It can be seen from Fig. 6 that the nucleation catalyst aged for 96 h at −20 °C began to get deactivated at 84 °C and that all of them were deactivated at 89 °C. This deactivation temperature of the nucleation catalyst is a little lower than that of the nucleation catalyst aged for 96 h at 20 °C. These phenomena are also similar to those observed with $Na_4P_2O_7$. However, the

aging-temperature dependence of the deactivation temperature is not so pronounced as in the case of $Na_4P_2O_7$.

Discussion

Previously, we investigated the preheating effect on crystallization of $CH_3CO_2Na \cdot 3H_2O$ from a solution containing a small amount of nucleation catalyst ($Na_4P_2O_7$ or Na_2HPO_4).[8,9] In that investigation we did not fully take into account the aging effect on nucleation catalysis. However, in every experiment previously reported, we kept the coagulum containing a nucleation catalyst for more than one week at room temperature, in order to obtain some steady, reproducible deactivation temperature. Therefore, the reported deactivation temperatures are considered to corresponde to fully aged nucleation catalysts.

Two general explanations have been applied to the thermal history of heterogeneous nucleation. One is that crystalline germs are retained in fissures or cavities in the nucleation catalyst surface as a result of a (postulated) concave crystalline meniscus under such condition as preclude the existence of bulk crystals.[13] The other is that adsorbed crystalline layers are retained on the nucleation catalyst surface, as illustrated in Fig. 1 (B). The first explanation has received most attention because, when certain assumptions are given concerning the size of fissures and the contact angle of the crystal thereon, estima-

tion of the activated nucleation temperature (*i.e.*, the temperature at which crystallization is initiated) can be made.[14] However, we are not satisfied with this explanation because high, sharp deactivation temperatures of fully activated nucleation catalysts would require a very small associated fissure and a sharp limit to its geometry. The relation between the degree of supercooling and the preheating temperature for the nucleation catalysts, $Na_4P_2O_7$ and Na_2HPO_4, which will be reported in the near future, is not in agreement with the relation which is expected from the cavity model. In any cases of $Na_4P_2O_7$ and Na_2HPO_4 as nucleation catalysts, the degree of supercooling is not directly proportional to the difference between preheating temperature and bulk melting point, but is kept almost constant, about 6 °C, until catalysts begin to get deactivated. Furthermore, the theory is considered to be unable to explain the aging effect on nucleation catalyst as observed in the present experiment.

The second explanation, that is, the crystalline adsorption model, has received little consideration because thermodynamic properties of adsorbed layer have hitherto been speculative. Evans *et al.*[15–17] have studied the ability of a solid substrate to nucleate ice in supercooled water under high pressure, and explained results on the basis of an assumption that on certain substrates the heterogeneous nucleation of ice is preceded by a change of state (order-disorder transition) of the water monolayer adsorbed on the substrate.

Recently, the monolayer adsorbed on substrate has been studied extensively. From this study, possible phase diagrams of the adsorbed monolayer on substrate, such as that shown in Fig. 7,[18] are postulated.[19,20] The competition of adsorbate-adsorbate interaction with adsorbate-substrate lateral periodic potential can produce a structure which is either commensurate or incommensurate with the substrate, depending on the fitness between substrate and natural adsorbate lattice spacing; the fitness depends on both temperature and chemical potential (two-dimensional pressure). In Fig. 7, the low-dimensional (where the ratio of the periodicity of substrate to that of adsorbed monolayer is very simple) commensurate solid adsorbate is transformed directly into the fluid (liquid) adsorbate with rise in temperature (order-disorder transition), and the high-dimentional commensurate solid adsorbate is transformed into the fluid adsorbate through the incommensurate solid adsorbate with rise in temperature. Jaubert *et al.* evidenced the existence of a uniaxial commensurate-incommensurate transition in a solid monolayer of xenon adsorbed on the (110) face of copper by low-energy electron diffraction and Auger electron spectroscopy. The crystalline adsorption model, shown in Fig. 1, may be modified by considering the commensurate-incommensurate transition into solid adsorbate, as shown in Fig. 8. The results obtained in the present experiment will be dicussed on the basis of this modified crystalline adsorption model.

In a pervious paper, we considered that the crystalline adsorbate is formed on the nucleation catalyst as soon as $CH_3CO_2Na \cdot 3H_2O$ is forced to crystallize from a supercooled melt. However, $CH_3CO_2Na \cdot 3H_2O$ solid adsorbate which is formed as soon as $CH_3CO_2Na \cdot 3H_2O$ is forced to crystallize from a supercooled melt containing a nucleation catalyst (adsorbent), is considered to be incommensurate with the adsorbent. The negative heat of adsorption of metastable incommensurate solid adsorbate on the nucleation catalyst is not so large as that of liquid (fluid) adsorbate. Therefore, the incommensurate solid adsorbate melts near the bulk melting point of $CH_3CO_2Na \cdot 3H_2O$ and thus the deactivation temperature of the nucleation catalyst in this state is not so high.

The incommensurate solid adsorbate is transformed into the commensurate solid adsorbate (crystalline adsorbate) with elapse of time, because incommensurate solid adsorbate is considered to be a metastable phase. The negative heat of adsorption

of commensurate solid adsorbate on the adsorbent is considered to be much larger than that of liquid adsorbent. Therefore, the commensurate solid adsorbate does not melt near the bulk melting point of $CH_3CO_2Na \cdot 3H_2O$ and thus the deactivation temperature of the fully aged nucleation catalyst is much higher.

The transformation of incommensurate into commensurate solid adsorbate is considered to proceed with atomic (ionic) diffusion, because the rate of transformation is dependent on aging temperature. In the modified adsorption model illustrated in Fig. 8 as well as the crystalline adsorption model shown in Fig. 1, the commensurate solid adsorbate is transformed directly into the liquid adsorbate at elevated temperatures.

According to the modified crystalline adsorption model, a satisfactory, though qualitative, explanation has been given to the obserbations on the heterogeneous nucleation of $CH_3CO_2Na \cdot 3H_2O$, including the aging effect on nucleation catalyst. The modified crystalline adsorption model is expected to apply to heterogeneous nucleation of other salt hydrates such as $CaCl_2 \cdot 6H_2O$. Some quantitative explanation of these crystal nucleation catalytic actions remains to be given.

The authors wish to express their thanks to Dr. Ryoichi Kiriyama for his helpful discussion and to Drs. Eiichi Hirota, Tsuneharu Nitta, and Masanari Mikoda and Mr. Yukihiko Ise for their continuous encouragements. They are also grateful to Drs. Yoshihiro Matsuo and Ryoichi Yamamoto for their discussions throughout this work.

(Received August 31, 1984)

Resonance Raman and ^{129}I Mössbauer spectroscopy have been used in a study of iodine doped poly(thienylene)s, which are chemically synthesized by the polymerization of dibromothiophenes. It is shown that the iodine species in the polymers are present predominantly in the form of a polyiodide which consists of unsymmetrical I_3^- and I_2 units. That is, the iodine molecule doped is reduced by taking electrons from the polymer in a similar manner to iodine doped in polyacetylene. This result is consistent with the fact that poly(thienylene)s undergo an increase in electrical conductivity upon doping with iodine.

Extensive studies have been made of electrically conducting organic polymers doped with either strong electron acceptors or donors. Polyacetylene especially, the simplest linear conjugated polymer, has attracted attention because the electrical conductivity can be varied over 12 orders of magnitude from insulator to semiconductor and metal by doping with arsenic pentafluoride (AsF_5) or iodine (I_2).[1] Polymers containing a phenylene ring in the polymer chain, poly(*p*-phenyline),[2,3] poly(phenylene vinylene),[4] and poly(phenylene sulfide),[5-7] also undergo a large increase in electrical conductivity upon doping with AsF_5. This behavior is similar to that of polyacetylene. However, when these polymers are exposed to iodine vapor, a relatively weak electron acceptor, the conductivities do not increase as is observed for polyacetylene. ^{129}I Mössbauer studies have revealed that iodine doped in poly(*p*-phenylene) exists as an almost free iodine molecule, whereas iodine doped in poly(phenylene sulfide) interacts weakly with the sulfur atoms of the polymer chain.[8,9]

Recently poly(thienylene), which consists of a linear sequence of thiophene rings, as shown in Fig. 1, has been found to exhibit a high conductivity ($\approx 10^{-1}$ S/cm) upon exposure of I_2 vapor at room temperature.[10] This is the second polymer which exhibits a high conductivity with the iodine doping. It is important for the understanding of the conduction mechanism to determine the chemical form and the electronic structure of the iodine species present in the polymer. Resonance Raman and ^{129}I Mössbauer spectroscopy are useful methods for investigating the chemical and electronic structures of iodine, and have been successfully applied for iodine-doped polyacetylenes.[11-14] In the present work we report on resonance Raman and ^{129}I Mössbauer spectroscopic studies of the iodine species in poly(2,5-thienylene) and in poly(3-methyl-2,5-thienylene).

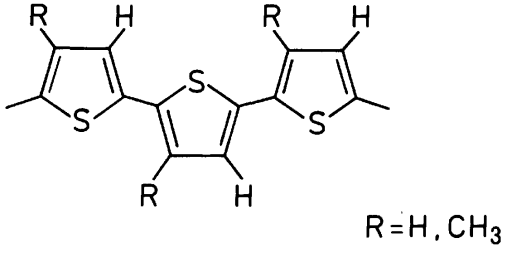

Fig. 1. Idealized chemical structure of poly(2,5-thienylene) or poly(3-methyl-2,5-thienylene).

Experimental

Poly(2,5-thienylene) and poly(3-methyl-2,5-thienylene) were synthesized by the polymerization of 2,5-dibromothiophene and 3-methyl-2,5-dibromothiophene, according to the method described previously.[10] Both powdery polymers used in this work were $CHCl_3$-insolvable fractions. The iodine-doping was carried out by immersing the polymer in a CCl_4 solution of iodine at room temperature for 1 d. The iodine content of the specimen used for the resonance Raman measurement was determined to be 43 wt-% for poly(2,5-thienylene) and 52 wt-% for poly(3-methyl-2,5-thienylene) by gravimetric analysis. Radioactive $^{129}I_2$ ($t_{1/2}=1.7\times10^7$ y), which was prepared by oxidizing Na ^{129}I in Na_2SO_3 solution with 6 M-H_2SO_4 (1 M=1 mol dm^{-3}) and 10%-H_2O_2 and extracting with CCl_4, was used for the Mössbauer sample. The iodine content was found to be 24 wt-% for poly(2,5-thienylene) and 12 wt-% for poly(3-methyl-2,5-thienylene). The sample thickness for the Mössbauer measurement was about 20 mg $^{129}I/cm^2$.

Laser Raman spectra were measured with Ar^+ (514.5 nm) excitation by using a JEOL-JRS-400T triple monochromator. The data were obtained with compressed pellets of the powdery samples by the front surface reflection method using 60 mW of laser power and a spinning cell, in order to prevent decomposition of the iodine species. No decomposition was observed within this laser power, though the scans were made repeatedly for each iodine-doped sample.

^{129}I Mössbauer effect measurements were performed in a transmission geometry by cooling the source and the absorber sample at 16 K with a closed cycle helium refrigerator "Cryodyne 1020." The Mössbauer source, $^{66}Zn^{129}Te$ ($t_{1/2}$=70 min) was prepared by neutron irradiation

of a 140 mg $^{66}Zn^{128}Te$ compound at flux of 2×10^{13} neutrons/cm^2·s for 1 h in the Kyoto University Reactor (KUR). The source was used repeatedly. The constant acceleration drive was calibrated with an Fe foil.

Results and Discussion

A. Resonance Raman Spectroscopic Study. In Fig. 2 are presented resonance Raman spectra of iodine-doped poly(2,5-thienylene) (iodine content 43 wt-%) and iodine-doped poly(3-methyl-2,5-thienylene) (52 wt-%) excited by the Ar^+ 514.5 nm line. Both spectra (170 s, 145 w, 108 m, 63 w, cm^{-1}) are very similar to each other, indicating that the iodine species in both polymers has a similar chemical form. The possibility for the presence of free iodine molecules is clearly ruled out by finding no Raman band around 210 cm^{-1}. It is of interest to compare these spectra with those of iodine-doped polyacetylene. The Raman band at 108 cm^{-1}, also observed for iodine-doped polyacetylene at 105—107 cm^{-1},[11,12] can be assigned to the symmetric stretching vibration of a linear triiodide anion (I_3^-). Isolated and symmetrical I_3^- ions in methanol[15] and $(C_6H_5)_4As^+I_3^-$[16] show the Raman bands at 112 and 113 cm^{-1}, respectively, while the bands for unsymmetrical I_3^- ions and I_3^- units in polyiodides are observed in the 100 to 120 cm^{-1} region.[16,17] The latter distorted I_3^- ions give rise to a second weak band around 150 cm^{-1}, assigned to the antisymmetric stretching vibration. Therefore, the relatively weak band at 145 cm^{-1} observed in iodine-doped poly(thienylene)s is assigned to the antisymmetric vibration band of the distorted I_3^- ion.

On the other hand, the strong Raman band at 170 cm^{-1} seems to be due to an iodine molecule coordinated to the I_3^- ion. It is well known that molecular I_2 acts as a Lewis acid and coordinates to Lewis bases such as I^- and I_3^-. The coordination weakens the I-I bonding and shifts the I-I stretching band to lower frequency. Actually a few polyiodides which consist of I_3^- and I_2 units show the strong Raman bands for the I-I stretching vibration; 172 cm^{-1} for Cs_2I_8[16] and 173 cm^{-1} for $(\alpha\text{-CD})_2Li^+I_5^-8H_2O$.[17] The bands for I_3^- unit in these polyiodides are observed in the 105—110 cm^{-1} region as described previously. Notably the resonance Raman spectra of iodine-doped poly(thienylene)s are similar to the spectrum observed for the $(\alpha\text{-CD})_2Li^+I_3^-I_2 8H_2O$ inclusion compound, in which the iodine chain, constructed of alternate I_3^- and I_2 units, is slightly zigzagged and is included in the cavity of the α-cyclodextrin dimer.[18] Another example of the polyiodide is found in the perylene-iodine complex, which exhibits a high electrical conductivity ($\approx10^{-1}$ S/cm) at room temperature. This complex shows resonance Raman bands at 115 m and 145 w cm^{-1} assigned to the unsymmetrical I_3^- unit and at 175 s cm^{-1} to the weakly coordinated I_2 unit.[16] The agreement between the Raman spectra of this complex and of iodine-doped poly(thienylene)s is extremely close.

These results suggest strongly that iodine doped in poly(thienylene)s exists predominantly as a polyiodide

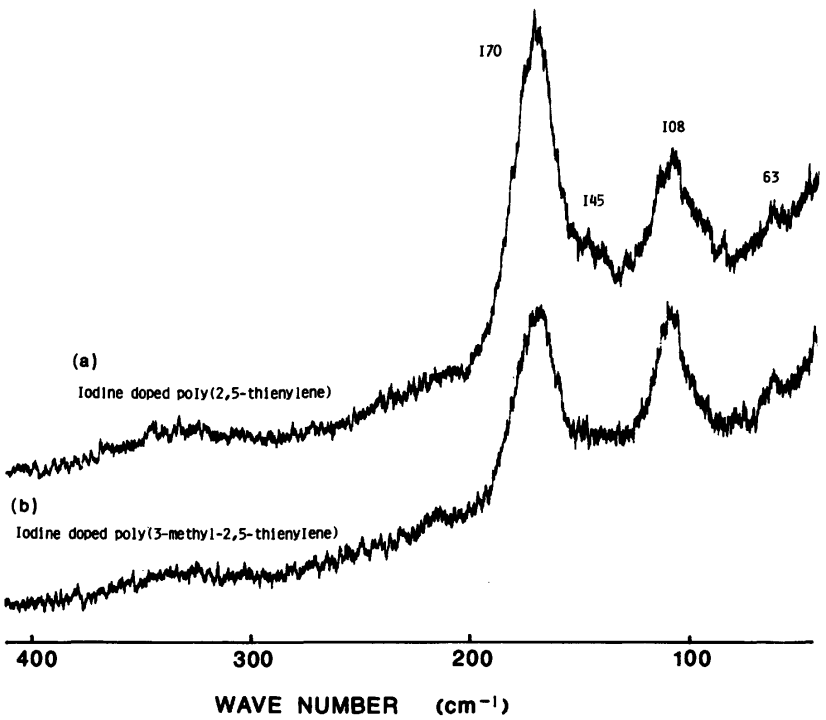

Fig. 2. Resonance Raman spectra of (a) iodine-doped poly(2,5-thienylene) and (b) iodine-doped poly(3-methyl-2,5-thienylene), observed with the 514.5 nm excitation.

made up of alternate I_3^- and I_2 units. In polyacetylene heavily doped with iodine, the strong Raman band is not observed at 170 cm^{-1} but another band appears at 150—160 cm^{-1}.[11,12] The intensity of this band is relatively weak compared to the intensity of the 105—107 cm^{-1} band and depends on the sample treatment. This band, different obviously from the 170 cm^{-1} band observed in iodine-doped poly(thienylene)s, is assigned to the linear I_5^- ion, because of the similarity of the Raman frequency (162 cm^{-1}) of (trimesic acid $H_2O)_{10}$ $H^+I_5^-$, which contains the linear and symmetrical I_5^- chain.[19] That is, the iodine species are present in polyacetylene heavily doped with iodine as the I_3^- chain and the linear I_5^- chain. Both iodine molecules doped in poly(thienylene)s and in polyacetylene act as electron acceptors and form polyiodides, though the chemical forms of these polyiodides differ slightly from each other.

Resonance Raman spectroscopy is obviously useful for the identification of the chemical form of the iodine species in the polymers, but there is a limitation with regard to the quantification of the relative amount of each iodine species, because the relative intensites of the resonance Raman bands are strongly dependent on the excitation wavelength. Furthermore, information about the electronic structure such as the charge distribution and the charge density can not be obtained in this method. ^{129}I Mössbauer spectroscopy can compensate for such disadvantages and has been actually applied to the iodine species in polyacetylene,[13,14] poly(*p*-phenylene),[8] or poly(phenylene sulfide).[9]

B. Mössbauer Spectroscopic Study. ^{129}I Mössbauer spectra of iodine doped in poly(2,5-thienylene) (iodine content 24 wt-%) and in poly(3-methyl-2,5-thienylene) (12 wt-%) are presented in Figs. 3 and 4, respectively. In spite of the different iodine contents, both spectra are similar to each other, which agrees with the result of the resonance Raman spectra. The Mössbauer spectra clearly rule out the presence of the isolated I^- ion, which is inactive and undetectable by Raman spectroscopy. The presence of the I^- ion, observed in polyacetylene extremely lightly doped with iodine,[13] would show the single absorption peak at −0.5 mm/s in the spectrum. Since the spectra are complicated, the presence of the free iodine molecule is not clear. However, the resonance Raman spectra of more heavily doped samples do not indicate the presence of any free iodine molecules.

We attempted first to analyze the spectra in terms of three different iodine sites, *i.e.*, the superposition of three quadrupole octet patterns, assuming those asymmetry parameters to be zero. In the case of the spectrum of iodine-doped poly(3-methyl-2,5-thienylene) (Fig. 4), the fitting analysis indicated acceptable agreement between observed and calculated spectra, though the line-width of the intermediate quadrupole split pattern was broadened considerably. This broadening is presumed to be due to an overlap of the spectra originated from two iodine sites which have slightly different values of the quadrupole coupling constant (e^2Qq) and the isomer shift (δ). The best fitted subspectra of each component and their peak positions for the three unequivalent iodine sites are represented

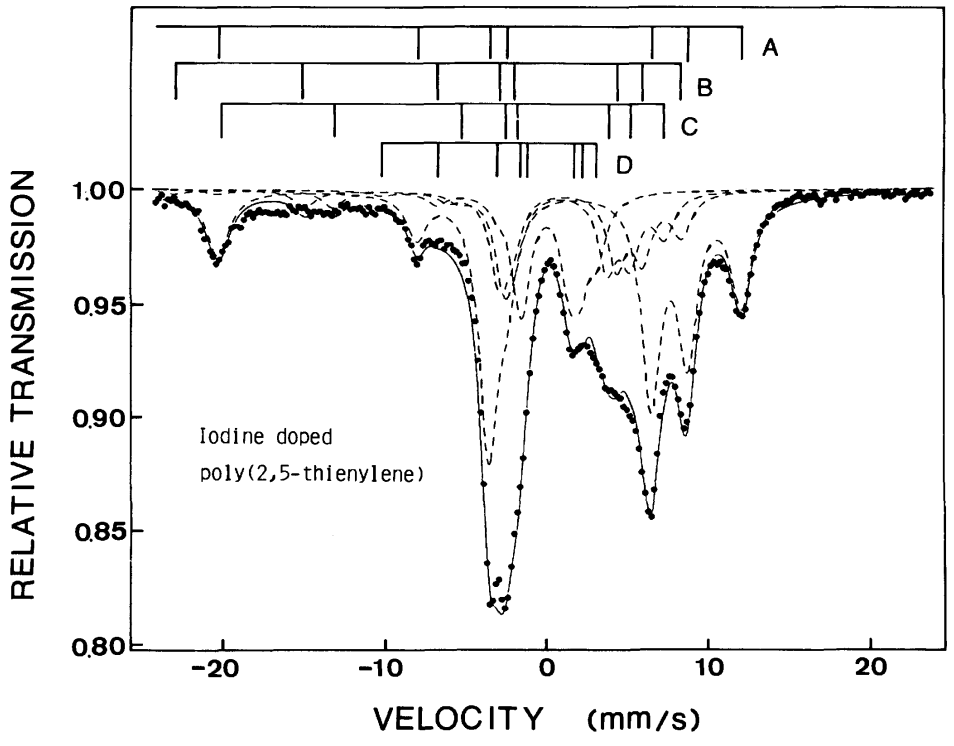

Fig. 3. ^{129}I Mössbauer spectrum of iodine doped in poly(2,5-thienylene) at 16 K.

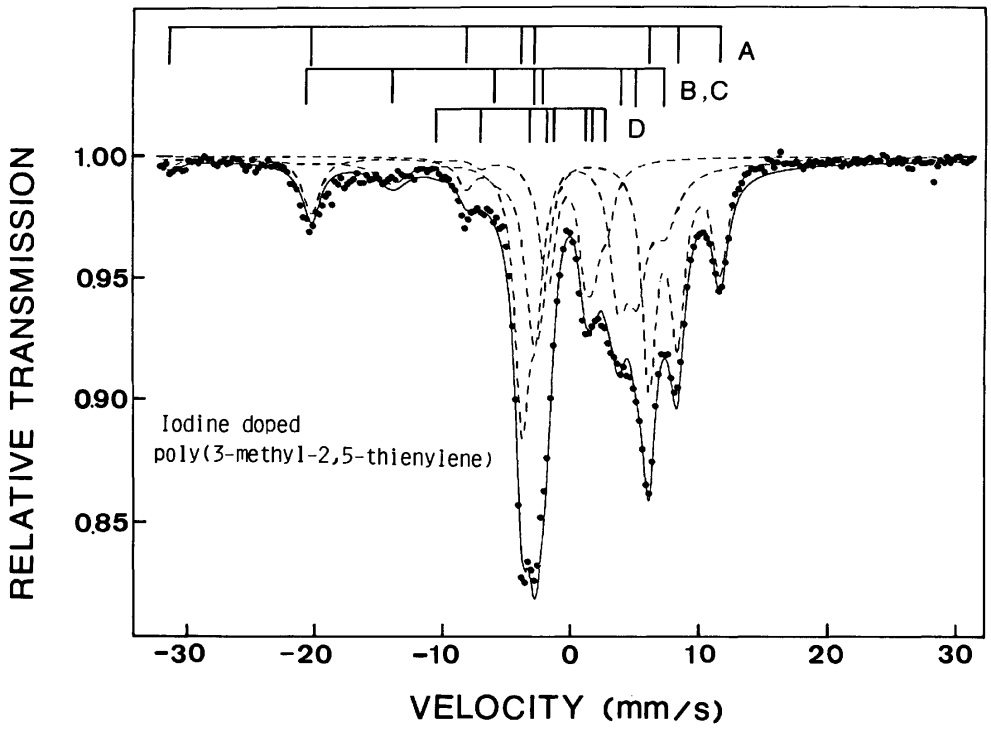

Fig. 4. ^{129}I Mössbauer spectrum of iodine doped in poly(3-methyl-2,5-thienylene) at 16 K.

by dashed curves and stick diagrams, respectively, as shown in Fig. 4. Since the sub-spectrum with the intermediate quadrupole splitting is expected to consist of two slightly different iodine sites, the notations B and C are used for these two iodine sites. On the other hand, for the more expanded spectrum of iodine-doped poly(2,5-thienylene) (Fig. 3), a satisfactory agreement was not obtained by the analysis with three different iodine sites. The analysis of the spectrum with four unequivalent iodine sites gave rise to a reasonable agreement, as shown in Fig. 3. The dashed curves represent the best fitted sub-spectra for each iodine site and the stick diagrams indicate the peak positions of the sub-spectra, where the four iodine sites are symbolized with A, B, C, and D. The obtained Mössbauer parameters, such as the quadrupole coupling constant (e^2Qq), isomer shift (δ), full-width at half-maximum (2Γ), and relative area, are summarized in Table 1.

The e^2Qq and δ values for site A are larger than those for the free iodine molecule in inert matrices (e^2Qq=−1587 MHz, δ=+0.98 mm/s for I_2 in hexane[20]), which indicates that the iodine atom of site A has a slightly positive charge density. Such an iodine atom is observed in the central iodine of linear triiodide anions (I_3^-); e^2Qq=−1750 MHz, δ=+1.40 mm/s for the central iodine of CsI_3:[21] e^2Qq=−1725 MHz, δ=+1.48 mm/s for $[Ru(cp)_2I]I_3$.[22] It is therefore reasonable to assign site A to the central iodine atom in an I_3^- ion. The e^2Qq values for the terminal iodine atoms of the unsymmetrical I_3^- in CsI_3 are found to be −1025 MHz and −580 MHz from the ^{129}I Mössbauer measurement.[21] These values are in good agreement with those obtained from the ^{127}I NQR method;[23] 1007 MHz and 574 MHz at 77 K, converted to ^{129}I using the ratio $^{129}Q/^{127}Q$=0.7013. For the symmetrical I_3^- in $[Ru(cp)_2I]I_3$, the e^2Qq value is −808 MHz for both terminal iodine atoms[22], and indicates the average of two e^2Qq values for the terminal iodines in the unsymmetrical I_3^-. Since each e^2Qq value for site C or D is comparable to that for each terminal iodine of CsI_3, we assign site C and site D to the two terminal iodine atoms in the unsymmetrical I_3^- ion.

These assignment are consistent with the resonance Raman spectra (108 cm^{-1} and 145 cm^{-1} bands), indicating the presence of an unsymmetrical I_3^- ion, as previously described. Since the unsymmetrical I_3^- ion consists of three unequivalent iodine sites with relative populations of 1:1:1, the relative absorption areas of the sub-spectra corresponding to sites A, C, and D are expected to be 1:1:1. However, the absorption area obtained for the sub-spectrum of the site A is 2.7 to 2.8 times that of site D, as shown in Table 1. This result predicts the presence of another iodine atom (designated as site A′) with the same charge density as the central iodine atom in the I_3^- ion. The strong Raman band at 170 cm^{-1} suggests that the I_2 unit interacting with the I_3^- unit exists in iodine-doped poly(thienylene)s. Therefore, the iodine atom of site A′ and an iodine atom of site B seem to constitute this I_2 unit. It is appropriate to assign site A′ to the iodine atom coordinating to one (site D) of the unsymmetrical I_3^- ion and site B to the terminal iodine atom of the I_2 unit, because

TABLE 1. ^{129}I MÖSSBAUER PARAMETERS FOR IODINE DOPED IN POLY(2,5-THIENYLENE) AND POLY(3-METHYL-2,5-THIENYLENE)

	D	−533±20	−0.04±0.04	1.34±0.06	1.0	0.33	0.33

a) Isomer shifts (δ) are relative to the ZnTe source. b) Line-widths (2Γ) are full-width at half-maximum. c) Relative areas are normalized with respect to the D site. d) $U_p = e^2Qq/e^2Qq_{atom}$, $e^2Qq_{atom} = -1608$ MHz. e) $\delta = 1.5\,h_p - 0.54$ (mm/s).

the values of e^2Qq and δ suggest that the former (the bridging iodine atom) is positively charged and the latter is negatively charged.

Consequently the iodine species present in poly(thienylene)s have the following structure:

$$[I\text{——}I\text{——}I\cdots\cdots I\text{——}I]^-$$
site C A D A′ B

Taking into account the above structure of the iodine species, the absorption area for the sites A and A′ is still large compared with those for each site B, C, or D. The enhanced absorption area is explained on the basis of the difference in the recoilless fraction. That is, the recoilless fractions of sites A and A′ are larger than those of sites B, C, and D, because the central and bridging iodine atoms are bound to two neighboring iodine atoms. This effect is often observed for the I_3^- ions in $[Ru(cp)_2I]I_3$[22] and a β-carotene-iodine complex,[24] in which the central atom indicates stronger absorption intensity than each terminal atom. The fit achieved by assuming the asymmetry parameters to be zero gave rise to a satisfactory result. Accordingly even if they would not be zero, they may be small. This suggests that the iodine species made up of the I_3^- and I_2 units possesses a nearly linear arrangement.

The charge density localized on each iodine atom is calculated from the values of e^2Qq and δ by the usual procedure;[25,26]

$$e^2Qq = -U_p \cdot e^2Qq_{atom},$$
$$\delta(\text{mm/s}) = 1.5\,h_p - 0.54 \text{ (ZnTe source)},$$

where e^2Qq_{atom}, the atomic iodine quadrupole coupling constant, is equal to 1608 MHz for ^{129}I, and U_p, the number of unbalanced p electrons, is proportional to the difference of $5p_\sigma$ and $5p_\pi$ electron populations; h_p is the number of p electrons removed from the $5s^25p^6$ (I^-) configuration. Therefore, when the bonding of iodine is formed by only $5p_\sigma$ electrons, one expects the relationship $U_p = h_p = 1 \pm i$ to be valid, where i is the ionic character. When $5p_\pi$ electrons take part in bond formation, in addition to $5p_\sigma$ electrons, the relationship that $U_p < h_p$ is generally observed. On the other hand, the contribution of 5s electrons leads to the relationship that $U_p > h_p$ because of the decrease in the s electron density at the nucleus. The values of U_p and h_p obtained from the above expressions are given in Table 1. They are in good agreement with each other for the terminal iodine atoms of sites B, C, and D, indicating that the bonding is mainly due to $5p_\sigma$ electrons. The charge densites localized on sites B, C, and D are evaluated to be −0.22, −0.30, and −0.67 respectively, for the iodine species present in poly(2,5-thienylene). For the iodine species in poly(3-methyl-2,5-thienylene), the iodine atoms at sites B and C are negatively charged by about 0.27, and iodine at site D by 0.67.

On the other hand, it is evident that the U_p value is smaller than h_p for the central (site A) and bridging (site A′) iodine atoms. This tendency is generally observed for the central iodine atom in the I_3^- ions[21,22,24] and for the bridging iodine atom in amine-iodine charge transfer complexes.[27,28] In our previous paper[28] it was proposed that the tendency was explained in terms of the contribution of $4d_\sigma$ electrons to the bond formation rather than the participation of the π-bonding. That is, the chemical bond of the I_3^- ion is described by a mixture of a four-electron three-center bond and a covalent bond of the $d_\sigma p_\sigma$ hybrid orbitals. The contribution of the $4d_\sigma$ electrons remarkably increases the isomer shift but hardly increases the quadrupole coupling constant. The charge densities localized on the central and bridging iodine atoms are consequently evaluated to be +0.07 to +0.09 from the U_p values.

The total charge densities are close to unity for the iodine species present in both polymers, as can be seen below.

charge −0.30 +0.09 −0.67 +0.09 −0.22
I——I——I ····· I——I
site C A D A′ B
[iodine species in poly(2,5-thienylene)]

charge −0.27 +0.07 −0.67 +0.07 −0.27

I———I———I ..... I———I

site C A D A′ B

[iodine species in poly(3-methyl-2,5-thienylene)]

The charge densities for sites B and C are not rigorously equal because of the broad line-width of the corresponding sub-spectrum for iodine-doped poly(3-methyl-2,5-thienylene), then the value of −0.27 represents the average value of sites B and C. The iodine species observed in this polymer is essentially identical to that in poly(2,5-thienylene). The charge densities for sites A′ and B of the I_2 unit are close to those for sites A and C in the I_3^- unit, which suggests that the intermolecular $I_D \cdots I_{A'}$ bonding is considerably strong. This result is also supported by the fact that the I_2 unit shows the stretching vibration band at 170 cm^{-1}, largely shifted from 210 cm^{-1} of the isolated I_2 molecule.

In summary, resonance Raman and ^{129}I Mössbauer spectroscopy have revealed the chemical forms and the electronic structures of the iodine species in poly(2,5-thienylene) and in poly(3-methyl-2,5-thienylene). The iodine species are found to be present predominantly in the polymers as polyiodides consisting of unsymmetrical I_3^- and I_2 units. That is, the iodine molecule doped acts as an electron acceptor and produces the positive holes in the polymers, in a similar manner to iodine doped in polyacetylene. This result strongly suggests that poly(thienylene)s undergo an increase in electrical conductivity upon doping with iodine.

We wish to thank Professor Takenobu Higashimura (Research Reactor Institute, Kyoto University) for his encouragement. We are greateful to Professor Masamichi Kobayashi (Department of Polymer Chemistry, Osaka University) for his valuable discussion on the Raman spectra. We are also indebted to Mr. Shuichi Muraishi (JEOL Ltd.) for the measurements of the Raman spectra.

Solvation and Protonation of 1,10-Phenanthroline in Aqueous Dioxane Solutions

Shin-ichi ISHIGURO, Hideo WADA, and Hitoshi OHTAKI*
Department of Electronic Chemistry, Tokyo Institute of Technology at Nagatsuta, 4259, Nagatsuta-cho, Midori-ku, Yokohama 227
(Received October 6, 1984)

Solvation and protonation of 1,10-phenanthroline (phen) have been studied by potentiometry and calorimetry in various aqueous dioxane solutions. Protonation reactions were studied in the mixtures (the dioxane content x=0—0.4 mole fraction) containing 0.3 mol dm^{-3} NaCl as a constant ionic medium at 25 °C. Potentiometric and calorimetric titration curves obtained in the range of $-\log[H^+]$=2—7 were well explained in terms of the formation of Hphen$^+$ and H(phen)$_2^{2+}$, and the formation constants, enthalpies and entropies of formation of the species were determined. The formation constants of the both species gradually decreased with increasing x, and then the formation of H(phen)$_2^{2+}$ became negligibly small at x>0.1, while the enthalpy and entropy of formation of Hphen$^+$ first decreased and then increased with increasing x and thus minima were found at x=0.05. Enthalpies of solution of anhydrous 1,10-phenanthroline were also determined in both neutral (x=0—1) and acidic (0.1 mol dm^{-3} HCl, x=0—0.4) aqueous dioxane solutions. By knowing enthalpies of solution of 1,10-phenanthroline in acidic solutions and of formation of Hphen$^+$ in the mixed solvents, enthalpies of solution of 1,10-phenanthroline in neutral solutions (ΔH_s°(phen)) were evaluated and compared with those directly obtained in the neutral solutions ($\Delta H_{s,\text{neutral}}^\circ$). A significant difference was found between ΔH_s°(phen) and $\Delta H_{s,\text{neutral}}^\circ$ in the range x<0.3, which could be ascribed to the formation of stacked species of 1,10-phenanthroline molecules, (phen)$_n$. The variation of ΔH_s°(phen) with x was explained in terms of the enhanced solvation of dioxane to phenanthroline molecules owing to breaking of the hydrophobic water structure around them. Solvent effects on the formation of Hphen$^+$ and H(phen)$_2^{2+}$ were discussed in terms of different solvation behavior of 1,10-phenanthroline and proton with x.

Protonation reactions of 1,10-phenanthroline (phen) in aqueous solutions have so far been studied by potentiometry and calorimetry, and it has been reported that Hphen$^+$ and H(phen)$_2^{2+}$ were formed in the range of $-\log[H^+]$=2—7 and H$_2$phen^{2+} was also found in a solution of [H$^+$]>1 mol dm^{-3}.[1-5]

A proton NMR study of 1,10-phenanthroline solutions containing various concentrations of hydrochloric acid also suggested the formation of Hphen$^+$ and H(phen)$_2^{2+}$ and, in fact, the Hphen·ClO$_4$ and H(phen)$_2$·ClO$_4$ crystals were isolated.[6]

Due to the hydrophobicity of aromatic rings of 1,10-phenanthroline, the solubility of the neutral species is low in water, but remarkably increases in organic solvents and also in aqueous organic mixtures. With this point of view, protonation reactions of 1,10-phenanthroline have been studied in various aqueous alcohol solutions.[7]

Solvent effects on protonation reactions of 1,10-phenanthroline is very different from those of amines and amino acids. The protonation constant of Hphen$^+$ decreases with increasing concentration of an organic component in aqueous organic solutions, in contrast to protonation constants of amino and carboxyl groups which are practically invariable and remarkably increases, respectively, in the solutions.

The formation of H(phen)$_2^{2+}$ and different solvent effects on the formation of Hphen$^+$ from those on the formation of protonated amines or amino acids suggested an importance of solvation at aromatic rings of 1,10-phenanthroline in the course of protonation reactions of 1,10-phenanthroline. In order to elucidate the solvation phenomenon of 1,10-phenanthroline, enthalpies of solution of anhydrous 1,10-phenanthroline were determined both in neutral aqueous dioxane solutions (x=0—1) and in acidic ones containing 0.1 mol dm^{-3} HCl (x=0—0.4). Thermodynamic quantities, ΔG_n°, ΔH_n°, and ΔS_n°, for protonation reactions of 1,10-phenanthroline in various aqueous dioxane solutions will be discussed in connection with changes in solvation of the neutral and protonated species.

Experimental

Reagents. All chemicals used were of reagent grade. *1,10-Phenanthroline monohydrate* was recrystallized three times from water and then dried in a vacuum desiccator over P_2O_5 to prepare anhydrous 1,10-phenanthroline. *Sodium hydroxide* was prepared by electrolysis of an aliquot of a sodium chloride solution under an atmosphere of nitrogen gas in a polyethylene bottle. *Hydrochloric acid* and *sodium chloride* of super special grade were used without further purification. *Dioxane* was dried with metallic sodium and then distilled.

Method of Measurements and Analysis of Data. All potentiometric and calorimetric measurements were carried out in thermostated baths at (25.00±0.02) °C and (25.000±0.007) °C, respectively, which were placed in a room thermostated at (25.0±0.2) °C.

Throughout potentiometric and calorimetric titrations, 0.3 mol dm^{-3} NaCl was used as an ionic medium, except for the 0.4 mole fraction dioxane–water mixture in which a lower ionic medium of *ca.* 0.05 mol dm^{-3} NaCl was used because of the phase separation in a solution of a higher salt concentration. In the course of potentiometric titrations,

values of $-\log[H^+]$ in solutions were measured by using a glass electrode and an Ag–AgCl electrode as reference over the range 2 to 7. In calorimetric titrations, 1,10-phenanthroline solutions were titrated with a hydrochloric acid solution of *ca.* 0.3 mol dm^{-3}. The method of measurements were similar to those described elsewhere.[8]

Enthalpies of solution of anhydrous 1,10-phenanthroline were measured by dissolving a given amount of crystals of the anhydrous species in either neutral or acidic (0.1 mol dm^{-3} HCl) aqueous dioxane solution in which no medium salt was contained. Procedures of the measurements and analysis of data were described in a previous paper.[9]

Results and Discussion

The formation curves experimentally obtained, $\bar{n}_{H,obsd}=(C_H-[H^+])/C_L$, where C_H and C_L denote the total concentrations of proton and 1,10-phenanthroline in the solution, respectively, at each point of titration are depicted in Fig. 1. We found that experimental points systematically deviated from the theoretical curve (curve A in Fig. 1) calculated by assuming the formation of only Hphen$^+$. Thus we assumed the formation of other species such as H(phen)$_2^+$ and H(phen)$_3^+$ which may be expected to be formed at $-\log[H^+]=4$—6. As shown in Table 1, the introduction of H(phen)$_2^+$ (case 2) significantly improved the error square sum, $U=\sum\{(C_{H,obsd}-C_{H,calcd})^2+(C_{L,obsd}-C_{L,calcd})^2\}$, while further introduction of H(phen)$_3^+$ (case 3) did not improve the result anymore. Experimental points well fell on the curve (curve B in Fig. 1) calculated by assuming the formation of Hphen$^+$ and H(phen)$_2^+$. Therefore, we concluded that the Hphen$^+$ and H(phen)$_2^+$ species were formed in the solutions under the present experimental conditions.

Species	$\log\beta_n$		
	Case 1	Case 2	Case 3
Hphen$^+$	4.97(0.0061)	4.96(0.0032)	4.97(0.0025)
H(phen)$_2^+$	—	6.65(0.019)	6.63(0.10)
H(phen)$_3^+$	—	—	7.90(0.045)
U	8.3×10^{-7}	9.2×10^{-8}	9.1×10^{-8}

The values in parentheses refer to standard deviations.

Calorimetric titration curves are illustrated in Fig. 2 as the heat evolved, $\Delta H^\circ=q/vC_{H,tit}$, at the addition of a potion of a standard hydrochloric acid solution against the ratio C_H/C_L in the solution, where q, v, and $C_{H,tit}$ stand for heat measured and volume of the titrant added at each point of titration and concentration of hydrochloric acid in the titrant solution, respectively. The ΔH° curves obtained in the aqueous dioxane solutions depended on the ratio C_H/C_L, and the curves were well reproduced by assuming the formation of Hphen$^+$ and H(phen)$_2^+$ (the solid lines in Fig. 2).

The formation constants and enthalpies finally obtained by the least-squares procedure for the formation of Hphen$^+$ and H(phen)$_2^+$ in the aqueous dioxane solutions examined are summarized in Table 2. With increasing mole fraction of dioxane in the mixtures, the formation of H(phen)$_2^+$ became unfavorable and practically negligible in mixtures of $x>0.1$. It should

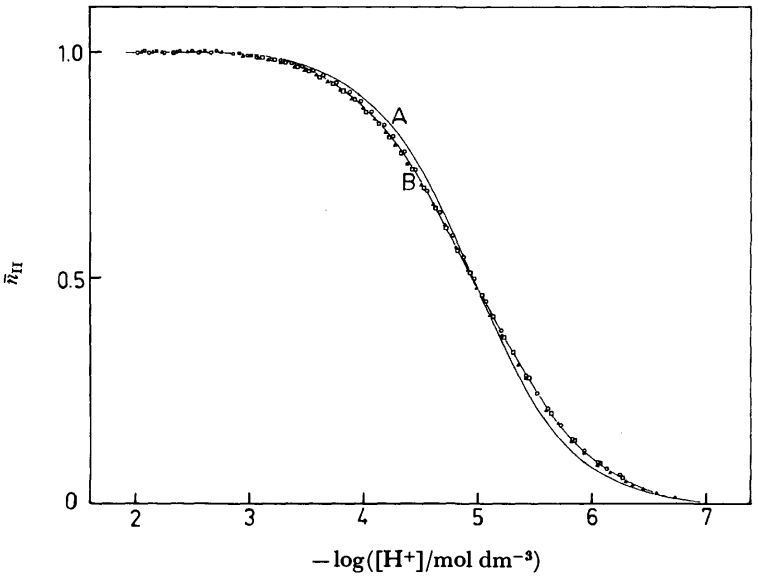

Fig. 1. Formation curves of protonated species of 1,10-phenanthroline (phen) in aqueous solution.
C_L(phen)/mmol dm^{-3}=7.215 (○), 10.84 (△), and 13.00 (□). The solid lines A and B were calculated in case 1 (Hphen$^+$ only) and case 2 (Hphen$^+$ and H(phen)$_2^+$), respectively.

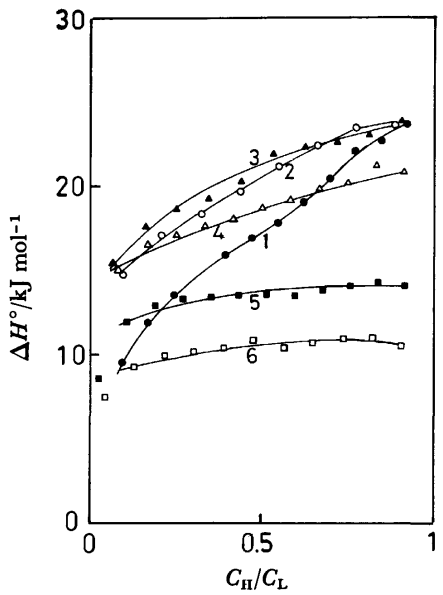

Fig. 2. Calorimetric titration curves of 1,10-phenanthroline aqueous dioxane solutions.
Curve 1: mole fraction of dioxane x=0.0; 2: 0.025; 3: 0.05; 4: 0.1; 5: 0.2; 6: 0.3. The solid lines show the curves calculated by using the constants obtained in Table 2.

be noted that the dependence of ΔH° on the ratio C_H/C_L became less pronounced with x in the mixtures (see Fig. 2). This reflected that the formation of $H(phen)_2^+$ became insignificant in the mixture of higher x.

The thermodynamic quantities, log (K_n/mol^{-1} dm^3), ΔG_n°/kJ mol^{-1}, ΔH_n°/kJ mol^{-1}, and ΔS_n°/JK^{-1} mol^{-1}, for the stepwise reactions, $H(phen)_{n-1}^+ + phen = H(phen)_n^+$ (n=1 and 2), are summarized in Table 3.

Enthalpies of solution of anhydrous 1,10-phenanthroline were determined in both neutral ($\Delta H^\circ_{s,neutral}$, x=0—1) and acidic ($\Delta H^\circ_{s,acid}$, x=0—0.4) aqueous dioxane solutions. In the neutral solvents, the formation of protonated species of 1,10-phenanthroline were negligible. In solutions involving 0.1 mol dm^{-3} HCl, 1,10-phenanthroline was fully converted into $Hphen^+$, but not into $H(phen)_2^+$ in such a highly acidic solution. Thus, the enthalpy of solution measured in an acidic solution at a given solvent composition was given as the sum of enthalpies of solution of 1,10-phenanthroline (ΔH_s°(phen)) and of formation of $Hphen^+$ (ΔH_1°), the latter value having been determined in the calorimetric titration experiment as described in the previous section. Thus ΔH_s°(phen)

was calculated according to Eq. 1.

$$\Delta H^\circ_s(\text{phen}) = \Delta H^\circ_{s,acid} - \Delta H^\circ_t \quad (1)$$

Values of ΔH°_s(phen), $\Delta H^\circ_{s,acid}$, and $\Delta H^\circ_{s,neutral}$ obtained in various aqueous dioxane solutions are summarized in Table 4.

Enthalpies of Solution of 1,10-Phenanthroline. If only monomeric 1,10-phenanthroline molecules were present in a neutral solution $\Delta H^\circ_{s,neutral}$ should be equal to ΔH°_s(phen). However, as seen in Fig. 3, ΔH°_s(phen) was appreciably different from $\Delta H^\circ_{s,neutral}$ in the dioxane-water mixtures of $x<0.3$. The difference may be ascribed to the formation of stacked neutral species of 1,10-phenanthroline, $(\text{phen})_n$, in the neutral solvent mixtures, as suggested by an NMR study in water.[10] The value of $\Delta H^\circ_{s,neutral}$ was always positive but smaller than ΔH°_s(phen) in the mixtures of $x<0.3$, which suggested that the enthalpy of formation of the stacks should be negative if such stacks of 1,10-phenanthroline are formed in the mixtures. Negative enthalpies for the formation of stacked species were also reported for Methylene Blue in aqueous mixtures of various alcohols.[11]

The value of ΔH°_s (phen) was practically the same as $\Delta H^\circ_{s,neutral}$ in the dioxane-water mixtures at $x=0.3$ and 0.4, and the results suggested that the stacks did not form in the solutions due, probably, to destruction of the hydrogen-bonded structure of water in the bulk, which led to the decomposition of the hydrophobic hydration sphere around the aromatic rings of 1,10-phenanthroline. Observations by means of X-ray diffraction[12] suggested the destruction of the hydrogen-bonded structure of bulk water at $x>0.3$.

Values of ΔH°_s(phen) were obtained in aqueous dioxane solutions at $x=0$—0.4, but not in solutions at $x>0.4$ on account of experimental difficulties for determination of ΔH°_t and $\Delta H^\circ_{s,acid}$. However, since self-

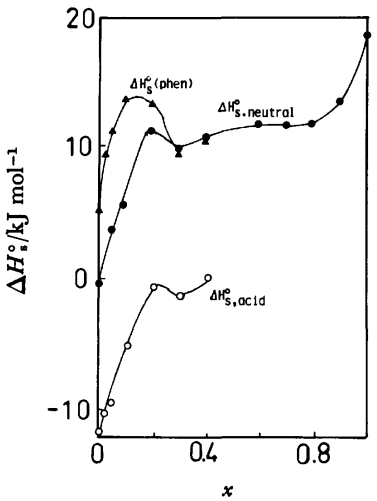

Fig. 3. Enthalpies of solution of 1,10-phenanthroline in neutral ($\Delta H^\circ_{s,neutral}$) and acidic ($\Delta H^\circ_{s,acid}$) solutions and ΔH°_s(phen) plotted against x.

stacking of 1,10-phenanthroline molecules was hardly expected in aqueous dioxane solutions at $x>0.4$ and, in fact, practically the same values of ΔH°_s(phen) as those of $\Delta H^\circ_{s,neutral}$ were found in the mixtures at $x=0.3$ and 0.4, we can reasonably assume that $\Delta H^\circ_s(\text{phen}) = \Delta H^\circ_{s,neutral}$ in aqueous dioxane solutions at $x>0.4$.

The value of ΔH°_s(phen) steeply increased with increasing x up to 0.1, and then slightly decreased in the range $x=0.1$—0.3. The sharp increase in ΔH°_s was also reported for the solution of 2,2′-bipyridyl in aqueous alcohol solutions with increasing alcohol content.[13] A further increase in x did not appreciably affect the ΔH°_s(phen) value until $x=0.8$. In the range $x>0.8$, ΔH°_s(phen) again steeply increased with x, and ΔH°_s(phen) in pure dioxane was more positive by about 13 kJ mol^{-1} than that in pure water. It is well known that the solubility of 1,10-phenanthroline markedly increases in organic solvents. Therefore,

the result that ΔH_s°(phen) was more endothermic in pure dioxane than in pure water indicated that the high solubility of 1,10-phenanthroline in dioxane was essentially owing to the contribution of a large entropy of solution of the species.

The variation of ΔH_s°(phen) in the range x=0—0.1 may be explained in terms of enhanced solvation of dioxane due to the breaking of the hydrophobic hydration structure around the aromatic rings of 1,10-phenanthroline molecules. A slight decrease of ΔH_s°(phen) in the range x=0.1—0.3 may be ascribed to the enhanced hydration of hydrophilic nitrogen atoms within 1,10-phenanthroline due to the breaking of the hydrogen-bonded water structure in the bulk. The enhancement of hydration of cations in aqueous dioxane solutions than in water has been suggested in a previous paper.[9]

The solvation structure of 1,10-phenanthroline with water at the sites of nitrogen atoms and with dioxane at the aromatic part may be practically remained unchanged in the range x=0.3—0.8, so that ΔH_s°(phen) was almost independent of solvent composition.

In solutions of the highest dioxane content x>0.8, water molecules solvating the nitrogen atoms within 1,10-phenanthroline may be replaced with dioxane molecules.

Solvent Effects on the Formation of Hphen$^+$.

The solvent effect on thermodynamic quantities for the formation of Hphen$^+$ was shown in Fig. 4, where the increments of ΔG_1°, ΔH_1°, and $T\Delta S_1^\circ$ in an aqueous dioxane solution from those in water, $\Delta\Delta G_1^\circ = \Delta G_1^\circ(\text{mix}) - \Delta G_1^\circ(\text{w})$, $\Delta\Delta H_1^\circ = \Delta H_1^\circ(\text{mix}) - \Delta H_1^\circ(\text{w})$, and $T\Delta\Delta S_1^\circ = T\Delta S_1^\circ(\text{mix}) - T\Delta S_1^\circ(\text{w})$, are plotted against x in the range x<0.4.

$\Delta\Delta G_1^\circ$ monotonously increased with increasing x, while $\Delta\Delta H_1^\circ$ and $T\Delta\Delta S_1^\circ$ first decreased and then increased after passing through minima at x=0.05 with increasing x. The change in $\Delta\Delta H_1^\circ$ can be expressed in terms of enthalpies of transfer, $\Delta H_t^\circ = \Delta H_s^\circ(\text{mix}) - \Delta H_s^\circ(\text{w})$, of the related species from water to the dioxane-water mixtures as follows:

$$\Delta\Delta H_1^\circ = \Delta H_t^\circ(\text{Hphen}^+) - \Delta H_t^\circ(\text{H}^+) - \Delta H_t^\circ(\text{phen}). \quad (2)$$

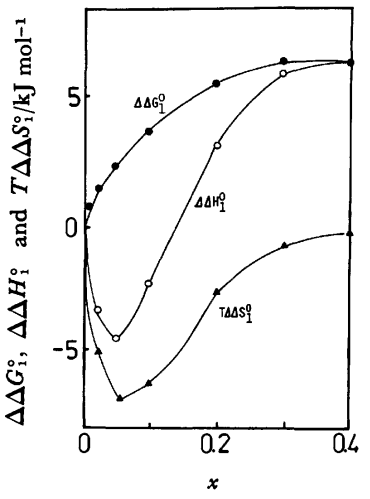

Fig. 4. Gibbs energies, enthalpies and entropies of formation of Hphen$^+$ in aqueous dioxane solutions relative to those in water.

By knowing values of $\Delta\Delta H_1^\circ$ and ΔH_t°(phen), the value of $\Delta H_t^\circ(\text{Hphen}^+) - \Delta H_t^\circ(\text{H}^+)$ was calculated according to Eq. 2, and the values of ΔH_1°, ΔH_t°(phen) and $\Delta H_t^\circ(\text{Hphen}^+) - \Delta H_t^\circ(\text{H}^+)$ thus calculated are summarized in Table 5. Since the enthalpy of transfer of proton $\Delta H_t^\circ(\text{H}^+)$ from water to the 0.2 mole fraction dioxane-water mixture was already reported in a previous paper,[9] $\Delta H_t^\circ(\text{Hphen}^+)$ from water to the mixture was also calculated and the values are also listed in Table 5.

Hphen$^+$ involves a hydrophilic $\gtrless$NH$^+$ group solvated with water and hydrophobic aromatic rings preferentially solvated with dioxane in aqueous dioxane solutions. The enthalpy of transfer of Hphen$^+$ from water to an aqueous dioxane solution should thus involve contributions of those of $\gtrless$NH$^+$ ($\Delta H_t^\circ(\gtrless\text{NH}^+)$) and aromatic rings ($\Delta H_t^\circ$(Ar)) within Hphen$^+$. The enthalpy of transfer of the $\gtrless$NH$^+$ group may be assumed to be similar to that of H$^+$, because it has been found that the enthalpy of transfer of the protonated ethylenediamine (Hen$^+$) from water to the 0.2 mole fraction dioxane-water mixture was very close to that of proton, *i.e.*, $\Delta H_t^\circ(\text{Hen}^+) \cong \Delta H_t^\circ(\text{H}^+)$.[9]

Table 5. Changes in enthalpy of formation of Hphen$^+$ relative to that in water and enthalpies of transfer ΔH_t°/kJ mol^{-1} of relevant species from water to aqueous dioxane solutions at 25 °C

x	$\Delta\Delta H_1^\circ$	ΔH_t°(phen)	$\Delta H_t^\circ(\text{Hphen}^+) - \Delta H_t^\circ(\text{H}^+)$	$\Delta H_t^\circ(\text{Hphen}^+)$	$\Delta H_t^\circ(\text{H}^+)$[a]
0.025	−3.1	4.5	1.4		
0.05	−4.1	6.3	2.2		
0.1	−2.1	8.7	6.6		
0.2	2.7	8.3	11.0	−11.7	−22.7

0.4	6.4	5.4	11.8		

a) Ref. 9.

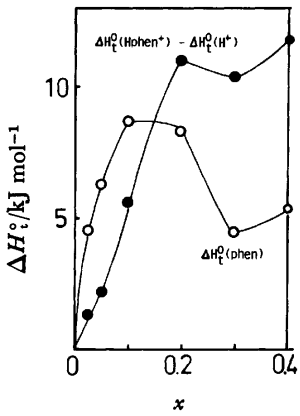

Fig. 5. Enthalpies of transfer, ΔH_t°(phen) and ΔH_t°(Hphen$^+$)$-\Delta H_t^\circ$(H$^+$), from water to aqueous dioxane solutions plotted against x.

If we assume that solvation of the protonated nitrogen atom $\gtrless$NH$^+$ within Hphen$^+$ with water varies in a similar manner to that of H$^+$ in the range x= 0—0.4, ΔH_t°(Hphen$^+$)$-\Delta H_t^\circ$(H$^+$) should approximately reflect the change in solvation of the aromatic rings within Hphen$^+$. Variations of ΔH_t°(Hphen$^+$)$-$ ΔH_t°(H$^+$) and ΔH_t°(phen) plotted against x (Fig. 5) show that they have a similar trend in the range x= 0—0.2. The result thus suggested that the aromatic rings within Hphen$^+$ was also significantly solvated with dioxane in the range of x up to 0.2. In the range x=0.2—0.3, ΔH_t°(phen) more steeply decreased with x than ΔH_t°(Hphen$^+$)$-\Delta H_t^\circ$(H$^+$), which may be caused by enhanced hydration at the sites of nitrogen atoms within 1,10-phenanthroline as discussed in a previous section.

The value ΔH_t°(Hphen$^+$) from water to the 0.2 mole fraction dioxane-water mixture was -11.7 kJ mol^{-1}, which should be represented as the sum of ΔH_t°($\gtrless$NH$^+$) and ΔH_t°(Ar). If we simply assume that ΔH_t°($\gtrless$NH$^+$)=ΔH_t° (H$^+$) in the range x=0—0.2, the value of ΔH_t°(Ar) from water to the 0.2 mole fraction dioxane-water mixture was estimated to be about 11 kJ mol^{-1}, which was slightly larger than ΔH_t°(phen) (8.3 kJ mol^{-1}). The slightly larger value of ΔH_t°(Ar) than ΔH_t°(phen) suggests that the hydration at the sites of nitrogen atoms within 1,10-phenanthroline was enhanced in the 0.2 mole fraction dioxane-water mixture relative to water.

Solvent Effects on the Formation of H(phen)$_2^+$. The formation of H(phen)$_2^+$ could be detected only in aqueous dioxane solutions of x<0.1, where the hydrogen-bonded structure of water in the bulk might still significantly remain and the stacks of 1,10-phenanthroline were expected to be formed.

Mitchell[14] suggested from measurements of the concentration dependence of the proton NMR spectrum of 1,10-phenanthroline in acidic solutions that considerable self-stacking occurred among 1,10-phenanthroline molecules to form the H(phen)$_2^+$ species. Considering that the H(phen)$_2^+$ species was not formed in aqueous dioxane solutions of relatively higher dioxane content in which the hydrogen-bonded structure of water in the bulk may be almost destructed, 1,10-phenanthroline molecules within H(phen)$_2^+$ may have a stacked structure. A suggested form for the structure of H(phen)$_2^+$ is illustrated in Fig. 6.

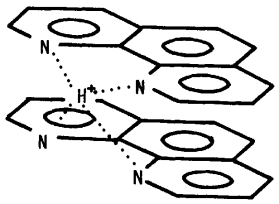

Fig. 6. The suggested structure of the H(phen)$_2^+$ species.

The values of ΔH_2° pertaining to the reaction, Hphen$^+$+phen=H(phen)$_2^+$, were negative in all aqueous dioxane solutions examined. The result can be expected because of negative enthalpies of formation of stacked oligomers of 1,10-phenanthroline (phen)$_n$.

The work has partially been supported by the Grant-in-Aid for Scientific Research No. 57470054 from the Ministry of Education, Science and Culture and Asahi Glass Foundation for Industrial Technology.

Oxygen-17 NMR Study of the Uranyl Ion. II.[1] Correlation between ^{17}O NMR Chemical Shifts and Wavelengths of UV-Visible Absorption Bands of Uranyl Complexes

Woo-Sik JUNG, Hiroshi TOMIYASU, and Hiroshi FUKUTOMI*
Research Laboratory for Nuclear Reactors, Tokyo Institute of Technology, O-okayama, Meguro-ku, Tokyo 152
(Received October 20, 1984)

^{17}O NMR chemical shifts, UV-visible and IR spectra of a series of $[UO_2L_n](ClO_4)_2$ (L=unidentate oxygen-donor ligand; n=coordination number) complexes in nonaqueous solvents have been measured. The electronic transition bands of the UO_2^{2+} entity shift toward lower energies with the increase in base strength of ligands in the equatorial plane. The asymmetric stretching frequencies of U=O bands are also affected by the base strength of equatorial ligands and correlated with the lowest electronic transition energies of uranyl complexes with the same geometry. The ^{17}O chemical shifts are shown to be related to the lowest electronic transition energies of uranyl complexes. It appears that oxygen isotope shifts in ^{17}O NMR spectra of the uranyl ion are predominantly attributed to the increase in the lowest electronic transition energies.

The electronic structure of dioxouranium(VI) (uranyl) ions has been extensively studied by UV-visible, infrared, and Raman spectroscopy.[2] In particular, much attention has been paid to ligation effects on the vibrational spectrum of the uranyl ion. Recently Bray and Kramer[3] showed that there are some correlations between spectroscopic parameters and ligand(L) basicity for UO_2(hexafluoroacetylacetonato)$_2$L. They reported that the asymmetric stretching frequencies of U=O bonds decrease with increasing the base strength of ligands L in the vapor phase and benzene solution.

Our interest in ligation effects on U=O bonds has led to the study of UV-visible, infrared, and ^{17}O NMR spectra of $[UO_2L_n](ClO_4)_2$,[4] in which the base strength of ligand L in the equatorial plane may be characterized by its donor number.[5] Electronic spectra of uranyl complexes exhibit a remarkable similarity, which implies that UV-visible absorption bands arise from electronic transitions within the UO_2^{2+} entity. The absorption bands could be divided into three groups with origins at 22050, 24150, and 27000 cm^{-1} representing the three components of the triplet state which is split by the equatorial field.[2a] Furthermore, the vibronic fine structure is superimposed on these absorption bands. We investigated the variation in the position of electronic transition bands by changing ligand L. It is also of interest to see whether the position of the bands is correlated with the uranyl asymmetric stretching frequency.

From the study of ^{17}O NMR spectroscopy of oxygen-containing compounds, it is evident that ^{17}O NMR chemical shifts are very sensitive to a change in the nature of oxygen bonding.[6] In this connection it is interesting to study ligation effects on the ^{17}O NMR spectrum of oxygen in the uranyl ion (uranyl oxygens hereafter). There are a few ^{17}O NMR studies of uranyl complexes,[7] but no systematic study has been carried out. In this paper ^{17}O chemical shifts of uranyl oxygens of some uranyl complexes are reported and interpreted in terms of the lowest electronic transition energies in UV-visible spectra. Oxygen isotope shifts in ^{17}O NMR spectra of enriched uranyl oxygens in aqueous solution[1] may also be interpreted in terms of the lowest electronic transition energies.

Experimental

Preparation of Uranyl Complexes. Methods in the literature[8] were used to prepare all the uranyl complexes used in this study. Hydrated uranyl perchlorate was refluxed with triethyl orthoformate at 50—60 °C for 1 h, followed by the addition of dried nonaqueous solvent L at room temperature. The resulting crystals of $[UO_2L_n](ClO_4)_2$ were filtered, washed with diethyl ether and dried under reduced pressure. In the case of DEF a yellow oil was formed at the bottom of the flask. The supernatant fraction was decanted and the residual oil was stirred with successive portions of diethyl ether. The resulting oil was dried under reduced pressure. Synthesized complexes, which are listed in Table 1, were identified by elemental analyses and/or ^1H NMR measurements.

NMR Measurements. ^{17}O NMR measurements of uranyl oxygens in natural abundance were carried out at 13.46 MHz on a JEOL JNM-FX 100 FT-NMR spectrometer. A spectral width of 20 kHz, 8 K data points, and a 90° pulse width of 10 μs were used. One hundred and fifty thousand transients were usually collected. All measurements were made at 20 °C and all chemical shifts were downfield relative to $H_2{}^{17}O$ in natural abundance. No bulk susceptibility correction was made.

Sample solutions for NMR measurements were prepared by dissolving uranyl complexes in nonaqueous solvent-(L)-CD_2Cl_2 (CD_3CN for LNO complex) mixture, where $5[UO_2L_n(ClO_4)_2]<$[free ligand]. An additional measurement was carried out in the case of TMU complex, where [free TMU]=0. The concentration of complexes was about 0.1 M (1 M=1 mol dm^{-3}), and less soluble complexes were studied in saturated solutions. Sample solutions were introduced into NMR microcells (Wilmad). The microcell was inserted in a 10 mm o.d. NMR tube (Wilmad) containing reference water.

^{17}O NMR measurements of uranyl oxygens enriched by

using $H_2{}^{17}O$ (Merck, ^{17}O, 42.1; ^{18}O, 31.7 atom%) were carried out at 54.10 MHz on a JEOL JNM-GX 400 FT-NMR spectrometer. Detailed procedure for preparation of enriched uranyl oxygens is described in a previous paper.[1] The temperature of the solution was maintained at 24.4±0.1 °C.

UV-Visible and IR Spectra Measurements. UV-visible spectra (350—550 nm) were measured on a Shimadzu UV-365 spectrophotometer using 1 cm quartz cells. IR spectra in the region 4000—400 cm^{-1} were taken on a Hitachi 270-30 IR spectrophotometer using KRS-5 cells (Horiba). Sample solutions for UV-visible and IR measurements were prepared by dissolving each uranyl complex in the solvent corresponding to the equatorial ligand. An additional measurement was carried out for the TMU complex, where [free TMU]=0. The concentrations of sample solutions for UV-visible and IR spectra measurements were usually 0.01 and 0.3 M, respectively, and less soluble complexes were measured by using saturated solutions.

Results and Discussion

UV-Visible and IR Spectra. The electronic spectra of most uranyl complexes in this study exhibited three band groups with a well-defined vibronic structure, which are characteristic of uranyl complexes. On the other hand, no vibronic structure was observed in the third band group with the origin at 27000 cm^{-1} for TMU, LNO, and HMPT complexes. This arises from the fact that the third band group is overshadowed by an intense ligand-to-uranyl charge-transfer band when the base strength of equatorial ligands is considerably high. Assignment of the electronic states involved in the electronic absorption spectrum of the uranyl ion is still a matter of controversy, but the interpretation by McGlynn and Smith[2a] is generally accepted. They suggested that the absorption band between 20500 and 30000 cm^{-1} results from excitation of an electron from the highest filled π-orbital to a nonbonding orbital on uranium (ϕ_u or δ_u).

It was found that an increase in base strength of equatorial ligands results in a bathochromic shift of the electronic transition bands. As shown in Fig. 1, 0′←0″ band in the first electronic transition (band number I_0 after De Jaegere and Görller-Walrand's notation[9]) shifts toward lower energies with the increase in base strength of equatorial ligands. The same trend was observed for 2′←0″ band in the second transition (band number II_2[9]) except for the HMPT complex. Belford *et al.*[10] reported the similar results, in which absorption bands in visible region shifted toward higher energies with successive fluorination of acetylacetone in the bis(acetylacetonato)dioxouranium(VI), *i.e.* with decreasing the base strength of ligands.

These ligation effects on UV-visible spectra can be explained by McGlynn and Smith's suggestion.[2a] According to the suggestion, the electron density of the ϕ_u or δ_u atomic orbitals of uranium might be enhanced by σ(L-M) electron donation of equatorial

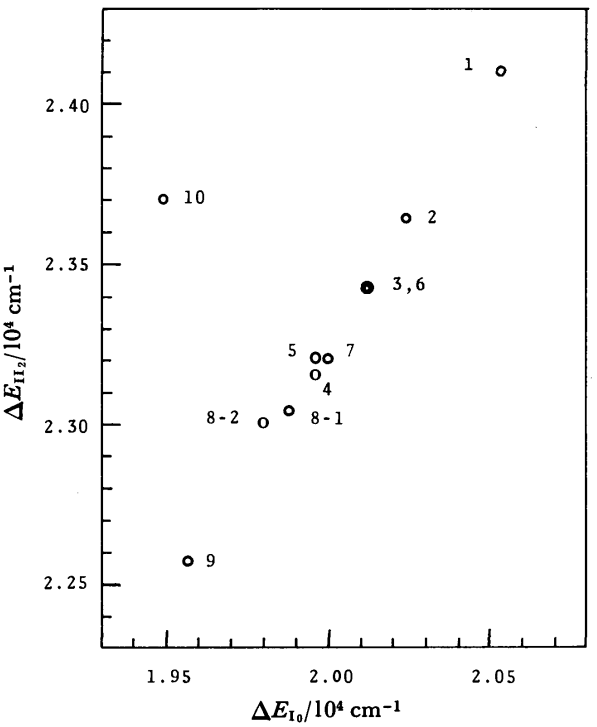

Fig. 1. Correlation of energies (ΔE_{II_2}) of 2′←0″ bands in the second electronic transition with energies (ΔE_{I_0}) of 0′←0″ bands in the first electronic transition. The figures correspond to those in Table 1.

ligands. This may result in stabilization of energy levels of nonbonding orbitals, thus lowering the electronic transition energies. The enhanced electron density on the uranium also causes a loosening of the U=O bond because of increased electrostatic repulsion with the highly negative axial uranyl oxygens.[2b] This is reflected in the asymmetric stretching frequency ν_{as} of the U=O bonds. It was observed, therefore, that the uranyl asymmetric stretching frequency is lowered by increasing base strength of equatorial ligands. These ligation effects on both UV-visible and infrared spectra give a good correlation between ν_{as} and the energy of 0′←0″ band in the first electronic transition (ΔE_{I_0}), as shown in Fig. 2. The fact that the results for four-coordinated HMPT and TMU complexes deviated from the correlation line in Fig. 2 may be explained in terms of the difference in geometry between four-coordinated complexes (D_{4h}) and the other complexes (D_{5h}), by considering that absorption spectra of uranyl complexes can be affected by difference in the number and geometric disposition of equatorial ligands.[2f] However, this explanation requires further study.

In addition to the electronic interaction as mentioned above, the uranyl asymmetric stretching frequency is also affected by vibrational interaction, which is attributed to the coupling between the U=O stretching and the bending of bonds between uranium and equatorial ligands. Jones[11] estimated

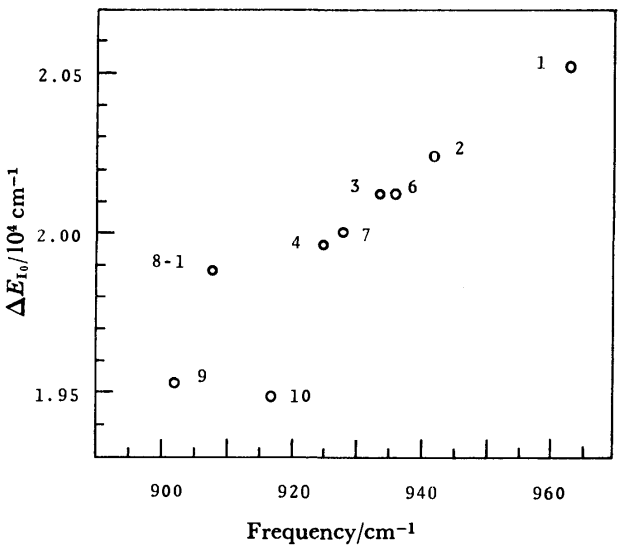

Fig. 2. Correlation of energies (ΔE_{I_0}) of 0′←0″ bands in the first electronic transition with the asymmetric stretching frequencies of the U=O bonds. The figures correspond to those in Table 1.

that the maximum alteration would be 3%. Furthermore, the effect of intermolecular interaction on ν_{as} can not be neglected when ν_{as} is measured in liquid sample. In the case of hydrated uranyl perchlorate, for example, ν_{as} measured in D_2O solution at pH 2.5 is about 10 cm^{-1} lower than that in H_2O solution at pH 2.5, while no variation in UV-visible spectra was observed in both the solutions. This phenomenon is ascribed to the solvent effect, where hydrogen bonds between uranyl oxygens and D_2O are stronger than those between uranyl oxygens and H_2O. It is known that the hydrogen bond contributes to weakening the U=O bond strength.[12] However, the solvent effect in aprotic solvents employed in this study is considered to be negligible.

From our results of ligation effects on both UV-visible and infrared spectra, we propose that ΔE_{I_0} in UV-visible spectra and ν_{as} in infrared spectra can be used as parameters of the complexing ability (or base strength) of equatorial ligands toward the uranyl ion. The parameters may be compared to the donor number,[5] which is defined as the enthalpy of complex formation between the given solvent and antimony pentachloride in 1,2-dichloroethane solutions. Figures 1 and 2 show that the base strengths of DEA and DEF toward the uranyl ion are almost equal to those of DMA and DMF, respectively, although there are considerable differences in the donor numbers each other. Fukutomi *et al.*[13] showed that the donor property of ligands is correlated with the E_B parameter[14] in equilibrium study on the anation reaction of uranyl complexes.

^{17}O NMR Chemical Shifts. ^{17}O chemical shifts ($\delta^{17}O$) measured in this study are summarized in Table 1. It is noted that ^{17}O resonances of uranyl oxygens shift downfield with increasing the base strength of equatorial ligands of the uranyl ion. This ligation effect on ^{17}O chemical shifts can be explained in terms of the electronic transition energy.

The nuclear shielding of ^{17}O nuclei can be approximated as the sum of diamagnetic (σ_d) and paramagnetic (σ_p) terms, $\sigma=\sigma_d+\sigma_p$.[15] It has been shown[16] that the paramagnetic term is principally responsible for the total shielding constant in ^{17}O nuclear shieldings. This paramagnetic term can be expressed as follows[17]:

$$\sigma_p^A = -\frac{2e^2\hbar^2}{3m^2c^2\Delta E}\langle r^{-3}\rangle_{2p}\sum_B Q_{AB},$$

where A is the nucleus under investigation, B represents all the other nuclei in the molecule, m is the electron mass, $\langle r^{-3}\rangle_{2p}$ is the average value of the reciprocal cube of the 2p orbital radius, and ΔE is the "mean" excitation energy of the molecule. $\sum Q_{AB}$ is related to the electronic charges and bond orders. To a first approximation, the ΔE can be equated to the excitation energy of the lowest excited state. Figgis *et al.*[18] established a linear relationship between the ^{17}O chemical shifts for oxyanions of the transition metals and the reciprocal of their lowest electronic transition energies. Kazanskii[19] also showed the correlation between the ^{17}O chemical shifts of both the terminal and bridge oxygen atoms in polyoxometalates and the wavelength of the first charge transfer. The data for the uranyl ion in aque-

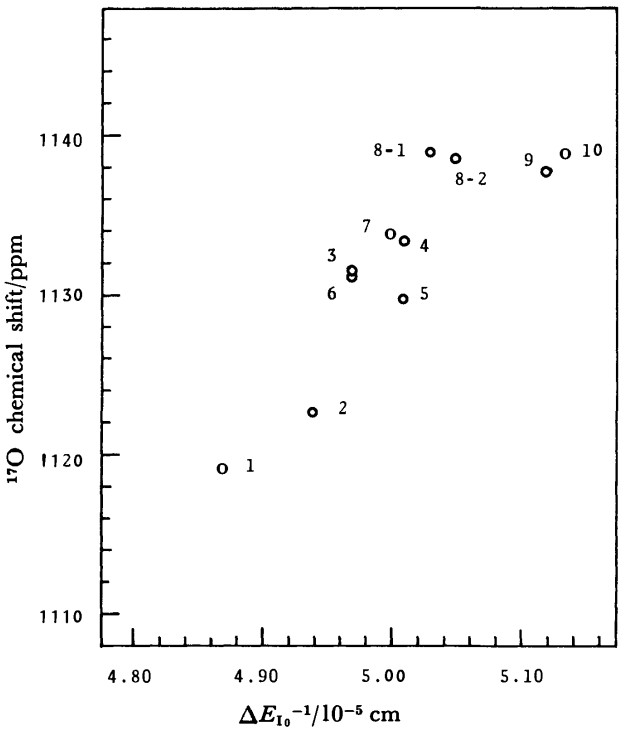

Fig. 3. Correlation of ^{17}O chemical shifts with the reciprocal of the lowest electronic transition energies. The figures correspond to those in Table 1.

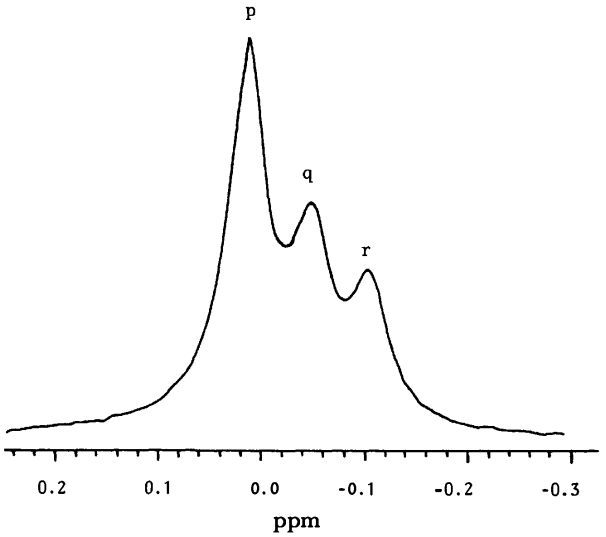

Fig. 4. ^{17}O NMR spectrum of the uranyl oxygens measured at 54.10 MHz. The uranyl oxygens were enriched by using $H_2{}^{17}O$ (42.1 atom%). $[UO_2{}^{2+}]$= 0.098 m and $[H^+]$=0.23 m (1 m=1 mol kg^{-1}). Typical ^{17}O spectral parameters are as follows: spectral width=1000 Hz, data points=16 K, scans=200, pulse width=10 μs. Peaks p, q, and r correspond to $[^{16}O{=}U{=}^{17}O]^{2+}$, $[^{17}O{=}U{=}^{17}O]^{2+}$, and $[^{18}O{=}U{=}^{17}O]^{2+}$, respectively.

ous solution (at pH 2.5, δ=1119.0 ppm; λ_{I_0}=487 nm) fall on the correlation line obtained by Figgis *et al.* This indicates that ΔE is the dominant factor in determining ^{17}O nuclear shielding of uranyl oxygens in uranyl complexes.

As shown in Fig. 3, a good correlation is observed between the ^{17}O chemical shifts and the reciprocal of the lowest electronic transition energies ($1/\Delta E_{I_0}$) of uranyl complexes. Besides the lowest electronic transition energy, the other factors such as U=O distance and the other electronic transition must be considered as minor factors. As mentioned above, the uranyl asymmetric stretching frequency, which can be a measure of the U=O bond distance,[20] changes with equatorial ligands. The variation in bond distance can affect ^{17}O nuclear shielding. Since an increase in U=O bond distance is expected to lead to an increase in ^{17}O nuclear shielding,[21] the ^{17}O chemical shift for the LNO complex may be lower than that expected from its lowest electronic transition energy (see Fig. 3). On the other hand, ΔE_{II_2} value for the HMPT complex is significantly higher than that expected from ΔE_{I_0} value, as shown in Fig. 1. Therefore, the contribution from the second electronic transition in the HMPT complex will be considerably smaller than in the other complexes, resulting in a low ^{17}O chemical shift.

Oxygen Isotope Shifts in ^{17}O NMR Spectra. In the previous paper[1] we assigned three peaks of ^{17}O-enriched uranyl oxygens to the signals of three isotopomers, *i.e.*, $[^{16}O{=}U{=}^{17}O]^{2+}$, $[^{17}O{=}U{=}^{17}O]^{2+}$, and $[^{18}O{=}U{=}^{17}O]^{2+}$. In order to support our previous results further, we measured the ^{17}O NMR spectrum of enriched uranyl oxygens at 54.10 MHz. As shown in Fig. 4, three peaks were much better resolved than those at 13.46 MHz. Chemical shifts for the signals of $[^{17}O{=}U{=}^{17}O]^{2+}$ and $[^{18}O{=}U{=}^{17}O]^{2+}$ isotopomers were observed to be -0.059 ± 0.004 and -0.117 ± 0.004 ppm, respectively, relative to $[^{16}O{=}U{=}^{17}O]^{2+}$, which are more accurate than values reported previously.[1] A few data on the isotope shift through two bonds have been reported,[22] but no data are available for the isotope shift through two bonds in ^{17}O NMR except for the oxygen isotope shifts in the uranyl ion. It may be, therefore, of interest to interpret these isotope shifts.

Heavy substitution of the molecule commonly leads to the reduction of the zero point vibrational energies.[23] Since this reduction is larger in the ground state than in the electronically excited state, the electronic transition energies of substituted molecules are generally shifted toward higher energies. In view of this fact the lowest electronic transition (0′←0″ band in the first electronic transition) of heavier isotopomers of the uranyl ion is expected to occur at higher energies. The increase in the lowest electronic transition energy, which is a dominant factor in determining the ^{17}O nuclear shielding of uranyl oxygens, will result in an increase in ^{17}O nuclear shielding. It is estimated from the correlation in Fig. 3 that the difference in chemical shifts between $[^{16}O{=}U{=}^{17}O]^{2+}$ and $[^{18}O{=}U{=}^{17}O]^{2+}$ at 24.4 °C corresponds to the difference of *ca.* 6.6 cm^{-1} in the lowest electronic transi-

tion energies. Unfortunately no experimental results are found for oxygen isotope shifts in the electronic absorption spectrum of the uranyl ion in aqueous solution. This small difference may be compared to the experimental value in $[UO_2Cl_4]^{2-}$, where the difference in the lowest electronic transition energies between $[^{16}O{=}U{=}^{16}O]^{2+}$ and $[^{18}O{=}U{=}^{18}O]^{2+}$ was observed to be 10 cm^{-1} at 4.2 K.[24]

Heavy substitution also leads to the change in U=O bond distance, but the contribution of this change to the ^{17}O nuclear shielding will be less important than that of the change in the lowest electronic transition energies, as indicated above. Mamayev *et al.*[25] demonstrated that, in a semi-empirical calculation of the isotope shifts in ^{13}C, ^{14}N, and ^{17}O NMR, the variation in the "mean" excitation energy cannot be left out of account on isotopic substitution of the molecule. It is considered that oxygen isotope shifts in ^{17}O NMR spectra of enriched uranyl oxygens can be explained only in terms of the change in the lowest electronic transition energies by isotopic substitution.

^{235}U-^{17}O Spin-Spin Coupling. Taking account of the fact that ^{17}O resonance of uranyl oxygens is very sharp, we intended to observe $^{235}U(I=7/2)$-^{17}O spin-spin coupling of enriched $^{235}UO_2^{2+}$ (*ca.* 90% ^{253}U) ion in aqueous solution. No fine structure was observed even at 65 °C. It appears that this is associated with a very small magnetic moment of ^{235}U nucleus. Oxygen isotope shifts measured at 65 °C for $^{235}UO_2^{2+}$ solution were somewhat lower than for $^{238}UO_2^{2+}$ solution at room temperature.

The authors wish to express their thanks to Messrs. Tohru Himoto and Naoyuki Fujii of JEOL, Ltd. for running some NMR spectra. This work was partially supported by a Grant-in-Aid for Scientific Research No. 5470035 from the Ministry of Education, Science and Culture.

(Received June 16, 1984)

Three geometrical isomers of [Co(NO$_2$)$_2$(NH$_3$)$_2$(en)]$^+$ were newly prepared. Two *cis*(NO$_2$) isomers (*trans*-(NH$_3$) and *cis,cis*) were clearly differentiated on the basis of the polarizabilities of the Raman bands due to Co-N(NH$_3$ and en) stretching vibrations. The Raman polarization measurement was also applied successfully to the determination of the geometrical configurations of two [Co(CN)$_2$(NH$_3$)$_2$(en)]$^+$ isomers. The structural assignments were substantiated by optical resolution of the *cis,cis* isomers of [Coa$_2$(NH$_3$)$_2$(en)]$^+$ (a=NO$_2^-$ and CN$^-$).

Three geometrical isomers (*trans*(a), *trans*(NH$_3$), and *cis,cis*) of [Coa$_2$(NH$_3$)$_2$(en)] type complex were first prepared by Bailar and Peppard[2] for a=Cl$^-$. In general, it is difficult to distinguish the two *cis*(a) isomers (*trans*(NH$_3$) and *cis,cis*) of [Coa$_2$(NH$_3$)$_2$(en)] type complexes on the basis of their electronic absorption spectra, since no definite difference could be expected between the spectra of the two *cis*(a) isomers because of the similarity in the ligand field strengths of NH$_3$ and ethylenediamine. Bailar and Peppard[2] distinguished the two *cis*(Cl) isomers of [CoCl$_2$(NH$_3$)$_2$(en)]$^+$ on the basis of their preparative method. Their assignment was confirmed later by optical resolution of the *cis,cis* isomer by Hawkins *et al.*[3] It is of interest to find a reliable spectroscopic method for differentiating the two *cis*(a) isomers of [Coa$_2$(NH$_3$)$_2$(en)] type complexes.

Raman spectra in the skeletal vibration region have been applied successfully to the differentiation of geometrical isomers of cobalt(III) complexes.[1,4,5] The Raman criteria established for the cobalt(III) complexes are expected to be profitably applied to the determination of the geometry of other metal analogs, whereas NMR method, although widely used in the stereochemistry of cobalt(III) complexes, would incur some difficulties in application to paramagnetic complexes such as chromium(III) complexes. In this paper, we report the preparation of three geometrical isomers of [Co(NO$_2$)$_2$(NH$_3$)$_2$(en)]$^+$ complex for the first time and the Raman method for differentiation between the two *cis*(a) isomers of [Coa$_2$(NH$_3$)$_2$(en)] type complexes.

Experimental

Three Geometrical Isomers of [Co(NO$_2$)$_2$(NH$_3$)$_2$(en)]ClO$_4$.

Method I: To a green solution of 0.9 g (3.5 mmol) of *trans*-(Cl)-[CoCl$_2$(NH$_3$)$_2$(en)]Cl[2] in 20 cm^3 of water containing a few drops of glacial acetic acid was added a solution of 0.9 g (13 mmol) of NaNO$_2$ in 10 cm^3 of water. After being stirred for 12 h, the color of the solution changed to yellowish brown. The solution was diluted to 2 dm^3 with water and poured onto a cation-exchange column (SP-Sephadex, C-25, Na$^+$ form; 3×50 cm). By eluting with 0.03 M NaClO$_4$ (1 M=1 mol dm^{-3}), two colored bands, both yellowish brown, descended. Each eluate was concentrated to a small volume in a rotary evaporator and ethanol was added to induce a precipitation of a yellowish brown powder. This powder was recrystallized from a small amount of warm water by adding ethanol. From the electronic absorption and Raman spectra the complex which was obtained from the first eluate was identified to be the *trans*(NO$_2$) isomer and that from the second eluate the *cis,cis* isomer. Yield: 0.3 g for the *trans*(NO$_2$) isomer and 0.2 g for the *cis,cis* one. Absorp. max. σ/10^3 cm^{-1} (log ε/mol^{-1} dm^3 cm^{-1}): 22.8 (2.28), 29.1 (3.54), 39.8 (4.22) for the *trans*(NO$_2$) isomer; 22.8 (2.24), 31.2 (3.65), 42.2 (4.30) for the *cis,cis* isomer. Found: C, 6.96; H, 4.16; N, 24.23% for the *trans*(NO$_2$) isomer. C, 6.96; H, 4.05; N, 24.42% for the *cis,cis* isomer. Calcd for [Co(NO$_2$)$_2$(NH$_3$)$_2$(en)]ClO$_4$=CoC$_2$ClH$_{14}$N$_6$O$_8$: C, 6.97; H, 4.10; N, 24.39%.

Method II: The *cis,cis* isomer was also prepared in a high yield by this method. To a solution of 3 g (10 mmol) of *cis*-[Co(CO$_3$)(NH$_3$)$_2$(en)]ClO$_4$[2] in 100 cm^3 of 3% HClO$_4$ was added 6.0 g (100 mmol) of NaNO$_2$. The mixture was kept at 60 °C for half an hour, then cooled in a refrigerator. The yellowish brown crystals which deposited were collected by filtration and recrystallized from a small amount of warm water. Yield: 2.0 g.

Method III: The remaining isomer, *trans*(NH$_3$), was obtained by this method. To a bluish violet solution of 1.5 g (6 mmol) of *trans*(NH$_3$)-[CoCl$_2$(NH$_3$)$_2$(en)]Cl[2] in 20 cm^3 of water was added a solution of 1.5 g (22 mmol) of NaNO$_2$ in 10 cm^3 of water. The mixture was stirred at 25 °C for 12 h, whereupon the color of the solution turned to yellowish brown. Addition of a large amount of solid NaClO$_4$ to this solution induced the precipitation of a yellowish brown solid. This solid was recrystallized from a small amount of warm water. Yield: 1.2 g. Absorp. max. σ/10^3 cm^{-1} (log ε/mol^{-1} dm^3 cm^{-1}): 23.0 (2.22), 31.0 (3.71), 41.9 (4.49). Found: C, 6.93; H, 4.09; N, 24.42%. Calcd for [Co(NO$_2$)$_2$(NH$_3$)$_2$(en)]-ClO$_4$=CoC$_2$ClH$_{14}$N$_6$O$_8$: C, 6.97; H, 4.10; N, 24.39%.

trans(*CN*)- *and* cis,cis-[*Co(CN)$_2$(NH$_3$)$_2$(en)*]*ClO$_4$*.

These had been obtained by Maki and Sakuraba.[6] The complexes were obtained more conveniently, however, by

the following methods. Powdered *trans*(Cl)-[$CoCl_2(NH_3)_2$(en)]Cl (4 g; 15 mmol) was added to a solution of KCN (2 g; 30 mmol) in 300 cm^3 of dimethyl sulfoxide (DMSO). After being stirred continuously at 80 °C for 3 h, the reaction mixture consisted of an orange yellow solution and a small amount of orange precipitate. The mixture was diluted to 2 dm^3 with water and poured onto a cation-exchanger column (SP-Sephadex, C-25, Na^+ form; 3×60 cm). By eluting with 0.03 M $NaClO_4$, two colored bands, orange and yellow, descended in that order. Each eluate was concentrated to dryness by a rotary evaporator and the residue washed with ethanol to remove the contaminated $NaClO_4$. The crude compound thus obtained was recrystallized from warm water. The electronic absorption spectra of the orange and yellow isomers coincide respectively with those of *trans*(CN)- and *cis*(CN)-[$Co(CN)_2(NH_3)_2$(en)]$^+$ reported by Maki and Sakuraba.[6] The *cis*(CN) isomer was identified to be *cis,cis* from the Raman spectrum. Yield: 1.7 g for the *trans*(CN) isomer and 0.2 g for the *cis,cis* one.

The *cis,cis* isomer was also prepared in a high yield by the following method.

To a solution of *trans*(Cl)-[$CoCl_2(NH_3)_2$(en)]Cl (2.6 g; 10 mmol) in 60 cm^3 of DMSO was added a solution of $AgNO_3$ (1.7 g; 10 mmol) in a small amount of DMSO. The silver chloride deposited was filtered off. To the filtrate was added 5.4 g (40 mmol) of AgCN and the resulting suspension was stirred continuously at 80 °C for 5 h. During this time, the color of the liquid phase changed from bluish violet to brownish yellow. To the suspension 1 dm^3 of water was added and the insoluble product filtered off. The filtrate was chromatographed in a similar manner as above. In this case, only one band, *cis,cis*, descended. Yield: 1.1 g. Absorp. max. $\sigma/10^3$ cm^{-1} (log ε/mol^{-1} dm^3 cm^{-1}): 21.5 sh (1.48), 24.2 (1.76), 31.9 (1.88), 47.4 (4.61) for the *trans*(CN) isomer; 23.5 sh (1.84), 25.1 (1.87), 32.2 (1.94), 47.7 (4.32) for the *cis,cis* one. Found: C, 15.72; H, 4.64; N, 27.63% for the *trans*(CN) isomer. C, 15.72; H, 4.67; N, 27.57% for the *cis,cis* one. Calcd for [$Co(CN)_2(NH_3)_2$(en)]ClO_4=$CoC_4ClH_{14}N_6O_4$: C, 15.77; H, 4.63; N, 27.59%.

Attempts to obtain the *trans*(NH_3) isomer from *trans*-(NH_3)-[$CoCl_2(NH_3)_2$(en)]Cl were not successful; the reaction with AgCN yielded only the *cis,cis* isomer and with KCN only the *trans*(CN) and *cis,cis* ones.

Optical Resolution of cis,cis *Isomers of [Coa$_2$(NH_3)$_2$(en)]$^+$ (a=NO_2^- and CN^-).* $(+)^{CD}_{450}$-cis, cis-*[Co(NO_2)$_2$(NH_3)$_2$(en)]Cl*: A solution of racemic *cis,cis*-[$Co(NO_2)_2(NH_3)_2$(en)]ClO_4 was passed through an anion-exchange resin column (Dowex 1×8, Cl^- form) and the eluate was evaporated to dryness. The crude product was recrystallized from a minimun amount of hot water and dried in air. Found: C, 8.27; H, 5.01; N, 29.76%. Calcd for [$Co(NO_2)_2(NH_3)_2$(en)]Cl= $CoC_2ClH_{14}N_6O_4$: C, 8.56; H, 5.01; N, 29.96%.

The chloride of the *cis,cis* isomer (0.5 g; 1.8 mmol) was dissolved in 10 cm^3 of water and to the solution was added solid $(+)_{546}$-K[Co(edta)]·$2H_2O$[7] (0.7 g; 1.8 mmol) at 40 °C with stirring. The resulting reddish violet solution was evaporated to half the initial volume below 20 °C and kept standing in a refrigerator overnight. The reddish violet crystals which deposited were collected by filtration and recrystallized from a small amount of warm water (at *ca.* 40 °C) to give crystals of the less-soluble diastereomer with a needle-like shape. Found: C, 23.54; H, 4.62; N, 18.36%. Calcd for [$Co(NO_2)_2(NH_3)_2$(en)][Co(edta)]·H_2O=$Co_2C_{12}H_{28}N_8O_{13}$: C, 23.61; H, 4.63; N, 18.36%.

The less-soluble diastereomer was converted into the chloride salt by passing a solution through an anion-exchange resin (Dowex 1×8, Cl^- form) and evaporating the eluate to dryness. CD $\sigma_{ext}/10^3$ cm^{-1} ($\Delta\varepsilon$/mol^{-1} dm^3 cm^{-1}): 21.6 (+0.34), 24.4 (−0.18), 29.7 (−1.49), 35 sh (+1.80), 38.6 (+2.56), 43.2 (−14.6). Found: C, 8.30; H, 5.10; N, 29.76%. Calcd for [$Co(NO_2)_2(NH_3)_2$(en)]Cl=$CoC_2ClH_{14}N_6O_4$: C, 8.56; H, 5.01; N, 29.96%.

$(+)^{CD}_{450}$-cis,cis-[Co(CN)$_2$(NH_3)$_2$(en)]ClO_4: A solution of racemic *cis,cis*-[$Co(CN)_2(NH_3)_2$(en)]ClO_4 (0.46 g; 1.5 mmol) in 20 cm^3 of warm water was passed through a Cl^- form ion-exchange resin. To the filtrate was added $(-)_{546}$-Ag[Co(edta)][8] (0.69 g; 1.5 mmol) with stirring and the silver chloride deposited was filtered off. The filtrate was evaporated to dryness and a small amount of methanol was added to the residue. The crude brownish violet powder of the less-soluble diastereomer was recrystallized from warm water; the dark reddish violet crystals which deposited were recrystallized from a minimum amount of warm water. Found: C, 27.72; H, 5.31; N, 18.35%. Calcd for [$Co(CN)_2$-(NH_3)$_2$(en)][Co(edta)]·$3H_2O$=$Co_2C_{14}H_{32}N_8O_{11}$: C, 27.73; H, 5.33; N, 18.48%.

The less-soluble diastereomer was converted to the perchlorate salt by adding $NaClO_4$ to a chloride solution obtained by means of a chromatographic method. CD $\sigma_{ext}/10^3$ cm^{-1} ($\Delta\varepsilon$/mol^{-1} dm^3 cm^{-1}): 20.5 (−0.01), 23.2 (+0.22), 26.6 (−0.22), 32.0 (+0.06), 35.5 sh (−0.01), 41.1 (−1.7), 45.4 (+9.7). Found: C, 15.62; H, 4.64; N, 26.98%. Calcd for [$Co(CN)_2(NH_3)_2$(en)]ClO_4=$CoC_4ClH_{14}N_6O_4$: 15.77; H, 4.64; N, 27.59%.

Measurements. Electronic absorption spectra were recorded on a Hitachi 220 spectrophotometer. Raman spectra were recorded in water on a JASCO R-800 Laser Raman spectrophotometer, using a He-Ne laser (632.8 nm; 50 mW) as an excitation source. A spinning sample cell was employed to avoid decomposition of the sample induced by laser illumination. Polarization measurements were carried out by employing a half-wave plate for incident light and a polarization analyzer for scattered light. Infrared spectra were recorded on a JASCO IRA-3 as Nujol mulls. Circular dichroism (CD) spectra were recorded on a JASCO MOE-1 spectropolarimeter in aqueous solution.

Results and Discussion

Electronic Absorption Spectra. Figure 1 shows the configurations of geometrical isomers of [$Coa_2(NH_3)_2$(en)] type complex (a denotes a monodentate ligand). The *trans*(a) and *cis*(a) (*trans*(NH_3) or

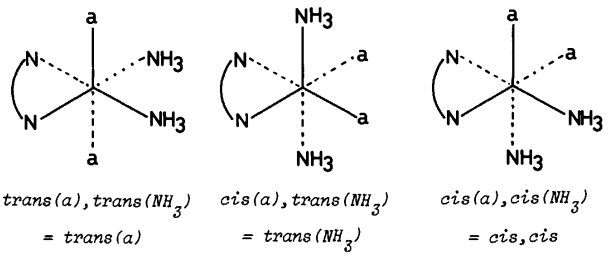

Fig. 1. Three geometrical isomers of [$Coa_2(NH_3)_2$(en)] type complex (a denotes a monodentate ligand).

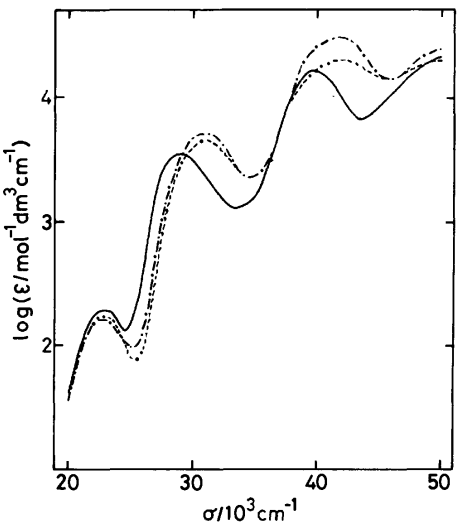

Fig. 2. Electronic absorption spectra of the three geometrical isomers of $[Co(NO_2)_2(NH_3)_2(en)]^+$ (——); *trans*(NO_2), (----); *trans*(NH_3), and (– – –); *cis,cis*.

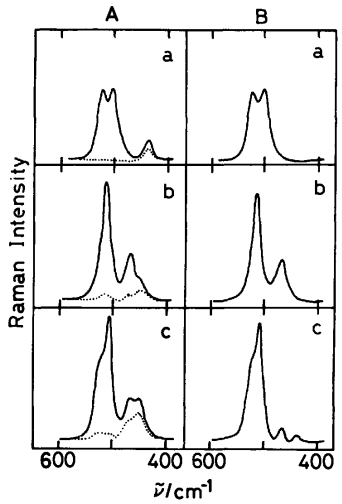

Fig. 3. Polarized Raman spectra (A) [(——), ∥; (----), ⊥] and difference Raman spectra (B) [$I_\parallel - I_\perp \times 4/3$] of the three isomers of $[Co(NO_2)_2(NH_3)_2(en)]^+$: a; *trans*($NO_2$), b; *trans*($NH_3$), and c; *cis,cis*.

cis,cis) isomers can be differentiated on the basis of their electronic absorption spectra in a similar manner as for the corresponding isomers of $[Coa_2(en)_2]$ or $[Coa_2(NH_3)_4]$ type complexes. Figure 2 shows the electronic absorption spectra of the three isomers of $[Co(NO_2)_2(NH_3)_2(en)]^+$. It has been shown for dinitro cobalt(III) complexes that the "nitro-specific" band of the *trans* isomer is always more bathochromic than the band of the *cis* isomer.[9] Therefore, the isomer which exhibits the "nitro-specific" band in the lower energy region (29100 cm^{-1}) than those of the other two isomers (31000 and 31200 cm^{-1}) can be unambiguously assigned to the *trans*(NO_2) isomer. It is difficult to differentiate the two *cis*(NO_2) isomers by their electronic absorption spectra, since their absorption bands are similar.

Maki and Sakuraba[6] obtained the two (orange and yellow) of the three geometrical isomers of $[Co(CN)_2(NH_3)_2(en)]^+$ complex. By comparing their absorption curves with those of the *trans* and *cis* isomers of $[Co(CN)_2(en)_2]^+$ and $[Co(CN)_2(NH_3)_4]^+$ complexes in the first d-d absorption band region, the orange isomer was assigned to the *trans*(CN) one and the yellow *cis*(CN). However, they did not mentioned further assignment for the *cis*(CN) isomer (*trans*(NH_3) or *cis,cis*). Also in this case, it is difficult to determine which *cis*(CN) isomer was obtained only from its absorption spectrum.

Raman Spectra. We examined what difference exists between the Raman spectra of the two *cis*(NO_2) isomers of $[Co(NO_2)_2(NH_3)_2(en)]^+$. The most striking difference was found in the polarizabilities of the Raman bands due to Co-N(NH_3 and en) stretching vibrations. Figure 3-A shows the polarized Raman spectra of the three isomers of $[Co(NO_2)_2(NH_3)_2(en)]^+$ in the 400—600 cm^{-1} region, where Co-N(NH_3 and en) stretching vibrations are expected.[4] If it is assumed that the molecular symmetry of the *trans*(a) isomer of $[Coa_2(NH_3)_2(en)]$ type complex is C_{2v}, that of the *trans*(NH_3) is C_{2v}, and that of the *cis,cis* is C_1, the Co-N(NH_3 and en) stretching vibrations are reduced to ($2A_1+2B_1$), ($2A_1+B_1+B_2$), and (4A), respectively. Although the apparent difference can be recognized in the number of the observed Raman bands between the two *cis*(NO_2) isomers (Fig. 3-A-b and -c), no explicit differences could be expected in the number of Raman bands, because of all the modes being Raman active. However, some differences would be expected in the polarizabilities of the Raman bands. Thus, a Raman band due to a totally symmetric vibration (A_1 or A mode) should be observed as a polarized band ($I_\perp/I_\parallel<3/4$), whereas that due to a non-totally symmetric vibration (B_1 or B_2 mode) as a depolarized band ($I_\perp/I_\parallel=3/4$). Therefore, the *trans*(a) and *trans*-(NH_3) isomers should have one or more depolarized bands in their Raman spectra, while all the Raman bands should be observed as polarized bands for the *cis,cis* isomer. Unfortunately, the accurate depolarization ratio, $\rho=I_\perp/I_\parallel$, can not be obtained directly from the Raman spectra of the three isomers of $[Co(NO_2)_2(NH_3)_2(en)]^+$, since the observed bands are partially overlapped (Fig. 3-A). Therefore, we calculated the difference spectra ($I_\parallel - I_\perp \times 4/3$) as shown in Fig. 3-B. The depolarized band would vanish completely in the difference spectra since $I_\perp=I_\parallel \times 3/4$. On the other hand, the polarized band would leave some trace in the difference spectra. A weak band at *ca.* 450 cm^{-1} completely disappeared in each of the difference spectra of the *trans*(NO_2) (Fig. 3-a) and one of the *cis*(NO_2) isomer (Fig. 3-b), *i.e.*, these bands can be regarded as depolarized. On the other hand, all the bands leave some traces in the difference

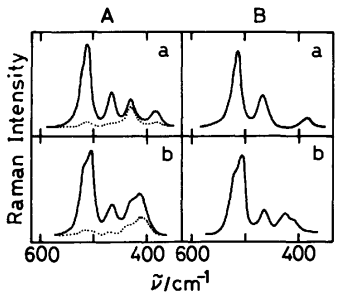

Fig. 4. Polarized Raman spectra (A) [(——), ∥; (----), ⊥] and difference Raman spectra (B) [$I_{\parallel} - I_{\perp} \times 4/3$] of the two isomers of $[Co(CN)_2(NH_3)_2(en)]^+$: a; *trans*(CN) and b; *cis,cis*.

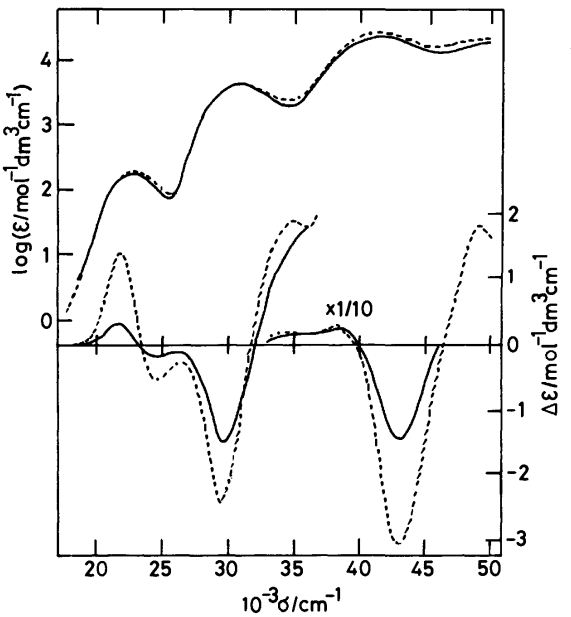

Fig. 5. Electronic absorption and CD spectra of $(+)^{CD}_{480}$-*cis-cis*-$[Co(NO_2)_2(NH_3)_2(en)]Cl$ (——) and *Λ*-$[Co(NO_2)_2(en)_2]Cl$ (----).

spectrum of another *cis*(NO_2) isomer (Fig. 3-c), *i.e.*, all can be regarded as polarized. It is concluded, therefore, that the *cis*(NO_2) isomer which has a depolarized band in its Raman spectrum has a *trans*(NH_3) configuration and that another *cis*(NO_2) isomer whose Raman bands are all polarized has a *cis,cis* configuration. The other Raman active depolarized bands of the *trans*(NO_2) and *trans*(NH_3) isomers would be very weak, and hidden by the strong polarized bands. An infrared band was observed at 491 cm^{-1} for the *trans*(NO_2) isomer and also at 496 cm^{-1} for the *trans*(NH_3) isomer, they being counterparts of the hidden Raman bands.

Figure 4 shows the polarized Raman spectra (A) and the difference spectra (B) of the two isomers of $[Co(CN)_2(NH_3)_2(en)]^+$. The bands around 400 cm^{-1} can be assignable to the Co-CN stretching vibrations. By a similar argument as above, it is concluded that the present *cis*(CN) isomer has the *cis,cis* configura-

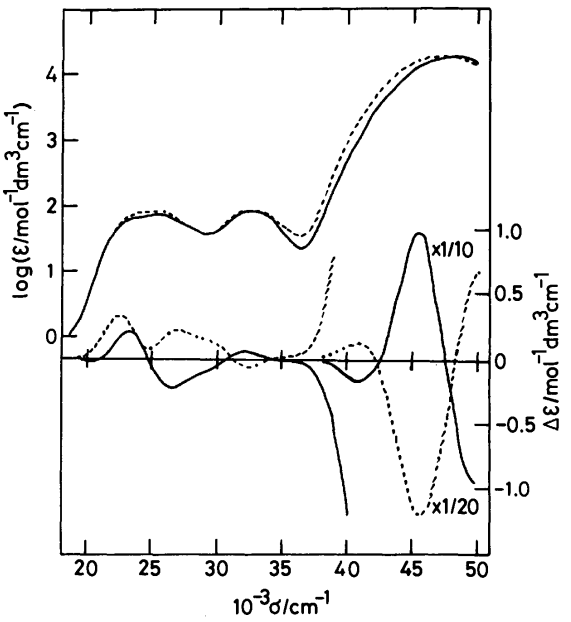

Fig. 6. Electronic absorption and CD spectra of $(+)^{CD}_{480}$-*cis,cis*-$[Co(CN)_2(NH_3)_2(en)]ClO_4$ (——) and *Λ*-$[Co(CN)_2(en)_2]Cl$ (----).

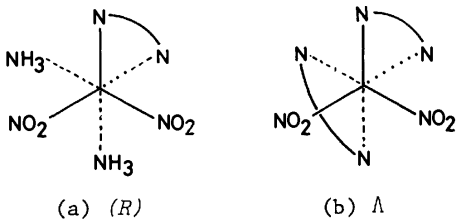

Fig. 7. Absolute configurations of $(+)^{CD}_{480}$-*cis,cis*-$[Co(NO_2)_2(NH_3)_2(en)]^+$ (a) and *Λ*-$[Co(NO_2)_2(en)_2]^+$ (b).

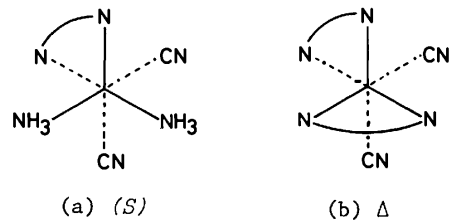

Fig. 8. Absolute configurations of $(+)^{CD}_{480}$-*cis,cis*-$[Co(CN)_2(NH_3)_2(en)]^+$ (a) and *Δ*-$[Co(CN)_2(en)_2]^+$ (b).

tion, since all the Raman bands are polarized.

Optical Resolution. The differentiation among the geometrical isomers of $[Coa_2(NH_3)_2(en)]$ type complexes (a=NO_2^- and CN^-) based upon the Raman spectra was confirmed by the optical resolution of the *cis,cis* isomers. Figure 5 shows the absorption and CD spectra of $(+)^{CD}_{480}$-*cis,cis*-$[Co(NO_2)_2(NH_3)_2(en)]^+$ complex which was obtained from the less-soluble diastereomer with *Λ*$(+)_{546}$-[Co(edta)]$^-$ and Fig. 6 those of $(+)^{CD}_{480}$-*cis,cis*-$[Co(CN)_2(NH_3)_2(en)]^+$ which was obtained from the less-soluble diastereomer with *Λ*$(-)_{546}$-[Co(edta)]$^-$. These figures also show the absorption

and CD spectra of Λ-$[Co(NO_2)_2(en)_2]^+$ and Λ-$[Co(CN)_2(en)_2]^+$, respectively, for comparison. The absolute configurations of these bis(ethylenediamine) complexes have been determined by previous CD[10] and X-ray[11,12] studies. The CD spectral pattern of $(+)^{CD}_{450}$-$[Co(NO_2)_2(NH_3)_2(en)]^+$ is similar to that of Λ-$[Co(NO_2)_2(en)_2]^+$ not only in the visible but also in the ultraviolet region, though the CD intensity of the former complex is about half that of the latter. Therefore, the absolute configuration of $(+)^{CD}_{450}$-$[Co(NO_2)_2(NH_3)_2(en)]^+$ corresponds to the Λ configuration of bis(chelate) complexes, being assigned to the (*R*) configuration by Cahn, Ingold, and Prelog's Nomenclature[13] (Fig. 7). Since the $(+)^{CD}_{450}$-$[Co(CN)_2(NH_3)_2(en)]^+$ isomer shows a reversed CD pattern with respect to Λ-$[Co(CN)_2(en)_2]^+$ except for the lowest energy region, the absolute configuration corresponds to the Δ configuration as is shown in Fig. 8 and can be assigned to the (*S*) configuration.

Phase Equilibria in the Ln_2O_3-V_2O_3-V_2O_5 (Ln=Pr, Tb, and Y) Systems at 1200 °C

Kenzo KITAYAMA* and Takashi KATSURA
Department of Chemistry, Faculty of Science, Tokyo Institute of Technology, Ookayama, Meguro-ku, Tokyo 152
(Received July 27, 1984)

The phase equilibria in the systems, Pr_2O_3-V_2O_3-V_2O_5, Tb_2O_3-V_2O_3-V_2O_5, and Y_2O_3-V_2O_3-V_2O_5, were established at 1200 °C by changing the oxygen partial pressure from −1.20 (in the CO_2) to 7.50 in $-\log(P_{O_2}/\text{Pa})$ for Pr_2O_3 and Tb_2O_3 systems, and from −4.32 (in the air) to 7.50 in $-\log(P_{O_2}/\text{Pa})$ for Y_2O_3 system. In the first system $0.81Pr_2O_3 \cdot 0.19V_2O_5$ (A) and $3Pr_2O_3 \cdot V_2O_5$ (B), in the second $0.81Tb_2O_3 \cdot 0.19V_2O_5$ (A′), and in the last one $4Y_2O_3 \cdot V_2O_5$ (A″) were stable in addition to Ln_2O_3, $LnVO_4$, $LnVO_3$, V_nO_{2n-1} (n= 2—7, and Ln means Pr, Tb, and Y), and VO_2 under the present experimental conditions. On the basis of the established phase diagrams, the standard Gibbs energies ($\Delta G°$) of reactions appeared in the systems were calculated. Compounds A, B, $PrVO_3$, A′, A″, and $LnVO_4$ have nonstoichiometric compositions. $\Delta G°$ values for the reactions and crystallographic values of the compounds were represented as a function of the ionic radius of lanthanoid (including Y) elements.

Phase equilibria in the Ln_2O_3-V_2O_3-V_2O_5 systems (Ln=Sm, Lu, Er, Gd, La, Nd, Tm, Eu, Yb, Dy, and Ho) at 1200 °C have been established[1-9] by changing the oxygen partial pressure from −4.32 to 7.50 or 9.00 in terms of $-\log(P_{O_2}/\text{Pa})$. The standard Gibbs energy of the reactions appeared in the established systems and the crystallographic data of the ternary compounds and the activities of the components in the solid solutions were also successfully obtained.

In the present study, Pr_2O_3, Tb_2O_3, and Y_2O_3 were chosen as Ln_2O_3. It was well known that Pr_2O_3 and Tb_2O_3 were unstable in air. They change compositions to Pr_6O_{11} and Tb_4O_7 or other compositions depending upon the oxygen partial pressure and the temperature.[10-14] Recently, the oxygen partial pressure ranges in which Pr_2O_3 and Tb_2O_3 are stable have been determined at 1000°, 1100°, and 1200 °C by Sugihara.[15] According to his results, Pr_2O_3 is stable in the log P_{O_2} range from 4.30 to −11.00 and Tb_2O_3 in the log P_{O_2} range from 3.25 to −11.00 at 1200 °C. Thus the oxygen partial-pressure range in the present experiments was confined to pressures lower than $10^{1.20}$ Pa (in the CO_2) for both systems. On the other hand, Y_2O_3 is stable in air and, thus, the experimental atmosphere was extended to an air atmosphere from a CO_2 atmosphere.

Livin[16] studied Y_2O_3-V_2O_5 in the temperature range from 650° to 1800 °C and found three compounds $4Y_2O_3 \cdot V_2O_5$, $5Y_2O_3 \cdot V_2O_5$, and YVO_4 with a melting point 1810±25 °C. He also pointed out that the Y_2O_3-YVO_4 subsystem is probably pseudo-binary because of oxygen losses from the 4:1 and 5:1 phases. Brusset *et al.*[17] studied three systems, Pr_2O_3-V_2O_5, Tb_2O_3-V_2O_5, and Y_2O_3-V_2O_5, in the temperature range from 600° to 1500 °C. $4Pr_2O_3 \cdot V_2O_5$, $6Pr_2O_3 \cdot V_2O_5$, $4Tb_2O_3 \cdot V_2O_3$, $5Tb_2O_3 \cdot V_2O_5$, $4Y_2O_3 \cdot V_2O_5$, and $5Y_2O_3 \cdot V_2O_5$ were found in addition to $LnVO_4$.

In the Pr_2O_3-V_2O_3, Tb_2O_3-V_2O_3, and Y_2O_3-V_2O_3[18] systems, $PrVO_3$, $TbVO_3$, and YVO_3 were well known, but these systems have not yet been completely studied, because V_2O_3 is unstable in the air. The crystallographic properties of these $LnVO_3$ have been investigated by McCarthy *et al.*[19] and Shin-ike *et al.*[20] and it has been confirmed that these compounds are orthorhombic.

The objectives of the present experiments were: (1) to establish the detailed phase equilibria in the systems at 1200 °C in order to confirm which compounds are stable under the present experimental conditions, (2) to calculate the standard Gibbs energies of reactions which appear in the established phase diagrams, and (3) to examine the fitness of the present data on the linear relationship between $\Delta G°$ values for the reaction, $LnVO_3 + 1/2\ O_2 = LnVO_4$ and the ionic radius of the lanthanoid elements, including Y.

Experimental

Pr_2O_3, Tb_2O_3, and Y_2O_3 (99.9%), V_2O_5 were used as starting materials. V_2O_5 was prepared by heating a guaranteed grade of NH_4VO_3 at 500 °C in air for about 24 h. Pr_2O_3 and Tb_2O_3 were prepared by reducing the commercial Pr_6O_{11} (99.9%) and Tb_4O_7 (99.9%) in an atmosphere of log (P_{O_2}/Pa)=−5.00 at 1200 °C for about 5 h. The hexagonal, light-green Pr_2O_3 and white Tb_2O_3 with C-form were confirmed by the powder X-ray diffraction method[21,22] and the compositions were determined to be $Pr_2O_{3.00}$ and $Tb_2O_{3.00}$ by EDTA titration. Desired Pr_2O_3/V_2O_5, Tb_2O_3/V_2O_5, and Y_2O_3/V_2O_5 mole ratios of samples were obtained by thoroughly mixing appropriate quantities in an agate mortar under ethyl alcohol. The mixtures, thus obtained, were treated by the same procedures in the previous paper.[1] The apparatus and procedures for controlling the oxygen partial pressure and keeping a constant temperature, the method of thermogravimetry, the criterion for an equilibrium establishment, and the method of the chemical analysis for the mixtures of Y_2O_3 and V_2O_5 were the same as those described in previous reports.[1,23-27] The vanadium content of the mixtures of V and Pr and of V and Tb was volumetrically determined after confirming that the consumption of the $KMnO_4$ standard solution by the coexisting Pr and Tb was within the experimental errors. Samples used for analysis

were prepared in the atmosphere, in which the stoichiometric V_2O_3, $LnVO_3$, and Ln_2O_3 were stable at 1200 °C. Pr_2O_3 and Tb_2O_3 contents were determined as a difference between the V_2O_3 weight and the total weight.

Results and Discussion

Phase Equilibria. Nine samples with Pr_2O_3/V_2O_5 mole ratios of 85/15, 8/2, 77/23, 7/3, 65/35, 1, 4/6, 3/7, and 15/85 were prepared to be used in the thermogravimetric experiments. In Figs. 1a and 1b the relationships between the oxygen partial pressure, $-\log(P_{O_2}/Pa)$, on the ordinate and the weight change, W_{O_2}/W_T, on the abscissa are shown as representative cases with four samples, 85/15, 77/23, 65/35, and 15/85. Here, W_{O_2} is the weight gain of the samples from the reference weight in an atmosphere of log P_{O_2}=−7.50, and W_T is the calculated total weight increase of samples which might be obtainable if V_2O_3 in the samples at the reference state would change to V_2O_5 in the higher oxygen pressures. The W_{O_2}/W_T ratio was usually shown in the range from 0.995 to 1.00. From Fig. 1 the oxygen partial pressure in equilibrium 6.75, 4.56, 4.14, and 4.02 in -log P_{O_2} were found in addition to those in the V_2O_3-VO_2 subsystem.[1]

The identification of the phases was performed with the quenched samples using a powder X-ray diffractometer with Cu $K\alpha$ radiation. The following phases and two-phase combinations are present under the present experimental conditions: $0.81Pr_2O_3 \cdot 0.19V_2O_5$(A), $3Pr_2O_3 \cdot V_2O_5$(B), Pr_2O_3(R), $PrVO_4$(T), $PrVO_3$(O), and VO_2(J) in addition to six compounds in the V_2O_3-VO_2 system,[1] and Pr_2O_3+A, A+B, B+$PrVO_4$, Pr_2O_3+$PrVO_3$, A+$PrVO_3$, B+$PrVO_3$, V_2O_3+$PrVO_3$, V_2O_3+$PrVO_4$, V_nO_{2n-1}(n=2—7)+$PrVO_4$, and VO_2+$PrVO_4$.

Based upon the above experimental results from the thermogravimetry and the identification of phases, a phase diagram of the system at 1200 °C was drawn and is shown in Fig. 2. As is apparent from Fig. 2, $6Pr_2O_3 \cdot V_2O_5$ is not stable but a new compound $3Pr_2O_3 \cdot V_2O_5$(Pr_3VO_7) was found. The compounds, $3La_2O_3 \cdot V_2O_5$ and $3Nd_2O_3 \cdot V_2O_5$ had been found in the La_2O_3-,[5] and Nd_2O_3-system[6] which have the same phase diagram pattern as that of the present system. $3Eu_2O_3 \cdot V_2O_5$ was known to be stable[28] although it could not be found in the Eu_2O_3-V_2O_3-V_2O_5 system[8] at 1200 °C. An X-ray powder pattern of Pr_3VO_7 is similar to those of La_3VO_7 and Nd_3VO_7. The crystal system of the compounds has not been determined yet. The spacing and relative intensities of the compound were determined and are shown in Table 1.

Compound A might be $4Pr_2O_3 \cdot V_2O_5$ reported by Brusset *et al.*[17] However, this compound does not have such a round mole ratio in the present case. This kind of compound has been found in La,[5] Nd,[6] Eu,[8] and Gd[4] systems, and will be found in a Tb system. It is interesting that these elements have a lower atomic

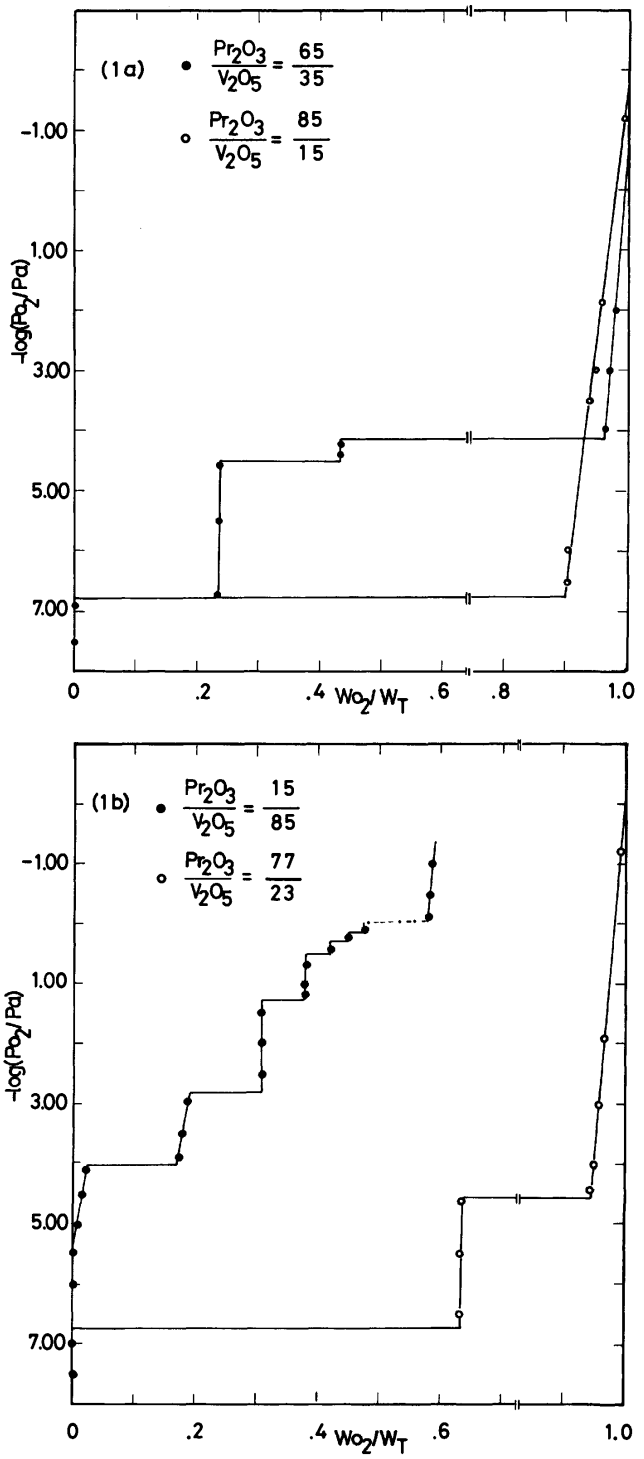

Fig. 1. The relationship between $-\log(P_{O_2}/Pa)$, and the composition, W_{O_2}/W_T, of samples. (1a) ●: Pr_2O_3/V_2O_5=65/35, ○: Pr_2O_3/V_2O_5=85/15, (1b) ●: Pr_2O_3/V_2O_5=15/85, ○: Pr_2O_3/V_2O_5=77/23.

number in the lanthanoid elements except for Sm in which system $5Sm_2O_3 \cdot V_2O_5$ was stable at 1200 °C. Since $4Ln_2O_3 \cdot V_2O_5$ was not detectable by our techniques, it might be nonstoichiometric toward the Ln_2O_3 side and mole ratio, Ln_2O_3/V_2O_5=81/19, might be rewritten to the ratio 4/1.

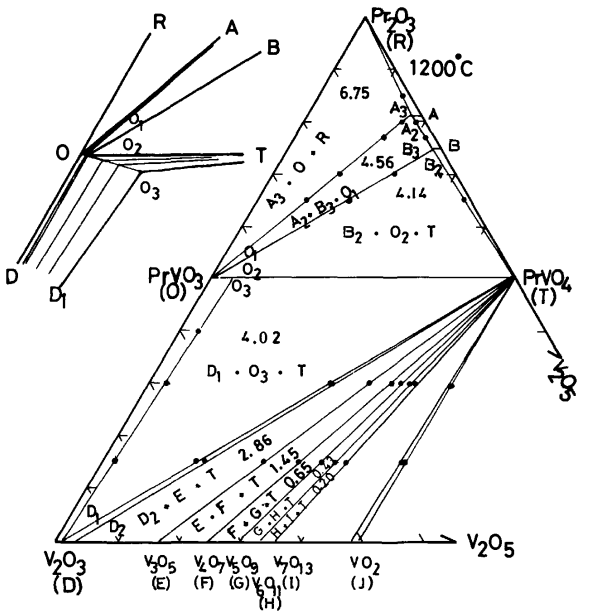

Fig. 2. Phase equilibria in the Pr_2O_3–V_2O_3–V_2O_5 system at 1200°C. Numerical values in the three-phase regions are the oxygen partial pressure in $-\log(P_{O_2}/Pa)$ in equilibrium. Symbols are the same as those in Table 3. A tentative, enlarged diagram near $PrVO_3$ was drawn on the left side with a little exaggeration.

Table 1. Spacings and relative intensities of $3Pr_2O_3 \cdot V_2O_5$ ($\log(P_{O_2}/Pa) = -4.30$, 47 h)

2.808	.49	1.678	.14
2.719	.43		

Compounds A, Pr_3VO_7, $PrVO_4$, and $PrVO_3$ have nonstoichiometric compositions. The relationship between the composition and the oxygen partial pressure is represented by a linear equation, $N_O/N_A = a \log P_{O_2} + b$. Here, N_O is the mole fraction of the oxygen atom and N_A is the mole fraction of component A in the compound. The a and b values obtained from the results of the thermogravimetry are tabulated in Table 2. However, those values for $PrVO_4$ were not obtained because of the shortness of the solid-solution range.

Log $P_{O_2} = -4.14$ is the oxygen partial pressure in equilibrium with $Pr_3VO_7(B_2)$, $PrVO_4(T_1)$, and $PrVO_3(O_2)$, and on the other hand, log $P_{O_2} = -4.02$ is that in equilibrium with $V_2O_3(D_1)$, $PrVO_4(T_1)$, and $PrVO_3(O_3)$. This sort of the difference of the pattern was not found in the other systems reported by us. The

Table 2. a and b values for the solid solutions ($N_O/N_X = a \log P_{O_2} + b$)

X	a	b
$PrVO_3$	0.0122	0.069
$0.81Pr_2O_3 \cdot 0.19V_2O_5$	4.00×10^{-3}	−0.018
$3Pr_2O_3 \cdot V_2O_5$	9.80×10^{-3}	−0.0124
$TbVO_4$	4.71×10^{-3}	2.07×10^{-3}
$0.81Tb_2O_3 \cdot 0.19V_2O_5$	7.00×10^{-3}	−0.015
$Y_8V_2O_{17}$	0.619	−0.124

solid-solution ranges for $PrVO_3$ with a mole ratio $Pr_2O_3/V_2O_5 \geqq 1$ and that for $PrVO_3$ with a mole ratio $Pr_2O_3/V_2O_5 < 1$ were apparently different. This phenomenum may be understood considering that $PrVO_3$ had a solid solution range toward the V_2O_3 and V_2O_5 side. A tentative phase diagram near $PrVO_3$ is depicted with a little exaggeration in the left side of Fig. 2.

Seven samples with Tb_2O_3/V_2O_5 mole ratio of 84/16, 8/2, 72/28, 65/35, 1, 3/7, and 15/85 were prepared to be used in thermogravimetric experiments. In Figs. 3a and 3b, the relationships between W_{O_2}/W_T and log (P_{O_2}/Pa) of samples, 84/16, 8/2, 72/28, and 15/85, are shown as representatives. Two oxygen partial pressures, 5.27 and 3.95 in $-\log P_{O_2}$, in equilibrium with three solid phases were obtained in addition to those in the V_2O_3–VO_2 subsystem. A phase diagram was depicted with the results of the thermogravimetry and the identification of phases and is shown in Fig. 4. The following phases are present; Tb_2O_3(R′), $0.81Tb_2O_3 \cdot 0.19V_2O_5$(A′), $TbVO_3$ (O′), and $TbVO_4$(T′) in addition to the compounds in the V_2O_3–VO_2 system.[1] The $5Tb_2O_3 \cdot V_2O_5$ was not stable. Using the quench method, the following two-phase combinations were confirmed; Tb_2O_3+A′, A′+$TbVO_4$, A′+$TbVO_3$, Tb_2O_3+$TbVO_4$, V_2O_3+$TbVO_3$, $TbVO_4$+V_nO_{2n-1} (n=2—7), and $TbVO_4$+VO_2. The pattern of Fig. 4 is similar to those of Eu_2O_3[8] and Gd_2O_3[4] systems which had been established.

Compounds A′ and $TbVO_4$ have nonstoichiometric compositions, but $TbVO_3$, on the other hand, is stoichiometric. a and b values for A′ and $TbVO_4$ are shown in Table 2 together with values for other compounds.

It has been confirmed that Y_2O_3 is stable under the present experimental conditions.[25] Seven samples with Y_2O_3/V_2O_5 mole ratios of 85/15, 8/2, 75/25, 65/35, 1, 25/75, and 1/9 were used for the establishment of the phase diagram in the thermogravimetry. The variation of the weight with log P_{O_2} for four samples, 85/15, 65/35, 1, and 1/9, were shown in Fig. 5 as representative cases. Two oxygen partial pressure, 4.62 and 3.98 in -log P_{O_2}, in equilibrium with three solid phases were found in addition to six values in the V_2O_3–VO_2 system. Compounds Y_2O_3(R″), $4Y_2O_3 \cdot V_2O_5$(A″), YVO_4(T″), and YVO_3-

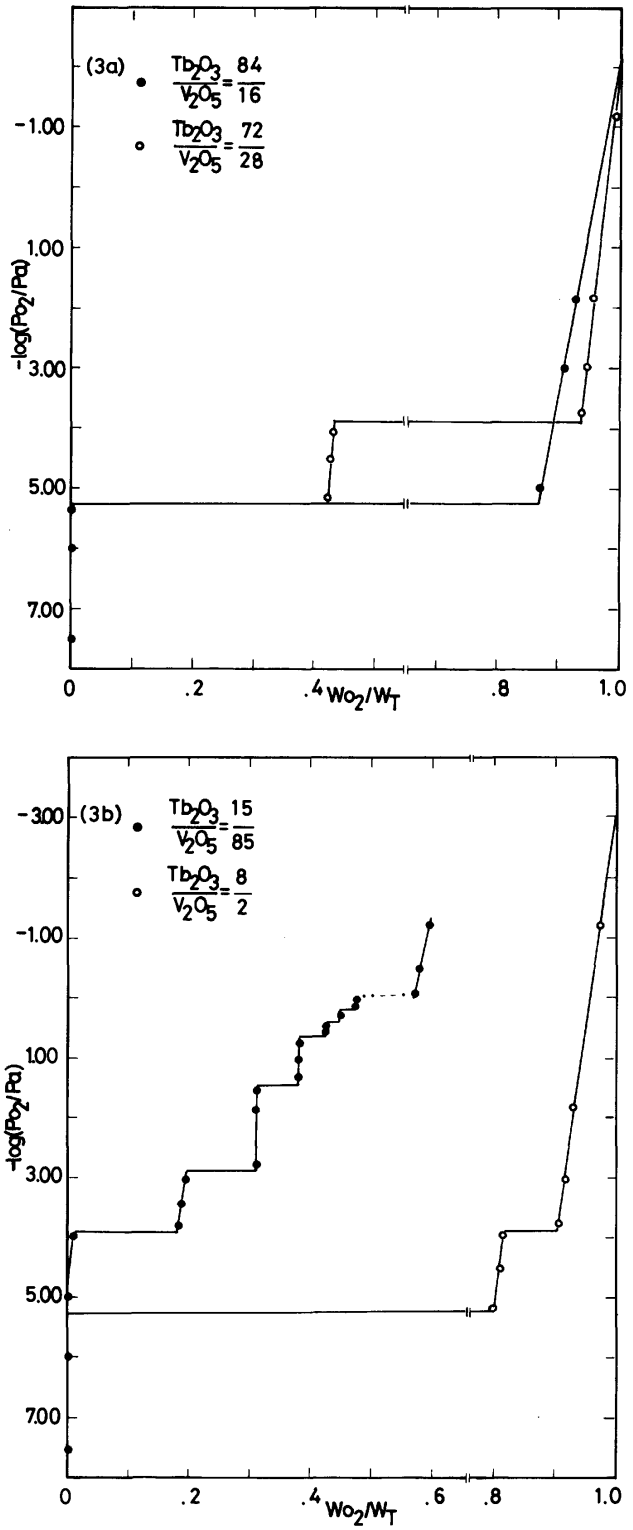

Fig. 3. The realtionship between $-\log(P_{O_2}/Pa)$ and the composition, W_{O_2}/W_T, of samples. (3a) ●: $Tb_2O_3/V_2O_5=84/16$, ○: $Tb_2O_3/V_2O_5=72/28$, (3b) ●: $Tb_2O_3/V_2O_5=15/85$, ○: $Tb_2O_3/V_2O_5=8/2$.

(O″) were confirmed to be stable by the quench method. Two-phase combinations are: Y_2O_3+A″, A″+YVO_4, A″+YVO_3, Y_2O_3+YVO_3, YVO_3+V_2O_3, YVO_4+V_{2n-1} (n=2—7), and VO_2+YVO_4. The $5Y_2O_3 \cdot V_2O_5$ was not found in the present system.

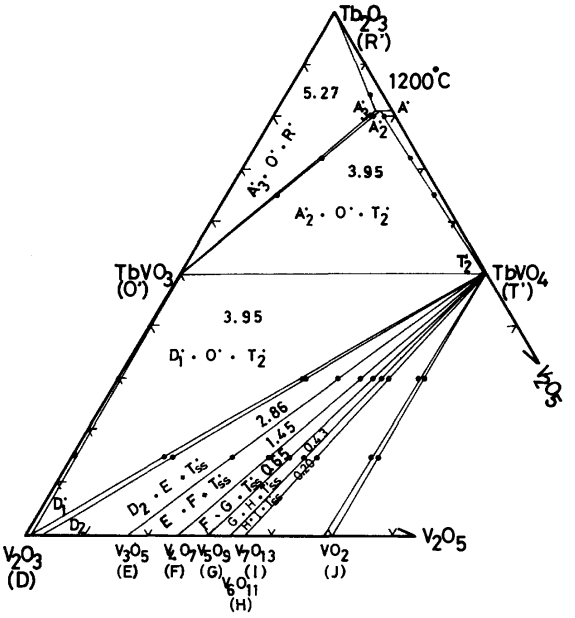

Fig. 4. Phase equilibria in the Tb_2O_3-V_2O_3-V_2O_5 system at 1200°C. Numerical values in the three-phase regions are the oxygen partial pressure in $-\log(P_{O_2}/Pa)$ in equilibrium. Symbols are the same as those in Table 3.

Compounds A″ and YVO_4 have nonstoichiometric compositions, and composition *vs.* $\log P_{O_2}$ for A″ is also tabulated in Table 2. The relation for YVO_4 could not determined because the non-stoichiomeric range is too narrow. Levin's report[16] regarding the pseudobinary of Y_2O_3-YVO_4 described above might imply the nonstoichiometry of $4Y_2O_3 \cdot V_2O_5$ and YVO_4.

Using the thermogravimetry results and the phase identification, a phase diagram at 1200 °C was drawn and is shown in Fig. 6. This diagram is a popular type and has one ternary compound, Ln_2O_3/V_2O_5= 4/1, in the Ln_2O_3-$LnVO_4$ subsystem. This diagram is similar to those of Dy_2O_3, Ho_2O_3, and Er_2O_3.

The activities of each components in a solid-solution were calculated using the Gibbs-Duhem equation and applying the relation between N_O/N_x and $\log P_{O_2}$ obtained above. The detailed method of the calculation has been discussed in a paper by Kimizuka and Katsura.[27] The results of the calculation are tabulated in Table 3 together with a composition of the compounds obtained by thermogravimetry, symbols of compounds, and the stability ranges of the compounds in terms of $\log P_{O_2}$. The activity of the $PrVO_3$ component at the composition O_2 was chosen as unity. The activity of the $PrVO_3$ component at the composition O_3 was not determined.

The lattice constants of the compounds A, A′, and A″ were successfully determined with the data of the assigment of $4Tm_2O_3 \cdot V_2O_5$[29] although errors were still large compared with the data of others. The values of the lattice constant of $LnVO_3$ and $LnVO_4$

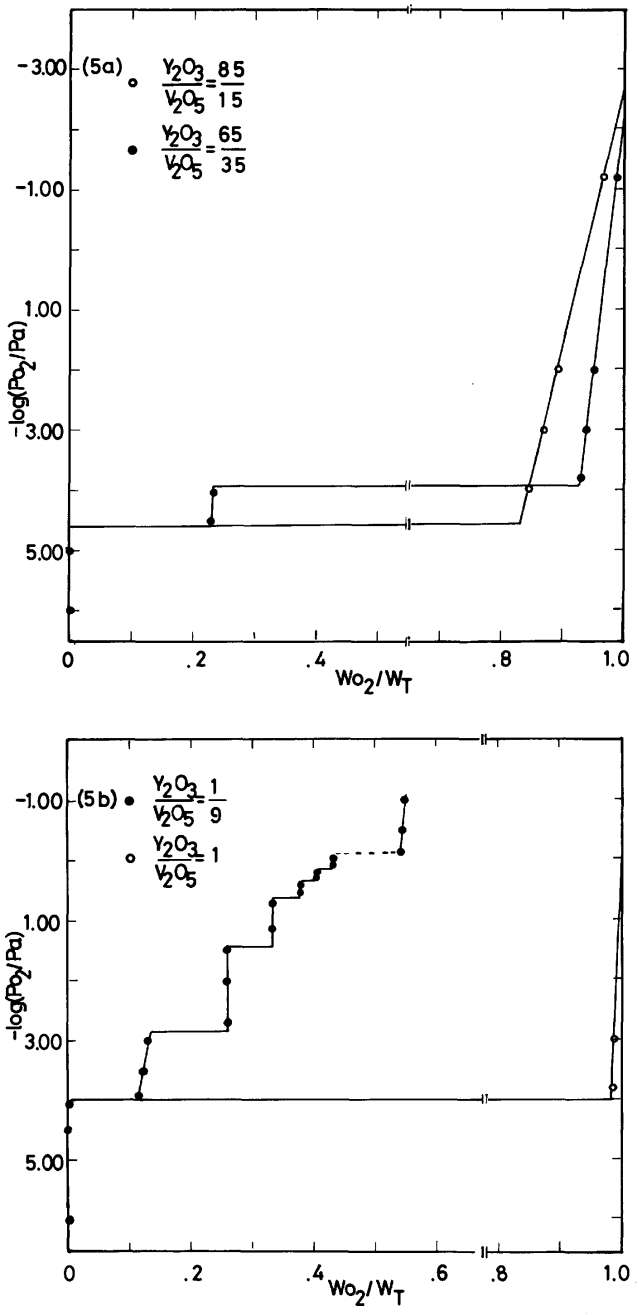

Fig. 5. The relationship between $-\log(P_{O_2}/Pa)$ and the composition, W_{O_2}/W_T, of samples. (5a) ○: $Y_2O_3/V_2O_5=85/15$, ●: $Y_2O_3/V_2O_5=65/35$, (5b) ●: $Y_2O_3/V_2O_5=1/9$, ○: $Y_2O_3/V_2O_5=1$.

were also determined by the powder X-ray diffractometer and tabulated in Table 4 together with previous values. The ternary compounds which were made in the different conditions of the oxygen partial pressure show no considerable difference in lattice constant. Instrumental errors were calibrated by measuring the diffraction angles of a standard specimen of silicon.

Calculation of the Standard Gibbs Energies of Reactions. On the basis of the established phase diagrams, the standard Gibbs energies of the reactions which are

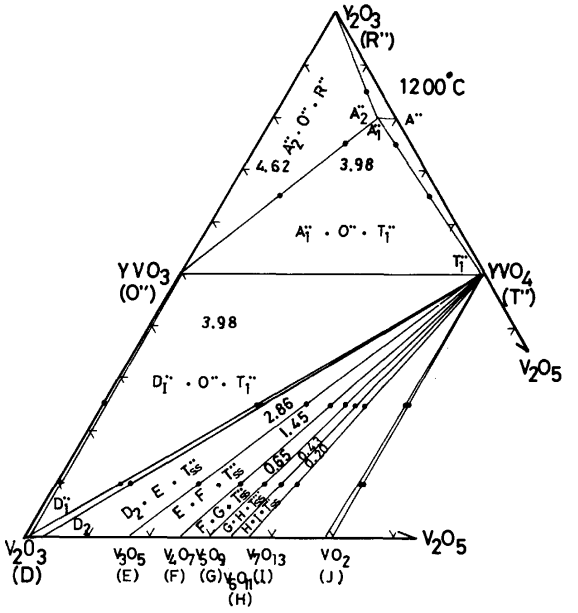

Fig. 6. Phase equilibria in the Y_2O_3-V_2O_3-V_2O_5 system at 1200 °C. Numerical values in the three-phase regions are the oxygen partial pressure in $-\log(P_{O_2}/Pa)$ in equilibrium. Symbols are the same as those in Table 3.

found in the phase diagrams can be calculated by the equation, $\Delta G°=-RT \ln K$, where the R is the gas constant, the T the absolute temperature, and the K the equilibrium constant of a reaction. Reactions and $\Delta G°$ values calculated are shown in Table 5 together with the oxygen partial pressures in equilibrium. The activities necessary for the calculation are shown in Table 3. The standard state can be arbitrarily chosen and, as described above, the activity of the $PrVO_3$ component at the composition O_2 was chosen as unity in this case. If the standard state are changed to that of the $PrVO_3$ component at the composition O_3, the $\Delta G°$ values for the reaction (3) is 127.2 kJ. The difference in $\Delta G°$ values is about 2 kJ.

The Relationship between $\Delta G°$ and Ionic Radius. In a previous report,[7] the relationship between the $\Delta G°$ value for the reaction, $LnVO_3+1/2\ O_2=LnVO_4$, and the ionic radius of lanthanoid elements in 8 coordination had been shown graphically. According to the result, the lanthanoid group is divided into two groups and the relation is linear within each of groups. After the report[7] was published, the values for Eu, Yb, Dy, and Ho systems have also been confirmed to fit well to the previous linear relation. The present values are plotted in Fig. 7 with open circles together with solid circles of the previous data. The present values for Pr and Tb fit well to the previous line, but the value for Y is widely different from what was anticipated. The reason for this difference could not be elucidated. Perhaps it might be one of the reasons why Y

has no property similar to lanthanoid contraction.

In the series of this study, a reaction, $3Ln_2O_3+2LnVO_3+O_2=4Ln_2O_3\cdot V_2O_5(Ln_8V_2O_{17})$, is often found although $0.8|Ln_2O_3\cdot 0.19V_2O_5$ is stable instead of $4Ln_2O_3\cdot V_2O_5$ for La, Nd, Pr, Eu, Gd, and Tb. As described above, the composition $0.8|Ln_2O_3\cdot 0.19V_2O_3$ is still unplausible and questionable, but the oxygen partial pressure in equilibrium with Ln_2O_3, $LnVO_3$, and $4Ln_2O_3\cdot V_2O_5$ or $0.8|Ln_2O_3\cdot 0.19V_2O_5$ are valid within experimental errors. Thus, the relation be-

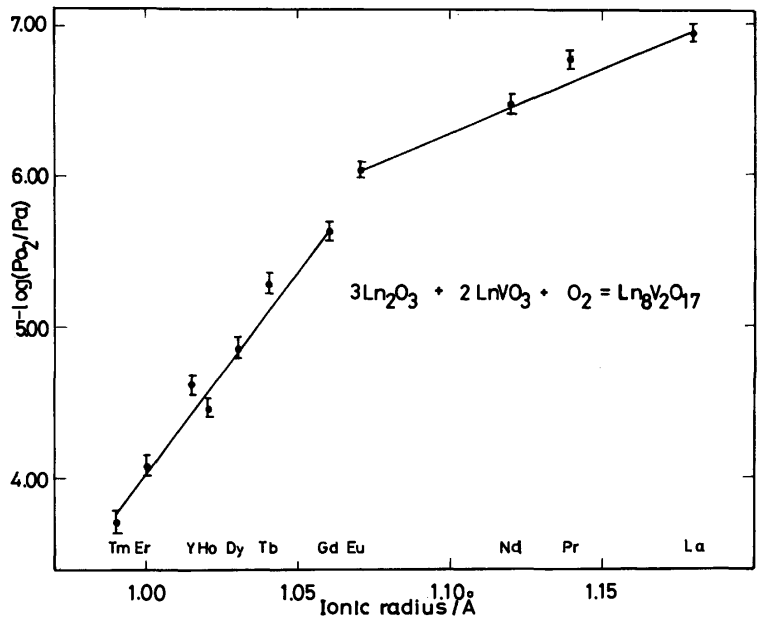

Fig. 8. The relationship between the ionic radius of lanthanoid elements in 8 coordination and the ΔG° values of reaction, $3Ln_2O_3+2LnVO_3+O_2=Ln_8V_2O_{17}$.

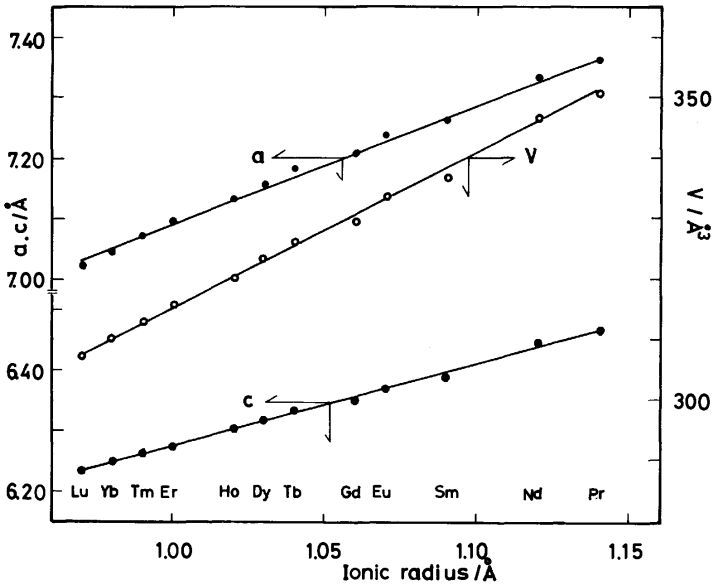

Fig. 9. Variations of the lattice parameter and the volume of $LnVO_4$ with Ln^{3+} radius (Å) in 8 coordination.

tween the oxygen partial pressure and the ionic radius of elements in the 8 coordination is plotted in Fig. 8. Comparing this with the previous case, the points are in a less linear fashion, but the same trend appears; that is, the lanthanoid elements are divided into two groups and in each group the relation is nearly linear.

Variations with Lattice Parameters with Ionic Radius. The lattice parameters and the volumes of $LnVO_4$ with a zircon structure are plotted as a function of the ionic radius in the 8 coordination in Fig. 9. Lattice parameters for other compounds have already been presented.[1-9] A smooth decreases in the *a*, *c*, and *V* values with atomic number is noted as would be expected from the lanthanoid contraction. The relation between lattice parameters and volumes of $LnVO_3$ and the ionic radius in 12 coordination is shown in Fig. 10. The *a*, *c*, and *V* values decrease with increasing atomic number and these values seem to form *a* gap at Gd. On the other hand, the *b* values show a gentle curve with a maximum near the intermeadiate atomic number. These characteristics were already pointed out by McCarthy *et al.*[19]

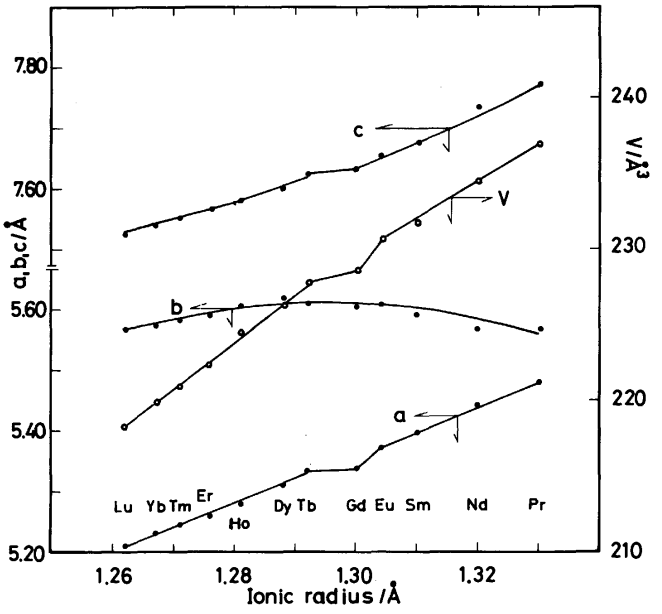

Fig. 10. Variations of the lattice parameter and the volume of $LnVO_3$ with Ln^{3+} radius (Å) in 12 coordination.

Classification of the Phase Diagram Pattern. According to a study of this series, systems at 1200 °C could be clssified into six groups with respect to the assemblages of ternary compounds. The La_2O_3–V_2O_3–V_2O_5 system belongs to the A-type in which three ternary compounds are stable in the Ln_2O_3–$LnVO_4$ subsystem, the (Pr and Nd)$_2O_3$–V_2O_3–V_2O_5 systems belong to the B-type in which two ternary compound, $0.8lLn_2O_3 \cdot 0.19V_2O_5$ and Ln_3VO_7, are stable in the subsystem, the (Sm, Eu, Gd, Tb, Dy, Ho, and Er)$_2O_3$–V_2O_3–V_2O_5 systems belong to the C-type in which one ternary compound, $4Ln_2O_3 \cdot V_2O_5$ or $0.8lLn_2O_3 \cdot 0.19V_2O_5$ or $5Ln_2O_3 \cdot V_2O_5$, is stable in the subsystem, the Tm_2O_3–V_2O_3–V_2O_5 system belongs to the D-type in which two ternary compounds, $4Tm_2O_3 \cdot V_2O_5$ and $Tm_7V_3O_{16}$, are stable, the Yb_2O_3–V_2O_3–V_2O_5 system belongs to the E-type in which one compound $Yb_7V_3O_{16}$ is stable, and the Lu_2O_3–V_2O_3–V_2O_5 system belongs to the F-type in which three ternary compounds, $Lu_7V_3O_{16}$, $Lu_2V_2O_7$, and LuV_4O_8, are stable.

It would be interesting to know whether the ternary compound assemblages change or not upon changing the experimental temperature.

Reduction of Nitrobenzenes on Thin Aluminium Oxide Utilized in Inelastic Electron Tunneling Spectroscopy

Hideaki MONJUSHIRO,* Katsuo MURATA, and Shigero IKEDA
Department of Chemistry, Faculty of Science, Osaka University, Toyonaka, Osaka 560
(Received September 22, 1984)

Chemical interactions between aromatic nitro compounds and thin aluminium oxide grown on aluminium film were studied by the combined use of inelastic electron tunneling spectroscopy (IETS) and X-ray photoelectron spectroscopy (XPS). IET spectra of nitrobenzoic acids and nitrophenols show that nitro groups of these compounds are reduced on the oxide and result in the corresponding amino compounds. In this conversion reaction, oxygen atoms of nitro group are consumed for the growth of the oxide layer and hydrogen atoms of the surface hydroxyl groups are used for the amidation reaction. The intermediate of the reaction is identified to the corresponding nitroso compounds from the XPS analysis.

Inelastic electron tunneling spectroscopy (IETS) is a useful technique to obtain a vibrational spectrum of trace amounts of chemical species adsorbed on aluminium oxide. In certain cases, vibrational spectra obtained by IETS partly differ from IR or Raman spectra of parent molecules. This is induced by chemical interaction between the sample molecules and aluminium oxide surface. Therefore the elucidation of the mechanism for the interactions between various samples and aluminium oxide surface is the present interest, in order to establish IETS as a useful analytical tool. The major chemicals whose IET spectra have been investigated are carboxylic acids,[1-4] alcohols,[5,6] amines,[7,8] sulfonic acids,[9] phenols,[10] unsaturated hydrocarbons,[11] and esters.[12]

Tremendous difference is found in the molecular vibrational spectra of nitro compounds between IETS and IR spectroscopy and we focussed a study on the isomers of nitrobenzoic acids and nitrophenols. The interactions between these aromatic nitro compounds and aluminium oxide surface are observed by both methods of IETS and X-ray photoelectron spectroscopy (XPS). We chose to study mainly on *p*-nitrobenzoic acid (PNBA), because the vibrational spectra of adsorbed PNBA on various substrates have been measured by other spectroscopic techniques such as surface enhanced Raman scattering,[13-15] surface picosecond Raman gain[16] and Fourier transform infrared emission spectroscopy.[17]

Experimental

The sample-loaded tunneling junctions for IETS measurements were prepared using procedures as described elsewhere.[18] Briefly, the aluminium oxide layer was formed on a vacuum deposited aluminium film (*ca.* 300 nm thick) by exposing the film to atmospheric pressure of oxygen containing H_2O or D_2O vapor for 5 min. Samples were then loaded with 0.1 and 1 mg cm^{-3} acetone solutions. Tunnel junctions of Al–AlO_x–sample–Pb sandwich structure were completed by depositing the top lead electrode (*ca.* 300 nm thick).

Usually, for single ring compounds, IET spectra were successfully obtained from 1 mm×1 mm junctions. In the case of nitrobenzene derivatives, however, 2 mm×3 mm junctions were employed to obtain the spectra of sufficient quality. Because the junctions loaded with nitrobenzene derivatives showed large resistance and junctions of large resistance result in the spectra of poor signal to noise ratio. IET spectra were recorded at 4.2 K with a modulation voltage of 1.2 mV rms using the circuit described previously.[18] The observed peak positions were converted from millivolt to wavenumber with correlation of 1 mV=8.065 cm^{-1}. And a correction of -7 cm^{-1} was made to cancel out the superconducting energy gap of lead electrode.

X-ray photoelectron spectra were measured at room temperature on a Shimadzu Hips-70 spectrometer with Mg $K\alpha$ radiation. In XPS measurement, samples were prepared in a similar manner as above but without lead top electrode. Loaded samples were washed with fresh acetone to remove multilayer physisorbed sample molecules. Binding energy of Al2p(metal) peak was taken to be 72.8 eV[19] and used as the energy standard.

Chemicals used were obtained from Wako Pure Chemical Ind. or Nakarai Chemical Co. They were recrystallized from water, ethanol or toluene before use. D_2O(99.85%) for preparing deuterated oxide, was purchased from Commissariat a l'Enerqie Atomique.

Results and Discussion

IET Spectra. IET spectrum of PNBA adsorbed on aluminium oxide is shown in Fig. 1-A. Since there observed a peak due to the symmetric stretching mode of carboxylato group at 1424 cm^{-1}, PNBA is considered to be adsorbed on the oxide by dissociating a proton of carboxyl group to form surface carboxylate. In the IET spectrum of PNBA, the most remarkable feature is that the peaks attributed to the vibrational modes of nitro substituent are all absent. Instead, there appear unexpected peaks for PNBA at 3340 cm^{-1} and at 3445 cm^{-1}. These peaks could be assigned to the symmetric and antisymmetric stretching modes of amino group respectively. Further, twisting mode of amino group is observed at 1058 cm^{-1}. This spectrum is essentially identical to the IET spectrum of *p*-aminobenzoic acid (PABA) shown in Fig. 1-B. The observed peak positions and their tentative assignments are listed in Table 1.

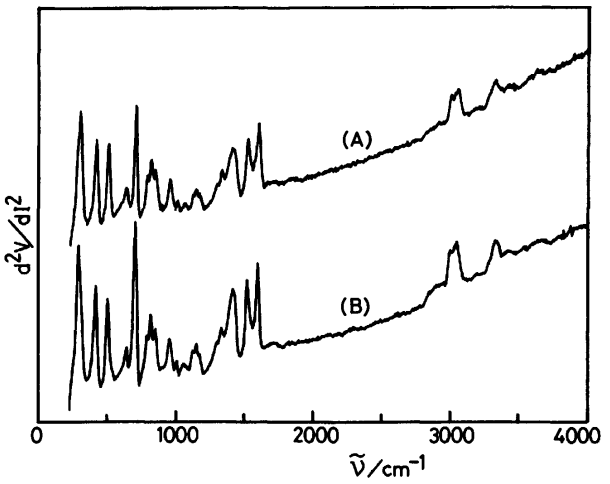

Fig. 1. IET spectra of *p*-nitrobenzoic acid(A) and *p*-aminobenzoic acid(B) adsorbed on aluminium oxide.

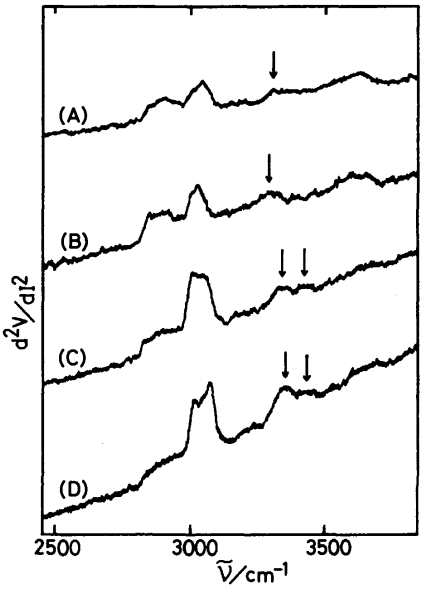

Fig. 2. Expanded IET spectra of *p*-nitrophenol(A), *o*-nitrophenol(B), *m*-nitrobenzoic acid(C) and *p*-nitrobenzoic acid(D) on aluminium oxide. Peaks due to N-H stretching modes are indicated by arrows.

These facts indicate that nitro group of PNBA is converted to amino group on the oxide, and PNBA and PABA give same adsorbed species. The similarity of the IET spectrum of PNBA to that of PABA has been suggested by Tsang *et al.*[15] But detailed analysis of the spectra and the conversion reaction was not cited in their study. Korman and Coleman[20] have also studied the IET spectrum of PNBA and assigned the peaks at 1343 cm^{-1} and at 1532 cm^{-1} to the symmetric and antisymmetric stretching modes of nitro group (in our observation 1337 cm^{-1} and 1527 cm^{-1}). However, these peaks are also observed in the IET spectrum of PABA. Thus these peaks should be assigned to the ring modes or modes of amino group and not to the modes of nitro group.

Table 1. IET spectral data of *p*-nitrobenzoic acid and *p*-aminobenzoic acid on aluminium oxide

a) Peak positions corrected as in the text, relative intensity also shown; s=strong, m=medium, w=weak, v=very, sh=shoulder, b=broad. b) Assignment based on IR and Raman spectra of *p*-disubstituted benzenes; Ref. 29, alkali metal benzoate; Ref. 30 and anilines; Ref. 31.

In the IET spectra of other nitrobenzene derivatives also there observed the peaks due to N-H stretching modes instead of the peaks corresponding to nitro substituent. Figure 2 shows the expanded IET spectra of several nitro compounds in 2500 to 4000 cm^{-1} region. In each spectrum, one or two peaks corresponding to N-H stretching modes are observed around 3300 cm^{-1} as disignated in arrows. Therefore the conversion reaction on the aluminium oxide is thought to be common for aromatic nitro compounds.

XPS Spectra. In order to obtain an IET spectrum, lead metal must be deposited on the sample as a

counter electrode. To investigate the effect of the lead cover electrode for the conversion reaction, X-ray photoelectron spectra were measured on the similar system discussed above without lead electrode.

Figure 3 shows Nls photoelectron spectra of PNBA and PABA on the aluminium oxide. As the spectrum of PNBA changed with the time-course, spectra were recorded at regular time interval. In the spectrum of PNBA immediately after loading (Fig. 3-a), there observed two peaks at 406.9 eV and at 401.6 eV. With the elapse of time, the relative intensity of the two peaks reverses and the low energy peak is shifted to lower binding energy. But the total intensity of the two peaks is kept constant. One hundred minutes after loading (Fig. 3-f), the peak at 406.9 eV is completely missing and only single peak at 400.6 eV is observed in the spectrum. The resultant spectrum well agrees with that of PABA on the oxide (Fig. 3-g).

The peak at 406.9 eV is considered to be attributed to nitro group and the peak at 400.6 eV is to be due to amino group from analogy with the XPS results[21,22] of nitrobenzenes and anilines. Therefore it is clear that the conversion reaction of nitro to amino group takes place without lead cover electrode and the conversion proceeds rather slowly after adsorption reaction.

The peak at 401.6 eV initially appears in the spectrum is considered to be transient intermediate. It is known that nitrosobenzene radical is produced as an intermediate species of electrochemical reduction of nitrobenzene.[23] And the observed binding energy is in good agreement with that of nitrosobenzene in solid state.[22,24] Thus the intermediate is considered to be nitrosobenzoate on the oxide. However, we cannot rule out the possibility of phenyl-hydroxyl amine like species as an intermediate, because this species is also proposed as an intermediate of the reduction of nitrobenzene.[25]

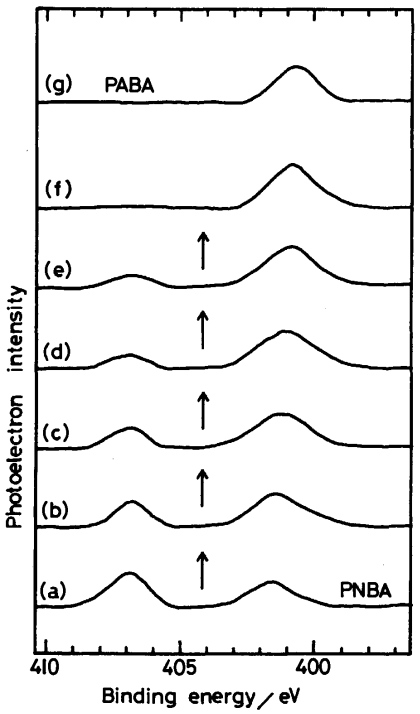

Fig. 3. Nls photoelectron spectra of PNBA on aluminium oxide measured 10 min(a), 25 min(b), 40 min(c), 55 min(d), 70 min(e), and 100 min(f) after loading, and that of PABA(g) on aluminium oxide.

Analysis of the Conversion Reaction. Although PNBA and PABA give the same adsorbed species on the oxide and the obtained IET spectra show similar intensities (indicating that the surface concentration of both compounds is comparable), the tunneling resistance of the junction loaded with PNBA is about 10 times that of the junction with PABA. This difference in tunnel resistance is considered to reflect the difference in the thickness of the insulating oxide layer. To obtain more precise information, the thickness of the oxide layer has been calculated from the XPS data as follows.

Figure 4 shows the schematic view of the surface layers of aluminium-aluminium oxide-adsorbate system and its XPS Al2p spectrum. By assuming that the oxide and the adsorbate layers are uniform, the Al2p photoelectron intensity from the metal substrate, I_m, can be expressed by

$$I_m = I_m^0 \exp(-d/\lambda_o \sin\theta) \exp(-l/\lambda_a \sin\theta), \quad (1)$$

where I_m^0 is the Al2p photoelectron intensity of the clean aluminium metal film, d is the thickness of the oxide layer, λ_o is the electron mean free path value in the oxide layer for the Al2p metal peak, θ is the photoelectron collection angle with respect to the sample plane, l is the thickness of the adsorbate layer and λ_a is the electron mean free path value in the adsorbate for the Al2p metal peak. As the kinetic energy of electrons for Al2p metal peak is nearly equal to that for Al2p oxide peak, the mean free path values for the two peaks are considered to be equal. Thus the intensity of the photoelectron from the oxide layer I_o can be expressed

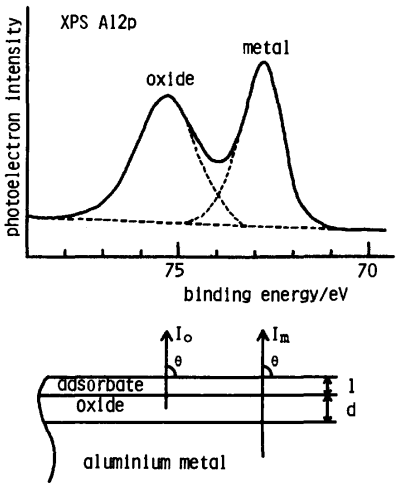

Fig. 4. Schematic view of surface layers and XPS Al2p spectrum.

Table 2. Resistance of tunnel junction and thickness of the oxide for various treatment

	Wet O_2 5 min (A)	(A) + acetone	(A) + PABA	(A) + PNBA
Junction resistance[a]/Ω	0—5	0—10	100—450	1400—8000
Oxide thickness[b]/nm	1.26±0.07	1.31±0.04	1.34±0.05	1.59±0.08

a) Resistance of 1 mm × 1 mm junction. b) Estimated from XPS Al2 p metal to oxide intensity ratio, see text.

as

$$I_o = I_o^0[1-\exp(-d/\lambda_o \sin\theta)]\exp(-l/\lambda_a \sin\theta), \quad (2)$$

where I_o^0 is the photoelectron intensity of the thick oxide layer without covering layer. By dividing Eq. 1 by Eq. 2, the terms including the effects of the adsorbate layer can be cancelled out and we obtain an equation:

$$\frac{I_m}{I_o} = \frac{I_m^0 \exp(-d/\lambda_o \sin\theta)}{I_o^0[1-\exp(-d/\lambda_o \sin\theta)]}. \quad (3)$$

Thus the thickness of the oxide layer, d, is given by

$$d = \lambda_o \sin\theta \ln[1+(I_m^0/I_o^0)(I_o/I_m)]. \quad (4)$$

In the present experiment, $\theta=\pi/2$ and the observed value of I_m^0/I_o^0 is 1.33 for Al2p photoelectron. And with assuming λ_o=1.50 nm for about 1180 eV kinetic energy electron,[26] the thickness of the oxide layer in nm can be expressed by

$$d = 1.50 \ln[1+1.33(I_o/I_m)]. \quad (5)$$

With Eq. 5, the thickness of the oxide layer can be estimated from the Al2p photoelectron intensity ratio, I_o/I_m, even if the surface is covered with unknown amounts of adsorbates.

In Table 2, junction resistance and estimated oxide thickness for various treatment are listed. The oxide thickness is little affected by the adsorption of PABA, while the adsorption of PNBA causes apparent enlargement of the thickness. This is also revealed in the difference of tunneling resistance. These facts imply that the conversion reaction results in the increase of the oxide thickness. Thus it is clear that the oxygen atoms of the nitro group are consumed for the growth of the oxide layer with conversion reaction.

The hydrogen required for the conversion is thought to be present on the substrate surface as hydroxyl group. If surface hydroxyl groups are deuterated, we can elucidate the mechanism of the conversion reaction. Figure 5 shows the expanded IET spectrum of PNBA on the oxide grown with oxygen containing D_2O vapor. Treatment with D_2O is expected to give the surface OD group. The observed peak positions are listed in Table 1. In the spectrum, characteristic peaks due to N-D stretcing modes are observed at 2500 cm^{-1} region. This observation indicates that the hydrogen atom or the surface hydroxyl group is used for the conversion

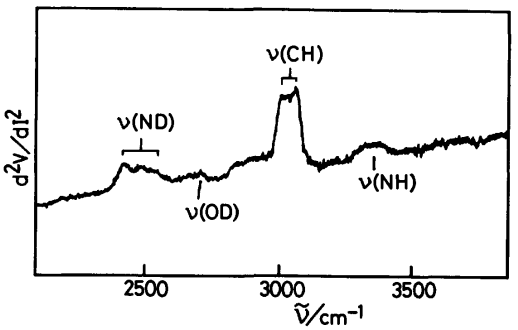

Fig. 5. Expanded IET spectrum of *p*-nitrobenzoic acid adsorbed on deuterated aluminium oxide.

reaction of nitro to amino group. The small peak at 3380 cm^{-1} is thought to appear by the reaction with residual surface OH group to form -NHD species.

On bulk alumina, it is concluded from ESR study[27] that nitrobenzene and their derivatives were adsorbed as anion radicals, and the conversion of nitro group to amino group has not been reported. Thus the conversion is thought to be specific reaction on the oxide utilized for IETS. This phenomena can be explained as follows. The oxide formed on aluminium metal is known to reach a limiting thickness of 4.5 nm after one month in air,[28] whereas the thickness of the oxide layer utilized for IETS is only *ca.* 1.3 nm (Table 2). So the oxide layer can easily grow by the reaction with oxidizing chemicals (in this case, nitro substituent). In the case of bulk alumina, this reaction cannot take place.

In previous paper,[18] we indicated that the oxide surface used in IETS behaves as base (OH donor) against acidic functional group such as -COOH, -OH, and -SH. In the case of conversion reaction reported here, however the surface hydroxyl group acts as hydrogen donor. Thus the oxide surface exhibits various properties in accordance with the property of the adsorbate and the reactivity is quite different from bulk alumina.

From the results obtained by this study, it is found that IETS cannot be used to distinguish between nitro group and amino group. It is a serious problem to apply IETS to the identification of unknown compounds containing amino or nitro group. Further studies on the property of the oxide used in IETS and the modification of the oxide are needed in order to solve this problem.

The Reaction of [CoL_2] (L=5-Chloro- or 5-Nitro-8-quinolinolate Ion) with Nitrogen Monoxide

Eiichi Miki,* Kazuomi Ishimaru, Kunihiko Mizumachi, Tatsujiro Ishimori, and Mikio Tanaka†

Department of Chemistry, College of Science, Rikkyo University, Nishi-Ikebukuro, Toshima-ku, Tokyo 171

†*Laboratory of Chemistry, Nippon Medical School, Kosugi, Nakahara-ku, Kawasaki 211*

(Received September 22, 1984)

[CoL_2]·$n$$H_2O$ (L=5-chloro-8-quinolinolate ion, n=4; L=5-nitro-8-quinolinolate ion, n=5) reacted with nitrogen monoxide in CH_2Cl_2 at *ca.* 253 K to give [CoL_2(NO)] with NO^- group. [CoL_2(NO)] reacted further with nitrogen monoxide in 10 v% pyridine–DMF at room temperature to give [$CoL_2(NO_3)$(py)]·nDMF·0.5py (L=5-chloro-8-quinolinolate ion, n=0; L=5-nitro-8-quinolinolate ion, n=1) with liberation of dinitrogen oxide. [CoL_2]·$n$$H_2O$ also reacted with nitrogen monoxide in the pyridine–DMF to give the same nitrato complexes. In pyridine, [CoL_2]·$n$$H_2O$ gave [$CoL_2(NO_3)$(py)]. In DMF, [CoL_2]·$n$$H_2O$ reacted with nitrogen monoxide at room temperature to give [CoL_2(NO)]·0.5H_2O (L=5-chloro-8-quinolinolate ion) or [$CoL_2(NO_2)$(DMF)]·2H_2O (L=5-nitro-8-quinolinolate ion).

Transition-metal complexes react with nitrogen monoxide, NO, causing the NO to disproportionate, or to give the nitrosyl or hyponitrito complexes. NO also reacts with transition-metal nitrosyls to bring about electrophilic attack by the NO on the coordinating NO or disproportionation of the NO, or to give the hyponitrito or further nitrosylated complexes. These reactions proceed separately or simultaneously, as the case may be.[1-3] Of the products obtained from the disproportionation, the product with most oxidized nitrogen atom has been reported to be nitrite ion. Recently, we reported that the reactions of NO with [Co(qn)$_2$] (qn=8-quinolinolate ion) and [Co(2mqn)$_2$]·H_2O (2mqn=2-methyl-8-quinolinolate ion) in CH_2Cl_2 at room temperature caused disproportionation of the NO in the presence of the cobalt ion; $Co^{2+}+9NO \rightarrow Co^{3+}+NO^++NO_2^-$(coord)$+NO_3^-$(coord)$+3N_2O$ (coord=coordinating), and $Co^{2+}+11NO \rightarrow Co^+ + 3NO^+ + NO_2^-$(coord)$+NO_3^-$(coord)$+3N_2O$, respectively.[4,5] One of the features of the reactions is that the NO disproportionates to produce nitrate ion and nitrosyl cation.

In this paper, we report the reaction of [Co(5cqn)$_2$]·4H_2O (5cqn=5-chloro-8-quinolinolate ion, $C_9H_5NOCl^-$), [Co(5nqn)$_2$]·5H_2O (5nqn=5-nitro-8-quinolinolate ion, $C_9H_5N_2O_3^-$), or their nitrosyl complexes with NO in CH_2Cl_2, DMF, 10 v% pyridine–DMF, or pyridine. The reactions were characterized by NMR (^{13}C and ^{15}N), IR (including ^{15}N-isotopic shifts), and MS measurements.

Experimental

Materials. Dichloromethane was distilled and stored under argon over Zeorum A-4. DMF was purified by distilling under reduced pressure after dried over barium oxide, and stored under argon over Zeorum A-4. JIS-GR pyridine dried over Zeorum A-4 and JIS-GR diethyl ether were used without further purification. ^{15}NO was derived from $K^{15}NO_3$ (^{15}N atom%=99—99.7). Starting materials, [Co(5cqn)$_2$]·4H_2O (Found: Co, 12.4. Calcd: Co, 12.1%) and [Co(5nqn)$_2$]·5H_2O (Found: Co, 11.2. Calcd: Co, 11.1%) were prepared by the ordinary method.

Measurements. The C, H, N, and Cl contents of the products were analyzed by the Organic Analysis Center of the Institute of Physical and Chemical Research. The magnetic susceptibilities were measured by the Gouy method at room temperature.

The IR spectra in the solid state were measured as Nujol and poly(chlorotrifluoroethylene) oil mulls on a JASCO A-202 and a JASCO IR-F spectrometers in the region 200—4000 cm^{-1}. Since the solid products showed a number of the bands due to the coordinating quinolinolate ions, the isotopic shifts upon ^{15}N-substitution were carefully measured at 80 K using a Liquid Nitrogen Cooling Unit-DN 70 (Oxford Instruments) in many cases.

The gaseous products from the reaction of the cobalt or nitrosylcobalt complex with NO were identified by a Hitachi M-80 double-focusing mass spectrometer equipped with a Hitachi M-003 data processing system and by the IR bands and their ^{15}N-isotopic shifts.[6] A relative molar ratio of the residual NO to the produced N_2O was measured by the mass spectrometer for examining stoichiometry of the reaction.

Nitrogen-15 NMR spectra of the obtained nitrato and nitro complexes were measured at 308—353 K in the Fourier transform mode with proton decoupling using a JEOL FX-90Q spectrometer operating at 9.04 MHz. For measuring the ^{15}N NMR spectra were used the samples with $^{15}NO_2^-$ and $^{15}NO_3^-$ (^{15}N atom%=99—99.7). Chemical shifts were referenced to the NH_4^+ signal of a saturated aqueous $^{15}NH_4{}^{15}NO_3$ solution employed as the external standard, and were converted to the liquid ammonia scale by addition of 20.68 ppm.[7] The saturated solutions in DMSO-d_6 were placed in egg-shaped sample tubes, and a sweep width of 5.0 kHz over 8 K data points was used. A pulse width corresponding to a tip angle of 30° and a repetition time of 4 s was used; 1—2 K transients were required for an adequate signal-to-noise ratio. Carbon-13 NMR spectra were recorded on the same spectrometer at 308—353 K at 22.5 MHz using the same solution. The chemical shifts were referenced to internal TMS. The spectral width was typically 5000 Hz with 8 K data points for acquisition. A pulse width of 15 μs (45°) and a delay of 3 s were used; 500—1000 transients were accumulated in the region where

the resonances of the quinolinolato and py ligands were observed.

The UV spectra were run on a Hitachi 340 spectrometer.

Reaction with Nitrogen Monoxide. All reactions were carried out in a vacuum line equipped with greaseless valves and O-ring joints. The organic solvents were carefully degassed by three cycles of freeze-pump-thaw or deaerated with argon or dinitrogen before use.

Reaction of [Co(5cqn)$_2$]·4H$_2$O or [Co(5nqn)$_2$]·5H$_2$O with NO in CH$_2$Cl$_2$: The starting cobalt(II) complexes (0.5—1 mmol) suspended in CH_2Cl_2 (20 cm^3) was brought into contact with NO (5—10 mmol) and stirred for 7 d at *ca.* 253 K to obtain [Co(5cqn)$_2$(NO)], **1**, or [Co(5nqn)$_2$(NO)], **2**. The product was collected by filtration, washed with diethyl ether, and then dried under vacuum.

Reaction of [Co(5cqn)$_2$]·4H$_2$O or [Co(5cqn)$_2$(NO)] with NO in DMF, 10 v% Pyridine-DMF, or Pyridine: NO (5 mmol) was trapped into a reaction vessel containing [Co(5cqn)$_2$]·4H$_2$O (0.25 mmol) dissolved in DMF (10 cm^3), and the solution was stirred at room temperature for 1 d. A small amount of **3** was obtained.

When the pyridine-DMF (10 cm^3) were used instead of DMF, **4** was precipitated by dropping deoxygenated diethyl ether (200 cm^3) in a clear reddish brown solution obtained by the reaction of NO (5 mmol) with [Co(5cqn)$_2$]·4H$_2$O or [Co(5cqn)$_2$(NO)] (0.25 mmol). The elementary analyses and the IR spectra for the product from [Co(5cqn)$_2$]·4H$_2$O were the same as those for the product from [Co(5cqn)$_2$(NO)]. In pyridine (10 cm^3), [Co(5cqn)$_2$]·4H$_2$O (0.25 mmol) reacted with NO (5 mmol) to give a clear reddish brown solution, to which **5** was precipitated by adding deoxygenated diethyl ether.

Reaction of [Co(5nqn)$_2$]·5H$_2$O or [Co(5nqn)$_2$(NO)] with NO in DMF, 10 v% Pyridine-DMF, or Pyridine: The reactions were carried out on the same scale as described in the preceding paragraph. A clear reddish brown solution obtained from the reaction of [Co(5nqn)$_2$]·5H$_2$O with NO in DMF for 1—4 d was dropped in deoxygenated diethyl ether (100 cm^3) to precipitate **6**. When the pyridine-DMF (10 cm^3) was used instead of DMF, reddish brown suspention was obtained from the reaction of [Co(5nqn)$_2$]·5H$_2$O or [Co(5nqn)$_2$(NO)] with NO. The precipitated **7** was collected by filtration. The elementary analyses and the IR spectra for the product from [Co(5nqn)$_2$]·5H$_2$O were the same as those for the product from [Co(5nqn)$_2$(NO)]. From the reaction of [Co(5nqn)$_2$]·5H$_2$O with NO in pyridine, **8** was obtained as precipitate.

Results and Discussion

Characterization of the Solid Products. Elementary analyses and chemical formulae for the obtained complexes, **1—8**, are shown in Table 1. The complexes were diamagnetic, suggesting that all the solid products are low-spin type cobalt(III) complexes since the formal oxidation number of the coordinating NO group for the nitrosyl complexes is −I as mentioned later.

The nitrosyl complexes in the solid state were stable in air, but unstable in deoxygenated organic solvents such as CH_2Cl_2 and DMF to gradually decompose with liberation of NO. The nitro and nitrato complexes were stable in common organic solvents such as CH_2Cl_2, pyridine, DMF, and DMSO.

Reactions in CH$_2$Cl$_2$: The nitrosyls, **1** and **2**, were prepared at 253 K, but could not be isolated at above 273 K. Upon ^{15}N-substitution, the IR band at 1669 cm^{-1} (vs)[8] for **1** shifted to 1636 cm^{-1}, and the 1720 cm^{-1}

A, [Co(5cqn)$_2$]·4H$_2$O; **B**, [Co(5nqn)$_2$]·5H$_2$O; 5cqn, 5-chloro-8-quinolinolate ion; 5nqn, 5-nitro-8-quinolinolate ion. a) The hydrogen content on the assumption that H$_2$O of **6** leaves during the preliminary treatments of the elementary analysis.

(vs) band for **2** shifted to 1688 cm^{-1}. These bands were assigned to the N-O stretching vibrations.[9] Difference in wave numbers of the N-O stretching vibrations for **1** and **2** arise from that electron-attractive power of the nitro group in the quinoline ring is larger than that of the chloro group. Of nitrosyl-cobalt complexes, the N-O stretching vibration of the NO^- complexes are observed in the region 1570—1710 cm^{-1}, while that of the NO^+ complex at *ca.* 1850 cm^{-1}.[1,5] Thus, the present nitrosyls are the NO^- complexes, which is also supported from an empirical rule in the value of the N-O stretching bands for transition-metal nitrosyl complexes proposed by Haymore and Ibers.[9] The reaction in CH_2Cl_2 can be regarded as an oxidative addition of NO to the Co^{2+}, $Co^{2+}+NO \rightarrow Co^{3+}+NO^-$(coord).

Reactions in DMF: The yield of **3** was very low. The IR spectrum was quite similar to that of **1**; the N-O stretching vibration was observed at 1667 cm^{-1}. The reaction over more than 2 d at room temperature made **3** decompose to uncharacterized product with liberation of N_2O.

The 3400(br) and the 1655 cm^{-1}(vs) bands for **6** could be assigned to the O-H stretching vibration of the water of crystallization and the C-O stretching one for the coordinating DMF, respectively.[10] The bands characteristic of the coordinating nitro group could be clearly observed; upon ^{15}N-substitution, the 792(w), 606(w), and 428 cm^{-1}(w) bands shifted to 787, 598, and 424 cm^{-1}, respectively, and were assinged to the NO_2 symmetric deformation, NO_2, wagging, and Co-NO_2 stretching vibrations, respectively.[4-6,11] However, the N-O stretching bands characteristic of the nitro group could not be observed because these bands were hidden under many strong bands due to the 5-nitro-8-quinolinolate ions. The reaction giving **6** was broken off halfway, and the obtained solution was poured into deoxygenated diethyl ether to precipitate a dark brown product. The IR spectrum showed the characteristic bands of **6** together with the 1720 cm^{-1} band assignable to the N-O stretching vibration of **2**. This suggests that [Co(5nqn)$_2$] reacts with NO to yield **2** followed by the further reaction of NO with the coordinating NO group of **2** to give the nitrite ion. Thus, the reaction may be shown as follows; $Co^{2+}+NO \rightarrow Co^{3+}+NO^-$(coord), NO^-(coord)$+2NO \rightarrow NO_2^-$(coord)$+N_2O$. Such electrophilic attack of NO on the coordinating NO group has already been reported by Gwost and Caulton.[12]

Reactions in 10 v% Pyridine-DMF or Pyridine: [Co(5cqn)$_2$]·4H_2O reacted with NO in the pyridine-DMF or in pyridine to give **4** or **5**, respectively, with liberation of N_2O. **1** gave also the same nitrato complex, **4**, in the pyridine-DMF. Table 2 shows wave numbers and the assignments of the bands on which ^{15}N-isotopic shifts were observed in the region 200—4000 cm^{-1}. The bands characteristic of a coordinating nitrate ion were observed for **4**. Separation of two N-O stretching bands due to the nitrate ion was less than 100 cm^{-1}, suggesting that the nitrate ion coordinates to the cobalt atom as a unidentate ligand.[4,5,13] **5** also showed one of the N-O stretching bands due to the coordinating nitrate ion at 1404 cm^{-1}(m). Upon ^{15}N-substitution, the another N-O stretching band could be observed at 1295 cm^{-1}(m, sh).

Table 2. Wave numbers and the assignments of coordinating nitrate ion for [Co(5cqn)$_2$(NO_3)(py)]·0.5 py and [Co(5nqn)$_2$(NO_3)(py)]·DMF·0.5 py at 80 K

[Co(5cqn)$_2$(NO_3)(py)]·0.5 py

^{14}N-compound	^{15}N-compound	Assignment
1414 m	1385 sh[a]	N-O antisym str of NO_3^-
1330 m[a]	1300 m	N-O sym str of NO_3^-
832 sh[a]	820 s	Out-of-plane bend of NO_3^-
596 w	584 w	NO_2 sym bend or NO_2 antisym bend of NO_3^-

[Co(5nqn)$_2$(NO_3)(py)]·DMF·0.5 py

^{14}N-compound	^{15}N-compound	Assignment
1421 m	1393 m	N-O antisym str of NO_3^-
1328 m	1308 sh[a]	N-O sym str of NO_3^-
820 vs[a]	810 vs[a]	Out-of-plane bend of NO_3^-
600 vs[a]	591 w	NO_2 sym bend or NO_2 antisym bend of NO_3^-
579 vs[a]	576 s, br[a]	

a) The bands due to the nitrate ion and the strong bands due to the coordinating 5-chloro- or 5-nitro-8-quinolinolate ions partially overlapped.
Abbreviations: str=stretching, bend=bending, sym=symmetric, antisym=antisymmetric, vs=very strong, s=strong, m=medium, w=weak, sh=shoulder, br=broad.

Both [Co(5nqn)$_2$]·5H_2O and **2** gave the same nitrato-complex, **7**, in the pyridine-DMF. In Table 2 are also shown the IR bands characteristic of a unidentate nitrate ion for **7** with their ^{15}N-isotopic shifts. The strong band at 1670 cm^{-1} could be assigned to the C-O stretching vibration due to the uncoordinating DMF.[10] **8** obtained from the reaction in pyridine also showed two N-O stretching bands at 1425(m) and 1326 cm^{-1}(m) due to the unidentate nitrate ion.

The reaction of [CoL_2] and [CoL_2(NO)] with NO can be shown as follows; $Co^{2+}+5NO \rightarrow Co^{3+}+NO_3^-$(coord)$+2N_2O$, and $Co^{3+}+NO^-$(coord)$+4NO \rightarrow Co^{3+}+NO_3^-$(coord)$+2N_2O$, respectively.

DMF in **6** and **7** could be also confirmed by the ^{13}C NMR measurements as mentioned later. The IR measurements could not confirm pyridine in **4**, **5**, **7**, and **8**, but the ^{13}C NMR ones suggest that **4** and **5** contain pyridine.

UV Measurements: The electronic spectra for the nitro and nitrato complexes are shown in Table 3.

Table 3. Electronic spectra of the solid products

Compound[a]	Solvent	σ/nm(ε/mol^{-1} dm^3 cm^{-1})
4	CH_2Cl_2	330(4.93×10^3), 346(5.14×10^3)
		428(7.68×10^3), 560 sh(4.9×10^2)
6	CH_2Cl_2	340(1.63×10^4)
		438(5.06×10^4), 580 sh(5.7×10^2)
7	CH_2Cl_2	344(1.59×10^4)
		442(4.35×10^4), 560 sh(3.5×10^2)
8	10 v% py-DMF	342(1.76×10^4)
		438(4.35×10^4), 560 sh(2.9×10^2)
A	10 v% py-DMF	352(5.78×10^3), 418(7.65×10^3)
B	10 v% py-DMF	344(1.26×10^4), 444(4.30×10^4)

a) Abbreviations of the compounds are the same as those shown in Table 1.

The bands at 330—440 nm may be assigned to the charge transfer absorption between the coordinating 8-quinolinolate ion and the cobalt(III) ion as compared with the absorption maxima and intensities for the spectra of [Co(5cqn)$_2$] or [Co(5nqn)$_2$]. The shoulder bands at 560—580 nm may be due to *d–d* absorption in the cobalt(III) ion.[14]

NMR Measurements: Since the obtained nitrosyl complexes, **1** and **2**, were unstable in deoxygenated common organic solvents, the NMR spectra could not be measured. The ^{15}N and ^{13}C NMR measurements of the nitro and nitrato complexes, **4**—**8**, were tried in DMSO-d_6 at 308—353 K to alleviate their sparing solubility to DMSO and the high viscosity of the solution at room temperature (the solubility is less than 10^{-3} mol dm^{-3} at room temperature).

The ^{15}N NMR spectra of the nitrato complexes, **4**, **5**, **7**, and **8**, showed a single resonance at 379.34, 388.06, 379.72, and 375.56 ppm, respectively. These values were comparable to 376.25 ppm of $^{15}NO_3^-$ in a saturated aqueous solution of $^{15}NH_4{}^{15}NO_3$, and 380.26 ppm of a DMSO-d_6 solution of $K^{15}NO_3$ (0.28 mg/0.35 cm^3) at 333 K. The ^{15}N NMR resonance of the nitro complex, **6**, was also observed at 371.12 ppm and the coordinating nitro ion showed a high-field resonance by 240 ppm compared with 610 ppm of free nitrite ion. Such a phenomenon has been found for [RhCl(NO_2)(NO)L_2](L=phosphine derivatives).[15] On the other hand, the ^{15}N resonance of the coordinating nitrate ion was found in the same region as that of free nitrate ion. Because the coordination of the nitrate ion to the cobalt(III) ion is through the oxygen atom, the shifts are small as observed for nitrato complexes of various metals.[16]

The ^{13}C NMR spectra of **4** and **5** were very complicated (see Fig. 1), and thus could not be clearly assigned. The resonances were observed in the region 112—166 ppm which coincided with the regions, 111—153 ppm for 5-chloro-8-quinolinol and 123—150 ppm for pyridine.[17] Number of the observed signals for **4** was 25, and that for **5** was 22. Assuming

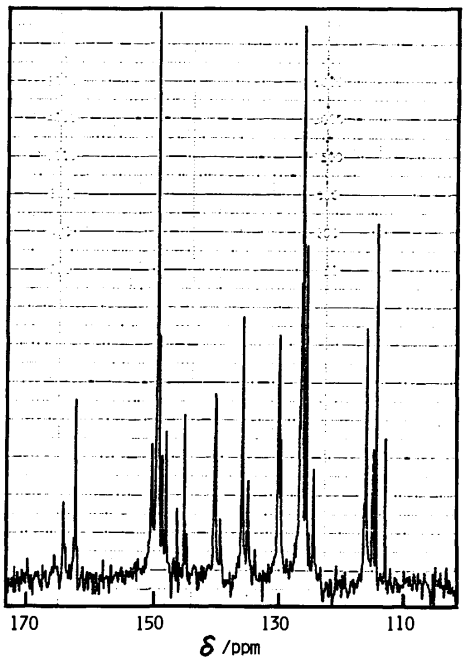

Fig. 1. ^{13}C NMR spectrum of [Co(5cqn)$_2$(NO_3)(py)]·0.5py in DMSO-d_6; standard, internal TMS.

that **4** contains two kinds of the coordinating 5-chloro-8-quiolinolate ions, a coordinating pyridine, and a free pyridine, number of the expected resonances becomes 24. Also, assuming that **5** consists of two kinds of the coordinating 5-chloro-8-quinolinolate ions and a coordinating pyridine, number of the expected signals becomes 21. The NMR data suggest that among **4** and **5**, the nitrato ligand is in *cis*-position to the pyridine. The ^{13}C NMR spectra of **6**, **7**, and **8** could not be measured clearly due to their solubilities, but two kinds of 5-nitro-8-quinolinolate ions seems to exist. The resonances due to DMF in **6** and **7** could be observed. The resonances at 28.97 and 33.90, and at 160.96 ppm for **6** could be assinged to the methyl carbons, and the carbonyl carbon, respectively.[17] The resonances at 30.66, 35.65, and 162.20 ppm for **7** were almost equal to those at 31.17, 36.27, and 162.39 ppm for free DMF, respectively.[17]

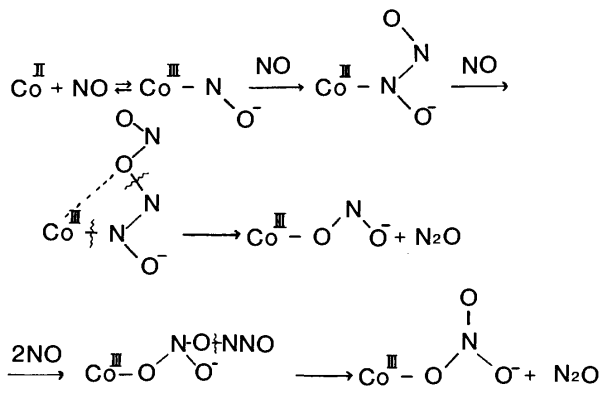
Gaseous Products. Gaseous product from the reaction in DMF, the pyridine-DMF, or pyridine was only N_2O. It has been reported that N_2 together with N_2O was liberated on disproportionation of NO in the presence of transition-metal complex.[3] N_2 was not liberated under the present experimental conditions.

For the reaction giving **4**, **5**, or **8**, the stoichiometry was examined by measuring the relative molar ratio of the residual NO to the produced N_2O. The molar ratio of NO to the cobalt complex was 20.0, and the cobalt complex and the organic solvent used were 0.25 mmol and 10 cm^3, respectively. The ratio observed was generally larger than that calculated on the assumption that the reaction proceeded completely, and the repro-

ducibility was not always good. The yield of the solid product calculated from the observed ratio was smaller than the yield obtained actually. These suggest that the total reaction with NO is not simple, and side reactions which could not be identified may consume the produced N_2O.

Effects of Organic Solvents on the Reactions. On the reaction of $[Co(qn)_2(NO)]$ (qn=8-quinolinolate ion) with NO in CH_2Cl_2 having very poor coordinating ability to metal ion, NO attacks the coordinating nitrosyl group, NO^-, electrophilically to give NO_2^- with retention of the Co-NO bond; the nitrogen atom in the nitro group comes from the nitrosyl group. This was confirmed by ^{15}N-labelled experiments.[4]

For examining the mechanism of the reaction of the nitrosyl complex, **1**, or **2**, with NO in the pyridine-DMF, the following combinations of nitrogen isotopes were used; A, (^{14}NO-complex)-(^{15}NO gas) and B, (^{15}NO-complex)-(^{14}NO gas). The molar ratio of the NO to the nitrosyl complex was *ca.* 6—7. In the case of A, the mass analysis showed that the relative molar ratio of ^{14}NO to ^{15}NO in the residual NO was almost equal to that of the ^{14}NO-complex to the ^{15}NO gas. The experiment using the isotopes suggests that the ^{14}NO-complex decomposes almost perfectly to liberate ^{14}NO and the liberated ^{14}NO together with ^{15}NO, original reactant, reacts with the resulting cobalt(II) complex to give the nitrato complex. In the case of B was also found the same phenomena as observed for the case A. The ^{14}N-^{15}N scramble was observed for the reaction of the nitrosyl complex with NO, hence the reaction mechanism could not be elucidated from the isotopic experiments. In solution containing strong σ-donor Lewis base such as pyridine, after the Co-NO bond in the original nitrosyl complex was broken and the resulting cobalt(II) complex was nitrosylated again, NO reacts with the NO^- group to give NO_2^- and N_2O with cleavage of the Co-NO bond, and the NO_2^- reacts further with NO to give NO_3^- and N_2O. Coordination of pyridine to the cobalt ion seems to unstabilize the Co-NO bond. The proposed mechanism for the reaction is pictured (Scheme 1).



Scheme 1. Proposed reaction mechanism.

The reaction of the nitrosyl complex with NO in DMF could not be elucidated. Since coordinating ability of DMF to metal ion is weaker than that of pyridine, the complicated reactions may proceed.

On the reaction of $[CoL_2]$ with NO in pyridine and 10 v% pyridine-DMF, the disproportionation of NO to NO_3^- and N_2O involving an oxidation of cobalt(II) to cobalt(III) was observed. The reaction is considered to be initiated from a nitrosylation of $[CoL_2]$ followed by the reaction of the resulting nitrosyl complex with NO as mentioned above. The reaction giving **6** is considered as follows; after $[Co(5nqn)_2]$ was nitrosylated, the resulting NO^- group seems to react further with NO to give NO_2^- without cleavage of the Co-NO bond, because DMF is not so strong Lewis base as break the Co-NO bond.

On metal-induced NO disproportionations which has been reported so far, the product with most oxidized nitrogen atom is nitrite ion.[3] In a series of our reaction system[4,5] including the present study, nitrate ion was produced. This phenomenon is considered to be usual on the disproportionation, especially in solvent with strong coordinating ability such as pyridine.

A number of studies on the disproportionation of NO have been reported,[3] but the stoichiometry of the reaction has been mentioned for only a few examples.[2,18] Since this type of the reaction is very complicated, it seems likely that stoichiometry of the total reaction can not be elucidated in many cases.

The authors wish to express their thanks to Professor Yoshito Takeuchi of the University of Tokyo, Assistant Professor Reiko Hirota of Rikkyo University, and Professor Minoru Hirota of Yokohama National University, for measuring the NMR spectra. The authors also would like to thank Professor Yoshito Takeuchi of the University of Tokyo for his kindhearted discussion of the NMR data, and Mr. Shigeaki Oyama of Rikkyo University for his technical assistance.

(Received October 8, 1984)

The benzonitrile adduct of copper(II) trichloroacetate, $[Cu(Cl_3CCOO)_2(PhCN)]_2$, was prepared and characterized. The dimeric structure was confirmed by an X-ray structural determination. This compound crystallizes in the triclinic space group $P\bar{1}$ with a=12.780(1), b=16.064(1), c=10.130(1) Å; α=108.39(1), β=113.34(1), γ=81.07(1)°. The crystal consists of two crystallographically independent dimeric units. Both units have the familiar dimeric copper(II) acetate monohydrate structure with Cu–Cu distances of 2.731(1) and 2.732(1) Å. Magnetic susceptibility data in the range of 80—300 K are well represented by the usual dimer equation with a singlet-triplet energy separation of $-2J$=224 cm^{-1}. The C≡N stretching frequency of benzonitrile in the compound shows an increase by 31 cm^{-1} from the free ligand value. On the basis of the X-ray crystallographic and IR spectroscopic results, the nature of the copper(II)–benzonitrile bond is discussed. For discussion magnetic and spectroscopic properties of some analogous nitrile adducts of copper(II) chloroacetates were also studied.

Studies on a number of dimeric copper(II) carboxylate adducts, $[Cu(RCOO)_2 \cdot L]_2$, have revealed some of the factors which determine the extent of antiferromagnetic interaction in these complexes. On the effect of addend ligand L, Jotham *et al.*[1] have stated that the singlet-triplet separation ($-2J$, a measure of the magnitude of the magnetic interaction) in $[Cu(RCOO)_2 \cdot L]_2$ complexes tends to increase as L becomes a stronger electron donor. On the other hand, Hibdon *et al.*[2] have reported that the magnetic interaction in a series of dimeric copper(II) acetate adducts with 4-substituted pyridine N-oxides becomes stronger as the π-back-donation from the metal ion to the addend ligand increases. However, Muto *et al.*[3] have recently found that, in a series of $[Cu(RCOO)_2 \cdot L]_2$ complexes, where R=CH_3, $ClCH_2$, and Cl_2CH, and L=pyridine analogues, the value of $-2J$ increases as the basicity of the addend ligands becomes weaker. Then a larger $-2J$ has been attributed to a weaker σ-donation of the addend ligand. These apparent discrepancies prompted us to investigate the bonding nature between Cu-L in $[Cu(RCOO)_2 \cdot L]_2$ complexes.

In the present study five complexes, $Cu(ClCH_2COO)_2(PhCN)$, $Cu(ClCH_2COO)_2(4\text{-}CH_3C_6H_4CN)$, $Cu(Cl_2CHCOO)_2(4\text{-}CH_3C_6H_4CN)$, $Cu(Cl_3CCOO)_2(PhCN)$, and $Cu(Cl_3CCOO)_2(4\text{-}CH_3C_6H_4CN) \cdot 1/2bz$, where PhCN=benzonitrile, $4\text{-}CH_3C_6H_4CN$=4-methylbenzonitrile and bz=benzene, have been prepared and characterized by means of magnetic susceptibility and IR spectroscopy measurements. The structure of the benzonitrile adduct of copper(II) trichloroacetate has been determined by a single-crystal X-ray structural analysis to obtain accurate information about the coordinating mode of the addend ligand. In particular relations of the stretching frequency of the C≡N group with its bond length have been studied.

Experimental

Syntheses. $Cu(ClCH_2COO)_2 \cdot L$(L=PhCN and $4\text{-}CH_3C_6H_4CN$): A solution of L (10 mmol) in benzene (10 ml) was added to a solution of $Cu(ClCH_2COO)_2$ (2 mmol) in acetone (20 ml). The resulting solution was filtered and then concentrated to one-third of its volume. When petroleum ether was added to the solution, green crystals precipitated. The crystals were collected, washed with a 1:2 benzene-petroleum ether mixture and dried *in vacuo* at room temperature.

$Cu(Cl_2CHCOO)_2(4\text{-}CH_3C_6H_4CN)$: This compound was prepared from $Cu(Cl_2CHCOO)_2$ and $4\text{-}CH_3C_6H_4CN$ in the same manner as with $Cu(ClCH_2COO)_2 \cdot L$.

$Cu(Cl_3CCOO)_2(PhCN)$: $Cu(Cl_3CCOO)_2 \cdot 3H_2O$ (2 mmol) and PhCN (10 mmol) were suspended in a mixture of benzene (30 ml) and 2,2-dimethoxypropane (1 ml). The mixture was warmed gently with stirring and then filtered. After the solution had been concentrated to one-third of its volume, it was allowed to stand overnight at *ca.* 5 °C in a refrigerator. The separated green crystals were collected, washed with a 1:2 benzene–petroleum ether mixture and dried *in vacuo* at room temperature.

$Cu(Cl_3CCOO)_2(4\text{-}CH_3C_6H_4CN) \cdot 1/2bz$: This compound was prepared from $Cu(Cl_3CCOO)_2 \cdot 3H_2O$ and $4\text{-}CH_3C_6H_4CN$ as described above.

The results of the elemental analyses are given in Table 1.

X-Ray Crystal Structure Determination of $Cu(Cl_3CCOO)_2(PhCN)$. A Rigaku AFC-5 automated four-circle diffractometer was used for all measurements. Crystal data and details of the data collection are summarized in Table 2. Lattice constants were determined by the least-squares refinement based on 35 reflections with $20° < 2\theta < 30°$. The intensity data were corrected for the Lorentz-polarization effects, but not for absorption.

The structure was solved by the heavy-atom method. Refinements were carried out by the block-diagonal least-squares method. Hydrogen atoms were inserted in their calculated positions and included in the refinement. The final R values were $R=\sum||F_o|-|F_c||/\sum|F_o|=0.058$, $R_w=[\sum w(|F_o|-|F_c|)^2/\sum w|F_o|^2]^{1/2}=0.086$. The weighting scheme was $w=(6.5+|F_o|+0.007|F_o|^2)^{-1}$. The final difference Fourier synthesis showed no peaks higher than 0.84 e Å^3.

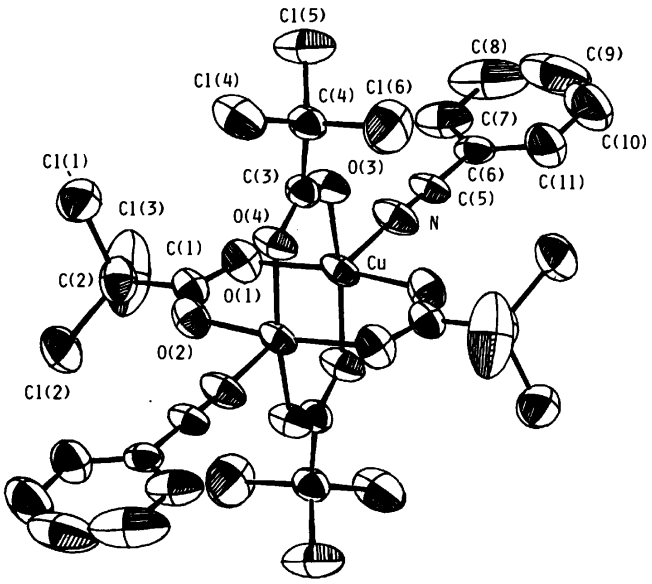

Fig. 1. Molecular structure of $[Cu(Cl_3CCOO)_2(PhCN)]_2$ with thermal ellipsoids (50% probability level).

for Cu, Cl, O, N, and C, were taken from the International Tables for X-Ray Crystallography.[4] All the calculations were carried out on the FACOM-200 computer in the Computer Center of Kyushu University by use of a local version[5] of the UNICS-II and the ORTEP programs. The final positional and thermal parameters with their estimated standard deviations are given in Table 3. The coordinates and isotropic temperature factors of the hydrogen atoms, the anisotropic thermal parameters of the non-hydrogen atoms, and the F_o-F_c tables have been deposited as Document No. 8514 at the Office of the Editor. A perspective drawing of the dimeric molecule and numbering system are illustrated in Fig. 1. The bond distances and angles are tabulated in Table 4.

Magnetic Measurement. Magnetic susceptibilities in the temperature range of 80—300 K were determined by the Faraday method. The correction for diamagnetic contribution (χ_{dia}) was made by use of Pascal's constants.[6] The cryomagnetic data were fitted to the Bleaney-Bowers equation (1) allowing for the presence of paramagnetic impurity,[7]

$$\chi_A = \frac{Ng^2\beta^2}{3kT}\left[1+\frac{1}{3}\exp\left(\frac{-2J}{kT}\right)\right]^{-1}(1-P) + \frac{Ng_i^2\beta^2}{4kT}\cdot P + N\alpha, \quad (1)$$

where P is the mole fraction of the noncoupled copper(II) impurity, g_i is the average g factor for the impurity, and the other symbols have their usual meanings. The values of $g_i=2.2$ and $N\alpha=60\times10^{-6}$ cgs emu (1 cgs emu$=4\pi\times10^{-6}$ m^3) were used throughout the present study. The best-fit parameters, $-2J$, g, and P, were obtained by using a non-linear least-squares program, SALS (model D).[3] As a convenient statistical indicator of the quality of the least-squares fits, the discrepancy index σ_{dis} ($\sigma_{dis}=[\Sigma(\chi_{obsd}-\chi_{calcd})^2/\Sigma\chi_{obsd}^2]^{1/2}$) was employed. The thermal magnetic data are shown in Figs. 2 and 3 as plots of χ_A *vs.* T. The values of χ_{dia}, g, P, $-2J$, and σ_{dis} are summarized in Table 5.

IR Measurement. IR spectra were recorded on a Hitachi 260-10 IR Spectrophotometer as Nujol mulls. The C≡N stretching frequencies observed for the complexes and those for the free nitriles are given in Table 6.

Results and Discussion

The crystal structure of the copper(II) trichloroacetate adduct with benzonitrile contains two independent centrosymmetric $[Cu(Cl_3CCOO)_2(PhCN)]_2$ molecules; they are abbreviated as A and B. The two

independent molecules are quite similar to each other in shape, although there are small differences in their interatomic distances and bond angles. As shown in Fig. 1, each molecule has the well-known dimeric copper(II) acetate monohydrate structure. The benzonitrile is bound to the copper atom in a linear fashion through the terminal nitrogen atom. The coordination geometry around each copper atom is best described as a distorted square pyramid with four carboxylato oxygen atoms in the basal plane (Cu-O 1.955—1.969 Å for A and 1.959—1.972 Å for B) and a nitrile nitrogen atom in the apical position (Cu-N 2.141(9) Å for A and 2.138(6) Å for B), in a similar way to that observed in $[Cu(Cl_3CCOO)_2(2\text{-chloropyridine})]_2$.[8] The basal

a) Ref. 17. b) Change in $\bar{\nu}C{\equiv}N$ on coordination.

atoms in both A and B are almost coplanar with the largest deviation of 0.004 Å. The copper atoms in A and B are shifted from the basal planes toward the apical nitrogen atoms by 0.251 and 0.247 Å, respectively. The Cu-Cu separation (2.731(1) Å for A and 2.732(1) Å for B) is slightly shorter than that in the 2-chloropyridine adduct (2.766(3) Å).[8] The other bond distances and angles about the coordination sphere (*cf.* Table 4) are comparable to those found for the 2-chloropyridine adduct. A noteworthy feature of the coordinated benzonitrile is the C-N distances of 1.113(12) Å (A) and 1.122(9) Å (B), which are significantly shorter than that in the free molecule (1.159(2) Å).[9] This apparent shortening indicates that the C≡N bond strength increased upon formation of the CN→metal coordination bond.[10,11]

The magnetic susceptibility data of the complexes prepared in the present study are well represented by Eq. 1 (*cf.* Figs. 2 and 3), indicating that all the complexes have a dimeric structure similar to that found for $[Cu(Cl_3CCOO)_2(PhCN)]_2$. The $-2J$ values found for the respective benzonitrile adducts are larger than those found for the corresponding 4-methylbenzonitrile adducts. This fact is in accord with the previous conclusion that the antiferromagnetic interaction in dimeric copper(II) carboxylate adducts becomes stronger as the basicity of the addend ligands becomes weaker,[3] because benzonitrile must be less basic than 4-methylbenzonitrile. From Table 5, we can also see that the $-2J$ values in both the benzonitrile and 4-methylbenzonitrile adducts decrease as the pK_a values of the parent carboxylic acids become smaller. This trend can be explained in terms of weakening of the ligand field strength of the four carboxylato oxygen atoms.[3,12,13]

A remarkable feature of the IR spectra of the present complexes is that, in each case, the C≡N stretching absorption appears at a higher wavenumber by 30—40 cm^{-1} than that of the free nitrile (*cf.* Table 6). Such an increase in $\tilde{\nu}$C≡N has been attributed to an increase in the C≡N bond strength resulting from a hybridization change in the coordinated CN group or a greater contribution of the donor atom N_{2s} orbital to the CN σ-bonding system upon σ-donation of the lone pair of electrons on the nitrile nitrogen atom.[14,15] Thus, both of the shortening of the CN bond and the increase of the $\tilde{\nu}$ C≡N observed for $[Cu(Cl_3CCOO)_2(PhCN)]_2$ can be ascribed to the formation of a CN→metal σ-donating bond. On the other hand, if the metal—addend ligand bond is, on the whole, the type of C≡N← metal π-back bonding, the CN bond order should decrease; consequently, the $\tilde{\nu}$C≡N is expected to decrease.[11,16,17]

Thus, the X-ray crystallographic, magnetic and IR spectroscopic results indicate that the nitriles in the present complexes act as the σ-donor ligands. This conclusion is in accord with the recent claim by Rao *et al.* that the pyridine molecule in $[Cu(CH_3COO)_2(py)]_2$ complex functions as a σ-donor base.[18]

Untersuchungen von Diiodogermylen und Triphenylphosphindiiodogermylen und die Kristallstruktur von Triphenylphosphindiiodogermylen

Yoshio INOGUCHI, Shuko OKUI, Kunio MOCHIDA,* und Akiko ITAI†
Chemisches Departement, Naturwissenshaftliche Fakultät, Gakushuin Universität, 1-5-1 Mejiro, Toshima-ku, Tokyo 171
†*Pharmazeutische Fakultät, Tokyo Universität, 7-3-1 Hongo, Bunkyo-ku, Tokyo 113*
(Eigegangen am August 2, 1984)

Reaktivitäten und chemische Eigenschaften von Diiodogermylen und Triphenylphosphindiiodogermylen wurden durch ihre Reaktionen mit Organolithium-Verbindungen oder Butadienen untersucht. Die Kristallstruktur von Triphenylphosphindiiodogermylen wurde röntgenographisch aufgeklärt.

Diorganogermylene, GeR_2, sind für metallorganische Synthesen als Carbenanaloge ebenso wie die homologen Silylene und Stannylene von großem Interesse; zahlreiche Arbeiten über diese Verbindungsklasse wurden in den letzten Jahren publiziert.[1] Diorganogermylene sind sehr instabil und konnten mit wenigen Ausnahmen nicht isoliert werden.[2] Wir haben durch Umsetzung von Diiodogermylen bzw. Triphenylphosphindiiodogermylen mit Organolithium-Verbindung untersucht, ob Diorganogermylen als Zwischenprodukt entsteht und eventuell durch das phosphankoordination stabilisiert werden kann:

$$:GeI_2 + RLi \longrightarrow [:GeR_2],$$
$$LGeI_2 + RLi \longrightarrow [LGeR_2] \quad (L=PPh_3).$$

Durch röntgenographische Aufklärung der Struktur von Triphenylphosphindiiodogermylen sollte es untersucht werden, wie Triphenylphosphan an Diiodogermylen koordiniert ist. Sie sollte außerdem Anhaltspunkte für die Reaktivität dieser Verbindung geben.

Ergebnisse und Diskussion

Diiodogermylen, GeI_2, reagiert mit Phenyllithium in Ether zu Tetraphenylgerman, Ph_4Ge, Triphenylgerman, Ph_3GeH, und polymeren Produkten[3]:

$$:GeI_2 + PhLi \xrightarrow[2)\ H_2O]{1)\ \text{Ether}} Ph_4Ge,\ Ph_3GeH,\ \text{Polymer.} \quad (1)$$

Die Umsetzung von Triphenylphosphindiiodogermylen, Ph_3PGeI_2, mit Phenyllithium in Ether nach anschließender Hydrolyse ergibt Ph_4Ge, Ph_3GeH und Polymer:

$$Ph_3PGeI_2 + PhLi \xrightarrow[2)\ H_2O]{1)\ \text{Ether}} Ph_4Ge,\ Ph_3GeH,\ \text{Polymer.} \quad (2)$$

In Tabelle 1 sind die Einzelheiten der durchgeführten Reaktionen zusammengestellt. Phenyllithium wurde bezogen auf zu GeI_2 bzw. Ph_3PGeI_2 in den Stöchiometrien 1:1, 2:1 und 4:1 verwendet. Je größer das Molarverhältnis von Phenyllithium zu GeI_2 ist, desto höher sind die Ausbeuten an Ph_4Ge. Ph_3GeH entsteht durch Hydrolyse von Triphenylgermyllithium, das als Zwiechenprodukt der dritten Stufe über PhGeI und Ph_2Ge aus GeI_2 und Phenyllithium gebildet wird.[3] Andere germaniumhaltige Produkte zersetzen sich wahrscheinlich zu den aufgefundenen Polymeren. Die Ausbeute an Ph_4Ge bei der Reaktion von Ph_3PGeI_2 mit Phenyllithium ist vom zugegebenen Phenyllithium abhängig. Auch freies Triphenylphosphan fiel in größeren Mengen an. Bei 1:1 und 1:2 in den beiden Reaktionen erschien kein Unterschied der Ausdeuten. Nur bei 1:4 trat ein Unterschied auf. Die hohe Ausbeute von 39% an Ph_3GeH

TABELLE 1. REAKTIONEN VON GeI_2 ODER Ph_3PGeI_2 MIT PHENYLLITHIUM

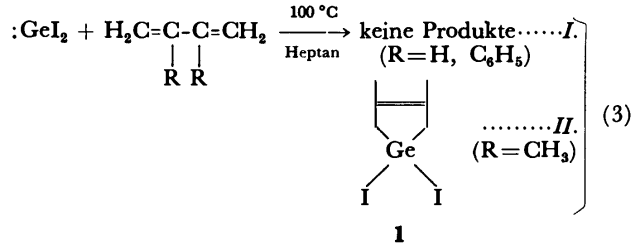
Verbindung[a]		Bedingungen	Produkte/%[b]			
GeI_2	: PhLi		PhI	Ph-Ph	Ph_3GeH	Ph_4Ge
1	: 1	5 d, Ether	4.9	3.8	1.9	1.6
1	: 2	5 d, Ether	7.3	13	0.6	11
1	: 4	5 d, Ether	40	62	0.7	32

Verbindung[a]		Bedingungen	Produkte/%[b]				
Ph_3PGeI_2	: PhLi		PhI	Ph-Ph	Ph_3GeH	Ph_4Ge	Ph_3P
1	: 1	5 d, Ether	2.9	2.9	1.9	14	82
1	: 2	5 d, Ether	7.7	9.6	1.3	19	79
1	: 4	5 d, Ether	10	13	39	36	100

a) Molarverhältnisse. b) Gerechnet aus der Konzentration von GeI_2 bzw. Ph_3PGeI_2.

in der Reaktion von Ph_3PGeI_2 mit PhLi bedeutet, daß Ph_3GeLi in größeren Mengen entsteht, das mit PhI zu Ph_4Ge nicht umsetzt wird. Daher könnte Ph_3GeLi oder GeR_2 bei Triphenylphosphan in dieser Reaktion stabilisiert werden.

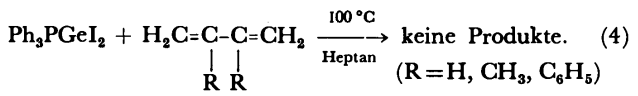
Umsetzungen von GeI_2 mit Butadienen in Heptan sollte eigentlich die entsprechenden Addukte ergeben:[4]



(3)

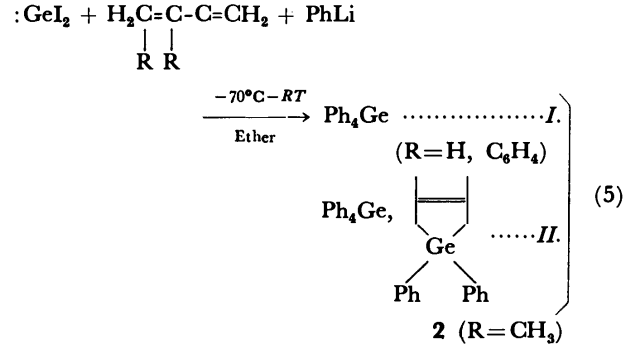
1

In dieser Untersuchung gelang nur *3II*, das Addukt 1,1-diiodo-3,4-dimethylgermacyclopent-3-en **1** zu ergeben. Dieser Unterschied der Addition hängt vielleicht von der Donatoreigenschaft der Doppelbindung von Butadien gegen Germanium ab. Im Fall *3I* wird die Doppelbindung wegen Wasserstoff bzw. Phenylgruppe nicht genug aktiviert, um an Germanium zu addieren. Nur die Methylgruppe bei *3II* gelang, die Elektronendichte an der Doppelbindung für Addition zu aktivieren. Umsetzungen von Ph_3PGeI_2 mit Butadienen unter denselben Bedingungen wie für GeI_2 ergeben keine Addukte:



Bei GeI_2 ist die Donatorfunktion der Doppelbindung zu leerem Orbital an Germanium möglich. Im Gegensatz dazu, kann die Doppelbindung bei Ph_3PGeI_2 wegen der Besetzung desselben Orbitals an Germanium durch Koordination von Triphenylphosphan keine Donatorfunktion ausüben.

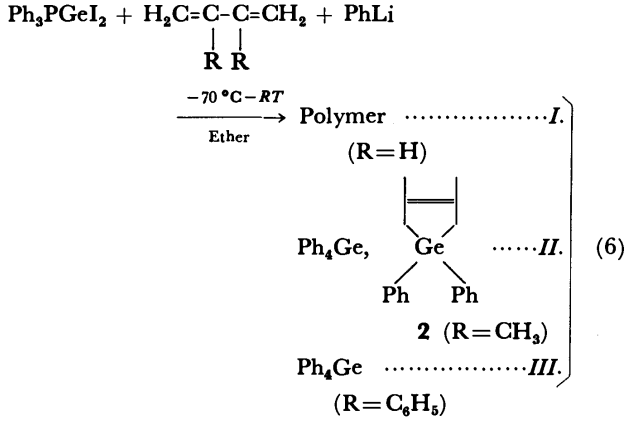
Die Umsetzungen von GeI_2 mit Phenyllithium in Gegenwart von Butadienen ergeben Ph_4Ge und erst bei *5II* ein zweites Produkt, das von der Phenylgruppe substituierte Addukt 3,4-Dimethyl-1,1-diphenylgermacyclopent-3-en **2**:



(5)

Ph_4Ge entsteht in dieser Reaktion aus der direkten Umsetzung von GeI_2 mit Phenyllithium wie *Gl. 1*. **2** entsteht aus der Reaktion von Phenyllithium und **1**, das nach *3II* aus GeI_2 und Butadien ergeben wird.

Die Reaktionen von Ph_3PGeI_2 mit Phenyllithium und Butadienen wurden auch für Vergleich mit *Gl. 5* durchgeführt:



(6)

Die Polymerisation bei *6I* kommt aus Butadien mit Phenyllithium, weil es kein Produkt aus Ph_3PGeI_2 mit Butadien ergibt (s. *3II*) und weil Ph_4Ge aus Ph_3PGeI_2 mit Phenyllithium entstehen soll (s. *Gl. 2*). Bei *6II* ergab es zwei Produkte, Ph_4Ge und Addukt **2**. Ph_4Ge entsteht aus der direkten Reaktion von Ph_3PGeI_2 mit Phenyllithium. Aber die Bildung von **2** erregte uns eine große Interesse. Die Umsetzung von Ph_3PGeI_2 mit Butadien (*Gl. 4*) ergibt Produkt **1** nicht, das sich mit Phenyllithium zu der Verbindung **2** überführen läßt. Mit anderen Worten entsteht die Verbindung **2** nicht über **1**. Ein möglicher Weg zu **2** in der Reaktion *6II* ist die Umsetzung von Butadien mit Ph_2Ge, das letzte Germylen, das als Zwischenprodukt in der Reaktion von Ph_3PGeI_2 mit Phenyllithium entstehen soll. Die Bildung von **2** bei *6II* ist ein Beweis für das Auftreten von Diphenylgermylen Ph_2Ge. Bei *6III* wird nur Ph_4Ge wie bei *5I* gegeben und das Butadien hat keinen Einfluß auf die Umsetzung von Ph_3PGeI_2 mit Phenyllithium.

Röntgenkristallstrukturanalyse von Ph_3PGeI_2. Die Kristallstruktur von Ph_3PGeI_2 wurde röntgenographisch untersucht. Ph_3PGeI_2 kristallisiert aus Xylol in monoklinen Würfeln in der Raumgruppe $P2_1/n$, $Z=8$, $a=11.858\,(3)$, $b=38.569\,(8)$, $c=9.304\,(2)$ Å, $\beta=111.217\,(4)°$, $R=10.0$ (Abb. 1, Tabelle. 2). Zwei verschiedene Strukturen von Ph_3PGeI_2 wurden gegeben. Jeder Bindungswinkel (P-Ge-I, I-G-I) von 90—99° an dem Germaniumatom ist kleiner als der von 109° in allgemeinem sp^3-Orbital. Die zwei Elektronen des Germaniums lokalisieren sich als ein Elektronenpaar an dem Germaniumatom in gegenseitigem Lappen von den zwei Iodatome und dem Phosphoratom. Triphenylphosphan ist an dem Germaniumatom einfach koordiniert und darum erscheint keine Rückbindung aus Germaniumatom zu Phosphoratom. Aus dieser Lokalisierung der Elektronen an Germaniumatom und dem Abstand von 2.503 bzw. 2.510 Å zwischen

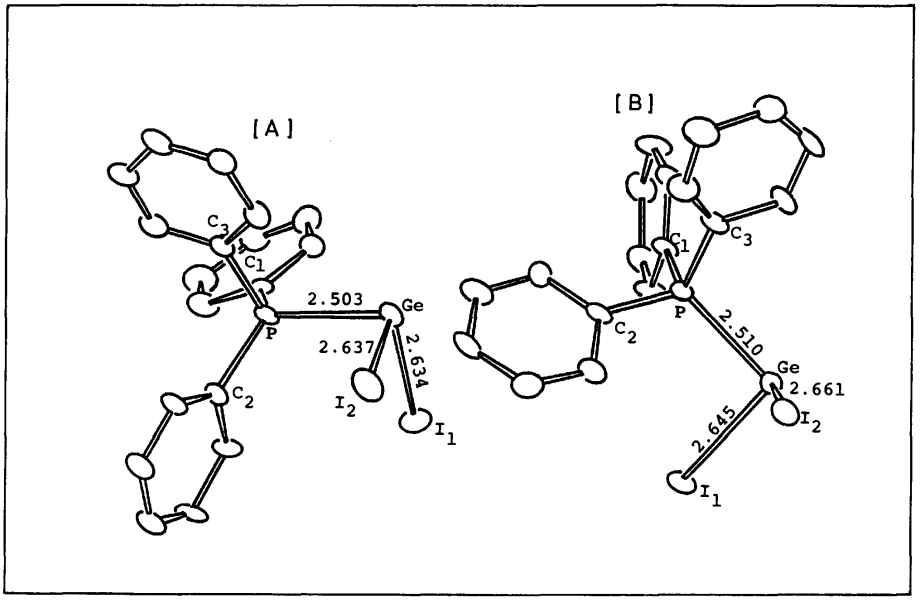


Abb. 1. Kristallstruktur von Ph_3PGeI_2.

dem Germaniumatom und Phosphoratom ist es deutlich, daß die Phosphor-Germanium Bindung keinen Doppelbindungscharakter hat.

Experimenteller Teil

Alle Arbeiten wurden zum Ausschluß von Sauerstoff und Feuchtigkeit unter Stickstoff durchgeführt. Lösungsmittel und Glasgeräte waren entsprechend vorbehandelt. GeI_2 wurde aus GeO_2 und HI nach dem Verfahren in Lef. 6 hergestellt. Ph_3PGeI_2 wurde aus GeI_2 mit Triphenylphosphan nach der Methode von King[7] dargestellt. NMR Spektren wurden mit einem Varian FT-80 und einem Jeol FX-90Q aufgenommen.

Spektroskopische Daten von Ph_3PGeI_2. ^{13}C NMR ($CDCl_3$) δ=126.12 (d, ^1J (PC)=40.9 Hz, C-1), 133.47 (d, ^2J (PC)=8.8 Hz, C-2,6), 129.34 (d, ^3J (PC)=10.3 Hz, C-3,5) und 132.17 (s, C-4); ^{31}P NMR ($CDCl_3$) δ=10.89 (br).

Reaktionen von GeI_2 mit Phenyllithium (Gl. 1). Zu einer Suspension von 0.40 g (1.23 mmol) GeI_2 in 5 cm^3 Ether wurde bei Raumtemperatur 2.8 cm^3 (1.23 mmol) Phenyllithium (0.44 M† Lösung in Ether) langsam zugetropft. Nach einem Rühren im Lauf von 5 Tagen beim Erwärmen unter Rückfluß wurde die Reaktionlösung hydrolysiert. Die Produkte wurden mit GLC untersucht. Zwei- und vierfach Phenyllithium wurden auch mit GeI_2 umgesetzt. Die Ausbeuten der Produkte sind in Tabelle 1 aufgenommen.

