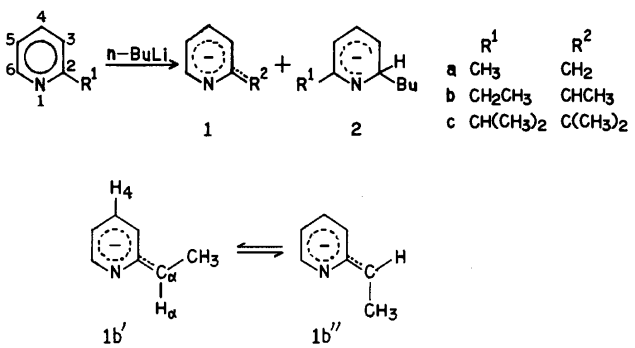
Fig. 2. ^{13}C spectrum of **1b** and **2b** in THF at 50.3 MHz.

First, it can be seen from Fig. 1 (a) that two kinds of anions, **1c** and **2c** (Scheme 1), are formed concomitantly by lithium-proton exchange and addition of butyllithium. In Fig. 2, eighteen signals, except for two large solvent peaks, are attributable to two kinds



Scheme 1.

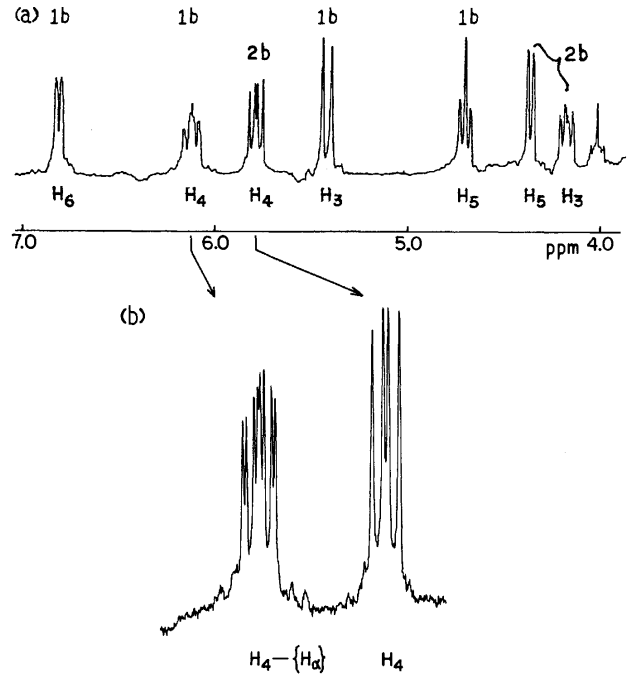


Fig. 3. (a) ^1H spectrum of the ring proton region of **1b** and **2b** in THF at 200 MHz, and (b) the expanded spectrum of the 4-proton peaks, where the 4-H of **1b** is decoupled to the α-H.

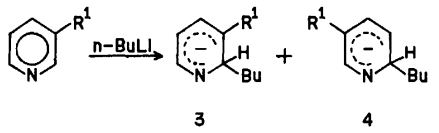
of anions, **1b** and **2b**. Thus, 2-ethyl- and 2-isopropylpyridines undergo both exchange and addition. 2-Methylpyridine appears to undergo only exchange to give **1a**, but, in a large scale preparation,[6] the presence of a small amount of **2a** was confirmed from a detailed inspection of the ^1H spectrum. Each of these two reactions occurs at a specific position as shown in Scheme 1. In any event, the 2-substituted pyridines undergo exchange to give **1**. The proportion of **1c** relative to **2c** is smaller than that of **1b** relative to **2b**, where **1b** and **2b** are in the ratio about 1:1. These facts indicate that the proton-releasing power of the α-carbon in the 2-substituted pyridines decreases in the order of methyl-, ethyl-, and isopropylpyridines.

In the ^{13}C spectra of **1**, the 5-carbon signal of each anion appears at a higher field in the order of **1a**, **1b**, and **1c**. The 5-carbon chemical shift is a well-defined index of negative charge delocalization, leading to the resonance stabilization, as stated before.[7] In the above order, therefore, these anions tend to take the resonance stabilization in a molecular plane. The resonance stabilization is enhanced by the α-positioned methyl group.

A typical ^1H spectrum of the ring proton region of **1b** and **2b**, prepared concomitantly from 2-ethylpyridine, is shown in Fig. 3. On the four signals assigned to **1b**, decoupling experiments show that the 4-H is coupled to the α-H with a coupling constant of 1.1 Hz.[8] This kind of long-range coupling was previously observed for **1a** at lower temperature.[9] Clearly, the α-carbon of **1b** is virtually sp^2-hybridized. These four signals for **1b** are attributable to the **1b'** isomer (Scheme 1). The presence of the **1b''** isomer could not be confirmed.[10] In **1c** and **2c**, the two methyl carbons bonded to the α-carbon of each anion show magnetic nonequivalence. The chemical shift difference between the two for **1c** is 6 ppm. This magnitude is appreciably larger than that for **2c** ($\Delta\delta_c$=2.3 ppm), whose α-carbon is in a sp^3 configuration.

