C m) in gas phase and the longitudinal bond polarizability of α=31.3×10^{-25} cm^3 [25] for hydrogen cyanide perturbed with both positive and negative point charges as an example. As seen in Fig. 1, the W_p values in the cases of negative and positive charges are mutually reverse in the sign, but the W_α values always correspond to stabilization for both charges. The contribution of W_α at very close distance (within r=2 Å) amounts to above 40% of W_p, but that at longer distances than 5 Å decreases up to below a few percents of W_p. Therefore, the magnitude of electrostatic field effects at such a longer distance can be approximately evaluated using only Eq. 4.

Table 5 summarizes the values p, θ, α, W_p, and W_α in the series **2**, where (4.7+0.5$r_{C\text{-}X}$) Å is used as r, and p and θ are the values calculated at the STO-3G level. Group polarizabilities of substituents (α)[26] were calculated from the values of bond refractivity (R_D) for the D line. The correlation between $\delta\Delta E_{(2)\cdot\cdot(\pm)}$ (Table 3) and W_p or (W_p+W_α) for both point charges in the series **2** are as follows:

$$\delta\Delta E_{(2)\cdot\cdot(-)} \begin{cases} = 0.994W_p^{(-)} - 0.153 & (r=0.993,\ n=8) \\ = 0.968(W_p+W_\alpha)^{(-)} + 0.057 & (r=0.992,\ n=8) \end{cases}$$

$$\delta\Delta E_{(2)\cdot\cdot(+)} \begin{cases} = 0.946W_p^{(+)} - 0.093 & (r=0.989,\ n=8) \\ = 0.971(W_p+W_\alpha)^{(+)} + 0.121 & (r=0.991,\ n=8) \end{cases}$$

Thus, it is clear again that $\delta\Delta E$ in the series **2** (at r=5.5 Å as a mean) can be nearly interpreted using only Eq. 4.

In order to clarify whether the substituent effect on the acid dissociation energy in vacuum can be explained by the interaction with the carboxylate group, we examined the correlation between the dissociation energies of **1** ($\delta\Delta E_{(1)}$, Table 1) and the perturbation energies of **2** ($\delta\Delta E_{(2)\cdot\cdot(-)}$, Table 3) with negative charge. In the both cases, the distance (r) is almost same. The following linear relationship having a slope of nearly 1 was obtained, indicating that σ-inductive effect is unimportant in the systems **1**.

$$\delta\Delta E_{(1)} = 0.988\delta\Delta E_{(2)\cdot\cdot(-)} + 0.078$$
$$(r=0.9999,\ n=8,\ f=0.019)$$

We now discuss the polarizability effect on $\delta\Delta E$ from a slightly different point of view. Figure 2 (A) shows a substantially linear plot of $\delta\Delta E$ for the series **4** perturbed with positive charge *vs.* those perturbed with a negative one. Figures 2 (B) and (C) are also similar plots for the series **3** and **2**, respectively, two separate lines being obtained as expected from the result of monosubstituted benzenes perturbed with point charges.[12]

These plots indicate that the substituent effects are not independent of the nature of probe charge and molecular system. Most substituents having relatively large polarizability fall below the dotted line drawn through hydrogen, fluorine atoms, and dipole substituent having rather small polarizability. In comparison of these series, the series **4** showed the least deviation among them, while, the extent of the deviation in the series **3** and **2** becomes larger as the size of substrate increases. Hence, the deviation is probably attributed to the difference in the polarizability of the whole molecule. Thus the substituent parameters defined from data of relatively large molecules are considered to result in broadly scattered values for both negative and positive reaction probes, even in the absence of any specific solvent effects.

The charges at the hydrogen atom in the H-X molecules are free from hyperconjugative interaction,[7] while σ- and π-interactions between substituent and methyl group in monosubstituted methanes occur in the same fashion as in monosubstituted benzenes.[27] Then, it is interesting to compare the $\delta\Delta E$ values in some series having π-character with the $\delta\Delta E$ values in the series **1**.

Figure 3 shows the plots of the $\delta\Delta E$ values in the series **3**, **2**, and monosubstituted benzenes *vs.* those in the series **4** using a negative point charge perturbation, respectively. The lines shown in Fig. 3 are those drawn through dipole substituent and hydrogen atom.

As pointed out by Streitwieser *et al.*,[12] the dipole substituent is a substituent having only "field effect," and the substituents which deviate from the line may be accompanied by some additional effects such as polarization and resonance effects. Since the direct resonance interaction with perturbing negative charge is impossible in the systems **2**—**4**, the deviation from

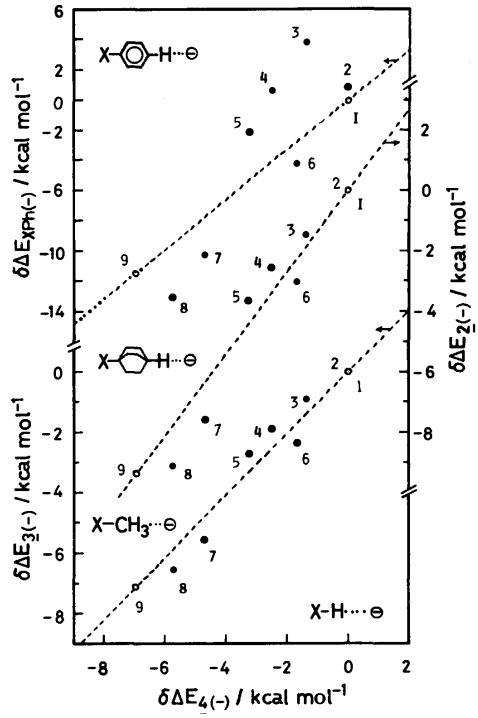

Fig. 3. Plots of the $\delta\Delta E$ in the series **3**, **2**, and monosubstituted benzenes *vs.* those in the series **4** using a negative point charge. 1: H, 2: CH_3, 3: NH_2, 4: OH, 5: F, 6: CHO, 7: CN, 8: NO_2, 9: Dipole.

the line shown in Fig. 3 must be attributed to the interaction of pseudo π-orbital of the methyl in the series **3** or alkyl group in the series **2** with appropriate orbital on the substituents.

Strong π-interaction is observed in the monosubstituted benzenes. For this negative point charge perturbation with substituted benzenes, the π-electron-donating groups such as fluoro, hydroxyl, amino, and methyl groups show a remarkable resonance destabilization, whereas the π-electron-withdrawing groups such as nitro, cyano, and formyl groups exhibit resonance stabilization.

However, deviation of electron-donating substituents from the line exhibits a different trend in aliphatic and aromatic series. From these analyses, it is concluded that pure field parameters for various substituents should reasonably be determined from the energy changes for the series of X-H··(±) system. Detailed analyses are in progress.

Finally, the correlation coefficients and slopes of the correlations between isodesmic energy changes ($\delta\Delta E$) and electrostatic energies (W_p) or various field parameters are summarized in Table 6. The σ_I(gas) values are those determined from acidities of phenols in gas phase.[2]

It is seen from Table 6 that the correlation coefficients using calculated electrostatic field energies (W_p) are generally quite good for all isodesmic energy changes. Correlations between $\delta\Delta E$ and σ_F or σ_I(gas) are generally better in the cases calculated at the 4-31G level than those calculated at the STO-3G level.

By the application of *ab initio* MO calculation, it was concluded that the field parameters, σ_I(gas), which were obtained from gas-phase acidities, can accurately be reproduced by $\delta\Delta E$ calculated at the 4-31G basis set. Thus, σ_I(gas) is a good measure of field effect in gas phase and *ab initio* calculation at the 4-31G basis set is the most suitable to examination of substituent effect, although the calculation is limited to rather small molecules for the present.

Cyclohepta[*b*][1,4]benzothiazines and Their Diazine Analogues. 1. Formation and Reactions of Cyclohepta-[*b*][1,4]benzothiazines[1]

Kimio SHINDO,* Sumio ISHIKAWA, and Tetsuo NOZOE*,†
Department of Chemistry, Faculty of Science, Josai University, 1-1 Keyakidai, Sakado-shi, Saitama 350-02

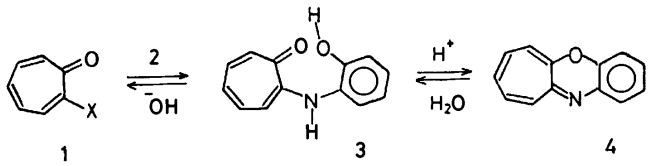
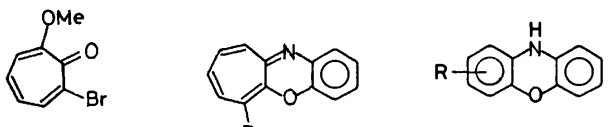
(Received July 18, 1984)

2-Chlorotropone reacted with *o*-aminobenzenethiol to give 2-(*o*-aminophenylthio)tropone, which readily cyclized in dilute methanolic HCl to afford the title benzothiazine (**9**). Although **9** was stable under basic conditions, its *N*-methyl cation reversibly afforded the ring-opened 2-[*o*-(methylamino)phenylthio]tropone in alkali. Oxidation of **9** with hydrogen peroxide in methanol underwent a rearrangement reaction to afford (exclusively) phenothiazine and its 1-formyl derivative. A similar H_2O_2 oxidation of 10-methoxycyclohepta[*b*][1,4]benzothiazine gave mainly methyl phenothiazine-1-carboxylate and 3-formyl-1-methoxy phenothiazine. Further oxidation of these products with hydrogen peroxide yielded thier *S*-oxides and *S,S*-dioxides. The reactivities of these cycloheptabenzothiazines are discussed in connection with those of the O- and N-analogues.

It was recently reported[2] by one of us (T.N.) that the condensation of 2-chloro- or 2-methoxytropone (**1a**, **b**) with *o*-aminophenol (**2**) gave 2-(*o*-hydroxyanilino)-tropone (**3**), which cyclized in acid to afford cyclohepta-[*b*][1,4]benzoxazine (**4**). Compound **4** and its derivatives were generally unstable in alkali (or, in some cases, even to the moisture in solvents) and readily reverted to **3** and further hydrolyzed to tropolone (**1**: X=OH) upon heating with an excess of alkali.[2,3]



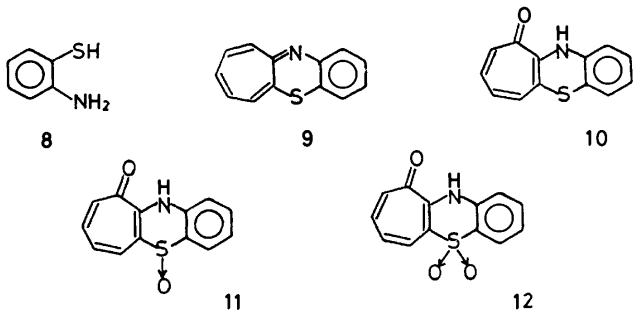
1 3 4



5 6 7

Moreover, reactive troponoids bearing two leaving groups, such as **5** and its isomers, were also found[4] to condense with **2**, to provide 6-bromocyclohepta[*b*]-[1,4]benzoxazine (**6**) and its isomers, which were then transformed into a wide variety of interesting derivatives of cycloheptabenzoxazine **4** and phenoxazine **7**.

This evidence led us to investigate the synthesis and properties of the S- and N-analogues of **4** in order to make a systematic study of these reactive troponoids fused with heterocycles.[5] Although the formation of cyclohepta[*b*][1,4]benzothiazine (**9**), corresponding 10(11*H*)-one **10**, and some of their derivatives from **1** (or **5**) and *o*-aminobenzenethiol (**8**), as well as the oxidative formation of *S*-oxide (**11**) and dioxide (**12**) with hydrogen peroxide, had been briefly reported earlier,[6,7] we now wish to describe their detailed preparation and



8 9 10

11 12

some new reactions of the title compound **9** and its derivatives.

Results and Discussion

We first studied the reaction of **1a** and **8** in methanol by means of reversed-phase, high-pressured liquid chromatography (HPLC). A stopped-flow apparatus was used to identify every product formed during the reaction[8] (see Fig. 1). It was found that an intermediate substance **14** that was formed at an early stage of the reaction was gradually transformed almost solely into the final product **9**. Besides these, the only remaining product detected was disulfide **13** from **8**. When the condensation of **1a** with **8** was conducted in the presence of an alkali in order to neutralize the liberated HCl, compound **14** (isolable as yellow needles, mp 120.5 °C) was produced exclusively. The 2-(*o*-aminophenylthio)tropone structure was unambiguously assigned to **14** on the basis of its IR, UV, NMR, and mass spectra as well as elemental analysis (for assignments of the spectral signals, see Experimental part). That the condensation of **1a** with **8** apparently took place by a nucleophilic attack of SH (rather than NH_2) group of **8** was in conformity with the generally known order of the nucleophilicity of these groups towards halotropones.[9]

The action of a trace amount of acid on **14** facilitated

cyclization to yield **9**, which remained stable and, in marked contrast to the afore-mentioned **4**, did not revert to **14** upon heating with methanolic potassium hydroxide. In a strong acid, compound **9** gave the red-colored monocation **9a** of a tropylium form as in the case of cation **4a** from **4**. It should be noted that these cationic species (**4a**,**9a**) are apparently different from the dark green-colored cation **15a** having a peripheral π-electron system which had been derived[5,10] from the N-analogue **15** in a strong acid.

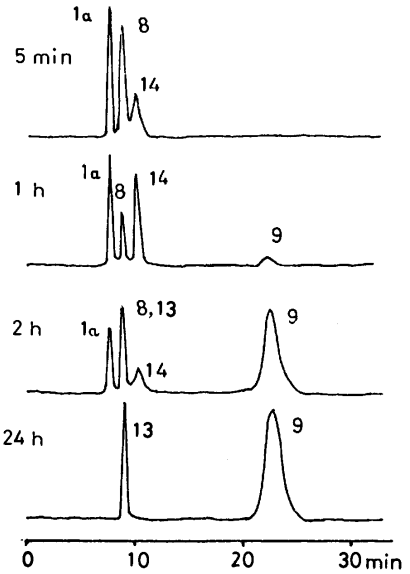


Fig. 1. Time dependent HPLC chromatogram of reaction of **1a** and **8** in MeOH at R.T.

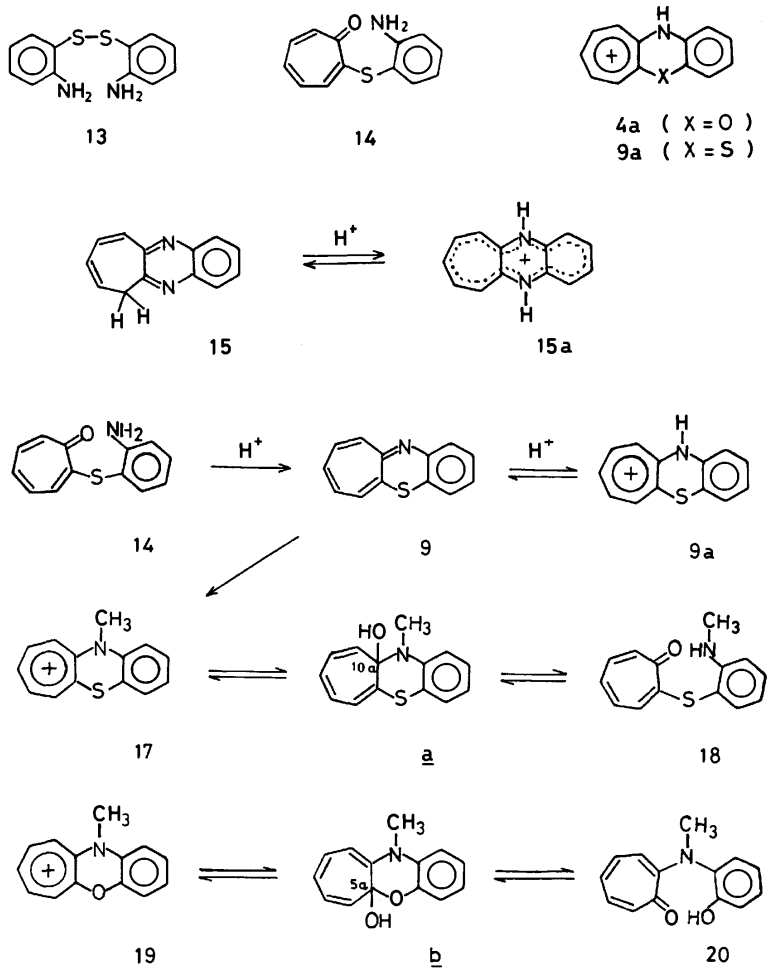
The treatment of **9** with methyl fluorosulfate (magic methyl) yielded an inseparable mixture of the *N*-methyl cation **17** (see below) and **9a**, which, on basification, gave yellow needless **18**, along with recovered **9**. The structure of **18** was established on the basis of the spectral data (see Experimental) which closely resembled those of **14**, except for the presence of the *N*-methyl proton signal (NMR) at δ 2.09. Upon acidification, **18** gave the cyclized product **17**, isolable as the dark red BF_4^- salt. An appreciable down-field shift of the proton signals of the seven-membered ring in the NMR spectrum was strongly indicative of the cation **17**, predominantly in the tropylium form.

When **4** was likewise treated with magic methyl for comparison, a mixture of a similar cation **19** and **4a** was produced, which in turn led to aminotropone **20** and **4** upon basification. The structure of **20** was derived from the spectral data. On acidification, **20**



was found to cyclize to give **19** (isolable as BF_4^- salt) much faster than the case of **18** to **17**. The fact that the cation **17** was susceptible to a nucleophilic attack by OH^- at the 10*a*-position to give thiotropone **18** *via* an intermediate a, whereas its O-analogue **19** afforded aminotropone **20** *via* intermediate b by the OH^- attack at the 5*a*-position, is in accord with the results of theoretical calculations regarding the reactivities of these systems.[11]

We then studied the behaviors of **4** and the S-analogue **9** towards hydrogen peroxide. Treatment of compound **4** with H_2O_2 in methanol gave mainly cyclohepta[*b*][1,4]benzoxazin-10(11*H*)-one (**21**), along with small proportions of the hydrolyzed product **3** (*ca.* 3%) and the rearranged 1-formylphenoxazine[4] (**22**) (<1%). In contrast to oxazine **4**, compound **9** was

21 22

found exclusively to give a wide variety of rearrangement products. A close examination of this reaction using time-dependent HPLC (see Fig. 2) revealed that at the initial stage of the reaction, two main peaks (due to intermediates **23** and **24**) were observed. These gradually transformed into **23a** and **24a** and a small proportion of an additional product (**25**), and then finally gave products **23a** and **24a,b** as the main products. Presumable sequences of this oxidation reaction are summarized in Scheme 1. Although

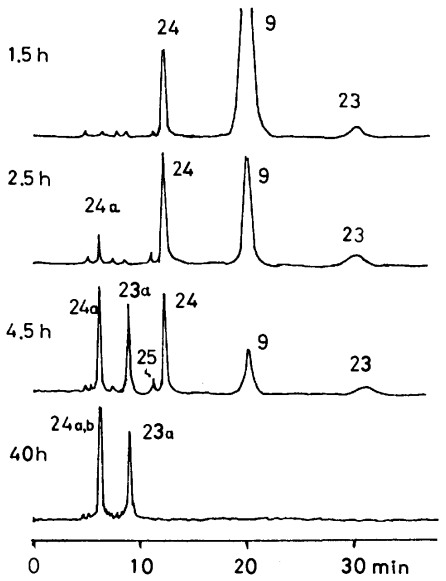


Fig. 2. Time dependent HPLC chromatogram of reaction of **9** and H_2O_2 in MeOH at R.T.

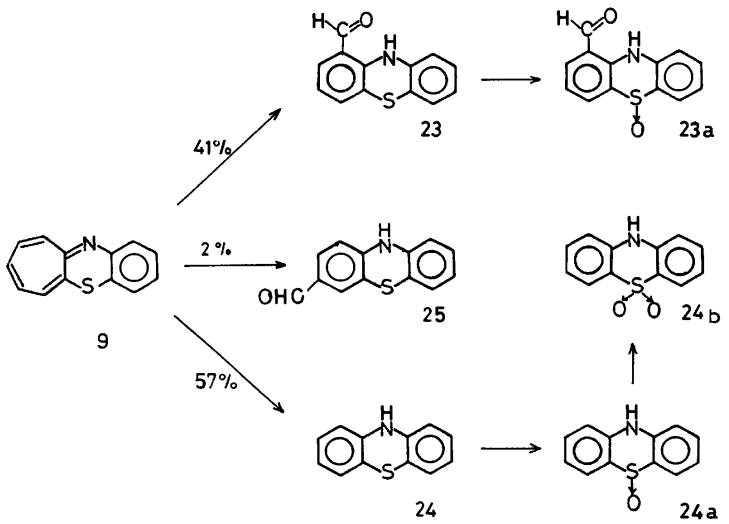

Scheme 1. H_2O_2 oxidation products from **9** in MeOH

compounds **23** and **25** both showed their molecular ion peaks at *m/z* 227 in the mass spectrum, the former (**23**) showed an IR absorption at 3300 cm^{-1} (NH) and characteristic ^{1}H-NMR signals at δ 10.00 (NH), 9.79 (CHO) and 7.17 (1H, dd, J=7.8 and 2.0 Hz), whereas the latter (**25**) showed the NH absorption at 3360 cm^{-1} and NMR signals at δ 8.90 (NH), 9.64 (CHO), and 7.30 (1H, d, J=1.8 Hz), thus permitting the assignments of 1-[12] and 3-formylphenothiazine structures to these products, respectively. Compound **24** was identified spectroscopically to be the known parent phenothiazine,[13] and **24a** and **24b** its *S*-monoxide and *S,S*-dioxides,[13] respectively. These *S*-oxides reverted to **23** and **24** upon redution with zinc duct.

In order to clarify the site of the H_2O_2 attack on the seven-membered ring of **9**, compound **26** (bearing a methoxyl group at the 10-position) was subjected to similar oxidation. The reaction was again monitored by periodical HPLC checking (see Fig. 3). Although the reaction appeared to be somewhat more complex compared with the oxidation of **9**, a transient product **27** and the final product **27a** were mainly formed. These compounds were identified by the spectral evidence to be methyl 1-phenothiazinecarboxylate[14] (**27**) and its *S*-oxide (**27a**). The probable sequences of this oxidation to yield these compounds and several minor products (**28**—**30**) are summarized in Scheme 2. The structure of 3-formyl-1-methoxyphenothiazine for **28** was derived from the NMR spectrum which showed two characteristic doublets at δ 7.12 and 7.04 (with J=1.5 Hz) due to isolated ring-protons, in addition to a singlet (δ 3.92) of a MeO group. Com ound **29** was identified to be 1-methoxyphenothia-

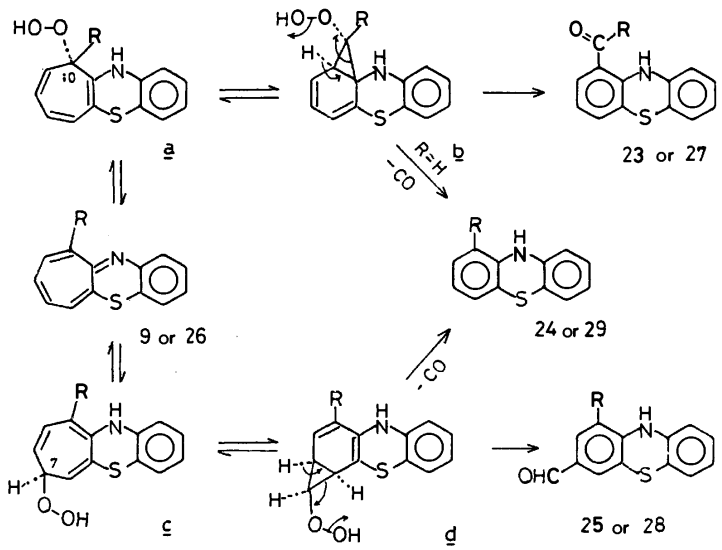
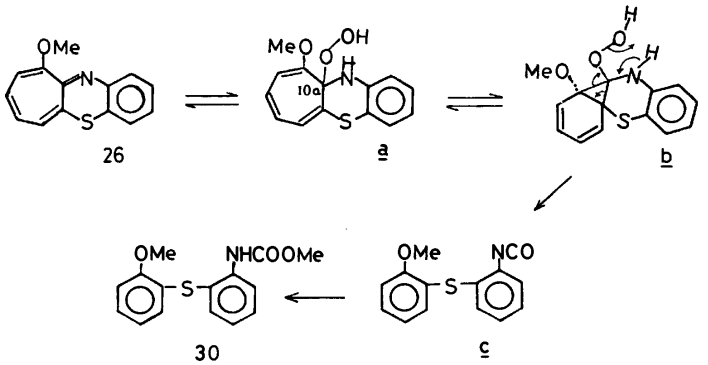


Scheme 3. R=H, OMe



Scheme 4.

zine[15] on the evidence of IR, NMR, and mass spectra. Oxidation of **29** was found to afford *S*-oxide **29a**. Compound **30** was assigned to be methyl 2-(*o*-methoxyphenylthio)phenylcarbamate from the IR, NMR, and MS spectra. In addition to these oxidation products, the hydrolyzed product **10** was also isolated.

Possible Reaction Pathways for the Oxidation of Cyclohepta[b][1,4]benzothiazines. The ring-contraction of **9** and **26** to **23—28** are most likely to proceed by a nucleophilic attack of H_2O_2 preferentially at the 10- and then, to a considerably less extent, 7-positions to yield the intermediates a and c, followed by the sequential steps illustrated in Scheme 3. On the other hand, the oxidative degradation of **26** to **30** is considered to be initiated by an attack of hydrogen peroxide at the 10*a* position, followed by similar ring-contraction (illustrated in Scheme 4). This order of reactivities of cycloheptabenzothiazines towards nucleophiles is generally in agreement with predictions based on theoretical calculations.[11]

Although the exact mechanism of these oxidations accompanied by such a variety of facile rearrengements (as well as other reactivities of the title compounds and their N-analogues) are currently under detailed investigation. The present experimental results further demonstrate a part of the diversity of chemical reactions involving troponoid compounds, particularly when fused with certain heterocycles.

Experimental

Melting points were determined with a Yanagimoto MP-3S and are uncorrected. The IR spectra were taken on a Shimazu IR-400 or IR-450, and the UV spectra were recorded with a Shimazu UV-202 or a Hitachi 557 spectrometer. The NMR spectra were recorded with JEOL JNM-PS100 (100-MHz) and GX270 (270-MHz) spectrometers using TMS as the internal standard. The mass spectra were taken on Shimazu LKB9000 and JEOL JMS-01SG mass spectrometers. The HPLC was carried out with Hitachi gel #3011 with MeOH–hexane (9:1) as the solvent. The UV spectra in acid and alkali were taken after adding a drop of 3M HCl or 3M NaOH (1M=1 mol dm^{-3}) to the sample solution. TLC analyses were carried out with Merk Kieselgel 60F-254 and Alminium oxide F-254 plates.

2-(o-Aminophenylthio)tropone (14). A solution of **1a** (200 mg, 1.4 mmol) in methanol (1 ml) was slowly added, with stirring at 0 °C, to a solution of **2** (200 mg, 1.6 mmol) and sodium hydroxide (170 mg, 4.2 mmol) in methanol (2 ml), and the mixture was allowed to stand for one day at −5—0 °C. The precipitates were collected and recrystallized from acetone to give **14** (304 mg, 93%) as yellow needles; mp 120.5 °C; UV (MeOH) 243, 340, and 367 nm (log ε 4.34, 3.98, and 3.97); IR (KBr) 3430, 3340 (NH_2), and 1610 cm^{-1} (C=O); ^1H NMR (270 MHz in C_6D_6) δ=3.55 (2H, br, NH_2), 5.93—5.98 (2H, m, H-4,5), 6.28 (1H, dd, *J*=8 and 1.5 Hz, H-3′), 6.31 (1H, m, H-6), 6.54 (1H, d, *J*=10 Hz, H-3), 6.55 (1H, m, *J*=8.8 and 1.5 Hz, H-5′ or 4′), 6.96 (1H, d, *J*=12 Hz, H-7), 7.01 (1H, m, *J*=8.8 and 1.5 Hz, H-4′ or 5′), and 7.28 (1H, dd, *J*=8 and 1.5 Hz, H-6′), (270 MHz in $CDCl_3$) δ=4.33 (2H, br, NH_2), 6.68 (1H, m, H-5 or 4), 6.80 (1H, t, *J*=8 Hz, H-5′), 6.88—6.92 (2H, H-3 and H-4 or 5), 6.86 (1H, d, *J*=8 Hz, H-3′), 7.13 (1H, d, *J*=12 Hz. H-7), 7.22 (1H, m, H-6), 7.30 (1H, t, *J*=8 Hz, H-4′), and 7.38 (1H, d, *J*=8 Hz, H-6′); ^{13}CNMR (67.8 MHz in $CDCl_3$) δ=183.5, 157.4, 149.3, 137.5, 136.4, 135.5, 132.8, 132.0, 130.5, 128.5, 115.7, and 112.2; MS *m/z* 229 (M^+);

Anal. ($C_{13}H_{11}NSO$) C, H, N.

N-Acetyl Derivative; Yellow plates; mp 150.5 °C; UV (MeOH) 243, 342, and 367 nm (log ε 4.34, 3.95, and 3.96); IR (KBr) 3305 (NH), 1690 (C=O), and 1610 cm^{-1} (C=O); ^1H NMR (100 MHz in $CDCl_3$) δ=2.08 (3H, s, CH_3), 6.45—7.59 (8H, m, ar-H), 8.10 (1H, s, NH), and 8.55 (1H, d, *J*=9 Hz, H-3′); MS *m/z* 271 (M^+);

Anal. ($C_{15}H_{13}NSO$) C, H, N.

Cyclohepta[b][1,4]benzothiazine (9). A solution of **14** (30 mg, 0.13 mmol), in methanol (2 ml) containing a drop of conc hydrochloric acid was allowed to stand for 30 min at 20 °C. After removal of the solvent *in vacuo*, the residue was neutralized with aqueous $NaHCO_3$ and extracted with benzene. The extracts were combined, dried (Na_2SO_4), and evaporated *in vacuo*, thus giving **9** (27 mg, 97%) as red plates; mp 87 °C (from acetone), (lit,[6] 86—87 °C); ^1H NMR (250 MHz in $CDCl_3$) δ=6.04 (1H, dd, *J*=8.5 and 1.0 Hz, H-6), 6.12 (1H, ddt, *J*=11.0, 7.3 and 1.0 Hz, H-8), 6.14 (1H, d, *J*=12.0 Hz, H-10), 6.25 (1H, dddd, *J*=11.0, 8.5, 1.4, and 1.0 Hz, H-7), 6.31 (1H, ddd, *J*=12.0, 7.3, and 1.4 Hz, H-9), 6.79 (1H, ddd, *J*=7.5, 1.6 and 0.6 Hz, H-4), 6.92 (1H, td, *J*=7.5, 7.0, and 1.8 Hz, H-3), 7.01 (1H, td, *J*=7.5, 7.0, and 1.6 Hz, H-2), and 7.07 (1H, ddd, *J*=7.5, 1.8, and 0.6 Hz, H-1). (250 MHz in CF_3COOD) δ=6.74—6.82 (2H, m), 6.81 (1H, d, *J*=11 Hz, H-10 or 6), 7.03—7.14 (3H, m), 7.17 (1H, dd, *J*=10 and 1.5 Hz, H-6 or 10), 7.22 (1H, td, *J*=10 and 1 Hz, H-7 or 9), and 7.36 (1H, ddd, *J*=11, 10, and 1 Hz, H-9 or 7). ^{13}C-NMR (67.8 MHz in

$CDCl_3$) δ=125.5 (d), 126.5 (d), 127.5 (d), 127.6 (d), 128.7 (d), 131.4 (d), 133.5 (d), 133.6 (d), 134.2 (d), 134.4 (s), 143.4 (s), and 159.4 (s).

2-[o-(Methylamino)phenylthio]tropone (18). A solution of **9** (50 mg, 0.24 mmol) and methyl fluorosulfate (200 mg, 1.75 mmol) in dichloromethane (0.5 ml) was allowed to stand in a sealed flask for 48 h at room temperature. After removing the solvent and the excess sulfate *in vacuo*, the residue was diluted with aqueous $NaHCO_3$ and then extracted with $CHCl_3$. The extracts were combined and evaporated *in vacuo*. The residue was chromatographed on silica-gel thin-layer plates with 10:1 benzene–MeOH as the eluant, thus giving **18** (36 mg, 63%) and unreacted **9** (15 mg).

18: Yellow needles (from $CHCl_3$); mp 156—157 °C; UV (MeOH) 248, 277sh, 324, 340, 366, and 384 nm (log ε 4.33, 3.78, 3.92, 3.96, 3.92, and 3.83), (MeOH+HCl) 242, 282, 342, and 454 nm (log ε 4.27, 4.13, 3.93, and 3.61); IR (KBr) 3350 (NH) and 1620 cm^{-1} (C=O); ^1H NMR (270 MHz in C_6D_6) δ=2.09 (3H, s, CH_3), 4.53 (1H, s, NH), 5.92 (1H, ddd, *J*= 10.4, 8.0, and 1.5 Hz, H-4) 5.95 (1H, ddd, *J*=10.4, 7.0, and 1.5 Hz, H-5), 6.30 (1H, m, H-6), 6.35 (1H, d, *J*=8.0 Hz, H-3′ or 6′), 6.57 (1H, dd, *J*=8.0 and 1.5 Hz, H-3), 6.59 (1H, td, *J*=8.0 and 1.5 Hz, H-5′ or 4′), 6.98 (1H, d, *J*= 11.7 Hz, H-7), 7.17 (1H, td, *J*=8.0 and 1.5 Hz, H-4′ or 5′), and 7.36 (1H, dd, *J*=8.0 and 1.5 Hz, H-6′ or 3′).

Found: *m/z* 243.0688. Calcd for $C_{14}H_{13}NSO$: M, 243.0816.

2-(N-Methyl-o-hydroxyanilino)tropone (20). The reaction of **4** and methyl fluorosulfate was conducted in a manner similar to that for **9** described above, thus giving **20** in 50% yield: Yellow meedles (from $CHCl_3$); mp 132—133 °C; UV (MeOH) 246, 344, and 410 nm (log ε 4.24, 4.02, and 3.93), (MeOH+HCl) 228, 262, 272, 320, and 428 nm, (log ε 4.42 4.33, 4.39, 3.89, and 3.95); IR (KBr) 3420 (OH) and 1600 cm^{-1} (C=O); ^1H NMR (270 MHz in C_6D_6) δ=2.64 (3H, s, CH_3), 6.12 (1H, t, *J*=9 Hz, H-5), 6.28 (1H, d, *J*=10 Hz, H-3), 6.41 (1H, t, *J*=10 and 9 Hz, H-4), 6.44 (1H, ddd, *J*=12, 9, and 1.5 Hz, H-6), 6.58 (1H, dd, *J*=8 and 2 Hz, H-3′ or 6′), 6.61 (1H, td, *J*=8 and 1.5 Hz, H-4′ or 5′), 6.85 (1H, d, *J*=12 Hz, H-7), 6.96 (1H, td, *J*=8 and 2 Hz, H-5′ or 4′), and 7.18 (1H, dd, *J*=8 and 1.5 Hz, H-6′ or 3′).

Found: *m/z* 227.0928. Calcd for $C_{14}H_{13}NO_2$: M, 227.0942.

11-Methylcyclohepta[b][1,4]benzothiazinium Tetrafluoroborate (17). To a solution of **18** (10 mg) in methanol (1 ml) was added 42% HBF_4 (40 mg), and the mixture was set aside at room temperature, depositting crystals after several hours. The precipitates were filtered off, giving **17** (11 mg, 85%, combined with the second crop): Dark red needles; mp 162—164 °C; UV (MeOH) 240, 282, 340, and 452 nm (log ε 4.39, 4.26, 4.04, and 3.68); ^1H NMR (270 MHz in CD_3CN) δ=3.75 (3H, s, CH_3), 7.21 (1H, dd, *J*=7 and 1.5 Hz, H-4 or 1), 7.29 (1H, dd, *J*=7 and 1.5 Hz, H-1 or 4), 7.34 (1H, td, *J*=7 and 1.5 Hz, H-3 or 2), 7.39 (1H, td, *J*=7 and 1.5 Hz, H-2 or 3), 7.46 (1H, d, *J*=12 Hz, H-10 or 6), 7.57 (1H, td, *J*=8 and 3 Hz, H-8), 7.73 (1H, td, *J*=8 and 1.5 Hz, H-7 or 9), 7.76 (1H, dd, *J*=8 and 3 Hz, H-6 or 10), and 7.91 (1H, m, *J*=12, 8, and 1.5 Hz, H-9 or 7).

Anal. ($C_{14}H_{12}BF_4NO$) C, H, N.

11-Methylcyclohepta[b][1,4]benzoxazinium Tetrafluoroborate (19). The same treatment of **20** with HBF_4 as above gave **19** (89%) as dark red needles; mp 156—157 °C; UV (MeOH+HBF_4)[16] 228, 264, 272, 320, and 428 nm (log ε 4.31, 4.22, 4.31, 3.78, and 3.83); ^1H NMR (270 MHz in CD_3CN) δ=3.31 (3H, s, CH_3), 6.79 (1H, m, H-4 or 1), 6.99—7.08 (3H, m, H-2, 3, and 1 or 4), 7.10 (1H, d, *J*=12 Hz, H-6 or 10), 7.15 (1H, d, *J*=12 Hz, H-10 or 6), 7.26 (1H, t, *J*=9.5 Hz, H-8), 7.55 (1H, ddd, *J*=12, 9.5, and 1.5 Hz, H-7 or 9), and 7.75 (1H, ddd, *J*=12, 9.5, and 1.5 Hz, H-9 or 7).

Anal. ($C_{14}H_{12}BF_4NO$) C, H, N.

Oxidation of 9 with H_2O_2. Compound **9** was treated with various molar ratios (1:4—10) of 28% H_2O_2 in methanol at room temperature. Each product was identified by means of periodical checking using HPLC and TLC; most of the products were separated by preparative HPLC, and the yields were based on the peak areas.

1-Formylphenothiazine (23): Orange needles (from EtOH–$CHCl_3$); mp 80.5—81.0 °C (lit,[12] 80—81 °C); UV (MeOH) 240, 288, and 431 nm (log ε 4.46, 3.83, and 3.60); IR (KBr) 3300 (NH), 2860, 2760, and 1665 cm^{-1} (CHO); ^1H NMR ($CDCl_3$) δ=6.55—7.07 (6H, m), 7.17 (1H, dd, *J*=7.8 and 2.0 Hz, H-2), 9.79 (1H, s, CHO), and 10.10 (1H, br, NH); (Found: C, 68.70; H, 3.80; N, 6.63%; M^+ 227).

1-Formylphenothiazine 5-Oxide (23a): Yellow needles (from EtOH); mp 196—197 °C; UV (MeOH) 228, 305, and 375 nm (log ε 3.98, 3.70, and 3.57); IR (KBr) 3250 (NH), 2870, 2780, and 1665 cm^{-1} (CHO); ^1H NMR ($CDCl_3$) δ=7.24—7.41 (3H, m, H-3,7,9), 7.64 (1H, t, *J*=8 Hz, H-8), 7.97 (2H, d, *J*=8 Hz, H-4,6), 8.23 (1H, d, *J*=8 Hz, H-2), 10.09 (1H, s, CHO), and 11.67 (1H, br, NH); MS, *m/z* 243 (M^+).

Anal. ($C_{13}H_9NSO_2$) C, H, N.

3-Formylphenothiazine (25): Yellow needles (from MeOH); mp 194.5—196 °C; UV (MeOH) 242, 288, and 405 nm (log ε 4.39, 4.49, and 3.93); IR (KBr) 3320 (NH), 2850, 2760, and 1660 cm^{-1} (CHO); ^1H NMR ($CDCl_3$) δ=6.64—6.97 (5H, m, H-1,6,7,8,9), 7.30 (1H, d, *J*=1.8 Hz, H-4), 7.46 (1H, dd, *J*=8.2 and 1.8 Hz, H-2), 8.90 (1H, br, NH), and 9.64 (1H, s, CHO); MS, *m/z* 227 (M^+).

Anal. ($C_{13}H_9NSO$) C, H, N.

Phenothiazine 5-Oxide (24a): Pale yellow needles (from EtOH); mp 246—247 °C (lit,[13] 242—242.5 °C); ^1H NMR (DMSO-d_6) δ=7.17 (2H, ddd, *J*=7.8, 6.8, and 1.5 Hz, H-3,7), 7.38 (2H, dd, *J*=8.3 and 1.5 Hz, H-1,9), 7.56 (2H, ddd, *J*=8.3, 6.8, and 1.5 Hz, H-2,8), 7.86 (2H, dd, *J*=7.8 and 1.5 Hz, H-4,6), and 10.78 (1H, br, NH).

Reaction of 10-Methoxycyclohepta[b][1,4]Benzothiazine (26) with H_2O_2: Compound **26** was prepared from 7-methoxy-2-bromotropone and *o*-aminobenzenethiol according to the reported method.[6] The reaction of **26** with H_2O_2 was conducted in a manner similar to that described earlier for **9**, thus giving **10—12** and **27—30**.

26: Red oil; ^1H NMR ($CDCl_3$) δ=3.89 (3H, s, OCH_3), 6.08—6.38 (4H, m), and 7.01—7.36 (4H, m); MS, *m/z* 241 (M^+). Picrate, mp 183—184 °C (lit,[6] 184—185 °C).

Methyl 1-Phenothiazinecarboxylate (27): Yellow needles (from $CHCl_3$); mp 113.1—114.4 °C (lit,[14] 113—113.5 °C); UV (MeOH) 210, 240, 256, 316, and 388 nm (log ε 4.58, 4.56, 4.57, 3.62, and 3.87); IR (KBr), 3300 (NH) and 1680 cm^{-1} (C=O); ^1H NMR ($CDCl_3$) δ=3.89 (3H, s, CH_3), 6.51—7.11 (6H, m), 7.67 (1H, dd, *J*=7.8 and 1.5 Hz, H-2), and 9.91 (1H, br, NH); (Found: C, 65.62; H, 4.31; N, 5.62%; M^+, 257).

Methyl 10H-Phenothiazine-1-carboxylate 5-Oxide (27a): Yellow needles (from $CHCl_3$); mp 167.0—169.2 °C; UV (MeOH) 209, 229, 250, 296, and 361 nm (log ε 4.34, 4.33, 4.04, 4.09, and 3.87); IR (KBr) 3260 (NH) and 1690 cm^{-1} (C=O); ^1H NMR ($CDCl_3$) δ=4.01 (3H, s, OCH_3), 7.21 (1H, dd, *J*=7.8 and 6.8 Hz, H-7), 7.28 (1H, t, *J*=7.8 Hz, H-3), 7.33 (1H, d, *J*=8.3 Hz, H-9), 7.61 (1H, ddd, *J*=8.3, 6.8, and 1.5 Hz, H-8),

7.93 (1H, d, J=7.8 Hz, H-6), 8.17 (1H, dd, J=7.8 and 1.5 Hz, H-2 or 4), 8.34 (1H, dd, J=7.8 and 1.5 Hz, H-4 or 2), and 11.58 (1H, br, NH); MS, m/z 273 (M^+).

Anal. ($C_{10}H_{11}NSO_3$) C, H, N.

3-Formyl-1-methoxyphenothiazine (28): Yellow needles (from MeOH) mp 121 °C; UV (MeOH) 207, 246, 298, and 407 nm (log ε 4.38, 4.41, 4.35, and 3.82); IR (KBr) 3300 (NH) and 1660 cm^{-1} (C=O); ^1H NMR ($CDCl_3$) δ=3.92 (3H, s, OCH_3), 6.57 (1H, d, J=6.8 Hz, H-6 or 9), 6.61 (1H, br, NH), 6.88 (3H, m, H-7,8, and 9 or 6), 7.04 (1H, d, J=1.5 Hz, H-2 or 4), 7.12 (1H, d, J=1.5 Hz, H-4 or 2), and 9.68 (1H, s, CHO); MS, m/z 257 (M^+).

Anal. ($C_{14}H_{11}NSO_2$) C, H, N.

Methyl 2-(o-Methoxyphenylthio)phenylcarbamate (30): Pale yellow needles (from $CHCl_3$); mp 93.0 °C; UV (MeOH) 209, 239, and 289 nm (log ε 4.60, 4.26, and 3.79); IR (KBr) 3370 (NH) and 1740 cm^{-1} (C=O); ^1H NMR ($CDCl_3$) 3.73 (3H, s, OCH_3), 3.92 (3H, s, OCH_3), 6.79—7.63 (7H, m), 8.07 (1H, br, NH), and 8.21 (1H, dd, J=8.3 and 1.5 Hz, H-3 or 6); MS (70 eV), m/z (rel intensity) 290 (18), 289 (100; M^+), 258 (12), 257 (62), 214 (10), 200 (16), 199 (25), 198 (21), 186 (15), 167 (8), 150 (43), and 77 (8).

Anal. ($C_{15}H_{15}NSO_3$) C, H, N.

Cyclohepta[b][1,4]benzothiazin-10(11H)-one (10): Red needles (from MeOH); mp 168—169 °C (lit,[6] 168—169 °C); ^1H NMR (270 MHz in C_6D_6) δ=5.74 (1H, m, H-4), 5.84 (1H, dd, J=11.0 and 8.8 Hz, H-7) 6.22 (1H, d, J=11.0 Hz, H-6), 6.25 (1H, dd, J=11.7 and 8.8 Hz, H-8), 6.45—6.50 (3H, m, H-1,2,3), 6.99 (1H, d, J=11.7 Hz, H-9), and 8.74 (1H, s, NH).

Cyclohepta[b][1,4]benzothiazin-10(11H)-one 5-Oxide (11): Yellow needles (from EtOH); mp 196—197 °C (lit,[7] 207 °C); ^1H NMR (270 MHz in C_6D_6) δ=6.17 (1H, dd, J=11.0 and 8.8 Hz, H-7), 6.24 (1H, d, J=8.1 Hz, H-1), 6.56 (1H, dd, J=11.7 and 8.8 Hz, H-8), 6.74 (1H, dd, J=8.1 and 7.3 Hz, H-3), 6.84 (1H, dd, J=8.1 and 7.3 Hz, H-2), 7.04 (1H, d, J=11.7 Hz, H-9), 7.29 (1H, d, J=11.0 Hz, H-6), 7.55 (1H, d, J=8.1 Hz, H-4), and 10.12 (1H, s, NH).

Cyclohepta[b][1,4]benzothiazin-10(11H)-one 5,5-Dioxides (12): Yellow needles (from AcOH); mp 264—265 °C (lit,[7] 266 °C); ^1H NMR (270 MHz in C_6D_6) δ=6.17 (1H, dd, J=11.0 and 8.8 Hz, H-7), 7.27 (1H, d, J=11.7 Hz, H-9), 7.53 (1H, t, J=8.0 Hz, H-2 or 3), 7.64 (1H, dd, J=11.7 and 8.8 Hz, H-8), 7.81 (1H, t, J=8.0 Hz, H-3 or 2), 7.85 (1H, d, J=11.7 Hz, H-6), 8.03 (1H, d, J=8.0 Hz, H-1 or 4), 8.21 (1H, d, J=8.0 Hz, H-4 or 1), and 11.45 (1H, s, NH).

We wish to thank Professor Hiroshi Yamamoto for his helpful discussions and Professor Sumio Umezawa and Dr. T. Miyake (Inst. Bio-org. Chem., Kawasaki) for the NMR measurements with the Brucker WE-250 (250 MHz) spectrometer.

Aggregation Behavior of Amphiphiles Functionalized with Dipeptide Segments and Enantioselective Ester Hydrolysis in Their Bilayer Membranes†

Yukito MURAKAMI,* Akio NAKANO,†† Hidetsugu IKEDA, Toru IMORI, and Kazunari AKIYOSHI
Department of Organic Synthesis, Faculty of Engineering, Kyushu University, Hakozaki, Higashi-ku, Fukuoka 812
(Received July 19, 1984)

Four amphiphiles having dipeptide segments, which consist of one histidyl residue and another amino acid residue, and the dihexadecyl moiety for the double-chain segment (N^+C_5AlaHis2C_{16}, N^+C_5LeuHis2C_{16}, N^+C_5PheHis2C_{16}, and N^+C_5HisAla2C_{16}) were synthesized, and the aggregate morphology of them was characterized by electron microscopy and differential scanning calorimetry. The amphiphiles, which have the histidyl residue bound to the dihexadecylamine component (N^+C_5AlaHis2C_{16}, N^+C_5LeuHis2C_{16}, and N^+C_5PheHis2C_{16}) formed both multi- and single-walled aggregates in the aqueous dispersion state, while their sonicated solutions involved only single-walled vesicles. On the other hand, the amphiphile, which has the alanyl residue bound to the dihexadecylamine component (N^+C_5HisAla2C_{16}) afforded tubular aggregates in the aqueous dispersion. The hydrolysis of enantiomeric esters of various hydrophobic nature, which was carried out in the single-walled vesicles, showed relatively small enantioselectivity. The reasons for such catalytic performance of the vesicles were discussed from the kinetic and mechanistic viewpoints; the kinetic analysis being carried out on the basis of the organic pseudo-phase concept.

We have previously clarified that peptide amphiphiles having various amino acid residues form chemically and morphologically stable bilayer membranes in aqueous media.[1] Among them, amphiphiles bearing the histidyl residue behave not only as apoenzyme models of vitamin B_6-dependent enzymes effective in the transamination reaction of amino acids[2] but also as a functional model of hydrolytic enzymes acting on enantiomeric esters.[3]

In this work, we prepared amphiphiles having dipeptide segments, which consist of one histidyl residue and another amino acid residue, and the dihexadecyl moiety for the double-chain segment. The amphiphiles having such double-chain segment are expected to show the phase transition between the gel and liquid-crystalline states in the room temperature range,[1c] so that organic reactions in the vesicular phase can be readily carried out above and below their phase transition temperatures. The aggregate morphology of these amphiphiles in aqueous media and the enantioselective ester hydrolysis in their single-walled bilayer membranes were investigated. The molecular formulae and abbreviations of the present peptide amphiphiles and of the ester substrates are shown above.

Experimental

Spectroscopic data were taken on a JASCO DS-403G grating IR spectrophotometer and a Hitachi Perkin-Elmer R-20 NMR spectrometer. Melting points were measured with a Yanagimoto MP-S1 apparatus (hot-plate type). Experimental procedures for electron microscopy and differential scanning calorimetry (DSC) have been described elsewhere.[1-3] Optical rotations were measured with a Union Giken PM-71 high-sensitivity polarimeter.

N-(*t*-Butoxycarbonyl)-L-alanine, *N*-(*t*-butoxycarbonyl)-L-leucine, *N*-(*t*-butoxycarbonyl)-L-phenylalanine, *N*-(*t*-butoxycarbonyl)-N^{im}-benzyl-L-histidine, and the corresponding D-isomers were prepared from the corresponding amino acids and *O*-*t*-butyl *S*-(4,6-dimethyl-2-pyrimidinyl) thiocarbonate after the methods of Nagasawa *et al.*[4] *p*-Nitrophenyl esters of several *N*-(*t*-butoxycarbonyl)-L/D-amino acids (BocAlaPNP, BocValPNP, and BocLeuPNP) were obtained according to the procedures reported by Schnabel[5] and the products were identified by elemental analyses as well as by spectroscopic (NMR and IR) and polarimetric measurements. N^{α}-Hexadecanoyl-L-histidine (HisC$_{16}$) was prepared in a manner similar to that reported by Gitler *et al.*[6] for the preparation of N^{α}-tetradecanoylhistidine.[7] Octadecyltrimethylammonium

chloride (STAC) of Ishizu Pharmaceutical Co. was recrystallized from aqueous ethanol.

p-*Nitrophenyl* N^{α}_{val}-*(*N^{α}_{gly}-*Dodecanoylglycyl)*-L-*valinate (*L-C_{12}*GlyValPNP).* L-BocValPNP (1.1 g, 3.3 mmol) was dissolved in dry dichloromethane (30 ml). To the solution was added trifluoroacetic acid (25 g, 0.22 mol), and the mixture was stirred for 40 min at room temperature. The solvent was removed *in vacuo*, and the solid residue was washed with diethyl ether to give a white solid (0.8 g; mp 159—162 °C (decomp)). Elimination of the *t*-butoxycarbonyl group was confirmed by NMR spectroscopy. The amine component (0.8 g, 2.3 mmol) thus obtained, *N*-dodecanoylglycine (0.6 g, 2.3 mmol), and 1-hydroxybenzotriazole[8] (0.38 g, 2.8 mmol) were dispersed in dry dichloromethane (20 ml), and the mixture was cooled to 0 °C. Triethylamine (0.24 g, 2.3 mmol) and dicyclohexylcarbodiimide (0.58 g, 2.8 mmol) were added to the mixture in this sequence. The resulting mixture was stirred for 3 h at 0 °C, and then precipitates were removed by filtration. The solvent was removed *in vacuo*, and the residue was dissolved in ethyl acetate (100 ml). The solution was washed sequentially with 10% aqueous citric acid, 4% aqueous sodium hydrogencarbonate, and saturated aqueous sodium chloride. After being dried (Na_2SO_4), the solution was evaporated *in vacuo* to give a yellow oil which was subsequently purified by gel-filtration chromatography (Sephadex LH-20, methanol as an eluant): a white solid, yield 400 mg (10%); R_f on Silica Gel IB of J. T. Baker, 0.65 (ethyl acetate) and 0.14 (benzene); mp 76—78 °C, $[\alpha]_D^{25}$ −30.3° (*c* 1.0, dioxane). Found: C, 62.46; H, 8.20; N, 8.75%. Calcd for $C_{25}H_{39}N_3O_6$: C, 62.87; H, 8.23; N, 8.80%.

p-*Nitrophenyl* N^{α}_{val}-*(*N^{α}_{gly}-*Dodecanoylglycyl)*-D-*valinate (*D-C_{12}*GlyValPNP)*: mp 74—76 °C, $[\alpha]_D^{25}$ +30.5° (*c* 1.0, dioxane). Found: C, 62.63; H, 8.54; N, 8.32%.

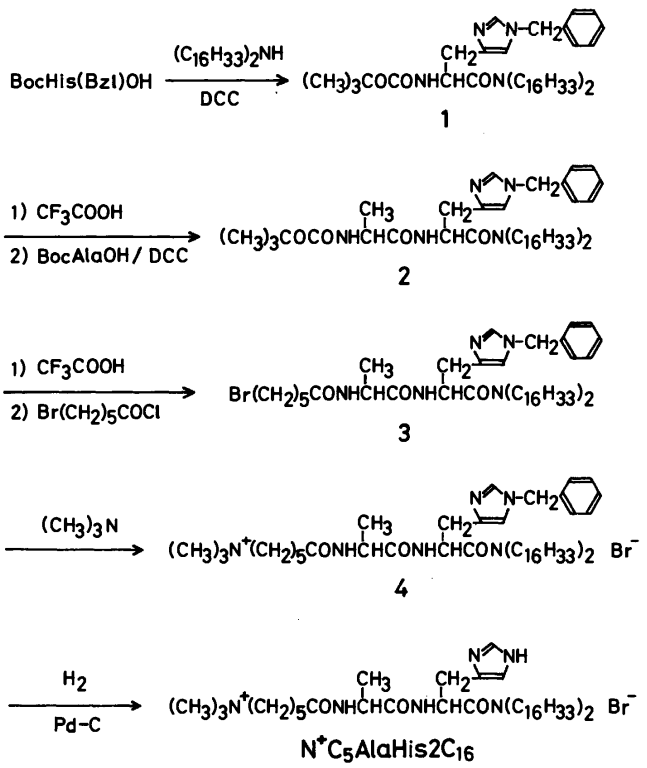
p-Nitrophenyl N^{α}-dodecanoyl-D/L-phenylalaninates were synthesized according to the procedure by Ingles.[9]

p-*Nitrophenyl* N^{α}-*Dodecanoyl*-L-*phenylalaninate (*L-C_{12}-*PhePNP)*: mp 110.5—111.0 °C (lit,[10] 107.0—107.5 °C), $[\alpha]_D^{25}$ −11.9° (*c* 2.0, $CHCl_3$) [lit,[10] −11.4° (*c* 2.0, $CHCl_3$)]. Found: C, 68.90; H, 7.76; N, 6.01%. Calcd for $C_{27}H_{36}N_2O_5$: C, 69.20; H, 7.74; N, 5.97%.

p-*Nitrophenyl* N^{α}-*Dodecanoyl*-D-*phenylalaninate (*D-C_{12}-*PhePNP)*: mp 110.5—111.0 °C (lit,[10] 107.5—108.0 °C), $[\alpha]_D^{25}$ +11.0° (*c* 2.0, $CHCl_3$) [lit,[10] +11.9° (*c* 2.0, $CHCl_3$)]. Found: C, 68.98; H, 7.76; N, 6.00%.

The synthetic procedure for *N,N*-dihexadecyl-N^{α}_{his}-[N^{α}_{ala}-(6-trimethylammoniohexanoyl)-L-alanyl]-L-histidinamide bromide ($N^+C_5AlaHis2C_{16}$) is outlined in Scheme 1.

N,N-*Dihexadecyl*-N^{α}-*(t-butoxycarbonyl)*-N^{im}-*benzyl*-L-*histidinamide (1).* Dicyclohexylcarbodiimide (4.7 g, 23 mmol) was added with stirring to a dry dichloromethane solution (100 ml) of *N*-(*t*-butoxycarbonyl)-N^{im}-benzyl-L-histidine (6.6 g, 19 mmol), dihexadecylamine (8.9 g, 19 mmol) and 1-hydroxybenzotriazole[8] (3.9 g, 29 mmol) at 0 °C. The mixture was stirred for 3 h at 0 °C and for further 15 h at room temperature, and precipitates (*N,N'*-dicyclohexylurea) were removed by filtration. The solvent was removed *in vacuo*, and the residual oil was dissolved in ethyl acetate (200 ml). The solution was then washed sequentially with 10% aqueous citric acid, 5% aqueous sodium hydrogencarbonate, and saturated aqueous sodium chloride. After being dried (Na_2SO_4), the mixture was evaporated *in vacuo* to give an oil which was subsequently purified by centrifugal liquid chromatography with a combination of silica gel



(Boc, t-butoxycarbonyl; Bzl, benzyl; DCC, dicyclohexylcarbodiimide)

Scheme 1.

(Wako Gel B5) and chloroform: a pale yellow solid, yield 8.1 g (54%); R_f (Silica Gel IB of J. T. Baker, ethyl acetate) 0.18, mp 63.0—65.5 °C; IR (Nujol) 3300 (NH), 1700 and 1640 cm^{-1} (C=O); ^{1}H-NMR ($CDCl_3$, TMS) δ=0.88 [6H, br t, $CH_3(CH_2)_{15}N$], 1.25 [56H, s, $CH_3(CH_2)_{14}CH_2N$], 1.40 [9H, s, $(CH_3)_3COCO$], 2.85 [2H, d, $CH(CH_2ImBzl)$], 2.9—3.4 [4H, m, $CH_3(CH_2)_{14}CH_2N$], 4.95 [2H, s, benzyl CH_2], 5.20 [1H, br t, $CH(CH_2ImBzl)$], 6.63 [1H, s, Im-5H], 7.0—7.3 [5H, m, phenyl H's], and 7.33 [1H, s, Im-2H].

N,N-*Dihexadecyl*-N^{α}_{his}-*[*N^{α}_{ala}-*(t-butoxycarbonyl)*-L-*alanyl]*-N^{im}-*benzyl*-L-*histidinamide (2).* Trifluoroacetic acid (25 g, 220 mmol) was added to a dry dichloromethane solution (20 ml) of **1** (4.7 g, 5.9 mmol), and the mixture was stirred for 2 h at room temperature. Evaporation of an excess amount of trifluoroacetic acid *in vacuo* below 40 °C gave a pale yellow oil (**1a**). Elimination of the *t*-butoxycarbonyl group was confirmed by NMR spectroscopy. The amine (**1a**) was dissolved in dry dichloromethane (30 ml) and the solution was cooled to 0 °C. Triethylamine (1.2 g, 11 mmol), *N*-(*t*-butoxycarbonyl)-L-alanine (1.1 g, 5.9 mmol), and 1-hydroxybenzotriazole[8] (1.2 g, 8.8 mmol), and subsequently dicyclohexylcarbodiimide (1.5 g, 7.1 mmol) were added to the solution at 0 °C with stirring. The resulting mixture was stirred for 3 h at 0 °C and for further 15 h at room temperature, and precipitates (*N,N'*-dicyclohexylurea) were removed by filtration. The solvent was removed *in vacuo*, and the residual oil was dissolved in ethyl acetate (200 ml). The solution was then washed sequentially with 10% aqueous citric acid, 4% aqueous sodium hydrogencarbonate, and saturated aqueous sodium chloride. After being dried (Na_2SO_4), the mixture was evaporated *in vacuo*

to give an oil which was subsequently purified by centrifugal liquid chromatography with a combination of silica gel (Wako Gel B5) and a dual solvent system (chloroform and then methanol): a pale yellow oil, yield 1.8 g (35%); R_f (Silica Gel IB of J. T. Baker, ethyl acetate) 0.56; IR (Nujol) 3200 (NH), 1720 and 1630 cm^{-1} (C=O); ^{1}H-NMR ($CDCl_3$, TMS) δ=0.85 [6H, br t, $CH_3(CH_2)_{15}N$], 1.25 [59H, s, $CH_3(CH_2)_{14}CH_2N$ and $CH(CH_3)$], 1.40 [9H, s, $(CH_3)_3$-COCO], 2.85 [2H, d, $CH(CH_2ImBzl)$], 2.7—3.8 [4H, m, $CH_3(CH_2)_{14}CH_2N$], 3.8—4.4 [2H, m, $CH(CH_2ImBzl)$ and $CH(CH_3)$], 4.95 [2H, s, benzyl CH_2], 6.60 [1H, s, Im-5H], 6.9—7.4 [5H, m, phenyl H's], and 7.33 [1H, s, Im-2H].

N,N-*Dihexadecyl*-N^{α}_{his}-[N^{α}_{ala}-(*6-bromohexanoyl*)-L-*alanyl*]-N^{im}-*benzyl*-L-*histidinamide* (**3**). Trifluoroacetic acid (25 g, 220 mmol) was added to a dry dichloromethane solution (10 ml) of **2** (1.8 g, 2.1 mmol), and the mixture was stirred for 2 h at room temperature. Evaporation of an excess amount of trifluoroacetic acid *in vacuo* below 40 °C gave a pale yellow oil (**2a**). Elimination of the *t*-butoxycarbonyl group was confirmed by NMR spectroscopy. The amine (**2a**) was dissolved in dry dichloromethane (30 ml), and the solution was cooled to 0 °C. After triethylamine (1.7 g, 16 mmol) being added dropwise, 6-bromohexanoyl chloride (0.9 g, 4.2 mmol) dissolved in dry dichloromethane (20 ml) was added dropwise to the mixture at 0 °C with stirring. The resulting mixture was stirred for 3 h at room temperature and then washed with 4% aqueous sodium hydrogencarbonate, 10% aqueous citric acid, and saturated aqueous sodium chloride in this sequence. After being dried (Na_2SO_4), the solution was evaporated *in vacuo* to give an oil which was subsequently purified by gel-filtration chromatography on a column of silica gel (Wako Gel C-100) with ethyl acetate as an eluant: a pale yellow oil, yield 0.88 g (45%); R_f (Silica Gel IB of J. T. Baker, ethyl acetate) 0.13; IR (Nujol) 3220 (NH) and 1650 cm^{-1} (C=O); ^{1}H-NMR ($CDCl_3$, TMS) δ=0.90 [6H, br t, $CH_3(CH_2)_{15}N$], 1.25 [59H, s, $CH_3(CH_2)_{14}CH_2N$ and $CH(CH_3)$], *ca.* 2.0 [6H, m, $BrCH_2(CH_2)_3CH_2CO$], 2.30 [2H, br t, $Br(CH_2)_4CH_2CO$], 2.9—3.5 [8H, m, $CH_3(CH_2)_{14}CH_2N$, $CH(CH_2ImBzl)$, and $BrCH_2(CH_2)_4CO$], 4.0—4.5 [2H, m, $CH(CH_2ImBzl)$ and $CH(CH_3)$], 5.40 [2H, s, benzyl CH_2], 6.95 [1H, s, Im-5H], 7.30 [5H, s, phenyl H's], and 8.95 [1H, s, Im-2H].

N,N-*Dihexadecyl*-N^{α}_{his}-[N^{α}_{ala}-(*6-trimethylammoniohexanoyl*)-L-*alanyl*]-N^{im}-*benzyl*-L-*histidinamide Bromide* (**4**). A benzene solution (60 ml) of **3** (880 mg, 0.94 mmol) was saturated with dry trimethylamine gas, and the solution was stirred overnight at room temperature. The solvent was removed *in vacuo* and the crude product was purified by gel-filtration chromatography on a column of Sephadex LH-20 with methanol as an eluant: a pale yellow solid, yield 610 mg (65%); R_f [Silica Gel IB of J. T. Baker, *t*-butyl alcohol-water-acetic acid (4:2:1 by volume; BWA)] 0.22; IR (Nujol) 3200 (NH) and 1630 cm^{-1} (C=O); ^{1}H-NMR ($CDCl_3$, TMS) δ=0.85 [6H, br t, $CH_3(CH_2)_{15}N$], 1.25 [59H, s, $CH_3(CH_2)_{14}CH_2N$ and $CH(CH_3)$], *ca.* 2.0 [6H, m, $N^+CH_2(CH_2)_3CH_2CO$], 2.30 [2H, br t, $N^+(CH_2)_4CH_2CO$], 2.8—3.7 [8H, m, $CH_3(CH_2)_{14}CH_2N$, $CH(CH_2ImBzl)$, and $N^+CH_2(CH_2)_4CO$], 3.40 [9H, s, $(CH_3)_3N^+$], 4.50 [2H, m, $CH(CH_2ImBzl)$ and $CH(CH_3)$], 5.30 [2H, s, benzyl CH_2], 7.00 [1H, s, Im-5H], 7.30 [5H, s, phenyl H's], and 8.10 [1H, s, Im-2H].

N,N-*Dihexadecyl*-N^{α}_{his}-[N^{α}_{ala}-(*6-trimethylammoniohexanoyl*)-L-*alanyl*]-L-*histidinamide Bromide* ($N^+C_5AlaHis2C_{16}$). A 700-mg sample of 10% PdC was added to **4** (610 mg, 0.61 mmol) dissolved in 80% aqueous acetic acid (40 ml), and hydrogen gas was introduced into the solution at 60 °C for 30 h with stirring. The catalyst was removed by filtration on Celite (Wako No. 545) with methanol. The filtrate was evaporated off *in vacuo*, and the residue was purified by gel-filtration chromatography on a column of Toyopearl HW-40 Fine with methanol as an eluant: a glassy solid, yield 360 mg (65%); R_f (Silica Gel IB of J. T. Baker, BWA) 0.20; mp 176 °C,[11] $[\alpha]_D^{26}$ −24.5° (*c* 1.0, ethanol); IR (Nujol) 1630 cm^{-1} (C=O); ^{1}H-NMR (CD_3OD, TMS) δ=0.90 [6H, br t, $CH_3(CH_2)_{15}N$], 1.25 [59H, s, $CH_3(CH_2)_{14}CH_2N$ and $CH(CH_3)$], *ca.* 2.0 [6H, m, $N^+CH_2(CH_2)_3CH_2CO$], 2.30 [2H, br t, $N^+(CH_2)_4CH_2CO$], 2.8—3.4 [8H, m, $CH_3(CH_2)_{14}CH_2N$, $CH(CH_2Im)$, and $N^+CH_2(CH_2)_4CO$], 3.10 [9H, s, $(CH_3)_3N^+$], 6.80 [1H, s, Im-5H], 7.60 [1H, s, Im-2H], the signals of $CHCH_3$ and $CH(CH_2Im)$ being obscured by the signal due to CD_3OH.

Similar experimental procedures were applied to the preparation of *N,N*-dihexadecyl-N^{α}_{his}-[N^{α}_{leu}-(6-trimethylammoniohexanoyl)-L-leucyl]-L-histidinamide bromide (N^+C_5-LeuHis2C_{16}), *N,N*-dihexadecyl-N^{α}_{his}-[N^{α}_{phe}-(6-trimethylammoniohexanoyl)-L-phenylalanyl]-L-histidinamide bromide (N^+C_5PheHis2C_{16}), and *N,N*-dihexadecyl-N^{α}_{ala}-[N^{α}_{his}-(6-trimethylammoniohexanoyl)-L-histidyl]-L-alaninamide bromide (N^+C_5HisAla2C_{16}).

$N^+C_5LeuHis2C_{16}$: mp 126 °C,[11] $[\alpha]_D^{26}$ −27.8° (*c* 1.0, ethanol), R_f (Silica Gel IB of J. T. Baker, BWA) 0.14; IR (Nujol) 1630 cm^{-1} (C=O); ^{1}H-NMR (CD_3OD, TMS) δ=0.70 [12H, m, $CH_3(CH_2)_{15}N$ and $CH_2CH(CH_3)_2$], 1.05 [59H, br s, $CH_3(CH_2)_{14}CH_2N$ and $CH_2CH(CH_3)_2$], *ca.* 2.0 [6H, m, $N^+CH_2(CH_2)_3CH_2CO$], 2.05 [2H, br t, $N^+(CH_2)_4CH_2CO$], 2.4—3.3 [8H, m, $CH_3(CH_2)_{14}CH_2N$, $CH(CH_2Im)$, and $N^+CH_2(CH_2)_3CH_2CO$], 2.90 [9H, s, $N^+(CH_3)_3$], 6.60 [1H, s, Im-5H], 7.30 [1H, s, Im-2H], the signals of $CHCH_2CH$-$(CH_3)_2$ and $CH(CH_2Im)$ being obscured by the signal due to CD_3OH.

$N^+C_5PheHis2C_{16}$: mp 130 °C,[11] $[\alpha]_D^{26}$ −11.4° (*c* 1.0, ethanol), R_f (Silica Gel IB of J. T. Baker, BWA) 0.09; IR (Nujol) 1640 cm^{-1} (C=O); ^{1}H-NMR (CD_3OD, TMS) δ= 0.90 [6H, br t, $CH_3(CH_2)_{15}N$], 1.20 [56H, s, $CH_3(CH_2)_{14}$-CH_2N], *ca.* 2.0 [6H, m, $N^+CH_2(CH_2)_3CH_2CO$], 2.30 [2H, br t, $N^+(CH_2)_4CH_2CO$], 2.7—3.5 [10H, m, $CH_3(CH_2)_{14}$-CH_2N, benzyl CH_2, and $N^+CH_2(CH_2)_4CO$], 3.20 [9H, s, $(CH_3)_3N^+$], 7.00 [1H, s, Im-5H], 7.20 [5H, s, phenyl H's], the signals of Im-2H, CHBzl, and $CH(CH_2Im)$ being obscured by the signal due to CD_3OH.

$N^+C_5HisAla2C_{16}$: mp 105 °C,[11] $[\alpha]_D^{26}$−11.9° (*c* 1.0, ethanol), R_f (Silica Gel IB of J. T. Baker, BWA) 0.20; IR (Nujol) 1625 cm^{-1} (C=O); ^{1}H-NMR (CD_3OD, TMS) δ=0.90 [6H, br t, $CH_3(CH_2)_{15}N$], 1.28 [59H, s, $CH_3(CH_2)_{14}CH_2N$ and $CH(CH_3)$], *ca.* 2.0 [6H, m, $N^+CH_2(CH_2)_3CH_2CO$], 2.30 [2H, br t, $N^+(CH_2)_4CH_2CO$], 2.9—3.5 [8H, m, $CH_3(CH_2)_{14}$-CH_2N, $CH(CH_2Im)$, and $N^+CH_2(CH_2)_4CO$], 3.10 [9H, s, $(CH_3)_3N^+$], 7.05 [1H, s, Im-5H], 8.10 [1H, s, Im-2H], the signals of $CH(CH_2Im)$ and $CHCH_3$ being obscured by the signal due to CD_3OH.

All the elemental analysis data for the present amphiphiles are summarized in Table 1.

Kinetic Measurements. Rates of *p*-nitrophenol liberation from *p*-nitrophenyl esters were measured at 400 nm with a Union Giken SM-401 high-sensitivity spectrophotometer.

Each run was initiated by adding a dioxane solution (20 μl) of a *p*-nitrophenyl ester (*ca.* 1.0×10^{-3} mol dm^{-3}) to a reaction medium (2.0 ml) which was pre-equilibrated at a desired temperature in a thermostated cell set in the spectrophotometer. The reaction medium was prepared as follows: an ethanol solution of a dipeptide amphiphile (90 μl, *ca.* 5.0×10^{-2} mol dm^{-3}) was taken into a sample tube and the solvent was removed completely. A 4.5-ml sample of an aqueous buffer was added to the residue, and the mixture was sonicated for 3 min with a probe-type sonicator at 30 W (W-220F, Heat Systems-Ultrasonics) and allowed to stand for 1 min at 5 °C. The ionic strength of sample solutions for the measurements was maintained at 0.05 with KCl.

Results and Discussion

Phase Transition and Aggregate Morphology. The phase transition parameters (enthalpy change, ΔH; temperature at peak maximum, T_m) of the molecular aggregates formed with the present amphiphiles in the aqueous dispersion were directly measured by differential scanning calorimetry (DSC) as summarized in Table 1. The T_m values of these amphiphiles are nearly identical with those of peptide amphiphiles having the same alkyl moieties (hexadecyl) in the double-chain portion. This indicates that the T_m value of the peptide amphiphile primarily depends on the alkyl-chain length of double-chain portion.[1c] On the other hand, the ΔH values are somewhat smaller than those of amphiphiles having the same double-chain segment prepared previously in our laboratory; *e.g.*, $N^+C_5Ala2C_{16}$, 32.6 kJ mol^{-1}.[1c] Since the ΔH value for the single-walled aggregate is generally much smaller than that for the corresponding multiwalled one,[1c] the present ΔH values seem to indicate that both single- and multi-walled aggregates are present in the aqueous dispersion state. This was clearly confirmed by electron microscopy. As shown in Fig. 1A, the aqueous dispersion of $N^+C_5LeuHis2C_{16}$ apparently involves single-walled vesicles in addition to multiwalled lamellae and vesicles. Similar electron micrographs were obtained with the aqueous dispersions of $N^+C_5AlaHis2C_{16}$ and $N^+C_5PheHis2C_{16}$. Such morphological behavior is reflected on the solubility properties of these amphiphiles; these three amphiphiles are more soluble and much less turbid in the

Table 1. Physical and analytical data of amphiphiles

Amphiphile	Formula	Elemental analysis[a]/%			DSC	
		C	H	N	T_m/°C	ΔH/kJ mol^{-1}
$N^+C_5AlaHis2C_{16}$	$C_{50}H_{97}BrN_6O_3+5/2H_2O$	62.78 (62.87)	10.57 (10.76)	8.60 (8.80)	24.8	27.6
$N^+C_5LeuHis2C_{16}$	$C_{53}H_{103}BrN_6O_3$	66.54 (66.84)	11.03 (10.90)	8.67 (8.83)	24.5	22.6
$N^+C_5PheHis2C_{16}$	$C_{56}H_{101}BrN_6O_3+3/2H_2O$	66.28 (66.37)	10.45 (10.34)	7.96 (8.29)	22.5	22.6
$N^+C_5HisAla2C_{16}$	$C_{50}H_{97}BrN_6O_3+3H_2O$	62.42 (62.28)	10.43 (10.76)	8.43 (8.71)	27.0	25.9

a) Calculated values are given in parentheses.

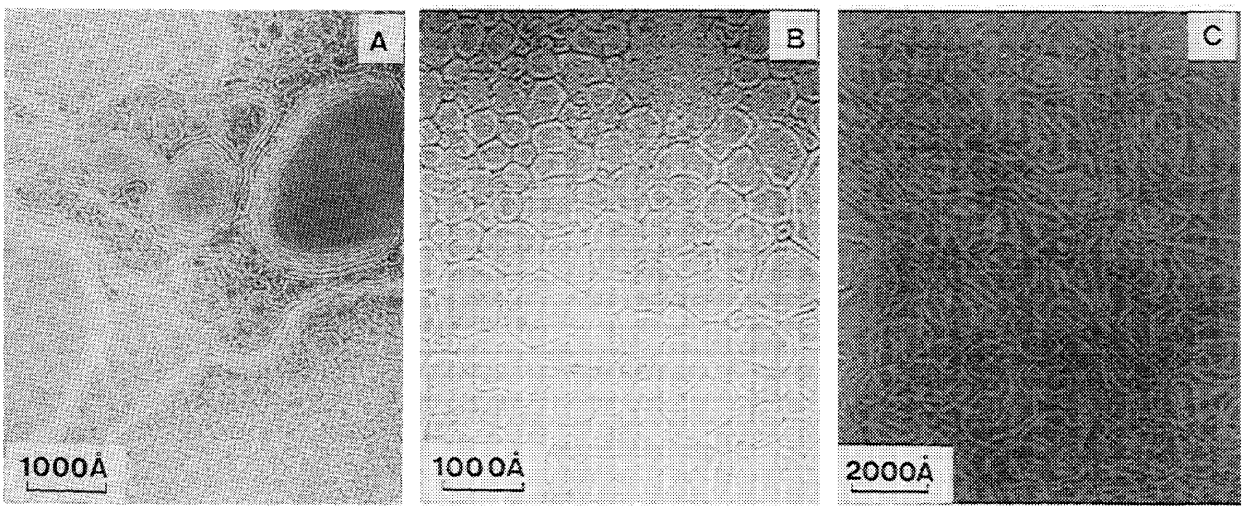


Fig. 1. Electron micrographs negatively stained with uranyl acetate: A, 5 mmol dm^{-3} aqueous dispersion of $N^+C_5LeuHis2C_{16}$; B, 5 mmol dm^{-3} aqueous solution of $N^+C_5LeuHis2C_{16}$ sonicated for 2 min at 30 W and subsequently allowed to stand for 5 min at 5 °C; C, 5 mmol dm^{-3} aqueous dispersion of $N^+C_5HisAla2C_{16}$.

dispersion state than other amphiphiles which have been synthesized previously in our laboratory.[1-3] The single-walled vesicles have never been observed with the latter amphiphiles in the dispersion state without sonication. The multiwalled aggregates were completely converted into the single-walled vesicles upon sonication of these aqueous dispersions for 2 min with a probe-type sonicator (Fig. 1B). Meanwhile, the aqueous dispersion of $N^+C_5HisAla2C_{16}$ involves exclusively tubular aggregates as clarified by electron microscopy (Fig. 1C). This indicates that the sequence of amino acid residues in the hydrogen-belt domain may largely control the aggregate morphology in the dispersion state.

Apparent Enantioselectivity in Ester Hydrolysis. The enantiomeric selectivity of the single-walled vesicles of the present amphiphiles exercised in the hydrolysis of various ester substrates was evaluated on the basis of apparent pseudo-first-order rate constants in an aqueous phosphate buffer (pH 7.47, μ 0.05 with KCl) at 15.0±0.1 °C. The first-order kinetics was found to hold at least up to 60% conversion of the substrate species under the conditions [S] ≪ [D]; S and D stand for substrate and amphiphile species, respectively (Table 2). In the micellar system of $HisC_{16}$ and STAC, the L-substrates are more favorably hydrolyzed than the corresponding D-isomers. On the other hand, the enantioselectivity demonstrated by the membrane systems depends on the hydrophobic nature of substrates employed; the L-isomers are more favorably hydrolyzed when less hydrophobic substrates are used (BocAlaPNP, BocValPNP, and BocLeuPNP), while the D-isomer is more reactive than the corresponding L-isomer in the case of C_{12}GlyValPNP that is largely hydrophobic. Above all, all the D-isomers are preferentially hydrolyzed in the single-walled vesicles of $N^+C_5LeuHis2C_{16}$ although the extent of selectivity is rather small.

Kinetic Analysis by Pseudo-Phase Concept. Various micellar reactions have been quantitatively analyzed on the basis of the Michaelis-Menten-type kinetics,[12] the ion-exchange model treatment,[13] and the pseudo-phase concept.[14] We employed in this work the pseudo-phase concept due to the following reasons. (i) The Michaelis-Menten treatment is based on the assumption that the interaction between substrate and aggregate species takes place at the 1 : 1 ratio; each aggregate incorporates only one substrate molecule. The aggregation number of the present single-walled vesicles is at least 4000—5000,[10] while that of ordinary micelles is *ca.* 100.[12] In the light of our previous study, a much larger number of substrate molecules are incorporated into each vesicle and the binding site concept needs to be introduced.[15] (ii) In the present reaction systems, the histidyl residue is covalently bound to amphiphile molecules, and consequently the catalyst species are exclusively placed in the vesicular domain and not in the bulk aqueous

a) In an aqueous phosphate buffer (5.0 mmol dm^{-3}) containing 1.0%(v/v) dioxane, 15.0±0.1 °C, pH 7.47, μ 0.05 (KCl). Initial concentrations in mol dm^{-3}: L-BocAlaPNP, 1.04×10^{-5}; D-BocAlaPNP, 1.01×10^{-5}; L-BocValPNP, 1.22×10^{-5}; D-BocValPNP, 1.29×10^{-5}; L-BocLeuPNP, 1.01×10^{-5}; D-BocLeuPNP, 1.07×10^{-5}; L-C_{12}PhePNP, 1.23×10^{-5}; D-C_{12}PhePNP, 1.10×10^{-5}; L-C_{12}GlyValPNP, 1.03×10^{-5} (vesicle), 5.15×10^{-6} (micelle); D-C_{12}GlyValPNP, 1.09×10^{-5} (vesicle), 5.45×10^{-6} (micelle). b) At the concentration (mol dm^{-3}) given in parentheses. c) Given as k_D/k_L.

phase. In addition, the ion-exchange treatment is not applicable to the present systems since all the substrates employed here are hydrophobic and nonionic. (iii) The bilayer domain may provide a steady and hydrophobic reaction site which is considered to be an organic pseudo-phase.

According to the Berezin's treatment based on the pseudo-phase concept, the pseudo-first-order rate constant, k_{obsd}, is given by Eq. 1 under the conditions employed for the present systems.[14,16]

$$k_{obsd} = \frac{k_m K_s D}{1 + K_s D} \quad (1)$$

This can be rearranged to give Eq. 2.

$$\frac{1}{k_{obsd}} = \frac{1}{k_m K_s D} + \frac{1}{k_m} \quad (2)$$

Here, k_m and K_s represent the intramembrane rate constant and the apparent binding constant for incorporation of a substrate into the single-walled vesicle, respectively; D designates the stoichiometric amphiphile concentration minus its critical aggregate concentration (CAC). A correlation of k_{obsd} with D is typically shown in Fig. 2a for the degradation of L-BocValPNP as catalyzed by $N^+C_5AlaHis2C_{16}$ and followed the saturation-type kinetics. The plot of $1/k_{obsd}$ *vs.* $1/D$ on the basis of Eq. 2 gave a straight line as illustrated in Fig. 2b. The k_m and K_s values for selected cases are summarized in Table 3. The K_s values for C_{12}GlyValPNP are larger than those for BocValPNP. This indicates that the substrate incorporation is largely controlled by the hydrophobic property of the substrates in addition to some orientational effect provided by the bilayer membranes.

As for the incorporation of BocValPNP, the binding constant increases in the following order with respect

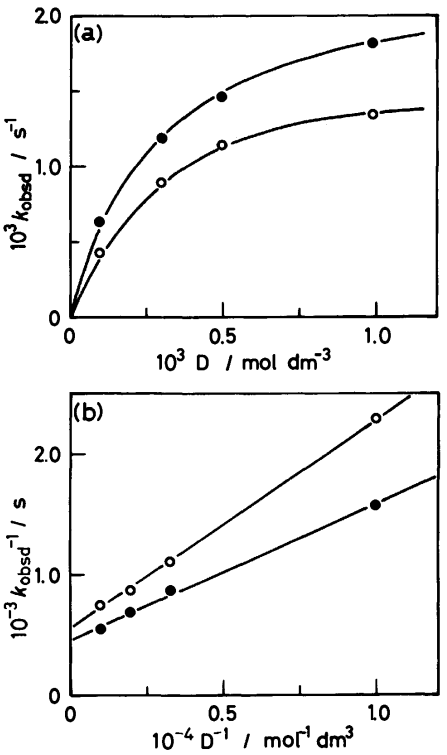

Fig. 2. Saturation-type kinetic behavior (a) and the corresponding double reciprocal plots (b) for the hydrolysis of L- (●) and D-BocValPNP (○) as catalyzed by $N^+C_5AlaHis2C_{16}$ in an aqueous phosphate buffer (5 mmol dm^{-3}) containing 1.0%(v/v) dioxane: pH 7.47, μ 0.05 (KCl), 15.5±0.1 °C. Initial concentrations: L-BocValPNP, 1.22×10^{-5}; D-BocValPNP, 1.29×10^{-5} mol dm^{-3}.

a) In an aqueous phosphate buffer (5.0 mmol dm^{-3}) containing 1.0%(v/v) dioxane, 15.0±0.1 °C, pH 7.47, μ 0.05 (KCl). As for initial concentrations of the substrates, see Table 2. b) At the concentration range (mol dm^{-3}) given in parantheses. c) Given as k_m^L/k_m^D and/or K_s^L/K_s^D. d) Given as k_m^D/k_m^L and/or K_s^D/K_s^L.

to the amphiphiles: N^+C_5LeuHis2C_{16}<N^+C_5PheHis2C_{16}<N^+C_5AlaHis2C_{16}. This means that the less the steric hindrance between the amino acid residue of the substrate and those of the amphiphiles is, the larger the substrate binding is. On the other hand, the k_m value does not change appreciably by the nature of the amphiphiles but increases largely by raising the hydrophobicity of the substrate: BocValPNP, $(1.6—6.3)\times10^{-3}$ s^{-1}; C_{12}GlyValPNP, $(0.4—1.4)\times10^{-2}$ s^{-1}. In addition, the apparent enantioselectivity (see the previous section) is primarily reflected on the k_m value.

pH Effect on Ester Hydrolysis. The pH-rate profiles for the hydrolysis of C_{12}GlyValPNP carried out in the micellar system composed of $HisC_{16}$ and STAC and in the vesicular phase of N^+C_5HisAla2C_{16} are shown in Fig. 3. The overall kinetic feature is in agreement with those of the previous studies which claim that the imidazolyl group is the catalytic species.[6,17] The acid dissociation from the cationic imidazolium group to the corresponding uncharged species gives the following pK_a values from the pH-rate profiles: $HisC_{16}$/STAC, 6.2; N^+C_5HisAla2C_{16}, 7.2. Thus, the present kinetic study mentioned above was carried out under the conditions that the uncharged imidazolyl group acts as the catalytic species. The imidazolyl group in the present micellar system must be placed in the cationic polar domain in the light of the previous investigations: *N*-tetradecanoylhistidine/CTAB, pK_a 6.20;[6] $HisC_{16}$/N^+C_5AlaC_{12}, pK_a 6.16.[7] On the other hand, the higher pK_a value observed in the vesicular system indicates that the imidazolyl group is placed in the significantly hydrophobic environment.

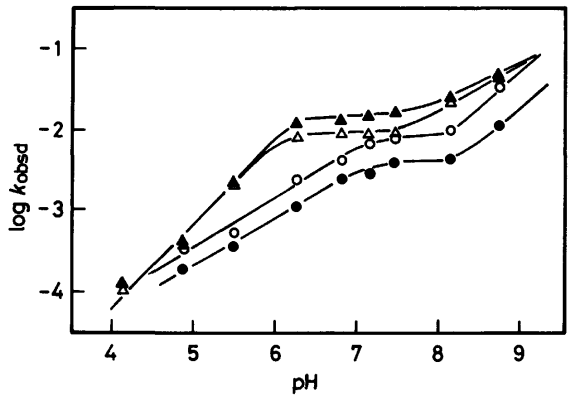

Fig. 3. Correlations of pH *vs.* rate for the hydrolysis of C_{12}GlyValPNP (L-Val, closed; D-Val, open) as catalyzed by the micellar system ($HisC_{16}$/STAC, triangle) and the vesicular system (N^+C_5HisAla2C_{16}, circle) in aqueous buffers containing 1.0% (v/v) dioxane at 15.0±0.1 °C and μ 0.05 (KCl): pH 4—6, citrate-borate buffer; pH 6—9, phosphate-borate buffer. Initial concentrations for the vesicular system: N^+C_5HisAla2C_{16}, 1.01×10^{-3}; L-C_{12}GlyValPNP, 1.03×10^{-5}; D-C_{12}GlyValPNP, 1.09×10^{-5} mol dm^{-3}. Initial concentrations for the micellar system: STAC, 1.01×10^{-3}; $HisC_{16}$, 6.73×10^{-5}; L-C_{12}GlyValPNP, 5.15×10^{-6}; D-C_{12}GlyValPNP, 5.45×10^{-6} mol dm^{-3}. Values of k_{obsd} are given in s^{-1}.

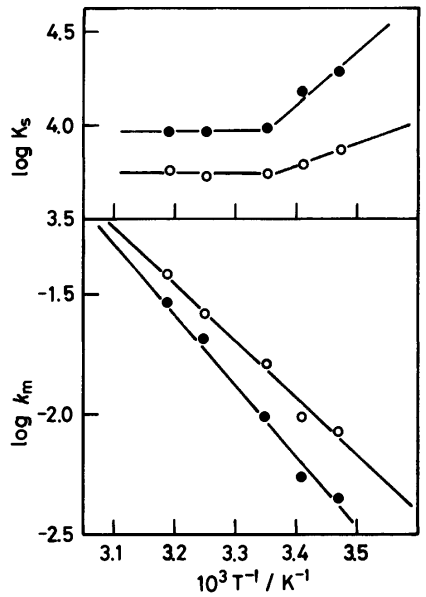

Fig. 4. Arrhenius plots for the hydrolysis of C_{12}-GlyValPNP (L-Val, ●; D-Val, ○) as catalyzed by N^+C_5HisAla2C_{16} in an aqueous phosphate buffer (5 mmol dm^{-3}) containing 1.0% (v/v) dioxane at pH 7.47 and μ 0.05 (KCl). Initial concentrations: N^+C_5HisAla2C_{16}, 1.01×10^{-3}; L-C_{12}GlyValPNP, 1.03×10^{-5}; D-C_{12}GlyValPNP, 1.09×10^{-5} mol dm^{-3}. Values of k_m and K_s are given in s^{-1} and mol^{-1} dm^3, respectively.

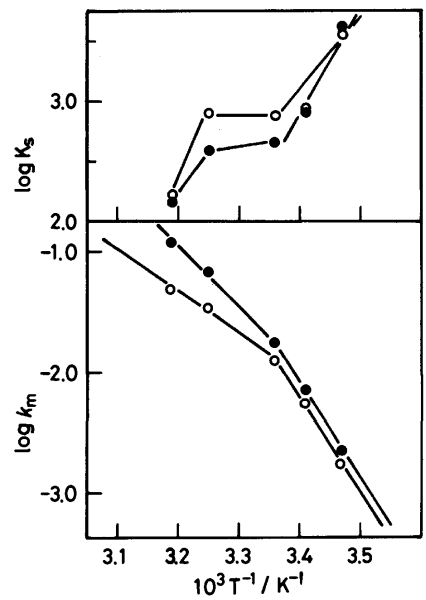

Fig. 5. Arrhenius plots for the hydrolysis of Boc-ValPNP (L-Val, ●; D-Val, ○) as catalyzed by N^+C_5AlaHis2C_{16} in an aqueous phosphate buffer (5 mmol dm^{-3}) containing 1% (v/v) dioxane at pH 7.47 and μ 0.05 (KCl). Initial concentrations: N^+C_5Ala-His2C_{16}, 1.00×10^{-3}; L-BocValPNP, 1.22×10^{-5}; D-BocValPNP, 1.29×10^{-5} mol dm^{-3}. Values of k_m and K_s are given in s^{-1} and mol^{-1} dm^3, respectively.

TABLE 4. ACTIVATION PARAMETERS FOR THE HYDROLYSIS OF ENANTIOMERIC ESTERS AS CATALYZED BY VESICLES[a)]

Amphiphile[b)]	Substrate	$\Delta G^{\ddagger}_{308}$ / kJ mol^{-1}	$\Delta H^{\ddagger}$ / kJ mol^{-1}	$\Delta S^{\ddagger}$ / J K^{-1} mol^{-1}
$N^+C_5HisAla2C_{16}$	L-C_{12}GlyValPNP	85.4	56.1	−95.8

a) In an aqueous phosphate buffer (5.0 mmol dm^{-3}) containing 1.0%(v/v) dioxane, pH 7.47, μ 0.05 (KCl). Initial concentrations in mol dm^{-3}: L-C_{12}GlyValPNP, 1.03×10^{-5}; D-C_{12}GlyValPNP, 1.09×10^{-5}; L-BocValPNP, 1.22×10^{-5}; D-BocValPNP, 1.29×10^{-5}. b) At the concentration (mol dm^{-3}) given in parentheses. c) For the range of 25—40 °C. d) For the range of 15—25 °C.

Phase-Transition Effect on Substrate-Binding and Intravesicular Rate Constants. The Arrhenius plots of the K_s and k_m values are shown in Figs. 4 and 5 for the combinations of $N^+C_5HisAla2C_{16}$–C_{12}GlyValPNP and $N^+C_5AlaHis2C_{16}$–BocValPNP, respectively. Apparently, the K_s values are much lower above the phase transition temperatures than the corresponding values below them. This seems to indicate that the fluidity of vesicular systems, which tends to be reduced as the hydrophobic and hydrogen-bonding interactions are enhanced, controls the substrate-binding process. As regards the Arrhenius plots of k_m values, there are break points in the phase transition range for the hydrolysis of both enantiomers of BocValPNP, while only a single straight line is drawn for the hydrolysis of each enantiomer of C_{12}GlyValPNP. This must reflect the fact that the BocValPNP molecules are placed in the vesicular surface domain between the charged head group and the hydrogen-belt region and consequently the molecular mobility of such substrates is much sensitive to their hydrogen-bonding interaction with the vesicular phase. On the other hand, the C_{12}GlyValPNP molecules are tightly fixed in the vesicular phase through the effective hydrophobic interaction, and the mobility of these molecules are hardly affected by the change in hydrogen-bonding mode. As for the hydrolysis of C_{12}GlyValPNP with $N^+C_5HisAla2C_{16}$ over the whole temperature range studied and that of BocValPNP with $N^+C_5AlaHis2C_{16}$ above the phase transition temperature, the unfavorable activation enthalpy is largely compensated by the favorable activation entropy. This is the reason why the enantioselectivity is not significantly large. Moreover, the absolute values of activation entropy are much smaller above T_m than those observed below it for the hydrolysis of BocValPNP. This must be due to the increased mobility of the substrate species above the phase transition temperature.

As regards the reaction mechanism, we have confirmed that the micelles formed with the peptide amphiphile having the histidyl residue enhances the ester hydrolysis partly by the general base catalysis.[7)] In the present vesicular systems, approximately half of the reaction proceeds through the general base mechanism; the hydrolysis of BocValPNP with $N^+C_5LeuHis2C_{16}$, 54% general base catalysis.[18)] This mechanism is operative in these molecular aggregate systems so as to reduce the direct steric hindrance between the substrate molecules and the active reaction sites within the vesicles. Thus, this mechanistic aspect provides the important reason why the enantioselectivity is not significantly large in the present systems.

In conclusion, the peptide amphiphiles having dipeptide segments yield characteristic molecular aggregates in the dispersion state, and the sequence of the amino acid residues may control the aggregate morphology. The hydrolysis reactions of enantiomeric esters of various hydrophobic nature, which were carried out in the single-walled vesicles, did not show large enantioselectivity primarily due to thermodynamic and mechanistic reasons. Since enzymes generally incorporate their specific substrates into their reaction sites most adequately for the transformation to the transition state from the stereochemical viewpoint,[19)] amphiphile molecules need to be designed so as to provide the efficient enantiomer-recognition sites through host-guest interactions.

16) The observed reaction velocity, v, is given by the following equation.

$$v = v_o D\overline{V} + v_w(1-D\overline{V}) = k_o[A]_o[S]_o D\overline{V} + k_w[A]_w[S]_w(1-D\overline{V}) \quad (1\text{-}1)$$

Here, D, $\overline{V}$, and k stand for the amphiphile concentration minus its critical aggregate concentration (CAC), the partial molar volume of the amphiphile in the membrane, and the second-order rate constant, respectively; [A] and [S] are the concentrations of the amphiphile and the ester substrate, respectively; the subscripts, o and w, denote the quantities in the organic pseudo-phase and the bulk aqueous phase, respectively. The distribution coefficient, P_s, and the initial substrate concentration, $[S]_T$, are given as follows.

$$P_s = [S]_o/[S]_w \quad (1\text{-}2)$$
$$[S]_T = [S]_o D\overline{V} + [S]_w(1-D\overline{V}) \quad (1\text{-}3)$$

The binding constant for incorporation of the substrate into the organic pseudo-phase, K_s, is defined by Eq. 1-4, and $[S]_w$ and $[S]_o$ are given by Eqs. 1-5 and 1-6, respectively.

$$K_s = (P_s-1)\overline{V} \quad (1\text{-}4)$$
$$[S]_w = [S]_o/(1+K_sD) \quad (1\text{-}5)$$
$$[S]_o = P_s[S]_o/(1+K_sD) \quad (1\text{-}6)$$

By combining the relations, $[A]_o=1/\overline{V}$ and $[A]_w$=CAC, together with Eqs. 1-1, 1-5, and 1-6, we obtain Eq. 1-7.

$$v = k_o\frac{P_s[S]_o}{\overline{V}(1+K_sD)}D\overline{V} + k_w(\mathrm{CAC})\frac{[S]_o}{1+K_sD}(1-D\overline{V}) = \frac{k_oP_sD+k_w(\mathrm{CAC})(1-D\overline{V})}{1+K_sD}[S]_o = k_{obsd}[S]_o \quad (1\text{-}7)$$

Since the $(1-D\overline{V})$ term approximately equals 1 because of the low amphiphile concentration and k_w(CAC) can be neglected under the present conditions in addition to the fact that K_s nearly equals $P_s\overline{V}$, Eq. 1-7 is rearranged and simplified to give Eq. 1-8.

$$k_{obsd} = \frac{k_oK_sD}{\overline{V}(1+K_sD)} \quad (1\text{-}8)$$

By substitution of k_m for $k_o/\overline{V}$, Eq. 1-8 is converted into Eq. 1.

Synthesis of 5-(Substituted Styryl)-2-aminotropones

Kimiaki IMAFUKU,* Toshio KOBAYASHI,† and Hisashi MATSUMURA††
Department of Chemistry, Faculty of Science, Kumamoto University, Kurokami, Kumamoto 860
(Received July 23, 1984)

The methylation of 4-styryltropolones with diazomethane afforded 2-methoxy-4-styryltropones (**2a**—g) and 2-methoxy-6-styryltropones. The reactions of **2a**—**g** with hydrazine gave 2-hydrazino derivatives, which were converted to 2-chloro derivatives **5a**—**g**. Ammonolysis of **5a**—**g** afforded 2-amino-5-styryltropones (**7a**—**g**) by *ciné* substitution reaction. The compounds **7a**—**g** were hydrolyzed to give the corresponding 5-styryltropolones. Some interesting by-products were also found in these synthetic processes.

Previously, we have studied long-range substituent effects on dissociation constants of some series of styryltropolone derivatives and transmission of the electronic effects between two aromatic rings which were connected by vinylene linkage.[1-4] In connection with these studies, the dissociation constants of some 5-(substituted styryl)-2-aminotropones were discussed.[5] This paper deals with their synthesis.

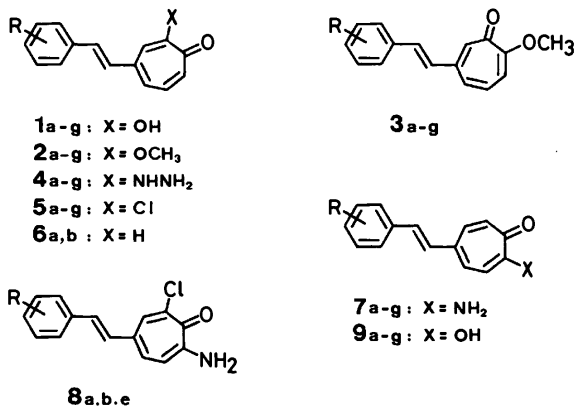
Results and Discussion

The condensations of 3-carboxy-4-carboxymethyltropolone with some substituted benzaldehydes gave 3-carboxy-4-styryltropolones, which were converted to 4-styryltropolones (**1a**—**g**) with carbon dioxide elimination.[6] Now, two new 4-styryltropolones (**1b**: R=*m*-CH_3 and **1d**: R=*m*-OCH_3) were obtained.

The methylations of **1a**—**g** with diazomethane afforded two isomeric 2-methoxy-4-styryl- (**2a**—**g**) and 2-methoxy-6-styryltropones (**3a**—**g**), which were previously reported[7] except for the new compounds **2b**, **d** and **3b**, **d**. Furthermore, treatments of **2a**—**g** with hydrazine gave 2-hydrazino-4-styryltropones (**4a**—**g**). The yields and characteristic data are summarized in Table 1.

Oxidative decompositions of **4a**—**g** in concentrated hydrochloric acid in the presence of copper(II) sulfate afforded 2-chloro-4-styryltropones (**5a**—**g**). The structures were confirmed by their analytical and spectral data, which are listed in Table 1. Further, in this reaction a trace amount of by-products were isolated. We could confirm structures of only two products from **4a** and **4b** to be 4-styryl- (**6a**)[8] and 4-(*m*-methylstyryl)tropone (**6b**). Other isolated ones were too small to analyze.

Reactions of 2-chloro-4-styryltropones (**5a**—**g**) with ammonia afforded 2-amino-5-styryltropones (**7a**—**g**) by *ciné* substitution reaction. These reactions also gave a new type of compounds, 2-amino-7-chloro-5-styryltropones (**8a**, **b**, **e**). These results were summarized in Table 1. Although some by-products were isolated in the cases of the ammonolysis of **5c**, **d**, **f**, **g**, their amounts were too small to establish their structures.



Scheme 1.

a R=H, **b** R=*m*-CH_3, **c** R=*p*-CH_3, **d** R=*m*-OCH_3, **e** R=*p*-OCH_3, **f** R=*m*-Cl, **g** R=*p*-Cl

The infrared spectra of the compounds **8a**, **b**, **e** are very similar to those of 2-amino-5-styryltropones **7** but show a little difference in the finger-print region. Their electronic spectra are also similar to those of **7** but show slightly bathochromic shift. These spectral data suggest that **8a**, **b**, **e** have a tropone ring and styryl group. The structure of **8a** was also confirmed by the fragmentation analysis in the mass spectrum.

In addition, 2-amino-5-styryltropones (**7a**—**g**) were hydrolyzed to afford 5-styryltropolones (**9a**—**g**).[9]

Experimental

The melting points were determined with a Yanagimoto MP-S2 apparatus and are uncorrected. The IR and UV spectra were taken on a JASCO IRA-1 and a Hitachi EPS-3T spectrophotometer, respectively. The NMR spectra were recorded with a Hitachi-Perkin-Elmer R-24 spectrometer (60 MHz). The mass spectrum was run on a JEOL JMS-01-SG2 apparatus.

4-Styryltropolones (1a—g). 4-Styryltropolones (**1a**—**g**) were prepared according to a previous work.[6]

2-Methoxy-4-styryltropones (2a—g) and 2-Methoxy-6-styryltropones (3a—g). An excess of diazomethane ethereal

a) Picrate. b) H. Matsumura, *Nippon Kagaku Zasshi*, **81**, 1763 (1960). c) In CF_3COOH.

solution was added to a solution of 4-styryltropolone (**1a—g**) (1.0 g, 3.3—4.2 mmol) in chloroform (10 ml), and the mixture was allowed to stand for 2 d in a refrigerator. After removal of the solvents, the residue was chromatographed on three Wakogel B-10 plates (30×30 cm) with ethyl acetate. 2-Methoxy-4-styryltropones (**2a—g**) and 2-methoxy-6-styryltropones (**3a—g**) were obtained from the upper and lower band, respectively. Each methyl ether was recrystallized from benzene.

2-Hydrazino-4-styryltropones (4a—g). To a solution of 2-methoxy-4-styryltropone (**2a—g**) (1.0 g, 3.7—4.2 mmol) in ethanol (5 ml) was added 80% hydrazine hydrate (1.0 ml). The mixture was allowed to stand overnight at room temperature. The precipitate was collected and recrystallized from methanol to give 2-hydrazino-4-styryltropones (**4a—g**).

2-Chloro-4-styryltropones (5a—g). A hot solution of copper(II) sulfate pentahydrate (5 g) in water (6 ml) was added to a hot suspended solution of 2-hydrazino-4-styryltropones (**4a—g**) (500 mg) in concentrated hydrochloric acid (5 ml). The mixture was immediately cooled, diluted with water, and extracted with chloroform. The extract was dried over sodium sulfate, concentrated, and chromatogrpahed on a Wakogel C-100 column (50 g) with chloroform to afford 2-chloro-4-styryltropones (**5a—g**) (from methanol).

4-Styryltropones (6a, b). In the preparation of 2-chloro-4-styryltropones (**5a, b**), the second band in the chromatography gave 4-styryltropones (**6a, b**).

6a: Yellow crystals. Yeild, 9%. Mp 89—92 °C (lit,[8] 89—91 °C).

6b: Oil. Yield, 19%. IR ($CHCl_3$) 1625 (C=O), 1565 (C=C), 960 cm^{-1} (CH). Found: C, 86.23; H, 6.39%. Calcd for $C_{16}H_{14}O$ C, 86.45; H, 6.35%.

2-Amino-5-styryltropones (5a—g). A suspended solution of 2-chloro-4-styryltropone (**5a—g**) (100 mg) in ammonia-saturated absolute ethanol (6 ml) in a sealed tube was allowed to stand for 2 d at room temperature. After removal of the ammonia and ethanol, the residue was chromatographed on a Wakogel B-10 plate (20×20 cm) with ethyl acetate to give 2-amino-5-stytyltropones (**7a—g**) (from ethanol).

2-Amino-7-chloro-5-styryltropones (8a, b, e). In the preparation of 2-amino-5-styryltropones (**7a, b, e**), the upper fraction in the chromatography gave 2-amino-7-chloro-5-styryltropones (**8a, b, e**), respectively.

8a: Yellow needles (from benzene). Yield, 35%. Mp 186 °C. IR ($CHCl_3$) 3510 (NH), 3360 (NH), 1590 (C=O), 950 cm^{-1} (CH); UV (CH_3OH) 251 ($\log \varepsilon$ 4.24), 289 (5.32), 392 nm (4.46); MS *m/z* (%) 259 (M', 38), 257 (M, 100), 231 (M'—CO, 14), 229 (M—CO, 40), 194 ([231 and 229]–Cl, 25), 193 ([231 and 229]–HCl, 42). Found: C, 69.86; H 4.92; N, 5.31%. Calcd for $C_{15}H_{12}NOCl$: C, 69.90; H, 4.70; N, 5.44%.

8b: Yellow prisms (from benzene). Yield, 3%. Mp 177 °C. IR ($CHCl_3$) 3510 (NH), 3350 (NH), 1595 (C=O), 970 cm^{-1} (CH); NMR ($CDCl_3$) δ=2.36 (3H, s, CH_3), 6.12 (2H, br, NH_2), 6.8—7.5 (9H, m). Found: C, 70.75; H, 5.23; N, 5.10%. Calcd for $C_{16}H_{14}NOCl$: C, 70.72; H, 5.19; N, 5.15%.

8e: Yellowish brown needles (from benzene). Yield, 30%. Mp 208—210 °C. IR ($CHCl_3$) 3500 (NH), 3340 (NH), 1600 (C=O), 960 cm^{-1} (CH). Found: C, 66.73; H, 4.96; N, 4.63%. Calcd for $C_{16}H_{14}NO_2Cl$: C, 66.78; H, 4.96; N, 4.87%.

We wish to thank Professor Hitoshi Takeshita, Kyushu University, for his kind measurement of the mass spectrum.

(Received July 23, 1984)

Epoxidation of alnus-5(10)-en-3β-yl acetate with *m*-chloroperbenzoic acid gave a 5α,10α-epoxide, treatment of which with boron trifluoride etherate afforded multiflora-5,8-dien-3β-yl acetate. On hydrogenation and hydrolysis, the diene gave isomultiflorenol.

In the previous paper,[2)] the boron trifluoride etherate ($BF_3 \cdot OEt_2$)-catalyzed backbone rearrangement of 5,6-epoxyalnusan-3β-yl acetate was reported. Further investigation on a behavior of carbonium ions generated on B-ring was attempted. This paper describes the epoxidation of alnus-5(10)-ene derivatives, the $BF_3 \cdot OEt_2$-catalyzed backbone rearrangement of a 5α,10α-epoxy acetate, and also a preparation of isomultiflorenol (**1**)[3–7)] from one of the rearranged products.

Alnus-5(10)-en-3β-yl acetate (**4**),[8)] prepared from dendropanoxide (**5**),[9)] was subjected to the epoxidation with *m*-chloroperbenzoic acid (MCPBA) to afford a single epoxide (**6**) in a good yield. However, no information on the configuration of the epoxide ring could be obtained from any spectrum of **6** (See Experimental).

In order to determine the configuration of the epoxide (**6**), the following epoxidation reactions were examined. Alnus-5(10)-en-3β-ol (**7**) and its benzoate (**8**) were epoxidized with MCPBA under the same conditions as above to afford single epoxides (**9** and **10**), respectively. On acetylation, the epoxide (**9**) yielded an epoxy acetate, which was identical with **6**. Treatment of **10** with lithium aluminium hydride afforded an epoxy alcohol identical with **9**. Therefore, the epoxide rings of **6**, **9**, and **10** are in all the same configurations.

Since the signals due to 3α-protons of alnus-5(10)-en-3β-ol (**7**), -3β-yl acetate (**4**), and -3β-yl benzoate (**8**) were observed as double doublets at δ 3.44 (J=10 and 4 Hz), δ 4.69 (J=10 and 4 Hz), and δ 4.94 (J=10 and 4 Hz), respectively, in the ^1H NMR spectra, the substituents at C-3β exist in an equatorial orientation. From these facts, it could be understood why the 3β-oxygen functions did not participate in these epoxidation reactions, hence the reagent attacked exclusively from the less hindered α-side of the molecule (4β- and 9β-methyl groups are perpendicular to the 5,10-double bond plane, while the 4α-methyl group lies in the plane). Therefore, the epoxide rings of **6**, **9**, and **10** were considered to be in the α-configuration.

Then, epoxidation reactions of alnus-5(10)-en-3α-*O*-derivatives were examined. In the case of these 3α-*O*-derivatives, since the substituents at C-3α exist in an axial orientation, the bulky substituents block the α-side of the molecule and the attack of the epoxidizing reagent from the α-side was considered to be hindered. Epoxidation of alnus-5(10)-en-3α-ol (**11**) and its acetate (**12**) under the same conditions as above gave single epoxides (**13** and **14**), respectively, while 3α-benzoate (**15**), on epoxidation, gave two epoxides (**16** and **17**) in a ratio of 7:1. The relative configurations of the epoxide rings of **13**, **14**, and **16** were confirmed by the derivatization as in the case of the 3β-*O*-derivatives, and proved to be in all the same. These substituent effects are explained by the steric hindrance due to 4β- and 9β-methyl groups and partly by the hydrogen bond formation between the reagent and the 3α-axial hydroxyl group in the case of **11**, resulting in the exclusive formation of the α-epoxide (**13**). In the case of the benzoate (**15**), the attack from the α-side of the molecule was sterically slightly hinderded by the bulky benzoyloxyl group to afford the β-epoxide (**17**) as the minor product, while the acetoxyl group was not large enough to prevent the attack from the α-side. Thus the configurations of the epoxide rings of **13**, **14**, and **16** are concluded to be α.

These assignments of the epoxide rings were further confirmed by the Sharpless epoxidation.[10)] Epoxidation of alnus-5(10)-en-3α-ol (**11**) with vanadyl acetylacetonate ($VO(acac)_2$) and *t*-butyl hydroperoxide afforded a single epoxide which was identical with 5α,10α-epoxide (**13**) obtained by MCPBA. However epoxidation of alnus-5(10)-en-3β-ol (**7**) with the same conditions gave a single epoxide, but it was different from the 5α,10α-epoxide (**9**) obtained by MCPBA. From the spectral data and formation mechanism, it was concluded to be a 5β,10β-epoxide (**18**).

The epoxy-3β-ol (**9**), obtained by the reaction with MCPBA, was oxidized to give a keto epoxide (**19**) which was identical with that obtained by the oxidation of the epoxy-3α-ol (**13**); thus the epoxide rings of the 3β-*O*-derivatives (**6**, **9**, and **10**) and the 3α-*O*-derivatives (**13**, **14**, and **16**) are the same.

From these facts, the epoxidation reaction of these 5(10)-ene derivatives was shown to occur from the α-side of the molecule exclusively except for 5(10)-en-3α-yl benzoate (**15**). These results are opposite from those obtained for the epoxidation of alnus-5-en-3β-ol and its derivatives.[2]

The assignments of these epoxide rings were supported by the NMR spectral measurement (see Tables 1 and 2). The protons at C-3 of alnus-5(10)-en-3β-ol (**7**) and -3α-ol (**11**) resonated at nearly the same magnetic fields, while a remarkable difference in shift values due to the protons at C-3 was observed between 5α,10α-epoxy-3β-ol (**9**) and 5α,10α-epoxy-3α-ol (**13**); the 3α-H of **9** is deshielded by 0.34 ppm relative to that of **13**. This observation is ascribed to an anisotropic effect of an oxygen atom of the epoxide caused by a proximation of the 3α-axial proton of **9** to the oxygen atom.

This anisotropic effect is also observed in the ^{1}H NMR spectra of the corresponding acetates (**6** *vs.* **14**) and benzoates (**10** *vs.* **16**).

The same observations were given in the ^{1}H NMR spectral examination of 5β,10β-epoxides, although the differences are not so large, because the 3β-protons exist in an equatorial orientation. The 3β-protons of 5β,10β-epoxy-3α-ol (**20**), 5β,10β-epoxy-3α-yl acetate (**21**), and 5β,10β-epoxy-3α-yl benzoate (**17**) appeared at

* Assignable to C-8. ** Assignable to C-3.

lower fields than the 3α-protons of the corresponding 3β-alcohol (**18**), 3β-acetate (**22**), and 3β-benzoate (**23**), respectively.

In the ^1H NMR spectra of **13** and **18**, signals due to hydroxyl protons were observed at δ 3.52 and 2.71, respectively. Appearance of these signals is ascribed to the formation of hydrogen bond between the epoxide oxygen atom and the hydroxyl proton, resulting in the retardation of the exchange rate of the hydroxyl proton. This observation also supports the assignment of the epoxides, because the hydrogen bond could not be formed in 5α,10α-epoxy-3β-ol (**9**) nor 5β,10β-epoxy-3α-ol (**20**).

In the ^{13}C NMR spectrum of α-epoxy-3β-ol (**9**), a signal due to C-3 atom to which the proton resonating in a low field (δ 3.58) was attached, was observed in a higher field by 3.3 ppm than that of C-3 atom of α-epoxy-3α-ol (**13**). In the ^{13}C NMR spectra of β-epoxy alcohols, it was shown that C-3 atom of 3α-alcohol (**20**) resonated in a higher field relative to that of 3β-alcohol (**18**).

From the same reason, it is understood that C-8 atoms, bearing hydrogen atoms in α-orientation, of α-epoxides (**9** and **13**) resonate in a higher field by *ca.* 9 ppm than those of 5(10)-en-3-ols (**7** and **11**), while C-8 atoms of β-epoxides (**18** and **20**) resonates at nearly the same magnetic field as 5(10)-en-3-ols.

These observations described above are strongly indicative of the correct assignment of the epoxide rings.

The unequivocal proof for the structure of 5α,10α-epoxyalnusan-3β-yl acetate (**6**) was provided by X-ray single crystal analysis. The crystals of **6** belong to a monoclinic space group C_2, and the lattice parameters are a=13.446(4), b=6.739(2), c=32.257(7) Å, and β=103.71(3)°; z=4. Intensity data were measured on a Philips PW1100 automatic four-circle diffractometer using monochromated Cu $K\alpha$ radiation. A total of 2951 independent reflections with $F_o \geqq 2.5\sigma(F_o)$ were obtained by $2\theta-\theta$ scanning mode. The structure was solved by the direct method using the MULTAN 80 program and was refined by the block-diagonal least squares method. All hydrogen atoms were located on a difference electron density map. The final R-value was 0.056 assuming the anisotropic temperature factors for the non-hydrogen atoms and the isotropic ones

for the hydrogen atoms. The final atomic coordinates are listed in Table 3 and bond lengths and bond angles are listed in Tables 4 and 5.[11] Figure 1 is a computer-generated perspective drawing of the molecule of 5α,10α-epoxyalnusan-3β-yl acetate (**6**).

5α,10α-Epoxyalnusan-3β-yl acetate (**6**) was treated with $BF_3 \cdot OEt_2$ (1.2 equiv) in benzene to afford a reaction mixture, which was shown to consist of a main product (**24**; *ca.* 80% yield) and more than seven minor components by HPLC examination. The reaction mixture was subjected to separation by column chromatography to give the pure main product (**24**), $C_{32}H_{50}O_2$ (determined by the high-resolution mass spectrum), showed no chracteristic absorption maxi-

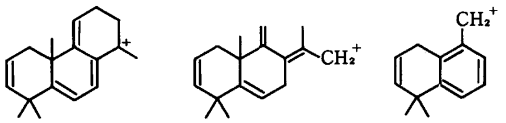
mum above 210 nm, while the ^{1}H NMR spectrum revealed the presence of a doubly allylic methylene (δ 2.60, 2H; m) and an olefinic proton (δ 5.71, 1H; dd). The spectral data and mechanistic considerations lead to the structure, multiflora-5,8-dien-3β-yl acetate for the main product (**24**). The proposed structure was supported by the mass spectral measurement; the appearance of the fragment peaks at *m/z* 239 (**A**), *m/z* 227 (**B**), and *m/z* 171 (**C**) indicates the presence of the 5,8-diene structure.



A $C_{18}H_{23}^+$ (*m/z* 239.1798) **B** $C_{17}H_{23}^+$ (*m/z* 227.1778) **C** $C_{13}H_{15}^+$ (*m/z* 171.1207)

The seven minor products obtained by the $BF_3 \cdot OEt_2$-catalyzed backbone rearrangement of **6** could not be identified, because of difficulty of the separation and a paucity of the material.

The diene (**24**) was treated with selenium dioxide[12] in boiling aqueous benzene to give a dehydrogenation product (**25**), the molecular formula, $C_{32}H_{48}O_2$, of which was given by the high-resolution mass spectrum. Since the ^{1}H NMR and UV spectra indicate the presence of a $\Delta^{5,7,9(11)}$-triene moiety, the stucture of the dehydrogenation product (**25**) is formulated as multiflora-5,7,9(11)-trien-3β-yl acetate.

The backbone rearrangement of 5α,10α-epoxyalnusan-3β-yl acetate (**6**) was shown to yield multiflora-5,8-dien-3β-yl acetate (**24**) as the main rearranged product, no further rearranged product being obtained much enough to be characterized. Although it is not clear the reason why further migration did not occur efficiently, the following account could be proposed. On attack of $BF_3 \cdot OEt_2$, the 5α,10α-epoxide ring would be cleaved to yield a carbonium ion on C-10 and a BF_3-coordinated oxygen-function at C-5α. A methyl group at C-9β would migrate to C-10 and then a migration of $C_{8\alpha}$–H to C-9α would follow immediately to afford a carbonium ion on C-8. If the BF_3-coordinated group is absent, it is expected to take place the further backbone rearrangement up to the C and D rings. However, since the BF_3-coordinated group at C-5α and the $C_{9\alpha}$–H are located in a 1,3-diaxial relationship, the neighboring group participation could assist the abstraction of the $C_{9\alpha}$–H, while the competitive migration of C_{14}–Me would be impeded, resulting in the interruption of the further backbone rearrangement.

The diene (**24**) in ethyl acetate was hydrogenated in the presence of 5% palladium on carbon for 3 d to give a hydrogenation product in 97% yield, which was shown to be a mixture of **26** and **27** in a ratio of 2:3 by GC examination. The mixture was subjected to separation by repeating column chromatography on silica gel to afford isomutiflorenyl acetate (**26**) and its 5β-*H* isomer (**27**). The spectral data of the former (**26**) were identical with those of literatures[4] and two compounds (**26** and **27**) exhibited nearly the same mass spectra characteristic of multiflor-8-ene skeleton.[13] Since the diene molecule (**24**) bends towards the α-side so much that the adsorption onto the surface of the catalyst was impeded, the hydrogenation from the α-side was hindered. On the other hand, the hydrogenation from the β-side was also hindered by the presence of 4β- and 10β-methyl groups. The fact that the hydrogenation had required a long reaction time could be explained by these two effects, which were estimated to be almost the same from the product ratio.

Isomultiflorenyl acetate (**26**) and its 5β-*H* isomer (**27**) were hydrolyzed with alkali to give isomultiflorenol (**1**)[6,14,15] and 5β-isomultiflorenol (**28**), respectively.

Thus the conversion of dendropanoxide (**5**) into isomultiflorenol (**1**) was achieved in 18% overall yield (6 steps) through thermodynamically favorable pathways,[16] which formally constitutes the total synthesis of isomultiflorenol (**1**).[17]

When the acetate mixture (**26** and **27**), obtained by the hydrogenation of the diene (**24**), was treated with 5% potassium hydroxide in methanol–tetrahydrofuran (5:1) at room temperature, the acetate (**26**) was easily hydrolyzed and afforded isomultiflorenol (**1**) within a half day, while most of the acetate (**27**) still remained intact; it required additional 4 d for completion of the hydrolysis of **27**.

Isomultiflorenol (**1**) and the 5β-*H* isomer (**28**) were subjected to Collins oxidation to give isomultiflorenone (**29**) and the 5β-*H* ketone (**30**), respectively. Isomultiflorenone (**29**)[15,18] exhibits IR absorption band at 1710 cm^{-1} and the positive Cotton effect. 5β-Isomultiflorenone (**30**) shows IR absorption band at 1715 cm^{-1}, intense fragment peaks at *m/z* 257 and *m/z* 245 chracteristic of the multiflor-8-ene skeleton,[13] and the negative Cotton effect.

Experimental[19]

Epoxidation of Alnus-5(10)-en-3β-yl Acetate (4). Alnus-5(10)-en-3β-ol (**7**), prepared from dendropanoxide (**5**), was acetylated with acetic anhydride in pyridine to give alnus-5(10)-en-3β-yl acetate (**4**), mp 289—293 °C. The acetate (**4**; 224 mg) was dissolved in chloroform (20 ml) and treated with MCPBA (208 mg) and disodium hydrogenphosphate dodecahydrate ($Na_2HPO_4 \cdot 12H_2O$; *ca.* 5 mg) at 0 °C for 7 h. The usual work-up gave a residue (224 mg; 97% yield), which was purified by silica-gel (30 g) column chromatography. Elution with benzene afforded 5α,10α-epoxyalnusan-3β-yl acetate (**6**), mp 272—273 °C (from $CHCl_3$–CH_3OH); IR (KBr) 1730, 1250, 1025, 990, and 980 cm^{-1}; ^{1}H NMR ($CDCl_3$) δ=0.97 (3H, s), 0.99 (6H, s), 1.02 (6H, s), 1.03 (6H, s), 1.15 (3H, s), 2.00 (3H, s), and 4.77 (1H, dd, J=10

and 4 Hz); MS *m/z* (%) 484 (M^+; 5), 466 (14), 406 (100), 391 (42), 227 (22), 205 (32), and 202 (46); Found: *m/z* 484.3867. Calcd for $C_{32}H_{52}O_3$: M, 484.3914.

Epoxidation of Alnus-5(10)-en-3β-ol (7). Alnus-5(10)-en-3β-ol (**7**; 118 mg) in chloroform (10 ml) was treated with MCPBA (122 mg) and $Na_2HPO_4 \cdot 12H_2O$ (*ca.* 5 mg) at 0 °C for 4 h. The usual work-up afforded 5α,10α-epoxyalnusan-3β-ol (**9**; quantitative yield), mp 247—248 °C (from acetone) (decomp); IR (KBr) 3450, 1690, 1050, 1020, 1000, and 970 cm^{-1}; ^1H NMR ($CDCl_3$) δ=0.94 (6H, s), 1.00 (6H, s), 1.01 (3H, s), 1.03 (3H, s), 1.07 (3H, s), 1.15 (3H, s), and 3.58 (1H, dd, *J*=10 and 5 Hz); MS *m/z* (%) 442 (M^+; 3), 427 (7), 424 (47), 409 (14), 406 (9), 391 (36), 245 (25), 206 (100), 201 (32), 109 (50), and 95 (54).

5α,10α-Epoxyalnusan-3β-ol (**9**; 37 mg) was treated with acetic anhydride (1 ml) and pyridine (4 ml) at room temperature for 14 h to give **6** in 95% yield.

Epoxidation of Alnus-5(10)-en-3β-yl Benzoate (8). Alnus-5(10)-en-3β-ol (**7**; 33 mg) was benzoylated with benzoyl chloride (1 ml) and pyridine (5 ml) at room temperature for 1 h to give the benzoate (**8**; 36 mg), mp 273—274 °C (from $CHCl_3$–acetone); IR (KBr) 1715, 1280, 1115, 705, and 685 cm^{-1}; ^1H NMR ($CDCl_3$) δ=0.96 (6H, s), 1.04 (12H, s), 1.14 and 1.18 (each 3H, s), 4.94 (1H, dd, *J*=10 and 4 Hz), and 7.35—8.14 (5H); MS *m/z* (%) 530 (M^+; 0.5), 515 (0.2), 408 (66), 393 (30), 365 (21), 205 (28), 203 (37), 190 (36), 189 (36), 187 (39), 175 (42), and 105 (100).

The benzoate (**8**; 33 mg) in chloroform (5 ml) was epoxidized with MCPBA (27 mg) and $Na_2HPO_4 \cdot 12H_2O$ (*ca.* 2 mg) at 0 °C for 3 h to afford 5α,10α-epoxyalnusan-3β-yl benzoate (**10**; 28 mg), mp 272—278 °C (from $CHCl_3$–CH_3OH) (decomp); IR (KBr) 1715, 1275, 1115, and 710 cm^{-1}; ^1H NMR ($CDCl_3$) δ=0.95, 0.99, 1.02, 1.04, 1.06, 1.08 (each 3H, s), 1.19 (6H, s), 5.02 (1H, dd, *J*=11 and 4 Hz), and 7.37—8.13 (5H); MS *m/z* (%) 546 (M^+; 0.6), 528 (3), 406 (43), 391 (41), 274 (18), 259 (20), 205 (30), 201 (19), 187 (24), 185 (25), 171 (41), and 105 (100).

On treatment with lithium aluminium hydride, the epoxy benzoate (**10**; 24 mg) afforded 5α,10α-epoxyalnusan-3β-ol (**9**; 15 mg) identical with an authentic sample.

Epoxidation of Alnus-5(10)-en-3α-ol (11). Alnus-5(10)-en-3α-ol (**11**, 21 mg), mp 255—258 °C, was dissolved in chloroform (5 ml) and treated with MCPBA (22 mg) and $Na_2HPO_4 \cdot 12H_2O$ (*ca.* 2 mg) at 0 °C for 1.5 h. The usual work-up gave 5α,10α-epoxyalnusan-3α-ol (**13**; 20 mg), mp 272—276 °C (from C_6H_6–CH_3OH) (decomp); IR (Nujol) 3480 cm^{-1}; ^1H NMR ($CDCl_3$) δ=0.95 (3H, s), 1.00 (9H, s), 1.02, 1.05 (each 3H, s), 1.17 (6H, s), 3.24 (1H, dt, *J*=11 and 3 Hz), and 3.52 (1H, d, *J*=11 Hz; disappeared on addition of D_2O); MS *m/z* (%) 442 (M^+; 0.8), 424 (79), 406 (17), 391 (46), 206 (100), 201 (48), 189 (38), 187 (35), 171 (35), 109 (65), and 95 (83).

5α,10α-Epoxyalnusan-3α-ol (**13**; 12 mg) was treated with acetic anhydride (3 ml) and pyridine (5 ml) at 120 °C for 4 h to give **14** in 53% yield.

Epoxidation of Alnus-5(10)-en-3α-yl Acetate (12). Alnus-5(10)-en-3α-yl acetate (**12**; 14 mg), mp 206—207 °C, in chloroform (3 ml) was epoxidized with MCPBA (21 mg) at 0 °C for 1.3 h to afford 5α,10α-epoxyalnusan-3α-yl acetate (**14**; 10 mg), mp 246—248 °C (from C_6H_6–CH_3OH); IR (KBr) 1740, 1255, 1030, 995, and 925 cm^{-1}; ^1H NMR ($CDCl_3$) δ=0.93 (3H, s), 1.03 (18H, s), 1.15 (3H, s), 2.03 (3H, s), and 4.47 (1H, dd, *J*= 7 and 4 Hz); MS *m/z* (%) 484 (M^+; 0.3), 409 (6), 406 (8), 391 (59), 248 (19), 227 (20), 205 (38), 201 (43), 189 (75), 187 (53), 137 (95), 109 (82), and 95 (100).

Epoxidation of Alnus-5(10)-en-3α-yl Benzoate (15). Alnus-5(10)-en-3α-ol (**11**) was treated with benzoyl chloride and pyridine to afford the benzoate (**15**), mp 175—177 °C (from $CHCl_3$–CH_3OH); IR (KBr) 1720, 1280, 1120, 755, and 710 cm^{-1}; ^1H NMR ($CDCl_3$) δ=0.96, 1.00, 1.01 (each 3H, s), 1.06, 1.09 (each 6H, s), 1.20 (3H, s), 4.96 (1H, dd, *J*=5 and 3 Hz), and 7.35—8.12 (5H); MS *m/z* (%) 530 (M^+; 4), 408 (93), 393 (36), 365 (33), 229 (21), 218 (24), 205 (39), 203 (37), 190 (39), 189 (45), 187 (40), 175 (39), and 105 (100).

Alnus-5(10)-en-3α-yl benzoate (**15**; 302 mg) in chloform (40 ml) was treated with MCPBA (246 mg) in the presence of $Na_2HPO_4 \cdot 12H_2O$ (*ca.* 10 mg) at 0 °C for 2 h. After the usual work-up, the reaction product was separated by column chromatography on silica gel (40 g) eluted with benzene to afford the major epoxide (**16**; 267 mg) and the minor epoxide (**17**; 35 mg). 5α,10α-Epoxyalnusan-3α-yl benzoate (**16**); mp 202—203 °C (from $CHCl_3$–CH_3OH); IR (KBr) 1720, 1275, 1115, and 715 cm^{-1}; ^1H NMR ($CDCl_3$) δ=0.96, 1.00, 1.03, 1.06 (each 3H, s), 1.10 (6H, s), 1.15, 1.17 (each 3H, s), 4.72 (1H, dd, *J*=7 and 3 Hz), and 7.38—8.18 (5H); MS *m/z* (%) 546 (M^+; 2), 528 (19), 406 (32), 391 (64), 310 (16), 205 (26), 201 (26), 189 (37), 187 (31), 137 (40), and 105 (100). 5β,10β-Epoxyalnusan-3α-yl benzoate (**17**); mp 154—155 °C (from $CHCl_3$–CH_3OH); IR (film) 1720, 1275, 1115, 1025, 940, and 710 cm^{-1}; ^1H NMR ($CDCl_3$) δ=0.97, 1.00, 1.02, 1.08 (each 3H, s), 1.09 (6H, s), 1.15, 1.20 (each 3H, s), 4.78 (1H, dd, *J*=5.5 and 3 Hz), and 7.33—8.18 (5H); MS *m/z* (%) 546 (M^+; 5), 424 (11), 406 (8), 391 (9), 288 (36), 274 (18), 273 (19), 219 (19), 218 (21), 205 (36), 189 (18), 185 (41), 137 (64), 109 (50), 105 (100), and 95 (61).

5α,10α-Epoxyalnusan-3α-yl benzoate (**16**; 22 mg) was treated with lithium aluminium hydride (5 mg) at room temperature for 30 min to give **13** in 68% yield.

5β,10β-Epoxyalnusan-3α-yl benzoate (**17**; 31 mg) was treated with a mixture of 5% potassium hydroxide (KOH) in methanol (6 ml) and tetrahydrofuran (THF) (2 ml) for 2 d to give 5β,10β-epoxyalnusan-3β-ol (**20**; 21 mg); mp 210—211 °C (from $CHCl_3$–CH_3OH); IR (KBr) 3580, 1070, and 965 cm^{-1}; ^1H NMR ($CDCl_3$) δ=0.95 (6H, s), 1.02 (12H, s), 1.03, 1.17 (each 3H, s), and 3.41 (1H, dd, *J*=7 and 3 Hz); MS *m/z* (%) 442 (M^+; 10), 427 (12), 424 (70), 406 (10), 391 (12), 218 (24), 206 (100), 205 (40), 201 (50), 187 (25), 179 (31), 137 (41), 109 (54), and 95 (60).

5β,10β-Epoxyalnusan-3α-ol (**20**; 14 mg) was treated with acetic anhydride (1 ml) and pyridine (3 ml) at 100 °C for 4 h to give 5β,10β-epoxyalnusan-3α-yl acetate (**21**; 15 mg); mp 173—174 °C (from $CHCl_3$–CH_3OH); IR (KBr) 1730, 1250, 1050, 1020, and 965 cm^{-1}; ^1H NMR ($CDCl_3$) δ=0.96 (6H, s), 0.98 (3H, s), 1.01 (9H, s), 1.05, 1.07, 2.03 (each 3H, s), and 4.57 (1H, dd, *J*=7 and 3 Hz); MS *m/z* (%) 484 (M^+; 41), 469 (16), 424 (19), 409 (18), 406 (17), 391 (12), 342 (11), 288 (98), 274 (62), 273 (60), 259 (21), 245 (28), 218 (79), 205 (91), 137 (100), 109 (59), and 95 (56).

Sharpless Epoxidation of Alnus-5(10)-en-3α-ol (11) and -3β-ol (7). Alnus-5(10)-en-3α-ol (**11**; 35 mg) was dissolved in benzene (7 ml) and treated with the benzene solution of *t*-butyl hydroperoxide (80 μl; 2.35 mmol/ml)[10a] and $VO(acac)_2$ (*ca.* 1 mg) at room temperature in nitrogen atmosphere for 4 h. The usual work-up afforded 5α,10α-epoxyalnusan-3α-ol (**13**; 32 mg), which was identical with that obtained by the MCPBA-epoxidation of **11**.

Alnus-5(10)-en-3β-ol (**7**; 47 mg) was treated with the ben-

zene solution of *t*-butyl hydroperoxide (100 μl) and VO (acac)$_2$ (*ca.* 1 mg) under the same conditions for 7 h to give 5β,10β-epoxyalnusan-3β-ol (**18**; 34 mg); mp 199—200 °C (from acetone); IR (film) 3380, 1055, 1030, 995, and 980 cm^{-1}; ^{1}H NMR ($CDCl_3$) δ=0.97 (6H, s), 1.03 (3H, s), 1.06 (9H, s), 1.10, 1.18 (each 3H, s), 2.71 (1H, br; disappeared on addition of D_2O), and 3.17 (1H, br; changed into a triplet (*J*=5 Hz) on addition of D_2O); MS *m/z* (%) 442 (M^+; 2), 424 (91), 409 (18), 406 (30), 391 (100), 227 (49), 206 (87), 205 (47), 201 (55), 189 (76), 187 (62), 137 (65), 109 (84), and 95 (95); high resolution MS *m/z* 442.3797. Calcd for $C_{30}H_{50}O_2$: M, 442.3809.

5β,10β-Epoxyalnusan-3β-ol (**18**; 30 mg) was treated with acetic anhydride (1 ml) and pyridine (2 ml) at room temperature for 40 h to give 5β,10β-epoxyalnusan-3β-yl acetate (**22**; 25 mg); mp 258.5—259.5 °C (from $CHCl_3$–CH_3OH); IR (KBr) 1735, 1250, and 1025 cm^{-1}; ^{1}H NMR ($CDCl_3$) δ=0.96 (6H, s), 1.01 (9H, s), 1.04 (6H, s), 1.17 (3H, s), 2.03 (3H, s), and 4.36 (1H, dd, *J*=11 and 4 Hz); MS *m/z* (%) 484 (M^+; 12), 469 (8), 466 (28), 451 (6), 424 (22), 409 (12), 406 (100), 391 (51), 342 (33), 288 (20), 274 (40), 259 (34), 218 (43), 205 (73), 137 (72), 109 (70), and 95 (83).

5β,10β-Epoxyalnusan-3β-ol (**18**; 31 mg) was benzoylated with benzoyl chloride (0.1 ml) and pyridine (2 ml) at room temperature for 1.5 h to give 5β,10β-epoxyalnusan-3β-yl benzoate (**23**; 23 mg); mp 245—246 °C (from $CHCl_3$–CH_3OH); IR (KBr) 1720, 1275, 1115, 1025, and 710 cm^{-1}; ^{1}H NMR ($CDCl_3$) δ=0.97, 1.03, 1.07, 1.20 (each 6H, s), 4.62 (1H, dd, *J*=10 and 5 Hz), and 7.38—8.12 (5H); MS *m/z* (%) 546 (M^+; 12), 424 (49), 409 (22), 406 (34), 391 (16), 342 (18), 288 (26), 274 (20), 273 (22), 249 (17), 218 (35), 205 (53), 137 (85), 105 (100), and 95 (52).

Oxidation of 5α,10α-Epoxyalnusan-3β-ol (9) and 5α,10α-Epoxyalnusan-3α-ol (13). 5α,10α-Epoxyalnusan-3β-ol (**9**; 56 mg) and -3α-ol (**13**; 22 mg) were oxidized with Collins reagent to give the same product, 5α,10α-epoxyalnusan-3-one (**19**; 43 mg and 11 mg, respectively), mp 261—263 °C (from $CHCl_3$–CH_3OH) (decomp); IR (KBr) 1710 and 980 cm^{-1}; ^{1}H NMR ($CDCl_3$) δ=0.94, 0.99 (each 3H, s), 1.04 (6H, s), 1.11, 1.13, 1.15, 1.17 (each 3H, s), and 2.24 (2H, t, *J*=6 Hz); MS *m/z* (%) 440 (M^+; 12), 425 (11), 422 (19), 407 (9), 205 (97), 204 (87), 177 (53), 137 (44), 123 (57), 109 (81), and 95 (100).

Backbone Rearrangement of 5α,10α-Epoxyalnusan-3β-yl Acetate (6). 5α,10α-Epoxyalnusan-3β-yl acetate (**6**; 121 mg) in benzene (30 ml) was treated with $BF_3 \cdot OEt_2$ (38 μl; 1.1 equiv) at room temperature in nitrogen atmosphere for 30 min. The reaction product, after addition of a saturated sodium hydrogencarbonate solution, was worked up as usual to give a residue (117 mg). The residue showed eight peaks at 12.8, 16.5, 18.9 (a main peak; a ratio of the product was estimated at *ca.* 80% from the peak hight), 21.1, 22.1, 23.9, 25.7, and 27.9 min on HPLC (column: μPORASIL, solvent system; 1% ether–hexane, 1 ml/min). The residue was chromatographed on alumina (Alumina Woelm N, Akt I. 35 g; impregnated with 15% silver nitrate). Elution with 5—10% ethyl acetate–hexane afforded a mixture (*ca.* 24 mg) of the minor products and the product, multiflora-5,8-dien-3β-yl acetate (**24**; 81.4 mg). The latter was purified by column chromatography on silica gel eluted with hexane–benzene to give pure **24**, mp 190—193 °C (from C_6H_6–CH_3OH); IR (KBr) 1735, 1250, 1035, 1020, and 990 cm^{-1}; ^{1}H NMR ($CDCl_3$) δ=0.98 (6H, s), 1.01 (3H, s), 1.10 (6H, s), 1.12, 1.14, 1.18, 2.04 (each 3H, s), 2.60 (2H, m), 4.50 (1H, dd, *J*=8 and 6 Hz), and 5.71 (1H, dd, *J*=5 and 3 Hz); ^{13}C NMR ($CDCl_3$) δ=19.2, 21.1, 21.3, 24.1, 25.1, 25.2, 25.2, 25.8, 27.1, 27.6, 28.3, 30.9, 31.1, 31.7, 33.1, 33.8, 34.2, 34.5, 34.5, 36.8, 36.8, 37.3, 38.4, 40.4, 40.7, 44.2, 79.1, 120.2, 131.1, 134.0, 146.4, and 170.7; MS *m/z* (%) 466 (M^+; 5), 406 (15), 391 (100), 239 (13), 227 (28), 187 (18), 185 (20), and 171 (43); high resolution MS *m/z* 466.3791 (Calcd for $C_{32}H_{50}O_2$: M, 466.3809), *m/z* 239.1798 (Calcd for $C_{18}H_{23}$: 239.1798), *m/z* 227.1778 (Calcd for $C_{17}H_{23}$: 227.1798), and *m/z* 171.1207 (Calcd for $C_{13}H_{15}$: 171.1174).

Dehydrogenation of Multiflora-5,8-dien-3β-yl Acetate (24). The diene (**24**; 39 mg) was heated with selenium dioxide in a mixture of benzene (5 ml) and water (5 drops) under reflux for 38 h to give multiflora-5,7,9(11)-trien-3β-yl acetate (**25**; 22 mg), mp 211—214 °C (from $CHCl_3$–CH_3OH); IR (KBr) 1740, 1250, 1035, 1005, 980, and 850 cm^{-1}; ^{1}H NMR ($CDCl_3$) δ=0.84, 0.96, 0.99, 1.02, 1.06, 1.09 (each 3H, s), 1.21 (6H, s), 2.07 (3H, s), 4.57 (1H, dd, *J*=6 and 5 Hz), 5.38 (1H, m), 5.57 (1H, d, *J*=6 Hz), and 5.89 (1H, d, *J*=6 Hz); UV λ(C_2H_5OH) 307 (ε 11600) and 317 nm (12200); MS *m/z* (%) 464 (M^+; 7), 404 (100), 389 (21), 251 (26), 237 (26), and 225 (80); high resolution MS *m/z* 464.3649 (Calcd for $C_{32}H_{48}O_2$: M, 464.3654), *m/z* 237.1645 (Calcd for $C_{18}H_{21}$: 237.1643), and *m/z* 225.1661 (Calcd for $C_{17}H_{21}$; 225.1644).

Hydrogenation of Multiflora-5,8-dien-3β-yl Acetate (24). A solution of multiflora-5,8-dien-3β-yl acetate (**24**; 103 mg) in ethyl acetate (70 ml) was hydrogenated in the presence of 5% palladium on carbon (470 mg) for 3 d to give hydrogenated products (101 mg), which showed two peaks at 16.3 and 21.4 min (peak hight ratio 3:2) on GC examination (column: Dexsil 300 GC, 2%, 1.5 m) and two peaks at 20.2 and 22.2 min (peak hight ratio 2:3) on HPLC examination. (column: μPORASIL, solvent system: 0.8% ether–hexane, 1 ml/min). The mixture was separated by repeating column chromatography on silica gel to give isomultiflorenyl acetate (**26**; 40 mg) and 5β-isomultiflorenyl acetate (**27**; 60 mg). Isomultiflorenyl acetate (**26**); mp 223—225 °C (from CH_2Cl_2–CH_3OH); IR (KBr) 1735, 1455, 1380, 1255, 1025, 1005, and 990 cm^{-1}; ^{1}H NMR ($CDCl_3$) δ=0.88, 0.96, 0.98 (each 6H, s), 1.06, 1.07, (each 3H, s), 2.03 (3H, s), and 4.48 (1H, dd, *J*=11 and 5 Hz); MS *m/z* (%) 468 (M^+; 58), 453 (15), 408 (21), 393 (23), 301 (28), 289 (17), 241 (26), 229 (27), 218 (64), 205 (100), 203 (47), and 189 (23). 5β-Isomultiflorenyl acetate (**27**); mp 151—152 °C (from CH_2Cl_2–CH_3OH); IR (film) 1730, 1245, and 1030 cm^{-1}; ^{1}H NMR ($CDCl_3$) δ=0.94 (3H, s), 0.97, 1.03 (each 6H, s), 1.06 (3H, s), 1.08 (6H, s), 2.04 (3H, s), and 4.54 (1H, t, *J*=3 Hz); MS *m/z* (%) 468 (M^+; 74), 453 (58), 408 (21), 393 (62), 301 (57), 289 (29), 241 (100), 229 (93), 205 (94), 203 (49), and 189 (58); high resolution MS *m/z* 468.3960. Calcd for $C_{32}H_{52}O_2$: M, 468.3965.

Hydrolysis of Isomultiflorenyl Acetate (26) and Its 5β-H Isomer (27). Isomultiflorenyl acetate (**26**; 15 mg) was treated with a mixture of 5% KOH in methanol (50 ml) and THF (10 ml) at room temperature in nitrogen atmosphere for 1 d. The usual work-up gave isomultiflorenol (**1**; 13 mg); mp 182—183 °C (from $CHCl_3$–CH_3OH); IR (Nujol) 3350 and 1025 cm^{-1}; ^{1}H NMR ($CDCl_3$) δ=0.80 (3H, s), 0.97 (9H, s), 0.99, 1.00, 1.06, 1.07 (each 3H, s), and 3.23 (1H, dd, *J*=11 and 5 Hz); MS *m/z* (%) 426 (M^+; 100), 411 (29), 408 (31), 393 (43), 259 (83), 247 (55), 241 (56), 229 (65), 218 (77), 205 (98), 204 (50), 191 (40), and 189 (44); high resolution MS *m/z* 426.3863. Calcd for $C_{30}H_{50}O$: M, 426.3862.

5β-Isomultiflorenyl acetate (**27**; 25 mg) was treated with

5% KOH in methanol–THF (5:1, 40 ml) under the same conditions as above for 4 d to afford 5β-isomultiflorenol (**28**; 20 mg); mp 159—159.5 °C (from ether-CH_3OH); IR (film) 3430, 1060, 950, and 935 cm^{-1}; ^1H NMR ($CDCl_3$) δ=0.98 (6H, s), 1.04 (12H, s), 1.09 (6H, s), and 3.33 (1H, t-like, J=3 Hz); MS m/z (%) 426 (M^+; 32), 411 (92), 408 (19), 393 (63), 259 (87), 247 (38), 241 (100), 229 (85), 205 (65), 203 (37), 189 (87), 109 (90), and 95 (88); high resolution MS m/z 426.3907 (Calcd for $C_{30}H_{50}O$: M, 426.3862), m/z 259.2060 (Calcd for $C_{18}H_{27}O$: 259.2060), m/z 247.2065 (Calcd for $C_{17}H_{27}O$: 247.2062), m/z 241.1944 (Calcd for $C_{18}H_{25}$; 241.1955), and m/z 229.1967 (Calcd for $C_{17}H_{25}$: 229.1956).

Oxidation of Isomultiflorenol (1) and 5β-Isomultiflorenol (28). Isomultiflorenol (**1**; 17 mg) in dichloromethane (5 ml) was oxidized with Collins reagent (4 ml; 17 eq) at room temperature for 16 min to give isomultiflorenone (**29**; 16 mg); mp 189—193 °C (from $CHCl_3$-CH_3OH); IR (KBr) 1710 cm^{-1}; ^1H NMR ($CDCl_3$) δ=0.97 (6H, s), 0.99 (3H, s), 1.06 (6H, s), 1.10 (9H, s), and 2.40—2.62 (2H, m); MS m/z (%) 424 (M^+; 16), 409 (7), 257 (48), 245 (39), 205 (100), 109 (38), and 95 (54). CD (c 0.016, $CHCl_3$, Amb. temp.) $[\theta]_{291}$ +1580 and $[\theta]_{323}$ −110.

5β-Isomutiflorenol (**28**; 18 mg) was oxidized with Collins reagent (4 ml; 16 eq) under the same conditions as above to give 5β-isomultiflorenone (**30**; 17 mg), mp 143—144 °C (from ether-CH_3OH); IR (KBr) 1715 cm^{-1}; ^1H NMR ($CDCl_3$) δ=0.97 (6H, s), 1.02 (3H, s), 1.10 (6H, s), 1.11, 1.14, 1.16 (each 3H, s) and 2.16—2.40 (2H, m); MS m/z (%) 424 (M^+; 16), 409 (11), 257 (73), 245 (60), 205 (100), 109 (39), and 95 (56); CD (c 0.016, $CHCl_3$, Amb. temp) $[\theta]_{314}$ −750, $[\theta]_{305}$ −880, and $[\theta]_{273}$ +120.

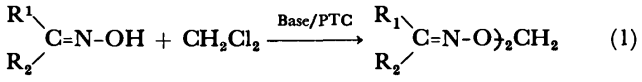
Alkylation of Ketoxime with Dichloromethane Using Bases under Phase-transfer Conditions. Formation of Methylene Dioxime and Novel Heteromacrocyclic Compounds

Takahiro HOSOKAWA,* Toshiyuki OHTA, Yoshihiro OKAMOTO, and Shun-Ichi MURAHASHI*
Department of Chemistry, Faculty of Engineering Science, Osaka University, Machikaneyama, Toyonaka, Osaka 560
(Received July 26, 1984)

Ketoximes, when treated with KO_2 (1 equiv) in the presence of di-μ-chlorobis(2-methylallyl)dipalladium-(II) (0.1 equiv per Pd) in dichloromethane, give methylene dioximes in moderate yields. This alkylation of ketoximes with CH_2Cl_2 is also promoted by the use of potassium carbonate in the presence of phase-transfer catalysts such as 18-crown-6. Study on the reactivity of a series of ketoximes in these reactions shows that proton abstraction by base is a crucial step in the latter reaction. By contrast, in the former system the reactivity is supposed to be controlled by nucleophilicity of the oximate anion coordinated to palladium(II). Application of the present reaction to (*E,E*)-1,2-diketone dioxime such as dimethylglyoxime leads to the formation of novel 21-membered ring heteromacrocyclic compounds in which oxime units are sequentially linked by methylene bridge.

Previously we have reported palladium-induced deoximation[1] and Beckmann fragmentation of ketoximes[2] by the use of peroxobis(triphenylphosphine)palladium(II), $(PPh_3)_2Pd\langle^{O}_{O}$. During the course of the studies, we have found that the alkylation of ketoximes (**1**) with dichloromethane is promoted by KO_2 in the presence of palladium(II) catalyst to give methylene dioximes (**2**) of a novel class of compounds.[3] Since the reaction is one of the rare examples of the use of dichloromethane as both solvent and electrophile,[4] we have studied this type of reactions in detail.

Use of a simple base such as potassium carbonate in combination with a phase-transfer agent such as 18-crown-6 has promoted the reaction as well. However,



(1)

1 **2**

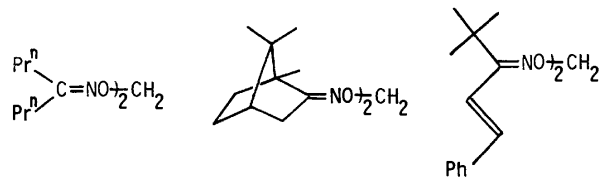
PTC: Phase-Transfer Catalyst

interestingly, these two systems have shown an inverse reactivity toward aryl and alkyl ketoximes.

Application of the reaction to 1,2-diketone dioximes, *e.g.*, dimethylglyoxime, has led to the synthesis of a novel heteromacrocyclic compound formed *via* a sequential oligomerization of the dioxime and dichloromethane. Although a variety of macrocyclic polyether and azacrown compounds have been reported in literatures,[5] there are few examples of heteromacrocycles containing oxime linkages. These are Vögtle's macrocyclic mono- and dioximes[6] prepared from 1,2-diketone dioximes and 1,ω-dichlorooligo-1-oxapropane $[Cl\{CH_2CH_2O\}_nCH_2CH_2Cl]$[7] and Sarlo's macrocyclic polyhydroximates formed *via* nucleophilic polymerization of acetonitrile oxide.[8] There has been, however, no precedent for the dioxime crowns such as **11** (*vide infra*) in which oxime units are sequentially linked by methylene bridges. This paper describes the alkylation of ketoximes with dichloromethane under phase-transfer conditions leading to the formation of methylene dioximes and dioxime crowns.

Results and Discussion

Reaction of Ketoximes with CH_2Cl_2 In the present study, ketoximes (**1**) have been generally allowed to react with an equimolar amount of KO_2 in dichloromethane in the presence of $[(2\text{-methylallyl})PdCl]_2$ (**3**) (0.1 equiv per Pd). Under the conditions, a relatively wide range of ketoximes, *e.g.*, 4-heptanone oxime, *d*-camphor oxime, and (*Z*)-2,2-dimethyl-5-phenyl-4-penten-3-one oxime, give the corresponding methylene dioximes (**2a**), (**4**), and (**5**) in moderate



2a **4** **5**

yields (23—53%). If 2 equiv of KO_2 was used, the yields increased up to 60—96%. However, if KO_2 alone was used, entirely no reaction took place. Use of other palladium(II) complexes such as $PdCl_2(CH_3CN)_2$ and $Pd(OAc)_2$ as the catalyst also led to the alkylation of ketoximes. Since KO_2 is insoluble in dichloromethane, palladium(II) complexes are considered to act as a phase-transfer agent.

In this system, aryl ketoximes such as benzophenone oxime gave no appreciable amount of the alkylation product. By contrast, when the aryl ketoximes were treated with potassium carbonate (1.1 equiv) in dichloromethane containing 18-crown-6 (0.1 equiv), the corresponding methylene dioximes were formed in good yield (*e.g.*, 80% yield with benzophenone oxime).

Table 1. Formation of methylene dioximes **2** from a series of ketoximes **1**

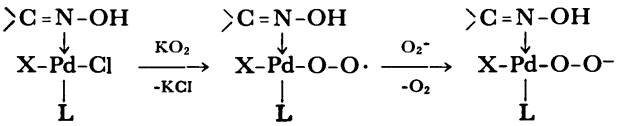
a) Isolated yield. b) In this system, yields were determined by ^1H NMR spectroscopy. c) Isolated yield when 2 equiv of KO_2 was used.

These results prompted us to examine the difference in reactivity between the two reaction systems using a series of ketoximes. From Table 1, it can be seen that in the former system aliphatic ketoximes afford higher yields of methylene dioxime than aryl ketoximes, whereas the opposite trend is observed in the latter (K_2CO_3/18-c-6). Further, the reactivities observed in both systems appear to change as a function of the p*K*a of ketoximes.[9]

Although potassium carbonate serves as an efficient, strong base in the presence of solid-liquid two phase catalysis,[10] it is not much basic as to promote the reaction with less acidic aliphatic ketoximes such as **1b** (Entries 1—3, Table 1). When K_2CO_3 was replaced with more basic Bu^tOK, the aliphatic ketoxime **1b** gives methylene dioxime **2b** in a good yield (74%). The use of KO_2 with 18-crown-6 gives **2b** only in 27% yield in accordance with the order of decrease in basicity ($Bu^tOK > KO_2 > K_2CO_3$).[11] Therefore, it is evident that proton abstraction from the oxime by base is a crucial step in this system. Note that there have been ample examples that KO_2 acts as a Brϕnsted base in the presence of phase-transfer agents.[12]

In the KO_2-Pd(II) system, more acidic ketoximes such as (**1d**)—(**1f**) led to the formation of palladium(II) complexes containing oximate ligands in 15—27% yield (based on Pd), along with the alkylation products. The complexes are formulated as $[(R_2C{=}NO)_2(R_2C{=}NOH)_2]Pd$ (**6**) by comparing the spectra data with those of the authentic complex **6a** (R= CH_2Ph) prepared from $Pd(acac)_2$ and dibenzyl ketone oxime.[13] Thus, when the oxime has lower pK_a, its anion is thought to successively coordinate to Pd(II) and has no nucleophilic ability enough to attack at the methylene carbon of dichloromethane.

The formation of methylene dioximes **2** is readily accounted for by succesive, nucleophilic displacement of an oximate anion to dichloromethane. In the former system (KO_2/Pd(II)), the oximate anion is probably formed *via* the following steps. At first, coordination of the nitrogen atom to Pd(II) complex takes place in dichloromethane solution. Superoxide anion ($O_2^{\cdot-}$) is then transfered into the organic phase *via* anion exchange (**7**→**8**) with the chloride ligand of Pd(II) complex. Electron transfer (**8**→**9**) followed by proton abstraction[14] results in the formation of oximate anion in the coordination sphere of palladium(II). Alternatively, the oximate anion may be



7 **8** **9**

directly formed from the coordinated oxime **7** by the action of KO_2 with releasing HOO·. In any case, depending on its nucleophilicity, the oximate anion thus produced attacks at the methylene carbon of CH_2Cl_2.[15] Since less acidic ketoximes readily undergo the reaction in this system, the acidity of oximes must be enhanced by its coordination to palladium(II).

Reaction of 1,2-Diketone Dioxime with CH_2Cl_2. Application of the present methods to 1,2-diketone dioximes (**10**) resulted in either formation of nitractable palladium complexes (KO_2/Pd(II)) or recovery of the starting materials (K_2CO_3/18-c-6). However, the use of Bu^tOK in the presence of 18-crown-6 led to a successful synthesis of novel dioxime crown compounds containing methylene linkages such as **11**.

The procedure for the synthesis of 21-membered ring compound **11a** is simple. To a suspended solution of (*E*,*E*)-2,3-butanedione dioxime (**10a**), Bu^t OK (2 equiv) and 18-crown-6 (0.1 equiv) in THF was slowly added an excess of dichloromethane, and the mixture

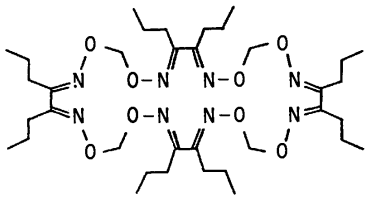
was refluxed. After filtration of the reaction mixture and evaporation of the solvent and excess CH_2Cl_2, the residue was thoroughly washed with methanol to remove unreacted oxime **10a**. The remaining solid was recrystallized from MeOH-THF to give **11a** in 20% yield as colorless crystals. In the absence of 18-crown-6, no reaction takes place. However, the use of trioctylmethylammonium chloride (Capriquat) as a phase-transfer agent is comparatively effective in promoting the reaction. If THF is not used as the co-solvent, the yield of **11a** is reduced to ≈2%. A poor yield (4%) of **11a** is also resulted, when **10a** was treated with aqueous 20% NaOH solution in the presence of tetrabutylammonium hydrogensulfate (0.1 equiv) in CH_2Cl_2.

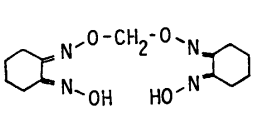
The same type of dioxime crown **11b** was obtained from (*E*,*E*)-2,5-dimethyl-3,4-hexanedione dioxime (**10b**) (R=Pr^i) in 21% yield by the same treatment (Bu^{t}OK/18-c-6). By contrast, (*E*,*E*)-dioxime **10c** of R=Pr^n gave **12**, in which four oxime units are linked by methylene bridges, in 40% yield.



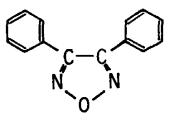
12

In the ^{1}H NMR spectra of **11a**, **11b**, and **12**, the -OCH_2O-protons appear as a singlet approximately at δ 5.50, and their $^{13}C\{^1H\}$ NMR spectra ($CDCl_3$) also exhibit only singlet due to the methylene carbon at δ 99.45 ppm for **11a** and δ 99.31 ppm for **12** relative to Me_4Si. These results indicate the equivalence of all the -OCH_2O- groups. In addition, the signal of alkyl substituent (R=Me, Pr^i, and Pr^n) in each compound has been shown to be magnetically equivalent (*vide infra*). These data also support the structures as illustrated above. The extent of oligomerization was determined by the mass spectra of the products.

Although (*E*,*E*)-dioximes appear to generally undergo the present sequential oligomerization, it is not the case for **10e** (R,R=-$(CH_2)_4$-) and **10d** (R=Ph). Thus, (*E*,*E*)-1,2-cyclohexanedione dioxime (**10e**) gave



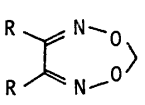
13



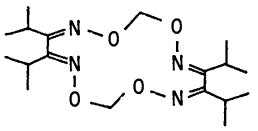
14

a 12% yield of **13**, a 2:1 adduct of the dioxime and CH_2Cl_2. (*E*,*E*)-benzil dioxime **10d** gave a 27% yield of 3,4-diphenylfurazan **14** formally *via* (*E*,*E*) ⇌ (*Z*,*E*) isomerization followed by dehydration.

As expected, the (*Z*,*Z*)-dioximes **10f** and **10g** do not undergo the present oligomerization, but intramolecular cyclization of a 1:1 adduct of the dioxime and CH_2Cl_2 takes place. Thus, **10f** (R=cyclohexyl) gave a 66% yield of 7*H*-3,4-dicyclohexyl-1,6,2,5-dioxadiazepine (**15a**), which is a previously unknown class of heterocyclic compounds. Similarly, (*Z*,*Z*)-dioxime **10g** afforded **15b** in 47% yield. In this case, a small amount (*ca.* ≈5%) of cyclic compound **16** containing



15



16

a; R=Cyclohexyl
b; R=Pr^i

two (*Z*,*E*)-oxime units was formed. The (*Z*,*E*)-configuration of this compound was assigned since the methyl signal of the two isopropyl group appears at different chemical shifts as two sets of doublets in its ^{1}H NMR spectrum.

The (*Z*,*E*)-dioxime **10h** (R=Pr^i) also gave the dioxadiazepine **15b** in 16% yield, but the expected product **16** was not formed. In any case, when the substituent is Pr^i, (*Z*,*E*) ⇌ (*Z*,*Z*) isomerization of the oxime group takes place during the reaction.

Experimental

General. NMR spectra were recorded on a 60-MHz Model JNM-MH-60 (Jeol) spectrometer; chemical shifts (δ) expressed in parts per million relative to Me_4Si. IR spectra were recorded on a Hitachi 215 spectrometer. Mass spectra were taken on a Hitachi RSM-4 mass spectrometer. Elemental analyses were determined on a Yanagimoto MT-2 CHN recorder. Potassium superoxide was obtained from Ventron, ground to a fine powder in a Ar-filled drybag, and stored in a desiccator prior to use. Di-μ-chlorobis(2-methylallyl)-dipalladium(II)[16] (**3**), palladium acetate(II),[17] bis(benzonitrile)dichloropalladium(II)[18] were prepared as the reported procedures. Dichloromethane was distilled from calcium hydride under argon or nitrogen. Ketoximes **1a-g** were prepared from the corresponding ketones according to the reported procedure. (*E*)-Benzil monoxime **1h** was prepared by the method of Taylor and Marks.[19] *d*-Camphor oxime, (*E*,*E*)-2,3-butanedione dioxime **10a** (dimethylglyoxime), (*E*,*E*)-benzil dioxime (**10d**), and (*E*,*E*)-1,2-cyclohexanedione dioxime (**10e**) are commercially available.

Three configurational isomers of (*E,E*)-**10b**, (*Z,Z*)-**10f**, and (*Z,E*)-**10h** were prepared from the oximation of 2,5-dimethyl-3,4-hexanedione. (*E,E*)-4,5-Octanedione dioxime (**10c**) and (*Z,Z*)-1,2-dicyclohexylethanedione dioxime (**10f**) were also prepared from the corresponding diketones. These details are described below.

*2,5-Dimethyl-3,4-hexanedione Dioxime (**10b**, **g**, and **h**).* To a solution of hydroxylamine hydrochloride (2.433 g, 0.035 mol) in 10 mL of water was added a soluton of 85% potassium hydroxide (2.307 g, 0.035 mol) in 6 mL of water in an ice bath. Into the cold solution was added 2,5-dimethyl-3,4-hexanedione[20] (1.990 g, 0.014 mol). The reaction mixture was stirred at 0 °C for 2 h and then at reflux for 2 h. After extraction with ether (10 mL×3), the extract was washed with water, shaken with brine, and dried over anhydrous magnesium sulfate. Concentration of the solvent followed by Kugelrohr distillation (55—60 °C/3 mmHg) (1 mmHg=133.322 Pa) gave 2,5-dimethyl-3,4-hexanedione monoxime (1.466 g, 67%). To a solution of the monooxime (1.415 g, 9.0 mmol) in 8 mL of 95% ethanol was added a solution of hydroxylamine hydrochloride (0.639 g, 9.2 mmol) and sodium acetate (1.292 g, 15.8 mmol) in 4 mL of water. The reaction mixture was refluxed for 4 h, and concentrated until the mixture became turbid, and then allowed to cool to room temperature. The white crystals were collected, washed thoroughly with water, and dried *in vacuo* at 50 °C. The crystals were found to contain three configurational isomers of the dioxime. Recrystallization from ether-petroleum ether afforded (*Z,Z*)-2,5-dimethyl-3,4-hexanedione dioxime **10g** (33%): mp 139—142 °C; IR (Nujol) 3260 (OH), 1100, 1048, 880, 715 cm^{-1}; ^1H NMR (DMSO-d_6) δ=0.73 (12H, d, J=7 Hz, $-CH_3$), 2.17 (2H, heptet, J=7 Hz, $\rangle CH$), 10.28 (2H, s, -OH). From the mother liquid, (*E,E*) and (*Z,E*)-isomers were separated by preparative TLC (SiO_2, ethyl acetate:hexane=3:7) in 2% and 6% yields, respectively. (*E,E*)-2,5-dimethyl-3,4-hexanedione dioxime (**10b**): R_f 0.45; IR (Nujol) 3250 (OH), 1155, 1102, 1060, 990, 970, 912, 845, 745 cm[1]; ^1H NMR (DMSO-d_6) δ=1.05 (12H, d, J=7 Hz, $-CH_3$), 2.30 (2H, heptet, J=7 Hz, $\rangle CH$), 10.78 (2H, s, -OH). (*Z,E*)-2,5-Dimethyl-3,4-hexanedione dioxime (**10h**): R_f 0.29; IR (Nujol) 3240 (OH), 1167, 1150, 1035, 1012, 932 895, 861, 742 cm^{-1}; ^1H NMR (DMSO-d_6) δ=0.99 (d, J=7 Hz, $-CH_3$, 6H), 1.03 (d, J=7 Hz, $-CH_3$, 6H), 2.30 (m, $\rangle CH$, 2H), 10.48 (s, -OH, 1H), 10.77 (s, -OH, 1H). The configuration assignment of these dioximes were made on the basis of their ^1H NMR signals of OH proton in DMSO-d_6, according to the method of Tanaka and Shinra.[21]

*(E,E)-4,5-Octanedione Dioxime (**10c**).* The oximation of 4,5-octanedione[20] by the similar manner as above gave (*E,E*)-4,5-octanedione dioxime (**10c**) as the sole product; mp 178—179.5 °C; IR (Nujol) 3220 (OH), 1150, 1042, 1020, 922, 893, 872, 761 cm^{-1}; ^1H NMR (DMSO-d_6) δ=0.70 (6H, m, $-CH_3$), 1.00—1.60 (4H, m, $-CH_2-$), 2.38 (4H, m, $-C(=N)-CH_2-$), 11.13 (2H, s, -OH). The (*E,E*)-configuration was assigned by the same method as above.

*(Z,Z)-1,2-Dicyclohexylethanedione Dioxime (**10f**).* The oximation of 1,2-dicyclohexylethanedione[20] by the similar manner as above gave the title compound as the sole product; mp 200 °C; IR (Nujol) 3250 (OH), 1115, 995, 960, 948, 893, 819, 810, 715 cm^{-1}; ^1H NMR (DMSO-d_6) δ=0.91—2.46 (20H, m, $-CH_2-$), 10.28 (2H, s, -OH). The configuration assignment of the dioxime was made similarly as above.

*Reaction of Ketoximes with Dichloromethane in the Presence of KO_2 and **3**. General Procedure.* In a drybag filled with argon, finely powdered potassium superoxide (4 mmol) was weighed and placed in a 100 mL flask containing a Teflon-coated magnetic stirrer bar, di-μ-chlorobis(2-methylallyl)dipalladium (**3**, 0.079 g, 0.2 mmol) and ketoxime (**1**, 4 mmol). Into the flask was added 40 mL of dichloromethane, and the reaction mixture was stirred for 72 h at room temperature under argon. After the resulting potassium chloride was removed by filtration, the filtrate was concentrated under reduced pressure. The products were separated by means of Al_2O_3 column chromatography. Generally, elution with a 7:3 mixture of hexane and ethyl acetate gave the methylene dioxime **2**. Unreacted ketoximes were recovered from further elution with ether or methanol. Analytically pure methylene dioximes were obtained by recrystallization or distillation. The results are summarized in Table 1. Spectral and analytical data of the methylene dioximes **2** obtained in this system are described below.