Reaktionen von Ph_3PGeI_2 mit Phenyllithium (Gl. 2). Zu einer Suspension von 1.16 g (1.97 mmol) Ph_3PGeI_2 in 5 cm^3 Ether wurde 1.97 mmol Phenyllithium bei RT zugetropft (zwei- und vierfach Phenyllithium wurden auch verwendet). Nach einem fünf tägigen Rühren beim Erwärmen unter Rückfluß wurde die Lösung hydrolysiert und getrocknet. Die erzeugte Verbindungen wurden mit GLC untersucht. Die Daten der Ausbeuten sind in Tabelle 1 dargestellt.

Reaktionen von GeI_2 mit Butadienen (Gl. 3). *3I*: Die Umsetzung von 3.0 g (9.2 mmol) GeI_2 mit 1.0 g (18.5 mmol) 1,3-Butadien bzw. 18.5 mmol 2,3-Diphenyl-1,3-butadien in 5 cm^3 Heptan nach dreitägigem Erwärmen bei 100 °C in einer Druckflasche ergab kein Produkt.[4,8]

3II: Die Umsetzung von 2.0 g (6.13 mmol) mit 0.51 g (6.21 mmol) 2,3-Dimethyl-1,3-butadien in 5 cm^3 Heptan bei 110 °C ergab nach 1 Tag 0.2 g (0.49 mmol) 1,1-Diiodo-3,4-dimethylgermacyclopent-3-en **1**. Ausbeute 8%.

Reaktionen von Ph_3PGeI_2 mit Butadienen (Gl. 4). Die Reaktionen von Ph_3PGeI_2 mit den Butadienen in Heptan unter den in *Gl. 3* bezeichnet Bedingungen ergaben keine Produkte.

Reaktionen von GeI_2 mit Phenyllithium und Butadienen (Gl. 5). *5II*: Zu einer Suspension von 2.0 g (6.13 mmol) GeI_2 und 0.51 g (6.21 mmol) 2,3-Dimethyl-1,3-butadien in 10 cm^3 Ether wurde bei −70 °C 25 cm^3 (12.3 mmol) Phenyllithium (0.49 M Lösung in Ether) zugetropft. Nach 1 Stunde wurde die Reaktionlösung bis Zimmertem-

†1 M=1 mol dm^{-3}

peratur langsam erwärmt, wobei sie sich von gelb zu braun änderte. Die Lösung wurde nach dem Rühren im Lauf von 2 Tagen bei RT hydrolysiert und mit Na_2SO_4 getrocknet. Das Produkt wurde mit GLC isoliert. 3,4-Dimethyl-1,1-diphenylgermacyclopent-3-en **2** ist ein farbloser Kristall mit einem Schmelzpunkt von 46—49 °C (Lit,[4,9] 40—41 °C). Ausbeute 19%. Spektroskopische Daten von **2**: ^1H NMR ($CDCl_3$) δ=1.78 (s, CH_3), 2.00 (s, CH_2) und 7.37 (m, C_6H_5). Ph_4Ge wurde mit einer Ausbeute von 3% ergeben.

5I: Umsetzung von 2.0 g (6.13 mmol) GeI_2 und 1.0 g (18.5 mmol) 1,3-Butadien mit 12.3 mmol Phenyllithium in Ether bei −70 °C ergab Ph_4Ge 5%. Reaktion von 0.65 g (1.99 mmol) GeI_2 und 0.41 g (1.99 mmol) 2,3-Diphenyl-1,3-butadien mit 4 mmol Phenyllithium ergab Ph_4Ge 6%.

Reaktionen von Ph_3PGeI_2 mit Phenyllithium und Butadienen (Gl. 6). *6I*: Die Reaktion von 2.6 g (4.42 mmol) Ph_3PGeI_2 und 1.0 g (18.5 mmol) 1,3-Butadien mit 8.87 mmol Phenyllithium in Ether bei −70 °C polymerisierte nach Erwärmen bis 0 °C.

6II: Zu einer Suspension von 0.85 g (1.45 mmol) Ph_3PGeI_2 und 0.12 g (1.46 mmol) 2,3-Dimethyl-1,3-butadien in 5 cm^3 Ether wurde bei −70 °C 6.5 cm^3 (2.95 mmol) Phenyllithium (0.45 M Lösung in Ether) zugetropft. Nach 1 Stunde wurde die Lösung bis RT erwärmt. Nach Hydrolyse und Vertrocken wurden die Produkte mit GLC untersucht. Es ergab 3,4-Dimethyl-1,1-diphenylgermacyclopent-3-en **2** 14% und Ph_4Ge 5%.

6III: Die Umsetzung von 0.75 g (0.93 mmol) Ph_3PGeI_2 und 0.19 g (0.92 mmol) 2,3-Diphenyl-1,3-butadien mit 18.5 mmol Phenyllithium in Ether bei −70 °C ergab Ph_4Ge 5%.

Röntgenstrukturanalyse von Ph_3PGeI_2. Einkristall mit der Größe von *ca.* 0.2×0.3×0.3 mm wurde aus einer langsamen Kühlung von warmem Xylol dargestellt. Der gelbe Kristall wurde in der abgeschmolzenen Kapillare unter Stickctoff röntgenographisch aufgenommen.

The Syntheses of the Corticoid Side Chain. I. An Improved Method for the Preparation of 17α-Hydroxyprogesterone from Androst-4-ene-3,17-dione

Issei NITTA,* Shinichiro FUJIMORI, and Hiroaki UENO
Biosciences Laboratory, Research Center, Mitsubishi Chemical Industries Limited, 1000 Kamoshida-cho, Midori-ku, Yokohama, Kanagawa 227
(Received August 9, 1984)

The 17β-cyano-17α-hydroxyandrost-4-en-3-one can be prepared from androst-4-ene-3,17-dione in an excellent yield. This derivative can be converted into 17α-hydroxyprogesterone, an intermediate of corticosteroids.

Since the microbial degradation of the side chain of cholesterol or sitosterol had been developed,[1] the transformation of androstan-17-one derivatives into corticoids became very important and recently, several efficient methods for partial synthesis of corticoid side chain from 17-oxo steroids have been published.[2]

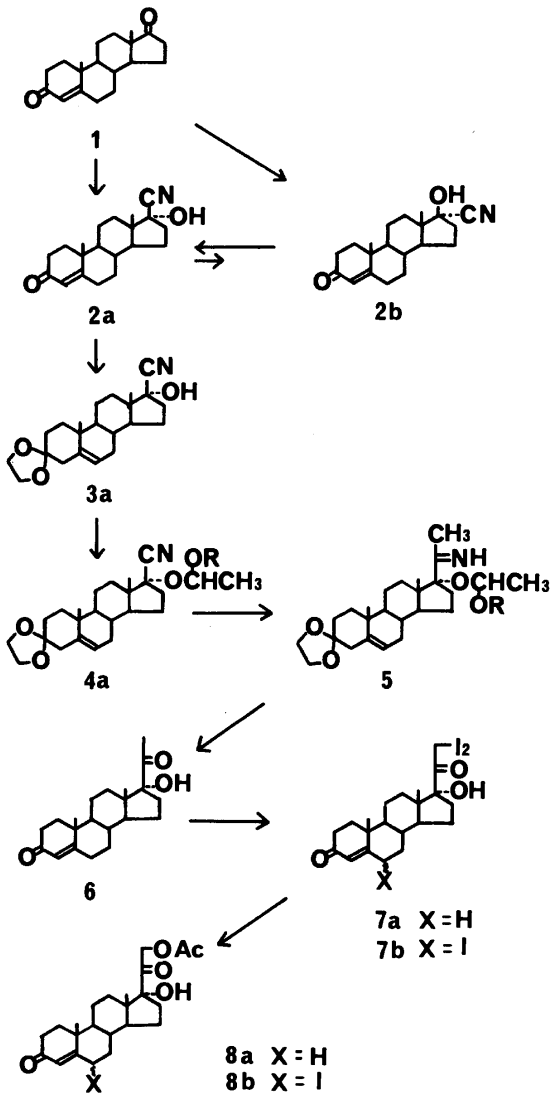
We present here an improved method for converting androst-4-ene-3,17-dione (**1**) into 17α-hydroxyprogesterone (**6**), an intermediate of corticoids, featuring a stereoselective one-step formation of 17β-cyano-17α-hydroxy group at the C-17 position of **1**.[3]

Results and Discussion

The methods employed in this conversion are summerized in Scheme 1.

The first step is the regio- and stereoselective addition of hydrogen cyanide to 17-keto function of **1**. According to the conventional procedure, the dione **1** was treated with alcoholic hydrogen cyanide.[4a] Many products were formed and it was expected that 17α-cyano and 17β-cyano compounds were formed in addition to 3,17-bis(cyanohydrin)s. The use of acetone cyanohydrin (in an exchange reaction in acetone cyanohydrin in the presence of a small amount of amine) afforded 17-monocyanohydrin **2b** quantitatively. In order to determine the configuration of the cyano group of **2b**, 3,3-ethylene acetal 17-silyl ether of **2b** was treated with excess methylmagnesium chloride at 70 °C, followed by deprotection of the 3-acetal. The isolated product was 17α-acetyl-17β-hydroxyandrost-4-en-3-one. This result indicated that the configuration of the cyano group at C-17 was α-configuration, which meant that an undesirable epimer was formed.

On the other hand, when acetic acid (5 equiv of **1**) was added to a suspension of **1** and KCN (10 equiv of **1**) in methanol at 25 °C, the poorly soluble isomer **2a** crystallized out. The HPLC analysis of the crystal showed that **2a**, having a retention time of 9.1 min, was formed as almost the sole product (the retention time of **2b** is 8.4 min). By means of NMR and IR, **2a** was identified as 17β-cyano-17α-hydroxyandrost-4-en-3-one. This process gives the required cyanohydrin **2a** in pure form yielding about 95%. This may be attributed to the fact that the 17α-cyanohydrin **2b** which was formed by the cyanide anion attack on C-17 from the least hindered side was converted to **2a** under equilibrium conditions (in the presence of KCN) and the poorly soluble **2a** crystallized out preferentially. We have also found that this procedure could be applica-



Scheme 1.

ble to the preparation of 17β-cyanohydrins of various androstanes. (see Experimental)

For the following step of the synthesis, it is necessary to protect the carbonyl and hydroxyl functions of **2a**. Treatment of **2a** in ethylene glycol with trimethyl orthoformate in the presence of TsOH led to the expected acetal **3a**. Without further purification, **3a** was treated with butyl vinyl ether in THF containing a small amount of TsOH to give **4a**. Without isolation, **4a** was treated with a 1 M† solution of methyllithium (1.2 equiv of **2a**). Aqueous acetic acid was added and the solution was heated to 110 °C for 1 h. 17α-hydroxyprogesterone, a versatile intermediate for the synthesis of corticoids, was obtained from **2a** with an overall yield of about 70%.

The 21-acetoxy introduction into **6** was accomplished by Stork's iodination procedure.[4b] Iodination of **6** in THF–methanol with excess iodine in the presence of calcium oxide gave the 21,21-diiodosteroid **7a**, which was converted directly to **8a** by treating it with potassium acetate in acetone. The HPLC analysis of the product showed that 17α,21-dihydroxypregn-4-ene-3,20-dione 21-acetate (about 60%) and a by-product (about 35%) were formed. The by-product was isolated by TLC on silica gel developed with ethyl acetate–benzene (1:2). From NMR spectra, it was assumed to be 17α,21-dihydroxy-6-iodopregn-4-ene-3,20-dione 21-acetate (**8b**), and **8a** was recovered from **8b** by treating it with zinc powder in acetic acid in a satisfactory yield.

Transformation of **8a** into hydrocortisone, a typical corticoid, was followed by microbilological process.

Experimental

Melting points were determined with a Mettler FP 61. Preparative TLC was accomplished with silica gel 60 F-254 plates (2 mm thick, E. Merck). HPLC was performed with a Shimadzu LC-2 liquid chromatograph instrument equipped with a Shimadzu Zorbax-ODS column (4.6 mm×25 cm) and a UV detector, and operated at flow rate of 2 ml min^{-1} by using a solvent consisting of MeOH–H_2O (8:2). Optical rotations were determined with a Jasco model DIP-digital polarimeter. NMR spectra were determined with a JEOL JNM-PS-100 spectrometer, with TMS as the internal standard. GLC analyses were performed on a Shimadzu GC-6A gas chromatograph equipped with a flame-ionization detector, using a column packed with 1% Silicone DC-QF-1 on Gaschrom Q (3 mm×0.5 m; column temp, 220 °C; carrier gas, N_2 60 ml/min; injector temp., 250 °C).

Materials. Androst-4-ene-3,17-dione (**1**) was obtained from Sigma. Androsta-4,9(11)-diene-3,17-dione was prepared according to the procedure in the literature[2f] from 9α-hydroxyandrost-4-ene-3,17-dione.

17β-Cyano-17α-hydroxyandrost-4-en-3-one (2a). Acetic acid (17.6 ml, 0.293 mol) was added over a period of 20 min at 25 °C to a stirred mixture of androst-4-ene-3,17-dione (**1**) (52.3 g, 0.182 mol) and potassium cyanide (50.0 g, 0.769 mol) in methanol (400 ml). The mixture was stirred at 25 °C. The starting material was completely dissolved within 1 h and product began to crystallize after reaction for 2 h. The mixture was kept overnight at room temp and then acetic acid (30 ml) was added. After dilution with water, the precipitated product was collected by filtration, washed with water and dried to give crude **2a** (57.5 g). The HPLC analysis indicated that the purity of **2a** (t_r: 9.1 min) was 95%, and 2% of **2b** and 2.5% of **1** were contained. Recrystallization from ethanol afforded the analytically pure sample: mp 169—172 °C dec.; $[\alpha]_D^{28}$ +120.3° (*c* 0.66, dioxane); IR (KBr) 3250 (OH), 2220 (C≡N) and 1640 cm^{-1} (C=O); NMR ($CDCl_3$) δ=0.98 (3H, s, 13-CH_3).

Found: C, 76.59; H, 8.72; N, 4.48%. Calcd for $C_{20}H_{27}O_2N$: C, 76.64; H, 8.68, N, 4.46%.

In a similar procedure, 17β-cyano-17α-hydroxyandrosta-4,9(11)-dien-3-one (**9a**), 3,3-ethylenedioxy-17β-cyanoandrosta-5,9(11)-dien-17α-ol (**10a**) were prepared.

(**9a**): Mp 199—201 °C dec.; $[\alpha]_D^{28}$ +95.6° (*c* 0.83, dioxane); NMR ($CDCl_3$) δ=0.95 (3H, s, 13-CH_3). Found: C, 77.17; H, 8.01; N, 4.45%. Calcd for $C_{20}H_{25}O_2N$: C, 77.13; H. 8.09: N, 4.50%.

(**10a**): Mp 202—205 °C; $[\alpha]_D^{28}$ +17.8° (*c* 0.53, dioxane); NMR ($CDCl_3$) δ=0.91 (3H, s, 13-CH_3). Found: C, 74.52; H, 8.28; N, 3.72%. Calcd for $C_{22}H_{29}O_3N$: C, 74.33; H, 8.23; N, 3.94%.

17α-Cyano-17β-hydroxyandrost-4-en-3-one (2b). Androst-4-ene-3,17-dione (**1**) (20.0 g) was dissolved by gentle warming in 30 ml of acetone cyanohydrin. Stirring was continued for 8 h at room temp, but the crystallization did not begin. Two drops of DBU was added. After five minutes crystallization began and was completed within 1 h at room temp. The resulting precipitated product was collected by filtration, washed with ether and dried to give 17-cyanohydrin **2** (23.0 g). The HPLC analysis showed that 17α-cyano-17β-hydroxyandrost-4-en-3-one (**2b**) (t_R: 8.4 min) formed as an almost sole product and no 17β-cyano-17α-hydroxyandrost-4-en-3-one (**2a**) (t_R: 9.1 min) was detected. Recrystallization from ethanol afforded the analytically pure sample, mp 153—155 °C (pre-melting point), 171—172 °C dec.; $[\alpha]_D^{28}$ +45.5° (*c* 0.72, dioxane); IR (KBr) 3250 (OH), 2230 (C≡N), and 1640 cm^{-1} (C=O); NMR ($CDCl_3$) δ=0.91 (3H, s, 13-CH_3).

Found: C, 76.87; H, 8.52; N, 4.43%. Calcd for $C_{20}H_{27}O_2N$: C, 76.64; H, 8.68: N, 4.46%.

According to the previous procedure,[5] 3,3-ethylenedioxy-17α-cyanoandrost-5-en-17β-ol (**3b**), 17α-cyano-17β-hydroxyandrosta-4,9(11)-dien-3-one (**9b**), 3,3-ethylenedioxy-17α-cyanoandrosta-5,9(11)-dien-17β-ol (**10b**) were also prepared.

(**3b**): Mp 194—195 °C dec.; $[\alpha]_D^{28}$ −71.4° (*c* 0.95, dioxane); NMR ($CDCl_3$) δ=0.83 (3H, s, 13-CH_3). Found: C, 73.72; H, 8.63; N, 3.82%. Calcd for $C_{22}H_{31}O_3N$: C, 73.91; H, 8.74; N, 3.92%.

(**9b**): Mp 201—204 °C dec.; $[\alpha]_D^{28}$ +20.8° (*c* 0.76, dioxane); NMR ($CDCl_3$) δ=0.88 (3H, s, 13-CH_3). Found: C, 77.07; H, 7.99; N, 4.31%. Calcd for $C_{20}H_{25}O_2N$: C, 77.13; H, 8.09; N, 4.50%.

(**10b**): Mp 185—186 °C; $[\alpha]_D^{28}$ −44.7° (*c* 0.49, dioxane); NMR ($CDCl_3$) δ=0.85 (3H, s, 13-CH_3). Found: C, 74.50; H,

† 1 M=1 mol dm^{-3}.

8.14; N, 3.95%. Calcd for $C_{22}H_{29}O_3N$: C, 74.33; H, 8.23; N, 3.94%.

*3,3-Ethylenedioxy-17β-cyanoandrost-5-en-17α-ol (**3a**).* *p*-Toluenesulfonic acid (1.5 g) was added to a suspension of **2a** (57.5 g) in trimethyl orthoformate (50 ml) and ethylene glycol (350 ml) and the mixture was stirred at 40 °C for 6 h. The solution was poured into water containing pyridine (1.5 ml). The resulting precipitated product was collected by filtration, washed with water and dried to give 3,3-ethylenedioxy-17β-cyanoandrost-5-en-17α-ol (**3a**) containing about 10% of 3,3-ethylenedioxy-17β-cyanoandrost-4-en-17α-ol (60.3 g). Without further purification, crude **3a** was used in the next step. Recrystallization from methanol afforded the analytically pure sample; mp 227—229 °C dec.; $[\alpha]_D^{28}$ −15.3 °C (*c* 1.00, dioxane); IR (KBr) 3450 (OH) and 2240 cm^{-1} (C≡N); NMR ($CDCl_3$) δ=0.94 (s, 3H, 13-CH_3).

Found: C, 73.90; H, 8.51; N, 3.88%. Calcd. for $C_{22}H_{31}O_3N$: C, 73.91; H, 8.74; N, 3.92%.

*17α-Hydroxyprogesterone (**6**).* To the crude **3a** (2.00 g), butyl vinyl ether (1.27 ml) and *p*-toluenesulfonic acid soln. (0.2% in THF, 3.0 ml) were added. After stirring for 20 min at room temp, methyllithium (1 M solution in ether, 10 ml) was added and stirred for 2 h at room temp. Acetic acid (8.0 ml) and water (4.0 ml) were added and heated at 110 °C for 1 h. After dilution with water containing sodium carbonate, the precipitated product was collected by filtration, washed with water and dried to give 17α-hydroxyprogesterone (**6**) (1.77 g, purity 72% which was determined by HPLC analysis, yield 69%). Recrystallization from ethyl acetate afforded the analytically pure sample. The NMR and IR spectrum were identical to that of an authentic specimen of 17α-hydroxyprogesterone and the melting point was undepressed on admixture with authentic specimen.

The Syntheses of the Corticoid Side Chain. III. A New Synthesis of 17α,21-Dihydroxypregna-1,4-diene-3,20-dione 17,21-Diacetate from Androsta-1,4-diene-3,17-dione

Issei NITTA,* Shinichiro FUJIMORI, Toshio HARUYAMA, Shinya INOUE, and Hiroaki UENO

Biosciences Laboratory, Research Center, Mitsubishi Chemical Industries Limited, 1000 Kamoshida-cho, Midori-ku, Yokohama, Kanagawa 227

(Received August 9, 1984)

An efficient synthesis of 17α,21-dihydroxypregna-1,4-diene-3,20-dione 17,21-diacetate (**10**) from androsta-1,4-diene-3,17-dione (**1**), a biodegradation product of cholesterol, is described, which involves the ethynylation of the 17-ketone, the epimerization of the 17α-ethynyl group and conversion of the ethynyl group to the 20-keto pregnane. Overall yield is relatively high (about 54%) and **10** will be a potential intermediate for prednisolone.

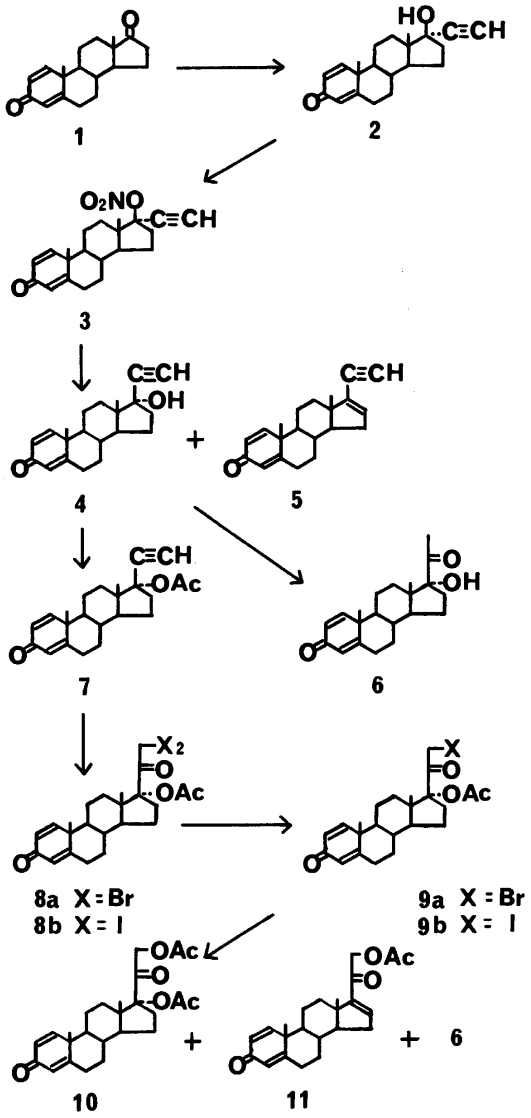
Corticosteroids are produced commercially from deoxycholic acid *via* a chemical process comprising many steps or from diosgenin and stigmasterol *via* a process involving a microbiological oxidation step at C-11.[1] Recent advances in the microbial degradation of cholesterol and abundant soya sterols allowed the production of androst-4-ene-3,17-dione and androsta-1,4-diene-3,17-dione,[2] from which various steroidal drugs such as estrone, testosterone, spironolactone, *etc.* have been produced. These 17-oxo steroids may be potentially useful starting materials for the synthesis of progestins and corticoids. Especially, androsta-1,4-diene-3,17-dione may be a useful starting material for prednisolone because the A ring is fully functionalized as 1,4-dien-3-one system and the 17-ketone provides a handle to elaborate the corticoid side chain.

Recently, efficient methods for partial synthesis of dihydroxyacetone side chain from 17-oxo steroids were published,[3] but most of them need protection of the 3-oxo group on ring A. Then they can not be simply applied for androsta-1,4-diene-3,17-dione because the protection of 3-carbonyl group of 1,4-diene-3,17-dione system is difficult. We present here an improved conversion of androsta-1,4-diene-3,17-dione into 17α, 21-dihydroxypregna-1,4-diene-3,20-dione 17,21-diacetate, an intermediate of artificial corticoids, especially prednisolone.

The methods employed in this conversion are summarized in Scheme 1.

The first step in the present conversion is the selective addition of a two-carbon fragment to the 17-keto function in androsta-1,4-diene-3,17-dione (**1**), *via* reaction with acetylene. Thus, by treating **1** with potassium acetylide in THF, 17α-ethynyl-17β-hydroxyandrosta-1,4-dien-3-one (**2**) was obtained in a quantitative yield, but this ethynyl compound **2** had the opposite configuration at C-17 to that required for the corticosteroids. Recently, a novel epimerization for converting 17α-ethynyl group into 17β-ethynyl group was reported,[4] which can be accomplished by the Ag^+-catalyzed hydrolysis of 17β-mesylate of 17α-ethynyl steroids.

However, the 17β-mesylate of **2** is extremely unstable and can be synthesized only in a very poor yield by limited procedure. Therefore, we examined various 17β-esters of **2** and selected 17α-ethynyl-17β-(nitro-



Scheme 1.

oxy)androsta-1,4-dien-3-one as the preferable one. Treatment of **2** with fuming nitric acid in acetic anhydride at −20 °C afforded 17α-ethynyl-17β-(nitrooxy) androsta-1,4-dien-3-one (**3**) in a high yield. The advantages of **3** were that the preparation was easy and the yield was very high.

Subsequently, **3** was stirred with $AgNO_3$ (0.2 mol equiv based on **3**) in a mixture of THF and distilled water for 72 h at 20 °C. The resulting reaction mixture was then poured into an aqueous NH_4Cl solution containing NaCN. The desired epimer **4** was obtained in an excellent yield (88.9%), together with a small amount of the enyne **5** (6.5%). Compound **4** could be easily purified from **5** by recrystallization from heptane–dichloromethane. The assignment of the configuration of **4** was conducted as follows. The desired epimer **4** was treated with mercury(II) chloride in benzene–water in the presence of aniline at 60 °C for 13 h to give 17α-hydroxypregna-1,4-diene-3,20-dione which was identified with the authentic sample prepared from 17α-hydroxypregn-4-ene-3,20-dione by treatment with 2,3-dichloro-5,6-dicyano-*p*-benzoquinone. NMR signals of the 13-CH_3 proton in **4** showed an upfield shift and that of the ethynylic proton showed a downfield shift when compared with **2**. Similar shifts of the signals have already been observed for the epimeric 17-ethynyl-17-hydroxy steroids.[5] Under the conditions in the absence of silver nitrate, the nitrate **3** was recovered quantitatively. Besides silver nitrate, copper(I) chloride also catalyzed the hydrolysis of **3** to give **4** in about 63% yield and **5** in about 30% yield. Then, many additives were examined in order to increase the yield of **4** and it became apparent that the addition of thiourea improved it to about 74%. (Table 1.)

In order to elucidate the mechanism of these silver ion and copper(I) ion-catalyzed solvolyses, we examined the solvolysis of the epimeric nitrate, 17β-ethynyl-17α-(nitrooxy)androsta-1,4-dien-3-one in the presence of copper(I) chloride. Main product was 17β-ethynyl compound **4** and 17α-ethynyl compound **2** was less than 2%. (Table 2.) That is to say, the substitution reaction of epimer of **3** proceeded with retention of configuration compared with the reaction of **3** proceeded with inversion of configuration. Hofmeister *et al.* reported the formation of 17β-ethynyl-17α-formyloxyandrost-4-en-3-one (yield 15%) in Ag-catalyzed solvolysis of 17α-ethynyl-17β-(nitrooxy)androst-4-en-3-one in the mixture of formic acid and hexamethylphosphoramide and proposed the mechanism which involve the S_N2 type attack of nucleophile to the intermediate (I), in which the silver ion that makes a bridged ion structure between metal ion and acetylenic bond electrons, can interact with the oxygen atom of nitrooxy group and weaken the bond between C-17 and the leaving nitrooxy group. However, this mechanism can not be applied to our reaction because the reaction of epimer of **3** dose not proceed with inversion.

Hence, we are forced to suggest the formation of a carbonium ion stabilized by the silver or copper(I) ion (II) (S_N1 mechanism). That is , if we assume that the hydroxide ion or water attacks the carbonium ion (II) derived from both epimeric nitrates and that

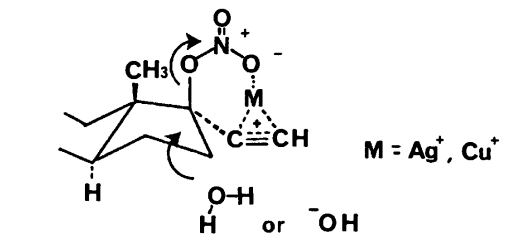
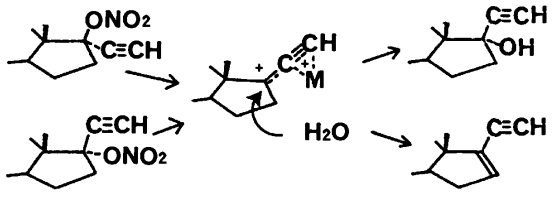
b) 17β-Ethynyl-17α-(nitrooxy)androsta-1,4-dien-3-one.



I



II

the attack occurs only from the least hindered side, opposite to the C-18 methyl group, formation of 17β-ethynyl compound **4** as the main product could be interpreted. As examples of metal-stabilized carbonium ions, cationic propargyl complexes $(RC{\equiv}CCR_2)$-$Co_2(CO)_6^+$ were reported.[6] But further study is required to elucidate a precise mechanism for these silver or copper(I) ion-catalyzed solvolysis.

The conversion of **4** into dihydroxyacetone side chain was accomplished as follows. Reaction of **4** with acetic anhydride in the presence of triethylamine and a catalytic amount of 4-(dimethylamino)pyridine in toluene gave the 17-acetate **7** in 96.7% yield. Treatment of 17-acetate **7** with *N*-bromoacetamide in buffered aqueous acetic acid furnished the dibromo ketone **8a**. This was converted to monobromo ketone **9a** in high yield (about 90% from **7**) on treatment with trimethyl phosphite in nitromethane at room temperature according to the "Perkow reaction."[7] According to conventional procedures for the acetoxylation of 21-bromo-17-hydroxy- or 21,21-dibromo-17-hydroxypregnane derivatives, the dibromide **8a** and monobromide **9a** were treated with potassium acetate in the presence or the absence of sodium iodide[8] in refluxing acetone, or with triethylammonium acetate in acetone.[9] But only unreacted **8a** or **9b** was recovered. Then, some dipolar aprotic solvents such as *N*,*N*-dimethylformamide, *N*,*N*-dimethylacetamide, dimethyl sulfoxide or acetonitrile were examined and it was found that on treatment with potassium acetate in *N*,*N*-dimethylformamide at around 60 °C the corresponding 21-acetate **10** was given from **9a** in moderate yield (50—70%). The major by-product was unsaturated product **11** and its amount increased when heating time or temperature was increased.

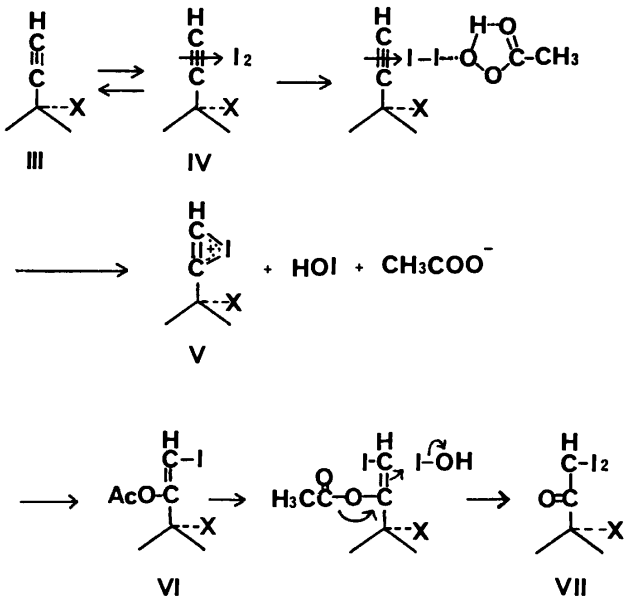
Next, the preparation of monoiodide **9b** was examined. Ogata and Urasaki reported the iodoacetoxylation of acetylenic compounds with a mixture of iodine and peracetic acid at 50 °C and suggested a mechanism involving slow formation of acetyl hypoiodite followed by its rapid addition to the triple bond to give α-iodo enol acetate[10] which may be converted to α-iodo ketone by hydrolysis.

$$I_2 + CH_3CO_3H + CH_3CO_2H \xrightarrow[\text{slow}]{\text{rate-determining step}} 2CH_3COOI + H_2O$$

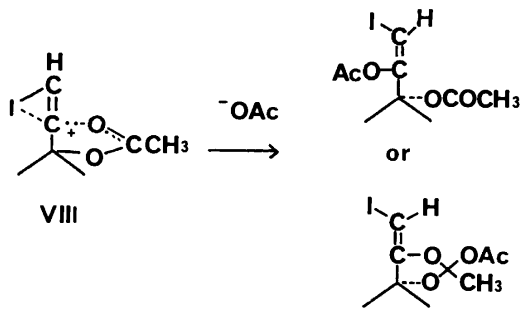
$$R\text{-}C{\equiv}C\text{-}R' + CH_3COOI \xrightarrow[\text{fast}]{} \begin{matrix} I \\ R \end{matrix}\!\!>\!C{=}C\!<\!\!\begin{matrix} R' \\ OCOCH_3 \end{matrix}$$

17-Acetate **7** was treated with a mixture of iodine and peracetic acid in 10% aqueous acetic acid at room temperature (mole ratio; **7**:I_2:CH_3CO_3H=1:1:1). This reaction was completed in 2 h at room temperature. In contrast, the rate of formation of acetyl hypoiodite was very slow, the second-order rate constant for the consumption of iodine k_2 being *ca.* $2{\times}10^{-5}\,M^{-1}\,s^{-1}$ at 25 °C, and the consumption of iodine was less than 2% in the reaction of iodine and peracetic acid alone in the absence of 17-acetate **7** in 2 h at room temperature. The product was not enol acetate but diiodo ketone **8b** which was afforded in quantitative yield. When the molar ratio of iodine and peracetic acid to **7** was reduced to one-half, **8b** and unreacted **7** yielded at about 50% each, instead of the enol acetate. Here we could say that the reaction of **7** with a mixture of iodine and peracetic acid did not involve the formation of acetyl hypoiodite, because the rate of the whole reaction was faster than that of the rate-determining acetyl hypoiodite formation.

These observations lead to a hypothetical mechanism involving a rapid complex formation between the triple bond and iodine followed by a rate-determining attack of peracetic acid on the π-complex (IV), which was discussed as an alternative mechanism of iodoacetoxylation by Ogata and Urasaki.[10] The initially formed π-complex (IV) can be converted to cyclic iodonium ion (V) by peracetic acid. Carbonium ion (V) reacts with acetate ion to form enol acetate (VI) and is successively attacked by hypoiodous acid to give diiodo ketone (VII).



When the acetoxyl group at C-17 position in **7** was replaced with a hydroxyl group, the reaction was significantly slow and many products were formed. (When X=OAc, conversion after 1 h at room temperature 100%. When X=OH, conversion after 2 h was 20%.) These observations also indicate that the present reaction involves a carbonium ion as an intermediate. That is, the neighboring acetoxyl group can delocalize the positive charge of the carbonium ion center, stabilize the carbonium ion and accelerate the reaction involving the carbonium ion. The proposed carbonium ion is (VIII).



Diiodo ketone **8b** could be converted to monoiodo ketone **9b** on treatment with sodium acetate or triethylammonium acetate in refluxing acetone in 94.4% yield from **7**. Moreover, **8b** was treated with pyridine *p*-toluenesulfonate in refluxing acetone to give 17α-hydroxypregna-1,4-diene-3,20-dione 17-acetate (**6**) in about 90% yield.

Monoiodo ketone **9b** resisted acetoxylation to give a diacetate **10** and gave large amounts of **11** and **6** by conventional methods. The use of tetramethylammonium acetate afforded **10** in 79% yield under optimum conditions (in *N*-methylpyrrolidone at 21 °C for 7 h). Crude **10** of 80% purity was obtained in 60% overall yield from **1** and was subsequently recrystallized from acetone-water to give practically pure **10** (94% purity) in 91% yield. (54% yield from **1**).

Transformation of **10** into a typical corticoid, prednisolone, was followed by microbiological C-11 hydroxylation process. In such a process, **10** was a more suitable substrate than 17α,21-dihydroxypregna-1,4-diene-3,20-dione or 17α,21-dihydroxypregna-1,4-diene-3,20-dione 21-acetate, because introduction of the acetoxyl group into C-17 prevented the hydroxylation at C-14 and could bring a higher yield of prednisolone.

From the above, we concluded that the overall yield was relatively high and this sequence could be applied to other 17-keto steroids to provide useful pregnane steroids such as 17α,21-dihydroxypregn-4-en-3-one 17,21-diacetate, possible intermediate of hydrocortisone, or 17α-hydroxyprogesterone acetate.

Experimental

Melting points were determined with a Mettler FP61. Preparative TLC was accomplished with silica gel 60 F-254 plates (2 mm thick, E. Merck). HPLC was performed with a Shimadzu LC-2 liquid chromatograph instrument equipped with a Shimadzu Zorbax-ODS column (4.6 mm×25 cm) and a UV detector, and operated at a flow rate of 2 ml/min by using a solvent consisting of MeOH–H_2O (8:2).

Optical rotations were determined with a Jasco model DTP-4 digital polarimeter. NMR spectra were determined with a JEOL JMN-PS-100 spectrometer, with TMS as the internal standard. GLC analyses were performed on a Shimadzu GC-6A gas chromatograph equipped with a flame-ionization detector, using column packed with 1% Silicone DC-QF-1 on Gaschrom Q (3 mm×0.5 m; column temp 220 °C; carrier gas, N_2 60 ml/min; injector temp 250 °C).

17α-Ethynyl-17β-hydroxyandrosta-1,4-dien-3-one (2). In a three-necked flask, 95% potassium hydroxide (200 g), tetrahydrofuran (1000 ml) and ethanol (120 ml) were stirred at 50 °C for 1 h under a nitrogen atmosphere and then cooled to 3 °C. Into the mixture prepared as above, pure dry acetylene was passed at 3 °C for 2 h. A solution of androsta-1,4-diene-3,17-dione (**1**) (100 g) in 200 ml of dry tetrahydrofuran was added and stirred for 2 h. The mixture was acidified with 10% aqueous HCl solution, stirred under reflux for half an hour and diluted with water. The resulting precipitated product was collected by filtration, washed with water and dried to give 17α-ethynyl-17β-hydroxyandrosta-1,4-dien-3-one (**2**) (110.3 g, purity 92.9%, yield 96.6%), which was satisfactorily pure for the subsequent reaction. Recrystallization from acetone-hexane afforded the analytically pure sample, mp 218.9—219.1 °C; IR (KBr) cm^{-1}: 3330, 3250, 1660, 1615, 1605; NMR ($CDCl_3$) δ=0.92 (s, 3H), 1.23 (s, 3H), 2.54 (s, 1H), 6.05 (d, 1H), 6.20 (q, 1H), 7.03 (d, 1H).

Found: C, 81.48; H, 8.43%. Calcd for $C_{21}H_{26}O_2$: C, 81.25; H, 8.44%.

17α-Ethynyl-17β-(nitrooxy)androsta-1,4-dien-3-one (3). To 17α-ethynyl-17β-hydroxyandrosta-1,4-dien-3-one (**2**) (8.00 g) was added acetic anhydride (64 ml) and the mixture was cooled to −20 °C. Thereafter, fuming nitric acid (6.4 ml) was added dropwise and stirred for 1 h at −20 °C. The reaction mixture was poured into 500 g of ice water and stirred. The resulting precipitated product was filtered off and then dissolved in ethyl acetate. The ethyl acetate solution was washed with water, dried and concentrated to give 17α-ethynyl-17β-(nitrooxy)androsta-1,4-dien-3-one (8.9 g, purity 98.1%, yield 96.1%). The product could be used as the starting material in the subsequent hydrolysis step without further purification. Recrystallization from benzene afforded the analytically pure sample, mp 137—139 °C; NMR ($CDCl_3$) δ=1.02 (s, 3H), 1.26 (s, 3H), 2.72 (s, 1H), 6.03 (s, 1H), 6.18 (q, 1H), 7.00 (d, 1H); IR (KBr) 1660, 1625, 1295 cm^{-1}; MS *m/z* 355 (M^+).

Found: C, 71.23; H, 7.06; N, 4.03%. Calcd for $C_{21}H_{25}O_4N$: C, 70.96; H, 7.09; 3.94%.

17β-Ethynyl-17α-hydroxyandrosta-1,4-dien-3-one (4).
(A) Silver Nitrate-catalyzed Hydrolysis. 17α-Ethynyl-17β-(nitrooxy)androsta-1,4-dien-3-one (**3**) (2.50 g) was dissolved in tetrahydrofuran (17 ml). Subsequently distilled water (3.0 ml) and silver nitrate (9.55 g) were added and the mixture was stirred for 24 h at 25 °C. The reaction mixture was poured into saturated ammonium chloride solution (70 ml) containing sodium cyanide (0.7 g). After stirring for 15 min, the reaction mixture was extracted with dichloromethane and the separated organic layer was washed with water and dried to give 2.40 g of white crystals. The crude crystals thus obtained were recrystallized from a mixture of tetrahydrofuran (20 ml) and hexane (140 ml) to give 17β-ethynyl-17α-hydroxyandrosta-1,4-dien-3-one (**4**) (1.10 g). Recrystallization from ethyl acetate twice afforded the analytically pure sample, mp 218—219 °C; $[\alpha]_D^{24}$ +90.9° (c: 1.02, tetrahydrofuran); IR (KBr) 1660, 1620 cm^{-1}; NMR ($CDCl_3$) δ=0.96 (s, 3H), 1.26 (s, 3H), 2.52 (s, 1H), 6.09 (s, 1H), 6.25 (q, 1H), 7.08 (d, 1H); MS *m/z* 310 (M^+).

Found: C, 81.79; H, 8.33%. Calcd for $C_{21}H_{26}O_2$: C, 81.25; H, 8.44%.

To 17α-ethynyl-17β-hydroxyandrosta-1,4-dien-3-one (**2**)

(100.2 g, purity 94.1%) was added acetic anhydride (250 ml) and cooled to −20 °C. Fuming nitric acid (55 ml) was added and stirred for 1 h at −20 °C. The reaction mixture was poured into ice water and the resulting precipitated product was filtered off. The wet product (153.5 g) was dissolved in tetrahydrofuran (3000 ml). Distilled water (2960 ml) and silver nitrate (11.6 g) were added and stirred for 72 h at room temperature. After tetrahydrofuran was distilled off, 150 ml of 60% nitric acid was added, and the mixture was extracted with dichloromethane, washed with water and concentrated to give crude 17β-ethynyl-17α-hydroxyandrosta-1,4-dien-3-one (100.7 g, purity 81.2%, yield 86.7% from **2**). The crude crystals were recrystallized from a mixture of dichloromethane and heptane to give 17β-ethynyl-17α-hydroxyandrosta-1,4-dien-3-one (84.2 g, purity 92.0%, yield 95.0%).

(B) Copper(I) Chloride-catalyzed Hydrolysis. To a mixture prepared by adding tetrahydrofuran (6.2 ml) and water (15.8 ml) to 17α-ethynyl-17β-(nitrooxy)androsta-1,4-dien-3-one (**3**) (2.50 g) was added copper(I) chloride (0.2 g), and the resulting mixture was stirred for 4 h at 65 °C in a nitrogen atmosphere. Benzene and saturated saline were added to the reaction mixture to extract the product into benzene. The separated benzene layer was further washed three times with saturated saline, dried over anhydrous sodium sulfate and concentrated to get crystals. HPLC analysis of the crystals showed that 17β-ethynyl-17α-hydroxyandrosta-1,4-dien-3-one (**4**) and 17-ethynylandrosta-1,4,16-trien-3-one (**5**) were formed in yields of 63 mole% and 32 mole%, respectively.

17α-Hydroxypregna-1,4-diene-3,20-dione (6). To 17β-ethynyl-17α-hydroxyandrosta-1,4-dien-3-one (**4**) (0.680 g) were added benzene (40 ml), distilled water (8 ml), murcury(II) chloride (1.12 g), and aniline (0.2 ml). The mixture was stirred at 60 °C for 13 h. The insoluble matters were filtered off and they were thoroughly washed with chloroform. The chloroform washings were combined with the filtrate (reaction mixture) and the aqueous layer was separated. The organic layer was washed successively with 5% hydrochloric acid and saturated sodium hydrogencarbonate solution and then dried over sodium sulfate. The solvent was then distilled off to give 17α-hydroxypregna-1,4-diene-3,20-dione (**6**) (0.616 g). Recrystallization from a mixture of tetrahydrofuran (40 ml) and octane (10 ml) gave analytically pure 17α-hydroxypregna-1,4-diene-3,20-dione (**6**) (0.499 g). High speed liquid chromatogram, thin layer chromatogram and infrared absorption, NMR and mass spectra of the product were all in agreement with those of an authentic sample, mp 258.0—258.7 °C; NMR ($CDCl_3$) δ=0.8 (s, 3H), 1.26 (s, 3H), 2.28 (s, 3H), 2.96 (s, 1H), 6.08 (s, 1H), 6.22 (d, 1H, J=10 Hz), 7.06 (d, 1H, J=10 Hz).

Found: C, 76.95; H, 8.48%. Calcd for $C_{21}H_{28}O_3$: C, 76.79; H, 8.59%.

17β-Ethynyl-17α-hydroxyandrosta-1,4-dien-3-one 17-Acetate (7). To 17β-ethynyl-17α-hydroxyandrosta-1,4-dien-3-one (**4**) (2.00 g) were added acetic anhydride (2.0 ml), triethylamine (2.0 ml), 4-(dimethylamino)pyridine (0.114 g) and toluene (5.0 ml) and the mixture was heated at 80—90 °C for 11 h. Upon cooling, the reaction product was extracted into dichloromethane. The organic layer was washed successively with 5% hydrochloric acid and 5% sodium hydrogencarbonate solution and the separated organic layer was dried over anhydrous sodium sulfate and concentrated. The liquid chromatograph analysis of the extract showed that 17β-ethynyl-17α-hydroxyandrosta-1,4-dien-3-one 17-acetate was formed in 96.7% yield. The concentrate was passed through a column filled with 250 g of alumina and eluted with 500 ml of a mixture of benzene and ethyl acetate (9:1) to give 2.3 g of crystals. Recrystallization of the crystals from octane-tetrahydrofuran (20:1), heptane–ethanol (5:1) and octane–tetrahydrofuran (30:7) gave 17β-ethynyl-17α-hydroxyandrosta-1,4-dien-3-one 17-acetate (**7**), mp 171.8—172.6 °C; NMR ($CDCl_3$) δ=1.00 (s, 3H), 1.26 (s, 3H), 2.02 (s, 3H), 2.56 (s, 1H), 6.04 (d, 1H), 6.15 (q, 1H), 6.98 (d, 1H).

Found: C, 79.02; H, 8.01%. Calcd for $C_{23}H_{28}O_3$: C, 78.38; H, 8.01%.

21-Bromo-17α-hydroxypregna-1,4-diene-3,20-dione 17-Acetate (9a). A mixture of 17β-ethynyl-17α-hydroxyandrosta-1,4-dien-3-one 17-acetate (**7**) (0.786 g), *N*-bromoacetamide (0.644 g), anhydrous sodium acetate (0.735 g), water (1.3 ml) and acetic acid (13 ml) was left at 0 °C for 1 h, then poured into ice–water and the resulting precipitate was collected by filtration, washed with water and dried to give crude 21,21-dibromo-17α-hydroxypregna-1,4-diene-3,20-dione 17-acetate (**8a**) (1.158 g). To this crude dibromide **8a** (0.134 g) in nitromethane (2.5 ml), trimethyl phosphite (0.2 ml) was added and stirred at room temp for 50 min. The reaction mixture was diluted with ether and washed with water. The separated organic layer was dried over anhydrous sodium sulfate and concentrated to give crude 21-bromo-17α-hydroxypregna-1,4-diene-3,20-dione (**9a**) (0.112 g). Recrystallization from octane–tetrahydrofuran gave an analytically pure sample (0.083 g). MS m/z 448, 450 (M^+).

Found: C, 61.59; H, 6.61; Br, 17.77%. Calcd for $C_{23}H_{29}O_4Br$; C, 61.47; H, 6.50; Br, 17.78%.

17α-Hydroxy-21-iodopregna-1,4-diene-3,20-dione 17-Acetate (9b). To a mixture prepared by adding iodine (0.408 g), acetic acid (4.5 ml), and water (0.5 ml) to 17β-ethynyl-17α-hydroxyandrosta-1,4-dien-3-one 17-acetate (**7**) (0.571 g), a mixture of 40% peracetic acid (0.26 ml), acetic acid (16 ml) and water (2 ml) was added dropwise and stirred at room temp for 2 h. The reaction mixture was poured into water (150 ml) and the resulting precipitate was collected with filtration, washed with water and dissolved in dichloromethane. The solution was washed successively with 7% aqueous KI solution, 10% aqueous sodium thiosulfate solution and water, dried over anhydrous sodium sulfate and concentrated to give crude 21,21-diiodo-17α-hydroxypregna-1,4-diene-3,20-dione 17-acetate (**8b**) (0.961 g), NMR ($CDCl_3$) δ=0.89 (s, 3H), 1.24 (s, 3H), 2.09 (s, 3H), 5.52 (s, 1H), 6.11 (d, 1H), 6.26 (q, 1H), 7.10 (d, 1H); MS m/z 496 (M^+).

To this crude iodide **8b** (0.200 g), triethylamine (0.83 ml), acetic acid (0.53 ml), and acetone (5 ml) were added and stirred under reflux for 1 h. The reaction mixture was poured into water (100 ml) and the resulting precipitate was collected by filtration and dried to give 17α-hydroxy-21-iodopregna-1,4-diene-3,20-dione 17-acetate (**9b**) (0.142 g). Without further purification, crude iodide was used for the next step. Recrystallization from acetone–heptane affored the analytically pure sample, mp 156.9—157.2 °C, NMR ($CDCl_3$) δ=0.78 (s, 3H), 1.26 (s, 3H), 2.12 (s, 3H), 3.92 (d, 2H), 6.10 (d, 1H), 6.26 (q, 1H), 7.09 (d, 1H); MS m/z 496 (M^+).

Found: C, 55.74; H, 5.92; I, 25.45%. Calcd for $C_{23}H_{29}O_4I$: C, 55.65; H, 5.89; I, 25.57%.

17α,21-Dihydroxypregna-1,4-diene-3,20-dione 17,21-Diacetate (10). To 17α-hydroxy-21-iodopregna-1,4-diene-3,20-dione 17-acetate (**9b**) (2.01 g), *N*-methylpyrrolidone (6.0 ml),

and tetramethylammonium acetate (0.80 g) were added and stirred at 21 °C for 7 h. Thereafter, 60 ml of water was slowly dropped while agitating. The resulting crystal was filtered off, washed with water, and dried to obtain 1.64 g of crystals. Recrystallization from ethanol (16 ml) yielded 17α,21-dihydroxypregna-1,4-diene-3,20-dione 17,21-diacetate (**10**), mp 207.7—208.0 °C; NMR ($CDCl_3$) δ=0.80 (s, 3H), 1.26 (s, 3H), 2.08 (s, 3H), 2.16 (s, 1H), 4.74 (q, 2H), 6.04 (broad, 1H), 6.18 (q, 1H), 7.02 (d, 1H), MS *m/z* 428 (M^+).

Found: C, 70.14; H, 7.56%. Calcd for $C_{25}H_{32}O_6$: C, 70.07; H, 7.53%.

Electrocatalytic Oxidation of Chlorpromazine in Phosphate Solution

Kiyoko TAKAMURA,* Satoshi INOUE, Fumiyo KUSU, and Noboru OYAMA†
Tokyo College of Pharmacy, Hachioji, Tokyo 192-03
†*Department of Applied Chemistry for Resources, Tokyo University of Agriculture and Technology, Koganei, Tokyo 184*
(Received August 13, 1984)

The kinetics of electrocatalytic oxidation process of chlorpromazine (CPZ) at a pyrolytic graphite electrode in a phosphate solution was investigated by rotating disk voltammetry. The reactions involving regeneration process of CPZ through the disproportionation of reaction intermediates are proposed and the rate constants of the chemical reaction (k_{obsd}), following the electrochemical oxidation of CPZ to the CPZ cation radical, were evaluated from the electrode rotation-rate dependence of the limiting currents obtained in the CPZ solution with and without phosphate. The proportional relations between the logarithm of k_{obsd} and pH, and between k_{obsd} and the concentration of $H_2PO_4^-$ were obtained.

In a previous paper,[1] we proposed an electrochemical oxidation mechanism of chlorpromazine (CPZ) involving the regeneration processes of CPZ through the disproportionation of reaction intermediates at the electrode surface, as given by Eqs. 1—4,

$$CPZ \underset{+e}{\overset{-e}{\rightleftharpoons}} CPZ^{\cdot+} \quad (1)$$

$$CPZ^{\cdot+} + H_2PO_4^- \overset{K_1}{\rightleftharpoons} [CPZ(HPO_4)]^{\cdot-} + H^+ \quad (2)$$

$$[CPZ(HPO_4)]^{\cdot-} + CPZ^{\cdot+} \underset{k_{-2}}{\overset{k_2}{\rightleftharpoons}} [CPZ(HPO_4)]^0 + CPZ \quad (3)$$

$$[CPZ(HPO_4)]^0 + H_2O \xrightarrow{k_3} CPZO + H_2PO_4^- + H^+ \quad (4)$$

where $CPZ^{\cdot+}$ and CPZO are the CPZ cation radical and CPZ S-oxide, respectively. Chlorpromazine is a well-known drug in phenothiazines and frequently used as a major tranquilizer. Thus, further confirmation of the oxidation mechanism of CPZ may give more significant informations for determination of the best conditions for highly sensitive electrochemical analysis of CPZ and understanding of the drug metabolic pathway.

In this paper, we examine in detail the mechanism of the electrocatalytic oxidation of CPZ in phosphate media. Although our proposed reaction mechanism of CPZ is somewhat complicated, it is reported that the following simplified expression, so-called "half-generation reaction";

$$A \xrightarrow{e} B$$

$$2B \xrightarrow{k} A + C$$

suffices Eqs. 1—4 and the k value can be obtained from the voltammetric limiting current, using a rotating disk electrode (RDE) according to the procedure of Holub.[2]

Experimental

Chemicals. Chlorpromazine hydrochloride was obtained from Sigma Chemical Co. All other chemicals were of analytical grade and were used without further purification. A perchlorate salt of the chlorpromazine cation radical was prepared electrochemically according to the procedure of McCreery *et al.*[3] Phosphate buffers, prepared by mixing of H_3PO_4 and NaOH solutions, were used as supporting electrolyte solution and the pH's of the buffers were measured at 25 °C with a Toa pH meter HM-5ES.

Apparatus. Measurements of current-potential curves and controlled potential electrolysis were carried out using an HA-301 potentiostat (Hokuto Denko Ltd.) and a function generator HB-104 (Hokuto Denko Ltd.). In these experiments, a pyrolytic graphite disk was chosen as a working electrode so as to render the adsorption of CPZ on the electrode surface negligibly small.[4] To prepare the rotating disk electrode, the pyrolytic graphite disk (Union Carbide Co.) was sealed with the heat shrinkable teflon tubing. The graphite disk was connected to a stainless steel shaft attached to rotating disk rotor RRDE-1 (Nikko Keisoku Ltd.) and motor speed controller SC-5 (Nikko Keisoku Ltd.). A fresh electrode surface with an area of 0.19 cm^2 was produced by cleaving the disk with a stainless steel cutter. The potentials are quoted with respect to a saturated calomel electrode (SCE). The electrolysis solution was deaerated by bubbling nitrogen gas. During the experiment, the solutions were shielded from light and air, and the temperature was maintained at 25 °C.

Measurements of ^{31}P-NMR spectra were carried out using a FX-200 spectrometer (JEOL). The crystallized $CPZ^{\cdot+}$ perchlorate was directly dissolved in methanol containing 7.8% D_2O with 1.0×10^{-2} mol dm^{-3} NaH_2PO_4 and the spectra of NaH_2PO_4–$CPZ^{\cdot+}$ solution were measured immediately.

Results and Discussion

The current-potential (i-E) curves of 1.0×10^{-3} mol dm^{-3} CPZ obtained by using the stationary graphite electrode are shown in Figs. 1 and 2. The oxidation peaks appear clearly on the anodic scan, and the peak current (i_p) at 0.65 V *vs.* SCE becomes large at higher pH and higher phosphate concentrations. This trend is essentially the same as that observed previously by using a stationary glassy carbon electrode.[1] Thus, the electrochemical oxidation of CPZ is also catalyzed by phosphate anion at the graphite electrode.

The anodic current-potential curves of 1.0×10^{-3} mol dm^{-3} CPZ obtained by RDE are shown in Figs. 3 and 4. A well-defined oxidation wave is observed with a half-wave potential of 0.60 V *vs.* SCE. The limiting current, i_{lim}, of the oxidation increases with increasing the phosphate concentration, whereas the half wave potential is independent of the phosphate concentration (Fig. 3). The value of i_{lim} also depends on pH. A larger i_{lim} is observed at higher pH (Fig. 4).

Figure 5 shows the Levich plot, *i.e.*, the reciprocal of the limiting current (i_{lim}^{-1}) *vs.* that of the square root of the rotation rate ($\omega^{-1/2}$) obtained for the CPZ oxidation wave. At a pH lower than 3, i_{lim}^{-1} is in proportion to $\omega^{-1/2}$, but not so at higher pH. This indicates that the limiting current is diffusion-controlled at lower pH, but kinetic in nature at higher pH. The contribution of chemical reactions to the overall electrode process of CPZ thus becomes apparent.

From the plot of log $(i/(i_{lim}-i))$ *vs.* E (Fig. 6), the number of electrons, n, involved in the oxidation process of CPZ (Eq. 1) is estimated to be unity.

The electrolysis products were produced by controlled potential electrolysis and detected by UV-visible absorption spectroscopy, and thin-layer chromatography. Electrolysis was carried out in a 0.1 mol dm^{-3} phosphate solution (pH 2—7) at a fixed potential of 0.72 V *vs.* SCE, until the limiting current dropped below 0.5% of the initial value. When the solution showed below pH 3, it was tinged red during the electrolysis. The solution showed an absorption peak due

to $CPZ^{\cdot+}$ at 524 nm. The final electrolysis product was found to be CPZO on the basis of a comparison with an authentic sample.

The above findings are important in regard to the validity of our assumption previously proposed for the electrode processes of CPZ.[1] The presence of an intermediary adduct between $CPZ^{\cdot+}$ and phosphate given in Eq. 2 is suggested from the data of ^{31}P-NMR of the $CPZ^{\cdot+}$-$H_2PO_4^-$ system. The ^{31}P-NMR spectra were measured in methanol containing 7.8% D_2O at pH 3.75 to avoid rapid decomposition of $CPZ^{\cdot+}$. A distinct peak can be seen in the ^{31}P-NMR spectrum of a 1.0×10^{-2} mol dm^{-3} NaH_2PO_4 solution (pH 3.75) without $CPZ^{\cdot+}$ (Fig. 7A). When 1.0×10^{-2} mol dm^{-3} $CPZ^{\cdot+}$ coexists with NaH_2PO_4, the peak of NaH_2PO_4 shifts upfield (Fig. 7B) and is little affected by the presence of 1.0×10^{-2} mol dm^{-3} CPZ (Fig. 7C). This implies an interaction between $CPZ^{\cdot+}$ and $H_2PO_4^-$.

(A): 1.0×10^{-2} mol dm^{-3} NaH_2PO_4, (B): 1.0×10^{-2} mol dm^{-3} NaH_2PO_4 with 1.0×10^{-2} mol dm^{-3} $CPZ^{\cdot+}$, (C): 1.0×10^{-2} mol dm^{-3} NaH_2PO_4 with 1.0×10^{-2} mol dm^{-3} CPZ.

Assuming the reaction given by Eq. 2 always to be in equilibrium and the reactions expressed by Eqs. 3 and 4 to be of comparable rate,[5] the observed rate constant, k_{obsd}, for a series of reactions expressed by Eqs. 2—4 may be written as

$$k_{obsd} = \frac{2K_1k_3(k_2/k_{-2})[H_2O][H_2PO_4^-]}{([CPZ]+k_3[H_2O]/k_{-2})[H^+]} \quad (5)$$

Provided the concentration of CPZ is virtually constant at the electrode surface, the following two relations can be expected to hold.

$$k_{obsd} \propto [H^+]^{-1} \quad (6)$$

$$k_{obsd} \propto [H_2PO_4^-] \quad (7)$$

The values of k_{obsd} can be calculated from the ratio of the kinetic current to diffusion current, according to Holub's analysis of the half-generation mechanism.[2] First, the quantity J, defined as $(i_c-i_0)/i_0$, is calculated, where i_c and i_0 are the limiting currents obtained in the CPZ solution with and without phosphate, respectively. It is then possible to obtain κ by using Holub's table which tabulates the relation between J and κ. The κ is expressed as

$$\kappa = (2k_{obsd}\,a^*/(0.51^{2/3}\omega))(\nu/D)^{1/3} \quad (8)$$

where a^* is the bulk concentration of CPZ, ν the kinematic viscosity and D the diffusion coefficient of CPZ. From the slope of the Levich plot, the value of D is obtained as 6.53×10^{-10} m^2 s^{-1}. The value of ν is then assumed to be 1.0×10^{-6} m^2 s^{-1}, the viscosity of water.

The plot of log k_{obsd} *vs.* pH and k_{obsd} *vs.* $H_2PO_4^-$ concentration are shown in Figs. 8 and 9, from which the relations 6 and 7 are found to hold except at pH

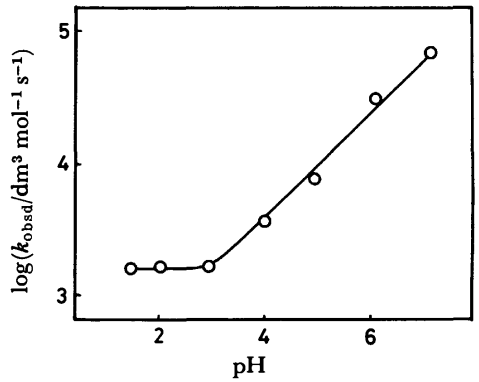

Fig. 8. Plot of the log k_{obsd} *vs.* pH.
1.0×10^{-3} mol dm^{-3} CPZ in a 0.1 mol dm^{-3} phosphate solution.

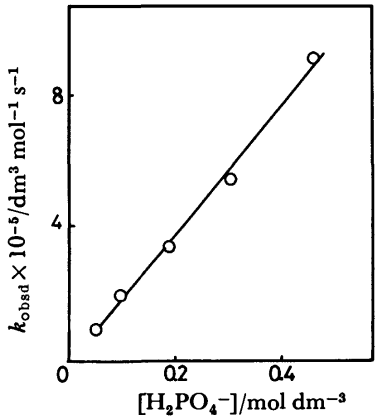

Fig. 9. Plot of k_{obsd} *vs.* $H_2PO_4^-$ concentration.
1.0×10^{-3} mol dm^{-3} CPZ; pH 6.8.

lower than 3. The deviation from the relation 6 at pH lower than 3.0 may attributed to the fact that the reaction expressed by Eqs. 2—4 is not established in the strong acidic solution and that other unknown regeneration processes of CPZ occur. Since the solubility of CPZ greatly decreases at pH higher than 7, the measurement of k_{obsd} cannot be made in such a pH region. Thus the kinetics of the electrocatalytic oxidation processes of CPZ described above is valid in the pH range 3—7.

McCreery *et al.*[3] studied the degradation of CPZ$^{\cdot+}$ in bulk solution by spectrophotometric technique and obtained the value of 177 dm^3 mol^{-1} s^{-1} for the rate constant (k_{obsd}) in a 0.1 mol dm^{-3} phosphate solution at pH 3.99 in the presence of 2.0×10^{-3} mol dm^{-3} CPZ, assuming the same reaction sequence as Eqs. 2—4. Under the same conditions, determination of k_{obsd} was made by the present method for comparison and the value of 142 dm^3 mol^{-1} s^{-1} was obtained. This value is essentially the same as above, indicating the validity of the electrode processes of CPZ presented by Eqs. 1—4.

The results presented in this paper confirm the mechanism previously proposed for the anodic oxidation processes of CPZ.[1]

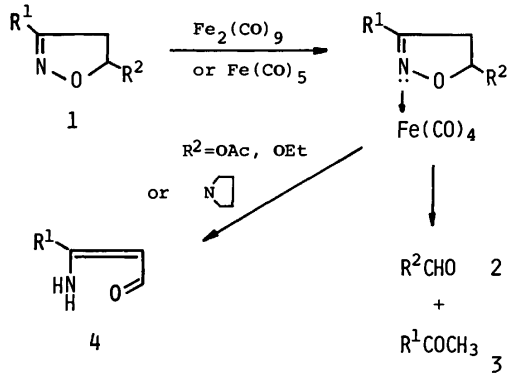
Nonacarbonyldiiron-, Pentacarbonyliron-, or Hexacarbonylmolybdenum-induced Reactions of 4,5-Polymethylene-substituted 2-Isoxazolines[1)]

Makoto NITTA,* Akihiro YI, and Tomoshige KOBAYASHI
Department of Chemistry, School of Science and Engineering, Waseda University, Shinjuku-ku, Tokyo 160
(Received September 26, 1984)

The reaction of 4,5-polymethylene-substituted 2-isoxazolines, 3-phenyl-3a,5,6,7a-tetrahydro-4*H*-pyrano-[3,2-*d*]isoxazole or 3-phenyl-3a,4,5,6a-tetrahydrofuro[3,2-*d*]isoxazole, with [$Fe_2(CO)_9$], [$Fe(CO)_5$], or [$Mo(CO)_6$] resulted in the formation of 5-hydroxy-1-phenyl-1-pentanone or 4-hydroxy-1-phenyl-1-butanone, *via* the N–O and C–C bond cleavage of the 2-isoxazoline ring and the subsequent hydrolysis. The similar reaction of 7a-morpholino- and 7a-(1-pyrrolidinyl)-3-phenyl-3a,4,5,6,7,7a-hexahydro-1,2-benzoisoxazoles undergoes the N–O bond cleavage and, the subsequent elimination of the amino group or the C-3a–C-7a bond fission. Although the reaction of 6a-morpholino- and 6a-(1-pyrrolidinyl)-3-phenyl-3a,4,5,6a-tetrahydro-4*H*-cyclopent[*d*]isoxazoles with [$Mo(CO)_6$] undergoes the N–O bond cleavage, and the subsequent elimination of the amino group or the C-3a–C-6a bond fission, the reaction of those 2-isoxazolines with [$Fe_2(CO)_9$] proceeds very slowly. The mechanisms are proposed for these reactions.

The 2-isoxazoline ring systems have been a subject of great synthetic interest, and they have been used for the synthesis of β-amino alcohol,[2)] α,β- or β,γ-unsaturated oximes,[3)] and β-hydroxy ketones.[4)] The versatility of 2-isoxazolines as precursors for a number of classes of compounds was also demonstrated recently.[5)] Previously, it has been shown that the reaction of 3,5-disubstituted 2-isoxazolines **1** with [$Fe(CO)_5$] under photoirradiation, or with [$Fe_2(CO)_9$] under thermal conditions undergoes the N–O bond and C-4–C-5 bond cleavage to give aldehydes **2** and ketones **3**, which are derived from reduction and the subsequent hydrolysis of the postulated vinylnitrene complexes.[6)] Furthermore, 2-isoxazolines bearing substituent such as an acetoxy or ethoxy group at C-5, undergo the N–O bond cleavage and the concomitant elimination of the acetoxy or ethoxy group leading to β-amino enones **4**.[6)] However, in the case of 2-isoxazolines bearing 1-pyrrolidinyl group at C-5, the N–O and C-4–C-5 bond cleavage giving **2** and **3** predominates over elimination of the C-5-substituent giving **4**.[6)] The facile metal carbonyl-induced N–O bond cleavage of 2-isoxazolines has a strong resemblance to the photochemically[7)] induced N–O bond fission of the various 2-isoxazolines. This fact seems to suggest the p-d electron delocalization from the central metal to the π* (LUMO) orbital of the C=N–O moiety of the complexed 2-isoxazolines.[6)] This effect would weaken the N–O bond to undergo a facile cleavage.

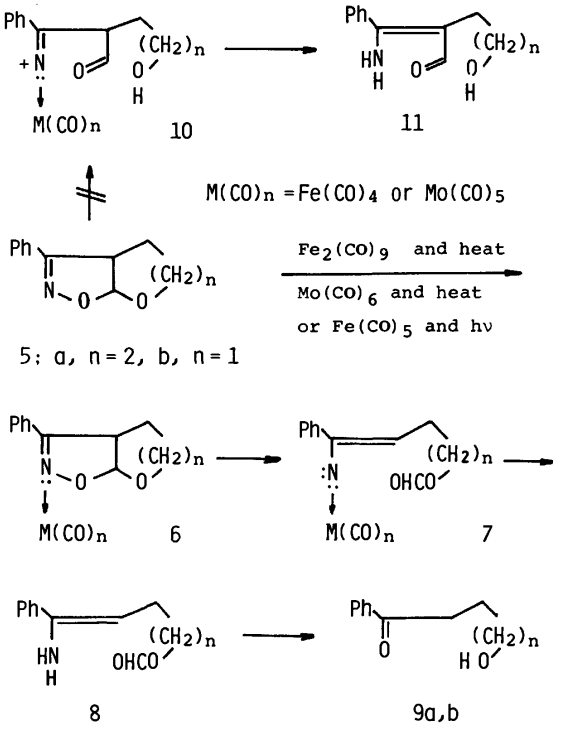


Scheme 1.

In search for further synthetic utilities of the 2-isoxazoline ring system and in connection with the previous studies,[6)] we have investigated the reaction of 4,5-polymethylene-substituted 2-isoxazolines in the presence of [$Fe_2(CO)_9$], [$Fe(CO)_5$], or [$Mo(CO)_6$]. The results are presented in this paper.

The thermal reaction of 2-isoxazolines **5a**[8)] and **5b**[8)] with 1.2 molar equivalent amounts of [$Fe_2(CO)_9$] in anhydrous methanol for 24 h and separation by TLC afforded 5-hydroxy-1-phenyl-1-pentanone (**9a**) and 4-hydroxy-1-phenyl-1-butanone (**9b**) in moderate yields. The photoirradiation of **5a,b** with [$Fe(CO)_5$] also afforded the similar results. In addition, the reaction of **5a,b** with [$Mo(CO)_6$] in anhydrous methanol was also found to result in the formation of **9a** and **9b**. The yields and the reaction conditions are listed in Table 1. The products are known compounds and were identified by comparison of the spectral properties with those reported in the literature.[9)]

The reaction seems to be selective and no other product was detected. The products obtained in these reactions correspond to those formed by the N–O and C–C bond cleavage of the 2-isoxazoline ring. Free or solvated [$Fe(CO)_4$] species is generally assumed to be the common intermediate in thermolysis (≥80 °C) or photolysis of [$Fe(CO)_5$] and thermolysis of [$Fe_2(CO)_9$] (≥20 °C).[10)] [$Mo(CO)_6$] has also been shown to give an N-donor complex of isoxazoles.[11)] Therefore the initial step is N-donor complexation of **5a,b** to give **6**. The following ring cleavage of **6** gives the complexed nitrene **7**, the reduction of which gives enamine **8**.[12)] The enamine moiety of **8** as well as the ester moiety would be hydrolyzed to give **9a,b** under the reaction conditions in the presence of stray water or under workup condi-

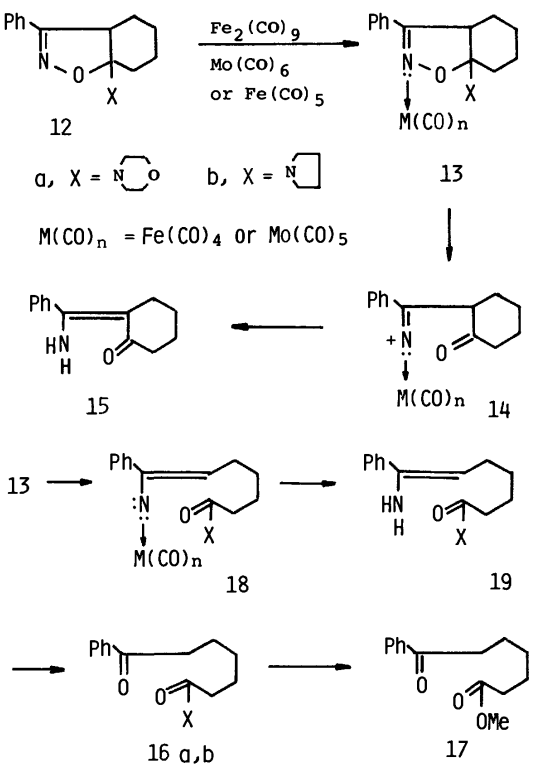


Scheme 2.

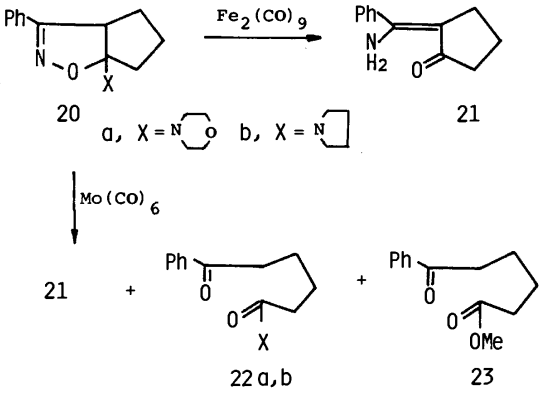
tions.[6,12] The N-O and C-O bond cleavage giving β-amino enone **11** *via* **10** did not occur, unlike in the case of **1** (R^2=OEt or OAc).[6]

The reaction of 7a-morpholino- and 7a-(1-pyrrolidinyl)-3-phenyl-3a,4,5,6,7,7a-hexahydro-1,2-benzoisoxazole (**12a** and **12b**)[13] with [$Fe_2(CO)_9$] at the refluxing temperature, or with [$Fe(CO)_5$] under photoirradiation, afforded the β-amino enone **15** and the ester **17**, in addition to the unreacted starting materials **12a,b** (Scheme 3). On the other hand, treatment of **12a** or **12b** with [$Mo(CO)_6$] in methanol resulted in the complete consumption of the starting material and gave **15** and **17**, in addition to the small amount of **16a** or **16b**. The reaction conditions and the yields of the products are listed in Table 2. The products **15**[11] and **17**[14] are known compounds. Furthermore, the structures of new compounds **16a,b** were confirmed by the independent preparations of the corresponding samples (see Experimental). The complexed 2-isoxazoline **13** undergoes the N-O bond cleavage and the concomitant elimination of morpholino or 1-pyrrolidinyl group to give β-amino enone **15**. The complex **13** also undergoes the N-O and C-3a-C-7a bond cleavage to give **18**, the reduction of which and the subsequent hydrolysis under the reaction conditions in the presence of stray water or under workup conditions gives **16a,b**. The compound **17** may be derived from the methanolysis of the amide group of **16** in the presence of oxidized-metal carbonyl species.

On the other hand, the reaction of 6a-morpholino- and 6a-(1-pyrrolidinyl)-3-phenyl-3a,4,5,6a-tetrahydro-4*H*-cyclopent[*d*]isoxazoles (**20a** and **20b**),[15] with



Scheme 3.



Scheme 4.

[$Fe_2(CO)_9$] is very slow, and β-amino enones **21**[11] were obtained in addition to the large amount of unreacted **20a,b**. However, [$Mo(CO)_6$] effects the complete reaction of **20a,b** to give β-amino enones **21**, the amide **22a,b**, and ester **23**[14,16] (Scheme 4). The yields and the reaction conditions are also listed in Table 2 (entries 7—10). The structures of new compounds **22a,b** were also confirmed by independent preparations of the corresponding samples (see Experimental). The formation of the products are explained by the pathways, which are similar to those of **12a,b**.

Regarding the product composition for the reaction of **12a,b**, the substituent such as morpholino or 1-pyrrolidinyl groups does not affect the reaction pathways giving **15**, **16**, and **17**. However, the size of the 4,5-polymethylene chain seems to affect the reaction

pathways. The N-O bond cleavage and the concomitant elimination of the morpholino or 1-pyrrolidinyl group giving β-amino enones become the major pathway for **20a,b**. The details for the ring size effect are ambiguous. Furthermore, $[Mo(CO)_6]$ is found to be more efficient for the ring cleavage of the 2-isoxazolines **12a,b** and **20a,b**, as compared to $[Fe_2(CO)_9]$.

In summary, these results demonstrate that $[Fe_2(CO)_9]$, $[Fe(CO)_5]$, and $[Mo(CO)_6]$ are useful reagents for the ring cleavage reaction of the appropriately substituted 2-isoxazoline ring system. Furthermore, the ring cleavage of the present 2-isoxazolines affords a series of interesting compounds, such as **9a,b**, **16a,b**, and **17** in modest yields.

Experimental

The IR spectra were recorded on a Shimadzu IR-400 spectrometer. The mass spectral studies were conducted using Shimadzu GCMS-QP1000 spectrometer. The NMR spectra were recorded on a Hitachi R-24 spectrometer, using tetramethylsilane as the internal standard. $[Mo(CO)_6]$ and $[Fe(CO)_5]$ (Strem Chemical, Inc.) were commercial samples. $[Fe_2(CO)_9]$ was prepared by the standard method.[17] Methanol was purified and dried by the standard method. All of the reactions were carried out under a dry nitrogen atmosphere. The desired 2-isoxazolines, **5a,b**,[8] **12a,b**,[13] and **20a,b**[14] were synthesized by the 1,3-dipolar cycloadditions of benzonitrile oxide with the corresponding olefins according to the literatures.

*General Procedure for the Reaction of 2-Isoxazolines **5a,b**, **12a,b**, or **20a,b** with $[Fe_2(CO)_9]$ or $[Mo(CO)_6]$.* A solution of **5**, **12**, or **20** (1 mmol) and $[Fe_2(CO)_9]$ (436 mg, 1.2 mmol) or $[Mo(CO)_6]$ (264 mg, 1 mmol) in anhydrous methanol (20 cm^3) was refluxed for an adequate period. After evaporation of the methanol, hexane–benzene (1/1, 20 cm^3) was added to the residue and the mixture was filtered through Celite to remove insoluble material. The filtrate was concentrated, and the resulting residue was separated by TLC on silica gel using the CH_2Cl_2–AcOEt (3/1) mixture as the eluent to give the products, which are summarized in Table 1 (entries 1, 3, 4, and 6) and Table 2 (entries 1, 3, 4, and 6—10). The products **9a,b**,[9] **15**,[11] **17**,[16] **21**,[11] and **23**[14,16] are known compounds and were identified by comparison of the physical properties with those reported in the literatures. The spectral data of the products, **16a,b**, **22a,b** were identical with those of the samples which were prepared independently by the following procedures.

*General Procedure for the Photoirradiation of **5a,b** or **12a,b** with $[Fe(CO)_5]$.* A solution of **5** or **12** (1 mmol) and $[Fe(CO)_5]$ (471 mg, 2.4 mmol) in anhydrous methanol (20 cm^3) was irradiated in a Pyrex vessel with RPR-350 nm lamps for an adequate period at an ambient temperature. The reaction mixture was filtered through Celite to remove insoluble material, and the filtrate was concentrated. The residue was separated by TLC on silica gel using CH_2Cl_2–AcOEt (3/1) as the eluent to give the products **9a,b**, **15**, **16a,b**, and **17** (Table 1, entries 2 and 5; Table 2, entries 2 and 5).

*Independent Preparation of **16a**.* To a stirred dichloromethane (4 cm^3) solution of 6-benzoylhexanoyl chloride, which was prepared from 6-benzoylhexanoic acid[16] (440 mg, 2 mmol) and thionyl chloride (1.29 g, 10 mmol), morpholine (4.35 g, 50 mmol) was added. After the reaction mixture was stirred for 1 h, water was added to the reaction mixture. The product was extracted with CH_2Cl_2 and the extract was dried over Na_2SO_4. After evaporation of the CH_2Cl_2, the resulting residue was distilled to give **16a** (301 mg, 52%): bp

Convenient Preparations of 3,5-Disubstituted 1,2,4-Thiadiazoles by Oxidative Dimerization of Thioamides

Yuji TAKIKAWA,* Kazuaki SHIMADA, Katsuyuki SATO, Shinichi SATO, and Saburo TAKIZAWA

Department of Applied Chemistry, Faculty of Engineering, Iwate University, Morioka, Iwate 020

(Received October 8, 1984)

3,5-Disubstituted 1,2,4-thiadiazoles **2** were prepared by reaction of thioamides **1** with DMSO in the presence of such an electrophilic reagent as 1-methyl-2-chloropyridinium iodide, benzoyl chloride, acetyl chloride, hydrochloric acid, or trimethylsilyl chloride in organic solvents at room temperature in high yields. Thiadiazoles **2** were also obtained by reaction of **1** with NBS at room temperature in high yields. Thioamide *S*-oxides reacted with electrophilic reagents at room temperature to give the corresponding thiadiazoles **2** in high yields.

Thiadiazoles are useful for bactericides,[1-3] fungicides,[1-4] herbicides,[5,6] antibiotics,[7-9] *etc.*, and a number of preparations for them have been reported. The preparation of 3,5-disubstituted 1,2,4-thiadiazoles can be roughly divided into three methods; intermolecular cyclization,[10,11] intermolecular cyclization of two different molecules,[12,13] and oxidative dimerization of the same molecules.[14-17] Some of the methods by the oxidative dimerization of thioamides, however, suffer disadvantages that substituents in 3,5-positions are limited mainly to aryl groups[14] and that by-products such as nitriles and isothiocyanates are formed.[5,18]

It is known well that the sulfur atom in thioamide easily reacts with electrophilic reagents and that resulting sulfonium salts[19-21] are very reactive with nucleophilic reagents to give various products. When an electrophilic reagent is constructed of a pair of a soft electrophile such as X^+ and a counter anion having a low nucleophilicity, the resulting sulfonium salt would eliminate HX immediately to form unstable thiazirine[17] or nitrile sulfide[22] equivalent, which is regarded as an oxidized form of thioamides and a precursor of thiadiazoles. On the basis of such a view, thioamide **1** was allowed to react with DMSO in the presence of an electrophilic reagent in organic solvent at room temperature to obtain thiadiazole **2** in high yields. In this paper, we report convenient preparations of 3,5-disubstituted 1,2,4-thiadiazoles by oxidative dimerization of thioamides using DMSO–electrophilic reagent systems and NBS. A preparation of thiadiazoles by reaction of thioamide *S*-oxides with electrophilic reagents is also described.

Results and Discussion

The conversion of thioamides **1** to 3,5-disubstituted 1,2,4-thiadiazoles **2** using DMSO–electrophilic reagent systems is shown in Table 1. These conversions do not occur in the absence of either DMSO or such electrophilic reagents as 1-methyl-2-chloropyridinium iodide **3** (Runs 1 and 2 in Table 1), and do not necessarily need one equivalent of **3** (Run 3 in Table 1). Moreover, the conversion to thiadiazole **2a** is successful in most organic solvents (Runs 3—7 in Table 1). The arenecarbothioamides **1a—g** could be converted to the corresponding thiadiazoles **2a—g** in high yields. The conversion of 2-(substituted phenyl)ethanethioamides **1h—j** to thiadiazoles **2h—j** was also achieved in moderate yield (Runs 18—20 in Table 1). When benzoyl chloride, acetyl chloride, 36% HCl, or trimethylsilyl chloride was used as electrophilic reagent thiadiazole **2a** was also obtained in high yield (Runs 21—24 in Table 1). However, thiobenzamide **1a** reacted with such sulfoxides as dibutyl sulfoxide and dibenzyl sufoxide in the presence of **3** at room temperature in CH_2Cl_2 giving thiadiazole **2a** in high yield (Runs 9 and 10 in Table 1). However, in the reaction with diphenyl sulfoxide having a low nucleophilicity, thiadiazole **2a** was obtained only in 9% yield at reflux for 6 h (Run 11 in Table 1). The corresponding sulfides were obtained in a series of these reactions. In the reaction of **3** with DMSO, 1-methyl-2(1*H*)-pyridineone was hardly obtained at room temperature, but it was quantitatively formed at 80 °C for 2 h along with iodine.

On the other hand, thiadiazoles **2** were obtained in high yields by the reaction of thioamide *S*-oxides **4** with an electrophilic reagent such as **3**, trimethylsilyl chloride, benzoyl chloride, acetic anhydride, or 36% HCl. It is interesting that the yields of 3,5-dibenzyl-1,2,4-thiadiazoles **2h—k** were enhanced. These results are shown in Table 2. No thiadiazole **2a** was obtained by stirring at room temperature for 24 h in CH_2Cl_2 in the absence of electrophilic reagent (Run 1 in Table 2), apparently implying that thiobenzamide *S*-oxide **4a** was activated by electrophilic reagent (Run 2 in Table 2). Consequently, the formation of thiadiazoles **2** may be as illustrated in Scheme 1.

As shown in Table 1, the reaction of thiobenzamide **1a** with DMSO gave quantitatively thiadiazole **2a** even with an addition of 0.03 equivalent of pyridinium salt **3** at 60 °C for 2.5 h. Thiobenzamide **1a** reacted also with 36% HCl in DMSO at room tem-

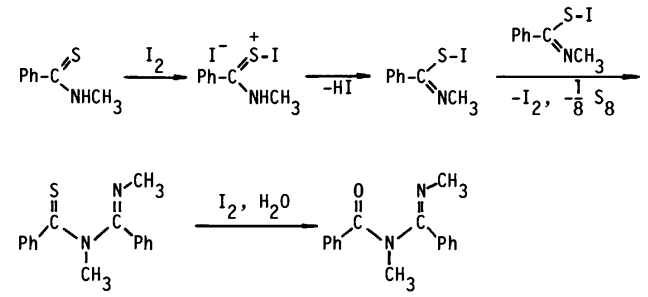
responding thiadiazoles **2** in high yields. These results are shown in Table 3.

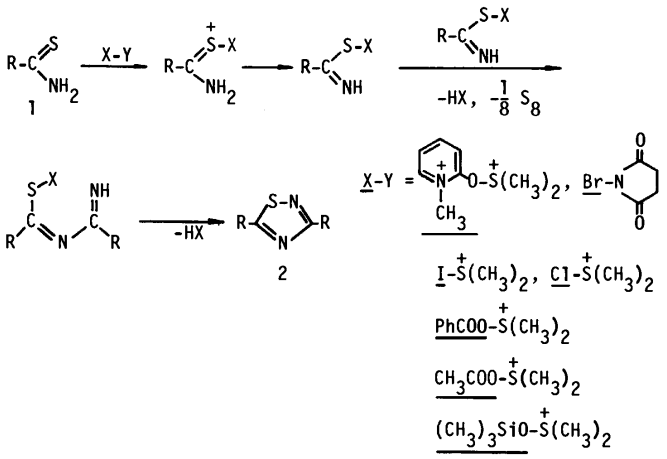
A few mechanisms have been reported for the formation of 3,5-disubstituted 1,2,4-thiadiazoles by the oxidative dimerization of thioamides. One of them[28)] comprises a route *via* dithiazoline, which is formed by the reaction of thioamide-bromine adduct with thioamide. Another mechanism[22)] resorts to the 1,3-dipolar adduct of nitrile sulfide, which is formed by way of photooxidation through extrusion of thioamide hydrogens under aerobic conditions. The conversion of thioamide into 3,5-disubstituted 1,2,4-thiadiazole *via* dithiazoline by bromine proceeds through the reaction of thioamide-bromine adduct with one more molecule of thioamide and accompanies loss of hydrogen sulfide. In a series of these reactions, however, the use of equimolar amounts of thioamide and NBS or DMSO–electrophilic reagent was needed for bringing the reaction to completion and no hydrogen sulfide but elemental sulfur was obtained in all reaction systems (Runs 4 and 5 in Table 1, and Runs 1 and 2 in Table 3). Consequently, the mechanism *via* dithiazoline is unlikely. On the other hand, the mechanism *via* thiazirine[17)] or nitrile sulfide[22)] also is considered infeasible for the following reason. Benzonitrile *N*-sulfide is known to undergo 1,3-dipolar cycloaddition with such a dipolarophile as dimethyl acetylenedicarboxylate,[29)] phenylacetylene,[22)] or benzonitrile[22)] to give dimethyl 3-phenylisothiazole-4,5-dicarboxylate, 3,4-diphenylisothiazole, or 3,5-diphenyl-1,2,4-thiadiazole, respectively. Thiobenzamide **1a** reacted with DMSO–pyridinium salt **3** in the presence of phenylacetylene in CH_2Cl_2 at room temperature for 13 h to give 3,5-diphenyl-1,2,4-thiadiazole **2a** and 1-methyl-2(1*H*)-pyridinethione in 83 and 18% yields, respectively, and no adduct with phenylacetylene was obtained. (Run 8 in Table 1). A solution of *p*-(methyl)thiobenzamide **1c** (1 mmol), *p*-methoxybenzonitrile (3 mmol), DMSO (1 mmol), and **3** (0.5 mmol) in CH_2Cl_2 (2 ml) was stirred at room temperature for 8 h to give only 3,5-di-*p*-tolyl-1,2,4-thiadiazole **2c** in 88% yield, and *p*-methoxybenzonitrile was quantitatively recovered. Both of these results suggest that the mechanism through thiazirine or nitrile sulfide is unlikely.

N-(methyl)thiobenzamide reacted with iodine in the presence of Et_3N in CH_2Cl_2 at room temperature for 1 d to give N^1-benzoyl-N^1,N^2-dimethylbenzamidine in

41% yield along with a trace amount of N^1-thiobenzoyl-N^1,N^2-dimethylbenzamidine and elemental sulfur



Scheme 3.



Scheme 4.

in 70% yield. N^1-thiobenzoyl-N^1,N^2-dimethylbenzamidine reacts with H_2O in the presence of iodine to give N^1-benzoyl-N^1,N^2-dimethylbenzamidine quantitatively. The pathway for this sequence would be given in Scheme 3.

It is apparent that the sulfonium intermediate **5** (X=I, Br, Cl, CH_3COO, PhCOO, $(CH_3)_3SiO$, or 1-methyl-2-pyridiniooxy) is present in a series of these reactions as judged from the reaction of thioamide *S*-oxides **4** with electrophilic reagents and of thioamides **1** with NBS. Therefore, conversion of thioamides **1** to 3,5-disubstituted 1,2,4-thiadiazoles **2** using DMSO-electrophilic reagents or NBS would proceed as shown in Scheme 4.

Experimental

General. The thioamides[30] and thioamide *S*-oxides[31] were prepared according to the literatures. The other reagents were commercial reagent grade materials and were purified by recrystallization or by distillation prior to use. IR spectra were recorded with a Hitachi 295 infrared spectrophotometer. ^{1}H NMR spectra were recorded with a Hitachi R-22 (90 MHz) spectrometer in carbon tetrachloride or deuteriochloroform solution containing tetramethylsilane as an internal standard. Mass spectra were recorded with a Hitachi RMU-6M spectrometer, with a direct inlet system, operating at 20 eV. For column chromatography Wakogel C-300 was used.

Preparation of 3,5-Diphenyl-1,2,4-thiadiazole **2a** *by DMSO-1-Methyl-2-chloropyridinium Iodide* **3**. A solution of

thiobenzamide **1a** 137 mg (1 mmol), DMSO 78 mg (1 mmol), and **3** 128 mg (0.5 mmol) in CH_2Cl_2 (2 ml) was stirred at room temperature for 4 h, and the reaction mixture was filtered. After removal of CH_2Cl_2, the residue was purified by silica-gel column chromatography using $CHCl_3$ as an eluent to afford thiadiazole **2a** in 94% yield. The preparation of 3,5-disubstituted 1,2,4-thiadiazoles **2** by DMSO–**3** also was carried out in a similar manner as above. The physical properties and elemental analyses of thiadiazoles **2** are shown in Table 4.

Preparation of 3,5-Disubstituted 1,2,4-Thiadiazoles 2 by DMSO–Electrophilic Reagents (Benzoyl Chloride, Acetyl Chloride, 36% HCl, Trimethylsilyl Chloride, Acetic Anhydride, and Methyl Iodide). A typical procedure is described below for the preparation of 3,5-diphenyl-1,2,4-thiadiazole **2a** by DMSO–benzoyl chloride. A solution of thiobenzamide **1a** 137 mg (1 mmol), DMSO 86 mg (1.1 mmol), and benzoyl chloride 78 mg (0.5 mmol) in CH_2Cl_2 (2 ml) was stirred at room temperature for 30 min, and the reaction mixture was filtered. After removal of CH_2Cl_2, the residue was purified by silica-gel column chromatography using $CHCl_3$ as an eluent to afford thiadiazole **2a** and benzoic acid in 100 and 93% yields, respectively.

Preparation of 3,5-Disubstituted 1,2,4-Thiadiazoles 2 by NBS. A typical procedure is described below for the preparation of 3,5-bis(*p*-methoxybenzyl)-1,2,4-thiadiazole **2k**. A solution of (*p*-methoxyphenyl)thioacetamide **1k** 181 mg (1 mmol) and NBS 196 mg (1.1 mmol) in CH_2Cl_2 (2 ml) was stirred at room temperature for 1 h. To this reaction mixture was added 2 ml of 10% NaOH and an extraction with $CHCl_3$ was applied. After removal of $CHCl_3$, the residue was purified by silica-gel column chromatography using $CHCl_3$ as an eluent to give thiadiazole **2k** in 88% yield.

Conversion of Thioamide S-Oxides 6 to 3,5-Disubstituted 1,2,4-Thiadiazoles 2 by Electrophilic Reagents (Pyridinium Salt 3, Benzoyl Chloride, Trimethylsilyl Chloride, Acetic Anhydride, and 36% HCl). A typical procedure is described below for the preparation of 3,5-bis(*p*-chlorophenyl)-1,2,4-thiadiazole **2c** by the reaction of *p*-(chloro)thiobenzamide *S*-oxide **4c** with 36% HCl. A solution of **4c** 188 mg (1 mmol) and 36% HCl 51 mg (0.5 mmol) in EtOH (5 ml) was stirred at room temperature for 9 d, and a large amount of water was added to the reaction mixture to precipitate white crystals. The crude crystals were collected and purified by silica-gel column chromatography using $CHCl_3$ as an eluent to afford thiadiazole **2c** quantitatively.

(Received October 11, 1984)

(±)-*Anti* head-to-head coumarin dimer was successfully resolved into a pair of optically active forms in good yields and in high optical purity by the fractional crystallization of both lactone-opened diamides with optically active 1-phenylethylamine followed by hydrolysis and relactonization. The absolute configuration of $(-)_{589}$-*anti* head-to-head coumarin dimer was confirmed to be (3*R*,3′*R*,4*R*,4′*R*) by X-ray crystal structure analysis, which showed puckering of the cyclobutane ring (32.5°) and some short nonbonded distances (2.15—2.60 Å).

In the previous papers it was shown that the lactone rings in *anti* head-to-head coumarin dimer, which can be easily prepared by the photochemical dimerization of coumarin,[1] are susceptible to nucleophilic ring-opening,[2] and the reaction was successfully applied to ring-opening polyaddition.[3] Although the optically active dimer may be useful as an optically active reagent with high reactivity and as an optically active diacid component in organic and polymer syntheses, respectively, no attempt at optical resolution of the dimer was reported. We have now optically resolved the dimer and determined the absolute configurations as reported in the preliminary paper.[4] This paper describes the optical resolution in detail and the absolute configuration on the basis of X-ray crystal structure analysis.

Results and Discussion

Optical Resolution of Anti *Head-to-head Coumarin Dimer (1).* It is known that *anti* head-to-head coumarin dimer (**1**) and the lactone-ring-opened derivative, *t*-3,*c*-4-bis(2-hydroxyphenyl)-*r*-1,*t*-2-cyclobutanedicarboxylic acid, are interconvertible.[1] The fractional crystallization of the salts of the cyclobutanedicarboxylic acid with chiral amines such as 1-phenylethylamine, brucine, strychnine, and quinidine has been carried out in an attempt to obtain optically active **1**, but all the trials resulted in failure. On the other hand, in our laboratory the relactonization of mono(lactone-ring-opened) *N*-butylamide of **1** has been found to occur smoothly on heating in solution.[5] The optical resolution of the diamide, prepared from **1** and an optically active amine by ring-opening reaction, was tried with the expectation that the diamide would be easily converted to the dimer (**1**).

When **1** was allowed to react with two molar amounts of (*S*)-(−)-1-phenylethylamine in dioxane at room temperature, white precipitate deposited. On the basis of elemental analysis, and ^{1}H NMR and IR spectral data, the precipitate was found to be one (**2a**) of a pair of diastereomeric diamides (79% yield). The residue, obtained from the filtrate on concentration, was crystallized from acetone/methanol (10/1 v/v) to give the other diastereomer (**2b**) in 81% yield. HPLC analyses of **2a** and **2b** thus-obtained each showed one peak only. The peak corresponding to the other diastereomer could not be detected, indicating that both of **2a** and **2b** were almost diastereomerically pure. Consequently both of the diastereomeric diamides could be obtained in good chemical yields and in high diastereomeric purity by crystallization from dioxane or acetone/methanol without recrystallization since their solubilities were extremely different.

Hydrolysis of **2** in ethanol/concd hydrochloric acid under refluxing proceeded without difficulty, and **2** was shown to be hydrolyzed completely within 20 h by TLC check. On heating the reaction mixture in acetic acid as described in the literature,[1] relactonization took place easily to give optically active **1**. The relactonization also proceeded efficiently on heating a toluene solution of the reaction mixture in the presence of a catalytic amount of *p*-toluenesulfonic acid.

Thus, $(+)_{589}$- and $(-)_{589}$-**1** were obtained from **2a** and **2b**, respectively. They were found to be almost optically pure since HPLC analyses of the diamides produced by the reaction of (+)- and (−)-**1** thus-obtained with (*S*)-(−)-1-phenylethylamine showed only one peak of the corresponding diastereomeric diamide. The result indicates that no racemization nor epimerization occurs in the course of the hydrolysis, the relactonization, and the nucleophilic ring-opening with an amine.

Absolute Configuration of (−)-1 Determined by X-Ray Crystal Structure Analysis. To determine the absolute configuration of optically active **1**, an X-ray crystal structure analysis of (−)-**1** was carried out. Differences of the calculated structure factors of ten selected Friedel pairs, *i.e.*, $\Delta F_c = |F_c(hkl)| - |F_c(\bar{h}\bar{k}\bar{l})|$ are compared in Table 1 with those of the observed

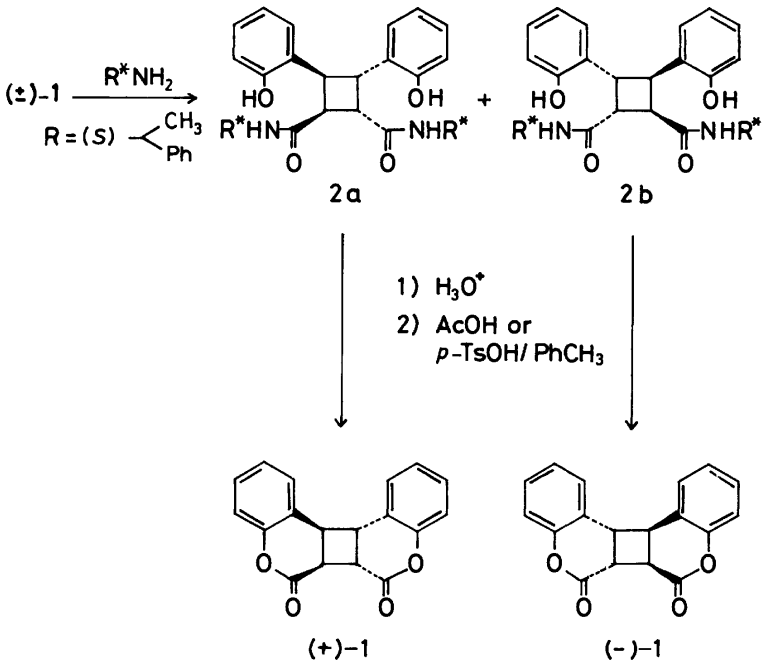

Table 1. Relation of $|F|$ in Friedel pairs

h	k	l	$\langle F_c \rangle$	$\langle F_o \rangle$	ΔF_c	ΔF_o	$\sigma(\Delta F_o)$
6	8	1	12.5	16.4	0.6	2.1	0.9
1	11	1	20.3	24.1	0.4	0.4	0.4
5	5	2	23.8	16.3	0.8	1.9	0.8
3	5	2	21.1	23.2	0.7	1.1	0.4
2	1	3	24.9	20.2	−0.7	−0.7	0.3
9	8	3	14.0	12.2	−0.3	−1.4	0.7
1	8	6	16.9	21.3	−0.8	−1.0	0.8
2	5	6	49.8	51.1	−1.0	−1.2	0.5
1	4	9	33.5	26.7	0.6	1.1	0.6
1	7	9	36.1	41.2	0.7	0.7	0.6

All $|F_c|$s are multiplied by 10.0 in the absolute scale.

ones, $\Delta F_o = |F_o(hkl)| - |F_o(\bar{h}\bar{k}\bar{l})|$. All the signs of ΔF_o are consistent with those of ΔF_c, indicating that the absolute configuration of (−)-**1** is correctly expressed by the atomic coordinates in Table 2 referred to a right-handed coordinate system. The configuration is drawn in Fig. 1, where the numbering system is also shown. From Fig. 1 the absolute configuration of (−)-**1** is concluded to be (3*R*, 3′*R*, 4*R*, 4′*R*).

Molecular Structure of (−)-1. The bond distances and angles are listed in Table 3. The dihedral angles between planes C(3′)-C(3)-C(4) and C(3′)-C(4′)-C(4), and between C(3)-C(4)-C(4′) and C(3)-C(3′)-C(4′) are the same value of 32.5°, showing that the cyclobutane ring in **1** crystal is puckered.

Some short nonbonded distances are found for C(2)···C(3′) (2.602(5) Å), C(3)···C(2′) (2.579(5) Å), C(4)···C(10′) (2.565(4) Å), and C(10)···C(4′) (2.515(4) Å), in addition to short ones in the cyclobutane ring, *i.e.*, C(3)···C(4′) (2.150(4) Å) and C(4)···C(3′) (2.152(4) Å), resulting from the puckering of the cyclobutane ring. This puckering and subsequent short contacts might be the reason for the instability and/or the high reactivity of lactones in **1**.

a) The equivalent isotropic temperature factors were computed using the following expression; $B_{eq} = 4/3(B_{11}a^2 + B_{22}b^2 + B_{33}c^2)$. The B_{ij}'s are defined by; $\exp[-(h^2B_{11} + k^2B_{22} + l^2B_{33} + klB_{23} + hlB_{13} + hkB_{12})]$.

^1H NMR Study of (−)-1. ^1H NMR spectrum of (−)-**1** (Fig. 2a) showed a singlet of four protons (Ha, Hb, Hc, Hd) on the cyclobutane ring at δ 3.86. But, in ^1H NMR spectra of the both lactone-ring-opened derivatives, such as (−)-*t*-3,*c*-4-bis(2-hydroxyphenyl)-*r*-1,*t*-2-cyclobutanedicarboxylic acid (Fig. 2b) and its dimethyl and diethyl esters, two *pseudo* doublets were observed at δ 3.5—3.6 and 4.6—4.7. As the signal of methine protons adjacent to an aryl group is known to appear at lower region in a magnetic field than that of methine protons adjacent to a carboxyl group, the lower signal is assigned to the signal of Hb′ and Hd′, and the higher one to that of Ha′ and Hc′, respectively (see Fig. 2). The large up-field shift of the signal of Hb and Hd in comparison with that of Hb′ and Hd′ would be explained by the shielding effect of the facing aryl group. HGS molecular models show that Hb and Hd are in the shielding zone of the facing aryl group on the assumption of some puckering of the cyclobutane ring.

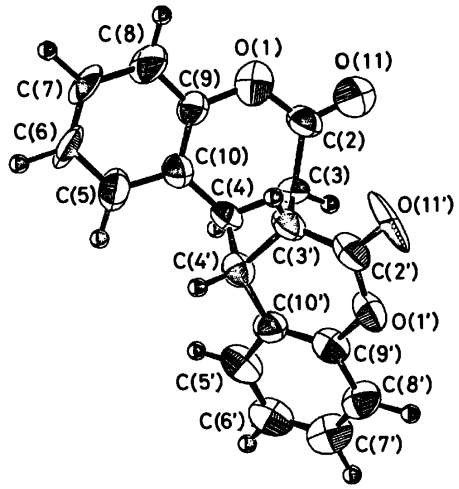

Fig. 1. Computer drawing of (−)-**1**.

The puckering, which would exist in a solution as well as in the crystalline state, conforms well to the up-field shift of Hb and Hd signals in the ^1H NMR spectrum of (−)-**1**.

CD Study of (+)-1. The absolute configuration of (+)-**1** was considered to be determinable on the basis of the CD exciton chirality theory,[6] if two phenolic

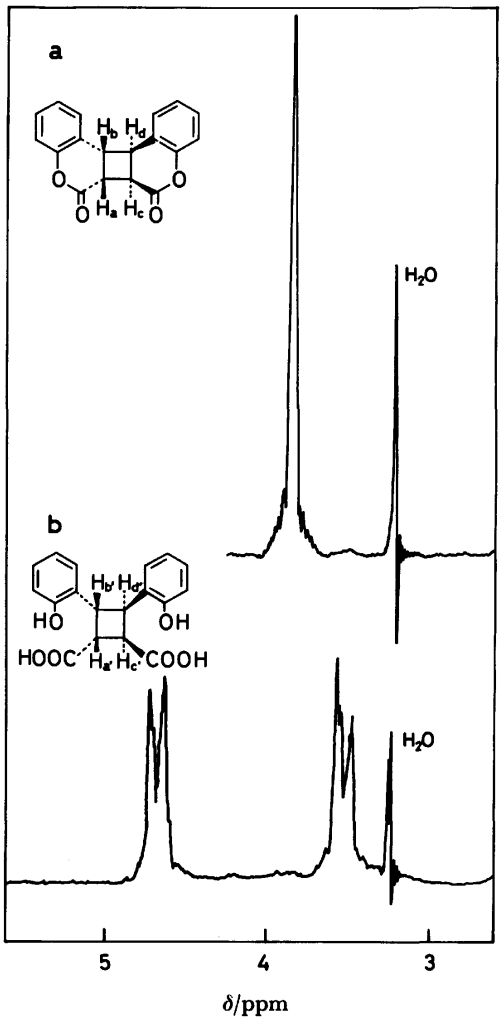

Fig. 2. The partial ^1H NMR spectra of (a) *anti* head-to-head coumarin dimer and (b) its both lactone-ring-opened derivative, *t*-3, *c*-4-bis(2-hydroxyphenyl)-*r*-1,*t*-2-cyclobutanedicarboxylic acid.

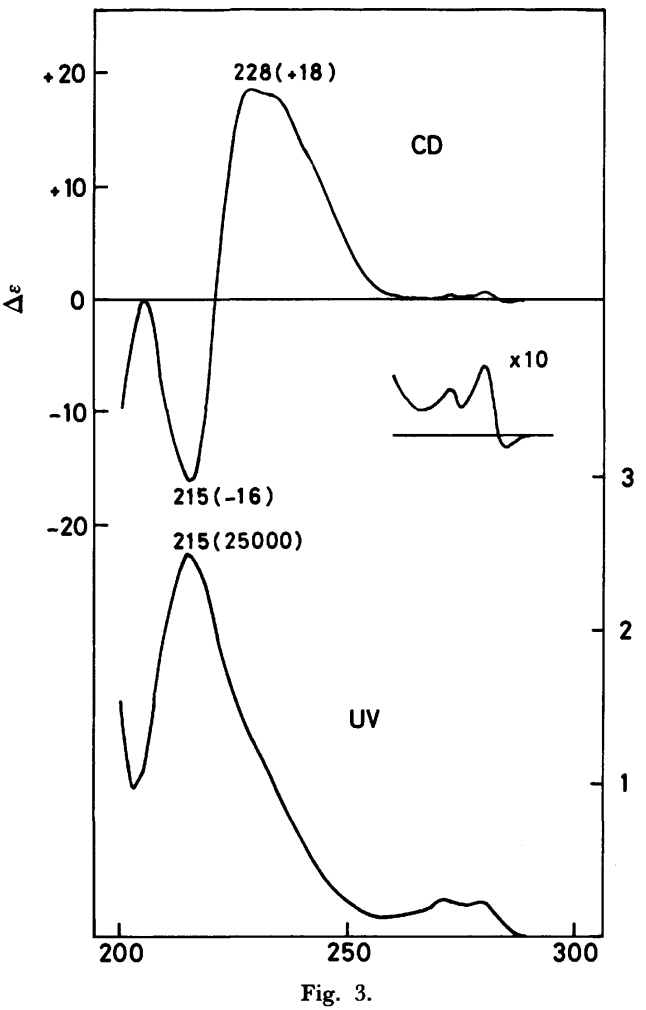

Fig. 3.

carbon–oxygen bonds in (+)-**1** are non-parallel. The UV spectrum of (+)-**1** in acetonitrile (Fig. 3) showed an absorption maximum at 215 nm, which would be attributable to $^1L_a \leftarrow {}^1A$ transition directed along the long axis of the acyloxyphenyls, namely, along the phenolic carbon–oxygen bonds.[6,7] The CD spectrum of (+)-**1** in acetonitrile (Fig. 3) showed a strong positive first Cotton effect at 228 nm and a negative second one at 215 nm, indicating a right-handed screw of the carbon–oxygen bonds.[6] Assuming that the predominant conformation of the lactone rings of (+)-**1** in a solution is a *pseudo*-boat form as well as that in the crystalline state (Fig. 1), an HGS molecular model constracted on the basis of a right-handed screw of the carbon–oxygen bonds shows that the absolute configuration of (+)-**1** is (3*S*, 3′*S*, 4*S*, 4′*S*), which is in good agreement with the result of the X-ray crystal structure analysis.

In the previous paper[4] the absolute configuration of (+)-**1** has been reported to be (3*R*,3′*R*,4*R*, 4′*R*), which is the opposite of that indicated above. The erroneous conclusion would result from the mistaken assumption that the predominant conformation of the lactone rings of (+)-**1** is a *pseudo*-chiar form.

Experimental

Melting points were determined on a Laboratory Devices Mel-Temp apparatus and are uncorrected. The IR spectra were measured on a JASCO IRA-1 Spectrophotometer. The ^1H NMR and UV spectra were recorded on a Hitachi R-40 Spectrometer (90 MHz) and on a Hitachi Model 100-60 Spectrophotometer, respectively. The specific rotations were measured on a JASCO DIP-181 digital polarimeter. The HPLC analyses were carried out on a LiChrosorb SI-60 column (4×250 mm, 0.5 ml/min) using a UV detector (280 nm).

Materials. (±)-*Anti* head-to-head coumarin dimer (**1**) was prepared by the method described in the literature.[1] Optically active 1-phenylethylamine (Yamakawa Chemical Industrial Co. Ltd.) was used without purification.

*Synthesis and Separation of Diastereomeric Diamides (**2a** and **2b**).* To a solution of (±)-**1** (58.46 g, 0.20 mol) in dry dioxane (870 ml) was added (*S*)-(−)-1-phenylethylamine (48.47 g, 0.40 mol). On stirring the mixture at room tem-

perature, a white precipitate appeared gradually. After stirring for 12 h at the temperature, the precipitate was collected by filtration, washed thoroughly with dioxane (70 ml×2), and dried over P_2O_5 to give 42.29 g (79%) of one of diastereomeric diamides (**2a**): mp 237—238 °C; $[\alpha]_D^{21}$ −19.0° (*c* 0.50, 99% MeOH); IR (KBr) 3360, 3200, 1635, 1520, 1450, 750, and 695 cm^{-1}; ^{1}H NMR (DMSO-d_6) δ 1.26 (6H, d, *J*=7 Hz), 3.74 (2H, *pseudo* d, *J*=7 Hz), 4.5—4.9 (4H, m), 6.4—7.2 (18 H, m), 7.64 (2H, d, *J*=7 Hz), and 9.42 (2H, s).

Found: C, 76.54; H, 6.27; N, 5.17%. Calcd for $C_{34}H_{34}N_2O_4$: C, 76.38; H, 6.40; N, 5.23%.

The filtrate was concentrated to dryness under reduced pressure, and the residue was crystallized from acetone/methanol (1,500 ml/150 ml), giving 35.54 g (67%) of the other diastereomeric diamide (**2b**): mp 246—247 °C; $[\alpha]_D^{21}$ −177.3° (*c* 0.51, 99% MeOH); IR (KBr) 3360, 3200, 1630, 1520, 1445, 750, and 695 cm^{-1}; ^{1}H NMR (DMSO-d_6) δ 0.85 (6H, d, *J*=7 Hz), 3.72 (2H, *pseudo* d, *J*=7 Hz), 4.5—4.9 (4H, m), 6.6—7.3 (18H, m), 7.43 (2H, d, *J*=7 Hz), and 9.56 (2H, s).

Found: C, 76.66; H, 6.16; N, 5.19%. Calcd for $C_{34}H_{34}N_2O_4$: C, 76.38; H, 6.40; N, 5.23%.

The evaporation of the filtrate followed by crystallization from acetone/methanol (600 ml/60 ml) gave 7.66 g (14%) of **2b** as a second crop. The total yield of **2b** was 43.20 g (81%). The diastereomeric purities of **2a** and **2b** were found to be more than 99% on the basis of HPLC analysis (eluent: benzene/ethyl acetate=60/40 v/v).

*Hydrolysis and Relactonization of **2a** and **2b**.* The suspension of **2b** (5.35 g, 0.01 mol) in 99% ethanol/concd hydrochloric acid (100 ml/50 ml) was refluxed for 20 h to give a clear solution. After concentration, water (200 ml) was added to the residue and it was extracted with ethyl acetate (150 ml×3). The extracts were dried over anhydrous sodium sulfate and concentrated under reduced pressure. To the remaining oil acetic acid (150 ml) was added, and the solution refluxed for 20 h. After evaporation of the solvent to dryness, purification of the crude product by silica-gel chromatography (eluent: benzene then benzene/ethyl acetate=90/10 v/v) followed by recrystallization from ethyl acetate/hexane (60/40 v/v) gave 1.92 g (66%) of (−)-**1**: mp 168.5—169 °C; $[\alpha]_D^{21}$ −9.0°, $[\alpha]_{435}^{21}$ −65.8° (*c* 1.00, benzene); IR (KBr) 1760, 1490, 1450, 775, and 765 cm^{-1}; ^{1}H NMR (DMSO-d_6) δ 3.86 (4H, s) and 6.9—7.4 (8H, m).

Similar treatment of **2a** gave (+)-**1** in 64% yield: mp 168—169 °C; $[\alpha]_D^{21}$ +9.0°, $[\alpha]_{435}^{21}$ +66.0° (*c* 1.00, benzene); IR (KBr) 1760, 1490, 1450, 775, and 765 cm^{-1}; ^{1}H NMR (DMSO-d_6) δ 3.86 (4H, s) and 6.9—7.4 (8H, m).

The relactonization also proceeded in toluene in the presence of *p*-toluenesulfonic acid. A toluene solution (120 ml) of the crude product, obtained by the similar hydrolysis of **2a** (5.35 g, 0.01 mol), and *p*-toluenesulfonic acid (156 mg, 1 mmol) was refluxed for 48 h. After cooling, the mixture was washed with water (100 ml×2), dried over anhydrous sodium sulfate, and concentrated under reduced pressure. Chromatographic purification followed by recrystallization in a similar manner gave 1.48 g (51%) of (+)-**1**.

To determine the optical purities of (+)- and (−)-**1**, small quantities of the dimers were again converted into both lactone-ring-opened diamides by the reaction with (*S*)-(−)-1-phenylethylamine in dioxane; they were found to be almost optically pure since the HPLC analyses of the diamides derived from them showed the sole formation of **2a** or **2b**, respectively.

Optically active **1** melting at 193—193.5 °C was sometimes obtained, while its ^{1}H NMR spectrum, HPLC retention time, and $[\alpha]_D$ value were identical with those of optically active **1** melting at 168—169 °C.

X-Ray Crystal Structure Determination. Colorless plate-shaped crystals of (−)-**1** (mp 168.5—169 °C) were grown from an acetone solution by slow evaporation at room temperature. The space group was determined from Weissenberg photographs. The precise lattice constants and intensity data were derived from measurements on an Enraf-Nonius CAD-4 diffractometer with graphite-monochromated Cu-$K\alpha$ radiation. The specimen used was a fragment of a plate, 0.20×0.20×0.20 mm. The density was measured by the floatation method in a mixture of cyclohexane and carbon tetrachloride. All reflections within the range of $\theta<75°$ were collected by use of the $\omega-2\theta$ scan mode with variable scan rate from 1.43 to 5°/min, of which 1593 were greater than $3\sigma(|F_o|)$ and were used for structure determination. No correction was made for absorption. Crystallographic data of (−)-**1**: $C_{18}H_{12}O_4$, M.W. 292.3. Orthorhombic, $P2_12_12_1$, a=8.711(1), b=12.493(4), c=12.728(3) Å, V=1385.1 Å^3. Z=4, D_x=1.407, D_m=1.40 g/cm^3.

The structure was solved by the direct method and was refined by the block-diagonal least-squares method.[8] The final refinement including isotropic hydrogen atoms reduced the R value to 0.055.[9] Atomic scattering factors were taken from International Tables for X-Ray Crystallography (1974). The final atomic coordinates are given in Table 2.

To determine the absolute configuration of (−)-**1**, structure factors of all the Friedel pairs (hkl and $\overline{hkl}$) were calculated using the parameters in Table 2. Among them, ten Friedel pairs were selected manually in order of difference in the intensities, and their intensities were measured on the diffractometer under the same conditions as those of the data collection described above.

UV and CD Measurements. The UV spectrum of a solution of (+)-**1** in acetonitrile (1.00×10^{-4} mol dm^{-3}) was recorded on a Shimadzu UV-260 Spectrophotometer. The CD spectrum of a solution of (+)-**1** in acetonitrile (3.23×10^{-4} mol dm^{-3}) was measured on a JASCO J-500 Automatic Spectropolarimeter under the following conditions using a 1 mm quartz cell: sensitivity 2m° cm^{-1}; time constant 8 s; wave length expansion 5 nm cm^{-1}; chart speed 2 cm min^{-1}; integration time 8 times.

The CD spectra of solutions of (+)-**1** in acetonitrile (4.04×10^{-5}, 8.07×10^{-5}, 8.07×10^{-6} mol dm^{-3}) were also measured, giving similar results to that shown in Fig. 3.

The authors wish to thank Miss Junko Umezawa of the University of Tokyo for the preparation of optically active *anti* head-to-head coumarin dimers and Dr. Noriaki Hirayama at Tokyo Research Laboratories of Kyowa Hakko Kogyo Co. Ltd. for the X-ray data collection. This work was partially supported by a Grant-in-Aid for Scientific Research (No. 58550557) from the Ministry of Education, Science and Culture.

Optically Active *Anti* Head-to-head Coumarin Dimer. A New Agent for the Determination of Enantiomeric Excess of Amines and Alcohols

Kazuhiko SAIGO,* Kazuhiro SEKIMOTO, Noriyuki YONEZAWA, Fumio ISHII, and Masaki HASEGAWA

(Received October 11, 1984)

The enantiomeric excess of chiral amines was successfully determined by ^{1}H NMR spectral and/or HPLC analysis of the diastereomeric diamides derived from optically active *anti* head-to-head coumarin dimer and the amines by lactone-ring-opening reaction without any condensing agent. This procedure also proved to be applicable to chiral alcohols.

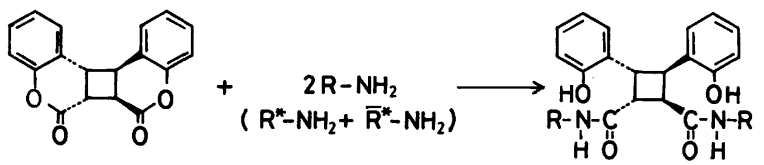
Methods for determining the enantiomeric excess of a chiral amine or alcohol include NMR spectral analysis using a chiral lanthanoid shift reagent[1] and chromatographic or NMR spectral analysis of a mixture of the diastereomeric amides or esters obtained by the reaction of an amine or alcohol with an optically active derivatizing agent such as 2-methoxy-2-phenyl-2-(trifluoromethyl)acetic acid,[2] 1-(1-naphthyl)ethyl isocyanate,[3] and 2-[1-(9-anthryl)-2,2,2-trifluoroethoxy] acetic acid.[4] The latter method gives more accurate values than the former and is applicable to the chromatographic separation of the diastereomers. The former method is more convenient and advantageous in the recovery of the amine or alcohol.

In the previous paper[5] it was shown that *anti* head-to-head coumarin dimer can be easily resolved into pure enantiomers by fractional crystallization of the lactone-ring-opened diastereomeric diamides with (*S*)-(−)-1-phenylethylamine followed by hydrolysis and relactonization. The optically active dimer reacts with two molar equivalents of (*S*)-(−)-1-phenylethylamine to give the corresponding diamides, which are diastereomeric and thus show different chemical shifts in the ^{1}H NMR spectra and retention time in HPLC. Accordingly, the optically active dimer was considered to be useful as a chiral derivatizing agent. We report here the use of the optically active dimer in the determination of the enantiomeric excess of a chiral amine or alcohol on the basis of ^{1}H NMR spectral and/or HPLC analysis.

Results and Discussion

The reaction of (*R,R,R,R*)-(−)$_{589}$-*anti* head-to-head coumarin dimer ((−)-**1**) with two molar equivalents of a racemic primary amine (**2**) at 60 °C for 3 h was effected smoothly to give a mixture of three diastereomeric diamides (**3**, **4**, and **5**) in high yield. For example, when 1-phenylethylamine (**2a**) was used as the racemic amine substrate, a mixture of diastereomeric diamides (**3a**, **4a**, and **5a**) was obtained in 99% yield. The diastereomer distribution was based on the ^{1}H NMR spectral data. The methyl proton signals of the diastereomer mixture appeared at two isolated magnetic fields, δ 0.7—1.0 ppm (one doublet) and δ 1.1—1.4 ppm (two doublets), and the area ratio of these two distinct regions was 1:1 as shown in Fig. 1. On the basis of the chemical shifts of methyl protons of **3a** and the enantiomer of **5a** as reported in our previous paper,[5] it is concluded that the methyl proton signal of **3a** appeared at a higher magnetic field than that of **5a** by virtue of the shielding by the cis-oriented hydroxyphenyl group. The two methyl proton signals arising from (*S*)- and (*R*)-1-phenylethylamino moieties in **4a** might be observed in almost the same regions of the magnetic field as those in **3a** and **5a**, respectively. Similarly, methyl proton signals were observed in two regions with an area ratio of 1:1 when either 1-(4-isopropylphenyl)ethylamine (**2b**), 1-phenylpropylamine (**2c**), *s*-butylamine (**2d**), norephedrine (**2e**), or 2-amino-1-butanol (**2f**) were employed as the primary amine substrate. The results from the synthesis of diastereomer mixtures and the chemical shifts of their methyl proton signals are shown in Table 1.

For amino alcohols such as **2e** and **2f**, the preferred reaction of the amino functions with **1** was established



1 (*R,R,R,R*) **2** **3**: R*-(*R,R,R,R*)-R̄* **4**: R̄*-(*R,R,R,R*)-R* **5**: R̄*-(*R,R,R,R*)-R̄*

by the exclusive formation of diastereomeric diamides, and no ester formation was detected in their IR spectra. The low reactivity of the alcohol under these conditions was confirmed by the separate reactions of (−)-**1** with methanol and ethanol, which gave no esters and resulted in the quantitative recovery of (−)-**1**. The versatility of **1** as an optically active derivatizing agent is enhanced by the observation that the β-methyl protons in the amine having an α-asymmetric carbon such as **2c** and **2f** are also shielded by the cis-oriented hydroxyphenyl group, yielding methyl proton signals of the diastereomer mixtures in two distinct regions. Moreover, it is advantageous that the amide formation requires no condensing agent.

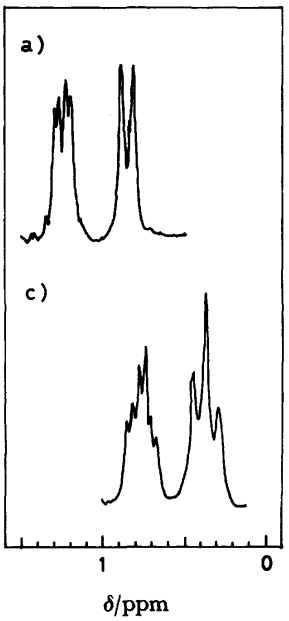


Fig. 1. ^{1}H NMR spectra of methyl protons of diastereomeric diamide mixtures: a) of **3a**, **4a**, and **5a**; c) **3c**, **4c**, and **5c**.

The HPLC of the diastereomer mixture (**3**, **4**, and **5**) showed three base-line separated peaks. Typical examples are shown in Fig. 2. The area ratio of **3a**, **4a**, and **5a** obtained from (−)-**1** and racemic **2a** was 25.4:49.7:24.9, giving the enantiomer ratio of 50.3:49.7. Moreover, the HPLC analysis of minus-enantiomer-enriched **2a** (49.4% optical purity based on its specific rotation) showed the area ratio of 56.7:40.4:2.9, representing 53.8% of enantiomeric excess. The ratios are in good agreement with those predicted. Similarly, the distribution of **3**, **4**, and **5**

Table 2. HPLC of diastereomeric diamide mixture (**3**, **4**, and **5**)

Diamide	Retention Time/min			Area ratio/%			Eluent
a	13.9	17.7	38.4	25.4	49.7	24.9	C_6H_6/AcOEt = 60/40
b	12.1	15.9	47.3	26.0	48.3	25.7	70/30
c	43.8	62.1	126.4	23.9	53.7	22.4	80/20
d	22.6	28.3	39.4	24.9	50.4	24.7	50/50
e	32.8	41.5	52.3	22.6	52.0	25.4	50/50
f	14.2	19.3	35.6	24.9	47.1	28.0	MeOH/AcOEt = 8/92

prepared from **2b—2f** was in nearly 1:2:1 area ratio as shown in Table 2. These results indicate that the HPLC analysis of the diastereomeric diamides prepared from optically active **1** and a given chiral amine is also useful for the determination of enantiomeric excess of the amine. No measurable kinetic resolution was considered to occur during the course of the ring-opening reaction since the reactions of racemic **1** with racemic amines (**2a—2f**) gave the corresponding diastereomer mixtures in high yields and in the area ratio of 1:2:1 as determined by HPLC.

The HPLC of the reaction mixture of (−)-**1** and **2a**, obtained without work-up, also showed three peaks of **3a**, **4a**, and **5a** in the area ratio of nearly 1:2:1. Small peaks due to impurities in different regions from the main peaks were also noted. The result indicates that the work-up is not always necessary for the HPLC analysis.

The reaction of **1** with an alcohol was reexamined to see if **1** can also be used as an optically active derivatizing agent for alcohols, since the reaction did not take place under the conditions of 60 °C for 3 h as mentioned above. After some elaboration, two equimolar amounts of lithium alcoholate were found to effect the reaction smoothly with (−)-**1** at room temperature to give a mixture of three diastereomeric esters (**7**, **8**, and **9**) in good yield. In the case of the diastereomeric diesters derived from alcohols having an α-asymmetric carbon and an α-methyl such as 1-phenylethanol (**6a**) and 2-butanol (**6b**), the methyl proton signals were also observed at two regions in the area ratio of 1:1 in their ^{1}H NMR spectra, respectively. However those of the diastereomer mixture obtained from 2-phenyl-1-propanol (**6c**) having a β-asymmetric carbon and a β-methyl were observed with difficulty in almost the same region. HPLC analysis of the diastereomer mixtures, obtained not only with **6a** and **6b** but also with **6c** gave satisfactory results. In all cases, three peaks were observed with base-line separation, and the area ratios of the peaks approximated to 1:2:1. The results are shown in Tables 3 and 4.

Table 3. Yield and chemical shifts of diastereomeric diester mixture (**7**, **8**, and **9**)

6a	99	0.83	1.21	1.23
6b	99	0.52	0.97	
6c	99	1.01		

Experimental

The ^{1}H NMR and IR spectra were recorded on a Hitachi R-40 Spectrometer (90 MHz) and a JASCO IRA-1 Spectrophotometer, respectively. The HPLC analyses were carried out on a LiChrosorb SI-60 column (4×250 mm) under the conditions of 70 kg/cm^2 and 0.5 ml/min using a Shimadzu SPD-2A UV detector (280 or 285 nm).

Materials. Optically active coumarin dimer (**1**) was prepared by the method reported in the previous paper.[5] The racemic amines (**2a—2d** and **2f**) were dried overnight with NaOH pellets and distilled carefully under an argon atmosphere or under reduced pressure in the presence of NaOH pellets. Norephedrine (**2e**) was regenerated from its hydrochloric acid salt, dried overnight, and used without recrystallization. The alcohols (**6a—6c**) were predried with molecular sieves 3A for 1 d and distilled before use.

General Procedure for the Preparation of Diastereomeric Diamide Mixture. A mixture of (−)-**1** (1.0 mmol) and the racemic amine (2.0 mmol) in dry dioxane (4.5 ml) was warmed at 60 °C for 3 h under an argon atmosphere. The residue, left after evaporation of the solvent, was dissolved in chloroform or ethyl acetate (150—200 ml) and washed successively with 1 M HCl solution (50 ml×2, 1 M=1 mol dm^{-3}), 4% $NaHCO_3$ solution (50 ml), and sat. NaCl solution (50 ml). After drying over anhydrous Na_2SO_4, evaporation of the solvent followed by drying under reduced pressure at about 45 °C for 1 d gave a mixture of three diastereomeric diamides (**3**, **4**, and **5**).

General Procedure for the Preparation of Diastereomeric Diester Mixture. To a solution of the alcohol (2.0 mmol) in dry dioxane (4 ml) was added a hexane solution of butyllithium (2.1 mmol) on cooling, and the mixture was stirred at room temperature for 1 h. A solution of (−)-**1** (1.0 mmol) in dry dioxane (4 ml) was added at room temperature dropwise during a period of 20 min. After stirring at the temperature for 24 h, the solvent was removed under reduced pressure. The remaining residue was dissolved in ethyl acetate (100 ml), washed successively with 0.2 M HCl solution (15 ml) and water (50 ml), and dried over anhydrous Na_2SO_4. Evaporation of the solvent to dryness gave the corresponding mixture of diastereomeric diesters (**7**, **8**, and **9**).

Determination of Formal Potentials of Multihemoprotein, Cytochrome c_3 by ^{1}H Nuclear Magnetic Resonance

Keisaku KIMURA,* Shinsuke NAKAJIMA,† Katsumi NIKI,† and Hiroo INOKUCHI
Institute for Molecular Science, Myodaiji, Okazaki 444
†*Department of Electrochemistry, Yokohama National University, Tokiwadai, Hodogaya-ku, Yokohama 240*
(Received November 2, 1984)

Macroscopic redox potentials of tetrahemoprotein, cytochrome c_3 from *D.* vulgaris, Miyazaki strain, were derived from 400 MHz ^{1}H NMR measurements. The formal potential, $E_1^{\circ\prime}$, was determined to be -0.245 ± 0.005 V *vs.* NHE compared with a value of -0.240 V obtained electrochemically. The distributions of the intermediate states from the NMR spectra during a redox titration are in good agreement with those previously determined by electrochemistry.

Cytochrome c_3 (cyt. c_3) has four hemes within a single polypeptide chain and functions as an electron carrier in the sulfate reducing bacteria, *Desulfovibrio vulgaris*. The oxidoreduction of cyt. c_3 is regulated by the catalytic action of hydrogenase, an iron-sulfur enzyme. The physicochemical properties of the cyt. c_3 have been well studied by Mössbauer spectroscopy,[1] photoelectron spectroscopy,[2] electrical conductivity,[3] electrochemical methods,[4,5] ESR,[6] and NMR.[7] These studies have revealed that this protein has unusual properties such as a very low ionization potential, high electrical conductivity, and a rapid and reversible redox reaction owing to its multiheme structure. It also has been suggested that the redox potentials of the hemes are connected with these properties.

The macroscopic redox potentials of this multihemeprotein derived from 400 MHz ^{1}H NMR measurements are reported. These potentials have previously been obtained by the simulation of the differential pulse voltammetric response during redox titrations. The redox potential, E, of cyt. c_3 is defined by

$$E = E^{\circ\prime}_{i+1} + (RT/F)\ln[f_i]/[f_{i+1}] \quad (1)$$

where $E^{\circ\prime}_{i+1}$ is the macroscopic formal potential for the $f_i \rightleftharpoons f_{i+1}$ equilibrium and where f_i is the ith oxidation state as shown in Fig. 1. It should be noted in this figure that there is an unity (one electron) difference for each oxidation state. There are five states corresponding to n=0, 1, 2, 3, and 4 electrons (designated by f_0 to f_4) while states f_1—f_3 can have multiplicities arising from the multicomponent electron sites.

Experimental

D. vulgaris cyt. c_3 was purified by a method previously reported.[8] The purity index $[A_{552}(Fe^{2+})/A_{280}(Fe^{3+})]$ was 3.0. The protein was lyophilized twice from 99.95% D_2O. Hydrogenase was also purified according to the method described by Yagi *et al.*[9] The lyophilized powder of cyt. c_3 and a trace amount of deuterized hydrogenase were dissolved into the deuterized phosphate buffer solution (pD=7.0), giving a final cyt. c_3 concentration of 5 mM (1 M=1 mol m^{-3}). The pD values were measured by a pH meter. The NMR spectra were recorded and analyzed using a JEOL GX 400 spectrometer. After measurements on the ferricytochrome c_3, it was reduced to the ferro-form by hydrogen. The samples of various intermediate oxidation states were prepared by the reoxidation of the fully reduced sample with air. All measurements were conducted at (25±0.5) °C, and the chemical shifts were quoted in part per million, down field from sodium 3-(trimethylsilyl) propionate-2,2,3,3-d_4(TSS).

The optical absorption spectra of the *ca.* 0.1 mM cyt. c_3 of an intermediate oxidation state were measured in the NMR tube before and after NMR measurement. We confirmed that there were no significant differences in the optical spectra taken before and after NMR measurement. In the case of the 0.1 mM cyt. c_3 solution, the number of accumulation of free induction decay was 10,000 in order to increase the signal to noise ratio. However, this acquisition number was still not large enough for a good signal to noise ratio and a smoothing technique was used to analyze the NMR lineshape.

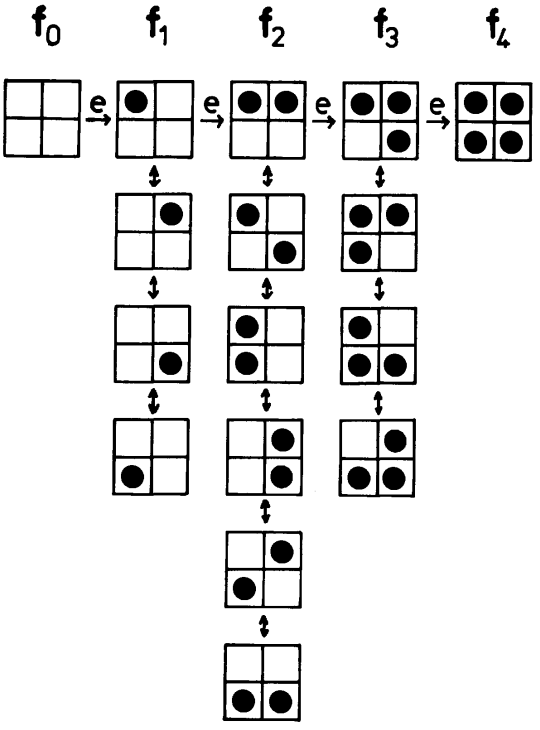

Fig. 1. Microscopic oxidation states of cyt. c_3. Solid circles indicate the reduced sites. f_0—f_4 indicate macroscopic oxidation states.

Results and Discussion

Figure 2 shows the NMR spectra in the lower field region for a redox titration of cyt. c_3. The sharp singlet peaks (A—P) with three-proton intensity in the region of 31—8 ppm were assigned to the heme methyl resonances of the f_0 state.[7,10] As the amount of reduction is incrementally increased, (spectra # 1—9 in Fig. 2) new peaks are seen to appear at the expense of the f_0 intensity. The height of all f_0 peaks decreased simultaneously. This is due to the fact that the intramolecular electron-exchange rate of cyt. c_3 is so rapid on the NMR time scale that the microscopic states in each intermediate oxidation state, f_1, f_2, and f_3, are indistinguishable, so it is the average fraction of each intermediate state that is determined by the NMR. From the intensity of five well-isolated peaks (A,B,C,F,I), the reduction ratio of the f_0 state was obtained. The new peaks that appeared at 27.7, 20.0, 19.55, and 18.0 ppm were assigned to f_1, and those at 15.36, 14.1, and 13.8 ppm were assigned to f_2. The assignment was done by the saturation transfer method.[7]

From the peak area of each of the oxidation states, one can calculate the fractions of the f_0, f_1, and f_2 states. The macroscopic formal potential, $E_1^{\circ\prime}$ for the equilibrium between f_0 and f_1, can be determined from the ratio of the f_0 state to the f_1 state and was estimated to be (-0.245 ± 0.005) V, which is in good agreement with that determined by the electrochemical method, -0.239 V, in D_2O. Similarly, one can calculate the macroscopic formal potentials of the intermediate states from the fraction of each intermediate state.

The macroscopic formal potentials of cyt. c_3 from *D. vulgaris* determined by electrochemical method in both H_2O and D_2O are given in Table 1. On the basis of the macroscopic formal potentials given in Table 1, we can calculate the relative concentrations of the five redox states defined in Fig. 1 as a function of the electrochemical potential as shown in Fig. 3. In the upper part of this figure, arrows designate the points at which UV and redox titration measurements were conducted. At the bottom of the figure, the four macroscopic formal potentials are shown. The broken line indicates the average fraction of the ferri-heme in cyt. c_3, which is observed by optical absorption spectroscopy. The ratios, f_1/f_0 and f_2/f_0, calculated from

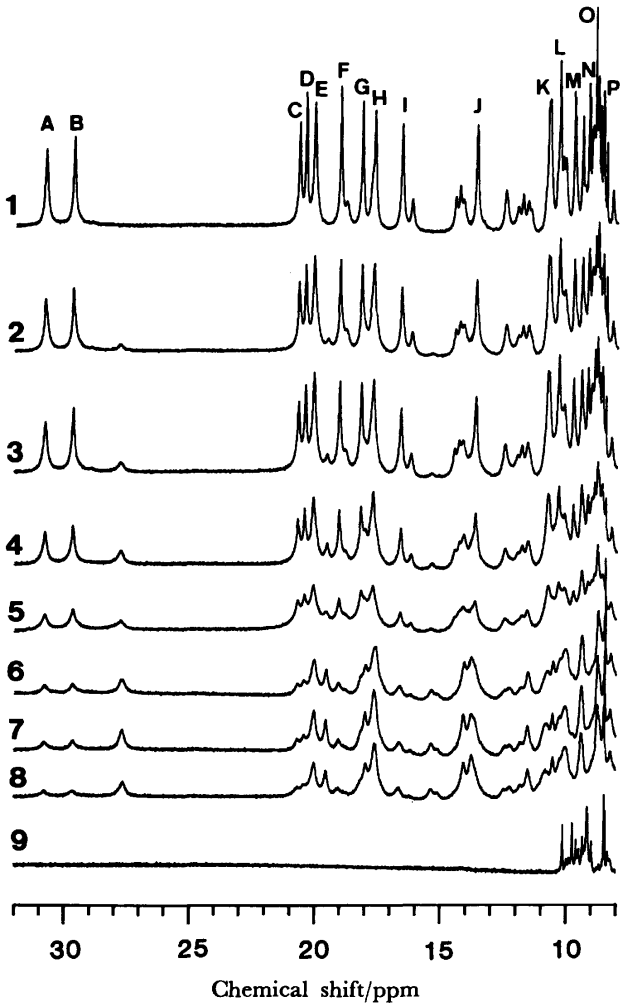

Fig. 2. NMR spectra for a redox titration of cyt. c_3 recorded on a 400 MHz NMR: spectrum (1) is fully oxidized cytochrome c_3, (2) $f_0=0.94$, (3) $=0.93$, (4)$=0.665$, (5)$=0.42$, (6)$=0.22$, (7)$=0.16$, (8)$=0.10$, and (9) is fully reduced cyt. c_3.

Table 1. Macroscopic formal potentials of cytochrome c_3, *D. vulgaris*, Miyazaki strain (V *vs.* NHE)

	in D_2O (pD=7.1)	in H_2O (pH=7.1)
$E_1^{\circ\prime}$	−0.239	−0.240
$E_2^{\circ\prime}$	−0.293	−0.297
$E_3^{\circ\prime}$	−0.310	−0.315
$E_4^{\circ\prime}$	−0.352	−0.357

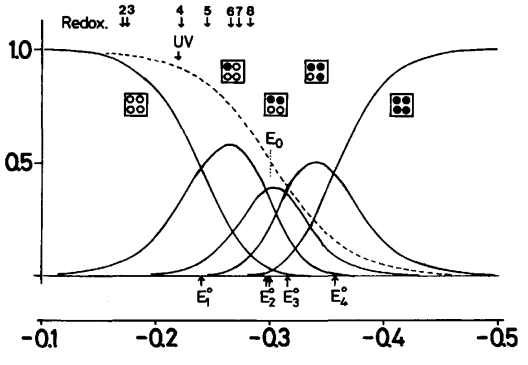

Fig. 3. Population of five macroscopic oxidation states calculated from the electrochemical data as a function of electrochemical potentials. Arrows on the top of the figure designate the intermediate oxidation states (2) to (8) shown in Fig. 2.

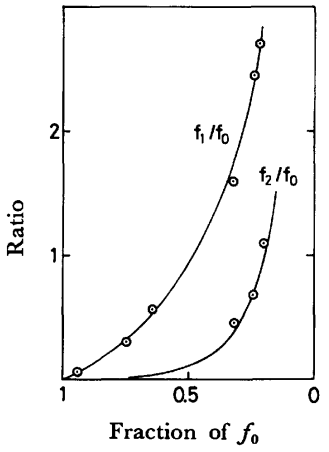

Fig. 4. The f_1/f_0 and f_2/f_0, as a function of the fraction of the f_0 state. Open circles are calculated from NMR data; solid lines, from electrochemical data.

the NMR data (open circles) and those from the data shown in Fig. 3 (solid lines) are plotted in Fig. 4 as a function of the fraction of the f_0 state. The NMR data fit well with the curve calculated from electrochemical methods. These results strongly suggest that the four macroscopic formal potentials of the cyt. c_3 are a unique set of formal potentials. The well resolved spectra in the present study gave the rigid foundation to assign the absorption lines, many of which were compatible with the early work.[7] Based upon their poorly resolved spectra.[11] Santos *et al.* derived four redox potentials of *D.* gigas which were quite different from the present study.

With respect to the reaction scheme between the microscopic states as shown in Fig. 1, we should emphasize that the intramolecular and intermolecular electron exchange rates and the microscopic formal potentials of cyt. c_3 must be studied. Further NMR studies are now in progress.

This work was supported by Grant-in-Aid for Special Project Research from the Ministry of Education, Science and Culture of Japan (No. 57102011) for which the authors would like to express their sincere thanks. Many useful discussions with Professor Ted Kuwana and Mrs. Jane Kuwana are greatefully acknowledged. The authors wish to acknowledge the kindly supply of sulfate reducing bacteria by Ajinomoto Co. as well as their continuous interest and help.

Reaction of Leucocrystal Violet with Tetracyanoethylene and Chloranil II.[1] Solvent Effects

Norio NISHIMURA* and Takushi MOTOYAMA
Department of Chemistry, School of Science, Okayama University, Tsushima, Okayama 700
(Received July 2, 1984)

The proton/deuteron transfer reaction of Leucocrystal Violet(LCV) with tetracyanoethylene(TCNE) and chloranil(CA) in various solvents has been followed spectrophotometrically. It was found that the reaction proceeds slower in polar solvents such as acetonitrile and acetone than in less polar solvents such as chloroform and 1,2-dichloroethane. The rate is remarkably accelerated by pressure indicating probably a substantial polarity increase in the rate processes. The formation of CT complexes was observed at low temperatures. Their nature is presumed to be similar to that of a complex formed by the reaction of CA with *N,N*-dimethyl-*p*-toluidine(DMT), and the latter is discussed in connection with the reaction rate of the LCV–TCNE and LCV–CA systems. A possible reaction path is proposed.

In a previous paper,[1] the rate of reaction of Leucocrystal Violet(LCV) with tetracyanoethylene(TCNE) and chloranil(CA), and the kinetic pressure and isotope effects were reported. For both reaction systems, it was found that the reaction follows the second-order rate law: first-order with respect to each reactant. In the LCV–CA system, a very large kinetic isotope effect ($k_H/k_D \approx 11$) was observed suggesting that the so-called proton tunneling is involved, while in the LCV–TCNE system, it was not so large ($k_H/k_D \approx 5$). From large kinetic pressure effects, it was suggested that the reaction proceeds *via* very polar transition states for both reactions. At low temperatures, the formation of CT complexes in equilibrium with the reactants was observed. From the above findings, the following alternative reaction schemes have been proposed:

$$\mathrm{LCV} + \mathrm{CA(TCNE)} \rightleftarrows \mathrm{X_1} \rightleftarrows \mathrm{X_2}$$
$$\mathrm{X_1\ or\ X_2} \xrightarrow{\text{slow}} \mathrm{CV^+} + \cdots\cdots$$

polar solvents. The rate is, however, faster in less polar solvents than in more polar solvents. The second notable point is the solvent dependency of the kinetic isotope effect. According to Isaacs *et al.*[3] and Sugimoto *et al.*,[4] if the atom (H or D) being transferred is strongly coupled with solvent molecules, the probability of tunneling will diminish, because the effective mass of the proton and deuteron should increase. In Scheme 2, a highly polarized transition state was assumed[1] in accordance with the large negative $\Delta V^{\neq}$-values. Substantial solvent effects on the ratio k_H/k_D can be expected in this case. However, the ratios are almost independent of solvent polarity.

TABLE 1. RATE CONSTANTS FOR THE REACTION BETWEEN LEUCOCRYSTAL VIOLET AND CHLORANIL AT 25 °C

Solvent	k_H	k_D	k_H/k_D
	10^{-2} dm^3 mol^{-1} s^{-1}	10^{-2} dm^3 mol^{-1} s^{-1}	
CH_3CN	11.0	1.01	10.9
CH_3COCH_3	5.28	0.502	10.5

CH_2Cl_2	25.6	2.31	11.1
$CHCl_3$	31.0	2.67	11.6
CH_3CCl_3	21.5	1.82	11.8

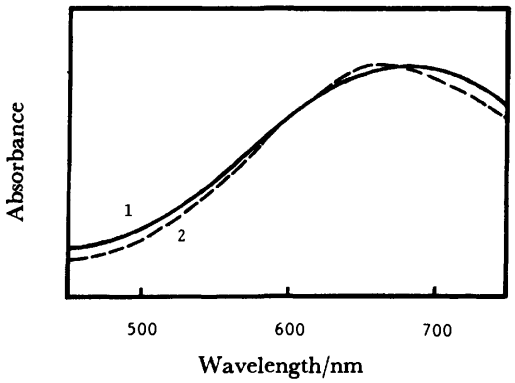

Fig. 3. Absorption spectra of the CT band appeared in the LCV+CA (1) and DMT+CA (2) systems; in EPA, 77K.

These two remarkable points have led us to the question about the single-step hydride ion shift mechanism[3] (Scheme 2). On the other hand, if Scheme 1 is the case, information about X_1 and X_2 is required. As reported previously, the formation of the outer CT complex between LCV and CA was observed at temperatures as low as below −50 °C, as identified by its characteristic spectrum. This made the spectrophotometric measurement of the CT band and hence, the assessment of the equilibrium constant in various solvents difficult. However, the CT band is very similar to that observed in the DMT-CA system (Fig. 3), as can be expected from the structural similarity between LCV and DMT. Hence, X_3 will not be so bad a model for X_1. We expected that informations about X_3 might shed light on the reaction mechanism we are interested in.

Table 2 shows the CT band of X_3 in various solvents. In Fig. 4, $\bar{\nu}_{max}$ is plotted against the E_T-value of the solvents. It appears that the plots can be divided into two groups: Group A containing an electronegative oxygen or nitrogen atom within a molecule, and Group B belonging to the other kind. Since CT complexes are more polar in the excited state than in the ground state, the red shift of the CT band can be expected. For Group A, however, $\bar{\nu}_{max}$ is scarcely sensitive to the solvent polarity parameters such as the E_T-value and Brownstein's *S*-value. Aihara *et al.*[5] investigated Aromatic-TCNE complexes in vari-

ous solvents and interpreted the spectral shift in terms of McRae's formula. They found that a series of solvents except for oxygen-containing solvents behave normally, and suggested that these solvents might change the nature of complexes. Relevant discussion will be made later.

In Fig. 5, ln k_H is plotted, on trial, against $\bar{\nu}_{max}$ in Table 2. It appears that there exists an affirmative correlation in spite of the fact that solvents are classified into two groups. Further, the equilibrium constants for the formation of X_3 in various solvents were estimated by means of the Benesi-Hildebrand plot (Fig. 6), and the results are given in Table 3. In Fig. 7, k_H is plotted against K, giving a fair correlation.

In Scheme 1, the reaction proceeds *via* X_1 and therefore, the equilibrium constant must be involved in the numerator of the second-order rate constant expressed in a composite form. If the values of the equilibrium constant for DMT-CA system in the solvents we used are related to those for LCV-CA system, this may be responsible for the above finding. On the other hand, the existence of the equilibria in Scheme 2 must scarcely affect the rate, since the equilibrium constant for the LCV-CA system must be small at the vicinity of room temperature(*vide supra*). Although the situation has not been clarified sufficiently, the above observations and considerations support the involvement of X_1 in the reaction process.

LCV-TCNE System. In the preceding paper, we reported the pressure dependence of the rate constant for this system. In order to examine the pressure effects in polar solvents, acetonitrile was chosen as representative, and the rate was followed under high pressures. The results are given in Table 4. The rate

was also followed in various solvents under atmospheric pressure, and the results are given in Table 5, together with the activation parameters. By inspection of these data, we notice some points. (1) The application of external pressure remarkably accelerates the rate in acetonitrile as well as in chloroform. It is generally accepted that a large polarity increase of reacting species gives rise to a large volume shrinkage of surrounding solvent molecules as exemplified by the pressure effect on the rate. It appears that during the course of reaction from the initial to the transition state, there exists a step in which a large polarity increase is involved. When we remember that the products in our systems are ionic ones, this presumption may be accepted. (2) The kinetic isotope effect(k_H/k_D) in acetonitrile is a little smaller than that in chloroform. This might be ascribed to the solvent-coupled proton transfer as stated above. The isotope effect is far smaller than that in the LCV–CA system. Therefore, the proton tunneling would, if any, be very small. (3) Much more remarkable kinetic solvent effects are observed in this system than in the LCV–CA system, *i.e.*, in polar solvents the rate is reduced greatly and the activation energy increased. This is apparently inconsistent with the fact stated in (1) by the reason explained in the previous section.

In this respect, we considered that the kinetic study in binary mixtures might afford useful informations about the solvent effect. Kondo *et al.*[6] have developed a theory of bimolecular reactions in binary mixed solvents 1 and 4. If one of the reactants is solvated by, say, 4, to form a kind of addition product, the simplified rate equation can be given by

$$\ln k_{mix} = x_1 \ln k_1 + x_4 \ln k_4 + x_4 \ln(K_x+1) - \ln(x_4 K_x + 1)$$

where K_x denotes the association constant expressed in terms of mole fractions for the formation of the addition product; x_1 and x_4 are the mole fractions of 1 and 4, respectively. This equation predicts that the ln k_{mix} *versus* x_1 plot should deviate downward from a straight line expected for ideal binary mixed solvents, the extent of the deviation depending on the value of K_x. On the other hand, according to the theory, if none of the reactants are solvated, but the activated complex is solvated, with one of the solvents, the upward deviation can be expected. In Table 6, the rate constants in chloroform–acetonitrile mixtures are given. By using these data, ln k_{mix} is plotted against the mole fraction of chloroform as shown in Fig. 8. It is seen that the plots constitute a curve shifted downward from the ideal line. Previously,[7] we reported that this type of curve was realized in the reaction of 2,2-diphenyl-1-picrylhydrazyl with phenols in dioxane–2,2,4-trimethylpentane, and cyclohexane–acetone mixed solvents. In that case, a special interaction through hydrogen bonding between phenols and the oxygen-containing solvents was assumed. Marrifield and Philipps reported[8] that the equilibrium constant for the π-complex formation between TCNE and various kinds of aromatic compounds is remarkably affected by variation of the solvent. According to them, this effect is due to the formation of a complex between TCNE and the solvent, as exemplified by a new weak band at 335 nm when TCNE is dissolved in diethyl ether. Although, owing to the experimental difficulties, conclusive evidence for the formation of

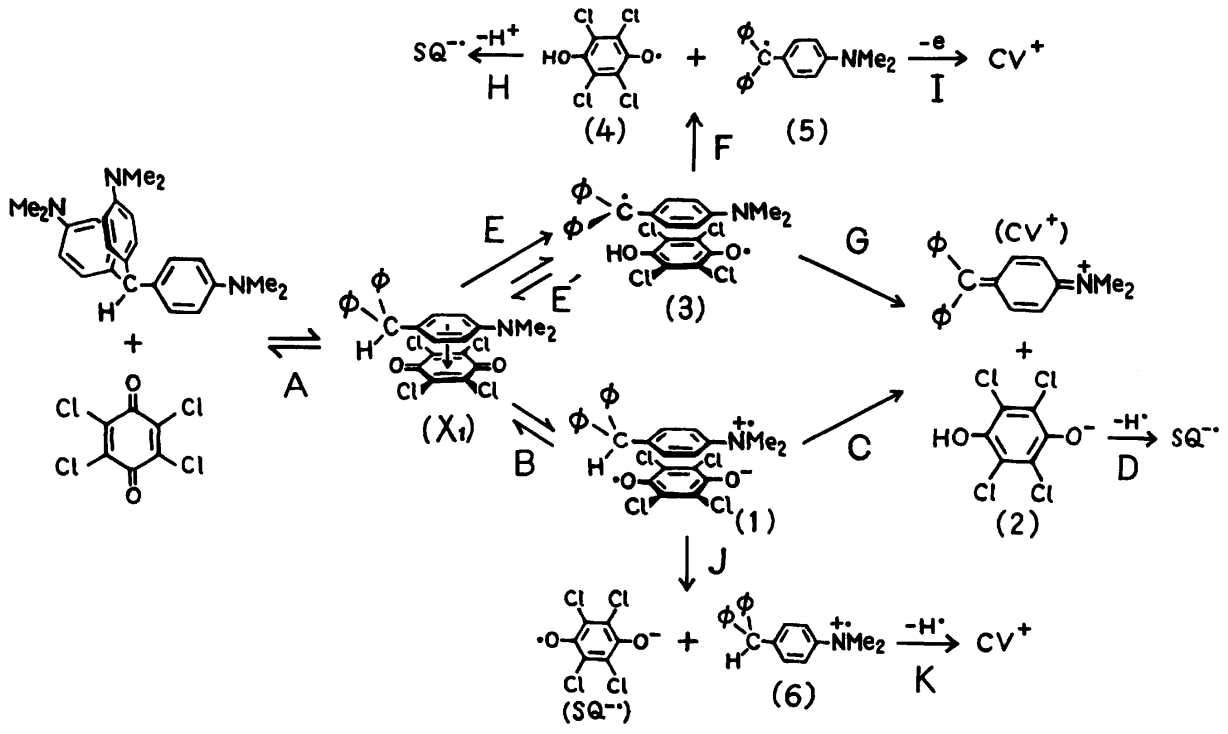
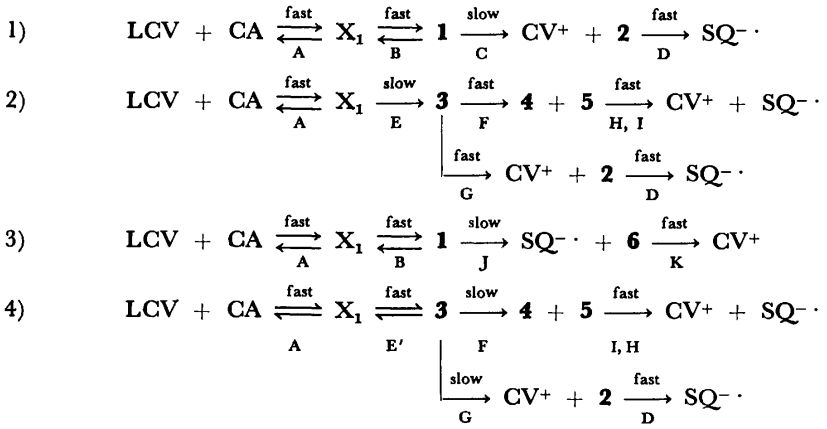
such TCNE/solvent complexes has not been obtained yet in the solvent we used, a special interaction between TCNE(CA) and the solvents belonging to Group A may be assumed to exist. The interaction with the TCNE as a reactant must be the greatest, intermediate with the TCNE in the ground CT complex, and the smallest with the TCNE in the excited CT complex, since the interaction between TCNE and LCV must increase in this order. If this is the case, the reactivity of "solvated" TCNE will diminish and this may be responsible for the decreased rate of reaction, the enhanced activation energy, the blue shift of the CT band of X_3 in acetonitrile and acetone, and the kinetic behavior in the binary mixtures.

Reaction Mechanism From the point of view of the kinetic solvent effects, and the correlation of the rate of reaction with the nature of X_3 chosen as a model of X_1, it may be concluded that the reaction proceeds probably *via* X_1. Although the processes thereafter have not necessarily been fully elucidated, we could presume probable reaction routes on the basis of the informations obtained so far: The second-order kinetics and simultaneous formation of CV^+ and semiquinone anion radicals and available informations on reactions which proceed through inner and outer CT complexes.[9–13] The following chart for the LCV–CA system may be proposed:



In accordance with this chart, the possible reaction routes are summarized as follows:



Of these reaction paths, the kinetic isotope effect precludes the possibility of 3) and 4), since proton transfer is not involved in the rate-determining steps. The volume change in Step A may be 0—−14 cm³/mol observed for most cases for the formation of CT complexes.[14] The volume change in step E in which hydrogen atom transfer is involved, will be no more than few cm³. Hence, the large negative value of $\Delta V^{\neq}$ obtained for our systems could eliminate the possibility of 2). We have noticed that X_3 decomposes gradually to produce $SQ^{-\cdot}$ in polar solvents, suggesting the existence of **1** instead of **3**. In the remaining possibility 1), Step C is assumed to be the rate-determining one. Proton transfer is involved in this step and this is in accord with the observed large isotope effect. A remarkable volume change can be expected in Step B where electron transfer is involved, and this is responsible for the large kinetic pressure effect. We have observed the correlation between $\ln k_H$ and $\bar{\nu}_{max}$. It could be assumed that $\bar{\nu}_{max}$ is proportional to the energy difference between **1** and X_1. As for the kinetic isotope effect, we consider as follows. Owing to the bulkiness of CA skeleton, the hydrogen atom being transferred is blocked from the surrounding solvent molecules. The effective mass of the hydrogen (and deuteron) is then not affected substantially by solvent polarity, thus accounting for the constant k_H/k_D-value in various solvents. This is in accord with the appreciable tunneling effect, too. In the LCV-TCNE system, the ratio is considerably smaller, and the tunneling effect, if any, so small. We tentatively consider that the difference would arise from the difference in the ability of protecting the hydrogen atom from the surrounding solvent molecules during its transfer. We conclude that the reactions of LCV-CA and LCV-TCNE systems probably proceed *via* Route 1).

Calorimetric Investigation of *N*-Acyl Amino Acids

Shigeyoshi MIYAGISHI,* Seiichi MATSUMURA, Kazuhiko MURATA, Tsuyoshi ASAKAWA, and Morie NISHIDA

Department of Industrial Chemistry, Faculty of Technology, Kanazawa University, Kanazawa 920

(Received September 12, 1984)

The melting characteristics of *N*-acyl amino acids were examined using a differential scanning calorimeter (DSC). The melting-point temperature of *N*-dodecanoyl L-amino acid increased with the size of its amino acid residue, while the order was opposite for the DL-amino acids. The racemic derivatives formed racemic compounds in their solid states. Each *N*-dodecanoyl L-amino acid had a larger enthalpy and entropy-of-fusion than its racemic isomer. Differences in the thermodynamic quantities between the optically active and racemic isomers were larger for *N*-dodecanoylvaline and -leucine compared with those of *N*-dodecanoylalanine. A mixture of these molecules were also studied. Each racemic isomer of *N*-dodecanoylalanine and -leucine partly formed a racemic pair in the liquid state.

Attention is presently being given to the stereochemical effects not only of micelle-catalyzed reactions but also to condensed systems of long hydrocarbon chain compounds. Tachibana and his coworkers[1-4] have investigated chiral and racemic 12-hydroxyoctadecanoic acids in their crystal aggregate and monolayer states. Iwahashi, *et al.*[5] studied the thermodynamic and structual relationship between optically active α-monostearin and its racemic isomer in their crystalline, molten, and dissolved states. They suggested that (*R*)- and (*S*)-molecules in the (*RS*)-form interacted to form a racemic pair not only in the crystalline state, but also in the molten state. Miyagishi and Nishida[6] reported that the smaller critical micelle concentration for a sodium salt of the optically active *N*-acyl amino acid resulted from a difference in the micellization enthalpy. The object of this paper is to describe the chirality effect on the melting characteristics of *N*-acyl amino acids.

Experimental

N-Acyl amino acids were prepared according to a procedure described before[6,7] and are tabulated in Table 1. The recrystallization of *N*-acyl amino acids was repeated until the DSC curve and a peak temperature became constant. A differential scanning calorimeter (Daini Seikosha DSC, model SSC/560S) was used for the measurement of the heat-of-fusion and melting temperature. A sample (about 5 mg) was sealed in an aluminium vessel (50 mm^3). The scanning rate was 5 K min^{-1}. Standard samples of phenanthrene and indium were used for calibration. A mixed sample was prepared as follows. A mixture of a known composition was dissolved in methanol and the resulting solution was allowed to stand for several hours. After the methanol was evaporated, a part of the mixture was used for the DSC measurement.

In the mixed systems, two peaks appeared on the DSC curve and each was detected as a separated peak. When the peaks approached each other, they began to overlap and became one broad peak with two peaks superimposed on it. The temperature at each peak was measured.

Results and Discussion

Melting Temperature. The melting temperatures of *N*-acyl amino acids are shown in Table 1 along with the heats-of-fusions. The melting-point temperature increased with the size of the amino acid residue in an L-series, while the order was opposite in a DL-series. The branched isomers of *N*-dodecanoylvaline all had similar melting-point temperatures. The same tendency was observed among the branched isomers of *N*-dodecanoylleucine. *N*-Acylglycine and -alanine each showed a tendency for the melting-point temperature to increase with the chain length of an acyl group. *N*-Acyl-DL-norleucine, however, gave melting-point temperatures scattered between 354—360 K and had no regular tendency.

Latent Heat of Fusion. The latent heat ΔH_f and entropy-of-fusion ΔS_f for *N*-dodecanoyl amino acids are plotted against the carbon number of their amino

acid part in Fig. 1. The values of ΔH_f and ΔS_f depended on the size and optical isomerism of the acyl amino acid (see also Fig. 2). We did not find a significant difference of thermodynamic quantity among the branched isomers.

Racemic compounds always had larger ΔH_f and ΔS_f values than the corresponding chiral isomers. For the optically active series, ΔH_f and ΔS_f decreased with the carbon number of the amino acid part, while for the racemic series, there were abrupt increases of ΔH_f and ΔS_f above a carbon number of 5. The difference of ΔH_f between the optically active and racemic isomers was 31.3 and 23.0 KJmol^{-1} for *N*-dodecanoylvaline and -leucine, and the difference of ΔS_f was 92 and 72 Jmol^{-1} K^{-1}, respectively. These values were very large compared to 7.1 KJmol^{-1} and 12 Jmol^{-1} K^{-1} for *N*-dodecanoylalanine.

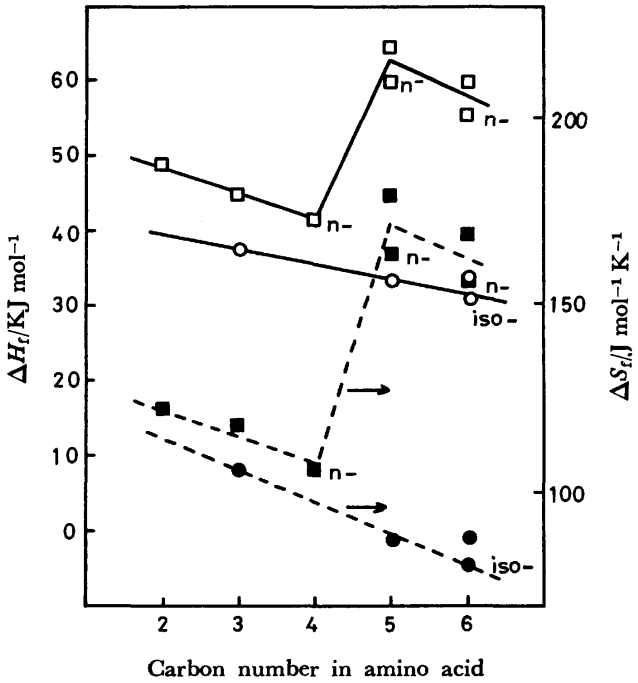

Fig. 1. Enthalpies and entropies of fusion of *N*-dodecanoyl amino acids. (○,●); L-form, (□,■); DL-form.

Figure 2 shows that the enthalpy and entropy-of-fusion depend on the size of an acyl group. For the alanine compounds, ΔH_f and ΔS_f increased linearly with the number of the methylene group in the acyl group. The enthalpy-of-fusion per methylene group was 4 KJmol^{-1}, which was identical with a figure found for normal alkane,[8] and monoglyceride.[9] The entropy-of-fusion increased by a factor 9 Jmol^{-1} K^{-1} for each additional methylene group added to the acyl chain. This value also agreed with that of normal alkane[8] and monoglyceride.[9] It can be concluded from the above results that the acyl group of the *N*-acyl DL-alanines behaves in the same manner as a normal alkane when it melts, and is hardly affected by the amino acid residue.

On the contrary, the theromodynamic quantities of *N*-acyl DL-norleucine varied, irregularly, with the size of the acyl group. It is suggested that the acyl group of the *N*-acyl DL-norleucines may interact somewhat with their amino acid residue, or at least perturbs the melting process.

Melting of Mixture. The temperatures cited in Figs. 3—6 are the peak temperatures on a DSC curve since it was difficult to determine the point at which the DSC curve started to deviate from the base line.

The melting-point temperatures of mixtures of *N*-

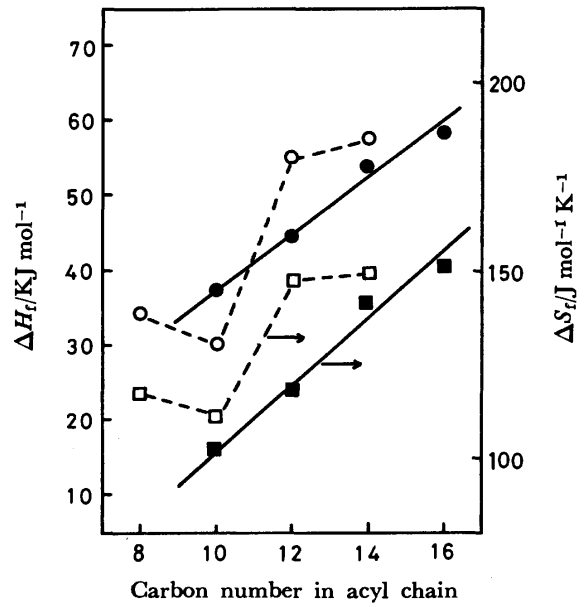

Fig. 2. Enthalpies and entropies of fusion of *N*-acyl DL-alanines and -DL-norleucines. (●,■); the alanines, (○,□); the leucines.

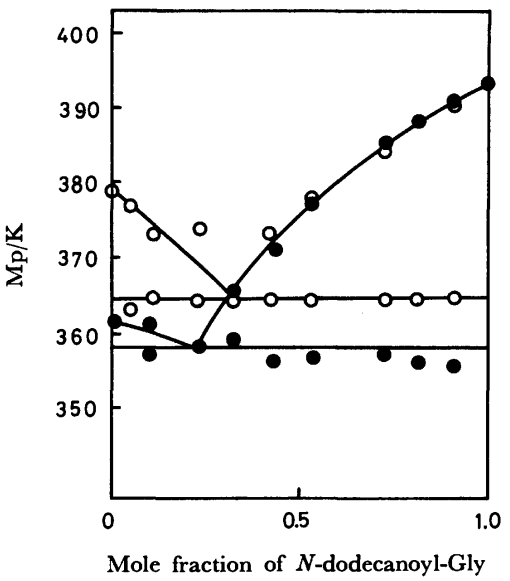

Fig. 3. Phase diagrams of mixtures of *N*-dodecanoylglycine and -valines. (○); L-form, (●); DL-form. The solid lines are the calculated values on the assumption of ideal mixing.

dodecanoylglycine and *N*-dodecanoyl-L-valine are shown in Fig. 3. This system has a single eutectic point and is a typical system with equilibrium between unmixed solid and mixed liquid states.

In a previous paper,[7] it was reported that a mixture of sodium salts of *N*-dodecanoylglycine and -L-valine could be treated as an ideal mixture in a micelle state. We attempted to apply the assumption of ideal mixing to the present system. The solid curves in Fig. 3 were calculated from Eq. 1[10] and are in good agreement with the experimental points.

$$\ln x = (\Delta H_0/R)(1/T_0 - 1/T) \quad (1)$$

where x is mole fraction of the first component and ΔH_0 and T_0 are the latent heat-of-fusion and melting point.

The system, where racemic *N*-dodecanoylvaline was used instead of the optically active isomer, was also examined. We considered a system composed of A moles of *N*-dodecanoylvaline (1 mole is a mole of an optically active isomer) and B moles of *N*-dodecanoylglycine (mole fraction in Fig. 3 is equal to $B/(A+B)$). If the racemic *N*-dodecanoylvaline formed a racemic compound in the liquid state, the mole fraction of *N*-dodecanoylglycine would be $B/(A/2+B)$ in the liquid mixture (which differs from the mole fraction used in Fig. 3). Consequently, this phase diagram should be different in all regions from one containing the optically active isomer. The experimental results did not agree with such a prediction. When *N*-dodecanoyl-DL-valine is a racemic mixture in a liquid state, the mole fraction of the glycine derivative is given as $B/(A+B)$ in the liquid mixture. The results calculated from this mole fraction and Eq. 1 are given in Fig. 3. This figure indicates that the racemic *N*-dodecanoylvaline is a racemic mixture in a liquid state rather than a racemic compound, although it forms a racemic compound in the solid state (described later).

Mixture of Optically Active and Racemic Isomers. The systems shown in Figs. 4—6 were examined. In all of them, the formation of racemic compounds occured. These results reflect the fact shown in Fig. 1, that the ΔH_f and ΔS_f values of a racemic isomer are always larger than those of a corresponding optically active one. The difference may correspond to the formation energy of a racemic compound.

We could not assume ideal mixing in these systems, but could roughly estimate an interaction parameter between two corresponding chiral isomers in a liquid state. The excess thermodynamic potential of the first

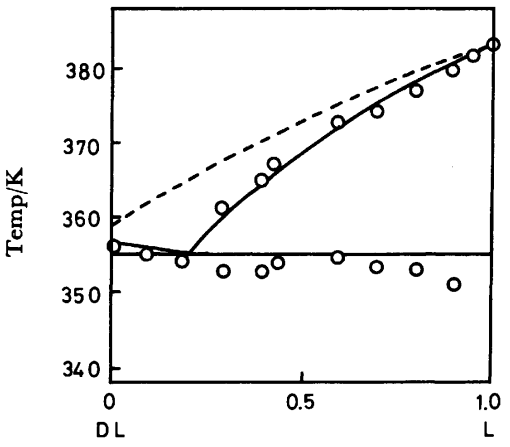
Fig. 4. Melting-point temperatures of mixture of *N*-dodecanoyl-L-alanine and -DL-alanine. The plotted points are experimental data, the solid and broken lines correspond the values calculated with β of -1.08 and 0, respectively.



Mole fraction of dodec-L-Leu

Fig. 6. Melting-point temperatures of mixture of *N*-dodecanoyl-L-leucine and -DL-leucine. The plotted points are experimental data, the solid and broken lines correspond the values calculated with β of -1.91 and 0, respectively.

component, $\mu^e(T,x)$ is in the most simple form[10]

$$\mu^e(T, x) = RT \ln f_1 = A(1-x_1)^2. \quad (2)$$

When we assume $A=RT\beta$, an activity coefficient f_1 is given by Eq. 3.

$$\ln f_1 = \beta(1-x_1)^2 \quad (3)$$

Substitution of Eqs. 2 and 3 into the following equation[11]

$$-\int_{T_1}^{T} \Delta S_f dT + RT \ln x_1 + \mu^e(T, x) = 0 \quad (4)$$

and a rearrangement gives:

$$T = \frac{\Delta H_1/R}{\Delta H_1/RT_1 - \ln x_1 - \beta(1-x_1)^2} \quad (5)$$
$$(0 \leqq x_1 \leqq x_{eu1}, \text{ and } x_{eu2} \leqq x_1 \leqq 1)$$

where x_1 and T_1 are the mole fraction and melting point of the first component. ΔS_f is its fusion entropy and is equal to $\Delta H_1/RT_1$. ΔH_1 is the latent heat-of-fusion. Our systems contain two components of L- and D-isomers, and the L-isomer corresponds to the first component. By using Eq. 3 and the method described by Oonk,[12,13] we obtain Eq. 6.

$$T = \frac{\Delta H_c}{\Delta H_c/T_c - R/2[\ln 4x_1(1-x_1) + \{x_1^2 + (1-x_1)^2 - 1/2\}\beta]} \quad (x_{eu1} < x_1 < x_{eu2}) \quad (6)$$

Here, T_c is the melting temperature of the racemic isomer, ΔH_c is its latent heat-of-fusion and x_{eu1} and x_{eu2} are the compositions at the eutectic points ($x_{eu1} < x_{eu2}$). The melting-point temperature can be calculated from Eqs. 5 and 6.[15]

The interaction parameter (β) was estimated from the experimental values using Eqs. 2—6. The value of β was −1.08, 0, and −1.91 for *N*-dodecanoylalanine, -valine, and -leucine, respectively. These values suggest that the L- and D-isomers interact with each other to form at least a racemic pair in the systems of the alanine and leucine derivatives.

Solution Properties of Low Molecular Weight Fractions of Poly(2-vinylpyridine)

Masafumi YOSHIDA, Shinsuke YAMAGUCHI,† Noriyuki SAKAMOTO, and Shizuo ARICHI*
Department of Chemistry, Faculty of General Education, Kumamoto University, Kurokami 2-40-1, Kumamoto 860
(Received September 19, 1984)

The relationships between the weight-average molecular weight M_w and the intrinsic viscosity $[\eta]$ of poly(2-vinylpyridine) [P2VP] in benzene and methyl alcohol at 25 °C, were investigated by the use of fractions with molecular weights ranging from 2.1×10^3 to 2.3×10^4. The exponent ν in the Mark-Houwink-Sakurada equation, $[\eta]=K_0M_w^{\nu}$, was 0.5 in both solvents when M_w was lower than about 10^4. A constant K_0 was approximately in accord with Flory's $K\theta$ value for ordinary high-molecular-weight P2VP, obtained earlier in respective solvents. By measuring $[\eta]$ for these low-molecular-weight fractions in several solvents at different temperatures, the temperature coefficients of an unperturbed dimension, $d\ln\bar{r}^2_0/dT$, of this polymer were estimated and averaged to be $-2.3\times10^{-3}\,K^{-1}$. These are quite different from the positive values calculated from the $K\theta$'s by Dondos *et al.* which were estimated using the extrapolation method for non-θ-solvents. Our results were further corroborated after adding a $K\theta$ value which was directly determined at another θ-state; *i.e.* in toluene at 63.7 °C, to that in benzene at 16.2 °C published earlier, which was found from phase-separation experiments in this work.

Extensive theoretical and experimental investigations regarding the temperature coefficient of the unperturbed dimension, $d\ln\bar{r}^2_0/dT$, have been made for linear polymers because they offer important information on the hindrance potential affecting rotation around bonds in the main chain.[1] The value of $d\ln\bar{r}^2_0/dT$ can be evaluated by measuring the stress-temperature coefficient for a cross-linked network,[2] or more directly by measuring the unperturbed mean-square end-to-end dimension,[3] $\bar{r}^2_0$, or the intrinsic viscosity,[4] $[\eta]_\theta$ in several θ-solvents with different θ-temperatures distributed within a certain temperature range. Naturally, the Stockmayer-Fixman plot, as an indirect method, is frequently used to evaluate $d\ln\bar{r}^2_0/dT$, for Flory's $K\theta$ values can be calculated from the $[\eta]$ values for different molecular-weight fractions in non-θ-solvents at several temperatures.[5,6] Flory *et al.* also proposed a method in which the temperature coefficient of $[\eta]$ of linear polymer is measured in athermal solvents.[7,8]

In general, it is often impossible to find the θ-solvent and/or θ-temperature for some polymers, since the elimination of the long-range interactions of a polymer in non-θ-solvent is troublesome, especially for polar polymers.[9] The method proposed by Bianchi *et al.* is effective in such cases.[9-11] According to them, the coil-expansion factor α, is essentially unity in many solvents when the molecular weight of the polymer is sufficiently low. Consequently, the temperature coefficient of the intrinsic viscosity of such low-molecular-weight fraction is equal to that of the unperturbed dimension. As for poly(2-vinylpyridine), P2VP, it is very difficult to determine a single component θ-solvent. Only values for benzene have been reported; 16.2 °C or 15 °C for this polymer.[12,13] Most of the reported values for the unperturbed dimension of P2VP were evaluated in non-θ-solvents and at very limited temperatures. In addition, even the sign of the temperature coefficients of the unperturbed dimension estimated from these literature values differs with each other.

The main purpose of this study was to determine the $d\ln\bar{r}^2_0/dT$ of P2VP according to the method of Bianchi *et al.* Moreover, the experimental evidence supporting the results was complementarily shown by the estimation of $d\ln\bar{r}^2_0/dT$ using the $K\theta$ values which were directly observed in θ-solvents, benzene and toluene. The latter was proved to be a θ-solvent at 63.7 °C.

Experimental

The monomer of 2-vinylpyridine was kindly supplied by Tokyo Yukigosei Co., and was distilled under a reduced pressure (bp 55 °C/15 Torr (1 Torr=133.322 Pa)) immediately before use. Polymerization was carried out either by the anionic method (Samples denoted below by BL and C) using butyllithium in tetrahydrofuran(THF) under a reduced pressure at −27 °C, or by the radical method (Samples denoted by A) with azobisisobutyronitrile in benzene at 50 °C. Fractionation of the polymer was carried out by the successive precipitation method using benzene and hexane as a solvent-precipitant pair, as outlined elsewhere.[14]

The phase separation was carried out in a thick glass capillary tube as described by Cowie *et al.*[15] After being measured with modified Ubbelohde-type dilution viscometers in a water bath (thermostatically controlled within ±0.01 °C), the intrinsic viscosity $[\eta]$ was calculated in dl/g with the Huggins plot.

Light scattering was carried out with a Fica 50 automatic light-scattering photometer with vertically polarized incident light of 436 nm. The vertically polarized component of the scattered light was measured for scattering angles of 30°—150° in methyl alcohol at 25 °C. The optical purification of each solution and solvent was achieved by filtration

through Millipore membrane filters "FG"(pore size: 0.2 μm). An antifluorescence filter of 436 nm was also used to remove the effect of the fluorescence which was confirmed not to be negligible. The weight-average molecular weight M_w was calculated using the double-extrapolation plots of Zimm.

The specific refractive-index increment dn/dc was measured in methyl alcohol at 25 °C with a Shimadzu DR-3 type refractometer.

Results and Discussion

Table 1 summarizes the $[\eta]$ results obtained in methyl alcohol and benzene and, also, those of M_w and dn/dc in methyl alcohol (all measured at 25 °C for the low-molecular-weight fractions of P2VP).

Concerning the molecular weight dependence of dn/dc, Kamata *et al.*[16] found considerable fluctuations for oligostyrene in an ethyl methyl ketone when the molecular weight was lower than 2000. As can be seen in Table 1, dn/dc for P2VP is essentially in accordance with each other for all the fractions measured in this study. Also, the average value of 0.262 is close to that of 0.270, reported for ordinary high-molecular-weight P2VP fractions in the same solvent.[17] Therefore, the value of 0.262 was used in the calculation of M_w from light-scattering data in this study.

In Figs. 1 and 2, the $[\eta]$'s for methyl alcohol and benzene are plotted against M_w, respectively. The points for the ordinary high-molecular-weight P2VP fractions (reported by one of the authors[12]) are represented by filled circles for comparison. As can be seen in both Figs., the points can be represented by two distinct straight lines. These are the so-called Mark-Houwink-Sakurada empirical equation:

$$[\eta] = KM_w^{\nu}, \quad (1)$$

where K and ν are constants. The point for the fraction BL6-2 in methyl alcohol, for example, is on the line for the higher molecular-weight fractions, however, the remaining points are on a different straight line. Using a least-squares method, the constants K_0 and ν of the lines for the lower-molecular-weight

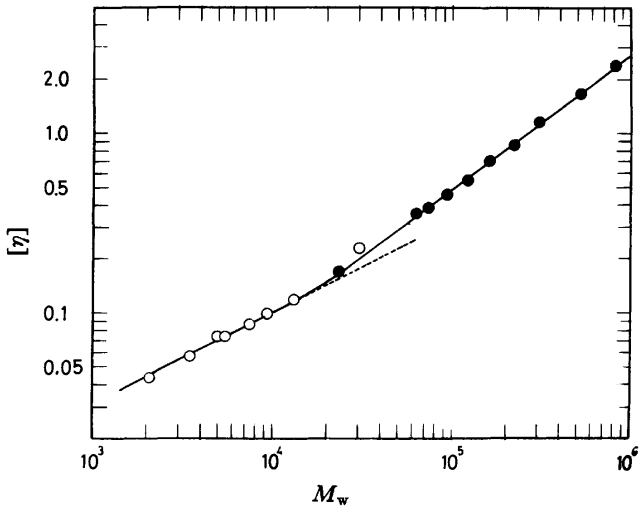

Fig. 1. Double logarithmic plot of $[\eta]$ against M_w for poly(2-vinylpyridine) in methyl alcohol at 25 °C. Filled circles represent the relationship obtained earlier.[12]

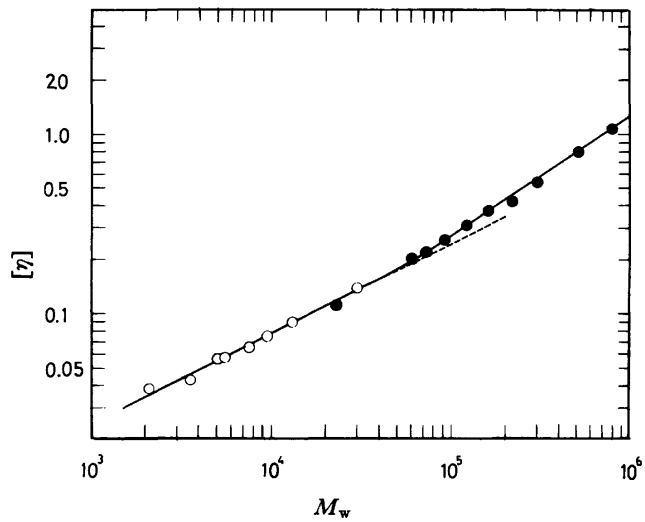

Fig. 2. Double logarithmic plot of $[\eta]$ against M_w for poly(2-vinylpyridine) in benzene at 25 °C. Filled circles represent the relationship obtained earlier.[12]

fractions were determined as follows:

$$[\eta] = 10.0 \times 10^{-4} M_w^{0.5} \quad \text{in methyl alcohol,} \quad (2)$$

$$[\eta] = 7.5 \times 10^{-4} M_w^{0.5} \quad \text{in benzene.} \quad (3)$$

The breaks for these two lines in Figs. 1 and 2 occur in the vicinity of $M_w \approx 1.5 \times 10^4$ in methyl alcohol, and 4×10^4 in benzene, respectively. The existence of such breaks has been reported for many polymers.[11,18-21] Hirai *et al.*[22] reported two distinct sections in $\log[\eta]$–$\log M_n$ plots for poly(4-vinylpyridine) fractions in *t*-butyl alcohol, methyl alcohol, and ethyl methyl ketone–isopropyl alcohol mixture (85:15 by wt.) at 30 °C, where M_n is the number-average molecular weight. They also found that the slope of the lines is 0.5 for all solvents in the region of molecular weight below 10^4.

According to Bianchi *et al.*,[10,11,23,24] when the molecular weight is sufficiently low, there is a molecular-weight range for many polymers where the expansion coefficient α is practically undistinguishable from unity. Hence, the K_0 constant of the Mark-Houwink-Sakurada equation in such a molecular-weight range is almost equal to K_θ, which is defined as follows:

$$[\eta]_\theta = K_\theta M^{1/2}, \tag{4}$$

$$K_\theta = \Phi_0(\bar{r}^2_0/M)^{3/2}. \tag{5}$$

Φ_0 is Flory's viscosity constant, and M is the polymer molecular weight. It is, therefore, interesting to compare the K_0 values in Eqs. 2 and 3 with K_θ reported in the literature for each corresponding P2VP-solvent system at 25 °C. In fact, the above-mentioned values of K_0=10.0×10^{-4} in methyl alcohol and 7.5×10^{-4} in benzene agreed fairly well with those of K_θ=9.3×10^{-4} and 7.9×10^{-4} in each solvent, derived from the Stockmayer-Fixman plot by one of the authors.[12]

From these results, it may be concluded that when the molecular weight of P2VP is lower than *ca.* 1×10^4 at least, the excluded volume effect can be considered negligible even in a very good solvent such as methyl alcohol. This was similarly reported for many other linear polymers. Thus, we can evaluate $d\ln\bar{r}^2_0/dT$ by measuring the temperature coefficient of $[\eta]$ in any solvent with a low molecular-weight fraction by means of the following equation:

$$d\ln \bar{r}^2_0/dT = (2/3)d\ln [\eta]/dT. \tag{6}$$

The intrinsic viscosities for P2VP fractions, BL6-7 (M_w=4.9$_5$×10^3) and Al-V (M_w=7.8$_7$×10^3) were measured in ethyl alcohol, chloroform, dioxane, THF, ethyl methyl ketone, and benzene in the temperature range of 14.9° to 60 °C. In Figs. 3 and 4, the $\ln[\eta]$ for the above two fractions was plotted against temperature, respectively. All plotted points fall on straight

lines for each solvent except the one at 14.9 °C in benzene. This deviation may be explained by the fact that a temperature of 14.9 °C is slightly lower than the θ-temperature, 16.2 °C for the P2VP–benzene system.[12]

The temperature coefficients of $d\ln[\eta]/dT$ were analyzed by a least-squares method, and the values of $d\ln\bar{r}^2_0/dT$ were calculated according to Eq. 6 and are summarized in Table 2. As shown in the Table, the values of $d\ln\bar{r}^2_0/dT$ estimated in this study were explicitly negative for all solvents used and were averaged to be $-2.3(\pm 1.1)\times 10^{-3}$ K^{-1}. Concerning those of P2VP, there has been no value in the literature except for the data on K_θ obtained at only two or three different temperatures. Our estimated values of $d\ln\bar{r}^2_0/dT$ from such data on K_θ reported by Dondos *et al.*[13,25,26] are cited in the last column of Table 2. Though a practical estimation of these values is indeed a delicate problem, it is noted that even the signs of $d\ln\bar{r}^2_0/dT$ (for the latter) are reverse to those obtained in this work (except in chloroform). This may, perhaps, be due to the inevitable ambiguity in the K_θ values of Dondos *et al.*, which were indirectly determined in non-θ-solvents with an extrapolation method based on the two-parameter theory for dilute polymer solutions.

Strictly, it will be better, therefore, to estimate $d\ln\bar{r}^2_0/dT$ from the K_θ obtained for an ordinary high-molecular-weight polymer in more than two single θ-solvents with different θ-temperatures. One of us has reported that benzene is the θ-solvent for P2VP at 16.2 °C and that the value of K_θ directly deduced by measuring the viscosity at the state is 9.1×10^{-4} (after a correction due to the molecular-weight heterogeneity in samples)[12] is different from the above-quoted value indirectly determined at 25 °C. However, no other single θ-solvent has been reported. We did find in this investigation that toluene is expectative. As is well

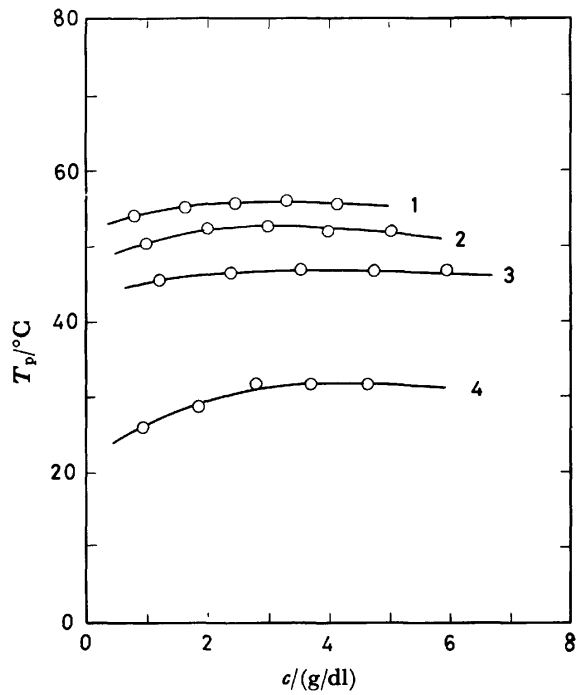

Fig. 5. Phase diagram for poly(2-vinylpyridine) fractions in toluene, whose weight-average molecular weights are respectively; 1: $50.0\cdot 10^4$, 2: $35.9\cdot 10^4$, 3: $12.1\cdot 10^4$, 4: $3.0\cdot 10^4$.

known, the unperturbed dimension of a linear polymer is often affected by the specific solvent effect, but benzene and toluene are homologous nonpolar solvents and the specific solvent effect on the unperturbed dimension of P2VP is considered to be the same and not so large. Hence, an estimation of $d\ln\bar{r}^2_0/dT$ from K_θ for these solvents will be useful.

The phase-separation experiments were, therefore, carried out for the P2VP–toluene system and the phase diagrams obtained are depicted in Fig. 5, where the numbers 1 and 2 denote the results for fractions BL21-1 and BL21-3 (in Table 3) and the other numbers, for fractions which were ionically polymerized at the same time (though not given in this Table). The reciprocal of the critical temperature, T_c^{-1}, was plotted in Fig. 6 against $M_w^{-1/2}$, according to the well known equation:[27]

$$1/T_c = (1/\theta)[1 + b/M_w^{1/2}], \quad (7)$$

where b is a constant and θ is the temperature at the theta state. The value of θ determined from the intercept of the line was 63.7 °C.

In Table 3, the M_w evaluated by light scattering in methyl alcohol at 25 °C and the $[\eta]$ in toluene at 63.7 °C for six fractions of P2VP, are summarized. In Fig. 7, $[\eta]$ is plotted against M_w on a double-logarithmic scale, from which the following equation was derived:

$$[\eta]_\theta = 7.54 \times 10^{-4} M_w^{0.5}. \quad (8)$$

The fact that the exponent of M_w is 0.5, indicates

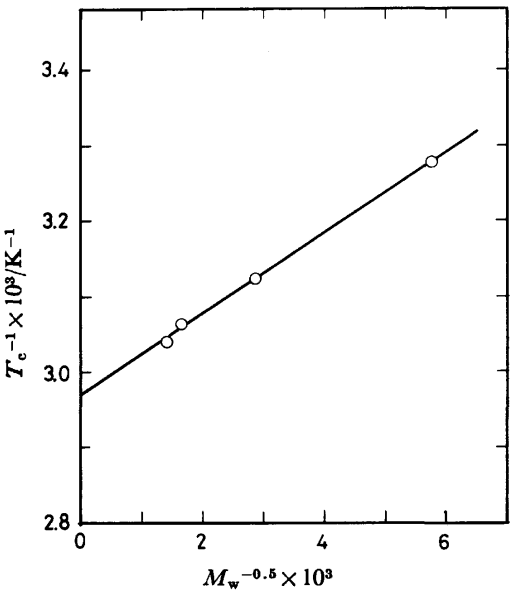

Fig. 6. Plot of reciprocal critical precipitation temperature of poly(2-vinylpyridine) in toluene, $1/T_c$, against $M_w^{-0.5}$.

Table 3. Light-scattering and viscosity data in toluene at 63.7 °C

Fraction	$M_w \times 10^{-4}$	M_w/M_n a)	$[\eta]_\theta$	$([\eta]_\theta/M_w^{0.5}) \times 10^4$
C-22	101.4	1.35	0.77	7.65
C-11	62.4	1.23	0.62	7.72

			(average)	7.54

a) Estimated by gel permeation chromatography.

that toluene is a θ-solvent at 63.7 °C for P2VP as predicted from the phase-separation method. Accordingly, the proportionality constant in the above equation was regarded as the K_θ for P2VP at 63.7 °C. The correct value of 7.66×10^{-4} was finally obtained by applying the polydispersity correction of molecular weight in the same manner as before,[12] using the M_w/M_n of each fraction (in Table 3). Here M_n was evaluated by GPC with the DMF solutions. As a result, the value of $d\ln\bar{r}^2_0/dT$ was estimated to be $-2.4(\pm1.0) \times 10^{-3}$ K^{-1} with the K_θ (both in benzene at 16.2 °C and in toluene at 63.7 °C) being expressed as in the following equation:

$$d\ln \bar{r}^2_0/dT = (2/3)d\ln K_\theta/dT. \quad (9)$$

This is almost the same as the average value, $-2.3(\pm1.1) \times 10^{-3}$ K^{-1}, obtained above from the temperature dependence of $[\eta]$ for low-molecular-weight P2VP fractions.

One more additional datum supporting the results obtained in this study was reported earlier by one of us[28]. The distinct negative temperature coefficient of K_θ for P2VP in ethyl alcohol (corresponding to $d\ln\bar{r}^2_0/dT = -2.1 \times 10^{-3}$ K^{-1}, estimated by the Stockmayer-Fixman plot for data of an intrinsic viscosity and molecular weight of ordinary high-molecular-weight P2VP fractions at temperatures from 10° to 65 °C) was noted. It agreed very closely with that of -2.4×10^{-3} K^{-1} presented here for the same solvent.

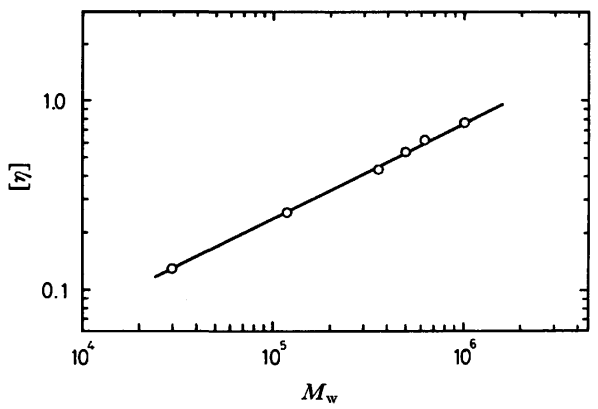

Fig. 7. Double logarithmic plot of $[\eta]_\theta$ against M_w for poly(2-vinylpyridine) in toluene at 63.7 °C.

Thus, we may conclude that the $d\ln\bar{r}^2_0/dT$ value for P2VP is negative, and its absolute value is considerably larger than those reported for many other polymers; *e.g.*, -0.17×10^{-3} K^{-1} for polyisobutylene,[9] -1×10^{-3} K^{-1} for polystyrene[10], $0.48(\pm0.3) \times 10^{-3}$ K^{-1} for poly(*p*-chlorostyrene).[4] However, the larger absolute values of $d\ln\bar{r}^2_0/dT$ have also been reported in the literature; *e.g.*, -24×10^{-3} K^{-1} for poly(ethylene oxide)[29] and $-4.7(\pm0.91) \times 10^{-3}$ K^{-1} for polystyrene.[3] A theoretical investigation of $d\ln\bar{r}^2_0/dT$ for P2VP has not yet been reported, but our results indicate that the extended conformation of P2VP must be associated with lower energies.

Comparative Studies of Anionic Molecular Assemblies as Mediums for Electron Transfer Quenching of Excited Ru[(bpy)$_3$]$^{2+}$ by Cationic Quenchers

Hiroshi SHIOYAMA, Akihiro TAKAMI, and Noboru MATAGA*
Department of Chemistry, Faculty of Engineering Science, Osaka University, Toyonaka, Osaka 560
(Received November 5, 1984)

Behaviors of excited [Ru(bpy)$_3$]$^{2+}$ bound to anionic molecular assemblies such as polymer electrolytes, vesicles and micelles together with electron-acceptor quencher MV^{2+} have been investigated by measurements of [Ru(bpy)$_3$]$^{2+}$ luminescence quenching and radical yields in electron-transfer quenching using a dye laser photolysis apparatus. Quenching behavior characteristic to each molecular assembly has been observed. A remarkable enhancement of quenching was observed in the presence of poly(vinyl sulfate). Such an effect was observed also in sodium dihexadecyl phosphate solution though it is less pronounced. However, no such specific quenching behavior was observed in sodium dodecyl sulfate micellar solution.

The photochemical and photophysical properties of [Ru(bpy)$_3$]$^{2+}$ and related metal complexes are the subject under lively investigations from the viewpoint of solar energy conversion.[1] The electron-transfer and energy-transfer phenomena of these complexes in the excited state have been studied in some details both in bulk and heterogeneous systems.[2-4] In relation to the photoinduced electron transfer and excitation transfer in heterogeneous systems involving molecular assemblies, it is important to elucidate the nature of these systems as microenvironments on which those reaction processes take place. For example, luminescence quenching of ruthenium complex by Cu^{2+} and methylviologen cation (MV^{2+}) bound to anionic micelles was used as a probe to investigate the nature of the micelle as a microenvironment.[5]

However, our recent studies of excitation transfer among dye ions adsorbed on various molecular assemblies indicate clearly that the mode of excitation transfer and trapping is very characteristic to each kind of molecular assembly,[6,7] which seems to reflect the different adsorbed state of dyes characteristic to each molecular assembly. This result suggests the importance of the comparative studies of various molecular assemblies as mediums for photochemical reactions by using a common photochemical probe system. Along this line, we have examined the luminescence quenching reactions of excited [Ru(bpy)$_3$]$^{2+}$ due to electron transfer to MV^{2+} in solutions containing various anionic molecular assemblies such as polymer electrolyte, vesicles and micelles.

Results of these investigations shows very clearly the different microenvironmental characteristics of these molecular assemblies as the mediums for photochemical electron transfer reactions between cations.

Experimental

[Ru(bpy)$_3$]$^{2+}$ was synthesized according to the standard method[8] and was recrystallized several times from water. MV^{2+} (G. R. Grade, Tokyo Kasei) was purified by repeated recrystallization from methanol. Purified propylviologen sulfonate (PVS°) was kindly supplied by Dr. M. Furue of this University and used as received. *p*-Benzoquinone (BQ) was purified by recrystallization from ethanol and subsequent sublimation. $CuCl_2 \cdot 2H_2O$ (G. R. Grade, Nakarai) was used as received.

Sodium dodecyl sulfate (SDS) (S. U. Grade, Nakarai) and three kinds of polyelectrolyte; potassium poly(vinyl solfate) (PVSK) (G. R. Grade, Nakarai), poly(vinyl alcohol) (PVA) (E. P. Grade, Nakarai) and poly(methacrylic acid) sodium salt (PMAS) (Polysciences, Inc.) were used without further purification. Sodium dihexadecyl phosphate (NaDHP) was obtained by treating dihexadecyl hydrogen phosphate, which was synthesized according to Ref. 9, with NaOH in ethanol solution. To prepare the vesicle, NaDHP was sonicated in water at 60 °C for 30 min., using a sonifier set (Branson, model 185).

Water was purified by distillation with a nonboiling type distillation apparatus. All solutions for measurements were deoxygenated by flushing with N_2 gas for at least 20 min. All measurements were carried out at room temperature.

Spectra and relative yields of [Ru(bpy)$_3$]$^{2+}$ emission were measured with an Aminco-Bowman spectrophotofluorometer. Radical yields in electron-transfer quenching of excited [Ru(bpy)$_3$]$^{2+}$ were measured by using a dye laser photolysis apparatus:[10] the lasing dye was Coumarin 503 (Phase-R Company), whose lasing wavelength, output power and fwhm were 498 nm, 35 mJ and 250 ns, respectively. The luminescence decay curves were determined by exciting the sample with the second harmonic of a mode locked Nd^{3+}:YAG laser and by observing the decay curve with a highspeed microchannel plate photomultiplier (HTV R-1194UX)-fast storage oscilloscope (Tektronix 7834) combination.

Results and Discussion

Luminescence Quenching of [Ru(bpy)$_3$]$^{2+}$ in Molecular Assemblies. It is well-known that the luminescence of [Ru(bpy)$_3$]$^{2+}$ (λ_{max}=610 nm, τ_0=650 ns) is quenched by MV^{2+} with a quenching rate constant of

$k_q \approx 5\times10^8\ M^{-1}\ s^{-1}$ (1 M=1 mol dm^{-3}) in water with a controlled ionic strength. However, when 0.01 M (in monomer unit) of PVSK was added to solution, a peculiar curves with a lump as shown in Figure 1 was obtained instead of the simple Stern-Volmer straight line. I_0/I shows a peak at 1.5×10^{-3} M of MV^{2+} where 98% of the $[Ru(bpy)_3]^{2+}$ emission is quenched, and the luminescence is restored with further addition of the quencher. When MV^{2+} concentration is higher than 5×10^{-3} M, the quenching is very similar to that in bulk solution.

Above results can be explained in terms of a limited capability of the anionic molecular assembly to adsorb cations. All $[Ru(bpy)_3]^{2+}$ cations may be adsorbed on PVSK when MV^{2+} concentration is low. Under these conditions, because both $[Ru(bpy)_3]^{2+}$ and MV^{2+} are concentrated by adsorption on PVSK, the luminescence is effectively quenched. With increase of the MV^{2+} concentration, all adsorption sites may be occupied by $[Ru(bpy)_3]^{2+}$ and MV^{2+}. With further increase of MV^{2+}, $[Ru(bpy)_3]^{2+}$ seems to be expelled into bulk solutions. Eventually, almost all of $[Ru(bpy)_3]^{2+}$ ions appear to be removed from the vicinity of PVSK, where the concentration of MV^{2+} is very high. The expelled $[Ru(bpy)_3]^{2+}$ ions undergo simple Stern-Volmer type of luminescence quenching quite similar to that in bulk solution.

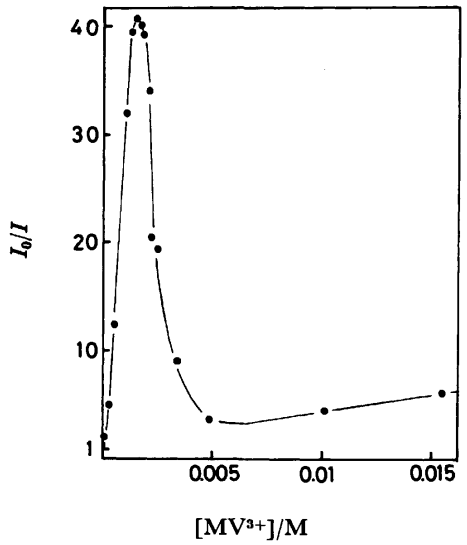

Fig. 1. $(I_0/I)\sim$[quencher] relation for the luminescence quenching of $[Ru(pby)_3]^{2+}$–MV^{2+} system in aqueous solution containing PVSK.
$[[Ru(bpy)_3]^{2+}]=6\times10^{-5}$ M. [PVSK]$=1\times10^{-2}$ M (in monomer unit)

We have examined the effect of PVSK concentration as indicated in Table 1. The MV^{2+} concentration that gives the peak value of I_0/I is proportional to the concentration of PVSK. This result suggests that PVSK is able to bind MV^{2+} at a ratio of *ca.* one MV^{2+} for 6 monomer units of PVSK. Another cationic quencher Cu^{2+} also causes the similar effect, but the extent of the quenching (the peak value of I_0/I) in this case is much smaller. The neutral quencher BQ or PVS°, however, does not give such a peculiar quenching. Moreover, when the anionic PVSK is replaced by neutral PVA, the lump in I_0/I *vs.* [quencher] relation disappears. After the completion of the present work we found similar report[11] on $[Ru(bpy)_3]^{2+}$–Cu^{2+}–PVSK system. However, the object of the present work is the comparative studies of various anionic molecular assemblies as microenvironment for the photochemical electron transfer quenching reaction between adsorbed cations. For this purpose, MV^{2+} which shows far greater quenching ability than Cu^{2+} in the ad-

sorbed state is much better system.

Above experimental results are summarized in Table 2, which suggests that the electrostatic force plays an important role for the adsorption of $[Ru(bpy)_3]^{2+}$ and MV^{2+} onto the molecular assemblies. Table 2 also indicates that each anionic molecular assembly shows characteristic behavior in the adsorption of cations. Not only the MV^{2+} concentration at $(I_0/I)_{peak}$ but also the luminescence quenching itself is characteristic to each kind of molecular assembly. Moreover, SDS micellar solution does not show such a peculiar behavior in luminescence quenching as observed in PVSK solution in the present experimental conditions. However, it should be noted here that there is some kind of specific interaction between SDS micelle and $[Ru(bpy)_3]^{2+}$ because a slight broadening of the absorption spectrum and a bathochromic shift of *ca.* 20 nm of the luminescence spectrum occurs by adsorption. We have observed similar spectral shift also in the case of NaDHP vesicle solution. As shown in Figure 2, the emission maximum of $[Ru(bpy)_3]^{2+}$ without MV^{2+} or with low concentration MV^{2+} lies at *ca.* 630 nm, in which case $[Ru(bpy)_3]^{2+}$ is supposed to be adsorbed on the NaDHP vesicle.

By adding more MV^{2+}, the emission intensity is a little recovered and the peak wavelength becomes the same as in pure water solution. Further increase of MV^{2+} concentration results in the simple Stern-Volmer type quenching in bulk solution. Contrary to these spectral shifts in SDS and NaDHP solutions which indicate more or less specific interaction between $[Ru(bpy)_3]^{2+}$ and detergent molecules, no such shift caused by adsorption was observed in the case of PVSK solution, where, although the adsorption due to electrostatic attraction is the strongest among the molecular assemblies used here, the environmental state for $[Ru(bpy)_3]^{2+}$ is very close to that in pure aqueous solution.

Emission Decay Curve. Figure 3 shows that the emission of $[Ru(bpy)_3]^{2+}$ -MV^{2+} system in PVSK solution does not show single exponential decay; the decay curves are composed of at least two components. The fast decay component corresponds to the quenching of excited $[Ru(bpy)_3]^{2+}$ on PVSK chain by the MV^{2+} which is also adsorbed on PVSK chain in the vicinity of the quencher. The slow one corresponds to the decay of $[Ru(bpy)_3]^{2+}$ in the bulk. The intensity of the slow component emission of sample A is higher than that of sample B, since the large part of $[Ru(bpy)_3]^{2+}$ of the former is expelled into bulk.

Laser Photolysis Experiments. In Table 3, the absorbances of transient MV^+ radical obtained with a dye laser photolysis system are listed. In simple aqueous solution, the absorbance of the transient radical observed in the samples with different quencher concentrations was proportional to the degree of quenching. This is in agreement with the result in our previous report.[10]

In the case of PVSK solution, however, the radical formation is strongly suppressed at the MV^{2+} concentration of 1.5×10^{-3} M, where I_0/I shows the peak of lump. In general, the radical yield is determined by the competition between the dissociation into free radicals and deactivation by back electron transfer in the geminate radical pair formed by the photoinduced electron transfer. When both radical ions are bound to PVSK in close proximity to each other, the back electron transfer will dominate in

TABLE 4. CHANGE OF $(I_0/I)_{peak}$ VALUE AND $[MV^{2+}]$ WHICH GIVES $(I_0/I)_{peak}$ DEPENDING UPON THE IONIC STRENGTH OF SOLUTION[a)]

Ionic strength	$(I_0/I)_{peak}$	$[MV^{2+}]$ which gives $(I_0/I)_{peak}$ /M
0.0045	40	0.0015
0.01	25	0.0013
0.023	9.5	0.0010
0.045	4.5	0.0009

a) In each measurement of $(I_0/I)_{peak}$, the ionic strength was kept constant by adjusting the NaCl concentration.

the pair leading to a very small free radical yield. With increase of MV^{2+} concentration, $[Ru(bpy)_3]^{2+}$ may be expelled into bulk solutions, where the free radical yield is considerably higher than in adsorbed state. We have observed analogous effect of adsorption upon free radical yield also in the case of NaDHP solution.

Effect of the Addition of Salt upon the Luminescence Quenching Behavior in PVSK Solution. In order to examine in a more detail the adsoprtion on molecular assembly and the luminescence quenching behaviors of $[Ru(bpy)_3]^{2+}$–MV^{2+} system, we have investigated the effect of addition of NaCl on the luminescence of PVSK solution. The results are summarized in Table 4, which shows that the MV^{2+} concentration that gives $(I_0/I)_{peak}$ and the $(I_0/I)_{peak}$ value itself decrease with increase of the ionic strength of the solution. This result means that, when NaCl is added into the solution, Na^+ may be attracted to the polymer electrolyte, shielding its electrostatic fields and preventing adsorption of $[Ru(bpy)_3]^{2+}$ and MV^{2+} on polymer electrolyte.

Concluding Remarks. In the present work, we have demonstrated the luminescence-quenching behaviors of $[Ru(bpy)_3]^{2+}$–MV^{2+} system adsorbed on anionic molecular assemblies. The remarkable enhancement of quenching observed when both $[Ru(bpy)_3]^{2+}$ and quencher cations are adsorbed on anionic moelcular assembly was the largest in PVSK solution. Such effect was observed also in NaDHP vesicle solution though it is less pronounced compared with PVSK solution. However, no such specific quenching behavior was observed in SDS micellar soluton. These results show clearly the difference among these anionic molecular assemblies in the capability to keep $[Ru(bpy)_3]^{2+}$-cationinc quencher pair in sufficiently close proximity to undergo photoinduced electron transfer. In this respect, SDS micelle seems to have the most disordered structure among these three molecular assemblies, which can be concluded also from several other experimental results.[6,7,12,13]

The present work was partly supported by the Grant-in-Aid from the Japanese Ministry of Education, Science and Culture to NM (58045097).

Formation Constants of Cyclodextrin Inclusion Complexes with Iodine in Aqueous Solutions

Isao SANEMASA,* Toyohisa KOBAYASHI, and Toshio DEGUCHI
Department of Chemistry, Faculty of Science, Kumamoto University, Kurokami 2-39-1, Kumamoto 860
(Received May 28, 1984)

Formation constants of cyclodextrin (CyD) inclusion complexes with iodine were determined by measuring solubilities of iodine vapor in water. The formation constants at 25 °C are 8.3×10^3 (α-CyD), 1.0×10^2 (β-CyD), and 13 $dm^3\,mol^{-1}$ (γ-CyD). The temperature dependence of α-CyD–I_2 complexation was studied. ΔH and ΔS, being 9.52 kJ mol^{-1} and 107 J K^{-1} mol^{-1} at 25 °C, respectively, are both largely dependent on temperature even within a rather small temperature range 15—35 °C studied. For the complexation with α-CyD, contribution of dehydration of iodine was estimated. The method proposed here is useful to study the formation of CyD association complexes with such substrates as are slightly soluble in water and easily vaporize from the aqueous phase.

The complex formation of cyclodextrin (CyD) with iodine has been studied with a view to understanding the far more complicated starch systems.[1,2] The molecular geometry of α-CyD–I_2 inclusion crystals has been determined by X-ray analysis as follows:[3] (a) The iodine molecule is coaxial with the host molecule, (b) one iodine atom of I_2 is situated near the opening on the primary alcohol side with a van der Waals contact with the cavity and the other is surrounded by six O(4) atoms with a contact greater than the van der Waals contact, and (c) the cavity is deep enough to enclose the whole iodine molecule. An iodine molecule can thus be suitably fitted with the α-CyD cavity. This may be responsible for giving the formation constant as large as 9.35×10^4 $dm^3\,mol^{-1}$ at 24 °C, the only data available so far in the literature.[2]

In our preceding paper[4] we reported a method of preparing an aqueous iodine solution saturated with its vapor. An important characteristic of this method is that the equilibrium solubility of iodine at a desired concentration can be obtained by adjusting the temperature of a solid iodine which is held separately isolated in space from an aqueous phase. The method seems to be suitable for studying possible interactions between iodine and a particular substance in an aqueous medium.

Here we have applied the method to aqueous CyD solutions. The equilibrium solubility of iodine vapor is increased by the presence of α-, β-, or γ-CyD, from which formation constants of inclusion complexes can be determined.

Experimental

Materials. Solid iodine of analytical reagent grade and cyclodextrins (α-, β-, and γ-CyD form Nakarai Chemicals) of guaranteed grade were used without further purification. A suitable amount of CyD, which had been dried over phosphorus pentaoxide, was weighed and dissolved in 1.0×10^{-3} mol dm^{-3} $HClO_4$ to prepare a CyD solution of known concentration. Perchloric acid was used instead of pure water to prevent hydrolysis of iodine.

Apparatus and Procedures. The apparatus used for preparing aqueous iodine solutions saturated with iodine vapor was essentially the same as that previously reported.[4] A 50 cm^3 aqueous CyD solution was placed in a separation funnel designated as the "solubility flask," and iodine crystals were packed in a column (ϕ 8 mm×200 mm) designated as the "solute reservoir." The temperatures of the solubility flask and the solute reservoir were held constant with water flows from separate thermostated baths circulating through their surrounding jackets. The assembled apparatus was placed in a chamber, where the temperature was kept higher than that of the solute reservoir. The iodine vapor, generated by a flow of air through the solute reservoir, was introduced into the solubility flask *via* a sintered glass ball and circulated by means of a Viton diaphragm air-pump. The circulation rate was set at 0.8 $dm^3\,min^{-1}$. At this rate, concentrations of iodine in CyD solutions had been found in advance to reach constant values after 60 min aeration. After attainment of solubility equilibrium, 10 cm^3 samples were withdrawn and the iodine concentrations were determined by solvent extraction-spectrophotometry at 514 nm. The solvent extraction was repeated twice for the same sample solution with a successive addition of 20 cm^3 of CCl_4.

Results and Discussion

Equilibrium Solubilities of Iodine Vapor in the Presence and Absence of Cyclodextrins. Solubility runs were made under the condition that the temperature of the solute reservoir was lower than that of the solubility flask, with the latter maintained constant. The vapor pressure of iodine at a given temperature of the solute reservoir was estimated from the equation, derived based on Ref. 5, $\log PT^{3/2}=16.945-3464/T$, where P is the vapor pressure in Pa and T is absolute temperature. At first, equilibrium solubilities were measured in the absence of CyD, and Henry's law constant, K_H, at each temperature of the aqueous phase was determined from the equation $K_H=P/X_2$, where X_2 is the mole fraction of dissolved iodine. The results are shown in Table 1, in which the K_H value obtained in iodic acid solution is also given since the use of HIO_3 was recommended in view of protecting iodine in aqueous medium from reduction.[2] If the reduction of iodine does occur in $HClO_4$ solution, an increase in

TABLE 1. HENRY'S LAW CONSTANTS OF IODINE VAPOR IN $HClO_4$ SOLUTIONS[a]

Temperature of aqueous phase / °C	Henry's law constant[b] / 10^6 Pa	ΔG_{dehyd}[c] / kJ mol^{-1}
15.00	1.08±0.04 (0.995)	−5.67
20.00	1.36±0.02 (0.999)	−6.33
25.00	1.81±0.03 (0.999)	−7.15
	1.72±0.02 (0.999)[d]	
30.00	2.32±0.02 (0.999)	−7.89
35.00	3.01±0.02 (0.999)	−8.69

a) The concentration of $HClO_4$ is 1.0×10^{-3} mol dm^{-3}. b) In parentheses are indicated the correlation coefficients derived from $K_H = P/X_2$. c) Estimated from K_H in atom units by using $\Delta G_{dehyd} = -RT \ln K_H$, where "dehyd" refers to the dehydration of iodine dissolved in the aqueous phase. ΔH_{dehyd} and ΔS_{dehyd} are estimated to be 38.2 kJ mol^{-1} and 152 J K^{-1} mol^{-1}, respectively, in the temperature range studied. d) Obtained in HIO_3 solutions of 0.20 mol dm^{-3}.

the apparent solubility of iodine would be expected from the equilibrium $I^- + I_2 \rightleftarrows I_3^-$. Yet, as seen from Table 1, the K_H value observed in HIO_3 solution is rather small compared with that in $HClO_4$ at the same temperature of the aqueous phase. There was observed an increase by *ca.* 5% in the solubility of iodine in iodic acid medium of 0.2 mol dm^{-3} relative to that in perchloric acid of 1.0×10^{-3} mol dm^{-3}. The reason for this is not clear, but some interaction between IO_3^- and I_2 may be responsible.

Equilibrium solubilities of iodine vapor were measured in α-, β-, or γ-CyD solutions and the results expressed as S_{obsd} are shown in Table 2, where are also listed the equilibrium solubilities in the absence of CyD, expressed as S_o.

Iodine molecules dissolved in a CyD solution are equilibrated with CyD molecules to form associated complex(es), while those in the free form are equilibrated with iodine vapor in the gaseous phase. If it is assumed that the solubility of *free* iodine is little affected by the presence of CyD in the aqueous medium, the S_o value at a given temperature of the aqueous phase can be estimated from Henry's law constant provided the temperature of solid iodine is known.

Estimation of Formation Constants. α-CyD is reported to from a 1:1 complex with iodine,[1] but there are no experimental data concerning the stoichiometry of β- and γ-CyD complexes. We have measured absorption spectra of iodine in CyD solutions of various concentrations; A clear isosbestic point was observed at 460 nm for α-CyD and a hardly recognizable one near 460 nm for β-CyD, but for γ-CyD the spectra appeared too closely superimposed to reveal any isosbestic point.

It may be valid to assume that, at the most, one CyD molecule is able to accept two iodine molecules, since even with γ-CyD the cavity is not large enough to receive more than three iodine molecules. Complex formation can then be written as

$$CyD + I_2 \rightleftharpoons CyD\cdot I_2, \quad K_1, \tag{1}$$

$$CyD\cdot I_2 + I_2 \rightleftharpoons CyD\cdot (I_2)_2, \quad K_2, \tag{2}$$

where K_1 and K_2 are stepwise formation constants. The total concentration of iodine present in the aqueous phase, C_{I_2}, and the total concentration of CyD, C_{CyD}, are expressed as

$$C_{I_2} = [I_2] + [CyD\cdot I_2] + 2[CyD\cdot (I_2)_2]$$
$$= [I_2](1 + K_1[CyD] + 2K_1K_2[CyD][I_2]), \tag{3}$$

$$C_{CyD} = [CyD] + [CyD\cdot I_2] + [CyD\cdot (I_2)_2]$$
$$= [CyD](1 + K_1[I_2] + K_1K_2[I_2]^2), \tag{4}$$

where $[I_2]$ and $[CyD]$ denote free concentrations of I_2 and CyD, respectively. Here, $[I_2]$ and C_{I_2} are equal to S_o and S_{obsd}, respectively. Combining Eqs. 3 and 4, we have

$$(S_{obsd} - S_o)/C_{CyD} = K_1S_o(1 + 2K_2S_o)/\{1 + K_1S_o(1 + K_2S_o)\}. \tag{5}$$

Suppose, as a first approximation, $1 + 2K_2S_o \approx 1 + K_2S_o$, that is, the product K_2S_o is small compared with unity, and Eq. 5 becomes

$$(S_{obsd} - S_o)/S_o(C_{CyD} - S_{obsd} + S_o) = K_1 + nK_1K_2S_o, \tag{6}$$

where n takes the value of 1 or 2. It can be seen from Table 2 that for a particular type of CyD the left-hand side of Eq. 6 is almost constant independently of S_o at a given temperature of the aqueous phase. This means that the K_2 term need not be considered, *i.e.*, α-, β-, and γ-CyD form 1:1 complexes with iodine.

The formation constants K_f ($=K_1$)$=[CyD\cdot I_2]/([CyD][I_2])$ are summarized in Table 3. The K_f value obtained for α-CyD at 25 °C in 0.20 mol dm^{-3} HIO_3 solution is in good agreement with the literature value included in Table 3 despite different experimental approaches employed in these two studies. The reason that the K_f value observed in $HClO_4$ solution is somewhat smaller than that in HIO_3 is not clear at present, but may be due to an inhibition effect of perchloric acid. It is agreed that $HClO_4$ can enter the α-CyD cavity, the formation constant being reported to be 40 dm^3 mol^{-1}.[6]

It can be seen from Table 3 that the formation constant of the complex with iodine decreases drastically on going from α- to γ-CyD. This is probably due to the size of the CyD cavity; β- and γ-CyD, especially the latter, have too large cavities to accommodate an iodine molecule tightly.

Thermodynamic Considerations of α-Cyclodextrin Complexation with Iodine. A striking feature of complex formation of α-CyD with iodine is the

temperature dependence of the formation constant. Table 3 shows that with rising temperature the K_f value increases at first, and then decreases. The thermodynamic parameters of the complexation were estimated from the temperature dependence of K_f with the aid of the equations $\Delta G=-RT \ln K_f=\Delta H-T\Delta S$ and $dH/dT=\Delta C_p=A+BT$, where ΔC_p is the heat capacity change, A and B are constants, and the other symbols have their usual meanings. We can express K_f as a function of T as

$$\ln K_f = (A/B) \ln T + (B/2R)T - (C/R)T^{-1} + C' - A/R, \quad (7)$$

where C and C' are integration constants. The data shown in Table 3 are best fitted by the equation

$$\ln K_f = 140.0 \ln T - 1.441\ T - 87500\ T^{-1} - 65.60. \quad (8)$$

The result is shown in Fig. 1 by a solid curve. The ΔH and ΔC_p are expressed, respectively, by $\Delta H=87500\ R+140.0\ RT-1.441\ RT^2$ and $\Delta C_p=140.0\ R-2.882\ RT$. The thermodynamic parameters thus estimated for the α-CyD-I_2 complex are summarized in Table 3. It is noteworthy that ΔH and ΔS values are both strongly temperature dependent, changing from positive to negative.

complexation have been obtained for a wide variety of substrates, and it has now become evident that ΔH takes usually negative value, whereas ΔS can be positive or negative.[7] Theoretical approaches have been made to elucidate the mechanism of CyD complexation with substrates,[8,9] but there are still some arguments in detail. It is now generally accepted that both the dehydration of a guest molecule on entering the CyD cavity and the interaction between a guest and CyD inside the cavity play an important role. The guest being hydrophobic, the interaction decreases with increasing temperature. On the other hand, the guest being a gaseous nonelectrolyte molecule, the dehydration increases with rising temperature, and in this case thermodynamic parameters can be easily determined by measuring the temperature dependence of the aqueous solubility of the guest in the absence of CyD. The results for iodine are shown in Table 1. Substracting the free energy change of dehydration from that of the overall process yields −14.4 (15 °C), −15.4 (20 °C), −15.3 (25 °C), −14.6 (30 °C), and −13.9 kJ mol^{-1} (35 °C). If it is assumed that these values provide a rough measure of iodine-CyD interaction, the order of the above figures at lower temperatures is not consistent with the view that the interaction can be explained by considering only hydrophobic interaction.

To shed light on what is really responsible for the present unusual temperature dependence of K_f observed for iodine, it seems desirable to study CyD complexations with nonelectrolytes, only sparingly soluble in water and volatile. For such a purpose the experimental technique proposed here is useful which utilizes vapor of nonelectrolyte.

Solubility and Synergistic Extraction Equilibria for [4-(2-Pyridylazo)resorcinolato] Nickel(II) Complexes

Hitoshi HOSHINO and Takao YOTSUYANAGI*
Department of Applied Chemistry, Tohoku University, Aoba, Aramaki, Sendai 980
(Received September 14, 1984)

The nickel(II) complex of 4-(2-pyridylazo)resorcinol (PAR, H_2L) is known to show somewhat anomalous and complicated behavior in solution. In this regard, the solubility and the synergistic extraction equilibria of the above complex are studied in connection with acid dissociation reactions. The intrinsic solubility and the acid dissociation constants are determined to be, $S_0=[[Ni(HL)_2]]=10^{-6.2\pm0.1}$ mol dm^{-3}, $K_{a1}=[[Ni(HL)L^-][H^+][[Ni(HL)_2]]^{-1}=10^{-6.2\pm0.1}$, and $K_{a2}=[[NiL_2]^{2-}][H^+][[Ni(HL)L]^-]^{-1}=10^{-7.1\times0.1}$, respectively in the solution with the ionic strength of 0.10 (Na_2SO_4) at 298 K. Using the above constants, the extraction constant of the neutral complex with trioctylphosphine oxide (TOPO) into chloroform is evaluated as $K_{ex}=[[Ni(HL)_2(TOPO)_2]]_o[[Ni(HL)_2]]^{-1}[TOPO]_o^{-2}=10^{3.1\pm0.2}$, where the subscript o denotes the organic phase. An equilibrium diagram for the nickel(II)-PAR complexes is proposed.

A well-known sensitive reagent, 4-(2-pyridylazo)-resorcinol (PAR, H_2L) has been used for the trace determination of nickel(II) ion.[1-4] In our previous studies[5-8] of the ion pair extraction of anionic PAR complexes with a quaternary ammonium salt (QCl),[9] it was shown that the nickel(II) ion yields the PAR complex having somewhat unusual properties in sharp contrast to those of other divalent ions, Fe(II), Cu(II), Zn(II), and Cd(II). (1) The ion pair of the mononegative complex, Q[Ni(HL)L] has much poorer extractability than that of the dinegative one, $Q_2[NiL_2]$. This seems to be contrary to the general rule found in ion pair extraction, *i.e.*an increase in the charge number of the anion leads to a decrease in the extractability. (2) The neutral complex, $[Ni(HL)_2]$ is slightly soluble in water as well as in chloroform or nitrobenzene, whereas the correponding iron(II) complex is partly distributed into these solvents. The neutral nickel(II) complex can be extracted synergistically with trioctylphosphine oxide (TOPO) as $[Ni(HL)_2(TOPO)_2]$, which is not an unusual matter as compared with the other neutral PAR complexes.[7,10]

These observations have prompted a more thorough investigation of the solubility, acid dissociation, and synergistic extraction equilibria of the nickel(II)-PAR complexes. This was expected to be an approach to interpret the somewhat anomalous and complicated behavior of the complexes in solutions, especially in the solvent extraction systems.

In this paper is established the equilibrium relation between nickel(II)-PAR complexes which has been sometimes ambiguous and inconsistent,[6,11-13] and the results are discussed in comparison with those of the other metal ion complexes.

Experimental

Apparatus and Reagents. A Hitach model 124 double beam recording spectrophotometer with 1 cm glass cells and a Horiba M-5 pH meter were used. In extraction procedures, samples were shaken in an Iwaki KM-type reciprocating shaker. A Yamato Coolnics Circulator model CTR200/CTE220 water bath was used at a constant temperature of 298 K.

TOPO, as obtained from Dojindo Lab. (Kumamoto, Japan) was dissolved in chloroform which was purified by distillation and saturated with water. Nickel(II)-PAR complex ($[Ni(HL)_2]\cdot2H_2O$) was prepared as described by Corsini *et al.*[14] The concentration of the PAR complex stock solution (pH 8) was determined spectrophotometrically.