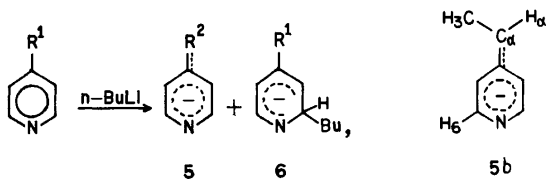
Second, the 3-substituted pyridines undergo addition to give **3** and **4** (Scheme 2) concomitantly, but fail to do exchange. In **3c** and **4c**, as shown in Fig. 1 (b), the signals appearing as doublets at δ 5.54 and 5.79 are attributable to the 4-protons of **3c** and **4c** respectively. The ratio of the two peak areas is about 1:1.8,



Scheme 2.

indicating that **3c** and **4c** are present in this ratio. In **3b** and **4b**, however, the ratio is about 1:1. This suggests that the 3-isopropyl group may tend to hinder the addition reaction occurring at the 2-position in the steric sense as compared with the 6-position.

Third, 4-methyl- and 4-ethylpyridines produce **6a** and **6b** (Scheme 3) together with **5a** and **5b** as by-products respectively. Further, 4-isopropylpyridine appears to produce **6c** only, as shown in Fig. 1(c), but the presence of a slight amount of **5c** was confirmed from a detailed inspection of the spectrum. In any



Scheme 3.

event, the 4-substituted pyridines undergo exchange with difficulty, as compared with the 2-substituted ones. It was reported before by Zoltewicz *et al.* that 4-methylpyridine was more acidic than 2-methylpyridine.[11] This implies that the proton-releasing power of the 4-methyl carbon is stronger than that of the 2-methyl one, that is, 4-methylpyridine tends to undergo exchange. In practice, however, **1a** is rather formed with ease as described above. This lithium-proton exchange reaction tends to occur at the substituent bonded to the position adjacent to nitrogen. This experimental result agrees with the observation of the anions produced from 2,4,6-trimethylpyridine,[1,9] and gives support to the view that the ring nitrogen (not α-carbon) can be regarded as the site where the anion–cation interaction takes place mainly in picolyl-

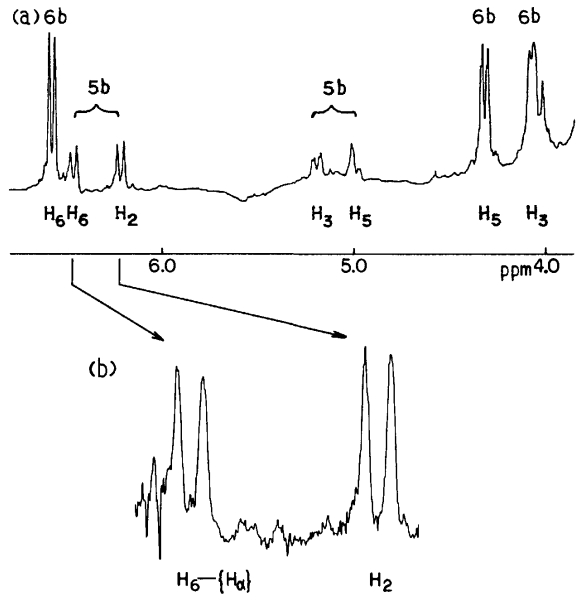


Fig. 4. (a) ^{1}H spectrum of the ring proton region of **5b** and **6b** in THF at 200 MHz, and (b) the expanded spectrum of the 6- and 2-proton peaks of **5b**, where the 6-H is decoupled to the α-H.

type carbanions with lithium as a counter ion.[3] The addition reaction also occurs at the position adjacent to nitrogen without substituent.

On the signals assigned to **5b** in Fig. 4, the *ortho*-protons (3- and 5-H) or *meta*-protons (2- and 6-H) are nonequivalent respectively at room temperature. Similar nonequivalence was observed before by Takahashi *et al.* for the α-methylbenzyl carbanion.[12] The *ortho*- or *meta*-carbons are also nonequivalent. This nonequivalence is explained by the restricted rotation around the bond between the ring and the α-carbon, caused by the resonance stabilization. Further, decoupling experiments show that the 6-H is coupled to the α-H (Scheme 3), and that the four signals appearing as doublets are attributable to the 6-, 2-, 3-, and 5-protons respectively in the upfield direction. The α-carbon of **5b**, as well as **1b**, is virtually in a sp^2 configuration.