*Methylene Dioxime **2a**:* Bp 108—109 °C/3 mmHg; IR (neat) 1630 (C=N), 1146, 1005 (OCH_2O) cm^{-1}; ^1H NMR (CCl_4) δ=0.92 (12H, t, J=7 Hz, $-CH_3$), 1.48 (8H, m, $-CH_2-$), 2.13 (8H, q, J=7 Hz, $-CH_2C=N-$), 5.37 (2H, s, $-OCH_2O-$). Found: C, 66.58; H, 11.38; N, 10.36%. Calcd for $C_{15}H_{30}N_2O_2$: C, 66.62; H, 11.18; N, 10.10%.

*Methylene Dioxime **2b**:* Mp 39 °C; IR (Nujol) 1640 (C=N), 1150, 1020 (OCH_2O) cm^{-1}; ^1H NMR (CCl_4) δ=1.80 (12H, s, $-CH_3$,), 5.30 (2H, s, $-CH_2-$). Found: C, 53.04; H, 8.92; N, 17.85%. Calcd for $C_7H_{14}N_2O_2$: C, 53.14; H, 8.91; N, 17.71%.

*Methylene Dioxime **2c**:* Mp 47—48.5 °C; IR (Nujol) 1645 (C=N), 1135, 1020 (OCH_2O) cm^{-1}; ^1H NMR (CCl_4) δ=1.60 (12H, m, $-CH_2-$), 2.18 (4H, m, $-CH_2-$), 2.47 (4H, m, $-CH_2-$), 5.37 (2H, s, $-OCH_2O-$). Found: C, 65.75; H, 9.41; N, 11.49%. Calcd for $C_{13}H_{22}N_2O_2$: C, 65.51; H, 9.31; N, 11.76%.

*Methylene Dioxime **2d**:* Mp 73 °C; IR (Nujol) 1628 (C=N), 1150, 1028 (OCH_2O) cm^{-1}; ^1H NMR (CCl_4) δ=2.20—3.03 (16H, m, $-CH_2-$), 5.71 (2H, s, $-OCH_2O-$), 7.03—7.40 (20H, m, aromatic). Found: C, 81.27; H, 7.38; N, 5.42%. Calcd for $C_{35}H_{38}N_2O_2$: C, 81.04; H, 7.38; N, 5.40%.

*Methylene Dioxime **2e**:* Mp 102 °C; IR (Nujol) 1630 (C=N), 1148, 1024 (OCH_2O) cm^{-1}; ^1H NMR (CCl_4) δ=3.43 (4H, s, $-CH_2-$), 3.63 (4H, s, $-CH_2-$), 5.80 (2H, s, $-OCH_2O-$), 7.00—7.27 (20H, m, aromatic). Found: C, 80.71, H, 6.55; N, 6.10%. Calcd for $C_{31}H_{30}N_2O_2$: C, 80.49; H, 6.54; N, 6.06%.

*Methylene Dioxime **2f**:* Mp 90—91 °C IR (Nujol) 1150, 1020 (OCH_2O) cm^{-1}; ^1H NMR (CCl_4) δ=5.70 (2H, s, $-CH_2-$), 7.10—7.60 (20H, m, aromatic). Found: C, 79.99; H, 5.32; N, 6.79%. Calcd for $C_{27}H_{18}N_2O_2$: C, 79.78; H, 5.46; N, 6.89%.

*Methylene Dioxime **2g**:* Mp 211—211.5 °C; IR (Nujol) 1620 (C=N), 1021 (OCH_2O) cm^{-1}; ^1H NMR (CCl_4) δ=6.20 (2H, s, $-CH_2-$), 7.10—7.93 (14H, m, aromatic), 8.00—8.37 (2H, m, aromatic). Found: C, 80.86; H, 4.35; N, 7.30%. Calcd for $C_{27}H_{22}N_2O_2$: C, 80.58; H, 4.51; N, 6.96%.

*Methylene Dioxime **2h**:* Mp 99—100 °C; IR (Nujol) 1679 (C=O), 1668 (C=N), 1035 (OCH_2O) cm^{-1}; ^1H NMR (CCl_4) δ=5.76 (2H, s, $-CH_2-$), 7.03—8.03 (20H, m, aromatic). Found: C, 75.40; H, 4.72; N, 6.16%. Calcd for $C_{26}H_{22}N_2O_4$: C, 75.31, H, 4.79; N, 6.06%.

*Methylene Dioxime **4**:* Yield 32%; mp 68 °C; IR (Nujol) 1675 (=N), 1005 (OCH_2O) cm^{-1}; ^1H NMR ($CDCl_3$) δ=0.77 (6H, s, $-CH_3$), 0.90 (6H, s, $-CH_3$), 1.00 (6H, s, $-CH_3$),

1.07—2.73 (14H, m, $-CH_2-$, and >CH), 5.38 (2H, s, $-OCH_2O-$). Found: C, 72.50; H, 9.83; N, 7.82%. Calcd for $C_{21}H_{34}N_2O_2$: C, 72.79; H, 9.89; N, 8.09%.

Methylene Dioxime **5**: Yield 23%; bp 185 °C/0.15 mmHg; IR (neat) 1615 (C=N), 1245, 1075 cm^{-1}; ^1H NMR ($CDCl_3$) δ=1.36 (18H, s, $-Bu^t$), 6.30 (2H, s, $-CH_2-$), 7.15—7.48 (10H, m, =CH- and aromatic), 7.58—7.80 (4H, m, =CH- and aromatic).

The use of $Pd(OAc)_2$ or $PdCl_2(PhCN)_2$ in place of [(2-methylallyl)PdCl]$_2$ (**3**) in the reaction of **1b** (R=CH_3) under the conditions described above also gave the methylene dioxime **2b**. The isolable yield of **2b** were 42% with $Pd(OAc)_2$ and 34% with $PdCl_2(PhCN)_2$. In the reaction using 2 equiv of KO_2 under otherwise the same conditions as above, the methylene dioximes **2a** and **4** were isolated in 96% and 61% yield from **1a** and *d*-camphor oxime, respectively.

Formation of Oximate Palladium(II) Complexes **6**. The general procedure described above was followed by using 1,3-diphenyl-2-propanone oxime (**1e**, 0.901 g, 4 mmol), KO_2 (0.284 g, 4 mmol), di-μ-chlorobis(2-methylallyl)dipalladium(II) (0.079 g, 0.2 mmol) and 40 mL of CH_2Cl_2. Alumina column chromatography (Al_2O_3, 18 g) of the reaction mixture gave the methylene dioxime **2e** (0.219 g, 24%) from the elution of hexane and ethyl acetate (7:3, 20 mL). Further elution with ethyl acetate gave unreacted **1e** (0.429 g, 48%). The oximate complex **6a** (R=CH_2Ph), (0.060 g, 15% based on Pd) was obtained from CH_2Cl_2 elution. Recrystallization from CH_2Cl_2 and petroleum ether afforded analytically pure **6a**: mp 145—147 °C; IR (Nujol) 1600, 1590, 1095, 1074, 1055, 1030, 742, 695 cm^{-1}; ^1H NMR (CD_2Cl_2-$CDCl_3$) δ=2.83—4.13 (16H, m, $-CH_2-$), 6.77—7.03 (40H, m, aromatic) Found: C, 71.68; H, 5.72; N, 5.63%. Calcd for $C_{60}H_{58}N_4O_4Pd$: C, 71.68; H, 5.81; N, 5.57%.

The same reaction with **1d** (0.506 g, 2 mmol) gave the oximate complex **6b** (R=CH_2CH_2Ph), (0.061 g, 27% based on Pd), along with methylene dioxime **2d** (0.188 g, 36%). **6b**: mp 151 °C (decomp) IR (Nujol) 1602, 1580, 1157, 1090, 1030 cm^{-1}; ^1H NMR (CCl_4) δ=2.75 (32H, m, $-CH_2-$), 7.00—7.37 (40H, m, aromatic). Found: C, 73.07; H, 6.67 N, 5.06%. Calcd for $C_{68}H_{74}N_4O_4Pd$: C, 73.07; H, 6,67; N, 5.01%.

Benzophenone oxime (**1f**) also gave this type of complex. However, no attempt to isolate the complex in a pure state was made, owing to its difficulty in the separation from unreacted ketoxime **1f**.

Preparation of Complex **6a** *(R=CH_2Ph).* A solution of $Pd(acac)_2$ (0.219 g, 0.72 mmol) and ketoxime **1e** (0.885 g, 3.9 mmol) in dichloromethane (5 mL) was stirred at room temperature for 0.5 h. After removal of the solvent, recrystallization (CH_2Cl_2-hexane) of the resulting complex gave 0.825 g of the complex **6a** (86%), whose spectral data were identical with those of the aforementioned complex.

Reaction of Ketoximes with Dichloromethane in the Presence of K_2CO_3 and 18-Crown-6. General Procedure. In a 25 mL flask containing a Teflon-coated magnetic stirrer bar were placed the oxime (1.0 mmol), potassium carbonate (0.152 g, 1.1 mmol), and 18-crown-6 (0.026 g, 0.1 mmol). Into the flask was then added 10 mL of dichloromethane (distilled from CaH_2), and the reaction mixture was refluxed for 12 h under argon with stirring. After the resulting potassium chloride was removed by filtration, the filtrate was concentrated under reduced pressure. The residues which contain the methylene dioxime and/or unreacted oxime were analyzed by ^1H NMR spectroscopy to determine the product yield. Results are also shown in Table 1.

A typical experiment in this system is described as followed. A mixture of oxime **1f** (0.197 g, 1 mmol), K_2CO_3 (0.152 g, 1.1 mmol), and 18-crown-6 (0.026 g, 0.1 mmol) in CH_2Cl_2 (10 mL) was refluxed for 12 h with stirring. After work-up as decribed above, NMR analysis of the reaction mixture showed the presence of methylene dioxime **2f** in 83% yield with 17% of unreactive oxime. The reaction mixture was then chromatographed on alumina column (12 g) to give methylene dioxime **2f** (0.157 g, 72%) from the elution with 20 mL of petroleum ether and 25 mL of ether.

*3,4,10,11,17,18-Hexamethyl-1,6,8,13,15,20-hexaoxa-2,5,9,12,16,19-hexaazahenicosa-2,4,9,11,16,18-hexaene (**11a**).* In a 300 mL of flask containing a Teflon-coated magnetic stirrer bar were placed (*E,E*)-2,3-butanedione dioxime **10a** (3.832 g, 33 mmol), Bu^tOK (7.406 g, 66 mmol) and 18-crown-6 (0.872 g, 3.3 mmol), and into the flask was added THF (100 mL). To the resulting suspended solution was added dichloromethane (100 mL) such a rate to maintain a gentle reflux with stirring. After the addition was complete, the mixture was refluxed for 18 h, cooled, and filtered. The solvent and excess CH_2Cl_2 were removed under reduced pressure. The residue was thoroughly washed with methanol and recrystallized from THF-MeOH. Pure **11a** (0.846 g) was obtined in 20% yield. **11a**: Mp 270—271 °C; IR (Nujol) 1600 (C=N), 1120, 1005 (OCH_2O), 870, 795, 690 cm^{-1}; ^1H NMR ($CDCl_3$) δ=2.04 (18H, s, $-CH_3$), 5.74 (6H, s, $-CH_2-$); ^{13}C NMR ($CDCl_3$) δ=10.57 ($-CH_3$), 99.46 ($-CH_2-$), 155.64 (-C=N-), mass spectrum *m/z* 384 (M^+). Found: C, 47.07; H, 6.31; N, 22.15%. Calcd for $C_{15}H_{24}N_6O_6$: C, 46.87; H, 6.29; N, 21.87%.

*3,4,10,11,17,18-Hexaisopropyl-1,6,8,13,15,20-hexaoxa-2,5,9,12,16,19-hexaazahenicosa-2,4,9,11,16,18-hexaene (**11b**).* The reaction of (*E,E*)-2,5-dimethyl-3,4-hexanedione dioxime **10b** (0.152 g, 0.88 mmol) with Bu^tOK (0.199 g, 1.77 mmol) and 18-crown-6 (0.023 g, 0.088 mmol) in THF (6 mL) and CH_2Cl_2 (6 mL) gave **11b** (0.033 g, 21%) which was purified by preparative TLC (SiO_2, ethyl acetate:hexane=1:10). **11b**: Mp 140—148 °C; IR (Nujol) 1595 (C=N), 1060, 1030 cm^{-1}; ^1H NMR ($CDCl_3$) δ=1.14 (36H, d, *J*=7 Hz, $-CH_3$), 3.33 (6H, heptet, *J*=7 Hz, -CH), 5.63 (6H, s, $-CH_2-$); mass spectrum *m/z* 551 (M^+-1).

*3,4,10,11,17,18,24,25-Octapropyl-1,6,8,13,15,20,22,27-octaoxa-2,5,9,12,16,19,23,26-octaazaoctacosa-2,4,9,11,16,18,23,25-octaene (**12**).* This compound was prepared by the reaction of (*E,E*)-4,5-octanedione dioxime **10c** (1.033 g, 6 mmol) with Bu^tOK (1.346 g, 12 mmol) and 18-crown-6 (0.159 g, 0.6 mmol) in THF (20 mL) and CH_2Cl_2 (20 mL). The product (40% yield) was isolated by preparative TLC (SiO_2, ethyl acetate: hexane=1:15). Analytically pure sample was obtained by two additional preparative TLC. **12**: Mp 143—146 °C; IR (Nujol) 1595 (C=N), 1135, 1020 (OCH_2O) cm^{-1}; ^1H NMR ($CDCl_3$) δ=0.84 (24H, t, *J*=7 Hz, $-CH_3$), 1.14—1.73 (16H, m, $-CH_2-$), 2.63 (16H, t, *J*=7 Hz, $-CH_2C=N-$), 5.70 (8H, s, $-OCH_2O-$); ^{13}C NMR ($CDCl_3$) δ=14.13 ($-CH_3$), 19.93 ($-CH_2-$), 26.12 ($-CH_2-$), 99.32 ($-OCH_2O-$), 158.32 (-C=N-), mass spectrum *m/z* 736 (M^+). Found: C, 58.58; H, 8.70; N, 15.29%. Calcd for $C_{36}H_{64}N_8O_8$: C, 58.67; H, 8.75; N, 15.21%.

*7H-3,4-Dicyclohexyl-1,6,2,5-dioxadiazepine (**15a**).* This compound was prepared by the reaction of (*Z,Z*)-dicyclohexylethanedione dioxime **10f** (1.001 g, 4 mmol) with Bu^tOK (0.898 g, 8 mmol) and 18-crown-6 (0.106 g, 0.4 mmol) in

THF (20 mL) and CH_2Cl_2 (20 mL). The product (66% yield) was purified by preparative TLC (SiO_2, ethyl acetate:hexane=1:15). **15a**: Bp 135—136 °C/1 mmHg; IR (neat) 1600 (C=N), 1035 (OCH_2O), 990, 975 cm^{-1}; ^1H NMR ($CDCl_3$) δ= 0.98—2.58 (22H, m, $-CH_2-$), 5.28 (2H, s, $-OCH_2O-$); mass spectrum m/z 265 (M^++1). Found: C, 67.79; H, 9.13, N, 10.42%. Calcd for $C_{15}H_{24}N_2O_2$: C, 68.15; H, 9.15; N, 10.60%.

Reaction of (Z,Z)-2,5-Dimethyl-3,4-hexanedione Dioxime ***10g*** *with Dichloromethane.* In a 100 mL flask containing a Teflon-coated magnetic stirrer bar were placed (*Z,Z*)-2,5-dimethyl-3,4-hexanedione dioxime **10g** (1.033 g, 6 mmol), Bu^{t}OK (1.346 g, 12 mmol) and 18-crown-6 (0.159 g, 0.6 mmol). Into the flask was added CH_2Cl_2 (20 mL) with stirring, and then THF (20 mL) was slowly added to the resulting suspended solution in an ice bath. After the addition was complete, the mixture was refluxed for 20 h. cooled, and filtered. After removal of THF and CH_2Cl_2 under reduced pressure, the products were chromatographed on Al_2O_3. A mixture of **15b** and **16** obtained from the elution of ether was purified by preparative TLC (SiO_2, ethyl acetate:hexane=1:10). Pure **15b** (0.517 g) and **16** (0.044 g) were obtained in 47% and 4% yield, respectively. **15b**: Bp 60—61 °C/1 mmHg; IR (neat) 1605 (C=N), 1035 (OCH_2O), 975 cm^{-1}; ^1H NMR ($CDCl_3$) δ=1.25 (12H, d, J= 7 Hz, $-CH_3$), 2.68 (2H, heptet, J=7 Hz, >CH), 5.30 (2H, s, $-CH_2-$); mass spectrum m/z 184 (M^+). Found: C, 58.61; H, 8.57; N, 15.26%. Calcd for $C_9H_{16}N_2O_2$: C, 58.67; H, 8.75; N, 15.21%. **16**: Mp 82—83 °C; IR (Nujol) 1615 (C=N), 1260, 1020 (OCH_2O); ^1H NMR ($CDCl_3$) δ=1.14 (12H, d, J= 7 Hz, $-CH_3$), 1.19 (12H, d, J=7 Hz, $-CH_3$), 2.60 (4H, m, -CH), 5.55 (4H, s, $-CH_2-$); mass spectrum m/z 368 (M^+). Found: C, 58.99; H, 8.61; N, 14.87. Calcd for $C_{18}H_{32}N_4O_4$: C, 58.66; H, 8.75; N, 15.21.

Reaction of (Z,E)-2,5-Dimethyl-3,4-hexanedione Dioxime ***10h*** *with Dichloromethane.* In a 50 mL flask containing a Teflon-coated magnetic stirrer bar were placed (*Z,E*)-2,5-dimethyl-3,4-hexanedione dioxime **10h** (0.360 g, 2.1 mmol), Bu^{t}OK (0.471 g, 4.2 mmol) and 18-crown-6 (0.055 g, 0.21 mmol). Into the flask was added CH_2Cl_2 (10 mL) with stirring, and then THF (10 mL) was slowly added to the resulting suspended solution in an ice bath. After the addition was complete, the mixture was refluxed for 20 h, cooled, and filtered. After removal of THF and CH_2Cl_2 under reduced pressure, the residue was purified by preparative TLC (R_f 0.70, SiO_2, ethyl acetate:hexane=3:7) to give **15b** (0.043 g, 16%).

Reaction of (E,E)-1,2-Cyclohexanedione Dioxime ***10e*** *with Dichloromethane.* The reaction of (*E,E*)-1,2-cyclohexanedione dioxime **10e** (0.976 g, 6.8 mmol), Bu^{t}OK (1.526 g, 13.6 mmol) and 18-crown-6 (0.186 g, 0.68 mmol) in CH_2Cl_2 (80 mL) gave **13** (0.112 g, 12%) which was purified by silica-gel column chromatography (ether as eluting solvent). **13**: Mp 178—180 °C; IR (Nujol) 3200 (OH), 1620 (C=N), 1140, 1015 (OCH_2O), 820, 765 cm^{-1}; ^1H NMR ($CDCl_3$) δ=1.43—1.93 (8H, m, $-CH_2-$) 2.45—2.95 (8H, m, $-CH_2-$), 4.20—5.30 (2H, br, -OH), 5.85 (2H, s, $-OCH_2O-$). Found: C, 52.62; H, 6.66; N, 18.65%. Calcd for $C_{13}H_{20}N_4O_4$: C, 52.69; H, 6.80; N, 18.91%.

Reaction of (E,E)-Benzil Dioxime ***10d*** *with Dichloromethane.* The reaction of (*E,E*)-benzil dioxime **10d** (0.961 g, 4 mmol), Bu^{t}OK (0.896 g, 8 mmol) and 18-crown-6 (0.106 g, 0.4 mmol) in CH_2Cl_2 (40 mL) gave 3,4-diphenylfrazan **14** (0.236 g, 27%) which was purified by Al_2O_3 column chromatography (pentane:ether=9:1). **14**: Mp 91—92 °C; IR (Nujol) 1580 (C=N), 1075, 990, 890, 780, 760, 695 cm^{-1}; ^1H NMR (CCl_4) δ= 7.25—7.68 (10H, m, aromatic). Found: C, 75.75; H, 4.49; N, 12.76%. Calcd for $C_{14}H_{10}N_2O$: C, 75.66; H, 4.54; N, 12.61%.

(Received July 30, 1984)

As electrochemical method was developed for converting 2,3-butanediol in dilute aqueous solutions to acetaldehyde by "in-cell" indirect anodic oxidation using a periodate/iodate redox mediatory system. Under optimum conditions, current efficiency for the desired acetaldehyde was close to 80% and the formation of by-products such as acetic acid, acetoin, and biacetyl was minimized or suppressed.

As part of a broad program pursued here and elsewhere whose main thrust is to explore the possibilites of converting electrochemically biomass-derived materials to (a) fuels or fuel components and/or (b) commercial organic chemicals, we have used 2,3-butanediol as a feedstock. Our results on the electrochemical conversion of this 1,2-diol to 2-butene (category *a* above)[1] and 2-butanone(category *b*)[2] had been reported; this paper concerns the conversion of the diol to acetaldehyde by electrooxidative cleavage.

It is well known that 1,2-diols,including 2,3-butanediol, can be cleaved with oxidizing reagents such as chromium(VI) oxide, peroxodisulfates, lead(IV) tetraacetate, diacetoxyiodobenzene and periodates to give two moles of the corresponding carbonyl compounds in a variety of yields and selectivities.[3,4] 1,2-Diols give also the carbonyl compounds by electrooxidation under a variety of electrolytic conditions.[5-14] The electrochemical method for the oxidative cleavage of the diols may be generally favorable from the point of view of avoiding the use of large amounts of expensive, poisonous and/or hazardous reagents. In this regard, we examined the electrochemical oxidation of 2,3-butanediol to acetaldehyde.

2,3-Butanediol is obtained as dilute aqueous solutions whose concentrations are lower than 10%, usually a few percent, by the fermentation of glucose and xylose.[15-18] Therefore, the electrolytic method suitable for such dilute solutions should be recommended, though the crude solutions from the fermentation can be concentrated by distillation; pure 2,3-butanediol is obtainable with considerable difficulty.[19,20]

In this work, either direct or indirect(using a redox mediator) electrooxidation of 2,3-butanediol to acetaldehyde in dilute (mainly *ca.* 1%) aqueous solutions was examined and it was found that the indirect oxidation using the periodate/iodate redox mediator resulted in high current efficiencies and selectivities for acetaldehyde.

Results and Discussion

Horányi *et al.*[21,22] reported that 2,3-butanediol was oxidized directly at a platinized platinum anode in a strongly acidic solution to give acetoin and biacetyl. In this oxidation, however, no cleaved products such as acetaldehyde and acetic acid were formed. In this work, the direct oxidation (Eq. 1) was first examined by using anodes other than platinized platinum in strongly acidic, neutral and strongly alkaline solutions. Electrolyses were carried out in a divided cell. Although acetaldehyde was formed in the direct oxidation, its current efficiency and selectivity were very low under a variety of conditions used. Even in the best case where a lead(IV) dioxide anode was used in a neutral solution, considerably large amounts of by-products such as acetic acid (15% current efficiency), acetoin(17%) and biacetyl(3%) were formed along with the desired acetaldehyde(24%).

$$CH_3\text{-}\underset{\displaystyle OH}{\underset{|}{CH}}\text{—}\underset{\displaystyle OH}{\underset{|}{CH}}\text{-}CH_3 \longrightarrow 2CH_3CHO + 2H^+ + 2e \qquad (1)$$

At the next stage of the investigation, the indirect oxidation using a suitable redox mediator was examined. Generally, either "in-cell" or "ex-cell" method may be available for indirect electrochemical oxidation and reduction. In this work, the "in-cell" method was favored, since it should be simpler in the whole system of electrolytic process.

As summarized by Torii,[23] a variety of organic and inorganic redox systems are available for indirect electro-oxidation of organic compounds. In this work, a periodate/iodate redox system was chosen as an electron-mediator, since 1,2-diols can generally cleaved by periodate oxidation to give the corresponding carbonyl compounds[3,4] and periodates are industrially produced by the electrochemical oxidation of iodates at lead(IV) dioxide anodes.[24-26] In addition, it has been confirmed by independent experiments that both periodates and iodates can not oxidize acetaldehyde. The indirect oxidation of 2,3-butanediol is pres-

ented by Eqs. 2 and 3.

At anode:

$$IO_3^- + 2OH^- \longrightarrow IO_4^- + H_2O + 2e \quad (2)$$

In solution:

$$CH_3\text{-}\underset{\underset{OH}{|}}{CH}\text{—}\underset{\underset{OH}{|}}{CH}\text{-}CH_3 + IO_4^- \longrightarrow 2CH_3CHO + IO_3^- + H_2O \quad (3)$$

The pH dependence of the chemical oxidation of 2,3-butanediol to acetaldehyde was first examined. As shown in Fig. 1, yields of acetaldehyde were high at pHs higher than 6, though no examination was carried out in alkaline solutions because in the latter case condensation reactions of aldehyde occur.

On the other hand, as shown in Fig. 2, current efficiencies for periodate formed in the electrooxidation of iodate at a lead(IV) dioxide anode were high at pHs lower than 6.

From these facts, it seemed to be difficult to obtain both the highest yield of acetaldehyde and the highest current efficiency for periodate at the same pH. It was expected that the best result in actual electrolysis of 2,3-butanediol in sodium iodate solutions would be obtained in a range of pH 5—7. As shown in Fig. 3, the current efficiency for acetaldehyde formed in the indirect electrochemical oxidation of 2,3-butanediol at the lead(IV) dioxide anode in phosphate buffer solutions containing sodium iodate was at a high level close to 80% at pH 5—9. The current efficiency was somewhat affected by anodic potentials and the highest value was obtained at 2.00 V *vs.* SCE.

Decrease of the current efficiency at lower pHs, shown in Fig. 3, might be due to unfavorable oxidation of 2,3-butanediol to by-products with anodically generated periodate(Eq. 2) since the oxidation proceeded more disadvantageously at such pHs, as shown in Fig. 1. However, no by-product was formed in the chemical oxidation with sodium periodate at such pHs. This fact suggests that the decrease of the current efficiency for acetaldehyde may be due to occurrence of electrochemical side reactions to form products other

than acetaldehyde. As shown in Fig. 4, the oxidation at the lower pHs provided larger amounts of by-products such as acetic acid and acetoin, while no biacetyl was formed at all pHs used. The oxidation potential of iodate seemed to be close to that of 2,3-butanediol (See Fig. 5) and the main products in the direct oxidation at the lead dioxide anode in the strongly acidic solution were acetic acid and acetoin. From these facts, the formation of the by-products at the lower pHs may be rationalized as due to the simultaneous direct oxidation with the indirect oxidation by electrogenerated periodate.

As shown in Fig.6 the highest current efficiency for acetaldehyde was obtained at 37 °C. Lower current efficiencies at higher temperatures might be partially due to loss of acetaldehyde by its evaporation.

The current efficiency for acetaldehyde was affected by the concentration of sodium iodate, as shown in Fig. 7. Lower efficiencies at lower concentrations may be due to simultaneous occurrence of the indirect and direct oxidation of 2,3-butanediol, the latter of which gave acetaldehyde in lower efficiencies. The direct oxidation should be relatively favorable at low concentration of sodium iodate, since the oxidation potential of 2,3-butanediol is not so far from that of sodium iodate even in a neutral solution (See Fig. 5). From the results in Fig. 7, concentrations higher than 0.2 M (1 M=1 mol dm^{-3}) should be desirable, but those higher than 0.3 M can not be actually used because of the limited solubility of sodium iodate in the electrolytic solution.

Curve(a) in Fig. 8 indicates that the current efficiency decreased with increase of concentration of 2,3-butanediol, when 0.67 F (1 F=96496 C) mol^{-1} of charge, which is proportional to the concentration, was passed. In such a manner of electrolysis, the ano-

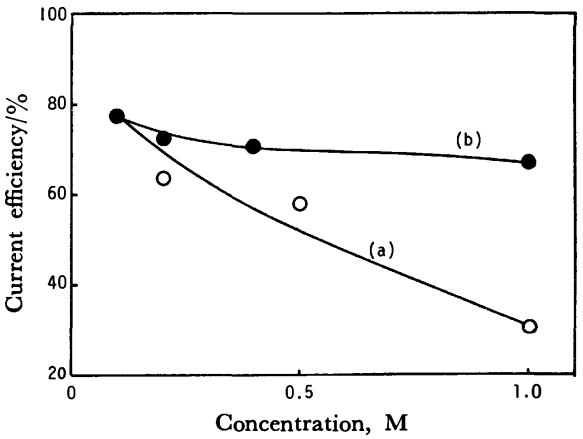

Fig. 8. 2,3-Butanediol Concentration-Dependence of Current Efficiency for Acetaldehyde Formed in the Indirect Electrochemical Oxidation of 2,3-Butanediol with a Periodate/Iodate Redox Mediator at a Lead Dioxide Anode.
Sodium iodate concentration, 0.2 M; pH, 7; Temperature, 37 °C; Anodic potential, 2.00 V *vs.* SCE; Charge passed, (a) 0.67 F mol^{-1} and (b) 0.0033 F for each concentration of 2,3-butanediol.

lyte should be acidified by the acid electrogenerated when large amounts of charge was passed at high concentration of 2,3-butanediol. In fact, after 0.67 F mol^{-1} (0.033 F for 50 mmol of 2,3-butanediol) was passed in 1.0 M 2,3-butanediol concentration, the pH decreased to 2.5 because of the insufficient buffering capacity of a phosphate solution used as the anolyte. Low current efficiency in this case also may be rationalized as due to simultaneous direct oxidation.

Curve(b) in Fig. 8 shows the results obtained by passing the same amount of charge(0.0033 F) at all the concentrations. In this case, a much smaller decrease of the current efficiency with increase of the concentration was observed, because the change of pH should be almost the same in each electrolysis.

From the above consideration, pH control is desired to obtain high current efficiencies, when such large amounts of charge are passed that high conversions of the starting 2,3-butanediol can be obtained when it is present in high concentrations. This point was further confirmed by Fig. 9. When large amounts of charge of 2.6 F mol^{-1} were passed without any pH control (to obtain almost 100% conversion), the current efficiencies for acetaldehyde and acetic acid were decreased and increased, respectively, as shown in Fig. 9.

Figure 9 also showes a result which was obtained by adjusting pH in the range of 7—6 by occasional addition of alkali during the electrolysis. Compared with the previous case, the result was improved.

When 2.5 F mol^{-1} of charge were passed in a high concentration (0.5 M, *ca.* 5%) of 2,3-butanediol under no pH control, the current efficiency for the desired acetaldehyde was lower than that for the by-product (acetic acid) as shown in Fig. 10. In this case, two more

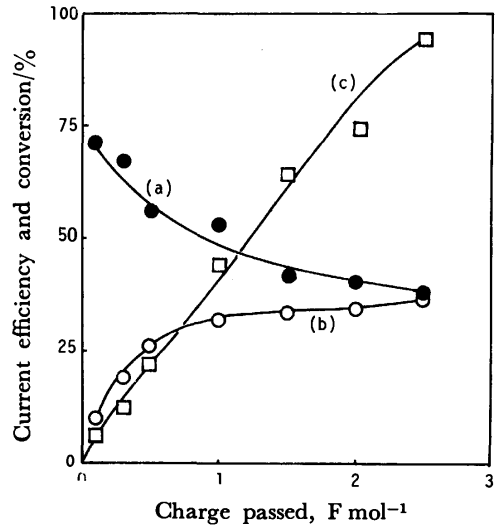

Fig. 11. Current Efficiency for (a) Acetaldehyde and (b) Acetic Acid, and Conversion (c) of 2,3-Butanediol in the Indirect Electrochemical Oxidation with a Periodate/Iodate Redox Mediator at a Lead Dioxide Anode.
2,3-Butanediol concenrtation, 0.5 M (*ca.* 5%); Sodium iodate concentration, 0.2 M; Initial pH, 7 (controlled at 7—6 by adding disodium hydrogenphosphate during the electrolysis); Anodic potential; 2.00 V. *vs.* SCE; Temperature, 37 °C.

by-products, acetoin and cyclic acetal of 2,3-butanediol(2,4,5-trimethyl-1,3-dioxolane), rose and fell in the course of the electrolysis. The pH control resulted in some improvements in the current efficiencies as shown in Fig. 11, but they were not satisfactory.

Acetaldehyde can not be oxidized with periodate, as described above, but it may be oxidized at an anode. In fact, acetaldehyde (0.48 M) was oxidized to acetic acid in 96% conversion and 78% current efficiency at 2.00 V *vs.* SCE (at lead(IV) dioxide anode) in a phosphate-buffered solution(pH 7) containing sodium iodate (0.2 M). Therefore, the decrease and increase of acetaldehyde and acetic acid, respectively, at high conversion of 2,3-butanediol is rationalized as due to the further oxidation of the former to the latter. To prevent the further oxidation, it should be effective to remove acetaldehyde from the anolyte by a suitable way during the electrolysis. This is a chemical engineering problem with which this paper is not concerned.

As described above, it was important to keep the pH in a suitable range and pH control was done by adding alkali to the anolyte during the electrolysis. There may be another way for the pH control, that is, the use of an undivided cell, which can be constructed more simply than divided ones. We attempted electrolyses in an undivided cell using a platinum cathode and lead(IV) dioxide anode, but good results could not be obtained because of the cathodic reduction of iodate to iodide (which was re-oxidized to iodine at the anode).

Conclusion

An optimization of the electrochemical conversion of 2,3-butanediol to acetaldehyde was established as follow: Electrolytic method, indirect oxidation; mediatory system, periodate/iodate redox; cell, divided; anode, lead(IV) dioxide; anodic potential, 2.00 V *vs.* SCE; pH, 7—6; temperature, 37 °C; concentration of sodium iodate, >0.2 M; concentration of 2,3-butanediol, several percent.

It is also recommended to remove acetaldehyde during the electrolysis so that it does not accumulate in the anolyte. For this purpose, continuous distillation and/or extraction may be available. If an efficient procedure for removing acetaldehyde is established, an "ex-cell" method for the indirect oxidation may become practicable, though it has not been established whether the "ex-cell" method is superior to the "in-cell" one.

Experimental

Materials. 2,3-Butanediol and lead(IV) dioxide anodes were supplied from Tokyo Kasei Kogyo Co. Ltd. and Sanwa Chemical Co. Ltd., respectively.

Electrolysis. An H-type divided cell with a sintered glass diaphragm and a potentiostat were used for controlled-potential electrolyses. Anodes were platinum (2.0×3.0 cm), lead(IV) dioxide (2.5×3.0 cm) and graphite (2.5×3.0 cm) plates. The direct oxidation of 2,3-butanediol was carried out in 0.5 M H_2SO_4, 1 M Na_2SO_4, and 1 M KOH, while anolytes for the indirect oxidation were phosphate-buffered solutions containing sodium iodate; 0.3 M Na_2HPO_4 (pH 9), Na_2HPO_4–NaH_2PO_4 (pH 8—4.5), 0.3 M Na_2HPO_4–0.5 M H_3PO_4 (pH 3), and NaH_2PO_4–H_2SO_4 (pH<3). Fifty mililiters of anolyte were used for each electrolysis.

Analysis. Starting 2,3-butanediol and all the products were analyzed by gas chromatography (1.5 m Chromosorb 101 column at 80—180 °C). Periodate was analyzed by the Fluery-Lange method.[22]

We are grateful to the Kajima Foundation for making possible Professor Chou's participation.

Photoinduced Reduction of Methylviologen by Ascorbate Using Chlorophyllin in Liposome System

Seiji HIDAKA,† Eizo MATSUMOTO, and Fujio TODA*
†*Department of Synthetic Chemistry, Faculty of University of Tokyo, Hongo, Bunkyo-ku, Tokyo 113*

(Received February 21, 1984)

Photoindeced electron transport across bilayer lipid membrane was studied, using chlorophyllin (Chln), a water-soluble derivative of chlorophyll. Photoreduction of methylviologen (MV^{2+}) by ascorbate was observed only in the liposome system containing ascorbate in the internal aqueous phase and MV^{2+} in the external aqueous phase. This suggests asymmetry of bilayer lipid membrane. This reaction rate was not affected by the addition of carbonyl cyanide *m*-chlorophenylhydrazone in the system buffered by tris(hydroxymethyl)aminomethane (Tris), but strongly affected by *N*-2-hydroxyethylpiperazine-*N'*-2-ethanesulfonic acid. In the system buffered by Tris, a proton carrier is not Chln having carboxyl groups but Tris possessing primary amine group. Replacement of the central Mg of Chln with Zn gives a higher rate of MV^{2+} photoreduction, but when Cu was used in place of Zn, photoreduction was not observed. The central metal may affect the redox potential and the life time of excited Chln.

Membrane-like structure plays an important role in bioenergetic systems. It is well-known that thylakoid membrane in chloroplast is indispensable to photosynthesis. There are three major functions in biological membrane. First, membrane is a barrier to separate the internal aqueous phase of cell from the external. Second, it can orient the functional units (enzyme, protein *etc.*) in the highly ordered forms. Third, it is a reaction medium of chemical and/or physical reactions. Consequently, thylakoid membrane enables active transport of electrons by interfering with back reaction and generates pH gradient to synthesize ATP.

There have been many reports on photoinduced electron transport across bilayer lipid membrane sensitized by chlorophyll,[1,2] amphiphilic Zn(II) porphyrins,[3,4] or Ru(II) complexes.[5,6] But these photosensitized redox reactions often occur effectively in homogeneous solutions.

We previously reported that photoinduced electron transport across bilayer lipid membrane can take place sensitized by chlorophyllin.[7] Chlorophyllin is a water-soluble derivative of chlorophyll, and a fairy green pigment which resembles chlorophyll in its photochemical reactivity.[8–10]

We report here that photoreduction of methylviologen by ascorbate using chlorophyllin as a sensitizer in liposome system. This reaction doesn't occur in homogeneous solution. Ascorbate is a reversible electron donor which is different from EDTA and triethanolamine as sacrificial electron donors.

Experimental

Materials. *Chlorophyllin* a: Chlorophyll a was extracted from fresh spinach leaves with cold acetone and purified according to the procedure of Omata and Murata.[11] Chlorophyllin a (Chln) was prepared from chlorophyll a by the method of Oster and his coworkers.[12]

Cu- and Zn-chlorophyllin a: Cu- and Zn-chlorophyll were prepared from their original chlorophyll using to the procedure of Onoue[13] and subsequently converted into Cu-chlorophyllin a (Cu-chln) and Zn-chlorophyllin a (Zn-chln).

Lecithin: Lecithin (phosphatidylcholine) was isolated from hen egg yolk and purified with the chromatographic procedure.[14]

Methylviologen (MV^{2+}) and carbonyl cyanide *m*-chlorophenylhydrazone (CCCP) were purchased from Sigma Chemical Co. and the other chemicals were reagent grade and used without further purification.

Liposome. Lecithin in chloroform was dissolved in benzene and colyophylized. Liposomes were prepared by sonicating lecithin in the solution buffered by 1 mol dm^{-3} Tris-Cl 0.1 mol dm^{-3} KCl (pH 7.5) under an N_2 atmosphere for 1 h at 4 °C. The dispersion was then centrifuged to remove metal fragments. External ions were separated from liposomes by gel-filtration on a 2×50 cm Sephadex G-50 column. The samples were purged of O_2 by bubbling a stream of Ar gas for 30 min at 4 °C.

Measurements. Photoreaction was carried out under an atmosphere of Ar gas sealed in the Pyrex tube with UV cell on the bottom. Light was irradiated with 500 W Xenon lamp (Ushio UXL-500D). Glass filters (Toshiba IRQ-25, OR-57) were used to isolate red light. Absorption spectra were measured on Hitachi spectrophotometer. Photoinduced electron transport was monitored by measuring the absorbance of reduced methylviologen ($MV^{+\cdot}$) at 605 nm.

Results and Discussions

Photoreduction of MV^{2+}. Transmembrane electron transport from ascorbate (Asc) to MV^{2+} sensitized by Chln was investigated in the various systems and the formation of $MV^{+\cdot}$ with time of irradiation as is shown in Fig. 1. In the homogeneous system, $MV^{+\cdot}$ was not observed. This is thought to be due to the rapid back reaction between oxidized ascorbate (DAH) and $MV^{+\cdot}$. In the liposome system containing MV^{2+} in the internal aqueous phase and Asc in the external, $MV^{+\cdot}$ didn't produce though the bilayer lipid membrane interfered with the back reaction. Photoreduc-

tion of MV^{2+} was observed only in the liposome system containing Asc in the internal aqueous phase and MV^{2+} in the external. The experimental results as described below were gained in this system.

The progressive spectral changes with time of irradiation are shown in Fig. 2. Chln in the liposome system showed a red absorption peak at 660 nm. However, on irradiation, a new absorption band appeared gradually at 690-nm as the 660 nm peak decreased. After the 690-nm peak was saturated, the absorption band due to $MV^{+\cdot}$ was observed to increase. From the previous experiment,[7,15] we confirmed the 690 nm absorbing species was an irreversible product of Chln (Chln'). In the present system, Chln didn't appear to sensitize MV^{2+} photoreduction but Chln' did and it was recycled because the spectrum after 20-min irradiation corresponded to that after 5-min irradiation when O_2 gas was added to the system to remove $MV^{+\cdot}$ absorption.

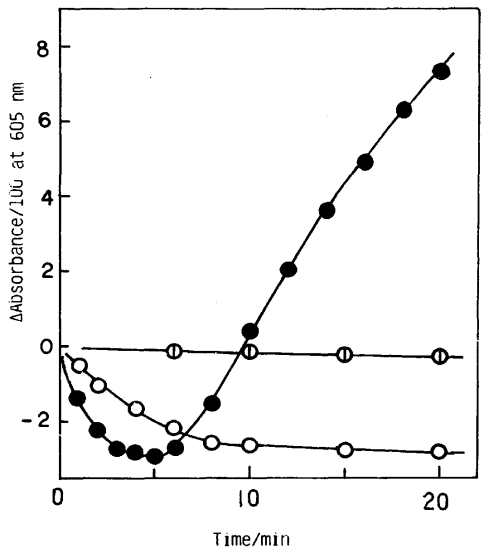

Fig. 1. Photoreduction of MV^{2+} in various systems. ①: [Chln] = 10 μmol dm^{-3}, [MV^{2+}] = 10 mmol dm^{-3}, [AscNa] = 10 mmol dm^{-3}, in Tris buffer, ○: [Chln] = 10 μmol dm^{-3}, [MV^{2+}] = 0.1 mol dm^{-3} (in), [AscNa] = 10 mmol dm^{-3} (out), in liposome system, ●: [Chln] = 10 μmol dm^{-3}, [AscNa] = 1 mol dm^{-3} (in), [MV^{2+}] = 10 mmol dm^{-3} (out) in liposome system.

The dependence of photoreduction rate of MV^{2+} on MV^{2+} concentration is shown in Fig. 3. The measurement of the concentration of $MV^{+\cdot}$ was based on the minimum absorbance at 605 nm as described above. The reduction rate increased rapidly with increasing the lower concentration region, and saturated at the higher concentration.

From these results, the reaction scheme is proposed and the difference of the reactivities of the two liposome systems is discussed. The reaction is thought to proceed as follows:

$$\text{Chln} \xrightarrow{h\nu} \text{Chln}' \quad (1)$$

$$\text{Chln}' \xrightarrow{h\nu} \text{Chln}'^{*} \quad (2)$$

$$\text{Chln}'^{*} + MV^{2+} \longrightarrow \text{Chln}'^{+\cdot} + MV^{+\cdot} \quad (3)$$

$$\text{Chln}'^{+\cdot} + \text{Asc}^{-} \longrightarrow \text{Chln}' + \text{DAH} \quad (4)$$

where Chln'* and Chln'$^{+\cdot}$ are excited Chln' and Chln' cation radical, respectively. The reaction (1) is the formation of the 690-nm absorbing species. The decrease of the absorbance at 605 nm at the initial step

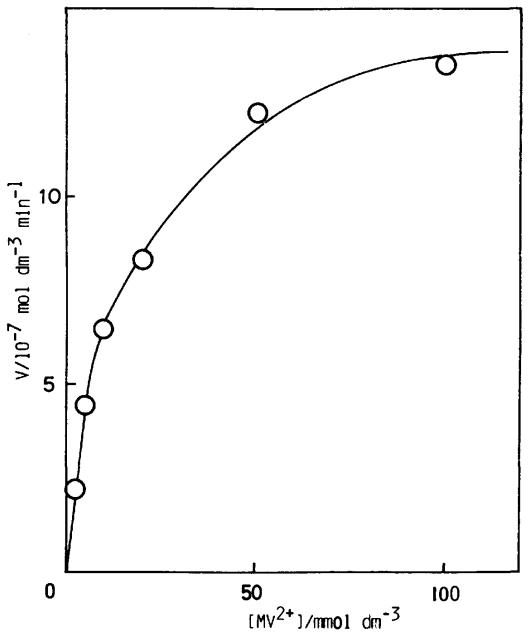

Fig. 3. Dependence of the reduction rate on MV^{2+} concentration.

was due to this reaction. The dependence of MV^{2+} photoreduction on MV^{2+} concentration is interpreted according to the scheme. In the lower MV^{2+} concentration, the reduction rate was determined by the reaction (3) and the observed rate was dependent on MV^{2+} concentration. On the other hand, as the reaction (3) was fast enough at the higher MV^{2+} concentration, the photoreduction rate was determined by the reaction (2). Therefore the observed rate was independent of MV^{2+} concentration.

The different results in the two liposome systems suggests asymmetry of bilayer lipid membrane. There have been several reports on asymmetry in sonicated liposomes.[16-20] The packing density of the inner-layer lipid molecules is more dense than that of the outer-layer lipid molecules owing to the difference of the curvature and causes the geometrical constraints to the head groups and the acyl chains of the inner-layer lipid molecules (Fig. 4[21]). This asymmetry facilitates the reaction (2) rather on the outer surface than on the inner surface. And another investigation indicates that the greater part of water-soluble Chln added to the liposome system exists on the outer surface.[15] Such a biased distribution of Chln is also more favorable to the reaction (2) on the outer surface than on the inner surface. Therefore, MV^{2+} photoreduction didn't occur in the liposome system containing MV^{2+}, in the internal and Asc in the external, but was observed in the liposome system containing Asc in the internal and MV^{2+} in the external.

Effect of CCCP. Chln was expected to play a role of a proton carrier as well as an electron carrier because Chln is tricarboxylic acid. The effect of CCCP was investigated in the liposome system buffered by

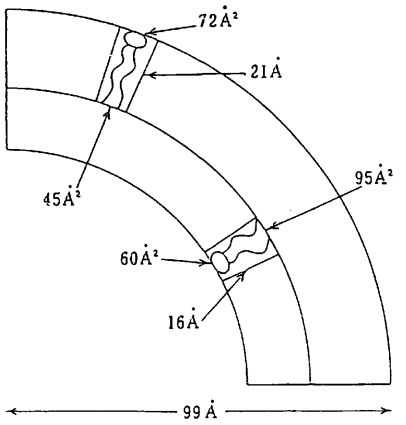

Fig. 4. Vesicle bilayer cross section showing the packing geometry of lipids within the inner and outer vesicle bilayer.

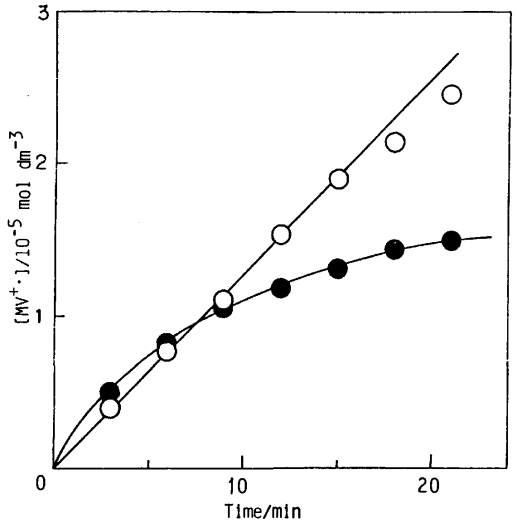

Fig. 5. Effect CCCP on MV^{2+} photoreduction in liposome system buffered by HEPES, pH 7.5.
●: without CCCP, ○: with 0.1 mmol dm^{-3} CCCP.

2-[4-(2-hydroxyethyl)-1-piperazinyl] ethanesulfonic acid (HEPES), pH 7.5 because HEPES is impermeable to membrane.[22,23] The addition of CCCP strongly affected MV^{2+} photoreduction as is shown in Fig. 5. Contrary to our expectation, Chln didn't transport protons with electrons in the absence of CCCP and the formation of membrane potential suppressed the photoreduction. But in the system buffered by Tris, pH 7.5 the effect of CCCP on the reaction rate was not observed. Without CCCP, $MV^{+\cdot}$ production was nearly linear, not saturated for our measurement time. It was reported that Tris could penetrate membrane and that 'Hill reaction' was hindered at the high concentration of Tris because Tris, having the primary amine group, acted as an uncoupler.[23,24] From a consideration of these reports, it is consistent to conclude that Tris played a part of a proton carrier in our system since the concentration of Tris was 1 mol dm^{-1}.

Effect of Central Metal. The effect of the central

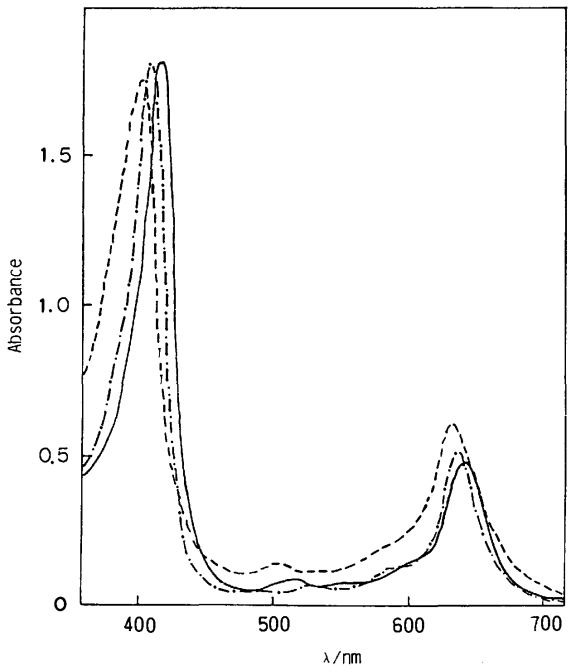

Fig. 6. Absorption spectra of chlorophyllin derivatives.
(——): Chln, (—·—): Zn-chln, (----): Cu-chln.

●: Chln, ○: Zn-chln ⦶: Cu-chln.

metal of Chln on photoredox reaction was investigated by replacement of the central Mg with Cu or Zn. Though the spectra of these pigments bear much resemblance as is shown in Fig. 6, different photocatalytic reactivities were observed in MV^{2+} reduction as is shown in Fig. 7. The reactivity of pigment decreased in the order Zn-chln>Chln>Cu-chln=0. It is remarkable that Zn-chln reactivity was better than that of Chln which has the same Mg as chlorophyll, a natural photosynthetic pigment. The result indicates the redox potential and/or the life time of the excited state of Chln may depend on the central metal. The relative order of the redox potentials of these excited pigments may be Zn-chln>Chln>MV^{2+}>Cu-chln. Therefore Cu-chln couldn't sensitize the photoreduction of MV^{2+}.

The authors wish to express their thanks to Professor Kennichi Honda of University of Tokyo.

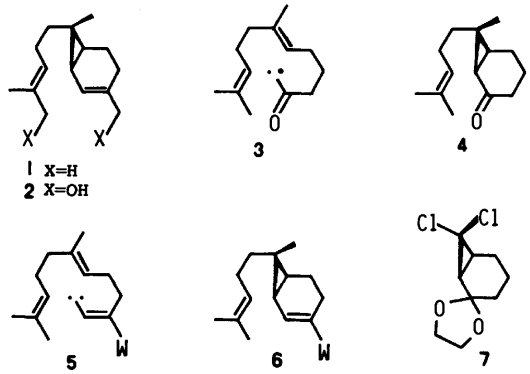
Rearrangement Approaches to Cyclic Skeletons. I. Photochemical Rearrangement Approaches to (±)-Sesquicarene and (±)-Sirenin, [3—6] Fused-Ring Sesquiterpenes†

Tadao UYEHARA,* Jun-ichi YAMADA, Koichi OGATA, and Tadahiro KATO
Department of Chemistry, Faculty of Science, Tohoku University, Aramaki-Aoba, Sendai 980
(Received June 21, 1984)

The 4-alkyl, 4-alkenyl, and 4-aryl derivatives of bicyclo[3.2.2]nona-3,6-dien-2-one (**9**) were prepared from **9** itself by ultrasound-promoted Barbier reaction followed by PCC oxidation. Photochemical transformation of the 4-(4-methyl-3-pentenyl) derivative of **9**, namely **13**, in THF–water gave *endo*-7-[*exo*-7-(4-methyl-3-pentenyl)bicyclo[4.1.0]hept-2-ene]acetic acid (**14**). Acid **14** was converted into *endo*-7-methyl-*exo*-7-(4-methyl-3-pentenyl)bicylo[4.1.0]heptan-2-one (**4**), a key intermediate of (±)-sesquicarene and (±)sirenin total syntheses. Furthermore, a highly stereospecific total synthesis of (±)-sesquicarene was acomplished by the photochemical transformation of the 1-methyl derivative of **13** prepared from 2-methyltropone (**21**).

Sesquiterpene analogues of 2-carene, such as sesquicarene (**1**)[3] and sirenin (**2**),[2] have attracted a good deal of synthetic attention.[3,4] The prominent step of the synthesis of **1** and/or **2** is the stereospecific elabolation of a 7,7-disubstituted bicyclo[4.1.0]heptane skeleton. Well established methods to prepare the bicyclo[4.1.0]-heptane system are based on intramolecular carbene additions, such as from the carbenes (**3**[3a,c–e,g–k] and **5**, W=CH_3,[3b,f,k] CO_2CH_3,[3l] and CN[3o]) to the cyclo-



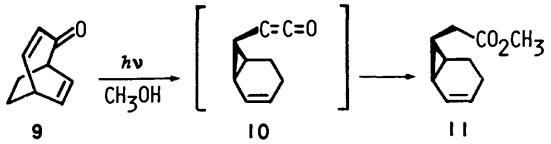
propanes (**4** and **6**), respectively. Another practical one is stereoselective displacement of the *exo*-chlorine of the acetal (**7**) by the cuprate derived from 5-bromo-2-methyl-2-propene followed by stereospecific transmetallation and then methylation to give the ethylene acetal of **4**.[3n]

Our interest in rearrangement approaches to terpene skeletons has prompted us to develop a new route to these [3—6] fused-ring compounds. In this paper, we wish to report the approaches to racemic sesquicarene (**1**) and sirenin (**2**) based on the photochemical transformation of the bridged compounds into the 2-carene derivatives (*vide infra*).

† A portion of this work has been published as a preliminary communication: T. Uyehara, K. Ogata, J. Yamada, and T. Kato, *J. Chem. Soc., Chem. Commun.*, **1983**, 17.

Results and Discussion

Bicyclo[3.2.2]nona-3,6-dien-2-one (**9**), derived from tropone (**8**) and ethylene as the 1,4-addition product,[5] is a photo-labile compound which was transformed into the methyl ester (**11**) by irradiation in methanol using a Hg-lamp through a Pyrex filter[6] (Scheme 1). This transformation is general not only for the bicyclo[3.2.2]nonadienones but also other bicyclo[3.2.x]dienones.[7,8] The process presumably involves the initial [3,3] sigmatropic rearrangement of **9** to the ketene intermediate (**10**) followed by addition of methanol.



Scheme 1.

Since the conversion proceeds stereospecifically, we made a plan to prepare **4**, an established synthetic intermediate for both sesquicarene (**1**) and sirenin (**2**), starting from **8** and adopting the photochemical process. The synthetic route to **4** is outlined in Scheme 2.

Barbier reaction promoted by ultrasound irradiation[9] was taken to prepare the 1,2-addition product (**12**) selectively. Oxidation of the tertiary allylic alcohol (**12**) by pyridinium chlorochromate (PCC)[10] gave the α,β-unsaturated ketone (**13**) in a good yield.

Now, this two-step transformation is a general method for preparation of the C_4-substituted derivatives of **9** (**20**) from **9** itself *via* the allylic alcohol (**19**) as shown in Table 1. Run c shows that the oxidative transformation proceeded preferably on the C_3 bridge rather than on the side chain.

TABLE 1. ULTRASOUND-PROMOTED BARBIER REACTION FOLLOWED BY PCC OXIDATION OF BICYCLO[3.2.2]-NONA-3,6-DIEN-2-ONE (**9**), AN EFFICIENT TRANSFORMATION INTO THE C_4-SUBSTITUTED DERIVATIVES (**20a—d**)

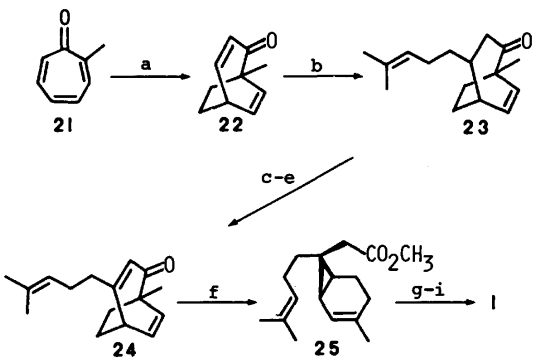
Run	Halide (RX)	Solvent	Sonication (min)	**19** (Yield/%)	**20** (Yield/%)
a	CH_3I	Ether	30	—	78[a]
b	$(CH_3)_2CHBr$	THF	30	90	88
c	$CH_2{=}CCH_3Br$	THF	25	—	59[a]
d	PhBr	THF	40	—[b]	33[a]

a) Overall yield from **9**. b) A crude mixture, obtained quantitatively, gave a satisfactory ^{1}H-NMR spectrum.

The photochemical transformation of **13** to the acid (**14**), the prominent step of the synthesis, was carried out in aqueous THF using a 100 W-high pressure mercury lamp through a Pyrex filter.

When **14** was treated with iodine in the presence of sodium hydrogencarbonate, the unstable iodo lactone (**15**) was obtained as the sole product. Formation of **15** means not only that the expected stereochemistry of the 7-position is proven but also that the new carbon-oxygen bond is formed at the desired position. However, we could not reduce the C-I bond of **15** to the C-H bond without change of the other functional group. When **15** was treated with tributyltin hydride in cyclohexane, the desired lactone was isolated only in 34% yield. Reduction of **15** with lithium aluminium hydride is thus far a useful way to remove the iodine and to obtain the diol (**16**).

In order to remove one carbon from the *syn* side chain, we wanted to adopt decarbonylation by chlorotris(triphenylphosphine)rhodium.[11] Thus, **16** was converted into the acetoxy aldehyde (**17**). We examined several routes to the aldehyde, and found that the secondary hydroxyl group of **16** is oxidized easily and that the primary one is not oxidized selectively before protection of the other.



Scheme 3. Synthesis of (±)-sesquicarene (**1**)[a]. a) (a) Ref. 13. (b) $(CH_3)_2C{=}CHCH_2CH_2MgBr$, CuI, THF, 66%. (c) LDA, THF, then TMS-Cl. (d) NBS, THF. (e) LiBr, Li_2CO_3, DMF, 81% (from **23**). (f) *hv*, MeOH, 66%. (g) $LiAlH_4$, ether. (h) CrO_3–2Py, CH_2Cl_2, 80%, (from **25**). (i) $[Rh(PPh_3)_3]Cl$, CH_3CN, 145 °C, 5 min, 43%.

With just one equivalent of Wilkinson's complex, heating of a benzonitrile solution of **17** at 145 °C for 5 min is the most suitable conditions for the decarbonylation to give the acetate (**18**). The yield of **18** decreased when heating time was extended, because of instability of **18** under the reaction conditions.

Reduction of **18** with lithium aluminium hydride followed by oxidation with Collins reagent gave the desired ketone (**4**). Thus, a new sythetic route from tropone (**8**) to (±)-sesquicarene (**1**) and that of (±)-sirenin (**2**) have been established formally.

Next, an analogous sequence has been used to prepare (±)-sesquicarene (**1**) itself (outlined in Scheme 3).

1-Methylbicyclo[3.2.2]nona-3,6-dien-2-one (**22**) is one of the 1,4-addition products of 2-methyltropone (**21**) and ethylene.[12] Regioselective addition of 4-methyl-3-pentenylmagnesium bromide to **21** was carried out in the presence of copper(I) iodide in tetrahydrofuran. The major product of the reaction

was the enone (**23**). The stereochemistry of the homoprenyl side chain is uncertain.

In order to convert **23** into the dienone (**24**), the enol trimethylsilyl ether of **23** was treated with *N*-bromosuccinimide,[13] and the resulting mixture of α-bromo ketones was dehydrobrominated by heating with lithium bromide and lithium carbonate in *N,N*-dimethylformamide.

Photochemical transformation of **24** into the 2-carene derivative (**25**) was carried out by irradiation of a methanolic solution of **24**.

The ester (**25**) was changed into the aldehyde (**26**) by lithium aluminium hydride reduction followed by Collins oxidation. The hydrocarbon (**1**) derived from **26** by heating vigorously with Wilkinson's complex in acetonitrile was identical spectroscopically with natural sesquicarene.

Thus, the photochemical transformation of bicyclo[3.2.2]nona-3,6-dien-2-ones to the [3—6] fused-ring compounds is applicable to the synthesis of sesquiterpene analogues of 2-carene.

Experimental

General. Melting and boiling points are uncorrected. IR spectra (in CCl_4, unless otherwise mentioned) were recorded on a Hitachi Model 215 spectrometer. NMR spectra (in CCl_4, unless otherwise noted) were obtained on Jeol JNM-PMX60, Varian EM-390 90 MHz, and Varian XL-200 NMR spectrometers, using tetramethylsilane as an internal standared. The mass spectral studies were conducted using a Hitachi M-52 spectrometer.

Photochemical reactions were carried out in an immersion well through a Pyrex filter using a Riko 100 W high pressure mercury lamp, under an inert atmosphere. A Shimmyodai 150 W ultrasonic cleaner was used for the Barbier reactions. Tetrahydrofuran (THF) and ether were distilled from benzophenone ketyl under argon, immediately prior to use. Dichloromethane was distilled from P_2O_5 and stored on 4A molecular sieves. Pyridine (from BaO), triethylamine, *N,N*-dimethylformamide (DMF, from BaO), and acetonitrile (from P_2O_5) were purified by distillation. Diisopropylamine was distilled from CaH_2 under argon immidiately prior to use. 4-Methyl-3-pentenyl bromide,[14] pyridinium chlorochromate (PCC),[15] Collins reagent,[16] and Wilkinson's complex[17] were prepared by using literature procedures.

All reactions were monitored by analytical TLC using E. Merck precoated silica gel $60F_{254}$ plates. E. Merck silica gel 60 (70—230 mesh ASTM, twenty to fifty times (w/w)) was used for column chromatography.

*Ultrasound-Promoted Barbier Reactions of Bicyclo[3.2.2]nona-3,6-dien-2-one (**9**). Preparation of 2-(4-Methyl-3-pentenyl)-bicyclo[3.2.2]nona-3,6-dien-2-ol (**12**).* In a 200 ml round bottomed flask with a septum inlet, equipped with a three way stopcock, were placed 1.341 g (9.99 mmol) of **9** and 2.477 g (15.0 mmol) of homoprenyl bromide, and then the system was flushed with argon. After addition of 50 ml of dry THF and 0.41 g (59 mmol) of lithium, the flask was partly submerged in the ice-water filled bath of an ultrasonic cleaner and sonicated for 45 min. The excess lithium and organolithium compounds were destroyed by stirring with methanol and then with water. The bulk of THF was removed and then the remaining pot residue was extracted with three portions of ether. The combined extracts were washed with water and with saturated aqueous NaCl, and then dried over $MgSO_4$. Romoval of the solvent afforded 2.22 g of a pale yellow oil, and which was purified by column chromatography (15:1 hexane, ethyl acetate) to give 1.951 g (89%) of **12** as a colorless oil. **12**: IR 3620 (w), 3475 (m), 1640 (w) and 710 cm^{-1}; NMR δ=6.33 (1H, dd, J=8.3 and 7.5 Hz), 5.95 (1H, dd, J=8.3 and 7.5 Hz), 5.70 (1H, dd, J=10.5 and 7.8 Hz), 5.08 (1H, dd, J=10.5 and 2.4 Hz), 5.00 (1H, tm, J=6.9 Hz), 1.65 (3H, bs), and 1.61 (3H, bs).

*2-Methylbicyclo[3.2.2]nona-3,6-dien-2-ol (**19a**).* To a mixture 2.449 g (18.25 mmol) of **9**, 405 mg (58 mmol) of lithium and 73 ml of dry ether, prepared under argon, was added 3.88 g (27.3 mmol) of methyl iodide at 0 °C. After 30 min of sonication, the reaction mixture was allowed to stand at 0 °C for 15 min. The excess lithium and methyllithium were decomposed by methanol, and the ethereal solution was washed with water and then with saturated brine. After dried over $MgSO_4$, evaporation of the solvent left **19a** as a colorless oil, which was supplied without further purification to PCC oxidation. Distillation of a small portion (45—48 °C/0.2 Torr (1 Torr=133.322 Pa)) furnished an analytical sample. The major of **19a**: NMR δ=6.33 (1H, bt, J=7.5 Hz), 5.95 (1H, bt, J=7.5 Hz), 5.68 (1H, dd, J=10.8 and 8.0 Hz), 5.02 (1H, dd, J=10.8 and 2.4 Hz), and 1.18 (3H, s).

*2-Isopropylbicyclo[3.2.2]nona-3,6-dien-2-one (**19b**). (As General Procedure.)* A mixture of 490 mg (3.65 mmol) of **9**, 90 mg (3.9 eq) of lithium, 680 mg (0.52 ml, 1.5 eq) of isopropyl bromide, and 18 ml (5 ml/1 mmol of **9**) of THF was sonicated for 30 min at 0 °C. After stirring with methanol and then water, the solution was extracted with three portions of ether. The combined extracts were washed with water and saturated brine, and dried over $MgSO_4$. The solvent was removed *in vacuo* and the remaining oil (636 mg) was chromatographed on silica gel (10:1 hexane, ethyl acetate) to yield 583 mg (90%) of **19b**. The major of **19b**: NMR δ=6.32 (1H, bt, J=7.5 Hz), 5.89 (1H, bt, J=7.5 Hz), 5.70 (1H, dd, J=10.8 and 8.0 Hz), 5.17 (1H, dd, J=10.8 and 2.4 Hz), 0.92 (3H, d, J=6.9 Hz), and 0.9 (3H, d, J=6.9 Hz).

*PCC Oxidation of Bicyclo[3.2.2]nona-3,6-dien-2-ols (**12** and **19**). 4-(4-Methyl-3-pentenyl)bicyclo[3.2.2]nona-3,6-dien-2-one (**13**). (As General Procedure.)* To a solution of 3.214 g (14.91 mmol) of PCC in 22 ml of CH_2Cl_2 was added a solution of 1.627 g (7.45 mmol) of **12** in 75 ml of CH_2Cl_2 at room temperature, and the mixture was stirred for 2.5 h. After addition of 30 ml of ether, the solution was decanted from the black solids. The residue was washed in turn with several portions of ether. The combined etherial extracts were washed succesively with 5% aqueous NaOH, 1 M HCl (1 M=1 mol dm^{-3}), saturated aqueous $NaHCO_3$, and saturated aqueous NaCl, and dried over $MgSO_4$. The solvent was removed under reduced pressure, and the residue was chromatographed (15:1 hexane, ethyl acetate) to give 1.407 g (87%) of **13** as a pale yellow oil. **13**: IR 1665 (s) and 1635 (m) cm^{-1}; NMR δ=6.38 (1H, ddd, J=8.1, 7.4, and 1.4 Hz), 6.05 (1H, ddd, J=8.1, 7.4, and 1.4 Hz), 5.40 (1H,

bs), 5.05 (1H, bm), 3.37 (1H, dm, J=7.4 Hz), 3.08 (1H, dm, J=7.4 Hz), 1.68 (3H, s), and 1.62 (3H, s); MS, m/z (rel intensity), 216 (M^+, 14), 188 (80), 142 (52), and 69 (100). The 2,4-DNP derivative of **13**: C, 63.73; H, 6.10; N, 14.05%. Calcd for $C_{21}H_{24}N_4O_4$: C, 63.62; H, 6.10; N, 14.13%.

*4-Methylbicyclo[3.2.2]nona-3,6-dien-2-one (**20a**)*: Bp 82—84 °C/0.9 Torr; IR 1665 (s) and 1635 (m) cm^{-1}; NMR δ=6.37 (1H, ddd, J=8.4, 7.2, and 1.5 Hz), 6.02 (1H, ddd, J=9.0, 7.2, and 1.5 Hz), 5.42 (1H, m), 3.33 (1H, b, $W_{1/2}$=14.3 Hz), 3.07 (1H, b, $W_{1/2}$=14.3 Hz), and 2.01 (3H, d, J=1.5 Hz); MS, m/z (rel intensity) 148 (M^+, 100) and 133 (86). Found: C, 80.78; H, 8.34%. Calcd for $C_{10}H_{12}O$: C, 81.04; H, 8.16%.

*4-Isopropylbicyclo[3.2.2]nona-3,6-dien-2-one (**20b**)*: Bp 57—59 °C/0.3 Torr; IR 1660 (s), and 1630 (m) cm^{-1}; NMR δ=6.32 (1H, ddd, J=8.7, 7.1, and 1.4 Hz), 6.04 (1H, ddd, J=8.7, 7.1, and 1.4 Hz), 5.36 (1H, m), 3.33 (1H, dm, J=7.1 Hz), 3.16 (1H, dm, J=7.1 Hz), 2.42 (1H, septet, J=6.7 Hz), and 1.12 (6H, d, J=6.7 Hz); MS m/z (rel intensity) 176 (M^+, 51) and 133 (100). Found: C, 82.05; H, 9.32%. Calcd for $C_{12}H_{16}O$: C, 81.77; H, 9.15%. The 2,4-DNP derivative of **20b**: mp 146.7—148.9 °C. Found: C, 60.73; H, 5.77; N, 15.77%. Calcd for $C_{18}H_{20}N_4O_4$: C, 60.67; H, 5.66; N, 15.72%.

*4-(2-Methyl-2-propenyl)bicyclo[3.2.2]nona-3,6-dien-2-one (**20c**)*: Bp 58—60 °C/0.1 Torr; IR 1660 (s) and 1635 (m) cm^{-1}; NMR δ=6.38 (1H, ddd, J=8.9, 7.1, and 1.2 Hz), 6.10 (1H, ddd, J=8.9, 7.4, and 1.2 Hz), 5.63 (1H, m), 5.37 (1H, bs), 5.16 (1H, bs), 3.63 (1H, dm, J=7.4 Hz), 3.38 (1H, dm, J=7.4 Hz), and 2.1—1.7 (7H, m); MS, m/z (rel intensity) 174 (M^+, 100) and 130 (46). The 2,4-DNP derivative of **20c**: mp 159.2—160.8 °C. Found: C, 61.21; H, 5.33; N, 15.81%. Calcd for $C_{18}H_{18}N_4O_4$: C, 61.01; H, 5.12; N, 15.81%.

*4-Phenylbicyclo[3.2.2]nona-3,6-dien-2-one (**20d**)*: Mp 73.8—74.6 °C; IR 1660 (s) and 1630 (m) cm^{-1}; NMR δ=7.5—7.1 (5H, m), 6.50 (1H, ddd, J=8.9, 7.1, and 1.2 Hz), 5.81 (1H, dd, J=2.3 and 1.5 Hz), 3.73 (1H, dm, J=7.1 Hz), 3.46 (1H, dm, J=7.1 Hz), and 2.4—1.7 (4H, m); MS, m/z (rel intenaity), 210 (M^+, 100), 192 (51), 167 (61), and 105 (62). Found: C, 85.67; H, 6.71%. Calcd for $C_{15}H_{14}O$: C, 85.68; H, 6.71%.

*Photochemical Transformation of **13** into* endo-*7-[exo-7-(4-Methyl-3-pentenyl)bicyclo[4.1.0]hept-2-ene]acetic Acid (**14**).* To a solution of 1.002 g (4.63 mmol) of **13** in 350 ml of THF was added 35 ml of water, and the mixture was irradiated for 4 h. After removal of the bulk of the solvents, to the residue was added 10% aqueous NaOH. The basic solution was extracted once with ether, and acidified with 6 M HCl. After addition of saturated aqueous NaCl, the aqueous phase was extracted with two portions of ether. The extracts were combined, and dried over $MgSO_4$. Removal of the solvent gave 998 mg of a yellow oil, which was purified by column chromatography (3:1 hexane, ethyl acetate) to yield 955 mg (88%) of **14**: IR 1705 (s) cm^{-1}; NMR δ=9.0 (1H, b), 5.87 (1H, dm, J=10.5 Hz), 5.66 (1H, dm, J=10.5 Hz), 5.07 (1H, tm, J=6.9 Hz), 2.42 (1H, d, J=16.5 Hz), 2.43 (1H, d, J=16.5 Hz), 1.67 (3H, bs), and 1.62 (3H, bs). The methyl ester of **14**: bp 70 °C/0.15 Torr. Found: C, 77.10; H, 9.62%. Calcd for $C_{16}H_{24}O_2$: C, 77.38; H, 9.74%.

*Iodolactonization of **14**. Preparation of 7-Iodo-2-(4-methyl-3-pentenyl)-5-oxabicyclo[4.4.0.0^{2,10}]decan-4-one (**15**).* To a solution of 681.6 mg (2.91 mmol) of **14** in 19 ml of saturated aqueous $NaHCO_3$ was added a solution of 740 mg (2.92 mmol) of iodine in 25 ml of ether over a period of 20 min at room temperature in the dark. After 1 h of stirring, the mixture was diluted with water and ether, and extracted with several portions of ether. The ethereal extracts were combined, washed with 5% aqueous $Na_2S_2O_3$ and with saturated brine, and then dried over $MgSO_4$. Evaporation of the solvent without heating from outside gave 1.156 g of a pale yellow oil, which was supplied directly to the $LiAlH_4$ reduction. Flush column chromatography of a small portion furnished an analytical sample of **15**: NMR δ=5.22 (H_8, dd, J=8.7 and 3.5 Hz), 5.00 (1H, tm, J=6.9 Hz), 4.35 (H_7, q, J=3.5 Hz), 2.60 (H_3, d, J=19.1 Hz), 2.28 (H_3, d, J=19.1 Hz), 1.67 (3H, bs) and 1.61 (3H, bs).

*Reduction of Iodo lactone **15**. Preparation of* endo-*7-(2-Hydroxyethyl)*-exo-*7-(4-methyl-3-pentenyl)bicyclo[4.1.0]heptan-2-ol (**16**).* To a mixture of 280 mg (7.38 mmol) of $LiAlH_4$ and 5 ml of dry THF was added a solution of 1.156 g of **15**, obtained from 681.6 mg (2.91 mmol) of **14**, in 30 ml of dry THF at 0 °C. The reaction mixture was heated under reflux for 2 h. After cooling to 0 °C, the resulting suspension was treated by successive dropwise addition of a few ml of ethyl acetate, 0.3 ml of water, 0.3 ml of 15% aqueous NaOH, and 0.9 ml of water, and then allowed to warm to room temperature with stirring. The THF solution was filtered, and concentration of the filtrate *in vacuo* afforded 622.6 mg of a colorless oil. Purification of the product by column chromatography (1:1 hexane, ethyl acetate) gave 587.9 mg (85% from **14**) of **16**: IR 3250 (m), 1070 (m), and 1040 (m) cm^{-1}; NMR δ=5.49 (2H, bs), 5.01 (1H, tm, J=6.9 Hz), 4.06 (1H, b, $W_{1/2}$=21 Hz), 3.75 (2H, m), 1.65 (3H, s), and 1.58 (3H, s); MS, m/z (rel intensity) 230 (M^+, 2), 139 (100), and 138 (85). The diacetate of **16**: C, 70.75; H, 9.46%. Calcd for $C_{19}H_{30}O_4$: C, 70.77; H, 9.38%.

*Transformation of Diol **16** into* endo-*7-(2-Oxoethyl)*-exo-*7-(4-methyl-3-pentenyl)bicyclo[4.1.0]heptan*-trans-*2-yl Acetate (**17**).* In order to protect the primary hydroxyl group selectively, to a solution of 304.7 mg (1.28 mmol) of **16**, 145.1 mg (0.2 ml, 1.1 eq) of triethylamine, and a small amount of 4-dimethylaminopyridine in 10 ml of dry CH_2Cl_2 was added a solution of 242.5 mg (1.2 eqive) of *t*-butyldimethylsilyl chloride in 10 ml of dry CH_2Cl_2 under argon. After standing for 24 h at room temperature, the sulution was washed with saturated aqueous NH_4Cl, and dried over $MgSO_4$. Removal of the solvent gave 456.7 mg of the oily products, which were purified by chromatography (15:1 hexane, ethyl acetate) to give 341.4 mg (76%) of the monosilyl ether of **16**: NMR δ=4.98 (1H, tm, J=6.9 Hz), 4.22 (1H, m), 3.70 (2H, m), 3.19 (1H, m), 1.63 (3H, bs), 1.57 (3H, bs), 0.93 (9H, s), and 0.10 (6H, s).

To protect the secondary hydroxyl group, 1 ml of acetic anhydride was added to 314.4 mg (0.97 mmol) of the monosilyl ether in 3 ml of dry pyridine. After standing overnight at room temperature, evaporation of the solvent *in vacuo* gave 375.3 mg of the residue, which was chromatographed (15:1 hexane, ethyl acetate) to afford 333.1 mg (88%) of the acetate: IR 1735 (s) and 1020 (m) cm^{-1}. Found: C, 69.96; H, 10.77%. Calcd for $C_{23}H_{42}O_3Si$: C, 70.00; H, 10.73%.

In order to remove the silyl group, 332.2 mg (0.84 mmol) of the acetate was treated with a mixture of 1.7 ml of THF, 1.7 ml of water, and 5.1 ml of acetic acid[18] for 19 h at room temperature. The mixture was diluted with ether, and washed successively with water (four times), saturated aqueous $NaHCO_3$, and saturated brine, and then dried over $MgSO_4$. The solvent was removed *in vacuo*, and the remaining was purified by chromatography (2:1 hexane, ethyl acetate). Thus obtained was 198.5 mg (85%) of the hydroxy

hydride (50 mg, 1.32 mmol) in ether (20 ml) at 0 °C. The acetate: IR 1735 (s) and 1015 (s) cm^{-1}, NMR δ=5.25 (1H, qm, J=7.5 Hz), 5.01 (1H, tm, J=6.9 Hz), 3.67 (2H, m), 2.01 (3H, s), 1.66 (3H, bs), and 1.61 (3H, bs).

To a solution of 1.54 g 5.96 mmol) of Collins reagent in 24 ml of dry CH_2Cl_2 was added a solution of 278.5 mg (0.99 mmol) of the hydroxy acetate in 7 ml of CH_2Cl_2. After 7 min stirring at room temperature, the solution was decanted, and the black residue was washed with several portions of ether. The organic layers were combined, and washed successively with 5% aqueous NaOH, 5% HCl, saturated aqueous $NaHCO_3$, and saturated brine, and then dried over $MgSO_4$. Evaporation of the solvent gave 265.6 mg of an oil, which was purified by column chromatography (10:1 hexane, ethyl acetate) to give 229.7 mg (83%) of the unstable aldehyde, **17**: IR 2720 (w), 1740 (s), 1730 (s), and 1245 (s) cm^{-1}; NMR δ=9.72 (1H, t, J=2.3 Hz), 5.25 (H_2, m, $W_{1/2}$=18.8 Hz), 4.97 (1H, tm, J=6.9 Hz), 2.47 (2H, d, J=2.3 Hz), 1.95 (3H, s), 1.64 (3H, bs), and 1.57 (3H, s); MS, m/z (rel intensity) 278 (M^+, 1), 137 (79), 136 (100), 121 (52), and 82 (74).

Decarbonylation of **17**. *Preparation of* endo-*7-Methyl*-exo-*7-(4-methyl-3-pentenyl)bicyclo[4.1.0]heptan-2-yl Acetate* (**18**). A flask containing of a mixture of 153.8 mg (0.55 mmol) of **17**, 509.7 mg (0.55 mmol) of Wilkinson's complex and 2 ml of benzonitrile, prepared under argon, was immersed in a preheated oil bath at 145 °C for 5 min with stirring. The bulk of benzonitrile was removed by Kugelrohr distillation (100 °C/3 Torr) and the residure was stirred with ethanol, and then filtered. Concentration of the filtrate gave 362.4 mg of an oil, chromatography (15:1 hexane, ethyl acetate) of which gave 110.5 mg (80%) of **18**: bp 70 °C/1.5 Torr; IR 1740 (s) and 1245 (s) cm^{-1}; NMR δ=5.21 (H_2, m), 5.02 (1H, tm, J=6.9 Hz), 1.99 (3H, s), 1.68 (3H, s), 1.61 (3H, s), and 1.14 (3H, s); MS, m/z (rel intensity) 250 (M^+, 2), 190 (52), 147 (78), 121 (100), and 82 (75). Found: C, 76.55; H, 10.49%. Calcd for $H_{16}H_{26}O_2$: C, 76.75; H, 10.47%.

Preparation of endo-*7-Methyl*-exo-*7-(4-methyl-3-pentenyl)bicyclo[4.1.0]heptan-2-one* (**4**). To a suspension of 20 mg (0.527 mmol) of $LiAlH_4$ in 2 ml of dry ether was added a solution of 79.3 mg (0.317 mmol) of **18** in 10 ml of ether at 0 °C. After 20 min stirring, to the reaction mixture were added successively one drop of water, one drop of 15% aqueous NaOH, and three drops of water. After stirring untill a granular precipitate was formed, $MgSO_4$ was added to the mixture and filtered. Concentration of the filtrate gave 66.4 mg of the alcohol. An analytical sample was purified by chromatography (10:1 hexane, ethyl acetate). Treatment of the crude alcohol (66.4 mg) with 500 mg of Collins reagent in 10 ml of dry CH_2Cl_2 at room temperature for 5 min, followed by work-up as described above gave 61.3 mg of the crude product. Chromatography on silica gel (15:1 hexane, ethyl acetate) gave 55.1 mg (84%) of pure **4**: IR 1685 (s) cm^{-1}; NMR δ=5.00 (1H, tm, 6.9 Hz), 1.66 (3H, bs), 1.60 (3H, bs), and 1.10 (3H, s). Found: C, 81.31; H, 10.84%. Calcd for $C_{14}H_{22}O$: C, 81.50; H, 10.75%.

1,4-Addition of 4-Methyl-3-pentenylmagnesium Bromide to 1-Methylbicyclo[3.2.2]nona-3,6-dien-2-one (**22**). 4-Methyl-3-pentenylmagnesium bromide was prepared from 1.07 g (6.55 mmol) of homoprenyl bromide and 140 mg (6 mmol) of magnesium in 17 ml of dry THF. The solution of the Grignard reagent was added to a mixture of 507.8 mg (3.28 mmol) of **22** and 140 mg (0.66 mmol) of copper(I) iodide in 2 ml of dry THF at −24 °C *via* a double ended needle. The mixture was allowed to warm to room temperature with stirring, and cooled to 0 °C, and then treated with 6 ml of 10% H_2SO_4. After filtration through a Celite layer, the filtrate was extracted with several portions of ether. The combined extracts were washed successively with water, saturated aqueous $NaHCO_3$, and saturated brine, and the dried over $MgSO_4$. The solvent was removed *in vacuo*, and the residue (861 mg) was purified by chromatography (15:1 hexane, ethyl acetate) to give 505.3 mg (66%) of 1-methyl-4-(4-methyl-3-pentenyl)-bicyclo[3.2.2]non-6-en-2-one (**23**) as a colorless oil. **23**: IR 1700 (s) cm^{-1}; NMR δ=6.11 (1H, dd, J=9.3 and 7.2 Hz), 5.80 (1H, d, J=9.3 Hz), 5.00 (1H, tm, J=6.9 Hz), 1.67 (3H, bs), 1.60 (3H, bs), and 1.11 (3H, s); MS, m/z (rel intensity) 232 (M^+, 100) and 161 (55). The 2,4-DNP derivative of **23**: mp 108—109 °C (dec). Found: C, 63.89; H, 6.91; N, 13.71%. Calcd for $C_{22}H_{28}N_4O_4$: C, 64.06; H, 6.84; N, 13.51%.

Preparation of 1-Methyl-4-(4-methyl-3-pentenyl)-bicyclo[3.2.2]nona-3,6-dien-2-one (**24**). To a solution of 252.7 mg (0.35 ml, 2.5 mmol) of diisopropylamine in 8 ml of dry THF, prepared under argon, was added 1.7 ml (2.55 mmol) of 1.5 M hexane solution of *n*-BuLi at −72 °C. After 20 min of stirring, to the LDA solution was added a solution of 505.3 mg (2.18 mmol) of **23** *via* a double ended needle. The solution was kept at −72 °C for 15 min, and then at 0 °C for 30 min. To the solution was added 513.6 mg (0.6 ml, 4.73 mmol) of chlorotrimethylsilane *via* a syringe at 0 °C. After stirring at room temperature for 30 min, the solvent and the volatile components of the mixture was removed by a rotary evaporator, and the residue was diluted with 8 ml of dry THF. *N*-Bromosuccinimide (390 mg, 2.2 mmol) was added to a solution at 0 °C, and the mixture was stirred for 1 h, and then diluted with ether. The ethereal solution was washed with a 1:1 mixture of saturated aqueous $NaHCO_3$ and saturated brine, and with saturated brine.

After dried over $MgSO_4$, evaporation of the solvent gave 868.7 mg of a yellow oil, which was dissolved in 6 ml of dry DMF. To the solution were added 570 mg (6.6 mmol) of LiBr and 810 mg (11.0 mmol) of Li_2CO_3, and the mixture was heated at 100 °C for 4 h under an argon atmosphere. Dilution with water followed by extraction with three portions of ether and the usual work-up gave 668.9 mg of a brown oil. Purification by chromatography (15:1 hexane, ethyl acetate) gave 405.7 mg (81%) of **24**: IR 1660 (s) and 1630 (s) cm^{-1}; NMR δ=6.34 (1H, dd, J=9.3 and 7.5 Hz), 5.62 (1H, d, J=9.3 Hz), 5.42 (1H, bs), 5.03 (1H, bm), 3.07 (1H, bm), 1.69 (3H, bs), and 1.20 (3H, s); MS, m/z (rel intensity) 230 (M^+, 45), 202 (48), 147 (90), and 69 (100). The 2,4-DNP derivative of **24**: mp 117—118 °C. Found: C, 64.29; H, 6.48; N, 13.88%. Calcd for $C_{22}H_{26}N_6O_4$: C, 64.38; H, 6.38; N, 13.65%.

Photochemical Transformation of **24** *into the 2-Carene Derivative* **25**. After 3 h irradiation of a solution of 460.2 mg (2.0 mmol) of **24** in 300 ml of methanol, evaporation of the solvent gave 586.2 mg of an orange oil. Column chromatography of the crude oil (20:1 hexane, ethyl acetate) gave 346.7 mg (66%) of pure **25**: IR 1735 (s) cm^{-1}; NMR δ=5.49 (1H, bs), 5.01 (1H, J=6.9 Hz), 3.59 (3H, s), 2.26 (1H, d, J=15.9 Hz), 2.07 (1H, d, J=15.9 Hz), 1.65 (6H, bs), and 1.59 (3H, bs); MS, m/z (rel intensity) 262 (M^+, 53), 177 (100), 145 (73), and 119 (100). Found: C, 77.52; H, 10.23%. Calcd for $C_{17}H_{26}O_2$: C, 77.82; 9.99%.

Conversion of **25** *into (±)-Sesquicarene* (**1**). Ester **25**

(193.3 mg, 0.74 mmol) was reduced by lithium aluminium usual work-up as described previously gave the corresponging alcohol (172.8 mg). Oxidation of the alcohol by Collins reagent (1.15 g, 4.45 mmol) in CH_2Cl_2 (23 ml) at room temperature for 10 min, followed by the usual work-up and purification by chromatography (10: 1 hexane, ethyl acetate), gave the aldehyde (**26**) (136.7 mg, 80%). **26**: IR 2710(m) and 1725 (s) cm^{-1}; NMR δ=9.58 (1H, t, J=2.3 Hz), 5.53 (1H, bs), 5.00 (1H, tm, J=6.9 Hz), 2.21 (1H, dd, J=16.5 and 2.3 Hz), 2.17 (1H, dd, J=16.5 and 2.3 Hz), 1.65 (6H, bs), and 1.59 (3H, bs); MS, m/z (rel intensity) 232 (M^+, 66), 147 (100), 119 (52), and 93 (45). The 2,4-DNP derivative of **26**: mp 140—142 °C. Found: C, 64.13; H, 6.95; N, 13.31%. Calcd for $C_{22}H_{28}N_4O_4$: C, 64.06; H, 6.84; N, 13.58%.

A flask containing a mixture of 74.5 mg (0.32 mmol) of the aldehyde, 296.3 mg (0.32 mmol) of Wilkinson's complex, and 2 ml of acetonitrile was immersed in a preheated (145 °C) oil bath for 5 min. After removal of the solvent by a rotary evaporator, to the residue was added pentane and the mixture was filtered. Concentration of the filtrate followed by chromatography (pentane) gave 28.2 mg (43%) of pure *(±)-sesquicarene* (**1**): IR (neat) 2980 (s), 2925 (s), 2860 (s), 2730 (w), 1670 (w), 1650 (w), 1450 (m), and 1380 (m) cm^{-1}; NMR ($CDCl_3$) δ=5.56 (1H, b, $W_{1/2}$=9.0 Hz), 5.12 (1H, triplets of septet, J=7.0 and 1.4 Hz), 2.14—1.48 (6H, m), 1.68 (6H, bs), 1.62 (3H, bs), 1.39—1.05 (2H, m), 1.01—0.76 (2H, m), and 0.83 (3H, s); MS, m/z (rel intensity) 204 (M^+, 100), 161 (45), 135 (42), 134 (55), 133 (40), 122 (28) and 105 (38). Found: m/z 204.1855. Calcd for $C_{15}H_{24}$: 204.3546.

We are grateful to Dr. Yoko Naya, Suntory Institute for Bioorganic Research, for kindly providing the spectra of sesquicarene. This work was partially supported by Foundation for the Promotion of Research on Medicinal Resources.

Reaction of Olefins with Malonamide in the Presence of Manganese(III) Acetate. Formation of α,β-Unsaturated γ-Lactones and γ-Lactams

Hiroshi NISHINO

Department of Chemistry, Faculty of Science, Kumamoto University, Kurokami, Kumamoto 860

(Received June 22, 1984)

The reaction of olefins with malonamide in the presence of manganese(III) acetate gave 2-buten-4-olides and/or 1*H*-pyrrol-2(5*H*)-ones in one-step, short reaction time, and moderate yields. The product distribution can be accounted for in terms of the stabilization of the intermediate carbocation in the oxidation process. The synthetic application and limitation, and the oxidation mechanism for the formations of α,β-unsaturated γ-lactones and γ-lactams are discussed.

It is known that ketones have been oxidized with manganese(III) acetate, $Mn(OAc)_3$, in acetic acid to form α-keto radicals, $\cdot CH_2COR$.[1,2] If the reaction is carried out in the presence of olefins, the α-keto radicals add to the olefins to give radical adducts which are converted to saturated or unsaturated ketones, or γ-keto esters either by gaining or losing hydrogen, or by further oxidation and taking up an acetate ion.[3] On the other hand, oxidation of readily enolizable ketones, such as β-diketones, with $Mn(OAc)_3$ gives the corresponding α,α'-diketo radicals, RCO-CH-COR.[4] Heiba and Dessau reported that acetylacetone was oxidized with $Mn(OAc)_3$ in the presence of olefins to form dihydrofurans in high yields.[5] In contrast, it was reported that the reaction of olefins and malonic acid in a 2:1 molar ratio (equivalent) in the presence of $Mn(OAc)_3$ yielded spirodi-γ-lactones in high yields.[6]

Recently, the author attempted the intramolecular oxidative cyclization of aromatic secondary amines with $Mn(OAc)_3$.[7] However, *N*-cyclized products were not obtained. These results led me to investigate the reaction of olefins with malonamide in the presence of $Mn(OAc)_3$. As the result, it was found that 2-buten-4-olides and/or 1*H*-pyrrol-2(5*H*)-ones were produced, but the desired spirodi-γ-lactams were not formed. In this paper, I will discuss the synthetic application and limitation, and the oxidation mechanism for the formations of α,β-unsatutrated γ-lactones and γ-lactams.

Results and Discussion

When malonamide was oxidized with $Mn(OAc)_3$ in the presence of 1,1-diphenylethene (**1a**), the reaction was finished within 1 min to give **2a**, **4a**, and benzophenone (**5a**). The major product **2a** showed a characteristic vinylic proton (δ=8.71) of 2-buten-4-olides in the lower field[8] and two broad singlets assigned to an amino group of which one was hydrogen-bonded according to the ^{1}H-NMR spectrum. Its IR spectrum revealed two carbonyl absorption bands and one olefinic absorption band. Therefore, the structure of **2a** was considered to be 2-carbamoyl-4,4-diphenyl-2-buten-4-olide, which was compatible with its mass spectrum. The minor product **4a** was determined to be 3,3,8,8-tetraphenyl-2,7-dioxaspiro[4.4]nonane-1,

6-dione of which ^{1}H-NMR, IR spectra, and the melting point were identical with those of an authentic sample.[6] The same reaction of 2-phenylpropene (**1b**), 1,1,2-triphenylethene (**1c**), fluorenylideneacetic acid (**1d**), and methylenecyclohexane (**1e**) gave the corresponding 2-buten-4-olides in moderate yields (Table 1).

On the other hand, when 1,1-bis(4-methoxyphenyl)-ethene (**1f**) was oxidized under the same reaction conditions, α,β-unsaturated γ-lactams (**3f** and **3f'**) were produced rather than the corresponding 2-buten-4-olide (**2f**). The structure of **3f** was determined to be 3-carbamoyl-5,5-bis(4-methoxyphenyl)-1*H*-pyrrol-2(5*H*)-one on the basis of the ^{1}H-NMR, ^{13}C-NMR, IR, and mass spectra. The ^{1}H-NMR spectrum of **3f'** was similar to that of **3f** except for the disappearance of a doublet assignable to a H-4 proton and the appearance of a broad singlet (δ=5.38) due to a hydroxyl group. Accordingly, the compound **3f'** was confirmed to be 3-carbamoyl-4-hydroxy-5,5-bis(4-methoxyphenyl)-1*H*-pyrrol-2(5*H*)-one. 3-Carbamoyl-3-[2,2-bis(4-methoxyphenyl)ethenyl]-5,5-bis(4-methoxyphenyl)-2-pyrrolidone (**10**) was also obtained.

The formation of the α,β-unsaturated γ-lactams deserves comment. It seems that the intermediate carbocation (**II**) tends to cyclize with a nitrogen atom of the carbamoyl group when it is stabilized by the resonance effect of the methoxyl group (Scheme 1). Then, the reaction of 1,1-bis(4-methoxyphenyl)-2-phenylethene (**1g**), 1,1,2-tris(4-methoxyphenyl)ethene (**1h**), 9-benzylidene-9*H*-xanthene (**1i**), and 9-benzylidene-9,10-dihydroanthracene (**1j**) with malonamide in the presence of $Mn(OAc)_3$ was tried. The reaction of **1g** or **1h** under the same reaction conditions certainly gave the corresponding α,β-unsaturated γ-lactam (**3g** or **3h**). However, the olefins (**1g** and **1h**) were also oxidized directly by $Mn(OAc)_3$ without the participation of malonamide to yield products (**5g**, **6g** and **6h**, **7g** and **7h**, **8g** and **8h**, and **9g** and **9h**). The same oxidation of **1i** and **1j** afforded the corresponding 1*H*-pyrrol-2-(5*H*)-ones (**3i** and **3j**) in good yields, as expected.

TABLE 1. REACTION OF OLEFINS WITH MALONAMIDE IN THE PRESENCE OF MANGANESE(III) ACETATE

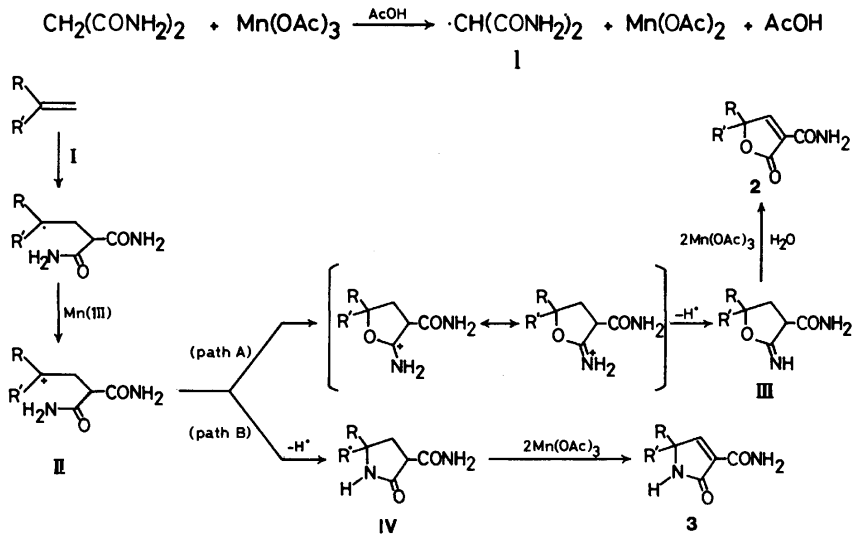
a) Substrate : malonamide : manganese(III) acetate. b) The yields were based on the amount of the substrate used.



Scheme 1.

It is suggested that this reaction consists of two competing mechanisms. One is the direct oxidation of the substrate with $Mn(OAc)_3$ without the participation of malonamide (product **5**, **6**, **7**, **8**, and **9**). This mechanism has been explained as the electron-transfer mechanism represented by the aromatic acetoxylation[9] or the oxidation of α-glycols[10] with $Mn(OAc)_3$ alone. The other is a radical mechanism involving the malonamide radical (**I**) (product **2**, **3**, **4**, **10**, and **13**). The mechanism for the formation of the α,β-unsaturated γ-lactones and γ-lactams as depicted in Scheme 1 is deduced from the reaction of olefins with acetylacetone in the presence of $Mn(OAc)_3$.[5] At first, malonamide is readily oxidized with $Mn(OAc)_3$ to give the corresponding radical (**I**) which attacks olefins to form a benzyl radical. Then, the benzyl radical is subsequently oxidized to generate the intermediate carbocation (**II**). If cyclization occurs at the carbonyl oxygen of the carbamoyl group of the carbocation **II**, the imine **III** is formed (path A). The intermediate **III** is further oxidized and hydrolyzed upon work-up to give the α,β-unsaturated γ-lactone (**2**). When the carbocation **II** cyclizes on a nitrogen atom of the carbamoyl group, the pyrrolidone **IV** is elaborated and further oxidized to yield the 1*H*-pyrrol-2(5*H*)-one **3** (path B). It seems that it depends on the lifetime of **II** whether the carbocation **II** cyclizes on oxygen or nitrogen atom of the carbamoyl group. That is to say, when the carbocation **II** is stabilized by the delocalization of a positive charge, the carbocation **II** cyclizes on a nitrogen atom of the carbamoyl group. In fact, **1f—h** having two or three methoxyl groups or **1i**, **j** having a large molecular structure which can delocalize the positive charge produced the corresponding 1*H*-pyrrol-2(5*H*)-ones. 4-Butanolides derived from an attack on the olefins of the carboxymethyl radical (which was generated directly by the thermolysis of $Mn(OAc)_3$[11]) were not detected. This indicates that the malonamide radical (**I**) rather than the carboxymethyl radical was preferentially produced by the reaction. The malonamide radical (**I**) might be generated by the direct interaction of malonamide and $Mn(OAc)_3$, which is similar to the aromatic acetonylation mechanism reported by Kurz *et al.*[12] In view of the product yield, it seems that the radical mechanism prefers the electron-transfer mechanism under these reaction conditions (except for **1g** and **1h**).

This reaction of styrene (**1k**) gave not only α,β-unsaturated γ-lactone and γ-lactam, but also spirodi-γ-lactones (**4k**) and γ-lactone (**13**). Cyclohexene, cyclooctene, octene, and acenaphthylene under the same reaction conditions resulted in an intractable mixture. Therefore, it is thought that the formation of α,β-unsaturated γ-lactones and γ-lactams using this reaction is effective for the polar olefins, such as the 1,1-disubstituted olefins. Although it is well known that olefins are oxidized with $Mn(OAc)_3$ in acetic acid to afford γ-lactones in good yields,[11] this reaction is the first example that α,β-unsaturated γ-lactones and/or γ-lactams are produced in one-step, with a short reaction time, and in moderate yields.

Experimental

Measurements. All melting points are uncorrected. The ^{1}H-NMR spectra were recorded on a Hitachi Perkin-Elmer R-24 (60 MHz) or a JEOL JNM-GX-270 spectrometer (270 MHz) at room temperature. The ^{13}C-NMR spectra were obtained with a JEOL JNM-GX-270 spectrometer (68 MHz). All chemical shifts are recorded in the δ scale relative to TMS as an internal standard. The IR spectra were taken on a JASCO A-102 infrared spectrophotometer and all IR spectral data are expressed in cm^{-1}. The mass spectra were measured on a JEOL JMS-DX-300 mass spectrometer using a direct-insertion probe at 70 eV ionizing voltage.

Materials. The olefins (**1a—c**, **e—g**) and manganese(III) acetate dihydrate used were prepared according to a method described in the literature.[6,14] Fluorenylideneacetic acid (**1d**) was obtained by the standard procedure[15] from fluorenone and ethyl bromoacetate, mp 231.7—232.7 °C (lit,[16] mp 232 °C). 9-Benzylidene-9*H*-xanthene (**1i**) and 9-benzylidene-9,10-dihydroanthracene (**1j**) were synthesized from 9-xanthenone and anthrone, **1i**: mp 114—115 °C (EtOH) (lit,[17] mp 116 °C); Anal. ($C_{20}H_{14}O$) C, H, and **1j**: mp 133.0—133.5 °C (benzene); Anal. ($C_{21}H_6$) C, H. Styrene, cyclooctene, octene, acenaphthylene, and malonamide were obtained from a commercial sample of the Wako Pure Chemical Industries, Ltd.

Reaction of Olefins with Malonamide. The typical procedure for the reaction of olefins with malonamide in the presence of manganese(III) acetate was as follows. To a heated solution of olefin (1 or 2 mmol) and malonamide in acetic acid (25 ml), manganese(III) acetate was added (see Table 1). The solution was heated under reflux until the brown color of Mn(III) ion disappeared. The solvent was removed *in vacuo* and the residue was triturated with 2 M hydrochloric acid (1 M=1 mol dm^{-3}), followed by extraction with chloroform. The products were separated on TLC (Wakogel B-10) with chloroform or diethyl ether as the developing solvent. The yields are summarized in Table 1.

*Oxidation Products of 1,1-Diphenylethene (**1a**).* *2-Carbamoyl-4,4-diphenyl-2-buten-4-olide (**2a**)*: Colorless needles (from benzene/light petroleum), mp 167.5—168.0 °C; IR ($CHCl_3$) 3500—3200 (NH_2), 1757 and 1685 (C=O), and 1645 (C=C); ^{1}H-NMR ($CDCl_3$) δ=6.30 (1H, br. s, NH), 7.30 (10H, s, ArH), 7.67 (1H, br. s, NH), and 8.71 (1H, s, H-3); MS *m/z* 279 (M^+), 262, 236, 202, 189, 174, 165, 131, and 105. Found: *m/z* 279.08925. Calcd for $C_{17}H_{13}O_3N$: M, 279.08954.

*3,3,8,8-Tetraphenyl-2,7-dioxaspiro[4.4]nonane-1,6-dione (**4a**)*: Colorless needles (from benzene), mp 285 °C (lit,[6] mp 284.5—285.0 °C).

*Benzopenone (**5a**)*: Colorless plates (from methanol), mp 47—48 °C (lit,[18] mp 47—48 °C).

*Oxidation Products of 2-Phenylpropene (**1b**).* *2-Carbamoyl-4-methyl-4-phenyl-2-buten-4-olide (**2b**)*: Colorless plates (from benzene/light petroleum), mp 151—153 °C; IR ($CHCl_3$) 3500—3200 (NH_2), 1755 and 1684 (C=O), and

1643 (C=C); ^{1}H-NMR ($CDCl_3$) δ=1.87 (3H, s, CH_3), 6.41 (1H, br. s, NH), 7.37 (5H, s, ArH), 7.75 (1H, br. s, NH), and 8.46 (1H, s, H-3); MS *m/z* (rel intensity), 217 (M^+, 12), 202 (40), 175 (100), 158 (66), 131 (74), 105 (100), and 77 (70). Found: C, 66.20; H, 5.29; N, 6.33%. Calcd for $C_{12}H_{11}O_3N$: C, 66.35; H, 5.10; N, 6.45%.

*3,8-Dimethyl-3,8-diphenyl-2,7-dioxaspiro[4.4]nonane-1,6-dione (**4b**)*: It was confirmed by the ^{1}H-NMR spectrum that this compound consisted of three stereoisomers, (3*R**, 5*R**, 8*R**), (3*S**, 5*R**, 8*S**), and (3*R**, 5*R**, 8*S**).[6]

*Acetophenone (**5b**)*: The product **5b** was identical with an authentic sample.

*Oxidation Products of 1,1,2-Triphenylethene (**1c**). 2-Carbamoyl-3,4,4-triphenyl-2-buten-4-olide (**2c**)*: Colorless needles (from benzene), mp 230—231 °C; IR ($CHCl_3$) 3500—3100 (NH_2), 1744 and 1688 (C=O), and 1629 (C=C); ^{1}H-NMR ($CDCl_3$) δ=6.03 (1H, br. s, NH), 6.7—7.5 (15H, m, ArH), and 7.94 (1H, br. s, NH); MS *m/z* (rel intensity), 355 (M^+, 16), 338 (12), 309 (18), 292 (11), 266 (19), 182 (12), 165 (13), 145 (100), 129 (87), 105 (80), and 77 (57). Found: *m/z* 355.11970. Calcd for $C_{23}H_{17}O_3N$: M, 355.12084.

*1,1,2-Triphenyl-1,2-ethanediol 2-Acetate (**6c**)*: Colorless microcrystals (from benzene), mp 227 °C (lit,[6] mp 224.5—225.5 °C).

*Oxidation Products of Fluorenylideneacetic Acid (**1d**). 4'-Carbamoylspiro[fluorene-9,2'(5'H)-furan]-5'-one (**2d**)*: Pale yellow needles (from benzene/light petroleum), mp 241.5—242.5 °C; IR ($CHCl_3$) 3600—3100 (NH_2), 1758 and 1687 (C=O), and 1640 (C=C); ^{1}H-NMR (DMSO-d_6) δ=6.95—7.93 (10H, m, ArH and NH_2), 8.12 (1H, s, H-4); MS *m/z* (rel intensity), 277 (M^+, 100), 260 (95), 232 (81), 222 (88), 205 (66), 189 (62), 176 (63), and 165 (52). Found: *m/z* 277.07332. Calcd for $C_{17}H_{11}O_3N$: M, 277.07389.

*9-Fluorenone (**5d**)*: All spectral data of **5d** were compatible with an authentic sample.

*Oxidation Product of Methylenecyclohexane (**1e**). 3-Carbamoyl-1-oxaspiro[4.5]dec-3-en-2-one (**2e**)*: Colorless needles (from benzene/light petroleum), mp 154—155 °C; IR ($CHCl_3$) 3500—3200 (NH_2), 1741 and 1684 (C=O), and 1642 (C=C); ^{1}H-NMR ($CDCl_3$) δ=1.74 (10H, br. s, 5×-CH_2-), 6.90 (1H, br. s, NH), 7.78 (1H, br. s, NH), and 8.32 (1H, s, H-4); MS *m/z* (rel intensity), 195 (M^+, 4), 178 (100), and 152 (13). Found: C, 61.81; H, 6.79; N, 7.02%. Calcd for $C_{10}H_{13}O_3N$: C, 61.52; H, 6.71; N, 7.18%.

*Oxidation Products of 1,1-Bis(4-methoxyphenyl)ethene (**1f**). 2-Carbamoyl-4,4-bis(4-methoxyphenl)-2-buten-4-olide (**2f**)*: Colorless prisms (from benzene/light petroleum), mp 157 °C; IR ($CHCl_3$) 3500—3200 (NH_2), 1752 and 1683 (C=O), and 1643 (C=C); ^{1}H-NMR ($CDCl_3$) δ=3.75 (6H, s, 2×OCH_3), 6.35 (1H, br. s, NH), 6.74—7.26 (8H, m, ArH), 7.68 (1H, br. s, NH), and 8.64 (1H, s, H-3); MS *m/z* (rel intensity), 339 (M^+, 37), 322 (3), 295 (100), 251 (22), 237 (13), 204 (58), 161 (21), 135 (100), and 107 (20). Found: *m/z* 339.10658. Calcd for $C_{19}H_{17}O_5N$: M, 339.11067.

*3-Carbamoyl-5,5-bis(4-methoxyphenyl)-1H-pyrrol-2(5H)-one (**3f**)*: Colorless needles (from chloroform/light petroleum), mp 203 °C; IR ($CHCl_3$) 3500—3100 (NH_2), 1700 and 1671 (C=O), and 1631 (C=C); ^{1}H-NMR (DMSO-d_6) δ=3.74 (6H, s, 2×OCH_3), 6.83—7.36 (8H, m, ArH), 7.68 (1H, br. s, NH), 7.98 (1H, br. s, NH), 8.48 (1H, d, J=1.8 Hz, H-4), and 10.00 (1H, br. d, J=1.8 Hz, NH); ^{13}C-NMR (CD_3OD) δ=55.8, 70.6, 115.1, 128.5, 129.3, 133.2, 142.6, 160.9, 164.8, and 171.6; MS *m/z* (rel intensity), 338 (M^+, 2), 321 (7), 294 (100), 280 (46), 231 (9), 158 (10), 134 (49), and 119 (12). Found: *m/z* 338.12978. Calcd for $C_{19}H_{18}O_4N_2$: M, 338.12666.

*3-Carbamoyl-4-hydroxy-5,5-bis(4-methoxyphenyl)-1H-pyrrol-2(5H)-one (**3f'**)*: Colorless needles (from chloroform/light petroleum), mp 130—131 °C; IR ($CHCl_3$) 3500—3100 (NH and OH), 1653 (C=O), and 1618 (C=C); ^{1}H-NMR ($CDCl_3$) δ=3.79 (6H, s, 2×OCH_3), 5.38 (1H, br. s, OH), 6.45 (1H, br. s, NH), 6.84—7.32 (8H, m, ArH), 7.59 (1H, br. s, NH), and 8.32 (1H, br. s, NH); ^{13}C-NMR (CD_3OD) δ=55.8 (q), 88.0 (s), 95.4 (s), 114.8 (d), 129.4 (d), 131.4 (s), 161.4 (s), 168.2 (s), 179.2 (s), and 194.4 (s); MS *m/z* (rel intensity), 354 (M^+, 35), 311 (82), 294 (25), 226 (100), 211 (100), 195 (16), 183 (18), 168 (17), 152 (19), 135 (43), 113 (52), 92 (11), and 77 (19). Found: *m/z* 354.12294. Calcd for $C_{19}H_{18}O_5N_2$: M, 354.12157.

*3-Carbamoyl-3-[2,2-bis(4-methoxyphenyl)ethenyl]-5,5-bis(4-methoxyphenyl)-2-pyrrolidone (**10**)*: Colorless microcrystals (from carbon tetrachloride/light petroleum), mp 121—124 °C; IR ($CHCl_3$) 3550—3100 (NH), 1692 (C=O), and 1606 (C=C); ^{1}H-NMR ($CDCl_3$) δ=2.57 (1H, d, J=13.2 Hz, CH_2), 3.31 (1H, d, J=13.2 Hz, CH_2), 3.67 (3H, s, OCH_3), 3.72 (3H, s, OCH_3), 3.75 (3H, s, OCH_3), 3.78 (3H, s, OCH_3), 5.87 (1H, br. s, NH), 6.12 (1H, s, =CH-), 6.57—7.26 (17H, m, ArH and NH), and 8.25 (1H, s, NH); MS *m/z* (rel intensity), 578 (M^+, 3), 535 (100), 492 (15), 427 (11), 384 (8), 371 (30), 295 (39), 265 (20), 227 (74), 189 (19), 134 (19), and 121 (38). Found: *m/z* 578.24302. Calcd for $C_{35}H_{34}O_6N_2$: M, 578.24169.

*Oxidation Products of 1,1-Bis(4-methoxyphenyl)-2-phenylethene (**1g**). 2-Carbamoyl-4,4-bis(4-methoxyphenyl)-3-phenyl-2-buten-4-olide (**2g**)*: Colorless microcrystals (from benzene/light petroleum), mp 98—99 °C; IR ($CHCl_3$) 3600—3100 (NH_2), 1741 and 1684 (C=O); ^{1}H-NMR ($CDCl_3$) δ=3.71 (6H, s, 2×OCH_3), 6.15 (1H, br. s, NH), 6.57—7.40 (13H, m, ArH), and 7.80 (1H, br. s, NH); MS *m/z* (rel intensity), 415 (M^+, 40), 371 (60), 329 (25), 242 (30), 227 (20), and 135 (100). Found: *m/z* 415.14532. Calcd for $C_{25}H_{21}O_5N$: M, 415.14197.

*3-Carbamoyl-5,5-bis(4-methoxyphenyl)-4-phenyl-1H-pyrrol-2(5H)-one (**3g**)*: Colorless needles (from chloroform/light petroleum), mp 134—136, 225—226 °C; IR ($CHCl_3$) 3600—3100 (NH), and 1698 (C=O); ^{1}H-NMR (DMSO-d_6) δ=3.74 (6H, s, 2×OCH_3), 6.65—7.35 (13H, m, ArH), 7.38 (1H, br. s, NH), 8.01 (1H, br. s, NH), and 9.48 (1H, s, NH); MS *m/z* (rel intensity), 414 (M^+, 45), 371 (100), 307 (50), 240 (40), 210 (45), 134 (55), and 77 (12). Found: *m/z* 414.15650. Calcd for $C_{25}H_{22}O_4N_2$: M, 414.15796.

*4,4'-Dimethoxybenzophenone (**5g**)*: Colorless plates (from ethanol), mp 143—144 °C (lit,[19] mp 144 °C).

*1,1-Bis(4-methoxypheny)-2-phenyl-1,2-ethanediol 2-Acetate (**6g**)*: Colorless microcrystals (from benzene), mp 200—201 °C; IR ($CHCl_3$) 3600—3100 (OH) and 1735 (OAc); ^{1}H-NMR ($CDCl_3$) δ=1.96 (3H, s, OAc), 2.67 (1H, s, OH), 3.70 (3H, s, OCH_3), 3.80 (3H, s, OCH_3), 6.54 (1H, s, >CH-), and 6.67—7.51 (13H, m, ArH). Found: C, 73.55; H, 6.10%. Calcd for $C_{24}H_{24}O_5$: C, 73.45; H, 6.16%.

*2-Hydroxy-2,2-bis(4-methoxyphenyl)-1-phenylethanone (**7g**)*: Colorless needles (from benzene/light petroleum), mp 138—140 °C; IR ($CHCl_3$) 3600—3100 (OH) and 1666 (C=O); ^{1}H-NMR ($CDCl_3$) δ=3.63 (6H, s, 2×OCH_3), 4.93 (1H, br. s, OH), 6.60—7.80 (13H, m, ArH); MS *m/z* (rel intensity), 348 (M^+, 5), 242 (100), 227 (65), 211 (85), 135 (70), and 107 (70). Found: *m/z* 348.13133. Calcd for $C_{22}H_{20}O_4$: M, 348.13616.

*1-Acetoxy-2,2-bis(4-methoxyphenyl)-1-phenylethene (**8g**)*:

Colorless microcrystals (from ethanol), mp 101—102 °C; IR ($CHCl_3$) 1753 (OAc); ^{1}H-NMR ($CDCl_3$) δ=1.95 (3H, s, OAc), 3.67 (3H, s, OCH_3), 3.75 (3H, s, OCH_3), 6.55—7.45 (13H, m, ArH); MS *m/z* (rel intensity), 374 (M^+, 10), 332 (28), 278 (14), 242 (30), 223 (30), 212 (52), 205 (12), 196 (92), 180 (41), 168 (25), 149 (100), 135 (70), and 107 (10). Found: *m/z* 374.15023. Calcd for $C_{24}H_{22}O_4$: M, 374.15181.

*Benzoic Acid (**9g**)*: ^{1}H-NMR and IR spectral data were in agreement with an authentic sample.

*Oxidation Products of 1,1,2-Tris(4-methoxyphenyl)ethene (**1h**). 2-Carbamoyl-3,4,4-tris(4-methoxyphenyl)-2-buten-4-olide (**2h**)*: Colorless microcrystals (from benzene/light petroleum), mp 118—119 °C; IR ($CHCl_3$) 3600—3100 (NH_2), 1736 and 1680 (C=O); ^{1}H-NMR ($CDCl_3$) δ=3.76 (9H, s, 3×OCH_3), 5.8 (1H, br. s, NH), 6.60—7.22 (12H, m, ArH), and 8.0 (1H, br. s, NH). Found: *m/z* 445.15133. Calcd for $C_{26}H_{23}O_6N$: M, 445.15254.

*3-Carbamoyl-4,5,5-tris(4-methoxyphenyl)-1H-pyrrol-2(5H)-one (**3h**)*: Colorless needles (from chloroform/light petroleum), mp 188—189 °C; IR ($CHCl_3$) 3600—3100 (NH) and 1692 (C=O); ^{1}H-NMR (DMSO-d_6) δ=3.70 (3H, s, OCH_3), 3.72 (6H, s, 2×OCH_3), 6.65—7.30 (12H, m, ArH), 7.38 (1H, br. s, NH), 8.01 (1H, br. s, NH), and 9.46 (1H, s, NH). Found: *m/z* 444.17383. Calcd for $C_{26}H_{24}O_5N_2$: M, 444.16852.

*1,1,2-Tris(4-methoxyphenyl)-1,2-ethanediol 2-Acetate (**6h**)*: Colorless microcrystals (from benzene), mp 187.0—187.5 °C; IR ($CHCl_3$) 3600—3200 (OH) and 1734 (OAc); ^{1}H-NMR ($CDCl_3$) δ=1.95 (3H, s, OAc), 2.79 (1H, s, OH), 3.73 (3H, s, OCH_3), 3.75 (3H, s, OCH_3), 3.83 (3H, s, OCH_3), 6.61—7.61 (12H, m, ArH), and 6.83 (1H, s, >CH-). Found: C, 70.91; H, 6.32%. Calcd for $C_{25}H_{26}O_6$: C, 71.07; H, 6.20%.

*2-Hydroxy-1,2,2-tris(4-methoxyphenyl)-1-ethanone (**7h**)*: Colorless needles (from benzene/light petroleum), mp 118—119 °C; IR ($CHCl_3$) 3600—3200 (OH) and 1654 (C=O); ^{1}H-NMR ($CDCl_3$) δ=3.72 (9H, s, 3×OCH_3), 5.20 (1H, br. s, OH), and 6.68—7.82 (12H, m, ArH). Found: *m/z* 378.14591. Calcd for $C_{23}H_{22}O_5$: M, 378.14673.

*1-Acetoxy-1,2,2-tris(4-methoxyphenyl)ethene (**8h**)*: Liquid; IR ($CHCl_3$) 1751 (OAc); ^{1}H-NMR ($CDCl_3$) δ=1.98 (3H, s, OAc), 3.71 (6H, s, 2×OCH_3), 3.78 (3H, s, OCH_3), and 6.60—7.25 (12H, m, ArH); MS *m/z* (rel intensity), 404 (M^+, 25), 362 (50), 333 (23), 242 (48), 194 (40), and 152 (100). Found: *m/z* 404.16293. Calcd for $C_{25}H_{24}O_5$: M, 404.16238.

p-*Anisic Acid (**9h**)*: ^{1}H-NMR and IR spectral data were compatible with an authenitic sample.

*2,3,3-Tris(4-methoxyphenyl)-2-propenal (**11**)*: Colorless needles (from light petroleum), mp 126—127 °C; IR ($CHCl_3$) 1723 (CHO); ^{1}H-NMR ($CDCl_3$) δ=3.78 (9H, s, 3×OCH_3), 6.73—7.30 (12H, m, ArH), and 10.13 (1H, s, CHO); MS *m/z* (rel intensity), 374 (M^+, 3), 333 (100), 242 (78), 227 (80), 211 (70), 135 (70), and 107 (47). Found: *m/z* 374.15161. Calcd for $C_{24}H_{22}O_4$: M, 374.15181.

*Oxidation Products of 9-Benzylidene-9H-xanthene (**1i**). 4-Carbamoyl-3-phenyl-1,5-dihydrospiro[2H-pyrrole-2,9′-xanthen]-5-one (**3i**)*: Colorless prisms (from ethanol), mp 251 °C; IR (KBr) 3600—3000 (NH) and 1697 (C=O); ^{1}H-NMR (DMSO-d_6) δ=6.50—7.48 (13H, m, ArH), 7.52 (1H, br. s, NH), 8.20 (1H, br. s, NH), and 9.80 (1H, s, NH); MS *m/z* (rel intensity), 368 (M^+, 100), 351 (16), 325 (81), 295 (7), 281 (12), 222 (30), 204 (20), 195 (40), 168 (12), 146 (28), and 129 (60). Found: *m/z* 368.11536. Calcd for $C_{23}H_{16}O_3N_2$: M, 368.11609.

*9-Xanthenone (**5i**)*: Colorless needles (from ethanol), mp 175 °C (lit,[20] mp 173—174 °C). Found: C, 79.38; H, 4.16%. Calcd for $C_{13}H_8O_2$: C, 79.58; H, 4.11%.

*9-(α-Acetoxybenzyl)-9-xanthenol (**6i**)*: Colorless microcrystals (from benzene), mp 141—142 °C; IR ($CHCl_3$) 3600—3100 (OH) and 1740 (OAc); ^{1}H-NMR ($CDCl_3$) δ=1.93 (3H, s, OAc), 3.90 (1H, br. s, OH), 5.87 (1H, s, >CH-), and 6.38—7.70 (13H, m, ArH). Found: *m/z* 346.12230. Calcd for $C_{22}H_{18}O_4$: M, 346.12051.

*α,α-Diacetoxytoluene (**12**)*: Colorless microcrystals (from light petroleum), mp 45 °C (lit,[21] mp 45—46 °C); IR ($CHCl_3$) 1758 (OAc); ^{1}H-NMR ($CDCl_3$) δ=2.01 (6H, s, 2×OAc), 7.23—7.52 (5H, m, ArH), and 7.55 (1H, s, >CH-).

*Oxidation Products of 9-Benzylidene-9,10-dihydroanthracene (**1j**). 4′-Carbamoyl-3′-phenyl-1′,5′-dihydrospiro[anthracene-9(10H), 2′-[2H]pyrrol]-5′-one (**3j**)*: Colorless microcrystals (from ethanol), mp 248—249 °C; IR (KBr) 3600—3100 (NH) and 1670 (C=O); ^{1}H-NMR (DMSO-d_6) δ=2.94 (2H, br. s, CH_2), 5.71 (1H, br. s, NH), and 6.8—7.9 (15H, m, ArH and NH_2); MS *m/z* (rel intensity), 366 (M^+, 43), 293 (100), 233 (54), 208 (46), and 91 (29). Found: *m/z* 366.13415. Calcd for $C_{24}H_{18}O_2N_2$: M, 366.13683.

*9-Acetoxy-9-benzoyl-9,10-dihydroanthracene (**7j**)*: Colorless needles (from light petroleum), mp 151.5—152.0 °C; IR ($CHCl_3$) 1751 (OAc) and 1663 (C=O); ^{1}H-NMR ($CDCl_3$) δ=2.12 (3H, s, OAc), 3.31 (2H, s, CH_2), and 6.0—8.2 (13H, m, ArH). Found: *m/z* 342.12724. Calcd for $C_{23}H_{18}O_3$: M, 342.12560.

*9-(α-Acetoxybenzylidene)-9,10-dihydroanthracene (**8j**)*: Pale yellow needles (from ethanol), mp 214 °C; IR ($CHCl_3$) 1762 (OAc) and 1622 (C=C); ^{1}H-NMR ($CDCl_3$) δ=2.59 (3H, s, OAc), 4.94 (2H, s, CH_2), and 7.0—8.3 (13H, m, ArH). Found: *m/z* 326.12870. Calcd for $C_{23}H_{18}O_2$: M, 326.13068.

*Reaction of Styrene (**1k**) with Malonamide in the Presence of Manganese(III) Acetate.* The reaction was carried out by the same procedure described above (molar ratio, **1k**: malonamide:$Mn(OAc)_3$=1:4:4; reaction time, 1 min).

Reactions of Dichloride Anion Radical with Nucleosides, Nucleotides, and Polynucleotides

Takeo TAKAHASHI, Kotaro YAMAUCHI, and Takahiro MASUDA*
Department of Chemistry, Faculty of Science, Tokyo Metropolitan University, Fukasawa, Setagaya-ku, Tokyo 158
(Received January 27, 1984)

Rate constants for reactions of dichloride anion radical with nucleosides, nucleotides, and polynucleotides were determined in neutral aqueous solutions of potassium chloride by the conventional flash photolysis. The reactivities of these compounds toward the anion radical are in the order: bases>nucleosides>nucleotides>polynucleotides. This trend is similar to that observed with the corresponding reactions with hydroxyl radical. A comparison of the reactivities of nucleosides, nucleotides, and polynucleotides toward dichloride anion radical with those toward hydroxyl radical has revealed that the reactivities of these compounds are governed mainly by their base moiety. This trend in the reactivities is discussed in terms of steric effect.

Reactions of nucleic acid and related compounds with dichloride anion radical produced in photolysis or radiolysis of aqueous chloride are of interest from biological point of view, considering their possible role in light or radiation induced damage on living cells. On the other hand, kinetic study on their reactions is expected to provide information on the relation between structure and reactivity of these biologically important molecules.

In previous studies,[1-3] rate constants for reactions of hydroxyl radical with nucleic acid bases, nucleosides, nucleotides, and polynucleotides were determined by the competition method using *N,N*-dimethyl-*p*-nitrosoaniline as a reference compound, and some trend observed in reactivities of bases, nucleosides, and nucleotides was explained in terms of steric hindrance, that is, mutual protection between base and sugar moieties. However, the applicability of this explanation is not examined for other radical reactions. Dichloride anion radical is known to resemble hydroxyl radical in oxidative nature but differ with respect to reactions with unsaturated compounds.[4-6] For the anion radical one-electron oxidation was found,[7,8] whereas addition to a double bond was observed for hydroxyl radical.

The present study was undertaken to ascertain whether or not the same explanation may apply to some trend in reactivities of a series of compounds toward dichloride anion radical. For this purpose, rate constants for reactions of dichloride anion radical with nucleosides, nucleotides, homopolynucleotides, and nucleic acids were determined in neutral aqueous solutions of KCl saturated with dinitrogen monoxide by the conventional flash photolysis. The rate constants obtained indicate that the trend in reactivities of these compounds is similar to that observed for reactions with hydroxyl radical. On the basis of these results, reactivities of these DNA related compounds are discussed from the view point of steric hindrance of substrates.

Experimental

Purine, 1-methylcytosine, D-ribose, 2-deoxyribose 5-phosphate, nucleosides, nucleotides, polynucleotides, ribonucleic acid (baker's yeast), and deoxyribonucleic acid (calf thymus) were obtained from Sigma Chemical Co. and used without further purification. The other chemicals were of reagent grade.

Solutions for irradiation were prepared by dissolving 1 mol dm^{-3} KCl and a desired amount of a substrate in triply distilled water and adjusting pH to 7. The solutions were subjected to bubbling of N_2O for 20 min immediately before flash photolysis. In UV-photolysis of the solutions, the following reactions are expected to take place:

$$Cl^- + h\nu \xrightarrow{197\ nm} Cl\cdot + e^-_{aq}, \quad (1)$$

$$Cl\cdot + Cl^- \rightleftharpoons Cl_2^-\cdot, \quad (2)$$

$$e^-_{aq} + N_2O \longrightarrow N_2 + \cdot OH + OH^-, \quad (3)$$

$$Cl_2^-\cdot + Cl_2^-\cdot \longrightarrow Cl_2 + 2Cl^-, \quad (4)$$

$$Cl_2^-\cdot + S \longrightarrow 2Cl^- + \text{product(s)}, \quad (5)$$

where S designates a substrate. By kinetic analysis of the rate of decay of dichloride anion radical due to Reactions 4 and 5, the rate constant of Reaction 5 was estimated. The procedure for the estimation was described in detail elsewhere.[6,9] Calculations in kinetic analysis and of solid angles were carried out with the aid of microcomputers PC-8001 and PC-8801 (Nippon Electric Co.).

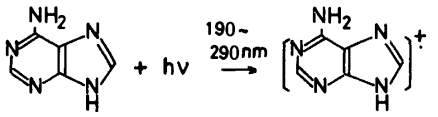
Flash photolysis was carried out under the conditions of 10 μs duration and 200 J input energy with the same conventional apparatus, that had been described in a previous paper,[10] except additional use of a transient recorder TM-1410 (Kawasaki Electronica Co.). Decay rate of dichloride anion radical was measured by using the absorption at 350 nm with 7600 dm^3 mol^{-1} cm^{-1} taken as its absorption coefficient.[11]

Results and Discussion

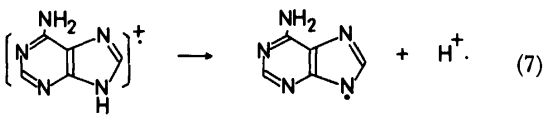
Rate Constants for Reaction of Dichloride Anion Radical with Nucleic Acid Components in Aqueous

Solution. Rate constants for reactions of dichloride anion radical with nucleosides, nucleotides, and some related compounds are summarized in Table 1, together with the values previously reported for nucleic acid bases.[6] These values were obtained from more than fifteen experiments and their errors are expressed in standard deviation.

We failed in determination of the rate constant for the reaction with guanine because of its low solubility in neutral solution. The rate constant for the reaction with adenine could not be determined either, because a relatively long-lived absorption of a maximum at 335 nm appeared in the region of the absorption due to dichloride anion radical so that the decay process of the anion radical could not be followed in this case. Since the transient absorption was observed even in the absence of chloride ion, it may be attributable to a cation radical of adenine produced by the photoionization in aqueous solution



The species responsible for the transient absorption will be a neutral radical formed from the cation radical after deprotonation of N-9, because no absorption was observed for adenosine or adenosine 5′-phosphate in the time scale of flash photolysis:



From the values given in Table 1, it is noticed that the reactivities of nucleic acid components may be arranged in the order: bases>nucleosides>nucleotides. The only exception was found for adenosine 5′-diphosphate. A duplicate determination resulted in fairly good reproducibility and this high value cannot be explained at the present stage of study. D-ribose or 2-deoxyribose 5-phosphate was chosen as a model compound of sugar or sugar phosphate moiety, respectively. Their low reactivities toward dichloride anion radical suggest that a hydrogen atom abstraction from these compounds occurs, as discussed by Hasegawa and Neta.[5]

In Table 2, rate constants for reactions with homopolynucleotides, ribonucleic acid, and deoxyribonucleic acid are summarized. They are presented as a value per nucleotide unit. Before flash photolysis, heat treatment was carried out on nucleic acids at 80 °C for 40 min in order to investigate the effect of conformational change on reactivity. An apparent increase in reactivity was observed after the treatment.

Mechanism of Reaction of Dichloride Anion Radical with Nucleoside. It has already been reported that dichloride anion radical reacts with a nucleic acid base to form 5 yl radical through one-electron oxidation and deprotonation[7,8]

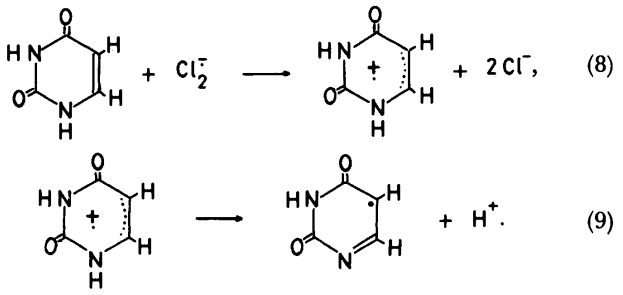


TABLE 1. RATE CONSTANTS FOR REACTIONS OF DICHLORIDE ANION RADICAL WITH NUCLEIC ACID BASES, NUCLEOSIDES, NUCLEOTIDES, AND RELATED COMPOUNDS

	Compound	Rate constant 10^8 dm^3 mol^{-1} s^{-1}
1.	Uracil[a]	2.8±0.1
2.	Uridine	1.6±0.3
3.	Uridine 5′-phosphate	1.5±0.2
4.	Cytosine[a]	3.5±0.1
5.	Cytidine	2.5±0.8
6.	Cytidine 5′-phosphate	2.2±0.6
7.	Thymine[a]	3.2±0.3
8.	Thymidine	2.4±0.2
9.	Thymidine 5′-phosphate	1.8±0.3
10.	Adenosine	3.2±0.5
11.	Adenosine 5′-phosphate	3.0±0.5
12.	Adenosine 5′-diphosphate	3.6±0.2
13.	Adenosine 5′-triphosphate	2.0±0.6
14.	Guanosine	14±7
15.	Guanosine 5′-phosphate	8.8±0.8
16.	D-Ribose	0.11±0.02
17.	2-Deoxyribose 5-phosphate	0.19±0.08
18.	Purine	0.52±0.08
19.	1-Methylcytosine	3.3±0.5

TABLE 2. RATE CONSTANTS FOR REACTIONS OF DICHLORIDE ANION RADICAL WITH HOMOPOLYNUCLEOTIDES AND NUCLEIC ACIDS

	Compound	Rate constant 10^8 dm^3 mol^{-1} s^{-1}
20.	Polyuridylic acid	0.98±0.22
21.	Polycytidylic acid	1.1±0.3
22.	Polyadenylic acid	1.5±0.1
23.	Ribonucleic acid	1.1±0.2
24.	Ribonucleic acid pretreated at 80 °C, 40 min	2.2±0.1
25.	Deoxyribonucleic acid	0.74±0.11
26.	Deoxyribonucleic acid pretreated at 80 °C, 40 min	1.4±0.3

On the other hand, it is well known that anion radical $Cl_2^{-}\cdot$ abstracts a hydrogen atom from an aliphatic compound as follows:[12,13]

$$RH + Cl_2^{-}\cdot \longrightarrow R\cdot + H^+ + 2Cl^-. \quad (10)$$

Therefore, two types of reactions are expected for nucleoside; one-electron oxidation of base ring (Reaction 8) and hydrogen abstraction from sugar moiety. Thus the apparent rate constant for the reaction of nucleoside, k, may be expressed by

$$k = f_1 k_b + f_2 k_s, \quad (11)$$

where k_b and k_s designate the rate constants independently determined for base and sugar, respectively, and f_1 and f_2 are correction factors for k_b and k_s, respectively, with respect to the bonding between base and sugar.

The correction factors will be evaluated by considering the following causes for the decrease in reactivity toward dichloride anion radical: 1) change in energy state due to formation of glycoside bond; 2) decrease in diffusion rate owing to increase in molecular size; 3) steric hindrance, that is, mutual protection of two moieties.

The effect of energy state on reactivity is evaluated from the rate constant determined for 1-methylcytosine. As shown in Table 1, the value for 1-methylcytosine, $(3.3\pm0.5)\times10^8$ dm^3 mol^{-1} s^{-1}, is closer to the value of cytosine than to that of cytidine or cytidine 5′-phosphate. This suggests that the change in energy state due to formation of glycoside bond does not significantly affect the reactivity toward dichloride anion radical at least in neutral aqueous solution.

Furthermore, the first ionization potentials determined by photoelectron spectroscopy for the nucleic acid components and related compounds are in the following orders for each series: uracil (9.6—9.45 eV) >uridine (9.0 eV)>1-methyluracil (8.74 eV); thymine (9.20—9.02 eV)>thymidine (8.7 eV); cytosine (9.1 eV)> 1-methylcytosine (8.655 eV)>cytidine (8.6 eV); adenine (8.48 eV)>adenosine (8.4 eV)>9-methyladenine (8.39 eV); guanine (8.28 eV)>9-methylguanine (8.02 eV)> guanosine (8.0 eV).[14-20] If the order of magnitude in gas phase does not change in the liquid phase, the order of magnitude suggests that a nucleoside or an *N*-methyl derivative is more reactive than a base in one-electron oxidation reaction.

In relation to diffusion rate, the reactivity would be affected by the encounter number of reactants in solution. The degree of this contribution will be evaluated by Smoluchowski's equation. Bowen and Martin[21] reported diffusion constants of some nucleosides, nucleotides, and purine bases in the presence and absence of salt such as KCl, $MgCl_2$, or $CaCl_2$. The values for adenine, adenosine, and adenosine 5′-phosphate are 7.7×10^{-6}, 5.2×10^{-6}, and 4.3×10^{-6} cm^2 s^{-1} in the presence of 5×10^{-3} mol dm^{-3} $MgCl_2$, respectively. From these values and the diffusion constant of the anion radical, 1.67×10^{-5} cm s^{-1}, which has been estimated from the rate constant of Reaction 4 by Debye's equation for diffusion-controlled reactions between charged species, 0.90 and 0.86 can be obtained as the relative reactivities of adenosine and adenosine 5′-phosphate, respectively, with unity taken for adenine. Since the observed values given in Table 1 are much less than the values estimated above from diffusion rate, the second cause will be eliminated.

The third possible cause is steric hindrance, namely mutual protection between base and sugar moieties. In Fig. 1, rate constants of nucleic acids and related compounds for hydroxyl radical are plotted against those for dichloride anion radical. In a previous paper,[6] we reported that a linear correlation with slope 11 was found between reactivities of pyrimidine bases toward hydroxyl radical and those toward dichloride anion radical.

For bases, nucleosides, nucleotides, polynucleotides, and nucleic acids, a similar correlation was observed, except for 2-amino derivatives of pyrimidine and purine. The slope 15 in the correlation is close to that found for pyrimidine bases. On the other hand, a slope of the correlation found for D-ribose and 2-deoxyribose 5-phosphate, 87.5, is close to that found for aliphatic dipeptides, 65.8.[6] These results suggest that the overall reactivity of a nucleoside, nucleotide,

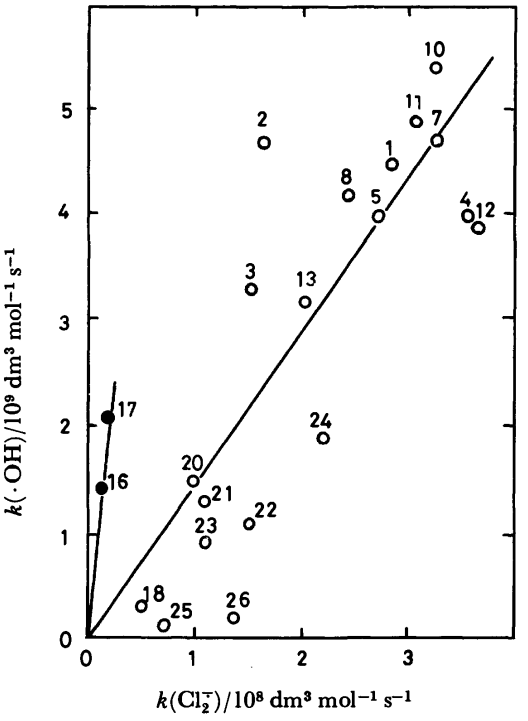

Fig. 1. $k(\cdot OH)$ *vs.* $k(Cl_2^-)$.
Figure associated with each plot corresponds to the number used in Tables 1 and 2.

polynucleotide, or nucleic acid is governed mainly by base moiety, the contribution of sugar or sugar phosphate moiety being negligible. Therefore, Eq. 11 is rewritten to $k=f_1k_b$.

The rate constant of a nucleoside will be predicted by the above equation, if f_1, the degree of protection of base moiety by sugar moiety, is estimated from the solid angle open to the attack of dichloride anion radical, as discussed in the case of hydroxyl radical.[2] Although for the addition reaction of hydroxyl radical C-5 has been proposed as the reaction site by ESR studies,[22,23] the reaction site on a pyrimidine base is not clear for one-electron oxidation. However, π-electron has been suggested to react with the anion radical (Reaction 8) by ESR studies.[7,8]

Therefore, by assuming that the reaction site on nucleoside for the anion radical is C-5 of pyrimidine ring, a calculation of f_1 was attempted for reactions of the anion radical with nucleosides. With each atom of sugar moiety projecting on the surface of unit sphere centered at C-5 of a base, the area of projection was determined as described in a previous paper.[2] Coordinates of nucleoside reported by Lakshiminarayanan and Sasisekharan[24] were used for the calculation of solid angles. Area was calculated for stepwise change of the torsional angle about the bond between N-1 and C-1′. Contact distances were taken as the sum of van der Waals radii. For the anion radical, the van der Waals radius was assumed as the average of the long and short axes, 0.25 nm. The estimated rate constants for uridine, cytidine and thymidine are given in Table 3.

They are presented as the values estimated for the upper and lower limits of protection. Compared with the case of hydroxyl radical, the agreement with the observed values is not good except uridine. This may be due to the assumption of the reaction site, because the effective size of π-orbital was neglected in the calculation. However, steric hindrance could provide values closer to observed ones.

The results obtained for homopolynucleotides and nucleic acids indicate that the reactivity toward dichloride anion radical depends on their conformation. The reactivity of a polynucleotide is 0.5—0.65 times as high as that of the corresponding nucleotide. This may be due to a protection by the sugar phosphate backbone. The reactivity of a nucleic acid is relatively high, in spite of its tight conformation. This will be explained in terms of the presence of guanosine 5′-phosphate, which is included in the molecules and very reactive to the anion radical. The increase in reactivity induced by heat treatment may also be understood in terms of conformational degradation.

Table 3. Estimated rate constants of reactions of nucleosides with dichloride anion radical

Compound	Rate constant 10^8 dm^3 mol^{-1} s^{-1}
Uridine	1.3—1.8
Cytidine	1.7—2.3
Thymidine	1.5—2.1

The results obtained for the reaction of dichloride anion radical can be understood in the same way with the reaction of hydroxyl radical. The explanation based on steric effect is probably applicable to reactions of these compounds with some other radicals in aqueous solutions.

Determination of Rate Constants for Reactions of Dichloride Anion Radical with Some Dipeptides in Aqueous Solution of KCl and $K_2S_2O_8$ by Flash Photolysis

Osamu NEDA, Kotaro YAMAUCHI, and Takahiro MASUDA*
Department of Chemistry, Faculty of Science, Tokyo Metropolitan University, Fukasawa, Setagaya-ku, Tokyo 158
(Received July 27, 1984)

Determination of rate constants for reactions of dichloride anion radical was conducted by conventional flash photolysis of aqueous solutions of KCl and $K_2S_2O_8$, where no participation of $HOCl^{-}\cdot$ is expected in decay kinetics of dichloride anion radical. The optimum conditions found for the determination are 0.1 mol dm^{-3} KCl and 10^{-4} mol dm^{-3} $K_2S_2O_8$. Under the present experimental conditions, $S_2O_8^{2-}$ serves to convert chloride ion to dichloride anion radical through reaction with hydrated electron produced by photolysis of chloride ion. For glycyltryptophan, the competition method was employed, because its transient absorption overlaps the absorption due to dichloride anion radical. The rate constants determined are almost the same as those obtained in N_2O-saturated aqueous solution of KCl (1 mol dm^{-3}). The reactivity of dipeptides toward dichloride anion radical is discussed.

Reaction of dichloride anion radical produced by radiolysis or photolysis of aqueous chloride with a protein molecule is an interesting subject, because physiological concentrations of the chloride ion in living cells are relatively high and because other dihalide anion radicals such as $Br_2^{-}\cdot$ were reported to react with proteins in a specific manner.[1-5] Rate constants for reactions of dichloride anion radicals with a variety of substrates have been determined in neutral aqueous solutions by radiation-chemical and photochemical method.[6-10] However, there remain some problems for the reported methods, because $HOCl^{-}\cdot$. is inevitably produced in radiolysis of neutral aqueous chloride and photolysis of N_2O-saturated aqueous chloride and because its absorption overlaps the absorption due to dichloride anion radical.[11] Furthermore, concentrations of chloride ion were inadequately high for protein, particularly in photolysis.

Peroxodisulfate ion reacts with hydrated electron to form $SO_4^{-}\cdot$, which oxidizes chloride ion to chlorine atom.[12,13] Chlorine atom is readily converted to dichloride anion radical in aqueous solution of potassium chloride:

$$e_{aq}^{-} + S_2O_8^{2-} \longrightarrow SO_4^{-}\cdot + SO_4^{2-}, \quad (1)$$

$$SO_4^{-}\cdot + Cl^{-} \longrightarrow SO_4^{2-} + Cl\cdot, \quad (2)$$

$$Cl\cdot + Cl^{-} \rightleftharpoons Cl_2^{-}\cdot. \quad (3)$$

In the present study, a determination of rate constants for reactions of dichloride anion radical with some biomolecules, especially dipeptides, was attempted in aqueous solutions of KCl including $K_2S_2O_8$, where no participation of $HOCl^{-}\cdot$ is expected. A comparison of the results obtained by the present method with those determined in N_2O-saturated solutions disclosed no essential difference between them.

Experimental

Peptides obtained from Nutritional Biochemicals Corp. were used without further purification. The other chemicals were all of reagent grade. Solutions for irradiation were prepared with triply distilled water by dissolving 0.1 mol dm^{-3} KCl, 10^{-4} mol dm^{-3} $K_2S_2O_8$, and a desired amount of substrate. The solutions were adjusted to pH 7 and subjected to bubbling of nitrogen for 20 min. Flash photolysis was carried out with a conventional apparatus under the conditions of 10 μs duration and 200 J input energy. Decay process of dichloride anion radical was monitored at 350 nm and analyzed on the basis of the following reactions:

$$Cl_2^{-}\cdot + Cl_2^{-}\cdot \longrightarrow Cl_2 + 2Cl^{-}, \quad (4)$$

$$Cl_2^{-}\cdot + S \longrightarrow 2Cl^{-} + \text{product(s)}. \quad (5)$$

The procedure of kinetic analysis was described in detail elsewhere.[9,10] Calculation was carried out with the aid of a microcomputer PC 8001 of Nippon Electric Co.

Results and Discussion

Optimum Conditions. In the presence of $S_2O_8^{2-}$, formation of dichloride anion radical was markedly enhanced even at low concentrations of chloride ion. Peroxodisulfate ions are photolyzed to give $SO_4^{-}\cdot$ as follows:[14,15]

$$S_2O_8^{2-} + h\nu \longrightarrow 2SO_4^{-}\cdot. \quad (6)$$

In addition to Reaction 1, therefore, Reaction 6 produces $SO_4^{-}\cdot$ and in turn increases the yield of dichloride anion radical through Reactions 2 and 3. However, formation of a large amount of the anion radical was found to be inadequate for analysis of the decay process, because it gave rise to a practical difficulty in monitoring absorption in the initial stage. Consequently, nitrogen-saturated solution of 0.1 mol dm^{-3} KCl and 10^{-4} mol dm^{-3} $K_2S_2O_8$ was chosen as an optimum condition for experimental reasons.

In this system, reaction of $SO_4^{-}\cdot$ with a substrate of dichloride anion radical was neglected because Reaction 2 takes place predominantly ($k_2=3.1\times10^8$ dm^3 mol^{-1} s^{-1}).[13] Similarly, bimolecular decay of $SO_4^{-}\cdot$ was neglected since the rate constant of Reaction 7 was reported to be 1.0×10^9 dm^3 mol^{-1} s^{-1} [16] and since $k_7[SO_4^{-}\cdot]$ was much less than $k_2[Cl_2^{-}\cdot]$:

$$SO_4^{-}\cdot + SO_4^{-}\cdot \longrightarrow S_2O_8^{2-}. \quad (7)$$

In fact, no absorption at 460 nm due to sulfate radical was observed in flash photolysis of the above solution. This implies that a decay of sulfate radical is almost complete within flash duration. The lifetime of sulfate radical was estimated to be 3.2×10^{-8} s from rate data for Reaction 2. In the present system, a complete consumption of hydrated electrons by Reaction 1 cannot be expected, because rate data of Reaction 1 suggest a possibility that at least several percent of hydrated electrons may react with dichloride anion radicals; this reaction causes a decrease in the yield of dichloride anion radicals. In any cases, the greater part of hydrated electrons will be consumed within flash duration, because the life time is estimated to be 1 μs. At 40 μs after start of flash, when analysis of the decay process starts, there may remain dichloride anion radicals as an overwhelming majority of reactive transients in the system.

Comparison of Rate Constants. Table 1 shows the rate constants determined by the present method, together with those obtained in N_2O-saturated solutions. Two kinds of substrates were taken for comparison, because dichloride anion radical abstracts a hydrogen atom from an aliphatic compound and oxidizes an unsaturated compound.[6,16,17] The values determined in the present study are in good agreement with those previously obtained in N_2O-saturated solutions. This implies that the contribution of $HOCl^{-}\cdot$ may be neglected in kinetic analysis based on the decay of the absorption at 350 nm. Since an OH-adduct of 5-aminouracil was observed in neutral N_2O-saturated solution,[10] the formation of hydroxyl radicals is confirmed. In neutral N_2O-saturated solutions, reactions

$$e_{aq}^{-} + N_2O \longrightarrow N_2 + \cdot OH + OH^{-}, \quad (8)$$

$$\cdot OH + Cl^{-} \rightleftharpoons HOCl^{-}\cdot \quad (9)$$

take place. The equilibrium constant of Reaction 9 was reported to be (0.70±0.13) dm^3 mol^{-1} by Jayson *et al.*[11] and hence the initial concentration of $HOCl^{-}\cdot$ is estimated as 70 percent of dichloride anion radicals on the assumption that Reaction 8 proceeds with 100 percent efficiency. Since the absorption coefficient at 350 nm is approximately half that of the dichloride anion radical,[11] the contribution of $HOCl^{-}\cdot$ amounts to about 26 percent of the absorbance at 350 nm. However, the decay constant of dichloride anion radical ($2k$ for Reaction 4) in N_2O-saturated solution was found to be essentially the same as that determined in the present system. Studying pulse radiolysis, Anbar and Thomas[8] pointed out that hydroxyl radicals formed in the bulk of a solution containing 10^{-3} mol dm^{-3} H_2O_2 do not produce any dichloride anion radicals (no change in absorbance at 365 nm). However, Jayson *et al.*[11] reported the transient spectrum of $HOCl^{-}\cdot$ and kinetic data for this species. The discrepancy cannot be interpreted at present, although the present results agree with the former.

Rate Constants of Dipeptides. In our previous paper,[8] rate constants for several aliphatic dipeptides reacting with dichloride anion radical were reported. The present method was applied to other dipeptides whose corresponding rate constants for the anion radical had not been determined. Values determined by the present method are listed in Table 2. The present method could not be applied to glycyltryptophan because of a transient absorption appearing in the region of the absorption due to dichloride anion radical. Tryptophan is known to yield an indolyl radical on one-electron oxidation and deprotonation.[19-22] The indolyl radical has another absorption with a maximum at 510 nm and is relatively long-lived. The decay constant in 0.1 mol dm^{-3} KCl was determined to be $(6.9\pm0.6)\times10^8$ dm^3 mol^{-1} s^{-1}. Since the dichloride anion radical has no absorption at 510 nm, a com-

Glycyltyrosine	59±2
Glycyltryptophan	280±30[a]

a) Competition method.

petition kinetics was attempted to determine the rate constant for glycyltryptophan, in which use was made of the absorption at 510 nm due to the indolyl radical produced from glycyltryptophan through oxidation by dichloride anion radical:

$$Cl_2^{-\cdot} + TH \longrightarrow 2Cl^- + TH^{+\cdot}, \quad (10)$$

$$TH^{+\cdot} \longrightarrow T^{\cdot} + H^+, \quad (11)$$

where TH represents glycyltryptophan and TH^+ is the cation radical of glycyltryptophan produced by one-electron oxidation. $T^{\cdot}$ designates a neutral radical formed from the cation radical after deprotonation. Since glycyltryptophan yields also indolyl radical by photoionization according to

$$TH + h\nu \longrightarrow TH^+ + e_{aq}^-, \quad (12)$$

Reactions 5, 10, 11, and 12 should be considered in the competition kinetics. For the decrease in the absorbance at 510 nm caused by the presence of a substrate, the following equation is derived:

$$\frac{1}{A_0 - A} = \frac{1}{\varepsilon l[T^{\cdot}]}\left(1 + \frac{k_{10}[TH]}{k_5[S]}\right), \quad (13)$$

where A_0 and A designate the absorbances at 510 nm in the absence and presence of substrate, respectively at 150 μs after start of flash. A reciprocal plot of $(A_0 - A)$ *vs.* [TH]/[S] provides a straight line and k_{10}/k_5 is obtained from the slope and intercept as shown in Fig. 1. As reference substrates, were used glycylvaline, glycylleucine, glycylnorleucine, and glycyl-α-aminobutyric acid, because their reaction products have no absorption at 510 nm.

As shown in Table 2, dipeptides having C=C double bonds are more reactive than saturated ones toward the anion radical. For aliphatic dipeptides, the ratio of the rate constant with hydroxyl radical to that with the anion radical has been found to be about 66.[9] The reactivity of glycylproline can be explained in terms of this correlation. However, a large deviation from the correlation was observed for aliphatic dipeptides having such a functional group as hydroxyl, carboxyl, or carbamoyl group. Since the ratio of the rate constant with hydroxyl radical to that with dichloride anion radical is much less than 66 for the aliphatic dipeptide having some functional group, these groups may affect the reaction rate differently from hydroxyl radical working in hydrogen atom abstraction reaction.

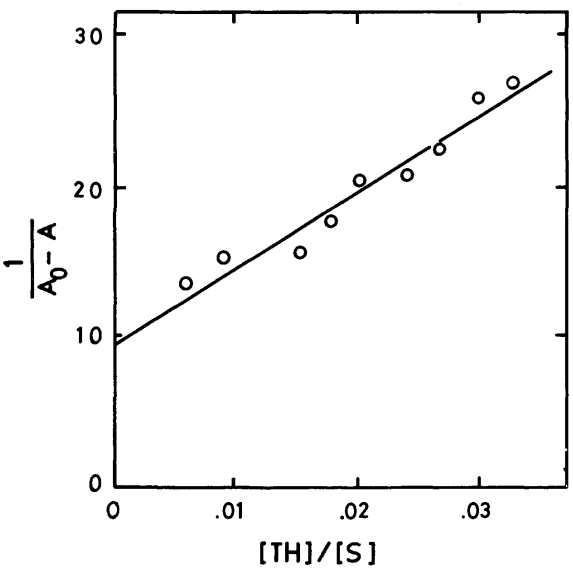

Fig. 1. Kinetic plots according to Equation 13. [TH] = 10^{-4} mol dm^{-3}. S: Clycylleucine.

Aromatic and heterocyclic dipeptides seem to undergo one-electron oxidation, because they are very reactive toward dichloride anion radicals. Glycyltryptophan is most reactive toward the anion radical in neutral solution as well as in acid solution.[1] Since tryptophan is often found in active sites of enzyme proteins and the physiological concentration of chloride ion is considerably high, the role of dichloride anion radical must be taken into consideration in radiation- or light-induced damage on biological systems.

††*Chemical Laboratory, Meiji-gakuin University, Minato-ku, Tokyo 108*
(Received January 28, 1984)

The structures of two dihydroxycoumarin glucosides, esculetin 6-glucoside (**E6G**) and esculin 7-glucoside (**E7G**) have been determined by the X-ray analysis. The crystal data are: **E6G**, $C_{15}H_{16}O_9 \cdot 1.5H_2O$, orthorhombic $P2_12_12_1$ with a=11.358(2), b=36.850(9), c=7.663(1) Å and Z=8: and **E7G**, $C_{15}H_{16}O_9 \cdot 2H_2O$, orthorhombic $P2_12_12_1$ with a=4.507(1), b=13.077(3), c=27.748(5) Å and Z=4. Both structures were solved by the direct method and refined by the least-squares to the final R values of 0.073 (2036 reflections) for **E6G** and 0.069 (1037 reflections) for **E7G**. The geometries of the glucosyl linkages in **E6G** and **E7G** are different: the torsion angles around the glucosidic C-O bond are −58.2° and 14.3° for the two crystallographically independent **E6G** molecules and 9.9° for **E7G**. The glucosidation at the 6-hydroxyl group causes little effect on the conjugation of the coumarin moiety, whereas the conjugation is greatly decreased in the glucosidation at 7-hydroxyl group. This fact suggests that **E6G** is energetically more stable than **E7G**. The enzymatic transglucosidation from 7- to 6-hydroxyl group may proceed utilizing such an energy difference.

In the course of investigation on the biosyntheses of hydroxylated coumarin glucosides, characteristic transglucosidases were isolated from *Daphne odora* and *Cichorium intybus*. In *C.intybus*, it is considered that 7-*O*-(β-D-glucosyloxy)-6-hydroxycoumarin (or esculetin 7-glucoside: **E7G**) is formed from *p*-glucosyloxycinnamic acid, and that it is changed into 6-*O*-(β-D-glucosyloxy)-7-hydroxycoumarin (or esculetin 6-glucoside: **E6G**) by the action of transglucosidase.[1] A similar reaction has been observed for 7,8-dihydroxycoumarin (or daphnetin: **D**), where glucose is transferred from 7- to 8-hydroxyl group.[2] The transglucosidation to 7-hydroxyl group from 6- or 8-hydroxyl group was undetectable in either case. Figure 1 shows the above reactions schematically. In order to elucidate the mechanism, the structures of esculetin(**E**),[3] **D**,[4] daphnetin 8-glucoside(**D8G**)[5] and daphnetin 7-glucoside(**D7G**)[6] have been determined. The coumarin moiety of **D8G** has approximately the same structure as those of **D** and **E**, whereas that of **D7G** is significantly different from that of **D8G**. The glucosidation at 7-hydroxyl group has an important role in the resonance system of the coumarin moiety. Moreover, the geometries of the glucosyl linkages of **D8G** and **D7G** are different. It has been proposed that such structural difference is a factor for the transglucosidation from **D7G** to **D8G**. Present paper reports the structures of **E6G** and **E7G** and discusses the mechanism of another transglucosidation from **E7G** to **E6G** on the basis of the two structures.

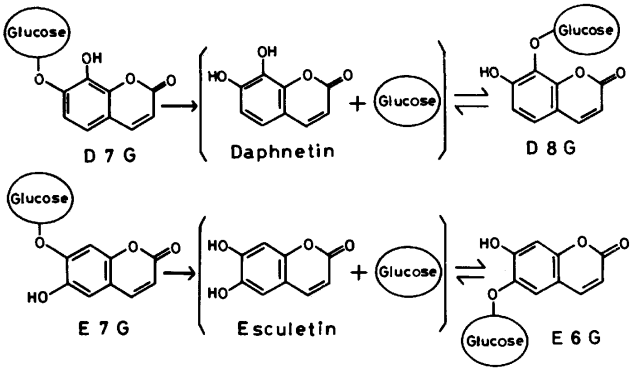

Fig. 1. Interconversions of dihydroxycoumarin 7-glucoside to 6- or 8-glucoside.

Experimental

Both crystals were prepared by slow evaporation from an aqueous ethanol solution. The lattice parameters and the intensity data up to 2θ=120° were obtained on a Nicolet P3/F four-circle diffractometer with graphite monochromated Cu $K\alpha$ radiation. An $\omega/2\theta$ scanning mode was applied with the scanning range and rate of 1.0° (ω) plus α_1—α_2 divergence and 1° (2θ)min^{-1}, respectively. Space groups were assigned from systematic absences. No correction was made for absorption. The densities were measured by flotation method in a mixture of dichloromethane and carbon tetrachloride. Crystal data of **E6G**; $C_{15}H_{16}O_9 \cdot 1.5H_2O$, F.W=367.3, orthorhombic $P2_12_12_1$, a=11.358(2), b=36.850(9), c=7.663(1) Å, U=3207.3 (11) Å^3, Z=8, needle, 0.08×0.04×0.18 mm^3 in size, D_x=1.524 g cm^{-3}, D_m=1.52 g cm^{-3}, μ(Cu $K\alpha$)=13.0 cm^{-1}, 2552 reflections measured of which 2036 had net intensities. Crystal data of **E7G**; $C_{15}H_{16}O_9 \cdot 2H_2O$, F.W=376.3, orthorhombic $P2_12_12_1$, a=4.507(1), b=13.077(3), c=27.748(5) Å, U=1635.4(6) Å^3, Z=4, thin plate, 0.08×0.04×0.02 mm^3 in size, D_x=1.528 g cm^{-3}, D_m=1.53 g cm^{-3}, μ(Cu $K\alpha$)=13.1 cm^{-1}, 1354 reflections measured of which 1037 had net intensities.

Structure Determination

Both structures were solved by the direct method[7] and the structural parameters were refined by the block-diagonal least-squares method. Anisotropic thermal parameters were applied for the non-hydrogen atoms. All the hydrogen atoms were located on difference electron density maps. The refinement including the

contribution of the hydrogen atoms with isotropic temperature factors converged to the R values of 0.073 and 0.069 for **E6G** and **E7G**, respectively. The weighting scheme used in the final stages were $w=((\sigma|F_o|)^2+(0.00012|F_o|)^2)^{-1}$ and $w=((\sigma|F_o|)^2+(0.00016|F_o|^2)^{-1}$ for **E6G** and **E7G**, respectively. Atomic scattering factors were taken from Ref. 8. The final atomic parameters are shown in Table 1.[9]

Results

The perspective drawings of the two crystallographically independent **E6G** molecules, **E6G(A)** and **E6G(B)**, and **E7G** with the numbering system of the atoms are shown in Fig. 2. Bond lengths and angles are listed in Table 2. The coumarin moieties are nearly planar.[9] The conformations of glucosyl linkages are different among the three molecules. In **E6G(B)** and **E7G**, the torsion angles around the glucosidic C-O bond, C(5)-C(6)-O(1')-C(1') for **E6G(B)** and C(8)-C(7)-O(1')-C(1') for **E7G**, are 14.3° and 9.9°, respectively, whereas the corresponding angle in **E6G(A)** is −58.2°. The former "in-plane" conformation appears to cause considerable intramolecular repulsion between the coumarin and glucose moieties, compared with the latter "out-of-plane" conforma-

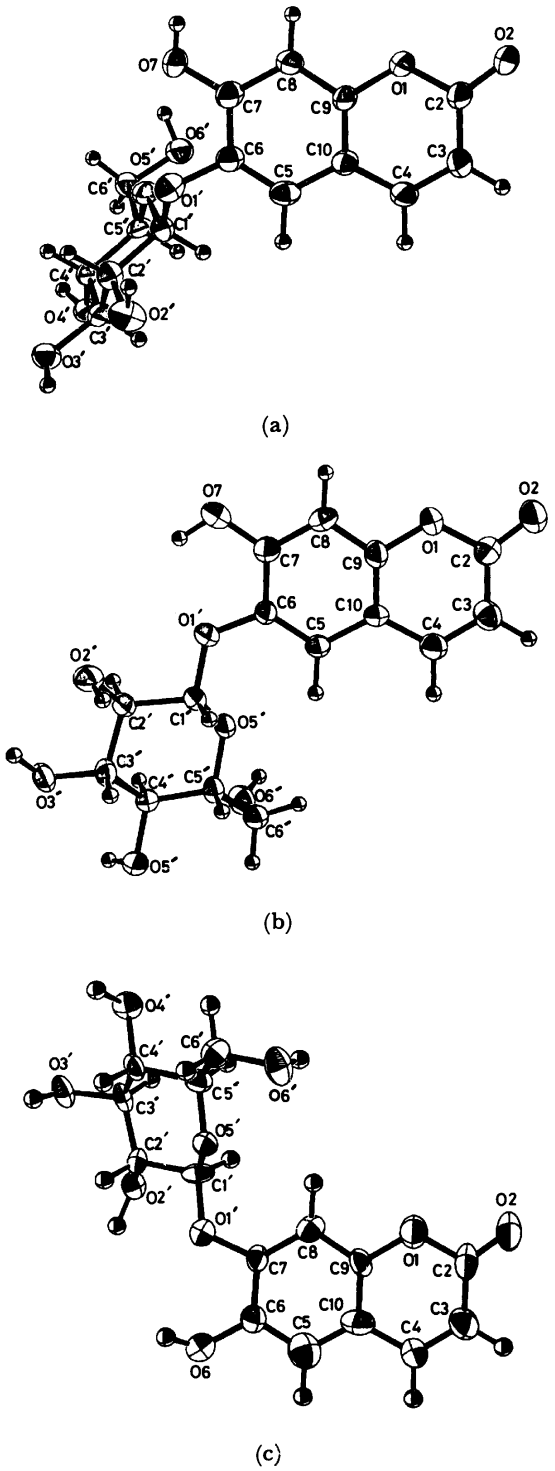

Fig. 2. Perspective drawing of the molecules with the numbering systems; (a): **E6G(A)**, (b): **E6G(B)**, (c): **E7G**.

tion. The angles of C(6)-O(1')-C(1') and C(5)-C(6)-O(1') in **E6G(B)** are 118.5(8)° and 126.2(8)°, which are significantly larger than those in **E6G(A)**, 113.7(7)° and 121.4(9)°, respectively. The corresponding angles in **E7G**, C(7)-O(1')-C(1') and C(8)-C(7)-O(1'), are 119.5(6)° and 125.4(7)°, respectively, and are similar to those of **E6G(B)**. They must be expanded to avoid the short contacts between the coumarin and glucose moieties.

In the benzene rings of **E6G(A)** and **E6G(B)**, the C(5)-C(6) bonds are significantly shorter than C(5)-C(10) and C(6)-C(7), and C(8)-C(9) is slightly shorter than C(7)-C(8). Such a quinonoid structure has been found in the structures of **D8G** and other 7-hydroxylated coumarins. In **E7G**, however, the six bonds in the benzene ring are approximately equivalent, as observed in **D7G**.

The glucose moieties in the three molecules are in C_1 chair conformations. The endo- and exocyclic torsion angles in the glucose portions are in good agreement with each other. The conformations around the C(5')-C(6') bond are trans-gauche in **E6G(A)** and **E7G** and gauche-gauche in **E6G(B)**. Each conformation corresponds to either of the two favored arrangement of the primary alcohol group in glucopyranoside.[10]

The bond lengths in the sequence of C(5')-O(5')-C(1')-O(1')-R have been discussed as an anomeric effect. Sundaralingam claimed that in α-pyranose C(5')-O(5')>O(5')-C(1')≃C(1')-O(1'), while in β-anomer C(5')-O(5')≃O(5')-C(1')>C(1')-O(1').[11] In **E6G** and **E7G**, however, C(5')-O(5') are longer by 0.019—0.041 Å than O(5')-C(1') and C(1')-O(1'). The same trend is observed in other aromatic β-glucosides so far determined such as in **D7G**, **D8G** and 1-naphthyl tetra-*O*-acetyl-β-D-glucoside,[12] and even in the α-anomer such as in *p*-nitrophenyl α-D-glucoside.[13] This indicates that in aromatic glucopyranosides, not only in α-anomer but also in β-anomer, C(5')-O(5') is longer than O(5')-C(1') and C(1')-O(1').

Figure 3 shows the crystal structure of **E6G** viewed along the c axis. The coumarin planes of **A** and **B** molecules are stacked alternately along the c axis. All the hydroxyl groups and water molecules make hydrogen bonds and form a three-dimensional network. The hydrogen bonding schemes around the glucose moieties are different between **A** and **B** as shown in Fig. 4. All the hydroxyl groups of **E6G(B)** participate in hydrogen bonds as a donor and an acceptor. In **E6G(A)**, on the other hand, O(2')H acts as a very weak donor and not an acceptor. The hydrogen bonding system of **E6G(B)** is apparently more favorable than that of **E6G(A)**.

The crystal structure of **E7G** viewed along the a axis is shown in Fig. 5. The molecules are connected by the hydrogen bonds to form sheets perpendicular to the c axis. The sheets are stacked along the c axis with the van der Waals contacts.