All other reagents used were of analytical grade.

Procedure. Solubility Measurements: About 50 cm^3 of a phosphate buffer solution (2×10^{-3} mol dm^{-3}) containing nickel(II)-PAR complex (initially 10^{-3}—10^{-4} mol dm^{-3}) and sodium sulfate (0.033 mol dm^{-3}, I=0.10) with 5 cm^3 of chloroform was allowed to stand at 298 K for at least 5 h with occasional shaking. Sodium sulfate was used to maintain a constant ionic strength in conformity with the ion pair extraction study.[6] The initial pH of the solution was roughly adjusted with the buffer, dilute sulfuric acid and sodium hydroxide solutions. The pH range of 6 to 8 was chosen in order to prevent the decomposition of the complex due to protolysis and hydrolysis reactions. The concentration of the nickel complex in aliquots of the saturated solutions was determined spectrophotometrically after filtration through a G-4 sintered glass filter. The pH of the filtrate solution was measured. Because of the inert nature of the nickel(II)-PAR complexes, sulfate and phosphate ions in the solution had no significant effect on the above experiments. Partition of the neutral and the anionic complexes into chloroform phase occurs to a slight extent. However, such a phenomenon has no effect on the solubility measurements under the conditions where the precipitate is present in the system.

TOPO Extraction: Ten cm^3 of an aqueous solution containing phosphate buffer (2.5×10 mol dm^{-3}), sodium sulfate (I=0.10), and nickel(II)-PAR complex were equilibrated by shaking with an equal volume of chloroform containing an appropriate concentration of TOPO in a glass sample tube (50 cm^3), and allowed to stand in a thermostated bath at 298 K for more than 5 h with occasional shaking. Aliqouts of the organic phase were taken and the absorbance at 535 nm was measured (the molar absorption coefficient is 3.57×10^4 dm^3 mol^{-1} cm^{-1}).

Results and Discussion

The equilibrium saturation with respect to the nickel(II)–PAR complex was attained after 4 h; this was confirmed by the solubility-time curve obtained by heating the samples to 313—323 K followed by rapid cooling to the final temperature, 298 K.

The solubility-pH curve for the nickel(II)–PAR complex in water saturated with chloroform is shown in Fig. 1. Above pH 6, the complex is in part soluble as the anionic species of $[Ni(HL)L]^-$ and $[NiL_2]^{2-}$. Decomposition of the complex was negligible. The solubility equilibria can be expressed by the following reactions; the intrinsic solubility S_0 of the neutral complex is given by

$$[Ni(HL)_2]_s \rightleftharpoons [Ni(HL)_2], \quad S_0 = [[Ni(HL)_2]] \tag{1}$$

where the subscript s denotes the solid phase, and the acid dissociation constants are represented as

$$[Ni(HL)_2] \rightleftharpoons [Ni(HL)L]^- + H^+, \quad K_{a1} = \frac{[[Ni(HL)L]^-][H^+]}{[[Ni(HL)_2]]} \tag{2}$$

$$[Ni(HL)L]^- \rightleftharpoons [NiL_2]^{2-} + H^+, \quad K_{a2} = \frac{[[NiL_2]^{2-}][H^+]}{[[Ni(HL)L]^-]} \tag{3}$$

The solubility, S of the complexes is given by

$$S = [[Ni(HL)_2]] + [[Ni(HL)L]^-] + [[NiL_2]^{2-}] \tag{4}$$

From Eqs. 1—4 the following equation is obtained,

$$\left(\frac{S}{S_0} - 1\right)[H^+]^2 = K_{a1}[H^+] + K_{a1}K_{a2} \tag{5}$$

The intrinsic solubility, S_0 was obtained by extrapolation on the solubility-pH curve shown in Fig. 1 (dashed line).

$$\log S_0(\text{mol dm}^{-3}) = -6.2 \pm 0.1 \quad [I=0.10(Na_2SO_4),\ 298\ K]$$

From the plots of Eq. 5 given in Fig. 2, the values of K_{a1} and K_{a2} were determined to be

$$pK_{a1} = 6.2 \pm 0.1, \quad pK_{a2} = 7.1 \pm 0.1 \quad [I=0.10(Na_2SO_4),\ 298\ K]$$

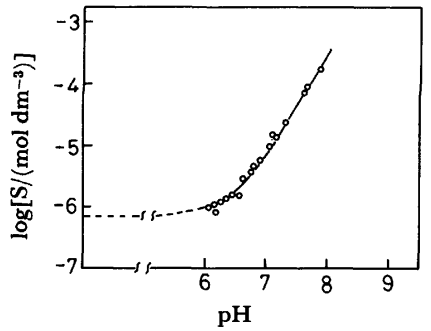

Fig. 1. Solubility *vs.* pH curve for Ni(II)–PAR complex at 298 K.
I=0.10 (Na_2SO_4), $C_{Phosphate}=2.0\times10^{-3}$ mol dm^{-3}.

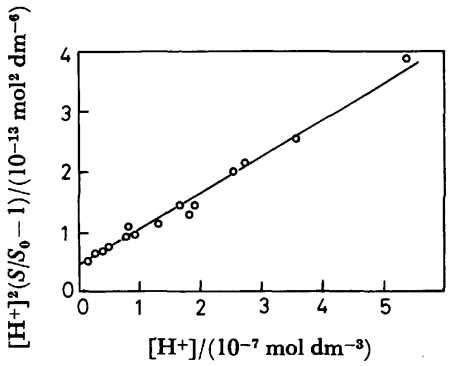

Fig. 2. Plots of Eq. 5.

The calculated log S *vs.* pH curve shown in Fig. 1 as the solid line is in good agreement with the experimental points.

The value of S_0 for the nickel(II)–PAR complex is very small. Although no quantitative solubility data of the other metal–PAR complexes are available, there is no evidence for the precipitation of the complexes at concentrations below 5×10^{-6} mol dm^{-3} in a similar medium. The iron(II) complex, $[Fe(HL)_2]$ was partly distributed into chloroform and still more so into nitrobenzene.[8] This fact demonstrates an interesting contrast between the nickel and iron PAR complexes.

The acid dissociation constants of 1-hydroxyl groups (para position to azo group) in the nickel(II)–PAR complex in 50% aqueous dioxane solution were reported by Corsini *et al.*[15] as pK_{a1}=7.7 and pK_{a2}=9.2. As these values were obtained in quite a different medium, these are not considered in greater detail. The values obtained here agree within a similar order of magnitude with those of the PAR complexes of divalent ions, iron(II); pK_{a1}=6.47, pK_{a2}=7.66 (I=0.10, 293 K),[8] copper(II); 6.54, 7.64 (I=0.10, 298 K),[16] zinc(II); 6.45, 7.55 (I=0.10, 298 K),[17] and cadmium(II); 6.67, 7.84 (I=0.10, 298 K),[18] respectively. The parallel order between the acidity of 1-hydroxyl groups and the stability of PAR complexes suggested by Corsini *et al.*[15] does not seem to be valid in the light of these data as the stability order may be $Fe^{II}>Ni^{II}>Cu^{II}>Zn^{II}>Cd^{II}$.[8,16–18]

At the pH condition for the photometric determination of nickel (pH 9.2, borate buffer)[2,3] the predominant species (99%) is, thus, the dianion, $[NiL_2]^{2-}$ which has the largest molar absorption coefficient of $(7.2—7.8)\times10^4$ dm^3 mol^{-1} cm^{-1} at 495 nm as compared with the other protonated ones.

Besides TOPO, typical monodentate adduct formers such as pyridine, pyridine *N*-oxide, and tributyl phosphate are effective for the extraction of the neutral complex $[Ni(HL)_2]$, while the bidentate ones, 1,10-phenanthroline, 2,2′-bipyridine, and ethylenediamine, fail to work.

The extraction with TOPO is represented by

$$[Ni(HL)_2] + 2TOPO_{(o)} \rightleftharpoons [Ni(HL)_2(TOPO)_2]_{(o)} \tag{6}$$

$$K_{ex} = \frac{[[Ni(HL)_2(TOPO)_2]]_o}{[[Ni(HL)_2]][TOPO]_o^2} \quad (7)$$

where the subscript o is used for the species in the organic phase. Using the total concentration of the complex species in the aqueous phase, $C_{a,Ni}$, Eq. 7 is rewritten as

$$K_{ex} = \frac{[[Ni(HL)_2(TOPO)_2]]_o}{C_{a,Ni}[TOPO]_o^2}\left(1+\frac{K_{a1}}{[H^+]}+\frac{K_{a1}K_{a2}}{[H^+]^2}\right) \quad (8)$$

where the aqueous concentration of $[Ni(HL)_2(TOPO)_2]$ is neglected. When the precipitate is present, $C_{a,Ni}$ is equal to the solubility, S(Eq. 4). At constant pH, the plots of $\log\{[[Ni(HL)_2(TOPO)_2]]_o(C_{a,Hi})^{-1}\}$ *vs.* $\log\{[TOPO]_o\}$ give a straight line of a slope 2 as shown in Fig. 3. Because of the upward deviation at low organic concentration of TOPO (<0.05 mol dm^{-3}, curve 1 in Fig. 3), the calculation of the K_{ex} value was made using the experimental points on the straight line portion. Under the conditions where the precipitate is in the system at pH≤7.05, the concentration of $[Ni(HL)_2]$ is held constant according to Eq. 1, thus,

$$K_{ex} = \frac{[[Ni(HL)_2(TOPO)_2]]_o}{S_0[TOPO]_o^2} \quad (9)$$

Under higher pH conditions (pH≥7.40) where no precipitate is in the system, Eq. 8 is used for calculation of the K_{ex} value, where $C_{a,Ni}$ is given by $C_{a,Ni}=C_{Ni}-[[Ni(HL)_2(TOPO)_2]]_o$, ($C_{Ni}$ is the total concentration of the nickel(II)-PAR complexes). The calculated values of log K_{ex} at various pH and TOPO concentrations are shown in Table 1. The mean value was determined to be,

$$\log K_{ex} = 3.1\pm0.2 \quad [I=0.10(Na_2SO_4),\ 298\ K]$$

0.20	3.0						

log K_{ex}=3.1±0.2 [I=0.10 (Na_2SO_4), at 298 K] (averaged value of 18 runs).

A few reports have dealt with this type of extraction of neutral PAR complexes.[7,19,20] Only one comparable datum is the extraction constant for the vanadium(V)-PAR-TOPO complex, $K_{ex}=[[VO_2(HL)(TOPO)]]_o[[VO_2(HL)]]^{-1}[TOPO]_o^{-1}=10^{2.17}$.[7] In general, in TOPO synergistic extraction systems, over-all extraction constants (including formation of parent complexes) and adduct formation constants in the organic phase have been most frequently used to describe the extraction processes.[21] However, they can not be directly compared with the data obtained in this work. The adduct formation constant in chloroform, $\beta_2=[[Ni(HL)_2(TOPO)_2]]_o[[Ni(HL)_2]]_o^{-1}[TOPO]_o^{-1}$ was roughly estimated as follows: when the distribution ratio, D_{Ni} is defined as $D_{Ni}=\{[[Ni(HL)_2]]_o+[[Ni(HL)_2(TOPO)_2]]_o\}(C_{a,Ni})^{-1}$, by extrapolating the $[TOPO]_o$ term (curve 1 in Fig. 3, pH 6.0) to zero, $D_{Ni}\approx[[Ni(HL)_2]]_o(C_{a,Ni})^{-1}\approx10^{-1}$ is obtained, and from Eq. 8, $\beta_2=K_{ex}\{D_{Ni}(1+K_{a1}/[H^+]+K_{a1}K_{a2}/[H^+]^2)\}^{-1}\approx10^{3.9}$. It is clearly recognized that this β_2 value is smaller by some order of magnitude than those for the other TOPO adducts in chloroform, in which TOPO molecules are directly bound to the central metal ions replacing aqua ligands, *i.e.* mixed ligand complex (for example, some β-diketone complex systems).[21,22] In the nickel(II)-PAR system, therefore, there is a little doubt about the possibility of a mixed ligand complex. It is also likely that two TOPO molecules are bound to each of two 1-hydroxyl groups on the PAR ligands *via* hydrogen bonding, which causes an increase in hydrophobicity of the parent PAR complex. This possibility seems to be supported by the fact that the complex is well distributed into some polar solvents having hydrogen bonding ability, alcohols, esters, and ketones. It is important to observe that the coordination mode of the PAR ligands (bidentate or tridentate) would decide between the alternative possibilities depending upon whether the complex is "coordinatively saturated" with two tridentate HL^- or "unsaturated" having two bidentate HL^- and two aqua ligands. Kawamoto *et al.* re-

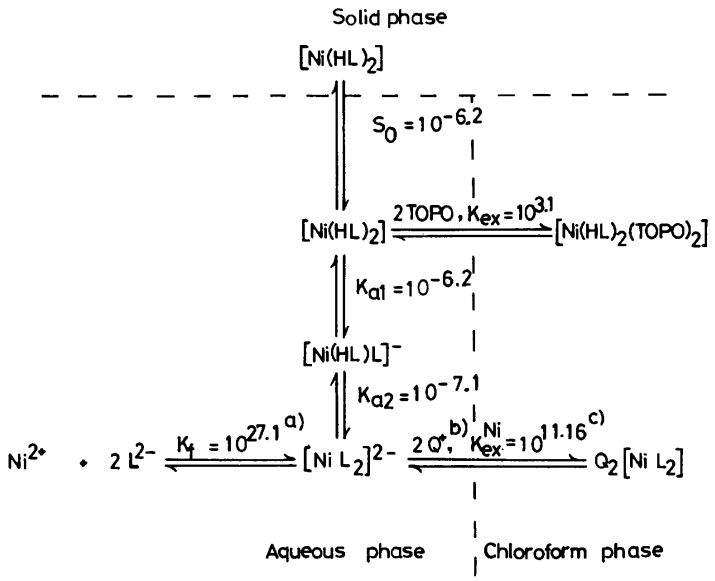

Fig. 4. Equilibrium diagram of Ni(II)–PAR system.

cently found the nickel(II)–PAR complex having the 1:3 stoichiometry in the ion pair extraction system with a highly lipophilic quaternary ammonium salt.[11] Detailed discussion of the extraction mechanism, in all events, will be the emphasis of a future study which will provide valuable information on the chemistry of PAR complexes.

Finally, several nickel(II)–PAR complex species in solutions and their equilibrium constants were verified as summarized in Fig. 4. These data serve as a quantitative basis for understanding and designing of the conventional spectrophotometric systems and the ion pair solvent extraction for the nickel determination.

Basic Properties of MgO Doped with Alkaline Metal Compounds

Tsuneo MATSUDA,* Yo SASAKI,† Hiroshi MIURA, and Kazuo SUGIYAMA
Department of Applied Chemistry, Faculty of Engineering, Saitama University, Shimo-ohkubo, Urawa 338
†*Tokyo Institute of Technology, Nagatsuda, Midoriku, Yokohama 227*
(Received August 24, 1984)

Synopsis Basic properties of MgO doped with NaOH, KOH, and Li_2CO_3 which was calcined at 550, 700, and 900 °C in air were examined. The basicity of the catalysts was determined from the irreversible amount of adsorption of phenol and BF_3, followed by evacuation at room temperature (for both adsorbates), 100, 200, and 300 °C (for phenol) after adsorption at room temperature. A good correlation was observed between the amount of phenol remained after evacuation at higher temperature than 200 °C and that of BF_3. By doping of 1 wt% of alkali metal compounds in MgO the isomerization activity of 1-butene was enhanced, but by 10 wt% the activity remarkably decreased.

The studies on the addition effects of sodium hydroxide on the physicochemical properties of MgO were reported by Malinowski *et al.*[1] in which any change in the acidic or basic strength of MgO was not found. In the literature[2] the basicity of the catalysts containing 0 to 0.82 mmol Na^+/g MgO were examined. However, there is no report on the studies of the catalysts containing more than 0.82 mmol and other alkali metal compounds except NaOH. In this study the effect of the addition of KOH, Li_2CO_3, and also NaOH on the basicity of MgO was examined in connection with 1-butene isomerization and, in part, reexamined the results of Malinowski *et al.*[2]

Experimental

Catalysts Preparation. Magnesium hydroxide was first prepared by precipitating with aqueous ammonia (6 mol dm^{-3}) from the saturated aqueous solution of magnesium nitrate. Thus prepared $Mg(OH)_2$ was impregnated into the aqueous solution of NaOH, KOH, and Li_2CO_3 of different concentration which was arranged to be 1 and 10 wt% as M^+ per MgO (M^+ is alkali metal ion) after calcination and then evaporated to dryness on the water bath. The dry $Mg(OH)_2$ doped with the each alkali metal compound (abbreviated simply as dopant) was arranged to the granule of 20 to 60 mesh, which were calcined at 550, 700, and 900 °C for 3 h in air. Magnesium oxide not doped with the dopants was prepared by the calcination of $Mg(OH)_2$ at 550, 700, and 900 °C for 20 h in air.

Measurement of Basicity. Basicity was determined from the irreversible amount of adsorption of phenol or BF_3 according to the spring balance method, *i.e.*, after the adsorption of phenol or BF_3 was attained to equilibrium at room temperature, the sample in the quartz basket was evacuated at room temperature (for both adsorbates) and at 100, 200, and 300 °C (for phenol) until the change of the reading of the quartz spring balance ceased. The strength of the basicity was qualitatively examined with the color change of indicators.[2]

Isomerization of 1-Butene. The isomerization of 1-butene was carried out at 0 °C in a closed vessel (dead volume=*ca.* 180 cm^3) equipped with a circulation system. The reaction products were analyzed by gas chromatography on a column of VZ-7 (4 m) at 0 °C.

Results and Discussion

The irreversible amounts of adsorption of phenol and BF_3, surface area, and basic strength of various samples are shown in Table 1. The adsorbed amounts of phenol decreased as the evacuation temperature of the adsorbed samples increased. The molecular sizes of both phenol and BF_3 were calculated to be 8.24×10^{-20} and 9.62×10^{-20} m^2, from the excluded volumes of the van der Waals equation estimated from the critical points. From the sizes and the adsorbed amounts of each adsorbate the adsorption of phenol can be calculated to be more than monolayer (for instance, 1.27 and 2.7 molecular layer on MgO–KOH (10) treated at 550 °C (evacuated at r.t.) and 900 °C (at 100 °C), respectively) and, on the other hand, BF_3 adsorbed less than monolayer. By the evacuation at higher temperature than 200 °C, the adsorbed amount of phenol was reduced to less than monolayer. At the temperature of lower than 100 °C phenol of physical adsorption seems to be still remained on the surface. Tanabe[3] reports that phenol adsorbs not only on the basic site but also on the acidic one, indicating that phenol is not necessarily suitable for the measurement of basicity. As shown in Fig. 1, however, a good correlation between the basicity obtained from the adsorption of BF_3 and that from phenol evacuated at 200 and 300 °C was obtained. The measurement of basicity by BF_3 adsorption is also reported by Niiyama and Echigoya.[4] Accordingly, it is possible to measure the basicity by phenol adsorption, if the evacuation treatment at 200 or 300 °C, is followed after the adsorption.

The surface areas of MgO–alkali metal system decrease as increasing the content of the dopants, indicating that they exert the shrinking effect on the surface by any kind of interaction with MgO. As shown in the case of Al_2O_3–$NaNO_3$ system,[5] the dopants will also interact with surface OH groups MgO, causing the decrease of the surface area. This effect was also found in other alkali compounds except those used in this study.[6] In doping of 10 wt% the strength of the basicity decreased, which would be difficult to ascribe to the interaction of the dopants with the OH groups on the surface. The OH groups on MgO will be of weak basic sites as those on CaO.[7] Therefore the dopants will interact with or block over Lewis base site on MgO, resulting to the reduction of the basic strength.

The results of the isomerization of 1-butene over the catalysts doped with the alkali compounds followed with calcination at 550°C are shown in Fig. 2. By doping of 1 wt% of the dopants the isomerization activity was enhanced, but the doping to 10 wt% caused the remarkable decrease of the activity. As shown in Fig. 2 the activity of the catalyst doped with Li_2CO_3 by 1 wt% was the highest, which might be due to both the higher surface area and suitable basicity produced by the interaction with MgO and Li_2CO_3.

Each points in the figure were obtained from the results of Table 1.

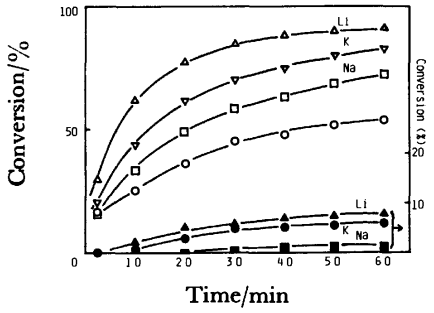

Fig. 2. Conversion *vs.* reaction time plot in 1-butene isomerization.
Open symbols 1 wt% doping.
Closed symbols 10 wt% doping.
○: no doping.

As Li_2CO_3 can be decomposed releasing CO_2 at lower temperature (618 °C) than the decomposition temperature of NaOH and KOH, a parts of Li_2CO_3 may be decomposed with the treatment at 550 °C, by which the suitable active sites may be formed. Anyway, by the doping of 1 wt% of the dopants the active sites of the suitable basic strength of H_-=22.3 and 27 for the isomerization[6] will be increased. Deactivation by the addition of 10 wt% of dopants may be ascribed to the considerable decrease in the surface area of the catalysts except the case of $MgO-Li_2CO_3$ and in the sites related with the suitable basic strength. The ratios of cis to trans isomers at the initial stage of the isomerization are shown in Table 2. The ratios exhibited the characteristic values[8] for the basic catalysts, but the correlation between the ratios and basicity including the basic strength could not be found, indicating that it is impossible to evaluate the basic strength of the catalysts from the ratios.

Table 2. Initial *cis* to *trans* ratio in 1-butene isomerization

Catalyst[a]	*cis*/*trans*
MgO-NaOH (1)	5.7
MgO-NaOH (10)	10.5

An Inspection of the Purity of Helium Used as the Carrier Gas in Pulse-adsorption Experiments

Hiroshi MIURA,* Toshiyuki NARITA, Makoto HARUTA, Kazuo SUGIYAMA, and Tsuneo MATSUDA

Department of Applied Chemistry, Faculty of Engineering, Saitama University, Shimo-ohkubo, Urawa 338

(Received September 4, 1984)

Synopsis. A novel method is proposed to inspect the oxygen content of the helium used as the carrier gas in pulse-adsorption experiments. The oxygen is first adsorbed on Pt/SiO_2 catalyst and then titrated by CO pulses. This method is very simple and requires only a conventional pulse-adsorption system.

The measurement of the metal surface area —dispersion— of supported metal catalysts is one of the most important techniques in the characterization of catalysts. The selective chemisorption of such gases as hydrogen, carbon monoxide, and oxygen is very frequently used for this purpose. This method is, however, based on the correspondence of the numbers of surface atoms and adsorbed molecules, and so the stoichiometry of chemisorption must be stable. Hydrogen chemisorption is believed to be most satisfactory[1] because the stoichiometry is stable for many metals, even when the dispersion is relatively high. On the other hand, CO adsorbs on noble metals very rapidly and attains the equilibrium of adsorption very easily at room temperature because of its strong affinity to metals, although the stoichiometry is sometimes complex.[2] Such behavior of CO is very advantageous for chemisorption using a pulse appararus, which is a very simple and convenient method of chemisorption. Thus, hydrogen adsorption is preferred by laboratories doing basic research, whereas CO adsorption is often selected by the researchers of catalysts for practical applications.

One of the most serious technical problems which we encounter when we try to perform pulse-adsorption experiments is that a very high purity is required for the carrier gas. For example, if helium carrier gas contains 1 ppm of oxygen and is passed through a Pt/SiO_2 catalyst (0.1 wt% Pt, 0.3 g) at a rate of 30 ml/min for 1 h (the time required to desorb H_2 and to cool it down to room temperature after pretreatment), then the number of oxygen atoms adsorbed on the catalyst surface is 10% of the total Pt atoms. Therefore, the oxygen content of helium must be less than 0.1 ppm for exact experiments. Obviously, it is important to inspect whether or not the carrier gas has a purity high enough of satisfy the demand. However, it is not easy to determine such a very low concentration of oxygen. Because the advantage of using the pulse-adsorption of CO is convenience, the inspection of the carrier gas is of no value unless the method is also very simple and convenient.

The reason why such a high purity of the carrier gas is required is that the reduced metal surface has a strong function to capture gaseous oxygen. Therefore, we tried to determine the oxygen content by utilizing the ability of metal catalysts to capture oxygen; *i.e.*, first flowing the carrier gas through a Pt catalyst to collect the small amount of oxygen on the Pt surface, and second analyzing the adsorbed oxygen by means of O_2–CO titration.

This method is based on the following surface reactions on supported Pt catalysts;[3]

$$1/2 \cdot O_2 + Pt(s) \rightarrow Pt\text{-}O(a), \quad (1)$$

$$2CO + Pt\text{-}O(a) \rightarrow Pt\text{-}CO(a) + CO_2, \quad (2)$$

$$CO + Pt(s) \rightarrow Pt\text{-}CO(a). \quad (3)$$

When the carrier gas is passed through the Pt catalyst for a period longer than in the pulse-adsorption experiment, the gaseous oxygen contained in the helium is captured on the Pt surface as in Eq. 1. The adsorbed oxygen easily reacts with CO pulses at room trremperature, and CO_2 is evolved following Eq. 2, so we can estimate the amount of adsorbed oxygen by measuring the amount of CO_2. If the Pt surface is only partly covered with oxygen, Reaction (3) also takes place on the surface. Because Reaction (2) occurs in preference to Reaction (3), CO_2 is easily detected, even if its amount is small.

Figure 1 illustrates the apparatus. Helium was purified by being passed through a reduced copper trap (500 K) and molecular sieves. CO was pulsed by means of a six-port valve with a sampling tube of 0.352 ml attached. This apparatus is similar to a conventional pulse-adsorption system except that an active carbon column is attached between the sample

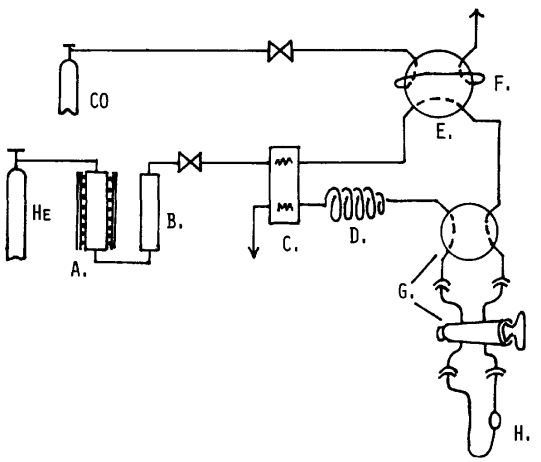

Fig. 1. Experimental apparatus both for purity check of carrier gas and pulse adsorption of CO. A. Oxygen trap (activated copper; normally kept at 500 K), B. Water trap (molecular sieves), C. Detector, D. Active carbon column, E. 6-port valve, F. Sampling tube, G. 4-port valve, H. Catalyst sample.

and the detector in order to separate the CO and CO_2. After the carrier-gas inspection is finished, experiments on CO adsorption or O_2–CO titration may be carried out using this apparatus unchanged.

The probe catalyst, Pt/SiO_2, was prepared by impregnating SiO_2 (aerosil 380) with an aqueous solution of hydrogen chroloplatinate(IV). The metal loading was 0.15 mmol/g (2.8 wt%). The pretreatment procedure was the same as in our previous studies of O_2–CO titration over $Pt–Ru/SiO_2$.[3,4] That is, after the catalyst had been evacuated at room temperature for 10 min, it was heated to 400 K and then evacuated for 1 h. In a flow of hydrogen, the temperature was increased to 600 K at a rate of 10 K/min. The catalyst was subsequently reduced at 600 K for 3 h, evacuated at 720 K for 30 min, and then cooled slowly to room temperature. After the pretreatment, the reactor was removed from the pretreatment apparatus to the pulse apparatus, keeping a vacuum. Such a pretreatment minimized the period (less than 30 min) during which the catalyst was in contact with the carrier gas compared with the case of desorbing hydrogen in a flow of helium.

Figures 2-A and B show typical examples of chromatograms resulting from this experiment. When the heating of reduced Cu was stopped and helium was passed through the catalyst without removing the oxygen for 1 h, we obtained the chromatogram shown in Fig. 2-A. CO was consumed almost completely in the first three pulses. A significant amount of CO_2 was evolved in the first pulse, but only a trace was evolved in the following pulses. Residual CO was detected after the fourth pulse. Because CO_2 is evolved as a single peak, as a result of the character of the Pt surface in preferring Reaction (2) to Reaction (3), it is easy to determine CO_2 even when the amount is very small. In this case, the oxygen content of helium was concluded to be 9.7 ppm.

When the Cu trap was working at 500 K, and when the system was in the same condition as in the CO adsorption experiments, we obtained the chromatogram shown in Fig. 2-B. In this case, no evolution of CO_2 was observed after the helium had flowed for 1.5 h. Supposing the peak height of CO_2 to be less than 1 mm (the same order as the baseline perturbation), the oxygen content of helium was calculated to be less than 0.1 ppm. Such a calculation is based on the assumption that all of the oxygen molecules are captured on the Pt surface. However, when the oxygen content is very low, the adsorption of oxygen (Reaction (1)) may be reversible and not all the oxygen may be captured. Thus, this method may be incomplete as a means of determining the oxygen content. Even so, it is sufficient as a means to judge whether or not the carrier gas is pure enough for pulse-adsorption experiments, because if the oxygen concentration is so small that oxygen is not captured on the metal surface, then the impurity can not affect the CO-adsorption experiments.

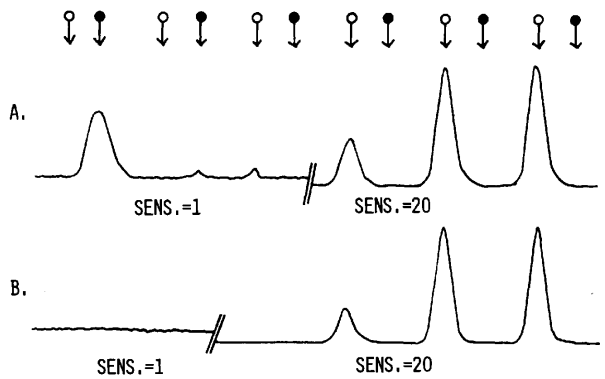

Fig. 2. Examples of chromatograms resulting from the CO titration of adsorbed oxygen contained in the helium carrier gas. ⚲: CO, ⚲: CO_2.
A. Heating of oxygen trap was stopped, B. Oxygen trap was kept at 500 K.

In this way, we could estimate the effect of oxygen impurity in the carrier gas on CO adsorption using a conventional pulse-adsorption system with quite a simple procedure.

General Formulas for Evaluating Ring Currents Induced in a Polycyclic Conjugated System

Jun-ichi AIHARA
Department of Chemistry, Faculty of Science, Shizuoka University, Oya, Shizuoka 422
(Received September 13, 1984)

Synopsis. Two apparently different but physically identical formulas were presented to evaluate bond currents (*i.e.*, ring currents in popular terminology) induced in a polycyclic conjugated system. They are applicable to all kinds of planar conjugated systems.

It was in 1979 that we reported a graph-theoretical formula for London susceptibility (*i.e.*, magnetic susceptibility attributable to ring currents) of a planar polycyclic hydrocarbon with no bond alternation.[1] It was later modified to estimate London susceptibility of a bond-alternate hydrocarbon.[2] In fact, this modified formula proved to be applicable to all kinds of planar conjugated systems, including heterocycles. In 1983, we formulated ring currents induced magnetically in a carbocyclic system with no bond alternation.[3] It is now easy to formulate ring currents induced in a heterocycle whose conjugated system is depicted with a variety of Coulomb and resonance integrals.

The term "ring current" has been used by many chemists. However, we hereafter use the term "bond current" instead of the term "ring current" since the latter term has so far borne some different meanings.[3-7] A bond current is defined as an entire current which is induced magnetically in a given π bond and passes through it. Mallion has once used this term in the same sense.[8]

We start with the modified graph-theoretical formula for London susceptibility.[2] It is expressed as

$$\chi_G = 9\chi_0 \sum_{i=1}^{M} \left(\frac{S_i}{S_0}\right)^2 \prod_{(lm)}^{r_i} k_{lm} \sum_{j=1}^{N} \frac{g_j P_{G-r_i}(X_j)}{P_G'(X_j)}. \quad (1)$$

Here, G stands for an entire conjugated system of a planar monocyclic or polycyclic molecule; r_i is the ith π-electron circuit in G,[9] which has been referred to as the ith π-electron ring in our previous papers;[1-3,10-13] G is assumed to have M conjugated atoms and N π-electron circuits; $G-r_i$ is the subsystem of G, obtained by deleting from G the ith π-electron circuit and all π bonds incident to it; $P_G(X)$ is the characteristic polynomial for G; $P_G'(X)$ is its first derivative with respect to X; $P_{G-r_i}(X)$ is the characteristic polynomial for $G-r_i$; X_j is the energy of the jth π-electron molecular orbital, obtained by solving the equation $P_G(X)=0$; g_j is the occupation number for the jth π-electron molecular orbital; S_i is the area of the ith π-electron circuit; S_0 is the area of the benzene ring; k_{lm} is the resonance integral parameter for the $l-m$ π bond, the resonance integral itself being expressed as $k_{lm}\beta$; (lm) runs over all π bonds constituting the ith π-electron circuit; and χ_0 is London susceptibility of benzene. π-Electron circuits denoted by r_i are nothing other than ring components defined in Sachs' graph theory.[14-17]

According to the same procedure as shown in a previous paper,[3] the circuit current induced in the ith π-electron circuit is expressible in the form:

$$I_i = 9I_0 \frac{S_i}{S_0} \prod_{(lm)}^{r_i} k_{lm} \sum_{j=1}^{N} \frac{g_j P_{G-r_i}(X_j)}{P_G'(X_j)}, \quad (2)$$

where I_0 is the circuit current induced in benzene under the same experimental condition. I_0 is equal to the bond current induced in benzene. Both I_0 and I_i are proportional to the intensity of the external magnetic field. The bond current induced in the $l-m$ π bond of G is then given by adding up all circuit currents passing through it. It is expressed as

$$J_{lm} = \sum_{i(lm)} I_i, \quad (3)$$

where i runs over all π-electron circuits with the $l-m$ π bond in common. Since Eq. 1 is applicable to all kinds of planar conjugated systems, Eq. 3 is again applicable to them all.

Equation 3 can be written explicitly in terms of χ_G. The signed area of the triangle formed by the origin of the coordinates and the $l\rightarrow m$ π bond, s_{lm}, can be defined in such a manner that it satisfies the following two conditions:[4,5]

$$s_{lm} = -s_{ml} \quad (4)$$

and

$$S_i = \sum_{(lm)}^{r_i} s_{lm}, \quad (5)$$

where (lm) runs over all π bonds constituting the ith π-electron circuit. By substituting S_i in Eq. 1 by Eq. 5 and then by differentiating Eq. 1 with respect to s_{lm}, we obtain the formula for a quantity proportional to the bond current induced in the $l-m$ π bond. This relationship can be written formally as

$$J_{lm} = \frac{S_0 I_0}{2\chi_0} \frac{\partial \chi_G}{\partial s_{lm}}. \quad (6)$$

This expression is necessarily identical with Eq. 3.

On the other hand, Veillard formulated the total π-electron energy of a heterocyclic conjugated system as a function of the external magnetic field.[18] By differentiating the energy twice with respect to the field strength, we obtain the following expression for London susceptibility of a heterocyclic system:

$$\chi_G = \frac{9\chi_0}{S_0^2}\left[\sum_{(lm)}^{G} k_{lm} p_{lm} s_{lm}^2 + \sum_{(lm)}^{G}\sum_{(l'm')}^{G} k_{lm}k_{l'm'}\bar{\pi}_{lm,l'm'}s_{lm}s_{l'm'}\right]. \quad (7)$$

Here, p_{lm} is the bond order for the $l-m$ π bond; $\bar{\pi}_{lm,l'm'}$ is what McWeeny defined as the imaginary bond-bond

polarizability of the $l-m$ and $l'-m'$ π bonds;[4,20] and both (lm) and $(l'm')$ run over all π bonds in G. Eq. 7 is applicable to bond-alternate hydrocarbons alike. In fact, Gayoso and Boucekkine reported a similar formula for bond-alternate hydrocarbons.[19]

Equation 7 is mathematically identical with Eq. 1 since these two formulas have been derived from the same field-dependent secular determinant.[2,18,19] They manifest two different physical features of London susceptibility. Accordingly, Eq. 6 can be applied to Eq. 7 to formulate the bond currents. By substituting χ_G in Eq. 6 by Eq. 7 and with the equality $\overline{\pi}_{lm,l'm'}=\overline{\pi}_{l'm',lm}$ in mind,[20] the following expression is obtained for the bond current induced in the $l-m$ π bond:

$$J_{lm}=\frac{9I_0}{S_0}\left[k_{lm}p_{lm}s_{lm}+k_{lm}\sum_{(l'm')}^{G}k_{l'm'}\overline{\pi}_{lm,l'm'}s_{l'm'}\right], \quad (8)$$

where $(l'm')$ runs over all π bonds in G. Equation 8 is again applicable not only to bond-alternate hydrocarbons but also to heterocycles as long as they are planar in shape. According to Mallion,[8] Haigh devised in 1971 a formula analogous to Eq. 8 to calculate bond currents in a hydrocarbon with no bond alternation. Equation 8 is a generalized form of it.

It is to be noted that both Eqs. 3 and 8 are general, in the sense that they can be applied to any planar cyclic conjugated system. All modifications of the Hückel molecular orbital method can be used to evaluate such quantities as k_{lm}, p_{lm}, and $\overline{\pi}_{lm,l'm'}$ which appear in Eqs. 3 and 8. Gayoso and Mallion recommended the iterative $\beta\omega'\omega''$ Hückel method for evaluating London susceptibility and bond currents.[19,21-23] Both Eqs. 3 and 8 naturally gave the same numerical results for naphthalene, biphenylene, anthracene, azulene, and pyracylene,[22,23] all with realistic carbon-carbon bond lengths.[19,21-23] The bond currents calculated by one of these formulas can be confirmed numerically by means of the other formula. Eq. 8 is much simpler in appearance than Eq. 3. If there is no need to obtain individual circuit currents, the former formula is best suited for evaluation of bond currents by computer.

Mössbauer Spectroscopic Study of Danalite, $Fe_4(BeSiO_4)_3S$

Yonezo MAEDA,* Yoshimasa TAKASHIMA, and Kiyotake ISHIDA†
Department of Chemistry, Faculty of Science, Kyushu University, Hakozaki, Higashiku, Fukuoka 812
†*Institute of Earth Science, College of General Education, Kyushu University, Ropponmatsu, Fukuoka 810*
(Received July 2, 1984)

Synopsis. The Mössbauer spectra for danalite have been examined in the temperature range 4.2 to 321 K. The strong temperature dependencies of the Mössbauer parameters are explained on the basis of a ligand field at a tetrahedral site for iron.

The helvite group is a general term of the mineral consisting of (Mn, Fe, Zn)$_4$(BeSiO$_4$)$_3$S in which the cations of the end members are manganese (helvite), iron (danalite), and zinc (genthelvite).[1-3] Metal ions are located in a tetrahedra made of three oxygen atoms and one sulfur atom. An iron(II) ion at a tetrahedral site has been found in spinel-type oxides[4,5] and $MFeCl_4$ type complexes.[6] Their Mössbauer spectra are usually temperature dependent since quadrupole splittings are sensitive to a splitting of the dγ-orbital. There has been no discussion so far regarding the distribution of the splittings of the dγ-orbital, except one paper.[5] In this paper the splitting of the dγ-orbital and its distribution in danalite are examined in terms of Mössbauer spectroscopy.

Experimental

Danalite and helvite occur in the Hirako mine, Hiroshima prefecture[7] and in the Yagisawa mine, Gunma Prefecture,[8] respectively. The apparatus used to carry out the Mössbauer measurements has been reported elsewhere.[9] Every spectrum was fitted to Lorentzian line shapes using a least-squares method at the Computer Center, Kyushu University. The velocity scale was normalized with respect to the center of the spectrum of an iron foil at 297 K.

Results and Discussion

The chemical composition of the danalite used in this study was measured using an X-ray microanalyzer. The distribution of cations was $Fe_{1.94}Mn_{1.58}Zn_{0.39}Ca_{0.09}$.

The Mössbauer spectra for the danalite at three different temperatures are shown in Fig. 1. The value of the quadrupole splitting for the danalite is small (QS=0.369 mm/s) at 321 K, but increases with a decrease in temperature (QS=2.740 mm/s at 4.2 K). The electric field gradient for a high-spin iron(II) ion may be considered as follows.

$$q = (1-R)q_{val} + (1-\gamma)q_{lat}.$$

The subscript *"val"* refers to the charge distribution of an aspherical 3d "valence" electron. The subscript *"lat"* refers to the charge distribution of the neighboring ions in a crystalline lattice. The Sternheimer factors (1-R) and (1-γ) were added to correct for the polarization of an iron(III)-like core. The large temperature dependence of quadrupole splitting of danalite indicates that the splitting of the

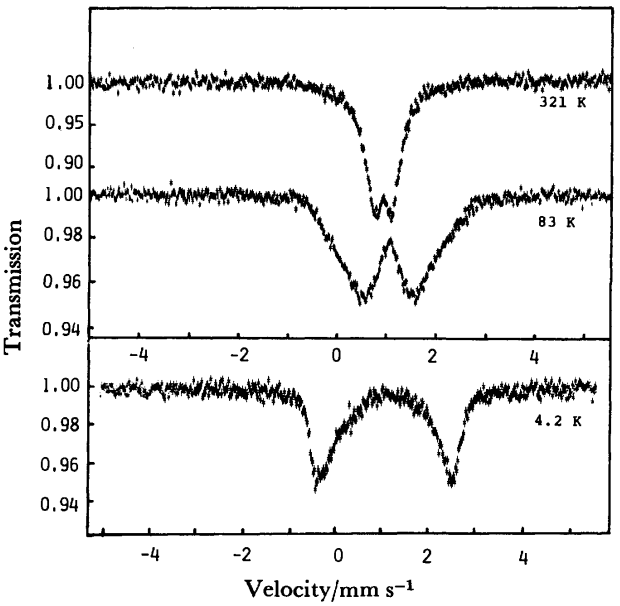

Fig. 1. Mössbauer spectra of the danalite at various temperatures.

dγ-orbitals of an iron(II) ion is small and the small quadrupole-splitting values at high temperatures confirm that the contribution of q_{lat} to the electric field gradient is small, although an iron(II) ion is located in an elongated tetrahedral site (one sulfur and three oxygens, "S3O"). From the crystallographic data for helvite, the bond length for Mn–S was found to be 0.2432 nm, and that for Mn–O 0.2082 nm. The bonding angle for S–Mn–O was 116.1 degrees, and that for O–Mn–O was 102.1 degrees.[2] If an electric field gradient $q_{lat}=(Z_i/r_i^3)(3\cos^2\theta_i-1)$ is applied for the 1-st nearest "S3O" core with the point charge model, a quadrupole splitting QS=−1.93 mm/s can be calculated using the values of Q=0.29 barn and 1−γ=−7.17. The calculated value of q_{lat} is large, due to the elongated tetrahedral structure. Values of q_{lat} are temperature independent on the first approximation and influences the QS value at high temperatures. However, the observed values of QS are smaller at high temperatures than the calculated values. This disagreement may result from the fact that the charge density at a sulfur atom is not the same as that for an oxygen atom and that the contributions to QS from the second nearest neighbor atoms and a further neighbor atoms are important. The splitting of the dγ-orbitals(Δ) may be calculated theoretically.[6]

$$QS = QS_0 \times \frac{1-\exp(-\Delta/kT)}{1+\exp(-\Delta/kT)},$$

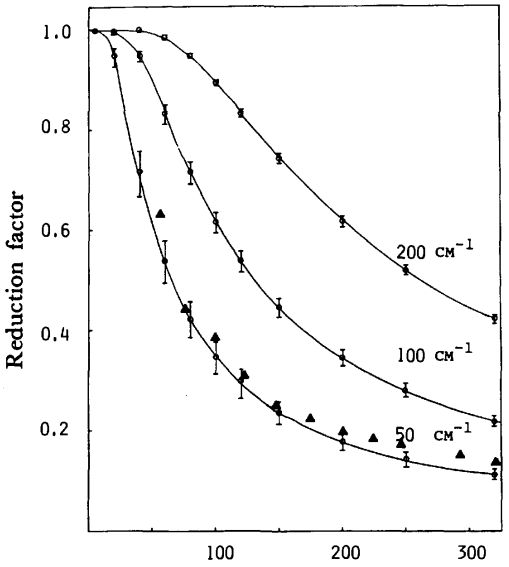

Fig. 2. Temperature dependence of the quadrupole splitting for $\Delta=50$, 100, 200 cm^{-1} and the experimental values. The bars on the circles show the difference of $\Delta\pm5$ cm^{-1}. Triangles show the QS values observed for the danalite. The value at 4.2 K is reduced to 1.00.

where k is the Boltzmann constant and QS_0 is taken to be 2.74 mm/s (the value at 4.2 K). Figure 2 shows the plots of the observed values of QS and some theoretical curves. A $\Delta=50$ cm^{-1} was calculated for the danalite by fitting the theoretical value to experimental measurements. This value seems to be so small for an iron(II) ion located in an elongated tetrahedral site.

The temperature dependence of the full widths at half maximum (FWHM) is plotted in Fig. 3. The differences of QS values between $\Delta=45$ cm^{-1} and $\Delta=55$ cm^{-1} at a certain temperature are also plotted as a solid line in the Figure. The difference becomes maximum at a particular temperature. The small geometrical distortion of a tetrahedra brings about the difference of the crystal field strength. This determines the distribution of quadrupole splittings and consequently causes the line width to broaden. The plots of the observed FWHM *vs.* T are similar to the shape of a theoretical curve. A gaussian distribution of Δ with a half width of 5 cm^{-1} explains the observed line broadening, if a gaussian distribution of it is postulated. The observed broad FWHM may come from the nonrandom distribution of cations in danalite.

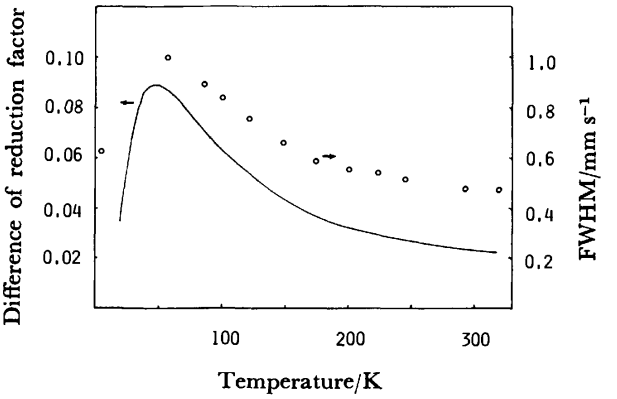

Fig. 3. Temperature dependence of the full width at half maximum for the danalite (open circles) and the differences of the theoretical reduction factors at $\Delta=50\pm5$ cm^{-1} (solid line).

The isomer shifts values are 1.13 (4.2), 1.08 (57), 1.07 (83), 1.06 (100), 1.06 (122), 1.04 (149), 1.03 (175), 1.01 (201), 0.999 (224), 0.986 (246), 0.959 (293), and 0.944 mm/s (at 321 K). The *IS* values decrease linearly with an increase in temperature and any changes in chemical bonding may not occur in the temperature range from 83 to 321 K. The discovery of the existence of a crystal-field distribution in one compound is due to the existence of a very small splitting of the dγ-orbitals of iron(II) in danalite. Similar QS values and line broadening were also observed for the helvite. This observation supports the idea that a nonrandom distribution of cations brings about such a wide broadening of a spectral line.

Thermodynamic Studies of Halogenocadmium Complexes in Nonaqueous Solvents

Yukio SASAKI,* Kazuya ABE, and Masao TAKIZAWA
Faculty of Engineering, Tokyo Institute of Polytechnics, Iiyama, Atsugi, Kanagawa 243-02
(Received August 4, 1984)

Synopsis. The thermodynamic constants for the formation of halogenocadmium complexes in *N,N*-dimethylformamide (DMF) and propylene carbonate (PC) were calculated by potentiometric titration. The differences in the order of the stability among the halide ions (X^-) for CdX_4^{2-} in nonaqueous solvents and water were found to be dependent mainly on the enthalpy changes of transfer from water to DMF and PC for the formation of CdX_4^{2-}.

Earlier studies on the stability of metal halide complexes (halogenocadmium, -lead and -copper complexes[1-3]) proved that the classification of metals by Ahrland[4] according to their complexation with halide ions in water was different from that in dipolar aprotic solvents. In the nonaqueous solvents the stability of the halogeno complexes on the metals described above decreases in the order of $Cl^->Br^->I^-$, which is the reversed order in water.

The purpose of the present paper is to investigate from the thermodynamic constants of the formation of halogenocadmium complexes the difference of the stability on metal halide complexes in *N,N*-dimethylformamide, propylene carbonate and water.

Experimental

Materials. The purification of *N,N*-dimethylformamide (DMF) and propylene carbonate (PC), the preparation and purification of tetraehylammonium perchlorate, tetraethylammonium halides, and the preparation of the saturated cadmium amalgam have been described elsewhere.[2,5] As a cadmium salt, cadmium perchlorate (Found: C, 28.8 ; H, 5.6 ; N, 11.2%. Calcd for $Cd(ClO_4)_2 \cdot 6DMF$: C, 28.3; H, 6.2; N, 11.5%.) obtained by twice recrystallization of the commercial reagent $[Cd(ClO_4)_2 \cdot 6H_2O)$ in DMF was used. The $Cd(ClO_4)_2 \cdot 6DMF$ was dried in a vacuum oven for two days at 30 °C.

Procedure. The experimental device for measuring the potential was described in the previous papers.[6,7] A solution of 10^{-3} mol dm^{-3} of $Cd(ClO_4)_2 \cdot 6DMF$ was titrated with a solution of 5×10^{-2} mol dm^{-3} of tetraethylammonium halides in 0.1 mol dm^{-3} tetraethylammonium perchlorate. Each temperature was controlled to an accuracy of 0.1 °C.

Results and Discussion

The titration curves for Cd^{2+} with Cl^- in PC at 15, 20, and 25 °C are shown in Fig. 1. The higher-order halogenocadmium complexes produced in DMF and PC are found to be CdX_4^{2-}, as shown in the previous paper.[2] The method for calculating the overall formation constants (β_4) of CdX_4^{2-} is described elsewhere.[2,8] The enthalpy changes ($\Delta H^\circ_{(CdX_4^{2-})}$) for the formation of CdX_4^{2-} were obtained graphically from the slope of the log β_4 *vs.* $1/T$ plot (Vant Hoff plot, Eq. 1).

$$\log \beta_4 = -\frac{\Delta H^\circ_{(CdX_4^{2-})}}{2.303R}\frac{1}{T} + \text{const.} \quad (1)$$

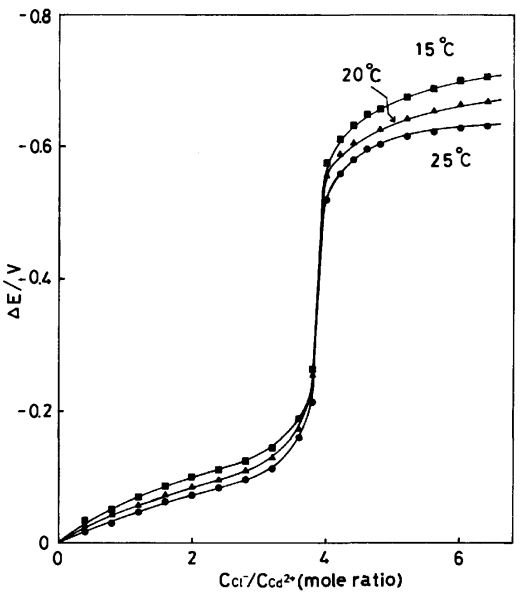

Fig. 1. Potentiometric titration curves for Cd^{2+} with Cl^- in PC at 15, 20 and 25 °C.
ΔE : potential shift caused by addition of Cl^-.

The free energy changes ($\Delta G^\circ_{(CdX_4^{2-})}$) for the formation of CdX_4^{2-} can be correlated to log β_4 with the temperature in Eq. 2, and

$$\Delta G^\circ_{(CdX_4^{2-})} = -2.303RT \log \beta_4 \quad (2)$$

the entropy changes ($T\Delta S^\circ_{(CdX_4^{2-})}$) were calculated from the $\Delta H^\circ_{(CdX_4^{2-})}$ and $\Delta G^\circ_{(CdX_4^{2-})}$. These thermodynamic constants in water have already been reported by many authors.[9] The overall formation constants in 0.1 mol dm^{-3} tetraethylammonium perchlorate and these thermodynamic constants in DMF, PC, and water at 25 °C are given in Table 1. These data in water were quoted from the literature.[9-12] The formation of $CdCl_4^{2-}$ in water is recognized polarographically by Marple.[10] However, its formation is not observed by calorimetric measurement.[11,12] In Table 1, the order of the stability of CdX_4^{2-} with $\Delta G^\circ_{(CdX_4^{2-})}$ in DMF and PC is found to be $CdCl_4^{2-}>CdBr_4^{2-}>CdI_4^{2-}$, while it is the reversed order in water. These thermodynamic constants in DMF were compared with those in dimethyl sulfoxide (DMSO).[13,14] The values of $-\Delta G^\circ_{(CdX_4^{2-})}$ in DMF are larger than those values in DMSO. It seems reasonable to consider that donicity of DMF is smaller than that of DMSO. The values of $\Delta H^\circ_{(CdX_4^{2-})}$ and $T\Delta S^\circ_{(CdX_4^{2-})}$ in DMF differ fairly from those in DMSO. The difference in $\Delta H^\circ_{(CdX_4^{2-})}$ and $T\Delta S^\circ_{(CdX_4^{2-})}$ in these solvents will be based on that of the measurements, because the calorimetric measurement takes account of the

	$CdBr_4^{2-}$	−150	−308	−158
	CdI_4^{2-}	−115	−240	−125

state of the bulk in solution and the potentiometric titration considers the state of the vicinity of the electrode. However, considering the fact that the difference in the enthalpy changes for free Cd^{2+} in DMF and DMSO is very small,[15] and that the difference in solvation of X^- is not so large between DMF and DMSO,[16] it is difficult to elucidate the reason of the large difference for $\Delta H^\circ_{(CdX_4^{2-})}$ in DMF and DMSO.

The thermodynamic constants for the formation of CdX_4^{2-} of the transfer from water to DMF and PC are listed in Table 2. From the values of $\Delta G^\circ_{tr(CdX_4^{2-})}$ it is manifest that $CdCl_4^{2-}$ becomes the most stable complex for transfer among the CdX_4^{2-} complexes. The difference in $\Delta H^\circ_{tr(CdX_4^{2-})}$ between the $CdBr_4^{2-}$ and CdI_4^{2-} complexes is larger than that in $T\Delta S^\circ_{tr(CdX_4^{2-})}$ as shown in Table 2. Therefore, it was found that the enthalpy changes in transfer from water to DMF and PC contribute much to the free-energy changes of the transfer. It may be concluded that the differences in the order of the stability for metal halogeno complexes in DMF, PC, and water depend mainly on the enthalpy changes ($\Delta H^\circ_{tr(CdX_4^{2-})}$) for the formation of CdX_4^{2-} complexes.

Preparation and Properties of the New High Pressure Phase β-$Zr(OH)PO_4$

Akira ONO* and Fujio Peter OKAMURA
National Institute for Research in Inorganic Material, Namiki, Ibaraki 305
(Received September 19, 1984)

Synopsis. A new phase with chemical formula $Zr(OH)PO_4$ was prepared above 1.5 GPa using a high pressure apparatus. Stability field of the compound was investigated, and X-ray study for a single crystal revealed that it is orthorhombic with space group Cmca or C2ca. The X-ray data are similar to those of $Zr_2O(PO_4)_2$.

Phosphate compounds in the system ZrO_2–P_2O_5–H_2O have been studied in relation to the inorganic ion exchanger, $Zr(HPO_4)_2 \cdot H_2O$[1] and the ceramic material with low thermal expansion, $Zr_2O(PO_4)_2$.[2,3] Other crystalline phases in this system are $Zr_{0.25}Zr_2(PO_4)_3$,[4] ZrP_2O_7 and $Zr(OH)PO_4$.[5] We have prepared a new high pressure compound isochemical with $Zr(OH)PO_4$ reported by Chernorukov *et al.*[9] Hereafter, the low and high pressure phases will be called α-$Zr(OH)PO_4$ and β-$Zr(OH)PO_4$, respectively. Preparation and properties of the new phase will be described below.

Experimental

Starting Materials. Reagents used for synthesis were $NH_4H_2PO_4$, ZrO_2, and $ZrOCl_2 \cdot 8H_2O$ of a high purity. Three kinds of starting materials were used. First one was prepared from a mixture of ZrO_2 and $NH_4H_2PO_4$ with the Zr/P ratio equal to 1/2. The mixture was dried at 473 K for 24 h and then heated at 873 K for 5 h, and crystalline ZrP_2O_7 was obtained. A mixture of ZrP_2O_7 and water was used as a starting material for obtaining single crystals large enough for X-ray studies. Second starting material was an equimolar mixture of ZrP_2O_7 and ZrO_2, which was used for most of the experiments carried out above 1 GPa. Third starting material was a gel prepared by mixing equimolar solutions of $ZrOCl_2 \cdot 8\ H_2O$ and H_3PO_4. The gel dried at 323 K was used as a starting material for experiments below 0.2 GPa.

High Pressure Experiments. A piston cylinder type high pressure apparatus was used for experiments above 1 GPa. A pressure cell consists of a concentric assemblage of NaCl with 10% MoS_2, a carbon heater and pure NaCl. A platinum capsule containing the starting material and water (10—50 wt%) was put in the center of the pressure cell. Sizes of the cell are 12.7 mm in diameter and 400 mm in length. Temperature was measured by an alumel-chromel thermocouple in contact with the Pt capsule. Pressure was gradually raised up to a desired value at a given temperature. Pressure is a nominal value not corrected for friction. Run durations are 48 to 72 h.

Experiments below 0.2 GPa were performed using a cold seal high pressure vessel in order to establish the stability range of α-$Zr(OH)PO_4$. Temperature was measured by an internal thermocouple, and pressure by a calibrated Heise Bourdon tube pressure gauge. Pressure medium is pure water. The third starting material was sealed in a gold capsule together with water.

Characterization of the Products. After washing with distilled water, experimental products were examined using an optical microscope, an X-ray diffractometer, a Weissenberg camera, an infrared spectrometer and a differential thermal analyzer. X-Ray powder patterns taken with a Toshiba ADG 301 diffractometer were obtained at room temperature in the range 2θ=7 to 60° using Cu $K\alpha$ radiation. Weissenberg photographs for a single crystal of β-$Zr(OH)PO_4$ were obtained using Ni-filtered Cu $K\alpha$ radiation. Infrared (IR) spectra recorded on a Hitachi model EPI-G3 IR spectrometer were measured in the frequency range 400 to 4000 cm^{-1} by using the normal KBr disk method. Thermal analyses were performed in air with an ULVAC TA-1500 at a heating rate of 10 K min^{-1}.

Synthetic crystals were analyzed using an electron probe microanalyzer, JXA 5A. Single crystals of ZrO_2, ZrP_2O_7, and $Zr_2O(PO_4)_2$ were used as standards. Apparent concentration was corrected after the Bence-Albee method.[6]

Results and Discussion

1) β-Zr(OH)PO₄. This phase was obtained above 1.5 GPa as shown by open circle in Fig. 1. Single crystals up to 100 μm were prepared together with $Zr(HPO_4)_2 \cdot H_2O$ when ZrP_2O_7 and water were used as the starting material. From Weissenberg photographs it was seen that β-$Zr(OH)PO_4$ crystallized in the orthorhombic system, the following reflexions being systematically absent, $hkl: h+k=2n$ (n: integer), $0kl: k=2n$, $h0l: l=2n$, $hk0: h=2n$, $00l: l=2n$. These extinctions indicate the space group to be Cmca or C2ca. Lattice constants are: a=0.6607, b=0.8657, c=1.1718 (nm). These are similar to those of $Zr_2O(PO_4)_2$: a=0.6624, b=0.8637, c=1.1872 (nm).[7]

Weight loss for β-$Zr(OH)PO_4$ took place in the temperature range 683 to 943 K. Amount of the water loss is 4.2 wt%, which is consistent with the theoretical value of 4.4%. The X-ray diffraction pattern of the final product is the same as that of $Zr_2O(PO_4)_2$. The X-ray data for β-$Zr(OH)PO_4$ and $Zr_2O(PO_4)_2$ obtained here are listed in Table 1.

An IR spectrum of β-$Zr(OH)PO_4$ illustrated in Fig. 2 A exhibits an absorption band at 3560 cm^{-1} which may be attributed to the OH stretching vibration and is absent for $Zr_2O(PO_4)_2$. Analytical result of β-$Zr(OH)PO_4$ using an electron probe microanalyzer is; Found: ZrO_2,60.32; P_2O_5,35.26; Total,95.58; H_2O,4.42

[100-Total]. Calcd for $Zr(OH)PO_4$: ZrO_2,60.64; P_2O_5,34.93 (wt%).

2) α-Zr(OH)PO₄. This phase was prepared below 1.2 GPa and represented by solid circle in Fig. 1. The X-ray powder pattern of α-$Zr(OH)PO_4$ obtained at 1.2 GPa is similar to that given in the literature.[5] Figure 2 D shows an IR spectrum for this material. An absorption band near 3560 cm^{-1} is attributed to the OH stretching vibration.

3) $Zr_2O(PO_4)_2$. An IR spectrum of this material prepared at 873 K, 1.15 GPa is illustrated in Fig. 2C. The X-ray powder pattern of this phase is the same as that listed in Table 1.

The structure of dizirconium diorthophosphate[7] consists of chains composed of edge sharing ZrO_7 polyhedra which are connected by the P atoms in tetrahedral coordination. The chains are, however, partly bonded directly with each other by sharing an oxygen atom. If hydration of $Zr_2O(PO_4)_2$ takes place at the site of this oxygen atom, Zr_1–O–Zr_2 may change to Zr_1–OH+Zr_2–OH where Zr_1 and Zr_2 represent different chains. We propose that the structure of β-$Zr(OH)PO_4$ is similar to that of $Zr_2O(PO_4)_2$, but each chain is not joined directly. A structure similar to the proposed one is known for $Hf(OH)_2SO_4$.[8] $Hf(OH)_2SO_4$ contains chains of $[Hf(OH)_2]_n^{2+}$ which are joined by sulfate groups. The chains do not share any oxygen atom with each other.

The Structure of Diaquatris[(methylthio)acetato]-ytterbium(III), $[Yb(CH_3SCH_2CO_2)_3(H_2O)_2]_n$

Akira Ouchi,* Mamoru Shimoi, and Satoshi Kondo
Department of Chemistry, College of Arts and Sciences, the University of Tokyo, Komaba, Meguro-ku, Tokyo 153
(Received October 8, 1984)

Synopsis. The crystal and molecular structure of the title complex has been determined by the use of single-crystal X-ray diffraction. The crystal of $YbC_9H_{19}O_8S_3$, $F.W.$= 524.48, was monoclinic, with a space group of $P2_1/a$; a= 12.501(6), b=25.096(9), c=10.788(2) Å, β=90.25(3)°, U=3384 (2) Å^3, Z=8, D_m=2.07(3), D_x=2.06 Mg m^{-3}, and μ(Mo $K\alpha$)= 6.20 mm^{-1}. Both Yb(1) and Yb(2) are octa-coordinated and are in a dodecagedral geometry. They are in a linear polymer form, parallel to the c axis; Yb(1) and Yb(2) are arrayed in a line alternatively, bridged by one carboxylate ligand.

In a previous paper,[1] the present authors showed the structure of the neodymium(III) complex of (methylthio)acetic acid (Hmesa), $[Nd_2(mesa)_6(H_2O)_3]_n$, which is isostructural to its cerium(III), praseodymium(III), and europium(III) salts.

In that paper, the dysprosium(III) and ytterbium(III) complexes of the same ligand were found to have the $[M(mesa)_3(H_2O)_2]$ formula (where M=Dy or Yb).[1] Therefore the crystal and molecular structures of the ytterbium(III) complex have now been determined by the single-crystal X-ray diffraction technique.

Experimental

Single-crystal X-Ray Analysis. The title complex is obtained as described in the previous paper[1] and is recrystallized from water. However, as the crystals thus obtained were mostly in thin plates and poor in the b-axis direction and as, moreover, many of them were twin crystals, we chose the best one from among the about 30 samples tested.

A 0.3×0.3×0.1 mm^3 crystal was used, without shaping. The reflections whithin the range of $3°<2\theta<55°$ were collected on a Rigaku AFC-6A four-circle automated X-ray diffractometer with graphite-monochromated Mo $K\alpha$ radiation by means of the ω-scan technique. From the 8019 independent reflections observed, 4046 $|F_o|>3\sigma(|F_o|)$ reflections were used for the refinement. The intensities were corrected for the Lorentz and polarization factors, but no correction was made for the absorption or extinction. All the calculations were carried out on a HITAC M-200H computer at the Computer Center of The University of Tokyo, using the local version of the UNICS.[2] The scattering factors were taken from the tables.[3]

The structure was solved by the heavy-atom method. All the non-hydrogen atoms were found; the final R-value was 0.086,[4] with anisotropic temperature factors for all atoms.

Results and Discussion

The selected interatomic distances and bond angles are shown in Table 1.[5] A perspective drawing of the complex with the numbering scheme is given in Fig. 1, and a schematic presentation to show the positions of the ligating atoms around Yb(1) and Yb(2), in Fig. 2.[5]

As is shown in the figures, both the central metal atoms of the complex are octa-coordinated, and they are in a deformed dodecahedral geometry; their coordi-

nation number is smaller than that of the neodymium(III) complex of the same ligand, where both types of metal atoms are ennea-coordinated.[1] Although lanthanoid(III) carboxylates, such as *m*-hydroxybenzoates[6] and nicotinates,[7] are also in octa-coordination, they are rather in a square-antiprism geometry. The deviations of the atomic positions of the four oxygen atoms and the central metal atom from each average trapezium plane are relatively large: 0.316 Å at the maximum (O(17)) and 0.124 Å on the average. The dihedral angles between the two trapezia around the same metal atom are 83.9 and 87.2° respectively.

The arrangements of the ligated atoms around both metal atoms are about the same; as is shown in Fig. 2, two oxygen atoms of one carboxylate occupy both the apexes of an oblique edge of each trapezium, forming a four-membered chelate ring. On the other oblique edge of each trapezium, the oxygen atom of the coordinated water takes the bottom-end position, and the oxygen atom of the bridging ligand, the other-end one.

The Yb–O bond lengths of the complex are classified into three groups. The shortest ones are those of the bridging ligand oxygen atoms (2.223 Å on the average), the second ones are those of the water oxygen atoms (2.293 Å on the average), and the longest ones are those of the chelating oxygen atoms (2.383 Å on the average). As the ionic radii of Yb^{III} and of O^{2-} are 0.985 and 1.38 Å respectively,[8] the bridging oxygen atoms bond to the metal atoms strongly, consequently, the bridges are likely to be stable. As shown in Table 1, Yb(1)···Yb(2), and Yb(1)···Yb(2^{i}) are 5.573(2) and 5.777(2) Å respectively, not much different from one another. Both of the bridges are of the *Z–E* type,[9] where the Yb–O–C angles of the *Z*-side (O(17) and O(28) sides) are 169.9(16) and 168.8(19)°, while those of the *E*-side (O(18) and O(27) sides) are 143.4(17) and 140.0(16)° respectively. None of the sulfide sulfur atoms are coordinated to any metal atoms, as in the case of the neodymium(III) complex.

Thus, the complex chains in a zig-zag form lie nearly parallel to the c-axis, and there is almost no interaction between the chains.

The authors are greatly obliged to the Shin-Etsu Chemical Ind. Co., Ltd., for aiding this study by presenting the highly pure ytterbium(III) oxide. The present work was partially supported by a Grant-in-Aid for Scientific Research (No. 57430011) from the Ministry of Education, Sciences, and Culture.

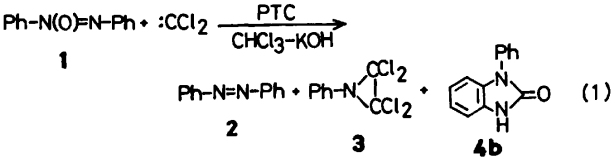
Reaction of Azobenzene with Dichlorocarbene in Phase-transfer-catalyzed System

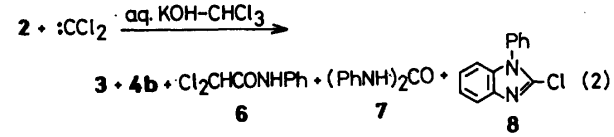
Tomohisa FUJIU, Kazuo IZUMI, and Shizen SEKIGUCHI*
Department of Synthetic Chemistry, Gunma University, Kiryu, Gunma 376
(Received August 4, 1984)

Synopsis. Azobenzene (**2**) reacted with dichlorocarbene at 40 °C in the presence of several phase-transfer catalysts in a binary solvent ($CHCl_3$–aqueous KOH), giving 2,2,3,3-tetrachloro-1-phenylaziridine (**3**), 1-phenyl-1,3-dihydro-2*H*-benzimidazol-2-one (**4b**), dichloroacetanilide (**6**), *N*,*N*′-diphenylurea (**7**), and trace amounts of 2-chloro-1-phenylbenzimidazole (**8**).

We have recently reported the reaction of azoxybenzene (**1**) with dichlorocarbene (DC) in the presence of a phase-transfer-catalyst (PTC 18-crown-6 or tributylamine) in the binary solvent ($CHCl_3$-aq KOH), in which azobenzene (**2**), 2,2,3,3-tetrachloro-1-phenylaziridine (**3**), and 1-phenyl-1,3-dihydro-2*H*-benzimidazol-2-one (**4b**) were formed[1] (Eq. 1).



These results are very different from those of Seyferth *et al.*,[2] who reported the reaction of **1** with DC generated from $PhHgCCl_2Br$ in benzene, giving **2**, **3**, and 1,1-dichloro-*N*-phenylmethanimine (**5**) as products. Especially, the formation of **4b** in the reaction (Eq. 1) led us to study the reaction of **2** with DC, where **3**, **4b**, dichloroacetanilide (**6**), *N*,*N*′-diphenylurea (**7**), and 2-chloro-1-phenylbenzimidazole (**8**) (trace amounts) were formed (Eq. 2).



The results are summarized in Table 1. The compound (**8**) was produced in trace amounts in every run. The results that **4**, **6**, **7**, and **8** were obtained are conspicuously different from those of Seyferth *et al.*[2] and Sasaki *et al.*[3] With TBA the product yields are higher than with 18-crown-6: The higher catalytic activity of the former is atrributed to the intermediate formation of trialkyl(dichloromethyl)-ammonium trichloromethanide (Eq. 4), as represented in Eqs. 3—5.[4]

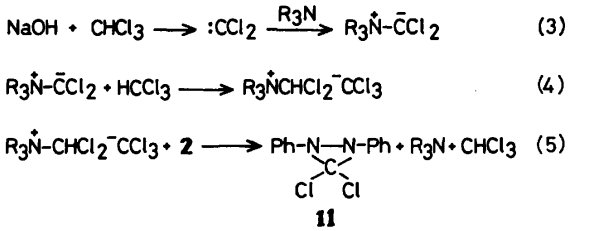


Table 1. Reactions of azobenzene (**2**) with dichlorocarbene[a]

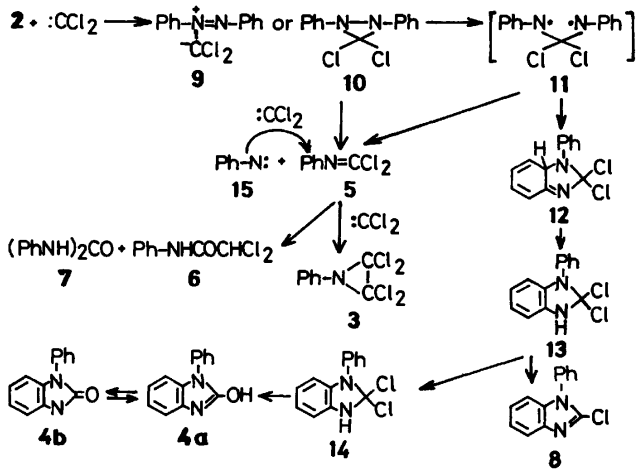
a) Reaction conditions: **2** 15.0 mmol; $CHCl_3$ 226 mmol; aq KOH (50%) 223 mmol; temperature 40 °C; 18-crown-6 0.39 mmol. b) Based on **1** consumed. c) Conversion of **2**. d) Tributylamine (TBA, 0.39 mmol) used in the place of 18-crown-6. e) Benzyltriethylammonium chloride (0.38 mmol) used in the place of 18-crown-6. f) Benzyltributylphosphonium chloride (0.39 mmol) used in the place of 18-crown-6.

The PTCs other than 18-crown-6 and TBA were tested (Runs 11 and 12). Although benzyltriethylammonium chloride is reported to be very effective,[5] its activity is quite similar to TBA under the present conditions. However, benzyltributylphosphonium chloride is much less effective: the poor migratory aptitude of the corresponding ion pair (Eq. 5) from the aqueous to the organic layer may be responsible for it.

The reaction path is shown in Scheme 1.

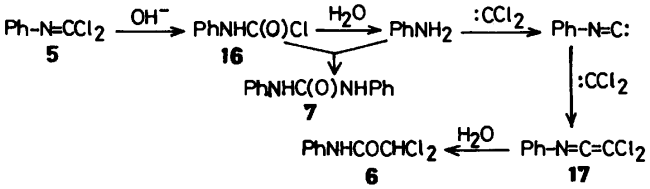


Scheme 1.

The formation of **15** and **5** may be formed *via* an acylic (9) or a cyclic (**10**) intermediate.[2] Further, the intermediacy of **10** is required, because the benzimidazole derivatives (**4** and **8**) are expected to be formed from **11**.[3]

The reaction sequences (**5**+**15**→**3**+**6**+**7**) are proposed from the following results (see Experimental): First, **6** was not formed in the reaction of **3** with DC under the conditions (PTC TBA, reaction time 4 h) similar to those described in Table 1, whereas the reaction of carbanilides with sodium hypochlorite giving 1,3-dihydro-2*H*-benzimidazol-2-ones was reported by Rosanti[6] and Oftedahl *et al.*;[7] second, **6** was not formed in the reaction of **7** with DC under the same conditions to those described in the first item; third, in the reaction of **5** with DC under the same conditions as those described in the first item except for the absence of TBA, **7** and **6** were formed in only 2.0 and 0.1% yields, respectively, which indicated that **7** and **6** are formed *via* the reaction of **5** not with DC but with OH^- (see Scheme 2): fourth, **3** was formed in a 30% yield in the reaction of **5** with DC under the conditions similar to those described in the first item.

The products (**6** and **7**) are presumed to be formed *via* the reaction shown in Scheme 2 from the following experimental results: First, Seyferth *et al.* reported that 1-chloro-1-trichloromethyl-*N*-phenylmethanimine hydrolyzes to produce trichloroacetanilide [$Cl_3C(O)NHPh$] in a 95% yield;[2] second, **6** was formed in a 2% yield in the reaction of aniline with DC under the conditions similar to those described in Table 1 (PTC TBA, reaction time 1 h),[8] during the course of which the disagreeable isocyanide-like odor evolved, indicating the possibility of the production of Ph-NC.[9]



Scheme 2.

In conclusion it is found that the kind of products depends largely on reaction conditions-especially polarities of solvents.

Experimental

General Comments. The products were identified by using NMR and Mass spectrometers, UV and IR spectrophotometer, and elemental analyses. The boiling point of ligroin used was 80—100 °C. All the capillary melting points were uncorrected.

Reaction of Azobenzene (2) with Dichlorocarbene for Isolation of the Products. The reaction and the isolation of products were carried out according to the procedure described in the revious work,[1] where the physical and chemical properties of **3** and **4b** were indicated.

2-Chloro-1-phenylbenzimidazole (8); mp 67—68 °C; IR (KBr) 1600, 1450, 760, 740, 690 cm^{-1}; NMR (DMSO-d_6) δ=7.7 (s, 1-phenyl 5H), 7.2—7.5 (m, phenyl 4H); Found: C, 68.66; H, 4.11; N, 12.43%; M^+ 228. Calcd for $C_{13}H_9ClN_2$: C, 68.27; H, 3.94; N, 12.25%; M, 228.

Dichloroacetanilide (6); mp 117—118.5 °C; IR (KBr) 3260, 1670, 1550, 1240, 860, 810, 760, 730, 690, 670 cm^{-1}; NMR (DMSO-d_6) δ=10.5 (s, NH 1H), 7.1—7.7 (m, phenyl 5H), 6.6 (s, CH 1H); Found: C, 47.51; H, 3.31; N, 7.08%; M^+, 203. Calcd for $C_8H_7Cl_2NO$: C, 47.17; H, 3.44; N, 6.88%, M, 203.

N,N'-Diphenylurea (7); mp 238—239 °C; IR (KBr) 3300, 1650, 1590, 1230, 750, 690 cm^{-1}; NMR (DMSO-d_6) δ=8.6 (s, NH 2H), 6.8—7.8 (m, phenyl 10H); Anal. ($C_{13}H_{12}N_2O$) C. H. N.

The NMR and IR spectra show that 2-hydroxy-1-phenylbenzimidazole (**4a**) considerably tautomerizes to **4b**.

Reaction of 2,2,3,3-Tetrachloro-1-phenylaziridine (3) or N,N'-diphenylurea (7) with Dichlorocarbene. To an 18 ml chloroform solution containing 18 mmol of **3** (3.85 g) or **7** (3.18 g) and 0.076 g (0.41 mol) of TBA was added a 25 g (223 mmol) aqueous KOH (50 wt%) solution. After the mixture was stirred for 4 h at 40 °C, it was processed according to the method described in the reaction of **2** with DC. In the both reactions **6** was not obtained but the substrate was recovered.

Reaction of 1,1-Dichloro-N-phenylmethanimine (5) with Dichlorocarbene. In the reaction of **5** (2.61 g, 15 mmol), prepared according to the method of Seyferth *et al.*,[2] with DC under the same conditions as those in the reaction of **3** with DC except for the absence of TBA, **7** and **6** were obtained 0.031 g (2%) and 0.0016 g (0.1%), respectively [both yields are based on **5** consumed (60% conversion)].

Reaction of Aniline with Dichlorocarbene. In the reaction of aniline (1.38 g, 15 mmol) with DC under the same conditions as those in the reaction of **3** with DC, **6** was obtained in a 2% yield (0.06 g).

The determination of products was carried out according to the method described in the previous paper.[1]

The Reaction of (*Z*)-2-(3-Oxo-1-propenyl)-2*H*-azirine Derivative with Molybdenum Carbonyl Complexes

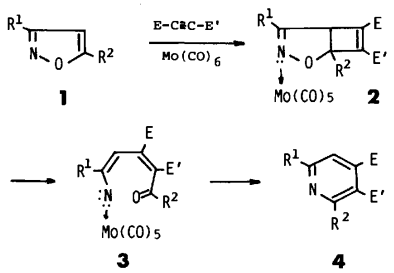
Tomoshige KOBAYASHI and Makoto NITTA*

Department of Chemistry, School of Science and Engineering, Waseda University, Shinjuku-ku, Tokyo 160

(Received August 17, 1984)

Synopsis. The thermal reaction of (*Z*)-2,3-diphenyl-2-(2,3-diphenyl-3-oxo-1-propenyl)-2*H*-azirine with [Mo(CO)$_6$] or [Mo(CO)$_3$(MeCN)$_3$] was reinvestigated to afford 2,3,5,6-tetraphenylpyridine along with the pyrroles and 1,3-oxazepine derivative. The formation of 1,3-oxazepine was demonstrated to be the purely thermal process. The 1,2,4,5-tetraphenyl-5-oxo-1,3-pentadienylnitrene complex was shown to give the pyridine and the pyrrole derivatives.

It has previously been shown that [Mo(CO)$_6$] effects a reaction of isoxazoles **1** to undergo a novel insertion of acetylenic esters across the C-4–C-5 bond and elimination of an oxygen atom to give pyridine derivatives.[1] Complex **2** and the complexed nitrene **3** were proposed as the intermediates. Independent reaction of 3-phenyl-2-oxa-3-azabicyclo[3.2.0]hepta-3,6-diene (**5**) with [Mo(CO)$_6$] giving 2-phenylpyridiene (**7**) *via* the nitrene complex **6** (R^1=Ph, R^2=E=E′=H in **3**) supports the proposed mechanism.[1] The facile N–O and C-1–C-5 bond cleavage of the complexed **5** (or **2**) giving **6** (or **3**) is similar to the photochemical reaction of **5** to give 3-(3-phenyl-2*H*-azirin-2-yl)acrylaldehyde,[2] suggesting the delocalization of the p-d electron from the molybdenum atom to the π^* orbital of the C=N–O moiety in the complex such as **2**.[1b,3]



1 **2** **3** **4**

R^1, R^2 = Phenyl or Alkyl

E = CO_2Me; E′ = CO_2Me or H

On the contrary, the complexed nitrene **15**, which is similar to **3** or **6**, has been proposed as an intermediate in the reaction of (*Z*)-2-(3-oxo-1-propenyl)-2*H*-azirine derivative **8** with [Mo(CO)$_6$] leading to the 1,3-oxazepine **9** and the pyrroles **10**, **11**, and **12**. The yields of the products are not mentioned, and no pyridine is obtained.[4] We report here the reaction of **8** with [Mo(CO)$_6$] or [Mo(CO)$_3$(MeCN)$_3$] giving 2,3,5,6-tetraphenylpyridine **13**, in addition to the 1,3-oxazepine **9** and the pyrroles **10**—**12**. The reaction conditions and the yields of the products are summarized in Table 1.

The reaction of **8**[5] with [Mo(CO)$_6$] in tetrahydrofuran (THF) at an ambient temperature, or in boiling benzene, gave the 1,3-oxazepine **9** and the pyridine **13**, along with the pyrroles **10**—**12** (entry 1 or 3 in Table 1). However, the thermal reaction of **8** without [Mo(CO)$_6$] in THF or in benzene afforded only **9** (entry 2 or 4). Thus **9** seems to have been derived by the purely thermal process which involves a C-2–C-3 bond fission of the azirine ring.[4,5] The reaction of **9** with [Mo(CO)$_6$] under the similar conditions to the [Mo(CO)$_6$]-induced reaction of **8** gave no product, and **9** was recovered quantitatively. Therefore, the pyridine **13** and the pyrroles **10**—**12** are supposed to be the primary products of the reaction of **8** with [Mo(CO)$_6$].

It has been shown that the ligand exchange of [Mo(CO)$_3$(MeCN)$_3$] with **5** proceeded under mild conditions to afford **7**.[1b] The reaction of **8** with [Mo(CO)$_3$(MeCN)$_3$] (prepared *in situ*, see Experimental) in acetonitrile also proceeded very fast even at an ambient temperature giving the pyrroles **10** and **11** as well as the pyridine **13**, in addition to the small amount of 1,3-oxazepine **9** (entry 5). The purely thermal reaction giving **9** is reduced under these conditions.

The formation of the pyrroles **10**—**12** is explained as follows. The n-donor complexation of the azirine ring of **8** seems to give the complexed nitrene **15** *via* **14**.[4,7,8] A ring-annelation of **15** and the subsequent decomplexation gives an intermediate **16**. In **16**, the benzoyl migration to the adjacent carbon atom and the subsequent hydrogen migration gives **10**, while benzoyl

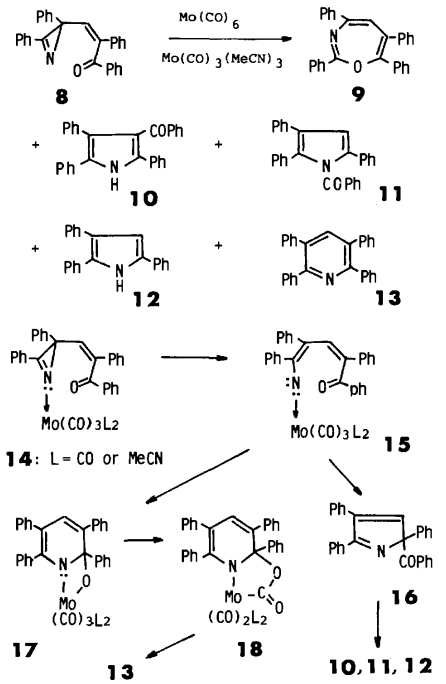
Table 1. Reaction of the azirine **8** in the presence or absence of [Mo(CO)$_6$]

Entry	Reaction Conditions		Time/h	Products (Yield/%)					
	[Mo(CO)$_6$]	Solvent		**8**	**9**	**10**	**11**	**12**	**13**
1	Added[a]	THF[b]	65	—	54	39	0.8	0.7	1.3
2	None	THF	65	39	49	—	—	—	—
3	Added[a]	PhH[c]	1	—	71	17	1.5	1.7	2.6
4	None	PhH	1	—	99	—	—	—	—
5	Added[d]	MeCN	0.5	—	3	53	2	—	4

a) 1.0 Molar equivalent amount of [Mo(CO)$_6$] was used. b) Stirred at an ambient temperature. c) Stirred at the refluxing temperature. d) [Mo(CO)$_3$(MeCN)$_3$], prepared from 2.0 molar equivalent amount of [Mo(CO)$_6$], was used at an ambient temperature.

migration to the adjacent nitrogen atom leads to **11**.[4] The attempted reaction of the pyrrole **11** with [Mo(CO)$_6$] in anhydrous or moist benzene gave no **12**, and **11** was recovered quantitatively. Furthermore, **12** was not obtained in the reaction of entry 5 in Table 1. Thus the possibility for the formation of **12** may be ascribed to a stray water-assisted debenzoylation (elimination of benzoyl group as benzoic acid) of the intermediate **16**. The pyridine **13** can be obtained by a cyclization of **15** to give **17**, followed by a ligand migration giving **18**, which would collapse to **13**.[1,8]

In conclusion, the complexed nitrene **15** was shown to give the pyrroles **10**—**12** along with the pyridine **13**, the formation of which was not observed in the previous study.[4] The complexed nitrene **3** or **6** was found to give only pyridine.[1] The steric and/or the electronic effect of the tetraphenyl-substituted derivative, **15**, may be reflected in the pathway giving the pyrroles and the pyridine derivative.



Experimental

All of the reactions were carried out under a dry nitrogen atmosphere. Solvents were purified and dried by the standard methods. All of the melting points were uncorrected.

Reaction of 8 with [Mo(CO)$_6$]. The reaction of **8** (399 mg, 1 mmol) and [Mo(CO)$_6$] (264 mg, 1 mmol) was carried out in 10 cm^3 of THF at an ambient temperature for 65 h, in boiling benzene for 1 h. After the solvent was evaporated, the residue was separated by TLC on silica gel using CCl_4 as an eluent to give **9**, **10**, **11**, **12**, and **13** (Table 1, entries 1 and 3). For **9**: mp 138—139 °C (from EtOH) (lit,[5] 146—147 °C). For **10**: mp 198—199 °C (from EtOH) (lit,[5] 200—201 °C). For **11**: mp 152—153 °C (from EtOH) (lit,[9] 154—155 °C). For **12**: mp 137—139 °C (from CCl_4) (lit,[10] 137—138 °C). For **13**: mp 228—230 °C (from AcOEt) (lit,[11] 228.5—229.5 °C).

Reaction of 8 with [Mo(CO)$_3$(MeCN)$_3$]. A solution of [Mo(CO)$_3$(MeCN)$_3$] was prepared from [Mo(CO)$_6$] (528 mg, 2 mmol) in 10 cm^3 of acetonitrile under reflux for 4 h[6] After this solution was cooled to an ambient temperature, **8** (399 mg, 1 mmol) was added to the solution, and it was stirred for 0.5 h. A similar workup as described above gave **9**, **10**, **11**, and **13** (Table 1, entry 5).

Reaction of 8 in the Absence of [Mo(CO)$_6$]. A solution of **8** (150 mg, 0.37 mmol) in THF (5 cm^3) was stirred at an ambient temperature for 65 h and the subsequent separation by TLC on silica gel using benzene as the eluent gave **9** and **8**. A similar reaction of **8** (150 mg, 0.37 mmol) in boiling benzene (10 cm^3) for 1 h gave only **9** (Table 1, entries 2 and 4).

Reaction of 1,3-Oxazepine 9. A solution of **9** (100 mg, 0.25 mmol) and [Mo(CO)$_6$] (66 mg, 0.25 mmol) in THF (3 cm^3) was stirred at an ambient temperature for 65 h. After the evaporation of the THF, the residue was purified by TLC on silica gel using benzene as the eluent to recover **9** (89 mg, 89%). A similar reaction of **9** (150 mg, 0.37 mmol) and [Mo(CO)$_6$] (98 mg, 0.37 mmol) in boiling benzene 10 cm^3) for 1 h also gave the unreacted **9** (142 mg, 95%).

Reaction of 11 with [Mo(CO)$_6$]. A solution of **11** (100 mg, 0.25 mmol) and [Mo(CO)$_6$] (66 mg, 0.25 mmol) in 5 cm^3 of anhydrous or moist benzene was refluxed for 1 h. After the evaporation of the benzene, the residue was purified by TLC on silica gel to give **11** in 96% (in anhydrous benzene) or in 94% (in moist benzene).

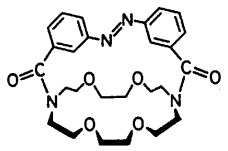
Synthesis and Properties of a New Photoresponsive Crown Ether with a Fluorescent Stilbene-cap[1)]

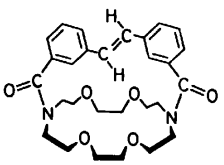
Seiji SHINKAI,* Kiminori MIYAZAKI, Mikio NAKASHIMA, and Osamu MANABE*
Department of Industrial Chemistry, Faculty of Engineering, Nagasaki University, Nagasaki 852
(Received October 13, 1984)

Synopsis. A new photoresponsive crown ether **2** with a stilbene-cap was synthesized. The crown *trans*-**2** could extract Li^+ and Na^+ into the organic phase, and UV light irradiation which produces photoisomerized *cis*-**2** enhanced the extractability. Thus, the stilbene-cap induces the conformational change in the crown ether moiety by photoirradiation.

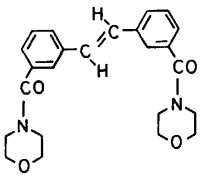
Macrocyclic polyethers contain intramolecular cavities delineated with molecular segments capable of binding cations. Previously, we synthesized an azobenzene-capped crown ether *trans*-**1**[2,3)] which was one of the early examples of photoresponsive crown ethers.[4—6)] In **1**, the azobenzene-cap undergoes photoinduced reversible interconversion between the trans- and cis-configuration, and thus the three-dimensional cavity structure changes in response to photoirradiation. Here, we wish to address a new photoresponsive crown ether, **2** which has a photoresponsive stilbene-cap on the N_2O_4 crown ether. We used **3** as a reference compound.



trans-1



trans-2



trans-3

Experimental

Materials. Stilbene-3,3′-dicarboxylic acid was prepared according to the method of Toland *et al.*[7)] This was treated with thionyl chloride to yield 3,3′-bis(chloroformyl)-stilbene: mp 179—181 °C, yield 73%. Found: C, 62.64; H, 3.30%. Calcd for $C_{16}H_{10}O_2Cl_2$: C, 62.98; H, 3.30%.

The crown *trans*-**2** was prepared in chlorobenzene from equimolar amounts of 1,4,10,13-tetraoxa-7,16-diazacyclooctadecane(N_2O_4 crown) and 3,3′-bis(chloroformyl)stilbene according to the high-dilution method. The basic operation is similar to that described for the preparation of *trans*-**1**.[3)] The raw product was subjected to the TLC separation (silica gel, chloroform–ethyl acetate (1:1 v/v) and finally recrytallized from benzene: mp 193.5—195 °C, yield 8.8%. IR (KBr) $\nu_{C=O}$ 1625 cm^{-1} and $\nu_{C=C}$ 1600 cm^{-1}; ^1H NMR ($CDCl_3$) δ=3.08—3.35 (8H, m), 3.65—4.32 (16H, m), 7.07 (2H, s), and 7.41—7.58 (8H, m); M^+ (*m/z*) 494. Found: C, 68.02; H, 7.02; N, 5.63%. Calcd for $C_{28}H_{34}N_2O_6$: C, 68.00; H, 6.93; N, 5.66%.

The compound *trans*-**3** was prepared by treatment of 3,3′-bis(chloroformyl)stilbene with excess morpholine in chlorobenzene. Recrystallization from benzene gave white crystals: mp 198—200 °C, yield 93%. IR (KBr) $\nu_{C=O}$ 1625 cm^{-1}; ^1H NMR ($CDCl_3$) δ=3.68 (16H, s), 7.07 (2H, s), and 7.20—7.51 (8H, m). Found: C, 70.28; H, 6.47; N, 6.83%. Calcd for $C_{24}H_{26}N_2O_4$: C, 70.92; H, 6.45; N, 6.89%.

Results

Absorption Spectra, Fluorescence Spectra, and Photoisomerization. Absorption maxima of *trans*-**2** and *trans*-**3** were 290 nm (ε_{max} 21900) and 297 nm (ε_{max} 26800) in acetonitrile at 30 °C, respectively. The light-mediated trans-to-cis isomerization was carried out by using a 100 W high-pressure Hg-lamp through a color glass filter (330 nm<λ<380 nm). The lamp and a N_2-substituted Thunberg cuvette containing 1-butanol solution of *trans*-**2**(or *trans*-**3**)(1.12×10^{-5} M (1 M=1 mol dm^{-3})) were immersed in a thermostated (30 °C) water bath. The absorption maxima decreased with photoirradiation time and finally reached equilibrium values: *cis*%'s at the photostationary state were 52% for **2** and 48% for **3**. The time-dependence could be approximated by a first-order rate equation with r>0.99: k_1 (first-order rate constant)= 3.25×10^{-3} s^{-1} for **2** and 1.15×10^{-3} s^{-1} for **3**. In the trans-to-cis photoisomerization of **1** and its reference compound, 3,3′-bis-(morpholinocarbonyl)azobenzene, we could not find a significant rate difference between these two compounds.[3)] The larger rate constant for **2** relative to **3** suggests, therefore, that *trans*-**2** in the initial state should be somewhat destabilized.

Fluorescence maxima of *trans*-**2** and *trans*-**3** appeared at 373 nm and 365 nm in acetonitrile at 30 °C, respectively (excitation 320 nm). The absolute fluorescence intensity of *trans*-**3** was greater by about 4-fold than that of *trans*-**2**.[8)] We found, interestingly, that fluorescence emission of *trans*-**2** is quenched by LiI and NaI more efficiently than that of *trans*-**3** (Fig. 1). Such a large difference was not observed for KI, RbI, and CsI. As described below, Li^+ and Na^+ are bound to the crown ether moiety of *trans*-**2**, while other alkali metal ions are not. The finding suggests, therefore, that the metal-crown interaction is responsible for the efficient fluorescence quenching observed for *trans*-**2**. The efficiency of fluorescence quenching was similar between Li^+ and Na^+ in spite of the efficient binding of Li^+ relative to Na^+ (*vide post*). This reason is not clear yet. Conceivably, the quenching can occur through the weak metal-crown interaction in dehydrated acetonitrile.

Two-Phase Solvent Extraction of Alkali Metal Ions. The ionophoric functions of *trans*-**2** and *cis*-**2** were evaluated through solvent extraction. We used the mixture containing 44% *cis*-**2** for solvent extraction. First, we employed extraction conditions used for **1**[3)]

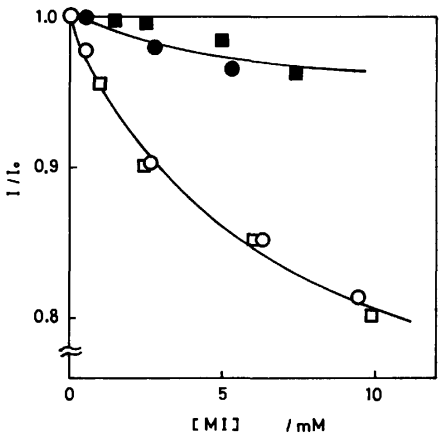


Fig. 1. Relative fluorescence intensity of *trans*-**2** and *trans*-**3** (3.20×10^{-5} M) plotted against the concentration of alkali iodides. ○: *trans*-**2**+LiI, □: *trans*-**2**+NaI, ●: *trans*-**3**+LiI, ■: *trans*-**3**+NaI.

Na^+	4	11
K^+	1	6
Rb^+	(<1)	(<1)
Cs^+	(<1)	(<1)

a) Organic phase: $[2]=2.70\times10^{-3}$ M. Aqueous phase: [MCl]=0.50 M, [MOH]=7.00×10^{-3} M, [picric acid]=5.00×10^{-3} M. b) *Cis*-form 44%.

but none of alkali metal salts was extracted into the benzene phase. This indicates that the stilbene-cap has some negative effect on the metal-binding ability of the N_2O_4 crown moiety. We thus changed the extraction conditions as recorded in a footnote to Table 1.

Examination of Table 1 reveals that in contrast to the ion selectivity of *trans*-**1** for Na^+ and K^+,[3] *trans*-**2** shows the highest selectivity for Li^+ having the smallest ion radius. It extracts K^+ only by 1%. Interestingly, the extractabilities for Na^+ and K^+ are efficiently improved by photoirradiation. The finding suggests that apparently, the size of the crown ether ring is enlarged upon photoinduced *trans*-to-*cis* isomerization of the stilbene-cap.

Discussion

The crown *trans*-**2**, in comparison with *trans*-**1** or *trans*-**3**, can be characterized by (i) low yield in the high-dilution synthesis, (ii) low fluorescence intensity, (iii) fast light-mediated trans-to-cis isomerization, and (iv) specific ion-selectivity for Li^+. These results consistently suggest that *trans*-**2** should be destabilized by some steric strain. Two possible explanations emerge. According to X-ray crystallographic studies and theoretical calculations,[9,10] the C=C bond of *trans*-stilbene (1.453 Å) is longer than the N=N bond of *trans*-azobenzene (1.23 Å) by 0.22 Å. One possible explanation is, therefore, that the distance between two carbonyl groups of 3,3′-bis(chloroformyl)stilbene is a little too longer to intramolecularly react with 7-*N* and 16-*N* of N_2O_4 crown. If so, this explanation can readily accommodate the low yield and the inferior ion-binding ability of *trans*-**2**. N_2O_4 crown ether itself shows the K^+-selectivity.[11] The previous X-ray studies on an analogue of *trans*-**1** showed that the crown ether ring is oval-shaped,[12] and the N_2O_4 crown ether moiety in *trans*-**1** showed the Na^+-selectivity.[3] The result implies that when the crown ether is stretched and enforced to adopt the oval-shaped conformation, the crown ether ring would favorably bind smaller alkali metal ions. The Li^+-selectivity observed for *trans*-**2** suggests that the N_2O_4 crown of *trans*-**2** is more stretched than that of *trans*-**1**.

Examination of Corey-Pauling-Koltun (CPK) molecular models of *trans*-**2** offers another possible explanation: one of the olefin protons in the CH=CH bond, which are absent in the azo linkage, deeply penetrates into the crown cavity and seems to interfere metal-binding. The low metal-affinity of *trans*-**2** relative to *trans*-**1** may be related to this steric disadvantage. On the other hand, CPK models of *cis*-**2** show that the olefinic protons in the *cis*-stilbene-cap exist apart from the crown ether plane. This favorable configuration would largely improve the metal-binding ability (especially, for large metal ions).

In conclusion, the present study indicates that the N_2O_4 crown with a fluorescent stilbene-cap acts as a new photoresponsive crown ether. Furthermore, the stilbene unit which apparently seems to be sterically equivalent to the azobenzene unit brought forth several marked differences in ion-binding ability, isomerization process, *etc.* The efforts to modify *trans*-**2** as a metal-selective fluorescence probe are now continued in this laboratory.

Sterically Controlled Synthesis of Aspartic Acid by Addition of Dialkyl Malonate to *N*-Benzyloxycarbonyl-L-alanyl-2-chloroglycine Methyl Ester

Shozo SHIONO and Kaoru HARADA*

Department of Chemistry, University of Tsukuba, Sakura-Mura, Niihari, Ibaraki 305
(Received September 12, 1984)

Synopsis. Aspartic acid was synthesized stereoselectively by addition of dialkyl malonate to *N*-benzyloxycarbonyl-L-alanyl-2-chloroglycine methyl ester, followed by hydrolysis. Substituent effect of the alkyl group of dialkyl malonate on the stereoselectivity was observed. Higher optical purity of aspartic acid was obtained as the alkyl group of dialkyl malonate became bulkier.

Several studies on the asymmetric addition reactions of malonic acid ester have been reported.[1-3] Recently, the preparation of *N*-benzyloxycarbonyl-3-carboxyaspartic acid derivatives from *N*-benzyloxycarbonyl-2-chloroglycine methyl ester was reported.[4] In the present paper, we describe a sterically controlled synthesis of aspartic acid by the addition of dialkyl malonate to *N*-benzyloxycarbonyl-L-alanyl-2-chloroglycine methyl ester (Z-L-Ala-Cl-Gly-OMe)(**2**), which was obtained from *N*-benzyloxycarbonyl-L-alanyl-2-hydroxyglycine methyl ester (Z-L-Ala-OH-Gly-OMe) (**1**) by treatment with thionyl chloride, followed by hydrolysis (Scheme 1).

The results are summarized in Table 1. Dimethyl malonate reacted with compound **2** in THF at −10 °C and aspartic acid was obtained with 29% enantiomeric excess after hydrolysis (Table 1, entry 1). Substituent effect of the ester residue of malonic acid on the stereoselectivity was observed. As the ester residue of malonic acid became bulkier, the optical purity of aspartic acid obtained became higher. When di-*t*-butyl malonate was used, the optical purity of the resulting aspartic acid reached 48% enantiomeric excess (Table 1, entry 6).

The sterically controlled synthesis of aspartic acid shown in Scheme 1 involves three stereochemical steps in which the configuration of the product would be controlled by each reaction. These are: 1) the condensation reaction between *N*-benzyloxycarbonyl-L-alaninamide with methyl glyoxylate hemiacetal to form compound **1**, 2) the chlorination reaction of compound **1** to form compound **2**, and 3) the coupling reaction of compound **2** with dialkyl malonate.

In order to examine the asymmetric induction in the condensation reaction between *N*-benzyloxycarbonyl-L-alaninamide with methyl glyoxylate hemiacetal, the diastereomeric ratio of synthesized compound **1** was determined by HPLC. Though the configuration of each diastereomer, which was separated by HPLC, was unknown, the diastereomer eluted first on HPLC ver-

a) Diastereomeric ratio of Z-L-Ala-OH-Gly-OMe. b) Ester residue of malonic acid. c) Reaction temperature in the addition reaction of dialkyl malonate. d) Solvent used in the addition reaction of dialkyl malonate. e) Chemical yield based on Z-L-Ala-OH-Gly-OMe. f) Enantiomeric excess of aspartic acid obtained. g) Configuration of aspartic acid.

sus that eluted second was 54:46. Compound **1** was recrystallized twice, and the diastereomeric ratios after first and second recrystallization were found to be 56:44 and 74:26, respectively. These were converted to compound **2**, and **2** was allowed to react with sodium salt of dimethyl malonate without purification to avoid diastereomeric fractionation. The enantiomeric excess of the resulting aspartic acid was 29% and 32%, respectively (Table 1, entry 1 and 2). These results indicate that the enantiomeric ratio of aspartic acid does not depend strongly on the diastereomeric ratio of Z-L-Ala-OH-Gly-OMe.

The stereochemistry of the chlorination reaction of compound **1** was not examined. The chemical property of compound **2** was too labile to determine the diastereomeric ratio by using HPLC. Therefore, the stereochemical relation between compound **2** and aspartic acid was unknown.

The substituent effect of the alkyl group of dialkyl malonate on the stereoselectivity shown in Table 1 indicates that the reaction with dialkyl malonate could be an important stereochemical step in the synthesis of optically active aspartic acid.

Experimental

All the melting points were uncorrected. NMR spectra were obtained with a Hitachi R-24A spectrometer and the chemical shifts were given in δ values (ppm) from tetramethylsilane (TMS). All the gas chromatographic analyses were carried out with a Hitachi 163 gas chromatograph. HPLC was carried out on a Jasco component consisting of a TRI ROTAR-V pump and a UVIDEC-100-IV UV spectrometer using a OA-1000 column. Amino acid analyses were carried out with a Hitachi 835-50 instrument.

Preparation of Z-L-Ala-OH-Gly-OMe (1). *N*-Benzyloxycarbonyl-L-alaninamide (0.88 g, 4×10^{-3} mol) was suspended in 10 ml of benzene, and methyl glyoxylate hemiacetal (0.48 g, 4×10^{-3} mol) was added to the suspension. The reaction mixture was refluxed for 3 d and then concentrated *in vacuo*. The residue was purified by column chromatography on silica gel using $CHCl_3$-MeOH (19:1 v/v) as an eluent. The solid obtained was recrystallized from hexane–ethyl acetate, yield 0.77 g (62%), mp 105—110 °C, ^{1}H NMR (CD_3OD): δ=1.33 (d, 3H), 3.69 (s, 3H), 4.12 (q, 1H), 5.02 (s, 2H), 5.53 (s, 1H), 7.24 (s, 5H). Found: C, 53.98; H, 5.86; N, 9.04%. Calcd for $C_{14}H_{18}N_2O_6$: C, 54.18; H, 5.84; N, 9.02%. Diastereomeric ratio of compound **1** was determined by HPLC using hexane-2-propanol (12:1 v/v) as an eluent.

Preparation of Z-L-Ala-Cl-Gly-OMe (2). Z-L-Ala-OH-Gly-OMe (**1**)(783 mg, 2.53×10^{-3} mol) was suspended in 10 ml of CH_2Cl_2, and 1 ml of thionyl chloride was added to the suspension. The reaction mixture was refluxed for 1 h and then concentrated *in vacuo*. The crude product obtained was recrystallized from CH_2Cl_2–hexane, yield 671 mg (81%), mp 120—124 °C, ^{1}H NMR ($CDCl_3$): δ=1.37 (d, 3H), 3.81 (s, 3H), 4.27 (m, 1H), 5.10 (s, 2H), 5.42 (d, 1H), 6.35 (d, 1H), 7.29 (s, 5H), 7.60 (d, 1H). Found: C, 51.20; H, 5.20; N, 8.40%. Calcd for $C_{14}H_{17}N_2O_5Cl$: C, 51.14; H, 5.21; N, 8.52%.

Reaction of Z-L-Ala-OH-Gly-OMe with Thionyl Chloride Followed by Addition of Dialkyl Malonate. General Procedure: Z-L-Ala-OH-Gly-OMe (**1**)(31 mg, 1×10^{-4} mol) was suspended in 1 ml of CH_2Cl_2, and 1 ml of thionyl chloride was added to the suspension. The reaction mixture was refluxed for 1 h and then concentrated *in vacuo*. The residue was dissolved in 1 ml of THF, and a suspension of sodium salt of dimethyl malonate in 1 ml of THF (prepared from 13 mg of dimethyl malonate and 4 mg of NaH (60%)) was added to the solution at −10 °C. After stirring for 2 h at −10 °C, 3 ml of MeOH saturated with hydrogen chloride was added to the mixture, and the mixture was concentrated *in vacuo*. The residue was refluxed with 6 M HCl (1 M=1 mol dm^{-3}) for 10 h and the hydrolyzate was concentrated *in vacuo*. A part of the residue was diluted appropriately and analyzed with an amino acid analyzer to determine the chemical yield of aspartic acid (48%, based on **1**). A part of the resulting aspartic acid was converted to *N*-(trifluoroacetyl)aspartic acid diisopropyl ester in the usual manner and then subjected to gas chromatographic analysis employing a chiral stationary phase (Chirasil-Val[5]).

The Use of *N,N*-Dimethylformamide-Sulfonyl Chloride Complex for the Preparation of Thiophenesulfonyl Chlorides

Tyo SONE,* Yukio ABE, Norio SATO, and Manabu EBINA

Department of Applied Chemistry, Faculty of Engineering, Yamagata University, Yonezawa 992

(Received September 14, 1984)

Synopsis. A 1:1 *N,N*-dimethylformamide-SO_2Cl_2 complex was found to be a useful agent for the one-step preparation of thiophenesulfonyl chlorides.

Thiophenesufonyl chlorides, key intermediates of the syntheses of sulfur derivatives of thiophene, have been mostly prepared by the chlorosulfonation of thiophenes with chlorosulfuric acid.[1] In the reaction of acid-sensitive thiophenes, however, polymerization and the rearrangement and/or elimination of the substituent such as halogen on the thiophene ring disturb the formation of the desired sulfonyl chlorides. In addition, the thiophenesulfonic acids are formed as the main products in some cases, and further tedious procedures are needed for converting the sulfonic acids to the sulfonyl chlorides. It is also the case with an alternative method *via* sulfonation using SO_3-organic compound adducts.[2]

It has been briefly reported by Kojtcheff *et al.* that a 1:1 *N,N*-dimethylformamide (DMF)-SO_2Cl_2 complex serves as a chlorosulfonating agent depending on the substrate.[3] Despite the potential utility, little systematic study of the direct chlorosulfonation using DMF-SO_2Cl_2 complex seems to have been made. On searching for a simple and convenient procedure for the preparation of thiophenesulfonyl chlorides, we studied the reactions of some thiophene derivatives with the complex.

The reaction procedure simply consits of heating a mixture of the thiophene derivatives and the complex at an appropriate temperature for 1—3 h.

The results are summarized in Table 1.

By this procedure, all thiophene derivatives examined, except 2-methoxy- (**1d**), 2-(1-cyclohexenyl)- (**1j**), and 2-acetylthiophenes, gave the corresponding sulfonyl chlorides as the main products. It is noteworthy

that methylthiophenes (**1b** and **1c**), which were expected to be much more reactive than anisole[4] and to yield the aldehydes,[3] afforded the sulfonyl chlorides. With 2-iodothiophene (**1g**), a replacement of the iodine atom by a chlorosulfonyl group was observed, but to a lesser extent than by the chlorosulfuric acid procedure.[1h] In some cases, the corresponding aldehydes were produced as the by-products in yields of up to *ca.* 20%, which could be easily separated from the sulfonyl chlorides by usual methods. The reaction of methyl 2-thiophenecarboxylate (**1k**) was attained only with difficulty, affording a mixture of the two isomeric sulfonyl chlorides (**2k** and **2'k**) in low yield.

Repeated attempts to chlorosulfonate **1d** and **1j** with the complex gave only tars, and when the reactions were carried out under mild conditions, only the aldehydes (**3d** and **3j**) were isolated from the reaction products. The results offer a sharp contrast with those of anisole[3] and styrene,[5] which were chlorosulfonated with the complex in the ring and in the side chain, respectively. 2-Acetylthiophene reacted easily with the complex to give unidentified materials. In this case DMF-SO_2Cl_2 complex probably functioned as a chloroformylating agent, and 2-acetylthiophene underwent the reaction in the side chain as in the Vilsmeier reaction.[6,10] Actually, the reaction of cyclohexanone with the complex was found to afford 2-chlorocyclohex-1-enecarbaldehyde in *ca* 40% yield.

In conclusion, the DMF-SO_2Cl_2 procedure is particularly useful for the preparation of several thiophenesulfonyl chlorides. The yields are approximately equal or superior to the previously reported ones. The principal advantages of this procedure over the conventional ones are the operational simplicity, one-step procedure, and the use of easy-to-handle reagents.

Experimental

All melting and boiling points are uncorrected. The IR spectra were obtained on a Hitachi EPI-S2 spectrometer, and the NMR spectra on Hitachi R-22 spectrometer at 90 MHz using TMS as an internal reference.

*Reaction of Thiophene (**1a**) with DMF-SO_2Cl_2 Complex (Typical Procedure).* Freshly distilled SO_2Cl_2 (17.6 g, 0.13 mol) was added dropwise with shaking to ice-cooled DMF (9.5 g, 0.13 mol); the temperature was kept below 25 °C during the addition. The hygroscopic solid complex, thus formed within 10 min, was held at the same temperature for additional 30 min. Thiophene (**1a**; 8.4 g, 0.1 mol) was added to the complex and the mixture was heated on a water-bath at 95—98 °C for 1 h with occasional shaking. The viscous brown mixture was cooled, poured into ice-water, and then extracted with $CHCl_3$. The $CHCl_3$ solution was washed successively with water, 5% $NaHCO_3$ solution, and water and dried. Evaporation of the solvent left a liquid, which was distilled *in vacuo* to give 2-thiophenesulfonyl chloride (**2a**; 13.5 g, bp 88—93 °C/2.5 mmHg (1 mmHg≈133.322 Pa)).

*Reaction of 2-Phenylthiophene (**1i**) with DMF-SO_2Cl_2 Complex (Typical Procedure).* 2-Phenylthiophene (**1i**; 3.2 g, 0.02 mol) was heated with 1.3 molar equivalent of DMF-SO_2Cl_2 complex at 95—98 °C on a water-bath for 1 h. Water was added to the cooled reaction mixture. The products were extracted with $CHCl_3$. The combined extracts were washed with water and dried. After evaporating the solvent, the residue was chromatographed (silica gel/hexane-$CHCl_3$ (1:3)) to give 5-phenyl-2-thiophenesulfonyl chloride (**2i**; 2.1 g, mp 86—87 °C) and 5-phenyl-2-thiophenecarbaldehyde (**3i**; 0.3 g, mp 93—94 °C). The aqueous layers were concentrated under reduced pressure to *ca* 10 ml and extracted with ether. Evaporation of the solvent from the extracts gave another crop of **3i** (0.5 g, mp 91—93 °C) **2i**: IR (CCl_4) 1175, 1385 cm^{-1} (ν_{SO_2}). NMR (CCl_4) δ=7.23 and 7.75 (1H, d each, $J_{3,4}$=4.0 Hz, 3-H and 4-H), 7.3—7.7 (5H, m, phenyl). Anal. ($C_{10}H_7ClO_2S_2$) C, H. Sulfonamide: Anal. ($C_{10}H_9NO_2S_2$) C, H.

*5-Benzyl-2-thiophenesulfonyl Chloride (**2h**)*: IR ($CHCl_3$) 1175, 1385 cm^{-1} (ν_{SO_2}). NMR (CCl_4) δ=6.86 and 7.70 (1H, d each, $J_{3,4}$=3.9 Hz, 3-H and 4-H), 7.1—7.5 (5H, m, phenyl), 4.20 (2H, s, CH_2). Sulfonamide: Anal. ($C_{11}H_{11}NO_2S_2$) C, H.

Tetrabromooxomolybdate(V) Complex. The Catalytic Reactivity for the Reaction of *t*-Butyl Hydroperoxide

Yasuhiko KURUSU,* Yoshiro MASUYAMA, and Mikio SAITA
Department of Chemistry, Faculty of Sciencae and Technology, Sophia University, 7-1, Kioicho, Chiyoda-ku, Tokyo 102
(Received September 21, 1984)

Synopsis. The nature of an ammonium counter cation of tetrabromooxomolybdate complex influences the rate of decomposition of *t*-butyl hydroperoxide(*t*-BuOOH) and oxidation with *t*-BuOOH. The catalytic activity of the ammonium for the decomposition of *t*-BuOOH decreased as the following order; benzyltrimethylammnium, -*N*-methyl pyridinium, -trimethylene bispyridinium, ≫pyridinium, -quinolinium, >1,3-propanediammonium, -1,6-hexanediammonium. However, the reverse order was observed in the catalytic activity for the epoxidation by *t*-BuOOH, and the rate of oxidation of alcohol by *t*-BuOOH was independent of the nature of ammonium cation.

In the synthetic applications of catalytic oxygen transfer process a metal catalyst mediates the selective transfer of an oxygen atom from alkyl hydroperoxides to the substrate.[1] A few examples of this application are epoxidation and other oxidation with alkyl hydroperoxides. For epoxidation of olefin with hydroperoxides molybdenum compounds are effective well-known catalysts.

We have investigated the epoxidation of olefin with *t*-butyl hydroperoxide(*t*-BuOOH) in the presence of various molybdenum compounds.[2] In the process, we found that oxomolybdate complex showed an interesting character for the reaction of *t*-BuOOH; the reactivity of *t*-BuOOH was dependent on the counter cation of the tetrabromooxomolybdate-(V) complex. In order to clarify this tendency, we prepared tetrabromooxomolybdate(V) complexes containing benzyltrimethylammonium(**1**), *N*-methylpyridinium(**2**), trimethylene bispyridinium(**3**), pyridinium(**4**), quinolinium(**5**), 1,3-propanediammonium(**6**), and 1,6-hexanediammonium(**7**) as a counter cation.

The decomposition of *t*-BuOOH in the presence of various complexes mentioned above was examined.

TABLE. DECOMPOSITION OF *t*-BuOOH, EPOXIDATION OF CYCLOHEXENE, AND OXIDATION OF 2-OCTANOL IN THE PRESENCE OF AMMONIUM TETRABROMOOXOMOLYBDATE(V) COMPLEX

Mo complex	Decomposition of *t*-BuOOH conversion/%	Epoxidation of cyclohexene yield of/% cyclohexene oxide	Oxidation of 2-octanol yield of/% 2-octanone[a]
1	85	0	80
2	96	0	44
3	91	0	46
4	37	66	78
5	35	68	—
6	10	78	77
7	6	85	—

a) The residue compound is only 2-octanol unreacted.

The results are shown in Table. **1** shows the highest activity in the decomposition of *t*-BuOOH. When an ammonium cation of tetrabromooxomolybdate(V) complex has no hydrogen on the nitrogen atom such as **1**, **2**, and **3**, decomposition of *t*-BuOOH and oxidation of alcohols to carbonyl compounds took place smoothly, but the epoxidation of olefins with *t*-BuOOH did not proceed. On the other hand, the decomposition is rarely found in **6** and **7**. The decomposition of *t*-BuOOH is essentially free-radical-induced decomposition initiated by metal-hydroperoxide interaction,[3] since the addition of 2,6-xylenol, 2,6-xylidine or *N*-phenyl-2-naphthylamine as a radical scavenger depressed the decomposition of *t*-BuOOH. For example, only 4% of *t*-BuOOH were decomposed when a mole of four of 2,6-xylenol to one of **4** was used.

The epoxidation of cyclohexene with *t*-BuOOH was carried out in the presence of a catalytic amount of various ammonium tetrabromooxomolybdate(V) complexes. As can be seen from Table, the tendency in the rate of decomposition of *t*-BuOOH reversely relates to that of the epoxidation, that is, in the case of high activity for epoxidation, decomposition activity is low. For example, **6** and **7** are effective for epoxidation with *t*-BuOOH but not for decomposition. On the other hand, oxidation activity for alcohol is independent of the decomposition activity for *t*-BuOOH. **1**, **2**, and **3** show no activity for epoxidation but have high effectivity for oxidation of 2-octanol. Also, we have already reported that unsaturated alcohols were oxidized to unsaturated carbonyl compounds.[4]

It is worth noting that *t*-BuOOH shows no activity for olefinic compound in the presence of **1**, **2**, and **3**, thus unsaturated alcohol can be oxidized selectively by *t*-BuOOH with **1**, **2**, and **3** without disturbing carbon-carbon double bond. It is interesting that ammonium as a counter-cation of tetrabromooxomolybdate(V) complex profoundly affects the reactivity of *t*-BuOOH.

Experimental

Materials. Pyridinium tetrabromooxomolybdate(V) (**4**) and quinolinium tetrabromooxomolybdate(V)(**5**) were prepared according to the procedure of Allen and Newmann.[5] Similar procedures were used with a little modification for the preparation of other ammonium tetrabromooxomolybdate(V) complexes. These complexes were identified by the elemental analysis (Mo:EDTA method and Br: Volhard method), and spectral measurements. Benzyltrimethylammonium tetrabromooxomolybdate(V)(**1**): Found: Mo, 15.8; Br, 54.6%. Calcd for $C_{10}H_{16}Br_4MoNO$: Mo, 16.5; Br, 54.9%. *N*-Methylpyridinium tetrabromooxomo-

lybdate(V)(**2**): Found: Mo, 18.2%. Calcd for $C_6H_8Br_4MoNO$: Mo, 18.3%. Trimethylenebispyridinium tetrabromoxomolybdate(V)(**3**): Found: Mo, 18.3%. Calcd for $C_{13}H_{16}Br_8Mo_2N_2O_2$: Mo, 18.0%. 1,3-propanediammonium tetrabromooxomolybdate(V)(**6**): Found: Mo, 20.0; Br, 64.0%. Calcd for $C_3H_{12}Br_8Mo_2N_2O_2$: Mo, 20.4; Br,68.1%. 1,6-hexanediammonium tetrabromooxomolybdate(V)(**7**): Found Mo, 19.0; Br, 63.8%. Calcd for $C_6H_{18}Br_8Mo_2N_2O_2$: Mo, 19.6; Br, 65.1%. *t*-BuOOH supplied by Nippon Oils & Fats Co. was used after the purification by vacuum distillation.

General Procedure for Decomposition. In a test tube with a screw cap, benzene(50 cm^3) and *t*-BuOOH(0.05 mol) were mixed with a catalytic amount of molybdenum complex(0.2 meq). Then the tube contents were stirred at 60 °C for 60 min in an aluminum block thermostat. The products were analyzed by GC; column packing material was DOP/Chromosorb PNAW, carrier gas was hydrogen.

General Procedure for Epoxidation. Cyclohexene (0.05 mol) was dissolve in benzene(50 cm^3) and the mixture was stirred at 60 °C. Then molybdenum catalyst(0.2 meq) and *t*-BuOOH (0.05 mol) were added to the solution. The stirring was continued at 60 °C for 60 min. Cyclohexene oxide was separated by GC (DOP/Chromosorb PNAW, carrier gas; nitrogen or helium) and identified by NMR and IR.

General Procedure for Oxidation of 2-Octanol. Molybdenum catalyst(0.15 meq), *t*-BuOOH(5 mmol), and 2-octanol(3 mmol) were added into benzene(3 cm^3) and stirred at 60 °C for 24 h. After evaporation, the product, 2-octanone, was separated by column chromatography(Wako gel C-200/hexane; ethyl acetate (3:1)) and identified by NMR and IR.

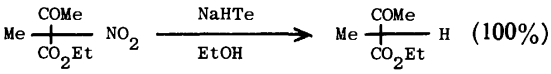
A Facile Displacement of Tertiary Nitro Group by Hydrogen with Sodium Hydrogentelluride

Hitomi SUZUKI,* Koji TAKAOKA, and Atsuhiro OSUKA†
Department of Chemistry, Faculty of Science, Ehime University, Bunkyo-cho, Matsuyama 790
(Received September 25, 1984)

Synopsis. Sodium hydrogentelluride is a useful reagent for replacement of a class of tertiary nitro group by hydrogen.

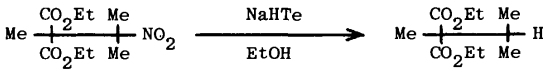
In recent years, reductive removal of nitro group from nitroalkanes has been the subject of extensive investigation in connection with the versatile utilities of nitroalkanes in organic syntheses, which have been well demonstrated in the last two decades.[1] As a result, several methods have been developed to bring about such a conversion — a) sodium salt of methanethiol in dipolar aprotic solvents,[2] b) potassium hydroxide in ethylene glycol,[3] c) *N*-benzyl-1,4-dihydronicotinamide,[4] and d) tributyltin hydride in the presence of azobis-isobutyronitrile.[5] However, these methods have certain drawbacks such as the necessity of high temperature (method a, b, and c), long reaction time (method a), and chromatographic separation (method d), the formation of side products (method a), or the incompatibility of other functional groups (method b).

Herein we disclose the results of our new procedure for the replacement of tertiary nitro group by hydrogen through the use of sodium hydrogentelluride (NaHTe).[6] The experimental procedure is marked by its simplicity in that it involves just the treatment of nitro compounds with NaHTe in ethanol for 15 min at room temperature.



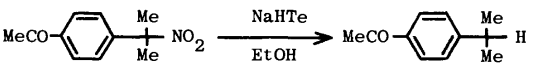
(100%) (1)

1 **2**



(98%) (2)

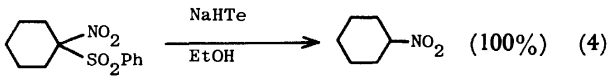
3 **4**



9 **10** (85%) (3)

Tertiary nitro group at α or β-position of ketone and ester was readily replaced by hydrogen (Eqs. 1 and 2). Similarly, α-nitrocumene derivative **9** was transformed into the corresponding 4-substituted cumene **10** in 85% yield (Eq. 3). Other examples were listed in Table 1. It should be noted that the isolated yields were excellent, the chromatographic separation was unnecessary, and other functional groups such as keto, cyano, ester, and sulfonyl groups remained unaffected under the present conditions.

However, to our surprise, nitro compounds, **17**, **18**, and **19** in which nitro group is situated at γ-position of ketone, ester, and nitrile, were quantitatively recovered after prolonged treatment with NaHTe even at refluxing conditions in ethanol. Finally, the reaction of 1-nitro-1-(phenylsulfonyl)cyclohexane **20** with NaHTe gave rise to the replacement of phenylsulfonyl group, instead of nitro group, by hydrogen (Eq. 4).



(100%) (4)

20 **21**

Although the reaction mechanism has not been studied yet, it appears to involve one-electron transfer to the nitro compound from NaHTe and the subsequent detachment of nitrite anion from the resulting nitro compound anion radical. Thus, in the case of compound **20**, phenylsulfonyl group which is a better leaving group than nitro group, was preferentially cleaved from the anion radical intermediate over nitro group.[8] In addition, the reluctance of nitro compounds **17**, **18**, and **19** toward NaHTe might be ascribed to the failure of the initial electron transfer from NaHTe to these compounds.

Experimental

Tertiary nitro compounds were prepared according to

† Present address: Department of Chemistry, Faculty of Science, Kyoto University, Kyoto 606.

the reported procedure.[7]

General Procedure for the Replacement of Tertiary Nitro Group by Hydrogen with Sodium Hydrogentelluride (NaHTe). A solution of tertiary nitro compound (4 mmol) in ethanol (4 ml) was added at room temperature under nitrogen atmosphere to a solution of NaHTe,[6] prepared *in situ* by reacting tellurium powder (1.30 g, 10 mmol) and sodium borohydride (0.90 g, 24 mmol) for 1 h in refluxing ethanol (40 ml). An instantaneous reaction occurred and the color of the reaction mixture changed to deep black. After 15 min, water (50 ml) was added, and the resulting mixture was left open to air with stirring. The solution became clear after 1 h with the deposition of tellurium powder. It was then filtered through Celite 545 and the filtrate was extracted with three portions of dichloromethane (30 ml). The combined extracts were washed with water, dried over Na_2SO_4, and evaporated to give the crude product, which was purified by Kugelrohr distillation or recrystallization. The products were identified by comparison with authentic samples.

The present work was partially supported by a Grant-in-Aid for Scientific Research No. 59740251 from the Ministry of Education, Science and Culture.

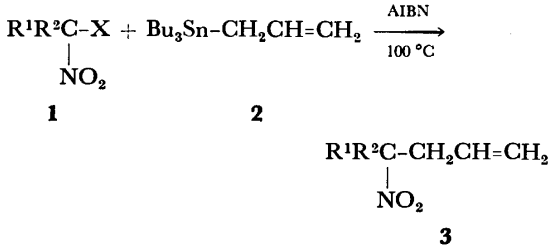
A New Preparation of Aliphatic Nitro Compounds by S_H2' Reactions of *gem*-Halo Nitro Compounds with Allyltributylstannane

Noboru ONO,* Klaus ZINSMEISTER, and Aritsune KAJI*
Department of Chemistry, Faculty of Science, Kyoto University, Kyoto 606
(Received October 3, 1984)

Synopsis. α-Nitroalkyl radicals generated from *gem*-halo nitro compounds are reactive enough to undergo the carbon-carbon bond forming reaction with allyltributylstannane *via* radical chain processes, which provides a new method for the introduction of an allyl group into nitroalkanes.

The chemistry of aliphatic nitro compounds has recently recieved much attention because of their importance in organic synthesis.[1] Although aliphatic nitro compounds can be prepared by numerous methods, a new method is still desired. The method *via* the carbon–carbon bond formation at the α-position of the nitro function is particularly useful among them. This has be done so far mainly by Michael addition reactions of nitroalkanes,[1] nitro-aldol condensation reactions,[1] or single-electron transfer reactions involving α-nitroalkyl radicals as intermediates.[2] However, it is very difficult to introduce alkyl groups such as methyl, ethyl, or allyl groups at the α-position of the nitro function, for reactions of alkyl halides with the α-anions of nitroalkanes give exclusive *O*-alkylation products in general,[1] and the inverse reactions using *gem*-halo nitro compounds and alkyl anions such as Grignard reagents or alkyllithium reagents fail to give the alkylated products.[3] In this paper we wish to report a simple method for the introduction of an allyl group at the α-position of the nitro function by application of S_H2' reactions of allyltin compounds developed by Migita and his coworkers[4] to the reaction of *gem*-halo nitro compounds (**1**) with allyltributylstannane (**2**).

Various *gem*-halo nitro compounds (**1**) were allowed to react with **2** in the presence of a radical initiator (azobisisobutyronitrile, AIBN) at 100 °C. The reaction was also initiated by light, which was achieved by using a conventional medium-pressure mercury lamp equipped with a pyrex filter at 25 °C. Monoallylated products (**3**) were isolated from the reaction mixture by distillation and further purified by chromatography. The results are summarized in the Table.



1 **2** **3**

Thus, *gem*-bromo nitro or *gem*-chloro nitro compounds undergo S_H2' reactions, but the reactions of *gem*-iodo nitro compounds with **2** proceed in the different way from S_H2' reactions. Although it is reported that simple alkyl halides such as isopropyl bromide react with **2** to give the allylated products in good yields,[4] **1** is much more reactive than simple alkyl halides in the present S_H2' reactions. For example, treatment of a mixture of 2-bromo-2-nitropropane and isopropyl bromide with **2** resulted in selective formation of **3a** was recovered unchanged.

Table. Preparation of 4-nitro-1-alkenes

R^1	R^2	X	Time/h	Yield of **3**/%[a]

H	H	Br	15	**3f**, 35

a) Yields refer to pure and isolated products. b) Photoinitiation at 25 °C. c) Allyl iodide was formed.

Although the reactions of various organic halides with **2** have been already reported,[4] the present alkylation of **1** with **2** may find its synthetic value, because compounds **3** cannot be prepared by ordinary S_N2 reactions of allyl bromides with the α-carbanions of nitroalkanes,[5] and also **3** can be converted into various important compounds such as ketones, aldehydes, carboxylic acids, nitriles, oximes, or amines through the manipulation of the nitro function.[1]

Experimental

Materials. Allyltributylstannane was prepared by the reaction of allymagnesium bromides with tributyltin chloride in diethyl ether.[4] *gem*-Halo nitro compounds were prepared according to the literature method; 2-bromo-2-nitropropane[6] (bp 72—75 °C/50 mmHg, 1 mmHg=133.32 Pa), 2-bromo-2-nitrobutane[7] (bp 65—68 °C/30 mmHg), 1-bromo-1-nitrocyclopentane[7] (bp 100—103 °C/20 mmHg), 1-bromo-1-nitroethane[8] (bp 70 °C/50 mmHg), 1-bromo-1-nitropropane[8] (bp 70—74 °C/50 mmHg), bromonitromethane[9] (bp 143—145 °C), 2-chloro-2-nitropropane[6] (bp 57 °C/50 mmHg), 2-iodo-2-nitropropane.[6]

Preparation of 4-Methyl-4-nitro-1-pentene (3a). Method A: A mixture of 2-bromo-2-nitropropane (1.7 g, 10 mmol), **2** (6.5 g, 15 mmol), and AIBN (0.5 g, 3 mmol) was heated at 100 °C for 24 h. In the course of the reaction, AIBN was added in three portions. The products were distilled off by Kugelrohr distillation and purified by column chromatography on silica gel with hexane to give pure **3a** (0.86 g, 67% yield). IR (neat) 3040, 1610, 1540, 1380 cm^{-1}; ^1H-NMR ($CDCl_3$) δ=1.56

(s, 6H), 2.66 (d, 2H, J=7.5 Hz), 4.9—5.2 (m, 2H), 5.5—5.8 (m, 1H). Found: C, 55.72; H, 8.76; N, 10.92%. Calcd for $C_6H_{11}NO_2$: C, 55.72; H, 8.53; N, 10.86%. Method B: The same procedures of method A using 2-chloro-2-nitropropane (1.3 g, 10 mmol) gave **3a** in 65% yield. Method C: A solution of 2-bromo-2-nitropropane (0.51 g, 3 mmol) and **2** (2 g, 4.5 mmol) in 100 ml of benzene was internally irradiated for 10 h with a 300 W medium-pressure mercury lamp using a Pyrex filter. The same work-up as described in method A have pure **3a** in 65% yield.

Following compounds were prepared by the method A.

4-Methyl-4-nitro-1-hexene (3b): IR (neat) 3040, 1610, 1535, 1375 cm^{-1}; ^{1}H-NMR ($CDCl_3$) δ=0.88 (t, 3H, J=7.0 Hz), 1.52 (s, 3H), 1.6—2.1 (m, 2H), 2.5—2.7 (m, 2H), 4.9—5.2 (m, 2H), 5.5—5.8 (m, 1H). Found: C, 58.38; H, 9.14; N, 9.63%. Calcd for $C_7H_{13}NO_2$: C, 58.76, H, 9.09; N, 9.78%.

1-Allyl-1-nitrocyclopentane (3c): IR (neat) 3040, 1610, 1540, 1380 cm^{-1}; ^{1}H-NMR ($CDCl_3$) δ=1.2—1.4 (m, 8H), 2.50 (d, 2H, J=7.2 Hz), 4.9—5.2 (m, 2H), 5.4—5.8 (m, 1 H). Found: C, 61.74; H, 8.13; N, 9.16%. Calcd for $C_8H_{13}NO_2$: C, 61.95; H, 8.39; N, 9.03%.

4-Nitro-1-pentene (3d): IR (neat) 3040, 1610, 1540, 1380 cm^{-1}; ^{1}H-NMR ($CDCl_3$) δ=1.54 (d, 3H, J=7.0 Hz), 2.4—2.8 (m, 2H), 4.4—4.8 (m, 1H), 5.0—5.2 (m, 2H), 5.5—5.9 (m, 1H). Found: C, 52.19; H, 8.12; N, 12.35%. Calcd for $C_5H_9NO_2$: C, 52.16; H, 7.88; N, 12.17%.

4-Nitro-1-hexene (3e): IR (neat) 3030, 1610, 1540, 1380 cm^{-1}; ^{1}H-NMR ($CDCl_3$) δ=0.98 (t, 3H, J=7.0 Hz), 1.7—2.1 (m, 2H), 2.4—2.8 (m, 2H), 4.2—4.6 (m, 1H), 5.0—5.2 (m, 2H), 5.4—5.8 (m, 1H). Found: C, 55.63; H, 8.83; N, 11.04%. Calcd for $C_6H_{11}NO_2$: C, 55.79; H, 8.53; N, 10.86%.

4-Nitro-1-butene (3f): IR (neat) 3030, 1610, 1540, 1380 cm^{-1}. ^{1}H-NMR ($CDCl_3$) δ=2.8 (q, 2H), 4.6 (t, 2H), 5.2—5.5 (m, 2H), 5.6—6.2 (m, 1H). These spectral data are in good agreement with those of authentic sample of **3a** which is prepared from 4-bromo-1-butene.[1)]

Stereochemistry on the Catalytic Hydrogenation of 1-*t*-Butyl-4-methylenecyclohexane over Modified Raney Ni, Co, and Fe Catalysts

Shin IMAIZUMI,* Hitoshi MURAYAMA, Jun-ichi ISHIYAMA, and Yasuhisa SENDA
Department of Engineering Science (Chemistry), Faculty of Engineering, Tohoku University, Aoba, Sendai 980
(Received October 12, 1984)

Synopsis. Contrary to a fresh catalyst, aged Raney Ni in ethanol provided exclusively a less stable product in the hydrogenation of the title compound. A similar stereoselectivity was observed over a catalyst which was refluxed in ethanol as well as that treated with carbon monoxide. These results indicate that the catalyst stored in ethanol is modified with carbon monoxide generated by the decomposition of the solvent.

Mitsui and his coworkers found that the Raney Ni catalyst stored in ethanol shows; i) a different stereoselectivity to Pt, Rh, and Pd catalysts in the hydrogenation of alkylmethylenecyclohexanes[1] and alkylmethylcyclohexenes,[2] ii) the appreciable anchor effect of a hydroxyl group in the hydrogenation of substituted cyclohexanols.[3] They suggested that the product-controlling step of the hydrogenation over Raney Ni is the adsorption of the substrate on the catalyst.[1-3] Tyman reported that the hydrogenation of 1-methyl-3- and 4-methylenecyclohexane over Raney Ni aged in methanol preferably gave the thermodynamically less stable of two possible products, while alternatives were obtained over a new catalyst.[4]

In order to examine the characteristics of the Raney Ni catalyst aged in ethanol, 1-*t*-butyl-4-methylenecyclohexane (**1**) and 4-*t*-butyl-1-methylcyclohexene (**3**) were hydrogenated under various selected conditions.

Results and Discussion

The stereoselectivity on the hydrogenation of **1** over Raney Ni varied appreciably depending on the origin of the catalysts and the reaction conditions (Tables 1 and 2). A thermodynamically more stable product, *trans*-1-*t*-butyl-4-methylcyclohexane (**2e**), was predominantly obtained over fresh Raney Ni. The amount of **2e** decreased in an atmosphere of hydrogen, and increased with the amount of the catalyst. This suggests that the amount of hydrogen available on the catalyst surface is also responsible for the stereochemistry on the hydrogenation of a reactive substrate such as **1**.[5,6] When Raney Ni which had been stored in ethanol for 40 d was used, a thermodynamically less-stable product, *cis*-1-*t*-butyl-4-methylcyclohexane (**2a**), was selectively yielded regardless of the amount of the catalyst and pressure of the hydrogen. Contrary to this, the stereoselectivity over a catalyst aged in water or cyclohexane was not as high as that over a catalyst aged in ethanol (Table 1).

The proportion of products over a catalyst modified under various conditions are shown in Table 2. The catalyst refluxed in methanol and ethanol under a nitrogen atmosphere showed a similar stereoselectivity to that aged in ethanol, while **2e** was still predominant over the catalyst refluxed in 2-propanol, 2-methyl-2-propanol, tetrahydrofuran or cyclohexane. The catalyst which was stirred in ethanol or cyclohexane under an atmosphere at room temperature for 2 h showed a stereoselectivity analogous to the aged catalyst in the respective solvent for 40 d. Moreover, **2a** was selectively formed over a fresh catalyst which was treated with carbon monoxide in cyclohexane as well as in ethanol. It has been shown that ethanol is decomposed to carbon monoxide and methane by refluxing over Raney Ni.[7] Consequently, it is clear that the high selectivity of the axial methyl product on use of the catalyst stored in ethanol is attributed to

carbon monoxide formed from ethanol rather than the partial oxidation of the catalyst.

The hydrogenation of **1** over Raney Ni aged in ethanol for a long time gave exclusively **2a** irrespective of the hydrogen pressure and the amount of catalyst. This indicates the following: i) The interaction between the catalyst and the substrate plays a major role in determining the product distribution, ii) the hydrogen available on a catalyst surface does not directly contribute to the determination of the product distribution. These results indicate that the product-controlling step is the adsorption of the substrate on the catalyst in the hydrogenation over Raney Ni which is poisoned by carbon monoxide. On the other hand, the product-controlling step is not primarily defined to be the adsorption of the substrate on fresh Raney Ni.

3, which is generated by the double-bond migration of **1** during the hydrogenation, was also hydrogenated. No appreciable stereoselectivity was observed and the apparent rate of reaction was very slow compared to that of **1**. This means that the stereoselectivity which appears in Tables 1 and 2 is primarily the results from the direct hydrogenation of **1**.

The thermodynamically more stable product (**2e**) was preferred in the hydrogenation of **1** over fresh Raney Co. No effect of a storing period as well as refluxing under a nitrogen atmosphere was observed on the product ratio. The effects of air and carbon monoxide on Raney Co were not appreciable compared to those on Raney Ni. When the catalysts were treated with *n*-$BuNH_2$, the amount of **2a** increased over Raney Ni compared to that over the parent catalyst, while more than 80% of **2e** was yielded over Raney Co (Table 2). No endocyclic olefin which was derived from the starting material by the double bond migration was detected in the hydrogenation (Tables 1 and 2). Such differences in the effects regarding the modification of Raney Ni and Raney Co give important information to elucidate the characteristics of both Ni and Co catalysts.

Experimental

Catalyst. Raney Ni was prepared from Raney Ni NDH (Kawaken Fine Chemicals Co.) by the W-4 method.[8] The catalyst was stored at room temperature. Raney Co and Fe were prepared from Raney Co OD and Fe ND (Kawaken Fine Chemicals Co.) by an analogous method as Raney Ni.

Catalytic Hydrogenation. 0.5 mmol of substrate and a known amount of catalyst (contains *ca.* 40 wt% of solvent) in a solvent (5 ml) were stirred with hydrogen at an atmospheric or a high pressure and room temperature. The reaction was followed gas chromatographically by analyzing aliquots of the reaction mixture at appropriate time intervals.

The present work was partially supported by a Grant-in-Aid for Scientific Reseach No. 56550601 from the Ministry of Education, Science and Culture, Japan.

Preparation and Conversion of Aminodiphenylcyclopropenium Salts to 1,2,3-Triazines

(Received October 18, 1984)

Synopsis. Diphenylcyclopropenone gave aminodiphenylcyclopropenium fluorosulfate (**3**) by ethylation with ethyl fluorosulfate, followed by treating with secondary amine in one-pot operation. The salt **3** reacted with sodium azide to afford 1,2,3-triazine in a good yield.

In a continuation of our studies of the monoalkylthiocyclopropenium salts,[1] we have become interested in the chemistry of monoaminocyclopropenium compounds.

Some aminodiphenylcyclopropenium salts have been prepared by the reaction of diphenylcyclopropenone with triethyloxonium tetrafluoroborate (Meerwein reagent), followed by treating with secondary amines.[2,3]

In this communication we report an improved one-pot synthesis of 1-amino-2,3-diphenylcyclopropenium salts using commercially available ethyl fluorosulfate and its application to the synthesis of 5-amino-1,2,3-triazines.

Since the Meerwein reagent decomposes in atmospheric moisture, we used ethyl fluorosulfate (Aldrich Chem. Co.) which is easy to handle. The reagent reacted with diphenylcyclopropenone (**1**) in dry dichloromethane to yield the cyclopropenium salt **2**. The salt was *in situ* treated with equimolar amount of secondary amines to give 1-amino-2,3-diphenylcyclopropenium fluorosulfates (**3**) in moderate yields. The structure of **3** was elucidated on the basis of their IR (at around 1900 cm^{-1}) and ^1H-NMR data (Table 1).

It has been reported that cyclopropenium salts substituted with triamino[4] or triaryl[5] groups react with azide ion to yield 3-azidocyclopropenes which gave 1,2,3-triazines on heating. Although the reaction of 1-bis(1-methylethyl)amino-2,3-diphenylcyclopropenium perchlorate (**3b** analogue) and potassium azide has been reported[4] to give 5-bis(1-methylethyl)amino-4,6-diphenyl-1,2,3-triazine (**4b**), the structure elucidation seems to be uncertain. The reaction of **3** with sodium azide gave 5-amino-1,2,3-triazines **4**

whose structures were confirmed unambiguously by their ^{13}C-NMR spectra and chemical transformations. The ^{13}C-NMR spectra of **4a** and **4e** showed the symmetric structure for these compounds. Physical properties of **4** are shown in Table 2.

The reactions of **4a** and **4e** with methyl iodide took place easily to give 2-methyl derivatives **5a** and **5e**, respectively. Hydrolysis of **5e** with aqueous sodium hydroxide afforded 4,6-diphenyl-1,2,3-triazin-5(2*H*)-one (**6**). The structures of **5a**, **5e**, and **6** were confirmed on the basis of ^{1}H- and ^{13}C-NMR data (Tables 3 and 4).

Experimental

Preparation of 3: General Procedure. A mixture of **1** (4.8 mmol) and ethyl fluorosulfate (5.3 mmol) in dry CH_2Cl_2 (10 cm^3) was stirred at room temperature for 1 h. To the resulting solution was added a dichloromethane solution of an amine (4.8 mmol in 5 cm^3) under nitrogen. After 30 min to the solution was added 25 cm^3 of ethanol and the mixture was condensed to 30 cm^3. The precipitated salt was recrystallized from CH_3CN (or $CHCl_3$) and ethanol to afford pure salt **3**.

The Reaction of 3 with Sodium Azide: General Procedure. A suspension of **3** (0.9 mmol) and sodium azide (2.7 mmol) in CH_2Cl_2 was stirred at room temperature for 16 h. The mixture was evaporated and benzene-soluble product was separated. Recrystallization from chloroform–ethanol gave pure triazine **4**.

Reaction of 4a, e, and 4f with Methyl Iodide. A mixture of **4a** (1 mmol) and MeI (10 mmol) in CH_2Cl_2 (5 cm^3) was stirred at room temperature for 12 h. Then the solution was evaporated and benzene-insoluble salt **5a** was separated. Similar treatment of **4e** and **4f** gave **5e** and **5f**.

Hydrolysis of 5e. A mixture of **5e** (1 mmol) in benzene (10 cm^3) and 5 cm^3 of aq NaOH (10%) was stirred at room temp for 2 h, the organic layer was separated, and dried under reduced pressure. Recrystallization from ethanol afforded faint yellow needles **6** in 52% yield.

(Received October 23, 1984)

Synopsis. Palladium-catalyzed reaction of α-bromo ketones with hexabutylditin in the presence of trimethylsilyl chloride gave enol trimethylsilyl ether in moderate to good yields.

There have been so far known two methods for the preparation of tributyltin enolates (α-tributylstannyl ketones and/or enol tributylstannyl ethers).[1] The one is the reaction of enol acetates with tributyltin methoxide, and the other is the addition of tributyltin hydride to α,β-unsaturated ketones.

$$RHC{=}CHOAc + Bu_3SnOMe \longrightarrow RHC{=}CHOSnBu_3 + AcOMe$$

$$RHC{=}CH\text{-}COR' + Bu_3SnH \longrightarrow RCH_2CH{=}CR'OSnBu_3$$

For the preparation of organotin compounds, the coupling reaction between hexabutylditin and organic halides in the presence of palladium complexes is recently developped.[2]

$$RX + Bu_3SnSnBu_3 \xrightarrow{[Pd]} RSnBu_3 + Bu_3SnX$$

In order to develop another route for preparation of tributyltin enolates, we applied the above coupling reaction to α-bromo ketones.

$$BrCH_2COR + Bu_3SnSnBu_3 \xrightarrow{[Pd]} CH_2{=}CROSnBu_3 + Bu_3SnBr$$

Initially we carried out the reaction of α-bromoacetophenone with hexabutylditin in the presence of a catalytic amount of tetrakis(triphenylphosphine)palladium. However, isolated products were tributyltin bromide and acetophenone. This means that tin enolate was not produced or was not stable enough under the reaction conditions. According to Lutsenko *et al.*[3] addition of trimethylsilyl chloride into tin enolate gave stable enol trimethylsilyl ether in good yield as the result of tin-silicon exchange. Then we tried to convert the tin enolate produced into enol silyl ether, by carring out the reaction in the presence of trimethylsilyl chloride. Results are shown in Table 1.

TABLE 1. Pd-CATALYZED REACTION OF α-BROMO KETONES WITH HEXABUTYLDITIN IN THE PRESENCE OF TRIMETHYLSILYL CHLORIDE

$$\underset{12\ mmol}{Bu_3SnSnBu_3} + \underset{10\ mmol}{R\text{-}Br} + \underset{12\ mmol}{Me_3SiCl} \xrightarrow[80\,^\circ C,\ 20\,h\ in\ tetralin\ 10\,cm^3]{[Pd]\ 0.1\ mmol}$$

R-Br	Catalyst[a]	Product	Yield/%[b]
$BrCH_2COEt$	A	$CH_2{=}CEtOSiMe_3$	69
$BrCH_2COBu^t$	A	$CH_2{=}CBu^tOSiMe_3$	81
$MeCHBrCOMe$	A	$MeCH{=}CMeOSiMe_3$	77
$Me_2CBrCOMe$	A	$Me_2C{=}CMeOSiMe_3$	75
$BrCH_2COPh$	A	$CH_2{=}CPhOSiMe_3$	65
$BrCH_2CO_2Et$	B[c]	$Me_3SiCH_2CO_2Et$	79
$MeCHBrCO_2Et$	B[c]	$Me_3SiCHMeCO_2Et$	49
$BrCH_2CN$	B	Me_3SiCH_2CN	61
$BrCH_2NO_2$	B	$Me_3SiCH_2NO_2$	—

a) A: $Pd(PPh_3)_4$, B: $PdCl_2[P(o\text{-tolyl})_3]_2$. b) Isolated yield based on R-Br. c) HMPA was used as solvent.

As Table 1 shows, moderate to good yields of enol silyl ethers were obtained. From the reaction of α-bromo carboxylates, α-trimethylsilyl carboxylates were produced, but not ketene silyl acetals, even when the reaction was carried out in the presence of trimethylsilyl iodide.[3] Similarly, from the α-bromoacetonitrile, trimethylsilylacetonitrile was obtained, but (trimethylsilyl)nitromethane could not be obtained from the reaction of bromonitromethane.

The following three possible reaction sequences can be considered for the formation of the enol silyl ether from this reaction system.

The first:

$$2Me_3SiCl + Pd(PPh_3)_4 \longrightarrow Me_3SiSiMe_3 + PdCl_2(PPh_3)_2$$[4]

$$Me_3SiSiMe_3 + BrCH_2COR \xrightarrow{[Pd]} CH_2{=}CROSiMe_3 + Me_3SiBr$$[5]

The second:

$$Bu_3SnSnBu_3 + Me_3SiCl \xrightarrow{[Pd]} Bu_3SnSiMe_3 + Bu_3SnCl$$

$$Bu_3SnSiMe_3 + BrCH_2COR \xrightarrow{[Pd]} CH_2{=}CROSiMe_3 + Bu_3SnBr$$[6]

The third:

$$Bu_3SnSnBu_3 + BrCH_2COR \xrightarrow{[Pd]} CH_2{=}CROSnBu_3 + Bu_3SnBr$$

$$CH_2{=}CROSnBu_3 + Me_3SiCl \longrightarrow CH_2{=}CROSiMe_3 + Bu_3SnCl$$

Since the reaction in the absence of hexabutylditin did not give the enol silyl ether, and the reaction of hexamethyldisilane with α-bromo ketone in the presence of palladium complex did not occur, the first possibility is excluded. The second one is also unlikely, because the reaction of hexabutylditin with trimethylsilyl chloride in the presence of palladium catalyst also did not produce the (trimethylsilyl)tributyltin. Thus, the third one is most plausible, that is, the coupling between hexabutylditin and α-bromo ketone is thought to actually occur, forming the tin enolates. In the absence of trimethylsilyl chloride, the tin enolate seemed to collapse to the corresponding ketone.

Other trial for trapping tin enolates also shows the formation of tin enolates in this reaction, although trapping efficiency was not so high. For example, the palladium-catalyzed reaction of α-bromoacetophenone with hexabutylditin in the presence of benzaldehyde gave 1,3-diphenyl-2-propen -1- one[7] in 30% yields.

Experimental

IR spectra were recorded on a Jasco A-100 spectrophotometer. ^{1}H NMR spectra were recorded on a Varian EM-360 instrument. GLC analyses were carried out with Ohkura 802 instrument, using columns (1.5 m) packed with 10% Silicone SF-96 and SE-30 on Celite 545.

Materials. α-Bromo ketones and palladium complexes were used reported previously.[6] Ethyl bromoacetate, ethyl 2-bromopropionate, and bromoacetonitrile were commercially available. Bromonitromethane was prepared by the method described in literature.[8]

Reaction Procedure. The mixture of hexabutylditin (12 mmol), bromide (10 mmol), trimethylsilyl chloride (12 mmol), palladium complex (0.1 mmol), and tetralin (10 cm^3) as solvent is heated under argon at 80 °C for 20 h. Products were collected in cold trap by vacuum distillation under room temperature.

Products. All the products were known. Enol trimethylsilyl ethers were reported previously.[6] ^{1}H NMR and IR data using in identification of ethyl trimethylsilylacetate, ethyl 2-(trimethylsilyl)propionate, and trimethylsilylacetonitrile were recorded here.

Ethyl Trimethylsilylacetate; ^{1}H NMR (CCl_4) δ=0.15 (s, 9H), 1.24 (t, J=7 Hz, 3H), 1.78 (s, 2H), and 4.02 (q, J=7 Hz, 2H). IR (neat): 1720 (C=O), 1365, 1245, 1240, 1100, and 850 cm^{-1}.

Ethyl 2-(Trimethylsilyl)propionate; ^{1}H NMR (CCl_4) δ=0.05 (s, 9H), 1.20 (t, J=7 Hz, 3H), 1.25 (d, J=7 Hz, 3H), 1.87 (q, J=7 Hz, 1H), and 4.07 (q, J=7 Hz, 2H). IR (neat): 1730 (C=O), 1350, 1245, 1235, 1095, and 870 cm^{-1}.

Trimethylsilylacetonitrile; ^{1}H NMR (CCl_4) δ=0.15 (s, 9H) and 1.44 (s, 2H). IR (neat): 2220 (CN), 1390, 1255, and 850 cm^{-1}.

The gift of tributyltin oxide by Kohriyama Kasei Co. is gratefully acknowledged.

Catalytic Functionalities of Molybdenum Catalysts Supported on Brazilian Bentonites

Gerhard W. SCHULTZ,† Hiromichi SHIMADA,* Yuji YOSHIMURA, Toshio SATO, and Akio NISHIJIMA

National Chemical Laboratory for Industry, Yatabe, Ibaraki 305

(Received August 16, 1984)

Synopsis. Two kinds of Brazilian bentonites were applied to supports of molybdenum catalysts to improve the catalytic selectivities of the hydrotreating catalysts. Separate model tests reactions showed that bentonite-supported molybdenum catalysts have higher activities for hydrocracking and hydrodesulfurization as compared to a standard Al_2O_3 supported catalyst, while the Al_2O_3 was superior to the bentonites for hydrogenation activity.

Some kinds of natural clays such as bentonite, have been recognized as suitable for cracking catalysts. In fact, acid-treated clays of montmorillonite type were the first fluid cracking catalysts widely employed by the industry, though the clays were abandoned in favor of synthetic alumina and silica-alumina. Then zeolites came to dominate the petroleum refining industry. Recently, an application of molybdenum catalysts to hydrotreating of petroleum residue or coal derived oil has rekindled interest in these clays as the catalyst supports because of their large pores.

Sakata and Hamrim[1] reported hydrodesulfurization(HDS) and hydrodenitrogenation(HDN) over several clays found in coal mineral matter. Takeuchi *et al.*[2] showed that sepiolite-supported molybdenum catalysts are applicable to the hydrotreating of petroleum residue. Mochida *et al.*[3] also mentioned roles of sepiolite as the support of nickel-molybdenum catalysts in the selective hydrotreating of solvent refined coal. With other clays as the support for molybdenum catalyst, catalytic functionalities of hydrotreating catalysts such as hydrocracking or hydrogenation, still remain unresolved, although a lot of patents were applied in this field. In the present paper, Brazilian bentonites were used as supports of molybdenum catalysts to improve the catalytic selectivity of hydrotreating catalyst. Hydrocracking of diphenylmethane(DPM), HDS of dibenzothiophene(DBT) and hydrogenation of 1-methylnaphtalene(1-MN) were performed under a high pressure of H_2 using bentonite-supported catalysts and a standard alumina-supported catalyst to elucidate their catalytic functionalities.

Experimental

Catalyst supports used in this experiment were two kinds of Brazilian bentonites (Bentonite S and V, Somipal S/A. Co.). These natural minerals were activated chemically with H_2SO_4 (35%), followed by washing until no sulfur could be detected. Then, the samples were heated at 500 °C for 3 h in a presence of air. A commercial type of γ-Al_2O_3 (Sumitomo Aluminium Co.), which was selected as a standard support in our work, was also used. Properties of the bentonites and the alumina are given in Table 1. A 10 wt% of MoO_3 catalysts were prepared by impregnating the carriers with a solution of ammonium heptamolybdate. After drying at 100 °C for 8 h, the samples were calcined at 500 °C for 1 h. Then the catalysts were presulfided in a stream of 10 vol% of H_2S (balance H_2) at 430 °C for 1 h before reaction.

For hydrocracking, HDS and hydrogenation, the reactions were carried out in a stainless steel microreactor (50 cm^3) charged with 10 cm^3 of the commercial reagent and 0.5 g of the catalyst. The unit was pressurized with H_2 to an initial pressure of 70 kg/cm^2 and then injected into an oven heated at 430 °C. Hydrocracking and HDS reactions were performed at 400 °C for 60 min, while 90 min of reaction were selected for hydrogenation. At least the reactions were done twice, and values given in Table 2 are averaged. Reaction products were analyzed by a gas cromatography (Shimadzu GC-6AM). More thorough analyses were done by obtaining mass spectra (Shimadzu GC-MS QP-1000) of the individual products.

Results and Discussion

The catalytic functionalities obtained on the various supports are summarized in Table 2.

Hydrocracking, HDS and hydrogenation activities for the sulfided molybdenum catalysts are given in Runs 1—4. MoS_2 catalyst supported on bentonite gave higher hydrocracking activities as compared to that on γ-Al_2O_3. Among the bentonite supports examined, hydrocracking activities of the catalysts increased after acid treatment of the bentonites. Bentonite S was superior to Bentonite V for hydrocracking of DPM.

Acid treated Bentonite S was the most effective to achieve maximum hydrocracking and HDS activities. In contrast to these results, presulfided molybdenum catalyst supported on γ-Al_2O_3 showed the highest hydrogenation activity.

Runs 5—7 shows the results obtained on oxide catalysts. Similar trends were observed for hydrocracking and hydrogenation in the case of MoO_3 supported catalyst. Higher hydrocracking and HDS activities were given on the bentonite supports. While, higher hydrogenation activity was obtained on the Al_2O_3 support, though hydrogenation activities of the oxide catalyst were lower than those of the sulfided catalyst. HDS activity obtained on MoO_3/Al_2O_3 catalyst was higher than that on MoS_2/Al_2O_3 catalyst. This may be due to the sulfiding of MoO_3. XPS analyses showed that after HDS reactions, MoO_3 changed to MoS_2 to some extent.

Large differences in hydrocracking activities were also obtained for the reactions over the support. The bentonites were found to contribute to hydrocracking activity by itself, as shown in Runs 8—10. This is the most evident in the results obtained in the present work, where the bentonite-supported catalysts gave high hydrocracking performances, in line with the known high activities of these protonic acid supports for cracking reactions.[4] Almost no hydrogenation activity was observed on the Al_2O_3 and the bentonite supports.

From these results it is considered that the role of molybdenum ions in bentonite-supported molybdenum catalyst is to give the activities for HDS and hydrogenation. Molybdenum ions also seem to improve the selectivity of the catalysts, because polymerization products decreased after impregnating MoO_3 on the bentonite. On the other hand, presulfurization seems to enhance hydrogenation activities of the catalysts, by comparing Run 2 with Run 6. In the case of the alumina-supported molybdenum catalyst, molybdenum ions gave the hydrocracking activity as well as HDS and hydrogenation activities. The presulfurization was found to contribute to the enhancement of the hydrogenation activity.

The Thermal Properties of Liquid Crystalline Materials Incorporating Piperazine Skeleton

Shunsuke TAKENAKA,* Toshiro HIROHATA, and Shigekazu KUSABAYASHI
Department of Applied Chemistry, Faculty of Engineering, Osaka University, Suita, Osaka 565
(Received August 24, 1984)

Synopsis. The thermal and electric properties of the homologous series of liquid crystalline materials incorporating a piperazine skeleton have been examined. Some piperazine compounds having a cyano group as the terminal function give rise to a wide-range nematic phase. On the other hand, the homologous series of α,α′-bis(4-alkyl-1-piperadinylimino)-*p*-xylenes and 1,4-bis-(4-alkylbenzylideneamino)piperazines show strong smectic properties.

Liquid crystalline materials incorporating a saturated cyclic system such as cyclohexane,[1] and 1,3-dioxane[2] are currently of interest for applications involving optical devices. Piperazine is a saturated six-membered ring incorporating two nitrogen atoms at the 1 and 4 positions. Some piperazine compounds are known to exhibit mesomorphic properties.[3,4] In this paper, we describe the thermal properties of a new homologous series of liquid cyrstalline materials incorporating piperazine.

Experimental

The preparation of *N*-alkylpiperazine compounds has been described in a previous paper.[3]

Results and Discussion

The transition temperatures and latent heats of series **1**, **2**, **3**, and **4** are summarized in Tables 1, 2, 3, and 4, respectively.

One of the characteristics of the piperazine core is that a tautomerization around the nitrogen atoms at the 1 and 4 positions gives rise to cis and trans isomers in which the former would be very unfavorable for mesophase stability. However, we can assume that the cis isomer should be energetically very unstable because of a relatively strong repulsive interaction between both substituents at the 1 and 4 positions.

As a whole, the piperazine compounds show apparent smectic properties compared with the corresponding phenyl and cyclohexyl compounds, as shown in Table 5.

Series **1** reveals the nematic and smectic phases, though the thermal stability of the nematic phase is lower than that of compound **5**. Series **2** reveals only highly stable smectic phases, while the phenyl and cyclohexyl compounds **6** and **7** show a nematic phase. A similar trend is observed in series **3**, and also **4**, having alkyl groups at the terminals. Furthermore, these compounds tend to reveal relatively tight smectic phases such as the smectic B modification. For series **1** and **2**, the smectic-isotropic transition temperatures tend to decrease while increasing the carbon number in the alkyl or the alkoxyl chains (similar to usual nonpolar mesogens). The nonpolar interaction around the piperazine and phenyl cores along the lateral direction of the molecules would facilitate a layer arrangement of the molecules, increasing the smectic properties.

When the terminal function is replaced by a cyano group, series **3** and **4** tend to exhibit highly stable nematic phase. The effective order for the nematic stability is benzene>cyclohexane>piperazine, though the difference is quite small. In general, mesogens having a cyano group at a terminal function tend to show strong nematic properties, *e.g.*, **8** and **9**. Opposite to the general trend, the butyl homolog of series **3** and thereafter show a smectic B phase and the hexyl homolog also shows a smectic A phase, while these

homologs have a cyano group at the terminal function. In series **4**, the butoxy homolog shows a smectic A phase in addition to a nematic one, while compound **10** shows only a nematic phase. On the other hand, the cyano compounds in series **4** show only a nematic phase, while compound **11** shows smectic A and B phases in addition to a nematic one. The opposite trend indicates that an electric circumstance around the piperazine cores is very important in determining the mesomorphic properties of these compounds.

(Received August 9, 1984)

Synopsis. 17α,21-Dihydroxypregna-1,4-diene-3,20-dione, a potentially useful intermediate of prednisolone, can be prepared from 21-hydroxy-20-methylpregna-1,4-dien-3-one, a biodegradation product of cholesterol.

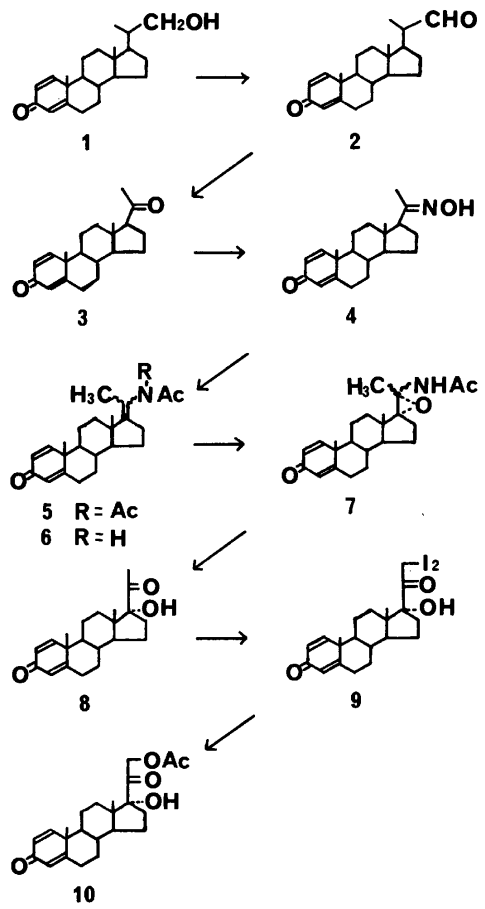
Corticosteroids are commercially produced from deoxycholic acid, stigmasterol or diosgenin. Recently, it was reported that cholesterol could be degraded to 21-hydroxy-20-methylpregna-1,4-dien-3-one (**1**) by a mutant of *Mycobacterium* sp.[1] Compound **1** may be one of the ideal starting materials for prednisolone synthesis. We present here a new conversion of **1** into 17α,21-dihydroxypregna-1,4-diene-3,20-dione 21-acetate (**10**), a precursor of prednisolone.

Results and Discussion

The methods employed in this conversion are summerized in Scheme 1. The first step is the oxidation of **1** to the aldehyde **2**. The oxidation of **1** was conducted by using the complex obtained from dimethyl sulfide and *N*-chlorosuccinimide[2] in toluene–dichloromethane to give **2** in 90% yield. The conversion of **2** into the ketone **3** was followed by a known oxidative decarboxylation procedure.[3] By bubbling air through a mixture of **2**, DBU and copper (II) acetate-2,2′-bipyridyl complex in DMF, the ketone **3** was obtained in 90% yield. The ketone **3** was converted to the oxime **4** easily in 92% yield.

Modifying the synthetic method of 3-acetylamino-5α-cholest-2-ene,[4] the oxime **4** was heated in acetic anhydride–pyridine for 40 h. The resulting solution was evaporated to dryness and the black tarry residue was partitioned into benzene and aqueous sodium hydrogencarbonate solution layers. Further processing including chromatography on silica gel yielded the enamide **5**. The NMR spectra of **5** showed that **5** was a 4:1 mixture of E and Z isomers. The hydrolysis of **5** in aqueous potassium hydrogencarbonate–methanol gave the enamide **6** as an amorphous product. Without further purification, **6** was treated with peracetic acid in the presence of sodium acetate in dichloromethane in the usual way.[5] After usual treatment, **8** was obtained in 43% yield from **4**. This was identified with the authentic sample which was derived from 17α-hydroxyprogesterone by the dehydrogenation with 2,3-dichloro-5,6-dicyano-*p*-benzoquinone.

The 21-acetoxy introduction into **8** was accomplished by Stork's iodination procedure.[6] Iodination of **8** in THF–methanol with an excess of iodine in the presence of calcium oxide gave the iodide **9**, which was converted directly to **10** by treatment with triethylammonium acetate in acetone. Overall yield of **10** was 88% from **8** and 28% from **1**. The transformation of **10** into prednisolone can be followed by a microbiological process.



Scheme 1.

Experimental

20-Methyl-3-oxopregna-1,4-dien-21-al (2). To a stirred solution of *N*-chlorosuccinimide (8.0 g) in toluene (150 ml), dimethyl sulfide (6.0 ml) in toluene (50 ml) was added at 0 °C under nitrogen atmosphere. The mixture was cooled to −25 °C and a solution of 21-hydroxy-20-methylpregna-1,4-dien-3-one (**1**) (6.0 g) in dichloromethane (100 ml) was added dropwise. The stirring was continued for 2 h at −25 °C and then a solution of triethylamine (3.0 g) in dichlomethane (5.0 ml) was added dropwise. The cooling bath was removed and after 5 min, ether was added. The organic layer was

washed with 1% hydrochloric acid and then with water. Removal of dried (sodium sulfate) solvents produced **2** in 90% yield. Recrystallization from ethyl acetate–hexane afforded the analytically pure sample; mp 154.4—154.8 °C dec., NMR ($CDCl_3$) δ=0.91 (s, 3H), 1.14 (d, 3H, J=4 Hz), 1.24 (s, 3H), 6.08 (s, 1H), 6.22 (d, 1H, J=10 Hz), 7.06 (d, 1H, J=10 Hz), 9.54 (d, 1H, J=4 Hz); m/z 326 (M^+).

Found: C, 81.03; H, 9.25%. Calcd for $C_{22}H_{30}O_2$: C, 80.98; H, 9.20%.

Pregna-1,4-diene-3,20-dione (3). Through a rapidly stirring mixture of **2** (0.5 g), DBU (0.1 g), $Cu(OAc)_2 \cdot H_2O$ (8 mg), and 2,2′-bipyridyl (7 mg) in *N,N*-dimethylformamide (10 ml), air was bubbled at 20 °C for 14 h. The reaction mixture was extracted with chloroform and the organic layer was washed with 1% hydrochloric acid and then with water. Removal of solvents afforded **3** in 89.6% yield. Recrystallization from tetrahydrofuran-octane provided the analytically pure sample; mp 152.0—152.3 °C; NMR ($CDCl_3$) δ=0.7 (s, 3H), 1.24 (s, 3H), 2.12 (s, 3H), 6.08 (s, 1H), 6.24 (d, 1H, J=10 Hz), 7.06 (d, 1H, J=10 Hz).

Found: C, 80.93; H, 9.03%. Calcd for $C_{21}H_{28}O_2$: C, 80.73; H, 9.03%.

Pregna-1,4-diene-3,20-dione 20-Oxime (4). To a stirred solution of **3** (10.0 g) and sodium acetate (5.0 g) in aqueous methanol (90%, 150 ml), hydroxylamine hydrochloride (2.3 g) was added at 3—5 °C and stirred for 1.5 h. Water was added and the resultant precipitate was separated by filtration to give **4** (10.3 g) in 91.9% yield. Recrystallization from tetrahydrofuran-octane afforded the analytically pure sample; NMR ($CDCl_3$) δ=0.72 (s, 3H), 1.24 (s, 3H), 1.88 (s, 3H), 6.08 (s, 1H), 6.24 (d, 1H), 7.06 (d, 1H); m/z 327 (M^+).

Found: C, 77.24; H, 8.83; N. 4.28%. Calcd for $C_{21}H_{29}NO_2$: C, 77.02; H, 8.93; N, 4.28%.

20-(Diacetylamino)pregna-1,4,17(20)-trien-3-one (5). The oxime **4** (2.91 g) in dry pyridine (75 ml) and acetic anhydride (50 ml) was refluxed under nitrogen atmosphere for 40 h. The solvent was evaporated off under reduced pressure, the resultant black tar was taken up in benzene and saturated sodium carbonate solution.

The mixture was shaken and then filtered through a Celite pad, which was washed thoroughly with benzene. The benzene layer was separated, washed with water, dried and evaporated. The product in benzene was chromatographed on silica gel (Wakogel C-100, 15 g). The elution with benzene afforded **5** (3.77 g). This product was a mixture of E:Z=4:1, which was determined by NMR. NMR ($CDCl_3$) δ(E-form)=1.00 (s, 3H), 1.24 (s, 3H), 2.28 (s, 3H), 2.32 (s, 3H), 6.06 (s, 1H), 6.22 (d, 1H, J=10 Hz), 7.06 (d, 1H, J=10 Hz), δ(Z-form)=0.88 (s), 1.24 (s), 2.26 (s), 2.38 (s), 6.04 (s), 6.20 (d, J=10 Hz), 7.04 (d, J=10 Hz); m/z 395 (M^+).

20-(Acetylamino)pregna-1,4,17(20)-trien-3-one (6). Diacetylamino compound **5** (3.77 g) was added to methanol (60 ml) and potassium hydrogencarbonate (3.5 g) and refluxed for 1.5 h. The reaction mixture was extracted with dichloromethane and the organic layer was washed with water, dried and evaporated to give **6** (3.14 g). NMR ($CDCl_3$) δ(E-form)=0.96 (s, 3H), 1.24 (s, 3H), 2.00 (s, 6H), 6.06 (s, 1H), 6.22 (d, 1H, J=10 Hz), 6.56 (broad, 1H), 7.06 (d, 1H, J=10 Hz), δ(Z-form)=0.94 (s), 1.22 (s), 1.98 (s), 6.06 (s), 6.20 (d, J=10 Hz), 6.76 (broad), 7.04 (d, J=10 Hz); m/z 353 (M^+).

17α-Hydroxypregna-1,4-diene-3,20-dione (8). To a mixture of **6** (1.54 g) and sodium acetate (0.22 g) in dichloromethane (5 ml), 40% peracetic acid (0.99 g) in dichloromethane (15 ml) was added dropwise at 3—5 °C. After 1 h, sat. sodium hydrogencarbonate solution was added and the organic layer was separated, washed successively with 5% potassium iodide solution, sodium thiosulfate solution and water, dried and evaporated. To the residue, methanol (20 ml) and 0.3 M(1M=1 mol dm^{-3}) sodium hydroxide solution (20 ml) were added and the mixture was heated under reflux for 1.5 h. After cooling, the mixture was neutralized with acetic acid and then concentrated. The products were extracted with dichloromethane and the organic layer was washed with water and dried. Removal of solvents afforded crude **8** (1.39 g), which was chromatographed on a column of silica gel with benzene–methanol (85:15) to give **8** (0.61 g) in 43% yield from **4**. Recrystallization from octane–tetrahydrofuran (1:1) afforded the analytically pure sample; mp 258.0—258.7 °C, NMR ($CDCl_3$) δ=0.8 (s, 3H), 1.26 (s, 3H), 2.28 (s, 3H), 2.96 (s, 1H), 6.08 (s, 1H), 6.22 (d, 1H, J=10 Hz), 7.06 (d, 1H, J=10 Hz).

Found: C, 76.95; H, 8.48%. Calcd for $C_{21}H_{28}O_3$: C, 76.79; H, 8.59%.

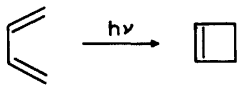
Nonadiabatic Transitions in Photochemical Electrocyclic Reaction of Acrylaldehyde to Form 2*H*-Oxete

Kenji MORIHASHI,* Hiroshi KUBOTA, and Osamu KIKUCHI*
Department of Chemistry, The University of Tsukuba, Sakura, Ibaraki 305
(Received July 16, 1984)

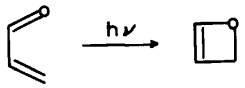
The photochemical electrocyclic reaction of *s-cis*-acrylaldehyde to form 2*H*-oxete was examined on the basis of the nonadiabatic interaction between potential energy surfaces. The nonadiabatic coupling *g* terms were calculated by the reduced classical-trajectory method along two postulated reaction paths, the concerted path and the step-by-step path. The calculated *g* terms were characteristic of the avoided crossing between the potential energy surfaces. The calculated *g* terms and the transition probabilities indicated that the step-by-step path was very efficient in the formation of 2*H*-oxete from the π-π^* state of acrylaldehyde.

The photochemical electrocyclic reaction of *s-cis*-butadiene, **1**→**2**, has been investigated theoretically by several researchers.[1,2] During the disrotatory mode of



1 2

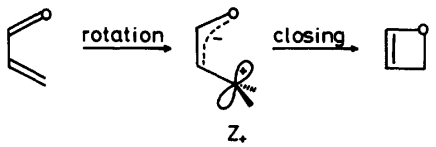
this isomerization reaction, there is an avoided crossing[3,4] between the ground state (S_0) and the lowest excited singlet state (S_1) surfaces. This avoided crossing plays a significant role in the isomerization reaction, and its existance can be easily predicted from an MO correlation diagram.[4] In the case of a formal electrocyclic reaction of *s-cis*-acrylaldehyde, **3**→**4**, such



3 4

a simple prediction is impossible because of a lack of symmetry in the molecular structure.

Since the **3**→**4** system is isoelectronic with the **1**→**2** system, the **3**→**4** reaction may be considered to proceed along the concerted reaction path as is expected for the **1**→**2** reaction. However, a recent analysis of the potential energy surfaces of the **3**→**4** reaction[5] has given evidence of the existance of another reaction path, a step-by-step path in which the ring closing occurs after a rotation of the methylene group. In this path, the Z_+



Z_+

zwitterion, in which the positive charge is localized on the terminal carbon atom, can undergo the ring closing very easily because of the strong attraction between the positive charge and the in-plane lone-pair electrons on the oxygen atom. It is thus very interesting to compare the efficiencies of the two reaction paths, the concerted path and the step-by-step path.

Since a photochemically-excited reactant molecule decays to the ground state of the reaction product *via* some nonadiabatic transitions, the transition-probability calculation as well as the potential-energy-surface analysis is necessary in order to understand the photochemical reaction processes. This is especially true for the **3**→**4** system, in which the symmetry argument of the MO correlation diagram is not effectively used. In our previous paper,[5] the **3**→**4** reaction paths were discussed on the basis of the potential energy surfaces obtained by the MINDO/3[6] CI calculations. In this paper, the nonadiabatic coupling term between the electronic states and the transition probability were calculated using the reduced classical-trajectory method,[2] and the efficiencies of the two postulated reaction paths, the concerted path and the step-by-step path, were examined on the basis of the nonadiabatic interaction between the potential energy surfaces.

Method

The method employed here is the reduced classical-trajectory method.[2] This method has been demonstrated to be a simple method for estimating nonadiabatic transition probabilities in polyatomic systems where transitions between the Ψ_1 and Ψ_2 states are induced, mainly, by the reaction-coordinate-coupling term:

$$g = \langle \Psi_2 | \partial/\partial s | \Psi_1 \rangle. \tag{1}$$

The reaction coordinate, *s*, is defined as the mass-weighted distance along the postulated reaction path A:[7]

$$s = \int_A ds. \tag{2}$$

The coupling term can be written as a sum of the CI and MO terms.[8] These terms were calculated by means of the finite-difference method for the reaction coordinate:[2]

$$g = g_{CI} + g_{MO}, \tag{3}$$

$$g_{CI} = \sum_m B_m(\partial A_m/\partial s),$$

$$g_{MO} = \sum_{\substack{m \\ (m \neq n)}} \sum_n B_m A_n \langle \Phi_m | \partial/\partial s | \Phi_n \rangle,$$

where A_m and B_m are the coefficients of configurations Φ_m in each each state function, *i.e.*,

$$\Psi_1 = \sum_m A_m \Phi_m$$
$$\Psi_2 = \sum_m B_m \Phi_m.$$

The transition probability from the Ψ_2 state to the Ψ_1 state, $P_{2\to1}=|a_1|^2$, was obtained from the solution of the reduced classical-trajectory equations:[2b]

$$\dot{a}_1 = +g\dot{s}\exp\left[-(i/\hbar)\int^t \Delta E\,dt\right]a_2,$$
$$\dot{a}_2 = -g\dot{s}\exp\left[+(i/\hbar)\int^t \Delta E\,dt\right]a_1, \quad (4)$$

where ΔE is the energy gap between Ψ_1 and Ψ_2, *i.e.*, $\Delta E=E_2-E_1>0$. Thus the reduced classical-trajectory equations have a one-dimensional form for nuclear motions, and are derived by neglecting all of the 3N-7 vibrational-coupling terms in the N-atom system.[2b] The transition probability was estimated from the Landau-Zener model:[9]

$$P_{2\to1} = \exp\left[-(\pi/4)\xi\right], \quad (5)$$

with the Massey parameter,[10]

$$\xi = \Delta E(s_c)/\hbar\,\dot{s}_c\,g(s_c). \quad (6)$$

ξ was calculated for the s_c point where the g value becomes maximum. The velocity $\dot{s}_c$ was obtained from knowledge of the kinetic energy in the direction of the reaction coordinate, $T_s=(\dot{s}_c)^2/2$.

Linear reaction paths were assumed for the concerted and step-by-step paths of the **3**→**4** reaction. For the concerted path, all geometrical variables were varied simultaneously between the structures of acrylaldehyde and 2*H*-oxete. These values were first optimized using the MINDO/3 SCF calculation.[5] The step-by-step path was expressed by two linear paths. In the first linear path, only the twisting angle of the methylene group was varied to make the methylene CH_2 plane become perpendicular to the C-C-C-O skeleton. In the second linear path, all the geometrical variables, except for that of the methylene rotation, were simultaneously varied between the structures of the twisted acrylaldehyde and of 2*H*-oxete molecules.

Although the MINDO/3 parameters had been determined so as to well reproduce the ground-state properties of molecules, the MINDO/3 CI calculations gave reasonable results for several photochemical reaction processes.[5,11,12] We thus feel that the nonadiabatic coupling terms calculated with the MINDO/3 CI wavefunctions can be employed for the qualitative consideration regarding a decay process from the excited state.

Results and Discussion

Concerted Path. The total distance between the optimized structures of acrylaldehyde and 2*H*-oxete is **10.47** (atomic mass unit)$^{1/2}$ (bohr). This value was obtained by numerical integration of Eq. 2. The three lowest singlet states along this reaction path are shown in Fig. 1. The S_1 and S_2 states correspond to the n→π^* and $\pi\to\pi^*$ states of acrylaldehyde, respectively. Two avoided crossings were observed along the reaction path, *i.e.*, the A1 avoided crossing between the S_2 and S_1 state and the A2 avoided crossing between the $S_1$and S_0 states. The reaction proceeds from the n→π^* state of acrylaldehyde and reaches the ground state of 2*H*-oxete through the two avoided crossings. On the other hand, the 2*H*-oxete formation from the $\pi\to\pi^*$ is inefficient due to a potential barrier on the S_1 state. This agrees well with the experimental evidence reported by Friedrich and Schuster.[13] Therefore, the efficiency of the concerted path, which starts from the $\pi\to\pi^*$ state of acrylaldehyde, depends on the transition probabilities at the two avoided crossing regions.

The nonadiabatic coupling terms calculated along the concerted path are shown in Fig. 2. The coupling term between S_2 and S_1, which is related to the A1 avoided crossing, has a narrow shape and the CI term is dominant. On the other hand, a broad shape is observed for the coupling term between S_1 and S_0, which is related to the A2 avoided crossing; the MO term is dominant for the g shape. A remarkable observed feature in the concerted path is the overlapping between the two coupling regions. This overlapping indicates that nonadiabatic transitions are expected to occur over a wide range of the two coupling regions. Thus, the shape of the coupling term clearly reflects the property of the nonadiabatic interaction which is not directly observed from the potential energy curves.

Step-by-step Path. The total distance, 3.76(amu)$^{1/2}$

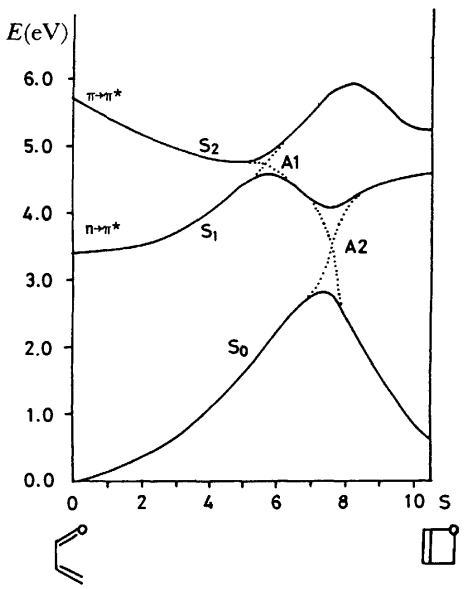


Fig. 1. Potential energy curves along the concerted path for the acrylaldehyde-2*H*-oxete system. Two avoided crossings, A1 and A2, are involved in the process. Unit of reaction coordinate is (amu)$^{1/2}$-(bohr).

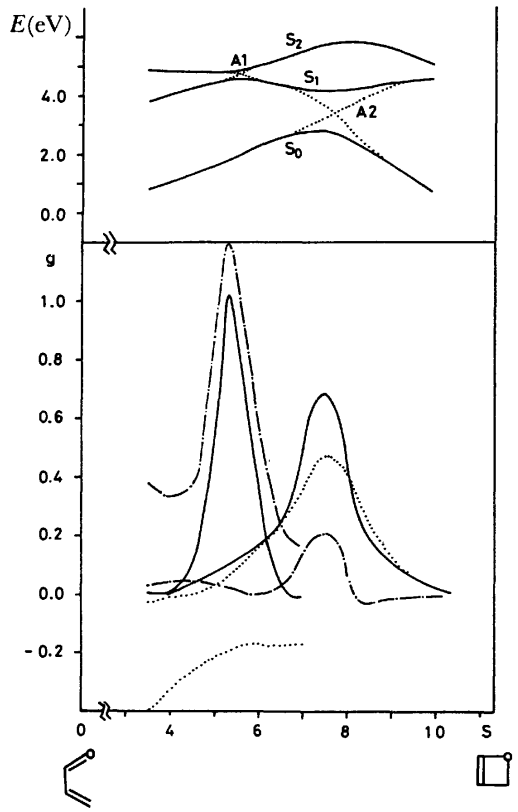

Fig. 2. Nonadiabatic coupling terms calculated along the concerted path(lower part) and the corresponding potential energy curves(upper part).
The lower part; (—·—): g_{CI}(CI term); (·····): g_{MO}(MO term); (——): $g=g_{CI}+g_{MO}$. Unit of g: $(amu)^{-1/2}(bohr).^{-1}$

(bohr), of the reaction coordinate in the first step is very short, since only hydrogen atoms with small masses move along the path. In the second step, the total distance, 9.62 $(amu)^{1/2}$ (bohr), is longer than that of the first step, since the heavy carbon and oxygen nuclei move. Figure 3 shows the potential energy curves along the step-by-step path. The rotation of the methylene group easily occurs in the $\pi\rightarrow\pi^*$ state of acrylaldehyde to give the twisted structure through the A3 avoided crossing between the S_1 and S_2 surfaces.

In the ring-closing step, the symmetry property with respect to the molecular plane is preserved. The S_1 and S_0 states are allowed to intersect since they belong to different symmetry representations.[5] If the symmetry property is destroyed, even slightly, an intersection between S_0 and S_1 is avoided. Such an intersection is called the conical intersection.[14] In order to investigate the nonadiabatic property of the conical intersection, the reaction path, in which the symmetry property was slightly destroyed, was adopted for the ring-closing step. The twisting angle of methylene group was fixed at 87.5° (not at 90°). The potential energy curves along this step-by-step path, therefore, involve two avoided crossings, A3 and A4, as shown in Fig. 3.

The calculated nonadiabatic coupling terms for the two avoided crossing regions are shown in Fig. 4. The

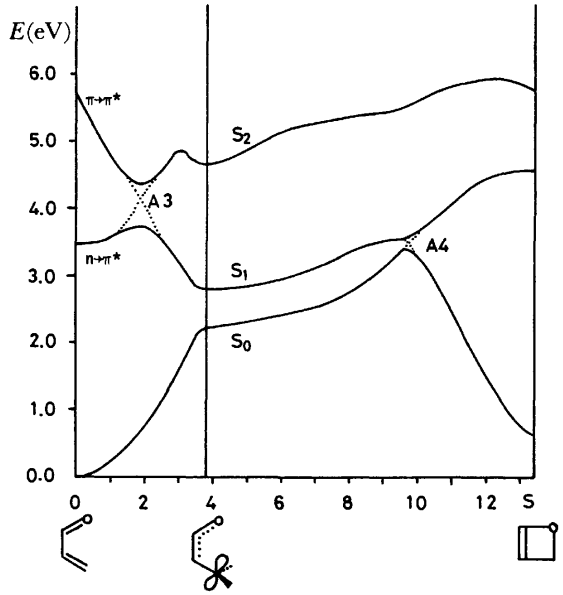

Fig. 3. Potential energy curves along the step-by-step path for the acryaldehyde-2*H*-oxete system. Two avoided crossings, A3 and A4, are involved in the process.

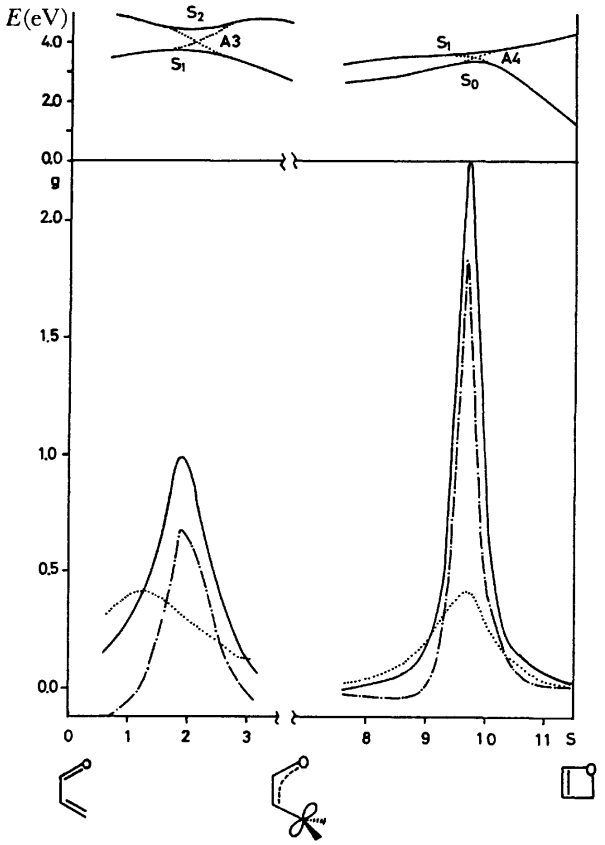

Fig. 4. Nonadiabatic coupling terms calculated along the step-by-step path(lower part) and the corresponding potential energy curves (upper part).
The lower part; (—·—): g_{CI}; (·····): g_{MO}; (——): $g=g_{CI}+g_{MO}$. Unit of g: $(amu)^{-1/2}(bohr).^{-1}$

total g shape for the A3 avoided crossing is similar to that of the A1 avoided crossing in the concerted path, although the shape of the MO and CI components are

TABLE 1. TRANSITION PROBABILITIES AND THEIR RELATED QUANTITIES FOR THE CONCERTED AND STEP-BY-STEP PATHS IN THE ACRYLALDEHYDE-2*H*-OXETE SYSTEM.

Avoided crossing		T_s[a]	$\Delta E(s_c)$	$g(s_c)$[b]	ξ	P
		eV	eV	R		
Concerted	A1	1.25	0.25	0.980	1.32	0.35
	A2	1.95	1.32	0.686	7.96	0.0019
Step-by-step	A3	1.63	0.66	0.974	3.07	0.090
	A4	2.46	0.18	2.23	0.30	0.79

a) T_s is the nuclear kinetic energy. The velocity $\dot{s}_c$ in the Massey parameter ξ was obtained from T_s by the equation. $\dot{s}_c=(2T_s)^{1/2}$. b) $g(s_c)$ indicates the maximum value of coupling term in each avoided crossing region, and the unit, (R), is equal to $(\text{amu})^{-1/2}$ $(\text{bohr})^{-1}$.

quite different between the A1 and A3 regions. A very sharp peak is observed in the variation of the coupling term between S_0 and S_1. The character of the conical intersection is clearly reflected in the *g* shape. It can be seen from the *g* shape that the nonadiabatic interaction suddenly increases near the allowed crossing, and the nonadiabatic transition occurs, effectively, in the very narrow region. If the symmetry property with respect to the molecular plane is preserved during the ring-closing step, the *g* shape would be that of a delta function at the crossing point.

Figure 3 may indicate that the $S_1 \rightarrow S_0$ transition occurs, effectively, at the twisted form of acrylaldehyde ($s=3.76$). This transition is induced by the rotation of the terminal methylene group and can be understood by the analogy of the photochemical *cis-trans* isomerization process of simple olefins.[15] The nonadiabatic coupling for this transition was not calculated, since this process is not important for the 2*H*-oxete formation.

Transition Probability. The reaction was assumed to start from the $\pi \rightarrow \pi^*$ state of acrylaldehyde, and the transition probability was calculated for each avoided crossing according to Eq. 5. The results are summarized in Table 1. The kinetic energy, T_s, was calculated from the difference between the energies of the upper state at each avoided crossing point and of the $\pi \rightarrow \pi^*$state of acrylaldehyde. The excitation energy of acrylaldehyde was assumed to be 6 (eV); this value was determined so as to be slightly higher than that of the calculated $\pi \rightarrow \pi^*$ state of acrylaldehyde.

Let us compare the possibility of the step-by-step path with that of the concerted path. If the reaction starts from the $\pi \rightarrow \pi^*$ state of acrylaldehyde, two nonadiabatic transitions are involved in each reaction path. In the first transition from the S_2 state to the S_1 state, the probability of the A1 avoided crossing in the concerted path is higher than that of the A3 avoided crossing in the step-by-step path. In the second transition from S_1 to S_0, however, the A4 avoided crossing has a much higher transition probability than that of the A2 avoided crossing. By the large difference in the probabilities of the second transition, the step-by-step path is considered to be the more effective reaction path in the two postulated paths.

It is noted that some shortcomings are involved in the above consideration. One of them involves the estimation of the kinetic energies employed in the transition-probability calculation. The kinetic energy along the reaction coordinate was estimated from the $\pi \rightarrow \pi^*$ excited-state energy, and the energy distribution among several degrees of nuclear freedom was not taken into account. This may be unrealistic and more reliable statistical methods[16] are necessary to determine the decay-rate constant.

The efficiencies of the two postulated reaction paths were compared on the basis of the nonadiabatic interaction, and the effect of the potential energy barriers on the S_0 and S_1 surfaces was not quantitatively considered. The discussion is, thus, a qualitative one and the most probable reaction path was not determined by the present treatment, although the step-by-step path was expected to be involved in the isomerization reaction.

The possibility of the existance of the step-by-step path in the photochemical electrocyclic reaction of acrylaldehyde was supported by means of the reduced classical-trajectory method. The step-by-step path *via* a zwitterion has been proposed not only for the **3**→**4** reaction but also for the various types of hetero-atom conjugated systems.[11] The present study indicates the importance of this reaction path in the photochemical electrocyclic reaction of heteroatom conjugated systems.

The Photochemical Magnetic Field Effect of Isoquinoline *N*-Oxides

Norisuke HATA
Department of Chemistry, College of Science and Engineering, Aoyama Gakuin University, Chitosedai, Setagaya-ku, Tokyo 157
(Received August 2, 1984)

The irradiation of isoquinoline *N*-oxide in ethanol resulted in the formation of lactam in a *ca.* 67% yield *via* the S_1 state (Process I). When the photochemical isomerization was carried out in the presence of a magnetic field, the chemical yield of lactam was found to show a minimum at approximately 1T. In order to interpret this new phenomenon, Process I was assumed to be initiated by electron transfer from the excited singlet *N*-oxide to the hydrogen-bonded ethanol (the formation of a singlet hydrogen-bonded radical ion pair). Thus, the new type of magnetic-field effect was excellently explained in terms of an electron-nuclear hyperfine interaction mechanism including the electron-exchange interaction in the radical-ion pair (the magnetic-field effect due to HFI-J mechanism). This implies that the magnetic-field effect is unambiguous evidence that Process I (*N*-oxide→lactam) does not involve the oxaziridine intermediate, but proceeds *via* the singlet hydrogen-bonded radical-ion pair (radical-ion-pair mechanism of Process I). The irradiation of 1-cyanoisoquinoline *N*-oxide in ethanol resulted in the formation of 1,3-oxazepine in a *ca.* 66% yield *via* the S_1 state (Process II). The photochemical isomerization was not affected at all by an external magnetic field. This is consistent with the idea that Process II (*N*-oxide→oxazepine) does not involve a field-sensitive intermediate, but occurs with the intervention of oxaziridine (the oxaziridine mechanism of Process II).

It is one of the most interesting and challenging problems in chemistry to determine whether or not a magnetic field has an effect on chemical reactions. Although a number of studies of this subject had been made over a long period, corroborating evidence for the existence of an external magnetic-field effect upon chemical reactions in a liquid solution had never been obtained until 1970.[1] In 1971, on the basis of the radical-pair model of CIDNP (Chemically Induced Dynamic Nuclear Polarization),[2,3a] Lawler and Evans predicted the influence of a magnetic field on radical-pair reactions in solution.[4] In 1972 and later, as was expected from the radical-pair model, the magnetic-field effect arising from electron-nuclear hyperfine interaction (HFI mechanism) or electronic Zeeman interaction (Δg mechanism) was observed by Molin's group in the thermal reaction of pentafluorophenylmethyl chloride or decafluorodiphenylchloromethane with butyllithium.[5] Such magnetic-field effects (HFI and Δg mechanisms) were also observed in several photochemical systems by Tanimoto *et al.*,[6a] Schulten *et al.*,[6b] and Michel-Beyerle *et al.*,[6c] in 1976.

In that same year (1976), the present author found a very interesting and unexpected effect of the magnetic field which was quite different from the above two types of magnetic-field effects;[7] when the photochemical isomerization of isoquinoline *N*-oxide in ethanol was carried out in either the absence or presence of a magnetic field, the chemical yield of the product (1-isoquinolone) was observed to show a minimum at approximately 1T. In 1978 this new phenomenon was successfully interpreted in terms of a hyperfine interaction mechanism including an electron-exchange interaction in the singlet hydrogen-bonded radical-ion pair assumed to be a transient intermediate of this reaction;[8] thus, it has been termed the magnetic-field effect due to the HFI-J mechanism. These studies were partly reported in preliminary form.[7-10] The purpose of the present and succeeding papers is to present further details of the new type of external magnetic-field effect, together with a novel mechanism of the photochemical isomerization of isoquinoline *N*-oxide.

Experimental

The isoquinoline *N*-oxide **1** used as a sample was synthesized by treating isoquinoline with 35% aqueous hydrogen peroxide and acetic anhydride according to the method given in the literature;[11] it was then purified by vacuum distillation, followed by alumina-column chromatography (the eluent, chloroform–ethanol (40:1)); mp 103—105 °C. The 1-cyanoisoquinoline *N*-oxide **4** used as the other sample was prepared from 1-isoquinolinecarbonitrile according to Ochiai's method[12] and recrystallized from ethanol three times; mp 205—206 °C.

A 50-cm^3 portion of ethanolic solution containing 35 mg of isoquinoline *N*-oxide **1** (or 20 mg of 1-cyanoisoquinoline *N*-oxide **4**) in a quartz vessel was placed in an electromagnet (EEO-1815) supplied by the Maezumi Electric Company and subsequently, illuminated with a 500W Ushio Super-high-pressure Mercury Lamp (USH-500D) equipped with a Toshiba filter UV-31 (or a Toshiba filter UV-35) for 10 min (or 15 min) at room temperature while nitrogen was being bubbled in. The ethanol used as the reaction medium was a reagent-grade product (99.5%) of Wako Pure Chemical Industries. The photoproduct **2** (or **5**) and unreacted *N*-oxide **1** (or **4**) were separated by means of silica-gel TLC (Merck silica-gel plate $60F_{254}$; layer thickness, 2 mm; the eluent, benzene–ethanol–diethyl ether (5:1:2) for **1** and **2**, or hexane–diethyl ether (1:2) for **4** and **5**), and the amounts were determined spectrophotometrically. The UV absorption spectra were taken with a Shimadzu recording spectrophotometer, UV-220.

Results

The irradiation of isoquinoline *N*-oxide **1** in ethanol resulted in the formation of lactam **2** (1-isoquinolone)[13] in a *ca.* 67% yield (Eq. 1). Figure 1 shows the results when the reaction was carried out

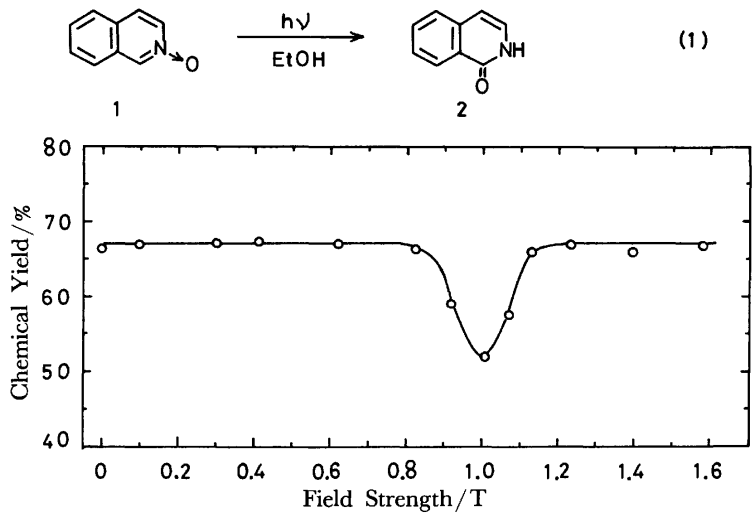

Fig. 1. The magnetic-field dependence of the chemical yield of lactam **2** in the photochemical reaction of isoquinoline *N*-oxide **1**. [*N*-oxide **1**]=4.82×10^{-3} mol dm^{-3}. Conversion: *ca.* 17%. Solvent: 50 cm^3 of ethanol.

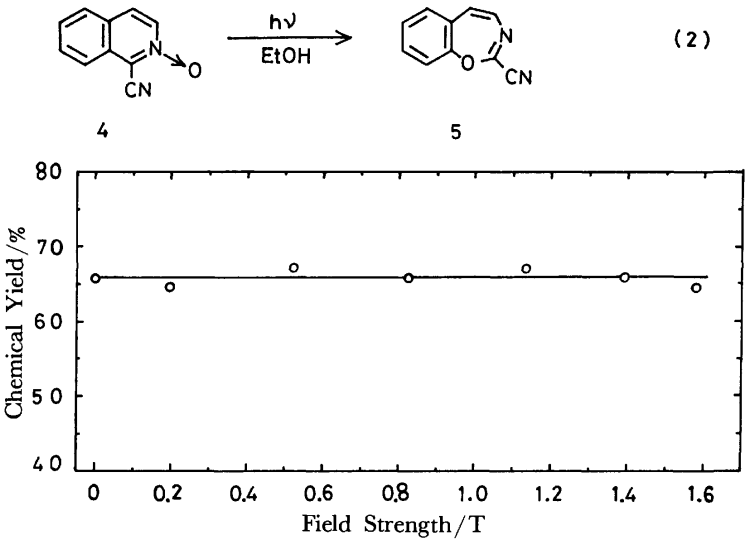

Fig. 2. The chemical yield of oxazepine **5** *vs.* magnetic-field strength in the photochemical reaction of 1-cyanoisoquinoline *N*-oxide **4**. [*N*-oxide **4**]=2.35×10^{-3} mol dm^{-3}. Conversion: *ca.* 30%. Solvent: 50 cm^3 of ethanol.

in the absence and in the presence of a magnetic field; the chemical yield of lactam **2** was determined as a function of the field strength. As can be seen from the figure, the chemical yield of lactam **2** was *ca.* 67% at a magnetic field below 0.8T, but it decreased steeply with an increase in the field strength to be *ca.* 52% at about 1T. A further increase in the magnetic field resulted in a steep increase in the chemical yield until it approached an approximately constant value (*ca.* 67%). The conversion remained almost constant (*ca.* 17%).

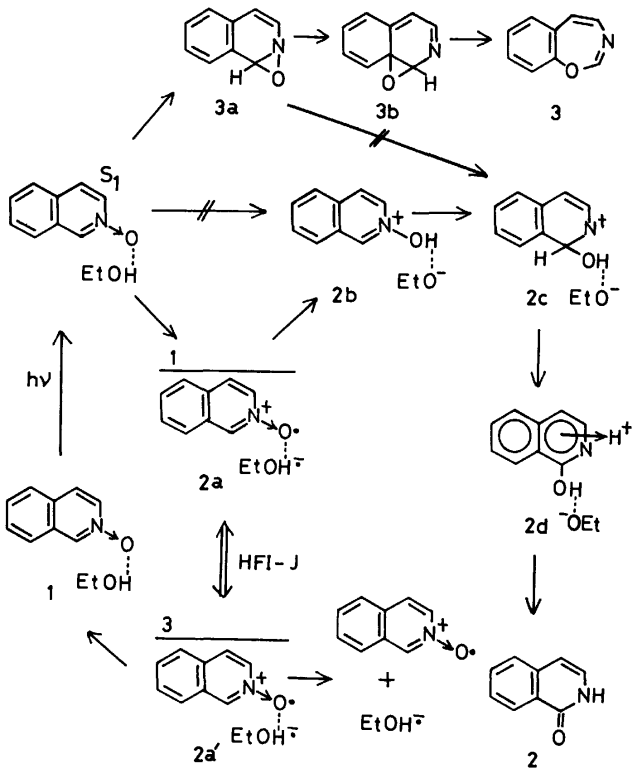
In the case of 1-cyanoisoquinoline *N*-oxide **4**, unlike the case of isoquinoline *N*-oxide **1**, the oxazepine **5** (2-cyano-1,3-benzoxazepine)[14] was obtained in the yield of *ca.* 66% (Eq. 2). Figure 2 shows a plot of the chemical yield of oxazepine **5** against the field strength, from which the chemical yield was proved to be independent of an external magnetic field. Here, also, the conversion remained almost constant (*ca.* 30%).

Discussion

It is well known that, the irradiation of isoquinoline *N*-oxide as well as that of quinoline *N*-oxide in solution results in the formation of a lactam and/or 1,3-oxazepine, depending on the nature of the reaction medium or the substituent group;[15] the photochemical isomerization of the *N*-oxides into lactam and oxazepine are referred to as Process I and Process II respectively. In non-hydroxylic solvents, the *N*-oxide is predominantly transformed into its oxazepine (Process II), whereas in hydroxylic solvents (ROH), Process I

(*N*-oxide→lactam) becomes much more important than Process II (*N*-oxide→oxazepine). When *N*-oxide has a CN or CF_3 group at the carbon atom adjacent to the ring nitrogen, however, only Process II occurs to yield the 1,3-oxazepine, independent of the nature of the reaction medium. Both Processes I and II have been revealed to proceed through the lowest excited singlet state (S_1), whereas the deoxygenation products (the parent amines) are formed from the lowest triplet state (T_1) in only a trace or in a yield of a few percent.[15-17]

Reactive Intermediate. In order to account for Processes I and II, oxaziridine **3a** has been custamarily postulated as the primary photoproduct (reactive intermediate) from which all the products (lactam **2** and oxazepine **3**) are derived[15a] (*cf.* Scheme 1). Since 1972, however, several experimental data conflicting with this idea have been documented in the literature.[11,15b,15c,16-18] We ourselves have demonstrated that the photochemical isomerizations are closely related to whether or not the *N*-oxide oxygen atom forms hydrogen bond with a solvent molecule;[18] that is, such a hydrogen-bonding interaction turns out to be essential for the photochemical rearrangement to the lactam **2** (Process I), but not for the photoisomerization into the oxazepine **3** (Process II). On the basis of these facts, as is shown in Scheme 1, Process I has been assumed to proceed *via* the hydrogen-bonded ion pair **2b** which is formed by the protonation of the N→O group with the hydrogen-bonded solvent molecule (EtOH) in the S_1 state (ion-pair mechanism of Process I), whereas Process II occurs with the formation of the oxaziridine intermediate **3a** from the S_1 state (oxaziridine mechanism of Process II). Such reaction mechanisms have been strongly supported by the studies of quenching by inorganic anions.[19] However, there has still been considerable doubt as to the ion-pair mechanism of Process I; the formation of the ion-pair **2b** through the hydrogen-bonding interaction was not considered to be favorable from the S_1 state, because a hydrogen-bonding ability of the oxygen atom of the N→O group was much lower in the S_1 state than in the S_0 state.[20]

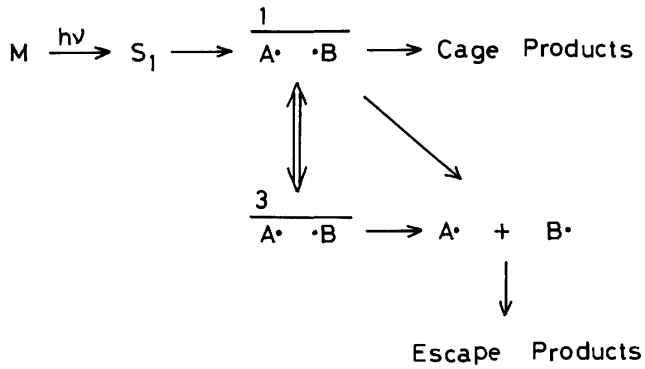


Scheme 1.

As a general rule, if a chemical reaction in solution is subject to a magnetic-field effect, then it may be taken as definite evidence that the reaction proceeds *via* a radical-pair intermediate.[3] As has been described in the Experimental section, the photochemical rearrangement of isoquinoline *N*-oxide **1** to the lactam **2** (Process I) showed an unexpected magnetic-field effect (Fig. 1), whereas the photoisomerization of 1-cyanoisoquinoline *N*-oxide **4** into the 1,3-oxazepine **5** (Process II) was not at all affected by an external magnetic field (Fig. 2). The results indicate unambiguously that Process I involves a field-sensitive radical pair as a reactive intermediate, while Process II does not. Hence, as will be described below, some modifications are required for the ion-pair mechanism of Process I.

Isoquinoline *N*-oxide molecule has two pairs of 2p non-bonding electrons on the oxygen atom of the N→O group; one of them is in conjugation with the π-electron system of the isoquinoline ring (πO:), while the other remains as a nonbonding pair (σO:). The photoelectron spectrum of this molecule shows the first band at 7.98 eV to be due to πO:,[21] indicating that the *N*-oxide cation radical is a π-radical with a radical center at the oxygen atom of the N→O group. Therefore, as is shown in Scheme 1, if an electron (πO:) is transferred from the excited singlet *N*-oxide (S_1) to the hydrogen-bonded ethanol to form the singlet hydrogen-bonded radical-ion-pair **2a** in a solvent cage, the following reactions will take place between the two radical ions constituting the pair; the *N*-oxide cation radical attributable to an odd π-electron on the oxygen atom will abstract hydrogen from the hydrogen-bonded ethanol anion radical, resulting in the formation of the hydrogen-bonded ion-pair **2b** responsible for Process I. This idea makes it possible to explain clearly not only the formation of the ion-pair **2b** which is not explicable by the ion-pair mechanism, but also the observed magnetic field effect. Hereafter, the above reaction mechanism postulated the initial formation of hydrogen-bonded radical ion pair **2a** will be termed the radical ion pair mechanism of Process I.

Magnetic-field Effect. An external magnetic-field effect can generally be expected for chemical reactions proceeding *via* radical-pair intermediates in solution, becuase an external magnetic field may influence the rate of the intersystem crossing of a radical pair.[3]



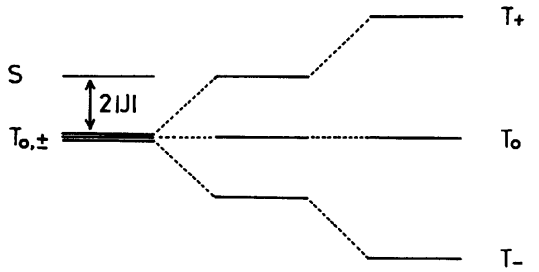
Scheme 2.

Scheme 2 shows the case of a compound M in solution absorbing light and so being exctied into the S_1 state, thus forming a singlet radical-pair intermediate. The radical pair, because of its singlet character, mostly undergoes recombination or disproportionation within a solvent cage to give a cage product. The transition of the singlet radical pair to the triplet, however, results in the formation of an escape product. If the intersystem crossing undergoes an external magnetic perturbation, the chemical yield of the cage product or the escape product can be expected to show a magnetic-field dependence.

If the exchange interaction between the unpaired electrons in a radical pair is disregarded, the following two mechanisms are currently accepted for the magnetic-field effect upon the rate of the intersystem crossing of a radical pair:[3] (i) The external magnetic field causes the intersystem crossing of a radical pair by virtue of the different *g*-values of the component radicals; therefore, the chemical yield of the cage product (or of the escape product) decreases (or increases) quadratically with an increase in the field strength (the magnetic-field effect due to the Δg mechanism). (ii) The external magnetic field results in a reduction in the number of effective working channels for the hyperfine-induced intersystem crossing of a radical pair. As a result, the chemical yield of the cage product (or of the escape product) increases (or decreases) remarkably at a very low field (the magnetic-field effect due to the HFI mechanism).

The magnetic-field effect observed in the present photochemical system (Fig. 1) is quite different from the above two cases; it can not be interpreted in terms of either the Δg or the HFI mechanism. As is shown in Scheme 1, however, if we assume the singlet hydrogen-bonded radical-ion pair **2a** as a reactive intermediate of Process I, the observed magnetic-field effect can be reasonably explained as follows:

The exchange interaction between the unpaired electrons in the radical ion-pair **2a** may be considered to be much greater than the electron-nuclear hyperfine energy because the radical centers are in close proximity as a result of hydrogen-bonding interaction between the two radical ions; as is shown in Scheme 3,



Scheme 3.

the singlet (S) and triplet ($T_{0,\pm}$) levels of the pair are nondegenerate, having an energy gap of $2|J|$, where J denotes the electron-exchange integral. Therefore, the singlet-triplet mixing due to hyperfine interaction does not occur in the zero field. However, the triplet level is resolved into three sublevels, T_0, T_+, and T_-, by the application of the magnetic field to this system; the T_+ level approaches the S level as the field strength increases. Consequently, the S–T_+ mixing becomes possible at the field strength in which the S–T_+ energy gap is of the order of the hyperfine interaction. The S–T_+ mixing is maximal at the magnetic field in which the singlet level (S) is in resonance with the T_+ level. A further increase in the field strength results in an increase in the separation between the levels of S and T_+; consequently, the mixing of S and T_+ decreases steeply. Thus, the chemical yield of lactam **2** comes to show a minimum at the resonance magnetic field (*ca.* 1T) in which the intersystem crossing of the singlet radical ion-pair **2a** is most favorable.

As has been mentioned above, the new type of magnetic-field effect observed in the present investigation was proved to be explicitly accounted for by an electron-nuclear hyperfine interaction mechanism including electron-exchange interaction in the singlet hydrogen-bonded radical ion-pair **2a** assumed as a reactive intermediate. Hereafter, this will be referred to as the "magnetic-field effect due to the HFI-J mechanism." Needless to say, if the electron-exchange interaction in a pair is neglected (J=0), the magnetic-field effect due to the HFI or Δg mechanism can be expected in lieu of the HFI-J magnetic-field effect.

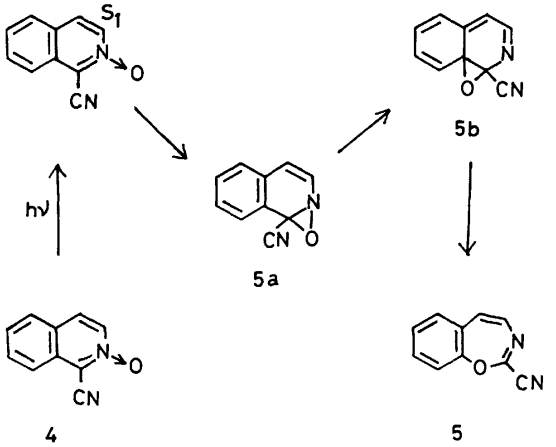
The magnetic-field effect due to the HFI-J mechanism is thought to be particularly interesting and important from the viewpoint of mechanistic photochemistry, because it can be expected when a photoexcited molecule in solution undergoes chemical interaction with the hydrogen-bonded species to form an appropriate hydrogen-bonded radical pair or radical ion-pair intermediate in a solvent cage.[22]

Reaction Mechanism. An examination of the photochemical magnetic-field effect of isoquinoline *N*-oxide **1** or 1-cyanoisoquinoline *N*-oxide **4** in ethanol leads to the conclusion that Process I (*N*-oxide→lactam) is initiated by the formation of the singlet hydrogen-bonded radical ion-pair **2a** from

the S_1 state, while Process II (*N*-oxide→oxazepine) proceeds through the formation of oxaziridine **3a** (or **5a**) from the S_1 state, as is shown in Schemes 1 and 4.

In the case of isoquinoline *N*-oxide **1** (Scheme 1), the primary photochemical step is an electron (πO:) transfer from the excited singlet *N*-oxide (S_1) to the hydrogen-bonded ethanol to produce the singlet hydrogen-bonded radical ion-pair **2a** which is sensitive to the external magnetic field. Subsequently, hydrogen transfer takes place from the ethanol anion radical to the hydrogen-bonded *N*-oxide cation radical, the hydrogen-bonded ion-pair **2b** responsible for Process I being produced. The oxaziridine intermediate **3a** which is involved in Process II is also formed from the S_1 state in competition with the formation of the radical ion-pair **2a**. The conversion of the ion-pair **2b** to the lactam **2** may be supposed to follow the carbonium-ion rearrangement mechanism proposed by Kaneko,[23] because the *N*-oxide bearing a CN or CF_3 group at the carbon atom adjacent to the ring nitrogen does not undergo Process I. Kaneko has assumed the oxaziridine **3a** to be a precursor of the ion-pair **2c** and proposed the oxaziridine mechanism (**3a**→**2c**→**2d**→**2**) for Process I.[23] However, it is now clear, from the observation of HFI-J magnetic-field effect, that Process I does not involve the oxaziridine intermediate **3a**, but proceeds according to the radical ion-pair mechanism (**2a**→**2b**→**2c**→**2d**→**2**). This mechanism has been also supported by the examination of the quenching of the photochemical isomerization of 4-methylquinoline *N*-oxide by inorganic anions.[19]

In the case of 1-cyanoisoquinoline *N*-oxide **4** (Scheme 4), the formation of the oxaziridine intermediate **5a** occurs first from the S_1 state, followed by isomerization into the oxazepine **5** (Process II). Unlike the case of isoquinoline *N*-oxide **1**, no electron transfer occurs between the excited singlet *N*-oxide (S_1) and the solvent molecule; therefore, Process I does not occur. This is probably because the strong electron-withdrawing CN group at the 1-position of an isoquinoline nucleus may cause a lowering of the hydrogen-bonding ability of the oxygen atom of the N→O group and an increase in the ionization potential; also, it may render the carbonium-ion rearrangement unfeasible, even though a radical ion-pair responsible for Process I is formed. The intervention of an oxaziridine in Process II has been demonstrated, in the case of 2-cyanoquinoline *N*-oxide, from the quenching studies using inorganic anions.[19]



Scheme 4.

The author wishes to thank Professor Saburo Nagakura of the Institute for Molecular Science for his kind discussion.

The effect of such inorganic anions as $SeCN^-$, I^-, SCN^-, and Br^- upon the photochemical isomerization of 4-methylquinoline *N*-oxide into the lactam (Process I) or of 2-cyanoquinoline *N*-oxide into the oxazepine (Process II) in aqueous ethanol was examined. Both Processes, I and II, were quenched by the addition of inorganic anions, resulting in the formation of a deoxygenation product; the quenching was more pronounced in the order of the redox potential of these anions. Even more noticeable was the fact that the irradiation of 2-cyanoquinoline *N*-oxide (Process II) in the presence of I^- brought about the liberation of iodine, while in the case of 4-methylquinoline *N*-oxide (Process I) no such iodine liberation was observed. The lifetimes of the transient intermediates responsible for the quenching were estimated, from the Stern-Volmer quenching constant, to be *ca.* 1.4 ns in the case of Process I and *ca.* 370 ns in the case of Process II; these values correspond to the lifetime of the S_1 state and the oxaziridine respectively. The quenching studies by inorganic anions led to the conclusion that Process II proceeds *via* the oxaziridine intermediate, while Process I does not involve such an intermediate.

The electric conductivities of aqueous solutions of the diastereoisomeric salts, Δ(−)$_{589}$-*cis*-[Co(NO$_2$)$_2$(en)$_2$]Δ(+)$_{589}$-[Co(mal)$_2$(en)] and Λ(+)$_{589}$-*cis*-[Co(NO$_2$)$_2$(en)$_2$]Δ(+)$_{589}$-[Co(mal)$_2$(en)](en=ethylenediamine and mal=malonate ion), have been measured at several temperatures from 15 to 35 °C. From the analysis of the conductivity data using the Pitts equation, it was found that the Δ- or Λ-*cis*-[Co(NO$_2$)$_2$(en)$_2$]$^+$ and Δ-[Co(mal)$_2$(en)]$^-$ ions are appreciably associated in spite of the large monovalent ions and that the ion association is almost nonstereoselective and is endothermic in contrast to the exothermic ion association between Δ- or Λ-*cis*-[Co(NO$_2$)$_2$(en)$_2$]$^+$ and Δ-[Co(edta)]$^-$ (edta=ethylenediaminetetraacetate ion). By considering the obtained values of thermodynamic parameters of ion association and the significantly large Stokes radius of Δ-[Co(mal)$_2$(en)]$^-$ compared to the effective radius estimated from its partial molar volume, this complex anion was presumed to have two hydration water molecules and to release one of them by associating with the complex cations. Possible short-range interactions between the complex ions were also discussed by considering the structures of the complex ions and the chemical properties of the ligands.

In a previous conductivity study[1] of the diastereoisomeric salts, Δ(−)$_{589}$-*cis*-[Co(NO$_2$)$_2$(en)$_2$]Δ(+)$_{546}$-[Co(edta)] and Λ(+)$_{589}$-*cis*-[Co(NO$_2$)$_2$(en)$_2$]Δ(+)$_{546}$-[Co(edta)], we have found that the Δ- or Λ-*cis*-[Co(NO$_2$)$_2$(en)$_2$]$^+$ and Δ-[Co(edta)]$^-$ ions are appreciably associated in water in spite of being large and monovalent. The ion association, though not stereoselective, was an exothermic reaction entirely unable to be explained by the usual electrostatic theories of ion association,[2-4] suggesting the presence of short-range interactions which are operative on the surface of the complex ions and which are almost independent of the dielectric constant of the medium. Such interactions are considered to be of interest in connection with the problem of the stereoselectivity in the ion association of optically active complex ions, and of importance for the elucidation of the ion-ion and ion-solvent interactions in solutions containing complex ions and also for that of the mechanisms of various reactions of dissolved complex ions involving ion-pair formation in the reaction process.

In the present study, in order to accumulate information about the short-range interactions and make this nature clearer, the electric conductivities of aqueous solutions of the diastereoisomeric salts, Δ(−)$_{589}$-*cis*-[Co(NO$_2$)$_2$(en)$_2$]Δ(+)$_{589}$-[Co(mal)$_2$(en)] and Λ(+)$_{589}$-*cis*-[Co(NO$_2$)$_2$(en)$_2$]Δ(+)$_{589}$-[Co(mal)$_2$(en)], were measured at several temperatures from 15 to 35 °C and the ion association between Δ- or Λ-*cis*-[Co(NO$_2$)$_2$(en)$_2$]$^+$ and Δ-[Co(mal)$_2$(en)]$^-$ was examined. The reasons for the use of these diastereoisomeric salts are as given below.

We can expect to obtain exact thermodynamic information about the short-range interactions, if present, between the complex ions, because such a system containing only monovalent complex ions of large size can be treated almost without considering the Bjerrum-type ion association[2-4] and the usual Born-type hydration[5a] of ions. The absolute configuration and structure of Δ(−)$_{589}$-*cis*-[Co(NO$_2$)$_2$(en)$_2$]Δ(+)$_{589}$-[Co(mal)$_2$(en)], less soluble in water than the other diastereoisomeric salt, have been determined by an X-ray diffraction study.[6] This can help the stereochemical consideration of the ion pairs formed. Further, it is of interest what differences are present between the ion associations of Δ- or Λ-*cis*-[Co(NO$_2$)$_2$(en)$_2$]$^+$ with Δ-[Co(mal)$_2$(en)]$^-$ and Δ-[Co(edta)]$^-$, since the Δ-[Co(mal)$_2$(en)]$^-$ ion is similar to Δ-[Co(edta)]$^-$ in having four carboxyl groups and two coordinated nitrogen atoms.

Experimental

Materials. *Δ- and Λ-cis-[Co(NO$_2$)$_2$(en)$_2$]X(X=Br and I)*: These salts were prepared in the manner described previously.[1] The [α]$_{589}$ values of Δ- and Λ-*cis*-[Co(NO$_2$)$_2$(en)$_2$]Br were −44°±1° and +44°±1° respectively, while those of the iodides of Δ- and Λ-complexes were −38°±1° and +39°±1° respectively.

KΔ-[Co(mal)$_2$(en)]·2H$_2$O: This salt was prepared following the method of Dwyer *et al.*[7] The recrystallization was effected from water by the addition of ethanol and repeated until a constant value of the optical rotation was reached. After air-drying at room temperature, the [α]$_{589}$ and [α]$_{546}$ values of the salt were +1530°±30° and +1260°±30° respectively.

Δ-cis-[Co(NO$_2$)$_2$(en)$_2$]Δ-[Co(mal)$_2$(en)] and Λ-cis-[Co(NO$_2$)$_2$(en)$_2$]Δ-[Co(mal)$_2$(en)]: These diastereoisomeric salts were prepared as follows. The Δ- or Λ-*cis*-[Co(NO$_2$)$_2$(en)$_2$]I salt was transformed to the acetate by shaking silver acetate in warm water (*ca.* 40°C). After the removal of the silver iodide, an equimolar amount of KΔ-[Co(mal)$_2$(en)]·2H$_2$O was dissolved in the filtrate and ethanol was added to precipitate the diastereoisomeric salt. The recrystallization was carried out several times from water by the addition of ethanol. After air-drying, both salts were ascertained to be anhydrous by the use of an Abderhalden dryer and by the Kahl-Fischer method. The [α]$_{589}$ and [α]$_{546}$ values of Δ-*cis*-[Co-

$(NO_2)_2(en)_2]\Delta$-[Co(mal)$_2$(en)] were +1010°±20° and +780° ±20° respectively. The $[\alpha]_{589}$ and $[\alpha]_{546}$ values of Λ-*cis*-[Co-$(NO_2)_2(en)_2]\Delta$-[Co(mal)$_2$(en)] were +1060°±20° and +900° ±20° respectively.

ORD and Electronic Absorption Spectra of Diastereoisomeric Salts in Dilute Aqueous Solution. Measurements of the ORD and the absorption spectra were carried out with a JASCO ORD/UV-5 spectropolarimeter and a Hitachi 139 spectrophotometer. The molar rotation of Δ-*cis*-[Co$(NO_2)_2$-$(en)_2]\Delta$-[Co(mal)$_2$(en)] in water was identical with the sum of those of Δ-*cis*-[Co$(NO_2)_2$(en)$_2$]Br and KΔ-[Co(mal)$_2$(en)] at any wavelength from about 370 to 700 nm, within the limits of experimental error. A similar additivity was observed for Λ-*cis*-[Co$(NO_2)_2(en)_2]\Delta$-[Co(mal)$_2$(en)]. The absorption spectra of both diastereoisomeric salts in the same wavelength region as above agreed with each other and with the sum of those of *cis*-[Co$(NO_2)_2$(en)$_2$]Br and K[Co(mal)$_2$(en)], within the limits of experimental error.

Conductivity Measurements. Conductivity measurements were made at 15.0, 20.0, 25.0, 30.0, and 35.0°C using a Fuso 360 linear-bridge conductometer in the manner described previously.[1] The cell constant of the cell used in the present study was 0.11400 cm^{-1}.

The observed conductivity data were corrected for the conductivity of water, lower than 2.1×10^{-7} S cm^{-1} at 25°C, and for the minor conductivity change due to the aquation of *cis*-[Co$(NO_2)_2$(en)$_2]^+$.[8] Each solution was completely measured within about 3.5 h after the preparation of the solution. Throughout the measurements, the solution was protected from light. The reproducibility of the conductivity measurements was about ±0.1%. The precision of the temperature measurements was ±0.003°C.

Densities and Concentrations of Solutions. The solutions used for the conductivity measurements were made up by weight. The concentration, c, at each temperature was calculated from the molality, m, by the use of the density data. The densities, d, at (25.00±0.02)°C were measured for all solutions by using an Ostwald-type pycnometer with capacity of 50 cm^3. Approximately linear relationships were found between m and d (25°C):

for Δ-*cis*-[Co$(NO_2)_2(en)_2]\Delta$-[Co(mal)$_2$(en)],

$$d(25°\text{ C})/\text{g cm}^{-3} = (0.99703\pm0.00002) + (0.284\pm0.003)m, \quad (1)$$

and for Λ-*cis*-[Co$(NO_2)_2(en)_2]\Delta$-[Co(mal)$_2$(en)],

$$d(25°\text{ C})/\text{g cm}^{-3} = (0.99704\pm0.00002) + (0.283\pm0.003)m. \quad (2)$$

The densities at the other temperature, t, were measured only for the most concentrated solution. The observed $d(t)$ values agreed, within the limits of experimental error, with those calculated by assuming:

$$d(t)/\text{g cm}^{-3} = d(H_2O, t) + pm, \quad (3)$$

where $d(H_2O, t)$ is the density of water and where p is identical with the coefficient of m given in Eq. 1 or 2. The $d(t)$ values of the other solutions were estimated by using Eq. 3.