In conclusion, two interesting facts should be noted. One is that two kinds of anions are formed concomitantly by lithium-proton exchange and addition of butyllithium from 2-ethyl-, 2-isopropyl-, 4-methyl-, and 4-ethylpyridines. The former reaction tends to occur at the substituent bonded to the position adjacent to nitrogen, and the latter one occurs at the position adjacent to nitrogen without substituent. Another is that a specific ring proton is coupled to the α-carbon in the anions formed by the exchange from 2- and 4-ethylpyridines, and, further, that the *ortho*- or *meta*-protons (or -carbons) in the latter anion are nonequivalent respectively at room temperature. The α-carbons in these anions are virtually sp^2-hybridized.

Effect of High Surface Coverage on the Rate of Methanol Oxidation at Platinum Electrode

Hiroshi MATSUI* and Takeo HISANO
Department of Applied Chemistry, Faculty of Engineering, The University of Tokushima, Minami-josanjima-cho, Tokushima 770
(Received January 23, 1985)

The rates of the methanol oxidation and the CO_{ad} formation at Pt electrodes in solutions of CH_3OH+ 0.5 mol dm^{-3} H_2SO_4 were investigated under the conditions minimizing the harmful effect of impurities. Under the particular conditions, the both rates decreased remarkably towards zero at a limiting coverage of about 0.8. Namely, the CO_{ad} hindered both the formation of the CO_{ad} itself and the oxidation of methanol *via* some unidentified intermediate other than CO_{ad}. This fact was explained by assuming an aggregate with two vacant sites indispensable for the CO_{ad} formation and the methanol oxidation to CO_2.

It is well known[1-4] that the stationary-state rates of the methanol oxidation on platinum electrodes in acid media increase and, in succession to a maximum, decrease with an increase in the methanol concentration, and that the decrease is remarkable at low potentials and high methanol concentrations. Similar maxima and the subsequent decreases of rate are also observed on each system of formaldehyde,[5] ethanol,[6] ethylene,[7,8] and so on. For the case of ethylene, Bockris *et al.*[8] gave an explanation on the basis of their hydroxyl-radical mechanism. Bagotzky *et al.*[1] however, observed variations in the rate of the methanol oxidation with potential differing from those predicted by the hydroxyl-radical mechanism. Biegler *et al.*[4] related the retardation of the methanol oxidation to the effect of high surface coverage with adsorbate formed from methanol, while Bagotzky *et al.*[1] showed that it also occurred even at low coverages. Breiter[9] proved that the presence of chloride ion, even in its very low concentrations, resulted in the inhibition of the methanol oxidation. Belanger[10] also reported similar effects of several anions such as nitrate as well as halogen ions.

In short, there were certain serious disagreements among groups of workers about the experimental data, particularly about the rates in the range of medium to limiting coverages. Thus it appeared of necessity to establish in the first place reliable data that were practically uninfluenced by impurities.

The data obtained with such a particular attention were different from those of the previous workers[1,4] in certain respects, *e.g.*, whether there were stationary-state rates in the methanol oxidation to CO_2. Above all, the rates of the formation of the adsorbate, CO_{ad}, and the overall oxidation of methanol decreased remarkably, in many cases towards zero, as soon as the coverage with CO_{ad} attained to a limiting value of 0.8, though the definition of the coverage here differed from that adopted by the previous investigators.[1,4] The phenomenon was explained by assuming that at the high coverage the CO_{ad} would damage the aggregates, each consisting of two vacant sites, indispensable for the formation of the CO_{ad} itself and for the oxidation of methanol *via* some unidentified intermediate other than CO_{ad}.

Experimental

The cells, electrodes, reagents, and the procedures were the same as those described in the previous paper.[11]

The coverages with adsorbate, θ_1 and θ_2, were expressed as

$$\theta_1 = (Q_H^0 - Q_H)/Q_H^0 \quad (1)$$

$$\theta_2 = Q^{ox}/(Q^{ox})_{max} \quad (2)$$

where Q_H^0 was the electric quantity required to cover fully the electrode surface with a monolayer of adsorbed hydrogen atoms in the absence of the carbon-containing adsorbate, Q_H was that in the presence. Q^{ox} was the quantity required to oxidize an amount of the adsorbate, and $(Q^{ox})_{max}$ was the maximum Q^{ox}. Q_H and Q_H^0 were determined by the conventional hydrogen-deposition method, in which the scan rates of potential were 20 and 100 V s^{-1} at the concentrations of methanol below and above 0.3 mol dm^{-3}, respectively. Q^{ox} and $(Q^{ox})_{max}$ were determined by the method described previously.[11]

In order to minimize the disturbing effect of adsorbed impurities on the rate of methanol oxidation, the temperature was lowered to 0°C, and roughened electrodes were used. Under these conditions, the decrease of Q_H^0 due to the adsorption of impurities did not exceed 3% within the oxidation time of 400 s.