Discussion

The glucose moiety at the 7-position takes the "in-plane" conformation in **E7G** as in **D7G**. The torsion

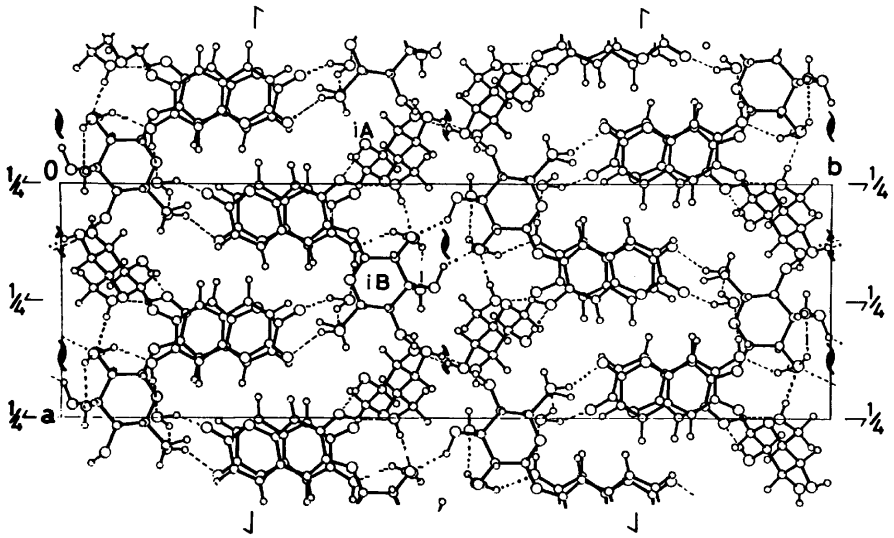

Fig. 3. The crystal structure of **E6G** viewed down the c axis. Hydrogen bonds are indicated by broken lines.

angles in the aromatic β-glucosides so far determined are summarized in Table 3. The glucose or alkyl moiety bonded to the hydroxyl group tend to take the "in-plane" conformation, in which π electrons of the oxygen atom of glucosyl linkage would take part in the resonance of the aromatic ring. Such an "in-plane" conformation would cause the intramolecular repulsion between the coumarin and glucose moieties as observed in the structures of **E7G** and **D7G**. The resonance energy brought about by the "in-plane" conformation may be compensated by the distorsion of the structure. **E6G** or **D8G**, however, is not required to take the "in-plane" conformation, since 6- and 8-hydroxyl group has little effect on the resonance of the coumarin moiety.

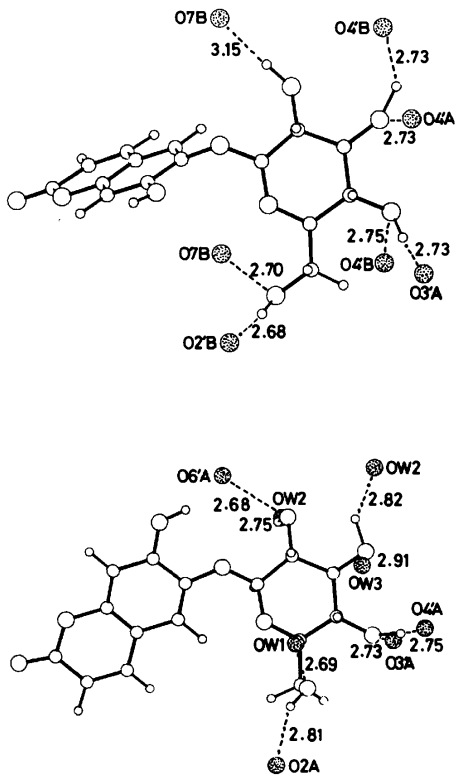

Fig. 4. Hydrogen bonding systems around the glucose moieties of **E6G**(upper; **A**, lower; **B** molecule).

Although **E6G(A)** has an "out-of-plane" conformation, **E6G(B)** is in an "in-plane" conformation. This may be explained by the difference of the hydrogen bond systems of the two molecules as shown in Fig. 4. The intramolecular repulsion in **E6G(B)** would be stabilized by the fairly strong intermolecular hydrogen bonds. In solution, therefore, **E6G** would have the structure close to that of **E6G(A)**.

The structures of the 7-hydroxylated coumarins are well explained by the resonance shown in Fig. 6. The benzene ring apparently takes a quinonoid structure in 7-hydroxycoumarin (umbelliferone: U),[16] 4-methylumlbelliferone,[17] **D**[4] and **E**.[3] Since **E6G** and **D8G** have essentially the same structure as those observed in the 7-hydroxylated coumarins, the glucosidation at the 8-hydroxyl group or at the 6-hydroxyl group causes little effect on the structure of the coumarin moiety. In **E7G** and **D7G**, however, the contributions of the limiting structure(II) is significantly smaller than those in **E6G** and **D8G**, respectively. In the structure of 7-ethoxycoumarin, recently determined, the contribution of (II) are apparently lowered compared with the structure of 7-hydroxycoumarin.[16] The glucosidation at the 7-hydroxyl group tends to decrease the cojugation effect. This seems to indicate that **E6G** and **D8G** are energetically more stable than **E7G** and **D7G**, respectively.

Although the structure of the active site of the enzyme is still unknown, the mechanism of the transglucosidation, as shown in Fig. 1, can be explained by the thermodynamic properties of the substrates and products. From the intermediate stationary state, both of forward and backward reactions could occur.

NTAG e)	11.2	119.7	12
U7E f)	2.6	117.7	16

a) Torsion angle around the bond between glycosidic O and aromatic C atoms (e.g., C(1')-O(1')-C(7)-C(8) in E7G). b) Valence angle of glycosidic oxygen atom. c) *p*-Nitrophenyl *β*-*N*-acetylglucosaminide. d) *p*-Nitrophenyl *β*-D-xylopyranoside. e) 1-Naphthyl tetraacetyl-*β*-D-glucoside. f) 7-Ethoxycoumarin.

However, the formation of **D8G** or **E6G** would be more favorable than that of **D7G** or **E7G**, since the former is energetically more stable than the latter. This should be a reason why glucose is transferred from 7-hydroxyl group to 8- or 6-hydroxyl group by the action of transglucosidase and the reverse is undetectable.

The authors are grateful to Professor Yoshio Sasada and Dr. Yuji Ohashi of Tokyo Institute of Tochnology for their valuable discussions and encouragement.

Fischer Tropsch Reaction over Reduced Molybdenum Catalysts Derived from Various Heteropoly Compounds

Hiroshi MIURA,* Hitoshi ISHIGURO, Masashi OSAWA, Kazunori SASAGAWA, Kazuo SUGIYAMA, and Tsuneo MATSUDA

Department of Applied Chemistry, Faculty of Engineering, Saitama University, Shimo-ohkubo, Urawa 338

(Received March 22, 1984)

The Fischer-Tropsch reaction was examined over reduced molybdenum catalysts using heteropoly compounds as catalyst precursors. Improvement in reducibility was realized by the use of heteropoly compounds. Metallic molybdenum powder with a very large surface area was obtained by the reduction of $H_3PMo_{12}O_{40}$. Its catalytaic activity was one order higher than conventional Mo catalysts. Using different salts of 12-molybdophosphoric acid, various additives were introduced under equivalent conditions and their addition effects were studied.

The catalytic hydrogenation of CO to form various hydrocarbons, the Fischer-Tropsch (FT) reaction, has been studied in detail for a long time. It is well known that group VIII elements such as Fe, Co, Ru, and Rh are active for this reaction, and most research regarding the FT reaction has been focused on these metal catalysts.[1-5] On the other hand, only a few studies have been reported for reactions over catalysts other than group VIII metals.[6-8]

The dissociation of CO is believed[9] to be an important process in the catalytic hydrogenation of CO. Fe and Ru have a great ability to dissociate CO, the reason for their high activity in the FT reaction. Among elements other than those from group VIII, molybdenum is reported[10] to have a high ability for CO dissociation and is worth noticing as a catalyst for the FT reaction. Saito and Anderson[7] examined CO hydrogenation over metallic molybdenum and several molybdenum compounds and found that reduced molybdenum is an active catalyst for the FT reaction. They reported the following order in activity: $Ni>Mo_2C>Mo(metal)>Mo_2N>MoO_2>MoO_3$. Murchison and Murdick[11] reported that molybdenum catalysts containing potassium are selective in the formation of C_2—C_5 hydrocarbons (LPG) and have a relatively high torelance for sulfur poisoning.

However, these studies have been carried out within a reaction temperature range of 623 to 673 K (more than 100 K higher than the group-VIII metals), indicating the mild activity of molybdenum. Because MoO_3 is not easily reduced, Saito and Anderson reduced their molybdenum catalysts at 873K. In order to obtain a more active catalyst, we tried to lower the reduction temperature using more reducible compounds as the catalyst precursors. Niiyama *et al.*[12] studied the initial stage of the reduction of heteropoly compounds and found that $H_3PMo_{12}O_{40}$ (HPMo) and its transition-metal salts are more easilly accessible to H_2 reduction than MoO_3. Therefore, we examined heteropolymolybdates as precursors of molybdenum catalysts. In addition, the use of heteropoly compounds makes it easy to estimate the effect of various additives which are introduced as the counter cation of heteropoly acid since each cation is placed in an equivalent position of the precursors.

Experimental

Catalyst Preparation. Although each catalyst was reduced with hydrogen before use (and its form changed), the chemical formula before reduction is used to express each catalyst.

MoO_3. Reagent grade ammonium heptamolybdate ($(NH_4)_6Mo_7O_{24}\cdot 4H_2O$, Wako Pure Chem.) was calcined in a flow of dry air at 773 K for 5 h. The resulting grey powder was submitted for catalytic studies. The grey MoO_3 was further purified following a method from the literature[13] and white powder was obtained. This MoO_3 was catalytically inactive and was used only as the raw material for heteropoly catalysts.

HPMo($H_3PMo_{12}O_{40}\cdot xH_2O$). According to the method of Tsigdinos[14] and Drechsel,[15] 12-molybdophosphoric acid was prepared as follows. 2.46 g of phosphoric acid (reagent grade, Wako Pure Chem.) was added to 150 ml of pure water and boiled with reflux for 30 min. 50 g of purified MoO_3 (white) was added stepwise and the mixture was allowed to boil for 6 h. After cooling, the insoluble contamination was removed by filtration. The objective compound was extracted with ether from the filtrate and dried. A yellow powder was obtained.

KPMo($KH_2PMo_{12}O_{40}\cdot xH_2O$).[14] A calculated amount of K_2CO_3 (reagent grade, Wako Pure Chem.) was added to an aqueous solution of HPMo so that the atomic ratio of K/Mo was 1/12. The solution was heated in a water bath until no more CO_2 was formed. After drying, a yellow powder was obtained.

MePMo($MeH_2PMo_{12}O_{40}\cdot xH_2O$; Me=Li, Na, Cs, Mg, Ca, Mn, Fe, Co, Ni, Cu, Zn). Alkali metal, alkaline earth and transition metal salts of HPMo were prepared in the same manner as the KPMo, following the method of Tsigdinos.[14] The atomic ratio Me/Mo was fixed at 1/12, except for CsPMo. In this case, the ratio was changed from 0.5/12 to 2/12.

Pretreatment. 1.0 g of catalyst was packed in a U-tube reactor attached with a 4-port valve, the weight of the reactor being measured in advance. After evacuating at room temperature for 10 min, the temperature was increased at a rate of 10 K/min. The temperature change

was controlled by a temperature programmer, Ohkura PG 3001, and the evacuation continued at 453 K for 1 h. After the evacuation treatment, the water content of the HPMo was found to be 0.2% from the weight loss after evacuation at 823 K. After cooling to room temperature, the 4-port valve was closed and the weight was measured. In a flow of hydrogen (high purity grade, Showa Denko Co., passed through activated copper and molecular sieve) the catalyst temperature was increased at a rate of 10 K/min and kept at 773 K for 4 h. After cooling slowly to room temperature in hydrogen, the weight of the catalyst was again measured. From the weight loss during the reduction treatment, the degree of reduction was determined.

Activity Measurement. The reactor was attached to a flow system in order to examine the CO hydrogenation. A premixed gas ($H_2/CO=2.98$, Takachiho Chem. Co.) was used as a reactant gas. After increasing the temperature in a hydrogen flow, the reactant gas was (30 ml/min, atmospheric pressure) passed through the catalyst at 503 K until the activity was stabilyzed (for 6 h). Then the activity was measured at 473—573 K. Products (CO, CO_2, and C_1—C_7 hydrocarbons) were analyzed by gas chromatography.

X-Ray Diffraction. In order to keep the sample from being exposed to air, the reduced (or spent) catalyst was removed from the reactor to a glass sample holder in a nitrogen atmosphare, covered with mylar film, and then submitted to an X-ray diffraction process.

Results and Discussion

MoO_3. The reduction of purified MoO_3 (white) was examined, but it was difficult to reduce it to metallic molybdenum. Even when the reduction temperature was raised to 873 K, the degree of reduction was less than 40% and it was catalytically inactive for the FT reaction. Unpurified MoO_3(grey) was also difficult to reduce and catalytically inactive when the reduction temperature was 773 K. However, when it was reduced at 873 K, the degree of reduction increased to 97.8%. An X-ray diffraction study of the reduced catalyst suggested that metallic molybdenum was formed by reduction. In this case, a mild activity in the FT reaction was found, consistent with Saito and Anderson.[7] In addition, the reduction of ammonium heptamolybdate (NH_4-Mo) was examined. NH_4-Mo was more easily reduced than MoO_3. Even at 773 K, the degree of reduction was 66%. Its catalytic activity was comparable to MoO_3 reduced at 873 K (Table 1).

HPMo. When HPMo was reduced in a hydrogen flow at 773 K, the degree of reduction was 98.1%. Apparently, the reduction of HPMo was easier than MoO_3. However, when HPMo was heated at 773 K *in vacuo* before reduction (so that the Keggin unit was destroyed), the reduction stopped at about 40%. Thus, not only the presence of phosphorus, but also the Keggin structure is required to improve the reducibility. The reduction temperature also affected the reducibility. The optimum temperature was 773 K and both higher and lower temperatures resulted in a lower degree of reduction (Fig. 1). The reduction of HPMo seems to proceed accompanied by the decomposition of the Keggin unit and at higher temperatures (when the rate of decomposition exceeds that of reduction), the reduction ceased before completion.

The reduced catalyst was submitted to X-ray diffraction analysis and only the diffraction lines of metallic molybdenum were found. By means of X-ray fluorescence, it was found that the P/Mo ratio does not change during the reduction process (Table 2). On the other hand, the IR band of the P-O bond disappeared

Specimen	P/Mo (atomic ratio)
HPMo (before reduction)	1.1/12
HPMo (after reduction)	0.9/12
NiPMo (after reaction)	1.1/12

after reduction. Nozaki *et al.*[16] reported that the formation of nickel phosphides such as Ni_3P or Ni_7P_3 was observed by the hydrogen reduction of $Ni_3(PO_4)_2$. Probably the phosphorus in HPMo is also reduced and is included in the metallic molybdenum phase.

The BET surface area after reduction was 64.7 m^2/g, which was in agreement with the particle size calculated from the X-ray line broadening (Table 1). This surface area was more than five times larger than MoO_3 (reduced at 873 K). The presence of phosphorus seems to inhibit the crystal grouth of molybdenum. As a metal powder obtained by the hydrogen reduction of an oxide at high temperatures, this metallic molybdenum has a very small particle size.

The catalytic activity of HPMo was much higher than MoO_3, owing to its large surface area. The reaction rate was even higher than for molybdenum carbide, which was reported[7] to be the most active among Mo compounds. However, the product distribution for HPMo was in agreement with that of MoO_3 (Fig. 4), suggesting that the presence of phosphorus had little effect on selectivity. The product distribution followed the Schulz-Flory distribution, with a propagation coefficient 0.44.

One of the features of the Mo catalysts (HPMo and MoO_3) compared with the group-VIII metals (such as Ru) is that the former produces CO_2 as an oxygen compound, whereas the latter forms H_2O. Another is that Ru changes the product distribution extensively with reaction temperature (Fig. 2), whereas Mo changes it only a little. As shown in Figs. 2 and 3, the selectivities of C_1—C_3 were almost constant for Mo at 483—533 K. Only the olefin/paraffin ratio changed with temperature. Such a stability in selectivity against reaction temperature is advantageous in practical operation because this reaction is exothermic and the heat of reaction tends to disturb the reaction.

We also tried to estimate the turnover frequency of this reaction over HPMo on the basis of the number of surface Mo atoms calculated from the BET surface area supposing that 1.73×10^{19} atoms are exposed per square meter.[17] The resulting turnover frequency was $2.6\times10^{-3}\ s^{-1}$ at 523 K, a value comparable to that of Ir ($2.6\times10^{-3}\ s^{-1}$ at 523 K)[18] which was the least-active metal among group-VIII elements.

Alkali Metal and Alkaline Earth Salts. HPMo has three protons per heteropolyanion which can be exchanged with various cations. We prepared three Cs salts, changing the content of Cs from 0.5 to 2 per

polyanion. The degree of reduction of $Cs_{0.5}$ and Cs_1 catalysts was 81—82%, in contrast to Cs_2 which was reduced only 52%. The activity of Cs_2 was also lower than $Cs_{0.5}$ and Cs_1, although no significant change in the product distribution was found for the Cs_1 and Cs_2 catalysts. Thus, the optimum content of an alkali metal seemed to be one cation per heteropolyanion.

The introduction of various alkali metals and alkaline earth cations into HPMo caused a decrease in the degree of reduction from 98.1% (HPMo) to 60(NaPMo)—82% (CsPMo). The catalytic activity also decreased, compared with HPMo. However, no correlation was found between the degree of reduction and activity. In order to increase the degree of reduction of KPMo, we prepared KNiPMo (which contain each one K^+ and Ni^+ per polyanion) and examined its catalytic activity. Although the degree of reduction of KNiPMo increased to 91% (compared with KPMo (74%)), the activity was lower than KPMo. Therefore, the change

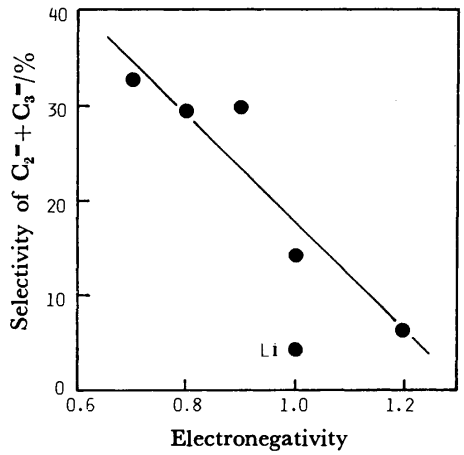

Fig. 5. Relation between electronegativity of alkali metals and alkaline earth metals and olefin selectivity over each salt of HPMo.

in the degree of reduction is not the main reason for activity loss by the introduction of K^+ and other alkali metal cations. Rather, the intrinsic interaction of cations and Mo seems to cause the effect.

The product distribution also changed with the introduction of these cations. Alkali metal salts produced less C_1 (methane) than HPMo or MoO_3 except LiPMo, which showed a product distribution similar to HPMo (Fig. 4). An increase in the C_2—C_3 selectivity was accompanied by a decrease in the C_1 selectivity. MgPMo and CaPMo showed an intermediate property between the two groups in selectivity. A sharp increase in olefin selectivity was observed for Na-, K-, and CsPMo. For CsPMo, the selectivity of the lower olefins (ethylene+propylene; $C_2^=+C_3^=$) was one order higher than that of HPMo. An increase in olefin selectivity was also observed for CaPMo, however it was only small for Li-and MgPMo. The formation of trace amounts of alcohols (mainly methanol) was found for na-, K-, and CsPMo.

Such a tendency of change in the product distribution caused by alkali metals (decrease in C_1 and increase in olefins) has also been observed for group-VIII metals such as Ru[19] and Fe.[20] As shown in Fig. 5, a correlation between the electronegativities of the cations and the olefin selectivity was found with the exception of LiPMo.

Transition Metal Salts. Various transition metal salts (Mn, Fe, Co, Ni, Cu, Zn) of HPMo were prepared and submitted to FT reactions. The amount of the bivalent cations introduced was fixed to one cation per

heteropolyanion. The activities of these catalysts were inferior to HPMo. A significant decrease in activity was observed after the introduction of Mn, Zn, and Cu. On the other hand, there was only a small decrease over Fe, Co, and Ni salts. The degree of reduction exceeded 90% (except Mn; 89%), and so the transition-metal salts appear to be easily reduced. (Especially, Fe-, Ni-, and CuPMo were almost completely reduced.) Perhaps these transition metals were reduced first and activated the hydrogen to accerelate the reduction of Mo.

A decrease in the C_1 selectivity was also observed as clearly as for the alkali metal salts. The C_1 selectivity of CoPMo (20.9%) was comparable to that of KPMo (21.0%). In the case of the alkali metal salts, the effect to suppress the C_1 selectivity was obtained at the expense of an activity loss, but Fe- and CoPMo realized the same effect with only a slight loss of activity. For Na-, K-, and CsPMo, a significant increase in the olefin selectivity was accompanied by a decrease of C_1. However, for the transition metal salt, olefin selectivity was less than half of that of the alkali metal salts even though the C_1 selectivity was in the same range. The relation between the C_1 selectivity and the olefin ($C_2^=+C_3^=$) selectivity is illustrated in Fig. 6. A clear correspondence between the two factors was observed except for Na-, K-, Cs-, and CaPMo.

If both a decrease in the C_1 selectivity and an increase in the olefin selectivity are brought about by a single driving fource (for example the electron donation from added elements to Mo), there must be a correspondence between the two selectivities. The behavior of the catalysts which fit on the curve of Fig. 3 seems to be such a case. On the other hand, Na-, K-, Cs-, and CaPMo also significantly promote olefin formation. The characteristic that distinguish these elements from others is that they have a strong common basicity. When basic sites are formed on a catalyst surface, they will abstract hydrogen from the surface alkyl group, which is formed by the surface polymerization of CH_2, and promote the formation of olefins.[19]

Mo Compounds Containing Co. In order to compare the additional effect of Co with CoPMo (which proved to be active and selective to C_2—C_3 among various heteropoly compounds) other Mo compounds containing Co were examined. Co-Mo-O (Co/Mo=1/12) was prepared by drying a mixture of aqueous solutions of cobalt nitrate and ammonium heptamolybdate. The product was calcined in air at 773 K for 5 h. X-Ray diffraction showed that it was a mixture of $CoMoO_4$ and MoO_3. $(NH_4)_3H_6[CoMo_6O_{24}]$ contains Co as a heteroatom, and is a different type of heteropoly compound from HPMo or CoPMo. We prepared it following a method described in the literature.[21]

The degree of reduction of Co-Mo-O was only 45.2%, and its activity for CO hydrogenation (conversion 1.8% at 523 K) was one order lower than CoPMo. The product distribution for Co-Mo-O was (as shown in Fig. 7) almost equal to that of HPMo or MoO_3, showing a poor addition effect of Co. Even though the ratio of Co and Mo is the same, CoPMo shows a more clear effect of Co than Co-Mo-O. This is because CoPMo (before reduction) contains Co and Mo in uniform concentrations in atomic level which results in a close interaction between the two elements after reduction. On the other hand, Co-Mo-O is a mixture of $CoMoO_4$ and MoO_3 and, thus, the ratio of Co/Mo is not uniform. Thus, the advantage of using heteropolymolybdates as the raw materials for a Mo catalysts is again suggested.

$(NH_4)_3H_6[CoMo_6O_{24}]$ is also a kind of heteropoly compound, but it was not as easily reduced as HPMo or CoPMo (the degree of reduction was 59.2%). The conversion of CO was only 5.2% at 523 K, perhaps due to the low degree of reduction. The product distribution (Fig. 7) showed the effect of Co, *i.e.* a decrease in

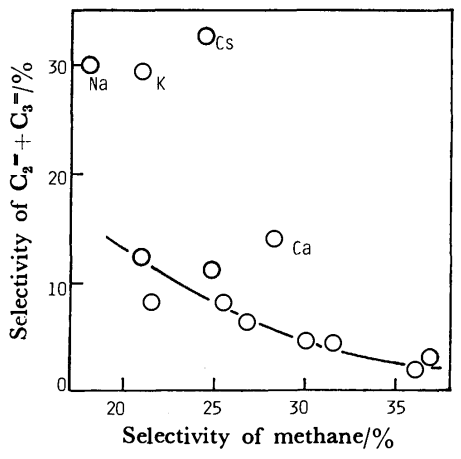

Fig. 6. Relation between methane selectivity and olefin selectivity over various salts of phosphomolybdate.

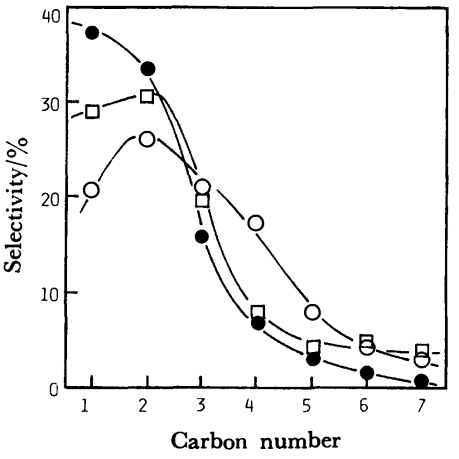

Fig. 7. Product distribution over Mo catalysts containing Co.

the selectivity of C_1. It was not as clear as the case of CoPMo. Therefore, the effect of Co is more clearly observed when Co is the counter cation rather than the heteroatom.

Conclusions

1) 12-molybdophosphoric acid is an excellent precursor of metallic molybdenum owing to its reducibility. Thus, we could get a Mo catalyst with a very large surface area. Its activity for CO hydrogenation was one order higher than the conventional Mo catalyst. It was more active than Mo_2C, which was reported to be the most active among various molybdenum compounds.

2) It is possible to introduce various cations as additives using their salts of molybdophsphoric acid, and enables us to estimate their addition effect in equivalent conditions. Alkali metal and alkaline-earth cations suppressed the activity, but improved the selectivity for C_2—C_3 hydrocarbons, especially in the olefin formation.

3) Transition metal salts were reduced as easily as HPMo but the activity was lower than HPMo. By the addition of transition metals, the selectivity of methane decreased in the same manner as for the alkali metals. However, the addition effect was not so clear on the olefin formation as the alkali metals. Correlation was found between C_1 selectivity and olefin ($C_2^=+C_3^=$) selectivity except the salts of strong base cations (Na^+, K^+, Cs^+, and Ca^+).

4) The addition of cobalt was most effective on selectivity when cobalt was introduced as the counter cation of heteropoly acid.

Microwave Spectrum and Barrier to Internal Rotation of 4-Chlorophenol

Masao ONDA,* Takashi MOTODA, and Ichiro YAMAGUCHI
Department of Chemistry, Faculty of Science and Technology, Sophia University, Tokyo 102
(Received May 30, 1984)

Microwave spectra of 4-chlorophenol were observed in the frequency ranges 8—18 and 26.5—40 GHz. Rotational constants were obtained for the ground vibrational states of three isotopic species, $^{35}ClC_6H_4OH$, $^{37}ClC_6H_4OH$, and $^{35}ClC_6H_4OD$, and for the first excited state of C-Cl out-of-plane bending mode for $^{35}ClC_6H_4OH$. All the b-type Q-branch transition lines of the OH species split into doublets, but those of the OD species do not. The separation of doublets is 158.99±0.16 MHz for the ground state of $^{35}ClC_6H_4OH$. An analysis of the doublets on the basis of the pseudo-symmetric internal rotor model gives the barrier height to the internal rotation of hydroxyl group as V_2=13.98±0.37 kJ mol^{-1} for the ^{35}Cl species. The V_2 value obtained is compared with the theoretical V_2 value calculated for 4-X-phenols (X=H, F, Cl) by means of *ab initio* MO with the 4-31G basis set.

The microwave spectrum of phenol was reported for the first time by Kojima.[1] The barrier height V_2 was determined to be 13.16±1.20 kJ mol^{-1} from the observed splitting. In his method the hydroxyl group was assumed to be a pseudo-symmetric internal rotor. Following Kojima's paper, many theoretical and experimental articles on phenol have appeared.[2-6] One of them is the article on a strict Rotation-Internal Rotation (RIR) treatment by Mathier *et al.* and a more reliable V_2 value is given.[5]

The molecule of 4-fluorophenol has the same symmetry as that of phenol with respect to the overall and internal rotations. The far IR spectra of 4-fluorophenol were analyzed with the exact RIR treatment by Larsen and Nicolaisen.[7] In this paper, we report microwave spectra of three isotopic species of 4-chlorophenol and the value of V_2 as estimated according to Kojima's approximation.[1]

Experimental

The sample was obtained commercially and distilled *in vacuo*. The deuterated species (OD) was produced by mixing the normal species with D_2O in a wave-guide cell. The content of the *d*-species thus produced was estimated to be about 30% from the intensity ratio between the same rotational transitions of the deuterated and normal species. The microwave spectrum was measured with a conventional spectrometer using 100 kHz square-wave Stark modulation. The measured frequency regions were 8—18 and 26.5—40 GHz. The microwave sources for them were a synthesizer (HP-8672A) and a YIG tuned GaAs oscillator (Watkins-Johnson 5610-302FD), respectively. Measurements were made at room temperature with sample pressures of 3—7 Pa. The accuracy of the measured frequency was better than 0.1MHz for all lines except broadened ones with hyperfine components due to chlorine nucleus.

Results and Discussion

Analysis of Spectrum. Frequencies of spectral lines were predicted from a structural model which was constructed with structural parameters transferred from chlorobenzene[8] and phenol.[9] The components of the dipole moment were estimated as μ_a=1.65 D and μ_b=1.22 D from those of the two molecules mentioned above. From these predictions it was expected that the a-type transitions would be observed strongly for this molecule. This is in contrast to the case of phenol where μ_a=0.133 D and μ_b=1.217 D.[9] The spectrum consisted of many lines in the observed region. This complexity of the spectrum comes from the existence of two chlorine isotopic species in their ground and low frequency excited vibrational states. The initial step of assignment was made for the a-type R-branch transitions which were expected to appear as singlets with the assumed barrier to internal rotation of hydroxyl group. Some of the transitions with high K_{-1} were observed as doublets due to nuclear quadrupole coupling of chlorine. For $8_{3,6}$—$7_{3,5}$, $8_{3,5}$—$7_{3,4}$, $7_{2,6}$—$6_{2,5}$, and $7_{2,5}$—$6_{2,4}$, the separations of the doublets were about 1 MHz, which is consistent with those predicted by using χ-values obtained for chlorobenzene.[10] The assigned a-type R-branch transitions are given in Tables 1 and 2.

The b-type Q-branch transitions were expected to be doublets due to the internal rotation as seen in the b-type transitions of phenol.[1] The separation of the doublets depends on the barrier height of the internal rotor. It was predicted to be 27.6 to 467 MHz for V_2=18 to 12 kJ mol^{-1}. The upper and lower components of the doublets were searched for in the frequency region, which are located at the same distances from the predicted unperturbed frequencies as calculated from the results of analysis of the a-type R-branch transitions. The observed separations of the doublets were about 159 MHz. The observed b-type Q-branch transition frequencies and their splitting widths are given in Tables 1 and 2 and Table 3, respectively. Each component of b-type Q-branch transitions listed in the tables was observed as single line despite the perturbation of quadrupole coupling.

The rotational constants were obtained by least-

squares fitting of the transition frequencies listed in Tables 1 and 2. The values derived for the parameters are given in Table 4. Satellites which formed a series of lines with decreasing intensity were observed for low K_{-1} transitions near the ground vibrational lines. The most intense satellite lines were assigned to the transitions in the first excited state as specified in Table 1. On the basis of their intensity and inertia defect, this excited state is ascribed to the out-of-plane mode with the lowest vibrational frequency, namely, the C-Cl out-of-plane bending (165 cm^{-1}).[11] A search for the lines due to the OH torsional excited state was not successful.

Barrier to Internal Rotation. The splitting in the b-type Q-branch transitions was analyzed by using the same approximation as assumed for phenol molecule; a pseudo-symmetric internal rotor was assumed for O-H group.[1] The observed splittings of the doublets were almost independent of J for each K_{-1}–K'_{-1} series as seen in Table 3. However, the observed splittings for the two series of transitions, $J_{2,J-2}$–$J_{1,J-1}$ and $J_{5,J-5}$–$J_{4,J-4}$ of $^{35}ClC_6H_4OH$ (v=0), indicate that the splitting of the doublet varies depending on the K_{-1} values. Mathier *et al.*[5] pointed out the same K_{-1} dependency for phenol and gave an empirical formula for this dependency. Their empirical formula* was applied to the present analysis of 4-chlorophenol, and a virtual value of splitting independent of K_{-1} was obtained as 158.99±0.16 MHz (Table 5).

For the evaluation of barrier height the most uncertain parameter is I_1, the moment of inertia of the

* Split/MHz=158.99(16)−0.0175(25)×(K_{-1}^2+K'_{-1}^2) for $J_{K-1,K+1}$–$J_{K'-1,K'+1}$ of 4-$^{35}ClC_6H_4OH$. The virtual splitting was obtained by means of the least-squares method using the splitting widths in Table 3.[5]

hydroxyl group about the internal rotation axis. In the present analysis the following approximation is adopted: The a-axis coincides with the internal rotation axis and the center of mass of the hydroxyl group lies on the a-axis. The first moment equation was used to calculate the I_1 value, together with using the r_s b-coordinate of hydroxyl hydrogen (0.833±0.002 Å). The values of I_1 for the two molecules coincided well with each other as shown in Table 5.

The barrier height V_2 was calculated from the parameters in Table 5 by using the perturbation coefficients given by Lin and Swalen.[12] The error for I_1 arises from the ambiguity in the b-coordinate of the hydrogen atom, ±0.01 Å, which seems to be in the maximum allowable range. The b-type Q-branch transitions for $^{35}ClC_6H_4OD$ were not observed as doublet. The splittings, if any, were smaller than 0.2 MHz because no line broadening was recognized. They were predicted to be 0.41 MHz from the V_2 value obtained. The smaller splittings than 0.2 MHz of the transitions correspond to the higher V_2 than 15 kJ mol^{-1}. This result that the V_2 value for the OD species is higher than that of the OH species, is apparently the same as those in the case of phenol and 4-fluorophenol.[7]

To compare the V_2 value of 4-chlorophenol with that of phenol, the same approximation was applied to phenol; I_1 was calculated from the r_s coordinate of hydroxyl hydrogen because I_1 was roughly estimated in Kojima's paper. The V_2 value of phenol obtained on this approximation coincides with the value based on the RIR treatment within 2% as shown in Table 5.

Campagnero and Wood[13] assumed that the barrier height of 4-X-phenols is dependent mainly on the degree of double bond character in the C-O bond; if substituent X at 4-position is a strong π donor, the double bond character will decrease and thus the barrier height will decrease.[13] Larsen and Nicolaisen[7] explained the lower barrier height of 4-fluorophenol than that of phenol by the above theory. According to their theory, our result may be taken to indicate that the ability of chlorine as a π donor is lower than that of fluorine in 4-X-phenol.

Recently, the barrier in phenol has been calculated for a fully-optimized structure based on the STO-3G basis set[14] and also based on 4-31G for a rigidly rotating structure.[15] To compare the experimentally obtained barrier heights of 4-substituted phenols with MO theoretical ones, we calculated the total energies of the molecules with standard geometry and rigidly rotating hydroxyl group by using the 4-31G basis set without geometry optimization. The benzene ring was assumed as a regular hexagon in which the C-C bond length is equal to the mean value for the r_s length in phenol, 1.3912 Å. The other assumptions adopted were that the C-O bond lies on the C_{2v} axis of the ring and that the hydroxyl group rotates about the axis rigidly. The energy difference between the planar and orthogonal structures was taken as the theoretical barrier height. The results are given in Table 6. The MO theoretical barriers in Table 6 are lower than the experimental ones. However, it is interesting to have almost a constant ratio 1.5 of the experimental to theoretical value for the three molecules.

The *ab initio* calculation was carried out at the

A Thermodynamic Study on Micellization of Nonionic Surfactant in Water and in Water-Ethanol Mixture by Gel Filtration

Ayako GOTO,* Masumi TAKEMOTO, and Fumio ENDO
Shizuoka College of Pharmacy, 2-2-1 Oshika, Shizuoka 422
(Received July 13, 1984)

Micellization of hexa(oxyethylene) dodecyl ether ($C_{12}E_6$) was studied in water and in ethanol-water mixtures at different temperatures by gel filtration on Sphacryl S-200. Standard enthalpies and entropies of micellization were determined from variation of critical micelle concentration(cmc) with temperature. Compensation plots were obtained, slopes for alcohol-water mixtures being indentical with that for pure water. Therefore, the micelle formation in water and ethanol-water mixtures has been explained in terms of its bulk structure. Gel fitration of $C_{12}E_6$ micelle with addition of a large amount of ethanol has led to a finding that the micelle size gradually becomes small with increasing ethanol content until micelles disappear above 35%v/v.

Thermodynamic studies on micellization are based on the assumption that monomer concentration is constant above cmc. However, any of the general methods, *e.g.*, the surface tension[1-3] and dye methods,[4,5] cannot verify the constancy of monomer concentration above cmc. We previously reported[6] that gel filtration of aqueous nonionic surfactant gave more reasonable cmcs than other methods, pointing out that monomer concentration became nearly constant at high concentrations of nonionic surfactant. Therefore, this method is effective for obtaining useful thermodynamic information regarding micellization.

In this research, we investigated the effect of temperature on the cmc of hexa(oxyethylene) dodecyl ether ($C_{12}E_6$) in water and in water-ethanol mixture by means of gel filtration for the purpose of elucidating thermodynamically the effect of ethanol on the micellization and the process of destruction of micelles by added ethanol.

Experimental

Materials. Hexa(oxyethylene) dodecyl ether,H-$(OCH_2CH_2)_6OC_{12}H_{25}$ ($C_{12}E_6$), was supplied from Nikko Chemical Co., Ltd. Sephacryl S-200 and Sephadex LH-60 used for gel filtration were purchased from Pharmacia Fine Chemicals. Distilled water was used after degassing *in vacuo*.

Gel Filtration. Sephacryl S-200 was mainly used because this gel hardly shrinks by added ethanol. The gel column was jacketed and maintained at a constant temperature within 0.1 °C. Tail analysis was carried out as previously reported.[6] Retention volumes of micelles (V_m) and monomer (V_f) and monomer concentration (C_f) were measured by the same method as described in our previous paper.[6]

Results and Discussion

Thermodynamic Studies on Micellization in Water. The effect of temperature (0—30 °C) on the behavior of $C_{12}E_6$ micelle in water was studied. Monomer concentrations measured on solutions in the range 4×10^{-5}—2×10^{-2} M (1 M=1 mol dm^{-3}) were plotted against total concentration (C_t) of $C_{12}E_6$ (Fig. 1). The monomer concentration increases toward a limiting concentration with increase in C_t at each temperature. The limiting concentration corresponding to cmc increases with lowering temperature. The plots, in Fig. 2, against temperature of ratio V_m/V_f obtained by gel filtration of 5×10^{-3} M $C_{12}E_6$ solution indicate that the hydrated micellar size increases with increase in temperature, in accord with Suzuki.[7] On the basis of the cmcs obtained by this tail analysis at various temperatures (Fig. 1), the standard free energy (ΔG°_m), standard enthalpy (ΔH°_m), and standard entropy (ΔS°_m) of micellization

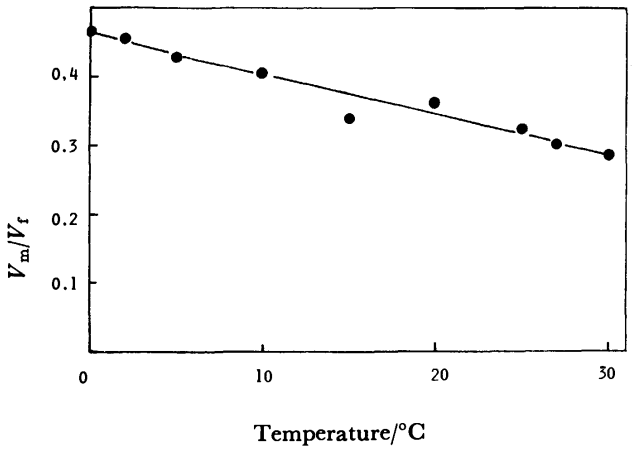

Fig. 2. Plots of V_m/V_f against Temperature.

were determined by use of the phase separation model. The standard free energy is obtained by

$$\Delta G_m^\circ \approx RT \ln \text{cmc}, \quad (1)$$

where cmc is expressed in mole fraction. The standard enthalpy of micellization can be obtained by

$$\Delta H_m^\circ = -RT^2[\mathrm{d}(\ln \text{cmc})/\mathrm{d}T]. \quad (2)$$

However, since ΔH_m° is dependent on temperature, values of ΔH_m° were obtained by fitting a quardratic function of the form[8]

$$\ln \text{cmc} = a/T^2 + b/T + c \quad (3)$$

to observed data and applying subsequently Eq. 2; values of ΔH_m° were calculated with a computer. Standard entropies of micellization were calculated from values of ΔH_m° and ΔG_m° by

$$\Delta S_m^\circ = (\Delta H_m^\circ - \Delta G_m^\circ)/T. \quad (4)$$

As shown in Table 1, the large positive entropy is responsible for the negative free energy of micellization since the enthalpy change is positive. This is caused by release of the ordered water from around the hydrocarbon chain on micellization.[14]

The Effect of Added Ethanol on Micellization. Figure 3 shows a tail analysis of aqueous $C_{12}E_6$ solution in the presence of ethanol using a column of Sephacryl S-200 at 25 °C. The retention volume of micelle and the monomer concentration increase with increase in ethanol content, indicating that the micelle becomes progressively unstable with decrease in its size. As the ethanol concentration rose to 20, 25, and 30%v/v, as shown in Fig. 4a, it became difficult to observe the presence of micelles from the tail part of $C_{12}E_6$ elution curve. Based on the finding from the elution curves of propyl *p*-hydroxybenzoate that the propyl ester is solubilized into $C_{12}E_6$ micelle in water,[9] a similar analysis was made on the system of $C_{12}E_6$-propyl *p*-hydroxybenzoate in ethanol-water mixtures (Fig. 5). The result suggested that micelles might be present even in 30%v/v ethanol. However, since Sephacryl S-200 can be used only for fractionation of substances with molecular weights 5000—250000, it seems difficult to distinguish clearly between micelles and monomer in higher concentrations than 30%v/v ethanol. When Sephadex LH gel was used (Fig. 4b) which can fractionate substances with molecular weights ranging from 500 to 10000 and is less influenced by organic additive, it could differentiate clearly the micelle and monomer even in 30%v/v ethanol. However, it seems likely that micelles are scarcely present above 35%v/v ethanol. The above results directly

demonstrated that no micelles having a limiting size disappear suddenly with increasing ethanol content, whereas the micelle size becomes gradually small with micelles slowly disappearing. Deguchi *et al.*[10] assumed on the basis of charge-transfer interaction that the concentration of ethanol required for the destruction of $C_{12}E_7$ micelle is in the range 30—35%v/v, in consistency with the present result.

Figure 6 is a plot of C_f obtained by the gel filtration on Sephacryl S-200 against C_t at 2, 5, 10, and 15% v/v at 25 °C. Since the value of C_f increased toward a limiting concentration with increase in C_t at each ethanol content, it was also possible in the presence of ethanol to estimate cmc and to discuss the micellization thermodynamically. A general expression[11] for the solvent effect on nonionic surfactant micelle formation is

$$RT \ln [\mathrm{cmc}]/[\mathrm{cmc}]_0 = -(\mu_2^{s\circ} - \mu_2^{s\circ\prime}) + RT \ln X + RT \ln f, \quad (5)$$

where $[\mathrm{cmc}]_0$ is the cmc without organic additive, $\mu_2^{s\circ}$ and $\mu_2^{s\circ\prime}$ are the standard chemical potentials of the surfactant in bulk solutions of water and water-organic additive mixture, respectively, and X and f are the mole fraction and the activity coefficient of surfactant in the mixed micelle, respectively, both of which become unity when the solvent is pure water. The cmc-lowering effect of a solubilizate is explained in terms of mixed entropy and the reduction of activity on adding solubilizates.[11,12] If the organic additive is not solubilized into the micellar phase, the solvent effect on micellization may be due mainly to the contribution of $-(\mu_2^{s\circ} - \mu_2^{s\circ\prime})$. In this experiment, $\ln[\mathrm{cmc}]/[\mathrm{cmc}]_0$ increased with in-

creasing ethanol content at room temperature and hardly varied with ethanol content at low temperatures (Fig. 7). Therefore, the cmc-increasing effect of ethanol at room temperature is attributable to the increasing solvent power of these alcohol-water mixtures. It is of interest that the added ethanol hardly affects the micellization at low temperatures. This phenomenon may be explained as follows: the cmc-increasing effect attributable to the increasing solvent power of water-alcohol mixture would be compensated by the cmc-decreasing effect resulting from the solubilization of ethanol into $C_{12}E_6$ micelle. However, Nishikido *et al.*[13] reported that the solubilization of ethanol in nonionic micelle was negligible. We also investigated this system thermodynamically. Table 2 shows ΔG_m°, ΔH_m°, and ΔS_m° for the micellization in ethanol-water mixtures. The added ethanol caused a decrease in ΔH_m° and the micelle formation became exothermic in the neighborhood of room temperature as the content of ethanol increased (Table 2), while the micelle formation in water was endothermic as shown in Table 1. The entropy of micellization which has a large positive value in water, became small as the ethanol content increased (Table 2). Therefore, the cmc-increasing effect of ethanol at room temperature is ascribed to the weakness of the hydrophobic bond.[14] However, at low temperatures, the micellization in the presence of ethanol is responsible for the positive entropy. This indicates that the added ethanol might hardly destroy the structure of water at low temperatures.

Linear correlation between enthalpy and entropy changes has been observed for solution processes in aqueous media. This correlation is called the compensation phenomenon.[15-18] According to Lumry[15] the slope of compensation line has the dimension of temperature, T_c, in the range 220—290 K in

TABLE 3. T_c VALUES FOR MICELLIZATION IN DIFFERENT SYSTEMS

aqueous media. Krishnan and Friedman[18] suggested that the entropy-enthalpy compensation was also observed in hydrophobic interactions. Sigh *et al.*[8] and Aoki *et al.*[19] found that their compensation plots obtained for the micellization of ionic surfactants in aqueous media were in accordance with Lumry's law.[15] Figure 8 shows compensation plots for nonionic surfactant micelle in water and in alcohol-water mixture. The compensation temperature of $C_{12}E_6$ micelle in water is 284 K, equal to that of ionic surfactant.[8] The compensation temperatures for alcohol-water mixtures are also in fair agreement with Lumry's law[15] (Table 3). Therefore, it is assumed that the micellization of $C_{12}E_6$ in water is related closely to the bulk structural property and proceeds even in the presence of ethanol essentially in a process similar to that in water.

The Conformers of 2,2′-Bipyridine in the Phosphorescent Triplet State as Studied by Electron Spin Resonance and Phosphorescence

Mikio YAGI,* Kazuhiro MAKIGUCHI, Atsushi OHNUKI, Kazuhiro SUZUKI, Jiro HIGUCHI, and Shigeru NAGASE†

Department of Chemistry, Faculty of Engineering, Yokohama National University, Tokiwadai, Hodogaya-ku, Yokohama 240

†*Department of Chemistry, Faculty of Education, Yokohama National University, Tokiwadai, Hodogaya-ku, Yokohama 240*

(Received July 19, 1984)

Two sets of triplet-state ESR spectra corresponding to the *s-cis* and *s-trans* conformers of 2,2′-bipyridine have been observed in mixtures of water with various alcohols at 77K. The intensity ratio of the ESR signal for the *s-cis* conformer to that for the *s-trans* conformer depends on the composition of the mixture and on the sample-cooling rate. From the analysis of the phosphorescence spectra, the lowest triplet state of the *s-cis* conformer is estimated to be close to that of the *s-trans* conformer. An anomalous ESR signal which cannot be ascribed to either the *s-cis* conformer or the *s-trans* conformer has been observed in a 1-propanol-water mixture. The geometries of these conformers are discussed from their observed zero-field splitting parameters, together with their potential energy diagrams, as obtained by an *ab initio* calculation.

2,2′-Bipyridine (BPY) is a typical chelating agent for metal ions. The photophysics and photochemistry of complexes of BPY are under active investigation, with particular interest being taken in their application to solar-energy-conversion schemes. The *s-cis* and *s-trans* conformations are possible in BPY, as is shown in Fig. 1. The ground-state molecule has the *s-trans* conformation in solutions[1-3] or in the crystalline state.[4] The excited-state molecule also has the *s-trans* conformation in rigid solutions at low temperatures.[5] Although the *s-cis* conformer of free BPY was not observed until a few years ago, the chelated *s-cis* conformer undoubtedly exists in the metal-chelate compounds of BPY.[6-8]

Recently, we have succeeded, by using a poly(vinyl alcohol) (PVA) film as a host, in finding two sets of ESR spectra originating from the *s-cis* and *s-trans* conformers in the phosphorescent triplet states.[9,10] In rigid solutions, however, the triplet state BPY has for many years been considered to be in the *s-trans* conformation. In the present work, we have observed two sets of triplet-state ESR spectra of free BPY using mixtures of water with various alcohols (methanol, 1-propanol, 2-propanol, ethylene glycol, 1,2-propanediol, 1,3-propanediol, and glycerol) as rigid solvents.

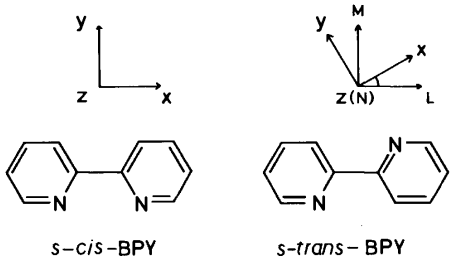

Fig. 1. Molecular structures and coordinate systems chosen for *s-cis*- and *s-trans*-2,2′-bipyridines.

The magnetic fine structure in an external magnetic field $\boldsymbol{B}$ can be described by the spin Hamiltonian:

$$\begin{aligned}\mathscr{H} &= g\mu_B \boldsymbol{B}\cdot\boldsymbol{S} + \boldsymbol{S}\cdot\boldsymbol{D}\cdot\boldsymbol{S} \\ &= g\mu_B \boldsymbol{B}\cdot\boldsymbol{S} - XS_x^2 - YS_y^2 - ZS_z^2 \\ &= g\mu_B \boldsymbol{B}\cdot\boldsymbol{S} + D[S_z^2 - (1/3)\boldsymbol{S}^2] + E(S_x^2 - S_y^2).\end{aligned}$$

Here, D is the zero-field splitting (ZFS) tensor with principal values of $-X$, $-Y$, and $-Z$, and D and E are the ZFS parameters. In the present work, the anisotropy of the g-tensor was neglected. Assuming a planar structure of the molecule in the phosphorescent triplet state, the coordinate axes were taken to be as shown in Fig. 1. For *s-cis*-BPY with the C_{2v} symmetry, the x axis is taken to be parallel to the central carbon-carbon bond which connects the two pyridine rings (hereafter, we will refer to such a direction as L), while for *s-trans*-BPY with the C_{2h} symmetry, the x axis should not be parallel to the direction L. Using such a difference in the direction of the principal axes of the ZFS tensor relative to the molecular axes, the two sets of X and Y peaks observed in the stretched PVA film were assigned as is shown in Fig. 2c.[10]

Experimental

The 2,2′-bipyridine (Aldrich) was purified by sublimation *in vacuo*. 1-Propanol (Tokyo Kasei G. R. Grade) was purified by distillation. The methanol (Dotite Spectrosol), 2-propanol (Dotite Spectrosol), ethylene glycol (Tokyo Kasei G. R. Grade), 1,2-propanediol (Tokyo Kasei G. R. Grade), 1,3-propanediol (Tokyo Kasei E. P. Grade), and glycerol (Wako Spectrosol) were used without further purification. The solvent mixtures were checked for the absence of an extraneous ESR signal prior to use. The solutions of BPY were prepared at the concentration of 3×10^{-3} mol dm^{-3}.

For the ESR measurements, the excitations were carried out using a Canrad-Hanovia 1 kW Xe-Hg lamp through a Toshiba UV-D33S glass filter, 5 cm of distilled water, and a Copal DC-495 electromechanical shutter. The decays of the ESR signals were measured by using a 1024-channel Kawasaki Electronica TM-1610S signal-averager system. The details of the ESR measurements were essentially the same as those reported previously.[10]

For the phosphorescence measurements, the excitations were done by the use of an Ushio USH-500D 500W mercury-arc lamp equipped with the glass filter mentioned above. The emissions from a sample were passed through a Jobin-Yvon HR-1000 monochromator and detected by means of a Hamamatsu Photonics R453 photomultiplier tube. All the measurements were carried out at 77K.

Results and Discussion

The ESR spectra of the phosphorescent triplet state of BPY were measured in ethanol and methanol-water (MeOH-H_2O) mixtures at 77K. The observed ESR spectra of the low-field $\Delta m_S=1$ transitions are shown in Fig. 2. For comparison, Fig. 2c shows the ESR spectrum observed in a stretched PVA film when the applied magnetic field $\boldsymbol{B}$ is parallel to the stretched direction s.

In the MeOH-H_2O mixtures, two sets of X and Y peaks and one set of Z peaks were observed, while in the ethanol solution only one set of X, Y, and Z peaks was observed. The X and Y peaks which can not be observed in the ethanol solution can reasonably be assigned to the *s-cis* conformer, for their resonance fields are almost the same as those for the *s-cis* conformer observed in the stretched PVA film. The ZFS parameters obtained are listed in Table 1.

The X and Y peaks assigned to the *s-cis* conformer of free BPY should not be attributed to signals from the complex with Zn^{2+}, which results from the contamination of polar solvents with traces of Zn^{2+}. The reasons for this assignment are as follows: (1) The ZFS parameters of the *s-cis* conformer are different from those of the Zn^{2+} complex, as is shown in Table 1; (2) the observed phosphorescence lifetime of the *s-cis* conformer in MeOH-H_2O (4:1 by volume) at 77K is 0.97s, while that of the Zn^{2+} complex is 1.16 s in the same solvent at the same temperature; (3) the intensity ratio of X peaks for the *s-cis* conformer to those for the *s-trans* conformer decreases as the MeOH content increases above 35wt% of MeOH, as is shown in Fig. 3. The last phenomenon suggests that the two sets of ESR

a) Obtained from the observed resonance field of the $\Delta m_S=2$ transition with Kottis-Lefebvre's correction.[22] b) Obtained from X and Y by using the $X+Y+Z=0$ relation. c) MeOH-H_2O (4:1 by volume). d) *n*-PrOH-H_2O (35wt% of *n*-PrOH). e) Solutions of the complexes were prepared by the addition of $Zn(NO_3)_2$ (3×10^{-2} mol dm^{-3}) and free BPY (3×10^{-3} mol dm^{-3}) to the MeOH-H_2O (4:1 by volume) solution.

spectra should not be attributed to the formation of aggregates of BPY in MeOH-H_2O mixtures.

The intensities of the X peaks for the *s-cis* and *s-trans* conformers, $I_X(c)$ and $I_X(t)$ respectively, were measured as a function of the weight percentage of MeOH. The results are shown in Fig. 3. The $I_X(c)/\{I_X(c)+I_X(t)\}$ value increases with an increase in the amount of MeOH and gives a maximum at about 35wt% of MeOH.

In 1-propanol-water (*n*-PrOH-H_2O) mixtures, the situation is more complex. As is shown in Fig. 3, only one set of ESR signals corresponding to the *s-trans* conformer was observed in the *n*-PrOH-H_2O mixtures below 22wt% of *n*-PrOH. In the range from 23 to 29wt% of *n*-PrOH, the relative intensity of the X peaks for the *s-cis* conformer to those for the *s-trans* conformer increases with an increase in the amount of *n*-PrOH. In the range from 32 to 36wt% of *n*-PrOH, only one set of X peaks corresponding to the *s-cis* conformer was observed. As can clearly be seen in Fig. 3, there is a distinct discontinuity at 37wt% of *n*-PrOH. In the range from 38 to 100wt% of *n*-PrOH, only one set of the *s-trans* conformer signals was observed. At present we can not find the reason for the discontinuity observed at 37wt% of *n*-PrOH. However, it should be noted that, at 37wt% of *n*-PrOH, the mixed solvent forms a clear glass with a low cracking frequency and that the $\Delta m_S=1$ signals are too weak to be observed because of the very fast photochemical decomposition.

In *n*-PrOH-H_2O mixtures, the intensity ratio of the ESR signal for the *s-cis* conformer to that for the *s-trans* conformer depends on the sample-cooling rate. The results presented above were obtained with rapidly frozen samples. The sample-cooling rate was controlled by changing the penetration rate of a quartz sample tube (5 mm o.d.) into liquid nitrogen. In this experiment, the penetration rate could be changed between 2.5 and 300mm/min. In mixtures of 35wt% of *n*-PrOH, only one set of the *s-cis*-conformer signals was observed from rapidly frozen samples, while only one set of the *s-trans*-conformer signals was observed from slowly frozen samples. As is shown in Fig. 4c, two sets of the ESR signals which are not ascribed to the *s-cis* or *s-trans* conformer were observed for the samples precooled in the following manner: The bottom of the sample tube was placed in contact with the surface of liquid nitrogen for at least 10 min and then immersed in liquid nitrogen. The conformer which gives the relatively strong ESR signals at 260.1 and 270.8 mT will hereafter be denoted as the *A* conformer, while the conformer which gives the weak ESR signal at 265.7 mT will hereafter be denoted as the *B* conformer. On the other hand, the ESR signal at about 212 mT is broad and shows no structure. Although the conformation of the *A* conformer seems to be unclear, the ZFS pattern for this conformer may be assumed to be the same as those for the *s-cis* and *s-trans* conformers. The ZFS parameters thus obtained are listed in Table 1. The ZFS parameters of the *B* conformer was difficult to obtain because of its weak ESR signals. The phosphorescence lifetimes obtained from the decay of the ESR $\Delta m_S=1$ transition signal are also listed in Table 1. It is difficult to separate the observed ESR spectra into four component spectra by using a time-resolved technique because they have almost the same phosphorescence lifetime.

The *D* values of the *s-cis* and *s-trans* conformers are nearly the same, while that of the *A* conformer is smaller than those of these conformers. So long as the simple LCAO-MO's are used for the evaluation of spin distribution, however, one may roughly infer that the *D* values of the planar *s-cis* and *s-trans* conformers are nearly the same, this is in accord with the experimental results.[10] On the other hand, a preliminary π electron calculation made in our laboratory suggests that the *D* value of biphenyl becomes smaller by twisting

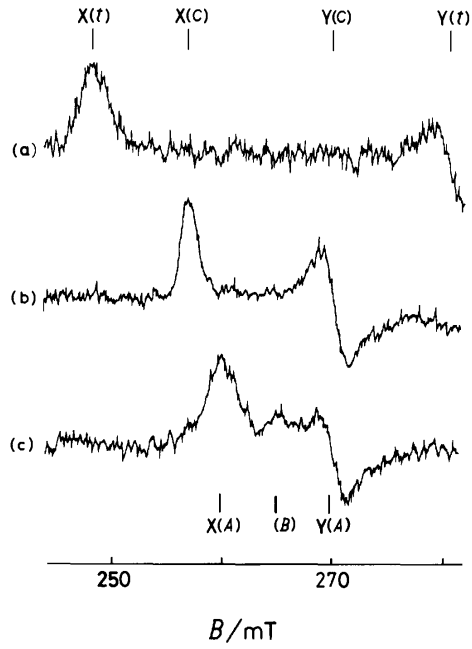

Fig. 4. ESR spectra of the low-field $\Delta m_S=1$ transitions for the phosphorescent triplet state of 2,2-bipyridine in *n*-PrOH–H_2O (35wt % of *n*-PrOH) at 77K. (a): For the slowly frozen sample, (b): for the rapidly frozen sample, (c): for the precooled sample.

around the inter-ring bond. As a result, it may be deduced that the *A* conformer has a nonplanar triplet state. In order to discuss the conformations of the lower electronic states more thoroughly, an *ab initio* calculation with a STO-3G basis set[11] was carried out for BPY, changing its inter-ring angle. At first, the optimized geometries of planar *s-cis*- and *s-trans*-BPY, with symmetries of C_{2v} and C_{2h} respectively, were determined by using the energy-gradient method.[12] The bond lengths and the bond angles thus obtained are shown in Fig. 5. When the geometry of each pyridine ring is maintained the same as in the *s-trans*-BPY, as given in Fig. 5, the SCF-MO's of the lowest-energy state were calculated by rotating the pyridine rings around the central single bond, C_2–$C_{2'}$. Using these SCF-MO's, the excitation energies of the lower electronic states were evaluated, including interactions among configurations which arise from one of the six highest occupied MO's to one of the four lowest unoccupied MO's in the ground state. The potential energy diagrams of BPY thus obtained are shown in Fig. 6.

The energy curve of the ground state (^{1}A) shown in Fig. 6 is nearly the same as that reported by Agresti *et al.*, in which the geometry of each pyridine ring was the same as the experimental one of *s-trans*-BPY.[13,14] In the present SCF-MO calculation, the geometry-optimized energy of the planar *s-cis* conformer obtained is 0.277 eV high in energy compared with that of the *s-trans* conformer. Therefore, the energy of the ground state near $\theta=180°$ can be expected to be lowered somewhat compared with that shown in Fig. 6. The lowest triplet state (^{3}B) is most stable at $\theta=0°$, and its energy curve is, in general, similar to that of biphenyl as obtained semiempirically by Imamura and Hoffmann.[15] On the other hand, the highest and the second highest occupied orbitals, and also the lowest and the second lowest unoccupied orbitals in the ground state, both degenerate at an angle of twist near $\theta=90°$. In this region, therefore, the second excited triplet state (^{3}A) is most stable and is located close to the lowest triplet state (^{3}B), as is shown in Fig. 6. As a result, the spin distributions and the ZFS parameters of these states may not differ much from each other

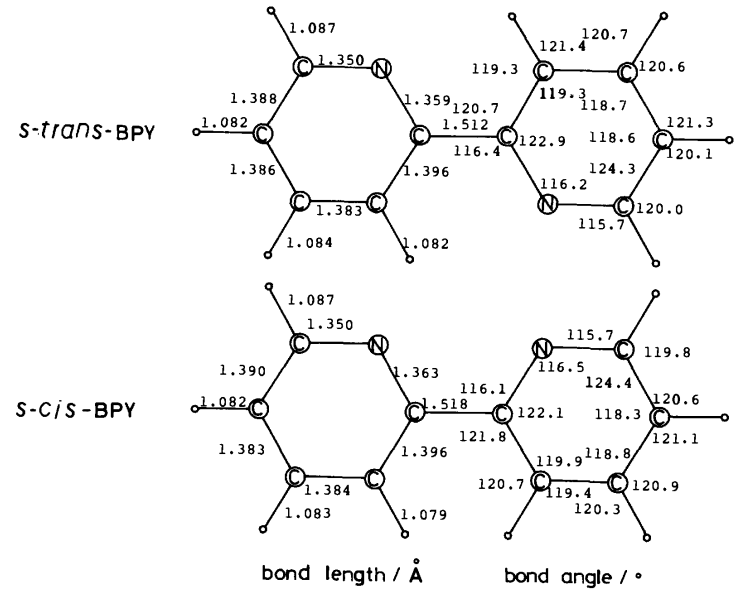

Fig. 5. Optimized geometries of *s-cis*- and *s-trans*-2,2'-bipyridines.

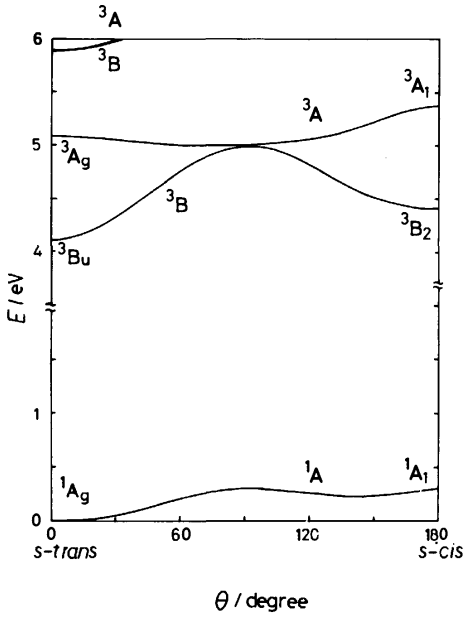

Fig. 6. Potential energy diagrams of 2,2'-bipyridine as a function of the angle of twist θ between the pyridine rings.

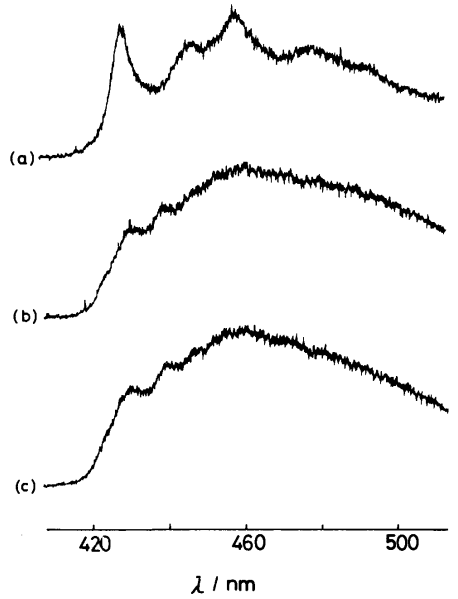

Fig. 7. Phosphorescence spectra of 2,2'-bipyridine in *n*-PrOH–H_2O (35wt % of *n*-PrOH) at 77K. (a): For the slowly frozen sample, (b): for the rapidly frozen sample, (c): for the precooled sample.

near θ=90°. Such a tendency may not be essentially changed if the approximations adopted are improved. Although the *A* conformer is most probably the nonplanar ^{3}B state, there remains another possibility that the *A* or *B* conformer is the ^{3}A state, if this state becomes the lowest excited triplet state near θ=90° under the influence of the medium. In the present work, however, a more detailed calculation of the triplet-state geometry with the intermolecular interaction was not carried out.

The phosphorescence spectra of BPY were measured in *n*-PrOH–H_2O (35wt% of *n*-PrOH) when the samples were cooled under the same conditions as in the ESR measurements. The results are shown in Fig. 7. When those results are compared with those of the ESR measurements, the phosphorescence spectra shown in Figs. 7a, 7b, and 7c may be interpreted as due to the *s-trans*, *s-cis*, and *A* and *B* conformers respectively. The phosphorescence spectrum shown in Fig. 7a is similar to that observed in ethanol at 90K.[16] The phosphorescence spectra of the *A* and *B* conformers (Fig. 7c) are almost the same as that of the *s-cis* conformer (Fig. 7b). The lineshape of the phosphorescence spectrum of the *s-trans* conformer is sharper than that of the *s-cis* conformer, while the lineshape of the ESR spectrum of the *s-trans* conformer is broader than that of the *s-cis* conformer. Although the phosphorescence spectra of the *s-cis*, *A*, and *B* conformers can not be exactly observed because of their broadness, the lowest triplet states of these conformers are estimated to be close to that of the *s-trans* conformer, 23400 cm^{-1}.

The ESR spectra of the *s-cis* and *s-trans* conformers were measured in MeOH–H_2O (4:1 by volume) with

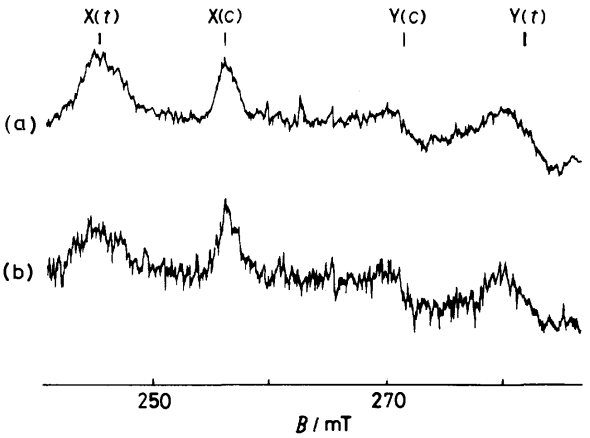

Fig. 8. ESR spectra of the low-field $\Delta m_S = 1$ transitions for the phosphorescent triplet state of 2,2'-bipyridine in MeOH–H_2O (4 : 1 by volume). (a): With A-type excitation, (b): with B-type excitation.

various filter combinations: A-type excitation, Toshiba UV-D33S glass filter; B-type excitation, Toshiba UV-D33S and UV-31 glass filters to cut off the short-wavelength region and obtain a transmission of 40% at 310 nm. The results are shown in Fig. 8. The intensity of the ESR signal of the *s-cis* conformer relative to that of the *s-trans* conformer increases under lower-energy excitation (B-type excitation). Therefore, the *s-cis* conformer has an absorption at a longer wavelength region than the *s-trans* conformer. This is in accord with the fact that the absorption of BPY coordinated to Zn^{2+} is shifted to a longer wavelength region than that of

free *s-trans*-BPY.[7]

Two sets of ESR spectra corresponding to *s-cis*- and *s-trans*-BPY's were observed in mixtures of water with 2-propanol, ethylene glycol, 1.2-propanediol, 1,3-propanediol, or glycerol, as well as with methanol or 1-propanol. The triplet-state BPY, which has for many years been considered to be in the *s-trans* conformation in rigid solutions, can easily be trapped in the *s-cis* conformation by the interactions between BPY and the solvent molecules in mixtures of water with various alcohols.

On the other hand, only one set of ESR spectra corresponding to *s-trans*-BPY has been observed in ethanol and in ethanol–water mixtures. Ethanol is generally used as a matrix for isolating free radicals or excited molecules. It is particularly interesting that ethanol acts as an exceptional solvent on the conformation of BPY. The reason for the unexpected behavior of ethanol could not be found in the present work. However, it should be noted that two sets of triplet-state ESR spectra have been observed with steric interactions for 2,2′- and 3,3′-dimethylbiphenyls in neat ethanol solutions at 77K.[17]

The heat-capacity measurements by Suga and Seki suggest that a rapid cooling of liquid ethanol yields the glassy liquid, but a slow cooling of the liquid yields a crystalline phase.[18,19] The dependence of the sample-cooling rate on the stable conformation of BPY observed in *n*-PrOH–H_2O may be related to the structures of the rigid solutions. We would expect that the use of a semirigid molecule like BPY as a probe would contribute to a deeper understanding of the molecular aspect of the rigid solution.

The calculation of geometry optimization was carried out at The Computer Center of The Institute for Molecular Science, using the IMSPAK,[20] while that of the configuration interaction was done at The Computer Centre of The University of Tokyo, using the GSCF2.[21] The authors wish to thank Dr. Nobuhiro Kosugi, Department of Chemistry, The University of Tokyo, for his kind advice in the use of the GSCF2. The present work was partially supported by Grand-in Aid for Scientific Research No. 57470004 and No. 58740213 from the Ministry of Education, Science and Culture.

Optically Active (2-Aminoethyl)methylphenylarsine and (2-Aminoethyl)butylphenylarsine and Their Palladium(II) and Platinum(II) Complexes

Yoshiro SHIGETOMI, Masaaki KOJIMA, and Junnosuke FUJITA*
Department of Chemistry, Faculty of Science, Nagoya University, Nagoya 464
(Received August 28, 1984)

The chiral bidentate ligands, (2-aminoethyl)methylphenylarsine (mpan) and (2-aminoethyl)butylphenylarsine (bpan) were prepared and resolved by preparing their palladium(II) complexes containing, respectively, (*R*)-*N*,*N*-dimethyl-1-(2-naphthyl)ethylamine and (*S*)-*N*,*N*-dimethyl-α-methylbenzylamine. The optically actaive free arsine ligands can be readily liberated from the palladium(II) complexes, and complexes of the type, $[M^{II}X_2L]$ (M^{II}=Pd, Pt; X=Cl, Br, I; L= *R*-mpan, *S*-bpan) were prepared. The absorption and circular dichroism (CD) spectra of these and related complexes were recorded, and the absolute configurations of the arsenic atoms were assigned by comparing the CD spectra with those of analogous phosphine complexes. The optically active arsines in diethyl ether solution racemize by the addition of hydrochloric acid at room temperature, but their palladium(II) complexes in acetonitrile–ethanol solution containing hydrochloric acid are very optically stable and do not racemize by refluxing for a long time.

Otsuka *et al.* resolved chiral tertiary phosphines by fractional crystallization of their diastereomeric palladium(II) complexes containing optically active ortho-metallated *N*,*N*-dimethyl-α-methylbenzylamine or its analogs.[1,2] This method has been successfully applied to the resolution of bidentate chiral phosphines[3–6] and arsines.[5–8] The bidentate arsine ligands so far resolved, however, have a rigid framework such as *o*-phenylene[6–8] and quinolyl groups,[5] and no sterically flexible one such as (aminoalkyl)arsines has been reported, although several optically active metal complexes containing a flexible, linear quadridentate tetraarsine having two chiral arsenic donor atoms have been isolated.[9] We have succeeded in resolving (2-aminoethyl)methylphenylarsine (mpan) and (2-aminoethyl)butylphenylarsine (bpan) by use of $(-)_{589}$-di-μ-chloro-bis[(*R*)-*N*,*N*-dimethyl-1-(2-naphthyl)ethylamine-3*C*,*N*]dipalladium(II) and $(+)_{589}$-di-μ-chloro-bis[(*S*)-*N*,*N*-dimethyl-α-methylbenzylamine-2*C*,*N*]dipalladium(II), respectively. In this paper, we describe the preparation of these optically active arsines and their metal complexes of the type, $[M^{II}X_2L]$ (M^{II}=Pd, Pt; X=Cl, Br, I; L=mpan, bpan) as well as the analogous (2-aminoethyl)diphenylarsine (dpan) complexes, absorption and circular dichroism (CD) spectra of these complexes, and the absolute configurations and racemization of the chiral arsenic atoms.

Experimental

Free (aminoalkyl)arsines were handled under a nitrogen atmosphere until they formed air-stable palladium(II) and platinum(II) complexes. Tetrahydrofuran was dried with sodium and deoxygenated by distillation in a stream of nitrogen. Absorption, CD, and ^{1}H NMR spectra were recorded on a Hitachi 323 spectrophotometer, a JASCO J-40CS spectropolarimeter, and a JEOL JNM PMX 60 spectrometer, respectively. Optical rotations at 589 nm were measured with a JASCO DIP-4 polarimeter.

Diphenylarsine. Diphenylarsine was prepared by the method of Aquiar and Archibald,[10] and distilled under reduced pressure, bp 103—104 °C (133 Pa) (lit,[11] 87—90 °C (33 Pa)). ^{1}H NMR ($CDCl_3$) δ=4.97 (1H, s, AsH) and 7.13—7.76 (10H, m, C_6H_5).

(2-Aminoethyl)diphenylarsine, dpan. This compound was prepared by a method similar to that for (2-aminoethyl)diphenyl phosphine.[12,13] To a stirred solution of diphenylarsine (15.2 g, 66 mmol) in tetrahydrofuran (300 cm^3) was added a 15% (w/w) solution of butyllithium in hexane (45 cm^3, 73 mmol) over a period of 30 min at room temperature. After 1 h, aziridine (4.5 cm^3, 87 mmol) was added to the solution at 0 °C over a 15 min period. The mixture was heated at 50 °C for 1 h, then refluxed for 6 h, and allowed to stir at room temperature for 12 h. To the resulting brown solution was added deoxygenated water (2.5 cm^3), and after a while anhydrous sodium sulfate to remove excess water. After a few hours, the desiccant was filtered off, the solvent was removed by distillation, and the residual oil was distilled *in vacuo* to give (2-aminoethyl)diphenylarsine as a pale yellow viscous oil, bp 151—153 °C (133 Pa) (lit,[13] 140 °C (53 Pa)). Yield: 12.6 g (70%), ^{1}H NMR ($CDCl_3$) δ=1.25 (2H, s, NH_2), 2.15 (2H, t, $AsCH_2$), 2.91 (2H, t, NCH_2), and 7.17—7.77 (10H, m, C_6H_5).

(2-Aminoethyl)methylphenylarsine, mpan. Small pieces of sodium (2.4 g, 0.10 mol) were dissolved in liquid ammonia (150 cm^3). To this deep blue solution dpan (14.3 g, 5.2 mmol) was added with stirring. After 3 h, methyl iodide (18.2 g, 0.13 mol) was added to the resulting deep red solution, the color of which turning orange. Liquid ammonia was evaporated, and the residue was shaken with deoxygenated water–diethyl ether (60 cm^3–60 cm^3). The ethereal layer was separated and dried with anhydrous sodium sulfate. The desiccant was filtered off, the ether evaporated, and the residue was distilled at 95—98 °C and 133 Pa to give a colorless liquid. Yield: 7.0 g (63%). ^{1}H NMR ($CDCl_3$) δ=1.07 (2H, s, NH_2), 1.20 (3H, s, $AsCH_3$), 1.81 (2H, t, $AsCH_2$), 2.82 (2H, t, NCH_2), and 7.18—7.75 (5H, m, C_6H_5).

(2-Aminoethyl)butylphenylarsine, bpan. This compound was prepared by the same method as for mpan except that butyl bromide was used instead of methyl iodide. Bp 105—107 °C (133 Pa). Yield: 40%. ^{1}H NMR ($CDCl_3$)

δ=0.88 (3H, t, butylic CH_3), 1.1—1.8 (m, butylic $-CH_2-$), 1.23 (s, NH_2), 1.87 (t, $AsCH_2$), 2.87 (2H, t, NCH_2), and 7.23-7.77 (5H, m, C_6H_5).

The Diastereomers of [(R)-N,N-Dimethyl-1-(2-naphthyl)ethylamine-3C,N][(2-aminoethyl)methylphenylarsine]palladium(II) Complex, 1a and 1b. To a solution of $(-)_{589}$-di-μ-chloro-bis[(*R*)-*N*,*N*-dimethyl-1-(2-naphthyl)ethylamine-3*C*,*N*]dipalladium(II)[2] (2.04 g, 3.00 mmol) in benzene–methanol (10 cm^3–2 cm^3) was added a solution of mpan (1.28 g, 6.06 mmol) in benzene (3 cm^3). The mixture was stirred for 2 h at room temperature and then evaporated at 35 °C under reduced pressure until a small amount of white precipitate began to form. The precipitate was dissolved by heating at 45 °C, and the solution was allowed to stand overnight to yield colorless crystals. They were collected by filtration and recrystallized from methanol by adding benzene. No change in the $\Delta\varepsilon$ value was observed by repeated recrystallization. Yield (**1a**): 1.08 g. Found: C, 52.08; H, 5.82; N, 4.42%. Calcd for $PdC_{26.5}H_{35}N_2AsClO_{0.5}$=[Pd{(*R*)-$C_{10}H_6CH(CH_3)N(CH_3)_2$}(*R*-mpan)]Cl·1/2$CH_3OH$·1/2$C_6H_6$: C, 52.49; H, 5.82; N, 4.62%. $[\alpha]_{589}^{23}$ +135° (c 0.16, CH_3OH). Mp 175—179 °C. ^1H NMR ($CDCl_3$) δ=1.81 (3H, d, C-CH_3), 1.96 (3H, s, As-CH_3), 2.1—2.8 (4H, m, $-CH_2-$), 3.06 (6H, s, N-CH_3), 3.48 (1.5H, s, $C\underline{H}_3OH$), 3.93 (1H, q. -$\underline{C}H$-), 5.20 (2H, broad s, NH_2), and 7.2—8.1 (14H, m, $C_{10}H_6$, C_6H_5, and C_6H_6).

The mother liquor was evaporated to a volume of *ca.* 10 cm^3, and an aqueous solution (2 cm^3) of ammonium hexafluorophosphate (*ca.* 70 mg) was added to form a white precipitate. The mixture was heated at 50 °C and methanol was added dropwise until the precipitate dissolved completely. The solution was then allowed to stand at room temperature to yield a white powder. It was collected and recrystallized from methanol by adding benzene. Yield (**1b**): 0.69 g. Found: C, 42.74; H, 4.79; N, 3.67%. Calcd for $PdC_{23}H_{30}N_2AsPF_6$=[Pd{(*R*)-$C_{10}H_6CH(CH_3)N(CH_3)_2$}(*S*-mpan)]$PF_6$: C, 41.81; H, 4.58; N, 4.24%. $[\alpha]_{589}^{23}$ −229° (c 0.095, CH_3OH). Mp 208—211 °C (dec). ^1H NMR (CD_2Cl_2) δ=2.00 (3H, s, As-CH_3), 1.72 (3H, d, C-CH_3), 2.1—2.6 (4H, m, $-CH_2-$), 2.73 (3H, s, N-CH_3), 2.90 (3H, s, N-CH_3), 3.16 (2H, broad s, NH_2), 4.13 (1H, q, -$\underline{C}H$-), and 7.1—8.1 (11H, m, C_6H_5 and $C_{10}H_6$).

The Diastereomers of [(S)-N,N-Dimethyl-α-methylbenzylamine-2C,N][(2-aminoethyl)butylphenylarsine]palladium(II) Complex, 2a and 2b. To a solution of $(+)_{589}$-di-μ-chloro-bis[(*S*)-*N*,*N*-dimethyl-α-methylbenzylamine-2*C*,*N*]-dipalladium(II)[2,3] (1.13 g, 1.95 mmol) in benzene (10 cm^3) was added a solution of bpan (1.00 g, 3.95 mmol) in benzene (5 cm^3), and the mixture was stirred for 2 h at room temperature. Hexane (3 cm^3) was added with stirring. The mixture was allowed to stand for 1 h at room temperature to yield colorless crystals, and then cooled at 0 °C for 1 h to complete precipitation. The crystals were collected, washed with hexane, and recrystallized repeatedly from methanol by adding benzene until no change in the $\Delta\varepsilon$ values was observed. Yield (**2a**): 0.68 g. Found: C, 48.67; H, 6.39; N, 5.39%. Calcd for $PdC_{22}H_{34}N_2AsCl$=[Pd{(*S*)-$C_6H_4CH(CH_3)$-$N(CH_3)_2$}(*S*-bpan)]Cl: C, 48.64; H, 6.31; N, 5.16%. $[\alpha]_{589}^{23}$ +37° (c 0.042, CH_3OH). Mp 203—207 °C. ^1H NMR ($CDCl_3$) δ= 0.86 (3H, t, butylic CH_3) 1.1—2.8 (m, $-CH_2-$), 1.72 (d, -CHC$\underline{H}_3$-), 3.08 (6H, s, N-CH_3), 3.72 (1H, q, -$\underline{C}H$-), 5.20 (2H, broad s, NH_2) and 6.7—8.1 (9H, m, C_6H_4 and C_6H_5).

The mother liquor was evaporated to dryness. The residue was mixed with boiling water (200 cm^3), and the mixture was reduced in volume to about 40 cm^3. Ammonium hexafluorophosphate (*ca.* 60 mg) was added to yield a white precipitate. It was dissolved in a minimum amount of methanol, and the solution was allowed to evaporate slowly at room temperature to form colorless crystals, which were collected and recrystallized from methanol by adding benzene. Yield (**2b**): 0.89 g. Found: C, 40.56; H, 5.24; N, 4.29%. Calcd for $PdC_{22}H_{34}N_2AsPF_6$=[Pd{(*S*)-$C_6H_4CH(CH_3)N(CH_3)_2$}(*R*-bpan)]PF_6: C, 40.48; H, 5.25; N, 4.29%. $[\alpha]_{589}^{23}$ +75° (c 0.098, CH_3OH). Mp 169—173 °C. ^1H NMR ($CDCl_3$) δ=0.91 (3H, t, butylic CH_3), 1.2—2.6 (m, $-CH_2-$), 1.62 (d, -CHC$\underline{H}_3$-), 2.73 (3H, s, N-CH_3), 2.92 (3H, s, N-CH_3), 3.20 (2H, broad s, NH_2), 4.03 (1H, q, -$\underline{C}H$-), and 6.3—8.1 (9H, m, C_6H_5 and C_6H_4).

[(R)-N,N-Dimethyl-1-(2-naphthyl)ethylamine-3C,N][(2-aminoethyl)diphenylarsine]palladium(II) Chloride, 3. To a stirred solution of $(-)_{589}$-di-μ-chloro-bis[(*R*)-*N*,*N*-dimethyl-1-(2-naphthyl)ethylamine-3*C*,*N*]dipalladium(II)[2] (200 mg, 2.94×10^{-4} mol) in benzene (8 cm^3) was added a benzene solution (3 cm^3) of dpan (180 mg, 6.59×10^{-4} mol). After 2 h, hexane (2 cm^3) was added and the mixture was allowed to cool at 0 °C for 30 min to yield a white precipitate. It was collected by filtration, and recrystallized from methanol by adding benzene. Yield: 0.36 g. Found: C, 54.77; H, 5.83; N, 4.69%. Calcd for $PdC_{28}H_{32}N_2AsCl$=[Pd{(*R*)-$C_{10}H_6$-$CH(CH_3)N(CH_3)_2$}(dpan)]Cl: C, 54.83; H, 5.26; N, 4.57%. $[\alpha]_{589}^{23}$ −42° (c 0.103, CH_3OH). Mp 218—222 °C (dec). ^1H NMR ($CDCl_3$) δ=1.76 (3H, d, C-CH_3), 2.5—3.0 (4H, m, $-CH_2-$), 3.07 (3H, s, N-CH_3), 3.11 (3H, s, N-CH_3), 3.99 (1H, q, -$\underline{C}H$-), 5.31 (2H, broad s, NH_2), and 6.9—7.9 (16H, m, C_6H_5 and $C_{10}H_6$).

[(S)-N,N-Dimethyl-α-methylbenzylamine-2C,N][(2-aminoethyl)diphenylarsine]palladium(II) Chloride Monohydrate, 4. This complex was prepared from $(+)_{589}$-di-μ-chloro-bis-[(*S*)-*N*,*N*-dimethyl-α-methylbenzylamine-2*C*,*N*]dipalladium-(II)[2,3] and dpan by a method similar to that used for **3**. Yield: 90%. Found: C, 49.32; H, 5.52; N, 4.68%. Calcd for $PdC_{24}H_{32}N_2AsClO$=[Pd{(*S*)-$C_6H_4CH(CH_3)N(CH_3)_2$-}(dpan)]Cl·H_2O: C, 49.59; H, 5.55; N, 4.82%. $[\alpha]_{589}^{23}$ +41° (c 0.093, CH_3OH). Mp 208—211 °C (dec). ^1H NMR ($CDCl_3$) δ=1.66 (3H, d, C-CH_3), 2.4—2.9 (4H, m, $-CH_2-$), 3.04 (3H, s, N-CH_3), 3.12 (3H, s, N-CH_3), 3.86 (1H, q, -$\underline{C}H$-), 5.18 (2H, broad s, NH_2), 6.5—7.9 (14H, m, C_6H_5 and C_6H_4).

[PdCl2(R-mpan)]. A mixture of **1a** (56 mg, 9.20×10^{-5} mol) and sodium cyanide (45 mg, 9.18×10^{-4} mol) in water–diethyl ether (10 cm^3–10 cm^3) was stirred vigorously for 10 min and allowed to stand for a while. The ethereal phase was added to a stirred solution of palladium(II) chloride (17 mg, 9.59×10^{-5} mol) in acetonitrile (30 cm^3), the color of the mixture changing from orange to yellow. The mixture was stirred for 6 h at room temperature and then filtered. The filtrate was evaporated to a volume of *ca.* 5 cm^3, and the concentrate was applied on a column (ϕ12 mm×50 mm) of acid alumina. The product was eluted with 4:1 acetonitrile–ethanol. The eluate containing the main yellow band was collected and evaporated to a small volume to give yellow flocculent crystals of the palladium-(II) complex. Yield: 28 mg. Found: C, 28.20; H, 3.61; N, 4.06%. Calcd for $PdC_9H_{14}NAsCl_2$: C, 27.83; H, 3.63; N, 3.61%.

[$PdCl_2L$] (L=S-bpan and dpan). These complexes were prepared by a method similar to that for [$PdCl_2$(*R*-mpan)]. Yields: *ca.* 70%. Found: C, 33.55; H, 4.41; N, 3.17%. Calcd for $PdC_{12}H_{20}NAsCl_2$=[$PdCl_2$(*S*-bpan)]: C, 33.48; H, 4.68; N, 3.25%. Found: C, 37.46; H, 3.56; N, 3.33%. Calcd for $PdC_{14}H_{16}NAsCl_2$=[$PdCl_2$(dpan)]: C, 37.32; H, 3.58; N, 3.11%.

[$PdBr_2L$] (L=R-mpan, S-bpan, and dpan). These complexes were prepared by methods similar to those for the corresponding dichloro complexes using palladium(II) bromide instead of palladium(II) chloride. The complexes were isolated as orange crystals in 60—90% yields. Found: C, 22.64; H, 2.93; N, 2.94%. Calcd for $PdC_9H_{14}NAsBr_2$=[$PdBr_2$(*R*-mpan)]: C, 22.65; H, 2.94; N, 2.93%. Found: C, 27.10; H, 3.60; N, 2.55%. Calcd for $PdC_{12}H_{20}NAsBr_2$=[$PdBr_2$(*S*-bpan)]: C, 27.75; H, 3.88; N, 2.70%. Found: C, 31.79; H, 2.97; N, 2.94%. Calcd for $PdC_{14}H_{16}NAsBr_2$=[$PdBr_2$(dpan)]: C, 31.17; H, 2.99; N, 2.60%.

[PdI_2L] (L=R-mpan, S-bpan, and dpan). These complexes were prepared from [$PdCl_2L$] and NaI by metathesis. To a stirred solution of [$PdCl_2L$] (L=*R*-mpan, *S*-bpan, dpan; 9.0×10^{-5} mol) in 2:1 acetonitrile–ethanol (7 cm^3) was added an excess of sodium iodide (0.2 g, 1.33×10^{-3} mol), the color of the solution changing immediately from yellow to orange red. The solution was stirred for 1 h at 40 °C, and then evaporated to dryness. The residue was dissolved in a small amount of acetonitrile, and the solution was applied on a column (ϕ12 mm×60 mm) of acid alumina. On elution with 10:1 acetonitrile–ethanol, two red bands developed. The eluate containing the slower moving main band was collected and evaporated to a small volume to form red crystals in 50—65% yield. Found: C, 19.22; H, 2.33; N, 2.62%. Calcd for $PdC_9H_{14}NAsI_2$=[PdI_2(*R*-mpan)]: C, 18.92; H, 2.47; N, 2.45%. Found: C, 24.37; H, 3.15; N, 2.64%. Calcd for $PdC_{12.5}H_{20.75}N_{1.25}AsI_2$=[$PdI_2$(*S*-bpan)]·1/4$CH_3CN$: C, 24.07; H, 3.35; N, 2.81%. Found: C, 27.05; H, 2.64; N, 2.66%. Calcd for $PdC_{14}H_{16}NAsI_2$=[PdI_2(dpan)]: C, 26.55; H, 2.55; N, 2.21%.

[$PtCl_2$(R-mpan)]1/4CH_3CN. This complex was prepared by a method similar to that for the corresponding palladium(II) complex. A mixture of **1a** (250 mg, 4.12×10^{-4} mol) and sodium cyanide (200 mg, 4.08×10^{-3}mol) in water–diethyl ether (40 cm^3–40 cm^3) was stirred for 10 min, and then allowed to stand for a while. The ethereal layer was added to a stirred suspension of platinum(II) chloride (120 mg, 4.51×10^{-4} mol) in acetonitrile (300 cm^3). The resulting yellow solution was refluxed for 1 h, and then filtered. The filtrate was evaporated to a small volume to give a pale yellow precipitate. It was collected by filtration, dissolved in a small amount of acetonitrile, and the solution was applied on a column (ϕ12 mm×100 mm) of Toyopearl HW-40 (fine). The product was eluted with acetonitrile. The eluate containing the main yellow band was collected and evaporated to *ca.* 10 cm^3. The concentrate was applied again on a column (ϕ12 mm×100 mm) of acid alumina. By elution with acetonitrile–ethanol (5:1) the column showed a single pale yellow band. The yellow eluate was collected and evaporated slowly at room temperature to give pale yellow crystals. Yield: 50%. Found: C, 23.59; H, 3.00; N, 3.63%. Calcd for $PtC_{9.5}H_{14.75}N_{1.25}AsCl_2$: C, 23.41; H, 3.05; N, 3.59%.

[$PtCl_2$(dpan)]. This complex was prepared by a method similar to that for [$PtCl_2$(*R*-mpan)]1/4CH_3CN. When a solution of dpan in diethyl ether was mixed with a suspension of platinum(II) chloride in acetonitrile, a white precipitate formed. The mixture was refluxed for 2 h to give a clear pale yellow solution, from which the complex was obtained and purified in the same way as the above *R*-mpan complex. Yield: 50%. Found: C, 31.33; H, 2.90; N, 2.76%. Calcd for $PtC_{14}H_{16}NAsCl_2$: C, 31.19; H, 2.99; N, 2.60%.

[$PtBr_2$(R-mpan)]1/2CH_3CN. To a solution of [$PtCl_2$(*R*-mpan)]1/4CH_3CN (40 mg, 8.21×10^{-5} mol) in acetonitrile–ethanol (30 cm^3–30 cm^3) was added lithium bromide monohydrate (130 mg, 1.25×10^{-3} mol). The mixture was stirred at 60—65 °C for 3 h, cooled to room temperature, and then evaporated to dryness under vacuum. The residue was mixed with dichloromethane–H_2O (1:1) to extract the complex into the organic solvent. The dichloromethane was evaporated to 2 cm^3 and the concentrate was mixed with acetonitrile (1 cm^3) to give pale yellow crystals. They were purified by the same method as that for [$PtCl_2$(*R*-mpan)]·1/4CH_3CN. Yield: 50%. Found: C, 20.97; H, 2.68; N, 3.24%. Calcd for $PtC_{10}H_{15.5}N_{1.5}AsBr_2$: C, 20.48; H, 2.66; N, 3.58%.

[PtI_2(R-mpan)]. This complex was prepared by a method similar to that for [$PtBr_2$(*R*-mpan)]1/2CH_3CN using sodium iodide instead of lithium bromide. The complex was isolated as brownish orange plates in a 60% yield. Found: C, 16.47; H, 2.04; N, 2.03%. Calcd for $PtC_9H_{14}NAsI_2$: C, 16.38; H, 2.14; N, 2.12%.

[PtI_2(dpan)]. This complex was prepared from [$PtCl_2$(dpan)] by a method analogous to that for [PtI_2(*R*-mpan)]. Yield: 65%. Found: C, 23.34; H, 2.32; N, 1.61%. Calcd for $PtC_{14}H_{16}NAsI_2$: C, 23.29; H, 2.23; N, 1.94%.

Recemization of R-mpan**, *[$PdCl_2$(R-mpan)], and [$PdCl_2$(S)-bpan)].* A mixture of **1a** (50 mg, 8.25×10^{-5} mol) and sodium cyanide (40 mg, 8.16×10^{-4} mol) in water–diethyl ether (15 cm^3–15 cm^3) was stirred for 30 min. After a while, the ethereal phase was withdrawn and mixed with hydrochloric acid (*ca.* 0.08 cm^3, *ca.* 10^{-3} mol). The mixture was stirred for 1h at room temperature, and then mixed with a solution of palladium(II) chloride (15 mg, 8.46×10^{-5} mol) in acetonitrile (40 cm^3). The mixture was stirred for 2 h and then filtered. The filtrate was evaporated to *ca.* 20 cm^3, and neutralized with an ethanol solution of sodium hydroxide. The resulting yellow solution was applied on a column (ϕ12 mm×60 mm) of acid alumina, and the product was eluted with acetonitrile–ethanol (5:1). The eluate containing the main yellow band was confirmed to contain [$PdCl_2$(mpan)] by the absorption spectrum. However, the eluate showed no detectable CD in the region of 500—200 nm.

Solutions of [$PdCl_2$(*R*-mpan)] in acetonitrile–ethanol (4:1) and in the same solvent saturated with LiCl were refluxed for 4 h, and then the CD spectra were measured. Either spectrum was the same as that of the starting solution. To a solution of the complex in acetonitrile–ethanol (4:1) was added an excess of hydrochloric acid. The color of the solution changed immediately from yellow to red, indicating the formation of [$PdCl_3$(*R*-Hmpan)], where Hmpan represents $^+NH_3CH_2CH_2As(CH_3)(C_6H_5)$ coordi-

** The notation of the absolute configurations, *R* and *S*, for the tertiary arsine ligand is reversed upon liberation from a metal complex according to the rule.[14] However, the same notation as that for the coordinated arsine is used for the uncoordinated one throughout this paper.

nated to the Pd^{II} ion only through the arsenic atom. The solution was refluxed for 6 h, and then neutralized with an ethanol solution of sodium hydroxide. The resulting solution showed the same CD spectrum as that of the starting solution. The CD spectrum of [$PdCl_2$(*S*-bpan)] did not change by the same experiments, either.

Results and Discussion

Preparation and Characterization of the Arsine Ligands and the Complexes. The known compound, (2-aminoethyl)diphenylarsine (dpan) was prepared in fairly high yield (70%) by reaction of lithium diphenylarsenide with aziridine:

$$(C_6H_5)_2AsH \xrightarrow{n\text{-}C_4H_9Li} (C_6H_5)_2AsLi \xrightarrow{CH_2-CH_2 \diagdown\diagup NH} (C_6H_5)_2AsCH_2CH_2NHLi \xrightarrow{H_2O} \text{dpan}$$

This method is analogous to that for the corresponding phosphine.[12,13] To obtain dpan in good yield, it is essential to use pure $AsH(C_6H_5)_2$ isolated by distillation. New chiral (2-aminoethyl)methylphenylarsine (mpan) and (2-aminoethyl)butylphenylarsine (bpan) were prepared from dpan in liquid ammonia by a method similar to that for the corresponding phosphine analogs:[4]

$$\text{dpan} \xrightarrow{Na} NaC_6H_5AsCH_2CH_2NH_2 \xrightarrow[(RX=CH_3I,\ n\text{-}C_4H_9Br)]{RX} RC_6H_5AsCH_2CH_2NH_2$$

The chiral arsines, mpan and bpan were resolved into their enantiomers by fractional crystallization of the diastereomeric palladium(II) complexes, **1a** and **1b**, and **2a** and **2b**, containing, respectively, ortho-metallated (*R*)-*N*,*N*-dimethyl-1-(2-naphthyl)-ethylamine and (*S*)-*N*,*N*-dimethyl-α-methylbenzylamine. The less soluble **1a** and **2a** were isolated as the chlorides, whereas the more soluble **1b** and **2b** as the hexafluorophosphates. Except **2b** the diastereomers were separated in high purity as confirmed by the ^1H NMR and CD spectra. The separation of pure **2b** was difficult.

The optically active free (aminoalkyl)arsines were obtained from the diastereomers by treating with sodium cyanide in water, and by extracting with diethyl ether. The liberated ligands were used to prepare the [PdX_2L] (X=Cl, Br) and [$PtCl_2L$] complexes. The other halogeno complexes, [PdI_2L] and [PtX_2L] (X=Br, I), were prepared by metatheses from the dichloro complexes and sodium iodide or lithium bromide.

For complexes **1** and **2**, there are two possible geometrical isomers; the two nitrogen atoms can be either in the cis or trans positions to each other. For each complex only one of the geometrical isomers was formed as confirmed by ^1H NMR spectra. Kinoshita *et al.*[4] resolved (2-aminoethyl)butylphenylphosphine by forming a pair of diastereomeric palladium(II) complexes, **2a′** and **2b′**, with ortho-metallated (*S*)-*N*,*N*-dimethyl-α-methylbenzylamine. They assigned both diastereomers to the *cis*(*N*,*N*) isomer, since the ^1H NMR and ^{13}C NMR spectra exhibit large long-range couplings between the ^{31}P atom and the *N*-methyl protons ($^4J_{PPdNCH}$), and the *N*-methyl carbons ($^3J_{PPdNC}$), respectively. Such long-range couplings would be very small for the *trans*(*N*,*N*) configuration. Although such argument on couplings cannot be applied to the arsine complexes, the results that isomers **2a** and **2a′**, and **2b** and **2b′**, respectively show very similar ^1H NMR patterns strongly suggest that **2a** and **2b** also have the *cis*(*N*,*N*) configuration.

Since the σ-bonded carbon and the arsenic atoms induce the stronger trans effect than the amine nitrogen atom, the formation of the *cis*(*N*,*N*) isomer would be more favorable than the *trans*(*N*,*N*) one. Examination of molecular models indicates that the *trans*(*N*,*N*) isomer involves considerable steric interactions between the *N*-methyl groups and the substituent on the arsenic atom. Thus, all isomers **1a**—**4** can be assigned as the *cis*(*N*,*N*) configuration. Recently Allen *et al.*[5] resolved methylphenyl(8-quinolyl)phosphine and its arsenic analog with di-μ-chloro-bis[(*R*)-*N*,*N*-dimethyl-1-(1-naphthyl)ethylamine-C^2,*N*]dipalladium(II). In each case only one of geometrical isomers was formed, and X-ray crystal structure analysis of one of the diastereomers revealed the *cis*(*N*,*N*) configuration.

The optical activity of diastereomers **1a**—**2b** can be explained as a superposition of the two effects; one from the chiral arsine ligand and the other from the chiral ortho-metallated amine ligand. The observation that the CD spectra are nearly enantiomeric between diastereomers **1a** and **1b**, and between **2a** and **2b** suggests that the chiral arsine ligand has a dominating influence on the CD spectra (Figs. 1 and 2). In fact, the corresponding dpan complexes, **3** and **4** whose arsenic atoms are achiral show very weak CD. Thus the absolute configurations of the chiral arsenic atoms can be assigned from the CD spectra of the diastereomers. The CD pattern of **2a** is similar to that of the phosphine analog, **2a′** of the known absolute configuration (*S*(P)).[4] Thus the absolute configuration of the arsenic atom of **2a** is assigned as *S*. Diastereomer **1b** which shows a similar CD pattern to that of **2a** can be assigned to have the *S* configuration. Accordingly, the absolute configurations of the arsenic atoms of **2b** and **1a** can be assigned as *R*. Half the sum of the CD spectra of a pair of diastereomers should give the contribution due to the amine ligand. Actually, the calculated CD curves, $1/2[\Delta\varepsilon(\mathbf{1a})+\Delta\varepsilon(\mathbf{1b})]$ and $1/2[\Delta\varepsilon(\mathbf{2a})+\Delta\varepsilon(\mathbf{2b})]$ are similar to the observed spectra of **3** and **4**, respectively over the whole region (Figs. 1 and 2), indicating that the additivity in CD between the two effects holds for the diastereomers, and that

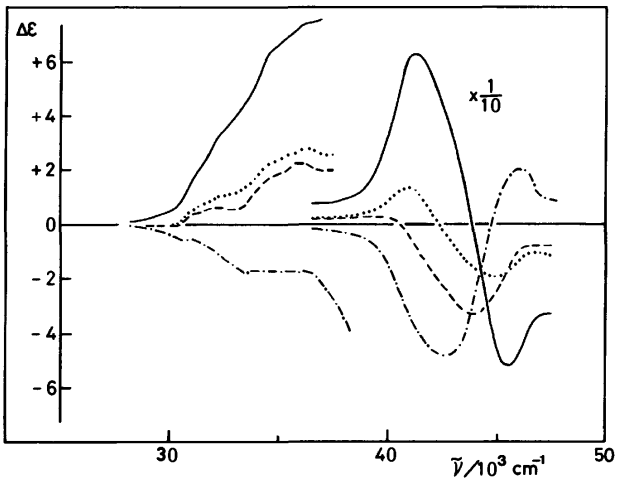

Fig. 1. CD spectra of [Pd{(*R*)-$C_{10}H_6CH(CH_3)N(CH_3)_2$}-(*R*-mpan)]Cl·1/2$CH_3OH$·1/2$C_6H_6$(**1a**, ——), [Pd{(*R*)-$C_{10}H_6CH(CH_3)N(CH_3)_2$}(*S*-mpan)]$PF_6$(**1b**, —·—), and [Pd{(*R*)-$C_{10}H_6CH(CH_3)N(CH_3)_2$}(dpan)]Cl(**3**, ----), and the mean CD curve of the two spectra for **1a** and **1b**.(·····).

a) Shoulder.

the contribution from the chiral amine ligand is small.

Absorption and CD Spectra of [$M^{II}X_2L$] (M^{II}=Pd, Pt; X=Cl, Br, I; L=R-mpan, S-bpan). The elemental analyses and a comparison of the absorption spectral data (Table 1) with those of related complexes of dpan[15,16] support that these complexes are four-coordinate and square-planar. The low energy absorption bands with intensities log ε=3.0—3.5 may be assigned to predominantly a d-d transition, while those observed at energies higher than 30×10^3 cm^{-1} for the palladium(II) complexes and 35×10^3 cm^{-1} for the platinum(II) complexes will be assigned to charge-transfer transitions[15,17] (Figs. 3—6). The platinum(II) complexes show a shoulder (log $\varepsilon\approx$2.3) at the low energy side of the d-d absorption band, and the absorption may be assigned to the spin-forbidden transition. The patterns of the absorption spectra of [PtX_2(*R*-mpan)] (X=Cl, Br, I) are similar to those of the corresponding palladium(II) complexes, although all the bands of the former complexes are shifted by 5000—7000 cm^{-1} toward higher energy compared to the corresponding bands of the latter complexes. The spin-forbidden band at the lowest energy is pronounced for platinum(II) complexes (Figs. 4 and 6). In any series [$M^{II}X_2L$] (M^{II}=Pd, Pt), the energy of the d-d absorption band decreases in the order Cl>Br>I. When the phenyl group attached to the arsenic atom is replaced by an alkyl group, the d-d absorption band shifts to higher energy. Thus, the spectrochemical series of the arsine ligands is mpan≧bpan>dpan. For a series of bis(acetylacetonato)cobalt(III) complexes with analogous phosphine ligands a similar order has been reported; $NH_2CH_2CH_2P(CH_3)(C_6H_5)\geqq NH_2CH_2CH_2P(n\text{-}C_4H_9)(C_6H_5)>NH_2$-

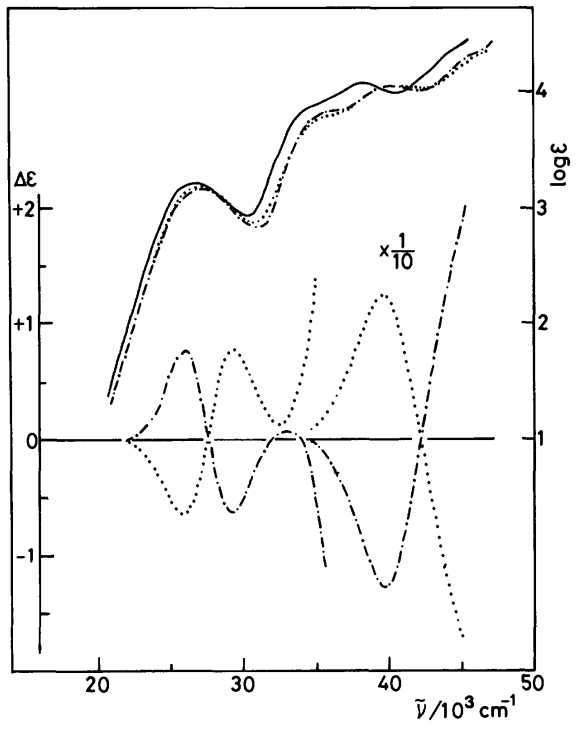

Fig. 3. Absorption and CD spectra of [$PdCl_2$(*R*-mpan)](—·—) derived from **1a**, and [$PdCl_2$(*S*-bpan)] (·····) derived from **2a**, and absorption spectrum of [$PdCl_2$(dpan)](——).

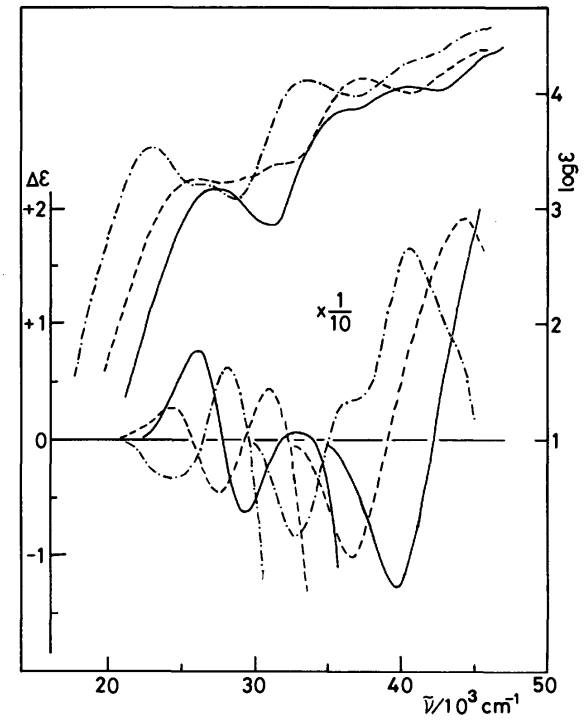

Fig. 4. Absorption and CD spectra of [PdX_2(*R*-mpan)], X=Cl(——), Br(----), and I(—·—).

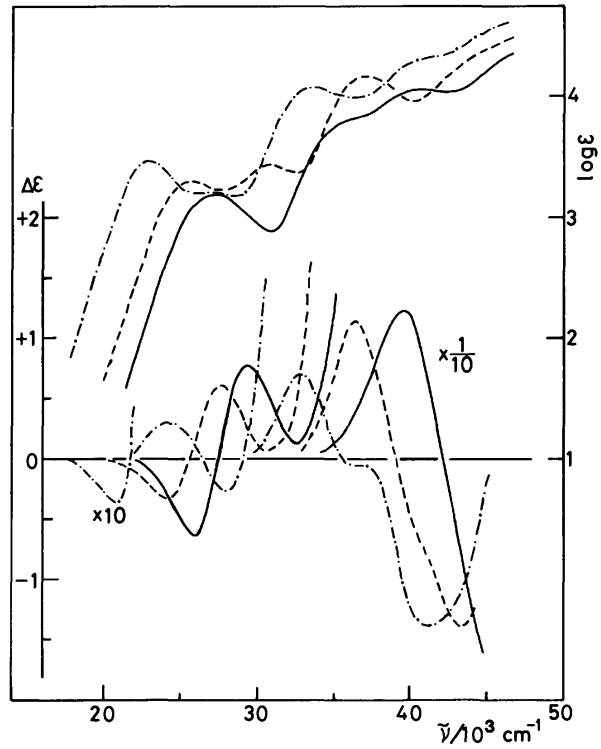

Fig. 5. Absorption and CD spectra of [PdX_2(*S*-bpan)], X=Cl(——), Br(----), and I(—·—).

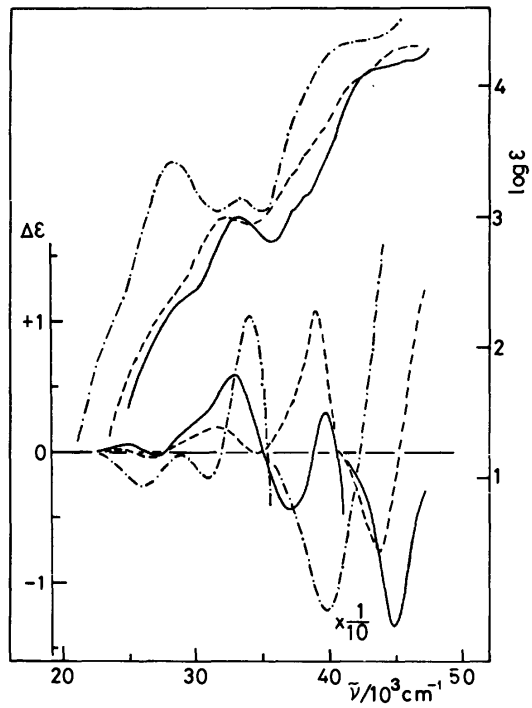

Fig. 6. Absorption and CD spectra of $[PtX_2(R\text{-mpan})]$, X=Cl(——), Br(----), aud I(—·—).

$CH_2CH_2P(C_6H_5)_2$.[18] The $[PdCl_2\{NH_2CH_2CH_2P(n\text{-}C_4H_9)(C_6H_5)\}]$ complex exhibits the d-d absorption band at a little higher energy than the corresponding bpan complex,[4] suggesting that an (aminoalkyl)phosphine ligand exerts a ligand field slightly greater than the corresponding arsine ligand.

Figure 3 shows the CD spectra of the dichloro-*R*-mpan and *S*-bpan palladium(II) complexes derived from **1a** and **2a**, respectively. The spectra are nearly enantiomeric over the whole region. The *S*-bpan complex shows the same CD pattern as that of $[PdCl_2\{(S)\text{-}NH_2CH_2CH_2P(n\text{-}C_4H_9)(C_6H_5)\}]$; a negative and a positive band from lower wave numbers in the region of the first absorption band.[4] These results support the previous assignments for the absolute configurations of the arsenic atoms of **1a—2b**. It should be noted that the CD strength of the bpan complex is about 2.5—3 times smaller than that of the phosphine analog. A similar decrease in CD strength accompanying the change of donor atom from the third to the fourth-row atom has been observed for the vicinal effect of $NH_2CH_2CH(CH_3)X^-$-*N*,*X* (X= S, Se) in the cobalt(III) complexes.[19]

In Figs. 4 and 5 the CD spectra of the complexes, $[PdX_2(R\text{-mpan})]$ (X=Cl, Br, I) and $[PdX_2(S\text{-bpan})]$ (X=Cl, Br, I), respectively, are shown. In either series of complexes all of the CD bands cause a systematic shift to smaller wave numbers as X proceeds from Cl through Br to I. The CD components in the region of the d-d absorption band decreases in magnitude in the order Cl>Br>I. For $[PdI_2(R\text{-mpan})]$ no positive CD band could be observed at *ca.* 21000 cm^{-1}, while the corresponding weak CD band for $[PdI_2(S\text{-bpan})]$ was observed at 20830 cm^{-1}.

The CD spectra of $[PtX_2(R\text{-mpan})]$ (X=Cl, Br, I) are similar to those of the corresponding palladium(II) complexes except that the former spectra shift to higher energy side by 5000—7500 cm^{-1} compared to the latter ones. The spectra of the Pt^{II} complexes show CD bands in the spin-forbidden band region, the corresponding CD bands being not observed in the spectra of the Pd^{II} complexes (Figs. 4 and 6).

Racemization of R-*mpan and Attempted Racemization of* $[PdCl_2$(R-*mpan*)*]* and $[PdCl_2$(S-*bpan*)*]*. It has been known that arsines and phosphines can be racemized catalytically, although in general they are thermally stable toward racemization.[21] For example, Horner and Hofer[21] reported that (+)-methylpropylphenylarsine in methanol solution racemizes in the presence of strong acid (HX). The rate is anion dependent and increases in the order $X=ClO_4^-<F^-<Cl^-<I^-$, the process presumably involving the rapid pseudorotation of a five-coordinate arsenic species.[22] Roberts and Wild[7] showed that *meso-o*-phenylenebis(methylphenylarsine) undergoes a halide-ion assisted epimerization in acidic methanol solution. The optically active arsine ligand, *R*-mpan, liberated from the diastereomeric palladium(II) complex (**1a**) was allowed to react with hydrochloric acid in diethyl ether at room temperature. The $[PdCl_2(mpan)]$ complex which was prepared from this mpan showed no detectable CD. The result shows that the arsine ligand undergoes racemization in the presence of hydrochloric acid.

Optically active quarternary phosphonium and arsonium salts also undego racemization in the presence of some anions such as Cl^- or Br^-, acid being not required.[24] Here again a similar account in terms of rapidly pseudorotating five-coordinate arsenic may be applicable. A metal complex with a chiral arsine ligand might undergo a halide-ion assisted racemization at the arsenic atom, if the metal ion assumes the role of a proton of a tertiary arsine or an alkyl group of a quarternary arsonium ion. Epimerization of a coordinated tertiary arsine within a chelate ring has been observed in $[CoX_2(tetars)]X$ (X=Cl, Br; tetars= $[(CH_3)_2As(CH_2)_3As(C_6H_5)CH_2\text{-}]_2$).[9,25] However, refluxing a solution of $[PdCl_2(R\text{-mpan})]$ (or $[PdCl_2(S\text{-bpan})]$) in acetonitrile-ethanol (4:1) for several hours in the presence of saturated lithium chloride or excess hydrochloric acid resulted in no racemization at a chiral arsenic center. These results indicate that the stability of chiral arsines toward racemization is greatly enhanced by coordination to a metal ion.

Three-dimensional Aromaticity of Ferrocene

Jun-ichi AIHARA
Department of Chemistry, Faculty of Science, Shizuoka University, Oya, Shizuoka 422
(Received December 23, 1983)

The conjugated systems of ferrocene and related compounds were constructed using five equivalent 3d orbitals of iron and carbon $2p_z$ orbitals of the cyclopentadienyl or pentadienyl groups. Ferrocene with such a conjugated system was found to have positive resonance energy due to cyclic conjugation, and was characterized as a three-dimensional aromatic species.

Aromatic compounds have cyclic conjugated systems.[1,2] They are usually planar in geometry. In 1978, we showed that the concept of aromaticity can be extended to three-dimensional conjugated systems.[3,4] Graph-theoretical analysis identified tricarbonyliron complexes of olefins and *closo*-boranes as typical aromatics. Many compounds of this kind are in fact very stable, and undergo electrophilic substitution reactions.[5,6] Ferrocene is the most famous organometallic compound. However, its possible aromaticity has not been elucidated theoretically. In this paper, the author intends to resolve this problem by introducing a simplified bonding model of ferrocene[7,8] in combination with our graph theory of aromaticity.[1,2]

Theory

Ferrocene has strong covalent bonding between iron and cyclopentadienyl rings.[9,10] A large number of molecular orbital calculations have shown that the major bonding interactions between iron and rings involve a degenerate pair of iron 3d orbitals (d_{xz}, d_{yz}) and the π bonding orbitals of the rings.[9,10] Overlapping of these 3d orbitals with rings gives a three-dimensional conjugated system.

A convenient way of representing this situation is to use five equivalent hybridized 3d orbitals of iron as described by Powell[11] and by Pauling and McClure.[12] It was Herndon and Agranat who first constructed a Hückel-type molecular orbital model of ferrocene, using five equivalent 3d orbitals of iron.[7,8] We adopt their bonding model in what follows.

The directional character of five equivalent 3d orbitals is drawn in **1**, and overlap with $2p_z$ orbitals of two cyclopentadienyl rings generates a diagram which corresponds very closely to a staggered D_{5d} depiction of ferrocene with ten carbon-iron bonds given in **2**.[7,8] It is graphically shown in **3**, where five hybridized 3d orbitals of iron are represented by short horizontal lines. This indicates that the 3d orbitals can be treated formally as five hetero atoms. Eighteen valence electrons are then accommodated in this delocalized electron network.

The structure of ferrocene in the solid state deviates slightly from the staggered configuration.[13] However, in the gas phase it has an eclipsed configuration.[14] The rings are essentially free to rotate, and the configuration adopted in the crystal is susceptible to packing forces. No intrinsic barrier to internal rotation is predicted from the symmetry consideration of the occupied molecular orbitals.[9] The very low barrier observed may be attributable to van der Waals forces between the rings.[9] This allows us to take a staggered configuration of ferrocene for analyzing the degree of its aromaticity.

The resonance integral between each hybridized iron 3d and carbon $2p_z$ orbitals is set equal to that between two bonded carbon $2p_z$ orbitals. This is essentially the same approximation as adopted by Mingos to rationalize the stability of tricarbonyliron complexes of olefins.[15]

The Coulomb integral for iron 3d orbitals can be written as

$$\alpha = \alpha_c + h\beta_{c-c} \quad (1)$$

Here, α_c is the Coulomb integral for carbon $2p_z$ orbitals; β_{c-c} is the resonance integral between two bonded carbon $2p_z$ orbitals; and h is an appropriate constant. According to the widely accepted extended Hückel molecular orbital model, the Coulomb integral for iron 3d orbitals is -12.63 eV, which is slightly smaller than that for carbon 2p orbitals, -11.40 eV.[16] This implies that h might be positive in sign. However, the Coulomb integral for iron 3d orbitals is here set equal to that for carbon $2p_z$ orbitals. We dare adopt $h=0.0$ in order to have the iron 3d orbitals retain some electron-donating ability. This kind of treatment is required due to the neglect of iron 4s and 4p orbitals. Mingos adopted $h=1.0$ when he modeled conjugated systems of tricarbonyliron complexes of olefins using olefin π systems and only two of the iron 3d orbitals (d_{xz}, d_{yz}).[15] Our graph theory of aromaticity[1,2] was applied to the above bonding model of ferrocene pictured with $h=0.0$.

Results and Discussion

All atomic orbitals forming the ferrocene conjugated system are numbered as shown in **3**. The Hückel-type secular determinant for it can then be written as

$$D(X) = \begin{vmatrix} -X & 1 & 0 & 0 & 1 & 1 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 \\ 1 & -X & 1 & 0 & 0 & 0 & 1 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 \\ 0 & 1 & -X & 1 & 0 & 0 & 0 & 1 & 0 & 0 & 0 & 0 & 0 & 0 & 0 \\ 0 & 0 & 1 & -X & 1 & 0 & 0 & 0 & 1 & 0 & 0 & 0 & 0 & 0 & 0 \\ 1 & 0 & 0 & 1 & -X & 0 & 0 & 0 & 0 & 1 & 0 & 0 & 0 & 0 & 0 \\ 1 & 0 & 0 & 0 & 0 & -X & 0 & 0 & 0 & 0 & 1 & 0 & 0 & 0 & 0 \\ 0 & 1 & 0 & 0 & 0 & 0 & -X & 0 & 0 & 0 & 0 & 1 & 0 & 0 & 0 \\ 0 & 0 & 1 & 0 & 0 & 0 & 0 & -X & 0 & 0 & 0 & 0 & 1 & 0 & 0 \\ 0 & 0 & 0 & 1 & 0 & 0 & 0 & 0 & -X & 0 & 0 & 0 & 0 & 1 & 0 \\ 0 & 0 & 0 & 0 & 1 & 0 & 0 & 0 & 0 & -X & 0 & 0 & 0 & 0 & 1 \\ 0 & 0 & 0 & 0 & 0 & 1 & 0 & 0 & 0 & 0 & -X & 1 & 0 & 0 & 1 \\ 0 & 0 & 0 & 0 & 0 & 0 & 1 & 0 & 0 & 0 & 1 & -X & 1 & 0 & 0 \\ 0 & 0 & 0 & 0 & 0 & 0 & 0 & 1 & 0 & 0 & 0 & 1 & -X & 1 & 0 \\ 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 1 & 0 & 0 & 0 & 1 & -X & 1 \\ 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 1 & 1 & 0 & 0 & 1 & -X \end{vmatrix} \quad (2)$$

This determinant can be expanded into the characteristic polynomial $P(X)$ in this form:

$$\begin{aligned} P(X) &= (-1)^{15}D(X) \\ &= X^{15} - 20X^{13} + 155X^{11} - 4X^{10} - 600X^{9} \\ &\quad + 40X^{8} + 1245X^{7} - 160X^{6} - 1378X^{5} \\ &\quad + 300X^{4} + 760X^{3} - 240X^{2} - 160X + 64. \end{aligned} \quad (3)$$

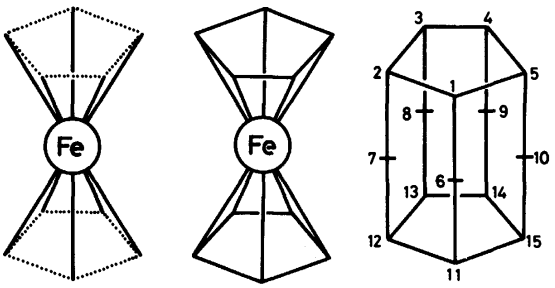
The corresponding reference polynomial $R(X)$ can be constucted graph-theoretically.[1,2] It is expressed as

$$\begin{aligned} R(X) &= X^{15} - 20X^{13} + 155X^{11} - 590X^{9} + 1155X^{7} \\ &\quad - 1112X^{5} + 460X^{3} - 60X. \end{aligned} \quad (4)$$

$R(X)$ has been interpreted as a characteristic polynomial for the olefinic reference structure.

Roots of the equation $D(X)=0$ or $P(X)=0$ represent the orbital energies of the ferrocene conjugated system **3**. They are given relative to α_c and in units of $\beta_{c\text{-}c}$. Total electron energy is equal to twice the sum of the energies of all occupied orbitals. It is $18\,\alpha_c+20.780\beta_{c\text{-}c}$ for this eighteen-electron system. Roots of the equation $R(X)=0$ represent the orbital energies which the ferrocene conjugated system would possess if it were hypothetically olefinic in nature. They are also given relative to α_c and in units of $\beta_{c\text{-}c}$. Total electron energy calculated for this reference structure is $18\alpha_c+20.527\beta_{c\text{-}c}$.

The energy difference between the ferrocene conjugated system and its olefinic reference structure is 0.253β, where β is the absolute value of $\beta_{c\text{-}c}$. This is our way of evaluating the resonance energy arising from cyclic conjugation.[1-4] It follows that the resonance energy of **3** is 0.253β. This positive value indicates that the ferrocene conjugated system is more stable than its olefinic reference structure by this amount. Positive and negative resonance energies represent aromaticity and antiaromaticity, respectively.[1-4] Accordingly, ferrocene is classified as an aromatic compound.



1 2 3

The resonance energy of ferrocene is comparable to that of benzene, 0.273β.[1-2] Considering that ferrocene is about twice as large as benzene, aromaticity of ferrocene, normalized with respect to the molecular dimension, is estimated to be about half that of benzene. In line with this ferrocene has been considered to be aromatic in its chemical behavior.[6,9,10] It is quite analogous in chemical reactivity to benzene. Furthermore, ferrocene is much more reactive toward electrophilic reagents than benzene. It rather resembles more reactive thiophene and phenol. In a previous paper,[17] we showed that more aromatic compounds are generally less reactive toward electrophiles. In this sense, ferrocene is chemically less aromatic than benzene. Theory and experiment thus agree qualitatively for the ferrocene conjugated system.

The resonance energy of a ferrocene-like conjugated system is a function of the h value defined in Eq. 1. It is maximized when h=0.3—0.4, and then takes the value of 0.296β. As far as h is larger than −0.5 but smaller than 1.5, the resonance enrgy stays positive in sign. This indicates that the system stays aromatic. Thus, not only tricarbonyliron complexes of olefins[3] but also ferrocene-like compounds

are highly delocalizable iron-organic systems with a considerable degree of aromatic stabilization.

Someone may depict ferrocene as a combination of two cyclopentadienide ions and one ferrous ion, attributing its aromaticity to the former ions. However, this model is not realistic at all. The resonance energy of the cyclopentadienide ion is 0.317β.[1,2] The resonance energy of ferrocene is much less than twice the resonance energy of this ion. Perturbation by the central iron atom is so great as to remove any simple prediction of aromaticity based on the cyclopentadienide ions only.

The resonance energy of open ferrocene,[18] *i.e.*, bis-(pentadienyl)iron, **4**, can be estimated according to the same procedure. Its conjugated system is similar in shape to that of ferrocene, but two C-C bonds are lacking. For simplicity, this open ferrocene is again assumed to take a staggered configuration. There still are three orientational isomers. They are pictured in **5**, **6**, and **7**. There of course is a possibility of facile rotation of the ligands in solution or in the gas phase.[18]

For isomer **5**, the two types of polynomials are

$$P(X) = X^{15} - 18X^{13} + 126X^{11} - 444X^{9} + 849X^{7} - 882X^{5} + 464X^{3} - 96X \quad (5)$$

and

$$R(X) = X^{15} - 18X^{13} + 126X^{11} - 436X^{9} + 783X^{7} - 698X^{5} + 266X^{3} - 32X. \quad (6)$$

For isomer **6**, the two types of polynomials are

$$P(X) = X^{15} - 18X^{13} + 126X^{11} - 442X^{9} + 832X^{7} - 8X^{6} - 832X^{5} + 36X^{4} + 408X^{3} - 44X^{2} - 76X + 16 \quad (7)$$

and

$$R(X) = X^{15} - 18X^{13} + 126X^{11} - 436X^{9} + 784X^{7} - 704X^{5} + 276X^{3} - 34X. \quad (8)$$

For isomer **7**, the two types of polynomials are

$$P(X) = X^{15} - 18X^{13} + 126X^{11} - 442X^{9} + 839X^{7} - 12X^{6} - 864X^{5} + 44X^{4} + 450X^{3} - 48X^{2} - 92X + 16 \quad (9)$$

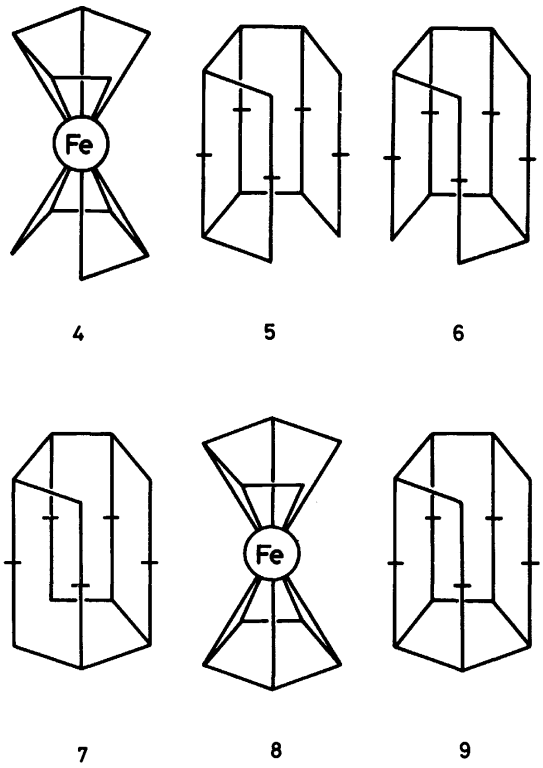
and

$$R(X) = X^{15} - 18X^{13} + 126X^{11} - 436X^{9} + 785X^{7} - 708X^{5} + 280X^{3} - 36X. \quad (10)$$

The resonance energies are then calculated to be -0.189β for **5**, -0.160β for **6**, and -0.071β for **7**. This clearly shows that open ferrocene must be slightly antiaromatic and reactive in nature. In accord with this, open ferrocene is a relatively less tractable material, which readily decomposes to dipentadienyl and ferromagnetic iron byproducts.[18] It decomposed on attempted sublimation.

Wilson *et al.* determined the actual geometry of a tetramethyl derivative by X-ray crystallography,[18] and the structure was found to correspond closely to a geometry intermediate between **6** and **7**. It is not unlikely that this structure is chosen as a result of packing forces in the crystal. It is far from the most antiaromatic isomer **5**. By the way, **6**, represents the conjugated system of **4**.

Cyclopentadienyl(pentadienyl)iron, **8**, comes between ferrocene and open ferrocene. This semi-open



4 5 6

7 8 9

ferrocene has not been prepared yet. If this compound is assumed to have a staggered configuration, **9**, the following two polynomials are obtained:

$$P(X) = X^{15} - 19X^{13} + 140X^{11} - 2X^{10} - 516X^{9} + 18X^{8} + 1023X^{7} - 70X^{6} - 1089X^{5} + 134X^{4} + 580X^{3} - 112X^{2} - 120X + 32 \quad (11)$$

and

$$R(X) = X^{15} - 19X^{13} + 140X^{11} - 508X^{9} + 953X^{7} - 887X^{5} + 358X^{3} - 46X. \quad (12)$$

The resonance energy is then calculated to be 0.048β. Semi-open ferrocene is thus predicted to be essentially nonaromatic and olefinic in reactivity. Therefore, this compound may not be stable.

Comparing the resonance energies of ferrocene, semi-open ferrocene, and open ferrocene, we note that the resonance energy decreases in this order. This fact suggests that the cyclopentadienyl rings may play a key

role in stabilizing ferrocene-like conjugated systems. As we have seen, ferrocene is far from being an ionic species in the form of ferrous dicyclopentadienide. Its pentagonal substructures are firmly incorporated in the three-dimensional conjugated system. However, they still seem to be crucial to aromatic stabilization. It is quite possible that the electron-rich pentagonal rings are responsible for most part of the resonance energy.

Concluding Remarks

Our graph theory of aromaticity[1,2] is mathematically exact, in the sense that no parametrization is used in the framework of the theory. Its predictive capability depends solely on the validity of the bonding model employed. The bonding model adopted above for ferrocene and related compounds is fairly rough with omission of iron 4s and 4p valence orbitals. We believe that this bonding model is still practical enough to account for the aromatic origin of stabilization since it takes account of the predominant effect of iron 3d orbitals. At present, the resonance energy cannot be estimated for ferrocene of D_{5h} symmetry.

Our choice of Hückel parameters may not be based on physically sound grounds. However, the obtained resonance energies are consistent with chemical stabilities of the compounds. As has been referred to, the resonance energy of ferrocene is rather insensitive to the h value in Eq. 1. It is also fairly insensitive to the resonance integral between carbon $2p_z$ and hybridized iron 3d orbitals. Let this resonance integral be denoted by $k\beta_{c\text{-}c}$. The resonance energy of ferrocene is calculated to be 0.352β for $h=0$ and $k=0.8$ and 0.331β for $h=0$ and $k=0.5$. This further supports our view that ferrocene is basically aromatic in a thermodynamic sense. This compound can now be characterized as another example of three-dimensional aromaticity. This way of reasoning would become a new guiding principle in the field of organometallic chemistry, and would aid in developing simplified bonding models for a variety of complex organometallic compounds.

I gratefully acknowledge very helpful suggestions and comments from Prof. W. C. Herndon, without which this work would not have been finished.

The Structure of Liquid Alcohols by Neutron and X-ray Diffraction. III. Liquid Structure of Methanol

Yukio TANAKA,† Norio OHTOMO,† and Kiyoshi ARAKAWA*
Research Institute of Applied Electricity, Hokkaido University, Sapporo 060
†*Faculty of Engineering, Hokkaido University, Sapporo 060*
(Received January 13, 1984)

A structure analysis of neutron and X-ray diffraction data of liquid methanol was performed by applying a general theoretical procedure for the fluid system composed of molecular clusters. The calculated structure factor curves are found to reproduce the essential features of observed ones. It was concluded that in liquid methanol chain clusters consisting of three or four hydrogen-bonded molecules are dominant on the average.

In the preceding neutron diffraction study of methanol[1] the structure of the molecule within liquid was determined. Its geometry was found to be different from that in gaseous phase,[2-4] which occurs from the strong influence of hydrogen-bond formation between molecules. Concerning the intermolecular structure of liquid methanol, however, there is still very few information.[5] Then, we aim here to elucidate the structure of the liquid, further, by applying a general theoretical procedure of analysis for the fluid system composed of molecular clusters, which was proposed recently.[6,7] Thus, we attempt to reproduce below the neutron and X-ray structure factors for comparing those with experimental data[1-5] comprehensively.

Theoretical Procedure of Analysis

Theory. The structure factor for molecular liquids obtained in diffraction experiments (neutron and X-ray) is generally expressed in the following form[8,9]

$$S_{m\eta}(Q) = N_m^{-1}\{\sum_n f_{n,\eta}\}^{-2}\langle \sum_{p,q} f_{p,\eta} f_{q,\eta} \exp(i\vec{Q}\cdot\vec{r}_{pq})\rangle, \quad \eta = N,X \qquad (1)$$

where p and q denote the p-th and q-th atoms in a sample, n the n-th atom in the molecule, $f_{p,\eta}$, $f_{q,\eta}$, and $f_{n,\eta}$ are the scattering amplitude of atoms p, q, and n, respectively, $\vec{r}_{pq}$ is the vector between the p-th and q-th atoms, N_m the number of molecules in the sample and $\hbar\vec{Q}$ the momentum transfer. The angular bracket $\langle\cdots\rangle$ means statistical average.

When a liquid is composed of molecular clusters of various sizes including monomers, the structure factor $S_{m\eta}(Q)$ is given in general by[7]

$$S_{m\eta}(Q) = \sum_\nu \frac{x_\nu}{\nu} f_1^\nu(Q) + \bar{f}_{2U}(Q)\{S_c(Q)-1\} + \sum_{\nu\geqq 2}\frac{x_\nu}{\nu} f_c^\nu(Q), \qquad (2)$$

where,

$$f_1^\nu(Q) = \{\sum_n f_{n,\eta}\}^{-2}\{\langle \sum_l^\nu |\sum_{n_l} f_{n_l,\eta}\exp(i\vec{Q}\cdot\vec{r}_{cn_l})|^2\rangle\}_\nu, \qquad (3)$$

$$f_c^\nu(Q) = \{\sum_n f_{n,\eta}\}^{-2}[\langle \sum_{l\neq l'}^\nu \exp(i\vec{Q}\cdot\vec{r}_{cll'}) \sum_{n_l,n_{l'}} f_{n_l,\eta} f_{n_{l'},\eta} \times \exp\{i\vec{Q}\cdot(-\vec{r}_{cn_l}+\vec{r}_{cn_{l'}})\}\rangle - \sum_{l\neq l'}^\nu \langle\exp(i\vec{Q}\cdot r_{cll'})\rangle \times \langle\sum_{n_l} f_{n_l,\eta}\exp(-i\vec{Q}\cdot\vec{r}_{cn_l})\rangle \times \langle\sum_{n_{l'}} f_{n_{l'},\eta}\exp(i\vec{Q}\cdot\vec{r}_{cn_{l'}})\rangle]_\nu, \qquad (4)$$

$$S_c(Q) = N_m^{-1}\langle\sum_{i,j}\exp(i\vec{Q}\cdot\vec{r}_{cij})\rangle \qquad (5)$$

and

$$\bar{f}_{2U}(Q) = \{\sum_n f_{n,\eta}\}^{-2}\sum_\nu \frac{x_\nu}{\nu}[\sum_l^\nu\{\sum_{n_l} f_{n_l,\eta} \times \langle\exp(i\vec{Q}\cdot\vec{r}_{cn_l})\rangle\}^2]_\nu. \qquad (6)$$

$x_\nu = \nu N_\nu/N_m$ (N_ν; the number of clusters consisting of ν molecules within the liquid). l and l' denote the molecules within a cluster and, i and j molecules in the sample. n_l labels the n-th atom in the l-th molecule within the cluster. $\vec{r}_{n_l n_{l'}}$ denotes the vector distance between atoms n_l and $n_{l'}$, $\vec{r}_{n_l}$ that from the center of molecule l to its n-th atom, $\vec{r}_{cll'}$ that between the centers of molecules l and l' and $\vec{r}_{cij}$ that between the centers of molecules i and j. $f_1^\nu(Q)$ and $f_c^\nu(Q)$ are the intramolecular and intermolecular contribution within the cluster, respectively, and $S_c(Q)$ the molecular center structure factor of liquids. $\sum_\nu (x_\nu/\nu) f_1^\nu$ ($=f_1(Q)$) is the overall averaged intramolecular contribution in the liquid.

Replacing $f_{n,N}$ in Eqs. 3, 4, and 6 with the coherent neutron scattering length b_n of atom n, we obtain the neutron structure factor $S_{mN}(Q)$. In the same way, we obtain the X-ray structure factor $S_{mX}(Q)$ by replacing the $f_{n,X}$ with the atomic form factor $f_n(Q)$ of atom n.[9]

Table 1. The structure of methanol molecule in liquid phase determined by neutron diffraction[1)]

Fig. 1. The structure of the tetramer models I and II.

Structural Model of Liquid Methanol and Procedure of Calculation. According to the theory presented in the preceding item, we can calculate the two structure factors $S_{mX}(Q)$ and $S_{mN}(Q)$. The intramolecular structure of molecules in liquid methanol was determined uniquely in the preceding paper[1)] except the rotational angle of the methyl group: the two models with respect to the angle remain undiscriminated (the fixed angular position and the freely rotating one, Table 1). Then we calculate the $S_{mX}(Q)$ and $S_{mN}(Q)$ for the two intramolecular models in the present study.

The cluster model of liquid methanol is shown in Fig. 1, where two forms of linear tetramers are given.[10)] Concerning the model, we assumed the chain structure,[11)] *i.e.*, we neglect a branched conformation of clusters. Concerning the associated structure of the liquid, we performed calculation for five classes of liquids which are composed of identical clusters of ν molecules: The liquid consists of unbonded monomers ($\nu=1$), that of dimers ($\nu=2$), that of trimers ($\nu=3$) and that of tetramers ($\nu=4$, I and II in Fig. 1). The geometry of clusters are characterized by seven structural parameters: the hydrogen-bonded O–O distance r_{OO}, the angluar parameters α, β, γ, θ, ϕ, and ψ. The magnitudes of these parameters were varied in reference to the values tabulated in Table 2. In these cases, Eq. 2 is reduced to the following form,

Table 2. Range of parameters

Parameter	Range	Interval of variation
ν	1, 2, 3 and 4 (I and II)	
r_{HS}/Å	3.40—3.80	0.20
r_{OO}/Å	2.75—2.90	0.05
α,β,γ/degree	109.5—120.0	10.5
θ,ϕ,ψ/degree	0.0—360.0	45.0

r_{HS} is the effective hard-sphere diameter of molecules.

$$S_{m_\nu}(Q) = \frac{1}{\nu} f_i^\nu(Q) + \bar{f}_{2U}(Q)\{S_c(Q)-1\} + \frac{1}{\nu} f_c^\nu(Q). \tag{9}$$

Especially, for the liquid composed of monomer molecules,

$$S_{m_\nu}(Q) = f_i^1(Q) + \bar{f}_{2U}(Q)\{S_c(Q)-1\}, \tag{10}$$

which corresponds to the completely uncorrelated orientation model given by Page and Powles.[9)]

For calculating $S_{mX}(Q)$ and $S_{mN}(Q)$ with Eq. 9, the molecular center structure factor $S_c(Q)$ is required. The distribution of molecular centers in liquid methanol is assumed to be represented by the distribution for hard sphere fluids, and we substitute the structure factor $S_{HS}(Q)$ of hard sphere fluid[12)] (effective hard-sphere diameter, r_{HS}) for the $S_c(Q)$.

With respect to the magnitudes of Debye-Waller factors, we assume that the mean-square variation $2\gamma_{n|m|'}$ is in proportion to the interatomic distance $r_{n|m|'}$, *i.e.*, $\gamma_{n|m|'}=1/2D^2_{n|m|'}r_{n|m|'}$.[6,7,18)] The values of $D_{n|m|'}$ assigned are tabulated in Table 3.

Interpretation of X-ray and Neutron Diffraction Data

X-Ray and Neutron Data. Recently, X-ray structure factor data of liquid CH_3OH at 21.5 °C were reported by Magini *et al.*,[5)] which are shown in

Table 3. Root mean-square variation per unit length

Fig. 2 by full circles.** As seen in the figure, we can point out several distinctive features: the height and the position of its first peak, the hump at *ca.* Q=2.8 Å^{-1}, the broad peak at *ca.* 4—6 Å^{-1} and the shoulder at *ca.* Q=7.0 Å^{-1}. These features suggest the existence of interactions between molecules in the liquid. The neutron structure factor $S_{mN}(Q)$ of liquid CD_3OD at 10.0 °C obtained by authors[1] is given in Fig. 3 by open circles. In the figure, the behavior in the region of the hump ($Q\simeq$4 Å^{-1}) is distinctive as well as that of the first peak. The feature of the hump is due to the superposition of the contributions of intramolecular structure and intermolecular one.[1] Then, in our calculation, the structural model of liquid methanol is required to make a reproduction of these features on both experimental results.

Unbonded Monomer Model of Liquid Methanol. For the present purpose, we first calculated the X-ray and neutron structure factors for the liquid model consisting of unbonded monomers by using Eq. 10. The $S_{mX}(Q)$ and $S_{mN}(Q)$ curves obtained with r_{HS}=3.60 Å are compared with the X-ray and neutron diffraction results in Figs. 2 and 3, respectively. As clearly seen in these figures, the calculated curves can reproduce the fundamental behaviors of the experimental data, though discrepancies still remain in its detailed behavior. This means the dominance of the liquid structure as a randomly packed state of effective hard spheres, and shows the availability of the hard-sphere expression[12] for the molecular center distribution adopted in the present calculation.

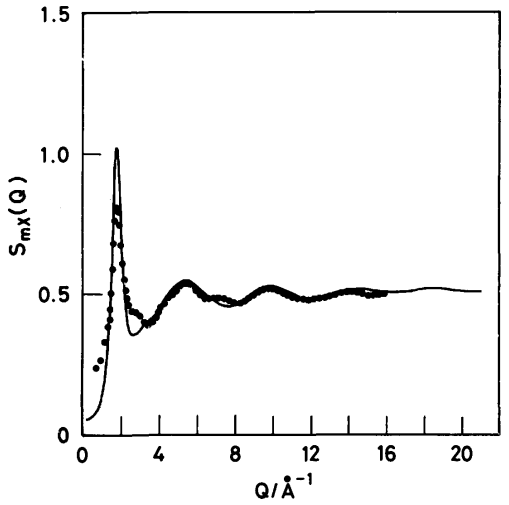

Fig. 2. Comparison between the calculated $S_{mX}(Q)$ for the unbonded monomer model and the observed X-ray structure factor $S_{mX}(Q)$.
——: Calculated $S_{mX}(Q)$ for the model with freely rotating methyl group,†† ●: observed $S_{mX}(Q)$. Observed data was transformed from the interference function $I(Q)$ by Magini et al.[5] by using the relation,[9]
$$S_{mX}(Q)=N_m^{-1}\{\sum_n f_n(Q)\}^{-2}I(Q).$$
††Concerning the rotation angle of the methyl group, there is no difference between the calculated $S_{mX}(Q)$ results for the two models (Table 1).

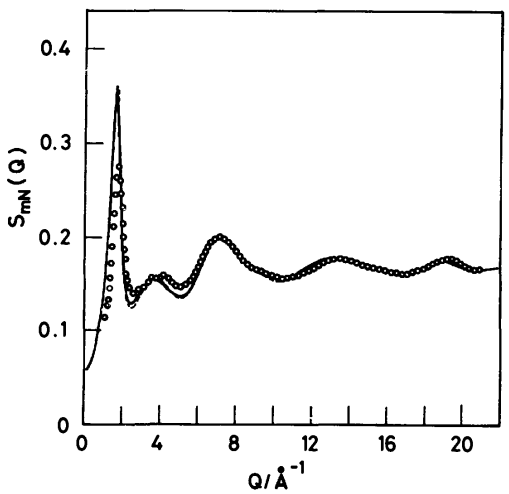

Fig. 3. Comparison between the calculated $S_{mN}(Q)$ curves for the unbonded monomer models and the observed neutron structure factor $S_{mN}(Q)$.
——: Calculated $S_{mN}(Q)$ for the model with freely rotating methyl group (Table 1), ----: calculated $S_{mN}(Q)$ for the model with fixed methyl group (Table 1), ○: observed $S_{mN}(Q)$.[1]

** Quite recently, Narten and Habenschuss have reported and X-ray diffraction study on liquid alcohols (*J. Chem. Phys.* **80**, 3387 (1984)). Their data is found substantially in agreement with that of Magini *et al.*, and concerning the intramolecular structure of methanol, they assignied a quite identical value of the C-O distance with that of Magini *et al.*

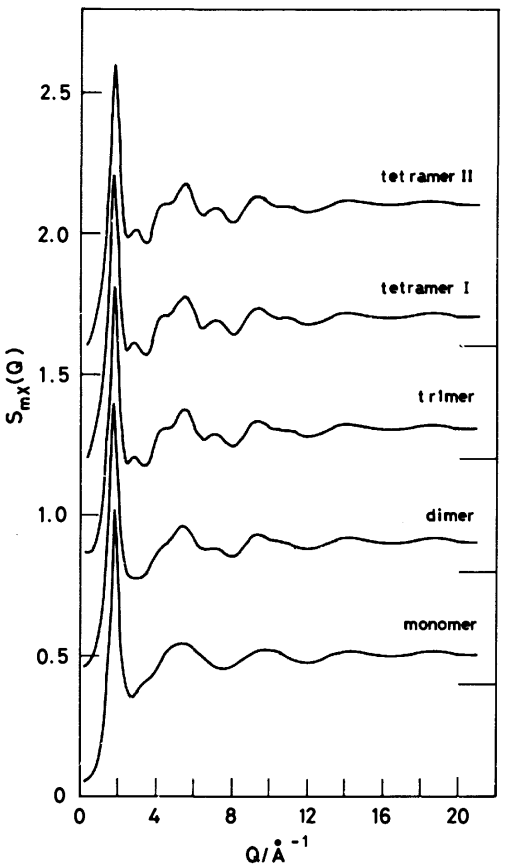

Fig. 4. The calculated $S_{mX}(Q)$ curves for five models.

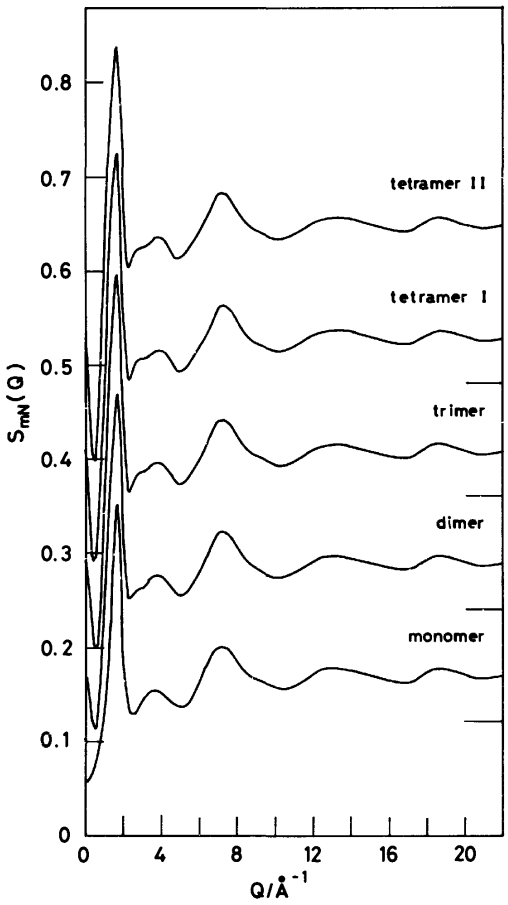

Fig. 5. The calculated $S_{mN}(Q)$ curves for five models with freely rotating methyl group.

The Best Fit Cluster Model. In Figs. 2 and 3 the discrepancies between the calculated curves and the observed data are seen in the intermediate Q region, 2.3—8.0 Å^{-1} for the X-ray result and 2.5—5.8 Å^{-1} for the neutron result. To explain these features, the calculations of $S_{mX}(Q)$ and $S_{mN}(Q)$ are required for the models of the liquid consisting of molecular culsters. The orientational configuration of the nearest neighbor molecules within liquid methanol is obtained from the combination of the X-ray and the neutron results.

We calculated the $S_{mX}(Q)$ and $S_{mN}(Q)$ for dimer fluid, trimer fluid and tetramer fluids (I and II) and the calculated curves are shown in Figs. 4 and 5. The geometrical parameters of the cluster model are determined as follows: r_{OO}=2.85 Å, $\alpha=\beta=\gamma=109.5°$, $\theta=\phi=\psi=0.0°$ and hard sphere diameter r_{HS}=3.6 Å (ξ= 0.363, ξ; packing fraction), which all are found to be identical for each oligomer fluid. As clearly seen in these figures, the characteristic features observed in the intermediate Q region (the hump at 2.8 Å^{-1}, the shoulder at *ca.* 4 Å^{-1} and that at 7.0 Å^{-1} in the X-ray curve and the hump at *ca.* 4 Å^{-1} in the neutron curve) are well-reproduced in the calculated curves for the trimer and tetramer models. Thus, we conclude that the liquid structure of methanol is regarded as the aggregates of the molecular clusters consisting of three or four linearly hydrogen-bonded molecules. The calculated curves of X-ray and neutron structure factors for trimer fluid are compared with the diffraction data in Figs. 6 and 7, respectively. Concerning the fitness of the calculated curves with the observed ones, we can not discriminate, which of the trimer and tetramer is better. In Fig. 7, the curves for the two models of the methyl-group rotation (freely rotating model and fixed one)[1] are shown.

Discussion

Molecular Center Distribution. In the present calculation, we assumed that the molecular center distribution in liquid methanol can be represented by the distribution in hard-sphere fluids and we substituted the $S_{HS}(Q)$ for the term $S_c(Q)$ in Eqs. 9 and 10. As mentioned in the preceding section, the features of the X-ray and neutron diffraction data were reproduced by the theoretical curves calculated under this assumption (Figs. 2—7). Especially, it is emphasized that the fundamental behaviors of diffraction data were explained by the use of the model of monomer fluid (Figs. 2 and 3). These facts mean the adequacy of

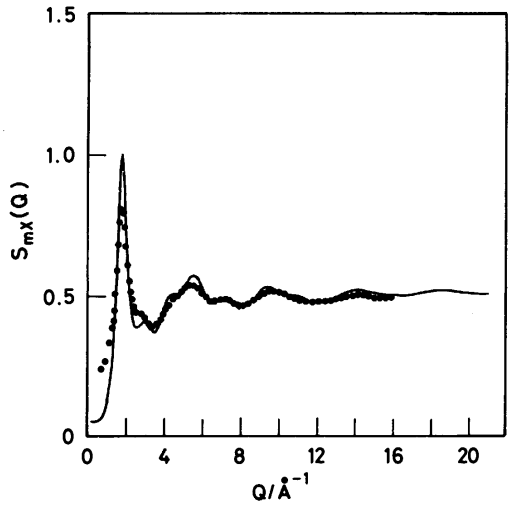

Fig. 6. Comparison between the calculated $S_{mX}(Q)$ for the trimer model and the observed X-ray structure factor $S_{mX}(Q)$.
——: Calculated $S_{mX}(Q)$, ●: observed $S_{mN}(Q)$.[5]

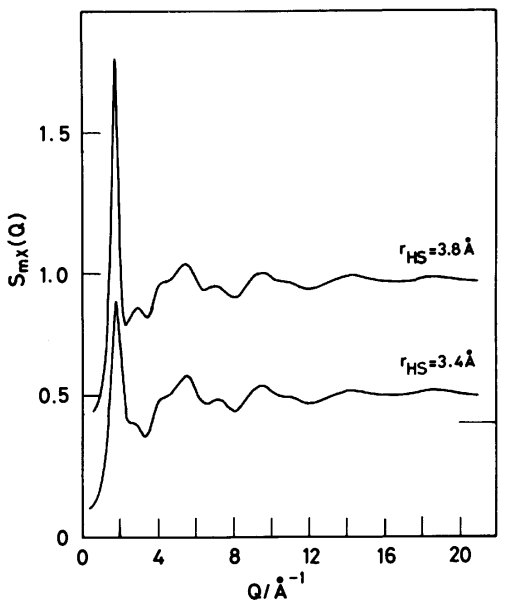

Fig. 8. The calculated $S_{mX}(Q)$ curves for the trimer models with r_{HS}=3.4Å and 3.8Å.

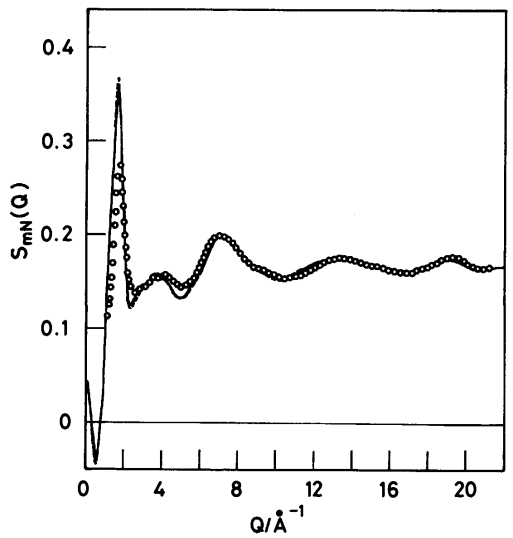

Fig. 7. Comparison between the calculated $S_{mN}(Q)$ for the trimer models and the observed neutron structure factor $S_{mN}(Q)$.
——: Calculated $S_{mN}(Q)$ for the model with freely rotating methyl group, ----: calculated $S_{mN}(Q)$ for the model with fixed methyl group, ○: observed $S_{mN}(Q)$.[1]

the assumption, and we can conclude that the liquid structure of methanol is expressed by the randomly-packed hard-sphere model as a rough approximation.

Concerning the hard sphere diameter as the effective size of molecules, we performed the calculation of X-ray and neutron structure factors, $S_{mX}(Q)$ and $S_{mN}(Q)$, for various magnitude of r_{HS}. When the r_{HS} increases, the height of the first peak increases rapidly as seen in Figs. 8 and 9. In the case of r_{HS}=3.4 Å (ξ= 0.306), the $S_{mX}(Q)$ curve in Fig. 8 shows improved agreement with the X-ray diffraction data, but, the first peak position of the $S_{mN}(Q)$ curve in Fig. 9 shifts to lower Q side and disagrees with the neutron diffraction data (Fig. 7). On the other hand, in the case of r_{HS}=3.8 Å (ξ=0.427), the heights of the first

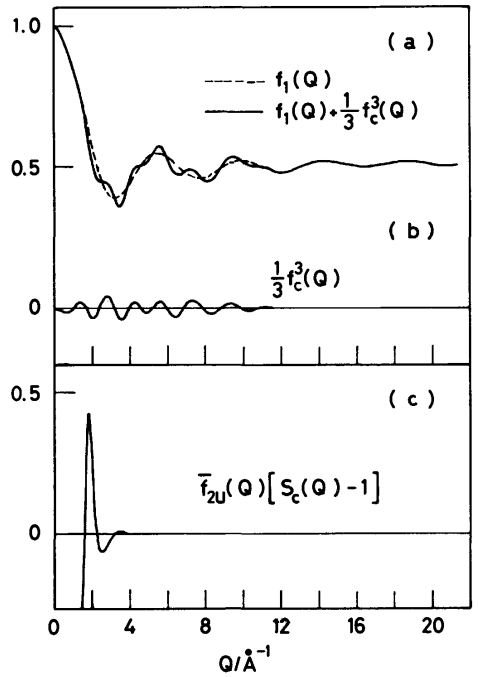

Fig. 10. Contribution of (a) $f_1(Q)$ $(=\frac{1}{3}f_1^3(Q))$ and $f_1(Q)+\frac{1}{3}f_c^3(Q)$, (b) $\frac{1}{3}f_c^3(Q)$ and (c) $\bar{f}_{2U}(Q)$ $\{S_c(Q)-1\}$ to the total $S_{mX}(Q)$ for the trimer model.

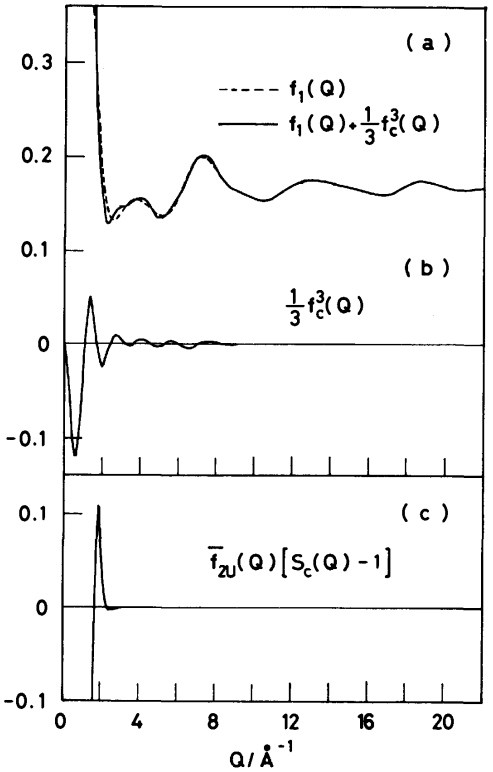

Fig. 11. Contribution of (a) $f_1(Q)$ $(=\frac{1}{3}f_1^3(Q))$ and $f_1(Q)+\frac{1}{3}f_c^3(Q)$, (b) $\frac{1}{3}f_c^3(Q)$ and (c) $\bar{f}_{2U}(Q)\{S_c(Q)-1\}$ to the total $S_{mN}(Q)$ for the trimer model with freely rotating methyl group.

peaks of the $S_{mX}(Q)$ and $S_{mN}(Q)$ curves are too high compared with experimental results. The hard sphere diameter is thus determined to be 3.6 Å (ξ= 0.363) at room temperature. Formerly, in crystals, Tauer and Lipscomb[11] gave the value of 3.88 Å for the methyl-methyl-interchain distances at −110 °C and 3.64 Å at −160 °C, and Wertz and Krue reported the value of 3.8 Å in the liquid state by X-ray diffraction.[13] Pettitt and Rossky showed the value of 3.9 Å for the distance as the result of the recent RISM calculation.[14] Concerning the packing fraction, there is no systematic studies for molecular fluids and only the cases of liquid alkali metals are available. According to the results, the packing fraction of liquid metals is about 0.45 near the melting point,[12,15] and decreases rapidly as the temperature increases.[16] Then, since the melting point of methanol is far below the room temperature, −94 °C for CH_3OH and −98 °C for CD_3OD, the present result that ξ=0.363 (r_{HS}=3.6 Å) at room temperature is acceptable. The value r_{HS}=3.6 Å is thus considered to be reasonable.

Hydrogen-bonded Structure in Liquid Methanol. In order to elucidate further the structure factors we examined the ingredients of the $S_{mX}(Q)$ and $S_{mN}(Q)$ for the trimer, by considering the terms in Eq. 9 and gave the terms in Figs. 10 and 11. In the higher Q region, the structure factor curve is practically composed of the $f_1(Q)$ term only.[17] On the other hand, the first peak is mainly composed of the sum of the curve $f_1(Q)$ and the curve $\bar{f}_{2U}(Q)\{S_c(Q)-1\}$. The sum of these curves corresponds to the $S_{mX}(Q)$ and $S_{mN}(Q)$ for monomer fluids. As seen in the figures, the shoulders and the hump for the $S_{mX}(Q)$ curve are originated from the term $1/3f_c^3(Q)$, which reflects the hydrogen-bonded structures within the cluster. The influence of the factor $1/3f_c^3(Q)$ appears mainly in the lower Q region. It is noticeable that the term $1/3f_c^3(Q)$ contributes to the total structure factor in a different way for $S_{mX}(Q)$ and $S_{mN}(Q)$. In the case of X-ray, its contribution remains up to 10—11 Å^{-1} (Fig. 10(b)). On the other hand in the case of neutron, it disappears virtually beyond the range of Q, 6—7 Å^{-1} (Fig. 11(b)).[1] The same trend is seen in the term $\bar{f}_{2U}(Q)\{S_c(Q)-1\}$ for each case (Figs. 10(c) and 11(c)).

Concering the hydrogen-bonded O-O distance r_{OO} which gives a criterion for the strength of hydrogen bonds as well as the O-D (or O-H) distance in liquid phase, no significant changes occur in calculated $S_{mX}(Q)$ and $S_{mN}(Q)$ curves when its magnitude is varied from 2.75 to 2.90 Å. Then, we assigned the value of r_{OO} to be 2.85 Å, which is identical with the value in the tetrahedral pentamer cluster in water.[6,7,18] Magini *et al.*[5] showed the value of 2.8 Å for the O-O distance by X-ray diffraction study. As the result of the Monte Carlo simulations for liquid methanol

at 25 °C, Jorgensen gave the value of 2.8 Å for the distance.[19] The present value is consistent with these values.

In the present study, we performed a structure analysis of X-ray and neutron diffraction data for methanol as an associated liquid by using a newly-proposed structure factor formula. The complete elucidation of the liquid structure of methanol is still left for future studies, of course, and we obtained here a chain-cluster model to represent its fundamental features approximately. The liquid methanol is thus considered as an aggregate of chain clusters consisting of three or four molecules linked with hydrogen bonds on the average.

Biionic Potential across Liquid Membranes with Some Anionic Surfactants

Kazuo NOMURA,* Akira MATSUBARA, and Hideo KIMIZUKA†
Laboratory of Chemistry, College of General Education, Kyushu University 01, Ropponmatsu, Fukuoka 810
†*Department of Chemistry, Faculty of Science, Kyushu University 33, Hakozaki, Fukuoka 812*
(Received August 13, 1984)

The biionic membrane potential was measured with the system in which a solution of calcium chloride was separated by a liquid membrane from a solution of another metal chloride. Four kinds of liquid membranes were prepared by dissolving calcium hexadecyl sulfate, stearate, cholate or deoxycholate in aqueous 1-octanol. All of the membranes studied were nearly permselective to cation. The membrane potential was analysed according to the Goldman-type equation based on the irreversible thermodynamics. The slope of a linear portion of the biionic potential *vs.* logarithmic activity curve showed fairly good agreement with the theoretical slope, *i.e.*, $2.303\times 2RT/(Z_{Ca}+Z_M)F$ per a ten-fold increase in activity, where Z_{Ca} and Z_M were the valencies of calcium ion and another metal ion M existing across a membrane, respectively. The selective permeation coefficients of various metal ions were estimated for each membrane. The surprisingly small differences in the selective permeation coefficient between uni- and bi-valent cations were observed for the liquid membranes with calcium stearate, cholate or deoxycholate, while the about ten-fold increase in the coefficient per valency was observed for the liquid membrane with calcium hexadecyl sulfate. These results were discussed according to the theory previously presented.

The ion transport across membrane has usually been explained by the Goldman-type equation. The equation of this type has been presented for a fixed-site membrane as a limiting form of the general equation on the basis of the irreversible thermodynamics by Kimizuka *et al.*[1-3] In the theory, the general expression of multiionic membrane potential has been derived without any assumptions concerning the distribution of concentration as well as that of potential within membrane. The theory has successfully been applied to the biionic system in which different multivalent ions exist across the membranes of some permselective ion-exchangers.[4,5]

The equation of the membrane potential for a liquid membrane with mobile sites has been derived on the basis of the Nernst-Planck equation by Sandblom *et al.*[6] The equation is expressed as a sum of the two logarithmic terms in the case of strong association between counter ion and membrane site, while being expressed as the single logarithmic term in the case of complete dissociation. Only when the unlikely assumption that the mobility of free site is much larger than that of counter ion is made, the equation for strong association can be reduced to the familiar form with the single logarithmic term. On the other hand, it is well known facts that the membrane potentials measured with liquid membranes can be expressed by the equation with the single logarithmic term, even when liquid membranes are prepared from solvents of low dielectric constant.[7,8]

The total flux of a permeable ion across a liquid membrane can be expressed by the equation of the same form as that for a fixed-site membrane, although the physical contents of the permeability coefficients are somewhat modified.[9-11] Thus, the Goldman-type equation with the single logarithmic term can also be derived from the flux equation in the same way as described elsewhere,[1-3] and is equally applicable to the liquid membrane systems.[10,11]

In the present study, the membrane potential was measured in the biionic systems with four kinds of thin liquid membranes. The results were analysed and discussed according to the Goldman-type equation.

Experimental

Materials. Calcium hexadecyl sulfate, $Ca(HS)_2$, was prepared from sodium hexadecyl sulfate according to the method of Lottermoser and Püschel.[12] Sodium hexadecyl sulfate was prepared from purified 1-hexadecanol obtained by fractional distillation of a commercial sample, as stated elsewhere.[13] Stearic, cholic and deoxycholic acids from Merck were neutralized with sodium hydroxide to sodium salts, from which calcium stearate, cholate and deoxycholate, abbreviated as $Ca(ST)_2$, $Ca(CH)_2$, and $Ca(DC)_2$, respectively, were prepared by metathesis in aqueous ethanol with the same procedure as described elsewhere.[14] All other reagents were of guaranteed grade and used without further purification.

Liquid membrane was prepared by dissolving a site species in water-saturated 1-octanol. The concentration of the site species in liquid membranes was *ca.* 10^{-3} M (1 M= 1 mol dm^{-3}).

Procedure. The following cell assembly, connected to the Orion digital pH meter, Model 701, was used for the measurement of membrane potential.

Ag|AgCl|Internal Solution (1.10×10^{-2} M $CaCl_2$)|
Liquid Membrane|External Solution|Calomel

For the liquid membranes with $Ca(ST)_2$, $Ca(CH)_2$, and $Ca(DC)_2$, the internal and external solutions were adjusted to pH=8.5 with 2×10^{-3} M Tris buffer. A body of the Orion calcium ion selective electrode and a Teflon millipore film (Fluoro Pore, No. FP080, 0.8 μm of pore size, 50 μm in thickness, Sumitomo Electric Co. Ltd.) as an inert porous matrix for liquid membranes were employed for construct-

ing the membrane electrode.

The external solution was stirred and all measurements were carried out at 25±0.02 °C.

Results and Discussion

For the liquid membranes with $Ca(ST)_2$, $Ca(CH)_2$, or $Ca(DC)_2$, the pH dependence of the membrane electrode potential, V, was studied at constant calcium ion concentration, as shown in Fig. 1. The potential for the liquid membrane with $Ca(ST)_2$ was independent of pH in the alkaline region of pH>8.5. A similar pH dependence was also observed with the calcium ion selective liquid membrane electrode using didecyl hydrogenphosphate site.[15] The potentials for the liquid membranes with $Ca(CH)_2$ or $Ca(DC)_2$ were unstable below pH 7, possibly being due to the dissolution of membrane site into aqueous phase.