The concentrations of solutions at the temperature, t, could be reproduced within the limits of experimental error by the use of the following equation:

$$c(t) = c(25°\text{ C}) \times f, \quad (4)$$

where $c(t)$ and $c(25°C)$ are concentrations at t and 25°C respectively and where f is equal to the ratio of $d(H_2O, t)/d(H_2O, 25°C)$: $f=1.00206$, 1.00116, 0.99860, and 0.99698 for $t=15$, 20, 30, and 35°C respectively.[9]

Results and Discussion

Molar Conductivities of Diastereoisomeric Salts. The observed values of the molar conductivity, Λ(obsd), are summarized in Tables 1 and 2 and are plotted against $\sqrt{c}$ for each salt in Fig. 1. No appreciable difference in the plot is found between the two diastereoisomeric salts at any temperature. This relation is similar to that found between Δ-*cis*-[Co$(NO_2)_2(en)_2]\Delta$-[Co(edta)] and Λ-*cis*-[Co$(NO_2)_2$(en)$_2]\Delta$-[Co(edta)].[1]

Analysis of Conductivity Data. The conductivity data were analyzed by assuming an ion association between Δ- or Λ- *cis*-[Co$(NO_2)_2$(en)$_2]^+$ and Δ-[Co(mal)$_2$-(en)]$^-$. The analysis was made in terms of the Pitts conductivity equation,[10] modified by considering the obstruction effect in the manner described previously.[1,11]

The ion-association constant, K, and the limiting molar conductivity, Λ^∞, were calculated by the least-squares procedure minimizing $\sum[\Lambda(\text{obsd})-\Lambda(\text{calcd})]^2$. The values of the closest distance of approach of the ions, a, involved in the theoretical equations of conductivity and activity coefficient were estimated by considering the effective ionic radii of the dissolved complex ions to be reported in the following section.

Effective Ionic Radii of Complex Ions. The partial molar volume of a salt at an infinite dilution, V^∞(salt), can be estimated to be 176±2 $cm^3\,mol^{-1}$ for K[Co-(mal)$_2$(en)] according to the conventional manner[12] from d (0.008745 mol dm^{-3}, 25°C)=0.99868 g cm^{-3}. The partial molar volume, V^∞(ion), for [Co(mal)$_2$(en)]$^-$ is, therefore, evaluated to be 172±2 $cm^3\,mol^{-1}$, taking V^∞-(K^+, 25°C)=3.6 $cm^3\,mol^{-1}$.[12,13] By substituting the obtained value for V^∞(ion) into Glueckauf's expression of the partial molar volume of an ion,[1,12,14] the ionic radius, r, corresponding to the crystallographic radius, can be estimated to be 3.5$_9$ Å for [Co(mal)$_2$(en)]$^-$ on the assumption that the shape of the complex ion is spherical.

The A^∞ values of Δ-*cis*-[Co$(NO_2)_2(en)_2]\Delta$-[Co(mal)$_2$-(en)] and Λ-*cis*-[Co$(NO_2)_2(en)_2]\Delta$-[Co(mal)$_2$(en)] at 25°C were determined to be 50.52±0.04 and 50.55± 0.02 S cm^2mol^{-1} respectively, from an analysis assuming that a=7.0 Å. Both values of A^∞, in accord with each other within the limits of experimental error, were almost independent of the assumed value of a. The limiting molar conductivity, A^∞(ion), for [Co-(mal)$_2$(en)]$^-$ can be calculated to be 23.7±0.1 S cm^2 mol^{-1} by using A^∞(ion)=26.8±0.1 S cm^2mol^{-1} for *cis*-[Co$(NO_2)_2$(en)$_2]^+$.[1] The Stokes radius, r_s, is thus obtained to be 3.8$_9$ Å for [Co(mal)$_2$(en)]$^-$.

The values of r and r_s for *cis*-[Co$(NO_2)_2$(en)$_2]^+$ and [Co(edta)]$^-$ were as follows: r=3.3$_7$ Å and r_s=3.4$_4$ Å for the former ion and r=3.6$_3$ Å and r_s=3.5$_2$ Å for the latter

ion.[1] It is obvious that the r and r_s values are close to each other for these complex ions. On the other hand, a significant difference is found between the r and r_s values for $[Co(mal)_2(en)]^-$. Considering the closeness between the r values of $[Co(mal)_2(en)]^-$ and $[Co(edta)]^-$, the r_s value of the former complex ion seems to be significantly large. This may imply that the $[Co(mal)_2(en)]^-$ ion is hydrated. That is, the Stokes radius of $[Co(mal)_2(en)]^-$ can be well explained by assuming that this complex ion has two hydration water molecules, because an r value of 3.85 Å close to that of 3.89 Å for r_s, can be obtained for the hydrated complex ion from its partial molar volume, $V^\infty([Co(mal)_2(en)]^- \cdot 2H_2O)$=208±2 cm^3 mol^{-1}, where the molar volume of the hydration water molecule was assumed to be 18.1 cm^3 mol^{-1}, equal to the partial molar volume of water.[9] Further discussion about the hydration of $[Co(mal)_2(en)]^-$ will be made later.[15]

In a previous study,[1] the value of a between *cis*-$[Co(NO_2)_2(en)_2]^+$ and $[Co(edta)]^-$ was taken to be 7.0 Å, equal to the sum of the r or r_s values of the complex ions. The sums of the ionic radii of *cis*-$[Co(NO_2)_2(en)_2]^+$ and $[Co(mal)_2(en)]^-$ become 7.0 Å with r and 7.3 Å with r_s. The results obtained by assuming both a=7.0 Å and a=7.3 Å will be discussed below.

Ion Association. In Table 3, the ion-association constants (K) and the limiting molar conductivities (Λ^∞) obtained by assuming a=7.0 and 7.3 Å are summarized, together with the standard deviations, σ.[16] The values of Λ^∞ are almost the same between a=7.0 and 7.3 Å at a given temperature, while those of K are

a) Cited from Ref. 1.

slightly changed, depending on the assumed value of a, but still within the limits of experimental error.

No appreciable difference in the obtained K values is found between *Δ-cis*-[Co(NO₂)₂(en)₂]*Δ*-[Co(mal)₂(en)] and *Λ-cis*-[Co(NO₂)₂(en)₂]*Δ*-[Co(mal)₂(en)] at any temperature, considering the experimental error. A similar relation has also been obtained between *Δ-cis*-[Co(NO₂)₂(en)₂]*Δ*-[Co(edta)] and *Λ-cis*-[Co(NO₂)₂(en)₂]*Δ*-[Co(edta)]. The ion-association constants of these diastereoisomeric salts were as follows: K/dm³ mol⁻¹= 12.9±0.4 (15 °C), 11.9±0.6 (25 °C), and 11.1±0.8 (35 °C) for the former salt and 13.2±0.7 (15 °C), 12.0±0.5 (25 °C), and 11.4±0.5 (35 °C) for the latter.[1)]

The K values obtained in the present study are about half of those for the ion association between *cis*-[Co(NO₂)₂(en)₂]⁺ and [Co(edta)]⁻. However, they are considerably larger than the previously reported theoretical ion-association constants: K (25 °C, a=7.0 Å)/dm³ mol⁻¹=0 (by Bjerrum[2)]), 2.41 (by Fuoss[3)]), and 0.24 (by Ebeling[17)] and Yokoyama-Yamatera[4)]).[1)] This implies that interactions other than the simple electrostatic one are also present between *cis*-[Co(NO₂)₂(en)₂]⁺ and [Co(mal)₂(en)]⁻.

The ion association of *cis*-[Co(NO₂)₂(en)₂]⁺ with [Co(mal)₂(en)]⁻ is endothermic, since the K value increases with an increase in the temperature, as is shown in Table 3. This temperature dependence is the opposite of that observed for the ion association of this complex cation with [Co(edta)]⁻,[1)] but it is seemingly similar to that observed for such 2:2 electrolytes as MgSO₄[18)] or that predicted from the ion-association theories.[1,3,4,17)]

The standard enthalpy and entropy of ion association, $\Delta H°$ and $\Delta S°$, were estimated from the temperature dependence of the ion-association constant. The values of $\Delta H°$, $\Delta S°$, and the standard Gibbs free energy, $\Delta G°$, at 25 °C are shown in Table 4 with a=7.0 Å; the $\Delta H°$ and $\Delta S°$ values obtained with a=7.3 Å were the same as those given in Table 4 within 1%. Slight differences in the $\Delta H°$ and $\Delta S°$ values might seem to be present between *Δ-cis*-[Co(NO₂)₂(en)₂]*Δ*-[Co(mal)₂(en)] and *Λ-cis*-[Co(NO₂)₂(en)₂]*Δ*-[Co(mal)₂(en)], but the situation is ambiguous because of the experimental error.

In Table 4, the $\Delta H°$ and $\Delta S°$ values are also shown for the ion association between *Δ-* or *Λ-cis*-[Co(NO₂)₂(en)₂]⁺ and *Δ*-[Co(edta)]⁻. In the previous paper,[1)] by considering the small $\Delta S°$ value to be close to zero and the $\Delta H°$ value to be negative, these ion associations were interpreted as being caused by short-range interactions between the complex ions, almost independent of the dielectric constant of the medium, and to be performed without any release of hydration water molecules. The last argument was consistent with the presumption, based on the likeness between the r and r_s values, that the ions of both *cis*-[Co(NO₂)₂(en)₂]⁺ and [Co(edta)]⁻ are not appreciably hydrated.

The $\Delta H°$ and $\Delta S°$ values for the ion association between *cis*-[Co(NO₂)₂(en)₂]⁺ and [Co(mal)₂(en)]⁻ are in contrast with those between this complex cation and [Co(edta)]⁻, as is to be expected from the temperature dependence of the ion-association constant. The

present results can be explained well by assuming that the $[Co(mal)_2(en)]^-$ ion is hydrated. That is, the large positive $\Delta S°$ value implies that the ion association is accomplished by the release of hydration water molecules of the complex anion. The positive $\Delta H°$ value is considered to result from the energy requirement for the release of hydration water molecules. The assumption of the hydration of $[Co(mal)_2(en)]^-$ is consistent with the presumption from its Stokes radius described in the preceding section.

The most effective short-range interaction of *cis*-$[Co(NO_2)_2(en)_2]^+$ with $[Co(edta)]^-$ was considered to be hydrogen-bonding between the amino group in the complex cation and the carboxyl group in the complex anion.[1] The ion association of *cis*-$[Co(NO_2)_2(en)_2]^+$ with $[Co(mal)_2(en)]^-$ may also be caused mainly by the hydrogen-bonding between the above two groups as well as by that between the nitro ion in the complex cation and the amino group in the complex anion. The possibility of the presence of the former hydrogen-bonding between the complex cation and anion in the *Δ-cis*-$[Co(NO_2)_2(en)_2]$*Δ*-$[Co(mal)_2(en)]$ crystal has been revealed by an X-ray diffraction study.[6]

The hydration of $[Co(mal)_2(en)]^-$ is thought to be due to specific interactions of the complex ion with water molecules, since the usual Born-type hydration[5a] of such a large monovalent complex ion is considered to be very weak. The most effective interaction is probably also hydrogen-bonding. Both the carboxyl and amino groups of $[Co(mal)_2(en)]^-$ can contribute to the hydrogen bonding with water molecules. Especially, the amino groups may play an important part, together with the carboxyl groups, considering the difference in the degree of hydration between $[Co(mal)_2(en)]^-$ and $[Co(edta)]^-$. The two hydration water molecules of the former anion, estimated from the deviation between the r and r_s values, may be related to the fact that this complex anion has two amino groups. From the structural point of view, two spaces favorable for accepting such water molecules exist on the surface of $[Co(mal)_2(en)]^-$. Each space is adjacent to an amino group of the ethylenediamine and two coordinated oxygen atoms of different malonate ions, and is located on the side opposite another one across the central cobalt(III) ion.

The entropies of ion association between *cis*-$[Co(NO_2)_2(en)_2]^+$ and $[Co(mal)_2(en)]^-$ were more positive by about 20—30 $J\,mol^{-1}K^{-1}$ than those between this complex cation and $[Co(edta)]^-$, as is shown in Table 4. Assuming that the difference in the entropy is mainly attributable to that in the number of hydration water molecules released on the ion association, and that the entropy of hydration is to be regarded as -25 $J\,mol^{-1}K^{-1}$, according to Ulich's treatment,[19] the difference in the number of released hydration water molecules can be estimated to be about one. Since the *cis*-$[Co(NO_2)_2(en)_2]^+$ and $[Co(edta)]^-$ ions probably have no hydration water molecule, only one of the two hydration water molecules of $[Co(mal)_2(en)]^-$ comes to be released on the ion association of this complex anion with *cis*-$[Co(NO_2)_2(en)_2]^+$. This is conceivable, because it is geometrically difficult for the associated *cis*-$[Co(NO_2)_2(en)_2]^+$ ion to occupy simultaneously the two spaces situated apart from each other on the surface of $[Co(mal)_2(en)]^-$, described above, by removing the two hydration water molecules from these spaces. In other words, this implies that the occupation of one of the two spaces by *cis*-$[Co(NO_2)_2(en)_2]^+$ is required for the short-range interactions between these complex ions.

The stereoselectivity in the formation of the diastereoisomeric ion pairs, *Δ-cis*-$[Co(NO_2)_2(en)_2]^+$*Δ*-$[Co(mal)_2(en)]^-$ and *Λ-cis*-$[Co(NO_2)_2(en)_2]^+$*Δ*-$[Co(mal)_2(en)]^-$, seemed to be absent or slight, if present, with respect to the thermodynamic parameters of ion association given in Tables 3 and 4. This implies that the ease of approaching the complex cation and anion to interact and the strength of the interactions are not so very different between the two diastereoisomeric ion pairs.

15) The information about the interaction of $[Co(mal)_2(en)]^-$ with water can also be obtained from the temperature dependence of the Walden product, $\Lambda^\infty(ion)\eta_0$, where η_0 is the viscosity of the solvent. The values of $\Lambda^\infty(ion)\eta_0/10^{-5}$ S Ns mol^{-1} [21] for *cis*-$[Co(NO_2)_2(en)_2][Co(mal)_2(en)]$ can be estimated to be 0.450, 0.450, 0.450, 0.449, and 0.448 at 15, 20, 25, 30, and 35 °C respectively, from the Λ^∞(salt) values given in Table 3. Hence, the temperature coefficient of the Walden product at 25 °C, $d\{\Lambda^\infty(salt)\eta_0\}/dT/10^{-5}$ S Ns mol^{-1} K^{-1}, becomes -1×10^{-4}, which is larger than the value of -3×10^{-4} obtained for *cis*-$[Co(NO_2)_2(en)_2][Co(edta)]$.[1] This means that the temperature coefficient for $[Co(mal)_2(en)]^-$ is more positive by 2×10^{-4} than that for $[Co(edta)]^-$. Considering that the temperature coefficient of the Walden product usually becomes more positive with an increase in the strength of the hydration, as is seen in the case of alkali metal or halide ions,[5b,22] the hydration of $[Co(mal)_2(en)]^-$ seems more likely than that of $[Co(edta)]^-$.
16) Almost the same values of K and Λ^∞ as those given in Table 3 were obtained from the analysis using the Fuoss-Hsia equation.[20]

Decomposition of Crystalline Potassium Hexacyanoferrate(II) Trihydrate by Incident Energetic Argon Ions†

Shin-ichi OHNO* and Katsutoshi FURUKAWA
Department of Chemistry, Japan Atomic Energy Research Institute, Tokai-mura, Ibaraki 319-11
(Received November 9, 1984)

Ar^+ ions in the energy range of 0.4 to 2 MeV was found to induce a chemical reaction in solid potassium hexacyanoferrate(II) trihydrate giving rise to Fe^{3+}-ion clusters which have been evidenced by EPR observations. γ-Irradiations at high doses ($>10^9$ rad) followed by heating (>150 °C) were found to induce the same reaction. Irradiations with γ-rays, protons, or low-energy (<40 keV) Ar^+ ions alone did not induce this reaction, nor did a thermal activation. A possible mechanism for this reaction is discussed mainly from a qualitative point of view on the basis of experimental observations and results of atomic collision physics. It is concluded that the reaction is caused by a highly inelastic excitation of iron(II) in the complex which is accompanied with a simultaneous momentum transfer.

Radiation chemical reactions in matter due to energetic ion passage, and different from those due to γ-irradiations, are generally interpreted in terms of an LET (linear rate of energy transfer per unit length) effect.[1,2] An LET value itself for an energetic ion traversing a given medium increases with decreasing ion velocity and different LET radiations generally produce different spatial distributions of the initial products of radiolysis.[1,2]

On the other hand, recent results in atomic collision physics,[3-5] suggest that slow-moving particle collisions (in the energy range of 10 to 1000 keV) may result in such primary processes as inner shell or multiple excitations of an atom or molecule, which would involve an energy transfer per event much larger than outer-shell or single excitations. Thus, low-energy particle collisions may induce chemical reactions different from those induced by γ- and UV-irradiations. The importance of these highly inelastic processes in chemical or biological effectiveness was pointed out a long time ago,[6,7] and the processes themselves have been studied rather extensively[3-5] since then, but their chemical or biological consequences remain unexploited except for a few cases.[5,7,8] Atomic displacements in a collision cascade zone may also be important for possible chemical reactions in a material bombarded with energetic ions.[7]

In this paper we report that Ar^+ ions of a certain energy range induce a chemical reaction in solid cyanide complexes giving rise to Fe^{3+}-ion clusters, which have been evidenced by EPR observations. γ-Irradiations at doses higher than 10^9 rad (1 rad=10^{-2} J kg^{-1}) followed by heating (>150 °C) were found to induce the same reaction. Irradiations with γ-rays, protons, or helium ions alone did not induce this reaction, nor did a thermal activation. It seems that the reaction is caused through electronic excitations of the iron(II) in the complex which are accompanied by a simultaneous momentum transfer.

Experimental

Sample Preparation. Single crystals of potassium hexacyanoferrate(II) trihydrate (Koso Chemicals Co., Inc.) were grown from aqueous solutions. In some cases powders were pressed into disks of the diameter of 1 cm.

For comparison of the EPR spectra of the irradiated sample, some EPR spectra of solid solutions of aluminum oxide containing various amount of iron(III) were recorded. These solid solutions were prepared from aqueous solutions of $KAl(SO_4)_2 \cdot 12H_2O$ containing varing concentrations of iron(III) sulfate, reacted with NH_3+NH_4Cl to form precipitate, and then fired in a crucible for 20 min at 1000 °C.

Irradiations. The samples to be irradiated were mounted onto the sample holder by means of clamps or with the aid of adhesives and were irradiated at ambient temperatures in vacuum (*ca.* 10^{-5} Pa) with energetic ion beams or γ-rays.

i) Van de Graaf accelerator: Ar^+ ions in the energy range of 0.4 to 2 MeV were from a Van de Graaf accelerator equipped with PIG- and RF-type ion sources. Other ions like H^+, N^+, and O^+ were also used in the present study.

ii) Low-energy ion accelerator: Ions with lower energies were from a small accelerator[9] which has been constructed in our laboratory. The Ar^+ ions were extracted from a Duoplasma-type source operated at a pressure of 20 to 50 Pa and further accelerated to a desired energy (10—100 keV), focussed by an electrostatic lens system, and analyzed electromagnetically before impinging on the target.

iii) Beam intensity: The intensity of the beam was from 0.1 to 10 μA depending on the ion used, and typically ≈10^{12} ions s^{-1} through an aperture of 0.4 cm^2.

iv) γ-Irradiation: γ-Irradiations were performed with a 4.5 kCi ^{60}Co source in aerated conditions. Irradiations were also done in vacuum for analysis of the evolved gases.

EPR Measurement. EPR spectra of irradiated samples were obtained with a JP-1 X-band (9.5 GHz) spectrometer (Japan Electron Optics Co., Ltd.) with a modulation of 100 kHz using a polycrystalline DPPH as a magnetic field marker and Mn^{2+} in MgO as a reference for the magnetic field strength.

The signal intensity of the absorption was measured by using an approximation $h \cdot \Delta H_m^2$, where h is the peak-to-peak height and ΔH_m the peak-to-peak linewidth of the first derivative of the spectrum, respectively.

Secondary Ion Mass Spectrometry. Secondary ions emitted from the surface of the sample during ion bombardment were mass analyzed with a quadrupole mass filter (MSQ-300, Ulvac Co., Tokyo). Bombardment were performed through an aperture of 2 mmφ. Current densities were adjusted to 0.1 μA cm^{-2} for the convenience of getting relative yields of the emitted ions due to different kind of bombarding ions with

† Chemical Reactions Induced by Energetic Particles. I.

different energies.

Results

EPR Measurements. Potassium hexacyanoferrate(II) trihydrate, a low spin Fe(II) complex, is a diamagnetic compound and shows no EPR signals. On exposure to a beam of 1.8 MeV Ar^{2+} or 450 keV Ar^+ ion the bombarded (010) surface of a single crystal of the sample was decomposed to give EPR-absorption spectra. In Fig. 1 are shown some of the spectra thus obtained.

The signal intensities of the central absorption at $g=2.0$ as a function of irradiation time are shown in Fig. 2, together with the values of the linewidth. As may be seen in Fig. 2, the signal grows linearly with irradiation time up to 2—3 min and then levels off. The linewidths are also dependent on irradiation time, ranging from 140 at the beginning to 300 G in cases of 1.8 MeV Ar^{2+} bombardment, and from 100 to 150 G in cases of 450 keV Ar^+ bombardment.

It should be noted that (i) these spectra were obtained at 300 K and stable for several months at room temperature, (ii) the central absorption at $g=2.0$ with a large width has a Lorentzian shape, and (iii) the ratio of the signal intensities taken at 300 and 77 K, I_{300}/I_{77}, for this absorption is remarkably large compared with the corresponding ratio for the absorption lines of Mn^{2+} in MgO.

Irradiations of the sample with 40 or 20 keV Ar^+ ions at the beam intensity of 0.3 and 10 $\mu A\,cm^{-2}$ produced no remarkable EPR signal and, only after prolonged irradiations over 10 min at the intensity of 10 $\mu A\,cm^{-2}$, yielded the spectra which are shown in Fig. 3 (a) and (b). Besides the distinct line at the lower field, the central portion of the spectrum became gradually with irradiation time like that which would be obtained from the sample pre-heated at temperatures higher than 200 °C.

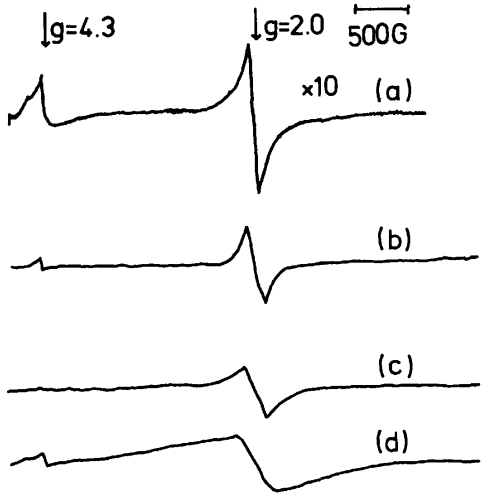

Fig. 1. EPR spectra of 1.8 MeV Ar^{2+}-irradiated (010) surface of $K_4[Fe(CN)_6]\cdot 3H_2O$. Current density: 0.75 $\mu A\,cm^{-2}$; irradiation time: (a) 10 s, (b) 1 min, (c) 5 min, and (d) 15 min.

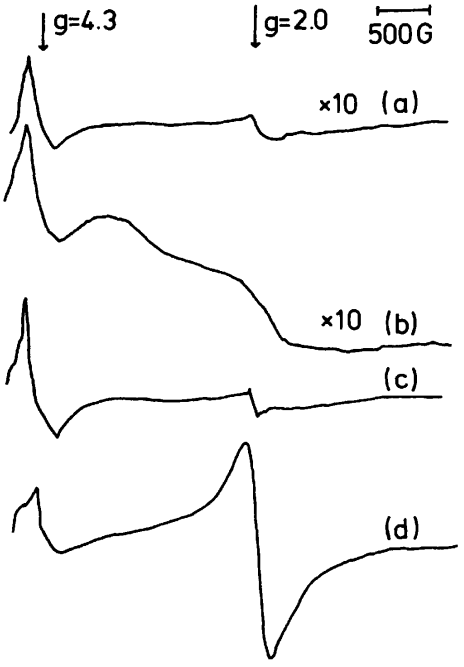

Fig. 3. EPR spectra of irradiated pellets of $K_4[Fe(CN)_6]\cdot 3H_2O$.
(a) 40 keV Ar^+-bombarded at 10 $\mu A\,cm^{-2}$ for 10 min,
(b) 40 keV Ar^+-bombarded at 10 $\mu A\,cm^{-2}$ for 30 min,
(c) 1.45 MeV H^+-bombarded at 1.5 $\mu A\,cm^{-2}$ for 10 min, (d) ^{60}Co-γ irradiated at 4×10^9 rad followed by heating at 150 °C for 30 min.

Irradiations with 0.4 or 1.6 MeV H^+ ions were also performed at the intensity of 0.6 $\mu A\,cm^{-2}$ with the results of Fig. 3 (c), similar to those obtained in the 20

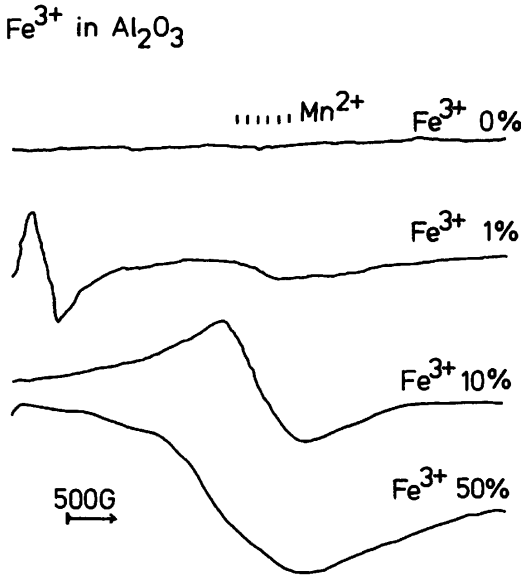

Fig. 4. EPR spectra of solid solutions of iron(III) oxide in aluminum oxide. The concentration of Fe^{3+} (*vs.* Al^{3+}): (a) 0, (b) 1, (c) 10, (d) 50%.

or 40 keV Ar^+-ion case.

γ-Irradiations at room temperature of the powder sample at doses below 10^9 rad were found to produce a line at g=4.3 alone and no other signals near at g=2.0. Further irradiations of the sample with γ-rays up to 10^{10} rad produced a single absorption line at g=2.06 of the linewidth ≈5 G at room temperature. This spectrum remained unchanged when treated at temperatures below 100 °C for an hour or so. When treated at higher temperatures, however, it disappeared to produce a strong absorption at g=2.0 with a large width as is shown in Fig. 3(d).

EPR spectra of solid solutions of aluminum oxide containing various amount of Fe^{3+} are shown in Fig. 4. Main features of the spectrum are as follows: (i) The sample of the low iron concentrations (≈1% with respect to Al) reveals an EPR absorption due to isolated Fe^{3+} ions at g=4.3, and (ii) at higher iron concentrations this spectrum is replaced by a Lorentzian signal which behaves as the absorption at g=2.0 in Fig. 1 and which has been attributed by Gesumundo *et al.*[10-12] to clusters of Fe^{3+} ions coupled by a strong exchange interaction.

Anisotropic Nature of the Line at g=2.0. The crystal type of potassium hexacyanoferrate(II) trihydrate is monoclinic, pseudo-tetragonal with lattice constants a=c=9.3 Å, b=16.8 Å, β=90°, four molecules in unit cell and space group C_{2h}^6.[13] The crystals grow in flat rectangular plates parallel to the ac plane, thus having well developed (010) faces. Energetic ions were bombarded onto a (010) plane. The EPR-absorption line at g=2.0 thus obtained was found to have an anisotropy of g factor. When the applied magnetic field is parallel to the direction of the incident beam, hereafter, denoted by b, g factor, $g(H//b)$, is around 1.98—1.99 and when the field is in the (010) plane, g factor, $g(H\perp b)$, is 2.02—2.03. The results are included in Table 1. We have verified that this anisotropic feature of the g factor is due to the direction of the Ar^+ beam and not to crystallographic anisotropy by having examined various factors which might be responsible for this anisotropy, *e.g.*, changes in the direction of the Ar^+ beam and the sizes and geometries of the sample to be bombarded, employment of the disk sample made from powders and as well as possible effects of the orientation of the specimen in the EPR cavity.

Table 1. EPR g factors and linewidths, and the relative yields of Fe^{3+} clusters from ion-bombarded $K_4[Fe(CN)_6]\cdot 3H_2O$.

Ion	Energy	$g(H//b)$[a]	$g(H\perp b)$[a]	ΔH_m	Relative yields
Ar^{2+}	1.8 MeV	1.98	2.03	140-300 G[b]	2.9
Ar^+	450 keV	1.99	2.02	100-150 G	0.23
Ar^+	20—40 keV	—	—	—	0
H^+	0.4—1.6 MeV	—	—	—	0

a) H=magnetic field; b=axis of irradiation beam. b) G=10^{-4} T.

It must be noted that the absorption at g=2.0 appearing in the sample which has been γ-irradiated at doses higher than 10^9 rad and then heated at 100—200 °C shows no anisotropy of g factor.

Secondary Ion Mass Spectrometry. When crystals of potassium hexacyanoferrate(II) trihydrate were bombarded with energetic ions, various secondary ions were emitted from the bombarded surface. Positive secondary ions were mainly composed of H^+, C^+, O^+, K^+, and Fe^+. Such ions as C^{2+}, N^+, K_2^+, and probably K_2O^+ and KFe^+ in small yields were also included. Negative secondary ions were H^-, C^-, CH^-, O^-, and a small amount of OH^-, C_2^-, and KO^-. Effects of the kinetic energy of bombarding particle were examined in the case of Ar^+ ion in the energy range of 10 keV to 1.8 MeV. The yields of emitted ions were nearly unchanged when the energy of the bombarding Ar^+ ion varied from 1.8 MeV down to 70 keV, though increased as the Ar^+-ion energy decreased to 10—30 keV. In Fig. 5 are shown the results of changing the bombarding ion while the bombarding energy and the beam intensity were maintained at 450 keV and 0.3 μA cm^{-2}, respectively.

Gas Analysis. The gas evolved by the irradiation of the complex with ^{60}Co-γ rays at the dose of 3×10^7 rad was submitted to mass analysis. While the main peaks in the mass spectrum were due to the water molecule, other peaks at mass number of 14 (N_2^{2+}), 28 (N_2^++CO^+), and 44 (CO_2^+) were remarkably significant, indicating that the ligand CN^- had been decomposed by γ-irradiation.

Discussion

When potassium hexacyanoferrate(II) trihydrate are subjected to ionizing radiations, *e.g.*, γ-rays or high-energy charged particles, many electronic processes will

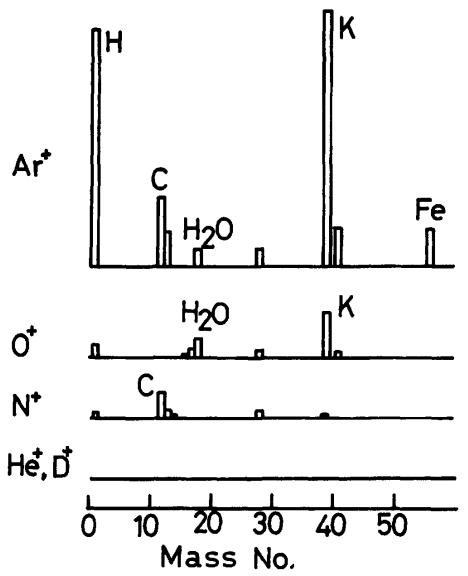

Fig. 5. Emitted positive ion spectrum from $K_4Fe(CN)_6]\cdot 3H_2O$ bombarded by various ions. Bombarding energy: 450 keV, Ion current density: 0.3 μA cm^{-2}.

occur. Among them only those processes which require a relatively small energy transfer per event have been studied from the viewpoint of chemical consequence of the initial process, the electronic transitions between d orbitals of Fe which induce the dissociation of the metal(Fe)–ligand(CN) bond and the electron transfer from metal(Fe) to ligand(CN) which results in oxidation of the Fe.[14] The oscillator strength for these electronic processes amounts only to 0.6.[15] The chemical consequence of the many other processes including inner shell and multiple excitations with a big energy transfer per event remain unstudied. In cases of the energetic particle penetrating a solid, the energy is also deposited into atomic motion, thus giving rise to a collision cascade or a thermal spike. A chemical effectiveness of the atomic motion is not clear for the present moment.[7,16,17]

Comparing the EPR spectra of Figs. 1 and 3 with those of Fig. 4, it is suggested that the spectrum at $g=4.3$ observed in the irradiated sample can be attributed to the isolated Fe^{3+} ions and that the strong absorption at $g=2.0$ to Fe^{3+}-ion clusters. The EPR spectrum of Fe^{3+}-ion clusters have been studied by many workers[10–12,18,19] and it is known that their linewidth depends on two features, the dipole–dipole interaction which produces a broadening of the line and the exchange interaction which produces a narrowing.[10,18]

γ-Irradiations. It is expected that a single and isolated electronic excitation of the complex will be annealed at the ambient temperature without any effect of radiations, since the electronic system relaxes quickly while the atoms are still at rest.[20] The results of analyzing the evolved gas, however, indicate that γ-irradiation *does* decompose the ligand or crystalline water of the sample. Two possible processes may be assumed: (i) The electron ejected in the ionization event and having kinetic energy larger than 6 eV may be captured by H_2O molecule to form H^- and OH.[21] (ii) Ionizations of inner-shell orbital followed by the Auger process and double ionization and/or excitations of cyanides would result in the atomic displacement by Coulomb explosion mechanism.[8,22,23] In either processes the decomposition of the ligands may occur. The *G* value of these processes may be estimated to be 0.1.[24]

Further irradiations at doses of 10^9 rad may produce isolated Fe^{3+} ions (≈50% ligand decomposed) the d-shell electrons of which are now free from being quenched by the presence of the ligand and are responsible for an EPR signal at $g=4.3$.

However, γ-irradiations up to 4×10^{10} rad did not produce an EPR signal due to Fe^{3+} clusters, indicating that the distances between Fe^{3+} ions in the γ-irradiated sample were too large to interact with each other by an exchange process. By heating at *e.g.* 150 °C, displacement of Fe^{3+} ions in the irradiated solid may occur to aproach each other within the distances smaller than 7 or 8 Å.[10] It is interesting that a *g* factor of an EPR absorption of the Fe^{3+} clusters thus formed is isotropic in contrast to an EPR signal of Fe^{3+} clusters formed by the Ar^+-ion bombardment.

Proton Irradiations. Most of the energy of fast protons (0.4—1.6 MeV) goes into electronic excitations, though energetic recoil atoms (C, N, and O) with kinetic energies of 10 keV or less may be created.[7] Thus, the action of a fast proton is essentially the same as that of γ-rays. The present results may be understood as such.

Ar^+-ion Bombardment. An Ar^+ ion in the energy range below *ca.* 40 keV loses most of its energy to create energetic recoil atoms (C, N, and O)[7] which in turn form collision cascades or thermal spikes. The results of Fig. 5 indicate that, among the various incident ions examined, the Ar^+ ion is most effective for the atomic displacement. Moreover, the further results showed that displacement by the energetic Ar^+ ion is most effective in the energy range of 10 to 30 keV.

By 40 keV Ar^+-ion bombardment of the complex, an EPR signal due to isolated Fe^{3+} ions alone has been observed. Further irradiations with 40 keV Ar^+ ions modified the spectrum to a one similar to that observed when the complex was heated at temperatures higher than 200 °C (Fig. 3; b).

At higher bombarding energies, the kinetic energy of Ar^+ ion goes more and more into electronic excitations.[7] Moreover, many collisions between Ar^+ ions and atoms in the solid will be highly inelastic due to inner-shell or multiple excitations which are pronounced in the energy range from 50 keV to 1 MeV.[3,5] As examples of this type of collisions, it should be mentioned: Collision of two Ar atoms (≈100 keV) produced a number of highly charged particles like Ar^{2+}, Ar^{4+}, and Ar^{5+}, apparently due to successive processes of autoionization and electron shake off after

the deposition of some 1000 eV energy into electron cloud of two Ar atoms.[25] Probably C, N, and O atoms, and especially Fe atoms will show the same effects in the case of Ar^+ bombardment at the energy higher than 100 keV. This could lead to a violent destruction of the complex, as has been discussed by Stöcklin in the case of biological compounds.[8]

In fact, the present results at Ar^+-ion bombarding energies of 450 keV or 1.8 MeV demonstrate that an EPR absorption due to Fe^{3+} clusters was obtained even at the lowest doses examined, *i.e.* 5 s irradiation at the ion current density of 0.3 $\mu A\,cm^{-2}\,s^{-1}$ which corresponds to 10^{13} Ar^+ ions cm^{-2}. At this dose, the tracks of incident Ar^+ ions probably do not overlap each other (radius of track $\approx$3 Å). Thus, one may conclude that Fe^{3+} clusters are formed even in a single track of an incident Ar^+ ion.

It should be further noted that an EPR absorption of Fe^{3+} clusters thus formed has an anisotropic g factor which is axially symmetric with respect to the direction of the incident beam (Table 1), in remarkably contrast to that obtained by thermal decomposition of heavily γ-irradiated complex.

In cases of Ar^+-ion collisions, highly inelastic excitations of Fe may be accompanied with a simultaneous momentum transfer from the incident Ar^+ ion. This would cause a production of a Fe^{3+} cluster, the structure of which retains some axially symmetric feature with respect to the direction of an incident beam.

The authors wish to thank Mr. Chiaki Kobayashi and Mr. Susumu Kanda for their kind operation of the 2 MV Van de Graaff accelerator.

(Received November 17, 1984)

A simulation method of molecular dynamics using internal coordinates for polyatomic molecule is described. The method permits intramolecular interaction to be expressed in terms of the internal coordinate, and produces translation, rotation, and vibration of molecule. As the first application, infrared spectra of sulfur dioxide both at gas and liquid phases are simulated by the method with an aid of the techniques proposed by Berens and Wilson. The spectrum at gas phase exhibits the pure rotational band and the vibrational-rotational bands for fundamental modes. The ν_1 and ν_2 vibrations show B-type band shape, and the ν_3 mode shows A-type band shape, in accord with the experimental result and the selection rule for a prolate symmetrical top which may practically represent the molecule. At liquid phase, multiple peaks due to rotational structure disappeared, and single-peaked bands are simulated as expected. The method can be extended so as to describe more realistic intermolecular interactions than pairwise atom-atom potentials.

Molecular dynamics simulation has become a powerful tool for the study of average structures and dynamic properties of molecular systems. Except for the simplest molecules,[1,2] however, molecules have been usually dealt with as rigid or partially flexible ones.[3] In order to perform a more physically realistic simulation, it may be necessary to make molecules flexible, that is, all degrees of freedom of atomic motion should be included. Because it is hard to describe the intramolecular potential by Cartesian coordinates for polyatomic molecules, it is desirable to express explicitly the potential in terms of the internal coordinates such as bond stretching, valence angle bending, out-of-plane bending, and torsion. We describe, in this paper, a simulation method satisfying the above requirements for polyatomic molecules. The method permits the calculation of molecular dynamics including all degrees of freedom, and produces translation, rotation and vibration of molecule.

As the first application of the method, infrared spectra are simulated of sulfur dioxide, which has two stretching and one bending coordinates, both at gas and liquid phases. The spectra are obtained with the aid of the techniques proposed by Berens and Wilson[1,2] who have reproduced surprisingly accurate infrared and Raman spectra of diatomic molecules from classical molecular dynamics, classical linear response theory and classical statistical mechanical ensemble averaging, with the use of simple quantum corrections. The spectrum obtained by the molecular dynamics simulation is compared with the experimental one.[4-6]

Method and Model

Molecular Dynamics. We consider a system of N atoms interacting through intra- and intermolecular potentials at a given energy and density. The force $\boldsymbol{F}_i$ on the ith atom is assumed to be the sum of the intra- and intermolecular forces, $\boldsymbol{F}_i^{\text{intra}}$ and $\boldsymbol{F}_i^{\text{inter}}$.

$$\boldsymbol{F}_i = \boldsymbol{F}_i^{\text{intra}} + \boldsymbol{F}_i^{\text{inter}} = -\frac{\partial V^{\text{intra}}}{\partial \boldsymbol{r}_i} - \frac{\partial V^{\text{inter}}}{\partial \boldsymbol{r}_i}, \quad i = 1, \cdots, N, \tag{1}$$

where V^{intra} and V^{inter} are the intra- and intermolecular potential energies, respectively, and $\boldsymbol{r}_i$ is the position expressed for each atom i by a vector whose components are along the three Cartesian coordinates.

The intramolecular potential energy V^{intra} is expressed in terms of the internal coordinates as

$$V^{\text{intra}} = \frac{1}{2}\sum_{tt'} f_{tt'} \cdot S_t \cdot S_{t'} + \frac{1}{6}\sum_{tt't''} g_{tt't''} \cdot S_t \cdot S_{t'} \cdot S_{t''} + \cdots \tag{2}$$

in which $f_{tt'}$ and $g_{tt't''}$ are the quadratic and cubic force constants, respectively, and S_t, $S_{t'}$, and $S_{t''}$ are tth, t'th, and t''th internal coodinates, respectively. The internal coordinate is related to the Cartesian displacement vector $\Delta \boldsymbol{r}_i$ by

$$S_t = \sum_{i=1}^{L} \boldsymbol{s}_{ti} \cdot \Delta \boldsymbol{r}_i \tag{3}$$

where the coefficient $\boldsymbol{s}_{ti}$ is the well known $\boldsymbol{s}$-vector determined by the geometry of the internal coordinate,[7] L is the number of the constituent atoms for the coordinate, and the dot represents the scalar product of the two vectors. Consequently one can write the intramolecular force as follows,

$$\boldsymbol{F}_i^{\text{intra}} = -\sum_{tt'} f_{tt'} \cdot \boldsymbol{s}_{ti} \cdot S_{t'} - \frac{1}{2}\sum_{tt't''} g_{tt't''} \cdot \boldsymbol{s}_{ti} \cdot S_{t'} \cdot S_{t''} + \cdots \tag{4}$$

Internal coordinates written in our program of molecular dynamics are increases in bond lengths Δr, in valence bond angles $\Delta\varphi$, in angles between a bond and a plane defined by two bonds $\Delta\theta$, and in torsion $\Delta\tau$. The $\boldsymbol{s}_{ti}$ vectors for these coordinates are calculated for every instantaneous structure of each molecule so as to take account of the higher-order terms omitted in Eq. 3 implicitly.

For the intermolecular part, we use the sum of the pairwise atom-atom potential terms of the two types,

$$V_1^{\text{inter}} = \sum_{ij} [-Ar_{ij}^{-6} + B \exp(-Cr_{ij})] \tag{5}$$

and

$$V_2^{\text{inter}} = \sum_{ij} e_i e_j / r_{ij} \tag{6}$$

where r_{ij} is the distance between the atoms i and j the index i runs over a single molecule and j over the others, and A, B, and C are parameters for the potential. The potential V_1^{inter} represents the exchange repulsion and dispersion interaction for atom pairs, and V_2^{inter} arises from the Coulomb interaction between the atomic charges e_i and e_i.

The classical trajectories $r_1(t)$, $\cdots$, $r_N(t)$ are obtained by integrating Newton's second law

$$F_i = m_i \frac{d^2 r_i}{dt^2}, \quad i = 1, \cdots, N \tag{7}$$

where m_i is the mass of the ith atom. A modified Verlet integration algorithm[8] was used with a periodic boundary condition.

Infrared Spectra. We use the same approach presented by Berens and Wilson[1] who calculated the pure rotational and vibrational-rotational absorption bands of carbon monoxide from the time history of dipole moment computed using the trajectories, classical linear response theory and classical statistical mechanical ensemble averaging, with the use of simple quantum corrections. We modified the approach so as to be applicable to oriented system. The dipole moment time history of the system $\mu_d(t)$ for the d direction is calculated by using the trajectories of the atoms and $(\partial\mu/\partial Q_i)$, where d is x, y, or z Cartesian coordinate, μ the molecular dipole moment, and Q_i is the ith normal coordinate.

The absorption spectrum for a system at equilibrium is obtained from the linear response equations:

$$\alpha_d(\omega) = \frac{4\pi^2\omega^2\beta}{3cn} I_d(\omega), \quad d = x, y, z, \tag{8}$$

and

$$I_d(\omega) = \frac{3}{2\pi}\left[\lim_{\tau\to\infty} \frac{1}{2\tau}\left|\int_{-\tau}^{\tau} dt \exp(-i\omega t)\mu_d(t)\right|^2\right], \quad d = x, y, z \tag{9}$$

in which $\alpha_d(\omega)$ is the absorption cross section as a function of angular frequency ω, $\beta=(k_BT)^{-1}$ in which k_B is Boltzmann's constant and T is the temperature, c is the velocity of light, and n is the refractive index of the medium. $I_d(\omega)$ is defined as the absorption band shape, and may be computed in the form of the power spectrum by fast Fourier-transform techniques. The equations are written in the form applicable to oriented systems and can be used for isotropic systems by taking an average of the three $\alpha_d(\omega)$.

For the comparison with an experimental spectrum, it is necessary to obtain an ensemble average of spectra computed from very small system consisting of an order of several hundreds atoms, from very short time period, and especially from weakly interacting system such as low pressure gas phase. Therefore, for gas phase, many sets of the initial values are chosen randomly from the Maxwell-Boltzmann distribution. In order to satisfy a thermal equilibrium condition under a given temperature with the Maxwell-Boltzmann distribution, initial values of translational velocity and angular momentum of molecule and amplitude of each fundamental vibrations are chosen from normal random numbers. On the other hand, initial translational and rotational coordinates of molecule and phase of each fundamental vibrations are chosen from uniform random numbers. For liquid phase where intermolecular interaction must be dominant, the final values in one period of the time history are used as the initial values of the next.

Quantum correction for the pure rotational band contour is usually small and is

$$I^Q(\omega)/I^C(\omega) = \frac{\sinh(\beta\hbar\omega/2)}{\beta\hbar\omega/2} \tag{10}$$

in which the superscripts Q and C indicate quantum and classical, respectively, and $\hbar=h/2\pi$ where h is Planck's constant. The correction for the vibrational band is the frequency shift of $-4\pi r_e x_e$ due to anharmonicity in the potential. The rotational lineshape correction for a rotational-vibrational band is achieved by multiplying the classical band by $\exp[\beta\hbar(\Delta\omega)/2]$, in which $\Delta\omega$ is the frequency measured from the center of the vibrational band. For the liquid phase spectrum, no quantum corrections were applied.

Resolution and Frequency Range. As the resolution, we employed the most popular criterion of the full-width at half-height (FWHH). The minimum value of the FWHH ($\tilde{\nu}_{1/2}$), *i.e.* resolution, in a calculated spectrum depends on the time of one period of the time history (Δ) as follows:

$$\tilde{\nu}_{1/2} = \frac{1}{c\Delta}. \tag{11}$$

In practice, however, the resolution is lowered by an apodization (window) function,[9] which must be used to avoid distortion of the spectra caused by the use of finite time history.

Frequency range (0—$\tilde{\nu}_{\max}$) depends on the sampling time interval (Δt) and is given by

$$\tilde{\nu}_{\max} = \frac{1}{2c\Delta t}. \tag{12}$$

For example, when Δt is 1/1024 psec, $\tilde{\nu}_{\max}$ is 17067 cm^{-1}.

Model. As the first application of the molecular dynamics method using internal coordinates, a simple model of gaseous and liquid systems was adopted. The systems consist of 125 sulfur dioxide molecules, periodic in three dimensions (x, y, z). The box sizes are 3.322^3 nm^3 for gas phase, and 0.419^3 nm^3 for liquid phase. The SO bond length and OSO bond angles were assumed to be 1.43 Å and 119.05°, respectively.[10] The atomic charges on the S and O atoms were estimated from the observed values of the dipole moment;[10] $e_s=-2e_o=0.46$ in the electronic charge unit.

For the SO stretching and OSO bending harmonic force constants (k_{st} and k_{bend}/l^2) of 9.97 and 0.81 mdyne/Å respectively, were taken from the literature values.[11]

Table 1. Parameters of the nonbonded atom–atom interaction

Atomic pair	A (kcal·Å^6·mol^{-1})	$B\times10^{-3}$ (kcal·mol^{-1})	C (Å^{-1})
S···S	1430	220.8	3.62
O···O	800	745.9	4.55
S···O	1070	405.9	4.09

The parameters A, B, and C used in the Eq. 5 for the S···S, O···O, and S···O intermolecular atom-atom interactions were listed in Table 1.[11] The summation limit is placed at the distance of 8.15, 7.35, and 6.85 Å for the V_1^{inter} of the S···S, S···O, and O···O, respectively, and 16 Å for the V_2^{inter}. To reduce the error in the use of truncated potentials, the shifted force potentials were adopted.[12]

Although V_2^{inter} was calculated by the fixed charge model, the dipole moment time history of the system is evaluated by using the $(\partial\mu/\partial Q_i)$ of 0.780, −0.820, and 2.138 for ν_1, ν_2, and ν_3, respectively, in the unit of D amu$^{1/2}$Å^{-1}.[13] Normal coodinates are obtained from the following relation,

$$\boldsymbol{Q} = \tilde{\boldsymbol{L}}_x \boldsymbol{M} \boldsymbol{X}_p \qquad (13)$$

where $\tilde{\boldsymbol{L}}_x$ denotes the inverse matrix of the transformation matrix, $\boldsymbol{M}$ is a diagonal matrix consisting of the mass of constituting atoms, and $\boldsymbol{X}_p$ is a matrix of Cartesian displacement coordinates with respect to the coordinate system of principal axes of moment of inertia. The calculation was carried out using a FACOM M-180 II AD computer of the Institute for Chemical Research, Kyoto University. The calculations for one psec time history of the gaseous and liquid systems required 85 and 107 min of the computer, respectively.

Results and Discussion

Figure 1 demonstrates the simulated infrared spectra for the gas phase sulfur dioxide at 320 K from classical molecular dynamics using internal coordinates, and the technique proposed by Berens and Wilson.[1] The spectra were obtained by averaging over 7500 single-molecule 8 psec time histories. Ensemble average were taken over 15 runs of 42 psec duration in which initial coordinates and velocities were different and first 10 psec are discarded for thermal equilibrium. The value of the resolution is 4.17 cm^{-1} from Eq. 11, and becomes to be 6.15 cm^{-1} by using the Gaussian apodization function.[9] As one of the moment of inertia (I_A) is quite smaller than the other two (I_B and I_C), as listed in Table 2, the molecule may be regarded as a prolate symmetrical top molecule. The ν_1 and ν_2 vibrations, whose directions of transition moments are parallel to the B axis, show B-type band shape, and the ν_3 mode, whose direction of the transition moment is parallel to the A axis, shows A-type band shape, in accord with the experimental result.[5] This is consistent with the selection rule for symmetrical top molecule. The band shape and the frequency of about 50 cm^{-1} for the pure rotational band are quite similar to those of the observed spectrum.[14] The integrated intensities and standard deviations for the simulated spectrum are 24.8±5.0, 30.5±9.6, and 180.8±47.5 km mol^{-1} for ν_1, ν_2, and ν_3, fundamental bands of gaseous sulfur dioxide, respectively, and agree with the corresponding values observed of 20.6—26, 25.2—28, and 188—197 km mol^{-1}.[15–17]

Figure 2 shows the simulated infrared spectra of liquid phase sulfur dioxide at 230 K on average. The spectra were obtained by averaging over 7500 single molecule 4 psec time histories. The value of the resolution is 8.34 cm^{-1} from Eq. 11, and 12.3 cm^{-1} from the Gaussian appodization function.[9] The spectrum shows that the multiple peaks observed at gas phase disappear at liquid phase, and single-peaked bands are found at 1172, 521, and 1359 cm^{-1} for ν_1, ν_2, and ν_3 respectively. Statistical noises appeared typically at peaks of the lowest bands seen in Figs. 1 and 2, are due

Table 2. Moment of inertia of sulfur dioxide[a]

I_A	I_B	I_C
1.38	8.13	9.53

a) in 10^{-43}·g·m^2

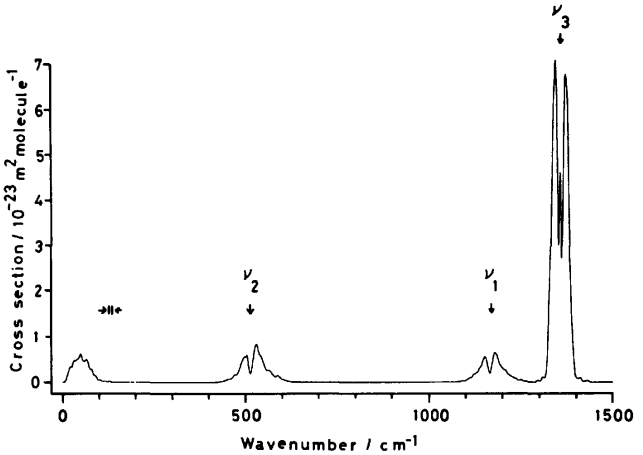

Fig. 1. Infrared spectrum for gas phase sulfur dioxide at 320 K on average.

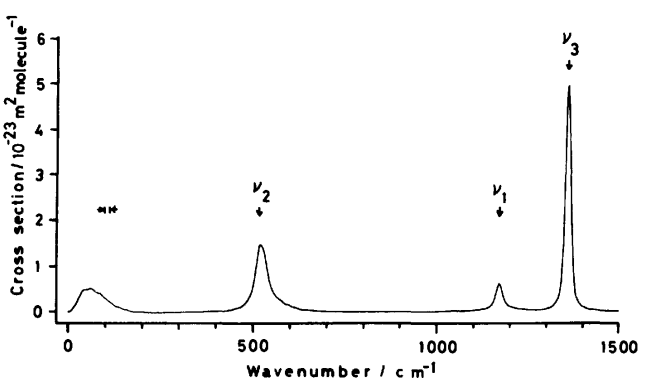

Fig. 2. Infrared spectrum for liquid phase sulfur dioxide at 230 K on average.

to ensemble sampling with only 60 runs for gas and liquid phases. Much more prolonged computation will improve the shapes of peakes, thus enabling the more detailed analysis.

Conclusion

A simulation method of molecular dynamics using internal coordinates for polyatomic molecule is proposed, and was applied to a simulation of the infrared spectra of sulfur dioxide both at gas and liquid phases. The frequencies of the fundamental vibrations of the spectra agree with those calculated by normal coordinate analysis. The bands of the ν_1 and ν_2 vibrations show B-type band shape, while that of the ν_3 mode shows A-type band shape in accordance with the selection rule. At liquid phase, the multiple peaks due to rotational structure disappeared, and single peaked bands are simulated.

The method using internal coordinates can be extended so as to describe more realistic intermolecular interactions containing multibody effects, as well as intramolecular potential, than pairwise atom-atom potentials. Although potential surfaces of multibody systems, especially in chemical reaction systems, are usually complicated, these are able to be expressed by using the four kinds of coordinates, Δr, $\Delta\varphi$, $\Delta\theta$, and $\Delta\tau$.

The authors wish to thank Dr. Y. Kataoka and Dr. K. Ishizuka of this university for their valuable discussions.

Synthetic Inorganic Ion-exchange Materials. XXXVIII. Acid-base Properties of a Cryptomelane-type Hydrous Manganese(IV) Oxide and Some Chromatographic Applications

Masamichi Tsuji* and Mitsuo Abe
Department of Chemistry, Faculty of Science, Tokyo Institute of Technology, 2-12-1, Ookayama, Meguro-ku, Tokyo 152
(Received July 12, 1984)

The pH titration curves of a cryptomelane-type hydrous manganese(IV) oxide(CRYMO) apparently showed a dibasic Brönsted-acid towards Li^+, Na^+, K^+, and Rb^+ ions and a monobasic Brönsted-acid towards Cs^+ ions, instead of an amphoteric character, using a mixed solution of alkali metal nitrate and nitric acid or each hydroxide with the ionic strength of 0.1. The apparent ion-exchange capacities(meq/g) of alkali metal ions increased in this order: $Li^+(0.50)<Na^+(0.55)<Cs^+(0.85)<Rb^+(1.00)<K^+(1.10)$ at pH 2 and $Cs^+(1.20)<Rb^+(1.72)<Na^+(1.78)<Li^+(1.80)<K^+(1.81)$ at pH 10. The point of zero charge(PZC) of CRYMO was estimated to be much lower than 2. The unusual selectivity for K^+ and Rb^+ ions can be successfully applied to some ion-exchange separations: *e.g.*, the removal of K^+ ions from $NaNO_3$ and $NaMnO_4$ solutions, the removal of Rb^+ ions from a $CsNO_3$ solution, and the selective uptake of K^+ ions from seawater.

An ion-exchange property has been known for a long time in manganese(IV)-oxide minerals.[1-3] Hydrous manganese(IV) oxide is considered to be a multifunctional ion-exchanger with an amphoteric nature.[4] The colloid-chemical properties of synthesized hydrous manganese(IV) oxides have been investigated by many authors.[5-9] The PZC or isoelectric points (IEP) of hydrous manganese(IV) oxides have been reported to change depending on the modifications.:[10] Mn(II)-manganite(1.8 ± 0.5)<δ-type(2.8 ± 0.3)<α-type(4.5 ± 0.5)<γ-type(5.5 ± 0.2)<β-type(7.3 ± 0.2). Of these modifications, α- and γ-type manganese(IV)-oxide minerals exhibit a relatively large ion-exchange capacity (0.6 meq/g of MnO_2 at pH 11).[4] Hydrous manganese(IV) oxides show only cation-exchange properties at pH>1.[11]

Recently, much attention has been paid to manganese(IV) oxides as scavengers in analytical chemistry and nuclear-waste processing; they have attracted this attention because of their high selectivities towards certain elements and their stability against various chemicals or the strong fields of various radiations.[11-17]

The present authors have reported that a cryptomelane-type hydrous manganese(IV) oxide behaves as a so-called ion-exchange material. It shows an excellent selectivity towards alkali and alkaline earth metal ions with an effective ionic radius (EIR)[18] of about 1.4 Å (1 Å=0.1 nm).[19] The ion-exchange selectivity for micro-amounts increased in this order: $Li^+<Na^+<Cs^+\ll Rb^+$, K^+ for the alkali metal ions and $Mg^{2+}<Ca^{2+}<Sr^{2+}<Ba^{2+}$ for the alkaline earth metal ions. This performance could be successfully utilized for the separation of micro-amounts of Ca^{2+} or Sr^{2+} ions from large amounts of K^+ or Rb^+ ions respectively.[20] This behavior is very different from that of the hydrous manganese(IV) oxides reported by other authors.[4]

This paper will describe the acid-base properties of the CRYMO and some chromatographic applications.

Experimental

Ion-exchange Materials and Characterization. The CRYMO in the H^+ form was prepared as has been described previously.[19] The CRYMO was identified by an X-ray powder analysis and thermal studies (TG and DTA). The X-ray powder diffraction and the thermal studies were carried out by using a JEOL-7E diffractometer and a Rigaku Denki thermal analyzer, Model 8001, with a heating rate of 20 °C/min respectively. The characteristics of the product obtained showed a good agreement with those reported previously:[19] the chemical composition was $MnO_2 \cdot 0.28H_2O \cdot 0.003K_2O$, and the lattice constants (a_o and c_o) were 9.77 Å and 2.85 Å respectively in the tetragonal system.

pH Titration Curve. An aliquot of the sample solution(12.5 cm^3), adjusted to the ionic strength of 0.1 with MNO_3 and HNO_3 or MOH (M=Li, Na, K, Rb, and Cs), was equilibrated with the CRYMO in the H^+ form (0.125 g) at 30 ± 0.5 °C. After the equilibration, the metal ion concentration and the pH of the solution were determined. The metal concentration was determined as follows: A 10 cm^3-aliquot of the equilibrated solution was neutralized with the standardized 0.05 M (1 M=1 mol dm^{-3}) NaOH or HNO_3; it was then percolated through a Dowex 50W-X8 cation-exchange resin column in the H^+ form. After the column had been washed with demineralized water (>10^6 S cm^{-1}) until the effluent was neutral, the amount of H^+ ions liberated by the CRYMO was determined. Thus, the equilibrium concentration of the M^+ ions was deduced by subtracting the amount of NaOH used for neutralization from the amount of H^+ ions titrated. The amount of M^+ ions exchanged was determined from the difference between the initial and equilibrated concentrations.

Preparation of CRYMO in the Na^+ Form. The CRYMO in the H^+ form was converted into the Na^+ form by charging a 0.1 M $NaNO_3$ solution onto the top of a CRYMO column in the H^+ form until the pH of the effluent attained that of the feed (pH 7). The column was washed with water and used in the subsequent experiments.

Column Experiment. A relatively small column (4.6 cm×0.5 cm I.D. or 3 cm×0.4 cm I.D.) of the CRYMO in the H^+ or Na^+ form was used at the ambient temperature. The flow rate was regulated by means of a high pressure pump (Nihon Seimitsu Kagaku, Model NSP-800-5UDX). The effluent was collected by using a drop-counting type fraction collector (Ohtake Works, Model UM-200).

Determination of Alkali and Alkaline Earth Metals. The alkali and alkaline earth metal ions were determined by

emission and absorption spectrophotometries respectively by means of a Varian-Techtron atomic absorption spectrometer, Model 1100. The standard addition method was used in both cases.

Optical Spectrophotometry. A Shimadzu double beam optical spectrophotometer, Model UV-150-02, was used for the identification of the Mn(VII) ions.

Reagents. All the chemicals were of an analytical grade from Wako Pure Chemical Ind. Ltd. (Japan), except for Rb_2CO_3, Cs_2CO_3, and $NaMnO_4 \cdot H_2O$. The two carbonates (>99%) and $NaMnO_4 \cdot H_2O$ (>97% purity) were obtained from Soekawa Chemicals (Japan) and Aldrich Chemical Company, Inc. (USA) respectively. They were employed without further purification. Rubidium and cesium hydroxide solutions were prepared by percolating the nitrate solution through a Dowex2-X4 anion-exchange resin column in the OH^- form(2.5 cmϕ×20 cm) with bubbling N_2 gas. The seawater used was collected 1 km off shore at Takamatsu, Kagawa Prefecture, Japan, and filtered through a membrane filter (0.45 μm pore). The chemical composition of the seawater sample was 0.464 M Na^+, 0.00995 M K^+, 0.0492 M Mg^{2+}, and 0.00983 M Ca^{2+} ions.

Results and Discussion

pH Titration Curves. The pH titration curves on the CRYMO in the H^+ form showed a break point at pH 7, except in the case of the Cs^+ ions(Fig. 1). It behaves apparently as a dibasic acid towards these alkali metal ions, while apparently as a monobasic acid for Cs^+ ions. A purple color was observed in a small amount of Mn(VII) ions when the H^+ ions in the CRYMO were exchanged with any alkali metal ions except Cs^+ ions at pH values higher than 10. The CRYMO was broken into fine particles when the H^+ ions in the CRYMO were exchanged with Cs^+ ions at pH values higher than 10. The pH titration curves indicate that there are stronger Brönsted-acid sites in the CRYMO than those of hydrous oxides of other quadrivalent metals, such as Si, Ti, Sn, and Zr.[11]

The amounts of the replaceable protons responsible for the ion-exchange reactions can be estimated by the differences between the blank run (the dotted line) and each titration curve. The apparent capacity thus determined agreed well with the amount estimated from the titration curve (Fig. 2). These results indicate that the cation uptake obeys the ion-exchange reaction in the pH range studied. The ion-exchange capacity increases in this order: $Li^+ < Na^+ < Cs^+ < Rb^+ < K^+$ at pH values lower than 5. The affinity sequence agrees well with our earlier results in acidic media.[19] The apparent capacity of Cs^+ ions almost reaches a saturated value at pH 5. It results in a different sequence of the affinity: $Cs^+ < Rb^+ < Na^+ < Li^+ < K^+$ at pH 10 because of the large steric effect for large cations. The largest ion-exchange capacity (2.4 meq/g) was obtained for Li^+ ions at pH> 11. This value is quite large compared with those of the α- and γ-types hydrous manganese(IV) oxide (0.6 meq/g) reported by other authors.[4]

This ion-exchange behavior can be well understood on the basis of the crystal structure of a cryptomelane.[21] It has been considered that the unit cell contains eight manganese ions (chiefly quadrivalent), with vacancies at two positions of (0, 0, 1/2) and (1/2, 1/2, 0), and sixteen oxygen ions. The two sites are surrounded by eight oxygen ions at a distance of 2.74 Å, forming a cube, and by four oxygen ions at a greater distance of 3.31 Å, forming a square at the same z level as the vaca-

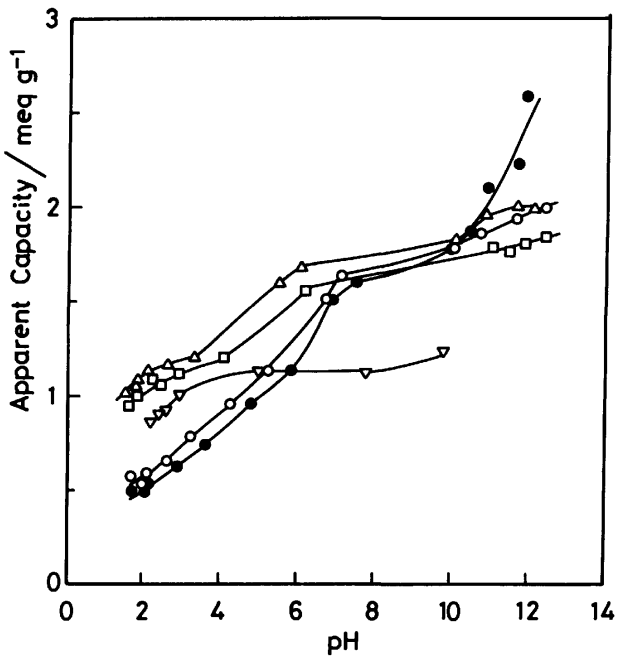

Fig. 2. pH Dependence of the apparent capacity for the alkali metal ions on the CRYMO. The experimental conditions and the marks are the same as in Fig. 1.

ncy. Both ion-exchange sites have the same electrostatic field and are 7.05 Å apart. The sites are estimated to be 2.68 Å long along the a axis and 2.84 Å long along the c axis, based on r ($^{VI}O^{2-}$)=1.40 Å. Hence, because of the electrostatic repulsion, Cs^+ ions with a radius of 1.88 Å cannot occupy all the ion-exchange sites, while Li^+ ions with a radius of 0.74 Å can enter almost all the ion-exchange sites.

The electron configuration of alkali metal ions as well as of alkaline earth metal ions is represented by s^2p^6. The metal ions of this group are less polarized under the influence of the electrical field of the crystal. For this reason, K^+ and Rb^+ ions, with about the same dimentions as the size of the ion-exchange site, are selectively exchanged.

It has been considered that the charges of the entering cations are compensated for by this reaction:[22]

$$V_2Mn_8O_{16} + M^{n+} \rightleftharpoons (V_{2-x}, M_x)Mn^{IV}_{8-y}Mn^{II}_yO_{16}$$

In fact, however, the sorptions of alkali, alkaline earth, and divalent transition-metal ions obey the stoichiometric ion-exchange reaction.[19,23] No such reduction occurs when these metal ions are sorbed. Instead, equivalent amounts of H^+ ions are released. Therefore, H^+ ions lie at the positions of the vacancy considered above.

The strength of hydrous oxide as an acid or base can be well described by the corresponding dissociation constants:[24,25] at a high pH:

$$RH \rightleftharpoons R^- + H^+,$$

$$K_{R^-} = \frac{[R^-][H^+]}{[RH]}$$

and
at a low pH:

$$R'OH \rightleftharpoons R'^+ + OH^-,$$

$$K_{R'^+} = \frac{[R'^+][OH^-]}{[R'OH]}$$

or

$$R'OH + H^+ \rightleftharpoons R'OH_2^+,$$

$$K_{R'OH_2^+} = \frac{[R'OH_2^+]}{[R'OH][H^+]}$$

where R or R′ denote the framework of the exchanger. The densities of the "surface" charges, $[R^-]$, $[R'^+]$, and $[R'OH^+_2]$, are often determined by titrating with alkali metal nitrates, and the corresponding hydroxide having less complexing.[6] The PZC is defined by a pH value yielding a zero-charge surface,[25,26] *i.e.*, giving the following relation:

$$[R^-] = [R'^+] + [R'OH_2^+]$$

The pH titration curve shows that the CRYMO releases H^+ ions equal in amount to the alkali metal ions exchanged. Even at pH 2, no appreciable uptake of nitrate ions was observed. Therefore, $[R'^+]$ or $[R'OH^+_2]$ is nearly null at a pH value of 2, and the PZC of the CRYMO can be estimated to be considerably lower than 2.

Healy *et al.* have reported that a cryptomelane-type hydrous manganese(IV) oxide showed a PZC value of 4.5±0.5.[10] Their specimen showed an X-ray pattern corresponding exactly with that given by Butler and Thirsk,[27] whose samples have larger lattice constants (a_o 9.85 Å, c_o 2.852 Å) than those reported by the present authors. The K^+ ions in this specimen cannot be removed by washing with water alone. When a considerable amount of K^+ ions is present in the material, increased lattice constants can be observed.[19] Hence, in their sample, a considerable amount of the dissociable protons can be inferred to be replaced by K^+ ions. For this reason, their sample probably showed a larger PZC value.

Selective Uptake of a Small Amount of Alkali Metal Ions from a Large Amount of Alkali Metal Salts by Using the Batch Technique. Generally, the synthetic inorganic ion-exchange materials are more stable against an attack of oxidizing reagents than the organic ion-exchange resins. The CRYMO was stable for a week in such oxidizing reagents as Cr(VI) and Mn(VII) salts solution containing a 1 M H_2SO_4 solution at room temperature. The K^+ impurity in a 0.5 M $NaMnO_4$ solution containing 1 M H_2SO_4 could be removed using the CRYMO (Fig. 3). An X-ray diffraction pattern of the CRYMO used showed no change in the crystalline modification, and repeated use is possible by removing the K^+ ions sorbed.

The uptake of alkali and alkaline-earth metal ions from seawater was determined by changing the ratios of the volume of seawater to the weight of CRYMO (*R* value) (Table 1). The total uptake (Na^+, K^+, Mg^{2+}, and

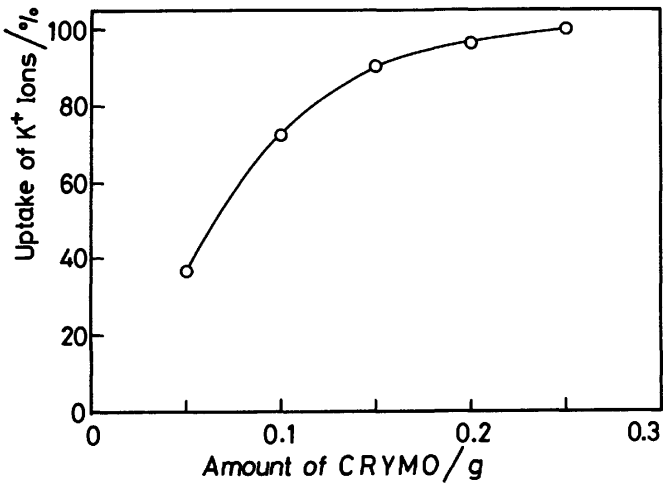

Fig. 3. Selective removal of K^+ ions from 0.5 mol dm^{-3} $NaMnO_4$ containing 1 mol dm^{-3} H_2SO_4 using the CRYMO by the batch technique. Concn. of K^+ ions: 3.65×10^{-3} mol dm^{-3}, Total vol: 25.0 cm^3. Temp: 30±0.5 °C. Immersing time: 4 d.

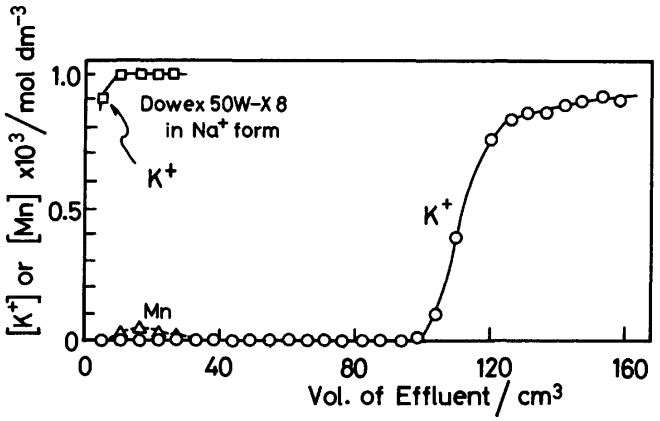

Fig. 4. Selective removal of K^+ ions from $NaNO_3$ solution with the CRYMO column in the Na^+ form. Column: 3×0.4 cm I.D. (100—200 mesh size, 0.50 g), Feed: (1 mol dm^{-3} $NaNO_3$+10^{-3} mol dm^{-3} KNO_3) mixed solution. Flow rate: 0.5—0.6 cm^3/min. □, ○: K^+ ion concn. in the effluent from Dowex 50W-X8 and CRYMO columns, respectively. △: Total manganese ions released to the soln.

Ca^{2+}), 1.3—1.6 meq/g, is nearly equal to the cation content of the CRYMO in the Na^+ form (1.32 meq $(Na^+ + K^+)$/g). Hence, a decreased amount of Na^+ ions in the CRYMO is compensated for by the K^+, Mg^{2+}, and Ca^{2+} ions through the ion-exchange process with Na^+ ions. The uptake of K^+ ions increases with an increase in the R values and attains about a constant value of 0.65 meq/g at the R value of 167.

The concentration factor was estimated by using the following equation by Abe and Hayashi[28] (Table 1):

$$f^{M}_{Na} = \frac{[(M)/(Na)]_{CRYMO}}{[(M)/(Na)]_{seawater}}$$

where M denotes K, Mg, and Ca.

The value of f^{K}_{Na} attains about 85 at the R value of 167, while f^{Ca}_{Na} gives the maximum of 55 at the R value of 100. At the pH values and metal concentrations studied, small f^{Mg}_{Na} values were obtained; hence, the selectivity for Mg^{2+} ions is slightly larger than for Na^+ ions. The results are in good agreement with those of our earlier report.[19]

Selective Removal of Alkali Metal Impurities from Salts of Alkali Metals by Using the Column Technique. The frontal chromatographic technique is one of the simplest procedures for the separation of a small amount of an element from a large amount of other elements. However, this technique is not very useful for the separation of a small amount of K^+ ions from a high concentration of Na^+ ions on a Dowex50W-X8 column because of its low selectivity. It is, however, evident from the selectivity studies of the CRYMO in our earlier report[19] that the separation of K^+ ions from Na^+ ions is feasible. The separation can be achieved with a much larger volume of the $NaNO_3$ solution containing 10^{-3} M K^+ ions on the CRYMO than that on Dowex 50W-X8 (Fig. 4).

K^+ ions in the feed solution were retained quantitatively on the column up to 97 cm^3. A faint purple color was observed in the effluent at the early stage of the injection of the feed. The chemical species of the colored component could be assigned spectrophotometrically as Mn(VII) ions. In the final stage, a large gas bubble generated by an unknown cause did not allow the percolation of the feed.

An unusual selectivity for Rb^+ ions on the CRYMO was applied to the separation of a micro-amount of Rb^+ ions from a 1 M $CsNO_3$ solution (Fig. 5). A trace amount of Rb^+ ions ($<10^{-6}$M) leaked out from the column up to 107 cm^3 of the effluent. The purified cesium nitrate (effluent up to 107 cm^3) showed an impurity level lower than 10^{-6} M for both Rb^+ ions and the total manganese. At 110 cm^3 of the effluent,

Feed: 1 mol dm^{-3} $CsNO_3$+8.8× 10^{-4} mol dm^{-3} $RbNO_3$. Flow rate: 0.2 cm^3/min. △: Total manganese ions released to the solution by the CRYMO.

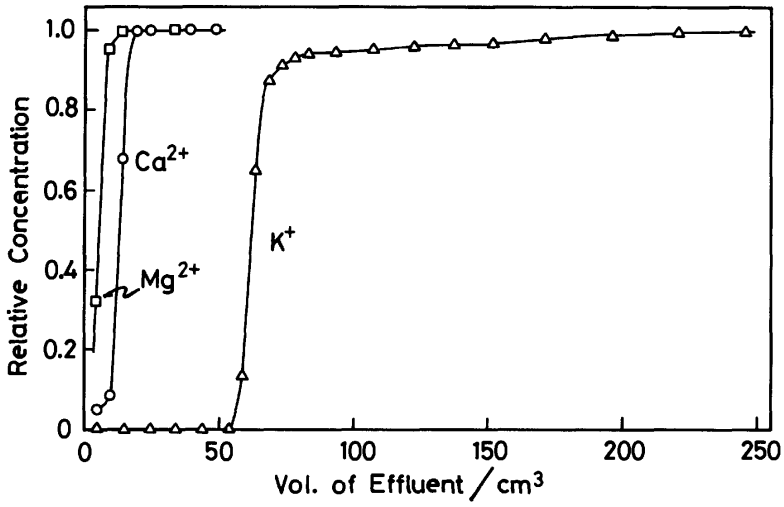

Fig. 6. Breakthrough behavior of metal ions in seawater on the CRYMO column. Column: 4.6×0.5 cm I.D. (100—200 mesh size, 1.0 g). Flow rate: 0.2 cm^3/min. The ordinate shows the concentration in the effluent relative to each metal ion concentration in seawater.

Mn(VII) ions were released from the column. Thus, commercial Cs salts can be very effectively purified by the use of the CRYMO column.

An effective separation of K^+ ions from seawater using a commercial cation-exchange resin is usually difficult because of the relatively low separation factor for K^+ to Na^+ ions, as has been pointed out above. The K^+ ions in seawater were collected batchwise as insoluble organic or inorganic compounds.[29,30] However, an effective separation cannot be expected using such a method. The separation technique using the CRYMO may give a better one.

The ion-exchange column technique allows a continuous operation, which is much superior to the batchwise process in terms of time and space. The breakthrough behavior for K^+, Mg^{2+}, and Ca^{2+} ions was studied by charging seawater continuously onto the top of the column of CRYMO in the Na^+ form (Fig. 6). Metal ions were eluted in this order: Mg^{2+}< Ca^{2+}<K^+. The breakthrough capacity showed 0.54 meq/g. The amount (0.65 meq/g) of K^+ ions sorbed up to 167 cm^3 of the feed solution is in good agreement with that of K^+ ions recovered in the batch equilibration technique at the R value of 167 cm^3/g.

By taking advantage of the large difference in the selectivity for K^+ and other ions, a more selective concentration of K^+ ions in seawater can be achieved by washing out Na^+ ions in the CRYMO column with an appropriate eluent. A 30-cm^3 aliquot of seawater was charged onto the column, and the column was washed with 250 cm^3 of a 1 M HNO_3 solution at a flow rate of 0.2 cm^3/min. By this operation, less concentration of

K^+ ions than 10^{-6} M was eluted, while almost all of the Mg^{2+} and Ca^{2+} ions and a considerable amount of Na^+ ions were eluted. Then, the K^+ ions exchange-adsorbed could be eluted by 250 cm^3 of a 13 M HNO_3 solution with an average yield of 90—95% in three runs. The concentration factor, f_{Na}^{K}=480—500, was obtained in the effluent by this once-through processing. The Mg^{2+} and Ca^{2+} ions in the effluent were less than 10^{-6} M.

(Received July 23, 1984)

A preferable atomic absorption spectrophotometric method has been established for trace determination of copper(I) *via* extraction of its ion-associated complex with 3-(4-phenyl-2-pyridyl)-5,6-diphenyl-1,2,4-triazine and tetraphenylborate into molten naphthalene. The optimum pH range for the extraction is 1.6—8.2. Solid naphthalene containing the copper(I) complex is separated by filtration and dissolved in *N,N*-dimethylformamide. The absorbance is measured at 324.7 nm. Beer's law is obeyed in the concentration range 2.5—80 μg of copper in 10 cm^3 *N,N*-dimethylformamide solution. Ten repeat analyses on a sample containing 35 μg of copper give a mean absorbance of 0.205 with a standard deviation of 0.0017 and a relative standard deviation of 0.83%. The method has been successfully applied to determination of copper in standard reference materials and biological samples.

Numerous chromogenic reagents like 2,2′-dipyridyl- and 3-(2-pyridyl)-5,6-diphenyl-1,2,4-triazine have been used for determination of copper(I) in various methods.[1-8] These reagents react with copper(I) to form water-soluble, colored complex cations, which in turn form water-insoluble, stable, ternary complexes with anions such as ClO_4^-, SCN^-, HgI_4^{2-}, $HgBr_4^{2-}$, and CdI_4^{2-}. Ternary complexes formed can be extracted into suitable organic solvents, and some metal ions or anions can thus be determined spectrophotometrically.[9]

In the present paper, 3-(4-phenyl-2-pyridyl)-5,6-diphenyl-1,2,4-triazine (PPDT) will be recommended as a reagent for extraction of copper(I) with naphthalene. PPDT forms a light brown complex with copper(I) which is partially soluble in water.[7] Perchlorate species of this complex is extremely insoluble in water and many nonaqueous solvents. Though it can be extracted into isopentyl alcohol, the color of the complex fades in a short time[7] and it is inconvenient to work with this solvent due to its unpleasant odor. These difficulties have been overcome by means of extraction with molten naphthalene.[10-14] In the presence of tetraphenylborate (TPB) anion, the Cu(I)—PPDT complex cation mentioned above forms a thermally stable, water-insoluble, ion-associated complex. This complex cannot be extracted into any organic solvents, but can easily be extracted into molten naphthalene. The extracted mixture is soluble in *N,N*-dimethylformamide, dimethyl sulfoxide, propylene carbonate, or acetonitrile, which are all miscible with water. Various conditions have been tested and a preferable method has been applied to determination of copper in some standard reference materials and biological samples.

Experimental

Reagents. Standard copper(II) solution of 5 ppm was prepared by diluting an aliquot of 1000 ppm standard copper(II) solution with distilled water. PPDT solution of 0.04% was prepared in ethanol. TPB solution of 1% was prepared in distilled water. Hydroxylammonium chloride solution of 2% was prepared in distilled water. Buffer solutions were prepared by mixing 1 M acetic acid (1 M=1 mol dm^{-3}) and 1 M ammonium acetate solution for pH 3—6 and 1 M aqueous ammonia and 1 M ammonium acetate solution for pH 8—11. *N,N*-dimethylformamide (DMF), naphthalene, and all the other reagents were of analytical-reagent grade.

Apparatus. All absorbance measurements were made with a Perkin-Elmer Model 403 atomic absorption spectrophotometer with an air-acetylene burner head. A hollow-cathode lamp for copper was obtained from Hamamatsu Photonics Ltd. Atomic absorption data were obtained in an air-acetylene mode at 324.7 nm. Measurements of pH were carried out with a Beckmann Model G pH meter.

General Procedure. To an about 25 cm^3 sample solution containing 2.5—80 μg copper(II) in a 100 cm^3 tightly stoppered Erlenmeyer flask are added 2.0 cm^3 of 2% hydroxylammonium chloride solution, 3.0 cm^3 of 1 M ammonium acetate solution, 2.0 cm^3 of 0.04% PPDT solution, and 2.0 cm^3 of a buffer (pH 5.8). The solution is stirred well and 2.0 cm^3 of 1% TPB solution added. After warming the solution on a water bath at about 60 °C for 5 min, 0.7 g naphthalene is added and the mixture is heated on a water bath at 85 °C to melt naphthalene completely. The solution is then shaken vigorously until naphthalene solidifies forming very fine crystals. The crystals are filtered out on a filter paper (No. 5A), washed with water and dried in an oven at 50—60 °C. The solid is dissolved in *N,N*-dimethylformamide and diluted to 10 cm^3. The solution is aspirated into an air-acetylene flame to be subjected to a measurement at 324.7 nm with a copper hollow-cathode lamp.

Results and Discussion

Effect of pH. To a copper solution was added 3 cm^3 of 1 M ammonium acetate solution and complex extractions were carried out at different pH with the other conditions kept the same. The optimum pH range was 1.6—8.2 (Fig. 1). Addition of 1.5—5.0 cm^3

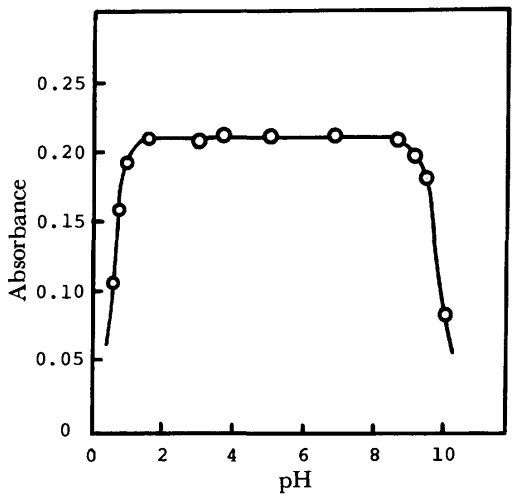

Fig. 1. Effect of pH.
Cu: 35μg; wavelength: 324.7 nm; 0.04% PPDT: 2.0 cm^3; 1% TPB: 2.0 cm^3; naphthalene: 0.7 g; 2% hydroxylammonium chloride: 2.0 cm^3; digestion time: 5 min; shaking time: 30 s; solvent: *N,N*-dimethylformamide.

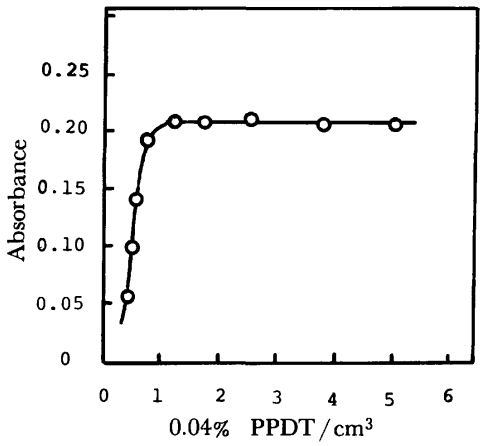

Fig. 2. Effect of PPDT concentration.
pH: 5.8; Conditions were the same as those in Fig. 1.

buffer (pH 5.8) caused virtually no variation in absorbance. Subsequent studies were conducted at pH 5.8 using 2.0 cm^3 of buffer solution.

Effect of Hydroxylammonium Chloride Concentration. Varying volumes of 2% hydroxylammonium chloride solution were added to sample solutions containing 35 μg of copper. Copper(II) was completely reduced to copper(I) by addition of 0.5—5.0 cm^3 of the 2% solution. For assured functioning, 2.0 cm^3 of the 2% solution of reducing agent was selected.

Effect of PPDT and TPB Concentrations. Extractions were carried out at fixed pH but different PPDT concentrations. It was observed that extractions were quntitative for 1.2—5.0 cm^3 of 0.04% PPDT solution. Similar studies with sodium tetraphenylborate showed that the absorbance remained constant for 0.8—4.0 cm^3 of 1% TPB solution. Thus 2.0 cm^3 of 0.04% PPDT solution and 2.0 cm^3 of 1% TPB solution were selected for the extraction of complex (Figs. 2—3).

Effect of Addition of Naphthalene. The amount of

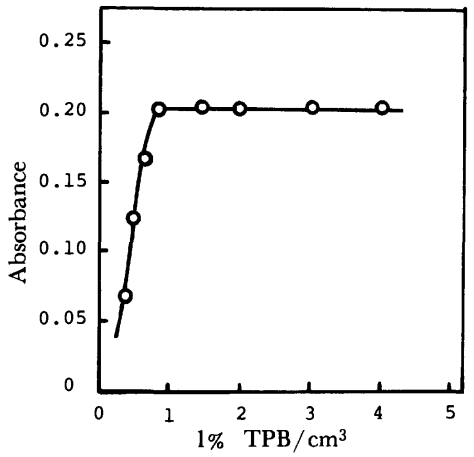

Fig. 3. Effect of TPB concentration.
Conditions were the same as those in Fig. 2.

naphthalene was varied from 0.2 to 1.5 g and extractions were carried out by the general procedure. The extraction was quantitative in the range 0.3—1.5 g of naphthalene, but beyond this range, naphthalene interfered with the determination of copper due to its deposition on the burner head. Hence 0.7 g naphthalene was selected as a suitable amount.

Effect of Digestion and Shaking Times. A solution containing the Cu(I)-PPDT-TPB complex at pH 5.8 was digested at 50—60 °C. The digestion time is not critical, 1 min being sufficient for completion of the complex formation. The extraction of complex into molten naphthalene (81—85 °C) was found to be very rapid and no change was observed when the shaking time was varied from 3 to 120 s.

Effect of Electrolytes. The extraction of complex was carried out in the presence of sodium chloride, potassium nitrate, sodium acetate, ammonium acetate, ammonium chloride, or sodium sulfate (0.02—1.0 M). It was found that ammonium acetate is the most suitable for the formation and extraction of complex when its ionic strength is in the range 0.05—1.0 M. In the absence of ammonium acetate, the pH range for extraction was 3.1—8.2 and the absorbance was low, indicating a salting-out effect.

Effect of the Volume of Aqueous Phase. Since the organic/aqueous phase ratio is an important factor in such procedures, the effect of the latter on the extraction of complex was studied. The extraction is quantitative when the volume of aqueous phase does not exceed 50 cm^3 (Fig. 4).

Choice of Solvent. Various organic solvents were tried to dissolve an extracted mixture of complex and naphthalene. The complex is insoluble in benzene, toluene, xylene, chlorobenzene, *o*-dichlorobenzene, nitrobenzene, chloroform, carbon tetrachloride, 1,2-dichloroethane, isopentyl acetate, diethyl ether, 1-pentanol, dioxane or isobutyl methyl ketone (IBMK), but it is soluble in dimethyl sulfoxide, propylene carbonate, acetonitrile, or *N,N*-dimethylformamide, which are miscible with water. Dimethyl sulfoxide and propyl-

a) pH: 5.8; 0.04% PPDT: 3.0 cm³; 1% TPB: 2.0 cm³; naphthalene: 0.7 g; 1 M CH_3COONH_4: 3.0 cm³; 2% hydroxylammonium chloride: 2.0 cm³. b) Extraction at pH 3.0.

ene carbonate are better solvents, but they are expensive and viscous. Acetonitrile may be used but the absorbance is rather low in this solvent. Hence *N,N*-dimethylformaide is preferable for dissolving the metal complex and naphthalene.

Calibration Curve. For the optimum conditions specified above, a calibration curve was constructed at 324.7 nm. It was found to be linear over the concentration range 2.5—80.0 μg of copper in 10 cm³ of *N,N*-dimethylformamide solution. Ten repeat analyses on a sample solution containing 35 μg of copper gave a mean absorbance of 0.205 with a standard deviation of 0.0017 and a relative standard deviation of 0.83%.

Effect of Diverse Ions. Sample solutions containing 35 μg of copper and various amounts of different alkali metal salts or metal ions were prepared, and the determination of copper was carried out by the general procedure. Tolerance limits of diverse ions are given in Table 1. Naturally the method is fairly selective and may be applied to determination of copper in various complex materials.

Determination of Copper in Standard Reference Materials. A 0.05—0.5 g sample of alloy was completely dissolved in 20—30 cm³ of hydrochroric acid (1+1) on a water bath. Then 3—5 cm³ of 30% hydrogen peroxide were added to it. The excess of peroxide was decomposed by heating the solution on a water bath. The mixture was cooled and filtered through a filter paper. The filtrate was diluted to 500 cm³ with distilled water in a flask. An appropriate volume of this solution was taken and the copper was determined by the general procedure. The results are given in Table 2.

Determination of Copper in Human Hair. A 10.0 g sample of human hair was taken and dissolved in 30 cm³ of concentrated nitric acid and 3.0 cm³ of concentrated perchloric acid by heating. This solution was cooled, filterd, and diluted to 200 cm³ with distilled water in a standard flask. An aliquot of this solution was taken and the copper was determined by the general procedure. The results in Table 2 are in reasonable agreement with those obtained by the standard

(Received August 3, 1984)

Seven optically active cobalt(III) complexes of [Co(bidentate-*N,S* or -*N,Se*)$(tn)_2$] type were prepared for the first time; bidentate-*N,S* or -*N,Se* denotes 2-aminoethanethiolato (aet), 2-aminoethaneselenolato (aes), 2-aminoethanesulfenato (aese), 2-aminoethanesulfinato (aesi), 2-(methylthio)ethylamine (mea), and 2-(methylseleno)ethylamine (mseea). These complexes were characterized from their absorption, CD, and ^{1}H NMR spectra. All complexes obtained were assigned to the *Λ* configuration. The $(+)^{CD}_{550}$ mea isomer took selectively the *Λ*-(*R*) configuration in solution, while the $(+)^{CD}_{550}$ mseea isomer a mixture of the *Λ*-(*R*) and *Λ*-(*S*) ones. The absorption and CD spectra of the complexes are discussed in comparison with those of the corresponding bis(ethylenediamine)cobalt(III) complexes. The *Λ*-(*R*)- and *Λ*-(*S*)-[Co(aese)$(tn)_2$]$^{2+}$ isomers showed the CD spectral change with time and it was suggested that the epimerization at sulfur was accompanied by the racemization of the skew pair of chelate rings.

Bis(ethylenediamine)cobalt(III) complexes with a bidentate-*N,S* or -*N,Se* ligand have extensively been investigated,[1–12] and these complexes showed some unique spectrochemical and stereochemical properties.[4–9] However, it has not been clarified whether the properties depend on the sulfur- or selenium-containing ligand itself or on the ethylenediamine chelate ring. Therefore, it is worthwhile to study the corresponding cobalt(III) complexes with six-membered trimethylenediamine chelate ring, [Co(bidentate-*N,S* or -*N,Se*)$(tn)_2$]. No report has been presented for the trimethylenediamine complexes up to now.

In this paper, the bis(trimethylenediamine)cobalt(III) complexes with 2-aminoethanethiolato, [Co(aet)$(tn)_2$]$^{2+}$, and 2-aminoethaneselenolato, [Co(aes)$(tn)_2$]$^{2+}$, were prepared and optically resolved. The other optically active cobalt(III) complexes, $(+)^{CD}_{550}$·$(+)^{CD}_{370}$- and $(+)^{CD}_{550}$·$(-)^{CD}_{370}$-[Co(aese)$(tn)_2$]$^{2+}$, $(+)^{CD}_{500}$-[Co(aesi)$(tn)_2$]$^{2+}$, and $(+)^{CD}_{550}$-[Co(mea)$(tn)_2$]$^{3+}$, were derived from $(+)^{CD}_{600}$-[Co(aet)$(tn)_2$]$^{2+}$, and $(+)^{CD}_{550}$-[Co(mseea)$(tn)_2$]$^{3+}$ was derived from $(+)^{CD}_{600}$-[Co(aes)$(tn)_2$]$^{2+}$.[13] The absorption and CD spectra of these complexes were discussed in comparison with those of the corresponding bis(ethylenediamine)cobalt(III) complexes. The rate constants of the epimerization at sulfur and the racemization of the skew pair of chelate rings of the complex were estimated for $(+)^{CD}_{550}$·$(+)^{CD}_{370}$- and $(+)^{CD}_{550}$·$(-)^{CD}_{370}$-[Co(aese)$(tn)_2$]$^{2+}$.

Experimental

1) Preparation and Resolution of the Complexes. a) $(+)^{CD}_{600}$*-[Co(aet)$(tn)_2$]$(ClO_4)_2$*: To a deoxygenated solution containing 4.0 g of $CoCl_2 \cdot 6H_2O$ in 15 cm^3 of water were successively added with stirring deoxygenated solutions containing 1.9 g of $(NH_2CH_2CH_2S\text{-})_2 \cdot 2HCl$ in 15 cm^3 of water and 4.0 g of $NH_2(CH_2)_3NH_2$ in 40 cm^3 of water. The mixture was continuously stirred under nitrogen atmosphere for 40 min in an ice bath. The dark brown solution was filtered and to the filtrate was added a solution containing 15 g of NaI in 50 cm^3 of ice-cold water. The solution was kept in a refrigerator overnight. The resultant dark brown crystals were collected by filtration and washed with ice-cold ethanol and ether. Found: C, 17.86; H, 4.89; N, 13.03%. Calcd for [Co(aet)$(tn)_2$]I_2=$C_8H_{26}N_5SCoI_2$: C, 17.88; H, 4.87; N, 13.03%.

One point five gram of [Co(aet)$(tn)_2$]I_2 was dissolved in 70 cm^3 of ice-cold water. To this were added with stirring a solution containing 1.0 g of $K_2[Sb_2(d\text{-}tart)_2] \cdot H_2O$ in 20 cm^3 of water and 20 cm^3 of ethanol. The solution was stirred for 20 min in an ice bath, though fine reddish brown crystals began to appear after a few minutes. The crystals were collected by filtration and washed with ethanol and ether. Found: C, 22.60; H, 3.88; N, 8.26%. Calcd for [Co(aet)$(tn)_2$][Sb_2(d-tart)$_2$]·$1.5H_2O$=$C_{16}H_{30}N_5O_{12}SCoSb_2 \cdot 1.5H_2O$: C, 22.72; H, 3.93; N, 8.28%.

Zero point seven gram of $(+)^{CD}_{600}$-[Co(aet)$(tn)_2$][Sb_2(d-tart)$_2$]·$1.5H_2O$ was dissolved in 20 cm^3 of an aqueous solution containing 4.0 g of $NaClO_4$ with stirring in an ice bath. When the solution was continuously stirred for 10 min, fine dark brown crystals appeared. The resultant crystals were collected by filtration and washed with ice-cold ethanol and ether. The concentration of this isomer was evaluated from the extinction coefficient of the racemic iodide salt.

b) $(+)^{CD}_{600}$*-[Co(aes)$(tn)_2$]$(ClO_4)_2$*: This complex was prepared by a procedure similar to that used for $(+)^{CD}_{600}$-[Co(aet)$(tn)_2$]$(ClO_4)_2$ described in *a)*, using $(NH_2CH_2CH_2Se)_2 \cdot H_2SO_4$[14] instead of $(NH_2CH_2CH_2S\text{-})_2 \cdot 2HCl$. The concentration of this isomer was evaluated from the extinction coefficient of the racemic iodide salt. Found: C, 15.69; H, 4.91; N, 11.86%. Calcd for [Co(aes)$(tn)_2$]$I_2 \cdot H_2O$=$C_8H_{26}N_5CoSeI_2 \cdot H_2O$: C, 15.96; H, 4.69; N, 11.63%. Found: C, 21.19; H, 3.73; N, 7.72%. Calcd for [Co(aes)$(tn)_2$][Sb_2(d-tart)$_2$]·$2H_2O$=$C_{16}H_{30}N_5O_{12}CoSeSb_2 \cdot 2H_2O$: C, 21.31; H, 3.80; N, 7.77%.

c) $(+)^{CD}_{550}$·$(+)^{CD}_{370}$*-[Co(aese)$(tn)_2$]$(ClO_4)_2$ and* $(+)^{CD}_{550}$·$(-)^{CD}_{370}$*-[Co(aese)$(tn)_2$]I_2*: The preparation procedure was operated without light. To a solution containing 0.2 g of $(+)^{CD}_{600}$-[Co(aet)$(tn)_2$]$(ClO_4)_2$ in 2 cm^3 of ice-cold water was added a calculated amount of 2% H_2O_2 (0.6 cm^3). The mixture was stirred for 20 min in an ice bath and the resultant precipitate of the $(+)^{CD}_{550}$·$(+)^{CD}_{370}$ aese isomer was collected by filtration. To the filtrate was soon added 0.5 g of NaI and the solution was stirred for 10 min in an ice bath. The resultant precipitate, which was found from the CD measurement to be the $(+)^{CD}_{550}$·$(-)^{CD}_{370}$ aese isomer containing a small amount of the $(+)^{CD}_{550}$·$(+)^{CD}_{370}$ one, was filtered off. To the filtrate were added 1.0 g of NaI and a large amount of 2-propanol–ether (2:1), and

then the solution was stood in a refrigerator overnight. The resultant orange-red precipitate of the $(+)^{CD}_{550}\cdot(-)^{CD}_{370}$ aese isomer was collected by filtration. The formation ratio of the two isomers, $(+)^{CD}_{550}\cdot(+)^{CD}_{370}$:$(+)^{CD}_{550}\cdot(-)^{CD}_{370}$, was about 6:5, which was evaluated from the CD spectra of the reaction solution. Found for $(+)^{CD}_{550}\cdot(+)^{CD}_{370}$ isomer: C, 19.31; H, 5.23; N, 14.03%. Calcd for $[Co(aese)(tn)_2](ClO_4)_2=C_8H_{26}N_5O_9SCl_2Co$: C, 19.28; H, 5.26; N, 14.05%. Found for $(+)^{CD}_{550}\cdot(-)^{CD}_{370}$ isomer: C, 16.61; H, 4.60; N, 12.04%. Calcd for $[Co(aese)(tn)_2]I_2\cdot H_2O=C_8H_{26}N_5OSCoI_2\cdot H_2O$: C, 16.83; H, 4.94; N, 12.26%.

d) $(+)^{CD}_{600}$*-[Co(aesi)(tn)$_2$](ClO$_4$)$_2$*: To a solution containing 0.1 g of $(+)^{CD}_{600}$-$[Co(aet)(tn)_2](ClO_4)_2$ in 2 cm^3 of ice-cold water was added an excess amount of 10% H_2O_2 (0.6 cm^3), followed by the addition of 0.3 cm^3 of 60% $HClO_4$. The solution was stirred for 20 min in an ice bath and stood in a refrigerator for 2 d. The solution was poured onto a column of QAE-Sephadex A-25 (ClO_4^- from, 2 cm×20 cm) and the adsorbed band was eluted with water. The eluate was concentrated to a small volume with a rotary evaporator and to this was added an appropriate amount of ethanol. The solution was kept in a refrigerator for several days and the resultant crystals were collected by filtration. Found: C, 18.59; H, 5.12; N, 13.51%. Calcd for $[Co(aesi)(tn)_2](ClO_4)_2=C_8H_{26}N_5O_{10}SCl_2Co$: C, 18.68; H, 5.09; N, 13.61%.

e) $(+)^{CD}_{550}$*-[Co(mea)(tn)$_2$](NO$_3$)$_3$*. To a solution containing 0.1 g of $(+)^{CD}_{600}$-$[Co(aet)(tn)_2](ClO_4)_2$ in 2 cm^3 of ice-cold water was added 2 cm^3 of ice-cold dimethyl sulfate. When the mixture was allowed to stand in a refrigerator overnight, it was separated into two layers. The red upper layer was poured onto a column of QAE-Sephadex A-25 (NO_3^- form, 2 cm×20 cm) and the adsorbed band was eluted with water. The eluate was concentrated to a small volume with a rotary evaporator and to this was added a small amount of ethanol. After cooling in a refrigerator overnight, the resultant crystals were collected by filtration and washed with ethanol and ether. Found: C, 22.01; H, 6.09; N, 22.77%. Calcd for $[Co(mea)(tn)_2](NO_3)_3\cdot0.5H_2O=C_9H_{29}N_8O_9SCo\cdot0.5H_2O$: C, 21.91; H, 6.13; N, 22.71%.

f) $(+)^{CD}_{550}$*-[Co(mseea)(tn)$_2$](NO$_3$)$_3$*. This complex was prepared by a procedure similar to that used for $(+)^{CD}_{550}$-$[Co(mea)(tn)_2](NO_3)_3$ described in *e)*, using $(+)^{CD}_{600}$-$[Co(aes)(tn)_2](ClO_4)_2$ instead of $(+)^{CD}_{600}$-$[Co(aet)(tn)_2](ClO_4)_2$. Found: C, 19.10; H, 5.74; N, 19.61%. Calcd for $[Co(mseea)(tn)_2](NO_3)_3\cdot2H_2O=C_9H_{29}N_8O_9CoSe\cdot2H_2O$: C, 19.05; H, 5.86; N, 19.75%.

g) Λ*-[Co(aet)(en)$_2$](ClO$_4$)$_2$,* Λ*-(R)- and* Λ*-(S)-[Co(aese)(en)$_2$](ClO$_4$)$_2$,* Λ*-[Co(aesi)(en)$_2$](ClO$_4$)$_2$, and* Λ*-(R)-[Co(mea)(en)$_2$](NO$_3$)$_3$.* These bis(ethylenediamine)cobalt(III) complexes were prepared by the methods described in previous papers.[8,11]

2) Measurements. The electronic absorption spectra were recorded with a JASCO UVIDEC-1 spectrophotometer, and the CD spectra with a JASCO J-20 spectropolarimeter. All measurements were carried out in an aqueous solution at room temperature. The ^1H NMR spectra were recorded in deuterium oxide on a JEOL JNM-FX-100 NMR spectrometer at probe temperature. Sodium 2,2-dimethyl-2-silapentane-5-sulfonate (DSS) was used as an internal reference. The absorption and CD spectral changes for the epimerization and racemization were followed at 24 °C in the room light which was (4.7±0.3)×10^2 lx with a lux-meter ANA-999 of Tokyo Photo-electric Co., Ltd.

Results and Discussion

Absorption and CD Spectra. Figures 1—4 and Tables 1 and 2 show the absorption and CD spectra of the bis(trimethylenediamine)cobalt(III) complexes. The absorption spectral behavior of the present complexes with a sulfur- or selenium-containing ligand is quite similar to that of the corresponding [Co(bidentate-*N,S* or -*N,Se*)(en)$_2$] type complexes.[4-11] All com-

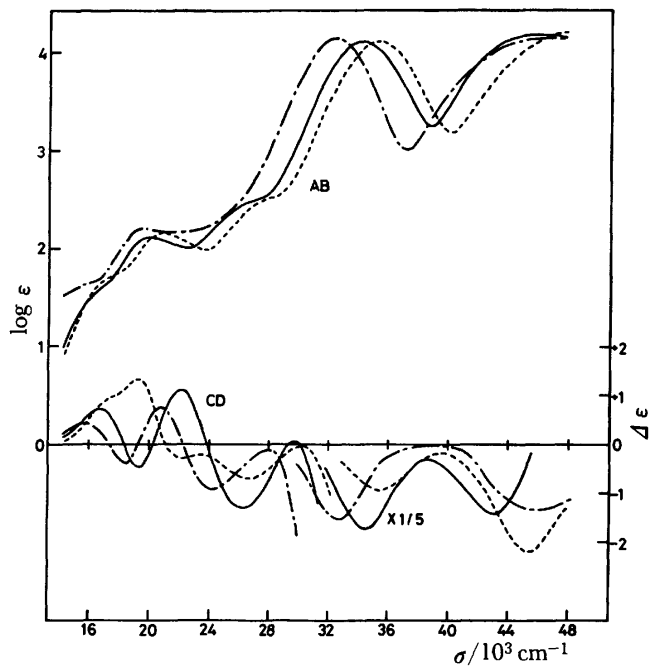

Fig. 1. Absorption and CD spectra of $(+)^{CD}_{600}$-$[Co(aet)(tn)_2]^{2+}$ (——), $(+)^{CD}_{600}$-$[Co(aes)(tn)_2]^{2+}$ (—·—), and Λ-$[Co(aet)(en)_2]^{2+}$ (-----).

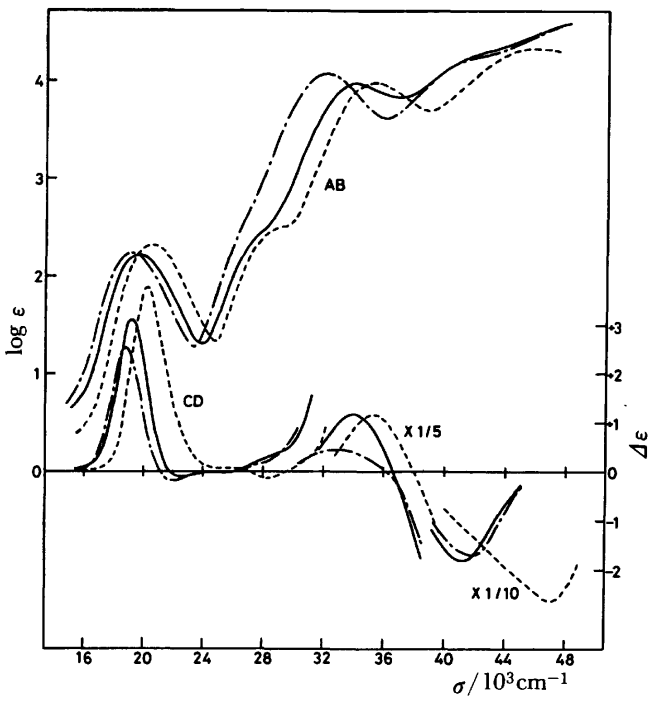

Fig. 4. Absorption and CD spectra of $(+)^{CD}_{550}$-[Co-(mea)(tn)$_2$]$^{3+}$ (——), $(+)^{CD}_{550}$-[Co(mseea)(tn)$_2$]$^{3+}$ (—·—), and *Λ*-(*R*)-[Co(mea)(en)$_2$]$^{3+}$ (-----).

plexes show the chalcogen-to-metal charge transfer band at 32—35×10^3 cm^{-1}, which shifts to lower energy than that of the corresponding bis(ethylenediamine) complexes. As for [Co(aese)(tn)$_2$]$^{2+}$, another characteristic charge transfer band appears at *ca.* 27×10^3 cm^{-1}, as in the case for [Co(aese)(en)$_2$]$^{2+}$.[6,8-10] The first absorption band of the [Co(bidentate-*N,S* or -*N,Se*)(tn)$_2$] type complexes shifts to lower energy than that of the corresponding [Co(bidentate-*N,S* or -*N,Se*)(en)$_2$] ones,[4-11] in analogous with the fact that the [Co(L)-(tn)$_2$] type complexes show the first absorption band at lower energy as compared with that of the corresponding [Co(L)(en)$_2$] ones; L denotes a bidentate ligand such as glycinate and oxalate.[15,16]

The *Δ* and *Λ* isomers are possible for each of [Co-(aet)(tn)$_2$]$^{2+}$, [Co(aes)(tn)$_2$]$^{2+}$, and [Co(aesi)(tn)$_2$]$^{2+}$. As shown in Fig. 1, the CD spectrum of $(+)^{CD}_{600}$-[Co(aet)-(tn)$_2$]$^{2+}$ agrees well with that of *Λ*-[Co(aet)(en)$_2$]$^{2+}$,[4,8] except for the two bands at higher energy in the first absorption band region (*ca.* 19 and 22×10^3 cm^{-1}). Furthermore, the stoichiometric oxidation of $(+)^{CD}_{600}$-[Co-(aet)(tn)$_2$]$^{2+}$ generated *Λ*-(*R*)- and *Λ*-(*S*)-[Co(aese)(tn)$_2$]$^{2+}$ (*vide infra*), as in the oxidation reaction of *Λ*-[Co(aet)-(en)$_2$]$^{2+}$.[7-9] These facts suggest that the starting thiolato complex, $(+)^{CD}_{600}$-[Co(aet)(tn)$_2$]$^{2+}$, takes the *Λ* configuration. As shown in Fig. 1, $(+)^{CD}_{600}$-[Co(aes)(tn)$_2$]$^{2+}$ exhibits a CD spectra quite similar to that of *Λ*-$(+)^{CD}_{600}$-[Co(aet)(tn)$_2$]$^{2+}$ over the whole region, and then can be assigned to the *Λ* configuration. The $(+)^{CD}_{500}$ aesi isomer, which is the oxidation product from *Λ*-$(+)^{CD}_{600}$-[Co(aet)(tn)$_2$]$^{2+}$, shows a positive CD band in the first absorption band region (Fig. 2), being also assigned to the *Λ* configuration. These facts indicate that the oxidation reaction for the starting thiolato complex proceeded with retention of its absolute configuration, as in the case for the bis(ethylenediamine) cobalt-(III) complexes.[7-9,11] In the present bis(trimethylenediamine)cobalt(III) complexes, *Λ*-[Co(aet) (tn)$_2$]$^{2+}$, *Λ*-[Co(aes)(tn)$_2$]$^{2+}$, and *Λ*-[Co(aesi)(tn)$_2$]$^{2+}$, which have no chirality due to the coordinated chalcogen atom, commonly show a negative CD band in the chalcogen-to-metal charge transfer band region similar to that of the corresponding bis(ethylenediamine) complexes, though the CD spectra in the first absorption band region are different from one another (Fig. 1 and 2).[4,7,8,11] This may suggest that the configurational chirality due to the skew pair of chelate rings can be deduced from the CD pattern in the chalcogen-to-metal charge transfer band region as for the bis-(diamine)cobalt(III) complexes with the aet, aes or aesi ligand.

Taking the asymmetric chalcogen donor atom, (*R*) and (*S*), into consideration, four isomers, *Δ*-(*R*), *Δ*-(*S*), *Λ*-(*R*), and *Λ*-(*S*), are possible for each of [Co(aese)-(tn)$_2$]$^{2+}$, [(Co(mea)(tn)$_2$]$^{3+}$, and [Co(mseea)(tn)$_2$]$^{3+}$. The two isomers, $(+)^{CD}_{550}$·$(+)^{CD}_{370}$- and $(+)^{CD}_{550}$·$(-)^{CD}_{370}$-[Co(aese)-(tn)$_2$]$^{2+}$, which are formed by the stoichiometric oxidation reaction of $(+)^{CD}_{600}$-[Co(aet)(tn)$_2$]$^{2+}$ with aqueous H_2O_2, show the CD spectra quite similar to those of *Λ*-(*S*)- and *Λ*-(*R*)-[Co(aese)(en)$_2$]$^{2+}$, respectively, over the whole region (Fig. 3).[8,9] This fact suggests that the $(+)^{CD}_{550}$·$(+)^{CD}_{370}$ and $(+)^{CD}_{550}$·$(-)^{CD}_{370}$ aese isomers take the

TABLE 1. ABSORPTION DATA OF [Co(bidentate-*N*,*S* or -*N*,*Se*)(tn)$_2$] TYPE COMPLEXES

Complex	First band	Second band	Charge transfer band

	22.47 (−0.11)		41.32 (−18.4)
$(+)^{CD}_{550}$-[Co(mseea)(tn)$_2$]$^{3+}$	18.80 (+2.57)		32.15 (+2.31)
	21.98 (−0.18)		41.59 (−17.2)

Wave numbers and $\Delta\varepsilon$ values (in parentheses) are given in 10^3 cm^{-1} and mol^{-1} dm^3 cm^{-1}, respectively. Sh denotes a shoulder.

Λ-(*S*) and *Λ*-(*R*) configurations, respectively. This assignment is confirmed by comparing the vicinal CD due to the asymmetric sulfur atom and the configurational CD due to the skew pair of chelate rings for [Co(aese)(tn)$_2$]$^{2+}$ with those for [Co(aese)(en)$_2$]$^{2+}$. Figure 5 shows the (*S*) vicinal and the *Λ* configurational CD curves calculated from the observed CD curves of *Λ*-(*R*)- and *Λ*-(*S*)-[Co(aese)(tn)$_2$]$^{2+}$, together with those calculated from *Λ*-(*R*)- and *Λ*-(*S*)-[Co(aese)(en)$_2$]$^{2+}$. The (*S*) vicinal CD curve for [Co(aese)(tn)$_2$]$^{2+}$ is quite similar to that for [Co(aese)(en)$_2$]$^{2+}$, showing two bands, (−) and (+), from lower energy in the first absorption band region, and two bands, (+) and (−), from lower energy in the sulfur-to-metal charge transfer band region. A similar relation is also observed for the *Λ* configurational CD curves; the dominant positive CD band is observed at the lower energy side of the first absorption band region and a negative band in the sulfenato charge transfer band region (*ca.* 28× 10^3 cm^{-1}), though the CD intensity for [Co(aese)(tn)$_2$]$^{2+}$ is weaker than that for [Co(aese)(en)$_2$]$^{2+}$ in the first absorption band region. The formation ratio of the two isomers, *Λ*-(*R*):*Λ*-(*S*), is about 5:6 for [Co(aese)(tn)$_2$]$^{2+}$ and this ratio is in contrast to the case for [Co(aese)(en)$_2$]$^{2+}$ (*Λ*-(*R*):*Λ*-(*S*)=3:1).[8] This may be due to the absence of the effective intramolecular hydrogen bond between the sulfenato oxygen atom and the adjacent amine proton in [Co(aese)(tn)$_2$]$^{2+}$, because of the flexibility of the six-membered trimethylenediamine cheate ring.

Each of $(+)^{CD}_{550}$-[Co(mea)(tn)$_2$]$^{3+}$ and $(+)^{CD}_{550}$-[Co(mseea)(tn)$_2$]$^{3+}$, which is the methylation product of *Λ*-[Co(aet)(tn)$_2$]$^{2+}$ and *Λ*-[Co(aes)(tn)$_2$]$^{2+}$, respectively, shows a major positive CD band in the first absorp-

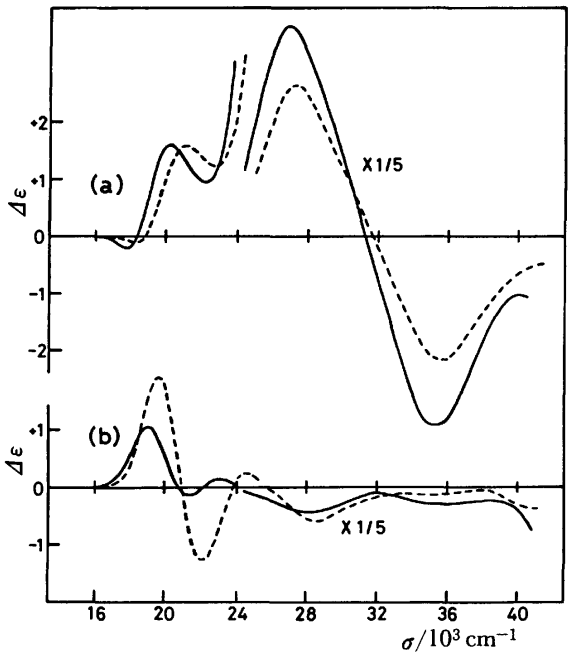

Fig. 5. (a): Vicinal CD curves ($\Delta\varepsilon(S)=1/2\{\Delta\varepsilon[\Lambda\text{-}(S)]-\{\Delta\varepsilon[\Lambda\text{-}(R)]\}$) of [Co(aese)(tn)$_2$]$^{2+}$ (——) and [Co(aese)(en)$_2$]$^{2+}$ (-----).
(b): Configurational CD curves ($\Delta\varepsilon(\Lambda)=1/2\{\Delta\varepsilon[\Lambda\text{-}(S)]+\{\Delta\varepsilon[\Lambda\text{-}(R)]\}$) of [Co(aese)(tn)$_2$]$^{2+}$ (——) and [Co(aese)(en)$_2$]$^{2+}$ (-----).

tion band region, as well as Λ-(+)$^{CD}_{500}$-[Co(mea)(en)$_2$]$^{3+}$ and Λ-(+)$^{CD}_{500}$-[Co(mseea)(en)$_2$]$^{3+}$ (Fig. 4).[4,7,8] Therefore, it is suggested that no isomerization occurs during the methylation procedure and the (+)$^{CD}_{550}$ mea and mseea isomers take the Λ configuration. The ^{1}H NMR spectrum of Λ-(+)$^{CD}_{550}$-[Co(mea)(tn)$_2$]$^{3+}$ exhibits a single peak in the methyl protons region (2.26 ppm from DSS), suggesting that the (+)$^{CD}_{550}$ mea isomer takes either the (*R*) or (*S*) configuration in solution. It is probable that the Λ-(+)$^{CD}_{550}$ mea isomer prefers to the (*R*) configuration as Λ-(+)$^{CD}_{500}$-[Co(mea)(en)$_2$]$^{3+}$,[4,8] because there is a nonbonded interaction between the methyl group and the adjacent diamine chelate ring when Λ-[Co(mea)(tn)$_2$]$^{3+}$ takes the (*S*) configuration. In the sulfur-to-metal charge transfer band region, Λ-(+)$^{CD}_{550}$-[Co(mea)(tn)$_2$]$^{3+}$ shows a positive CD band similar to that of Λ-(*R*)-[Co(mea)(en)$_2$]$^{3+}$ (Fig. 4). The CD band in this region is closely related to the chirality due to the chalcogen donor atom.[8] From these facts, it is suggested that (+)$^{CD}_{550}$-[Co(mea)(tn)$_2$]$^{3+}$ takes selectively the Λ-(*R*) configuration in solution. For Λ-(+)$^{CD}_{550}$-[Co(mseea)(tn)$_2$]$^{3+}$, the ^{1}H NMR spectrum shows two peaks in the methyl protons region (2.19 and 2.32 ppm, in the ratio 4:1). This indicates that the Λ-(+)$^{CD}_{550}$ mseea isomer takes a mixture of the Λ-(*R*) and Λ-(*S*) configurations in solution, contrary to the case of Λ-(+)$^{CD}_{550}$-[Co(mea)(tn)$_2$]$^{3+}$, although the (*R*) configuration seems to be dominant for the Λ-(+)$^{CD}_{550}$ mseea isomer. It is considered that the nonbonded interaction between the methyl group and the adjacent diamine chelate ring in Λ-(*S*)-[Co(mseea)(tn)$_2$]$^{3+}$ is not so conspicuous as that in Λ-(*S*)-[Co(mea)(tn)$_2$]$^{3+}$, because of the longer bond lengths of Co–Se and Se–C than those of Co–S and S–C.[8] The CD spectrum of Λ-(+)$^{CD}_{550}$-[Co(mseea)(tn)$_2$]$^{3+}$ shows a positive band in the chalcogen-to- metal charge transfer band region (*ca.* 32×10^3 cm^{-1}) as well as Λ-(*R*)-[Co(mea)(tn)$_2$]$^{3+}$, though the CD intensity of the former is weaker than that of the latter (Fig. 4). This supports that the Λ-(+)$^{CD}_{550}$ mseea isomer has dominantly the (*R*) configuration, because a negative CD band will appear in the chalcogen-to-metal charge transfer band region if not so.[8,12] The Λ-(+)$^{CD}_{550}$ mseea isomer chromatographed on SP-Sephadex column gave only one adsorbed band and all of its fractions showed the same CD spectra in the whole region. This suggests that the inversion at selenium in Λ-(+)$^{CD}_{550}$-[Co(mseea)(tn)$_2$]$^{3+}$ occurs as in the case for thioether or selenoether cobalt(III) complexes.[17–19]

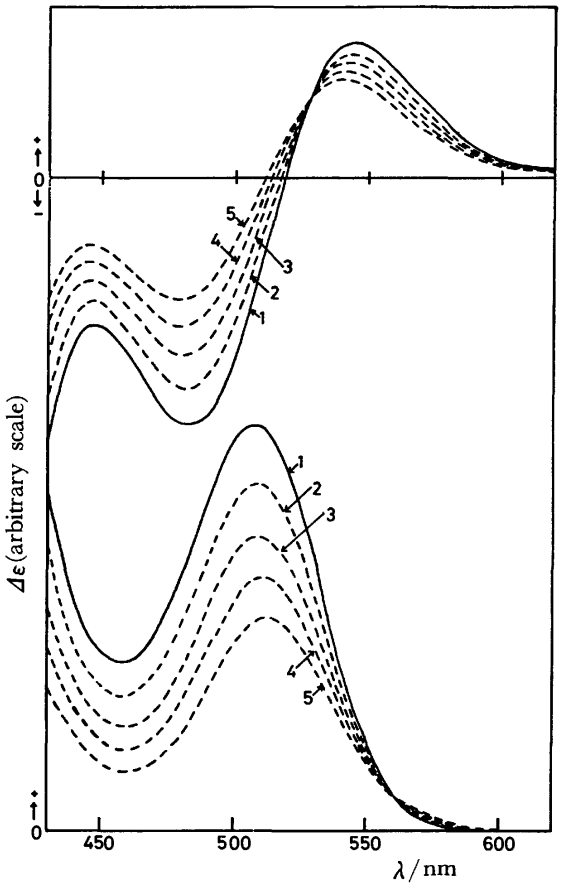

Fig. 6. CD spectral change with time for Λ-(*R*)-[Co(aese)(tn)$_2$]$^{2+}$ (upper) and Λ-(*S*)-[Co(aese)(tn)$_2$]$^{2+}$ (lower) in water at 24 °C. The curves 1—5 were measured at 0, 60, 120, 180, and 240 min, respectively.

Epimerization and Racemization of Λ-(R)- *and* Λ-(S)-*[Co(aese)(tn)$_2$]$^{2+}$.* Of the bis(trimethylenediamine)-cobalt(III) complexes in the present work, Λ-(*R*)- and Λ-(*S*)-[Co(aese)(tn)$_2$]$^{2+}$ exhibited the CD spectral change with time in water. Figure 6 shows the CD spectral change of Λ-(*R*)-[Co(aese)(tn)$_2$]$^{2+}$ (2.72×10^{-3} mol dm^{-3}) and Λ-(*S*)-[Co(aese)(tn)$_2$]$^{2+}$ (3.05×10^{-3} mol dm^{-3}) at 24 °C in the room light. Though the absorption spectral change was also observed for the isomers, the change

was negligibly small as compared with the CD spectral change. The isodichroic point was recognized at 528 nm for the *Λ*-(*R*) isomer and at 561 nm for the *Λ*-(*S*) one for at least 1.5 half-lives. These facts indicate that not only the epimerization at sulfur but the racemization of the skew pair of chelate rings takes place for these isomers under these conditions. The CD intensity change was also observed in the dark. However, this change was only 15% in the room light at the same intervals, and the rate constant could not be obtained because of the decomposition for the complex. Thus, the rate constants for the epimerization and racemization were tentatively estimated from the CD spectral change in the room light. The CD intensity change at 455 nm or 483 nm ($\Delta\varepsilon[\Lambda\text{-}(R)]=-\Delta\varepsilon[\Lambda\text{-}(S)]$) should be regarded as being caused by the epimerization at sulfur and that at 543 nm ($\Delta\varepsilon[\Lambda\text{-}(R)]=\Delta\varepsilon[\Lambda\text{-}(S)]$) by the racemization of the skew pair of chelate rings (Fig. 3). At these wavelengths, the plots of the logarithmic CD intensity change against time gave a straight line, from which the first-order rate constant was obtained; $4.9\times10^{-5}\,s^{-1}$ for the *Λ*-(*R*) isomer and $6.7\times10^{-5}\,s^{-1}$ for the *Λ*-(*S*) one at 455 nm, and $5.0\times10^{-5}\,s^{-1}$ for the *Λ*-(*R*) isomer and $7.2\times10^{-5}\,s^{-1}$ for the *Λ*-(*S*) one at 483 nm. These values may be taken as about the same, considering that the epimerization is affected by the light. The rate constant for the racemization obtained from the CD spectral change at 543 nm is $2.4\times10^{-5}\,s^{-1}$ for both of the *Λ*-(*R*) and *Λ*-(*S*) isomers. This value is smaller than that of the epimerization at sulfur and it is suggested that the epimerization at sulfur was accompanied by the racemization of the skew pair of chelate rings.

Rate and Mechanism of Ligand Exchange of Several Tris(β-diketonato)-iron(III) Complexes with 4-Isopropyltropolone in Carbon Tetrachloride

Tatsuya SEKINE* and Kazuho INABA
Department of Chemistry, Science University of Tokyo, Kagurazaka, Shinjuku-ku, Tokyo 162
(Received September 12, 1984)

The rate of ligand exchange of seven tris(β-diketonato)iron(III) in carbon tetrachloride with 4-isopropyltropolone was measured by a spectrometric method in order to determine the effect of the chemical properties of the leaving ligand on the reaction mechanism. It was found from the dependence of the rate on the leaving and entering ligands and also from the values of $\Delta H^{\neq}$ and $\Delta S^{\neq}$ that the exchange reaction of iron(III) complexes with acetylacetone and its two phenyl-substituted derivatives proceeds by a dissociative mechanism. It was also found that reactions with trifluoroacetylacetone and its phenyl- and 2-thienyl-substituted derivatives proceeds by an associative mechanism. An hexafluoroacetylacetonato complex formed an intermediate with the entering ligand in the first stage of the reaction and then a ligand exchange occured. It was concluded from these results that the ligand exchanges of more stable complexes were controlled by the break of a leaving ligand. Less stable ones were controlled by bond formation with the entering ligand.

In previous studies,[1-3] it was found that the ligand-exchange reaction producing a less stable complex of tris(β-diketonato)iron(III) in carbon tetrachloride proceeded by a dissociative mechanism while the one producing a more-stable complex proceeded by an interchange mechanism. In the present paper, the ligand exchange is further studied with seven tris(β-diketonato)iron(III) using only one entering ligand, 4-isopropyltropolone, which forms a complex more stable than any of these starting compounds. The effect of the nature of the leaving ligand on the reaction mechanism is also considered.

Experimental

All procedures were similar to ones described previously.[1] Iron(III) complexes with acetylacetone (2,4-pentanedione; Hacac), benzoylacetone (1-phenyl-1,3-butanedione; Hbza), dibenzoylmethane (1,3-diphenyl-1,3-propanedione; Hdbm), trifluoroacetylacetone (1,1,1-trifluoro-2,4-pentanedione; Htfa), benzoyltrifluoroacetone (1-phenyl-4,4,4-trifluoro-1,3-butanedione; Hbfa), and 2-thenoyltrifluoroacetone (1-(2-thienyl-)-4,4,4-trifluoro-1,3-butanedione; Htta) were synthesized by a conventional method.[4] The iron(III) complex with hexafluoroacetylacetone (1,1,1,5,5,5-hexafluoro-2,4-pentanedione; Hhfa) was supplied by Tokyo Kasei Co., Tokyo. The 4-isopropyltropolone (Hipt) was supplied by Takasago Perfumery Co., Tokyo. It was dissolved in an aqueous dilute sodium hydroxide solution and then precipitated by a small excess of acetic acid. The precipitates were filtered off and further purified by recrystallization from benzene–petroleum ether. Carbon tetrachloride was purified and dehydrated in the same manner as described previously.[1] A carbon tetrachloride solution containing one of the iron(III) complexes (FeA_3) and β-diketone (HA) in concentration ratios of two to ten FeA_3 to HA was mixed with a portion of the same solvent containing a certain amount of Hipt. The concentration of the complex in the resultant solution was 1×10^{-5} to 2×10^{-4} mol dm^{-3} and that of Hipt was 1×10^{-4} to 1×10^{-1} mol dm^{-3}. In each run, the optical absorption at a certain wavelength of the sample was measured as a function of time.

Data Treatment. When the ligand exchange of FeA_3 with Hipt is controlled by the first exchange reaction and the whole iron(III) species may be exchanged to $[Fe(ipt)_3]$ as under the conditions of the present study, the rate of the ligand-exchange reaction may be expressed from the decrease in the FeA_3 concentration as:

$$V = -\mathrm{d}[FeA_3]/\mathrm{d}t = k_{obsd}[FeA_3]. \quad (1)$$

The concentration of the unexchanged species may be given by:

$$[FeA_3] = [E-\varepsilon_3\times[Fe(III)]](\varepsilon_0-\varepsilon_3)^{-1} \quad (2)$$

where ε_0 and ε_3 give the molar absorption coefficients of the FeA_3 and $[Fe(ipt)_3]$ species and [Fe(III)] gives the total concentration of the iron(III) complex in the solutions.

Results

Under the conditions employed, it was found that the spectrum of the sample solution containing one of the starting complexes and Hipt always completely changed to that of $[Fe(ipt)_3]$ when an equilibrium was established. For this reason, the data analysis was achieved using Eq. 2. The molar absorption coefficient used for the data analysis was as follows: 160 for $[Fe(acac)_3]$ at 550 nm; 530 for $[Fe(bza)_3]$ at 550 nm; 220 for $[Fe(dbm)_3]$ at 590 nm; 270 for $[Fe(tfa)_3]$ at 550 nm; 130 for $[Fe(bfa)_3]$ at 590 nm; 360 for $[Fe(tta)_3]$ at 590 nm; 140 for $[Fe(hfa)_3]$ at 590 nm; and 3180 and 2130 for $[Fe(ipt)_3]$ at 550 and 590 nm.

Rate of Ligand Exchange of [Fe(acac)$_3$], [Fe(bza)$_3$], and [Fe(dbm)$_3$]. The rate of ligand exchange of $[Fe(acac)_3]$, $[Fe(bza)_3]$, and $[Fe(dbm)_3]$ with Hipt was first order with respect to the starting complex. The rate was independent of the leaving ligand but in all cases first order in Hipt in the higher and lower concentration regions. However, it was also found that the rate was independent of the entering ligand in the intermediate concentration region. Figure 1 gives the results as a function of the Hipt concentration at 298 K. The kinetic data in Fig. 1 may generally be represented by the following equation:

$$k_{obsd} = \frac{k_A(1+k_C[Hipt])[Hipt]}{k_B+[Hipt]}. \quad (3)$$

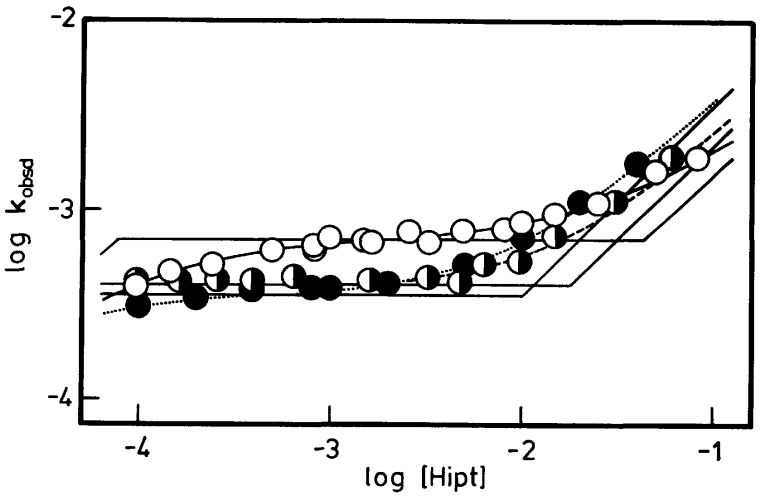

Fig. 1. Rate of [Fe(acac)$_3$] (-○-), [Fe(bza)$_3$] (--◑--), and [Fe(dbm)$_3$] (···●···) reaction with Hipt as a function of the entering ligand concentration at 298 K. The curves are calculated by introducing the constants in Table 1 into Eq. 3. The straight lines are the asymptotes for the curves.

Table 1. Summary of rate constants and activation parameters

	[Fe(acac)$_3$]	[Fe(bza)$_3$]	[Fe(dbm)$_3$]	[Fe(tfa)$_3$]	[Fe(bfa)$_3$]	[Fe(tta)$_3$]
log (k_A/s^{-1})	−3.16±0.06	−3.41±0.10	−3.45±0.05	—	—	—
log (k_B/mol dm^{-3})	*ca.* −4.5	<−5.0	*ca.* −4.9	—	—	—
log (k_C/mol^{-1} dm^3 s^{-1})	1.36±0.27	1.75±0.40	1.99±0.12	—	—	—
log (k_D/mol^{-1} dm^3 s^{-1})	—	—	—	0.16±0.09	−0.46±0.06	−0.53±0.05

ΔS^*/J K^{-1} mol^{-1}	−29±5	−12±5	−25±5	−84±2	−81±2	−81±2

The constants k_A, k_B, and k_C obtained from these data by a least-squares program are listed in Table 1.

Rate of Ligand Exchange of [Fe(tfa)$_3$], [Fe(bfa)$_3$], and [Fe(tta)$_3$]. The rate of ligand exchange between these complexes with Hipt was first order with respect to the starting complex and independent of the leaving ligand. However, in all cases, it was first order with respect to the entering ligand. Figure 2 gives the results as a function of the Hipt concentration at 298 K. These results may be represented by the following equation:

$$k_{obsd} = k_D[\text{Hipt}]. \quad (4)$$

The values of the constant k_D obtained from these data are listed in Table 1.

Rate of Ligand Exchange of [Fe(hfa)$_3$]. In the course of the study of the ligand exchange of [Fe(hfa)$_3$] with Hipt, it was found that the color of a sample solution changed rather rapidly from orange to green after mixing the complex and ligand solutions. The color then gradually changed due to the ligand exchange until the solution became completely that of [Fe(ipt)$_3$]. It was concluded from the absorption of the mixed solutions at equilibrium, that this change was not due to the formation of mixed complexes, [Fe(hfa)$_2$(ipt)] and [Fe(hfa)(ipt)$_2$], but due to an association between the [Fe(hfa)$_3$] and Hipt. However, the data in these experiments were not accurate enough to allow a further data analysis of such an association

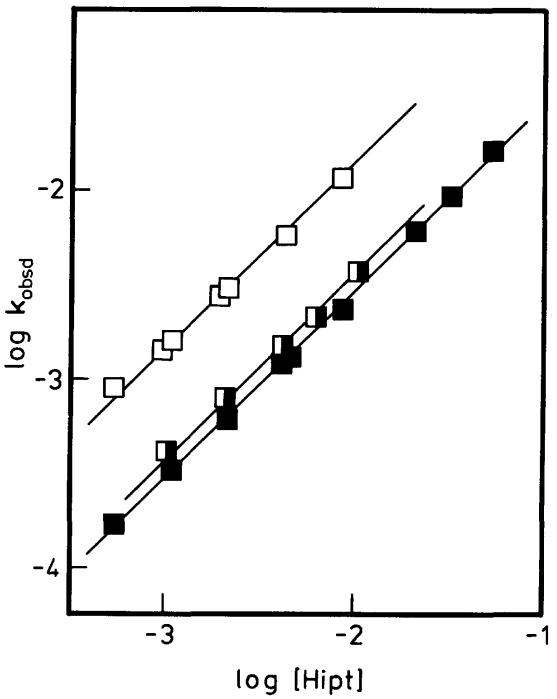

Fig. 2. Rate of [Fe(tfa)$_3$] (□), [Fe(bfa)$_3$] (◨), and [Fe(tta)$_3$] (■) reaction with Hipt as a function of the entering ligand concentration at 298 K. The straight lines are calculated by introducing the constants in Table 1 into Eq. 4.

reaction and no final conclusions regarding the mechanism of the ligand exchange reaction of [Fe(hfa)$_3$]

could be drawn.

Effect of Temperature. The ligand-exchange rate was also determined at various temperatures. Figures 3(a) and (b) give the $\log_e k_A$ or k_D *vs.* $1/T$ plot. As seen from Fig. 3(a), the results with [Fe(acac)$_3$], [Fe(bza)$_3$], and [Fe(dbm)$_3$] seems to be somewhat erroneous at high temperatures for some unknown reasons. This kind of inaccuracy was also observed in a previous study.[1] However, it can also be seen from the figure that the values of ΔH^* and ΔS^* obtained from the slope of the lines are reasonable. The values of the activation enthalpy and entropy obtained from these data are listed in Table 1.

Discussion

Since the ligand-exchange data for [Fe(acac)$_3$], [Fe(bza)$_3$], and [Fe(dbm)$_3$] with Hipt could be represented by Eq. 3, the reaction should proceed through a dissociative or an interchange mechanism. The values of the activation parameters of the ligand exchange of [Fe(acac)$_3$] with Hipt are similar to those when the entering ligand was Htfa or Htta in the previous paper.[1] For this reason, the mechanism of this reaction was concluded to be dissociative. The values of the activation parameters (ΔH^* and ΔS^*) of the reactions of [Fe(bza)$_3$] and [Fe(dbm)$_3$] with Hipt also indicate a dissociative nature of the mechanism and this seems to be reasonable because the leaving ligand from the complexes are chemically similar to that of [Fe(acac)$_3$]. Thus, it was assumed that the reaction mechanism for these three complexes should be similar to that found in the previous paper:[1]

$$FeA_3 \underset{k_{-1}}{\overset{k_1}{\rightleftharpoons}} FeA_3^* \xrightarrow[+Hipt]{k_2} [FeA_2(ipt)] + HA. \quad (5)$$

Here FeA_3^* gives a complex one of whose chelate ring is open. When the chemical species FeA_3^* is assumed to be in a steady-state, the rate may be written as:

$$V = \frac{k_1[Hipt]}{k_{-1}/k_2 + [Hipt]}[FeA_3]. \quad (6)$$

As seen from Eq. 3, k_1 in Eq. 6 corresponds with k_A and k_{-1}/k_2 with k_B. The k_C value was calculated from data obtained in a higher Hipt concentration region where the rate is dependent on the entering ligand. This dependence should be due to a catalytic reaction by Hipt.[1]

The first-order dependence on the entering ligand found with the three complexes of the β-diketones having one trifluoromethyl group, indicates that the reaction proceeds by an associative mechanism:

$$FeA_3 + Hipt \xrightarrow{k} [FeA_3(Hipt)] \xrightarrow{fast} [FeA_2(ipt)] + HA. \quad (7)$$

Thus the rate should be represented by:

$$V = k[Hipt][FeA_3]. \quad (8)$$

The value of k in Eq. 8 is naturally identical to the value of k_D in Table 1, which was obtained on the basis of Eq. 4. As seen from Table 1, the value k_D of [Fe(tfa)$_3$] is somewhat different from those of [Fe(tta)$_3$] and [Fe(bfa)$_3$]. This could be caused by various factors such as the difference in the ability of the complexes to accept an entering ligand and as the difference in the steric hindrance by these ligands.

Among complexes of a certain metal ion with homologous ligands such as β-diketones, the order of the ability as an acceptor of several neutral ligands to form adducts in nonpolar organic solvents is usually

opposit to that of their stability. In other words, less stable complexes tend to form more stable adducts. This has been observed in the "synergistic" solvent extraction of metal β-diketonates.[5] The replacement of a methyl group of a β-diketone with a trifluoromethyl group increases the acid-dissociation constant. This, consequently, causes a decrease in the ability to form complexes with metal ions. For example, the values of pK_a is about $10^{9.0}$, $10^{6.1}$, and $10^{4.3}$, respectively, for Hacac, Htfa, and Hhfa in a 1 mol dm^{-3} sodium perchlorate solution.[6] The values of β_3 are about 10^{27}, 10^{20}, and 10^{10}, respectively, for $[Fe(acac)_3]$,[7] $[Fe(tfa)_3]$,[8] and $[Fe(hfa)_3]$.[9] From these data, it can reasonablly be assumed that $[Fe(hfa)_3]$ should be the strongest acceptor for neutral ligand to form adducts and $[Fe(acac)_3]$ should be the weakest among these three.

In separate experiments, the absorption spectra of $[Fe(acac)_3]$, $[Fe(tfa)_3]$, and $[Fe(hfa)_3]$ in carbon tetrachloride and in 4-methyl-2-pentanone (MIBK) were measured. It was observed that each spectrum of $[Fe(acac)_3]$ and $[Fe(tfa)_3]$ was not affected by the solvents. However, that of $[Fe(hfa)_3]$ in the visible region was much lower in MIBK than in carbon tetrachloride. This change in the spectrum seems to be caused by stronger interactions between the MIBK molecules and the complex. The fact that this occured only with $[Fe(hfa)_3]$ also illustrates the higher ability of $[Fe(hfa)_3]$ to act as an acceptor of a neutral ligand than the other two complexes.

In previous studies[10,11] it was suggested that a reaction in aqueous solutions could be represented as $Fe^{3+}+HX \rightarrow FeX^{2+}+H^+$ where HX was an acid to form a chelate complex proceeded by an associative interchange mechanism. When this assumption is also valid with β-diketones, the order of complex formation ($V=k_{CF}[Fe^{3+}][HA]_{enol}$: log k_{CF} for Hipt is 1.3,[10] for Hacac is 0.7,[12] for Htfa is 0.8,[13] and for Htta is 0.1[14]) should indicates the order of nucleophilic tendency of these ligands. Furthermore, if the order of nucleophilic tendency would be similar to the order of the nucleophilic tendency of the ligands in nonpolar solvents, Hipt should be a stronger donor than any of the β-diketones studied in the previous paper, Hacac, Htfa, and Htta.[1]

The mechanism of the ligand-exchange reactions treated in this study may be written as follows. (1) The nature of the mechanism of the ligand-exchange reactions of $[Fe(acac)_3]$, $[Fe(bza)_3]$, and $[Fe(dbm)_3]$ whose ability to accept a donor was smaller than the other tris(β-diketonato)iron(III), was dissociative. (2) The ligand-exchange reaction of $[Fe(hfa)_3]$, whose ability to accept a donor was the greatest among the complexes studied here, proceeded after an association of the complex with the entering ligand. (3) The ligand-exchange reactions of $[Fe(tfa)_3]$, $[Fe(bfa)_3]$, and $[Fe(tta)_3]$ who had intermediate ability as an acceptor proceeded by an associative mechanism. In the previous paper,[1] it was assumed from the activation parameters that the exchange reactions of $[Fe(tfa)_3]$ with Hacac and Htta which are weaker donors than Hipt proceeded by an interchange mechanism. Those of $[Fe(tta)_3]$ with Hacac and Htfa also proceeded by a mechanism of the same type. These reactions indicate that the mechanism is very much affected by the nature of the bonds between the metal ion and leaving ligands.

Gutmann[15] pointed out that the rate of dissociation of a ligand from a complex is higher if the donecity of the other ligands is greater. A tendency of this type has been suggested by the present study though the complexes treated here contained only one kind of ligand. The mechanism of the ligand exchange of the three iron(III) chelates with the β-diketones having no trifluoromethyl group were always dissociative. On the other hand, those of the other complexes were in all cases not dissociative. This may be explained in terms of the fact that the donecity of the ligands in the latter complexes is lower than of the ligands in the former. At the same time, the latter complexes are better acceptors of the entering ligand to form associates.

Ishihara, Funahashi, and Tanaka[16] measured the activation volume of the complex formation of iron(III) with Hipt in water, *N,N*-dimethylformamide, and dimethyl sulfoxide. They interpreted the data of activation volume in terms of the bulkiness of both the entering ligand and the coordinated solvent molecules. The present results indicate that the ability of the complex as an acceptor and the ability of the entering ligand as a donor are also important factors which affect the type of the reaction mechanism.

The rate of ligand exchange of $[Fe(bza)_3]$ in hexane with Hacac and the effect of butanol as a catalyst for this reaction was studied using a spectrometric method.[17]

Kido and Saito[4] concluded that the ligand-exchange reaction of $[Fe(acac)_3]$ with Hacac in undiluted acetylacetone proceeds by an associative mechanism. Since the medium and the entering ligand in our study are different, no direct comparison of the results from the two studies is possible.

The authors are grateful to Miss Chiaki Mizuno and Mr. Eiji Yokose for their experimental help during this study. They are also grateful to Dr. Shigeru Suzuki of the Tokyo College of Pharmacy, for the elementary analysis of the complexes.

(Received October 17, 1984)

The selenoether (selenide) complexes, *t*-[Co(RSeCH$_2$CH$_2$NH$_2$)(tren)]$^{3+}$ (*t*=*trans*(*tertiary amine nitrogen, Se*); R=CH_3, CH_3CH_2, $C_6H_5CH_2$; tren=tris(2-aminoethyl)amine), *p*-[Rh(CH$_3$SeCH$_2$CH$_2$NH$_2$)(tren)]$^{3+}$ (*p*=*cis*-(*tertiary amine nitrogen, Se*)), and *t*-[Co(CH$_3$SeCH$_2$COO)(tren)]$^{2+}$ were prepared and resolved for the first time by the chemical or SP-Sephadex column chromatographic method. Racemization of these complexes in aqueous solutions was studied at an ionic strength of 0.25 ($NaClO_4$) in the pH and temperature ranges of 4.00—6.91 and 0.25—33.50 °C, respectively. The racemization rates were independent of pH and an intramolecular inversion mechanism was suggested. The $\Delta G^{\neq}_{25\,°C}$ values for inversion of *t*-[Co(RSeCH$_2$CH$_2$NH$_2$)-(tren)]$^{3+}$ decreases in the order of CH_3 (95.2 kJ mol^{-1})>CH_3CH_2 (89.4)>$C_6H_5CH_2$ (87.7), while the $\Delta H^{\neq}$ values are almost the same (95—97 kJ mol^{-1}). The variable-temperature ^{13}C NMR study of *p*-[Co(CH$_3$SeCH$_2$CH$_2$NH$_2$)-(tren)]$^{3+}$ yielded the inversion rate constant, 10 s^{-1} at the coalescence temperature (*ca.* 60 °C), which is much larger than that of the corresponding *t*-isomer (8.5×10^{-3} s^{-1} at 60 °C). The difference in inversion rate between the isomers seems to be related to the steric crowding around the Se-R group of the complex. The rhodium(III) complex racemizes slower than the corresponding cobalt(III) complex. The values of thermodynamic parameters for *t*-[Co(CH$_3$SeCH$_2$COO)(tren)]$^{2+}$ are nearly the same as those for *t*-[Co(CH$_3$SeCH$_2$CH$_2$NH$_2$)(tren)]$^{3+}$.

Many sulfonium ions have been resolved and the racemization can be followed in solution by conventional techniques such as polarimetry.[1] The activation energy for inversion has been reported to be 105—120 kJ mol^{-1}, and larger values are to be expected for inversion at selenium in analogous selenonium ions.[1] It is known that both thioethers (sulfides) and selenoethers (selenides) form metal complexes formally analogous to sulfonium and selenonium ions, respectively. However, activation energy for inversion at the sulfur and selenium donor atoms in metal complexes is much smaller than that for their organic counterparts.[2] For example, the rates of inversion at sulfur and selenium in the Pd^{II}, Pt^{II}, and Pt^{IV} complexes have been reported to be in the range of 10^4—10^{-1} s^{-1} by the ^1H or ^{13}C dynamic NMR method.[2] Thus, neither optically active thioether nor selenoether complexes, in which the sulfur or selenium atom is the sole source of optical activity, have been reported.

Studies on chiral cobalt(III)–thioether complexes,[3,4] on the other hand, suggest that the rate of inversion at sulfur in these complexes is slower than those for the Pd^{II}, Pt^{II}, and Pt^{IV} complexes. Since inversion at a coordinated selenoether site will be slower than that at a corresponding thioether site,[1] a selenoether ligand coordinated to cobalt(III) would be fairly stable toward inversion and might permit optical activity.

This paper reports resolution, characterization, and kinetic studies on inversion of *p*-[M^{III}(CH$_3$SeCH$_2$-CH$_2$NH$_2$)(tren)]$^{3+}$ [5] (M^{III}=Co, Rh; tren=tris(2-aminoethyl)amine), *t*-[Co(RSeCH$_2$CH$_2$NH$_2$)(tren)]$^{3+}$ [5] (R=CH_3, CH_3CH_2, $C_6H_5CH_2$), and *t*-[Co(CH$_3$SeCH$_2$-COO)(tren)]$^{2+}$ (Fig. 1). In these complexes, the configuration of the selenium atom is the sole source of chirality. A preliminary report on [Co(CH$_3$SeCH$_2$CH$_2$NH$_2$)-(tren)]$^{3+}$ has been published.[6]

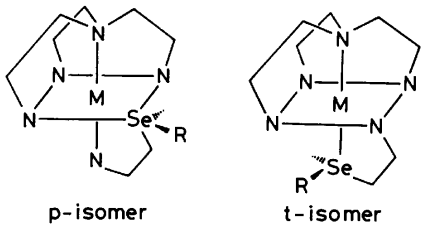

Fig. 1. Two geometrical isomers of [M(RSeCH$_2$-CH$_2$NH$_2$)(tren)]$^{3+}$.

Experimental

Materials. *p*-[Co(SeCH$_2$CH$_2$NH$_2$)(tren)](ClO$_4$)$_2$,[6,7] *t*-[Co(SeCH$_2$CH$_2$NH$_2$)(tren)]ZnCl$_4$·2H$_2$O,[6,7] and *p*-[Rh(Se-CH$_2$CH$_2$NH$_2$)(tren)](ClO$_4$)$_2$[7] were prepared as described earlier.

p-[Co(CH$_3$SeCH$_2$CH$_2$NH$_2$)(tren)]Cl$_3$·2.5H$_2$O. This complex was prepared by methylating *p*-[Co(SeCH$_2$CH$_2$NH$_2$)-(tren)](ClO$_4$)$_2$ according to the procedure analogous to that for *p*- and *t*-[Co(CH$_3$SCH$_2$CH$_2$NH$_2$)(tren)]$^{3+}$.[3] To a dimethyl sulfoxide (DMSO) solution (50 cm^3) of *p*-[Co(SeCH$_2$CH$_2$-NH$_2$)(tren)](ClO$_4$)$_2$ (2.64 g, 5 mmol) was added CH_3I (7.10 g, 50 mmol). Within a few minutes the color of the solution changed from dark brown to orange-red. The solution was allowed to stand for 5 h at room temperature, diluted with 1×10^{-3} mol dm^{-3} HCl (500 cm^3), and the excess CH_3I was extracted with $CHCl_3$ (150 cm^3×2). The orange-red aqueous layer was applied on a column (ϕ1.5 cm×2 cm) of SP-Sephadex C-25. The adsorbed product was washed with water, and then eluted with 1 mol dm^{-3} $NaClO_4$. The effluent was evaporated under reduced pressure to yield red crystals of the perchlorate of the complex (2.5 g). The complex was converted into the chloride by use of a column (ϕ1.5 cm× 6 cm) of Dowex 1X8 (Cl^- form). The effluent containing the chloride was evaporated to a small volume. On addition of ethanol the concentrate yielded red fine crystals, which were collected by filtration and recrystallized from water by adding ethanol. Yield: 0.8 g. Found: C, 21.84; H, 6.69; N, 14.36%. Calcd for $C_9H_{32}N_5Cl_3CoO_{2.5}Se$: C, 21.85; H, 6.52; N, 14.16%.

t-[Co(CH$_3$SeCH$_2$CH$_2$NH$_2$)(tren)]Br$_3$·H$_2$O, *t-[Co(CH$_3$CH$_2$-*

$SeCH_2CH_2NH_2$)(tren)]$Br_3 \cdot 4H_2O$, and t-*[Co($C_6H_5CH_2SeCH_2$-CH_2NH_2)(tren)]$Cl_3 \cdot 2H_2O$.* These complexes were prepared from *t*-[Co($SeCH_2CH_2NH_2$)(tren)]$ZnCl_4 \cdot 2H_2O$ and an appropriate alkylating reagent (CH_3I, CH_3CH_2I, and $C_6H_5CH_2Br$) by a method similar to that for *p*-[Co(CH_3-$SeCH_2CH_2NH_2$)(tren)]$Cl_3 \cdot 2.5H_2O$. The CH_3-, CH_3CH_2-, and $C_6H_5CH_2$-substituted complexes adsorbed on SP-Sephadex C-25 were eluted with 1 mol dm^{-3} NaBr, LiBr, and LiCl, respectively. Each eluate was concentrated to a small volume, and then mixed with ethanol, yielding crystals of the complex. Yields: 80—98%. Found: C, 17.95; H, 5.04; N, 11.99%. Calcd for $C_9H_{29}N_5Br_3CoOSe$: C, 17.98; H, 4.86; N, 11.65%. Found: C, 17.71; H, 4.93; N, 10.32%. Calcd for $C_{10}H_{37}N_5Br_3CoO_4Se$: C, 17.95; H, 5.57; N, 10.46%. Found: C, 32.11; H, 5.92; N, 12.85%. Calcd for $C_{15}H_{35}N_5Cl_3CoO_2Se$: C, 32.07; H, 6.28; N, 12.47%.

p-*[Rh($CH_3SeCH_2CH_2NH_2$)(tren)]X_3 (X=Br, ClO_4).* This complex was prepared from *p*-[Rh($SeCH_2CH_2NH_2$)(tren)]-$(ClO_4)_2$ and CH_3I by the same method as that described for *p*-[Co($CH_3SeCH_2CH_2NH_2$)(tren)]$^{3+}$, and isolated as the bromide and the perchlorate. Yields: 80—85%. Found: C, 17.43; H, 4.37; N, 11.14%. Calcd for $C_9H_{27}N_5Br_3RhSe$: C, 17.24; H, 4.34; N, 11.17%. Found: C, 15.67; H, 4.30; N; 10.50%. Calcd for $C_9H_{27}N_5Cl_3O_{12}RhSe$: C, 15.77; H, 3.97; N, 10.22%.

t-*[Co($SeCH_2COO$)(tren)]Cl and* t-*[Co(CH_3SeCH_2COO)(tren)]-$(ClO_4)_2$.* The *t*-[Co($SeCH_2COO$)(tren)]Cl complex was prepared by a method analogous to that for [Co($SeCH_2$-COO)$(en)_2$]$^{+}$[8] (en=ethylenediamine). Time required for the oxidation of Co^{II}-N_4 (N_4=tren or $(en)_2$) species with the diselenide, ($HOOCCH_2Se$-)$_2$[9] was longer for the tren complex than that for the en complex. To a deoxygenated aqueous solution (5 cm^3) of $CoCl_2 \cdot 6H_2O$ (2.20 g, 6.0 mmol) was added a deoxygenated aqueous solution (9 cm^3) containing tren·3HCl (1.53 g, 6.0 mmol) and NaOH (0.72 g, 18.0 mmol). The color of the solution changed from light red to violet. Then a deoxygenated aqueous solution (10 cm^3) containing ($HOOCCH_2Se$-)$_2$ (0.828 g, 3.0 mmol) and NaOH (0.24 g, 6.0 mmol) was added to the solution and the mixture was allowed to stir for 5 days under a nitrogen atmosphere. The color of the solution changed from violet to dark brown and brown fine crystals were deposited. The crystals were collected by filtration, washed with ethanol, and air dried. Yield: 0.18 g. No evidence indicative of the presence of the other isomer was obtained either in the ^1H NMR spectrum of the isolated complex or by column chromatography (column: SP-Sephadex C-25; eluent: 0.05 mol dm^{-3} Na_2SO_4) of the reaction mixture. The complex was used for the subsequent reaction without any purification.

The complex was methylated by the same method as that for *p*-[Co($CH_3SeCH_2CH_2NH_2$)(tren)]$^{3+}$, and the product was isolated as the perchlorate. Yield: 65%. Found: C, 19.44; H, 4.17; N, 10.08%. Calcd for $C_9H_{23}N_4Cl_2CoO_{10}Se$: C, 19.37; H, 4.16; N, 10.10%. The bromide of the complex was obtained from the perchlorate by means of Dowex 1X8 (Br^- form).

Resolution of the Complexes. All the complexes except for *p*-[Co($CH_3SeCH_2CH_2NH_2$)(tren)]$^{3+}$ were partially resolved. Complete resolution of the complexes was not attempted because they are likely to racemize.

$(-)^{CD}_{480}$-t-*[Co($CH_3SeCH_2CH_2NH_2$)(tren)]$Br_3 \cdot 1.5H_2O$.* To an aqueous solution (2 cm^3) of *t*-[Co($CH_3SeCH_2CH_2NH_2$)-(tren)]$Br_3 \cdot H_2O$ (0.21 g, 3.43 mmol) was added $Ag_2[Sb_2(d\text{-tart})_2]$ (0.258 g, 3.43 mmol, *d*-tart=(*R,R*)-tartrate ion). The silver bromide precipitated was removed by filtration, and the filtrate was slowly evaporated to dryness over P_2O_5 in a vacuum desiccator to yield a glassy material, which was broken up, suspended in ethanol, filtered, and washed with ethanol. The product was dissolved in a small amount of cold water. To the solution was added sodium tetraphenylborate to give a precipitate immediately. It was filtered, washed with water, and dissolved in a small amount of acetone. To this solution was added excess LiBr followed by addition of ethanol to yield an orange-red precipitate. It was collected by filtration, washed with ethanol, and air dried. Yield: 0.10 g. Found: C, 17.37; H, 4.85; N, 11.62%. Calcd for C_9H_{30}-$N_5Br_3CoO_{1.5}Se$: C, 17.19; H, 5.04; N, 11.99%.

t-[Co($CH_3SeCH_2CH_2NH_2$)(tren)]$^{3+}$ was also partially resolved by column chromatography. An aqueous solutoin of the complex (*ca.* 70 mg) was charged on the top of an SP-Sephadex C-25 column (ϕ2 cm×30 cm). By elution with 0.15 mol dm^{-3} $Na_2[Sb_2(d\text{-tart})_2]$, the column showed a single band, however, the front and the tail fractions of the band showed enantiomeric CD patterns.

$(-)^{CD}_{480}$-t-*[Co($CH_3CH_2SeCH_2CH_2NH_2$)(tren)]$^{3+}$*, $(-)^{CD}_{475}$-t-*[Co-($C_6H_5CH_2SeCH_2CH_2NH_2$)(tren)]$^{3+}$, and $(-)^{CD}_{330}$*-p-*[Rh(CH_3-$SeCH_2CH_2NH_2$)(tren)]$^{3+}$.* The racemic complexes were resolved by the same method as that for $(-)^{CD}_{480}$-*t*-[Co($CH_3SeCH_2CH_2NH_2$)(tren)]$^{3+}$ except that AgBCS·H_2O (BCS=(*1R,3S,4S,7R*)-3-bromo-9-camphorsulfonate ion) was used ([complex]:[BCS^-]=1:1) instead of $Ag_2[Sb_2(d\text{-tart})_2]$ for the former two complexes. The BCS^- and $[Sb_2(d\text{-tart})_2]^{2-}$ ions were not converted into achiral anions such as Cl^-, because these complexes racemize rather fast in solution.

$(-)^{CD}_{475}$- *and* $(+)^{CD}_{475}$-t-*[Co(CH_3SeCH_2COO)(tren)]$^{2+}$.* The racemic complex was resolved with AgBCS·H_2O([complex]:[BCS^-]=1:2) by a method similar to that for $(-)^{CD}_{480}$-*t*-[Co(CH_3-$SeCH_2CH_2NH_2$)(tren)]$^{3+}$. The silver bromide precipitated was filtered off, and the filtrate was evaporated over P_2O_5 in a vacuum desiccator to yield fine crystals consisting of two different colors, pink and deep orange-red. The two kinds of crystals which show enantiomeric CD patterns were separated by hand picking. The pink $(-)^{CD}_{475}$-isomer was converted into the perchlorate by the same method as that for $(-)^{CD}_{480}$-*t*-[Co($CH_3SeCH_2CH_2NH_2$)(tren)]$Br_3 \cdot 1.5H_2O$ except that $LiClO_4 \cdot 3H_2O$ was used instead of LiBr.

Racemization Studies. Rates of racemization were determined by monitoring the change in CD strength at 480 nm (*t*-[Co($RSeCH_2CH_2NH_2$)(tren)]$^{3+}$; R=CH_3, CH_3-CH_2), 475 nm (*t*-[Co($C_6H_5CH_2SeCH_2CH_2NH_2$)(tren)]$^{3+}$ and *t*-[Co(CH_3SeCH_2COO)(tren)]$^{2+}$), and 330 nm (*p*-[Rh(CH_3-$SeCH_2CH_2NH_2$)(tren)]$^{3+}$) as a function of reaction time. The complex concentrations were *ca.* 10^{-3} mol dm^{-3}, and the measurements were made at an ionic strength of 0.25 ($NaClO_4$) and in the pH and temperature ranges of 4.00—6.91 and 0.25—33.50 °C, respectively. The inversion rate of *p*-[Co-($CH_3SeCH_2CH_2NH_2$)(tren)]$^{3+}$ was determined by monitoring the change in the ^{13}C NMR spectrum in the temperature range of 30—60 °C.

Measurements. Absorption and circular dichroism (CD) spectra were recorded on a Hitachi 323 spectrophotometer and a JASCO J-40CS spectropolarimeter, respectively. ^{13}C NMR spectra were obtained in D_2O with a JEOL FX-60 FT NMR spectrometer using dioxane as an internal reference.

a) Shoulder.

of the Complexes. The selenoether complexes of cobalt(III) and rhodium(III) were prepared by alkylating the corresponding selenolato complexes with the appropriate alkyl halides. The reactions proceeded almost quantitatively. Column chromatography of the reaction mixtures showed a single band, and the selenoether complexes thus obtained should have the same geometrical configurations as those of the respective parent selenolato complexes. The geometrical configurations of [Co($SeCH_2CH_2NH_2$)(tren)]$^{2+}$ have been assigned on the basis of the elution order in column chromatography.[6,7] The structure of the rhodium(III) complex, *p*-[Rh($SeCH_2CH_2NH_2$)(tren)](ClO_4)$_2$ has been determined by the X-ray method.[7]

The first d-d absorption band of *t*-[Co($RSeCH_2CH_2NH_2$)(tren)]$^{3+}$ shifts to lower energy as R is changed from CH_3 through CH_3CH_2 to $C_6H_5CH_2$ (Table 1).

Both *p*- and *t*-isomers of [Co($RSeCH_2CH_2NH_2$)(tren)]$^{3+}$ exhibit a strong Se to Co^{III} charge-transfer (CT) band at 32000—33000 cm^{-1}, while the rhodium(III) complex gives the corresponding band at 41500 cm^{-1}. The positions of the CT bands are nearly the same as those for the parent selenolato complexes.[7]

The [Co(CH_3SeCH_2COO)(tren)]$^{2+}$ complex forms one geometrical isomer as confirmed by chromatography and ^1H NMR spectroscopy. The corresponding thioether complex, [Co(CH_3SCH_2COO)(tren)]$^{2+}$ and analogous [Co{$CH_3SCH(CH_3)COO$}(tren)]$^{2+}$ also form one geometrical isomer,[10] and the structure of the latter complex has been determined to have the *t*-configuration by X-ray analysis.[11] These thioether complexes show the first absorption band ([Co(CH_3SCH_2COO)(tren)]$^{2+}$: 20620 cm^{-1}, [Co{$CH_3SCH(CH_3)COO$}(tren)]$^{2+}$: 20640 cm^{-1}) between those of the *p*-(20530 cm^{-1}) and *t*-isomer (20790 cm^{-1}) of [Co($CH_3SCH_2CH_2NH_2$)(tren)]$^{3+}$.[10] The first absorption band (20160 cm^{-1}) of [Co(CH_3SeCH_2COO)(tren)]$^{2+}$ is also observed between the *p*-(20120 cm^{-1}) and *t*-isomer (20280 cm^{-1}) of [Co($CH_3SeCH_2CH_2NH_2$)(tren)]$^{3+}$. Selective formation of the thio and selenoether complexes

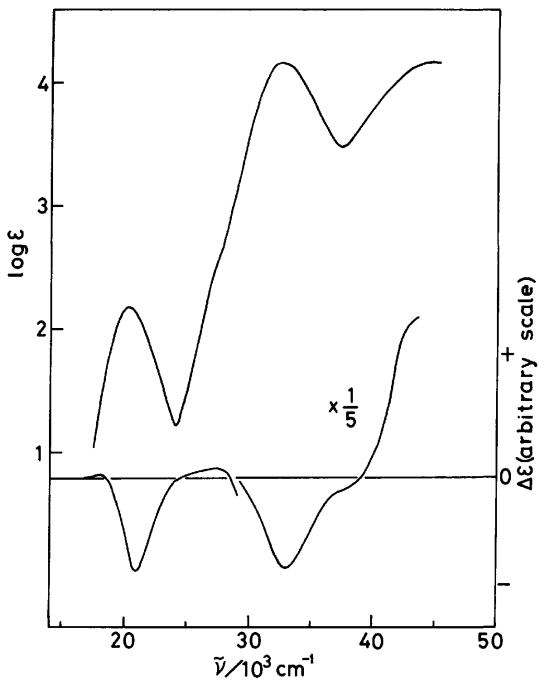

Fig. 2. Absorption and CD spectra of $(-)^{CD}_{480}$-*t*-[Co($CH_3SeCH_2CH_2NH_2$)(tren)]$Br_3 \cdot 1.5H_2O$ in water.

and similarities in absorption spectra between these complexes will strongly support that the present [Co(CH_3SeCH_2COO)(tren)]$^{2+}$ complex is the *t*-isomer.

The *t*-[Co($RSeCH_2CH_2NH_2$)(tren)]$^{3+}$ and *p*-[Rh($CH_3SeCH_2CH_2NH_2$)(tren)]$^{3+}$ complexes were partially resolved with [Sb_2(*d*-tart)$_2$]$^{2-}$ or BCS^-. The crystalline or glassy product obtained by slow evaporation of an aqueous solution containing the complex and the resolving agent shows strong CD in the d-d transition region when dissolved in water. The result indicates that the inversion occurs at selenium to form a less soluble diastereomer during slow evaporation. However, rates of inversion are moderately slow as discussed below. In the case of [Co(CH_3SeCH_2COO)(tren)]($BCS)_2$, the pair of diastereomeric salts crystallized in different forms, which can be separated by hand picking.

All the resolved complexes show CD spectra similar or almost enantiomeric to that of $(-)^{CD}_{480}$-*t*-[Co($CH_3SeCH_2CH_2NH_2$)(tren)]$^{3+}$ (Fig. 2). At present, the absolute configurations of selenium atoms in these tren complexes can not be assigned on the basis of the CD spectra. An analogous thioether complex, $(-)_{589}$-*S*(S),*R*(C)-*t*-[Co{$CH_3SCH(CH_3)COO$}(tren)]$^{2+}$, whose absolute configuration has been determined by the X-ray method,[11] exhibits a positive CD band in the S to Co^{III} CT band region (34000 cm^{-1}). On the other hand, *Δ*-[Co($CH_3SCH_2CH_2NH_2$)(en)$_2$]$^{3+}$[12] and *Λ*-[Co($CH_3SCH_2CH_2CH_2NH_2$)(en)$_2$]$^{3+}$[13] (en=ethylenediamine), in which both sulfur donor atoms are considered to have the same *R* configuration to reduce nonbonded interactions between the methyl group and the en chelate ring, also show a positive CD band in the corresponding CT region (35000 cm^{-1}). These results make

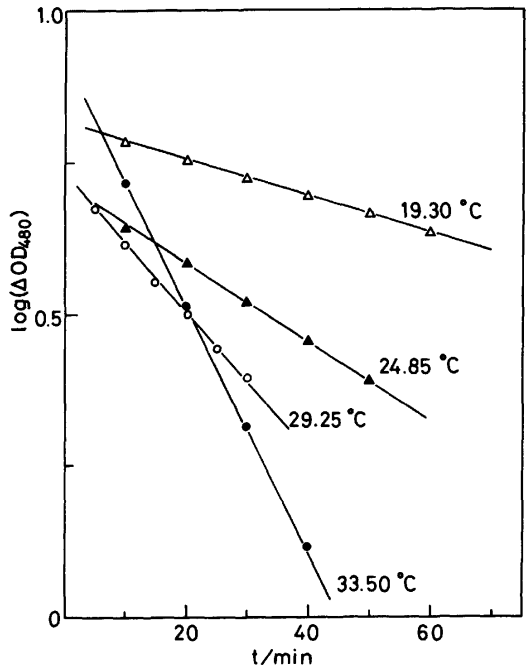

Fig. 3. Plot of $\log(\Delta OD_{480})$ against time for $(-)^{CD}_{480}$-*t*-$[Co(CH_3SeCH_2CH_2NH_2)(tren)]Br_3 \cdot 1.5H_2O$ in water (I=0.25, $NaClO_4$) at 19.30, 24.85, 29.25, and 33.50°C.

the assignment of the absolute configurations for chiral selenium donor atoms difficult.

Inversion at the Coordinated Selenium Atom. Rates of inversion at selenium of the resolved complexes were determined by monitoring the change in CD strength as a function of time. Measurements were carried out over the temperature range of 0.25 to 33.50°C in the pH region of 4.00 to 6.91. The CD strength at 480 nm of $(-)^{CD}_{480}$-*t*-$[Co(CH_3SeCH_2CH_2NH_2)(tren)]Br_3$ in water (I=0.25, $NaClO_4$) at a constant temperature decreases with time, and the plot of $\log(\Delta OD_{480})$ against time gave a straight line (Fig. 3), from which the first-order rate constants of racemization, k_r and inversion, $k_{inv}=k_r/2$ were obtained. No detectable change in the absorption spectra was observed during the measurements.

Except for *t*-$[Co(CH_3SeCH_2CH_2NH_2)(tren)]^{3+}$ and *t*-$[Co(CH_3SeCH_2COO)(tren)]^{2+}$ the optically active complexes were obtained as the diastereomeric salt with a resolving agent, and conversion into salts with achiral counter ions. was difficult because of racemization. Therefore, the effect of resolving agent on the rate of inversion should be taken into consideration. The inversion rate of $(-)^{CD}_{480}$-*t*-$[Co(CH_3SeCH_2CH_2NH_2)(tren)]$ $Br[Sb_2(d\text{-tart})_2]$ was compared with that of the bromide salt. The $Br^-[Sb_2(d\text{-tart})_2]^{2-}$ salt in water shows the same CD pattern as the bromide in the d-d transition region, and the CD strength decreases with passage of time. However, the solution shows weak CD (residual CD) even after the reaction attained equilibrium, and the pattern of the CD spectrum is almost the same as that of the starting solution. On the other hand, a solution of racemic $[Co(CH_3SeCH_2CH_2NH_2)(tren)]Br_3$ in 0.15 mol dm^{-3} $Na_2[Sb_2(d\text{-tart})_2]$ exhibits very weak CD (induced CD) immediately after dissolution of the complex, and the spectral pattern differs from that of the above residual CD. However, the spectrum gradually changes and finally gives the same pattern as that of the residual CD. These results indicate that the residual CD arises primarily from a shift of equilibrium between the (*R*)- and (*S*)-isomers caused by the presence of $[Sb_2(d\text{-tart})_2]^{2-}$, contribution of the induced CD being very small. For the reaction of $(-)^{CD}_{480}$-*t*-$[Co(CH_3SeCH_2CH_2NH_2)(tren)]Br[Sb_2(d\text{-tart})_2]$, a plot of log $(\Delta OD_{obsd} - \Delta OD_{res})$ against time gave a straight line, where ΔOD_{obsd} and ΔOD_{res} denote the observed and residual CD strengths, respectively, from which the rate of inversion was obtained (Fig. 4 and Table 2). The rate agrees with that of the corresponding bromide within the experimental error. The CD data for *p*-$[Rh(CH_3SeCH_2CH_2NH_2)(tren)]Br[Sb_2(d\text{-tart})_2]$ were analyzed in the same way. For kinetic studies on racemization of *t*-$[Co(RSeCH_2CH_2NH_2)(tren)]^{3+}$ ($R=CH_3CH_2$, $C_6H_5CH_2$) and *t*-$[Co(CH_3SeCH_2COO)(tren)]^{2+}$, the BCS^- salts were used. No CD remained after the reaction attained equilibrium, and the inversion rate was obtained from a straight line given by a plot of $\log(\Delta OD)$ *vs.* time.

Attempts to resolve *p*-$[Co(CH_3SeCH_2CH_2NH_2)(tren)]^{3+}$ by the chemical method with several resolving agents and by SP-Sephadex column chromatography were all unsuccessful. However, the complex exhibits nine signals in the ^{13}C NMR spectrum as shown in Fig. 5. The diastereotopic carbon resonances of the tren ligand (1,3 and 4,6 carbons in Fig. 5) arising from the presence

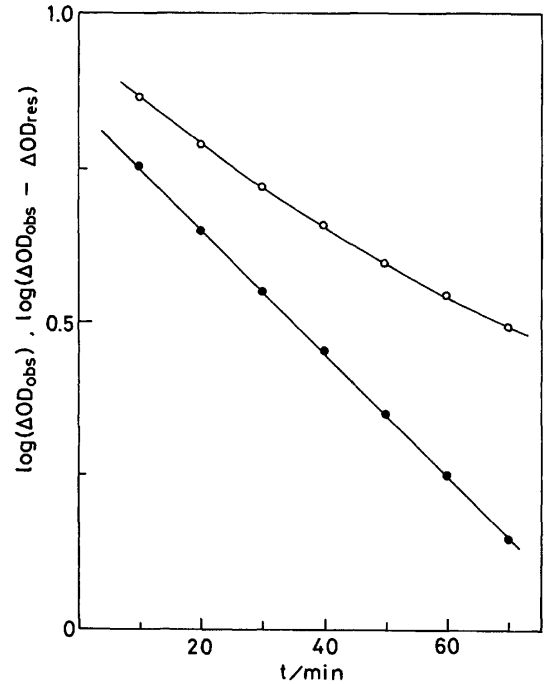

Fig. 4. Plots of $\log(\Delta OD_{obsd})$ *vs.* *t* (○) and $\log(\Delta OD_{obsd} - \Delta OD_{res})$ *vs.* *t* (●) for $(-)^{CD}_{480}$-*t*-$[Co(CH_3SeCH_2CH_2NH_2)(tren)]Br[Sb_2(d\text{-tart})_2]$ in water (I=0.25, $NaClO_4$) at 28.25°C.

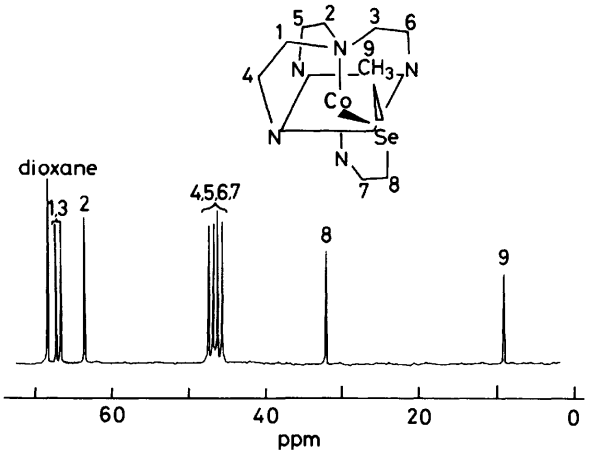

Fig. 5. ^{13}C NMR spectrum of p-[Co($CH_3SeCH_2CH_2NH_2$)(tren)]$^{3+}$ in D_2O at room temperature.

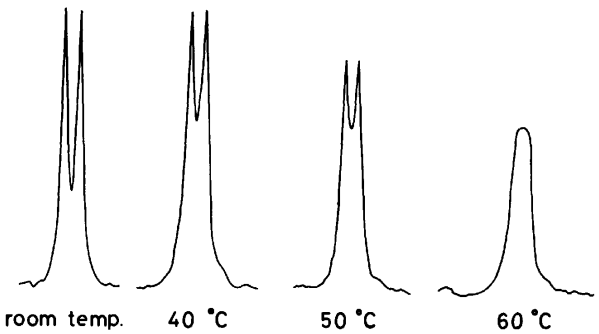

Fig. 6. Variable-temperature ^{13}C NMR spectra of the 1,3-carbon absorption region of p-[Co($CH_3SeCH_2CH_2NH_2$)(tren)]$^{3+}$ in D_2O (See Fig. 5 for carbon numbers).

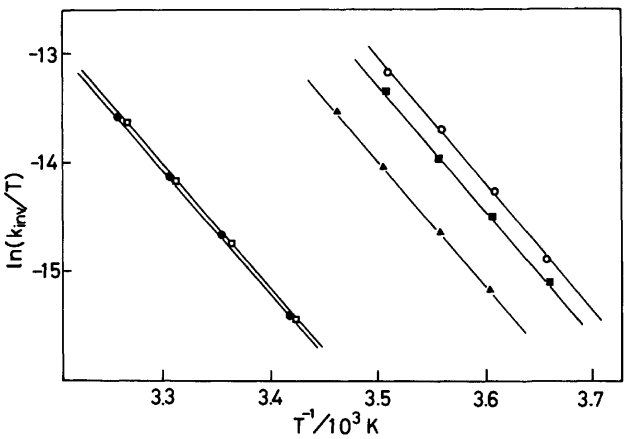

Fig. 7. Plot of $\log(k_{inv}/T)$ against T^{-1} for t-[Co($CH_3SeCH_2CH_2NH_2$)(tren)]$^{3+}$ (●), t-[Co(CH_3SeCH_2COO)(tren)]$^{2+}$ (◇), t-[Co($CH_3CH_2SeCH_2CH_2NH_2$)(tren)]$^{3+}$ (▲), t-[Co($C_6H_5CH_2SeCH_2CH_2NH_2$)(tren)]$^{3+}$ (■), and p-[Rh($CH_3SeCH_2CH_2NH_2$)(tren)]$^{3+}$ (○).

of the chiral selenoether group are clearly resolved at room temperature, demonstrating the stability toward inversion on the NMR time scale. Thus it can be concluded that the inversion at selenium in the p-isomer is slow on the NMR time scale , but not so slow as to be resolved by conventional techniques. With a rise in temperature, the two signals of 1 and 3 carbons broaden and coalesce at *ca.* 60 °C (Fig. 6). Although activation parameters of the inversion could not be obtained because of the instability of the complex at elevated temperatures, the rate at the coalescence temperature (*ca.* 60 °C) is roughly estimated to be *ca.* 10 s^{-1}.

Eyring treatments of $\log(k_{inv}/T)$ *vs.* T^{-1} yielded activation parameters (Fig. 7 and Table 3). The rate constant of t-[Co($CH_3SeCH_2CH_2NH_2$)(tren)]$^{3+}$ at 60 °C is calculated from the $\Delta H^{\ddagger}$ and $\Delta S^{\ddagger}$ values to be 8.5×10^{-3} s^{-1}. The value is smaller by a factor of 10^3 than that of the p-isomer at the same temperature. Jackson and Sargeson[3] studied the rates of sulfur inversion in t-[Co($CH_3SCH_2CH_2NH_2$)(tren)]$^{3+}$ and related complexes by the NMR method, and revealed that the rates are slow ($k_{inv}<10$ s^{-1}) on the NMR time scale at 25 °C, but

TABLE 3. THERMODYNAMIC PARAMETERS FOR INVERSION OF THE COMPLEXES

Complex	ΔS^*/J mol^{-1} K^{-1}	ΔH^*/kJ mol^{-1}	$\Delta G^*_{25°C}$/kJ mol^{-1}
t-[Co($CH_3SeCH_2CH_2NH_2$)(tren)]$^{3+}$	3.1±2.2	96.1±0.6	95.2±0.9
t-[Co($CH_3CH_2SeCH_2CH_2NH_2$)(tren)]$^{3+}$	19.4±3.4	95.2±0.6	89.4±1.4
t-[Co($C_6H_5CH_2SeCH_2CH_2NH_2$)(tren)]$^{3+}$	26.9±5.6	95.7±1.5	87.7±2.2
t-[Co(CH_3SeCH_2COO)(tren)]$^{2+}$	−0.2±2.2	95.1±1.7	95.1±1.0
p-[Rh($CH_3SeCH_2CH_2NH_2$)(tren)]$^{3+}$	35±13	97.6±4.4	87.2±5.9
p-[Co($CH_3SeCH_2CH_2NH_2$)(tren)]$^{3+}$			*ca.* 76 (60 °C)

exceeds 0.1 s^{-1}. For example, the ^{13}C NMR spectrum of *t*-[Co($CH_3SCH_2CH_2NH_2$)(tren)]$^{3+}$ showed clearly resolved diastereotopic carbon signals at 25 °C. On the other hand, the corresponding signals for the *p*-isomer were not resolved under the same conditions. These observations are consistent with our results that the inversion rate of the coordinated selenium atom is faster in the *p*-isomer than in the *t*-isomer. A similar trend was reported for sulfur inversion in *p*- and *t*-[Co{S(O)$CH_2CH_2NH_2$}(tren)]$^{2+}$.[14]

Studies of the variable-temperature NMR spectra of Pt^{II}–thioether and –selenoether complexes revealed the presence of coupling between ^{195}Pt and ^1H even above the coalescence temperature.[15,16] The result suggests that the inversion does not involve breaking of the Pt–S and Pt–Se bonds; pyramidal inversion mechanism is proposed, which proceeds *via* a trigonal planar intermediate.[17] Although such argument on couplings may not be applied on the present selenoether Co^{III} and Rh^{III} complexes, the facts that the rates of racemization are independent of pH and the presence of resolving agent strongly suggest that the racemization takes place intramolecularly by pyramidal inversion at the selenium atom. If the racemization would proceed by this mechanism, the difference in rate of inversion between the two isomers of [Co($CH_3SeCH_2CH_2NH_2$)(tren)]$^{3+}$ seems to stem from a difference in structure around the Se–R group. Molecular models of [Co($CH_3SeCH_2CH_2NH_2$)(tren)]$^{3+}$ show that the *p*-isomer involves fairly large steric interactions between the methyl group and the tren chelate ring, whereas the *t*-isomer does not have such large steric interactions around the Se–CH_3 group. In the trigonal planar transition state, on the other hand, both *p*- and *t*-isomers seem to have a similar structural situation involving no particular steric interaction around the Se–CH_3 group. Accordingly, the *p*-isomer will have a lower energy barrier for the inversion than that of the *t*-isomer, and racemizes faster than does the *t*-isomer.

The ΔG^* values for inversion of *t*-[Co($RSeCH_2CH_2NH_2$)(tren)]$^{3+}$ decrease in the order $CH_3 > CH_3CH_2 > C_6H_5CH_2$. The decrease in ΔG^* value comes from an increase in positive ΔS^*, the ΔH^* values being almost constant (95—97 kJ mol^{-1}) in these complexes. It seems that the entropy change associated with inversion arises from the gain of ratational freedom of the substituent on selenium upon going from the ground state to the transition state. Although the *t*-isomer is

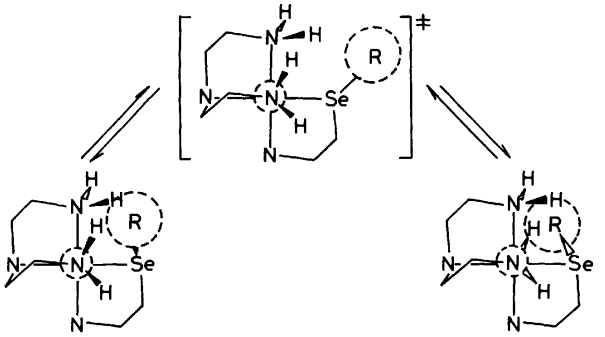

Fig. 8. A proposed mechanism for inversion of *t*-[Co($RSeCH_2CH_2CH_2NH_2$)(tren)]$^{3+}$ viewed from the *p*-N–Co–*p*-N bond axis.

sterically preferred in the ground state, the steric interaction in this isomer increases with an increasing size of the substituent, $CH_3 < CH_3CH_2 < C_6H_5CH_2$ to reduce the degree of rotational freedom of the substituent on the selenium atom in the ground state (Fig. 8). In the transition state, however, the substituent is far away from the tren chelate ring, and can rotate more easily than in the ground state (Fig. 8). Thus, the difference in degree of freedom between the ground and the transition states becomes larger with an increasing size of the substituent, which is reflected on the ΔS^* values (Table 3).

It is to be noted that the activation parameters of *t*-[Co(CH_3SeCH_2COO)(tren)]$^{2+}$ are nearly the same as those of *t*-[Co($CH_3SeCH_2CH_2NH_2$)(tren)]$^{3+}$. The effect of nature of the donor atom cis to selenium on the inversion barriers (cis effect) seems to be small in the present complexes. Similarly equivocal results for the cis effect on sulfur and selenium inversion barriers have been reported on *fac*-[$Pt^{IV}XMe_3${MeE(CH_2)$_n$EMe}] (X=Cl, Br, I; E=S, Se; n=2, 3).[18]

The inversion rate of *p*-[Rh($CH_3SeCH_2CH_2NH_2$)(tren)]$^{3+}$ is calculated to be *ca.* 2.3×10^{-1} s^{-1} at 60 °C from the ΔH^* and ΔS^* values, the rate being much smaller than that of the corresponding cobalt(III) complex (*ca.* 10 s^{-1}) at the same temperature. The difference can be explained by both steric and electronic factors. The M–Se and M–N bond distances should be longer in the Rh^{III} complex than in the Co^{III} complex,[2] and thus smaller steric interactions are expected for the Rh^{III} complex between the ligands to increase the activation energy for the inversion. The inversion is also related with the M–Se bond strength; the weaker the bond becomes, the faster the inversion occurs.[16] *p*-[M($CH_3SeCH_2CH_2NH_2$)(tren)]$^{3+}$ (M=Co, Rh) seems to

be the case; the Rh–Se bond is expected to be stronger than the Co–Se bond because a soft selenium donor atom will prefer Rh^{III} to Co^{III}.

The authors wish to thank the Ministry of Education for Scientific Research Grant-in-Aid No. 58470032.

Flavin Mononucleotide Chemiluminescence for Determination of Traces of Copper(II) by Continuous Flow and Flow Injection Methods

Masaaki YAMADA,* Hideshi KANAI, and Shigetaka SUZUKI
Department of Industrial Chemistry, Faculty of Technology, Tokyo Metropolitan University, Tokyo 158
(Received November 7, 1984)

Flow injection analysis, with chemiluminescence detection, is used to determine traces of copper(II) by means of the flavin mononucleotide-hydrogen peroxide-phosphate buffer system. This permits the determination of copper(II) more selectively than any other chemiluminescence system with a detection limit of 0.03 ng(20-μl sample injection) or 0.06 ng ml^{-1} (continuous sample flow). The linear range is 3 orders of magnitude, the sampling rate is 120 h^{-1}, and the relative standard deviation is 3.1% for 1 ng Cu(II)(n=10). Iron(II) and chromium(III and VI), the strongest enhancer after copper(II), provide signals 2—3% of that for copper(II). Effect of surfactant micelles on the signal for copper is also discussed. The method is successfully applied to real samples.

Chemiluminescence (CL) methods have been recognized as a valuable approach to sensitive analyses. In particular, the use of solution CL in analyses for inorganic and organic species at trace levels has received considerable attention because of the simplicity of instrumentation, the wide dynamic range, and the short analysis time as well as high sensitivity. An alkaline hydrogen peroxide solution of luminol, lucigenin, lophine, or gallic acid has mainly been utilized for trace metals, cobalt(II) being the most effective catalyst.[1] Copper(II) can be detected by means of its catalytic effect on the oxidation of CL reagent; its detection limit is 0.2 ppm in the lophine system,[2] 1×10^{-7} M (1 M=1 mol dm^{-3}) in the luminol system,[3] and 0.1 ppm in the lucigenin system.[4] These CL systems, however, suffer from lack of selectivity for copper determination. For instance, in the luminol system there are at least 30 different species that enhance light emission.[5]

Flow injection analysis(FIA) is very suitable for the determination of various kinds of analytes based on CL measurements. Cobalt(II) in the pg to sub-pg range has been detected by the gallic acid[6] or luminol system,[7] cadmium(II) and zinc(II) in the sub-ng range by their inhibiting effects on the luminol system,[8] hydrogen peroxide in the 10^{-8} to 10^{-9} M range by the oxalic ester[9] or luminol system,[10] iodine in the sub-ng range by the hypochlorite system,[11] sulfite in the ng range by the permanganate system,[12] fluorescent compounds in the fmol range by the oxalic ester system,[13] and albumin in the 10^{-8} M range by its inhibiting effect on the luminol system.[14]

In the preliminary work, we have made it clear that flavin mononucleotide (FMN) is usable as a CL reagent for sensitive, selective, and rapid determination of copper(II) by FI method.[15] It is based on the measurement of CL arising from the copper-catalyzed oxidation of FMN by hydrogen peroxide under nearly neutral conditions. The object of this paper is to further explore the combination of FIA and CL method and its analytical characteristics, and to verify the utility of the present FI-CL method in copper determination by applying to real samples.

Experimental

Apparatus. Prior to flow experiments, a batch system as shown in Fig. 1 was assembled in order to obtain CL decay curves, that is, to know how fast the present CL reaction proceeds. Each 0.2 ml of FMN, hydrogen peroxide, and copper(II) solutions is transferred in that order to a reaction vessel by a peristaltic pump. The light emitted is observed *via* a fiber optics by a photomultiplier tube (PMT, Hamamatsu Photonics R453) with no wavelength discrimination.

A schematic diagram of the flow system for FIA is given in Fig. 2. An aqueous solution containing FMN and phosphate

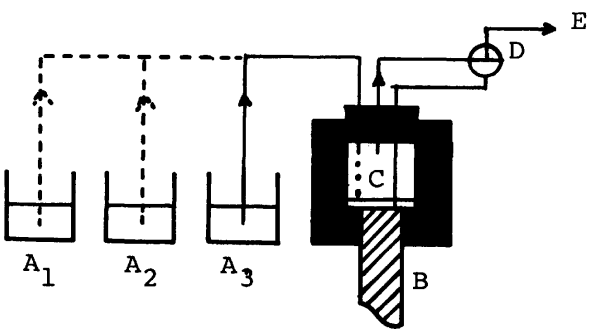

Fig. 1. Batch system for obtaining CL decay curves. A_1: 2.8×10^{-3} M FMN (phosphate buffer), A_2: 10% H_2O_2, A_3: 10^{-4} M Cu(II), B: fiber optics, C: reaction cell, D: 3-way cock, E: to peristaltic pump.

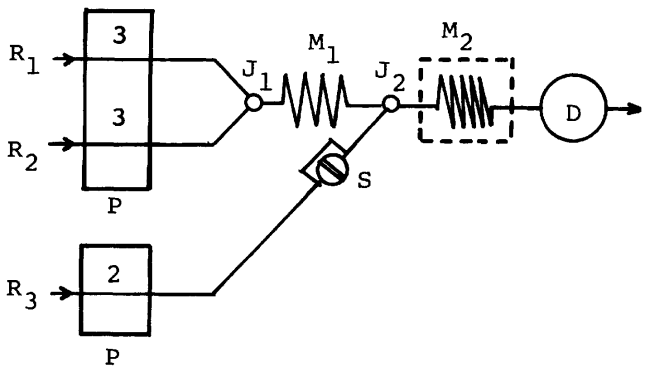

Fig. 2. Schematic diagram of the flow system for FIA (for key, see text).
Recommended conditions: 1.4×10^{-3} M FMN (pH 5.8) for R_1; 5% H_2O_2 for R_2; water for R_3. Flow rates are given as ml min^{-1}. Coil M_2 is held in a heating bath at 60°C.

buffer is supplied through R_1 and hydrogen peroxide through R_2. A flow line R_3, which is newly placed in this experiment, represents a carrier stream for copper(II) and others. This is an aqueous copper(II) solution for the continuous flow method, or pure water when copper(II) and other species are injected by means of a 20-μl rotary valve injector S (injection method). The streams are delivered by peristaltic pumps P and mixed at Y-joints J_1 and J_2. For adequate mixing of R_1 and R_2, a 0.5-m mixing coil M_1 is placed between J_1 and J_2; a second 1-m mixing coil (reaction coil) M_2 is placed in a heating bath controlled to ±0.5 °C between J_2 and D. Teflon tubing (1-mm i.d.) is used for flow lines except the pump tubes and detection flow cell D. The distance between J_2 and D is about 5 cm (the minimum distance achieved). For D a spiral flow cell is assembled as described previously.[16] The light emitted, which has an maximum emission between 500 and 600 nm similar to the fluorescence emission of FMN (λ_{max}=*ca.* 540 nm), is observed directly by a PMT (Hamamatsu Photonics R268) with no wavelength discrimination. The signal from the PMT is fed to an electrometer and then recorded *via* a laboratory-built low-pass active filter, whose frequency cut-off is *ca.*0.1 Hz.

Fluoresecence spectra were measured by a fluorescence spectrophotometer (Hitachi MPF-4). The measurements were performed with respect to the waste solution in the flow system in Fig. 2, in which the stream of hydrogen peroxide solution was substituted by that of water.

Reagents. Chemicals of reagent grade were used as received. The water used was prepared by distillation of Millipore (milli-R) water from an all Pyrex glass apparatus. FMN (monosodium riboflavin 5′-phosphate), phosphate buffer (M/15 KH_2PO_4–M/15 Na_2HPO_4), and hydrogen peroxide solutions were prepared daily.

Analysis of Real Samples. Each 0.7 g of Pepperbush and Pond Sediment (standard reference materials) from NIES (National Institute for Environmental Studies) and of Yabukita tea leaf from National Chemical Laboratory for Industry was boiled with *ca.* 20 ml of concentrated nitric acid on a hot plate until the appearance of white fumes, and with concentrated sulfuric acid until the solution became colorless. After cooling, the solution was diluted to 100 ml. A 40-ml portion of the acid-digested sample was neutralized to about pH 6 with 2 M sodium hydroxide and diluted to 100 ml. A 10-ml portion was added to each of several 100-ml volumetric flasks for standard addition of copper before dilution to volume, and copper was determined as described above.

Results and Discussion

Total Flow Rate and Reaction Temperature. Determinations of the total flow rate in the system and of the reaction temperature in the heating bath are very important for the FI-CL method in sensitivity and rapidity, although both are closely related to each other. At too low or too high total flow rate, most of the CL reaction, the speed of which is considerably slow at room temperature (see Fig. 3), proceeds outside the flow cell, resulting in low signal or low sampling throughput. In the previous work,[15] they were determined to be 8 ml min^{-1} and 60 °C, respectively. These are also employed in the present system, *i.e.*, 3 ml min^{-1} for R_1 and R_2, 2 ml min^{-1} for R_3, and 60 °C for M_2.

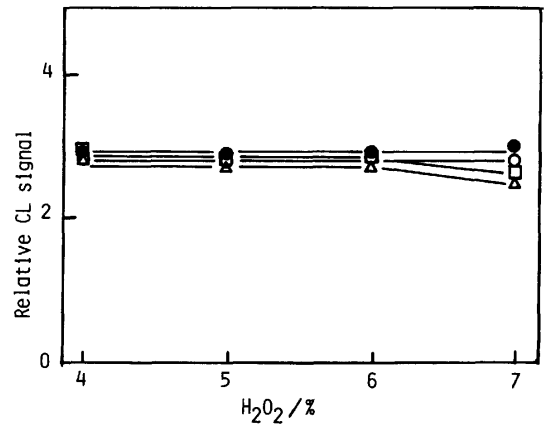

Fig. 4. Effect of the concentrations of hydrogen peroxide and FMN.
FMN concentration (10^{-3} M): △ 0.8; □ 1.0; ○ 1.2; ● 1.4, pH: 6.0, 20-μl injections of 5×10^{-7} M Cu(II), Other conditions as in Fig. 2.

Reagent Concentrations and pH of R_1. Three reaction variables, the concentrations of FMN and hydrogen peroxide and the pH of FMN solution were optimized. Figure 4 shows that the CL signal is almost independent of the reagent concentrations. The concentrations of 1.4×10^{-3} M for FMN and of 5% for hydrogen peroxide were chosen for further experiments, which were slightly higher than those in the previous system because of the dilution of reagent solution with water of R_3.

The effect of pH is shown in Fig. 5, indicating that the optimum pH is about 5.8. The nature of the buffer

components also influenced the signal, the phosphate buffer exhibiting maximum sensitivity. In sodium dihydrogencitrate-sodium tetraborate and disodium hydrogenphosphate-citric acid buffers the signals for 20-μl injections of 5×10^{-7} M copper solution were only *ca.*10 and 20% of that in the phosphate buffer, respectively; the use of sodium citrate-sodium hydroxide and sodium acetate-acetic acid buffers gave rise to no emission.

Effect of Surfactants. Over a narrow range of concentration (called the critical micelle concentration, cmc), amphiphilic surfactant molecules dynamically associate in aqueous solution to form aggregates called micelles, in which there is a sudden transition in the physical properties of aqueous surfactants. It is known that the local microenvironment in micellar media leads to significant increase in CL quantum yield.[17] We already found that the copper-catalyzed CL of 1,10-phenanthroline[18] and the FMN-sensitized CL of sulfur dioxide[19] were enhanced by some cationic and nonionic surfactant molecules, respectively.

In order to investigate whether micellar media function effectively for the present CL system, hexadecyltrimethylammonium bromide (CTAB) as a cationic surfactant, sodium dodecyl sulfate(SDS) as an anionic surfactant, and polyoxyethylene (20) sorbitan trioleate (Tween 85) as a nonionic surfactant were added to the carrier stream (R_3). However, no CL enhancement was observed, regardless of the presence or absence of buffer reagent, its components, and the reaction temperature. These surfactants, except Tween 85 at lower concentrations, suppressed the signal as shown in Table 1. In the table; the effect of surfactants on the fluorescence intensity of FMN is also represented; the micellar solution of CTAB causes decreased fluorescence intensity but those of SDS and Tween 85 increased fluorescence. It can be said from the table that the suppression of CL signal, especially for SDS,

Table 1. Effect of surfactants on CL signal for copper(II)

Surfactant[a]	Concentration	Relative CL signal	Relative fluorescence intensity of FMN
none		1.0	1.0
CTAB	1×10^{-4} M	0.88	
	1×10^{-3} M	0.29	0.72
	8×10^{-3} M	ND[b]	0.47
SDS	1×10^{-3} M	0.74	
	1×10^{-2} M	0.17	1.1
	8×10^{-2} M	0.04	2.9
Tween 85	0.5 g l^{-1}	1.0	
	7 g l^{-1}	1.0	2.1
	20 g l^{-1}	0.91	3.2

a) cmc: 9×10^{-4} M for CTAB, 8×10^{-3} M for SDS, unknown for Tween 85, b) Not detected.

is mainly ascribable to the inhibition of CL reaction due to the addition of surfactant, although for CTAB it is due in part to the decreased fluorescence yield of emitter (the similarity of CL spectrum to the FMN fluorescence spectrum indicates that the emitter has the flavin residue, *i.e.*, the isoalloxazine ring). At the CTAB and SDS concentrations over their cmcs, the signals are suppressed completely or markedly. In contrast, Tween 85 does not suppress the signal or the suppression is not so rigorous as the ionic surfactants even in the addition of large amount of surfactant over its cmc. These are rationalized in terms of the micellar effect that one of the ionic reactants (Cu^{2+} and FMN^-) is repelled electrostatically from the charged micellar surface which the ionic surfactant forms, while the other is attracted, resulting in an inhibition of the CL reaction. On the contrary, the ionic reactants are not influenced by the noncharged micellar surface which the nonionic surfactant forms. This is supported by the finding that the signal for chromium(VI) with a charge of the same sign as that of FMN is enhanced by CTAB, while it is suppressed by SDS and not changed by Tween 85. Other surfactants tested like zephiramine, didodecyldimethylammonium bromide, sodium oleate, Brij-35, and Triton X-100 also did not enhance the signal for copper.

Characteristics of the System. Under the recommended conditions (as specified in Fig. 2), the analytical characteristics of the system were investigated. The background and noise currents were 1.6×10^{-11} and 2.4×10^{-13} A, respectively. The detection limit is defined by the noise level, which depends on the background signal arising presumably from copper as an impurity in the reagents and water used. Accordingly, an improvement of the detection limit would be expected with decreased background. Thus, EDTA or tetraethylenepentamine was added to the reagent stream R_1 in an attempt to mask copper as the impurity. However, no decreased background signal was observed. This indicates that the background comes from noncatalyzed CL of FMN which can not be

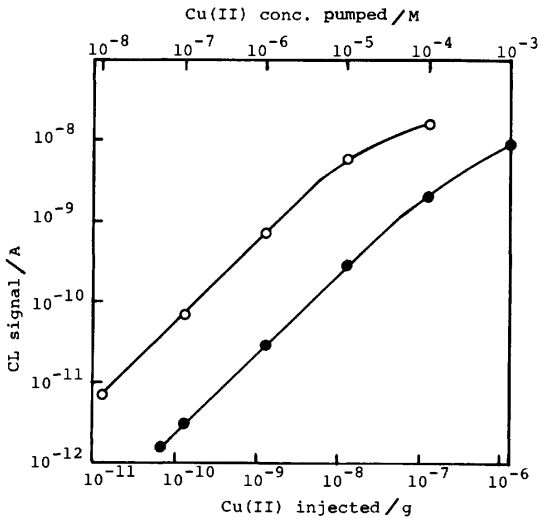

Fig. 6. Calibration graphs.
○: Continuous flow; ●: 20-μl injection.

eliminated.

Logarithmic calibration graphs were linear over three decades for 20-μl sample injections and for continuous sample flow (2 ml min^{-1}) (Fig. 6). The detection limit for a signal-to-noise ratio of 3 is 0.06 ng ml^{-1} for continuous sample flow and 0.03 ng for 20-μl sample injections. This is much lower than the 30 ng (30 ng ml^{-1}) achieved by the flash-photolytically initiated riboflavin CL[20] and the 6 ng ml^{-1} by the luminol electrochemiluminescence.[3] The relative standard deviation is 3.1% when 20-μl of the 1×10^{-6} M solution (*ca.* 1 ng) is successively injected ten times. The sampling rate is 120 h^{-1}.

Effect of Other Substances. Most solution CL methods suffer from poor selectivity. The luminol, lucigenin, and lophine systems permit 30, 20, and 11 species, respectively, to enhance the luminescent reaction.[5] In contrast, the FMN system is fairly selective and only iron(II) and chromium(III,VI) provide CL signals 2—3% of that for copper(II); other species enhance the emission very weakly, or give rise to no emission (Table 2). The signals which S^{2-}, SCN^-, and $S_2O_3^{2-}$ provide seem to derive from the FMN-sensitized CL produced by the energy transfer from excited sulfur molecules (max. emission wavelength= *ca.* 440 nm) to FMN molecules in such a way that the CL based on the hydrogen peroxide-oxidation of sulfide is sensitized by fluorescein (max. fluorescence wavelength λ_{fl}=535 nm) or rhodamine B (λ_{fl}=575 nm).[21] This is supported by the fact that the emission from these species are also sensitized by brilliant sulfoflavine (CI=56205, λ_{fl}=*ca.* 520 nm), another efficient sensitizer used in a previous work.[12] For ascorbic acid, cyanide, and EDTA, the emission may arise from the CL process involving singlet oxygen molecules as in the gallic acid-,[22] pyrogaroll-,[23] tannic acid-,[24] or formaldehyde-hydrogen peroxide CL system[25] and in the urea-, gelatin-, or guanidine-hypochlorite CL system.[25] The background suppression due to iodide is ascribable to the decreased fluorescence yield of emitter because the presence of 10^{-3} M iodide decreases the FMN fluorescence intensity by *ca.* 20%.

To check the effect of concomitant species on the signal for copper, 20 μl of a 10^{-4} to 10^{-6} M solution of each common species was injected into the stream R_3 of 2×10^{-8} M copper(II) solution. The results are

shown in Tables 3 and 4.

Interesting features which appear in Table 3 are that species (Zn, Hg, Cd, Ni, Sn) eliciting no emission *per se* enhance the copper(II)-catalyzed emission (Sn suppresses it) and that species which elicit emission *per se* provide larger signal than those which they provide in the absence of copper. Such interferences are reduced or eliminated by the addition of zinc(II) to the carrier stream as shown in parentheses in the table. On the other hand, the addition of zinc(II) slightly increases the signals for chromium(III,VI) and iron(II) (and also for copper). Although these phenomena can not be readily interpreted, it may be correlated with the stability of FMN–metal complex which is likely to be formed during the CL reaction;[26] the stability of the complex decreasing in the order Cu>Zn>Co>Mn>Ni[27] may account for the reduction and elimination of interference owing to the addition of zinc(II). For anionic species, oxalate which does not chemiluminesce by itself provides signal, in addition to the emissive species (Table 4). Although the interference due to oxalate is not fully explainable, it is closely related to the fact that the oxalate–hydrogen peroxide system emits weak light which is easily sensitized by an appropriate fluorescent compound.[28] It is conceivable that the presence of copper enhances the sensitized-emission which can not be detected in the absence of copper.

Application to Real Samples. The applicability of the proposed method was evaluated by assaying NIES standard reference materials (Pepperbush[29] and Pond Sediment[30]) and Yabukita tea leaf.[31] Standard additions of copper to the acid-digested samples indicated that the results obtained for Pepperbush (12, 13, 13 $\mu g\,g^{-1}$), Pond Sediment (220, 213, 222 $\mu g\,g^{-1}$), and Yabukita tea leaf (9.1, 9.0 $\mu g\,g^{-1}$) by the continuous sample flow method were within the certified values (12±1, 210±12, and 9.09±0.97 $\mu g\,g^{-1}$, respectively).

Conclusion

The above results indicate that ultratrace amounts of copper(II) can be selectively and rapidly determined by FIA based on the FMN CL system. This provides a lower detection limit (0.03 ng or 0.06 $ng\,ml^{-1}$) for copper(II) than that by any other method, the detection limit being lower than those for flame atomic-absorption (18 $ng\,ml^{-1}$) and -fluorescence methods (1.5 $ng\,ml^{-1}$)[32] and neutron activation analysis (0.1 ng),[33] and comparable to those for flameless atomic absorption and inductively coupled plasma emission methods (0.04 $ng\,ml^{-1}$).[32]

Although no micellar enhanced CL is observed here, CL in oriented systems like micelles is very attractive in the analytical point of view because there is much possibility of enhancing quantum efficiency or energy transfer efficiency and because they permits the use of CL reagents and sensitizers insoluble in water. Furthermore, electrostatic interaction between charged analytes and the ionic micellar surface serves to improve selectivity. In the present CL system, for instance, cationic surfactant micelles may enable selective detection of chromium (anionic analytes) because the micellar effect works to suppress emission for cationic analytes like copper and iron, the emission for copper being completely suppressed by the presence of CTAB micelles as shown in Table 1.

The authors thank S. Nakamura (National Chemical Laboratory for Industry) for providing a tea leaf sample.

Calorimetric and Spectrophotometric Studies on Formation of Copper(II) Chloride Complexes in *N,N*-Dimethylformamide

Shin-ichi ISHIGURO, Bojana G. JELIAZKOVA,† and Hitoshi OHTAKI*

Department of Electronic Chemistry, Tokyo Institute of Technology at Nagatsuta, 4259, Nagatsuta-cho, Midori-ku, Yokohama 227

†*Department of Analytical Chemistry, Sofia University, Anton Ivanov 1, Sofia, Bulgaria*

(Received November 7, 1984)

Formation of copper(II) chloride complexes has been studied by calorimetric and spectrophotometric titrations in *N,N*-dimethylformamide (DMF) containing different ionic media, 0.1 and 0.2 mol dm^{-3} $(C_2H_5)_4NClO_4$ and 1 mol dm^{-3} $LiClO_4$ at 25 °C. In all the DMF solutions examined, calorimetric and spectrophotometric titration curves were well explained in terms of formation of a series of four mononuclear complexes, $[CuCl_n]^{(2-n)+}$ (n=1—4), and formation constants, enthalpies and entropies of formation of the complexes were determined. Formation constants were determined by both calorimetry and spectrophotometry and most of the values obtained by the different methods were in good agreement each other. Calorimetric titration curves obtained in 0.1 and 0.2 mol dm^{-3} $(C_2H_5)_4NClO_4$ ionic media were practically the same, but they significantly differed from those obtained in 1 mol dm^{-3} $LiClO_4$ ionic medium, the result indicating that the formation of copper(II) chloride complexes was more favored in the former ionic media than in the latter. Stepwise enthalpies of formation were positive for $[CuCl]^+$, $[CuCl_2]$, and $[CuCl_3]^-$, but negative for $[CuCl_4]^{2-}$ in the $(C_2H_5)_4NClO_4$ DMF solutions, while the values in the 1 mol dm^{-3} $LiClO_4$ DMF solution were more negative by 6—8 kJ mol^{-1} than the respective values in the $(C_2H_5)_4NClO_4$ solutions. A significant difference was also found for stepwise entropies of formation of copper(II) chloride complexes between the ionic media. The ionic medium effect on the formation of the complexes found was ascribed to ion pairing of LiCl in the 1 mol dm^{-3} $LiClO_4$ DMF solution, ion pairing of $(C_2H_5)_4NCl$ being insignificant in the $(C_2H_5)_4NClO_4$ DMF solutions used. A largely negative ΔH_4° and a small ΔS_4° values in the $(C_2H_5)_4NClO_4$ DMF solutions suggested that solvation of the $[CuCl_3]^-$ complex was not strong, and thus, release of solvent molecules from the $[CuCl_3]^-$ complex did not play an important role for the formation of $[CuCl_4]^{2-}$. Therefore, the enthalpy and entropy of formation of $[CuCl_4]^{2-}$ were mainly attributable to those of desolvation of chloride ions and of bond formation between Cl^- and $[CuCl_3]^-$. The $[CuCl_4]^{2-}$ complex may have no DMF molecules in the primary coordination sphere of the central metal ion within the complex. Electronic spectra of individual copper(II) chloride complexes were determined from spectra at various concentrations of chloride ions by using the formation constants obtained.

Although a number of studies have so far been carried out for electronic spectra of copper(II) chloride complexes in both crystalline and solution states, only a few quantitative investigations were examined for the formation of the complexes in solutions. Khan and Schwing-Weill[1] reported the formation constants and electronic spectra of $[CuCl_n]^{(2-n)+}$ (n=1—4) in aqueous solution containing 5 mol dm^{-3} $Na(ClO_4,Cl)$ as a constant ionic medium. Ellev *et al.*[2,3] also spectrophotometrically studied the complex formation reactions in *N,N*-dimethylformamide (DMF) and dimethyl sulfoxide (DMSO) containing 1 mol dm^{-3} $LiClO_4$ and in propylene carbonate containing 0.1 mol dm^{-3} $(C_2H_5)_4NClO_4$. Manahan and Iwamoto[4] investigated the formation and electronic spectra of the copper(II) chloride complexes in acetonitrile by a combination of spectrophotometric and electrochemical methods. In weaker donor solvents such as acetonitrile and propylene carbonate, a series of four mononuclear complexes, $[CuCl_n]^{(2-n)+}$ (n=1—4), were found. However, the only formation of $[CuCl]^+$, $[CuCl_3]^-$, and $[CuCl_4]^{2-}$ were concluded in stronger donor solvents such as DMSO and DMF.

The formation of copper(II) chloride complexes was more favorable in aprotic solvents than in water, and it was more enhanced in weaker donor solvents. Although the formation constants of the $[CuCl_n]^{(2-n)+}$ (n=1—4) complexes have been determined by some authers,[1-4] no values of enthalpy and entropy of formation of the complexes have been reported.

The aim of our present study is to elucidate interactions between copper(II) and chloride ions and between the ions and solvent molecules in *N,N*-dimethylformamide from enthalpic and entropic points of view. The complex formation reactions of copper(II) with chloride ions in DMF containing various inert ionic media were investigated by calorimetry and formation constants, and enthalpies and entropies of formation of the complexes were determined. Spectrophotometric measurements were also carried out to determine the formation constants and electronic spectra of the individual copper(II) chloride complexes.

Experimental

Reagents. *Copper(II) perchlorate* was prepared from copper(II) oxide and perchloric acid of super special reagent grade. The copper(II) perchlorate thus prepared was recrystallized three times from water. The copper(II) perchlorate hexahydrate, $Cu(ClO_4)_2 \cdot 6H_2O$, thus obtained were dried in a vacuum oven at 70 °C for 48 hours.

Copper(II) perchlorate DMF solvates, $Cu(ClO_4)_2(DMF)_x$, were prepared by dissolving copper(II) perchlorate hexahydrate crystals in DMF and recrystallized six times from DMF and finally from a DMF–acetone mixture. The crystals thus obtained involved four to six DMF molecules per copper(II) ion, as already noted by Schneider,[5] and were dried at 40 °C in a vacuum oven for several days and kept in a vacuum desiccator over P_2O_5. Electrogravimetrical analysis showed that the copper(II) perchlorate DMF solvate crystals finally obtained were $Cu(ClO_4)_2(DMF)_4$.

Lithium perchlorate and *lithium chloride* were recrystallized from water and dried as described elsewhere.[6]

Tetraethylammonium perchlorate and *tetraethylammonium chloride* of reagent grade were used without further purification and dried at 100 °C.

N,N-*Dimethylformamide* was dried for several weeks over molecular sieves 4A 1/16, and then distilled at 40 °C under a reduced pressure (2 mmHg) and stored over the molecular sieves in a dark bottle with a P_2O_5 guard-tube. The residual water determined by Karl Fisher tests was less than 220 ppm.

As *N,N*-dimethylformamide is hygroscopic, all test solutions were prepared in a dry box over P_2O_5 and under an atmosphere of dried nitrogen gas.

Measurements. Calorimetric measurements were carried out in a thermostated bath controlled at (25.000±0.007) °C placed in a room thermostated at (25.0±0.2) °C. Throughout the calorimetric titrations, an ionic medium was kept constant by using either $(C_2H_5)_4NClO_4$ (0.1 and 0.2 mol dm^{-3}) or $LiClO_4$ (1 mol dm^{-3}). A 100 cm^3 of copper(II) perchlorate solution was first placed in a Dewar vessel, which was filled with nitrogen gas and prevented from moisture with a P_2O_5 guard-tube, and then titrated with a relevant chloride solution. The titrants employed were $(C_2H_5)_4NCl$ (0.1 and 0.2 mol dm^{-3}) and LiCl (1 mol dm^{-3}) solutions. The heat of dilution of chloride ions was separately determined by titrating either $(C_2H_5)_4NClO_4$ or $LiClO_4$ solution without copper(II) perchlorate with the relevant titrant solutions. The values were 0.06, 0.08, and 0.28 J cm^{-3} per the addition of a unit volume of the titrants, 0.1 and 0.2 mol dm^{-3} $(C_2H_5)_4NCl$ and 1 mol dm^{-3} LiCl, respectively. A heat q of reaction evolved at each point of titration was ranged −5 to 5 J with a certainty ±0.05 J. Calorimetric measurements were carried out by using a fully automatic on-line system as described in a previous paper.[6]

Spectrophotometric measurements were carried out in DMF solutions containing the same ionic media as those employed in calorimetric measurements. A flow cell with a light-path length of 0.5 cm was connected with a titration vessel through teflon and glass tubes. A 15 cm^3 of $Cu(ClO_4)_2$ DMF solution was placed in a vessel under a nitrogen atmosphere and then titrated with either a tetraethylammonium or a lithium chloride solution. Electronic spectra were measured with a HITACHI 340 spectrophotometer (HITACHI) equipped with a JEC 6 electronic computer (JEOL) which recorded data at selected wavelengths.

Analysis of Calorimetric and Spectrophotometric Data. A heat q_i evolved at a titration point i is represented by Eq. 1 by using formation constants β_n and overall enthalpies $\Delta H^\circ_{\beta n}$ of formation of the $[CuCl_n]^{(2-n)+}$ complexes.

$$q_i = -(V_i \sum_n \beta_n \Delta H^\circ_{\beta n} m_i x_i^n - V_{i-1} \sum_n \beta_n \Delta H^\circ_{\beta n} m_{i-1} x_{i-1}^n), \quad (1)$$

where V denotes the volume of a test solution, and m and x stand for concentrations of free copper(II) and chloride ions, respectively, which are related to their total concentrations C_M and C_X according to the mass-balance equations 2 and 3:

$$C_M = \sum_n \beta_n m_i x_i^n + m \quad (2)$$

$$C_X = \sum_n n\beta_n m_i x_i^n + x. \quad (3)$$

The formation constants and enthalpies were determined by minimizing the error-square sum, $U = \sum_i (q_{i,obsd} - q_{i,calcd})^2$ by using the program KALORI.[7]

Absorbance A_{ij} at a titration point i and a selected wavelength λ_j is represented by Eq. 4 by using the formation constants and molar extinction coefficients $\varepsilon_n(\lambda_j)$ of the $[CuCl_n]^{(2-n)+}$ complexes.

$$A_{ij} = \sum_n \varepsilon_n(\lambda_j) \beta_n m_i x_i^n \quad (\beta_0 = 1), \quad (4)$$

where the wavelengths λ_j selected in the present work were 262, 270, 280, 290, 300, 310, 320, 370, 410, and 440 nm. The formation constants and molar extinction coefficients were determined by minimizing the error-square sum, $U = \sum_i \sum_j (A_{ij,obsd} - A_{ij,calcd})^2$ by using the program SPEC.

Results and Discussion

Calorimetric titration curves obtained in 1 mol dm^{-3} $LiClO_4$ ionic medium are depicted in Fig. 1. The enthalpy ΔH°/kJ mol^{-1} per the addition of a unit mole of chloride ions at each titration point was plotted against the ratio C_X/C_M, where C_X and C_M denote total concentrations of chloride and copper(II) ions, respectively, in a solution. In DMF solution with the same ionic medium, Ellev *et al.*[2] reported the only formation of $[CuCl]^+$, $[CuCl_3]^-$, and $[CuCl_4]^{2-}$ from spectrophotometric measurements. Therefore, the formation constants and enthalpies were first optimized by assuming the formation of the three copper(II) chloride complexes. The theoretical curves calculated by using the constants thus obtained are illustrated by broken lines in Fig. 1, which appreciably deviated from experimental curves, especially in the range C_X/C_M=0.5—2. This indicated that the formation of the $[CuCl_2]$ complex can not be neglected in the DMF solution. Subsequently, we assumed the formation of four complexes, $[CuCl_n]^{(2-n)+}$ (n=1—4), and then the experimental points fit well the curves (solid lines) calculated by using the constants of the four complexes. A comparison for the formation constants and enthalpies obtained by different assumptions of three (case 1, n=1, 3, and 4) and four (case 2, n=1, 2, 3, and

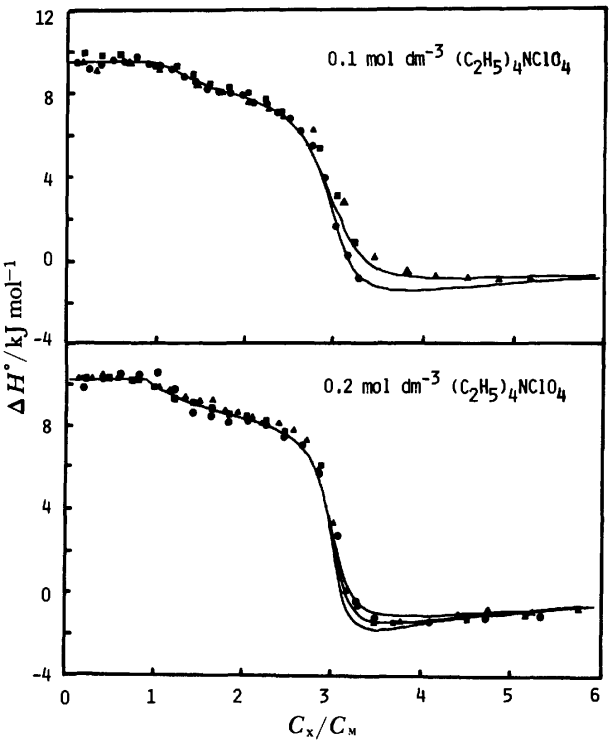

Fig. 2. Calorimetric titration curves of copper(II) chloride DMF solutions containing 0.1 and 0.2 mol dm^{-3} $(C_2H_5)_4NClO_4$. Initial concentrations of copper(II) perchlorate (C_M/mmol dm^{-3}): 7.30 (■), 15.20 (▲) and 20.25 (●) in 0.1 mol dm^{-3} $(C_2H_5)_4NClO_4$ DMF solution, and 9.80 (●), 14.66 (■) and 19.93 (▲) in 0.2 mol dm^{-3} $(C_2H_5)_4NClO_4$ DMF solution.

4) copper(II) chloride complexes is shown in Table 1. The error-square sum U and standard deviations were much smaller in case 2 than in case 1. Thus, we concluded that a series of four mononuclear complexes, $[CuCl_n]^{(2-n)+}$ (n=1—4), were formed in the 1 mol dm^{-3} $LiClO_4$ DMF solution.

Calorimetric titration curves obtained in DMF solutions containing 0.1 and 0.2 mol dm^{-3} $(C_2H_5)_4NClO_4$ are depicted in Fig. 2. Experimental points well fell on the curves (solid lines) calculated by using the formation constants in Table 2 and the enthalpies in Table 3 of the four mononuclear copper(II) chloride complexes in each $(C_2H_5)_4NClO_4$ DMF solution.

The stepwise formation constants obtained by calorimetry and spectrophotometry in each ionic medium are compared in Table 2. In all cases, the error-square sum U became small enough to explain experimental data in terms of the formation of $[CuCl_n]^{(2-n)+}$ (n=1—4). Standard deviations for each constant were not well evaluated because the product of diagonal elements of the error matrix exceeded 10^{-75}, which was the lowest limit of the computer ability employed. However, a reasonable agreement was obtained between the formation constants determined by calorimetry and spectrophotometry.

The overall enthalpies of formation of the complexes obtained by calorimetry are listed in Table 3, together with the enthalpy values obtained by employing the formation constants determined by spectrophotometry for the analysis of the calorimetric data. Except for the $\Delta H^\circ_{\beta_4}$ value in the 0.1 mol dm^{-3} $(C_2H_5)_4NClO_4$ ionic medium, all enthalpy values obtained by the both estimations were in good agreement. In the 0.1 mol dm^{-3} $(C_2H_5)_4NClO_4$ ionic medium, test solutions were titrated with a 0.1 mol dm^{-3} $(C_2H_5)_4NCl$ solution, and thus, the formation of the $[CuCl_4]^{2-}$ complex might be insufficient even after the addition of a large volume of the titrant. Therefore, the $\Delta H^\circ_{\beta_4}$ value thus estimated may involve a rather large uncertainty.

Formation of Copper(II) Chloride Complexes in $(C_2H_5)_4NClO_4$ Ionic Media. It is obvious from similar calorimetric titration curves in Fig. 2 that thermodynamic quantities in the 0.1 mol dm^{-3} $(C_2H_5)_4NClO_4$ ionic medium were not appreciably different from those in the 0.2 mol dm^{-3} $(C_2H_5)_4NClO_4$ ionic medium.

Thermodynamic quantities, ΔG°_n/kJ mol^{-1}, ΔH°_n/kJ mol^{-1}, and ΔS°_n/J K^{-1} mol^{-1}, for stepwise reactions, $CuCl_{n-1}^{(3-n)+} + Cl^- = CuCl_n^{(2-n)+}$ (n=1—4), in the 0.2 mol dm^{-3} $(C_2H_5)_4NClO_4$ ionic medium are summarized in Table 4, together with those in the 1 mol dm^{-3} $LiClO_4$ ionic medium.

Copper(II) ions are more strongly solvated in DMF than in water,[8] as is expected from a stronger donor property of DMF (the donor number (D_N)=26.6) than that of water (D_N=18.0).[9] On the other hand, chloride ions are less strongly solvated in DMF than in water.[10] The change in enthalpy of solvation of Cl^- between the solvents is much less significant than that of Cu^{2+}. Therefore, the formation of copper(II) chloride complexes should be less favored in DMF than in water from the enthalpic point of view. However, the reverse was the case, that is, the formation of copper(II) chloride complexes was more favorable in DMF than in water. The facts indicated that the formation of the complexes was more favored by the entropy term in DMF than in water, although the enthalpies and entropies of formation of the complexes in water have not been known.

According to Ahrland,[11] such a more favorable en-

tropy of complex formation reactions of metal ions in DMF than in water is not unexpected and it can be interpreted in terms of both different solvation structure of metal ions and different solvent structure between solvent molecules in DMF from those in water. In water, water molecules leave a hydrate structure and then enter another fairly well-ordered structure of bulk water. The entropy changes at the two stages compensate each other to yield a modest entropy gain, or even a net loss if the entropy change connected with the coordination of the ligand is not so favorable. In DMF, solvent molecules leave a solvate structure which may be more strictly ordered than the corresponding hydrate and then enter a bulk solvent that is fairly unstructured. Thus, a very large entropy gain may result.

Largely positive entropies ΔS°_n of formation were observed for the formation reactions of the $[CuCl_n]^{(2-n)+}$ (n=1—3) complexes in DMF containing 0.2 mol dm^{-3} $(C_2H_5)_4NClO_4$, which therefore suggested that the metal and chloride ions in the solution were extensively desolvated in the course of the formation of the complexes.

On the other hand, the ΔS°_4 value for the reaction, $CuCl_3^- + Cl^- = CuCl_4^{2-}$, was almost zero and remarkably smaller than the ΔS°_n (n=1—3) values in the 0.2 mol dm^{-3} $(C_2H_5)_4NClO_4$ DMF solution, indicating that the entropy gain due to desolvation of the $[CuCl_3]^-$ complex in the course of the formation of $[CuCl_4]^{2-}$ may not be significant if the extent of entropy loss accompaning the coordination of the ligand is similar at each consecutive step of the formation reactions, $CuCl_{n-1}^{(3-n)+}+Cl^- = CuCl_n^{(2-n)+}$ (n=1—4).