The potentials were referred to the reversible hydrogen electrode in 0.5 mol dm^{-3} H_2SO_4, and the current densities were expressed for the unit true surface area, which was determined by the hydrogen-deposition method.

Results and Discussion

As seen in Fig. 1, the rate of oxidation never became stationary within about 400 s at the methanol concentrations above about 0.1 mol dm^{-3}. Although longer times resulted eventually in stationary rates, then Q_H^0 decreased more than 3% and the disturbing effect of impurities became perceptible. Figure 2 shows the time dependence of the CO_{ad} coverage under the same conditions as in Fig. 1. The coverage reached an approximately constant value of 0.8 at

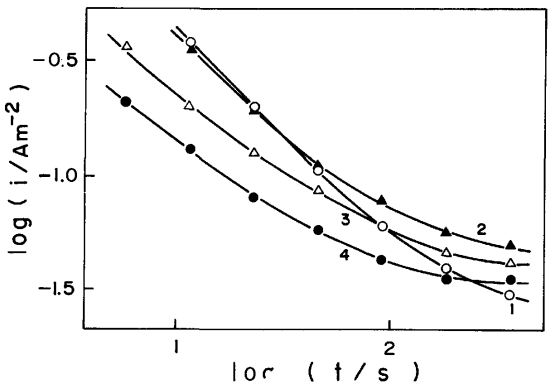

Fig. 1. Variation in oxidation rate with time (CH_3OH+0.5 mol dm^{-3} H_2SO_4, 0.6 V, 0 °C). Methanol: (1) 3.0; (2) 1.0; (3) 0.1; (4) 0.03 mol dm^{-3}.

all the methanol concentrations of 0.03—3 mol dm^{-3}. Respective curves in Fig. 3 show the typical rate-variations with the methanol concentration. The current densities plotted were ones at a particular time of 360 s when the coverages had already become stationary. Retarding of the oxidation rate at higher concentrations is obvious, and it becomes remarkable at lower potentials. These trends are in consistent with the observations by Bagotzky,[1] Biegler[4] *et al.* Contrary to their observations, however, the rates were not always stationary.

It is known[1,4,12] that the decay of current observed in the initial stage of the methanol oxidation at constant potentials is associated with the formation and accumulation of adsorbates. In order to know the time dependence of the oxidation rate uninfluenced by such a nonstationary current, i_N, subtraction of i_N from the observed current is necessary; the remainder is denoted hereafter by i_R. The present authors[11] showed that the formation and oxidation of the adsorbate that is experimentally identifiable could be written as

$$CH_3OH_{sol} = CO_{ad} + 4H^+ + 4e \quad (3)$$

$$CO_{ad} + H_2O = CO_2 + 2H^+ + 2e \quad (4)$$

Because part of the adsorbates formed are simultaneously oxidized unless the potential is very low, i_N at every moment solely contributes to the increase in the CO_{ad} coverage, θ_2. Expressing the mole number of CO_{ad} at its saturated coverage by N_s, and the Faraday constant by F,

$$i_N = 4FN_s d\theta_2/dt \quad (5)$$

according to Eq. 3. The i_N can also be expressed in terms of an electric quantity, Q_s^{ox} required to oxidize N_s moles of CO_{ad} to CO_2.

$$Q_s^{ox} d\theta_2/dt = 2FN_s d\theta_2/dt \quad (6)$$

From Eqs. 5 and 6,

$$i_N = 2Q_s^{ox} d\theta_2/dt \quad (7)$$

The time dependence of $i_R/(1-\theta_1)$ under the same conditions as those in Fig. 1 is shown in Fig. 4. Strictly speaking, no stationary rate was seen. In the course of the gradual fall of current, the coverages attained to a constant limiting value of about 0.8 at all the methanol concentrations when the potential was 0.6 V. The solid circle on each curve indicates the time at which the coverage attains to 0.75, and the time became shorter with an increase in the methanol concentration.