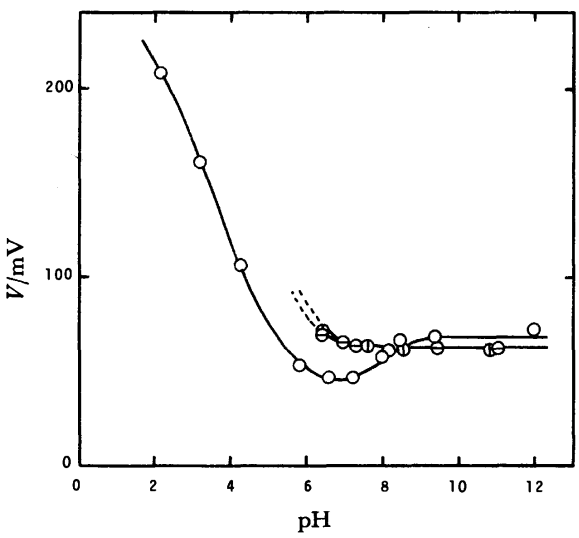

Fig. 1. Membrane electrode potential *vs.* pH curves. Liquid membranes with $Ca(ST)_2$, ○; $Ca(CH)_2$, ①; $Ca(DC)_2$, ⊖. $C_{Ca(I)}=C_{Ca(e)}=1.10\times10^{-2}$ M.

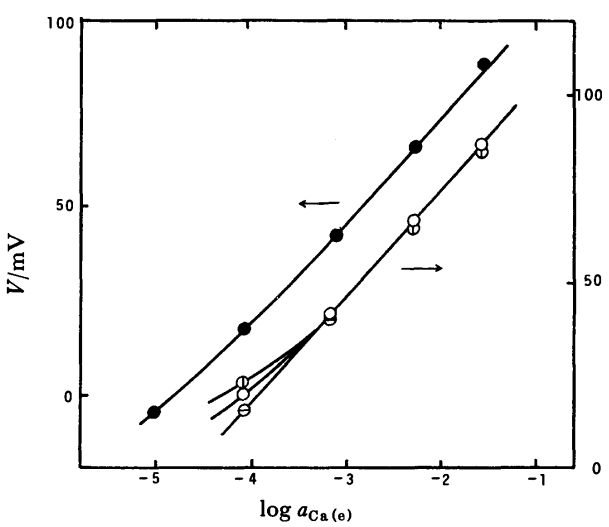

Fig. 2. Membrane electrode potential *vs.* logarithmic activity curves for the single electrolyte system of $CaCl_2$. Liquid membranes with $Ca(HS)_2$, ●; $Ca(ST)_2$, ○; $Ca(CH)_2$, ①; $Ca(DC)_2$, ⊖. $C_{Ca(I)}=1.10\times10^{-2}$ M. The pH's of aqueous phases were 5.6 for liquid membrane with sulfate site and 8.5 for those with carboxylate site.

The membrane electrode potential for the liquid membrane with $Ca(HS)_2$, measured at 10^{-1} M $CaCl_2$, was independent of pH in the range of pH>3.3.

The potentials of the membrane electrodes for all of liquid membranes studied were found to be linear against the logarithm of external calcium ion activity, as shown in Fig. 2. The values of ion activity were calculated according to the extended Debye-Hückel equation. Assuming that a membrane is ideally permselective to cation, the potential of the membrane electrode for the single electrolyte system of $CaCl_2$ is given as

$$V = V_{Ca} + V_o = -\frac{RT}{Z_{Ca}F}\ln\frac{a_{Ca(e)}}{a_{Ca(I)}} + V_o, \qquad (1)$$

where V_{Ca} is the membrane potential in the present system: $a_{Ca(e)}$ and $a_{Ca(i)}$, the activities of calcium ion in the external and internal solutions, respectively; R, gas constant: T, absolute temperature: F, Faraday constant: Z, valency; and V_o, the potential difference between the internal and external electrodes, including the liquid junction potential. Since the same internal solution was used throughout the experiment and the liquid junction potential is negligibly small, V_o can be regarded as constant. Therefore, the slope of the V *vs.* log $a_{Ca(e)}$ curve is approximately the same as that of the V_{Ca} *vs.* log $a_{Ca(e)}$ curve. The slopes of the linear portions shown in Fig. 2 are *ca.* 29 mV per decade for all of the liquid membranes studied, agreeing well with the theoretical slope predicted by Eq. 1. This indicates that these liquid membranes are ideally permselective to cation.

The measurements of the biionic potential were carried out on the systems in which the internal solution containing a constant concentration of $CaCl_2$ was separated by a liquid membrane from an external solution containing varying concentrations of another metal chloride. Typical results are shown in Figs. 3—5. When the membrane is ideally permselective to cation, the potential of the membrane electrode for the biionic system of Ca^{2+} and M^{Z_M+}, V', can be written as[4]

$$V' = V_{Ca,M} + V_o = \frac{2RT}{(Z_{Ca}+Z_M)F}\ln\frac{Z_M P_M a_{M(e)}}{Z_{Ca}P_{Ca}a_{Ca(I)}} + V_o, \qquad (2)$$

where $V_{Ca,M}$ is the membrane potential in the biionic system; and P, the membrane permeability. Assuming that the permeability ratio, P_M/P_{Ca}, and the concentration of $CaCl_2$ in the internal solution are constant, Eq. 2 becomes

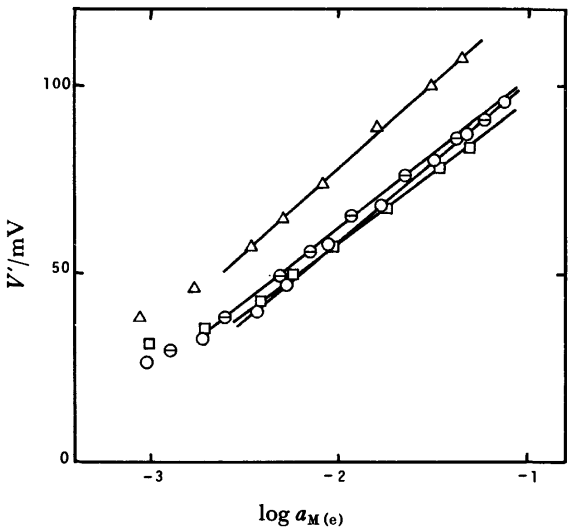

Fig. 3. Membrane electrode potential *vs.* logarithmic activity curves for the system Ca^{2+}(i)-M^{+}(e). Liquid membrane with $Ca(CH)_2$. M^+=Li^+, △; Na^+, ○; K^+, □; Cs^+, ⊖. $C_{Ca(I)}=1.10\times10^{-2}$ M. pH=8.5.

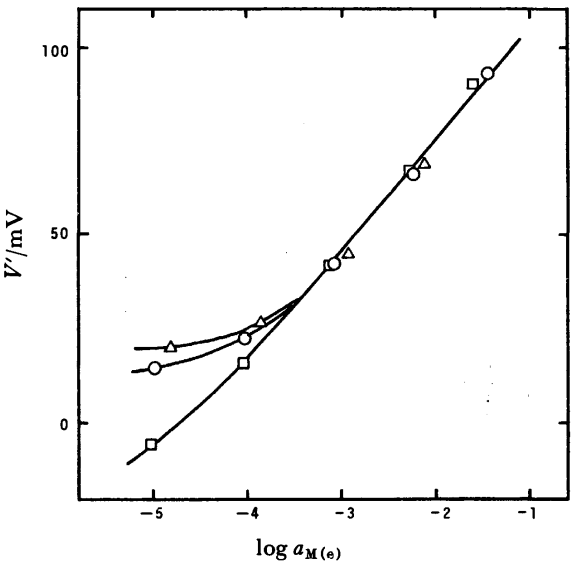

Fig. 4. Membrane electrode potential *vs.* logarithmic activity curves for the system Ca^{2+}(i)-M^{2+}(e). Liquid membrane with $Ca(HS)_2$. M^{2+}=Mg^{2+}, ○; Sr^{2+}, △; Ba^{2+}, □. $C_{Ca(I)}=1.10\times10^{-2}$ M. pH=5.6.

$$V' = \frac{2RT}{(Z_{Ca}+Z_M)F} \ln a_{M(e)} + \text{const.}, \quad (3)$$

where

$$\text{const.} = \frac{2RT}{(Z_{Ca}+Z_M)F} \ln \frac{Z_M P_M}{Z_{Ca} P_{Ca} a_{Ca(I)}} + V_o, \quad (4)$$

The slopes of linear portions in Figs. 3—5 were 37—41 (except 45 for the Ca^{2+}-Li^+ system), 30 and 21—22 mV per decade for the 2—1, 2—2, and 2—3 valent biionic systems, respectively, agreeing approximately with the theoretical slope predicted by Eq. 3, *i.e.*, 118/ (Z_{Ca}+Z_M) mV per decade.

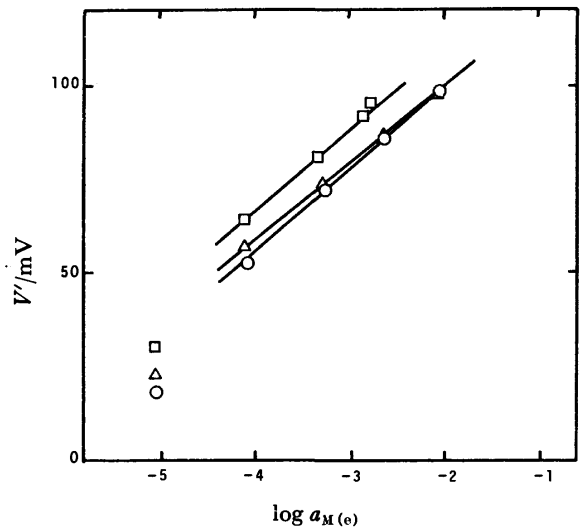

Fig. 5. Membrane electrode potential *vs.* logarithmic activity curves for the system Ca^{2+}(i)-M^{3+}(e). Liquid membrane with $Ca(HS)_2$. M^{3+}=Al^{3+}, ○; La^{3+}, △; $[Co(NH_3)_6]^{3+}$, □. $C_{Ca(I)}=1.10\times10^{-2}$ M. pH(i)= 5.6. The pH's of external solutions of Al^{3+}, La^{3+} and $[Co(NH_3)_6]^{3+}$ were 3.4—5.4, 5.2—5.5, and 5.5—5.4 depending upon the concentrations, respectively, where the electrode potential was independent of pH.

$[Co(NH_3)_6]^{3+}$	17	—	—	—

The selective permeation coefficients of Z_M valent cation M, relative to Ca^{2+} ion, $K_{Ca,M}=Z_M P_M/Z_{Ca} P_{Ca}$, were estimated from the potential difference, $V'-V$, by using Eqs. 1 and 2. The results are shown in Table 1.

According to the previous theory,[11] the membrane permeability to cation M, P_M, can be expressed as

$$P_M = RT\bar{u}_M C_M^{to}/\{a_{M(e)} a_{M(I)}\}^{1/2} d, \quad (5)$$

where

$$\bar{u}_M = \alpha_M u_M + (1-\alpha_M) u_I, \quad (6)$$

and C_M^{to} denotes the mean total concentration of cation

M: d, the membrane thickness: u_M and u_I, the mean mobilities of cation M and ion pair I formed between cation M and site anion, respectively; and α_M, the dissociated fraction of cation M ($\alpha_M = C_M/C_M^{to} = 1-\nu_M C_I/C_M^{to}$, where ν_M is the stoichiometric coefficient of cation M in the ion-pair formation), all referred to the values within membrane. Inserting the following relation for the site species[11]

$$(\nu_M/\nu_S)\alpha_M u_S - (1-\alpha_M)u_I = 0 \tag{7}$$

into Eq. 6, we have

$$\bar{u}_M = \alpha_M\{u_M + (\nu_M/\nu_S)u_S\} \tag{8}$$

where ν_S is the stoichiometric coefficient of site anion S in the ion-pair formation; and u_S, the mean mobility of site anion. Assuming that the selective permeation coefficient, $K_{Ca,M}$, can be expressed as the ratio of $Z_M P_M$'s in the single electrolyte system, we have from Eqs. 5 and 8

$$\begin{aligned} K_{Ca,M} &= Z_M P_M / Z_{Ca} P_{Ca} \\ &= Z_M \bar{u}_M C_M^{to}\{a_{Ca(e)} a_{Ca(i)}\}^{1/2} / Z_{Ca}\bar{u}_{Ca} C_{Ca}^{to}\{a_{M(e)} a_{M(i)}\}^{1/2} \\ &= Z_M \alpha_M\{u_M + (\nu_M/\nu_S)u_S\}K_M / Z_{Ca}\alpha_{Ca} \\ &\quad \times \{u_{Ca} + (\nu_{Ca}/\nu_S)u_S\}K_{Ca} \end{aligned} \tag{9}$$

where K_{Ca} and K_M are the apparent partition coefficients of cations Ca^{2+} and M between the membrane and aqueous phases. This expression of the selective permeation coefficient has the same form as that for a fixed-site membrane,[3] except that u_M and C_M are replaced by $\bar{u}_M$ and C_M^{to}. Considering Eq. 7, Eq. 9 is reduced to the same limiting form as that derived by Sandblom *et al.* in the case of complete dissociation.

The noticeable feature seen among the estimated values of $K_{Ca,M}$ is the surprisingly small differences in the $K_{Ca,M}$ value between uni- and bivalent cations for the membranes with $Ca(ST)_2$, $Ca(CH)_2$, and $Ca(DC)_2$. Let us consider the case of $M=Na^+$ for the liquid membrane with $Ca(ST)_2$. Assuming that the mobility ratio, $\{u_{Na}+(\nu_{Na}/\nu_S)u_S\}/\{u_{Ca}+(\nu_{Ca}/\nu_S)u_S\}$, can be replaced by that in aqueous solution and using 50.15, 119.0[16], and 19.95 (extrapolated from the values for fatty acid anions of C_1—C_{14})[17] $ohm^{-1}\,cm^2\,mol^{-1}$ for the values of the limiting molar conductances of Na^+, Ca^{2+}, and stearate ions, respectively, Eq. 9 can be rewritten as

$$K_{Ca,Na} = 0.504(\alpha_{Na}/\alpha_{Ca})(K_{Na}/K_{Ca}) \tag{10}$$

According to Eq. 10, the $K_{Ca,Na}$ value is governed by the two ratios, *i.e.*, α_{Na}/α_{Ca} and K_{Na}/K_{Ca}. In the case of complete dissociation, the selective permeation coefficient is solely determined by the partition ratio. Experimental results with liquid membranes formed from solvents of high dielectric constant can be explained according to this reasoning.[8] However, in the case of partial dissociation, these two ratios usually exert the opposite effects on the selective permeation coefficient, *i.e.*, the strong affinity of an ion to the membrane site is favorable to the partition ratio, but not to the dissociation ratio.

The very small value of K_{Na}/K_{Ca} can be expected from the partition data of metal ions between the aqueous and the water-saturated 1-octanol phase with a partially neutralized polycarboxylic acid,[18] while the large value of α_{Na}/α_{Ca} can be expected from the conductance data for metal salts of the above polycarboxylic acid in water-saturated 1-octanol.[19] Thus, the partial cancellation of the K_{Na}/K_{Ca} value by the α_{Na}/α_{Ca} value seems to bring the $K_{Ca,Na}$ value close to those for bivalent cations, leading to the diminished valency effect on the selective permeation coefficient.

Contrary to the above membranes, the about tenfold increase in the $K_{Ca,M}$ value per valency were observed for the liquid membrane with $Ca(HS)_2$, as seen in Table 1. Because of the dissociable sulfate site, the α_{Ca} value of $Ca(HS)_2$ reachs 0.25 at the concentration of 2.5×10^{-3} M even in aqueous 1-octanol.[11] On the other hand, the association constant of sodium dodecyl sulfate in the dioxan–water mixture of the same dielectric constant as that of aqueous 1-octanol, *i.e.*, 8.92,[19] was obtained by the extrapolation, from which the α_{Na} value was estimated to be *ca.* 0.25 at the concentration of 2.5×10^{-3} M.[20] It is obvious from the estimated values of the dissociated fraction that the observed valency effect on the selective permeation coefficient can primarily be attributed to the partition ratio.

Thermodynamic and Viscometric Studies on the Solution State of Surfynol 465 in Water

Shizuko SATO* and Hiroshi KISHIMOTO
Division of Physical Chemistry, Faculty of Pharmaceutical Sciences, Nagoya City University, Tanabe-dori, Mizuho-ku, Nagoya 467
(Received August 20, 1984)

The vapor-pressure depression, surface tension, density and viscosity of the aqueous solution of Surfynol 465, nonionic surfactant, α,α′-[2,4,7,9-tetramethyl-5-decyne-4,7-diyl]bis[ω-hydroxy-poly(oxyethylene)], were measured at various concentrations and 298.15 K, indicating cmc at 11—14×10^{-3} mol kg^{-1} and a second cmc at *ca.* 30×10^{-3} mol kg^{-1}. From vapor-pressure depression, the association numbers of first and second micelles were approximately estimated at 4 and 13—16, respectively. From the results of density and viscosity measurements, the molar volume and Einstein's parameter, *k*, were calculated, respectively. The cohesion between the two hydrophobic chains in monomer was suggested by the analysis of molar volume. It was estimated on the molar volume and *k* of Surfynol 465 that the hydration of two hydrophilic poly(oxyethylene) chains is significant in monomer as well as micelles, but scarcely changes through micelle formation. The effect of concentration on *k* was discussed with respect to the shape and interaction of micelles.

In comparison with the usual surfactant, whose molecule has a single group each for hydrophilic and hydrophobic moieties, such as sodium dodecyl sulfate or alkylphenol with poly(oxyethylene) side chain, surfactant with more than two hydrophilic or hydrophobic groups reveals very different characteristics in monomeric state as well as in micellar one with respect to various physicochemical properties. It is well known that such a polyfunctionality plays an important role in many biological systems, *e.g.* the role of phospholipid molecule with two hydrophobic groups in the membranes of cell and neuron. Concerning phosphatidylcholine,[1-3] a typical phospholipid known as forming a similar bilayer structure to red blood cell, and on sodium 1,2-bis(2-ethylhexyloxycarbonyl)ethane sulfonate, Aerosol OT, as well as its homologues,[4,5] which are typical anionic surfactants with two hydrophobic alkyl groups, we have investigated their physicochemical properties so far and found the characteristic features caused by their structures, *i.e.* amphiphiles with two hydrophobic chains. On nonionic surfactants, Kuwamura and Takahashi studied their surface-chemical properties, using acetal-type compounds which have one hydrocarbon chain and two poly(oxyethylene) hydrophilic groups.[6] Based upon the above informations, we are now studying various physicochemical properties of nonionic Surfynols which have two sets of one branched hydrocarbon chain and one poly(oxyethylene) chain at both sides of acetylene radical. In this work, we report the

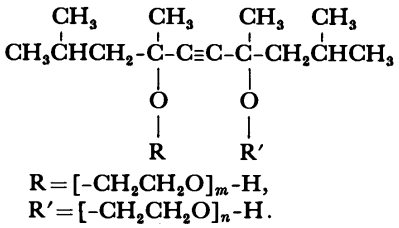

Fig. 1. Chemical structure of Surfynol 465. When m+n=10, the structure indicates Surfynol 465.

vapor-pressure depression, surface tension, density and viscosity of the aqueous solution of Surfynol 465, α,α′-[2,4,7,9-tetramethyl-5-decyne-4,7-diyl]bis[ω-hydroxyl-poly(oxyethylene)] with *ca.* ten oxyethylene segments in total (Fig.1).

Experimental

Materials. Surfynol 465 was obtained from Air Products and Chemicals, USA. NaCl was from Wako Pure Chemical Industries, Ltd., Japan. Deionized and twice-distilled water was used.

Procedures. The vapor-pressure depressions of Surfynol 465 and NaCl (reference) aq were measured with a Molecular Weight Apparatus model 115, Hitachi Ltd., Japan. Surface tension, σ, was measured by a drop-weight method, following Harkins, & Brown's correction.[7] Density, ρ, was determined with a digital precision densimeter (DMA 602/DMA 60, Anton Paar K.G., Austria) using air and water as calibration standards. Viscosity, η, was measured with a usual Ostwald viscometer. All measurements were carried out at 298.15 K±0.03 K for ρ and ±0.1 K for others.

Results and Discussion

Surfynol 465 is liquid and soluble in water at room temperature. The cloud point of 1—20 wt% aq solution exists in the range of 315—320 K, which was observed by the naked eye and plotted in Fig. 2. From the depression of vapor pressure in the very dilute aq solution, which is considered to be practically ideal, we estimated the number-average molar mass, *M*, of Surfynol 465 at 600 g mol^{-1}.

Using the molecular weight apparatus, we observed the difference in reading, Δ*R*, which indicates the vapor-pressure depression of water, against various molalities of Surfynol 465 in solution, *m*, and plotted the result in Fig. 3. The value of Δ*R* increased with *m*, approximately making a broken line, which had two breaks. The first sharp break is considered to indicate cmc (13.8×10^{-3} mol kg^{-1}) according to Brady *et al.*[8] The

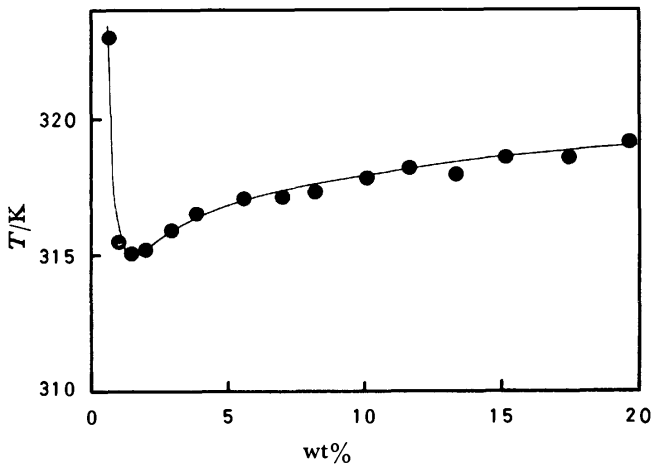

Fig. 2. Cloud point *vs.* wt% for Surfynol 465.

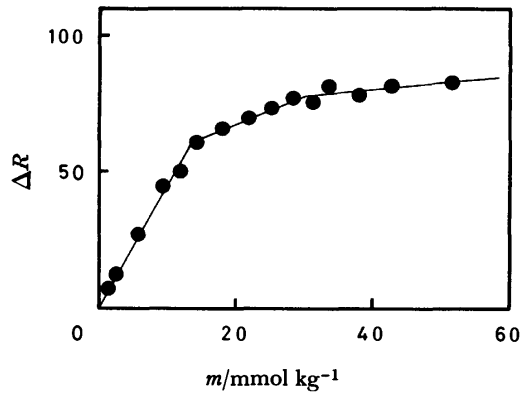

Fig. 3. Plots of ΔR *vs.* molality.

second slight break or bend suggests a second cmc.[4,5] Next, by the further analyses of the ΔR *vs.* m relation, we obtained the thermodynamic parameters for Surfynol 465, as follows. Since a real solution deviates from ideality with the increase of solute concentration, we must determine the activity coefficient of Surfynol 465, even if below cmc. Under the isopiestic condition between two solutions of reference and surfactant,

$$\nu_r m_r \phi_r = \nu m \phi, \tag{1}$$

where ν, m, and ϕ are the stoichiometric coefficient, molality and osmotic coefficient of water, respectively, for surfactant and those with suffix, r, are corresponding quantities for reference solute.[9,10] Adopting NaCl as reference, whose osmotic coefficient on $\nu_r=2$ is known over the necessary concentration range, and setting $\nu=1$, we obtained the ϕ *vs.* m relation shown in Fig. 4. The concentration, where ϕ dropped markedly, corresponds to cmc. The feature indicating the second cmc was scarcely recognized.

The activity coefficient, γ, and the activity, a, of surfactant can be calculated by Eq. 2 and 3.

$$-\ln \gamma = 1 - \phi + \int_0^m (1-\phi)/m \cdot dm \tag{2}$$

and

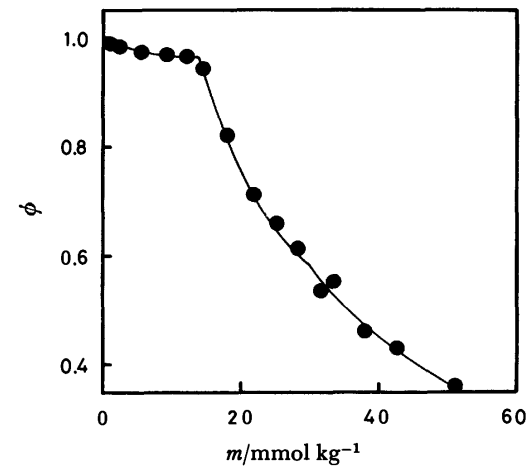

Fig. 4. Osmotic coefficient of water *vs.* molality.

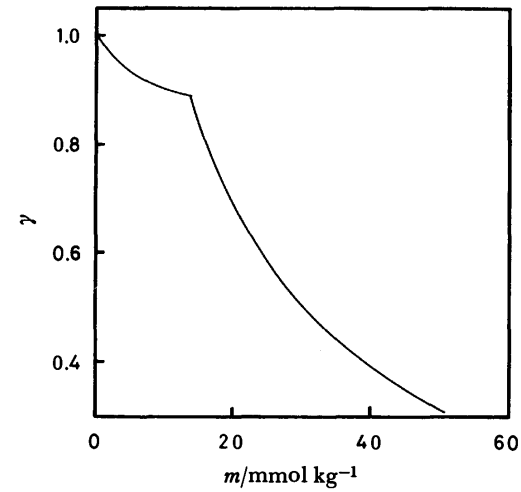

Fig. 5. Activity coefficient *vs.* molality.

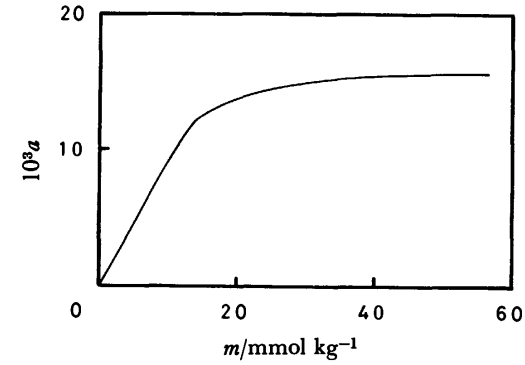

Fig. 6. Activity *vs.* molality.

$$a = \gamma m. \tag{3}$$

With the increase of m, γ decreased similarly to ϕ, also showing an abrupt fall at cmc (Fig. 5). As a result, above cmc the value of a became considerably restrained from increasing, hitherto almost proportionally to m (Fig. 6). The relation of a *vs.* m seems to be almost perfectly similar to the original relation of ΔR *vs.* m, in spite of the complex intermediates between them.

The similarity can be attributed to the nearly unit value of ϕ or the ideal nature of solute in low m.

Taking into consideration the general tendency that nonionic solutes behave more ideally than ionic solutes in water and in order to estimate the association number of Surfynol 465 in micelle, we approximately treated its aqueous solution as an ideal binary solution consisting of monomer and micelle, each of which has unit activity coefficient. As micellar species, we adopted a single kind of micelle with the association number, n, which is an average in the case of polydispersity. Then, we applied the Raoult's law to the ralation between ΔR and m (Fig. 3). The value of ΔR can be considered to be linear to the effective concentration of solute, C_{eff}, which is in an ideal solution the sum of molalities of surfactant in monomer and micelle, m_{mon} and m_{mic}, respectively, when C_{eff} is expressed in molality. Thus,

$$C_{\text{eff}} = m_{\text{mon}} + m_{\text{mic}}. \tag{4}$$

The molality of surfactant, which does not discriminate micelle from monomer, can be divided as

$$m = m_{\text{mon}} + nm_{\text{mic}}. \tag{5}$$

Then,

$$C_{\text{eff}} = m_{\text{mon}} + (m - m_{\text{mon}})/n. \tag{6}$$

The linearity of ΔR *vs.* m between cmc and second cmc can be simply explained, if both values of m_{mon} and n are assumed to be constant, m_{mon} being cmc. Calculating n as the ratio of two slopes of lines below and above cmc on ΔR *vs.* m, we obtained, *ca.* 4 for it.

For the analysis of ΔR *vs.* m relation above second cmc, the following two alternative approximations seems to be sufficient. First, approximating that the surfactant solution is an ideal ternary solution consisting of monomer, first micelle (hitherto simply called micelle) and second micelle, whose concentrations are cmc, second cmc minus cmc and m minus second cmc, respectively, we estimated the association number of second micelle at *ca.* 16 as the ratio of two slopes of lines below cmc and above second cmc on ΔR *vs.* m.[4,5] In this case, the linearity of ΔR *vs.* m holds at a constant association number of second micelle.

The second approximation assumes an ideal binary solution consisting of monomer and the second micelle, which forms from the transition of first micelle and grows in size, number or both with the increase of m above second cmc.[11] The association number of second micelle on the second approximation is not so easy to estimate directly from the slope of ΔR *vs.* m as the value on the first approximation, but is supposed to be somewhat smaller, owing to the consolidation of first micelles into second micelles at the second approximation.

Next in place of the above-mentioned phase-separation model, we considered an association equilibrium between monomer and micelle. For simplicity, we assumed also the monodispersity of micelle. Then,

$$(m_{\text{mic}}/\text{mol kg}^{-1})/(m_{\text{mon}}/\text{mol kg}^{-1})^n = K, \tag{7}$$

where K is the equilibrium constant. Combining Eq. 7 with Eqs. 4 and 5, which still hold, we have

$$\{(nC_{\text{eff}} - m)/\text{mol kg}^{-1}\}^n \cdot (n-1)^{1-n} = \{(m - C_{\text{eff}})/\text{mol kg}^{-1}\}/K, \tag{8}$$

or

$$n \ln \{(nC_{\text{eff}} - m)/\text{mol kg}^{-1}\} - (n-1) \ln (n-1) = \ln \{(m - C_{\text{eff}})/\text{mol kg}^{-1}\} - \ln K, \tag{9}$$

Converting ΔR into C_{eff} of Eq. 9 and calculating on a trial and error method, we obtained 15 for n, as seen in Fig. 7. To this value the association number of second micelle on the previously mentioned second approximation might be close.

From the inspection of σ *vs.* ln m curve, we assigned 11.1×10^{-3} mol kg^{-1} and 26.0 mN m^{-1} to cmc and the surface tension at cmc, σ_{cmc}, respectively (Fig. 8).

The surface excess, Γ, and the surface molecular area, A, of surfactant were calculated, by applying Gibbs' isotherm, Eq. 10, to the relation of σ with a, which had been calculated using Eq. 3.

$$\Gamma = -1/RT \cdot d\sigma/d\ln a, \tag{10}$$

and

$$A = 1/(L\Gamma), \tag{11}$$

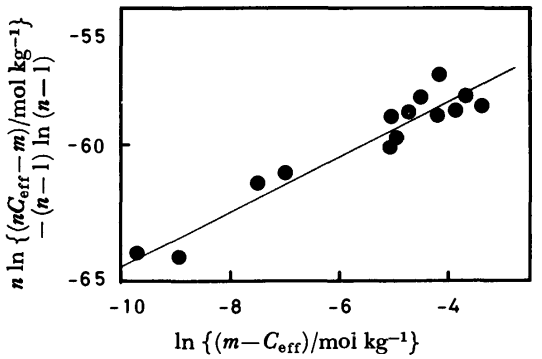

Fig. 7. Plot for the determination of association number.

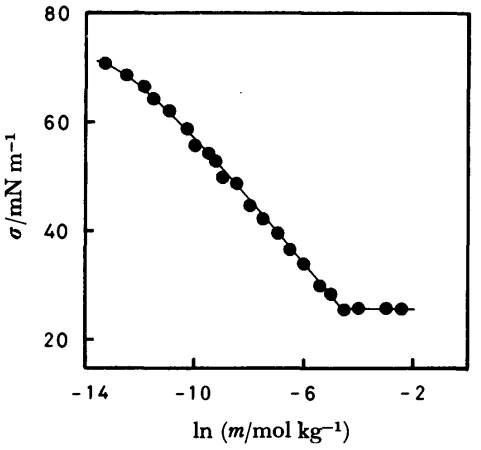

Fig. 8. Surface tension *vs.* logarithm of molality.

where L is Avogadro's number. We had 2.6×10^{-6} mol m^{-2} and 64.1 Å^2 molec^{-1} for Γ and A, respectively, near cmc.

In the course of study on acetal-type nonionic surfactant, Kuwamura and Takahashi[6] have reported that the cmc, σ_{cmc} and A of $CH_3(CH_2)_{12}CH(O(C_2H_5O)_5H)_2$, *i.e.* AG-14(10), at 293.15 K were 1.7×10^{-5} mol dm^{-3}, 36.2 mN m^{-1} and 54.5 Å^2 molec^{-1}, respectively. While the numbers of carbon, oxyethylene and poly (oxyethylene) chain of Surfynol 465 are same to those of AG-14(10), respectively, Surfynol 465 is about 650 times high in cmc, low by 10.2 mN m^{-1} in σ_{cmc} and large by 9.6 Å^2 molec^{-1} in A, each compared to AG-14(10). These discrepancies are considered to arise from the difference in the conformation of molecule in solution, wich is caused by the difference in the type of segment that connects two hydrophilic poly(oxyethylene) chains.

The relation between ρ and m makes two separate half lines, whose intersection gives cmc (12.4×10^{-3} mol kg^{-1}), as seen in Fig. 9. Owing to the lack of measurements beyond the second cmc, we could not describe the behavior of ρ or derived quantity *vs.* m at the formation of second micelle.

To obtain the apparent and partial molar volumes of surfactant, $^{\phi}V$ and V_s, respectively, we used the following relations.

$$^{\phi}V = \{(1+mM)/\rho - 1/\rho_o\}/m, \tag{12}$$

and

$$V_s = {}^{\phi}V + m(\mathrm{d}^{\phi}V/\mathrm{d}m), \tag{13}$$

where ρ_o is the density of water. The value of $^{\phi}V$ is plotted against m in Fig. 10.

Below cmc, surfactant exists only in monomeric form. There, the value of $^{\phi}V$ equals the apparent molar volume of monomer, $^{\phi}V_m$. According to Eq. 13, at infinite dilution the value of $^{\phi}V_m$ reduces to the standard partial volume of monomer, V_m°. From the inspection of Fig. 10, the following approximation can be expected at any concentration.

$$^{\phi}V_m \cong V_m^{\circ}. \tag{14}$$

Above cmc, assuming that $^{\phi}V$ is the average of monomeric and micellear contributions, we have

$$^{\phi}V = \mathrm{cmc}\cdot{}^{\phi}V_m/m + (m-\mathrm{cmc})^{\phi}V_M/m, \tag{15}$$

where $^{\phi}V_M$ is the apparent molar volume of surfactant in micelle. The $^{\phi}V$ of micelle formation, $\Delta_{mic}{}^{\phi}V$, is defined by Eq. 16.

$$\Delta_{mic}{}^{\phi}V \equiv {}^{\phi}V_M - {}^{\phi}V_m. \tag{16}$$

Then,

$$^{\phi}V = -\mathrm{cmc}\cdot\Delta_{mic}{}^{\phi}V/m + \Delta_{mic}{}^{\phi}V + {}^{\phi}V_m, \tag{17}$$

or

$$(m-\mathrm{cmc})/(^{\phi}V - {}^{\phi}V_m) = m/\Delta_{mic}{}^{\phi}V. \tag{18}$$

From plots of $^{\phi}V$ *vs.* $1/m$ (Fig. 11) and $(m-\mathrm{cmc})/(^{\phi}V-{}^{\phi}V_m)$ *vs.* m (Fig. 12), we can ascertain the validity of Eqs. 17 and 18 or retrospectively the assumption of Eq. 15, on the basis of the constancy of $^{\phi}V_M$ as well as $^{\phi}V_m$. From the above situation,

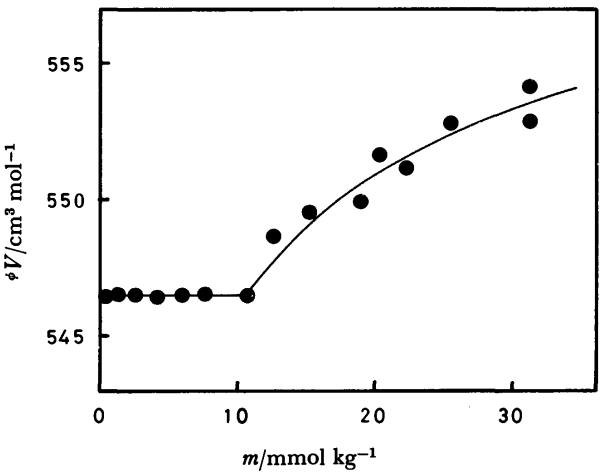

Fig. 10. Apparent molar volume *vs.* molality.

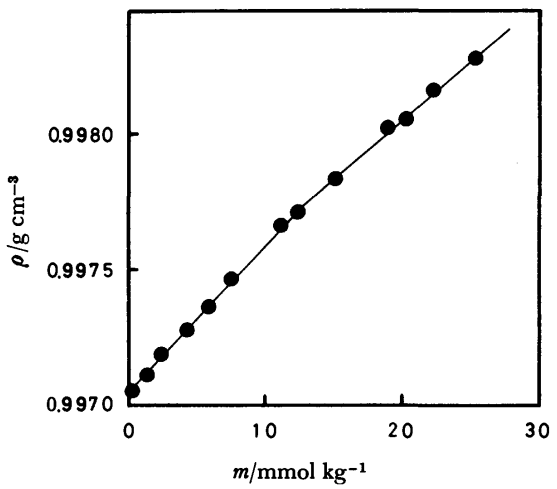

Fig. 9. Density *vs.* molality.

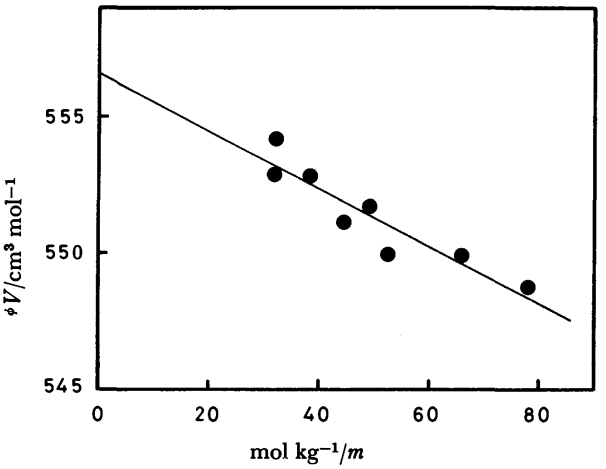

Fig. 11. Apparent molar volume *vs.* reciprocal of molality.

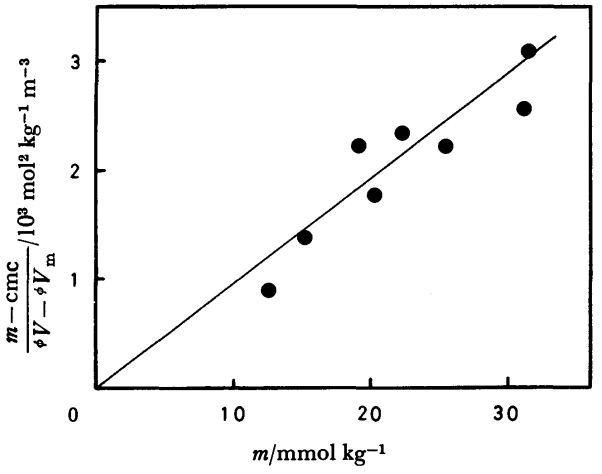

Fig. 12. $(m-\mathrm{cmc})/(^{\phi}V-^{\phi}V_{\mathrm{m}})$ *vs.* molality.

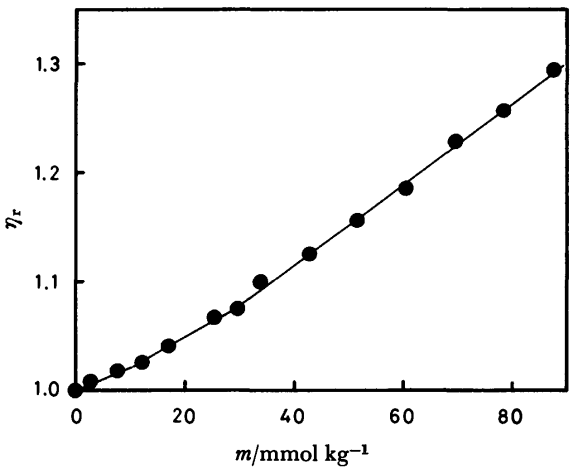

Fig. 13. Relative viscosity *vs.* concentration.

we can regard $^{\phi}V_{\mathrm{M}}$ and $\Delta_{\mathrm{mic}}{}^{\phi}V$ to be approximately equal to the standard partial volume of surfactant in micelle and of micelle formation, V°_{M} and $\Delta_{\mathrm{mic}}V^{\circ}$, respectively. From the analyses of Fig. 11 and 12, we estimated the V°_{m}, V°_{M}, and $\Delta_{\mathrm{mic}}V^{\circ}$ of Surfynol 465 at 546.5, 556.6, and 10.1 cm^3 mol^{-1}, respectively. As the optimal value of cmc for the above estimation, we used 10.6×10^{-3} mol kg^{-1} as cmc, which is slightly lower than the value estimated directly on the plot of ρ *vs.* m.

On the other hand, it is known with respect to $\Delta_{\mathrm{mic}}V^{\circ}$ that the contribution of methylene segment in one alkyl group is on the average *ca.* 1.5 cm^3 mol^{-1}, [12,13] which coincides with the molar volume change of methylene segment in paraffin at the transfer from solution state in water to liquid,[14] and the contribution of oxyethylene segment is considered to be negligible.[15] If the effect of acetylene group is ignored, the value of *ca.* 10 cm^3 mol^{-1} as $\Delta_{\mathrm{mic}}V^{\circ}$ of Surfynol 465, which has two hydrocarbon chains each with six carbons, suggests an entangling cohesion between the two chains in the surfactant molecule, dispersed in monomeric state, although the branching of hydrocarbon chains would also make the value of $\Delta_{\mathrm{mic}}V^{\circ}$ less in some degree. The above suggestion can be supported by the same case of Aerosol OT, which was studied by one of the authors and his co-worker using thermodynamic and spectrometric measurements.[4,5]

In order to study the micellar structure of Surfynol 465 from the rheological point of view, we measured the viscosity of its aqueous solution, η, against various m. The value of η increased rather monotonously with the increase of m, making only faint features near cmc and second cmc, as shown in Fig. 13 concerning the relative viscosity, η_r, *vs.* m. To make the effect of solute more conspicuous, we adopted the parameter of Einstein's formula, k, which is akin to reduced viscosity and defined by Eq. 19.[16]

$$k = (\eta_r - 1)/f, \tag{19}$$

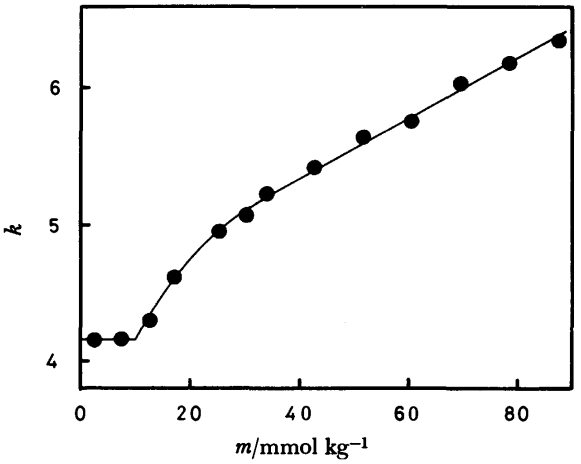

Fig. 14. Parameter of Einstein's viscosity formula *vs.* molality.

where f is the volume fraction of surfactant and can be approximately identified as the fraction of total apparent volume of surfactant, *i.e.* amount of surfactant, n_s, times $^{\phi}V$, in the volume of solution, V. Then,

$$f \cong n_s{}^{\phi}V/V = 1 - \rho/\{(1+mM)\rho_o\}, \tag{20}$$

The values of k were calculated from the results on η_r and ρ at various m and plotted in Fig. 14. Below *ca.* 10×10^{-3} mol kg^{-1}, which is approximately close to the previously described values of cmc, the value of k was constant at *ca.* 4, which is fairly higher than the theoretical value of 2.5 for spheres dispersed indepently of each other in medium. For its explanation, the deviation of molecular shape from sphere alone seems to be insufficient, since the monomer of Surfynol 465 dose not exist much differently from sphere, owing to the cohesion between its hydrophobic chains, which was previously mentioned. It is suggested that remarkable hydration occurs on the poly(oxyethylene) groups of Surfynol 465. As m increased above cmc, k increased and drew a parabola with a slight bend near second

cmc and a linear tail after it, showing the occurrence and multiplication of micelle having higher value of k than monomer. From the cause of higher k for micelle, the change in the hydration of poly (oxyethylene) group at micelle formation would be excluded, because the change is considered to be not significant, which was estimated on the analysis of $\Delta_{mic}V^{\circ}$, and might decrease k, even if it occurred, due to the dehydration and subsequent decrease of effective micellar size at micelle formation. Then, for the cause of higher k, there remain the following two factors: the shape and interaction concerning surfactant monomer and micelle.

In a dilute solution, the interaction between solutes can be excluded from discussion. Then, the shape of micelle is supposed to be significantly deviated from sphere in comparison with that of monomer, which is considered to be nearly spherical. With small n, the first micelle between cmc and second cmc is estimated to have the shape of either disk or short rod. The increase of k in this region with m is considered to result from the relative decrease of monomeric contribution to k, implying the convergence of k to the value of micelle itself. After passing through second cmc, the rate of increase in k on m recovered to show the linear increase of k, without any sign of convergence. Besides the long rod- or wide disk-like shape of second micelle with higher n, we might take into consideration the possible role played by the interaction between micelles, which facilitates a scaffold-structure, resulting in the so-called structural viscosity. Also, the possible increase of n with m might be the cause of increasing k. However, it seems to be necessary to study the micellar state above second cmc, or speaking with reserve, in a very higher concentration of Surfynol 465.

Use of Propagators in the Hückel Model. V. Polarizabilities

Shigeyuki AONO and Kiyoshi NISHIKAWA
Department of Chemistry, Faculty of Science, Kanazawa University, Marunouchi Kanazawa 920
(Received September 6, 1984)

The ordinary perturbation theory is reformulated in terms of propagators. It is well known that, if the perturbing interaction has a single particle character, the additional energy up to the second order of the perturbation is expressed by bond orders and various polarizabilities. This is easily rewritten by use of propagators. In addition, under the tight-binding approximation, the propagators of linear and ring polyenes are expressed in simple analytical forms, which enable us to give also analytical expressions for bond orders and polarizabilities. A simple application is given to determine which is more stable, anthracene or phenanthrene.

The wave function plays a central role in the perturbation treatment of the quantum chemistry. The molecular orbital (MO) is usually constructed by the linear combination of atomic orbitals (LCAO). Since AO's are given as the basis set, the essential part of MO is LCAO coefficients. If any perturbing interaction is introduced, we begin with determining this effect on the wave function, and then obtain the first or second order correction to the physical quantity of interest in terms of LCAO coefficients.

It has been pointed out by Coulson and Longuet-Higgins[1] that the above mentioned procedure is not always necessary, but once the Hamiltonian matrix is given, any physical quantity is directly obtained by manipulating the corresponding determinant, not *via* wave functions. Let the Hückel determinant be

$$D(z) = \begin{vmatrix} \alpha_1 - z & \beta_{12} & \beta_{13} & \cdot & \cdot & \cdot \\ \beta_{21} & \alpha_2 - z & \beta_{23} & \cdot & \cdot & \cdot \\ \beta_{31} & \cdot & \cdot & \cdot & \cdot & \cdot \\ \cdot & \cdot & & & & \\ \cdot & \cdot & \cdot & \cdot & \cdot & \alpha_n - z \end{vmatrix}, \quad (1)$$

then we have the total enery of the system,

$$E = \frac{1}{2\pi i}\int_c dz \frac{\partial}{\partial z} \log D(z), \quad (2)$$

or the bond order q_{rs} between atomic sites r and s,

$$q_{rs} = (-)^{r+s+1}\frac{1}{2\pi i}\int_c dz \frac{D_{rs}(z)}{D(z)}, \quad (3)$$

where D_{rs} is the r,s cofactor of D, and the integration is done along the so-called Coulson contour in Fig. 1a, which encloses the poles corresponding to the occupied levels. For simplicity, here and hereafter we assume the occupied levels have two electrons with up and down spins, and the spin summation is included in the integration.

The above expressions are nothing but ones by using propagators, *e.g.*, the integrand of Eq. 3 is the r,s matrix element of the matrix propagator, as will be clarified in the followings. In this sence, the work of Coulson and Longuet-Higgins is not old in spirit. In the present work the elementary perturbation theory is reformulated in terms of propagators. Procedures look abstract, but are much simpler than usual ones. For the simplest systems as linear and ring polyenes, we have already obtained analytical expressions of propagators,[2] which enable us to express bond orders and various polarizabilities also in analytical form.

Perturbation Theory

The Hamiltonian of the system in question is given in matrix form, $\boldsymbol{H}$ which satisfies the eigenvalue equation,

$$\boldsymbol{H}|i\rangle = \varepsilon|i\rangle, \quad (4)$$

where we assume that $|i\rangle$ is a single-particle state, and forms a complete set;

$$\sum_i |i\rangle\langle i| = 1. \quad (5)$$

Let us introduce the Green's operator,

$$G = \frac{1}{z-\boldsymbol{H}} \quad (6a)$$

$$= \sum_i \frac{|i\rangle\langle i|}{z-\varepsilon_i}, \quad (6b)$$

of which matrix element with respect to atomic sites r,s is

$$G_{rs}(z) = \sum_i \frac{\langle r|i\rangle\langle i|s\rangle}{z-\varepsilon_i}. \quad (7)$$

If we integrate this along the Coulson contour, we obtain immediately

$$q_{rs} = \frac{1}{2\pi i}\int_c dz G_{rs}(z) = 2\sum_i^{occ} \langle r|i\rangle\langle i|s\rangle = 2\sum_i^{occ} C_{ri}C_{si}^*, \quad (8)$$

where the factor 2 is due to the spin sum, and in the final expression we have used LCAO coefficients. We can understand here q_{rs} is the so-called bond order. Next we consider the integral which gives the total energy,

$$E = \mathrm{Tr}\frac{1}{2\pi i}\int_c dz z\boldsymbol{G}(z) = \sum_s\sum_i \frac{1}{2\pi i}\int_c dz z\frac{\langle s|i\rangle\langle i|s\rangle}{z-\varepsilon_i} = 2\sum_i^{occ}\varepsilon_i, \quad (9)$$

where the factor 2 is due to the spin sum and we have also assumed that the set $\{|s\rangle\}$ is complete:

$$\sum_s |s\rangle\langle s| = 1. \quad (10)$$

Now we turn to the perturbation treatments. Almost all of them have already been done,[3] and then concentrate ourselves to connect with the conventional theory. The total Hamiltonian is devided into two parts:

$$\boldsymbol{H} = \boldsymbol{H}^0 + \boldsymbol{v}, \quad (11)$$

and $\boldsymbol{v}$ is assumed to be much smaller than $\boldsymbol{H}^0$ and further the propagator $\boldsymbol{G}^0$ for $\boldsymbol{H}^0$ is known. The perturbation expansion of G is as follows:

$$\boldsymbol{G} = \boldsymbol{G}^0 + \boldsymbol{G}^0\boldsymbol{v}\boldsymbol{G}^0 + \boldsymbol{G}^0\boldsymbol{v}\boldsymbol{G}^0\boldsymbol{v}\boldsymbol{G}^0 + \cdots. \quad (12)$$

If we take the effect of $\boldsymbol{v}$ into account up to the first order and integrate the r,s matrix elements of both sides along the Coulson contour, we obtain

$$\frac{1}{2\pi i}\int_c G_{rs}dz = \frac{1}{2\pi i}\int_c dz G^0_{rs} + \frac{1}{2\pi i}\int_c dz \sum_{tu} G^0_{rt}v_{tu}G^0_{us}. \quad (13)$$

Then we have a small change of the bond order q_{rs} caused by a specified v_{tu}

$$\delta q_{rs} = \frac{1}{2\pi i}\int_c dz(G_{rs}-G^0_{rs}) = \frac{1}{2\pi i}\int_c dz(G^0_{rt}v_{tu}G^0_{us} + G^0_{ru}v_{ut}G^0_{ts}). \quad (14)$$

If v_{tu} is real, namely, $v_{tu}=v_{ut}$, it follows that

$$\frac{\delta q_{rs}}{\delta v_{tu}} = \frac{1}{2\pi i}\int_c dz(G^0_{rt}G^0_{us} + G^0_{ru}G^0_{ts}) = \pi_{rs;tu}. \quad (15)$$

where we rewrite v_{tu} as δv_{tu}, stressing it be small. This is the bond-bond polarizability defined by Coulson. Other simpler polarizabilities are obtained as special ones of the above.

When v_{tu} is pure imaginary, say $v_{ut}=-v_{tu}$, we get

$$\bar{\pi}_{rs;tu} = \frac{1}{2\pi i}\int_c dz(G^0_{rt}G^0_{us} - G^0_{ru}G^0_{ts}). \quad (16)$$

This is employed by McWeeny in analysis of the ring current of aromatic compounds.[6] It is mentioned that using a explicit form of G^0_{rs} in Eq. 7, we can easily derive the common expression of $\pi_{rs;tu}$ in terms of LCAO coefficients.

Next placing Eq. 12 in the first line of Eq. 9 we have

$$E = \mathrm{Tr}\frac{1}{2\pi i}\int_c dz z(\boldsymbol{G}^0 + \boldsymbol{G}^0\boldsymbol{v}\boldsymbol{G}^0 + \boldsymbol{G}^0\boldsymbol{v}\boldsymbol{G}^0\boldsymbol{v}\boldsymbol{G}^0\boldsymbol{v}\boldsymbol{G}^0 + \cdots)$$

so that, up to the second order with respect to $\boldsymbol{v}$,

$$\delta E = E - E^0 = \mathrm{Tr}\frac{1}{2\pi i}\int_c (dz z(\boldsymbol{G}^0\boldsymbol{v}\boldsymbol{G}^0 + \boldsymbol{G}^0\boldsymbol{v}\boldsymbol{G}^0\boldsymbol{v}\boldsymbol{G}^0) = \mathrm{Tr}\frac{1}{2\pi i}\int_c dz\left(\boldsymbol{G}^0\boldsymbol{v} + \frac{1}{2}\boldsymbol{G}^0\boldsymbol{v}\boldsymbol{G}^0\boldsymbol{v}\right), \quad (17)$$

where the last result is obtained as follows: Remembering that $\boldsymbol{G}^0=(z-\boldsymbol{H}^0)^{-1}$, we integrate by parts and use the permutation invariability inside Tr.[4] In general $\boldsymbol{v}$ being complex:

$$v_{rs} = v^0_{rs} + iv'_{rs}, \quad v_{sr} = v^0_{rs} - iv'_{rs}, \quad (18)$$

and then using Eqs. 8 and 15, we obtain

$$\delta E = 2\sum_{(rs)} v^0_{rs}q_{rs} + \sum_{(rs)}\sum_{(tu)}(v^0_{rs}\pi_{rs;tu}v^0_{tu} + v'_{rs}\bar{\pi}_{rs;tu}v'_{tu}) \quad (19)$$

where (rs) means that the summation is carried out with respect to the bond (r,s), or under the restriction, $r<s$.

Analytical Expression for Bond Order and Polarizability

In the Hückel approximation, the propagators of linear and ring polyenes are obtained in analytical forms.[2] The r,s matrix element of the chain propagator is given as, in unit of β

$$G^0_{rs} = \frac{\sin(r+1)\theta \sin(n-s)\theta}{\sin(n+1)\theta \sin\theta}, \tag{20}$$

where the linear chain with n atomic sites is numbered as Fig. 2, and we omit the index indicating the chain length n without confusion, and further

$$z = 2\cos\theta. \tag{21}$$

This variable transformation maps the Coulson contour in Fig. 1a to that in Fig. 1b.

For the ring polyene shown in Fig. 3, we have (β=1)

$$R^0_{0k} = \frac{-1}{4\sin^2(n\theta/2)\sin\theta}(\sin(n-k)\theta + \sin k\theta). \quad (k \geqq 0) \tag{22}$$

This propagator consists of two parts: The first term in the bracket represents the effect arised from the ordinary propagation, $0\rightarrow 1\rightarrow 2\rightarrow\cdots\rightarrow k$, while the second term the reverse propagation.

The bond order of them are already given:[2] For the linear chain

$$q^L_{r+1,s+1} = \frac{1}{n+1}\left[\frac{\sin(s-r)\pi/2}{\sin(s-r)\pi/2(n+1)} - \frac{\sin(s+r)\pi/2}{\sin(s+r)\pi/2(n+1)}\right], \tag{23}$$

and for the ring

$$q^R_{0k} = \frac{2}{n^2}[(n-k)+k]\frac{\sin k\pi}{\sin k\pi/n}. \tag{24}$$

In the latter, the first term in the square bracket is due to the ordinary propagation, while the second due to the reverse propagation. Such interpretation is one of the remarkable results of propagator analysis and gives a profound understanding of chemical reactivity and stability.[4,5,7] We can observe that at the limit, $k\rightarrow 0$, either $q^L_{r,r+k}$ and q^R_{0k} tend to 1 (Coulson-Rushbrooke theorem), and other properties of the bond order are to be derived from these expressions.

Now we begin to evaluate polarizabilities. For the linear chain the most general one is

$$\pi^L_{rs;tu} = \frac{1}{2\pi i}\int_c dz(G^0_{rt}G^0_{us} + G^0_{ru}G^0_{ts}). \tag{25}$$

We know a symmetrical property, $G^0_{rs}=G^0_{sr}$, but we have to stress that the analytical expression (20) is avairable, for G^0_{rt} only if $t\geqq r$. Therefore the calculation carried out under the condition that $t\geqq r$, $s\geqq u$, $u\geqq r$, and $s\geqq t$, which corresponds to the case shown in Fig. 2a. Substituting Eq. 20 into Eq. 25, we have

$$\pi^{L(a)}_{rs;tu} = \frac{1}{2}\frac{1}{2\pi i}\int_c d\theta(-2\sin\theta)\frac{1}{\sin^2\theta\sin^2(n+1)\theta} \times[\sin(r+1)\theta\sin(n-t)\theta\sin(u+1)\theta\sin(n-s)\theta + \sin(r+1)\theta\sin(n-u)\theta\sin(t+1)\theta\sin(n-s)\theta]. \tag{26}$$

Some comments should be added. The factor, 1/2 is needed due to the fact the contour in θ plane goes round the origin twice while the contour in z plane does once. As to poles, θ=0 is not the pole (as mentioned in the second paper of Ref. 1), and real poles are

$$\theta_\mu = \frac{\pi\mu}{n+1}, \quad \mu = \pm 1, \pm 2, \cdots, \pm n. \tag{27}$$

If we assume for simplicity that n is even and every site offers an electron, the levels are doubly occupied from the bottom to the $\pm n/2$ and the result is as follows:

$$\pi^{L(a)}_{rs;tu} = \frac{-4}{(n+1)^2}\sum_{\mu=1}^{n/2}\frac{1}{\sin\theta_\mu} \{\sin(r+1)\theta_\mu\sin(n-t)\theta_\mu\sin(u+1)\theta_\mu\sin(n-s)\theta_\mu [(r+1)\cot(r+1)\theta_\mu + (n-t)\cot(n-t)\theta_\mu + (u+1)\cot(u+1)\theta_\mu + (n-s)\cot(n-s)\theta_\mu - \cot\theta_\mu] + \sin(r+1)\theta_\mu\sin(n-u)\theta_\mu\sin(t+1)\theta_\mu\sin(n-s)\theta_\mu [(r+1)\cot(r+1)\theta_\mu + (n-u)\cot(n-u)\theta_\mu + (t+1)\cot(t+1)\theta_\mu + (n-s)\cot(n-s)\theta_\mu - \cot\theta_\mu]\}, \tag{28}$$

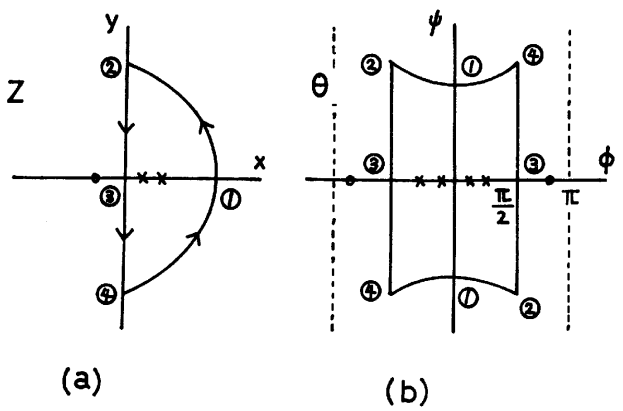

Fig. 1.

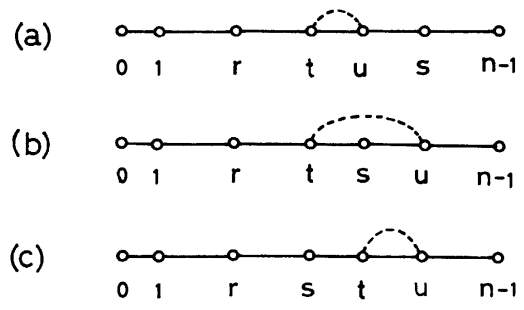

Fig. 2.

where the spin sum has been done. We can observe that the above result is valid for the exchange, $(r,s)\leftrightarrow(t,u)$.

There are other relations between pairs, (r,s) and (t,u) keeping $s>r$ and $u>t$, as shown in Figs. 2b and 2c. In the case of Fig. 2b, G^0_{us} in Eq. 25 should be read G^0_{su}, and then in order to obtain $\pi^{L(b)}_{rs;tu}$ we have to exchange u and s in the first square bracket of Eq. 28. In the case of Fig. 2c, $\pi^{L(c)}_{rs;tu}$ is obtained by exchanging not only u and s in the first term of the square bracket in Eq. 26 but also t and s in the second term. This makes two terms in Eq. 28 identical, and we denote the result for further investigations.

$$\pi^{L(c)}_{rs;tu} = \frac{-8}{(n+1)^2}\sum_{\mu=1}^{n/2}\frac{1}{\sin\theta_\mu}\{\sin(r+1)\theta_\mu \sin(n-t)\theta_\mu \sin(s+1)\theta_\mu \sin(n-u)\theta_\mu [(r+1)\cot(r+1)\theta_\mu + (n-t)\cot(n-t)\theta_\mu + (s+1)\cot(s+1)\theta_\mu + (n-u)\cot(n-u)\theta_\mu - \cot\theta_\mu]\}. \quad (29)$$

Other simpler polarizabilities will be obtained by the following procedures. One of self-polarizabilities, $\pi^L_{rs;tu}$ is obtained by putting $r=t$ and $s=u$, keeping $r,t<s,u$, therefore $\pi^{L(a)}_{rs;tu}$ or $\pi^{L(b)}_{rs;tu}$ should be used as a starting one, say,

$$\pi^L_{rs;rs} = (r=t,\ s=u \text{ in } \pi^{L(a)}_{rs;tu} \text{ or } \pi^{L(b)}_{rs;tu}). \quad (30)$$

Similar considerations lead to the followings:

$$\pi^{L(a)}_{r;tu} = (r=s \text{ in } \pi^{L(a)}_{rs;tu}) \text{ for } r \text{ inside } t-s,$$
$$\pi^{L(c)}_{r;tu} = (r=s \text{ in } \pi^{L(a)}_{rs;tu}) \text{ for } r \text{ outside } t-s,$$
$$\pi^{L(a)}_{rs;t} = \frac{1}{2}(t=u \text{ in } \pi^{L(a)}_{rs;tu}) \text{ for } t \text{ inside } r-s,$$
$$\pi^{L(a)}_{rs;t} = \frac{1}{2}(t=u \text{ in } \pi^{L(c)}_{rs;tu}) \text{ for } t \text{ outside } r-s,$$
$$\pi^L_{r;t} = \frac{1}{2}(r=s,\ t=s \text{ in } \pi^{L(c)}_{rs;tu}). \quad (31)$$

The last one is given explicitly as

$$\pi^L_{r;t} = \frac{-8}{(n+1)^2}\sum_{\mu=1}^{n/2}\frac{1}{\sin\theta_\mu}\sin^2(r+1)\theta_\mu \sin^2(n-t)\theta_\mu [(r+1)\cot(r+1)\theta_\mu + (n-t)\cot(n-t)\theta_\mu - \cot\theta_\mu] \quad (32)$$

which precisely coincides the result obtained by Coulson and Longuet-Higgins.[1] When $r=0$, the denominator cancels out one of the numerators, so that the summation can be carried out to get the result:

$$\pi^L_{0;t} = \frac{1}{2(n+1)^2}[(-)^t(2n-2t+1)\operatorname{cosec}(2t+3)\pi/2(n+1) + (-)^t(2n-2t+1)\operatorname{cosec}(2t+1)\pi/2(n+1) - 2\operatorname{cosec}\pi/2(n+1)], \quad (33)$$

which has been also obtained by the above-mentioned investigations.

Since $\bar{\pi}^L_{rs;tu}$ is expressed as

$$\bar{\pi}^L_{rs;tu} = \frac{1}{2\pi i}\int_c dz(G^0_{rt}G^0_{us} - G^0_{ru}G^0_{ts}), \quad (34)$$

the (a) and (b) types have non-vanishing values and the second half of Eq. 26 or 28 changes sign, but the (c) type not.

We turn to the case of ring polyenes with n sites which are numbered as shown in Fig. 3a. Using the ring propagators of Eq. 22 in Eq. 25, we have

$$\pi^{R(a)}_{rs;tu} = \frac{-1}{4}\frac{1}{2\pi i}\int_c d\theta(R^0_{rt}R^0_{us} + R^0_{ru}R^0_{ts}) = \frac{-1}{4}\frac{1}{2\pi i}\int_c d\theta\frac{1}{\sin^2(n\theta/2)\sin\theta}(\cos\bar{tr}\theta\cos\bar{su}\theta + \cos\bar{ur}\theta\cos\bar{st}\theta), \quad (35)$$

where, for example

$$\bar{tr} = n/2 - (t-r), \quad (36)$$

and the first and second terms of the second line are originated from the first and second terms of the first line, respectively. We present the result for each term separately, for convenience of the later investigation. Here we have poles:

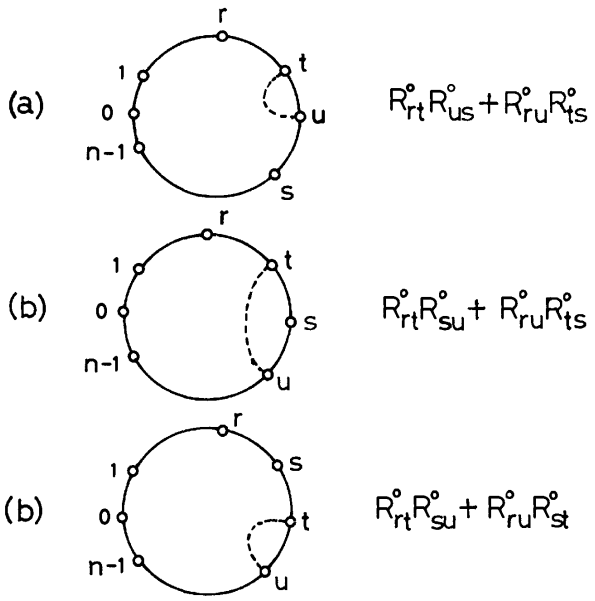

Fig. 3.

$$\theta_\mu = \frac{2\pi\mu}{n}, \quad \mu = 0, \pm 1, \pm 2, \cdots, n/2, \tag{37}$$

and the levels from 0 to $\pm n/4$ are doubly occupied. Unlike the case of the linear chain, $\theta=0$ is a real pole. The result are:

The first term of Eq. 35

$$= \frac{-1}{6} - \frac{1}{n^2}\left(\frac{1}{3} - \bar{tr}^2 - \bar{su}^2\right) + \frac{4}{n^2}\sum_{\mu=1}^{[n/4]} \frac{1}{\sin\theta_\mu} \cos\bar{tr}\theta_\mu \cos\bar{su}\theta_\mu \times (\cot\theta_\mu + \bar{tr}\tan\bar{tr}\theta_\mu + \bar{su}\tan\bar{su}\theta_\mu), \tag{38a}$$

and

The second term of Eq. 35

$$= \frac{-1}{6} - \frac{1}{n^2}\left(\frac{1}{3} - \bar{ur}^2 - \bar{st}^2\right) + \frac{4}{n^2}\sum_{\mu=1}^{[n/4]} \frac{1}{\sin\theta_\mu} \cos\bar{ur}\theta_\mu \cos\bar{st}\theta_\mu \times (\cot\theta_\mu + \bar{ur}\tan\bar{ur}\theta_\mu + \bar{st}\tan\bar{st}\theta_\mu). \tag{38b}$$

In the above the terms without summation arise from the pole, $\theta_u=0$, and others from poles, $\theta_u \neq 0$, and further $[n/4]$ is the Gauss notation, which means the maximum integer at most $n/4$. It is needless to say

$$\pi^{R(a)}_{rs;tu} = \text{Eq. 38a} + \text{Eq. 38b}. \tag{39}$$

For the cases shown in Fig. 3b and 3c, entirely the same treatments that have been done in the case of the linear chain hold. Namely

$$\pi^{R(b)}_{rs;tu} = [s\leftrightarrow u \text{ in the first term of Eq. 39}]$$
$$\pi^{R(c)}_{rs;tu} = [s\leftrightarrow u \text{ in the first term and } t\leftrightarrow s \text{ in the second term of Eq. 39}]. \tag{40}$$

but in $\pi^{R(c)}_{rs;tu}$ it does not happen that two terms are accidentally coincident as in $\pi^{L(c)}_{rs;tu}$. Further the relations as mentioned in Eqs. 30 and 31 also hold in this case.

It is rather striking that $\pi^{R}_{rs;tu}$ has a constant term, but it will be canceled out by a part of suceeding terms, as n tends to infinity.

The polarizability due to the imaginary perturbation, $\bar{\pi}^{R(a)}_{rs;tu}$ is simply obtained by changing the sign in Eq. 39:

$$\pi^{R(a)}_{rs;tu} = \text{Eq. 38a} - \text{Eq. 38b} \tag{41}$$

and for others the same relations hold.

Illustrative Example

As an example of previous treatments we consider which is more stable, anthracene (I) and phenanthrene (II). In each compound, the atomic sites are numbered as in Fig. 4. Namely, if we consider the ring polyene with fourteen sites as an unperturbed system, anthracene has additional bonds, (0,9) and (2,7), while phenanthrene has bonds, (0,9) and (1,6).

Considering that these bond formations are perturbation, we can estimate each stabilization energy. We begin with evaluating the first order energies:

$$\Delta E^{(1)}_{I} = 2v(q^R_{09} + q^R_{27}), \tag{42a}$$
$$\Delta E^{(1)}_{II} = 2v(q^R_{09} + q^R_{16}), \tag{42b}$$

where we put $v_{rs}=v_{sr}=v$. In the case of ring, the value of bond order depends only on the distance between sites along the ring perimeter, so that $q^R_{27}=q^R_{16}$ Therefore we can find no difference in the first order energies between I and II.

The second order energy is written in general as

$$\Delta E^{(2)} = \sum_{(rs)}\sum_{(tu)} v_{rs}\pi_{rs;tu}v_{tu}, \tag{43}$$

where the summations are carried out with repect to the bonds (r,s) and (t,u). Hence it follows that

$$\Delta E^{(2)}_{I} = v^2(\pi^R_{09;09} + \pi^R_{27;27} + 2\pi^R_{09;27}), \tag{44a}$$
$$\Delta E^{(2)}_{II} = v^2(\pi^R_{09;09} + \pi^R_{16;16} + 2\pi^R_{09;16}). \tag{44b}$$

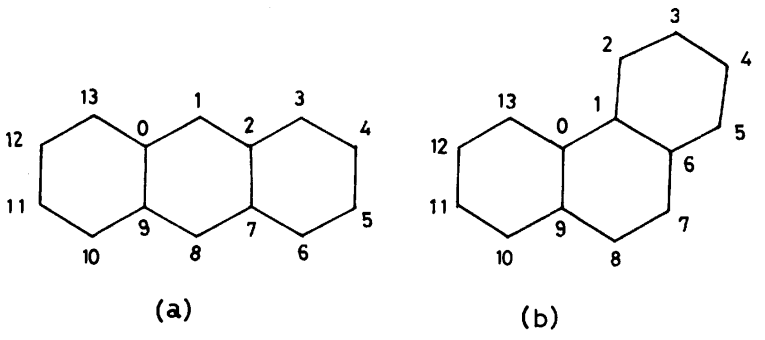

Fig. 4.

Thus we have a energy difference between I and II in the second order terms:

$$\begin{aligned}\Delta E &= \Delta E_{\mathrm{I}}^{(2)} - \Delta E_{\mathrm{II}}^{(2)} \\ &= 2v^2(\pi^R_{09;27} - \pi^R_{09;16}) \\ &= 2v^2(-0.00632/\beta - 0.08539/\beta) \\ &= -0.1834\beta, \end{aligned} \tag{45}$$

where in the final expression, β is recovered (note that polarizabilities are given in unit of β^{-1}), and we put $v=\beta$. Since β is negative, the result has a positive value. Therefore we can conclude that phenanthrene is more stable than anthracene.

Concluding Remarks

As long as the perturbing interaction is of a single particle character, the present treatment using propagator is quite general. Up to the second order of the perturbation, the additional energy and other physical quantities such as the diamagnetic susceptibility are expressed with bond orders and polarizabilities. The calculated results are solely depend upon, to what extent the zero-order propagators are already given.

As an advantage of our method, procedures are carried out without use of wave functions, so that we are able to analyze the problem under consideration in a compact and elegant way, and sometimes to insight the essential features of the subject. Some examples have been shown already in the analysis of chemical reactivities and stabilities.[4,7] For the simplest species such as linear or ring polyenes, the propagators are obtained in analytical forms. These are quite useful for qualitative and quantitative investigations of various chemical problems.

However we do not deny usefulness of the wave function. If we investigate too complicated species to take linear or ring polyene as an unperturbed system, the propagator of the starting substance is hardly obtained in an analytical way. Even in this case it is preferable that, at the stage of the general treatment, the problem is handled by the use of propagators, and then at the final calculating stage, the wave functions as accurate as possible should be used.

Use of Propagators in the Hückel Model. VI. Magnetic Perturbation and Ring Current

Takayuki OHMAE, Kiyoshi NISHIKAWA, and Shigeyuki AONO
Department of Chemistry, Faculty of Science, Kanazawa University, Marunouchi, Kanazawa 920
(Received September 6, 1984)

The electron propagator in the magnetic field is investigated under the Hückel approximation, and the electronic energy and the aromatic ring current are evaluated. The perturbation treatment for the ring current developed by McWeeny is easily reformulated in terms of propagator and then the physical features involved in this problem have been made considerably clearer.

The diamagnetic anisotropy of an aromatic hydrocarbon may be attributed to induced currents flowing round the aromatic rings. This picture first proposed by Pauling,[1] has been quantum mechanically formulated by London,[2] and extensively studied, *e.g.*, by Pople[3] or by McWeeny.[4] Recently this problem is investigated in connection with aromaticity by Aihara,[5] who uses a graph-theoretical formalism. In this paper we reformulate the above mentioned treatments in terms of propagator. The physical contents beyond the previous works will not be expected, but the general and compact analysis might be helpful in a deeper understanding of this problem.

Hückel Hamiltonian with Magnetic Field

In treating species in the magnetic field, we use the basis set:

$$\chi_s(\mathbf{r}) = \chi_s^0(\mathbf{r})e^{-iA_s\cdot r/\Phi}, \quad \Phi = \hbar c/e, \tag{1}$$

where x_s^0 is the atomic orbital at s site in the absence of the magnetic field, A_s is the vector potential there and $\mathbf{r}$ is the position vector of electron. Meanwhile we manipulate in unit of $\Phi=1$ for simplicity, but if necessary we recover this constant. As usual the transfer integral β_{st} is approximately estimated as,

$$\begin{aligned}\beta_{st} &= \int d\mathbf{r}\chi_s^* H\chi_t \\ &= \int d\mathbf{r}e^{i(A_s-A_t)\cdot r}\chi_s^{0*}H\chi_t^0 \\ &\fallingdotseq e^{i(A_s-A_t)\cdot(R_s+R_t)/2}\int d\mathbf{r}\chi_s^{0*}H\chi_t^0 \\ &= \beta_{st}^0 e^{i\theta_{st}},\end{aligned} \tag{2}$$

where $\boldsymbol{R}_s$ is the position vector of the site s, and β_{st}^0 is the transfer integral in the absence of the magnetic field. In the Hückel approximation for the conjugated hydrocarbons, β_{st}^0's are constant, β only for the adjacent r and s. We proceed in unit of $\beta=1$ without confusion. In the above

$$\theta_{st} = \frac{1}{2}(\boldsymbol{A}_s-\boldsymbol{A}_t)\cdot(\boldsymbol{R}_s+\boldsymbol{R}_t) \tag{3}$$

from which it is apparent that

$$\theta_{st} = -\theta_{ts}. \tag{4}$$

A little more calculation of θ_{st} is useful for the later investigations. Remebering that

$$\boldsymbol{A}_s = -\frac{1}{2}H\boldsymbol{R}_s\times\boldsymbol{n}, \tag{5}$$

when the magnetic field, $\boldsymbol{H}=H\boldsymbol{n}$ is constant along the z axis (see Fig. 1), we obtain

$$\begin{aligned}\theta_{st} &= \frac{1}{2}(\boldsymbol{A}_s-\boldsymbol{A}_t)\cdot(\boldsymbol{R}_s+\boldsymbol{R}_t) \\ &= -\frac{1}{4}H[(\boldsymbol{R}_s-\boldsymbol{R}_t)\times\boldsymbol{n}]\cdot(\boldsymbol{R}_s+\boldsymbol{R}_t) \\ &= \frac{1}{2}H\boldsymbol{n}\cdot(\boldsymbol{R}_s+\boldsymbol{R}_t) \\ &= \boldsymbol{S}_{st}.\end{aligned} \tag{6}$$

Here $\boldsymbol{S}_{st}$ is the signed area of the triangle formed by the origin and the bond s—t, and counted positive if $s\rightarrow t$ is right handed about the normal $\boldsymbol{n}$.

Then we have the Hückel Hamiltonian with magnetic field as

$$H = \sum_s |s\rangle\alpha_s\langle s| + \sum_{st} e^{i\theta_{st}}\beta_{st}^0|s\rangle\langle t|, \tag{7}$$

and then with abbreviations:

$$\alpha_s = \alpha = 0, \quad \beta_{st}^0 = \beta = 1, \quad e^{i\theta_{st}} = \omega_{st}, \tag{8}$$

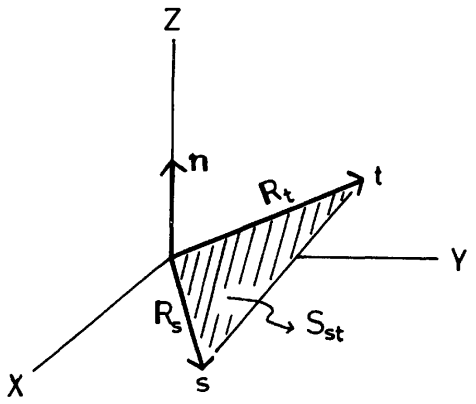

Fig. 1.

we can write, for example, for naphthalene, (see Fig. 4)

$$\begin{pmatrix} 0 & \omega_{12} & 0 & 0 & 0 & 0 & 0 & 0 & 0 & \omega_{1,10} \\ \omega_{21} & 0 & \omega_{23} & 0 & 0 & 0 & 0 & 0 & 0 & 0 \\ 0 & \omega_{32} & 0 & \omega_{34} & 0 & 0 & 0 & 0 & 0 & 0 \\ 0 & 0 & \omega_{43} & 0 & \omega_{45} & 0 & 0 & 0 & 0 & 0 \\ 0 & 0 & 0 & \omega_{54} & 0 & \omega_{56} & 0 & 0 & 0 & \omega_{5,10} \\ 0 & 0 & 0 & 0 & \omega_{65} & 0 & \omega_{67} & 0 & 0 & 0 \\ 0 & 0 & 0 & 0 & 0 & \omega_{76} & 0 & \omega_{78} & 0 & 0 \\ 0 & 0 & 0 & 0 & 0 & 0 & \omega_{87} & 0 & \omega_{89} & 0 \\ 0 & 0 & 0 & 0 & 0 & 0 & 0 & \omega_{98} & 0 & \omega_{9,10} \\ \omega_{10,1} & 0 & 0 & 0 & \omega_{10,5} & 0 & 0 & 0 & \omega_{10,9} & 0 \end{pmatrix} \tag{9}$$

Propagators

The propagators corresponding to the Hamiltonian in Eq. 7 are built similarly as the case without magnetic field.[6]

(i) The Edge of the Linear Chain Propagator. For the linear chain with n sites as numbered in Fig. 2a we have

$$\begin{aligned} {}^nG_0 &= {}^1G_0 + {}^1G_0 v_{01} {}^nG_{1\langle 0\rangle} v_{10} {}^nG_0 \\ &= {}^1G_0 + {}^1G_0 v_{01} {}^{n-1}G_0 v_{10} {}^nG_0, \end{aligned} \tag{10}$$

where ${}^nG_r$ is the $r-r$ matrix element of the matrix propagator for the n membered chain, and ${}^nG_{r\langle s\rangle}$ is one in the absence of the s site. Obviously

$${}^nG_0 = [({}^1G_0)^{-1} - v_{01} {}^{n-1}G_0 v_{10}]^{-1}. \tag{11}$$

Now we can understand that ${}^nG_0$ is independent of the magnetic field, because the phase factors of interaction terms arising from magnetic interactions cancel out with each other. Using abbreviations of Eq. 8 and changing variable as

$$z = 2\cos\theta, \tag{12}$$

we can obtain as before,[6]

$${}^nG_0 = \sin\theta / \sin(n+1)\theta, \tag{13}$$

(ii) The k-th Diagonal Element of the Linear Chain Propagator. In a similar way,

$${}^nG_k(\theta) = \frac{\sin(n-k)\theta \sin(k+1)\theta}{\sin(n+1)\theta \sin\theta}, \tag{14}$$

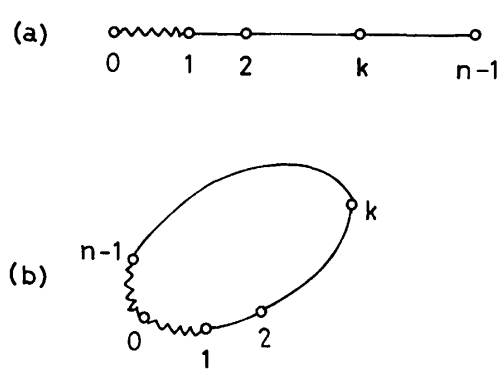

Fig. 2.

which also independent of the magnetic field.

(iii) The Off-diagonal Element of the Linear Chain Propagator. For simplicity, we deal with the three membered chain, a-b-c, and then obtain

$$\begin{aligned} {}^3G_{ac} &= {}^3G_a v_{ab} {}^3G_{b\langle a\rangle} v_{bc} {}^3G_{c\langle b\rangle} \\ &= \omega_{ab}\omega_{bc} {}^3G_{ac}^{(non)}, \end{aligned} \tag{15}$$

where ${}^3G_{ac}^{(non)}$ is the a—c matrix element of the 3-membered chain propagator in the absence of magnetic field. It is noted that in this case the propagator has a phase factor responsible to magnetic effect. In general,

$${}^nG_{k,k+l} = \omega_{k,k+1}\cdots\omega_{l-1,l} \frac{\sin(n-k-l)\theta \sin(k+1)\theta}{\sin(n+1)\theta \sin\theta}. \tag{16}$$

(iv) The Diagonal Element of the Ring Propagator. Observing Fig. 2b, we obtain

$$\begin{aligned} ({}^nR_0)^{-1} &= ({}^1G_0)^{-1} - v_{01} {}^nG_{1\langle 0\rangle} v_{10} - v_{0,n-1} {}^nG_{n-1\langle 0\rangle} v_{n-1,0} \\ &\quad - v_{01} {}^nG_{1,n-1\langle 0\rangle} v_{n-1,0} - v_{0,n-1} {}^nG_{n-1,1\langle 0\rangle} v_{n-1\text{-}0} \\ &= ({}^1G_0)^{-1} - 2^{n-1}G_0 - \omega_{01}\omega_{12}\cdots\omega_{n-1,0} {}^{n-1}G_{0,n-2}^{(non)} \\ &\quad - \omega_{0,n-1}\omega_{n-1,n-2}\cdots\omega_{10} {}^{n-1}G_{n-2,0}^{(non)}, \end{aligned} \tag{17}$$

where propagators appearing in the right-hand side are all non-magnetic. Noting that $\omega_{rs}=\omega_{sr}^*$, we get

$$\begin{aligned} ({}^nR_0)^{-1} &= ({}^1G_0)^{-1} - 2^{n-1}G_0 \\ &\quad - 2\cdot Re[\omega_{01}\omega_{12}\cdots\omega_{n-1,0}]^{n-1}G_{0,n-1}^{(non)} \\ &= 2\cos\theta - \frac{2\sin(n+1)\theta}{\sin\theta} - 2\cos HS \frac{\sin\theta}{\sin(n\theta)} \\ &= -\frac{4\sin\theta}{\sin n\theta} \sin(n\theta + HS/2)\cdot\sin(n\theta - HS/2). \end{aligned} \tag{18}$$

Here S is the area of ring counted positive, if the path goes round as $0\to1\to2\to\cdots\to n-1\to0$ in Fig. 2b.

(v) The Off-diagonal Element of the Ring Propagator. We devide ${}^nR_{ok}$ into two parts:

$${}^nR_{0k}^{(1)} + {}^nR_{0k}^{(2)}. \tag{19}$$

The former corresponds to the path with normal order, $0\to1\to2\cdots\to k$, while the latter to the reverse path $0\to n-1\to\cdots\to k$. Then we have

$$\begin{aligned} {}^nR_{0k}^{(1)} &= {}^nR_0 v_{01} {}^nG_{1k\langle 0\rangle} \\ &= {}^nR_0 {}^{n-1}G_{0,k-1}^{(non)} \omega_{01}\omega_{12}\cdots\omega_{k-1,k} \\ &= \frac{-\sin n\theta}{4\sin\theta\sin(n\theta+HS)/2\cdot\sin(n\theta-HS)/2} \\ &\quad \times \frac{\sin(n-k)\theta\sin\theta}{\sin n\theta\sin\theta} \omega_{01}\omega_{12}\cdots\omega_{k-1,k} \\ &= \frac{-\sin(n-k)\theta}{4\sin(n\theta+HS)/2\cdot\sin(n\theta-HS)/2} \cdot \omega_{01}\omega_{12}\cdots\omega_{k-1,k}, \end{aligned} \tag{20}$$

and similarly

$$\begin{aligned} {}^nR_{0k}^{(2)} &= \frac{-\sin k\theta}{4\sin\theta\sin(n\theta+HS)/2\cdot\sin(n\theta-HS)/2} \\ &\quad \times \omega_{k,k+1}^*\omega_{k+1,k+2}^*\cdots\omega_{n-2,n-1}^*\omega_{n-1,0}^*. \end{aligned} \tag{21}$$

Conclusively all the matrix elements of the ring propagator depend on magnetic field, while only the off-diagonal elements of the chain propagator does.

Energy

The total energies for various system will be calculated to estimate induced currents.

(i) Linear Chain with n *Sites and* n *Electrons.* The diagonal elements of this propagator in magnetic field are same as those of non magnetic case. Then the energy expression

$$E = \mathrm{Tr}\frac{1}{2\pi i}\int_c \mathrm{d}zzG(z) \tag{22}$$

leads to the same result as for the non-magnetic case. Namely

$$E = \sum_{k=0}^{n-1}\frac{-1}{\pi i}\int \mathrm{d}\theta \frac{\sin(n-k)\theta \sin(k+1)\theta \cos\theta}{\sin(n+1)\theta}$$
$$= 2\left[-1+\mathrm{cosec}\frac{\pi}{2(n+1)}\right]. \tag{23}$$

In the above, integration is carried out along the so-called Coulson contour mapped through the relation (12).[6,8] Poles of the first line of Eq. 23 are

$$\theta_r = \frac{\pi r}{n+1}, \quad r = \pm 1, \pm 2, \pm 3, \cdots, \pm n. \tag{24}$$

Among them poles up to $|n/2|$ are doubly occupied, which are enclosed by the contour. The integration above is assumed to include the spin sum.

(ii) Mono-ring with n *Sites and* N *Electrons.* Using Eq. 22, we obtain

$$E = \frac{n}{4\pi i}\int_c \mathrm{d}\theta \frac{\cos\theta \sin n\theta}{\sin(n\theta+HS/2)\cdot\sin(n\theta-HS/2)}. \tag{25}$$

Poles arising from the denominator are

$$\theta_r^+ = (2\pi r - HS)/n \text{ and } \theta_r^- = (2\pi r + HS)/n,$$
$$r = 0, \pm 1, \pm 2, \cdots, \pm(n/2-1), n/2 \tag{26}$$

in which ones up to $\pm n/4$ are occupied. Then calculations are straightforward:

$$E = \sum_\sigma \sum_r (-)^r\left[\frac{\cos(2\pi r-HS)/n\cdot\sin(2\pi r-HS)}{\sin(\pi r-HS)} + \frac{\cos(2\pi r+HS)/n\cdot\sin(2\pi r+HS)}{\sin(\pi r+HS)}\right]$$
$$= \sum_\sigma \sum_r \left(\cos\frac{2\pi r-HS}{n} + \cos\frac{2\pi r+HS}{n}\right)$$
$$= 2\sum_\sigma \sum_r \frac{\cos 2\pi r}{n}\frac{\cos HS}{n}, \tag{27}$$

where $\sum_\sigma$ indicates the spin sum which is carefully taken in the present case. In order to obtain Eq. 27 we have a useful relation

$$\sum_{r=1}^{k}\cos rx = \cos\frac{(k+1)x}{2}\sin\frac{kx}{2}/\sin\frac{x}{2} \tag{28}$$

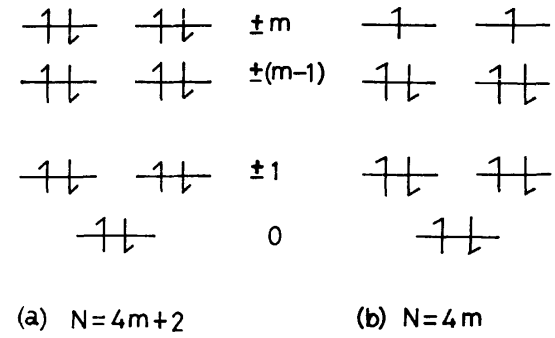

Fig. 3.

(a) The Closed System with N=4m+2 *Electrons:* In this case electrons occupy the levels as shown in Fig. 3a and then

$$\sum_\sigma \sum_{r=0}^{|m|}\cos\frac{2\pi r}{n} = 2\frac{\sin N\pi/2n}{\sin\pi/n}. \tag{29}$$

(b) The Open System with N=4m *Electrons:* Observing Fig. 3b, we get

$$\sum_\sigma \sum_{r=0}^{|m|}\cos\frac{2\pi r}{n} = 2\cos\frac{N\pi}{2n} + 2\frac{\sin(N-2)\pi/2}{\sin\pi/n} \tag{30}$$

Thus we have results; for the system with n sites and $4m+2$ electrons

$${}^nE_{4m+2} = 4\cos\frac{HS}{n}\cdot\frac{\sin N\pi/2n}{\sin\pi/n}, \tag{31}$$

and for the system with n sites ans $4m$ electrons

$${}^nE_{4m} = 4\cos\frac{HS}{n}\cdot\left(\cos\frac{N\pi}{2n} + \frac{\sin(N-2)\pi/2n}{\sin\pi/n}\right). \tag{32}$$

For special cases that number of sites is equal to that of electrons we have:

$${}^{4m+2}E_{4m+2} = 4\cos\frac{HS}{4m+2}\,\mathrm{cosec}\frac{\pi}{4m+2}, \tag{33}$$

$${}^{4m}E_{4m} = 4\cos\frac{HS}{4m}\cot\frac{\pi}{4m}. \tag{34}$$

Current

The ring current J is defined in terms of energy modified by magnetic field as follows.[7] The external field provokes an induced moment M opposing it and given by

$$M = -\frac{\delta E}{\delta H}, \tag{35}$$

or

$$M = \sum_k M_k = -\sum_k \frac{\delta E}{\delta f_k}\frac{\delta f_k}{\delta H}, \tag{36}$$

where

$$f_k = HS_k, \tag{37}$$

is the magnetic flux associated with the irreducible

circuit (ring). Our hypothesis is that the partial moment M_k of the k-th ring arises from an induced current J_k circulating around the ring and such that

$$M_k = \frac{1}{c} J_k S_k. \tag{38}$$

Therefore the current J_k is given by (recovering constant Φ_0)

$$J_k = -\frac{c}{\Phi_0}\frac{\delta E}{\delta f_k}. \tag{39}$$

It is needless to say that there is no current in the linear chain.

We want to apply Eq. 39 to various mono-ring compounds. For species corresponding to Eqs. 31 and 32

$${}^{n}J_{4m+2} = \frac{4\beta c}{n\Phi_0}\sin\frac{HS}{n\Phi_0}\frac{\sin N\pi/2n}{\sin \pi/n}, \tag{40}$$

$${}^{n}J_{4m} = \frac{4\beta c}{n\Phi_0}\sin\frac{HS}{n\Phi_0}\left(\cos\frac{N\pi}{2n} + \frac{\sin (N-2)\pi/2n}{\sin \pi/n}\right). \tag{41}$$

The area in the aboves is expressed by the use of the bond length d and the number of sites n as

$$S = \frac{nd^2}{4}\cot\frac{\pi}{n}. \tag{42}$$

At this stage it is instructive to make an order estimate of magnetic parameter such that for benzene $SH/\Phi_0 \sim 10^{-9}H$ which is very small even for $H \sim 10^4$ gauss. Accordingly it is good approximation that

$${}^{4m+2}J_{4m+2} = 4\beta\left(\frac{1}{4m+2}\right)^2\frac{cHS}{\Phi_0{}^2}\operatorname{cosec}\frac{\pi}{4m+2}, \tag{43}$$

$${}^{4m}J_{4m} = 4\beta\left(\frac{1}{4m}\right)^2\frac{cHS}{\Phi_0{}^2}\cot\frac{\pi}{4m}. \tag{44}$$

Next we calculate ${}^5J_6$, ${}^6J_6$, and ${}^7J_6$ which correspond to $C_5H_5^-$, C_6H_6, and $C_7H_7^+$, respectively. In the same approximation to obtain the previous results, we have

$$\begin{aligned} {}^5J_6 &= A\frac{\sin 6\pi/10}{\sin \pi/5} \fallingdotseq 1.6A, \\ {}^6J_6 &= A\frac{\sin 6\pi/12}{\sin \pi/5} = 2A, \\ {}^7J_6 &= A\frac{\sin 6\pi/14}{\sin \pi/5} \fallingdotseq 2.2A, \end{aligned} \tag{45}$$

with

$$A = \beta\frac{c}{\Phi_0{}^2}\frac{Hd^2}{4\pi}. \tag{46}$$

Hence ring currents increase significantly as number of sites increase although number of electrons remain constant.

Perturbation Treatment I

In the preceding section we have presented some examples in which propagators are obtained in a compact analytical form. Such a fortune can not be expected for more general or complicated systems. Hence a perturbation method will be preferable for the latter case. We are now going on as McWeeny has done.[4] In order to avoid the explicit use of the current density operator, we introduce a point dipole as a test body and evaluate the additional energy due to this effect and the effective magnetic field secondaly produced by the ring current. If a dipole moment $\boldsymbol{m}=m\boldsymbol{n}$ ($\boldsymbol{n}$ is the unit vector along z axis) is introduced at any point on the molecular plane, this point being chosen as origin, the vector potential at point r will be

$$A = -\frac{1}{2}H\boldsymbol{r}\times\boldsymbol{n} - m\frac{\boldsymbol{r}\times\boldsymbol{n}}{r^3}. \tag{47}$$

It is easily seen that Eq. 6 is replaced by

$$\begin{aligned} \theta_{st} &= S_{st}\left(H + \frac{m}{R_s^3} + \frac{m}{R_t^3}\right) \\ &= Ss_{st}\left(H + \frac{m}{\mathrm{d}^3}k_{st}\right), \end{aligned} \tag{48}$$

where areas are measured in unit of S, that of benzene ring, and distances are in unit of d, the C-C bond distance;

$$\begin{aligned} S_{st} &= Ss_{st}, \\ R_s &= r_s\mathrm{d}, \\ k_{st} &= \left(\frac{1}{r_s^3} + \frac{1}{r_t^3}\right). \end{aligned} \tag{49}$$

From the Hamiltonian in Eq. 7, we have a magnetic perturbation as

$$\begin{aligned} v &= \sum_{st}(e^{i\theta_{st}} - 1)|s\rangle\langle s| \\ &\fallingdotseq \sum_{st}\left(i\theta_{st} - \frac{1}{2}\theta_{st}^2\right)|s\rangle\langle s|. \end{aligned} \tag{50}$$

Here we have used the fact that $\theta_{st} \ll 1$, and note that v consists of the real and imaginary parts.

In general, if we wite the matrix element of v as

$$v_{rs} = v_{st}^0 + iv_{st}', \tag{51}$$

the energy change up to the second order of v is,[8]

$$\begin{aligned} \delta E = {} & 2\sum_{k<l} q_{kl}v_{kl}^0 \\ & + \sum_{k<l}\sum_{m<n}(v_{kl}^0\pi_{kl;mn}v_{mn}^0 + v_{kl}'\bar{\pi}_{kl;mn}v_{mn}'), \end{aligned} \tag{52}$$

where the bond order q_{rs} and the bond-bond polarizabilities $\pi_{kl;mn}$, $\bar{\pi}_{kl;mn}$ are given in terms of non-magnetic propagators as

$$q_{kl} = \frac{1}{2\pi\mathrm{i}}\int_c \mathrm{d}z\boldsymbol{G}_{kl}^0(z) \tag{53}$$

$$\pi_{kl;mn}(\bar{\pi}_{kl;mn}) = \frac{1}{2\pi\mathrm{i}}\int_c \mathrm{d}z(\boldsymbol{G}_{km}^0(z)\boldsymbol{G}_{nl}^0(z) \pm \boldsymbol{G}_{kn}^0(z)\boldsymbol{G}_{ml}^0(z)). \tag{54}$$

The above quantities are already been evaluated in analytic forms for simple species, linear chain and ring compounds.[8] However usual expressions in terms of LCAO coefficients are useful for more complicated molecules. It should be noted that if we use

$$G_{rs}(z) = \sum_i \frac{\langle r|i\rangle\langle i|s\rangle}{z-\varepsilon_i} \tag{55}$$

in Eqs. 53 and 54, we can easily obtain common expressions for them found in text-books.

$$q_{kl} = 2\sum_i^{\text{occ}} C_{ki}C_{li}^*, \tag{56}$$

$$\pi_{kl;mn}(\bar{\pi}_{kl;mn}) = 2\sum_i^{\text{occ}}\sum_j^{\text{un}} \frac{1}{\varepsilon_i-\varepsilon_j}(C_{ki}C_{mi}^*C_{lj}C_{mj}^* \pm C_{ki}C_{ni}^*C_{lj}C_{mj}^* + C_{kj}C_{mj}^*C_{li}C_{mi}^* \pm C_{kj}C_{nj}^*C_{li}C_{mi}^*). \tag{57}$$

Now the first order energy change $\delta E^{(1)}$ is

$$\begin{aligned}\delta E^{(1)} &= -\sum_{k<l} q_{kl}\theta_{kl}^2 \\ &= -\beta\left(\frac{S}{\Phi_0}\right)^2\sum_{k<l} q_{kl}s_{kl}^2\left[H^2+2H\left(\frac{m}{\mathrm{d}^3}\right)\times k_{kl}+\left(\frac{m}{\mathrm{d}^3}\right)^2 k_{kl}^2\right].\end{aligned} \tag{58}$$

The second order energy of which magnitude is same order to the first order one arises from the imaginary part of v, and then we obtain

$$\begin{aligned}\delta E^{(2)} &= \sum_{k<l}\sum_{m<n}\theta_{kl}\pi_{kl;mn}\theta_{mn} \\ &= \beta^2\left(\frac{S}{\Phi_0}\right)^2\sum_{k<l}\sum_{m<n}\bar{\pi}_{kl;mn}s_{kl}s_{mn}\left[H^2+\frac{mH}{\mathrm{d}^3}(k_{kl}+k_{mn})+\left(\frac{m}{\mathrm{d}^3}\right)^2 k_{kl}k_{mn}\right].\end{aligned} \tag{59}$$

The linear terms with respect to the test dipole m is needed to evaluate the effective field secondaly produced:

$$\begin{aligned}\delta E_{maq}(=-mH') &= \delta E_{maq}^{(1)} + \delta E_{maq}^{(2)} \\ &= -2\beta\left(\frac{S}{\Phi_0}\right)^2\frac{mH}{\mathrm{d}^3}(\sigma_1+\sigma_2),\end{aligned} \tag{60}$$

where σ_1 and σ_2 are dimensionless shielding constants:

$$\sigma_1 = \sum_{k<l} q_{kl}s_{kl}^2k_{kl}, \tag{61}$$

$$\sigma_2 = \sum_{k<l}\sum_{m<n}\beta\bar{\pi}_{kl;mn}s_{kl}s_{mn}\cdot\frac{1}{2}(k_{kl}+k_{mn}). \tag{62}$$

Thus we have completely reproduced the result obtained by McWeeny (see Eqs. (4,2) and (4,3) of Ref. 4).

Perturbation Treatment II

If we start with the transformed Hamiltonian given by McWeeny,[4] the procedure is much more simplified. McWeeny transformation is as follows: Introducing a new basis set,

$$\langle\bar{\chi}_a, \bar{\chi}_b, \bar{\chi}_c, \cdots| = \langle\chi_a, \chi_b, \chi_c, \cdots|U \tag{63}$$

where U is a diagonal matrix,

$$U = \mathrm{diag.}(1, \omega_{12}^*, \omega_{12}^*\omega_{23}^*, \cdots, \omega_{12}^*\omega_{23}^*\cdots\omega_{i-1,i}^*, \cdots). \tag{64}$$

Then we have a transformed Hamiltonian, $\tilde{H}=U^+HU$, or in details

$$\tilde{H}_{ij} = U_{ii}^*H_{ij}U_{jj}. \tag{65}$$

Remembering that $\omega_{ij}=\omega_{ji}^*$ and $|\omega_{ij}|=1$, we can see that H of naphthalene given in Eq. 9 is transformed to such that with all the near-diagonal ω's replaced by 1, say

$$\tilde{\omega}_{34} = \omega_{12}\omega_{23}\omega_{34}\omega_{12}^*\omega_{23}^*\omega_{34}^* = 1, \tag{66}$$

and

$$\tilde{\omega}_{10,1} = \omega_{12}\omega_{23}\cdots\omega_{9,10}\omega_{10,1} = e^{i\theta_{10\to1}}, \tag{67}$$

$$\tilde{\omega}_{10,5} = \omega_{12}\omega_{23}\cdots\omega_{9,10}\omega_{10,5}\omega_{12}^*\omega_{23}^*\cdots\omega_{45}^* = \omega_{56}\omega_{67}\cdots\omega_{9,10}\omega_{10,5} = e^{i\theta_{10\to5}}. \tag{68}$$

Thus we have

$$\tilde{H} = \begin{pmatrix} \cdot & 1 & \cdot & \cdot & \cdot & \cdot & \cdot & \cdot & \cdot & a \\ 1 & \cdot & 1 & \cdot & \cdot & \cdot & \cdot & \cdot & \cdot & \cdot \\ \cdot & 1 & \cdot & 1 & \cdot & \cdot & \cdot & \cdot & \cdot & \cdot \\ \cdot & \cdot & 1 & \cdot & 1 & \cdot & \cdot & \cdot & \cdot & \cdot \\ \cdot & \cdot & \cdot & 1 & \cdot & 1 & \cdot & \cdot & \cdot & b \\ \cdot & \cdot & \cdot & \cdot & 1 & \cdot & 1 & \cdot & \cdot & \cdot \\ \cdot & \cdot & \cdot & \cdot & \cdot & 1 & \cdot & 1 & \cdot & \cdot \\ \cdot & \cdot & \cdot & \cdot & \cdot & \cdot & 1 & \cdot & 1 & \cdot \\ \cdot & \cdot & \cdot & \cdot & \cdot & \cdot & \cdot & 1 & \cdot & 1 \\ a^* & \cdot & \cdot & \cdot & b^* & \cdot & \cdot & \cdot & 1 & \cdot \end{pmatrix}$$

$$= \begin{pmatrix} \cdot & 1 & \cdot & \cdot & \cdot & \cdot & \cdot & \cdot & \cdot & 1 \\ 1 & \cdot & 1 & \cdot & \cdot & \cdot & \cdot & \cdot & \cdot & \cdot \\ \cdot & 1 & \cdot & 1 & \cdot & \cdot & \cdot & \cdot & \cdot & \cdot \\ \cdot & \cdot & 1 & \cdot & 1 & \cdot & \cdot & \cdot & \cdot & \cdot \\ \cdot & \cdot & \cdot & 1 & \cdot & 1 & \cdot & \cdot & \cdot & 1 \\ \cdot & \cdot & \cdot & \cdot & 1 & \cdot & 1 & \cdot & \cdot & \cdot \\ \cdot & \cdot & \cdot & \cdot & \cdot & 1 & \cdot & 1 & \cdot & \cdot \\ \cdot & \cdot & \cdot & \cdot & \cdot & \cdot & 1 & \cdot & 1 & \cdot \\ \cdot & \cdot & \cdot & \cdot & \cdot & \cdot & \cdot & 1 & \cdot & 1 \\ 1 & \cdot & \cdot & \cdot & 1 & \cdot & \cdot & \cdot & 1 & \cdot \end{pmatrix}$$

$$+ \begin{pmatrix} \cdot & \cdot & \cdot & \cdot & \cdot & \cdot & \cdot & \cdot & \cdot & \bar{a} \\ \cdot & \cdot & \cdot & \cdot & \cdot & \cdot & \cdot & \cdot & \cdot & \cdot \\ \cdot & \cdot & \cdot & \cdot & \cdot & \cdot & \cdot & \cdot & \cdot & \cdot \\ \cdot & \cdot & \cdot & \cdot & \cdot & \cdot & \cdot & \cdot & \cdot & \cdot \\ \cdot & \cdot & \cdot & \cdot & \cdot & \cdot & \cdot & \cdot & \cdot & \cdot \\ \cdot & \cdot & \cdot & \cdot & \cdot & \cdot & \cdot & \cdot & \cdot & \bar{b} \\ \cdot & \cdot & \cdot & \cdot & \cdot & \cdot & \cdot & \cdot & \cdot & \cdot \\ \cdot & \cdot & \cdot & \cdot & \cdot & \cdot & \cdot & \cdot & \cdot & \cdot \\ \cdot & \cdot & \cdot & \cdot & \cdot & \cdot & \cdot & \cdot & \cdot & \cdot \\ \bar{a}^* & \cdot & \cdot & \cdot & \bar{b}^* & \cdot & \cdot & \cdot & \cdot & \cdot \end{pmatrix} \tag{69}$$

where

$$a = \omega_{1,10},\quad b=\omega_{5,10},\quad \bar{a}=1-a,\quad \bar{b}=1-b \tag{70}$$

The transformed Hamiltonian is thus written as

$$H = H_0 + v, \tag{71}$$

however, v has non-vanishing matrix elements only at bonds which complete circuits. In the case of naphthalene, if we draw the path seen in Fig. 4a, the bonds, 10→1 and 10→5 complete the naphthalene and benzene rings, respectively. The arrow showing enclosing direction suggests the sign of the ring area (see Eqs. 67 and 68).

The energy change due to magnetic interaction is

$$\begin{aligned}\delta E &= \mathrm{Tr}\frac{1}{2\pi \mathrm{i}}\int_c \mathrm{d}z z(\boldsymbol{G}(z)-\boldsymbol{G}^0(z)) \\ &= \mathrm{Tr}\frac{1}{2\pi \mathrm{i}}\int_c \mathrm{d}z z(\tilde{\boldsymbol{G}}(z)-\boldsymbol{G}^0(z)).\end{aligned} \tag{72}$$

In the above it is legitimate to replace $\boldsymbol{G}$ by $\tilde{\boldsymbol{G}}$ inside Tr.

The propagator $\tilde{\boldsymbol{G}}$ is given, by virtue of Eq. 71, as

$$\begin{aligned}\tilde{\boldsymbol{G}} &= \frac{1}{z-\boldsymbol{H}} = \frac{1}{z-\boldsymbol{H}_0-\boldsymbol{v}} \\ &= \frac{1}{z-\boldsymbol{H}_0} + \frac{1}{z-\boldsymbol{H}_0}\boldsymbol{v}\frac{1}{z-\boldsymbol{H}_0} \\ &\quad + \frac{1}{z-\boldsymbol{H}_0}\boldsymbol{v}\frac{1}{z-\boldsymbol{H}_0}\boldsymbol{v}\frac{1}{z-\boldsymbol{H}_0} + \cdots \\ &= \boldsymbol{G}^0 + \boldsymbol{G}^0\boldsymbol{v}\boldsymbol{G}^0 + \boldsymbol{G}^0\boldsymbol{v}\boldsymbol{G}^0\boldsymbol{v}\boldsymbol{G}^0 + \cdots\end{aligned} \tag{73}$$

Substituting this into Eq. 71 we can easily obtain, as has been done in the previous section, as

$$\begin{aligned}\delta E &= \mathrm{Tr}\frac{1}{2\pi \mathrm{i}}\int_c \mathrm{d}z\left(\boldsymbol{G}^0\boldsymbol{v} + \frac{1}{2}\boldsymbol{G}^0\boldsymbol{v}\boldsymbol{G}^0\boldsymbol{v}\right) \\ &= 2\sum_{m>n} q_{mn}v^0_{mn} + \sum_{m>n}\sum_{k>l} v'_{mn}\bar{\pi}_{mn;kl}v'_{kl},\end{aligned} \tag{74}$$

where v^0_{mn} and v'_{mn} are respectively the real and imaginary parts of v_{mn}, which is precisely

$$v_{mn} \doteqdot \beta\left(i\theta_{m\to n} - \frac{1}{2}\theta^2_{m\to n}\right), \tag{75}$$

with

$$\theta_{m\to n} = \frac{S}{\Phi_0}\left(s_{m\to n}H + \frac{m}{\mathrm{d}^3}\kappa_{m\to n}\right) \tag{76a}$$

and

$$\begin{aligned}s_{m\to n} &= s_{n,n+1} + s_{n+1,n+2} + \cdots s_{m-1,m} + s_{mn}, \\ \kappa_{m\to n} &= s_{n,n+1}k_{n,n+1} + s_{n+1,n+2}k_{n+1,n+2} + \cdots \\ &\quad + s_{mn}k_{mn}.\end{aligned} \tag{76b}$$

Namely, $s_{m\to n}$ is the area surrounded by the circle which goes round $n\to n+1\to\cdots\to m\to n$, and $\kappa_{m\to n}$ is understood similarly.

Using aboves in Eq. 74, we obtain

$$\delta E^{(1)} = -\beta\left(\frac{S}{\Phi_0}\right)^2\sum_{m>n} q_{mn}\left(Hs_{m\to n} + \frac{m}{\mathrm{d}^3}\kappa_{m\to n}\right)^2, \tag{77}$$

$$\delta E^{(2)} = \beta^2\left(\frac{S}{\Phi_0}\right)^2\sum_{m>n}\sum_{k>l}\bar{\pi}_{mn;kl}\left(HS_{m\to n} + \frac{m}{\mathrm{d}^3}\kappa_{m\to n}\right) \times\left(Hs_{k\to l} + \frac{m}{\mathrm{d}^3}\kappa_{k\to l}\right). \tag{78}$$

The linear terms with respect to m in Eqs. 77 and 78 yield

$$\begin{aligned}\delta E &= (-mH') = \delta E^{(1)}_{\mathrm{mag}} + \delta E^{(2)}_{\mathrm{mag}} \\ &= -2\beta\left(\frac{S}{\Phi_0}\right)^2\frac{m}{\mathrm{d}^3}(\sigma_1+\sigma_2),\end{aligned} \tag{79}$$

where

$$\begin{aligned}\sigma_1 &= \sum_{m,n} q_{mn}s_{m\to n}\kappa_{m\to n}, \\ \sigma_2 &= \sum_{m>n}\sum_{k>l}\beta\bar{\pi}_{mn;kl}\frac{1}{2}(s_{m\to n}\kappa_{k\to l} + s_{k\to l}\kappa_{m\to n}).\end{aligned} \tag{80}$$

In this treatment the summation is restricted to the bonds which complete circuits. Also note that $\bar{\pi}_{mn;kl}$ is given in unit of $1/\beta$. Eq. 79 gives the same result with that of the previous section, but with more transparent physical image.

Illustrative Examples

A few examples will be presented in order to faciliate understanding of the preceding treatment.

(1) Benzene. This is the case of one ring, and calculation becomes trivially simple. Go round the ring along the positive direction and the circuite is completed by the bond 6→1, then we have; $s_{6\to 1}=1$ and $\kappa_{61}=s_{12}k_{12}+s_{23}k_{23}+\cdots+s_{61}k_{61}$. Thus $\sigma_1=2/3\cdot\kappa_{1\to 6}$ and $\sigma_2=-5/9\cdot\kappa_{1\to 6}$. The secondary induced field at the test dipole is written as

$$H' = 2\beta\left(\frac{S}{\Phi_0}\right)^2\frac{H}{\mathrm{d}^3}\frac{1}{9}\kappa_{6\to 1}. \tag{81}$$

Further discussion is refered to Ref. 4.

(2) Naphthalene. It should be instructive to calculate in two alternative ways based on Fig. 4a and 4b. One of the purposes of the present example is that, as has been done intuitively, the whole effect of the (naphthalene) ring current is attributed to those of individual, constituent benzene rings.

(a) Bonds 10→5 and 10→1 together complete a positive circuite with $s_{10\to 5}=1$ and $s_{10\to 1}=2$. $\kappa_{10\to 5}$ is occuring

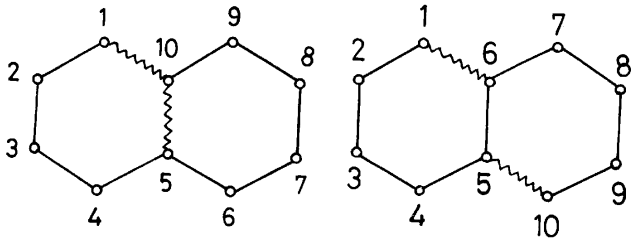

Fig. 4.

in the right hand side benzene ring, named R (while the left hand ring is called L). Then, if we write $\kappa_{10\to 1}=\kappa_R$, it should be that $\kappa_{10\to 1}=\kappa_R+\kappa_L$. Thus we obtain

$$\begin{aligned}\sigma_1 &= q_{1,10}(\kappa_R+\kappa_L) + q_{5,10}\kappa_L \\ &= 1.1094\kappa_R + 1.16277\kappa_L \end{aligned} \quad (82)$$

$$\begin{aligned}\sigma_2 &= -[\bar{\pi}_{5,10;5,10}\kappa_L + 2\bar{\pi}_{1,10;1,10}(\kappa_R+\kappa_L) \\ &\quad + \bar{\pi}_{5,10;1,10}(\kappa_R+3\kappa_L)] \\ &= -0.9880\kappa_R - 1.5063\kappa_L, \end{aligned} \quad (83)$$

where $\bar{\pi}$'s are in unit β. It should be stressed that as shown in Fig. 4, if we begin with drawing a path numbered there, circuits concerning with magnetic interaction are identically determined. In this respective, we call these circuits irreducible ones.

(b) The bonds 6→1 and 10→5 complete, respectively, the positive and negative circuits with $s_{6\to 1}=1$ and $s_{10\to 5}=-1$. Therefore noting that $\kappa_{6\to 1}=\kappa_R$ and $\kappa_{10\to 5}=-\kappa_L$, we obtain

$$\begin{aligned}\sigma_1 &= q_{16}(\kappa_R+\kappa_L) \\ &= 0.5547(\kappa_R+\kappa_L), \end{aligned} \quad (84)$$

and

$$\begin{aligned}\sigma_2 &= \bar{\pi}_{1,6;1,6}\kappa_R + \bar{\pi}_{5,10;5,10}\kappa_L + \kappa_{1,6;5,10}(\kappa_R+\kappa_L) \\ &= -0.4333(\kappa_R+\kappa_L), \end{aligned} \quad (85)$$

by the use of $\bar{\pi}_{1,6;1,6}=\bar{\pi}_{5,10;5,10}=-0.4660$ and $\pi_{1,6;5,10}=-0.0327$.

The both calculations (a) and (b) result in the same value,

$$\sigma_1 + \sigma_2 = 0.1214(\kappa_R+\kappa_L), \quad (86)$$

which tells us the invariant character, independent of choice of the original path. Finally we note that $-\kappa_p\to 1/r^3$ at large distance and each ring behaves like an induced dipole.

Conclusion

As has been seen in the previous sections, the propagator theory works well and easily reproduces the current results. One may say that it yields nothing new beyond traditional methods, but we insist that, by this way, the analysis is very much simplified, physical processes involved are made clearer, and the method itself is considerably general, even for the complicated phenomena.

Carbon-13 chemical shifts, azomethine proton chemical shifts, and azomethine carbon–hydrogen coupling constants have been determined for *N*-benzylideneaniline and its several derivatives bearing *o*-methyl and/or *p*-nitro groups on the aromatic ring on the nitrogen atom (ring A). The anomalous upfield shift of the azomethine proton caused by introduction of a 4-nitro group on the ring A can be attributed to the increase in the twist angle θ_N of the ring A from the molecular plane containing the C=N bond.

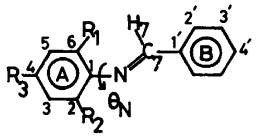
Molecular conformations of *N*-benzylideneanilines have been studied by many workers,[1] and in previous papers, the present authors have shown that introduction of a 4-nitro group as well as 2,6-dimethyl groups increases the twist angle θ_N (formula shown below) in solution by UV spectroscopy,[1] and in gas phase by photoelectron spectroscopy.[2]

Concerning NMR of *N*-benzylideneanilines, one of the present authors reported with collabolators an anomalous substituent effect on the azomethine proton (H_7) chemical shifts for a series of 4-substituted *N*-benzylideneanilines, $C_6H_5CH{=}NC_6H_4$-X-4, in which with the increase in electron-withdrawing property of the 4-substituents H_7 exhibited an unexpected upfield shift (ρ=+0.04) whereas for a series of 4'-substituted *N*-benzylideneanilines, 4-Y-$C_6H_4CH{=}NC_6H_5$, H_7 exhibited a normal downfield shift (ρ=−0.16) with the increase in the electron-withdrawing property of the substituents.[3] The origin of this anomalous substituent effect has been argued,[4–9] for example, in terms of a through-space field effect,[3,5,6] but still remains puzzling.

We now wish to propose that this anomalous substituent effect originates primarily from the change of molecular conformation with the substituent as previously shown by UV[1] and photoelectron spectroscopy.[2] The present proposition is based on consideration that the introduction of an electron-withdrawing nitro group on the C-4 position of the anilino benzene ring (ring A) enhances delocalization of lone-pair electrons on the nitrogen atom into the ring A accompanied by an increase in the twist angle θ_N in solution, which leads to changes of the ring current effect by the ring A exerted on H_7, resulting in the anomalous upfield shift of its chemical shift.

Results and Discussion

The following six *N*-benzylideneanilines **1**—**6** have been examined for their carbon-13 chemical shifts, H_7 chemical shifts, and azomethine carbon (C_7)-hydrogen coupling constants. The results are summarized in Table 1, and schematically illustrated for the selected quantities in Fig. 1.



1; $R_1=R_2=R_3=H$
2; $R_1=H$, $R_2=CH_3$, $R_3=H$
3; $R_1=R_2=CH_3$, $R_3=H$
4: $R_1=R_2=H$, $R_3=NO_2$
5; $R_1=H$, $R_2=CH_3$, $R_3=NO_2$
6; $R_1=R_2=CH_3$, $R_3=NO_2$

Figure 1 indicates that on successive introduction of methyl groups on 2- and 2,6-positions of **1**, the chemical shift of C_7 shows an upfield shift from **1** to **2** by

a) Ref. 3.

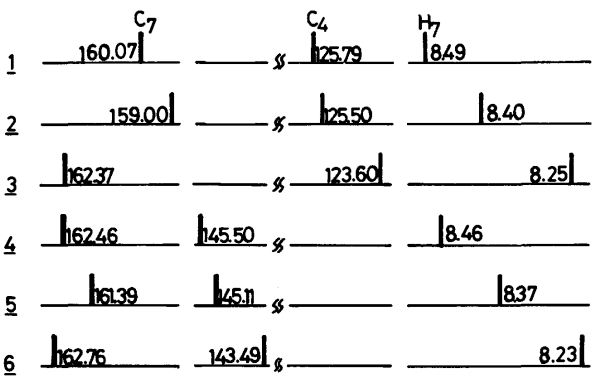

Fig. 1. Schematic illustration of the chemical shifts for C_4, C_7, and H_7 ($CDCl_3$, ppm downfield from TMS).

1.07 ppm, then a remarkable downfield shift from **2** to **3** by 3.37 ppm, C_7 of *3* resonating at much lower field than that of **1**. The chemical shift of C_4, as has already been reported by Kobayashi's group,[10] shows a slight upfield shift from **1** to **2** by 0.29 ppm, then a larger upfield shift from **2** to **3** by 1.90 ppm. The upfield shifts of C_4 and C_7 from **1** to **2** can be understood in terms of an inductive effect of the methyl group. However, the remarkable downfield shift of C_7 and the larger upfield shift of C_4 between **1** and **3** cannot be explained simply in terms of the inductive effect of the two methyl groups. These changes observed between **1** and **3** can be reasonably interpreted in terms that the introduction of the bulky 2,6-dimethyl groups forces the ring A to be highly twisted from the imino molecular plane. This distortion will cause the nitrogen lone pair to interact effectively with the aromatic π-system (n-π conjugation) to increase the electron density on C_4 leading to its upfield shift, as proposed previously.[11] The *N*-lone pair delocalization will succesively lead to the shift of electrons on C_7 to the nitrogen atom to decrease the electron density on C_7. The effect of the decrease in electron density on C_7 caused by the *N*-lone pair delocalization is predominant to the inductive effects of the two methyl groups finally giving the downfield shift of the C_7 chemical shift. The downfield shift of C_7 from **1** to **3** could also be explained in terms of a decrease of π-π conjugation throughout the π-system accompanied by the increase of the n-π conjugation. For example, β-vinyl carbon of 2,6-dimethylstyrene is reported to resonate at 6.2 ppm lower field than that of styrene, and this lower field shift was explained in terms of steric inhibition of resonance between the vinyl group and the phenyl group.[12] By analogy, the decrease of the π-π conjugation from **1** to **3** by the 2,6-dimethyl substitution may also cause a lowfield shift of C_7, which is in the same direction as predicted by the consideration on the increase of the n-π conjugation.

The above explanation that the twisting of the ring A from the molecular plane induces the significant lowfield shift of the C_7 carbon is supported by ^{13}C-H coupling constants. It is well known that the carbon-hydrogen coupling constant depends on the s character of the C-H bond,[13] and the larger s character is caused by the decrease of π electron density on the carbon atom. The ^{13}C-H coupling constant is increased from 157.3 (Hz) from **1** to 158.5 for **2**, then to 159.6 for **3**, which indicates that on successive introduction of the *o*-methyl groups on **1** the C_7-H bond increases in the s character possibly through the decrease in the π electron density on C_7.

On introduction of a 4-nitro group in **1**, C_7 exhibits a downfield shift by 2.39 ppm from **1** to **4**, which is of the same magnitude as observed between **1** and **3** with 2,6-dimethyl groups. However, 2,6-dimethyl substitution on **4**, in constrast with the effect on **1**, causes a very slight downfield shift of C_7 by only 0.30 ppm from **4** to **6**. These results suggest that the ring A of **4**, in spite of the absence of *o*-methyl groups, may be appreciably twisted like that of **3** in which the ring A is forced to be twisted by the effect of the *o*-methyl groups. The chemical shift of C_4 shows an upfield shift from **4** to **5** and to **6**, and the ^{13}C-H coupling constant for **4** is almost the same as for **2**, and then succssively increases on introduction of the *o*-methyl groups. These results suggest that, as in series of **1**, **2**, and **3**, the successive introduction of the *o*-methyl groups increases the twist angle θ_N accompanied by the decrease in the π electron density on C_7.

Concerning the H_7 chemical shifts, introduction of a nitro group on the C_4 position of each of **1**, **2**, and **3** anomalously shifts the H_7 chemical shifts to higher field by 0.02—0.03 ppm which is reproducible and beyond the experimental error. As to methyl substitution on **1** and **4**, monomethyl substitution of their 2-positions causes an upfield shift by 0.09 ppm, but further substitution by the second methyl group at their 6-positions results in a larger upfield shift by 0.14—0.15 ppm. Thus, the effect of the methyl group is not additive, which suggests that the larger upfield shift by the second methyl substitution might be due to the further distortion of the ring A by its introduction as well as its inductive effect. The increase in the twist angle θ_N by the successive methyl substitution will reduce the paramagnetic deshielding effect of the ring A exerted on H_7 resulting in its upfield shift. This view is further supported by a simple calculation of the chemical shift using McConnel's equation.[14] For example, when the unsusbtituted benzene ring (ring A) increases in the twist angle θ_N from 45° to 90°, H_7 can be estimated to resonate at a higher field of about 0.20 ppm.[15] These results coupled with the carbon-13 chemical shifts and the ^{13}C-H coupling constants suggest that the observed anomalous upfield shifts caused by the introduction of the 4-nitro group on **1**, **2**, and **3** could be attributed to the increase in the twist angle θ_N of the ring A from the molecular plane contaning C=N group.

Thus, introduction of the electron-withdrawing nitro group at the C_4 position of the ring A enhances the delocalization of the nitrogen lone pair electrons into the ring A, through so called n-π conjugation, accompanied by the increase in the twist angle θ_N which in turn reduces the paramagnetic deshielding effect of the ring A on H_7 finally resulting in its upfield shift. The observed values for the anomalous upfield shifts remain to be slight. This can be understood by partial cancelling of the upfield shift of H_7 by the twisting of the ring A, because the introduction of the 4-nitro group causes the decrease in electron density of C_7 which would lead to the downfield shift of H_7.

The above estimation that the 4-nitro group enhances the twist angle θ_N in solution is supported by our recent results by UV[1] and photoelectron spectroscopy[2] which indicates that the 4-nitro derivative **4** may be more twisted than **1** in solution and in gas phase, respectively. Also in view of the recent report by UV spectroscopy that the introduction of an electron-donating 4-dimethylamino group on **1** leads to reduction of the twist angle θ_N,[16] it is reasonable to consider that the introduction of an electron-withdrawing 4-nitro group tends to increase the twist angle θ_N.

Finally, it is worth noting that the present study shows that apparent substituent effects in NMR may arise from the changes of molecular conformations with substituents as well as from the electronic effects of the substituents.

Experimental

Materials. Preparations and characterizations of **1**—**6** are already reported.[1]

Spectral Measurements. *Carbon-13 NMR Spectra*: Carbon-13 NMR spectra were measured at room temperature (probe temperature 27 °C) on a JEOL FX-60 spectrometer operating in the Fourier transform mode with complete proton decoupling. The spectra were generally recorded at a pulse width of 4 μs, a pulse flip angle of 45°, and a repetition time of 5 s using $CDCl_3$ as a solvent. In some cases, single-frequency off-resonance decoupled spectra were also measured. Sample concentrations were usually 1 mol/dm³ in $CDCl_3$ solutions. Digital resolution was 0.74 Hz/point. Observed chemical shifts are reported in ppm downfield from internal tetramethylsilane.

Chemical shifts of the substituents (methyl group), which are not listed in the Table 1 are as follows; **2**: 17.79 (ppm), **3**: 18.23, **5**: 17.94, **6**: 18.33.

^1H-NMR Spectra: Azomethine proton chemical shifts were taken from a JEOL MH-100 spectrometer at room temperature in the external lock mode using $CDCl_3$ as a solvent and tetramethylsilane as an internal reference. We first examined the dilution shift for **4** as an example. The chemical shifts were as follows: 0.23 mol/dm³; 845.3 (Hz), 0.10 mol/dm³; 845.5, 0.08 mol/dm³; 845.6, 0.03 mol/dm³; 845.4. Thus, no dilution shifts were observed which allowed us to measure the chemical shifts for other componds in one concentration below *ca.* 0.1 mol/dm³. The chemical shifts listed in the Table 1 are those measured in the following concentrations: **1**: 0.10 (mol/dm³), **2**: 0.14, **3**: 0.11, **4**: 0.10, **5**: 0.09, **6**: 0.08.

Azomethine Carbon-Hydrogen Coupling Constants: The ^{13}C–H coupling constants were taken from a JEOL FX-60 or a Varian XL-100 spectrometer in $CDCl_3$ solutions by the gated decoupling technique combined with NOE mode.

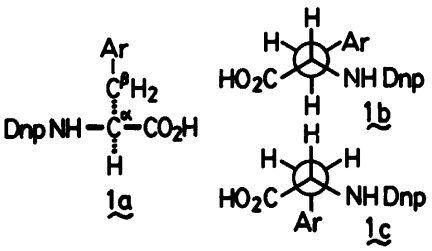
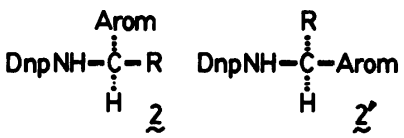
A Method for Determining Absolute Configuration of Cycloalkanamines and Related Compounds by CD Spectra of Their 2,4-Dinitrophenyl Derivatives

Masao KAWAI,* Teruhiko IWASE, Yasuo BUTSUGAN, and Ukon NAGAI†
Department of Synthetic Chemistry, Nagoya Institute of Technology, Showa-ku, Nagoya 466
†*Mitsubishi-Kasei Institute of Life Sciences, Minamiooya 11, Machida, Tokyo 194*
(Received July 16, 1984)

N-(2,4-Dinitrophenyl) derivatives of cycloalkanamines and related compounds having an amino and an aromatic groups in vicinal positions were prepared. Their CD spectra exhibited marked Cotton effect around 400 nm, the sign of which was shown to coincide with the chirality between the two chromophore-bearing bonds. This relation, as a special example of exciton chirality method, is useful for determining absolute configuration of cyclic compounds having a primary amino group.

Chiroptical properties of 2,4-dinitrophenyl (Dnp) derivatives of α-amino acids and related compounds have been investigated extensively.[1-10] Rules have been found which correlate the absolute configuration and the sign of the Cotton effect of the Dnp derivatives of chiral diamines,[1] arylalkylamines,[5] and cyclic secondary amines.[3] Dnp derivatives of L-α-amino acids with aromatic side chain (**1a**) exhibit characteristic CD spectra with negative Cotton effect around 400 nm.[2,5] Further study upon the related compounds led us to the proposal of Dnp-aromatic rule, which predicts negative and positive sign of $[\theta]_{\sim 400}$ value for the arylalkylamines of general formulas **2** and **2'**, respectively.[5] Based on ^{1}H NMR study and theoretical calculation of rotational strength it was concluded that staggered conformer **1b** is responsible for the negative Cotton effect around 400 nm of **1a**.[9] The conformer **1b**, designated as g^-, is characterized by the negative bond chirality between the C^α–NHDnp and C^β–Ar bonds. The present paper deals with CD spectra of carbocyclic analogs of **1a** in which the two chromophoric groups are conformationally fixed to have the same bond chirality as in **1b**. Theoretically, the chirality between electric dipole moments is the essential factor as discussed later. However, bond chirality is more familiar to organic chemists. So, "bond chirality" will be used throughout this paper as the reasonable and convenient approximation.

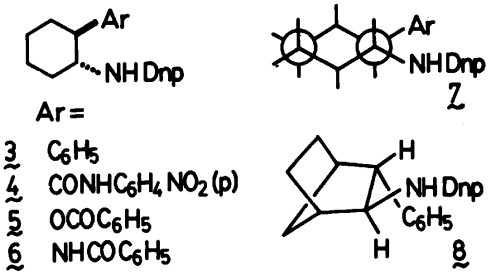




Arom : Achiral group which contains an aromatic chromophore

R : Nonaromatic group

Dnp derivatives of 2-substituted cyclohexanamines **3**—**6** were synthesized. Since the compounds **3**—**6** are considered to take stable chair conformation **7** with two bulky groups (DnpNH and Ar) in equatorial orientation, all of these Dnp derivatives **3**—**6** possess negative bond chirality between C–NHDnp and C–Ar bonds. CD spectra of **3**—**6** recorded in methanol solutions were reproduced in Fig. 1. As expected from theoretical consideration[9] all of these compounds exhibited marked negative Cotton effect around 400 nm. The conformationally fixed Dnp derivatives **3**, **4**, and **5** correspond to the staggered g^- conformers of Dnp derivatives of L-phenylalanine (**1a**, Ar=C_6H_5: $[\theta]_{410}$ −9100),[5] L-aspartic acid β-*p*-nitroanilide (**1a**, Ar=$CONHC_6H_4NO_2(p)$: $[\theta]_{400}$ −9200),[5] and *O*-benzoyl-L-serine (**1a**, Ar=$OCOC_6H_5$: $[\theta]_{408}$ −3400),[5] respectively. The magnitude of Cotton effect around 400 nm of **3**, **4**, and **5** were shown to be 2—3 times as large as the corresponding Dnp amino acids having conformational freedom, which supported the assumption that the staggered conformer g^- of Dnp derivatives of aromatic L-α-amino acids **1a** is responsible for their characteristic negative Cotton effect



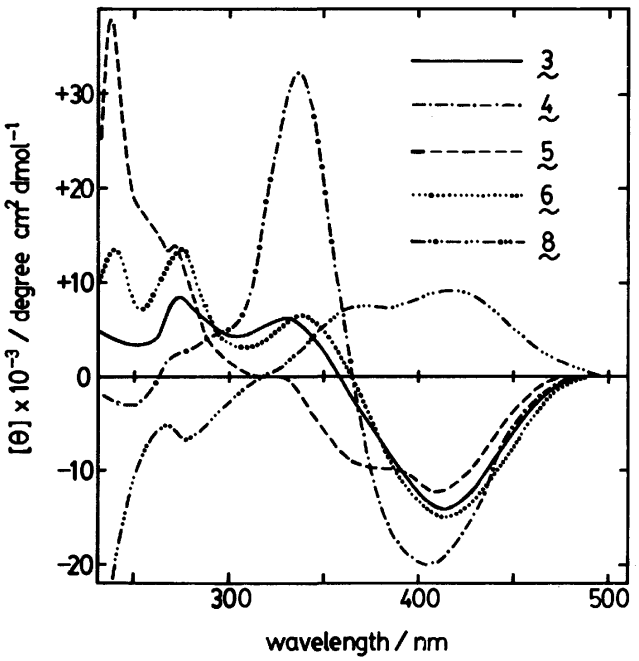


Fig. 1. CD spectra of **3**—**6** and **8** recorded in methanol.

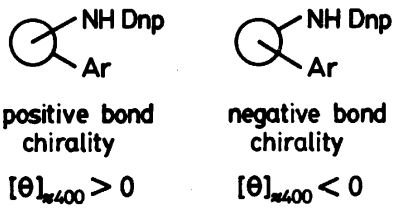

Fig. 2. Relation between bond chirality and sign of Cotton effect.
Ar implies a chromophore which contains an aromatic group.

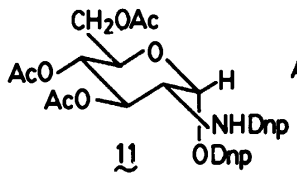
around 400 nm. In order further to confirm the validity of the relation between bond chirality and the Cotton effect, the norbornane derivative **8** was synthesized. The CD spectrum of the Dnp derivative **8**, as also given in Fig. 1, exhibited positive Cotton effect at 416 nm in accordance with positive bond chirality of the C-NHDnp and C-C_6H_5 bonds. Thus it has been established that sign of the Cotton effect around 400 nm agrees with the bond chirality between C-NHDnp and C-Ar bonds for the conformationally fixed derivatives as described in this paper (Fig. 2).

Wakamiya *et al.*[11] already reported successful application of the relation between bond chirality and the sign of Cotton effect to structure elucidation of a natural product. In order to determine absolute configuration of galantinic acid (**9**), a constituent amino acid of a peptide antibiotic galantin

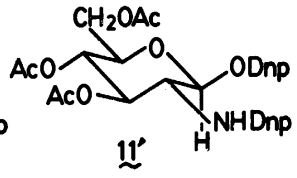
	R^1=	R^2=	R^3=
9	H	H	H
10	Dnp	COC_6H_5	CH_3

I,[12] micromolar amount of **9** was converted into *N*-Dnp-*O*-benzoyl derivative **10**. The CD spectrum of **10** exhibited prominent positive Cotton effect at 400 nm, which established the absolute configuration of **9** having positive chirality of the C-N and C-O bonds.[11]

Another example of application of the rule to oxacyclohexanamine derivative is the case of D-glucosamine derivative **11**, which was obtained apparently as a sole product by successive 2,4-dinitrophenylation and acetylation of D-glucosamine. Possible products of the reaction were anomers **11** and **11'**, which possess posi-



11



11'

tive and negative chirality between the C-NHDnp and C-ODnp bonds, respectively, corresponding to **1c** and **1b** in their chromophoric arrangement. Positive Cotton effect ($[\theta]^{25}_{400}$ +5100) and small coupling constant of the anomeric proton (δ_{DMSO-d_6} 6.48, d, J=3 Hz) in ^{1}H NMR spectrum established the structure **11**.

The agreement between bond chirality and the sign of Cotton effect is rationalized as follows: The Cotton effects in concern can be assumed to be due to exciton coupling of electric transition moments of the two chromophores as expressed by the equation[13]

$$R_a = \frac{\pi}{ch} \cdot \frac{\lambda_a \lambda_b}{\lambda_a^2 - \lambda_b^2} \cdot V \cdot [\boldsymbol{R} \cdot (\mu_a \times \mu_b)]$$

where R_a is rotational strength at wavelength λ_a generated by interaction of the electric transition moment μ_a at λ_a with μ_b at λ_b. V, $\boldsymbol{R}$, c, and h are interaction energy, directional vector from μ_a to μ_b, light velocity, and Planck's constant, respectively. Thus, the sign of term $V \cdot [\boldsymbol{R} \cdot (\mu_a \times \mu_b)]$ determines the sign of Cotton effect to be observed. The electronic spectra of DnpNH chromophore shows a shoulder band around 400 nm (ε 7000) along with strong main band at around 350 nm (ε 17000). SCF-MO[14] calculation showed that direction of the electric transition moment of the longest wavelength band of DnpNH chromophore is roughly parallel to the C-NHDnp bond.[1,15] Interaction of this transition moment with transition moments of the other chromophore is considered to generate the CD band observed around 400 nm. As for the other chromophore there usually exists a strong absorption band, the electric transition moment of which has a direction along the long axis of the chromophore;[16] *i.e.*, the direction of this transition moment is

exactly or approximately parallel to the C-Ar bond. Consequently the sign of the term $\boldsymbol{R}\cdot(\mu_a\times\mu_b)$ in the equation above is expected to coincide with the bond chirality between C-NHDnp and C-Ar bonds, when μ_a and μ_b are the transition moment of the longest wavelength band of DnpNH chromophore and the transition moment along the long axis of the other chromophore, respectively. Since the sign of V-term is positive in most cases usually encountered, the term $V\cdot[\boldsymbol{R}\cdot(\mu_a\times\mu_b)]$ also has the same sign as the bond chirality. Though the transition moments which are not parallel but rather perpendicular to the C-Ar bond are also present and interact with the moment of DnpNH chromophore, their contribution to the spectra are expected to be averaged out due to rotation around the C-Ar bond. Thus the sign of the Cotton effect around 400 nm is expected to agree with the bond chirality of C-NHDnp and C-Ar bonds of these compounds.

Cotton effect around 350 nm is assumed due to exciton coupling of the dipole moment of main band of DnpNH chromophore with dipole moments of the other chromophore. The extremum of CD spectrum at this region is shifted to longer wavelength when the Cotton effect has the same sign as that of 400 nm band as in **5** (shoulder) and **8** and at shorter wavelength when the sign of Cotton effects of 400 and 350 nm bands are different as in **3**, **4**, and **6** by overlapping of the two bands. In the case of **4** having *p*-nitroanilide group as the other chromophore whose absorption maximum is at about 315 nm,[8] another CD band which corresponds to this transition moment can be expected above 300 nm. No significant band is observed, however, around 315 nm in the CD spectrum of **4**, which is presumably due to the result of cancellation of opposite contributions from the two interactions with transition moments of 400 and 350 nm bands of DnpNH chromophore. Compounds **5** and **6** show different sign of Cotton effect around 350 nm in spite of the close similarity of the two compounds. Thus no simple relation seems to exist between the absolute configuration and the sign of Cotton effect around 350 nm, which is understandable from the dissimilarity between the direction of the correspoding transition moment and the C-NHDnp bond.[1]

In conclusion the relation between the absolute configuration of cycloalkanamines and the sign of Cotton effect around 400 nm of the Dnp derivatives was ascertained experimentally as given in Fig. 2 and was rationallized theoretically using exciton coupling mechanism. Thus it has been shown that absolute configuration can be determined chiroptically for a cyclic compound having a primary amino group, if suitable derivatization can afford a Dnp derivative in which C-NHDnp and C-Ar bonds possess unambiguous bond chirality.

The relation is valid when the chirality of interacting transition moments can be approximated by the bond chirality. In general, combination of conformational analysis and rotational strength calculation will afford useful information for predicting or explaining the CD spectra. The relation described here falls under the generalization "exciton chirality method" developed by Harada and Nakanishi.[17] Attempt to determine the absolute configuration of amino compounds with exciton chirality method using salicylideneamino chromophore was reported by Smith *et al.*[18,19]

Experimental

Melting points were uncorrected. UV and CD spectra were recorded in methanol solution at room temperature on a HITACHI 124 spectrometer and on a JASCO J-40 spectropolarimeter, respectively. Optical rotations were measured with a JASCO J-20 spectropolarimeter or a JASCO DIP-4 digital polarimeter. ^{13}C NMR spectra were determined with a Varian XL-200 spectrometer using sodium 2,2-dimethyl-2-silapentane-5-sulfonate as internal standard. ^{1}H NMR ($CDCl_3$, acetone-d_6, or DMSO-d_6 solution) and IR (KBr disk) spectra of all the derivatives, recorded on a HITACHI R-24 or R-24A spectrometer and on a JASCO IRA-1 or A-102 spectrophotometer, respectively, were consistent with the assigned structures.

(1R,2S)-N-(2,4-Dinitrophenyl)-2-phenylcyclohexanamine (3). (±)-*trans*-2-Phenylcyclohexanamine hydrochloride, mp 252—254 °C (lit,[20] mp 249—251 °C), was prepared from 2-phenylcyclohexanone oxime, mp 174—175 °C (lit,[20] mp 168—169 °C) as described by Masamune *et al.*[20] No significant amount of the *cis*-isomer was detected in the ^{13}C NMR of the dihydrochloride measured in D_2O solution (δ=24.8, 25.6, 31.4, 34.1, 49.0, 55.8, 128.5, 128.7, and 142.0). Optical resolution of (±)-*trans*-2-phenylcyclohexanamine using equimolar amount of (+)-tartaric acid was undertaken. Recrystallization from 3:1 (v/v) methanol–ether as described by Verbit and Price[21] afforded tartrate of (+)-amine as colorless needles, mp 150—151 °C, $[\alpha]_D$ +38° (c 0.85, methanol), while recrystallization from 1:5 (v/v) methanol–H_2O resulted in the crystallization of tartrate of (−)-amine as colorless prisms, mp 139—140 °C, $[\alpha]_D$ −16° (*c* 1.0, methanol). Usual workup of the tartrates gave (+)-(1*S*,2*R*)-2-phenylcyclohexanamine, mp 41.5—42 °C, $[\alpha]_D$ +51° (*c* 0.33, methanol) [lit,[21] mp 36—38 °C, $[\alpha]_D$ +45° (*c* 0.074, methanol)] and (−)-(1*R*,2*S*)-2-phenylcyclohexanamine, mp 43.5—44 °C, $[\alpha]_D$ −49° (*c* 0.28, methanol) [lit,[21] mp 37.5—39 °C, $[\alpha]_D$ −48° (*c* 0.2, methanol)]. A mixture of the levorotatory amine (70 mg, 0.43 mmol), 1-fluoro-2,4-dinitrobenzene (FDNB: 94 mg, 0.5 mmol), $NaHCO_3$ (53 mg, 0.63 mmol), acetone (5 mL), and H_2O (2 mL) was stirred at room temperature for 2 h. Usual workup followed by SiO_2 column chromatography (benzene–petroleum ether) gave **3** (125 mg, 85%), yellow needles from benzene–petroleum ether, mp 126.5—127 °C. UV 410 (sh, ε 6200), 353 (18500), and 257 nm (8800); CD $[\theta]_{415}$ −13600, $[\theta]_{358}$ 0, $[\theta]_{340}$ +6000, $[\theta]_{305}$ +4200, $[\theta]_{274}$ +8000, and $[\theta]_{250}$ +3400. Found: C, 63.50; H, 5.54; N, 12.30%. Calcd for $C_{12}H_{19}N_3O_4$: C, 63.33; H, 5.61; N, 12.31%.

(1R,2R)-2-(2,4-Dinitroanilino)cyclohexanecarboxylic Acid p-

Nitroanilide (4). (±)-*N*-Benzoyl-*trans*-2-aminocyclohexanecarboxylic acid was prepared from anthranilic acid as described by Hünig and Kahanek,[22] and was subjected to optical resolution according to Nohira *et al.*[23] to afford (−)-(1*R*,2*R*)-*N*-benzoyl-2-aminocyclohexanecarboxylic acid quinine salt, mp 134—136 °C, $[\alpha]_D$ −112° (*c* 2.3, ethanol) [lit,[23] mp 143—145 °C, $[\alpha]_D$ −111.6° (*c* 2.5, ethanol)]. Treatment of the quinine salt with 3M HCl (1M=1 mol dm^{-3}) gave (1*R*,2*R*)-*N*-benzoyl-2-aminocyclohexanecarboxylic acid, $[\alpha]_D$ −45° (*c* 0.66, ethanol) [lit,[23] $[\alpha]_D$ −44.5° (*c* 0.67, ethanol)]. The *N*-benzoyl derivative (96 mg, 0.39 mmol) was dissolved in a mixture of conc HCl (6 mL) and acetic acid (3 mL) and was refluxed for 24 h. Evaporation of the mixture afforded crude debenzoylated product, which was 2,4-dinitrophenylated with FDNB according to Sanger[24] to give (1*R*,2*R*)-2-(2,4-dinitroanilino)cyclohexanecarboxylic acid (101 mg, 83%). To the Dnp derivative (77 mg, 0.25 mmol) was added oxalyl dichloride (1.5 mL) and stirred overnight. Excess oxalyl dichloride was evaporated *in vacuo* and *p*-nitroaniline (250 mg, 1.8 mmol) in acetonitrile (2 mL) was added to the residue, which was stirred overnight. After the evaporation of the solvent the residue was washed with hot H_2O and recrystallized from acetone–ethyl acetate to give **4** (24 mg, 20%) as yellow needles, mp 259—261 °C. UV 400 (sh, ε 5800), 330 (24000), 266 (11000), and 219 nm (21800); CD $[\theta]_{406}$ −19800, $[\theta]_{368}$ 0, $[\theta]_{336}$ +32200, $[\theta]^{sh}_{275}$ +2400, $[\theta]_{263}$ 0, and $[\theta]_{250}$ −2500. Found: C, 52.67; H, 4.41; N, 16.00%. Calcd for $C_{19}H_{19}N_5O_7 \cdot 1/4H_2O$: C, 52.60; H, 4.53; N, 16.14%.

(1R,2R)-2-(2,4-Dinitroanilino)cyclohexyl Benzoate (5). (1*R*,2*R*)-2-Aminocyclohexanol (+)-tartrate[25] (44 mg, 0.17 mmol), supplied by Prof. T. Suami, was 2,4-dinitrophenylated with FDNB (62 mg, 0.33 mmol) and $NaHCO_3$ (76 mg, 0.90 mmol) in ethanol (1.7 mL) and H_2O (0.7 mL). The crude product was subjected to SiO_2 column chromatography (benzene–ethyl acetate) to afford (1*R*,2*R*)-2-(2,4-dinitroanilino)cyclohexanol (44 mg, 92%). To the ice-cooled solution of the Dnp derivative (44 mg, 0.16 mmol) in pyridine (0.4 mL) was added benzoyl chloride (0.06 mL, 0.5 mmol) and was stirred overnight at room temperature. After addition of 1 M H_2SO_4 (6 mL) the mixture was extracted with ethyl acetate. The extract was purified by SiO_2 column chromatography (benzene–hexane) and recrystallized from benzene–hexane to give **5** (43 mg, 71%) as yellow powder, mp 143—145 °C. UV 400 (sh, ε 6600), 349 (17700), 265 (9300), and 230 nm (22000); CD $[\theta]_{408}$ −12300, $[\theta]^{sh}_{370}$ −9600, $[\theta]_{320}$ 0, $[\theta]_{271}$ +13800, and $[\theta]_{238}$ +38100. Found: C, 59.39; H, 4.80; N, 10.73%. Calcd for $C_{19}H_{19}N_3O_6$: C, 59.21; H, 4.97; N, 10.90%.

(1R,2R)-N¹-Benzoyl-N²-(2,4-dinitrophenyl)-1,2-cyclohexanediamine (6). 1,2-Cyclohexanediamine (Tokyo Kasei Chemicals; 22.8 g, 0.2 mol) and adipic acid (29.2 g, 0.2 mol) were treated in 2-propanol as described in literature[26] to give *trans*-1,2-cyclohexanediamine adipate (50.0 g, 96%), which was converted into free diamine (13.0 g, 56%) with NaOH. The racemic diamine (8.0 g, 70 mmol) was resolved *via* (+)-tartrate according to Asperger *et al.*[27] to give (1*R*,2*R*)-1,2-cyclohexanediamine dihydrochloride (1.83 g, 27%): $[\alpha]_D$ −15.8° (*c* 2.53, H_2O) [lit,[27] $[\alpha]_D$ −15.8° (*c* 20, H_2O)]. A mixture of the hydrochloride (0.37 g, 2.0 mmol), FDNB (0.37 g, 2.0 mmol), and $NaHCO_3$ (0.60 g, 7.0 mmol) in ethanol (20 mL) and H_2O (10 mL) was stirred for 2 h at room temperature. After evaporation of ethanol benzoyl chloride (0.47 mL, 4 mmol) and 1 M NaOH (7.0 mL) were added and the mixture was stirred overnight. H_2O was added and the precipitate was collected by filtration and washed with H_2O. The precipitate was dissolved in ethanol and insoluble di-Dnp derivative was filtered off. The filtrate, which contained dibenzoyl derivative and *N*-benzoyl-*N'*-Dnp derivative, was concentrated *in vacuo* to induce crystallization of the latter compound. Recrystallization from ethanol gave **6** (63 mg, 8%) as yellow needles, mp 254—258 °C. UV 410 (sh, ε 7000), 352 (16000), 260 (sh, 10500), and 220 nm (17600); CD $[\theta]_{414}$ −15000, $[\theta]_{364}$ 0, $[\theta]_{338}$ +6400, $[\theta]_{310}$ +2900, $[\theta]_{274}$ +13500, $[\theta]_{253}$ +7000, and $[\theta]_{240}$ +13400. Found: C, 58.54; H, 5.25; N, 14.53%. Calcd for $C_{19}H_{20}N_4O_5 \cdot 1/4H_2O$: C, 58.68; H, 5.31; N, 14.41%.

(2S,3R)-2-(2,4-Dinitroanilino)-3-phenylnorbornane (8). Cyclopentadiene (60 g, 0.9 mol) and *trans*-β-nitrostyrene (60 g, 0.4 mol) in benzene (150 mL) were refluxed for 15 h to afford a mixture of stereoisomers of *trans*-5-nitro-6-phenyl-2-norbornenes (78.7 g, 91%), bp 126 °C/3 Torr (lit,[28] bp 110—115 °C/0.3 Torr; 1 Torr=133.322 Pa). This adduct (21.5 g, 0.1 mol) was treated with Sn (24 g, 0.2 mol) and acetic acid (90 mL) as described by Weinstock *et al.*[29] and the reaction mixture was purified by SiO_2 chromatography (ethyl acetate–acetone) to give *trans*-5-amino-6-phenyl-2-norbornenes (7.0 g, 38%), which was hydrogenated over 5% Pd–carbon in ethanol (120 mL) and 2M HCl (30 mL) at atmospheric pressure affording a mixture of 2-*endo*-amino-3-*exo*-phenyl- and 2-*exo*-amino-3-*endo*-phenylnorbornanes [TLC, SiO_2, benzene, R_f 0.7 (major) and 0.5 (minor), respectively]. The former (3.14 g, 15%) was separated from the latter by SiO_2 column chromatography (acetone–hexane) and resolved with (+)-tataric acid (2.35 g, 16 mmol) in ethanol according to Smith *et al.*[28] to give (2*S*,3*R*)-2-amino-3-phenylnorbornane (+)-tartrate (865 mg, 32%), mp 189—191 °C, $[\alpha]_D$ +42.7° (*c* 1.0, H_2O) [lit,[28] $[\alpha]_D$ +42° (*c* 1.0, H_2O)]. A mixture of the tartrate (169 mg, 0.5 mmol), FDNB (200 mg, 1.07 mmol), $NaHCO_3$ (200 mg, 2.38 mmol), ethanol (10 mL), and H_2O (5 mL) was stirred overnight at room temperature. Usual workup and preparative SiO_2 TLC (benzene) gave **8** (85 mg, 24%), yellow prisms from benzene–hexane, mp 168.5—169.5 °C. UV 410 (sh, ε 6000), 351 (16400), and 262 nm (8700); CD $[\theta]_{416}$ +9200, $[\theta]_{370}$ +7600, $[\theta]_{320}$ 0, $[\theta]_{280}$ −7100, and $[\theta]_{233}$ −44300. Found: C, 64.80; H, 5.47; N, 11.42%. Calcd for $C_{19}H_{19}N_3O_4$: C, 64.58; H, 5.42; N, 11.89%.

2,4-Dinitrophenyl 3,4,6-Tri-O-acetyl-2-deoxy-2-(2,4-dinitroanilino)-β-D-glucoside (11a). This compound was supplied by Dr. H. Kohno, who obtained **11a** during synthetic study of neamine[30] by 2,4-dinitrophenylation of 2-deoxy-2-amino-D-glucose followed by acetylation with acetic anhydride-pyridine. ^1H NMR (DMSO-d_6) δ=1.82 (3H, s, CH_3CO_2), 2.00 (3H, s, CH_3CO_2), 2.04 (3H, s, CH_3CO_2), 4.1—4.3 (3H, m, CH_2–O and CH–N), 5.1—5.6 (3H, m, 3×CH–O), 6.48 (1H, d, *J*=3 Hz, O–CH–O), 7.76 (2H, d, *J*=9 Hz, 2×*o'*–H of Dnp), 8.42 (1H, dd, *J*=9 and 3 Hz, *m'*–H of Dnp), 8.63 (1H, dd, *J*=9 and 3 Hz, *m'*–H of Dnp), 8.87 (1H, d, *J*=3 Hz, *m*–H of Dnp), and 8.90 (1H, d, *J*=3 Hz, *m*–H of Dnp); UV 400 (sh, ε 4400), 335 (18600) and 250 nm (19200); CD $[\theta]^{sh}_{400}$ +5100, $[\theta]_{334}$ +18000, $[\theta]_{315}$ 0, $[\theta]_{309}$ −6000, $[\theta]_{299}$ 0, $[\theta]_{278}$ +16000, $[\theta]_{258}$ 0, and $[\theta]_{248}$ −16000.

The authors are grateful to Professor Tetsuo Suami of Keio University and Dr. Hideki Kohno of Mitsubishi Chemical Industries Ltd. for their kind gifts of

optically active 2-aminocyclohexanol and D-glucosamine derivative, respectively. Thanks are also to Mrs. Motoko Arai for her technical assistances.

(Received July 23, 1984)

Each of 5- or 6-amino-, acetamido-, hydroxy-, methoxy-, and chloroindazoles (including an unsubstituted one) and β NAD were subjected to an NADase-catalyzed base-exchange reaction to produce a corresponding title compound with a 41—76% yield. A difficulty, due to the poor solubility in water of indazole bases, was overcome by the addition of DMSO (~20%) without a remarkable decrease in NADase activity. In most cases, the obtained dinucleotides were ascertained to be N^2-ribosylated compounds. From 5- and 6-aminoindazoles, however, N^1-ribosylated dinucleotide was also obtained as a minor product. In some of the N^2-ribosylated dinucleotides, an unusual tautomerism was suggested to occur on the benzene ring of an indazole moiety. Finally, the synthesized title compounds were examined for inhibition activity against NAD-linked inosine monophosphate dehydrogenase. Four compounds among them were markedly effective at a 10^{-3} M concentration.

Interestingly, porcine brain NADase catalyses an exchange reaction between the nicotinamide moiety of β NAD and the structurally related pyridine compound, besides the mere hydrolysis of the quaternary pyridinium linkage.[2-4)] Modifying this principle, we have previously prepared various new NAD analogs containing 3,4-disubstituted 1,4-dihydropyridine moiety.[5-7)] Moreover, the necessary conditions for the concerned replacing base for participating in the reaction have been discussed.[7)] Such NAD analogs can be useful intermediates leading to the naturally occurring pyridine nucleosides quantitatively.[6)] As for the biological aspect, some of the analogs have been observed to show significant immunological activities *in vitro*.[8)]

From the viewpoint of applying the enzymic synthesis to other nitrogen-containing heterocycle nucleotides, our interest has initially been focused on readily preparable indazole bases. Since no indazole adenine dinucleotide has been synthesized, chemically or enzymicly, this application of an exchange reaction to the indazole bases can be of great significance. On the other hand, in view of the NAD analogs, the dinucleotides are expected to show a possible inhibition activity against an NAD-linked dehydrogenase system, particularly inosine monophosphate (IMP) dehydrogenase which is a target enzyme for many antitumor agents.[9-10)] In this paper, we give a full account of the enzymic synthesis and characterization of new indazole adenine dinucleotides arising from 5- or 6-amino-, acetamido-, hydroxy-, methoxy-, and chloroindazoles (as well as an unsubstituted one), together with their biochemical activities against IMP dehydrogenase.

Results and Discussion

Preparation of Indazole Dinucleotides. When a replacing base shows a strong basicity ($pK_a \gtrsim 9$), no exchange reaction occurs because the concerned nitrogen atom is blocked by a protonation under the optimum conditions of NADase (pH 7.2).[7)] The indazole bases now used, however, are relatively weak in basicity ($pK_a \sim 5$)[11)] and have no substituent on the pyrazole ring which would cause a steric hindrance at the reaction site. Thus, the occurrence of a base exchange was expected. The only problem in carrying out the reaction was the poor solubility in water of the indazole compounds. The base concentration proved to be an important factor in promoting the formation of a new dinucleotide.[6)] Fortunately, the indazole bases were very soluble in DMSO, one of the typical aprotic solvents. Were it not for an extreme influence on the NADase activity, therefore, the addition of DMSO seemed favorable in view of enhancing base nucleophilicity as well as improving base concentration. In fact, no significant decrease in the activity was observed, even if DMSO (~20%) was added to get a suitable base concentration (20 mM††). The problem of base solubility in the reaction system was, thus, overcome.

Each indazole base and NAD were incubated with NADase at 37 °C in DMSO-containing Tris-HCl (pH 7.2) until the spot of NAD disappeared in TLC. After incubation, the rusulting mixture contained four major components: An unchanged indazole base, the NAD-derived nicotinamide, the desired product, and ADP-ribose. The mixture (after the removal of the enzyme, Tris-HCl, and DMSO) was subjected to column chromatography on DEAE-Sephadex to provide the desired dinucleotide in 41—76% yield (Table 1). Its purity was checked by TLC in two different develo-

†† 1 M=1 mol dm^{-3}.

ping systems and, if necessary, the chromatography was repeated.

Considering the two nitrogen atoms which form the indazole skeleton, though probably different in reactivity, the formation of two distinct dinucleotides can be anticipated in an enzymic reaction. In most cases, however, single dinucleotide was produced with no detectable amount of an alternative compound. As an exceptional case, a minor product was brought about from 5- and 6-aminoindazoles in *ca.* 10% yield besides the major one.

So far as we know, there has been no report concerning halogen-containing NAD analogs. Accordingly, an exchange reaction was also tried for the preparation of dinucleotides originating from 5-, 6-, and 4-chloroindazoles. As a result, we obtained the corresponding dinucleotides (**10—12**) in reasonable yield (Table 1), indicative of the availability of this method for halogen-containing bases as well.

Structural Characterization of Indazole Dinucleotides. In order to obtain structural information regarding the new compounds, we first compared their ^{1}H-NMR spectra with those of NAD and the corresponding indazole base. Relevant signals falling within δ 6.5—8.3 indicated the presence of indazole and adenine moieties (Table 1). In all cases, two anomeric protons appeared at δ 5.8—6.0 as clearly separate doublets, and ribose-linked ten protons at δ 4.2—4.8 overlapping one another. In addition, the phosphorus content was quantitatively analyzed to show 2 mol per molecule of the compound. These observations ascertained the indazole adenine dinucleotide of the products obtained.

By means of UV spectroscopy, we next examined the site of ribosylation in the indazole moiety of the dinucleotides. In the UV spectra, the absorption maxima of indazole chromophore was wrapped up with the adenine-derived strong absorption band at 260 nm, so that the dinucleotide (**1**) was led to the indazole mononucleotide (**15**) on cleavage of pyrophosphate linkage with phosphodiesterase (PDE), followed by chromatographic isolation. The UV spectrum of **15** was compared with those of 1- and 2-methylindazoles, because ribosylation or methylation was expected to produce similar inductive effects. Compound **15** closely resembles 2-methylindazole in its absorption curve, but differs markedly from 1-methylindazole (Fig. 1). Indazole mononucleotides formed from other dinucleotides also exhibited a similar

a) Chemical shifts of ribose-linked ten protons fell within δ 4.2—4.8 in all cases. b) Based on NAD used. c) Acetamido methyl protons of **4** and **5** appeared at δ 2.16 and 2.19, respectively, and methoxy methyl protons of **8** and **9** were observed at δ 3.76 and 3.81, respectively. d) J=4.2—4.4 Hz. e) J=4.0—5.4 Hz. f) Not observed.

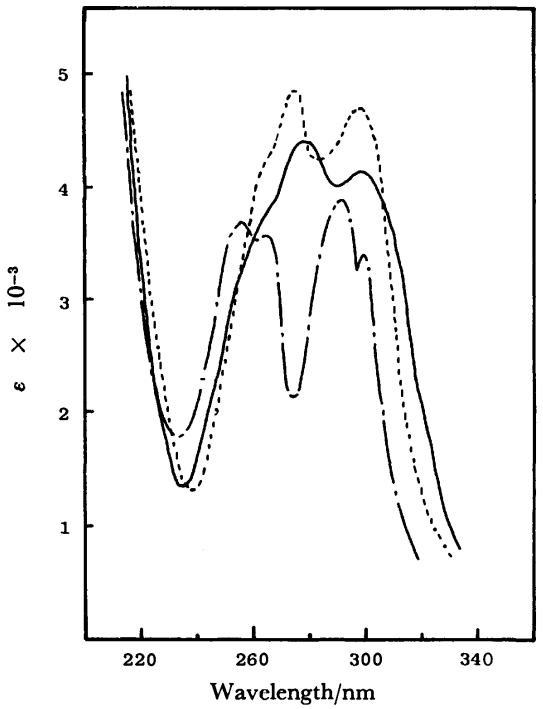

Fig. 1. UV spectral comparison of indazole mononucleotide (**15**) with 1- and 2-methylindazoles. (——): **15**; (— - —): 1-methylindazole; (-----): 2-methyl indazole.

bathochromic shift with somewhat hyperchromic effect. These observations indicate the quinonoid structure of mononucleotides, and consequently that the site of ribosylation is at the N^2-atom.

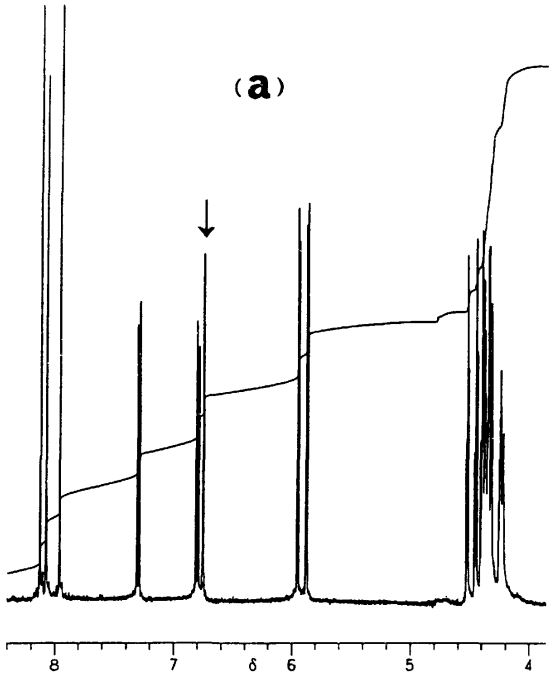
By ^{1}H-NMR spectroscopy, this reasoning could not be taken to a more definite conclusion. In order to gain further evidence, some appropriate N^1-acetylated indazoles (unsubstituted, 5-, and 6-acetamido ones) were submitted to the exchange reaction. Dinucleotides identical to **1**, **4**, and **5**, respectively, on ^{1}H-NMR spectral comparisons were produced in low yield. Upon incubation of the N^1-acetylated bases with NADase alone, however, no appreciable deacetylation occurred with N^1-acetyl group. These results strongly support the following conclusion: ADP-ribosylation occurred initially at the N^2-atom to form a 2-quaternary transient intermediate. Subsequently, the elimination of the N^1-acetyl group was accelerated by a strong electron-withdrawing effect of the quaternary nitrogen atom upon double-bond migrations, resulting in the quinonoid form of the indazole moiety.

Incidentally, the aforementioned minor products obtained with 5- and 6-aminoindazoles proved to be N^1-ribosylated dinucleotides (**13** and **14**) since their mononucleotides depicted a similar UV spectrum to that of the corresponding original base. Compounds **13** and **14** would arise from a certain proportion of the tautomeric 2*H*-indazole forms of the aminoindazoles although its existence has not been established.

The ^{1}H-NMR spectra in D_2O of compounds **2**, **3**, and **7** had no observable signal due to the aromatic proton (H_4 or H_7) adjacent to the amino or hydroxyl group. On the other hand, the corresponding signal was present as a singlet in compounds **4**, **5**, and **9** where the amino and hydroxyl substituents were blocked with acetyl and methyl groups, respectively (Table 1). Moreover, a signal was observed for the original amino- or hydroxyindazole, compound **13** and **14**. These facts suggest the occurrence of an unusual tautomerism on the benzene ring of the indazole moiety in **2**, **3**, and **7** which is probably dependent upon N^2-ribosylation. It is of interest to note that a signal due to H_4 appeared for compound **6**, whereas that due to H_7 disappeared for compound **7** under the same conditions (Fig. 2).

The assignment of the two doublets due to the anomeric protons remains unsettled. Thus, the respective coupling constants were estimated for the dinucleotides by a second-order approximation. As a consequence, the upfield signals were J=4.0—5.4 Hz, whereas the downfield ones were J=4.2—4.4 Hz. It can be expected that the dihedral angle between H-C_2'-C_1' and C_2'-C_1'-H in the ribose moiety of indazole side is somewhat changed by the difference in conformation of various kinds of the indazole bases. On the contrary, one can presume that the angle in the adenine side is little changed since the ribose moiety therein is under the influence of the same adenine base. Considering that the $J_{1',2'}$-value is reflected by the variation of the dihedral angle,[12] the upfield doublet can be assigned to the anomeric proton of indazole side, whereas the downfield one to that of adenine side (Table 1). In this connection, it is necessary to note that although respective chemical shifts and $J_{1',2'}$-values of a couple of mononucleotides were compared with each other, there was no unambiguous distinction between them in all cases.