A large difference between the enthalpies of formation of the copper(II) chloride complexes was also observed. The ΔH°_4 value was negative in contrast to the ΔH°_n (n=1—3) values which were all positive. The $[CuCl_3]^-$ complex may not be strongly solvated in DMF, and thus, DMF molecules weakly solvating the complex may be exothermically replaced with a chloride ion in the course of the formation of the $[CuCl_4]^{2-}$ complex. Consequently, it was suggested that the $[CuCl_4]^{2-}$ complex has no solvent molecules in the primary coordination sphere of copper(II) ion within the complex.

Formation of Copper(II) Chloride Complexes in $LiClO_4$ Ionic Medium. In the 1 mol dm^{-3} $LiClO_4$ DMF solution, the ΔH°_n value of formation of the $[CuCl_n]^{(2-n)+}$

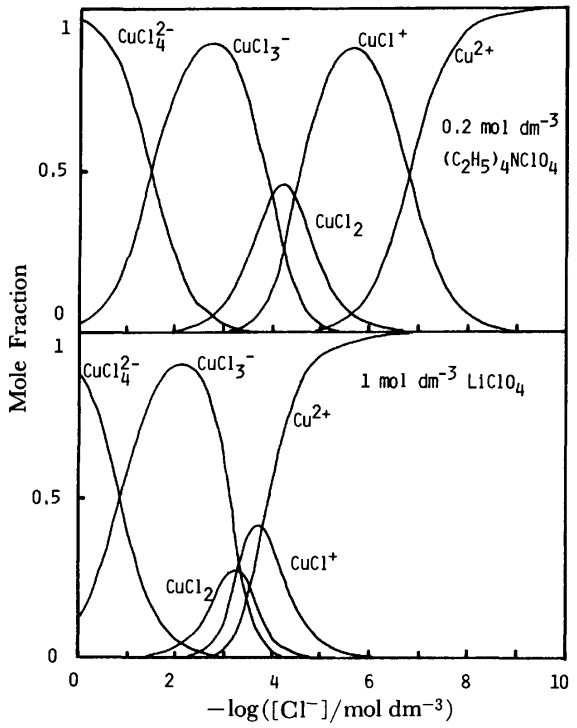

Fig. 3. Distribution of the copper(II) chloride complexes in 0.2 mol dm^{-3} $(C_2H_5)_4NClO_4$ and 1 mol dm^{-3} $LiClO_4$ DMF solutions, calculated by using the formation constants obtained by calorimetry.

complex was slightly positive for n=1 and 2, slightly negative for n=3 and largely negative for n=4, all the enthalpy values being more negative by 6—8 kJ mol^{-1} than the respective values in the 0.2 mol dm^{-3} $(C_2H_5)_4NClO_4$ DMF solution. As to the entropy of formation of $[CuCl_n]^{(2-n)+}$ in the 1 mol dm^{-3} $LiClO_4$ DMF solution, the ΔS_n° value was positive for n=1—3, but was negative for n=4, and all the values were significantly smaller than the respective entropy values in the 0.2 mol dm^{-3} $(C_2H_5)_4NClO_4$ DMF solution. Consequently, the formation of copper(II) chloride complexes was less favored in the 1 mol dm^{-3} $LiClO_4$ than in the $(C_2H_5)_4NClO_4$ DMF solutions as illustrated by the distribution curves in Fig. 3.

It has been reported that lithium ions associate with perchlorate[12] and chloride[13-15] ions to form solvent-shared and contact ion pairs in DMF solutions. Since it is expected that lithium ions are strongly solvated with DMF molecules,[16] ionic association of $LiClO_4$ may not be significant in solutions less than 2 mol dm^{-3} of the salt.[12] However, LiCl forms ion pairs even in relatively dilute solutions, the K_1 value for the formation of the ion pairs being reported to be 35 by conductivity[14] and 4 by emf measurements.[15] From these constants, we can estimate that 25—85% of chloride ions in the 1 mol dm^{-3} LiCl DMF solution may form ion pairs.

Enthalpies of solution of $(C_2H_5)_4NCl$ crystals measured in DMF solutions of various ionic media are listed in Table 5. The enthalpy of solution of $(C_2H_5)_4NCl$ in 1 mol dm^{-3} $LiClO_4$ DMF solution was more positive by 8—9 kJ mol^{-1} than the values in 0.1 and

Table 5. Enthalpies of solution of $(C_2H_5)_4NCl$ crystals in *N,N*-dimethylformamide solution at 25 °C

Ionic Medium	ΔH_S°/kJ mol^{-1}
Pure DMF	7.3
0.1 mol dm^{-3} $(C_2H_5)_4NClO_4$	9.7
0.2 mol dm^{-3} $(C_2H_5)_4NClO_4$	10.3
1 mol dm^{-3} $LiClO_4$	18.7

0.2 mol dm^{-3} $(C_2H_5)_4NClO_4$ DMF solutions. The difference may be mainly attributable to the enthalpy of formation of ion pairs between lithium and chloride ions in the 1 mol dm^{-3} $LiClO_4$ DMF solution, although enthalpies of solution of the crystals may vary depending on ionic media of the solutions examined. In fact, the enthalpy of solution of $(C_2H_5)_4NCl$ in the 0.1 mol dm^{-3} $(C_2H_5)_4NClO_4$ DMF solution was slightly more positive than that in pure DMF solution, but was practically the same as that in the 0.2 mol dm^{-3} $(C_2H_5)_4NClO_4$ DMF solution. The positive enthalpy of formation of the LiCl ion pair has also been suggested from concentration dependence of heat of solution of LiCl in DMF.[13]

Considering that $K_1>1$ and $\Delta H_{ip}^\circ>0$ for the formation of ion pairs between lithium and chloride ions in DMF, we can expect the relations between the thermodynamic quantities, ΔG_{ip}°, ΔH_{ip}°, and ΔS_{ip}°, for the ion pairs formation reaction, $Li^+ + Cl^- = LiCl$, in DMF as follows: $\Delta G_{ip}^\circ<0$ and $T\Delta S_{ip}^\circ>\Delta H_{ip}^\circ>0$. Therefore, the entropy of formation which may be mainly owing to desolvation of DMF molecules from lithium ions plays an important role for the formation of LiCl ion pairs in DMF.

Accordingly, the complex formation reactions between copper(II) and chloride ions should be accompanied by dissociation of LiCl ion pairs in 1 mol dm^{-3} $LiClO_4$ DMF solution. The enthalpy of dissociation of LiCl was negative, which led to more negative ΔH_n° (n=1—4) values of formation of $[CuCl_n]^{(2-n)+}$ in the 1 mol dm^{-3} $LiClO_4$ than in the 0.2 mol dm^{-3} $(C_2H_5)_4NClO_4$ where $(C_2H_5)_4NCl$ does not appreciably form ion pairs. The smaller entropies ΔS_n° of formation of $[CuCl_n]^{(2-n)+}$ (n=1—4) in the 1 mol dm^{-3} $LiClO_4$ than in the 0.2 mol dm^{-3} $(C_2H_5)_4NClO_4$ may be also ascribed to the ion pairing of LiCl in the former DMF solution.

Electronic Spectra of Copper(II) Chloride Complexes. Electronic spectra of copper(II) chloride at various concentrations of chloride ions were measured in 0.2 mol dm^{-3} $(C_2H_5)_4NClO_4$ and 1 mol dm^{-3} $LiClO_4$ DMF solutions. Each spectrum obtained was resolved into spectra of individual copper(II) chloride complexes by knowing the formation constants of the complexes in the solutions. Molar extinction coefficients of individual copper(II) chloride complexes at various wavelengths thus obtained in the 0.2 mol dm^{-3} $(C_2H_5)_4NClO_4$ and 1 mol dm^{-3} $LiClO_4$ DMF solutions are depicted in Fig. 4.

The calculated spectra of the $[CuCl]^+$, $[CuCl_3]^-$, and $[CuCl_4]^{2-}$ complexes in the 1 mol dm^{-3} $LiClO_4$ DMF solu-

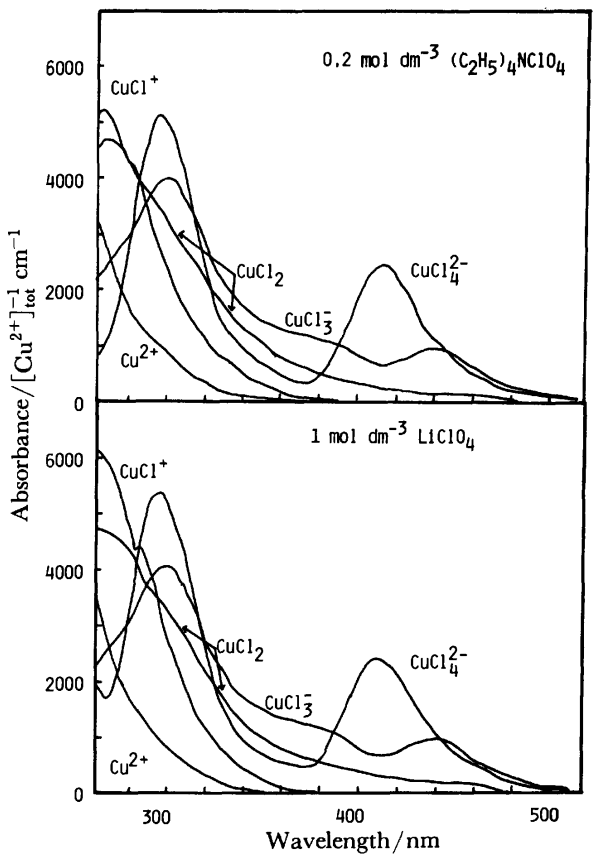

Fig. 4. Molar extinction coefficients of individual copper(II) chloride complexes at various wavelengths in 0.2 mol dm^{-3} $(C_2H_5)_4NClO_4$ and 1 mol dm^{-3} $LiClO_4$ DMF solutions.

tion were similar to those obtained in the same DMF solution by Ellev *et al.*[2] who neglected the formation of the $[CuCl_2]$ complex in the solution. Although the formation of the $[CuCl_2]$ complex was less significant in the 1 mol dm^{-3} $LiClO_4$ DMF solution than in the 0.2 mol dm^{-3} $(C_2H_5)_4NClO_4$ DMF solution as seen in Fig. 3, the formation of the complex was still appreciable even in the former solution. Thus, the spectrum of the $[CuCl_2]$ complex could be determined in both the 0.2 mol dm^{-3} $(C_2H_5)_4NClO_4$ and 1 mol dm^{-3} $LiClO_4$ DMF solutions, the spectra of the complex thus obtained in the solutions being practically the same. No absorption peak in the range of wavelength 300—500 nm was observed for the $[CuCl_2]$ complex as well as the $[CuCl]^+$ complex.

Molar extinction coefficients of individual copper(II) chloride complexes calculated were not appreciably different between the 0.2 mol dm^{-3} $(C_2H_5)_4NClO_4$ and 1 mol dm^{-3} $LiClO_4$ DMF solutions over the whole range of wavelengths measured, and therefore, structures of the copper(II) chloride complexes formed in the solutions might not essentially be affected by the inert ionic medium salts within the concentration range examined in the present study.

From electronic spectra measured in various nonaqueous solvents and in crystals, Furlani and Morpurgo[17] suggested a flattened tetrahedral structure with D_{2d} symmetry for the $[CuCl_4]^{2-}$ complex. However, structures of the copper(II) chloride complexes in DMF have not been directly determined by a diffraction method. Fergusson[18] suggested that the presence of an absorption peak between 435 and 455 nm of a copper(II) chloride complex was indicative of the D_{2d} form of the complex. If the consideration by Fergusson would be acceptable for the $[CuCl_3]^-$ complex in DMF, the complex should have the D_{2d} form with a DMF molecule solvating copper(II) ion within the complex, since the spectrum of the $[CuCl_3]^-$ complex showed an absorption peak at *ca.* 440 nm. However, the copper(II)-DMF bond within the $[CuCl_3]^-$ complex may not be so strong, as already discussed in a previous section. On the other hand, the spectrum of the $[CuCl]^+$ and also that of the $[CuCl_2]$ complex did not show any peak at the region of wavelength 435—455 nm.

The Structure–Reactivity–Chemoselectivity Relationship on the Reactions of 1-Unsubstituted Tautomeric 2-Pyridones with Benzyne

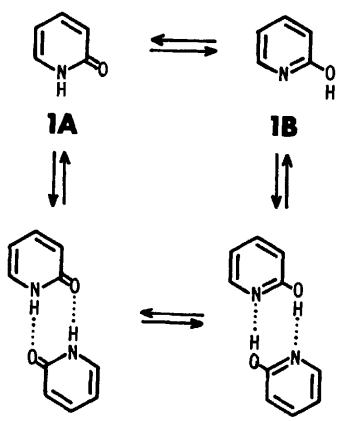
Masayuki KUZUYA,* Akihiro NOGUCHI, Ei-ichi MANO, and Takachiyo OKUDA
Gifu Pharmaceutical University, 6-1, Mitahora-higashi, 5-Chome, Gifu 502
(Received September 20, 1984)

The reactions of 2-pyridones with benzyne were investigated in order to gain some insight into the structure–reactivity–chemoselectivity relationship involved in the tautomeric systems. All reactions examined have resulted in the formation of Diels-Alder and Michael-type adducts. It has been shown that the Diels-Alder reactivities were well correlated with the HOMO energy levels of the 2-pyridone form and the yields of the Michael-type adduct were closely associated with the tautomeric equilibria. In summary, the chemoselectivities of 2-pyridones in the reaction with benzyne were largely affected by the tautomeric properties.

The tautomerism, 2-pyridone⇌2-pyridinol (**1a**), is one of the most frequently investigated tautomeric equilibria present in many heterocyclic systems. It has been well established experimentally and theoretically that there is no significant difference in the fundamental stabilities of the unimolecular state of the tautomers, **1A** and **1B**.[1] Most of 2-pyridone derivatives, however, are known to exist largely in the 2-pyridone form (**A**) as the self-associated dimer in the crystalline state[2] and in solution[3] due to the greater association ability of the 2-pyridone form (**A**), whereas derivatives bearing a 6-polar substituent exist predominantly in the 2-pyridinol form (**B**) in solution.[4]

A delicate balance of such tautomeric properties and/or aggregation forms in solution can be expected to exert an influence upon the chemical reactivity, and such reactions could provide some insight into the structure–reactivity–chemoselectivity relationship involved in the tautomeric systems. Thus, a study of the reaction of these compounds with benzyne will be interesting in connection with a variety of reactions, [*i. e.* Diels-Alder reaction and Michael-type addition].

However, in contrast to the substantial amount of experimental work on the Diels-Alder reaction of 1-substituted 2-pyridones with a variety of dienophiles in recent years,[6] similar reactions of 1-unsubstituted 2-pyrdiones have received only limited attention, and most of such reactions have been concerned only with the Michael-type addition to the oxygen and/or nitrogen atom.[6a,7] The only example of the formation of a Diels-Alder adduct to be found in the literature is the reaction with *N*-phenylmaleimides,[8] and the formation of Diels-Alder adduct with benzyne was not known prior to our preliminary publication.[9]



Scheme 1.

In view of these points of interest, we have studied the reactions of various substituted 2-pyridones with benzyne. In the present paper, we show that the product composition varied with the effect of the tautomeric properties exerted by a substituent, and discuss the structure–reactivity–chemoselectivity relationship observed in such reactions.

Experimental

Measurement of the Relative Diels-Alder Reactivity of 1-Methyl-2-pyridones (2) with Benzyne by Competitive Reactions. Two 2-pyridones (**2x**) and (**2y**) (0.001 mol of each) and isopentyl nitrite (0.53 g, 0.0045 mol) were dissolved in dry chloroform (80 ml). Then, anthranilic acid (0.38 g, 0.0028 mol) in a mixed solvent of acetone (20 ml) and dry chloroform (30 ml) was added dropwise to the solution over a period of 2 h under nitrogen bubbling at 70 °C. The whole was allowed to heat for an additional 2 h at 70 °C and the solvent evaporated under reduced pressure. The yields of the Diels-Alder adduct (**3x**) and (**3y**) were determined from the comparison of the integrated intensity of the peak between the product and the corresponding unreacted starting pyridones, respectively, in the ^{1}H NMR spectra of the reaction mixtures. None of the other product derived from 2-pyridones was observed. Based on the ^{1}H NMR inspection of authentic samples of the Diels-Alder adduct (**3**), the combination of two 2-pyridones (**2x**) and (**2y**) for the competitive reactions was selected so as to permit such a determination of the yield in the ^{1}H NMR spectrum of the reaction mixture. The yields(%) (Y(**3x**) and Y(**3y**)) in each set of competitive reactions are summarized in Table 1.

Reactions of 1-Unsubstituted 2-Pyridones (1) with Benzyne. The reactions were performed on 2-pyridones (**1a—j**, **1l—q**, and **1s—u**) in a similar manner as above. The Diels-Alder adduct (**4**), 2-phenoxypyridine (**5**), and 1-phenyl-2-pyridone (**6**) were isolated by chromatographic separation of the products on alumina in chloroform. The residue of each fraction was weighed after evaporation of the solvent.

Effects of Concentration on the Reactivity and Chemoselectivity. The procedures are essentially identical to those described above. For the reactions in 0.00625 mol dm^{-3} solution, each of 2-pyridones (**1h**), (**1i**), (**1m**), (**1n**), and

Table 1. Product yields in various pairs of competition reactions.

(**1o**) (0.004 mol of each) and isopentyl nitrite (1.06 g, 0.009 mol) in dry chloroform (640 ml) were treated with anthranilic acid (0.76 g, 0.0056 mol) in a mixed solvent of acetone (160 ml) and dry chloroform (320 ml). On a similar workup as above, the product yields of 2-phenoxypyridine (**5**), the Diels-Alder adduct (**4**) and the unreacted 2-pyridone (**1**) were determined from the integrated intensities of the peak characteristic of each compound in the ^{1}H NMR spectra except for **1o**. The crude mixture obtained from **1o** did not show the well defined ^{1}H NMR spectrum. The crude mixture of **1o**, therefore, was chromatographed on alumina in chloroform as an eluent and the product yield then determined from the isolated yield of each of the compounds (**4o**), (**5o**), and (**1o**). For the reactions in 0.1 mol dm^{-3} solution, each of 2-pyridones (**1h**), (**1i**), (**1m**), (**1n**), and (**1o**) (0.004 mol of each) and isopentyl nitrite (1.06 g, 0.009 mol) in dry chloroform (40 ml) were treated with anthranilic acid (0.76 g, 0.0056 mol) in a mixed solvent of acetone (10 ml) and dry chloroform (20 ml), and the product composition analyzed as above.

Molecular Orbital Calculations. The CNDO/2 calculations for methylated 2-pyridones and self-associated dimeric form of 2-pyridone and 2-pyridinol were described in a previous paper.[10] For the comparison of the relative energetics with the same level of approximation, the CNDO/2 calculations of benzyne were performed with the standard parametrizations.[11] The geometric parameters were taken from the *ab initio* (4-31G) study with geometry optimization for singlet benzyne.[12]

Results and Discussion

Substituent Effect on Diels-Alder Reactivity of 1-Methyl-2-pyridones with Benzyne. In order to evaluate the substituent effect on the Diels-Alder reactivity of the 2-pyridone tautomer, we have first studied the reactions of 1-methyl-2-pyridones (**2**) with benzyne to afford 1-methyl-5,6-benzo-2-azabarrelen-3(2*H*)-one derivatives (**3**), several members (**2a—e**) of which were initially studied under somewhat different conditions by Sheinin *et al.*[6a] (Scheme 2). The structural assignment and physicochemical properties of the products (**3**) will be published in a separate paper.[13]

The Diels-Alder reaction of **2** with benzyne is sensitive to the reaction conditions. In fact, the yields

Scheme 2.

of Diels-Alder adducts of 1-methyl-2-pyridones with benzyne were rather poorly reproduced. Accordingly the relative reactivities were determined by the competition reactions between two 1-methyl-2-pyridones (**2x**) and (**2y**). In a competitive reaction, the concentration of highly reactive benzyne to which the two pyridones (**2x**) and (**2y**) are exposed at any time is the same for both, since they are present in the same reaction mixture. So, from the yields(%) (Y(**3x**) and Y(**3y**)) obtained by the competition reaction of **2x** and **2y** (*vide supra*), the competition constant was calculated by

$$\frac{k_{2y}}{k_{2x}} = \frac{\ln([2y]/[2y]_0)}{\ln([2x]/[2x]_0)} = \frac{\ln(1-0.01Y(3y))}{\ln(1-0.01Y(3x))}$$

where $[2x]_0$ and $[2y]_0$ are the initial concentrations of **2x** and **2y**, respectively. From these competition constants, the relative reactivities (k_r) against the parent 1-methyl-2-pyridone (**2a**) were determined, and summarized in Table 2.

The reliability of this competition method was checked on several sets of the competition constants: the reactivity ratio of **2x** and **2x′** was calculated from the competition constants of two pairs of 2-pyridones (**2x**, **2y** and **2x′**, **2y**), and this value was checked against that obtained in a direct competition experiment of **2x** and **2x′**. The scrutinized results are as follows: k_{2k}/k_{2i}(=0.42) was calculated as 0.44 from k_{2i}/k_{2c} and k_{2k}/k_{2c}; k_{2m}/k_{2e}(=3.6) as 3.9 from k_{2e}/k_{2b} and k_{2m}/k_{2b}; k_{2n}/k_{2m}(=1.7) as 1.7 from k_{2m}/k_{2b}, k_{2j}/k_{2b} and k_{2n}/k_{2j}. Thus, the probable errors for the relative reactivities obtained are considered to be within ±10%.

Table 2. The relative Diels-Alder reactivity (k_r) of 1-methyl-2-pyridones with benzyne

Substrate	k_r	Substrate	k_r
2a	1.0	**2l**	2.6
2b	1.6	**2m**	5.4
2c	1.2	**2n**	9.2
2d	1.3	**2o**	15
2e	1.5	**2p**	18
2f	5.2	**2q**	12
2g	1.6	**2r**	0.96
2h	2.8	**2s**	3.0
2i	4.8	**2t**	0.33
2j	14	**2u**	9.0
2k	2.0	**2v**	2.8

Table 2 shows that on the whole the Diels-Alder reactivities were raised as the number of substituents increased. From the comparison of the results between 3,5-dimethyl (**2f**) and 4,6-dimethyl derivatives (**2g**), and between the two 4-phenyl derivatives (**2l**) and (**2o**), introduction of the substituent into the 3- and 5-position seems to exert the greater influence on enhancement of the reactivity; the 4-phenyl substituent also exhibited further enhancement of the reactivity in a series of 5,6-dimethyl derivatives (**2n**) and (**2o**).

Reaction of 1-Unsubstituted Derivatives with Benzyne. In order to discuss the reactivity and chemoselectivity observed with 1-unsubstituted 2-pyridone derivatives (**1**), the reactions of 1-unsubstituted 2-pyridones (**1**) with benzyne have been carried out according to the procedure similar to those for 1-methyl derivatives (**2**) (Scheme 3). The structural proof of the products (**4**), (**5**), and (**6**) will be published in a separate paper.[13]

The product composition in such reactions was listed in Table 3.

It can be seen from Table 3 that the reactivity and chemoselectivity apparently varied with the substituents. Special features disclosed include the following facts; the most favored reaction is the formation of 2-phenoxypyridine (**5**) which is one of the Michael-type adducts. In all cases, the Diels-Alder reaction also proceeded to give 5,6-benzo-2-azabarrelen-3(2*H*)-ones (**4**), and the polysubstitutions apparently raised the yields of the Diels-Alder adduct, this tendency is in accord with that observed for the 1-methyl derivatives (**2**).

Interestingly, the formation of 1-phenyl-2-pyridones (**6**), another Michael-type adduct, was not observed or occured only in a very low yield for the derivatives which exist in the 2-pyridone form in solution. However, in the case of the derivatives (**1s**) and (**1t**) which tend to exist in the 2-pyridinol form in solution, appreciable amounts of the 1-phenyl-2-pyridones (**6**) were obtained as well as the Diels-Alder adduct (**4**) and the 2- phenoxypyridine (**5**). These facts seem to indicate that the formation of **5** and **6** is derived from the reac-

a) Yields with a small amount of contamination. b) Based on a naphthalene derivative derived from a spontaneous retro Diels-Alder reaction. c) The low values are mainly due to the difficulty in recovery of the starting 2-pyridones.

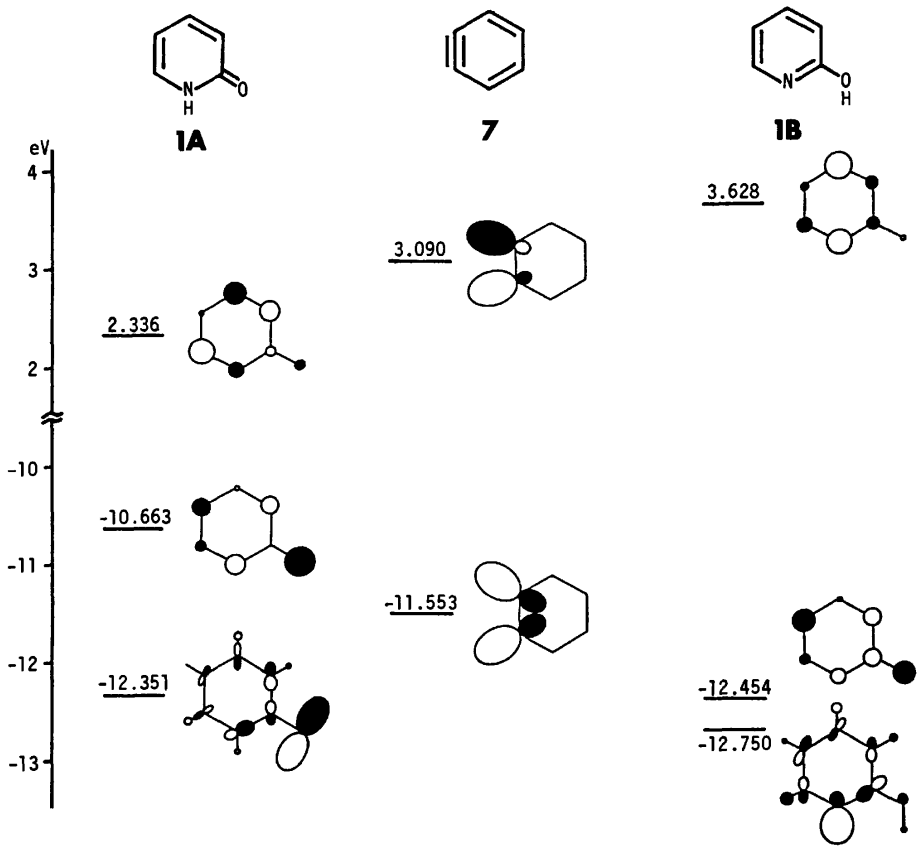

Fig. 1. Frontier molecular orbitals of 2-pyridone–2-pyridinol and benzyne calculated by the CNDO/2 method.

tion of the 2-pyridone form and the 2-pyridinol form with benzyne, respectively.

Another interesting feature is that there is a distinct difference in the yield of **5** between 6-methyl-substituted derivatives and 6-unsubstituted ones, that is, 6-methyl substitution leads to increase in the yield of **5**.

Molecular Orbital Consideration of the Structure–Reactivity–Chemoselectivity Relationship. In order to assess the substituent perturbation on the reactivity and to gain a fundamental insight into the factors controlling the chemoselectivity of this type reactions, the frontier molecular orbital (FMO) interactions were examined based on the CNDO/2 wavefunctions previously calculated.[10]

The FMO energies and the coefficient distributions of 2-pyridone (**1A**) and 2-pyridinol (**1B**) are presented in Fig. 1, together with those of benzyne (**7**).

Special features of these FMO are that the HOMO–LUMO energy separation of 2-pyridinol (**1B**) is larger than that of 2-pyridone (**1A**) and that of benzyne (**7**). This implies that the FMO interaction of **1B** with benzyne is smaller than that of **1A**. Thus, provided the reaction proceeds in accord with the FMO theory, the latter form may be more reactive with benzyne.

Figure 1 also shows that the LUMO of benzyne and the HOMO of 2-pyridone (**1A**) has a smaller separation in energy (13.753 eV) than the reverse pair (13.889 eV). Although the difference in the energy separation

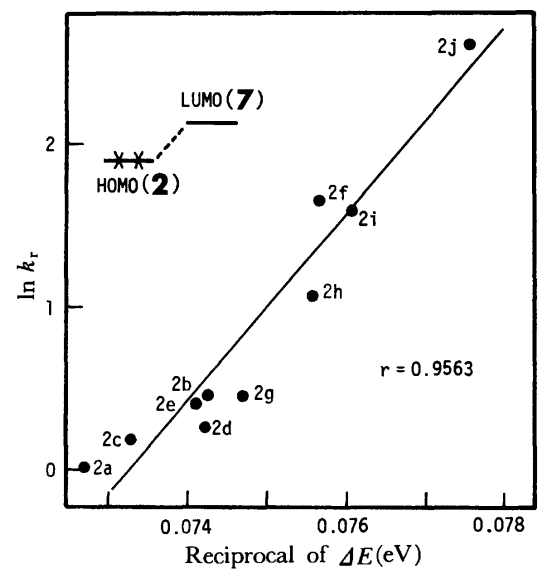

Fig. 2. Plots of the relative Diels-Alder reactivities (k_r) against the reciprocal of the FMO energy separations (ΔE).

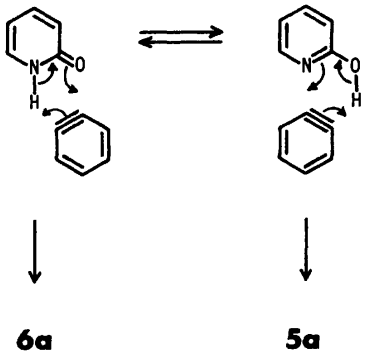
between the two pairs is small, plots of the logarithms of relative Diels-Alder reactivities (ln k_r) of 1-methyl derivatives (**2a—j**) against the reciprocal of the FMO energy separation between the HOMO of 2-pyridones and the LUMO of benzyne displayed a good correlation as shown in Fig. 2. Thus, the dominant HOMO–LUMO interaction for the Diels-Alder reaction should involve the LUMO of benzyne and the HOMO of the 2-pyridione, *i. e.* normal electron demand for a Diels-

Alder reaction.

Little improvement in the correlation was obtained by additional consideration of the orbital interactions of the reverse pair, due to the relatively small difference in the LUMO energies among 2-pyridones.

For reactions of the 1-unsubstituted derivatives which exist largely as self-associated dimers, the FMO of such dimers should be considered. However, the relevant orbital energy diagrams for the formation of the respective dimer in the 2-pyridone (**1A**) and 2-pyridinol (**1B**) calculated by the CNDO/2 method[10] indicated that the π-type orbitals have been little affected, although the σ-type orbitals have undergone a large energy perturbation. Therefore, the essential reactivity of Diels-Alder reaction of 1-unsubstituted 2-pyridones (**1**) would be similarly interpreted as that for the 1-methyl derivatives (**2**).

It should be noted that the formation of 2-phenoxypyridine (**5**) involves the ring structural conversion from the 2-pyridone form (**A**) to the 2-pyridinol form (**B**) and includes an abstruction of the NH proton which locates in the plane of the 2-pyridone ring. Likewise, the formation of 1-phenyl-2-pyridone (**6**) involves an abstruction of the OH proton of 2-pyridinol form as well as the reverse ring structural conversion. Such characteristic features should be associated with the tautomeric properties. It seems unlikely that π-type orbital interaction in the transition state is involved for such reactions and it can be rather otherwise considering that the reaction is charge controlled in view of the electrophilic nature of benzyne; the transition state may be better represented as shown in Scheme 4 for **1a** as an example.



Scheme 4.

We have shown previously, based on the quantum chemical calculations, that the tautomeric equilibria of 6-methyl derivatives were labile to the molecular environment. This is true particularly for 5,6-dimethyl derivatives due to an additional buttressing effect of the 5,6-dimethyl substituents.[10] Futhermore these derivatives are very effective catalysts for the mutarotation of TMG.[15] Also, our recent fluorescence study of various substituted 2-pyridones indicated that the tautomeric equilibria of 6-methyl derivatives were very sensitive to the solvent polarity and concentration. This results in a facile shift in the tautomeric equilibria leading to predominance of the 2-pyridinol form (**B**) over the 2-pyridone form (**A**) in less polar solvent and in diluted solution.[27] The above mentioned tautomeric properties of the 6-methyl derivatives account clearly for the higher yield of the formation of 2-phenoxypyridines (**5**) from the 2-pyridone form (**A**).

A similar rationalization may also be applicable for the 4-phenyl substituent effect on further enhancement of the Diels-Alder reactivity observed with 5,6-dimethyl derivatives. The Diels-Alder reactions involve the destruction of diene character of the pyridone form as the reaction proceeds. This ring structural modification bears some resembrance to the tautomeric conversion to the 2-pyridinol form. Thus, one explanation is the greater buttressing effect of the

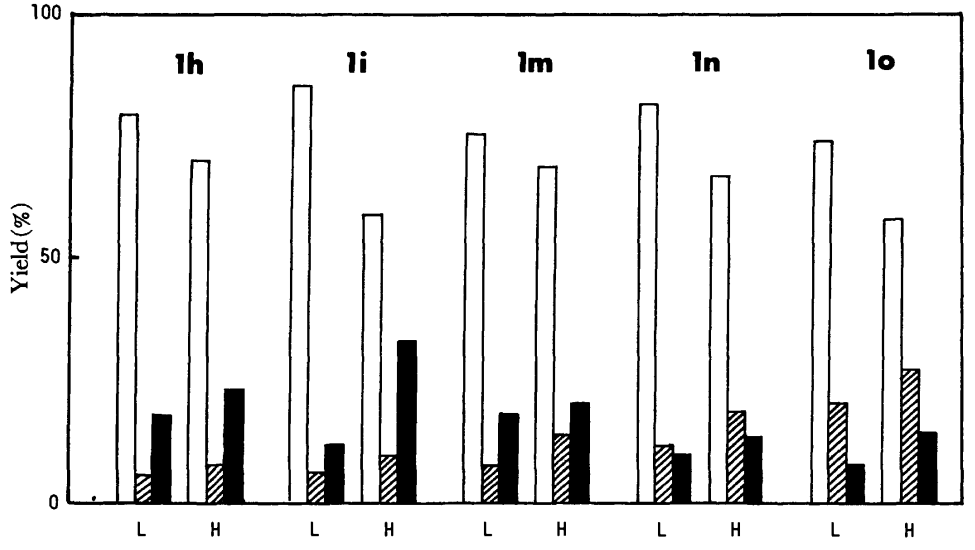


Fig. 3. Effect of concentration on the reactivity and chemoselectivity.
The products (**5**, **4**) and the unreacted 2-pyridone (**1**) were represented by □, ▨, and ■, respectively. L and H denote the reaction in 6.25×10^{-3} mol dm^{-3} solution and 0.1 mol dm^{-3} solution, respectively.

5,6-dimethyl substituents induced by the adjacent 4-phenyl group on lowering the activation energy of the transition state of the Diels-Alder reaction.

Concentration Dependency in Reactions of 1-Unsubstituted 2-Pyridones. Based on the foregoing facts and discussions, it can be considered that the factors determining the tautomeric equilibria [*i.e.* concentration, temperature and solvent] significantly affect the reactivity and the chemoselectivity of the reaction with benzyne. The concentration-dependencies for the reactions of several selected 2-pyridones such as **1h**, **1i**, **1m**, **1n**, and **1o** have been investigated and the results are illustrated in Fig. 3.

As shown in Fig. 3, the yields of 2-phenoxypyridines (**5**) were considerably lowered for the reactions in higher concentration. The recoveries of the starting 2-pyridones (**1**) were inversely raised to a similar extent and the yields of the Diels-Alder adducts (**4**) were slightly raised. Similar results were also obtained in the reaction of **1o** using a hydrogen-accepting solvent (dioxane) and in the reaction at lower temperature. It appears likely that the observed reversal in the yield of products was caused by the tautomeric properties, and indicated the importance of the abundance of the nonassociated forms for the formation of **5**. The observed chemoselectivity, therefore, could be rationalized for the formation of the Diels-Alder adduct (**4**) concomitantly increased as the major reaction (formation of **5**) was suppressed. These reaction schemes are summarized in Scheme 5 for **1a** as an example.

Thus, we have shown a novel example in which the tautomeric properties significantly affect the chemical reactivity and the chemoselectivity; it is of interest in connection with a widely accepted concept that the tautomeric equilibria are closely related to some biologically important properties of nucleic acids such as RNA transcription and DNA replication.

Inclusion Complex Formation of γ-Cyclodextrin. One Host-Two Guest Complexation with Water-soluble Dyes in Ground State

Hidefumi Hirai,* Naoki Toshima, and Satoshi Uenoyama
Department of Industrial Chemistry, Faculty of Engineering, The University of Tokyo, Hongo, Bunkyo-ku, Tokyo 113
(Received October 4, 1984)

β-Cyclodextrin forms the 1:1 inclusion complex with Crystal Violet, Methylene Blue, Methyl Orange, or Congo Red in water. On the other hand, γ-cyclodextrin forms the 1:2 complex with Crystal Violet, Methylene Blue, or Methyl Orange, while the 1:1 complex is given with Congo Red. The one host-two guest complexations are shown on the bases of the changes of the electronic spectra, dependence of induced circular dichroisms on the concentrations of dyes, and the continuous variation methods with induced circular dichroism. The dissociation constants for the 1:2 complexes are determined with the improved Benesi-Hildebrand equation. Alternation between the 1:1 and 1:2 complexation is discussed in terms of the cavity size of cyclodextrin and the aggregation character of dye.

Cyclodextrin, to be denoted here as CyD, forms the inclusion complex with a large number of organic or inorganic molecules and anions in an aqueous solution.[1,2] The internal diameters of hydrophobic cavities of α-CyD (cyclohexaamylose), β-CyD (cycloheptaamylose), and γ-CyD (cyclooctaamylose) are 4.5, 7.0, and 8.5 Å, respectively, and the depths of the cavities are given by the same value of 6.7—7.0 Å.[1] The inclusion complex of CyD has been vigorously investigated for a potential model of the enzyme in biomimetic chemistry[1,2] and also for the pharmaceutical application.[3] The stability of the inclusion complex depends mainly on the size and hydrophobicity of the CyD cavity. Since the cavity diameter of γ-CyD is nearly twice of that of α-CyD, γ-CyD seems to be able to include a large molecule. However, the stability of the complex of γ-CyD remains equivocal since the cavity diameter of γ-CyD is much larger than that of α- or β-CyD in spite of their common depths.

Recently, attentions have been paid for inclusion of two guest molecules in a cavity of CyD[4-14] from the viewpoint of conformational regulation of two molecules or as a model of CyD-catalyzed bimolecular reactions.[15,16] Ueno *et al.*[4] have shown the complexation of two molecules with one γ-CyD by enhancement of the excimer fluorescence. The enhancement gave the evidence for the inclusion of two molecules in the excited state, and gave the suggestion for the inclusion of two molecules in the ground state. We have separately communicated that a γ-CyD molecule forms the 1:2 complex in the ground state with three kinds of water-soluble dye molecules.[5] The present paper is a full paper of the previous letter. We would like to present here not only the detailed data but also the analytical methods supporting the 1:2 complexation.

Experimental

Materials. α- and β-CyD (Nakarai Chemicals) and dyes are used as received. γ-CyD used is also commercially available and its purity is more than 98%.

Sample Preparation. The aqueous solution of CyD or dyes are prepared by using the distilled water and phosphate buffer (pH=7.0, ion strength, μ=0.1). Stirring for 2 d at room temperature is performed for preparation of the aqueous solution of dye for the aggregated dye to come to equilibrium with its monomer form. The concentrations mainly used are 2.5×10^{-3} and 5×10^{-5} mol dm^{-3} for CyD and dyes, respectively.

Spectral Measurement. Electronic absorption spectra were measured by using a Hitachi 340 automatic spectrophotometer. Spectra of circular dichroism were obtained at 20°C with a JASCO J-20 automatic spectropolarimeter. The magnitude of circular dichroism induced by inclusion of a dye with CyD is presented by Eq. 1.

$$\theta_{tr} = \frac{c \cdot \Delta E_c}{x} \quad (1)$$

Here, θ_{tr}, ΔE_c, and x are the molar ellipticity of the complex, the circular dichroism measured, and the concentration of the complex, respectively. The term c is the constant. In the present paper, however, the initial concentration of dye is used instead of the concentration of the compelx, x, since x is unknown. Consequently, the apparent molar elipticity, θ, is used as the measure of the induced circular dichroism instead of θ_{tr}.

Determination of Dissociation Constant, K_d, for CyD–Dye Complex with Visible Spectral Measurement. The absorption spectra of dyes change with the concentration of CyD. For the 1:1 complex, the Benesi-Hildebrand equation can be applied for determination of K_d by plotting $(ab/\Delta E)$ against a, where a, b, and ΔE are initial concentrations of CyD and the dye, and difference of absorbance in the visible spectra, respectively. For the 2:1 complex, K_d must be determined from the intercept of the ordinate of the straight line obtained by a method of least squares for the plot of $(ab^2/\Delta E)$ against a. The details for providing the expression are shown in Appendix A.

Spectral Change Depending on the Concentration of Dyes. Induced circular dichroism changes with the concentration of dyes at the constant concentration of CyD. The measured magnitude of induced circular dichroism was plotted against the concentration of a dye under the conditions that the concentration of CyD is much larger than that of the dye. For the system of the 1:1 complexation, the straight line obtained passes through the point of the origin. For the 2:1 complex, on the other hand, no linear relationship exists between the concentration of dye and the magnitude of the induced circular dichroism as shown in Appendix B. Therefore, the linearities have been examined for four dyes by plotting ΔE_c of induced circular dichroism against the

concentration of the dye (5×10^{-6}—5×10^{-5} mol dm^{-3}) in order to determine the molar ratio of the inclusion complex.

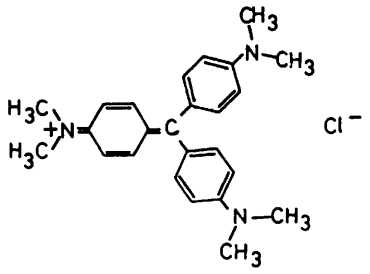
Continuous Variation Method. Continuous variation method was also applied to determine the molar ratio of the inclusion complex by assuming the equilibrium 2 as described in Appendix C.

$$n\cdot\text{Dye} + \text{CyD} \rightleftharpoons \text{Complex} \qquad (2)$$

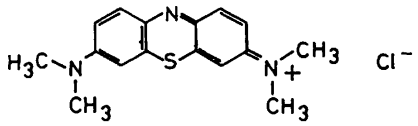
The kinds of aqueous solutions of CyD and the dye at various molar ratio were prepared with keeping the total concentration constant at 6×10^{-4} mol dm^{-3}. The apparent ellipticities, ΔE_c's, of the mixed solutions at different ratio were measured with a spectropolarimeter with a 1 mm-cell. The molar ratio with the maximum ellipticity indicates the ratio of the inclusion complex.

Results

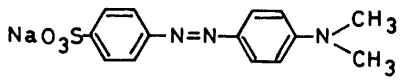
Electronic Spectra and Induced Circular Dichroism in the Presence of CyD. Inclusions of Crystal Violet (**1**, CV), Methylene Blue (**2**, MB), Methyl Orange (**3**, MO), and Congo Red (**4**, CR) with CyDs have been examined in the aqueous solutions by the electronic spectra and the circular dichroisms. Generally, the absorption band of the guest molecule shifts by inclusion with CyD and the new circular dichroism is induced by the inclusion. Results are shown in Figs. 1—4.



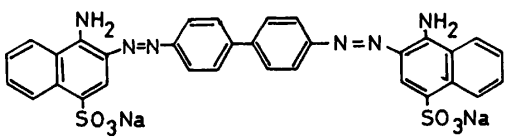
CRYSTAL VIOLET (1)



METHYLENE BLUE (2)



METHYL ORANGE (3)



CONGO RED (4)

The aqueous solution of CV at the concentration of 5×10^{-5} mol dm^{-3} had the absorption peak at 580 nm and no circular dichroism was observed. When γ-CyD were introduced to this solution at the concentration of 6.4×10^{-3} mol dm^{-3}, the absorption maximum shifted to 548 nm and the new circular dichroism appeared. Continuous change of the concentration of CyD indicated that the original absorption peak at 580 nm disappeared and the new peak at 548 nm appeared with increase of the concentration of CyD, as shown in Fig. 1a. The Silimar changes in the electronic spectra were observed in the case of MB and MO in the presence of γ-CyD (Figs. 2a and 3a). On the other hand, the small shift of the absorption band of CR was observed with addition of γ-CyD while the large circular dichroism were induced in this case (Fig. 4a).

When β-CyD was used as an additive instead of γ-CyD, the wavelength of the maximum absorption of CV shifted slightly to the longer wavelength (red shift by 5 nm) although γ-CyD provided large blue shift (32 nm). Similar small shift of the maximum wavelength as well as increase of the absorption coefficient was observed in the case of MB, MO, and CR with β-CyD as shown in Figs. 2b, 3b, and 4b, respectively. In these cases the circular dichroisms were also induced with the different shape from those with γ-CyD.

Addition of α-CyD resulted in no significant change in the electronic spectra of CV, MB, and CR and no circular dichroism were induced as well. In the case of MO, however, wavelength of the maximum absorption shifted from 462 nm to 454 nm with addition of α-CyD and the circular dichroism was induced. These effects of α-CyD on the spectra of MO is similar to those of β-CyD.

Change of Induced Circular Dichroism with Concentration of Dye. The magnitude of the induced circular dichroism increased with the concentration of the dye in the presence of large excess of CyD, so long as the circular dichroism was induced by addition of CyD. The apparent ellipticity of the solution was plotted against the concentration of the dye in the presence of 2.5×10^{-3} mol dm^{-3} of CyD as shown in Figs. 5 and 6. The linear relationships were clear in the cases of CR-γ-CyD (in Fig. 5) and MO-β-CyD (in Fig. 6), but the nonlinearly increasing curves were obtained in the cases of CV-γ-CyD, MB-γ-CyD, and MO-γCyD (Fig. 5).

Continuous Variation Method. Apparent ellipticity of the mixed solution of the dye and CyD was plotted against the molar fraction of the dye in the solution keeping the total concentration of the dye and CyD to be constant at 6.0×10^{-4} mol dm^{-3}. Here the fraction f is defined as molar ratio of dye to the sum of dye and CyD. In the solution of CR and γ-CyD, where

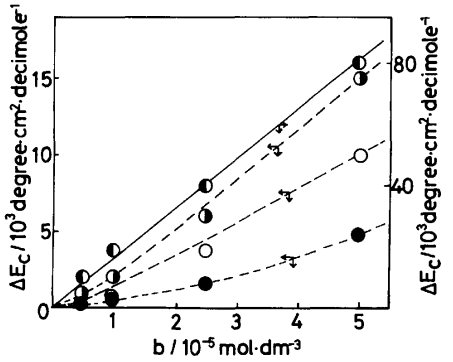

Fig. 5. The plot of the initial concentration of the dye (*b*) *vs.* the magnitude of circular dichroism (ΔE_c) induced by the complexes between the γ-cyclodextrin (2.5×10^{-3} mol dm^{-3}) and dyes (○, Crystal Violet, CD at 530 nm; ●, Methylene Blue, at 600 nm; ◑, Methyl Orange, at 456 nm; ◐, Congo Red, at 533 nm) in water. The broken curves follow the Eq. B-10, and the solid straight line follows the Eq. B-1.

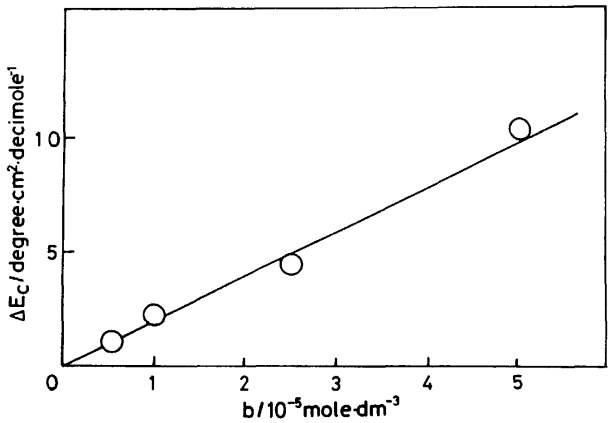

Fig. 6. The plot of the initial concentration of Methyl Orange (*b*) *vs.* the magnitude of circular dichroism (ΔE_c) induced by the Methyl Orange–β-cyclodextrin complex. [β-CyD]=2.5×10^{-3} mol dm^{-3} in water. ICD at 418 nm. The straight line follows Eq. B-1.

the linear relationship was shown in Fig. 5, the maximum ellipticity was obtained at the point of $f=1/2$ (Fig. 7), indicating the 1:1 complex formation of CR and γ-CyD. On the other hand, the peak was observed at $f=2/3$ in the case of the mixed solution of CV, MB, or MO (Fig. 7) with γ-CyD, suggesting the 1:2 complex formation of these three dyes with γ-CyD according to the Appendix C.

Dissociation Constant of the Inclusion Complex. The general Benesi-Hildebrand equation was applied to determine the dissociation constant of the 1:1 inclusion complex. For the complex of CV, MB, and MO with γ-CyD, the improved Benesi-Hildebrand equation shown in Appendix A was used for calculating the dissociation constant by assuming the 1:2 complex formation. These results are summerized in Table 1 as well as the electronic spectral data and the maximum apparent molar ellipticities of the circular dichroisms.

Discussion

Electronic Spectral Change of Dye by Addition of Cyclodextrin. Change in the electronic spectrum of

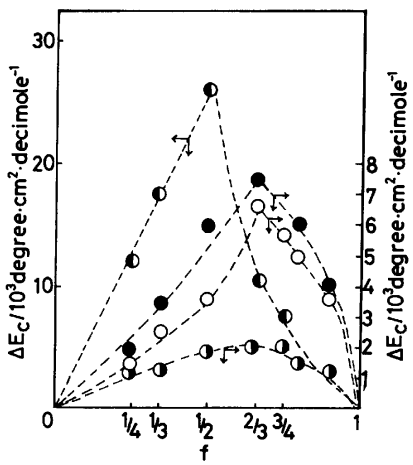

Fig. 7. Continuous variation method with induced circular dichroism (ΔE_c) for the complexes between γ-cyclodextrin and dyes (●, Crystal Violet, ◑, Methylene Blue, ○, Methyl Orange, ◐, Congo Red). [CyD]+[Dye]=6.0×10^{-4} mol dm^{-3}.

TABLE 1. DISSOCIATION CONTANTS OF THE COMPLEXES BETWEEN CYCLODEXTRINS AND DYES[a)]

a guest molecule by inclusion with CyD is generally explained by the effect of environment around the guest molecule, *i.e.*, so-called solvent effect. Among the present investigations, the small shifts, observed by addition of α- or β-CyD and by addition of γ-CyD to CR could take place due to the similar effect of the hydrophobic cavity of CyD. However, the spectral change observed by addition of γ-CyD to CV, MB, or MO is too large to be explained by the similar effect and must be caused by the completely different effect.

Dye can exist in a monomer form in a very dilute aqueous solution like 10^{-5} mol dm^{-3}. In a more concentrated solution, however, dye can aggregate each other. For example, the direct dye like CR forms the large ionic micelle,[17] whereas the basic dye like CV and MB stays as a stable dimer in a usual aqueous solution. The absorption peak of the dimer in an aqueous solution is well investigated. For example, the dimer peaks appear at 532 nm and 605 nm for CV and MB, respectively.[18,19] In the absence of CyD, CV, and MB stay mostly as a monomer form and some fractions as a dimer form in the present experimental conditions (5 or 2.5×10^{-5} mol dm^{-3}) as shown in curves 1 of Figs. 1 and 2. With addition of β-CyD, the absorbance at the wavelength of the dimer peak slightly decreases, as indicated in Figs. 1 and 2. On the other hand, the addition of γ-CyD increases the absorbance at the dimer peak and decreases the monomer peak dramatically to result in an appearance of a new peak. These spectral changes strongly suggest that γ-CyD includes the dimer forms of CV and MB while β-CyD does the monomer forms.

In case of MO, any sharp peak has not clearly been assigned as the dimer peak in literatures, but the peak at 462 nm has been reported to be the overlap peak of two bands of monomer and dimer forms.[20] The large blue shift observed with addition of γ-CyD is considered due to the inclusion of the species which have the absorption maximum at the shorter wavelength between the two species. Consequently, the unique change in the electronic spectra suggests that γ-CyD forms the 1:2 complex with MO as well as CV and MO.

Relationship between the Magnitude of the Induced Circular Dichroism and the Concentration of the Inclusion Complex. The dyes examined in the present paper do not indicate any circular dichroism by themselves. CyDs also have no circular dichroic absorption in the visible region. When the dye is included by CyD to form the inclusion complex, the circular dichroism is induced in the visible region where the complex has the electronic absorption. The magnitude of the induced circular dichroism is proportional to the amount of the complex produced. In case of the 1:1 complex formation, the amount of the complex is expected to increase with charged concentration of the dye. If the charged concentration of CyD is kept constant and is large excess compared with that of the dye, the linear relationship is expected as shown in Appendix B. Therefore, when the magnitude of the circular dichroism, ΔE_c, is plotted against the charged concentration of the dye, b, the linear relationship between ΔE_c and b is observed as shown in Eq. B-1 in Appendix B. Thus, the linear relationship is often used as the evidence of the 1:1 complex formation.[20] In the 1:n complex, however, ΔE_c is not proportional to b but the correlation is more complicated than that for the 1:1 complex as shown in Eq. B-10 of Appendix B.

The present results about the dependence of induced ellipticity on the initial concentration of the dye shown in Figs. 5 and 6 are well consistent with the above consideration. The linear relationship was observed indeed for the case of the 1:1 complex formation which had been suggested from the electronic spectral changes (solid lines in Figs. 5 and 6). Nonlinear relationship was observed for the case of the 1:2 complex formation (broken curves in Fig. 5). In the latter case, the induced ellipticity increased at the rate proportional to b^2 when the charged concentration of the dye, b, was small enough as estimated from Eq. B-10. In fact, the data plotted in Fig. 5 are considerably well fit to the broken curves calculated from Eq. B-10.

The 1:2 Complex Formation. Recently much attention has been paid to the inclusion of two guest molecules with the large cavity of γ-CyD. Enhance-

ment of excimer fluorescence by addition of γ-CyD has suggested the 1:2 complex formation.[4,6] However, no direct evidence for the 1:2 complexation had not been reported before the preliminary communication.[5] In the present investigation, the large blue shift in the electronic absorption spectrum and nonlinear relation between the ellipticity and the concentration of the dye suggest the complexation between two dye molecules (CV, MB, and MO) and one γ-CyD. The 1:2 complex formation is strongly supported by the continuous variation method by using the induced circular dichroism. As shown in Fig. 7, the maximum ellipticity was observed at the point that the molar fraction of the dye, f, equals to 2/3 for CV, MB, and MO. In the case of CR, the maximum appeares at f=0.5.

From the present results, CV, MB, and MO are concluded to form the 1:2 complex with γ-CyD, while CR results in the 1:1 complexation. These differences could be explicable from the viewpoint of aggregation character of the water-soluble dye, because the former three dyes are known to form the corresponding dimers by aggregation in water, while no report on dimer formation has been presented in case of CR. The fitness of the size of the guest molecules to the cavity of CyD is also an important factor for complexation, which will be discussed in the next section.

These observations could also suggest the complexation mechanism. The 1:2 complex could be produced not by including one more dye molecule with the 1:1 complex, but by directly including the dimer of the dye with γ-CyD (as Eq. A-3 in Appendix A).

Fitness of the Size for Inclusion Complex. The molecular size of the guest molecule has to fit to the size of the cavity of the host molecule for the inclusion complex formation.[1] Here the fitness of the molecular size is considered based on the CPK model.

Congo Red contains the naphthyl moiety having the large sulfonato group. The CPK model shows that CR is too large to pass through the small cavity of α-CyD. This result is consistent with the fact that CR cannot be included by α-CyD. In case of β-CyD, the CR molecule is still unable to be included completely within the cavity according to the CPK model. Thus, the induction of the circular dichroism in this case suggests the partial inclusion of CR by β-CyD.[21] On the other hand, γ-CyD can include a CR molecule completely. The sulfonato groups of CR could interact with the hydroxyl groups of γ-CyD and could lock the CyD molecule from both sides by a hydrogen bond. The model structure of the inclusion complex seems to suggest the very strong complex formation. This consideration is supported by the small dissociation constant observed for the complex of CR with γ-CyD.

Methyl Orange is an enough small molecule to be included with α-CyD.[22-24] The electronic spectra of MO with different concentrations of α-CyD have not an isosbestic point. This fact could be explicable by the simultaneous formation of both the 1:1 complex and the 2:1 complex (two molecules of α-CyD and one molecule of MO).[25-26] The CPK models of MO and CyDs suggest that β-CyD includes one molecule of MO, while γ-CyD does two molecules but never three molecules of MO. The apparent isosbestic point was observed in the electronic spectra of MO with different concentrations of γ-CyD as shown in Fig. 3a. This fact suggests the direct formation of a single complex, *i.e.*, the 1:2 complex of γ-CyD with MO.

With regard to MB and CV, the CPK molecular model indicates that (1) the cavity of α-CyD is too small to include these dyes, (2) β-CyD has an enough large cavity to include one molecule of MB or CV but not to include two molecules, and (3) the cavity size of γ-CyD does well fit to the two molecules of MB or CV. These demonstrations with a CPK model are completely consistent with the experimental results. The difference in the dissociation constants of CV and MB cannot arise from the molecular size, but from another character of the molecules.

Appendix A.

Improved Benesi-Hildebrand Equation for Determination of Dissociation Constant, K_d, of the 1:2 Inclusion Complex. The dissociation constant for the 1:1 complex has been determined by the Benesi-Hildebrand equation (A-1)[27] where a and b are the concentrations of CyD and the dye, respectively, l is the length of a cell, and ΔE and $\Delta\varepsilon$ present the differences of absorbance and molar absorption coefficient between the complex and the dye, respectively. It is assumed in the equation that all the dye molecules in the solution

$$\frac{a \cdot b \cdot l}{\Delta E} = \frac{K_d}{\Delta\varepsilon} + \frac{a}{\Delta\varepsilon} \qquad \text{(A-1)}$$

form the complexes with CyD if the concentration of CyD is large excess to that of the dye.

For the 1:2 complex, there are two way of formation. One case is the direct equilibrium between two molecules of the dye and a molecule of CyD (Eq. A-2) and the other is the coexistance of two equilibriums shown in Eq. A-3.

$$\mathrm{CyD} + 2\,\mathrm{Dye} \overset{K_d}{\rightleftharpoons} \mathrm{Complex} \qquad \text{(A-2)}$$

$$\left.\begin{aligned} 2\,\mathrm{Dye} &\overset{k_1}{\rightleftharpoons} (\mathrm{Dye})_2, \\ (\mathrm{Dye})_2 + \mathrm{CyD} &\overset{k_2}{\rightleftharpoons} \mathrm{Complex} \end{aligned}\right\} \qquad \text{(A-3)}$$

When a and b are used as the initial concentrations of CyD and the dye, respectively, and x is the concentration of the complex, the dissociation constant, K_d, for the former Eq. A-2, is presented by the following Eq. A-4.

$$K_d = \frac{(a-x)(b-2x)^2}{x} \qquad \text{(A-4)}$$

Even though the separate equations A-5 and A-6 exist instead of Eq. A-2 among these species, the overall dissociation constant from Eqs. A-5 and A-6 is the same with that of Eq. A-4.

$$\text{Dye} + \text{CyD} \rightleftharpoons (\text{Dye–CyD}) \quad \text{(A-5)}$$

$$\text{Dye} + (\text{Dye–CyD}) \rightleftharpoons (\text{Dye}_2\text{–CyD}) \quad \text{(A-6)}$$

In other words, the dissociation constant does not depend on whether the two molecules of the dye are included stepwise or at once.

On the other hand, the latter case (Eq. A-3) gives the little different results. The dissociation constants for dimer of the dye, k_1, and for the ternary complex, k_2, are given by the following by using y as the concentration of the dimer.

$$k_1 = \frac{(b-2y-2x)^2}{y}, \quad k_2 = \frac{y(a-x)}{x} \quad \text{(A-7)}$$

Thus, the over-all dissociation constant, K_d', is led as follows.

$$K_d' = \frac{(a-x)(b-2x-2y)^2}{x} \quad \text{(A-8)}$$

The difference between K_d and K_d' is very small since the concentration of the free dimer, y, is very small under the experimental conditions. Moreover, it is not so easy to determine the concentration of the free dimer of the dye or the dissociation constant, k_1. Therefore, K_d has been used in the present paper for the practical discussion. When a is much larger than b, $(a-x)$ and x can be replaced with a and $b/2$, respectively. So, the Eq. A-4 can be rewritten as follows:

$$K_d = \frac{ab^2}{x} - 4ab + 4ax = \frac{ab^2}{x} - 2ab \quad \text{(A-9)}$$

Since the concentration of the complex, x, is proportional to $\Delta E/(\Delta\varepsilon \cdot l)$, the Eq. A-9 can be rearranged as Eq. 10 like the Benesi-Hildebrand equation.

$$\frac{a \cdot b^2 \cdot l}{\Delta E} = \frac{K_d}{\Delta\varepsilon} + \frac{2b}{\Delta\varepsilon}a \quad \text{(A-10)}$$

Thus, the dissociation constant, K_d, for the 1:2 complex can be obtained from the intercept of the straight line by plotting $(a \cdot b^2 \cdot l)/\Delta E$ against a under the conditions that a is much larger than b and that b is constant.

Appendix B.

Nonlinear Relationship between the Concentration of Dye and the Induced Circular Dichroism for the 1:n Complex. The magnitude of induced circular dichroism changes with the concentration of the dye, when the concentration of CyD is much larger than that of the dye for the 1:1 complex, the linear relationship is given between ΔE_c and b according to Eq. B-1, where a and b are the initial concentration of CyD and the dye, respectively, and ΔE_c, θ_{tr}, and K_d are the measured magnitude of induced circular dichroism, the molar ellipticity of the complex, and the dissociation constant for the complex, respectively.

$$\Delta E_c = \frac{\theta_{tr}a}{100 \cdot (K_d + a)}b \quad \text{(B-1)}$$

For 1:n complex formation, the following equilibriums would be kept.

$$n\,\text{Dye} \overset{k_1'}{\rightleftharpoons} (\text{Dye})_n \quad \text{(B-2)}$$

$$(\text{Dye})_n + \text{CyD} \overset{k_2'}{\rightleftharpoons} \text{Complex} \quad \text{(B-3)}$$

Here,

$$k_1' = \frac{(b-ny-nx)^n}{y} \quad \text{(B-4)}$$

$$k_2' = \frac{y(a-x)}{x} \quad \text{(B-5)}$$

The term x and y present the concentrations of the CyD complex and of the n-mer of the dye, respectively.

When the concentration of CyD is much larger than that of the dye, ny is negligible small compared with b and nx. Therefore, the Eq. B-4 can be rewritten as Eq. B-6.

$$k_1' = \frac{1}{y}(b^n - {}_nC_1 \cdot nx \cdot b^{n-1} + {}_nC_2 \cdot (nx)^2 \cdot b^{n-2} - \cdots) \quad \text{(B-6)}$$

By using Eq. B-5, Eq. B-6 is rearranged as follows.

$$k_1' = \frac{(a-x)}{x \cdot k_2'}(b^n - {}_nC_1 \cdot nx \cdot b^{n-1} + {}_nC_2 \cdot (nx)^2 \cdot b^{n-2} - \cdots) \quad \text{(B-7)}$$

When the first and the second terms of the development equation are used, and $(a-x)$ is replaced with a since the concentration of CyD is very large, the overall dissociation constant for the CyD complex of the n-mer is presented as follows.

$$K_d'' = k_1' \cdot k_2' = \frac{a \cdot b^n}{x} - n^2 \cdot a \cdot b^{n-1} \quad \text{(B-8)}$$

Rearrangement of Eq. B-8 leads Eq. B-9.

$$x = \frac{a \cdot b^n}{K_d'' + n^2 \cdot a \cdot b^{n-1}} \quad \text{(B-9)}$$

Since the magnitude of the induced circular dichroism is proportional to the concentration of the complex, x can be replaced with $100 \cdot \Delta E_c/\theta_{tr}$. Then, Eq. B-9 can be rewritten as Eq. B-10.

$$\Delta E_c = \frac{\theta_{tr} \cdot a \cdot b^n}{100(K_d'' + n^2 \cdot a \cdot b^{n-1})} \quad \text{(B-10)}$$

One can compare Eq. B-10 for the 1:n complex with Eq. B-1 for the 1:1 complex to find the difference.

Appendix C.

Continuous Variation Method to Determine the Molar Ratio of the Inclusion Complex. When more than two equilibrium exist under experimental conditions, the continuous variation method is complicated. Therefore, one equilibrium (Eq. C-1) is considered in place of n equilibriums since the concentration of the intermediate $(\text{Dye})_n$ is thought negligible.

$$n\,\text{Dye} + \text{CyD} \rightleftharpoons \text{Complex} \quad \text{(C-1)}$$

The continuous variation method in the equilibrium C-1 is led as follows. When the concentrations of the dye, CyD, and the complex in the equilibrium are represented as c_1, c_2 and c_3, respectively, and the sum of the initial concentrations of the dye and CyD is constant equaling to m, then the following relations are obtained.

$$c_1 = m \cdot f - n \cdot c_3 \quad \text{(C-2)}$$

$$c_2 = m(1-f) - c_3 \quad \text{(C-3)}$$

$$K_d = \frac{c_1^n \cdot c_2}{c_3} \quad \text{(C-4)}$$

Here, f indicates the molar fraction of the dye.

The value f, that makes the concentration of the complex, c_3, maximum, can be obtained from the condition of $(dc_3/df)=0$. Differentiation of Eqs. C-2, C-3, and C-4 with f gives the following Eqs.

$$\frac{dc_1}{df} = m - n\frac{dc_3}{df} \quad \text{(C-5)}$$

$$\frac{dc_2}{df} = -m - \frac{dc_3}{df} \quad \text{(C-6)}$$

$$K_d \cdot \frac{dc_3}{df} = c_1{}^n \cdot \frac{dc_2}{df} + c_2 \cdot \frac{dc_1}{df} n \cdot c_1{}^{(n-1)} \quad \text{(C-7)}$$

Substitution of the condition $(dc_3/df)=0$ for the Eqs. C-5, C-6, and C-7, and rearrangement give the Eq. C-8.

$$n = \frac{f}{1-f} \text{ or } f = \frac{n}{1+n} \quad \text{(C-8)}$$

Therefore, if the concentration of the intermediate $(\text{dye})_n$ is assumed negligible, the concentration of the complex becomes maximum at the condition satisfying the Eq. C-8.

The fraction at the maximum induction of the circular dichroism observed gives the composition of the complex.

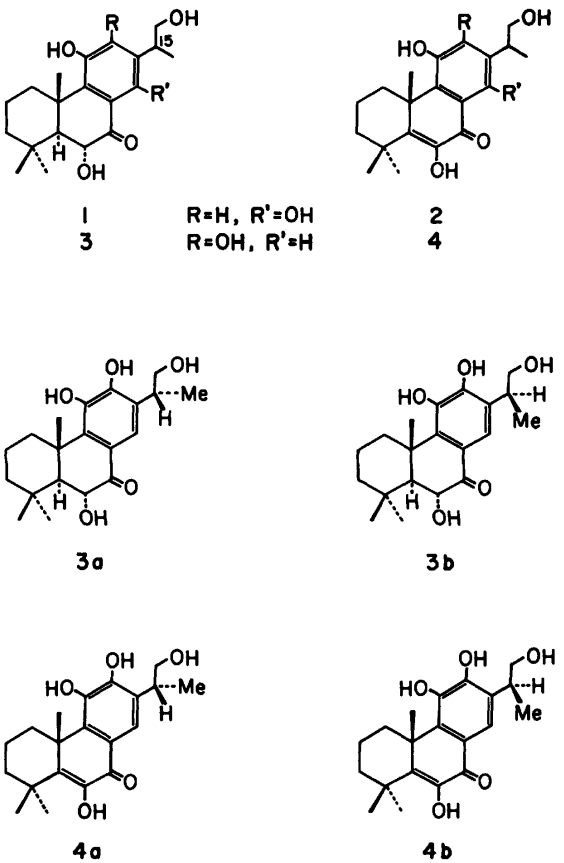
The Syntheses and Absolute Configurations of Nellionol and 5-Dehydronellionol

Takashi MATSUMOTO,* Sachihiko IMAI, and Takashi YOSHINARI
Department of Chemistry, Faculty of Science, Hiroshima University, Higashisenda-machi, Naka-ku, Hiroshima 730
(Received October 24, 1984)

To determine the absolute configurations of C-15 in natural nellionol and 5-dehydronellionol, (15*R*)-8,11,13-abietatriene-12,16-diol was converted into (15*R*)-6α,11,12,16-tetrahydroxy-8,11,13-abietatrien-7-one (**3a**) and (15*R*)-6,11,12,16-tetrahydroxy-5,8,11,13-abietatetraen-7-one (**4a**), which were identical with natural products. For direct comparisons with **3a** and **4a**, (15*S*)-6α,11,12,16-tetrahydroxy-8,11,13-abietatrien-7-one (**3b**) and (15*S*)-6,11,12,16-tetrahydroxy-5,8,11,13-abietatetraen-7-one (**4b**) were also synthesized from (15*S*)-8,11,13-abietatriene-12,16-diol. The synthetic **3b** and **4b** were not identical with the natural products. From the present study, the absolute configurations of nellionol and 5-dehydronellionol were conclusively assigned as 5*S*,6*R*,10*S*,15*R* (**3a**) and 10*R*,15*R* (**4a**), respectively.

Nellionol and 5-dehydronellionol have been isolated from the root bark of *Premna latifolia* Roxb. by Rao *et al.*[1] On the basis of chemical and spectroscopic studies they deduced the structures of nellionol and 5-dehydronellionol to be 6α,11,14,16-tetrahydroxy-8,11,13-abietatrien-7-one (**1**) and 6,11,14,16-tetrahydroxy-5,8,11,13-abietatetraen-7-one (**2**), respectively. However, our examination on the published ^{1}H NMR spectral data[1] suggested alternate structures, 6α,11,12,16-tetrahydroxy-8,11,13-abietatrien-7-one (**3**) and 6,11,-12,16-tetrahydroxy-5,8,11,13-abietatetraen-7-one (**4**), for nellionol and 5-dehydronellionol respectively. The correctness of these revised structures was supported by the syntheses of C-15 epimeric mixtures of **3** and **4**,[2] whereas the precise stereochemistry of C-15 in these natural products could not be determined. Burnell *et al.*[3] also reported independently the same revised structures, **3** and **4**, for nellionol and 5-dehydronellionol, but the stereochemistry of C-15 still remained unsettled. In order to determine the absolute configurations of C-15 in these natural products we have now attempted the syntheses of (15*R*)-6α,11,-12,16-tetrahydroxy-8,11,13-abietatrien-7-one (**3a**), (15*R*)-6,11,12,16-tetrahydroxy-5,8,11,13-abietatetraen-7-one (**4a**), and their (15*S*)-epimers (**3b** and **4b**). For this purpose, (15*R*)-8,11,13-abietatriene-12,16-diol (16-hydroxyferruginol) (**5a**) and its (15*S*)-isomer (**5b**) were chosen as convenient relay intermediates, because these compounds have recently been synthesized in our laboratory by an unambiguous method starting from (*R*)-(−)-α-cyclocitral.[4]

In the present study, however, new preparations of **5a** and **5b** using natural dehydroabietic acid (**6**) were carried out as follows. Dehydration of 12-methoxy-8,11,13-abietatrien-15-ol (**7**)[2] prepared from **6**, with refluxing acetic anhydride, followed by hydroboration-oxidation of the resulting tetraene (**8**),[2] afforded a mixture of the C-15 epimeric alcohols. The mixture was separated by repeated column chromatography on silica gel to give (15*R*)-12-methoxy-8,11,13-abietatrien-16-ol (**9a**) and its (15*S*)-epimer (**9b**). The alcohols, **9a** and **9b**, were demethylated respectively with anhydrous aluminium chloride, sodium iodide, and



acetonitrile in dichloromethane[5] at 35—40 °C under a stream of nitrogen to give the crystalline diols, which were shown to be identical with authentic **5a** and **5b**[4] by physical and spectral comparisons. Oxidation of the diol **5a** with benzoyl peroxide in refluxing chloroform, followed by reduction with lithium aluminium hydride in ether and subsequent acetylation with acetic anhydride in pyridine, afforded (15*R*)-11,12,16-triacetoxy-8,11,13-abietatriene (**10a**: 49.5%) along with (15*R*)-12,16-diacetoxy-8,11,13-abietatriene[4] (**11a**: 26.7%). Similar treatment of the diol **5b** also produced the corresponding (15*S*)-triacetate (**10b**: 47.0%) and (15*S*)-diacetate[4] (**11b**: 29.8%). The triacetates, **10a** and **10b**, were oxidized respectively with chromium trioxide in acetic acid at room temperature to give (15*R*)-11,12,16-

triacetoxy-8,11,13-abietatrien-7-one (**12a**: 73.2%) and its (15*S*)-isomer (**12b**: 76.1%). The 7-oxo compound **12a** was refluxed with isopropenyl acetate in the presence of *p*-toluenesulfonic acid to give an enol acetate (**13a**: 95.0%). This was converted into (15*R*)-6α,11,12,16-tetraacetoxy-8,11,13-abietatrien-7-one (**14a**: 91.3%), mp 185—187 °C, by oxidation with *m*-chloroperbenzoic acid in dichloromethane and subsequent acetylation with acetic anhydride in pyridine. Hydrolysis of **14a** with dilute hydrochloric acid in refluxing ethanol gave **3a** (77.3%), mp 222—224 °C. The synthetic **3a** and **14a** were identical with natural nellionol (mp 226—227 °C) and its tetraacetate (mp 185—186 °C). Subsequently the 7-oxo compound **12a** was reduced with sodium borohydride in methanol to give a mixture of C-7 epimeric alcohols, which was immediately converted into (15*R*)-11,12,16-triacetoxy-6,8,11,13-abietatetraene (**15a**: 75.5%) by refluxing with *p*-toluenesulfonic acid in dry benzene. The tetraene **15a** was further converted into (15*R*)-11,12,16-triacetoxy-8,11,13-abietatrien-6-one (**16a**: 85.5%) by a series of reactions: oxidation with *m*-chloroperbenzoic acid in dichloromethane at room temperature, refluxing with dilute hydrochloric acid in methanol, and acetylation with acetic anhydride in pyridine. Oxidation of **16a** with Jones reagent, followed by refluxing with sodium acetate in acetic anhydride, afforded (15*R*)-6,11,12,16-tetraacetoxy-5,8,11,13-abietatetraen-7-one (**17a**: 68.7%), mp 149—153 °C. Hydrolysis of **17a** with dilute hydrochloric acid in refluxing methanol afforded **4a** (82.3%), mp 211—213 °C. The synthetic **4a** and **17a** were identical with natural 5-dehydronellionol (mp 210—212 °C) and its tetraacetate (mp 141—142 °C). The specific rotation of **3a**, **14a**, and **17a** showed positive values, which were also in the same direction as those of the corresponding natural products.

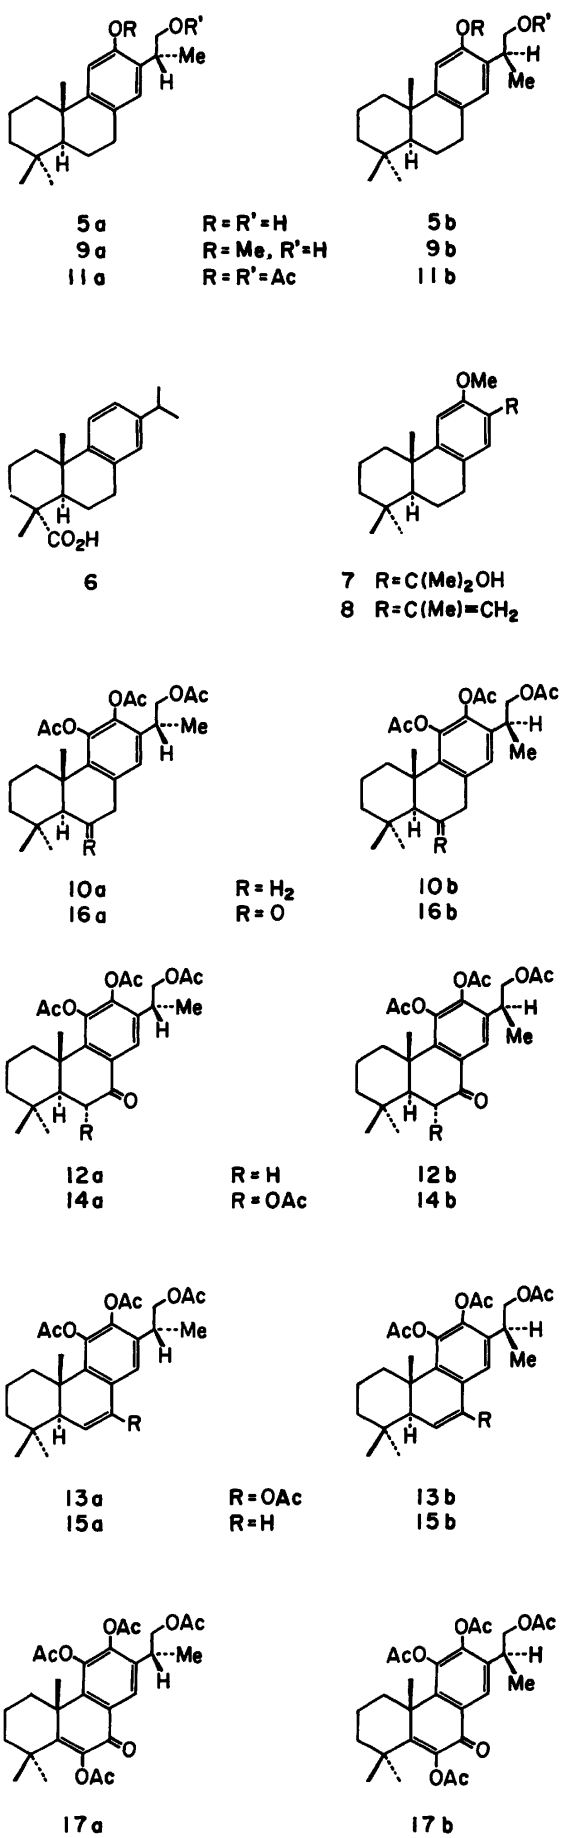
For direct comparisons with **3a** and **4a**, the syntheses of (15*S*)-isomers (**3b** and **4b**) were also carried out starting from **12b** in the same manner to that described for the preparation of **3a** and **4a**. The synthetic **3b** (mp 216—217 °C) and **4b** (mp 187—189 °C) were not identical with natural nellionol and 5-dehydronellionol.

From the present study, the absolute configurations of nellionol and 5-dehydronellionol were conclusively assigned as 5*S*, 6*R*, 10*S*, 15*R* (**3a**) and 10*R*, 15*R* (**4a**), respectively.

Experimental

All melting points are uncorrected. The IR spectra and optical rotations were measured in chloroform, and the ^1H NMR spectra in deuteriochloroform at 90 MHz, with tetramethylsilane as an internal standard, unless otherwise stated; s: singlet, bs: broad singlet, d: doublet, dd: double doublet, m: multiplet. The column chromatography was performed using Merck silica gel (0.063 mm).

12-Methoxy-8,11,13,15-abietatetraene (8). A solution of 12-methoxy-8,11,13-abietatrien-15-ol (**7**)[2] (18.6 g) in acetic anhydride (80 ml) was refluxed for 1 h. After removal of the



acetic anhydride *in vacuo*, the residue was chromatographed on silica gel (250 g), using hexane–benzene (7:3) as the eluent, to give **8** (16.0 g: 91.4%). The IR and ^{1}H NMR spectra of **8** were identical with those of the authentic sample.[2]

*(15R)-12-Methoxy-8,11,13-abietatrien-16-ol (**9a**) and Its (15S)-Epimer (**9b**).* A solution of borane–tetrahydrofuran complex (1 mol dm^{-3}: 18.1 ml) was added to a stirred solution of **8** (6.748 g) in dry tetrahydrofuran (67 ml) at −10 °C for 10 min under a stream of nitrogen. After the mixture had been stirred at −10—0 °C for 25 min and at 0—5 °C for 3 h, there were added successively aqueous tetrahydrofuran (50%: 7.8 ml), aqueous sodium hydroxide (12%: 7.8 ml), and hydrogen peroxide (30%: 7.8 ml) at −10—−4 °C. The mixture was stirred at −5—0 °C for 30 min and then at room temperature for 1 h, diluted with water, and extracted with ether. The ether extract was washed with brine, dried over sodium sulfate, and evaporated *in vacuo*. The residue was chromatographed on silica gel (250 g), using ether–benzene (1:99 and then 8.5:91.5) as the eluent, to give a mixture of C-15 epimers (**9a** and **9b**)[2] (6.873 g: 96.1%). The mixture was carefully separated by repeated column chromatography on silica gel to give **9a** and **9b**, by monitoring of doublet signal due to C-15 methyl group in the ^{1}H NMR spectra (60 MHz: δ in CCl_4, 1.17 for **9a** and 1.16 for **9b**)[2] of fractions.

*(15R)-8,11,13-Abietatriene-12,16-diol (**5a**) and Its (15S)-Epimer (**5b**).* *a)*: Anhydrous aluminium chloride (2.237 g), sodium iodide (2.514 g), and a solution of **9a** (265 mg, containing a small amount of **9b**) in dichloromethane (5.5 ml) were added in this order to acetonitrile (11.0 ml) with stirring at −5—5 °C under a stream of nitrogen over a 20 min period. The mixture was stirred at this temperature for 10 min and then at 35—40 °C for 5 h, poured into water, and extracted with ether. The ether extract was washed successively with aqueous sodium thiosulfate and brine, dried over sodium sulfate, and evaporated *in vacuo*. The residue was chromatographed on silica gel (15 g), using ether–benzene (3:97) as the eluent, to give the demethylated diol (242 mg: 95.6%). This was recrystallized from ether–hexane to give **5a**, mp 139—140 °C, $[\alpha]_D$ +64.5° (*c* 2.79), whose IR and ^{1}H NMR spectra were identical with those of the authentic sample.[2] Found: C, 79.29; H, 10.27%. Calcd for $C_{20}H_{30}O_2$: C, 79.42; H, 10.00%.

b): Anhydrous aluminium chloride (1.073 g), sodium iodide (1.206 g), and a solution of **9b** (127 mg, containing a small amount of **9a**) in dichloromethane (4.0 ml) were added in this order to acetonitrile (8.0 ml) with stirring at −5—5 °C under a stream of nitrogen over a 16 min period. The mixture was stirred at this temperature for 15 min and then at 35—40 °C for 5 h. After the work-up as described in *a)*, the crude product was chromatographed on silica gel (8.0 g), using ether–benzene (3:97) as the eluent, to give the demethylated diol (87 mg: 71.2%). This was recrystallized from ether–hexane to give **5b**, mp 178—179 °C, $[\alpha]_D$ +45.5° (*c* 2.18), whose IR and ^{1}H NMR spectra were identical with those of the authentic sample.[2] Found: C, 79.25; H, 10.13%. Calcd for $C_{20}H_{30}O_2$: C, 79.42; H, 10.00%.

*(15R)-11,12,16-Triacetoxy-8,11,13-abietatriene (**10a**) and Its (15S)-Epimer (**10b**).* *a)*: A solution of **5a** (215 mg) and benzoyl peroxide (269 mg) in chloroform (6.0 ml) was refluxed for 5 h, cooled, and diluted with ether (9.0 ml). After addition of acetic acid (1.26 ml) and aqueous potassium iodide (20%: 6.3 ml), the mixture was stirred at room temperature for 2 h and then washed successively with water, aqueous sodium thiosulfate, aqueous sodium hydrogencarbonate, and brine. The dried solution was evaporated *in vacuo* to give the crude product, which was used, without purification, in the next reaction.

A stirred suspension of the above crude product and lithium aluminium hydride (130 mg) in dry ether (20 ml) was refluxed for 80 min. The mixture was cooled, poured into ice-dilute hydrochloric acid, and extracted with ether. The ether extract was washed with brine, dried over sodium sulfate, and evaporated *in vacuo*. The residue was acetylated with acetic anhydride (2.0 ml) in pyridine (2.0 ml) at 75—80 °C for 2 h. After the usual work-up, the crude product was chromatographed on silica gel (20 g), using ether–benzene (1:99) as the eluent, to give a diacetate (**11a**) (73 mg: 26.7%), $[\alpha]_D$ +56.9° (*c* 3.59). The IR and ^{1}H NMR spectra of **11a** were identical with those of (15*R*)-12, 16-diacetoxy-8,11,13-abietatriene.[2] Found: C, 74.84; H, 9.01%. Calcd for $C_{24}H_{34}O_4$: C, 74.57; H, 8.87%.

Further elution with ether–benzene (1:9) gave **10a** (157 mg: 49.5%), $[\alpha]_D$ +61.3° (*c* 2.76); IR: 1765, 1730 cm^{-1}; ^{1}H NMR (60 MHz, CCl_4): δ=0.95 (6H, bs, $-\underset{|}{C}(CH_3)_2$), 1.19 (3H, d, *J*= 7 Hz, C_{15}–CH_3), 1.21 (3H, s, C_{10}–CH_3), 1.94 (3H, s, C_{16}–$OCOCH_3$), 2.21 (6H, s, C_{11}–$OCOCH_3$ and C_{12}–$OCOCH_3$), 3.92 (2H, d, *J*=7 Hz, $-C\underline{H}_2OAc$), 6.77 (1H, s, C_{14}–H).

b): A solution of **5b** (204 mg) and benzoyl peroxide (255 mg) in chloroform (6.0 ml) was refluxed for 5 h. The crude product was reduced with lithium aluminium hydride (130 mg) in dry ether (20 ml) and then acetylated with acetic anhydride (2.0 ml) in pyridine (2.0 ml) as described in *a)*. The product was purified by column chromatography on silica gel (20 g), using ether–benzene (1:99) as the eluent, to give a diacetate (**11b**) (78 mg: 29.8%), $[\alpha]_D$ +33.7° (*c* 3.29). The IR and ^{1}H NMR spectra of **11b** were identical with those of (15*S*)-12,16-diacetoxy-8,11,13-abietatriene.[2] Found: C, 74.79; H, 9.17%. Calcd for $C_{24}H_{34}O_4$: C, 74.57; H, 8.87%.

Further elution with ether–benzene (1:9) gave **10b** (141 mg: 47.0%), $[\alpha]_D$ +43.9° (*c* 4.00); IR: 1768, 1733 cm^{-1}; ^{1}H NMR (60 MHz, CCl_4): δ=0.95 (6H, bs, $-\underset{|}{C}(CH_3)_2$), 1.17 (3H, d, *J*= 7 Hz, C_{15}–CH_3), 1.22 (3H, s, C_{10}–CH_3), 1.95 (3H, s, C_{16}–$OCOCH_3$), 2.22 (6H, s, C_{11}–$OCOCH_3$ and C_{12}–$OCOCH_3$), 3.98 (2H, d, *J*=7.5 Hz, $-C\underline{H}_2OAc$), 6.78 (1H, s, C_{14}–H). Found: C, 70.45; H, 8.42%. Calcd for $C_{26}H_{36}O_6$: C, 70.24; H, 8.16%.

*(15R)-11,12,16-Triacetoxy-8,11,13-abietatrien-7-one (**12a**) and Its (15S)-Epimer (**12b**).* *a)*: A mixture of **10a** (965 mg) and chromium trioxide (413 mg) in acetic acid (20 ml) was stirred at room temperature for 23.5 h. The mixture was diluted with water and extracted with ether. The ether extract was washed successively with water, aqueous sodium hydrogencarbonate, and brine, dried over sodium sulfate, and evaporated *in vacuo*. The residue was chromatographed on silica gel (50 g), using ether–benzene (5:95) as the eluent, to give the starting **10a** (88 mg). Further elution with ether–benzene (5:95 and then 15:85) afforded **12a** (729 mg: 73.2%), $[\alpha]_D$ +66.8° (*c* 4.40); IR: 1775, 1734, 1687, 1608 cm^{-1}; ^{1}H NMR (60 MHz, CCl_4): δ=0.98 (6H, s, $-\underset{|}{C}(CH_3)_2$), 1.29 (3H, s, C_{15}–CH_3), 1.32 (3H, s, C_{10}–CH_3), 1.94 (3H, s, C_{16}–$OCOCH_3$), 2.25 (6H, s, C_{11}–$OCOCH_3$ and C_{12}–$OCOCH_3$), 3.95 (2H, d, *J*=7 Hz, $-C\underline{H}_2OAc$), 7.93 (1H, s, C_{14}–H). Found: C, 68.09; H, 7.51%. Calcd for $C_{26}H_{34}O_7$: C, 68.10; H, 7.47%.

b): A solution of **10b** (957 mg) in acetic acid (21 ml) was oxidized with chromium trioxide (409 mg) at room temperature for 22 h as described in *a)*. The crude product was

chromatographed on silica gel (50 g), using ether–benzene (5:95) as the eluent, to give **10b** (162 mg) and **12b** (667 mg: 67.6%), $[\alpha]_D$ +8.6° (*c* 14.35); IR: 1776, 1732, 1686, 1608 cm^{-1}; ^1H NMR (60 MHz, CCl_4): δ=1.00 (6H, s, $-C(CH_3)_2$), 1.27 (3H, d, *J*=7 Hz, C_{15}–CH_3), 1.34 (3H, s, C_{10}–CH_3), 1.96 (3H, s, C_{16}–$OCOCH_3$), 2.27 (6H, s, C_{11}–$OCOCH_3$ and C_{12}–$OCOCH_3$), 4.02 (2H, d, *J*=7 Hz, $-CH_2OAc$), 7.93 (1H, s, C_{14}–H). Oxidation of the recovered **10b** (162 mg) with chromium trioxide (69 mg) in acetic acid (3.5 ml) was then carried out as described above. The crude product was purified by column chromatography on silica gel (10 g) to give some additional **12b** (84 mg: 8.5%).

*(15R)-7,11,12,16-Tetraacetoxy-6,8,11,13-abietatetraene (**13a**) and Its (15S)-Epimer (**13b**).* *a)*: A mixture of **12a** (220 mg) and *p*-toluenesulfonic acid (20 mg) in isopropenyl acetate (5.0 ml) was refluxed for 18 h. The mixture was cooled and diluted with ether. The ether solution was washed with brine, dried over sodium sulfate, and evaporated *in vacuo*. The residue was chromatographed on silica gel (20 g), using ether–benzene (1:9) as the eluent, to give a mixture of **12a** and **13a** (61 mg). Further elution gave **13a** (176 mg: 73.3%), which was recrystallized from methanol, mp 140.5—141.5 °C, $[\alpha]_D$ +28.6° (*c* 3.40); IR: 1768, 1737sh, 1668, 1610 cm^{-1}; ^1H NMR: δ=0.94 (3H, s) and 1.02 (3H, s) ($-C(CH_3)_2$), 1.22 (3H, d, *J*=7 Hz, C_{15}–CH_3), 1.27 (3H, s, C_{10}–CH_3), 2.01 (3H, s, C_{16}–$OCOCH_3$), 2.25 (3H, s) and 2.28 (6H, s) (C_7–$OCOCH_3$, C_{11}–$OCOCH_3$, and C_{12}–$OCOCH_3$), 2.39 (1H, d, *J*=3 Hz, C_5–H), 3.15 (1H, m, C_{15}–H), 4.03 (2H, d, *J*=7 Hz, $-CH_2OAc$), 5.68 (1H, d, *J*=3 Hz, C_6–H), 7.01 (1H, s, C_{14}–H). Found: C, 67.05; H, 7.45%. Calcd for $C_{28}H_{36}O_8$: C, 67.18; H, 7.25%. The above mixture of **12a** and **13a** (61 mg) was then treated with *p*-toluenesulfonic acid (10 mg) in refluxing isopropenyl acetate (2.5 ml) for 15.5 h to give some additional **13a** (52 mg: 21.7%).

b): A mixture of **12b** (312 mg) and *p*-toluenesulfonic acid (30 mg) in isopropenyl acetate (7.0 ml) was refluxed for 18 h. After the work-up as described in *a)*, the crude product was chromatographed on silica gel (30 g), using ether–benzene (7:93) as the eluent, to give **13b** (285 mg, containing a small amount of **12b**: *ca.* 83.5%). This was recrystallized from methanol, mp 203—204 °C, $[\alpha]_D$ −7.8° (*c* 7.66); IR: 1765, 1738 sh, 1668, 1610 cm^{-1}; ^1H NMR (60 MHz): δ=0.93 (3H, s) and 1.01 (3H, s) ($-C(CH_3)_2$), 1.19 (3H, d, *J*=7 Hz, C_{15}–CH_3), 1.27 (3H, s, C_{10}–CH_3), 1.99 (3H, s, C_{16}–$OCOCH_3$), 2.25 (3H, s) and 2.29 (6H, s) (C_7–$OCOCH_3$, C_{11}–$OCOCH_3$, and C_{12}–$OCOCH_3$), 4.08 (2H, dd, *J*=7 and 3.5 Hz, $-CH_2OAc$), 5.65 (1H, d, *J*=3 Hz, C_6–H), 6.95 (1H, s, C_{14}–H). Found: C, 67.45; H, 7.34%. Calcd for $C_{28}H_{36}O_8$: C, 67.18; H, 7.25%.

*(15R)-6α,11,12,16-Tetraacetoxy-8,11,13-abietatrien-7-one (**14a**) and Its (15S)-Epimer (**14b**).* *a)*: A mixture of **13a** (67.0 mg) and *m*-chloroperbenzoic acid (80%: 40.4 mg) in dichloromethane (1.5 ml) was stirred at room temperature for 22.5 h. The mixture was diluted with ether and washed successively with aqueous potassium iodide, aqueous sodium thiosulfate, aqueous sodium hydrogencarbonate, and brine. The dried solution was evaporated *in vacuo* to give a mixture of 6α-acetoxy and 6α-hydroxy derivatives, which was immediately acetylated with acetic anhydride (0.7 ml) in pyridine (0.7 ml) at 75—80 °C for 2 h. After the usual work-up, the crude product was purified by column chromatography on silica gel (8.0 g), using ether–benzene (1:9) as the eluent, to give **14a** (63.1 mg: 91.3%). This was recrystallized from acetone–hexane, mp 185—187 °C, $[\alpha]_D$ +103.5° (*c* 2.54); IR: 1778, 1740, 1705, 1610 cm^{-1}; ^1H NMR: δ=1.05 (3H, s) and 1.14 (3H, s) ($-C(CH_3)_2$), 1.27 (3H, s, C_{15}–CH_3), 1.50 (3H, s, C_{10}–CH_3), 2.00 (3H, s, C_{16}–$OCOCH_3$), 2.24 (3H, s) and 2.30 (6H, s) ($C_{6\alpha}$–$OCOCH_3$, C_{11}–$OCOCH_3$, and C_{12}–$OCOCH_3$), 2.27 (1H, d, *J*=13 Hz, C_5–H), 3.20 (1H, m, C_{15}–H), 4.06 (2H, d, *J*=7 Hz, $-CH_2OAc$), 5.83 (1H, d, *J*=13 Hz, $C_{6\beta}$–H), 8.00 (1H, s, C_{14}–H). Found: C, 64.93; H, 7.04%. Calcd for $C_{28}H_{36}O_9$: C, 65.10; H, 7.03%. The synthetic **14a** was identical with natural nellionol tetraacetate (mp 185—186 °C).[1]

b): Oxidation of **13b** (245 mg, containing a small amount of **12b**) with *m*-chloroperbenzoic acid (80%: 148 mg) in dichloromethane (5.0 ml), followed by acetylation with acetic anhydride (1.5 ml) in pyridine (1.5 ml), were carried out as described in *a)*. The crude product was chromatographed on silica gel (10 g), using ether–benzene (5:95) as the eluent, to give **14b** (203 mg: *ca.* 80.3%) (67.1% from **12b**). This was recrystallized from acetone–hexane, mp 142.5—143 °C, $[\alpha]_D$ +35.4° (*c* 0.91); IR: 1778, 1740, 1705, 1610 cm^{-1}; ^1H NMR: δ=1.06 (3H, s) and 1.13 (3H, s) ($-C(CH_3)_2$), 1.23 (3H, d, *J*=7 Hz, C_{15}–CH_3), 1.51 (3H, s, C_{10}–CH_3), 2.00 (3H, s, C_{16}–$OCOCH_3$), 2.23 (3H, s) and 2.30 (6H, s) ($C_{6\alpha}$–$OCOCH_3$, C_{11}–$OCOCH_3$, and C_{12}–$OCOCH_3$), 3.18 (1H, m, C_{15}–H), 4.07 (2H, d, *J*=7 Hz, $-CH_2OAc$), 5.83 (1H, d, *J*=13 Hz, $C_{6\beta}$–H), 7.98 (1H, s, C_{14}–H). Found: C, 64.86; H, 7.05%. Calcd for $C_{28}H_{36}O_9$: C, 65.10; H, 7.03%.

*(15R)-6α,11,12,16-Tetrahydroxy-8,11,13-abietatrien-7-one (Nellionol) (**3a**) and Its (15S)-Epimer (**3b**).* *a)*: A mixture of **14a** (60.0 mg) and dilute hydrochloric acid (15%: 0.5 ml) in ethanol (3.0 ml) was refluxed for 6 h. After removal of the ethanol *in vacuo*, the residue was extracted with ether. The ether extract was washed with brine, dried over sodium sulfate, and evaporated *in vacuo*. The residue was chromatographed on silica gel (Mallinckrodt CC-4, 10 g), using hexane–chloroform (35:65) as the eluent, to give **3a** (31.3 mg: 77.3%). This was recrystallized from benzene, mp 222—224 °C, $[\alpha]_D$ +47.2° (*c* 0.36); IR (KBr): 3500, 3390, 1675, 1613 cm^{-1}; ^1H NMR (DMSO-d_6–D_2O): δ=1.13 (3H, s) and 1.16 (3H, s) ($-C(CH_3)_2$), 1.17 (3H, d, *J*=7 Hz, C_{15}–CH_3), 1.46 (3H, s, C_{10}–CH_3), 1.66 (1H, d, *J*=13 Hz, C_5–H), 3.0—3.4 (2H, m, $C_{1\beta}$–H and C_{15}–H), 3.53 (2H, d, *J*=6 Hz, $-CH_2OH$), 4.44 (1H, d, *J*=13 Hz, $C_{6\beta}$–H), 7.31 (1H, s, C_{14}–H). Found: C, 69.10; H, 8.20%. Calcd for $C_{20}H_{28}O_5$: C, 68.94; H, 8.10%. The synthetic **3a** was identical with natural nellionol (mp 226—227 °C).[1]

b): A mixture of **14b** (186.7 mg) and dilute hydrochloric acid (15%: 2.0 ml) in ethanol (10 ml) was refluxed for 6 h. After the work-up as described in *a)*, the crude product was chromatographed on silica gel (Mallinckrodt CC-4, 15 g), using hexane–chloroform (35:65) as the eluent, to give **3b** (79.4 mg: 63.1%). This was recrystallized from benzene, mp 216—217 °C, $[\alpha]_D$ +75.7° (*c* 0.52); IR (KBr): 3490, 3375, 3275, 1675, 1615 cm^{-1}; ^1H NMR (DMSO-d_6): δ=1.14 (3H, s) and 1.17 (3H, s) ($-C(CH_3)_2$), 1.18 (3H, d, *J*=7 Hz, C_{15}–CH_3), 1.48 (3H, s, C_{10}–CH_3), 1.68 (1H, d, *J*=13 Hz, C_5–H), 3.54 (2H, d, *J*=6 Hz, $-CH_2OH$), 4.47 (1H, d, *J*=13 Hz, $C_{6\beta}$–H), 7.32 (1H, s, C_{14}–H). Found: C, 69.13; H, 8.28%. Calcd for $C_{20}H_{28}O_5$: C, 68.94; H, 8.10%.

*(15R)-11,12,16-Triacetoxy-6,8,11,13-abietatetraene (**15a**) and Its (15S)-Epimer (**15b**).* *a)*: A mixture of **12a** (330 mg) and sodium borohydride (55 mg) in methanol (4.0 ml) was stirred at 0—5 °C for 30 min and then at room temperature for 1 h. The mixture was acidified with dilute hydrochloric acid and

extracted with ether. The ether extract was washed with brine, dried over sodium sulfate, and evaporated *in vacuo*. The residual oil was dissolved in dry benzene (3.5 ml) and then refluxed with *p*-toluenesulfonic acid (20 mg) for 1 h. The mixture was cooled, diluted with ether, and washed with brine. The dried solution was evaporated *in vacuo*. The residue was chromatographed on silica gel (18 g), using ether–benzene (5:95) as the eluent, to give **15a** (241 mg: 75.5%); IR: 1767, 1733 cm^{-1}; ^1H NMR (60 MHz, CCl_4): δ=0.97 (3H, s), 1.02 (3H, s), and 1.10 (3H, s) (–C(CH$_3$)$_2$ and C_{10}–CH$_3$), 1.22 (3H, d, J=7 Hz, C_{15}–CH$_3$), 1.93 (3H, s, C_{16}–OCOCH$_3$), 2.18 (3H, s) and 2.21 (3H, s) (C_{11}–OCOCH$_3$ and C_{12}–OCOCH$_3$), 3.92 (2H, d, J=7 Hz, –CH$_2$OAc), 5.89 (1H, dd, J=9.5 and 3 Hz, C_6–H), 6.44 (1H, dd, J=9.5 and 3 Hz, C_7–H), 6.77 (1H, s, C_{14}–H).

b): Reduction of **12b** (138 mg) with sodium borohydride (23 mg) in methanol (2.0 ml), followed by dehydration with *p*-toluenesulfonic acid (10 mg) in dry benzene (2.0 ml), were carried out as described in *a*). The crude product was chromatographed on silica gel (5.0 g) to give **15b** (112 mg: 84.0%); IR: 1766, 1735 cm^{-1}; ^1H NMR (60 MHz, CCl_4): δ=0.98 (3H, s), 1.03 (3H, s), and 1.12 (3H, s) (–C(CH$_3$)$_2$ and C_{10}–CH$_3$), 1.20 (3H, d, J=7 Hz, C_{15}–CH$_3$), 1.96 (3H, s, C_{16}–OCOCH$_3$), 2.20 (3H, s) and 2.23 (3H, s) (C_{11}–OCOCH$_3$ and C_{12}–OCOCH$_3$), 4.00 (2H, d, J=7 Hz, –CH$_2$OAc), 5.91 (1H, dd, J=9.5 and 2.5 Hz, C_6–H), 6.45 (1H, dd, J=9.5 and 2.5 Hz, C_7–H), 6.78 (1H, s, C_{14}–H).

(15R)-11,12,16-Triacetoxy-8,11,13-abietatrien-6-one (16a) and Its (15S)-Epimer (16b). *a*): A mixture of **15a** (219 mg) and *m*-chloroperbenzoic acid (80%: 160 mg) in dichloromethane (4.0 ml) was stirred at 0—5 °C for 1 h and then at room temperature for 14.5 h. The mixture was diluted with ether and washed successively with aqueous potassium iodide, aqueous sodium thiosulfate, aqueous sodium hydrogencarbonate, and brine. The ether solution was dried over sodium sulfate and evaporated *in vacuo*. The residual oil was refluxed with dilute hydrochloric acid (15%: 0.5 ml) in methanol (4.0 ml) for 1 h. The mixture was evaporated *in vacuo*, diluted with water, and extracted with ether. The ether extract was washed with brine, dried over sodium sulfate, and evaporated *in vacuo* to give an oil. This oil was acetylated with acetic anhydride (1.0 ml) in pyridine (1.0 ml) at 75—80 °C for 2 h. After the usual work-up, the crude product was chromatographed on silica gel (10 g), using ether–benzene (5:95) as the eluent, to give **16a** (194 mg: 85.5%), $[\alpha]_D$ +112.8° (*c* 3.13); IR: 1769, 1717 cm^{-1}; ^1H NMR (60 MHz): δ=1.03 (3H, s), 1.20 (3H, s), and 1.32 (3H, s) (–C(CH$_3$)$_2$ and C_{10}–CH$_3$), 1.22 (3H, d, J=7 Hz, C_{15}–CH$_3$), 2.00 (3H, s, C_{16}–OCOCH$_3$), 2.29 (6H, s, C_{11}–OCOCH$_3$ and C_{12}–OCOCH$_3$), 2.57 (1H, s, C_5–H), 3.20 (1H, m, C_{15}–H), 3:57 (2H, bs, –CH$_2$CO–), 4.02 (2H, d, J=7 Hz, –CH$_2$OAc), 6.85 (1H, s, C_{14}–H).

b): Oxidation of **15b** (112 mg) with *m*-chloroperbenzoic acid (80%: 82 mg) in dichloromethane (2.5 ml), followed by treatment with dilute hydrochloric acid (15%: 0.25 ml) in methanol (2.5 ml) and subsequent acetylation with acetic anhydride (0.7 ml) in pyridine (0.7 ml), were carried out as described in *a*). The crude product was chromatographed on silica gel (5.0 g) to give **16b** (82 mg: 70.8%), $[\alpha]_D$ +39.5° (*c* 2.99); IR: 1770, 1725 cm^{-1}; ^1H NMR (60 MHz): δ=1.05 (3H, s), 1.22 (3H, s), and 1.33 (3H, s) (–C(CH$_3$)$_2$ and C_{10}–CH$_3$), 1.21 (3H, d, J=7 Hz, C_{15}–CH$_3$), 2.02 (3H, s, C_{16}–OCOCH$_3$), 2.32 (6H, s, C_{11}–OCOCH$_3$ and C_{12}–OCOCH$_3$), 2.58 (1H, s, C_5–H), 3.21 (1H, m, C_{15}–H), 3.60 (2H, bs, –CH$_2$CO–), 4.07 (2H, d, J=7 Hz, –CH$_2$OAc), 6.90 (1H, s, C_{14}–H).

(15R)-6,11,12,16-Tetraacetoxy-5,8,11,13-abietatetraen-7-one (17a) and Its (15S)-Epimer (17b). *a*): A solution of **16a** (194 mg) in acetone (4.0 ml) was oxidized with Jones reagent (2.5 mol dm^{-3}: 0.26 ml) at 0—5 °C for 10 min and then at room temperature for 2 h. The mixture was diluted with water and extracted with ether. The ether extract was washed with brine, dried over sodium sulfate, and evaporated *in vacuo*. The residue was refluxed with acetic anhydride (6.0 ml) in the presence of anhydrous sodium acetate (350 mg) for 2.5 h with stirring. The mixture was cooled and diluted with ether. The ether solution was washed with water, dried over sodium sulfate, and evaporated *in vacuo*. The crude product was chromatographed on silica gel (10 g), using ether–benzene (1:9) as the eluent, to give **17a** (137 mg: 68.7%). This was recrystallized from hexane–benzene, mp 149—153 °C, $[\alpha]_D$ +88.0° (*c* 2.41); IR: 1778, 1730 sh, 1660, 1613 cm^{-1}; ^1H NMR: δ=1.29 (3H, d, J=7 Hz, C_{15}–CH$_3$), 1.40 (6H, s, –C(CH$_3$)$_2$), 1.64 (3H, s, C_{10}–CH$_3$), 2.00 (3H, s, C_{16}–OCOCH$_3$), 2.32 (3H, s) and 2.36 (6H, s) (C_6–OCOCH$_3$, C_{11}–OCOCH$_3$, and C_{12}–OCOCH$_3$), 3.25 (1H, m, C_{15}–H), 4.08 (2H, d, J=7 Hz, –CH$_2$OAc), 8.12 (1H, s, C_{14}–H). Found: C, 65.53; H, 6.91%. Calcd for $C_{28}H_{34}O_9$: C, 65.36; H, 6.66%.

b): Oxidation of **16b** (130 mg) in acetone (3.0 ml) with Jones reagent (2.5 mol dm^{-3}: 0.18 ml), followed by treatment with anhydrous sodium acetate (210 mg) in acetic anhydride (4.0 ml), were carried out as described in *a*). The crude product was purified by column chromatography on silica gel (5.0 g) to give **17b** (100 mg: 68.8%). This was recrystallized from hexane–benzene, mp 249—252 °C, $[\alpha]_D$ +43.0° (*c* 0.54); IR: 1778, 1733 sh, 1660, 1613 cm^{-1}; ^1H NMR: δ=1.27 (3H, d, J=7 Hz, C_{15}–CH$_3$), 1.39 (6H, s, –C(CH$_3$)$_2$), 1.64 (3H, s, C_{10}–CH$_3$), 2.01 (3H, s, C_{16}–OCOCH$_3$), 2.32 (3H, s) and 2.36 (6H, s) (C_6–OCOCH$_3$, C_{11}–OCOCH$_3$, and C_{12}–OCOCH$_3$), 3.23 (1H, m, C_{15}–H), 4.10 (2H, d, J=7 Hz, –CH$_2$OAc), 8.11 (1H, s, C_{14}–H). Found: C, 65.61; H, 6.82%. Calcd for $C_{28}H_{34}O_9$: C, 65.36; H, 6.66%.

(15R)-6,11,12,16-Tetrahydroxy-5,8,11,13-abietatetraen-7-one (5-Dehydronellionol) (4a) and Its (15S)-Epimer (4b). *a*): A mixture of **17a** (115.3 mg) and dilute hydrochloric acid (15%: 1.5 ml) in methanol (10 ml) was refluxed for 3 h. After removal of the methanol *in vacuo*, the residue was extracted with ether. The ether extract was washed with brine, dried over sodium sulfate, and evaporated *in vacuo*. The crude product was chromatographed on silica gel (Mallinckrodt CC-4, 10 g), using hexane–chloroform (35:65) as the eluent, to give **4a** (63.9 mg: 82.3%). This was recrystallized from hexane–benzene, mp 211—213 °C, $[\alpha]_D$ 0° (*c* 0.55); IR: 3600, 3500, 3370, 3150, 1633, 1597, 1565 cm^{-1}; ^1H NMR: δ=1.38 (3H, d, J=7 Hz, C_{15}–CH$_3$), 1.45 (6H, s, –C(CH$_3$)$_2$), 1.66 (3H, s, C_{10}–CH$_3$), 2.91 (1H, br, C_{16}–OH), 3.0—3.4 (2H, m, $C_{1\beta}$–H and C_{15}–H), 3.80 (1H, dd, J=8 and 10 Hz) and 4.08 (1H, dd, J=3 and 10 Hz) (–CH$_2$OH), 7.58 (1H, s, C_{14}–H), 6.36 (1H, s), 7.08 (1H, s), and 9.56 (1H, br) (C_6–OH, C_{11}–OH, and C_{12}–OH). Found: C, 69.61; H, 7.67%. Calcd for $C_{20}H_{26}O_5$: C, 69.34; H, 7.57%. The synthetic **4a** was identical with natural 5-dehydronellionol (mp 210—212 °C).[1]

b): A solution of **17b** (143.0 mg) in methanol (16 ml) was hydrolyzed with dilute hydrochloric acid (15%: 2.5 ml) as described in *a*). The crude product was purified by column chromatography on silica gel (Mallinckrodt CC-4, 15 g) to

give **4b** (59.9 mg: 62.2%). This was recrystallized from hexane–benzene, mp 187—189 °C, $[\alpha]_D$ +52.4° (*c* 0.52); IR: 3610, 3500, 3375, 3150, 1633, 1598, 1565 cm^{-1}; ^1H NMR: δ=1.37 (3H, d, *J*=7 Hz, C_{15}-CH_3), 1.44 (6H, s, $-\underset{|}{C}(CH_3)_2$), 1.68 (3H, s, C_{10}-CH_3), 2.9—3.45 (3H, m, $C_{1\beta}$-H, C_{15}-H, and C_{16}-OH), 3.80 (1H, dd, *J*=8 and 10 Hz) and 4.07 (1H, dd, *J*=3 and 10 Hz) ($-C\underline{H}_2OH$), 7.58 (1H, s, C_{14}-H), 6.38 (1H, s), 7.07 (1H, s), and 9.60 (1H, br) (C_6-OH, C_{11}-OH, and C_{12}-OH). Found: C, 69.56; H, 7.64%. Calcd for $C_{20}H_{26}O_5$: C, 69.34; H, 7.57%.

An Improved Method for Synthesis of L-Homoglutamic Acid *via* Epsilon-*N*-deamination of L-Lysine Derivative

Michio KONDO,* Koujiro MIYAZAKI, Hiroaki KODAMA, and Hideaki HORIMOTO
Department of Chemistry, Faculty of Science and Engineering, Saga University, Honjo-machi, Saga 840
(Received November 9, 1984)

A convenient procedure to prepare L-homoglutamic acid (L-2-aminoadipic acid; L-Aad) is described. Chlorination of ε-amino group in acetyl-L-lysine ethyl ester with *t*-butyl hypochlorite (*t*-BuOCl) followed by dehydrochlorination with pyridine gave ethyl 5-cyanovalerate which on acid hydrolysis afforded L-Aad in good yield.

2-Aminoadipic acid (Aad) is an intermediate in lysine metabolism and has been found in peptide antibiotics precursor of penicillin and cephalosporin biosynthesis. The absolute configuration of Aad from *penicillium chrysogenum* was determined to be the L-configuration by Chan *et al.*[1] Chemical synthesis of L-Aad has proceeded under optical resolution of DL-hydantoin derivative[2] or 2-(hydroxyimino)adipic ester.[3] In recent years Scott and Wilkinson[4] reported an alternative procedure based on the conversion of ε-amino group of N^{α}-benzyloxycarbonyl-L-lysine to the corresponding acid using NaOCl and a strong base, such as 1,8-diazabicyclo[5.4.0]undec-7-ene. L-Aad was obtained in 35% overall yield from the lysine derivative.

In a previous paper,[5] we reported a new method for the detection of intramolecularly hydrogen-bonded peptide NH by chlorine replacement reaction, which was initiated by adding a peptide to a solution containing Cl_2 or by adding *t*-BuOCl to a solution of peptide. The rate of chlorination measured by ^1H NMR showed that intramolecularly hydrogen-bonded peptide NH's were much more susceptible to the chlorination than solvent-exposed NH's in the peptide antibiotics, gramicidin S and tuberactinamin N. To make sure these new findings, substituent effects of alkyl (R-) or aryl (Ar-) group of CH_3CONHR (or -Ar) on H–Cl replacement reaction were also examined by ^1H NMR. The results well explained the differences in the reactivity of the amide NH protons: the more easily the amide nitrogen releases the proton (*viz.*, the more downfield NH proton signal appears), the more susceptible the NH proton is to chlorination. We postulated a mechanism to account for the H–Cl replacement reaction.[6]

We report here an improved method for the synthesis of L-Aad in optical form from N^{α}-acetyl-L-lysine ethyl ester by a deamination procedure. The procedure consists of chlorination of ε-amino group in the lysine derivative with *t*-BuOCl, dehydrochlorination of the *N,N*-dichloro amine derivative with pyridine, and hydrolysis of the nitrile. The overall yield was 60% from the lysine derivative. The present method provides a superior procedure for the synthesis of L-Aad to previously reported procedures[2–4] in high yield and in ease of operation.

Results and Discussion

Synthesis of L-*Glutamic Acid from* L-*Ornithine.* In the course of study on structure-activity relationship of gramicidin S, we found that amino acid analysis of the hydrolysis products of chlorinated gramicidin S gave three unknown peaks except ones of constituent amino acids in gramicidin S. Among the three peaks, one which appeared in the acidic region seemed to be glutamic acid derived from ornithine during chlorination of gramicidin S followed by acid hydrolysis. To confirm the results, we carried out chlorination of Ac-L-Orn-OEt and acid hydrolysis of the dichloro amine derivative. The preliminary experiments using the model compound, Ac-L-Orn-OEt, showed that the δ-NH_2 group was not susceptible to chlorination with Cl_2, but that in the case of *t*-BuOCl a chlorinated product having δ-NHCl or δ-NCl_2 group was detected by ^1H NMR and mass spectrometers. After a methanol solution of the dichloro amine derivative was tightly stoppered and stored in the dark for a month, the δ-NCl_2 group remained without decomposition, which was ascertained by appearance of its absorption band (310 nm, λ_{max}) in UV spectrum and by thin-layer chromatography. The dichloro amine derivative chlorinated with *t*-BuOCl was hydrolyzed with 6 mol dm^{-3} hydrochloric acid. Amino acid analysis of the products gave two peaks. One was ascertained to be ornithine and the other to be glutamic acid from the data of paper chromatography (PPC) and paper electrophoresis. In the above procedure, glutamic acid was obtained only in a small amount.

Nitrile synthesis from amine *via* *N,N*-dihalo amine followed by dehydrohalogenation was carried out by several procedures.[7–9] For example, the dehydrohalogenation was carried out by heating dihalo amine with cesium fluoride. In the conversion of 1,6-hexanediamine into adiponitrile the fluorinated derivative was successfully isolated.[9] Therefore, to obtain a high yield of glutamic acid, formation of nitrile by dehydrochlorination was carried out with triethylamine and pyridine. However, use of triethylamine as a base was no advantage to the yield of glutamic acid. On the other hand, application of excess pyridine gave a good yield of glutamic acid as a main product. Amino acid analysis and the value of $[\alpha]_D$ of the glutamic acid thus

Table 1. Reaction products of Ac-L-Lys-OEt with *t*-BuOCl under various conditions and acid hydrolysis of nitrile

Chlorination conditions		Chlorinated[a] NH/%		Acid hydrolysis of nitrile		
t-BuOCl[b]	time	α-NH	ε-NH_2	Aad[c]:	Lys:	insoluble

10 eq	5 min	5	100	52	18	30
5 eq	5 min	0	100	75	7	18

a) Data from ^{1}H NMR. b) In MeOH at 0 °C and then room temperature. c) Weight ratio.

obtained were in fair agreement with those of an authentic sample. These results suggest that L-ornithine is converted into L-glutamic acid without racemization *via* the dichloro amine derivative in good yield.

Synthesis of L-Aad from L-Lysine. We are very interested in the preparation of L-homoglutamic acid (L-Aad) which is not easily available in large quantities. The above results prompted us to study for a convenient and practical synthesis of L-Aad from L-lysine derivative.

In order to find out suitable reaction conditions, chlorination of Ac-L-Lys-OEt (**2**) with *t*-BuOCl was carried out under various conditions shown in Table 1. The most satisfactory result was obtained by using 5 equivalents *t*-BuOCl for 5 min, and also acid hydrolysis of the nitrile derived from the dichloro amine under these conditions showed the best yield of L-Aad. After chlorination with *t*-BuOCl (5-equiv) in methanol for 5 min, the reaction mixture was concentrated *in vacuo* to give an oil (**3**). This oil was used in the next reaction without further purification because of its unstableness. The formation of the dichloro amine derivative was detected by ^{1}H NMR and UV spectra. As shown in Fig. 1, compound **3** was dehydrochlorinated by excess pyridine for 20 h at room temperature, the reaction mixture was concentrated *in vacuo*, and the oily residue was dissolved in chloroform. The solution was washed successively with 0.5 mol dm^{-3} sodium hydrogencarbonate, 0.5 mol dm^{-3} citric acid, and water to give the nitrile (**4**). The formation of **4** was detected by the 2260 cm^{-1} ν C≡N band of the product in the IR spectrum and further confirmed by ^{1}H NMR and mass spectra. The nitrile was refluxed with 6 mol dm^{-3} hydrochloric acid to yield L-Aad, lysine, and insoluble material. After filtering off the insoluble material, these products were subjected to ion-exchange column chromatography to afford L-Aad in 60% yield from Ac-L-Lys-OEt (**2**) which was easily obtained by catalytic hydrogenolysis of Ac-L-Lys(ε-Z)-OEt (**1**). Amino acid analysis, CD, and $[\alpha]_D$ data of the synthetic L-Aad (**5**) thus obtained were identical with those of an authentic sample.

By the above results, the deamination procedure proved to be a facile and convenient method for the synthesis of L-homoglutamic acid in optical form from L-lysine derivative.

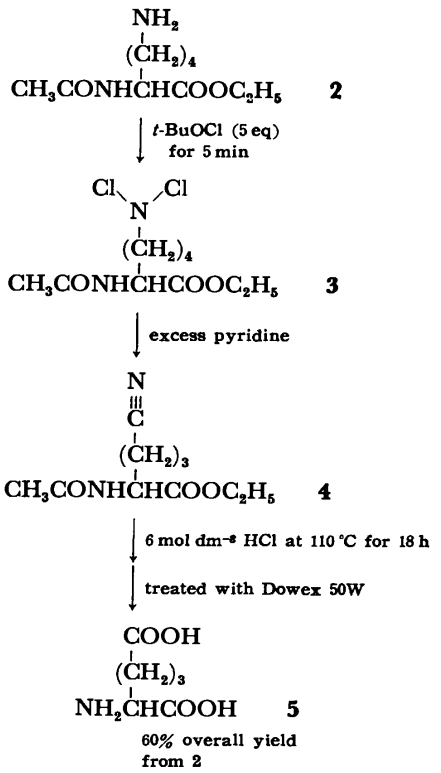

Fig. 1. Synthetic Procedure of L-2-Aminoadipic Acid.

Experimental

The melting point is uncorrected. All chemicals used for preparative experiments were of reagent grade and solvents were distilled before use. An authentic sample of L-Aad was obtained from Calbiochem-Behring Corp., La Jolla., Calf., U.S.A. Thin-layer chromatography was carried out on silica gel GF_{254} (Merck) with the following solvent system: R_f^1, $CHCl_3$-MeOH-AcOH (8:1:1, v/v). Compounds with protected amino groups were detected by spraying with 50% hydrochloric acid followed by ninhydrin. Chlorinated compounds were detected by spraying with the mixed solution (1:1, v/v) of 0.1 mol dm^{-3} potassium iodide in water and 2.1 mmol dm^{-3} *o*-tolidine in 2% AcOH. Paper chromatography was performed on Toyo Roshi No. 50 paper with the following solvent systems: R_f^2, *n*-BuOH-AcOH-H_2O (4:1:2, v/v) and R_f^3, *n*-BuOH-AcOH-pyridine-H_2O (4:1:1:2, v/v). Optical rotations were measured on a Yanagimoto polarimeter OR-50 and CD spectra with a Jasco J-20 spectropolarimeter. Mass spectra were taken on an ESCO EMD-05A and NMR spectra on a JEOL JNM-MH-100. Infrared spectra were recorded on a Hitachi 260-10 instrument using KCl plate. Amino acid analysis was carried out by amino acid analyzer model, JLC-6AH.

Ac-L-Lys(ε-Z)-OEt (1). To a solution of L-Lys(ε-Z)-OEt·*p*-TosOH[10] (7.21 g, 15 mmol) in pyridine (35 mL) was added acetic anhydride (7.1 mL, 75 mmol) at 0 °C. The mixture was stirred for 18 h at room temperature and then evap-

orated *in vacuo*. The residue was diluted with ethyl acetate (400 mL). The ethyl acetate solution was washed successively with 0.5 mol dm^{-3} citric acid, 0.5 mol dm^{-3} $NaHCO_3$, and water. The solution was dried over anhydrous Na_2SO_4 and evaporated under reduced pressure. The product was obtained as an oil; yield 4.73 g (90%); R_f^1 0.65; ^1H NMR ($CDCl_3$): δ 7.32 (s, 5H, aromatic), 6.33 (d, 1H, -NH-), 5.00 (m, 1H, -NH-), 4.52 (q, 1H, -CH), 4.16 (q, 2H, $-CH_2-$), 3.16 (q, 2H, $-CH_2-$), 1.98 (s, 3H, $-CH_3$), 1.26 (t, 3H, $-CH_3$); Found: *m/z* 350. Calcd for $C_{18}H_{26}N_2O_5$: M, 350.

Ac-L-Lys-OEt (2). Compound **1** (3.8 g, 10.8 mmol) was hydrogenated in EtOH (35 mL) in the presence of palladium black for 4.5 h. The solution filtered from the catalyst was evaporated to dryness *in vacuo*. The oily product weighed 2.3 g (98%); R_f^2 0.57, R_f^3 0.61; ^1H NMR (DMSO-d_6): δ 8.38 (d, 1H, -NH-), 4.32 (m, 1H, -CH), 4.22 (q, 2H, $-CH_2-$), 2.60 (m, 2H, $-NH_2$), 1.91 (s, 3H, $-CH_3$), 1.23 (t, 3H, $-CH_3$); Found: *m/z* 216. Calcd for $C_{10}H_{20}N_2O_3$: M, 216.

N^{ε}-Dichloro-N^{α}-acetyl-L-lysine Ethyl Ester (3). To a solution of **2** (2.3 g, 10.6 mmol) in MeOH (30 mL) was added *t*-butyl hypochlorite (5.96 mL, 53 mmol) at 0 °C. After 5 min at room temperature, the solution was evaporated to dryness *in vacuo* at 5 °C. The compound was obtained as an oil. All experimental procedures were carried out in the dark; yield 3.0 g (99%); R_f^1 0.64; ^1H NMR (DMSO-d_6): δ 8.28 (d, 1H, -NH-), 4.10 (q, 2H, $-CH_2-$), 3.00 (t, 2H, $-CH_2-$), 1.88 (s, 3H, $-CH_3$), 1.20 (t, 3H, $-CH_3$).

Ethyl 2-Acetamido-5-cyanovalerate (4). To a solution of **3** (1.51 g, 5.3 mmol) in MeOH (15 mL) was added excess pyridine (93 mL) at 0 °C in the dark. After 20 h at room temperature, the reaction mixture was evaporated and dissolved in $CHCl_3$ (200 mL). The solution was washed with 0.5 mol dm^{-3} citric acid and aq NaCl, dried over anhydrous Na_2SO_4, and then concentrated under reduced pressure to an oil. The formation of nitrile **4** by dehydrochlorination was confirmed with the 2260 cm^{-1} ν C≡N band of the product in the IR spectrum. It weighed 1.04 g (93%); R_f^1 0.67; ^1H NMR ($CDCl_3$): δ 6.52 (d, 1H, -NH-), 4.60 (m, 1H, -CH), 4.22 (q, 2H, $-CH_2-$), 2.42 (t, 2H, $-CH_2-$), 2.04 (s, 3H, $-CH_3$), 1.31 (t, 3H, $-CH_3$); Found: *m/z* 212. Calcd for $C_{10}H_{16}N_2O_3$: M,212.

L-2-Aminoadipic Acid (5). Compound **4** (1.04 g, 4.9 mmol) was refluxed with 6 mol dm^{-3} HCl (150 mL) for 18 h. The cooled solution was evaporated to give an oil, which was dissolved in water (100 mL). After filtering off a small amount of insoluble material, the solution was applied on a column (2.1×25 cm) of Dowex 50 W (H^+ form). The column was washed with water (200 mL) and was eluted with 2 mol dm^{-3} aqueous ammonia (200 mL). The collected effluents were evaporated to leave an oily product, which was dissolved in water (90 mL). Chromatography of this solution with Dowex 50 W (NH_4^+ form) separated Aad by elution with water (200 mL) and lysine was successively recovered with 2 mol dm^{-3} aqueous ammonia (200 mL). The effluent containing Aad from the column (NH_4^+ form) was evaporated to a small volume and precipitated by the addition of EtOH. The crude product was dissolved in dil HCl and the solution was adjusted to pH 3.5 with 1 mol dm^{-3} aqueous ammonia and then crystallized by the addition of EtOH; yield 525 mg (60% from **2**); R_f^2 0.27, R_f^3 0.16; mp 199—200 °C; $[\alpha]_D^{21}$ +24.4° (*c* 2, 5 mol dm^{-3} HCl). Authentic L-Aad: R_f^2 0.27, R_f^3 0.16; mp 200—201 °C; $[\alpha]_D^{21}$ +24.6° (*c* 2, 5 mol dm^{-3} HCl). Amino acid analysis and CD spectrum of L-Aad were in fair agreement with the authentic L-Aad.

Found: C, 44.54; H, 7.07; N, 8.65%. Calcd for $C_6H_{11}NO_4$: C, 44.72; H, 6.88; N, 8.69%.

Electrophoresis. Electrophoresis of compound **5**, using Toyo Roshi No. 51A paper, was carried out with the following solvent systems: Ep^1, pyridine–AcOH–H_2O (1:10:89, v/v, pH 3.6) and Ep^2, pyridine–AcOH–H_2O (25:1:225, v/v, pH 6.5) at 500 V/30 cm for 2 h. Compound **5** and L-homoglutamic acid (Aad) showed the equal mobilities, which migrated towards the cathode, 0.4 cm in Ep^1 and the anode, 2.8 cm in Ep^2, respectively.

The Photolysis of *N,O*-Diacyl-*N*-phenylhydroxylamines[1)]

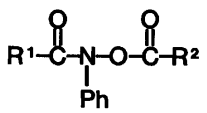
Tadamitsu SAKURAI,* Hirofumi YAMAMOTO, Shuichi YAMADA, and Hiroyasu INOUE
Department of Applied Chemistry, Faculty of Technology, Kanagawa University, Rokkakubashi, Kanagawa-ku, Yokohama 221
(Received November 9, 1984)

The photochemical decomposition of the title compounds yielded the rearrangement products derived from 1,3- and 1,5-aroyloxyl migrations in addition to the fragmentation products typical of the aroyloxyl and amido radicals, while only 1,3-aroyloxyl migration was observed on thermolysis. The results of crossover experiments indicate an intramolecular rearrangement, probably involving homolysis of the N-O bond in the excited states. Triplet quenching studies demonstrate that the rearrangement and fragmentation proceed exclusively *via* the first excited singlet state. No formation of the rearrangement products on triplet sensitization was explained on the basis of the spin multiplicity effects on a radical-radical recombination process within a solvent cage.

The elegant and pioneering works of Ochiai and his coworkers in the field of the chemistry of heteroaromatic amine *N*-oxides have greatly stimulated mechanistic investigations of the reactions between these *N*-oxides and acylating agents.[2)] The devotion of many workers to this mechanistic study has resolved many questions concerning the mechanism of the reactions, which heteroaromatic and aromatic amine *N*-oxides undergo, and led to the syntheses of many biochemically and pharmaceutically important compounds.[3)] In connection with the rearrangements of *O*-acylated amine *N*-oxides, the acyloxyl migration of *N,O*-diacyl-*N*-arylhydroxylamines has attracted much attention mainly because these *N*-arylhydroxylamines have a closely related structure to "anhydrobase" which is a key intermediate for the rearrangement reactions of tertiary amine *N*-oxides.[4)]

In addition, mechanistic studies of *N,O*-diacyl-*N*-arylhydroxylamines[5)] have contributed to clarifying the mode of the N-O bond cleavage that has been a question of controversy for a long time in the rearrangement of heteroaromatic *N*-oxides and related compounds.[6)] Based on both kinetic and oxygen-18 tracer studies it was suggested that the electronic effects on the heterolysis of the N-O bond play a crucial role in determining the mechanism of 1,3-rearrangement.[5)] However, it is difficult to exclude completely the possibility of a radical rearrangement *via* the homolysis of the N-O bond although the rearrangement is now believed to proceed *via* the exclusive heterolytic cleavage of the N-O bond.[6,7)]

On the other hand, Walling and Naglieri have found that the photolysis of *N,O*-diacylhydroxylamines gives the products derived from the homolysis of the N-O bond.[8)] Their work suggested us that a systematic study of the photolysis of *N,O*-diacyl-*N*-arylhydroxylamines would lead to a new information on the mechanism of acyloxyl migrations of these hydroxylamines and related compounds. Because there are only a few investigations of the photochemical rearrangement of hydroxamic acid derivatives,[9)] we have prepared *N,O*-diacyl-*N*-phenylhydroxylamines (**Ia—d**) and examined their photochemical behavior, hoping to gain further insight into the mechanism of acyloxyl migration. In this paper we present the first observation of photorearrangements of **Ia—d** and discuss the mechanism of the photolysis of these hydroxylamines.

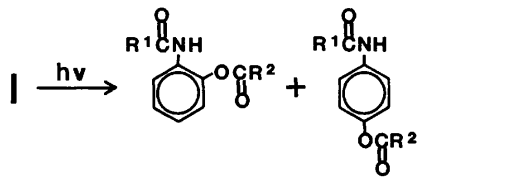


Ia-d

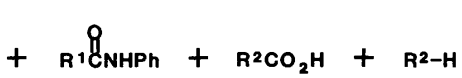
Ia: R^1=1-naphthyl (1-Np), R^2=p-tolyl (p-Tl)
Ib: R^1=p-Tl, R^2=1-Np
Ic: R^1=R^2=1-Np
Id: R^1=R^2=p-Tl

Results and Discussion

*Products from the Photolyses of **Ia—d**.* An oxygen-free acetonitrile solution of **I** was irradiated with Pyrex-filtered light. The irradiation was done in a water bath so that the reaction temperature was maintained constant during the photolysis (23±1 °C). Each of reactions gave two rearrangement products **II** and **III** together with arenecarboxanilide **IV**, carboxylic acid **V**, and hydrocarbon **VI** as summarized in Table 1.



II **III**



IV **V** **VI**

These products were identified by comparing their HPLC behavior at two different wavelengths (230 and 270 nm) with that of independently prepared authentic samples. In addition to the HPLC peaks of **II—VI** one can see some unknown peaks on the chromatogram, which will be discussed in a later section. Starting

Id	60.8								

a) The initial concentrations of **Ia—d** were all 0.0066 M. Deaerated solutions were irradiated for 2 h with Pyrex-filtered light in a water bath (20±1 °C). b) Based on starting hydroxylamines. c) Could not be determined because of overlapping with the HPLC peak of starting **Ia**. d) The HPLC peak of starting **Ib** made this yield determination impossible. e) Could not be determined because of overlapping with unknown HPLC peak(s) derived from **Ia**. f) The HPLC peak of starting **Id** interfered with exact evaluation of this yield.

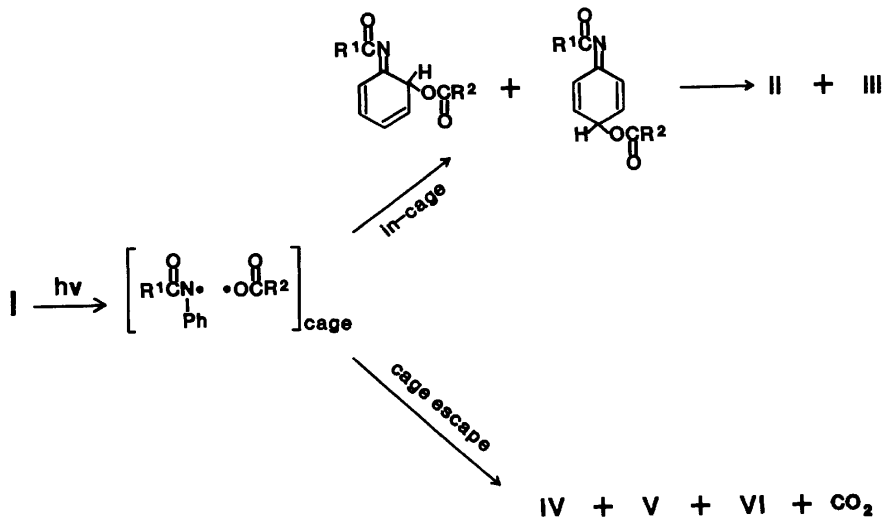
hydroxylamines **Ia—d** were recovered quantitatively without the irradiation, of course. To get more unambiguous proof of the structure for the photoproducts, irradiation of one of the starting hydroxylamines **Ia** was continued under the same conditions as above until disappearance of **Ia** was complete (monitored by TLC). Chromatography of the photolyzate allowed isolation and identification of **IIa** (4%, isolated yield), **IIIa** (8%), **IVa** (20%), **Va** (10%), and **VIa** (9%, GLC yield) except carbon dioxide (about 30%) which was characterized as barium carbonate. This product distribution is qualitatively consistent with that obtained by HPLC analysis of the photolyzate. We obtained also tarry product mixtures from which attempts to isolate any crystalline materials were not fruitful.

Independent irradiation of the photoproducts clearly shows that the rearrangement and fragmentation products undergo undesirable photodecompositions to different extent depending on the structure of the products (**IIa**, **IId**, and **IIIb**, 30% decomposition on 2 h irradiation; **IIIa** and **IIId**, 40—50%; **IIb**, **IIc**, and **IIIc**, 70—80%; **IV**, **V**, and **VI**, 2—7%). The decomposition of the fragmentation products during the irradiation is minor, whereas that of the rearrangement products takes place remarkably. Thus the low yields of **II** and **III**, especially **IIb**, **IIc**, and **IIIc**, may be ascribed in part to this low photostability.

Crossover Experiment and Thermolysis. To ascertain the intra- or intermolecularity of this interesting photorearrangement, an equimolar mixture of **Ia** and **Ib** in acetonitrile was irradiated with Pyrex-filtered light in the same manner. Careful HPLC analysis of the photolyzate indicates the formation of negligible amounts of the crossover products (**IIc**, **d**, and **IIIc**, **d**) in addition to the noncrossover rearrangement products (**IIa**, **b**, and **IIIa**, **b**) (see Table 2). A similar finding was obtained also on irradiation of a mixture of **Ic** and **Id**. These findings demonstrate that the photorearrangements proceed by an exclusively intramolecular aroyloxyl shift.

Since the photoreactions of **Ia—d** are formally analogous to the photo-Fries reactions that proceed through a caged radical mechanism in solution,[10] it is reasonable to assume that the photolysis of these hydroxylamines involves homolytic cleavage of the N–O bond in an excited state forming the amido and aroyloxyl radicals, which either recombine within a solvent cage to afford the rearrangement products or escape out of the cage to give the fragmentation products by hydrogen abstraction from the solvent or otherwise as shown in Scheme 1. The homolysis of the N–O bond is supported by the facts that the products derived from the amido and aroyloxyl radicals were identified, and that *N,O*-diacylhydroxylamines, whose structure is very similar to that of **Ia—d**, undergo the homolytic photolysis.[8]

In order to examine possible involvement of hetero-



Scheme 1.

lysis of the N–O bond, **Ia—d** were heated at 120—130 °C in dimethyl sulfoxide. If participation of an ionic mechanism would be responsible for the formation of **II** and **III**, the same rearrangement products should be obtained thermally because the rearrangement of closely related *N,O*-diacyl-*N*-arylhydroxylamines is well known to proceed through the heterolytic scission of the N–O bond.[5] As seen from Table 3 the thermolyses gave only the ortho-migrated products **II** accompanied by the recovered starting materials, whereas neither fragmentation nor migration of an aroyloxyl group to the para-position could be observed. Clearly the products of the photolysis are quite different from those of the thermal decomposition, indicating that at least the para-migrated rearrangement and fragmentation products originate from the homolytic cleavage of the N–O bond. The fact that the N–O bond of diacylhydroxylamines readily undergoes homolytic cleavage in the excited states[8] allows us to propose a radical mechanism to account for the formation of **II** as well as **III—VI**.

*Solvent Effects on the Photolysis of **Ia**.* A free radical mechanism requires that anilide **IV** and carboxylic acid **V** should be found in comparable amounts because of the minor process of decarboxylation giving eventually either toluene or naphthalene. Table 1 shows, however, that there are always lower yields of **IV** than those of **V** at any conversion irrespective of the structure of starting hydroxylamines. This observation leads us to speculate that hydrogen abstraction to yield **IV** is not the only reaction pathway for the amido radical in acetonitrile. It is likely that hydrogen abstraction of the photochemically generated amido radical competes with such processes as dimerization, disproportionation, and addition[11] owing to the relatively low reactivity of acetonitrile toward hydrogen abstraction. These competing pathways might be responsible for the observation of some unknown HPLC peaks. We felt that solvent effects on the rearrangement and fragmentation pathways may clarify this point. The hydroxylamine **Ia** was chosen for this purpose. The results are given in Table 4. As expected the fragmentation products **IV** and **V** are found in comparable yields in 1,2-dichloroethane whose hydrogen atoms seem much more reactive to hydrogen abstraction compared with other two solvents used. In addition, some unknown HPLC peaks, which were observed in the photolysis in acetonitrile and benzene, could not be detected on the HPLC chromatogram of the photolyzate in 1,2-dichloroethane, supporting the view mentioned above.

Quenching and Sensitization Experiments. *N,O*-Diacyl-*N*-phenylhydroxylamines used in this work exhibit a fluorescence with maxima between 370 and 390 nm except **Id** whose fluorescence is too weak to be observed. We estimated the first singlet excitation energy (E_S) of **Ia—c** from the absorption and fluorescence spectral data to tabulate in Table 5. The phosphorescence of **Ia—c** with 0,0 bands around 490 nm could be detected in acetonitrile at 77 K, while **Id** shows a broad phosphorescence at 422 nm. Table 5 also includes the first triplet excitation energy (E_T) estimated from the 0,0 bands of **Ia—c** and the emission maximum of **Id**. In Fig. 1 are typically shown the absorption and emission spectra of **Ia** in acetonitrile.

The phosphorescence of **Ia—d** (2×10^{-4} M, 1 M=1 mol dm^{-3}) is quenched by 1,3-cyclohexadiene (0.01 M), showing that this diene becomes a good triplet quencher in view of endothermicity of singlet-singlet energy transfer from **I** to the diene. Sensitization of the phosphorescence of **Ia—d** (2×10^{-4} M) by benzo-

phenone (2×10^{-3} M) was observed accompanying the quenching of sensitizer's phosphorescence (Fig. 2). This finding indicates benzophenone to be an excellent triplet sensitizer. Also in this case singlet-singlet energy transfer from sensitizer to **I** is endothermic. In order to decide whether the photolysis occurs from the excited singlet or triplet state, triplet quenching (313-nm light) and sensitization (mostly 366-nm light) experiments were performed. The results are summarized in Tables 6 and 7. Evidently, neither product formation nor disappearance of starting hydroxylamines was affected by 1,3-cyclohexadiene within the limits of experimental accuracy (Table 6), suggesting that the rearrangement and fragmentation products come from the reaction in the excited singlet state.[12]

The diacylhydroxylamines **Ia—d** undergo greatly accelerated photodecompositions in the presence of benzophenone (Table 7). The fragmentation products are formed by the sensitized photolysis in which no benzophenone was consumed within the experimental error, whereas benzophenone does not sensitize the rearrangement. The finding that the triplet state photolysis gives the rearrangement products in a negligible yield is compatible with the result of triplet quenching experiment. Irradiation of the photoproducts **II—VI** with 366-nm light resulted in their negligible decomposition (less than 5% on 15 min irradiation) in the presence of the sensitizer (0.05 M). Another prominent facet in this triplet sensitization is that the yields of **IVa—c** are much low even at high conversion of **Ia—c**. The increased intensity of unknown HPLC peaks compensates for this decreased yield of anilide **IV**. Thus the fragmentation products including **IV** are undoubtedly formed by the sensitized photolysis.

Mechanism of the Photolyses. The triplet quenching and sensitization results establish that the rearrangement takes place *via* the excited singlet state, whereas the fragmentation products are obtained from both the excited singlet and triplet state reactions. As already noted the direct photolysis of **I** causes the homolytic scission of the N-O bond in the molecule

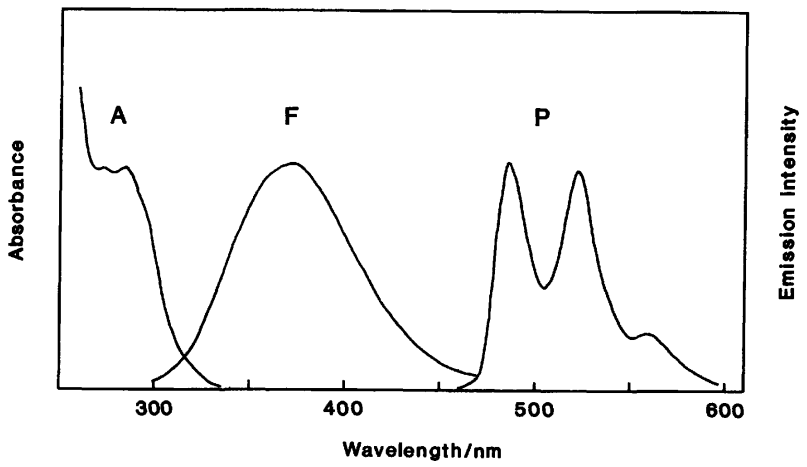

Fig. 1. UV absorption and emission spectra of **Ia** (2×10^{-4} M) in acetonitrile. Intensities have been adjusted for the sake of clarity.

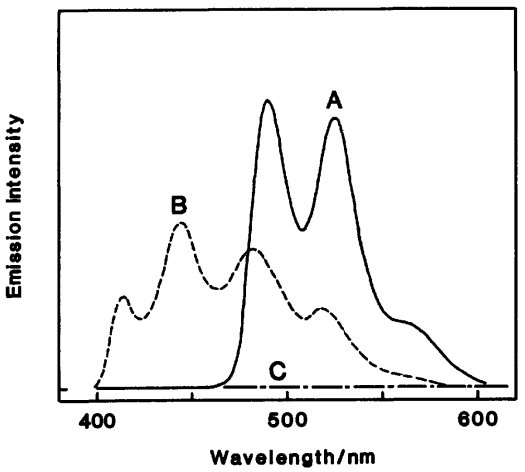

Fig. 2. Sensitization of the phosphorescence of **Ia** by benzophenone in acetonitrile at 77 K. (A): Sensitized phosphorescence of **Ia**, excitation wavelength=380 nm; [**Ia**]=2×10^{-4} M, [benzophenone]=2×10^{-3} M; (B) and (C): Phosphorescence of benzophenone (B) and **Ia** (C) under the same conditions.

affording the caged singlet radical pairs which undergo efficient cage reactions to give the rearranged products **II** and **III**, in competition with escape from the solvent cage (Scheme 2).

Since the rate of escape of the triplet radical pairs from the cage should be faster than the rate of the triplet→singlet intersystem crossing in the radical pairs,[13,14] no rearrangement products are formed by the triplet sensitized photolysis of **I**. Thus the sensitized reaction leads to the exclusive formation of "out-of-cage" reaction products as shown in Scheme 2, being consistent with the conviction that triplet radical pairs, in general, undergo very inefficient cage reactions.[15]

Experimental

All melting points were uncorrected. IR spectra were recorded on a Hitachi EPI-G3 infrared spectrometer. ^{1}H NMR spectra were obtained on a JEOL model PS-100 100 MHz spectrometer with TMS as an internal standard. UV and emission spectral data were collected with a Shimadzu UV-210A spectrophotometer and a Shimadzu RF-500 spectrophotofluorimeter, respectively. Phosphorescence spectra were taken with a cylindrical rotating sector at 77 K. GLC analysis was carried out on a Hitachi 063 gas chromatograph using 2-m column packed with 10% Silicone SE-30 on Uniport B (60/80 mesh, Gasukuro Kogyo Inc.). HPLC separation of the photoproducts was performed on a Hitachi 638-50 high performance liquid chromatography apparatus with a 2.6×500-mm ODS (Hitachi gel #3050) column.

path a, 'out-of-cage' reaction; path b, 'in-cage' reaction

Scheme 2.

Materials. Acetonitrile was purified according to the modified procedure of Walden and Birr.[16] Benzene and 1,2-dichloroethane (spectrograde from Dojin Chemical Inc.) were used without further purification. Acetonitrile and water (HPLC grade from Wako Pure Chemical Industries, Ltd.) were used as received for HPLC analysis. 1,3-Cyclohexadiene (Aldrich Chemical Co.) was fractionally distilled prior to use and stored in a refrigerator. Benzophenone (reagent grade, Wako) was purified by column chromatography over silica gel (70/230 mesh) followed by repeated recrystallization from aqueous ethanol. 1-Naphthoic and *p*-toluic acids (reagent grade, Wako) were recrystallized from benzene and aqueous ethanol, respectively. Naphthalene (reagent grade, Wako) was purified by sublimation at reduced pressure. Toluene (spectrograde, Dojin) was used as received.

Preparation of Starting N,O-*Diacyl*-N-*phenylhydroxylamines* (***Ia—d***). *N*-Phenylhydroxylamine was prepared by the reduction of nitrobenzene with zinc dust in water containing ammonium chloride, then recrystallized from hexane, mp 80.5—81.5 °C (lit,[17] 81 °C). *N*-(*p*-Toluoyl)-*N*-phenylhydroxylamine was obtained from the reaction of *p*-toluoyl chloride with two equiv of *N*-phenylhydroxylamine in ether with stirring in an ice bath. After the usual workup which consisted of washing the reaction mixture with water, drying the ethereal solution over $MgSO_4$, and removing the solvent on a rotary evaporator, recrystallization of the crude product from benzene-hexane gave colorless crystals, mp 121—122 °C; IR (KBr) 3200 and 1610 cm^{-1}. *N*-(1-Naphthoyl)-*N*-phenylhydroxylamine was prepared similarly from the reaction of 1-naphthoyl chloride with two equiv of *N*-phenylhydroxylamine, then recrystallized from benzene-hexane, mp 129—130 °C; IR (KBr) 3220 and 1620 cm^{-1}. The reactions of these *N*-aroyl-*N*-phenylhydroxylamines with the corresponding aroyl chlorides in the presence of pyridine in dichloromethane gave **Ia—d** whose physical properties are the followings.

N-(*1-Naphthoyl*)-O-(p-*toluoyl*)-N-*phenylhydroxylamine* (***Ia***). Mp 134.5—135.5 °C (from benzene-hexane); NMR ($CDCl_3$) δ=2.36 (3H, s), 7.08—7.90 (15H, m), and 8.36 (1H, d, J=8 Hz); IR (KBr) 1750 and 1680 cm^{-1}. Found: C, 79.19; H, 4.94; N, 3.73%. Calcd for $C_{25}H_{19}NO_3$: C, 78.74; H, 4.99; N, 3.67%.

N-(p-*Toluoyl*)-O-(*1-naphthoyl*)-N-*phenylhydroxylamine* (***Ib***). Mp 164—165 °C (from benzene-hexane); NMR ($CDCl_3$) δ=2.30 (3H, s), 7.00—8.22 (15H, m), and 8.74 (1H, d, J=8 Hz); IR (KBr) 1775 and 1690 cm^{-1}. Found: C, 79.11; H, 4.99; N, 3.71%. Calcd for $C_{25}H_{19}NO_3$: C, 78.74; H, 4.99; N, 3.67%.

N,O-*Di*(*1-naphthoyl*)-N-*phenylhydroxylamine* (***Ic***). Mp 116—117 °C (from benzene-hexane); NMR ($CDCl_3$) δ=7.12—8.02 (17H, m), 8.40 (1H, d, J=8 Hz), and 8.70 (1H, d, J=8 Hz); IR (KBr) 1740 and 1670 cm^{-1}. Found: C, 80.99; H, 4.59; N, 3.37%. Calcd for $C_{28}H_{19}NO_3$: C, 80.58; H, 4.56; N, 3.36%.

N,O-*Di*(p-*toluoyl*)-N-*phenylhydroxylamine* (***Id***). Mp 122—123 °C (from benzene-hexane); NMR ($CDCl_3$) δ=2.26 (3H, s), 2.36 (3H, s), 6.96 (2H, d, J=8 Hz), 7.14—7.48 (9H, m), and 7.90 (2H, d, J=8 Hz); IR (KBr) 1760 and 1660 cm^{-1}. Found: C, 76.82; H, 5.52; N, 4.03%. Calcd for $C_{22}H_{19}NO_3$: C, 76.52; H, 5.51; N, 4.06%.

Photolyses of ***Ia—d***. A nitrogen purged solution of **I** (0.0066 M) in acetonitrile, benzene, or 1,2-dichloroethane (10 mL), which was placed in a sealed Pyrex tube, was irradiated for a given period of time with a 400 W high pressure mercury lamp set in a Pyrex cooling jacket. Parallel irradiations of the solutions were done on a merry-go-round apparatus (Riko model RH400-10W) immersed into a water bath (23±1 °C). The photolyzate thus obtained were subjected to the HPLC analysis. The yields of the products were determined by employing the linear calibration curves made for each product under the same analytical conditions. For the purpose of isolating the photoproducts a solution of **Ia** (0.0087 M) in acetonitrile (300 mL), placed in a Pyrex vessel, was irradiated for 70 min under purified and dried nitrogen with a Pyrex-filtered 400 W high pressure mercury lamp. After evaporation of the solvent, the resulting residue was chromatographed on silica gel (230 mesh, Merck) eluting with benzene and then with chloroform. This separation procedure allowed isolation and identification of **IIa**, **IIIa**, and **IVa**, whose structures were determined by comparing their physical properties with those of authentic samples prepared independently. In another experiment the photolyzate concentrated *in vacuo* was extracted with a 5% sodium hydrogencarbonate solution (50 mL). The extract was washed with dichloromethane twice and then acidified to pH 2 with 4M HCl giving *p*-toluic acid as a white solid. The carbon dioxide formed by this photolysis was introduced into a 0.1 M $Ba(OH)_2$ (150 mL) after having been passed through a cold trap by a nitrogen stream. The precipitate $BaCO_3$ was removed by quick filtration and the filtrate was titrated with 0.1 M HCl. The failure to avoid contamination with carbon dioxide in the air during this procedure resulted in overestimation of the yield of photochemically generated carbon dioxide. In order to detect toluene as a product a nitrogen purged acetonitrile solution of **Ia** (0.052 M) in a sealed Pyrex

tube was irradiated for 4 h. The photolyzate was submitted for the GLC analysis that led to identification of toluene whose yield was estimated by a linear calibration curve.

Thermolyses of ***Ia—d.*** A nitrogen purged dimethyl sulfoxide solution of **I** (2 mmol) in a sealed ampule was heated at 120—130 °C in an oil bath for a given period of time. The reaction mixture was poured onto water (100 mL) and extracted three times with chloroform. The combined chloroform extracts were washed twice with water and then dried over Na_2SO_4. Removal of the solvent on a rotary evaporator gave the solid residue from which **II** was isolated along with the starting **I** by column chromatography over silica gel (70/230 mesh, Merck) with benzene–chloroform (1:1 v/v) as eluent.

Preparation of Authentic Samples (II, III, and IV). *N*-(*p*-Toluoyl)-*o*-aminophenol and *N*-(1-naphthoyl)-*o*-aminophenol were prepared by *N*-aroylation of two equiv of *o*-aminophenol with *p*-toluoyl and 1-naphthoyl chlorides in dichloromethane, respectively. Recrystallization of the crude products from aqueous ethanol gave colorless crystals, mp (the former anilide) 157.5—158.5 °C; IR (KBr) 3410, 3080 (broad), and 1640 cm^{-1}. Mp (the latter anilide) 194.5—195.5 °C; IR (KBr) 3400, 3100 (broad), and 1640 cm^{-1}. *N,O*-Diacyl-*o*-aminophenols (**IIa—d**) were derived from the reactions between *N*-acyl-*o*-aminophenols and the corresponding acyl chlorides in the presence of triethylamine in dichloromethane or ether. Physical properties are the followings. *N*-(1-Naphthoyl)-*O*-(*p*-toluoyl)-*o*-aminophenol (**IIa**), mp 168—170 °C (from benzene–hexane); IR (KBr) 3180, 1730, and 1650 cm^{-1}. Found: C, 79.02; H, 4.96; N, 3.65%. Calcd for $C_{25}H_{19}NO_3$: C, 78.74; H, 4.99; N, 3.67%. *N*-(*p*-Toluoyl)-*O*-(1-naphthoyl)-*o*-aminophenol (**IIb**), mp 137—138 °C (from benzene–hexane); IR (KBr) 3430, 1735, and 1675 cm^{-1}. Found: C, 78.87; H, 4.92; N, 3.67%. Calcd for $C_{25}H_{19}NO_3$: C, 78.74; H, 4.99; N, 3.67%. *N,O*-Di(1-naphthoyl)-*o*-aminophenol (**IIc**), mp 177.5—178.5 °C (from benzene–hexane); IR (KBr) 3200, 1730, and 1640 cm^{-1}. Found: C, 80.95; H, 4.54; N, 3.36%. Calcd for $C_{28}H_{19}NO_3$: C, 80.58; H, 4.56; N, 3.36%. *N,O*-Di(*p*-toluoyl)-*o*-aminophenol (**IId**), mp 108.5—109.5 °C (from benzene–hexane); IR (KBr) 3270, 1735, and 1640 cm^{-1}. Found: C, 76.58; H, 5.53; N, 4.07%. Calcd for $C_{22}H_{19}NO_3$: C, 76.52; H, 5.51; N, 4.06%.

N-(*p*-Toluoyl)-*p*-aminophenol and *N*-(1-naphthoyl)-*p*-aminophenol were prepared by the reactions of two equiv of *p*-aminophenol with *p*-toluoyl and 1-naphthoyl chlorides in dichloromethane, respectively. These reactions were heterogeneous because of the low solubility of *p*-aminophenol so that vigorous stirring was required during the course of these acylations. The crude products were recrystallized from aqueous ethanol affording colorless crystals, mp (the former anilide) 212.5—214 °C; IR (KBr) 3380, 3320, and 1650 cm^{-1}. Mp (the latter anilide) 198.5—199 °C; IR (KBr) 3240, 3190, and 1605 cm^{-1}. *N,O*-Diacyl-*p*-aminophenols (**IIIa—d**) were prepared by treatment of *N*-acyl-*p*-aminophenols with the corresponding acyl chlorides in the presence of triethylamine in dichloromethane. These reactions were also heterogeneous. Physical properties are the followings. *N*-(1-Naphthoyl)-*O*-(*p*-toluoyl)-*p*-aminophenol (**IIIa**), mp 214—215 °C (from ethyl acetate); IR (KBr) 3270, 1730, and 1645 cm^{-1}. Found: C, 79.04; H, 5.03; N, 3.69%. Calcd for $C_{25}H_{19}NO_3$: C, 78.74; H, 4.99; N, 3.67%. *N*-(*p*-Toluoyl)-*O*-(1-naphthoyl)-*p*-aminophenol (**IIIb**), mp 235.5—236.5 °C (from ethyl acetate); IR (KBr) 3300, 1730, and 1650 cm^{-1}. Found: C, 78.95; H, 4.98; N, 3.67%. Calcd for $C_{25}H_{19}NO_3$: C, 78.74; H, 4.99; N, 3.67%. *N,O*-Di(1-naphthoyl)-*p*-aminophenol (**IIIc**), mp 190—191 °C (from ethyl acetate); IR (KBr) 3260, 1720, and 1645 cm^{-1}. Found: C, 80.85; H, 4.56; N, 3.38%. Calcd for $C_{28}H_{19}NO_3$: C, 80.58; H, 4.56; N, 3.36%. *N,O*-Di(*p*-toluoyl)-*p*-aminophenol (**IIId**), mp 245.5—246.5 °C (from ethyl acetate); IR (KBr) 3320, 1725, and 1645 cm^{-1}. Found: C, 76.71; H, 5.46; N, 4.10%. Calcd for $C_{22}H_{19}NO_3$: C, 76.52; H, 5.51; N, 4.06%.

1-Naphthanilide (**IVa, c**) and *p*-toluanilide (**IVb, d**) which were prepared by the reactions of 1-naphthoyl and *p*-toluoyl chlorides with two equiv of aniline in dichloromethane under usual conditions, respectively, had the following physical properties: **IVa, c**, mp 162—163 °C (from benzene); IR (KBr) 3270 and 1650 cm^{-1}. Found: C, 82.95; H, 5.26; N, 5.88%. Calcd for $C_{17}H_{13}NO$: C, 82.59; H, 5.26; N, 5.67%. **IVb, d**, mp 145—146 °C (from benzene); IR (KBr) 3330 and 1645 cm^{-1}. Found: C, 79.77; H, 6.19; N, 6.71%. Calcd for $C_{14}H_{13}NO$: C, 79.62; H, 6.16; N, 6.64%.

Triplet Quenching and Sensitization. Ten milliliters of an acetonitrile solution of **I** (0.0066 M) and either quencher (0.1 M) or sensitizer (0.05 M) was placed in a Pyrex tube, degassed by bubbling purified nitrogen through it for 10 min, and sealed. Deaerated solutions with and without these additives were irradiated in parallel for the same period of time on a merry-go-round apparatus with either 313- or 366-nm light through a Pyrex-cylindrical solution filter (1-cm in length, 6-cm in diameter, and 22-cm in height) from a 400 W high pressure mercury lamp. All the irradiations were carried out in a water bath whose temperature was kept constant during the photolysis by circulating water through it. The 313-nm light for quenching experiment was isolated with a potassium chromate (0.002 M) in a 1% aqueous solution of potassium carbonate. A solution of copper sulfate pentahydrate (250 g dm^{-3}) was used as the filter for sensitization experiment. The band passed had a 90% transmittance (T) at 366 nm and a 9% T at 313 nm. Molar absorption coefficients of **Ia**, **Ib**, **Ic**, and **Id** were estimated to be 1940, 6740, 9180, and 290 ($M^{-1}cm^{-1}$) at 313 nm, respectively, and 2.6, 2.8, 3.3, and 0.5 ($M^{-1}cm^{-1}$) at 366 nm, respectively, in acetonitrile at room temperature.

12) The formation of carboxylic acid **V** is seen to be slightly suppressed in the presence of 1,3-cyclohexadiene. This difference in the yields of **V** with and without the diene becomes larger at higher conversion of **I**, whereas the extent of disappearance of **I** is not influenced by the diene at any stage of the reaction. The observation that no reaction of **V** with the diene takes place in the ground state implies that the generated aroyloxyl radical is scavenged by the diene in competition with hydrogen abstraction and decarboxylation processes. Because of the presence of this triplet quencher in large excess, the reaction with the aroyloxyl radical resulted in negligible decrease in the quencher concentration.

Preparation and Enzymatic Hydrolysis of Polymers Anchoring Biphenyl-2-ol

Tomomichi ISHIKAWA* and Youji TANAKA
Department of Chemistry, Faculty of Technology Tokyo Metropolitan University, Fukasawa, Setagaya-ku, Tokyo 158
(Received October 24, 1984)

Polymers anchoring fungicidal biphenyl-2-ol(BPOL) were prepared by the polymerization and copolymerization of 2-biphenylyl methacrylate(BPMA) with various comonomers such as styrene, vinyl acetate, 2-hydroxyethyl methacrylate, *N*-methacryloylglycine, and *N*-methacryloyl-DL-alanine. The reactivity ratios of BPMA with the comonomers were evaluated. The α-chymotrypsin-catalyzed hydrolysis of the polymers was also studied. The release of BPOL from the polymers was represented by means of the Michaelis constant K_m and the catalytic-rate constant k_{cat}. The BPMA homopolymer gave higher K_m and k_{cat} values than the copolymers, and the copolymers with a higher content of substrate units underwent cleavage more readily. It was found that the hydrolysis of the polymeric substrates is affected by the structure and character of the comonomer rather than the arrangement order of the repeating monomer units in the polymer sequence.

Recently, the usefulness of biodegradable poly(α-amino acid)s in drug delivery systems has been reported. The rate of *in vivo* enzymatic degradation of the polymers can be controlled, and the drugs stored in matrix rods and capsules[1,2] or covalently bonded to polymer matrixes[3] are released with nearly zero-order kinetics. Nakajima and co-workers[4] studied the hydrolysis of poly(*N*-hydroxyalkyl-L-glutamine) by papain to simulate the *in vivo* degradation. On the other hand, Kopecek and co-workers[5–8] reported the cleavage of free 4-nitroaniline from amino acid 4-nitroanilide terminal groups in the origopeptidic side chains of the copolymers by α-chymotrypsin. In a previous paper[9] we reported on the hydrolytic process of homopolymer and copolymers of 2-biphenylyl acrylate under physiological conditions. If the polymers are attacked by a microorganism such as fungus, the ester gruops linking fungicidal biphenyl-2-ol (BPOL) will also be hydrolyzed enzymatically. In this work we describe the polymerization and copolymerization of 2-biphenylyl methacrylate (BPMA) and a study of the hydrolytic release of BPOL from the polymers by α-chymotrypsin. It is known that α-chymotrypsin effectively cleaves ester linkages as well as peptide linkages, but no data are available about the hydrolysis of a polymeric substrate such as poly(2-biphenylyl methacrylate) anchoring bulky and hydrophobic biphenyl groups.

Experimental

Materials. 2-Hydroxyethyl methacrylate (HEMA), styrene (St), vinyl acetate (VAc), and BPOL were distilled under reduced pressure prior to use. α-Chymotrypsin (51 ATEE units, Tokyo Chem. Ind. Co.) was used without further recrystallization. Solvents were dried by the usual methods and distilled. Other chemicals were of reagent grade.

Monomer Preparation. BPMA was prepared by the reaction of BPOL with methacryloyl chloride in the presence of triethylamine in benzene by a method similar to that described in a previous paper.[9] Purification was achieved by distillation under reduced pressure in the presence of 4-*t*-butylcatechol to yield BPMA (71.1%): bp 123 °C (133Pa); ^{1}H-NMR ($CDCl_3$) δ=1.85 (3H, s, CH_3), 5.51 (1H, d, CH=); 6.06 (1H, d, CH=) and 6.93—7.53 (9H, m, Aromatic).

N-Methacryloylglycine (MAG) was obtained by the reaction of glycine with methacryloyl chloride in an aqueous sodium hydroxide solution according to Ref.[5] Yield 60.8%: mp 101—102 °C (lit, 101—102 °C); ^{1}H-NMR(DMSO-d_6) δ= 1.85 (3H, s, CH_3), 3.78 (2H, d, CH_2), 5.35 (1H, d, CH=), 5.70 (1H, d, CH=), 7.70—8.30 (1H, t, NH) and 10.80—12.40 (1H, s, OH); IR (KBr) 3330 (NH), 1715 (C=O), 1640 (C=O) and 1570 (C=C).

N-Methacryloyl-DL-alanine (MAA) was obtained from DL-alanine with methacryloyl chloride according to Ref.[5] Yield 84.5%; mp 116—117.5 °C (lit, 117—118 °C); IR (KBr) 3290 (NH), 1695, 1640 (C=O) and 1600 (C=C); ^{1}H-NMR (DMSO-d_6) δ=1.32 (3H, d, CH_3), 1.85 (3H, s, CH_3), 4.17 (1H, m, CH), 5.33 (1H, d, CH=), 5.70 (1H, d, CH=), 7.70—8.20 (1H, d, NH) and 9.00—10.00 (1H, broad, OH).

General Procedure for Polymerization. All the polymerization experiments were carried out using a solution polymerization technique at 60 °C in the presence of 1 mol% AIBN. The polymers obtained were purified by repeated precipitation from a solvent system into a non-solvent system. The purified polymers were dried at 40 °C (under vaccum) to constant weight. Analyses of the copolymers obtained were carried out using ^{1}H-NMR and an elemental analysis.

General Procedure for Hydrolysis with α-Chymotrypsin. All the hydrolysis experiments were carried out in 50 cm^3 of a buffer solution (0.08 mol dm^{-3} 2-amino-2-hydroxymethyl-1,3-propanediol (Tris) and 0.1 mol dm^{-3} $CaCl_2$ adjusted with HCl to pH=8.0) in the presence of α-chymotrypsin. The temperature was maintained at 25 °C with a regulated water bath. The progress of the hydrolysis was followed by recording any increase in the absorbance at 240.0 nm. The activity of α-chymotrypsin was checked by the hydrolysis of a model compound, 2-biphenylyl propionate[9] at the beginning and the end of the experiments. They gave the same value.

Results and Discussion

Copolymerization. The solution copolymerization of VAc with BPMA was carried out in toluene. St, HEMA, MAG, and MAA were copolymerized with BPMA in ethanol. The contents of each component in the monomer and the compositions of the copolymers obtained by ^{1}H-NMR or elemental analysis are summarized in Tables 1—5. The monomer reactivity ratios

of these compounds were estimated (using the Fineman-Ross equation) from these data. The results are given in Table 6.

From Table 6 it appears that the polymer derived from BPMA with St shows a tendency towards alternation since r_1r_2 is relatively small (0.22). On the other hand, from the very high r_2 and low r_1 values, BPMA shows a homopropagation tendency in the copolymerization with VAc. In the copolymerization of HEMA, MAG, and MAA with BPMA, the r_1r_2 values were larger than unity. In any case, BPMA shows a random-propagation tendency. The copolymers of St with BPMA are perhaps the most interesting of the series. When the copolymers are used as coating films, the above results suggest that the fungicidal BPOL residues are distributed equally on the films.

6a, 6b	CH_3	$CONHCHCOOH$ $\vert$ CH_3

Hydrolysis with α-Chymotrypsin. Polymeric substrates **1—6** anchoring BPOL were obtained by homopolymerization and copolymerization of BPMA. We have chosen hydrophobic and hydrophilic comonomers. The two classes of copolymers containing about 30 and 50 mol% BPOL residues were prepared for each comonomer. All the polymers were water insoluble. Kopecek and co-workers[5] reported on the water-soluble copolymers of various 4-nitroanilides of *N*-methacryloylorigopeptides with *N*-(2-hydroxypropyl)methacrylamide. In this paper, however, even the BPMA-HEMA copolymer contained 72 mol% of HEMA units was water insoluble. The polymeric substrates prepared are shown in Table 7. It is expected from the structure of the polymers **1—6** that the complete hydrolysis of the homopolymer and copolymers other than the St-BPMA copolymer gives a water-soluble polymer which can more readily be remove from biological systems.

The polymeric substrates were hydrolyzed with α-chymotrypsin in Tris-buffer solution (pH 8). The amount of BPOL released was determined periodically using UV. When the homopolymeric substrates were

hydrolyzed for 3 and 24 h in the presence of 0.4 mol% α-chymotrypsin, the conversion was 0.9 and 7 mol%, respectively. In the case of a model compound such as 2-biphenylyl propionate, the conversion reached 13 mol% after 3 h of reaction under the same conditions. The release rate of BPOL from the copolymers was slower than that for the homopolymer. The enzymatic catalyzed hydrolysis was evaluated from Michaelis constant K_m and the catalytic rate constant k_{cat} determined by a method developed by Lineweaver and Burke.[10] The enzymatic hydrolysis data for the polymeric substrates were summarized in Table 8.

It can be seen from Table 8 that the k_{cat} for the polymer **1** indicates the highest value of the series, and that the copolymers with higher contents of the substrate units undergo cleavage more readily. The K_m values for the copolymers **3a** and **3b** are smaller than those for any other of the polymers. As described above, the values of the reactivity ratios of both BPMA and St indicate that the monomers in these pairs tend to alternate during its copolymerization. Therefore, these results suggest that the hydrophobic phenyl group adjacent to the BPOL ester group is contributed to the formation of chymotrypsin-substrate complex. However, the lower k_{cat} values for the copolymers **3a** and **3b** indicate that the reaction of the complex is slow, and that the BPOL is released very slowly from the St-BPMA copolymers. This is in agreement with the results of a study of the hydrolytic release rate of drugs made from copolymers containing 5-fluorouracil.[11] It can also be seen that both the K_m and k_{cat} for the St-BPMA copolymers decrease with an increase in the content of St units. This must be due to a dilution effect of the substrates with the St units, because of cross-propagation tendency in its copolymerization.

In the copolymers of VAc, HEMA, MAG, and MAA with BPMA, α-chymotrypsin cleaves the ester linkages in VAc or HEMA units and the amide linkages in MAG or MAA units as well as the ester linkages in BPMA units. In these cases, the comonomer units may act as inhibitors in the enzymatic hydrolysis of the substrate. The hydrolysis is affected by the intensity of affinity of α-chymotrypsin towards the inhibitor. For the copolymers **4a** and **4b** derived from HEMA and BPMA, the K_m value increases with an content increased of the HEMA units, while the k_{cat} values for the copolymers are similar to the value for the BPMA homopolymer. These results indicate that the hydroxyethyl ester groups and the substrate groups compete for the enzyme. Therefore, the hydroxyethyl ester groups become a competitive inhibitor in this reaction. On the other hand, the K_m values for the copolymers of VAc, MAG, and MAA with BPMA are similar to that for the BPMA homopolymer. However, the values of k_{cat} for the copolymers of same BPMA content are in the order, BPMA homopolymer>MAG-copolymer>VAc-copolymer>MAA-copolymer. The hydrolysis of these copolymers gives glycine, alanine and acetic acid, respectively. It is well known that chymotrypsin-catalyzed reaction rate decreases with an addition of various carboxylic acids, and that carboxylic acids with higher hydrophobic groups undergo a greater decrease.[12,13] Brot and co-workers[14] reported that a more suitable substrate exhibits a higher k_{cat}/K_m value. According to this conclusion, the BPMA homopolymer is the most suitable substrate of the series, and the copolymers with VAc are unsuitable substrates for chymotrypsin-catalyzed hydrolysis. As described above, BPMA shows a homopropagation tendency during copolymerization with VAc. Nevertheless, the values of k_{cat}/K_m for the copolymers **2a** and **2b** are smaller to those for the polymer **1**. These facts can be explained in terms of the product inhibition which is caused by the by-product in the hydrolysis of the copolymeric substrate.

From the above results, it is concluded that the chymotrypsin-catalyzed hydrolysis of polymeric substrates is affected by the structure and character of the comonomer rather than the arrangement order of the monomer unit in a polymer sequence.

Multiple Substituent Effects on ^{13}C Chemical Shifts of *N*-Benzylideneanilines. Evidence for Substituent-Substituent Interactions and Their Implications of Conformational Changes with Substituents

Ryoichi AKABA, Hirochika SAKURAGI, and Katsumi TOKUMARU*
Department of Chemistry, University of Tsukuba, Sakura-mura, Ibaraki 305
(Received October 31, 1984)

Carbon-13 chemical shifts are reported for series of *N*-benzylideneanilines; 4-$YC_6H_4CH{=}NC_6H_4NMe_2$-4, 4-$NO_2C_6H_4CH{=}NC_6H_4X$-4, 4-$YC_6H_4CH{=}NC_6H_4NO_2$-4, and 4-$YC_6H_4CH{=}NC_6H_3(CH_3)_2$-2,6. Multiple substituent effects on the azomethine carbon chemical shifts were examined, and nonadditivity observed for 4-$YC_6H_4CH{=}NC_6H_4NMe_2$-4 and 4-$NO_2C_6H_4CH{=}NC_6H_4X$-4 is interpreted in terms of substituent-substituent interactions accompanied by conformational changes with substituents in these *N*-benzylideneanilines. Effects of the substituents Y (on the benzylidene benzene ring) on the azomethine carbon chemical shifts were also studied in detail. The results suggest that there are two competetive electronic factors responsible for chemical shift variation, and that the substituent effects should be treated separately between electron-releasing and electron-withdrawing groups. The latter groups always exert inverse (the chemical shifts undergo upfield shifts with increase in the electron-withdrawing properties of the substituents) substituent effects, whereas the former exhibit normal (the chemical shifts undergo upfield shifts with increase in the electron-releasing properties of the substituents) or inverse substituent effects depending on the degree of electron demand developed on the azomethine carbons.

It is well-known that *N*-benzylideneaniline (NBA) takes a conformation in which the benzene ring on the nitrogen atom (ring A) is twisted from the molecular plane containing the C=N bond.[1] However, only a few studies have been made on the role of electronic effects of substituents on the molecular conformations of *N*-benzylideneanilines in solution.[2] We have recently shown that *N*-benzylidene-4-nitroaniline takes a more twisted conformation than NBA itself in solution and in gas phase by UV[1] and photoelectron spectroscopy.[2a] On the other hand, Zollinger[2b] and Kubota[2c] reported that *N*-(4-nitrobenzylidene)-4-dimethylaminoaniline takes a nearly planar conformation in solution. They suggested that the planar conformation of the disubstituted NBA would be ascribed to a through-conjugative interaction of the dimethylamino group with the nitro group. These studies suggest that electronic effects of a 4′-substituent on the benzylidene benzene ring (ring B) as well as those of a 4-substituent on the ring A will play an important role to determine the molecular conformations of NBAs.

In a previous paper, we demonstrated the anomalous substituent effects on the azomethine proton chemical shift of 4-substituted *N*-benzylideneanilines that the

Scheme 1.

azomethine proton of the 4-nitro derivative resonates at a higher field than that of NBA, and interpreted them in terms of the change of molecular conformations induced by the 4-nitro group.[3] In order to get deeper insight into the conformational change with substituents in *N*-benzylideneanilines, we have undertaken a detailed study of multiple substituent effects on carbon-13 chemical shifts in several *N*-benzylideneanilines.

In the present paper, ^{13}C NMR data are presented for series of multiply substituted *N*-benzylideneanilines, **3**—**6**. Special attention is paid to additivity of the multiple substituent effects on the azomethine carbon chemical shifts in these *N*-benzylideneanilines. Effects of the substituents Y on the ring B are also analyzed and discussed in detail.

Results and Discussion

Assignment of the ^{13}C NMR Spectra. For analysis of the ^{13}C NMR chemical shifts of **3**—**6** ^{13}C NMR data of the corresponding monosubstituted NBA derivatives, series **1** and **2**, are necessary. The ^{13}C NMR spectra of **1** and **2** are already reported by Inamoto *et al.*[4] Since reinvestigation on the ^{13}C NMR spectra of some of the monosubstituted derivatives was found to give the same chemical shifts as reported within the experimental error, only the derivatives of X=NMe_2, F, and CO_2Et, Y=Br and CN were measured in the present study. The results are summarized in Table 1. The results of the multiply substituted derivatives **3**—**6** are listed in Table 2.

Assignment of the chemical shifts of some derivatives of **1** and **2** was already described.[4] Assignment of the chemical shifts in **3**—**6** has been made maily by using substituent-induced chemical shifts (SCS) of **1**, **2**, and substituted benzenes.[5] Consideration of the signal intensities also permitted to distinguish the ortho and meta carbons from the ipso carbons, the carbons attached directly to the substituents. In some cases, off-resonance decoupled spectra were used to differentiate the carbons bearing a hydrogen.

Aromatic Carbons. The SCS values of the aromatic carbons of **1** and **2** are not considered here since they were already analyzed and discussed.[4] For **3**—**6**, the Hammett relationship was examined. The results are shown in Table 3.

Generally, good correlations were found for the ipso carbons except those attached directly to the variable substituents X or Y. For example, C-1, C-1′, and C-4 in V exhibit a good correlation with Hammett σ constants; however, C-4′, which is directly attached to Y, does not show any good correlation. Furthermore,

not shown) for C-2, C-3, C-2′, and C-3′ on the rings bearing the substituent X or Y, that is, C-2′ and C-3′ in **3**, **5**, and **6**, and C-2 and C-3 in **4**, may be attributed to predominance of secondary perturbations such as anisotropy and/or neighboring effects over the substituent electronic effects.

Substituent-Substituent Interactions in Disubstituted N-Benzylideneanilines. For disubstituted *N*-benzylideneanilines, 4-$YC_6H_4CH{=}NC_6H_4X$-4, if the effects of both substituents on the chemical shifts are additive as expressed by a simple addition of the effects of the substituents X in **1** and Y in **2**, the chemical shift of the azomethine carbon of a disubstituted NBA can be calculated according to Eq. 1, where ΔX and ΔY are differences in the chemical shifts between the unsubstituted NBA, δH, and the monosubstituted compounds with substituents X, δX, and Y, δY, respectively. The value of 160.07 denotes the chemical shift of the unsubstituted NBA. The $(\Delta X+\Delta Y)$ corresponds to a calculated SCS (Eq. 2), and the observed SCS is given by Eq. 3, where δ C_{obsd} X–Y refers to the chemical shift observed for the disubstituted NBA. For **3** and **4** δ C_{calcd} X–Y and SCS_{calcd} X–Y are obtained according to Eqs. 1 and 2, and are listed in Table 4 together with the corresponding observed values. If the additivity holds for **3** and **4**, SCS_{calcd} X–Y should be the same as SCS_{obsd} X–Y. However, Table 4 shows a large difference between them. This may reflect a strong interaction between the two substituents X and Y. This situation can well be visualized by plotting SCS_{obsd} X–Y against SCS_{calcd} X–Y, as shown

$$\delta C_{calcd}X\text{–}Y = 160.07 + (\Delta X+\Delta Y) \quad (1)$$

$$SCS_{calcd}X\text{–}Y = \Delta X + \Delta Y \quad (2)$$

$$SCS_{obsd}X\text{–}Y = 160.07 - \delta C_{obsd}X\text{–}Y \quad (3)$$

$$\Delta X = \delta H - \delta X$$

$$\Delta Y = \delta H - \delta Y$$

in Figs. 1 and 2 for **3** and **4**, respectively, in which SCS values for the corresponding monosubstituted NBAs are also plotted to provide a scaling for the deviation.[7] As shown in Fig. 1, the discrepancy between SCS_{calcd} X–Y and SCS_{obsd} X–Y is noticed for NBAs with an electron-releasing or an electron-withdrawing substituent. Thus, the actual azomethine carbon chemical shifts deviate to the downfield from the calculated values for **3** with the electron-releasing groups. In a striking contrast, the deviations are to the upfield for **3** with the electron-withdrawing groups. On the other hand, Fig. 2 shows that the observed values accord well with the calculated ones for **4** with the electron-withdrwaing groups whereas significant deviations are noticed for **4** with the electron-releasing groups such as a dimethylamino and a methoxyl.

The Hammett treatment with σ values[6] of these deviations, $\Delta\delta$ (defined by SCS_{obsd} X–Y−SCS_{calcd} X–Y), for **3** gives a fairly good linear relationship with a correlation coefficient of 0.967 as shown in Fig. 3a. A similar plot for **4** gives a relationship with a correlation coefficient of 0.900; however, a plot with σ^+ values[6] affords a better linear relationship with a correlation coefficient of 0.957 (Fig. 3b). No significant trend of $\Delta\delta$ can be found for **5**.

Multiple substituent effects have been extensively studied on reaction rates, thermal and spectroscopic parameters in various organic π-systems.[8] Although nonadditivity has been observed in the multiple substi-

benzenes,[8i] on stabilization energies of trityl cations[8c] and anions,[8b] and on proton and carbon chemical shifts of several conjugated π-systems,[8f,g,j,l,m] few reports have appeared on the systems in which substituent–substituent interactions may lead to conformational changes of molecules.

We interpret the nonadditivity of multiple substituent effects on the azomethine carbon chemical shifts in **3** and **4** as a consequence of the substituent–substituent interaction which may be accompanied by conformational changes of the NBA derivatives. The downfield deviation of $\Delta\delta$ for NBAs with the electron-releasing groups in **3** may be reasonably interpreted in terms of suppression of the electron donation from the 4-dimethylamino group on the ring A toward the azomethine carbon by strongly electron-donating groups such as a 4′-dimethylamino and a 4′-methoxyl. In contrast, strongly electron-withdrawing groups such as 4′-cyano and a 4′-nitro enhances the electron donation resulting in an upfield deviation of $\Delta\delta$ as observed for **3** (Fig. 1). Thus, the net electron-releasing ability of the 4-dimethylamino group depends on the electronic properties of the 4′-substituents. Actually, $\Delta\delta$'s for **3** give a good linear elationship with Hammett σ constants with a correlation coefficient of 0.967 as shown above (Fig. 3a). The degree of the variable electronic effect of the 4-dimethylamino group may be evaluated by $\Delta\Delta\delta$ (defined by a difference in $\Delta\delta$'s) among the 4′-substituents. For example, for **3** $\Delta\delta(NMe_2)-\Delta\delta(NO_2)$ gives $\Delta\Delta\delta$ of 2.51 in a chemical shift unit, indicating that the net variation of the electronic effect of the 4-dimethylamino group corresponds to 2.51 ppm. This seems to be significant since the magnitude is as large as SCS of the methoxyl group in **1**. The systematic change in $\Delta\delta$ clearly indicates the interaction between the 4-dimethylamino group and the 4′-substituents. Such substituent–substituent interactions have often been observed by other workers.[8] With respect to the multiple substituent effects on the chemical shifts, Dubois, Doucet and their coworkers undertook a detailed study on electronic structures of diarylcarbenium ions.[8l,j] They observed a clear nonadditivity of the effects of two methoxyl groups on the α-carbon chemical shift. For example, for bis(4-

methoxyphenyl) carbenium ions, the first methoxyl group induces a change of 20.3 ppm in the α-carbon chemical shift whereas the second one induces only a 5.5 ppm change. Apparently, as the authors describe, saturation of the electronic effect occurs. Our own observation that the electron-donating effect of the 4-dimethylamino group is strongly suppressed by the 4'-dimethylamino and 4'-methoxyl groups is consistent with that by Dubois *et al.*, and will represent an example of a neutral system in which the electronic effect of a substituent will depend on another substituent in the molecule.

In the case of **4**, the discrepancy may also be explained similarly in terms of the interactions between the 4'-nitro group and the variable substituents, especially the electron-releasing groups on the ring A. The through-conjugative interaction between the 4'-nitro group and the electron-releasing groups will give the upfield deviations of $\Delta\delta$'s. A better correlation of $\Delta\delta$'s with σ^+ than with σ values also supports this interpretation (Fig. 3b).

We point out here that the substituent-substituent interactions in **3** and **4** may be accompanied by conformational change in these disubstituted NBAs. It is well-known that besides the π-π conjugation throughout the π-systems the n-π conjugation, which involves delocalization of the lone pair electrons on the nitrogen atom to the ring A and thus favors a highly twisted conformation, plays an important role in determining the molecular conformation of NBAs in solution.[2b,9] Since the through-conjugative interaction in the whole π-system will lead to a less twisted conformation,[2] it is reasonable to consider that the decrease in the electron donation from the 4-dimethylamino group in **3** will give rise to a less planar conformation.

Consider first the case of **4**. It is quite reasonable to assume that *N*-(4-nitrobenzylidene)-4-nitroaniline, **4j**, takes a conformation twisted as much as *N*-benzylidene-4-nitroaniline, **1j**, in solution,[1] since it is not likely that the 4'-nitro group may change the twist angle θ_N. If, for example, *N*-(4-nitrobenzylidene)-4-dimethylaminoaniline, **4a**, also adopts a considerably twisted conformation, the enhanced electron donation from the 4-dimethylamino group toward the azomethine carbon should not be observed since such electron donation must be greatly suppressed by the twisting of the conjugated π-system. Therefore, the electron donation from the 4-dimethylamino group in **4a** will be accompanied by a certain decrease in the twist angle θ_N in going from **4j** to **4a** Actually, it is reported by Zollinger[2b] and Kubota[2c] that **4a** will take a nearly planar conformation in solution as revealed by the UV and ESR spectra. A Hammett correlation of the azomethine carbon chemical shifts in **4** may also be supporting evidence. As illustrated in Fig. 4, treatment of SCS_{obsd} of the azomethine carbon chemical shifts with Hammett σ^+ constants shows an excellent linear

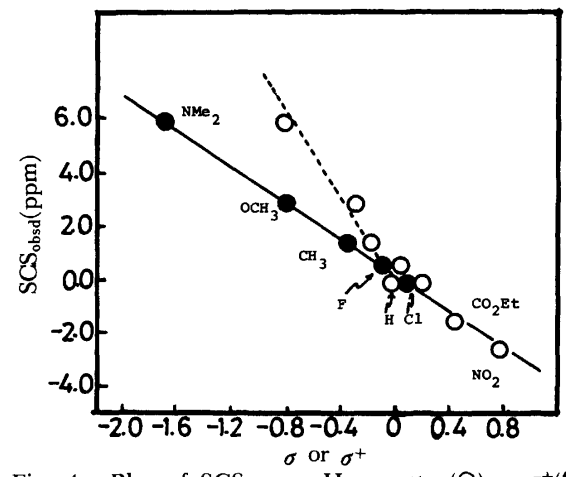

Fig. 4. Plot of SCS_{obsd} *vs.* Hammett σ(○) or σ^+(●) constants in **4**.

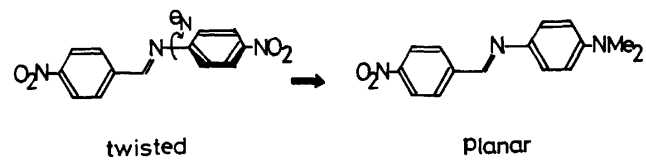
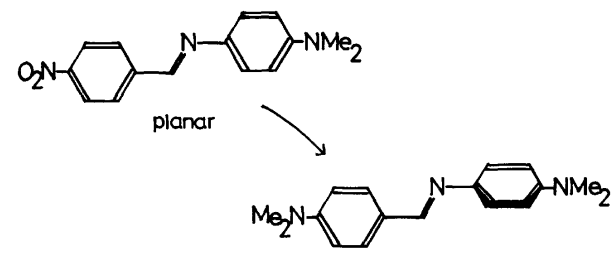


Scheme 2.



Scheme 3.

relationship with a correlation coefficient of 0.999 (correlation coefficient with σ values is 0.978). This can be best interpreted in terms of the enhanced electron donation from the electron-donating groups toward the azomethine carbon, and thus, in terms of a certain decrease in the twist angle θ_N in going from **4h** and **4j** to **4b** and **4a** (Scheme 2). A Similar concept can also be advanced to account for $\Delta\delta$'s in **3**. As already pointed out, the *N*-lone pair delocalization may be suppressed by the electron-releasing effect of the 4-substituents resulting in less twisted conformations. In other words, the more electron-donating the 4-substituent, the smaller twist angle θ_N would result. Since the electron donation from the 4-dimethylamino group is considerably suppressed in **3a** and **3b**, as shown by the larger $\Delta\delta$'s, resulting in the decrease in the through-conjugative interaction, it is reasonable to consider that **3a** and **3b** will take less planar conformations compared with a nearly planar conformation of **3j**. A feature of such a conformational change with the substituents based on the above discussion is illustrated in Scheme 3.

It is of interest noting that Freedman and his coworkers[8d] reported a substituent dependence of

rotational barriers of *N*-aryl bonds in 4′-substituted 4-dimethylaminotrityl cations. Our study may represent a new example that the change of molecular conformation can be induced by the substituent-substituent interactions.

Effects of Substituents Y on the Azomethine Carbon Chemical Shifts. Examination of the SCS data of the azomethine carbon chemical shift indicates that the modes of the substituent effects are different between the 4-substitution and 4′-substitution. Thus, in **1** and **4** which carry the variable substituents X on the ring A, the electron-releasing groups cause significant upfield shifts, whereas the electron-attracting groups generate appreciable downfield shifts. Accordingly, the substituent effect is normal in these cases. In contrast, in the series of **2**, **3**, **5**, and **6** in which the variable substituents Y are on the ring B, the electron-withdrawing groups cause upfield shifts, whereas the variation of SCS values remain small (≈1 ppm) with the electron-releasing groups. The overall SCS variation ia smaller (2—5 ppm) in **2**, **3**, **5**, and **6** than in **1** and **4** (7—8 ppm). Thus, the azomethine carbon chemical shift is more sensitive to the electronic effect of the substituents on the ring A than to that on the ring B.

However, careful examination of the SCS values in **2**, **3**, **5**, and **6** reveals that the electron-donating and electron-attracting groups behave in different ways to transmit the electronic effect on the azomethine carbon as illustrated in Figs. 5 to 8 which show plots of the azomethine carbon chemical shifts against the C-1′ chemical shifts which remarkably suffer the electronic effect of the 4′-substituents as mentioned in a previous section (halogen atoms are omitted from the consideration since they apparently deviate from the lines). Figures 5—8 clearly indicate that in all the series studied the electron-withdrawing groups on the ring B generally cause upfield shifts, whereas the effects of the electron-releasing groups are different from each other, and seem to depend on electron demand on the azomethine carbon induced by the fixed substituent on the ring A. Thus, the chemical shifts are not very sensitive to the electron-releasing groups in **2**. However, the azomethine carbon suffers a roughly inverse substituent effect (the NMe_2 derivative resonates at a lower field than the unsusbtituted derivative) in **3** which carry the 4-dimethylamino group. In a striking contrast, opposite trends can well be seen in **5** and **6**, where the azomethine carbon chemical shift suffers a roughly normal substituent effect with the electron-releasing groups to give rise to the V-shape correlation with the C-1′ chemical shifts (Figs. 7 and 8).

The above finding that 4′-substituents exert a relatively small electronic effect on the azomethine carbon chemical shift seems to be in keeping with reported results on the α-carbon chemical shifts in styrenes,[10,11] acetophenones,[12] and benzaldehydes.[13] These have been interpreted in terms that the 4-substituents do not change significantly the electron densities on the α-carbons as dipicted for 4-substituted

Scheme 5.

styrenes in Scheme 4 as an example. However, lack of systematic studies as well as the relatively minor variation of the chemical shifts and their poor correlation with structural parameters such as Hammett constants have made it difficult to get deeper insight into the substituent effects on the α-carbon chemical shifts in benzilidene-type conjugated systems. In this respect, the correlation of the azomethine carbon chemical shifts with the C-1′ chemical shifts is of particular interest. The present study with systematic changes of the substituents on the ring A clearly indicates that 4′-substituent effects should be treated separately between the electron-releasing and the electron-withdrawing groups. Thus, the electron-withdrawing groups cause the inverse substituent effects in all the series, whereas the effects with the electron-releasing groups may be normal, inverse, or even absent depending on the electron demand developed on the azomethine carbons by the structural and/or electronic effects of the substituents on the ring A.

As depicted in Figs. 7 and 8, the effects with the electron-releasing groups is normal in **5** and **6** in which the electron demand on the azomethine carbons seems to increase compared with **2**. In **5**, the 4′-nitro group will generate significant electron deficiency on the azomethine carbons compared with those of **2**. Likewise, the *N*-lone pair delocalization in **6** to the ring A enhanced by twisting of the C–N bond by the 2,6-dimethyl groups will result in the increase in electron demand on the azomethine carbon.[3] Under these circumstances, the electron-releasing groups will donate electrons more efficiently toward the azomethine carbon resulting in the normal upfield shift, as shown in Scheme 5. Actually, the normal substituent effect on the α-carbon chemical shift was observed in methyldiphenylcarbenium and hydroxydiphenylcarbenium ions by Doucet and his coworkers, [81] in which the strong electron demand on the cationic carbons enhances the electron donation from the electron-releasing groups to give rise to the normal upfield shift. The proposed concept can be further supported by examining available data for 4-substituted β,β-dichloro-,[14] **7**, and β,β-dicyanostyrenes,[15] **8**. We treated the results in a similar manner to that employed for the present study, and the correlations for these two series are illustrated in Figs. 9 and 10. In the case of the dichlorostyrenes, the α-carbon chemical shift suffers a inverse substitu-

X: electron-releasing groups

Scheme 6.

ent effect with the electron-withdrawing groups, whereas the chemical shifts remain roughly constant with the electron-releasing groups, as found for **2**. This indicates that the substituent effects must also be treated separately between the electron-releasing and electron-withdrawing groups. Such a situation can well be seen in the dicyanostyrenes in which a clear V-shape correlation was observed. The normal substituent effect with the electron-releasing groups can be reasonably interpreted in terms of the proposed concept that the electron demand on the α-carbon plays an important role in determining the mode of the substituent effect (Scheme 6).

The inverse substituent effects on the proton and carbon chemical shifts have been occasionally observed by other workers. For example, Reynolds *et al.*[11] reported that introduction of a 4-nitro group caused an upfield shift of the α-carbon chemical shift in 4-substituted styrenes. Inamoto and his coworkers also reported[4] the inverse substituent effect on the azomethine carbon chemical shifts in **2**, and attributed this phenomenon to the effect of charge alternation

originally proposed by Pople.[16,17] The similar observation in the present study may also be explicable by the same effect. It should be pointed out, however, that this explanation cannot be advanced for the effect of the electron-releasing groups on the azomethine carbons. Even for **2** originally reported by Inamoto *et al.* and for **3** which carry the 4-dimethylamino group on the ring A, it is clear that the correlations cannot be treated in a single line. Whether the substituent effect is normal or inverse must depend on the degree of the electron demand developed on the azomethine carbons.

In summary, the present study revealed importance of two competetive factors responsible for the 4′-substituent effects on the azomethine carbon chemical shifts in *N*-benzylideneanilines. It should be also pointed out that similar mode of the substituent effects may be extended to the α-carbon chemical shifts in other benzylidene-type conjugated systems.

Conclusion

Multiple substituent effects on the azomethine carbon chemical shift were examined for a few series of disubstituted *N*-benzylideneanilines. Nonadditivity of the multiple substituent effects was observed for **3**, 4-$YC_6H_4CH{=}NC_6H_4NMe_2$-4, and **4**, 4-$NO_2C_6H_4CH{=}NC_6H_4X$-4. It is pointed out that the observed nonadditivity can be understood in terms of the substituent–substituent interactions accompanied by the conformational changes with the substituents in these NBAs. The present study also revealed that there are two modes of the 4′-substituent (on the ring B) effects on the azomethine carbon chemical shift. Depending on the degree of the electron demand developed on the azomethine carbons, the effects with the electron-releasing groups may be normal or inverse; the former effects result from the efficient electron donation from the substituents and the latter can be explained in terms of the charge alternation on the carbon frameworks induced by the substituents.

Experimental

Materials. *N*-benzylideneaniline, *N*-benzylidene-4-nitroaniline, and *N*-benzylidene-2,6-dimethylaniline were available from the previous work.[1] All other *N*-benzylideneanilines were similarly prepared, and fully characterized by physical constants, spectral data, and/or elemental analyses. All new compounds gave satisfactory elemental analyses. To our knowledge, the physical constants of the following compounds are not reported previously; **3b**, mp 141.5—143 °C (uncorrected), **3d**, mp 144—145 °C, **3f**, mp 162—163 °C, **3g**, mp 170.5—171 °C, **3i**, mp 194.5—195.5 °C, **4e**, mp 109—110 °C, **4h**, mp 177—178 °C, **5c**, mp 137—138 °C, **5f**, mp 164.5—165.5 °C, **5i**, mp 183—183.5 °C, **6a**, mp 74.5—76 °C, **6b**, mp 40—41 °C, **6c**, mp 162—163 °C, **6f**, mp 157—158 °C, **6g**, mp 152—153 °C, **6i**, mp 68-69 °C, **6j**, mp 98—100 °C.

^{13}C NMR Spectra. ^{13}C NMR spectra were recorded on a JEOL FX-60 spectrometer operating in a Fourier Transform mode with complete proton decoupling as described previously.[3] Off-resonance decoupled spectra were also recorded in some cases. The spectra were usually taken at room temperature; however, samples of **4** were run at *ca.* 40—55 °C of the probe temperature at saturated concentrations. Solvent was $CDCl_3$ in all cases.[18]

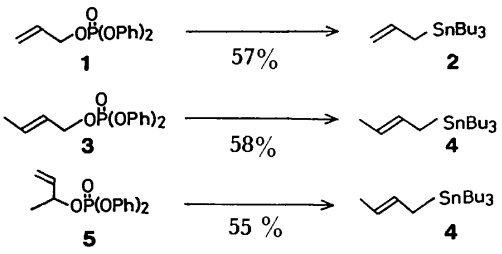
(Received November 27, 1984)

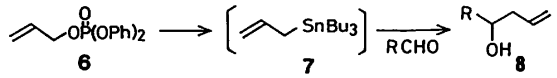
Treatment of allylic phosphates with the reagent prepared from *n*-Bu_3SnLi and Et_2AlCl or from SnF_2 and Et_2AlCl affords allyltin compounds which react with aldehydes to produce homoallylic alcohols in good yields. The formation of allyltin compounds requires the catalytic amount of $Pd(PPh_3)_4$ and proceeds with inversion of the stereochemistry predominantly.

The addition of allylmetal species[2)] to carbonyl compounds is one of the most important methods for C–C bond formation. The stereoselectivity of the reaction as well as the yields of products depend on the nature of the element such as Si,[3)] Sn,[4)] Cr,[5)] Sm,[6)] Y,[6)] Mn,[7)] Ti,[8)] and Zr.[8)] Among them the organotin compounds are widely used because of their easiness of handling and high reactivity. For instance, the reaction of allylstannanes with carbonyl compounds in the presence of Lewis acid provides erythro homoallylic alcohols with high stereoselectivity.[4b)] The allylation of carbonyl compounds also proceeds effectively with allylstannanes generated from allylic halides and tin metal[4c)] or divalent tin compounds.[4d)] Limitations associated with availability of the allylic halides[4c,d)] in these reactions have led us to examine allylic phosphates[9)] as an alternative starting material.



n-Bu_3SnLi (2 eq), Et_2AlCl (2 eq), $Pd(PPh_3)_4$ (0.1 eq)

Scheme 1.



Scheme 2.

An organoaluminum reagent produced from *n*-Bu_3SnLi[10)] and Et_2AlCl, is considered to have an aluminum–tin single bond[11)] and has proved to be useful for synthetic reactions.[1)] Treatment of allyl diphenyl phosphate **1** with this reagent in the presence of $Pd(PPh_3)_4$ catalyst gave allylstannane **2** in 57% yield,[12)] and (*E*)-2-butenyl diphenyl phosphate **3** produced (*E*)-2-butenyltributylstannane **4** in 58% yield. Diphenyl 1-methyl-2-propenyl phosphate **5** also afforded (*E*)-2-butenyltributylstannane **4** contaminated by a small amount of its *Z* isomer in a 55% combined yield (Scheme 1). The yields of these products could not be improved over 70% in spite of various attempts because of the difficulty in isolating allylic stannane in a pure form.

The presence of an equimolar amount of aldehyde in this reaction system resulted in the direct formation of homoallylic alcohol **8** in good yields (Scheme 2). For example, the treatment of a mixture of allyl diphenyl phosphate and benzaldehyde with *n*-Bu_3Sn–$AlEt_2$ in the presence of $Pd(PPh_3)_4$ provided 1-phenyl-3-buten-1-ol in 82% yield after aqueous work-up. The results are summarized in Table 1.

The high reaction temperature (200 °C) is neces-

TABLE 1. SYNTHESIS OF HOMOALLYLIC ALCOHOLS FROM ALLYLIC PHOSPHATES AND ALDEHYDES WITH *n*-Bu_3SnLi–Et_2AlCl SYSTEM

Run	Phosphates	Aldehydes	Products[a)]	Yields[b)]	*E*/*T*
1		PhCHO		82%	—
2	〃	Hexanal		70%	—
3		PhCHO		70%	(41/59)[c)]
4	〃	Hexanal		65%	(47/53)[d)]
5		PhCHO		82%	(38/62)[c)]

a) All compounds gave satisfactory spectra data. See Ref. 5. b) Isolated yields. c) Ratios of the stereoisomers (erythro and threo) were determined by the examination of ^1H-NMR signal of the methine (H–C–OH) proton. See experimental section. d) A ratio of the stereoisomer was determined by GLPC analysis. See experimental section.

Table 2. Synthesis of homoallylic alcohols from allylic phosphates and aldehydes with SnF_2–Et_2AlCl system

Run	Phosphates	Aldehydes	Products[a]	Yields[b]	*E*/*T*

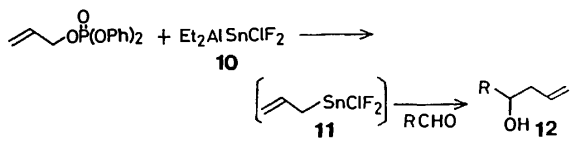


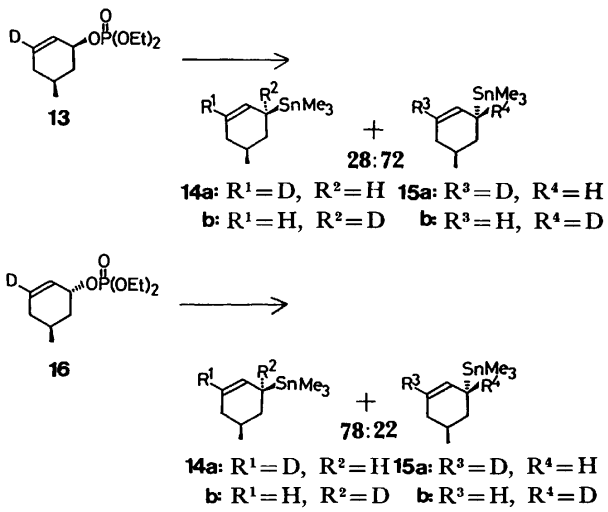
Scheme 4.

sary for the allylation of benzaldehyde with allyltributylstannane in the absence of Lewis acid.[4e] In contrast, the reaction proceeds at room temperature in the presence of Lewis acid. The stereoselectivity of the reaction between allylstannane and aldehyde depends on the nature of Lewis acids employed.[4f] In our case, Et_2Al–OP(O)(OPh)$_2$(compound **18** in Ref. 15) could behave as a Lewis acid giving poor selectivity.

Treatment of SnF_2 with an equimolar amount of Et_2AlCl in CH_2Cl_2 gave a dark red homogeneous solution. The reagent **10** thus prepared is assumed to have an aluminum–tin single bond (Scheme 3), and proved to be effective in the homoallylic alcohol synthesis from allylic phosphate and aldehyde. The results are summarized in Table 2.

The reaction is expected to involve an allylstannane **11** (Scheme 4) which has failed to be isolated. The threo stereoselectivity in the reaction with SnF_2–Et_2AlCl is slightly superior (run 3, 4) to that observed in *n*-Bu_3Sn–$AlEt_2$ reagent system.

The stereochemistry of the allylstannane synthsis from $R_3SnAlEt_2$ and allylic phosphate is shown in Scheme 5. Treatment of cis allylic phosphates **13** with Me_3Sn–$AlEt_2$ in the presence of a catalytic amount of $Pd(PPh_3)_4$ provided a mixture of cis and trans allylic stannanes **14a,b** and **15a,b** in 28:72 ratio. Both ratios of **14a**:**14b** and **15a**:**15b** were 1:1. Similar reaction of the trans isomer **16** gave **14a,b** and **15a,b** in 78:22 ratio, the ratios of **14a**:**14b** and **15a**:**15b** being 1:1 again. The stereochemistry of the allylstannanes was determined



Scheme 5.

by the examination of ^{119}Sn NMR spectra.[13] These results showed that the reaction has proceeded predominantly with the net inversion of the phosphates stereochemistry[14,15,16]

Experimental

The IR spectra were determined on a Shimadzu IR-27-G spectrometer, the mass spectra on a Hitachi M-80 machine, and the proton NMR spectra on a Varian EM-390 spectrometer and a Varian XL-200 spectrometer. The ^{119}Sn NMR and ^{13}C NMR spectra were determined on a JEOL-FX 90Q spectrometer. The chemical shifts of the proton NMR and the ^{13}C NMR are given in δ, with tetramethylsilane as an internal standard, and those of the ^{119}Sn NMR are given in δ, with tetramethylstannane as an internal standard. Tetrahydrofuran was freshly distilled from sodium benzophenone ketyl. Dichloromethane was dried over P_2O_5 and distilled. All the experiments were carried out under an argon atmosphere. Purification of products was performed by preparative thin-layer chromatography (PLC), or column chromatography on silica gel (Wakogel C-100) or alumina (Merck,

Art. 1077 Aluminiumoxid 90 aktiv neutral, 70—230 mesh). Analytical GLPC was performed with a Yanagimoto GCG-550-F and a Shimadzu GC-4CPT. Preparative GLPC was performed with a JEOL-JGC-20K apparatus.

Preparation of Allyltributylstannane with the Reagent Derived from n-*Bu*$_3$*SnLi and Et*$_2$*AlCl.* A hexane solution of butyllithium (1.6 M,† 3.8 ml, 6.0 mmol) was added to a suspension of anhydrous tin(II) chloride (0.38 g, 2.0 mmol) in THF (4.0 ml) at 0 °C. After being stirred for 20 min, the reaction mixture was treated with a hexane solution of diethylaluminum chloride (1.0 M, 2.0 ml, 2.0 mmol) at 0 °C. The resulting mixture was stirred for another 20 min, and a mixture of allyl diphenyl phosphate (0.29 g, 1.0 mmol) and Pd(PPh$_3$)$_4$ (0.12 g, 0.1 mmol) in THF (4 ml) was added. The whole was stirred for 1 h, then the reaction mixture was poured into 5% NaOH (70 ml) and extracted with ether (30 ml×3). The combined organic layers were washed with 5% NaOH (60 ml×2), dried over anhydrous sodium sulfate and concentrated. The crude product was purified by alumina column chromatography (hexane) followed by distillation (bp 120 °C/0.1 Torr,†† bath temp) to give allyltributylstannane in 57% yield as a colorless oil. This compound was identical with the authentic sample.[12a]

(E)-2-Butenyltributylstannane:[12a] The title compound was produced stereospecifically in 58% yield from (*E*)-2-butenyl diphenyl phosphate. Treatment of diphenyl 1-methyl-2-propenyl phosphate with *n*-Bu$_3$SnAlEt$_2$ as described above gave the *E* and *Z* isomeric mixture of 2-butenyltributylstannane in 55% yield. The stereochemistry was determined by ^{13}C NMR spectra.[17] The ratio of the intensity of olefinic carbon for *E*:*Z* was 10:1.

The Synthesis of Homoallylic Alcohols with the n-*Bu*$_3$*SnLi–Et*$_2$*AlCl Reagent.* A mixture of diphenyl 1-methyl-2-propenyl phosphate (0.61 g, 2.0 mmol), benzaldehyde (0.11 g, 1.0 mmol), and Pd(PPh$_3$)$_4$ (0.12 g, 0.1 mmol) was added at 0 °C to a THF solution of *n*-Bu$_3$SnAlEt$_2$ (2.0 mmol) prepared following the procedure described above. After being stirred for 1 h at room temperature, the reaction mixture was poured into 1 M hydrochloric acid (40 ml) and extracted with ether. The combined organic layers were washed with saturated NaHCO$_3$ aqueous solution, dried over anhydrous sodium sulfate, and concentrated. The purification by PLC (hexane–ethyl acetate, 5:1) gave 2-methyl-1-phenyl-3-buten-1-ol[5] in 68% yield: Bp 110 °C (bath temp, 4 Torr); IR (neat): 3400, 1635, 1492, 1011, 908, 758, 698 cm^{-1}; NMR (CCl_4): δ= 0.83 (d, J=7.2 Hz, 1.8 H, threo isomer), 0.94 (d, J=6.6 Hz, 1.2 H, erythro isomer), 2.15 (bs, 1H), 2.3—2.5 (m, 1H), 4.26 (d, J=6.8 Hz, 0.59 H, threo isomer), 4.43 (d, J=5.8 Hz, 0.41 H, erythro isomer), 4.9—5.2 (m, 2H), 5.5—5.9 (m, 1H), 7.23 (s, 5H); MS *m/z* (%): 162 (M$^+$, 0.5), 145 (10), 107 (99), 105 (36), 79 (100), 77 (96), 51 (16).

The Synthesis of Homoallylic Alcohol with SnF$_2$*–Et*$_2$*AlCl Reagent.* A hexane solution of diethylaluminum chloride (1.0 M, 2.0 ml, 2.0 mmol) was added to a suspension of anhydrous tin(II) fluoride (0.31 g, 2.0 mmol) in CH_2Cl_2 (5 ml) at 0 °C. The solution turned to red immediately. After the resulting mixture was stirred for 20 min, a mixture of diphenyl 1-methyl-2-propenyl phosphate (0.61 g, 2.0 mmol), hexanal (0.10 g, 1.0 mmol), and Pd(PPh$_3$)$_4$ (0.12 g, 0.1 mmol) was added, and the whole was stirred for 2 h at 20 °C. The reaction mixture was poured into 1 M hydrochloric acid and extracted with ether. The combined organic layers were washed with saturated NaHCO$_3$ aqueous solution, dried over anhydrous Na$_2$SO$_4$, and concentrated. The Purification by PLC (hexane–ethyl acetate, 5:1) gave an isomeric mixture of 3-methyl-1-nonen-4-ol[5] as a colorless oil (0.12 g, 80%). The isomeric ratio of the product (erythro/threo=1/1) was determined by GLPC [PEG 20 M 5%, on Celite 545, 1.5 m, 110 °C, T_r (threo)=9.0 min, T_r (erythro)=10.6 min]: Bp 90 °C (bath temp, 10 Torr); IR (CCl_4): 3380, 1638, 1260, 1081, 1000, 911 cm^{-1}, NMR (CCl_4): δ=0.92 (t, J=7.5 Hz, 3H), 1.04 (d, J=6.6 Hz, 3H), 1.0—1.6 (m, 8H), 1.80 (bs, 1H), 2.0—2.4 (m, 1H), 3.2—3.5 (m, 1H), 5.01 (dd, J=17.1, 2.7 Hz, 1H), 5.18 (dd, J=10.8, 2.7 Hz, 1H), 5.6—5.9 (m, 1H); MS *m/z* (%): 156 (M$^+$, 1.0), 133 (3), 101 (12), 83 (53), 56 (100), 55 (89), 43 (20), 41 (41).

The Stereochemical Study on the Allylic Stannane Synthesis. An ether solution of methyllithium (1.8 M, 5.0 ml, 9.0 mmol) was added to a suspension of anhydrous tin(II) chloride (0.57 g, 3.0 mmol) in THF (4 ml) at 0 °C. After being stirred for 20 min, the reaction mixture was treated with a hexane solution of Et$_2$AlCl (1.0 M, 3.0 ml, 3.0 mmol) at 0 °C. The resulting mixture was stirred for 20 min, and a mixture of *cis*- or *trans*-3-deuterio-5-methyl-2-cyclohexen-1-yl diethyl phosphate[18] (0.37 g, 1.5 mmol) and Pd(PPh$_3$)$_4$ (0.17 g, 0.15 mmol) was added. The whole was stirred for another 2 h at 20 °C, then the solution was poured into 5% NaOH (70 ml) and extracted with ether (30 ml×3). The combined organic layers were washed with 5% NaOH (60 ml×2), dried over anhydrous Na$_2$SO$_4$, and concentrated. The ratio of four isomers, **14a**, **14b**, **15a**, **15b**, was determined by the examination of ^{119}Sn NMR spectra of crude products.[13]

cis- *and* trans-*5-Methyl-2-cyclohexen-1-ol:*[18] According to the previously reported procedure,[18] *cis* isomer of the title compound was prepared from 5-methyl-2-cyclohexen-1-one[19] by reduction with lithium aluminum hydride. The aluminum triisopropoxide reduction of 5-methyl-2-cyclohexen-1-one gave the mixture of *cis* and *trans* isomers in 4:3 ratio, which was transformed into *p*-nitrobenzoates with *p*-nitrobenzoyl chloride and pyridine. Recrystallization from ethanol gave *trans* isomer which was hydrolyzed to give *trans*-5-methyl-2-clohexen-1-ol.[20] The ^{1}H NMR spectra in $CDCl_3$ for both isomers are shown as follows.

cis-*5-Methyl-2-cyclohexenyl* p-*Nitrobenzoate*: δ=1.05 (d, J= 6.4 Hz, 3H), 1.15—2.25 (m, 6H), 5.65—5.75 (m, 2H), 5.80—5.95 (m, 1H), 8.10—8.35 (m, 4H).

tans-*5-Methyl-2-cyclohexenyl* p-*Nitrobenzoate*: δ= 1.04 (d, J= 6.5 Hz, 3H), 1.15—2.25 (m, 6H), 5.49—5.60 (m, 1H), 5.80—5.95 (m, 1H), 6.05—6.20 (m, 1H), 8.10—8.35 (m, 4H).

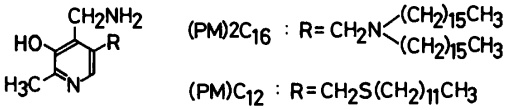
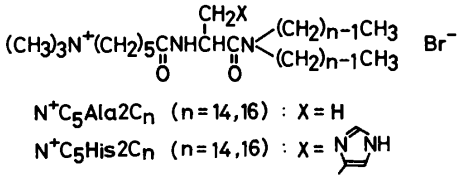
The copper(II)-catalyzed transamination of 4-aminomethyl-5-[(dihexadecylamino)methyl]-2-methyl-3-pyridinol [(PM)2C_{16}] with sodium pyruvate was investigated in an aqueous medium at pH 6.9, μ 0.10 (KCl), and 30.0±0.1 °C in the presence of single-walled bilayer vesicles of *N,N*-dihexadecyl-*N*$^{\alpha}$-[6-(trimethylammonio)-hexanoyl]-L-alaninamide bromide [N^+C_5Ala2C_{16}] and *N,N*-dihexadecyl-*N*$^{\alpha}$-[6-(trimethylammonio)hexanoyl]-L-histidinamide bromide [N^+C_5His2C_{16}]. The binding mode of the pyridoxamine moiety in the vesicles was clarified by comparing the reaction behavior of the (PM)2C_{16}-pyruvate-Cu^{II} system with that of the 4-aminomethyl-5-dodecylthiomethyl-2-methyl-3-pyridinol [(PM)C_{12}]-pyruvate-Cu^{II} system. The pyridoxamine moiety of (PM)2C_{16} was more tightly anchored in the hydrogen-belt domain of the membranes than that of (PM)C_{12} as confirmed by fluorescence polarization spectroscopy. The difference in binding mode between (PM)2C_{16} and (PM)C_{12} is reflected on the copper(II)-coordination equilibria for the formation of the copper(II)-ketimine intermediates. The copper(II)-catalyzed transamination of (PM)2C_{16} with pyruvate in the N^+C_5His2C_{16} vesicle was most enhanced among related reaction systems treated here. The rate enhancement was attributed to the favorable formation of the reactive 2:1 ketimine-copper(II) chelate and the general-base catalysis by the coordination-free imidazolyl group of the lipid.

Bilayer membranes have been utilized as effective media for various organic reactions, exhibiting marked functional assistance.[1-5] The interior hydrophobic domain of bilayer membranes may provide a microenvironment favorable for such reactions due to the following effects: (i) desolvation of reacting species to a significant extent relative to those in homogeneous media; (ii) proximal alignment of reacting species, which is forced by the hydrophobic interactions with organized lipid molecules; (iii) catalytic assistance by some functional groups substituted on lipid molecules. In this regard, the functional simulation of a holoenzyme system composed of an apoprotein and a relevant coenzyme is expected to be made by utilizing a combination of a synthetic bilayer membrane and the corresponding coenzyme factor modified with some hydrophobic substituents.

We have previously reported that the single-walled vesicles composed of synthetic peptide lipids, *N,N*-ditetradecyl-*N*$^{\alpha}$-[6-(trimethylammonio)hexanoyl]-L-alaninamide bromide [N^+C_5Ala2C_{14}] and *N,N*-ditetradecyl-*N*$^{\alpha}$-[6-(trimethylammonio)hexanoyl]-L-histidinamide bromide [N^+C_5His2C_{14}], provide reaction environments favorable for functional simulation of the vitamin B_6-dependent transaminase.[6,7] For the transamination of a hydrophobic pyridoxamine derivative, (PM)C_{12}, with pyruvate in the molecular aggregates, the copper(II) ion effectively catalyzed the isomerization of the ketimine Schiff-base to the corresponding aldimine Schiff-base, and the subsequent addition of ethylenediaminetetraacetate afforded the corresponding pyridoxal analogue and alanine as the final products. The kinetic analysis has shown the following characteristic features. (i) The 2:1 and 1:1 ketimine-copper(II) chelates are present during the reaction, and the reactivity of the former chelate is much larger than that of the latter in the N^+C_5Ala2C_{14} vesicle. (ii) The N^+C_5His2C_{14} vesicle allowed the formation of the 1:1 chelate in preference to that of the 2:1 chelate, and the coordination-free imidazolyl group of the lipid molecule effectively catalyzes the isomerization as a general base.

In order to improve the catalytic function of such an artificial transaminase, we prepared a pyridoxamine derivative bearing a hydrophobic double-chain, (PM)-2C_{16}, which is able to interact with matrix membranes more tightly than (PM)C_{12} having only a single hydrophobic chain.[8] We report in this article the reaction behavior of (PM)2C_{16} with pyruvate in the individual vesicles of N^+C_5Ala2C_{16} and N^+C_5His2C_{16} as effected by the copper(II) ion. A kinetic feature observed by anchoring the pyridoxamine moiety in the so-called hydrogen-belt domain[9] of the vesicles is to be discussed in terms of the proximity and orientation effects.





Experimental

General Analyses and Measurements. Elemental analyses were performed at the Microanalysis Center of Kyushu University. ^{1}H-NMR spectra were taken on a Hitachi R-24B spectrometer. A Beckman Φ 71 pH meter equipped with a Beckman 39505 combined electrode was used for pH-measurements after calibration with a combination of appropriate standard aqueous buffers. Electronic absorption spectra were taken on a Union Giken SM-401 high-sensitivity spec-

†Contribution No. 761 from this Department.

trophotometer. Fluorescence polarization measurements were made on a Union Giken FS-501A spectrophotometer equipped with a Sord M200 Mark II microcomputer. The steady-state fluorescence anisotropy (r_s) originated from the pyridoxamine moiety of (PM)2C_{16} or (PM)C_{12} was calculated by Eq. 1, where I is the fluorescence intensity, and the subscripts v and h refer to the orientations, vertical and horizontal, respectively, for the excitation and analyzer polarizers in this sequence. C_f is the grating correction factor, given by I_{hv}/I_{hh}.

$$r_s = (I_{vv} - C_f I_{vh})/(I_{vv} + 2C_f I_{vh}) \quad (1)$$

Materials. Preparation and characterization of hydrophobic pyridoxamines, (PM)C_{12}[7] and (PM)2C_{16},[8] and a peptide lipid having the L-alanine residue, N^+C_5Ala2C_{16},[10] have been described elsewhere. A peptide lipid having the L-histidine residue, N^+C_5His2C_{16}, was prepared by the method adopted for the synthesis of N^+C_5His2C_{14}:[6] a colorless glassy solid, $[\alpha]_D^{20}$ −9.5° (*c* 0.84, EtOH); ^{1}H-NMR ($CDCl_3$, Me_4Si) δ= 0.85 [6H, t, $(CH_2)_{15}\underline{CH_3}$], 1.23 [56H, m, $CH_2(\underline{CH_2})_{14}CH_3$], 1.90 [6H, m, $N^+CH_2(\underline{CH_2})_3CH_2CO$], 2.20 [2H, br t, $N^+(CH_2)_4\underline{CH_2}CO$], 2.80—3.50 [8H, m, N^+CH_2, NCH_2, and $CHC\underline{H_2}Im$], 3.30 [9H, s, $(CH_3)_3N^+$], 5.00 [1H, m, $NHC\underline{H}CO$], 6.91 [1H, s, Im-5H], 7.60 [1H, d, NH], 7.95 [1H, s, Im-2H].

Found: C, 66.60; H, 10.85; N, 8.03%. Calcd for $C_{47}H_{92}BrN_5O_2\cdot(1/2)H_2O$: C, 66.56; H, 11.05; N, 8.26%.

Kinetic Measurements. The copper(II)-catalyzed transamination reaction of (PM)2C_{16} with pyruvate in the single-walled vesicles was monitored spectrophotometrically in an aqueous 2-[4-(2-hydroxyethyl)-1-piperazinyl]ethanesulfonate (HEPES) buffer (2.5×10^{-3} mol dm^{-3}, pH 6.9) containing 0.10 mol dm^{-3} potassium chloride at 30.0±0.1 °C. The experimental details are analogous to those reported previously for the copper(II)-catalyzed reaction of (PM)C_{12} with pyruvate in the individual vesicles of N^+C_5Ala2C_{14} and N^+C_5His2C_{14}.[7]

Results and Discussion

Microenvironments Around the Pyridoxamine Moiety in Vesicles. The peptide lipids, N^+C_5Ala2C_{16} and N^+C_5His2C_{16}, form single-walled vesicles in aqueous media upon sonication as confirmed by electron microscopy.[10] The amino acid residues of the lipids are placed in the so-called hydrogen-belt domain[9] interposed between the hydrophobic region formed with aliphatic double chains and the hydrophilic zone with ionic head groups. In order that an effective catalytic assistance is performed by the imidazolyl group of N^+C_5His2C_{16} in the transamination, it is desirable that the pyridoxamine moiety is anchored in the hydrogen-belt domain so tightly as to interact with the imidazolyl group. The microenvironmental polarity around the pyridoxamine moiety of (PM)C_{12} incorporated into the individual vesicles of N^+C_5Ala2C_{14} and N^+C_5His2C_{14} was evaluated from its electronic absorption spectra, and found to be equivalent to that provided by dioxane-water (1:1 v/v); Kosower's *Z*-value,[11] 87.[7] This polarity value is in good agreement with that for the hydrogen-belt domain of the vesicle composed of *N,N*-dihexadecyl-*N*$^\alpha$-[1-(6-trimethylammoniohexyl)-1,4-dihydro-3-pyridylcarbonyl]-L-alaninamide bromide (*Z*-value, 89);[3] evaluated with attention to the 1,4-dihydronicotinamide moiety which is inevitably fixed in the vicinity of the domain. The pyridoxamine moiety of (PM)2C_{16} is also placed in the similar microenvironment within the vesicles of N^+C_5Ala2C_{16} (*Z*-value, 87).[8]

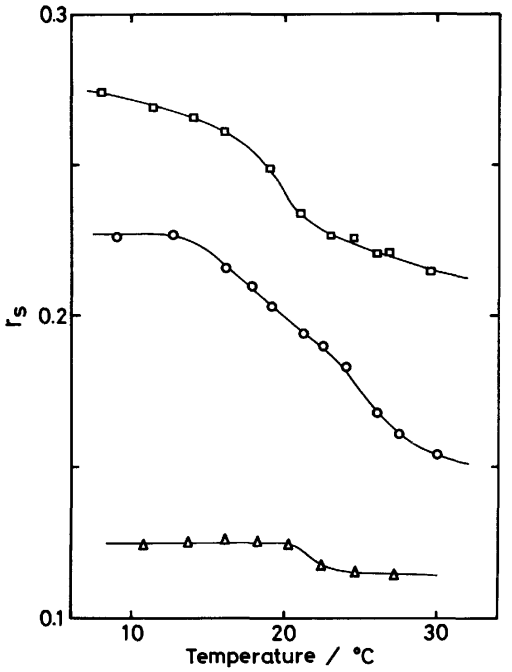


Fig. 1. Correlations between temperature and steady-state fluorescence anisotropy (r_s) for the pyridoxamine moiety (5.0×10^{-5} mol dm^{-3}) in an aqueous HEPES buffer (2.5×10^{-3} mol dm^{-3}) at pH 6.9 and μ 0.10 (KCl) in the presence of single-walled vesicles of peptide lipids (1.0×10^{-3} mol dm^{-3}): ○, (PM)2C_{16} in N^+C_5Ala2C_{16} (taken from Ref. 8); □, (PM)2C_{16} in N^+C_5His2C_{16}; △, (PM)C_{12} in N^+C_5Ala2C_{16}. Excitation and emission wavelengths: 360 and 450 nm for (PM)2C_{16}; 335 and 390 nm for (PM)C_{12}, respectively.

The parameters for steady-state fluorescence anisotropy (r_s) originated from the pyridoxamine moieties of (PM)2C_{16} and (PM)C_{12} in the vesicles were much different from each other. As shown in Fig. 1, the r_s values for (PM)2C_{16} in the individual vesicles of N^+C_5Ala2C_{16} and N^+C_5His2C_{16} are large relative to the corresponding values for (PM)C_{12} in the N^+C_5Ala2C_{16} vesicle over the whole temperature range studied here. The single-walled N^+C_5Ala2C_{16} vesicle shows a broad phase transition range (20±5 °C) as confirmed by differential scanning calorimetry[10] as well as by fluorescence polarization spectroscopy with 1,6-diphenyl-1,3,5-hexatriene embedded in the vesicle.[8] The r_s values for (PM)2C_{16} in the individual vesicles of N^+C_5Ala2C_{16} and N^+C_5His2C_{16} are more sensitive to the phase transition than that for (PM)C_{12} in the N^+C_5Ala2C_{16} vesicle. The result strongly suggests that the pyridoxamine moiety of (PM)2C_{16} is tightly anchored in the hydrogen-belt domain in the vesicles through the hydrophobic interaction of its double-chain portion with the hydrophobic domain of the vesicles. On the other

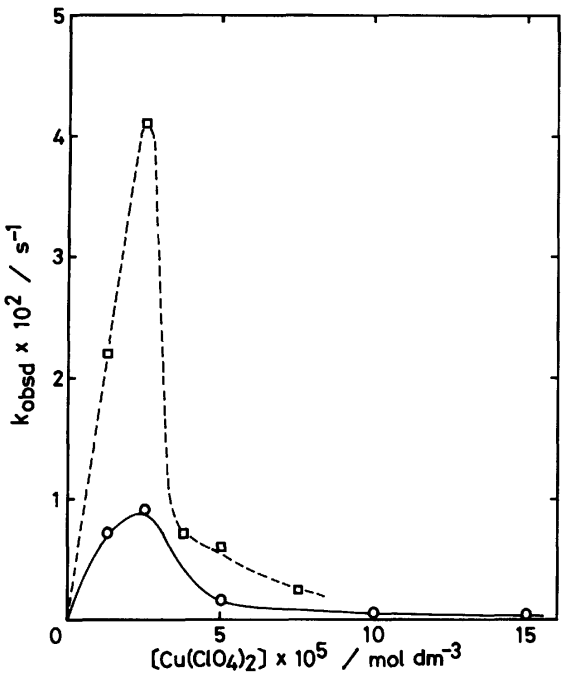

Fig. 2. Correlations between total concentration of $Cu(ClO_4)_2$ and first-order rate constant for the isomerization of Cu^{II}-ketimine to Cu^{II}-aldimine in an aqueous HEPES buffer (2.5×10^{-3} mol dm^{-3}) at pH 6.9, μ 0.10 (KCl), and 30.0±0.1 °C in the presence of $N^+C_5Ala2C_{16}$ (○, 1.0×10^{-3} mol dm^{-3}) and $N^+C_5His2C_{16}$ (□, 1.0×10^{-3} mol dm^{-3}) with initial concentrations: $(PM)2C_{16}$, 5.0×10^{-5} mol dm^{-3}; sodium pyruvate, 5.0×10^{-3} mol dm^{-3}. A solid line refers to the calculated data on the basis of Scheme 2 and evaluated kinetic parameters (Table 1).