Relations between $i_R/(1-\theta_1)$ and θ_1 at various methanol concentrations and at a constant potential of 0.6 V are shown in Fig. 5. The fall of the rate became extremely remarkable with an increase of the coverage in its range of about 0.75 to 0.80. At the concentration of 0.03 mol dm^{-3}, the coverage could not reached 0.8, and no further fall of current could be measured. Because the rate of Reaction 3 is relatively small at low concentrations and exponentially decreases with an increase in θ_1, the coverage would be unable to come up to 0.8 within the limited measurement time. The electrode potential also exerted an effect upon the value

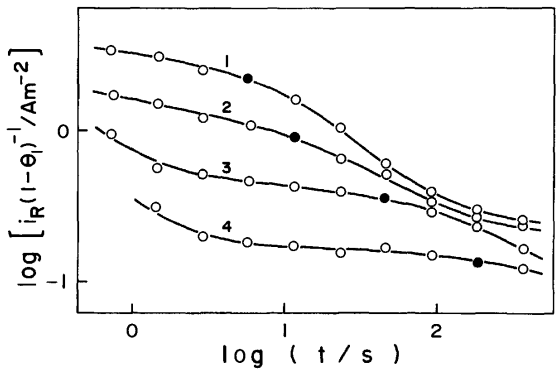

Fig. 4. Variation in oxidation rate with time (CH_3OH+0.5 mol dm^{-3} H_2SO_4, 0.6 V, 0°C). Methanol: (1) 1.0; (2) 0.3; (3) 0.1; (4) 0.03 mol dm^{-3}. Solid circle indicates when coverage attains to *ca.* 0.75.

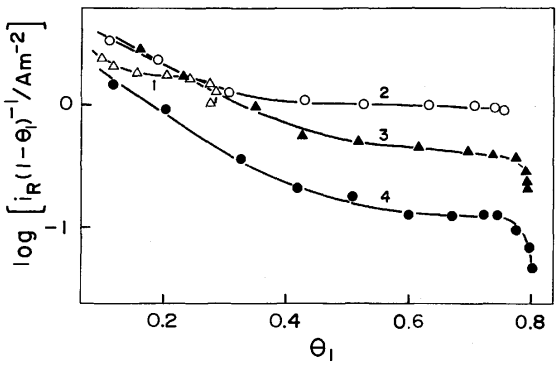

Fig. 6. Variation in oxidation rate with coverage (0.1 mol dm^{-3} CH_3OH+0.5 mol dm^{-3} H_2SO_4, 0°C). Potential: (1) 0.75; (2) 0.65; (3) 0.60; (4) 0.55 V.

of limiting coverage and the subsequent rate fall as illustrated in Fig. 6. Limiting coverages were 0.75 at 0.65 V, 0.3 at 0.75 V, and intermediate values ranging from 0.75 to 0.3 at the potentials from 0.65 to 0.75 V. In every case of higher potentials above 0.65 V, the current hardly continued falling after the limiting coverage, though an indication of the fall was observed. A potential increase accelerates the oxidation of the

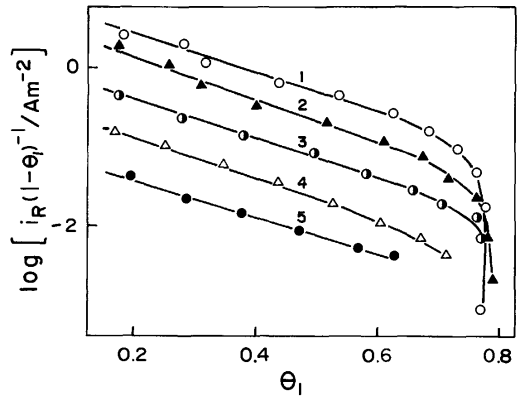

Fig. 7. Variation in CO_{ad} formation rate with coverage at 0.4 V (CH_3OH+0.5 mol dm^{-3} H_2SO_4, 0°C). Methanol: (1) 3.0; (2) 1.0; (3) 0.3; (4) 0.1; (5) 0.03 mol dm^{-3}.

CO_{ad} exponentially,[13] but doesn't the formation so much.[1,4] Therefore, the both rates would become balanced at a coverage lower than 0.8.

Similar remarkable falls of the rate of CO_{ad} formation took place whenever the coverage approached a limiting coverage of about 0.8 as shown in Fig. 7. The formation currents, i_F, were ones, except for Curve 2, corrected for the simultaneous oxidation of CO_{ad} by the method described in the preceding paper.[11] Coincidence in the value of the limiting coverages between the methanol oxidation and the CO_{ad} formation suggests that their causes would be similar.

Rate Fall before and after the Coverage of 0.8. As shown above, both the rates of the CO_{ad} formation and the overall methanol oxidation under the particular conditions markedly decrease, in some cases towards zero, immediately after the CO_{ad} coverage attains to a limit of about 0.8. A few explanations[1,4,7,8] have been given for the decrease in the oxidation rate at high coverages before the limits, but not an explanation for the unusual fall after the limiting coverage of 0.8. The definition of the coverage adopted here differs from those used by previous workers;[1,4] the value of 1 in their definition corresponds to about 0.8 in ours.