Biochemical Activity of Indazole Dinucleotides against IMP Dehydrogenase. NAD-linked IMP dehydrogenase is known as one of the key rate-controlling enzymes of nucleic acid biosynthesis,[13] and many compounds which inhibit the enzyme have a more or less antitumor activity.[14,15] It is, therefore, of interest whether or not the indazole dinucleotides prepared here show an inhibitory effect on the dehydrogenase system. Some of those dinucleotides were examined for their ability to inhibit a partially purified IMP dehydrogenase from P388 leukemic cells. Among them, compounds **1**, **2**, **3**, and **6** showed an inhibition by 33 to 75% at a 10^{-3} M concentration (Table 2). At a 10^{-4} M concentration, however, none of them showed a significant level of inhibition, except for **2** which showed a 14% inhibition. Further investigations to correlate these results with actual features of cell proliferation are now in progress.



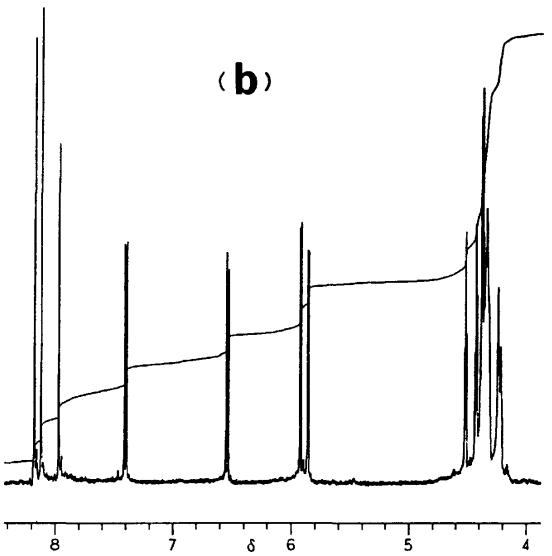


Fig. 2. 500 MHz ^1H NMR spectra of **6** (a) and **7** (b) in D_2O. (a) A signal assignable to H_4 is existent (an arrow). (b) A signal assignable to H_7 is nonexistent.

Experimental

General. Melting points were measured with a Yamato MP-1 melting-point apparatus and are uncorrected. UV spectra were recorded on a Hitachi 200-20 spectrophotometer. ^1H-NMR spectra were determined on a JEOL GX-500 or a Varian XL-200 spectrometer in deuterium oxide with sodium 2,2-dimethyl-2-silapentane-5-sulfonate (DSS) as the internal standard. The abbreviations "s, d, and dd" denote "singlet, doublet, and double doublet," respectively. Optical rotations were measured on a Union PM-101 digital polarimeter. The ionic-strength and pH measurements were made with a Emuesu CD-35M II conductivity meter and a Radiometer PHM-26 pH meter equipped with a G-202 glass electrode, respectively. TLC was carried out on silica gel $60F_{254}$ HPTLC plates (Merck, 10 cm×10 cm) using 2-propanol–0.2% aq ammonia (7:3, v/v) and/or 1-propanol–0.3% aq acetic acid (3:2, v/v) as developing system. Column chromatographies were carried out on DEAE-Sephadex A-25 (HCO_3^--form) (column size: 2.5 cm×45 cm) monitored by LKB Uvicord II (254 nm). Phosphorus was determined colorimetrically by the method of Bartlett.[16] 1-Methyl- and 2-methylindazoles were obtained by the decarboxylation of respective 3-carboxylic acids.[17] β NAD (Grade III) and phosphodiesterase (PDE) (EC 3.1.4.1) were purchased from Sigma Chemical Co. Indazole, 5-, and 6-aminoindazoles were obtained from Aldrich Chemical Co.

Porcine Brain NADase (EC 3.2.2.5). The Crude particulate enzyme was prepared from a fresh porcine brain by the method of Zatman *et al.*[18] The colloidal supernatant fluid containing *ca.* 0.4 U[19]/ml of NADase activity was used without further purification.

N^1-*Acetylindazole.* Prepared by acetylation of indazole with acetic anhydride, and recrystallized from petroleum ether: Mp 44—46 °C (lit,[20] 42—43 °C).

N^1-*Acetyl-5-acetamidoindazole.* Prepared by acetylation of 5-aminoindazole with acetic anhydride, and recrystallized from benzene: Mp 167—169 °C. Found: C, 60.74; H, 5.12; N, 19.26%. Calcd for $C_{11}H_{11}N_3O_2$: C, 60.83; H, 5.07; N, 19.35%.

5-Acetamidoindazole. Prepared by the partial hydrolysis of the above compound with methanol–0.3% aq ammonia (60 °C, 3h), and recrystallized from methanol: Mp 203—205 °C. Found: C, 61.68; H, 5.16; N, 24.07%. Calcd for $C_9H_9N_3O$: C, 61.71; H, 5.14; N, 23.99%.

N^1-*Acetyl-6-acetamidoindazole.* Prepared by the acetylation of 6-aminoindazole with acetic anhydride, and recrystallized from benzene: Mp 187—189 °C. Found: C, 60.78; H, 5.06; N, 19.31%. Calcd for $C_{11}H_{11}N_3O_2$: C, 60.83; H, 5.07; N, 19.35%.

6-Acetamidoindazole. Prepared by the partial hydrolysis of the above compound, and recrystallized from methanol: Mp 253—255 °C. Found: C, 61.75; H, 5.18; N, 23.94%. Calcd for $C_9H_9N_3O$: C, 61.71; H, 5.14; N, 23.99%.

5-Hydroxyindazole. Prepared from 5-aminoindazole by the method of Davies,[21] and recrystallized from water: Mp 187—189 °C (lit,[21] 186 °C).

6-Hydroxyindazole. Prepared from 6-aminoindazole, and recrystallized from water: Mp 212—214 °C (lit,[21] 216 °C).

5-Methoxyindazole. Prepared from 4-methoxy-2-

methylaniline by diazotization followed by intramolecular cyclization, and recrystallized from ethanol–petroleum benzine: Mp 168—170 °C (lit,[22] 168—169 °C).

6-Methoxyindazole. Prepared from 6-hydroxyindazole by *O*-methylation with dimethyl sulfate, and recrystallized from petroleum benzine: Mp 125—127 °C (lit,[23] 124 °C).

5-Chloroindazole. Prepared from 2-amino-5-chlorotoluene, and recrystallized from benzene: Mp 122—124 °C (lit,[20] 118—120 °C).

6-Chloroindazole. Prepared from 2-amino-4-chlorotoluene, and recrystallized from benzene: Mp 175—177 °C (lit,[20] 175—177 °C).

4-Chloroindazole. Prepared from 2-amino-6-chlorotoluene, and recrystallized from benzene: Mp 158—160 °C (lit,[20] 155—157 °C).

Inhibition Activity against IMP Dehydrogenase. The assay was performed by the radiometric technique as reported previously:[24] NAD (1 mM), [2-^{3}H]IMP (0.075 mM), and each dinucleotide (1 mM or 0.1 mM) were incubated with P388 leukemic cell IMP dehydrogenase at 37 °C for 10 min, and then the reaction was terminated by 1 min of heating at 95 °C. The ^3H_2O arising from the oxidation of [2-^{3}H]IMP *via* [^{3}H] NAD was isolated by quantitative microdistillation and its tritium content was measured with a scintillation counter.

2H-Indazole Adenine Dinucleotide (1). Indazole (370 mg, 3.1 mmol) and NAD (780 mg, 1.1 mmol, neutralized to pH 7 with 0.2 M NaOH) were incubated with NADase (20 ml, 8 U) in DMSO (15 ml)-containing 0.1 M Tris-HCl (65 ml, pH 7.2) at 37 °C for 5 h. The incubation mixture was treated with 70% trichloroacetic acid (2 ml) and the denatured protein was removed by centrifugation. To the clear supernatant thus obtained, cold acetone (500 ml) was added, followed by standing overnight at 4 °C, to give white hygroscopic mass (708 mg). It was dissolved in water (30 ml) and then applied to a column (2.5 cm×25 cm) of DEAE-Sephadex (HCO_3^--form). The column was washed with 0.05 M NH_4HCO_3 (300 ml) to remove any free bases and then eluted with 0.4 M NH_4HCO_3 (pH 7.8). The first major component eluted, which showed a UV-absorption peak at 260 nm, was ADP-ribose. On further elution, the second major component was obtained and showed a UV-absorption peak at 264 nm. The eluate (200 ml) was immediately collected and lyophilized repeatedly to give **1** (375 mg) as ammonium salt. An analytical sample of **1** was obtained by drying over P_2O_5 *in vacuo* for 12 h at 40 °C: $[\alpha]_D^{23}$ −28.8° (*c* 0.59, H_2O); UV (H_2O) 264 (log ε 4.33) and *ca.* 293 nm (sh, log ε 3.78); ^{1}H-NMR (Table 1). Found: C, 34.17; H, 5.31; N, 16.76%. Calcd for $C_{22}H_{27}N_7O_{13}P_2 \cdot 2NH_3 \cdot 4H_2O$: C, 34.53; H, 5.36; N, 16.48%.

5-Amino-1H-indazole- and 5-Amino-2H-indazole Adenine Dinucleotides (13 and 2). 5-Aminoindazole (420 mg, 3.2 mmol) and NAD (620 mg, 0.9 mmol) were incubated with NADase (15 ml, 6 U) in DMSO (12 ml)-containing 0.1 M Tris-HCl (60 ml) for 5 h. The incubation mixture was treated in a similar manner as described above to give a pale-brown crude product (557 mg). It was dissolved in water (30 ml) and the water-insoluble part was removed by centrifugation. The clear supernatant was applied to a column (2.5 cm×40 cm) of DEAE-Sephadex. The column was then eluted with aq NH_4HCO_3, as described above. The eluate (60 ml) of the first major component posterior to the elution of ADP-ribose was immediately collected and lyophilized repeatedly to provide **13** (74 mg): $[\alpha]_D^{23}$ −33.0° (*c* 2.35, H_2O); UV (H_2O) 244 (log ε 4.31) and *ca.* 315 nm (log ε 3.55); ^{1}H-NMR (Table 1). Found: C, 35.39; H, 4.76; N, 16.81%. Calcd for $C_{22}H_{28}N_8O_{13}P_2 \cdot NH_3 \cdot 3H_2O$: C, 35.46; H, 4.97; N, 16.93%. After the elution of **13**, the second major component was eluted and showed a UV-absorption peak at 261 nm. The eluate (150 ml) was collected and lyophilized repeatedly to provide **2** (261 mg): $[\alpha]_D^{23}$ −38.7° (*c* 0.85, H_2O); UV (H_2O) 261 (log ε 4.27) and 330 nm (log ε 3.65); ^{1}H-NMR (Table 1). Found: C, 35.19; H, 4.90; N, 17.16%. Calcd for $C_{22}H_{28}N_8O_{13}P_2 \cdot NH_3 \cdot 3H_2O$: C, 35.46; H, 4.97; N, 16.93%.

6-Amino-1H-indazole- and 6-Amino-2H-indazole Adenine Dinucleotides (14 and 3). 6-Aminoindazole (390 mg, 2.8 mmol) and NAD (630 mg, 1.1 mmol) were incubated with NADase (15 ml, 6 U) in DMSO (15 ml)-containing Tris-HCl (70 ml) for 5 h. The pale brown crude mass (550 mg) obtained was separated by the chromatographic procedures as described for **13** to give **14** (55 mg) firstly: $[\alpha]_D^{23}$ −37.4° (*c* 0.19, H_2O); UV (H_2O) *ca.* 235 (sh, log ε 4.32), *ca.* 260 (log ε 4.21), and 296 nm (log ε 3.88); ^{1}H-NMR (Table 1). Found: C, 35.68; H, 5.09; N, 17.22%. Calcd for $C_{22}H_{28}N_8O_{13}P_2 \cdot NH_3 \cdot 3H_2O$: C, 35.46; H, 4.97; N, 16.93%. The chromatography was further continued as described for **2** to give **3** (276 mg) secondly: $[\alpha]_D^{23}$ −45.3° (*c* 0.19, H_2O); UV (H_2O) 263 (log ε 4.27) and 296 nm (log ε 3.92); ^{1}H-NMR (Table 1). Found: C, 35.39; H, 4.67; N, 16.67%. Calcd for $C_{22}H_{28}N_8O_{13}P_2 \cdot NH_3 \cdot 3H_2O$: C, 35.46; H, 4.97; N, 16.93%.

5-Acetamido-2H-indazole Adenine Dinucleotide (4). 5-Acetamidoindazole (540 mg, 3.0 mmol) and NAD (650 mg, 1.0 mmol) were incubated with NADase (15 ml, 6 U) in DMSO (5 ml)-containing Tris-HCl (60 ml) for 10 h. Chromatographic purification of the crude mass (600 mg) obtained, followed by repeated lyophilization, provided **4** (501 mg) as ammonium salt. An analytical sample of **4** was given by drying over P_2O_5 *in vacuo* for 12 h at 40 °C: $[\alpha]_D^{23}$ −31.2° (*c* 0.92, H_2O); UV (H_2O) 240 (log ε 4.38), *ca.* 260 (sh, log ε 4.22), and 310 nm (log ε 3.68); ^{1}H-NMR (Table 1). Found: C, 36.05; H, 5.70; N, 17.58%. Calcd for $C_{24}H_{30}N_8O_{14}P_2 \cdot 2NH_3 \cdot 3H_2O$: C, 35.85; H, 5.97; N, 17.43%.

6-Acetamido-2H-indazole Adenine Dinucleotide (5). 6-Acetamidoindazole (400 mg, 2.2 mmol) and NAD (600 mg, 0.9 mmol) were incubated with NADase (10 ml, 4 U) in DMSO (15 ml)-containing Tris-HCl (50 ml) for 12 h. The crude mass (545 mg) obtained was treated as described above to provide **5** (301 mg): $[\alpha]_D^{23}$ −20.6° (*c* 0.57, H_2O); UV (H_2O) 239 (log ε 4.32), *ca.* 265 (sh, log ε 4.13), and 297 nm (log ε 3.84); ^{1}H-NMR (Table 1). Found: C, 35.53; H, 5.78; N, 17.54%. Calcd for $C_{24}H_{30}N_8O_{14}P_2 \cdot 2NH_3 \cdot 3H_2O$: C, 35.85; H, 5.97; N, 17.43%.

Exchange Reaction with N^1-Acetyl Derivative of Indazole, 5-, and 6-Acetamidoindazoles. NAD (225 mg) and each of *N*^{1}-acetyl derivatives of indazole, 5-, and 6-acetamidoindazoles were incubated with NADase (5 ml, 2 U) in DMSO (5 ml)-containing 0.1 M Tris-HCl (30 ml) at 37 °C for 5—10 h. The, thus obtained, three dinucleotides (30—40 mg) were proved to be identical with **1**, **4**, and **5** from ^{1}H-NMR spectral comparisons, rcspectively. In all cases, no other detectable amount of dinucleotide was produced except for ADP-ribose.

5-Hydroxy-2H-indazole Adenine Dinucleotide (6).

NAD (958 mg, 1.4 mmol) and 5-hydroxyindazole (630 mg, 4.7 mmol) were incubated with NADase (10 ml, 4 U) in DMSO (5 ml)-containing Tris-HCl (50 ml) for 15 h. The reaction mixture was treated as previously described to provide a pale-brown mass of **6** (699 mg): $[\alpha]_D^{23}$ −38.3° (*c* 1.15, H_2O); UV (H_2O) 263 (log ε 4.33) and 319 nm (log ε 3.73); ^{1}H-NMR (Table 1). Found: C, 35.83; H, 5.01; N, 16.54%. Calcd for $C_{22}H_{27}N_7O_{14}P_2 \cdot 2NH_3 \cdot 2H_2O$: C, 35.42; H, 4.96; N, 16.90%.

6-Hydroxy-2H-indazole Adenine Dinucleotide (7). NAD (984 mg, 1.5 mmol) and 6-hydroxyindazole (625 mg, 4.7 mmol) were incubated with NADase (12 ml, 4.8 U) in DMSO (5 ml)-containing Tris-HCl (55 ml) for 12 h. The incubation mixture was treated as previously described to provide a pale-brown hygroscopic mass of **7** (764 mg): $[\alpha]_D^{23}$ −43.0° (*c*, 0.55, H_2O); UV (H_2O) 264 (log ε 4.30) and *ca.* 292 nm (sh, log ε 4.06); ^{1}H-NMR (Table 1). Found: C, 37.11; H, 4.82; N, 17.30%. Calcd for $C_{22}H_{27}N_7O_{14}P_2 \cdot 2NH_3 \cdot 1/2\,H_2O$: C, 36.75; H, 4.73; N, 17.54%.

5-Methoxy-2H-indazole Adenine Dinucleotide (8). A mixture of NAD (810 mg, 1.2 mmol), 5-methoxyindazole (420 mg, 2.9 mmol), and NADase (10 ml,4 U) was incubated in DMSO (8 ml)-containing Tris-HCl (70 ml) for 11 h. The incubation mixture was treated as previously described to give **8** (520 mg): $[\alpha]_D^{23}$ −25.5° (*c* 1.0, H_2O); UV (H_2O) 261 (log ε 4.27) and 310 nm (log ε 3.66); ^{1}H-NMR (Table 1). Found: C, 37.45; H, 4.92; N, 16.70%. Calcd for $C_{23}H_{29}N_7O_{14}P_2 \cdot 2NH_3 \cdot H_2O$: C, 37.27; H, 5.00; N, 17.01%.

6-Methoxy-2H-indazole Adenine Dinucleotide (9). A mixture of NAD (823 mg, 1.2 mmol), 6-methoxyindazole (325 mg, 2.2 mmol), and NADase (15 ml, 6 U) was incubated in DMSO (10 ml)-containing Tris-HCl (55 ml) for 15 h. The incubation mixture was treated as previously described to give a pale-yellow mass of **9** (452 mg): $[\alpha]_D^{23}$ −32.9° (*c* 0.78, H_2O); UV (H_2O) 266 (log ε 4.30) and *ca.* 290 nm (sh, log ε 4.04); ^{1}H-NMR (Table 1). Found: C, 37.22; H, 5.07; N, 16.68%. Calcd for $C_{23}H_{29}N_7O_{14}P_2 \cdot 2NH_3 \cdot H_2O$: 37.27; H, 5.00; N, 17.01%.

5-Chloro-2H-indazole Adenine Dinucleotide (10). A mixture of 5-chloroindazole (206 mg), NAD (750 mg), and NADase (10 ml) was incubated with DMSO (10 ml)-containing Tris-HCl (55 ml) for 10 h. The incubation mixture was treated as previously described to provide **10** (468 mg): $[\alpha]_D^{23}$ −22.1° (*c* 1.15, H_2O); UV (H_2O) 261 (log ε 4.18) and 305 nm (log ε 3.67); ^{1}H-NMR (Table 1). Found: C, 35.51; H, 4.57; N 16.64%. Calcd for $C_{22}H_{26}ClN_7O_{13}P_2 \cdot 2NH_3 \cdot H_2O$: C, 35.44; H, 4.56; N, 16.91%.

6-Chloro-2H-indaole Adenine Dinucleotide (11). A mixture of 6-Chloroindazole (310 mg), NAD (660 mg), and NADase (10 ml) was incubated in DMSO (8 ml)-containing Tris-HCl (50 ml) for 12 h. The reaction mixture was treated as previously described yielding a white hygroscopic mass of **11** (347 mg): $[\alpha]_D^{23}$ −33.1° (*c* 2.7, H_2O); UV (H_2O) 263 (log ε 4.17), *ca.* 300 (log ε 3.77), and *ca.* 310 nm (log ε 3.48); ^{1}H-NMR (Table 1). Found: C, 34.97; H, 4.62; N, 16.74%. Calcd for $C_{22}H_{26}ClN_7O_{13}P_2 \cdot 2NH_3 \cdot H_2O$: C, 35.44; H, 4.56; N, 16.91%.

4-Chloro-2H-indazole Adenine Dinucleotide (12). A mixture of NAD (660 mg), 4-chloroindazole (310 mg), and NADase (10 ml) was, similarly, incubated as described above. The incubated mixture was treated as previously described to give **12** (342 mg): $[\alpha]_D^{23}$ −35.6° (*c* 1.45, H_2O); UV (H_2O) 262 (log ε 4.19), 299 (log ε 3.74), and *ca.* 310 nm (sh, log ε 3.61); ^{1}H-NMR (Table 1). Found: C, 34.80; H, 4.66; N, 16.49%. Calcd for $C_{22}H_{26}ClN_7O_{13}P_2 \cdot 2NH_3 \cdot 2H_2O$: C, 34.60; H, 4.72; N, 16.51%.

Hydrolytic Cleavage of Dinucleotides to Mononucleotides. Compound **1** (120 mg) was incubated with PDE (0.4 U) in 0.2 M Tris-HCl (pH 8.8, 2 ml) containing 0.2 ml of 0.2 M $MgCl_2$ at 37 °C for 6 h. The reaction mixture, upon dilution with water (30 ml), was applied to a column (2.5 cm×15 cm) of DEAE-Sephadex. The column was eluted with 0.3 M NH_4HCO_3 to provide, in turn, AMP (54 mg) and 2*H*-indazole mononucleotide (**15**) (52 mg), separately. Spectral data regarding **15** were as follows: UV (H_2O) 276 (log ε 3.63) and 295 nm (log ε 3.56); ^{1}H-NMR (δ, D_2O) 8.64 (1H, s), 7.82 (1H, d, *J*=8.8 Hz), 7.68 (1H, d, *J*=8.8 Hz), 7.43 (1H, dd, *J*=8.8, 7.2 Hz), 7.18 (1H, dd, *J*=8.8, 7.2 Hz), 6.12 (1H, d, *J*=5.6 Hz), and 4.2—4.7 (5H, ribose). 5-Amino-2*H*-indazole mononucleotide (10 mg) was likewise obtained from compound **2** (20 mg), and its spectral data were as follows: UV (H_2O) 269 (log ε 3.72), 279 (log ε 3.70), and 330 nm (log ε 3.65); ^{1}H-NMR (δ, D_2O) 8.39 (1H, s), 7.57 (1H, d, *J*=9.0 Hz), 7.07 (1H, d, *J*=9.0 Hz), 6.04 (1H, d, *J*=5.4 Hz), and 4.1—4.7 (5H, ribose). The spectral data of 5-amino-1*H*-indazole mononucleotide (3.2 mg) obtained from compound **13** (8 mg) were as follows: UV (H_2O) 235 (log ε 4.17), *ca.* 270 (sh, log ε 3.65), and 311 nm (log ε 3.67); ^{1}H-NMR (δ, D_2O) 8.57 (1H, s), 7.54 (1H, s), 7.33 (1H, d, *J*=9.2 Hz), 7.22 (1H, d, *J*=9.2 Hz), 6.09 (1H, d, *J*=5.3 Hz), 4.1—4.7 (5H, ribose). Other mononucleotides also gave satisfactory spectral data compatible with the conclusion described in the text.

Iron–sulfur and molybdenum–iron–sulfur clusters with ferrocenethiolate, $[Fe_4S_4(SFc)_4]^{2-}$ and $[Mo_2Fe_6S_8X_3(SFc)_6]^{3-}$ (Fc=$C_5H_4FeC_5H_5$, X=EtS and MeO), have been prepared as tetraalkylammonium salts. The reduction potentials of these clusters are more negative than those of the corresponding clusters with benzenethiolate suggesting that the ferrocencethiolate ligand has an electron donor ability stronger than the benzenethiolate ligand. Electronic absorption spectra reveal that the ferrocenethiolate ligand dissociates from the cluster anions in the electrochemically reduced states. The clusters can catalyze the reduction of C_2H_2 in water at pH 7.0 under the controlled potential electrolysis conditions. The rate of the reduction and the selectivity for the C_2H_4 formation are largely dependent on the clusters; the iron–sulfur cluster shows a higher activity than the molybdenum–iron clusters in the C_2H_2 reduction.

Studies of nitrogenase isolated from a variety of microorganisms have revealed that both iron and molybdenum–iron proteins are essential components in biological N_2 fixation.[1,2] The iron protein containing a Fe_4S_4 cluster is believed to function only as an electron-transfer catalyst.[3–5] The molybdenum–iron cofactor (MoFe-co) extracted from nitrogenase involves a novel molybdenum–iron–sulfur cluster,[6] which may be an active center for the reduction of N_2 to NH_3.[7–9] Although the structure of the MoFe-co is still ambiguous, the EXAFS studies suggest that both molybdenum and iron atoms in the MoFe-co are placed in sulfide-rich coordination sphere.[10–13] Most probable atomic ratios of Mo:Fe:S in the MoFe-co are 1:6:8—9, as determined by various chemical and physical techniques.[14] Holm *et al.* have developed a series of synthetic methods for molybdenum–iron single and double cuban clusters with chloride, alkanethiolate, and arenethiolate ligands.[9] The molybdenum–iron clusters prepared so far, however, seem to have still low iron contents relative to molybdenum in comparing with the MoFe-co. The present work was undertaken to incorporate extra iron atoms into the Fe_4S_4 as well as $MoFe_3S_4$ cores, using ferrocenethiolate in place of alkane- or arenethiolate as a ligand. The substitution of the ferrocenethiolate ligand at the cores may result in the increased stability of the cluster toward the oxidation owing to a strong electron-donating property of ferrocene. The stabilization of the cluster to the oxidation, particularly in the $[Fe_4S_4]^{2+}$ core, seem to be important in connection with high potential iron sulfur proteins which exhibit a stable $[Fe_4S_4]^{2+}/[Fe_4S_4]^{3+}$ redox couple.[15]

This paper reports the preparation and characterization of the title clusters I and II, and their catalytic abilities for the reduction of C_2H_2 in aqueous suspension under controlled potential electrolysis conditions.

Experimental

General Procedure and Materials. All manipulations were carried out under N_2 atmosphere. Solvents used for preparations and physical measurements were purified by distillation over dehydration chemicals; CaH_2 for MeCN, magnesium methoxide for MeOH, Na for THF, and CaO for DMF under reduced pressures of N_2. Ferrocenethiol,[16] $(Me_4N)_2[Fe_4S_4(SEt)_4]$,[17] and $(Et_4N)_3[Mo_2Fe_6S_8(SEt)_9]$,[18] were prepared according to the literature methods.

Preparation of $(Me_4N)_2[Fe_4S_4(SFc)_4]$ (Fc=$C_5H_4FeC_5H_5$). An MeCN (80 cm³) solution containing $(Me_4N)_2[Fe_4S_4(SEt)_4]$ (1.01 g, 1.17 mmol) and FcSH (2.04 g, 9.36 mmol) was stirred at 50 °C for 2 h during which time N_2 gas was bubbled into the solution about every 10 min. The resulting solution was evaporated to dryness under reduced pressure. The residual solid was dissolved in MeCN (40 cm³) and the solution was filtered on warming (35 °C). To the filtrate was added diethyl ether (15 cm³), and the solution was allowed to stand at 0 °C for 24 h to give black plates, which were collected by filtration, washed with diethyl ether, and dried *in vacuo*, 25% yield. Anal. Calcd for $C_{48}H_{60}Fe_8N_2S_8$: C, 42.12; H, 4.42; N, 2.04. Found: C, 41.77; H, 4.52; N, 2.07.

Preparation of $(Et_4N)_3[Mo_2Fe_6S_8(SEt)_3(SFc)_6]$. An MeCN (30 cm³) solution containing $(Et_4N)_3[Mo_2Fe_6S_8(SEt)_9]$ (0.36 g, 0.21 mmol) and FcSH (0.61 g, 2.78 mmol) was treated by the same procedure as the synthesis of $(Me_4N)_2[Fe_4S_4(SFc)_4]$ to afford black plates, in which only the terminal EtS group has been substituted by the FcS group, 62% yield. Anal. Calcd for $C_{90}H_{129}Fe_{12}Mo_2N_3S_{17}$: C, 40.36; H, 4.89; N, 1.59. Found: C, 40.20; H, 5.00; N, 1.72.

Preparation of $(Bu^n_4N)_3[Mo_2Fe_6S_8(OMe)_3(SFc)_6]$. As an attempt to incorporate the FcS group in the bridging position of Mo-Fe-S double cubane clusters, the following reaction was performed; to an MeOH (20 cm³) solution containing FcSH (4.31 g, 20 mmol) and MeONa (1.08 g, 20 mmol) was added a filtered MeOH solution (15 cm³) of $FeCl_3$ (0.81 g, 5.0 mmol), followed by the addition of $(NH_4)_2MoS_4$ (0.44 g, 1.60 mmol). After stirred for 17 h, the solution was diluted with MeOH (10 cm³) and filtered. To the filtrate was added slowly Bu^n_4NBr (1.61 g, 5.0 mmol) in MeOH (10 cm³) to give a black precipitate, which was collected by filtration and dissolved in MeCN (20 cm³) at 50 °C. After slow addition of MeOH (20 cm³), the solution was cooled to −10 °C to afford black plates of an Mo-Fe-S double cubane cluster with bridging MeO groups, which were collected by filtration, washed with MeOH, and dried *in vacuo*, 20% yield. Anal. Calcd for $C_{111}H_{171}Fe_{12}Mo_2N_3O_3S_{14}$: C, 45.87; H, 5.93; N, 1.45. Found: C, 45.62; H, 5.64; N, 1.44. The presence of three MeO groups in the cluster was confirmed as follows; HNO_3 (0.2 cm³) was added slowly to a small amount of the product (10 mg) in a test tube with a rubber stopper at 0 °C. The solution was heated at 50 °C to decompose the cluster completely, neutralized with concd aq NaOH at 0 °C, and then diluted with water to 2 cm³. The solution was analyzed on a gas chromatograph with a 2 m column filled with Gaschropack 54 (Gaschro Kogyo Co. Ltd) at 80 °C, then three moles of MeOH per one mole of the cluster decomposed were detected in the solution.

Reduction of C_2H_2 *in Water.* The reduction of C_2H_2 was carried out in a C_2H_2-saturated aqueous suspension of the tetraalkylammonium salt of $[Fe_4S_4(SFc)_4]^{2-}$ or $[Mo_2Fe_6S_8X_3(SFc)_6]^{3-}$ (7.0 μ mol, X=SEt, MeO) under the controlled potential electrolysis conditions using an Hg working electrode at −1.30—−1.40 V *vs.* SCF in a cell described in the previous papers.[19,20] pH Values of the suspension were maintained at 7.0±0.2 with an NaOH-H_3PO_4 buffer. Reaction products in the gaseous phase were determined quantitatively on a gas chromatograph with a 2 m column filled with unibeads 1S at 100 °C.

Physical Measurements. Electronic absorption and ^1H NMR spectra were measured with a Union SM 401 spectrophotometer and a JEOL PS-100 spectrometer, respectively. Cyclic voltammetry measurements were performed on a Hokuto Denko Model HA-301 potentiostat/galvanostat in DMF containing 0.1 mol dm⁻³ $Bu^n_4NClO_4$ as a supporting electrolyte, using a platinum disk-type electrode and a saturated calomel reference electrode (SCE).

Results and Discussion

It is well known that Bu^{t}S group of $[Fe_4S_4(SBu^t)_4]^{2-}$ is labile in solution.[21] Thus, $[Fe_4S_4(SFc)_4]^{2-}$ (Fc=$C_5H_4FeC_5H_5$) has easily been obtained as the tetramethylammonium salt by heating an MeCN solution containing $(Me_4N)_2[Fe_4S_4(SBu^t)_4]$ and excess FcSH at 50 °C with bubbling N_2 into the solution at a fixed time interval to remove Bu^{t}SH liberated. The ^1H NMR spectrum of the product in DMSO-d_6 shows three ring proton signals due to FcS at δ 4.60, 4.12, and 4.09 (Fig. 1a); the Bu^t proton signal originally observed in $[Fe_4S_4(SBu^t)_4]$ (δ 2.68)[22] completely disappeared, indicating that Bu^{t}S was substituted by FcS. Two different results have been reported in the substitution reaction of $[Mo_2Fe_6S_8(SEt)_9]^{3-}$ with alkanethiols; one is that both the terminal and bridging EtS groups are easily substituted,[23] and the other is that only the terminal EtS groups are active toward the substitution reaction.[24] The ^1H NMR spectrum for DMSO-d_6 solution of the product in the reaction of $[Mo_2Fe_6S_8(SEt)_9]^{3-}$ with FcSH shows the presence of three Fc-ring proton signals at δ 8.24, 4.16, and 3.85 as well as a S-CH_2 signal of the bridging EtS groups at δ 16.90, whereas the terminal EtS groups whose signals were observed in $[Mo_2Fe_6S_8(SEt)_9]^{3-}$ (S-CH_2-, δ 52.86 and S-CH_2-CH_3, δ 3.37) disappears (Fig. 1b). Similarly, the $[Mo_2Fe_6S_8(OMe)_3(SFc)_6]^{3-}$ cluster exhibits three signals due to Fc-ring protons at δ 8.20, 4.10, and 3.96 (Fig. 1c). No MeO proton signal has, however, been observed because of a large paramagnetic broadening, though the bridging MeO protons of $[Mo_2Fe_6S_8(OMe)_3(SPh)_6]^{3-}$ was reported to appear as a broad signal around δ −3.1 above 50 °C.[18]

Electrochemistry. The cyclic voltammogram of $[Fe_4S_4(SFc)_4]^{2-}$ in DMF gives a pair of cathode and anode peaks (E_c=−1.25 V, E_a=−1.10 V *vs.* SCE) which are a pseudo-reversible (2-/3-) couple (a in Fig. 2). The redox potential approximated by $E_{1/2}$ (Table 1) is about 40 mV negative compared with that of

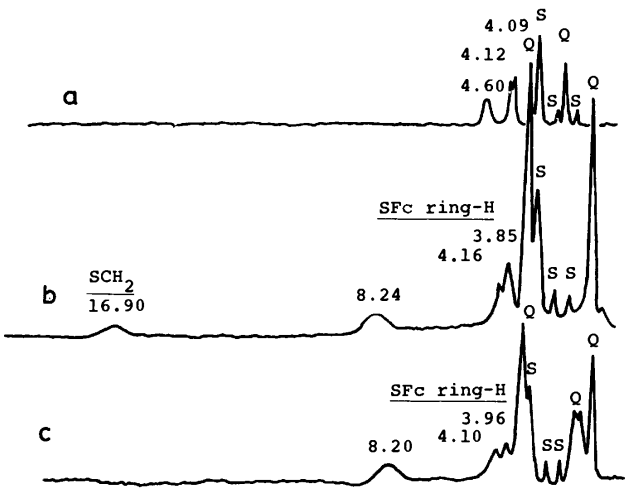

Fig. 1. Proton magnetic resonance spectra of $(Me_4N)_2[Fe_4S_4(SFc)_4]$ (a), $(Et_4N)_3[Mo_2Fe_6S_8(SEt)_3(SFc)_6]$ (b), and $(Bu^n_4N)_3[Mo_2Fe_6S_8(OMe)_3(SFc)_6]$ (c) in $(CD_3)_2SO$ at 298 K. Peaks due to the protons of the quaternary ammonium ion and the solvent are indicated by *Q* and *S*, respectively.

Table 1. Electrochemical and electronic spectral data for the clusters in DMF

Cluster	E/V *vs.* SCE			λ_{max}/nm (ε_M/mol^{-1} dm^2)		
	4-/5-	3-/4-	2-/1-			
$[Fe_4S_4(SFc)_4]^{2-}$		−1.18		310 (250000)	430 (140000)	600 (sh) [a]
$[Mo_2Fe_6S_8(SEt)_3(SFc)_6]^{3-}$	−1.34	−1.13	−0.08	308 (520000)	420 (290000)	580 (sh) [a]
$[Mo_2Fe_6S_8(OMe)_3(SFc)_6]^{3-}$	−1.37	−1.11	−0.12	308 (580000)	440 (220000)	

a) Shoulder.

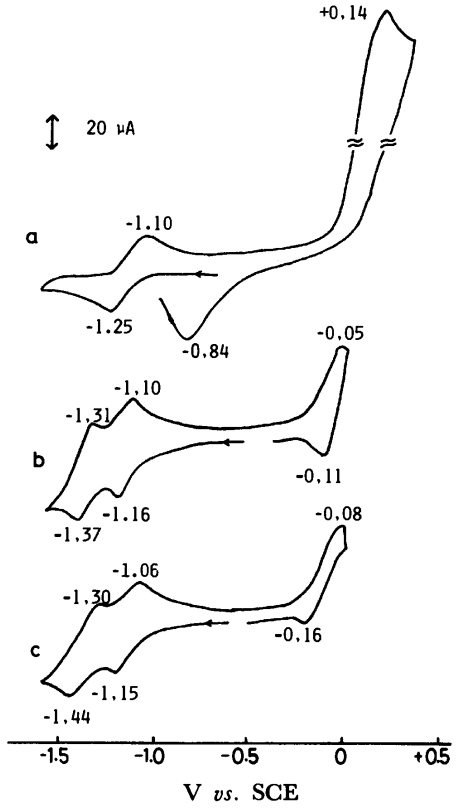

Fig. 2. Cyclic voltammograms of $[Fe_4S_4(SFc)_4]^{2-}$ (a), $[Mo_2Fe_6S_8(SEt)_3(SFc)_6]^{3-}$ (b), and $[Mo_2Fe_6S_8(OMe)_3(SFc)_6]^{3-}$ (c) in DMF containing 0.1 mol dm^{-3} $Bu^n_4NClO_4$; the scan rate 0.2 Vs^{-1}.

$[Fe_4S_4(SPh)_4]^{2-}$ in the same solvent.[25] This may be due to a donor ability of FcS stronger than PhS, as suggested for some cubane type clusters in which the more the electron-donating property of substituents is, the more negative shift the redox potential occurs.[26] On sweeping to positive potentials following to the occurrence of the pseudo-reversible couple, a strong anode peak appears at +0.14 V, followed by a cathode one at −0.84 V in the reverse scan (a in Fig. 2). The anode peak current is about 5—6 times larger than the cathode peak current and the potential difference between the these peaks is about 1 V. These results reveal that $[Fe_4S_4(SFc)_4]^{2-}$ is subject to the oxidation not only at the Fe_4S_4 core but also at the Fc moiety at +0.14 V, followed by irreversible chemical reactions. Thus, there has been observed no evidence for the presence of a stable (2-/1-) couple in $[Fe_4S_4(SFc)_4]^{2-}$, which is known to exist in high potential Fe-S proteins.[15]

In contrast to $[Fe_4S_4(SFc)_4]^{2-}$, $[Mo_2Fe_2S_8(SEt)_3(SFc)_6]^{3-}$ exhibits three reversible redox couples (3-/2-), (3-/4-), and (4-/5-) (b in Fig. 2), as confirmed by the observation that the potential difference between the anode and cathode peaks of each couple is 60 mV. The $[Mo_2Fe_6S_8(OMe)_3(SFc)_6]^{3-}$ cluster also displays three redox couples, the anode and cathode peak potentials being close to those of $[Mo_2Fe_6S_8(SEt)_3(SFc)_6]^{3-}$. The potential difference of each couple, however, is larger than 60 mV (c in Fig. 2), suggesting that the redox processes are pseudo-reversible. In addition, the cathode peak current at −0.16 V at sweep rate 0.2 Vs^{-1} is much smaller than that of the corresponding anode peak current at −0.08 V, and the cathode wave almost disappeared at sweep rate 0.02 Vs^{-1}. This result indicates that $[Mo_2Fe_6S_8(OMe)_3(SFc)_6]^{2-}$ generated by electrochemical oxidation is unstable even in the time scale of cyclic voltammetry. Thus, the Mo-Fe-S double cubane cluster bridged by EtS group may be more stable than that bridged by MeO.

Electronic Spectra. The electronic spectra of both $[Fe_4S_4(SFc)_4]^{2-}$ and $[Mo_2Fe_6S_8(SEt)_3(SFc)_6]^{3-}$ in DMF show two absorptions around 430 and 600 nm (solid line in Fig. 3), the latter of which has not been evident in the spectrum of $[Mo_2Fe_6S_8(OMe)_3(SFc)_6]^{3-}$ (Table 1). No distinct shoulder around 600 nm has been observed also in the corresponding clusters with PhS, $[Fe_4S_4(SPh)_4]^{2-}$ and $[Mo_2Fe_6S_8(SPh)_9]^{3-}$, however, the $[Fe_4S_4X_4]^{2-}$ cluster anions where X=Cl[27] and OPh[28] display a shoulder assignable to a transition within the Fe_4S_4 core in the 600—700 nm range. Thus, the shoulder around 600 nm of the present clusters may be ascribed to transitions within the Fe_4S_4 or $MoFe_3S_4$ cores. Another band around 430 nm of the present clusters is assigned to the charge-transfer transitions from terminal sulfur atoms to metal atoms of the cores on the basis of the close similarity of the spectral features to those of $[Fe_4S_4(SPh)_4]^{2-}$ [25] and $[Mo_2Fe_6S_8(SPh)_9]^{3-}$.[29]

The spectra in the course of the reduction of clusters were measured by the use of a OTTLE cell[30] under the controlled potential electrolysis conditions at 0.10—0.25 V more negative than the

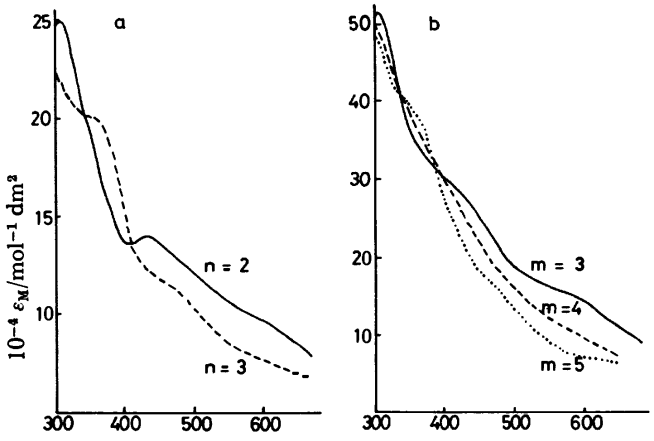

Fig. 3. Absorption spectra of (a) $[Fe_4S_4(SFc)_4]^{n-}$ (n= 2, 3) and (b) $[Mo_2Fe_6S_8(SEt)_3(SFc)_6]^{m-}$ (m=3, 4, 5) in DMF; the reduced forms with n=3 (a) and m= 4, 5 (b) were generated in an OTTLE cell by applying the potentials −1.50, −1.30, and −1.70 V (*vs.* SCE), respectively.

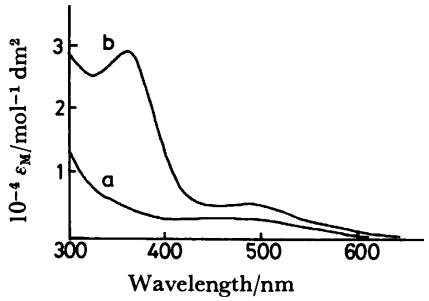

Fig. 4. Absorption spectra of FcSH (a) and FcS$^-$ (b) in DMF ; the latter was generated in an OTTLE cell by applying the potential −1.50 V (*vs.* SCE) to a solution of the Bu^n_4 N salt.

cathode peak potentials. The reduction of $[Fe_4S_4(SFc)_4]^{2-}$ at −1.50 V (*vs.* SCE) in DMF results in the decrease of absorbances around 430 and 600 nm, instead two new bands around 360 and 480 nm appear as shoulders (a broaken line in Fig. 3). The position of these shoulders are coincidence with those of absorptions appearing in the reduction of FcSH to FcS$^-$ by the controlled potential electrolysis at −1.50 V (*vs.* SCE) in DMF, as shown in Fig. 4. Thus, the reduction of $[Fe_4S_4(SFc)_4]^{2-}$ may result in a partial dissociation of FcS$^-$ as expressed in Eq. 1.

$$[Fe_4S_4(SFc)_4]^{2-} \underset{-e^-}{\overset{+e^-}{\rightleftharpoons}} [Fe_4S_4(SFc)_4]^{3-} \rightleftharpoons [Fe_4S_4(SFc)_3]^{2-} + FcS^- \quad (1)$$

The spectral change in the course of reduction was almost ceased in 30 min, except for the 360 nm band whose intensity continued to increase slowly for 1 h. The reoxidation of the resulting solution at −0.90 V (E_a=−1.10 V *vs.* SCE) recovered the 430 nm band up to more than 95%, and the 480 nm shoulder almost disappeared, although the 360 nm band still remained as a shoulder. Further oxidation at −0.50 V for 30 min resulted in complete disappearance of the 360 nm shoulder and the spectrum obtained finally was consistent with that of $[Fe_4S_4(SFc)_4]^{2-}$.

The spectral change during the electrochemical redox cycle of $[Mo_2Fe_6S_8(SEt)_3(SFc)_6]^{3-}$ in DMF is similar to that of $[Fe_4S_4(SFc)_4]^{2-}$; the reduction of $[Mo_2Fe_6S_8(SEt)_3(SFc)_6]^{3-}$ at −1.30 V (*vs.* SCE) results in weakening of the shoulder at 420 and 580 nm, and the appearance of a shoulder at 360 nm (a broken line in Fig. 3b). Further reduction at −1.70 V (*vs.* SCE) to produce $[Mo_2Fe_6S_8(SEt)_3(SFc)_6]^{5-}$ strengthens the absorbance at 480 nm as a shoulder as well as 360 nm (a broaken line in Fig. 3b). Further reduction at −1.70 V (*vs.* SCE) to produce $[Mo_2Fe_6S_8(SEt)_3(SFc)_6]^{5-}$ strengthens the absorbance at 480 nm as a shoulder as well as 360 nm (a dotted line in Fig. 3b). The absorbance at 360 nm attained to a constant value in about 30 min, which is much longer than the time required for the disappearance of the 420 nm band. The reoxidation at −0.50 V (*vs.* SCE) of the resulting solution also required more time for the disappearance of the 360 nm band than for the recovery of the intensity of the 420 nm band; the final spectrum of the solution was consistent with that of $[Mo_2Fe_6S_8(SEt)_3(SFc)_6]^{3-}$. Similar spectral changes were observed in the reduction (−1.30 and −1.70 V *vs.* SCE) and oxidation (−0.50 V *vs.* SCE) cycle of $[Mo_2Fe_6S_8(OMe)_3(SFc)_6]^{3-}$ in DMF, while no distinct shoulder appeared at 480 nm in the electrolysis at −1.70 V (*vs.* SCE). The reduction of $[Mo_2Fe_6S_8X_3(SFc)_6]^{3-}$ (X=SEt and OMe), therefore, also results in a partial dissociation of FcS$^-$ in DMF as expressed in Eq. 2.

$$[Mo_2Fe_6S_8X_3(SFc)_6]^{z-} \rightleftharpoons [Mo_2Fe_6S_8X_3(SFc)_5]^{(z-1)-} + FcS^- \quad (2)$$

z=4 and 5; X=SEt and OMe

Reduction of C_2H_2 by Clusters. It has been reported that $[Fe_4S_4(SPh)_4]^{3-}$ can reduce C_2H_2 in an aprotic solvent in the presence of CH_3COOH to give C_2H_4 selectively in a 60% yield,[31] and both $[Fe_4S_4(SPh)_4]^{2-}$ and $[Mo_2Fe_6S_8(SPh)_9]^{3-}$ catalyze the reduction of C_2H_2 to C_2H_4 in MeOH/THF under the controlled potential electrolysis conditions.[19] These results may be similar to the reduction of C_2H_2 by nitrogenase, where only C_2H_4 is produced with-

Table 2. Conditions for the reduction of C_2H_2 and the products distribution in H_2O (pH 7.0)

Catalyst[a]	Potential V *vs.* SCE	$\frac{C_2H_4}{H_2}$	$\frac{C_2H_4}{C_2H_6}$	TN[b]
$[Fe_4S_4(SFc)_4]^{2-}$	−1.30	0.79	11.1	1.65
$[Mo_2Fe_6S_8(SEt)_3(SFc)_6]^{3-}$	−1.40	0.29	11.1	1.38
$[Mo_2Fe_6S_8(OMe)_3(SFc)_6]^{3-}$	−1.40	0.22	10.0	0.63

a) 7 μmol. b) Turnover number; C_2H_4 mol/(cluster mol h).

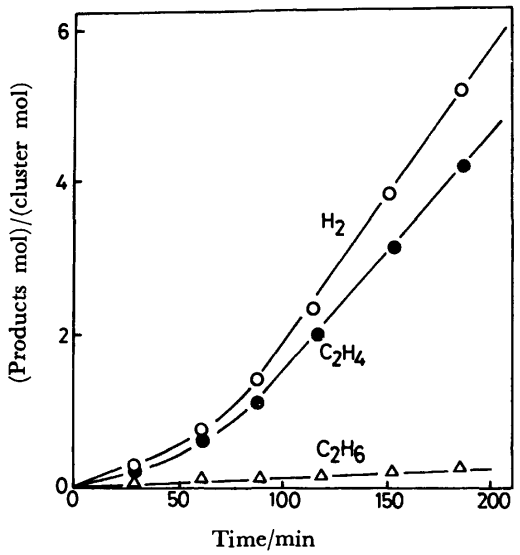

Fig. 5. Reduction of C_2H_2 catalyzed by $[Fe_4S_4(SFc)_4]^{2-}$ under the controlled potential electrolysis at −1.30 V (*vs.* SCE) in H_2O at pH 7.0.

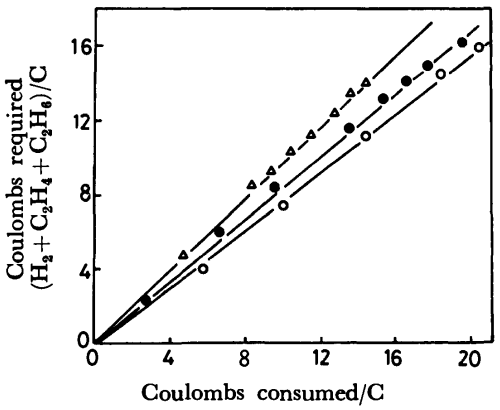

Fig. 6. Plots of the total number of coulombs required for the formation of all the products ($H_2+C_2H_4+C_2H_6$) *vs.* coulomb consumed in the reduction of C_2H_2 catalzed by $[Fe_4S_4(SFc)_4]^{2-}$ (○), $[Mo_2Fe_6S_8(SEt)_3(SFc)_6]^{3-}$ (●), and $[Mo_2Fe_6S_8(OMe)_3(SFc)_6]^{3-}$ (△) under the controlled potential electrolysis conditions in H_2O at pH 7.0.

out evolving C_2H_6 nor H_2.[32] Thus, the reduction of C_2H_2 by the reduced species of the present clusters may be of interest in comparing with that by nitrogenase. Since the present clusters are sparingly soluble in water, they were dispersed in water; a DMSO solution (1.0 cm³) of $[Fe_4S_4(SFc)_4]^{2-}$ (7 μ mol) was injected into C_2H_2-saturated water (20 cm³) containing Triton X-100 (0.01 cm³) as a surfactant and a supporting electrolyte. The controlled potential electrolysis of the solution at −1.30 V *vs.* SCE evolves C_2H_4 together with a small amount of C_2H_6 and a considerable amount of H_2, as shown in Fig. 5; the total mole of C_2H_4 and C_2H_6 produced in about 60 min exceeds the number of moles of the cluster used, confirming that the reduction of C_2H_2 proceeds catalytically. Similar catalytic reduction of C_2H_2 have occurred in water involving dispersed $[Mo_2Fe_6S_8X_3(SFc)_6]^{3-}$ (X=EtS, MeO) under the electrolysis at −1.40 V *vs.* SCE. The total numbers of coulombs required for the formation of all the products are related linearly with those consumed in the electrolysis conditions, as shown in Fig. 6, which indicates that the current efficiency for the C_2H_4, C_2H_6, and H_2 formation is essentially constant during the reaction. In addition, the electronic spectrum of the propylene carbonate extract of an aqueous suspension of either cluster in the working electrode cell after the electrolysis was identical in appearance with that in the same solvent, suggesting that most of the cluster used as a catalyst for the reduction of C_2H_2 has not been decomposed during the reaction.

The results of the reduction of C_2H_2 by the present clusters under the electrolysis conditions are collected in Table 2. Although the mole ratio C_2H_4/C_2H_6 evolved is nearly the same irrespective of the nature of the clusters used, the concomitant H_2 evolution in the reduction of C_2H_2 largely depends on the clusters; the mole ratio C_2H_4/H_2 increases in the order $[Mo_2Fe_6S_8(OMe)_3(SFc)_6]^{3-} < [Mo_2Fe_6S_8(SEt)_3(SFc)_6]^{3-} < [Fe_4S_4(SFc)_4]^{2-}$, and the rate of the C_2H_4 formation increased also in the same order. Thus, the Fe-S cluster may be concluded to exhibit not only a higher activity but also a better selectivity for the C_2H_2 reduction than the Mo-Fe-S clusters in the present reaction conditions, while the latter involves a skeltal more or less similar to MoFe-co as suggested by the EXAFS technique.[10,13]

(Received July 28, 1984)

A stable "phenoxyl-veratrole" (**2**), a veratrole analogue of "phenoxyl-benzo-15-crown-5" (**1**), was prepared and the complex formation between **2** and the alkali and alkaline earth metal salts has been studied by the ESR technique. Existence of the 2:1 complex of **2** with K^+, Rb^+, and Cs^+ salts was confirmed by the observation of the triplet ESR spectra in ethanol rigid matrix at 77 K. Essentially the same ***g***- and ***D***-tensor values were observed for all the 2:1 complexes, indicating similar conformation of the ligand molecule **2**. By comparing the observed *D* and *E* parameters with those of the 2:1 complexes reported for the alkali and alkaline earth metal complexes of **1** in a previous paper (Ref. 10), the structure of the 2:1 complex in ethanol rigid matrix was discussed. On the other hand, the results of the ESR measurements of the Li^+, Na^+, and alkaline earth metal complexes suggested a 1:1 complex formation between **2** and the metal salts.

Many investigations have been performed for the complex formation between crown ether and alkali and alkaline earth metal salts.[1-3] The stoichiometry of the crystalline complexes depends on the relative size of the "hole" in the crown ether and of the cation.[2-6] Such complex formations will be induced by the ion-dipole interaction between the positive ion and the cyclic polyether ring. On the other hand, Ungaro *et al.* have shown that a change in the 4-substituent for benzo-15-crown-5 (B15C5) can cause a significant change in the complex formation constant.[7] They reported that the effect may be as large as that caused by a change in the structure of the polyether ring.

The spin label investigation of the crown ether has given useful and important information about the formation and structure of the crown-metal complexes, as described in previous papers:[8,9] For instance, both the nitroxide- and galvinoxyl-labeled B15C5 compounds form 1:1 complexes with NaSCN and 2:1 complexes with KSCN, as reported for the native benzo-15-crown-5. However, the structure of the above 2:1 complexes in frozen solution is different from that of B15C5 obtained by X-ray analysis.[6]

Recently, we have prepared a stable phenoxyl derivative of benzo-15-crown-5 (hereafter called "phenoxyl-B15C5" (**1**)) (see Fig. 1) and studied the complex formation between the spin-labeled crown ether **1** and the alkali (Li^+, Na^+, K^+, and Rb^+) and alkaline earth (Mg^{2+}, Ca^{2+}, Sr^{2+}, and Ba^{2+}) metal salts by the ESR technique.[10] The result of ESR observation has established the new fact that two kinds of 2:1 complexes (hereafter called the dimer I_c and II_c complexes) having different structures (see Fig. 7 in Ref. 10) and a 1:1 complex coexist at equilibrium in all the ethanol solutions of **1** containing the above metal salts. The result is contrary to the well-known fact that the stoichiometry of the crystalline complexes depends on the relative size of the "hole" in the crown ether and of the cation, and suggests that van der Waals interaction between the aryloxyl groups substituted to the cyclic polyether ring may play an important role in the complex formation and in fixing the conformation of the complex, in addition to the above ion-dipole interaction.

In the present paper, in order to obtain further information on such complex formations, we have prepared a veratrole analogue of **1** (hereafter called "phenoxyl-veratrole" (**2**)) (see Fig. 1), in which the cyclic polyether ring is substituted by two methoxyl groups, and observed ESR spectra of its alkali and alkaline earth metal complexes in ethanol at 77 K.

Experimental

Quinol Derivative of Veratrole (3). **3** was synthesized by the reaction of lithium derivative of 4-bromoveratrole with 2,6-di-*t*-butyl-*p*-benzoquinone, according to the procedure used by us to prepare the quinol precursor of **1**.[10] **3** was recrystallized twice from ligroin (bp 90—105 °C) to give white crystals: Mp 122—123 °C; UV (EtOH) λ_{max} 282 nm (log ε=3.89); NMR (CCl_4) δ=1.18 (18H, s, *t*-Bu), 2.18 (1H, s, OH), 3.70 (6H, s, OCH_3), 6.38 (2H, s, *m*-ring), 6.68 (2H, s, aromatic H), 6.78 (1H, s, aromatic H) with Me_4Si as internal

Quinol-Veratrole (**3**) Phenol-Veratrole (**4**)

Phenoxyl Derivative of Veratrole (Phenoxyl-veratrole) (2). Phenoxyl-veratrole (**2**) was prepared by the oxidation of corresponding phenol (**4**) with alkaline potassium hexacyanoferrate(III) in diethyl ether solvent under a nitrogen atmosphere, with the temperature kept between 0 and 5 °C.[12] **2** was isolated as stable dark brown crystals from the etherial solution: UV-vis (cyclohexane) λ_{max} 373 (log ε=3.71), 576 (log ε=2.93), 625 nm (log ε=3.05).

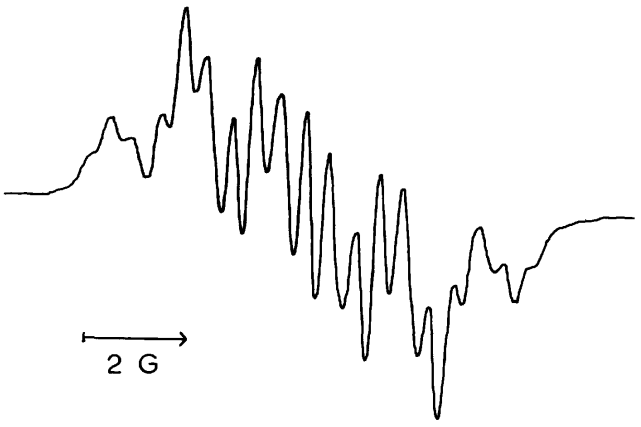

Fig. 2. ESR spectrum of **2** in ethanol at 20 °C.

The radical concentration was obtained from the results of the paramagnetic susceptibility measurements at 20 °C, after correcting for the diamagnetic contribution (χ_{dia}=−0.237×10^{-3} emu mol^{-1}) calculated by Pascal's method. The value of the radical concentration was 95%, assuming the Curie law. All the ESR spectra were measured in a sealed, degassed system.

Results and Discussion

Ethanol Solution ESR Spectrum of 2. The ethanol solution ESR spectrum of **2** has been measured at 20 °C (see Fig. 2). The observed hyperfine couplings are listed in Table 1. The value of each hyperfine splitting of phenoxyl-veratrole (**2**) is very close to the corresponding value of phenoxyl-B15C5 (**1**) radical,[10] except for the β-methyl and -methylene proton hyperfine splitting at O-4 (see Table 1). The g_{iso}-value (2.00416±0.00005) of **2** in an ethanol solution also show a good agreement with that (g_{iso}=2.00421± 0.00005) of **1** within the limits of experimental error. These results indicate that the effects of the substitution of the cyclic polyether ring by two methoxyl groups are very small to induce a change in the unpaired spin distribution of aryloxyl group.

Ethanol Rigid-matrix ESR Spectra of the Alkali and Alkaline Earth Metal Complexes of 2. An ethanol solution of **2** (3.0×10^{-3} mol dm^{-3}) containing equimolar KI salt gives an ESR spectrum consisting of (i) a central strong singlet and (ii) three pairs of absorption lines (X, X′; Y, Y′; and Z, Z′) on both sides of the central singlet at 77 K, as shown in Fig. 3 (a). A slightly asymmetric central line with a width of about 7.6 G at $g\cong2.0043$ shows a shape essentially the same as that of the metal-free **2** (ΔH_{msl}=6.9 G and $g\cong2.0042$), and the relative intensity of this central line changes depending on the ratio of the potassium salt to **2**. Therefore, this line is attributable to the 1 : 1 complex (hereafter called the monomer complex) between **2** and KI. The three pairs of absorption lines apparently represent zero-field splittings (zfs) arising from the intermolecular spin-spin dipolar interaction of two electrons in a triplet state. The result clearly indicates the formation of the 2 : 1 complex (hereafter called the dimer II_v complex) between **2** and KI. The zfs parameters (*D* and *E*) and *g*-tensor values observed for the dimer II_v complex are listed in Table 2.

First, the effects of positive ions on the complex for-

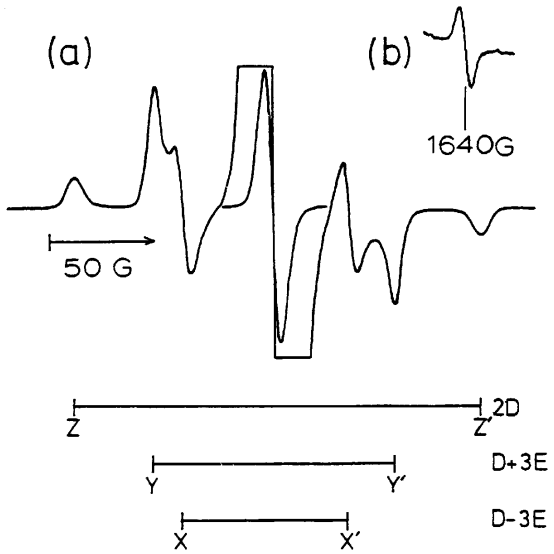

Fig. 3. ESR spectrum of the KI complex of **2** in ethanol at 77 K: (a) $\Delta m_s=\pm 1$ transition and (b) $\Delta m_s=\pm 2$ transition.

mation and on the molecular structure of the complex were studied. The ESR spectra of both the RbI and CsI complexes of **2** in ethanol at 77 K show shapes essentially the same as that of the KI complex, indicating the coexisting of a dimer and a monomer. As it is clear from the results shown in Table 2, the variation in zfs parameters with cations (K^+, Rb^+, and Cs^+) is almost negligible in the present dimer II_v complexes. On the other hand, ethanol solutions of **2** (3.0×10^{-3} mol dm^{-3}) containing equimolar alkali (LiI and NaI) and alkaline earth ($MgCl_2$, $SrCl_2$, and BaI_2) metal salts show a slightly asymmetric single line with a width of about 7 G located at $g\cong 2.004$ at 77 K, respectively, unequivocally suggesting 1 : 1 complex formation between **2** and the above salts.

Second, the effects of the negative ions (Br^-, I^-, SCN^-, IO_4^-, and SO_4^{2-}) on the complex formation and on the molecular structure of the complex have been studied. The anions were varied in the K^+ and Na^+ salts. ESR spectra of the KBr and KSCN complexes of **2** in ethanol rigid-matrix at 77 K are very similar to that of the KI complex, except for the difference in the central signal intensity, indicating the coexisting of a dimer II_v and a monomer. The observed ***D***- and ***g***-tensor values are summarized in Table 2. The result indicates that the effect of the change in anions is too small to induce the change in the molecular structure of the 2:1 complex. However, triplet ESR spectrum was not observed for the KIO_4 and K_2SO_4 complexes of **2**, suggesting the effect of anions on complex formation. On the other hand, similar single line ESR spectra were observed in all the Na complexes of **2** studied, indicating the 1:1 complex formation.

Here, an attempt to establish the molar ratio of the monomer and dimer II_v was achieved by observing the ethanol rigid-matrix ESR spectrum of **2** containing equimolar KI salt. The approximate ratio can be determined from the integrated spectral intensity of a first-derivative ESR absorption line.[13] The ratio obtained is monomer:dimer II_v=4:1.

The Structure of the 2:1 Complexes of **2** *with K^+, Rb^+, and Cs^+ Metal Salts.* As reported in a previous paper,[10] the results of the ESR observations have established the new fact that two kinds of 2:1 complexes (the dimer I_c and II_c complexes) having different structures and a 1:1 complex coexist at equilibrium in all the ethanol solutions of phenoxyl-B15C5 (**1**) containing the eight kinds of the alkali and alkaline earth metal salts. In addition, both in dimer I_c and II_c, the *D* and *E* values and *g*-tensor values observed for all the alkali and alkaline earth metal complexes remain constant, respectively, within the limit of experimental error, except for the small change in dimer II_c complexes of **1** with $SrCl_2$ and BaI_2. For instance, the *D* and *E* values and *g*-tensor values observed for the KI complex of **1** are $|D_I|$= 24.1 G, $|E_I|$=0.9 G, g^I_{xx}=2.0047, g^I_{yy}=2.0040 for dimer I_c, and $|D_{II}|$=97.6 G, $|E_{II}|$=6.5 G, g^{II}_{xx}=2.0061, g^{II}_{yy}=

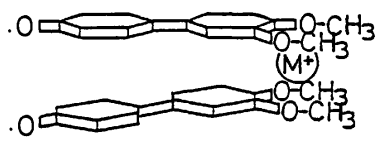

Fig. 4. Conformation of dimer II_v.

2.0036, g_{zz}^{II}=2.0026 for dimer II_c.

The result of the present ESR observations showed that a kind of 2:1 complex and a 1:1 complex coexist at equilibrium in the ethanol solutions of **2** containing the K^+, Rb^+, and Cs^+ metal salts. For instance, the *D*, *E*, and *g*-tensor values observed for the KI complex of **2** in ethanol rigid-matrix are $|D|$=96.1 G, $|E|$=5.8 G, g_{xx}=2.0062, g_{yy}=2.0041, and g_{zz}=2.0031, as listed in Table 2. It is very interesting that the phenoxyl-veratrole (**2**) having no crown ether ring forms 2:1 complex with alkali metal salts. And, further, these values are very similar to those observed for the dimer II_c complex of KI salt of **1**. As has been descrived in a previous section, **1** and the veratrole analogue (**2**) have similar spin distribution in a fluid solution. Therefore, the similarity of the *D*, *E*, and *g*-values observed for **1** and **2** suggests that the dimer II_v structure of the KI complex of **2** is similar to that of the dimer II_c structure of the KI complex of **1** (see Fig. 7 in Ref. 10). That is, the dimer II_v has a structure in which the aryloxyl radical parts of the complex overlap each other. From the results of the observed zfs parameters, a preferable conformation of the dimer II_v complex of **2** was assumed as illustrated in Fig. 4.

Many investigations have been performed for the complex formation between crown ether and alkali and alkaline earth metal salts, including B15C5, in solution and in the solid state.[1-7] The stoichiometry of the crystalline complexes depends on the relative size of the hole in the crown ether and of the cation. For instance, B15C5 with a hole 1.7—2.2 Å in diameter usually forms a 1:1 complex with Na^+ (diameter, 1.90 Å), because the Na^+ cation fits tightly in the crown cavity. But, it forms a 2:1 complex with K^+ (2.66 Å), the ion larger than the hole. Such complex formations will be induced by the ion-dipole interaction between the positive ion and the cyclic polyether ring. Therefore, by substituting the two methoxyl groups for the cyclic polyether ring, the above ion-dipole interaction will decrease considerably, and thus the complex formation will not be observed.

However, the result of the present investigation showed that the phenoxyl-veratrole (**2**), having no polyether ring, forms 2:1 complexes with alkali metal salts (K^+, Rb^+, and Cs^+). Further, the 2:1 complexes of **2** have a structure, in which the aryloxyl skeletons stack over one another, as shown in Fig. 4. It is probable that the van der Waals interaction between the two substituted aryloxyl groups induces such a complex formation and a conformation. On the other hand, the fact that the phenoxyl-veratrole (**2**) does not form 2:1 complex with LiI, NaI, and alkaline earth salts suggests that the ion-dipole interaction also play an important role in the above complex formation.

We are very grateful to Mr. Minoru Yamashita and Mr. Kyozo Ueda for their kind help in the synthesis of **2**. We also wish to thank Mr. Kazuyuki Fukuda for his kind help in the measurement of the ESR spectra.

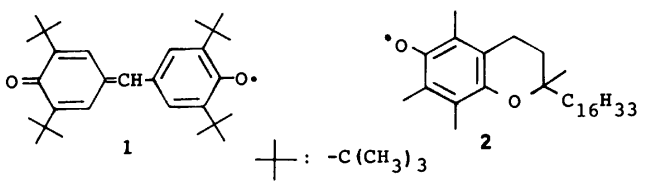
Interaction of Galvinoxyl Radical with Ascorbic Acid, Cysteine, and Glutathione in Homogeneous Solution and in Aqueous Dispersions

Jyunichi TSUCHIYA, Teruaki YAMADA, Etsuo NIKI,* and Yoshio KAMIYA
Department of Reaction Chemistry, Faculty of Engineering, University of Tokyo, Hongo, Tokyo 113
(Received August 17, 1984)

The rates of interaction of galvinoxyl radical with ascorbic acid, cysteine, and glutathione have been studied in homogeneous solution and in water dispersions as a model reaction of vitamin E radical with these reducing agents in biological systems. The rate was measured by following the disappearance of galvinoxyl radical with absorption spectroscopy and electron spin resonance. In every system, galvinoxyl reacted with these reducing substrates and their relative reactivities decreased in the order of ascorbic acid>cysteine>glutathione. For any reducing substrate, the rate was fastest in homogeneous solution and slowest in micelle in Triton X-100 aqueous solution, and the rate in liposome system was in between.

The oxidation of polyunsaturated fatty acids in the lipids and its inhibition has received much attention recently in connection with its pathological effects in biological systems and preservation of foods.[1-8] Vitamin E has been known to act as an effective antioxidant.[9-12] A synergistic inhibition of oxidation by the combination of vitamin E with reducing agents has been suggested[13-19] and it has been observed experimentally that vitamin E radical reacts with ascorbic acid[13,20,21] and glutathione[21,22] to regenerate vitamin E.

In biological systems, most of vitamin E is present in lipophylic membranes, whereas ascorbic acid, glutathione, and cysteine are found in aqueous phase. Therefore, the interaction of vitamin E radical with these reducing agents must be more restricted than in homogeneous system and the effect of reaction medium must be quite important. In order to study the effect of reaction medium, the rates of interaction of galvinoxyl radical (**1**) with ascorbic acid, glutathione, and cysteine were measured both in homogeneous solution and in aqueous dispersions. Galvinoxyl was chosen as a model of vitamin E radical, since both are relatively stable phenoxyl radicals and galvinoxyl is much easier to locate in liposomal membranes and micelles than vitamin E radical (**2**).



Experimental

Materials. Galvinoxyl, L-ascorbic acid, cysteine, and glutathione (reduced form) were of the highest grade available and used as received. *N,N'*-dioxide-2-methyl-*N*-(4-pyridinylmethylene)-2-propanamine (POBN) used as a spin trap was obtained from Aldrich. Dimyristoylphosphatidylcholine (PC) was obtained from Sigma and used without further purification. Ethyl palmitate, ascorbyl-6-stearate, and Triton X-100 were purchased from Tokyo Kasei Kogyo Co. and used as received.

Procedure. The micelle was prepared as follows using Triton X-100 as a nonionic surfactant. Appropriate amount of galvinoxyl was dissolved into ethyl palmitate and then 0.01 M (1 M=1 mol dm^{-3}) Triton X-100 aqueous solution was added. The mixture was shaken vigorously with a Vortex mixer for 1 min to obtain pale brownish micelle solution.

The liposome was prepared by the following method. PC and galvinoxyl (and other oil-soluble additives, when necessary) were dissolved in benzene or in benzene–ethanol (1:1 by volume) and the solution was taken into a small flask. The solvent was removed by evacuation on a water aspirator using a rotary evaporator to obtain a thin film on the flask wall. It was further evacuated under high vacuum. Appropriate amount of 0.1 M NaCl aqueous solution was then added and the film was slowly peeled off by shaking to obtain a milky liposome solution. In several experiments, the solution was sonicated using a Branson Sonifier Model 185.

The rate of disappearance of galvinoxyl was followed by absorption spectroscopy at 429 nm. The reaction was started by mixing the galvinoxyl solution with the reducing agent solution in a Pyrex glass ampoule immersed in a water bath maintained at the desired temperature. The solution was taken out periodically and analyzed.

The rate was also followed by electron spin resonance (ESR) spectroscopic analysis. ESR spectra were recorded on X-band JEOL FE1X spectrometer using a quartz flat cell.

Results

ESR Spectra of Galvinoxyl Radical. Figure 1 shows the ESR spectra of galvinoxyl radical in different media at different temperatures. In homogeneous solution, an isotropic ESR spectrum of galvinoxyl radical with good hyperfine splitting was observed. In micelle, the hyperfine structure showed good split at higher temperature. Similarly, the hyperfine splitting

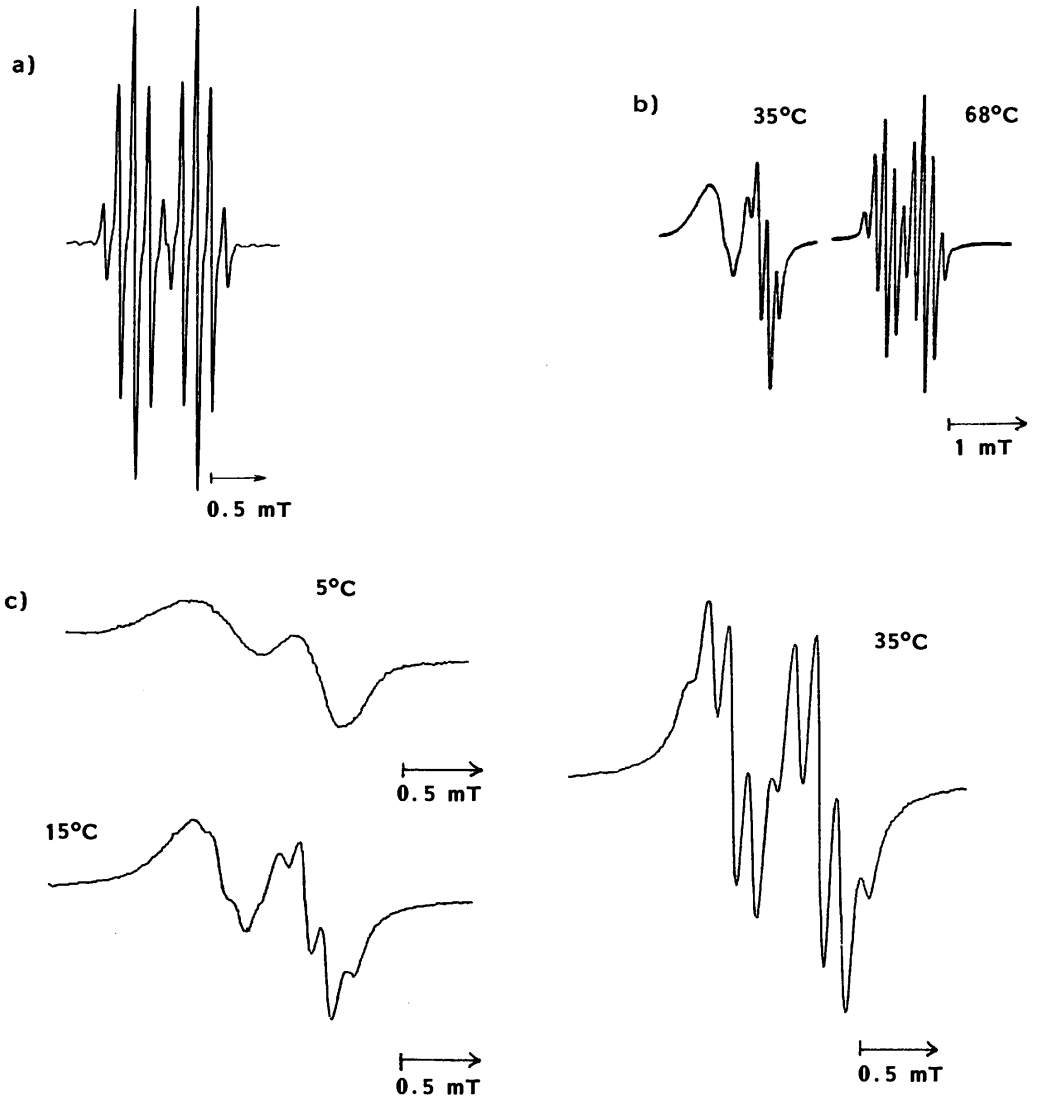


Fig. 1. ESR spectra of galvinoxyl radical in various media.

was not satisfactory below 15 °C for the galvinoxyl incorporated into dimyristoyl PC liposome. The coupling constants for galvinoxyl are summarized in Table 1.

Interaction of Galvinoxyl Radical with Reducing Agents in Homogeneous Solution. When two methanol solutions containing 2.5 mM galvinoxyl and 25 mM ascorbic acid, respectively, were mixed at room temperature, galvinoxyl disappeared instantaneously. On the other hand, when galvinoxyl was mixed with cysteine or glutathione, galvinoxyl disappeared gradually with time and the first order plot gave a good straight line. The pseudo-first order rate constants obtained from this plot are summarized in Table 2.

Interaction in Micelle System. The galvinoxyl incorporated into micelle reacted with ascorbic acid, cysteine, and glutathione. Figure 2 shows an example

Table 1. Coupling constants of galvinoxyl radical in various media[a)]

Medium	Temp °C	a_p^{CH} mT	a_m^H mT
In homogeneous solution of benzene

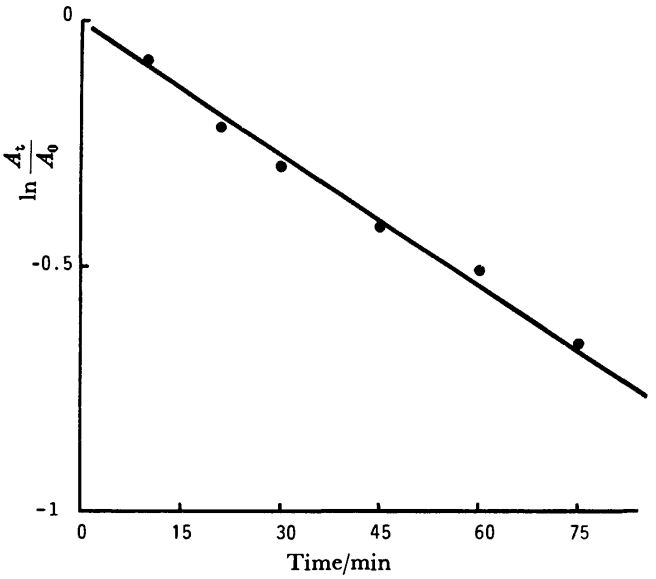

Fig. 2. Pseudo-first order plot of galvinoxyl radical for the reaction with ascorbic acid at 37 °C in Triton X-100 aqueous dispersion: 4 ml ethyl palmitate containing 10 mM galvinoxyl and 4 ml of 50 mM ascorbic acid in 10 mM Triton X-100 aqueous solution were mixed.

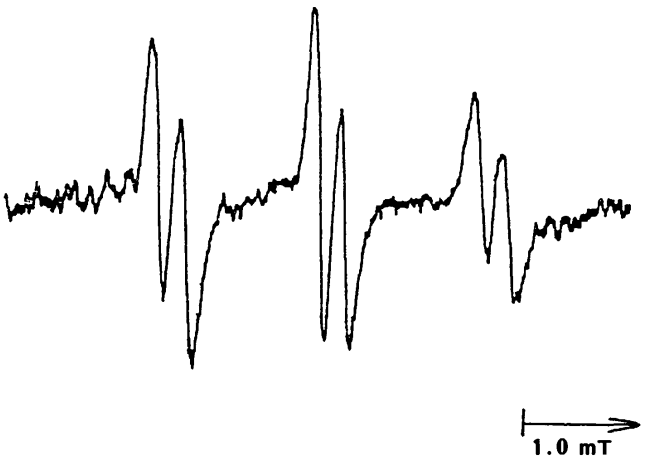

Fig. 3. ESR spectrum observed when POBN was dissolved in an aqueous solution during the interaction of galvinoxyl radical with glutathione in micelle system.

of the first order plot of the galvinoxyl radical in the reaction with ascorbic acid at 37 °C. The galvinoxyl is stable in the absence of ascorbic acid. The results with ascorbic acid are summarized in Table 3. The pseudo-first order rate constant was insensitive to the concentration of ascorbic acid and surfactant and also to the ratio of organic to aqueous fractions.

Interaction in Liposome System. Galvinoxyl incorporated into dimyristoyl PC liposome reacted with ascorbic acid, cysteine, and glutathione faster than in micelle system. Satisfactory first order plot was obtained. The results obtained in different systems are summarized in Table 4. In every case, the

a) In 100 mM Triton X-100 aqueous solution.

results obtained by absorption spectroscopy and ESR were in satisfactory agreement.

Discussion

Galvinoxy radical must interact with the reducing agents by a hydrogen atom abstraction. In fact, when a spin trap, POBN, was also dissolved in an aqueous phase in micelle system, new ESR spectra were observed as galvinoxyl disappeared in the presence of cysteine and glutathione. The example of the ESR spectrum is shown in Fig. 3 and the hyperfine

Table 4. Pseudo-first order rate constant (s^{-1}) for the interaction of galvinoxyl radical with ascorbic acid, cysteine, and glutathione in various reaction media at 37 °C

	Homogeneous solution[a]	Micelle[b]	Liposome[c]
Ascorbic acid	Too fast	1.7×10^{-4}	Too fast
Cysteine	1.0×10^{-3}	4.5×10^{-5}	6.5×10^{-4}
Glutathione	1.8×10^{-4}	1.7×10^{-5}	2.0×10^{-4}

Table 5. Hyperfine splitting constants for the spin adducts of glutathione and cysteine radicals by POBN[a]

	a^N/mT	a^H_β/mT
Glutathione	1.495	0.230
Glutathione[b]	1.513	0.232
Cysteine	1.504	0.230

a) 1.18 mM galvinoxyl in Triton X-100 aqueous dispersion was reacted with 10 mM glutathione or cysteine. b) In ethanol/water (5/1 by v/v).[21]

splitting constants are given in Table 5. The same ESR spectra were observed when *t*-butoxyl radical was generated from di-*t*-butyl diperoxyoxalate containing POBN and glutathione or cysteine. Therefore, these spectra may well be ascribed to the spin adduct of glutathione radical or cysteine radical by POBN.[21]

Table 4 summarizes the rate constants for the interaction of galvinoxyl with the reducing agents in different systems. It shows that in every system the relative reactivities decrease in the order of ascorbic acid>cysteine>glutathione. It also shows that for any reducing agent the interaction proceeds most rapidly in homogeneous solution and most slowly in micelle system. The rate of interaction in liposome system was in between.

The lower reactivities in liposome and in micelle systems than in homogeneous solution must be ascribed to a lower mobility of galvinoxyl and to a lower accesibility of the reducing agent to galvinoxyl.

It must be important to compare the present results with the antioxidant activities of vitamin E and reducing agents. As reported previously,[13] vitamin E and vitamin C inhibited synergistically the oxidation of methyl linoleate in homogeneous solution. It was suggested that vitamin E scavenges the chain carrying peroxyl radical quickly and the resulting vitamin E radical reacts with vitamin C to regenerate vitamin E. As a consequence, only vitamin C was consumed at first and vitamin E decayed after vitamin C was depleted.

In the oxidation of soybean PC liposome initiated with an oil-soluble azo compound, vitamin C was not as good antioxidant as in the oxidation initiated with a water-soluble azo compound, but vitamin C was still suggested to react with vitamin E radical in the bilayer, regenerate vitamin E and reduce the rate of disappearance of vitamin E.[24]

Interestingly, in contrast to the oxidation in homogeneous solution and in liposome system mentioned above, vitamin C was not an effective antioxidant in the oxidation of methyl linoleate micelle in Triton X-100 aqueous dispersion initiated with an oil-soluble azo compound. However, even in this case, vitamin C could prolong the suppression period when 2,2,5,7,8-pentamethyl-6-chromanol, a vitamin E model, was located in micelle.

It may be also worth noting, that, although galvinoxyl incorporated into liposome reacted with vitamin C in an aqueous phase so rapidly, it reacted only slowly with ascorbyl-6-stearate incorporated into different liposome in the same water dispersion.

The results obtained in the present study and those of oxidations described above are in accordance with each other, although it must be considered that the location and behavior of galvinoxyl and vitamin E radicals in the membrane may not be identical. Furthermore, the location of phenoxyl radicals in micelle and liposome and the accesibility of reducing agents must also depend on the type of surfactant, composition of fatty acids in micelle and liposome, and other experimental variables.

In conclusion, the present results show that stable phenoxyl radicals react with reducing agents such as ascorbic acid, cysteine, and glutathione by a hydrogen atom abstraction not only in homogeneous solution but also in heterogeneous aqueous dispersions. This is another experimental support to the possible contribution of vitamin E and reducing agents in synergistic inhibition of peroxidation in biological systems.

Natural Homologs of Gramicidin S. II.[1] Synthesis of Gramicidin S-2 and S-3

Sukekatsu NOZAKI* and Ichiro MURAMATSU†

Faculty of Pharmaceutical Sciences, Josai University, Sakado, Saitama 350-05

†*Department of Chemistry, College of Science, Rikkyo University, Nishi-Ikebukuro, Tokyo 171*

(Received August 21, 1984)

Two cyclic dodecapeptides corresponding to newly found members of gramicidin S family, gramicidin S-2: *cyclo*(-Val-Orn-Leu-D-Phe-Pro-Abu-Orn-Leu-D-Phe-Pro-), and gramicidin S-3: *cyclo*(-Abu-Orn-Leu-D-Phe-Pro-Abu-Orn-Leu-D-Phe-Pro-), were synthesized. In the synthesis, the linear decapeptide precursors of the antibiotics prepared by a combination of the "hold-in-solution" method and the usual liquid phase method were converted to cyclic ones in excellent yields by one-pot reaction using 1-ethyl-3-(3-dimethylaminopropyl)carbodiimide hydrochloride and 1-hydroxybenzotriazole. The synthesized antibiotics were identical with the natural products in HPLC analysis and assays of the antibiotic activities. The proposed structures for gramicidin S-2 and S-3 were confirmed. The CD spectra showed that the ring conformations of gramicidin S-2 and S-3 closely resemble each other and also that of gramicidin S-1, which has the already known structure.

In studies of gramicidin S, a peptide antibiotic produced by *Bacillus brevis* strain ATCC 9999 or the Nagano strain, it is known that replacement of the constituent amino acids in the antibiotic by other ones can occur because of the rather broad specificities of gramicidin S synthetases.[2] However, as the natural product only a single compound has been known, in which two identical pentapeptides join head to tail (Fig. 1. Gramicidin S-1).[3]

Recently we found that natural gramicidin S consists of at least 3 compounds; gramicidin S-1 as the major component with the known structure, and two minor ones, gramicidin S-2: *cyclo*(-Val-Orn-Leu-D-Phe-Pro-Abu-Orn-Leu-D-Phe-Pro-) and gramicidin S-3: *cyclo*(-Abu-Orn-Leu-D-Phe-Pro-Abu-Orn-Leu-D-Phe-Pro-) (Fig. 1).[1]

For investigation of the properties of the newly found minor components, chemical synthesis of them is required since isolation of the less abundant compounds from the mixture of the natural products exclusively depends on HPLC technique; providing of them in a sufficient amount is difficult in practice from the natural source.

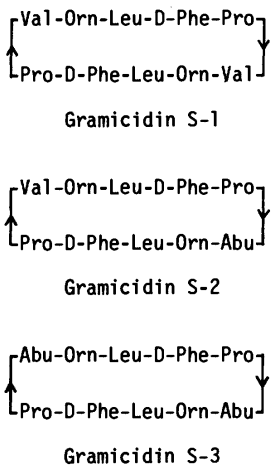

Fig. 1. Structures of gramicidin S-1, S-2, and S-3.

A convenient method was adopted for the preparation of gramicidin S-2 and S-3. The method (Fig. 2) includes rapid preparation of the tetrapeptide (**1**), effectual fragment condensation to give the C-terminal free decapeptides (**5a** and **5b**), and one-pot cyclization to afford the cyclic decapeptides (**7a** and **7b**).

The tetrapeptide (**1**) was synthesized by the "hold-in-solution" method[4] in an overall yield of 48% based on the C-terminal amino acid ester. The pentapeptides (**2a** and **2b**) derived from **1** were saponified to give the C-terminal free peptides (**3a** and **3b**), which were further converted to the N- and C-terminal free peptides (**4a** and **4b**). The coupling reaction of **3a**, which was preactivated by 1-ethyl-3-(3-dimethylaminopropyl) carbodiimide hydrochloride (WSCD·HCl)[5] and 1-hydroxybenzotriazole (HOBt)[6], and the amine components (**4a** and **4b**) afforded the C-terminal free decapeptides (**5a** and **5b**) in 96 and 93% yields, respectively. By acidolysis, the decapeptides (**5a** and **5b**) were converted to the N- and C-terminal free decapeptides (**6a** and **6b**), each of which was allowed to cyclize in anhydrous pyridine-DMF (1:1, 3×10^{-3} M peptide in the solvent (1 M=1 mol dm^{-3})) for 3 d at room temperature with the aid of 10 fold excess moles of WSCD·HCl and HOBt per mole of the peptide. After purification by gel filtration, the cyclic peptides, **7a** and **7b**, were obtained in 75 and 82% yields, respectively. Hydrogenolysis of the cyclic peptides (**7a** and **7b**) gave the desired peptides (**8a** and **8b**), whose homogeneities were confirmed by HPLC analysis, elemental analysis, and amino acid analysis of their acid-hydrolysates.

The present synthesis of gramicidins S demonstrates utility of the WSCD·HCl/HOBt procedure in preparation of the antibiotics. The procedure is quite effective not only for fragment condensation but also for cyclization. Recently successful one-pot cyclization using 5-nitro-2-pyridyl diphenylphosphinate was reported in a preparation of gramicidin S-1.[7] The

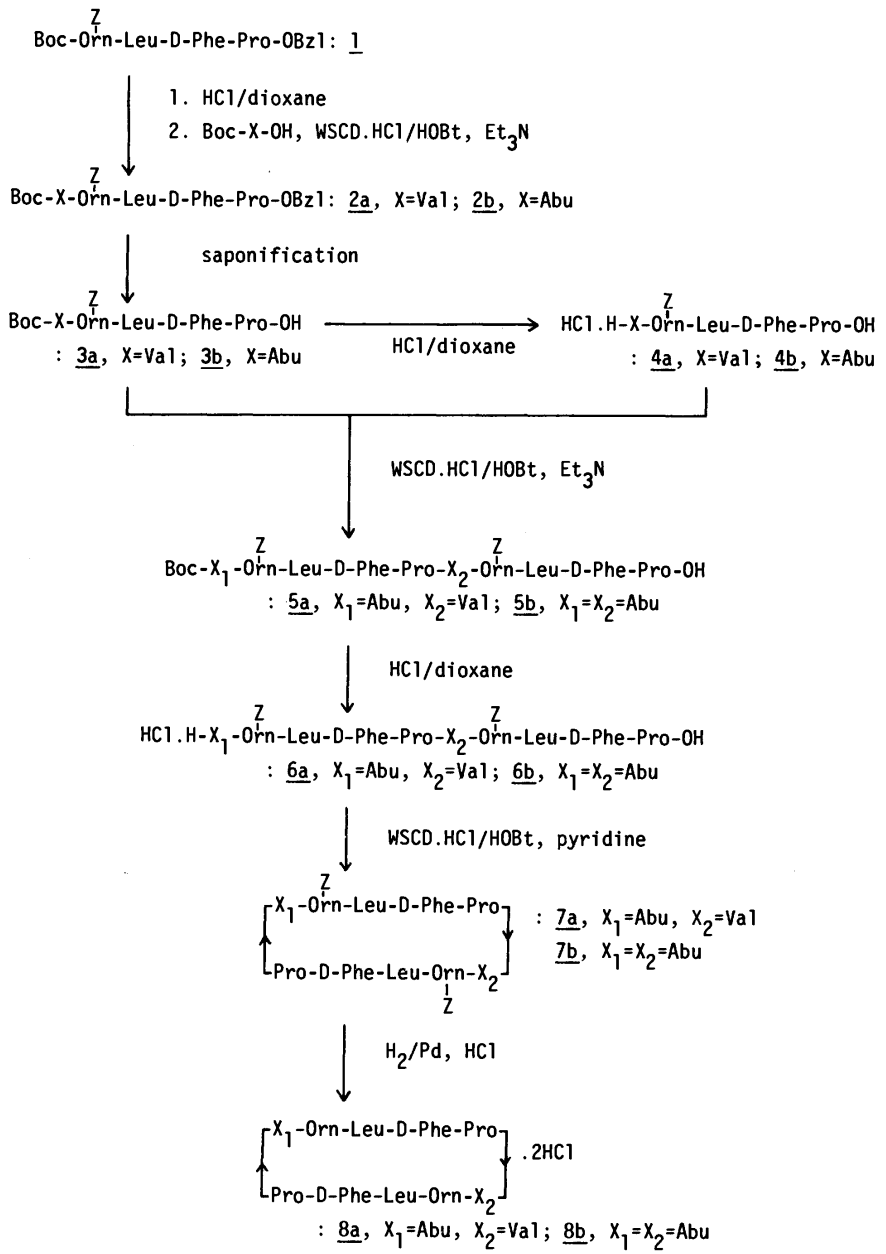

Fig. 2. Synthesis of gramicidin S-2 and S-3.

present convenient method employing the WSCD·HCl/HOBt procedure for one-pot cyclization may also be useful for synthesis of many cyclic peptides.

By HPLC analysis, **8a** and **8b** showed identical retention times with those of natural gramicidin S-2 and S-3 (hydrochlorides), respectively. The acetyl derivatives of **8a** and **8b** also gave identical HPLC profiles with those of the derivatives obtained from the natural antibiotics. The synthetic antibiotics showed the same degree of antibiotic activities as the natural ones (perchlorates) (Table 1). The CD spectra of **8a** and **8b** in ethanol were closely similar to those of the natural peptides (perchlorates). The data indicate that **8a** and **8b** are identical with natural gramicidin S-2 and S-3, respectively. The structures proposed for gramicidin S-2 and S-3 were confirmed.

The CD spectra of **8a** and **8b**, and of natural gramicidin S-1 (hydrochloride) in ethanol closely resembled each other with troughs near 207 nm and shoulders near 219 nm (Fig. 3-A). Addition of water to the peptides in ethanol produced slight decreases of the negative ellipticities near 207 nm, while the similarity found in the spectra of the three peptides was held unchanged (Fig. 3-B). The facts show that the ring conformations of the three gramicidins S are closely similar to each other.

The antibiotic activities of gramicidin S-1, S-2, and S-3 toward some test microorganisms resembled each other (Table 1).

Experimental

Melting points were determined on a Mel-Temp apparutus and were uncorrected. CD spectra were obtained on a J-20A automatic recording spectropolarimeter (JASCO) using a calibrated 0.5 mm quartz cell. Amino acid analysis was carried out on a JLC-6AS automatic amino acid analyzer (JEOL). HPLC analysis was performed on a Partisil-10 ODS-3 column (4×250 mm, Whatman Ltd.) at a flow rate of 1.83 ml/min, which was maintained by a Milton Roy instrument minipump equipped with a JASCO PG-350D pulse dampener. The column effluent was monitored at 220 nm by a JASCO Uvidec 100-II spectrophotometer. The following solvent systems were used for the analysis; a: MeOH-water, 5/1; b: MeOH-water, 7/1; c: MeOH-5% $NaClO_4$, 4/1; d: MeOH-5% $NaClO_4$, 5/1; e: MeOH-4% ammonium acetate, 4/1; f: 2-propanol-5% $NaClO_4$, 2/3. For TLC, precoated silica-gel plates (Merck & Co., #5715) were used with the following solvent systems; a: 1-butanol-AcOH-water, 4/1/1; b: $CHCl_3$-MeOH-AcOH, 95/5/1. For elemental analysis, the samples were dried over P_2O_5 in high vaccum at 40 °C for 1 h unless otherwise noted. The natural peptides were isolated as the perchlorates by a similar method described in lit. 1. The hydrochlorides were obtained as follows: Gramicidin S-1 hydrochloride; The perchlorate was converted to the free peptide by reprecipitation from MeOH-0.5M $NaHCO_3$. The peptide was further converted to the hydrochloride by reprecipitation from MeOH-1 M HCl. Gramicidin S-2 and S-3 hydrochlorides;

Each perchlorate was dissolved in $CHCl_3$ and washed successively with 0.5 M $NaHCO_3$ and water. After removal of the solvent, the residue was dissolved in MeOH–1 M HCl and the solvent was evaporated to give a solid, which was reprecipitated from MeOH–ether.

Boc-Orn(Z)-Leu-D-Phe-Pro-OBzl (1). H-Pro-OBzl·HCl (1.209 g, 5 mM) in 1,2-dichloroethane (30 ml) was acylated successively by Boc-D-Phe-OH, Boc-Leu-OH, and Boc-Orn(Z)-OH (6 mM each) according to the procedures described in the literature.[4] The following reagents were used; Operation A: HOBt (6 mM), WSCD·HCl (7 mM). Operation B: 0.5 M $NaHCO_3$ (20 ml×2), water (20 ml), 0.1 M HCl (20 ml×2), water (20 ml×3). Operation C: 5.47 M HCl/dioxane (12 ml). Operation D: 2 M Na_2CO_3 (18 ml). Operation E: water (20 ml×3). After the final acylation, the reaction mixture was subjected to operation B and the organic layer was concentrated to give an oil. The desired peptide was obtained as a solid after chromatography on a silica-gel column (2.2×15 cm, $CHCl_3$–MeOH) followed by trituration in hexane: 1.960 g (48%), mp 76—85 °C (dec), $[\alpha]_D^{28}$ −59.9° (*c* 1, EtOH). Found: C, 66.22; H, 7.49; N, 8.26%. Calcd for $C_{45}H_{59}O_9N_5$: C, 66.40; H, 7.31; N, 8.60%.

Boc-Val-Orn(Z)-Leu-D-Phe-Pro-OBzl (2a). Boc-Val-OH (0.434 g, 2.0 mM), HOBt (0.270 g, 2.0 mM), HCl·H-Orn(Z)-Leu-D-Phe-Pro-OBzl (0.841 g, 1.12 mM, derived from **1**), Et_3N (0.16 ml, 1.12 mM) and WSCD·HCl (0.383 g, 2.0 mM) were allowed to react in DMF (3 ml) at room temperature overnight to give a mass, which was dissolved in AcOEt and washed successively with 0.1 M HCl, water, 0.5 M $NaHCO_3$, and water. The organic layer was concentrated and diluted with hexane to give precipitates, which were recrystallized from MeOH-AcOEt-hexane: mp 178—182 ° (dec), 0.667 g (65%), $[\alpha]_D^{29}$ −71.0° (*c* 1, EtOH). Found: C, 65.54; H, 7.78; N, 9.13%. Calcd for $C_{50}H_{68}O_{10}N_6$: C, 65.77; H, 7.51; N, 9.20%

Boc-Abu-Orn(Z)-Leu-D-Phe-Pro-OBzl (2b). Prepared in a similar way described above. Recrystallized from MeOH–AcOEt-hexane; mp 189—191 °C (dec), yield: 63%, $[\alpha]_D^{28}$ −68.8° (*c* 1, EtOH). Found: C, 65.22; H, 7.60; N, 9.24%. Calcd for $C_{49}H_{66}O_{10}N_6$: C, 65.46; H, 7.40; N, 9.35%.

Boc-Val-Orn(Z)-Leu-D-Phe-Pro-OH (3a). To a suspension of **2a** (0.612 g, 0.670 mM) in EtOH (30 ml) was added 2 M NaOH (3 ml) and the mixture was stirred for 2 h at room temperature. After addition of 1 M HCl (6 ml), the mixture was concentrated to a small volume, diluted with AcOEt and washed with 0.05 M HCl and water. The organic layer was concentrated and ether was added to give a solid: 0.468 g (85%), mp 122—125 °C (dec), $[\alpha]_D^{29}$ −41.2° (c 1, DMF). Lit:[8] mp 122—125 °C, $[\alpha]_D^{20}$ −39.0° (c 2.05, DMF).

Boc-Abu-Orn(Z)-Leu-D-Phe-Pro-OH (3b). Prepared from **2b** in a similar way described above. Reprecipitated from AcOEt–ether; mp 115—130 °C (dec), yield: 89%, $[\alpha]_D^{29}$ −41.6° (*c* 1, DMF). Found: C, 61.89; H, 7.79; N, 10.27%. Calcd for $C_{42}H_{60}O_{10}N_6$: C, 62.36; H, 7.48; N, 10.39%.

Boc-Abu-Orn(Z)-Leu-D-Phe-Pro-Val-Orn(Z)-Leu-D-Phe-Pro-OH (5a). Compound **3b** (0.400 g, 0.494 mM), HOBt (0.101 g, 0.75 mM), and WSCD·HCl (0.096 g, 0.5 mM) were allowed to react in DMF (3 ml) at room temperature for 40 min. To the solution was added **4a** (0.395 g, 0.521 mM, derived from **3a**, R_f^a 0.62), Et_3N (0.20 ml) and DMF (0.5 ml), and the mixture was stirred for 2 d. After removal of the solvent the desired peptide was solidified by addition of 0.1 M HCl. Reprecipitated from DMF–water: 0.727 g (96%), mp 174—180 °C (dec), R_f^b 0.36, $[\alpha]_D^{29}$ −67.3° (*c* 1, DMF). Found: C, 62.62; H, 7.67, N, 11.02%. Calcd for $C_{80}H_{112}O_{17}N_{12}\cdot H_2O$: C, 62.73; H, 7.50; N, 10.97%.

Boc-Abu-Orn(Z)-Leu-D-Phe-Pro-Abu-Orn(Z)-Leu-D-Phe-Pro-OH (5b). Prepared from **3b** (0.400 g, 0.494 mM) and **4b** (0.392 g, 0.529 mM, derived from **3b**, R_f^a 0.63) in a similar way described above. Reprecipitated from DMF-water: 0.701 g (93%), mp 111—116 °C (dec), R_f^b 0.32, $[\alpha]_D^{29}$ −53.5° (*c* 1, DMF). Found: C, 62.37; H, 7.41; N, 11.26%. Calcd for $C_{79}H_{110}O_{17}N_{12}\cdot H_2O$: C, 62.51; H, 7.44; N, 11.07%.

Cyclo*(-Abu-Orn(Z)-Leu-D-Phe-Pro-Val-Orn(Z)-Leu-D-Phe-Pro-) (7a).* A mixture of **6a** (0.207 g, 0.136 mM, derived from **5a**. Found in air-dried sample: C, 59.25; H, 7.48; N, 11.19%. Calcd for $C_{75}H_{104}O_{15}N_{12}\cdot HCl\cdot 4H_2O$: C, 59.14; H, 7.48; N, 11.03%), HOBt (0.193 g, 1.43 mM), and WSCD·HCl (0.274 g, 1.43 mM) were stirred in anhydrous DMF–pyridine (21 ml each, dried over Molecular Sieve 4 Å, Merck & Co., #5708) for 3 d at room temperature. After removal of the solvent, the residue was dissolved in $CHCl_3$ and was washed successively with 1 M HCl, water, 0.5 M $NaHCO_3$, and water. Removal of the solvent gave a crude product, which was purified by gel filtration on a Sephadex LH-20 column (1.2×96 cm, MeOH). Reprecipitated from MeOH–ether–hexane; mp 265—269 °C (dec), Retention time on the HPLC (RT)[b] 15.68 min, 0.146 g (75%), $[\alpha]_D^{28}$ −283° (*c* 0.3, EtOH). Found: C, 62.49; H, 7.40; N, 11.63%. Calcd for $C_{75}H_{102}O_{14}N_{12}\cdot 2H_2O$: C, 62.92; H, 7.46; N, 11.74%.

Cyclo*(-Abu-Orn(Z)-Leu-D-Phe-Pro-Abu-Orn(Z)-Leu-D-Phe-Pro-) (7b).* Prepared from **6b** (0.208 g, 0.138 mM, derived from **5b**. Found in air-dried sample: C, 59.23; H, 7.36; N, 11.15%. Calcd for $C_{74}H_{102}O_{15}N_{12}\cdot HCl\cdot 4H_2O$: C, 58.89; H, 7.41; N, 11.14%) in a similar way described above. Reprecipitated from MeOH–ether–hexane; mp 256—261 °C (dec), RT^b 12.30 min, 0.160 g (82%), $[\alpha]_D^{28}$ −289° (*c* 0.3, EtOH). Found: C, 62.84; H, 7.35; N, 11.91%. Calcd for $C_{74}H_{100}O_{14}N_{12}\cdot 2H_2O$: C, 62.69; H, 7.39; N, 11.86%.

Cyclo*(-Abu-Orn-Leu-D-Phe-Pro-Val-Orn-Leu-D-Phe-Pro-)·2HCl (8a).* Compound **7a** (0.109 g) was hydrogenated over Pd black (0.047 g) in EtOH (20 ml)-AcOH (10 ml). After removal of the catalyst by filtration, 1 M HCl (4 ml) was added to the filtrate, and the solvent was evaporated to give the desired peptide. Reprecipitation from EtOH–ether, 0.093 g (93%). Mp 270—273 °C (dec), $[\alpha]_D^{27}$ −267° (*c* 0.3 EtOH). RT^c 10.10 min, RT^e 17.97 min, RT^f 25.63 min. (Natural gramicidin S-2 hydrochloride: RT^c 10.12 min, RT^e 18.05 min, RT^f 25.62 min). Amino acid composition in acid-hydrolysate (6 M HCl, 110 °C, 20 h): Pro 2.09, Abu 1.07, Val 0.98, Leu 2.04, Phe 1.94, Orn 1.89. Found: C, 54.40; H, 7.92; N, 12.80%. Calcd for $C_{59}H_{90}O_{10}N_{12}\cdot 2HCl\cdot 6H_2O$: C, 54.16; H, 8.01; N, 12.85%. Acetyl derivative; mp 265—275 °C (dec). Found: C, 59.32; H, 7.88; N, 13.13%. Calcd for $C_{63}H_{94}O_{12}N_{12}\cdot 4H_2O$: C, 58.95; H, 8.01; N, 13.09%. RT^a 13.20 min, RT^d 12.60 min. SIMS *m/z*: 1211 $(M+H)^+$. (Acetyl derivative from the natural product: RT^a 13.20 min, RT^d 12.65 min. SIMS *m/z*: 1211 $(M+H)^+$).

Cyclo*(-Abu-Orn-Leu-D-Phe-Pro-Abu-Orn-Leu-D-Phe-Pro-)·2HCl (8b).* Prepared from **7b** (0.111 g) in a similar way as described above. Reprecipitated from

EtOH–ether, 0.090 g (89%), mp 272—274 °C (dec), $[\alpha]_D^{27}$ −263° (*c* 0.3, EtOH). RT^c 7.60 min, RT^e 13.12 min, RT^f 18.30 min. (Natural gramicidin S-3 hydrochloride: RT^c 7.62 min, RT^e 13.10 min, RT^f 18.37 min). Amino acid composition: Pro 2.05, Abu 2.07, Leu 2.04, Phe 1.93, Orn, 1.91. Found: C, 53.55; H, 7.75; N, 12.89%. Calcd for $C_{58}H_{88}O_{10}N_{12}\cdot 2HCl\cdot 6H_2O$: C, 53.82; H, 7.94; N, 12.99%. Acetyl derivative; mp 274—279 °C (dec). Found: C, 58.18; H, 7.69; N, 13.05%. Calcd for $C_{62}H_{92}O_{12}N_{12}\cdot 5H_2O$: C, 57.84; H, 7.99; N, 13.05%. RT^a 10.05 min, RT^d 9.57 min. SIMS *m/z*: 1197 $(M+H)^+$. (Acetyl derivative from the natural product: RT^a 10.08 min, RT^d 9.58 min. SIMS *m/z*: 1197 $(M+H)^+$).

We are indebted to the members of the Central Research Laboratory of Meiji Seika Kaisha Ltd. for measurement of mass spectra and for assays of the activity.

4,4′,4″-Tris(levulinoyloxy)trityl as a New Type of Primary Hydroxyl Protecting Group

Mitsuo SEKINE* and Tsujiaki HATA
Department of Life Chemistry, Tokyo Institute of Technology, Nagatsuta, Midoriku, Yokohama 227
(Received August 27, 1984)

The 4,4′,4″-tris(levulinoyloxy)trityl (TLTr) group was introduced selectively on the 5′-oxygen of thymidine by use of *in situ* generated 4,4′,4″-tris(levulinoyloxy)trityl bromide. The TLTr group was found to be sufficiently stable to acids and readily removed by hydrazinolysis followed by warming to 50 °C in pyridine–acetic acid without damage of other protecting groups such as the *O*-acetyl and 4,4′-dimethoxytrityl groups. The utility of this new protecting group was demonstrated by the successful synthesis of thymidylyl(3′—5′)-thymidine where the TLTr group was employed as the 5′-hydroxyl-protecting group.

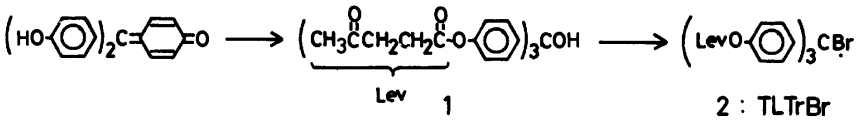
For synthetic work on polyfunctional natural products, a protecting group, which is removed under as mild conditions as possible, has often been required. Among a wide variety of unblocking agents reported, hydrazine has proved to be accessible in nucleotide chemistry.[1-4] Letsinger[1a] first reported β-benzoylpropionyl as a hydrazine-lable hydroxyl blocking group. Later, van Boom[2a] described levulinoyl as a more easily removable group. Very recently, Ogilvie[3] reported the use of the latter for protection of the exo amino groups of nucleosides. Matteucci[4] and we[5] also communicated dialkylamidines and phthaloyl, respectively, as hydrazine-labile blockers for the deoxyadenosine N^6-amino function.

We have found that the 4,4′,4″-tris(benzoyloxy)trityl (TBTr) group was rather stable to acids but yet susceptible to cleavage under alkaline conditions.[6] This hydrolytic cleavage was explained as the result of alkali-mediated elimination of rosolic acid from a 4,4′,4″-trihydroxytrityl ether initially formed. If the 4,4′,4″-trihydroxytrityl group could be removed under certain nonbasic conditions, we could choose various substituents capable of hydrolysis under mild conditions to design new "protected" protecting groups which satisfied the above mentioned stipulation.

Therefore, we have studied levulinoyloxy-substituted trityl as hydrazine-labile protecting groups. First, 4,4′,4″-tris(levulinoyloxy)tritanol (**1**) was prepared in 43% yield by levulination of rosolic acid. The tritanol was then converted to the trityl bromide (**2**) by treatment with acetyl bromide. This new reagent underwent facile 5′-*O*-tritylation with thymidine (**3**) in pyridine giving rise to the product (**4**) in 81% yield. Treatment of **4** with 80% acetic acid showed that the 4,4′,4″-tris(levulinoyloxy)trityl (TLTr) group had the same stability as the TBTr group ($T_{1/2}$=1 d, T_{com}=5 d).[6] On the other hand, hydrazinolysis of **4** with 1 M† H_2NNH_2 in hydrazine–acetic acid (3:2, v/v) at room temperature for 3 min gave quantitatively 5′-*O*-(4,4′,4″-trihydroxytrityl)thymidine (**5**). The latter was rapidly converted to **3** and rosolic acid by treatment with 80% acetic acid. Since our ultimate aim was to convert **5** to **3** under essentially neutral conditions, several experiments have been conducted. Some attempts to cleave the $(HO)_3Tr$–O ether bond of **5** oxidatively by using various metal salts[7] involving $FeCl_3$ and $CuCl_2$ have failed. Although **5** was expected to be decomposed to thymidine by passing it slowly through a silica-gel column, elution with CH_2Cl_2–MeOH gave a 80% recovery of **5** and a small amount (10%) of **3**. The final goal to conversion of **5** to **3** was achieved in pyridine–acetic acid (1:2, v/v) at 50 °C for 30 min. The hydrazine reaction of **4** followed by extraction and then warming in pyridine–acetic acid resulted in quantitative formation of **3**.

In order to see if the TLTr group can be used in the presence of other acid- or alkali-labile protecting groups, the syntheses of 3′-*O*-acetylthymidine (**6**) and 3′-*O*-(4,4′-dimethoxytrityl)thymidine (**7**) were conducted. Acetylation of **4** followed by unblocking of the TLTr group gave an 87% overall yield of **6**. Similarly, **7**, was obtained in 94% yield from **4**. The conditions for removal of the TLTr group described here proved to be very mild because the DMTr and acetyl groups were virtually stable.

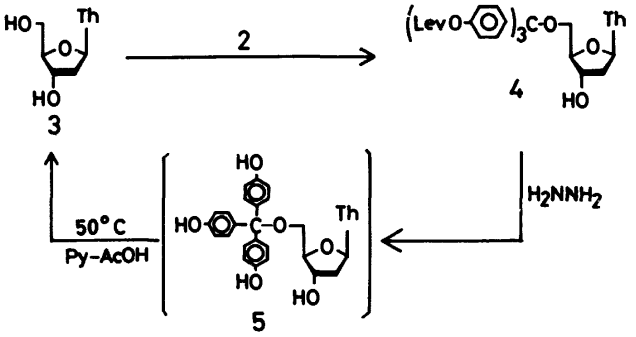
Furthermore, to demonstrate the synthetic utility of the TLTr group, we tried to synthesize thymidylyl-(3′—5′)-thymidine 3′-phosphate (TpTp) by using this new hydroxyl-protecting group. Phosphorylation of **4** with cyclohexylammonium *S,S*-diphenyl phosphorodithioate (**8**)[8] in the presence of mesitylenedisulfonyl chloride (MDS)[9] gave the 3′-phosphorylated product



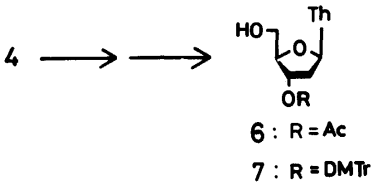
Scheme 1.

(**9**) in 86% yield. A similar hydrazinolysis of **9** and successive workup gave *S,S*-diphenyl thymidine 3'-phosphorodithioate (**10**) in 86% yield. The base-labile bis(phenylthio)phosphoryl group was found to be stable during these treatments. On the other hand, treatment of **9** with 3.3 M pyridinium phosphinate,[10,11] in pyridine resulted in quantitaive formation of Triethylammonium *S*-phenyl 5'-*O*-tris(levulinoyloxy)trityl]thymidine 3'-phosphorothioate (**11**). Upon this treatment, the TLTr group remained also intact. Condensation of **10** with **11** in the presence of MDS and 3-nitro-1,2,4-triazole (NT)[12] gave the dimer (**12**) in 82% yield. Treatment of **12** with AgOAc[5,13] in aqueous pyridine followed by ammonia gave TpTp in 91% yield.

Since the skeleton of the TLTr group is derived from a dye of rosolic acid, compounds containing the TLTr group can be readily detected as distinct orange spots upon heating TLC plates.



Scheme 2.



Scheme 3.

We have also examined the 9-[(4-levulinoyloxy)-phenyl]-9-xanthenyl and 4-dimethylamino-4',4''-bis(levulinoyloxy)trityl groups as the possible hydrazine-labile protecting groups. However, the former was found to be too unstable during silica-gel column chromatography, and the latter was stable on silica gel but the corresponding hydroxyl-substituted xanthenyl group resulted from the hydrazine treatment was resistant to the pyridine–acetic acid treatment even at 60 °C.

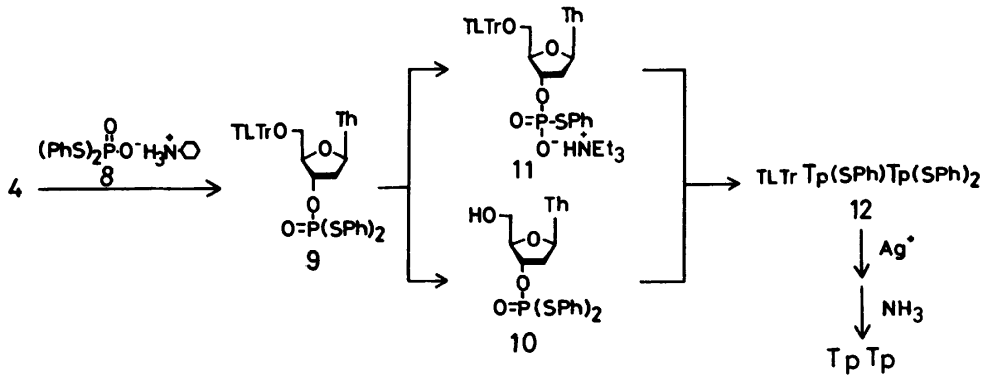
In conclusion, the TLTr group can be selectively introduced into a primary hydroxyl as an easily detectable group and used substantially as an equivalent of the levulinoyl group.

Experimental

^{1}H NMR spectra were recorded at 100 MHz on a JEOL JNM PS-100 spectrometer using tetramethylsilane as an internal standard. Column chromatography was performed with silica gel C-200 purchased from Wako Co. Ltd., and a mini pump for a goldfish basin was conveniently used to gain a medium pressure for rapid chromatographic separation. Rosolic acid and the other regents were purchased from Wako Co. Ltd.

4,4',4''-Tris(levlinoyloxy)tritanol (1). To a mixture of rosolic acid (29 g, 0.1 mol) and levulinic acid (23.2 g, 0.2 mol) in pyridine was added dicyclohexylcarbodiimide (41.2 g, 0.2 mol). After the solution was stirred for 2 h, water (1.8 ml) was added to hydrolyze the quinomethane initially formed to 4-hydroxy-4',4''-bis(levulinoyloxy)tritanol. After being stirred at 55 °C for 50 min, the solution was dried over powdered molecular sieves 3A (23 g) for 20 min and treated with levulinic acid (23.2 g, 0.2 mol) and dicyclohexylcarbodiimide (41.2 g, 0.2 mol) for 3 h. The mixture was quenched with water, filtered, extracted with CH_2Cl_2, dried over Na_2SO_4, and chromatographed on a silica-gel column with CH_2Cl_2 to yield **1** (26 g, 43%) as an oily material which gradually solidified upon standing: ^{1}H NMR ($CDCl_3$) δ=2.20 (s, 9H, $CH_3C(O)$), 2.81 (s, 12H, CH_2), 3.58 (br, 1H, OH), 6.93 (d, 6H, J=8.6 Hz, ArH), 7.22 (d, 6H, J=8.0 Hz, ArH). Calcd for $C_{34}H_{34}O_{10}$: C, 67.77; H, 5.69. Found: C, 67.82; H, 5.81.

5'-O-[4,4',4''-tris(levulinoyloxyl)trityl]thymidine (4). To a solution of **1** (5.0 g, 8.3 mmol) in benzene (28 ml) was added acetyl bromide (3.9 ml, 53 mmol). The mixture was



Scheme 4.

refluxed for 15 min, and then the benzene and excess reagent were removed by evaporation. The residue was coevaporated three times with dry benzene under reduced pressure and finally dissolved in pyridine (30 ml). This solution was added to **3** (1.34 g, 5.5 mmol) predried by repeated coevaporations with dry pyridine. The resulting solution was stirred for 10 h and then water was added. Extraction with CH_2Cl_2 followed by chromatography on silica gel gave **4** (3.7 g, 81%) as foam: ^1H NMR ($CDCl_3$) δ=1.61 (s, 3H, CH_3), 1.33 (m, 2H, 2'-H), 3.22 (m, 2H, 5'-H), 3.78 (s, 3H, CH-O), 4.01 (m, 1H, 4'-H), 4.40 (m, 1H, 3'-H), 5.03 (d, 1H, J=4 Hz, OH), 6.42 (t, 1H, J=7 Hz, 1'-H), 6.83 (d, 2H, J=5.2 Hz, ArH), 7.00—7.52 (m, 10H, ArH), 7.66 (s, 1H, 6-H), 10.71 (br, 1H, NH). Calcd for $C_{44}H_{46}O_{14}N_2$: C, 63.92; H, 5.61; N, 3.39. Found: C, 63.76; H, 5.48; N, 3.24.

3'-O-Acetylthymidine (6). To a solution of **4** (414 mg, 0.5 mmol) in dry pyridine (5 ml) was added acetic anhydride (1 ml). After being stirred for 3 h, the solution was quenched with water and extracted with CH_2Cl_2 (3×20 ml). The combined extracts were dried over Na_2SO_4, concentrated to dryness, and the residue was dissolved in 1 M H_2NNH_2 in pyridine–acetic acid (3:2, v/v, 7.5 ml). The same workup as described in the synthesis of **10** gave **6** (123 mg, 87%). This compound was identified with an authentic sample by comparison of their ^1H NMR spectra.

3'-O-(4,4'-Dimethoxytrityl)thymidine (7). To a solution of **4** (414 mg, 0.5 mmol) in dry pyridine (5 ml) was added 4,4'-dimethoxytrityl chloride (339 mg, 1 mmol). The mixture was kept at 70 °C for 4 h. Then, the same workup as described in the synthesis of **10** gave **7** (255 mg, 94%). This compound was identified with an authentic sample by comparison of their ^1H NMR spectra.

S,S-*Diphenyl 5'-O-[4,4',4''-tris(levulinoyloxy)trityl]thymidine 3'-Phosphorodithioate (9).* A mixture of **4** (3.26 g, 3.94 mmol) and **8** (1.81 g, 4.73 mmol) were rendered anhydrous by repeated evaporations with dry pyridine (2×5 ml) and finally dissolved in dry pyridine (20 ml). MDS (1.88 g, 5.92 mmol) was added to the solution and the mixture was stirred for 30 min. The solution was diluted with CH_2Cl_2 and washed with water and 5% $NaHCO_3$. The usual workup followed by chromatography gave **9** (4.06 g, 94%): ^1H NMR ($CDCl_3$) δ=2.22 (s, 9H, $CH_3C(O)$), 2.30 (m, 2H, 2'-H), 2.82 (s, 12H, CH_2), 3.28 (m, 2H, 5'-H), 4.01 (m, 1H, 4'-H), 5.25 (m, 1H, 3'-H), 6.23 (t, 1H, J=7.5 Hz, 1'-H), 6.95 (d, 6H, J=8.5 Hz, ArH), 7.28 (d, 6H, J=8.5 Hz, ArH), 7.15—7.62 (m, 11H, ArH and 5-H), 8.47 (br, 1H, NH). Calcd for $C_{56}H_{55}O_{15}N_2PS_2$: C, 61.64; H, 5.08; N, 2.57. Found: C, 61.53; H, 5.21; N, 2.44.

S,S-*Diphenyl Thymidine 3'-Phosphorodithioate (10).* Compound **9** (546 mg, 1 mmol) was dissolved with stirring in 1 M H_2NNH_2 in pyridine–acetic acid (3:2, v/v, 15 ml). After being kept for 3 min, the solution was diluted with CH_2Cl_2 and washed with water and 5% $NaHCO_3$. The CH_2Cl_2 extract was dried over Na_2SO_4, filtered, and evaporated to dryness under reduced pressure. The residue was dissolved in pyridine–acetic acid (1:2, v/v, 15 ml) and the solution was warmed at 50 °C for 30 min. At this time the TLTr group was completely removed. The solution was extracted with CH_2Cl_2 and washed with water and 5% $NaHCO_3$. After filtration the solvent was removed under reduced pressure, and the residue was chromatographed on a silica gel to yield **10** (218 mg, 86%). This compound was identified with an authentic sample by comparison of their ^1H NMR spectra.

Synthesis of Dimer 12. Compound **9** (262 mg, 0.24 mmol) was treated with a mixture of 5 M phosphinic acid in pyridine (2.4 ml) and triethylamine (1.2 ml) at room temperature for 30 min. At this time one of the two phenylthio group was removed completely. The mixture was diluted with CH_2Cl_2 and washed with water and 0.2 M triethylammonium hydrogencarbonate (10 ml). The CH_2Cl_2 extract was dried over Na_2SO_4, filtered, and evaporated to dryness under reduced presure. The residue was mixed with **10** (253 mg, 0.2 mmol) and 3-nitro-1,2,4-triazole (82 mg, 0.72 mmol), and rendered anhydrous by evaporation with dry pyridine (3×5 ml). The mixture was dissolved in dry pyridine (2 ml) and MDS (228 mg, 0.72 mmol) was added. After being stirred for 30 min, the solution was worked up as descrived in the case of **9**. Chromatography yielded **12** (244 mg, 82%).

Full Deprotection of 12. Compound **12** (58 mg, 0.04 mmol) was dissolved in a solution of silver acetate (668 mg, 4 mmol) in pyridine–water (2:1, v/v, 4 ml) and the solution was stirred at 50 °C for 9 h. The resulting solution was diluted with pyridine-water (2:1, v/v, 40 ml). Then, hydrogen sulfide gas was bubbled into the solution at 0 °C until a clear supernatant had been obtained. The excess gas was removed under reduced pressure with stirring and the solution was centrifuged to remove the precipitate. The supernatant was evaporated to dryness under reduced pressure and dissolved in pyridine (5 ml). Concentrated aqueous ammonia (45 ml) was added and the solution was kept with stirring at 50 °C for 4 h. Then, the excess ammonia was evaporated with stirring by an aspirator and rosolic acid was removed by extraction with CH_2Cl_2. The aqueous layer was concentrated under reduced pressure and the residue was chromatographed on Whatman 3 MM papers developed with 2-propanol-concentrated ammonia–water (6:1:3, v/v/v). A band at R_f 0.2 was cut and eluted with water to give TpTp (630 OD, 91%). This product (20 OD) was incubated with spleen phosphodiesterase (10 μg, Boehringer) in a mixture of 0.05 M ammonium acetate (pH 6.5, 0.4 ml) and 0.01 M pyrophosphate buffer (pH 6.5, 0.2 ml) for 10 h gave only Tp (21 OD).

This work was supported by a Grant-in-Aid form the Ministry of Education, Science and Culture of Japan.

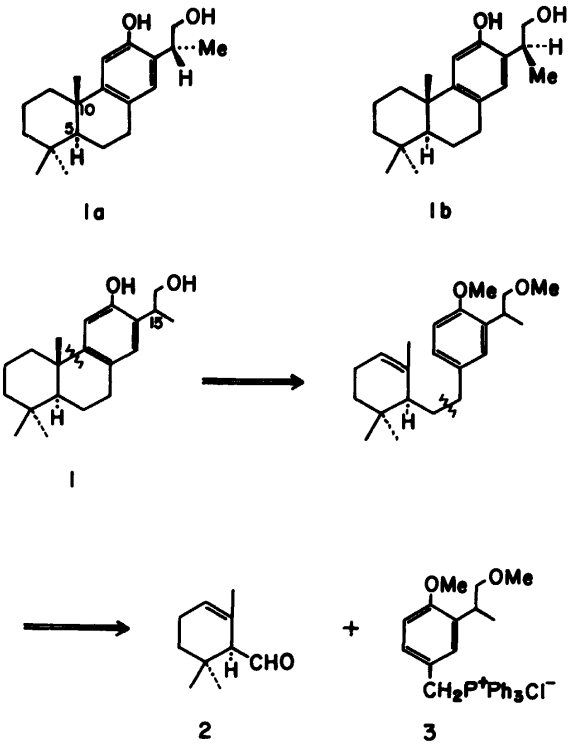
The Total Synthesis of (15*R*)- and (15*S*)-16-Hydroxyferruginol

Takashi MATSUMOTO,* Sachihiko IMAI, Shigekazu MIUCHI, and Hidenori SUGIBAYASHI
Department of Chemistry, Faculty of Science, Hiroshima University, Higashisenda-machi, Naka-ku, Hiroshima 730
(Received August 27, 1984)

In order to assign the absolute configuration of C-15 in natural 16-hydroxyferruginol, (5*S*,10*S*,15*R*)- (**1a**) and (5*S*,10*S*,15*S*)-8,11,13-abietatriene-12,16-diol (**1b**) have been synthesized. Optical resolution of 2-(2-methoxyphenyl)propanoic acid, prepared from methyl (2-methoxyphenyl)acetate, with cinchonidine afforded (*R*)- and (*S*)-enantiomers, which were converted into [(*R*)-4-methoxy-3-(2-methoxy-1-methylethyl)benzyl]triphenylphosphonium chloride (**3a**) and its (*S*)-isomer (**3b**) respectively. The Wittig reaction of (*R*)-(−)-α-cyclocitral with **3a**, followed by partial catalytic hydrogenation and intramolecular cyclization gave (5*S*,10*S*,15*R*)-12,16-dimethoxy-8,11,13-abietatriene (**16a**) together with its (5*S*,10*R*,15*R*)-isomer. Similarly, **3b** was also converted into (5*S*,10*S*,15*S*)-12,16-dimethoxy-8,11,13-abietatriene (**16b**) and its (5*S*,10*R*,15*S*)-isomer. Demethylation of **16a** gave **1a** which was identical with natural 16-hydroxyferruginol. The dimethoxy compound **16b** was also demethylated to give **1b**.

16-Hydroxyferruginol (**1**), a new tricyclic diterpene phenol possessing an abietane skeleton, has recently been isolated from the seed of *Thujopsis dolabrata* Sieb. et Zucc. var. *dolabrata* by Hasegawa and Hirose.[1] The structure **1** was elucidated by spectroscopic studies and by chemical transformation to the known (+)-ferruginol methyl ether. However, the absolute configuration at C-15 remained unsettled. In order to elucidate the unknown stereochemistry at C-15, we have attempted the total syntheses of (15*R*)-(**1a**) and (15*S*)-16-hydroxyferruginol (**1b**). The synthetic strategy was developed from the retrosynthetic analysis of the natural product (**1**), which involved the disconnection illustrated in Scheme 1.



Scheme 1.

First, the optically active [4-methoxy-3-(2-methoxy-1-methylethyl)benzyl]triphenylphosphonium chloride (**3**) was prepared starting from methyl (2-methoxyphenyl)acetate (**4**) in the following manner. Methylation of **4** with methyl iodide in hexamethylphosphoric triamide and tetrahydrofuran in the presence of potassium *t*-butoxide afforded methyl 2-(2-methoxyphenyl)propanoate (**5**) which was hydrolyzed with aqueous sodium hydroxide in refluxing methanol to give the corresponding racemic acid (**6**). The racemic acid **6** was then resolved by means of cinchonidine to give (-)-acid (**6a**) and (+)-acid (**6b**), which were methylated with diazomethane to give the methyl esters, **5a** and **5b** respectively. Reduction of **5a** and **5b** with lithium aluminium hydride gave the corresponding alcohols, **7a** and **7b**. The absolute configurations of **7a** and **7b** were determined by the following correlation. Acetylation of **7a** with acetic anhydride in pyridine, followed by demethylation of the resulting acetate (**8a**) with anhydrous aluminium chloride and ethanethiol[2] in dichloromethane, afforded the phenolic compound (**9a**). This was then submitted to ozonization and the resulting acid was methylated with diazomethane to give the known methyl (*S*)-(+)-3-acetoxy-2-methylpropanoate[3] (**10a**). Similarly, the alcohol **7b** was correlated to methyl (*R*)-(−)-3-acetoxy-2-methylpropanoate (**10b**) *via* the corresponding acetate (**8b**) and phenol (**9b**). Thus, the absolute configurations of **7a** and **7b** were assigned to *R* and *S* respectively. The alcohols, **7a** and **7b**, were methylated respectively with methyl iodide and sodium hydride in 1,2-dimethoxyethane to give the dimethoxy compounds, **11a** and **11b**. Chloromethylation of **11a** with chloromethyl methyl ether in acetic acid, followed by treatment of the resulting benzyl chloride derivative (**12a**) with triphenylphosphine in refluxing benzene produced the desired [(*R*)-4-methoxy-3-(2-methoxy-1-methylethyl)benzyl]triphenylphosphonium chloride (**3a**). The

dimethoxy compound **11b** was also converted into the corresponding (*S*)-isomer (**3b**) *via* the benzyl chloride derivative (**12b**).

The Wittig reaction of (*R*)-(−)-α-cyclocitral (**2**)[4,5] with **3a** in benzene in the presence of butyllithium gave 6-[4-methoxy-3-(2-methoxy-1-methylethyl)styryl] -1,5,5-trimethylcyclohexene (**13a**) in 56.1% yield. The ^{1}H NMR spectrum of **13a** showed signals at δ 5.76 (double doublet, J=8.5 and 15 Hz) and 6.25 (doublet, J=15 Hz) due to the newly formed olefinic protons. These vicinal coupling constants (J=15 Hz) suggested the presence of a *trans*-disubstituted double bond in **13a**. The compound **13a** in ethanol was submitted to partial catalytic hydrogenation over Pd-C to afford the corresponding phenethyl derivative (**14a**: 94.1%). The intramolecular cyclization of **14a** with anhydrous aluminium chloride in benzene afforded (5*S*, 10*S*, 15*R*)-12,16-dimethoxy-8,11,13-abietatriene (**16a**: 49.0%) $[\alpha]_D$ +35.0° ($CHCl_3$) and its (5*S*,10*R*,15*R*)-isomer (**15a**: 35.3%). The *cis*-configuration of the A/B ring junction in **15a** was supported by its ^{1}H NMR spectrum which showed a signal due to the $C_{4\beta}$-methyl group at high field (δ 0.48) owing to the shielding effect of the aromatic C-ring. The Wittig reaction of **2** with **3b**, followed by partial catalytic hydrogenation of the resulting styryl derivative (**13b**: 54.9%) afforded the phenethyl derivative (**14b**: 89.4%). The intramolecular

cyclization of **14b** with anhydrous aluminium chloride produced (5*S*,10*S*,15*S*)-12,16-dimethoxy-8,11,13-abietatriene (**16b**: 50.8%) $[\alpha]_D$ +60.4° ($CHCl_3$) together with its (5*S*,10*R*,15*S*)-isomer (**15b**: 40.5%). In order to increase the optical purity, the cyclization products (**16a** and **16b**) were oxidized with Jones reagent to give the crystalline 7-oxo derivatives, **17a** and **17b**. After recrystallization, **17a** and **17b** were converted into **16a** $[\alpha]_D$ +46.7° ($CHCl_3$) and **16b** $[\alpha]_D$ +68.7° ($CHCl_3$) by catalytic hydrogenation over Pd-C in the presence of perchloric acid. Demethylation of **16a** in dichloromethane with anhydrous aluminium chloride and sodium iodide in acetonitrile[6] at 35—40 °C under a stream of nitrogen afforded (5*S*,10*S*,15*R*)-8,11,13-abietatriene-12,16-diol (**1a**: 95.7%), mp 141—142.5 °C, $[\alpha]_D$ +65.7° ($CHCl_3$), which was identical with natural 16-hydroxyferruginol (lit,[1] mp 141—142 °C, $[\alpha]_D$ +36.6° ($CHCl_3$)). Similarly, the dimethoxy compound **16b** was also demethylated to give (5*S*,10*S*,15*S*)-8,11,13-abietatriene-12,16-diol (**1b**: 95.5%), mp 178—179 °C, $[\alpha]_D$ +44.6° ($CHCl_3$). Acetylation of **1a** and **1b** with acetic anhydride in pyridine gave the corresponding diacetates, **18a** and **18b**. Since the optical rotation value of the synthetic **1a** was somewhat larger than that reported for the natural product, the absolute configurations at C-5 and C-10 in **1a** and **1b** were subsequently confirmed by the following conversion. Methylation of **1a** with methyl iodide and anhydrous potassium carbonate in refluxing ethyl methyl ketone yielded 12-methoxy-8,11,13-abietatrien-16-ol (**19a**), which was converted into a tosylate[1] (**20a**). Reduction of **20a** with lithium aluminium hydride in ether afforded (+)-ferruginol methyl ether (**21**) $[\alpha]_D$ +63.3° ($CHCl_3$) (lit,[7] $[\alpha]_D$ +63.1° ($CHCl_3$)). The diol **1b** was also converted into **21** *via* the corresponding methyl ether (**19b**) and tosylate (**20b**).

From the above synthesis the absolute configuration of natural 16-hydroxyferruginol was conclusively assigned as 5*S*, 10*S*, 15*R*.

Experimental

All melting points are uncorrected. The IR spectra and optical rotations were measured in chloroform, and the ^1H NMR spectra in carbon tetrachloride at 60 MHz, with tetramethylsilane as an internal standard, unless otherwise stated; s: singlet, bs: broad singlet, d: doublet, dd: double doublet, m: multiplet. The column chromatography was performed using Merck silica gel (0.063 mm).

Methyl (±)-2-(2-Methoxyphenyl)propanoate (5). (2-Methoxyphenyl)acetic acid in ether was methylated with diazomethane to give a methyl ester (**4**).

To a solution of **4** (25.00 g) and hexamethylphosphoric triamide (25.0 ml) in dry tetrahydrofuran (300 ml) under a stream of nitrogen at −40—−30 °C was added potassium *t*-butoxide (15.57 g) over a 5 min period and then methyl iodide (8.70 ml) over a 20 min period. The mixture was stirred at −40—−30 °C for 30 min, poured into dilute hydrochloric acid, and extracted with ether. The ether extract was washed successively with aqueous sodium thiosulfate and brine, dried over sodium sulfate, and evaporated *in vacuo*. The residue was chromatographed on silica gel (300 g), using benzene as eluent, to give **5** (24.31 g: 93.7%). Found: C, 67.73; H, 7.36%. Calcd for $C_{11}H_{14}O_3$: C, 68.02; H, 7.27%.

(±)-2-(2-Methoxyphenyl)propanoic Acid (6). A mixture of **5** (2.58 g) and aqueous sodium hydroxide (20%: 4.8 ml) in methanol (20 ml) was refluxed for 1.5 h. After the methanol had been evaporated *in vacuo*, the residue was diluted with water, and then washed with ether. The alkaline solution was acidified with dilute hydrochloric acid and extracted with ether. The ether extract was washed with brine, dried over sodium sulfate, and evaporated *in vacuo* to give **6** (2.23 g: 93.1%) as a solid. This was recrystallized from acetone–petroleum benzine, mp 101—102 °C. Found: C, 66.39; H, 6.65%. Calcd for $C_{10}H_{12}O_3$: C, 66.65; H, 6.71%.

Resolution of (±)-6. A mixture of (±)-**6** (34.69 g) and cinchonidine (56.68 g) in ethyl acetate (1000 ml) was refluxed for 20 h. The solution was concentrated, allowed to stand at room temperature, and then filtered to give colorless crystals. This was recrystallized from ethyl acetate to give a cinchonidine salt (35.72 g), mp 106—111 °C, $[\alpha]_D$ −46.1°.

The above cinchonidine salt was suspended in dilute hydrochloric acid and extracted with ether. The ether extract was washed with brine, dried over sodium sulfate, and then evaporated to dryness. The residue was recrystallized from acetone–petroleum benzine to give (*S*)-(+)-2-(2-methoxyphenyl)propanoic acid (**6b**) (9.87 g), mp 94—96 °C, $[\alpha]_D$ +62.7° (*c* 2.32). Found: C, 66.65; H, 6.81%. Calcd for $C_{10}H_{12}O_3$: C, 66.65; H, 6.71%.

The mother liquor from the above recrystallization of the cinchonidine salt was evaporated *in vacuo*. The residue was suspended in dilute hydrochloric acid and extracted with ether. The ether extract was washed with brine, dried over sodium sulfate, and evaporated *in vacuo*. The residue was recrystallized from acetone–petroleum benzine to give (*R*)-(−)-2-(2-methoxyphenyl)propanoic acid (**6a**) (8.91 g), mp 94—96°C, $[\alpha]_D$ −67.8° (*c* 2.62). Found: C, 66.63; H, 6.84%. Calcd for $C_{10}H_{12}O_3$: C, 66.65; H, 6.71%.

(R)-(−)-2-(2-Methoxyphenyl)-1-propanol (7a) and Its (S)-(+)-Isomer (7b). *a)*: **6a** (8.914 g) was methylated with a solution of diazomethane in ether. After the usual work-up, the crude product was chromatographed on silica gel (200 g), using benzene as eluent, to give (*R*)-(−)-ester (**5a**) (8.791 g: 91.6%), $[\alpha]_D$ −69.4° (*c* 3.35).

A solution of **5a** (7.959 g) in dry ether (50 ml) was added dropwise to a stirred suspension of lithium aluminium hydride (1.436 g) in dry ether (80 ml) with cooling in an ice-water bath over a 15 min period. The mixture was stirred at room temperature for 1.5 h, poured into a mixture of ice and dilute hydrochloric acid, and extracted with ether. The ether extract was washed with brine, dried over sodium sulfate, and evaporated *in vacuo*. The residue was chromatographed on silica gel (50 g), using ether–benzene (1:9) as eluent, to give **7a** (6.530 g: 95.7%), $[\alpha]_D$ −6.1° (*c* 17.9).

b): **6b** (9.870 g) was methylated with diazomethane in ether to give (*S*)-(+)-ester (**5b**) (10.594 g: 99.6%), $[\alpha]_D$ +65.2° (*c* 4.68).

A solution of **5b** (11.915 g) in dry ether (50 ml) was reduced with lithium aluminium hydride (2.333 g) in dry ether (150 ml) to give **7b** (9.939 g: 97.5%), $[\alpha]_D$ +6.5° (*c* 18.8).

(R)-(−)-1-Acetoxy-2-(2-hydroxyphenyl)propane (9a) and Its

(S)-(+)-Isomer (9b). *a)*: A mixture of **7a** (659 mg) and acetic anhydride (2.0 ml) in pyridine (3.0 ml) was heated at 80—85 °C for 1.5 h. After the usual work-up, the crude product was chromatographed on silica gel (15 g), using benzene as eluent, to give (*R*)-(−)-acetate (**8a**) (695 mg: 84.2%), $[\alpha]_D$ −20.2° (*c* 3.92). Found: C, 69.01; H, 7.69%. Calcd for $C_{12}H_{16}O_3$: C, 69.21; H, 7.74%.

Anhydrous aluminium chloride (2.40 g) was added to a stirred solution of **8a** (620 mg) and ethanethiol (1.5 ml) in dichloromethane (7.0 ml) at 5—10 °C. The mixture was stirred at room temperature for 1 h, poured into a mixture of ice and dilute hydrochloric acid, and extracted with ether. The ether extract was washed with brine, dried over sodium sulfate, and evaporated *in vacuo*. The residue was chromatographed on silica gel (15 g), using ether–benzene (2:98) as eluent, to give **9a** (566 mg: 97.9%), $[\alpha]_D$ −11.6° (*c* 5.08).

b): **7b** (612 mg) was acetylated with acetic anhydride (1.5 ml) in pyridine (3.0 ml) to give (*S*)-(+)-acetate (**8b**) (652 mg: 85.0%), $[\alpha]_D$ +21.0° (*c* 9.72). Found: C, 68.91; H, 7.58%. Calcd for $C_{12}H_{16}O_3$: C, 69.21; H, 7.74%.

8b (647 mg) was demethylated with anhydrous aluminium chloride (2.481 g) and ethanethiol (2.3 ml) in dichloromethane (7.0 ml) to give **9b** (523 mg: 86.6%), $[\alpha]_D$ +12.4° (*c* 3.96).

Ozonization of 9a and 9b. *a)*: A solution of **9a** (523 mg) in methanol (20 ml) was ozonized at −20—−10 °C for 4 h. The solution was evaporated *in vacuo* and the residue was methylated with diazomethane in ether. The ether solution was washed successively with dilute hydrochloric acid and brine, dried over sodium sulfate, and evaporated. The residue was chromatographed on silica gel (15 g), using hexane–chloroform (3:7) as eluent, to give an ester (**10a**) (155 mg: 36.5%), $[\alpha]_D$ +14.9° (*c* 4.16), whose IR and ^{1}H NMR spectra were identical with those of methyl (*S*)-(+)-3-acetoxy-2-methylpropanoate.[3]

b): Ozonization of **9b** (523 mg) in methanol (20 ml), followed by esterification with diazomethane yielded methyl (*R*)-(−)-3-acetoxy-2-methylpropanoate (**10b**) (244 mg: 56.6%), $[\alpha]_D$ −15.2° (*c* 4.54).

(R)-(−)-1-Methoxy-2-(2-methoxyphenyl)propane (11a) and Its (S)-(+)-Isomer (11b). *a)*: A mixture of **7a** (6.530 g) and methyl iodide (3.3 ml) in 1,2-dimethoxyethane (20 ml) was added to a stirred suspension of sodium hydride (55%: 1.900 g) in 1,2-dimethoxyethane (20 ml) with cooling in an ice–water bath over a 35 min period. The mixture was stirred at room temperature for 2 h. After the addition of methanol, the mixture was poured into ice–dilute hydrochloric acid, and extracted with ether. The ether extract was washed successively with aqueous sodium thiosulfate and brine, dried over sodium sulfate, and evaporated *in vacuo*. The residue was chromatographed on silica gel (50 g: Merck 0.063—0.200 mm), using benzene as eluent, to give **11a** (6.726 g: 95.0%), $[\alpha]_D$ −29.8° (*c* 12.5).

b): The alcohol **7b** (9.939 g) was similarly methylated with methyl iodide (4.9 ml) and sodium hydride (55%: 2.890 g) in 1,2-dimethoxyethane (55 ml) to give **11b** (10.287 g: 95.5%), $[\alpha]_D$ +27.6° (*c* 10.6).

(R)-4-Methoxy-3-(2-methoxy-1-methylethyl)benzyl Chloride (12a) and Its (S)-Isomer (12b). *a)*: A round-bottomed flask containing a solution of **11a** (4.00 g) and chloromethyl methyl ether (2.8 ml) in acetic acid (4.0 ml) was fitted with a rubber stopper and then heated at 35—40 °C for 6 h. The mixture was cooled, poured into ice–aqueous sodium hydrogencarbonate, and extracted with ether. The ether extract was washed with brine, dried over sodium sulfate, and evaporated *in vacuo* to give the crude **12a** (5.00 g). This was used without purification in the next reaction. ^{1}H NMR: δ=1.21 (3H, d, J=7 Hz, $-\overset{|}{C}HCH_3$), 3.25 (3H, s, $-OCH_3$), 3.73 (3H, s, $-OCH_3$), 4.42 (2H, s, $-CH_2Cl$).

b): A solution of **11b** (5.00 g) and chloromethyl methyl ether (3.5 ml) in acetic acid (5.0 ml) was treated as described in *a)* to give the crude **12b** (5.90 g). This was used without purification in the next reaction.

[(R)-4-Methoxy-3-(2-methoxy-1-methylethyl)benzyl]triphenylphosphonium Chloride (3a) and Its (S)-Isomer (3b). *a)*: A mixture of **12a** (5.00 g) and triphenylphosphine (5.73 g) in dry benzene (5.0 ml) was refluxed for 1 h and then cooled. The precipitates were collected by filtration and washed with dry benzene to give the crude **3a** (10.29 g), mp 175—185 °C. This was used without purification in the next reaction.

b): A mixture of **12b** (5.90 g) and triphenylphosphine (6.77 g) in dry benzene (6.0 ml) was refluxed for 1.5 h and then treated as described in *a)* to give the crude **3b** (11.92 g), mp 176—186 °C. This was used without purification in the next reaction.

The Wittig Reaction of (R)-(−)-α-Cyclocitral with 3a and 3b. *a)*: A solution of butyllithium in hexane (15%: 4.0 ml) was added at 10—20 °C to a stirred suspension of **3a** (2.500 g) in dry benzene (15 ml) under a stream of nitrogen. The mixture was stirred at room temperature for 15 min and a solution of (*R*)-(−)-α-cyclocitral (**2**) (0.485 g) in dry benzene (2.5 ml) was added at 10—20 °C. After stirring at room temperature for 1.5 h, the reaction mixture was poured into dilute hydrochloric acid, and extracted with ether. The ether extract was washed with brine, dried over sodium sulfate, and evaporated *in vacuo*. The residue was triturated with hexane and the precipitated triphenylphosphine oxide was removed by filtration. The filtrate was evaporated and the residue was chromatographed on silica gel (30 g), using ether–hexane (2:98) as eluent, to give 6-[4-methoxy-3-(2-methoxy-1-methylethyl)styryl]-1,5,5-trimethylcyclohexene (**13a**) (0.583 g: 56.1%), $[\alpha]_D$ −316° (*c* 0.31); ^{1}H NMR: δ=0.89 (3H, s) and 0.95 (3H, s) ($-\overset{|}{C}(CH_3)_2$), 1.23 (3H, d, J=7 Hz, $-\overset{|}{C}HCH_3$), 1.63 (3H, bs, $=\overset{|}{C}CH_3$), 3.28 (3H, s) and 3.79 (3H, s) ($2-OCH_3$), 5.40 (1H, br, $-CH=\overset{|}{C}-$), 5.76 (1H, dd, J=8.5 and 15 Hz, $-\overset{|}{C}HCH=CH-$), 6.25 (1H, d, J=15 Hz, $-\overset{|}{C}HCH=CH-$).

b): A solution of butyllithium in hexane (15%: 88.0 ml) was added at 10—20 °C to a stirred suspension of **3b** (48.0 g) in dry benzene (250 ml) under a stream of nitrogen. The mixture was stirred for 5 min and a solution of **2** (9.31 g) in dry benzene (50 ml) was added at 10—20 °C. After stirring at room temperature for 1.5 h, the mixture was treated as described in *a)* to give the styryl derivative (**13b**) (11.0 g: 54.9%), $[\alpha]_D$ −287° (*c* 0.53). ^{1}H NMR: δ=0.89 (3H, s) and 0.95 (3H, s) ($-\overset{|}{C}(CH_3)_2$), 1.25 (3H, d, J=7 Hz, $-\overset{|}{C}HCH_3$), 1.64 (3H, bs, $=\overset{|}{C}CH_3$), 3.28 (3H, s) and 3.76 (3H, s) ($2-OCH_3$), 5.40 (1H, br, $-CH=\overset{|}{C}-$), 5.77 (1H, dd, J=8.5 and 15 Hz, $-\overset{|}{C}HCH=CH-$), 6.26 (1H, d, J=15 Hz, $-\overset{|}{C}HCH=CH-$).

Partial Catalytic Hydrogenation of 13a and 13b. *a)*: A suspension of **13a** (438 mg) and 5% Pd–C (253 mg) in ethanol (10 ml) was stirred at room temperature in an atmosphere of hydrogen. After one mol equivalent of hydrogen had been absorbed, the mixture was filtered. The filtrate was evaporated *in vacuo* and the residue was chromatographed on

silica gel (20 g), using ether–benzene (3:97) as eluent, to give the phenethyl derivative (**14a**) (414 mg: 94.1%), $[\alpha]_D$ −107° (*c* 5.22). Found: C, 79.65; H, 10.55%. Calcd for $C_{22}H_{34}O_2$: C, 79.95; H, 10.37%.

b): A suspension of **13b** (6.486 g) and 10% Pd-C (3.00 g) in methanol (50 ml) was stirred at room temperature in an atmosphere of hydrogen. After one mol equivalent of hydrogen had been absorbed, the mixture was treated as described in *a)* to give the phenethyl derivative (**14b**) (5.836 g: 89.4%), $[\alpha]_D$ −85.5° (*c* 6.12). Found: C, 79.85; H, 10.59%. Calcd for $C_{22}H_{34}O_2$: C, 79.95; H, 10.37%.

Intramolecular Cyclization of 14a and 14b. *a)*: Anhydrous aluminium chloride (2.246 g) was added at 5—15 °C to a solution of **14a** (5.565 g) in dry benzene (60 ml). The mixture was stirred at room temperature for 50 min, poured into ice-dilute hydrochloric acid, and extracted with ether. The ether extract was washed with brine, dried over sodium sulfate, and evaporated *in vacuo*. The residue was chromatographed on silica gel (300 g), using ether–hexane (2:98) as eluent, to give (5*S*,10*R*,15*R*)-12,16-dimethoxy-8,11,13-abietatriene (**15a**) (1.963 g: 35.3%). This was recrystallized from methanol: mp 79—80 °C, $[\alpha]_D$ −48.4° (*c* 2.03); ^{1}H NMR (C_6D_6): δ=0.48 (3H, s) and 0.93 (3H, s) (−C(CH$_3$)$_2$), 1.17 (3H, s, C_{10}–CH$_3$), 1.40 (3H, d, *J*=7 Hz, C_{15}–CH$_3$), 3.18 (3H, s, C_{16}–OCH$_3$), 3.50 (3H, s, C_{12}–OCH$_3$), 6.76 (1H, s) and 6.93 (1H, s) (C_{11}–H and C_{14}–H). Found: C, 79.83; H, 10.53%. Calcd for $C_{22}H_{34}O_2$: C, 79.95; H, 10.37%.

Further elution gave (5*S*,10*S*,15*R*)-12,16-dimethoxy-8,11,13-abietatriene (**16a**) (2.727 g: 49.0%) as an oil, $[\alpha]_D$ +35.0° (*c* 4.28); ^{1}H NMR (C_6D_6): δ=0.92 (6H, s, −C(CH$_3$)$_2$), 1.20 (3H, s, C_{10}–CH$_3$), 1.42 (3H, d, *J*=7 Hz, C_{15}–CH$_3$), 3.19 (3H, s, C_{16}–OCH$_3$), 3.53 (3H, s, C_{12}–OCH$_3$), 6.70 (1H, s) and 6.95 (1H, s) (C_{11}–H and C_{14}–H). Found: C, 79.77; H, 10.67%. Calcd for $C_{22}H_{34}O_2$: C, 79.95; H, 10.37%.

b): A solution of **14b** (5.836 g) in dry benzene (60 ml) was treated with anhydrous aluminium chloride (2.355 g) as described in *a)*. The crude product was chromatographed on silica gel (300 g), using ether–hexane (2:98) as eluent, to give (5*S*,10*R*,15*S*)-12,16-dimethoxy-8,11,13-abietatriene (**15b**) (2.166 g: 40.5%). This was recrystallized from methanol: mp 81—82 °C, $[\alpha]_D$ −16.9° (*c* 3.56); ^{1}H NMR (C_6D_6): δ=0.51 (3H, s) and 0.95 (3H, s) (−C(CH$_3$)$_2$), 1.20 (3H, s, C_{10}–CH$_3$), 1.44 (3H, d, *J*=7 Hz, C_{15}–CH$_3$), 3.18 (3H, s, C_{16}–OCH$_3$), 3.50 (3H, s, C_{12}–OCH$_3$), 6.80 (1H, s) and 6.96 (1H, s) (C_{11}–H and C_{14}–H). Found: C, 79.87; H, 10.59%. Calcd for $C_{22}H_{34}O_2$: C, 79.95; H, 10.37%.

Further elution gave (5*S*,10*S*,15*S*)-12,16-dimethoxy-8,11,13-abietatriene (**16b**) (2.769 g: 50.8%) as an oil, $[\alpha]_D$ +60.4° (*c* 4.56); ^{1}H NMR (C_6D_6): δ=0.92 (6H, s, −C(CH$_3$)$_2$), 1.19 (3H, s, C_{10}–CH$_3$), 1.45 (3H, d, *J*=7 Hz, C_{15}–CH$_3$), 3.21 (3H, s, C_{16}–OCH$_3$), 3.53 (3H, s, C_{12}–OCH$_3$), 6.65 (1H, s) and 6.90 (1H, s) (C_{11}–H and C_{14}–H). Found: C, 79.68; H, 10.63%. Calcd for $C_{22}H_{34}O_2$: C, 79.95; H, 10.37%.

(5S,10S,15R)-12,16-Dimethoxy-8,11,13-abietatrien-7-one (17a) and Its (5S,10S,15S)-Isomer (17b). *a)*: Jones reagent (2.5 mol dm^{-3}: 4.25 ml) was added to a stirred solution of **16a** (2.465 g) in acetone (35 ml) with cooling in an ice-water bath over a 5 min period. The mixture was stirred at this temperature for 10 min and then at room temperature for 2 h, diluted with water, and extracted with ether. The ether extract was washed with brine, dried over sodium sulfate, and evaporated *in vacuo*. The residue was chromatographed on silica gel (150 g), using ether–benzene (2:98) as eluent, to give the recovered **16a** (0.236 g: 9.6%). Further elution with ether–benzene (2:98 and then 5:95) gave **17a** (1.968 g: 76.6%). This was recrystallized from ethanol: mp 128—134 °C, $[\alpha]_D$ +27.8° (*c* 2.10); IR: 1664, 1601 cm^{-1}; ^{1}H NMR (C_6D_6): δ=0.74 (3H, s) and 0.80 (3H, s) (−C(CH$_3$)$_2$), 1.04 (3H, s, C_{10}–CH$_3$), 1.32 (3H, d, *J*=6 Hz, C_{15}–CH$_3$), 3.11 (3H, s, C_{16}–OCH$_3$), 3.42 (3H, s, C_{12}–OCH$_3$), 6.56 (1H, s, C_{11}–H), 8.33 (1H, s, C_{14}–H). Found: C, 76.78; H, 9.57%. Calcd for $C_{22}H_{32}O_3$: C, 76.70; H, 9.36%.

b): A solution of **16b** (2.610 g) in acetone (40 ml) was oxidized with Jones reagent (2.5 mol dm^{-3}: 4.50 ml) as described in *a)* to give the recovered **16b** (0.227 g: 8.7%) and (5*S*,10*S*,15*S*)-12,16-dimethoxy-8,11,13-abietatrien-7-one (**17b**) 2.405 g: 88.2%). This was recrystallized from ethanol: mp 140—141.5 °C, $[\alpha]_D$ +30.7° (*c* 4.53); IR: 1662, 1600 cm^{-1}; ^{1}H NMR (C_6D_6): δ=0.75 (3H, s) and 0.80 (3H, s) (−C(CH$_3$)$_2$), 1.05 (3H, s, C_{10}–CH$_3$), 1.33 (3H, d, *J*=6 Hz, C_{15}–CH$_3$), 3.13 (3H, s, C_{16}–OCH$_3$), 3.46 (3H, s, C_{12}–OCH$_3$), 6.58 (1H, s, C_{11}–H), 8.28 (1H, s, C_{14}–H). Found: C, 76.74; H, 9.46%. Calcd for $C_{22}H_{32}O_3$: C, 76.70; H, 9.36%.

Catalytic Hydrogenolysis of 17a and 17b. *a)*: A suspension of **17a** (254 mg), 10% Pd-C (125 mg), and 60% perchloric acid (0.15 ml) in ethyl acetate (5.0 ml) was stirred at room temperature in an atmosphere of hydrogen. After the hydrogen had been absorbed, the mixture was filtered. The filtrate was washed with brine, dried over sodium sulfate, and evaporated *in vacuo*. The crude product was chromatographed on silica gel (15 g), using ether–benzene (2:98) as eluent, to give **16a** (233 mg: 95.5%), $[\alpha]_D$ +46.7° (*c* 1.65). Found: C, 79.78; H, 10.53%. Calcd for $C_{22}H_{34}O_2$: C, 79.95; H, 10.37%.

b): A suspension of **17b** (500 mg), 10% Pd-C (250 mg), and 60% perchloric acid (0.30 ml) in ethyl acetate (10 ml) was hydrogenated to give **16b** (466 mg: 97.2%), $[\alpha]_D$ +68.7° (*c* 3.70). Found: C, 79.93; H, 10.55%. Calcd for $C_{22}H_{34}O_2$: C, 79.95; H, 10.37%.

(5S,10S,15R)-8,11,13-Abietatriene-12,16-diol (16-Hydroxyferruginol) (1a) and Its (5S,10S,15S)-Isomer (1b). *a)*: Anhydrous aluminium chloride (714 mg), sodium iodide (803 mg), and a solution of **16a** (177 mg) in dichloromethane (5.0 ml) were added in this order to acetonitrile (10.0 ml) with stirring at 0—5 °C under a stream of nitrogen over a 15 min period. The mixture was stirred at this temperature for 15 min and then at 35—40 °C for 5 h, poured into water, and extracted with ether. The ether extract was washed successively with aqueous sodium thiosulfate and brine, dried over sodium sulfate, and evaporated *in vacuo*. The residue was chromatographed on silica gel (20 g), using ether–hexane (1:1) as eluent, to give **1a** (155 mg: 95.7%). This was recrystallized from ether–hexane: mp 141—142.5 °C, $[\alpha]_D$ +65.7° (*c* 1.85) (lit,[1] mp 141—142 °C, $[\alpha]_D^{29}$ +36.6°); IR (KBr): 3505, 3275 cm^{-1}; ^{1}H NMR (90 MHz, $CDCl_3$): δ=0.94 (3H, s) and 0.96 (3H, s) (−C(CH$_3$)$_2$), 1.16 (3H, s, C_{10}–CH$_3$), 1.27 (3H, d, *J*=7 Hz, C_{15}–CH$_3$), 3.15 (1H, m, C_{15}–H), 3.64 (1H, dd, *J*=9 and 7 Hz) and 3.87 (1H, dd, *J*=9 and 4 Hz) (−CH$_2$OH), 6.76 (2H, s, C_{11}–H and C_{14}–H). Found: C, 79.51; H, 10.18%. Calcd for $C_{20}H_{30}O_2$: C, 79.42; H, 10.00%.

A mixture of **1a** (31.4 mg) and acetic anhydride (0.5 ml) in pyridine (0.5 ml) was heated at 75—80 °C for 1 h. After the usual work-up, the crude product was chromatographed on silica gel (5.0 g), using ether–hexane (15:85) as eluent, to give a diacetate (**18a**) (35.0 mg: 87.3%), $[\alpha]_D$ +59.4° (*c* 1.75);

^{1}H NMR ($CDCl_3$): δ=0.95 (6H, s, $-C(CH_3)_2$), 1.19 (3H, s, C_{10}–CH_3), 1.24 (3H, d, J=6 Hz, C_{15}–CH_3), 2.04 (3H, s, C_{16}–$OCOCH_3$), 2.31 (3H, s, C_{12}–$OCOCH_3$), 4.06 (2H, d, J=7 Hz, $-CH_2OAc$), 6.87 (1H, s) and 6.91 (1H, s) (C_{11}–H and C_{14}–H). Found: C, 74.92; H, 9.05%. Calcd for $C_{24}H_{34}O_4$: C, 74.57; H, 8.87%.

b): Anhydrous aluminium chloride (706 mg), sodium iodide (794 mg), and a solution of **16b** (175 mg) in dichloromethane (5.0 ml) were added in this order to acetonitrile (10.0 ml) with stirring at 0—5 °C under a stream of nitrogen over a 15 min period. The mixture was stirred at this temperature for 15 min and then at 35—40 °C for 5 h. After the work-up as described in *a)*, the crude product was recrystallized from acetone–hexane to give a diol (**1b**) (153 mg: 95.5%): mp 178—179 °C, $[\alpha]_D$ +44.6° (*c* 1.12); IR (KBr): 3545, 3260 cm^{-1}; ^{1}H NMR (90 MHz, $CDCl_3$): δ=0.92 (6H, s $-C(CH_3)_2$), 1.15 (3H, s, C_{10}–CH_3), 1.28 (3H, d, J=7 Hz, C_{15}–CH_3), 3.16 (1H, m, C_{15}–H), 3.68 (1H, dd, J=9 and 7 Hz) and 3.91 (1H, dd, J=9 and 4 Hz) ($-CH_2OH$), 6.77 (2H, s, C_{11}–H and C_{14}–H). Found: C, 79.28; H, 10.24%. Calcd for $C_{20}H_{30}O_2$: C, 79.42; H, 10.00%.

A mixture of **1b** (82.9 mg) and acetic anhydride (0.5 ml) in pyridine (0.5 ml) was heated at 75—80 °C for 1 h. After the usual work-up, the crude product was chromatographed on silica gel (10 g), using ether–hexane (7.5:92.5) as eluent, to give a diacetate (**18b**) (93.9 mg: 88.7%), $[\alpha]_D$ +37.1° (*c* 4.60), ^{1}H NMR ($CDCl_3$): δ=0.93 (6H, s, $-C(CH_3)_2$), 1.18 (3H, s, C_{10}–CH_3), 1.20 (3H, d, J=7 Hz, C_{15}–CH_3), 2.02 (3H, s, C_{16}–$OCOCH_3$), 2.31 (3H, s, C_{12}–$OCOCH_3$), 4.08 (2H, d, J=7 Hz, $-CH_2OAc$), 6.86 (1H, s) and 6.91 (1H, s) (C_{11}–H and C_{14}–H). Found: C, 74.52; H, 9.16%. Calcd for $C_{24}H_{34}O_4$: C, 74.57; H, 8.87%.

(5S,10S,15R)-12-Methoxy-8,11,13-abietatrien-16-ol (19a) and Its (5S,10S,15S)-Isomer (19b). *a)*: A mixture of **1a** (80.0 mg), methyl iodide (0.24 ml), and anhydrous potassium carbonate (320 mg) in ethyl methyl ketone (3.2 ml) was refluxed for 5 h. The mixture was cooled, diluted with water, and extracted with ether. The ether extract was washed successively with aqueous sodium thiosulfate and brine, dried over sodium sulfate, and evaporated *in vacuo*. The residue was chromatographed on silica gel (10 g), using ether–benzene (5:95) as eluent, to give **19a** (80.0 mg: 95.6%), $[\alpha]_D$ +62.3° (*c* 4.00); ^{1}H NMR: δ=0.95 (6H, s, $-C(CH_3)_2$), 1.17 (3H, d, J=6.5 Hz, C_{15}–CH_3), 1.18 (3H, s, C_{10}–CH_3), 3.74 (3H, s, C_{12}–OCH_3), 6.59 (1H, s) and 6.68 (1H, s) (C_{11}–H and C_{14}–H). Found: C, 79.72; H, 10.48%. Calcd for $C_{21}H_{32}O_2$: C, 79.70; H, 10.19%.

b): A mixture of **1b** (100 mg), methyl iodide (0.30 ml), and anhydrous potassium carbonate (400 mg) in ethyl methyl ketone (4.0 ml) was refluxed for 5 h. After the work-up as described in *a)*, the crude product was chromatographed on silica gel (10 g), using ether–hexane (5:95) as eluent, to give **19b** (96.5 mg: 92.3%), $[\alpha]_D$ +45.4° (*c* 4.83); ^{1}H NMR: δ=0.94 (6H, s, $-C(CH_3)_2$), 1.16 (3H, d, J=6.5 Hz, C_{15}–CH_3), 1.18 (3H, s, C_{10}–CH_3), 3.74 (3H, s, C_{12}–OCH_3), 6.60 (1H, s) and 6.68 (1H, s) (C_{11}–H and C_{14}–H). Found: C, 79.56; H, 10.46%. Calcd for $C_{21}H_{32}O_2$: C, 79.70; H, 10.19%.

(+)-Ferruginol Methyl Ether (21). *a)*: A mixture of **19a** (80.0 mg) and *p*-toluenesulfonyl chloride (80.0 mg) in pyridine (1.5 ml) was heated at 70—75 °C for 3.5 h. The mixture was cooled and diluted with ether. The ether solution was washed successively with dilute hydrochloric acid and brine, dried over sodium sulfate, and evaporated *in vacuo*. The residue was chromatographed on silica gel (10 g), using ether–benzene (3:97) as eluent, to give a tosylate (**20a**) (50.0 mg) and recovered **19a** (16.0 mg).

A mixture of **20a** (50.0 mg) and lithium aluminium hydride (45.0 mg) in dry ether (3.5 ml) was stirred at room temperature for 5 h. The mixture was poured into ice–dilute hydrochloric acid and extracted with ether. The ether extract was washed with brine, dried over sodium sulfate, and evaporated *in vacuo*. The crude product was chromatographed on silica gel (8.0 g), using hexane–benzene (9:1) as eluent, to give **21** (7.0 mg), $[\alpha]_D$ +63.3° (*c* 0.30) (lit,[7] $[\alpha]_D$ +63.1°). Further elution with ether–benzene (5:95) gave the alcohol **19a** (20.2 mg).

b): A mixture of **19b** (86.0 mg) and *p*-toluenesulfonyl chloride (78.0 mg) in pyridine (1.5 ml) was heated at 70—75 °C for 3.5 h. The mixture was treated as described in *a)* to give a tosylate (**20b**) (73.0 mg).

A mixture of **20b** (73.0 mg) and lithium aluminium hydride (65.0 mg) in dry ether (4.0 ml) was stirred at room temperature for 5 h. The mixture was treated as described in *a)* to give **21** (15.3 mg), $[\alpha]_D$ +61.4° (*c* 0.70) and **19b** (36.5 mg).

The authors are grateful to Professor Yoshiyuki Hirose, Science University of Tokyo, for kindly supplying the natural sample and the spectral data.

(Received September 3, 1984)

Conversion of 3-methoxy-4,5-methylenedioxybenzaldehyde into (2*RS*,3*SR*,4*RS*)-2-methoxycarbonyl-4-(3-methoxy-4,5-methylenedioxyphenyl)-3-methyl-4-butanolide (**11**) was carried out in seven steps *via* 1-acetoxy-1-(3-methoxy-4,5-methylenedioxyphenyl)propanone. The butanolide **11** was further converted into (2*RS*,3*SR*,3a*RS*,5*RS*)-3,3a,4,5-tetrahydro-5-methoxy-2-(3-methoxy-4,5-methylenedioxyphenyl)-3-methyl-3a-(2-propenyl)-6(2*H*)-benzofuranone (**22**) in eight steps. Reduction of **22** with lithium aluminium hydride followed by acetylation with acetic anhydride in pyridine afforded (±)-megaphyllone acetate.