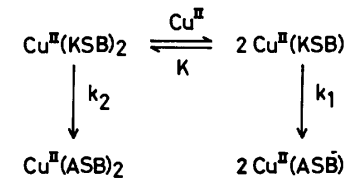
hand, the pyridoxamine moiety of $(PM)C_{12}$ is more mobile in the vesicles than that of $(PM)2C_{16}$, although the equilibrium locations of the pyridoxamine moieties of both pyridoxamine derivatives are nearly identical. In addition, the larger r_s values for $(PM)2C_{16}$ in the $N^+C_5His2C_{16}$ vesicle relative to the corresponding values in the $N^+C_5Ala2C_{16}$ vesicle over the whole temperature range may reflect the associative interactions, hydrogen-bonding and π-π interactions, between the pyridoxamine moiety and the imidazolyl group of the former lipid. Such interactions result in repression of the molecular motion of $(PM)2C_{16}$.

Transamination Reaction in $N^+C_5Ala2C_n$ Vesicles. The reaction was initiated by adding copper(II) perchlorate and sodium pyruvate to the covesicles of $N^+C_5Ala2C_{16}$ and $(PM)2C_{16}$, and the progress of the transamination was monitored by spectrophotometric



KSB: ketimine Schiff-base
ASB: aldimine Schiff-base

Scheme 2.

means. In a manner as observed for the copper(II)-catalyzed transamination of $(PM)C_{12}$ with pyruvate in the $N^+C_5Ala2C_{14}$ vesicle,[7] the reaction proceeded through the fast equilibrated formation of the copper(II) complexes of ketimine Schiff-base (**A** in Scheme 1), followed by much slower conversion into the copper(II) complexes of aldimine Schiff-base (**B** in Scheme 1). The isomerization was followed by monitoring an absorption increase at 390 nm, attributable to the formation of the copper(II)-aldimine chelates, and consistent with the first-order kinetics for each run. The observed rate constant, k_{obsd}, was plotted against the total concentration of $Cu(ClO_4)_2$ as shown in Fig. 2. The rate constant reaches a maximum and then falls down as the copper(II) concentration further increases. This kinetic feature is similar to that observed for the copper(II)-catalyzed reaction of $(PM)C_{12}$ with pyruvate in the $N^+C_5Ala2C_{14}$ vesicle.[7] The kinetic analysis was performed on the basis of Scheme 2 in a manner as reported previously[7] under conditions that both of the 2:1 and 1:1 (ketimine:Cu^{II}) chelate species are present. The kinetic parameters thus obtained for the isomerization are listed in Table 1, and the calculated molar distributions of the individual chelate species are shown in Fig. 3 against the copper(II) concentration. The reactivity of the 2:1 chelate is much larger than that of the 1:1 chelate in each reaction system, and the effective charge on the copper(II) atom seems to exert much effect on the reactivity as discussed previously.[7]

The formation of all the copper(II)-ketimine species, evaluated from the amounts of the copper(II)-aldimine chelates produced by the isomerization, is more pronounced in the $(PM)2C_{16}$-pyruvate-Cu^{II} system than in the $(PM)C_{12}$-pyruvate-Cu^{II} system: 88 and 78% mole fractions of the pyridoxamine moiety are transformed into the copper(II)-ketimine chelates for the former and the latter, respectively, at 2.5×10^{-5}

Table 1. Specific rate constants for isomerization reaction of Cu^{II}–ketimine to Cu^{II}–aldimine and stability constants for Cu^{II}–ketimine chelates in $N^+C_5Ala2C_n$ (1.0×10^{-3} mol dm^{-3}) vesicles at 30.0 ± 0.1 °C[a)]

k_1/s^{-1}	2.7×10^{-4}	6.8×10^{-4}
k_2/s^{-1}	1.0×10^{-2}	1.2×10^{-2}
K	170	20

a) In an aqueous HEPES buffer (2.5×10^{-3} mol dm^{-3}) at pH 6.9 and μ 0.10 (KCl). b) Initial concentrations in mol dm^{-3}: (PM)2C16, 5.0×10^{-5}; sodium pyruvate, 5.0×10^{-3}; $Cu(ClO_4)_2$, 1.3×10^{-5}—1.5×10^{-4}. c) Ref. 7.

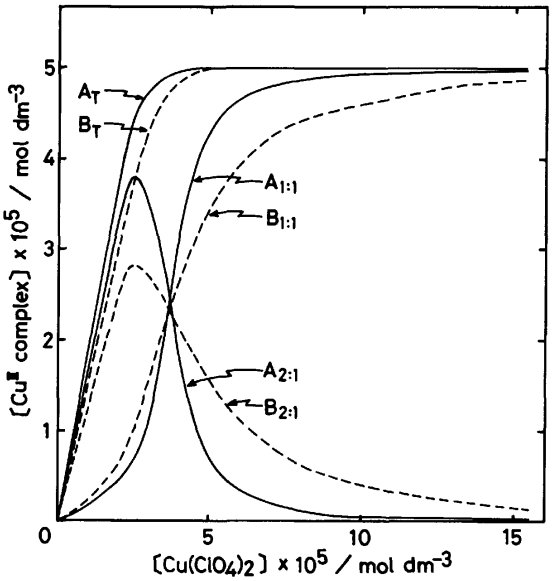

Fig. 3. Distributions of Cu^{II}-ketimine chelates in an aqueous HEPES buffer (2.5×10^{-3} mol dm^{-3}) at pH 6.9, μ 0.10 (KCl), and 30.0 ± 0.1 °C in the presence of $N^+C_5Ala2C_n$ (1.0×10^{-3} mol dm^{-3}): A, (PM)2C16 (5.0×10^{-5} mol dm^{-3})-pyruvate (5.0×10^{-3} mol dm^{-3})-Cu^{II} in $N^+C_5Ala2C_{16}$; B, (PM)C12 (5.0×10^{-5} mol dm^{-3})-pyruvate (5.0×10^{-3} mol dm^{-3})-Cu^{II} in $N^+C_5Ala2C_{14}$ (taken from Ref. 7). Subscripts T, 1:1 and 2:1 denote the total, 1:1 and 2:1 (ketimine:Cu^{II}) chelate species, respectively; [Cu^{II} complex] is given in terms of the Schiff-base unit.

mol dm^{-3} of $Cu(ClO_4)_2$ where the maximum rates were observed for the respective systems (Fig. 3). This clearly indicates that the tight fixation of the pyridoxamine moiety of (PM)2C16 in the hydrogen-belt domain entropically favors the formation of the copper(II)-ketimine chelates and further enhances the formation of the 2:1 ketimine-copper(II) chelate, as compared with the corresponding reaction system involving (PM)C12, in a lower concentration range of the copper(II) ion ([$Cu(ClO_4)_2$]<3.8×10^{-5} mol dm^{-3}): *i.e.*, molar ratios of the 2:1 chelate to the 1:1 chelate (in terms of the Schiff-base unit) at 2.5×10^{-5} mol dm^{-3} $Cu(ClO_4)_2$ are 6.3 and 2.5 for the (PM)2C16 and (PM)-C12 systems, respectively (Fig. 3).

Comparison of the stability constants for the formation of the 1:1 ketimine-copper(II) complex, as defined by Eq. 2, provides another important information.

$$K = [Cu^{II}(KSB)]^2/[Cu^{II}(KSB)_2][Cu^{II}] \quad (2)$$

The K value for the (PM)2C16 system is larger than that for the (PM)C12 system, and this requires some explanation. The efficient hydrophobic interaction of the two double-chain segments of the 2:1 ketimine-copper(II) chelate derived from (PM)2C16 with the hydrophobic vesicle domain acts to anchor the pyridoxamine moieties tightly in the intramembrane region, and consequently mobility of the pyridoxamine moieties are much repressed relative to those of the corresponding complex of (PM)C12. The resulting side-by-side arrangement of the pyridoxamine moieties of (PM)2C16 molecules with the lipid molecules in the hydrogen-belt domain induces a large steric strain within the chelate molecule since the copper(II) ion is forced to take some distorted coordination geometry away from its favorite square-planar one under such circumstances. The strain energy released upon formation of the 1:1 chelate must be greater than that for the corresponding chelate derived from (PM)C12. The steric strain effect is reflected on the activation entropy values observed above the phase transition temperature of $N^+C_5Ala2C_{16}$: for the 2:1 chelate, −2.43; for the 1:1 chelate, +23.3 J K^{-1} mol^{-1}.[8)]

Transamination Reaction in $N^+C_5His2C_n$ Vesicles. The reaction behavior of the copper(II)-catalyzed transamination in the $N^+C_5His2C_n$ vesicles is much influenced by the nature of coenzyme factors. In the (PM)2C16–pyruvate–Cu^{II}–$N^+C_5His2C_{16}$ system, the rate constant reaches a maximum at a 1:2 molar ratio of copper(II) to (PM)2C16 and then falls down sharply as the copper(II) concentration further increases (Fig. 2). The conversions to the aldimine-copper(II) chelate are 50 and 100% on the pyridoxamine base at the 4:1 and 2:1 molar ratios of (PM)2C16 to copper(II), respectively, as confirmed by electronic absorption spectroscopy. This clearly indicates that the copper-(II) ion is quantitatively converted into the 2:1 ketimine-copper(II) chelate under such conditions. On this basis, the specific rate constant evaluated for the 2:1 ketimine-copper(II) chelate in the $N^+C_5His2C_{16}$ vesicle, 0.041 s^{-1}, is 4 times larger than that for the same complex in the $N^+C_5Ala2C_{16}$ vesicle, indicating that the catalytic assistance is performed by the imidazolyl group of $N^+C_5His2C_{16}$ as a general base.

In the copper(II) concentration range higher than the 1:2 molar ratio of copper(II) *vs.* (PM)2C16, the reactivity is sharply reduced. This behavior is presumably originated from the two factors: transformation of the 2:1 ketimine-copper(II) chelate into the 1:1 chelate, which has lower reactivity relative to the former; coordination of the imidazolyl group to the copper(II) atom which results in masking of its catalytic activity.

As for the (PM)C12–pyruvate–Cu^{II}–$N^+C_5His2C_{14}$ system, conversion to the aldimine-copper(II) chelate reaches a value of 50% on the pyridoxamine base at

the 2:1 molar ratio of (PM)C_{12} to copper(II), indicating that the 1:1 ketimine–copper(II) chelate is present as the predominant species.[7] Even though the 2:1 chelate may be more reactive than the 1:1 complex in the light of the above observations, the larger fractional distribution of the 1:1 chelate over the whole copper(II) concentration range studied seems to be responsible for the lower reactivity relative to the reaction system involving (PM)2C_{16}.

In conclusion, it became apparent that the binding mode of the pyridoxamine moiety of the coenzyme analogues in the synthetic bilayer membranes appreciably controls the reaction behavior of the copper(II)-catalyzed transamination with pyruvate. The tight anchoring of the pyridoxamine moiety in the hydrogen-belt domain of the vesicles as observed with (PM)-2C_{16} results in the favorable formation of the reactive 2:1 ketimine–copper(II) chelate, and consequently the transamination reaction is much accelerated. The holoenzyme model system composed of (PM)2C_{16}, N^+-C_5His2C_{16}, and the copper(II) ion showed the extremely large reactivity for the transamination with pyruvate, which is originated from the bifunctional assistance by the copper(II) ion and the coordination-free imidazolyl group of N^+C_5His2C_{16}; the former acts to produce the reactive 2:1 chelate while the latter catalyzes the reaction as a general base.

(Received March 31, 1984)

Membrane structure and crystal-liquid crystal phase transition behaviors were investigated for two kinds of artificial amphiphiles with single alkyl chain and *N*-benzylideneaniline moiety. These artificial amphiphiles showed both thermotropic and lyotropic mesomorphisms in a similar manner to biological lipids. Artificial amphiphile with one polar head group formed the multilayer liposome even in a low concentration region of amphiphile/water system. Artificial amphiphile with two polar head groups at both ends of the molecule does not form the multilayer liposome but forms monomolecular lamellae. Addition of cholesterol to the two polar-headed amphiphile changed its aggregated structure drastically from monomolecular lamellae to large single liposomes composed of monomolecular layer. In the case of two polar-headed amphiphile/water system, two endothermic peaks were observed, which were assigned to gel I to gel II and gel II to mesophase transitions. These transitions may correspond to meltings of partial and whole part of hydrophobic portion in amphiphilic molecule, respectively.

Biological membranes are mainly composed of phospholipids which are composed of one polar head group and two alkyl chains. It has been extensively discussed on the reason why phospholipids form the bimolecular-layered membrane in water at a low concentration region, instead of globular micells or two-dimensional lamellae.[1] Many artificial amphiphiles were synthesized by Kunitake *et al.*[2-5] For some of these amphiphiles, membrane structures and permeation properties were investigated on the basis of X-ray diffraction, differential scanning calorimetry and osmosis experiments.[6-9] It was concluded that existence of two alkyl chains played an important role for formation of the stabler bilayer structure. Also, it was confirmed that these artificial amphiphiles with two alkyl chains exhibited similar characteristics with respect to molecular aggregation states, thermal properties and permeation properties of water and metal cations to those of biological phospholipids.

Ordinary amphiphiles with single alkyl chain such as soap or detergent form bimolecular lamellae in water only at a high concentration region, while they do not form bimolecular layers but form cylindrical or globular micelles at a low concentration.[10] A series of ammonium amphiphiles composed of *N*-benzylideneaniline moiety and single alkyl chain were synthesized.[11-13] It is well known that *N*-benzylideneaniline moiety is capable of forming liquid crystalline structures due to its additional intermolecular interaction and rigid character.[14] Therefore, it is interesting to investigate the effect of *N*-benzylideneaniline moiety on the formation of single- or bimolecular-layered membrane in water at a low concentration region.

The purpose of this paper is to investigate the membrane structure and the crystal-liquid crystal phase transition behavior of artificial amphiphiles in water system, which are composed of single alkyl chain, mesogenic group and one or two polar head groups.

Experimental

Materials. Figure 1 shows the chemical structures of artificial amphiphiles studied in this paper. *N*-[*p*-(trimethylammonio)benzylidene]-*p*-dodecylaniline bromide ($C_{12}BBN^+3C_1$: sample 1) was prepared by reaction of *p*-dodecylaniline and (*p*-formylphenyl)trimethylammonium bromide.[11] *N*-[*p*-[10-(trimethylammonio)decyloxy]]-*p*-[10-(trimethylammonio)-decyloxy]aniline dibromide ($N^+C_{10}BBC_{10}N^+$: sample 2) was prepared by condensation reaction of [10-(*p*-formylphenoxy)-decyl]trimethylammonium bromide and [10-(*p*-aminophenoxy)-decyl]trimethylammonium bromide in refluxing ethanol for 1 h in the presence of a small amount of acetic acid.[13] These artificial amphiphiles are designated as monoalkyl-monocation ($C_{12}BBN^+3C_1$) and monoalkyl-dication ($N^+C_{10}BBC_{10}N^+$).

Electron Microscopic Observation. Several mg of amphiphiles were dissolved in deionized water and subjected to ultrasonic treatment. Almost equal volume of 2 wt% aqueous solution of uranyl acetate was added to the resulting suspension. A drop of the solution was placed and dried on a carbon grid for an electron microscopic observation (TEM).

Differential Scanning Calorimetry. The thermal behavior of the crystal-liquid crystal phase transition in the amphiphile/water system was studied with differential scanning calorimeter (DSC).

X-Ray Analysis. The membrane structure in the amphiphile/water system was studied by wide and small angle X-ray measurements. X-Ray diffraction photographs

Results and Discussion

Membrane Structure and Phase Transition of $C_{12}BBN^{+}3C_1$. Figure 2 shows the electron micrograph of $C_{12}BBN^{+}3C_1$ negatively stained with uranyl acetate. $C_{12}BBN^{+}3C_1$ favorably forms multilayer liposomes in a similar fashion to those of biological lipids. An apparent mean distance between dark striations was 5.8—6.0 nm which nearly corresponds to the bimolecular length of $C_{12}BBN^{+}3C_1$ (5.9—6.0 nm) calculated by the CPK molecular model. Since the deposition of uranyl acetate for negative staining amounts to 1—2 nm thick,[8,9] the exact repeating distance was evaluated from the small angle X-ray scattering (SAXS) measurement as mentioned later.

The multilamellar liposome was observed even in a fairly dilute aqueous solution of C=0.001 (weight fraction of amphiphile in water system) by means of an electron microscopy. This concentration is quite lower in comparison with the case for ordinary surfactants with monoalkyl chain which form the bimolecular lamellar structure at a higher concentration range above $C\simeq0.6$.[10] The stable liposome formation at an extremely low concentration in the case of $C_{12}BBN^{+}3C_1$ must be due to introduction of the rigid segment of *N*-benzylideneaniline moiety which enhances the intermolecular interaction.

Figure 3 shows the phase diagram and the concentration, (C: weight fraction) dependence of the long spacing, (L) for $C_{12}BBN^{+}3C_1$. Thermal analytical studies of $C_{12}BBN^{+}3C_1$ were carried out over the concentration range of $0.1<C\leq1.0$. The endothermic transition due to melting of alkyl chains was observed over whole concentration range studied here. The endothermic peak due to melting of ice was observed at 273 K in the concentration range lower than about C=0.83. In the concentration range of $0.83<C\leq1.0$, no endothermic transition due to melting of ice was observed in heating curve. Water molecules hydrated to the polar head groups did not form ice on cooling the $C_{12}BBN^{+}3C_1$/water mixture below 273 K.[6] The critical concentration at which nonhydrated (free) water appeared was determined by extrapolating the

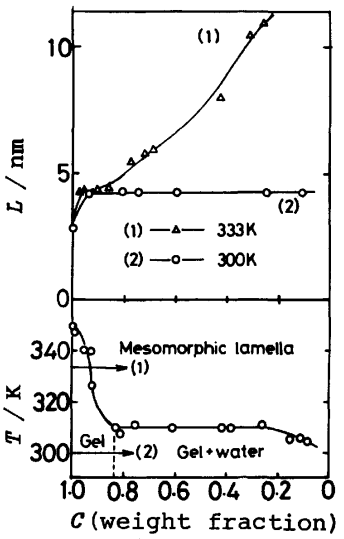

Fig. 3. Variation of the phase transition temperature (lower) and the long spacing (upper) with the concentration of $C_{12}BBN^{+}3C_1$.

magnitude of the heat of fusion of ice at 273 K *vs.* the concentration of $C_{12}BBN^{+}3C_1$ to zero. The critical concentration between gel and gel+water phases was determined to be 0.83, where the gel phase means the crystalline phase with bound water hydrated to the hydrophilic polar head groups. This value of the critical concentration indicates that on an average, five water molecules hydrate to one polar head group of $C_{12}BBN^{+}3C_1$ and these bound water molecules do not form ice on cooling even to 220 K.[8] The gel to mesophase transition temperature decreases steadily with a decrease of $C_{12}BBN^{+}3C_1$ concentration to the limiting value of 310 K over the concentration range of $0.83<C\leq1.0$. The phase diagram of the $C_{12}BBN^{+}3C_1$/water system has a very similar behavior to those of biological lipids[15] and artificial amphiphiles with two alkyl chains.[6,7,9] It is apparent from the phase transition behavior that $C_{12}BBN^{+}3C_1$ has characteristics of both thermotropic and lyotropic liquid crystals in a similar fashion to phospholipids or artificial lipids with two alkyl chains. L measured at 300 K increases with decreasing the $C_{12}BBN^{+}3C_1$ concentration down to C=0.83, where free water appears in the $C_{12}BBN^{+}3C_1$/water mixture. As mentioned before, the hydrophilic polar head group can incorporate limited amount of water and therefore, the bimolecular lamellae of $C_{12}BBN^{+}3C_1$ were gradually spread with an increase in the water concentration up to C=0.83.

The formation of lamellar structure was confirmed by the result that the ratio of reciprocal of long spacing for higher order scatterings were 1:2:3. The long spacing of the lamellar layer in a gel state is approximately one-half of the bimolecular length estimated from the CPK molecular model on the assumption of planar zigzag conformation of hydrocarbon chains. This result may be explained by the following two possible models for the assembly of $C_{12}BBN^{+}3C_1$

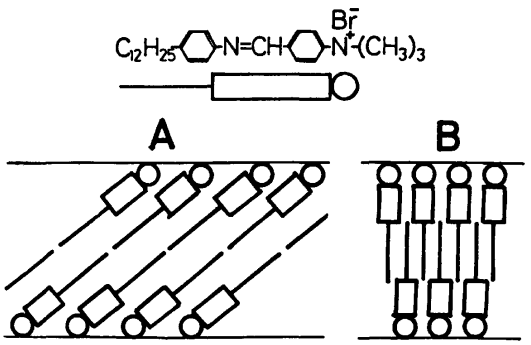

Fig. 4. Schematic assembly models for $C_{12}BBN^+3C_1$ bilayer.

molecules as shown in Fig. 4. Figure 4A is the model that hydrocarbon chains tilt with an angle of 30° to the lamellar surface. Figure 4B shows the mutual insertion of hydrocarbon chains from the opposite directions. Structure amplitudes were calculated for the two models of Figs. 4A and 4B and compared with an observed relative structure amplitude. The most plausible packing model for the $C_{12}BBN^+3C_1$/water system was determined to be the latter one (the mutual insertion of hydrocarbon chains) on the basis of the electron density distribution obtained by means of SAXS measurement.[16,17] In this case, the alkyl chains are almost perpendicular to the membrane surface. The detailed results will be reported elsewhere.[17]

Membrane Structure and Phase Transition of $N^+C_{10}BBC_{10}N^+$. $N^+C_{10}BBC_{10}N^+$ has the two polar head groups at both ends and *N*-benzylideneaniline moiety of a rigid segment in hydrocarbon chains at the para-position. In general, chemical substances containing a rigid segment such as *N*-benzylideneaniline moiety can form liquid crystalline phase. Therefore, amphiphile of monoalkyl-dication type makes us expect that the monomolecular membrane can be easily formed in a dilute aqueous solution owing to existence of the two polar head groups at both ends of molecule.

Figure 5 (a) shows the electron micrograph of $N^+C_{10}BBC_{10}N^+$ negatively stained with uranyl acetate. $N^+C_{10}BBC_{10}N^+$ amphiphile could not form multilayer liposome, but the parallel aggregation of lamellae. Taking into account the deposition of uranyl acetate, the thickness of parallel aggregated lamellae (5.3—6.4 nm) is considered to correspond to the one molecular length of $N^+C_{10}BBC_{10}N^+$ (4.4—4.5 nm) calculated by use of the CPK model. Figure 5(b) exhibits that incorporation of cholesterol to $N^+C_{10}BBC_{10}N^+$ induces a transformation from monomolecular lamellae to single- or multi-layer liposome. The diameter of vesicles are 100—200 nm and their membrane thickness is 5—20 nm. It is reasonably expected that cholesterol molecules mostly locate in the outer half of the layer, creating suitable curvature for the vesicle formation as shown in Fig. 5 (c). Figure 5(c) represents schematic speculations with respect to formation of monolayer liposome for $N^+C_{10}BBC_{10}N^+$ with

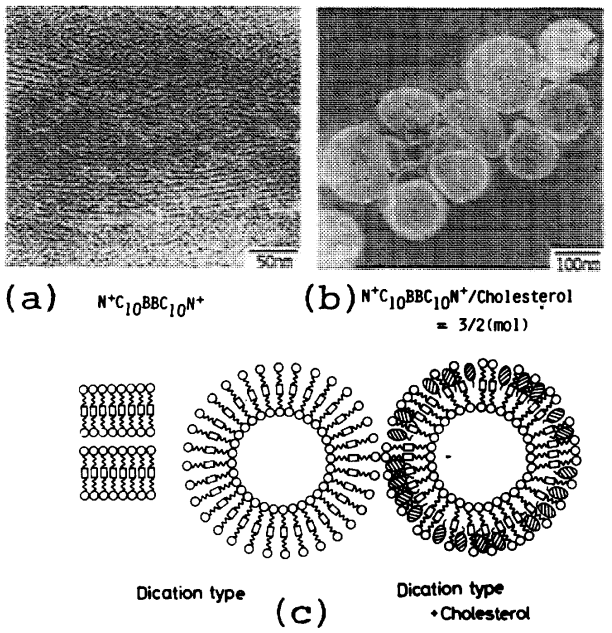

Fig. 5. (a) Electron micrograph of $N^+C_{10}BBC_{10}N^+$ negatively stained with uranyl acetate. (b) Electron micrograph of $N^+C_{10}BBC_{10}N^+$+cholesterol (3:2 molar mixture). (c) Schematic packing model of $N^+C_{10}BBC_{10}N^+$ and possible formation of monolayer liposome.

and without cholesterol. In the case of bimolecular membrane of dialkyl- or monoalkyl-monocation artificial amphiphiles, then number of molecules must be different in the outer and the inner layers because of the different spherical surface area for the inner and the outer shells. On the other hand, $N^+C_{10}BBC_{10}N^+$ forms monomolecular layer due to existence of dication groups at the both ends of the molecule as shown in the left assembly model of Fig. 5 (c). Considering the liposome formation of $N^+C_{10}BBC_{10}N^+$ in the case of this assembly, however, a large amount of vacancy or defect is produced especially in the outer half of spherical shell as shown by the middle aggregation model of Fig. 5 (c). These vacancies or defects may be reduced by addition of the second components such as cholesterol as shown in the right assembly model of Fig. 5 (c). Therefore, the monomolecular liposome of $N^+C_{10}BBC_{10}N^+$ was stably formed by addition of cholesterol.

Figure 6 shows the variation of the phase transition temperature with the weight fraction of $N^+C_{10}BBC_{10}N^+$. This phase diagram shows that $N^+C_{10}BBC_{10}N^+$ has characteristics of both thermotropic and lyotropic liquid crystals in a similar manner to those of phospholipids in biomembrane or other artificial amphiphiles. In the case of $N^+C_{10}BBC_{10}N^+$, the two endothermic peaks were recognized by DSC measurement. These were assigned to the gel I to gel II and the gel II to mesophase transitions with consideration of the wide angle X-ray diffraction as discussed later. Also, the critical concentration of C=0.84 between gel I and gel I+water (shown by the brokenline in Fig. 6)

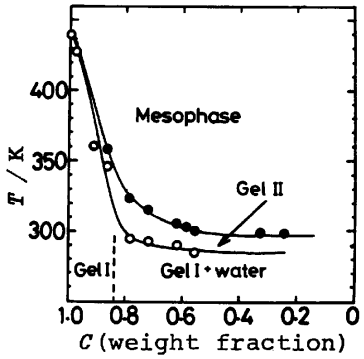

Fig. 6. Variation of the phase transition temperature with the concentration of $N^+C_{10}BBC_{10}N^+$.

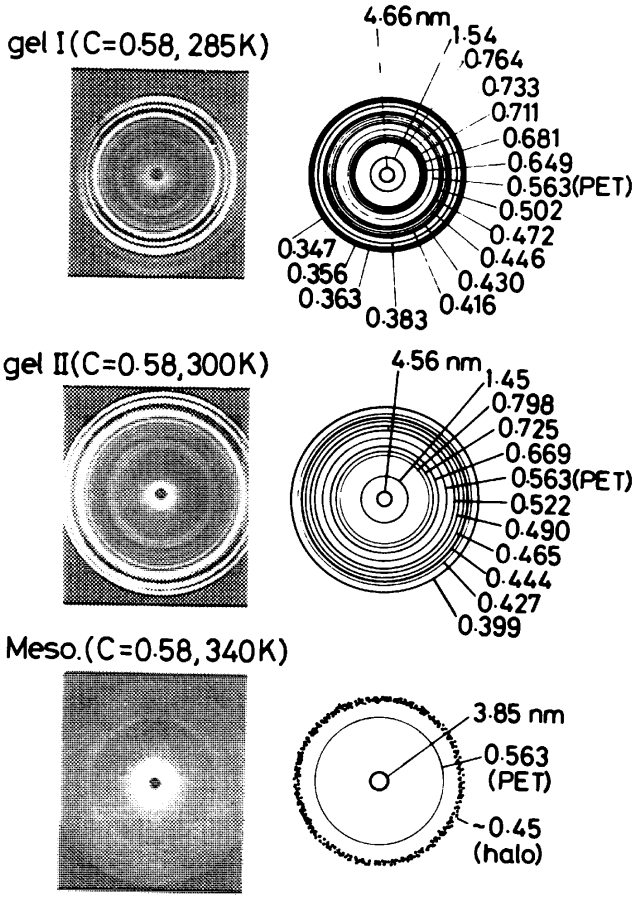

Fig. 7. Wide angle X-ray diffraction patterns for gel I, gel II and mesophase of $N^+C_{10}BBC_{10}N^+$.

was decided in a similar manner to that for $C_{12}BBN^+3C_1$ as mentioned before.

In the case of gel I (C=0.58 at 285 K), many sharp Debye rings were observed as shown in Fig. 7. A spacing of 0.563 nm is due to poly(ethylene terephthalate) (PET) film used as a window of the cell for X-ray measurements. The most inner ring corresponds to the long spacing of $N^+C_{10}BBC_{10}N^+$ (4.66 nm). This value is nearly equal to the single molecular length. In the intermediate range of gel II (C=0.58 at 300 K), the almost all diffraction rings became broader in comparison with those of gel I and their spacings were slightly changed. Also, some diffraction rings corresponding to the short spacing between alkyl chains disappeared, for example, 0.711, 0.649 and 0.416 nm spacings in gel I. Furthermore, the long spacing in gel II became slightly shorter (4.56 nm) than that in gel I. The crystallographic analysis of $N^+C_{10}BBC_{10}N^+$ will be reported in detail elsewhere. The variation of the X-ray diffraction patterns indicates the partial melting of hydrocarbon chains which locate between the polar head and the *N*-benzylideneaniline moiety. Since many fairly sharp diffraction rings were yet remained, it seems that the lateral order of the hydrophobic chains in a gel II state still remained considerably. In the case of mesophase (C=0.58 at 340 K), the sharp Debye rings corresponding to the interchain distance among the hydrophobic chains changed into diffuse ones but the scattering ring in small angle region still retained (3.85 nm), indicating the existence of the layer structure in the mesomorphic phase. These results apparently indicate that the lateral order in the interchain distance among the hydrophobic chains, was lost by melting of the whole part of the hydrophobic portion in $N^+C_{10}BBC_{10}N^+$ molecule without disappearance of layered structure of dication artificial amphiphile in a mesomorphic state as shown in Fig. 8.

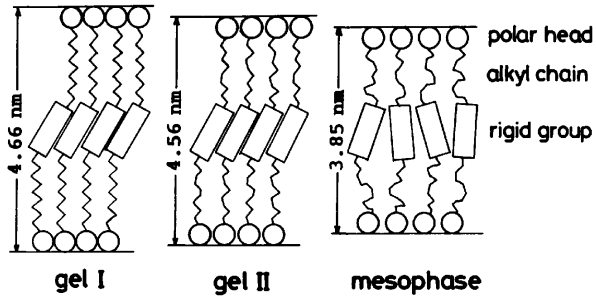

Fig. 8. Schematic representation of molecular membrane structures of $N^+C_{10}BBC_{10}N^+$ for gel I, gel II, and mesophase.

The membrane structures or the aggregation states of $N^+C_{10}BBC_{10}N^+$ for gel I, gel II, and mesomorphic phases were schematically represented in Fig. 8, although they are not clarified yet by the detailed structural analysis. In gel I phase, the alkyl chain has all trans conformation in a crystalline state. In gel II phase, the alkyl chain partially melts, but the lateral order of polar head and rigid *N*-benzylideneaniline moiety remains. In the mesophase, the alkyl chain and the rigid group are in a disordered state but the layer structure are retained.

Conclusion

The artificial amphiphiles which have one or two polar head groups and *N*-benzylideneaniline moiety as a rigid segment in hydrocarbon chains at the para-position formed bimolecular or monomolecular liposomes in an extremely low concentration, depending on the number of the polar heads. The rigid segment is required for inducing an ordered packing

of amphiphilic molecules in a dilute solution. The aggregated structure of the two polar-headed amphiphile (monoalkyl-dication type) is varied drastically from parallel aggregation of monomolecular lamellae to monomolecular or multilayered liposome by adding cholesterol.

The phase transition temperatures of $C_{12}BBN^{+}3C_1$ and $N^{+}C_{10}BBC_{10}N^{+}$ in water system decreased to the limiting value with an increase in water concentration in a concentration range of C=1.0—0.85. Since the long spacing corresponding to the thickness of lamellae was clearly observed above phase transition temperature, it is apparent that melting of hydrocarbon chains is not accompanied by appearance of isotropic phase but the mesomorphic one. The phase diagrams of the amphiphile/water system exhibited that the amphiphiles had characteristics of both thermotropic and lyotropic mesomorphisms.

Conformation Analyses of Poly(L-lysine) Induced by Various Surfactants

Kunio TAKEDA

Department of Applied Chemistry, Faculty of Science, Okayama University of Science, 1-1 Ridai-cho, Okayama 700

(Received June 29, 1984)

The relative proportion of α-helix, β, and random-coil structures in each conformation of poly(L-lysine) (PLL) caused by surfactants was computed by simulating a mixed spectrum of typical circular dichroism(CD) spectra for these structures to the experimentally obtained spectrum. Simulation was done in both the 190—250 nm and 200—250 nm regions at 1-nm intervals. The results show that PLL assumed 52 and 75% α-helix (at largest) in sodium octyl sulfate (SOS) and sodium 1-octanesulfonate solutions, respectively. The α-helical structure was found to coexist with considerable amounts of β and random-coil structures in these surfactant solutions. For instance, 51% α-helical structure coexisted with 29% β-structure and 20% random-coil structure in 6.0 mmol dm^{-3} SOS. In contrast, PLL did not assume any α-helical structure in the concentration range of 0 to 10 mmol dm^{-3} sodium dodecyl sulfate(SDS). Rather, the random-coil structure was transformed to a β-structure when SDS was added to PLL. The effects of NaCl and of 1-octanol on the relative proportions of the three structures in PLL were also examined.

Conformational changes of homopolypeptides have been extensively studied using circular dichroism (CD) measurements. Poly(L-lysine) (PLL) has been frequently selected as a typical polypeptide because of its diversity in conformations.[1-8] The conformational change of PLL induced by surfactants has been studied by a number of investigators.[3-8] The conformation of PLL transforms to α-helix and then β-structure with an increase of sodium octyl sulfate (SOS)[3,7], while it transforms to the β-structure and then to the α-helical structure with an increase of sodium 1-octanesulfonate.[6] The PLL assumes a β-structure in solutions of sodium alkyl sulfates with hydrophobic chains longer than ten carbons.[3-5,8] However, few attempts have been made quantitatively to estimate the relative proportions of α-helix, β, and random-coil structures in the conformations of homopolypeptides induced by surfactants.

The CD spectra of the various structural conformations in a polypeptide chain are assumed to be additive.[9-18] This is now commonly accepted even for proteins which have more complex conformations than the homopolypeptides.[9-18] The relative proportion of α-helix, β, and random-coil structures can be estimated from the experimentally obtained spectrum of a polypeptide with known reference spectra of the three structures. In the present study, the relative proportion of the three structures in PLL has been computed at various concentrations of the three surfactants, SOS, sodium 1-octanesulfonate, and sodium dodecyl sulfate (SDS). This has been achieved by simulating a mixed spectrum of the typical CD spectra for these structures to the experimentally obtained spectrum according to the method of Greenfield and Fasman.[9]

Experimental

The source of PLL has been described elsewhere.[7] The SOS and SDS used were the same samples as used before.[8,19] The 1-octanol was purchased from Aldrich Chemical Co. (purity: 99%).

CD measurements were made with a JASCO J-500A spectropolarimeter equipped with a DP-501 data processor. Details of the CD measurements have been described previously.[7] All measurements were carried out at 20 °C and at a neutral pH.

Results and Discussion

The CD spectrum is a curve of continuous values of the residue ellipticity of structural elements averaged over a certain wavelength region. By examining the shape and strength of the CD spectrum over the region of π-π* and n-π* transitions,[9] the relative proportions of α-helix, β, and random-coil structures could be obtained on each conformation of PLL which was considered to partially assume these three structures in surfactant solutions.[3-8]

It has been found that PLL assumes an α-helical structure only in solutions of SOS[3,7] and sodium 1-

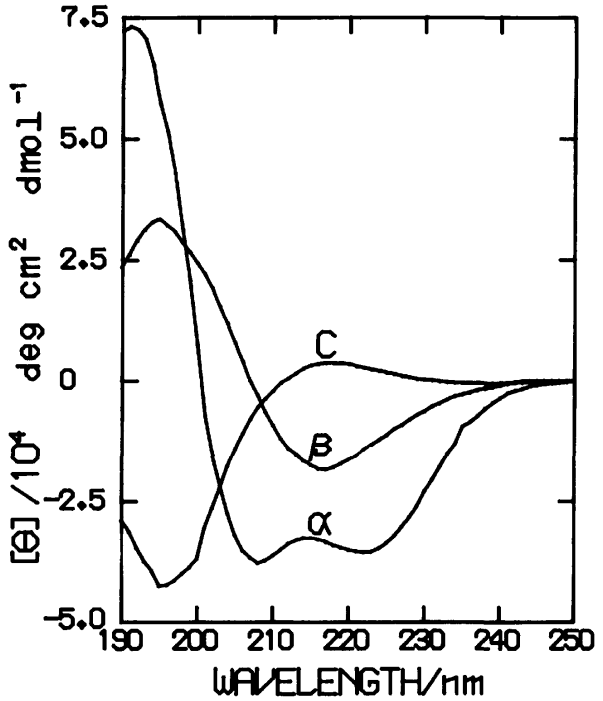

Fig. 1. Three reference spectra of α-helix (α), β-structure (β), and random coil structure (C) of PLL. Preparations of the three forms were described in text.

octanesulfonate[6] which have the same hydrophobic chain of 8 carbons. The CD spectra of PLL, in SOS concentrations between 4 and 6 mM (1 M=1 mol dm^{-3}), show a double-negative maximum which is indicative of the α-helix.[7] PLL also displays two types of CD spectra which characterize random-coil and β structures below and above the concentration range of SOS, respectively.[7] In sodium 1-octanesulfonate solutions, the CD spectra of PLL are dependent on the concentration. At concentrations of the surfactant below 6 mM, they are characteristic of a random conformation, of the β-structure between 6 and 8 mM, and of the α-helix structure above 8 mM.[6]

Figure 1 shows three reference CD spectra[9] corresponding to the three structures. The reference spectra were used to analyse the experimentally obtained spectrum of PLL. The spectrum of the α-helical structure was determined at a concentration of 0.56 mM PLL (residue) at pH 11.6. The same sample of PLL was heated to 52 °C for 15 min and then cooled to obtain the spectrum of the β-structure.[20] The spectrum of PLL obtained at a neutral pH in the absence of a surfactant was used as a typical spectrum of the random-coil structure. The negative intensities of the π-π* and n-π* transitions of the α-helical PLL in surfactant solutions (Fig. 1 in Ref. 3 and Fig. 1 in Ref. 7) are considerably smaller than that of the polypeptide in the alkaline pH range (Fig. 1). This was first observed by Grourke and Gibbs with a CD spectrum of poly(L-ornithine) in the α-helical state in SDS.[21] It is not clear whether this is due to an environmental effect of the surfactant ions on the rotational strength of the two transitions or due to an incomplete α-helix formation. However, when PLL adopts a β-structure in SDS, the positive intensity of the π-π* transition becomes larger[8] than that of a typical reference spectrum (Fig. 1). The intensities of both transitions are somewhat less in β-structured PLL in SOS[7] than in SDS[3,8] in spite of the fact that SOS has a shorter chain length than SDS. The environmental effect is expected to decrease with a decrease in the chain length of the surfactant. Furthermore, the CD spectra of α-helical PLL shows stronger negative intensities in sodium 1-octanesulfonate[6] than in SOS,[7] although both have the same chain length. These facts are not sufficient to conclude that there is no appreciable environmental effect on the two transitions, but lead us to suspect that the low intensities of the CD spectra are due to an incomplete formation of the ordered structures in these surfactant solutions. Then, it is assumed that surfactant ions have little effect on the rotational strengths of the transitions. This assumption is also supported by the results of the present computation on the relative proportions of the three structures. This will be discussed further.

If PLL takes either of the three structures—α-helix, β, and random-coil structures, the observed residue ellipticity, $[\theta]_{obsd}$, is represented by

$$[\theta]_{obsd} = f_\alpha[\theta]_\alpha + f_\beta[\theta]_\beta + f_c[\theta]_c$$

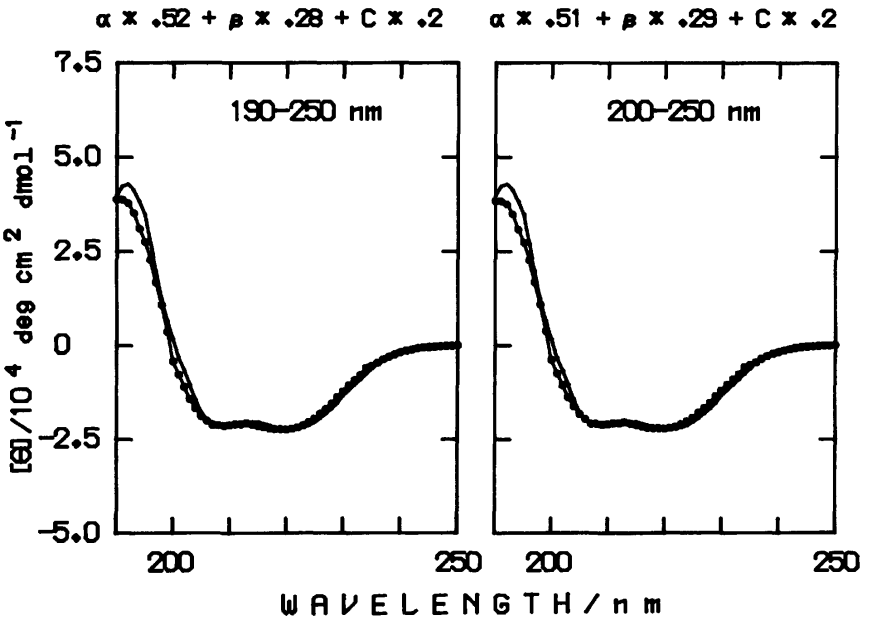

Fig. 2. The computed (—●—) and the experimental (——) CD spectra of PLL in 6.0 mM SOS. The concentration of PLL was 0.56 mM (residue). The simulation was done in two wavelength regions of 190—250 nm (left) and 200—250 nm (right). In the simulation done in 200—250 nm (right), the spectrum was calculated also in the range of 190—200 nm using the relative proportions of the three structures determined in 200—250 nm. The formula on each figure indicate that the computed spectrum consists of the three structural elements with given fractions.

where $[\theta]_\alpha$, $[\theta]_\beta$, and $[\theta]_c$ are the residue ellipticities of the reference spectra of the α-helix, β, and random-coil structures, respectively and f_α, f_β, and f_c are the relative proportions of the corresponding structures. No constraints are imposed on the relative proportions, f_i, except that they add up to unity: $\sum f_i = 1$. The computation was done in the 190—250 nm and 200—250 nm regions at 1-nm intervals by varying the amounts of each structure at 1% intervals. Figure 2 shows simulations of CD spectra of PLL which had a double-negative maximum indicative of the α-helical structure. The results indicate that the PLL contains 51—52% α-helix, 28—29% β-structure, and 20% random-coil structure. Figures 3 and 4 present the simulated spectra when PLL adopted predominantly β and random-coil structures, respectively. There is a considerable difference between the relative proportions obtained by the simulations in the 190—250 nm and 200—250 nm regions in Fig. 4. In this case, the greatest difference appeared between the two simulated spectra over the wavelength regions of this investigation. This might be due to the assumption used here that only the three structures are adopted. It appears possible that PLL may also contain slight amounts of structures other than these three since the cationic PLL is not fully neutralized in low concentrations of the surfactant. The simulation was conducted in the two wavelength regions stated above. It is well known that the signal-to-noise ratio decreases with a decrease in wavelength, especially below 200 nm. Therefore, if possible, the simulation should be done above 200 nm. However, when PLL predominantly assumes a random-coil structure, it shows a distinct spectrum only in the region below 210 nm. The values computed in the 190—250 nm region were useful in the case of PLL rich in the random-coil structure. When PLL assumes α-helix and β-structure (both of which show characteristic CD curves in the 200—250 nm region), the relative proportions computed in this wavelength region are considered to be reliable.

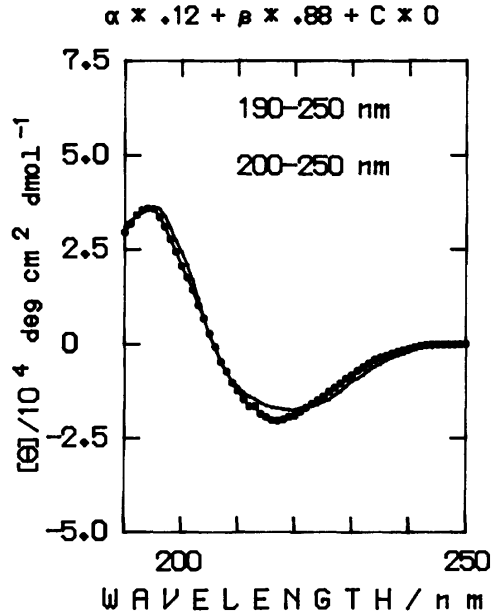

Fig. 3. The computed (—●—) and the experimental (——) CD spectra of PLL in 8.0 mM SOS. The simulations in both wavelength regions of 190—250 nm and 200—250 nm gave the same relative proportions in SOS of this concentration.

Figure 5 shows changes in the relative proportions of the three structures as a function of SOS concentration. As can be seen, PLL assumes an α-helical structure between 2 and 9 mM SOS. The α-helix content was around 52% in 4 to 6 mM SOS. The content of the β-structure increased with an increase in SOS concentration, while that of the random-coil structure decreased with an increase in surfactant concentra-

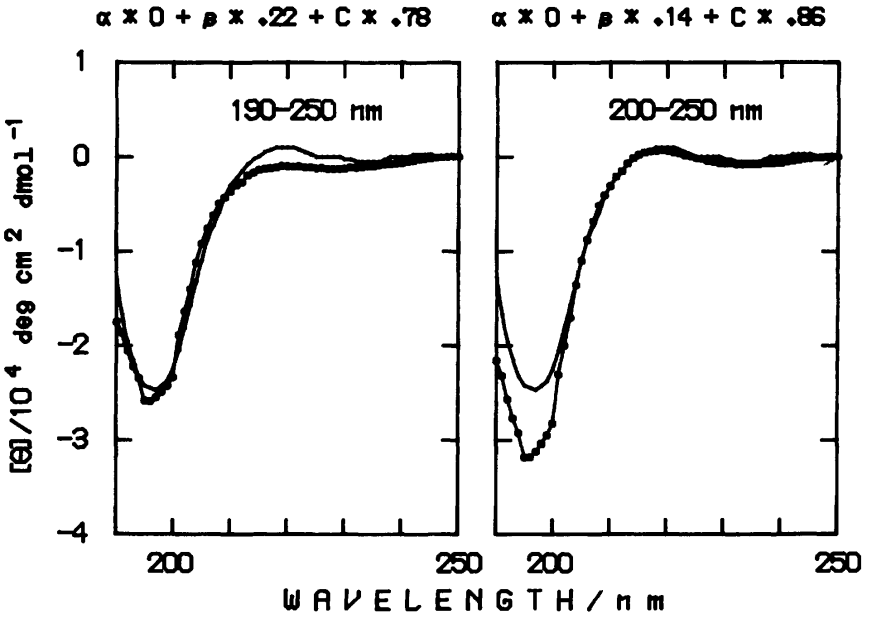

Fig. 4. The computed (—●—) and the experimental (——) CD spectra of PLL in 2.0 mM SOS.

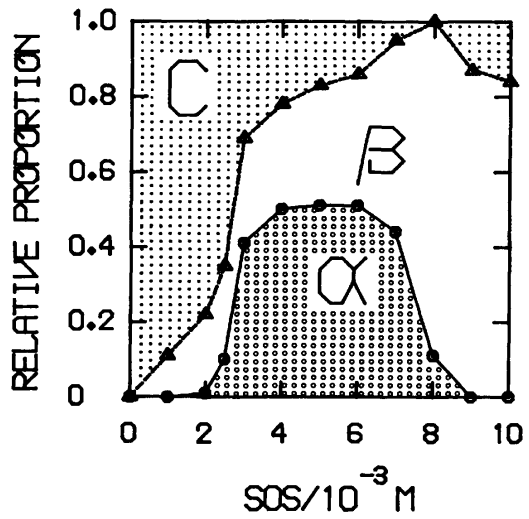

Fig. 5. The relative proportions of α-helix (α), β-structure (β), and random coil structure (C) of PLL as a function of SOS concentration. The boundary between the α-helix and the β-structure is plotted (—○—) and that between the β-structure and the random coil done (—△—). Then each area gives the fraction of the corresponding structure. The same method was used in following figures.

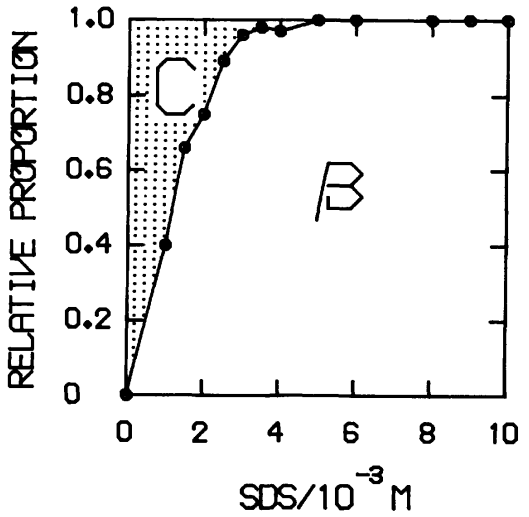

Fig. 6. The relative proportions of β-structure (β) and random coil structure (C) of PLL as a function of SDS concentration. The simulation was done by the same program as applied to the case of PLL in SOS solutions. The α-helix fraction was zero over the entire SDS concentrations in both the computations in 190—250 and 200—250 nm.

tion. The relative proportion of the β-structure and the random-coil structure was 29—35% and 26—14%, respectively in an SOS concentration range of 4 to 6 mM, while PLL assumed predominantly the α-helix structure in this range. Simulation was done for the CD spectra measured in 0.14 to 0.79 mM PLL (residue). However, a change in the concentration of PLL did not have any effect on the relative proportions of the three structures.

PLL assumes a β-structure in solutions of sodium decyl sulfate[5] and SDS.[3,4,8] Figure 6 shows changes in the relative proportions of the α-helix, β, and random-coil structures in an SDS solution. The computation was carried out by a similar simulation method as was done for the PLL conformation in SOS to obtain the relative proportions of the three structures. The α-helix content was negligible over the entire range of SDS concentration. The β-structure content increased with an increase in SDS concentration upto 5.0 mM and finally attained 100%. If there is an environmental effect of surfactant ions to decrease the CD intensities,[21] we cannot estimate 100% proportion of the ordered structure in surfactant solutions without taking into account the fading of the CD spectra. Nevertheless, the present simulation shows that PLL assumes a 100% β-structure in SDS solutions. This result also indicates that there is no appreciable environmental effect of surfactant ions on the CD intensities.

Simulation was also done on the CD spectra of PLL in sodium 1-octanesulfonate solutions containing 21.3 mM NaCl measured by Hayakawa *et al.*[6] Table 1 presents the relative proportions of the three structures in conformations of PLL caused by sodium 1-octanesulfonate. The result shows that the random-coil structure of PLL is sharply transformed to the β-structure between 5.57 and 6.07 mM of the surfactant and the β-structure content decreased above 8.30 mM. The α-helical structure is formed above 8.10 mM of the surfactant. At a surfactant concentration of 10.1 mM where the residue ellipticity at 222 nm becomes constant (see Fig. 2 in Ref. 6), 75% α-helix coexists with 11% β-structure and 14% random-coil. It is interesting to note that the coil to β-structure transition occurs predominantly in lower concentrations of sodium 1-octanesulfonate and the coil to α-helix transition in higher concentrations, in contrast to the transitions in

Table 1. Relative proportion of α-helix, β-structure, and random-coil structure of PLL in sodium 1-octanesulfonate solutions[a]

Concentration of sodium 1-octanesulfonate/mM	α-Helix	β-Structure	Random-coil	Simulated region of wavelength/nm[b]

a) Values simulated in 200—250 nm region.

SOS. It has been reported that PLL assumes an α-helical structure only in SOS[7)] and sodium 1-octanesulfonate[6)] solutions of a neutral pH. However, it is not clear to what degree the α-helical structure is formed. An important result of the present simulation is the knowledge that the α-helical structure coexists with the other two structures in both the surfactant solutions.

The effect of the addition of 1-octanol on the relative proportions of the three structures was examined on the conformation of PLL in 6.0 mM SOS. Figure 7 shows the changes in relative proportions of the three structures as a function of 1-octanol concentration. The α-helix content increased until 2.0 mM octanol and abruptly decreased beyond 2.6 mM. A small amount of octanol seems to provide the best condition to form the α-helical structure, but a greater hydrophobic atmosphere enhances the β-structure. The content of the random-coil structure decreased from 14% to 0% upto 2.6 mM octanol. Therefore, only the α-helix and β-structure exist above 2.6 mM octanol in the presence of 6.0 mM SOS.

We have previously found that the double-negative maximum of PLL, which is a characteristic of the α-helical structure, fades out with an increase in the added NaCl concentration in an SOS solution (Fig. 4 in Ref. 8). These fading CD spectra of PLL by the addition of NaCl were simulated in the same manner. The results are shown in Table 2. The presence of 20—25 mM NaCl reduces the α-helix content to approximately half of that found in the absence of the electrolyte. The content of the random-coil structure was essentially constant below 25 mM of NaCl. Therefore, it appears that the addition of NaCl changes the relative proportions of only the α-helix and β-structure. In the presence of about 20 mM NaCl, the α-helix content of PLL in SOS is one third of that in sodium 1-octanesulfonate. The present result indicates that in addition to the chain length of the hydrophobic group and charge of the hydrophilic group of surfactant, the structural features of the hydrophilic group are also important for the induction of the α-helical structure.

Structure Model for Liquid Carbon Tetrachloride

Keiko NISHIKAWA* and Takao IIJIMA
Department of Chemistry, Faculty of Science, Gakushuin University, Mejiro, Toshima-ku, Tokyo 171
(Received April 25, 1984)

The X-ray scattering intensity for the visualized structure model of a liquid is formulated. It is ascertained that by the bcc model for liquid carbon tetrachloride the experimental intensity has been simulated well.

The structures of gases and crystals have been studied extensively by diffraction methods. For liquids, however, the structure analysis is rather difficult. The fundamental difficulty is that there is no idealized abstraction of the liquid state such as an ideal gas or a perfect crystal. In the gaseous state, the interaction between molecules can be neglected in many cases and only one molecule is taken into consideration for the structure analysis. Crystals are characterized by the regularity in their configuration. So, we know the crystal structure only by studying the arrangement of molecules or atoms within a unit cell. However, in the liquid state which is a condensed phase and has no such regularity in the arrangement of molecules in crystals, it is difficult to obtain the information about the molecular arrangement immediately from experimental diffraction intensities or from radial distribution functions.

One approach to overcome the difficulty is to construct a model in which we visualize a structure of liquids,[1,2] and to calculate the diffraction intensity for the structure model, which is to be tested against the experimental intensity. In constructing a model we may describe the structure of the liquid as follows. We assume a certain nearest-neighbor configuration around a central molecule and repeat this structural unit by some specified rule. According to this model the average molecular positions, as viewed from the location of a given central molecule, conform to a certain lattice structure. Unlike the crystalline case, however, repetition of the structure unit is imperfect and therefore is accompanied by rapid loss of positional correlation as the distance between the central molecule and surrounding ones increases. This loss of correlation may be embodied in the model in the form of mean-square amplitudes of distribution of the separation between atoms which increase rapidly with the distance. At least beyond a few molecular radii away from any starting point, the structure can be regarded as a continuum. This relative distribution must obviously be independent of the choice of the central molecule. Such a structure model for liquids may be called the "local lattice structure model." Some investigators have denied such crystalline-like model for the liquids,[3] but there are in fact some examples in which diffraction intensities are explained by the "local lattice structure model." Moreover, such a lattice model may be useful in serving to keep away from the inherent difficulty of statistical theories of liquids, because such local structure of the liquid reflects directly the strong molecular interactions, which are essential to the properties of the liquid.

The analysis of the diffraction intensity for liquids by constructing a structure model has been made by several authors.[4-8] However, there has been some confusion in formulating the scattering intensities from structure models. So, we feel it necessary to reproduce the correct formulation of the scattering intensity for the visualized structure model of liquids originally put forward by Narten and Levy.[2,4]

In a preceding paper we reported improved X-ray diffraction data of liquid carbon tetrachloride.[9] So, we determine a structure model for liquid carbon tetrachloride on the basis of the correct formulation of the scattering intensity. Among the various models which have so far been suggested for the structure of liquid carbon tetrachloride,[6-8] the bcc model is confirmed to be the one that gives the best agreement between theory and experiment.

Scattering Intensity from Liquids[2,4]

In the following, we consider X-ray scattering intensity from a liquid sample. The region denoted by C in Fig. 1 shows the effective volume radiated by X-rays. The total coherent intensity scattered from this region which contains N molecules is given by[10]

$$I' = \sum_{j}^{N}\sum_{i}^{N} f_i f_j \frac{\sin sr_{ij}}{sr_{ij}} \exp\left(-\frac{l_{ij}^2}{2}s^2\right), \qquad (1)$$

where f_i is the atomic scattering factor of the i-th atom and s is the scattering parameter defined by $4\pi\sin\theta/\lambda$, λ: wavelength, 2θ: scattering angle. The notation l_{ij} is the root mean-square amplitude due to the dis-

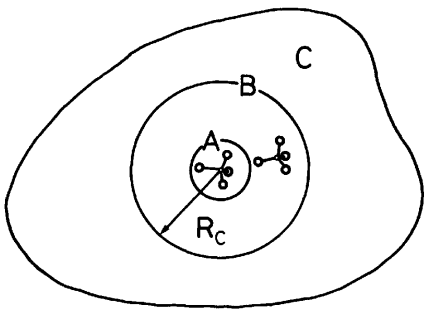

Fig. 1. Schematic model of a liquid. The region A shows a molecule or one stoichiometric unit of the liquid. The molecule "feels" the "structure" around itself up to the distance R_c. This structure region is denoted by B. The region C shows the effective volume irradiated by X-rays, and the region (C-B) is viewed as continuous from A.

tribution averaged over both time and space around the mean interatomic distance r_{ij}. The summation is over all atoms in the volume C. Here, we can define by I the scattering intensity per molecule or one stoichiometric unit in the liquid. Namely,

$$I = I'/N = \sum_{j\subset C}\sum_{i\subset A} f_i f_j \frac{\sin sr_{ij}}{sr_{ij}} \exp\left(-\frac{l_{ij}^2}{2}s^2\right), \quad (2)$$

where the summation is now over the stoichiometric unit A (Fig. 1) for i and over all atoms in the sample for j. The region A shows a central molecule or a unit as is mentioned in the introductory section. It is noted that any molecule or any stoichiometric unit in the liquid except for surface molecules is eligible to be this central unit.

In Eq. 2, however, it is hardly possible to perform the summation for j for the assumed liquid structure. For such a model of the liquid structure to be tractable, Narten and Levy terminated the series of terms of j at a distance R_c from a central molecule, and assumed a continuous distribution beyond this distance.[2,4] The sphere with the radius R_c is shown by the region B. Namely, a molecule or one stoichiometric unit (region A) "feels" the "structure" around itself up to the distance R_c and the region beyond R_c is regarded as a continuum in the distribution of the molecules. So, the scattering intensity per molecule in a liquid is given by

$$I = I_d + I_c, \quad (3)$$

where I_d is the contribution from the interference of a central molecule and those in the region of discrete structure B around it, given by

$$I_d = \sum_{j\subset B}\sum_{i\subset A} f_i f_j \frac{\sin sr_{ij}}{sr_{ij}} \exp\left(-\frac{l_{ij}^2}{2}s^2\right). \quad (4)$$

The summation for j is over all atoms in the region B. The contribution from the interference of a molecule and the continuous region is given by

$$I_c = \sum_{i\subset A} f_i \langle F\rangle \rho_0 \int_{R_c}^{\infty} 4\pi r^2 \frac{\sin sr}{sr} dr, \quad (5)$$

where ρ_0 is the bulk number density of molecules of the liquid and the mean scattering amplitude of the molecule $\langle F\rangle$ is given by

$$\langle F\rangle = \sum_{i\subset A} f_i. \quad (6)$$

On integration of Eq. 5 we obtain[11]

$$I_c = \sum_{i\subset A} f_i \langle F\rangle 4\pi\rho_0 \frac{sR_c\cos(sR_c) - \sin(sR_c)}{s^3} \exp\left(-\frac{l_c^2}{2}s^2\right) = \sum_{i\subset A} f_i \langle F\rangle n \frac{3\{sR_c\cos(sR_c) - \sin(sR_c)\}}{(sR_c)^3} \exp\left(-\frac{l_c^2}{2}s^2\right). \quad (7)$$

A "temperature factor" l_c is included in Eq. 7 in order to connect the continuous region to the discrete region as smoothly as possible. The notation n is the number of molecules included in region B. Using Eqs. 4 and 7, we can calculate the scattering intensity for any structure model of the liquid.

Sometimes there was confusion in making the summation for Eq. 4 in previous papers on the simulation study of the liquid structure. In some papers, the summation is taken over all the atoms in the region B, namely for i and j. The intensity thus calculated will not be the intensity of the liquid but that of a cluster floating in a continuous medium. For example, Narten and Levy described the theory correctly in deriving the scattering intensity for the model structure of water.[2,4] In the meantime, however, they gave a different expression for the scattering intensities for liquid carbon tetrachloride[6] and liquid benzene,[5] as if they had calculated the intensities of their "clusters." For the case of the simulation studies for liquid carbon tetrachloride, Reichelt *et al.*[7] and Nishikawa and Murata[8] took the summation over all the atoms in the discrete structure. Recently Arakawa *et al.* criticized[12] the correct summation of Narten and Levy.[2,4]

There is also some other confusion about the formulation of the scattering intensity mentioned in this section. Powles stated that the contribution from the continuous region diverged,[13] namely, the integration given by Eq. 5 in the present paper diverged. So he asserted that the "local lattice structure model" was inadequate for the description of the liquid structure. However, the integration of Eq. 5 coverges[14] as given by Eq. 7 excluding the term of $\exp(-l_c^2 s^2/2)$. Powles also remarked that the term of $\exp(-l_c^2 s^2/2)$ was introduced in order to circumvent the divergence of the integration.[13] However, this explanation is not correct. The problem in the "local lattice structure model" is the discontinuity between the discrete region and the continuous region. The introduction of the term $\exp(-l_c^2 s^2/2)$ in Eq. 7 is only to smear this discontinuity.

The Structure Models for Liquid Carbon Tetrachloride

Many diffraction experiments for liquid carbon tetrachloride have been carried out.[6-8,15-19] However, the visualized structure models were proposed by Narten and Levy,[6] by Egelstaff *et al.*,[18] by Reichelt *et al.*,[7] and by Nishikawa and Murata.[8] Also, Lowden and Chandler proposed a model for liquid carbon tetrachloride on the basis of their RISM (reference interaction site model) calculation,[20] although it is not the result of diffraction experiments. These models have been summarized briefly in Ref. 21.

For these models, namely, the Pa3 model,[6] the monoclinic model[7] and the bcc model,[8] the respective scattering intensities were calculated, though all the calculations were imperfect as noted in the previous section. However, the imperfection did not cause any serious defect, because the calculated intensities were those for respective clusters and they are different from

the correct intensities of the liquid in the weight for each atomic distance. Although some errors may have been contained in the intensities or the estimated root mean square amplitudes, the main features, especially the phases for the intensity curve, are reproduced. These three models are different from each other in three-dimensional packing, but the one dimensional scattering intensity curves happen to be similar to each other.

One cause of the difficulty in the structure analysis of liquids is that there is no general method to determine the structure of the liquid uniquely from the scattering intensity. Even if we are lucky enough to obtain a model whose calculated intensity agrees well with the experimental one, there is no assurance that the model is correct. Especially for molecular liquids, we must determine the molecular orientation and the intermolecular distances from a halo-pattern.

In the case of carbon tetrachloride, there exist plastic crystal phases. The plastic crystal can be regarded as an intermediate state between the ordered crystal and the liquid. The result of the structure analysis of the plastic crystal of carbon tetrachloride gives a helpful suggestion for the structure of the liquid carbon tetrachloride, as was mentioned in a previous paper.[21] In the structure analysis of the plastic phase Ia of carbon tetrachloride, the following result has been obtained.[21] Namely, the intermolecular distance between carbon tetrachloride molecules is 5.90 Å and the orientational correlation of neighboring molecules is explained by the head-tail head-tail packing.

Simulation of the Weighted Structure Function by the bcc Model

As is mentioned above, the most probable packing for the molecules of liquid carbon tetrachloride is the head-tail head-tail packing. By the repetition of this head-tail head-tail packing with eclipsed form for the off-axis chlorine atoms, we obtain a bcc lattice. Accordingly, we calculate here the scattering intensity from the bcc model and compare it with the experimental one.[9]

We examine how many molecules are suitable to be arranged around a central molecule with the nearest neighbor distance R of 5.9 Å.[22] For the values of the intramolecular distances $r_{C\text{-}Cl}$ and $r_{Cl\text{-}Cl}$ and their root mean square amplitudes $l_{C\text{-}Cl}$ and $l_{Cl\text{-}Cl}$, the results obtained by gas electron diffraction[23] are used. They are almost the same as the recent result for the liquid by neutron scattering experiments.[24]

Using Eqs. 4 and 7, we calculated the total coherent intensity and derived the weighted structure function $si(s)$,

$$si(s) = s(I - \sum_{i \subset A} f_i^2) = s(I_d - \sum_{i \subset A} f_i^2 + I_c) \quad (8)$$

for the bcc lattice where eight molecules are arranged as the first nearest neighbors around one molecule ($n=9$) and the distribution of molecules is assumed to be continuous beyond the distance R_c. The critical radius R_c is determined by the relationship

$$n = \frac{4}{3}\pi R_c^3 \rho_0, \quad (9)$$

where ρ_0 is the bulk number density of carbon tetrachloride molecules in the liquid phase. The mean square amplitudes are determined according to the "structural diffusion" model[1]

$$l_{ij}^2 = Dr_{ij}. \quad (10)$$

The calculated structure function reproduces main peaks and valleys of the experimental $si(s)$ curve, but their heights and depths can not be simulated even if the value D in Eq. 10 is changed. So, we repeat the same procedure one after another with the increase of the number n contained in B region (Fig. 1). At the number of $n=51$ (up to the fourth nearest neighbors around the central molecule), the experimental curve is simulated satisfactorily and further increase of n no longer changes the feature of the calculated curve.

Next, we investigate the root mean square amplitude l_{ij} in detail. Until now, we use the Prins relation (Eq. 10) for estimating the value of l_{ij} in relation to its interatomic distance r_{ij}. A value 0.0716 for D is suitable. This means that the root mean square variation of the distance between the nearest neighbor molecules is about 0.65 Å, which is about 11% of the equilibrium separation of the two molecules (5.9 Å). However, by only one value for D, the third peak of $si(s)$ curve at $s \approx 3.2$ Å^{-1} shifts to about 3 Å^{-1}, so we use two constants for the relation of Eq. 10. Namely,

$D_1 = 0.0716$ for the 1-st nearest neighbor molecules.
$D_2 = 0.1224$ for the 2-nd, 3-rd, and 4-th nearest neighbor molecules.

The result is shown in Fig. 2 by the solid curve with the experimental $si(s)$ curve[9] denoted by circles. The region from $s=0$ to 6 Å^{-1} is shown, because the $si(s)$ curve in the region of s larger than 6 Å^{-1} is approximately represented by a free carbon tetrachloride molecule and is hardly affected by intermolecular interference.

By theoretical investigations on the quasi-crystalline model for liquids, Medvedev *et al.*[25] and Baer[26] proposed a further modified "structural diffusion" relation

$$l_{ij}^2 = D(r_{ij} - r_0) \quad (11)$$

in place of the equation given by Eq. 10. Using this relation, we carried out the least-squares analysis for the parameters R, D, r_0, R_c, and l_c, with the number n fixed at 51. The result is shown in Table 1. The $si(s)$ curve calculated by using these parameters is in slightly poorer agreement with the experimental one in the

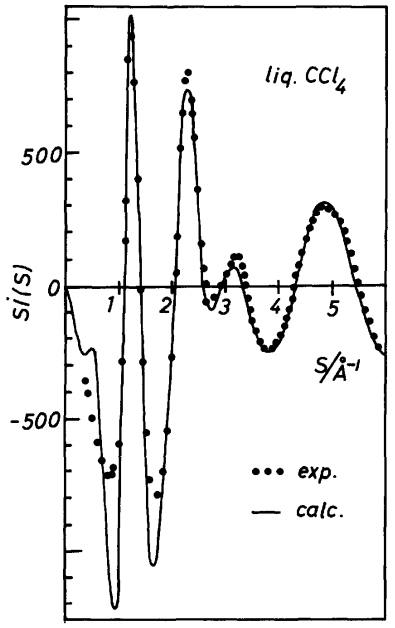

Fig. 2. The weighted structure functions $si(s)$ for liquid carbon tetrachloride. The solid curve is the calculated one for the bcc model with two D coefficients. The circles are experimental values.[9]

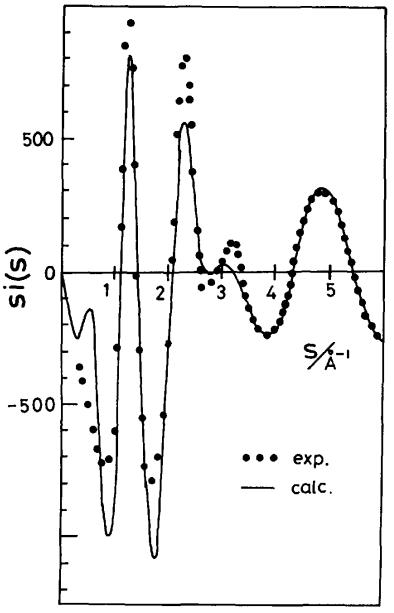

Fig. 3. The weighted structure functions $si(s)$ for liquid carbon tetrachloride. The solid curve is the calculated one for the bcc model with the relation of the root mean square amplitudes given by Eq. 11.

TABLE 1. THE REFINED PARAMETERS FOR THE BCC MODEL[a]

R/Å 5.90 (2)	R_c/Å 12.41 (3)
D/Å 0.158 (23)	l_c/Å 1.76 (76)
r_0/Å 2.46 (74)	

a) The values in the parenthesis are standard deviations.

peak height of the first and second peak as is shown in Fig. 3, than the case of the calculated $si(s)$ curve using the two D_1 and D_2 coefficients. The result in Table 1 shows that the parameters for the distances converge very well, but not for the mean square amplitudes. This may indicate that the theoretical expression for the loss of positional correlation of the molecules from the equilibrium position in the liquid is not satisfactory. In the least squares analysis, R_c is changed as a fitting parameter, and its value has converged exactly to the value obtained by Eq. 9.

Discussion

In Fig. 2, the circles are the experimental intensities which are obtained by the improved and revised analysis of the energy-dispersive X-ray diffractometry.[9] This experimental result is in good agreement with Narten's result obtained by the angle-dispersive method.[19] In the previous work, one of the present authors (K. N.) reported that there were fine structures in the diffraction pattern of liquid carbon teterachloride,[8] but it has been proved that they are not fine structures from the liquid but are the parasitic scattering from Myler windows of the sample holder.

As is shown in Fig. 2, the calculated intensity for the bcc model is in good agreement with the experimental one except for the depth of the valley at $s=1.7$ Å^{-1} and the intensity ranging from 0 to 1.2Å^{-1}. The disagreement in the intensity at $s=1.7$Å^{-1} has not been explained. We could not simulate the depth of the valley by changing the value of D without disturbing the balance of the other peaks and valleys in the intensity curve.

The discrepancy of the intensity ranging from 0 to 1.2Å^{-1} between the calculated and experimental intensities is explained by the unreasonable connection of the discrete structure region (B in Fig. 1) and the continuum region. In order to connect the two regions as smoothly as possible, we introduce the "temperature factor" intentionally in Eq. 7 in the form of $\exp(-l_c^2 s^2/2)$, but there is is no physical reason for this expression. In other words, l_c is not the root mean square amplitude of the radius R_c.

In the case of liquid carbon tetrachloride, the success in modeling the structure by the "local lattice structure model" may be due to the long range correlation of the liquid; that is, the discrete region is comparably large, so the ghost peaks in the scattering curve caused by an unreasonable connection appear at small s-values and are easily distinguishable from the relevant peaks of the liquid.

The method of structure simulation of the scattering intensity mentioned above can be called "real space expansion," where we calculate the scattering intensity by summing up the contributions from each atomic distance in the liquid described by a real space. It is concluded that for the simulation method of the "real space expansion" the convergence is very poor in the small s-region of the intensity curve. To achieve a much better convergence of the simulation for the scattering intensity at the small s-region, a different formulation called "reciprocal space expansion" seems

to be promising.[27]

In order to express the structural diffusion of the liquid, we tried two methods, namely, one introducing two D coefficients for Eq. 10 and the other using the relation described by Eq. 11. The former leads to a more satisfactory simulation. However, it has been reported that the latter expression is more suitable to describe the temperature factor of monoatomic liquid than the expression of Eq. 10.[25,26] In the case of a molecular liquid such as carbon tetrachloride, the shape of the molecules itself seems to play an important role. Especially for liquid carbon tetrachloride, the gear-like packing of tetrahedral molecules may be important in determining the structure. We have therefore derived a more sophisticated formulation for the mean square amplitudes for liquid carbon tetrachloride, taking into account the shape of the molecules; the result is reported in a succeeding paper.[28]

In conclusion the bcc model for liquid carbon tetrachloride explains well the scattering intensity. Of course, the bcc model may not be the only one model representing the experimental intensity. However, few other arrangements seem to be left for the structure model, because almost all the fundamental packings acceptable for tetrahedral molecules were checked in the structure study of the plastic crystal phase.[21] The head-tail head-tail packing shows that the octopole interaction is important in determining the structure of the liquid. The head-tail head-tail packing is highly stabilized for the molecules with an octopole moment.[29]

Mean Square Deviations of Interatomic Distances in Liquid Carbon Tetrachloride

Keiko NISHIKAWA* and Takao IIJIMA
Department of Chemistry, Faculty of Science, Gakushuin University, Mejiro, Toshima-ku, Tokyo 171
(Received July 10, 1984)

In simulating the X-ray scattering intensity of liquid carbon tetrachloride, the structural diffusion model for the bcc local structure has been refined by formulating the mean square deviations of interatomic distances by dividing them into two parts, namely, translational and rotational contributions. By this treatment, the simulation has not been improved in comparison with the modified Prins relation, but the description of the motion of carbon tetrachloride molecules in the liquid becomes clear. The degree of depolarization of the ν_1 Raman line is well accounted for by the use of the translational mean square deviations determined.

The structure of liquids has long been the least understood among those of the three phases of matter, and it still is. Nevertheless, it is fair to say that many works, especially recent diffraction experiments[1-5] and computer simulations,[6,7] have made it clear to a great extent.

From the stand-point of diffraction studies, it is convenient to use a visualized structure model for a liquid and calculate the diffraction intensity for the strùcture model, which is to be tested against the experimental intensity. In order to calculate the diffraction intensity of the structure model, it is necessary to construct a local lattice structure around a molecule and to express the structural diffusion by the width of atomic pair distribution. This will increase with the increase of the interatomic separations. Even in a molecular liquid, the expression for the diffraction intensity becomes more tractable if it is based on the atomic pair distribution, than on the molecular pair correlation function which is usually expanded in terms of Wigner rotation matrices.[8]

The mean square deviation of the interatomic distances due to the width of the pair distribution is often called the mean square amplitude,[2] by analogy with atomic distances in a free molecule where the distribution is caused exclusively by vibrational motion. If the local lattice structure is determined and the mean square deviation is given to each atomic pair by the use of a reasonably small number of parameters, the structure of a liquid may be said to be elucidated.

In previous papers,[2,3] it has been shown that the experimental X-ray scattering intensity of liquid carbon tetrachloride[4] is simulated in good approximation by the bcc model for the local lattice structure. In this model a chlorine atom of one molecule lies in a hollow formed by three chlorine atoms of the adjacent molecule, and the threefold axes of these molecules are aligned (see Fig. 2). This packing is called head-tail head-tail packing. By the repetition of this head-tail head-tail packing with the eclipsed arrangement for the off-axis chlorine atoms a bcc lattice is obtained. Accordingly our model for the local structure of liquid carbon tetrachloride is called a bcc model. The head-tail head-tail packing is highly stabilized for molecules with an octopole moment.[9] Moreover, this packing is known to be the fundamental orientational correlation in the plastic phase (Ia) of carbon tetrachloride.[5] It is scarcely to be doubtful that the bcc structure is the best and physically reasonable model for the local lattice structure of liquid carbon tetrachloride.

However, our knowledge about the mean square deviation to express the structural diffusion has not been satisfactory.[2] Usually, the mean square deviation l_{pq}^2 is related to the distance between the p-th and q-th atoms, r_{pq}, by the Prins relation,[10]

$$l_{pq}^2 = Dr_{pq},$$

or a modified structural diffusion relation proposed by Baer,[11]

$$l_{pq}^2 = D(r_{pq}-r_0).$$

However, it has been found that these relationships are not adequate expressions to simulate the X-ray scattering intensity from a molecular liquid such as carbon tetrachloride.[2] In this case, the distribution of the orientational fluctuation of each molecule as well as the distribution of the distance between molecular centers must be taken into account. On the basis of this inference, we derive in the present work a more sophisticated formulation for the mean square deviations for liquid carbon tetrachloride.

Mean Square Deviations

The reduced scattering intensity per molecule of liquid carbon tetrachloride is given by[2]

$$\begin{aligned} i(s) = {} & [8f_C f_{Cl} j_0(sr_{C\text{-}Cl}) \exp(-l_{C\text{-}Cl}^2 s^2/2) \\ & + 12 f_{Cl}^2 j_0(sr_{Cl\text{-}Cl}) \exp(-l_{Cl\text{-}Cl}^2 s^2/2)] \\ & + \sum_{p \neq q} f_p f_q j_0(sr_{pq}) \exp(-l_{pq}^2 s^2/2) + I_e \end{aligned} \quad (1)$$

where $j_0(x)$ is the 0-th order spherical Bessel function, *i.e.*, $\sin x/x$; f_p is the atomic scattering factor of the p-th atom, and s is the scattering parameter defined by $4\pi\sin\theta/\lambda$, λ: wavelength, 2θ: scattering angle. The first bracketed term expresses the intensity of the atomic interference in the representative or central molecule itself, and $r_{C\text{-}Cl}$, $r_{Cl\text{-}Cl}$, $l_{C\text{-}Cl}$, and $l_{Cl\text{-}Cl}$ are interatomic distances and respective root mean-square deviations of a molecule, for which the values obtained by gas electron diffraction[12] are used. l_{pq} is the root mean-square deviation for the distance r_{pq}, and I_e is the inten-

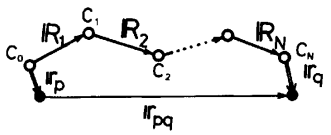

Fig. 1. The interatomic distance vector r_{pq}. The notation C_i shows the center of the i-th molecule; C_0 is the center of the representative or central molecule.

sity due to the interference of a central molecule and the continuum region. For the second term the summation for p is taken over atoms in the central molecule and for q over all atoms in the discrete structure region except for the central molecule.

We assume as a first approximation that the translational and rotational intermolecular motions are mutually independent. Then the mean square deviation l_{pq}^2 is divided into two parts, the translational contribution which reflects the distribution of the distance between molecular centers and the rotational contribution which is due to the orientational fluctuation, namely,

$$\begin{aligned} l_{pq}^2 &= \langle \Delta r_{pq}^2 \rangle \\ &= \langle \Delta r_{pq}^2 \rangle^{\mathrm{tr}} + \langle \Delta r_{pq}^2 \rangle^{\mathrm{rot}}, \end{aligned} \tag{2}$$

where Δr_{pq} is the displacement from the equilibrium distance r_{pq}. We neglect the intramolecular vibrational contribution to Δr_{pq}, which is smaller than those from the intermolecular translational and rotational motions.

Translational Contribution. Let $\boldsymbol{R}_i$ be the vector which links the centers of the $(i-1)$-th and i-th molecules that are the nearest neighbors to each other as is shown in Fig. 1. The vector $\boldsymbol{r}_p$ is the positional vector of the p-th atom from the center of the central molecule. The q-th atom belongs to the N-th molecule. The translational displacement $\Delta r_{pq}^{\mathrm{tr}}$ is given by

$$\Delta r_{pq}^{\mathrm{tr}} = \boldsymbol{\lambda}_{pq} \cdot (\Delta \boldsymbol{R}_1 + \Delta \boldsymbol{R}_2 + \cdots + \Delta \boldsymbol{R}_N) \tag{3}$$

where $\Delta \boldsymbol{R}_i$ is the displacement vector of $\boldsymbol{R}_i$ and $\boldsymbol{\lambda}_{pq}$ is the unit vector parallel to $\boldsymbol{r}_{pq}$, namely

$$\boldsymbol{\lambda}_{pq} = (-\boldsymbol{r}_p + \boldsymbol{R}_{1N} + \boldsymbol{r}_q)/|-\boldsymbol{r}_p + \boldsymbol{R}_{1N} + \boldsymbol{r}_q|. \tag{4}$$

The vector $\boldsymbol{R}_{1N}$ is given by

$$\boldsymbol{R}_{1N} = \boldsymbol{R}_1 + \boldsymbol{R}_2 + \cdots + \boldsymbol{R}_N. \tag{5}$$

In general there are many choices for the path connecting the central molecule to the N-th molecule. In the present treatment the shortest possible path is chosen in considering that Eq. 6 below is exact only when the contributions from the translational motion perpendicular to $\boldsymbol{R}_i$ can be ignored, in other words, when all $\boldsymbol{R}_i$ are on a straight line (see Appendix).

Let the unit vector along the average direction of $\boldsymbol{R}_i$ be $\boldsymbol{t}_i$. Then Eq. 3 becomes approximately

$$\Delta r_{pq}^{\mathrm{tr}} = \boldsymbol{\lambda}_{pq} \cdot (\Delta R_1 \boldsymbol{t}_1 + \Delta R_2 \boldsymbol{t}_2 + \cdots + \Delta R_N \boldsymbol{t}_N) \tag{6}$$

where ΔR_i is the component of $\Delta \boldsymbol{R}_i$ along the vector $\boldsymbol{t}_i$. Now we make assumptions as follows;

$$\langle \Delta R_i^2 \rangle = A \quad \text{for all } i, \tag{7}$$

and

$$\langle \Delta R_i \Delta R_j \rangle = \begin{cases} a & \text{for neighboring } i \text{ and } j, \\ 0 & \text{otherwise.} \end{cases} \tag{8}$$

The assumptions mean that the mean square deviation of the intermolecular separation of the neighboring molecules is A, the magnitude of the effect of coupling of adjacent intermolecular distances is described by the parameter a, and that the direct interference to the mean square deviation from the non-neighboring intermolecular distances is neglected. We obtain the following relation by using the assumptions described above,

$$\langle \Delta r_{pq}^2 \rangle^{\mathrm{tr}} = [\sum_{i=1}^{N} (\boldsymbol{\lambda}_{pq} \cdot \boldsymbol{t}_i)^2] A + [2 \sum_{i,j}{}' (\boldsymbol{\lambda}_{pq} \cdot \boldsymbol{t}_i) \cdot (\boldsymbol{\lambda}_{pq} \cdot \boldsymbol{t}_j)] a \tag{9}$$

where $\sum_{i,j}{}'$ shows the summation for i and j only when the i-th and j-th intermolecular distances are in neighbors. The coefficients for A and a can be determined when the equilibrium position and orientation for each molecule are given by a visualized structure model of the liquid.

Rotational or Librational Motion in the Liquid. The rotational displacement $\Delta \boldsymbol{r}_p$ for the p-th atom in a molecule is approximately given by

$$\Delta \boldsymbol{r}_p = \boldsymbol{r}_p \times \Delta \boldsymbol{\Omega} \tag{10}$$

where $\Delta \boldsymbol{\Omega}$ is the rotational vector with the components $\Delta \Omega_x$, $\Delta \Omega_y$, and $\Delta \Omega_z$, which are the angles of rotation around the temporarily chosen space-fixed x, y, and z-axes, respectively. Equation 10 is exact to the first order of $\Delta \boldsymbol{\Omega}$, that is, when the magnitude of $\Delta \boldsymbol{\Omega}$ is small. The displacement of the p-th and q-th atoms due to the rotational or librational motion becomes

$$\Delta r_{pq}^{\mathrm{rot}} = \boldsymbol{\lambda}_{pq} \cdot (\Delta \boldsymbol{r}_p - \Delta \boldsymbol{r}_q). \tag{11}$$

Now we also assume that for a molecule

$$\langle \Delta \Omega_s \Delta \Omega_t \rangle = W \delta_{st} \tag{12}$$

and for the neighboring i-th and j-th molecules

$$\langle \Delta \Omega_s^i \Delta \Omega_t^j \rangle = w \delta_{st}, \tag{13}$$

where

$$s \text{ or } t = x, y, \text{ or } z$$

and δ is Kronecker's delta. For non-neighboring molecules, w is assumed to be zero. When we use the components x_p, y_p, and z_p for the vector $\boldsymbol{r}_p$, we rewrite Eq. 10 as

$$\Delta \boldsymbol{r}_p = X_p \cdot \Delta \boldsymbol{\Omega} \tag{14}$$

where

$$X_p = \begin{pmatrix} 0 & -z_p & y_p \\ z_p & 0 & -x_p \\ -y_p & x_p & 0 \end{pmatrix}$$

TABLE 1. THE COEFFICIENTS OF A, a, W, AND w FOR THE BCC MODEL[a)]

	r_{pq}/Å	Trans 1	Trans 2	Rot 1	Rot 2	l_{pq}^2/Å^2

C_0-Cl_{21}	7.967	0.689	0.601	1.527	0.0	0.434
C_0-Cl_{22}	5.968	0.628	0.628	2.721	0.0	0.549
Cl_{01}-Cl_{11}	5.90	1.0	0.0	0.0	0.0	0.203
Cl_{01}-Cl_{12}	3.914	0.818	0.0	3.671	2.658	0.361
Cl_{01}-Cl_{21}	6.813	0.667	0.667	4.177	0.0	0.713
Cl_{01}-Cl_{22}	5.188	0.667	0.460	5.690	0.0	0.817

a) Trans 1 and Trans 2 are the coefficients of A and a, in Eq. 9, respectively. Similarly, Rot 1 and Rot 2 are the coefficients of W and w, in Eq. 19, respectively.

From Eq. 11, we obtain the following relation

$$\langle \Delta r_{pq}^2 \rangle^{\mathrm{rot}} = \langle (\boldsymbol{\lambda}_{pq}\cdot\Delta\boldsymbol{r}_p)^2 \rangle + \langle (\boldsymbol{\lambda}_{pq}\cdot\Delta\boldsymbol{r}_q)^2 \rangle - 2\langle (\boldsymbol{\lambda}_{pq}\cdot\Delta\boldsymbol{r}_p)(\boldsymbol{\lambda}_{pq}\cdot\Delta\boldsymbol{r}_q) \rangle. \quad (15)$$

Here,

$$\boldsymbol{\lambda}_{pq}\cdot\Delta\boldsymbol{r}_p = \tilde{\boldsymbol{\lambda}}_{pq}\cdot X_p\cdot\Delta\boldsymbol{\Omega} \quad (16)$$

where $\tilde{\boldsymbol{\lambda}}_{pq}$ is the transposed vector of $\boldsymbol{\lambda}_{pq}$. Therefore, we have

$$\langle (\boldsymbol{\lambda}_{pq}\cdot\Delta\boldsymbol{r}_p)^2 \rangle = \langle \tilde{\boldsymbol{\lambda}}_{pq} X_p \Delta\boldsymbol{\Omega} \Delta\tilde{\boldsymbol{\Omega}} \tilde{X}_p \boldsymbol{\lambda}_{pq} \rangle = W \tilde{\boldsymbol{\lambda}}_{pq} X_p \tilde{X}_p \boldsymbol{\lambda}_{pq}. \quad (17)$$

In the same way, we obtain the following relation,

$$\langle (\boldsymbol{\lambda}_{pq}\cdot\Delta\boldsymbol{r}_p)(\boldsymbol{\lambda}_{pq}\cdot\Delta\boldsymbol{r}_q) \rangle = \langle \tilde{\boldsymbol{\lambda}}_{pq} X_p \Delta\boldsymbol{\Omega}^p \Delta\tilde{\boldsymbol{\Omega}}^q \tilde{X}_q \boldsymbol{\lambda}_{pq} \rangle = w \tilde{\boldsymbol{\lambda}}_{pq} X_p \tilde{X}_q \boldsymbol{\lambda}_{pq}. \quad (18)$$

By using Eqs. 17 and 18, Eq. 15 becomes

$$\langle \Delta r_{pq}^2 \rangle^{\mathrm{rot}} = [\tilde{\boldsymbol{\lambda}}_{pq}(X_p\tilde{X}_p + X_q\tilde{X}_q)\boldsymbol{\lambda}_{pq}]W + [-2\tilde{\boldsymbol{\lambda}}_{pq} X_p \tilde{X}_q \boldsymbol{\lambda}_{pq}]w. \quad (19)$$

According to the assumptions, the second term vanishes except for the case that the p-th and q-th atoms belong to the neighboring molecules, respectively.

Results and Discussion

In our previous papers,[2,3] it was shown that the bcc model for the local lattice structure of liquid carbon tetrachloride was the best model for simulating the experimental X-ray scattering intensity. So we use the bcc model for the calculation of the bracketed coefficients in Eqs. 9 and 19.

After the calculation of the coefficients for all pairs p and q, we can set up an equation for the weighted structure function $si(s)$ with the parameters A, a, W, and w for the bcc model, where $i(s)$ is the reduced intensity (Eq. 1). The values for the structure parameters of the bcc model are the same as the ones in the previous paper,[2] namely, the first nearest neighbor distance R is 5.9 Å, the molecules up to the fourth nearest neighbors are included in the discrete structure region, and the radius of this structure region is 12.41 Å with the intentional damping factor l_c of 1.76 Å. In Table 1, the values of the coefficients of A and a in Eq. 9, and W and w in Eq. 19 for main atomic pairs are shown. The numbering of atoms is shown in Fig. 2.

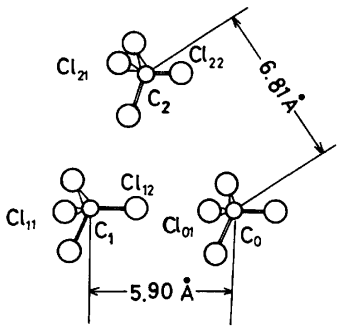

Fig. 2. The arrangement of the first and second nearest neighbor molecules in the bcc local lattice structure model for liquid carbon tetrachloride.

TABLE 2. THE REFINED PARAMETERS[a)]

A/Å^2	0.203 (0.041)	W/rad^2	0.101 (0.023)
a/Å^2	0.233 (0.122)	w/rad^2	−0.066 (0.023)

a) The values in the parentheses are standard deviations.

Carrying out a least-squares analysis by the use of our experimental $si(s)$ of the liquid carbon tetrachloride,[4] we determine the values of the fitting parameters A, a, W, and w. The s-region ranging from 1.5 to 6 Å^{-1} is used for the least-squares analysis. The result is shown in Table 2. The reliability factor defined by

$$R = \left[\sum |si(s)_{\mathrm{exp}} - si(s)_{\mathrm{calcd}}|^2 / \sum |si(s)_{\mathrm{exp}}|^2 \right]^{1/2} \quad (20)$$

is 0.23. The calculated $si(s)_{\mathrm{calcd}}$ curve using these refined parameters is shown by the solid curve in Fig. 3, with the experimental values denoted by circles.

As is shown in Fig. 3, the agreement between the experimental and calculated $si(s)$ curves has not been improved by the present treatment, in comparison with the case of using the modified Prins relation with two D constants as described in Ref. 2. By comparing the mean square amplitudes of the present treatment with respective ones obtained by the latter treatment,[2] it has proved that the values for chlorine-chlorine atomic pairs are very similar to each other, while the values

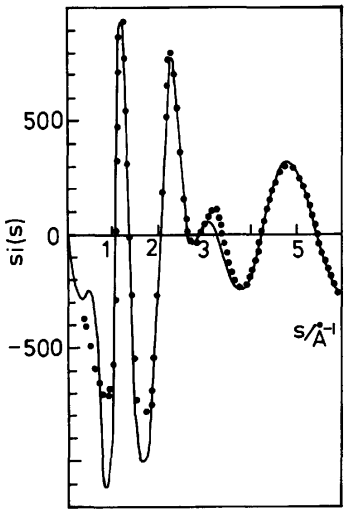

Fig. 3. The weighted structure functions $si(s)$ for liquid carbon tetrachloride. The solid curve is the calculated one and circles are experimental values.[4]

for carbon–carbon atomic pairs are significantly different. The smaller scattering power of carbon–carbon pairs makes no difference in the agreement of the $si(s)$ curves. From the point of view of only simulating the experimental $si(s)$ curve, the modified Prins relation with two D constants and the present treatment are in fair agreement. However, the physical meaning of the parameters is clear and the description of the motion of carbon tetrachloride molecules in the liquid becomes considerably clear by the present analysis.

From the value of A, 0.203 Å^2, the translational root mean-square deviation between the central and the first nearest-neighbor molecules (pair C_0–C_1) becomes 0.45 Å. The translational root mean-square deviation between the central molecule and the second nearest neighbors (pair C_0–C_2) becomes 0.54 Å. For the chlorine atoms in neighboring molecules (Cl_{01}–Cl_{11}), the value l_{pq} becomes 0.60 Å.

From the magnitude of W, 0.101 rad^2, we obtain

$$\sqrt{\langle\Delta\Omega^2\rangle} = \sqrt{\langle\Delta\Omega_x^2+\Delta\Omega_y^2+\Delta\Omega_z^2\rangle} = 0.551 \text{ rad} = 31.5\,^\circ \quad (21)$$

This value shows that the root mean-square of the librational or the orientational fluctuation of a molecule is 31.5°. The error caused by using the approximated equation (Eq. 10) is estimated to be about 10% in the worst case for this considerably large amplitude of $\sqrt{<\Delta\Omega^2>}$.

The negative sign of w shows that the rotational motion is gear-like. When a molecule rotates, the nearest molecules rotate in the reverse direction, being dragged by the first molecule. Since the magnitude of $|w/W|$ is less than unity, the rotation of the first molecule is not conveyed to the nearest molecules in the perfectly coherent phase. This incoherence causes the disturbance in rotation of the molecules, *i.e.*, the rotational diffusion. However, the ratio of $|w/W|$ amounts to 0.66, which shows that by the direct effect of the rotation of a molecule the nearest neighboring molecules are dragged about 0.66× (the rotational amplitude of the molecule). It may be said that carbon tetrachloride molecules have a tendency to keep the most stabilized orientational correlation, namely, the head-tail head-tail packing in the liquid even if the molecules are vigorously moving.

Bartoli and Litovitz discussed the motion of carbon tetrachloride molecule in the liquid[13] from an analysis of the orientational broadening of Raman bands. However, it is difficult to relate the present results to their values, because both analyses are based on different theoretical points of view; in the present work a time-averaged quantity is looked for, while in the Raman studies time-correlation is the main concern.

Steinhauser and Neuman carried out molecular dynamics study for liquid carbon tetrachloride.[14] According to their result about the velocity autocorrelation function, the period of the vibratory motion of the reference particle in the cage of its neighbors was roughly 0.3 ps. If we assume that the molecules move translationally with a velocity determined by the thermal energy, half of the mean free path for the collision, which is the distance corresponding to a fourth of the period of the vibratory motion mentioned above, can be estimated as 0.10 Å, which agrees in order of magnitude with our value of 0.45 Å for the translational root mean-square deviation of the neighboring molecules. However, we are somewhat uncertain about the extent to which the correspodence between the two quantities can be physically meaningful.

Hyodo and Fujiyama ascribed the small but significant depolarization degree of the ν_1 Raman line of liquid carbon tetrachloride to the fluctuation of the local field which is felt by each molecule in the condensed phase, and formulated the expression for the degree of depolarization in terms of the mean square amplitudes of the distances between molecular centers.[15] Calculating the degree of depolarization by the use of their formula (Eq. 25 in Ref. 15) and the present translational amplitudes, we obtain the value of 0.0042. The magnitude is in good agreement with the experimental value of 0.0039.[16]

The present study suggests that by the detailed analysis of the mean square deviations of interatomic distances in liquids obtained by diffraction methods we can obtain information on the dynamics of liquids, which may be complementary to that obtained by spectroscopic techniques.

The authors wish to thank Professor Toshiko Kato of Seibo Women's Junior College for directing their attention to the papers on Raman scattering studies of liquid carbon tetrachloride.

Appendix

Expressions where Perpendicular Displacements are Included. Let s_i be the unit vector perpendicular to t_i and on the plane

formed by t_i and λ_{pq}, and ΔP_i the displacement along s_i. The motion perpendicular to both t_i and s_i has no effect at all. Then we have in place of Eq. 6,

$$\Delta r_{pq}^{tr} = \lambda_{pq}\cdot(\Delta R_1 t_1+\Delta P_1 s_1+\Delta R_2 t_2+\Delta P_2 s_2+\cdots) \quad (A.1)$$

The following assumptions are reasonably made in addition to Eqs. 7 and 8;

$$\begin{aligned}
&\langle \Delta P_i^2\rangle = B \\
&\langle \Delta P_i \Delta P_j\rangle = 0 \qquad \text{for } i \neq j \\
&\langle \Delta P_i \Delta R_i\rangle = 0 \\
&\langle \Delta P_i \Delta R_j\rangle = \begin{cases} b & \text{for } j = i+1 \\ 0 & \text{otherwise.} \end{cases}
\end{aligned} \quad (A.2)$$

Then we have

$$\begin{aligned}
\langle \Delta r_{pq}^2\rangle^{tr} = &\sum_{i=1}^{N}(\lambda_{pq}\cdot t_i)^2 A + \sum_{i=1}^{N}(\lambda_{pq}\cdot s_i)^2 B \\
&+ 2\sum_{i,j}'(\lambda_{pq}\cdot t_i)\cdot(\lambda_{pq}\cdot t_j)a \\
&+ 2\sum_{i,j}'(\lambda_{pq}\cdot s_i)\cdot(\lambda_{pq}\cdot t_j)b
\end{aligned} \quad (A.3)$$

corresponging to Eq. 9 in the text.

In comparing Eqs. 9 and A.3, we must regard the parameter A in the text as the effective value of

$$A + \frac{\sum(\lambda_{pq}\cdot s_i)^2}{\sum(\lambda_{pq}\cdot t_i)^2}B \quad (A.4)$$

and a as that of

$$a + \frac{\sum'(\lambda_{pq}\cdot s_i)\cdot(\lambda_{pq}\cdot t_j)}{\sum'(\lambda_{pq}\cdot t_i)\cdot(\lambda_{pq}\cdot t_j)}b. \quad (A.5)$$

In the case of the present study, the maximum value of $(\lambda_{pq}\cdot s_i)$ is about 1/2 and the minimum value of $(\lambda_{pq}\cdot t_i)$ is $\sqrt{3}/2$, and most of the $(\lambda_{pq}\cdot s_i)$ terms are nearly zero, so the coefficient of B in Eq. A.5 is much smaller than 1/3. In the same way, the coefficient of b is much smaller than $1/\sqrt{3}$. The averaged quantity B is probably of the same order of magnitude as A, but it is ignored because of the small coefficients that appear in the practical computation for the case of carbon tetrachloride. Little is known about a and b, which must be strongly dependent on the angle between R_i and R_j. At the present stage of investigations, we should be content with the fact that only the effective value of Eq. A.5 can be determined.

Temperature Effect on Transference Numbers for KCl in Ethanol-Water Mixtures

Masakatsu UENO,* Shōgo I, and Kiyoshi SHIMIZU
Department of Applied Chemistry, Faculty of Engineering, Doshisha University, Karasuma Imadegawa, Kamigyo-ku, Kyoto 602
(Received October 4, 1984)

Cation-transference numbers were determined by the moving boundary method for 0.02 mol dm^{-3} KCl in 5-, 10-, 15-, 20-, and 30 mol% ethanol-water mixtures at 15 and 35 °C. The cation-transference number has a maximum around 10 mol% of ethanol at each temperature studied, and becomes larger with decreasing temperature in the solvent of the same composition. From the temperature dependence of the transference number, the differences in the activation energy of transport between K^+ and Cl^- ions were estimated, and it was found that the activation energy of the K^+ ion is less than that of the Cl^- ion and the difference becomes larger in the range of 5—20 mol% of ethanol. These results are discussed in terms of structural effects and ion-solvent interactions.

Transference number measurement is a matter of considerable importance in the study of electrolyte solutions by the conductivity method since individual ionic conductances can be determined without any assumptions by combining transference numbers with electrolyte conductances. Such a single-ion property at infinite dilution is closely related to the ion-solvent interaction. The investigation of the temperature and pressure dependence of limiting ionic conductances and correlated quantities in water has led to the important concept on the ion-solvent interaction in relation to the unique structure properties of water.[1-4] Since a small addition of alcohols to water increases the degree of structure of solution,[5] it is interesting to measure the transference numbers and conductances of electrolytes in these mixtures as a function of temperature and pressure. However, a few papers have been published for the temperature[6] and pressure[7] effects on transference numbers in alcohol-water mixtures. In a previous paper,[7] we reported transference numbers for KCl in ethanol-water mixtures up to 30 mol% of ethanol under high pressure at 25 °C and discussed specific interactions between the ions and solvent. Here the temperature effect on transference numbers for KCl in ethanol-water mixtures is reported.

Experimental

Potassium chloride of high purity was obtained from Merck and dried above 130 °C prior to use. Purification of ethanol and water was the same as described before.[7] The solutions of 0.02 mol dm^{-3} KCl were prepared by weighing on the assumption that the densities of the solutions were equal to those of the solvent.[8]

Cation-transference numbers t_+ were determined by the autogenic moving-boundary method using a cadmium anode and a silver-silver chloride cathode. The velocity of the moving boundary formed by KCl and $CdCl_2$ solutions was detected by measuring a change in resistance between two platinum probe electrodes. The volume between the probe electrodes was determined by calibration runs at each temperature using 0.02 mol dm^{-3} KCl aqueous solution and the values of t_+=0.4924 at 15 °C and 0.4885 at 35 °C by Allgood *et al.*[9] The calibrated volume had a standard deviation better than 0.2%. Details of cell construction, other apparatus, and the procedure for calculating the apparent and final transference numbers have been described previously.[7]

Results and Discussion

The cation-transference numbers t_+ obtained are listed in Table 1. The variation of t_+ with the ethanol content is similar at various temperatures studied as seen in Fig. 1. The cation-transference number initially increases up to about 10 mol% of ethanol and then decreases. The characteristic features for the temperature effect on t_+ are the following: The cation-transference number in the solvent of the same composition becomes larger at lower temperature, and the initial increase and the following decrease in t_+ with increasing ethanol content become more rapid with decreasing temperature. These features will be maintained for the limiting cation-transference number t_+° since there is very little concentration dependence in t_+ in the case of t_+ which is close to 0.5 as shown by the following Kay-Dye equation:[10]

$$t_+^\circ = t_+ + (0.5 - t_+)\Lambda_e/\Lambda^\circ, \quad (1)$$

where Λ_e is the electrophoretic contribution to conductance and Λ° is the limiting molar conductance of KCl. In Fig. 1, the data at 5 °C by Erdey-Grúz and Majthényi[6] are also shown. The initial increase in

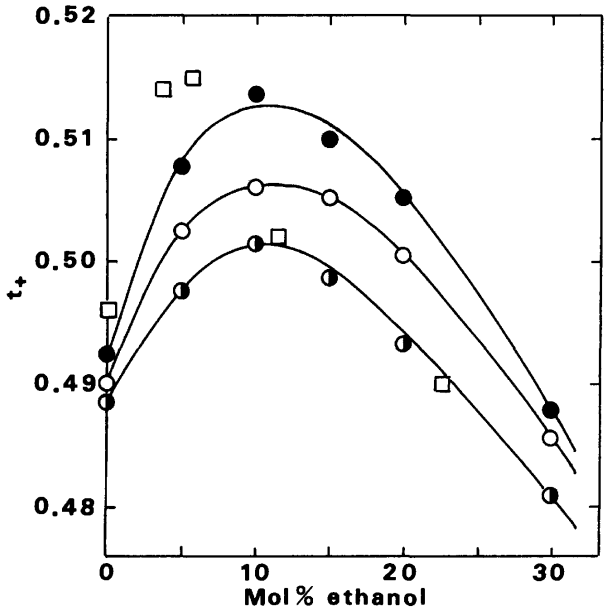

Fig. 1. Variation of the transference number for the K^+ ion with mol% of ethanol at various temperatures. ●: 15 °C, ○: 25 °C, ◑: 35 °C, □: 5 °C, Ref. 6.

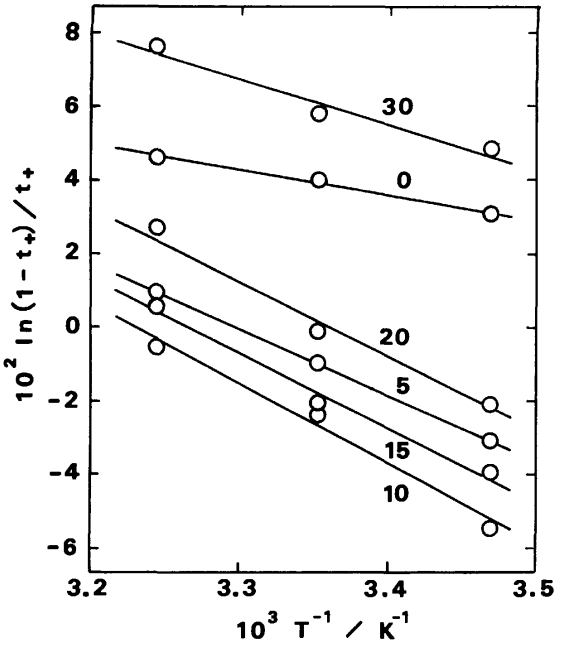

Fig. 2. A logarithmic plot of the ratio of anion- to cation-transference number against the reciprocal of the absolute temperature. Mol% of ethanol is shown in the plot.

t_+ at 5 °C is larger than that at 15 °C obtained by us, although the values above 10 mol% of ethanol at 5 °C in Ref. 6 appear to be fairly small just as those at 25 °C.

In the previous paper,[7] it has been shown that the Zwanzig dielectric friction theory[11] could not account for the variation of the transference number with the ethanol content. One of the reasons for it could be due to the neglect of the delicate difference in the ion-solvent interaction between K^+ and Cl^- ions although it is considered from a wide variety of thermodynamic and transport data that the influence of K^+ and Cl^- ions on the solvent structure is similar and almost equal in magnitude: The B-coefficients of the viscosity for K^+ and Cl^- ions were assumed to be equal in water.[1] However, the variation of the transference number with solvent composition as well as temperature and pressure sensitively reflects the relative difference in the ion-solvent interaction between these ions.

The slope of $\ln(1-t_+^\circ)/t_+^\circ$ plotted against the reciprocal of the absolute temperature $1/T$ should yield the difference in the activation energy of transport between K^+ and Cl^- ions at infinite dilution. Figure 2 shows such a plot where the concentration dependence of the transference number is neglected. The difference in the activation energy, $E(K^+)-E(Cl^-)$, was roughly estimated by assuming the linearity between $\ln(1-t_+)/t_+$ and $1/T$. The values obtained in 0-, 5-, 10-, 15-, 20-, and 30 mol% of ethanol are −0.6, −1.5, −1.8, −1.7, −1.7, and −1.0 kJ mol^{-1}, respectively: The activation energy for the K^+ ion is less than that for the Cl^- ion and the difference becomes larger in the water-rich region, 5—20 mol%. In ethanol-water mixtures, selective solvation would arise. It is considered that both the K^+ and the Cl^- ions interact more strongly with water molecules than with ethanol molecules because the dipole moment of a water molecule is larger than that of an ethanol molecule. The ion-solvent interaction of the Cl^- ion also involves the additional contribution of a hydrogen bond with water molecules.[12] In ethanol-water mixtures, the interaction of the Cl^- ion with water molecules would be weaker than in pure water, while that of the K^+ ion with water molecules would be stronger because of the enhanced basicity of water molecules.[13] Therefore, the radius of the solvated K^+ ion would be expected to be larger than that of the solvated Cl^- ion in the mixtures. According to the Eyring theory of transport process in solution,[14] the activation energy corresponds to the energy required to provide a hole in the liquid for an ion to migrate and is anticipated to be larger for a larger ion. However, it is contrary to the prediction of the theory that the activation energy for the larger solvated ion K^+ is less than that for the smaller solvated ion Cl^-. This would suggest that the structure-breaking effect of the K^+ ion is greater than that of the Cl^- ion in the mixtures as well as in water.[15]

A small addition of ethanol to water enhances the structure of the solvent.[5] If the structure-breaking effect of the K^+ ion is greater than that of the Cl^- ion, the K^+ ion obtains the larger structural excess mobility than the Cl^- ion and the mobility of the K^+ ion becomes larger relative to the Cl^- ion in the mixtures. The intial increase in t_+ up to about 10 mol% of ethanol, where the slope of the viscosity of the mixtures plotted against the ethanol content shows a maximum,[16] would be primarily ascribed to the relative structure-breaking properties of these two ions. The concept mentioned above is readily applied to the temperature effect on transference numbers for KCl. Since the structure of

the solvent is more enhanced at lower temperature, the difference in the structure-breaking effect between K^+ and Cl^- ions would become greater. Accordingly, the K^+ ion would obtain the larger structural excess mobility relative to the Cl^- ion and t_+ increases with decreasing temperature.

In addition to the structural effect, the sorting effect may be taken into consideration.[16] Since the viscosity of ethanol–water mixtures increases up to about 25 mol% of ethanol,[8,16] the effective viscosity around a solvated ion would become smaller than the bulk viscosity by selective enrichment of water molecules around a solvated ion, and the ion would have an excess mobility. This effect is larger for K^+ than for Cl^- ions since the crystallographic radius of a K^+ ion is smaller than that of a Cl^- ion. Hence the initial increase in t_+ would be also attributed to the difference in the sorting effect between these two ions. The sorting effect is expected to become greater at lower temperature since the sharper maximum of the bulk viscosity appears at lower temperature.[8,16]

(Received October 11, 1984)

The rate constants for the reactions of ground-state oxygen atoms with ethene and five fluoroethenes have been measured over the temperature range of 240—450 K, using a pulse radiolysis-resonance absorption technique. The rate constants were well expressed by the following Arrhenius expressions: $k(O+C_2H_4)=8.4\times10^6\exp(-712/T)$; $k(O+C_2H_3F)=3.1\times10^6\exp(-622/T)$; $k(O+CH_2=CF_2)=2.4\times10^6\exp(-638/T)$; $k(O+cis\text{-}CHF=CHF)=1.9\times10^6\exp(-500/T)$; $k(O+C_2HF_3)=3.0\times10^6\exp(-544/T)$; $k(O+C_2F_4)=8.1\times10^6\exp(-634/T)$, in units of $m^3mol^{-1}s^{-1}$. The change in the preexponential factors with the degree of fluorination is discussed in terms of the conventional transition-state theory.

The temperature dependence of the rate constant for the reactions of ground-state oxygen atoms with simple olefins has been widely investigated over the last two decades.[1] Especially, the rate constants for ethene have been measured extensively.[2-10] On the other hand, only a limited number of data are available for the reactions of O(^{3}P) with fluoroethenes.[11-19] The room-temperature rate constants for the reactions of O(^{3}P) with fluoroethenes have been measured by several groups, including the members of our laboratory.[12-19] It has been found that the rate constants do not change monotonously with the number of the substituted fluorine atoms.[12,14] Ethene and tetrafluoroethene are more reactive than the others, while difluoroethene has the lowest reactivity. According to the competitive experiments by Jones and Moss,[12] this change in reaction rate is due to the change in activation energies. However, their conclusion is based only on the rate measurements at two temperatures, 298 and 423 K. It is hard, we believe, to estimate the Arrhenius parameters from only two points of data. In order to make it clear if the change in the room-temperature rate constants is due to the change in the preexponential factors or to that in the activation energies, we measured the temperature dependence of the rate constants for the reactions of O(^{3}P) with ethene and five fluoroethenes.

Experimental

The experimental apparatus and the procedure were similar to those described previously.[20-22] Briefly, a mixture of CO_2 (70—140 Pa) and ethene or fluoroethenes (7—31 Pa) diluted with excess Ar (90 kPa) was irradiated with an electron pulse generated by a Febetron 706 (Hewlett Packard Co.). Oxygen molecules were not used as the O-atom source, since O_2 molecules are reactive to O atoms and disturb the estimation of the rate constants.[21] After the pulse, the concentration of the ground-state oxygen atoms was monitored by the light absorption of resonance triplet lines around 130 nm. As the source of the resonance radiation of oxygen atoms, a microwave-powered lamp with a flow of He and a trace amount of O_2 was used. Ar (Jonan Kyodo Sanso), He (Japan Helium Center), and O_2 (Nihon Sanso) were used from cylinders without further purification. The sources of the other materials were: Takachiho Kako: CO_2 and C_2H_4, Daikin Co.: C_2H_3F and C_2HF_3, Japan Halon Co.: $CH_2=CF_2$, and PCR: *cis*-CHF=CHF. The C_2F_4 was prepared by the thermal decomposition of Teflon. These gases were used after purification through several freeze-thaw cycles. The purity of the C_2H_4, C_2H_3F, and C_2HF_3 has been checked in a previous work.[14] The purity of the $CH_2=CF_2$, *cis*-CHF=CHF, and C_2F_4 was checked mass-spectroscopically. There was no detectable impurity, except that C_2F_4 contained about 1% of C_3F_6, which is much less reactive than C_2F_4.[11]

Results

The first-order rate constants were determined by a procedure similar to that described in previous papers.[21,22] Although the room-temperature rate constant for O+C_2H_4 did not change systematically with the partial pressure of C_2H_4 over 15 Pa, it did increase with the decrease in the partial pressure of ethene below 12 Pa. Similar results have also been reported by Sugawara *et al.*[21] This increase in the apparent rate constant has been considered to be the result of secondary processes, such as reactions between O atoms and the CH_3 radicals formed in the reaction of O and C_2H_4.[21] Such secondary reactions seem less important in the cases of O+fluoroethenes. For example, in the case of C_2HF_3, no increase in the apparent rate constants could be observed at pressures higher than 7 Pa at 295 K. In general, secondary reactions are considered to become more important at low temperatures. Therefore, at low temperatures, more attention was paid and the experiments were performed with partial pressures of over 21 Pa. Although the scatter of the data was more severe at low temperatures, no systematic partial pressure dependence of the rate constants could be observed. The rate constants at each temperature are summarized in Table 1 and plotted in Fig. 1 in the form of Arrhenius plots. All the data are well characterized by Arrhenius equations. The Arrhenius parameters, as determined by the least-squares method, are listed in Table 2.

Discussion

Comparison with Literature Values. A number of measurements have been performed on the temperature dependence for the reaction of atomic oxygen with

C_2H_4. The Arrhenius parameters previously obtained for this reaction are summarized in Table 3. The agreement among the activation energies is rather good. However, the agreement among the preexponential factors is rather poor. The present value of the preexponential factor seems to be a little large, but this discrepancy is not considered to be serious, since these values were all obtained by extrapolation.

The room-temperature rate constants for ethene and fluoroethenes are listed in Table 4. Unfortunately, for $CH_2=CF_2$ and C_2F_4 there is some disagreement between the present values and those of Sugawara *et al.*, who used the same technique and the same apparatus.[14] The only difference is that they used a He/O_2 mixture as the O atom source, while we used Ar/CO_2. Since O atoms react with O_2, Sugawara *et al.* had to correct their data to estimate the reaction rates. The rate for the O+O_2 reaction under the conditions of Sugawara *et al.* was comparable to or larger than the rates for the O+fluoroethenes reactions. This may be the cause of the discrepancy. Apart from the values of Sugawara *et al.*, the present values seem to be a little larger than those obtained with different techniques. This cannot be accounted for by secondary reactions, as has been discussed in detail in a previous paper, since no partial-pressure dependence could be observed.[21] Figure 2 compares the Arrhenius plot obtained by Atkinson and Pitts for C_2H_3F[13] and the present one. The rate constants obtained in this work are larger than those of Atkinson and Pitts by a factor of 2. The cause of this discrepancy is not certain. Figure 2 also shows the results of the competitive work by Jones and Moss.[12] Since their values are relative ones, they were placed on an absolute basis using the rate constants for ethene determined in the present work.

Effect of the Substitution by F Atoms on the Arrhenius Parameters. As is shown in Table 2, the activation energies do not change greatly with the number of substituted fluorine atoms. This is not unexpected since the ionization potentials of ethene and fluoroethenes are not very different.[23] It is now well established that there is a good correlation between the activation energies and the ionization potentials in the reactions of O(^{3}P) with alkenes and alkynes.[24] On the other hand, the preexponential factors change by a factor of 4. It should also be noted that this factor first decreases upon fluorine substitution, and then increases again, so that the values for ethene and tetrafluoro-

ethene are nearly the same. Sugawara *et al.* tried to interpret the change in the room-temperature rate constants in terms of "approachability," the reactivity index calculated by the INDO method.[14] However, approachability is a conception correlated to the activation energy and cannot be employed to explain the change in the preexponential factors. Any correlation between the approachability and the room-temperature rate constants must be fortuitous.

The temperature dependence of the rate constant for the O+C_2H_4 reaction, including the nonlinearity in the Arrhenius plot at high temperatures, has been successfully explained by the conventional transition-state theory.[7,10] According to this theory, the rate constant is expressed by:

$$k_r = \kappa L \frac{kT}{h} \frac{F_t^{\dagger}}{F_t^{O} F_t^{R}} \frac{f_r^{\dagger}}{f_r^{R}} \frac{f_v^{\dagger}}{f_v^{R}} \frac{f_e^{\dagger}}{f_e^{O}} \exp(-E/kT). \quad (1)$$

Here, the symbols have their ordinary meanings; κ is the transmission coefficient, L is the path degeneracy, and F_t, f_r, f_v, and f_e are the translational, rotational, vibrational, and electronic partition functions respectively. Symmetry numbers are not included in the rotational partition functions. The superscripts, O, R, and †, are used to designate O atoms, reactant molecules (ethene or fluoroethene), and the transition states respectively. If we restrict the present discussion to the relative values of the rate constants, the common terms for all reactions of O+ethene or fluoroethenes, such as the partition functions for O atoms, may not be taken into account. The electronic states of the transition states are correlated to the spin-orbit states of the O(^3P_J) atoms. Since the spin-orbit splittings of the O(^3P_J) atoms are small, 1.89 and 0.82 kJ/mol, it can be assum-

ed that the energy separations of the electronic states of the transition states are small and that the electronic partition functions, $f_e^{\dagger}$, are almost the same. Singleton and Cvetanović have postulated that, in the reaction of O(^{3}P) with aliphatic olefins, the two new vibrations of the bending mode of the transition state are harmonic and have equal frequencies, ν, and that the partition functions for all the other vibrations in the transition state and the reactant cancel each other out.[7] If we employ this assumption, the temperature-dependent preexponential term in Eq. 1, A_T according to the notation of Singleton and Cvetanović,[7] can be written as:

$$A_T = C\kappa L\left[\frac{m^{\dagger}}{m^{R}}\right]^{3/2}\left[\frac{I^{\dagger}}{I^{R}}\right]^{1/2} T^{-1/2}\{1-\exp(-h\nu/kT)\}^{-2}. \quad (2)$$

Here, C is a constant independent of the nature of the reactant or the temperature, while m and I stand for the masses and the products of the three principal moments of inertia of the reactant or the transition state. The superscripts have the same meanings as in Eq. 1. The value of ν in Eq. 2 for ethene has been estimated by Singleton and Cvetanović[7] and by Perry[10] to be between 100 and 300 cm^{-1}, judging from the curvature in the Arrhenius plot. Substituting these values, it can easily be shown that the temperature dependence of the preexponential factor cannot be ignored compared to that of the exponential term. Since the experimentally obtained A factors listed in Table 2 are deduced under the assumption that the rate constants can be characterized by a simple Arrhenius equation, $k_r=A\exp(-E/kT)$, it is not fair to compare the values in Table 2 with those calculated by Eq. 2 at a certain temperature. Therefore, we re-analyzed the present results using the following equation:

$$k_r = A'T^{-1/2}\{1-\exp(-h\nu/kT)\}^{-2}\exp(-E/kT). \quad (3)$$

Here, A' is the temperature independent part of the preexponential factor:

$$A' = C\kappa L\left[\frac{m^{\dagger}}{m^{R}}\right]^{3/2}\left[\frac{I^{\dagger}}{I^{R}}\right]^{1/2}. \quad (4)$$

In order to estimate the magnitude of A' from the experimental results, it is necessary to know the value of ν. It was impossible, however, to determine the three parameters, A', ν, and E, uniquely from the present data alone. For the first step, we assumed that ν is independent of the degree of fluorination; we used the value for ethene determined by Singleton and Cvetanović and by Perry, between 100 and 300 cm^{-1}. The present experimental results could also be well characterized by Eq. 3 under such assumptions, and it was found that the relative values of A' are essentially the same as those of A listed in Table 2. The value of $(m^{\dagger}/m^{R})^{3/2}$, can easily be calculated. The results are shown in Table 5. In order to calculate the ratio of the rotational partition functions, $(I^{\dagger}/I^{R})^{1/2}$, it is necessary to know the geometry of the reactant molecule and the transition state. The structural parameters for the ground-state fluoroethene molecules have been determined experimentally by Carlos *et al.*[25] The geometry of the transition state of the C_2H_4O complex has been theoretically calculated,[26] but those of the fluoroethenes are not known. Therefore, for the first step, we assumed that the geometry of the intermediate complexes for all the fluoroethenes is analogous to that for ethene; *i.e.*, the C-O internuclear distance and the C-C-O angles are the same. The results are shown in Table 5. Both $(m^{\dagger}/m^{R})^{3/2}$ and $(I^{\dagger}/I^{R})^{1/2}$ decrease with the number of the substituted F atoms. As for C_2H_3F and $C_2H_2F_2$, the relative values of the products of $(m^{\dagger}/m^{R})^{3/2}$ and $(I^{\dagger}/I^{R})^{1/2}$ are comparable to the relative preexponential factors, A and A'. Therefore, the decrease in the preexponential factors from C_2H_4 to $C_2H_2F_2$ can be explained by assuming that the geometry of the transition states and the frequencies of the newly formed vibrations are similar for these reactants. However, it is difficult to explain the increase in the preexponential factors from $C_2H_2F_2$ to C_2F_4. In other words, it is hard to interpret why the preexponential factors for ethene and tetrafluoroethene are nearly the same under the assumptions that: 1) the geometries of the transition states are similar; 2) the newly formed vibrational frequencies of the transition states are the same, and 3) the transmission coefficients are the same. The identity of the A factors for C_2H_4 and C_2F_4 can not be accounted for by the change in the geometry of the transition states alone. For example, even if we assume

Table 5. Comparison of the relative A factors and the products of $(m^{\dagger}/m^{R})^{3/2}$ and $(I^{\dagger}/I^{R})^{1/2}$

Reactants	A or A'[a] (experimental)	$\left[\frac{m^{\dagger}}{m^{R}}\right]^{3/2}$	$\left[\frac{I^{\dagger}}{I^{R}}\right]^{1/2}$	$\left[\frac{m^{\dagger}}{m^{R}}\right]^{3/2}\times\left[\frac{I^{\dagger}}{I^{R}}\right]^{1/2}$[a]
C_2H_4	1.00	1.97	7.29	1.00

$CH_2=CF_2$	0.28	1.40	2.50	0.24
cis-CHF=CHF	0.23	1.40	2.59	0.25
C_2HF_3	0.36	1.31	1.94	0.18
C_2F_4	0.97	1.25	1.59	0.14
			2.98[b]	
			3.14[c]	

a) Values relative to that for ethene; the differences between A and A' are less than 5% when ν is a certain value between 100 and 300 cm^{-1}. b) Calculated by assuming that r(C-O) is twice as long as that for the transition state of C_2H_4O. c) Calculated by assuming that r(C-C) is twice as long as that for the transition state of C_2H_4O.

that the C-O or C-C internuclear distance of the transition state for C_2F_4 is twice as long as that for C_2H_4, the value of $(I^{\dagger}/I^{R})^{1/2}$ changes only by a factor of 2, as is shown in Table 5. The path degeneracy, L, must be 4 in both cases. Therefore, there remain only two possibilities. One is a change in κ; the other, one in ν. The present results for C_2H_4 and C_2F_4 can be explained if we assume that the degenerate vibrational frequencies of the bending mode of the transition states are 300 cm^{-1} and 110 cm^{-1} respectively. However, in this interpretation, it is necessary to assume that the vibrational frequencies of the transition states suddenly change from $C_2H_2F_2$ to C_2HF_3, which sounds unrealistic. The next problem is, then, to see if it is reasonable to assume that the values of κ for C_2HF_3 and C_2F_4 are larger than those for ethene or the other fluoroethenes. This will be discussed in the next section.

Detailed Mechanism of the Reaction. With regard to the change in κ, tunneling effects cannot be expected in the present cases, but the contribution of the reverse reaction from the intermediate diradical to its initial components may be expected. In the reaction of oxygen atoms with ethene, it is known that there are two main exit channels: the fragmentation into CH_2CHO+H and that into CH_3+HCO.[1,27] Under the beam conditions, only the CH_2CHO fragment could be detected,[28] while both could be detected in comparable yields under the bulk conditions.[27] In order to explain these experimental results, the following reaction mechanism was considered; it is similar to that proposed by Hunziker *et al.*:[27]

$$O + C_2H_4 \longrightarrow {}^3C_2H_4O^*, \quad (5)$$

$$O + C_2H_4 \rightleftarrows {}^3C_2H_4O^{**}, \quad (6)$$

$${}^3C_2H_4O^* \longrightarrow CH_2CHO + H, \quad (7)$$

$${}^3C_2H_4O^{**} + M \rightleftarrows {}^1C_2H_4O^* + M, \quad (8)$$

$${}^1C_2H_4O^* \longrightarrow CH_3 + HCO, \quad (9)$$

$${}^1C_2H_4O^* + M \longrightarrow C_2H_4O + M. \quad (10)$$

Here, ${}^3C_2H_4O^*$ and ${}^3C_2H_4O^{**}$ represent two different types of electronic states of the initial triplet diradicals, the (π,π) and (π,σ) states, following the nomenclature of Yamaguchi *et al.*[29] ${}^1C_2H_4O^*$ stands for the singlet-state diradical, which is isoenergetic to ${}^3C_2H_4O^{**}$. Although Hunziker *et al.* mention nothing about the precursor of CH_3 and HCO, this singlet state may be the precursor.[18] Now, if the rate for the reverse reaction of Reaction 6 is large enough compared to the rates for Reactions 9 and 10, the apparent value of κ will be less than unity. It is necessary to assume an equilibrium between the singlet and the triplet diradicals, Reaction 8, in order to explain the constancy of the yields of HCO at high pressures.[27] It should also be noted that the precursor of CH_3 and HCO may not necessarily be the singlet diradical. The important point in this discussion is that there must be a reverse reaction to reproduce atomic oxygen, even at high pressures. Gutman and his co-workers have studied the reactive routes for the O+fluoroethenes reactions by using mass-spectrometric detection.[17,18] They have found that the reactions for C_2H_4 and C_2H_3F do not proceed by C-C bond breakage, while those for C_2F_4 and C_2HF_3 appear to proceed exclusively by this route. This conclusion for C_2F_4 is consistent with the finding of other experimental work that the only exit channel is the decomposition to CF_2 and CF_2O:[19,30]

$$O + C_2F_4 \longrightarrow {}^3C_2F_4O^*, \quad (11)$$

$${}^3C_2F_4O^* \longrightarrow CF_2 + CF_2O. \quad (12)$$

Gorry *et al.* have shown that the triplet diradical, ${}^3C_2F_4O^*$, is very short-lived because of its great exoergicity and that it decomposes to $CF_2({}^3B_1)$ and CF_2O.[30] If the reverse reaction of Reaction 11 is minor, then the value of κ should be larger than that for the O+ethene reaction. The situation for C_2HF_3 must be similar to that for C_2F_4, while that for C_2H_3F must be similar to that for C_2H_4. As for the reactions of O+difluoroethenes, many reactive routes, including the C-C bond rupture, are possible, although the production of CH_2O and CF_2 from $O+CH_2=CF_2$ seems minor.[17] The present results imply that the values of κ for the reactions of O+difluoroethenes are similar to that for ethene. Therefore, if C-C bond rupture occurs in these cases, that process must be slow. Further experimental studies to determine the initial products of these reactions, as well as their yields, are to be desired.

The authors wish to express their thanks to Professor Soji Tsuchiya of Tokyo University and Professor Nobuo Ishikawa of this Institute for the supply of fluoroethenes. The present work was partially supported by a Grant-in-Aid for Scientific Research from the Ministry of Education.

(Received October 23, 1984)

The crystal structure of the β-cyclodextrin-benzyl alcohol (1:1) complex pentahydrate was determined by the X-ray diffraction method. The crystal is monoclinic with the space group $P2_1$, $Z=2$, $a=15.356(3)$, $b=10.101(2)$, $c=20.869(3)$Å, and $\beta=109.90(1)°$. The structure was solved by an inspection of a Patterson map and a trial-and-error method combined with a rigid-body least-squares technique. The structure was refined using the block-diagonal least-squares method to an R-value of 0.066 for 5290 reflections ($\sin\theta/\lambda<0.63$). The β-cyclodextrin molecule is somewhat elliptically distorted from the regular heptagonal symmetry because of the inclusion of a planar molecule. One primary hydroxyl group shows a *gauche-trans* conformation, while the others are in a *gauche-gauche* conformation. The secondary hydroxyl groups form intramolecular O(2)-H···O(3′) or O(3′)-H···O(2) hydrogen bonds, which maintain the round structure of β-cyclodextrin. The guest benzyl alcohol molecule is fully enclosed within the host cavity. Water molecules are distributed in intermolecular spaces between β-cyclodextrin molecules. The phenyl group of the guest is located at the primary hydroxyl side of the cavity. The hydroxyl group occupies a position at the secondary hydroxyl side of the cavity, and forms hydrogen bonds with adjacent β-cyclodextrin molecules. β-Cyclodextrin molecules are stacked along the b axis to form a typical cage-type structure with a herringbone-like packing pattern.

Inclusion complexes of cyclodextrins with many pharmaceuticals, aromas, *etc.* have been successfully utilized in pharmaceutical and food industries.[1-4] Aralkyl alcohols are widely used antiseptics in pharmaceutical preparations. We have previously reported that aralkyl alcohols form inclusion complexes with cyclodextrins in water and in the solid state, using various techniques such as the solubility method, UV, CD, and ^{1}H-NMR spectroscopies, and powder X-ray diffractometry.[5] In this study, we carried out a crystal- and molecular-structure determination of the β-cyclodextrin complex with benzyl alcohol to gain insight into the detailed geometry of the host-guest interaction in the solid state.

Experimental

Materials and Measurements. β-Cyclodextrin and benzyl alcohol with a 1:1 molar ratio were dissolved in hot water. The solution was kept at room temperature. Then, the β-cyclodextrin-benzyl alcohol (1:1) complex pentahydrate was crystallized to a rod-like form. The crystal used in the X-ray diffraction experiment was sealed in a quartz capillary with a drop of mother liquor to prevent deterioration in air. Lattice parameters and diffraction intensities were measured on a Nicolet P3/F diffractometer with graphite-monochromated Cu $K\alpha$ radiation. The lattice constants were determined by a least-squares method using 25 reflections in the 2θ range 40—45°. By using a θ—2θ scan mode, 5290 independent reflections with $|F_o|\geqq 3\sigma(F)$ were collected up to 150° in 2θ. No correction was made for an absorption or extinction effect.

Crystal Data: $C_{42}H_{70}O_{35}\cdot C_7H_8O\cdot 5H_2O$, F.W.=1333.2, monoclinic, space group $P2_1$, $Z=2$, $a=15.356$ (3), $b=10.101$ (2), $c=20.869$ (3)Å, $\beta=109.90$ (1)°, $V=3043.6$ (9)Å^3, $D_x=1.455$ g·cm^{-3}.

Determination and Refinement of the Structure. The orientation of the *pseudo* heptagonal axis of β-cyclodextrin was easily deduced from a Patterson map. The rotation around the *pseudo* heptagonal axis and the molecular position in the unit cell was determined from an R-map, which was calculated using a model structure of β-cyclodextrin with a seven-fold symmetry. The orientational and positional parameters of each glucose unit were corrected by a rigid-body least-squares method. After the refinement of the β-cyclodextrin structure by the block-diagonal least-squares method, benzyl alcohol and water molecules were found on Fourier and difference-Fourier maps. The block-diagonal least-squares refinement of the structure, including 85 hydrogen atoms, achieved an R-value of 0.066. The quantity minimized was $\sum\omega(|F_o|-|F_c|)^2$, with $\omega=1.0$ for all the reflections. Final atomic parameters and B_{eq} values are given in Table 1. Tables of observed and calculated structure

factors, anisotropic temperature factors of non-hydrogen atoms, atomic parameters of hydrogen atoms, bond distances, angles, conformation angles, and plane equations with atomic deviations from the plane are kept at The Chemical Society of Japan (Document No. 8520). The computation was carried out on a FACOM M-380 computer at the Center of the Research Information Processing System (RIPS), Agency of Industrial Science and Technology, Tsukuba.

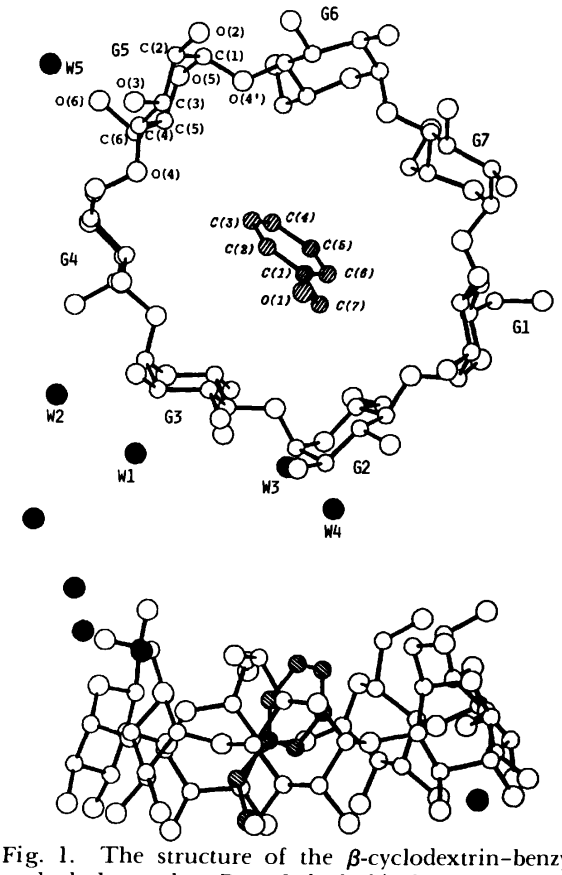

Fig. 1. The structure of the β-cyclodextrin-benzyl alcohol complex. Benzyl alcohol is shown by shaded circles. Water molecules are shown by full circles.

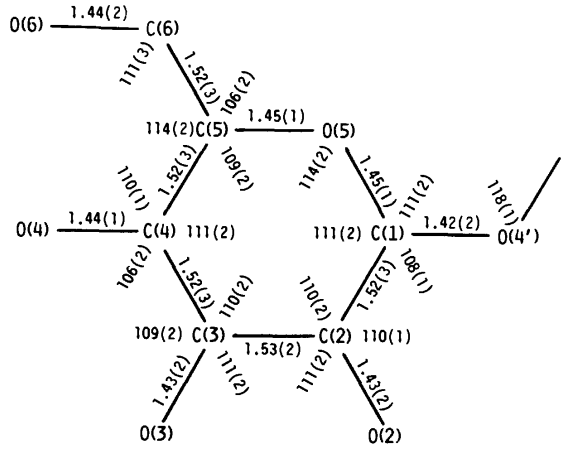

Fig. 2. Average bond distances and angles over seven glucose residues in β-cyclodextrin. Standard deviations in parentheses were estimated according to the equation:

$$\sigma = [\sum_{i=1}^{7} (x_i - \bar{x})^2/6]^{1/2}$$

where x_i refers to the bond distance or angle of the i-th residue and $\bar{x}$ is the average value.

Description and Discussion of the Structure

The structure of the β-cyclodextrin–benzyl alcohol complex is shown in Fig. 1. Average bond distances and angles of β-cyclodextrin are given in Fig. 2. Except for the orientation of C(6)–O(6) bonds, no significant structural difference was found among the seven glucose residues. The C(6)–O(6) bond in the G2 residue showed a *gauche-trans* conformation, while the other C(6)–O(6) bonds were in a *gauche-gauche* conformation. The average value of the glycosidic oxygen angles, 118 (1)°, is in good agreement with those of other β-cyclodextrin complexes.[6-8] The torsion-angle indices (Table 2), being in the range 109—140°, show a strong linear correlation with O(4)···O(4′) distances between adjacent glucose residues. Such a linear correlation is commonly observed in α- and β-cyclodextrin complexes.[7,9]

The β-cyclodextrin ring is somewhat elliptically distorted from the regular heptagonal symmetry. The radius and side length of the heptagon composed of seven O(4) atoms are in the range 4.71—5.28 Å and 4.17—4.55 Å, respectively. The radius (5.28 Å) measured from the O(4,G2) atom is 0.57 Å longer than the radius measured from the O(4,G4) atom. The largest values of radius and side length are found in a direction parallel to the plane of the guest molecule; O(4,G2)···center of the O(4) heptagon and O(4,G3)···O(4,G4), respectively. In spite of such elliptical distortion of the β-cyclodextrin ring, the average value of the radius (5.02 Å) and the side length (4.36 Å) of the O(4) heptagon are in good agreement with the corresponding values (5.05 and 4.38 Å, respectively) of the β-cyclodextrin complex with hexamethylenetetramine,[8] in which β-cyclodextrin shows a round structure owing to the inclusion of a spherically-shaped molecule. The

TABLE 2. GEOMETRICAL DATA FOR β-CYCLODEXTRIN

I. Radius of the O(4) heptagon[a]

Residue	Radius *l*/Å	Residue	Radius *l*/Å
G1	4.97	G5	5.26
G2	5.28	G6	5.18
G3	4.97	G7	4.78
G4	4.71	Average	5.02

a) The radius is measured from the center of gravity of seven O(4) atoms to each O(4) atom.

II. O(4)···O(4) distance between adjacent glucose residues

Distance *l*/Å		Distance *l*/Å	
O(4,G1)···O(4,G2)	4.29	O(4,G5)···O(4,G6)	4.20
O(4,G2)···O(4,G3)	4.17	O(4,G6)···O(4,G7)	4.45
O(4,G3)···O(4,G4)	4.55	O(4,G7)···O(4,G1)	4.50
O(4,G4)···O(4,G5)	4.39	Average	4.36

III. Tilt-angle[a] and torsion-angle index[b]

Residue	Tilt-angle ϕ/°	Torsion-angle index ϕ/°
G1	6.6	126
G2	20.5	140
G3	17.4	116
G4	−2.2	118
G5	11.4	132
G6	25.2	109
G7	17.0	105
Average	13.7	121

a) The tilt-angle is defined as the angle made by the O(4) plane and the plane through C(1), C(4), O(4), and O(4′) of each glucose residue. b) The torsion-angle index is defined as follows: $\phi=|\phi(C(1)\text{-}C(2))|+|\phi(C(2)\text{-}C(3))|-|\phi(C(3)\text{-}C(4))|-|\phi(C(4)\text{-}C(5))|+|\phi(C(5)\text{-}O(5))|+|\phi(O(5)\text{-}C(1))|$, where $\phi(C(1)\text{-}C(2))$ is the conformation angle of O(5)-C(1)-C(2)-C(3).

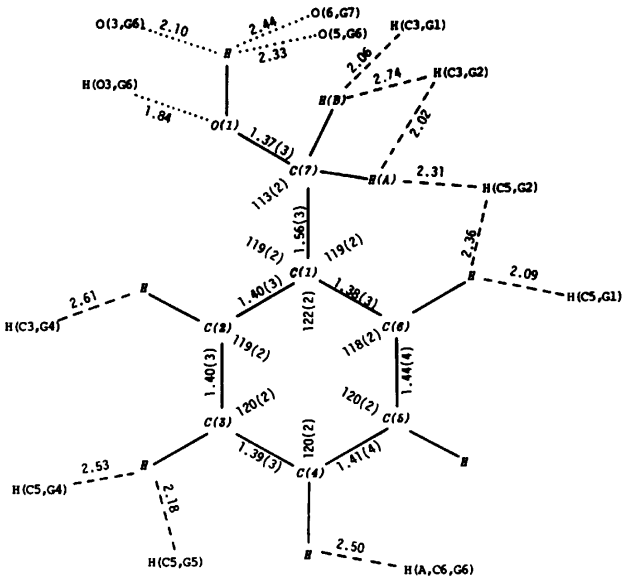

Fig. 3. Bond distances and angles in benzyl alcohol and host-guest distances less than 2.8 Å. Intermolecular contacts with adjacent β-cyclodextrin molecules are shown by dotted lines.

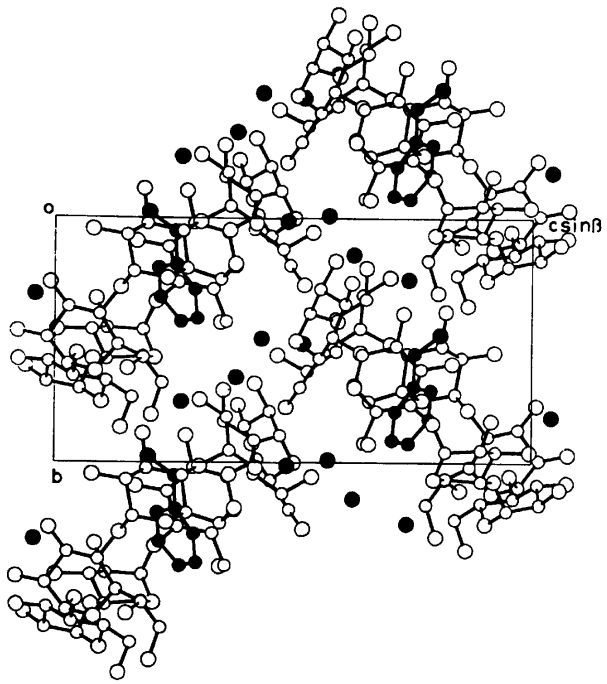

Fig. 4. The crystal structure viewed along the a axis. Benzyl alcohol and water molecules are shown by full circles.

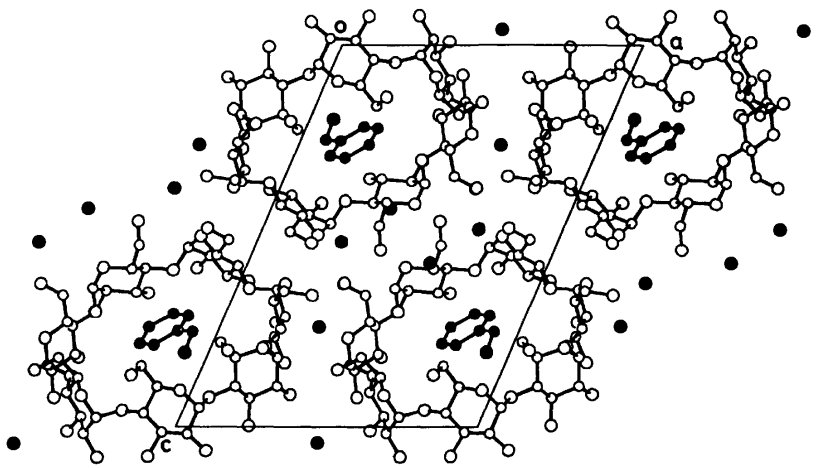

Fig. 5. The crystal structure viewed along the b axis. Benzyl alcohol and water molecules are shown by full circles.

seven O(4) atoms are coplanar within the maximum deviation of 0.228 Å.

The secondary hydroxyl groups form intramolecular hydrogen bonds, which may maintain the round shape of the β-cyclodextrin ring: four O(2)-H···O(3′) and three O(2)···H-O(3′) hydrogen bonds are found, as shown in Table 3. The O(2)···O(3′) distances are in the range 2.79—2.93 Å with the average value of 2.87

Å. The glucose residues are not perpendicular to the O(4) plane, but are inclined with their primary hydroxyl sides nearer to each other. The tilt-angles of glucose residues are in the range from −2.2 to 25.2°. The average value of 13.7° is greater than those found in the β-cyclodextrin dodecahydrate[6] and the β-cyclodextrin–hexamethylenetetramine complex[8] (12.5° and 11.4°, respectively). These larger tilt angles suggest that the glucose residues incline so as to make the shape and size of the host cavity more suitable for the accommodation of the guest molecule.

The guest benzyl alcohol molecule is fully enclosed within the β-cyclodextrin cavity. The phenyl group is located at the primary hydroxyl side of the cavity, and occupies the same position as that which the pyridyl group occupies in the β-cyclodextrin complex with nicotinamide.[10] Although in the nicotinamide complex the carbamoyl group protrudes outward from the primary hydroxyl side of the cavity, the hydroxyl group of benzyl alcohol is include within the cavity. The phenyl group has short contacts with C(5)–H methine groups of β-cyclodextrin: the C(3,BA)–H···H–C(5,G5) contact of 2.18 Å and the C(6,BA)–H···H–C(5,G1) contact of 2.09 Å, as shown in Fig. 3. The phenyl plane is not perpendicular to the O(4) plane, but makes an angle of 69.6°. As a result, the methylene group of benzyl alcohol has short contact with C(3)–H methine groups of the G1 and G2 residue: the C(7,BA)–H(A)···H–C(3,G2) contact of 2.02 Å and the C(7,BA)–H(B)···H–C(3,G1) contact of 2.06 Å. The hydroxyl group of benzyl alcohol forms hydrogen bonds with adjacent β-cyclodextrin molecules, as shown by dotted lines in Fig. 3.

β-Cyclodextrin molecules are stacked along the b axis (Figs. 4 and 5). As the O(4) plane of β-cyclodextrin makes an angle of 44.9° with the b axis, β-cyclodextrin molecules make a herringbone-like pattern along the bc plane. Adjacent β-cyclodextrin molecules block both ends of the β-cyclodextrin cavity. The isolated "cage", thus created, accommodates the guest molecule. Water molecules are not included within the host cavity, but fill intermolecular spaces between β-cyclodextrin molecules. As shown in Table 3, water molecules are involved in the formation of many hydrogen bonds. The W1 and W2 water molecules are linked to each other by the O(W1)–H···O(W2) hydrogen bond. The W3 water molecule forms the O(W3)–H···O(W4) hydrogen bond with the W4 water molecule. The W5 water molecule is isolated and forms hydrogen bonds with β-cyclodextrin molecules.

In many β-cyclodextrin complexes,[11–15] two β-cyclodextrin molecules are coupled to form a head-to-head dimer with the secondary hydroxyl sides facing each other. The cylindrical cavity formed by the dimerization can include a guest molecule with its size larger than the depth of a single β-cyclodextrin cavity. On the other hand, the shape and size of the guest molecule are quite restricted in the typical cage-type structure because of the limited space of the host cavity. In α-cyclodextrin complexes with the cage-type structure, for example, the host molecule includes only small molecules such as water,[16] iodine,[17] and alcohols,[18] *etc.* However, the present crystal structure demonstrates that the cage of β-cyclodextrin is sufficiently large to accommodate benzene derivatives. This is a first observation of the cage-structure in the β-cyclodextrin complex with benzene derivatives, although a similar structure was observed in the complex with nicotinamide having a pyridine ring.[10]

CO_2 Laser-induced Decomposition of 1,2-Dichloro-1-fluoroethane

Hiroo OGURA* and Takayuki YANO†

The Institute of Space and Astronautical Science, Komaba, Meguro-ku, Tokyo 153

†*Laboratory of Chemistry, Hitotsubashi University, Kunitachi, Tokyo 186*

(Received November 1, 1984)

$CH_2ClCHFCl$ was photolyzed with a TEA CO_2 laser at 1033.5 cm^{-1}. The infrared multiphoton dissociation mechanism of $CH_2ClCHFCl$ was investigated under various conditions: Sample gas pressure, additive gas pressure, pulse number, pulse energy, and pulse duration. It is concluded that primary process of the IRMPD is direct elimination of molecular HCl and HF, HCl elimination being predominant channel. Primary HCl elimination products *cis*-and *trans*-CHF=CHCl, and CH_2=CFCl are formed at high vibrational levels, from which additional photon absorption occurs in the secondary photolysis to give rise to CH≡CCl, CH≡CF, and CH_2=CHF. All of the secondary products are concluded to be derived from mainly CH_2=CFCl among the chlorofluoroethene isomers. CH_2=CFCl decomposes *via* HF and HCl elimination channels together with the C-Cl bond-rupture channel. CH≡CH appears to be generated by the H atom abstraction reaction of $C_2H\cdot$ radical, which may result from further decomposition of CH≡CCl and/or CH≡CF. The neat IRMPD at higher pressures gives quite similar primary product distribution, but markedly different secondary product distribution from those in shock tube pyrolysis.

Polyatomic molecules under the action of intense infrared laser radiation field can absorb a sufficient number of photons to undergo unimolecular decomposition. In generally accepted theoretical framework for infrared multiphoton excitation and dissociation (IRMPE and MPD) of polyatomic molecules,[1] the molecule is considered to be pumped through three distinct energy regions: In region I where the density of states is very low, the discrete vibrational states are excited by coherent pumping processes. After the absorption of several photons, the density of states increases dramatically, the molecule has entered region II. In this quasicontinuum region, the molecule can absorb the photons of eventually any frequency by incoherent single-photon processes. As the molecular energy increases beyond some dissociation threshold, the molecule has excited into the true continuum region, where unimolecular reactions can compete with the up-pumping processes.

A number of studies have been made of the IRMPD processes in which multiple unimolecular dissociation channels are accessible. The branching ratio between the various unimolecular pathways has been observed to be a strong function of the laser intensity or fluence, which has been explained in terms of the competition between the rates of optical pumping and the individual unimolecular reactions. The experimental advantage of such intramolecular competition together with the laser pumping processes is to probe the internal energy distribution of the excited molecule in comparison with the rates of the individual reaction channels.

Conventional end-product analysis,[2-11] infrared emission spectroscopic technique,[12-14] and molecular beam technique[15] have been employed to measure the branching ratios between the competing unimolecular dissociation channels, and have been analyzed by the RRKM unimolecular reaction theory or simulated on the basis of energy grained master equation.[16,17]

In the IRMPD processes, the energy required to overcome the reaction threshold for the unimolecular decomposition is, at least initially, deposited exclusively in the vibrational modes, while in thermal excitation both the internal and external degrees of freedom of the molecule are in the Boltzmann equilibrium distribution or very close to it. In many molecules studied, the products resulting from the IRMPD have been reported to be similar to those found in the thermal excitation. The product distribution, however, can be different from each other, reflecting the difference in the internal energy distribution of the excited molecule.

Gas cell experiments with focused geometry are valuable to study the unimolecular dissociation and subsequent reactions, because they are easier and more complete in the analysis of stable products than other techniques. Presented below are the results of the IRMPD of 1,2-dichloro-1-fluoroethane, which is expected to undergo unimolecular dissociation *via* at least two pathways, HCl and HF molecular elimination. In the present study, the final products of the photolysis were observed and the mechanisms for unimolecular decomposition and subsequent reactions are determined in as much detail as possible. Several single-pulse shock tube experiments were also carried out to compare the results with those of the IRMPD.

Experimental

A schematic drawing of the experimental arrangement is shown in Fig. 1. A multimode CO_2 TEA laser (Lumonics 103-2) which could be tuned over the various rotational lines of both vibrational bands of CO_2, was used with N_2 added to the lasing gas mixture. The output pulse was considered to consist of an initial sharp spike of 80—100 ns FWHM, followed by a low intensity tail of 1—2 μs.[9,18] The principal line used in these experiments was the P (34) line of the 9.6 μm CO_2 band at 1033.5 cm^{-1}. Determination of the laser transition line was performed with a calibrated grating monochromator blazed at 7.5 μm (JASCO model CT-50). The laser beam passed through a 14-mm circular aperture, could be attenuated selectively with CaF_2 flats, and was focused at the center of the photolysis cell by a 12.7-cm focal length antireflection coated germanium lens. All irradiations were carried out in a 22-cm long×46-mm diameter Pyrex glass cell

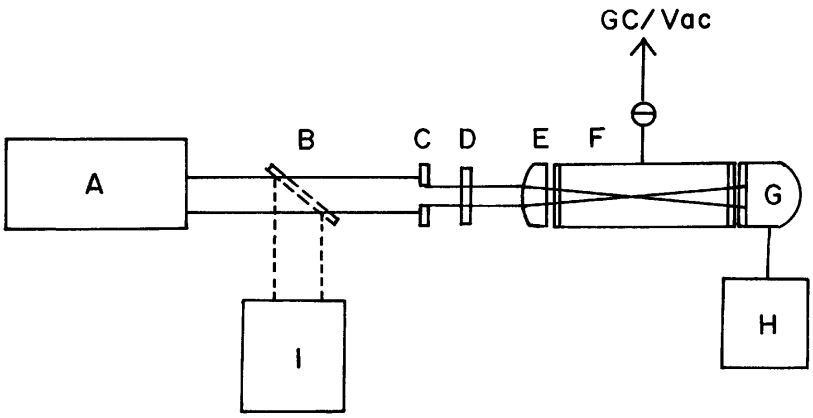

Fig. 1. Schematic diagram of experimental setup.
A: TEA CO_2 laser, B: mirror, C: aperture, D: CaF_2 flat, E: Ge lens, F: photolysis cell, G: pyroelectric detector, H: memory scope, I: monochromator.

with NaCl entrance and exit windows. The windows were compression fit to the Pyrex glass cell with Viton O-rings. The energy output per pulse was measured with a calibrated thermopile (Gen Tec ED-200). The laser was operated at 1 Hz repetition frequency for all runs. The shot-to-shot variation of the pulse energy was found to be within 5%. During the laser irradiation, the pulses were counted by an electronics of our own design.

A conventional glass vacuum system with an oil diffusion pump was used for sample preparation, greaseless stopcocks being used in the sampling manifolds. The pressures in the photolysis cell were measured with MKS Baratron Type 222BHS (0—10 Torr, 1 Torr=133.322 Pa) and 222AHS (0—1000 Torr) pressure transducers with a digital display (Iwatsu Electronics, VOAC 747).

After the focused irradiation of the test gas for 600 shots, the gas sample was analyzed by gas chromatography. The irradiated sample was directly introduced into the sampling loop of the gas chromatograph (Yanaco model G80), or was once condensed in an evacuated bulb of small volume cooled at liquid nitrogen temperature, and then transferred into the sampling loop. To insure the products are completely trapped, the freezeout times ran about 15 min. After the freezeout, the bulb was allowed to warm to room temperature, and to stand at least one hour for complete mixing.

The photolysis products were seperated on a Porapak N column (80—100 mesh, 3-m long) with helium as a carrier gas, and detected with flame ionization detector. The products were identified by comparing their retention times with those of authentic samples. When no authentic gases were available, the unknown products, being fractionated by gas chromatograph, were identified with a FT-IR spectometer (JEOL model JIR 10) and/or with a mass spectometer (Hitachi model RM 50) with library spectrum search.

The amount of each product was determined from its peak area relative to that of standard mixture. Quantitative calibrations were obtained empirically from the standard mixture made to approximate the actual photolysis samples, analytical errors being within 5—10%. The samples were run with temperature programming. In typical gas chromatographic analysis, initially the oven temperature was 60 °C for 18 min, then raised at the rate of 20 °C/min to 110 °C and maintained for 36 min, followed by a final increase to 160 °C.

The reactant $CH_2ClCHFCl$ (PCR min. 94% pure) was purified by using preparative gas chromatographic technique, and was further purified by low temperature distillation under vacuum. *trans*- and *cis*-CHCl=CHCl, and $CH_2=CCl_2$ were obtained from Tokyo Kasei Co. Ltd., and were purified by bulb-to-bulb distillation. Other gases were purchased from Takachiho Shoji Co. Ltd., and were used without further purification. The standard gases which were not available commercially, were prepared from appropriate gases by the IRMPD at high pressures (≈20 Torr), and were fractionated twice by gas chromatograph, and then were distilled several times at low temperatures under vacuum.

The experimetal details of single-pulse shock tube were fully described previously,[19] the analytical procedure being the same as that in the photolysis experiments.

Results

The infrared absorption spectrum of $CH_2ClCHFCl$ shows a maximum at 1033.2 cm^{-1}. No normal vibrational assignment has been made yet, but this band can be assigned to be the C–C stretching vibration in analogy to that in CHFClCHFCl and CH_2ClCF_2Cl.[14] The P (34) line of the 9.6 μm CO_2 band (1033.5 cm^{-1}) was used as the irradiation line for $CH_2ClCHFCl$ for all runs. The first step in the analysis of the stable species produced in the IRMPD of $CH_2ClCHFCl$ was to identify each particular species and to characterize this species in terms of gas chromatographic retention times: A large amount of the photolyzed sample gas was introduced into the gas chromatograph, and the products were isolated from the effluents and were analyzed by mass and FT-IR spectrometry. CH≡CF, CH≡CCl, $CH_2=CHF$, $CH_2=CFCl$, *trans*-, and *cis*-CHF=CHCl were idetified in this way.[20–23] These gases except for $CH_2=CFCl$ were prepared for the quantitative analysis by the IRMPD of $CH_2=CF_2$, $CH_2=CCl_2$, and $CH_2ClCHFCl$, $CH_2=CHF$ being obtained in smaller amounts from the photolysis of $CH_2=CF_2$. CH≡CF has the same retention time as $CH_2=CH_2$ at 60 °C, which could be seperated below 30 °C. No $CH_2=CH_2$ was found in the IRMPD of $CH_2ClCHFCl$.

a) Yields in % conversion per 600 shots at E_0= 0.144 J/pulse. b) Relative yields as compared to the yield of *c*-CHF=CHCl. c) *t* and *c* denote *trans* and *cis*, respectively.

yields as a function of $CH_2ClCHFCl$ pressure have been investigated with the same number of pulses, constant laser energy, same excitation line, and same geometry. Although no dielectric breakdown was observed, visible luminescence streaks were observed with a dark adapted eye around the focus of the lens at higher reactant pressures. The yields together with relative yields are shown in Table 1 in the sequence of their elution times. Major products are *cis*- and *trans*-CHF=CHCl, CH_2=CFCl, *cis*- and *trans*-CHCl=CHCl, CH≡CCl, and CH≡CF. Two lessrer, yet relatively important products are CH≡CH and CH_2=CHF. As minor products, CH_2=CF_2, *trans*- and *cis*-CHF=CHF, and *trans*- and *cis*-CHCl=CFCl are formed, their yields being about one order of magnitude smaller than those listed in Table 1.

At $CH_2ClCHFCl$ pressures below 0.2 Torr, the yields as well as relative yields appear to be relatively constant. As the reactant pressure is increased, each product yield changes in particular way: The yields of *cis*-, *trans*-CHF=CHCl, and CH_2=CFCl increase remarkably, and those of CH≡CF, CH≡CH, and CH_2=CHF slightly with increasing pressure, while the yields of *cis*-, *trans*-CHCl=CHCl, and CH≡CCl decrease. In particular, the yield of CH_2=CFCl increases more rapidly than those of CHF=CHCl isomers with higher $CH_2ClCHFCl$ pressure, while those of *cis*-, *trans*-CHCl=CHCl, and CH≡CCl show an opposite trend. In the case of CH≡CF, CH≡CH, and CH_2=CHF relative yields, there appear to be little pressure dependence.

Dependence on He and H_2 Pressure. The product yields as a function of He and H_2 pressure up to 10 Torr were examined, other photolysis parameters being same or constant. The $CH_2ClCHFCl$ pressure were constant at 0.5 and 1.0 Torr for He and H_2, respectively.

E_0(J/pulse)	0.145	0.143	0.142	0.146	0.138	0.144	0.149

a) Yields in % conversion per 600shots. The pressures of added gases are 2.0 Torr for these runs, reactant pressure being 1.0 Torr.

CH_2=CFCl, *cis*-, *trans*-CHCl=CHCl, CH≡CCl, and CH≡CF decrease rapidly in their yields with increasing He and H_2 pressure. Therefore, rotational hole-filling effect, which has been observed for small molecules,[24,25] is not important for the IRMPD of $CH_2ClCHFCl$ due to its higher density of vibrational-rotational states. Upon the addition of H_2, two lesser products in the neat IRMPD, CH≡CH and CH_2=CHF, increase in their yields at lower pressures, and then decrease at higher pressures, whereas their yields decrease monotonically by the addition of He gas.

In view of relative yields, those for all major products show an increase with higher pressure, but CH_2=CFCl yield shows an opposite trend. The realtive yield of CH_2=CFCl at reactant pressure of 1.0 Torr appears to decrease more quickly than that at 0.5 Torr, both approaching to similar values at higher bath gas pressures. In contrast to the neat IRMPD of $CH_2ClCHFCl$, the rapid decrease of CH_2=CFCl relative yield seems to be accompanied by the rapid increase of CH≡CCl relative yield with higher bath gas pressure. Similarly, the relative yields of CHCl=CHCl isomers show an opposite trend in the absence and presence of bath gases. The relative yield of *trans*-CHF=CHCl increases slowly in the presence of He and H_2. The relative yields of CH≡CH and CH_2=CHF increase much more rapidly in the presence of H_2 than those in the presence of He.

Effects of Additives. Three pairs of gases of 2.0 Torr were added into the parent gas of 1.0 Torr, each pair of gases being considered to have similar efficiency of vibrational energy transfer.[26] The other parameters of photolysis were kept same or constant. The results on the product yields are tabulated in Table 4. Each pair shows a quite different effect on the yield of CH_2=CFCl: He, H_2, and CH_4 reduce the yield of CH_2=CFCl significantly compared with Ar, N_2 and CF_4. At the same time, upon the addition of H_2 and CH_4 the yields of CH≡CH and CH_2=CHF increase, but in the case of CH_4 addition the increase is smaller than that of H_2

addition. The yields of CH≡CF and CH≡CCl appear to be smaller in the presence of H_2 than those on the addition of N_2. The yields of *cis*- and *trans*-CHF=CHCl decrease upon the addition of He and H_2 in relation to those in the presence of Ar and N_2, while in the CH_4–CF_4 pair they show no significant difference. Remarkable reduction in the yield of CH_2=CFCl were also observed on the addition of C_2H_6, C_3H_8, and C_2H_4, which hardly absorb IR photons at the excitation line. Effects of NO were quite similar to those of N_2.

Dependence on Pulse Energy. The dependence of total yield on pulse energy at $CH_2ClCHFCl$ pressure of 0.2 Torr is shown in a log-log plot in Fig. 4. The plots are linear and obey the relationship: Y (yield)$\propto E_0^n$ (pulse energy). From the slope the value of the exponent is found to be n=1.62 and very close to 1.5, of which fluence dependence has been observed in many systems with focused geometry.[27] The 3/2 power dependence can be readily interpreted in terms of a simple threshold model[28,29] which is based on the assumption that all molecules contained in a conical zone where the laser fluence is above some threshold, decompose with unit probability, and neglects any reactions outside this zone. The relative yields as a function of pulse energy are given in Table 5. The relative yields appear to be rather insensitive to the laser energy: About 10 fold increase in energy affected, as an example, the relative yield of *trans*-CHF=CHCl by only 33%. Such insensitivity to the laser energy can be attributed to the focused geometry employed in the present experiments.[6,17]

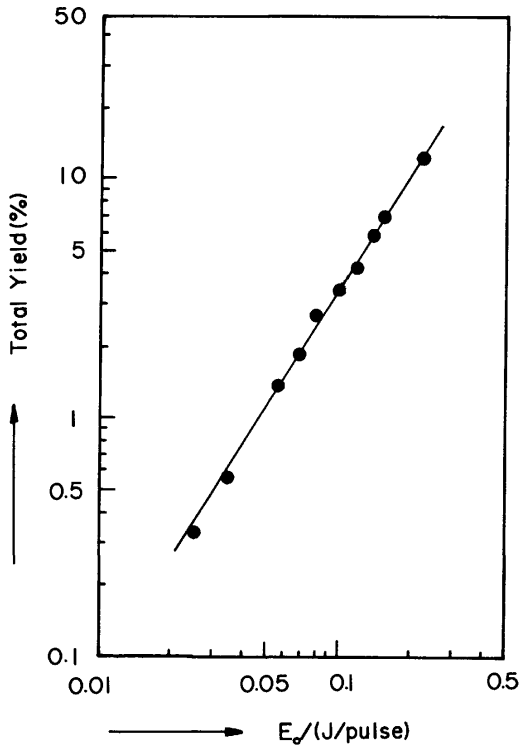

Fig. 4. Total product yield as a function of incident laser energy.

Secondary Photolysis. To investigate the formation pathways to haloethynes, primary HCl elimination products from $CH_2ClCHFCl$, CHF=CHCl isomers and CH_2=CFCl were photolyzed. The sample gas pressures were kept at 0.2 Torr, and the laser energy was the same as that in the neat IRMPD of $CH_2ClCHFCl$ at various pressures. The irradiation lines were so chosen to match their normal absorption spectrum maxima. The results together with that of *trans*-CHCl=CHCl are summarized in Table 6. Table 6 shows that CH≡CCl, CH≡CF, and CH≡CH are generated from the chlorofluoroethene isomers, in particular from CH_2=CFCl, which has no strong absorption at 1033.5 cm^{-1}. Major channels of *trans*-, *cis*-CHF=CHCl, and *trans*-CHCl=CHCl are the isomerization to the other isomers. *cis*-CHCl=CHCl has no absorption band in the CO_2 laser range, but in analogy to *trans*-CHCl=CHCl, the major channel would be also isomerization. It has been recognized that decomposition reaction is markedly reduced in the IRMPD of *trans*-CHCl=CHCl, since the isomerization reaction has lower energy threshold than that of decomposition.[30] This may be also the case for the IRMPD of CHF=CHCl isomers.

At $CH_2ClCHFCl$ pressure of 3.0 Torr, the absolute yield of CH_2=CFCl is about 0.1 Torr. Assuming CH≡CCl, CH≡CF, and CH≡CH be derived entirely from CH_2=CFCl, the % conversions of CH≡CCl, CH≡CF, and CH≡CH would be 26.5, 14.0, and 6.3, respectively, in the IRMPD of $CH_2ClCHFCl$ at the same laser energy. These % conversions are at least 50 times greater in the IRMPD of $CH_2ClCHFCl$ than those in the

a) The reactant pressure is 0.20 Torr, the yields being expressed in % conversion per 600 shots. b) Irradiation wave number used. c) Yields are too small to be quantitatively determined.

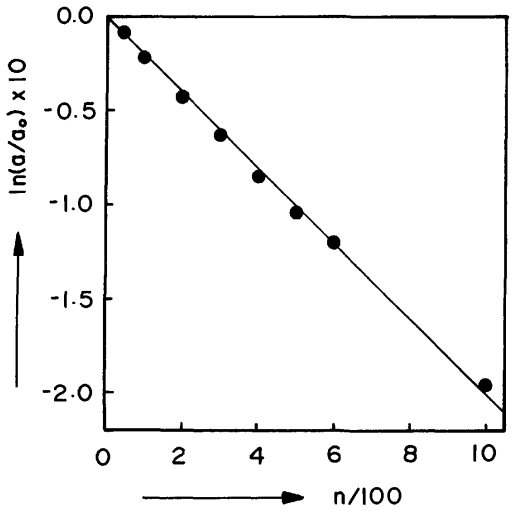

Fig. 5. Total conversion as a function of pulse number.

IRMPD of CH_2=CFCl at the maximum absorptoion wave number of CH_2=CFCl. This suggests that CH≡CCl and CH≡CF are not formed consecutively by the secondary photolysis of primarily generated chlorofluoroethenes accumulating in the system during the laser irradiation.

Dependence on Pulse Number. The product yields as a function of pulse number were tested at the reactant pressure of 0.2 Torr. The results are shown in Fig. 5. Unreacted fraction (a/a_0), where a and a_0 denote final and initial reactant pressures, respectively, deceases exponentially with the increase in pulse number n, indicating pseudo-first order decay over a wide range of pulse number up to 1000. $(a/a_0)=\exp(-dn)$, where d corresponds to the slope and can be regarded to be an apparent dissociation rate constant for $CH_2ClCHFCl$. Each yield versus n is plotted in Fig. 6. As can be seen from Fig. 6, each product yield is proportional to pulse number up to 400 in the lower conversion range, which suggests that the formation of each product is one shot event. This does not necessarily mean that each product is formed during the pulse duration, but formed within the time interval between pulses.

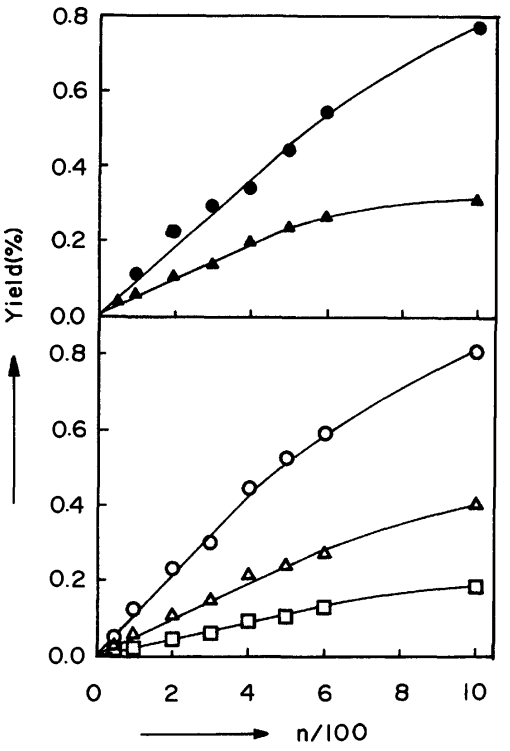

Fig. 6. Individual product yields as a function of pulse number.

a) Yields in % conversion per 600 shots, reactant pressure being 0.2 Torr. b) The yield of *c*-CHF=CHCl is taken equal to 100.

Dependence on Pulse Duration. The effects of Pulse duration on the product yields were examined by two different pulses with the same pulse energy. The laser pulse duration can be varied by changing the ratio of N_2 in lasing gas mixture. In the present experiments two pulses of different duration were generated by shutting or adding N_2 into the lasing gas mixture. The pulse with N_2 added consists of a sharp spike of about 100 ns FWHM with a low intensity tail of about 1 μs,[9] while the pulse without N_2 consists of a sharp spike of about 80 ns FWHM without tailing.[13] The results are given in Table 7. Table 7 shows that the yields of the chlorofluoroethenes, CH≡CCl, and CH≡CF are increased slightly by the irradiation of the short pulse, but the yields of CH≡CH and CH_2=CHF are little affected by the duration of pulse. It is also shown that there

a) Temperature behind reflected shock wave. b) The yield of *c*-CHF=CHCl in % conversion(in parenthesis) is taken to be 100. c) Product yield is too small to be quantitatively determined.

are little effects of the pulse duration on the relative yields. Since almost the same energy is contained in the two pulses, the short pulse has higher intensity than the long pulse with the same fluence. However, the increase of the product yields is very small, at most 18%, and that of the relative yields among competing channels is not observed. Thus intensity is not an important factor in the IRMPD of $CH_2ClCHFCl$.

Pyrolysis. Several pyrolysis experiments were carried out with a single-pulse shock tube. A reaction mixture of 0.285% $CH_2ClCHFCl$ diluted with argon was used. Reaction temperatures ranged from 1060 to 1325 K, the dwell times, total pressures, and reactant pressure being about 840 μs, 660 Torr, and 1.9 Torr, respectively. Under these conditions the decomposition yields ranged from about 3 to 98% (Table 8). All major products found in the IRMPD of $CH_2ClCHFCl$ were also obtained. At the lowest conversions, only chlorofluoroethene isomers are formed. HF elimination channel to produce CHCl=CHCl isomers opens up at higher temperatures. At highest temperature, secondary reactions of the chlorofluoroethenes become significant to give rise to CH≡CCl and CH≡CF together with CH≡CH. The relative yields of the chlorofluoroethene and CHCl=CHCl isomers are similar to those obtained in the IRMPD of $CH_2ClCHFCl$ at higher temperatures. The most remarkable difference is in the relative yields of CH≡CCl and CH≡CF, *viz*, CH≡CF formation is more important than that of CH≡CCl in the high temperature shock tube pyrolysis.

Discussion

Mechanism of Primary Photolysis. The elimination of molecular hydrogen halide from the parent molecule is in line with previous IRMPD studies of halogenated ethanes[31,32] together with thermal[33] and chemical activation studies.[34,35] The intersting feature in chlorofluoroethanes is that a number of competitive dissociation channels seem to be possible:

$$CH_2ClCHFCl \longrightarrow CHF{=}CHCl + HCl \qquad \Delta H^\circ \simeq 19.0 \text{ kcal/mol}^{36}$$

$$\longrightarrow CH_2{=}CFCl + HCl \qquad \Delta H^\circ \simeq 21.1 \text{ kcal/mol}$$

$$\longrightarrow CHCl{=}CHCl + HF \qquad \Delta H^\circ \simeq 10.3 \text{ kcal/mol}$$

$$\longrightarrow \cdot CH_2CHFCl + Cl$$

$$CH_2ClCHF\cdot + Cl \qquad \Delta H^\circ \simeq 80\text{—}90 \text{ kcal/mol}$$

$$\longrightarrow CH_2Cl\cdot + CHFCl\cdot \qquad \Delta H^\circ \simeq 85\text{—}90 \text{ kcal/mol}$$

$$\longrightarrow CH_2{=}CHF + Cl_2 \qquad \Delta H^\circ \simeq 45.0 \text{ kcal/mol}$$

Heats of reaction ΔH° (kcal/mol, 1 cal_{th}=4.184 J) were evaluated at 298 K. The observed product distributions under various conditions in the photolysis and pyrolysis that the chlorofluoroethene isomers are by far the major products, strongly suggest that the principal mode of reaction in the IRMPD of $CH_2ClCHFCl$ is direct elimination of molecular HCl. Similarly, the products CHCl=CHCl isomers formed in lower, yet significant yields, can be ascribed to the molecular elimination of HF:

$$CH_2ClCHFCl + nh\nu \longrightarrow \textit{cis}\text{-}CHF{=}CHCl + HCl \quad (1)$$

$$\longrightarrow \textit{trans}\text{-}CHF{=}CHCl + HCl \quad (2)$$

$$\longrightarrow CH_2{=}CFCl + HCl \quad (3)$$

$$\longrightarrow \textit{cis}\text{-}CHCl{=}CHCl + HF \quad (4)$$

$$\longrightarrow \textit{trans}\text{-}CHCl{=}CHCl + HF \quad (5)$$

IR emission of HCl and HF was observed in related systems,[13] which suggests the HCl and HF formed in Reactions 1—5 are also in their vibrationally excited states. In chemical activation studies coupled with isotopic labelling technique,[37] it has been shown clearly that three-center reaction ($\alpha\alpha$ elimination) competes with four-center reaction ($\alpha\beta$ elimination), if two halogen atoms are located at the same carbon atom. It is thought that the carbene such as CH_2XCX: (X=Cl, F) is thermodynamically more stable than CH_2XCH: due to π bonding between the halogen and the vacant p orbital of the carbene.[38] By analogy with the chemical activation studies of CH_2XCHX_2, $CH_2ClCHFCl$ could eliminate HCl and HF *via* three-center reaction together with more common four-center reaction:

$$CH_2ClCHFCl + nh\nu \longrightarrow CH_2ClCF: + HCl \quad (6)$$

$$\longrightarrow CH_2ClCCl: + HF \quad (7)$$

Three-center reaction is followed by a rapid rearrangement of the carbene. Thus CHF=CHCl and CHCl=CHCl geometrical isomers may be formed by $\alpha\alpha$ elimination processes. $CH_2ClCHFCl$, however, does not permit to distinguish $\alpha\alpha$ elimination from $\alpha\beta$ elimination by their poroducts, the contribution of $\alpha\alpha$ elimination being estimated to be much smaller than $\alpha\beta$ elimination process.[37]

The products expected from the C–C and C–Cl bond scissions of $CH_2ClCHFCl$, *e.g.*, CH_3Cl, CH_2=CHCl, and CH_3CHFCl, were found in trace amounts or not

detected at all. The contribution of the C–C and C–Cl bond scissions could be concluded to be very small under the present conditions. Molecular elimination of halogen was proposed for the IRMPD of $CHCl=CCl_2$,[5] but recent study shows that $CHCl=CCl_2$ decomposes by consecutive Cl atom elimination.[39] If $CH_2=CHF$ were formed directly *via* Cl_2 elimination, its yield would have decreased upon the addition of H_2 as CHF=CHCl and CHCl=CHCl yields did. On the contrary, the increase of $CH_2=CHF$ yield was observed in the presence of H_2 (Fig. 3). Summing up the above considerations, the primary processes in the IRMPD of CH_2Cl-CHFCl under our conditions are direct eliminations of HCl and HF molecules, $\alpha\beta$ elimination of HCl being the predominant channel.

Mechanism of Secondary Photolysis. CH≡CCl, CH≡CF, and CH≡CH were found in the IRMPD of the chlorofluoroethene isomers, which can be interpreted that they result from the secondary photolysis of the primary products in the IRMPD of $CH_2ClCHFCl$. Furthermore, the IRMPD results of chlorofluoroethene isomers (Table 6) may suggest that CH_2CFCl contributes primarily to the formation of CH≡CCl, CH≡CF, and CH≡CH, in which there is no isomerization channels with lower threshold energy among the isomers. CH_2≡CFCl has a number of competing decomposition channels:

$$CH_2=CFCl \longrightarrow CH{\equiv}CCl + HF \qquad \Delta H^\circ \simeq 19.4 \pm 10 \text{ kcal/mol}$$
$$\longrightarrow CH{\equiv}CF + HCl \qquad \Delta H^\circ \simeq 41.3 \pm 15 \text{ kcal/mol}$$
$$\longrightarrow CH_2{=}CF\cdot + Cl \qquad \Delta H^\circ \simeq 80\text{—}90 \text{ kcal/mol}$$
$$\longrightarrow CH{\equiv}CH + FCl \qquad \Delta H^\circ \simeq 75.5 \text{ kcal/mol}$$

Vinylidenecarbene CH_2=C: has very low barrier for the rearrangement,[40,41] and rapidly isomerizes to CH≡CH. In the IRMPD study of deterium labelled chloroethenes, it has been shown that HCl elimination proceeds mainly *via* three-center reaction.[5] In CH_2=CFCl molecule there are no three-center elimination reactions of HCl and HF but for that of FCl.

As mentioned earlier (Table 6), the chlorofluoroethene isomers in their vibrational ground states give rise to much smaller yields of CH=CCl and CH≡CF in their IRMPD even at their maximum absorption bands than those in the IRMPD of $CH_2ClCHFCl$ at 1033.5 cm^{-1}. In addition, the dependence of CH≡CCl and CH≡CF yields on pulse number (Fig. 6) shows that CH≡CCl and CH≡CF are generated within the time period between pulses. Furthermore, it has been shown that longer pulse does not increase the yields of CH≡CCl and CH≡CF in relation to the chlorofluoroethene isomers. Markedly enhanced secondary photolysis in one pulse points to the change in states of the primary photolysis products. Primarily formed chlorofluoroethenes must be excited into the quasicontinuum region or very close to it, in order to readily absorb many photons which are not resonant with the absorption lines of the chlorofluoroethenes;

$$CH_2=CFCl^{\#} + mh\nu \longrightarrow CH{\equiv}CCl + HF \quad (8)$$
$$\longrightarrow CH{\equiv}CF + HCl \quad (9)$$
$$trans\text{-}CHF=CHCl^{\#} + mh\nu \longrightarrow cis\text{-}CHF=CHCl \quad (10)$$
$$\longrightarrow CH{\equiv}CCl + HF \quad (11)$$
$$\longrightarrow CH{\equiv}CF + HCl \quad (12)$$
$$cis\text{-}CHF=CHCl^{\#} + mh\nu \longrightarrow trans\text{-}CHF=CHCl \quad (13)$$
$$\longrightarrow CH{\equiv}CCl + HF \quad (14)$$
$$\longrightarrow CH{\equiv}CF + HCl \quad (15)$$

where $CH_2=CFCl^{\#}$ stands for the CH_2=CFCl molecule vibrationally excited into its quasicontinuum levels. Vibrational excitation of the chlorofluoroethene isomers in line with the chemical activation studies of CH_2XCHX_2:[34,35] The *trans*- and *cis*-CHX=CHX produced from chemically activated CH_2XCHX_2 undergo isomerization, decomposition to CH≡CX being unobserved. Chemically activated $CH_2ClCHCl_2$ and CH_2FCHF_2 are estimated to have average energies of 89.5 and 95 kcal/mol, nearly equal to bond dissociation energies of the C–C bond, respectively. In the IRMPD of $CH_2ClCHFCl$ the contribution of the C–C bond-rupture channel is concluded to be very small. The average energy of $CH_2ClCHFCl$ excited by IRMPE would be smaller than those by chemical activation. Therefore, $CH_2=CFCl^{\#}$, at least, would absorb additional photons in order to decompose to CH≡CCl and CH≡CF, although *cis*- and *trans*-CHF=CHCl might isomerize without absorbing any additional photons.

In a similar manner to CHF=CHCl isomers, major channels of CHCl=CHCl isomers would be isomerization to the other isomers. Smaller yields of CHCl=CHCl isomers in the IRMPD of $CH_2ClCHFCl$ indicates smaller contribution to the formation of CH≡CCl by HCl elimination:

$$trans\text{-}CHCl=CHCl + mh\nu \longrightarrow cis\text{-}CHCl=CHCl \quad (17)$$
$$cis\text{-}CHCl=CHCl + mh\nu \longrightarrow trans\text{-}CHCl=CHCl \quad (18)$$

Activation energies for the isomerization of *cis*-CHF=CHCl and *cis*-CHCl=CHCl are reported to be 58.3 and 56.9 kcal/mol, *cis*-forms being thermodynamically more stable than *trans*-forms by 0.780 and 0.650 kcal/mol, respectively.[42,43]

The increase in the yield of CH_2=CHF upon the addition of H_2 strongly suggests that the C–Cl bond rupture is occurring in the secondary photolysis of the chlorofluoroethenes, in particular, of CH_2=CFCl. In our study of the IRMPD of CF_2ClCH_2Cl,[44] we found that the yield together with relative yield of $CH_2=CF_2$ increased upon the addition of H_2 (D_2), a large amount of $CDF=CF_2$ being observed by mass spectrometry. It is proposed that the observed $CH_2=CF_2$ is produced

primarily *via* H atom abstraction by CF_2=CH· radical, which, in turn, originates from the secondary photolysis of the primary product CF_2=CHCl. This seems to be also the case for the IRMPD of $CH_2ClCHFCl$:

$$CH_2=CFC^{\#} + mh\nu \longrightarrow CH_2=CF\cdot + Cl \quad (19)$$

$$CH_2=CF\cdot + RH \longrightarrow CH_2=CHF + R\cdot \quad (20)$$

where RH denotes any H atom donors, $CH_2ClCHFCl$ molecule itself being RH in the absence of any additives.

Molecular elimination of FCl from CH_2=CFCl to generate CH≡CH seems to be possible in view of smaller heat of reaction than that of the C–Cl bond rupture. However, due to very rapid rearrangement of CH_2=C: to CH≡CH, the formation reaction of CH≡CH is unimolecular in nature, and the addition of H_2 would have resulted in the decrease in its yield with increasing H_2 pressure as that of He did (Figs. 2 and 3).

In a similar manner to the CH_2=CHF formation, CH≡CH may be generated by H atom abstraction reaction of some radical produced during the photolysis. Possible radical would be CH≡C· radical resulting from the decomposition of CH≡CCl and/or CH≡CF. In previous study it was shown that the haloetynes dissociate to give rise to halogen atoms, instead of hydrogen halides,[45] F atom requiring about 20 kcal/mol more energy than Cl scission. CH≡CCl appears to be responsible for the generation of CH≡C· radical, but we will return to this point later. Vibrationally excited haloetynes were observed in the IRMPD of related systems.[13] Therefore, it might be possible that the haloetynes formed in the secondary photolysis are excited to high vibrational levels and dissociate by further photon absorption as in the case of the secondary photolysis:

$$CH{\equiv}CCl^{\#} + m'h\nu \longrightarrow CH{\equiv}C\cdot + Cl \quad (21)$$

$$CH{\equiv}CF^{\#} + m'h\nu \longrightarrow CH{\equiv}C\cdot + F \quad (22)$$

$$CH{\equiv}C\cdot + RH \longrightarrow CH{\equiv}CH + R\cdot \quad (23)$$

Effects of Pressure on Mechanism. As shown in Table 1, all product yields increase linearly with higher pressure up to 0.2 Torr, above which they show nonlinear behaviors. In the primary photolysis direct elimination of HCl and HF is apparently dominant mechanism of dissociation at both lower and higher pressures. However the mechanism operative at lower pressures may not be the same as that at higher pressures. In the high pressure region, true MPD still can occur, but here there are several factors which may influence the dissociation mechanism.

One of the factors which might result in a different dissociation mechanism is the collisions between the laser excited species prior to dissociation. These collisions may serve to randomize the energy among the laser excited collision partners, resultant radomization will show an effective distribution which may be different at higher pressures from that at lower pressures. These randomizations come in the form of energy gain/loss collisions, energy-pooling process, where one molecule gains and the other molecule loses energy.

The chlorofluoroethene yields increase remarkably with increasing reactant pressure, while higher channel product yields of CHCl=CHCl isomers are insensitive to the increase of $CH_2ClCHFCl$ pressure. At higher pressures energy-pooling process mentioned above can take place between two excited parent molecules with the energy below the lower energy threshold, one gaining energy beyond the lower critical energy:

$$2CH_2ClCHFC^{\#} \longrightarrow CH_2ClCHFCl^{*} + CH_2ClCHFCl \quad (24)$$

where $CH_2ClCHFCl^{\#}$ and $CH_2ClCHFCl^{*}$ represent the $CH_2ClCHFCl$ molecules excited below and above the critical energy for HCl elimination, respectively. The insensitivity of the CHCl=CHCl yields to the reactant pressure indicates that $CH_2ClCHFCl^{*}$ does not gain energy by the collision beyond the higher energy threshold:

$$CH_2ClCHFCl^{*} \longrightarrow cis\text{-}CHF{=}CHCl + HCl \quad (25)$$

$$\longrightarrow trans\text{-}CHF{=}CHCl + HCl \quad (26)$$

$$\longrightarrow CH_2{=}CFCl + HCl \quad (27)$$

In a gas cell IRMPD experiment with a focused geometry, the irradiation zone becomes optically inhomegeneous, and the results on the yields are average over the fluence distribution of the focused laser beam. As noted earlier, the dependence of total yield on laser energy at lower reactant pressures (Fig. 6) was rationalized by a simple threshold model. As the pressure is increased, this model is not applicable, since in high pressure range molecular collisions cannot be neglected. The simple extended threshold model presented by Hackett *et al.*[6] will be convenient to discuss the pressure dependence observed in the present study. In this model for a two-channel system, the conical beam is divided into three volume elements: The lower decomposition channel is induced for all molecules with unit efficiency at some threshold fluence F_1. At some higher fluence F_2, the irradiation field is sufficiently intense to derive all molecules to internal energies where upper decomposition channel predominates. The irradiated volume which is subjected to fluence between F_0 and F_1 is inhomogeneously excited by the field, where F_0 denotes incident fluence. When reactant pressure is low enough, the excited molecules would be cooled without any chance to collide with other excited molecules. At these pressures, the relative yields from various processes are equal to the ratios of volumes defined by the threshold fluence contours which describe them, being shown to be insensitive to pulse energy in this model. Our results on the relative yields versus pulse energy (Table 5) are consistent with the prediction based on this extended threshold model. The molecules outside the reaction

zone are excited by laser to an energy level not enough to decompose haloethene and HCl spontaneously. At higher reactant pressures, collision-induced decomposition by energy-pooling process can take place efficiently outside the reaction zone. It is not unreasonable that the collision-induced dissociation exits preferentially by the lower channels, increasing HCl elimination product yields with increasing pressure. The relative yields of HF elimination products CHCl=CHCl decrease with higher reactant pressure: The branching ratio between HCl and HF elimination channels is about 100:11 and 100:4 at 0.1 and 3.0 Torr reactant pressure, respectively. The yields of CHCl=CHCl isomers appear decrease slightly at higher pressures. IRMPD *via* HF elimination channels will take place efficiently only inside the inner reaction zone, where the laser fluence is higher than the threshold fluence F_2. At higher reactant pressures the energy absorption along the laser beam reduces the volume of the inner reaction zone, which results in the decrease of the CHCl=CHCl yields.

The yield of CH≡CCl does not increase but decrease to the same extent as those of CHCl=CHCl isomers with increasing substrate pressure. This strongly suggests that secondary photolysis is occurring primarily inside the outer reaction zone with the fluence between F_1 and F_2, and that the chlorofluoroethenes generated by the collision-induced decomposition outside the reaction zone remain undecomposed by the secondary photolysis. The relative yield of CH_2=CFCl increases by about 8.5 times more rapidly than that of *trans*-CHF=CHCl with increasing reactant pressure. This rapid increase of CH_2=CFCl relative yield with higher reactant pressure can be ascribed to the formation of CH_2CFCl outside the reaction zone *via* collision-induced decomposition, and indicates that decomposition of the chlorofluoroethene isomers occurs predominantly from CH_2=CFCl inside the reaction zone. Curiously, the yield of CH≡CF increases slightly with higher pressure. Other mechanism for the formation of CH≡CF may be operative at higher pressures.

Another intermolecular energy transfer process is collisional deactivation. This is the collision between vibrationally hot and cold molecules. When buffer gas is added to the reactant, energy pooling between excited parent molecules is suppressed by the buffer gas. In the presence of buffer gas, collision-induced decomposition is markedly reduced by collisional deactivation. As shown in Figs. 2 and 3, even the yields of CHCl=CHCl and CH≡CCl, which are thought to be formed primarily inside the reaction zone, decrease rapidly even at low He and H_2 pressures. Therefore, the collisional vibrational deactivation of the excited parent molecules inside the reaction zone starts even at low buffer gas pressure in the IRMPD of CH_2ClCHFCl. However, quenching of energy-pooling process is revealed in the relative yield of CH_2=CFCl: As discussed above, the increase of CH_2=CFCl relative yield with rising substrate pressure results from the energy-pooling processes outside the reaction zone. Therefore, more rapid decrease in the relative yield of CH_2=CFCl at 1.0 Torr CH_2ClCHFCl at lower buffer gas pressures than that at 0.5 Torr could be ascribed to the quenching of energy-pooling processes by the buffer gases outside the reaction zone.

An opposite trend of the relative yields of CHCl=CHCl, CH≡CCl, and CH_2=CFCl observed in the absence and presence of buffer gas indicates that the collisional deactivation derives the energy distribution of the dissociating parent molecules to higher energy distribution with higher buffer gas pressure, resulting in greater relative yields for most products. However, at higher energy distribution more CH_2=CFCl is decomposed to CH≡CCl and CH≡CF, the decrease in CH_2=CFCl and increase in CH≡CCl and CH≡CF relative yields being observed. Very slight increase of *trans*-CH=FCHCl relative yield as compared with that of CH_2=CFCl with rising He a H_2 pressure will support our finding that the decomposition channels of CHF=CHCl isomers contribute to smaller extent for the formation of secondary products. By the same reason as CH≡CCl and CH≡CF, the relative yields of CH≡CH and CH_2=CHF increase slightly upon the addition of He, being much enhanced by the presence of H_2: In the presence of H_2, much more H atom donors are available than in the presence of He, in which only the substrate molecule acts as H atom donor.

By the addition of buffer gases with similar energy transfer efficiency, the excited molecules would be quenched collisionally, and the products yields would be suppresses to a similar extent. Actually, no significant difference is observed in the yields of *trans*- and *cis*-CHF=CHCl, CH≡CCl, and CH≡CF upon the addition of CH_4 and CF_4. On the other hand, there appear to be remakable difference in the yield of CH_2=CFCl between CH_4 and CF_4. In our mechanism, CH≡CCl and CH≡CF are formed primarily from CH_2=CFCl. Therefore, the C–Cl bond-scission channel Reaction 19 will cause the difference in the yield of CH_2=CFCl. The radicals formed *via* a bond-scission reaction will recombine initially inside the reaction zone:

$$CH_2{=}CF\cdot + Cl \xrightarrow{M} CH_2{=}CFCl \qquad (28)$$

Other recombination reactions such as

$$2CH_2{=}CF\cdot \xrightarrow{M} CH{\equiv}CF + CH_2{=}CHF,\ CH_2{=}CFCF{=}CH_2$$

$$2Cl + M \longrightarrow Cl_2$$

are slower processes than Reaction 28. In the presence of H atom donor RH, abstraction reactions of the radicals become competitive with the recombination reaction, and CH_2=CF· radical and/or Cl atom are lost, being unrecovered as CH_2=CFCl by Reaction 28:

$$CH_2{=}CF\cdot + RH \longrightarrow CH_2{=}CHF + R\cdot \qquad (20)$$

$$Cl + RH \longrightarrow HCl + R\cdot \quad (29)$$

Upon the addition of H_2, $CH_2=CF\cdot$ radical is lost, while upon the addition of CH_4, Cl atom is lost by Reaction 29. The rate constant of Cl with CH_4 is about one order of magnitude greater that that with H_2.[46] In the IRMPD of CF_3I, the yield of I atom is observed to be much smaller than the real yield due to the recombination reaction between I atom and $CF_3\cdot$ radical.[47] This is in line with our observation that the C-Cl bond-scission channel is masked by the recombination reaction. In the case of Ar and He pair, there will be no chemical reaction with the rare gases added. Collisional quenching is only possible process to affect the product yields. Similar effects of collisional quenching and chemical reactions on the yields of *trans*- and *cis*-CHF=CHCl are observed to smaller extent in the presence of monoatomic and diatomic pairs (Table 4). CH≡CCl and CH≡CF are supposed to further decompose to generate CH≡C· radical by Reactions 21 and 22. Similar effects of the additives can be expected for these decomposition reactions, since these reactions generate radicals. These effects appear to be demonstrated in H_2 and N_2 pair: The yields of CH≡CCl and CH≡CF are decreased upon the addition of H_2 as compared with those on N_2 addition, probably due to the abstraction reaction of CH≡C· radical from H_2. Relatively significant decrease is observed for CH≡CF yield, indicating that a large fraction of CH≡CF is decomposed to CH≡C· and F. The observed increase of CH≡CF yield with higher reactant pressure in the neat IRMPD (Table 1), may be interpreted in terms of the enhanced recombination rate with higher substrate pressure. The effect of the recombination reaction may be very small for the yield of CH≡CCl, since the yield of CH≡CCl is much greater than that of CH≡CF.

Comparison with Thermal Excitation. As can be seen from Tables 1 and 8, the primary product distribution obtained in the shock tube pyrolysis bears a strong resemblance to that of the neat IRMPD of $CH_2ClCHFCl$ at 3.0 Torr. According to the simple extended threshold model, the volume of the reaction zone in which the fluence exceeds the lowest critical fluence value is constant at a given pulse energy, the absorption along the laser beam being neglected. The difference of the % conversions between 0.1 Torr and 3.0 Torr could be ascribed to the contribution from the collision-induced decomposition outside the reaction zone. Therefore, the similarity of the primary product distribution between the shock tube pyrolysis and the neat IRMPD at 3.0 Torr might not be surprising, since at 3.0 Torr more than one halves of CHF=CHCl and almost all $CH_2=CFCl$ molecules are generated by the collision-induced decomposition outside the reaction zone where the laser excited $CH_2ClCHFCl$ molecules are rapidly being thermalized by collisions, and the collision-induced decomposition *via* energy pooling resembles intrinsically the dissociation processes in a thermal excitation system such as shock tube pyrolysis. However, the relative yields of the haloethenes derived from the the collision-induced decomposition are estimated to be *cis*-CHF=CHCl:*trans*-CHF=CHCl:$CH_2=CFCl \simeq 100:72:59$ at 3.0 Torr, assuming that the % conversions inside the reaction zone be unchanged and corrected for the absorption along the laser beam to the same extent as those of CH≡CF and CHCl=CHCl yields. The estimated relative yields are much greater than those of shock tube pyrolysis at 1060 K, where the decomposition *via* upper channel is not appreciable as well as outside the reaction zone. This may suggest that the initial energy distribution created by the laser pulse outside the reaction zone is transferred by the energy-pooling process to a new energy distribution which has more enhanced tail between the lower and upper energy thresholds than that of corresponding Boltzmann thermal distribution.

In the shock tube pyrolysis at higher temperatures, the Boltzmann thermal distribution has a higher energy tail which crosses the upper HF elimination channels. At lower reactant pressures, where the contribution of the decomposition outside the reaction zone is negligible, the relative yields of CHCl=CHCl isomers are about three times greater in the IRMPD than those in the shock tube pyrolysis. In the present model, all molecules contained inside the outer and inner reaction zone are excited to internal energies above the lower and higher critical energies for the decomposition, respectively. Therefore, the internal energy distribution inside the reaction zone, in a similar manner to that outside the reaction zone, has also more enhanced tail above the higher energy threshold than that of the Boltzmann distribution corresponding to the temperatures examined in the shock tube pyrolysis. In a thermal excitation system, the energy distribution is an explicit function of temperature, while the energy distribution inside the reaction zone with a focused laser beam is not affected by the incident laser energy. Consequently, the comparison of the energy distribution inside the reaction zone with that in the pyrolysis remains superficial, and the fluence effect on the energy distribution would not be persued properly by such a bulk IRMPD experiment with a focused geometry as mentioned above.

In contrast to the primary product distribution, the seconary product distributions are quite different from each other in the IRMPD and shock tube pyrolysis of $CH_2ClCHFCl$. IR emission investigation on the $CH_2=CFCl$ IRMPD by Jalenak and Nogar[12] also shows that the intensity of HF emission is much greater than that of HCl. The branching ratio between CH≡CCl and CH≡CF formation channels observed in the IR emission study is in line with that obtained by gas chromatographic analysis of CH≡CCl and CH≡CF in the present IRMPD study of $CH_2ClCHFCl$, where CH≡CCl and CH≡CF are derived mainly from the primary product $CH_2=CFCl$. In the shock tube pyro-

lysis, CH_2=CHF was found in very small amounts, which might suggest some mechanistic change to give rise to CH≡CCl and/or CH≡CF in the shock tube pyrolysis.

The authors wish to express their thanks to Professor Kenji Kuratani, the Insitute of Space and Astronautical Science, for his encouragement and interest in this work. One of the authors (T. Y) is grateful to Professor Tschuikow-Roux, University of Calgary, for valuable discussions.

(Received November 2, 1984)

The effects of a magnetic field on electrolytic currents in hexacyanoferrate(II) and hexacyanoferrate(III) solutions were studied under various conditions by means of potentiometry. These effects were observed for a wide range of current densities (10^{-6}—10^{-3} A/cm^2). The results were interpreted in terms of the magnetohydrodynamic effect, including a change in the solution density during electrolysis. The present observation suggests that a magnetohydrodynamic flow strongly affects the electrochemical processes on an electrode surface.

Studies regarding magnetic field effects on chemical reactions have attracted the attention of many chemists because of their novelity as a phenomenon and their wide utility and potentiality such as for the regulation of reaction products, the elucidation of a reaction mechanism, and isotope separation.[1] Some of the present authors have studied the magnetic field effect on various photochemical reactions taking place in solutions.[2] As an extension of our research program, we have undertaken to study magnetic field effects on electrochemical reactions in solutions.

A number of studies has, hitherto, been carried out on magnetic field effects on electrolytic properties,[3] electrolytic mass transport,[4] electrode kinetics,[5] and others.[6] However, only a few papers have been published concerning magnetic field effects upon electrochemical reactions, including the electron transfer processes in which we are much interested.

In this paper, we report several electrochemical reactions which were undertaken by means of potentiometry in the presence and absence of an external magnetic field. The magnetic field is known to remarkably affect the electrolytic reduction of Fe^{3+} and the oxidation of Fe^{2+} in the high current-density region where the reaction is diffusion-controlled.[5] We have succeeded in observing the magnetic field effect even in a low current-density region (10^{-5}—10^{-6} A/cm^2), where the process is usually believed to be reaction-controlled. All the results have been interpreted in terms of the magnetohydrodynamic effect.

Experimental

Figure 1 is a schematic diagram of the present experimental set-up. An electrolytic cell and electrodes were placed between the poles of an electromagnet (Tohoku Kinzoku Kogyo Co., model SEE-15). A magnetic field did not affect the potential of a saturated calomel electrode (SCE) used as a reference electrode.

Two orientations of the magnetic field with respect to the working electrode were employed for electrolysis as schematically shown in Figs. 2, 3, and 4. One side of the working electrode (5×10 mm Pt plate) was covered with

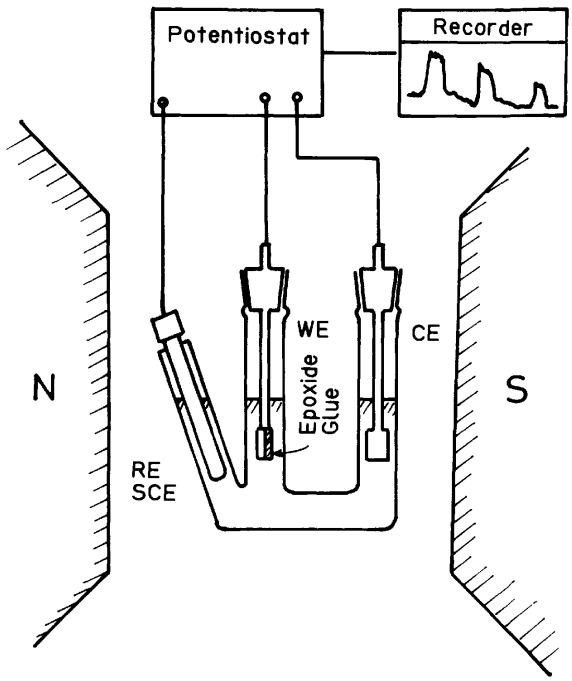

Fig. 1. Schematic diagram of experimental set-up. RE (reference electrode, SCE), WE (working electrode), and CE (counter electrode).

epoxide glue. The electrode plate was always kept parallel to the magnetic flux, and only the polarity of the magnetic field was changed (by alternating the direction of the electromagnet's current).

The electrolysis was carried out without stirring using a potentio/galvano stat (Hokuto Denko, model HA-102). Values of electrolytic current in the presence and absence of a magnetic field (represented hereafter I_H and I_O, respectively) were measured at a controlled potential of the working electrode. Argon gas was passed through the electrolytic solution to purge any dissolved oxygen before electrolysis took place.

Special grade $K_4[Fe(CN)_6]$ and $K_3[Fe(CN)_6]$, and a nonfluorescent grade glycerol were used without further purification. Potassium sulfate, which was used as a supporting electrolyte, was recrystallized from water. All the chemicals were obtained from Katayama Chemical Industries Co., Ltd.

Results

The effects of a magnetic field upon the potential/current curves of hexacyanoferrate(II) oxidation and hexacyanoferrate(III) reduction in a 1.0×10^{-1} mol/dm^3

†Adjunct Associate Professor of IMS, 1983—1984. Faculty of Pharmaceutical Sciences, Kanazawa University.

††Visiting Research Fellow from Hamamatsu Photonics K.K.

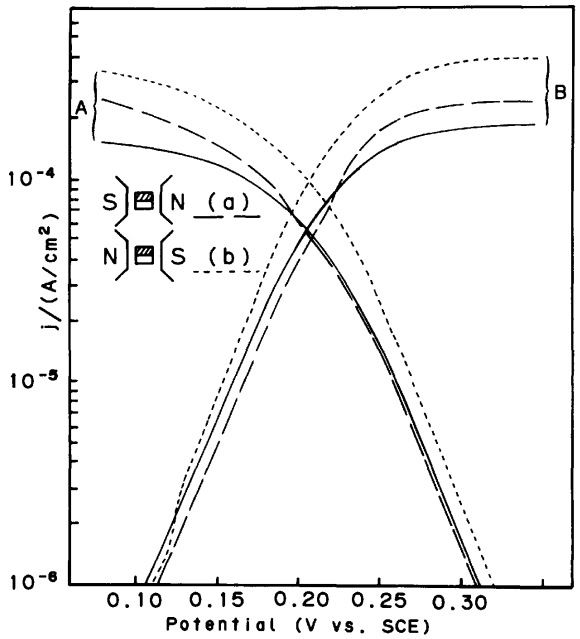

Fig. 2. Potential/current curves for (A) reduction of $K_3[Fe(CN)_6]$ (1.0×10^{-2} mol/dm^3) and (B) oxidation of $K_4[Fe(CN)_6]$ (1.0×10^{-2} mol/dm^3). Concentration of K_2SO_4 supporting electrolyte is 1.0×10^{-1} mol/dm^3). (——), at the residual magnetic field (6.2 mT); (— —), magnetic field orientation-(a) at 1.7 T; (·····), magnetic field orientation-(b) at 1.7 T. potassium sulfate aqueous solution were measured. The results are shown in Fig. 2. When a magnetic field was applied, the electrolytic current gradually changed for several tens of minutes and then reached a constant value. The magnetic field effects were observed in a limiting current (diffusion-controlled) region as have been reported in the literature.[4,5] The same is true for the low current density (reaction-controlled) region.

The effect of hexacyanoferrate(II) concentrations on a magnetic field-induced change in a limiting current is shown in Fig. 3. As the concentration increases, the ratio $R(=I_H/I_0)$ increases in magnetic field orientation-(b), while in orientation-(a) it decreases gradually to 0.8, and then increases rapidly up to 2.5. At the higher concentration, the ratio seems to become almost constant. In order to investigate the influence of the viscosity of a solution upon the current in the presence and absence of a magnetic field, a measurement was made with a 1.0×10^{-2} mol/dm^3 hexacyanoferrate(II) aqueous solution containing 3.0 mol/dm^3 glycerol. The results are also shown in Fig. 3.

The influences of the external magnetic field on the anodic current in various concentrations of hexacyanoferrate(II) are presented in Fig. 4. The curves for 3.0×10^{-2} mol/dm^3 or 1.0×10^{-2} mol/dm^3 in Fig. 4 are very similar in their shapes to the corresponding ones with regard to the magnetic field orientations in Fig. 3B. This means that the dependence of R upon the concentration is similar to that upon the magnetic field.

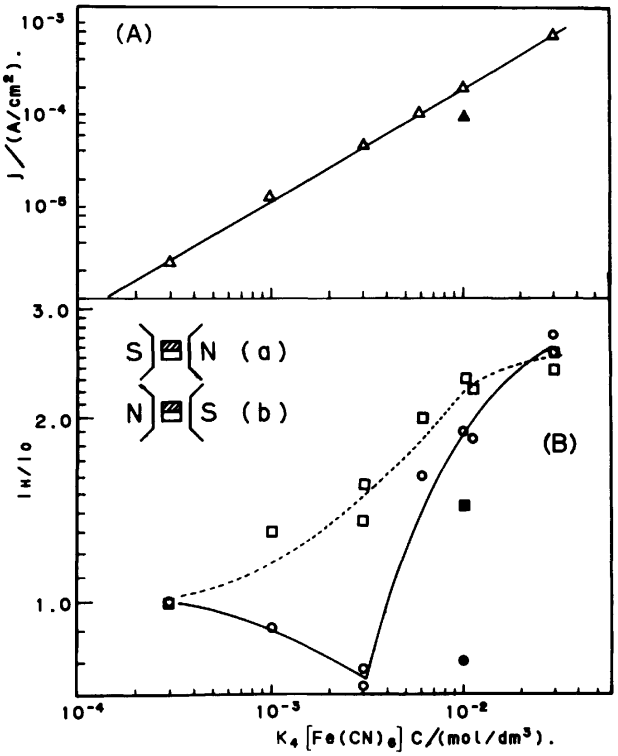

Fig. 3. Concentration dependence of $K_4[Fe(CN)_6]$ in the prssence of 1.0×10^{-1} mol/dm^3 K_2SO_4 at 0.45 V *vs.* SCE.

Discussion

An increase in the electrolytic current in the presence of a magnetic field has already been interpreted in terms of a magnetohydrodynamic model where the magnetohydrodynamic force induces a flow of the solution and enhances the rate of diffusional mass transfer.[4,5]

According to Aogaki *et al.*[7] under the conditions where the magnetohydrodynamic flow is mostly predominant, the ratio R is proportional to the 1/3 power of the magnetic field strength B and to the 1/3 power of the electrolyte concentrations. The concentration dependence of R in Fig. 3B and the magnetic field dependence of R in Fig. 4 seem to agree with this theoretical prediction in the high concentration region ($\geq5\times10^{-2}$ mol/dm^3) and in the strong magnetic field strength ($\geq$ 0.5 T), respectively.

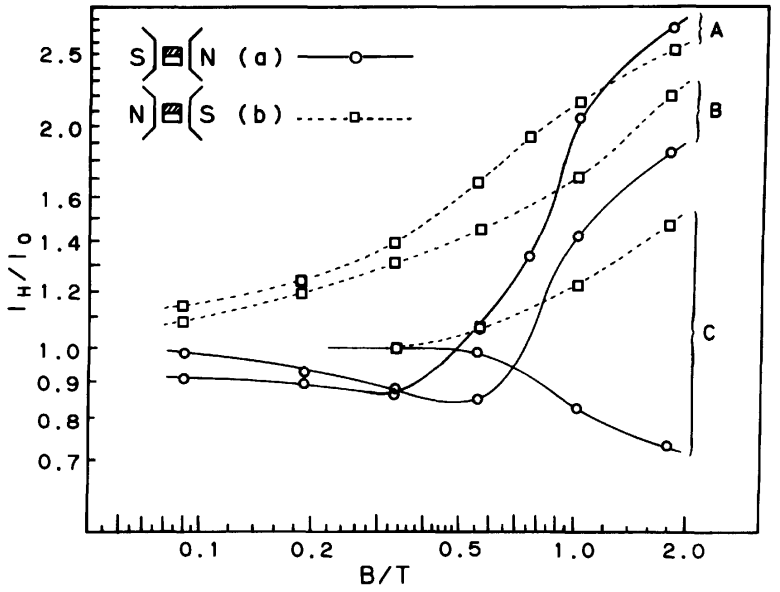

Fig. 4. Magnetic field dependence for $K_4[Fe(CN)_6]$ aqueous solution at 0.45 V *vs.* SCE. The concentration of K_2SO_4 is 1.0×10^{-1} mol/dm^3. (A), 3.0×10^{-2} mol/dm^3 $K_4[Fe(CN)_6]$ (B), 1.0×10^{-2} mol/dm^3 $K_4[Fe(CN)_6]$ and (C), 3.0×10^{-3} mol/dm^3 $K_4[Fe(CN)_6]$. (—○—) magnetic field, orientation-(a) (···□···), magnetic field orientation-(b).

Thus, under these conditions, the magnetic field effect on the electrolytic current can be explained in terms of the magnetohydrodynamic mechanism.

On the other hand, in the low concentration region or in a weak magnetic field, we observed not only an increase in the current under the magnetic field but also its decrease (shown in Figs. 2, 3, and 4).

In the case of hexacyanoferrate(II) oxidation in Fig. 2, upon electrolysis a density of the electrolyte solution localized near the working electrode may become smaller than that of the bulk solution, because the specific gravities of potassium hexacyanoferrate(III) and potassium hexacyanoferrate(II) aqueous solution are 1.002_4 at 3.0×10^{-2} mol/dm^3 and 1.003_9 at 2.7×10^{-2} mol/dm^3, respectively.[8] Therefore, the solution on the surface of the electrode may flow upward. On the other hand, the direction of the magnetohydrodynamic force is downward in magnetic field orientation-(a). This means that the magnetohydrodynamic force prevents a natural convection flow under these conditions, and the anodic current may decrease under the field in the low current density region (10^{-5}—10^{-6} A/cm^2), where the magnetohydrodynamic force is smaller than the natural convection force. In the high current density region ($>10^{-4}$ A/cm^2), the magnetic field increases the current density because the flow due to the magnetohydrodynamic force is much stronger than for convective flow. The magnetic field in orientation-(b) always increases the electrolytic current, because the direction of a magnetohydrodynamic force is parallel to that of the natural convective flow. Thus, we can explain the magnetic field effects upon the potential/current curves of hexacyanoferrate(II) oxidation as shown in Fig. 2. This interpretation is supported by the slow response of the electrolytic current to an applied magnetic field.

The potential/current curves of hexacyanoferrate(III) reduction in Fig. 2 are explained in a manner similar to that of the hexacyanoferrate(II) oxidation mentioned above. In this case, both the directions of the magnetohydrodynamic force and the natural convection flow become opposite. This can be compared with the case for hexacyanoferrate(II) oxidation. Therefore, a decrease in the electrolytic current density in the presence of a magnetic field was observed also for magnetic field orientation-(a).

According to the relation $\boldsymbol{F}=j\times\boldsymbol{B}$ (where $\boldsymbol{F}$ is a magnetohydrodynamic force and j is a electrolytic current density), the concentration dependence and the magnetic field dependence of R should resemble each other. As shown in Figs. 3B and 4, our observations are in good agreement with this prediction. This confirms our interpretation that all results presented here can be explained in terms of magnetohydrodynamics.

A magnetohydrodynamic flow velocity is affected by the viscosity of a solution. Figure 3 shows the measured results for a solution containing 1.0×10^{-2} mol/dm^3 hexacyanoferrate(II) and 3.0 mol/dm^3 glycerol, the viscosity of which is higher than that of the glycerol-free solution by a factor of 2.3. From this figure we can see that the limiting current density and R decrease for a viscous solution containing glycerol compared with a corresponding glycerol-free solution.

Photocatalytic Oxidation of Sulfur on the Doped TiO_2 Catalysts

Yasumichi MATSUMOTO,* Yasuhide YAMAGUCHI, and Ei-ichi SATO
Department of Industrial Chemistry, Faculty of Engineering, Utsunomiya University, Ishi-icho 2753, Utsunomiya 321
(Received November 5, 1984)

TiO_2(anatase) doped with various elements was used as the photocatalyst in the production of sulfuric acid from sulfur in water into which O_2 was bubbled. The catalysts doped with typical elements having one and two valencies showed high catalytic activity, but some doped with typical elements having four and five valencies showed low activity. The intermediate, *i.e.*, O_2H radical, in the O_2 reduction produced by photoproduced electrons will probably play an important part in the production of sulfuric acid. Therefore, it was suggested that the Ti^{3+} ion in the TiO_2 lattice which contribute to direct O_2 reduction will inhibit sulfuric acid production. In the case of transition metal dopants, the transition metal cation in the TiO_2 lattice will directly affect the O_2 reduction. The catalyst doped (deposited) with Pt shows the highest catalytic activity of all the catalysts used in the present study.

Photocatalytic reactions are very important when using solar energy as a substitute for activation energy (downhill reaction), and in the chemical storage of solar energy (uphill reaction). We have discovered that sulfur is directly oxidized to SO_4^{2-}, *i.e.*, sulfuric acid, on a TiO_2 photocatalyst in water into which O_2 is bubbled.[1] This is a downhill reaction. Solar energy is used as a substitute for activation energy in this process. The direct production of sulfuric acid from sulfur by a photocatalyst is very important to the chemical industry.

However, the prodution rate of the sulfuric acid is very slow, if TiO_2 is used as the photocatalyst.[1] It is well known that the photocatalytic activity of TiO_2 is enhanced significantly by doping or deposition of some elements onto the TiO_2 surface.[2-11] Therefore, doped TiO_2 was used as the catalyst in the photocatalytic oxidation of sulfur in the present study. Some of the dopants gave higher activity, but others gave lower activity in this catalysis. In the present paper, we have discussed the catalysis bv doped TiO_2 as well as the mechanism for the photocatalytic oxidation of sulfur.

Experimental

Solid sulfur (99.99%, Rare Metallic Co. Ltd.,) and TiO_2 powder (99.6%, anatase, Merck) were used as the reactant and the catalyst, respectively. Unless otherwise stated, the doping was done by thermal decomposition of metal salts (nitrate, acetate, oxalate and chloride) on TiO_2 powder at 500 °C for 3 h, since the maximum catalytic activity was obtained at a heat treatment temperature of about 500 °C. Only TiO_2 (anatase) was detected for 1 atm% doped TiO_2 except for Pt doped TiO_2 by X-ray analysis. In the case of the latter sample, Pt metal as well as TiO_2 were detected. Pt probably is not doped into the TiO_2 lattice but is instead deposited on the surface.

Sulfur (0.4 g) was mixed with the doped TiO_2 (0.02 g) and water (50 ml). This suspension was poured into a quartz vessel and magnetically stirred with bubbling O_2 gas. It was then illuminated with an ultrahigh-pressure mercury lamp (500 W). A cutoff filter which transmits 50% of 290 nm of light, but completely cuts off light shorter than 240 nm was used in order to suppress the photoreaction of the sulfur itself, unless otherwise stated. The products were analyzed in the same manner as described in the previous paper.[1] When SO_4^{2-} ion could not be gravimetrically determined as $BaSO_4$ because it was present in a very small amount, the SO_4^{2-} was calculated from the pH value of the solution.

Results

Figure 1 shows the production rates of SO_4^{2-} and H_2S on the doped TiO_2 as a function of the concentration of the dopants. Similar tendencies to those in this figure were observed for other dopants. The production rates of SO_4^{2-} and H_2S show the maximum and the minimum at about 1 atm% concentration of the dopants, respectively. This result suggests that the elements, except for Pt, are doped into anatase lattice up to about 1 atm% but not above this range, as described in the latter section. No other products, for example $S_2O_3^{2-}$ or SO_3^{2-}, were detected for all catalysts. Photoreaction products were scarcely detected when doped rutile powder was used as the catalyst. Therefore, the anatase structure is very important for catalysis in the photooxidation of sulfur in the case of the doped TiO_2 as well as nondoped TiO_2.[1]

Figure 2 shows the relationship between the production rate of SO_4^{2-} and the ionic valency of the dopant in the TiO_2 lattice. The ionic valencies of the dopants used in this figure are those of their oxides which are the most stable under ordinary conditions. Pt was classified for convenience as a zero value, because Pt metal was detected by X-ray analysis as stated above. In general, the catalytic activity decreases with the increase in the ionic valency of the dopant. This tendency is especially clear for the typical element. Typical element dopants, having ionic valencies of one, two and three, will lead to a decrease in the amount of Ti^{3+}, while those having an ionic valency of five will lead to an increase of Ti^{3+} in the TiO_2 lattice, if the amounts of the oxygen anion vacancies are constant in the lattice. The catalytic activity of the nondoped anatase (SO_4^{2-} production rate=0.2×10^{-4} mol h^{-1}) is almost the same as those doped with typical elements having ionic valencies of three and four. This will be in agreement with the fact that the Ti cation exists as Ti^{3+} or Ti^{4+} in the TiO_2 lattice. It may be concluded from the above results that the existence of Ti^{3+} in the TiO_2 lattice will inhibit the produc-

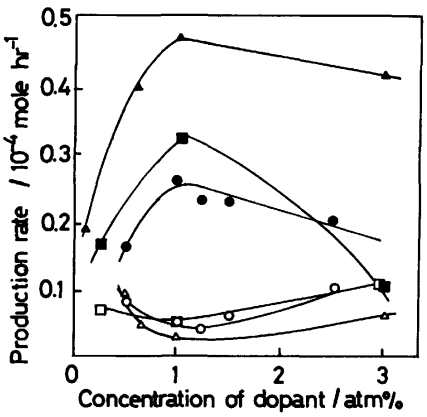

Fig. 1. Production rates of SO_4^{2-} and H_2S as a function of the concentration of dopants. Closed symbols represent the production rates of SO_4^{2-}, while open symbols represent the production rates of H_2S. Circles, squares and triangles represent TiO_2 catalysts doped with Ru, Na, and Pt, respectively.

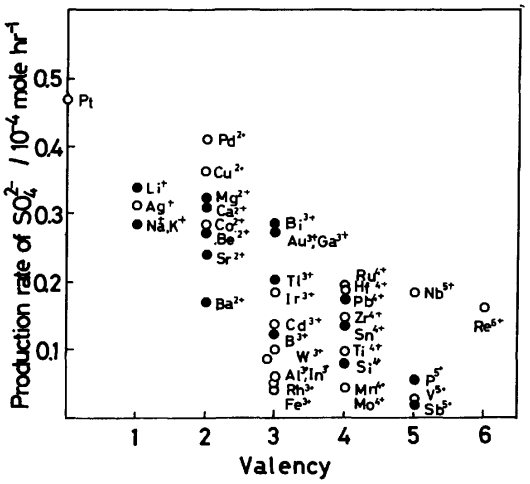

Fig. 2. Relationship between the production rate of SO_4^{2-} and the ionic valency of the dopant. Closed symbols represent typical elements and open symbols represent transition metals.

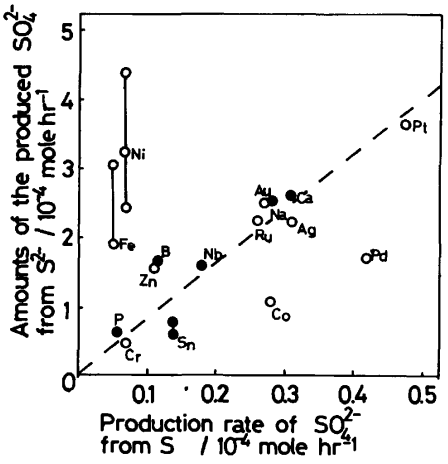

Fig. 3. Relationship between the production rate of SO_4^{2-} from sulfur and the amounts of SO_4^{2-} produced from S^{2-}.

TABLE 1. PHOTOPRODUCTS FROM S, S^{2-}, $S_2O_3^{2-}$, AND SO_3^{2-} ON TiO_2/Pt

Reactants	Products/10^{-4} mole				
	H_2S	S^{2-}	$S_2O_3^{2-}$	SO_3^{2-}	SO_4^{2-}
S(0.4 g)	0.05	0	0	0	0.47
S^{2-}(1×10^{-3} mol)	0.03	—	1.10	2.12	3.64
$S_2O_3^{2-}$(1×10^{-3} mol)	0.08	0	—	0	4.16
SO_3^{2-}(1×10^{-3} mol)	0.01	0	0	—	9.93
SO_3^{2-}(10×10^{-3} mol)	0.04	0	0	—	76.70

tion of SO_4^{2-}.

Figure 3 shows the relationship between the production rate of SO_4^{2-} from sulfur and the amount of photoproduced SO_4^{2-} from S^{2-} (Na_2S) in one hour. The initial concentration of S^{2-} in the solution was 10^{-3} mol/50 ml in this test. With the exceptions of Ni and Fe dopants, it was found that catalytic activity of the doped anatase for both reactions had almost the same tendency. Other ions, for example $S_2O_3^{2-}$ and SO_3^{2-}, were also produced when the S^{2-} ion was used as the starting reactant. On the other hand, amounts of less than 50% $S_2O_3^{2-}$ ($Na_2S_2O_3$) were also photooxidized to SO_4^{2-} on doped TiO_2 under illumination, but the tendency of the activity did not agree with that from sulfur to SO_4^{2-}, and no SO_3^{2-} was detected. When SO_3^{2-} (Na_2SO_3) was used as the reactant, large amount of SO_4^{2-} were obtained even in the dark. Under illumination, 90—100% of the SO_3^{2-} was changed to SO_4^{2-}, but no $S_2O_3^{2-}$ was detected. Table 1 shows typical results for the above tests on Pt-doped TiO_2. Thus, S^{2-} and $S_2O_3^{2-}$ will not be the intermediates in the mechanism of photocatalytic oxidation of sulfur on TiO_2, because no $S_2O_3^{2-}$ was detected in this process.

Figure 4 shows the wavelength dependencies of the photocatalytic production rate of SO_4^{2-} from sulfur on the doped TiO_2. These results show that the photocatalytic oxidation in this process is based on the hole and the electron produced by the bandgap photon of anatase (<390 nm). Figure 5 shows the photocatalytic production rate of SO_4^{2-} from sulfur on the Pt-doped TiO_2 as a function of the light intensity. Linear relationships of $\log V/\log I$ were observed, and the slope was about 1.0, where I denotes the light intensity. The same dependencies of the photoproduction of SO_4^{2-} from S^{2-} and from $S_2O_3^{2-}$ on the wavelength and the light intensity were also observed for the doped TiO_2.

Discussion

Figure 6 illustrates the process of photooxidation of sulfur to SO_4^{2-} on a TiO_2 catalyst. Sulfur is directly converted to $S_2O_3^{2-}$, SO_4^{2-}, and H_2S (S^{2-}) by the catalyst under illumination, and a small amount of S^{2-} in the solution are oxidized to $S_2O_3^{2-}$, SO_3^{2-}, and SO_4^{2-} as described in the previous section. In practice, a large portion of the produced S^{2-} is evolved from the solution as H_2S gas, because the solution changes to the acid due to the production of SO_4^{2-}. Therefore, neither $S_2O_3^{2-}$ nor SO_3^{2-} is detected in the solution. If SO_3^{2-}

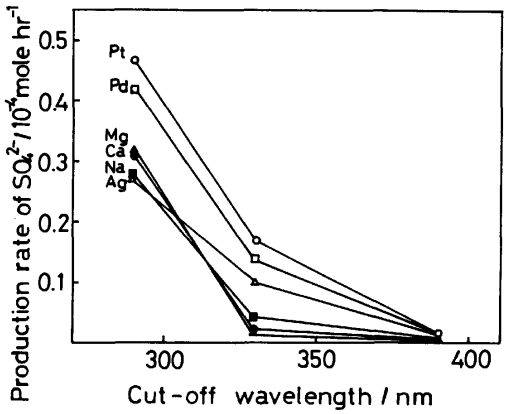

Fig. 4. Wavelength dependence of the photoproduction ate of SO_4^{2-} from sulfur.