We have the data proving the oxidation rate of the CO_{ad} itself to be very small at its high coverages compared with the rate of the overall methanol oxidation to CO_2, the detail of which will be reported before long. Therefore, we are with Breiter *et al.*[12,14,15] about the opinion that different paths of CO_2 production exist in parallel. And we consider that at high coverages methanol is oxidized to CO_2 mostly without passing through the intermediate CO_{ad}.

Generally, such an adsorbate as is hard to react further can diminish the rate of an electrode reaction down to zero at a high coverage, if the adsorbate hinders sterically the approach of reactant species to the vacant sites adjacent to the preoccupied site, or if it prevents the availability of a site-aggregate that is indispensable for the electrode reaction to occur. The

CO_{ad} formed in the methanol oxidation is unlikely to exert the steric hindrance, because the coverage with the CO_{ad} formed from an aqueous solution of CO[16,17] is able to attain to 1. The aggregate-damaging effect is now under intensive investigation[18–20] in connection with the catalytic activity of an electrode modified with adatoms. This effect is operable provided the following conditions are satisfied.

(1) For the reaction under consideration to occur, an aggregate consisting of some of the vacant sites is necessary.

(2) The aggregate-damaging adsorbates are uniformly distributed on the surface.

(3) One molecule of the adsorbate occupies less sites than has one aggregate.

The CO_{ad} forming in the methanol oxidation can satisfy these requirements, the reasons are as follows.

(1) It would be reasonable to consider that the CO_{ad} formation takes place in a series of successive stages at which 4 hydrogen atoms of a methanol molecule are abstracted. Thus one or more sites are necessary in addition to the site(s) for the CO_{ad} eventually formed. Such site-aggregates would also be required for another path of the methanol oxidation to CO_2, though any stable intermediate is not yet experimentally identified.

(2) When the potential and the methanol concentration were below 0.5 V and 1 mol dm^{-3} respectively, no oxidation of methanol to CO_2 took place, and therefore the currents for the CO_{ad} formation, i_F, were directly measurable. The plots of log i_F $(1-\theta_1)^{-1}$ *vs* θ_1 were approximately linear within the limits of $0.1<\theta_1<0.75$ (Fig. 7), and expressed as

$$i_F = k(1-\theta_1)\exp(-3.84\,\theta_1) \qquad (8)$$

where k is a potential dependent constant. This experimental rate equation is substantially the same as the theoretical one[21] derived on the assumption that the heat of adsorption on a uniform surface increases linearly with an increase in the coverage. In other words, the CO_{ad} formation will occur in order of the increasing heat of adsorption, which will result in a uniform distribution of the CO_{ad}. At higher potentials above 0.5 V, an approximately uniform distribution would also be expected.

(3) Gilman *et al*[13,17] reported that the CO_{ad} formed from an aqueous solution of CO showed two states of binding with Pt surface atoms, *i.e.*, one-site (or linear) and two-site (or bridged) adsorptions. Since the value of 2 $(Q_H^0-Q_H)/Q^{ox}$ represents the number of sites occupied by one CO_{ad}, the number can be determined from the slope of plots, Q^{ox}/Q_H^0 *vs.* $(Q_H^0-Q_H)/Q_H^0$, the latter equals to θ_1. Figure 8 shows the case in which the methanol concentration is 1 mol dm^{-3} and the potential 0.35—0.75 V. The number of sites, 1.89, indicates that most adsorbates at $\theta_1<$ about 0.6 are the bridged type, and the number 1.08 that the adsorbates at about $0.6<\theta_1<0.8$ are mainly linear type.

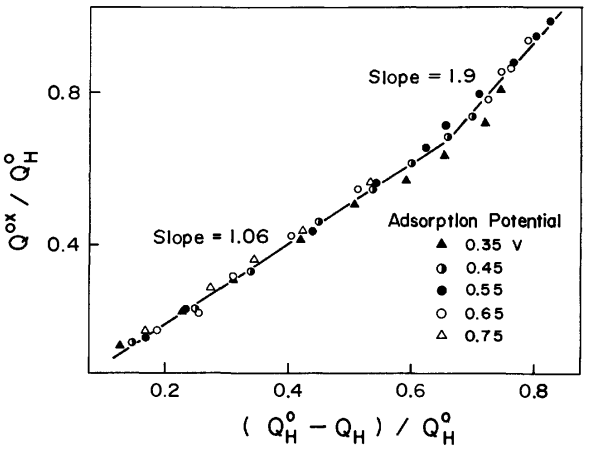

Fig. 8. Variation in Q^{ox} with coverage (1 mol dm^{-3} CH_3OH+0.5 mol dm^{-3} H_2SO_4, 0 °C).