Three cytotoxic neolignans, megaphone (**1**), megaphone acetate (**2**), and megaphyllone acetate (**3**), have been isolated from the root of *Aniba megaphylla* Mez. (Lauraceae) by Kupchan and his co-workers.[1] Each of these neolignans possesses four asymmetric centers and exhibits an *in vitro* inhibitory activity against cells derived from human carcinoma of the nasopharynx (KB). Recently, the total synthesis of racemic megaphone (**1**) and megaphone acetate (**2**) have been reported independently by four groups, Büchi,[2] Zoretic,[3] Hoye,[4] and ours.[5] As an extension of a previous work,[5] we describe here the stereoselective total synthesis of racemic megaphyllone acetate (**3**) starting from 3-methoxy-4,5-methylenedioxybenzaldehyde (myristicaldehyde)[6] (**5**) which was prepared from 3,4-dihydroxy-5-methoxybenzoic acid[7] (**4**). Our synthetic strategy was essentially the same as that reported in our previous work.

Condensation of **5** with methyl 2-chloropropanoate in tetrahydrofuran in the presence of potassium *t*-butoxide afforded a glycidic ester (**6**), which was hydrolyzed with aqueous sodium hydroxide in ethanol to give a sodium glycidate (**7**). This was decarboxylated with lead tetraacetate and pyridine in refluxing benzene[8] to afford 1-acetoxy-1-(3-methoxy-4,5-methylenedioxyphenyl)propanone (**8**) in 64% overall yield from **5**. Condensation of **8** in tetrahydrofuran with dimethyl malonate in the presence of titanium tetrachloride and pyridine yielded methyl 4-acetoxy-2-methoxycarbonyl-4-(3-methoxy-4,5-methylenedioxyphenyl)-3-methyl-2-butenoate (**9**) in 74% yield. The butenoate **9** was refluxed with concentrated hydrochloric acid in methanol to give a butenolide ester (**10**). Reduction of **10** with sodium borohydride in methanol followed by esterification with diazomethane gave a butanolide ester (**11**) in 33% yield along with its stereoisomer (**12**) and a keto diester (**13**) in 3% and 6% yields, respectively. A similar reduction of **13** with sodium borohydride provided **11** and **12** in 33% and 22% yields, respectively. The ^{1}H NMR spectrum of **11** showed a doublet signal due to the C-3 methyl at δ 0.81, while that of **12** showed a corresponding signal at δ 1.17. The appearance of the C-3 methyl signal in **11** in a very high field must be attributable to the shielding effect of the C-4 aromatic ring. Thus, the relative configurations of the methyl and aryl groups in **11** and **12** were assigned to be *cis* and *trans* dispositions, respectively. The *cis*-configurations of the methyl at C-3 and the hydrogen at C-2 in both **11** and **12** were also supported by the NOE measurements: irradiation of the methyl signals at δ 0.81 and 1.17 resulted in 16% and 14% enhancements of the C-2 proton signals at δ 3.35 and 3.39. Michael reaction of **11** in methanol with methyl vinyl ketone in the presence of triethylamine at 0—5 °C yielded a single keto lactone ester (**14**). This was hydrolyzed with aqueous sodium hydroxide in refluxing methanol and then decarboxylated with dilute hydrochloric acid to give a C-2 epimeric mixture of keto lactones (**15**) in 87% overall yield from **11**. Treatment of **15** with 1,2-ethanediol, trimethyl orthoformate, and boron trifluoride in dichloromethane afforded a mixture of the corresponding acetals (**16**) in 87% yield. To introduce an allyl group the acetal **16** was treated with allyl bromide and lithium diisopropylamide in 1,2-dimethoxyethane under a stream of nitrogen. The resulting single product (**17**) was hydrolyzed with dilute hydrochloric acid to give a keto lactone (**18**) in 68% overall yield from **16**. The relative configuration of the C-2 allyl and C-3 methyl groups in **17** was assigned to be *trans* by assuming the

introduction of the allyl group from the less hindered side of the molecule. Intramolecular aldol condensation of **18** with potassium *t*-butoxide in refluxing benzene was carried out and the crude product was immediately refluxed with *p*-toluenesulfonic acid in benzene to give an α,β-unsaturated ketone (**19**) in 66% yield. Subsequently, the introduction of a hydroxyl group at C-5 in **19** was carried out as follows.[9] The enone **19** in 1,2-dimethoxyethane was treated with chlorotrimethylsilane and lithium diisopropylamide under a stream of nitrogen to give a silyl enol ether. This was oxidized with *m*-chloroperbenzoic acid in dichloromethane in the presence of sodium hydrogencarbonate and then treated with triethylammonium fluoride to give the desired hydroxy enone (**20**) and its C-5 epimer (**21**) in 60% and 5% yields, respectively. In the ^{1}H NMR spectrum of the major alcohol **20**, a methine proton adjacent to the hydroxyl group exhibits both axial-axial (J=12 Hz) and axial-equatorial (J=5.5 Hz) vicinal coupling; while the corresponding proton in the minor alcohol **21** exhibits two equatorial-equatorial (J=5.5 and 3 Hz) vicinal coupling. Consequenly the hydroxyl groups in **20** and **21** are pseudoequatorial and pseudoaxial respectively. From these spectral data, the relative configurations of the hydroxyl and allyl groups in **20** and **21** were assigned respectively to be *trans* and *cis* dispositions. Methylation of **20** with diazomethane in ether in the presence of silica gel[10] afforded a methoxy enone (**22**) in 74% yield. This was reduced[11] with lithium aluminium hydride in refluxing tetrahydrofuran and the resulting alcohol was immediately acetylated with acetic anhydride in pyridine under a stream of nitrogen to give an acetate (**3**) in 71% yield. The ^{1}H NMR spectrum of the synthetic **3** was in good agreement with that published for natural megaphyllone acetate. A similar reduction of the enone **19** with lithium aluminium hydride followed by acetylation gave the corresponding acetate (**23**) in 82% yield.

Experimental

All melting points are uncorrected. The IR spectra were measured in chloroform and the ^{1}H NMR spectra in deuteriochloroform at 90 MHz, with tetramethylsilane as an internal standard, unless otherwise stated; s: singlet, bs: broad singlet, d: doublet, bd: broad doublet, dd: double doublet, t: triplet, dt: double triplet, q: quartet, bq: broad quartet, m: multiplet. The column chromatography was performed using Merck silica gel (0.063 mm).

Methyl 3,4-Dihydroxy-5-methoxybenzoate. According to the method of Scheline,[7] 3,4-dihydroxy-5-methoxybenzoic acid (**4**) was prepared from gallic acid.

A mixture of the crude **4** (57 g) and concentrated sulfuric acid (6.0 ml) in methanol (250 ml) was refluxed for 6 h with a water separator containing 4-Å Molecular Sieves. The mixture was concentrated to a half volume, diluted with

brine, and extracted with ether. The ether extract was washed, successively, with aqueous sodium hydrogencarbonate and brine, dried over sodium sulfate, and evaporated *in vacuo*. The residue was recrystallized from benzene to give methyl 3,4-dihydroxy-5-methoxybenzoate (52 g: 76% from gallic acid), mp 115—118 °C, IR: 3550, 3350, 1713, 1622, 1521 cm^{-1}; ^1H NMR (60 MHz): δ=3.90 (6H, s, $-CO_2CH_3$ and $-OCH_3$), 5.4—6.4 (2H, br, 2-OH), 7.18 (1H, d, J=2 Hz) and 7.32 (1H, d, J=2 Hz) (aromatic protons).

3-Methoxy-4,5-methylenedioxybenzaldehyde (5). *a)*: Anhydrous potassium fluoride (88 g) was added to a stirred solution of methyl 3,4-dihydroxy-5-methoxybenzoate (50.0 g) in *N,N*-dimethylformamide (500 ml) and the mixture was stirred for 15 min. After the addition of dibromomethane (25.4 ml), the stirred mixture was refluxed for 2.5 h, cooled, diluted with ether, and then filtered. The filtrate was washed, successively, with brine, aqueous sodium hydroxide, and brine. The dried solution was evaporated *in vacuo* to give the crude methyl 3-methoxy-4,5-methylenedioxybenzoate (49.7 g). ^1H NMR (60 MHz): δ=3.89 (3H, s) and 3.95 (3H, s) ($-CO_2CH_3$ and $-OCH_3$), 6.04 (2H, s, $-OCH_2O-$), 7.17 (1H, d, J=2 Hz) and 7.28 (1H, d, J=2 Hz) (aromatic protons).

b): Lithium aluminium hydride (9.0 g) was added portionwise to a stirred solution of the above crude ester (49.7 g) in tetrahydrofuran (350 ml) with cooling in an ice-water bath. The mixture was refluxed for 2 h, cooled, poured into a mixture of ice and aqueous ammonium chloride, and then filtered. The filtrate was extracted with ethyl acetate. The ethyl acetate solution was washed with brine, dried over sodium sulfate, and evaporated *in vacuo* to give the crude 3-methoxy-4,5-methylenedioxybenzyl alcohol (41.0 g). ^1H NMR (60 MHz): δ=3.28 (1H, s, -OH), 3.85 (3H, s, $-OCH_3$), 4.46 (2H, s, $-C\underline{H}_2OH$), 5.90 (2H, s, $-OCH_2O-$), 6.46 (2H, s, aromatic protons).

c): Pyridinium dichlorochromate (186 g) was added to a stirred solution of the above crude alcohol (41.0 g) in dichloromethane (657 ml). The mixture was stirred at room temperature for 2 h and then filtered from a tarry residue, which was washed with ethyl acetate. The combined organic solution was washed with aqueous sodium hydrogencarbonate and brine, dried over sodium sulfate, and evaporated *in vacuo*. The residue was recrystallized from methanol to give **5** (26.0 g), mp 130—132 °C (lit,[6] mp 130—131 °C); IR: 1692, 1637, 1604 cm^{-1}; ^1H NMR (60 MHz): δ=3.98 (3H, s, $-OCH_3$), 6.10 (2H, s, $-OCH_2O-$), 7.04 (1H, d, J=2 Hz) and 7.12 (1H, d, J=2 Hz) (aromatic protons), 9.78 (1H, s, -CHO).

1-Acetoxy-1-(3-methoxy-4,5-methylenedioxyphenyl)propanone (8). *a)*: Potassium *t*-butoxide (50.50 g) was added to a stirred solution of 3-methoxy-4,5-methylenedioxybenzaldehyde (**5**) (54.05 g) and methyl 2-chloropropanoate (55.17 g) in tetrahydrofuran (810 ml) with cooling in an ice-water bath over a 10-min period. The mixture was stirred at 0—5 °C for 1.5 h and then at room temperature for 3 h, poured into ice-dilute hydrochloric acid, and extracted with ether. The ether extract was washed with brine, dried over sodium sulfate, and evaporated *in vacuo* to give a crude glycidic ester (**6**) (82.67 g) as an oil; IR: 1727, 1628 cm^{-1}; ^1H NMR (60 MHz): δ=1.36 (3H, s, $-\overset{|}{C}CH_3$), 3.80 (3H, s) and 3.90 (3H, s) ($-CO_2CH_3$ and $-OCH_3$), 4.22 (1H, s, $-\overset{|}{C}H-O-$), 5.97 (2H, s, $-OCH_2O-$), 6.47 (2H, s, aromatic protons).

b): Aqueous sodium hydroxide (13.2 g in 135 ml of water) was added, dropwise, to a stirred solution of the above crude **6** (82.67 g) in ethanol (1800 ml) with cooling in an ice-water bath. The mixture was stirred at room temperature for 3 h. The precipitates were collected by filtration and washed with ethanol to give a sodium glycidate (**7**) (68.00 g) as a colorless solid. Some additional **7** (8.00 g) was obtained from the filtrate.

Lead tetraacetate (112 g) was added to a stirred suspension of **7** (54.874 g) and pyridine (21.8 ml) in dry benzene (2000 ml) under a stream of nitrogen. The mixture was stirred at room temperature for 30 min, refluxed for 5 h, and then cooled. After the addition of 1,2-ethanediol (20 ml), the mixture was extracted with ether. The ether extract was washed with brine, dried over sodium sulfate, and evaporated *in vacuo*. The residue was chromatographed on silica gel (1200 g), using ether–benzene (1:99) as the eluent, to give **8** (34.254 g: 64.3% from **5**) as an oil. IR: 1743, 1731, 1639 cm^{-1}; ^1H NMR: δ=2.11 (3H, s) and 2.17 (3H, s) ($-COCH_3$ and $-OCOCH_3$), 3.91 (3H, s, $-OCH_3$), 5.87 (1H, s, $-C\underline{H}(OAc)-$), 6.00 (2H, s, $-OCH_2O-$), 6.59 (2H, s, aromatic protons). Found: C, 58.50; H, 5.34%. Calcd for $C_{13}H_{14}O_6$: C, 58.64; H, 5.30%.

Methyl 4-Acetoxy-2-methoxycarbonyl-4-(3-methoxy-4,5-methylenedioxyphenyl)-3-methyl-2-butenoate (9). A solution of **8** (26.638 g), dimethyl malonate (22.9 ml), and pyridine (145.3 ml) in dry tetrahydrofuran (270 ml) was added (over a 15-min period) to a stirred solution of titanium tetrachloride (65.9 ml) in dry tetrahydrofuran (850 ml) with cooling in an ice-water bath under a stream of nitrogen. The mixture was stirred at room temperature for 3.5 h, poured into ice–dilute hydrochloric acid, and extracted with ether. The ether extract was washed with brine, dried over sodium sulfate, and evaporated *in vacuo*. The residue was chromatographed on silica gel (600 g), using ether–benzene (2:98) as the eluent, to give **9** (28.046 g: 73.7%) as an oil. IR: 1730, 1640 cm^{-1}; ^1H NMR (60 MHz): δ=1.95 (3H, s), and 2.15 (3H, s) ($=\overset{|}{C}CH_3$ and $-OCOCH_3$), 3.78 (3H, s), 3.84 (3H, s), and 3.90 (3H, s) ($2-CO_2CH_3$ and $-OCH_3$), 5.95 (2H, s, $-OCH_2O-$), 6.65 (2H, s, aromatic protons), 6.87 (1H, s, $-C\underline{H}(OAc)-$). Found: C, 56.77; H, 5.18%. Calcd for $C_{18}H_{20}O_9$: C, 56.84; H, 5.30%.

2-Methoxycarbonyl-4-(3-methoxy-4,5-methylenedioxyphenyl)-3-methyl-2-buten-4-olide (10). A mixture of **9** (3.783 g) and concentrated hydrochloric acid (1.0 ml) in methanol (38 ml) was refluxed for 4 h. The mixture was concentrated and extracted with ethyl acetate. The ethyl acetate solution was washed with brine, dried over sodium sulfate, and evaporated *in vacuo* to give a crude **10** (2.953 g) as a solid, which was used without purification in the next reaction. IR: 1775, 1760 sh, 1720, 1633 cm^{-1}; ^1H NMR (60 MHz): δ=2.23 (3H, s, $=\overset{|}{C}CH_3$), 3.89 (6H, s, $-CO_2CH_3$ and $-OCH_3$), 5.60 (1H, s, C_4–H), 5.97 (2H, s, $-OCH_2O-$), 6.33 (1H, d, J=2 Hz) and 6.37 (1H, d, J=2 Hz) (aromatic protons).

Reduction of 10 with Sodium Borohydride. Sodium borohydride (0.376 g) was added to a stirred solution of the crude **10** (2.953 g) in methanol (38 ml) with cooling in an ice-water bath over a 5 min period. The mixture was stirred at room temperature for 30 min, poured into ice–dilute hydrochloric acid, and extracted with ethyl acetate. The ethyl acetate solution was washed with brine, dried over sodium sulfate, and evaporated *in vacuo*. The residue was

methylated with diazomethane in ether and the crude product was repeatedly chromatographed on silica gel, using ether–benzene (2:98) as the eluent, to give the following three compounds: **13**, **11**, and **12** in the order of elution.

a): Methyl 2-methoxycarbonyl-4-(3-methoxy-4,5-methylenedioxyphenyl)-3-methyl-4-oxobutanoate (**13**) (0.201 g: 6.0%), which was recrystallized from methanol, mp 83—85 °C. IR: 1747, 1728, 1672, 1628, 1602 cm^{-1}; ^1H NMR: δ= 1.18 (3H, d, J=7 Hz, $-CH(C\underline{H}_3)-$), 3.67 (3H, s) and 3.80 (3H, s) ($2-CO_2CH_3$), 3.94 (3H, s, $-OCH_3$), 3.5—4.3 (2H, m, $-C\underline{H}(CH_3)C\underline{H}(CO_2CH_3)_2$), 6.07 (2H, s, $-OCH_2O-$), 7.19 (1H, d, J=1.5 Hz) and 7.30 (1H, d, J=1.5 Hz) (aromatic protons). Found: C, 56.64; H, 5.57%. Calcd for $C_{16}H_{18}O_8$: C, 56.80; H, 5.36%.

b): (2*RS*,3*SR*,4*RS*)-2-Methoxycarbonyl-4-(3-methoxy-4,5-methylenedioxyphenyl)-3-methyl-4-butanolide (**11**) (0.999 g: 32.6%), which was recrystallized from methanol, mp 91.5—92.5 °C. IR: 1782, 1738, 1640 cm^{-1}; ^1H NMR: δ= 0.81 (3H, d, J=7 Hz, C_3-CH_3), 3.17 (1H, m, C_3-H), 3.35 (1H, d, J=6.5 Hz, C_2-H), 3.83 (3H, s) and 3.90 (3H, s) ($-CO_2CH_3$ and $-OCH_3$), 5.65 (1H, d, J=6.5 Hz, C_4-H), 5.98 (2H, s, $-OCH_2O-$), 6.38 (2H, s, aromatic protons). Found: C, 58.60; H, 5.41%. Calcd for $C_{15}H_{16}O_7$: C, 58.44; H, 5.23%.

c): (2*RS*,3*SR*,4*SR*)-2-Methoxycarbonyl-4-(3-methoxy-4,5-methylenedioxyphenyl)-3-methyl-4-butanolide (**12**) (0.084 g: 2.7%) as an oil. IR: 1782, 1738, 1640 cm^{-1}; ^1H NMR: δ=1.17 (3H, d, J=7 Hz, C_3-CH_3), 2.84 (1H, m, C_3-H), 3.39 (1H, d, J=12 Hz, C_2-H), 3.83 (3H, s) and 3.91 (3H, s) ($-CO_2CH_3$ and $-OCH_3$), 4.78 (1H, d, J=9.5 Hz, C_4-H), 5.99 (2H, s, $-OCH_2O-$), 6.55 (2H, s, aromatic protons). Found: C, 58.74; H, 5.22%. Calcd for $C_{15}H_{16}O_7$: C, 58.44; H, 5.23%.

Reduction of 13 with Sodium Borohydride. A solution of **13** (920 mg) in methanol (9.5 ml) was reduced with sodium borohydride (103 mg) as described above. The crude product was chromatographed on silica gel (50 g), using ether–benzene (2:98) as the eluent, to give the recovered **13** (85 mg: 9.2%), **11** (204 mg: 24.4%), and a 1:2.5 mixture of **11** and **12** (259 mg: 30.9%).

Michael Condensation of 11 with Methyl Vinyl Ketone. Triethylamine (1.40 ml) was added to a stirred solution of **11** (6.125 g) and methyl vinyl ketone (2.43 ml) in methanol (120 ml) with cooling in an ice–water bath. The mixture was allowed to stand in a refrigerator for 23 h, poured into ice–dilute hydrochloric acid, and extracted with ethyl acetate. The ethyl acetate solution was washed with brine, dried over sodium sulfate, and evaporated *in vacuo* to give a crude keto lactone ester (**14**) (7.592 g), which was used without purification in the next reaction. IR: 1773, 1715, 1633 cm^{-1}; ^1H NMR: δ=0.65 (3H, d, J=7.5 Hz, C_3-CH_3), 2.00—2.48 (2H, m, $-C\underline{H}_2CH_2CO-$), 2.14 (3H, s, $-COCH_3$), 2.48—3.08 (3H, m, $-C\underline{H}_2COCH_3$ and C_3-H), 3.74 (3H, s) and 3.89 (3H, s) ($-CO_2CH_3$ and $-OCH_3$), 5.66 (1H, d, J=6.5 Hz, C_4-H), 5.97 (2H, s, $-OCH_2O-$), 6.43 (1H, d, J=1.5 Hz) and 6.46 (1H, d, J=1.5 Hz) (aromatic protons).

Hydrolysis and Decarboxylation of 14. A mixture of the crude **14** (7.592 g) and 10% aqueous sodium hydroxide (5.0 ml) in methanol (86 ml) was refluxed for 3 h. The mixture was cooled, acidified with dilute hydrochloric acid, and then allowed to stand at room temperature for 30 min. After the methanol had been removed *in vacuo*, the residue was diluted with brine, and extracted with ethyl acetate. The ethyl acetate solution was washed with brine, dried over sodium sulfate, and evaporated *in vacuo*. The residue was chromatographed on silica gel (200 g), using ether–benzene (1:9) as the eluent, to give a mixture of (2*RS*,3*SR*,4*RS*)- and (2*SR*,3*SR*,4*RS*)-4-(3-methoxy-4,5-methylenedioxyphenyl)-3-methyl-2-(3-oxobutyl)-4-butanolide (**15**) (5.537 g: 87.0% from **11**); IR: 1771, 1716, 1637 cm^{-1}. The ^1H NMR spectrum of the mixture suggested the ratio of two C-2 epimers to be 57:43. ^1H NMR of the major compound: δ=0.78 (3H, d, J=6.5 Hz, C_3-CH_3), 2.16 (3H, s, $-COCH_3$), 3.88 (3H, s, $-OCH_3$), 5.45 (1H, d, J=7 Hz, C_4-H), 5.97 (2H, s, $-OCH_2O-$), 6.33 (2H, s, aromatic protons). ^1H NMR of the minor compound: δ=0.58 (3H, d, J=7 Hz, C_3-CH_3), 2.16 (3H, s, $-COCH_3$), 3.88 (3H, s, $-OCH_3$), 5.38 (1H, d, J=5.5 Hz, C_4-H), 5.97 (2H, s, $-OCH_2O-$), 6.42 (1H, d, J=2 Hz) and 6.46 (1H, d, J=2 Hz) (aromatic protons). Found: C, 63.49; H, 6.22%. Calcd for $C_{17}H_{20}O_6$: C, 63.74; H, 6.29%.

Acetalization of 15. A mixture of **15** (6.495 g), 1,2-ethanediol (11.3 ml), trimethyl orthoformate (22.0 ml), and boron trifluoride etherate (0.6 ml) in dichloromethane (130 ml) was stirred at room temperature for 12.5 h. The mixture was poured into water and extracted with ethyl acetate. The ethyl acetate extract was washed with brine, dried over sodium sulfate, and evaporated *in vacuo*. The residue was chromatographed on silica gel (200 g), using ether–benzene (1:9) as the eluent, to give a C-2 epimeric mixture of acetals (**16**) (6.395 g: 86.6%); IR: 1770, 1637 cm^{-1}. ^1H NMR of the major compound: δ=0.77 (3H, d, J=6.5 Hz, C_3-CH_3), 1.32 (3H, s, $-\underset{|}{C}CH_3$), 3.89 (3H, s, $-OCH_3$), 3.94 (4H, s, $-OCH_2CH_2O-$), 5.45 (1H, d, J=7 Hz, C_4-H), 5.97 (2H, s, $-OCH_2O-$), 6.36 (2H, s, aromatic protons). ^1H NMR of the minor compound: δ=0.58 (3H, d, J=7 Hz, C_3-CH_3), 1.32 (3H, s, $-\underset{|}{C}CH_3$), 3.89 (3H, s, $-OCH_3$), 3.94 (4H, s, $-OCH_2-CH_2O-$), 5.39 (1H, d, J=4 Hz, C_4-H), 5.97 (2H, s, $-OCH_2O-$), 6.43 (1H, d, J=2 Hz) and 6.47 (1H, d, J=2 Hz) (aromatic protons). Found: C, 62.69; H, 6.70%. Calcd for $C_{19}H_{24}O_7$: C, 62.62; H, 6.64%.

(2SR,3SR,4RS)-2-(3,3-Ethylenedioxybutyl)-4-(3-methoxy-4,5-methylenedioxyphenyl)-3-methyl-2-(2-propenyl)-4-butanolide (17). A solution of butyllithium in hexane (1.6 mol dm^{-3}, 9.38 ml) was added to a stirred solution of diisopropylamine (2.10 ml) in dry tetrahydrofuran (43 ml) at −70 °C under a stream of nitrogen. The mixture was stirred at −70 °C for 25 min and a solution of **16** (2.186 g) in dry tetrahydrofuran (6.0 ml) was added over a 5-min period. After 30 min, allyl bromide (3.57 ml) was added. The mixture was stirred at −70 °C for 25 min and then at −5—0 °C for 75 min, quenched with water, diluted with aqueous ammonium chloride, poured into dilute hydrochloric acid, and extracted with ethyl acetate. The extract was washed, successively, with dilute hydrochloric acid and brine, dried over sodium sulfate, and evaporated *in vacuo* to give the crude **17** (2.624 g), which was used without purification in the next reaction. IR: 1760, 1633 cm^{-1}; ^1H NMR (60 MHz): δ=0.67 (3H, d, J=7.5 Hz, C_3-CH_3), 1.29 (3H, s, $-\underset{|}{C}CH_3$), 2.47 (2H, bd, J=7 Hz, $-C\underline{H}_2CH=CH_2$), 3.88 (7H, bs, $-OCH_3$ and $-OCH_2CH_2O-$), 4.95—5.35 (2H, m, $-CH_2CH=C\underline{H}_2$), 5.54 (1H, d, J=6 Hz, C_4-H), 5.6—6.1 (1H, m, $-CH_2C\underline{H}=CH_2$), 5.94 (2H, s, $-OCH_2O-$), 6.37 (2H, bs, aromatic protons).

(2SR,3SR,4RS)-4-(3-Methoxy-4,5-methylenedioxyphenyl)-3-

methyl-2-(3-oxobutyl)-2-(2-propenyl)-4-butanolide (18). A mixture of the crude **17** (2.624 g) and 5% hydrochloric acid (1.3 ml) in methanol (26 ml) was stirred at room temperature for 3 h. The mixture was poured into brine and extracted with ethyl acetate. The extract was washed with brine, dried over sodium sulfate, and evaporated *in vacuo*. The residue was chromatographed on silica gel (100 g), using ether–benzene (5:95) as the eluent, to give **18** (1.463 g: 67.6% from **16**). This was recrystallized from chloroform–hexane, mp 114—114.5 °C IR: 1765, 1715, 1638 cm^{-1}; ^1H NMR: δ=0.68 (3H, d, J=7.5 Hz, C_3–CH_3), 1.42—2.13 (2H, m, $-C\underline{H}_2CH_2CO-$), 2.16 (3H, s, $-COCH_3$), 2.43 (2H, bd, J=7 Hz, $-C\underline{H}_2CH=CH_2$), 2.26—3.10 (3H, m, C_3–H and $-CH_2C\underline{H}_2CO-$), 3.90 (3H, s, $-OCH_3$), 5.04—5.33 (2H, m, $-CH_2CH=C\underline{H}_2$), 5.54 (1H, d, J=7 Hz, C_4–H), 5.56—6.03 (1H, m, $-CH_2C\underline{H}=CH_2$), 5.97 (2H, s, $-OCH_2O-$), 6.40 (1H, d, J=1.5 Hz) and 6.45 (1H, d, J=1.5 Hz) (aromatic protons). Found: C, 66.94; H, 6.72%. Calcd for $C_{20}H_{24}O_6$: C, 66.65; H, 6.71%. Further elution with ether–benzene (1:9) gave the recovered **15** (0.222 g).

(2RS,3SR,3aSR)-3,3a,4,5-Tetrahydro-2-(3-methoxy-4,5-methylenedioxyphenyl)-3-methyl-3a-(2-propenyl)-6(2H)-benzofuranone (19). Potassium *t*-butoxide (0.875 g) was added, portionwise, to a stirred solution of **18** (2.162 g) in dry benzene (22 ml) with cooling in an ice–water bath. The mixture was stirred at the same temperature for 5 min and then refluxed for 3 h. The mixture was cooled, poured into ice–dilute hydrochloric acid, and extracted with ethyl acetate. The extract was washed with brine, dried over sodium sulfate, and evaporated *in vacuo* to give an oily product.

A mixture of the above oily product and *p*-toluenesulfonic acid monohydrate (50 mg) in benzene (40 ml) was refluxed for 1 h, cooled, and diluted with ethyl acetate. The ethyl acetate solution was washed with aqueous sodium hydrogencarbonate and brine, dried over sodium sulfate, and evaporated *in vacuo*. The residue was chromatographed on silica gel (100 g), using ether–benzene (1:9) as the eluent, to give **19** (1.351 g: 65.8%). This was recrystallized from chloroform–hexane, mp 134—135 °C, IR: 1628 cm^{-1}; ^1H NMR: δ=0.53 (3H, d, J=7.5 Hz, C_3–CH_3), 2.56 (2H, d, J=7 Hz, $-C\underline{H}_2CH=CH_2$), 3.91 (3H, s, $-OCH_3$), 5.12—5.38 (2H, m, $-CH_2CH=C\underline{H}_2$), 5.54 (1H, s, C_7–H), 5.64—6.11 (1H, m, $-CH_2C\underline{H}=CH_2$), 5.78 (1H, d, J=5.5 Hz, C_2–H), 5.97 (2H, s, $-OCH_2O-$), 6.42 (2H, s, aromatic protons). Found: C, 69.90; H, 6.52%. Calcd for $C_{20}H_{22}O_5$: C, 70.16; H, 6.48%.

Hydroxylation of 19. A solution of butyllithium in hexane (1.6 mol dm^{-3}: 1.56 ml) was added dropwise to a stirred solution of diisopropylamine (0.42 ml) in dry 1,2-dimethoxyethane (6.8 ml) at −15 °C under a stream of nitrogen. The mixture was stirred at −15 °C for 15 min and a solution of **19** (342 mg) in dry 1,2-dimethoxyethane (3.0 ml) was added. After 15 min, chlorotrimethylsilane (0.64 ml) was added at −15 °C. The mixture was further stirred at room temperature for 2 h and the solvent was evaporated *in vacuo* under a stream of nitrogen. The residue was dissolved in dry hexane (30 ml) and then filtered. The filtrate was evaporated *in vacuo* under a stream of nitrogen to give a crude silyl enol ether.

A solution of the above crude product in dichloromethane (2.0 ml) was added to a stirred mixture of *m*-chloroperbenzoic acid (purity>90%: 326 mg) and sodium hydrogencarbonate (151 mg) in dichloromethane (20 ml) at −15 °C. The mixture was stirred at room temperature for 1 h, diluted with chloroform, and washed with aqueous sodium hydrogencarbonate. The dried solution was evaporated *in vacuo*. The residue was dissolved in dichloromethane (3.0 ml) and the resulting solution was added to a stirred solution of triethylammonium fluoride (484 mg) in dichloromethane (20 ml). The mixture was stirred at room temperature for 13.5 h, diluted with chloroform, and then washed successively with aqueous sodium hydrogencarbonate, dilute hydrochloric acid, and aqueous sodium hydrogencarbonate. The dried solution was evaporated *in vacuo*. The crude product was repeatedly chromatographed on silica gel (Merck 0.040—0.063 mm), using hexane–chloroform (4:6) as the eluent, to give the starting **19** (33.6 mg: 9.8%) and the following two alcohols.

(2*RS*,3*SR*,3a*RS*,5*RS*)-3,3a,4,5-Tetrahydro-5-hydroxy-2-(3-methoxy-4,5-methylenedioxyphenyl)-3-methyl-3a-(2-propenyl)-6(2*H*)-benzofuranone (**20**) (213.5 mg: 59.6%), which was recrystallized from chloroform–hexane, mp 160—161.5 °C. IR: 3480br, 1656sh, 1637sh, 1625 cm^{-1}; ^1H NMR: δ=0.54 (3H, d, J=7.5 Hz, C_3–CH_3), 1.81 (1H, t, J=12 Hz) and 2.37 (1H, dd, J=12 and 5.5 Hz) ($-C\underline{H}_2CH(OH)-$), 2.61 (2H, d, J=7 Hz, $-C\underline{H}_2CH=CH_2$), 3.52 (1H, bs, -OH), 3.90 (3H, s, $-OCH_3$), 4.34 (1H, dd, J=12 and 5.5 Hz, C_5–H), 5.15—5.43 (2H, m, $-CH_2CH=C\underline{H}_2$), 5.63 (1H, s, C_7–H), 5.70—6.18 (1H, m, $-CH_2C\underline{H}=CH_2$), 5.83 (1H, d, J=5.5 Hz, C_2–H), 5.98 (2H, s, $-OCH_2O-$), 6.40 (2H, s, aromatic protons). M^+, 358. Calcd for $C_{20}H_{22}O_6$: M^+, 358.

(2*RS*,3*SR*,3a*RS*,5*SR*)-3,3a,4,5-Tetrahydro-5-hydroxy-2-(3-methoxy-4,5-methylenedioxyphenyl)-3-methyl-3a-(2-propenyl)-6(2*H*)-benzofuranone (**21**) (17.6 mg: 4.9%), which was recrystallized from chloroform–hexane, mp 166—168 °C. IR: 3575, 3400br, 1637sh, 1624 cm^{-1}; ^1H NMR: δ=0.54 (3H, d, J=7.5 Hz, C_3–CH_3), 2.07 (1H, dd, J=15 and 5.5 Hz) and 2.22 (1H, dd, J=15 and 3 Hz) ($-C\underline{H}_2CH(OH)-$), 2.57 (1H, dd, J=13.5 and 8 Hz, $-C\underline{H}_AH_BCH=CH_2$), 2.86 (1H, dd, J=13.5 and 6 Hz, $-CH_A\underline{H}_BCH=CH_2$), *ca.* 2.6 (1H, m, C_3–H), 2.92 (1H, br, -OH), 3.91 (3H, s, $-OCH_3$), 4.10 (1H, dd, J=5.5 and 3 Hz, C_5–H), 5.11—5.40 (2H, m, $-CH_2CH=C\underline{H}_2$), 5.61 (1H, s, C_7–H), 5.89 (1H, d, J=5.5 Hz, C_2–H), 5.67—6.25 (1H, m, $-CH_2C\underline{H}=CH_2$), 5.79 (2H, s, $-OCH_2O-$), 6.40 (2H, bs, aromatic protons). M^+, 358. Calcd for $C_{20}H_{22}O_6$: M^+, 358.

(2RS,3SR,3aRS,5RS)-3,3a,4,5-Tetrahydro-5-methoxy-2-(3-methoxy-4,5-methylenedioxyphenyl)-3-methyl-3a-(2-propenyl)-6(2H)-benzofuranone (22). A cold solution of diazomethane (*ca.* 100 mmol) in ether (200 ml) was added to a stirred mixture of **20** (179.0 mg) and silica gel (9.0 g: Merck 0.040—0.063 mm) in dry tetrahydrofuran (15 ml) with cooling in an ice–water bath. Afer stirring at 0—5 °C for 30 min and then at room temperature for 1.5 h, the mixture was filtered to remove silica gel, which was washed well with chloroform. The filtrate was evaporated *in vacuo*. The residue was recrystallized from methanol to give **22** (101.0 mg: 54.1%), mp 154—155 °C. The mother liquor of recrystallization was evaporated *in vacuo* and the residue was chromatographed on silica gel (10 g: Merck 0.040—0.063 mm), using hexane–chloroform (6:4) as the eluent, to give an additional **22** (26.9 mg: 19.8%). IR: 1659sh, 1636, 1632 cm^{-1}; ^1H NMR: δ=0.54 (3H, d, J=7.5 Hz, C_3–CH_3), 1.88 (1H, t, J=12 Hz) and 2.28 (1H, dd, J=12 and 5.5 Hz) ($-C\underline{H}_2CH(OMe)-$), 2.33—

2.83 (3H, m, $-C\underline{H}_2CH=CH_2$ and C_3-H), 3.60 (3H, s, C_5-OCH_3), 3.91 (3H, s, $-OCH_3$), 3.98 (1H, dd, J=12 and 5 Hz, C_5-H), 5.17—5.43 (2H, m, $-CH_2CH=C\underline{H}_2$), 5.56 (1H, s, C_7-H), 5.70—6.18 (1H, m, $-CH_2C\underline{H}=CH_2$), 5.80 (1H, d, J= 5.5 Hz, C_2-H), 5.98 (2H, s, $-OCH_2O-$), 6.40 (2H, s, aromatic protons). Found: C, 67.47; H, 6.65%. Calcd for $C_{21}H_{24}O_6$: C, 67.73; H, 6.50%.

(±)-Megaphyllone Acetate (3). Lithium aluminium hydride (9.5 mg) was added to a stirred solution of **22** (93.1 mg) in dry tetrahydrofuran (5.0 ml) at room temperature. The mixture was refluxed for 2 h, cooled, poured into ice-water containing 15% hydrochloric acid (1.0 ml), and extracted with ether. The extract was washed with brine, dried over magnesium sulfate, and evaporated *in vacuo* under a stream of nitrogen. The residue was immediately acetylated with acetic anhydride (0.5 ml) in pyridine (5.0 ml) at 50 °C for 15 h in an atmosphere of nitrogen. After the usual work-up, the crude product was chromatographed on silica gel (20 g: Merck 0.040—0.063 mm), using hexane-chloroform (1:1) as the eluent, to give **3** (73.8 mg: 70.9%) as an oil, whose spectral data were identical with those reported for natural megaphyllone acetate. IR (CCl_4): 1745, 1676, 1636 cm^{-1}; ^1H NMR: δ=0.90 (3H, d, J=7 Hz, $-CH(C\underline{H}_3)-$), 1.87 (1H, dd, J=14 and 10 Hz) and 2.27 (1H, d of dd, J=14, 6, and 2 Hz) ($-C\underline{H}_2CH-(OCH_3)-$), 2.09 (3H, s, $-OCOCH_3$), 2.34 (2H, bd, J=7 Hz, $-C\underline{H}_2CH=CH_2$), 2.51 (1H, bq, J=7 Hz, $-C\underline{H}(CH_3)-$), 3.44 (3H, s, $-CH(OC\underline{H}_3)-$), 3.91 (3H, s, $-OCH_3$), 4.04—4.30 (1H, m, $-C\underline{H}(OCH_3)-$), 4.87—5.12 (2H, m, $-CH_2CH=C\underline{H}_2$), 5.35—5.82 (1H, m, $-CH_2C\underline{H}=CH_2$), 5.67 (1H, bs, $-C\underline{H}-(OCOCH_3)-$), 5.93 (2H, s, $-OCH_2O-$), 6.00 (1H, dd, J=10 and 2 Hz, $-COC\underline{H}=CH-$), 6.49 (1H, d, J=1.5 Hz) and 6.55 (1H, d, J=1.5 Hz) (aromatic protons), 6.89 (1H, dt, J=10 and 2 Hz, $-COCH=C\underline{H}-$). Found: C, 66.07; H, 6.88%; M^+, 416. Calcd for $C_{23}H_{28}O_7$: C, 66.33; H, 6.78%; M^+, 416.

(±)-Demethoxymegaphyllone Acetate (23). Reduction of a solution of **19** (250 mg) in dry tetrahydrofuran (20 ml) with lithium aluminium hydride (27.7 mg), followed by acetylation with acetic anhydride (2.5 ml) in pyridine (20 ml), was carried out as described regarding the preparation of **3**. The crude product was recrystallized from methanol to give **23** (179 mg: 63.2%), mp 115.5—116.5 °C. The mother liquor of recrystallization was evaporated *in vacuo* and the residue was chromatographed on silica gel (10 g), using ether-benzene (5:95) as the eluent, to give an additional **23** (51.3 mg: 18.2%). IR: 1737, 1666, 1640 cm^{-1}; ^1H NMR: δ=0.88 (3H, d, J=7.5 Hz, $-CH(C\underline{H}_3)-$), 2.09 (3H, s, $-OCOCH_3$), 2.33 (2H, bd, J=7 Hz, $-C\underline{H}_2CH=CH_2$), 2.47 (1H, bq, J=7.5 Hz, $-C\underline{H}(CH_3)-$), 3.91 (3H, s, $-OCH_3$), 4.83—5.11 (2H, m, $-CH_2CH=C\underline{H}_2$), 5.37—5.86 (1H, m, $-CH_2C\underline{H}=CH_2$), 5.71 (1H, bs, $-C\underline{H}(OCOCH_3)-$), 5.93 (2H, s, $-OCH_2O-$), 5.98 (1H, dt, J=10 and 2 Hz, $-COC\underline{H}=CH-$), 6.51 (1H, d, J=1.5 Hz) and 6.57 (1H, d, J= 1.5 Hz) (aromatic protons), 6.86 (1H, dt, J=10 and 4 Hz, $-COCH=C\underline{H}-$). Found: C, 68.44; H, 6.88%. Calcd for $C_{22}H_{26}O_6$: C, 68.38; H, 6.78%.

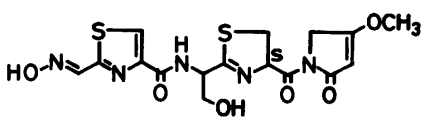
Total Synthesis of Antibiotic Althiomycin[1]

Kaoru INAMI and Tetsuo SHIBA*
Department of Chemistry, Faculty of Science, Osaka University, Toyonaka, Osaka 560
(Received September 3, 1984)

Total Synthesis of antibiotic althiomycin has been achieved starting from D-cysteine. The imide bond between thiazoline and the pyrrolinone part was constructed by coupling reaction of sodium salt of pyrrolinone with cysteine active ester or by photoreaction with diketene. The hydroxymethyl group attached on the carbon adjacent to C-2 of the thiazoline ring, was introduced by aldol condensation posterior to the thiazoline ring formation. The thiazole part was introduced in a final step in whole process of the total synthesis of the antibiotic. The synthetic althiomycin was identical with the natural antibiotic in all respects.

Althiomycin (**1**) was first isolated from *Streptomyces althioticus* by Umezawa and his collaborators in 1957[2] and then from other microorganisms by Sensi *et al.*[3] as well as Kunze *et al.*[4] This antibiotic inhibits the protein synthesis in both Gram-positive and negative bacteria.[5] The structural determination of althiomycin was carried out by Umezawa *et al.*,[6] Kirst *et al.*,[7] and us.[8] Althiomycin has two asymmetric centers, one of which, C-4 of the thiazoline ring, was deduced to be of *S* configuration, corresponding to D-cysteine residue, while the *exo* carbon atom adjacent to C-2 of the thiazoline ring, is still ambiguous, because this antibiotic is always isolated as the mixture of epimers concerning this asymmetric carbon. The geometric configuration of the aldoxime has been determined as *E* form from the result of X-ray analysis of the methanolysis product of althiomycin[7] as well as our synthetic study.[8] In order to investigate the structure-activity relationship of althiomycin, we first attempted the total synthesis of this antibiotic.

The synthetic pathway is based on the "stepwise elongation method" from C-terminal to N-terminal. Concerning the preparation of pyrrolinone part, 2,4-pyrrolidinedione (**2**) synthesized according to the method of Lowe *et al.*[9] was methylated with ethereal diazomethane to give 4-methoxy-3-pyrrolin-2-one (**3**) (yield 52.9%) as the major product and 2-methoxy-4-one isomer (**4**) (7.1%) as the minor one. The mixture was purified and separated by silica-gel column chromatography using the developing solvent of ethyl acetate–methanol 9:1. The predominant product (**3**) is completely identical with naturally derived pyrrolinone in all respects. As a preliminary experiment of acylation of the pyrrolinone, acid chloride method is solely successful among various kinds of acylation methods applied.



Althiomycin (1)

Fig. 1.

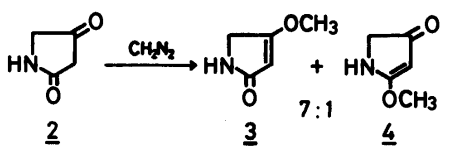


Fig. 2.

Secondly, the synthesis of the thiazoline part was performed by coupling method of the imino ether of *N*-protected glycine and D-cysteine ester. *N,S*-Ditrityl-D-cysteine diphenylmethyl ester (**6**) was prepared from D-cysteine *p*-toluenesulfonate *via* successive procedures of tritylation of mercapto and amino groups and esterification with diphenyldiazomethane. Both trityl (Trt) groups were removed with silver nitrate to give cysteine derivative with free amino and mercapto groups (**7**). The compound was coupled with ethyl benzyloxycarbonylaminoacetimidate[10] to obtain the thiazoline ester (**8**) (yield 73.9%). Removal of diphenylmethyl (DPM) group afforded the thiazolinecarboxylic acid (**9**).

With reference of results of the preliminary acylation of the pyrrolinone, the coupling of the thiazolinecarboxylic acid (**9**) with methoxypyrrolinone (**3**) was attempted using several carboxylic activation methods such as acid chloride, active ester, mixed anhydride, dicyclohexylcarbodiimide-4-dimethylaminopyridine, *N*-ethyl-5-phenylisoxazolium-3-sulfonate (Woodward's reagent "K"), azide, or triphenylphosphine-di-2-pyridyl disulfide (Mukaiyama's method). Amino activation methods like triethyloxonium tetrafluoroborate (Meerwein's reagent), 2-chloro-1-methylpyridinium iodide,[11] phosphazo, phosphite ester, and trimethylsilylation-acid chloride method[12] were also tried. However, the desired coupling product (**10**) could never be obtained by these methods because of a low reactivity of the imino group of the pyrrolinone and an instability of the thiazoline ring. Therefore, we next tried to apply a photoreaction of the thiazolinecarbonyl azide (**12**) with diketene according to the method exploited in the case of substituted benzoyl azides by Kato *et al.*[13] The corresponding azide (**12**) was synthesized from carboxylic acid **9** *via* successive procedures of conversion to the protected hydrazide with *t*-butyl carbazate, water-soluble carbodiimide (*N*-[3-(dimethylamino)propyl]-*N'*-ethylcarbodiimide), and

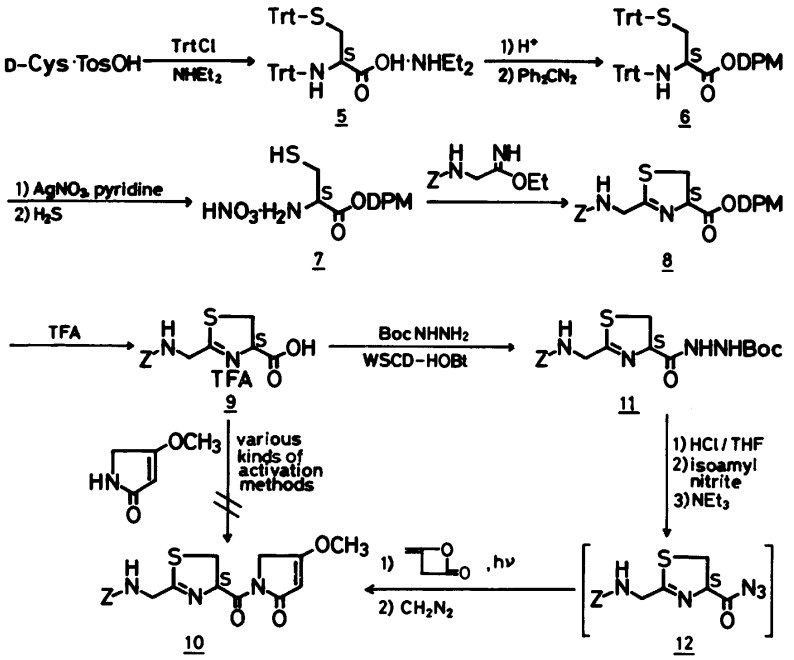

Fig. 3.

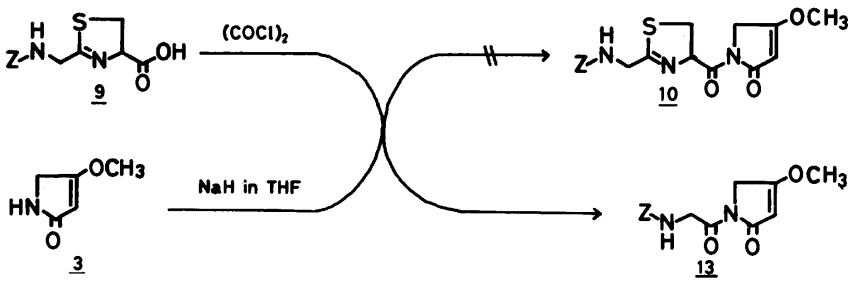

Fig. 4.

1-hydroxybenzotriazole, and then azidation with isopentyl nitrite followed by removal of *t*-butoxycarbonyl (Boc) group. A mixture of the azide (**12**) thus obtained without isolation and diketene distilled just before use was irradiated with a high-pressure mercury lamp through a quartz filter (HALOS PIH-100) in chloroform for 6 h at 0 °C under nitrogen atmosphere. The product was methylated with diazomethane to give the desired thiazoline-pyrrolinone compound (**10**). This route was, however, found to be disadvantageous concerning yield and reproducibility despite of searches of the good reaction condition.

Thus, we reinvestigated the coupling of the thiazoline part with the pyrrolinone to improve this synthesis. The defects in the above reaction seemed to be due to a low nucleophilicity of the imino group of the pyrrolinone ring. Therefore, we next tried a coupling of thiazolinecarbonyl chloride with sodium salt of the pyrrolinone prepared from **3** and sodium hydride. Actually the reaction afforded only glycylpyrrolinone (**13**), but not the desired thiazoline-pyrrolinone derivative (**10**), presumably because of the situation that C-2 of the thiazoline ring is more reactive than the carbonyl carbon of the acid chloride under these conditions. From results mentioned above, we then attempted the formation of the thiazoline ring after coupling of the cysteine active ester with sodium salt of the pyrrolinone. Each active ester (**14**—**16**) prepared from *N*-hydroxysuccinimide (HONSu), *N*-hydroxy-5-norbornene-*endo*-2,3-dicarboximide (HONb), or *p*-nitrophenol (HONp), was coupled with sodium salt of the pyrrolinone respectively. The products from both ONb and ONp esters were the cysteinylpyrrolinone (**18**), whereas that from ONSu ester was found to be *N*-[3-(cysteinyloxyaminocarbonyl)propionyl]-3-pyrrolin-2-one derivative (**17**) formed by ring opening of the succinimide. By comparison of two reactions using ONb and ONp esters, the former is superior to the latter both in respects of easiness in the treatment of the active esters and $[\alpha]_D$ of the product. The protected cysteinylpyrrolinone (**18**) thus obtained was deprotected with silver nitrate and hydrogen sulfide,

and then coupled with the imidic ether of benzyloxycarbonylglycine to afford the thiazoline-pyrrolinone derivative (**10**) in 39% yield. Formations of the thiazoline ring and the imide bond between the thiazoline and the pyrrolinone part were confirmed in long-range coupling (1 Hz) between the *exo* methylene of C-2 and the proton of C-4 in the thiazoline ring, and downfield shift (0.3 ppm) of methylene protons of the pyrrolinone ring in NMR respectively.

The aldol condensation for the thiazoline moiety with aqueous 35% formaldehyde solution in dimethyl sulfoxide at room temperature for 3 d afforded the hydroxymethyl compound (**19**) and its anhydro derivative in ratio of about 1 : 1 on TLC. However, when the aldol condensation was carried out by use of paraformaldehyde instead of formalin in degassed and anhydrous dimethyl sulfoxide, only the desired hydroxymethyl derivative was obtained as a sole product. The result of this reaction seems to be much dependent to the solvent used since this type of reaction for model compounds gave the β-hydroxy derivative in aprotic polar solvents such as dimethyl sulfoxide or *N*,*N*-dimethylformamide, while, in a protic solvent like methanol its anhydro derivative was obtained.[14]

The thiazole moiety, namely (*E*)-2-(hydroxyiminomethyl)-4-thiazolecarbonyl azide (**29**), was synthesized as shown in the scheme. For ethyl diethoxyacetate (**20**)[15] amidation, dehydration, and addition of hydrogen sulfide were successively carried out to result in the production of diethoxythioacetamide (**23**), which was then coupled with ethyl 3-bromopyruvate[16] to yield thiazole acetal (**24**). After removal of the acetal, the aldehyde was converted to oximes (**26**, **27**) with hydroxylamine hydrochloride. The (*E*)-aldoxime (**26**) was separated from (*Z*)-isomer (**27**) by silica-gel column chromatography and fractional recrystallization. The compound (**26**) thus obtained was then converted into thiazolecarbonyl azide (**29**) in the usual way.

Deprotection of the thiazoline-pyrrolinone compound **19** with anhydrous hydrogen fluoride followed by coupling with the thiazole part by the azide method was carried out under following conditions; the thiazoline-pyrrolinone derivative (**19**) was dissolved in anisole, and then anhydrous hydrogen fluoride was introduced to the solution at −78 °C. After deprotection procedure for 20 min at 0 °C, hydrogen fluoride

was evaporated off *in vacuo* as quickly as possible. The residual oil was neutralized with potassium carbonate, and coupled with thiazolecarbonyl azide in *N,N*-dimethylformamide for 3 h at room temperature. The product after purification by preparative silica-gel TLC (chloroform-methanol 9:1) was completely identical with natural althiomycin as shown in Table 1. Antibacterial activities of the synthetic althiomycin were also quite identical with those of the natural antibiotic (Table 2).

Experimental

All melting points are uncorrected. The IR spectra were determined on a JASCO A-100 grating infrared spectrophotometer; and the ^1H- and ^{13}C-NMR spectra, on a Varian XL-100-15 NMR spectrometer, a Jeol FX-90Q NMR spectrometer, a Jeol JNM-PMX 60 NMR spectrometer, and a Varian T-60 NMR spectrometer. The chemical shifts are given in δ, with TMS as the internal standard. The UV spectra were obtained with a Hitachi 124 spectrophotometer. The electron-impact and field-desorption mass spectra were obtained with a Jeol JMS-OlSG-2 mass spectrometer and Hitachi RM-50 spectrometer. The optical rotations were obtained with a Perkin-Elmer 141 polarimeter. The high performance liquid chromatography was performed on a Yanako liquid chromatograph model L-2000 and Shimadzu LC-5A liquid chromatograph. TLC was carried out by the ascending method on a Merck Kieselgel F_{254} and Woelm Kieselgel F_{254}.

4-Methoxy-3-pyrrolin-2-one (3). To a solution of 2,4-pyrrolidinedione (**2**)[9] (1.19 g, 12.0 mmol) in 100 ml of acetonitrile, was added excess diazomethane in ether and allowed to react for 10 h. After evaporation of excess diazomethane at 50 °C, the solution was concentrated *in vacuo* to give brown needles. Purification and separation by silica-gel column chromatography gave pale yellow solid (R_f 0.80 on TLC using a developing solvent chloroform–methanol 7:1). This solid was recrystallized from ethyl acetate and hexane; yield 0.72 g (53%). Mp 128—128.5 °C. Found: C, 53.05; H, 6.21; N, 12.36%. Calcd for $C_5H_7NO_2$: C, 53.09; H, 6.24; N, 12.38%. EI-MS: *m/z* (rel intensity) 113 (100), 98 (14), 86 (50), 83 (31), 70 (100), and 28 (52). 60 MHz ^1H-NMR ($CDCl_3$) δ=7.0 (1H, br.), 5.18 (1H, s), 3.98 (2H, s), 3.85 (3H, s).

1-Acetyl-4-methoxy-3-pyrrolin-2-one. To a solution of **3** (100 mg, 0.885 mmol) in 0.9 ml of chloroform, was added triethylamine (134 mg, 1.33 mmol) and acetyl chloride (208 mg, 2.65 mmol). A mixture was stirred for 2 h under ice-cooling and then diluted with chloroform. After washing with saturated aqueous sodium hydrogencarbonate and brine, the organic layer was dried over anhydrous magnesium sulfate and concentrated *in vacuo*. Purification by preparative silica-gel TLC (chloroform-methanol 9:1) gave

colorless needles; yield 121 mg (100%). Mp 92—92.5 °C. Found: C, 54.05; H, 5.86; N, 8.94%. Calcd for $C_7H_9NO_3$: C, 54.19; H, 5.85; N, 9.03%. EI-MS *m/z* (rel intensity), 155 (64), 113 (86), 99 (83), 70 (47), and 43 (100). 60 MHz ^{1}H-NMR ($CDCl_3$) δ=5.20 (1H, s), 4.30 (2H, s), 3.90 (3H, s), 2.50 (3H, s).

N,S-*Dityrityl-*D*-cysteine Diethylamine Salt (5).* To a solution of D-cysteine *p*-toluenesulfonate (13.1 g, 44.7 mmol) in 85 ml of degassed water, a solution of diethylamine (24.6 ml, 0.237 mol) in 85 ml of water was added dropwise with stirring for 5 min at 0 °C. To the reaction mixture, a solution of trityl chloride (37.4 g, 0.134 mol) in 290 ml of ether was added dropwise with a vigorous stirring for 10 min at −20 °C. After additional stirring for 1.5 h, the reaction mixture was extracted with chloroform and washed with water. The organic layer was concentrated *in vacuo* and residual oil was dissolved in 300 ml of 99% ethanol. To the solution, diethylamine (8 ml) was added and colorless prisms precipitated was collected; yield 27.2 g (89.8%). Mp 193—194 °C (dec). $[\alpha]_D^{20}$ −62.1° (*c* 1.50, chloroform). Found: C, 79.38; H, 6.72; N, 3.91; S, 4.50%. Calcd for $C_{45}H_{46}N_2O_2S$: C, 79.61; H, 6.83; N, 4.13; S, 4.72%.

Diphenylmethyl N,S-*Dityrityl-*D*-cysteinate (6).* To a suspension of *N,S*-ditrityl-D-cysteine diethylamine salt (19.9 g, 29.4 mmol) in 300 ml of ether, 10 ml of 3M aqueous (1 M= 1 mol dm^{-3}) citric acid was added with vigorous stirring for 40 min at 0 °C. The ethereal solution was washed with water and dried over anhydrous magnesium sulfate. The solution was concentrated *in vacuo* to 100 ml. To the solution, diphenyldiazomethane (5.70 g, 29.4 mmol) was added. After stirring for 1 d, the insoluble material was filtered off and the solution was concentrated *in vacuo*. The residue was recrystallized from ether and methanol; yield 19.3 g (84.8%). Mp 155—156 °C. $[\alpha]_D^{20}$ −44.4° (*c* 0.468, acetone). Found: C, 83.75; H, 5.87; N, 1.90; S, 4.09%. Calcd for $C_{54}H_{45}NO_2S$: C, 84.01; H, 5.88; N, 1.81; S, 4.15%. 60 MHz ^{1}H-NMR ($CDCl_3$) δ=7.30 (40H, m), 7.10 (1H, s), 6.30 (1H, s), 3.50 (1H, br.), 2.80 (1H, d), 2.40 (2H, d).

Diphenylmethyl D*-Cysteinate Nitrate (7).* To a solution of diphenylmethyl *N,S*-dityrityl-D-cysteinate (**6**) (19.2 g, 24.9 mmol) in 25 ml of benzene, a solution of silver nitrate (4.65 g, 27.4 mmol) and pyridine (2.20 ml, 27.4 mmol) in 40 ml of methanol was added and stirred for 1 d at room temperature. Through the reaction mixture, hydrogen sulfide was bubbled with stirring for 30 min at room temperature. Silver sulfide was filtered off and the filtrate was concentrated *in vacuo*. The residue was recrystallized from methanol and ether; yield 6.30 g (72.2%). Mp 123—125 °C. $[\alpha]_D^{20}$ +15.7° (*c* 2.84, *N,N*-dimethylformamide). Found: C, 54.95; H, 5.35; N, 7.78; S, 8.65%. Calcd for $C_{16}H_{18}N_2O_5S$: C, 54.84; H, 5.18; N, 8.00; S, 9.15%. 60 MHz ^{1}H-NMR ($CDCl_3$) δ=7.30 (10H, s), 6.93 (1H, s), 4.50 (1H, t, *J*=4Hz), 3.30 (2H, d, *J*=4Hz).

Diphenylmethyl (S)-2-(Benzyloxycarbonylaminomethyl)-2-thiazoline-4-carboxylate (8). To a solution of ethyl (benzyloxycarbonylamino)acetimidate[10] (4.25 g, 18.0 mmol) in 120 ml of absolute ethanol, diphenylmethyl D-cysteinate nitrate (6.30 g, 18.0 mmol) was added. The reaction mixture was stirred for 16 h at room temperature and concentrated *in vacuo*. The residual oil was dissolved in ethyl acetate and washed with water. The organic layer was dried over anhydrous magnesium sulfate and concentrated *in vacuo*. Recrystallization from acetone–hexane gave colorless crystals; yield 6.12 g (73.9%). Mp 94—96 °C. $[\alpha]_D^{14}$ −51.9° (*c* 1.15, benzene). Found: C, 67.76; H, 5.30; N, 6.06; S, 7.09%. Calcd for $C_{26}H_{24}N_2O_4S$: C, 67.81; H, 5.26; N, 6.08; S, 6.96%. 60 MHz ^{1}H-NMR ($CDCl_3$) δ=7.45 (15H, s), 6.88 (1H, s), 5.40 (1H, br.), 5.13 (1H, dt, *J*=2Hz, 10Hz), 5.08 (2H, s), 4.18 (2H, dd, *J*=2Hz, 7Hz), 3.52 (2H, d, *J*=10 Hz).

(S)-2-(Benzyloxycarbonylaminomethyl)-4-carboxy-2-thiazolinium Trifluoroacetate (9). A mixture of diphenylmethyl (*S*)-2-(benzyloxycarbonylaminomethyl)-2-thiazoline-4-carboxylate (6.12 g, 13.3 mmol) and trifluoroacetic acid (19.8 ml, 0.266 mol) was stirred for 30 min at 0 °C. To the reaction mixture, 200 ml of ether was added. The precipitate was collected and washed with ether, yield 4.43 g (81.6%). Mp>200 °C. 60 MHz ^{1}H-NMR (CF_3COOD) δ=7.34 (5H, s), 5.24 (2H, s), 4.70 (1H, br. t), 4.27 (2H, s), 3.74 (2H, br. d).

*(S)-N′-(*t*-Butoxycarbonyl)-2-(benzyloxycarbonylaminomethyl)-2-thiazoline-4-carbohydrazide (11).* To a solution of **9** (4.43 g, 10.9 mmol) in 20 ml of tetrahydrofuran, *t*-butyl carbazate (3.01 g, 22.8 mmol), 1-hydroxybenzotriazole (3.08 g, 22.8 mmol), and *N*-[3-(dimethylamino)propyl]-*N′*-ethylcarbodiimide hydrochloride (4.37 g, 22.8 mmol) were added successively and the mixture was stirred for 2 h at 0 °C. After additional stirring for 16 h at room temperature, the reaction mixture was concentrated *in vacuo* and dissolved in ethyl acetate. The solution was washed with saturated aqueous sodium hydrogencarbonate and brine. The organic layer was dried over anhydrous magnesium sulfate. The solution was concentrated *in vacuo*. Purification by silica-gel column chromatography (120 g, benzene–ethyl acetate 3:1) gave colorless oil; yield 2.60 g (58.7%). Found: *m/z* 408.1458. Calcd for $C_{18}H_{24}N_4O_5S$: *m/z* 408.1466. Found: C, 52.76; H, 6.31; N, 12.54; S, 6.61%. Calcd for $C_{18}H_{24}N_4O_5S \cdot 0.5C_4H_8O_2$: C, 53.08; H, 6.24; N, 12.38; C, 7.09%. 60 MHz ^{1}H-NMR ($CDCl_3$) δ=8.63 (1H, d, *J*=3Hz), 7.30 (5H, s), 6.85 (1H, d, *J*=3Hz), 6.00 (1H, br.t, *J*=6 Hz), 5.06 (2H, s), 5.03 (1H, tt, *J*=2Hz, 9Hz), 4.10 (2H, dd, *J*=2Hz, 6Hz), 3.53 (2H, d, *J*=9Hz), 1.45 (9H, s).

(S)-2-(Benzyloxycarbonylaminomethyl)-2-thiazoline-4-carbohydrazide Dihydrochloride. The protected hydrazide **11** (2.60 g, 6.37 mmol) was dissolved in 4.67 M hydrogen chloride in tetrahydrofuran (27.3 ml, 0.127 mol) and allowed to react for 2 h at 0 °C. To the reaction mixture, 300 ml of ether was added and the precipitate was collected; yield 2.05 g (84.4%). Mp 132—134 °C (dec). Found: C, 38.59; H, 5.18; N, 14.62; S, 8.03; Cl, 17.67%. Calcd for $C_{13}H_{18}N_4O_3SCl_2 \cdot H_2O$: C, 39.10; H, 5.05; N, 14.03; S, 8.41; Cl, 17.76%.

N,S-*Dityrityl-*D*-cysteine 5-Norbornene-*endo*-2,3-dicarboximidyl Ester (15).* To a suspension of *N,S*-ditrityl-D-cysteine diethylamine salt (**5**) (2.98 g, 3.86 mmol) in 200 ml of ether, 2 ml of 3 M aqueous citric acid was added. The reaction mixture was vigorously stirred for 30 min at 0 °C. An organic layer was washed with water and dried over anhydrous magnesium sulfate. The solution was concentrated *in vacuo* and the residual oil was dissolved in 15 ml of tetrahydrofuran. To the solution, *N*-hydroxy-5-norbornene-*endo*-2,3-dicarboximide (1.04 g, 5.79 mmol) and dicyclohexylcarbodiimide (0.950 g, 4.63 mmol) were added and stirred for 2 h at 0 °C. After additional stirring for 10 h at room temperature, the reaction mixture was concentrated *in vacuo*. The residual oil was dissolved in ethyl acetate, and the insoluble material was filtered off. The filtrate was washed with saturated aqueous sodium hydrogencarbonate and brine. The organic layer was dried over anhydrous magnesium sulfate and concentrated *in vacuo*. The residue

was recrystallized from ethyl acetate and hexane; yield 2.88 g (97.3%). Mp 194—195 °C (dec). $[\alpha]_D^{18}$ −63.4° (*c* 1.45, chloroform). Found: C, 78.10; H, 5.61; H, 3.67; S, 4.21%. Calcd for $C_{50}H_{42}N_2O_4S$: C, 78.31; H, 5.52; N, 3.65; S, 4.18%. 60 MHz ^{1}H-NMR ($CDCl_3$) δ=7.30 (30H, m), 7.00 (1H, br. s), 6.07 (2H, br. s), 3.78 (1H, m), 3.50 (2H, br. s), 3.25 (2H, br. s), 2.50 (2H, br. d), and 1.45—1.85 (2H, br. m).

1-(N,S-Dirityl-D-cysteinyl)-4-methoxy-3-pyrrolin-2-one (18). To a solution of 4-methoxy-3-pyrrolin-2-one (**3**) (5.60 g, 49.6 mmol) in 155 ml of anhydrous tetrahydrofuran, 60% sodium hydride (1.59 g, 39.7 mmol) was added. The mixture was heated under reflux for 10 min. To the solution, *N,S*-ditrityl-D-cysteine 5-norbornene-*endo*-2,3-dicarboximidyl ester (**15**) (24.0 g, 33.1 mmol) was added with vigorous stirring for 20 min at room temperature. Ethyl acetate was added to the reaction mixture, and the solution was washed with saturated aqueous sodium hydrogencarbonate and brine. An organic layer was dried over anhydrous magnesium sulfate and concentrated *in vacuo*. The residue was recrystallized from ethyl acetate and hexane; yield 20.3 g (87.9%). Mp 214—215 °C (dec). $[\alpha]_D^{21}$ −23.6° (*c* 2.02, chloroform). Found: C, 78.40; H, 5.94; N, 3.89; S, 4.50%. Calcd for $C_{46}H_{40}N_2O_3S$: C, 78.83; H, 5.75; N, 4.00; S, 4.57%. 100 MHz ^{1}H-NMR ($CDCl_3$) δ=7.0—7.6 (30H, m), 4.86 (1H, s), 4.84 (1H, br. s), 3.78 (3H, s), 3.77 (1H, d, *J*=18 Hz), 3.43 (1H, br. t), 3.34 (1H, d, *J*=18 Hz), 2.80 (1H, dd, *J*=6 Hz, 12 Hz), 2.58 (1H, dd, *J*=4 Hz, 12 Hz). 22.5 MHz ^{13}C-NMR ($CDCl_3$) δ=175.9, 172.2, 168.8, 146.1, 145.0, 129.8, 129.0, 127.8, 127.5, 126.5, 126.2, 94.3, 71.2, 66.5, 58.5, 54.4, 48.2, 36.8.

1-[(S)-2-(Benzyloxycarbonylaminomethyl)-2-thiazoline-4-carbonyl]-4-methoxy-3-pyrrolin-2-one (10). *i)* Via *Photoreaction*: To a suspension of (*S*)-2-(benzyloxycarbonylaminomethyl)-2-thiazoline-4-carbohydrazide dihydrochloride (1.33 g, 3.48 mmol) in 32 ml of degassed ethanol-free chloroform, isopentyl nitrite (0.673 ml, 3.44 mmol) and 4.20 M hydrogen chloride in tetrahydrofuran (0.815 ml, 3.44 mmol) were added at −18 °C and the stirring was continued for 25 min at −18 °C. The reaction mixture was neutralized with triethylamine (1.54 ml, 11.1 mmol). To the solution, diketene (2.65 ml, 3.48 mol) was added and irradiated with a 100 watt high-pressure mercury lamp (HALOS PIH-100) with a quartz filter under nitrogen atmosphere at 0 °C for 6 h. After concentration *in vacuo*, the residual oil was dissolved in 10 ml of chloroform and methylated with excess ethereal diazomethane with stirring for 2.5 h. After evaporation of diazomethane under reduced pressure, the solution was washed with saturated aqueous sodium hydrogencarbonate and brine. The organic layer was dried over anhydrous magnesium sulfate, and concentrated *in vacuo*. Purification by silica-gel preparative TLC (benzene–ethyl acetate 1:3) gave colorless oil; yield 67.7 mg (5.0%).

ii) Via *Sodium Salt of Pyrrolinone*: To a suspension of 1-(*N,S*-dirityl-D-cysteinyl)-4-methoxy-3-pyrrolin-2-one (**18**) (1.14 g, 1.63 mmol) in the mixture of 5.70 ml of methanol and 4.00 ml of benzene, pyridine (144 μl, 1.79 mmol) and silver nitrate (304 mg, 1.79 mmol) were added and stirring was continued for 4 h at room temperature. Hydrogen sulfide was bubbled through the reaction mixture for 20 min at room temperature. Silver sulfide was filtered off and the filtrate was concentrated *in vacuo*. To a solution of the residual oil in 22 ml of 99% ethanol, ethyl (benzyloxycarbonylamino)acetimidate[10] (385 mg, 1.63 mmol) was added and stirred for 20 h at room temperature. After concentration, the residual oil was dissolved in ethyl acetate and washed with saturated aqueous sodium hydrogencarbonate and brine. The organic layer was dried over anhydrous magnesium sulfate and concentrated *in vacuo*. The residue was recrystallized from ethyl acetate and hexane; yield 250 mg (39.4%). Mp 185—186 °C (dec). $[\alpha]_D^{20}$ +21.0° (*c* 0.879, chloroform). Found: C, 55.54; H, 4.94; N, 10.73; S, 8.02%. Calcd for $C_{18}H_{19}N_3O_5S$: C, 55.52; H, 4.92; N, 10.79; S, 8.23%. 100 MHz ^{1}H-NMR ($CDCl_3$) δ=7.36 (5H, s), 6.24 (1H, tt, *J*=1 Hz, 9 Hz), 5.54 (1H, br. s), 5.16 (1H, s), 5.15 (2H, s), 4.30 (2H, s), 4.26 (2H, dd, *J*=1 Hz, 5 Hz), 3.90 (3H, s), 3.61 (1H, dd, *J*=6 Hz, 9 Hz), and 3.50 (1H, dd, *J*=6 Hz, 9 Hz). 22.5 MHz ^{13}C-NMR ($CDCl_3$) δ=176.6, 171.9, 169.5, 169.0, 155.9, 136.4, 128.5, 128.0, 94.5, 78.1, 67.1, 58.8, 48.5, 43.7, and 35.7.

1-[(4S)-2-[1-(Benzyloxycarbonylamino)-2-hydroxyethyl]-2-thiazoline-4-carbonyl]-4-methoxy-3-pyrrolin-2-one (19). To a solution of 1-[(*S*)-2-(benzyloxycarbonylaminomethyl)-2-thiazoline-4-carbonyl]-4-methoxy-3-pyrrolin-2-one (**10**) (50.0 mg, 0.129 mmol) in 500 μl of degassed dimethyl sulfoxide, pulverized paraformaldehyde (77.0 mg, 2.57 mmol) was added. The mixture was stirred for 7 d at room temperature. The insoluble material was filtered off and the filtrate was dissolved in ethyl acetate. The solution was washed with water and dried over anhydrous magnesium sulfate. The solution was concentrated *in vacuo*. The residue was lyophilized; yield 52.7 mg (97.6%). Mp 71—73 °C. 100 MHz ^{1}H-NMR ($CDCl_3$) δ=7.34 (5H, s), 6.29 (1H, m), 5.88 (1H, m), 5.16 (1H, s), 5.13 (2H, s), 4.75 (1H, m), 4.28 (2H, s), 3.95—4.08 (3H, m), 3.90 (3H, s), 3.48 (1H, d, *J*=6 Hz), and 3.35 (1H, d, *J*=6 Hz). 22.5 MHz ^{13}C-NMR ($CDCl_3$) δ=177.0, 176.9, 169.7, 169.5, 156.6, 136.3, 128.5, 128.0, 94.4, 78.2, 67.1, 66.5, 58.9, 52.7, 48.4, and 34.1.

Diethoxyacetamide (21). A solution of ethyl diethoxyacetate[15] (42.7 g, 0.243 mol) in 2 l of 99% ethanol, was saturated with ammonia in a pressure bottle and kept at room temperature for 2 d. Concentration *in vacuo* gave colorless plates; yield 36.4 g (100%). Mp 80—81 °C. IR (Nujol) 1670 cm^{-1}. Found: C, 48.70; H, 8.91; N, 9.49%. Calcd for $C_6H_{13}NO_3$: C, 48.96; H, 8.90; N, 9.52%. 60 MHz ^{1}H-NMR ($CDCl_3$) δ=6.8 (2H, br.), 4.88 (1H, s), 3.73 (2H, q, *J*=7 Hz), 1.27 (6H, t, *J*=7 Hz).

Diethoxyacetonitrile (22). To a solution of diethoxyacetamide (**21**) (1.00 g, 6.80 mmol) in 16 ml of pyridine, phosphoryl chloride (1.15 g, 7.49 mmol) was added dropwise with stirring at −18 °C for 30 min. After additional stirring for 30 min, the reaction mixture was poured into about 100 g of cracked ice carefully. The mixture was extracted with ether and washed with 1M hydrochloric acid, brine, saturated aqueous sodium hydrogencarbonate, and brine successively. The organic layer was dried over anhydrous magnesium sulfate, and concentrated *in vacuo*. The residual oil was distilled under reduced pressure and collected a fraction boiling at 63—63.5 °C/ 22 mmHg: yield 0.78 g (89%). Found: C, 55.82; H, 8.69; N, 10.92%. Calcd for $C_6H_{11}NO_2$: C, 55.79; H, 8.59; N, 10.85%. 60 MHz ^{1}H-NMR ($CDCl_3$) δ=5.48 (1H, s), 3.73 (4H, q, *J*=7 Hz), and 1.25 (6H, t, *J*=7 Hz).

Diethoxythioacetamide (23). *i) From 21*: To a solution of diethoxyacetamide (**21**) (4.00 g, 27.2 mmol) in 50 ml of dry benzene, phosphorus pentasulfide (2.00 g, 9.00 mmol) was added portionwise with stirring during a period of 10 min at room temperature. After additional stirring for 10 min, an insoluble material was removed by decantation, and the

supernatant was washed with saturated aqueous sodium hydrogencarbonate and brine. The organic layer was dried over anhydrous magnesium sulfate, and concentrated *in vacuo*. The residue was recrystallized from benzene and hexane; yield 2.86 g (64.3%).

ii) From **22**: Through a solution of diethoxyacetonitrile (**22**) (580 mg, 4.50 mmol) in 300 ml of dry methanol containing 18 g of ammonia, hydrogen sulfide was bubbled with stirring for 16 h at room temperature. After hydrogen sulfide was removed by aeration, the solution was concentrated *in vacuo*. Recrystallization from benzene–hexane gave colorless needles; yield 0.73 g (100%). Mp 81—82 °C. IR (Nujol) 1600 cm^{-1} ($\nu_{C=S}$). Found: C, 44.18; H, 8.06; N, 8.54; S, 19.50%. Calcd for $C_6H_{13}NO_2S$: C, 44.15; H, 8.03; N, 8.58; S, 19.69%. 60 MHz ^{1}H-NMR ($CDCl_3$) δ=8.2 (2H, br.), 5.10 (1H, s), 3.75 (4H, q, J=7 Hz), and 1.20 (6H, t, J=7 Hz).

Ethyl 2-(diethoxymethyl)-4-thiazolecarboxylate (24). Ethyl 3-bromopyruvate[18] (0.37 g, 1.9 mmol) was added to a solution of diethoxythioacetamide (**23**) (0.37 g, 2.3 mmol) in 4 ml of dry ethanol, and the mixture was heated under reflux in the presence of Molecular Sieves 3A (about 1 g) for 30 min. The solution was concentrated *in vacuo*, extracted with ethyl acetate and washed with saturated aqueous sodium hydrogencarbonate and brine. The organic layer was dried over anhydrous magnesium sulfate and concentrated *in vacuo*. Purification by preparative TLC (chloroform–methanol 50:1) gave colorless oil; yield 0.49 g (100%). Found: C, 51.19; H, 6.68; N, 5.25; S, 11.79%. Calcd for $C_{11}H_{17}NO_4S$: C, 50.95; H, 6.61; N, 5.40; S, 12.36%. 60 MHz ^{1}H-NMR ($CDCl_3$) δ=8.30 (1H, s), 5.78 (1H, s), 4.48 (2H, q, J=7 Hz), 3.77 (4H, q, J=7 Hz), 1.40 (3H, t, J=7 Hz), and 1.25 (6H, t, J=7 Hz).

Ethyl 2-Formyl-4-thiazolecarboxylate (25). To a solution of ethyl 2-(diethoxymethyl)-4-thiazolecarboxylate (**24**) (1.59 g, 6.13 mmol) in 125 ml of acetone, 1 M hydrochloric acid (12.5 ml) was added and heated under reflux for 45 min. The reaction mixture was concentrated *in vacuo*, and the residual oil was extracted with ethyl acetate and washed with saturated aqueous sodium hydrogencarbonate and brine. The organic layer was dried over anhydrous magnesium sulfate, and concentrated *in vacuo*. The residue was recrystallized from ether and hexane; yield 1.13 g (100%). Mp 67—68 °C. IR (Nujol) 1720 and 1695 cm^{-1}. Found: C, 45.54; H, 3.75; N, 7.55; S, 17.25%. Calcd for $C_7H_7NO_3S$: C, 45.39; H, 3.81; N, 7.56; S, 17.31%. 60 MHz ^{1}H-NMR ($CDCl_3$) δ=10.13 (1H, d, J=1 Hz), 8.63 (1H, d, J=1 Hz), 4.53 (2H, q, J=7 Hz), and 1.43 (3H, t, J=7 Hz).

Ethyl (E)- and (Z)-2-(Hydroxyiminomethyl)-4-thiazolecarboxylate (26, 27). To a solution of ethyl 2-formyl-4-thiazolecarboxylate (**25**) (8.14 g, 44.0 mmol) in 70 ml of dry ethanol, pyridine (70.0 ml, 0.871 mol) and hydroxylamine hydrochloride (13.0 g, 0.187 mol) were added and heated under reflux for 1 h. The reaction mixture was concentrated *in vacuo*, and water (100 ml) was added to the residual oil. The precipitate was recrystallized from ethyl acetate and hexane; yield 8.04 g (91.4%). This solid is a mixture of (*E*)- and (*Z*)-aldoxime in ratio of about 1:1. Fractional recrystallization of the mixture from either ethyl acetate–hexane or methanol–ether gave colorless needles (**26**) and colorless powder (**27**). (*E*)-isomer **26**: Mp 183—184 °C. Found: C, 42.08; H, 4.01; N, 13.85; S, 15.91%. Calcd for $C_7H_8N_2O_3S$: C, 41.99; H, 4.03; H, 14.00; S, 16.01%. 100 MHz ^{1}H-NMR (DMSO-d_6): δ=12.24 (1H, s), 8.50 (1H, d, J=1 Hz), 8.40 (1H, d, J=1 Hz), 4.38 (2H, q, J=7 Hz), 1.36 (3H, t, J=7 Hz); (*Z*)-isomer **27**: mp 163—164 °C. Found: C, 42.09; H, 4.01; N, 13.87; S, 16.04%. Calcd for $C_7H_8N_2O_3S$: C, 41.99; H, 4.03; N, 14.00; S, 16.01%. 100 MHz ^{1}H-NMR (DMSO-d_6) δ=13.12 (1H, br. s), 8.67 (1H, d, J=1 Hz), 8.10 (1H, d, J=1 Hz), 4.39 (2H, q, J=7 Hz), 1.36 (3H, t, J=7 Hz).

(E)-2-(Hydroxyiminomethyl)-4-thiazolecarbohydrazide (28). To a solution of ethyl (*E*)-2-(hydroxyiminomethyl)-4-thiazolecarboxylate (**26**) (4.50 g, 22.5 mmol) in 40 ml of *N,N*-dimethylformamide, 100% hydrazine hydrate (24.0 ml, 0.494 mol) was added at 0 °C and allowed to react for 18 h at 5 °C. Colorless needles precipitated was collected and washed with a small amount of methanol; yield 3.50 g (89.7%). Mp>200 °C. Found: C, 32.30; H, 3.30; N, 29.70; S, 17.35%. Calcd for $C_5H_6N_4O_2S$: C, 32.25; H, 3.25; N, 30.09; S, 17.22%. 60 MHz ^{1}H-NMR (DMSO-d_6) δ=8.40 (1H, s), 8.32 (1H, s).

(E)-2-(Hydroxyiminomethyl)thiazole-4-carbonyl Azide (29). To a suspension of (*E*)-2-(hydroxyiminomethyl)-4-thiazolecarbohydrazide (**28**) (500 mg, 2.69 mmol) in 3 ml of *N,N*-dimethylformamide, *t*-butyl nitrite (350 μl, 2.96 mmol) and 4.67 M hydrogen chloride in tetrahydrofuran (1.27 ml, 5.92 mmol) were added at −50 °C. The reaction mixture was stirred for 3 h at −30 °C, extracted with ethyl acetate and washed with water. The organic layer was dried over anhydrous magnesium sulfate and concentrated *in vacuo*. The residue was recrystallized from acetone and hexane; yield 330 mg (62.3%). Mp 165—166 °C (dec). IR (Nujol) 2160 cm^{-1}. Found: C, 30.69; H, 1.64; N, 35.04; S, 16.58%. Calcd for $C_5H_3N_5O_2S$: C, 30.46; H, 1.53; N, 35.52; S, 16.26%. 60 MHz ^{1}H-NMR ($CDCl_3$–CD_3OD 1:1) δ=8.33 (1H, s), 8.32 (1H, s).

Althiomycin (1). To a solution of **19** (79.0 mg, 0.189 mmol) in 204 μl of anisole, anhydrous hydrogen fluoride (about 1 ml) was introduced at −78 °C within 10 min and stirred for a period of 20 min at 0 °C. Hydrogen fluoride was evaporated off *in vacuo* at 0 °C for 20 min. To a solution of the product in 1 ml of *N,N*-dimethylformamide, anhydrous potassium carbonate (781 mg, 5.66 mmol) was added at −78 °C. The reaction mixture was vigorously stirred for 5 min at room temperature under reduced pressure. Under cooling with Dry Ice–methanol bath, (*E*)-2-(hydroxyiminomethyl)-4-thiazolecarbonyl azide (**29**) (37.1 mg, 0.189 mmol) was added to the reaction mixture, which was stirred for 30 min at 0 °C and then for 2.5 h at room temperature. Ethyl acetate was added to this solution and washed with 0.1 M potassium phosphate buffer (pH 7.15) and water. The organic layer was dried over anhydrous magnesium sulfate and concentrated *in vacuo*. Purification by silica-gel preparative TLC using a developing solvent chloroform–methanol (9:1) gave colorless powder; yield 14.8 mg (17.9%). Mp 175—176 °C (dec). $[\alpha]_D^{27}$ +22.3° (*c* 0.065, Methyl Cellosolve). UV_{max} (CH_3OH) 223 nm (ε 34000), 240 nm (ε 25800), 286 nm (ε 8460). Found: C, 43.78; H, 4.38; N, 13.97; S, 12.95%. Calcd for $C_{16}H_{17}N_5O_6S_2 \cdot 0.5\ H_2O \cdot 0.5\ C_4H_8O_2$: C, 43.89; H, 4.50; N, 14.22; S, 13.02%. 90 MHz ^{1}H-NMR (DMSO-d_6) δ=8.40 (1H, br.s), 8.37 (1H, s), 8.35 (1H, s), 6.16 (1H, dt, J=3 Hz, 9 Hz), 5.43 (1H, s), 5.10 (1H, m), 4.90 (1H, m), 4.33 (2H, s), 3.89 (3H, s), 3.83 (2H, m), and 3.50 (2H, t).

The authors express our sincere thanks to Dr. Hamao Umezawa of Institute of Microbial Chemistry, and Dr. Hideo Sakakibara of the Research Laborato-

ries, Toyo Jozo Co. Ltd., for supplying natural althiomycin and giving kind suggestions. We also thank the Research Laboratories, Toyo Jozo Co. Ltd., for measurement of antibacterial activity. Authors deeply indebted to Mr. Kozo Sawada for his contribution in the initial stage of this work.

Preparation and Properties of Oligocytidylates with 2′—5′ Internucleotide Linkage

Hiroaki SAWAI* and Masaji OHNO
Faculty of Pharmaceutical Sciences, University of Tokyo Hongo, Bunkyo-ku, Tokyo 113
(Received September 3, 1984)

Oligocytidylates upto a pentamer were prepared by lead(II) ion catalyzed polymerization of cytidine 5′-phosphorimidazolide in aqueous solution. 2′—5′ internucleotide linkage was preferentially formed. The yields of the 2′—5′ linked dimer, trimer, tetramer and pentamer were 17.0, 5.5, 1.9, and 0.7%, respectively. Some of their properties were studied by NMR, CD, UV, and chromatography and compared with the corresponding 3′—5′ linked oligomers which were prepared enzymatically.

Biological and physicochemical properties of 2′—5′ linked oligonucleotides have attracted widespread interest because unusual 2′—5′ linked oligoadenylates were isolated from interferon-treated cell and shown to be associated with the interferon's action.[1-3] Previously we have reported the preparation of 2′—5′ linked oligoadenylates by lead(II) ion catalyzed polymerization of adenosine 5′-phosphorimidazolide in aqueous solution.[4] The method provided a very simple preparative procedure for the 2′—5′ oligonucleotides. Preparation of other 2′—5′ linked oligonucleotides has been conducted by a similar procedure.[5,6] Oligoribonucleotides with 2′—5′ internucleotide linkage were preferentially formed by the reaction, though the yield and distribution of the resulting oligomers were different depending on the base moiety. In this paper, we report the synthesis of 2′—5′ linked oligocytidylates from cytidine 5′-phosphorimidazolide by lead(II) ion catalysis. Physicochemical properties of the 2′—5′ linked oligocytidylates are described and compared with the corresponding 3′—5′ linked oligocytidylates which were prepared by partial enzyme digestion of polycytidylate.

Results and Discussion

Cytidine 5′-phosphorimidazolide (ImpC) was prepared from cytidine 5′-phospate and imidazole using di-2-pyridyl disulfide and triphenylphosphine as a condensing agent.[5,7] Polymerization of ImpC was carried out in neutral aqueous solution in the presence of lead(II) nitrate as a catalysis. The starting ImpC disappeared almost completely in 3 d at room temperature. The reaction mixture was treated with Versenol solution to break the Pb^{2+}-nucleotide complex which was checked by HPLC. The solution was applied to a QAE-Sepahdex A-25 column and eluted with a linear gradient of triethylammonium hydrogencarbonate buffer. The elution profile is shown in Fig. 1. The separated products were further purified by paper chromatography when necessary. The peak identification and the yields of the products are given in Table 1. Oligocytidylates upto a pentamer were formed in the reaction. The lead(II) ion catalyzed internucleotide-bond formation is shown in Scheme 1. The oligocytidylates thus obtained were characterized by enzyme digestions, TLC and NMR. The 2′—5′ internucleotide linkage is not degraded with nuclease P_1 (N. P_1) and RNAse T_2 which degrades 3′—5′ internucleotide linkage. Both 2′—5′ and 3′—5′ internucleotide linkages are hydrolyzed with snake venom phosphodiesterase (VPDase) and by alkaline digestion. The internucleotide linkage and the chain length of the oligocytidylates were determined by sequential enzyme digestion using bacterial alkaline phosphatase (BAPF), N. P_1, VPDase and alkaline digestion. The yields of 2′—5′ linked dimer, trimer, tetramer and pentamer were 17.0, 5.5, 1.9, and 0.7%, respectively. The 3′—5′ linked dimer and trimer were isolated in 1.6 and 0.3%, respectively. Two linkage isomers, pC2′p5′pC3′p5′C and pC3′p5′pC2′p5′C, which appeared in peaks 10 and 11 were obtained in 2.8 and 1.4% yields, respectively. Three tetramers, containing one 3′—5′ and two 2′—5′ internucleotide linkage in a different position, were present in peak 12 along with 2′—5′ $(pC)_4$. The compound with a pyrophosphate bond, CppC, was obtained as a minor byproduct. Cytidine 3′,5′-cyclic phosphate which was formed by intramolecular phosphodiester bond formation was present in peak 4. Cyclic dicytidylates were obtained in 11.4% yield in peak 7. In contrast to the linear oligomers, 3′—5′ internucleotide linkage was predominant in the cyclic dicytidylates, as 3′—5′ linkage is conformationally preferable for the cyclic nucleotides. The cyclic dicytidylate with two 3′—5′ linkages was degraded with N. P_1 to cytidylic acid and insensitive to BAPF. The 3′—5′, 2′—5′ linked cyclic dicytidylate was hydrolyzed with N. P_1 to pC2′p5′C. The 2′—5′, 2′—5′ linked cyclic dimer was insensitive to N. P_1 but was digested with VPDase. The major feature of the reaction is preferential formation of 2′—5′ linked linear oligocytidylates. The yield and distribution of the products are comparable to those of the lead-ion catalyzed oligouridylates formation.[5] The yields and the selectivity of the 2′—5′ linked oligomers are lower than those of the oligoadenylates

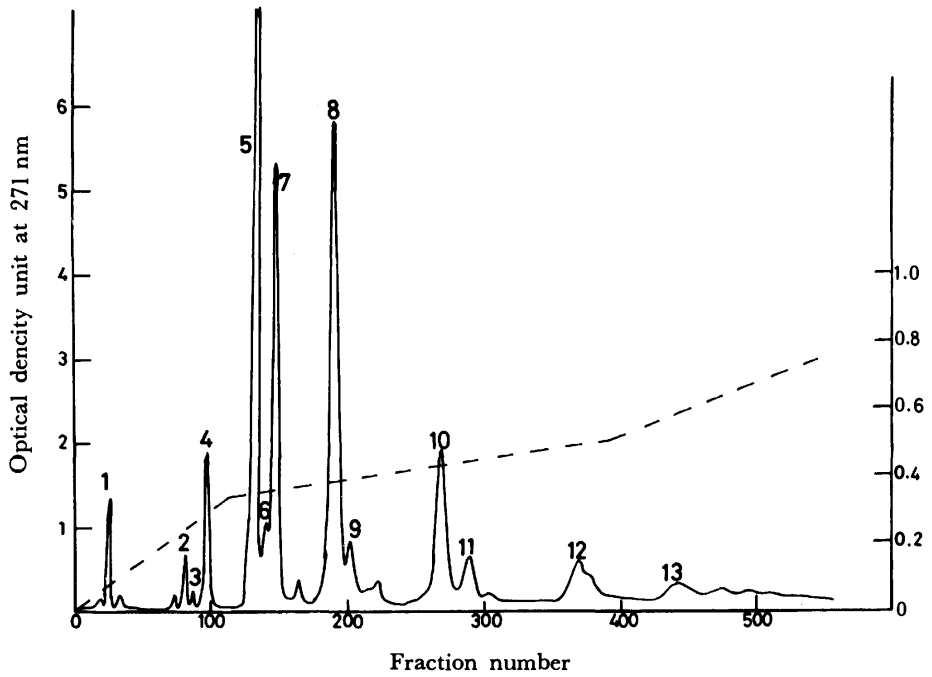

Fig. 1. Chromatography of the Products on QAE-Sephadex A-25 column. A linear gradient of triethylammonium hydrogencarbonate was used for elution (dotted line). The characterization of the peaks is listed in Table 1.

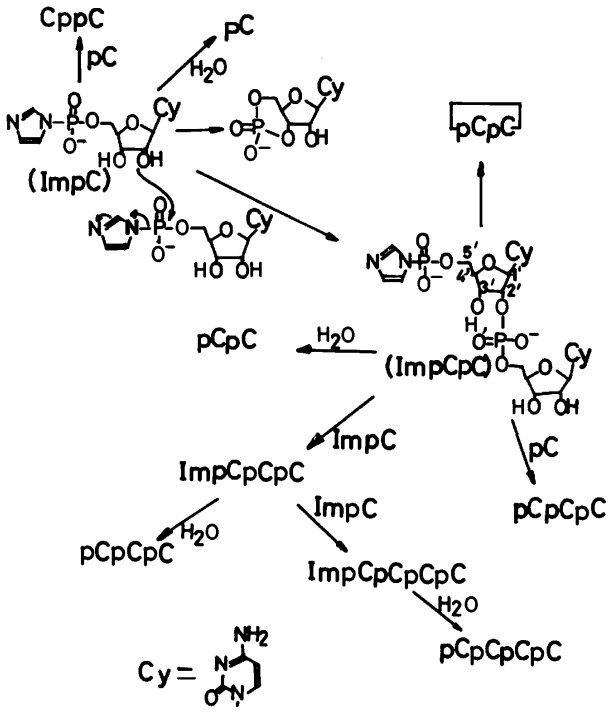
a) Hypochromicity estimated from alkaline hydrolysis. b) Yield obtained from UV_{271} after allowing the hypochromicity of each oligocytidylate. Total ODU_{271} of starting ImpC was 4160 (0.45 mmol). c) Mean hypochromicity of the compounds in the peak.



formation.[4] However, this procedure provides a simple synthetic method to the 2′—5′ linked oligocytidylates.

Table 2 lists R_f values of the 2′—5′ and 3′—5′ linked oligocytidylates. Paper chromatographic mobilities of 2′—5′ linked oligomers are large compared to those of the corresponding 3′—5′ linked

oligomers when buffer of high salt concentration was used as a developing solvent (solvent II). The result suggests that 2′—5′ linked oligomers have hydrophilic character and 3′—5′ linked oligomers have hydrophobic character. The same tendency was also observed in the 2′—5′ and 3′—5′ linked oligoadenylates, where the difference of the mobilities were larger.[4,8]

NMR data of the 2′—5′ and 3′—5′ linked oligocytidylates are listed in Table 3. Cytosine H-5 and H-6 protons of the 2′—5′ linked oligomers shows high-field shift compared to those of the 3′—5′ linked oligomers.

Figure 2 shows CD spectra of the 2′—5′ and 3′—5′ linked oligocytidylates at 27 °C. CD spectra of 2′—5′ and 3′—5′ linked tetracytidylates at 4, 27, and 55 °C are shown in Fig. 3. CD band of 3′—5′ linked oligomers is stronger than that of the 2′—5′ linked oligomers and increases with increasing the chain length. Temperature dependance and chain length dependance of the CD spectra of 3′—5′ linked oligomers are larger than those of 2′—5′ linked oligomers

which are similar to those of monomeric cytidylic acid. The CD data suggest that 3′—5′ linked oligomers possess higher ordered but more flexible structure than 2′—5′ linked oligomers. The character is also observed in the 2′—5′ and 3′—5′ linked oligoadenylates.[8] We tentatively believe that 3′—5′ linked oligomers can possess various conformations depending on the change of environment such as temperature and salt concentration, which is important for the function of RNA.

Experimental

Materials. Cytidine 5′-phosphoric acid was obtained from Yamasa. Cytidine 5′-phosphorimidazolide was prepared from pC and imidazole using di-2-pyridyl disulfide and triphenylphospine as a condensing agent by the similar method as published procedure.[5,7] Bacterial alkaline phosphatase (BAPF) and snake venom phosphodiestearase (VPDase) were from Worthington. Polycytidylic acid (sodium salt), nuclease p_1 (N. P_1) and nuclease SW were

purchased from Seikagaku Kogyo.

Paper Chromatography and HPLC. Paper chromagtography was carried out by a descending technique on Whatman 3MM paper using solvent system (I), 1-propanol–aqueous ammonia (55:45), and (II), saturated ammonium sulfate–0.1 M sodium (1 M=1 mol dm^{-3}) acetate (pH 6.5)–2-propanol (79:19:2).

HPLC was performed with a Hitachi 638 using a RPC-5 column (4 mm×25 cm). RPC-5 was prepared from fine grannular poly(chlorotrifluoroethylene) and Adogen 464 by the modification of the method according to Pearson *et al.*[9] Elution was carried out with a linear gradient of $NaClO_4$ solution (0—0.01 M) buffered with 2.5 mM Tris acetate (pH 7.5).

Spectrometric Method. UV absorption spectra were recorded by a Shimazu MPS-5000 instrument in 0.1 M phosphate buffer (pH 6.7). NMR spectra were taken by a JEOL-GX-400 instrument using TSP-d_4 as an internal standard. The sample was passed through a short Dowex 50WX-8 (Na^+ form) column, evaporated under vacuum and repeated coevaporation with D_2O (1 ml×3). Concentration of the sample was about 5 mM per cytidine residue in D_2O (0.1 M phosphate buffer, pH 6.7). CD spectra were measured by a JASCO J-40 spectrometer using a 2 mm cell in 0.1 M phosphate buffer (pH 6.7).

Polymerization of ImpC. To an aqueous solution (6.8 ml) of ImpC (189 mg, 0.4 mmol, 4160 ODU_{270}), 0.8 ml of imidazole buffer (2 M, pH 6.5) and 0.4 ml of 0.25 M lead nitrate were added with stirring. The reaction mixture was kept at 20 °C for 5 d with stirring. Versenol buffer (0.6 ml×0.25 M, pH 7.0) was added to the reaction mixture to remove Pb(II) ion by Versenol-Pb^{2+} complex formation. HPLC of an aliquot showed the formation of oligocytidylates and the disapperance of ImpC. The solution was applied to a QAE-Sephadex A-25 column (30 mmϕ×45 cm). The column was eluted with a stepwise linear gradient of triethylammonium hydrogencarbonate buffer (1) H_2O-0.33 M (2×0.9 l), (2) 0.33 M—0.5 M (2×2 l), (3) 0.5 M—0.75 M (2×1 l). 15 ml of each fraction was collected every 12 min. UV absorption of each fraction was measured at 271 nm. The UV absorbing fractions were pooled and evaporated under vacuum below 30 °C. The excess triethylammonium hydrogencarbonate was removed by repeated evaporation after addition of water. The products were further purified by paper chromatography using solvent system (I) when necessary. The yield was calculated from ODU_{271} after allowing for the hypochromicity of each oligocytidylate. The hypochromicity was estimated by the ratio of UV absorption at 270 nm after and before alkaline hydrolysis of the oligocytidylate.

Enzymatic Synthesis of 3′—5′ Linked Oligocytidylates. Polycytidylic acid sodium salt (25 mg, 0.055 mmol) was digested with nuclease SW (400 units) in the solution (6 ml) containing sodium carbonate buffer (0.05 M, pH 10.3), NaCl (0.1 M), $MgCl_2$ (1 mM) and sodium acetate (2 mM) at 37 °C for 20 h. The reaction mixture was applied to a DEAE-Sephadex A-25 column (25 mmϕ×35 cm) and eluted with a linear gradient of triethylammonium hydrogencarbonate buffer (0.25 M—0.5 M, 2×1 l). 10 ml of each fraction was collected every 10 min. The UV absorbing fractions were pooled and evaporated under vacuum below 30 °C. The 3′—5′ linked di-, tri-, and tetra-cytidylates with 5′-terminal phosphate were obtained in 29% (1350 ODU_{270}, 0.016 mmol), 42% (1180 ODU_{270}, 0.023 mmol) and 18% (780 ODU_{270}, 0.01 mmol) yields, respectively.

Chracterization of the Oligocytidylates. Characterization of the products was carried out by means of sequential enzyme and alkaline hydrolysis. Each oligocytidylate was subjected to paper chromatography in solvent system (I) and (II). The UV absorbing spot on the paper developed with solvent system (I) was eluted with water and incubated with BAPF to remove 5′-terminal phosphate. The mixture was chromatographed on the paper with solvent system (I). The UV absorbing spot on the paper was eluted with water and incubated with N. P_I to degrade 3′—5′ internucleotide linkage. The mixture was analyzed by HPLC and paper chromatography in solvent system (I). The UV absorbing spot on the paper was eluted with water and incubated with VPDase and NaOH solution to degrade 2′—5′ internucleo-

tide linkage. The degraded products were analyzed by HPLC.

Digestion with BAPF was carried out by incubating a mixture of 0.5—1 μmol of nucleotide material in a 50 μl solution containing 0.1 M Tris-HCl (pH 8.05), 0.001 M $MgCl_2$ and 0.1 unit of the enzyme, at 37 °C for 2.5 h.

Digestion with N. P_1 was performed at 37 °C for 2.5 h in a mixture (50 μl) containing the nucleotide material (0.4—0.8 μmol), 0.006 M veronal acetate buffer (pH 5.75) and an enzyme (5 μg).

Degradation with VPDase was carried out at 37 °C for 2.5 h in a mixture (50 μl) containing the substrate (0.1—0.2 μmol), 0.01 M Tris-acetate (pH 8.0), 0.01 M $MgCl_2$ and enzyme solution (0.01 unit).

Alkaline hydrolysis was carried out at room temperature for 1 d in a mixture (50 μl) containing the substrate (0.1—0.2 μmol) in a 0.5 M NaOH solution.

The structure of the oligocytidylates was further confirmed by NMR, and by comparing the paper chromatography and HPLC with that of the authentic sample when available.

The authors are very grateful to professor H. Hirai, Mr. T. Kawamura, and Mrs. Y. Goto for their help in taking 400 MHz NMR, and to Dr. S. Higuchi for his aid in measuring CD spectra.

(Received September 7, 1984)

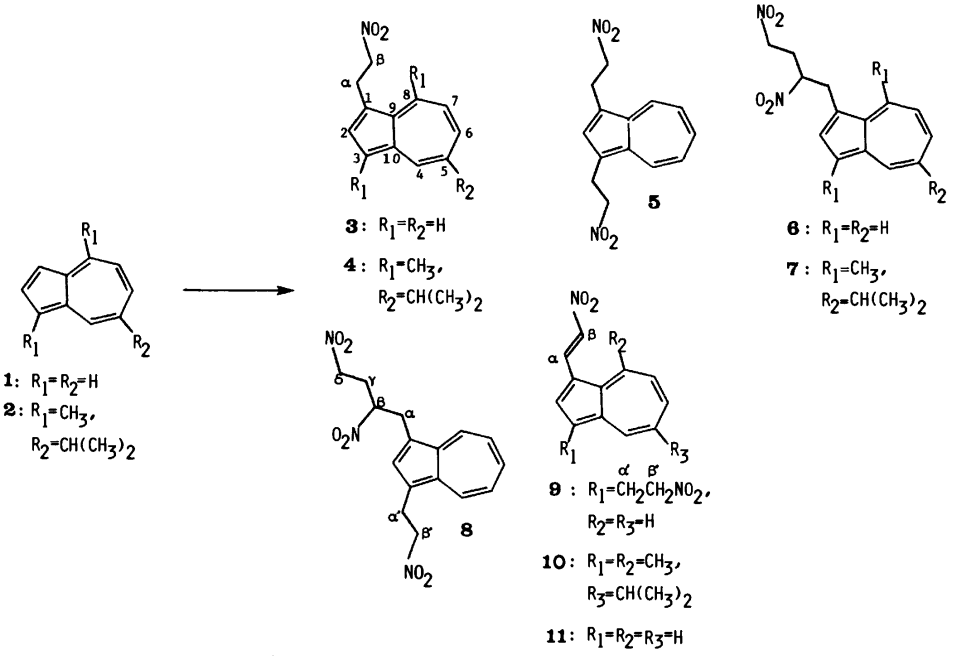
Azulene and guaiazulene react with nitroethene to form substitution products having 2-nitroethyl, 2,4-dinitrobutyl, or 2-nitroethenyl groups at the 1(3)-position in low yields. The presence of formic acid prevented the formation of the dinitrobutyl compound, and increased the yield of the 2-nitroethyl derivative. A reaction course leading to these products is proposed. Reduction of 1-(2-nitroethyl)azulene and 1-(2-nitroethyl)-guaiazulene gave the corresponding amine compounds in good yields. This two-step process provides a new, improved route to 2-(1-azulenyl)ethanamines having a primary amino group. The amine products, like related biogenic amines, inhibited the contraction of smooth muscle.

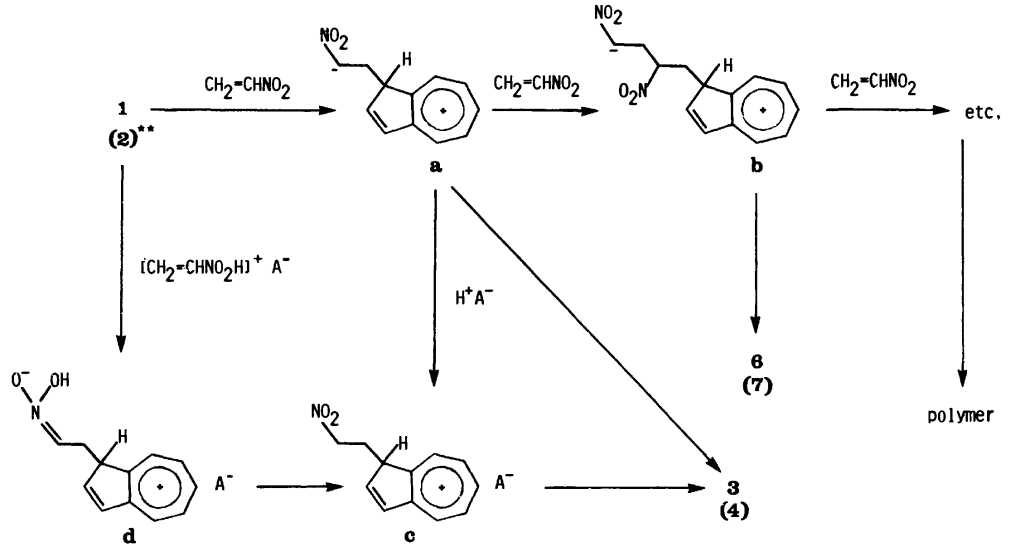
2-Arylethanamine derivatives constitute an important class of physiologically active compounds related to biogenic amines.[1] In studying azulene analogs of biologically active amines, we have previously reported the synthesis of some *N*-alkyl and *N*-acyl derivatives of 2-(1-azulenyl)ethanamines[2] and 2-(4-azulenyl)ethanamine[3,4] compounds by ring aminoethylation and methyl side chain aminomethylation methods, respectively, and the effect of these compounds on specific enzyme activity.[2,4] These methods, however, were not successful for the preparation of azulenylethanamines having a primary amino group as in norepinephrine (noradrenaline), dopamine, serotonin, *etc.* The search for a synthetic route to this type of azulene compound led the investigation of the reaction of azulene and guaiazulene with nitroethene to form the corresponding 1-(2-nitroethyl) derivatives,[5] and the reduction of these to the primary amines.

Results and Discussion

Nitroethene (*ca.* 10% in benzene)[6] reacted with azulene (**1**) at room temperature to yield 1-(2-nitroethyl)azulene (**3**) (8%). Three by-products, **5** (6%), **6** (5%), and **8** (3%), were also formed. The structures of these compounds were determined by spectral analyses.

For example, the ^{1}H NMR spectrum of **6** showed a complicated splitting pattern for the 2,4-dinitrobutyl moiety. Analysis according to an ABX spin system[7] composed of nonequivalent (adjacent to an asymmetric center) α-methylene protons (3.61 and 3.82 ppm for AB) and a β-methine proton (4.94 ppm for X) afforded reasonable coupling constant of J_{AB}= 14.7, J_{AX}=6.3, J_{BX}=6.8 Hz. A coupling through 4σ-bonds (1.1 Hz)[8] was observed between the β-methine and δ-methylene protons (4.34 ppm) of the dinitro-





Scheme 1.

butyl group. The ^{1}H NMR spectrum of **8** showed the same splitting pattern for the dinitrobutyl group.

Analogously, guaiazulene (**2**) under the same conditions afforded **4** (9%), **7** (3%), and **10** (2%). The 2,4-dinitrobutyl group of **7** exhibited the same ^{1}H NMR splitting pattern as that of **6**. It was further characterized by its ^{13}C NMR spectrum which showed triplet signals for the α-, γ-, and δ-carbons and a doublet for the β-carbon of the assigned structure.

The 2-nitroethenyl product (**10**) had been previously prepared by the reaction of 1-formylguaiazulene with nitromethane,[9] but the configuration of the double bond was not determined. Our data indicate a trans configuration: i) The coupling constant ($J_{\alpha,\beta}$=13.0 Hz) for the olefinic protons in the ^{1}H NMR spectrum has the expected value when the electronegative nitro substituent is taken into account.[10] ii) The chemical shifts for the olefinic protons (7.56 and 8.93 ppm) show full conjugation of the double bond with the azulene ring. Molecular models indicate this to be possible only for the trans geometry. iii) The IR absorption at 956 cm^{-1} corresponds to a trans alkene.

A large amount of insoluble, polymeric material was also observed in these reactions. This was thought to be produced by polymerization of the nitroethene initiated by a nucleophile (*e.g.* **1** or **2**) (*cf.* Scheme 1. **1**→**a**→**b**→polymer). The formation of **6**, **7**, and **8** having a dinitrobutyl side chain provides support for this concept. This polymerization process would be suppresses if an acid was present to react with the intermediate to form **c** (Scheme 1). The effects of trifluoroacetic acid, formic acid, and ether-boron trifluoride (1/1) were examined (Table 1). As expected, the reaction yielding **7** was blocked, but also the yield of **4** was reduced except with formic acid.

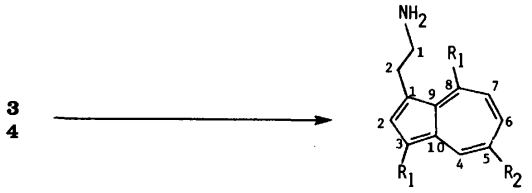
Table 1. Reaction of guaiazulene (**2**) and nitroethene in the presence of acid (nitroethene: acid: **2**=1.5:1.5:1 in mole ratio. Benzene as the solvent)

Acid	Reaction conditions		Yield/%		
	Temp	Time/h	**4**	**7**	**10**
CF_3COOH	0 °C	1.5	5	—	0.2
HCOOH	Ambient	1.5	9	—	2
$BF_3 \cdot O(C_2H_5)_2$	Ambient	1.4	0.8	—	10
None	50 °C	3.5	47	9	2
HCOOH	50 °C	5	50	—	2

In another modification, nitroethene was added slowly to a solution of **2** preheated to 50 °C. This minimized the polymerization process and markedly increased the yield of **4** (47%) but also raised the yield of **7** to 9%. This procedure was then used in the presence of formic acid to give 50% of **4** with no detectable amount of **7**. In two runs, the one with the slower addition of nitroethene gave the higher yield of **4**.

Application of the improved method using 1.5 equivalents of nitroethene to **1**, however, gave only 21% of **3** along with 5% of the disubstitution product (**5**). With 3 equivalents of nitroethene at 60 °C the yields of **3** and **5** were 15 and 71%, respectively. A trace amount (≤0.4%) of 1-(2-nitroethenyl)-3-(2-nitroethyl)-azulene (**9**) was also obtained from these reactions. The structures of **9** was assigned by comparison of its spectral characteristics with those of **11**, which was prepared from 1-formylazulene by an established procedure.[11] As described earlier for **10**, the ^{1}H NMR and IR spectra were indicative of a trans double bond in **9** and **11**. Attempted nitroethylation of **11** to form **9** was unsuccessful. This suggests that the nitroethenyl group in **11** is deactivating the

** Corresponding guaiazulene derivatives are shown in parentheses.



12 : $R_1=R_2=H$
13 : $R_1=CH_3$, $R_2=CH(CH_3)_2$

azulene ring and is formed after the nitroethyl group in the formation of **9** from **1**.

Scheme 1 summarizes the proposed reaction process of **1** with nitroethene. Intra- or intermolecular proton migration forms **3** from intermediate **a**. Alternatively, **a** can nucleophilically react with another molecule of nitroethene to form **b**, which can be converted to **6** or, by repetition of the process for **a**→**b** give polymeric material. The reaction of **3** with nitroethene would yield **5** or lead to **8**. The latter may also be formed by the reaction of **6** with nitroethene. Reaction of **a** with a protic acid would form **c** and prevent the process leading to **6** and polymer. The abstraction of a proton from **c** afford **3** if a sufficiently basic species is present. The action of formate ion to form **3** would account for the observation of the 1,3-disubstituted products, as **3** was shown to react further with nitroethene.

When a strong acid is present (*e.g.* trifluoroacetic acid), the conjugate acid of nitroethene could be formed and be the primary electrophilic reagent. If that event, **d** (formed directly from **1**) could tautomerize to give **c**, and **3** would be formed upon neutralization.

Hydride abstraction from the intermediate corresponding to **a** by one of the acidic species present would form the nitroethenyl side chains in **9** and **10**. This could have accounted for the increase in the yield of **10** when a Lewis acid was added (*cf.* $BF_3 \cdot O(C_2H_5)_2$ in Table 1). An indication of a possible oxidative dehydrogenation pathway (by air or nitro compounds[12]) to **9** and **10** from **5** and **4**, respectively, was provided by the observation that **4** yielded **10** readily when treated with palladized charcoal at room temperature, and even under reductive conditions.

The conversion of **3** and **4** into the corresponding primary amines (**12** and **13**) in good yields (79 and 77%) was effected by reduction with iron and acetic acid.[13] Other reduction trials with palladized charcoal and sodium borohydride[14] or lithium aluminum hydride were unsatisfactory. The chemical shifts and splittig patterns in the ^1H and ^{13}C NMR spectra of **12** and **13** compounds were in agreement with the assigned structures. Allyl fission of the aminoethyl side chain gave rise to the most abundant ion in the mass spectra, as previously observed for other azulenylethanamines.[2-4]

Compounds **12** and **13**, like related biogenic amines, strongly inhibited the contraction of smooth muscle.[15] Details of these studies will be reported elsewhere.

Experimental

All the melting points are uncorrected. Spectral data were recorded on the following instruments: UV, Hitachi 624 digital spectrometer with a Hitachi 056 recorder; IR, Hitachi 260-10 spectrometer; ^1H NMR, JEOL MH-100; ^{13}C NMR, JNM-FX 100; MS, JEOL-D 300 at 70 eV.

Nitroethene. This reagent was prepared from 2-nitroethanol and phthalic anhydride, and made into a *ca.* 10% benzene solution immediately after distillation:[6] ^1H NMR ($CDCl_3$) δ=4.78 (broad d, J=7.0 Hz, anti H), 5.94 (dd, J=15.0 and 2.0 Hz, syn H), and 6.41 (dd, J=7.0 and 15.0 Hz, $=C(NO_2)H$). The solutions of two preparative runs contained 9.7 and 11 wt% (by ^1H NMR) of nitroethene, respectively, and in the former case 3.4% of nitroethane was also noted: ^1H NMR ($CDCl_3$) δ=1.10 (t, J=7.0 Hz, CH_3) and 3.30 (q, J=7.0 Hz, CH_2).

Reaction of Azulene (1) and Nitroethene. A) Without Acid at Room Temperature. To an ice-cooled, stirred solution of 640 mg (4.99 mmol) of azulene in 35 cm^3 of dry dichloromethane was added dropwise, under dry nitrogen, 20 g of 9.7% benzene solution of nitroethene (containing 27 mmol of nitroethene) over a period of 30 min, and stirring was continued for 20 h more at room temperature. Removal of the solvent (reduced pressure) afforded a violet oil (7 spots on TLC over silica gel with benzene), which was chromatographed on a silica-gel column (elution with benzene) to give four products besides 80.2 mg (13%) of unchanged azulene eluted at first and recovered as violet crystals.

From the second eluate, 81.4 mg (8%) of 1-(2-nitroethyl)-azulene (**3**) was obtained as a blue oil: UV (C_2H_5OH) 237 (log ε 4.28), 263 (sh, 4.42), 268 (sh, 4.57), 272 (sh, 4.67), 276 (4.73), 280 (sh, 4.69), 286 (sh, 4.54), 295 (sh, 3.89), 328 (sh, 3.42), 332 (3.64), 342 (3.76), 524 (sh, 2.25), 550 (sh, 2.40), 571 (sh, 2.47), 588 (2.53), 608 (sh, 2.49), 638 (2.45), 668 (sh, 2.20), and 705 nm (2.02); IR (CCl_4) 3060, 3030 (aromatic CH), 2925 (CH_2), 1545, and 1378 cm^{-1} (NO_2); ^1H NMR ($CDCl_3$) δ=3.76 (2H, t, J=7.4 Hz, α-CH_2), 4.54 (2H, t, J=7.4 Hz, β-CH_2), 7.09 (1H, t, J=9.7 Hz, 5-H), 7.12 (1H, t, J=9.7 Hz, 7-H), 7.28 (1H, d, J=4.0 Hz, 3-H), 7.56 (1H, t, J=9.7 Hz, 6-H), 7.71 (1H, d, J=4.0 Hz, 2-H), and 8.22 (2H, dd, J=9.7 and 1.7 Hz, 4- and 8-H); ^{13}C NMR ($CDCl_3$) δ=25.5 (α-CH_2), 76.1 (β-CH_2), 117.3 (3-C), 122.4 (7-C), 123.0 (5-C), 122.9 (1-C), 132.9 (8-C), 136.1 (9-C), 136.7 (4-C), 136.9 (6-C), 137.9 (2-C), and 140.8 (10-C); MS

m/z (rel intensity) 201 (M^+; 80), 155 (M^+-NO_2; 100), and 141 ($M^+-CH_2NO_2$; 55).

Found: C, 71.97; H, 5.72; N, 6.37%. Calcd for $C_{12}H_{11}NO_2$: C, 71.63; H, 5.51; N, 6.96%.

From the third eluate, 67.5 mg (5%) of 1-(2,4-dinitrobutyl)-azulene (**6**) was obtained as blue crystals, mp 75—76 °C: UV (C_2H_5OH) 237 (log ε 4.47), 268 (sh, 4.69), 273 (sh, 4.79), 276 (4.84), 281 (4.80), 286 (sh, 4.68), 295 (sh, 4.17), 342 (4.01), 357 (3.86), 524 (sh, 2.44), 549 (2.56), 569 (sh, 2.62), 585 (2.66), 606 (sh, 2.62), 635 (2.58), 669 (sh, 2.30), and 701 nm (2.17); IR ($CHCl_3$) 1555 and 1370 cm^{-1} (NO_2); ^1H NMR ($CDCl_3$) δ=2.56 (2H, m, γ-CH_2), 3.61 and 3.82 (2H, symmetrical 8 lines, J=14.7, 6.8, and 6.3 Hz, α-CH_2), 4.34 (2H, dt, J=6.8 and 1.1 Hz. δ-CH_2), 4.94 (1H, m, β-CH), 7.14 (1H, t, J=9.7 Hz, 5-H), 7.16 (2H, t, J=9.7 Hz, 7-H), 7.30 (1H, d, J=4.0 Hz, 3-H), 7.60 (1H, t, J= 9.7 Hz, 6-H), 7.70 (1H, d, J=4.0 Hz, 2-H), 8.19 (1H, d, J=9.7 Hz, 4-H), and 8.27 (1H, d, J=9.7 Hz, 8-H); MS *m/z* (rel intensity) 274 (M^+; 24), 180 (M^+-2HNO_2; 11), 167 ($M^+-HNO_2-CH_2NO_2$; 18), and 141 ($M^+-C_3H_5N_2O_4$; 100).

Found: C, 61.11; H, 5.26; N, 9.96%. Calcd for $C_{14}H_{14}N_2O_4$: C, 61.31; H, 5.15; N, 10.21%.

From the fourth eluate, 76.7 mg (6%) of 1,3-bis(2-nitroethyl)azulene (**5**) was obtained as blue crystals, mp 95—96 °C: UV (C_2H_5OH) 238 (log ε 4.42), 271 (sh, 4.67), 275 (sh, 4.75), 279 (4.80), 283 (4.78), 289 (sh, 4.23), 346 (3.92), 362 (3.83), 560 (sh, 2.52), 600 (2.62), 647 (2.55), and 717 nm (sh, 2.14); IR ($CHCl_3$) 1550 and 1380 cm^{-1} (NO_2); ^1H NMR ($CDCl_3$) δ=3.72 (4H, t, J=7.4 Hz, α-CH_2), 4.64 (4H, t, J=7.4 Hz, β-CH_2), 7.12 (2H, t, J=9.7 Hz, 5- and 7-H), 7.59 (1H, t, J=9.7 Hz, 6-H), 7.59 (1H, s, 2-H), and 8.18 (2H, dd, J=9.7 and 1.7 Hz, 4- and 8-H); ^{13}C NMR ($CDCl_3$) δ=25.2 (α-CH_2), 76.1 (β-CH_2), 122.1 (1,3-C), 122.8 (5,7-C), 133.2 (4,8-C), 136.6 (9,10-C), 136.9 (6-C), and 138.5 (2-C); MS *m/z* (rel intensity) 274 (M^+; 63), 228 (M^+-NO_2; 47), 227 (M^+-HNO_2; 51), 214 ($M^+-CH_2NO_2$; 28), 182 (M^+-2NO_2; 23), 181 ($M^+-NO_2-HNO_2$; 83), and 167 ($M^+-HNO_2-CH_2NO_2$; 100).

From the last fraction, 53.1 mg (3%) of 1-(2,4-dinitrobutyl)-3-(2-nitroethyl)azulene (**8**) was obtained as a green oil: UV (C_2H_5OH) 238 (log ε 4.28), 266 (sh, 4.40), 270 (sh, 4.52), 275 (sh, 4.63), 279 (4.70), 284 (sh, 4.57), 298 (sh, 4.08), 345 (3.75), 363 (3.69), 446 (2.79), 562 (sh, 2.49), 585 (sh, 2.54), 596 (2.56), 640 (sh, 2.47), and 711 nm (2.02); IR ($CHCl_3$) 1560 and 1380 cm^{-1} (NO_2); ^1H NMR ($CDCl_3$) δ= 2.56 (2H, m, γ-CH_2), 3.70 (2H, symmetrical 8 lines, α-CH_2), 3.73 (2H, t, J=6.9 Hz, α'-CH_2), 4.37 (2H, dt, J= 6.9 and 1.7 Hz, δ-CH_2), 4.65 (2H, t, J=6.9 Hz, β'-CH_2), 4.90 (1H, m, β-CH), 7.61 (1H, t, J=10.3 Hz, 6-H), 8.16 (1H, d, J=10.3 Hz, 4-H), and 8.20 (1H, d, J= 10.3 Hz, 8-H); MS *m/z* (rel intensity) 347 (M^+; 54), 301 (M^+-NO_2; 52), 300 (M^+-HNO_2; 58), 287 ($M^+-CH_2NO_2$; 12), 254 ($M^+-NO_2-HNO_2$; 21), 253 (M^+-2HNO_2; 33), 227 ($M^+-2CH_2NO_2$; 12), 214 ($M^+-C_3H_5N_2O_4$; 75), 167 ($M^+-HNO_2-C_3H_5N_2O_4$; 100), and 153 ($M^+-CH_2NO_2-C_3H_5N_2O_4-H$; 80).

Found: C, 55.16; H, 4.87; N, 12.08%. Calcd for $C_{16}H_{17}N_3O_6$: C, 55.33; H, 4.93; N, 12.10%.

After the separation of these products, the solvent of the chromatography was changed to chloroform to afford an additional fraction, which was concentrated (reduced pressure) to leave 393 mg of brown solid. This material was insoluble in all organic solvents tested, but was soluble in mineral acid.

B) With Formic Acid at 50 °C. To a stirred solution of 130 mg (1.01 mmol) of azulene in 2 cm^3 of benzene, kept at 50 °C under dry nitrogen, was added dropwise a mixed reagent of 1.00 g (1.51 mmol) of 11% nitroethene solution and 69.4 mg (1.51 mmol) of formic acid during a period of 1 h, and stirring was continued for an additional 2 h at 50 °C. The reaction mixture was taken up in 100 cm^3 of benzene, washed with 10% potassium carbonate solution (50 cm^3×2), then with water (50 cm^3×3), dried on sodium sulfate, and concentrated (reduced pressure) to give a blue oil. Chromatography of the blue oil over silica gel (elution with benzene) gave 65.3 mg (50%) of unchanged **1**, 43.1 mg (21%) of **3**, 14.4 mg (5%) of **5**, and a small amount of brown crystalline material as the last fraction. The last fraction was rechromatographed over silica gel (benzene) to give 0.13 mg (0.5%) of 1-(2-nitroethenyl)-3-(2-nitroethyl)azulene (**9**) as dark brown crystals, mp 187—189 °C: UV (C_2H_5OH) 230 (log ε 4.20), 275 (sh, 4.22), 283 (4.26), 289 (sh, 4.24), 307 (sh, 3.95), 337 (3.88), 436 (sh, 4.11), and 448 nm (4.13); IR (KBr) 1550, 1318 (NO_2), and 950 cm^{-1} (trans CH); ^1H NMR ($CDCl_3$) δ=3.78 (2H, t, J=7.0 Hz, α'-CH_2), 4.73 (2H, t, J=7.0 Hz, β'-CH_2), 7.43 (1H, t, J=10.0 Hz, 5-H), 7.45 (1H, t, J=10.0 Hz, 7-H), 7.67 (1H, d, J=13.0 Hz, β-H), 7.81 (1H, t, J=10.0 Hz, 6-H), 7.96 (1H, s, 2-H), 8.31 (1H, d, J=10.0 Hz, 4-H), 8.58 (1H, d, J=13.0 Hz, α-H), and 8.55 (1H, d, J=10.0 Hz, 8-H); MS *m/z* (rel intensity) 272 (M^+; 72), 226 (M^+-NO_2; 42), 225 (M^+-HNO_2; 69); 178 (M^+-2HNO_2; 100), and 165 ($M^+-HNO_2-CH_2NO_2$; 98).

Found: N, 10.13%. Calcd for $C_{14}H_{12}N_2O_4$: N, 10.29%.

C) With Formic Acid at 60 °C. To a stirred solution of 64.0 mg (0.499 mmol) of azulene in 2 cm^3 of benzene, kept at 60 °C, was added dropwise a mixed reagent of nitroethene and formic acid (1.51 mmol in each) over a period of 1 h, and stirring was continued for an additional 2 h at 60 °C. The reaction mixture was worked up as described in *B* to give 1.50 mg (2%) of unchanged **1**, 14.8 mg (15%) of **3**, 97.1 mg (71%) of **5**, and 0.54 mg (0.4%) of **9**.

Synthesis of 1-(2-Nitroethenyl)azulene (11). To a stirred solution of 320 mg (1.47 mmol) of 1-formylazulene, which was prepared in a 76% yield according to Ref. 11, in 5 cm^3 of ethanol was added a mixed reagent of 100 mg (1.64 mmol) of nitromethane and 130 mg (1.55 mmol) of piperidine over a period of 10 min, and stirring was continued for 4 h more. Chromatography of the reaction mixture on a silica-gel column (dichloromethane) gave 31.4 mg (11%) of **11** as reddish-brown solid, besides 63 mg of reddish brown oil. After recrystallization from methanol containing a trace amount of acetone, **11** was obtained as dark brown crystals, mp 149—150 °C: UV (C_2H_5OH) 231 (log ε 4.22), 272 (sh, 4.28), 278 (4.32), 282 (4.32), 285 (4.31), 295 (sh, 4.19), 327 (sh, 3.82), 337 (3.85), 350 (sh, 3.81), 422 (sh, 4.05), 428 (sh, 4.08), and 443 nm (4.11); IR ($CHCl_3$), 1560, 1330 (NO_2), and 960 cm^{-1} (trans CH); ^1H NMR ($CDCl_3$) δ=7.20—7.68 (2H, m, 5- and 7-H), 7.56 (1H, d, J=4.0 Hz, 3-H), 7.85 (1H, d, J= 13.0 Hz, β-H), 7.94 (1H, t, J=10.0 Hz, 6-H), 8.24 (1H, d, J=4.0 Hz, 2-H), 8.52 (1H, d, J=10.0 Hz, 4-H), 8.74 (1H, d, J= 10.0 Hz, 8-H), and 8.78 (1H, d, J=13.0 Hz, α-H); MS *m/z* (rel intensity) 199 (M^+; 43) and 152 (M^+-HNO_2; 100).

Found: C, 72.31; H, 4.45; N, 6.97%. Calcd for $C_{12}H_9NO_2$: C, 72.35; H, 4.55; N, 7.03%.

In the attempted synthesis of **9** from **11**, **11** was treated at first with a 2 molar equivalent of the mixed reagent of nitroethene and formic acid at 50 °C, followed by treatment with an additional 2 molar equivalent of nitroethene at 80 °C. The recovery of **11** from each process was indicated by TLC (benzene–silica gel).

Reaction of Guaiazulene (2) and Nitroethene. A) Without Acid at Room Temperature. To an ice-cooled, stirred solution of 1.72 g (8.67 mmol) of guaiazulene in 35 cm^3 of dry dichloromethane was added dropwise 35 g (47 mmol) of 9.7% nitroethene solution during a period of 30 min, and stirring was continued for an additional 20 h at room temperature. Removal of the solvent (reduced pressure) and chromatography of the residue over silica gel (benzene) gave 2.38 g of blue oil, which was taken up in a mixed solvent of petroleum ether–benzene (220 cm^3) and extracted with 85% phosphoric acid (100 cm^3, then 50 cm^3×3). The acid layer was washed with petroleum ether (100 cm^3×3), diluted with ice-water (500 cm^3), and extracted with petroleum ether (100 cm^3, then 50 cm^3×3). The organic extract, after being washed with water (100 cm^3, then 50 cm^3×3), dried (sodium sulfate), and concentrated (reduced pressure), was chromatographed on a silica-gel column (benzene) to give three products.

From the first eluate, 203 mg (9%) of 1-(2-nitroethyl)-guaiazulene (**4**) was obtained as blue crystals, mp 85—89 °C: UV (C_2H_5OH) 246 (log ε 4.40), 287 (4.65), 291 (sh, 4.63), 305 (4.20), 336 (sh, 3.63), 346 (sh, 3.70), 352 (3.79), 369 (3.75), 544 (sh, 2.48), 614 (2.70), 668 (sh, 2.60), and 734 nm (sh, 2.23); IR (CCl_4) 1542 and 1378 cm^{-1} (NO_2); ^1H NMR ($CDCl_3$) δ=1.30 (6H, d, J=7.0 Hz, $CH(CH_3)_2$), 2.58 (3H, s, 3-CH_3), 2.82 (3H, s, 8-CH_3), 2.99 (1H, m, J=7.0 Hz, $CH(CH_3)_2$), 3.76 (2H, t, J=8.0 Hz, α-CH_2), 4.44 (2H, t, J=8.0 Hz, β-CH_2), 6.84 (1H, d, J=10.0 Hz, 7-H), 7.29 (1H, dd, J=10.0 and 2.0 Hz, 6-H), 7.37 (1H, s, 2-H), and 8.16 (1H, d, J=2.0 Hz, 4-H); ^{13}C NMR ($CDCl_3$) δ=12.8 (q, 3-CH_3), 24.6 (q, $CH(CH_3)_2$, 26.8 (q, 8-CH_3), 29.4 (t, α-CH_2), 37.7 (d, $CH(CH_3)_2$), 77.2 (t, β-CH_2), 120.1 (s, 1-C), 124.7 (s, 3-C), 127.1 (d, 7-C), 132.8 (s, 9-C), 133.8 (d, 4-C), 135.1 (d, 6-C), 138.1 (s, 10-C), 138.9 (d, 2-C), 139.9 (s, 5-C), and 144.6 (s, 8-C); MS m/z (rel intensity) 271 (M^+; 85), 225 (M^+-NO_2; 100), 224 (M^+-HNO_2; 44), and 211 ($M^+-CH_2NO_2$; 80).

Found: C, 75.52; H, 7.86; N, 5.12%. Calcd for $C_{17}H_{21}NO_2$: C, 75.25; H, 7.80; N, 5.16%.

From the second eluate, 89.2 mg (3%) of 1-(2,4-dinitrobutyl)guaiazulene (**7**) was obtained as a blue oil: UV (C_2H_5OH) 246 (log ε 4.29), 287 (4.50), 290 (sh, 4.49), 305 (4.08), 340 (sh, 3.54), 352 (3.64), 369 (3.62), 524 (sh, 2.31), 572 (sh, 2.50), 609 (2.57), 658 (sh, 2.48), and 731 nm (sh, 2.01); IR (CCl_4) 1540 and 1380 cm^{-1} (NO_2); ^1H NMR ($CDCl_3$) δ=1.31 (6H, d, J=7.0 Hz, $CH(CH_3)_2$), 2.54 (2H, m, γ-CH_2), 2.56 (3H, s, 3-CH_3), 2.90 (3H, s, 8-CH_3), 3.01 (1H, m, J=7.0 Hz, $CH(CH_3)_2$), 3.64 and 3.96 (2H, symmetrical 8 lines, J=14.9, 7.2, and 7.2 Hz, α-CH_2), 4.26 (2H, t, J=7.0 Hz, δ-CH_2), 4.88 (1H, m, β-CH), 6.91 (1H, d, J=11.0 Hz, 7-H), 7.32 (1H, dd, J=11.0 and 2.0 Hz, 6-H), 7.37 (1H, s, 2-H), and 8.13 (1H, d, J=2.0 Hz, 8-H); ^{13}C NMR ($CDCl_3$) δ=12.8 (q, 3-CH_3), 24.5 (q, $CH(CH_3)_2$), 26.9 (q, 8-CH_3), 29.7 (t, α-CH_2), 35.6 (t, γ-CH_2), 37.6 (d, $CH(CH_3)_2$), 71.0 (t, δ-CH_2), 87.1 (d, β-CH), 118.8 (s, 1-C), 124.8 (s, 3-C), 127.5 (d, 7-C), 133.0 (s, 9-C), 234.0 (d, 4-C), 135.2 (d, 6-C), 138.3 (s, 10-C), 139.8 (d, 2-C), 140.3 (d, 5-C), and 144.4 (s, 8-C); MS m/z (rel intensity) 344 (M^+; 48), 298 (M^+-NO_2; 15), 297 (M^+-HNO_2; 7), and 211 ($M^+-C_3H_5NO_2$; 100).

Found: C, 66.45; H, 6.96; N, 8.44%. Calcd for $C_{19}H_{24}N_2O_4$: C, 66.26; H, 7.02; N, 8.13%.

From the last fraction, 5.00 mg (2%) of 1-(2-nitroethenyl)-guaiazulene (**10**) was obtained as reddish-brown crystals, mp 154—155 °C. It was identical with that of Ref. 9 in its mp, IR, and ^1H NMR: UV (C_2H_5OH) 227 (log ε 4.02), 241 (4.06), 281 (sh, 4.01), 291 (4.07) 305 (sh, 3.91), 313 (sh, 3.77), 341 (3.77), 354 (3.76), 367 (sh, 3.44), 424 (sh, 3.88), 442 (4.06), and 466 nm (4.05); IR (CCl_4) 1540, 1310 (NO_2), and 956 cm^{-1} (trans CH); ^1H NMR ($CDCl_3$) δ=1.36 (6H, d, J=7.0 Hz, $CH(CH_3)_2$), 2.57 (3H, s, 3-CH_3), 3.11 (3H, s, 8-CH_3), 3.14 (3H, m, J=7.0 Hz, $CH(CH_3)_2$), 7.24 (1H, d J=10.5 Hz, 7-H), 7.48 (1H, dd, J=10.5 and 2.0 Hz, 6-H), 7.56 (1H, d, J=13.0 Hz, β-H), 7.75 (1H, s, 2-H), 8.12 (1H, d, J=2.0 Hz, 4-H), and 8.98 (1H, d, J=13.0 Hz, α-H); MS m/z (rel intensity) 269 (M^+; 59), 254 (M^+-CH_3; 11), 223 (M^+-NO_2; 27), 222 (M^+-HNO_2; 45), and 211 (M^+-CNO_2 100).

B) With Trifluoroacetic Acid at 0 °C. To an ice-cooled, stirred solution of 11% nitroethene in benzene (5.00 g; 7.53 mmol) was added dropwise 860 mg (7.54 mmol) of trifluoroacetic acid. This reagent was mixed dropwise with an ice-cooled, stirred solution of 1.00 g (5.04 mmol) of guaiazulene in 5 cm^3 of benzene over a period of 20 min; stirring was continued for a further 1 h under ice-cooling. The reaction mixture was poured into 100 cm^3 of ice-water, extracted with ether (500 cm^3×4), organic extract washed with 10% potassium carbonate solution (50 cm^3×2), then with water (50 cm^3×3), dried (sodium sulfate), and concentrated (reduced pressure) leaving a green oil. Chromatography of the oil on a silica-gel column (benzene) gave 226 mg (23%) of unchanged **2**, 64.0 mg (5%) of **4**, and 2.99 mg (0.2%) of **10**.

C) With Formic Acid at Room Temperature. A mixed reagent of nitroethene (7.53 mmol) and formic acid (7.54 mmol) was prepared in the same manner as described in *B*. This reagent was mixed dropwise with a stirred solution of 1.00 g (5.04 mmol) of guaiazulene in 6 cm^3 of benzene during a period of 20 min and stirring was continued for 1 h more at room temperature. After being extracted with ether (50 cm^3, then 25 cm^3×2), dried (sodium sulfate), and concentrated (reduced pressure), the reaction mixture was chromatographed over silica gel (benzene) to give a blue oil. This oil was taken up in 100 cm^3 of petroleum ether and extracted with 85% phosphoric acid (100 cm^3×3). The acid extract was diluted with 1 dm^3 of ice-water, and extracted with benzene (100 cm^3×3). Removal of the solvent and subsequent chromatography over silica gel (benzene) gave 157 mg (16%) of unchanged **2**, 129 mg (9%) of **4**, and 46.0 mg (2%) of **10**.

D) With Ether-Boron Trifluoride (1/1) at Room Temperature. To an ice-cooled, stirred solution of 1.00 g (5.04 mmol) of guaiazulene in 5 cm^3 of benzene was added dropwise 1.00 g (7.05 mmol) of ether-boron trifluoride (1/1) over a period of 5 min, and stirring was continued for an additional 20 min at room temperature. This solution was mixed dropwise with 5.00 g (7.53 mmol) of 11% nitroethene solution during a period of 30 min and stirring was continued for 3.5 h more. The reaction mixture was taken up into 100 cm^3 of petroleum

ether and extracted with 85% phosphoric acid (50 cm^3×3). Similar work up as described in *C* and subsequent chromatography over silica gel (benzene) gave 50.8 mg (5%) of unchanged **2**, 11.0 mg (0.8%) of **4**, and 134 mg (10%) of **10**.

E) Without Acid at 50 °C. To a stirred solution of 1.00 g (5.04 mmol) of guaiazulene in 5 cm^3 of benzene, kept at 50 °C, was added 5.00 g (7.53 mmol) of 11% nitroethene solution over a period of 1 h, and stirring was continued for additional 2 h at room temperature. The reaction mixture, after the usual work up as described in *D*, gave 162 mg (16%) of unchanged **2**, 637 mg (47%) of **4**, 163 mg (9%) of **7**, and 31.6 mg (2%) of **10**.

F) With Formic Acid at 50 °C. To a stirred solution of 2.00 g (10.1 mmol) of guaiazulene in 10 cm^3 of benzene was added a mixed reagent of 10.0 g (15.1 mmol) of 11% nitroethene solution and 700 mg (15.2 mmol) of formic acid during a period of 2 h, and stirring was continued for additional 3 h at 50 °C. The reaction mixture, after being worked up as in *D*, gave 44.0 mg (2%) of unchanged **2**, 1.36 g (50%) of **4**, and 61.2 mg (2%) of **10**.

A small scale experiment with the use of 200 mg (1.01 mmol) of **2**, accompanied with changes of the reaction time (1 h for addition of the mixed reagent, followed by 4 h for additional stirring), gave 10.0 mg (5%) of unchanged **2**, 133 mg (49%) of **4**, and 20.1 mg (7%) of **10**.

Reduction of 1-(2-Nitroethyl)azulene (3) with Iron and Acetic Acid. Ninety milligrams (1.61 mmol) of fine iron powder (200 meshes) was mixed with 1 cm^3 of 5% hydrochloric acid, rinsed with acetic acid (1 cm^3×2), and transferred to the reaction vessel with 2 cm^3 of acetic acid. To the stirred suspension of iron in acetic acid was added dropwise, under dry nitrogen, a solution of 38.6 mg (0.192 mmol) of **3** in 1 cm^3 of acetic acid over a period of 30 min (washed in with additional 1 cm^3 of acetic acid), and stirring was continued for 38 h more at room temperature. The progress of the reaction was checked by TLC (silica gel–benzene). The reaction mixture was poured into 30 cm^3 of ice-water. The precipitated iron powder was collected by decantation, washed throughly with 20 cm^3 of water and then with 50 cm^3 of chloroform, and the combined organic and aqueous solution was made alkaline by the addition of 50 cm^3 of 30% sodium hydroxide solution under ice-cooling. The chloroform layer was separated, and the aqueous solution was extracted with chloroform (50 cm^3, then 30 cm^3×2). The combined, dried (sodium sulfate), and concentrated (reduced pressure) organic extracts were chromatographed on a silica-gel column (7:3 chloroform–methanol) to give 0.75 mg (2%) of unchanged **3** and 25.8 mg (79%) of 2-(1-azulenyl)ethanamine (**12**) as blue prisms, mp 104—105 °C: UV (C_2H_5OH) 237 (log ε 4.22), 268 (sh, 4.52), 273 (sh, 4.64), 277 (4.71), 282 (4.66), 287 (sh, 4.52), 296 (sh, 3.79), 331 (sh, 3.55), 343 (3.68), 358 (3.38), 556 (sh, 2.41), 578 (sh, 2.47), 597 (2.52), 620 (sh, 2.46), 650 (2.43), 682 (sh, 2.15), and 720 nm (1.97); IR (CCl_4) 3390 and 1625 cm^{-1} (NH); ^1H NMR ($CDCl_3$) δ=1.36 (2H, s, NH_2), 3.21 (4H, 8 lines, CH_2-CH_2), 7.15 (1H, t, J=10.0 Hz, 5-H), 7.18 (1H, t, J=10.0 Hz, 7-H), 7.45 (1H, d, J=4.0 Hz, 3-H), 7.65 (1H, t, J=10.0 Hz, 6-H), 7.91 (1H, d, J=4.0 Hz, 2-H), 8.37 (1H, d, J=10.0 Hz, 4-H), and 8.42 (1H, d, J=10.0 Hz, 8-H); ^{13}C NMR ($CDCl_3$) δ=30.8 (2-CH_2), 53.3 (1-CH_2), 116.8 (3-C), 121.5 (7-C), 122.1 (5-C), 127.9 (1-C), 133.5 (8-C), 136.3 (4- and 9-C), 137.1 (6-C), 137.3 (2-C), and 140.6 (10-C); MS *m/z* (rel intensity) 171 (M^+; 14) and 141 ($M^+-CH_2NH_2$; 100).

Found: C, 84.06; H, 7.05; N, 8.20%. Calcd for $C_{12}H_{13}N$: C, 84.17; H, 7.65; N, 8.18%.

Reduction of 1-(2-Nitroethyl)guaiazulene (4). A) With Iron and Acetic Acid. To a suspension of 500 mg (8.95 mmol) of iron powder (200 meshes), treated as above with hydrochloric acid and acetic acid, in 12 cm^3 of acetic acid was added a solution of 270 mg (0.995 mmol) of **4** in 10 cm^3 of acetic acid over a period of 30 min (washed in with additional 5 cm^3 of acetic acid), and stirring was continued for 16 h more at room temperature. The reaction mixture, after being worked up as described in **3**, gave 60.2 mg (22%) of unchanged **4** and 184 mg (77%) of 5-isopropyl-3,8-dimethyl-2-(1-azulenyl)ethanamine (**13**) as a greenish blue oil: UV (log ε 4.02), 248 (4.19), 282 (sh, 4.40), 288 (4.47), 293 (4.46), 307 (4.02), 338 (sh, 3.45), 353 (3.62), 371 (3.58), 546 (sh, 2.33), 576 (sh, 2.52), 600 (sh, 2.57), 623 (2.59), and 673 nm (2.51); IR (CCl_4) 3390 and 1610 cm^{-1} (NH); ^1H NMR (CCl_4) δ=1.29 (6H, d, J=7.0 Hz, $CH(CH_3)_2$), 2.59 (3H, s, 3-CH_3), 2.87 (3H, s, 8-CH_3), 2.81—3.07 (1H, m, $CH(CH_3)_2$), 2.95 (2H, t, J=6.0 Hz, 1-CH_2), 3.32 (2H, t, J=6.0 Hz, 2-CH_2), 3.63 (2H, broad s, NH_2), 6.73 (1H, d, J=11.0 Hz, 7-H), 7.20 (1H, dd, J=11.0 and 2.0 Hz, 6-H), 7.49 (1H, s, 2-H), and 8.11 (1H, d, J=2.0 Hz, 4-H); ^{13}C NMR ($CDCl_3$) δ=12.8 (q, 3-CH_3), 24.5 (q, $CH(CH_3)_2$), 26.9 (q, 8-CH_3), 30.8 (t, 2-CH_2), 37.6 (d, $CH(CH_3)_2$), 52.9 (t, 1-CH_2), 124.2 (s, 3-C), 125.4 (s, 1-C), 126.2 (d, 7-C), 132.5 (s, 9-C), 133.2 (d, 4-C), 134.5 (d, 6-C), 137.7 (s, 10-C), 138.9 (d, 5-C), and 145.0 (s, 8-C); MS *m/z* (rel intensity) 241 (M^+; 14) and 211 ($M^+-CH_2NH_2$; 100).

Found: C, 84.21; H, 9.90; N, 5.32%. Calcd for $C_{17}H_{23}N$: C, 84.59; H, 9.60; N, 5.80%.

B) With Palladized Charcoal and Sodium Borohydride. To a stirred suspension of 5.0 mg (0.0047 mmol) of 10% palladized charcoal in 3 cm^3 of methanol, with bubbling of nitrogen below the surface, was added dropwise a solution of 10 mg (0.26 mmol) of sodium borohydride in 2 cm^3 of water, and then another solution of 27.0 mg (0.0995 mmol) of **4** in 5 cm^3 of 2 mol dm^{-3} methanolic sodium hydroxide. The mixture was refluxed for 1.5 h and cooled to room temperature. After the addition of 10 cm^3 of 1 mol dm^{-3} hydrochloric acid, the mixture was filtered to remove the catalyst, and the catalyst was washed with chloroform (30 cm^3×2). The combined organic and aqueous solution was worked up as described in *A* to give 7.06 mg (36%) of unchanged **4** and 5.10 mg (21%) of **13**.

Similar treatment of **4** with palladized charcoal in water and at low reaction temperature (30 min at room temperature) yielded 0.93 mg (5%) of **2**, 17.5 mg (65%) of unchanged **4**, and 1.23 mg (5%) of **10**.

C) With Lithium Aluminum Hydride. To a cooled (−50 °C), stirred solution of 10 mg (0.26 mmol) of lithium aluminum hydride in 0.5 cm^3 of THF was added dropwise another solution of 18.4 mg (0.0678 mmol) of **4** in 1 cm^3 of THF over a period of 5 min. This mixture was gradually brought to −4 °C, and kept for 20 min at −4 to −3 °C, during which period the color of the solution changed from blue to green. The reaction mixture was again cooled to −50 °C, mixed slowly with 2 cm^3 of 10% sodium hydroxide solution, and extracted with ether (5 cm^3×4). The usual work up of the organic extract gave 15.4 mg of dark resinous material and 1.34 mg (8%) of **13**.

We wish to thank Professor Hitoshi Takeshita

of Kyushu University for his kind measurements of the ^{13}C NMR spectra, and Dr. Koichi Sato of Hosei University, for generously giving us the specimen of 1-(2-nitroethenyl)guaiazulene.

Ternary Coordination Complexes Formed by Copper(II) with Thio- or Dithiodialkanoic Acids and Some Selected Ethyl-substituted Malonic Acids*

D. N. SHELKE
Chemistry Department, Marathwada University, Aurangabad 431004, India
(Received December 21, 1982)

Binary and ternary complexes formed by copper(II) with thio- or dithiodialkanoic acids and ethyl-substituted malonic acids have been investigated potentiometrically in an aqueous solution and the relevant stability constants have been evaluated using computer technique. Thio- and dithiodialkanoic acids were thiodiacetic, dithiodiacetic, 3,3′-thiodipropionic, and 3,3′-dithiodipropionic acids. The results are discussed in terms of substituent influences upon the chelation of the malonate dianions to the systems copper(II)–thiodialkanoic acids. It is suggested that in the mixed copper chelates containing thiodiacetic acid, the geometrical characteristics of the more basic ligand, governs the coordination of the other ligand.

The study of the coordination chemistry of transition metal complexes with thiodialkanoic (CT) acid ligands has received much attention in recent years and the applications of such complexes to a wide variety of problems of structure, bonding and mechanism are considerable. Initially the major attention was focussed to tridentate thiodialkanoic acids but now, with the advent of X-ray data, interest has been extended to ligands of greater or smaller denticity[1-3]. As part of our interest[4] in the bonding sites of thiodialkanoic aicds in mixed-ligand complexes, we have examined the coordinating tendencies of thiodialkanoic acids to the metal ions on the basis of thermodynamic parameters. We report here, in addition to a few data for binary complexes already reported[5-7], the equilibrium studies on mixed-ligand complex formation occurring, when copper(II) is mixed with thiodialkanoic acids and ethyl-substituted malonic acids. The mode of bonding in the ternary complex species involved is also examined.

Experimental

The ligands thiodiacetic acid (AT), dithiodiacetic acid (ADT), 3,3′-thiodipropionic acid (PT), 3,3′-dithiodipropionic acid (PDT), ethylmalonic and diethylmalonic (L) acids were obtained from Fluka (purum) or B.D.H. (AnalaR) and were used without purification. Metal ion was added as copper perchlorate and the concentration was estimated by EDTA titration.[8] All solutions were prepared in glass distilled water (pH=6.8 and conductivity=1.6×10^{-6} Mho). Details regarding other chemicals and the measurements have been described previously.[9,10]

Copper complex formation constants were evaluated from potentiometric titration curves of thiodialkanoic (CT) and ethyl-substituted malonic acids in the absence and presence of copper(II). Changes in pH were followed using glass and calomel electrodes and a ELICO Digital pH meter (L1-10 No. 1275). The accuracy of the pH meter was ±0.01 pH Unit. The glass electrode was calibrated in terms of hydrogen ion concentrations and titrations were carried out at 30 °C with an ionic background of 0.10 mol dm^{-3} ($NaClO_4$). Calculations were made with the aid of a computer programme[11] and carried out at the Tata Institute of Fundamental Research, Bombay.

* Presented at All India Symposium on "Mixed ligand chelates" Aurangabad, November 1982.

Results and Discussion

The protonation constants of the thiodialkanoic acids and ethyl-substituted malonic acids and the formation constants of copper(II) mono- and bis-complexes with these acids are presented in Table 1. The errors in the data obtained for the formation constants of binary and ternary systems were estimated to be 1±0.05 log units. Besides the direct experimental errors, the standard deviation of the equilibrium constants were between 0.01 and 0.05 for the systems studied. A representative data *i.e.*, copper(II)–ADT–ethylmalonic acid system, explains adequately the precision of the work (Table 2).

The overall stability constants $\beta^{Cu}_{Cu(CT)L}$ of the ternary complexes, together with the stability constants $K^{Cu(CT)}_{Cu(CT)L}$ and $K^{CuL}_{CuL(CT)}$, according to the following expression:

$$Cu + CT + L \rightleftharpoons Cu(CT)L ,$$

$$\beta^{Cu}_{Cu(CT)L} = \frac{[Cu(CT)L]}{[Cu][(CT)][L]} ,$$

$$Cu(CT) + L \rightleftharpoons Cu(CT)L ,$$

$$K^{Cu(CT)}_{Cu(CT)L} = \frac{[Cu(CT)L]}{[Cu(CT)][L]} ,$$

$$CuL + (CT) \rightleftharpoons CuL(CT) ,$$

$$K^{CuL}_{CuL(CT)} = \frac{[CuL(CT)]}{[CuL][(CT)]} ,$$

are presented in Table 3. The percentage distribution of the complexes formed in the copper(II)–dithiodiacetic–(ADT)–ethylmalonic (L) acid systems as a function of pH, is presented in Fig. 1.

In our earlier studies on mixed-ligand complexes, the tridentate nature of AT with copper(II) ion, has been reported.[5] These conclusions have been amply confirmed in subsequent studies involving tridentate thiodialkanoic acids particularly, copper(II) complex of AT.[12,13] The bonding nature of PT with copper (II) through the oxygen of the carboxylato group has been confirmed by Krebs *et al.*[14] by X-ray measurements. The structure consists of centrosymmetric complex unit in which the central Cu^{II} is in tetragonal planar arrangement, of two *trans*-coordinated water molecules and the carboxylato groups of two organic ligands. In view of the above, our potentiometric studies and observed stability constants (Table 1) suggest that PT and PDT bond through the oxygen atom of the carboxylato group whereas AT is coordinated through both oxygen atoms of the carboxylato groups and the sulfur atom. The stability constants obtained for ethylmalonic and diethylmalonic acids are also understandable.

Consequently, no simple relation exists between the stability of the ternary complexes and the basic properties of the dialkanoic acids. In these systems we note the sole formation of the 1 : 1 : 1 ternary species, with stability constant values higher than 0.6 would be expected from statistical considerations[15,16] as is apparent from Table 4, on examining the values of the stabilization parameters log K_r and Δ log K, defined by the following expressions:

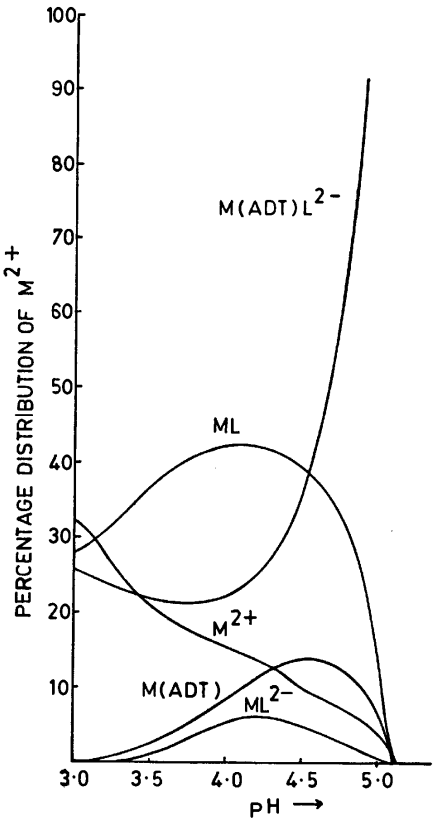

Fig. 1. Percentage distribution of various species present in ternary copper(II)–dithiodiacetic (ADT), ethylmalonic (L) acid system as a function of pH, M_2^+= copper ion_{free}, ML= copper ion-ethylamlonic, ML_2^{2-}= copper ion–(ethylmalonic)$_2$, M(ADT)=copper ion-dithiodiacetic and M (ADT)L^{2-}=copper ion-dithiodiacetic-ethylmalonic, $\mu = 0.1$ mol dm^{-3} ($NaClO_4$), Temp$= 30 \pm 0.1$ °C, $C_M = C_L = C_{ADT} = 2.0 \times 10^{-3}$ mol dm^{-3}.

$$Cu(CT)_2 + CuL_2 \rightleftharpoons 2Cu(CT)L\ ,$$

$$\log K_r = 2\log \beta^{Cu}_{Cu(CT)L} - (\log \beta^{Cu}_{Cu(CT)_2} + \log \beta^{Cu}_{CuL_2})$$

$$Cu(CT) + CuL \rightleftharpoons Cu(CT)L + Cu$$

$$\Delta \log K = \log \beta^{Cu}_{Cu(CT)L} - (\log K^{Cu}_{Cu(CT)} + \log K^{Cu}_{CuL}).$$

These results are of the same order of magnitude as

TABLE 4. STABILIZATION PARAMETERS $\Delta \log K$ AND $\log K_r$ FOR TERNARY COMPLEX FORMATION AT $\mu=0.1$ mol dm^{-3} AND 30 ± 0.1 °C

System	$-\Delta \log K$	$\log K_r$
AT-ethylmalonic	0.60	2.31

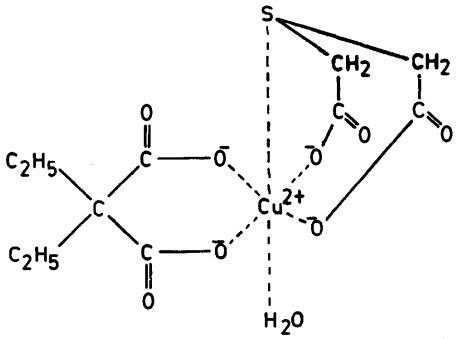
PDT-diethylmalonic	0.01	2.19



(Structure I)

those for previously studied complexes of copper(II) with thiodialkanoic acids and O–O donor ligands[17] and the following important conclusions may be drawn from the tabulated data.

(a) The $\Delta \log K$ values which are greater than −0.6 (Table 4) indicates the preferential formation of ternary complexes compared to the binary ones. This tendency to form mixed-ligand chelates is the same in the case of PT–ethylmalonic, PT–diethylmalonic and ADT–ethylmalonic acid system wherein $\Delta \log K$ are −0.37, −0.33, and −0.30 respectively.

(b) In the systems under investigation, the values of $\log K_r$ are significantly greater than 0.6 log units, demonstrating that the mixed-ligand complexes are more stable than the binary ones.[15]

(c) The introduction of two substituents increases the stability of ternary complexes in proportion to the size of the alkyl groups[18] (Table 3).

(d) The values of $\log K^{Cu(CT)}_{Cu(CT)L}$ and $\log K^{CuL}_{CuL_2}$ (Table 3) show the preferential formation of the ternary over the binary complexes. A comparison of $\log K^{CuL}_{CuL(CT)}$ with $\log K^{Cu(CT)}_{Cu(CT)_2}$ values, especially in the systems involving thiodiacetic acid as a secondary ligand, reveals the preferential formation of the ternary complexes over the corresponding binary bis ones.

(e) AT forms mixed complexes of exceptionally high stability with ethylmalonic and diethylmalonic acid because the ligand is coordinated through the thio group and two carboxyl groups. The highest value of $\log K_r$ for the AT–diethylmalonic acid system (2.55) accompanied by the highest stability for a $\log \beta^{Cu}_{Cu(CT)L}$ is due to the respective tridentate and bidentate nature of the two ligands. The bidentate diethylmalonic acid ligand occupies an equatorial position while the AT assumes an equatorial-axial coordination as shown in structure (I). The equatorial-axial coordination of AT with Cu^{II} has been recently reported on the studies of mixed-ligand complexes from X-ray data.[19]

(f) It can be seen from the experimental values of $\beta=^{Cu}_{Cu(CT)L}$ and the stabilization parameters $\Delta \log K$ and $\log K_r$ (Tables 3, 4) that the inductive effect of the alkyl group has no great influence on the stability of these systems. The presence of one or two substituents affects the reciprocal coplanarity of the two carboxylato group in different ways, giving rise to a different stability order in both binary and ternary complexes. In particular the presence of two bulky substituents as in the case of Cu(CT) DEt-mal. seems especially to favour the formation of the ternary species, probably by forcing the two carboxylato groups into the best position of chelation.

The computer was made available by the Tata Institute of Fundamental Research, Bombay. Thanks are due to Dr. D. V. Jahagirdar and Dr. L. G. Pardeshi for valuable suggestions. This research work is supported by the UGC, New Delhi.

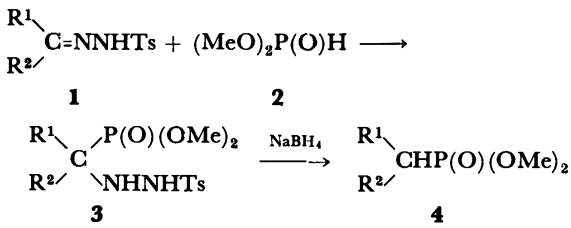
(Received June 11, 1984)

Synopsis. Dehydrazination of adducts of phenylsulfonylhydrazones and phosphorus compounds was promoted by a nitro substituent on the ring to afford derivatives of a phosphine oxide and phosphonates.

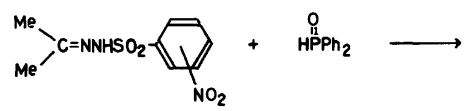
Addition reaction of *p*-tolylsulfonylhydrazones with dimethyl phosphonate was reported to give the corresponding adducts, dimethyl 1-(*N'*-*p*-tolylsulfonylhydrazino)alkylphosphonates **3**, in 71—78% yields.[1] Adducts **3** was then dehydrazinated by a treatment with sodium tetrahydroborate to give **4** in 50—84% yields. The method provided a good tool to prepare phosphonates such as dimethyl isopropylphosphonate and *s*-butylphosphonate. However, in some cases where steric and ring strain factors operate, the dehydrazination reaction competed with the β-elimination reaction of dimethyl phosphonate from compound **3** giving the starting hydrazone.[2] The present paper deals with the preparation of *o*- and *p*-nitrophenylsulfonylhydrazones **5** and the reaction of **5** with some phosphorus compounds to improve the dehydrazination reaction by the nitro substituent by virtue of its electron withdrawing nature.



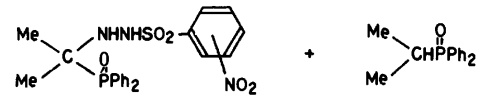
Results and Discussion

o- And *p*-nitrophenylsulfonylhydrazones **5** were prepared by the reaction of *o*- and *p*-nitrobenzenesulfonhydrazide with ketones in 1 M hydrochloric acid (1 M=1 mol dm^{-3}) at room temperature.

The reaction of **5a** (*o*-nitro derivative) with diphenylphosphine oxide (1:1.2, molar ratio) gave directly alkyldiphenylphosphine oxide **7** together with adduct **6**. The same reaction of **5b** (*p*-nitro derivative) gave solely **6b**. These results are summarized in Table 1. The table shows that the reaction at higher temperature gave higher yield of **7** than that at room temperature and that product **7** may be generated *via* intermediary **6**. Adduct **6b**, being produced from **5b** and diphenylphosphine oxide, was reduced by sodium tetrahydroborate to afford isopropyldiphenylphosphine oxide in overall yield of 66% from compound **5b**.



5a,b



6a,b **7**

The reaction of **5** with dimethyl phosphonate was carried out in the presence of trifluoromethanesulfonic acid (condition A) or of excess dimethyl phosphonate (condition B) to give directly dimethyl alkylphosphonate **9** together with adduct **8** or to give solely compound **8** or **9** according to the substrate and reaction condition. The results are summarized in Table 2. The result that the ortho nitro substituent affords directly compound **7** or **9** in higher yield than the para one does may attribute more effective electron-withdrawal property of the ortho one and/or ortho effect. Enhancements of acidity constant of benzoic acids and anilinium salts in water and equiliblium constant of the reaction of benzoic acids with diphenylguanidine in benzene by ortho nitro substituent are known.[3]

The present results show that the dehydrazination of adducts **6** and **8** was promoted by the nitro substituent of benzenesulfonhydrazides giving phosphorus compounds **7** and **9**, and that the phosphorus compounds having a C-P bond such as tertiary phosphine oxides and phosphonates were prepared by one operation from hydrazone and phosphorus compounds having a P-H bond, *i.e.*, diphenylphosphine oxide and dimethyl phosphonate

Experimental

Measurements. ^{1}H NMR spectra were measured on Hitachi R-24 (60 MHz) spectrometer with tetramethylsilane as an internal standard. IR spectra were recorded with Japan Spectroscopic Co., Ltd. A-3 infrared spectrophotometer. MS spectra were measured by Hitachi RMU DMG GC-MS spectrometer.

Materials. The following materials were synthesized according to reported methods: *o*-Nitrobenzenesulfonhydrazide, mp 101—102 °C (lit,[4] mp 101 °C), 92% yield from *o*-nitrobenzenesulfonyl chloride and 100% hydrazine hydrate; *p*-nitrobenzenesulfonhydrazide, mp 145 °C (lit,[5] mp 150—152 °C), 78% yield; diphenylphosphine oxide, mp 49 °C (lit,[6] mp 51—54 °C), 87% yield from phosphorus trichloride and benzene in the presence of aluminium chloride.

Synthesis of Acetone o-Nitrophenylsulfonylhydrazone (5a; R= Me, o-). Reaction of acetone (1.8 g, 30 mmol) with *o*-nitrobenzenesulfonhydrazide (6.0 g, 28 mmol) in 1 M hydrochloric acid overnight at room temperature gave precipitate. Recrystallization of the product from ethanol-water gave pure **5a** (4.2 g) in 59% yield, mp 144—147 °C (lit,[5] mp 147—148 °C), ^{1}H NMR ($CDCl_3$) δ, 1.77, 1.78 (2s, 6H, $2CH_3$), 7.2—7.3 (m, 1H, NH), and 7.6—8.4 (m, 4H, C_6H_4); IR ν_{max}^{KBr} cm^{-1}, 3250 (NH), 1650 (C=N), 1540, 1350 (NO_2), and 1180 (SO_2).

The following *o*- and *p*-nitrophenylsulfonylhydrazones (**5**) were prepared silimarly: Acetone *p*-nitrophenylsulfonylhydrazone (**5b**; R=Me, *p*-), 51% yield, mp 183—185 °C (lit,[7] 183—184 °C); 2-butanone *o*-nitrophenylsulfonylhydrazone (**5c**; R=Et, *o*-), 58% yield, mp 141—143 °C (lit,[7] mp 143—144 °C); 2-butanone *p*-nitrophenylsulfonylhydrazone (**5d**; R= Et, *p*-), 74% yield, mp 155—158 °C (lit,[7] mp 155—156 °C); acetophenone *p*-nitrophenylsulfonylhydrazone (**5f**; R= Ph, *p*-), 71% yield, mp 213—215 °C (lit,[7] mp 192 °C).

Reaction of 5a with Diphenylphosphine Oxide. Reaction of **5a** (0.50 g, 1.9 mmol) with diphenylphosphine oxide (0.46 g, 2.3 mmol) in methanol (5 ml) for 24 h at room temperature followed by evaporation of the solvent and separation of the reaction products by TLC gave isopropyldiphenylphosphine oxide **7a** (0.30 g) in 65% yield, mp 143—144 °C (lit,[8] mp 144—145 °C), together with **6a** (0.23 g) in 26% yield.

Spectral data for compound **7a** was as follows: ^{1}H NMR ($CDCl_3$) δ, 1.13 (dd, 6H, J_{HH}=7.0 Hz, J_{HP}=16.0 Hz, $2CH_3$), 2.1—2.8 (m, 1H, CH), and 7.0—8.2 (m, 10H, $2C_6H_5$); IR ν_{max}^{KBr} cm^{-1}, 1440 (P-Ph), 1180 (P=O), and 710 (C-P); MS, *m/z*, 244 (M^+).

^{1}H NMR for compound **6a** ($CDCl_3$) δ, 1.40 (d, 6H, J_{HP}=16.0 Hz, $2CH_3$) and 6.9—8.1 (m, 16H, $2C_6H_5$, C_6H_4, 2NH).

Reaction of 5a with Dimethyl Phosphonate. Reaction of compound **5a** (0.20 g, 0.78 mmol) with large excess of dimethyl phosphonate (6 ml) for 20 h at 30 °C followed by work-up gave dimethyl isopropylphosphonate[1] (0.11 g) in 93% yield.