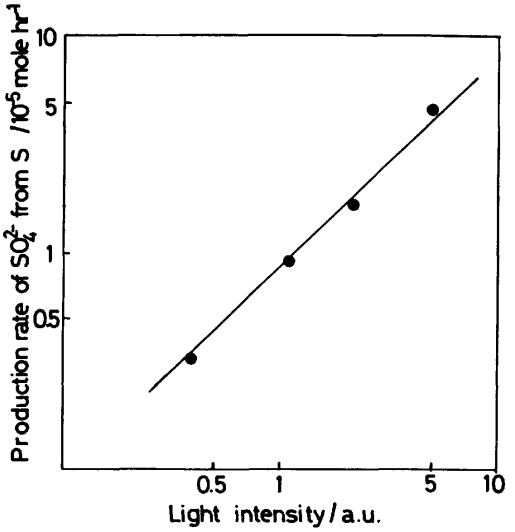

Fig. 5. Photocatalytic production rate of SO_4^{2-} from sulfur on the Pt-doped TiO_2 as a function of light intensity.

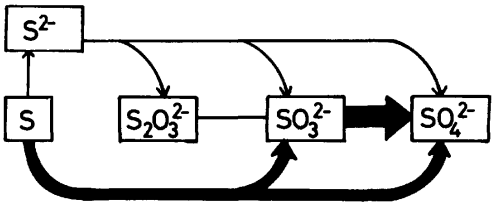

Fig. 6. Photocatalytic oxidation process of sulfur on TiO_2 catalyst.

is photoproduced in the solution, this is immediately oxidized to SO_4^{2-}.

Figure 7 shows the ratio of the rate/H_2S production rate as a function of the SO_4^{2-} production rate in the photocatalytic oxidation of sulfur on the doped TiO_2. It was found that the ratio increases with the increase in the production rate of SO_4^{2-}. If we assume the linear relationship in the figure, it can be seen that the production rate of H_2S (about 0.05×10^{-4} mol h^{-1}) is constant for all samples. It should also be noted that the minimum value of the ratio is about one.

The following reaction will proceed on the catalyst surface under illumination:

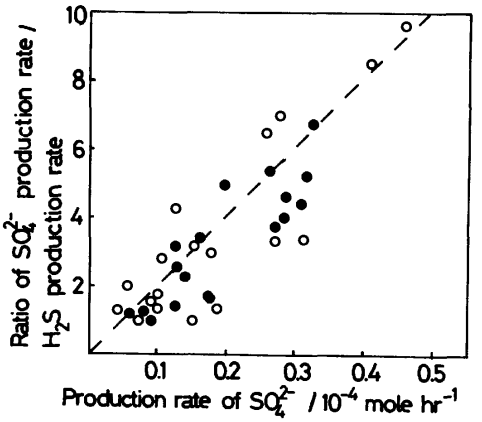

Fig. 7. Relationship between the ratio of SO_4^{2-} production rate/H_2S production rate and the production rate of SO_4^{2-}.

$$H_2O + h^+ \longrightarrow \dot{O}H + H^+ \quad (1)$$

$$O_2 + 2H_2O + 4e^- \longrightarrow 4OH^- \quad (2)$$

$$OH^- + h^+ \longrightarrow \dot{O}H \quad (3)$$

$\dot{O}H$ will be produced from both H_2O and OH^-, which are produced from the direct reduction process of O_2 (Eq. 3). After all, sulfur reacts with $\dot{O}H$ as follows, leading to unity as the value of the ratio of the SO_4^{2-} production rate/H_2S production rate:

$$2S + 4\dot{O}H \longrightarrow H_2S + H_2SO_4 \quad (4)$$

This reaction process is suitable for the catalysts which give unity for the value of the above ratio. If a relatively stable intermediate, for example $\dot{O}_2H$ is produced in the O_2 reduction process, this species will contribute to the direction production of SO_3^{2-} or SO_4^{2-} as follows:

$$O_2 + e^- \longrightarrow O_2^- \quad (5)$$

$$O_2^- + H_2O \longrightarrow \dot{O}_2H + OH^- \quad (6)$$

$$\dot{O}H + \dot{O}_2H + S \longrightarrow H_2SO_3 \quad (7)$$

$$3\dot{O}H + \dot{O}_2H + S \longrightarrow H_2SO_4 + H_2O \quad (8)$$

Many other reaction processes in which the intermediate $\dot{O}_2H$ is contained, will exist in the photocatalytic oxidation process of sulfur as a matter of course. However, this intermediate must surely contribute to the reaction process on the catalysts which gives values of more than unity in the ratio of the SO_4^{2-} production rate/H_2S production rate. Because the values of the ratio are always unity, if only the process (4) occurs in the photocatalytic oxidation of sulfur. In conclusion, only small amounts of SO_4^{2-} will be produced on the catalysts on which O_2 is immediately reduced to OH^-, but large amounts of SO_4^{2-} will be produced on the catalysts on which O_2 is not immediately reduced to OH^-.

The former catalysts are TiO_2 doped with the typical elements having ionic valences of five; therefore, relatively large amount of Ti^{3+} exist in the lattice. On

the other hand, the latter catalysts have only small amounts of Ti^{3+} in the lattice, because the catalysts are doped with the typical elements having valencies of one, two and three. That is, the Ti^{3+} ion probably will take part in the immediate reduction of O_2. In the case of doping with a transition metal, the transition metal cations in the TiO_2, as well as the titanium cations, will directly affect the O_2 reduction.

This doped area which affects the O_2 reduction will be dotted on the TiO_2 surface. When the amounts of the dopants increase beyond about 1 atm%, the dopants will deposit on the doped area as oxides. Therefore, the doped area decreases and the doped TiO_2 becomes like that of the nondoped TiO_2. The results shown in Fig. 1 are explained by this phenomenon. In the case of the Pt dopant, Pt metal on the TiO_2 will act as the site which produces the intermediate $\dot{O}H$ in the O_2 reduction. However, the increase of the deposited Pt metal will bring about inhibition of the illumination on the TiO_2 surface, leading to a decrease in the production rate of SO_4^{2-} as shown in Fig. 1. As a matter of course, the deposited oxides will cause the light passing to the TiO_2 surface to be disturbed as in the case of the other dopants.

A Conductance Study of Benzo-18-crown-6- and Its Analogs-Alkali Metal Ion Complexes in Various Solvents

Yasuyuki TAKEDA

Department of Chemistry, Faculty of Science, Chiba University, Yayoi-chō, Chiba 260

(Received November 10, 1984)

Limiting ionic molar conductivities of benzo-18-crown-6 (B18C6)-alkali metal ion complexes in various nonaqueous solvents were determined at 25 °C. The mobilities of the B18C6 complexes were compared with those of 18-crown-6 (18C6)- and dibenzo-18-crown-6 (DB18C6)-alkali metal ion complexes. Regardless of varieties of alkali metal ions held in the crown ether cavity, the larger is the size of the crown ether complex, the less mobile the complex is. For aprotic solvents (acetonitrile, DMF, DMSO, propylene carbonate), the mobility of the B18C6-K^+ complex is smaller than that of $(n\text{-}C_4H_9)_4N^+$; however, for the protic solvent (methanol), they are almost the same. Walden product value of the B18C6-K^+ complex as well as 18C6- and DB18C6-K^+ complexes somewhat changes with the variation of solvents. For these three crown ether-K^+ complexes, Walden product values of acetonitrile and propylene carbonate are larger than or nearly equal to those of DMF and DMSO. This may indicate that, for the aprotic solvents, donicity is a very important factor in determining the magnitude of mobility of the crown ether-K^+ complexes. The B18C6-K^+ complex as well as 18C6- and DB18C6-K^+ complexes seems to act as a structure breaker in a hydrogen-bonding solvent.

In a previous paper,[1] solvation behavior of 1:1 complexes of benzo-18-crown-6 (B18C6) with alkali metal ions in various nonaqueous solvents was studied by transfer activity coefficients. The B18C6-alkali metal ion complex is more strongly solvated in DMF and DMSO than in acetonitrile and propylene carbonate. In methanol, owing to hydrogen bonds between ether oxygen atoms of B18C6 and methanol, the B18C6 complex is more strongly solvated than the corresponding free alkali metal ion, compared to the case of the aprotic solvents.

In this work, in order to investigate solvation property for B18C6-alkali metal ion complexes from the viewpoint of transport phenomena, limiting ionic molar conductivities of B18C6-alkali metal ion complexes in various nonaqueous solvents were determined at 25 °C. The limiting ionic molar conductivities of the B18C6 complexes were compared with those of 18-crown-6 (18C6)- and dibenzo-18-crown-6 (DB18C6)-alkali metal ion complexes, and, moreover, Walden products of these three crown ether complexes were discussed in detail.

Experimental

Most of the reagents, solvents, and procedures were the same as those described previously.[1-5] The conductivities of final products of acetonitrile, propylene carbonate, methanol, DMF, and DMSO were less than 2×10^{-7}, 6×10^{-8}, 3×10^{-7}, 3×10^{-7}, and 6×10^{-8} $\Omega^{-1}cm^{-1}$, respectively. Alkali metal chlorides were used for the methanol system and perchlorates for the other solvent systems. The conductance measurements were made on a Fuso conductivity apparatus, model 362A, in a water bath thermostated at 25±0.005 °C. Two cells were used with cell constants of 0.059709 and 0.097766 cm^{-1}.

Results and Discussion

Limiting ionic molar conductivities ($\lambda°$) of B18C6 complexes with alkali metal ions were obtained in the same way as previously described.[2] In this study, it is assumed that the association between a cation and an anion is negligible (total concentration of an alkali metal ion $\approx6\times10^{-4}$ M; 1 M=1 mol dm^{-3}) and that B18C6 forms a 1:1 complex with an alkali metal ion. Corrections for viscosity changes were neglected (total concentration of B18C6$<2.5\times10^{-3}$ M). The $\lambda°$ values of B18C6 complexes with alkali metal ions in various solvents are listed in Table 1.

It is seen from Table 1 that, for acetonitrile and propylene carbonate, B18C6-alkali metal ion complexes, where the alkali metal ions closely fit into the

* η_0 denotes viscosity and 1 P=0.1 Pa s. ** DN denotes donor number. *** ε_r denotes dielectric constant. a) Propylene carbonate. b) G. J. Janz and R. P. T. Tomkins, "Nonaqueous Electrolytes Handbook," Academic Press, New York and London (1972), Vol. 1.

B18C6 cavity, have larger mobilities. Mobilities of free alkali metal ions in acetonitrile and propylene carbonate increase in the order $Na^+<K^+<Rb^+<Cs^+$.[2,12] This indicates that the central alkali metal ion, which has the optimum size for the B18C6 cavity, is effectively screened by the B18C6 from surrounding solvent molecules; for a smaller or larger alkali metal ion than the B18C6 cavity, the interaction between the ion trapped in the B18C6 cavity and solvent molecules may decrease the mobility of the B18C6-alkali metal ion complex.

The size sequences of the three crown ethers are 18C6<B18C6<DB18C6. For the same solvent, the λ° value series of the K^+-crown ether complexes are given in the order DB18C6<B18C6<18C6. This indicates that the mobility sequences of the K^+-crown ether complexes are determined completely by the size ones of the complexes (*i.e.*, the larger is the complex size, the less mobile it is). Limiting ionic molar conductivities at 25 °C of 18C6-Na^+, Rb^+, Cs^+ complexes in propylene carbonate[2] and DB18C6-Na^+, Rb^+ complexes in acetonitrile[6] are 8.5_1, 8.8_6, 8.7_8 and 52.7, 55.5, respectively. It can be seen from these data and Table 1 that a B18C6-alkali metal ion complex is less and more mobile than the corresponding 18C6 complex in propylene carbonate and the corresponding DB18C6 complex in acetonitrile, respectively. This shows that, regardless of varieties of central alkali metal ions, the smaller crown ether-alkali metal ion complex is more mobile than the corresponding larger one.

It is interesting to compare the mobility of a B18C6-K^+ complex with that of $(n\text{-}C_4H_9)_4N^+$. For aprotic solvents (acetonitrile, DMF, DMSO, and propylene carbonate), the λ° value of the B18C6-K^+ complex is smaller than that of $(n\text{-}C_4H_9)_4N^+$; however, for the protic solvent (methanol), they are almost the same. A similar tendency was observed for the case of a 18C6-K^+ complex and $(n\text{-}C_4H_9)_4N^+$ and that of a DB18C6-K^+ complex and $(n\text{-}C_5H_{11})_4N^+$.[5] The size of a 18C6-$K^+$ complex is nearly identical with that of $(n\text{-}C_4H_9)_4N^+$.[2] Thus, it can be considered that the B18C6-K^+ complex is larger than $(n\text{-}C_4H_9)_4N^+$ by a benzene ring. For $(n\text{-}C_4H_9)_4N^+$, it is symmetrical and the charge of the nitrogen atom is well shielded; while, for the B18C6-K^+ complex, it is unsymmetrical and there exists a possible interaction of the central K^+ with solvent molecules on two axial sides of the B18C6 plane. From the above discussion, the fact that the B18C6-K^+ complex is less mobile than $(n\text{-}C_4H_9)_4N^+$ in the aprotic solvents may be attributed to the differences in the size and the structure between the B18C6-K^+ complex and $(n\text{-}C_4H_9)_4N^+$. From the results for methanol, it seems that enforcement of the hydrogen-bonded structure for the B18C6-K^+ complex is weaker than that for $(n\text{-}C_4H_9)_4N^+$.

Walden products at 25 °C of the B18C6-K^+ complex for various solvents are compiled in Table 2, together with those from the literature. From the more detailed examination of the data in Table 2, it was concluded that $\lambda^\circ\eta_0$ value of the same crown ether-K^+ complex as well as $(n\text{-}C_4H_9)_4N^+$ somewhat changes with the variation of solvents. For the same crown ether-K^+ complex, $\lambda^\circ\eta_0$ value of DMSO is the smallest and that of DMF is smaller than those of the other solvents except DMSO and nitrobenzene of the DB18C6-K^+ system; $\lambda^\circ\eta_0$ values of acetonitrile and propylene carbonate are larger than or nearly equal to those of DMF and DMSO. Dimethyl sulfoxide and DMF have extremely strong donicity compared to the other solvents listed in Table 2.[13] It thus appears that, for the aprotic solvents (CH_3CN, PC, DMF, DMSO), donicity is a very important factor in determining the magnitude of mobility of the crown ether-K^+ complexes. For $(n\text{-}C_4H_9)_4N^+$, the $\lambda^\circ\eta_0$ value of the aprotic solvent increases with an increase in dielectric constant except nitrobenzene (Table 2). The dielectric constant of nitrobenzene, however, is nearly equal to those of acetonitrile and DMF; the $\lambda^\circ\eta_0$ value of nitrobenzene is smaller than those of propylene carbonate and DMSO, and is slightly larger than that of DMF. Consequently, for the aprotic solvents, the magnitude of mobility of $(n\text{-}C_4H_9)_4N^+$ is considered to be governed largely by the dielectric constant. The difference in factors influencing mobilities of the crown ether-K^+ complexes and $(n\text{-}C_4H_9)_4N^+$ in the aprotic solvents may be attributed to the difference in structures of the cations as mentioned above. For the B18C6-alkali metal ion complex other than the B18C6-K^+ complex, $\lambda^\circ\eta_0$ value of propylene carbonate is larger than or nearly equal to that of acetonitrile. This is the same tendency for the B18C6-K^+ complex.

Generally, mobilities of 18C6-, B18C6-, and DB18C6-K^+ complexes in protic solvents are greater than those in aprotic solvents, and contrary holds for $(n\text{-}C_4H_9)_4N^+$

(Table 2). These results may be caused by the effect of hydrogen-bonded structure of the protic solvents. Methanol and ethanol have larger donicities than propylene carbonate, acetonitrile, and nitrobenzene, and have the smallest dielectric constants of all the solvents; hydrogen bonds between protic solvent molecules and ether oxygen atoms of these crown ethers would decrease the mobility of the crown ether–K^+ complexes; however, for B18C6- and DB18C6–K^+ complexes, $\lambda^\circ\eta_0$ values of the protic solvents are the largest of all the solvents. This suggests that the crown ether–K^+ complexes act as a structure breaker in the protic solvents. For the 18C6–K^+ complex, $\lambda^\circ\eta_0$ value of methanol is smaller than that of propylene carbonate, and on the contrary for B18C6- and DB18C6–K^+ complexes. For B18C6- and DB18C6–K^+ complexes, the difference in $\lambda^\circ\eta_0$ value between methanol and propylene carbonate increases on moving from B18C6 to DB18C6. A possible explanation for this is as follows. On account of lower basicity of aromatic ether oxygen atoms compared to aliphatic ones and steric hindrance caused by a benzo group, the interaction between ether oxygen atoms and methanol molecules may decrease in the order 18C6–K^+>B18C6–K^+> DB18C6–K^+. Thus, the mobility of the 18C6–K^+ complex in propylene carbonate is greater than that in methanol, and the reverse is true for B18C6- and DB18C6–K^+ complexes; moreover, the difference in the mobility of the K^+ complex between methanol and propylene carbonate increases on going from B18C6 to DB18C6. The fact that $\lambda^\circ\eta_0$ value of the 18C6–K^+ complex for water is higher than that for methanol may reflect the difference in characteristics of hydrogen bonds for water (three-dimentional structure) and methanol (one-dimentional structure). The 18C6–K^+ complex seems to act as a structure breaker more effectively in water than in methanol, resulting in the excess mobility in water.

The author would like to thank Professor Sadatoshi Akąbori of Toho University for the generous gift of benzo-18-crown-6.

Cathodic Cleavage of Some Aryl Phenacyl Sulfides

Akira KUNUGI,* Akinori MUTO,† and Taketsugu HIRAI
Department of Applied Chemistry, Faculty of Engineering, Osaka City University, Sugimoto, Sumiyoshi-ku, Osaka 558
(Received November 12, 1984)

The electrolytic reduction of some aryl phenacyl sulfides in aqueous ethanol and anhydrous acetonitrile solutions has been investigated by means of polarography and controlled potential electrolysis. Dc polarograms of these compounds exhibit two waves in all solutions studied, the first of which corresponds to a one-electron and a two-electron transfer depending upon the absence and presence of proton donor. The electrode reaction taking place at the first reduction step involves cleavage of the carbon-sulfur bond, resulting in formation of acetophenone and the corresponding thiols in good yields even in an acetonitrile solution containing no proton donor. The second reduction step corresponds to the reduction of the acetophenone produced.

The electrolytic desulfurization of organosulfur compounds has attracted considerable attention because most of them are valuable synthetic precursors. β-Keto sulfoxides,[1-3] for instance, are electrochemically reduced by cleavage of a carbon–sulfur bond with formation of methyl ketones and thiol derivatives. The other organosulfur compounds such as β-hydroxy sulfones,[4,5] sulfoxides,[6] and sulfides,[7] vinyl sulfones,[8] sulfoxides,[9] and sulfides,[10] and alkyl imidazolyl sulfoxide[11] and sulfides[11,12] are also electrochemically reduced to afford the corresponding desulfurated compounds.

With the consumption of small quantities of electricity compared with the case of electrolytic reduction of β-keto sulfoxides, β-keto sulfides will be expected to undergo the cathodic cleavage of the carbon–sulfur bond to yield the desulfurated compound, methyl ketones. Therefore, it is considered of interest to investigate electrolytic reduction of β-keto sulfides from the standpoint of the conversion of carboxylic esters to the corresponding methyl ketones, which contain one more carbon atom than the starting esters:

$$\mathrm{Ar\text{-}S\text{-}CH_2^-\ Li^+ + PhCO_2C_2H_5 \longrightarrow Ar\text{-}S\text{-}CH_2COPh} \xrightarrow{\text{electrolysis}} \mathrm{PhCOCH_3 + ArSH}$$

In the present work, the electrolytic reduction of some aryl phenacyl sulfoxides was investigated in both aqueous ethanol and anhydrous acetonitrile solutions by means of polarography, coulometry, and macroelectrolysis.

Experimental

Chemicals. Phenacyl *p*-tolyl sulfide (**1a**), phenacyl phenyl sulfide (**1b**), and *p*-methoxyphenyl phenacyl sulfide (**1c**) were prepared from the corresponding lithiomethyl aryl sulfides and ethyl benzoate on the basis of the procedure described for the synthesis of aryl phenacyl sulfoxides,[13] which were identified by their physical properties and ^{1}H NMR spectra.[14] **1a**; mp 32—34°, NMR ($CDCl_3$) δ 2.29 (3H, s, $-CH_3$), 4.21 (2H, s, $-CH_2-$), 7.04—8.09 (9H, m, aromatic). **1b**; mp 51—52° (lit,[15] 52—53°), NMR ($CDCl_3$) δ 4.24 (2H, s, $-CH_2-$), 7.14—7.99 (10H, m, aromatic). **1c**; NMR ($CDCl_3$) δ 3.73 (3H, s, CH_3O-), 4.14 (2H, s, $-CH_2-$), 6.77—8.07 (9H, m, aromatic).

The aqueous alcoholic buffer solutions contained 40% (v/v) ethanol and their ionic strengths were adjusted to 0.6 M (1 M=1 mol dm^{-3}) with KCl. All buffer compounds were of reagent grade. The pH reading was taken in the aqueous alcoholic buffer solutions with a pH-meter standardized against aqueous buffer solutions. A 95% (v/v) ethanol buffer solution of pH 5.8 contained 0.12 M lithium acetate, 0.08 M acetic acid, and 0.5 M lithium chloride. Anhydrous acetonitrile solutions were prepared from the pre-deoxygenated acetonitrile (MeCN) and tetrabutylammonium perchlorate (TBAP) or tetrabutylammonium tetrafluoroborate (TBAB) which were purified and dried as described previously.[16] The concentrations of the supporting electrolytes were 0.1 M.

Controlled potential macroelectrolysis and coulometry as well as polarography were carried out in both aqueous ethanol and anhydrous acetonitrile solutions, using the same experimental set-up and type of procedure as in the previous papers.[2,16] A saturated calomel electrode (SCE) and a Ag/0.1 M $AgNO_3$ in MeCN electrode (Ag/Ag^+) were used as the reference electrodes in aqueous and nonaqueous solutions, respectively.

Substrate[a)]	First wave		Second wave	
	Half-wave potential (V *vs.* SCE)	Limiting current (mA mol^{-1})	Half-wave potential (V *vs.* SCE)	Limiting current (mA mol^{-1})
1a	−1.29	3.7	−1.56	3.4
1b	−1.29	3.8	−1.56	3.4
1c	−1.29	3.7	−1.56	3.3

a) **1a**: phenacyl *p*-tolyl sulfide, **1b**: phenacyl phenyl sulfide, **1c**: *p*-methoxyphenyl phenacyl sulfide.

1b, and **1c** in a 40% ethanol buffer solution of pH 7.4 are presented in Fig. 1 and Table 1. Figure 1 shows Tast polarograms of **1a** as a representative example. The polarogram exhibited two waves with a large maximum in the absence of maximum suppressors. The addition of 0.008% Triton X-100 essentially eliminated the maximum and resulted in two well-defined waves. As can be seen from Table 1, the half-wave potentials ($E_{1/2}$) of both the first and second reduction waves of **1a**, **1b**, and **1c** are independent of the Ar group of aryl phenacyl sulfides (Ar-S-CH_2COPh). The $E_{1/2}$ of each second wave coincides with that of acetophenone in the same solution, the height of the second wave being somewhat smaller than the height of the polarographic wave of an equimolar solution of acetophenone. These suggest that the second wave is ascribed to the reduction of the acetophenone produced during the polarographic reduction. The above suggestion was confirmed by controlled potential coulometry and macroelectrolysis as will be shown later.

The ratio of the first wave-height to the second one for all three sulfides are approximately 1, indicating that each first wave corresponds to a two-electron transfer process. This was also supported from the polarographic result of phenacyl phenyl sulfoxide[2)]: This sulfoxide gives two waves with the wave-height of approximately 2:1, $E_{1/2}$ of the second wave coincides with that of **1b**, and the ratio of the first wave-height of the sulfoxide to that of **1b** is approximately 2. Furthermore, a two-electron transfer process was supported by the coulometric experiment as will be shown later. The first wave for **1a** was found to be diffusion-controlled as evidenced from the linear plots of the limiting current (i_l) against the square root of the height of the mercury head. Moreover the average temperature coefficient was of the order of 2%/°C as for a diffusion-controlled process. The other substrates, **1b** and **1c**, are also inferred to give diffusion-controlled waves from analogy with **1a** with regard to the polarographic behavior.

Figure 2 shows the dependence of $E_{1/2}$ and i_l, on pH for the first wave of **1a**, where polarograms were measured in 40% ethanol buffer solutions containing 0.008% Triton X-100. The values of i_l were substantially pH-independent. On the other hand, a plot of $E_{1/2}$ against pH gave two straight-line segments, the intersection of which corresponded to approximately

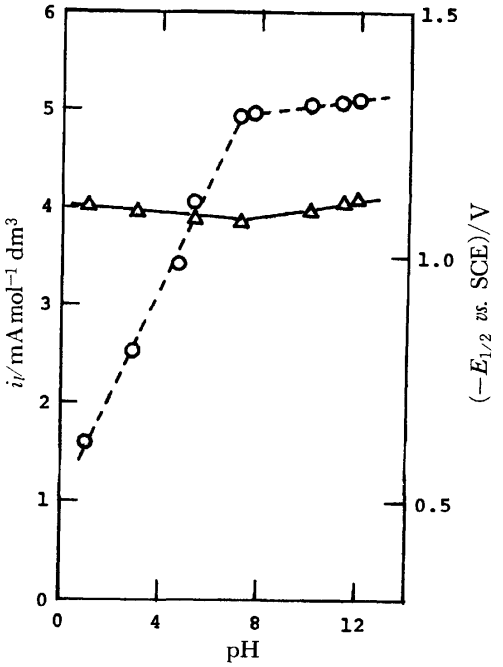

Fig. 2. Dependence of limiting current (——) and half-wave potential (----) on pH for first wave of **1a** in 40% ethanol buffer solution containing 0.008% Triton X-100 at 27 °C.

pH 7. Similarly the pH-dependence of $E_{1/2}$ and i_l of the second wave is shown in Fig. 3, together with that of acetophenone in the same solutions. The $E_{1/2}$ of the second wave of **1a** coincided with that of acetophenone over the whole pH region, but i_l of the second wave was significantly smaller than that of acetophenone.

Figure 4 shows typical Tast polarograms of **1a** in MeCN containing 0.1 M TBAP, in the absence and presence of phenol as a proton donor. In the absence of the proton donor, **1a** gave two waves with the wave-height ratio of approximately 3:1, the value of $E_{1/2}$ of the first wave indicating that **1a** is easier to reduce than alkyl phenyl sulfides bearing no carbonyl group.[17)] The addition of phenol caused both wave-heights to increase. The dependence $E_{1/2}$ and i_l of the first wave on phenol concentration is presented in Fig. 5, in which the values of i_l of di-*p*-tolyl disulfide also is included. As shown in Fig. 5, the $E_{1/2}$ was independent of the phenol concentration, but the i_l increased with an increase in the phenol concentration and reached twice of the original value when the molar ratio of phenol

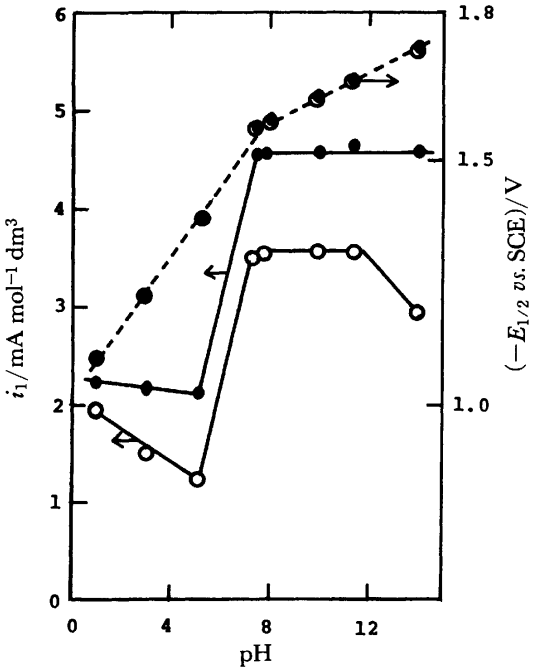

Fig. 3. Dependence of limiting current (——) and half-wave potential (----) on pH in dc polarography in 40% ethanol buffer solution containing 0.008% Triton X-100 at 27 °C.
O: Second wave of **1a**, ●: Wave of acetophenone.

to the substrate was more than approximately 1. The electrode reaction taking place at the first wave of **1a** in anhydrous acetonitrile containing sufficient phenol is estimated to be a two-electron transfer process from comparison with the values of i_l of **1a** and di-*p*-tolyl disulfide. Thus, the first wave of **1a** in the absence of proton donors corresponds to a one-electron transfer process. Both values of $E_{1/2}$ and i_l for the second wave

were dependent on the phenol concentration in the same fashion with acetophenone.

Coulometry. To determine the apparent number of electrons transfered (n-value) for the reduction of **1a**, **1b**, and **1c** under different electrolytic conditions, a series of controlled potential coulometric experiments were performed. The substrate concentrations were within the range, in which a linear i_l *vs.* concentration behavior is observed. The electrolyses were interrupted at several points and then the exhausted amounts of the substrate were monitored by means of polarography as a function of the quantity of electricity passed. Figure 6

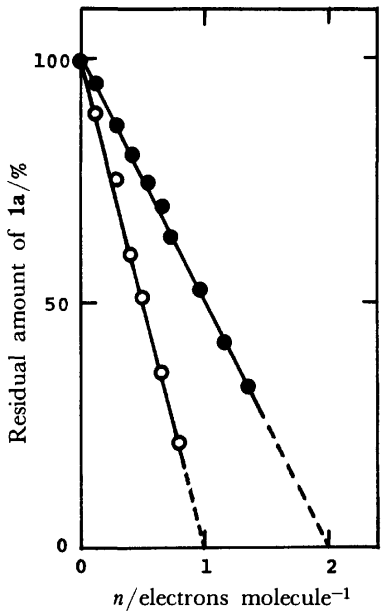

Fig. 7. Coulometric n-values of **1a** in acetonitrile containing 0.1 mol dm^{-3} TBAB at Hg cathode of −2.1 V *vs.* Ag/Ag$^+$. Molar ratio of phenol/**1a**: (○) 0, (●) 2.5.

shows a typical result of the coulometric experiment with **1a** in 40% ethanol buffer solution of pH 7.4 in the presence of Triton X-100 at a stirred mercury pool cathode. The coulometric n-value was estimated by extrapolation to be 2 electrons per molecule, which is agreement with the polarographic n-value.

Similarly typical coulometric results of **1a** at a stirred mercury pool cathode in MeCN containing 0.1 M TBAB are presented in Fig. 7, which also illustrates the effect of phenol on the n-value. Figure 7 definitely shows that the coulometric n-values in the absence and presence of phenol are 1 and 2 electron (s) per molecule, respectively. When a platinum plate electrode in place of the mercury pool was used, the same n-values were obtained.

Macroelectrolysis. Controlled potential macroelectrolyses of some β-keto sulfides were carried out at the plateau potential of the first wave of their polarograms, in 40% ethanol buffer solution of pH 7.4, 95% ethanol buffer solution of pH 5.8, and MeCN containing 0.1 M TBAB with and without phenol. These results are summarized in Table 2, with the coulometric n-values. In a series of macroelectrolyses, the amounts of acetophenone formed were almost equivalent to the sum of the diaryl disulfides and arenethiols and the yields of the isolated acetophenone were 66—76% under all conditions studied. As can be seen from Table 2, in aqueous ethanol solutions and anhydrous acetonitrile solution containing sufficient phenol, coulometric n-values all were close to 2 electrons per molecule, whereas the n-value was 1 electron per molecule in the acetonitrile with no proton donor. Namely, Table 2 shows the curious result that the yields of acetophenone are essentially invariable, no matter whether the n-values are 1 or 2 electrons per molecule. This implies that there is a difference between the reduction mechanisms of aryl phenacyl sulfides to acetophenone in the absence or presence of sufficient proton donor.

The data in Table 2 also show that, with regard to the yields and the coulometric n-values, the electrolytic reduction of aryl phenacyl sulfides is independent of the nature of the electrode material.

Discussion

As shown in Fig. 3, the second wave of **1a** in 40% ethanol buffer solutions gave somewhat underestimated values in wave-height over the whole pH region. This may be interpreted as follows: The electrode reaction taking place at the first wave leads to formation of phenacyl anion ($PhCOCH_2^-$) which is electroinactive. Of course, acetophenone, produced by protonation of the phenacyl anion, is electroactive so that it gives the second wave. Therefore, if all phenacyl anions produced are not protonated within a period of the polarograpic measurement, the second wave will result in a somewhat underestimated wave-height. This idea was supported by the following polarography in a 95% ethanol buffer solution of pH 5.8. As shown in Fig. 8, the polarogram of **1a** exhibited two waves, but the ratio of the second wave-height to the first one was small compared to that in the 40% ethanol buffer solu-

tion (curve b in Fig. 1). This can be attributed to the weakness of proton donor of the 95% ethanol solution compared to the 40% ethanol solution.

In Table 2, one is faced with the apparent paradox of the isolation of diaryl disulfides in spite of the fact that they are easily reduced to arenethiols at the potential at which the macroelectrolysis was to be run.[18] This may be resolved in terms of an air oxidation of arenethiols, *i.e.*, the thiols easily undergo an air oxidation, particularly in anhydrous media during the work-up procedure after electrolysis, resulting in formation of diaryl disulfides.

The electrolytic reduction of aryl phenacyl sulfides in the absence of proton donors afforded acetophenone and the corresponding thiols in good yields despite of the coulometric n-value of 1, suggesting that such β-keto sulfides undergo a one-electron reduction to yield phenacyl radical ($PhCOCH_2\cdot$) and the corresponding thiolate anions (ArS^-). However, the following results suggest formation of phenacyl anion rather than its radical: (1) The dimer of phenacyl radical was not detected under the present reaction conditions. (2) Phenacyl anion seems to be more stable than its radical because the phenacyl anion is stabilized through the acetyl anion in which the charge is highly delocalized onto the oxygen atom of the carboxyl group. In view of the above reasons, at the present stage, it cannot be concluded whether the electrode reaction taking place at the first wave of aryl phenacyl sulfides in MeCN containing no proton donor, involving a one-electron uptake, leads to formation of phenacyl anion or its radical.

In the sufficiently proton-donor-containing solutions such as aqueous ethanol solutions and anhydrous acetonitrile solutions containing excess phenol, the electrolytic reduction of aryl phenacyl sulfides at the first wave potential, involving a two-electron transfer, will yield phenacyl anion and the corresponding thiolate anions. Hence a plausible mechanism may be illustrated as follows:

(Received December 4, 1984)

The cation radical of dimethylketene produced in γ-irradiated solid solutions of various halocarbons has been investigated by ESR over a temperature range from 77 K to the melting point of each matrix. The cation radical in CCl_4 was stable up to about 180 K and the spectrum was well resolved to allow the determination of the anisotropic ESR parameters. In CCl_2FCClF_2 and CCl_2FCCl_2F, a series of irreversible spectral changes was observed with an increase in temperature. This process was interpreted in terms of the formation of the dimer cation. In the matrix of CCl_3F, the ESR spectrum exhibited extra structure, which varied reversibly with temperature. The analyses of the spectra suggested that the cation radical in CCl_3F weakly interacts with surrounding matrix molecules to form adducts.

The employment of a CCl_3F matrix for the radiolytic generation and stabilization of molecular cation radicals has been established and proved to yield ESR spectra with no serious interference by the matrix radicals.[1] Since a theoretical analysis of the spectrum without any consideration of the matrix usually gives satisfactory results, little attention has been paid to the matrix effect.

Other media such as SF_6,[2] CCl_2FCClF_2,[3] and CCl_3CF_3[4] have subsequently been found to also be useful. Use of these compounds along with CCl_3F revealed that the behavior of some cation radicals depends upon the matrix employed. For example, two types of thermal reactions of alkane cations occur depending upon the matrix.[5–7] It seems that in general, unimolecular reactions occur preferentially in CCl_3F and CCl_3CF_3, while bimolecular reactions through molecular diffusion are easy in SF_6 and CCl_2FCClF_2.[5–10]

Recently, we have examined the ESR spectra of dimethylketene cation radicals in several matrices over a wide range of temperatures, and found a drastic dependence of the spectrum upon the matrices. In the present contribution, we describe the results of detailed analyses of these ESR spectra and discuss the reactions occurring in the matrices to gain an insight into the matrix effect at low temperatures.

Experimental

Dimethylketene was kindly supplied by Dr. N. Washida of National Institute of Environmental Studies. After the purity was checked by gas chromatography, the compound was kept in liquid nitrogen to avoid polymerization. Other reagents including halocarbons (CCl_4, CCl_3F, CCl_2FCClF_2, and CCl_2FCCl_2F) from Tokyo Kasei Co. were used without further purification.

For the ESR measurement, dimethylketene was dissolved in each halocarbon to a concentration of 10^{-1}—10^{-3} in mole ratio, then degassed and sealed off in a Suprasil quartz tube. The samples, thus prepared, were γ-irradiated at 77 K to a dose of about 0.8 Mrad (1 Mrad=10^4 Jkg^{-1}) to generate the cation radicals. The ESR spectra were recorded on a JES FE-2XG spectrometer at 77 K and higher temperatures. The ESR parameters of cation radicals were determined using a proton magnetic-resonance probe and a digital frequency counter (Takeda Riken Co. TR 5211C).

Results and Discussion

Determination of Anisotropic ESR Parameters. As was briefly described in a previous paper,[11] singly occupied molecular orbitals of cation radicals of ketenes are characterized mainly by $\pi_{C=C}$ (π orbital on C=C bond), similar to olefin cation,[8] rather than by $n_{C=O}$ (lone pair orbital on C=O bond) as in the case of aldehyde and ketone cations.[12–14] The dimethylketene cation showed a nearly isotropic septet spectrum by the hyperfine interactions of six equivalent methyl protons (23.0 G (1 G=1×10^{-4} T)). In this section, the results of our further investigations with the use of CCl_4 as matrix are presented.

Though the CCl_4 matrix has been employed for the optical absorption study of various radical cations,[15] it is not generally used for ESR studies because the concomitantly produced radicals such as CCl_3 and CCl_4^+ are bothersome.[16] However, the spectrum of dimethylketene cation obtained for the solution in CCl_4 at 153 K (Fig. 1a) is not interfered with by the by-products and is highly resolved. This indicates that the local magnetic environment of the cation radical in CCl_4 varies little from site to site and that the line width of the underlying absorption of the by-products is much broader than that of the septet lines.

The spectral pattern of the septet is essentially the same as that found in our previous results,[11] but it may be noticed that there are slight splittings due to an anisotropy in the outermost component at low field. Thus, we performed a simulation of the ESR line shape for powder samples.[17] Figure 1b represents the best fit spectrum calculated by the use of the parameters listed in Table 1. From the excellent agreement between Figs. 1a and 1b, it is concluded that the hyperfine interaction of methyl protons in dimethylketene cation is slightly anisotropic. The parameters determined in this way are also applicable to the cation radicals in other matrices, which will be discussed later.

components of g tensor and g_{iso}	^1H hyperfine couplings, G
$g_{\parallel}$=2.0028	$A_{\parallel}$=22.75
$g_{\perp}$=2.0037	$A_{\perp}$=23.62
g_{iso}=2.0034	A_{iso}(6H)=23.33

dimethylketene cation in CCl_2FCClF_2 or CCl_2FCCl_2F exhibited additional small subpeaks even at 77 K.[11] The intensities were dependent upon the concentration. Figures 2a and 2b demonstrate the spectra observed for CCl_2FCClF_2 solutions with $10^{-3}$and 10^{-2} mole ratio of dimethylketene, respectively. These figures show that at lower concentrations the subpeaks are suppressed. Even in this case, however, strong subpeaks appeared by keeping the sample at 77 K overnight after γ-irradiation. These results suggest that subpeaks are due to the species formed by a reaction of dimethylketene cation with a neutral molecule of dimethylketene. Figure 2c represents the simulated spectrum for Fig. 2b. The simulation was obtained by assuming a composite of a septet (I) of dimethylketene cation and a nonet (II) as indicated by the stick diagram. The good agreement indicates the coexistence of the nonet (II) whose g factor and sum of the coupling constants are identical to those of septet (I) (17.3 G×8= 23.1 G×6).

Upon warming, the spectral feature of this system changed completely; *i.e.*, a series of irreversible change was observed. Figure 2d shows the observed spectrum at 98 K, which again can be decomposed into two components demonstrated by the stick diagrams under Fig. 2e. One is the nonet (II) mentioned above and the other is a new septet (III) with a splitting of 20.5 G which is slightly smaller than that of (I). It is noteworthy that this septet shows a considerably large positive shift of g factor. Further elevation of temperature results in the disappearence of the nonet

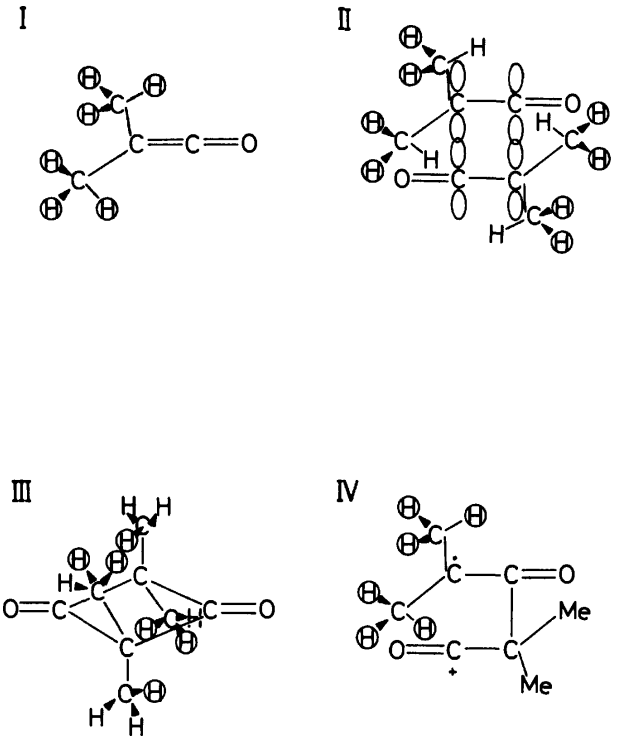
a) Formed from dimethylketene dimer by positive charge transfer.

of spectral changes, it is necessary to identify (II) and (III). We carefully examined a variety of candidates for the septet (III) in Fig. 2f in literatures, but no one agreed with the observed spectrum. On the other hand, we found (experimentally) a system which gives a very similar spectrum to (III). The system is the γ-irradiated Freon solution of dimethylketene dimer (2,2,4,4-tetramethyl-1,3-cyclobutanedione), $(CH_3)_4C_4O_2$. The spectra observed for the three Freon solutions are shown in Fig. 3 (see also, Fig. 4c). The ESR parameters of this spectrum are comparable with those obtained from the spectrum (III) (Table 2), although the line width of the septet in Fig. 2f is slightly smaller than those in Figs. 3 and 4c.

On the basis of above assignment, the spectral change observed in Fig. 2 may be explained in the following manner. Septet (I) is associated with the isolated dimethylketene cation, which is presumed to have a C_{2v} symmetry with six magnetically equivalent rapidly rotating methyl protons (Structure I). Upon the elevation of temperature from 77 to 98 K, molecular diffu-



sion and/or reorientation may take place to produce a dimer cation, a possible conformation being shown in Structure II. If the rotation of the methyl groups is hindered to make the eight encircled protons in Structure II magnetically equivalent, we may associate the nonet (II) underlying in Figs. 2b and 2d with this dimer cation of dimethylketene. Such a dimer cation has been observed for tetramethylethylene;[18] the spectrum is characterized by a 25-line pattern, the splitting constant of which is one half that of the 13-line pattern of the monomer cation. Since the spectrum changed from a septet to a nonet in the present case, it is provisionally assumed that the methyl groups in the dimer cation are fixed in a restricted conformation and only eight protons participate in the revelation of the 9-line hyperfine structure. The fact that the g factor and the sum of coupling constants are common to both spectra (I) and (II) indicates the similarity of electronic structure between the two species and suggests that the spectral change from (I) to (II) corresponds only to the change in the number of the protons giving rise to the observed hyperfine splitting.

Further elevation of temperature yields another septet (III) in Fig. 2f which is attributed to a cation radical of dimethylketene dimer. As for the structure of the cation radical, there are two possibilities; one is the symmetric structure III in which six encircled protons are assumed to be magnetically equivalent. The other is the ring opened structure IV.[19]

Essentially the same spectral change as in Figs. 2a—f was observed for the matrix of CCl_2FCCl_2F as shown in Fig. 4. In this case, the nonet associated with the dimer cation was observed unambiguously at 108 K. The observed ESR parameters in CCl_2FCCl_2F are summarized in Table 2 along with those obtained in CCl_2FCClF_2.

Cation-matrix Interaction. Different behavior of dimethylketene cation was found in the case of CCl_3F matrix. Figure 5a shows the observed spectrum of the cation in CCl_3F at 77 K. The overall features of the septet due to the monomer cation of dimethylketene are similar to those observed in other matrices, except for the small peaks flanking each component of the septet.

The extra structure might be considered as due to the anisotropy of the proton hyperfine splitting. However, any reasonable set of parameters of anisotropy for the protons could not yield comparable simulation spectra. On the other hand, we found that, if the extra structure in Fig. 5a is ignored, the rest of the spectrum can be reproduced by using the anisotropic parameters determined in the previous section. Figure 5b shows the spectrum thus calculated. The variation of line widths for individual components is well reproduced. The substructure, therefore, cannot be attributed to the anisotropy of the spectrum. Moreover, the warming of the system caused a drastic and reversible change of the substructure as shown in Fig. 6. Such a change cannot be associated with a simple motional averaging

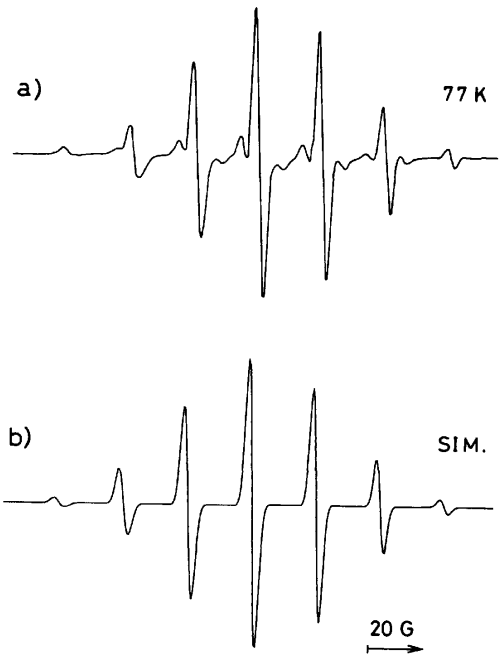


Fig. 5. (a) ESR spectrum of dimethylketene cation in CCl_3F at 77 K; (b) Simulation for (a) using the parameters given in Table 1 and a line width, ΔH_{msl}= 3.0 G.

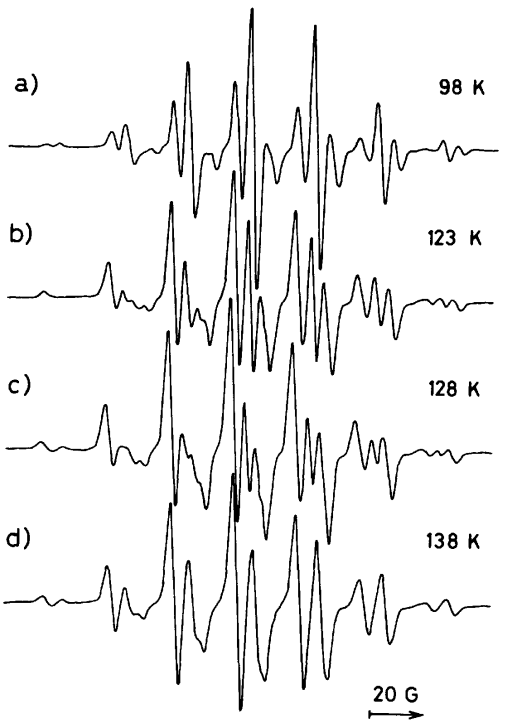

Fig. 6. ESR spectra of dimethylketene cation in CCl_3F at (a) 98 K; (b) 123 K; (c) 128 K; (d) 138 K after γ-irradiation at 77 K, showing the reversible change of substructures with temperature.

of anisotropy. Examination of Fig. 6 reveals that the substructure which is barely seen at 77 K is emphasized on warming, and the triplet feature of each component of the septet changes to a doublet (see also, Fig. 7).

Thus, the temperature dependence of the spectra observed in CCl_3F is quite different from that observed

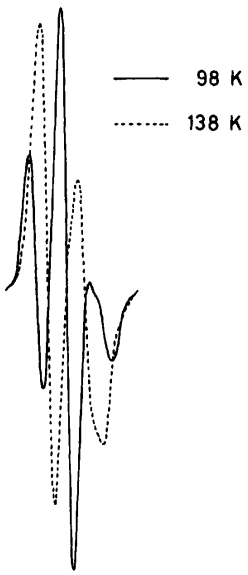

Fig. 7. The central part of the spectra of dimethylketene cation in CCl_3F recorded at 98 K (solid line) and 138 K (dotted line).

in CCl_2FCClF_2 or CCl_2FCCl_2F and evidently cannot be explained in terms of the bimolecular reaction. In addition, the perturbation causing the extra structure should not be strong, because the proton ESR parameters previously determined in the CCl_4 matrix are applicable to the present system with a good accuracy. A weak interaction between the cation and surrounding matrix molecules is conceivable. In the case of CCl_3F, the chlorine ($I=3/2$) or the fluorine ($I=1/2$) atom can cause a superhyperfine interaction. The latter seems to be more probable from the spectral features and the fact that no substructure was observed with CCl_4. Since the fluorine nucleus has a large hyperfine coupling ($A_{iso}=17160$ G for $\rho_{2s}=1$),[20] a very small spin density is enough to give the observed extra structure.

From this point of view, we attempted to simulate the observed spectra using ESR parameters in Table 1 plus the assumption that there are additional nuclei with $I=1/2$ in the system. In Figs. 8 and 9, we show the spectra obtained after repeated curve fittings to those observed at 98 and 138 K, respectively. The existence of two equivalent nuclei with splitting constants of $A_{\parallel}=8.0$ G and $A_{\perp}=4.2$ G for Fig. 8b and one nucleus with $A_{\parallel}=12.0$ G and $A_{\perp}=3.5$ G for Fig. 9b was assumed. The agreement between each pair of spectrum is satisfactory. Such a large anisotropy of the extra interaction is compatible with the involvement of the fluorine atom.

We tested various values of the g factor and the proton anisotropic hyperfine coupling constant. However, a slight change in the parameters (from those listed in Table 1) caused a remarkable deviation from the observed spectra and no improved spectra could be obtained. This indicates that the proton ESR parameters in Table 1 are valid whether there is a superhyperfine interaction or not, which, in turn, allows us to estimate

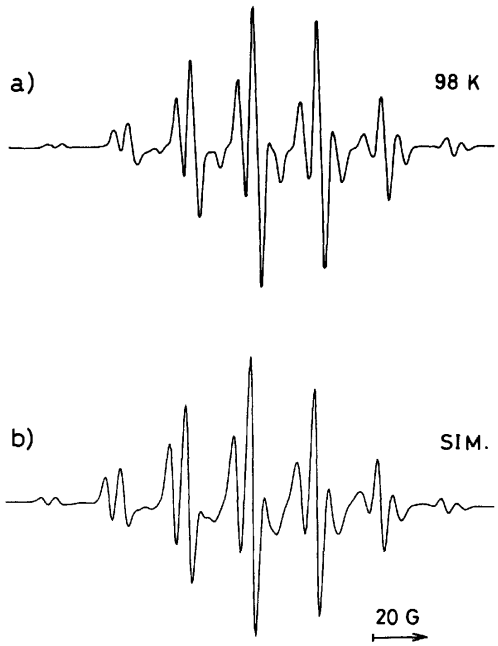

Fig. 8. (a) ESR spectrum of dimethylketene cation in CCl_3F at 98 K; (b) Simulation for (a) using the parameters given in Table 1 for protons in the cation and $A_{\parallel}=8.0$ G, $A_{\perp}=4.2$ G for two fluorine nuclei in the matrix molecules interacting with the cation.

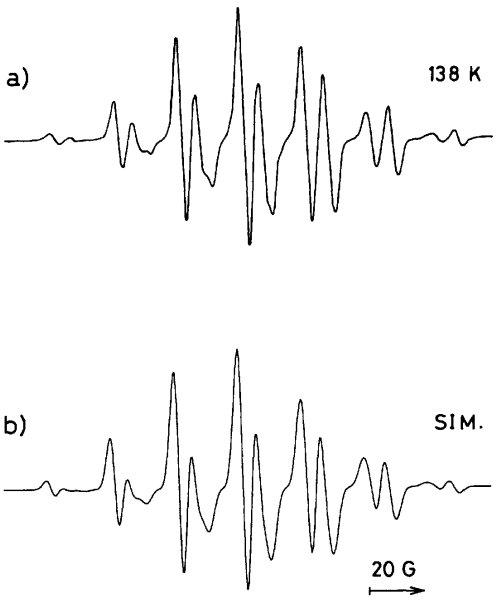

Fig. 9. (a) ESR spectrum of dimethylketene cation in CCl_3F at 138 K; (b) Simulation for (a) using the parameters given in Table 1 for protons and $A_{\parallel}=12.0$ G, $A_{\perp}=3.5$ G for one fluorine nucleus.

the superhyperfine coupling constants. The fact that we needed two sets of the superhyperfine parameters for the different temperatures may indicate that either the intermolecular complex or the mechanism of the interaction is different between the two temperatures. However, the attempt to reproduce the spectra observed in the intermediate range of the temperature by a simple superposition of the three spectra (Figs. 5b, 8b, and 9b), was not successful. Some dynamic process such as

the line alternation effect resulting from the spin exchange[21] might be related to the observed spectral change.

The superhyperfine interaction has been discussed for several cations in the matrix, in particular, in CCl_3F.[22-29] In most cases, the cations exhibit superhyperfine structures which change reversibly with the temperature. For example, the cation radical of acetaldehyde shows such behavior. Two different interpretations have been proposed for this reversibility. One is the motional averaging of the anisotropy[25] and the other is a reversible thermal dissociation.[14,26] The complete analysis of the spectral change with temperature in relation to the dynamical process is subject to further study.

Studies of Quenching Processes in NE-213 and Insta-Gel Liquid Scintillators by Using Pulse Shape Discrimination Technique

Kazutoyo ENDO,* Tadafumi SAOTOME, Keiko TANAKA, and Hiromichi NAKAHARA
Department of Chemistry, Faculty of Science, Tokyo Metropolitan University, Fukasawa, Setagaya, Tokyo 158
(Received September 12, 1984)

Quenching processes for different excitation sources such as alpha-particles and electrons in NE-213 and Insta-Gel were studied by the use of the pulse shape discrimination technique and pulse height analysis. The dependence on electron energies of time spectra due to the difference in pulse shape was observed for NE-213 by setting energy windows to Compton scattered electrons. The results were interpreted on the basis of the linear energy transfer of electrons in liquid scintillator solution. The chemical and oxygen quenchings in Insta-Gel were compared with each other by using conversion electrons and alpha-particles. Quenching constants for those particles were found to be the same for each organo halogen compound used, irrespective of the excitation sources used. Paramagnetic quenchings were also examined for such agents as oxygen, Gd^{3+} ($4f^7$), and Yb^{3+} ($4f^{13}$) by using the above two excitation sources in Insta-Gel. Possible mechanisms of their effects on the quenching processes were discussed in terms of the spin conversion between the paramagnetic quencher and the excited solvent.

The liquid scintillation counting technique has been widely used for the determination of soft beta-emitting nuclides such as tritium, carbon-14 and calcium-45 because of its excellent detection efficiency and of its simplicity in sample preparation.[1-5] In addition, this technique has been found to be very useful for the determination of low level radon in the environment.[6-10] However, quenching phenomena caused by various impurities often make the observable pulse heights lower. On the other hand, several studies have been made on quenching mechanisms in liquid scintillation systems by using monochromatic photons in the UV region,[11,12] but only a few by using radioactive nuclides for excitation of the scintillation system.[13-15]

Quenching effects have so far been classified into three categories; chemical quenching, color quenching, and oxygen quenching. The chemical quenching is caused by some energy transfer reactions between solvents or between the solvent and fluorescent molecules that do not take part in the emission of fluorescence. The color quenching is the process due to the absorption of fluorescence by quenching molecules. This process is caused by the superposition of the emission spectrum of the scintillator and the absorption spectrum of the quenching molecules. The oxygen quenching is considered to be the process related to the strong electron affinity and paramagnetism of oxygen, but details remain unknown.

It is known that the mean life time of fluorescence emission is affected by the chemical and oxygen quenchings. Hence, the pulse shape discrimination is a useful technique to get information regarding variation of such life times. The technique has been successfully applied to neutron spectroscopy, separating gamma-rays and recoil protons in inorganic[16-19] and organic scintillation countings.[20-21] Recently, this has been also effectively applied to alpha- and beta-countings by using liquid scintillator solution.[22-24]

In the present work, we studied the chemical and oxygen quenching processes in NE-213 (a product of Nuclear Enterprises) and Insta-Gel (a trade name of Packard Co., Inc.), using the pulse shape discrimination technique and pulse height analysis, and laid stress on the following points. Firstly, the relative resolving power of pulse shape discrimination between alpha-particles and electrons was examined as a function of electron energy. Secondly, the oxygen quenchings for different excitation sources such as alpha-particles and electrons were compared with each other by using the pulse shape discrimination technique. Thirdly, the effects of these different excitation sources on the chemical and oxygen quenching were studied by means of pulse height analysis. Lastly, the paramagnetic effects of oxygen, Gd^{3+} ($4f^7$), and Yb^{3+} ($4f^{13}$) were studied in order to clarify their quenching processes by the pulse shape discrimination technique. Among lanthanoid ions, Gd^{3+} shows high paramagnetic moments whereas Yb^{3+} does the least. The comparative study by the use of such ions as quenchers will make the quenching mechanism clear. The results will be discussed in terms of possible spin conversion mechanisms. In the present study, the alpha-particles from ^{210}Po and the conversion electrons from ^{139}Ce were used in order to compare the quenching effects for their excitation sources. It is expected that the quenching reactions involved will be simple for the electrons with a simple energy spectrum.

Experimental

Chemicals. *a) Sources for Insta-Gel.* For an alpha-ray source, ^{210}Po in 1 M[†] hydrochloric acid solution was used, and for a conversion electron source, ^{139}Ce in the cerium-(III) chloride form was used. The 1 M hydrochloric acid solution (1 ml) of these radioisotopes was put into a standard vial containing Insta-Gel (15 ml). The content was deoxygenated by argon gas bubbling, unless otherwise stated.

Gadolinium and ytterbium chlorides were prepared from their oxides. After dissolving the oxides into small amounts of nitric acid, their salts were converted to chlorides by repeated addition of hydrochloric acid and heating. Finally, the chlorides were obtained by evaporating the solution to

[†] 1 M=1 mol dm^{-3}.

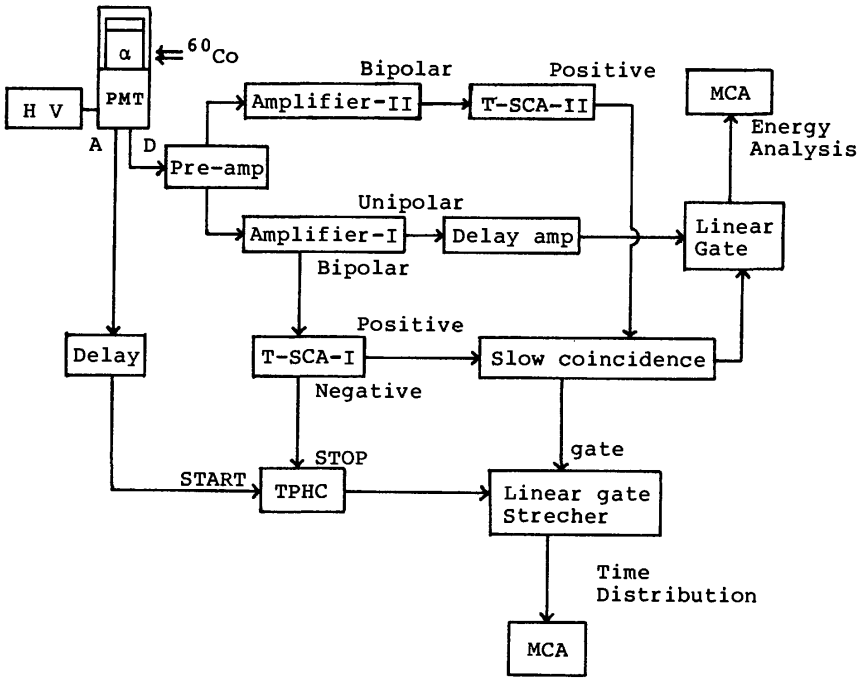

Fig. 1. A block diagram of a zero-crossing pulse shape discrimination system.

dryness.

b) Sources for NE-213. Polonium-210 and cerium-139 were extracted from each 1 M hydrochloric acid solution with a toluene solution of di(2-ethylhexyl)phosphoric acid (volume ratio of 1:1). For investigation of the electron energy dependence on the zero-crossing time, a vial containing the ^{210}Po source (the extracted solution, 1 ml) and 15 ml of NE-213 was externally irradiated with gamma-rays of ^{60}Co. The alpha-ray source was used to generate a standard zero-crossing time of alpha-rays on a time spectrum.

Measurements of Dissolved Oxygen. An oxygen analyzer manufactured by Beckman Instrument Inc. was used to measure the partial pressure of oxygen dissolved in Insta-Gel. We used the value for the partial pressure of oxygen in atmosphere, *i.e.*, 21% as the standard partial pressure of oxygen dissolved in Insta-Gel, assuming that the oxygen in solution is in equilibrium with that in air. In the case of oxygen quenching experiments, the gel was bubbled by oxygen through a glass capillary and the oxygen contents were measured before and after the pulse height and pulse shape measurements.

Measurement System. The schematic counting system used in this experiment is shown in Fig. 1. The vial was surrounded by an aluminium foil and directly connected at the bottom with optical greese to a RCA 8575 photomultiplier. All the electric instruments used were ORTEC NIM modules. In order to measure normal pulse shape distributions of alpha-particles and electrons, we used a simple system of a time pick-off at the zero-crossing point of slow bipolar signals. Anode pulses shaped with the constant fraction discriminator inside the ORTEC 270 photomultiplier base were used as start signals for a time-to-pulse height convertor (TPHC). The voltage signals from the dynode were passed through the pre-amplifier, and shaped with the main amplifier-I. The resulting bipolar signals were fed to a timing SCA-I and the fast negative signals were used as stop signals for the TPHC. In order to reduce the shifts of zero-crossing time due to pulse height variation, the range of the pulse height to be measured was kept constant by timing SCA-I and -II. The lower level of the pulse height range was selected with the timing SCA-I. For selecting the upper level of the specified range, the upper level discriminator of the timing SCA-II was used, and the lower level discriminator was set to be zero. The gain of the amplifier-I was changed to adjust the pulse height of a given electron energy to the window selected by the above two SCA.

Results and Discussion

Dependence of Zero-crossing Time Distribution on Electron Energy. Dependence of the time spectrum on the energy of electrons was examined by using Compton scattered electrons of various energies and alpha-particles of ^{210}Po in NE-213. The latter was used as a standard source for the time distribution of alpha-particles. The time spectrum of the alpha-particles from ^{210}Po and the Compton scattered electrons from ^{60}Co in NE-213 is shown in Fig. 2. The resolving power of zero-crossing time distribution between the electrons and alpha-particles was analyzed by a figure of merit, $M_{\alpha,e}$, defined as

$$M_{\alpha,e} = \frac{\Delta S}{T_1 + T_2}$$

where ΔS is the separation between two peaks, T_1 and T_2 are the full widths at half maximum (fwhm) of electrons and alpha-particles, respectively. For the present experiment, the T_2 value was constant for alpha-particles of ^{210}Po. The $M_{\alpha,e}$ values for the electrons of selected energy ranges were evaluated from the observed ΔS, T_1, and T_2 values as shown in Fig. 3. As the electron energy decreases, the $M_{\alpha,e}$ value becomes smaller. A similar trend has been reported

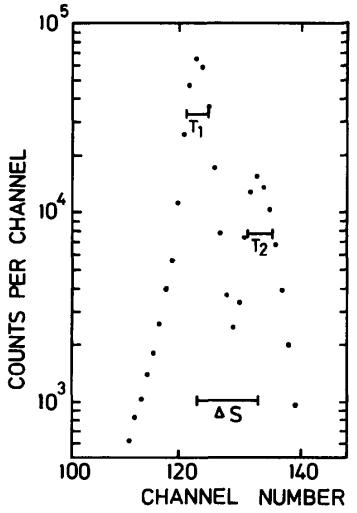

Fig. 2. Time spectrum of alpha-particles from ^{210}Po and of Compton scattered electrons in oxygen-free NE-213 irradiated with gamma-rays of ^{60}Co. T_1 and T_2 indicate the full widths at half maximum of electrons and alpha-particles, respectively.

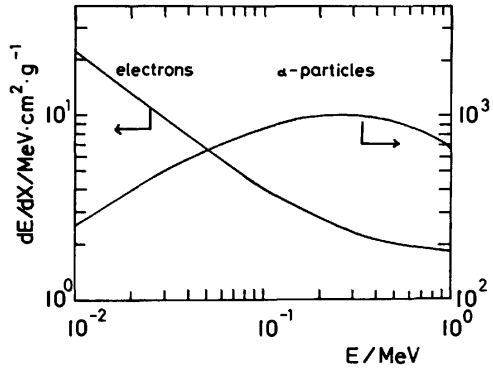

Fig. 4. Stopping powers of alpha-particles and electrons calculated by using Bethe's equation in a system of PPO (4 g), POPOP (0.1 g), and toluene (10^3 ml).

for neutron and gamma-ray separation.[19,27] The energy loss of electrons can be calculated by using Bethe's equation.[28] Although the exact chemical composition of NE-213 is not available, the energy loss of electron for an analogous material, toluene-

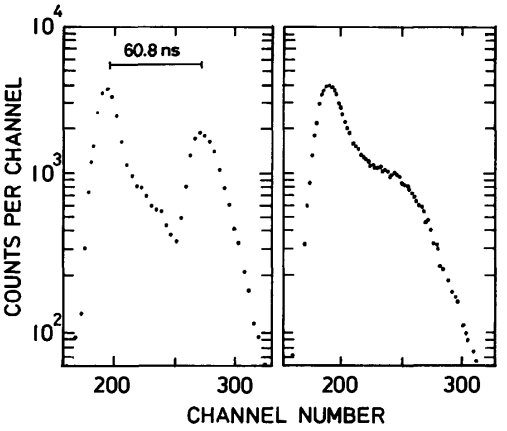

Fig. 5. Time spectra of conversion electrons from ^{139}Ce and alpha-particles from ^{210}Po in NE-213 liquid scintillator under oxygen-free (left side) and oxygen-saturated (right side) conditions.

PPO system, is shown in Fig. 4, together with that of alpha-particles.[29] The chemical compositions used for calculation are 4 g of PPO ($C_{15}H_{11}NO$, 2,5-diphenyloxazole), 0.1 g of POPOP ($C_{24}H_{16}N_2O_2$, 1,4-bis-2-(5-phenyloxazole)-benzene), and 10^3 ml of toluene. The stopping power becomes greater as the electron energy decreases. On the other hand, the value corresponding to the 5.3 MeV alpha-particles of ^{210}Po is calculated to be 2.20×10^2 MeV/cm^{2}g^{-1} in the system by using Bethe's equation,[29] which is at least two order of magnitude greater than that of electrons of the same energy. The high linear energy transfer causes localized ionization, molecular damages, and free radical formation along the path, which are closely related to the overall fluorescence conversion efficiency. The highly ionized species in a small limited spur recombine with electrons, resulting in the excited triplet state of a neutral molecule in the absence of spin correlation between the ion and an electron. The neutralization into a triplet state is favored by spin statistics. The present result of the $M_{\alpha,e}$ dependence on electron energy suggest that the energy loss processes of electrons in liquid scintillation system is similar to those of alpha-particles as the electron energy decreases.

Effects of Oxygen for Pulse Shape Discrimination. Since the time spectra of electrons were found to be dependent upon the energy in the preceding section, we used conversion electrons from ^{139}Ce as an electron source of simple energy spectrum. The time spectra of the conversion electrons and the alpha-particles from ^{210}Po in NE-213 are shown in Fig. 5. Although the center of the pulse shape distribution due to conversion electrons was not affected by oxygen, that of alpha-particles was shifted to shorter direction. The time difference of peaks was found to be 60.8 ns for oxygen-free NE-213, and to be 42 ns for oxygen saturated one. Diamagnetic compounds such as chloroform, carbon tetrachloride, bromoform, dibromomethane, and aniline did not cause variations in the time spectrum for

alpha-particles and electrons within the experimental errors, compared with those of NE-213 containing no quenching agents. The results obtained on Insta-Gel were similar to those on NE-213, except that the separation of two peaks on the time spectrum was inferior to that of the latter.

It is known in radiation chemistry that a large number of excited molecules generated through decomposition or ionization, followed by recombination of an ion and an electron, are in a triplet state as described in the preceding section. Such a triplet state will subsequently be quenched through the spin conversion process between the excited solvent and paramagnetic oxygen to the singlet state, which results in a shortening of the decay time of scintillation. The excited molecules due to the recombination of an ion and an electron will be produced in much larger quantities by alpha-particles than electrons because of the greater linear energy transfer of the former.

Shifts of the Pulse Height by Chemical and Oxygen Quenchers. The chemical and oxygen quenchings were examined by means of the pulse height analysis. Relative pulse heights (I_0/I) are plotted in Fig. 6 against the concentration of each quencher, where I and I_0 are the peak channels of the pulse height spectra observed with a given quencher and without the quencher, respectively. The linear relationship between I_0/I and the concentration was observed for each quencher. Hence, the relation can be analyzed by the following equation:

$$I_0/I = 1 + \gamma[C]$$

where γ is the quenching constant, and [C] the quencher concentration. The quenching constant was evaluated from the slope in Fig. 6, and the results are listed in Table 1. The constants were the same for alpha-particles and conversion electrons for given halogeno compounds. This would suggest that there are no remarkable differences between the chemical reactions due to the halo methanes and the excited solvents produced through the energy loss processes of alpha-particles and electrons.

Takiue and Ishikawa reported quenching constants for a series of organo halogen compounds in the toluene-PPO system using conversion electrons from ^{113}Sn.[14] For the same quencher, the quenching constant for the Insta-Gel system was found to be roughly one-half of the value in the toluene-PPO system as seen in Table 1. The quenching constant should be inversely proportional to the viscosities of the solvent from the bimolecular reaction theory.[30] The observed values, however, are not consistent with this. The discrepancy seems to be ascribed to the reasons that the scintillator solution is a mixtured solution containing PPO and a surface-active agent.

Effects of Paramagnetic Species on Time Spectrum. In order to examine in greater details the effects of paramagnetic species revealed in the time spectrum of alpha-particles and conversion electrons, we studied the effects of $GdCl_3$ ($4f^7$, S=7/2) and $YbCl_3$ ($4f^{13}$, S=1/2) in Insta-Gel. The time spectra of alpha-rays of ^{210}Po and conversion electrons of ^{139}Ce in Insta-Gel (containing 50 mM $GdCl_3$ used as a quenching agent) are shown in Fig. 7a, and the time difference between the peak channels was plotted against the concentration of $GdCl_3$ as shown in Fig. 7b. The results on $YbCl_3$ used as a quenching agent were the same as those obtained on $GdCl_3$. The oxygen effect in the foregoing arguments raises an expectation that a time spectrum of alpha-particles from ^{210}Po would be affected by the lanthanoid ions through spin conversion process. The experimental results, however, failed to show this. Unlike oxygen, paramagnetic lanthanoid ions did not shift the time spectrum for alpha-particles and conversion electrons. In order to find a reasonable explanation, the shortening process of the time distribution by paramagnetic quenchers may be considered as follows.

When the spin conversion process takes place between an unpaired electron of a paramagnetic quencher and the excited triplet state of a solvent molecule, a spin pairing will occur in the paramagnetic quencher if the partly filled electron shell has more than one electron or hole. Therefore, for the spin

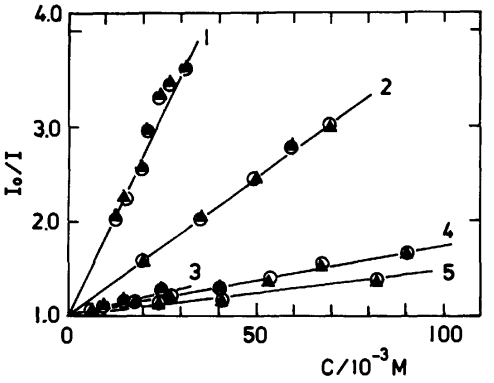

Fig. 6. Values of I_0/I plotted against the quencher concentration; 1: CBr_4, 2: $CHBr_4$, 3: CCl_4, 4: CH_2Br_2, 5: $CHCl_3$. ○: alpha-particles, ▲: electrons.

Table 1. Quenching constants of halomethanes and oxygen observed in Insta-Gel excited with conversion electrons from ^{139}Ce and alpha-particles from ^{210}Po

Compound	Quenching constant $10^3\gamma_1/M^{-1}$ (in Insta-Gel)	$10^3\gamma_2/M^{-1}$ [a] (in toluene-PPO)	(γ_1/γ_2)
CBr_4	88.7	164.0	0.54
$CHBr_3$	30.2	57.0	0.53
CCl_4	26.3	50.8	0.52
CH_2Br_2	7.39	13.3	0.56
$CHCl_3$	3.95	6.83	0.58
O_2	57.8[b]	—	—

a) The data of toluene-PPO system were cited from Ref. 14. b) In the case of oxygen, the value was obtained by the least squares method on seven data points (up to 8 mM).

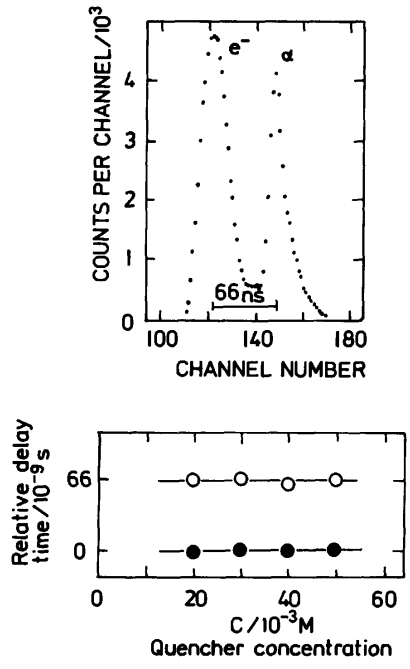

Fig. 7. (a) Time spectra of conversion electrons from ^{139}Ce and alpha-particles from ^{210}Po in oxygen-free Insta-Gel containing 50 mM $GdCl_3$. (b) Relative peak delay on the time spectra of conversion electrons and alpha-particles against the concentration of $GdCl_3$; open and full circles show the peak positions due to alpha-particles and conversion electrons, respectively.

conversion to occur, the spin pairing energy of the quenching molecule or ion must be at least lower than the energy of the lowest excited triplet state of the solvent molecule. The spin pairing energies of low lying states of oxygen are reported to be 1.46 and 0.98 eV.[31] The lowest excited triplet states of such solvents as xylene, toluene, and benzene are reported to be 3.49, 3.57, and 3,65 eV, respectively.[32–34] Thus, the spin conversion process is energetically allowed for the oxygen quencher. However, the energy balance between the solvent molecule and the paramagnetic quencher is not a sole dominant factor for the process. The lowest spin pairing energy of trivalent gadolinium ions is estimated to be 3.9 eV ($^6P_{7\,2} \leftarrow {}^8S_{7\,2}$), while trivalent ytterbium ions require no spin pairing energy with the electric confiration of $4f^{13}$,[35] so that the latter would be expected to act as a good paramagnetic quencher. However, no meaningful difference in quenching effect was found between the above two lanthanoid ions. This observation may be explained if we recall that trivalent lanthanoid ions have unpaired electrons of 4f-orbitals inside the filled 5s–5p orbitals, and probably have little overlap with an orbital of an unpaired electron of an excited solvent molecule. The spin conversion in the scintillation process is, therefore, forbidden for lanthanoid ions not only because of the energy balance but also because of the inertness of 4f-electrons. These results may lead us to conclude that the spin conversion process for oxygen is allowed from two reasons of the energy balance and the overlap of orbitals.

Conclusion. 1) The time spectra of electrons were affected by electron energies. The results may be explained in terms of the energy loss of electrons in liquid scintillator solutions as follows. As the electron energy decrease, the stopping power increases. The increased energy loss per unit length causes localized ionizations, radiation decompositions, and radical formations. The ionized species recombine in a short time with electrons, and subsequently lead to the formation of an excited triplet state in the absence of spin correlation between a positive ion and an electron. The energy transfer from the decay of a long-lived triplet state and the subsequent fluorescence of PPO will result in the delayed distribution on the time spectrum.

2) The chemical quenching constants for alpha-particle and electron excitations were found to be identical with the same organo halogen compound. The results suggest that the chemical reactions of organo halogen compounds with the excited solvents lead to practically the same reduction of the fluorescence yields for alpha-particles and electrons.

3) The time spectra of alpha-particles were shifted by oxygen, whereas those of electrons were not. In addition, they were not also affected by lanthanoid ions. The facts may be explained in terms of spin conversion mechanism. For the spin conversion to occur, the molecule must be excited at least to an excited state whose spin multiplicity is smaller by two than that of the ground state. In the case of spin doublet state, the process is expected to be allowed energetically. However, the results on the lanthanoid ions showed that the overlap of an unpaired electron of the paramagnetic quencher and that of the excited solvent is also important for the process.

The authors are grateful to Dr. H. Ishikawa of Radioisotope Nuclear Reactor School at Japan Isotope Research Institute for the use of an oxygen analyzer, and to Prof. Y. Murakami at Kitasato University for kind suggestions throughout this work.

Preparation and Structural Studies of Tris[(1*R*,2*R*)- or (1*R*,2*S*)-2-(Aminomethyl)cyclohexylamine]cobalt(III) Complexes

Masahide Noji,* Haruo Toida, and Yoshinori Kidani
Faculty of Pharmaceutical Sciences, Nagoya City University, 3-1 Tanabe-dori, Mizuho-ku, Nagoya 467
(Received September 25, 1984)

New cobalt(III) complexes containing (1*R*,2*R*)- or (1*R*,2*S*)-2-(aminomethyl)cyclohexylamine(=amcha) have been synthesized and separated into diastereoisomers. $[Co(1R,2R\text{-amcha})_3]^{3+}$ gives two diastereoisomers, structures of which were deduced to be *mer*-Δ and *fac*-Δ based upon their ^{13}C-NMR and CD spectra. $[Co(1R,2S\text{-amcha})_3]^{3+}$ gives three diastereoisomers, structures of which were determined to be *mer*-Λ, *mer*-Δ, and *fac*-Λ. The conformations of the six-membered chelate rings were investigated in the absence or presence of sulfate ions.

The structural study of antitumor Pt(II) complexes of 2-(aminomethyl)cyclohexylamine(=amcha) isomers showed that the chelate ring of (1*R*,2*R*)-amcha is interconvertible between the two chair forms through a λ-skew form, and that of (1*R*,2*S*)-amcha exists in the fixed-chair form, as shown in Fig. 1.[1,2] Since tris(amcha)Co(III) complexes have an octahedral structure, they are expected to form crowded structures rather than square planar Pt(II) complexes. Therefore, the influence of steric interactions among the adjacent ligands is considered to contribute greatly to the conformation of the ligands. In order to investigate the conformation of the six-membered chelate rings of tris(amcha)Co(III) complexes, the authors prepared and separated them into diastereoisomers.

In this paper, the authors will discuss the structures of Co(III) complexes of amcha isomers and the conformations of the chelate rings, based upon their electronic absorption, circular dichroism, and ^{13}C-NMR spectra. This information should be useful in understanding antitumor Pt(IV) complexes of amcha isomers, which are now under investigation.

Experimental

Ligand. A synthesis of *cis*- and *trans*-2-(aminomethyl)cyclohexylamine: These ligands were synthesized from corresponding 1,2-cyclohexanedicarboxylic acids according to a method reported by Armarego *et al.*[3] Resolution of *cis*- and *trans*-amcha was achieved to give (1*R*,2*R*)- and (1*R*,2*S*)-amcha, respectively, according to a method described in the literature.[1]

Preparation of Tris[(1R,2R)- or (1R,2S)-amcha]cobalt(III) Complexes. *trans*-$[CoCl_2(1R,2R\text{- or }1R,2S\text{-amcha})_2]Cl$. To an aqueous solution (15 cm³) containing 2.42 g of $Na_3[Co(NO_2)_6]$ was added an aqueous suspension (20 cm³) of (1*R*,2*R*)- or (1*R*,2*S*)-amcha (1.5 g). The mixture was heated for 4 h at 70 °C with continuous agitation. To the resultant orange solution were added 25 cm³ of conc HCl and stirred for 2 h at 70 °C. Deposited green crystals were collected, washed with ethanol and dried *in vacuo*. Yield: 1.5 g for $[CoCl_2(1R,2R\text{-amcha})_2]Cl$ and 2.3 g for $[CoCl_2(1R,2S\text{-amcha})_2]Cl \cdot 1.5\ H_2O$.

Tris(amcha)cobalt(III) Complexes. To a DMSO solution (20 cm^3) of *trans*-$[CoCl_2(1R,2R\text{-amcha})_2]Cl$ (or *trans*-$[CoCl_2(1R,2S\text{-amcha})_2]Cl$)(1.0 g) was added a methanol solution (5 cm^3) of (1*R*,2*R*)- (or 1*R*,2*S*-)amcha (0.3 g). The mixture was stirred overnight at 60°C. A reddish-orange solution was diluted with 3 dm^3 of water and was adsorbed on SP-Sephadex C-25. These adsorbed complexes were separated by the following procedures.

a) Separation of Tris(1R,2R-amcha)Co(III) Complexes. The complexes adsorbed on the resin were placed on a column (3.0 IDX120 cm) of SP-Sephadex C-25 and were developed with 0.2 mol dm^{-3} sodium(+)$_{589}$-tartratoantimonate(III). The complexes were separated into two bands, $F_{C\text{-}1}$ and $F_{C\text{-}2}$, in the order of eluation. The fractions were diluted with water as many as ten times, followed by adsorption in an SP-Sephadex column.

mer-Δ-$[Co(1R,2R\text{-}amcha)_3](ClO_4)_3$. The $F_{C\text{-}1}$ fraction loaded in an SP-Sephadex column was washed with a large volume of 0.005 mol dm^{-3} $HClO_4$ solution and was then eluated with a 0.5 mol dm^{-3} $HClO_4$ solution. The eluate was concentrated in a desiccator *in vacuo* over P_4O_{10} and NaOH. Deposited orange crystals were collected and dried in a desiccator over P_4O_{10} and NaOH. Yield: 20 mg

fac-Δ-$[Co(1R,2R\text{-}amcha)_3](ClO_4)_3$. This complex was obtained from the $F_{C\text{-}2}$ fraction by the same procedure as that for the *mer*-Δ isomer. Yield: 50 mg.

b) Separation of Tris(1R,2S-amcha)Co(III) Complexes. The adsorbed band of tris(1*R*,2*S*-amcha)Co(III) complexes was placed on an SP-Sephadex column and was developed with 0.2 mol dm^{-3} sodium(+)$_{589}$-tartratoantimonate(III). The band split into two bands, $F_{T\text{-}1}$ and $F_{T\text{-}2}$, in the order of eluation. The $F_{T\text{-}1}$ fraction was diluted with water as many as ten times and was loaded on an SP-Sephadex column (2.0 IDX110 cm) and rechromatographed with 0.2 mol dm^{-3} Na_2SO_4. The band split into two bands, $F_{T\text{-}1\text{-}1}$ and $F_{T\text{-}1\text{-}2}$.

mer-Λ *and* mer-Δ-$[Co(1R,2S\text{-}amcha)_3](ClO_4)_3\cdot nH_2O$. The *mer*-Λ *and mer*-Δ complexes were obtained from the $F_{T\text{-}1\text{-}1}$ and $F_{T\text{-}1\text{-}2}$ fractions, respectively, by a similar procedure to that of *mer*-Δ-$[Co(1R,2R\text{-amcha})_3](ClO_4)_3$. Yield: 30 mg for *mer*-Λ and 50 mg for *mer*-Δ.

fac-Λ-$[Co(1R,2S\text{-}amcha)_3](ClO_4)_3\cdot 2H_2O$. The complex was obtained from the $F_{T\text{-}2}$ fraction by a similar procedure to that indicated above. Yield: 140 mg.

The results of elemental analyses of the Co(III) complexes, thus obtained, are shown in Table 1.

Measurements. Absorption and circular dichroism spectra were measured with a Hitachi 557 spectrophotometer and a JASCO J-40 spectropolarimeter. FT ^{13}C-NMR spectra were obtained with a JEOL JNM-FX-100 spectrometer.

Results and Discussion

^{13}C-NMR Spectra. There are two geometrical isomers, *i.e.*, *mer* and *fac*, for tris(1*R*,2*R*-amcha)Co(III) complexes. The $F_{C\text{-}1}$ and $F_{C\text{-}2}$ fractions separated through an SP-Sephadex column exhibited ^{13}C-NMR spectra (Fig. 2). The ^{13}C-NMR spectrum of the $F_{C\text{-}2}$ fraction showed 7 singlet resonance lines, indicating the *fac*-isomer, where the three coordinated amcha are chemically equivalent. The $F_{C\text{-}1}$ fraction showed a similar ^{13}C-NMR pattern to that of the *fac*-isomer, except that each resonance peak was composed of a doublet or triplet, indicating a lower symmetric *mer*-isomer with unequivalent ligands. Assignments of the resonance lines were tentatively made based on the assignments for [Pt(en)(1*R*,2*R*-amcha)]Cl_2.

Tris(1*R*,2*S*-amcha)Co(III) complexes were separated into three fractions, *i.e.*, $F_{T\text{-}1\text{-}1}$, $F_{T\text{-}1\text{-}2}$, and $F_{T\text{-}2}$, typical two ^{13}C-NMR spectra of which are illustrated in Fig. 2. The $F_{T\text{-}2}$ fraction exhibited 7 singlet resonance lines in the ^{13}C-NMR spectrum and was assigned to the symmetric *fac*-isomer. The $F_{T\text{-}1\text{-}1}$ and $F_{T\text{-}1\text{-}2}$ fractions showed a similar ^{13}C-NMR spectral pattern to that of $F_{T\text{-}2}$, except that each resonance peak was composed of a doublet or triplet, suggesting the *mer* configuration. The assignments of the resonance lines for these Co(III) complexes were made as shown in Fig. 2, based upon the assignments of [Pt(en)(1*R*,2*S*-amcha)]Cl_2.[1]

Absorption Spectra. The absorption maxima of the first absorption bands of Co(III) complexes containing 1,3-diamines were reported to shift depending upon the configurations of the complexes. For example, the tris(meso-ptn)Co(III) complex was reported to have *fac*- and *mer*-isomers with a chair conformation. The interaction among the ligands was larger in the *mer*-isomer than the *fac*-isomer and the absorption maximum of the former shifted 2 nm toward a longer-wavelength region compared to that of the latter.[4]

a) Tris(1R,2R-amcha)Co(III) Complexes. Comparing the absorption maxima of the *fac*- and *mer*-isomers of tris(1*R*,2*R*-amcha)Co(III), the maximum of the *fac*-isomer was at 489 nm and that of the *mer*-isomer

Complex	AB λ_{max}/nm (log ε/mol^{-1} dm^3 cm^{-1})	CD λ_{max}/nm (Δε/mol^{-1} dm^3 cm^{-1})
mer-Δ-[Co(1*R*,2*R*-amcha)$_3$](ClO$_4$)$_3$	495.0 (1.97)	517.0 (−0.853)
		530.0 (−0.365)[a]
		475.0 (+0.436)[a]
fac-Δ-[Co(1*R*,2*R*-amcha)$_3$](ClO$_4$)$_3$	489.0 (2.09)	521.0 (−0.666)
		458.5 (+0.089)
		535.0 (−0.239)[a]
		478.0 (+0.749)[a]
mer-Λ-[Co(1*R*,2*S*-amcha)$_3$](ClO$_4$)$_3$ HClO$_4$·7H$_2$O	485.0 (1.97)	505.0 (+0.749)
		505.0 (+0.632)[a]
mer-Δ-[Co(1*R*,2*S*-amcha)$_3$](ClO$_4$)$_3$ HClO$_4$·2H$_2$O	485.0 (2.01)	505.0 (−0.890)
		507.0 (−0.721)[a]
fac-Λ-[Co(1*R*,2*S*-amcha)$_3$](ClO$_4$)$_3$ HClO$_4$·7H$_2$O	485.0 (1.97)	495.0 (+1.025)
		497.0 (+0.437)[a]

a) CD data in 0.2 mol dm^{-3} Na_2SO_4 solutions.

at 495 nm. This shift can be explained by the fact that the *mer*-isomer is stereostructurally more crowded than the *fac*-isomer.

b) Tris(1R,2S-amcha)Co(III) Complexes. All three isomers showed absorption maxima at 485 nm, indicating little interaction among the ligands. The fact that the absorption maximum observed for *fac*-[Co(1*R*,2*S*-amcha)$_3$] shifted 4 nm towaed a longer-wavelength region compared to that of the corresponding *fac*-[Co(1*R*,2*R*-amcha)$_3$] may be explained by a more crowed structure of the former than of the latter.

Circular Dichroism Spectra. In tris(diamine)Co(III) complexes with five-membered chelate rings, there exists a good correlation between the signs of the CD bands corresponding to the E component of the first absorption bands and the configurations. However, in tris(diamine)Co(III) complexes with six-membered chelate rings, the correlation between the signs of the CD bands and the configurations has not been well established. A typical example was found for [Co(tn)$_3$]$^{3+}$.[5-9] However, in the case of tris(*S*-bn)(bn=1,3-butanediamine) complexes, the correlation was well maintain-

ed, giving positive CD bands for *mer*-Λ and *fac*-Λ isomers and negative ones for the *mer*-Δ and *fac*-Δ isomers.[10]

The CD spectral behavior of tris(1*R*,2*R*- or 1*R*,2*S*-amcha) Co(III) complexes resembles that of tris(*S*-bn)Co(III) complexes, and the configurations of the former were elucidated based on the correlations found in the latter ones.

*a) Tris(1*R,2R*-amcha)Co(III) Complexes.* As shown in Fig. 3, both *mer*- and *fac*-isomers of tris-(1*R*,2*R*-amcha)Co(III) complexes showed negative CD bands at 517 and 521 nm with $\Delta\varepsilon$ values of −0.853 and −0.666 in the first absorption region, respectively. Their configurations were deduced to be Δ. The *fac*-Δ isomer also showed a small positive CD band at 458 nm ($\Delta\varepsilon$=+0.089). In a 0.2 mol dm^{-3} sodium sulfate solution, the CD band of the *mer*-Δ isomer split into two bands, giving negative and positive bands at 530 and 475 nm with $\Delta\varepsilon$ values of −0.365 and +0.436, respectively. The increment of the positive band was also observed for the *fac*-Δ isomer (Fig. 3(b)). The occurrence of the positive CD bands can be explained by taking account of the λ-gauche conformation due to a hydrogen bond formation between sulfate ions and the amino protons. This was confirmed by the molecular model speculations.

As shown in Fig. 1, 1*R*,2*R*-amcha has the possibility to assume chair conformations, one of which has an axial amino group and an equatorial aminomethyl group (chair I). The other has a reverse orientation-(chair II). As to the *fac*-Δ isomer, a (chair I)$_3$ conformer is advantageous over a (chair II)$_3$ conformer, which has a large steric hindrance than the former. However, an interconversion between the chair conformers is possible. Therefore, the small positive CD band in H_2O which was observed for the *fac*-Δ isomer may suggest the existence of a (chair I)$_2$ (λ-skew) conformer. The molecular models of (chair I)$_3$, (chair II)$_3$, and (λ-skew)$_3$ conformers indicate that a (λ-skew)$_3$ conformer can be stabilized by ion-pairs between sulfate ions and amino protons. That is, in the presence of sulfate ions, the (λ-skew)$_3$ form is more stable than other forms.

Concerning the *mer*-Δ isomer, the (chair I)$_3$ conformer is the most stable form and the (chair II)$_3$ conformer was not considered due to its steric hindrances. The other possible structure is a (chair I)$_2$ (chair II) conformer. Thus, an equilibrium between (cahir I)$_3$ and (chair I)$_2$ (chair II) is probable, but the frequency of the interconversion, which can take place through the λ-skew, is low compared to that between (chair I)$_3$ and (chair II)$_3$ for the *fac*-Δ isomer. The model of a *mer*-Δ(λλλ) conformer indicates that two ion-pairs are also possible similar to the *fac*-Δ isomer, giving an enhanced intensity of the positive CD band in the presence of sulfate ions.

*b) Tris(1*R,2S-amcha)Co(III) Complexes.* CD spectra of the mer isomers exhibited a positive and a negative CD band at 505 nm in H_2O for $F_{T\text{-}1\text{-}1}$ and $F_{T\text{-}1\text{-}2}$ fractions, respectively. The *fac*-isomer showed positive CD band at 505 nm. From these CD data, the configurations of $F_{T\text{-}1\text{-}1}$ and $F_{T\text{-}1\text{-}2}$, and $F_{T\text{-}2}$ complexes were deduced to be *mer*-Λ, *mer*-Δ, and *fac*-Λ, respectively. Their CD spectra are illustrated in Fig. 5.

In the presence of sulfate ions, the *fac*-Λ isomer exhibited a significant decrease in $\Delta\varepsilon$ (from +1.02 to +0.43). On the other hand, both the *mer*-Λ and *mer*-Δ isomers showed only a little decrease in $\Delta\varepsilon$ in 0.2 mol dm^{-3} sodium sulfate solutions. These CD spectra are also illustrated in Fig. 5. The CD spectral behavior of tris(1*R*,2*S*-amcha)Co(III) complexes suggested different conformations to those of the tris(1*R*,2*R*-amcha)-Co(III) complexes. The differences may arise due to the fact that the conformations of 1*R*,2*S*-amcha were restricted to the chair and λ-skew forms, as shown in [Pt(en)(1*R*,2*S*-amcha)]$^{2+}$.

From the molecular models of the tris(1*R*,2*S*-amcha) Co(III) complexes the following conclusions were obtained concerning the stereostructures of the three isomers. For the *fac*-Λ isomer, (chair)$_3$ and (λ-skew)$_3$ conformers are stable and in the former ion-pairs can be formed between sulfate ions and amino protons, while in the latter ion-pair formation is not possible due to its (ob)$_3$-type structure. That is, in H_2O the *fac*-Λ isomer exists as a (Λ-skew)$_3$ conformer, which changes conformations and the (chair)$_3$ conformer becomes stable in a 0.2 mol dm^{-3} sodium sulfate solution by ion-pair formation. This explains the observed decrease in $\Delta\varepsilon$.

For the *mer*-Λ isomer, a (λ-skew)$_3$ conformer is more stable than (chair)$_3$, in which steric hindrance exists between ligand A and B as shown in Fig.7. The presence of sulfate ions brought about a slight decrease in $\Delta\varepsilon$ (from +0.749 to +0.632), suggesting a partial conformational change among the three ligands. Among the three possibe (λ-skew)$_2$(chair) conformers, the one involving ligand C in a chair conformation stabilized with less steric hindrance and was able to form ion-pairs. Another conformer, containing ligand B in a chair conformation, was also stable but it could not form the ion-pairs. The other conformer containing ligand A in chair was less stable than the other two conformers due to its steric hindrance. The molecular models indicate that *mer*-Λ isomer exists as a (λ-skew)$_3$ conformer in H_2O and in the presence of sulfate ions a (λ-skew)$_2$ (chair) conformer with ligand C in a chair conformation is stabilized by the ion-pair formation with a slight decrease in $\Delta\varepsilon$.

The molecular models of the last isomer, *mer*-Δ indicate that it can also exist as a (λ-skew)$_3$ or (λ-skew)$_2$ (chair) conformer, in the latter of which ligand A or B in the chair conformation. Its CD spectral behavior in H_2O and a 0.2 mol dm^{-3} sodium sulfate solution seems to indicate that a partial conformational change from chair to λ-skew takes place with a decreased absolute $\Delta\varepsilon$ in the latter solution. That is, the *mer*-Δ isomer exists in a (λ-skew)$_2$(chair) form in H_2O and a (λ-skew)$_3$ form in the presence of sulfate ions. How-

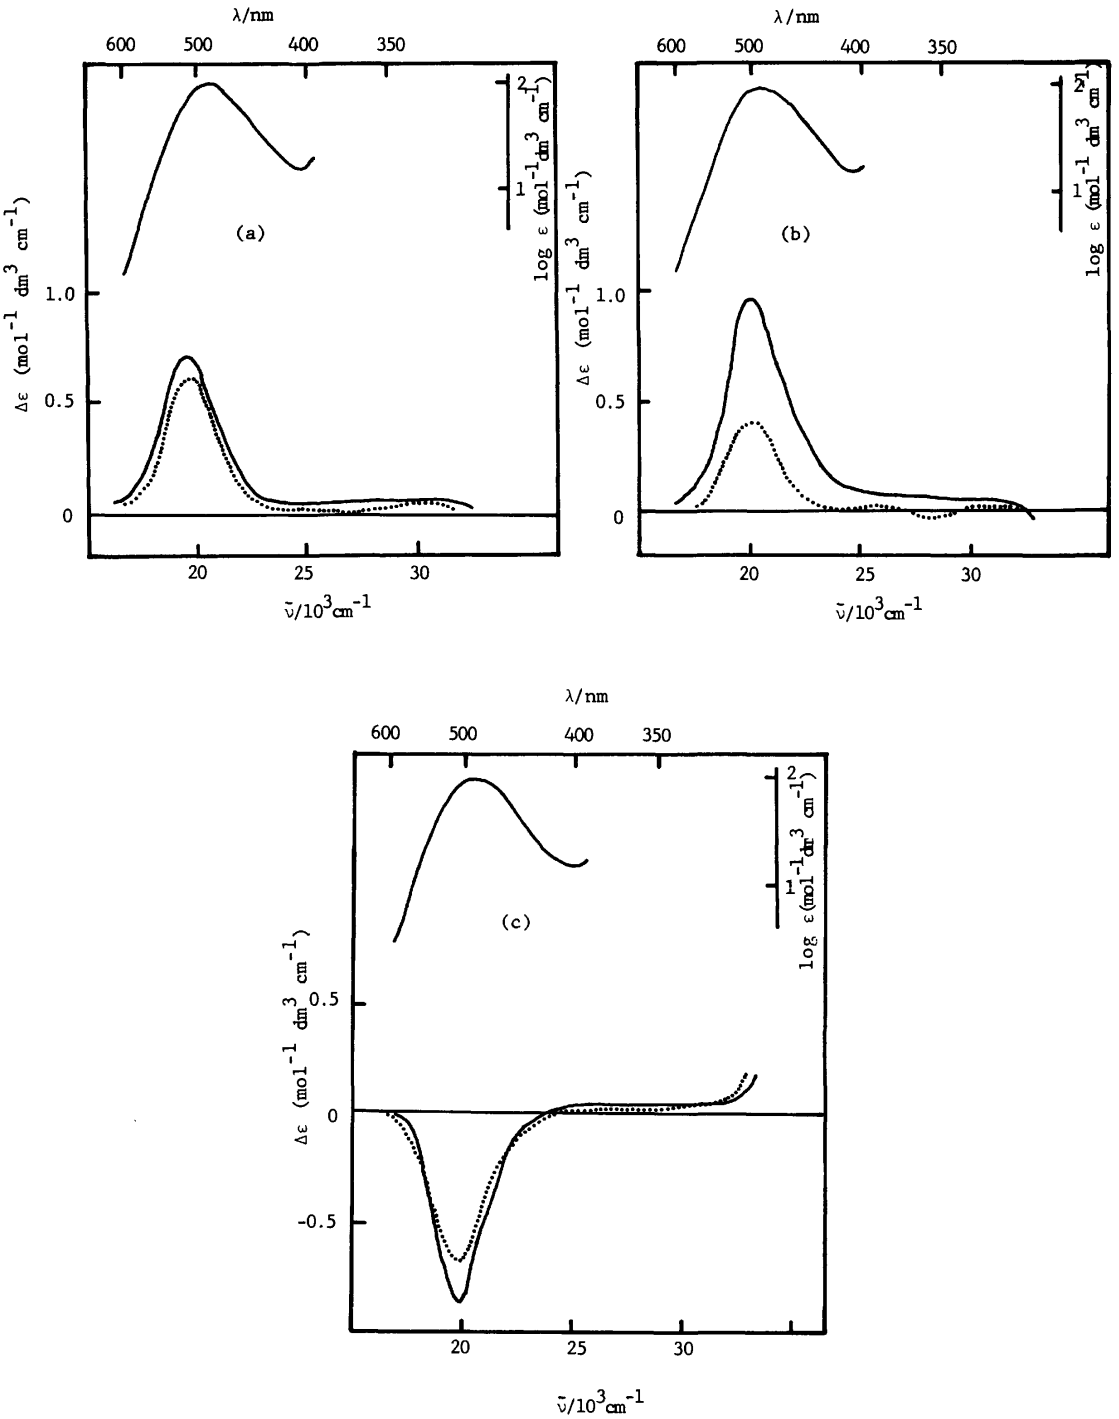

Fig. 5. Absorption and CD spectra of tris(1*R*,2*S*-smcha)cobalt(III) complexes.
(a): *mer*-Λ-[Co(1*R*,2*S*-amcha)$_3$]$^{3+}$, CD spectra of 5.19×10^{-3} mol dm^{-3} in water (——) and 0.2 mol dm^{-3} Na_2SO_4 (·····), (b): *fac*-Λ-[Co(1*R*,2*S*-amcha)$_3$]$^{3+}$, CD spectra of 5.16×10^{-3} mol dm^{-3} in water (——) and 0.2 mol dm^{-3} Na_2SO_4 (·····), (c): *mer*-Δ-[Co(1*R*,2*S*-amcha)$_3$]$^{3+}$, CD spectra of 5.73×10^{-3} mol dm^{-3} in water (——) and 0.2 mol dm^{-3} Na_2SO_4 (·····).

ever, this explanation is in conflict with the $\Delta\varepsilon$ value of −0.89 in H_2O for the *mer*-Δ isomer, because the combination of a Δ configuration and λ conformations would be expected to give a somewhat smaller absolute $\Delta\varepsilon$ than the value of +0.749 observed for the *mer*-Λ isomer with (λ-skew)$_3$ conformations. Therefore, the conformation of *mer*-Δ was not possible to determine with the present CD spectral data.

Relative Acidity of Bis(2,4-pentanedionato)(diamine)cobalt(III) Complexes in Lower Dielectric Solvents

Kazuaki ITO,† Etsuro IWAMOTO, Kazuko HASEGAWA, Manabu YAMAMOTO, and Yuroku YAMAMOTO*
Department of Chemistry, Faculty of Science, Hiroshima University, Naka-ku, Hiroshima 730
(Received October 30, 1984)

The conductances of bis(2,4-pentanedionato)(diamine)cobalt(III) complexes ([Co(acac)$_2$(diamine)]X, diamine: ethylenediamine (en) and *N,N'*-dimethylethylenediamine (*N,N'*-dmen), X=Br^- and ClO_4^-) were measured in aprotic solvents covering the approximate range of dielectric constant 5—28 at 25 °C. It was found that a) in spite of the larger size of the methyl derivative the ionic association constants (K_a) for [Co(acac)$_2$(*N,N'*-dmen)]$^+$ complexes are larger than those for [Co(acac)$_2$(en)]$^+$ complexes in all the composition of nitrobenzene ($PhNO_2$)–carbon tetrachloride (CCl_4) mixtures (wt % CCl_4: 20, 40, 60, 70). b) The reverse trend was obtained in dichloromethane (DCM), 1,1,2,2-tetrachloroethane (1,1,2,2-TCE), and chloroform ($CHCl_3$). These results were explained in terms of hydrogen bonding between the NH protons in the chelate cations and the anions ClO_4^- and Br^-, selective solvation of the NH group side by nitrobenzene, and the desolvation due to the introduction of the *N*-methyl groups. The relative acidity of NH protons which is controlled by solvation plays an important role in ionic association for the chelate cations with NH protons.

It is known that when *N*-alkyl groups are introduced into some amines coordinated to a metal ion, the acidity of the residual NH protons increases.[1,2] For example, the acid dissociation constant (pK_a=7.2) of $[Pt(NH_3)_6]^{4+}$ in water increases with the replacement of ammonia (NH_3) by ethylenediamine (en) (pK_a: 5.5 for $[Pt(en)_3]^{4+}$). However, the source of the increasing acidity is not clear although the basicity of *N*-methyl-substituted amines and polyamines has been examined in great deal by vapor pressure, EMF, calorimetry, UV, NMR measurements, and *ab initio* calculation.[3]

In our previous studies,[4-6] we have employed a series of bis(β-diketonato)(diamine)cobalt(III) complexes as probes to obtain the information on solute-solvent interactions in electrolyte solutions. It is interesting to note that the ionic association constants (K_a) for [Co(acac)$_2$(*N,N'*-dmen)]X (X=ClO_4^- and Br^-) in $PhNO_2$ are larger than those for [Co(acac)$_2$(en)]X in spite of decreasing the number of the NH protons capable of hydrogen bonding with the anions. We have proposed that the results can be interpreted in terms of the difference in acidities of the NH protons owing to an ion–solvent dipole interaction. Therefore, it is considered that the properties of mixed solvents become much clear using the ion association processes of [Co(acac)$_2$(en)]$^+$ and [Co(acac)$_2$(*N,N'*-dmen)]$^+$ complexes.

In this study, we applied these ideas to the mixed solvents of nitrobenzene ($PhNO_2$) and carbon tetrachloride (CCl_4), and pure solvents dichloromethane (DCM), 1,1,2,2-tetrachloroethane (1,1,2,2-TCE), and chloroform ($CHCl_3$). Carbon tetrachloride is nonpolar aprotic and the properties of $PhNO_2$–CCl_4 mixtures (dielectric constant, viscosity, and specific gravity) change linearly with the increase in a fraction of CCl_4, so carbon tetrachloride acts only as a diluent.[7]

Experimental

The metal chelate electrolytes, [Co(acac)$_2$(en)]X and [Co(acac)$_2$(*N,N'*-dmen)]X (X=Br^- and ClO_4^-) were prepared and purified as described previously.[4,5] All the solvents employed were commercial products (Wako Pure Chemical Industries, Ltd.). Reagent grade carbon tetrachloride (CCl_4) was distilled under nitrogen atmosphere, after being shaken with $NaHCO_3$ solution, then with water, and dried over $CaCl_2$. The middle fraction was collected. Dichloromethane (DCM) was washed with $NaHCO_3$ solution and then with water, dried over $CaCl_2$, and fractionally distilled. The method of purification of nitrobenzene ($PhNO_2$) has been described previously.[5] Spectrograde chloroform was washed with water and passed through a molecular sieve (4A) ($CHCl_3$: Density 1.4799 g cm^{-3}, viscosity 0.5470 mPa s at 25 °C). Reagent grade 1,1,2,2-tetrachloroethane was used without further purification (1,1,2,2-TCE: Density 1.5866 g cm^{-3}, viscosity 1.610 mPa s at 25 °C).

Conductance measurements were carried out by a LCR-type bridge (Ando Electric Company Ltd.) having a frequency of 1592 Hz. The procedure used for the conductance measurements and other measurements (viscosity and density of solvent) have been described previously.[5] The solvent mixtures of nitrobenzene and carbon tetrachloride were prepared by weight (corrected to vaccum) under nitrogen atmosphere in a dry box. The dielectric constant (ε) and viscosity (η in mPa s) of the solvent mixtures used for analysis were obtained from interpolation of those determined by Fuoss *et al.*;[7] wt % CCl_4 20, ε=27.9, η=1.612; 40, ε=21.2, η=1.400; 60, ε=14.5, η=1.201; 70, ε=11.4, η=1.105. The dielectric constant[8] and viscosity of pure solvents are as follows: DCM, ε=8.90, η=0.416; 1,1,2,2-TCE, ε=8.01, η=1.610; $CHCl_3$, ε=4.72, η=0.5470.

Results and Discussion

The measured molar conductances Λ (S cm^2 mol^{-1}) and corresponding electrolyte concentrations C (mol dm^{-3}) at 25 °C were given in Tables 1 and 2 for [Co(acac)$_2$(diamine)]Br in $PhNO_2$–CCl_4 mixtures and [Co(acac)$_2$(diamine)]ClO_4 in chloroalkane solvents and $PhNO_2$–CCl_4 (wt % 70) mixture, respectively. The data were analyzed by using the expanded Fuoss-Hsia equation with $E=E_1\Lambda_0-2E_2$ as in the following[9]

$$\Lambda = \Lambda_0 - S(C\gamma)^{1/2} + EC\gamma \log C\gamma + J_1C\gamma - J_2(C\gamma)^{3/2} - K_aC\gamma f_\pm^2\Lambda \quad (1)$$

where K_a is the ionic association constant and Λ_0 is the limiting conductance. The molar conductances of [Co(acac)$_2$(N,N'-dmen)]ClO_4 in $CHCl_3$ indicated a minimum conductance Λ_{min} at *ca.* 3.5×10^{-3} mol dm^{-3} (Table 2). The Fuoss-Kraus theory[10] of triple ion formation showed that the position C_{min} of Λ_{min} is the product of K_{a3} by electrostatic theory and Λ_0/Λ_{03}. This relation coincides with the empirical rule, $C_{min} \simeq (\varepsilon^3/3) \times 10^{-4}$, discoverd by Walden.[10] The solubility of [Co(acac)$_2$(en)]ClO_4 is too small to obtain a minimum

conductance. The data were analyzed by using the Fuoss-Kraus equation[10]

$$\Lambda C^{1/2}g(C) = \Lambda_0/K_a^{1/2} + (\Lambda_{03}K_{a3}/K_a^{1/2})(1-\Lambda/\Lambda_0)C \quad (2)$$

where $g(C)$ is given by $g(C)=\exp[-2.303A_f(C\Lambda/\Lambda_0)^{1/2}]/[1-A_\lambda(C\Lambda/\Lambda_0)^{1/2}/\Lambda_0]$ $(1-\Lambda/\Lambda_0)^{1/2}$, K_{a3} is the triple ion formation constant and Λ_{03} is the sum of the limiting conductances of the two kinds of triple ions. A_f and A_λ are the limiting slopes of the Debye-Hückel theory and of the Onsager theory, respectively. In this study, $\Lambda_{03}/\Lambda_0=1/2$[11] was assumed and Λ_0 was estimated from the average Walden product of each chelate electrolyte in 1,2-DCE, DCM, and 1,1,2,2-TCE. The conductance parameters are given in Table 3 ([Co(acac)$_2$(en)]Br and [Co(acac)$_2$(N,N'-dmen)]Br in $PhNO_2$–CCl_4 mixtures) and Table 4 ([Co(acac)$_2$(en)]ClO_4 and [Co(acac)$_2$(N,N'-dmen)]ClO_4 in chloroalkane solvents and $PhNO_2$–CCl_4 (wt%70) mixture).

Figure 1 shows that the K_a values for [Co(acac)$_2$(diamine)]Br in $PhNO_2$–CCl_4 mixtures are much larger than those for n-Bu_4NBr,[7] this being attributed to hydrogen bonding between the NH protons of the chelate cations and the Br^- ion. However, the K_a values for [Co(acac)$_2$(N,N'-dmen)]Br are larger than those for [Co(acac)$_2$(en)]Br in spite of decreasing the number of the NH protons from four to two. Similar results were

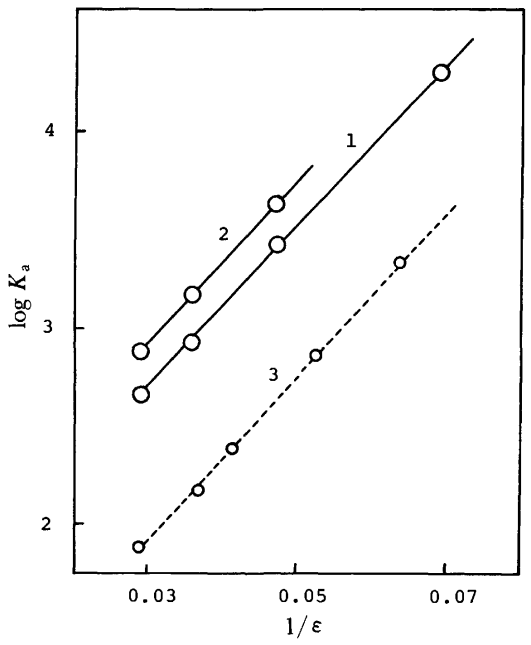

Fig. 1. Dependence of ionic association constant on dielectric constant in $PhNO_2$–CCl_4 mixtures at 25 °C. 1, [Co(acac)$_2$(en)]Br; 2, [Co(acac)$_2$(N,N'-dmen)]Br; 3, n-Bu_4NBr.[7]

obtained for $[Co(acac)_2(en)]ClO_4$ and $[Co(acac)_2(N,N'\text{-dmen})]ClO_4$ in $PhNO_2$–CCl_4 (wt% 70) mixture although the difference is small owing to the weakness of hydrogen bonding ability of the ClO_4^- ion.[5,6] On the other hand, in chloroalkane solvents (1,2-DCE, DCM, 1,1,2,2-TCE, and $CHCl_3$) the K_a values for $[Co(acac)_2(en)]ClO_4$ are all larger than those for $[Co(acac)_2(N,N'\text{-dmen})]ClO_4$ (Table 4).

The dipole moment of $PhNO_2$ (μ=4.22) is larger than that of 1,2-DCE, DCM, 1,1,2,2-TCE, and $CHCl_3$ (1,40, 1.60, 1.32, and 1.01, respectively).[8] The NH protons of the $[Co(acac)_2(en)]^+$ ion in $PhNO_2$ are solvated by an ion–solvent dipole interaction and the introduction of *N*-methyl groups removes partly the solvation sheath of the residual protons by steric hindrance, resulting in the increasing K_a.[5] This view is valid in $PhNO_2$–CCl_4 mixtures in which CCl_4 acts only as a diluent. Thus, the significant difference in K_a between $PhNO_2$–CCl_4 mixtures and the chloroalkane solvents is attributed to the selective solvation by nitrobenzene molecules. For the ionic association of *n*-Bu_4NBr and *n*-Bu_4NI in $PhNO_2$–CCl_4 mixtures,[7] the selective solvation of the cation by nitrobenzene was not observed. In addition, the ion pair extraction of R_4NI (R=Et, *n*-Pr, *n*-Bu, and *i*-C_5H_{11} from water to $PhNO_2$–CCl_4 mixtures can be interpreted mainly in terms of the dielectric constant and solubility parameter.[12] These are because of the long-range ion–solvent interaction between the cation R_4N^+ and nitrobenzene molecules. On the other hand, the selective solvation of the chelate cations by nitrobenzene molecules is due to the active NH groups in the coordinated diamine.

In $PhNO_2$–CCl_4 mixtures, the ratios of K_a for $[Co(acac)_2(en)]Br$ to that for $[Co(acac)_2(N,N'\text{-dmen})]Br$ (Table 3) are almost equal and the plots of $\log K_a$ *vs.* $1/\varepsilon$ for these two salts are linear (Fig. 1), suggesting the similar effective size (5.9 Å, ionic distance parameter from the Fuoss equation).[13] In the chloroalkane solvents, the correlation of plots for $[Co(acac)_2(en)]ClO_4$ and $[Co(acac)_2(N,N'\text{-dmen})]ClO_4$ is not good (Fig. 2). However, the ratios of K_a for the en complex to the *N*,*N*′-dmen complex in each solvent are increased with the increase in K_a (Table 4). The K_a values for each salt in 1,1,2,2-TCE are smaller than those in DCM although the bulk dielectric constants of both solvents are nearly equal, suggesting that the effective dielectric constant of 1,1,2,2-TCE is larger than that of DCM. This is due to that the effective dielectric constant of 1,2-DCE[14] and 1,1,2,2-TCE in the vicinity of an ion is appreciably greater than the macroscopic dielectric constant due to the conversion of gauche to trans molecules. The ionic distance parameters obtained tentatively from the slopes between 1,2-DCE and $CHCl_3$ are 6.1 Å for $[Co(acac)_2(en)]ClO_4$ and 6.5 Å for $[Co(acac)_2(N,N'\text{-dmen})]ClO_4$. This result indicates that the effective size of $[Co(acac)_2(N,N'\text{-dmen})]^+$ is larger than that of $[Co(acac)_2(en)]^+$ by the volume of two methyl groups in the chloroalkane solvents whcih

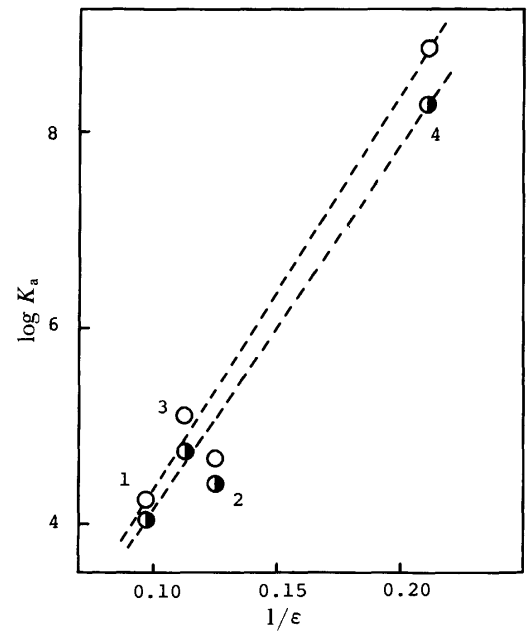

Fig. 2. Dependence of ionic association constant on dielectric constant in chloroalkane solvents at 25 °C.
○, $[Co(acac)_2(en)]ClO_4$; ◑, $[Co(acac)_2(N,N'\text{-dmen})]ClO_4$.
1, 1,2-DCE; 2, 1,1,2,2-TCE; 3, DCM; 4, $CHCl_3$.

have lower solvation ability.

In conclusion, the increasing acidity of the residual NH protons due to *N*-methylation in $PhNO_2$–CCl_4 mixtures is attributed to the appearance of the naked nitrogen protons by the steric hindrance rather than to the reduction in electron density of the protons. Thus, this leads to the results that the K_a values for $[Co(acac)_2(N,N'\text{-dmen})]X$ are larger than those for $[Co(acac)_2(en)]X$ in solvents with stronger solvation ability for the NH protons, in spite of the larger size and the decrease in the number of the protons for the former salt.

Studies of the Hydrous Tin(IV) Oxide Ion Exchanger. IV. The Effect of Heat Treatment

Yasushi INOUE,* Hiromichi YAMAZAKI, and Hiroshi NAKAMIZO
Department of Nuclear Engineering, Faculty of Engineering, Tohoku University, Aramaki, Sendai 980
(Received November 1, 1984)

The effects of heat treatments in air or water at high pressure have been studied regarding the properties of a hydrous tin(IV) oxide ion exchanger. The exchanger in a H^+ form was stable against heat treatments in both air and water up to around 80 °C; thereafter the exchange capacity progressively decreased with temperature until 300 °C, at which point it was reduced to about a quarter of the initial value. The exchanger began to crystallize at 300 °C, and formed nearly-complete cassiterite crystals at 500 °C,(where the capacity disappeared). In contrast, the exchanger in a Na^+ form was more stable against heat treatment than the H^+ form; at 400 °C, the Na^+ form retained 40 per cent of the initial exchange capacity. An examination of the uptake curves showed that more acidic exchange sites were stronger than less acidic sites against heat treatment. The existence of three kinds of water in the exchanger (adherent, zeolitic, and bound) has been suggested on the basis of the ion-exchange capacity, the thermal-analysis curves, and the recovery of water brought about by humidifying.

In a previous paper, the acid-base property, the ion-exchange selectivity for various cations and other important properties were studied on an hydrous tin(IV) oxide ion exchanger prepared by a method previously proposed by the present authors.[1] The study on the effect of heating regarding ion-exchange properties is also important since most inorganic ion exchangers are expected to be superior to ion-exchange resins regarding thermal stability. As hydrous tin(IV) oxide has an amorphous structure, this investigation may be helpful in considering the structure of this exchanger by adding some strong circumstantial evidence. As to the effect of thermal treatment, there have been many studies regarding the composition and the physical properties,[2-7] while there have been few reports on the ion-exchange properties.

The present paper describes the effect of heat treatment in both air and water with regards to the composition and ion-exchange properties of hydrous tin(IV) oxide. Furthermore, a classification of various water forms present in the exchanger is discussed.

Experimental

Reagents and Apparatus. The hydrous tin(IV) oxide ion exchanger was prepared by a method described previously[1] and then converted into a H^+ or Na^+ form. The other chemicals were of the highest purity (Wako Pure Chemical Industries, Ltd.).

A thermal analysis was undertaken using a Shimadzu micro thermal analyzer, Model DT-20B, connected to a thermal balance, Model TGC-20H, for thermogravimetric analysis (TGA), and a high-temperature sample holder, Model MDH-20, for differential thermal analysis (DTA). The reference material for DTA was α-alumina. The measurement was performed in air at a heating rate of 10 °C/min.

X-Ray diffraction patterns were obtained by means of a Shimadzu X-ray diffraction unit, Model XD-3A, using Ni-filtered Cu $K\alpha$-radiation. The diffraction angle was calibrated using silicon powder.

The infrared (IR) absorption spectra were measured with a Nihon Bunko infrared spectrometer, Model IR-G, using the KBr disk method. The wave number was calibrated using polystyrene.

Heat Treatment. About 7 g of the exchanger in a desired ionic form was heated in air to a constant weight at a constant temperature (controlled with an accuracy of 1% by using an automatic temperature controller; Chino Workers, Ltd.). After cooling, a sample in the Na^+ form was converted into the H^+ form by conditioning with a 0.1-mol dm^{-3} HCl solution; that in the H^+ form was immersed in water. Thereafter, they were both subjected to the humidifying operation described previously.[1]

The hydrothermal treatment was carried out in a Sakashita autoclave, Model SR-100 (inner volume, 1 dm^3), by controlling the temperature whthin an accuracy of 5 °C. In this autoclave, 5 g of the exchanger in the H^+ form was immersed in 400 cm^3 of distilled water; this was treated at temperatures from 100 to 250 °C for 6 h under a pressure of 100 atm, which was regulated by pressurized N_2 gas. After cooling, a portion of the sample was conditioned with 0.1 mol dm^{-3} HCl. The rest was washed with only water. Thereafter, they were both subjected to the humidifying operation.

The other experimental procedures were the same as those described previously.[1]

Results and Discussion

Thermal Stability of the Exchanger in the H^+ Form. The results for the H^+ form exchanger are shown in Table 1. It should be noted that values at the left of the two columns (showing the exchange capacity) were those normalized to the capacity per 1 mole of tin. The right-hand values (marked C) show the amount of water per 1 mole of tin that is liberated by the condensation of the hydroxyl groups (which may act as ion-exchange sites). In the case of the exchanger without heat treatment (designated as sample R. T.), the dissolution of a part of the exchanger in strong basic solutions limits the maximum cation-exchange capacity to the value at pH 11.3.

The maximum cation-exchange capacity did not change up to 80 °C, and then it decreased with temperature; at 500 °C it was reduced to a tenth of the value of the sample R. T. The amount of water contained in the exchanger immediately after the heat treatment (marked A) at 80 °C was reduced to 37% of the original value; then, it gradually decreased with

temperature, and finally reached zero at 500°C. The ratio of the water originated from the exchange sites (OH groups) to the total water remaining in the exchanger immediately after the heat treatment, C/A, did not change up to 400°C, while at 500°C it suddenly increased to around unity. Hence it is considered that the water molecules remaining in the exchanger immediately after the heat treatment were liberated cooperatively with the condensation of the OH groups, so that the water molecules might be fixed in the exchanger by OH groups through some kind of interaction such as a hydrogen bond (bound water). This bound water was completely liberated at 500°C.

Next, let us consider the relation between the water content immediately after the heat treatment (marked A) and that of the exchanger subjected to the humidifying operation (marked B). For the exchangers heated up to 300°C, the amount of water recovered by humidifying was nearly constant, while for samples heated over 400°C it decreased suddenly; the exchanger heated at 500°C recovered water only slightly. Figure 1 shows the X-ray diffraction patterns of the samples subjected to the humidifying operation. The samples heated up to 300°C, together with the sample R. T., show three weak broad peaks (d=0.335, 0.264, 0.176 nm) and, hence, have poor crystallinity. The peaks sharpened with increasing temperature, indicating an enhanced crystallization. When a sample was heated at 500°C, it reflected most of the peaks characteristic of cassiterite. At 850°C, the exchanger completely crystallized as cassiterite. Therefore, the sudden decrease of water recovery at a temperature above 400°C may be associated with the crystallization of the exchanger. This brings about a decrease in the space which can hold water molecules.

In order to examine the effect of a heat treatment on the acid-base property of the exchanger, the uptake curves for Na^+ and Cl^- were measured as a function of pH. Figure 2 shows the change in the cation-exchange behavior. For the sample heated at 80°C, the exchange

capacity in a pH range higher than the breaking point in the curve decreased slightly, while in a pH range lower than that point, the curve was the same as that of the sample R. T. When the exchangers were heat-treated at 150 °C or higher, the capacity decreased in the whole pH range with the temperature; the main part of the exchange capacity remaining after the heat treatment as 300 °C was in a pH region lower than the breaking point. The exchange sites were almost completely destroyed at 500 °C. The uptake curves for Cl^- are shown in Fig. 3, which reveals that the highest pH of anion uptake was lowered with the increase in temperature. This means that basic exchange sites are liable to be destroyed. From the above observations it is considered that the resistance to thermal decomposition is greater for more acidic rather than for less acidic ion-exchange sites.

Figure 4 shows the TGA and the DTA curves for the exchangers in the H^+ form. The TGA curve of the sample heat-treated at 80 °C was similar to that of the sample R. T. except the amount of the water released below 150 °C; the sample lost weight suddenly up to around 150 °C and then, gradually, up to about 650 °C, where the weight became constant. In contrast, the weight of the sample heat-treated at 300 °C decreased sharply below 80 °C, then became constant between 150 and 300 °C, and gradually decreased again up to 650 °C. In the DTA curves, large endothermic peaks appearing in the range lower than 200 °C sharpened as the temperature for heat treatment became higher. The position of the peak, observed at 70 °C for the samples heated below 200 °C, shifted to 40 °C and its area became very small when the sample was heated at 500 °C. Apparently, this observation is compatible with the change in the exchange capacity and in the degree of the recovery of water with the temperature for heat treatment, if the peak is considered to correspond mainly to the release of water recoverable by humidifying, that is, a certain kind of zeolitic water. The shoulders observed at the high- and low-temperature sides, respectively, of the peak for the samples heat-treated at temperatures below 200 °C are attributable to the bound water liberated by the condensation of the hydroxyl groups and to the adherent water in the exchanger matrix. Mikhail *et al.* observed a small broad exothermic peak at 470 °C,[2] and Durand and Masdupuy observed a large sharp exothermic peak at 300 °C and three small ones at 400, 500, and 620 °C.[8] The DTA curves were measured at varying heating rates, but these high-temperature peaks were not observed in the present experiment.

Figure 5 shows the IR spectra of the exchangers in the H^+ form heat-treated at different temperatures. The asymmetric absorption band near 3400 cm^{-1} is attributable to the sum of the contribution from water and hydroxyl-group bonding to tin; the former at the lower, and the latter at the higher, wave-number sides. The absorption band near 1630 cm^{-1} is due

to the bending mode of water and the absorption in the $<900\,cm^{-1}$ range, to Sn–O band.[9,10] The comparison of the spectra for the exchangers heat-treated at different temperatures shows that the water and hydroxyl bands were weaken with increasing temperature, while the Sn–O band was intensified. Accordingly, it is considered that the exchanger dried at room temperature contains a Sn–O band, a OH group, and water. Thus the formula of the exchanger may be written as $SnO_{2-x}(OH)_{2x}\cdot nH_2O$ in analogy with the formula proposed by Vivien *et al.*[9]

The observations described above can be summarized as follows. When the exchanger in the H^+ form is heated to 80°C, the release of adherent water is accompanied by the stabilization of a network structure. By the heat treatment at temperatures between 150 and 300°C the irreversible release of the bound water proceeds gradually and, thereby, the exchange capacity decreases with the increasing temperature of the treatment. However, the network structure remains essentially unchanged and the stabilized matrix can accommodate an approximately constant amount of a zeolitic water when humidified. The further release of the bound water at temperatures higher than 300°C leads to the partial crystallization of the exchanger. At 500°C the crystallization proceeds to an extreme and the structure changes completely. Therefore, almost all the water is not recovered by the humidifying operation.

Thermal Stability of the Exchanger in the Na^+ Form in Air. The effect of the heat treatment on the Na^+ form is shown in Table 2. The water content of the exchangers immediately after heat treatment (composition A) appears to be nearly the same as that of the exchangers heat-treated in the H^+ form as shown in Table 1. To make the comparison valid, however, the values for the Na^+ form should be corrected by adding 0.115±0.002 mol H_2O/mol Sn, which corresponds to the amount of the hydroxyl groups fixed by sodium ions. Thus, the water content of the exchanger heat-treated is larger in the Na^+ form than in the H^+ form, and it is considered that Na^+ in the exchanger hinders the release of water by heat treatment. Next, let us consider the composition of the samples converted to the H^+ form after being heat-treated in the Na^+ form (composition B). The composition of the exchanger without heat treatment became that of the original exchanger in the H^+ form. This observa-

tion is compatible with the reversibility of the exchange reaction between Na^+ and H^+, as reported previously.[1] The decrease of the water content with increasing temperature for heat treatment showed a tendency similar to the exchanger heat-treated in the H^+ form except for the exchanger heat-treated at 400 °C, which recovered nearly the same amount of water as the exchanger heat-treated at 300°C.

On the other hand, the decrease of the exchange capacity was less for the Na^+- than for the H^+ form; even at 400°C, the former still had exchange capacity five times as large as the latter. This tendency can be seen from Fig. 6, which shows the acid-base property of the exchangers heat-treated in the Na^+ form; the exchange groups in the Na^+ form appears resistant to the heat treatment especially at such high temperature as 400°C.

Figure 7 shows the DTA and the TGA curves of the exchanger heat-treated in the Na^+ form. These curves show general features similar to those for the exchangers heat-treated in the H^+ form. The amount of water released up to 150°C, however, was less for the Na^+- than for the H^+ form, which is a natural result of the difference of water content of the exchangers between the H^+ and Na^+ form. Furthermore, the curves for the samples heat-treated at 300 and 400°C do not differ from each other. It was consequently concluded that the sodium ion in the exchanger retards the release of water at temperatures beyond 300°C.

Figure 8 shows the X-ray diffraction patterns of the

samples heat-treated as the Na^+ form. It is apperent from a comparison with the H^+ form that the exchangers in the Na^+ form do not crystallize as disodium tin(IV) trioxide but as cassiterite. In addition, the broadness of the peaks indicates that the rate of the crystallization is slower for the Na^+- than for the H^+ form.

The observations described above can be summarized as follows. Although the substitution of the hydrogen ions by sodium ions is considered to stabilize the exchanger against the condensation of hydroxyl groups by a heat treatment, the matrix of the exchanger changes into a thermally stable phase by the irreversible release of water, ultimately to crystallize into cassiterite. Accordingly, the water content and the ion-exchange capacity of the exchanger decrease with the heat treatment temperature. However, the sodium ions in the exchange sites retard the change and stabilize the exchanger considerably. The difference in the thermal stability of the exchangers between the H^+- and the Na^+ form became prominent in a temperature range higher than 300 °C.

Thermal Stability in Water. The effect of a hydrothermal treatment on the properties of the exchanger in the H^+ form was studied under a pressure of 100 atm as is shown in Table 3 and Fig. 9. The symbols

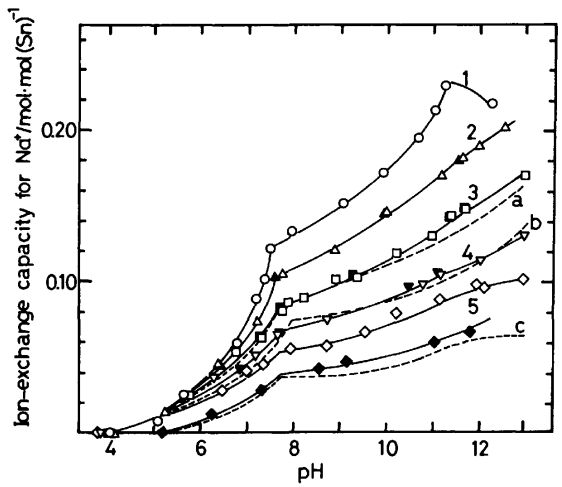

Fig. 9. Uptake curves for Na^+ (Hydrothermal treatment in H^+ form).

A and B, respectively, in Table 3 indicate the exchangers subjected to only the humidifying operation and to both the conditioning and humidifying operations. Obviously, the change in the uptake curves for sodium ions with temperature followed a tendency similar to that of the exchanger heat-treated in air. The degree of crystallization (examined by the X-ray analysis) also shows a similarity to the exchanger heated in air. On the other hand, decreases of water content with thermal treatment were less in water than in air.

Figure 10 shows the TGA and the DTA curves of the exchangers treated hydrothermally. These curves indicate the similar behavior of dehydration to the sample heat-treated in air. The amount of water released (up to 100 °C) was, however, larger with a hydrothermal treatment than with a heat treatment in air. For the exchanger heat-treated in air, most of the adherent water and the zeolitic water were lost below 100 °C and the release of the bound water occurred mainly at temperatures higher than 80 °C. Accordingly, the amount of the adherent and the zeolitic water was not reduced by the hydrothermal treatment in spite of the irreversible release of the bound water.

The conditioning did not affect the composition and the exchange capacity except for the sample heat treated at 250 °C; the conditioning increased the water content and the exchange capacity by an amount 0.2 mol H_2O/mol Sn and 0.03 mol Na^+/mol Sn, respectively. The reason for this observation is not clear, but may be due to a slight increase in the recovery of bound water, which can be seen from the increase in the area of endothermic peak higher than 72 °C.

The observations described above can be summarized as follows. When the exchanger in a hydrogen form is heat treated in water at 100 atm, the matrix crystallizes to cassiterite along with the loss of the bound water which cannot be recovered only by the humidifying operation, and the exchange capacity decreases by an amount about the same as in the case of heat treatment in air. The amount of the adherent and the zeolitic water is maintained at the original value. Thus, the loss of water is smaller in this case than in the case of heat treatment in air.

The authors wish to express their thanks to Professor Wataru Suëtaka and to Yoshio Matsumoto, Depart-

Immunoassay Using a Metal-complex Compound as a Chemiluminescent Catalyst. V. Continuous Immunoassay by the Use of CLCCIA

Tadashi HARA,* Motohiro TORIYAMA, and Masakatsu IMAKI†
Department of Chemical Engineering, Faculty of Engineering, Doshisha University, Karasuma Imadegawa, Kamigyo-ku, Kyoto 602
†*Horiba Ltd., Kisshoin, Minami-ku, Kyoto 601*
(Received November 13, 1984)

Immunoassay, using as a labeling reagent a synthesized metal-complex compound having catalytic activity for a chemiluminescence reaction, was continuously carried out by the sandwich method. The time necessary for all the processes (including: an immune reaction, B/F separation, a sandwich reaction, and a chemiluminescence reaction) was reduced to 50 min. Human serum albumin in the range of 5 ng to 1 μg could be determined (continuously) up to 5 times by the use of the same column (immobilized with an antibody).

In order to determine a trace amount of the component in a biological sample, immunoassay is an important method. So far, enzyme immunoassay and radioimmunoassay have been used for practical purposes. Unfortunately, they have necessitated a tedious batchwise operation. Accordingly, studies regarding automatic and continuous immunoassay have been made for nonlabeled immunoassay such as laser nephelometry and latex-photometric immunoassay. However, few such attempts have been made for a labeled immunoassay, which is theoretically suitable for a very sensitive assay. This is attributed to the instability of labeling reagents such as enzymes and radioactive materials.

Chemiluminescence complex catalyst immunoassay (CLCCIA),[1-4] in which a synthesized metal-complex compound acting as a catalyst for a chemiluminescence reaction between 5-amino-2,3-dihydro-1,4-phthalazinedione (luminol) and hydrogen peroxide (H_2O_2) was used as a labeling reagent, was reported by the authors for the determination of human serum albumin (HSA) as a model compound for the protein. In a previous paper,[3] the immune complex after the immune reaction could be dissociated in a liberating solution(pH 11.4) without losing its catalytic activity for the chemiluminescence reaction since the synthesized metal-complex as a labeling reagent in CLCCIA was stable. Then, the measurement of the catalytic activity of the dissociated labeling reagent resulted in a rapid and accurate immunoassay. However, the method was far from the immunoassay in which all the processes (including: an immune reaction, B/F separation, a chemiluminescence reaction, and the cyclic use of the immobilized antibody) could be continuously carried out.

The present study deals with a method and a support suitable for the immobilization of an antibody and with an immune reaction in order to establish continuous CLCCIA in which all the immunoassay processes (including: an immune reaction, B/F separation, a sandwich reaction, a chemiluminescence reaction, and the cyclic use of the immobilized antibody) are continuously carried out.

Experimental

Preparation of a Labeled Antibody. [1,8,15,22-tetrakis-(chloroformyl)phthalocyaninato]iron(III) ([Fe(tccp)]) as a labeling reagent was synthesized as described in a previous paper.[2] 500-mm³ of a phosphate buffer solution was added to 2 cm³ of an immunoglobulin G(IgG) fraction of anti-human serum albumin(TAGO) so as to maintain the mixed solution at pH 7.2. Five mg of [Fe(tccp)] was dissolved in the above mixed solution, and the resulting solution was then reacted for 1 h at room temperature. Then, the mixed solution was incubated for 18 h at 4 °C. After the reaction, 2.5 cm³ of a potassium dihydrogenphosphate–disodium hydrogenphosphate buffer solution (0.01 mol/dm³, pH 7.2) (Buffer A) was added to the mixture. The mixture was centrifuged at 6000 min^{-1}, and the supernatant liquid was separated from the precipitate. The precipitate was treated with 2.5 cm³ of Buffer A and the supernatant liquid was again obtained by centrifuge. To the combined supernatant liquid, 5 cm³ of saturated ammonium sulfate solution was added and it was left standing at 4 °C overnight. The precipitate was separated by centrifuging and then dissolved in 2 cm³ of Buffer A. After the obtained solution was dialysed against Buffer A, the contents were separated on a column (160 cm³) charged with TOYOPEARL HW-50, and a 20-cm³ fraction corresponding to IgG was collected.

Preparation of Glass Beads Immobilized with Antibody. Five g of porous glass beads (CPG-3000, 120/200 mesh, 31250 nm mean pore diameter, ELECTRO-NUCLEONICS, INC.) were heated at 100 °C for 1 h on a water bath in 75 cm³ of a 1 mol/dm³ hydrochloric acid solution and a nitric acid solution. The beads were filtered, washed with water, and dried at 60 °C in an oven. The purified porous glass beads were suspended in 200 cm³ of 1% [3-(glycidyloxy)propyl]trimethoxysilane solution. The slurry was degassed under vacuum in an ultrasonic bath and then was heated at 90 °C for 2 h with stirring. The pH of the mixture was adjusted to 3 with a 1 mol/dm³ hydrochloric acid solution, and the mixture was heated again at 90 °C for 1 h. The diol-bonded porous glass beads, thus obtained, were washed with water and dried. Two g of the porous glass beads were placed in 20 cm³ of 6 mmol/dm³ of sodium periodate solution. A vacuum was applied for about 2 min to degas the slurry. The slurry was stirred for 1 h at room temperature, and then was washed with 100 cm³ of Buffer A. A 500-mm³ of phosphate buffer solution was added to 2 cm³ of IgG fraction of anti-human serum

albumin(TAGO) to adjust the pH at 8.8. The aldehyde-type porous glass beads recovered from the above slurry were added to the mixed antibody solution and were reacted with the antibody for 50 h at 4 °C. After the reaction, the porous glass beads were washed with Buffer A, and were suspended in 200 cm^3 of Buffer A. Each 100-mm^3 of 40 mg/cm^3 sodium borohydride solution was added four times to the suspended solution every 30 min, and then the mixed solution was reacted for 2 h. The porous glass beads immobilized with the antibody were washed and stored in Buffer A at 4 °C.

Apparatus and Procedure. A schematic flow diagram of the apparatus used for the continuous CLCCIA is shown in Fig. 1. Its operating procedure is shown in Scheme 1.

Each bottle in Fig. 1 was filled with (a) a 1.0×10^{-3} mol/dm^3 luminol solution (pH 10.4, 0.4 mol/dm^3 boric acid-0.4 mol/dm^3 potassium hydroxide buffer solution), (b) a tartrate buffer solution (pH 3.1, 4.45×10^{-3} mol/dm^3 tartaric acid- 1.11×10^{-3} mol/dm^3 sodium tartrate buffer solution) as a liberating solution, (c) Buffer A, and (d) a 7.5×10^{-3} mol/dm^3 H_2O_2 solution. Each solution, except Buffer A(c), was fed at a flow rate of 1.65 cm^3/min by the pump (e_1, e_2, e_4) (Atto,

SJ1211). Buffer A in Fig. 1(c) was fed at a flow rate of 1.65 cm^3/min or 0.24 cm^3/min by the pump(e_3)(Atto, SJ1211). The porous glass beads immobllized with antibody were charged into a 88 mm^3 column(k).

The capacity of the sampling loop(h) was 200 mm^3, and each definite volume of HSA solution as an analyte model was injected into a flow line by the use of a sample injection six-way cock(i). Injected sample(antigen) was introduced into the column(k) at a flow rate of 0.24 cm^3/min and was made to react with the immobilized antibody. After the immune reaction, the six-way cock(i) was operated and B/F separation was accomplished by washing the column with Buffer A for 10 min at a flow rate of 1.65 cm^3/min. Then, 200 mm^3 of labeled antibody fraction(which was 50 times diluted with Buffer A) was taken in a sampling loop(f) and was injected at a flow rate of 0.24 cm^3/min by operating a six-way cock(g) into a flow line. The injected labeled antibody was subjected to a sandwich-type reaction in the column. After the reaction, a labeled antibody which was adsorbed unspecifically was eliminated by washing the column with Buffer A for 5 min at the flow rate of 1.65 cm^3/min by operating again the six-way cock(g). By operating the six-way cock(j), a tartrate buffer solution was fed into the column and the immune complex was liberated from the column. The liberated labeled antibody was mixed with H_2O_2 and luminol, and the chemiluminescence intensity of the mixture was measured by a system consisting of a flow-cell, a photomultiplier, and a photon counter as described in a previous paper.[2]

Results and Discussion

Preparation of Labeled Antibody. In order to label efficiently [Fe(tccp)] to antibody, the conditions of labeling reaction were investigated.

Labeling reactions were produced at various pH of buffer solutions, and the labeled HSAs were obtained by the procedure discussed in the experimental section. By assuming that the molar absorptivity of HSA at 280 nm and of [Fe(tccp)] at 639 nm does not change upon labeling, the approximate mole ratio of [Fe(tccp)] to HSA was obtained by the use of the calibration curves for [Fe(tccp)] and HSA. Here, the mole ratio is referred to as a labeling ratio, and HSA is used as a antibody model only in this part of the present study (to make the experiment easier). The relationship between the pH of a solution in the labeling reaction and a labeling ratio of HSA was studied. The results are shown in Fig. 2.

As can be seen from Fig. 2, the reaction between an acyl chloride group of [Fe(tccp)] and an amine group of HSA proceeded efficiently in a reacting solution at pH 7 to 8. Therefore, the labeling of the antibody was carried out in Buffer A (pH 7.2).

Preparation of Immobilized Antibody. The three methods (glutaraldehyde method, cyanogen bromide method, and periodate method) as an immobilization procedure of antibody were compared with each other.

The glutaraldehyde method by which an immobilization reaction can be easily produced, has been applied to the immobilization of many kinds of enzymes[5] and antibodies.[6] In the previous CLCCIA an

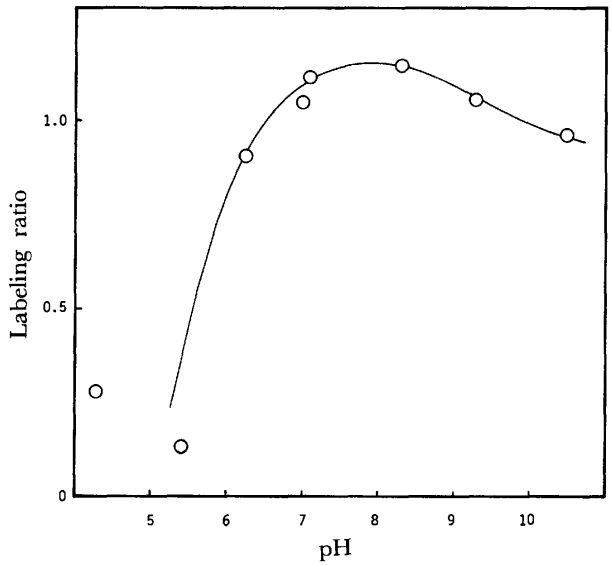

Fig. 2. Relationship between pH of solution in labeling reaction and labeling ratio of HSA.

antibody was immobilized on a glass bead of 4-mm diam. by the glutaraldehyde method. The antibody was combined with the support through an imine-type bond by the use of glutaraldehyde. As this imine-type bond is relatively weak, it dissociates easily in an acidic solution. Therefore, the immobilized antibody glass bead could not be used again after the dissociation of the immune complex on the glass bead with an acidic liberating solution.

There have been many reports in which various kinds of enzymes and proteins were immobilized on activated cellulose with cyanogen bromide. The authors were also able to immobilize albumin and galactose oxidase with good results[7] by the cyanogen bromide method. Immobilization of an antibody onto cellulose beads (Cellulofine, GC-700m, Chisso) by the cyanogen bromide method was further attempted, but the immobilized antibody, thus obtained, did not react with an antigen. This seemed to be due to the fact that the distance between the support and the antibody was too short to allow the antibody to react with the antigen.

Finally, the immobilization of an antibody on glass beads (CPG-3000) was attempted by the periodate method.[8] Glycosil bonded glass beads were converted to their aldehydic form by oxidation with sodium periodate. This formyl group and an amino group of antibodies were made to react. An imine-type bond was formed. The imine-type bond was reduced to amine-type bond with sodium borohydride, and the bond between the antibody and the support was strengthened. The immobilized antibodies, thus obtained by the periodate method, could not only be used repeatedly for an immune reaction, but also they showed little unspecific adsorption of other proteins.[9] In the present study, the periodate method was chosen as the immobilization method of the antibody.

An attempt was made to reduce an antibody im-

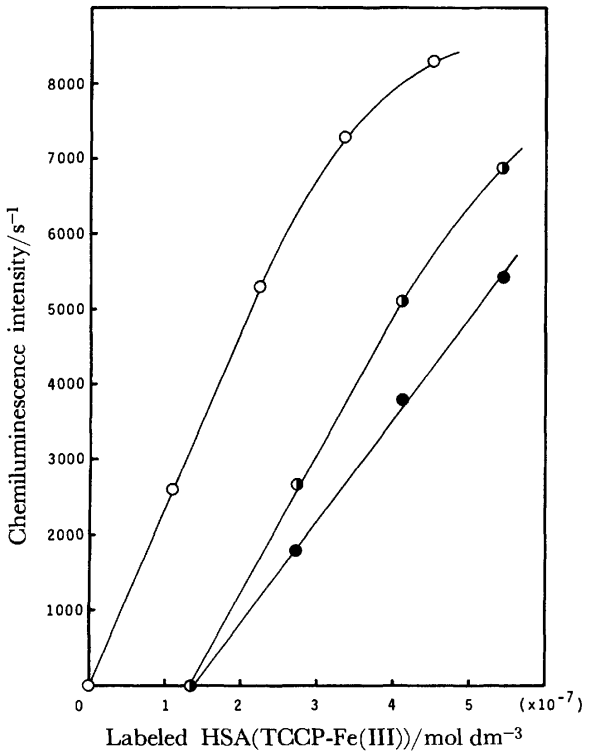

Fig. 3. Effect of volume of immobilized antibody in column.
○: 88 mm^3, ◑: 177 mm^3, and ●: 357 mm^3.

mobilized by the glutaraldehyde method with sodium borohydride, but the immobilized antibody did not show an effective immune reaction.

Immunoassay. There are competitive and sandwich methods as labeled immunoassay. A competitive immunoassay technique was used in a previous CLCCIA because the operation of the immunoassay was simple. However, the conditions of an immune reaction (the mixing ratio of a sample antigen to a labeled antigen, the desired amount of immobilized antibody, *etc.*) must be closely controlled. The control of these conditions of immune reaction is easy in the case of batchwise immunoassay, but it is difficult for continuous immunoassay in which an immobilized antibody is repeatedly used because the activity of an immobilized antibody for an immune reaction may be changed. Therefore, use was made, for immunoassay in this investigation, of the sandwich method which could be expected to be highly sensitive, though it was accompanied with a number of steps.

In order to determine the optimum volume of an immobilized antibody column, the following experiment was carried out. An immune reaction was carried out by passing labeled HSA with [Fe(tccp)] as a sample through the immobilized antibody column (Fig. 1 (k)). Here, three kinds of immobilized antibody columns were used. The catalytic activity of the labeled HSA in a liberating solution was measured for the chemiluminescence reaction between luminol and H_2O_2. The results are shown in Fig. 3. The chemiluminescence intensity increased with a decrease in the volume of the immobilized antibody column, that is, the labeled HSA liberated from the immobilized antibody column increased. Much labeled HSA was found to be unspecifically adsorbed with an increase of the column volume. On the basis of this experimental result, the volume of the immobilized antibody column was determined to be 88 mm^3.

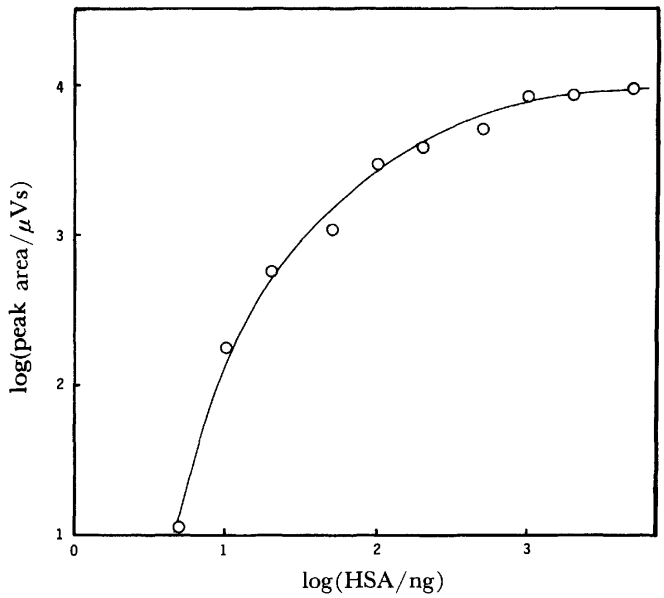

Fig. 4. Standard curve of HSA.

The relationship between the immune reaction time in the immobilized antibody column and a peak area of chemiluminescence was examined. The experiment was made as follows: 1) labeled HSA was used as a sample, 2) the flow rate of Buffer A, which was used to feed labeled HSA into the column was changed so as to give various immune reaction times. The immune reaction time was defined as the residence time of a sample in the column. The peak area of chemiluminescence increased with an increasing immune reaction time. The capacity of pump (e_3) allowed the flow rate of the sample solution to be brought to 0.24 cm^3/min, and the immune reaction time became 11 s.

To determine the washing time necessary for the removal of an excess labeled antibody from the immobilized antibody column, the relationship between washing time and intensity of chemiluminescence blank was examined. The intensity of the chemiluminescence blank was found to be almost constant at a washing time of more than 4 min. Hereafter, the immobilized antibody column was washed with Buffer A for 5 min after the sandwich reaction.

In accordance with the procedure shown in Scheme 1, a standard curve of HSA was obtained (Fig. 4). A peak area of a sample was presented by subtracting the blank peak area of unspecifically adsorbed labeled antibody from the peak area of experimental data. According to the present method, HSA in the range from 5 ng to 1 μg could be determined. The detection limit became a

much smaller value than that in the previous competitive CLCCIA (20 ng). Further, the time necessary for all the immunoassay processes (including: an immune reaction, B/F separation, a sandwich reaction, and a chemiluminescence reaction) could be reduced to 50 min from 10 h or more in the previous CLCCIA. The immunoassay of 20 ng HSA as a sample was by the use of the same immobilized antibody column. The coefficient of variation was 17% for 5 replicate analyses while 40% for 10 replicate analyses. Since the coefficient of variation up to about 20% for the immunoassay of the present level had been generally allowed, it was concluded that a continuous CLCCIA of up to 5 times could be carried out by the use of the same immobilized antibody column. In order to make continuous CLCCIA a practical automatic method of immunoassay, the immobilized antibody has to be further improved so as to increase the number of continuous analyses.

†*Department of Chemistry, College of Arts and Sciences, The University of Tokyo, Komaba, Meguro-ku, Tokyo 153*

(Received November 15, 1984)

The crystal and molecular structure of the title metal complex was determined by the X-ray diffraction method. The crystal is triclinic, with the space group $P\bar{1}$, $Z=1$, $a=11.934(2)$, $b=14.642(9)$, $c=11.801(6)$Å, $\alpha=90.41(5)$, $\beta=94.04(2)$, and $\gamma=83.82(2)°$. The final R value for 6928 reflections is 0.065. The cobalt(II) atom is in a tetrahedral geometry, ligated by four nitrogen atoms of the thiocyanato (SCN) ligands, while the mercury(II) atom is in a trigonal-bipyramidal geometry, where two phosphorus atoms of both the triphenylphosphine ligands bond axially and three sulfur atoms of SCN's equatorially; however, these Hg-S bonds are very long. Thus, the pairs of cobalt(II) and mercury(II) atoms are linked by one SCN bridge, forming a sixteen-membered ring of $Co_2Hg_2(SCN)_4$, and this ring is linked with the next ones on both sides in the a-axis direction with two longer bondings.

Tetrakisthiocyanatocobalt(II)mercury(II), $CoHg(SCN)_4$ (**1**), is known as a "diamond-like" three-dimensional polymeric type of complex where each metal atom is linked with four metal atoms of another kind by thiocyanate (SCN) bridges. Its structure was clarified by Jeffery,[1] and its characteristic structure was discussed by Wells.[2a] Some of its Lewis-base adducts were also synthesized,[3,4] and the structures of the pyridine (py) adduct, $CoHg(SCN)_4(py)_2$,[5] and of *N,N*-dimethylformamide (dmf), $CoHg(SCN)_4(dmf)_2$,[6] were also elucidated. In both of the adducts, the cobalt(II) atom is in the octahedral geometry, and the mercury(II) atom, in the tetrahedral configuration, although the three-dimensional network by the SCN bridges was retained. Because of the octahedral geometry of cobalt(II) in the adducts, they are reddish in color. On the other hand, Makhija has also obtained the title complex, which is deep blue in color; this fact shows that it contains tetrahedral cobalt(II) atoms.[4] Mainly on the base of infrared absorption spectral considerations, Makhija proposed a monomer structure for it, where a cobalt atom and a mercury atom are bridged by two SCN ligands. According to his formula, the cobalt(II) atom is bonded with two phosphorus atoms of triphenylphosphine (Ph_3P) ligands as well as two nitrogen atoms of SCN ions while the mercury(II) atom is ligated by four sulfur atoms of SCN ions. This formula was not yet been proved by the single crystal X-ray diffraction method, and the former concept receives some support even now.[3,7,8] Although cobalt(II) complexes including phosphine derivatives have been reported elsewhere,[9-11] as the ligands are soft ones, they may prefer to bond with the mercury(II) atom, which is softer than cobalt(II).[12] The observed affinity of Ph_3P in the title complex seems to be higher than those of dmf or *N,N*-dimethylacetamide (dma). When the dmf or dma adduct $CoHg(SCN)_4L_2$ (where L=dmf or dma) in its solid phase was left standing in an acetonitrile solution of Ph_3P, they turned into the title Ph_3P adduct rapidly and the base was removed, on the other hand, when the title complex was stirred in an acetonitrile solution of dmf or dma, no substitution reaction occurred. Therefore, we were not able to believe the traditional formula; we have now determined its structure by the single-crystal X-ray diffraction method.

Experimental

Synthesis of Tetrakisthiocyanatobis(triphenylphosphine)-cobalt(II)mercury(II) (2). Although the title complex was synthesized by Makhija from the tetrahydrofuran (thf) adduct of **1**, $CoHg(SCN)_4(thf)_2$, which had itself been obtained from cobalt(II) and mercury(II) thiocyanates and thf, we could obtain the title complex **2**, easier by the following method.

The complex, **1**, obtained by Figgis' method,[13] was finely powdered (2.0 g, 4.1 mmol) and then poured into 20 cm^3 of an acetonitrile solution containing Ph_3P (2.4 g, 9.2 mmol), after which the mixture was stirred for 6 h at the ambient temperature. The addition reaction occurred rapidly, and the solid product thus obtained was filtered off, washed by acetonitrile, and dried on silica-gel in a vacuum desiccator. Yield, 3.5 g, (85%). By the gradual evaporation of the filtrate, some additional crop was obtained in larger-crystal grains, some of which were used for the X-ray diffraction measurement. Anal. of the main and the additional crops: ($Co_2Hg_2C_{80}H_{60}N_8P_4S_8$) Co, C, H, N. The infrared and visible absorption spectra of the product were similar to those reported by Makhija.[4]

Intensity-data Collection. A crystal with the dimensions of 0.3×0.3×0.4 mm^3 was used for the measurement without shaping. The crystallographic data are: $Co_2Hg_2C_{80}H_{60}N_8P_4S_8$, F.W.=2032.87, triclinic, space group $P\bar{1}$, $Z=1$, $a=11.934(2)$, $b=14.642(9)$, $c=11.801(6)$ Å, $\alpha=90.41(5)$, $\beta=94.04(2)$, $\gamma=83.82(2)°$, $V=2045(1)$ Å^3, $D_m=1.64(3)$, $D_x=1.65$ g cm^{-3}, $\mu(Mo\,K\alpha)=4.56$ mm^{-1}. The reflections within the range of $3°<2\theta<50°$ were collected on a Rigaku AFC-6A automated four-circle X-ray diffractometer with graphite monochromated Mo $K\alpha$ radiation, the θ—2θ scan technique being employed (scan speed, 4° min^{-1} in 2θ; scan width, $1.20+0.5\tan\theta$). The crystal was stable during the exposure to X-rays. Of the 7243 independent reflections thus obtained, 6928 with $|F_o|>3\sigma(|F_o|)$ were selected and used for the structure determination. The intensities were corrected for the Lorentz and polarization factors, but no correction was

made for absorption and extinction.

Structure Determination. The structure was solved by the heavy-atom method. The positions of the cobalt(II), mercury(II), and some sulfur and phosphorus atoms were deduced from a three-dimensional Patterson map, while the other non-hydrogen atoms were located by means of successive Fourier syntheses. Their positional, isotropic, and then anisotropic thermal parameters were refined by the block-diagonal least-squares method. The positions of all the non-hydrogen atoms were found. All the hydrogen atoms were fixed at calculated positions with B_{iso}=10.0 (the C–H length was assumed to be 1.08 Å). In the last cycle of the refinement, all the parameter-shifts of the non-hydrogen atoms were less than $\sigma/3$.

All the calculations were carried out on a HITAC M-200H computer at the Computer Center of The University of Tokyo, using the local version of the UNICS program system.[14] The atomic scattering factors were taken from the tables.[15]

Results and Discussion

The final atomic parameters of non-hydrogen atoms are listed in Table 1,[16] while the bond lengths and bond-angles are tabulated in Table 2.[16] The perspective drawings around the cobalt(II) and mercury(II) atoms, together with the numbering scheme, are shown in Figs. 1 and 2. The crystal packing diagram is shown in Fig. 3, while the schematic drawing to show the bondings in a unit cell is in Fig. 4.

The cobalt(II) atom is tetra-coordinated and is in a tetrahedral geometry, where four nitrogen atoms of four SCN ions are ligated. Although S(3) of the SCN does not bond with any metal atom, the other three SCN ligands bridge to three mercury(II) atoms, as is shown in Fig. 4. The average Co–N bond length is 1.954 Å, which is not much different from the sum of the respective atomic radii (Co=1.25, N=0.70 Å).[17] The average Co–N–C angle is 173.48°, and these atoms are almost collinear, although the deviation from 180° is a little larger than that of **1** (178.66°).[1]

The mercury(II) atom is bonded with two phosphorus atoms of the respective Ph_3P ligands in an approximately collinear geometry (P–Hg–P=166.63(10)°), and the average Hg–P bond length is 2.430 Å, which is about the same as the sum of the two atomic radii (Hg=1.50, P=1.10 Å).[17] Three sulfur atoms of the SCN ligands take their positions about perpendicular to the P–Hg–P axis, and the sulfur atoms as well as the central metal atom are almost on one plane: the average positional deviation of the atoms from the plane is 0.043 Å (maximum 0.085 Å for Hg). The S–Hg–P angles are between 81.4 to 100.2° (90.6° on the average). The S(1)–Hg–S(2^i) angle (101.0°) is a little smaller than the other two (133.6 and 125.0°). From these angular observations, the geometry around the mercury(II) atom is thought to be trigonal-bipyramidal; however, the bond lengths of Hg–S are long (Hg–S(1)=2.990(3), Hg–S(2^i)=2.745(4), and Hg–S(4^{ii})=3.323(4) Å), while the atomic radii of the two atoms are Hg=1.50 and S=1.04 Å.[17] In many mercury(II) compounds where the sulfur atom is ligated to the metal atom, the Hg–S bond length is found to be about 2.5 Å. Even in the related complexes, the normal values are shown to be writen

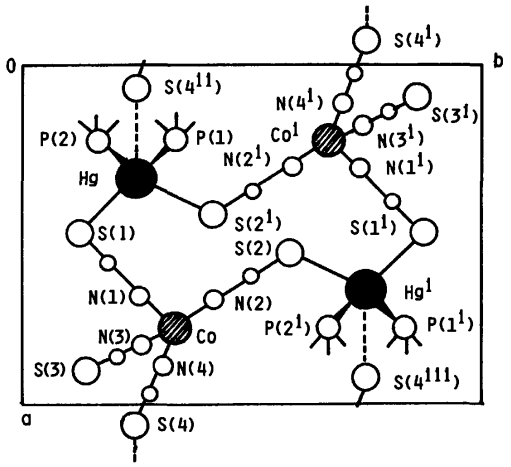

Fig. 4. Schematic presentation to show the bondings in a unit cell (Key to the symmetric operations; i, 1.0−x, 1.0−y, 1.0−z; ii, −1.0+x, y, z; iii, 2.0−x, 1.0−y, 1.0−z).

as follows: $CoHg(SCN)_4$, 2.558(4) Å;[1] $CoHg(SCN)_4(dmf)_2$, 2.539 Å on the average,[5] $CoHg(SCN)_4(py)_2$, 2.525 Å on the average;[6] and $Hg(SCN)_2(Ph_3P)$, 2.503 Å[18] and 2.528 Å[19] on the average.

Although there has been no report about such an elongated Hg-S bond as is found in this complex, it is a well-known fact that, in some multi-coordinated mercury(II) complexes, several groups of bond lengths are found;[2b] for example, in $HgSO_4 \cdot H_2O$, which is in about an octahedral geometry around the central metal atom, two Hg-O bond lengths of one axis are normal, while the other four equatorial Hg-O lengths are much longer.[20] As Ph_3P is a base which is softer than SCN,[12] it is not impossible that the Hg-P bonds take priority over the Hg-S bonds in the title complex; however, as the Hg-S bond has commonly been thought to be a typically strong bond, this kind of the long Hg-S bond has rarely been reported.

The trigonal-bipyramidal configuration of the ligating atoms around the central mercury(II) atom in its complexes has been reported in only a few cases, such as $(CH_3)_3SHgI_3$[23] and $Hg(SCN)_2(Ph_3P)$.[18,19] In these complexes, however, the axially ligating atoms take abnormally far positions: Hg-I=3.52 and 3.69 Å in the former, and Hg-N=2.74 and 2.89 Å in the latter complex. On the other hand, in the title complex, the equatorially bonded atoms are still farther apart; such a type of mercury(II) complex has not previously been reported.

The Hg-S-C angles in the title complex are 95.79 (S(1)), 108.65 ($S(2^i)$), and 111.14° ($S(4^{ii})$). In comparison with the other thiocyanato complexes of mercury(II), where the angles are about 95—98°, and where even the large one in $Hg(SCN)_2(Ph_3P)$ is only 104.5°,[18] these angles in the title complex, especially the latter two, are exceptionally large.

As Hg-$S(4^{ii})$ is longer than the other two Hg-S bonds, a sixteen-membered ring including two mercury(II) and two cobalt(II) atoms which are linked by four SCN^- ions, as is shown in Fig. 4, is considered to be the unit structure, which is linked to the next ones on both sides by means of two relatively long bondings (Hg-$S(4^{ii})$); they lie parallel to the a-axis as a ladder lying perpendicular to the bc-plane. No bridgings are found in either the b- or the c-axis direction between the rings. This type of structure is unique and has never been reported for the thiocyanate-bridged metal complexes.

As Porai-Koshits has already shown, the mixed complex $CoHg(SCN)_4(tu)_4$ (where tu=thiourea) consists of discrete $[Hg(tu)_4]^{2+}$ and $[Co(SCN)_4]^{2-}$ ions, and both of them are bonded only electrostatically; all thiocyanato sulfur atoms are far from the mercury(II) atoms.[24] Therefore, the title complex is thought to belong to an intermediate group between the three-dimensional polymeric-type complexes such as **1** and those consisting of discrete anionic and cationic complexes such as the thiourea adduct of **1**.

A New Calibration Method for the Measurement of CCl_4 Concentration at 10^{-10} v/v Level and the Behavior of CCl_4 in the Atmosphere

Akihito YOKOHATA, Yoshihiro MAKIDE,* and Takeshi TOMINAGA
Department of Chemistry, Faculty of Science, The University of Tokyo, Hongo, Bunkyo-ku, Tokyo 113
(Received November 27, 1984)

A new technique was developed for the accurate determination of atmospheric CCl_4 at about 100 pptv ($=10^{-10}$ v/v) concentration level, since at such extremely low concentration CCl_4 was found to be adsorbed readily and strongly on clean metal surfaces under dry conditions. The analysis of CCl_4 by gas chromatography/electron-capture detector and the preparation of CCl_4 primary calibration standard were improved by introducing water vapor into the system to prevent the adsorption of CCl_4 and to obtain stable and reproducible results. The total amount of CCl_4 in the atmosphere was studied on the basis of our newly calibrated data of CCl_4 concentration, and a reasonable lifetime of CCl_4 was obtained assuming that its sink is only the UV photodissociation in the stratosphere.

The release of chlorine atoms following UV photodissociation of man-made halocarbons (CCl_2F_2, CCl_3F, CCl_4, *etc.*) in the stratosphere is believed to change equilibria among chemical species in the stratosphere, which have been maintained for a long time.[1-9] In particular, the dissociation of ozone by Cl-induced chain reactions and the consequent change in the vertical profile of ozone in the stratosphere may end up affecting severely the earth's environment. Accumulated amounts of man-made CCl_2F_2 and CCl_3F in the atmosphere have been sharply increasing since 1950's due to their growing uses as aerosol propellants and refrigerants. Therefore, extensive efforts have been made to estimate the Cl-atom effect on the stratospheric ozone layer. While carbon tetrachloride (similar to CCl_2F_2 and CCl_3F) is almost of anthropogenic origin as well, its behavior in the atmosphere has not been understood well. During 1920 through 1940's, all the produced CCl_4 was released into the atmosphere after its uses as industrial solvent, dry cleaning agent, fire extinguisher, and grain fumigant. Since 1950's, however, CCl_4 has been mostly used as starting chemicals in the production of CCl_2F_2 and CCl_3F and its release into the atmosphere has been considered to be limited.[10-13] Accordingly its concentration in the atmosphere had been believed to remain nearly constant. The recent estimation, however, has suggested much larger release of CCl_4 in 1970's, and it has been increasing as well with the growing production of CCl_2F_2 and CCl_3F.[14] Since the reported atmospheric concentrations of CCl_4 vary among investigators, the distribution, annual change and absolute amount of CCl_4 in the atmosphere are not completely known yet. Carbon tetrachloride is an ultratrace constituent in the atmosphere at about 100 pptv (pptv=10^{-12} v/v) and tends to be strongly adsorbed or decomposed on the internal surface of sample canisters, which results in poor precision and accuracy in its analysis as compared with the analyses of CCl_2F_2 and CCl_3F.[15,16] Therefore we have improved the procedure of CCl_4 analysis with a gas chromatograph/electron-capture detector (GC-ECD) and also established a new method of preparation of CCl_4 standard by adding water vapor to prevent the CCl_4 adsorption. In this paper we report a new method of preparation of CCl_4 primary standards at 100 pptv level and discuss the behavior of CCl_4 in the atmosphere based on the background atmospheric concentrations determined by our new measurements.

Experimental

Sampling Procedures. A 2-dm^3 stainless steel (SS) canister equipped with an all SS bellows valve (Nupro SS-4H) was mainly used for atmospheric sampling. The canister was made by welding a 2-dm^3 beaker and a top plate with a welded tube, all of which had been washed carefully with neutral detergent and then with acetone in an ultrasonic cleaner. Electropolishing was not used because it chemically activates the surface. After the installation of the bellows valve, the canister was evacuated overnight to below 10^{-3} Pa at elevated temperatures from 50 to 300 °C. After the evacuation, ambient air was temporarily introduced into the canister at room temperature and pumped out again in order to deactivate the internal surface with adsorbable ingredients (probably H_2O). The canisters once used for sampling in remote areas were used after only the evacuation at room temperature. Sample air was introduced into the evacuated canister up to the ambient pressure by simply opening the valve at sampling locations. Background air samples were collected on the coast of Hokkaido and west Tohoku area (in 40—45 °N) when the wind was blowing from the sea in order to avoid the pollution from industrialized areas and local sources in Japan.[17-20]

Analysis. Atmospheric samples were analyzed in the laboratory with a gas chromatograph (Varian GC3700) equipped with an ECD (8 mCi ^{63}Ni). The experimental set-up for analysis and the procedure were described in detail previously.[19,20] The vacuum line for handling of the sample and the flow path in the gas chromatograph are all made of stainless steel to avoid contaminations with halocarbons from organic polymers such as silicone and Teflon. An atmospheric sample was introduced into the 50 cm^3 sample loop to about 200 Torr (1 Torr=133.3 Pa) (≈13 cm^3 STP) measuring the pressure precisely with a metal diaphragm pressure gauge and was injected to the GC. Eluted halocarbons were detected by the ECD and recorded with an analog recorder (Shimadzu R-12) and a degital integrator (Shimadzu C-R2AX). The precision in the pressure measurement was about 0.3% and the reproducibility in CCl_4 measurement was better than 1%. Pure nitrogen (Nippon Sanso, grade B) was further purified successively with mole-

cular sieve 5A, activated charcoal, and molecular sieve 13X, and was used as the carrier gas at a flow rate of 80 cm^3 min^{-1}. Methane was added (6 cm^3 min^{-1}) to the carrier gas nitrogen at just before ECD in order to improve the stability, sensitivity and signal-to-noise ratio of the detector. Halocarbons were separated by the temperature programming of the column (4.25 mm i.d. ×3 m, packed with 10% Silicone OV-101 on Chromosorb-W HP) from −40 to 70 °C at 5 °C min^{-1}. The ECD was usually purged with the purified nitrogen at a flow rate of 80 cm^3 min^{-1} and was connected to the separation column by switching a four-way valve only when the halocarbons were eluted: air was by-passed to avoid the sensitivity change of ECD. After the elution of CCl_2CCl_2 at about 25 min, the column temperature was raised to 150 °C for 10 min to purge other high boiling components.

Preparation of the Calibration Standards of Halocarbons. An all SS vacuum line installed in a temperature controlled room was used for preparation of the calibration standards of halocarbons. Internal volume of each part of the line was determined at a precision below 1%. Calibration standards were prepared by static dilution of pure materials with purified nitrogen or zero air which had been purified in the same manner as carrier gas nitrogen. Since the atmospheric concentration of CCl_4 is about 100 pptv, the calibration standards with similar concentrations were prepared by 3-step dilutions (to about 100 ppmv, 100 ppbv, and 100 pptv). In preparation of pptv-level calibration standards of CCl_4 and CH_3CCl_3, zero air saturated with water vapor at 23 °C (H_2O saturated zero air) was introduced into the flask before the dilution so that the water vapor pressure in the standards finally becomes about 10 Torr.

Results and Discussion

Difficulty in CCl_4 Measurement. Previous data of CCl_4 measurements reported by several groups[14,21–38] are plotted in Fig. 1. Most measurements were made with GC-ECD by comparing the corresponding peaks with prepared calibration standards. As shown in Fig. 1 the reported values are widely scattered over 100—170 pptv in 1975—1980. Such a large fluctuation (≈50%) cannot be attributed to natural variation in CCl_4 concentration in view of the chemical inertness (long lifetime) of CCl_4 in the atmosphere. The measurements made by a group with the common method and secondary standard, however, showed only a small variation, indicating that the CCl_4 concentration increases by about 2% per year.[14,27,28] Therefore, the poor accuracy of CCl_4 measurements must be ascribed to the difficulty in the preparation of calibration standards. Another calibration method with GC-ECD-coulometry[12] based on several premises has produced widely scattered values due to poor reproducibility. The measurement of CCl_4 in the stratosphere has been limited only to the lower stratosphere, and it has suffered from severe problem of the decomposition of CCl_4 in metal canisters.[15,16,24,30–33,36,37] We have found that even in dry tropospheric samples (dew point below −5 °C) the CCl_4 concentrations decrease after stored in the metal canisters. On the other hand, in relatively humid surface level samples, the CCl_4 concentrations remain unchanged over a long storage time, probably due to the contained water vapor. Water can be strongly adsorbed on the metal surface of the canister and cover the active sites on it. We have confirmed this assumption experimentally; when a dry sample was introduced into a stainless steel

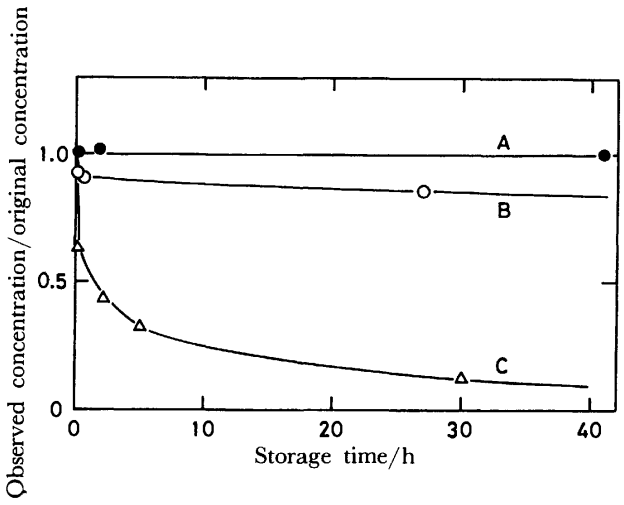

Fig. 2. Recovery of CCl_4 in dry samples stored in metal canisters: **A**, previously used for sample of background air and evacuated at room temperature; **B**, evacuated at 200 °C for 1 d; **C**, evacuated at 300 °C for 1 d.

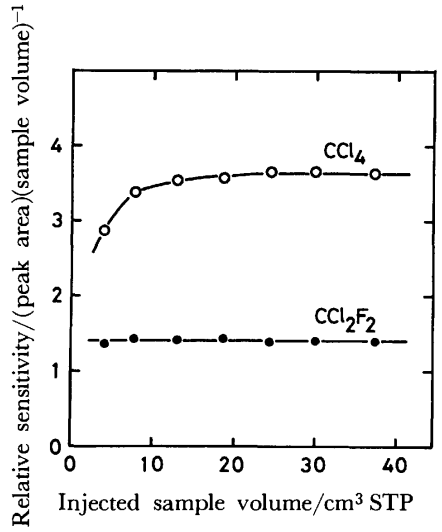

Fig. 3. Dependency of the relative sensitivity (peak area/injected sample amount) for CCl_4 and CCl_2F_2 on the injected volume of a dry sample (absolute humidity: ≈3 Torr).

canister baked at a higher temperature (300 °C, 1 d), much larger decrease in the CCl_4 concentration was observed as shown in Fig. 2. Furthermore, when the primary standards of CCl_4 at 100 pptv concentration level were prepared by dilution of 100 ppbv level standards in the metal canister with extremely purified dry air or nitrogen, the CCl_4 concentration found in the prepared standards was sometimes lower than expected even immediately after dilution, or often decreased drastically during the storage and completely diminished within a few days. These results must be explained in terms of the quick adsorption of CCl_4 on the inner surface (1) at the moment of introduction of the higher cocentration standard into the highly evacuated metal container to about several Torr, and (2) after the dilution with a water-free extremely pure dilution gas (air or nitrogen) which cannot cover the active sites on the metal surface.

Improvement of Analytical Procedures. Since we adopted the temperature-programming for the separation of 6 compounds (CCl_2F_2, CCl_3F, CH_3CCl_3, CCl_4, $CHClCCl_2$, and CCl_2CCl_2) with a single column, the commercially available high-pure grade nitrogen was further purified with purification columns for use as carrier gas. The concentrations of halocarbons in the purified nitrogen and in the purified zero air (processed with the same procedure) were: CCl_2F_2<0.01 pptv, CCl_3F<0.003 pptv, CCl_4<0.003 pptv, and CH_3CCl_3< 0.01 pptv. The separation column was therefore thoroughly cleaned by flowing the purified carrier gas nitrogen continuously for more than 5 years and by heating up to 150 °C after every run of analysis. Under these extremely clean conditions, CCl_4 in dry samples tended to be adsorbed on the column packing material during analysis and its recovery from the column was incomplete. Figure 3 shows the dependence

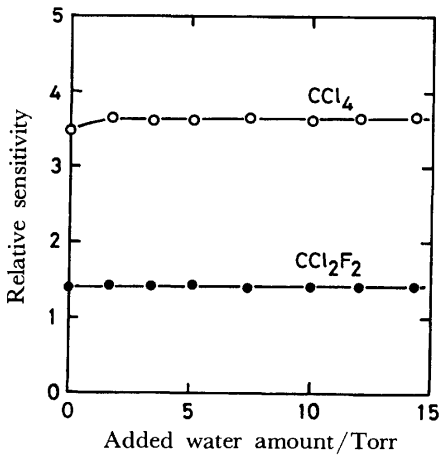

Fig. 4. The effect of preaddition of water-saturated zero air to the separation column during the analysis on the observed peak area of CCl_4 and CCl_2F_2. Water amount is shown by the corresponding vapor pressure of H_2O in the atmospheric sample.

of the relative sensitivity of CCl_4 and CCl_2F_2 (peak area/sample amount) upon the injected amount of a dry sample (dew point −5 °C, *i.e.*, absolute humidity is about 3 Torr). While the sensitivity of CCl_2F_2 was virtually independent of the injected sample amount, the CCl_4 sensitivity decreased at below 10 cm^3 STP sample injected. In order to avoid such problem, water vapor present in the purified zero air was introduced intentionally into the column at −40 °C just before the sample injection. The amount of the water-containing zero air was adjusted so as to keep the humidity in the sample constant at 15 Torr; the difference in the retention behavior of halocarbons in the GC column can also be canceled out. Each halocarbon concentration in the water saturated zero air was confirmed to be below the detection limit by GC-ECD. Figure 4 shows the change of the sensitivity of CCl_4 in the atmospher-

ic sample (13 cm^3 STP, absolute humidity 3 Torr) with preaddition of the water-saturated zero air. Since water is introduced into the column prior to the sample injection in this case, the amount of water-containing air necessary to deactivate the reactive sites was much less than in the case of Fig. 3. The recovery of CCl_4 at plateau regions in Figs. 3 and 4 agreed well and can be considered to be complete.

Preparation of Calibration Standard. The calibration standards of CCl_2F_2 and CCl_3F prepared with dry purified zero air were stored more than 2 years without change of their concentrations (<0.5%) in the 2-dm^3 SS canister equipped with a SS bellows valve. In the dry CCl_4 calibration standards prepared in the SS canister with concentrations at and below ppbv, however, the concentration decreased rapidly (*e.g.*, 80% loss in 1 d), much more rapidly at pptv levels. In a Pyrex glass flask (2—5 dm^3) equipped with the same SS bellows valve, the dry CCl_4 calibration standards at ppbv levels were stable (<0.3%) for more than 3 months, but dry CCl_4 standards at pptv levels decreased to half in a day, probably due to the metal part connected to the glass flask (*i.e.*, SS tube and the valve). Therefore, we prepared CCl_4 calibration standards at pptv levels in the Pyrex flask using water-containing zero air. More than ten calibration standards of CCl_4 at about 100 pptv were prepared by changing the water vapor pressure. The peak area of CCl_4 observed for these standards is plotted in Fig. 5 against the water vapor pressure, where the injected pressure, the presumed CCl_4 concentration, and the detector sensitivity have been normalized. The peak area of CCl_3F diluted at the same time in the same standards showed a constant value over the whole range of water pressure. While the observed CCl_4 peak area was also constant in the presence of sufficient humidity (≥6 Torr), it became unstable (*i.e.*, poor reproducibility) and decreased with the decrease in the water vapor pressure below 5 Torr. The CCl_4 peak area without addition of water vapor in the standard was about half of that with addition of water. Therefore, the CCl_4 calibration standard was prepared hereafter in the glass flask so that the water vapor pressure became about 10 Torr. The CCl_4 calibration standard prepared by this method was very stable and reproducible (<1.5%). The reliability of the concentration value in the prepared standard (*i.e.*, accuracy) was estimated to be within 6% considering all the possible systematic and random errors involved in the system and during the procedure. By using our new calibration standards and the improved analytical method, we are now able to discuss the observed concentrations of CCl_4 and the behavior of CCl_4 in the atmosphere.

The Source and Sink of CCl_4. Carbon tetrachloride has been believed to be of anthropogenic origin and no natural sources have been known.[10-14] Before 1950, most CCl_4 was used as industrial solvent, fire extinguisher and grain fumigant and eventually

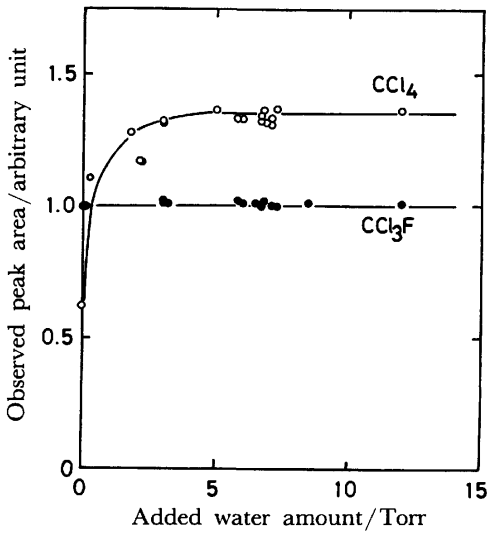

Fig. 5. The effect of water vapor pressure precedently introduced into the calibration standard at about 100 pptv concentration level prepared in a Pyrex glass flask. The peak areas of CCl_4 and CCl_3F observed in the standards are normalized for the presumed CCl_4 concentration, the injected pressure, and the ECD sensitivity.

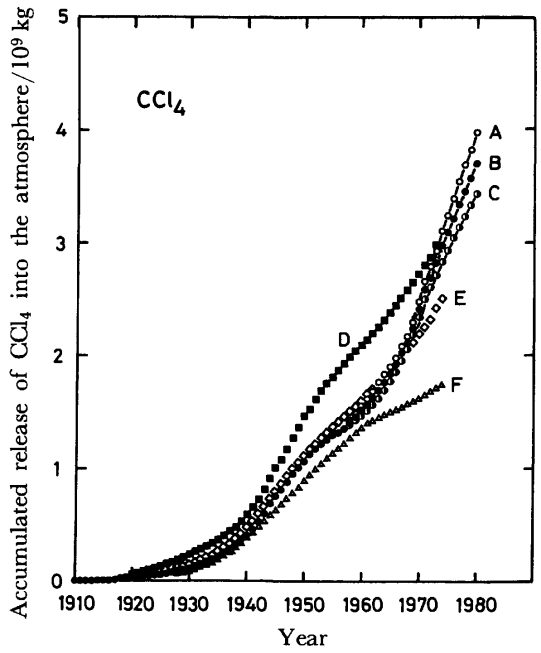

Fig. 6. Esimation of annual release of CCl_4 made by several groups: **A** (○) upper limit, **C** (◑) lower limit, **B** (●) the average of **A** and **C** by Simmonds *et al.* (Ref. 14); **D** (◆) by Galbally (Ref. 12); **E** (◇) by Singh *et al.* (Ref. 11); **F** (△) by Altshuller (Ref. 10).

released to the atmosphere. However, since 1950's, CCl_4 for solvent has been replaced by other solvents such as CH_3CCl_3, CCl_2CCl_2, and $CHClCCl_2$. On the other hand, CCl_4 has mainly been consumed as starting chemicals for the production of CCl_2F_2 and CCl_3F, so that its release into the atmosphere was estimated to be only several percent of its production.[10-14] The estimates of the total release of anthropogenic CCl_4 made by several groups are shown in Fig. 6. While these

estimates vary in amounts, they are similar in trend with the first release peak in 1940's as solvent and the recent increase accompanying the increase of the production of CCl_2F_2 and CCl_3F. Since the estimation by Simmonds *et al.* (curves **A**, **B**, and **C** in Fig. 6: **A**, upper limit; **C**, lower limit; and **B**, the average of **A** and **C**) is the most recent one and appears to be most reliable at present, we have compared our measurement data with their release estimation. The most effective sink of the atmospheric CCl_4 has been proved to be stratospheric UV photodissociation, and its lifetime in the atmosphere was calculated by Molina and Rowland as 30—50 years assuming vertical atmospheric transport parameters and solar flux at each altitude.[39] On the basis of recent values for such parameters (*i.e.*, about 10% lower UV-absorption cross-section of CCl_4 in 190—220 nm region,[6] and the increase of estimated solar flux due to the revised 30% lower absorption cross section of O_2[40,41]), the lifetime of CCl_4 in the atmosphere may become slightly shorter than the previous estimate. Other dissociation mechanisms of CCl_4 such as reactions with active species like OH, $O(^1D)$ in the atmosphere, or the hydrolysis in the ocean have been neglected because of their small reaction rates.[3,12,21,42,43] If the estimated lifetime based on the observed concentration is significantly shorter than the calculated ones based on the stratospheric photodissociation alone, we may have to reexamine or search for other dissociation mechanisms of CCl_4.

Observed Concentration and Lifetime of CCl_4 in the Atmosphere. The background concentration is defined here as the concentration observed in remote areas far enough from local emission sources. Because each halocarbon is released continuously in specified regions on the earth, the balance of its emission, diffusion, mixing, and removal processes will give a stationary concentration in remote areas, which is considered to be the background concentration at that location. As for the halocarbons, their emission has been limited to urban areas in highly industrialized countries, predominantly in the Northern Hemisphere (N. H.) such as the United States of America, Western Europe, and Japan. Table 1 shows our data of CCl_4 concentration measured in January 1981 on the coast of Hokkaido and west Tohoku area (40—45°N). The concentration is given as in dry air. The background concentration representing the mid-latitude N. H. thus obtained was 91 pptv in January 1981. For the estimation of the total amount of CCl_4 in the global atmosphere, the concentration of CCl_4 in the Southern Hemisphere (S. H.) was obtained by referring to the S. H./N. H. ratio reported in Ref. 14; while absolute concentration values are different from ours, the latitudinal distribution profile should be free from the calibration problem as discussed before. The CCl_4 concentration in the S. H. is nearly uniform due to the absence of large source in the S. H.. The S. H./N. H. ratio of the CCl_4 concentrations at mid latitudes in

a) pptv=10^{-12} v/v in dry air.

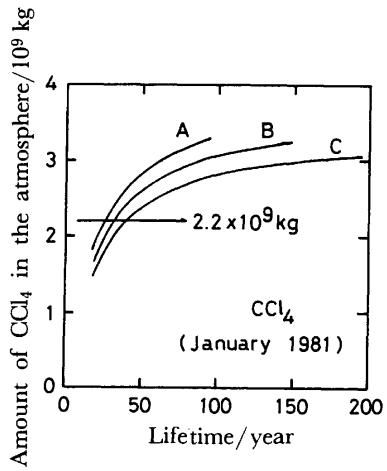

Fig. 7. Expected total amount of CCl_4 in the atmosphere in January 1981 against supposed atmospheric lifetime of CCl_4 for each emission scenario (**A**, **B**, and **C** corresponds to that in Fig. 6). The value of 2.2×10^9 kg calculated from our observation gives 33-year lifetime for the most probable emission scenario **B**.

January 1981 was thus calculated from Ref. 14 as $(S.H./N.H.)_{mid\text{-}lat.}$=(Tasmania data+American Samoa data)/(Cape Mears data+Adrigole data)=0.92. The CCl_4 concentration at the low-lat. N. H. (represented by Barbados data[14]) was calculated as 0.96 of that at the mid-lat. N. H. Since the amount of air in high and mid latitudes (>30°) is nearly equal to that in low latitude (0—30°), the global tropospheric average concentration of CCl_4 was estimated as 0.95 (=(1.0+0.96+0.92+0.92)/4) times the mid-lat. N. H. concentration. The average mixing ratio of CCl_4 in the stratosphere (where about 20% of air exists) was calculated as 60% of the global average tropospheric mixing ratio (mixing ratio denotes pressure-normalized concentration) as in the case of CCl_3F (same with Ref. 14). Since the amount of dry air on the earth is about 5.12×10^{18} kg, the total amount of CCl_4 in the whole atmosphere was calculated to be 2.2×10^9 kg in January 1981. On the other hand, the total amount remaining in the atmosphere $S(t_1)$ at time t_1 is calculated from the worldwide CCl_4 release data $I(t)$ and

CCl_4 atmospheric lifetime τ by

$$S(t_1) = \int_{t_0}^{t_1} I(t) \exp(-(t_1-t)/\tau)dt.$$

Figure 7 shows the expected total amount of CCl_4 in the atmosphere in January 1981 with the supposed lifetime of CCl_4 for each case of the emission scenario (*i.e.*, curves **A**, **B**, and **C** in Fig. 6). By comparing with the amount of 2.2×10^9 kg calculated from our measurement data, the lifetime of CCl_4 in the atmosphere is estimated as 33 years for the most probable emission scenario **B**, or 27 and 42 years for the emission scenarios **A** and **C**, respectively. These values are close to or slightly shorter than the lifetime of 30—50 years calculated by Molina and Rowland[39] assuming the UV photodissociation in the stratosphere as the only sink. For the global atmospheric concentration of CCl_4 118 pptv in January 1980 previously reported by Simmonds *et al.* in their Atmospheric Lifetime Experiment (ALE) program,[14] the calculated lifetime for CCl_4 should be about 70, 100, and 200 years for emission scenarios **A**, **B**, and **C**, respectively.[44] These lifetimes are even longer than those for CCl_3F and CCl_2F_2; this is unreasonable in view of their UV absorption cross-sections or their chemical reactivities. Furthermore, the larger atmospheric concentrations reported by other groups (Ref. 14, 21—38,45) and/or other scenarios with smaller emission (Ref. 10—13) will give much longer lifetime for CCl_4 and cannot be reasonably explained. We therefore suppose that such higher CCl_4 concentrations must have been based on inaccurate (unstable and overestimated) calibration standards.

Conclusion

Since CCl_4 was found to be readily and strongly adsorbed on clean metal surface under dry conditions, we developed new methods for analysis of CCl_4 and preparation of CCl_4 primary calibration standards by introducing water vapor into the system. This method is also effective for analysis and preparation of standards of high-boiling-point and readily-adsorbable compounds such as CH_3CCl_3, $CHCl{=}CCl_2$, and $CCl_2{=}CCl_2$. The absolute amount, distribution and lifetime of CCl_4 in the atmosphere were studied based on our newly calibrated measurement data.

Thermodynamic Study for Complexation Reactions of Dibenzo-24-crown-8 with Alkali Metal Ions in Acetonitrile

Yasuyuki TAKEDA,*Yasuki KUDŌ, and Shizuo FUJIWARA
Department of Chemistry, Faculty of Science, Chiba University, Yayoi-chō, Chiba 260
(Received May 30, 1984)

Synopsis. Formation constants for 1:1 complexes of dibenzo-24-crown-8 with alkali metal ions in acetonitrile have been determined by conductometry at different temperatures. Enthalpy ($\Delta H°$) and entropy changes ($\Delta S°$) were calculated. All the $\Delta H°$ and $\Delta S°$ values are negative. The $-\Delta H°$ and $-\Delta S°$ sequences are $Na^+>Cs^+>Rb^+>K^+$ and $Na^+\geq Cs^+>Rb^+>K^+$, respectively.

In the previous papers,[1,2] enthalpy ($\Delta H°$) and entropy changes ($\Delta S°$) of a 1:1 dibenzo-24-crown-8 (DB24C8) complex with an alkali metal ion in propylene carbonate and methanol, and transfer activity coefficients of the complex among nonaqueous solvents were determined. Behavior of the DB24C8–alkali metal ion complexes in nonaqueous solvents was discussed from a thermodynamic point of view. For further study on factors affecting stabilities of the DB24C8 complexes, more data on $\Delta H°$ and $\Delta S°$ are required. However, there are few data on $\Delta H°$ and $\Delta S°$ at present for complexation reactions between DB24C8 and alkali metal ions.[3,4]

In the present work, formation constants for 1:1 complexes of DB24C8 with alkali metal ions in acetonitrile have been determined by conductometry at different temperatures in order to obtain $\Delta H°$ and $\Delta S°$ values. The results were compared with those of other solvents. Solvent effect were elucidated.

Experimental

Materials. Most of the reagents were the same as those described previously.[1,2] Acetonitrile was allowed to stand in contact with molecular sieves for several days. The acetonitrile was then distilled twice. The middle 70% of the distillate was used. The water content of the purified acetonitrile, as determined by means of Karl Fischer titration, was less than 0.01%. The conductivity of the final product was less than $2\times10^{-7}\ \Omega^{-1}cm^{-1}$.

Apparatus and Procedure. Conductance measurements were conducted on a Fuso conductivity apparatus, model 362A, in a thermostated water bath 17, 21, 25, 29, 33, and 37±0.02°C. Two cells were used with cell constants of 0.059701 and 0.093938 cm^{-1}. The experimental procedure to obtain formation constants of DB24C8–alkali metal ion complexes in acetonitrile was the same as those described in the previous paper.[1]

Results

The molar conductivity (Λ) *vs.* $[L]_t/[M]_t$ plots for caesium perchlorate at 17, 21, 25, 29, 33, and 37°C in acetonitrile are illustrated in Fig. 1, $[L]_t$ and $[M]_t$ being total concentrations of DB24C8 and alkali metal ion respectively. The Λ *vs.* $[L]_t/[M]_t$ plots show a monotonous decrease in Λ with an increase in the DB24C8 concentration. The Λ *vs.* $[L]_t/[M]_t$ plots for the other alkali metal perchlorates are similar to those for $CsClO_4$. In this work, it is assumed that the association between a cation and a perchlorate ion is negligible and that DB24C8 forms 1:1 complexes with the alkali metal ions. Corrections for viscosity changes caused by the addition of DB24C8 were neglected. The procedure for obtaining formation constant (K_{ML^+}) of a DB24C8–alkali metal ion complex was just the same as that mentioned in the previous paper,[1] where $K_{ML^+}=[ML^+]/[M^+][L]$, and M^+ and L denote an alkali metal ion and DB24C8 respectively. For each alkali metal system, K_{ML^+} values decrease with an increase in temperature, and the log K_{ML^+} *vs.* T^{-1} plot shows a linear relationship. Values of $\Delta H°$ and $\Delta S°$ calculated from these results are listed in Table 1, together with log K_{ML^+} values at 25°C. It is seen from Table 1 that, except for methanol, values of $\Delta H°$ and $\Delta S°$ for a DB24C8–Cs^+ complex obtained by us using conductometry are in good agreement with those by the NMR method.[4]

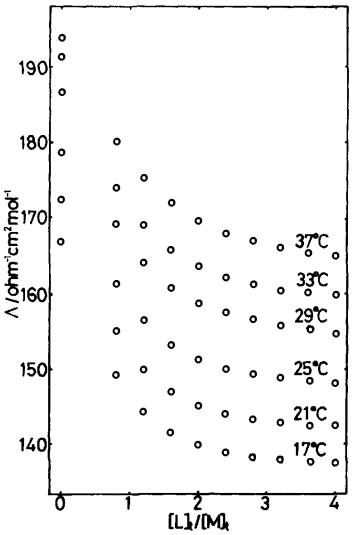

Fig. 1. Λ *vs.* $[L]_t/[M]_t$ plots for caesium perchlorate in acetonitrile at different temperatures. $[M]_t=5\times10^{-4}$ M.

Discussion

Table 1 shows that all the $\Delta H°$ and $\Delta S°$ values for complexation reactions of DB24C8 with alkali metal ions in acetonitrile are negative as well as in propylene carbonate and methanol. Since DB24C8 is a large crown ether and has a great ligand-ring flexibility, the negative $\Delta S°$ values may be primarily due to large conformational changes when a complexation reaction occurs. For the DB24C8–acetonitrile system, the $-T\Delta S°$ value is much smaller than the $-\Delta H°$ value; thus, the magnitude of log K_{ML^+} value of the alkali metal ion complex is determined largely by the $\Delta H°$ value.

TABLE 1. log (K_{ML}^+/mol^{-1}dm^3), $\Delta H°$, AND $T\Delta S°$ VALUES FOR THE COMPLEXATION OF DB24C8 WITH ALKALI METAL IONS IN NONAQUEOUS SOLVENTS

Crown ether	Cation	Solvent	log K_{ML}^+ (at 25 °C)	$-\Delta H°$ / kJ mol^{-1}	$-T\Delta S°$ / kJ mol^{-1} (at 25 °C)
DB24C8	Na^+	AN[a]	4.1_2	34.9	11.4
		PC[b, 1]	4.1_6	37.7	13.7
	K^+	AN[a]	3.8_4	27.7	5.5
		PC[b, 1]	3.7_3	34.5	13.2
		CH_3OH[1]	3.5_7	35.3	14.7
	Rb^+	AN[a]	3.8_0	30.7	8.4
		PC[b, 1]	3.5_5	32.9	12.6

	Cs^+	AN[a]	3.9_5	33.1	10.7
				34.0[4]	10.8[4]
		PC[b]	3.4_6[1]	32.3[1]	12.6[1]
				33.9[4]	14.21[4]
		CH_3OH	3.8_4[1]	36.8[1]	14.6[1]
				41.3[4]	20.08[4]

a) Acetonitrile. b) Propylene carbonate.

For DB24C8 complexes, there is no large difference in both $\Delta H°$ and $\Delta S°$ among alkali metal ions except $\Delta S°$ value of a DB24C8–K^+ complex for acetonitrile. A sodium ion is the smallest and has the highest charge density of all the alkali metal ions (Na^+, K^+, Rb^+, Cs^+). If the sodium ion has the most suitable size for favorable arrangement of ether oxygen atoms of DB24C8 for the metal ion held in the cavity, the strongest interaction of the metal ion with the ether oxygen atoms and the largest ligand-ring conformational change would be observed for the Na^+–DB24C8 complex among all the alkali metal ion–DB24C8 complexes. The following data may support the above discussion. For acetonitrile and propylene carbonate, both $-\Delta H°$ and $-\Delta S°$ values of the Na^+–DB24C8 complex are the greatest of all the alkali metal ion complexes (Table 1), and also is $-\Delta S°$ value of the Na^+–DB24C8 complex for 70 wt% CH_3OH in H_2O.[3]

Generally, for a given DB24C8–alkali metal ion complex, both $\Delta H°$ and $\Delta S°$ values are somewhat dependent on the variation of solvent; unexpectedly, the $-\Delta H°$ value increases with an increase in the donicity of solvent (acetonitrile (14.1), propylene carbonate (15.1), methanol (19.0)[5]). For the same DB24C8–alkali metal ion complex, both $-\Delta H°$ and $-\Delta S°$ values of acetonitrile are the smallest of all the solvents except $-\Delta H°$ value of acetonitrile for a Cs^+ complex; although acetonitrile and propylene carbonate are non-structural solvents, the difference in $\Delta S°$ between the solvents is comparable to that between propylene carbonate and methanol, which has a hydrogen-bonded structure. This may be attributed to the specific interaction between uncomplexed DB24C8 and acetonitrile.[4,6] The reason why, for a given DB24C8–alkali metal ion complex, the $-\Delta H°$ value of methanol is the largest of all the solvents cannot be explained at the present time.

(Received August 2, 1984)

Synopsis. Iron-modified crystalline silicas prepared from an Fe(II) compound were more active than those prepared from an Fe(III) compound. The (C_2H_4+C_3H_6) selectivity of the former was lower than that of the latter. By the addition of alkaline earth metals, the (C_2H_4+C_3H_6) selectivity of the catalysts prepared from the Fe(II) compound increased remarkably.

An intensive research effort is now being directed towards the development of highly selective Fischer-Tropsch catalysts. Recently, there has been considerable interest involving the use of zeolites supports for such catalysts.[1-3] Among these zeolite-based catalysts are the modified crystalline silica catalysts in which a portion of the silicon atoms in the crystal lattice were replaced by iron, ruthenium *et al.*[4-7] These catalysts have improved the product distribution.

From this point of view, the authors have also prepared zeolite-based catalysts modified with iron.[8] In this paper the hydrogenation of CO over such modified crystalline silica catalysts prepared from Fe(II), $FeSO_4$, and Fe(III), $Fe(NO_3)_3$ compounds is discussed.

The syntheses conditions regarding the various crystalline silica catalysts are shown in Table 1 together with some analytical data determined by atomic-absorption spectrophotometry.

The synthetic iron-modified crystalline silica catalyst had a well defined crystalline ZSM-5 type structure, as demonstrated by an X-ray powder diffraction pattern and a scanning electron micrograph. Peaks corresponding to iron oxide were not observed. The iron may have been highly dispersed in the catalysts.

These catalysts were used for the hydrogenation of CO after being reduced under hydrogen at 450°C for 15 h. Hydrogenation of CO was carried out in a flow reactor at 420°C and 10 kg/cm² (H_2:CO:Ar=45:45:10). Conversion and carbon-based selectivity (excluding CO_2 yield) were calculated on the basis of argon as an internal standard. Figure 1-(A) shows the CO conversion plotted against the Fe/Si atomic ratio. On the other hand, Fig. 1-(B) shows the selectivity to CH_4, (C_2H_4+C_3H_6) and (C_2H_4+C_2H_6+C_3H_6+C_3H_8) plotted against the selectivity to total gaseous hydrocarbons (C_1—C_5). It should be noted that both the catalytic activity and the product selectivity are affected by the source of iron. The catalysts prepared from an Fe(II) compound are more active than those prepared from an Fe(III) compound. The selectivity to total gaseous hydrocarbons decreased much after using the Fe(II) compound instead of the Fe(III) compound as a source of iron and by increasing the amount of the Fe(II) compound. However, a linear relationship exists between the selectivity to CH_4, (C_2H_4+C_3H_6) and (C_2H_4+C_2H_6+C_3H_6+C_3H_8) and the selectivity to gaseous hydrocarbons. This suggests that each selectivity in the gaseous hydrocarbons is constant. It may be concluded that the C_1 to C_5 hydrocarbons are produced over the same active sites.

In order to elucidate these differences involving the activity and the selectivity, X-ray powder diffraction patterns of various catalysts (after preparation) were measured using silicon as an internal standard. As shown in Fig. 2, in the case of the crystalline silica catalysts prepared from the Fe(III) compound, the d(084)-spacing sharply increased with the Fe/Si atomic ratio. On the other hand, in the case of the catalysts

prepared from the Fe(II) compound, the spacing remained unchanged.

From these results, it may be concluded that only Fe(III) can replace a portion of the silicon atoms in the crystal lattice and that Fe(II) is present in an enveloped form with the crystalline silica. The differences of both the catalytic activity and the product selectivity may be attributed to the amount of iron which does not replace a portion of the silicon atoms.

This concept can be supported by the following fact. The crystalline silica catalyst prepared from the Fe(III) compound was treated with 3 M HCl (1 M=1 mol dm^{-3}) at room temperature for 2 d with vigorous stirring. The catalyst, thus obtained, did not show any activity in spite of a considerable amount of iron present in the catalyst.

It may also be considered that a part of the iron enveloped with crystalline silica can easely be moved to the external surface of a crystal upon treatment with hydrogen. This iron will produce higher carbon-

number hydrocarbons (C_6^+) because of the lack of restrictions caused by the zeolitic structure. Therefore, to restrict this moving of iron, an alkaline earth metal (acetate) was added. Figure 3 shows the effect of alkaline earth metals on the selectivity. A remarkable increase in total gaseous hydrocarbons was observed over the alkaline earth metal-modified crystalline silica catalysts prepared from the Fe(II) compound. The selectivity to (C_2H_4+C_3H_6) also increased in the order: Sr<Mg<Ca<Ba. However, this effect was not observed for catalysts prepared from the Fe(III) compound. The activity of these catalysts were about 30 percent lower than those of catalysts containing no alkaline earth metals. Moreover, the activity and the selectivity of these catalysts hardly changed at 420°C even after 50—60 h.

This work was supported by the National Research and Development Program of the Ministry of International Trade and Industry.

The Crystal Structure of the β-Form of α-Monolaurin

Midori GOTO* and Toshimichi TAKIGUCHI
National Chemical Laboratory for Industry, 1-1, Higashi, Yatabe, Ibaraki 305
(Received September 8, 1984)

Synopsis. The crystal structure of the β form of α-monolaurin has been determined. The space group is $P2_1$, with a=9.2472(3), b=74.310(2), c=4.9523(1) Å, β=97.514 (3)°, and Z=8. Two types of molecular conformations of monolaurin exist in the crystal.

The α-monoglycerides have been shown by powder X-ray diffractions to exist in four crystalline forms, 1) α-form, 2) subα-form, 3) β′-form, and 4) β-form.[1] The β-form is a stable form at room temperature. Larsson found two different forms of the β-form and named them the β_1- and β_2- forms.[2] Both were monoclinic and had the same cell dimentions, but they differed in the absent reflections. He assigned the space group of $P2_1/m$ and Am for β_1 and β_2 respectively. He described the chain packing, but did not solve the structure of the glycerol parts.[2] The present authors obtained a single crystal of the β-form (β_1-form by Larsson's nomenclature) of α-monolaurin and undertook an X-ray crystal structure analysis.

Experimental and Structure Determination

The α-monolaurin was prepared by the Nihon Glyceride Co. Ltd. The β-form crystal was obtained by crystallization in a chloroform solution. The cell dimensions and diffraction intensities were measured on a Rigaku-Denki four-circle diffractometer by using graphite monochromated Cu-$K\alpha$ radiation at room temperature. 963 independent reflections with 2θ values up to 120° ($|F_o| \geqq 3\sigma(|F_o|)$) were used for the analysis. No correction was made for absorption. The systematic absences ($k=2n+1$ for $0k0$) and intensity statistics indicated $P2_1$ as the space group. The crystal data were as follows: $C_{15}H_{30}O_4$; monoclinic, $P2_1$; Z=8; a=9.2472 (3), b=74.310 (2), c=4.9523 (1) Å, β=97.514 (3)°; D_x=1.06 gcm^{-3}; mp=63.0°C. The structure was solved by MULTAN.[3] The hydrogen atoms except for the one near the end of the carbon chains were placed at the calculated positions. The structural parameters were refined by a block-diagonal least-squares method, using the UNICS III system.[4] The final refinement led to the R value of 0.070. The other possible space group $P2_1/m$ was found to be definitely incorrect because the R value did not decrease to less than 0.3.

Results and Discussion

The asymmetric unit contains four crystallographicaly independent molecules. They will hereafter be named the A_1, A_2, B_1, and B_2 molecules. Two pairs, A_1 and A_2, and B_1 and B_2, are enantiomers to each other. The numbering of atoms in the molecules is shown in Fig. 1, while the final atomic coordinates are given in Table 1.[5]

The difference in the conformation of monolaurin between A and B exists in the glycerol parts, as illustrated in Fig. 1. The dihedral angles φ (O2–C13–C14–O3) are 177° (A_1) and 175° (A_2) for the A molecules, and 62° (B_1) and −58° (B_2) for the B molecules. The dihedral angles φ (O3–C14–C15–O4) are −66° (A_1) and 60° (A_2) for the A molecules and 165° (B_1)

and 171° (B_2) for the B molecules. The dihedral angles φ (O2-C13-C14-C15) are 64°, −69°, −52°, and 54° for the A_1, B_1, A_2, and B_2 molecules respectively. Therefore, the A and B molecules take a *trans-gauche* and a *gauche-trans* conformation respectively. The molecules are linked by hydrogen bonds, the average hydrogen-bond distance being 2.68 Å. The packing of the molecules in the crystal is shown in Fig. 2.

We are indebted to Dr. T. Sakurai and Miss K. Kobayashi of the Institute of Physical and Chemical Research for the UNICS III programs used in this work; we are also indebted to the Nihon Glyceride Co., Ltd., for providing the compound.

Department of Chemistry, Faculty of Science, Fukuoka University, Jonan-ku, Fukuoka 814
†*Department of Chemistry, Faculty of Science, Kyushu University 33, Hakozaki, Higashi-ku, Fukuoka 812*
(Received November 12, 1984)

Synopsis. Assignments of the normal vibrations of tetramethyl-d_{12}-pyrazine were made based on the polarization behavior of the Raman and infrared bands and also on the normal coordinate calculation. The result ascertains the assignments of the normal vibrations given previously for tetramethylpyrazine.

Very recently we gave assignments of the normal vibrations for tetramethylpyrazine.[1] In order to confirm the results, tetramethyl-d_{12}-pyrazine was synthesized and the normal vibrations were studied.

Experimental

Material. Tetramethyl-d_{12}-pyrazine(TMP-d_{12}) was synthesized by the reaction of tetramethylpyrazine (TMP-d_0) and D_2O with DCl. Isotopic purity of the product was determined by the nuclear magnetic resonance measurement.

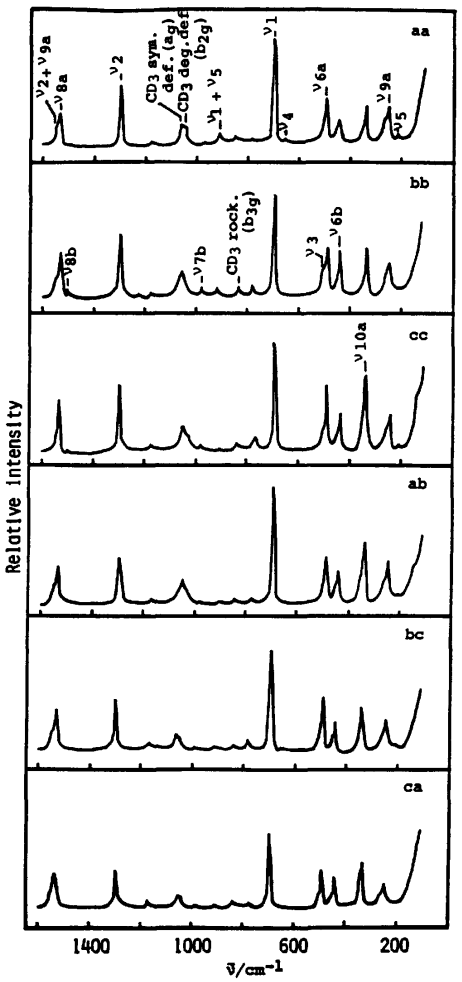

Fig. 1. Polarized Raman spectrum of tetramethyl-d_{12}-pyrazine.
The first letter in ab spectrum *etc.* refers to the direction of polarization of the excitation light and the second to that of the scattering light.

Optical Measurements. The apparatus and methods used for the measurements of the polarized Raman and infrared spectra of TMP-d_{12} single crystals were exactly the same as those described previously.[1]

Results and Discussion

The polarized Raman and infrared spectra of TMP-d_{12} single crystals are shown in Figs. 1 and 2. The polarization behavior of the Raman and infrared bands, and the rotational envelope of the infrared bands of TMP-d_{12} belonging to the same symmetry species are expected to be the same as those of TMP-d_0, because both molecules have the same molecular and crystal structures, and the nearly equal moments of inertia. The potential field and the force constants used for the normal coordinate calculation of TMP-d_{12} were taken to be exactly the same as those used in TMP-d_0 and the calculated vibrational frequencies

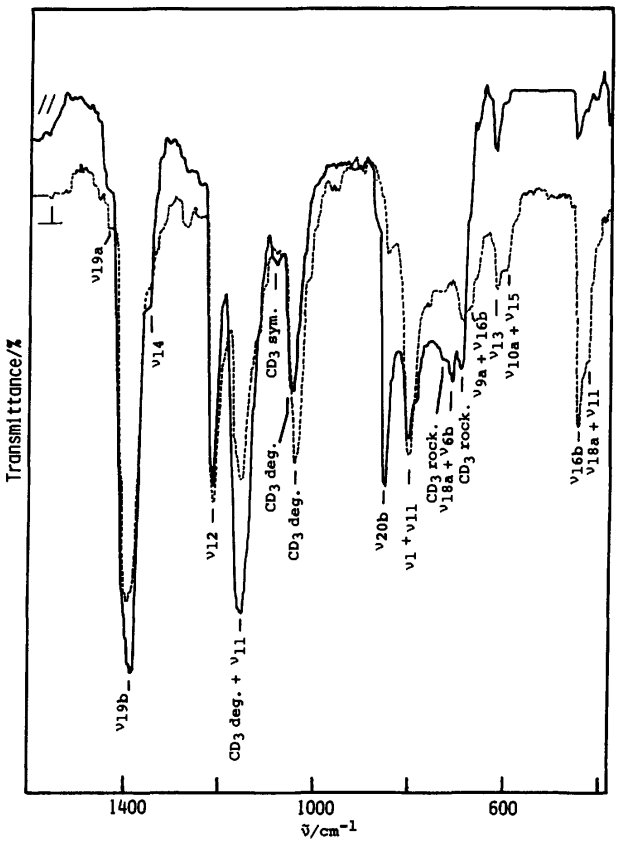

Fig. 2. Polarized infrared sectrum of tetramethyl-d_{12}-pyrazine.
// and ⊥ spectra refer to the infrared spectra measured with the incident light polarized parallel and perpendicular to the crystal growth direction. Polarization behaviors are classified into three types. The relative intensities of the // and ⊥ bands are the following; $I_{//} \approx I_{\perp}$ for type-I, $I_{//} > I_{\perp}$ for type-II, and $I_{//} < I_{\perp}$ for type-III.

a) Frequencies were estimated from combination bands.

and modes are given in Table 1. Vibrational analyses of the Raman and infrared bands were made in the same way as that described for TMP-d_0.[1]

a_g Species: Strongly polarized Raman bands observed at 1533, 1296, 695, and 489 cm^{-1} in the depolarization measurements in liquid phase were straightforwardly assigned to the totally symmetric ν_{8a}, ν_2 (ϕ-CD_3 stretching), ν_1, and ν_{6a} vibrations, respectively. A weak and almost depolarized Raman band observed at 247 cm^{-1} in liquid does not show any polarization behavior corresponding to non-totally symmetric vibrations in single crystal, thus, this band was assigned to the ν_{9a}(CD_3 bending) vibration.

b_{3g} Species: Raman bands observed at 1507, 970, 503, and 439 cm^{-1} have stronger intensity in the bb and cc spectra than in other spectra, therefore, these were assigned to the ν_{8b}, ν_{7b} (ϕ-CD_3 stretching), ν_3(CD_3 bending), and ν_{6b} vibrations, respectively.

b_{2g} Species: Raman bands at 667 and 215 cm^{-1} were found only in the aa and cc spectra with very weak intensity, therefore, these were assigned to the ν_4 and ν_5 (CD_3 wagging) vibrations, respectively.

b_{1g} Species: A Raman band observed at 340 cm^{-1} has strong intensity in the cc and ab spectra, thus this was assigned to the ν_{10a} (CD_3 wagging) vibration.

b_{1u} Species: Infrared bands observed at 1210 and 615 cm^{-1} showed the B band-type and the type-I polarization, thus, these were assigned to the ν_{12} and ν_{13} (ϕ-CD_3 stretching) vibrations, respectively. A weak infrared band observed at 1435 cm^{-1} showing the type-I polarization was assigned to the ν_{19a} vibration. A medium intense infrared band observed at 710 cm^{-1} showed the A band-type and the type-II polarization, therefore, this could be assigned to a combination band of the ν_{6b} (b_{3g}) and ν_{18a} (b_{1u}) vibrations. This gives frequency of 270 cm^{-1} for the ν_{18a} (CD_3 bending) vibration.

b_{2u} Species: A very strong infrared band observed at 1390 cm^{-1} and a medium intense band at 840 cm^{-1} showed the A band-type and the type-II polarization. Therefore, these bands were assigned to the ν_{19b} and ν_{20b} (ϕ-CD_3 stretching) vibrations, respectively. A shoulder band observed at 1337 cm^{-1} showing the type-II polarization was assigned to the ν_{14} vibration. A weak infrared band at 595 cm^{-1} showing the type-III polarization could be assigned to a combination band of the ν_{10a} (b_{1g}) and ν_{15} (b_{2u}) vibrations. This gives frequency of 250 cm^{-1} for the ν_{15} (CD_3 bending) vibration.

b_{3u} Species: A medium intense band observed at 445 cm^{-1} showed the C band-type and the type-III polarization, thus, this was assigned to the ν_{16b} vibration. A strong infrared band observed at 1150 cm^{-1} showing the b_{2u} polarization behavior could be assigned to a combination band of the CD_3 degenerate deformation (b_{1g}) and ν_{11} (b_{3u}) vibrations, which is generally observed very strongly in the six-membered aromatics. This assignment gives frequency of 110 cm^{-1} for the ν_{11} (CD_3 wagging) vibration. The summary of assignments is given in Table 1.

The calculation indicates that the ν_4 vibration couples with the CD_3 rocking vibration in TMP-d_{12}. This was supported by our assignments, which show that the frequency of the ν_4 vibration of TMP-d_{12} is lower than those of pyrazine and TMP-d_0. The calculated frequencies and modes well coincide with the observed frequencies and polarization behavior of the Raman and infrared bands of TMP-d_{12}. This indicates that the assignments given for the normal vibrations of TMP-d_0 are quite reasonable.

Mössbauer Emission Spectra of ^{119m}Sn in Tin Organosol

Sumio ICHIBA* and Toshio SAKAMOTO
Department of Chemistry, Faculty of Science, Hiroshima University, Higashisenda-machi, Naka-ku, Hiroshima 730
(Received July 26, 1984)

Synopsis. The electron-scavenging effects of adding various solutes to a suspension of tin in ethanol were studied by Mössbauer emission spectroscopy. The yield of the aliovalent species of Sn^{4+} as the after-effects of the converted isomeric transition in ^{119m}Sn varied from the value of the suspension of tin in ethanol, depending on the properties of electron trapping of the solute added.

After-effects of converted isomeric transition (CIT) in ^{119m}Sn have been studied by means of Mössbauer spectroscopy.[1-3] As the after-effects, the aliovalent species of oxidized Sn^{4+} were observed in the emission spectra of ^{119m}Sn in the $SnCl_2$ adducts and rapidly frozen solutions of $SnCl_2$, and the species of reduced Sn^{2+} in the $SnBr_4$ adducts.[4-6] The mechanisms of the competing acceptors for the electrons between hot atoms and the surrounding medium for the stabilization of the oxidized Sn^{4+} and autoradiolysis of the ligands for the stabilization of reduced Sn^{2+} were elucidated by taking the properties of the ligands and solvents into consideration.

In this study, an organosol of tin in ethanol containing ^{119m}Sn was prepared and the emission spectra were measured by adding various solutes to the suspension to determine the reactivity of the solute toward the electrons produced in the Auger cascade following CIT in ^{119m}Sn.

Experimental

The sources of the tin organosol were prepared from ^{119m}Sn metal obtained from New England Nuclear Co., according to the method reported previously.[7] For each source, 0.25 mCi of ^{119m}Sn with the specific activity of 0.082 mCi mg^{-1} was suspended in 5 ml of ethanol. The concentration of the solutes added to the suspension in ethanol was 1 mol dm^{-3} except for CH_3I, the concentration of which was 3 mol dm^{-3}.

The emission spectra were measured against the ^{119}Sn enriched $CaSnO_3$ absorber (2.0 mg ^{119}Sn cm^{-2}) at room temperature by cooling the source in a liquid nitrogen cryostat. Mössbauer parameters were deduced from Lorentzian curves computer-fitted to the spectra by the least-squares method.

Results and Discussion

The concentration of tin in the suspension was 0.6 mg cm^{-3}, so that the particle size would be about 300 Å and/or less as reported previously.[7] The Mössbauer emission and absorption spectra of the organosol of tin in ethanol are shown in Fig. 1. The absorption spectrum of the organosol of tin in Fig. 1(a) showed that the tin in the suspension was purely β-Sn, but a portion of the oxidized aliovalent species of Sn^{4+} was observed at about 0 mm s^{-1} in the emission spectrum. The emission spectra on adding various solutes to

CH_3I	2.41	2.39	0.17	2.39	5.22

a) Equal line-width. b) Constraining to the value of the suspension in ethanol.

the suspension are shown in Fig. 2. The Mössbauer parameters deduced by constraining the line-width to be equal in both lines of β-Sn and Sn^{4+} and the isomer shift of Sn^{4+} to be 0.17 mm s^{-1} of the value of the suspension in ethanol are shown in Table 1 along with the area ratio of Sn^{4+} to the total. The suspension of tin is similar to the solution of $SnCl_2$ in that the electrons emitted by an Auger cascade enter the medium and are trapped by it, stabilizing the aliovalent species of Sn^{4+} in tin microcrystals. The recapture of electrons from the surroundings to return the atom to a normal valence state may be impeded by an insulator formed on the surface of the particle in consequence of the radiolytic effects. The yield of Sn^{4+} in the suspension, 12.32%, was naturally lower than the yield of 28% in the solution of $SnCl_2$ in ethanol reported previously.[6] However, the increased yield of Sn^{4+} is detected in the suspension by adding CCl_4 and C_5H_5N and the decreased yield by adding $(CH_3)_2SO$, $(C_6H_5)_2SO$, and CH_3I compared with the value of the suspension in ethanol, though the differences in the yield of Sn^{4+} among the emission spectra of the solutions of $SnCl_2$ in C_2H_5OH, $(CH_3)_2SO$, and C_5H_5N are not distinguished clearly.[6]

In glassy ethanol, the trapped excess electrons generated by ionization have been explained in terms of a small polaron model.[8,9] This model suggests that the generated Auger electrons following the CIT in ^{119m}Sn are assumed to be trapped by OH groups and shallower traps associated with the alkane moiety; thus the oxidized aliovalent Sn^{4+} species are stabillized. The increased yield of Sn^{4+} by adding CCl_4 can be explained in terms of the well known electron scavenging properties of CCl_4 toward the Auger electrons. Pyridine also increases the yield of Sn^{4+} so that it traps Auger electrons and acts as an electron scavenger in the ethanol solution.

The yield of Sn^{4+} decreases considerably on adding CH_3I though it is a good electron scavenger.[10] It is well known that CH_3I decomposes to methyl radical-halide anion pairs formed by dissociative electron capture.[11] The methyl radicals thus created would reduce a portion of aliovalent species of Sn^{4+} to the original state. The decreased yield of Sn^{4+} by adding $(CH_3)_2SO$ can also be explained in the same way as for CH_3I, because $(CH_3)_2SO$ also decomposes to methyl radical-methanesulfenate anion pairs by dissociative electron capture.[12]

Synthesis and Swelling Properties of Fluorine Micas with Variable Layer Charges

Kunio KITAJIMA,* Fumihiko KOYAMA, and Nobuo TAKUSAGAWA
Department of Synthetic Chemistry, Faculty of Engineering, Shinshu University, Wakasato, Nagano 380
(Received September 25, 1984)

Synopsis. A series of tetrasilicic Na-micas with variable layer charges (x) between x=1 and x=0.32, $Na_xMg_{3-x}Li_x(Si_4O_{10})F_2$, was synthesized. The expansibility of the synthesized Na-micas upon swelling increased with decreasing layer charge.

Some of the synthetic fluorine micas are swellable with water.[1] However, detailed studies on the effect of the magnitude of layer charge upon the expansibility of fluorine micas have been lacking. The layer charge results generally from positive charge deficiencies in both tetrahedral and octahedral sheets. The value of layer charge, which is expressed as the net negative charge per formula unit, is an important parameter for the classification of layer silicates. Na-taeniolite[2] $NaMg_2Li(Si_4O_{10})F_2$ is a representative species of these synthetic expansible fluorine micas. In this note, the substituted analogues of Na-taeniolite with decreasing layer charge, $Na_xMg_{3-x}Li_x(Si_4O_{10})F_2$ ($1 \leqq x \leqq 0.1$), are synthesized to examine the limit of variability in layer charge and also to elucidate the correlation between the magnitude of layer charge and the swelling properties. In this series the layer charge results from charge deficiency only in octahedral sheet and its value is the same as the x-value.

Raw materials used were chemically pure NaF, MgO, MgF_2, LiF, and SiO_2. Raw materials mixed in proportions corresponding to the formula described above, were sealed in platinum tubes and heated at 1420 °C for 2 h. The temperature was then lowered at a rate of 2—3 °C per minute to 800 °C and the tube was taken out of the furnace to cool in air. The crystal aggregates thus obtained were powdered and purified by sedimentation in distilled water. The products were investigated by powder X-ray diffractometry, electron scanning microscopy, and infrared spectroscopy. The chemical analysis was done for Na and Li by a flame-emission method after the purified samples were dissolved in HF–H_2SO_4 solutions. The layer charge for micas is determined from the content of interlayer Na. The infrared spectra were measured by a KBr pellet method. Swelling of the micas was investigated by an X-ray diffraction method through the measurements of basal spacing (d_{001}) of the samples wetted with water, ethylene glycol, or glycerol.

The batches with the x-value of 1.0—0.6 were melted at 1420 °C, whereas the batches with the x-value smaller than 0.6 was not melted but sintered. The size of mica crystals decreased with decreasing x-value. X-Ray diffraction patterns indicated that only mica was formed from the batches having the x-value of 1.0—0.8. However, the traces of coexistent minerals such as fluor-richterite, α-cristobalite, and α-tridymite were observed for the batches having the x-value of 0.7—0.5, and their contents were not negligible at x= 0.4—0.1.

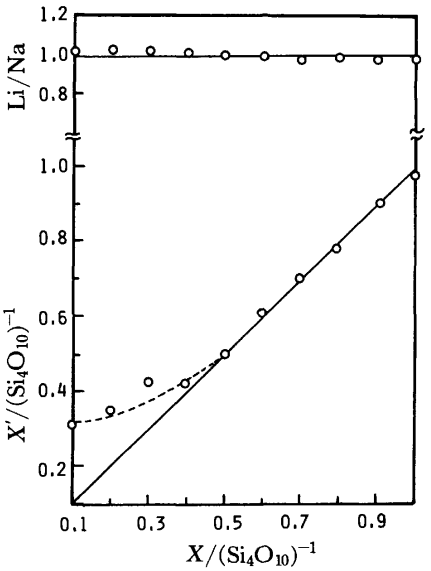

Fig. 1. The determined layer charge (x') and Li/Na mole ratio of synthesized Na-micas plotted against the ideal layer charge (x) calculated from batch composition.