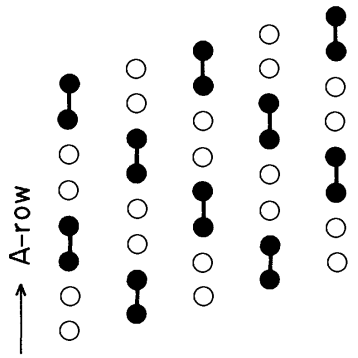

Fig. 9. Uniform distribution of bridged CO_{ad} at $\theta_1=0.5$ under minimum repulsion among CO_{ad} molecules.

To sum up, the CO_{ad} probably has such an aggregate-damaging effect as diminishes the rates of both the methanol oxidation to CO_2 and the further formation of CO_{ad} itself at its high coverage less than 1.

It is shown below first that the number of the aggregates, each consisting of 3 or more adjacent vacant sites, should be reduced to zero at $\theta_1=0.5$, if the bridged CO_{ad} species are distributed uniformly. And then that the linear adsorbates forming at $\theta_1>0.6$ should make all the aggregates consisting of two vacant sites each vanish at the coverage of 0.8.

The actual surface of the Pt electrodes used in the experiment was a mixture of crystal faces with the different indices and not a completely flat plane. However it can be represented by an orderly gathering of parallelograms as a simplest approximation, the apices representing the lattice sites (Fig. 9). In Fig. 9, rows of the nearest sites are called A-rows, and those of the next nearest ones B-rows.

A bridged CO_{ad} is considered[22] to be attached with its carbon atom to a pair of Pt sites. Since the atomic radius of Pt is larger than that of C, it must be energetically favorable for a bridged CO_{ad} to occupy those two sites which are nearest with each other. Thus

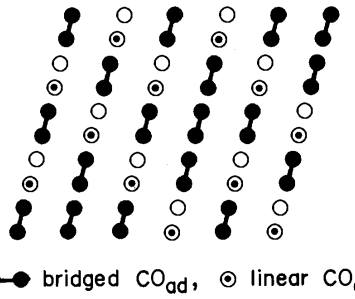

Fig. 10. An example of vacant-site distribution when coverage with bridged CO_{ad} (●—●) is 0.6 and that with linear CO_{ad} (⊙) 0.2.

the adsorbates will preferentially line up in the A-rows.

The negative value of the exponent, $-3.84\,\theta_1$, in Eq. 8, indicates that there are mutual repulsions between the CO-adsorbates, the adsorbed methanol molecules, or the both species, and that the repulsions make the adsorption energy of the CO_{ad} increasingly high with an increase in θ_1. In an A-row, the bridged CO_{ad} should align at intervals of some vacant sites in order to make the mutual repulsion small. If the maximum amount and the minimum repulsion of the adsorbates over the whole surface are required, every two pairs of sites situated directly abreast with a CO_{ad} should always be vacant as shown in Fig. 9. In this distribution of the adsorbates, the number of the aggregates with 3 or more adjacent vacant sites each is zero at $\theta_1=0.5$. However the experiment shows that the rate of the methanol oxidation does not fall to zero at the coverage of 0.4 to 0.75. It can thus be concluded that the number of sites in the aggregate indispensable to the oxidation of methanol to CO_{ad} or CO_2 is probably 2.

By assuming that the respective adsorbates at $\theta_1 \leq 0.6$ and >0.6 are exclusively bridged and linear types, the number of the remaining aggregates with two vacant sites each, A_2, can be deduced in the following way. Although the uniform distribution of the bridged adsorbates is probable at $\theta_1=0.5$ as shown in Fig. 9, a local irregularity cannot be avoidable at $\theta_1=0.6$. The distribution of the solid circles in Fig. 10 gives an example. At this coverage, A_2 is equal to a half of the remaining vacant sites, *i.e.*, $(1-0.6)\,S_t/2$; S_t is the total number of sites on the electrode surface. When $\theta>0.6$ and the linear adsorbates are distributed as uniformly as possible (Fig. 10), one linear adsorbate damages one aggregate. Consequently, A_2 is expressed as

$$A_2 = (1-0.6)S_t/2 - M_1 \qquad (9)$$

where M_1 is the number of the linear adsorbates, and equal to $(\theta_1-0.6)\,S_t$. Then the expression 9 becomes

$$A_2 = S_t(0.8-\theta_1) \qquad (10)$$

If i_R, the current for the oxidation of methanol to CO_2, is proportional to A_2, then

$$\log i_R(1-\theta_1)^{-1} = \log (kS_t) + \log (0.8-\theta_1)(1-\theta_1)^{-1} \qquad (11)$$

This theoretical equation shows that the rate of the oxidation decreases towards zero as θ_1 approaches 0.8, as indicated by Curve 1 of Fig. 5. This is in substantial agreement with the experimental fact. The rate decreases in the CO_{ad} formation at 0.8 can also be explained in the same way.