Reaction of 5b with Diphenylphosphine Oxide. Reaction of **5b** (3.1 g, 12 mmol) with diphenylphosphine oxide (2.4 g, 12 mmol) in methanol (25 ml) for 24 h at room temperature followed by filtration of the product gave diphenyl-2-(*N'*-*p*-nitrophenylsulfonylhydrazino)propylphosphine oxide in 63% yield, mp 101—106 °C: ^{1}H NMR ($CDCl_3$) δ, 1.20 (d, J_{HP}=16.0 Hz, 6H, $2CH_3$), 3.40 (s, 2H, 2NH), and 7.4—8.4 (m, 14 H, $2C_6H_5$, C_6H_4).

(Received March 7, 1984)

Synopsis. The effect of mechanochemical treatment on some neodymium phosphates was investigated. It is worth noting that on mechanochemical treatment $NdPO_4 \cdot 0.5H_2O$ (hexagonal) is gradually transformed into $NdPO_4$ (monoclinic) at room temperature, while thermal change of $NdPO_4 \cdot 0.5H_2O$ to $NdPO_4$ (monoclinic) happens at above 600 °C. Condensed phosphates, meta- and ultraphosphates, easily turned to X-ray amorphous structure by grinding.

Mechanochemical treatment influences structures, physical and chemical properties, and reactivity of solids. We have investigated the mechanochemical effect of various phosphates by grinding. In the present study, four neodymium phosphates ($NdPO_4$, $NdPO_4 \cdot 0.5H_2O$, $Nd(PO_3)_3$, and NdP_5O_{14}), were used. Rare earth phosphates were used for the laser materials, semiconductor, and ceramics, which have been studied for the last several years[1,2] The effecat of mechanochemical treatment on 1) X-ray diffraction patterns, 2) IR spectra, 3) DTA-TG diagrams, and 4 solubility of neodymium phosphates, was investigated.

Experimental

Neodymium phosphates used were prepared by the procedure described in a previous paper.[3] Grinding was performed with Ishikawa's grinding mill, AG-Z type, at a temperature range of 20—30 °C, humidity at 15—30%, in nitrogen atmosphere. The X-ray diffraction analysis was carried out with a Rigaku Denki Geigerflex diffractometer using nickel-filtered Cu $K\alpha$ radiation. Thermal analysis (DTA-TG) was carried out by a Rigaku 8002 SD thermal analyzer. The IR spectra were taken by means of a KBr tablet.

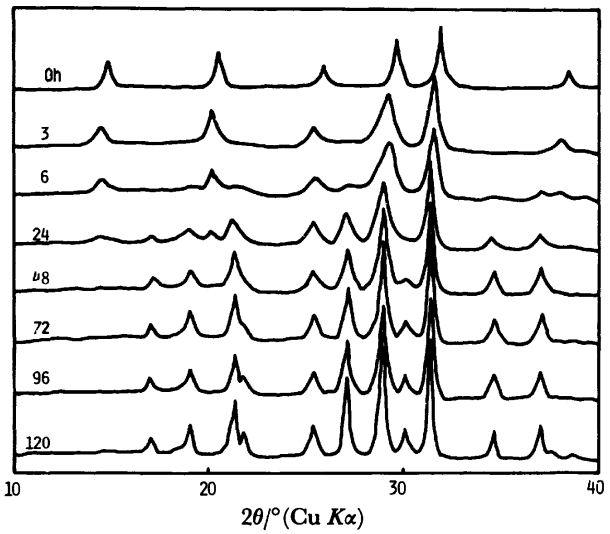

Fig. 1. X-Ray diffraction patterns of ground $NdPO_4 \cdot 0.5H_2O$.

Results and Discussion

Mechanochemical Changes of Orthophosphates. Figure 1 shows the X-ray diffraction patterns of $NdPO_4 \cdot 0.5H_2O$ at various stages of grinding. With grinding over 24 h, some new diffraction peaks, at 2θ= 17.5, 19.5, 22, 27.5, 30.5, 35, and 37.5°, appeared. These peaks coincided in position with those of $NdPO_4$ (monoclinic), and their intensities increased with further grinding. It is clear from this fact that $NdPO_4 \cdot 0.5H_2O$ turned to anhydrate ($NdPO_4$) by grinding. On the other hand, as for $NdPO_4$ (monoclinic), a remarkable change of X-ray diffraction patterns was not observed.

Figure 2 shows the IR spectra of $NdPO_4 \cdot 0.5H_2O$ by grinding. With grinding, the intensity of each absorption peak gradually decreased. Also, characteristic absorptions due to the O-H bond of water of crystallization in the region of 3400—3500 and 1600 cm^{-1} became weak, while those attributable to the P-O bond were gradually increased at about 960 and 560—580 cm^{-1}, and IR spectrum after 24 h's grinding coincided with that of anhydrate, that is, the water of crystallization was released and turned to the anhydrate ($NdPO_4$).

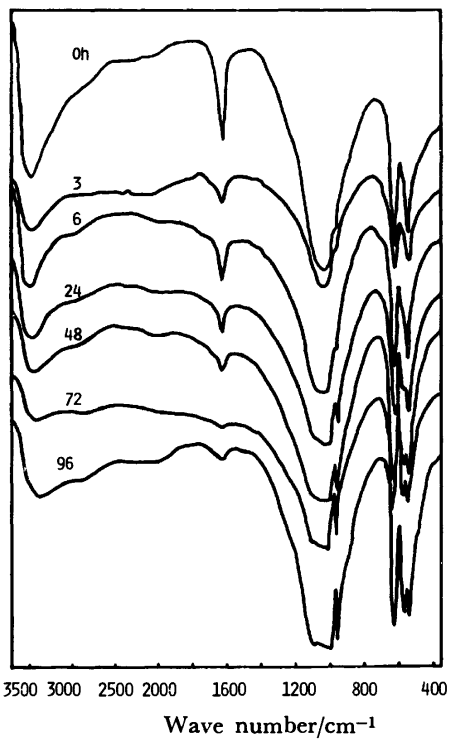

Fig. 2. IR spectra of ground $NdPO_4 \cdot 0.5H_2O$.

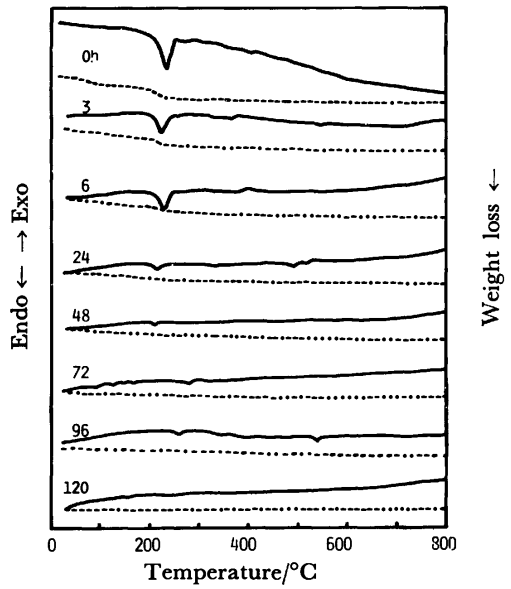

Fig. 3. DTA-TG curves of ground $NdPO_4 \cdot 0.5H_2O$. Solid line: DTA, dotted line: TG.

Figure 3 shows the DTA-TG curves of $NdPO_4 \cdot 0.5H_2O$ by grinding. An endothermic peak in the 210—220 °C region with a weight loss, being due to the dehydration of water of crystallization, decreased gradually with increasing the grinding time and almost disappeared in the samples ground for more than 24 h. When $NdPO_4$ (monoclinic) was ground, a remarkable change of DTA-TG curves was not observed. On heating, the thermal changes of $NdPO_4 \cdot 0.5H_2O$ were shown as follows:[3]

$$NdPO_4 \cdot 0.5H_2O(\text{hexagonal}) \underset{\text{standing in air}}{\overset{210-220\,^\circ C}{\rightleftarrows}}$$

$$NdPO_4(\text{hexagonal}) \begin{cases} \xrightarrow[\text{long time}]{600\,^\circ C} NdPO_4(\text{monoclinic}) \\ \xrightarrow[\text{short time}]{800\,^\circ C} NdPO_4(\text{monoclinic}) \end{cases}$$

On the other hand, in the case of mechanochemical treatment, the conversion of $NdPO_4 \cdot 0.5H_2O$ (hexagonal) to $NdPO_4$ (monoclinic) proceeds at room temperature for above 24 h. This finding is very interesting in view of the fact that the mechanochemical treatment had the same effect as heat energy on the transition of $NdPO_4 \cdot 0.5H_2O$ (hexagonal) to $NdPO_4$ (monoclinic), and this transition took place without X-ray amorphous structure.

Mechanochemical Changes of Condensed Phosphates. In order to compare the difference in mechanochemical changes of the structure of phosphates, two condensed phosphates, neodymium metaphosphate ($Nd(PO_3)_3$) and ultraphosphate (NdP_5O_{14}), were examined. Because an ultraphosphate is generally very unstable, crystalline substances are almost unknown.[4] Neodymium ultraphosphate is one of the stable, crystalline ones and their mechanochemical investigation have not been reported. The X-ray diffraction intensities of $Nd(PO_3)_3$ and NdP_5O_{14} decreased with increasing the grinding time, the line-width broadened, and their diffraction peaks disappeared at last. From their IR spectra, with grinding, the intensities of their absorption peaks decreased and the peak-width broadened because of X-ray amorphous structure. From the results of DTA-TG, the ground $Nd(PO_3)_3$ has an endothermic peak at about 100 °C with a weight loss by the dehydration of adsorbed water, and an exothermic one at about 650 °C, being due to the restoring of the lattice distortion produced by grinding. The exothermic peak increased gradually with grinding time. This shows that its crystal structure was distorted by grinding, and finally transformed to the X-ray amorphous structure; metaphosphate showed the structure change similar to alkaline metaphosphates,[5] that is, the increasing of amorphous substance with grinding time and the yielding of shorter-chain phosphate molecules as a result of random cleavage of the P-O-P linkage upon grinding. When NdP_5O_{14} was ground for more than 3 h, large weight loss at about 100 and 300—400 °C was observed. It is suggested from the results of X-ray diffraction patterns, IR spectra, and DTA that the crystal structure of neodymium ultraphosphate was very unstable for grinding.

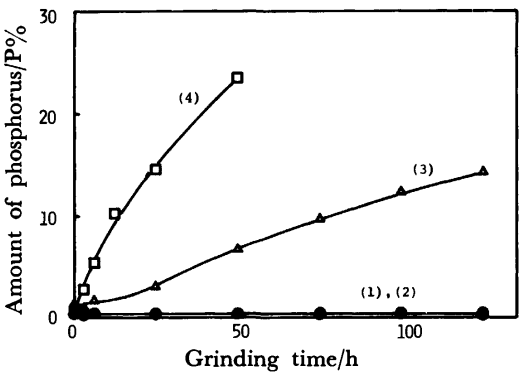

Fig. 4. Changes in the solubility of ground samples in water. (1): $NdPO_4$, (2): $NdPO_4 \cdot 0.5H_2O$, (3): $Nd(PO_3)_3$, (4): NdP_5O_{14}.

Solubility of Ground Samples in Water. Figure 4 shows the changes in the solubilities of various ground phosphates in water. Species dissolved was almost orthophosphate, seldom, pyrophosphate. The amounts of dissolved phosphates were 23.5% for ultraphosphate ground for 48h, and 14.3% for metaphosphate ground for 120h. But the ground samples of orthophosphates ($NdPO_4$ and $NdPO_4 \cdot 0.5H_2O$) were not entirely dissolved, showing that the crystal structure of condensed phosphates was rather unstable than those of orthophosphates on grinding.

Phase Relations in the System $NH_4Ti_2P_3O_{12}$-$NH_4Zr_2P_3O_{12}$

Akira ONO
National Institute for Research in Inorganic Materials, 1-1 Namiki, Ibaraki, 305
(Received June 13, 1984)

Synopsis. Crystalline phases in the system $NH_4Ti_2P_3O_{12}$–$NH_4Zr_2P_3O_{12}$ were prepared in a high pressure vessel, and were investigated by X-ray method. New compounds, $(NH_4)_{1+x}Ti^{3+}{}_x(Ti^{4+},Zr)_{2-x}P_3O_{12}$ ($1 \geqq x$), with the langbeinite-type structure were produced under reducing conditions.

In recent years a number of compounds with the Nasicon-type structure have been studied in relation to the superionic conductor, Nasicon ($Na_3Zr_2Si_2PO_{12}$).[1-4] A characteristic framework of these compounds is that all the oxygen atoms are shared between MO_6 and TO_4 where M is Ti or Zr and T is Si,Al or P. Each octahedron is surrounded by six tetrahedra, and each tetrahedron by four octahedra. This framework with the formula $M_2(TO_4)_3$ can exist in three modifications: Nasicon-type, langbeinite-type and garnet-type structures.[5,6]

These structures may be conveniently described as a body-centered cubic rod packing or hexagonal packing of parallel cylinders.[7] For example, in the case of $KTi_2P_3O_{12}$ with cubic langbeinite-type structure,[8] the rods consist of a repeating sequence K, (K),O_3TiO_3,O_3TiO_3, where (K) is vacancy. The rods extend along four nonintersecting directions, parallel to the body diagonals of a cube. The P atoms in tetrahedral coordination hold the rods together. On the other hand, rods consist of a repeating sequence of K,O_3TiO_3,O_3TiO_3 in the rhombohedral $KTi_2P_3O_{12}$. The rods are oriented along the real axis $\bar{3}$.

Rhombohedral $NH_4Ti_2P_3O_{12}$ and $NH_4Zr_2P_3O_{12}$ were prepared,[9-11] but no cubic phase was obtained. However, solid solutions with cubic structure were produced during an investigation of the system $NH_4Ti_2P_3O_{12}$–$NH_4Zr_2P_3O_{12}$. The purpose of this work is to ellucidate phase relations in this and related systems.

Experimental

Reagents used for synthesis were $NH_4H_2PO_4$, TiO_2, and ZrO_2. All of them have a purity higher than 99%. These materials were weighed according to the prescribed proportion and mixed in an alcohol medium, and then dried at 323 K for 10 h. The ratio of P to (Ti+Zr) is 1.5 for all the starting materials except for two experimental runs where small amount of $NH_4H_2PO_4$ was added as a flux component to promote chemical reaction.

Three kinds of experiments were carried out. First, starting material was sealed in a gold capsule of 6 mm in diameter and 35 mm long with no water added. Second, double capsules were used. Starting material was sealed in an inner platinum capsule, and then hematite and water were put in between the inner and outer capsules in order to maintain low hydrogen fugacity. Third, a small amount of acetone was added to the starting material in a gold capsule in order to produce high hydrogen fugacity. The ratio $Ti^{4+}/(Ti^{4+}+Ti^{3+})$ in crystalline materials may be controlled by the hydrogen fugacity of fluid phase.

Synthesis was carried out in a cold seal high pressure vessel. Temperature was measured by an internal thermocouple, and pressure by a calibrated Heise Bourdon tube gauge.

X-ray powder patterns were recorded with a Toshiba diffractometer using Cu $K\alpha$ radiation. For unit cell determinations, the pattern was obtained at room temperature by the scanning speed of 0.25 degree 2θ per min. KCl or quartz powder was used as an internal standard.

Chemical analyses of the synthetic crystals were carried out with an electron probe microanalyzer (JXA 5A). $NH_4Ti_2P_3O_{12}$ prepared and analyzed before[10] was used as a standard. Apparent concentration was corrected by the procedure proposed by Bence and Albee.[12]

Results and Discussion

Experimental results are listed in Table 1 together with experimental conditions. X-ray studies on the products of the first kind of experiments (1—9 in Table 1) indicate that most of X-ray reflections could be indexed as a rhombohedral form. However, extra weak reflections were observed in four experimental products. These reflections could be indexed as a cubic form with the langbeinite-type structure. Cubic phases were not prepared by the second kind of experiments (10—13 in Table 1), suggesting that cubic phase is unstable under low hydrogen fugacity. On the other hand, cubic phases with blue colour were main products when acetone was added to the starting materials(14—19 in Table 1). These results suggest the presence of Ti^{3+} in the cubic phases. Further evidence for the existence of Ti^{3+} will be described afterward.

Formula unit volumes are presented on Fig. 1 as a function of the ratio Zr/(Zr+Ti) in the starting material. As is seen from Fig. 1, formula unit volumes slightly deviate from the Vegard's law. Two rhombohedral phases with different unit cell volume were present in the product obtained by the experiment 7 in Table 1. Chemical compositions of the coexisting phases were determined by using the relationship between composition and formula unit volume shown in Fig. 1, and plotted as circles A and B. The compositions of A and B are 0.56±0.03 and 0.09±0.01 in the Zr/(Zr+Ti) ratio, respectively.

The first and second kinds of experiments were unsuccessful in yielding a pure cubic phase. However, cubic phase with or without graphite was obtained by the third kind of experiments. Formula unit volume of the cubic phase is shown by the cross in Fig. 1. Two cubic phases with different unit cell volume were crystallized in two products (15 and 18), suggesting presence of an immiscibility field in the cubic solid solution system. One of the cubic phases in the product of experiment 15 showed weak X-ray peaks partially superimposed on nearby higher peaks.

Weight loss for the cubic phases(15 in Table 1) was 9.4 wt% at 1273 K, which was larger than the weight loss for $NH_4Ti_2P_3O_{12}$ (6.4%). Excess ammonium

R: rhombohedral phase, C: cubic phase, gr: graphite, (—): minor product.
a) Small amount of $NH_4H_2PO_4$ was added. b) Fluid phase is present in all products.

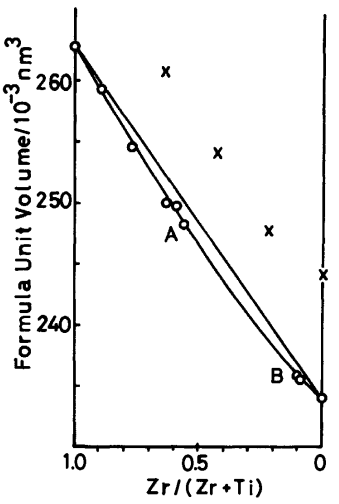

Fig. 1. Formula unit volume versus composition of starting materials. circle: rhombohedral phase not associated with cubic phase, cross: cubic phase prepared under reducing conditions, A—B; immiscibility field at 853 K, 0.17 GPa.

content may be explained by the presence of Ti^{3+} in the octahedral site. Chemical formula derived from the weight loss datum and the ratio of Zr to (Zr+Ti) in the cubic phase (0.22) is as follow: $(NH_4)_{1.55}Ti^{3+}_{0.55}Ti^{4+}_{1.01}Zr_{0.44}P_3O_{12}$.

Zirconium-free crystals were of sufficient sizes for analysis using an electron probe microanalyzer. Composition of the cubic phase is: TiO_2=37.68; P_2O_5=50.52 (wt%). Because discrimination of TiO_2 and Ti_2O_3 contents is impossible for our analytical method, value of TiO_2 is total titanium calculated as TiO_2. The analytical data is consistent with the theoretical value for $(NH_4)_2Ti^{3+}Ti^{4+}P_3O_{12}$: TiO_2=37.74; P_2O_5=50.29 (wt%). On the other hand, rhombohedral phase coexisiting with graphite and cubic phase gave the same composition as the standard $NH_4Ti_2P_3O_{12}$.

Crystal Structure of Binuclear Copper(II) Complex with 3-Ethyl-2-pyridone and Magnetism of Its Homologues

Yuzo NISHIDA* and Sigeo KIDA
Department of Chemistry, Faculty of Science, Kyushu University 33, Fukuoka 812
(Received July 14, 1984)

Synopsis. The crystal structure of bis(*N*,*N*-dimethylformamide)tetrakis(3-ethyl-2-pyridonato)dicopper(II) was determined by X-ray diffraction method. Crystal data: Space group $P2_1/n$(monoclinic), a=9.906(1), b=13.494(3), c=14.029(2) Å, β=103.81(1)°. The crystal consists of centrosymmetric binuclear units in which two copper(II) ions are linked by four pyridonate anions similarly to copper(II) acetate monohydrate. The Cu–Cu distance is 2.55 Å. The cryomagnetic data revealed that $-2J$ values are in the range 360—405 cm^{-1} for the series of complexes.

It is well known that copper(II) acetate monohydrate consists of binuclear structure in which two copper(II) ions are bridged by four acetate anions with a short Cu–Cu distance(2.64 Å).[1] Similar structures were also observed for copper(II) complexes with 1,3-diphenyltriazene,[2] 1,7-diazaindene,[3] and adenine.[4] It is also known that 2-pyridone forms binuclear complexed with Ph(II), Mo(II), and Ru(II) ions similar to that of copper(II) acetate monohydrate.[5]

In 1972, Emori *et al.*[6] reported the preparation of Cu(2-pyridonato)$_2$·(2-pyridone), and they assumed that this complex has a structure similar to that of copper(II) acetate monohydrate based on the magnetic property. In this study a series of copper(II) complexes with 2-pyridone and its homologues have been prepared and characterized by the spectral and magnetic measurements. In order to confirm the binuclear structure, the crystal structure of one of them, bis(*N*,*N*-dimethylformamide)tetrakis(3-ethyl-2-pyridonato)dicopper(II) has been determined by X-ray diffraction method.

Experimental

Preparations. 2-Pyridone was obtained commercially. The substituted 2-pyridones were prepared by the published method.[7] The copper(II) complexes were prepared by the following way. A DMF (or DMSO) solution containing substituted 2-pyridone (0.01 mol) and copper(II) hydroxide (0.005 mol) was kept at 50 °C for five hours. From the filtrate, the complex was obtained as dark prisms.[8]

Magnetic Measurements. Magnetic susceptibilities were measured in the temperature range 90—300 K by the published method.[9] Magnetic moments were calculated by the equation, $\mu_{eff}=2.828\sqrt{(\chi-N\alpha)T}$, where χ and $N\alpha$ have usual meanings.[1]

Determination of the Cell Constant and Collection of the Intensity Data. A crystal with the approximate dimension of 0.3×0.2×0.3 mm^3 was used for the determination and the collection of intensity data at 294 K. The cell dimensions and the diffraction intensities were measured on a Rigaku AFC-5 Automatic Diffractometer by using graphite monochromated Mo $K\alpha$ radiation. Crystal data. Cu(3-ethyl-2-pyridonato)$_2$·DMF, FW=380.9, space group $P2_1/n$(monoclinic), a=9.906(1), b=13.494(3), c=14.029(2) Å, β=103.81(1)°, Z=4, D_c=1.39 g cm^{-3}, D_m=1.44 g cm^{-3} (by floatation method). All independent reflections within the range $3°<2\theta<55°$ were collected by the use of $2\theta-\theta$ scan mode with a scanning rate 6°(2θ) min^{-1}. A total 1973 independent reflections with $|F_o|>3\sigma(|F_o|)$ were used for the determination of crystal structure. The data were corrected for the Lorentz and polarization effects.

Structure Determination

The position of the copper atom was obtained from the three dimensional Patterson map. The positions of the other non-hydrogen atoms were located by the Fourier synthesis. There was a disorder in ethylcarbon atom (see Table 1). The structure was refined to R=0.065 for the observed reflections by a block-diagonal least-squares method using anisotropic temperature factors for non-hydrogen atoms. At the final stage of the refinement the difference Fourier map showed only featureless peaks. Anisotropic temperature factors of the non-hydrogen atoms and the complete F_o-F_c data are deposited as Documents No. 8506 at the Office of the Editor of the Bulletin of the Chemical Society of Japan. The final atomic coordinates, and the equivalent isotropic temperature factors are given in Table 1. All the calculations were carried out on a M-200 computer at the Computer Center of Kyushu University using the local version[10] of the UNICS system.[11] The atomic scattering factors were taken from the International Tables for X-Ray Crystallography.[12]

Results and Discussion

The perspective drawing of the structure of bis(*N*,*N*-dimethylformamide)tetrakis(3-ethyl-2-pyridonato)dicopper(II) is shown in Fig. 1 with selected bond lengths and bond angles. As has been expected, the crystal consists of centrosymmetric binuclear unit similar to that of copper(II) acetate monohydrate. The Cu–Cu distance is 2.55 Å, which is shorter than that of copper(II) acetate monohydrate (2.64 Å). The DMF molecule coordinates to the copper(II) atom at the apical position, forming a five-coordinated environment around the copper(II) ion.

The magnetic moments are summarized in Table 2. The magnetic moments of the complexes at room temperature are in the range 1.18—1.26 BM, implying that antiferromagnetic interaction is operating between two copper(II) ions. The temperature dependence of magnetic susceptibilities(90—300 K) of these complexes can be interpreted in terms of Bleaney-Bowers equation with the $-2J$, g and $N\alpha$ values listed in the Table 2.

All the electronic spectra of the compounds are similar to each other. In DMF the d-d band and the shoulder were observed at 17.4×10^3 cm^{-1} (log ε=2.41) and

Synthesis of 2,6,8-Trinitro-4*H*-cyclopenta[*def*]phenanthren-4-one as an Electron Acceptor

Masahiro MINABE,* Masaaki YOSHIDA, and Okitoshi KIMURA

Department of Industrial Chemistry, Faculty of Engineering, Utsunomiya University, Ishiicho, Utsunomiya 321

(Received May 23, 1984)

Synopsis. 2,6,8-Trinitro-4*H*-cyclopenta[*def*]phenanthren-4-one (TNC) was synthesized by the nitration of the parent ketone. TNC formed charge-transfer complexes with polycyclic aromatic hydrocarbons (PAH). The property of TNC as an electron acceptor was compared with that of 2,4,7-trinitro-9*H*-fluoren-9-one (TNF). TNC was found to be a better complexing agent than TNF.

Many mono- and disubstituted derivatives of 4*H*-cyclopenta[*def*]phenanthrene (**1**) have been synthesized by electrophilic substitution.[1] However, there are few reports relating to polysubstituted derivatives of **1**.[2] Since polynitro ketones of **1** could be expected to be good electron acceptors as 2,4,7-trinitro-9*H*-fluoren-9-one (TNF),[3] we investigated the preparation of a polynitro derivative of 4*H*-cyclopenta[*def*]phenanthren-4-one (**2**).[4]

The present paper deals with the synthesis of 2,6,8-trinitro-4*H*-cyclopenta[*def*]phenanthren-4-one (TNC) and with a comparison of the properties of TNC with those of TNF.

Nitration of **2** with nitric acid in sulfuric acid at 0—55 °C afforded TNC in 70% yield as light-yellow needles. The positions of nitro groups were confirmed by a stepwise synthesis: nitration of the 2-nitro ketone (**3**)[4] gave TNC that was also obtained by reaction of the isomeric 8-nitro ketone (**4**).[4] Moreover, TNC was obtained by the nitration of the 2,6-dinitro ketone (**5**) that was isolated by the oxidation of 2,6-dinitro-8,9-dihydro compound (**6**).[4]

Carbonyl absorption in the IR spectrum of TNC is observed at higher wavenumber than that of TNF, while absorptions of parent **2** and 9*H*-fluoren-9-one appear at the same position. The red shift of the maximum of TNC in the UV spectra from that of **1** is greater than the case between TNF[3a] and 9*H*-fluoren-9-one.

The cyclic voltammogram of TNC is very similar to that of TNF.[5-8] TNC and TNF both exhibit the first reversible one-electron reductions at −0.38 V and −0.48 V *vs.* SCE, respectively, the latter of which agrees well with the reported value.[5,6] These findings suggest that charge transfer in the case of TNC may occur easier than for the case of TNF.

The π-π charge-transfer complexes of TNC with some PAH were isolated as stable solids of 1:1 molar ratio (Table 1). The shift of the nitro absorptions to a long-wavelength region of the IR spectra of these complexes may be associated with the charge-transfer energy of each complex as the relation between TNF complexes and their transition energies.[9]

The ability of TNC to act as an electron acceptor was compared with that of TNF using the binding constant (B*) which was the reverse of the *B*-value proposed by Harvey and Halonen.[10] The *B*-value is defined as $(R_{f_1}-R_{f_{11}})\times 100/R_{f_1}$, where R_{f_1} is the R_f-value of any PAH on the usual thin-layer chromatograph, and $R_{f_{11}}$ is the R_f-value of the same PAH on a plate doped with an acceptor. The constant *B** (which is defined as $R_{f_{11}}'/R_{f_1}$) is determined by a comparison of the R_f-value ($R_{f_{11}}'$) of a given acceptor on a plate doped by a donor with the R_{f_1} of the same acceptor on the usual plate. A large *B**-value indicates a large equilibrium constant in the donor-acceptor interaction. Table 2 illustrates the comparison of the *B**-constant of TNC with that of TNF using the plate doped with 9*H*-fluorene (**7**) as an electron donor. This finding apparently suggests that TNC is superior to TNF as an electron acceptor.

The CT absorption spectrum of TNC with diethylamine (DEA) is illustrated along with that of TNF-

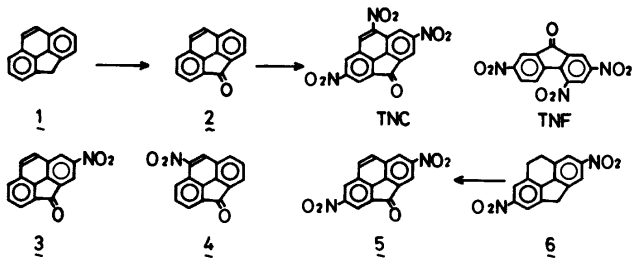

Table 2. Binding constants (*B**) of TNC and TNF

Compd	R_{f_1}	$R_{f_{11}}'$	*B**-value
TNC	0.37	0.46	1.24
TNF	0.42	0.47	1.12

Table 1. Properties of CT complexes of TNC with PAH

Donor	Yield %	Mp θ_m/°C (dec)	Color	IR (KBr) cm^{-1}	
				$\nu_{C=O}$	ν_{NO_2}
Phenanthrene	79	225—226	Yellow	1739	1537, 1530(s), 1335
7	88	211.0—211.5	Orange	1739	1537, 1335
1	89	240.0—240.5	Orange	1737	1544(s), 1530, 1337
Pyrene	87	291—292	Red	1740	1546, 1527, 1336

DEA in Fig. 1. A composit of the TNC-DEA system shows two maxima (450 and 560 nm). Also, the TNF-DEA curve has two maxima (520 and 630 nm) but the absorbance is less than that of the TNC complex. The formation constants (K) of these complexes were obtained at 25 °C by the Benesi-Hildebrand method:[11] K=1.88 lmol^{-1} for TNC at 560 nm and K=1.32 lmol^{-1} for TNF at 630 nm. The results suggest that TNC is a better complexing agent than TNF.

Experimental

All the melting points are uncorrected. The ^{1}H NMR, UV, and IR spectra were recorded on a Jeol JNM-C-60 HL, a Shimadzu UV-180, and a Jasco IRA-2 instrument, respectively. Satisfactory analytical data regarding the new compounds were obtained by elemental analyses (C, H, N, within ±0.3%) and a mass-spectra investigation.

Cyclic voltammograms were obtained with HMDE as the working electrode in aqueous dioxane (1:1 by volume) containing 50 mmol of $NaClO_4$. The solution was deoxygenated by bubbling for 30 min with dry nitrogen (99.999%).

Nitration of **2**. To a solution of **2** (4.1 g, 20 mmol) in H_2SO_4 (d=1.84 g cm^{-3}, 20 ml) was added a mixed acid of HNO_3 (d=1.49 g cm^{-3}, 5 ml) and concd H_2SO_4 (5 ml) below 0 °C for 15 min. The mixture was stirred at that temperature for a period of 1 h followed by stirring at 55 °C for an additional 15 min. A precipitate, formed after adding the mixture to ice water (300 ml), was filtered and washed with water. It was then dried overnight at 60 °C and chromatographed on a Kieselguhr column (45 mmϕ, 25 cm) with benzene. The yellow eluate was concentrated to a small volume to give 4.75 g (70%) of TNC, as light-yellow needles from ethyl acetate: mp 237—239 °C (dec). IR (KBr): $\nu_{C=O}$ 1740, ν_{NO_2} 1551, 1528, 1360, and 1342 cm^{-1}. NMR (DMSO-d_6): δ= 8.62—8.68 (2H, m) and 9.36—9.45 (3H, m). UV_{max} (EtOH): 207 (log ε 4.43), 266 (4.57), and 303 nm (4.23).

Oxime of TNC: mp 273.5—274.5 °C (dec). IR (KBr): ν_{OH} 3330, ν_{NO_2} 1544, 1536, and 1331 cm^{-1}. NMR (DMSO-d_6): δ=3.34 (1H, s, OH), 8.17 (1H, s), 8.42 (1H, s), 8.91 (1H, s), and 8.98—9.05 (2H, m). UV_{max} ($CHCl_3$): 250 (4.51), 313 (4.37), 380 (3.72), and 403 nm (3.61). B*-value: 1.15.

Hydrazone: mp 255.5—256.5 °C (dec). IR (KBr): ν_{NH_2} 3450, 3330, 3240, ν_{NO_2} 1552, 1524, and 1336 cm^{-1}. NMR (DMSO-d_6): δ=7.69—7.84 (1H, m), 8.43—8.57 (2H, m), 8.61—8.75 (2H, m), and 9.20 (2H, s, NH_2). UV_{max} ($CHCl_3$): 256 (4.41), 325 (4.34), and 416 nm (3.70). B*-value: 1.11.

Ethylene Dithioacetal: mp 310—311 °C (dec). IR (KBr): ν_{NO_2} 1543, 1529, and 1333 cm^{-1}. NMR (DMSO-d_6): δ=4.13 (4H, s), 8.95 (2H, s), 9.46 (1H, s), 9.59 (1H, s), and 9.68 (1H, s). UV_{max} ($CHCl_3$): 245 (4.27) and 292 nm (4.46).

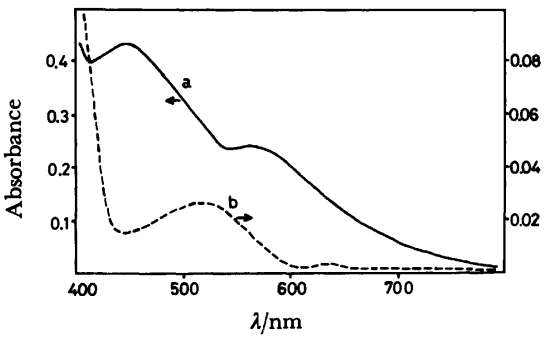

Fig. 1. CT absorption spectra of TNC and TNF with DEA in 1,2-dichloroethane at 25 °C.
(a): TNC(1.003×10^{-4} M, 1 M=1 mol dm^{-3})-DEA (4.71×10^{-1} M), (b): TNF(1.002×10^{-4} M)-DEA (4.71×10^{-1} M).

Nitration of **3**. Ketone **3** (75 mg, 0.3 mmol) was nitrated with HNO_3 (0.05 ml) in H_2SO_4 (10 ml) at 55 °C for 15 min to give 65 mg (64%) of TNC.

Nitration of **4**. A mixture of **4** (440 mg, 1.77 mmol), HNO_3 (0.5 ml), and H_2SO_4 (3.5 ml) was stirred at 70 °C for 1 h to afford TNC (175 mg, 28%).

Synthesis and Nitration of **5**. A nitro compound **6** (564 mg, 2 mmol) in benzene (120 ml) was refluxed with MnO_2 (10 g) for 12 h, followed by chromatography on a Kieselguhr column with benzene. The yellow eluate gave 361 mg (61%) of **5**: mp 351—352 °C (dec). IR (KBr): $\nu_{C=O}$ 1724, ν_{NO_2} 1524, and 1342 cm^{-1}. UV_{max} ($CHCl_3$): 262 (4.78), 312 (4.05), 322 (4.08), and 349 nm (3.74).

A mixture of **5** (60 mg, 0.2 mmol), HNO_3 (0.05 ml), and H_2SO_4 (10 ml) was maintained at 55 °C for 15 min to yield TNC (46 mg, 68%).

CT Complex of TNC with PAH. Typical Procedure. TNC (34 mg, 0.1 mmol) and **7** (17 mg, 0.1 mmol) were dissolved in a minimum quantity of HOAc with refluxing and allowed to cool to room temperature. A 45-mg (88%) of the complex was obtained as orange needles, mp 211.0—211.5 °C (dec).

Thin-layer Chromatography of Doped and Undoped Plates. TLC plates used in this experiment were purchased from E. Merck (TLC Silica gel 60; thickness 0.25 mm; 20×5 cm). The R_f-value was obtained using EtOAc/cyclohexane (1:2 by volume) as a developing solvent with the plate that was soaked in EtOAc/cyclohexane (1:2) for 5 min followed by drying at 60 °C for 20 min.

The R_f-value was determined on a plate that was soaked in a solution of EtOAc/cyclohexane (1:2) containing **7** (2%) for 5 min and dried at 60 °C for 20 min, using a developing solvent of EtOAc/cyclohexane (1:2) containing 2% of **7**. The value given in Table 2 is the average value for 10 runs.

The authors wish to thank Professor A. Yamada of the Technological University of Nagaoka for obtaining the cyclic voltammograms. Also, they thank Professor T. Toda for reading the manuscript.

^{119}Sn NMR Spectroscopic Determination of Diastereomeric Ratio of Some Optically Active Organotin Compounds

Junzo OTERA* and Toru YANO
Okayama University of Science, Ridai-cho, Okayama 700
(Received June 11, 1984)

Synopsis. Diastereomeric ratio of optically active organotin compounds, $R^*_2SnX_2$ and $R^1R^2R^3SnR^*$, was successfully determined by means of ^{119}Sn NMR spectra.

In the study of optically active organotin compounds, diastereomeric organotins play a versatile role[1] in the asymmetric induction at tin, the optical resolution, and the determination of optical purity. Accordingly, it is of great importance to determine the diastereomeric ratio conveniently. ^{1}H and ^{13}C NMR spectra may be applicable in some cases where spectra are simple and signals due to diastereomers are fully separated though these requirements being not always fulfilled. Development of an alternative method, therefore, is highly desirable. Pereyre *et al.* have reported that diastereomers of (*s*-Bu)$_4$Sn[2a] and $R_3SnCH(CH_3)CH_2CO_2(-)Men$[2b] (Men=menthyl) are distinguishable by means of ^{119}Sn NMR spectra. In the course of our studies on optically active allyltin compounds,[3] $R^*_2SnX_2$ and $R^1R^2R^3SnR^*$ proved to be versatile starting materials. Thus an effective method for quantitative determination of these diastereomers has been highly required for evaluating the degree of stereospecificity in the reaction of optically active allyltin compounds with aldehydes. Herein we wish to describe the usefulness of ^{119}Sn NMR spectra for this purpose.

On account of facile optical resolution of 2-phenylbutyric acid with various degree of optical purity,[4] 2-phenylbutyltin derivatives are suitable for attesting applicability of the ^{119}Sn NMR spectroscopy to quantitative diastereomeric determination. As shown in Fig. 1, optically active PB_2SnBr_2 (**1a**) (PB=2-phenylbutyl) that was prepared employing optically pure (*R*)-2-phenylbutylmagnesium chloride exhibits a singlet at δ 58.3 while racemic **1a** gives rise to two signals at 53.3 and 58.3. Thus it is reasonably concluded that the signal at lower field can be attributed to the (*R,R*)- and (*S,S*)-isomers and the other at higher field to the (*R,S*)- and (*S,R*)-isomers. The results of other compounds are summarized in Table 1. Since each signal of PB_2SnX_2 is unambiguously assigned analogously, one can deduce the diastereomeric ratio from the relative integral ratio. The results obtained by employing a PB group with various degree of optical purity are depicted in Fig. 2. Apparently the observed values are in good agreement with calculated ones based on ee of the used PB group.

Of particular interest is that this method can be applied to estimation of the degree of asymmetric induction at tin in the following type of reaction that is the most common method for introduction of a chirality at tin. Two optically active groups, (*R*)-PB and (*S*)-2-methylbutyl (MB) groups, were employed for this purpose. As shown in Table 1, ^{119}Sn NMR spectra of these compounds indeed gave rise to two signals, indicating diastereomeric selectivity to be 54 and 53%, respectively. It is also to be noted that the diastereomeric ratio itself is not affected by optical purity of R.

TABLE 1. ^{119}Sn NMR SPECTRA OF DIASTEREOMERIC ORGANOTIN COMPOUNDS

Compound		δ/ppm	
		Racemic	Optically active
1a	PB_2SnBr_2	53.5, 58.3[a]	58.3
1b	PB_2SnCl_2	90.5, 92.0[a]	92.0
1c	$PB_2Sn(CH_2CH=CH_2)_2$	−38.7, −39.1[a]	−39.1
2a	PhMeEtSnPB	−36.0, −36.9 (46 : 54)[b]	−36.0, −36.9 (46 : 54)[b]
2b	PhMeEtSnMB	−35.8, −36.0 (47 : 53)[b]	−35.8, −36.0 (47 : 53)[b]

a) Relative integral ratio is *ca.* 1 : 1. b) Relative integral ratio.

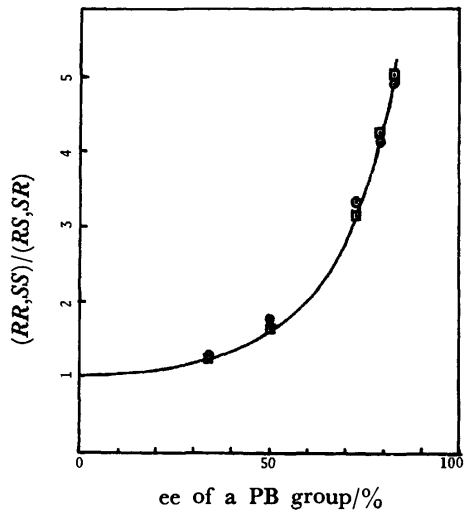

Fig. 2. Relation between ee of a PB group and (*RR*, *SS*)/(*RS*,*SR*) ratio. —— Calcualted; ⊙: Observed for **1a**, □: Observed for **1c**.

measured using a JEOL FX-100 spectrometer operating at 37.08 MHz at 22 °C. Field-frequency control was made with a deuterium-labelled solvent ($CDCl_3$) lock. The chemical shifts were determined relative to internal Me_4Sn, positive signs indicating low-field shifts from the reference, and were found to be accurate to ±0.1 ppm.

Optical resolution of 2-phenylbutyric acid was performed as the cinchonidine salt[4] into various degree of ee. Optically active 2-phenylbutyric acid thus obtained was converted into the corresponding chloride.[5] Optically active 2-methylbutyl bromide (ee>99%) was obtained by bromination of commercially available optically active 2-methyl-1-butanol (Aldrich Chemical Co.) with PBr_3.

Preparation of ***1a*** *and* ***1b***. To a dichloromethane solution (10 cm^3) of **1c**[3] (467 mg, 1 mmol) was added dropwise bromine (320 mg, 2 mmol) at 0 °C. The reaction mixture was evaporated to leave an oil that was chromatographed on silica gel (500:1 hexane-ether) to give **1a** (491 mg, 90%); ^1H NMR (CCl_4): δ=0.70 (6H, t, *J*=7.0 Hz), 0.96—2.21 (8H, m), 2.21—2.88 (2H, m), and 6.58—7.22 (10H, m). Found: C, 44.42; H, 4.54%. Calcd for $C_{20}H_{26}Br_2Sn$; C, 44.08; H, 4.81%. $[\alpha]_D^{22}$ for optically active **1a** −38.9 (*c* 2.14, benzene).

The chloride **1b** was prepared analogously employing sulfuryl chloride in place of bromine in 65% yield; ^1H NMR (CCl_4): δ=0.70 (6H, t, *J*=7.2 Hz), 0.90—2.17 (8H, m), 2.17—2.97 (2H, m), and 6.62—7.24 (10H, m). Found: C, 52.88, H, 6.03%. Calcd for $C_{20}H_{26}Cl_2Sn$; C, 52.68; H, 5.75%. $[\alpha]_D^{22}$ for optically active **1b** −51.9° (*c* 1.02, benzene).

Preparation of ***2a*** *and* ***2b***. To a THF solution (10 cm^3) of 2-phenylbutylmagnesium chloride prepared from 2-phenylbutyl chloride (471 mg, 2.79 mmol) and magnesium turnings (134 mg, 5.58 mmol), was added dropwise PhMeEtSnBr[6] (300 mg, 0.93 mmol) in THF (2 cm^3) at 0 °C. After being stirred for 2 h at room temperature, the reaction mixture was extracted with hexane-saturated ammonium chloride solution. The organic layer was washed with water and dried ($MgSO_4$). Evaporation and column chromatography (silica gel, hexane) of the resulting oil yielded **2a** (218 mg, 59%); ^1H NMR (CCl_4): δ=0.16, 0.18 (3H, s, diastereomeric), 0.66—2.10 (12H, m), 2.81 (1H, m), and 6.86—7.50 (10H, m). Found: C, 61.21; H, 7.60%. Calcd for $C_{19}H_{26}Sn$; C, 61.17; H, 7.22%.

The preparation of **2b** was carried out analogously employing 2-methylbutyl bromide in place of 2-phenylbutyl chloride in 63% yield; ^1H NMR (CCl_4); δ=0.48 (3H, s), 0.75—2.20 (16H, m), and 7.20—7.59 (5H, m). Found: C, 53.72; H, 8.30%. Calcd for $C_{14}H_{24}Sn$; C, 54.06; H, 7.78%.

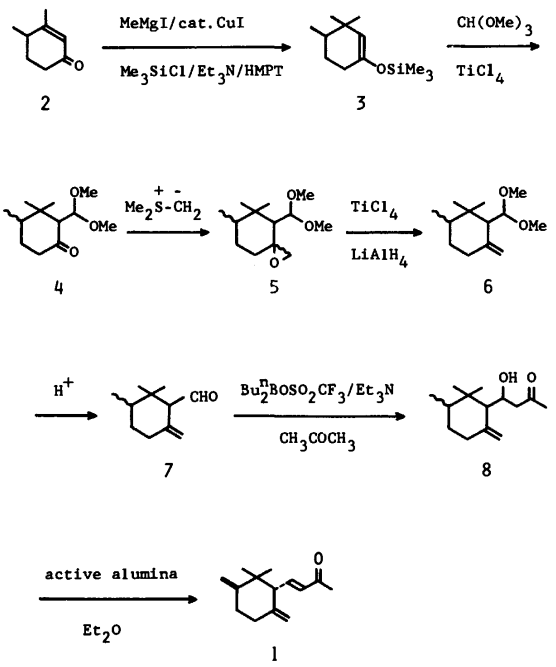
New Synthesis of *trans*-γ-Irone

Osamu TAKAZAWA,* Kunio KOGAMI, and Kazuo HAYASHI
Kawasaki Research Laboratories, T. Hasegawa Co., Ltd., 335 Kariyado, Nakahara-ku, Kawasaki 211
(Received June 20, 1984)

Synopsis. *trans*-γ-Irone was successfully synthesized starting from 3,4-dimethyl-2-cyclohexenone by seven-step reactions including $TiCl_4$-promoted reaction of enol silyl ether and cross-aldol reaction of vinyloxyborane.

Irones have been isolated from Iris oil as very important fragrant constituents.[1] Recently, Ohloff et al. have further identified *trans*-γ-irone (**1**) in Iris oil.[2] Concerning the synthesis of **1**, three methods have been reported.[3] Previously, we reported an efficient method for preparation of γ-ionone.[4] In this paper, we will describe an alternative method for synthesis of **1** starting from an easily accessible 3,4-dimethyl-2-cyclohexenone (**2**) in the similar manner as above. Our synthetic route is outlined in the following scheme.



The reaction of 3,4-dimethyl-2-cyclohexenone (**2**) with methylmagnesium iodide in the presence of a catalytic amount of copper(I) iodide, followed by quenching with trimethylchlorosilane, triethylamine, and hexamethylphosphoric triamide, gave 3,3,4-trimethyl-1-trimethylsiloxy-1-cyclohexene (**3**) in a 70% yield.[5] 2-Dimethoxymethyl-3,3,4-trimethylcyclohexanone (**4**) was obtained in a 72% yield by the reaction of **3** with trimethyl orthoformate in the presence of $TiCl_4$.[6] The conversion of **4** to 4-dimethoxymethyl-5,5,6-trimethyl-1-oxaspiro[2.5]octane (**5**) was carried out in almost the same manner as reported,[7] that is, the reaction of **4** with dimethylsulfonium methylide gave **5** in a 61% yield. The deoxygenation of **5** with low valent titanium compound, prepared from $TiCl_4$ and $LiAlH_4$, afforded 6-methylene-2,2,3-trimethylcyclohexanecarbaldehyde dimethyl acetal (**6**) in an 83% yield, which was further converted to 6-methylene-2,2,3-trimethylcyclohexanecarbaldehyde (**7**)[3a] in a 79% yield by hydrolysis with 2 M HCl (1 M= 1 mol dm^{-3}).

Dibutyl(isopropenyloxy)borane, formed from acetone and dibutylboryl trifluoromethanesulfonate,[8] reacted with **7** to give a mixture of two stereoisomers (**8a** and **8b**) of 4-(6-methylene-2,2,3-trimethylcyclohexyl)-4-hydroxy-2-butanone (**8**) in a 79% yield, which was separated by silica-gel column chromatography. The aldols, **8a** and **8b**, were converted to *trans*-γ-irone (**1**) without accompanying *cis*-isomer on treatment with active alumina in 57% and 36% yields, respectively.

Experimental

Spectra. All bps are uncorrected. ^1H NMR spectra were recorded on a Hitachi R-24A spectrometer. Chemical shifts are reported on the δ scale relative to Me_4Si as an internal standard. IR spectra were taken using a JASCO IRA-2 spectrometer.

3,3,4-Trimethyl-1-trimethylsiloxy-1-cyclohexene (3). To a mixture of 2.8 M methylmagnesium iodide (50 ml, 140 mmol) in ether and copper(I) iodide (400 mg) was added dropwise a solution of 3,4-dimethyl-2-cyclohexenone (**2**) (12.40 g, 100 mmol) in dry ether (40 ml) at 0 °C, and the mixture was stirred for 1 h at 0 °C. Trimethylchlorosilane (30 ml), triethylamine (40 ml), and hexamethylphosphoric triamide (20 ml) were successively added at 0 °C and the mixture was stirred for 24 h at room temperature. The mixture was processed and the product was distilled to give **3** (14.80 g, 70%). Bp 90—93 °C/16 mmHg (1 mmHg=133.322 Pa); IR (neat) 1665 cm^{-1}; NMR (CCl_4) δ=0.15 (s, 9H), 0.82 (s, 3H), 0.88 (d, *J*=6.0 Hz, 3H), 0.98 (s, 3H), 1.2—2.1 (m, 5H), and 4.53 (m, 1H). Found: C, 67.83; H, 11.29%. Calcd for $C_{12}H_{24}SiO$: C, 67.86, H, 11.39%.

2-Dimethoxymethyl-3,3,4-trimethylcyclohexanone (4). To a cold solution (−78 °C) of trimethyl orthoformate (6.89 g, 65 mmol) in dry dichloromethane (100 ml) was added $TiCl_4$ (12.35 g, 65 mmol) under argon atmosphere. A solution of **3** (10.60 g, 50 mmol) in dry dichloromethane (10 ml) was added and the reaction mixture was stirred for 2 h at −78 °C. The mixture was quenched with methanol (20 ml) and poured into a 15% solution of K_2CO_3. After evaporation of the solvent, the residue was distilled to give **4** (7.70 g, 72%). Bp 88—90 °C/1.5 mmHg; IR (neat) 1715, 1125, and 1060 cm^{-1}; NMR (CCl_4) δ=0.75 (s, 3H), 0.90 (d, *J*=6.5 Hz, 3H), 0.97 (s, 3H), 1.2—2.5 (m, 5H), 2.28 (d, *J*=7.0 Hz, 1H), 3.20 (s, 3H), 3.27 (s, 3H), and 4.67 (d, *J*=7.0 Hz, 1H). Found: C, 67.14; H, 10.29%. Calcd for $C_{12}H_{22}O_3$: C, 67.26; H, 10.35%.

4-Dimethoxymethyl-5,5,6-trimethyl-1-oxaspiro[2.5]octane (5). A mixture of NaH (10 mmol) and dimethyl sulfoxide (5 ml) was stirred for 1 h at 65—70 °C and cooled to room temperature, and then tetrahydrofuran (30 ml) was added. A solution of trimethylsulfonium iodide (2.04 g, 10 mmol) in dimethyl sulfoxide (5 ml) was added dropwise at −20—−15

°C and stirred for 5 min. A solution of **4** (428 mg, 2 mmol) in tetrahydrofuran (5 ml) was added dropwise at the same temperature as above and the mixture was stirred overnight at 0 °C. The mixture was worked up and the product was subjected to silica-gel column chromatography to afford **5** (280 mg, 61%). IR (neat) 3030, 1130, 1075, and 1050 cm^{-1}; NMR (CCl_4) δ=0.80 (d, J=6.5 Hz, 3H), 0.86 (s, 3H), 1.05 (s, 3H), 1.3—2.2 (m, 6H), 2.46 (s, 2H), 3.30 (s, 3H), 3.37 (s, 3H), and 4.47 (d, J=3.0 Hz, 1H). Found: C, 68.23; H, 10.41%. Calcd for $C_{13}H_{24}O_3$: C, 68.38, H, 10.59%.

6-Methylene-2,2,3-trimethylcyclohexanecarbaldehyde Dimethyl Acetal (6). Tetrahydrofuran (16 ml) was added dropwise to $TiCl_4$ (1.29 g, 6.8 mmol) at −78 °C under argon atmosphere and the resulting complex was warmed to room temperature. $LiAlH_4$ (258 mg, 6.8 mmol) was added to the complex, and the mixture was stirred for 1 h, and then triethylamine (5.55 g, 55 mmol) was added. To this was added dropwise a solution of **5** (1.41 g, 6.2 mmol) in tetrahydrofuran (10 ml) on a water bath and the mixture was stirred for 1 h at room temperature. The mixture was worked up and the product was distilled to give **6** (1.09 g, 83%). IR (neat) 1120, 1060, and 890 cm^{-1}; NMR (CCl_4) δ=0.73 (s, 3H), 0.87 (d, J=6.0 Hz, 3H), 0.92 (s, 3H), 1.1—1.8 (m, 3H), 1.9—2.4 (m, 3H), 3.18 (s, 3H), 3.24 (s, 3H), 4.48 (d, J=6.5 Hz, 1H), 4.52 (m, 1H), and 4.70 (m, 1H).

6-Methylene-2,2,3-trimethylcyclohexanecarbaldehyde (7). To a solution of **6** (1.09 g, 5.1 mmol) in ether (30 ml) was added 2 M HCl (30 ml) and the mixture was stirred overnight at room temperature. After separation of the organic layer, it was washed with a saturated solution of $NaHCO_3$ and concentrated. The residue was distilled to give **7** (675 mg, 79%). Bp (bath temperature) 100—110 °C/10 mmHg; IR (neat) 1720, 1640, and 895 cm^{-1}; NMR (CCl_4) δ=0.78 (s, 3H), 0.84 (d, J=6.5 Hz, 3H), 1.05 (s, 3H), 1.2—2.1 (m, 3H), 2.25 (m, 2H), 2.71 (d, J=3.5 Hz, 1H), 4.74 (s, 1H), 4.90 (s, 1H), and 9.73 (d, J=3.5 Hz, 1H). Found: C, 79.36, H, 10.79%. Calcd for $C_{11}H_{18}O$: C, 79.47, H, 10.91%.

4-(6-Methylene-2,2,3-trimethylcyclohexyl)-4-hydroxy-2-butanone (8). To dibutylboryl trifluoromethanesulfonate (303 mg, 1.1 mmol) was added a solution of triethylamine (111 mg, 1.1 mmol) in ether (1.5 ml) at −78 °C under argon atmosphere and the mixture was warmed to room temperature. A solution of acetone (64 mg, 1.1 mmol) in ether (1 ml) was added at −78 °C and the mixture was stirred for 20 min. Then a solution of **7** (158 mg, 0.95 mmol) in ether (2 ml) was added dropwise and the mixture was stirred for 2.5 h at −78 °C. To the reaction mixture was added 1 M buffer solution (pH 7.0) of phosphoric acid (3 ml), methanol (10 ml), and a 30% solution of H_2O_2 (2 ml), successively, and the mixture was stirred for 20 min at room temperature. After addition of water (10 ml), methanol was removed under reduced pressure. The residue was extracted with dichloromethane and the solution was concentrated. Purification by silica-gel column chromatography afforded two stereoisomers (**8a** and **8b**) of **8** (169 mg, 79%). **8a** (117 mg, 55%): IR (neat) 3470, 3070, 1710, 1640, and 890 cm^{-1}: NMR (CCl_4) δ=0.75 (s, 3H), 0.79 (d, J=6.5 Hz, 3H), 1.08 (s, 3H), 1.2—2.3 (m, 6H), 2.15 (s, 3H), 2.52 (m, 2H), 3.22 (s, 1H), 4.50 (m, 2H), and 4.90 (m, 1H). Found: C, 74.86, H, 10.70%. Calcd for $C_{14}H_{24}O_2$: C, 74.95, H, 10.78%; **8b** (52 mg, 24%): IR (neat) 3500, 3070, 1705, 1635, and 885 cm^{-1}; NMR (CCl_4) δ=0.75 (s, 3H), 0.85 (d, J=6.5 Hz, 3H), 1.10 (s, 3H), 1.2—2.3 (m, 6H), 2.10 (s, 3H), 2.42 (d, J=6.0 Hz, 2H), 3.05 (s, 1H), 4.25 (m, 1H), 4.62 (m, 1H), and 4.75 (m, 1H). Found: C, 74.81, H, 10.84%. Calcd for $C_{14}H_{24}O_2$: C, 74.95, H, 10.78%.

trans-*γ-Irone (1).* To a solution of **8a** (55 mg, 0.25 mmol) in ether (5 ml) was added active alumina (0.5 g) and the mixture was stirred overnight at room temperature. Then the mixture was filtered and concentrated. The residue was subjected to silica-gel column chromatography to afford **1** (29 mg, 57%). IR (neat) 1675, 1620, and 890 cm^{-1}; NMR (CCl_4) δ=0.80 (s, 3H), 0.85 (d, J=6.0 Hz, 3H), 0.90 (s, 3H), 1.1—2.4 (m, 5H), 2.15 (s, 3H), 2.60 (d, J=9.0 Hz, 1H), 4.67 (s, 1H), 4.72 (s, 1H), 6.00 (d, J=16.0z4Hz, 1H), and 6.98 (dd, J=16.0 and 9.0 Hz, 1H). Spectral data of **1** were consistent with those of the authentic sample prepared by the method of Yoshikoshi *et al.*[3b]

In the same manner, **8b** was treated with active alumina to give **1** (36%).

The authors wish to express their thanks to Professor Teruaki Mukaiyama and Associate Professor Kazuhiko Saigo, the University of Tokyo for their helpful discussions.

The Preparation of a Highly Active Raney Nickel Catalyst with Formation of a Recoverable Bayerite

Shigeo NISHIMURA,* Satoshi IKEDA, Makoto KINOSHITA, and Masaaki KAWASHIMA
Department of Applied Chemistry for Resources, Tokyo University of Agriculture and Technology, Koganei, Tokyo 184

(Received June 23, 1984)

Synopsis. In the presence of a properly prepared bayerite and a small amount of sodium hydroxide, Raney nickel–aluminium alloy is developed with water to give a highly active catalyst with formation of a recoverable bayerite. In hydrogenation of typical organic compounds the catalyst is even more active than the T-4 Raney nickel.

In 1959 one of the authors (S. N.) described a method for the preparation of a highly active Raney nickel catalyst in which the reaction of Raney alloy with water was initiated by partly leaching the alloy with a small amount of sodium hydroxide at 50 °C.[1] After an induction period of about 1 h, the alloy began to react with water violently and was developed extensively to give a product which had been covered with a large quantity of bayerite, a modification of crystalline aluminium trihydroxides. To obtain a highly active catalyst a concentrated sodium hydroxide solution was then added to remove the bayerite from the catalyst and complete the development. The Raney nickel thus prepared (denoted as T-4 when prepared from 40% nickel alloy) was more active than those prepared by usual procedures.[1] It seems that the extensive reaction of Raney alloy with water is promoted by the sodium hydroxide which has been regenerated by the hydrolysis of initially formed sodium aluminate, as suggested by Dirksen and Linden.[2] The violent reaction of Raney alloy with water that occurs after the induction period is probably caused by the transformation of the sodium aluminate into crystalline bayerite which in turn promotes the subsequent crystallization of amorphous aluminium hydroxide† and hence the hydrolysis of sodium aluminate, producing continuously sodium hydroxide for further development of the alloy (see Eq. 1). In fact, Taira and Kuroda

$$\mathrm{NaAlO_2} + 2\mathrm{H_2O} \rightleftharpoons \text{amorphous } \mathrm{Al(OH)_3} + \mathrm{NaOH} \xrightarrow{\text{bayerite}} \text{crystalline } \mathrm{Al(OH)_3} \text{ (bayerite)} \quad (1)$$

have shown that the addition of bayerite promotes the reaction of Raney alloy with water and prepared an active catalyst which was supported on bayerite and claimed to be resistant to deactivation, by developing the alloy with addition of bayerite.[3,4]

We have intended to improve the T-4 procedure with use of bayerite by which it may be possible to reduce the amount of sodium hydroxide required. In the course of this study it has been recognized that the action of bayerite to promote the reaction in Eq. 1 greatly depends on its preparation as well as reaction conditions, and, by using a properly prepared bayerite and suitable reaction conditions, the catalyst that is not combined with the bayerite formed can be prepared. Under these conditions the alloy can be developed extensively at a low temperature with use of only a small amount of sodium hydroxide to give a highly active catalyst, and at the same time the bayerite initially added as well as newly formed can easily be separated from the resulting catalyst merely by decantations. The bayerite thus recovered has been found to become reusable after treatment with a dilute hydrochloric acid. Whether the bayerite formed is deposited on the catalyst or not appears to depend on the nature of bayerite initially added as well as on the mode of the addition of sodium hydroxide. As described in the experimental part, the bayerite that promotes efficiently the reaction in Eq. 1 and gives the catalyst not combined with bayerite is prepared by the reaction of CO_2 gas with a rather concentrated solution of sodium aluminate at 40 °C. Such conditions suggest that the contamination of amorphous aluminium hydroxide or gelatinous boehmite should be avoided.[5] Further, to prepare a catalyst free from bayerite it is advisable to add the bayerite prior to the addition of sodium hydroxide. If we add the bayerite to the alloy after partly leached with sodium hydroxide, a catalyst which is firmly combined with bayerite tends to result, just as in the T-4 preparation where it is necessary to use a concentrated sodium hydroxide solution to remove the bayerite from the catalyst.[1]

As an example of the preparation, 0.5 g of Raney alloy powder (40% Ni) and 1 g of the bayerite prepared by the procedure given in Experimental are stirred in 10 ml of water at 40 °C. To this 0.03 ml of 20% sodium hydroxide is added and the mixture stirred for 30 min in which a violent reaction of the alloy with water almost subsides. At this stage the alloy is already developed to the extent of *ca.* 70% and the catalyst is sufficiently active for most hydrogenations (see the example in Table 1). To obtain the catalyst of the highest activity 0.3 ml of 20% sodium hydroxide is then added and the mixture stirred for 1 h at 40 °C. With one preparation the degree of oxidation of the aluminium in the alloy was estimated to be 81% at the final stage.[6] The catalyst thus prepared (denoted as N-4) has been more active than the T-4 catalyst in typical hydrogenations (Table 1). With benzonitrile, however, treatment with a larger amount of sodium hydroxide was

† The transformation of sodium aluminate to bayerite has been shown to occur according to the following scheme: sodium aluminate solution →amorphous hydroxide→gelatinous boehmite→bayerite [B. C. Lippens, "Structure and Texture of Aluminas," Uitgeverij Waltman, Delft (1961), p. 15].

Table 1. Hydrogenation of typical organic compounds with N-4 and T-4 Raney nickel catalysts[a]

Compound	Amount / mmol	Catalyst	Rate of H_2 uptake[b] / ml at STP min^{-1}	Time for hydrogenation / min
Cyclohexene	15	N-4	20.0	20
		T-4	18.0	26
Cyclohexanone	15	N-4	12.4	36
		N-4[c]	11.1	41
		N-4[d]	12.1	38
		T-4	9.4	45
Nitrobenzene	10	N-4	14.1	62
		T-4	11.1	90
Benzonitrile	5	N-4[e]	4.4	130
		T-4	4.4	130

a) The catalyst was prepared from 0.5 g of Raney alloy (40% Ni) each time before use. The compound was hydrogenated in 10 ml of methanol at 25 °C and atmospheric pressure. b) Average rate from 0 to 50% hydrogenation. c) The catalyst was prepared with use of 0.03 ml of 20% sodium hydroxide. d) The catalyst was prepared with the bayerite recovered two times. e) The catalyst was prepared with use of 0.5 ml of 20% sodium hydroxide.

favorable for the activity and both N-4 and T-4 catalysts showed the same activity.

The bayerite becomes grey in its color during the preparation. By treatment of the bayerite with a dilute hydrochloric acid, the bayerite turns almost white and becomes reusable for the N-4 preparation to give the catalyst of the same activity (see Table 1). Since the hydrochloric acid after the treatment was found to contain only a trace amount of nickel, the grey color of the bayerite after the preparation is presumed mostly due to the presence of fine particles of aluminium.

The procedure for the preparation of Raney nickel catalyst described here is advantageous not only for the use of only a small amount of sodium hydroxide but also for the easiness in controlling the highly exothermic reaction of aluminium oxidation which is often too violent to control in the reaction with a concentrated sodium hydroxide solution or in a sudden reaction with water after an induction period in the T-4 procedure. Further, it is also advantageous in that the degree of the development of the alloy can readily be controlled to a desired extent by the amount of sodium hydroxide employed and/or the reaction time. The present method is also recommended for obtaining a catalyst of reproducible activity.

Experimental

Preparation of the Bayerite Suitable to the Development of Raney Alloy. Twenty grams of aluminium grains are dissolved into a sodium hydroxide solution prepared from 44 g of sodium hydroxide and 100 ml of water. The solution is diluted to 200 ml and CO_2 gas is bubbled into the solution at 40 °C until small amounts of white precipitates are formed. The precipitates are filtered off and more CO_2 gas is bubbled into the filtrate. Then the solution is gradually cooled to room temperature under good stirring and left overnight with continued stirring. The precipitates thus formed (20—24 g) are collected, washed with warm water, and dried *in vacuo* over silica gel.[7]

Preparation of N-4 Raney Nickel and Recovery of Bayerite. In a 10 ml conical flask are placed 0.5 g of Raney alloy powder (40% Ni) and 1 g of the bayerite prepared by the procedure described above. To this 10 ml of distilled water is added and stirred well at 40 °C. Then 0.03 ml of 20% sodium hydroxide solution is added and the mixture stirred for 30 min at 40 °C in which a violent reaction almost subsides. Further 0.3 ml of 20% sodium hydroxide is added and the mixture stirred for 1 h at 40 °C. The upper layer is decanted with care not to let the catalyst flow away. The catalyst is washed three times with each 10 ml of distilled water and then three times with the same volume of methanol. The bayerite suspensions are combined and acidified with a dilute hydrochloric acid, and then warmed to 50—60 °C, when the grey color of the bayerite turns almost white. The bayerite is collected, washed well which water, and then dried *in vacuo* over silica gel. The bayerite thus recovered amounts to 1.4—1.6 g and can be reused repeatedly for the catalyst preparation. A specimen of the catalyst contained 0.192 g of nickel, 0.050 g of aluminium, and 0.036 g of acid insoluble materials.

Hydrogenation. All hydrogenations were performed in a small glass apparatus driven vibrationally at 25 °C and atmospheric pressure. After the catalyst had been shaken with hydrogen in methanol for 5 min, the compound to be hydrogenated was added with a syringe through a silicone rubber septum.

6) The degree of aluminium oxidation was determined from the amounts of evolved hydrogen (293 ml at STP) and adsorbed hydrogen (13.4 ml at STP, estimated from the hydrogenation of cyclohexanone in *t*-BuOH under an atmosphere of argon), on the basis that the alloy contained 39% of nickel.
7) The bayerite thus prepared usually contains a small amount of gibbsite as observed by an X-ray diffraction analysis. The bayerite recovered from the catalyst preparation has been found less contaminated with gibbsite.

Ring Transformation of 1,4 (or 1,6)-Disubstituted 3,5-Dinitro-2-pyridones with Sodio β-Keto Esters[1)]

Masahiro ARIGA,* Yasuo TOHDA, and Eizo MATSUMURA

Department of Chemistry, Osaka Kyoiku University, Minamikawahori-cho, Tennoji-ku, Osaka 543

(Received July 2, 1984)

Synopsis. The ring transformation of 1,6-dimethyl-, 1,4-dimethyl- and 4-methoxy-1-methyl-3,5-dinitro-2-pyridones with sodio β-keto esters to nitrosalicylic esters was investigated concerning the electronic effects of 4 and 6-substituents. The results were explained by the HSAB principle.

In the previous paper of this series,[2)] we reported the nucleophilic ring transformation of 1-substituted 3,5-dinitro-2-pyridones with some sodio β-keto esters to give nitrophenol derivatives together with *N*-substituted 2-nitroacetamides, and proposed a plausible reaction course including the stepwise formation of a bicyclic intermediate. Our interests have been directed to the investigation of the scope and limitation of these reactions. In this paper we describe the effects of the electron-donating substituents at the 4 or 6-position of 3,5-dinitro-2-pyridone on the nucleophilic attack of enolate ions of the β-keto esters.

Results and Discussion

As substrates 1,6-dimethyl- (**1a**), 1,4-dimethyl- (**1b**) and 4-methoxy-1-methyl- (**1c**) 3,5-dinitro-2-pyridones were employed, and diethyl sodio-3-oxopentanedioate (Na.DOPD) and ethyl sodioacetoacetate (Na. EAA) were used as the uncleophiles.

Treatment of **1a** with Na.DOPD at 50 °C in pyridine gave diethyl 2-hydroxy-4-methyl-5-nitro-1,3-benzenedicarboxylate (**2a**)[3)] and *N*-methyl-2-nitroacetamide (**3**) in 94.3 and 25.9%, respectively. Under somewhat milder conditions (25 °C) a colorless crystalline product (**4a**) was obtained in addition to **2a** and **3**. The product **4a** was easily converted to **2a** and **3** by the treatment with bases at 70 °C, and the ^{1}H-NMR spectrum of **4a** (see Experimental) behaved analogously to the bicyclic compounds reported in the previous paper.[2)] On the bases of these data **4a** was assigned to be diethyl 7-hydroxy-1,2-dimethyl-4,9-dinitro-3-oxo-2-azabicyclo[3.3.1]non-6-ene-6,8-dicarboxylate, an adduct of **1a** and DOPD.

From the reaction of **1b** with Na.DOPD, **2a**, **3**, and bicyclic compound, **4b**, were obtained. The similar reaction of **1c** with Na.DOPD gave diethyl 2-hydroxy-4-methoxy-5-nitro-1,3-benzenedicarboxylate (**2c**) together with **3** and bicyclic compound, **4c**.

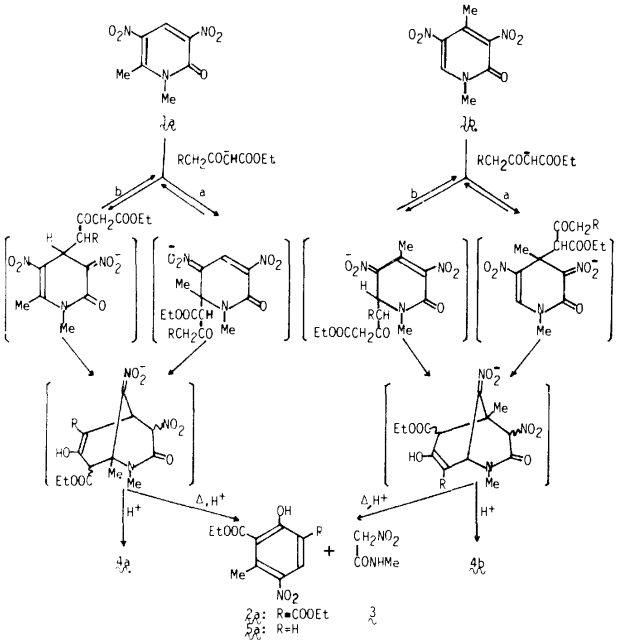
From both the reactions of **1a** and **1b** with Na.EAA, ethyl 6-hydroxy-2-methyl-3-nitrobenzoate (**5a**)[4)] was solely yielded in addition to **3**; ethyl 2-hydroxy-4-methyl-5-nitrobenzoate which was anticipated as the alternative product was not obtained.

These facts suggest a probable course involving a preferential attack of the somewhat softer C-2 anion of EAA at the softer methyl-substituted 6 and 4-position of **1a** and **1b**, respectively. The subsequent intramolecular nucleophilic attack of the C-4 anion of EAA at the harder methyl-unsubstituted 4 or 6-position of the parent pyridone may lead to the same products, **4a** and **3** *via* the bicyclic intermediates.[5)] (Scheme 1, course a) The alternative course (b), however, is not to be discounted. Thus, the attack of the harder nucleophilic center of EAA, C-4 anion, at the harder methyl-unsubstituted position was followed by attack of the softer C-2 anion of EAA at the other position.[6)]

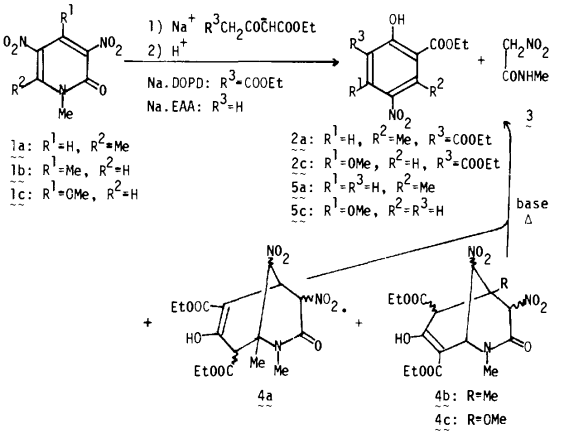
From the above results, it is difficult to decide which of the courses is more plausible.

On the other hand, from the reaction of **1c** with Na.EAA ethyl 2-hydroxy-4-methoxy-5-nitrobenzoate (**5c**) and **3** were obtained. The structure of **5c** was supported by the ^{1}H-NMR data and by the hydrolysis to 2-hydroxy-4-methoxy-5-nitrobenzoic acid.[7)]

This fact is interpreted as follows: The resonance effects of the nitro groups are decreased by the steric



Scheme 1.



hydrance of the 4-methoxyl group, and the inductive effect of the 4-methoxyl group makes the C-4 position of the pyridone harder than the C-6 position, so the C-2 anion of Na.EAA attacks at the C-6 of the pyridone and C-2 of EAA at the C-4 of the pyridone.

Consequently, the sequence of the reaction steps could not be decided, neverthless the regiochemistry of the reaction could be explained by the HSAB principle, considering the electronic effects of the substituents.

Experimental

*Substrates, **1a**, **1b**, and **1c**.* These compounds were obtained from corresponding *N*-methyl-2-pyridones by the nitration with fuming nitric acid in acetic anhydride at room temperature.

*1,6-Dimethyl-3,5-dinitro-2-pyridone (**1a**).* Mp 135.5—136.0 °C. IR: 1695 cm^{-1} (C=O), 1570, 1340 (NO_2). NMR (acetone-d_6): δ=2.94 (3H, s), 3.78 (3H, s), 8.87 (1H, s).

*1,4-Dimethyl-3,5-dinitro-2-pyridone (**1b**).* Mp 155.0—156.0 °C. IR: 1695 cm^{-1} (C=O), 1570, 1340 (NO_2). NMR (acetone-d_6): δ=2.47 (3H, s), 3.74 (3H, s), 9.12 (1H, s).

*4-Methoxy-1-methyl-3,5-dinitro-2-pyridone (**1c**).* Mp 114.5—115.5 °C. IR: 1690 cm^{-1} (C=O), 1570, 1340 (NO_2). NMR (acetone-d_6): δ=3.72 (3H, s), 4.02 (3H, s), 9.12 (1H, s).

*The Reaction of **1** with Sodium Salts.* The method used here was the same as that described ealier.[2] Poor yield of **3** in all cases would be caused by acidity and lability of **3** to decompose under the reaction conditions.

*Diethyl 2-Hydroxy-4-methyl-5-nitro-1,3-benzenedicarboxylate (**2a**).* Colorless prisms (petroleum benzine), mp 69.0—70.0 °C. IR: 3100 cm^{-1} (O-H), 1745 (C=O), 1530, 1340 (NO_2). NMR ($CDCl_3$): δ=1.30 (3H, t, J=7 Hz), 1.44 (3H, t, J=7 Hz), 2.54 (3H, s), 4.44 (2H, q, J=7 Hz), 4.55 (2H, q, J=7 Hz), 8.49 (1H, s), 11.55 (1H, s).

*Diethyl 2-Hydroxy-4-methoxy-5-nitro-1,3-benzenedicarboxylate (**2c**).* Colorless needles (petroleum benzine), mp 100.0—100.5 °C. IR: 3200 cm^{-1} (O-H), 1740 (C=O), 1540, 1340 (NO_2). NMR ($CDCl_3$): δ=1.36 (3H, t, J=7 Hz), 1.39 (3H, t, J=7 Hz), 3.95 (3H, s), 4.39 (2H, q, J=7 Hz), 4.40 (2H, q, J=7 Hz), 8.57 (1H, s), 11.74 (1H, s).

*Diethyl 7-Hydroxy-1,2-dimethyl-4,9-dinitro-3-oxo-2-azabicyclo[3.3.1]non-6-ene-6,8-dicarboxylate (**4a**).* Colorless prisms (ethanol), mp 170.0—171.0 °C. IR: 1735 cm^{-1} (C=O), 1690 (C=O), 1550, 1320 (NO_2). NMR ($CDCl_3$): δ=1.28 (3H, t, J=7 Hz), 1.35 (3H, t, J=7 Hz), 1.53 (3H, s), 3.05 (3H, s), 3.72 (1H, s, H-8), 4.27 (4H, q, J=7 Hz), 4.37 (1H, dd, J=4 and 6 Hz, H-5), 5.59 (1H, *d*, J=6 Hz, H-9), 5.77 (1H, d, J=4 Hz, H-4), 12.64 (1H, s, 7-OH).

*Diethyl 3,7-Dihydroxy-2,5-dimethyl-4,9-dinitro-2-azabicyclo[3.3.1]nona-3,7-diene-6,8-dicarboxylate (**4b**).* Colorless prisms (ethanol), mp 151.0—152.0 °C. IR: 1750 cm^{-1} (C=O), 1670 (C=O), 1570, 1360 (NO_2). NMR ($CDCl_3$): δ=1.35 (3H, t, J=7 Hz), 1.41 (3H, t, J=7 Hz), 1.65 (3H, s), 3.16 (3H, s), 4.24 (1H, s, H-6), 4.27 (2H, q, J=7 Hz), 4.38 (2H, q, J=7 Hz), 4.85 (1H, d, J=3 Hz, H-1), 5.82 (1H, d, J=3 Hz, H-9), 12.41 (1H, s, 7-OH), 19.01 (1H, s, 3-OH, enol form).

*Diethyl 7-Hydroxy-5-methoxy-2-methyl-4,9-dinitro-3-oxo-2-azabicyclo[3.3.1]non-7-ene-6,8-dicarboxylate (**4c**).* Colorless prisms (ethanol), mp 198.0—199.0 °C. IR: 1750 cm^{-1} (C=O), 1690 (C=O), 1560, 1330 (NO_2). NMR ($CDCl_3$): δ=1.32 (3H, t, J=7 Hz), 1.45 (3H, t, J=7 Hz), 3.16 (3H, s), 3.60 (3H, s), 3.90 (1H, s, H-6), 4.30 (2H, q, J=7 Hz), 4.39 (2H, q, J=7 Hz), 4.93 (1H, d, J=4 Hz, H-1), 6.09 (1H, d, J=4H, H-9), 6.17 (1H, s, H-4), 12.38 (1H, s, 7-OH).

*Treatment of **4** with Sodium Ethoxide.* The raction was carried out according to the procedure described in Lit 2. From 208 mg of **5a** were obtained 112 mg (76.2%) of **2a** and 21 mg (41.3%) of **3**. Similarly, **2a** and **3** were yielded from **4b** in 58.7% and 28.8% yield, respectively, and **2c** in 27.9% and trace of **3**.

*Ethyl 6-Hydroxy-2-methyl-3-nitrobenzoate (**5a**).* Colorless needles (petroleum benzine), mp 58.0—58.5 °C. IR: 3200 cm^{-1} (O-H), 1670 (C=O), 1530, 1340 (NO_2). NMR ($CDCl_3$): δ=1.43 (3H, t, J=7 Hz), 2.60 (3H, s), 4.47 (2H, q, J=7 Hz), 6.85 (1H, d, J=9.5 Hz, H-5), 7.76 (1H, d. J=9.5 Hz, H-4), 11.33 (1H, s, 6-OH).

*Ethyl 2-Hydroxy-4-methoxy-5-nitrobenzoate (**5c**).* Colorless needles (petroleum benzine), mp 137.5—138.5 °C. IR: 3200 cm^{-1} (O-H), 1670 (C=O), 1540, 1340 (NO_2). NMR ($CDCl_3$): δ=1.41 (3H, t, J=7 Hz), 3.95 (3H, s), 4.31 (2H, q, J=7 Hz), 6.51 (1H, s, H-3), 8.48 (1H, s, H-6), 11.49 (1H, s, 2-OH).

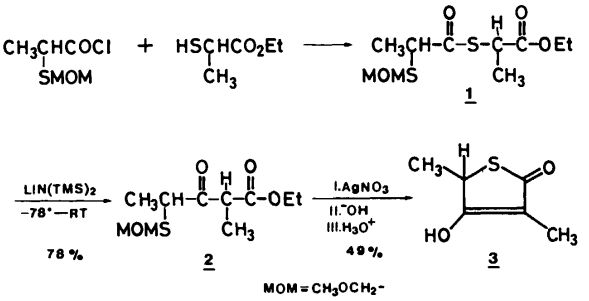
Sulfur-Extrusive Rearrangement of α-Acylthio Ester by Lithium Amide

Kazuo Tsuzuki, Masaharu Akeyoshi, and Satoshi Ōmura*
School of Pharmaceutical Sciences, Kitasato University and The Kitasato Institute, Shirokane, Minato-ku, Tokyo 108
(Received August 11, 1984)

Synopsis. α-Acylthio esters readily undergo facile rearrangement to give β-keto esters on treatment with lithium amide at −78 °C. Thiolactone **3**, a key intermediate for thiolactonic antibiotics, was synthesized by utilizing the rearrangement.

In the course of synthetic studies[1] on the thiolactonic antibiotics, thiotetromycin[2] and thiolactomycin,[3] we treated ethyl 2-(benzoylthio)propanoate in dry tetrahydrofuran with 1.1 equiv lithium diisopropylamide at −78 °C (20 min) to obtain the corresponding β-keto ester [*m/z* 206(M^+), ν (neat) 1740 and 1690 cm^{-1}, δ ($CDCl_3$) 1.50 (3H, d, *J*=7 Hz) and 4.39 (1H, q, *J*=7 Hz)] in 93% yield. These spectral data suggest that it is ethyl 2-benzoylpropanoate. A similar reaction, using potassium *tert*-amylate and triphenylphosphine as a desulfurating agent which removes sulfur atom of the thiirane intermediate, was reported by Eschenmoser *et al.*[4] However, in our case the additive effect of desulfurating agent was not detected completely. In order to prove the generality and limitation of this rearrangement, several *S*-acyl derivatives obtained by *S*-acylation of 2-mercaptopropanoate and mercaptoacetate were treated with lithium amide and the results are summarized in Table 1. α-Acylthio esters except the *S*-acetyl (R^1=CH_3) derivative undergo facile rearrangement to yield the corresponding β-keto esters without a desulfurating agent in synthetically acceptable yield.

Attention was then turned to the application of this reaction to the synthesis of a key intermediate **3** containing the latent C-2 symmetry for thiolactonic antibiotics. Compound **1**[5] obtained by acylation of 2-mercaptopropanoate, on exposure at −78 °C with 1.1 equiv of lithium hexamethyldisilazanide for 20 min and then warming to room temperature in 1.5 h, provided β-keto ester **2**[5] as a mixture of diastereoisomers in 78% yield. Conversion of **2** to thiolactone **3**[5] was successfuly achieved in 49% yield by the following sequence: (1) deprotection of methoxymethyl group with $AgNO_3$; (2) hydrolysis of ester group; (3) thiolactonization by acidic work-up.



The ease of obtaining α-acylthio esters and the relatively mild conditions required for the rearrangement reaction might provide a useful tool for the construction of natural products.

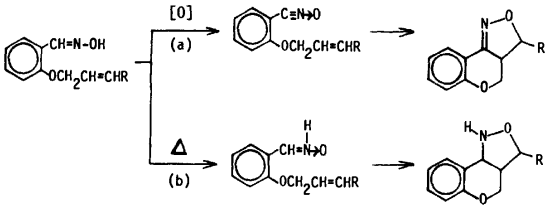
Intramolecular [3+2] Cycloaddition of 2-Alkenyloxy-1-naphthaldehyde Oximes

Tomio SHIMIZU,* Yoshiyuki HAYASHI, and Kazuhiro TERAMURA
Department of Color Chemistry and Technology, Faculty of Industrial Arts, Kyoto Institute of Technology, Matsugasaki, Sakyo-ku, Kyoto 606
(Received August 11, 1984)

Synopsis. The thermal treatment of the mixture of 2-alkenyloxy-1-naphthaldehydes and hydroxylamine hydrochloride in ethanol gave intramolecular [3+2] cycloadducts, 1,3a,4,11c-tetrahydro-3*H*-naphtho[1′,2′:5,6]pyrano-[4,3-*c*]isoxazole hydrochlorides.

We have reported several intramolecular 1,3-dipolar cycloadditions of 2-(alkenyloxy)benzaldehyde (or 1-naphthaldehyde) arylhydrazones.[1] From the studies, it was found that the acid-catalyzed [3+2] cycloaddition was the most effective method for the preparation of cycloadducts.[1d] Several cycloadditions of analogous oximes have been reported; routes (a)[2] and (b)[3], respectively, consist of the intramolecular 1,3-dipolar cycloaddition of nitrile oxide or nitrone intermediates which were prepared from the oxidation or the thermal isomerization of aldehyde oximes. We report here the intramolecular [3+2] cycloaddition of 2-(alkenyloxy)-1-naphthaldehyde oximes.



Results and Discussion

After the treatment of 2-(alkenyloxy)-1-naphthaldehyde (**1a—e**) with an excess amount of hydroxyamine hydrochloride in refluxing ethanol for 20 h, the intramolecular [3+2] cycloadducts, 1,3a,4,11c-tetrahydro-3*H*-naphtho[1′,2′:5,6]pyrano[4,3-*c*]isoxazole hydrochlorides (**2**), were obtained in the yields shown in Table 1. The treatment of **2** with triethylamine gave the free bases (**3**). The structures of **2** and **3** were established on the basis of elemental analyses and spectral data. The methine proton at 4-position of the isoxazolidine ring of **2** and **3** was observed as a multiplet at about δ 3 in ^{1}H NMR. An ambigous doublet at about δ 4.5 in the NMR spectra of **3** was assigned to be a proton at 3-position and it was converted into a simple doublet after adding D_2O. On the other hand, the proton of compounds **2** was observed as a doublet at about δ 5.6 because of the presence of the neighboring quaternary ammonium group. The observed coupling constants (6—7.5 Hz) of the bridgehead proton at 3-position suggest *cis* relationship with the bridgehead proton at 4-position and coupling constants (6—8 Hz) observed for the proton at 5-position suggest *trans* relationship with the proton at 4-position.[4]

Compounds **2** were also obtained after refluxing an ethanol solution containing 8% hydrogen chloride

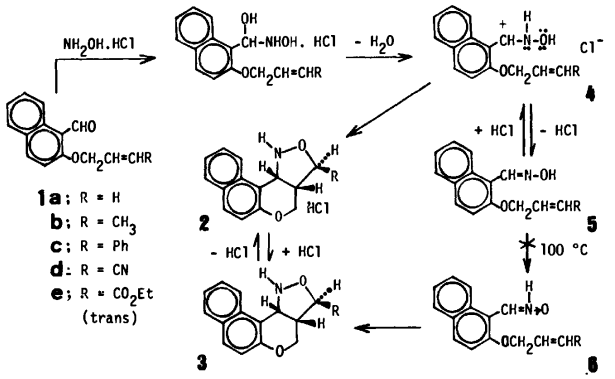
a) **2** were dissolved in DMSO-d_6 and **3** in $CDCl_3$. Coupling constants (J) are shown in hertz (Hz). b) This peak was disappeared by adding D_2O.

of 2-alkenyloxy-1-naphthaldehyde oximes (**5**). From the fact that **5** was stable for the thermal treatment in ethanol and recovered quantitatively, the formation of **2** can not be explained by the reaction *via* a nitrone intermediate (**6**), but a cationic intermediate (**4**).



No cycloadducts could be obtained from the reaction mixture of 2-(alkenyloxy)benzaldehydes (**7a—7e**) and hydroxylamine hydrochloride, and only isolable compounds were salicylaldehyde oxime hydrochloride (**8**) (in 40—60% yields from **7a—c**) and 2-(alkenyloxy)benzaldehyde oximes (**9**) (in 90 and 10% yields from **7d** and **7e**, respectively). Phenol could not be detected after refluxing allyl phenyl ether in ethanol containing 8% HCl for 24 h, thus, the formation of **8** may be interpreted in terms of an acid-catalyzed intramolecular hydrolysis of **9**.

The results that **7** gave no cycloadduct (**10**) in the reaction may be explained by the comparison of the frontier molecular orbitals of the cationic intermediates (**4** and **11**). It is well-known[5] that the introduction of conjugated substituents (phenyl or naphthyl group) at the dipole increase in the HOMO energy and decrease in the LUMO energy and these effects of naphthyl group may be larger than those of phenyl group. While the intramolecular cycloaddition of **4** is only slightly more favorable than the other competitive reactions, the similar cycloaddition of **11** would be more unfavorable than the other competitive reactions, thus, **8** and **9** were formed.

Experimental

Measurements. All melting points are uncorrected. Satisfactory analytical data were obtained for the cycloadducts (**2a—c**, **3a**, **3b**, and **3d**)(±0.3% for C, H, and N).

Materials. The 2-(alkenyloxy)benzaldehydes (or -1-naphthaldehydes)(**7** or **1**)[1b] and those oximes (**9** and **5**)[2a] were prepared according to the method in the literature.

Reaction of 2-(Alkenyloxy)-1-naphthaldehydes (I) with Hydroxylamine Hydrochloride. A mixture of **1** (5 mmol) and hydroxylamine hydrochloride (1.0 g, 14 mmol) was refluxed in ethanol (50 ml) for 20 h with stirring. Evaporation of the solvent from the reaction mixture gave crystals, which were mixed well with benzene (30 ml) and filtered off, and the residue was washed with water and then dried *in vacuo* to give **2** in the yields shown in Table 1. The NMR spectra of **2** were shown in Table 2. The compounds **2** obtained above generally showed the broad melting points ranges (*ca.* 140—180 °C). In the case of **1a**, 2-allyloxy-1-naphthonitrile was also obtained in 80% yield from the filtrate by evaporation of the solvent (benzene); mp 64—65 °C (from ethanol), IR (Nujol): 2220 cm^{-1}, NMR ($CDCl_3$) δ: 4.73 (d, 2H, J=4 Hz), 5.1—5.6 (m, 2H), 5.7—6.4 (m, 1H), and 7.0—8.1 (m, 6H), Calcd for $C_{14}H_{11}NO$: C, 80.36; H, 5.30; N, 6.69%. Found: C, 80.25; H, 5.29; N, 6.71%. In the other cases, we could not isolate any by-products.

The Treatment of 2 with Triethylamine. Into a suspension of **2** in chloroform was added an excess mol of triethylamine, after which the mixture was stirred for 30 min at room temperature. The reaction mixture was then washed with water several times, and the organic layer was dried over anhydrous sodium sulfate. Evaporation of the solvent yielded crude naphthopyranoisoxazoles (**3**), which were recrystallized from ethanol to give pure materials in the yields shown in Table 1.

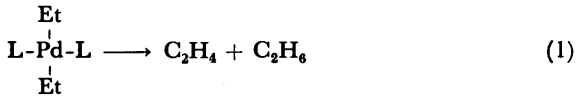
Alteration of Reaction Course in Thermolysis of *cis*-Diethylbis(tertiary phosphine)palladium(II) from Reductive Elimination to β-Elimination Process Induced by Addition of Tertiary Phosphine Ligand

Fumiyuki OZAWA, Kunihiko KURIHARA, Takakazu YAMAMOTO, and Akio YAMAMOTO*
Research Laboratory of Resources Utilization, Tokyo Institute of Technology, 4259 Nagatsuta, Midori-ku, Yokohama 227
(Received August 20, 1984)

Synopsis. Addition of tertiary phosphine to a solution containing *cis*-diethylbis(tertiary phosphine)palladium(II) alters thermolysis course of the complex from reductive elimination process liberating butane to β-hydrogen elimination process in which ethane and ethylene are released. Study with a deuterium-labeled ethyl complex indicates involvement of an internal metalation process.

Studies on thermolysis mechanisms of isolated dialkylpalladium complexes provide essential information for understanding basic properties of organopalladium complexes. Two most important concerted thermolysis pathways of dialkylpalladium complexes relevant to organic synthesis are reductive elimination and β-elimination.[1] Thus, information concerning controlling factors of these two pathways is of crucial importance for designing selective organic reactions promoted by palladium complexes.

In the previous reports[2,3] we showed that thermolysis courses of diethylbis(tertiary phosphine)palladium(II) complexes were dictated by their configurations, cis or trans.



(L=PEt_3, PMe_2Ph, PEt_2Ph, $PMePh_2$, and $PEtPh_2$)

(L=PMe_2Ph and PEt_2Ph)

Trans isomers decompose through a clean β-elimination process to give ethylene and ethane in a 1:1 ratio, whereas cis isomers afford butane as the reductive elimination product. The β-elimination process of trans isomers is scarcely affected by addition of free tertiary phosphines to the systems and the reaction is assumed to proceed predominantly from four-coordinate species without predissociation of phosphine ligand.[3] In contrast, reductive elimination of the cis isomers is severely hindered by addition of phosphine ligands and a reaction mechanism proceeding through three-coordinate intermediates formed by partial dissociation of tertiary phosphine ligand has been proposed.[2,4] Further studies on the thermolysis reactions of *cis*-diethyl complexes revealed that addition of free phosphine ligands to the system not only retards the reductive elimination reaction but also forces to change the thermolysis course from the reductive elimination to the β-elimination process.

a) [Complex]=0.05—0.10 mol dm^{-3}. Solvent: toluene (run 1), Ph_2CH_2 (runs 2—12). Thermolysis temp (°C): r.t. (run 1), 70 (runs 2—12). b) Total amounts (mol/mol of complex)=$\{(1/2)(C_2H_4+C_2H_6)+C_4H_{10}\}$/(complex).

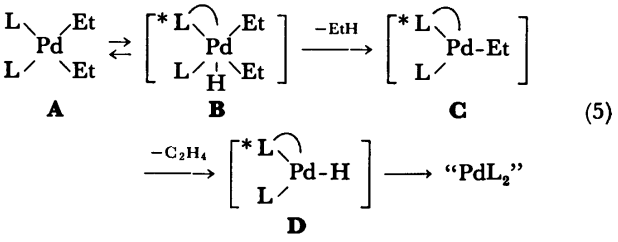
Table 1 summarizes distributions of hydrocarbons produced on thermolysis of four kinds of *cis*-diethyl complexes in solution in the presence and absence of free tertiary phosphines. Most of these reactions were carried out in the presence of dimethyl maleate (dmm). As previously mentioned,[2,3] dmm serves to trap $Pd(0)L_2$ species formed in thermolysis preventing decomposition of the $Pd(0)L_2$ species but does not affect the thermolysis of *cis*-$PdEt_2L_2$. The results in Table 1 clearly indicate that thermolysis course is effectively altered from the reductive elimination to the β-elimination pathway on addition of free phosphine ligands. Diphosphine coordinated compelexes **2—4** are more sensitive to addition of phosphines than complex **1** having monodentate ligand. Thermolysis rates in the systems with added phosphines were much slower than those without added phosphines. For example, complex **1** readily decomposes at room temperature to yield butane, while thermolysis of **1** (0.17 mol dm^{-3}) in Ph_2CH_2 containing 0.70 mol dm^{-3} of PMe_2Ph does not proceed at room temperature and takes place only at 60 °C. The reaction obeys the first order kinetics with respect to diethylpalladium concentration ($k_{obsd}=3.0\times10^{-5}\ s^{-1}$) and liberates ethylene and ethane in a 1 : 1 ratio.

Examination of the thermolysis products of *cis*-$Pd(CH_2CD_3)_2(PMe_2Ph)_2$ (**5**) provides further information on the thermolysis mechanisms of *cis*-diethyl complexes. Thermolysis of **5** in solution without added PMe_2Ph affords an almost quantitative yield of $CD_3CH_2CH_2CD_3$ as reported previously.[2] On the other hand, thermolysis of **5** in Ph_2CH_2 or C_6D_6 containing a ten fold excess amount of PMe_2Ph per palladium liberates a quantitative yield of CD_3CH_3, instead of CD_3CH_2D, together with a quantitative amount of $CD_2{=}CH_2$.

$$cis\text{-}Pd(CH_2CD_3)_2(PMe_2Ph)_2 \xrightarrow{\text{with } PMe_2Ph} CD_3CH_3 + CD_2{=}CH_2 \qquad (4)$$

Evidently no H-D scrambling in the ethyl groups is involved in these reductive elimination and β-hydrogen elimination processes. Furthermore, the ethane formation in thermolysis of the cis isomer arises by abstraction of hydrogen not from disproportionation of the two ethyl groups or from solvent but from the PMe_2Ph ligand. A similar hydrogen abstraction process from phosphine ligand has been suggested in thermolysis of *cis*-$Pt(CH_2CD_3)_2(Me_2P(CH_2)_2PMe_2)$ producing CD_3CH_3 and $CH_2{=}CD_2$.[5]

When the reductive elimination pathway is blocked in thermolysis of *cis*-$PdEt_2L_2$ by addition of tertiary phosphine ligand, the complex is forced to take another course. The most probable process suggested by the present study is internal ortho metalation of the starting *cis*-diethyl complex (**A**) involving C–H bond cleavage at the phenyl group in PMe_2Ph[6] to give **B**. The internally metalated diethyl(hydrido)palladium-(IV) species **B** then reductively eliminates ethane to give a monoethyl complex (**C**). Species **C** then undergoes β-elimination process liberating ethylene and forming a hydridopalladium complex (**D**), which is



(5)

spontaneously converted into Pd(0) complex.

Experimental

All manipulations were carried out as reported previously.[2,3] Analysis of the gases evolved by thermolysis of *cis*-$Pd(CH_2CD_3)_2(PMe_2Ph)_2$ (**5**)[2] was carried out by GC-mass spectrometry (Hitachi M-80 spectrometer; column, Porapak Q; FD mass method). Structure of deuterated ethylene was confirmed by IR spectroscopy.[8] The rate constant for thermolysis of *cis*-$PdEt_2(PMe_2Ph)_2$ (0.17 mol dm^{-3}) in Ph_2CH_2 containing PMe_2Ph (0.70 mol dm^{-3}) at 60 °C was obtained by measuring the amounts of ethylene and ethane evolved with time using a Toepler pump.

Preparation of cis-*PdEt*$_2$*(dppp) (3) and* cis-*PdEt*$_2$*(dppb) (4).* *Cis*-diethyl complexes **3** and **4** were prepared by the reactions of $Pd(acac)_2$, $Al_2Et_3(OEt)_3$, and corresponding phosphine ligands in a manner similar to the preparation of *cis*-$PdEt_2$(dppe) (**2**)[9] and were identified by means of elemental analysis and IR and ^1H and $^{13}C\{^1H\}$ NMR spectroscopy.

Characterization of Catalyst for Coal Liquefaction. Exchange of Hydrogen Attached to Condensed Aromatics with Deuterium in Heavy Water over Catalyst

Tetsuro YOKONO,* Taro KOHNO, and Yuzo SANADA
Faculty of Engineering, Hokkaido University, North 13, West 8, Sapporo 060
(Received June 23, 1984)

Synopsis. The H-D exchange reaction of hydrogen atoms attached to condensed aromatics with deuterium atoms in D_2O over catalyst for coal liquefaction was studied by means of D-NMR. MoO_3/ZrO_2, MoO_3/SiO_2, Fe_2O_3-SO_4^{2-}, $SbCl_3$ and $ZnCl_2$ showed a significant catalytic activity for the exchange reaction. The H-D exchange ability was discussed in terms of the acidic properties and concentration of Mo^{5+} over supports for coal liquefaction catalysts.

There is a continuing interest in the surface properties of catalyst, particularly in their acid strength, the number and nature of the active sites, and the question of how the activity at these sites can be controled by chemical or physical treatment.

Little detailed information is available about catalytic activity of catalysts at high temperatures. The effect of the surface properties of catalysts on their role in coal liquefaction remains unclear. Our previous ESR study in the anthracene/$ZnCl_2$/H_2O system[1,2] suggested that an exchange reaction takes place between the hydrogen atoms in H_2O which is adsorbed on $ZnCl_2$ and the hydrogen atoms in anthracene (which is a model compound of coal). Furthermore, the hydrogen transfer reaction is known to play an important role in coal liquefaction and hydrogen exchange is one of these hydrogen transfer reactions. Thus the object of this study, as a model reaction for coal liquefaction, is to examine the H-D exchange reaction between the hydrogen atoms attached to condensed aromatics and the deuterium atoms in D_2O over metal oxide and metal chloride catalysts at high temperature by means of D-NMR.

Experimental

The metal oxide catalysts selected were as follows: MoO_3-SiO_2, MoO_3-ZrO_2, MoO_3-MgO, Fe_2O_3 and Fe_2O_3-SO_4^{2-}. These catalysts were prepared and supplied by Drs. K. Tanabe and H. Hattori, the Faculty of Science, Hokkaido University.[3] $ZnCl_2$ and $SbCl_3$ of guaranteed grade, as Lewis acid catalysts, were used for the experiments without further purification. Anthracene of G. R. grade was used as a model compound of coal.

Anthracene, catalyst and D_2O (molar ratio; 1:1:10) were mixed and sealed in a Pyrex tube reactor (10 mm diam× 500 mm) and heated in a vertical i.r. image furnace at a given temperature for a given time and then rapidly quenched. The heating rate was 10 K/min. The product was extracted with $CHCl_3$ in a ultrasonic vibrater. D-NMR spectra of the $CHCl_3$ soluble materials were obtained at room temperature using a Varian XL-200 spectrometer.

The ESR spectra of Mo^{5+} ions in the Mo-containing catalysts were obtained using a Varian E109 spectrometer employing 100 kHz modulation and a nominal operating frequency of 9 GHz.

Results and Discussion

Molybdenum Containing Catalyst Systems. Several metal oxide catalysts with different acidities were tested with respect to the H-D exchange reaction. The D-NMR spectrum of the product from the anthracene/MoO_3-ZrO_2/D_2O system which was allowed to react at 573 K for 15 min is shown in Fig. 1a. It is apparent that the H-D exchange reaction takes place over an acidic catalyst, MoO_3-ZrO_2. Assignment of deuterium atoms attached to anthracene is made by comparison with the proton chemical shifts of anthracene.[4] A similar spectrum was observed when MoO_3-SiO_2 was used. On the other hand, no significant exchange reaction was observed for the basic catalyst MoO_3-MgO, as shown in Fig. 1b.

The fact that MoO_3-ZrO_2 and MoO_3-SiO_2 are more active than MoO_3-MgO for the H-D exchange reaction might be explained by a great ability of ZrO_2 and SiO_2 to reduce MoO_3 to form lower bonding stages of Mo, such active species as Mo^{5+}, Mo^{4+} and so on.[5] Since Mo^{5+} is a paramagnetic

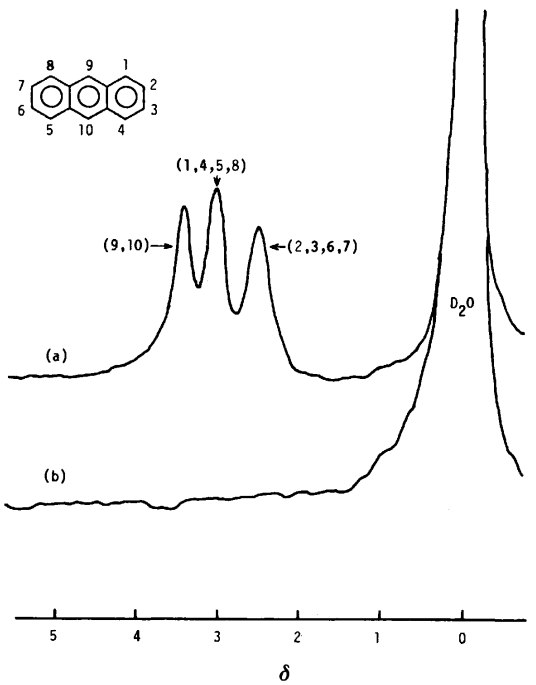

Fig. 1. D-NMR spectra of products from Anthracene/Catalyst/D_2O system.
(a): Anthracene/MoO_3-ZrO_2/D_2O 573 K, 15 min,
(b): Anthracene/MoO_3-MgO/D_2O 573 K, 15 min.

Table 1. Catalytic activity of MoO_3 over metal oxides for H-D exchange reaction on anthracene and their Mo^{5+} concentration

Catalyst	Exchanged product (%)	Mo^{5+} spin concentration (spins/g)
MoO_3/ZrO_2	8.3	2.52×10^{19}
MoO_3/SiO_2	8.2	1.42×10^{19}
MoO_3/MgO	0.0	0.77×10^{19}

species, it is detectable by ESR spectroscopy.[2] Table 1 shows the correlation between the propotion of the deuterium atoms incorporated in anthracene by the H-D exchange reaction and the Mo^{5+} spin concentrations in Mo-containing catalysts. The presence of reduced form of Mo species may be responsible for the H-D exchange reaction.

Iron Oxide Catalyst Systems. Fe_2O_3 is one of the most promising catalysts for the coal liquefaction process, because iron oxides and iron ore are disposable catalysts. One modification of Fe_2O_3 catalyst was attempted by including SO_4^{2-} ions.[3,6] The Fe_2O_3-SO_4^{2-} catalyst showed higher activity and selectivity for the liquefaction of both Akabira coal and Taiheiyo coal than those of pure Fe_2O_3 catalyst.[6]

The effect of SO_4^{2-} ion in Fe_2O_3 catalyst on coal liquefaction may be partly due to the increase in acid strength of catalyst. Therefore, it can be expected that SO_4^{2-} ion in Fe_2O_3 catalyst has an influence on the H-D exchange reaction of the anthracene/Fe_2O_3/D_2O system. In fact, evidence of such influence on the exchange reaction was obtained from the D-NMR spectrum of the product from the Fe_2O_3-SO_4^{2-}/anthracene/D_2O system which was allowed to react at 573 K for 15 min. On the other hand, any evidence of the H-D exchange reaction could not be obtained for pure Fe_2O_3 catalyst system.

Lewis Acid Catalyst Systems. Available evidence about metal chloride catalysts[7] suggests that Lewis acids first convert to Brönsted acids in the presence of water. Therefore, one can easily invoke a direct adduct of Lewis acid and anthracene as the intermediate allowing the H-D exchange. This consideration was confirmed directly by means of D-NMR for Lewis acid catalysts ($SbCl_3$, $ZnCl_2$) with anthracene.

The D-NMR spectrum of the product from the anthracene/$ZnCl_2$/D_2O system which was allowed to react at 483 K for 15 min is shown in Fig. 2a. It can be seen that the deuterium atoms are especially concentrated at the (9, 10) positions of anthracene. Fig. 2b indicates that a significant H-D exchange reaction also takes place over $SbCl_3$ catalyst, mainly at the (9, 10) and (1, 4, 5, 8) positions of the nuclei of anthracene.

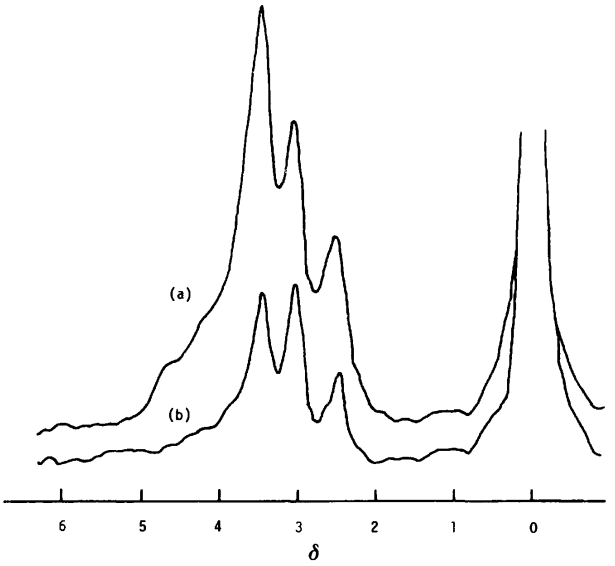

Fig. 2. D-NMR spectra of products from Anthracene/Lewis acid catalyst/D_2O system.
(a): Anthracene/$ZnCl_2$/D_2O 483 K, 15 min, (b): Anthracene/$SbCl_3$/D_2O 418 K, 15 min.

The deuterium distribution differs clearly from the case of the $ZnCl_2$ catalyst.

The D-NMR investigation of the H-D exchange reaction was extended to various polynuclear aromatics such as perylene, pyrene, phenathrene, benz[*a*]anthracene and naphthacene. Among the hydrocarbons so far tested, phenanthrene had the highest degree of H-D exchange reaction with respect to $ZnCl_2$ catalyst.

Optical and Magnetic Properties of Alkali-(18-Crown-6)-TCNQ Salts

Hideyuki NAKAYAMA and Kikujiro ISHII*
Department of Chemistry, Faculty of Science, Gakushuin University, Mejiro, Toshima-ku, Tokyo 171
(Received June 26, 1984)

Synopsis. Absorption spectra, ESR and static susceptibility were measured on TCNQ salts which incorporate Na^+- or K^+-(18-crown-6) as the cation unit. Results indicate that charge-transfer interaction between TCNQ anions is weak in the Na^+ salt, whereas it is very strong in the K^+ salt.

Physical processes in TCNQ (7,7,8,8-tetracyanoquinodimethan) salts are usually discussed laying stress only on the interaction between TCNQ molecules. We have recently shown,[1] however, that interaction of TCNQ with the cations is sometimes important in determining the electronic state in the TCNQ chain. Metal-(crown ether)-TCNQ ternary salts[2a-c] are good candidates for studying the effect of the cation-TCNQ interaction. We previously reported anomalous magnetic properties of some alkali-(crown ether)-TCNQ salts.[3] In the present note, we report an example in which a difference in the diameter of alkali cation causes a difference in the shape of the metal-(crown ether) unit, and the latter difference greatly affects the optical and magnetic properties of the TCNQ stacks. Substances studied were 1:1 TCNQ salts with N^+- or K^+-(18-crown-6) cation units, where 18-crown-6 stands for 1,4,7,10,13,16-hexaoxacyclooctadecane. The experimental procedures were almost the same as before.[3] Absorption spectra and ESR were measured on polycrystalline samples. On the K^+ salt, in addition, static magnetic susceptibility was measured. The absorption spectrum of the K^+ salt has been outlined.[2a]

Results and Discussion

Absorption Spectra. Absorption spectra of the two salts are shown in Fig. 1. In the spectrum of the Na^+ salt, the lowest energy band at 7.5×10^3 cm^{-1} is assigned to the charge-transfer(CT) excitation between TCNQ anions, since many alkali-TCNQ simple salts show CT band in this region.[4,5] Among the three small bands at 11.7, 13.0, and 15.0×10^3 cm^{-1}, the former two and the third are similar respectively to the absorptions of monomer $TCNQ^-$ and $TCNQ^-$ dimer in solution.[6] Therefore, these three bands could be explained by assuming the existence of $TCNQ^-$ monomers embedded at the impurity sites in a dimer-type crystal. However, these bands as a whole may reflect the electronic structure of the TCNQ molecules since the former two bands are too strong to be attributed to the impurity. A large peak at 27.2×10^3 cm^{-1} and a shoulder around 23×10^3 cm^{-1} are ascribed to local excitations in the TCNQ molecules. Energies of this peak and shoulder are almost the same as those respectively of other dimer and monor absorptions in solution.[6] Thus, the Na^+ salt is inferred to involve TCNQ columns with a weakly dimerized structure.

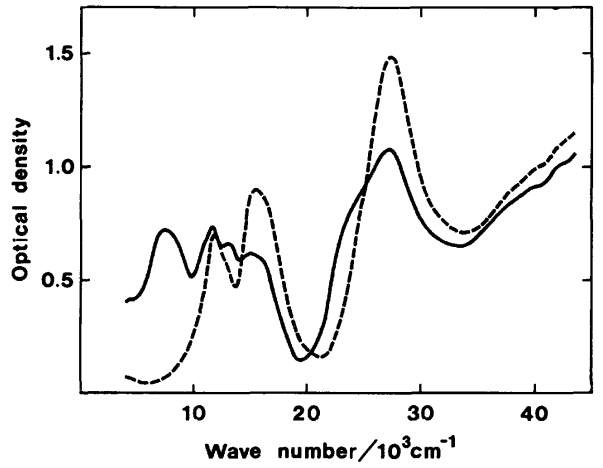

Fig. 1. Absorption spectra of powder samples; Na^+-(18-crown-6)- $TCNQ^-$ (——) and K^+-(18-crown-6)-$TCNQ^-$ (----).

The absorption spectrum of the K^+ salt (Fig. 1) is less complicated. There are three prominent bands at 11.8, 15.5, and 27.3×10^3 cm^{-1}. The first band is located in the energy region of one of the monomer $TCNQ^-$ excitations described before. However, it may be assumed that this band is a CT band associated with the excitation between two TCNQ anions since there is no absorption band in the lower-energy region beyond this band. The CT-band energy of a $TCNQ^-$ dimer is determined mainly by three terms,[4] *i.e.*, on-site Coulomb energy U, configuration-interaction(CI) energy t between ground and CT configurations, and CI-energy t' between CT- and locally-excited configurations. t increases the CT-band energy, whereas t' acts to decrease it. The above energy of the CT band implies that t is very large and, probably at the same time, t' is small in this salt. The crystal structure analyzed by Hirano *et al.*[7] indicates the existence of strong and isolated dimers of $TCNQ^-$ bound by the Coulomb interaction with K^+, the vector connecting two $TCNQ^-$ being almost perpendicular to their molecular plane. Thus the above assumptions for the molecular integrals are in harmony with the crystal structure, and the first assumption that the lowest-energy band is the CT band is reasonable. The local-excitation band at 27.3×10^3 cm^{-1} is sharp and has no shoulder on its lower-energy side. This fact is also in agreement with the crystal structure for which the thermal excitation of the monomer-like molecular arrangement seems to be difficult.

Magnetic Properties. The Na^+ salt showed a sharp and fairly strong ESR signal at room temperature at a g-value of 2.0029. The spin density was estimated to be 1.4×10^{23} mol^{-1} using purified DPPH as the standard. The temperature variation of the integrated intensity is shown in Fig. 2. While a thermally

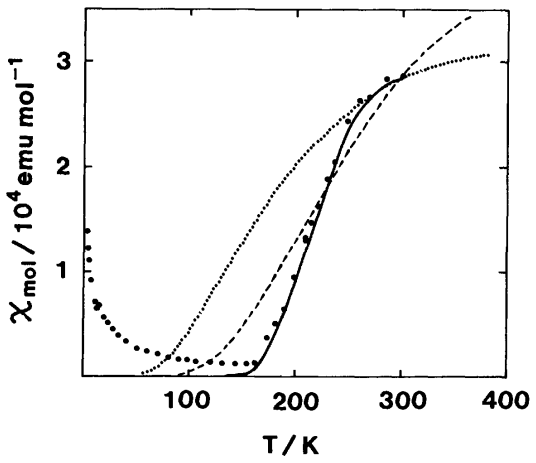

Fig. 2. Temperature dependence of the integrated ESR intensity of Na^+-(18-crown-6)-$TCNQ^-$. Solid line is the result obtained by subtracting the Curie-type contribution. Dashed and dotted lines are respectively the theoretical curves by the singlet-triplet model with J=0.069eV and the linear-Ising model with J= 0.038eV.

activated sharp signal is seen above 160 K, a weak and broad signal which obeys Curie's law is seen below this temperature. The latter signal is considered to come from isolated $TCNQ^-$ at the impurity sites in the crystal.[8] The variation of the thermally activated signal is revealed by subtracting the contribution from the impurity signal. Rise of the solid line thus obtained (Fig. 2) is steeper than the theoretical curves given by the singlet-triplet(ST) model[9] and the linear-Ising(LI) model.[10] The spin density at room temperature corresponds to those of a ST system with J=0.069 eV and a LI system with J=0.038 eV (Fig. 2). One possible cause of the steep rise of the present result is that the magnetic interaction between TCNQ anions is large in the low-temperature region and becomes weaker as the temperature is raised. This explanation is reasonable since the average distance between molecules increases because of the thermal expansion. The fact that the signal of the thermally activated spins is sharp over the whole temperature range where it is observed means that the magnetic excitons are mobile. These results imply that the dimerization of TCNQ anions is weak in this salt in agreement with the absorption spectrum.

We could not detect an ESR signal for the K^+ salt at room temperature at the maximum sensitivity of our instrument. To confirm that there are no spins, the static magnetic susceptibility was measured. The result $\chi=-2.9_8\times10^{-4}$ emu mol^{-1} agrees well with the diamagnetism estimated by Pascal's law. These observations indicate that the magnetic interaction between TCNQ anions is very strong in this salt, which agrees well with the absorption spectra and the crystal structure.

Shape of the Cation Unit and Property of the Crystal. The marked contrasts observed for the optical and magnetic properties of these two salts imply that their crystal structures are very different. It has been known that the size of the inner space of 18-crown-6 fits to the diameter of K^+ giving a cation unit with symmetric shape, but the diameter of Na^+ is smaller and consequently the shape of the cation unit is distorted.[11] This distortion seems not to favor good packing in the crystal. The structure and properties of TCNQ salts are determined by a critical balance between the Coulomb energy and the CT energy.[12] In the isolated dimer structure of the present K^+ salt,[7] the Coulomb attraction between K^+ and the cyano groups of the TCNQ molecules is inferred to compensate effectively for the repulsion between the TCNQ anions. Stabilization of the singlet ground state is, then, attained by the strong CT interaction.

Formation Constants of Lanthanoid(III) Complexes with 4-(2-Thiazolylazo)resorcinol

Emiko OHYOSHI
Yatsushiro College of Technology, Hirayamashinmachi 2627, Yatsushiro, 866
(Received June 18, 1984)

Synopsis. The formation constants of the protonated (MHR) and normal (MR) complexes (1:1) of lanthanoids(III) with 4-(2-thiazolylazo)resorcinol (TAR, H_2R) have been determined spectrophotometrically by estimation of the free ligand. The MR complexes of TAR were less stable than the corresponding 4-(2-pyridylazo)resorcinol (PAR) complexes, but the relative stabilities were reversed for the MHR complexes.

4-(2-Thiazolylazo)resorcinol (TAR) gives intensely colored complexes with most metals and is widely used in analytical chemistry.[1] Shimizu and Momo reported that TAR is the most useful reagent for determination of Sc(III).[2] It is of interest to study complexation of lanthanoids(III) with TAR. As described previously, the method[3] developed for determination of complex formation constants by estimation of the free ligand was applicable to study the lanthanoid(III)-4-(2-pyridylazo)resorcinol (PAR) complexes.[4] In the present work, the method[3] was applied to the lanthanoid(III)-TAR system and the results were compared with those of the lanthanoid(III)-PAR system.[4]

Experimental

Materials. All chemicals used were of G.R. grade. TAR was obtained from Dojindo Chemical Co., and its purity was checked by using thin-layer chromatography.[5] A weighed quantity of TAR was dissolved in a small volume of 1.0 M (1 M=1 mol dm^{-3}) NaOH and the solution was diluted with distilled water to prepare the stock solution of 2.0×10^{-3} M. The lanthanoid(III) nitrate solutions except for Ce(III) were prepared by dissolving the calculated amounts of the respective oxides in nitric acid. The cerium(III) nitrate solution was prepared by dissolving $Ce(NO_3)_3\cdot2(NH_4NO_3)\cdot4H_2O$ in 10^{-2} M HNO_3 and the concentration was determined by EDTA titration. Hexamine and sodium nitrate were used to maintain the pH at 5—6.3 and the ionic strength at 0.1, respectively.

Procedure. The metal solution was added in small aliquots, 50 μl each, using a microliter pipet to a 10 ml of the buffered solution of TAR ($1.5—2.0\times10^{-5}$ M), to give the concentrations of $10^{-4}—5\times10^{-3}$ M. Before and after the addition of the metal for each 50 μl, the absorbance at the peak of TAR (420 or 440 nm) was measured by using a Shimadzu UV 200s spectrophotometer. No precipitation occurred under these experimental conditions.

Results and Discussion

As described previously,[3] metal complexes of TAR (H_2R), MHR, and MR, can indirectly be estimated by utilizing the ligand absorption peak. The absorbance at the free ligand peak measured in the absence (A_o) and the presence (A) of the metal under conditions where $C_M \gg C_R$ (C_M and C_R are the total concentrations of the metal and the ligand), *i.e.*, formation of the 1:1 complexes, MHR and MR, is assumed, can be related to their formation constants, K_{MHR} and K_{MR}, as follows (the charges are omitted for simplicity):

$$C_R = [MHR] + [MR] + [R'] \quad (1)$$

$$A = \varepsilon_{MHR}[MHR] + \varepsilon_{MR}[MR] + \varepsilon_{R'}[R'], \quad (2)$$

where R′ is the free ligand not combined with metal, and ε_{MHR}, ε_{MR}, and $\varepsilon_{R'}$ are the molar extinction coefficient of MHR, MR, and R′ at the free ligand peak, respectively. With the formation constants, $K_{MHR}=[MHR]/([M][HR])$ and $K_{MR}=[MR]/([M][R])$, the acid dissociation constants of H_2R, $K_1=[H][HR]/[H_2R]$ and $K_2=[H][R]/[HR]$, and α coefficient,[6] $\alpha_R=[R']/[R]$, Eqs. 1 and 2 can be brought into the following expressions:

$$[M](K_{MHR}K_1[H]+K_{MR}K_1K_2)/(\alpha_RK_1K_2) = C_R/[R'] - 1, \quad (3)$$

$$A/\varepsilon_{R'} = [R']\{1+(\varepsilon_{MHR}K_{MHR}K_1[H] + \varepsilon_{MR}K_{MR}K_1K_2)[M]/(\varepsilon_{R'}\alpha_RK_1K_2)\}. \quad (4)$$

Combining Eq. 3 with Eq. 4, and substituting C_M for [M] (since $C_M \gg C_R$) and A_o for $C_R\varepsilon_R$, we obtain

$$\frac{K_{MHR}K_1[H]+K_{MR}K_1K_2}{\alpha_RK_1K_2} - \frac{\varepsilon_{MHR}K_{MHR}K_1[H]+\varepsilon_{MR}K_{MR}K_1K_2}{\varepsilon_{R'}\alpha_RK_1K_2} \times\frac{A_o}{A} = (A_o/A-1)/C_M. \quad (5)$$

From Eq. 5, a linear relation between $(A_o/A-1)/C_M$ and A_o/A should be obtained at a constant pH where $\varepsilon_{R'}$ remains constant. The product of the intercept of the y axis ($y=(A_o/A-1)/C_M$), y_o, at a fixed pH and $\alpha_RK_1K_2$ is given as a function of [H]:

$$y_o \times \alpha_RK_1K_2 = K_{MHR}K_1[H] + K_{MR}K_1K_2 \quad (6)$$

According to Eq. 6, a linear plot of the left-hand side of Eq. 6 *vs.* [H] should be obtained in a pH range where no hydrolysis of metal ion occurs. From the slope and the intercept of the line, both K_{MHR} and K_{MR} can be determined.

By measuring the decrease of the absorbance at the peak of TAR (420 nm) with increasing metal concentrations at a constant pH, we plotted the relation expressed by Eq. 5. All the plots obtained at different pH values for different lanthanoids(III) yielded a straight line with a negative slope as expected. Since TAR shows a broad peak (410—440 nm), we tried to plot the data at another wavelength of 440 nm and ascertained the line having the same intercept (the slope is different). Figure 1 shows a typical set of plots at pH 5.50. The experimental data showed no detectable difference in the plots for Yb(III) and Lu(III) (line 1), for Dy(III) through Er(III) (line 3), and for Sm(III)

Table 1. Formation constants, K_{MHR} and K_{MR}, and proton dissociation constants of MHR, K^{H}_{MHR}, for TAR and PAR complexes of lanthanoids(III) $I=0.1$ ($NaNO_3$), 25 °C

Lu	4.77	8.78	5.43	4.39	10.70	5.99

The relative errors of K_{MHR} and K_{MR} are 5—10% and 8—15% respectively.

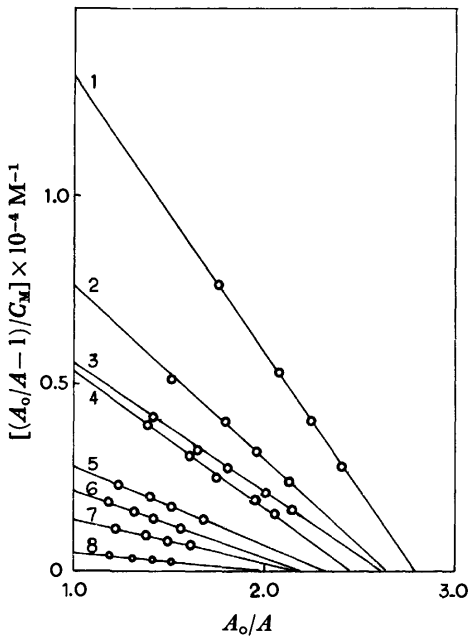

Fig. 1. Plots according to Eq. 5 at a constant pH of 5.50 for the system of TAR and lanthanoids (III). 1) Lu, Yb; 2) Tm; 3) Er, Ho, Dy; 4) Tb, Gd, Eu, Sm; 5) Nd; 6) Pr; 7) Ce; 8) La.

through Tb(III) (line 4), respectively. It is noted that lines 3 and 4 have a slightly different slope but almost the same intercept. This suggests that the degree of complex formation for Sm(III) through Er(III) is very similar to each other.

To determine the formation constants of MHR and MR complexes the relationship expressed by Eq. 6 was plotted for various lanthanoids(III). The values, $K_1=10^{-6.23}$ and $K_2=10^{-9.44}$[7] were used for calculation of $\alpha_R K_1 K_2$. All the plots exhibited straight lines, each of which had an intercept, indicating the presence of both MHR and MR, complexes. Table 1 shows the formation constants of MHR and MR, K_{MHR} and K_{MR}, obtained from the slope and the intercept of the plot of Eq. 6, and the proton dissociation constant of MHR, K^{H}_{MHR}, calculated by: $K^{H}_{MHR}=K_2K_{MR}/K_{MHR}$. The values were obtained by the least squares method. For comparison corresponding values for PAR are included.

In general, TAR forms less stable complexes with metal ions than PAR because of the lower basicity of the thiazole rings. From our results for the lanthanoids(III), this is valid only for the MR complexes. The MHR complexes are more stable than those of PAR. This parallels the protonation constants of the two ligands, HR^- and R^{2-} for TAR[7] ($pK_1=6.23$ and $pK_2=9.44$) and PAR[8] ($pK_1=5.50$ and $pK_2=12.30$). From the variation in the formation constants, K_{MHR} and K_{MR} (Table 1), with the atomic number, it is noticed that there are marked similarities between the coordinating tendencies of TAR and PAR to the lanthanoids(III): 1) The stabilities of MHR and MR complexes increase up to Sm(III); 2) After Sm(III) the K_{MHR} values are very close to each other; 3) The acidity of MHR which parallels the stability order of MR increases with the atomic number.

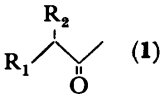
The Facile Synthesis of Unsymmetrical Ketones Using Acetone Dimethylhydrazone

Masakazu YAMASHITA,* Kaoru MATSUMIYA, Minako TANABE, and Rikisaku SUEMITSU
Department of Applied Chemistry, Doshisha University, Kamikyo-ku, Kyoto 602
(Received June 27, 1984)

Synopsis. Unsymmetrical ketones were prepared by successive alkylation of acetone dimethylhydrazone. Application of this reaction to the synthesis of dihydrojasmone is described.

Ketones are one of the most important groups of compounds in the field of organic synthesis and many synthetic methods for their preparation have been reported. In this paper, we wish to report a facile and one stage synthetic method to synthesize unsymmetrical ketones using acetone dimethylhydrazone.[1] The outline of this method is shown in Scheme 1. After addition of butyllithium to a solution of acetone dimethylhydrazone[2] in THF at −5 °C under argon, 1-iodopentane was added and the mixture was stirred for 10 h at room temperature. After cooling the mixture to −5 °C again, butyllithium was again added followed by benzyl bromide. After stirring for 10 h, 2 mol dm^{-3} hydrochloric acid was added to hydrolyze the mixture and the organic material was extracted with ethyl acetate. Usual work up afforded pure 1-phenyl-3-nonanone in 94% yield. Other results are listed in Table 1.

The high yields of the products, the facility of the reaction procedure, and the mildness of the reaction conditions may make it possible to utilize this method for the syntheses of unsymmetrical ketones. The formation of the corresponding isomeric ketones (**1**) was negligible.[3]



(**1**)

Using this method, synthesis of dihydrojasmone was carried out (Scheme 2). After successive alkylations and hydrolysis, 1-undecen-5-one (**2**) was obtained in 87% yield from acetone dimethylhydrazone. Oxidation of the terminal double bond to 2,5-undecanedione (95% yield) and the succeeding cyclization afforded the desired dihydrojasmone in 61% yield.

Experimental

The IR spectra were recorded on a Hitachi 260-10 Infrared Spectrophotometer, the NMR spectra were measured on a Hitachi R-600 FT-NMR Spectrometer, and the mass spectra were measured on a Hitachi RM-50 GC-MS. All the experiments were carried out under an atmosphere of argon. The tetrahydrofuran (THF) was dried by distillation from

lithium aluminum hydride. The iodomethane, 1-iodopentane, benzyl bromide, allyl bromide, and 2-bromobutane were all commercial products and were distilled before use. Acetone dimethylhydrazone was prepared in 71% yield by refluxing acetone and dimethylhydrazine in benzene in the presence of catalytic amount of trifluoroacetic acid.

Representative Synthesis of 1-Phenyl-3-nonanone. Butyllithium (2.6 mmol) was added *via* a syringe at −5 °C to a solution of acetone dimethylhydrazone (2.4 mmol) in THF under argon. After 1 h, 1-iodopentane (2.4 mmol) was added and the mixture was stirred for 10 h at room temperature. After cooling the mixture to −5 °C again, butyllithium (2.6 mmol) and then benzyl bromide (2.6 mmol) were added, and the reaction mixture was stirred for 10 h at room temperature. Two mol dm^{-3} hydrochloric acid (10 ml) was added for hydrolysis and the organic material was extracted with ethyl acetate. The organic layer was washed with brine, dried over sodium sulfate, filtered, and concentrated *in vacuo*. The preparative TLC of the crude residue (silica gel, hexane–ethyl acetate 10:1) afforded pure 1-phenyl-3-nonanone (0.492g 94% yield).

Acetone Dimethylhydrazone. Bp 95 °C/760 Torr (1 Torr=133.322 Pa); NMR ($CDCl_3$) (δ): 1.93 (3H, s, C-CH_3), 1.97 (3H, s, C-CH_3), 2.04 (6H, s, N(CH_3)$_2$); IR (cm^{-1}): 1660, 1170, 1090; MS *m/z* (%): 100 (M^+, 8), 44 (90), 42 (83), 28 (100).

1-Undecen-5-one. NMR ($CDCl_3$) (δ): 0.88 (3H, t, -CH_3), 1.27—1.70 (10H, m, -CH_2-×5), 2.44 (4H, t, -CH_2COCH_2-), 4.86—6.18 (3H, m, -CH=CH_2); IR (cm^{-1}): 1710, 1640, 1130, 1080, 1000, 910; MS *m/z* (%): 168 (M^+, 18), 113 (56), 98 (68), 85 (100), 66 (79).

5-Methyl-1-phenyl-3-heptanone. NMR ($CDCl_3$) (δ): 0.83 (3H, d, -CHCH_3), 0.90 (3H, t, -CH_2CH_3), 1.15—1.38 (2H, m, -CH_2CH_3), 1.66—2.05 (1H, m), 2.20—2.38 (2H, m, -CHCH_2CO-), 2.78 (2H, t, -CH_2Ph), 2.83 (2H, t, -$COCH_2$-CH_2-), 7.24 (5H, s, -C_6H_5); IR (cm^{-1}): 1710, 1600, 1140, 1060, 1030; MS *m/z*: 204 (M^+).

The other compounds listed in Table 1 were identified by comparison of their IR, NMR, and mass spectra with those of authentic samples.

Synthesis of Dihydrojasmone from 1-Undecen-5-one. To a mixture of palladium chloride (60.5 mg, 0.34 mmol) and copper(II) chloride (173 mg, 1.0 mmol) in aqueous *N,N*-dimethylformamide (1.6 ml), 1-undecen-5-one (**2**) (0.191 g, 1.13 mmol) was gradually added under oxygen atmosphere. The mixture was stirred at room temperature for 40 h, poured into 5 mol dm^{-3} hydrochloric acid (15 ml), and extracted with ethyl acetate. The organic layer was washed with brine, dried over sodium sulfate, filtered, and concentrated *in vacuo*. Preparative TLC of the residual liquid gave 2,5-undecanedione 0.20 g (95% yield). The diketone (0.126 g, 0.68 mmol) was added to ethanol (3 ml) and 0.5 mol dm^{-3} aqueous sodium hydroxide (3 ml), and the mixture was refluxed for 7 h. The mixture was diluted with water and extracted with ethyl acetate. The organic layer was washed with brine, dried over sodium sulfate, filtered, and concentrated *in vacuo*. The preparative TLC of the residual liquid gave dihydrojasmone (0.070 g) in 61% yield. This compound was identified by comparison of IR, NMR, and mass spectra with those of a authentic sample.

Structural Studies of Cyclo(L-histidyl-L-histidyl) and Its Metal Complexes

Yoshitane KOJIMA,* Tetsushi YAMASHITA, Shinya NISHIDE, Ken HIROTSU,* and Taiichi HIGUCHI
Department of Chemistry, Faculty of Science, Osaka City University, Sugimoto, Sumiyoshi-ku, Osaka 558
(Received June 25, 1984)

The crystal structure of cyclo(L-histidyl-L-histidyl) was determined by X-ray diffraction techniques, and was refined to a final R index of 0.066 for 680 reflections. This showed that one imidazolyl group of this compound faces the piperazine ring(folded) whereas the other is kept away from the ring(unfolded). A calculation using the α-β coupling-constant data of this peptide obtained by an ^1H NMR measurement shows that the ratio of a folded conformation to an unfolded one is 49:51 in D_2O. Also, NMR investigations of zinc(II) and silver(I) complexes with this peptide were carried out in D_2O.

Cyclic dipeptides(3,6-disubstituted 2,5-piperazinedione) are the simplest cyclic peptides of biological interest. The cyclic character of 2,5-piperazinedione simplifies the interpretation of NMR and other spectroscopic data and greatly limits the number of the preferred conformations. Numerous cyclic dipeptides have been studied in solution using NMR measurements.[1] Some of them have been studied the solid state by X-ray structural analyses.[2]

The most interesting result from the studies of cyclic dipeptides is that molecules containing an aromatic side chain (such as phenylalanyl, tyrosyl, and histidyl residues) tend to have a folded conformation with the aromatic ring facing the piperazine ring.[1a] An interaction between the aromatic ring and the piperazine ring (probably a dipole-induced dipole one) appears to have a great influence on the overall conformation of cyclic dipeptides.[2a]

We have mainly engaged in a study[3] of the metal complexes of cyclic dipeptides, including a histidyl residue in the solid state and in solution using X-ray diffraction methods and NMR techniques, respectively. These peptides are good model compounds for metalloproteins.

In a series of studies of the metal complexes of cyclic dipeptides, we suggested that the conformation of the cyclic dipeptide greatly affects the formation and conformation of the metal complex.[3]

This paper describes the X-ray crystallographic structure of cyclo(L-histidyl-L-histidyl)(abbreviated to CHH)·5/2H_2O with two imidazole rings on the same side of the piperazine ring. Also, the conformations of CHH and its metal complexes in an aqueous solution are discussed using NMR (^1H and ^{13}C) and the molecular-weight data.

Experimental

CHH and its silver(I) complexes were prepared according to methods reported earlier.[3a]

Preparations of Zinc(II) Complexes. A mixture of CHH (0.70 mmol) and zinc(II) nitrate (0.35 mmol) was completely dissolved in hot water (70 mdm^3). After standing at room temperature for a few days, a formed precipitate was filtered off. Mp 240—260° dec., Yield; 95%. Found: C, 36.87; H, 4.11, N; 24.65%. Calcd for Zn $(C_{12}H_{14}N_6O_2)_2(NO_3)_2\cdot 5/2H_2O$: C, 36.81; H, 4.25; N, 25.04%. Another complex was similarly obtained by the above procedure. Mp 209—222° dec., Yield; 85%. Found; C, 33.04; H, 3.65; N, 19.08%. Calcd for Zn-$(C_{12}H_{14}N_6O_2)_2(ClO_4)_2\cdot 7/2H_2O$: C, 32.91; H. 4.03; N, 19.19%.

X-Ray Crystallographic Procedure. A crystal (0.4×0.2×0.04 mm) grown from slow evaporation of an aqueous solution was used for data collection. Crystal data: $C_{12}H_{14}N_6O_2\cdot 5/2H_2O$ for CHH·5/2H_2O: M=319.3, orthorhombic, space group $P2_12_12$. On the basis of 20 reflections, the following unit-cell parameters were obtained: a=19.91(1), b=12.66(1), c=6.163(3) Å, V(for Z=4)=1553(2) Å^3, D_c=1.56 gcm^{-3}, and μ(Mo $K\alpha$)=1.31 cm^{-1}.

All unique diffraction maxima with $2°\leq 2\theta \leq 48°$ were recorded in the ω-scan mode using a computer-controlled four-circle diffractometer and graphite monochromated Mo $K\alpha$(0.7107 Å) X-rays. Of the 1448 reflections surveyed, 680 (47%) were judged observed ($I>3\sigma(I)$) after correction for Lorenz, polarization and background effects. No absorption correction was applied.

The structure was solved by MULTAN.[4a] All hydrogen atoms were located on difference electron density syntheses. Full matrix least-squares refinements of positional and anisotropic thermal parameters for non-hydrogen atoms and of positional parameters only for hydrogen atoms (to which isotropic temperature factors 1.0 Å^2 greater than those of the atoms bonded to them were assigned) led to a convergence at R=0.066 (R_w=0.054).[4b] Neutral atomic-scattering factors of Cromer and Waber[5] were used for all atoms.[6]

Other Measurements. The ^1H and ^{13}C NMR data were obtained in D_2O at 50°C using sodium 3-trimethylsilyl-1-propanesulfonate as an internal reference. The molecular weights of the zinc(II) complexes were measured in H_2O at 56°C using urea as a standard material. JEOL FX-100 (for ^1H and ^{13}C NMR spectra), PS-100 (for ^1H NMR spectra), and Knauer Vapor Pressure Osmometer (for molecular weight) apparatus were used for the measurements of the samples.

Results and Discussion

Crystal and Molecular Structures of CHH·5/2H_2O. The standard peptide notations and bond distances are shown for CHH in Fig. 1. All bond distances and angles agree well with the values for other related compounds.[2] A stereoscopic view of the molecular packing in a unit cell is shown in Fig. 2.[4c] There are nine protons (four from CHH and five from water molecules) available for hydrogen bonding, all of

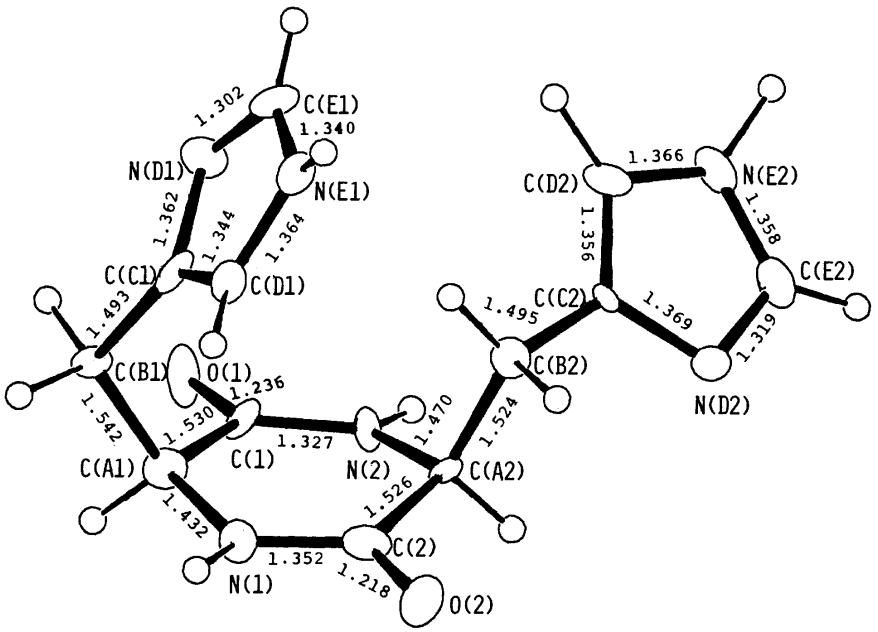

Fig. 1. Peptide notations and bond distances in cyclo(L-histidyl-L-histidyl). Standard deviations are 0.011—0.016 Å for all bond distances.

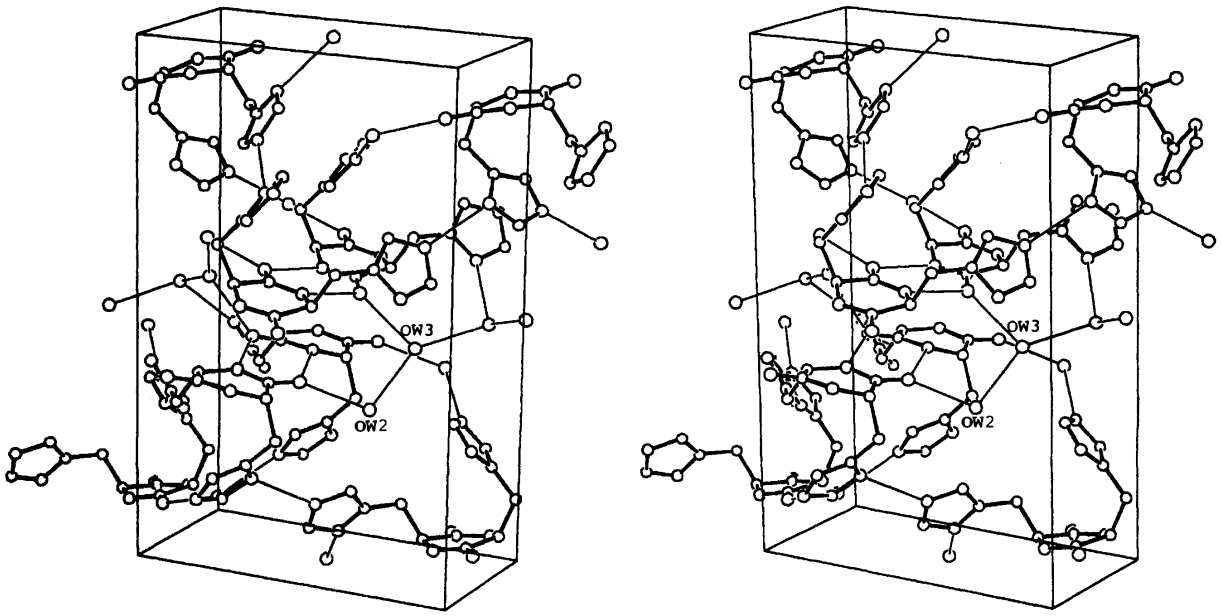

Fig. 2. Stereopicture of the molecular packing in cyclo(L-histidyl-L-histidyl). Thin lines indicate hydrogen bonding.

which are involved in intermolecular hydrogen bonds. Hydrogen bonds of the N-H···O type bind translationally equivalent piperazine rings in ribbons parallel to the c axis. Pairs of ribbons lie face-to-face across a two-fold axis such that one ribbon is connected to another ribbon through a O(1)···OW2···OW3···O(2) hydrogen-bonding scheme.

N(1), C(1), N(2), and C(2) atoms of the piperazine ring are coplanar within 0.03(1) Å with C(A1) and C(A2) deviate from this plane by 0.16(1) and 0.19(1) Å, respectively. The interplanar angles between the plane defined by N(1), C(1), N(2), and C(2) and the planes defined by C(1), C(A1), and N(1) and defined by C(2), C(A2), and N(2) are 12(1) and 13(1)°, respectively. Thus, the piperazine ring has a 'flagpole boat' conformation with cis α-carbon substituents quasi-axial. Both imidazole rings are planar within 0.02(1) Å, making angles of 56.8(5) and 46.6(5)° with the piperazine ring, respectively. Selected dihedral angles are given in Table 1. One imidazole ring is folded back over the piperazine ring with another imidazole ring kept away from the piperazine ring. This conformation is commonly found in 2,5-piperazinediones with aromatic residues.[2] The folded conformation of CHH with a 'flagpole boat' piperazine ring makes the intimate contacts between the imidazole ring and the piperazine ring possible and is compared with cyclo(glycyl-L-tyrosyl)[2a] and cyclo(L-leucyl-L-histidyl).[2e]

The short intramolecular contacts between the atom, five or more bonds apart are for N(1)···C(D1)= 3.26(1), C(1)···N(D1)=3.52(1), C(B2)···N(D1)= 3.87(1), C(B2)···N(E1)=3.74(1), C(B2)···C(D1)= 3.68(2), C(B2)···C(E1)=3.87(2), and C(2)···C(D1)=3.54(1) Å.

NMR of CHH and its Metal Complexes in D_2O. Table 2 shows β-proton chemical shifts, α-β coupling constants, and side-chain conformations for CHH and its metal complexes in D_2O. There are three possible conformations of CHH in solution. These conformations are described as follows: a folded-unfolded conformation (the same conformation in solid state), a folded-folded conformation (both imidazole rings hang over the piperazine ring) and an unfolded-unfolded (both imidazole rings are kept away from the piperazine ring). The results (folded/unfolded=49/51) for CHH shown in Table 2 appear to be consistent with a folded-unfolded conformation of CHH, but do not exclude the remaining two conformations when these two conformational isomers are present in an almost equal amount. According to the molecular structure of solid CHH, a folded-folded conformation is unlikely since the rotation of the unfolded imidazole ring around the C(A2)-C(B2) bond into a folded position produces unusual short contacts between the two imidazole rings. Cyclic dipeptides with aromatic rings usually prefer a folded conformation, but not an unfolded one in solution, as known from NMR studies.[1a] Thus, the major conformers of CHH in solution is a folded-unfolded one, which is similar to that of the solid state.

The ^1H NMR data in Table 2 indicates that the ratio of a folded form to an unfolded one is 8:92 for an $Ag(CHH)^+$ ion. Furthermore, the extremely low solubility of silver(I) complexes with CHH in protic and aprotic solvents suggests the preference of a polymeric form.

In addition, Table 2 shows that the chemical shift (2.7—3.1 ppm) of β-protons of a zinc(II) complex with CHH almost does not change from those (2.39 and 2.86 ppm) of CHH in spite of the broad and unresolved signals. Therefore, the side chain conformations of a zinc(II) complex are essentially identified with those of CHH. The broad and unresolved signal may be attributed to the rapid rotations about α-β carbon single bonds and the exchangeable coordination of nitrogen atoms [N(D1) or N(E1) and N(D2) or N(E2)] of imidazolyl groups to Zn^{2+} ions.

Table 3 shows the data of ^1H and ^{13}C NMR for CHH and its zinc(II) complex. It is suggested from Table 3

Table 1. Dihedral angles in cyclo(L-histidyl-L-histidyl)

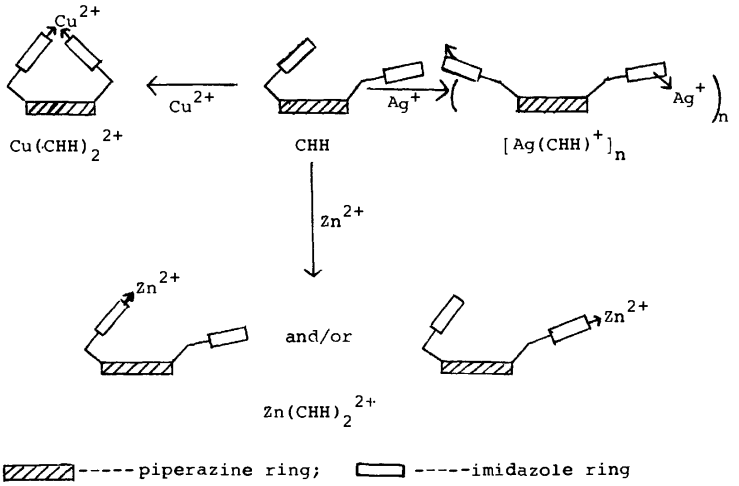

Fig. 3. The predominant conformations of cyclo(L-histidyl-L-histidyl) in complexations of Cu^{2+}, Ag^{+}, and Zn^{2+} ions.

that the imidazole nitrogen atom [N(Dn) or N(En); n=1 or 2] links to the Zn^{2+} ion on the basis of the up- or down-field shifts ($\Delta\delta$=0.26, −1.6, −2.7, and 2.1) of HCEn, C(Bn), C(Cn), and C(Dn) (n=1 and 2) of $Zn(CHH)_2^{2+}$ from CHH, respectively. This distinct shift may be due to the redistribution of electron densities owing to the binding of the imidazole nitrogen atom to the Zn^{2+} ion.[1c] On the other hand, it is indicated that the oxygen atoms of 2,5-piperazinedione do not coordinate to the Zn^{2+} ion on the basis of no distinct shifts ($\Delta\delta$=0.09, 0.1, and −0.2) of HCAn, C(n), and C(An)(n=1 and 2) of $Zn(CHH)_2^{2+}$ from CHH, respectively. Also, the earlier NMR measurements suggested that the imidazole nitrogen atom of CHH coordinates to the Ag^{+} ion, exclusively.[3a]

The molecular weights of zinc(II) complexes were obtained as follows. The perchlorate and nitrate of the $Zn(CHH)_2^{2+}$ ion are a monomeric form, and dissociate only into a complex ion and two anions: $Zn(CHH)_2^{2+}+2ClO_4^-$ (Calcd 813/3=271, Found 304) or $Zn(CHH)_2^{2+}+2NO_3^-$ (Calcd 738/3=246, Found 266). The molecular weight of a silver(I) complex could not be measured because of its extremely low solubility.

X-Ray, molecular weight, ^1H NMR, and CD studies of a copper(II) complex with CHH(reported earlier[3c]) reveal that both of the folded imidazole rings of CHH link to the Cu^{2+} ion, forming a 13-membered chelate rings by the N(E1) and N(E2) atoms. This observation is attributed to the coordination of CHH for the Cu^{2+} ion because of the too short distance(2.76 Å) between N(E1) and N(E2) makes the existence of a folded-folded conformer of free CHH impossible. In the case of the silver(I) complex ion (as described above) CHH prefers two unfolded imidazole rings whose nitrogen [N(Dn) or N(En); n=1 or 2] linearly coordinates to the Ag^{+} ion to give a polymeric material. In the zinc(II) complex ion, CHH has a folded imidazole ring and an unfolded one. However, at this stage, it is difficult to determine which (folded or unfolded) imidazole ring coordinates and, furthermore, which [N(Dn) or N(En); n=1 or 2] nitrogen atom of the imidazole ring links to the Zn^{2+} ion.

From a series of experimental results regarding CHH and its metal complexes, the predominant conformations of CHH in complexations of Cu^{2+}, Ag^{+}, and Zn^{2+} ions are assumed as shown in Fig. 3.

The authors wish to thank Prof. Toshio Miwa for his measurements of the NMR spectra and for helpful comments. They also wish to thank Mr. Junichi Gohda for the measurements regarding the elemental analyses. Also, the authors are indebted to the Crystallographic Research Center, Institute for Protein Research, Osaka University, for computer calculations.

Department of Applied Chemistry, School of Science and Engineering, Waseda University, Okubo, Shinjuku-ku, Tokyo 160

†*Microelectronics Research Labs, NEC Corporation, Miyazaki, Miyamae-ku, Kawasaki 213*

(Received July 7, 1984)

A complete magnetic anisotropy film was formed by an electroless plating method for a high-density perpendicular recording medium. The Co alloy plating bath, using ammoniacal malonate-tartrate-succinate mixed complexing agents was studied mainly by varying three main metal ion factors in the bath: *i.e.*, the concentrations of $NiSO_4$, NH_4ReO_4, and $MnSO_4$. The fine columnar structure of magnetic film in a cross section was confirmed by SEM observation. Three different kinds of eight-inch disks A, B, and C, were prepared under selected conditions with magnetic film thickness of 0.50, 0.25, and 0.20 μm respectively. The recording performance was evaluated with a Winchester ring head with a 0.33 μm gap length under various head-medium spacings. A perpendicular recording mode was confirmed, and the following recording densities were obtained: D_{50}=54 and 58 kFRPI for disk A, and 57 and 63 kFRPI for disk B when using 0.20 and 0.15 μm practical usable spacing respectively, and D_{50}=68 kFRPI for disk C when using the more advanced 0.12 μm spacing. It was suggested that the electroless cobalt alloy plating has a high potential as a process for producing perpendicular recording media.

Since the proposal of a perpendicular recording system by the Iwasaki school,[1,2] interest in it has exploded as a high potential technology to extend the limit of the present longitudinal recording system. Many workers have reported on perpendicular recording media, such as sputtered Co-Cr,[3] sputtered Ba ferrite,[4] evaporated Co-Cr[5] and coated Ba ferrite.[6] Recently, many extensive studies have been reported, not only of the medium but also of the perpendicular recording system, such as the spacing effect of the read/write conditions,[7] a comparison of the read/write characteristics between using a ring head and using a perpendicular head,[8] and the evaluation of the whole system for a perpendicular recording floppy disk drive.[9]

However, only a few attempts[10-13] have been made to use the electroless plating method to produce a medium which has higher productivity and cost performance. If the perpendicular medium could be obtained by means of an electroless plating method, as well as the longitudinal-recording-mode disk developed by NEC Corporation,[14] the realization of the system, with its merits of mass production and wear durability, would be accelerated.

With such considerations in view, the present authors attempted to prepare perpendicular recording media by means of an electroless plating. It was first reported by the present authors[10] that the perpendicular oriented c-axis of the cobalt hcp structure can be easily obtained by means of manganese codeposition into Co-Ni-P films; nevertheless, a very small amount of manganese is codeposited.[13] Moreover, the decrease in the saturation magnetization, which produces the completely magnetic anisotropy film, was performed by the rhenium codeposition into Co-Ni-Mn-P film.[15-18]

This communication reports the preparation of a new stable electroless bath for completely magnetic anisotropy films and their recording performance.

Experimental

Electroless cobalt alloy films were plated from an ammoniacal malonate-tartrate-succinate complexing-agent bath, whose composition and conditions were listed in Table 1. A polished electroless plated Ni-P film, composed of amorphous states, was usually used as a substrate, and an activated copper sheet was used only for the compositional analysis. The film composition of Co, Ni, Re, Mn, and P was determined 0.5 μm thick films by EPMA and X-ray fluorescence methods. The X-ray diffraction patterns and rocking curves for the plated films were measured by means of X-ray diffractometer with an Fe target. The magnetic properties were measured in 0.5μm thick films by the use of a vibrating sample magnetometer and a torgue magnetometer in a 10 kOe maximum applied field. Coercivities $Hc(\perp)$ and $Hc(//)$ were evaluated from the M-H hysteresis loops measured in perpendicular(⊥) and parallel(//) magnetic fields. The anisotropy field, Hk, was evaluated from the in-plane M-H hysteresis loop. SEM photographs for a cross section of the magnetic film were obtained by means of an Hitachi S-700 field emission SEM with a magnification of

TABLE 1. ELECTROLESS PLATING BATH COMPOSITION AND CONDITIONS

Chemicals	Concentration/mol dm^{-3}
$NaH_2PO_2 \cdot H_2O$	0.30
$(NH_4)_2SO_4$	0.50
$CH_2(COONa)_2 \cdot H_2O$	0.30
$C_2H_2(OH)_2(COONa)_2 \cdot 2H_2O$	0.20
$C_2H_4(COONa)_2$	0.30
$CoSO_4 \cdot 7H_2O$	0.06
$NiSO_4 \cdot 7H_2O$	0.06—0.16
NH_4ReO_4	0—0.009
$MnSO_4 \cdot 4$—$6H_2O$	0—0.09
Bath temperature	80°C
pH adjusted by NH_4OH	9.2

20000 and 50000. Eight inch disks were prepared with the bath conditions selected. The disk structure was the same as that reported in a previous paper.[12] The protective SiO_2 overcoat was formed by means of a spin-coat method.

Results and Discussion

Electroless Plating Bath for Perpendicular Recording Media. On the basis of various investigations for complexing agents, the ammoniacal malonate-tartrate-succinate mixed system was first selected, considering that sodium malonate and sodium tartrate tend to be favorable complexing agents for cobalt and perrhenate ions respectively, and further that sodium succinate tends to improve the $\Delta\theta_{50}$ value of the c-axis orientation. Moreover, the bath stability was improved by using a mixture of the three complexing agents.

Since the bath pH hardly affected the perpendicular orientation of the hcp structure and the magnetic anisotropy properties in the region between pH 8.8 and 9.4 in a manner dissimilar to that reported in the previous research,[13] the bath pH of 9.2, showing relatively favorable conditions, was chosen in this research.

The metal ion concentrations are a very important factor, like the complexing agents, in controlling magnetic properties. The cobalt sulfate was first fixed at 0.06 mol dm^{-3} in order to obtain optimum conditions for the other metal ion concentrations on the basis of the experimental results regarding the effect of the ratio of cobalt and phosphinate ions on the magnetic properties. Under the conditions at a fixed 0.06 mol dm^{-3} $CoSO_4$, the effects of the other metal ion concentrations of $NiSO_4$, NH_4ReO_4, and $MnSO_4$ on film properties were also investigated, as shown later.

The effects of the $NiSO_4$ concentration on the magnetic properties and the half width for the rocking curves of the (002) plane, $\Delta\theta_{50}$, have already been indicated in previous papers.[16,17] It was also reported there[16,17] that the optimum conditions for perpendicular magnetic anisotropy film were obtained in the $NiSO_4$ concentration region between 0.12 and 0.16 mol dm^{-3} at the fixed concentrations of 0.005 mol dm^{-3} NH_4ReO_4 and 0.05 mol dm^{-3} $MnSO_4$. In the above region, the magnetic anisotropy energy, *Ku*, became positive and reached its maximum value (1.6×10^5 erg cc^{-1}) at 0.12 mol dm^{-3} $NiSO_4$. The saturation magnetization, *Ms*, was also reported to gradually decrease with an increase in the $NiSO_4$ concentration.

From the effect of the $NiSO_4$ concentration on the compositional analysis for plated films, shown in a previous paper,[18] it was concluded that the increase in the $NiSO_4$ concentration caused the cobalt content to decrease and the nickel content to increase with constant values of 6 at% Re, 0.2 at% Mn, and 11 at% P.

The effect of the ammonium perrhenate concentration on the magnetic properties and the $\Delta\theta_{50}$ at the fixed concentrations of 0.12 mol dm^{-3} $NiSO_4$ and 0.05 mol dm^{-3} $MnSO_4$ is shown in Fig. 1. Since the Co-Ni-Mn-P films previously reported[12] did not become a complete magnetic anisotropy film, because of their higher *Ms* value, the rhenium codeposition into Co alloy film was intended to produce the *Ms* decrease in films. The demagnetized field, $Hd=4\pi Ms$, decreases with the decrease in Ms; therefore, a proper decrease in the *Ms* values could realize complete magnetic films with positive *Ku* values. Since it was very difficult to codeposit chromium into Co alloy film by means of an electroless plating method, whose codeposition could be easily deduced as a candidate from a sputtered Co-Cr film, the codeposition of rhenium, instead of chromium, was attempted in an effort to make the *Ms* decrease. The very small amount of NH_4ReO_4 into the bath made the Ms value decrease as shown in Fig. 1(b). Consequently, it produced a change in the *Ku* value from negative to positive, as may be seen in Fig. 1 (a). The other magnetic factors of *Hk* and ΔHc ($=Hc(\perp)-Hc(//)$) also showed optimum values in the concentration region between 0.003 and

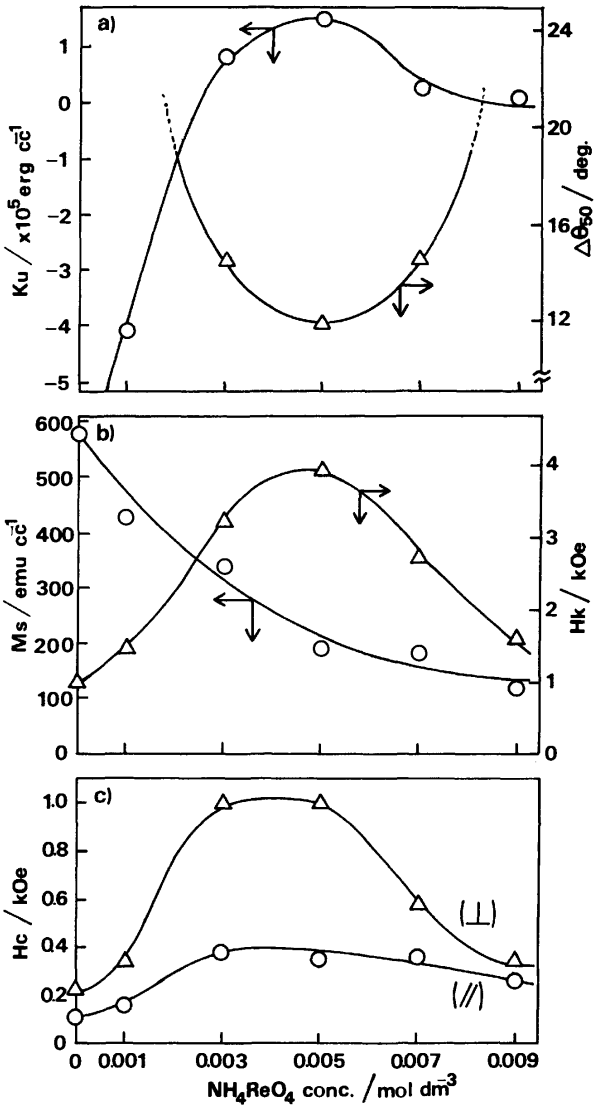

Fig. 1. Effects of NH_4ReO_4 concentration on magnetic properties and $\Delta\theta_{50}$ of (002) plane for plated films using 0.5 μm thickness.

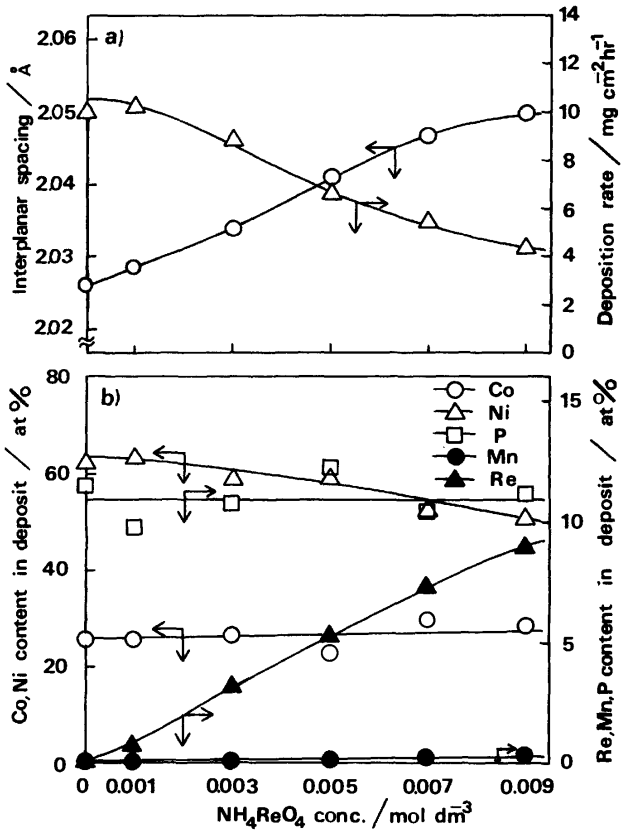

Fig. 2. Effect of NH_4ReO_4 concentration on film composition, interplanar spacing and deposition rate for plated films using 0.5 μm thickness.

0.006 mol dm^{-3} NH_4ReO_4. The $\Delta\theta_{50}$ value also reached its minimum in the same concentration region and reached the minimum value of 12 degrees at 0.005 mol dm^{-3} NH_4ReO_4.

The compositional analysis for the variation in the NH_4ReO_4 concentration is demonstrated in Fig. 2(b). The film composition for Co and P was independent of the NH_4ReO_4 concentration, while the increase in the NH_4ReO_4 concentration made the rhenium content increase linearly, accompanied by the decrease in the Ni content. The very small manganese codeposition (Mn=0.05—0.40 at%) slightly increased with the increase in the NH_4ReO_4 concentration. In Fig. 2(a), the interplanar spacing value, d, from the hcp structure, calculated from the X-ray diffraction patterns, increased with an increase in the NH_4ReO_4 concentration, *i.e.*, the increase in the Re content. This is unlike the case of the $NiSO_4$ variation, in which the d value was independent of the $NiSO_4$ concentration. It can be concluded by the above results that the replacement of Re atoms with Co atoms produces a widening of the d value in the hcp lattice, because the atomic radius of Re is larger than that of Co. For reference, the deposition rate of the films is also shown in Fig. 2(a). The deposition rate decreased with an increase in the NH_4ReO_4 concentration. It became 6—7 mg $cm^{-2}h^{-1}$ in the optimum condition region.

Figure 3 shows the effect of the $MnSO_4$ concentration on the magnetic properties and the $\Delta\theta_{50}$ value. As has already been stated, the $MnSO_4$ addition to the bath causes a perpendicular orientation of the hcp structure, in spite of the very small manganese codeposition into the film. The Ku and the $\Delta\theta_{50}$ values greatly increased and decreased, respectively, up to 0.04 mol dm^{-3} $MnSO_4$. The Ku value decreased with the increase in the $MnSO_4$ concentration from the above concentration. The X-ray diffraction peaks were not obtained in a $MnSO_4$ concentration region more than 0.05 mol dm^{-3}. The optimum conditions for magnetic properties lie in the region between 0.03 and 0.05 mol dm^{-3} $MnSO_4$. In Fig. 4(b), the dependence of the $MnSO_4$ concentration on the film composition indicates that each content is almost independent of the $MnSO_4$ concentration up to 0.03 mol dm^{-3}. Further, the phosphorus content increases

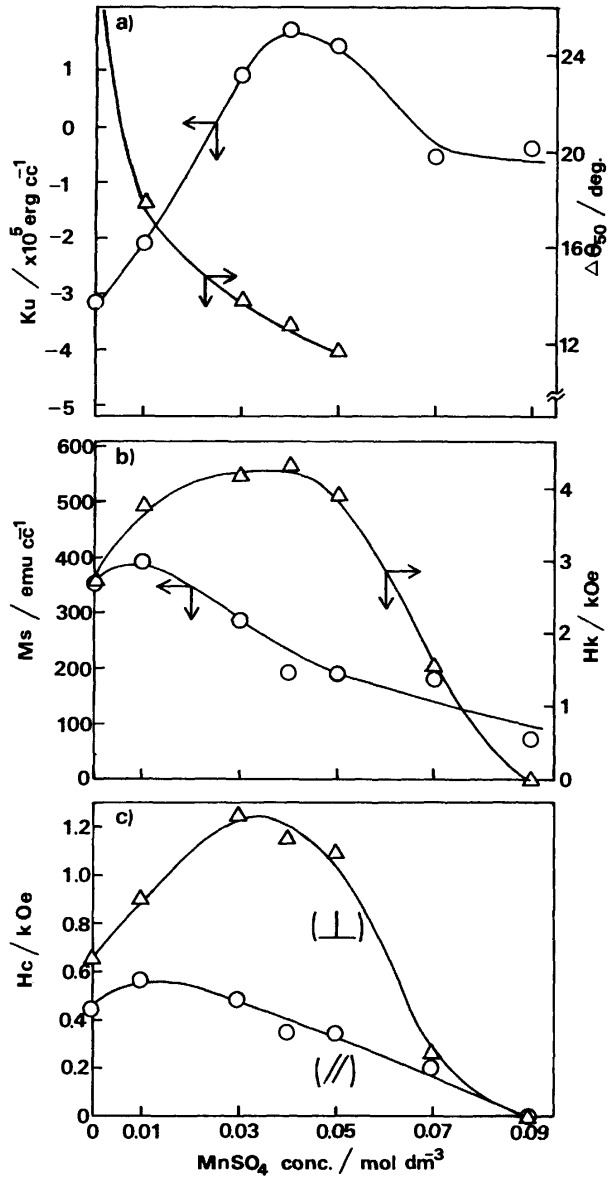

Fig. 3. Effect of $MnSO_4$ concentration on magnetic properties and $\Delta\theta_{50}$ of (002) plane for plated films using 0.5 μm thickness.