The infrared spectra of the micas showed that the main absorption band at 980 cm^{-1} for x=1.0, which is assigned to e_1^1 mode of Si_2O_5 group,[3] gradually shifted towards higher frequencies with decreasing x-value although the shifting was not observed below x=0.4. On the other hand, another main band at 1110 cm^{-1}, which is assigned to a_1^1 mode of Si_2O_5 group,[3] shifted reversely to lower frequencies with decreasing x-value. The linear relationship is obtained between x-values and wavenumber ($\tilde{\nu}$) in the range x=1.0—0.5 as follows:

$$e_1^1;\ \tilde{\nu} = 980 + 28x\ (cm^{-1})$$
$$a_1^1;\ \tilde{\nu} = 1110 + 40x\ (cm^{-1})$$

This implies that the tetrahedral lattice vibrations are affected by the magnitude of layer charge and/or the changes of octahedral and interlayer compositions.

Figure 1 shows the relationship between the determined layer charge (x') of the synthesized micas and the ideal layer charge (x) calculated from batch composition. The observed mole ratio of Na and Li in mica crystals is also plotted against the x-value in Fig. 1. The ratios of Na to Li are 1.00±0.03 corresponding to the theoretical value of 1.00 throughout the series. The dotted line shows the variation of x'-values, while the full line shows that of x-values. If the synthesis was fully successful, the x'-value should be equal to the x-value. As seen in Fig. 1, the curve of x'-values almost agrees with that of x-values in the range of x=1.0—0.4. However, the x'-value deviates from the x-value below x=0.3, converging to about

Table 1. Basal spacings[a] of Na-micas upon water, ethylene glycol, and glycerol solvation

	$x/(Si_4O_{10})^{-1}$	1.0	0.9	0.8	0.7	0.6	0.5	0.4	0.3	0.2	0.1
$\frac{d_{001}}{Å}$	Water	15.1 (12.2)	15.1 (12.2)	15.1	15.1	18.4 (15.1)	18.4 (15.1)	f.s.[b] (18.4)	f.s.	f.s.	f.s.
	Ethylene glycol	12.3	12.3	12.3 (16.7)	12.3 (16.7)	16.7 (12.3)	16.7 (12.3)	16.7	16.7	16.7	16.7
	Glycerol	12.7	12.6	14.3 (12.6)	14.2 (12.6)	14.5	14.3 (17.7)	18.0 (14.3)	18.0	17.9	17.8

a) The basal spacing of minor phase is shown in parenthesis. b) f.s. shows free swelling.

x'=0.32 with decreasing x-value. Although solid state reaction was attempted repeatedly for the samples of x=0.2—0.1 at 1450°C for prolonged times in a sealed platinum tube, no x'-value lower than 0.32 was found. These results suggest that the micas having the desired compositions precipitated in the range x=1.0—0.4 and that there is a limitation in the variability of layer charge for the Na-micas. At present it is not clear whether this limitation originates from synthetic conditions or crystallochemical factors such as the weakening of the interlayer bonding in the mica structure.

Table 1 gives the basal spacings of the Na-micas which were wetted with water, ethylene glycol, and glycerol for at least 2 h. The basal spacings of minor phases simultaneously observed are also shown in parentheses. In contact with water, all the micas of the series with layer charge lower than 0.5 exhibited so-called free swelling: X-ray patterns show diffuse scattering at low angles. It is clearly seen in Table 1 that the Na-micas undergo either free swelling or limited swelling according to the magnitude of layer charge. Our study shows also that there is a critical point at the layer charge where the maximum basal spacing is limited to either 15.1 Å of double-layer hydrate or 18.4 Å of three-layer hydrate state. The coexistence of two hydrate phases can be explained by the heterogeneity of layer charge in successive layers and also by the kinetics of swelling. Accordingly, the actual layer charge obtained from chemical analysis should be considered as the mean value of the successive layers. In contact with ethylene glycol, the formed complexes gave the basal spacing ranging from 12.3 Å to 16.7 Å, suggesting that the arrangement of ethylene glycol molecules in the interlayer regions is dependent upon the magnitude of layer charge. The basal spacings of 12.3 Å and 16.7 Å correspond to a single-layer[4] and a double-layer complex,[5] respectively. The boundary between the double-layer complex and single-layer one appears at about x=0.7. In contact with glycerol, the complexes gave the basal spacing ranging from 12.7 Å (single-layer) to 18.0 Å (double-layer). The 14.2 Å phase may also correspond to a single-layer complex with a different arrangement of glycerol molecules. The boundaries between the complexes of glycerol appear at the layer charge of x=0.9 and x=0.5.

It is concluded from these results that the expansion of basal spacings in the expansible fluorine micas becomes greater as the layer charge decreases whatever the solvation is. This can be attributed to the weakening of interlayer coulombic force resulted from the decrease of layer charge and also to the increase of the density of interlayer vacancies.

Redox Behavior of *N,N'*-Ethylenebis(salicylideneaminato)-bis(triphenylphosphine)ruthenium(II)

Hideo DOINE,* Francis F. STEPHENS, and Roderick D. CANNON†
College of Industrial Technology, Nihon University, 2-1 Izumicho, Narashino-shi, Chiba 275
†*School of Chemical Sciences, University of East Anglia, Norwich NR4 7TJ, England*
(Received October 1, 1984)

Synopsis. Visible spectra and electrochemical behavior of the title complex [Ru{C_2H_4(N=CHC_6H_4O-*o*)$_2$}{P(C_6H_5)$_3$}$_2$] (**I**) are reported. The redox potentials of the ruthenium complex were determined at 25 °C to be E°= 0.27±0.01 V (in CH_2Cl_2) and −0.161±0.005 V (in CH_3OH), relative to $E^\circ(Fe(C_5H_5)_2)^{+/0})$=0.400 V.

In the previous electrochemical studies of binuclear complexes,[1] cyclic voltammetric data on ruthenium-(II) Schiff-base complexes were reported. In this study, the redox potentials of the title compound **I** have been first measured and the compound was found to be a convenient reference material for testing the electrochemical cell system from the following fact: the title complex is soluble enough for the electrochemical measurement in both polar and nonpolar solvents, and the oxidation states of ruthenium ion in the complex **I** have no influence on the observed redox potentials. The complex was first synthesized by Thornback and Wilkinson[2] and found to be extremely air-sensitive. When the absorption spectra of the carefully prepared solutions of the complex **I** in deaerated solvents are compared with those previously reported,[3] it appears that the latter corresponds to an oxidized ruthenium(III) species. We have reinvestigated the preparation, handling and redox properties of the complex.

Preparation

The complex $RuCl_2(PPh_3)_3$[4] (0.20 g) was added under nitrogen to a solution of *N,N'*-ethylenebis (salicylideneamine) (H_2L)[5] (0.058 g) and Et_3N (1 ml) in THF in a flask having sintered glass filter-outlet already fitted. After refluxing 2 h some white solid was filtered off under nitrogen pressure. The solvent was removed, and the product was pumped dry, washed with petroleum (40—60°), and recrystallized under nitrogen by dissolving in a little THF and adding excess petroleum. The by-product Et_3NHCl was effectively removed in this way, mp 130—140°(dec). Found: C, 69.1; H, 5.07; N, 3.16%. Calcd for $C_{52}H_{44}N_2O_2P_2Ru$, C, 70.0; H, 4.94; N, 3.14%.

Results

Oxidation State. The complex **I** is readily oxidized by iodine and $FeCl_3$ in nonaqueous solvents but attempts to verify the stoichiometry by spectrophotometric and potentiometric titrations gave irreproducible results. This problem was overcome using a two-phase method as follows. An aliquot of **I** was weighed into a dry flask. The air was displaced with oxygen-free nitrogen, and a measured volume of a freshly prepared solution of resublimed iodine in methanol was added. After the reaction was complete

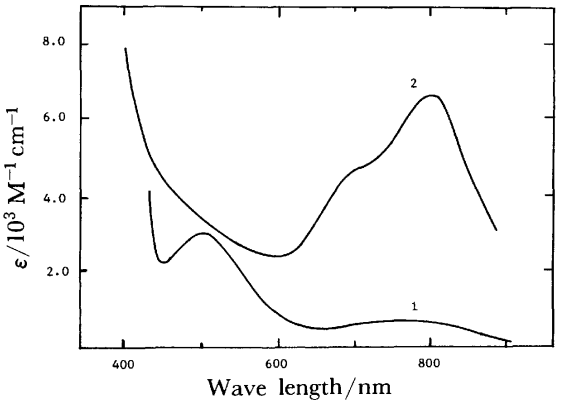

Fig. 1. Spectrum (1) of $RuL(PPh_3)_2$, and (2) of the product on air-oxidation, both in THF, where 1 M=1 mol dm^{-3}.

(5 min were allowed) 5 ml of toluene was added, then an aliquot of aqueous sodium thiosulfate. After shaking, the aqueous layer was run off, and the organic phase was washed with water. The combined extracts were back-titrated with iodine in methanol using starch indicator. The iodine solution was standardized by direct titration with the $Na_2S_2O_3$, and the experiment was repeated with various amounts of **I** and iodine. Molar ratios [Ru complex (added)]/[I_2(consumed)] were found to be 1.94±0.09 from 10 titrations.

Absorption Spectra and Electrochemical Properties. The purple-brown crystalline complex **I** is stable in air when dry, but for quantitative work it was stored under nitrogen. The solution in THF is pink-brown with λ_{max}=770 nm and 505 nm (Fig. 1). On admitting oxygen the THF solution changed rapidly to green with an increase in intensity, and the resulting absorption spectrum (2 in Fig. 1) was similar to that reported by West *et al.*[3] Similar color changes were noted in the solvents CH_2Cl_2 and MeOH, ease of oxidation increasing in the order THF<CH_2Cl_2<MeOH.

The spectra of oxidized and reduced forms have sharp isosbestic points (Fig. 2).

Cyclic voltammetry, in organic solvents under nitrogen, showed a single wave with equal anodic and cathodic peak heights, proportional to Ru concentration. The free ligand H_2L was inactive in the range studied (−0.8 to +0.9 V). The same signal was observed for both the solutions of **I** and air-oxidized form of **I**. On adding iodine, the anodic wave was supressed. In the presence of oxygen also, the anodic wave was supressed but on resuming the nitrogen flow the original peaks reappeared. The wave is assigned to the $Ru^{III/II}$ couple. In methanol, the couple is highly reversible, as judged by the peak-to-peak separations ΔE_{pp} and by the lack of dependence on scan rate. (ΔE_{pp}=60 mV, scan rate 100 to 2000 mV s^{-1}, with 0.1

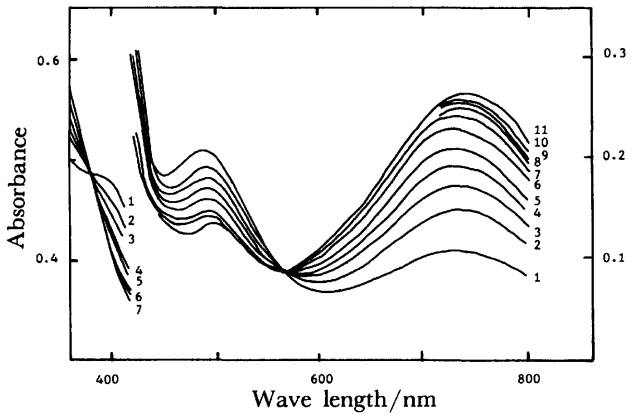

Fig. 2. Spectra (1) of $RuL(PPh_3)_2$, and (2—11) with successive addition of O_2. In methanol, $[Ru]_T = 3.34 \times 10^{-5}$ mol dm^{-3}, cell length of 1 cm.

mol dm^{-3} $NaClO_4$ supporting electrolyte. With 0.1 mol dm^{-3} [n-Bu_4N][BF_4], ΔE_{pp}=90 mV). In CH_2Cl_2, ΔE_{pp} increased from 120 mV at V=20 mV s^{-1} to 150 mV at 100 mV s^{-1}, and at 1000 mV s^{-1} another wave appeared at *ca.* −0.55 V. In THF the couple was found to be quasi-reversible, ΔE_{pp}=170 mV. Redox potentials were determined as $E_{1/2}$=0.27±0.01 V (in CH_2Cl_2); and $E_{1/2}$=−0.161±0.005 V (in MeOH, with 0.1 mol dm^{-3} n-$Bu_4N[ClO_4]$), based on $E^\ominus$ ($Fe(C_5H_5)_2^{+/0}$)=0.400 V.[6]

Enantioface-differentiating Addition of Butyllithium to Acetophenone by the Use of (1*S*,2*S*,5*S*)-3-[(*S*)-2-Methoxy-1-alkylethylimino]-2-pinanols as Chiral Ligands

Yuhsuke KAWAKAMI,* Toshiki AOKI, and Yuya YAMASHITA

Department of Synthetic Chemistry, Faculty of Engineering, Nagoya University, Furo-cho, Chikusa-ku, Nagoya 464

(Received May 30, 1984)

Synopsis. Butyllithium and acetophenone gave optically active 2-phenyl-2-hexanol (33% e.e.) in good yield in the presence of (1*S*,2*S*,5*S*)-3-[(*S*)-2-methoxy-1-alkylethylimino]-2-pinanol (**1**).

Although successful asymmetric reductions of prochiral ketones to optically active secondary alcohols by chiral hydride reagents have been extensively reported,[1,2] studies on enantioface-differentiating additions by metal alkyls to yield optically active tertiary alcohols are limited.[3-6] We wish to report here an example of asymmetric addition of butyllithium (BuLi) to acetophenone in the presence of chiral ligands.

Experimental

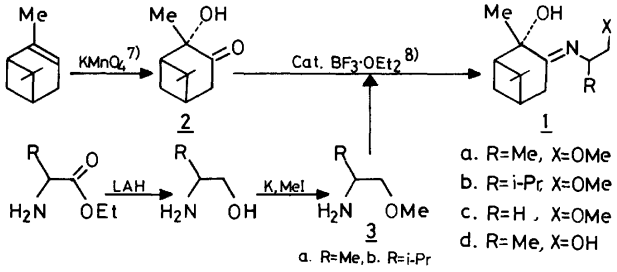
General. The ^{1}H NMR spectra were recorded at 60 MHz with tetramethylsilane as an internal standard, and the chemical shifts are given in δ values.

Syntheses of the Schiff Bases. The Schiff bases (**1a—1d**) used in this study as chiral ligands were synthesized according to Scheme 1.

(1S,2S,5S)-3-[(S)- or (R)-2-Methoxy-1-methylethylimino]-2-pinanol ((S)- or (R)-1a): (1*S*,2*S*,5*S*)-2-Hydroxy-3-pinanone (**2**) (4.1 g, 25 mmol) was caused to react with (*S*)-1-methoxy-2-propanamine ((*S*)-**3a**) (3.3 g, 37 mmol) in dichloromethane under reflux for 4 h. After quenching with sodium carbonate, (*S*)- or (*R*)-**1a** was isolated by distillation (3.7 g, 67%). Other Schiff bases (1*S*,2*S*,5*S*)-3-[(*S*)-2-methoxy-1-isopropyl-ethylimino]-2-pinanol ((*S*)-**1b**), (1*S*,2*S*,5*S*)-3-[2-methoxyethylimino]-2-pinanol **1c**), and (1*S*,2*S*,5*S*)-3-[(*S*)-2-hydroxy-1-methylethylimino]-2-pinanol ((*S*)-**1d**) were synthesized similarly to (*S*)-**1a**. Physical constants of the schiff bases are shown in Table 1.

Typical Asymmetric Addition Reactions to Aectophenone. In situ *System*: BuLi (4.6 mmol) was subjected to react with (*S*)-**1a** (0.3 g, 1.3 mmol) for 1 h in hexane (23 ml) at room temperature. After the reaction system was cooled down to −78 °C, acetophenone (0.16 g, 1.3 mmol) was added, and the reaction was quenched with 1 M hydrochloric acid (6 ml (1 M = 1 mol dm^{-3})) after 2 h. After usual work-up, 2-phenyl-2-hexanol was isolated by column chromatography (silica gel, ethyl acetate).

Prereacted System: After the reaction of BuLi with (*S*)-**1a** in specified molar ratio for 1 h, the reaction system was evacuated under vacuum, and the solid product was washed with hexane for several times. The product was suspended in hexane and treated with newly added one equivalent BuLi for 1 h. Acetophenone was added to the reaction system and allowed to react for 2 h.



Scheme 1. Synthetic routes to the chiral ligands. Me, MeO, and *i*-Pr are methyl, methoxyl, and isopropyl groups, respectively.

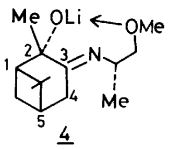
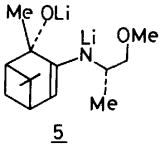
The enantiomeric excess (% e.e.) was determined by the α-methyl signal splitting in ^{1}H NMR using chiral shift reagent, tris[3-(trifluoromethylhydroxymethylene)-*d*-camphorate]europium (III) (Eu(tfc)$_3$).[9]

Results and Discussion

Species Responsible for Asymmetric Induction. ^{1}H NMR and IR spectra of the reaction system of BuLi and (*S*)-**1a** indicated the structure **4** for the reaction product in 1:1 molar ratio. Peak broadening of the methylene protons of BuLi in the ^{1}H NMR of the reaction system in 2:1 molar ratio suggested that the principal product in this molar ratio was the associated species of BuLi with **4**. In the ^{1}H NMR of the product in 3.5:1 molar ratio, not only peak broadening but also further changes were observed: C-4 Methylene signal decreased and a new peak appeared around at 4.5 ppm. This signal is assignable to olefinic proton of lithioenamine.[10] Quantitative analysis of Li (5.68%) and incorporation of deuterium atom at 4-position by quenching with dilute D_2O–DCl strongly suggested the formation of lithioenamine **5** in the reaction of 3.5:1 molar ratio.



4



5

The results of asymmetric addition are shown in Table 2. The reaction did not proceed when less than two equimolar amounts of BuLi to (*S*)-**1a** were used. No reaction was observed either, when one equivalent BuLi was added to prereacted system **4** (run No. 9). Only small optical yield was obtained in 3:1 *in situ* system (No. 2), or when one equivalent BuLi was added to the prereacted system (2:1) (No. 10), although high chemical yield could be attained. The species of 3.5:1 systems gave reasonably high chemical and optical yields (No. 3, 11), and the highest optical yield was obtained when one equivalent BuLi was used with 3.5:1 prereacted system (No. 12). Only small asymmetric induction was observed when acetophenone was added immediately after (*S*)-**1a** was mixed with 3.5 mole equivalent BuLi at −78°C. Since formation of **5** from BuLi and **4** takes a little time, the above mentioned facts strongly indicate the importance of the formation of lithioenamine **5** in the asymmetric induction. It seems that species responsible for the asymmetric addition is formed through the interaction of BuLi with **5**, and that the contribution of the species is the highest at 3.5:1 molar ratio in *in situ* system. The optical yield decreased when the molar ratio became higher than 4:1, although chemical yield remained high. Under this condition, proportion of free BuLi which added to acetophenone without the influence of chiral ligand system **5** is high, resulting in a decrease of the optical yield.

Effects of α-Substituent on Optical Yield. The effects of the configuration, and alkyl substituent at α-carbon of imino ether component of **1** are also shown in Table 2. Bulky substituent at α-carbon seems to have higher regulating power (No. 6). (*R*)-**1a** gave opposite sign in the product (No. 4). These facts indicate that α-substituent directly influences the enantioface-selection, and that in BuLi-(*S*)-**1** systems, the regulation by α-alkyl group and pinane skeleton work to same direction, but in (*R*)-**1** to opposite direction. This speculation is supported by that in BuLi-**1c** system, where no substituent was attached to α-carbon, small positive value was observed by the influence of pinane skeleton (No. 7). Racemic **1a** gave small (−) value for the product (No. 5). Imino alcohol ligand (*S*)-**1d** showed only a weak regulating power (No. 8), which indicates the importance of methoxyl group in the ligand **1** to form species responsible for the asymmetric induction.

Change of Orientation in Photoreaction by Oxygen. Effect of Oxygen on Photo-methoxylation of Dimethyl Esters of 2,4- and 3,4-Pyridinedicarboxylic Acid

Toru SUGIYAMA,* Mitsuharu KANAI, Setsuko TAKENAKA, and Akira SUGIMORI*

(Received August 7, 1984)

Synopsis. The UV-irradiation of dimethyl 2,4- and 3,4-pyridinedicarboxylates in methanol in the presence of H_2SO_4 under O_2 brings about methoxylation at the β- position of the pyridine ring, while under N_2 methoxylation occurs at the α-position.

In a preceding paper,[1] we described a remarkable effect of oxygen on the photoreaction of methyl 4-pyridinecarboxylate in methanol: Even a small amount of oxygen causes a change of orientation in the photo-methoxylation. The role of oxygen cannot be explained by any generally accepted effect (the acceleration of intersystem crossing or charge-transfer interaction). To survey the scope of this novel types of effect, we have studied the effect of oxygen on the photoreactions of dimethyl pyridinedicarboxylates in acidic methanolic solutions.

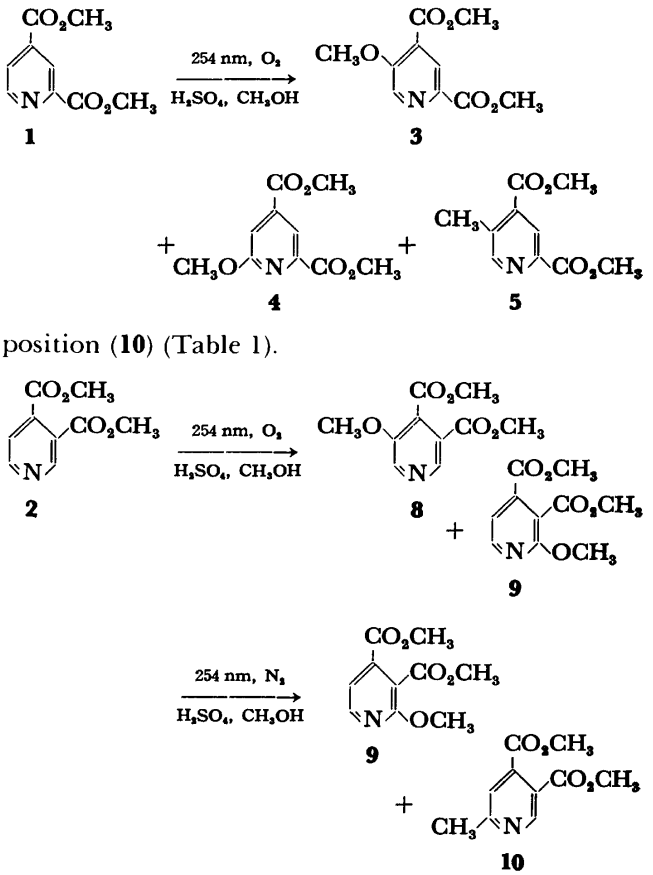
Results and Discussion

Photoreactions in the Presence or in the Absence of O_2. Similar to the photoreaction of 4-pyridinecarboxylic ester, the photoreactions of dimethyl pyridinedicarboxylates show a remarkable oxygen effect: Oxygen causes the change of the position of methoxylation at the α-position of the pyridine ring into that at the β-position.

UV-irradiation of dimethyl 2,4-pyridinedicarboxylate (**1**) under N_2 in methanol in the presence of H_2SO_4 brings about methoxylation mainly at the 6-position of the pyridine ring (**4**), accompanied by the methylation at the 5- and 6-positions (**5**),(**6**) and hydroxymethylation at the 6-position (**7**) in low yields (Table 1).[2]

On the other hand, under O_2 these reactions are supperssed and the methoxylation at the 5-position (**3**) predominates (Table 1).

Dimethyl 3,4-pyridinedicarboxylate (**2**) undergoes photo-methoxylation at the 5-position (**8**) under O_2, while under N_2 the methoxylation occurs only at the 2-position (**9**), accompanied by methylation at the 6-position (**10**) (Table 1).



Role of Oxygen for the Methoxylation at the β-Position. Similar to the case of 4-pyridinecarboxylic ester in the photo-methoxylation at the β-position,[1] oxygen does not serve as an oxidant in the methoxylation at the β-position of pyridinedicarboxylic esters because after the irradiation of **1** under N_2 the addition of $K_3[Fe(CN)_6]$ or bubbling oxygen has no effect on the formation of the methoxylated product at the 5-position (Table 1).

a) $[\mathbf{1}]=[\mathbf{2}]=0.01\,mol\,dm^{-3}$; $[H_2SO_4]=1.0\,mol\,dm^{-3}$; Irradiation time, 1 h; Temp., 30 °C. b) Yields are based on the amount of **1** and **2** consumed. c) O_2 was bubbled after the irradiation. d) $K_3[Fe(CN)_6]$ was added after the irradiation. e) $[Ph_2CO]=0.05\,mol\,dm^{-3}$; irradiated for 2.5 h with a 100 W high pressure mercury lamp through 365 nm filter.

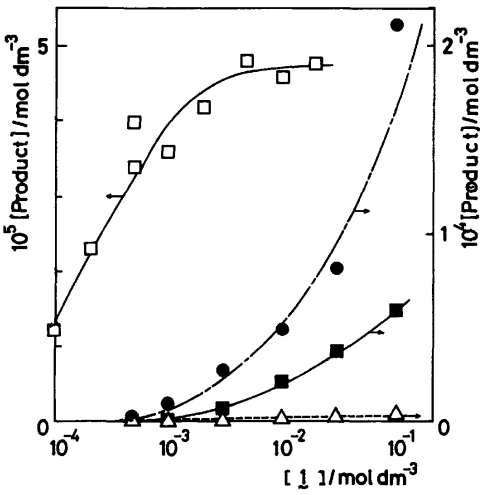

Fig. 1. Dependences of the photoreactions of **1** under O_2 and under N_2 on the concentration of **1**.
-●---: **3**; -■—: **4**; --△---: **5** (under O_2); -□—: **4** (under N_2).

When the irradiation of **1** with 365 nm light was carried out in the presence of benzophenone under N_2, the methoxylation at the 5-position was not observed as is shown in Table 1. *trans*-1,3-Pentadiene, a triplet quencher, does not quench the reaction. These facts indicate that the methoxylation at the β-position occurs from an excited singlet state of the pyridinium form of **1** and thus oxygen does not accelerate the intersystem crossing from the excited singlet state to the triplet excited state.

Because the UV-absorption spectra of **1** in acetonitrile were not markdly affected by oxygen, it is concluded that under these conditions the contribution of a ground state contact charge-transfer complex between the protonated **1** and O_2 is very improbable. Similar oxygen effects were also observed in the photomethoxylation at the β-position of 4-pyridinecarboxylic ester.[1]

Since the methoxylation at the 6-position of **1** under N_2 shows the dependence on the concentration of the substrate, the reaction may proceed *via* an excimer.[2] The methoxylation of **1** at the 6- and 5-positions under O_2 are also more dependent on the concentration of the substrate over the range of higher concentration than that under N_2 as are shown in Fig. 1. It is noteworthy that the concentration dependence curves of the methoxylations are not reduced by oxygen but are shifted to the region of higher concentrations in the presence of oxygen. These results indicate that the decrease of the methoxylation at the 6-position is not due to the quenching of the excimer by oxygen. The participation of another excited complex in the reaction can be presumed. It may be an excited terplex which consists of two molecules of protonated **1** and one molecule of oxygen.

Experimental

Materials. Dimethyl pyridinedicarboxylates (**1**, **2**) were synthesized by the esterification of pyridinedicarboxylic acids with methanol in the presence of hydrogen chloride.

UV-irradiation. Through the solutions of **1** or **2** (0.01 mol dm^{-3}) containing 1.0 mol dm^{-3} of H_2SO_4, O_2, or N_2 were bubbled for 45 min before irradiation. The solutions were irradiated with a 17 W low pressure mercury lamp at 30 °C.

Isolation and Identification of Photo-products. After the irradiation, the solutions were concentrated under reduced pressure, were neutralized with sodium carbonate, and were extracted with ethyl acetate. The products were separated by means of TLC (plate, GF_{254} (Type 60) of E. Merck Co.; developing solvent, ethyl acetate–dichloromethane 1:4) or by means of GLC (column, PEG 20 M 2%, 2 m on Celite 545 (60/80 mesh); Temp., 200 °C) with a Ohkura gas chromatograph model GC 103.

Dimethyl 5-methoxy-2,4-pyridinedicarboxylate (**3**), mp 142—144 °C; ^{1}H NMR ($CDCl_3$) δ=8.52 (1H, s, H at 6-position), 8.42 (1H, s, H at 3-position), 4.09 (3H, s, OCH_3), 3.99 and 3.94 (6H, s, CO_2CH_3); IR (KBr) 1726 and 1714 (ester C=O) and 1255 cm^{-1} (C–O–C); MS (70 eV), *m/z* (rel intensity), 225 (M^+; 11), 195 (14), 194 (18), 167 (100), and 166 (18). Found: *m/z* 225.0649. Calcd for $C_{10}H_{11}NO_5$: M, 225.0636; Found: C, 53.01; H, 5.02; N, 6.38%. Calcd for $C_{10}H_{11}NO_5$: C, 53.33; H, 4.92; N, 6.22%.

Other photo-products of **1** (**4**—**7**) see Ref. 2.

Dimethyl 5-methoxy-3,4-pyridinedicarboxylate (**8**), mp 67—68 °C (lit,[3] 78—80 °C); ^{1}H NMR ($CDCl_3$) δ=8.82 (1H, s, H at 2-position), 8.48 (1H, s, H at 6-position), 3.93 (3H, s, OCH_3), 3.90 and 3.88 (6H, s, CO_2CH_3); IR (KBr), 1750 and 1730(ester C=O) and 1245 cm (C–O–C); MS (70 eV), *m/z* (rel intensity), 225 (M^+; 37), 194 (100), 193 (21), 166 (24), and 135 (20). Found: *m/z* 225.0637.

Dimethyl 2-methoxy-3,4-pyridinedicarboxylate (**9**), mp 48—51 °C; ^{1}H NMR ($CDCl_3$) δ=8.24 (1H, d, J=5 Hz, H at 6-position), 7.32 (1H, d, J=5 Hz, H at 5-position), 3.96 (3H,s,OCH_3), 3.90 and 3.87 (6H, s, CO_2CH_3); IR (KBr), 1730 (ester C=O) and 1270 cm^{-1}(C–O–C); MS (70 eV), *m/z* (rel intensity), 225 (M^+; 43), 195 (11), 194 (100), 193 (31), 180 (39), and 135 (31). Found: *m/z* 225.0637. Calcd for $C_{10}H_{11}NO_5$: M, 225.0636; Found: C, 53.23; H, 5.04; N, 6.18%. Calcd for $C_{10}H_{11}NO_5$: C, 53.33; H, 4.92; N, 6.22%.

Dimethyl 6-methyl-3,4-pyridinedicarboxylate (**10**), mp 63—64 °C; ^{1}H NMR ($CDCl_3$) δ=8.96 (1H, s, H at 2-position), 7.30 (1H, s, H at 5-position), 3.93 and 3.90 (6H, s, CO_2CH_3), and 2.65 (3H, s, CH_3); IR (KBr), 1742 and 1720 cm^{-1} (ester C=O); MS (70 eV), *m/z* (rel intensity), 209 (M^+; 19), 208 (12), 179 (24), 178 (100), and 150 (11). Found: *m/z* 209.0691.

Qunatitative Analysis of Photo-products. The yields of the products were determined by means of HPLC (column, 4.0 mm×25 cm column of Lichrosorb RP-18, 7 μm: eluent, H_2O–CH_3CN 8:2 or 81:19 v/v) with a Shimadzu liquid chromatograph model LC 3A or with a Hitachi model 655 and/or by means of GLC (column, PEG 20 M 5%, 1 m on Celite 545 (60/80 mesh)) with a Shimadzu gas chromatograph model GC 6A.

Spectral Measurements. ^{1}H NMR spectra were recorded on a Hitachi R 22 NMR spectrometer (90 MHz) with tetramethylsilane as an internal standard and IR spectra were measured on a Hitachi 260—50 spectrometer. Mass spectra were determined with a JEOL D-300 spectrometer. UV spectra were recorded on a Hitachi 228 spectrophotometer.

Synthesis of Cylindrical Large Ring Crown Hosts

Kazuya KOBIRO,* Katsuhiro OHNISHI, Kiyomi KAKIUCHI, Yoshito TOBE, and Yoshinobu ODAIRA
Department of Applied Fine Chemistry, Faculty of Engineering, Osaka University, Suita, Osaka 565
(Received September 20, 1984)

Synopsis. New cylindrical crown hosts, tridecalino-27-crown-9, tridecalino-21-crown-7, didecalino-cyclohexano-21-crown-7, and didecalinio-21-crown-7 have been synthesized.

In resemblance to naturally occurring cyclic antibiotics, increasing interests are being shown in the large ring crown hosts such as 27-crown-9 and 21-crown-7.[1] As part of the study of a new type of cylindrical crown host (Fig. 1), we have previously revealed that didecalino-18-crown-6† exhibits an excellent complexing ability and conspicuous stoichioselectivity toward alkali metal ions due to the remarkable embedding effect of decalin moieties.[2,3] In this connection, we report herein the synthesis of novel cylindrical large ring crown hosts, *i.e.*, tridecalino-27-crown-9 (**8**), tridecalino-21-crown-7 (**9**), didecalino-cyclohexano-21-crown-7† (**10**), and didecalino-21-crown-7 (**11**), which would be expected to form complexes with organic guest cations.

Cylindrical crown host tridecalino-27-crown-9 (**8**) was synthesized as outlined in Scheme 1. Reaction of *cis*-4*a*,8*a*-decalindiol (**1**) with diethylene glycol ditosylate gave didecalinodiol **2** in 27% yield. Williamson synthesis of **2** with chloroacetic acid followed by esterification and hydride reduction produced "two-arm" alcohol **4** in 36% overall yield. Similarly, "two-arm" tosylate **7** was synthesized from **1** in 57% overall yield. According to similar synthetic routes, **9**, **10**, and **11** were also synthesized from **2** with appropriate "two-arm" tosylates (**9**: 6.5%, semisolid; **10**: 2.0%, oily; **11**: 4.9%, oily). Thus we could synthesize cylindrical crown hosts in spite of difficulties which were easily expected for the etherification of the tertiary alcohol. Moreover, it was proved that the synthetic method using chloroacetic acid was very useful for the synthesis of cylindrical crown hosts.

Studies on the complexing abilities of these cylindrical large ring crown hosts with various organic cations, such as guanidinium cation,[4] are in progress.[5]

Experimental

IR spectra were recorded using a Hitachi 260-10 spectrometer. ^1H and ^{13}C NMR spectra were obtained on a JEOL JNM-PS-100 and JEOL JNM-FX-60 spectrometer respectively, using Me_4Si as an internal standard and $CDCl_3$ as a solvent unless otherwise stated. Mass spectra were measured with a Hitachi RMU-6E spectrometer.

1,2:10,11-Didecalino-3,6,9-trioxaundecane-1,11-diol (2). A mixture of 10.0 g (59 mmol) of **1**,[2] 1.68 g (70 mmol) of NaH, and 80 ml of *N*,*N*-dimethylformamide (DMF) was stirred for 1 h at room temperature. To this mixture a solution of 12.0 g (29 mmol) of diethylene glycol ditosylate[6] in 80 ml of DMF was added dropwise and the mixture was stirred for 57 h. After addition of small amount of water, the reaction mixture was filtered through Celite. The filtrate was evaporated, and the residue was extracted with chloroform. The organic layer was washed with water, dried ($MgSO_4$), and evaporated. 5.80 g (58%) of **1** was recovered by vacuum distillation (155 °C/1.5 Torr (1 Torr=133.322 Pa)) and the residue (>160 °C/1.5 Torr) was chromatographed over silica gel to give additional 0.47 g (5%) of **1** (ether/petroleum ether=3/7) and 3.3 g (27%) of **5** (ether/petroleum ether=5/5) as a colorless oil: IR (neat) 3550, 1080 cm^{-1}; ^1H NMR δ=1.00—2.16 (m, 32H), 2.42 (br s, 2H), 3.48—3.88 (m, 8H); MS *m/z* 392 (M^+-H_2O). Found: C, 70.27; H, 10.61%. Calcd for $C_{24}H_{42}O_5$: C, 70.20; H, 10.31%.

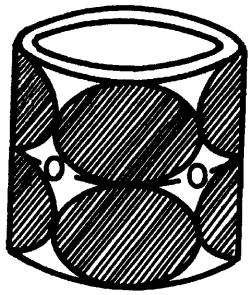

Fig. 1.

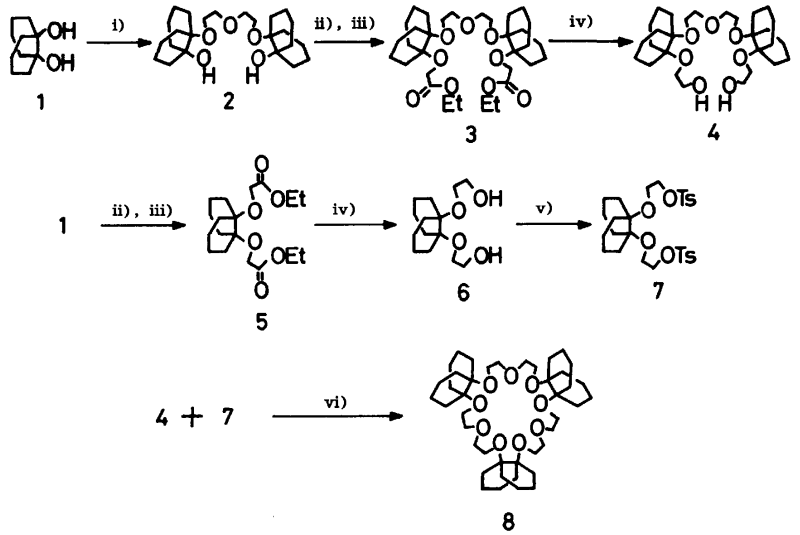
4,5:13,14-Didecalino-3,6,9,12,15-pentaoxaheptadecanedioic Acid Diethyl Ester (3). A mixture of 6.36 g (16 mmol) of **2** and 2.23 g (93 mmol) of NaH in 150 ml of tetrahydrofuran (THF) was refluxed for 1.5 h under N_2. To this suspension was added dropwise a solution of 3.66 g (39 mmol) of chloroacetic acid in 50 ml of THF. The mixture was stirred under reflux for 15 h. After addition of water (2 ml), the solvent was evaporated and 50 ml of water was added to the residue. The aqueous solution was acidified with concentrated aqueous HCl and extracted with chloroform. The organic phase was dried ($MgSO_4$) and evaporated to afford 10.1 g of oil. This crude oil was dissolved in 90 ml of 1:1 mixture of absolute ethanol and benzene, and 0.13 g of *p*-toluenesulfonic acid was added. The mixture was refluxed for 10 h, with continuous circulation of condensed vapor through anhydrous Na_2SO_4. After removal of the solvent, the residue was dissolved in dichloromethane, washed with aqueous $NaHCO_3$ and brine, and dried ($MgSO_4$). The solvent was evaporated to afford 9.27 g of oil. The crude product was chromatographed over silica gel to give 3.78 g (42%) of **3** and 1.51 g (24%) of unreacted diol **2** (ether/petroleum ether=3/7): IR (neat) 1750, 1720 cm^{-1}; ^1H NMR δ=1.00—2.60 (m, t at 1.28, 38H), 3.32—3.88 (m, 8H), 4.18 (q, 4H), 4.32 (d, 4H); MS *m/z* 582 (M^+). Found: C, 66.04; H, 9.64%. Calcd for $C_{32}H_{54}O_9$: C, 65.95; H, 9.34%.

4,5:13,14-Didecalino-3,6,9,12,15-pentaoxaheptadecane-1,17-diol (4). Ester **3** (3.65 g, 6.27 mmol) was reduced with 0.63 g (17 mmol) of lithium aluminum hydride (LAH) in 30 ml of boiling THF. Usual workup gave 2.63 g (84%) of **4** as a colorless oil: IR (neat) 3400, 1090 cm^{-1}; ^1H NMR δ=1.00—2.20 (m, 32H), 3.00—4.00 (m, 18H); MS *m/z* 498 (M^+). Found: C, 67.25; H, 10.29%. Calcd for $C_{28}H_{50}O_7$: C, 67.43; H, 10.11%.

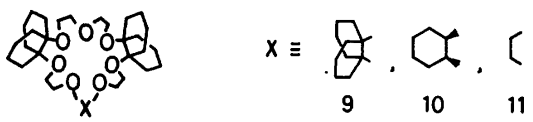
4,5-Decalino-3,6-dioxaoctane-1,8-diol (6). Ester **5** was prepared from **1** according to the similar procedure described for **3** in 70% yield as an oil: bp 131—132 °C/0.3 Torr; IR (neat) 1750, 1730 cm^{-1}; ^1H NMR (CCl_4) δ=1.00—2.20 (m, t at 1.24, 22H), 3.92—4.24 (m, 8H); MS *m/z* 342 (M^+).

†Ortho-fused cyclic compounds are tentatively named "decalino" and "cyclohexano" for decahydronaphtho[4*a*,8*a*] and perhydrobenzo respectively.



i) $TsOCH_2CH_2OCH_2CH_2OTs$, NaH, DMF; ii) $ClCH_2COOH$, NaH, THF; iii) EtOH, TsOH, C_6H_6; iv) $LiAlH_4$, THF; v) TsCl, C_5H_5N; vi) NaH, THF.

Scheme 1.



Found: C, 63.42; H, 8.93%. Calcd for $C_{18}H_{30}O_6$: C, 63.13; H, 8.83%. LAH reduction of **5** gave **6** in 85% yield after recrystallization from ligroin: mp 83—85 °C; IR (KBr) 3400, 3310, 1095, 1060 cm^{-1}; ^1H NMR (CCl_4) δ=1.00—2.40 (m, 16H), 3.00—4.12 (m, 10H); MS *m/z* 258 (M^+). Found: C, 64.96; H, 10.17%. Calcd for $C_{14}H_{26}O_4$: C, 65.08; H, 10.14%.

4,5-Decalino-3,6-dioxaoctane-1,8-diol Ditosylate (7). **7** was prepared from **6** by the method similar to that of Dale and Kristiansen[6] in 96% yield after recrystallization from ethanol: mp 97—99 °C; IR (KBr) 3050, 1595, 1350, 1170 cm^{-1}; ^1H NMR δ=1.00—2.00 (m, 16H), 2.40 (s, 6H), 3.20—3.80 (m, 4H), 3.92—4.12 (2d, 4H), 7.42 (AB q, 8H). Found: C, 59.05; H, 6.80; S, 11.25%. Calcd for $C_{28}H_{38}O_8S_2$: C, 59.34; H, 6.76; S, 11.31%.

Tridecalino-27-crown-9 (8). To a refluxing mixture of 1.99 g (4.0 mmol) of diol **4** and 0.48 g (20 mmol) of NaH in 100 ml of THF was added dropwise over 10 h a solution of 2.26 g (4.0 mmol) of **7** in 50 ml of THF. The mixture was refluxed for 36 h, and then another 2.26 g (4.0 mmol) of **7** in 50 ml of THF was added over 10 h. The mixture was refluxed for 36 h and cooled. Water (2 ml) was added and the solvent was evaporated. The residue was extracted with dichloromethane and dried ($MgSO_4$), and the solvent was removed to give 4.69 g of oil. This oil was chromatographed over silica gel (ether/petroleum ether=5/5) to afford 1.01 g (35%) of **8**, which was recrystallized from ether: mp 90—91 °C; IR (KBr) 1080 cm^{-1}; ^1H NMR δ=1.00—2.00 (m, 48H), 3.20—3.92 (m, 24H); ^{13}C NMR (57 °C) δ=22.0 (t, 12C), 30.3 (t, 12C), 60.7 (t, 6C), 71.2 (t, 6C), 77.9 (s, 6C); MS *m/z* 614 ($M^+-C_4H_{10}O_3$ (diethylene glycol)). Found: C, 69.95; H, 10.07%. Calcd for $C_{42}H_{72}O_9$: C, 69.96; H, 10.07%.

Tridecalino-21-crown-7 (9). A solution of 0.33 g (0.58 mmol) of **7** and 0.24 g (0.58 mmol) of **2** in 20 ml of DMF was added to a suspension of 0.28 g (12 mmol) of NaH in 50 ml of DMF over 3 h under N_2 at room temperature and the mixture was stirred for 7 d. Workup as described above gave 24 mg (6.5%) of **9** as a semisolid and 155 mg of recovered diol **2** (65%): IR (neat) 1080 cm^{-1}; ^1H NMR δ=1.00—2.40 (m, 48H), 3.28—4.00 (m, 16H); MS *m/z* 632 (M^+). Found: C, 72.33; H, 10.30%. Calcd for $C_{38}H_{64}O_7$: C, 72.11; H, 10.19%.

Didecalino-cyclohexano-21-crown-7 (10). Reaction of 3.86 g (9.4 mmol) of **2**, 4.82 g (9.4 mmol) of 4,5-cyclohexano-3,6-dioxaoctane-1,8-diol ditosylate prepared from *cis*-cyclohexane-1,2-diol according to the similar method described for **7**, and 4.5 g of NaH in 300 ml of DMF for 7 d gave 3.5 g (93%) of unreacted diol **2** and 11 mg (2.0%) of **10** as an oil: IR (neat) 1080 cm^{-1}, ^1H NMR δ=1.00—2.20 (m, 40H), 3.20—4.00 (m, 18H); MS *m/z* 578 (M^+). Found: C, 70.31; H, 10.21%. Calcd for $C_{34}H_{58}O_7$: C, 70.55; H, 10.10%.

Didecalino-21-crown-7 (11). Reaction of 11.4 g (27.8 mmol) of **2**, 57.6 g (126 mmol) of triethylene glycol ditosylate,[6] and 12.6 g (525 mmol) of NaH in 550 ml of DMF for 7 d gave 7.5 g (66%) of unreacted diol **2** and 72 mg (4.9%) of **11** as an oil: IR (neat) 1080 cm^{-1}; ^1H NMR δ=1.12—2.10 (m, 32H), 3.24—4.00 (m, 20H); MS *m/z* 419 ($M^+-C_4H_9O_3$ (diethylene glycol-H)). Found: C, 68.54; H, 9.95%. Calcd for $C_{30}H_{52}O_7$: C, 68.67; H, 9.99%.

Synopsis. Several vicinal dibromides were debrominated to olefins by potassium disulfite in the presence of catalytic amounts of bis(4-methoxyphenyl) telluride in a two-phase system.

In recent years, there has been remarkable interest in the development of new synthetic methods using organotellurium compounds.[1] However, there have been only a limited number of successes involving the catalytic use of organotellurium compounds and/or tellurium salts.[2,3] Now we wish to report that several vicinal dibromides have been debrominated to their corresponding olefins by potassium disulfite in the presence of catalytic amounts of diaryltellurium compounds.

First, the debromination of *erythro*-1,2-dibromo-1,2-diphenylethane (**1**) in the presence of bis(4-methoxyphenyl) telluride (**3**) was investigated. The reaction system was composed of an aqueous potassium disulfite solution (0.5 mol dm^{-3}, 20 cm^3) and benzene (30 cm^3) as an organic phase that included the dibromide (**1**) and catalytic amounts of **3**. Upon stirring the two-phase system at a benzene-refluxing temperature, dibromide **1** was reduced to *trans*-stilbene (**2**) at varying rates, depending upon the amounts of **3** (Fig. 1). In this experiment, *cis*-stilbene was not found in detectable amounts by GLPC (<1%). In a blank experiment without **3**, the formation of **2** was not observed even after 24 h. Thus, apparently the presence of the diaryl telluride **3** is necessary for the conversion of **1** into **2**. It is interesting that **1** was quantitatively reduced to **2** in the presence of only 5% mol amounts of **3** after a 24 h run (Run 3, Fig. 1). Debromination was speeded up as the concentration of **3** was increased. Thus, in the presence of 10 and 20% mol amounts of **3**, debromination was complete in 12 h and 2 h, respectively (Runs 1 and 2, Fig. 1). On the other hand, in experiments with much smaller amounts of **3**, debromination was incomplete even after prolonged heating; 63% in the presence of 2% mol amounts of **3** and 33% in the presence of 1% mol amounts of **3** (Runs 4 and 5, Fig. 1). From the latter two experiments, the maximum turnover number of the diaryl telluride **3** can be roughly estimated to be 30.

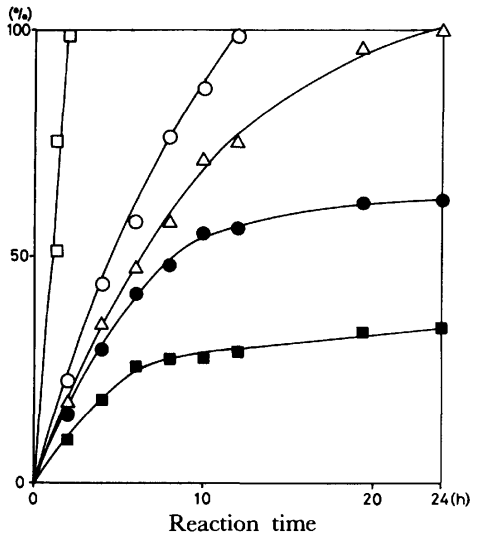

Fig. 1. Catalytic debromination of *meso*-1,2-dibromo-1,2-diphenylethane by $K_2S_2O_5$ using bis(4-methoxyphenyl) telluride (**3**).
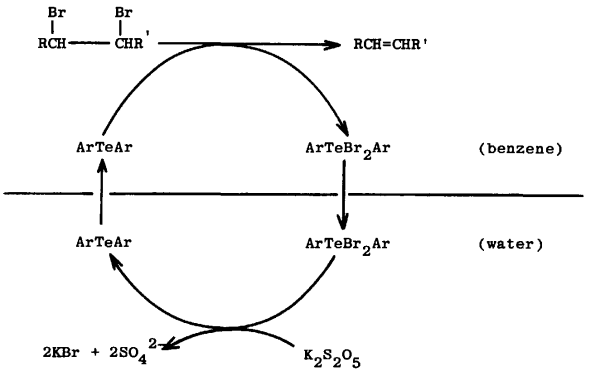
Run 1, □: 20% mole amounts, Run 2, ○: 10% mole amounts, Run 3, △: 5% mole amounts, Run 4, ●: 2% mole amounts, Run 5, ■: 1% mole amounts.

It is widely known that a class of diaryltellurium(II) species are easily brominated to diaryltellurium(IV) dibromides with a variety of brominating reagents, including vicinal dibromide, and that the debromination of diaryltellurium(IV) dibromides can be achieved upon treatment with potassium disulfite in hot water.[4] Therefore, the catalytic cycle of the debromination of **1** can be plausibly depicted as shown in Scheme 1, where the diaryltellurium compound, itself, acts as an electron carrier. Indeed, bis(4-methoxyphenyl) tellurium dibromide (**4**) is soluble enough in water to be consistent with the mechanism in Scheme 1. Further, the addition of **4**, instead of **3**, to the reaction mixture also effected the debromination of **1** with a similar efficiency.

The debromination of other vicinal dibromides was tried under the same conditions as Run 3 in Fig. 1. The results are summarized in Table 1. Only *trans*-stilbene and *trans*-4-styrylpyridine were obtained from *erythro*-dibromides, whereas debromination from *threo*-1,2-dibromo-1,2-diphenylethane was modestly stereoselective. Chalcone and ethyl cinnamate were similarly obtained from corresponding dibromides in 61 and 57% yields, respectively. However, 1,2-dibromocyclohexadecane was not debrominated under these conditions.[6]



Scheme 1.

6	$R^1=$H, $R^2=C_{14}H_{29}$	$CH_2=CHC_{14}H_{29}$	0

a) All reactions were performed as described in detail in the text. b) GLPC yield. c) Isolated yield.

Experimental

Bis(4-methoxyphenyl) telluride was prepared according to the method of Bergman.[5]

General Procedure for the Catalytic Debromination of Vicinal Dibromides by Potassium Disulfite Using Bis(4-methoxyphenyl) Telluride. To a solution of vicinal dibromide (1 mmol) and bis(4-methoxyphenyl) telluride (17 mg, 0.05 mmol) in 30 cm^3 of benzene was added a solution of potassium disulfite (2.22 g, 10 mmol) in 20 cm^3 of water. The resulting mixture was refluxed with vigorous stirring for a suitable time. The progress of the reaction was followed by GLPC (a Hitachi Model 163, using a 3 mm×2 m stainless steel column packed with 10% SE 30 on Celite 545 AW). After completion of the reaction , the reaction mixture was cooled to room temperature. The organic layer was separated, washed with water, dried over Na_2SO_4, and evaporated to give the crude product, which was purified by chromatography over silica gel. The products were identified by comparison with the authentic samples.

6) Irradiation with high-pressure Hg lamp of benzene solution of 1,2-dibromohexadecane and equimolar amounts of bis(4-methoxyphenyl) telluride gave rise to the formation of 1-hexadecene in 70% yield. However, irradiation of two-phase system described in this paper in the presence of catalytic amounts of **3** did not give the olefin.

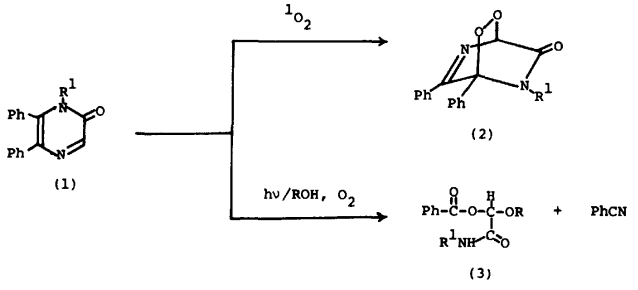
The Solid State Photochemistry of 2(1*H*)-Pyrazinones. Structural Revision of the Photoproduct

Takehiko NISHIO,* Naoko NAKAJIMA, Masaji KONDO, and Yoshimori OMOTE
Department of Chemistry, University of Tsukuba, Sakura-mura, Niihari-gun, Ibaraki 305
(Received October 6, 1984)

Synopsis. Irradiation of 1-methyl-5,6-diphenyl-2(1*H*)-pyrazinone (**1a**) and 1-methyl-5,6,7,8-tetrahydro-2(1*H*)-quinoxalinone (**1b**) in the solid state gave the [4+4] *syn-trans* cyclodimers (**4a—b**) in almost quantitative yields, while these pyrazinones in solution phase were inert upon irradiation. On the other hand, the 2(1*H*)-pyrazinones (**1c—e**) were inert to photolysis in both the solution and solid states.

The [2+2] and [4+4] photocyclodimerization of aromatic compounds is a well-established photoreaction; examples of both inter- and intramolecular [4+4] cycloadditions of naphthalenes and anthrathenes are known.[1] However, those of heteroaromatic compounds have received little attention. The photochemical [4+4] cyclodimerizations of 2-pyridones and 2-pyrones in the solution phase have been reported by Taylor and Kan,[2] Paquette and Slomp,[3] and de Mayo and Yip.[4] A similar photochemical [4+4] cyclodimerization of 4,6-diphenyl-2-pyrone in both solution and the solid state was reported by Rieke and Copenhafer.[5] The photocyclodimer, thus obtained, was assigned to be an *anti-trans* configuration. In a series of photochemical studies on the 2(1*H*)-pyrazinones (**1**), we have reported that the 2(1*H*)-pyrazinones (**1**) reacted with singlet oxygen to give stable *endo*-peroxides (**2**),[6,7] and irradiation of **1** in alcohol under an oxygen atmosphere yielded amide derivatives (**3**).[7] The solid state photochemistry of the 2(1*H*)-pyrazinones (**1**) was also studied. In a previous paper[8] we reported the photoreaction of 2(1*H*)-pyrazinone (**1a**) in the solid state and the structure of *anti-trans* cyclodimer (**5**) was erroneously given to the photoproduct. An X-ray crystallographic analysis,[9] which was measured by Kaftory however, clarified the photoproduct was *syn-trans* cyclodimer (**4a**). In this paper we like to revise the structure of the photoproduct.

The 2(1*H*)-pyrazinones (**1a—e**) were photochemically inert in the solution phase under an argon atmosphere.[10] Meanwhile, the irradiation of 1-methyl-5,6-diphenyl-2(1*H*)-pyrazinone (**1a**) in the solid state with a high-pressure mercury lamp at room temperature for 20 min gave the [4+4] *syn-trans* cyclodimer (**4a**) in a quantitative yield. The structure of **4a** was confirmed



Scheme 1.

on the basis of spectroscopic properties, elemental analysis, and furthermore, X-ray crystallographic analysis.[9] The usual analytical and mass spectral data (*m/z* 524, M^+: $C_{34}H_{28}N_4O_2$, field desorption mass) of **4a** indicate the photoproduct to be dimer. The IR spectrum of **4a** showed a carbonyl stretching at 1660 cm^{-1}, versus 1640 cm^{-1} for **1a**. The ^{1}H-NMR specrum of **4a** showed two singlets at δ 2.58 and 6.35, and a multiplet at δ 6.85—7.35 in the ratio of 3:1:10 assignable to methyl, methine, and aromatic protons, respectively, while that of **1a** showed two singlets at δ 3.31 (3H) and 8.30 (1H), and the multiplet at δ 7.1—7.45 (10H) assignable to methyl, olefinic, and aromatic protons, respectively. The singlet absorption at δ 6.35, which was assigned to methine protons at the 3 and 3′ positions, was shifted further downfield than the expected value of δ (about 4.5).[11] A molecular model of **4a** showed that these hydrogens can be affected by a strong anisotropic deshielding effect from the four phenyl groups in the 5-, 5′-, 6-, and 6′-positions. Furthermore, ^{13}C-NMR spectrum of **4a** displayed peaks at 31.9 (q), 70.1 (d) 76.7 (s), 169.8 (s), and 178.5 ppm (s) due to carbons at 7-, 3-, 6-, 5-positions, and carbonyl carbon, respectively, in addition to aromatic carbon signals. One of four possible structures such as *syn-trans*, *syn-cis*, *anti-trans*, and *anti-cis* cyclodimers might be adopted for the photocyclodimer (**4a**).

The structure of **4a** was finally clarified to be *syn-trans* configuration by an X-ray crystallographic analysis.[9] Similar irradiation of the 2(1*H*)-pyrazinone (**1a**) in the solid state at 254 nm for 4 h through a quartz filter also gave the [4+4] *syn-trans* cyclodimer (**4a**) in 86% yield. The [4+4] *syn-trans* dimer (**4a**) thus obtained was stable at room temperature, however, heating of **4a** to reflux in benzene or to its melting point (148—150 °C) regenerated the starting 2(1*H*)-pyrazinone (**1a**) quantitatively. Furthermore, irradiation of a solution of [4+4] *syn-trans* dimer (**4a**) in methanol through a quartz tube at 254 nm for 30 min causes reversion to the starting 2(1*H*)-pyrazinone (**1a**) in almost quantitative yield. The [4+4] *syn-trans* dimer (**4b**) was also obtained in quantitative yield when 1-methyl-5,6,7,8-tetrahydro-2(1*H*)-quinoxalinone (**1b**) was irradiated in the solid state under the same conditions as described above. On the other hand, irradiation of 1-ethyl-5,6-diphenyl-(**1c**), 1-methyl-5,6-di-*p*-tolyl-(**1d**), and 1,3-dimethyl-5,6-diphenyl-2(1*H*)-pyrazin-one (**1e**) in the solid state did not give the corresponding cyclodimers and the starting 2(1*H*)-pyrazinones (**1c—e**) were recovered quantitatively. These results suggest that the ability of the molecules to react is highly dependent on the mutual orientation and close proximity of possible reacting centers[9] and these conditions seem to be provided by the crystal lattice and are not achieved in the solution phase.

Scheme 2.

Experimental

Melting points are uncorrected and were measured with a Yanaco micro-melting apparatus (MP-J3). UV spectra were determined with a JASCO UVIDEC-505 spectrometer and IR spectra were recorded on a Hitachi 260-30 spectrometer. NMR spectra were run on a JEOL FX 100 spectrometer (100 MHz).

Starting Materials. The 2(1*H*)-pyrazinones (**1a** and **1c—d**) were prepared according to the method previously described.[7] The 2(1*H*)-pyrazinones (**1b** and **1e**) were prepared by modification of this method.

1-Methyl-5,6,7,8-tetrahydro-2(1H)-quinoxalinone (1b); mp 126.5—128°C; UV (EtOH) (ε) 231 (8300) and 340 nm (6900); IR (KBr) 1645 cm^{-1} (C=O); ^{1}H-NMR ($CDCl_3$) δ=1.7—1.9 (4H, m, methylene), 2.5—2.8 (4H, m, methylene), 3.48 (3H, s, NCH_3), and 8.01 (1H, s, 3-H); ^{13}C-NMR ($CDCl_3$) δ=21.7 (t), 21.8 (t), 26.1 (t), 29.6 (t), 29.5 (q, NCH_3), 131.4 (s, C-5 or C-6), 135.0 (s, C-6 or C-5), 144.2 (d, C-3), and 156.3 (s, C=O). Found: C, 65.58; H, 7.34; N, 16.96%. Calcd for $C_{19}H_{12}N_2O$: C, 65.83; H, 7.36; N, 17.06%.

1,3-Dimethyl-5,6-diphenyl-2(1H)-pyrazinone (1e); mp 169—170°C; UV (EtOH) (ε) 268 (11300) and 338 nm (8700); IR (KBr) 1645 cm^{-1} (C=O); ^{1}H-NMR ($CDCl_3$) δ=2.58 (3H, s, CH_3), 3.29 (3H, s, NCH_3), and 7.1—7.4 (10H, m, ArH); ^{13}C-NMR ($CDCl_3$) δ=21.1 (q, CH_3), 33.9 (q, NCH_3), 126.8 (d), 127.7 (d), 128.2 (d), 128.9 (d), 129.3 (d), 130.1 (d), 132.3 (s), 132.6 (s), 136.5 (s, C-5 or C-6), 137.9 (s, C-6 or C-5), 155.2 (s, C-3), and 155.9 (s, C=O). Found: C, 78.24; H, 5.78; N, 10.12%. Calcd for $C_{18}H_{16}N_2O$: C, 78.23; H, 5.83; N, 10.13%.

Photochemical Reactions of the 2(1H)-Pyrazinones (1a—e) in the Solid State. The recrystallized 2(1*H*)-pyrazinone (**1**) (100 mg) was sandwiched between a pair of Pyrex plates or quartz plates (thickness 2 mm) and this solid sample was irradiated with a high-pressure (300 W) or low-pressure mercury lamp (20 W) for 20 min—4 h at a distance *ca.* 5 cm at room temperature. After irradiation, the reaction product was purified by recrystallization from chloroform-hexane to afford the [4+4] *syn-trans* cyclodimer (**4**).

The [4+4] syn-trans *cyclodimer (4a)*; mp 148—150°C; UV (EtOH) (ε) 261 (3600) and 351 nm (450); IR (KBr) 1660 cm^{-1} (C=O); ^{1}H-NMR ($CDCl_3$) δ=2.58 (6H, s, NCH_3), 6.35 (2H, s, 3-H), and 6.85—7.35 (20H, m, ArH); ^{13}C-NMR ($CDCl_3$) δ= 31.9 (q, NCH_3), 70.1 (d, C-3), 76.7 (s, C-6), 127.1 (d), 127.4 (d), 128.4 (d), 128.6 (d), 136.5 (s), 138.4 (s), 169.8 (s, C-5), and 178.5 (s, C=O); *m/z* (Field desorption mass) 524 (M^+). Found: C, 77.84; H, 5.37; N, 10.67%. Calcd for $C_{34}H_{28}N_4O_2$: C, 77.86; H, 5.25; N, 10.62%.

The [4+4] syn-trans *cyclodimer (4b)*; mp 138.5—140°C; IR (KBr) 1660 cm^{-1} (C=O); ^{1}H-NMR ($CDCl_3$) δ=1.53—2.18 (10H, m, methylene), 2.2—2.36 (2H, m, methylene), 2.38—2.8 (4H, m, methylene), 2.75 (6H, s, NCH_3), and 4.48 (2H, s, 3-H); ^{13}C-NMR ($CDCl_3$) δ=18.6 (t), 22.1 (t), 32.4 (t), 36.2 (t), 30.5 (NCH_3), 67.3 (s, C-6), 72.2 (d, C-3), 172.0 (s, C-5), and 177.9 (s, C=O); *m/z* (Chemical ionization mass) 329 (QM^+). Found: C, 65.59; H, 7.32; N, 16.79%. Calcd for $C_{18}H_{24}N_4O_2$: C, 65.83; H, 7.36; N, 17.06%.

Tha authors thank Dr. M. Kaftory for providing the photograph of stereoscopic view of the photodimer (**4a**).

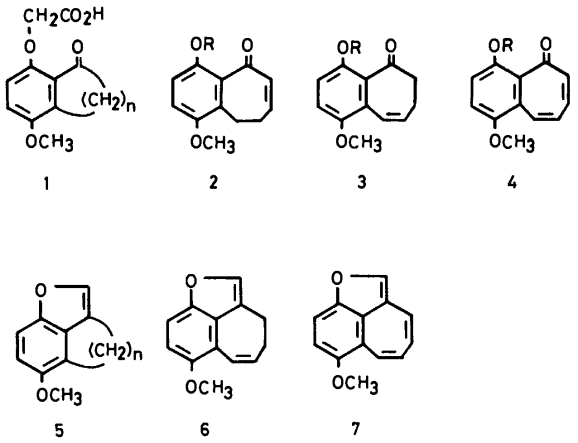
(Received October 15, 1984)

Synopsis. 7-Methoxy-3,4-dihydrocyclohepta[*cd*]benzofuran and 7-methoxycyclohepta[*cd*]benzofuran were synthesized.

Benzofurans are readily synthesized by heating (2-acylphenoxy) acetic acids with sodium acetate in acetic anhydride.[1] In the previous paper,[2] we applied the reaction to acids **1a**, **1b**, and **1c** which had a cyclic ketone (n=2, 3, and 4). The five-membered cyclic ketone **1a** gave no furan **5a**, and the six-membered cyclic ketone **1b** afforded a furan **5b** and a lactone in 1:1 ratio. However, the seven-membered cyclic ketone **1c** produced almost a furan **5c**. Royer *et al.*[3] early reported that a seven-membered cyclic ketone was more effective for furan-ring formation than a six-membered cyclic ketone. The facile furan-ring formation of **1c** is attributed to flexibility of the seven-membered cyclic ketone.[2,4] For the furan-ring formation, an anion such as **8** attacks the carbonyl carbon atom from the upper side of the carbonyl plane.[5] If the carbonyl plane is fixed in the same plane with the benzene ring, the furan-ring formation would be difficult. We introduced double bonds in the seven-membered cyclic ketone to reduce flexibility of the ring and to examine whether the furan-ring formation is possible or not. In this paper, the reaction of acids **3a** and **4a** with sodium acetate in acetic anhydride is reported. However, we abandoned synthesis of **2a** because a ketone **2b** was thermally unstable and polymerized easily. The results are summarized along with the reaction of the related acid **1c** in Table 1.

The acid **3a** produced a furan **6** in 93% yield and the corresponding lactone was not detected. The facile furan-ring formation suggests that seven-membered cyclic ketone in **3a** is still flexible and the carbonyl group can take a favorable conformation for the attack of an anion. We are particularly interested in the furan-ring formation from the acid **4a** as the seven-membered cyclic ketone is fully unsaturated and considered to be rigid. Indeed, the acid **4a** gave easily a furan **7** in 81% yield. It shows that the carbonyl group is yet flexible. The furan **7** is an interesting new class of compound because it has both structures and properties of benzofuran and benzoheptafluvene. The furan **7** is not so stable and polymerizes during storage. Thus, the furan-ring formation was very easy in spite of the additional double bonds in the seven-membered cyclic ketone.



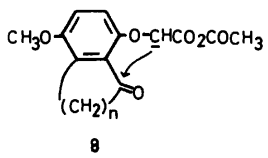


TABLE 1. REACTION OF ACIDS **1c**, **3a**, AND **4a** WITH SODIUM ACETATE IN ACETIC ANHYDRIDE[a]

Compound	Product	Yield/%
1c	**5c**	89[b]
	lactone	3[c]
3a	**6**	93[b]
	lactone	0[d]
4a	**7**	81[b]

a) Reactions were carried out at 150°C for 1 h. b) Isolated yield. c) Lactone was initially produced but it was hydrolyzed to the starting material during isolation procedure. d) Lactone was not produced.

Experimental

The column chromatography was performed on silica gel. ^{1}H and ^{13}C NMR spectra were determined at 90 MHz on a JEOL JNM-FX 90Q FT NMR spectrometer.

(1-Methoxy-5-oxo-6,7-dihydro-5H-benzocyclohepten-4-yloxy)-acetic Acid (3a). A mixture of **3b** (4.11 g; prepared from 8[2] through four steps[6]), ethyl bromoacetate (8.22 g), potassium phosphate (12.0 g), and acetone (50 ml) was refluxed for 10 h. The mixture was poured into ice-water, acidified with 6 M hydrochloric acid (1 M = 1 mol dm^{-3}), and extracted with ether. The ethereal layer was washed, dried, and evaporated. The residue was dissolved in ethanol and saponified with a 2 M potassium hydroxide solution. The alkaline solution was acidified with 6 M hydrochloric acid and the resulting acid was extracted with ether. The ethereal layer was washed, dried, and evaporated. The residue was chromatographed and eluted with benzene(9)-ether(1) to give **3a** (2.20 g, 42%), colorless needles from acetone, mp 129—130 °C. IR (KBr) ν_{max} 1770, 1750 (COOH), 1685, and 1670 cm^{-1} (CO). ^{1}H NMR (CD_3COCD_3) δ=2.34—2.56 (2H, m), 2.89—3.05 (2H, m), 3.82 (3H, s), 4.69 (2H, s), 6.17 (1H, dt, J=6 and 12 Hz), 6.73 (1H, d, J=12 Hz), and 7.05 (2H, s). ^{13}C NMR (CD_3COCD_3) δ=25.5 (t), 47.6 (t), 56.8 (q), 68.7 (t), 114.6 (d), 116.4 (d), 125.1 (s), 125.3 (d),

132.5 (s), 132.7 (d), 149.4 (s), 152.7 (s), 170.2 (s), and 204.4 (s). Found: C, 63.98; H, 5.48%. Calcd for $C_{14}H_{14}O_5$: C, 64.12; H, 5.38%.

(1-Methoxy-5-oxo-5H-benzocyclohepten-4-yloxy)acetic Acid (4a). The compound **4a** (40%) was prepared from **4b** (synthesized from **8**[2] through three steps[7]) in a manner similar to synthesis of **3a**, colorless prisms from acetone, mp 150—151 °C. IR (KBr) ν_{max} 1770 (COOH) and 1640 cm^{-1} (CO). ^1H NMR ($CDCl_3$) δ=3.95 (3H, s), 4.85 (2H, s), and 6.64—8.06 (6H, m). ^{13}C NMR ($CDCl_3$) δ=56.7 (q), 68.7 (t), 113.2 (d), 116.7 (d), 126.7 (s), 127.1 (d), 129.8 (s), 129.9 (d), 134.1 (d), 134.9 (d), 149.3 (s), 152.7 (s), 170.2 (s), and 191.5 (s). Found: C, 64.39; H, 4.68%. Calcd for $C_{14}H_{12}O_5$: C, 64.61; H, 4.65%.

7-Methoxy-3,4-dihydrocyclohepta[cd]benzofuran (6). A mixture of **3a** (1.0 g), acetic anhydride (15 ml), and sodium acetate (4.6 g) was heated at 150 °C for 1 h. The mixture was poured into ice-water (200 ml), stirred for 5 min to decompose excess acetic anhydride, and extracted with ether. The ethereal layer was washed three times with a 0.5 M potassium carbonate solution (30 ml) and then with water, dried, and evaporated. The residue was chromatographed and eluted with benzene to give **6** (0.71 g, 93%), colorless oil, bp 112—115 °C (0.7 Torr). ^1H NMR ($CDCl_3$) δ=2.40—2.60 (2H, m), 2.70—2.90 (2H, m), 3.83 (3H, s), 6.10 (1H, dt, J=7 and 12 Hz), 6.83 (1H, d, J=9 Hz), 6.95 (1H, d, J=12 Hz), 7.23 (1H, d, J=9 Hz), and 7.29 (1H, s). ^{13}C NMR ($CDCl_3$) δ=24.3 (t), 28.2 (t), 57.1 (q), 109.4 (d), 109.8 (d), 119.9 (s), 122.2 (s), 123.8 (d), 127.8 (s), 131.2 (d), 140.4 (d), 150.5 (s), and 152.2 (s). Found: C, 77.80; H, 6.10%. Calcd for $C_{13}H_{12}O_2$: C, 77.98; H, 6.04%.

7-Methoxycyclohepta[cd]benzofuran (7). The compound **7** (81%) was prepared from **4a** in a manner similar to synthesis of **6**, yellow oil, bp 128—130 °C (1 Torr (1 Torr=133.322 Pa)). ^1H NMR ($CDCl_3$) δ=3.72 (3H, s), 5.19—6.35 (4H, m), 6.56 (1H, d, J=9 Hz), 6.86 (1H, d, J=9 Hz), and 6.91 (1H, s). ^{13}C NMR ($CDCl_3$) δ=56.9 (q), 111.7 (d), 111.8 (d), 123.1 (s), 125.0 (s), 125.6 (d), 125.6 (d), 126.7 (d), 127.0 (d), 131.6 (s), 138.5 (d), 150.5 (s), and 151.6 (s). Found: C,78.78; H, 5.20%. Calcd for $C_{13}H_{10}O_2$: C, 78.77; H, 5.08%.

The authors wish to thank Mr. Yoshiaki Matsuda for the elemental analyses.

Pressure-induced Proton NMR Chemical Shift of Some Simple Hydrocarbon Molecules in Hexane Solution. Marked Low Field Shift of Ethynyl Proton Resonance

Hiroaki YAMADA,* Shuji ONISHI, Masako YOKOYAMA, and Akira SERA
Department of Chemistry, Faculty of Science, Kobe University, Nada-ku, Kobe 657
(Received October 24, 1984)

Synopsis. Pressure dependence of the ethynyl proton chemical shift of phenylacetylene was studied in comparison with some simple hydrocarbons. The pronounced low field displacement is interpreted taking account of a geometric feature of the ethynyl group, where the terminal hydrogen atom is exposed to a closer contact with solvent molecules.

High-pressure high-resolution NMR spectroscopy represents one of the promising new area of research at high pressure.[1] Considerable efforts with use of this technique have been devoted to the investigation of high pressure effect on the rate process and chemical equilibrium. However, little is known about the pressure sensitivities of the NMR chemical shifts.

In preceding paper, we reported a notable pressure dependence of the ethynyl proton chemical shift of neat phenylacetylene.[2] The result was interpreted in terms of the increased effect in the solvent magnetic anisotropy, σ_a, which is caused by the intensified intermolecular hydrogen bonding (I) at high pressure.

$$\begin{array}{l} C_6H_5-C\equiv C-H \\ \quad\quad\quad | \\ \quad\quad H-C\equiv C-C_6H_5 \end{array} \quad (I)$$

We have now made a re-examination of phenylacetylene in a hexane solution in comparison with some simple hydrocarbons and have found a recurrence of the low field pressure shift of the ethynyl proton resonance. Since hexane behaves as a magnetically isotropic solvent, an interpretation of the low field shift can no longer be sought in the solvent magnetic anisotropy effect. The present paper attempted to offer a preliminary account of this anomalous pressure shift.

Experimental

High-pressure NMR experiment was conducted on a Jeol PS-100 spectrometer (ν_0=100 MHz) using a thermal expansion type high-pressure cell with sample spinning conditions.[3] Most measurements were carried out with 5 mol% solutions in hexane. The temperature of the sample under the NMR conditions was maintained at 35.0±0.2°C. At least ten measurements were made at a fixed pressure. The standard deviation of the chemical shift was ±0.1—0.2 Hz.

Results and Discussion

Observed relative pressure shifts $\delta\Delta(150)$[4] are presented in Table 1. The ethynyl proton resonance, as compared with the other hydrocarbon resonances, evidently exhibits a marked low field displacement by the application of hydrostatic pressure.

It might be possible that the self association of the type (I)[5] still exists in the 5 mol% solution. In this association mode, both the hydrogen-bonding shift σ_H and the magnetic anisotropy shift σ_a, caused by $\Delta\chi_{C\equiv C}$ of another molecule, contribute to down field displacement of the ethynyl proton signal. Therefore, if the association mode (I) is favored at high pressure, a negative pressure shift, $\delta\Delta(150)<0$ would be induced. In order to examine this possibility, concentration dependence of the relative pressure shift was carefully measured for phenylacetylene. As shown in Fig. 1, no significant change was observed in the pressure shift upon dilution of the solution. On this basis, we consider that the contribution of the self association effect to the pressure shift is negligibly small at 5 mol% concentration. It is also approximated that the data for the other hydrocarbons, being based on the 5 mol% solution, represent the pressure shifts which are free from self association effects.

Table 1. Relative pressure shifts,[a] 5 mol% in hexane, ν_0=100 MHz, 35.0°C

Compounds	$\delta\Delta(150)$/Hz	Compounds	$\delta\Delta(150)$/Hz
Ph_3CH[b]	+1.9	H_2CCl_2	+0.1
$(CH_2)_6$	+1.5	$CH_3(CH_2)_4CH_3$	0.0
$HCCl_3$	+1.2	$PhCH_3$	−0.7
$CH_3(CH_2)_4CH_3$	+1.0	$Ph_2C=CH_2$	−1.9
Ph_2CH_2	+0.5	$PhC\equiv CH$	−5.3

a) Relative to the hexane CH_3 pressure shift. b) Because of the poor solubility, a 1 mol% solution was used.

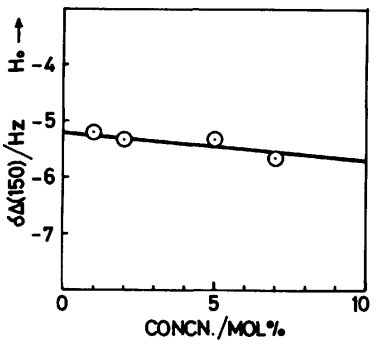

Fig. 1. Concentration dependence of the ethynyl proton relative pressure shift. For a 95 mol% solution, $\delta\Delta(150)=-7.7$ Hz.

Under the present experimental conditions, the solvent effect on the proton chemical shift can be divided into two kinds of main contribution:[6] (i) The σ_E effect which is related to the C-H bond polarization induced by so-called reaction field;[7] This should be mainly governed by the polarity of the solute molecule and the dielectric constant of the medium. (ii) The σ_w contribution arising from the weak van der Waals interaction between the resonating proton and solvent molecules;[6,8] When the resonating proton is more

strongly subject to the van der Waals contact with medium molecules, a greater σ_w contribution (*i.e.*, a pronounced low field shift) should be expected.[9] Since the pressurization produces an increase in the dielectric constant of the medium and also intensifies the intermolecular van der Waals contacts, both the effects, (i) and (ii), would be amplified at high pressure, giving rise to a possible low field contribution to the pressure shift.

In an attempt to evaluate the contribution of the effect (i), the data were examined in connection with polar properties of the solute molecule. Although the examinations are only qualitative, several interesting points arise. For example, the pressure shifts for chloroform (μ=1.2 D) and phenylacetylene (μ=0.5 D, with a negative end directing toward the ethynyl group) exhibit a trend evidently opposite to that expected from the reaction field consideration. Furthermore, toluene shows a larger negative pressure shift relative to triphenylmethane, whereas, considering acidities of these hydrocarbons (pK_a=41, 32, respectively), one would predict the opposite. On these grounds, we conclude that the effect (i) cannot be a main contributor to the pressure shift.

We may now turn to the effect (ii). In Table 1, it will be noticed that the steric environment near the resonating proton is playing a dominant role in determining the pressure shift. For instance, a regular trend toward larger negative pressure shift can be seen as the steric overcrowding is liberated in the order of triphenylmethane, diphenylmethane, and toluene. In this view, the pronounced negative pressure shift of the ethynyl proton seems to be best rationalized on the basis of the geometric feature of the ethynyl group where the proton is located at the end of a rod shaped C≡C bond and, in the absence of a geminal hydrogen, it is well exposed to the van der Waals contact with solvent molecules. Axially symmetric electronic environment around the ethynyl proton should also lead to pronounced susceptibility to the σ_w effect.[6] Present result indicates that the previously observed pressure shift, −9 Hz, for neat phenylacetylene[2] could largely be interpreted as being due to this van der Waals contact effect rather than the σ_a effect.

This study has shown that a protrusion of a C≡C bond out of the molecule plays an important role in causing the marked low field pressure shift of the ethynyl proton. It should be pointed out that this stand out in sharp contrast to the ring proton of 1,4-di-*t*-butylbenzene,[10] which, being located in a cavity in the molecule, has proved to give a considerable high field pressure shift.

The present work was supported by Grant-in-Aid for Scientific Research No. 56550572 from the Ministry of Education, Science and Culture.

Synopsis. A new type of tetrathiafulvalene derivatives, fused with crown ethers, was prepared, which did not form a complex with sodium cation or TCNQ acceptor but readily with silver cation.

With an attempt to develop the new character of tetrathiafulvalene (TTF) by use of a functional heterocyclic ring, we have studied novel TTF derivatives **1** and **2** which are fused with crown ethers. Complexation with metal cation at the crown ligand might make some influence on the donor character of the TTF.

The metallic[1] or electrochemical[2] reduction of carbon disulfide in aprotic media provides a synthetic entry for the preparation of thio-substituted derivatives of TTF.[3] Thus, sodium 2-thioxo-1,3-dithiole-4,5-dithiolate **4**, generated in situ by reduction of carbon disulfide with sodium in dry *N,N*-dimethylformamide, was allowed to react with methyl iodide to give 4,5-bis(methylthio)-1,3-dithiole-2-thione **5** in 70% yield.[1] On the other hand, a similar treatment of the dianion **4** with tetraethylene glycol ditosylate gave crown-fused 1,3-dithiole-2-thione **6** in only 0.8% yield as well as its dimer **7** in rather higher yield (6.5%). The yield of the key compound **6** was fairly increased up to 14% by effecting the reaction under a high dilution technique. Subsequently, heating of **6** at 110°C in triethyl phosphite resulted in self-coupling to bis-crowned tetrathiafulvalene **1** in 44% yield. A cross reaction of two 1,3-dithiole-2-thiones **5** and **6** led to a mixture of **1** (31%), **2** (21%), and **3**[4] (13%), which were readily separated from one another by column chromatography. Another type of crowned tetrathiafulvalene **8** was, in addition, prepared in a very low yield (2.9%) by a similar cross reaction of **5** and **7**.

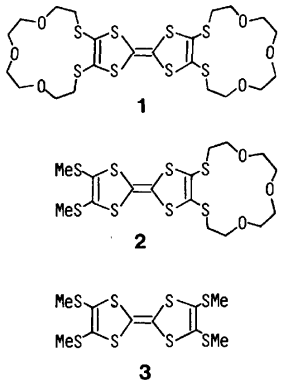

Fig. 1.

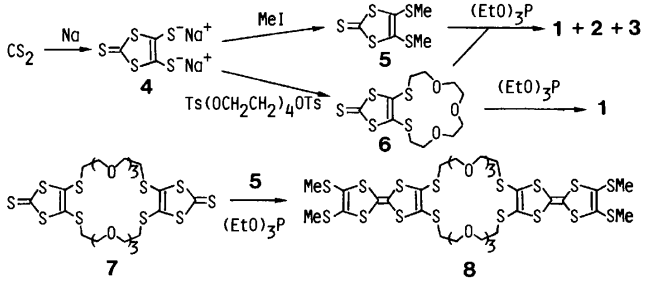

Fig. 2.

The cyclic voltammograms of TTF derivatives **1**, **2**, and **3** exhibit two reversible oxidation waves due to TTF, whose half-wave potentials are situated at 0.521 and 0.748 V for **1**, at 0.509 and 0.757 V for **2**, and at 0.498 and 0.805 V for **3** *vs.* a silver reference electrode in dichloromethane. The almost identical voltammetric behaviors indicate that their π-donor abilities are nearly equal. However, crowned TTF **1** and **2**, in contrast to **3**,[3] did not form crystalline charge-transfer complexes with tetracyanoquinodimethane (TCNQ). The steric requirement of the crown ligand seems to prevent the complexation of the TTF. In addition, the crown ligand failed to complex sodium salts such as Na^+TCNQ^- and NaSCN. However, crowned TTF **1** and **2** strongly interacted with silver nitrate, forming crystalline 1:2 and 1:1 complexes, respectively. The electrical conductivities of these complexes are relatively low; σ_{RT} (compressed pellet) 6×10^{-9} $\Omega^{-1}cm^{-1}$ for $2AgNO_3$ complex of **1** and 4×10^{-7} $\Omega^{-1}cm^{-1}$ for $AgNO_3$ complex of **2**.

This work was supported by the grant in aids of special research project on properties of molecular assemblies (No. 59112003) from the Ministry of Education, Science and Culture, Japan.

Experimental

NMR spectra were determined on a JEOL PMX-60 spectrometer (60 MHz), MS spectra on a JEOL JMS-DX 300 spectrometer at 70 eV using a direct insertion technique, and IR spectra on a Hitachi 260-30 spectrophotometer. Cyclic voltammetry was made at 100 mVsec^{-1} scan rate in 2 mV dichloromethane solution with added tetrabutylammonium perchlorate by a Hokuto Denko HA-301 potentiostat and a Hokuto Denko HB-104 functional generator using a Ag/AgCl reference electrode, a glassy carbon working electrode, and a platinum counter electrode. Electrical conductivity was measured on a compressed pellet with a two probe method.

Crowned 1,3-Dithiole-2-thione (6). Sodium (1.68 g, 73 mmol) was added into a solution of carbon disulfide (12 ml) and dry *N,N*-dimethylformamide (20 ml) under nitrogen. The mixture was gently refluxed with stirring overnight, and meanwhile sodium gradually dissolved to bring about a viscous dark red solution containing dianion **4**. It was then diluted with ethanol (55 ml, previously bubbled by nitrogen gas) and introduced into a dropping funnel through a needle bridge. A solution of tetraethylene glycol ditosylate (18.32 g, 36.5 mmol) in tetrahydrofuran (100 ml) was placed in another dropping funnel. Both the solutions were dropwise and simultaneously added into a stirred ethanol solution (250 ml) at 50°C under nitrogen. The addition took half a day, and heating was continued further overnight. After the resulting insoluble salt was removed by filtration, the filtrate

was evaporated and extracted with dichloromethane. The extract was washed, dried (Na_2SO_4), and evaporated. The residual red oil was purified by flash chromatography on silica gel with 1:2 dichloromethane–ether and then gel-permeation liquid chromatography with chloroform, giving **6** (1.79 g, 14%), yellow columns from hexane–dichloromethane, mp 70—74 °C. ^{1}H NMR ($CDCl_3$): δ=3.04 (t, J=6 Hz, 4H, CH_2S), 3.66 (s, 8H, CH_2O), 3.77 (t, J=6 Hz, 4H, CH_2O). MS: m/z 356 (M^+). IR (KBr): 1055 (C=S), 1120 (C–O) cm^{-1}. Found: C, 36.78; H, 4.51%. Calcd for $C_{11}H_{16}O_3S_5$: C, 37.05; H, 4.52%.

The same reaction without the above dilution technique gave a mixture of **6** (0.8%) and **7** (6.5%). The dimer **7** was separated from **6** by liquid chromatography, yellow fine crystals from ethanol–dichloromethane, mp 84.5—85.5 °C. ^{1}H NMR ($CDCl_3$): δ=3.08 (t, J=6 Hz, 8H, CH_2S), 3.62 (s, 16H, CH_2O), 3.73 (t, J=6 Hz, 8H, CH_2O). MS: m/z 712 (M^+). IR (KBr): 1065 (C=S), 1120 (C–O) cm^{-1}. Found: C, 36.95; H, 4.50%. Calcd for $C_{22}H_{32}O_6S_{10}$: C, 37.05; H, 4.52%.

Bis-crowned TTF (1). Compound **6** (356 mg, 1.0 mmol) was heated in triethyl phosphite (2 ml) under nitrogen. The starting material completely dissolved with a rise of temperature, and orange microcrystals precipitated at 110 °C. After 30 min at 110 °C, the product **1** was collected by filtration and washed with hexane (142 mg, 44%), orange fine crystals from acetonitrile, mp 211—212 °C. ^{1}H NMR ($CDCl_3$): δ=2.99 (t, J=6 Hz, 8H, CH_2S), 3.65 (s, 16H, CH_2O), 3.74 (t, J=6 Hz, 8H, CH_2O). MS: m/z 648 (M^+). IR (KBr): 1120 (C–O) cm^{-1}. Found: C, 40.71; H, 4.85%. Calcd for $C_{22}H_{32}O_6S_8$: C, 40.72; H, 4.97%.

Mono-crowned TTF (2). A mixture of **5** (226 mg, 1.0 mmol) and **6** (356 mg, 1.0 mmol) was heated at 110 °C in triethyl phosphite (3 ml) for 30 min under nitrogen. After evaporation, the residue was chromatographed on silica gel to give a red eluate with dichloromethane and then two red eluates with 1:20 ether–dichloromethane. The first red eluate gave **3** (25 mg, 13%), orange columns from acetonitrile, mp 93—94 °C (lit,[3] 94.5—96 °C). The second red eluate gave **2** (108 mg, 21%), orange plates from ethanol–chloroform, mp 125—126 °C. ^{1}H NMR ($CDCl_3$): δ=2.43 (s, 6H, CH_3), 2.97 (t, J=6 Hz, 4H, CH_2S), 3.64 (s, 8H, CH_2O), 3.73 (t, J=6 Hz, 4H, CH_2O). MS: m/z 518 (M^+). IR (KBr): 1115 (C–O) cm^{-1}. Found: C, 36.90; H, 4.10%. Calcd for $C_{16}H_{22}O_3S_8$: C, 37.04; H, 4.27%. The third red eluate gave **1** (100 mg, 31%).

Crowned bis-TTF (8). Compound **7** (142 mg, 0.2 mmol) was heated together with **5** (180 mg, 0.8 mmol) in triethyl phosphite (2 ml) at 110 °C under nitrogen. The reaction mixture was worked up as described for **2**, giving **8** (6 mg, 2.9%), orange fine crystals from acetonitrile, mp 109—111 °C. ^{1}H NMR ($CDCl_3$) δ=2.43 (s, 12H, CH_3), 3.02 (t, J=6 Hz, 8H, CH_2S), 3.64 (s, 16H, CH_2O), 3.69 (t, J=6 Hz, 8H, CH_2O). IR (Neat): 1115 (C–O) cm^{-1}. Found: C, 37.19; H, 4.13%. Calcd for $C_{32}H_{44}O_6S_{16}$: C, 37.04; H, 4.27%.

Complexation with Silver Nitrate. A mixture of **2** (52 mg, 0.1 mmol) and silver nitrate (17 mg, 0.1 mmol) was dissolved in hot ethanol (*ca.* 20 ml). The clear solution was cooled in a refrigerator, giving reddish orange fine crystals of mono-crowned TTF·$AgNO_3$ complex (34 mg), dec. 150 °C with melt. IR (KBr): 1385 (NO_3), 1115 (C–O) cm^{-1}. Found: C, 27.87; H, 3.20; N, 1.63%. Calcd for $C_{16}H_{22}NO_6S_8Ag$: C, 27.90; H, 3.22; N, 2.03%.

Bis-crowned TTF·$2AgNO_3$ complex was prepared in a similar manner; orange fine crystals, dec. 218 °C with melt. IR (KBr): 1380 (NO_3), 1115 (C–O) cm^{-1}. Found: C, 27.02; H, 3.28; N, 2.60%. Calcd for $C_{22}H_{32}N_2O_{12}S_8Ag_2$: C, 26.72; H, 3.26; N, 2.83%.

(Received October 31, 1984)

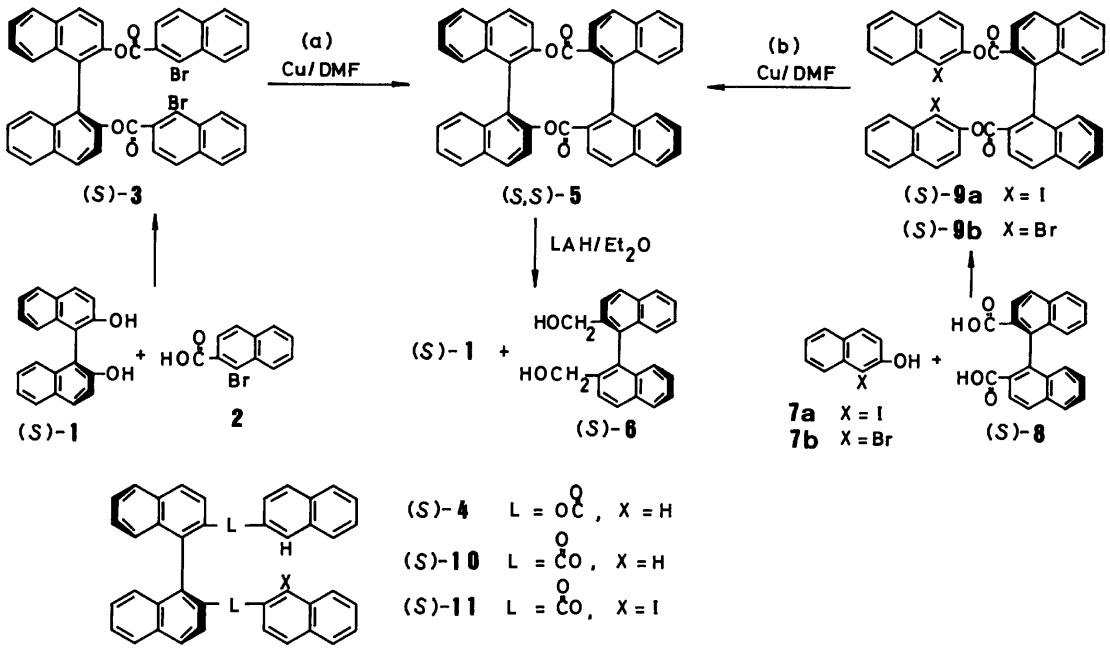
Synopsis. The intramolecular Ullmann coupling of the title diester proceeded in low yield but with virtually complete asymmetric induction in joining the two naphthyl units leading to the 12-membered cyclic diester of (*S,S*)-configuration, which is the same diastereomer obtained from the reaction of (*S*)-2,2′-bis(1-bromo-2-naphthoyloxy)-1,1′-binaphthyl.

In our previous paper,[1] we have reported that the intramolecular Ullmann coupling of chiral diester (*S*)-**3** derived from *chiral diol* (*S*)-**1** and *1-bromo-2-naphthoic acid* **2** proceeds with complete asymmetric induction in joining the two naphthyl units leading to the formation of only (*S,S*)-cyclic diester ((*S,S*)-**5**) without (*S,R*)-diastereomer, although accompanied by the formation of reduction product ((*S*)-**4**) and others derived by intermolecular reactions (Scheme). We reasoned that the remarkable stereoselectivity of the unimolecular coupling should be ascribed to the steric requirement in the product 12-membered cyclic diester which contains two sets of bulky, and rigid 1,1′-binaphthyl moieties; as CPK molecular models of the two possibilities indicate, severe steric compression in (*S,R*)-**5** as compared to (*S,S*)-**5** would exclude the formation of the former, irrespective of the mechanism of the coupling process.

If this is the case, the other feasible route to the cycle **5** *via* aryl coupling, namely the Ullmann reaction of another chiral bifunctional diester (*S*)-**9**, which is derived from *axially chiral binaphthyldicarboxylic acid* (*S*)-*8* and *1-halo-2-naphthol* **7**, should also give rise to exclusive formation of (*S,S*)-**5** as the unimolecularly coupled product.

To test this hypothesis, optically active (*S*)-**9a** was prepared from axially chiral (*S*)-**8** (91% e.e.) and 1-iodo-2-naphthol **7a**. The Ullmann reaction was carried out by slowly adding a DMF solution of (*S*)-**9a** to a vigorously stirred suspension of an activated copper powder in DMF heated at reflux. Although the ease of copper-promoted halogen displacement from the aromatic ring is generally I>Br, (*S*)-**9a** was much less reactive than (*S*)-**3**, suggesting the importance of the activation of the halogen by the carbonyl function in the *ortho*-position in the latter.[2] Thus, deiodination of (*S*)-**9a** was incomplete under the comparable conditions where (*S*)-**3** reacted completely.[3,4] This and concurrent occurrence of intermolecular reaction resulted in somewhat complex products, while HPLC analysis of the mixture revealed only three components, (*S,S*)-**5**, (*S*)-**10**, and (*S*)-**11**, as the unimolecular products from (*S*)-**9a**.

Unfortunately, the dominant reaction of (*S*)-**9a** with copper was reductive substitution to (*S*)-**10**.[5] However, the first eluting component on HPLC, which was recovered in a 11% yield by column chromatography followed by TLC purification, showed the IR and MS spectrum similar to those of the authentic (*S,S*)-**5** obtained in the previous work *via* path **a**.[1] As there seemed little possibility of enantiomeric concentration of the monomeric cycle during the chromatographic purification (see Experimental), the recovered sample of (*S,S*)-**5** should represent the component in the reaction mixture. The ester linkage of the sample of (*S,S*)-**5** was reductively cleaved by treatment with LAH



Scheme 1.

to give (*S*)-**1** and (*S*)-**6**; the optical purity of these diols was essentially identical (88—90%), as determined by comparison of the optical rotations with those of pure enantiomers.[6] This is likely to suggest that the enantiomeric purity of the recovered (*S,S*)-**5** should be close to 90%; this value is in turn in fairly good agreement with that estimated from the optical rotation of the (*S,S*)-**5** itself by comparing with that of the enantiomerically pure cycle ($[\alpha]_D^{23}$ −457.6°) obtained in the previous work.[1] Thus, as the enantiomeric purity of the recovered cycle practically coincided with that of the starting (*S*)-**8**, it follows that the unimolecular Ullmann coupling of (*S*)-**9a** (path **b**) also proceeded with virtually complete diastereoselectivity to give the (*S,S*)-cycle.

In conclusion, the stereochemistry of the intramolecular coupling of the two aryl units attached, with appropriate spacing groups, at the 2,2′-positions of 1,1′-binaphthyl skeleton is likely to be highly controlled by the axial chirality of the parent binaphthyl moiety as well as the steric requirement of the product cycle.

Experimental

Measurement and materials were similar to those described in the previous paper unless otherwise noted.[1] Melting points are uncorrected. **7a** was prepared by a literature procedure, mp 92—93 °C (lit,[7] 92 °C).

(S)-8. According to the procedure by Hall and Turner,[8] the less soluble quinine salt was recrystallized three times from EtOH to give hexagonal plates, mp 173—175 °C; $[\alpha]_D^{23}$ −85.8° (*c* 1.00, acetone). Decomposition of the salt gave the free acid, which was dried *in vacuo* at 120 °C, mp 152—154 °C; $[\alpha]_D^{24}$ −99.7° (*c* 1.08, 0.1 M NaOH (1 M = 1 mol dm^{-3})).[9] Found: C, 77.27; H, 4.06%. Calcd for $C_{22}H_{14}O_4$: C, 77.18; H, 4.12%. A sample of the (*S*)-**8** was boiled with LAH in ether to give (*S*)-**6**, $[\alpha]_{546}^{24}$ −78.8° (*c* 1.80, acetone).

(S)-9a. After (*S*)-**8** (2.80 g, 8.19 mmol) had been refluxed in $SOCl_2$ (*ca.* 30 ml) for 3 h, volatiles were removed *in vacuo*. The organic residue was dissolved in benzene (60 ml) and pyridine (10 ml), to which was added **7a** (5.30 g, 19.6 mmol). The mixture was stirred overnight at room temperature and then heated at reflux for 3 h. The reaction was worked up as usual, and the crude diester was purified by an alumina column chromatography with benzene as eluant, 5.95 g (86%); mp 144—147 °C; $[\alpha]_D^{22}$ +72.3° (*c* 1.03, PhH); IR (KBr) 1750, 1200, and 1090 cm^{-1}. Found: C, 60.08; H, 2.93; I, 29.56%. Calcd for $C_{42}H_{24}I_2O_4$: C, 59.60; H, 2.86; I, 29.98%.

Ullmann Reaction of (S)-9a. According to the procedure described before,[3] (*S*)-**9a** (2.67 g, 3.16 mmol) in 30 ml of DMF was added over a 5 h period to a vigorously stirred copper powder (5.0 g, 79 mmol) in DMF (100 ml) heated at reflux. The mixture was refluxed for another 2 h, and it was worked up as before to give 1.77 g of a pale brown residue, which contained 1.54% of iodine by combustion analysis; $[\alpha]_D^{22}$ −82.0° (*c* 1.1, PhH). HPLC analysis (JASCO SC-01 column, MeCN/H_2O (10/1)) showed the presence of, in the order of elution, (*S,S*)-**5** (1.00), (*S*)-**10** (1.63), and (*S*)-**11** (2.26), and other higher oligomeric products (in parentheses are shown retention volumes relative to (*S,S*)-**5**). The mixture (1.70 g) was subjected to a silica-gel column chromatography (Wako Gel C-200) using $CHCl_3$ (1% EtOH) as eluant to give a 245 mg of the first fraction comprised mostly of (*S,S*)-**5** and small amount of (*S*)-**10**; $[\alpha]_D^{23}$ −385° (*c* 1.03, PhH). A part of the sample (*ca.* 85 mg) was treated with LAH, and the products were purified by TLC (silica gel, $CHCl_3$/AcOEt (4/1)) to give 2-naphthol (trace), (*S*)-**1**, 25 mg, $[\alpha]_D^{23}$ −30.9° (*c* 1.15, THF) and (*S*)-**6**, 32 mg, $[\alpha]_{546}^{24}$ −77.8° (*c* 1.28, acetone). The remainder of the fraction was further purified by TLC (silica gel, PhH) to give (*S,S*)-**5** which appeared to be homogeneous by HPLC, 130 mg; $[\alpha]_D^{24}$ −409° (*c* 0.352, PhH); IR (KBr) 1750, 1250, 1220, and *ca.* 1110 cm^{-1}; MS (70 eV) *m/z* (rel intensity) 592 (M^+, 19.0), 280 (9.9), 268 (21.8), and 252 (6.9). LAH treatment of the (*S,S*)-**5** (107 mg, 0.181 mmol) gave (*S*)-**1**, 41 mg, $[\alpha]_D^{23}$ −31.4° (*c* 1.18, THF) and (*S*)-**6**, 47 mg, $[\alpha]_{546}^{24}$ −78.0° (*c* 1.31, acetone).

From the second fraction of the column effluent was recovered (*S*)-**10**, 590 mg; $[\alpha]_D^{23}$ +39.0° (*c* 1.03, PhH); 182—185 °C; IR (KBr) 1740, 1230, 1210, and 1120 cm^{-1}. Found: C, 84.57; H, 4.32%. Calcd for $C_{42}H_{26}O_4$: C, 84.83; H, 4.41%. LAH treatment of the sample (250 mg) gave 2-naphthol (85 mg) and (*S*)-**6**, 110 mg, $[\alpha]_{546}^{24}$ −77.3° (*c* 1.55, acetone). (*S*)-**11** was deduced from MS (M^+ 720) and from positive Beilstein test conducted on the third fraction of the column effluent.

We are grateful for support of this work by Takeda Science Foundation.

Electrogenerated Acid as an Efficient Catalyst for the Protection and Deprotection of Alcohols with Dihydropyran and Transesterification of Glyceride

Sigeru Torii,* Tsutomu Inokuchi, Kazumi Kondo, and Hiroshi Ito

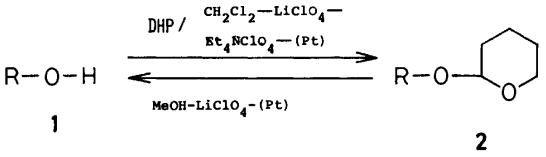
Synopsis. Protection of alcohols with 3,4-dihydro-2*H*-pyran and hydrolysis of the resulting tetrahydropyranyl ethers are cleanly performed by using an electrogenerated acid (EG acid) as a catalyst. Transesterification of glyceride was also achieved with EG acid.

The protection of hydroxyl groups with 3,4-dihydro-2*H*-pyran (DHP) and deprotection of the resulting tetrahydropyranyl (THP) ethers into hydroxyl groups are two essential procedures in modern synthetic chemistry and a variety of catalysts have been already proposed for this purpose.[1] In the course of our study on electrolyses with perchlorate salts, we recently found prominent aspects of acid-catalyzed reactions in an MeOH–$LiClO_4$–(Pt) electrolysis system, which comprise an acid-catalyzed hemiacetalization of α-hydroxy ketones with methanol and the subsequent oxidative fission of 1,2-diol groups, giving keto esters.[2] As the results of our continuing studies on electrogenerated acid,[3] we disclose here a simple procedure for the protection of alcohol **1** with DHP by using an electrochemically generated acid[4] *in situ* after passing a small amount of electricity in a CH_2Cl_2–$LiClO_4$–(and/or Et_4NClO_4)–platinum electrodes system.



1 2

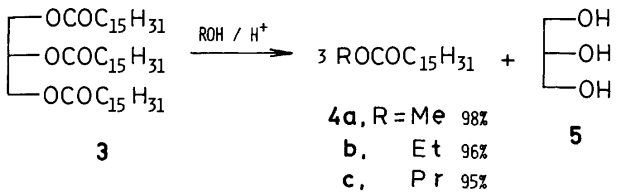
It is noted that *p*-toluenesulfonic acid is frequently used for tetrahydropyranylation of alcohols as a routine catalyst,[5] and it seems to be superior to other catalysts such as hydrochloric acid,[6] phosphoryl chloride,[7] and boron trifluoride etherate.[8] Owing to its strong acidity, however, some milder and more efficient catalysts, *i.e.*, pyridinium *p*-toluenesulfonate (PPTS),[9a] poly(2- or 4-vinylpyridinium *p*-toluenesulfonate),[9b] and bis(trimethylsilyl) sulfate [$(Me_3Si)_2SO_4$],[10] have been devised for this purpose. The present electrochemical procedure for the preparation of THP ether **2** can constitute a facile alternative to reported ones due to its high efficiency (most of the operations complete within several minutes and provide excellent yields).

The electrochemical protection of alcohol **1** (1 mmol) with DHP was carried out using platinum electrodes in a simple undivided cell. Thus, electrolysis of cinnamyl alcohol **1a** and an excess equivalent (1.2—2.0 equiv) of DHP in dichloromethane containing lithium perchlorate ($LiClO_4$, 1 mg) and/or tetraethylammonium perchlorate (Et_4NClO_4, 5 mg) gave the corresponding THP ether **2a** in more than 90% yield only by passing a catalytic quantity of electricity.

Some typical results of the electrochemical tetrahydropyranylation of alcohols are summarized in Table 1.

The acid catalyst generated in the electrolysis medium is also effective for removal of the THP group from **2**. Stirring of **2a** at 55—60 °C for 5 min in methanol containing a small amount of $LiClO_4$ after passing 0.01 F/mol of electricity in the anode compartment of a divided cell gave the parent alcohol **1a** in 95% yield. The results of deprotection experiments are also summarized in Table 1.

In addition to the above results, the electrogenerated acid can be used as a catalyst for the transesterification of glyceride **3**.[11] Heating of **3** with the pre-electrolyzed solution of $LiClO_4$ in either methanol, ethanol, or 1-propanol provided the corresponding palmitates **4a—c** in 95—98% yields.



Experimental

General Procedure for Protection of Alcohol 1 with Dihydropyran. A mixture of cinnamyl alcohol (**1a**, 134 mg, 1.0 mmol), 3,4-dihydro-2*H*-pyran (101 mg, 1.2 mmol), and $LiClO_4$[12] (1 mg, 0.009 mmol) was dissolved in CH_2Cl_2[13] (5 ml) in an undivided cell. Two platinum foil electrodes were immersed in the solution and voltage of 10 V (current: 0.4 mA) was applied. TLC monitoring revealed that the reaction has terminated after passage of about 0.0002 F/mol of electricity (it took about 1 min) based on **1a**. Pyridine (45 mg, 0.57 mmol) was then added. Evaporation of volatile material and column chromatography (SiO_2, hexane–AcOEt 15:1) of the residue gave the corresponding THP ether **2a** in 92% yield (Table 1).

Spectral data along with elemental analyses of the THP ether of carbohydrates **1e**, **1g**, and **1h** are as follows. **2e**: IR (neat) 1450, 1385, 1375, 1335, 1285, 1250, 1205, 1165, 1127, 1080, 972, 915, 870, 786, 733 cm^{-1}; ^1H NMR (60 MHz) δ 1.30—1.80 (m, 6, CH_2), 1.35, 1.40 (s, 6, CH_3), 1.41 (s, 6, CH_3), 3.30—4.95 (m, 10, CH_2O, CH–O). Anal. Calcd for $C_{17}H_{28}O_7$: C, 59.29; H, 8.19. Found: C, 59.36; H, 8.20. **2g**: IR (neat) 1450, 1435, 1375, 1365, 1245, 1207, 1148, 1118, 1068, 965, 840, 760 cm^{-1}; ^1H NMR (100 MHz) δ 1.30—2.00 (m, 6, CH_2), 1.35 (s, 6, CH_3), 1.45, 1.52 (s, 6, CH_3), 3.44—4.96 (m, 9, CH_2O, CH–O), 5.96 (d, J=4 Hz, 1, CH–O). Anal. Calcd for $C_{17}H_{28}O_7$: C, 59.29; H, 8.19. Found: C, 59.27; H, 8.11. **2h**: IR (neat) 1446, 1435, 1375, 1366, 1255, 1200, 1155, 1060, 1005, 955, 845, 810 cm^{-1}; ^1H NMR δ 1.20—1.90 (m, 6, CH_2), 1.36, 1.40 (s, 6, CH_3), 1.51 (s, 6, CH_3), 3.50—5.08 (m, 9, CH_2O, CH–O), 5.80 (s, 1, CH–O). Anal. Calcd for $C_{17}H_{28}O_7$: C, 59.29; H, 8.19. Found: C, 59.25; H, 8.18.

General Procedure for Deprotection of 2. An MeOH solution (6 ml) containing $LiClO_4$ (12 mg) was placed in each compartment of the electrolysis cell. Electric current was

Pressure Dependence of L-Leucine-*p*-nitroanilide Hydrolysis by Leucine Aminopeptidase

Mitsuhiro FUKUDA,* Hiroshi SHIMA, and Shigeru KUNUGI†
Department of Polymer Chemistry, Kyoto University, Sakyo-ku, Kyoto 606
†*Department of Applied Chemistry, Fukui University, Bunkyo, Fukui 910*
(Received November 10, 1984)

Synopsis. The effect of pressure on the hydrolysis of L-leucine-*p*-nitroanilide catalyzed by leucine aminopeptidase from pig kidney was investigated. The activation volumes for k_{cat} process were $-8\,cm^3/mol$ and $-9\,cm^3/mol$ for the native enzyme and the modulated one by Mg^{2+}, respectively. The volume changes for the K_m process were $\simeq 0\,cm^3/mol$ for both enzymes.

Aminopeptidase is most widely distributed in the living organisms,[1] but least studied among the several types of proteinases and peptidases. Leucine aminopeptidase (LAP) from pig kidney has a molecular weight of 320000 composed of six identical subunits[2] and contains one Zn^{2+} per subunit at the active site.[3] LAP from various sources requires divalent metal ions for their activities.[4] Recently, Van Wart and Lin purified pig kidney enzyme by affinity chromatography[2] and found that one subunit has an additional metal binding site for activating metal ion such as Mg^{2+} or Mn^{2+} (regulatory site) beside the one occupied by Zn^{2+} (catalytic site).

We have investigated the pressure dependence of catalytic reactions of several proteases[5] and obtained important informations on their mechanisms. In the present study, we applied this technique to the hydrolysis of L-leucine-*p*-nitroanilide (Leu-*p*NA) catalyzed by LAP to investigate its reaction mechanism.

Experimental

LAP from porcine kidney (type III-CP, Lot 111F-8015) was purchased from Sigma Chemical Co. (St. Louis, USA) and purified by affinity chromatography over L-leucylglycyl-AH-Sepharose according to the literature.[2] For native enzyme with Zn^{2+} (represented by [(LAP)Zn_6-]) and Mg-incubated enzyme ([(LAP)Zn_6Mg_6]), metal analysis was carried out by atomic absorption spectroscopy with a Jarrel ash AA 780 instrument. The metal content was 5.6—5.9 mol per mol enzyme for Zn^{2+} and Mg^{2+} on the basis of protein absorbance ($\varepsilon_{280nm}=400000\,M^{-1}cm^{-1}$ ($1\,M=1\,mol\,dm^{-3}$)).[2] Leu-*p*NA was obtained from the Protein Research Foundation (Osaka). An ultraviolet-visible spectrophotometer with a high pressure optical cell was used as previously described.[5] The concentration of Leu-*p*NA was determined spectrophotometrically by using $\varepsilon_{320nm}=13900$ ($M^{-1}cm^{-1}$) and the initial velocities were calculated from the slope of the absorbance change by using $\varepsilon_{405nm}=9900$ ($M^{-1}cm^{-1}$). The extinction coefficient under high pressure was corrected as previously described.[5] The k_{cat} and K_m values were evaluated from Eadie plot. Tris(hydroxymethyl)aminomethane (Tris) buffer was used[1,2,6] and the pressure dependence of its pK_a was corrected.[5a]

Results and Discussion

Figure 1 shows the pH dependence of k_{cat}/K_m for [(LAP)Zn_6Mg_6] at 0.1 MPa ($\simeq$1 atm) and 100 MPa ($\simeq$1000 atm). Under 100 MPa the activity increased

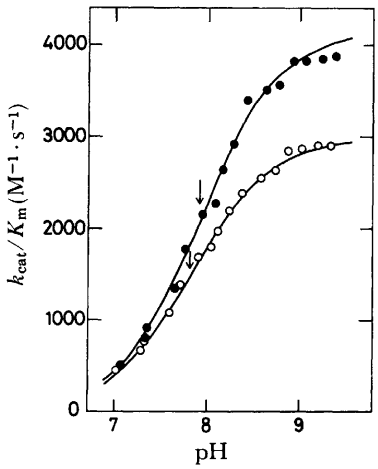

Fig. 1. The pH dependence of k_{cat}/K_m for the hydrolysis of Leu-*p*NA catalyzed by [(LAP)Zn_6Mg_6] at (○) 0.1 MPa and (●) at 100 MPa
$[S]_0<0.05$ mM, $[E]_0=0.018\,\mu M$, 25 °C. 0.02 M Tris-HCl, containing 5 mM $MgCl_2$, 0.5 M KCl and 0.8% (v/v) dimethyl sulfoxide. Arrows indicate the position of pK_a.

1.36 fold for [(LAP)Zn_6Mg_6] and 1.40 fold [(LAP)Zn_6-] at pH around 9. The logarithm of k_{cat}/K_m *vs.* pressure showed a linear correlation for both enzyme forms. The pressure effect was fully reversible in the present pressure range (0.1 MPa—100 MPa) and the observed time scale (less than one hour). These results indicate that there occurs no significant pressure-induced denaturation or dissociation of the hexamer under our experimental conditions,[7] though several oligomeric enzymes were reported to be denaturated or inactivated by medium pressure.[8] The apparent pK_a value was determined for [(LAP)Zn_6Mg_6] by nonlinear regression[5a] and it shifted toward higher pH (pK_a=7.91) under 100 MPa from atmospheric value (7.82). The moderate increase in enzyme activity and the slight pK_a shift to a higher value by pressure increase apparently resemble those of a neutral protease from *Bacillus subtilis*, another type of zinc protease.[5c]

Table 1 shows $\Delta V^{\neq}$ of k_{cat} and ΔV of K_m for [(LAP)-Zn_6Mg_6] and [(LAP)Zn_6-]. Mg^{2+} enhanced the enzyme activity more than 10 fold, which is related not to K_m but k_{cat}.[2] For both forms of the enzyme, k_{cat} increased with increasing pressure, while K_m values were rather pressure independent. Interestingly $\Delta V^{\neq}$ values of the two forms of the enzyme are practically equal. Activation by Mg^{2+} doesn't accompany drastic structural or hydrational change. The reaction mechanisms of LAP was proposed more than twenty years ago[9] and no significant interpretation has been made since then. $\Delta V^{\neq}$ values similar to the present ones were obtained in other zinc protease such as carboxypeptidase

TABLE 1. ACTIVATION VOLUMES AND VOLUME CHANGES FOR Leu-*p*NA HYDROLYSIS AT 0.1 MPa[a)]

Enzyme	k_{cat}	$\Delta V^{\neq}$ for k_{cat}	K_m	ΔV for K_m	k_{cat}/K_m	$\Delta V^{\neq}$ for k_{cat}/K_m
	s^{-1}	cm^3/mol	mM	cm^3/mol	$M^{-1}s^{-1}$	cm^3/mol
[(LAP)Zn_6Mg_6]	1.73	−8±1	0.60	−1±1	2890	−7.6±0.7
[(LAP)Zn_6^-]	0.13	−9±3	0.61	0±3	210	−8.9±1.0

a) Assays are carried out in 0.02 M Tris-HCl buffer containing 0.5 M KCl and 5.6%(v/v) dimethyl sulfoxide, pH 9.0 at 25 °C, except for the presence of 5 mM $MgCl_2$ for [(LAP)Zn_6Mg_6]. [Leu-*p*NA]=0.03—0.57 mM.

A (CPA)[5b)] where the ligating group of the substrate on the active site zinc ion is considered as carbonyl oxygen of the scissile bond. These $\Delta V^{\neq}$'s are to be interpreted by a common mechanism for these metalloproteases.[10)]

The nearly zero ΔV values for K_m show that the substrate binding process does not primarily contain the electrostatic interaction, provided that the apparent K_m value mainly reflects the properties of the substrate binding process, which is consistent with the lack of the evidence of acyl-enzyme intermediate.[11)] This result is also consistent with the facts that LAP favors more hydrophobic side chain in both the amino-terminal and the next residues and that the hydrolysis requirs free amino group.[1,6)] The volume change upon the formation of hydrophobic interaction is considered to be very small.[12)] In this context LAP reaction is in contrast with the reaction of CPA,[5b)] which also favors hydrophobic side chain but requires an ionized (carboxylate) terminal to give a large ΔV value (20—35 cm^3/mol) of K_m^{-1}, reflecting the electrostatic aspect of the substrate recognition. With respect to the pressure dependence of the catalytic process, LAP resembles CPA[5b)] but as for the substrate binding it resembles the mesophilic neutral protease,[5c)] where mostly the hydrophobic nature of the enzyme-substrate interaction was observed.

We gratefully acknowledge Professor N. Ise, Kyoto University, for his advice and encouragement throughout the study. We wish to thank Dr. E.Nakayama, Instrumental Analysis Research Center, Kyoto University for his atomic absorption measurement.

Reverse Osmosis Separations of Aqueous NaCl-Organic Solute Systems

Yoshiaki Kiso and Takane Kitao
Laboratory of Sanitary Engineering, Faculty of Engineering, Toyohashi University of Technology, Tenpaku-cho, Toyohashi 440
(Received September 13, 1984)

Synopsis. Some of alcohols, amides, aromatic hydrocarbons and surfactants were used as organic solute. Addition of NaCl increased the rejections of aromatic hydrocarbons and decreased the rejections of amides. It was also found that the permeability of NaCl was influenced by organic solutes.

In reverse osmosis process, it is well known that the solute permeability in multi-component solution system is different from that in single solute system. The results of bisolute systems containing only inorganic salts indicate that univalent ions may permeate more easily by addition of multivalent ions, and that rejections of multivalent ions are increased.[1,2] However, very little are known concerning the effects of inorganic salts on the permeabilities of nonionic organic solutes. As the effective forces between membrane and organic solutes are different from the forces between membrane and ions, it is difficult to evaluate the effects of salt addition on the permeabilities of nonionic organic solutes. The object of this work is to examine the effects of NaCl addition on the rejections of organic solutes (*i.e.* alcohols, amides, aromatic hydrocarbons and surfactants).

Experimental

Cellulose acetate membranes were prepared by the previous method.[1] The membranes were anealed in a water bath at 351—357 K for 10 min followed by precompaction under 7 MPa during 24 h. The reverse osmosis cell used was batch type one reported previously.[1] The experiments were carried out at 4.0 MPa at 303 K. The concentrations of the solutions used in feed solution except aqueous aromatic hydrocarbon and surfactant solutions were 10×10^{-3} mol dm^{-3}. The concentrations of surfactant solutions were above the critical micell concentration. The organic solutes used in this work were listed in Table 1. Na^+ ion was analysed by an atomic flame spectrometer and the concentrations of organic solutes were measured by a total organic carbon (TOC) analyser and a UV-spectrometer. NaCl rejections (R_{NaCl}) and solution flux (J_v; g cm^{-2} s^{-1}) of the used membranes were as follows: Memb. 1 (R_{NaCl}=97.3%, $J_v=4.565\times10^{-4}$), Memb. 2 (R_{NaCl}=89.3%, $J_v=9.276\times10^{-4}$, and Memb. 3 (R_{NaCl}=83.9%, $J_v=7.879\times10^{-4}$).

Results and Discussion

When R^S_{org} and R^M_{org} denote the rejections of single organic solutes and of organic solutes with NaCl, respectively, the relationship between R^S_{org} and R^M_{org} is shown in Fig. 1. Although difference between R^S_{org} and R^M_{org} were not large, it was found that each group of organic solutes indicated different tendency. The addition of NaCl reduced the rejections of aromatic hydrocarbons by 1.1—10.2% and the largest depression of rejection was found in biphenyl whose rejection in a single solute system was the highest in all of this group. On the other hand, the rejections of amides were increased by NaCl addition. The results of the experiment on the effect of NaCl concentration on the rejection of amides are shown in Fig. 2. It was recognized that the rejection of amides increased as increasing NaCl concentrations and that this effect appeared clearly in formamide and acetamide whose rejections in single solute systems were lower than others. The rejections of alcohols and surfactants, however, were not affected very much by NaCl addition.

When R^S_{NaCl} and R^M_{NaCl} mean the NaCl rejection in single solute system and mixed solute system, respectively, the relationship between ΔR_{org} ($=R^M_{org}-R^S_{org}$) and ΔR_{NaCl} ($=R^M_{NaCl}-R^S_{NaCl}$) is shown in Fig. 3. Although ΔR_{NaCl} is smaller than ΔR_{org}, the sign of ΔR_{NaCl} also varies by the group of organic solute. The effects of NaCl addition on the solute rejection were summarised as follows: as to aromatic hydrocarbons and surfactants $\Delta R_{org}<0$ and $\Delta R_{NaCl}>0$, amides $\Delta R_{org}>0$ and $\Delta R_{NaCl}<0$, and alcohols $\Delta R_{NaCl}<0$.

If, even in the mixed solutes system, the diffusibities of solutes in the pore of membrane remain the same as in single solute systems, the solute permeabilities may be influenced by the partition of solute between bulk solution and membrane surface or pore of membrane.

●: Alcohols, ○: Amides, ◇: Aromatic hydrocarbons, ▲: Surfactants.

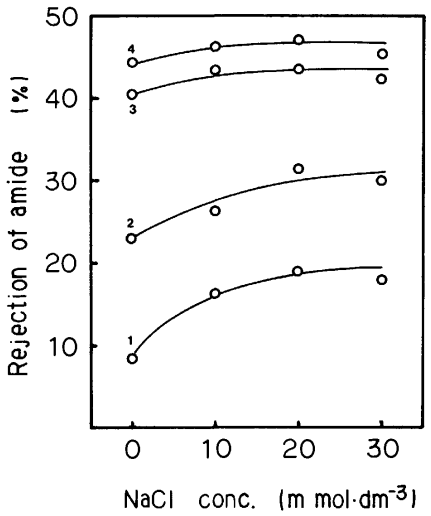

Fig. 2. The effect of NaCl concentration on the rejection of amides.

Kesting *et al.*[3] and Kamizawa and Ishizaka[4] previously indicated that surfactants are adsorbed on the surface of cellulose acetate membrane. Matsuura and Sourirajan[5] mentioned that the preferential sorption layer of aromatic hydrocarbon was formed on the membrane surface. As the solubilities of aromatic hydrocarbons decrease by NaCl addition, these solutes may be adsobed more easily on the membrane and therfore

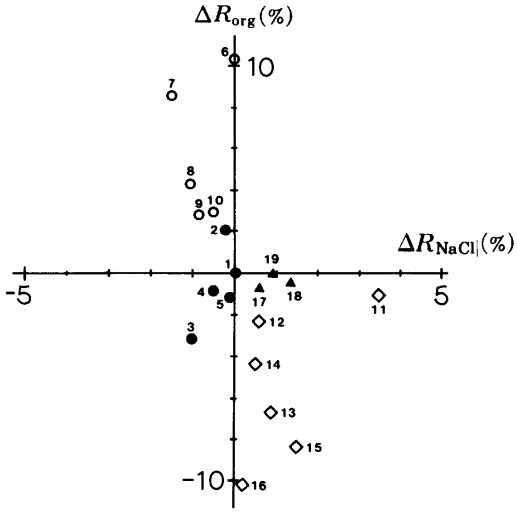

Fig. 3. ΔR_{org} *vs.* ΔR_{NaCl}.
●: Alcohols, ○: Amides, ◇: Aromatic hydrocarbons, ▲: Surfactants.

the rejection of the aromatic hydrocarnons may decrease. On the other hand, it is considered that the sorption layer of the aromatic hydrocarbons or surfactants hindered the permeation of ions through the membrane by following reasons: 1) The pore size of membrane decreases by sorption of organic solute, 2) ionic solutes are difficult to come near the membrane due to the increase of hydrophobic hydration, and 3) the sorption layer of ionic surfactant particularly acts as a kind of ionic membrane. As to amides, the mechanism of the effect of NaCl addition on solute rejection are not clear. The results, however, suggested that ionic solute might hindered the transport of amides into the pore of membrane. From the results of this work, it is concluded that the effect of NaCl addition on the rejection of organic solute depended on the permeation mechanism of the organic solute.

Photoelectrochemical Reduction Products of Carbon Dioxide at Metal Coated p-GaP Photocathodes in Aqueous Electrolytes

Shoichiro IKEDA,* Makoto YOSHIDA, and Kaname ITO
Department of Synthetic Chemistry, Nagoya Institute of Technology, Gokiso-cho, Showa-ku, Nagoya 466
(Received September 3, 1984)

In order to increase the current efficiency of the photoelectrochemical reduction of CO_2 in aqueous electrolytes, metals such as Pb and Zn, which have a higher overpotential for the hydrogen evolution reaction, were coated on a p-GaP photocathode by sputtering and electroplating. Au was also coated by sputtering. Then, the photoelectrolytic experiments were carried out in a gas-tight cell with a cyclic gas-flow system. The products in a gas phase were determined as well as the products in the electrolyte. Accordingly, CO in addition to HCOOH as a reduction product of CO_2 was found to be produced as well as substantial amount of H_2 as a by-product. However, other products such as HCHO and CH_3OH were not found at all. In the case of the Pb coated p-GaP electrode, the current (faradaic) efficiency, η, for HCOOH formation was increased up to 48.2%, although in the case of bare p-GaP it was only 4.8% at maximum. On the other hand, the η for CO formation at the Zn-coated p-GaP electrode went up to 16.5%. While, in the case of an Au-coated p-GaP, the η for the CO_2 reduction was not so changed as for the bare p-GaP photocathode.

In a previous paper,[1] we reported that the some organic compounds such as formic acid, formaldehyde and methanol, which had been reported as photoelectrochemical reduction products of carbon dioxide (CO_2) by a few authors,[2,3] were also produced by the photolysis of cell materials such as electrolytes and epoxy resins. Also, the real reduction product of CO_2 at the p-GaP photocathodes in aqueous electrolytes was experimentally confirmed to be only formic acid, for which the current (faradaic) efficiency, η, was 4.8% at maximum.

The photoelectrochemical reduction of CO_2 is a competitive reaction with the reduction of water, *i.e.*, the hydrogen-evolution reaction (HER). Therefore, η for a CO_2 reduction may be increased if the electrode surface is covered with a thin layer of a metal such as Zn or Pb which have higher overvoltages for HER.

In the present paper, the discussed photoelectrolytic experiments were carried out in a gas-tight cell with a cyclic gas-flow system. The products in the gas phase were determined as well as the products in the electrolytes. In order to increase η for the CO_2 reduction, coatings using such metals as Au, Zn, and Pb were placed on the surfaces of p-GaP photocathodes and the effects on the reduction products and the characteristic properties as a photocathode were investigated. In this paper, mainly an analysis of the reduction products is reported. The properties of the metal-coated electrodes will be the subject of our next paper.

Experimental

Materials. The photocathode was prepared by molding a p-GaP wafer, Sanyo Electric Co. Ltd., Zn-doped 2.8—6.0×10^{17} cm^{-3}, of 1.0 cm^2 with epoxy resin, after an ohmic contact was made with an In-Zn (2%) alloy solder. It was etched in aqua regia for 1 min before use. In order to prevent the photolysis of the epoxy resin, the epoxy region of an electrode was shaved off only to the extent as not to cause a failure of the insulation (Fig. 1).

The electrolytes used were 0.1 mol dm^{-3} aqueous solutions of $(C_2H_5)_4NClO_4$ [TEAP], $(C_2H_5)_4NBr$ [TEABr], and $(n\text{-}C_4H_9)_4NBr$ [TBABr]. TEAP was synthesized with TEABr and perchloric acid.[4] The other reagents were all commercial grade and were used without further purification except for the case of TBABr, which was twice recrystallized with distilled water because it contained detectable amounts of methanol and ethanol.

Apparatus and Procedure. A photoelectrolytic cell with a quartz glass window, (made of Teflon), was designed to separate the cathode and anode chambers with an ion-exchange membrane, Nafion-315, and to be able to operate with a small volume (*ca.* 5 ml) as a catholyte for the easy determination of products (Fig. 2). The cell was gas-tight and the gas, CO_2 or N_2, was supplied by a cyclic gas-flow system which was assembled with a mini peristaltic pump, a manometer and a gas sampler (Fig. 3). The cell and a UV-37 filter, which was used to cut off ultraviolet rays shorter than 370 nm in order to prevent the photolysis of

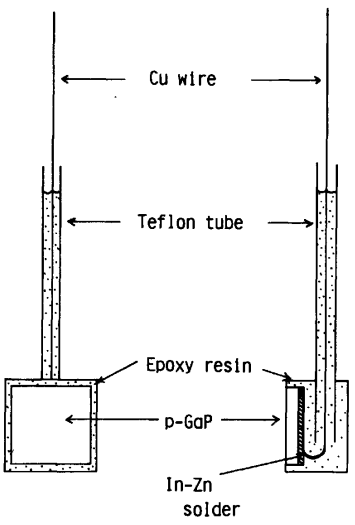

Fig. 1. Structure of p-GaP electrode.

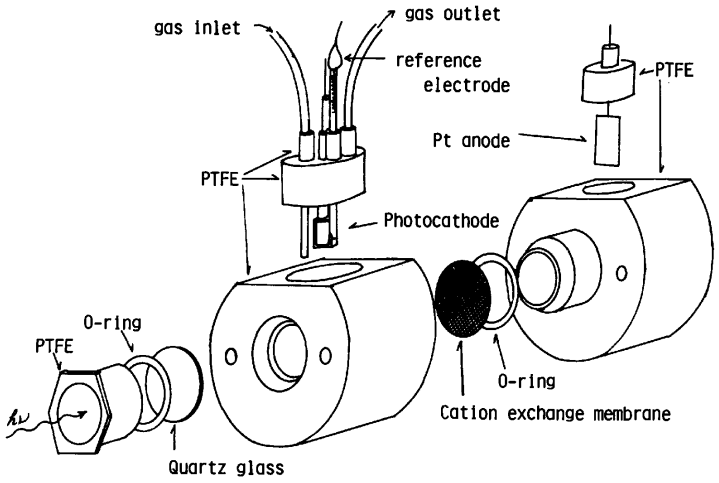

Fig. 2. Structure of photoelectrolytic cell.

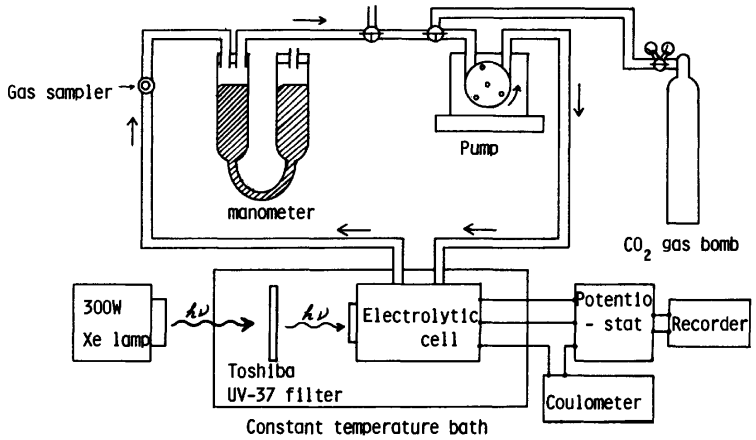

Fig. 3. Diagram of photoelectrolytic apparatus with cyclic gas flow system.

cell materials, were immersed in a water bath for the prevention of overheating due to illumination.

The photoelectrochemical reduction was carried out potentiostatically using a potentiostat and a xenon lamp, Model VIX-300; Varian Co. Ltd. The photocurrent was recorded using a conventional pen-recorder. The quantity of charge passed was monitored with an electronic coulometer, Model HF-102; Hokuto Denko Co. Ltd. After CO_2 or N_2 gas was blown into the cell from each cylinder and was exhausted through the cyclic gas-flow system for about 30 min, the line was closed to make it gas-tight. During the experiment, the gas in the system was circulated using a peristaltic pump with a rate of 1 ml/min.

Analysis. The products in the gas phase were determined qualitatively and quantitatively by gas chromatography, Model GC-3AH, Shimadzu Corp., having a TC detector on a column of activated charcoal 60/80, 3 mm×3 m, at 100 °C using He gas as a carrier with a rate of 13 ml/min. The products in the electrolyte were sampled after the line was exposed to the atmosphere and were then determined by high-performance liquid chromatography. The equipment used was a Model HSLC-022; Atto Corp., with RI and UV detectors with 225 nm on a column of Shodex HC-125S using 1% H_3PO_4 aqueous solution at 1.0 ml/min and 35 °C as an elueant. An analysis was also performed using steam chromatography, SSC-1 Model 103; Ohkura Riken, with a FID on a column of Chromosorb 101, 2 mm×3 m, at 120 °C using steam as a carrier at 8.6 ml/min (5.4 μl/min as water) for the determination of alcohols and aldehydes, although they were not detected at all in the present work.

Metal Coating. The molded p-GaP electrode was coated with a thin layer of Au, Pb, or Zn by sputtering and electroplating methods. The sputtering was carried out at DC 700 V under *ca.* 1 Pa air using an ion cleaner, Model IB-1; Eiko Co. Ltd., where the coverage was controlled by the sputtering time *i.e.*, 7, 15 or 20 min. Au of 99.99%, Pb of 99.99% and Zn of 99.9999% were used as the target metal. Typical weights of coated metals measured by weighing method were 0.06, 0.07, and 0.02 mg cm^{-2} in the cases of Au, Pb and Zn, respectively, for 10-min sputtering.

The electroplating method under photo-illumunation was also used for the coating of Pb and Zn. The electroplating was carried out potentiostatically usig an H-type Pyrex cell with a quartz window under the illumination of a xenon lamp. The amounts of the coated metals were monitored with a coulometer connected in series between the anode and the potentiostat.

In the case of Pb plating, 0.5 mol dm^{-3} of lead acetate was used as an electrolyte, and a p-GaP electrode, a Pb sheat

(99.99%) electrode and a Ag/AgCl/sat'd KCl electrode served as a cathode, an anode and a reference electrode, respectively. The electroplating was carried out at a potential of −0.4 V *vs.* Ag/AgCl/sat'd KCl, during which almost a uniformly deposited gray film of Pb was obtained.

In the case of Zn coating, the electrolyte was a solution of zinc sulfate (300 g) and ammonium chloride (20 g) dissolved into 1 dm^3 of distilled water; a zinc plate (99.9999%) served as an anode. Electroplating was carried out at −0.2 V, and a uniform film of Zn was deposited.

Under these experimental conditions, no hydrogen evolution was observed at all, so that the deposited amounts per coulomb should correspond to 1.0 mg C^{-1} and 0.33 mg C^{-1} for Pb and Zn, respectively. Therefore, the amounts of metals coated on the p-GaP electrodes were controlled by the quantities of electricity passed.

In the present paper, these metal coated p-GaP electrodes are named as Au(s)-p-GaP, Pb(s)-p-GaP, and Zn(s)-p-GaP prepared by sputtering and Pb(e)-p-GaP and Zn(e)-p-GaP by electroplating, respectively.

Results and Discussion

Photoelectrochemical Reduction Products of CO_2. The photoelectrochemical reduction products of CO_2, when metal coated p-GaP electrodes by sputtering were used as a photocathode and the photoelectrolysis was carried out at −1.2 V up to 100 C in various aqueous solutions, are summerized in Table 1. This table demonstrates that the reduction products are only formic acid in the electrolytes and hydrogen and carbon monoxide in the gas phase. No products such as other carboxilic acids, alcohols or aldehydes were observed at all, although these organic compounds had been reported as photoelectroreduction products by some authers.[2,3,5]

In the case of the metal-coated p-GaP electrodes prepared by electroplating (Table 2), the products were also formic acid, carbon monoxide and hydrogen. The current efficiency for CO production increased up to about 16.5% at the Zn(e)-P-GaP

Q_e; quantity of electricity for electroplating. † 1 M = 1 mol dm^{-3}.

electrode and that for formic acid production increased up to 48.2% at Pb(e)-p-GaP electrode. These results suggest that formic acid is effectively produced at the Pb(e)-p-GaP photocathode, as the side reactions such as HER is depressed by coating the metal with a high overpotential for HER. These results are thought to be due to the fact that the metal is deposited preferably onto the active sites of the p-GaP electrode. Thus, the metal plays the role more effectively than that deposited by sputtering.

In the case of a Pb(s)-p-GaP photocathode, the surface changed to a silvery color upon the reduction of lead during the photoelectrolysis. Figure 4 shows the current efficiencies for HCOOH and CO production plotted with respect to the quantity of charge passed. At the point of 25 C (coulomb), where the surface was not silvery, current efficiencies for HCOOH and CO were as small as 5.6% and 1.0%, respectively, while, over the point of 50 C, they became about twice a large as before. In order to clarify this situation, the gas in the cyclic gas-flow system was progresively analysed while watching the surface state of the Pb(s)-p-GaP. The results are shown in Fig. 5. The open triangle in that figure represents the point where the surface became silvery. The formation of H_2 became smaller and, in contrast to this, that of CO became larger after this point. The content of CO_2 gradually decreased with the passage of current and air gradually penetrated into the line. Although the products in the electrolytes were not analyzed, the current efficiency for HCOOH formation may be estimated to increase after this point by the depression of HER.

	Pb(e)-P-GaP	50	605	95	36.5	8.5	3.3	120	48	39.8	87.7
TBABr	p-GaP	100	345	11	2.2	5.4	1.0	480	92	3.2	95.2
	Zn(e)-p-GaP	20	745	19	18.6	9.0	8.7	39	37	27.3	64.3
	Pb(e)-p-GaP	40	715	42	20.0	11	5.1	110	54	25.1	79.5

In order to check the mechanism of CO formation, a blank test was carried out using a Pb(s)-p-GaP electrode in an 0.1 mol dm^{-3} TEABr aq solution previously containing 0.01 mol dm^{-3} HCOOH under N_2 atomsphere for 100 C at -1.2 V *vs.* Ag/AgCl. The product was only hydrogen and CO was not observed. Also, the concentration of formic acid did not change. Therefore, it may be concluded that the CO obtained in the above-mentioned experiments was not obtained through HCOOH from CO_2 but was produced by the direct reduction of CO_2.

Table 3 shows the effect of the supporting electrolyte on the current efficiencies for the reduction products when bare p-GaP, Zn(e)-p-GaP, or Pb(e)-p-GaP were used as photocathodes. In the cases of TEAP and TEABr, the current efficiencies, η, for HCOOH, CO and H_2 productions were not so much affected by the electrolytes, but were largely affected by the coating metals. The η for CO_2 reduction became about 50% at Pb(e)-p-GaP photocathode in TEAP aq. In the case of TBABr, however, a bare p-GaP electrode showed extremely lower η for HCOOH or CO production. The η for CO was up to the same values in the former electrolytes by coating of Pb or Zn. The η for HCOOH, however, was only recovered up to half values. These results indicate that the η for CO_2 reduction is affected not by an anion but the cation size of the supporting electrolytes. The favorable formation of nonaqueous circumstance by large cation of tetrabutylammonium salts on the electrode surface may depress the effect of a lead or zinc coating.

Reduction Mechanism. The photoelectrochemical reduction of CO_2 starts from the formation of a carbon dioxide anion radical, $\cdot CO_2^-$, by the electron acceptance of a CO_2 molecule,[6] and the anion radical is thought to be adsorbed on the electrode surface. The HER also takes place on the same electrode surface and becomes adsorbed atomic hydrogen as follows.[7]

$$CO_2 + e^- \rightarrow \cdot CO_{2\,ad}^- \quad (1)$$

$$H^+ + e^- \rightarrow H_{ad} \quad (2)$$

Now, formic acid, the main reduction product of CO_2 in aqueous electrolytes, is produced according to Reactions 3 and/or 4.

$$\cdot CO_{2\,ad}^- + H_{ad} \rightarrow HCOO^- \quad (3)$$

$$\cdot CO_{2\,ad}^- + H^+ + e^- \rightarrow HCOO^- \quad (4)$$

Hydrogen is produced by HER as follows.

$$H_{ad} + H^+ + e^- \rightarrow H_2\uparrow \quad (5)$$

$$H_{ad} + H_{ad} \rightarrow H_2\uparrow \quad (6)$$

By coating the electrode surface with metals such as Pb and Zn having a higher overpotential for the HER, the rates of Reactions 5 and 6 become slow and the HER is suppressed. Concequently, the rate of formic acid formation by Reaction 3 or 4 through Reaction 1 becomes larger.

On the other hand, carbon monoxide is produced by the disproportionation reaction of the CO_2 anion radical according to Reaction 7.[8]

$$\cdot CO_{2\,ad}^- + \cdot CO_{2\,ad}^- \rightarrow CO + CO_3^{2-} \quad (7)$$

This reaction is thought to be competitive with Reaction 3 or 4. In the case of the Pb(e)-p-GaP electrode, the rates of Reaction 3 and/or 4 are larger than that of Reaction 7. Thus, the formic acid is the predominant product from CO_2. For the case of the Zn(e)-p-GaP electrode, the rate of Reaction 7 is approximately equal to that of Reaction 3 or 4, so that substantial amounts of formic acid and CO are produced.

Infrared Multiphoton Decomposition of 1-Chloro-1-fluoroethene

Hiroo OGURA
The Institute of Space and Astronautical Science, Komaba, Meguro-ku, Tokyo 153
(Received November 13, 1984)

Unimolecular dissociation and subsequent reactions of CH_2=CFCl subjected to the infrared multiphoton excitation were studied with a focused geometry using the P(10) line of the 10.6 μm CO_2 band at 952.9 cm^{-1}. The final products of the photolysis observed were CH≡CCl, CH≡CF, CH≡CH, CH_2≡CHF, and CH_2=CF_2. A series of diagnostic experiments shows that the primary processes of photolysis involve the molecular elimination of HF and HCl, to minor extent C-Cl bond rupture. The relative importance of the primary steps is tentatively estimated to be approximately 100:65:25, respectively. Primarily formed CH≡CCl and CH≡CF suffer from secondary photolysis, absorbing additional photons. More fraction of CH≡CF primary yield is decomposed than that of CH≡CCl, due to the accidental resonance with the laser excitation line. CH≡CH and CH_2=CHF are concluded to be formed by the H atom abstraction reactions of CH≡C· and CH_2=CF· radicals generated during the photolysis, respectively, CH_2=CF_2 being formed by the recombination reaction between CH_2=CF· radical and F atom. In the shock tube pyrolysis the formation of CH≡CF predominates over that of CH≡CCl. A mechanistic change to form CH≡CF in the shock tube pyrolysis is suggested.

Infrared multiphoton excitation (IRMPE) could be a novel method to energize polyatomic molecules on the ground electronic potential, by depositing energy into particular vibrational modes, and to study the dynamics of highly vibrationally excited polyatomic molecules such as unimolecular decomposition.[1] The study of polyatomic molecules with multiple competitive exit channels can provide information about the internal energy distribution of the excited molecules. Partially chlorofluorinated ethanes and ethenes are some of the most suitable molecules for such studies of infrared multiphoton decomposition (IRMPD), since they usually show strong absorption for CO_2 laser lines and have at least two competitive unimolecular dissociation pathways, *i.e.*, HF andHCl molecular elimination channels.[2-7] Jalenak and Nogar studied the IRMPD of CH_2=CFCl by monitoring the emission intensities from HF and HCl, and measured the branching ratio between HF and HCl elimination channels as a function of pressure and pulse energy.[4]

The elimination of molecular fragments also facilitates the IRMPD study by means of final product analysis in gas cell experiments. However, secondary photolysis in the IRMPD has been shown to occur in a very short time scale in the pulse duration, and true primary processes might be masked by such secondary photolysis to generate radicals or atoms due to radical-substrate and radical-atom interactions.[7-9] It has been recognized that the dynamics of unimolecular dissociation processes is not properly addressed by gas cell experiments with focused geometry, where total chemical transformations are observed.[10-12] The results do, however, serve as a useful basis set with which to discuss the unimolecular dissociation, subsequent reactions, and the effects of collisional processes. Several shock tube pyrolysis experiments were also carried out, since in many cases thermal excitation results are helpful to establish the photolysis mechanism.

Experimental

The experimental apparatus and analytical procedure used here are essentially the same as in a previous study,[7] and have been described fully. The pulsed beam from a Lumonics 103-2 TEA CO_2 laser was passed through an aperture with a diameter of 14-mm and focussed in an irradiation cell (46-mm diameter, 22-cm long, NaCl windows) by means of a planoconvex Ge lens with a focal length of 12.7 cm. The pulse consisted of a sharp initial spike (80—100 ns FWHM), followed by a low intensity tail of 1—2 μs.[13] The laser was tuned to the P(10) line of the 10.6 μm at 952.9 cm^{-1}, which falls within the ν_6 mode of CH_2=CFCl corresponding to a CH_2 planar rock,[14] and operated at 1 Hz repetition rate for all runs. The output pulse was attenuated by CaF_2 flats, and the incident pulse energy was measured with a calibrated pyroelectric detector, shot-to-shot fluctuation being within 5%. MKS Baratron transducers were used for the pressure measurements.

All photolysis products were identified by comparative GC retention times with known samples, in particular, with the IRMPD products of CH_2ClCHFCl,[7] identification being straightforward. For quantitative determination of the photolysis products, temperature programmed gas chromatographic analyses (flame ionization detector) were carried out using Porapak N column. The reactant CH_2=CFCl (PCR Inc.) was purified by gas chromatography, and then further distilled under vacuum at low temperature. The experimental details of single-pulse shock tube were fully described previously.[15]

Results

Upon the photolysis at 952.9 cm^{-1}, serveral products were observed. A gas chromatographic analysis of a photolyzed sample shows that major products are CH≡CCl and CH≡CF, three minor, yet important products being CH≡CH, CH_2=CHF, and CH_2=CF_2.

Dependence on Reactant Pressure. The product yields as a function of CH_2=CFCl pressure were investigated with the same number of pulse, excitation line, geometry, and constant laser energy. The results on product yields are shown in Fig. 1, the relative yields being summarized in Table 1. As can be seen from Fig. 1, all product yields increase as the reactant pressure is increased. Major product CH≡CF increases more rapidly in its yield than that of CH≡CCl at higher pressures. Minor product CH≡CH and CH_2=CHF yields increase in a similar manner with higher pressure, while the other minor product CH_2=CF_2 yield increases very gradually with increasing CH_2=CFCl pressure. The relative yields of CH≡CF, CH≡CH, and CH_2=CHF show a very rapid increase at higher pressures, on the other hand, that of CH_2=CF_2 shows a slight decrease with higher reactant pressure.

Dependence on Pulse Energy. The dependence of total yield on pulse energy at CH_2=CFCl pressure of 0.4 Torr (1 Torr=133.322 Pa) is shown in a log-log plot in Fig. 2. The plots are linear and obey the relationship: $Y(\text{yield}) \propto E_0^{1.44}$ (pulse energy). The value of the exponent obtained is very close to 3/2, of which fluence dependence has been observed in many systems with "tightly" focused geometry.[12] At the pressures and fluences where the yield-energy relationship of 3/2 power dependence is observed, a simple threshold model is applicable, in which the reaction zone can be approximated simply by a "double cone" geometry.[16] This model is based on the assumption that all molecules contained in a conical zone where the laser fluence is above some critical fluence ϕ_c, decompose with unit probability (reaction zone), any reactions outside the reaction zone being neglected. In the fluence range where a simple threshold model is applicable, it has been recognized that relative yields are insensitive to the change of pulse energy.[10,11] Actually, very small variance is observed for the relative yields.

	(0.789)	(0.857)	(0.957)	(0.998)	(0.966)	(1.50)	(1.74)

a) Relative yields at E_0=0.255 J/pulse and 500 shots. The yield of CH≡CCl in % conversion per 500 shots is in parenthesis, being taken as 100. b) The yield is too small to be determined quantitatively.

Dependence on Pulse Number. The total yield as a function of pulse number was examined at 1.0 Torr substrate pressure, the other photolysis parameters being kept the same. The results on the total yield is shown in Fig. 3. Unreacted fraction (a/a_0), where a and a_0 denote final and initial pressure, respectively, decreases exponentially with increasing pulse number n up to 1000. $(a/a_0)=\exp(-dn)$, where d corresponds to the slope and can be regarded as an apparent first-order dissociation rate constant for CH_2=CFCl. Furthermore, d corresponds to the fractional volume of the reaction zone(V_r) to the cell volume(V) in a simple threshold model ($d=V_r/V$), where the laser fluence exceeds the lowest critical fluence for the dissociation of CH_2=CFCl.

●: CH≡CCl, ○: CH≡CF, ▲: CH≡CH(×10), △: CH_2=CHF(×10), ■: CH_2=CF_2(×10).

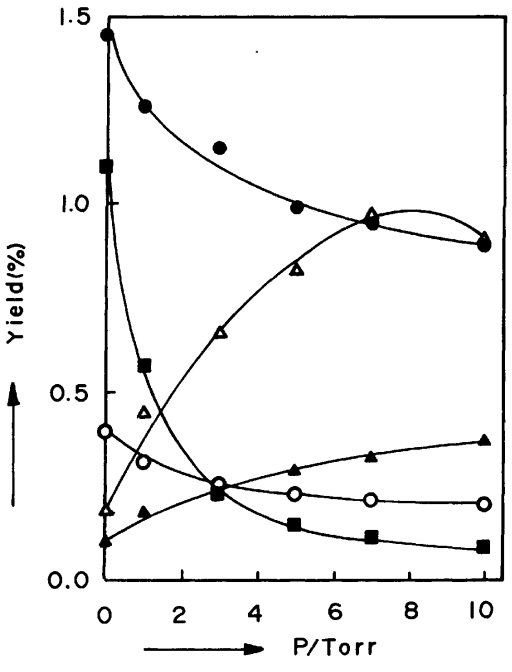

Fig. 6. Product yields as a function of H_2 pressure. (Reactant pressure=1.0 Torr, E_0=0.255 J/pulse, n=500, ν=952.9 cm^{-1}).
●: CH≡CCl, ○: CH≡CF, ▲: CH≡CH, △: CH_2=CHF(×10), ■: CH_2=CF_2(×10).

From the d value obtained (4.05×10^{-5}), the lowest critical fluence ϕ_c for CH_2=CFCl is estimated as 15.3 J/cm^2. Each product yield is plotted in Fig. 4 as a function of n. As can be seen from Fig. 4, each product yield is proportional to pulse number up to 1000, which strongly suggests that formation of each product is one shot event.

Dependence on N_2 and H_2 Pressure. Effects of buffer gas on the product yields were investigated as a function of N_2 and H_2 pressure up to 10 Torrr, the other parameters being the same and the reactant pressure kept constant at 1.0 Torr. The product yields with increasing N_2 and H_2 pressure are shown in Figs. 5 and 6, the relative yields being summarized in Table 2. Upon the addition of N_2 into the reactant, the yields of major products CH≡CCl and CH≡CF together with CH_2=CF_2 decrease in a similar manner, while the yields of CH≡CH and CH_2=CHF increase at lower N_2 pressures and then decrease at higher pressures. Rotational hole filling effect, which has been observed for small molecules,[17] is appreciable for CH≡CH and CH_2=CHF at lower pressures, but is not so clear for CH≡CCl and CH≡CF as observed in the IR emission study by Jalenak and Nogar.[4] Plausible explanation for this apparent discrepancy may be sought in the experimental arrangements: While the reported product yields in the present study represent the averages over all reaction zone corresponding to different fluence values, the observations conducted by Jalenak and Noger were near the focal point, where the fluence is considered to be rather uniform. However, the yields of CH≡CCl and CH≡CF decrease more slowly at lower pressures than those at pressures above 3.0 Torr. In the presence of H_2, the yields of CH≡CCl and CH≡CF decrease more rapidly even at lower pressures, while the yields of CH≡CH and CH_2=CHF increase significantly with increasing H_2 pressure.

In view of relative yields, those for all products show a slight increase with higher N_2 pressure, but CH_2=CF_2 yield shows a slight decrease. Upon the addition of H_2, the relative yields for CH≡CH and CH_2=CHF increase rapidly with increase in H_2 pressure, whereas that of CH_2=CF_2 decreases remarkably with higher H_2 pressure, that of CH≡CF decreasing very slightly.

Effects of Nature of Additives. Effects of collisional deactivation on the yields were examined by

Table 2. Dependence of relative yields on N_2[a] and H_2[b] pressure

	P/Torr	0.0	1.0	3.0	5.0	7.0	10.0
a)	CH≡CF	25.0	26.5	26.8	27.2	28.5	27.2

a) Product yield in % conversion. b) Temperature behind reflected shock wave. c) Dwell time. d) Total pressure behind reflected shock wave. e) Reactant gas pressure behind reflected shock wave.

adding three pairs of gases of 3.0 Torr into the parent gas of 1.0 Torr. The results are tabulated in Table 3, NO being included. On the addition of H containing molecules such as H_2 and CH_4, the increase in the yields of CH≡CH and CH_2=CHF is accompanied by significant decrease in the yield of CH_2=CF_2. Considerable decrease in the yields of CH≡CCl and CH≡CF is observed upon the addition of He and H_2 in the He–Ar and H_2–N_2 pairs.

Shock Tube Pyrolysis. Several shock tube experiments were carried out with a single-pulse shock tube. A reaction mixture of 0.8% CH_2=CFCl diluted with argon was used. Reaction temperature[13] ranged from 1237 to 1417 K, the dwell times and reactant pressures being about 810 μs and 5.5 Torr, respectively. Under these conditions, the conversions ranged from 0.57 to 23.4%. The results are summarized in Table 4. All products found in the IR photolysis of CH_2=CFCl were also obtained in the shock tube pyrolysis. Minor products CH_2=CF_2, CH≡CH, and CH_2=CHF were formed only at higher temperatures. At 1417 K, % yields of CH_2=CF_2, CH≡CH, and CH_2=CHF were 0.899, 0.434, and 0.0934, respectively, these yields being omitted from Table 4. Table 4 shows that the yield of CH≡CF, in contrast to that in the IRMPD of CH_2=CFCl, is greater than that of CH≡CCl over the temperature range examined. The branching ratio between CH≡CF and CH≡CCl formation channels increases with increasing temperature.

Discussion

Mechanism of Primary Photolysis. The elimination of molecular hydrogen halide from the parent molecule is in line with previous IRMPD studies of halogenated ethenes[18,19] together with thermal activation studies.[20,21] Other competitive dissociation channels may be available for CH_2=CFCl:[7]

$$\begin{aligned} CH_2{=}CFCl &\rightarrow CH{\equiv}CCl + HF \quad \Delta H^\circ \simeq 19.4 \pm 10 \text{ kcal/mol}, \\ &\rightarrow CH{\equiv}CF + HCl \quad \Delta H^\circ \simeq 41.3 \pm 15 \text{ kcal/mol}, \\ &\rightarrow CH_2{=}CF\cdot + Cl \quad \Delta H^\circ \simeq 80-90 \text{ kcal/mol}, \\ &\rightarrow CH{\equiv}CH + FCl \quad \Delta H^\circ \simeq 75.5 \text{ kcal/mol}. \end{aligned}$$

In the FCl elimination reaction, the vinylidenecarbene CH_2=C: very rapidly isomerizes to CH≡CH due to very low barrier for the rearrangement. Therefore, this channel can be regarded as a direct pathway to form CH≡CH. The standard enthalpy change of reactions ΔH° (1 cal_{th}=4.184 J) was estimated at 298 K.

Final product analysis shows that CH≡CCl and CH≡CF are major products in the IRMPD of CH_2=CFCl in the reactant pressure range up to 5 Torr. Coupled with the IR emission study by Jalenak and Nogar, primary photolysis processes are concluded to be direct eliminations of HF and HCl:

$$CH_2{=}CFCl + nh\nu \rightarrow CH{\equiv}CCl + HF, \quad (1)$$

$$\rightarrow CH{\equiv}CF + HCl. \quad (2)$$

Reactions 1 and 2 produce vibrationally excited HF and HCl. A significant increase in the yield of CH_2=CHF upon the addition of H_2 and CH_4 strongly suggests that C–Cl bond rupture is occurring at the same time, CH_2=CHF being formed by the H atom abstraction reaction of CH_2=CF· radical from H_2 and CH_4:

$$CH_2{=}CFCl + nh\nu \rightarrow CH_2{=}CF\cdot + Cl, \quad (3)$$

$$CH_2{=}CF\cdot + RH \rightarrow CH_2{=}CHF + R\cdot, \quad (4)$$

where RH denotes any H atom donors, CH_2=CFCl molecule itself being RH in the absence of any additives. The yield of CH≡CH as well as CH_2=CHF increases with increasing H_2 pressure, which can be attributed to the H atom abstraction reaction of CH≡C· radical from H atom donor, but not to the FCl molecular elimination.[7] The source of CH≡C· radical would be the secondary photolysis of the primary products CH≡CCl and CH≡CF:

$$\begin{aligned} CH{\equiv}CCl &\rightarrow CH{\equiv}C\cdot + Cl \quad \Delta H^\circ \simeq 100 \pm 15 \text{ kcal/mol},^{22} \\ CH{\equiv}CF &\rightarrow CH{\equiv}C\cdot + F \quad \Delta H^\circ \simeq 111 \pm 20 \text{ kcal/mol}, \\ CH{\equiv}C\cdot &+ RH \rightarrow CH{\equiv}CH + R\cdot. \quad (5) \end{aligned}$$

Effects of Pressure on Mechanism. At higher pressure where collisional effects can not be neglected, a simple threshold model is not sufficient, but the simple extended threshold model presented by Hackett *et al.*[11] is useful to discuss the photolysis mechanism in bulk experiments with focused

geometry. In the extended threshold model, collision induced dissociation by energy pooling process of excited molecules is taken into account outside the reaction zone. For multiple channel system, the relative yields from various dissociation channels are the ratios of volumes defined by the critical fluence contours which describe them.

Primary dissociation reaction induced by infrared multiphoton absorption occur inside the reaction zone. The threshold energy for C-Cl bond rupture is much greater than those of HF and HCl elimination reactions, which are estimated to be 54.7 and 56.5 kcal/mol, respectively.[4] As a result, the critical fluence for C-Cl bond scission will be also much greater than those of HF and HCl elimination. In the primary photolysis, HF and HCl elimination occurs inside the outer reaction zone, while the C-Cl bond rupture predominates inside the inner reaction zone. As the reactant pressure is increased, collision induced decomposition occurs outside the reaction zone, increasing the yields of the products generated inside the outer reaction zone, *i.e.*, CH≡CCl and CH≡CF:

$$2CH_2{=}CFCl^* \rightarrow CH_2{=}CFCl^* + CH_2{=}CFCl, \quad (6)$$

$$CH_2{=}CFCl^* \rightarrow CH{\equiv}CCl + HF, \quad (7)$$

$$\rightarrow CH{\equiv}CF + HCl, \quad (8)$$

where CH_2=CFCl* and CH_2=CFCl** denote the CH_2=CFCl molecules excited below and above the energy threshold for the unimolecular dissociation, respectively. It is not unreasonable that collision induced decomposition exits preferentially *via* the lower HF and HCl elimination channels.

The relative yield of CH≡CF increases rapidly at higher reacatant pressures (Table 1), which indicates that the yield of CH≡CF increases more rapidly than that of CH≡CCl with increasing substrate pressure. According to the simple extended threshold model, the increase in the yields of CH≡CCl and CH≡CF results from the collision induced decomposition, *viz.* Reactions 6—8. In addition, the CH≡CCl and CH≡CF bormed by the collision induced decomposition outside the reaction zone appear to remain undecomposed by the secondary photolysis, since the relative yield of CH≡CF at higher pressures is greater than that at lower pressues. On the other hand, the CH≡CCl and CH≡CF primarily formed inside the reaction zone suffer from the secondary photolysis:

$$CH{\equiv}CCl + mh\nu \rightarrow CH{\equiv}C\cdot + Cl, \quad (9)$$

$$CH{\equiv}CF + mh\nu \rightarrow CH{\equiv}C\cdot + F. \quad (10)$$

In view of the heat of reaction, C-F bond rupture would require more activation energy than that of C-Cl, indicating smaller decomposition yield for CH≡CF than that for CH≡CCl. The relative yield dependence of CH≡CF on the reactant pressure indicates, on the contrary, that more fraction of primary CH≡CF yield is decomposed than that of CH≡CCl in the secondary photolysis. If in the primary photolysis CH≡CF and CH≡CCl were formed in the vibrationally excited states of their quasicontinuum, CH≡CCl would decompose more easily than CH≡CF because of its lower energy threshold. The enhancement of CH≡CF decomposition could be attributed to the enhanced absorption of CH≡CF due to the accidental resonance with the laser excitation line at 952.9 cm^{-1}.[23] On the other hand, CH≡CCl has no absorption bands in the CO_2 laser range.

The presence of F atom in the photolysis system is supported by the formation of CH_2=CF_2. Two possible reactions are:

$$F + CH_2{=}CFCl \rightarrow \cdot CH_2CF_2Cl^* \rightarrow CH_2{=}CF_2 + Cl,$$

$$\cdot CH_2CF_2Cl^* \xrightarrow{M} \cdot CH_2CF_2Cl,$$

$$CH_2{=}CF\cdot + F \xrightarrow{M} CH_2{=}CF_2. \quad (11)$$

The addition reaction mentioned above appears to be unimportant, since CH_2=CF_2 formation *via* the addition reaction would decrease with increasing reactant pressure. On the contrary, the yield of CH_2=CF_2 increases slightly with higher substrate pressure. Another support for Reaction 11 is obtained upon the addition of H_2 and CH_4. F atom abstracts H atom very rapidly from H_2 and CH_4,[24] decreasing the yield of CH_2=CF_2 remarkably in the presence of H_2 and CH_4 (Table 3):

$$F + H_2 \rightarrow HF + H, \quad (12)$$

$$F + CH_4 \rightarrow HF + CH_3\cdot. \quad (13)$$

Furthermore, CH≡CF yield decreases significantly on the addition of H_2 as compared with that on the addition of N_2. In the presence of H_2, the recombination reaction between CH≡C· radical and F atom to regenerate CH≡CF competes with the H atom abstraction reactions of F atom and CH≡C· radical one another:

$$CH{\equiv}C\cdot + F \xrightarrow{M} CH{\equiv}CF, \quad (14)$$

$$F + H_2 \rightarrow HF + H, \quad (12)$$

$$CH{\equiv}C\cdot + H_2 \rightarrow CH{\equiv}CH + H. \quad (5')$$

In a similar manner to CH_2=CF_2, the yield of CH≡CF is decreased by the addition of H_2. Similarly, CH≡CCl yield starts decreasing more rapidly on the addition of H_2 than that upon the addition of N_2. Therefore, H atom abstraction reactions would compete with the recombination reaction between CH≡C· radical and Cl atom:

$$CH{\equiv}C\cdot + Cl \xrightarrow{M} CH{\equiv}CCl, \quad (15)$$

$$CH{\equiv}C\cdot + H_2 \rightarrow CH{\equiv}CH + H, \quad (5')$$

$$Cl + H_2 \rightarrow HCl + H. \quad (16)$$

In the He-Ar pair no chemical reactions of CH≡C· radical and the atoms with the rare gases are expected. Therefore, considerable difference in the yields of CH≡CCl and CH≡CF in the He-Ar pair could be explained in terms of the difference in the collisional quenching efficiency between He and Ar to Reactions 14 and 15. The recombination reaction between CH_2=CF· radical and Cl atom may be also occurring, but is hidden by the presence of a large amount of CH_2=CFCl parent gas:

$$CH_2{=}CF\cdot + Cl \xrightarrow{M} CH_2{=}CFCl \qquad (17)$$

The pressure behaviors of CH≡CH and CH_2≡CHF observed on the addition of N_2 (Fig. 5) can be explained qualitatively in terms of a competition between rotational hole filling and collisional deactivation. Rotational hole filling is related to the rotational relaxation of particular rotational-vibrational state depopulated by the laser pumping, while collisional deactivation is vibrational energy transfer from the laser excited species. Apparently enhanced yields of CH≡CF and CH≡CCl at lower N_2 pressures in relation to those on the addition of H_2, result from the coupled effects of rotational hole filling and the recombination reactions to regenerate CH≡CCl and CH≡CF, *viz.* Reactions 14 and 15: By the addition of N_2, the yields of CH≡CF and CH≡CCl are increased apparently by the hole filling effect. However, more fraction of the primary CH≡CF and CH≡CCl yields are decomposed by the secondary photolysis to CH≡C· radical, resulting in the increase in the yield of CH≡CH at lower N_2 pressures (Fig. 5). On the other hand, CH≡CF and CH≡CCl are regenerated to some extent by Reactions 14 and 15, resulting in an apparent increase in the yields of CH≡CF and CH≡CCl relative to that on the addition of H_2. In the case of H_2 addition, H atom abstraction reaction of CH≡C· radical, Reaction 5′ is much faster than the recombination reactions to regenerate CH≡CF and CH≡CCl, more rapid decrease in the yields of CH≡CF and CH≡CCl being observed at lower H_2 pressures than that on the addition of N_2.

Product Distribution: Summing up the above considerations of the photolysis mechanism, primary photolysis occurs *via* HF, HCl molecular eliminations, and C-Cl bond rupture, the product species being CH≡CCl, CH≡CF, and CH_2=CF· radical, respectively. Primarily formed CH≡CF and CH≡CCl are decomposed by the secondary photolysis to unknown extent, yielding CH≡C· radical. Primary product yields could be given by $[CH{\equiv}CCl]_0=[CH{\equiv}C\cdot]^{Cl}+H[CH{\equiv}CCl]$, $[CH{\equiv}CF]_0=[CH{\equiv}C\cdot]^{F}+[CH{\equiv}CF]$, and $[CH{=}CF\cdot]_0$, where $[CF{\equiv}CCl]_0$, $[CH{\equiv}C\cdot]^{Cl}$, and [CH≡CCl] denote the yield of CH≡CCl primarily formed. that of CH≡CCl decomposed, and that survived in the secondary photolysis, respectively. In the present gas chromatographic analysis of the final products, CH≡C· and CH_2=CF· radicals are converted to CH≡CH, CH_2=CHF, and CH_2=CF_2. No C_4H_2 was found in the GC analysis. The recombination reaction between two CH≡C· radicals together with that of CH_2=CF· radical would contribute to much smaller extent than the H atom abstraction reactions and the recombination reactions between the radicals and the atoms, to regenerate stable species from CH≡C· and CH_2=CF· radicals for the GC analysis. he yields of CH≡C· and CH_2=CF· could be approximated by those of CH≡CH and CH_2=CHF plus CH_2=CF_2, respectively. As can be seen from Fig. 1, the yield of CH_2=CF_2 is relatively constant in the reactant pressure range examined, indicating that the yields of CH_2=CF· radical and F atom (consequently CH≡C· radical as well) remain rather constant at these pressures. More fraction of CH≡C· and CH_2=CF· radical yields is scavenged with increasing CH_2=CFCl pressure by H atom abstraction reactions of CH≡C· and CH_2=CF· radicals from CH_2=CFCl molecules. Accordingly, the estimate of the yields of CH≡C· and CH_2=CF· radicals could be made at 5.0 Torr reactant pressure rather than at 0.2 Torr. The yields of stable species could be estimated at 0.2 Torr reactant pressure, where the contribution from the collision induced decomposition is minimized in the present substrate pressure range. In the neat IRMPD at 5.0 Torr CH_2=CFCl, the yield of CH≡CF increases by about 4 times more rapidly than that of CH≡CCl, more fraction of primarily formed CH≡CF yield being decomposed by the secondary photolysis than that of CH≡CCl inside the reaction zone. It might be fair to assume that CH≡C· radical arises from CH≡CF only. In the neat IRMPD of CH_2=CFCl, the product distribution could be estimated as $[CH{\equiv}CCl]_0:[CH{\equiv}CF]_0:[CH_2{=}CF\cdot]_0 \simeq 100:65:25$.

As is seen from Fig. 6, H_2 molecule serves to scavenge efficiently CH≡C· and CH_2=CF· radicals. The increase and decrease in the product yields become very slow at higher H_2 pressures, showing an approach to a steady product distribution. From Table 2, at 10 Torr the product distribution is obtained as $[CH{\equiv}CCl]_0:[CH{\equiv}CF]_0:[CH_2{=}CF\cdot]_0 \simeq 100:63:11$. CH_2=CFCl and H_2 as the radical scavengers give similar value for $[CH{\equiv}CF]_0$, but give considerably different value for $[CH_2{=}CF\cdot]_0$. For the present estimation of the product distribution, greater values would be preferred:

$$[CH{\equiv}CCl]_0 : [CH{\equiv}CF]_0 : [CH_2{=}CF\cdot]_0 \simeq 100 : 65 : 25 \qquad (18)$$

The C-Cl bond rupture channel would contribute significantly at high fluences, where IR emission study could not detect this channel directly, DX(X=Cl, F) emission being unobserved upon the addition of D_2CO.[4]

Comparison with Shock Tube Pyrolysis. The product distribution estimated above indicates that in the IRMPD of CH_2=CFCl, HF molecular elimination is dominant channel over that of HCl. In addition, Jalenak and Nogar have reported that the intensity ratio $I(HCl)/I(HF)=[CH{\equiv}CF]_0/[CH{\equiv}CCl]_0$ increases with increasing laser fluence (0.29—0.43 in the pulse energy range 0.2—0.9 J/pulse), showing HCl elimination might predominate at higher fluences. In the shock tube pyrolysis of CH_2=CFCl, the formation of CH≡CF is preferred channel to that of CH≡CCl, apparently showing that HCl molecular elimination, in contrast to the IRMPD, predominates over that of HF. The ratio [CH≡CF]/[CH≡CCl], however, also increases with increasing temperature (2.0—4.6 in the temperature 1237—1367 K).

In a thermal system a higher channel can predominate over the lower channel above a certain temperature, as far as some requirements for activation energy and frequency factor are satisfied, the same being true for the system subjected to uniform laser fluence. However, in a "tightly" focused geometry, according to the simple extended threshold model, branching ratio is the ratio of reaction volumes divided by the critical fluences. As a result, branching ratio of a higher channel, in general, never exceeds 1.0 in relation to the lower channel.

While in the present shock tube experiments, no direct observations of HF and HCl elimination processes were made, the IR emission study did observe the HF and HCl elimination processes, since HF and HCl emission was monitored. The Arrhenius parameters of HF and HCl elimination reactions on thermal excitations have been reported on a number of halogenated ethanes and ethenes: $\log A$=13—15 and E_a=55—85 kcal/mol for HF elimination; $\log A$=11—14 and E_a=40—70 kcal/mol for HCl elimination.[20,21,25] Generally, HCl elimination is lower channel, Ishikawa and Arai showing in their IR emission studies of CH_2ClCF_2Cl and CHFClCHFCl IRMPD that at very high fluences HF emission exceeds that of HCl.[5,6]

With the assumption that CH≡CF and CH≡CCl formation was first-order in CH_2=CFCl, the rate constants were evaluated from Table 4. Apparent activation energies and frequency factors for CH≡CCl and CH≡CF formation reactions were obtained as 64.4 and 80.0 kcal/mol, and 4.8×10^{11} and 6.4×10^{14} s^{-1}, respectively. These values seemingly fall within nomal value range quoted above, except that the values for HCl and HF elimination are exchanged each other, which would not be unreasonable, since HF elimination is the lower channel in CH_2=CFCl. The activation energy of 80.0 kcal/mol for CH≡CF formation reaction is comparable to that of the C-Cl bond rupture in CH_2=CFCl molecule. Therefore, in the present IRMPD experiments with a "tightly" focused geometry, CH≡CF would have been generated inside the inner reaction zone, where the C-Cl bond dissociation channel predominated. In reality, CH≡CF was formed by the collision induced decomposition outside the reaction zone, indicating CH≡CF formation *via* IRMPD predominated inside the outer reaction zone, but not inside the inner reaction zone. The CH≡CF formation pathway with an apparent activation energy of 80.0 kcal/mol obtained in the shock tube pyrolysis does not correspond exactly to the HCl molecular elimination which generates CH≡CF molecule at the same time, but would suggest that this channel might be closely related to the C-Cl bond rupture channel, which generates CH_2=CF· radical. As shown by the IR emission study, the HCl molecular elimination to generate CH≡CF does occur but would not predominate over HF molecular elimination at the temperatures examined in the shock tube experiments. However, the C-Cl bond rupture channel coluld predominate over those of HF and HCl elimination in the present temperature range due to its greater frequency factor and higher activation energy. Thus plausible explanation for the reversed predominance of CH≡CF formation in the shock tube pyrolysis would be that primarily formed CH_2=CF· radical undergoes secondary unimolecular decomposition:

$$CH_2{=}CFCl \rightarrow CH{\equiv}CCl + HF, \quad (19)$$

$$\rightarrow CH{\equiv}CF + HCl, \quad (20)$$

$$\rightarrow CH_2{=}CF\cdot + Cl, \quad (21)$$

$$CH_2{=}CF\cdot \rightarrow CH{\equiv}CF + H, \quad (22)$$

$$CH{\equiv}CCl \rightarrow CH{\equiv}C\cdot + Cl, \quad (23)$$

$$CH{\equiv}CF \rightarrow CH{\equiv}C\cdot + F. \quad (24)$$

Activation energy for Reaction 22 could be estimated as in the range of 40—50 kcal/mol by analogy with that for CH_2=CH· radical.[26] Due to very low activation energy for CH_2=CF· radical decomposition, sequential bond rupture might occur. The C-X(X=Cl, F) bond scissions of CH≡CCl and CH≡CF require more than 100 kcal/mol, and secondary decomposition of CH≡CCl and CH≡CF would occur to much smaller extent in the shock tube pyrolysis.

In the IRMPD of CH_2=CFCl, primarily formed CH≡CCl and CH≡CF are shown to decompose by the secondary photolysis. In a thermal system, the excitation is uniform to all species. As a result, in the shock tube pyrolysis, CH_2=CF· radical with the lowest activation energy among the primary pyrolysis products is decomposed to much greater extent. In infrared multiphoton excitation, on the other hand, the excitation depends on the vibrational states of the primarily formed species. When the primary products are in their quasicontinuum region, they can absorb any laser photons. As a result, the mechanism

in both pyrolysis and IR photolysis would become similar to each other, except for the form of excitations, *i.e.*, molecular collisions and photon absorption. In the present IRMPD experiments, CH≡CH together with CH_2=CHF shows, as noted earlier (Fig. 5), a clear bottleneck upon the addition of N_2, indicating that CH≡CCl and CH≡CF are lowerly excited below the quasicontinuum region in the primary photolysis. More enhanced decomposition of CH≡CF than that of CH≡CCl has been ascribed to the accidental resonance of the CH≡CF band with the excitation laser line. The excess energy of the dissociating parent molecule would be greater for HF and HCl molecular elimination channels with the lower energy thresholds than that for the C-Cl bond rupture channel. Since even the CH≡CCl and CH≡CF formed primarily *via* the lower channels appear to be lowerly excited, the excess energy of the dissociating parent molecule would hardly be partitioned into the vibration of the CH_2=CF· radical generated *via* the higher channel. Thus primarily formed CH_2=CF· radical would be hardly dissociated by the additional IR photon absorption, except for the accidental coincidence of CH_2=CF· absorption band with the laser excitation line.

The author would like to thank Professor Kenji Kuratani, the Institute of Space and Astronautical Science, for his encouragement and interest in this work.

Vibrational Spectra of β-Lactams. I. 2-Azetidinone and Its Isotopic Compounds

Kazuhiko HANAI,* Yoshifumi MAKI, and Akio KUWAE†
Gifu Pharmaceutical University, Mitahora-higashi, Gifu 502
†*Faculty of General Education, Nagoya City University, Mizuho-ku, Nagoya 467*
(Received November 16, 1984)

The infrared and Raman spectra of 2-azetidinone and its 1-*d*, 3,3-d_2, and 1,3,3-d_3 and their ^{15}N compounds have been recorded, and the observed bands have been assigned on the basis of the isotope effects and the normal coordinate analysis. The refined force constants have reproduced the observed frequencies satisfactorily. The C–N stretching mode is strongly coupled with the N–H bending vibration to give a band near 1380 cm^{-1}. However, this coupling does not give rise to any bands corresponding to the amide II and III bands. The concentration dependence of the infrared spectrum suggests the presence of an equilibrium of monomer $\rightleftharpoons$ cyclic dimer in carbon tetrachloride solution. The solvent effects on the N–H and C=O stretching bands have also been examined.

2-Azetidinone (2-AZ) is the simplest four-membered lactam. For penicillins and cephalosporins known as β-lactam antibiotics, the relationship between their biological activities and lactam C=O stretching frequencies has been reported in the literature.[1,2] This correlation arises from the fact that the amide resonance affects both the lactam C=O stretching frequency and the ease of hydrolysis of the lactam amide bond.[1–3] Therefore, it is interesting to compare the C=O stretching force constants (or C=O frequencies) or the C–N stretching force constants with the ease of hydrolysis for simple β-lactams. The present paper deals with the vibrational analysis of 2-azetidinone and its seven isotopic compounds.

Experimental

Materials. 2-Azetidinone (2-AZ) was prepared from β-alanine by using Mukaiyama's reagent.[4] β-Alanine (0.89 g) was suspended in 1 L of acetonitrile, and 3.15 g of triphenylphosphine and 2.64 g of di-2-pyridyl disulfide were added with stirring. After the reaction mixture was refluxed for 5 h, the solvent was distilled off and the residue was subjected to sublimation under reduced pressure. The sublimate (0.44 g) was collected and recrystallized three times from hexane–chloroform; mp 77 °C. Its purity was checked by elemental analysis.

2-AZ-^{15}N was prepared from β-alanine-^{15}N, which was obtained by the same method as described in the literature[5] except that an anion exchange resin (Amberlite IRA-45) was used for the isolation of free β-alanine (an isotopic purity of starting material, ammonium-^{15}N sulfate, 99.9%, SHOKO Co., Ltd., Japan); mp 77 °C.

The α-position(to the carbonyl group)-deuterated compounds (2-AZ-3,3-d_2 and 2-AZ-3,3-d_2-^{15}N) were prepared from β-alanine-α,α-d_2 and β-alanine-α,α-d_2-^{15}N, respectively, which were obtained by the following methods. β-Alanine was dissolved in an excess of deuterium oxide, and the solvent was distilled away *in vacuo*. The β-alanine-*N*,*N*,*O*-d_3 thus obtained was dried over phosphorus pentaoxide and heated in an excess of 19.9% hydrochloric acid-*d* (CEA, France, an isotopic purity of 99.5%) under reflux for 80 h,[6] and the solution was evaporated *in vacuo* to dryness. The aqueous solution was passed through an Amberlite IRA-45 column and the water was distilled away *in vacuo*. The β-alanine-α,α-d_2 obtained was purified by recrystallization from aqueous ethanol. β-Alanine-α,α-d_2-^{15}N was obtained by hydrolysis of methyl 3-(phthalimido-^{15}N)-propionate, which was the intermediate product in the preparation of β-alanine-^{15}N, in an excess of 19.9% hydrochloric acid-*d* under reflux for 55 h, and then by treatment with Amberlite IRA-45. The crude azetidinones were recrystallized from hexane–chloroform; mp 77.5 °C for both 2-AZ-3,3-d_2 and 2-AZ-3,3-d_2-^{15}N. Their deuteration degree was checked by NMR spectroscopy and mass spectrometry and estimated to be over 95%. The N-deuterated compounds were obtained by the exchange reaction with deuterium oxide.

Spectra. The infrared spectra of the solids were recorded in KBr disks and Nujol or hexachlorobutadiene mulls on a JASCO DS-403G grating infrared spectrophotometer. The infrared spectra of carbon tetrachloride, chloroform, and benzene solutions were measured. Carbon tetrachloride and benzene were of spectrophotometric grade. Chloroform was purified by a usual method. Raman spectra in the solid state were recorded on a JEOL S-1 laser Raman spectrometer equipped with an argon ion laser (excitation line: 488.0 or 514.5 nm).

The infrared and Raman spectra are shown in Figs. 1—4, and the observed frequencies are listed in Tables 1—4 together with the calculated values.

Results and Discussion

CH_2 Group Vibrations. Assignment of some CH_2 vibrations is straightforwardly made by comparison between Figs. 1 and 2 and between Figs. 3 and 4. In Fig. 3 the two bands at 3003 and 2956 cm^{-1} are attributed to the α-CH_2 stretching vibrations, since they clearly disappear on α-C-deuteration. However, three bands of medium to strong intensity are observed in the CD_2 stretching region of the Raman spectra. The corresponding infrared absorptions are observed as weak bands at the same frequencies. The third band can be explained in terms of Fermi resonance. The highest frequency band at 2255 cm^{-1} which does not shift on N-deuteration is assigned to the CD_2 antisymmetric stretching vibration. Fermi resonance occurs probably between the CD_2 symmet-

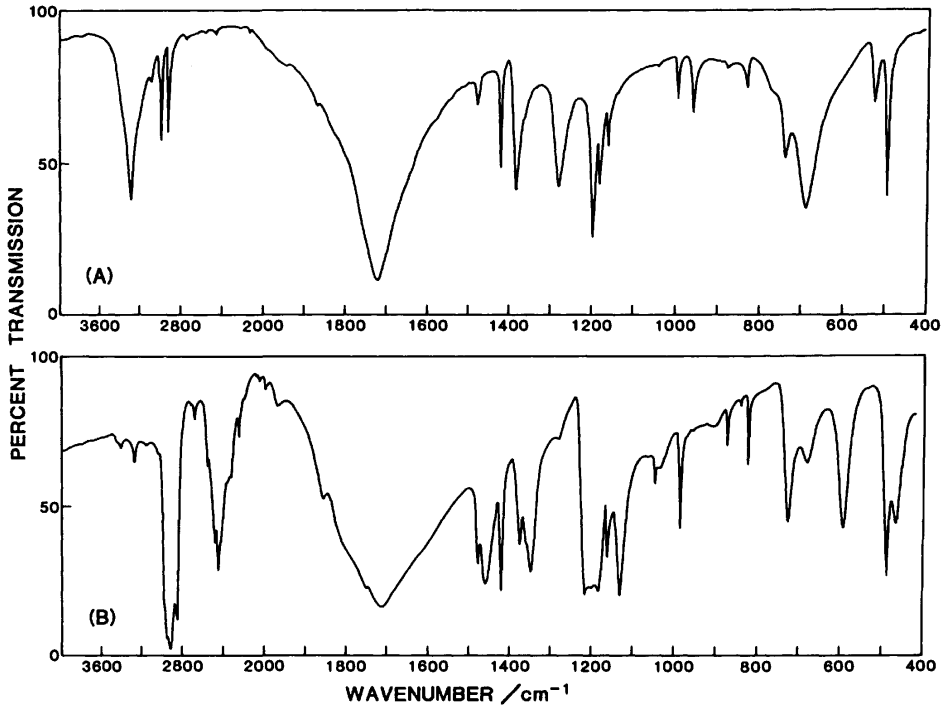

Fig. 1. (A) Infrared spectrum of 2-azetidinone (in a KBr disk); (B) infrared spectrum of 2-azetidinone-1-*d* (in a Nujol mull).

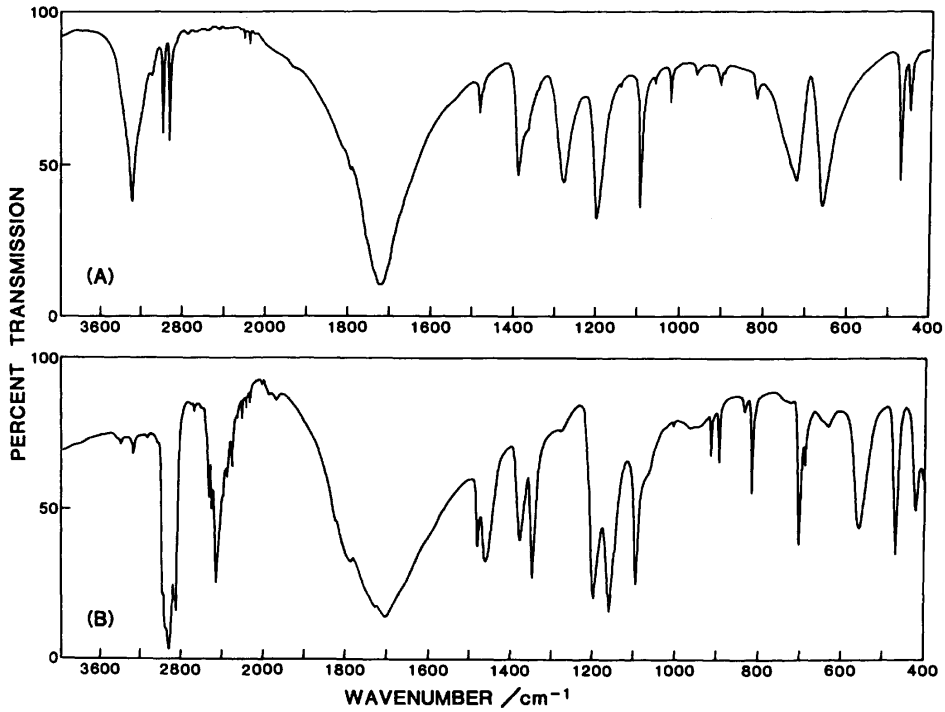

Fig. 2. (A) Infrared spectrum of 2-azetidinone-3,3-d_2 (in a KBr disk); (B) infrared spectrum of 2-azetidinone-1,3,3-d_3 (in a Nujol mull).

ric stretching vibration and the first overtone of the CD_2 bending vibration (1098 cm^{-1}) and gives rise to the two Raman bands at 2209 and 2156 cm^{-1} in 2-AZ-3,3-d_2. From the ^{15}N-isotopic shift, however, it seems that the resonance in 2-AZ-1,3,3-d_3 occurs between the CD_2 symmetric stretching and a combination of the 1350 and 815 cm^{-1} vibrations. A correction for Fermi resonance[7] has revealed that the intrinsic CD_2 symmetric stretching frequencies are 2177 cm^{-1} in 2-AZ-3,3-d_2 and 2175 cm^{-1} in 2-AZ-1,3,3-d_3.

In general a CH_2 bending vibration is the most localized mode of CH_2 deformation vibrations. The 1479 and 1422 cm^{-1} infrared bands of 2-AZ are assigned to this mode; the former is due to the β-CH_2

a) ^{15}N-Isotopic shifts in the infrared spectrum. b) Potential energy distributions, 100 $F_{kk}L_{ki}^2/\lambda_i$, are given in parentheses, where contributions less than 10% have been omitted. The coordinate numbers refer to the following descriptions: 1, NH(ND) stretch; 2, α-$CH_2(CD_2)$ sym stretch; 3, β-CH_2 sym stretch; 4, CO stretch; 5, NH(ND) in-plane bend; 6, α-$CH_2(CD_2)$ bend; 7, β-CH_2 bend; 8, α-$CH_2(CD_2)$ wag; 9, β-CH_2 wag; 10, CO in-plane bend; 11, CN stretch; 12, NC^β stretch; 13, CC^α stretch; 14, $C^\alpha C^\beta$ stretch; 15, CNC^β bend; 16, NCC^α bend; 17, $CC^\alpha C^\beta$ bend; 18, $C^\alpha C^\beta N$ bend; 19, α-$CH_2(CD_2)$ antisym stretch; 20, β-CH_2 antisym stretch; 21, α-$CH_2(CD_2)$ twist; 22, β-CH_2 twist; 23, α-$CH_2(CD_2)$ rock; 24, β-CH_2 rock; 25, NH(ND) out-of-plane bend; 26, CO out-of-plane bend; 27, CN torsion; 28, NC^β torsion; 29, CC^α torsion; 30, $C^\alpha C^\beta$ torsion.

group and the latter to the α-CH_2 group as is evident from the deuteration behavior. The bands at 1281 and 1182 cm^{-1} can be assigned to the wagging vibrations of the β-CH_2 and α-CH_2 groups, respectively. The band at 1198 cm^{-1} which does not disappear on N- and C-deuteration may be ascribed to a CH_2 deformation of the *a″* species.

Amide Group Vibrations. The N-H stretching band occurs at 3282 cm^{-1} and is at a higher frequency than those of 2-pyrrolidinone (γ-butyrolactam) and 2-piperidinone (δ-valerolactam), which are observed at 3252[8,9] and 3226 cm^{-1},[9,10] respectively. The infrared C=O stretching band is observed at 1723 cm^{-1} higher in frequency than those of 2-pyrrolidinone (1690 cm^{-1})[8,9] and 2-piperidinone (1664 cm^{-1}).[9,10]

There is noncoincidence of frequencies in many bands, particularly the C=O band, between the infrared and Raman spectra. This fact suggests that the two molecules of 2-AZ form a cyclic dimer which has the center of symmetry. In this case the C=O vibration which is symmetric with respect to the center of symmetry is observed at 1697 cm^{-1} in the Raman spectrum and the asymmetric stretching mode

at 1723 cm^{-1} in the infrared spectrum. 2-Pyrrolidinone and 2-piperidinone also form such dimers and show similar frequency differences[8,10] as given in Table 9.

The C-N stretching vibration is expected to be coupled with other ring stretchings or deformations to give complicated modes. However, it is possible to assign the band to which the C-N stretching vibration contributes considerably. The ^{15}N isotopic compounds are useful for this purpose. The infrared band at 1385 cm^{-1} shows a ^{15}N shift of 14 cm^{-1} to a lower frequency as given in Table 1 and can be assigned to this vibration. For 2-AZ-3,3-d_2 the corresponding band is observed at 1389 cm^{-1} with a ^{15}N shift of 12 cm^{-1}. The N-H bending bands in 2-AZ and 2-AZ-3,3-d_2 occur at 1370 cm^{-1} and show ^{15}N shifts of about 10 cm^{-1}. Although these bands are observed as poorly-characterized shoulders, the corresponding vibration of 2-AZ-3,3-d_2-^{15}N appears at 1361 cm^{-1} as a clear-cut band. 2-AZ does not show any band in the 1550 cm^{-1} region; the amide II band, which is very characteristic of *trans* secondary amides, is absent from the spectra of small ring lactams.[9] The infrared bands at 690 and 527 cm^{-1} are ascribed to the N-H and C=O out-of-plane modes, respectively, or their coupled modes.

Skeletal Vibrations. For 2-AZ the three infrared bands (999, 961, and 880 cm^{-1}), which have the strong Raman counterparts, are observed in the 1000—800 cm^{-1} region and exhibit ^{15}N-isotopic shifts of about 7 cm^{-1}. Therefore, these bands are assigned to the skeletal vibrations, although an appreciable contribution of other vibrations must be considered as can be seen from the deuteration behavior.

Combination and Overtone Bands. In addition to the bands due to the fundamentals, a number of weak bands are observed and assignable to combinations or overtones. They are listed for 2-AZ and 2-AZ-3,3-d_2 in Table 5.

The origin of a weak band around 3100 cm^{-1} was discussed for *cis* secondary amides by Miyazawa[11a,b] and explained in terms of the combination of the C=O stretching and N-H in-plane bending vibrations. In the present study this conclusion was confirmed by the ^{15}N shift; the ^{15}N substitution shifts the frequency by 16 cm^{-1} depending upon the shift of the N-H bending frequency, whereas the α-C-deuteration does not affect it.

Normal Coordinate Analysis. The normal coordinate calculations were carried out according to the GF matrix method. A 2-AZ molecule was assumed to have the symmetry plane, *i.e.*, to belong to the point group C_s. This assumption seems to be reasonable from the X-ray studies on 1-substituted 2-azetidinones[12,13] and from the quantum chemical studies on 2-AZ.[14,15] The bond lengths and angles were taken from 1-(4-bromophenyl)-2-azetidinone,[12] 1-(2-bromophenyl)-2-azetidinone[13] and 5-iodomethyl-2-pyrrolidinone.[16] Table 6 gives the structural parameters used in the calculation. The internal symmetry coordinates were constructed in the usual form. A Urey-Bradley force field, to which some constants of valence force type for the *a''* species were added, was used in the calculation. In the initial calculation the force constants were transferred from *N*-acetylglycine methylamide[17] and 2-piperidinone[18] and refined by the least-squares method. The final force constants which give the best fit between the observed and calculated frequencies are given in Table 7. For the two force constants (F(HC$^{\beta}$H) and F(C$^{\alpha}$CO)), the negative values seem to be inevitable in the force field where only a small number of interaction constants are included.

The agreement between the observed and calculated frequencies is satisfactory. Although the observed frequencies of the ^{15}N compounds have not been used in the force constant refinement, the force constants in Table 7 reproduce well the ^{15}N shifts as given in Tables 1—4. It can be seen from the potential energy distributions (P. E. D.) that the vibrations below 1400 cm^{-1} are highly coupled modes as is to be expected.

In *trans* secondary amides, the N–H bending vibration is strongly coupled with the C–N stretching mode to give two bands near 1550 (amide II) and 1270 cm^{-1} (amide III). In 2-AZ the 1385 cm^{-1} band arises from mixing of the C–N stretching and N–H bending vibrations. However, this mixing does not give rise to any bands corresponding to the above characteristic frequencies for *trans* amides. The vibrational modes of *cis* *N*-methylacetamide and 2-piperidinone are interesting in connection with the

stretching (71%) and the C-CH_3 stretching (24%). On the other hand, in 2-piperidinone,[18] the 1425 cm^{-1} band originates in the N-H bending (56%) and the C=O stretching vibration (14%). However, the C-N stretching mode is dispersed in several vibrations, and there are no bands to which it contributes largely. From these results it seems that the *cis* CONH group does not have any characteristic bands similar to those of the *trans* CONH group except for the N-H stretching and C=O stretching bands owing to the coupling of the CONH vibrations with other modes in varying degrees.

Solution Spectra. Figure 5 shows the infrared spectra of 2-AZ in carbon tetrachloride over the concentration range from 0.06 to 0.001 M. The relative intensities of the free N-H stretching band at 3435 cm^{-1} and the hydrogen-bonded N-H band at 3236 cm^{-1} change with concentration in the expected manner, but their frequencies remain invariant within experimental deviation over the whole concentration range. Furthermore, the shape of the 3236 cm^{-1} band remains symmetric in different con-

centrations; this band does not seem to be overlapped with other bands. These findings suggest that the two species are predominantly present in carbon tetrachloride solution, namely an equilibrium of monomer $\rightleftharpoons$ dimer occurs in this solution as in 2-pyrrolidinone[8,9] and 2-piperidinone.[9,19] Possibly this associated species is the same cyclic dimer as in the crystal. The weak band at 3113 cm^{-1} is ascribed to a combination of the C=O stretching and N-H in-plane bending vibrations. The C=O stretching bands also exhibit the behavior corresponding to the above spectra. The free and hydrogen-bonded C=O stretchings occur at 1781 and 1769 cm^{-1}, respectively. The band at 1756 cm^{-1}, which is observed as a shoulder, may be ascribed to an overtone or combination.

Table 8. EFFECT OF SOLVENTS ON THE INFRARED N-H AND C=O STRETCHING FREQUENCIES (cm^{-1}) OF 2-AZETIDINONE

		Crystal (KBr disk)	CCl_4[a] (0.06 −0.001M)	$CHCl_3$[a] (0.1 −0.01M)	Benzene[a] (0.1 −0.01M)

			1756[c]	1753[c,d]	

a) 1 M = 1 mol dm^{-3}. b) Very weak even in 0.1 M. c) Shoulder bands. d) The intensity does not vary with concentration.

Table 8 gives the infrared N-H and C=O stretching frequencies in a few solvents. The solvent dependence of the spectra of the free molecule can be explained as follows. In chloroform solution the lactam C=O associates weakly with chloroform to give the 1767 cm^{-1} band, which is at a lower frequency by 14 cm^{-1} than the C=O band in carbon tetrachloride. On the other hand, benzene appears to interact with the lactam hydrogen to a considerable extent, since the free N-H frequency is lowest in benzene; it is observed at 3408 cm^{-1}, which is lower by 27 cm^{-1} than that in carbon tetra-

chloride. Other amides and lactams also exhibit this effect.[8,20,21]

Comparison with γ-, δ-, and ε-Lactams. The C=O frequencies of alicyclic ketones depend on the ring size.[22] Table 9 gives the N–H and C=O stretching frequencies of 2-AZ compared with those of five-, six-, and seven-membered lactams reported in the literature.[8,9,10] In the crystalline or liquid states, the N–H stretching and C=O stretching frequencies decrease with increase of the ring size. However, in carbon tetrachloride solution both the associated and free N–H stretching frequencies do not change regularly with the ring size, whereas the C=O stretching frequencies decrease in the expected manner. An explanation for the former behavior cannot be given, but there is a possibility that the steric effect of the CH_2 group adjacent to the N–H is responsible for it.

We wish to thank Professor Katsunosuke Machida of Kyoto University for the use of a JEOL laser Raman spectrometer. Thanks are also due to Mrs. Michiko Hosokawa and Mrs. Masako Hayashi of Gifu Pharmaceutical University for the elemental and mass spectral analyses. Throughout this work an ACOS SYSTEM 650 computer of Nagoya City University was used.

A Novel Iterative Transfer Perturbation Method and Its Application to the Extended Hückel Method

Akira IMAMURA* and Yuriko AOKI
Department of Chemistry, Faculty of Science, Hiroshima University, Higashisenda-machi, Hiroshima 730
(Received December 14, 1984)

An efficient iterative transfer perturbation method, which enabled us to take into account the contribution of the high order terms in the perturbation series without directly deriving the formulas for terms above third order, is proposed. Consequently we can calculate an infinite series of higher order terms in the perturbation expansion by applying this method iteratively until convergence in the expansion is obtained. By applying this method to methanol, the validity and applicability of our theory are shown at the level of the extended Hückel method.

Various types of perturbation methods have been developed in the field of quantum chemistry and have been applied to many interesting problems in physical chemistry. However, in many cases, the higher order terms in the perturbation expansion have been neglected past the second or the third order because of the intractability in the explicit expression of these terms. However, this truncation often leads to unreliable results.

In the present article, we propose a novel perturbation method in the Hartree-Fock-Roothaan formalism, in which the higher order terms are automatically transfered to the first and second order terms by iteration of this perturbation expansion, that is, by carrying over the perturbation terms into the next zero-order terms. This iterative procedure should be repeated until convergence in the density matrix and the total energy are achieved. For the simple test of this perturbation method, we applied this method to a simple system (methanol and its analogs) at the level of the extended Hückel method,[1] since the fundamental points in the perturbation method should be included even at the level of the extended Hückel method. In these test calculations, it is found that this novel perturbation method is able to remove completely the error caused by neglecting the terms of higher than second order.

Theoretical

The perturbation expansion is carried out with Roothaan's Hartree Fock SCF matrix equation,

$$FC = SCE \tag{1}$$

where F is the Fock matrix, C is the coefficient matrix, S is the overlap matrix and E the orbital energy matrix. These orbitals are normalized through the matrix equation

$$C^{\mathrm{T}}SC = 1. \tag{2}$$

Here, C^{T} is the transpose of the C matrix.

At the beginning, each matrix of Eq.1 is expanded in a perturbation series as follows

$$F = F^{(0)} + F^{(1)} + F^{(2)} + \cdots, \tag{3}$$

$$S = S^{(0)} + S^{(1)}, \tag{4}$$

$$C = C^{(0)} + C^{(1)} + C^{(2)} + \cdots, \tag{5}$$

$$E = E^{(0)} + E^{(1)} + E^{(2)} + \cdots, \tag{6}$$

where in the overlap matrix, all the difference between the zero order term and the perturbed terms is included in the first-order perturbed term, $S^{(1)}$. On the other hand, in the Fock matrix, the integral for the perturbed terms includes the change in the density matrix, and this density matrix should be expanded in an infinite series because of Eq. 5. Consequently, the Fock matrix given by Eq. 3 should be expanded also in an infinite series. For the zero-order terms, the following equations are satisfied.

$$F^{(0)}C^{(0)} = S^{(0)}C^{(0)}E^{(0)} \tag{7}$$

$$C^{(0)\mathrm{T}}S^{(0)}C^{(0)} = 1 \tag{8}$$

By using formulas from general perturbation theory for the extended Hückel method, which had been reported previously,[2] the matrix elements of the perturbed matrices $C^{(1)}$, $C^{(2)}$, $E^{(1)}$, and $E^{(2)}$ are given as follows:

$$\begin{aligned} C_{ti}^{(1)} = & -\sum_{\substack{j \\ (j\neq i)}}{}' C_{tj}^{(0)}/(E_j^{(0)} - E_i^{(0)}) \\ & \sum_r\sum_s (F_{rs}^{(1)} - S_{rs}^{(1)}E_i^{(0)})C_{rt}^{(0)}C_{sj}^{(0)} \\ & -\frac{1}{2}C_{ti}^{(0)}\sum_r\sum_s C_{rt}^{(0)}C_{si}^{(0)}S_{rs}^{(1)}, \end{aligned} \tag{9}$$

$$E_i^{(1)} = \sum_r\sum_s (F_{rs}^{(1)} - S_{rs}^{(1)}E_i^{(0)})C_{ri}^{(0)}C_{si}^{(0)}, \tag{10}$$

$$\begin{aligned} C_{ti}^{(2)} = & -\sum_{\substack{j \\ (j\neq i)}}{}' C_{tj}^{(0)}/(E_j^{(0)} - E_i^{(0)}) \\ & [\sum_r\sum_s \{F_{rs}^{(2)} - (S_{rs}^{(2)}E_i^{(0)} + S_{rs}^{(1)}E_i^{(1)})\}C_{ri}^{(0)}C_{sj}^{(0)} \\ & + \sum_r\sum_s \{F_{rs}^{(1)} - (S_{rs}^{(0)}E_i^{(1)} + S_{rs}^{(1)}E_i^{(0)})\} \\ & \times C_{ri}^{(1)}C_{sj}^{(0)}] \\ & -\frac{1}{2}C_{ti}^{(0)}\sum_r\sum_s \{C_{ri}^{(1)}C_{si}^{(1)}S_{rs}^{(0)} \\ & + (C_{ri}^{(1)}C_{si}^{(0)} + C_{ri}^{(0)}C_{si}^{(1)})S_{rs}^{(1)}\}, \end{aligned} \tag{11}$$

$$E_i^{(2)} = \sum_r \sum_s (F_{rs}^{(2)} - S_{rs}^{(1)} E_i^{(1)}) C_{ri}^{(0)} C_{si}^{(0)} + \sum_r \sum_s \{F_{rs}^{(1)} - (S_{rs}^{(0)} E_i^{(1)} + S_{rs}^{(1)} E_i^{(0)})\} \times C_{ri}^{(1)} C_{si}^{(0)}, \quad (12)$$

where i,j denote molecular orbitals and r,s atomic orbitals, and $\sum_j'$ means that the summation covers all levels except i. Strictly speaking, Eqs. 9—12 should be solved iteratively since the Fock matrices $F_{rs}^{(1)}$ and $F_{rs}^{(2)}$ include the perturbed density matrix that is calculated by using $C_{ri}^{(1)}$ and $C_{ri}^{(2)}$. By using Eqs. 9—12, we can obtain the first and the second order terms of C and E.

Next, we redefine the zero-order terms for C and E as follows:

$$C^{(0,1)} = C^{(0)} + C^{(1)} + C^{(2)}, \quad (13)$$

$$E^{(0,1)} = E^{(0)} + E^{(1)} + E^{(2)}, \quad (14)$$

where matrix elements of $C^{(1)}$ and $C^{(2)}$ are given by Eqs. 9 and 11 and that of $E^{(1)}$ and $E^{(2)}$ by Eqs. 10 and 12. The superscript (0,1) in $C^{(0,1)}$ and $E^{(0,1)}$ denotes the zero-order term defined by Eqs. 13 and 14 in the first iteration. In order that $C^{(0,1)}$ and $E^{(0,1)}$ are the zero-order terms, the corresponding zero-order Fock matrix $F^{(0,1)}$ and the overlap matrix $S^{(0,1)}$ must fulfill the following relations:

$$F^{(0,1)} C^{(0,1)} = S^{(0,1)} C^{(0,1)} E^{(0,1)}, \quad (15)$$

$$C^{(0,1)\mathrm{T}} S^{(0,1)} C^{(0,1)} = 1. \quad (16)$$

In other words, $F^{(0,1)}$ and $S^{(0,1)}$ are determined from the Eqs. 15 and 16. The explicit expressions for $S^{(0,1)}$ and $F^{(0,1)}$ are obtained by using $C^{(0,1)}$ and $E^{(0,1)}$ as follows. Multipling the Eq.16 on the left by $(C^{(0,1)\mathrm{T}})^{-1}$, on the right by $(C^{(0,1)})^{-1}$, the overlap matrix of the zero-order is

$$S^{(0,1)} = (C^{(0,1)\mathrm{T}})^{-1}(C^{(0,1)})^{-1} = (C^{(0,1)} C^{(0,1)\mathrm{T}})^{-1} = (P^{(1)})^{-1} \quad (17)$$

where the matrix $P^{(1)}$ has its element given by the Eq. 18.

$$P_{rs}^{(1)} = \sum_i^{\mathrm{all}} C_{ri}^{(0,1)} C_{si}^{(0,1)} \quad (18)$$

Eq. 15 is multiplied by $(C^{(0,1)})^{-1}$ on the right followed by a substitution of Eq. 17.

$$F^{(0,1)} = S^{(0,1)} C^{(0,1)} E^{(0,1)} (C^{(0,1)})^{-1} = (C^{(0,1)\mathrm{T}})^{-1}(C^{(0,1)})^{-1}(C^{(0,1)} E^{(0,1)} (C^{(0,1)})^{-1} = (C^{(0,1)\mathrm{T}})^{-1} E^{(0,1)} (C^{(0,1)})^{-1} = (P_E^{(1)})^{-1}, \quad (19)$$

where, $P_E^{(1)}$ is defined as follows:

$$P_E^{(1)} = \sum_i^{\mathrm{all}} C_{ri}^{(0,1)} C_{si}^{(0,1)} / E_i^{(0,1)}. \quad (20)$$

The perturbed terms in the first iteration are defined by using the Eqs. 3 and 4 as follows:

$$F^{(1,1)} = F - F^{(0,1)} = (F^{(0)} + F^{(1)} + F^{(2)}) - F^{(0,1)}, \quad (21)$$

$$S^{(1,1)} = S - S^{(0,1)} = (S^{(0)} + S^{(1)}) - S^{(0,1)}. \quad (22)$$

In the Eq. 21, the expansion is truncated at the second order term. $F^{(2,1)}$ should be calculated by including $C^{(1,1)}$ and $C^{(2,1)}$. In the present perturbation method, the perturbed terms change their value each iteration and the higher order terms in the perturbation expansion are incorporated automatically by iterations of the above-mentioned procedure. Therefore, for the t-th iteration, the following general expressions are obtained.

Each matrix of Eq. 1 is expanded in the perturbation series as follows:

$$F = F^{(0,t)} + F^{(1,t)} + F^{(2,t)}, \quad (23)$$

$$C = C^{(0,t)} + C^{(1,t)} + C^{(2,t)} + \cdots, \quad (24)$$

$$S = S^{(0,t)} + S^{(1,t)}, \quad (25)$$

$$E = E^{(0,t)} + E^{(1,t)} + E^{(2,t)} + \cdots, \quad (26)$$

where the subscript t denotes the iterative step. Throughout this process the zero order coefficient matrix and orbital energy matrix are obtained as follows, respectively:

$$C^{(0,t)} = C^{(0)} + C^{(1)} + C^{(2)}, \quad (27)$$

$$E^{(0,t)} = E^{(0)} + E^{(1)} + E^{(2)}. \quad (28)$$

By means of these equations perturbation calculations are iterated until convergence on $C^{(0,t)}$ and $E^{(0,t)}$ is obtained. The matrices $C^{(1)}$, $E^{(1)}$, $C^{(2)}$, and $E^{(2)}$ can be obtained for each iteration from Eps. 9—12 derived by the usual perturbation expansion up to second order.

Calculations

In the present work, the test calculations for the iterative transfer perturbation method are carried out using the extended Hückel method. The concrete procedures for this test calculation are as follows:

1. The Hamiltonian $F^{(0,0)}$, overlap integral $S^{(0,0)}$, eigenvector $C^{(0,0)}$ and energy $E^{(0,0)}$ matrices obtained by the extended Hückel method in the non-perturbed system are stored as the zero order matrix.
2. In a similar manner, the Hamiltonian matrix and overlap integrals in the perturbed system are also obtained.
3. The difference between the non-perturbed system 1 and the perturbed system 2 for the Hamiltonian matrix and the overlap integrals are taken to be the first order terms, $F^{(1,0)}$ in the Eq. 23 and $S^{(1,0)}$ in the Eq. 25, respectively.
4. From these matrix elements the first and second order terms in the eigenvector and energy, that is $C^{(1)}$, $E^{(1)}$, $C^{(2)}$, and $E^{(2)}$ in the Eqs. 9—12, are obtained by using general perturbation theory for the extended Hückel method. Theoretical details of this perturbation method have been extensively described in the previous paper.[2]
5. By using the Eqs. 13 and 14, we can obtain the next zero order terms in the eigenvector $C^{(0,1)}$ and energy $E^{(0,1)}$ equal

to the sum up to second order terms in this iterative step; then the next iteration is started.

6. Using the matrices $C^{(0,1)}$ and $E^{(0,1)}$ obtained at 5, zero-order terms in the Hamiltonian $F^{(0,1)}$ and the overlap $S^{(0,1)}$ matrices in the next iterative step are determined again from the Eqs. 17—20.

7. The first order terms of the Hamiltonian and the overlap integrals in the iterative step are defined as the difference between the zero-order terms obtained in 6 and the sum up to the initial second order term obtained in 1 and 2, that is, $F^{(1,1)}$ in an Eq. 21 and $S^{(1,1)}$ in an Eq. 22, respectively.

8. If these first order terms obtained in 7 are larger than some fixed threshold value, the succeeding iteration is restarted by returning to 4. This means that if there are relatively large contributions of the terms higher than second order, the third and fourth order terms are introduced in succession. These perturbation calculations are iterated until the first order terms converge to a negligibly small value.

Results

This iterative transfer perturbation theory was tested on methanol with bond distances of C-O=1.43 Å (Fig. 1(a)) for the zero-order terms and C-O=1.63 Å (Fig. 1(b)) for the perturbed terms. Furthermore, this procedure was also applied to the perturbed system shown in Fig. 1(c), in which N is substituted for C. The results of these perturbation calculations are

E. H.: Extended Hückel method. I. P.: Iterative transfer perturbation method.

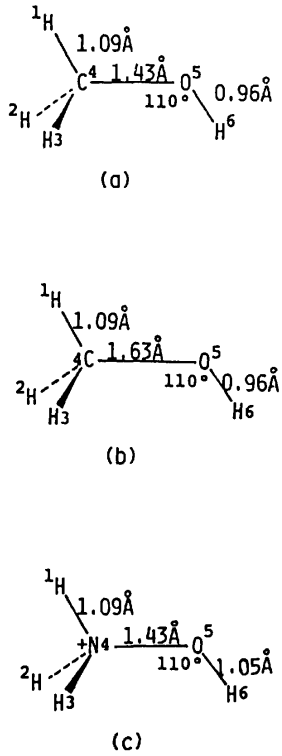

Fig. 1. (a) Structure of methanol in the non-perturbed system. (b), (c) Structures of model molecules in the perturbed systems.

listed in Table 1 compared to the direct extended Hückel calculations. The first column of Table 1 contains the orbital energies and coefficients of the highest occupied molecular orbitals for the non-perturbed system in Fig. 1(a) from the usual extended Hückel method. The second and third columns are for the perturbed system shown in Fig. 1(b) and the fourth and fifth are for the one in Fig. 1(c), showing the extended Hückel and iterative transfer perturbation methods for comparison. In Table 2 the energy of the highest occupied molecular orbitals are listed each iteration for the perturbed systems shown in Fig. 1(b) and (c). After the orbital energies have quickly converged within four iterations (Table 2), they are in good agreement with the direct method (Table 1). This shows that the approximations made within this iterative transfer perturbation method are comparable to those made in the general extended Hückel method.

Conclusions

We could concisely show the validity and the applicability of this method that incorporates the higher order terms in the perturbation expansion in a fairly simple way. There is little advantage of this method compared to direct extended Hückel calculations in the present case using these simple molecules. But it should be mentioned further that this perturbation method can be applied also in the case that a polymer interacts with an impurity molecule at short range and the change of the charge is localized within only a part of the polymer. This approach is rather straightforward if the perturbation method for the interaction between polymers[3] is applied to the above-mentioned problem. This method may be of use to us in the interpretation of various phenomena in the electronic states of biopolymers. However, for the general use of this method it is indispensable to formulate equations, in which the divergence due to the nearly degenerate molecular orbitals is avoided, as has already been done by O'Shea and Santry.[4] Based on this, work is in progress applying this iterative transfer perturbation method to *ab initio* calculations on polymer systems.

Numerical calculations were performed on the HITAC M-200H computer system at the Information Center of Hiroshima University. The authors are grateful to Dr. D. Munch for his stimulating suggestions.

Characterization of α- and β-Dodecamolybdophosphate Complexes Formed in Aqueous Solutions Including Acetonitrile, Acetone, or Dioxane

Toshitaka HORI* and Taitiro FUJINAGA†
Department of Chemistry, College of Liberal Arts and Sciences, Kyoto University, Sakyo-ku, Kyoto 606
†*Nara University of Education, Takabatake-cho, Nara 630*
(Received September 5, 1984)

On the basis of a spontaneous conversion reaction of molybdophosphate (formed in an aqueous medium including acetonitrile, acetone, or dioxane), the existence of β-modification of dodecamolybdophosphate has been substantiated. The conversion reaction was highly affected by the presence of the organic solvents. In the absence and/or the presence of the organic solvent of less than 20% by volume, the reaction proceeded instantaneously and, in consequence, β-modification practically did not exist, but α-modification existed entirely. Whereas, in the presence of the organic solvent ranging from 30 to 60%, β-modification was so stable, it could be observed for a fairly long duration. However, it was still thermodynamically unstable and finally converted to α-modification at a certain rate depending on the concentration of the organic solvent. With more of the organic solvent than 65%, the formation of β-modification and thence α-modification, were prohibited. As a result of these facts, α- and β-modifications were individually prepared in solutions consisting of 0.05 M Mo(VI)/1.2 M HCl/40% acetonitrile. On each modification thus formed, a chemical reduction (with such metals as nickel, iron, or lead) and solvent-extraction isolation (using chloroform as an auxiliary solvent) were performed. The inherent absorption spectra of the two modifications were clearly distinguished in both oxidized yellow and reduced blue forms. The utility of β-modification in a sensitive spectrophotometric determination of phosphate ion was also discussed.

It has been well known that the yellow color of molybdophosphate in aqueous solutions is markedly enhanced by the presence of certain water-miscible organic solvents such as acetone,[1,2,3] dioxane,[4] ethanol,[5] tetrahydrofuran,[6] and acetonitrile.[7] The enhanced yellow color has been widely utilized for spectrophotometric determinations of the orthophosphate ion.

Chalmers and Sinclair investigated[2] in detail the color enhancement in an aqueous acetone medium and ascribed it to the formation of β-modification of dodecamolybdophosphate (abbreviated as β-molybdophosphate, hereafter). This modification might exhibit higher absorbances in the near-ultraviolet region than the ordinary α-modification of dodecamolybdophosphate (abbreviated α-molybdophosphate). They explained that β-molybdophosphate might be stabilized to exist in an aqueous acetone medium since acetone molecules preferably replace with water molecules in the coordination sphere of the molybdate complex and suppress the hydrolytic dissociation of the complex (which dissociation would be the initial step for the spontaneous conversion of β to α). On the basis of these concepts, Chalmers and Sinclair[2] postulated a possible structure for β-molybdophosphate. The similar structure was found, in fact, by Matsumoto *et al.*[8] in β-modification of dodecatungstosilicate. Nevertheless, as for molybdophosphate, the spontaneous conversion reaction itself, which must be the most inherent property to β-molybdophosphate and is most likely to occur from the analogy with the β to α conversion in molybdosilicate,[9] has not been substantiated yet. It is only known that the two modifications of α and β would also exist in molybdophosphate and would be distinguishable from their different intensities in the yellow color.

Employing acetonitrile as an organic solvent, we[10] previously investigated the color enhancement of molybdophosphate as a function of the concentration of the solvent. As a result, it was found that the solvent had two different effects on the yellow color.

The first effect was observable at acetonitrile concentrations of around 5% by volume. It became evident with an increase of the solvent up to 20%, and finally saturated with more of the solvent. The most notable point regarding this effect was that it was a reversible reaction, that is, the yellow color of molybdophosphate was intensified up to the same extent in either case when the organic solvent was present before or was added after the formation of the molybdate complex. This effect might be attributable to the reversible formation equilibrium of α-molybdophosphate, which is favoured by the presence of the organic solvent.

The second effect of the organic solvent was only appreciated when molybdophosphate was formed in the presence of acetonitrile more than 30%. Most strikingly, it involved the irreversible reaction. Actually, the yellow color had an intensity approximately twice as strong as that due to the first effect, but faded gradually on standing and reached the same intensity as that attained by the first effect. This extraordinary intense yellow color was then estimated to be due to β-molybdophosphate and the fading of the yellow color was due to the conversion of β to α-molybdophosphate.

According to these previous observations,[10] we report in the present paper on preparation of individual α- and β-molybdophosphate using an aqueous

medium containing acetonitrile, acetone, or dioxane. Specifically, regarding β-molybdophosphate, its inherent properties were carefully investigated and distinguished from those of the well-established α-molybdophosphate. The so-called solvent effects on the color development of molybdophosphate can be thoroughly explained in terms of the charactersistic conversion reaction between α and β. Some confusions which have been hitherto experienced regarding the different intensities of the yellow color of molybdophosphate, are considered consistent.

Experimental

Reagents. A standard 0.100 M (1 M=1 mol dm^{-3}) phosphate solution and 0.5 M molybdate(VI) solution were prepared from KH_2PO_4 and $Na_2MoO_4 \cdot 2H_2O$, respectively.

A mixed molybdate reagent, with which phosphate ion was reacted to form molybdophosphate, was prepared by mixing 20 cm^3 of a 0.5 M molybdate(VI) solution, 20 cm^3 of concentrated hydrochloric acid and the desired amounts (usually 80 cm^3) of acetonitrile, and diluting to 200 cm^3 with water. The acetonitrile (Wako Pure Chemicals, GR grade) was used without further purification. The mixed reagent, otherwise indicated, was a 40%(v/v) acetonitrile solution. It was stored in a polyethylene bottle without appreciable deterioration for at least one month. Also, a mixed molybdate reagent in acetone or dioxane was similarly prepared using acetone and dioxane (Wako Pure Chemicals, GR grade) in place of acetonitrile.

Nickel metal with 99.95% purity (in a sponge type and pulverized to a size to pass through a 300-mesh filter) was used for the reduction of molybdophosphate. The metal could be used as supplied (Wako Pure Chemicals), but, if necessary, further purified by washing with 40% aqueous acetonitrile including 1.2 M hydrochloric acid. It was subsequently washed with 40% aqueous acetonitrile and dried in the open air for 2 d. Iron with 99.99% purity (in a sponge type and pulverized to pass through a 100-mesh filter), cobalt with 99% purity (in a powder form), copper with 99.85% purity (in a powder form), and lead with 95% purity (in a powder form) were also commercially available products and were used in the comparative studies with the nickel reduction. These metals were usually weighed into a 60-mg dose and wrapped in glazed paper.

As an auxiliary solvent, chloroform was used after the removal of a stabilizer ethanol, just before use, by washing three times with water and drying over anhydrous sodium sulfate.

Apparatus. A Shimadzu UV 240 automatic recording spectrophotometer equipped with a constant-temperature housing (kept at 25±0.2 °C) for the cuvettes, was used. Quartz cuvettes with path-lengths of 1 (with a glass-stopper), 0.2, and 0.1 cm were properly used according to the magnitude of the absorbances of the samples.

Results and Discussion

Formation and Conversion of β-Molybdophosphate in Aqueous Media Including Acetonitrile, Acetone, or Dioxane. At various concentrations of acetonitrile in the reaction medium, the formation of molybdophosphate was monitored by measuring the changes in absorbance at 420 nm according to the following techniques.

Into a quartz cuvette having a path-length of 1 cm, take a 4-cm^3 aliquot of mixed molybdate reagent composed of 0.05 M Mo(VI)/1.2 M HCl/ acetonitrile ranging from nil to 70% (v/v), and equilibrate it at 25 °C. Into the reagent solution, inject 40 mm^3 of 0.1 M phosphate standard solution using a calibrated micropipette. Shake it quickly. Then, set the reaction time to zero and record the absorbance change with regard to time.

The typical absorbance-time curve obtained in the 40% acetonitrile medium is shown in Fig. 1. It can be seen from the curve that the absorbance increases rapidly and reaches a higher stational level (1.600 in absorbance unit) within 2 s, and then decreases quite slowly, until it goes down to a lower constant level (0.970 in abs. unit). The higher absorbances temporarily observed at the initial period seem to be attributable to the formation of an extraordinary molybdophosphate other than the ordinary α-molybdophosphate. The extraordinary one was expected to be β-molybdophosphate. In a later paragraph, this will be further confirmed by discussion involving both the extraction isolation and the chemical reduction of the complex.

The final absorbance, on the other hand, was due to α-molybdophosphate. This was confirmed from the fact that the same absorbance could be attained with a solution which was prepared by dissolving into 40% aqueous acetonitrile a corresponding amount of synthesized crystal of molybdophosphate, *i.e.*, $24MoO_3 \cdot P_2O_5 \cdot 3H_2O$,[11] which had been well-

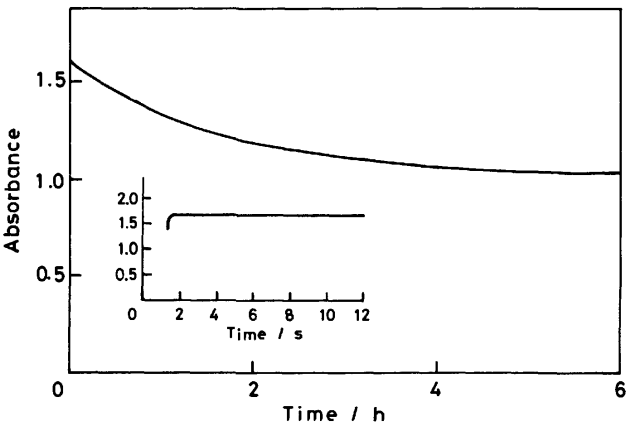

Fig. 1. Formation and conversion of β-molybdophosphate in the 40% aqueous acetonitrile medium at 25 °C.
A 40 mm^3 of 0.1 M phosphate standard solution was injected into a 4 cm^3 aliquot of the mixed molybdate reagent consisting of 0.05 M Mo(VI)/1.2 M HCl/40 % acetonitrile, and the absorbance change at 420 nm of the mixture was recorded against time.

established as Keggin structure.[12]

In consequence, it can be said that the decreasing absorbance recorded in Fig. 1 corresponds to the spontaneous conversion of β to α-molybdophosphate. By the kinetic analysis for the absorbance-time curve, it was assured that the conversion proceeded according to first-order reaction kinetics with respect to the concentration of β-molybdophosphate, and the rate constant in the 40% acetonitrile medium was observed as 1.79×10^{-4} s^{-1}.†

Although the formation and the conversion of β-molybdophosphate were similarly observed in an aqueous medium including more than 20% of acetonitrile, the reaction rate depended on the acetonitrile concentration. This dependence is featured in Fig. 2. As shown in the right-hand part of curve a in the Figure, extraordinarily higher absorbances were recorded at an early period around 2 min, indicating the formation of β-molybdophosphate. Upon standing, however, these absorbances decreased gradually through curves b—e and finally reached curve f (which was the ordinary absorbance level attributable to the formation of α-molybdophosphate).

In a 60% acetonitrile medium, for instance, it can be seen from the Figure that β-molybdophosphate takes more than 30 h to convert completely to α-molybdophosphate.

With the presence of more acetonitrile than 65% in the medium, the formation of β-molybdophosphate, thence that of α-molybdophosphate as well, was fairly prohibited. The reason, however, has not been explained yet.

In the absence and/or the presence of acetonitrile less than 20% (see the left-hand part of Fig. 2), the absorbances of molybdophosphate solutions increased rapidly and reached directly to those indicated by curve a, neither the extraordinarily higher absorbances nor the gradual decrease of the absorbance being

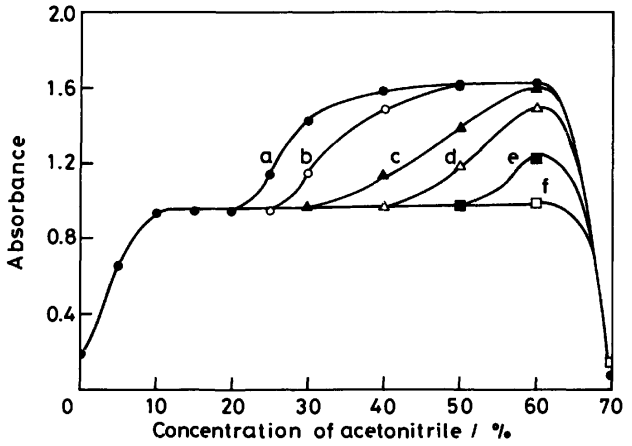

Fig. 2. Profile for the formation and survival of β-molybdophosphate in aquoeus acetonitirle media at the time: (a) 2 min, (b) 20 min, (c) 2 h, (d) 5 h, (e) 14 h, and (f) 38 h, elasped since the injection was made of a 40 mm^3 of 0.1 M phosphate solution into a 4 cm^3 of the mixed molybdate reagent consisting of 0.05 M Mo(VI)/1.2 M HCl/varing concentrations of acetonitrile.

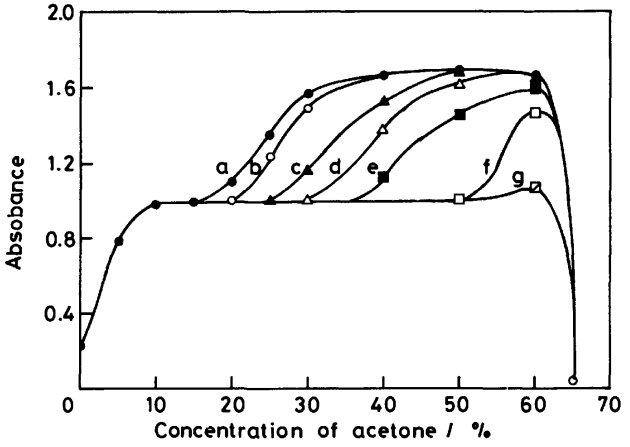

Fig. 3. Profile for the formation and survival of β-molybdophosphate in aqueous acetone media at the time: (a) 6 min, (b) 20 min, (c) 2 h, (d) 5 h, (e) 14 h, (f) 38 h, and (g) 262 h.
The same conditions as those in Fig. 2 were applied except that acetone was used.