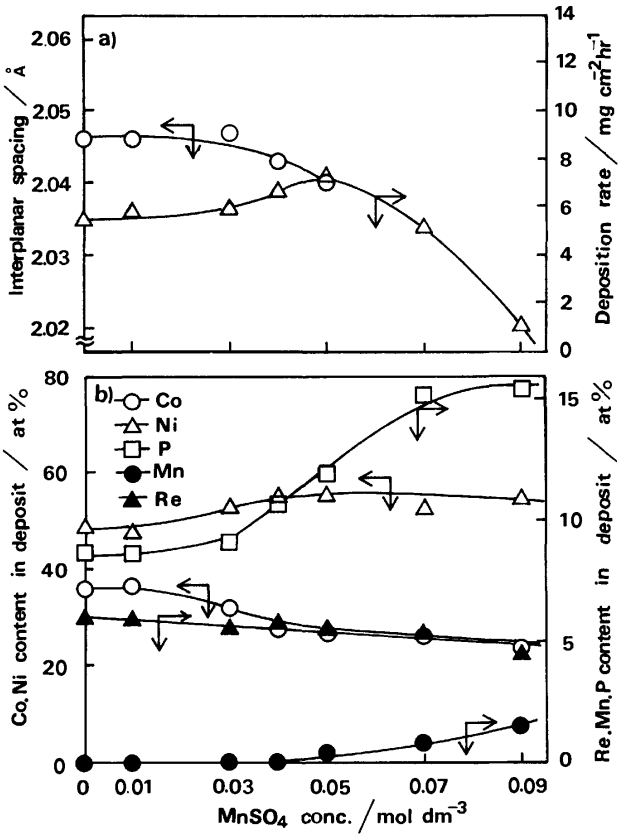

Fig. 4. Effect of $MnSO_4$ concentration on film composition, interplanar spacing and deposition rate for plated films using 0.5 μm thickness.

when the manganese starts to codeposit into the film. A small decrease in the *d* value also appeared from the initial point of Mn codeposition, as may be seen in Fig. 4(b). Thus, the variation in the *d* value and the increase in the P content simultaneously occurs upon the small amount of Mn codeposition. The effect of the manganese codeposition on the structure and its deposition mechanism are considered to be quite different from the rhenium codeposition, considering the reverse results regarding the *d* value variation in the Re and Mn codeposition. The amorphous states for non X-ray diffraction peaks in the concentration region of more than 0.05 mol dm^{-3} $MnSO_4$ is probably caused by the increase in the phosphorus content. The perpendicular orientation phenomenon produced by the addition of $MnSO_4$ can't be explained clearly in the present state. However, it might be assumed from the results of the small amount of manganese codeposition, in spite of the addition of a large amount of $MnSO_4$ to the bath, that the specifically adsorbed manganese intermediate at the interface causes the selective deposition at the initial deposition stage, and that, furthermore, thus the perpendicular orientation of the c-axis epitaxially grows on the initially selective deposited particles.

In Fig. 5, the most typical film thickness effect on the magnetic properties was obtained at one of the optimum conditions listed in Table 1, with the fixed

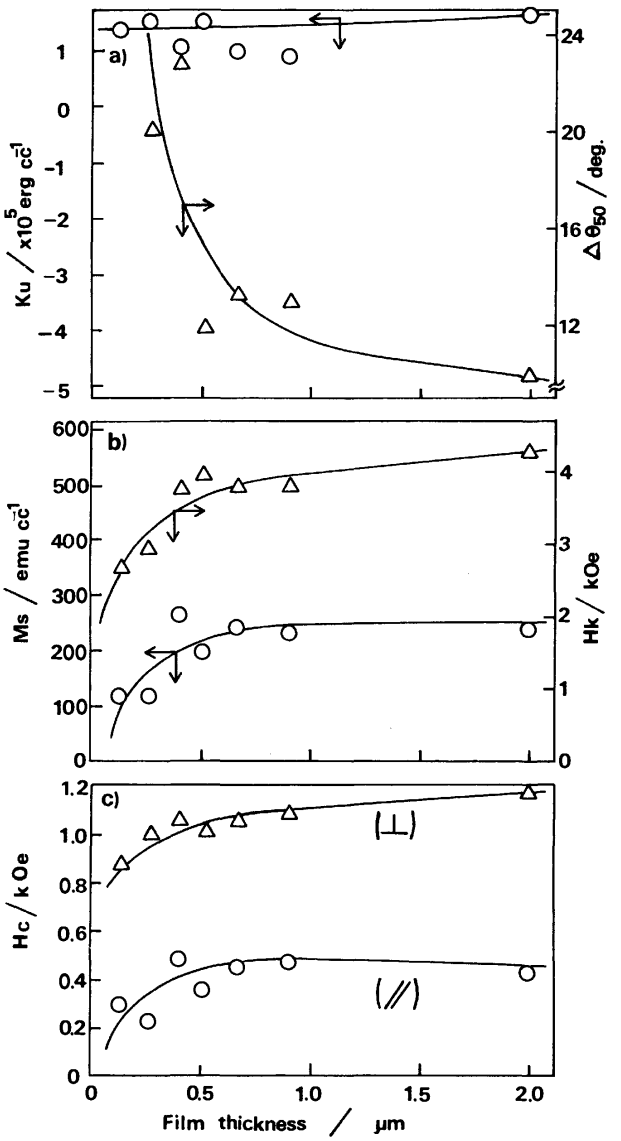

Fig. 5. Effect of film thickness on magnetic properties and $\Delta\theta_{50}$ of (002) plane for plated films.

concentrations of 0.12 mol dm^{-3} $NiSO_4$, 0.005 mol dm^{-3} NH_4ReO_4, and 0.05 mol dm^{-3} $MnSO_4$. The *Ku* value was interestingly independent of the film thickness. However, the other magnetic factors, *i.e.*, *Hk*, *Hc*(⊥), *Hc*(//), and *Ms*, depended on the film thickness in the initial thin region, up to 0.5 μm, and then reached constant values at a thickness of more than 0.5 μm. The structural factor, $\Delta\theta_{50}$, showed the largest dependence in the initial thin film region. It greatly improved with the increase in the film thickness, as may be seen in Fig. 5(a).

SEM Observation of Cross Section of Co Alloy Films. Figure 6 shows a typical cross section of Co alloy films plated to 0.5 μm under the same conditions as those in Fig. 5. Figures 6(a) and 6(b), which show the same cross section portion with different magnifications of 20000 and 50000 respectively, indicate the columnar growth structure of the hcp structure, although no clear columnar structure such as that shown

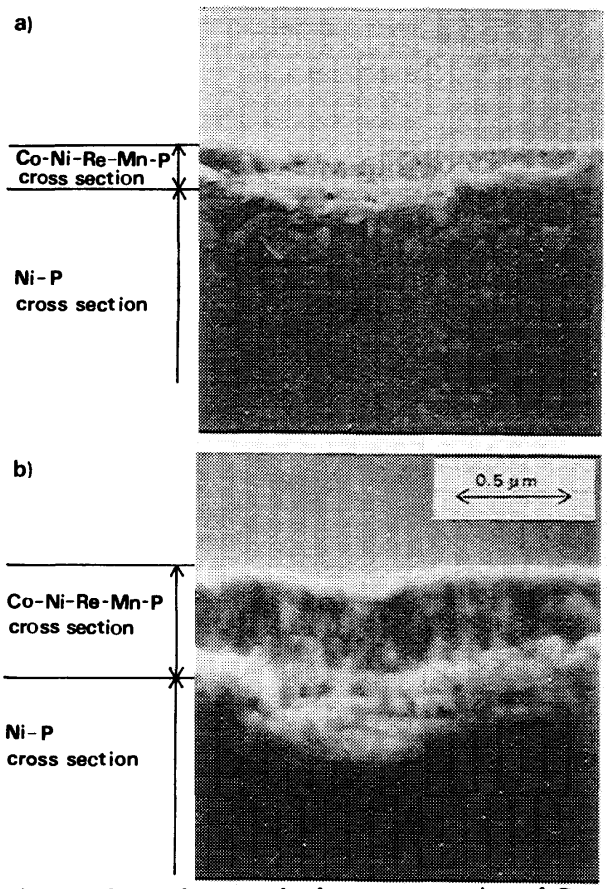

Fig. 6. SEM photographs for a cross section of Co alloy film plated 0.5 μm thick on Ni-P substrate. a) ×20000, b) ×50000.

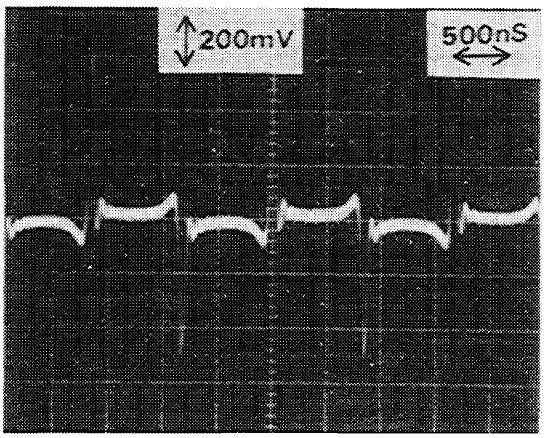

Fig. 7. Reproduced waveform at low recording density of 2540 FRPI for disk A using 0.20 μm spacing.

in previous results[12] is observed. Since the shape of the columnar structure at the cross section is reported to become unclear for the uniformly finer oriented film,[19] the film might be a finer oriented one, then the previously reported one.[12] By the SEM observation, the plated film is also concluded to be suitable for a perpendicular recording medium.

Read/Write Characteristics for Eight Inch Disks with a Combination of the Ring Head. Eight inch disks were prepared by using the optimum plating bath conditions listed in Table 1 at the fixed concentrations

TABLE 2. DISK AND HEAD CHARACTERISTICS

Items \ Disks	Disk A	Disk B	Disk C
Medium material		Co-Ni-Re-Mn-P	
Medium thickness/μm	0.50	0.25	0.20
Overcoat thickness/μm	0.05	0.05	0.02
Substrate material		Polished Ni-P on Al alloy	
Core material		Mn-Zn ferrite	
Gap length/μm		0.33	
Track width/μm		155	
Flying height/μm	0.10, 0.15 at 7.9 m/s at 12 m/s	0.10, 0.15 at 7.9 m/s at 12 m/s	0.10 at 7.9 m/s

of 0.12 mol dm^{-3} $NiSO_4$, 0.005 mol dm^{-3} NH_4ReO_4, and 0.05 mol dm^{-3} $MnSO_4$. The results for disks prepared at 0.10 mol dm^{-3} $NiSO_4$, under the same conditions as for the other factors, have already been reported in a previous paper.[16,17] The disk and head characteristics, as well as the read/write conditions, are shown in Table 2. The three medium thicknesses, *i.e.*, 0.20, 0.25, and 0.50 μm, and three head-medium spacings, 0.12, 0.20, and 0.25 μm, were used in these experiments. Here, the disks with magnetic film 0.50, 0.25, and 0.20 μm thick are designated as Disk A, Disk B, and Disk C respectively.

Figure 7 shows a typical reproduced waveform at a low bit density of 2540 FRPI for Disk A, with 0.20 μm head-medium spacing. The output voltage waveform at a low bit density in perpendicular magnetic recording in combination with the ring head is confirmed to display a dipulse shape.[20] As may be seen in Fig. 7, the dipulse shape at the low bit density recording is clearly observed. This finding supports the concept that the perpendicular recording mode is performed in a system using the plated disk combined with a ring head.

Figure 8 shows the recording density characteristics for Disks A, B, and C with the read/write conditions listed in Table 2. The recording density value at a half output voltage for a long wavelength, D_{50}, always became over 50 kFRPI under these conditions. The D_{50} values of the disks prepared at 0.12 mol dm^{-3} $NiSO_4$ were somewhat higher than the values for those prepared at 0.10 mol dm^{-3} $NiSO_4$, which were shown in the previous paper,[16,17] when the same read/write conditions are compared. This is due to the more advanced magnetic properties at the point of the 0.12 mol dm^{-3} $NiSO_4$ concentration. When considering the 0.33 μm head gap length, such recording density D_{50} values are fairly high. The recording density D_{50} values are scarcely restricted at all by the film properties, but are mainly restricted by the read/write conditions for such a magnetic anisotropy film, when using these read/write conditions. Figures 8(a) and 8(b) show the spacing effects on the recording characteristics for Disks A and B. The spacing decrease from 0.20 to 0.15 μm makes the D_{50} value higher. Furthermore, the medium thickness decrease also somewhat improves the D_{50}

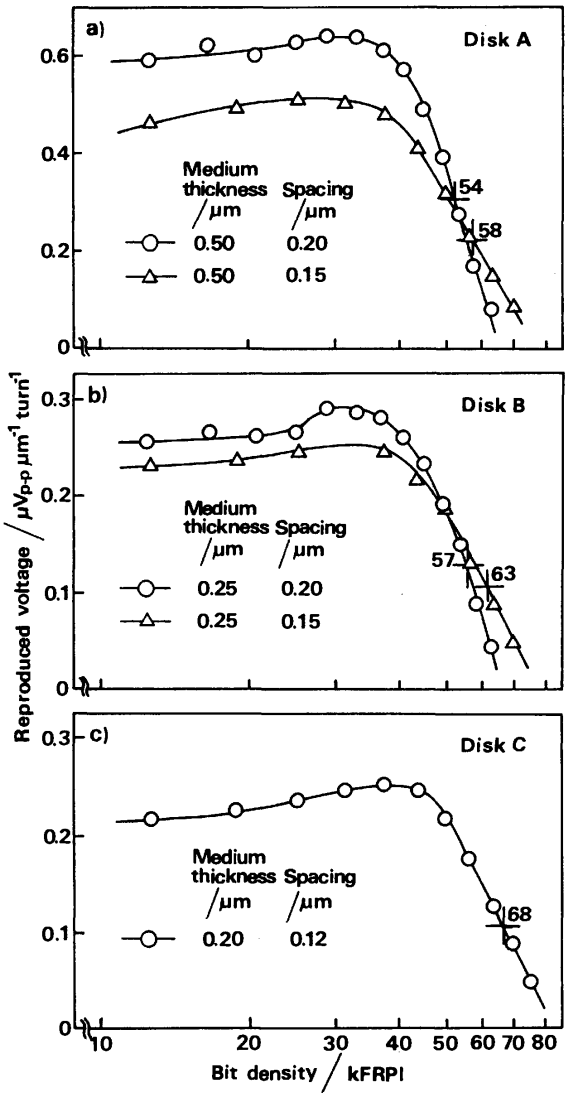

Fig. 8. Reproduced voltage dependence on recording density for Disks A, B, and C.

value. The spacing decrease from 0.25 to 0.20 μm more greatly developed the recording density D_{50} from 40 to 54 kFRPI, as was shown in previous papers.[17,18] Since a favorable *SNR* value and a flattened envelope were also obtained for these disks, with practically usable 0.20 μm spacing conditions, as in the previous data,[17] the electroless plated disks have been found to have a high potential for practical use. When the medium thickness and spacing values were reduced to 0.20 and 0.12 μm respectively, in obtaining a higher recording density, a high recording density, D_{50}= 68 kFRPI, was attained by using the 0.33 μm gap length head. The spacing used here means the total value of the 0.02 μm overcoat thickness and the 0.10 μm flying height. A very high potential for these plated disks as a perpendicular recording medium is also supported by such a high recording density with the more advanced read/write conditions.

The authors would like to thank Mr. Koichi Matsumi, Mr. Youji Suganuma, and Mr. Susumu Ito, in the Microelectronics Research Laboratories, NEC Corporation, for their encouragement during the research. The authors also wish to acknowledge the financial support of a grant from the Broadcasting Culture Foundation (Hoso Bunka Kikin).

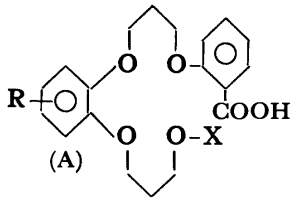
Spectroscopic Behavior of the Alkali Salts of Noncyclic Polyethers: Evidence for Interaction between the End Groups[1)]

Kazuhisa HIRATANI
Industrial Products Research Institute, Higashi 1-chome, Yatabe-machi, Tsukuba-gun, Ibaraki 305
(Received July 7, 1984)

The electronic and fluorescence spectra of the alkali salts of noncyclic polyethers exhibiting selective transport for the lithium ion were investigated. In the electronic spectra hypochromicity in CH_2Cl_2 dependent on the kind of alkali metal ions was observed, and the magnitude of the hypochromic effect decreased in the following order: $Li^+>Na^+>K^+>Rb^+>Cs^+$. Using the polar solvents, EtOH and MeCN, instead of nonpolar CH_2Cl_2, the hypochromicity is small. Also, in the fluorescence spectra, the quenching phenomenon dependent on the kind of alkali metal ions appeared in the same sequence as the hypochromicity in the electronic spectra. It is suggested that these results, together with our previous results, support a stacking structure between the terminal aromatic rings of the lithium salt in a nonpolar solvent, which has been proposed from the inspection of the CPK model building.

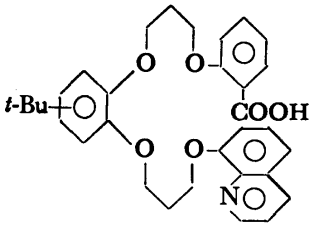
We recently reported that a group of noncyclic polyethers, which have essentially the following framework (A), exhibit Li^+-selective transport through liquid membranes by functioning as a cation carrier.[2)]



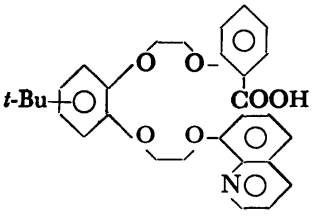
(A) X=aromatic group

When inspecting the CPK model building, it has been presumed that these compounds can form a pseudocyclic structure, the cavity of which has a diameter of 1.4—1.6Å. Furthermore the terminal groups (X= aromatic group) are presumed to overlap one another face-to-face to form a stacking structure, when hetero atoms are spatially directed to the inside. We concluded, therefore, that the lithium ion best fits the size of the cavity formed and can be transported by the (A)-type compound with high selectivity.

Here, the author attempts to verify this presumption by spectrophotometric methods. For this purpose, 1-[3-(*o*-carboxyphenoxy)propoxy]-2-[3-(8-quinolyloxy)propoxy]-4(or 5)-*t*-butylbenzene (**1**) (X=8-quinolyl, R=*t*-butyl in (A)) was used as a polyether carrier. This compound was chosen because the 8-quinolyl group has a strong absorbance maximum and strong fluorescence. The spectroscopic behavior of a 8-quinolyl terminal group may be able to give some information about the interaction between the polyether and the alkali metal ion as a counter cation of the carboxylate ion. For comparison, polyether **2** containing two oxyethylene chains was used as a **1**-analog.



(1)



(2)

There are many reports that the stacking structure between inter- or intramolecular aromatic rings can be recognized by the electronic and NMR spectra. For example, it has been reported that the stacking between nucleic acid bases could be elucidated by the magnitude of their hypochromic effect on the absorbance of the aromatic rings, which increases with increasing stacking between them.[3)] In addition, the extent of the stacking between them can also be recognized by the chemical shifts of the protons on the aromatic rings in the NMR spectra.[3,4)] As previously-reported, we observed the upfield shift of the 2-position proton on the quinolyl group of **1** in the case of the lithium salt compared with other alkali salts of **1**.[2a)]

Results and Discussion

Electronic Spectra of the Salts of the Polyethers. The author first investigated the effect of the kind of alkali metal ions as a counter cation of the carboxylate ion of **1** and **2** on the absorptivity of their alkali salts. Figure 1 shows the results for the electronic spectra of the salts of **1** in CH_2Cl_2.[5)] The spectrum of each salt of **1** has one peak (*ca.* 280 nm) and one shoulder (303 nm). The shoulder at 303 nm was confirmed to be due to the absorbance of the quinolyl group because the position of the absorbance and the absorptivity of 8-(3-chloropropoxy)quinoline (λ_{max} 303 nm(CH_2Cl_2), ε 3.50×10^3) are almost in accord with those of the salts of **1**. The absorbance at *ca.* 280 nm for each salt of **1** is attributed to the other aromatic groups. The absorptivity appreciably changes in the electronic spectra with the kind of the alkali metal ion, whereas the positions of both absorbances change little in the range of 278 to 280 nm.

In Fig. 1, the absorptivity in CH_2Cl_2 increases with the increase of the size of the ionic diameter as follows: $Li^+<Na^+<K^+<Rb^+<Cs^+$. Apparently, the absorptivity of one terminal substituent (quinolyl group) is influenced by the kind of counter cation of the carboxylate ion of the other terminal substituent (*o*-carboxyphenyl group). Based on CPK model building, the linear distance between two terminal groups is at

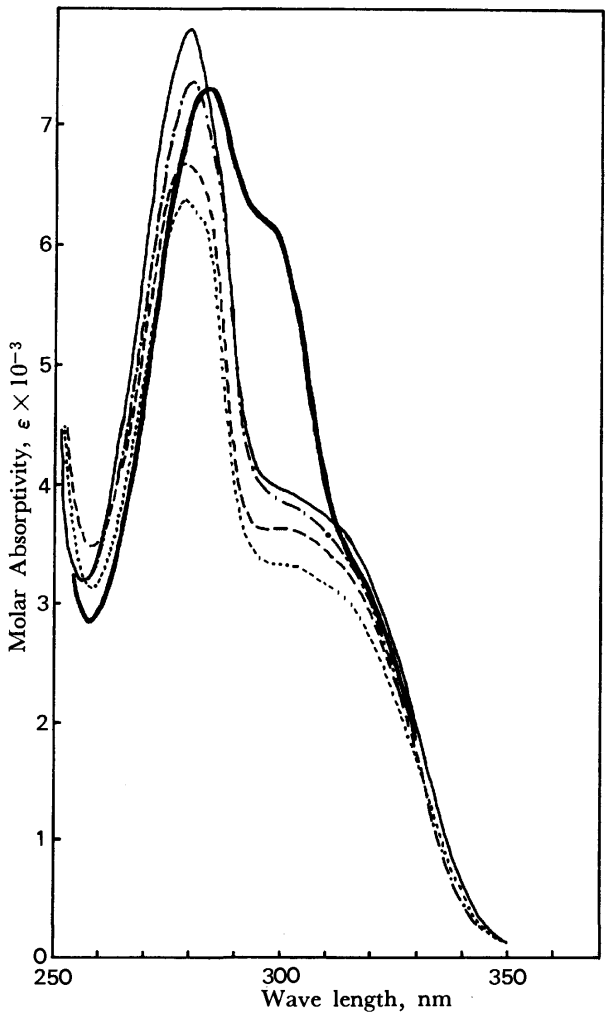


Fig. 1. Electronic absorption spectra of **1** and its alkali salts in methylene dichloride; concentration: 5.66 μmol/50 ml.[6] **1**: ——, Li^+ salt: ------, Na^+ salt: ----, K^+ salt: —·—·—, Cs^+ salt: ——

least 12 Å, when the molecule is linearly extended. The hypochromic effect (H, %) based on the absorptivity of the Cs^+-salt has been defined[3c] by the following equation:

$$H(\%) = \left(1 - \frac{\varepsilon_{M^+}}{\varepsilon_{Cs^+}}\right) \times 100 \qquad (1)$$

ε: molar absorptivity

M^+: alkali metal ions

Table 1 shows the hypochromic effect (H, %) at 303 nm calculated from this equation (1), which is based on the absorption maximum (shoulder) of the quinolyl group in the salts of **1**. The absorption spectra of the alkali salts of **2** were also measured under the same conditions, and the hypochromic effect at the absorption maximum (shoulder, 303 nm) are also shown in Table 1. In the case of the salts of **2**, it was observed that there is little difference in their hypochromic values. That is, their hypochromic effect is hardly dependent on the kind of alkali metal ion. The results in Table 1 may be closely associated with the following consideration

Table 1. Hypochromic effect (H, %)

Cation	Li	Na	K	Pb	Cs[a]
Ionic radius, Å	0.66	0.95	1.33	1.48	1.69
(1)	15.6	6.5	4.3	2.2	0
(2)	6.7	4.9	6.4	6.4	0

a) Molar absorptivity of the Cs^+-salt at 303 nm: (**1**) $\varepsilon_{Cs^+}=3.98\times10^3$, (2) $\varepsilon_{Cs^+}=3.89\times10^3$.

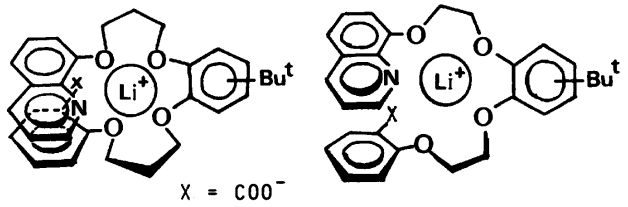

Fig. 2. Molecular structures of the lithium salt of the polyethers, **1** and **2**, on the basis of the CPK model building; a: Li^+ salt of **1**, b: Li^+ salt of **2**.

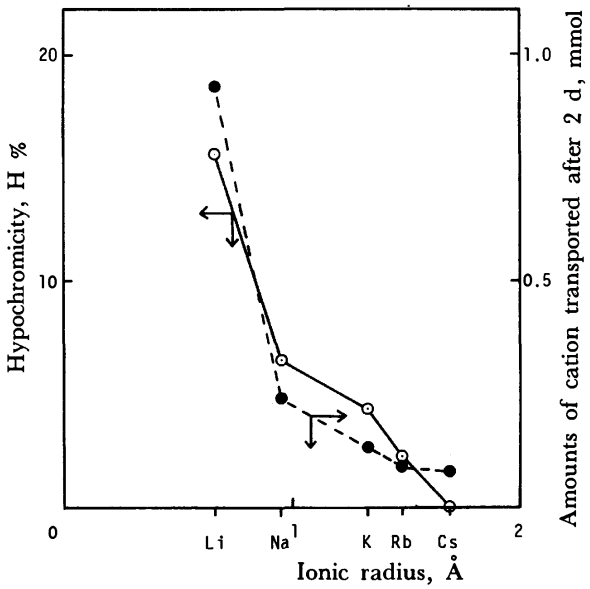

Fig. 3. Influence of the ionic radius of the alkali metal ions on the hypochromicity and the amounts of the cation transported.

based on CPK model building as previously-reported: i) when polyether **1** can form pseudocyclic structure, the lithium ion best fits the size of the cavity formed, which has a diameter of 1.4—1.6 Å, and then the terminal aromatic rings overlap one another face-to-face to form a stacking structure (Fig. 2-a), and ii) the terminal aromatic rings of **2**, on the contrary, can not overlap one another structurally, *i.e.*, on account of the bond angle, size of the terminal groups, *etc.*, as is shown in Fig. 2-b. Furthermore it is noted that the results of the selectivity for alkali metal ions in the transport experiment through a chloroform membrane by these polyethers are consistent with the spectroscopic behavior. The relationship between the hypochromicity and the amounts of cation transported[7] dependent on the kind of alkali metal ions is shown in Fig. 3.

Thus, the maximum hypochromic effect of the lithium salt of **1** in the electronic spectra is presumed to

TABLE 2. SOLVENT EFFECT IN THE ELECTRONIC SPECTRA OF THE SALTS OF (1) ON THE MOLAR ABSORPTIVITY

	CH_2Cl_2		MeCN		EtOH	
	λ_{max}	$\varepsilon\times10^{-3}$	λ_{max}	$\varepsilon\times10^{-3}$	λ_{max}	$\varepsilon\times10^{-3}$

	303	3.81	303	3.45	303	3.18

reflect the stacking structure of the polyether carrier in the nonpolar solvents such as $CHCl_3$ and CH_2Cl_2. The solvent effects of the alkali salts of **1** on the hypochromic effect in the electronic spectra has been investigated: polar protic EtOH and polar aprotic MeCN used as solvents, and the results are shown in Table 2. Using EtOH, no change of absorptivity due to the kind of the alkali metal ions could be observed. For MeCN, the hypochromic effect by the kind of the alkali metal ions is not as large as in the case of a nonpolar aprotic solvent, CH_2Cl_2. From these results, it is considered that it is not necessary for the noncyclic polyether compound in such a polar solvent to form a pseudocyclic structure in order to wrap around the polar moiety (the alkali ion of the carboxylate), because the salts in a polar solvent could be solvated by the solvent and be solved in it.

The Fluorescence Spectra of the Alkali Salts of the Polyether 1. The fluorescence spectra of the alkali salts of **1** were measured in order to investigate further the interaction between the end groups of the salts of **1** in a nonpolar solvent.[8] The results are shown in Fig. 4. The fluorescence band, which appears on exposure to ultraviolet light by xenon lamp at 321 nm in CH_2Cl_2, is based on the quinolyl group. The relative intensity of the fluorescence maximum apparently decreases with the decrease of the ionic diameter of the alkali metal ion, although the maximum wave length of the fluorescence changes in the range of 386 to 391 nm is dependent on the kind of alkali metal ion.

The dependence of the quenching phenomenon on the kind of alkali metal ion is consistent with the hypochromicity in the electronic spectra, which suggests some interaction between the terminal aromatic groups. As reported recently,[2a] it has been presumed that in the NMR spectra the upfield shift of the proton at the 2-position of the quinolyl group in the case of the Li^+-salt of **1** is to be attributed to the shielding effect (ring-current effect) of the aromatic rings on account of the stacking structure between them. This phenomenon is in accord with the behavior both in the electronic and fluorescence spectra.

Thus, the results, which have been obtained here concerning the spectroscopic behavior of the alkali metal salts of the polyethers, reflect those of the cation selective transport by the polyether carriers through a chloroform liquid membrane. In conclusion, the mechanism of cation transport, which we have proposed,[2a] is supported spectrophotometrically: their cation selective transport might occur when the cation can become well incorporated into the pseudocavity of the polyethers formed and then they form the stacking structure between two terminal aromatic groups.

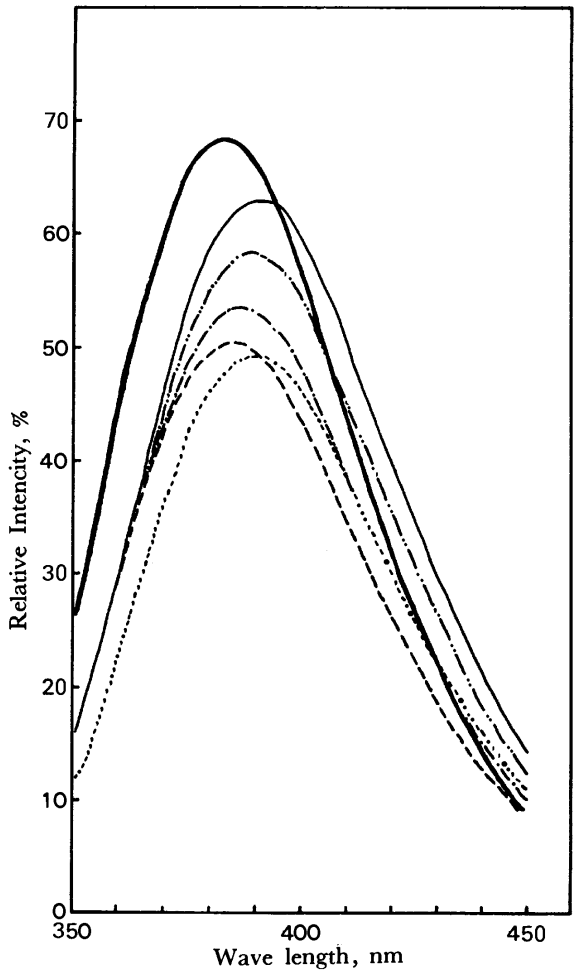

Fig. 4. Fluorescence spectra of the alkali metal salts of **1**; concentration: 5.66 μmol/50 ml of CH_2Cl_2, excitation at 321 nm. **1**: ——, Li^+ salt: ------, Na^+ salt: ----, K^+ salt: —·—·—, Rb^+ salt: —·····—, Cs^+ salt: ——

Experimental

Materials. 1-[3-(*o*-Carboxyphenoxy)propoxy]-2-[3-(8-quinolyloxy)propoxy]-4(or 5)-*t*-butylbenzene (**1**) and 1-[2-(*o*-carboxyphenoxy)ethoxy]-2-[2-(8-quinolyloxy)ethoxy]-4-(or 5)-*t*-butylbenzene (**2**) were obtained by the procedure reported previously.[2a] All solvents used were extra-pure grade reagents of Wako Pure Chemical Industries, LTD.,

which were tested for impurities spectrophotometrically before use. Sodium and potassium hydroxides were analytical grade reagents. Lithium, rubidium, and caesium hydroxides were reagent-grade.

General Spectrophotometric Measurement. Absorption spectra were measured on a Hitachi 330 spectrophotometer in the ultraviolet region. Fluorescence spectra were recorded on a Hitachi 204 fluorescence spectrophotometer.

Exactly, 3.0 mg of the polyether prepared was weighed into a 50 ml-measuring flask. About 5 ml of dichloromethane and 0.1 ml of aqueous solution containing 1.0 M (1 M=1 mol dm^{-3}) alkali metal ion were added. The flask was vigorously shaken for several hours and then the measuring flask filled with dichloromethane to the 50 ml mark. Both the electronic and fluorescence spectra of this solution were measured at room temperature. The alkali metal ions used were Li^+, Na^+, K^+, Rb^+, and Cs^+. In the case of the other solvents, the same procedure was followed. The molar absorptivity for each cation is shown in Fig. 1 and Table 2 for the electronic spectra. For the fluorescence spectra, the relative intensity for each cation is shown in Fig. 4.

5) Dichloromethane was used as a solvent for the spectroscopic measurement; its properties resemble those of chloroform used as a liquid membrane in the cation transport,[2] and it is more stable in the basic media than is chloroform.

6) The spectrum of the Rb^+ salt is not depicted because the curve is located in the narrow region between the curves of the Cs^+ and K^+ salts (*cf.* Table 1).

7) The results were obtained in the cation transport by **1** for five alkali metal ion species existing together in the source phase (see Ref. 2a).

8) It is difficult to conclude that the fluorescence quenching phenomenon necessarily reflects the formation of the stacking structure of **1**, because many other reasons for the phenomenon can also be considered. However, the results of the fluorescence is interestingly parallel with those of the electronic spectra.

The Effects of the pH and the Temperature on the Oxidation-reduction Properties of Adriamycin Adsorbed on a Mercury Electrode Surface

Kenji KANO, Tomonori KONSE, and Tanekazu KUBOTA*
Gifu Pharmaceutical University, 6-1 Mitahora-higashi 5-chome, Gifu 502
(Received July 18, 1984)

The effects of the pH and the temperature on the oxidation-reduction properties of the quinone moiety in adriamycin adsorbed on a mercury electrode surface have been investigated by means of cyclic d.c. voltammetry. The quinone waves have been fundamentally interpreted in terms of a two-step one-electron surface-redox reaction, even in a neutral or an alkaline solution, where the reduced product is liable to cause the following chemical reaction. The pH dependences of the standard surface-redox potential of the adsorbed adriamycin are −60 mV/pH (pH 2—6), −30 mV/pH (pH 7—8), and −60 mV/pH (pH 9—12). The semiquinone formation constant is 0.15 at pH 2—6 and 5 at pH 9—12. These results can be well explained by considering the protolytic equilibria of the phenolic hydroxyl groups among the oxidized, semiquinone, and reduced forms of adriamycin, the pK_a's of which are 8.53, 6.93, and 6.83 respectively. The thermodynamic constants of the semiquinone formation reaction at pH 4.5 have been determined to be $\Delta H=-24.6$ kJ mol^{-1} and $\Delta S=-99.7$ J K^{-1} mol^{-1}.

In a previous paper,[1] we have shown that adriamycin is strongly adsorbed on a mercury electrode surface and that the electrochemical redox reaction of the quinone moiety of the adsorbed adriamycin in an acidic solution can be well explained by the theory of a two-step one-electron redox reaction.[2] The apparent charge-transfer rate constants, redox potentials, and semiquinone formation constants of the surface-redox reaction have been determined at pH 2.69 and 4.54 using cyclic d.c. and a.c. voltammetry. These electrochemical and thermodynamic properties could be useful in an elucidation of the biological action mechanism of adriamycin.

In this paper, we have studied the pH dependence of the redox potential and the semiquinone formation constant in order to obtain information about the protolytic equilibria of the reduced and semiquinone forms as well as the oxidized (or parent) form of the adsorbed adriamycin. The protolytic equilibrium and the chemical stability of the oxidized form of adriamycin in the bulk solution have also been studied spectrophotometrically. Furthermore, we have investigated the thermodynamic property of the semiquinone formation reaction.

Experimental

Chemicals. Adriamycin hydrochloride and all the other chemicals used have been described elsewhere.[1]

Electrochemical Measurements. Cyclic d.c. voltammograms were recorded with a Yanagimoto P-1000 voltammetric analyzer, equipped with a Watanabe WX-4401 X-Y recorder. In the cyclic voltammetry at a sweep rate of more than 500 mV s^{-1}, an Iwatsu DM7100-DM711D digital memory (12 bit×1024 word, 5 μs/word) was used with the above system, while the voltage ramp was applied with an NF circuit FG-121B function generator.

All the voltammetric measurements were performed under potentiostatic conditions with a three-electrode system consisting of a hanging mercury drop working electrode (HMDE), a coiled platinum counter electrode, and a saturated calomel reference electrode (SCE). A fresh mercury drop from the HMDE was exposed to the electrolysis solution for a given period of time, t_{exp}, at a constant d.c. initial potential, E_i. Then the d.c. voltage scan was started from the E_i. Buffer solutions (0.2 mol dm^{-3} sodium acetate-nitric acid for pH 2.11—6.13; 0.1 mol dm^{-3} disodium hydrogenphosphate-nitric acid for pH 6.27—7.44; 0.2 mol dm^{-3} tris-(hydroxymethyl) methanamine-nitric acid for pH 7.89—9.00; 0.1 mol dm^{-3} sodium carbonate-nitric acid for pH 9.90—10.72; 0.05 mol dm^{-3} trisodium phosphate-nitric acid for pH 11.7) were used as the base solutions. The ionic strength of the base solutions was adjusted to 0.5 mol dm^{-3} with potassium nitrate. The other details of the electrochemical measurements have been described elsewhere.[1]

Spectral Measurements. The absorption spectra were recorded at room temperature in the usual manner with a Hitachi 323 spectrophotometer. To minimize decomposition errors, 20.0 μl of the adriamycin stock solution in methanol was injected into 2.00 ml of the buffer solution in a measuring cell just before recording the spectra. The concentration of adriamycin in the cell was chosen to be less than 1×10^{-5} mol dm^{-3} in order to eliminate the effect of the self-aggregation of adriamycin.[3,4]

Results and Discussion

A. pH Effect. Figure 1 shows the cyclic d.c. voltammogram of 1.46×10^{-6} mol dm^{-3} adriamycin at pH 4.54; it was recorded after $t_{exp}=4$ min at $E_i=-0.2$ V.

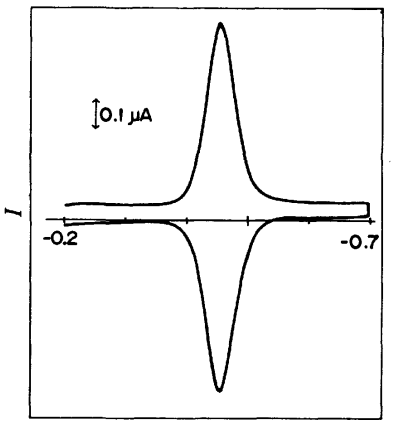

Fig. 1. Cyclic d.c. voltammogram of 1.46×10^{-6} mol dm^{-3} adriamycin at a pH 4.54 acetate buffer. $t_{exp}=4$ min at $E_i=-0.200$ V with $v=100$ mV s^{-1}.

A symmetrical pair of cathodic and anodic waves is observed. These waves are clearly to be ascribed to the surface-redox reaction of the quinone moiety in the adriamycin adsorbed on the mercury electrode.[1] When the voltammogram is recorded with an E_i value more positive than −0.3 V at pH 4.54, the peak potential, E_p^{dc}, and the half-peak width, $\Delta E_{p/2}^{dc}$, are −0.450 V and 52 mV respectively, regardless of the sweep rate, v, and the surface concentration of adriamycin, Γ.[5]

As has been described in a previous paper,[1] this wave can be interpreted in terms of a d.c. reversible two-step one-electron surface-redox reaction:[2,6]

$$\begin{aligned} O_{ad} + e &\rightleftharpoons S_{ad} \\ S_{ad} + e &\rightleftharpoons R_{ad} \end{aligned} \quad (1)$$

where O_{ad}, S_{ad}, and R_{ad} denote the oxidized (parent), semiquinone, and reduced forms of the adsorbed adriamycin respectively. In Scheme (1), the semiquinone formation constant, K, of the adsorbed adriamycin is defined by:

$$\begin{aligned} K &= [S_{ad}]^2/[O_{ad}][R_{ad}] \\ &= \exp[(F/RT)(E'_{o1} - E'_{o2})] \end{aligned} \quad (2)$$

where E'_{o1} and E'_{o2} are the standard surface-redox potentials of the O_{ad}/S_{ad} and S_{ad}/R_{ad} couples respectively. When $K<16$, the d.c. voltammogram has its maximum at the standard surface-redox potential of the O_{ad}/R_{ad} couple, E'_o, where E'_o is given by:

$$E'_0 = (E'_{o1} + E'_{o2})/2 \quad (3)$$

We can estimate the K value from $\Delta E_{p/2}^{dc}$ according to:

$$\zeta^4 - K\zeta^3 + (K - 4\sqrt{K} - 6)\zeta^2 - K\zeta + 1 = 0 \quad (4)$$

where $\zeta = \exp[(F/2RT)\Delta E_{p/2}^{dc}]$, or from the peak current, i_p, *vs.* the electricity, Q, plot according to:

$$i_p = (F/RT)Qv/(2+\sqrt{K}) \quad (5)$$

The K value at pH 4.54 has been determined to be 0.138±0.043 by the use of Eq. (4) and 0.126±0.034 by the use of Eq. (5). These values agree well with each other. The E'_{o1} and E'_{o2} values can be estimated by using the K value in Eq. (2) and the E'_o value in Eq. (3). The results are given in Table 1.

10.59	5.16	−0.755	−0.734	−0.776
10.68	5.37	−0.758	−0.736	−0.780
11.70	5.32	−0.829	−0.807	−0.850

Figure 2A shows the d.c. cyclic voltammogram of adriamycin at pH 7.44, which was recorded with v= 100 mV s^{-1} after t_{exp}=1 min at E_i=−0.4 V. Under these conditions, the cathodic and anodic waves are not symmetrical, and the peak potentials of the cathodic and anodic waves are −0.610 V and −0.642 V respectively. Where the voltammogram is recorded with v= 1000 mV s^{-1}, however, a symmetrical pair of cathodic and anodic waves is observed. These results indicate that the reversible electrochemical redox process of the parent compound is prevented at a relatively small v, *i.e.*, for a period of a few seconds, because of a subsequent irreversible chemical reaction of the semiquinone and/or reduced form adriamycin, and that the effect of the following chemical reaction can be disregarded at a large v. As was stated in the previous paper, this kind of chemical reaction can be observed even at pH 4.54 on electrolysis for a period of several minutes, but not in the voltammetry with v> 10 mV s^{-1}. This reaction may be considered as an irreversible elimination of the amino-sugar moiety, giving rise to 7-deoxyadriamycinone.[7] The chemical reaction rate of the reduced products increases with the pH. At any rate, we can estimate the E'_o and K values, and also the E'_{o1} and E'_{o2} values, from the cyclic voltammogram obtained with so large a v as to neglect the following chemical reaction.

With an increase in the pH to more than 8.5, the orange-red solution (pH<8) of the adriamycin turns blue-violet, indicating the acid dissociation of phenolic hydroxyl group in the parent molecule. Figure 3 shows the visible spectra of adriamycin at pH 6.00 and 10.72; they were recorded immediately after prep-

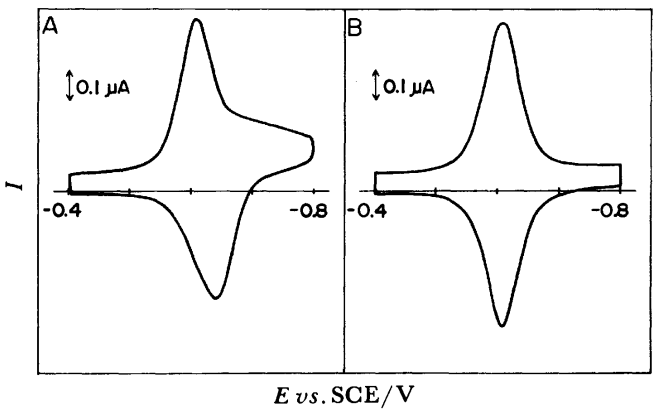

Fig. 2. Cyclic d.c. voltammograms of 4.77×10^{-6} mol dm^{-3} adriamycin at a pH 7.44 phosphate buffer with v=A) 100 mV s^{-1} and B) 1000 mV s^{-1}. t_{exp}=4 min at E_i=−0.400 V.

aration. In Fig. 4, the absorbance for 9.70×10^{-6} mol dm^{-3} adriamycin at 483.2 nm is plotted against the pH. Considering the protolytic equilibrium of the hydroxyl group of adriamycin, the total absorbance, A, at a constant analytical concentration is given by:

$$A = A_a + (A_b - A_a)\frac{K_a(\text{bulk})}{[H^+]+K_a(\text{bulk})} \quad (6)$$

where A_a and A_b represent the absorbance of the sufficiently acidic and alkaline solutions respectively, K_a (bulk) being the acid-dissociation constant of adriamycin in the solution. Regression analysis of A *vs.* pH plot was done using Eq. (6), where the absorbances at pH 6.00 and 10.72 were used for A_a and A_b respectively. The result is pK_a (bulk)=9.33±0.06. At pH 10.0, however, the absorbance decreases with the time, and the solution becomes almost colorless after about 2 h. This reaction can be interpreted as a base-catalyzed hydrolysis of the "deprotonated" adriamycin.[8]

To minimize the effect of the decomposition at pHs higher than 8.5, we recorded the voltammogram with v=1000 mV s^{-1} immediately after injecting the adriamycin stock solution into the deaerated base solution and exposing the electrode to the solution. The solid line in Fig. 5 represents the first scan of the multicyclic voltammogram recorded at pH 9.00 after t_{exp}=1 min at E_i=−0.400 V and with v=1000 mV s^{-1}. Two cathodic waves, I_c and I_c', are observed; their peak potentials are −0.680 V for the I_c wave and −0.772 V for the I_c' wave. In the anodic scan, only a symmetrical wave, I_a, is observed. The peak potential of the I_a wave is −0.680 V, coinciding with that of the I_c wave. The broken line in Fig. 5 represents the second scan, where we see that, although the I_c' wave disappears almost completely, the decrease in the wave height of I_c and I_a is small. In addition, the wave shape of the latter (I_c and I_a) is almost symmetrical, and the peak potentials coincide with those of the first scan. As a result, the pair of waves, I_c and I_a, may be considered to be practically d.c. reversible; then, the values of E_o', E_{o1}', E_{o2}' and K can be estimated. The origin of the I_c' wave is not clear at the present stage, but it may be due to the reorientation of the adsorbed molecules. In another interpretation, the appearance of the I_c' wave may be related to a following chemical reaction, such as the dimerization of the reduced form.[6]

Table 1 summarizes the electrochemical and thermodynamic parameters determined by means of the cyclic voltammetry. The K values are 0.1—0.2 at pH<6 and 3—5 at pH>9. In other words, the semiquinone formation reaction is thermodynamically favored at higher pHs. Figure 6 shows the pH dependence of E_o', E_{o1}', and E_{o2}'. The E_o' *vs.* pH plot is composed of three linear relations, the slopes being −60 mV/pH (pH 2—6), −30 mV/pH (pH 7—8), and −60 mV/pH (pH 9—12). The first and the second inflection points at pH 6.8 and 8.5 correspond to the acid-dissociation constants of the reduced and oxidized forms of the adsorbed adriamycin respectively. These findings lead us to consider the following protolytic and electrochemical equilibria:

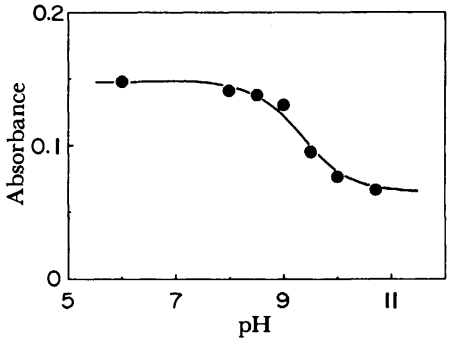

Fig. 4. pH dependence of absorbance for 9.70×10^{-6} mol dm^{-3} adriamycin at 483.2 nm. The solid line represents the regression curve calculated using the values of pK_a=9.33 for Eq. 6. (See text).

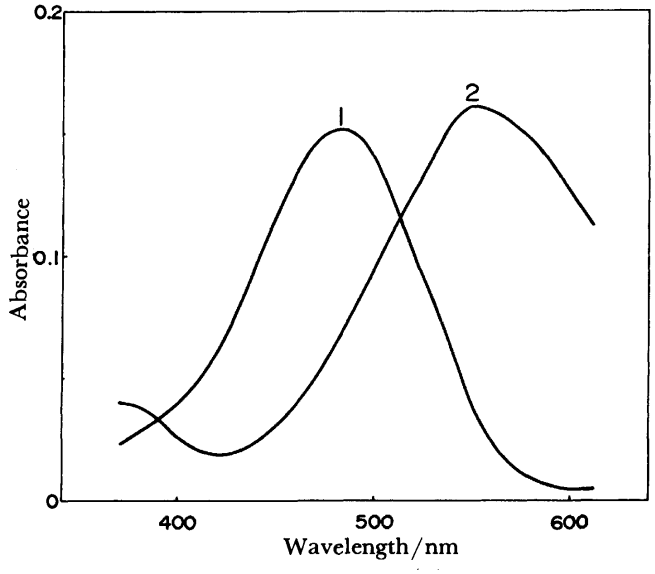

Fig. 3. Visible spectra of 9.70×10^{-6} mol dm^{-3} adriamycin at pH=1) 6.00 and 2) 10.72. The spectra were recorded immediately after preparation. (See text).

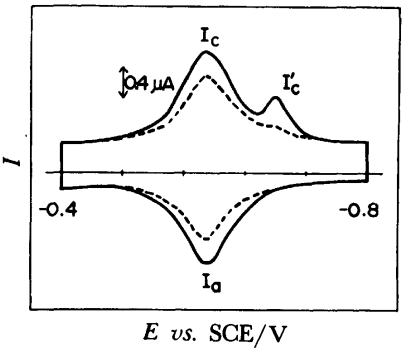

Fig. 5. Multi cyclic d.c. voltammogram of 1.38×10^{-6} mol dm^{-3} adriamycin at pH 9.00 tris buffer. t_{exp}= 1 min at E_i=−0.400 V. v=1000 mV s^{-1}. The solid and broken lines represent the first and second scans, respectively.

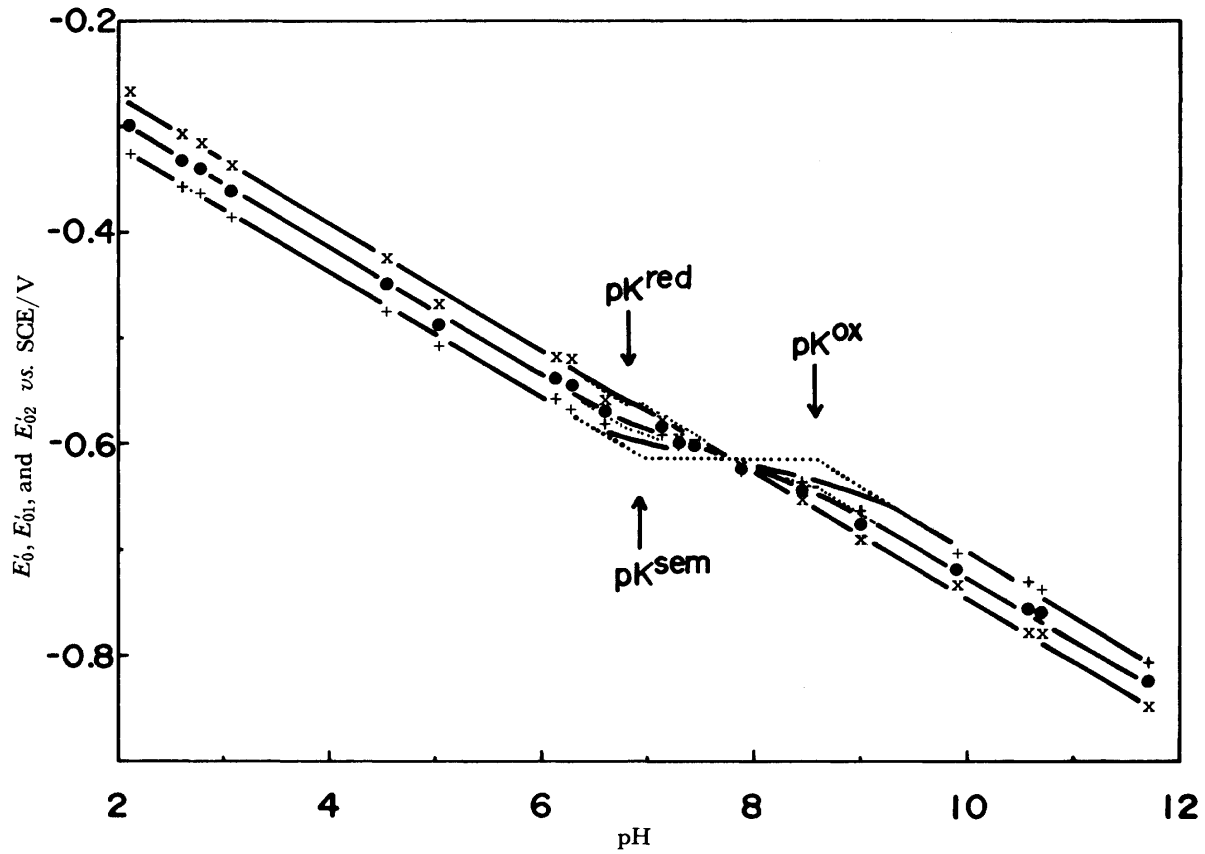

Fig. 6. Plots of E'_0 (●), E'_{01} (+), and E'_{02} (x) against pH. The solid lines represent the regression curves calculated using the values of $\bar{E}'_{01}$=−0.200 V, $\bar{E}'_{02}$= −0.153 V, pK_a^{ox}=8.53, pK_a^{sem}=6.93 and pK_a^{red}=6.83 for Eqs. 8—10.

$$\begin{array}{ccccc} (\text{Ox-H}_p)_{ad} & \overset{e,H^+}{\rightleftharpoons} & (\text{Sem-H}_{p+1})_{ad} & \overset{e,H^+}{\rightleftharpoons} & (\text{Red-H}_{p+2})_{ad} \\ H^+ \Big\| K_a^{ox} & & H^+ \Big\| K_a^{sem} & & H^+ \Big\| K_a^{red} \\ (\text{Ox-H}_{p-1})_{ad} & \overset{e,H^+}{\rightleftharpoons} & (\text{Sem-H}_p)_{ad} & \overset{e,H^+}{\rightleftharpoons} & (\text{Red-H}_{p+1})_{ad} \end{array} \quad (7)$$

where K_a^{ox}, K_a^{sem}, and K_a^{red} represent the acid-dissociation constants of the oxidized, semiquinone, and reduced forms respectively of the adriamycin adsorbed on a mercury electrode. The pH dependences of the E'_0, E'_{01}, and E'_{02} are now given by:

$$E'_0 = \frac{\bar{E}'_{01} + \bar{E}'_{02}}{2} + \frac{RT}{2F}\ln\left[\frac{[H^+]^3 + [H^+]^2 K_a^{red}}{[H^+] + K_a^{ox}}\right] \quad (8)$$

$$E'_{01} = \bar{E}'_{01} + \frac{RT}{F}\ln\left[\frac{[H^+]^2 + [H^+]K_a^{sem}}{[H^+] + K_a^{ox}}\right] \quad (9)$$

$$E'_{02} = \bar{E}'_{02} + \frac{RT}{F}\ln\left[\frac{[H^+]^2 + [H^+]K_a^{red}}{[H^+] + K_a^{sem}}\right] \quad (10)$$

where $\bar{E}'_{01}$ and $\bar{E}'_{02}$ correspond to E'_{01} and E'_{02} at pH=0 respectively. We have fitted Eqs.(8)—(10) to the three plots of E'_0, E'_{01}, and E'_{02} against the pH, using 5 parameters, $\bar{E}'_{01}$, $\bar{E}'_{02}$, pK_a^{ox}, pK_a^{sem}, and pK_a^{red}. Nonlinear least-squares analysis is performed by means of an NEC 8001 personal computer. The refined parameters are $\bar{E}'_{01}$=−0.200±0.002 V, $\bar{E}'_{02}$=−0.153±0.002 V, pK_a^{ox}= 8.53± 0.09, pK_a^{sem}=6.93±0.08 and pK_a^{red}=6.83± 0.09. In adriamycin, both the phenolic and amino groups should ionize in the pH region investigated. However, the amino group is located in the side-chain amino-sugar moiety separated from the aromatic ring by several saturated carbon atoms, so that the effect of the acid dissociation of the amino group on the redox potential should be negligible. Thus, we consider the phenolic hydroxyl group as an ionizable group in Scheme (7).[9] The present value of pK_a^{ox} (8.53) is smaller than the pK_a value of adriamycin (9.33) in the bulk solution. This disagreement is attributable to the difference between the adsorbed and dissolved states of adriamycin.

To our present knowledge, the determination of the acid-dissociation constant of the reduced and semiquinone forms of adriamycin is the first such case, though the values correspond not to the bulk state, but to the adsorbed state. The potentiometric titration may give information about the standard redox potential and the semiquinone formation constant of the bulk species.[10,11] This method, however, can not be applied to an unstable species such as adriamycin in a neutral or an alkaline solution.

On the other hand, the accelation of the chemical reaction rate following the electrochemical reduction in a neutral or an alkaline solution may be attributable to the instability of the deprotonated form of the reduced adriamycin and/or semiquinone intermediate. Here it is noteworthy to consider that, if the reduced (or

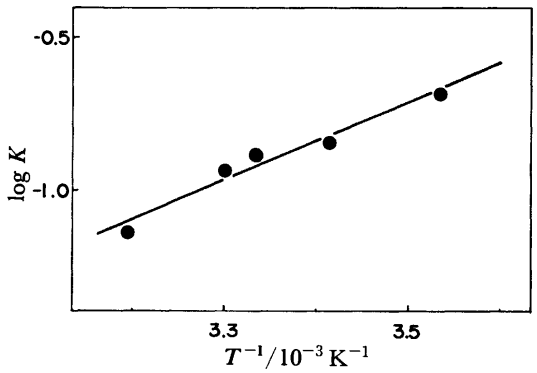

Fig. 7. Temperature dependence of the semiquinone formation constant of the adsorbed adriamycin in an acetate buffer (pH 4.54 at 25 °C).

semiquinone) form is generated in biological media (pH≈7.4), this species easily undergoes the elimination of the amino-sugar moiety to give 7-deoxyadriamycinone. This coincides with the fact that 7-deoxyaglycon is an important metabolite.[12,13]

B. Temperature Effect. We have further studied the temperature effect on the cyclic voltammogram of the adriamycin adsorbed on the HMDE in an acetate buffer (pH 4.54 at 25 °C). In the temperature range from 10 °C to 40 °C, the d.c. voltammogram is reversible and resembles that shown in Fig. 1. The peak potential shifts to the negative side with the increase in the temperature, the slope being $-0.9\,mV\,K^{-1}$. The half-peak width decreases with the increase in the temperature; in other words, the semiquinone formation constant, K, decreases with the temperature. Figure 7 shows the temperature dependence of the K value as determined by the use of Eq. 4.[14,15] The value of log K increases linearly with the reciprocal of the absolute temperature. The linear plot gives the enthalpy $\Delta H=-24.6\,kJ\,mol^{-1}$ and the entropy $\Delta S=-99.7\,J\,K^{-1}\,mol^{-1}$[16,17] for the semiquinone-radical-formation reaction ($O_{ad}+R_{ad}\rightarrow 2S_{ad}$). These values indicate that, because of the large negative entropy, the semiquinone formation reaction is not thermodynamically favored above 0 °C in an acidic solution.

16) In this discussion, the change in the pH with the temperature is not taken into account; it is calculated to be 4.51 to 4.57 for the temperature change from 10 °C to 40 °C in the acetate buffer.[17] In this pH region, the K value is practically independent of the pH. Therefore, this correction for the pH change should not affect the estimated thermodynamic constants.

The Near Infrared Emission Band Observed in Electron Irradiated Xe and Xe in Other Rare Gases

Masako TANAKA,* Susumu SASAKI,† and Meiseki KATAYAMA
Department of Atomic Science and Nuclear Engineering Faculty of Engineering, Hokkaido University, Sapporo 060
(Received August 6, 1984)

The near-infrared emission spectra were studied for xenon diluted with krypton, argon, and neon, respectively, in order to estimate the origin of an emission band at 1260 nm which was previously observed at several hundred Torr (1 Torr=133.2 Pa) of pure Xe irradiated with pulses of high-energy electrons. A continuous band around 1260 nm was observed only in Xe-Ar mixtures. This band appeared at Xe pressures above 20 Torr (diluted in 600 Torr of Ar) while it was detected above 190 Torr in pure Xe. In Xe-Ar mixtures, three emission lines due to Xe $5d(3/2)_1$were also observed at 1700, 2020, and 2650 nm. On the basis of the reported kinetic data for the reactions of rare gas mixtures, the present results led to the conclusion that the band at 1260 nm was due to emission from highly excited excimer states, of which the dissociation limits were higher Rydberg states above the energy level of the Xe_2^+ ion.

The spectroscopy and kinetics of rare gas excimers have been studied mainly in the VUV region. Here, the continuous emissions (due to transitions from the lowest bound states to the repulsive ground state) were observed. According to theoretical studies of the excited states of Xe by Mulliken,[1] the emission or absorption due to the transitions between the energy levels of excited diatomic molecules is expected to occur in the NIR region. In this regard, Arai and coworkers reported the presence of absorption bands in the NIR region and the reactivity of the excimer with a number of simple molecules.[2] On the other hand, the deexcitation processes of higher Rydberg states have not been well studied, especially at high pressures such as are used for excimer lasers. As previously reported, we have found a new continuous band in the emission spectra of Xe in the NIR region, which occurs upon the irradiation of Xe and Xe (diluted with Ar) with pulses of high-energy electron. This band seemed to be due to molecular transitions related to higher Rydberg states. However, an assignment has not yet been made.[3] In this paper the NIR emission spectra of Xe and Xe, which were diluted in other rare gases, were studied in order to estimate the excited states of Xe leading to the new band. The emission spectra were qualitatively interpreted on the basis of the recently reported kinetic models.

Experimental

The experimental apparatus has been previously described.[3] The source of the electron pulses was the 45 Mev linac at Hokkaido University and the duration of the pulses was 3 μs. The emissions from the sample gases were detected in the reverse direction to the electron beam so that interference due to intense Cerénkov light in the Xe gas (upon irradiation) could be avoided in the infrared observation. A Hamamatsu TV p791 PbSe detector with a time constant of 2.5 μs was used. The spectra were obtained by plotting the peak intensities of the time-resolved signals against wavelength. The spectra region examined was 800—1600 nm for Xe-Ne and Xe-Kr mixtures, and 800—3200 nm for pure Xe and Xe-Ar mixtures. The observed band width of the spectra was about 15 nm at 825 nm with the 1.5-mm slit used during most of the experiment. When using a narrower slit, the signal accumulation and averaging were performed by using a Sord M223 Mark III computer.

Research-grade Xe (99.995%), Ar (99.999%), and Kr (99.995%) supplied by Nippon Sanso, Ne (99.999%) by Takachiho Kagaku Kogyo were used.

Results and Discussion

Emission Spectra in Pure Xe. Th emission spectrum which was obtained upon the irradiation of 635 Torr of Xe is shown in Fig. 1. The spectrum is essentially the same as that reported peviously,[3] but the present one was measured with a better optical resolution. The emission lines observed at 830, 890—910, 990, and 1080 nm were due to known atomic transitions: 6p—6s and 6p′—6s′. The continuous band at around 1260 nm was first reported by the authors in a previous paper.[3] It starts at about 1100 nm and continues to 1350 nm. The insert in Fig. 1 shown this

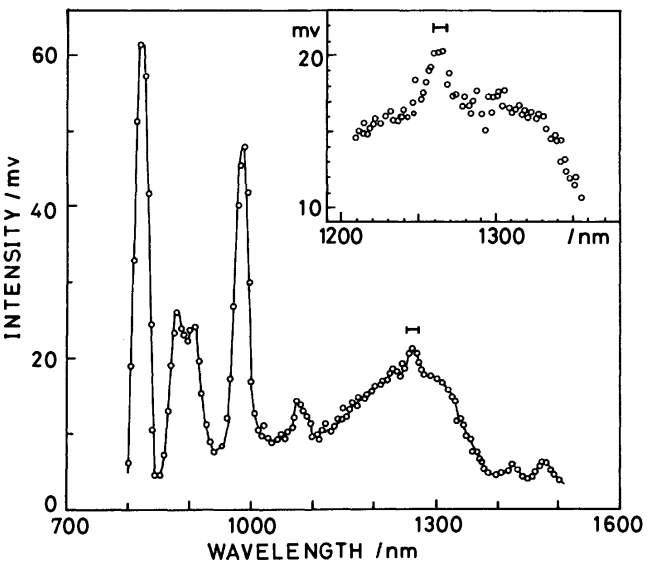

Fig. 1. The emission spectra of Xe in pure Xe at 630 Torr. The optical resolution is 20 nm. The spectrum in the insert was measured with 10 nm resolution.

†Present address: Central Research Laboratory, Mitsubishi Rayon Co. Ltd., Miyuki-cho, Otake 739-06.

band measured at a resolution of less than 10 nm. A narrow peak, which had not been detected at lower resolution, appeared and was assigned to the emission due to one of the 7s—6p atomic transitions. The possibility that this band was due to a 7p—5d transition ($3p_{10}$—$3d_5$ in Paschen notation, 1259.4 nm) was excluded since it has been reported that the branching ratio to $3d_5$ is very low.[4] No vibrational structures were observed at a 10-nm resolution, as shown in the insert. The band began to appear clearly at pressures above 190 Torr, and the pressure dependence of the peak intensity at 1260 nm was quadratic, which indicates that the band was due to a molecular transition.

One of the most important results reported in the previous paper was that the intensity of the band at 1260 nm was not affected by adding a small amount of SF_6, while the intensities of atomic lines decreased significantly. It is known that ion recombination and collisional state mixing are effectively inhibited by a small amount of SF_6.[5-7] Therefore, the ionic processes such as dissociative recombination of Xe_2^+ were ruled out as being the entity responsible for the 1260 nm band. Instead, the contribution of the direct excitation by the interaction of high-energy electron was considered.

Emission Spectra of Xe in Ne. Figure 2 shows the emission spectra of Xe in Ne. When 50 Torr of Xe was added to 510 Torr of Ne, the emission due to Ne completely disappeared, and the emission lines of Xe, which are due to the transitions 6p—6s and 7s—6p, were observed. However, no continuum emission was observed at 1260 nm except for a sharp 7s—6p line. Among the 6p—6s emission lines, the intensities of the lines due to the transition from $6p(1/2)_1$ ($2p_{10}$ in Paschen notation) at 980 and 1080 nm were very intense when the Xe pressure was low. The intensities of all emission lines decreased in the same manner as the Xe pressure increased, which indicates that these emissions were produced by energy transfer from excited Ne, and that the collisional state mixing occurred efficiently. Since all of the excited states of the Ne atoms lie at levels higher than the level of Xe^+ (12.127 ev), the excited Ne atoms can induce Penning ionization of Xe atoms, which leads to the production of an excited Xe atoms as follows; $Ne^*+Xe \rightarrow Ne+Xe^++e^-$, $Xe^++Ne+Xe \rightarrow Xe_2^++Ne$, $Xe_2^++e^- \rightarrow Xe^*+Xe$. It was estimated that the resultant energy levels of Xe* are the 6p states, if the electrons are thermalized and the dissociation energy of Xe_2^+ ion is about 1 ev.[6,8] Thus, it is considered that the 6p emissions which were observed in Fig. 2 were produced directly from the above-mentioned dissociative recombination. From the result that the 1260 nm band did not appear, it was concluded that the 6p states do not take part in the formation of the species responsible for the 1260 nm band.

Emission Spectra of Xe in Kr. The emission spectra in the irradiated Xe-Kr mixtures are shown in Fig. 3. Four emission lines due to 6p—6s transitions were observed at 830, 910, 980, and 1080 nm. The 7s—6p emission at 1260 nm, which was strong in the Xe-Ne mixtures, was very weak. The continuous band was not detected even at 100 Torr of Xe pressure.

It was considered that in this experiment the major part of the channel of energy transferred from the excited Kr to Xe was the excited Kr atoms in the 5s states. These were produced by deactivation in a cascade after the dissociative recombination of Kr_2^+. The role of the diatomic molecules, Kr_2^*, was less important, since the rate of the two-body collision of 5s Kr ($Kr^*+Xe \rightarrow Xe^*+Kr$) was much faster than that of the three-body collision ($Kr^*+2Kr \rightarrow Kr_2^*+Kr$) under the present experimental condition (P_{Xe}=higher than 5 Torr), where the former rate was 2.0×10^{-10} $cm^3 s^{-1}$[9] and the latter was 1.4×10^{-33} $cm^6 s^{-1}$.[9] An efficient dipole-dipole type energy transfer is possible between Kr $^3P_1$ and Xe $5d(7/2)_3$ and between Kr $^3P_2$ and Xe

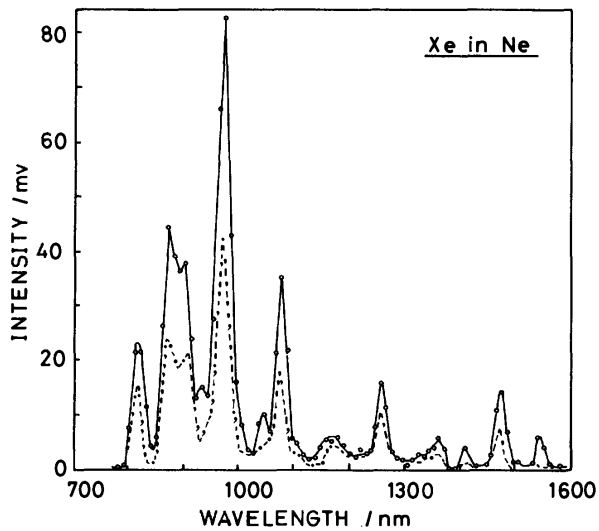

Fig. 2. The emission spectra of Xe in Xe-Ne mixtures at 50 Torr (——) and 80 Torr (----) of Xe in 510 Torr of Ne, respectively.

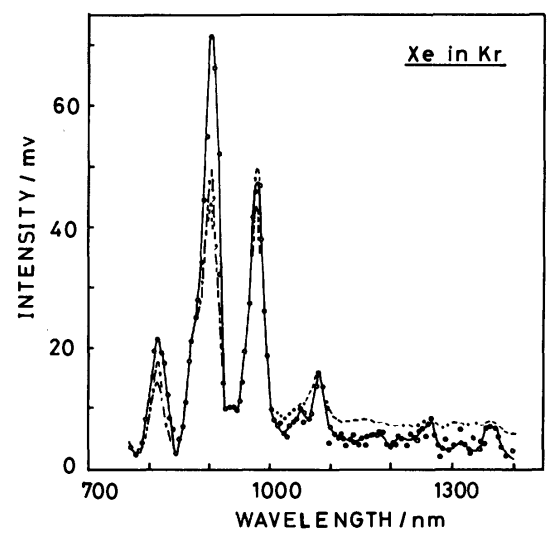

Fig. 3. The emission spectra of Xe in Xe-Kr mixtures at 20 Torr (——), 50 Torr (----), and 100 Torr (----) of Xe in 510 Torr of Kr, respectively.

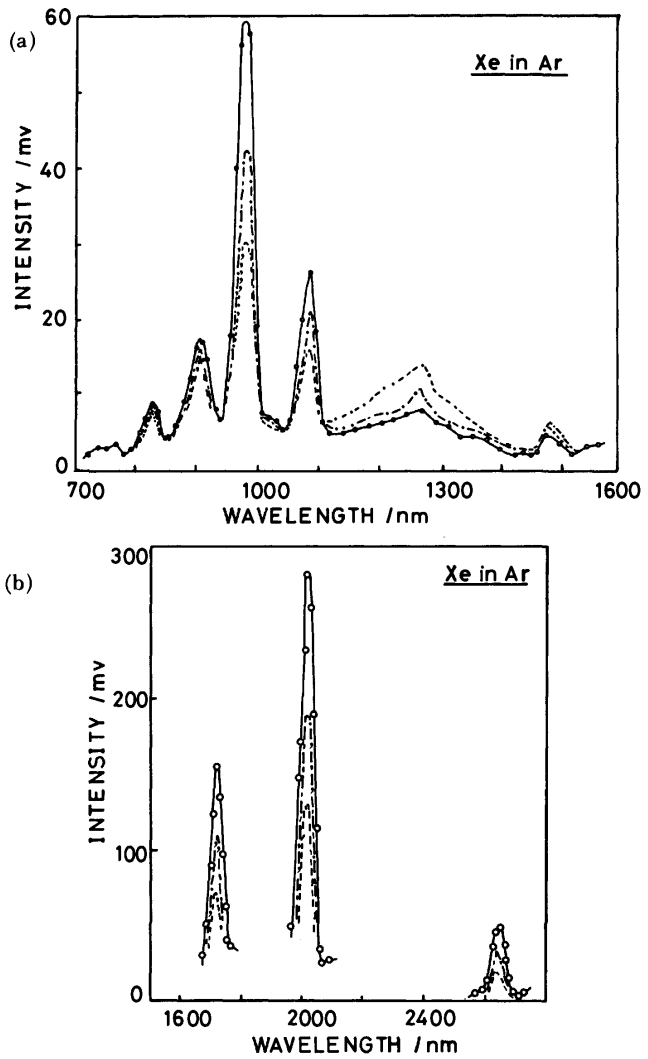

Fig. 4. (a) The emission spectra of Xe in Xe-Ar mixtures at 20 Torr (——), 50 Torr (----), and 80 Torr (----) of Xe in 640 Torr of total pressure, respectively.
(b) The emission bands of Xe 5d(3/2)$_1$ in Xe-Ar mixtures at 5 Torr (——), 10 Torr (----), and 20 Torr (----) of Xe in 640 Torr of total pressure, respectively.

5d(1/2)$_1$. Similarly, the second resonant state of Kr, $^1P_1$, can correlate with Xe 7s(3/2)$_1$. Accordingly, the observed emission lines due to 6p—6s transitions (Fig. 3) would be produced mainly by the de-excitation from lower 5d states and in a cascade from the 7s state. The absence of the continuous band at 1260 nm in the spectra implies that the lower 5d and 7s states of Xe are not involved in the formation of the species responsible for this band.

Emission Spectra in Xe-Ar Mixtures. In the Xe-Ar mixtures, the emissions due to the transition of 6p—6s of Xe and the 1260 nm band were observed, as shown in Fig. 4a. Figure 4b shows the emission lines due to Xe 5d(3/2)$_1$ at the wavelength from 1600 to 2800 nm, where the lines at 1700, 2020, and 2650 nm were observed. The lower states of these emissions are 6p(5/2)$_2$, 6p-(3/2)$_1$ and 6p(1/2)$_0$ (2p$_9$, 2p$_7$, and 2p$_5$ in Paschen notation), respectively. The intensities of the emission due to 6p(1/2)$_1$ (Paschen 2p$_{10}$) at 980 and 1080 nm were the most intense and decreased as the Xe pressure increased, whereas the emission lines at 825 and 900 nm were weak and insensitive to the Xe pressure. The Xe pressure dependence of the 5d emission was very similar to the 2p$_{10}$ emission. The band at 1260 nm began to appear at a Xe pressure greater than 20 Torr. The Xe pressure required to produce the appearance of this band was much lower in Ar compared with that observed in pure Xe, where the band began to appear above 190 Torr. Therefore, it is obvious that this band was induced by an energy transfer from Ar. The major part of the channel of the energy transfer from the excited Ar to Xe was considered to be the Ar atoms in 4s states rather than the lowest excimer state, Ar_2^*, as was considered for the reactions in Xe-Kr. Since all of the 4s states of Ar lie just below the ionization potential of Xe, the energy transfer from the excited Ar to Xe atoms will produce high Rydberg states in Xe. King, Piper and Setser studied the energy-transfer processes of metastable Ar atoms to Xe atoms and identified the emission lines extending from 7d to 10s[10] The production of similar highly excited states is possible in this type of experiment. In fact, the appearance of the emission due to Xe 5d(3/2)$_1$, shown in Fig. 4b, indicates the production of excited Xe atoms at higher Rydberg states, because it is known that in Xe-Ar mixture, the excitation of Ar $^3P_1$, or the selective excitation of higher Rydberg states of Xe above Xe_2^+ state leads to the 5d(3/2)$_1$ emission in VUV region.[11] The de-activation process of such higher Rydberg states has not been investigated except in studies of the collisional and radiative de-excitation of 7p states by Horiguchi and coworkers.[4] However, as the most probable reaction, the Hornbeck-Molner reaction, $Xe^*+Xe \rightarrow Xe_2^+ + e^-$, is known for the excited atoms above the energy state of Xe_2^+ ion (11.16 eV). According to the energetic model of the H-M reaction described by Hurst and Klots,[12] the formation of a highly excited diatomic molecule, Xe_2^{**}, would occur simultaneously with the H-M reaction, if the potential-energy curves for the collision of the highly excited atoms with a ground state atom are essentially parallel with those of the ion-atom system ($Xe^+ + Xe \rightarrow Xe_2^+$). Otherwise, the Xe_2^+ ions produced from the H-M reaction possibly undergo electron-ion recombination to form such highly excited excimers, as suggested by Mulliken[1] and Brodmann and coworkers.[13]

We attributed the band at 1260 nm to the emission from these highly excited excimer states. The Xe level closely resonant with Ar $^3P_1$ are the 9s states (11.58 eV). Then, if the potential minimum of the Xe_2^{**} formed from the 9s atom is as deep as that of the Xe_2^+ ion (0.97 eV), the lower state of this emission is estimated to be about 9.6 eV, which corresponds to the repulsive parts of the potential curves converging to the 6p levels. The band is so broad that it possibly involves several

deactivation processes.

In pure Xe, such highly excited excimer states can be formed by the direct excitation of the ground-state atoms or the vertical excitation of van der Waals molecules. The occurrence of direct excitation is supported by the fact that the addition of a small amount of SF_6 did not affect the emission intensity of the continuous band. On the other hand, the small effect of the addition of SF_6 was observed for the emission of Xe in Ar, in which a small decrease in the emission intensity at 1260 nm was clearly seen. This small decrease is considered to indicate that the ionic processes, such as the dissociative recombination of Ar_2^+, were involved in the formation of Xe_2^{**} in the Xe–Ar mixtures. However, the effect of the SF_6 observed was too small to give a reasonable interpretation so far.

It is less likely that the present band is related to the NIR absorption bands which were observed by Arai and coworkers,[2] because the emission bands could be detected only in the pure Xe and in Xe–Ar mixtures. The species, Xe_2^{**}, in this experiment may have a larger internuclear distance than the $^3\Sigma_u^+$ type excimers.

In conclusion, the continuous band which was observed at 1260 nm in irradiated pure Xe and in the Xe in Ar can be attributed to a transition from molecular states which were related to high Rydberg states just below the ionization potential of Xe and were formed by the Hornbeck-Molnar reaction, followed by ion recombination, or were formed simultaneously with the H–M reaction.

The authors would like to thank Dr. Takeaki Enoto, and Messrs. Hiroaki Tanida and Koichi Sato for their help in the operation of the linac.

Asymmetric Transformation of DL-*p*-Hydroxyphenylglycine by a Combination of Preferential Crystallization and Simultaneous Racemization of the *o*-Toluenesulfonate

Chikara HONGO,* Masanori TOHYAMA, Ryuzo YOSHIOKA, Shigeki YAMADA,† and Ichiro CHIBATA††

Research Laboratory of Applied Biochemistry, Tanabe Seiyaku Co., Ltd., 16-89, Kashima-3-chome, Yodogawa-ku, Osaka 532

(Received October 8, 1984)

The asymmetric transformation of DL-*p*-hydroxyphenylglycine was achieved between two enantiomers by a combination of preferential crystallization of a desired enantiomer of *p*-hydroxyphenylglycine *o*-toluenesulfonate (HPG·*o*-TS) and the simultaneous racemization of the antipode. L-HPG·*o*-TS was easily racemized by heating at 100 °C in aqueous 95% (v/v) acetic acid in the presence of small amounts of salicylaldehyde and free DL-HPG. A supersaturated solution of DL-HPG·*o*-TS placed under such conditions for racemization was seeded with the crystals of D-HPG·*o*-TS, and added with DL-HPG and *o*-toluenesulfonic acid in order to provide continuously the supersaturated state of DL-HPG·*o*-TS as a driving force. As a result, 77.2% of DL-HPG added was transformed to D-isomer.

D-*p*-Hydroxyphenylglycine is useful as a side chain of semisynthetic penicillins or cephalosporins. Our previous paper[1] reported that DL-*p*-hydroxyphenylglycine was resolved by a preferential crystallization procedure in the form of salts with aromatic sulfonic acids such as benzenesulfonic acid, *o*-toluenesulfonic acid, and the like. The preferential crystallization procedure is considered to be a useful method for industrial purposes since it enables the desired optically active isomer to crystallize preferentially from a supersaturated solution of the racemic modification by the simple inoculation of the same isomer. In this procedure, however, there are several disadvantages[2-4] resulting from the fact that the crystallization of the desired isomer by inoculation leads to an excess of the undesired isomer in the solution and the resolution system is racemic as a whole.

The asymmetric transformation[3-5] by a combination of preferential crystallization of the desired isomer and the simultaneous racemization of the undesired isomer is very promising for industrial applications without the disadvantages described above. The asymmetric transformation of *N*-acyl amino acids has been successful[3,4] because *N*-acyl amino acids were easily racemized in the presence of a catalytic amount of acetic anhydride. Many DL-amino acids can be resolved in the form of salts with aromatic sulfonic acids or mineral acids.[1,6] In order to apply the asymmetric transformation to such amino acid salts, it is necessary to determine the conditions of racemization of amino acid salts.

We recently reported[7,8] that the salts of optically active amino acids with sulfonic acids or mineral acids could be racemized by heating moderately in a medium of acetic acid in the presence of small amounts of an aldehyde and free DL-amino acid, and the racemization method could be applied to asymmetric transformation of amino acids. Using the racemization method, we studied the asymmetric transformation by a combination of the optical resolution of DL-*p*-hydroxyphenylglycine *o*-toluenesulfonate (DL-HPG·*o*-TS) and the simultaneous racemization of the salt.

Since the solubility of DL-HPG·*o*-TS in acetic acid is very low (at 80 °C and 100 °C, 1.80 and 3.06 g/100 ml AcOH, respectively), it is preferable to use aqueous acetic acid to obtain a practical starting concentration for the asymmetric transformation. The effects of salicylaldehyde and DL-HPG on racemization of L-HPG·*o*-TS in aqueous acetic acid were examined. As shown in Table 1, the racemization of the salt was accelerated in the presence of salicylaldehyde, DL-HPG, or both. Although the rate of racemization, which is an important factor in this kind of asymmetric transformation, decreased with an increase in the water content of the acetic acid, a racemization rate sufficient for the asymmetric transformation was obtained by the presence of both salicylaldehyde and DL-HPG in aqueous 95% (v/v) acetic acid. Therefore, the asymmetric transformation was thereafter carried out in aqueous 95% (v/v) acetic acid. The rate of racemization was greatly influenced by temperature as shown in Fig. 1. A temperature higher than 90 °C was necessary for practical racemization.

When DL-HPG·*o*-TS was crystallized from a solution placed under the racemizing conditions as described above, the IR-spectrum and the melting point of the DL-HPG·*o*-TS obtained were identical with those of

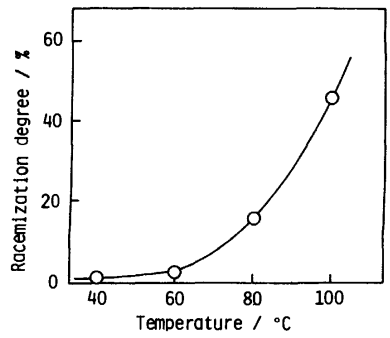

Fig. 1. Effect of temperature on racemization of L-HPG·*o*-TS.
The reactions were carried out for 1 h in aqueous 95% acetic acid in the presence of salicylaldehyde and DL-HPG.

racemic mixture of DL-HPG·*o*-TS obtained in our previous paper;[1] this indicates that DL-HPG·*o*-TS crystallizes as a racemic mixture suitable for the preferential crystallization procedure also under such racemizing conditions. The crystals of D-HPG·*o*-TS were confirmed to be not racemized under the above conditions for racemization in a liquid phase. Thus, the most essential requirement for this kind of asymmetric transformation was fulfilled.

Then, to find the possibility of the asymmetric transformation of DL-HPG, a batch-asymmetric transformation was carried out. The supersaturated solution of DL-HPG·*o*-TS placed under the racemizing conditions described above was seeded with the crystals of D-HPG·*o*-TS and stirred for 2 h. The crystallized crop and the second crop obtained from the mother liquor were analyzed. As a result, it was found that the preferential crystallization of seeded D-HPG·*o*-TS and the racemization of unseeded L-HPG·*o*-TS took place at the same time and 17% of DL-HPG·*o*-TS was transformed to D-HPG·*o*-TS.

Since the driving force for the preferential crystallization of a seeded isomer is provided only by the supersaturated state of the racemic modification, the yield of the enantiomer produced by this type of asymmetric transformation is dependent on the extent of the supersaturated state of the racemic modification. In a batch transformation, the yield is relatively low because the starting supersaturation degree is limited by the stability of the supersaturated state. To obtain a higher yield of the enantiomer, it is necessary to make up for the decrease of the supersaturation degree due to the preferential crystallization.

In the asymmetric transformation of DL-HPG·*o*-TS, the supersaturated state could not be continuously provided by cooling the solution because the racemization did not proceed at a low temperature (Fig. 1). In the present work, the supersaturated state was maintained continuously by suspending free DL-HPG in the reaction mixture and then by adding *o*-toluenesulfonic acid, thereto, to form the salt of DL-HPG·*o*-TS in the liquid phase. In this case, fortunately,

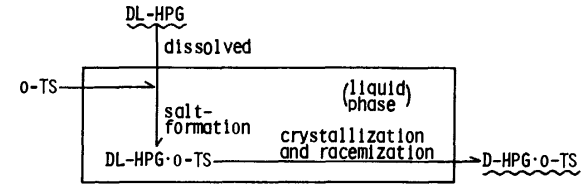

Fig. 2. Continuous asymmetric transformation of DL-HPG. ~~~, solid state.

the suspension of free DL-HPG is preferable since the presence of free DL-HPG in the liquid phase is essential for accelerating the racemization of L-HPG·*o*-TS. DL-HPG·*o*-TS resulting from free DL-HPG and the added *o*-toluenesulfonic acid can exist in a supersaturated state under an appropriate rate of the addition of *o*-toluenesulfonic acid, and can serve for the asymmetric transformation. The continuous asymmetric transformation presented here was carried out in such a suspension system in expectation of a repetition of the following process: dissolution of suspended DL-HPG, formation of DL-HPG·*o*-TS to result a supersaturated state, and preferential crystallization and simultaneous racemization toward the resulting DL-HPG·*o*-TS. The pathway is shown in Fig. 2.

o-Toluenesulfonic acid has two moles of water of crystallization which can not be easily removed. The addition of the dihydrate into the reaction mixture results in an increase of the water content in the reaction system and consequently in the lowering of the racemization rate. Therefore, *o*-toluenesulfonic acid dihydrate was dissolved in acetic anhydride, which reacted with the water of crystallization at 100°C to form acetic acid. This was added to the reaction system in the form of an acetic anhydride solution of *o*-toluenesulfonic acid dihydrate. The pouring speed of the *o*-toluenesulfonic acid solution, *i. e.*, the speed of producing a supersaturated state, was controlled to meet the rate of crystallization of D-HPG·*o*-TS and the rate of racemization of L-HPG·*o*-TS. Namely, into a heterogeneous mixture consisting of 19.0 g of DL-HPG·*o*-TS, 1.25 ml of salicylaldehyde, 51.0 g of free DL-HPG, and 100 ml of aqueous 95% (v/v) acetic acid, 2.0 g of crystals of D-HPG·*o*-TS was seeded at 100°C. Then, the solution consisting of 62.5 g of *o*-toluenesulfonic acid dihydrate and 62.5 ml of acetic anhydride was poured at the rate of 5.0 ml/h into the mixture maintained at 100°C under stirring. The precipitated crystals were separated to give 82.8 g of almost optically pure D-HPG·*o*-TS. The material remaining in the filtrate was nearly racemic. The change in the composition of both enantiomers by the reaction is shown in Fig. 3. The result suggests that 77.2% of suspended DL-HPG was transformed to D-HPG *via* the pathway as shown in Fig. 2. The D-HPG·*o*-TS obtained above was easily decomposed to D-HPG without racemization by neutralization.

The asymmetric transformation between two dia-

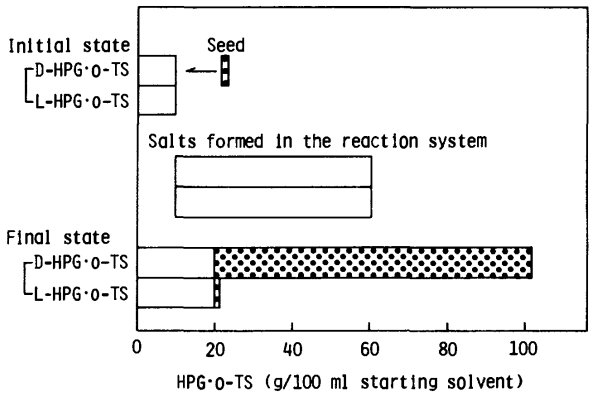

Fig. 3. The change in the composition of both enantiomers by continuous asymmetric transformation. ▩, crystals of HPG·*o*-TS; □, HPG·*o*-TS in solution.

stereoisomers by a combination of selective precipitation of the less soluble diastereoisomer and epimerization of the soluble diastereoisomer is well-known as an asymmetric transformation of the second order.[9] However, an asymmetric transformation between two enantiomers by a combination of preferential crystallization of a desired enantiomer and the simultaneous racemization of the antipode is unique and has not been reported except for a few examples.[3-5] It is necessary in this kind of asymmetric transformation to devise a way in which the supersaturated state is provided as a driving force. In the case of the asymmetric transformation of DL-HPG proposed here, the supersaturated state of DL-HPG·*o*-TS could be easily produced by adding DL-HPG and *o*-toluenesulfonic acid into the reaction system. If DL-HPG·*o*-TS in a supersaturated state is formed at a rate which meets the rates of preferential crystallization and racemization, the reaction proceeds in a high concentration of slurry state. The proposed method seems very promising for the industrial production of D-HPG because of its operational simplicity and high yield.

Experimental

Materials and Analyses. Optically active and racemic HPG manufactured by our company, Tanabe Seiyaku Co., Ltd., were used. *o*-Toluenesulfonic acid, salicylaldehyde, and other chemicals were obtained from Tokyo Kasei Kogyo Co., Ltd. Optically active and racemic HPG·*o*-TS were prepared in a manner described in a previous report.[1] All samples were dried overnight *in vacuo* at 40°C. Optical rotation was measured with a Perkin-Elmer 141 automatic polarimeter. The water content of samples was determined by the Karl-Fischer's method.

Racemization of L-*HPG·o-TS.* Unless otherwise noted, a mixture of L-HPG·*o*-TS (50 mg), DL-HPG (5 mg), salicylaldehyde (3 μl), and acetic acid containing 5% water (5 ml) was heated in a sealed tube at 100°C for 1 h or 3 h. After the reaction mixture was diluted with 1 M hydrochloric acid (5 ml (1 M=1 mol dm^{-3})), the optical rotation was measured. The racemization degree was calculated in the same way as described in a previous report.[7] The effect of DL-HPG or salicylaldehyde in acetic acid containing water and the effect of the reaction temperature are shown in Table 1 and Fig. 1, respectively.

Crystallization of DL-*HPG·o-TS from Racemizing Solution.* A mixture of DL-HPG·*o*-TS (3.8 g), DL-HPG (0.2 g), and salicylaldehyde (0.25 ml) was dissolved in acetic acid (20 ml) containing 5% water under reflux and maintained at 100°C. The solution was seeded with finely pulverized crystals of DL-HPG·*o*-TS (10 mg) and stirred for 5 h at the same temperature. The precipitated crystals were quickly separated by filtration, washed with a small amount of AcOH, and dried to give DL-HPG·*o*-TS (0.92 g) crystallized from racemizing solution. The melting point (213—215°C, dec) and IR-spectrum of the DL-HPG·*o*-TS were identical with those of racemic mixture of DL-HPG·*o*-TS shown in previous report.[1]

Stability of Crystalline D-*HPG·o-TS under Conditions for Racemization.* A mixture of DL-HPG·*o*-TS (1.0 g), DL-HPG (40 mg), and salicylaldehyde (50 mg) was dissolved in AcOH containing 2% water under reflux to prepare a solution saturated with DL-HPG·*o*-TS at 100°C. To the saturated solution maintained at 100°C, crystals of D-HPG·*o*-TS (2.0 g) were added. The heterogeneous reaction mixture was stirred for 5 h at the same temperature. The insoluble crystals were quickly separated by filtration, washed with a small amount of AcOH, and dried. The insoluble crystals proved to be optically pure D-HPG·*o*-TS (1.9 g), $[\alpha]_D^{25}$ −66.6° (c=1, water).

Asymmetric Transformation. Batch Transformation: A mixture of DL-HPG·*o*-TS (3.8 g), DL-HPG (0.2 g), salicylaldehyde (0.25 ml) and AcOH (20 ml) containing 5% water was heated under reflux until a complete solution occurred and was maintained at 100°C. The supersaturated solution was seeded with finely pulverized crystals of D-HPG·*o*-TS (0.2 g) and stirred for 2 h at the same temperature. The precipitated crystals were quickly separated by filtration, washed with a small amount of AcOH, and dried to give D-HPG·*o*-TS (0.85 g), $[\alpha]_D^{25}$ −66.6° (c=1, water), optical purity 100%. Subtracting 0.2 g of seeded D-HPG·*o*-TS, 0.65 g of pure D-HPG·*o*-TS was obtained. After the separation of D-HPG·*o*-TS, the filtrate was stirred at 20°C for 2 h and the precipitated crystals were collected by filtration to give DL-HPG·*o*-TS (2.66 g), $[\alpha]_D^{25}$ +0.6° (c=1, water). The mother liquor did not show any optical rotation. Therefore, the whole reaction mixture became 17.1% enantiomeric excess.

Continuous Transformation: A mixture of DL-HPG·*o*-TS (19.0 g) and aqueous 95% (v/v) acetic acid (100 ml) in a three-necked flask fitted with a mechanical stirrer and a condenser was heated under reflux until complete solution occurred. Then the flask was placed in an oil bath controlled at 100°C. Salicylaldehyde (1.24 ml) was added to the solution and DL-HPG (51.0 g) was suspended therein. After 20 min, into the heterogeneous reaction mixture were added under stirring finely pulverized crystals of D-HPG·*o*-TS (2.0 g) as seed crystals. To this was poured a solution consisting of *o*-toluenesulfonic acid dihydrate (62.5 g) and acetic anhydride (62.5 ml) at the rate of 5.0 ml/h by a Micro Feeder JP-W (Furue Science Co., Ltd.). At 5 h and 20 h after the addition of the seed crystals, 1.3 ml and 0.7 ml of salicylaldehyde were added to the mixture, respectively. The mixture was stirred at the same temperature for total 30 h. The precipitated crystals were quickly collected by filtration, washed with a small amount of acetic acid, and dried to give D-HPG·*o*-TS (82.8 g), $[\alpha]_D^{25}$ −64.9° (c=1, water), optical purity 97.4%.

After the separation of D-HPG·*o*-TS, the filtrate was stirred for 2 h at room temperature and the precipitated crystals were collected by filtration to recover DL-HPG·*o*-TS (18.2 g), $[\alpha]_D^{25}$ 0.0° (c=1, water). The filtrate did not show any optical rotation. The change in the composition of both enantiomers by the reaction is shown in Fig. 3.

Preparation of D-*HPG.* The D-HPG·*o*-TS (82.0 g) obtained above was dissolved in water (230 ml) at an elevated temperature and was treated with charcoal. The solution was adjusted to pH 6 with 5 M sodium hydroxide and allowed to stand in a refrigerator overnight. The resulting precipitates were collected, washed with water, and dried to give D-HPG (34.0 g), $[\alpha]_D^{25}$ −158.2° (c=1, M-HCl).

Crystal and Molecular Structures of Fenethazine Hydrochloride and Its Cation Radical-Copper(II) Complex Salt

Atsuo OBATA, Masahiro YOSHIMORI, Koh-ichi YAMADA, and Hiroshi KAWAZURA*
Faculty of Pharmaceutical Sciences, Josai University, Keyakidai, Sakado, Saitama 350-02
(Received June 25, 1984)

The crystal structures of fenethazine hydrochloride hydrate (FTZ·HCl) and $[FTZ\,H]^{2+}\cdot[CuCl_4]^{2-}$ (FTZ-Cu) were determined. FTZ·HCl crystallized in the monoclinic space group $P2_1/a$ with $a=8.686(1)$, $b=31.660(2)$, $c=6.140(1)$ Å, $\beta=100.44(1)°$, $V=1660.5(3)$ Å^3, and $Z=4$. FTZ-Cu crystallized in the triclinic space group $P\bar{1}$ with $a=20.433(5)$, $b=12.721(4)$, $c=7.526(2)$ Å, $\alpha=91.31(3)$, $\beta=94.56(3)$, $\gamma=99.69(2)°$, $V=1920.9(1)$ Å^3, and $Z=4$. The structures were solved using the heavy-atom method and were refined by the block-diagonal least-squares method. The final R values were determined to be 0.052 for FTZ·HCl and 0.050 for FTZ-Cu. The formation of a cation radical causes the phenothiazine ring of the FTZ molecule to be flattened; the dihedral angle between benzene rings is increased from 140.3° for FTZ·HCl to 174.7 or 167.5° for FTZ-Cu. The 2-aminoethyl chain holds a trans conformation in FTZ-Cu and a near gauche form in FTZ·HCl. In FTZ·HCl crystals, the FTZ molecules form a layer along a in which the molecules array the phenothiazine ring as faced with the ring in the neighboring layer. In FTZ-Cu, two FTZ molecules form a pair with a close overlap of the phenothiazine rings, directed approximately perpendicular to a. The $CuCl_4^{2-}$ is located so as to counterbalance both the positive charge of the ring and the protonated amino group of the side chain.

It is well known that phenothiazine drugs have many therapeutical uses and that variations of substituents at the 2- and 10-positions in the tricyclic ring system are responsible for the diversity of pharmacological activities. Conformational studies on drugs with a 3-aminopropyl chain at the 10-position, which are mainly employed as tranquilizers, have been reported in connection with the structure-activity relationship.[1,2] However, no structural analysis has been described yet on drugs bearing a 2-aminoethyl substituent at the same position, showing the efficacy of antihistaminics. These types of drugs are easily converted into one-electron-oxidation products under relatively mild conditions owing to the low ionization potential of the phenothiazine ring.[3] Horse-radish peroxidase catalyzes 2-chloro-10-(3-dimethylaminopropyl)phenothiazine (chlorpromazine, CPZ) *in vitro* in the presence of hydrogen peroxide to the cation radical species.[4] Thus, it is expected that such cation radicals of the drugs may be generated *in vivo* and may play some kind of pharmacological role.[5]

	R_1	R_2
CPZ :	Cl	$(CH_2)_3N(CH_3)_2$
PMZ:	H	$(CH_2)_3N(CH_3)_2$
FTZ :	H	$(CH_2)_2N(CH_3)_2$

In the course of our study regarding the interaction between neuroleptics and copper ions, we prepared stable complex salts of CPZ[6] and 10-(3-dimethylaminopropyl)phenothiazine (promazine, PMZ)[7] cation radicals with $[CuCl_4]^{2-}$ and determined their structures. So far, only the perchlorate salt of the CPZ cation radical has been obtained in crystal form among this type of drug,[8-10] though the structure has not been clarified. An application of a similar synthetic method[6] to 10-(2-dimethylaminoethyl)phenothiazine (fenethazine, FTZ) afforded stable crystals of the cation radical salt composed of $[FTZ\,H]^{2+}\cdot[CuCl_4]^{2-}$ (FTZ-Cu). In this paper we describe the crystal and molecular structures of FTZ·HCl and FTZ-Cu and discuss the structural differences between them.

Experimental

The FTZ·HCl was prepared by coupling *N,N*-dimethyl-2-chloroethylamine with phenothiazine[11] and crystallizing with water to yield white needles with the composition FTZ·HCl·H_2O. The FTZ-Cu was obtained as black plates according to a previously reported method.[7] Found: C, 40.06; H, 3.60; N, 5.57%. Calcd for $[FTZ\,H]^{2+}\cdot[CuCl_4]^{2-}$ ($C_{16}H_{19}N_2SCuCl_4$): C, 40.31; H, 4.02; N, 5.88%. The crystals were stable in air for several months when dried, although they decomposed slowly in aqueous solutions.

The X-ray diffraction data were measured on a Rigaku AFC-5 automatic four-circle diffractometer using graphite-monochromated Cu $K\alpha$ radiation ($\lambda=1.5418$ Å). The unit-cell parameters were refined from least-squares fits of 24 2θ values ($48<2\theta<52°$) for FTZ·HCl and 50 ($48<2\theta<53°$) for FTZ-Cu. The crystal data and a part of the experimental details are tabulated in Table 1. Intensities were measured by the θ–2θ scan technique and the counting time was 1 s. Each background was measured for 10 s at the begining and end of the scan range. During data collection, three standard reflections were monitored every 100 or 50 reflections and showed no significant variation in their intensities. For FTZ·HCl, 3226 reflections with $2\theta\leq130°$ were measured and 2297 independent reflections with $|F_o|>3\sigma(|F_o|)$ were used for the structure determination. For FTZ-Cu, 5557 reflections with $2\theta\leq120°$ were collected and 4478 reflections with $|F_o|>12\sigma(|F_o|)$ were used in the subsequent analysis. Each data set was corrected for Lorentz and polarization effects, but not for absorption.

The structures were solved using the heavy-atom and Fourier methods and were refined by the block-diagonal least-squares method. The minimized function was $\sum w(|F|-|F_c|)^2$,

where $w=1/[\sigma^2+(0.02F_o)^2]$. All the positional parameters and anisotropic thermal parameters for non-hydrogen atoms, and isotropic thermal parameters for hydrogen atoms were refined. All the parameter shifts in the final cycle of the refinement were less than 0.2σ for both compounds. The final R values were 0.052 for FTZ·HCl and 0.050 for FTZ-Cu.

The neutral atomic-scattering factors were taken from the International Tables for X-ray Crystallography.[12] All the calculations were carried out on a FACOM M-160F computer at Josai University using the UNICS III[13] and ORTEP[14] programs. The final positional and thermal parameters (with standard deviations) are given in Tables 2 and 3. Data regarding structure factors, anisotropic thermal parameters, and hydrogen-atom coordinates have been deposited in the office of the Chemical Society of Japan (Document No. 8507).

Results and Discussion

The FTZ-Cu displays a maximum (electronic spectrum) at 513 nm (ε 9500) in aqueous solution and at 560—580 nm (broad band) in the solid state. These appear also for the CPZ-Cu and PMZ-Cu complex salt and are ascribable to the cation radical species of the phenothiazine ring in agreement with the maximum wavelengths reported for the cation radicals of the same ring.[15]

The molecular structures and atom-numbering are given in Figs. 1 and 2, and the bond lengths and angles are listed in Table 4. As the difference Fourier maps revealed the hydrogen atom attached to the N(17) atom

in both compounds, a positive charge in FTZ·HCl is located on the amino group of the side chain, and the same group together with the tricyclic ring in FTZ-Cu

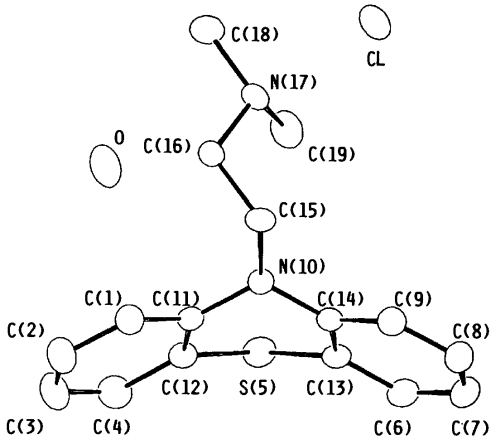

Fig. 1. Perspective view of FTZ·HCl·H_2O with 50% probability ellipsoids.

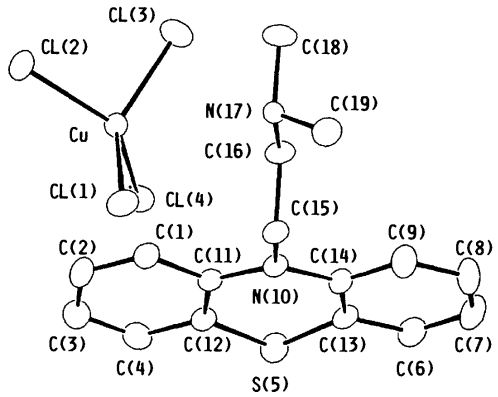

Fig. 2. Perspective view of $[FTZ\ H]^{2+}\cdot[CuCl_4]^{2-}$ (A) with 50% probability ellipsoids.

bears a positive charge. In the FTZ-Cu crystals there are two crystallographically independent FTZ molecules and two independent $[CuCl_4]^{2-}$ ions with different bond lengths and angles (hereafter discriminated by the notation A and B, respectively).

The conversion into the cation radical salt causes the almost planar geometry of the phenothiazine ring in the FTZ molecule as is obvious by a comparison of Figs. 1 and 2. The dihedral angle between the lateral benzene rings is 174.7° in FTZ-Cu (A) and 167.5° in FTZ-Cu (B). All the component atoms in the ring lie on a near plane, while the angle in FTZ·HCl is 140.3° owing to the folding of the ring around the S-N axis. This results in a bent boat-form. The C-N and C-S bond lengths in the thiazine ring of FTZ·HCl are approximately the same as those of *N*-methylphenothiazine (the C-N and C-S bond lengths are 1.402 and 1.764 Å, respectively).[16] The C-N-C and C-S-C angles in the ring are also in accordance with the 118° of the C-N-C angle and the 97° of the C-S-C in *N*-methylphenothiazine. These facts indicate that the positive charge on the protonated amino group of the side chain causes no significant perturbation in the structure of the phenothiazine moiety. On the other hand, the geometry of the thiazine ring in FTZ-Cu reveals a clear difference in comparison with that in

FTZ·HCl. The C-N and C-S bonds are shortened by the ranges of 0—0.03 and 0.04—0.05 Å, respectively. The C-N-C and C-S-C angles are spread by 5.4 (A) and 4.8 (B), and 3.3°, respectively, implying an increase of the double-bond characteristics of both bonds. In particular, the C-S bond lengths become shorter than the value of 1.740 Å reported regarding an aromatic molecule, dibenzothiophene.[17] The sums of the three bond angles around the N(10) atom amount to 359.6(9) (A) and 360.0(9)° (B). This indicates that the N(10) atom sustains a substantial sp^2 hybridization in contrast to the large sp^3 character of the corresponding N atom in the phenothiazine molecule.[18] These geometrical features signify that the π-electrons are delocalized over the tricyclic ring system by forming a cation radical salt. This situation is similar to the cases of the CPZ-Cu and PMZ-Cu complex salt.

The 2-aminoethyl chains of both compounds elongate into the direction approximately bisecting the external angle of C(11)-N(10)-C(14). The N(10)-C(15)-C(16)-N(17) torsion angles of 174.7° in FTZ-Cu (A) and of 181.7° in FTZ-Cu (B), holding trans conformations, are much greater than that of 89.0° in FTZ·HCl, being in a near gauche conformation. On the assumption that the cationic charge on the phenothiazine ring localizes in the center of the ring, tentative calculations demonstrate that the distances from the middle point between the S(5) and N(10) atoms in the ring to the N(17) atom in the side chain attain 4.002 Å in FTZ·HCl, and 4.650 (A) and 4.724 Å (B) in FTZ-Cu. This difference suggests that the two positive charges in the FTZ molecule of FTZ-Cu keep each other apart to make the electrostatic repulsion between them as small as possible.

Figures 3 and 4 show the crystal packing diagrams of both compounds. In the FTZ·HCl crystals, the FTZ molecules arrange themselves in layers along the a axis. Along the b axis, the phenothiazine moieties of the two FTZ molecules are coupled with the insertion of one of the lateral benzene rings into the void volume of the bent plane to one another. This packing fashion resembles that of 10H-phenothiazine-10-propionic acid as reported by S. M. C. Malmstrom *et al.*[19] It is interesting that the different substituents with an opposite polarity, such as a carboxyl and amino group, afford similar packing arrangements. The closest in-

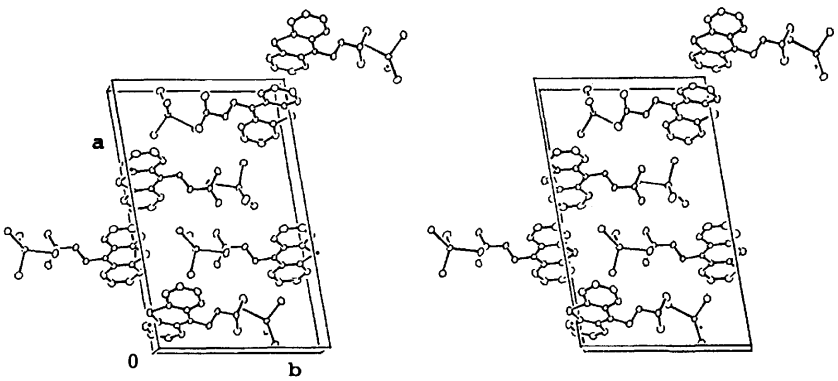

Fig. 4. Stereoscopic diagram of the crystal structure of $[FTZ\ H]^{2+\cdot}$-$[CuCl_4]^{2-}$ viewed down c.

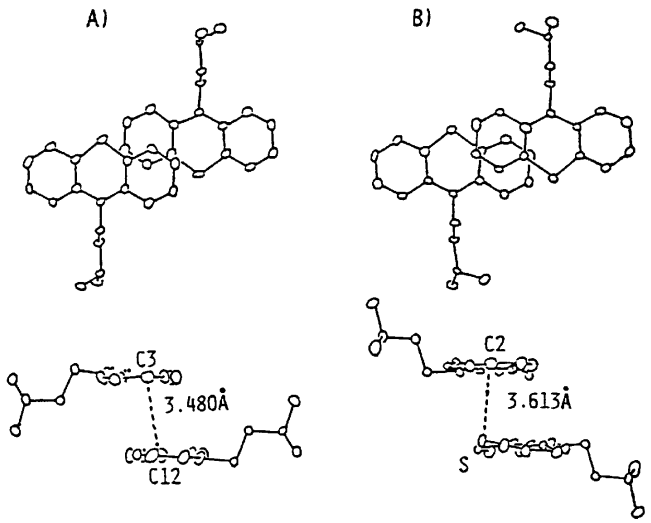

Fig. 5. Intermolecular overlap of the FTZ molecular pair in the $[FTZ\ H]^{2+\cdot}$ $[CuCl_4]^{2-}$ crystals.

termolecular contact is observed for C(7)-C(12^{ii}) [symmetry code: ii) $-x$, $-y$, $-z$] as 3.495(5) Å and all the other nonbonded contacts are greater than the sum of the van der Waals radii of the atoms. The chloride ions and the water molecules of crystallization are located in the vicinity of the ammonium groups of the side chains. The close contacts between these groups reveal the existence of a bridge structure linked with the hydrogen bonds (two hydrogen atoms of water are expressed as H(O1) and H(O2)): N(17)-Cl 3.042(2), H(17)-Cl 2.08(3), Cl-H(O2) 2.55(4), and H(O1)-Cl^{ii} 2.19(5) Å. In the case of the FTZ-Cu crystals, two crystallographically equivalent FTZ molecules form a pair with each other with the inversion centers to give a parallel overlap of the flattened phenothiazine rings. The side chains of the different pairs are stretched out in alternative directions as shown in Fig. 5; inside the faced planes (A) and outside the faced planes (B). The shortest intermolecular contact between the faced planes is seen for C(3)-C(12^{ii}) as 3.480(8) Å in an A pair, and for C(2)-S(5^{ii}) as 3.613(6) Å in a B pair. These values are within the van der Waals distances of the atoms, sufficiently indicating the intermolecular interaction between the faced rings. This type of dimer-like structure is widely seen in many organic radicals[20] and may contribute to the stabilization of the compounds in crystals. However, in the present case the degree of the ring overlap is relatively small.

The tetrachlorocuprate(2-) ions in which the copper atom has a pseudotetrahedral coordination sphere are positioned so as to neutralize the cationic charges of the phenothiazine ring and the protonated amino group in one pair and that of the ring in another pair. Among the coordinating chlorine atoms, the close nonbonded contacts occur around the Cl(4) (A) and Cl(1) (B) atom: Cl(4)(A)-N(17) 3.312(4), Cl(4)(A)-H(17) 2.56(5), Cl(1)(B)-N(17) 3.238(5), and Cl(1)(B)-H(17) 2.49(7) Å. These Cl-H distances are within the accepted hydrogen-bond range[21] and the Cl-N distances are considerably shorter than the van der Waals distances. This fact suggests that the electrostatic bonds that stand between N(17) and Cl(4)(A) or Cl(1)(B) are mediated through the hydrogen bonds.

In conclusion, FTZ-Cu differs largely from FTZ·HCl not only in its molecular structure but also in its crystal-packing mode. This differenece arises from the cation radical formation of the FTZ molecule. This fact might provide a clue to the explication of the pharmacological effect of the drug from a structural point of view, though it remains uncertain at the present stage.

The authors wish to express their thanks to Dr. Hiroshi Miyamae of the Faculty of Science at this University for sharing his expertize on X-ray analysis techniques.

Mössbauer Spectroscopic Studies of the Correlation between Molecular Structure and Sign of Quadrupole Splitting in Tris(β-diketonato)-iron(III) Complexes Utilizing Paramagnetic Relaxation Effects

Shigeru YAMAUCHI, Yoichi SAKAI, and Takeshi TOMINAGA*
Department of Chemistry, Faculty of Science, The University of Tokyo, Hongo, Bunkyo-ku, Tokyo 113
(Received July 16, 1984)

The change of the Mössbauer line shape with the paramagnetic relaxation time was studied in several tris(β-diketonato)iron(III) complexes to determine the sign of the quadrupole splitting. The correlation observed between the molecular structure and the sign of the quadrupole splitting demonstrates that the sign should depend on the bond angle (∠O-Fe-O) in iron(III) complexes.

The paramagnetic relaxation effects in Mössbauer spectroscopy have been ascribed to fluctuations of magnetic fields arising from flips of electronic spins.[1-3] Such magnetic fluctuations are either a spin-spin or spin-lattice relaxation process. The overall relaxation rate λ_t is expressed as $\lambda_t=\lambda_{SS}+\lambda_{SL}$, where λ_{SS} and λ_{SL} are relaxation rates *via* spin-spin and spin-lattice interactions, respectively. The relaxation time τ_t is the reciprocal of λ_t.

The line shape of the observed Mössbauer spectrum greatly depends on λ_t (or τ_t). The paramagnetic relaxation effects have been studied mainly for high-spin iron(III) species.[4-10] This is because there is a very small contribution from λ_{SL} to the relaxation rates which facilitates a discussion of the correlation between the Mössbauer line shape and the molecular structure.

It has been shown that the sign of the electric-field gradient can be determined by examining the asymmetry in a Mössbauer spectra *via* the paramagnetic relaxation processes.[11,12] Bancroft and co-workers[5] claimed that the asymmetric line shapes observed in Mössbauer spectra of a few tris(β-diketonato)iron(III) complexes indicate the presence of positive electric-field gradients. However, the experimental evidence seems to be too ambiguous to support their conclusion. Recently, we studied the paramagnetic relaxation effects in the Mössbauer spectra of eleven tris(β-diketonato)iron(III) complexes using the Mössbauer linewidth as a measure of the relaxation time. We found that the relaxation time increases with an increase in the iron-iron distance but decreases with an increasing temperature.[13] Although the Mössbauer spectra of most complexes were composed of a broad symmetric singlet, asymmetric peaks were observed in several complexes with relatively short relaxation times. Besides, there were complexes which seemed to have negative quadrupole splittings.

In general, it is difficult to definitely prove the presence of small quadrupole splittings. However, it should be possible to determine the sign as well as the presence of a small quadrupole splitting in high-spin iron(III) compounds by examining the change of the Mössbauer line shape associated with the paramagnetic relaxation time.

In the present work, we have measured the Mössbauer spectra of iron(III) complexes diluted in diamagnetic compounds in order to vary the paramagnetic relaxation time due to the spin-spin interaction. The temperature-dependence of the Mössbauer line shape in these systems was also examined because the relaxation time was varied with the temperature through the spin-lattice interaction.

Based on the sign of the quadrupole splitting determined utilizing paramagnetic relaxation effects, we discuss here the molecular structures, especially the coordinating bond angle of tris(β-diketonato)iron(III) complexes.

Experimental

Materials. The iron(III) compounds studied in this work are summarized in Table 1. Most compounds were synthesized and/or purified by modifying some procedures mentioned in the literature.[14-16] The purities of the ob-

tained compounds were checked by elementary analysis, and UV-visible and infrared spectroscopy. The results of the elementary analyses are summarized in Table 1.

Solid solutions of (Fe, Al)(oxin)$_3$ were prepared by coprecipitating oxinates of iron(III) and aluminum(III). After an 8-quinolinol (oxine) ethanol solution was added (slightly in excess) to an aqueous solution of $FeCl_3$ and $AlCl_3$ with known concentrations, the pH in the mixed solution was quickly adjusted to about 7 with a sodium acetate aqueous solution. The mole fraction of Fe(oxin)$_3$ in the precipitate was determined by means of colorimetry. Solvated compounds, Fe(acac)$_3$·2$CHCl_3$ and Fe(acac)$_3$·2CH_2Cl_2, were prepared by recrystallizing from each solvent[17] and their compositions were checked by measuring the weight-loss during storage in air after a Mössbauer measurement.

Measurements of Mössbauer Spectra. Mössbauer spectra were recorded at 78, 195, and 295 K using a Shimadzu MEG-2 or an Austin S-600 Mössbauer spectrometer. An iron foil was used for the calibration of Doppler velocity.

Results and Discussion

Determination of Sign of Quadrupole Splitting from Change in Mössbauer Line Shape. (a) Solid Solution: Figure 1 shows the Mössbauer spectra at 78 K of neat Fe(oxin)$_3$ and solid solutions of (Fe,Al)(oxin)$_3$. The line shape may be regarded as a symmetric doublet in the neat Fe(oxin)$_3$. The right (higher energy side) component of the doublet tends to collapse and broaden as the Fe(oxin)$_3$ content in solid solutions decreases, leading to larger distance between Fe(oxin)$_3$ molecules and thus to longer relaxaton time. The two peaks eventually merge into an asymetric single peak.[18] Since the electric-field gradient and the quadrupole splitting have the same sign in ^{57}Fe-Mössbauer spectroscopy, it is expected that the right side peak broadens first in the presence of positive quadrupole splitting whereas the left side peak collapses first in case of negative quadrupole splitting.[19] Accordingly, the change in the Mössbauer line shape shown in Fig. 1 reveals that the iron in Fe(oxin)$_3$ experiences a positive electric-field gradient and, hence, the sign of the quadrupole splitting is positive. Thus, it is shown that the sign of the quadrupole splitting in high-spin iron(III) compounds can be determined by examining the change in the Mössbauer line shape with a relatively small change in the relaxation time caused by the reduced spin-spin interaction due to the increased distance between Fe(oxin)$_3$ molecules in the (Fe, Al)(oxin)$_3$ system.

(b) Solvated Compound: Similar experiments were carried out to determine the sign of the quadrupole splitting in Fe(acac)$_3$. However, it proved quite difficult to determine the sign in the systems of (Fe,Al)-(acac)$_3$ and (Fe, Co)(acac)$_3$ with this method because of the very small quadrupole splitting expected in Fe-(acac)$_3$ and the difficulty in preparing solid solutions with slightly different Fe(acac)$_3$ contents. Accordingly, two solvated compounds, Fe(acac)$_3$·2$CHCl_3$ and Fe(acac)$_3$·2CH_2Cl_2, were prepared instead to increase the iron-iron distance slightly. The spectra of the solvated compounds at 78 K are shown in Fig. 2 together with neat Fe(acac)$_3$. In Fig. 2, a very small quadrupole splitting is seen in Fe(acac)$_3$ while a sharp singlet peak is observed in each solvated compound. The sharp peak-top position in the solvated compounds agrees exactly with that of the left-component peak in Fe-

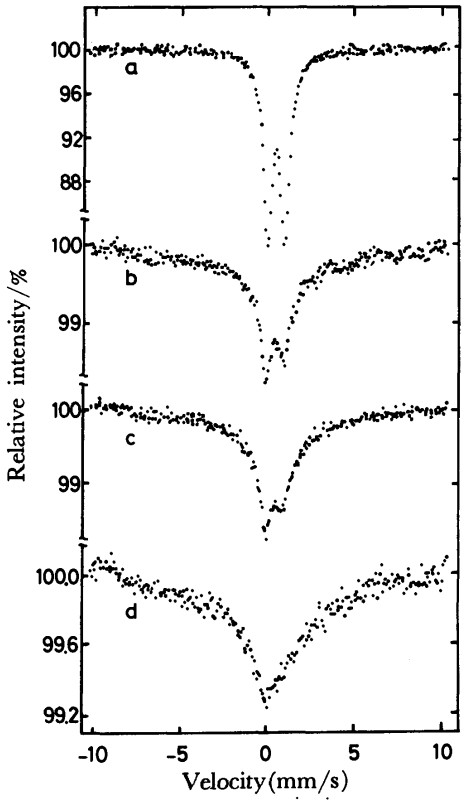

Fig. 1. Mössbauer spectra at 78 K of (Fe,Al) (oxin)$_3$ solid solutions with the Fe(oxin)$_3$ mole fraction of a) 1.0, b) 0.5, c) 0.4, and d) 0.3.

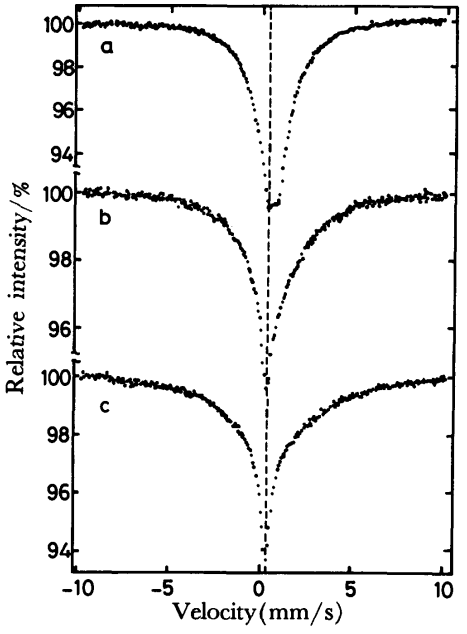

Fig. 2. Mössbauer spectra at 78 K of Fe(acac)$_3$ and its solvated compounds: a) Fe(acac)$_3$, b) Fe(acac)$_3$·2$CHCl_3$, and c) Fe(acac)$_3$·2CH_2Cl_2.

$(acac)_3$, indicated by the broken line. Furthermore, a slight asymmetry is observed in the line shape of the solvated compounds with a (probably) longer iron-iron distance than in $Fe(acac)_3$. Therefore, it is likely that the sign of the quadrupole splitting in $Fe(acac)_3$ is also positive.

(c) Temperature-dependence: The sign of the quadrupole splitting was determined for five kinds of tris(β-diketonato)iron(III) complexes and $Fe(trop)_3$[20] by examining the temperature-dependence of the Mössbauer line shape. For example, the Mössbauer spectra at 78, 195 and 295 K of $Fe(tfa)_3$ and $Fe(3\text{-}NO_2acac)_3$ are illustrated in Figs. 3 and 4, respectively.

It is seen in Fig. 3 that the absorption peak of $Fe(tfa)_3$ at 295 K splits in two: at 195 K the right side peak collapses. The spectrum at 78 K apparently has a single peak, although there remains a slight asymmetry. Such a change in the line shape of $Fe(tfa)_3$ with temperature (*i.e.*, relaxation time) may suggest the presence of a positive quadrupole splitting. Since the Mössbauer spectra of $Fe(3\text{-}Meacac)_3$ and $Fe(trop)_3$ showed a temperature-dependence similar to that of $Fe(tfa)_3$, their quadrupole splittings should be positive.

In contrast, the left component of the $Fe(3\text{-}NO_2acac)_3$ peak in Fig. 4 tends to collapse at lower temperatures, indicating the presence of a negative quadrupole splitting. Since the Mössbauer line shapes of $Fe(3\text{-}Phacac)_3$ and $Fe(3\text{-}Clacac)_3$ showed a temperature-dependence similar to that of $Fe(3\text{-}NO_2acac)_3$, the sign of their quadrupole splitting may be negative.

Correlation between Sign of Quadrupole Splitting and Molecular Structure. The sign of the quadrupole splitting may be correlated to the molecular structure in accordance with the point-charge model.[21] The

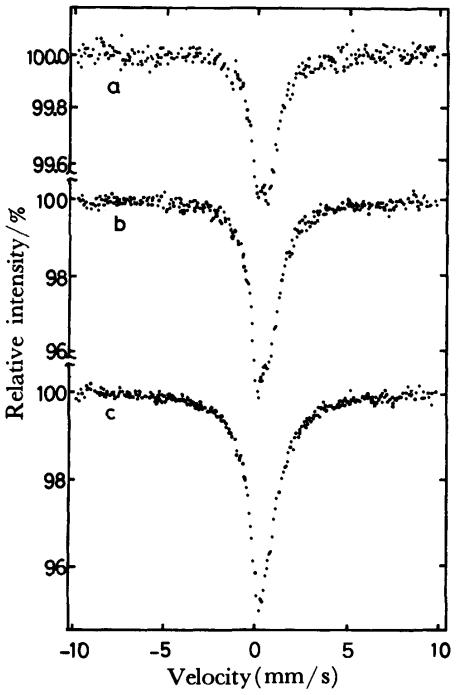

Fig. 3. Mössbauer spectra of $Fe(tfa)_3$ at a) 295 K, b) 195 K, and c) 78 K.

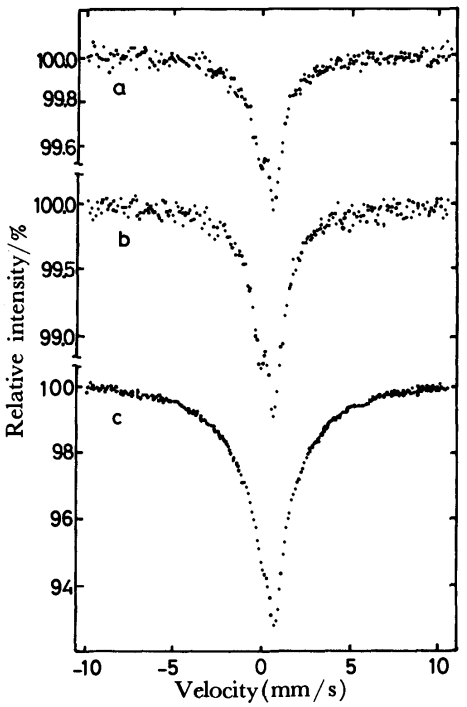

Fig. 4. Mössbauer spectra of $Fe(3\text{-}NO_2acac)_3$ at a) 295 K, b) 195 K, and c) 78 K.

quadrupole splitting in high-spin iron(III) compounds is determined by the electric-field gradient produced only by neighboring ions and atoms. The electric field gradient (eq) in tris(β-diketonato)iron(III) can be written as

$$eq = -12\rho \cos\alpha \cdot r^{-3}, \quad (1)$$

where ρ is the negative charge on an oxygen atom in β-diketonato ligand, r the iron-oxygen bond length, and α the bond angle $\angle$O-Fe-O (see Appendix). The quadrupole splitting (ΔEq) is given by

$$\Delta Eq = 1/2e^2qQ(1+\eta^2/3)^{1/2}, \quad (2)$$

where Q denotes the electric quadrupole moment of nucleus ($Q>0$ in ^{57}Fe) and η the asymmetric constant ($\eta=0$ in this case).

By putting equation(1) into equation(2), we obtain

$$\Delta Eq = -6e\rho Q \cos\alpha \cdot r^{-3}, \quad (3)$$

which implies that the sign of quadrupole splitting depends only on the angle α: the sign should be positive when $\alpha<90°$ and negative when $\alpha>90°$.

Meanwhile, average α values in $Fe(acac)_3$ and $Fe(trop)_3$ determined by X-ray diffractometry are 87.1°[22] and 77.8°[23] respectively. Based on the present model, the sign of a quadrupole splitting should be positive for both compounds, in agreement with the results deduced from the Mössbauer line shape in the present work. Thus, it may be assumed that the bond angle α is also smaller than 90° for $Fe(tfa)_3$ and $Fe(3\text{-}Meacac)_3$ whose quadrupole splittings proved to be positive based on the Mössbauer line shape.

It appears that α is larger than 90° in compounds complexed with ligand β-diketones containing more bulky 3-substituent groups such as $-NO_2$, $-C_6H_5$, and -Cl, while α is smaller than 90° in the compounds with ligands containing relatively smaller 3-substituent groups, *i.e.*, -H and $-CH_3$. Accordingly, it may be concluded that the bond angle α could be enlarged by the steric hindrance between complex molecules with a bulky 3-substituent group. A further study of these systems will be necessary to validate such a conclusion.

Appendix

If an ^{57}Fe nucleus is located at the origin of the coordinate system (Fig. 5), the electric-field gradient ($V_{zz}=eq$) due to point charges about the nucleus is given by

$$eq = \sum_i \rho_i r_i^{-3}(3\cos^2\theta_i - 1), \tag{4}$$

where ρ_i denotes the i-th point electric charge, θ_i the acute angle between the line segment from the i-th point to the origin and the Z axis (in accordance with the principal axis of electric-field gradient), r_i the distance between the i-th point charge and the origin, and e the protonic charge.

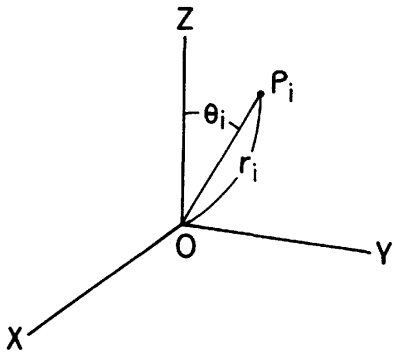

Fig. 5. Coordinates of point charges.

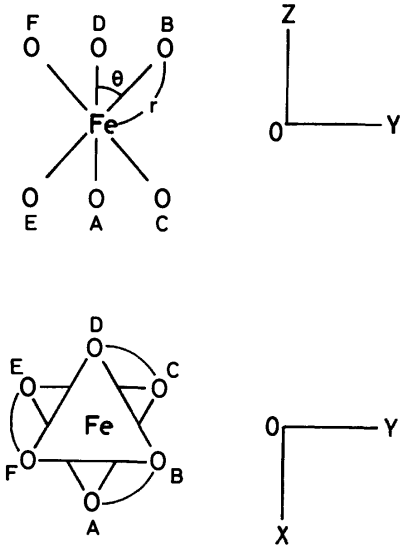

α = ∠AOB = ∠COD = ∠EOF

Fig. 6. Arrangement of coordinate atoms in tris(β-diketonato)iron(III) (Iron atom is situated on the origin(0,0,0)).

The Z axis can be determined in tris(β-diketonato)iron(III) complexes as illustrated in Fig. 6. If space coordinate of oxygen atom(A) in a ligand β-diketone is (rsin θ, 0, $-r\cos\theta$), that of oxygen atom(B) is ($1/2r\sin\theta$, $\sqrt{3}/2r\sin\theta$, $r\cos\theta$). The distance $\overline{AB}$ is given by

$$\overline{AB} = r(1+3\cos^2\theta)^{1/2}.$$

and ∠AOB (*i.e.* ∠O–Fe–O=α) is expressed as follows:

$$\cos\alpha = (1-3\cos^2\theta)/2. \tag{5}$$

Equation(5) also holds for the other two β-diketone ligands. Hence, putting equation(5) into equation(4), we obtain

$$eq = -2\cos\alpha \cdot \sum_i (\rho_i r_i^{-3}).$$

Assuming that each ρ_i or r_i is equivalent in three ligands, we can express the electric-field gradient as

$$eq = -12\rho\cos\alpha \cdot r^{-3}. \tag{6}$$

18) The Mössbauer spectrum at 78 K of (Fe,Al)(oxin)$_3$ was previously reported at a lower concentration Fe(oxin)$_3$ (3%) than in the present work, showing the line shape with the slower relaxation time reasonably.[24]
19) The magnetic hfs in the ^{57}Fe Mössbauer spectrum corresponds to six transitions ($\pm3/2\rightarrow\pm1/2$, $\pm1/2\rightarrow\pm1/2$ and $\pm1/2\rightarrow\mp1/2$), or combination of three doublets. In the presence of a quadrupole splitting, two lines corresponding

to $\pm 3/2 \rightarrow \pm 1/2$ and $\pm 1/2 \rightarrow \pm 1/2, \mp 1/2$ transitions respectively appear in the spectrum: the right hand (higher energy) component is attributed to the $\pm 3/2 \rightarrow \pm 1/2$ transitions if quadrupole splitting is positive, while the left hand component is attributed to the $\pm 3/2 \rightarrow \pm 1/2$ transitions for negative quadrupole splitting. Furthermore, the doublet due to the $\pm 3/2 \rightarrow \pm 1/2$ transitions has the largest splitting. Hence, there exists a range of magnetic relaxation time in which the $\pm 3/2 \rightarrow \pm 1/2$ line broadens whereas the $\pm 1/2 \rightarrow \pm 1/2, \mp 1/2$ lines are still sharp.[3]

20) Tropolone is not β-diketone, but $Fe(trop)_3$ is similar to tris(β-diketonato)iron(III) in magnetic properties and molecular structure.

A New Synthetic Model for Myoglobin: "Tulip Garden" Porphyrin

Shigeru TAKAGI, T. Ken MIYAMOTO,* and Yukiyoshi SASAKI
Department of Chemistry, Faculty of Science, The University of Tokyo, Hongo, Bunkyo-ku, Tokyo 113
(Received July 20, 1984)

A new model compound "tulip garden" porphyrin, has a long half-lifetime, thus satisfying the demand for the synthetic analogue of myoglobin. At the same time, "tulip garden" porphyrin has high O_2 affinities as compared to other protected porphyrins; especially, its Co(II) complex shows almost the same affinity ($P_{1/2}O_2$) as coboglobins. The difference in oxygen affinities between "tulip garden" and "picket fence-type" porphyrins can be ascribed to the bulkiness of pendant groups. The strong "side" influence of the adamantyl group can be expected to bring about a high O_2 affinity.

Considerable efforts have recently been made to develop synthetic model compounds which bind O_2 reversibly in a manner analogous to that of hemoglobin (Hb) and myoglobin (Mb).[1] These model compounds satisfy the demands for the formation of more stable oxygen adducts at room temperature and show high O_2 affinities equal to those of natural respiratory hemoprotein. In Hb and Mb, an important function of the heme pocket is to prevent dimeric interactions between hemes. In accordance with this requirement, sterically protected porphyrins ("superstructure porphyrins"[2]) have been synthesized in recent years. Such superstructures have a *hydrophobic pocket* on the single face of the porphyrin plane and help to *inhibit irreversible autoxidation*.[3] At room temperature, however, only a limited number of the protected porphyrins, most notably the "picket fence,"[4] "pocket,"[5] "capped,"[6] "doubly bridged,"[7] "hanging imidazole,"[8] and "cofacial"[9] porphyrins, bind O_2 reversibly.

The O_2 affinities and half-lifetimes of oxygen complexes differ from compound to compound. This variation is attributable to the electronic nature of porphyrins,[10] local polarity at the binding site,[2-11] the effect of solvation on the binding site,[12] and the steric effects on coordination to the metal center.[13] As far as the steric effects are concerned, we may consider two types of model compounds. In "capped" porphyrin[13] and "cyclophane heme,"[14] a series of compounds has been synthesized by changing the cavity size between the porphyrin plane and the capping aromatic ring, and the influence of the steric hindrance upon O_2 binding has been studied. On the other hand, the oxygen-binding properties of the "picket fence" porphyrins containing different pendant groups have hardly been investigated at all. In order to investigate of the steric effect caused by the bulkiness of the pendant groups, we need to design new model compounds.

We wish to report here the synthesis of a new model compound of Mb, "tulip garden" porphyrin **5a** (Fig. 1), which is "modified picket fence porphyrin." A reversible oxygenation based on its Fe(II) and Co(II) complexes is also described. We further synthesized "picket fence-type" porphyrin **5b** (Fig. 1), whose pendant moiety is the *t*-butyl group. The bulkiness of the adamantyl group may lead to very strong steric effect on the porphyrin **5a**. In order to compare the local polarity effects of binding sites, we also furthermore synthesized "camphanoyl fence" porphyrin **5c** (see Scheme 1).

Experimental

The synthetic procedure[15] to **5a**, **5b**, and **5c** is shown in Scheme 1, while the metallation procedure to the Co(II) and Fe(II) complexes is shown in Scheme 2.

5,10,15,20-Tetrakis(2-nitro-4-t-butylphenyl)-21H,23H-porphyrin **2**. The porphyrin **2** was prepared by the Rothemund condensation of pyrrole with a nitrobenzaldehyde derivative **1**.[16] A 259-g portion of **1** (1.25 mol) was dissolved in 2 dm^3 of glacial acetic acid. The solution was then heated to its boiling point with continuous stirring. A 95-g portion of pyrrole (1.42 mol) was added, drop by drop, to the boiling solution. The solution was then allowed to reflux for 3 h. After the solution has cooled to room temperature, the resulting black solution was left overnight. The purple crystals were filtered by suction and purified by silica gel chromatography, using

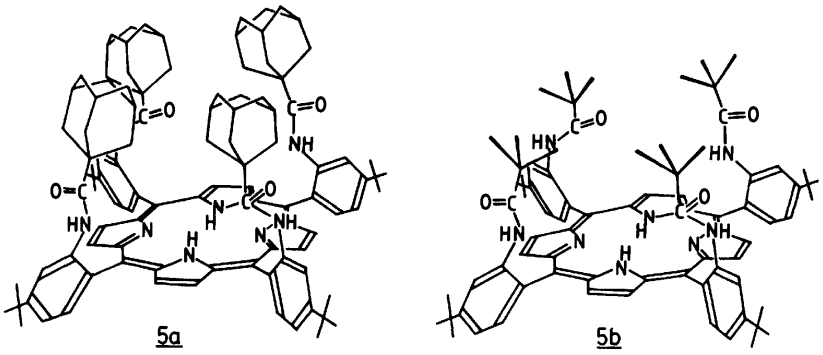

Fig. 1. "Tulip garden" porphyrin **5a** and "picket fence type" porphyrin **5b**.

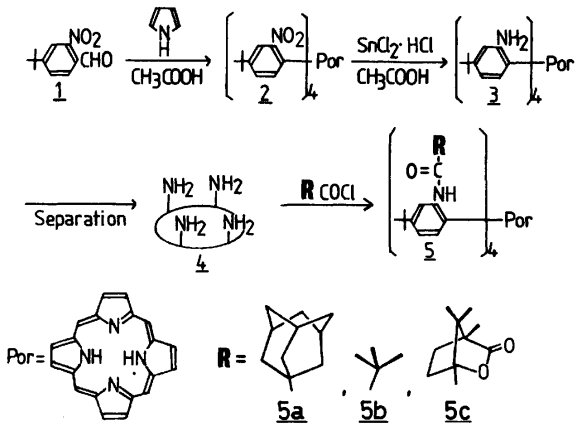


Scheme 1. Synthetic procedure to **5a**, **5b**, and **5c**.

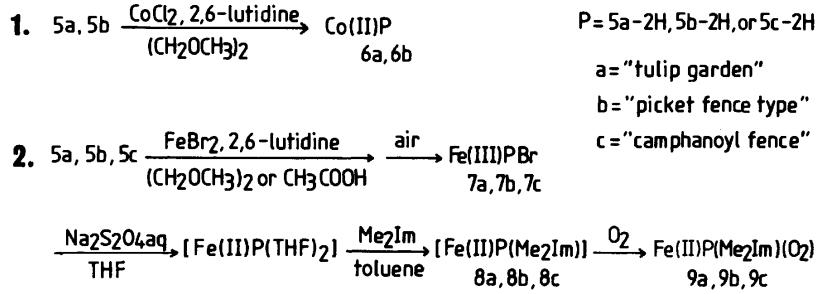
$CHCl_3$ as the eluent. A 46.0-g portion of the porphyrin **2** (0.0451 mol) was thus obtained; the overall yield was 14.4% based on the **1** consumed: Anal. Calcd for $C_{60}H_{58}N_8O_8$: C, 70.71; H, 5.74; N, 10.99. Found: C, 70.76; H, 5.70; N, 11.14. ^1H NMR ($CDCl_3$) δ=−2.6 (2H, s, internal pyrrole H), 1.7 (36H, s, *t*-butyl H), 8.0—8.5 (12H, m, phenyl H), 8.6 (8H, s,β-pyrrole H). UV-*vis*. ($CHCl_3$) λ/nm (ε/$M^{-1}cm^{-1}$)[17] 423 (3.3×10^5), 517 (2.0×10^4), 553 (7.2×10^3), 594 (6.0×10^3), 651 (2.6×10^3).

5,10,15,20-Tetrakis(2-amino-4-t-butylphenyl)-21H,23H-porphyrin **3**. A 4.0-g portion of the porphyrin **2** (3.9 mmol) was dissolved in a mixture of concentrated hydrochloric acid (500 cm^3) and glacial acetic acid (1 dm^3) at room temperature. The resulting green solution was heated to 65 °C, and then a solution of 14 g (62 mmol) of $SnCl_2\cdot2H_2O$ dissolved in 100 cm^3 of the mixed solvent (HCl:CH_3COOH=1:2) was slowly added during a 30-min period. After heating for 1.5 h, crushed ice and water were poured into this solution. The porphyrin **3** was extracted with $CHCl_3$ from the resulting solution. The product was purified by alumina-column chromatography ($CHCl_3$). The average yield was 3.2 g (3.6 mmol, 92%): Anal. Calcd for $C_{60}H_{66}N_8$: C, 80.14; H, 7.40; N, 12.46. Found: C, 79.92; H, 7.67; N, 12.71. ^1H NMR ($CDCl_3$) δ=−2.6 (2H, s, internal pyrrol H), 1.5 (36H, s, *t*-butyl H), 3.4 (8H, s, NH_2), 7.0 (8H, d, phenyl H), 7.7 (4H, d, phenyl H), 8.8 (8H, s,β-pyrrole H). UV-*vis*. ($CHCl_3$) λ/nm (ε/$M^{-1}cm^{-1}$): 422 (2.3×10^5), 517 (1.7×10^4), 553 (6.1×10^3), 591 (5.3×10^3), 647 (2.8×10^3).

Separation of $\alpha,\alpha,\alpha,\alpha$-Isomer. The resulting porphyrin **3** was a mixture of four atropisomers in statistical abundance. The most polar one, the $\alpha,\alpha,\alpha,\alpha$-isomer, could be easily separated from the other three atropisomers by thin-layer[18] and column chromatography. Before isomer separation, the preferential isomerization to the $\alpha,\alpha,\alpha,\alpha$-isomer was carried out by the a modification of literature methods.[19] Eight grams of the porphyrin **3** were dissolved in 1.5 dm^3 of toluene. This solution was refluxed under Ar, and a 40-g portion of alumina (Merck alumina 90) was added six times every three hours. After refluxing for 20 h, the solution was cooled to the ambient temperature. The isomerized product was then extracted from the alumina with a $CHCl_3$/acetone mixed solvent. After the solvent had been removed, the residue was redissolved in a minimum amount of benzene. The benzene solution was poured into a column of silica gel (Wako gel C-200) prepared as a slurry in benzene. All the material was loaded, and 2:1 benzene/diethyl ether was passed through the column until the eluate became very pale. The desired $\alpha,\alpha,\alpha,\alpha$-isomer was left in the column and eluted with 2:1 benzene/acetone. The solvent was removed using a rotary evaporator at 30 °C. Yield: 6.5 g (81%).

"Tulip Garden" Porphyrin 5a. A 3.0-g portion (3.3 mmol) of the $\alpha,\alpha,\alpha,\alpha$-isomer **4** was dissolved in CH_2Cl_2 (200 cm^3) containing 10 cm^3 of pyridine. A 15-g portion (76 mmol) of 1-adamantanecarboxylic acid chloride was added, after which the solution was stirred for 3 h at the ambient temperature. A 200-cm^3 portion of 20% aqueous ammonia was then added, and the solution was stirred for an additional 30 min. The organic layer was separated and subsequently washed, first with dilute hydrochloric acid and then with aqueous ammonia. The solvent was evaporated using a rotary evaporator. The product was purified by chromatography on a silica-gel column (benzene), eluting with 3:1 benzene/ether. Yield 4.7 g (3.0 mmol, 91%): Anal. Calcd for $C_{104}H_{122}N_8O_4\cdot H_2O$: C, 79.95; H, 7.98; N, 7.15. Found: C, 79.52; H, 7.80; N, 7.24. ^1H NMR ($CDCl_3$) δ=−2.6 (2H, s, internal pyrrole H), 0.9—1.2 (60H, m, adamantyl H), 1.6 (36H, s, *t*-butyl H), 7.4—7.5 (12H, m, phenyl H), 8.9 (8H, s,β-pyrrole H), 8.9 (4H, d, NHCO). UV-*vis*. ($CHCl_3$) λ/nm (ε/$M^{-1}cm^{-1}$): 438 (3.5×10^4), 555 (8.3×10^3), 593 (6.5×10^3), 652 (2.5×10^3).

"Picket Fence-type" Porphyrin 5b and "Camphanoyl Fence" Porphyrin 5c. The synthetic procedure for **5b** and **5c** was similar to that used for **5a**. The porphyrin, **5b** or **5c**, was obtained by coupling the $\alpha,\alpha,\alpha,\alpha$-isomer **4** with pivaloyl chloride[20] or (−)-camphanoyl chloride respectively. The overall yield of **5b** was 95%, and that of **5c** was 60%: **5b** Anal. Calcd for $C_{80}H_{98}N_8O_4\cdot H_2O$: C, 76.65; H, 8.04; N, 8.94. Found: C, 76.55; H, 7.78; N, 8.77. ^1H NMR ($CDCl_3$) δ=−2.6 (2H, s, internal pyrrole H), 0.1 (36H, s, pivaloyl H), 1.6 (36H, s, *t*-butyl H), 7.2—7.8 (12H, m, phenyl H), 8.8 (8H, s,β-pyrrole H), 8.9 (4H, d, NHCO). UV-*vis*. ($CHCl_3$) λ/nm (ε/$M^{-1}cm^{-1}$): 423 (3.5×10^5), 515 (2.1×10^4), 549 (6.2×10^3), 589 (6.4×10^3), 646 (2.5×10^3). **5c** ^1H NMR ($CDCl_3$) δ=−2.6 (2H, s, internal pyrrole H), −0.1—1.3 (52H, m, camphanoyl H), 1.5 (36H, s, *t*-butyl H), 7.3—7.8 (12H, m, phenyl H), 8.4 (4H, d, NHCO), 8.8 (8H, s,β-pyrrole H). UV-*vis*.



Scheme 2. Metallation procedure.

($CHCl_3$) λ/nm: 422, 517, 551, 582, 653.

Cobalt Insertion. A 1.0-g portion (0.65 mmol) of **5a**, 0.65 g (5.0 mmol) of anhydrous $CoCl_2$, and 0.20 cm^3 of 2.6-lutidine were dissolved in 100 cm^3 of 1,2-dimethoxyethane under Ar. The resulting solution was stirred for 3 h at room temperature. The solution was then brought to dryness, and the residue was redissolved in $CHCl_3$. The product was purified by alumina-column chromatography, using $CHCl_3$ as the eluent. Yield: 0.90 g (87%). The porphyrin **6b** was prepared by a similar procedure. Yield: (50%): **6a** Anal. Calcd for $CoC_{104}H_{120}N_8O_4 \cdot H_2O$: C, 76.96; H, 7.58; N, 6.90. Found: C, 77.03; H, 7.84; N, 6.65. UV-*vis.* ($CHCl_3$) λ/nm (ε/M^{-1} cm^{-1}): 419 (2.3×10^5), 532 (1.7×10^4). **6b** UV-*vis.* ($CHCl_3$) λ/nm: 414, 526.

Iron Insertion. **5a** (0.8 g), 2.6-lutidine (2 cm^3), and anhydrous $FeBr_2$[21] were dissolved in 200 cm^3 of 1,2-dimethoxyethane under oxygen-free conditions. The resulting solution was stirred for 3 h at the ambient temperature. The solution was then brought to dryness, and the product was purified using an alumina column ($CHCl_3$). The eluate was stirred with 10% hydrobromic acid. The solvent was then evaporated by means of a rotary evaporator. Yield: 0.82 g (95%). The porphyrin **7b** was prepared by a similar procedure. Yield: (60%). The porphyrin **7c** was obtained by the reaction in a mixed solvent of 1:1 $CHCl_3$/acetic acid. Yield: (70%). **7a** Anal. Calcd for $FeC_{104}H_{120}N_8O_4Br$: C, 74.24; H, 7.19; N, 6.66. Found: C, 73.90; H, 7.21; N, 6.77. UV-*vis.* ($CHCl_3$) λ/nm: 425, 514, 578, 660, 694. **7b** Anal. Calcd for $FeC_{80}H_{96}N_8O_4Br$: C, 69.94; H, 7.20; N, 7.96. Found: C, 70.17; H, 7.07; N, 8.18. UV-*vis.* ($CHCl_3$) λ/nm: 422, 512, 586, 656, 685. **7c** UV-*vis.* ($CHCl_3$) λ/nm: 421, 508, 578, 656.

Dioxygen Adducts of Fe(II) Complexes. A 2.0-g portion (1.2 mmol) of Fe(III) porphyrin **7a** was dissolved in a mixed solvent of 50% THF/benzene (v/v), after which the solution was purged with Ar to remove any O_2. Then a 100-cm^3 portion of the deoxygenated aqueous 0.2 M $Na_2S_2O_4$ solution was added to this solution of **7a**. When the mixture was vigorously stirred for 30 min, the dark brown solution turned red-orange. The aqueous layer was discarded, and the organic layer was dried using anhydrous Na_2SO_4. After removing the solution from Na_2SO_4 by filtration under Ar, the crude iron(II) complex was redissolved in 30 cm^3 of toluene containing 1,2-Me_2Im[22] and then 100 cm^3 of heptane was added, drop by drop, for crystallization. The precipitate **8a** was separated by filtration and dried *in vacuo*. All the operations were carried out under Ar or N_2 atmosphere. After the exposure of the **8a** to oxygen at atmospheric pressure for 1 d, a pure "dioxygen" complex **9a** was obtained as deep-violet crystals. The "dioxygen" complex **9b** was prepared by a similar procedure. **9c** was immediately oxidized to the iron(III) state, and so we could not obtain the pure "dioxgen" complex. For that reason, we used a THF/benzene solution of the crude iron(II) complex for the spectrophotometric measurement: **9a** Anal. Calcd for $FeC_{109}H_{128}N_{10}O_6$: C, 75.67; H, 7.46; N, 8.10. Found: C, 75.47; H, 7.57; N, 8.06.

Oxygen-affinity Measurement. The oxygen equilibria constants were determined by means of spectrophotometric O_2 titration. A Hitachi 340 recording spectrophotometer was used in all the experiments. The measurements were done at *ca.* 20 °C in a toluene[23] solution containing the corresponding imidazole.[24] In general, metalloporphyrin concentration of 50—80 μM were used, and the spectra were recorded in the 600—350 nm range. Any spectral changes were recorded, in the absence of O_2 and at various increasing partial pressures of O_2. The oxygen partial pressures were determined by the injection of known volumes O_2 into the tonometer. After the measurements, the reversibility was checked by bubbling a sample solution with Ar in order to obtain a spectrum identical with initial one.

Results

$$M(P)(B) + O_2 \rightleftharpoons M(P)(B)(O_2) \quad M = Co, Fe$$

In solution, five-coordinate porphyrin complexes are suitable for the measurement for the oxygen equilibrium, an appropriate N-base should, however, be chosen to ensure that the five-coordinate complex is the dominant species. Sterically hindered 2-substituted imidazoles exclusively form the five-coordinate adducts with Fe(II) porphyrins.[25,26] These hindered imidazole adducts are considered to mimic the T-state (low affinity) hemoglobin.[26] In the Fe(II) porphyrin/unhindered imidazole system, which can be expected to be a model system for the R-state (high affinity) hemoglobin,[26] six-coordinate bis-ligated adducts are the dominant species in solution.[25] Our porphyrin **5a** exerts a strong steric effect on the sixth coordinating position, but cannot restrain the coordination of 1-MeIm[27] in the pocket. In Co(II) porphyrins, both unhindered and hindered imidazoles form five-coordinate adducts.[28] For that reason, we choose the Fe(II) porphyrin/1,2-Me_2Im system the for T-state model and Co(II) porphyrin/1-MeIm system for the R-state model.

The spectrophotometric oxygen titrations of Fe(II) and of the Co(II) complexes were carried out in a toluene solution. Isosbestic points were found in all titrations. Figure 2 shows the spectral changes which took place when a toluene solution containing 1,2-Me_2Im

Fe"picket fence type" (5.0×10^{-2} M 1,2-Me_2Im)	84

of Fe(II) porphyrin **8a** was exposed to various pressures of oxygen. However, the "camphanoyl fence" porphyrin Fe(II) complex was oxidized irreversibly, probably to the hydroxy iron(III) complex while the O_2 titration was being measured.[29] Both **9a** and **9b** showed full reversible oxygenation, and no spectrum of an oxidative species was observed within the period of the measurements. The electron-absorption data are listed in Table 1.

The Soret bands of the spectra were used for the spectrophotometric determination of oxygen-binding equilibria, because the most remarkable spectral changes throughout oxygenation took place at the Soret bands. The half-saturation pressures ($P_{1/2}O_2$) thus determined are listed in Table 2. The O_2 affinities of **8a** and **6a** (1-MeIm) were nearly three times those of **8b** and **6b** (1-MeIm). The half-lifetime for irreversible oxidation is >4d on **9a** and 36 h on **9b** at *ca.* 25 °C. In these ($P_{1/2}O_2$) and half-lifetime data, toluene was used as the solvent. The polarity effect of the solvent is negligible.

Discussion

(A) Half-lifetime. In synthetic analogues of Hb-Mb, it is desirable to form a stable oxygen adduct at room temperature. In this section, we will discuss the static stability of oxygen complexes. We consider that the half-lifetime of oxygen adducts at the ambient temperature indicates its static stability. The half-lifetimes of various oxygen complexes of Fe(II) porphyrins are given in Table 3. These data allow for comparison among a variety of synthetic Fe(II) porphyrins.

The protected porphyrins which have a nonprotic cavity on one side of the porphyrin plane, **9a**, **9b**, "FeTTTPP,"[2] "cofacial,"[9] "picket fence,"[4] "capped,"[48] "pocket,"[5] "doubly bridged,"[7] "hanging imidazole,"[8] and "cyclophane heme,"[31] showed long half-lifetimes (>5 h) at room temperature. In these models, the protected superstructures prevented bimolecular reactions between oxygen adducts and inhibited autoxidation. Other protected porphyrins, *e.g.*, "FeT(OMe)$_3$PP," "FeT(OEt)$_3$PP,"[32,33] and "strapped heme,"[34] whose superstructures could not prevent dimerization, binded O_2 partly reversibly at the ambient temperature. The subsequent autoxidation, however, took place immediately. Compared with these protected porphyrins, which oxygenated reversibly at room temperature, unprotected "chelated heme" had a short half-lifetime.[35] These data suggest that the protected superstructure is essential to stabi-

TABLE 3. HALF-LIFETIMES OF Fe(II) PORPHYRINS

Compound (base concentration)	$t_{1/2}$	Conditions	Ref.

lizing the oxygen complex at room temperature.

In the simple protoporphyrin/imidazole system, the oxygen adduct was less stable than "chelated heme." Although the protection was not enough to prevent dimerization, "hanging imidazole" porphyrin showed a long half-lifetime (1d).[8] In both "chelated heme" and "hanging imidazole" porphyrin, the imidazole arm was covalently linked to the porphyrin moiety, hence, the axial coordination was stabilized. Traylor[36] and Tsuchida[37] found that rigid and stable imidazole-heme coordination should result in a more stable oxygen adduct.

These protected porphyrins had various polarities at the ligand-binding site. "FeTTTPP" had a completely nonpolar pocket,[2] but other protected porphyrins were somewhat polar at the binding site. A series of "picket fence" and "pocket" porphyrins, whose polarities were quite similar, showed rather different values for their half-lifetimes (from 7 h to 1 month; see Table 3). Half-lifetime of "FeTTTPP" was over 30 h. Considering these variations of stability, it seems that the polarity is not strictly relevant to halflife time of oxygen adduct.

We will try to speculate tentatively on the relevance between the static stability and the polarity of a binding site. A related "picket fence" porphyrin complex, Fe(T*tos*PP)(N-Bu'Im) (where *tos*=*p*-toluenesulfonamide), underwent irreversible oxidation.[4] Our **9c** was also autoxidized immediately at room temperature. Both these models contained an electron-withdrawing moiety. We attribute the rapid oxidation of these two models, in spite of the inhibition of dimerization by the "picket fence," to the strong polarity of the amide protons, which permits the protonation of coordinated dioxygen and consequent oxidation. These results suggest that the local polarity effect on the stability of the oxygen complex may be small unless the polarity is too strong to promote the protonation and subsequent autoxidation.

The half-lifetime of **9a**, which was more protected than **9b**, was longer than that of **9b**. This suggests that complete protection brings about good stability of the oxygen adduct. The relationship between the stability and the steric hindrance is vague. At present, though, we consider that the steric hindrance is not very relevant to the half-lifetime.

(B) Half-saturation Pressure of Oxygen. The dynamic stability of oxygen binding is estimated by means of the half-saturation pressures of oxygen ($P_{1/2}O_2$). Table 4 contains the half-saturation pressures for the oxygenation of unhindered-imidazole complexes of various Co(II) porphyrins. Table 5 contains similar data for hindered-imidazole complexes of Fe(II) porphyrins. The variations in these $P_{1/2}O_2$values, particularly the difference in oxygen affinities between **9a** and **9b**, lead to several speculations about O_2-binding behavior. We consider that the oxygen affinities of these model compounds depend on four factors. We will discuss these four factors in the following paragraphs.

Table 4. O_2 affinities of Co(II) porphyrins (1-MeIm)

Compound	$P_{1/2}O_2$	Conditions	Ref.
CoMb (sperm whale)	30	20°C Water	46,47

Local Polarity of Ligand-binding Site. The polarity of the ligand-binding site considerably influences the oxygen affinities. It has previously been suggested that an increased polarity should increase the oxygen affinities.[38] This suggestion has been based on the measurements on "flat," unprotected porphyrins. In protected porphyrins, also, however, we consider a similar tendency to be found.

Recently, structural studies of oxyMb[39] and oxyHb[40] have established that the N^{ε} of His E7 forms a hydrogen bond with the bound oxygen. The N^{ε} atom stabilizes the coordinated molecular oxygen with this hydrogen bond. Structural studies[41] have also shown that, in the solid state, there is no interaction between the amide proton and the bound dioxygen in the "picket fence" porphyrins. Consequently, we are unable to expect the stabilization of oxygen binding by means of the hydrogen bond in these model systems (not even in **9a**). However, these amide groups can be expected to increase the polarity at the ligand-binding site.

Momenteau and Lavallete[11] observed O_2 binding in two similar "hanging base" porphyrins. Changing the mode of attachment from amide to ether linkages resulted in a difference, by a factor of *ca.* 10, in $P_{1/2}O_2$ values. They concluded that the presence of the amide groups strongly increased the stability of the oxygenated complexes. "FeTTTPP," which had a completely nonpolar pocket, showed a rather low O_2 affinity in comparison to the "picket fence," "pocket," and **9a**. This large difference between the oxygen affinities was attributed primarily to the loss of polarity in the binding pocket of "FeTTTPP." A number of protected porphyrins, **9a**, **9b**, "picket fence," and "pocket" porphyrins, which included four amide groups around the binding site, showed high O_2 affinities.

These results suggest that the local polarity is a

significantly important factor in determining the O_2 affinity in encumbered model systems. As has been mentioned in Section (A), if the local polarity is too strong, as, *e.g.*, in **9c** and "FeT*tos*PP," the protonation and autoxidation happen rapidly even if the systems show high O_2 affinities. For that reason, these porphyrins are unsuitable as "biomimetic models" of natural oxygen carriers.

Polarity effects are expected to be similar within **9a**, **9b**, "picket fence," and "pocket" porphyrins. Therefore, the affinity differences among these model compounds, especially that between **9a** and **9b**, can not be explained by the local polarity effect. We must consider other factors in order to explain the differences.

Electronic Nature of the Porphyrin. Electronic effects have been extensively studied. Recently, Traylor *et al.*[10] found that the electronic nature of the heme had a striking effect on the O_2 affinity. The electronic nature of the series of protected porphyrins seems to be similar. Especially in **9a** and **9b**, we consider that the electronic natures of these two porphyrins quite resemble one another. As Collman *et al.*[12] mentioned in his report, other factors must be primarily responsible for the high O_2 affinities of the protected porphyrins.

Solvation Effect. Collman *et al.*[12] have discussed the solvation effects on "flat" and "protected" porphyrins. They suggested that, in "flat" iron porphyrins, the unligated five-coordinate form might be subject to a stronger solvation stabilization than the "protected" porphyrins. This stabilization of the five-coordinated species could account for the lower gaseous-ligand affinities of these "flat" porphyrins relative to "protected" porphyrins. They concluded that the solvation effect was the dominant factor responsible for the lower affinities of the "flat" hemes as compared to the "protected" hemes.

In "capped" porhyrins,[42] "[6.6]cyclophane,"[14] and "cofacial" porphyrins,[9] the O_2 affinities of these models were lower those of "flat" hemes ("chelated heme," or TPP), although a solution stabilization did not take place (see Table 6). The steric hindrance restrained the coordination of oxygen. This is reason why "capped," "[6.6]-cyclophane," and "cofacial" porphyrins indicated rather low O_2 affinities. In **9a** and **9b**, the solvation effects were considered to be almost the same. Even if the solvation effects of these two models were slightly different, the influence on the O_2 affinity should not be large. We consider that the solvation effect is the dominant factor in the difference between the O_2 affinities of "flat" hemes and those of "protected" hemes, however, among the "protected" hemes, a little difference in the solvation effect has no significant meaning on the O_2 affinities.

Steric Effect. The steric hindrance extensively influences the O_2 affinities of the protected porphyrins. Table 6 shows the $P_{1/2}O_2$ values of various porphyrin complexes.

TABLE 6. O_2 AFFINITIES OF SELECTED Fe(II) PORPHYRINS

Compound (base)	$P_{1/2}O_2$	Conditions	Ref.
[7.7]Cyclophane (1,5-DCI)	1.4	20°C Benzene	10

9a (1,2-Me_2Im)	9.5	20°C Toluene	This work
9b (1,2-Me_2Im)	26		This work

The steric hindrance caused by the capping aromatic ring was termed "central" and "peripheral" effects by Basolo.[13] We call this "top" hindrance. The "top" hindrance was investigated in several kinds of protected porphyrins; "capped,"[13] "cyclophane,"[14] "cofacial,"[9] and "pocket"[12] hemes. Clayden *et al.*[43] studied the cavity size of "C_2-Cap," "C_3-Cap," and "Np C_2-Cap" using the paramagnetic shift and relaxation effects observed in these Co(II) complexes. The cavity size was varied in this order; "Np C_2-Cap">"C_2-Cap">"C_3-Cap." The O_2 affinities of these porphyrins decreased in exactly the same order.[42] Traylor *et al.*[14] measured the O_2 affinity of "[6.6]cyclophane" and "[7.7]cyclophane." "[7.7]cyclophane," whose cavity was larger than that of "[6.6] cyclophane," indicated a higher O_2 affinity. Chang *et al.*[9] obtained a similar result using "cofacial" porphyrins, "Fe-4-Cu," and "Fe-5-Cu." These three model systems, "capped," "cyclophane," and "cofacial" hemes, revealed a large steric effect on O_2 binding. The cavity size of "C_3-Cap," "[6.6]cyclophane," and "Fe-4-Cu" was too small for the coordination of dioxygen, and these three models had lower O_2 affinities than those of "flat" porphyrins.

A similar tendency of "top" hindrance is observed in "pocket" porphyrins.[12] The cavity size was changed in this order: "FeTalPoc">"FeMedPoc">"FePocpiv," the O_2 affinity varying in the same order. "FeMedPoc" and "FePocpiv" porphyrins had almost the same values for resulted in a difference, by a factor of *ca.* 10, in $P_{1/2}O_2$. In both porphyrins, the covalently attached benzene rings are rigidly constrained above the porphyrin ring. In contrast to these two porphyrins, the benzene ring of "FeTalPoc" was "floppy", and the O_2 affinity of this porphyrin was three times as high as those of "FeMedPoc" and "FePocpiv."

In the "top" hindrance, if the cavity size becomes too far small, the oxygen affinity is considerably decreased.

In the "pocket" porphyrins, the effects of cavity size and of rigidity are not yet clear.

The adamantyl moiety, which was the pendant group of **5a**, was bulkier than the *t*-butyl group of **5b**. The steric congestion attributable to the bulkiness of the pendant groups is termed "*side*" influence. This "*side*" influence has been scarcely studied in model systems, and it is not clear that "*side*" influence causes either the inhibition or the promotion of O_2 binding. At the beginning of this work, we set up a hypothesis that a strong "side" influence may produce a high O_2 affinity. As was expected, $P_{1/2}O_2$ values of these two models (**8a** and **8b**, **6a** and **6b**) were different, by a factor of *ca.* 3 (see Tables 4 and 6). "Tulip garden" porphyrins, **8a** and **6a**, demonstrated high O_2 affinities. The electronic nature, local polarity, solvation effect, and "top" hindrance are expected to be quite similar in these two types of model compounds, "tulip garden" and "picket fence-type" porphyrins. Only the steric "*side*" influence is dissimilar. These results suggest that the O_2 affinity is clearly dependent upon the bulkiness of the pendant groups.

Camphanoyl group of **8c** had the almost same bulkiness as the adamantyl moiety. Unfortunately, **8c** was rapidly autoxidized to the iron(III) state. For that reason, we could not estimate the "*side*" influence of **8c**.