To sum up, the aggregate consisting of two vacant sites is indispensable for the formation of CO_{ad} and the overall oxidation of methanol. The CO_{ad} exerts the aggregate-damaging effect at the coverages of about 0.8, leading to the decrease of the both rates towards zero.

Additional Remarks about the Coverages by Different Definitions. As described above, the maximum coverage with the CO_{ad} varies according to whether the starting species, from which the CO_{ad} is formed, is methanol or carbon monoxide in a solution. Generally speaking, the maximum coverage with a particular adsorbate does not always take an invariable value even if the adsorbates are identical, which are eventually formed from different starting species *via* different paths. It is therefore not appropriate to use the following coverages, θ_2 and θ_3, for the purpose of comparison of the coverage values, unless the starting and the adsorbate species are respectively the same. In such cases, the coverage defined by Eq. 1 should be used.

$$\theta_3 = (Q_H^0 - Q_H)/[Q_H^0 - (Q_H)_{min}] \qquad (12)$$

where Q_H and Q_H^0 are previously stated when θ_1 is defined, and $(Q_H)_{min}$ are for the maximum amount of adsorbate, and $[Q_H^0-(Q_H)_{min}]$ corresponds to the maximum number of available hydrog hydrogen sites.

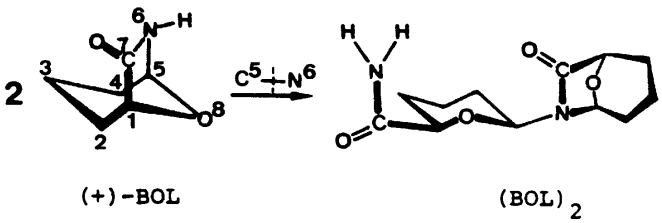
(Recieved March 18, 1985)

The structure of the dimerization product of bicyclic oxalactam, 8-oxa-6-azabicyclo[3.2.1] octan-7-one, was determined by the X-ray diffraction method. The final R value was 0.062 for 2009 reflections. The structure suggests that the cationic oligomerization of the bicyclic oxalactam proceeds through the C^5-N^6 scission, differing from the cases of other common lactams.

Cationic oligomerization of optically active bicyclic oxalactam, 8-oxa-6-azabicyclo[3.2.1]octan-7-one (abbreviated as BOL), produces the oligomer mixture.[1] The GPC analysis showed that the main product is the dimer, $(BOL)_2$. On the basis of IR and NMR data, an equatorial orientation of the BOL moiety with respect to the tetrahydropyran ring has been expected.[1] Therefore, the anticipated structure of $(BOL)_2$ and the dimerization mechanism are deduced as Eq. 1. It



Eq. 1.

shows that the reaction proceeds through the C^5-N^6 scission of the oxaamide unit in BOL, though the N^6-C^7 scission is generally observed in the cases of other common lactams. In order to confirm the molecular structure and to elucidate the oligomerization mechanism, the crystal structure of $(BOL)_2$ has been studied by the X-ray diffraction method.

Results and Discussion

Crystal Data. $C_{12}H_{18}N_2O_4$, M.W.=254.29, $P2_1$, a=10.814(1), b=9.964(1), c=11.975(2) Å, β=101.44(1)°, U=1264.6(3) Å^3, Z=4, D_m=1.33, D_x=1.333 gcm^{-3}, μ(Cu $K\alpha$)=8.6 cm^{-1}. Intensity data with $2\theta \leq 120°$ were collected on a Rigaku four-circle diffractometer using graphite-monochromated Cu $K\alpha$ radiation (λ=1.5405 Å). The structure was solved by the use of *MULTAN* 78.[2] The refinement was carried out by the block-diagonal least-squares method.[3] The function minimized was $\sum w(|F_o|-|F_c|)^2$, and the weighting scheme at the final stage of the refinement was $w=[\sigma^2(F_o)-1.566|F_o|+0.079|F_o|^2]^{-1}$ for $|F_o|>0$, and w=1.016 for $|F_o|=0$. The final R value is 0.062 for 2009 independent reflections. All the scattering factors were taken from the International Tables for X-Ray Crystallography, Vol. IV.[4] The final atomic parameters with equivalent temperature factors are listed in Table 1.* The bond distances and angles are given in Fig. 1,

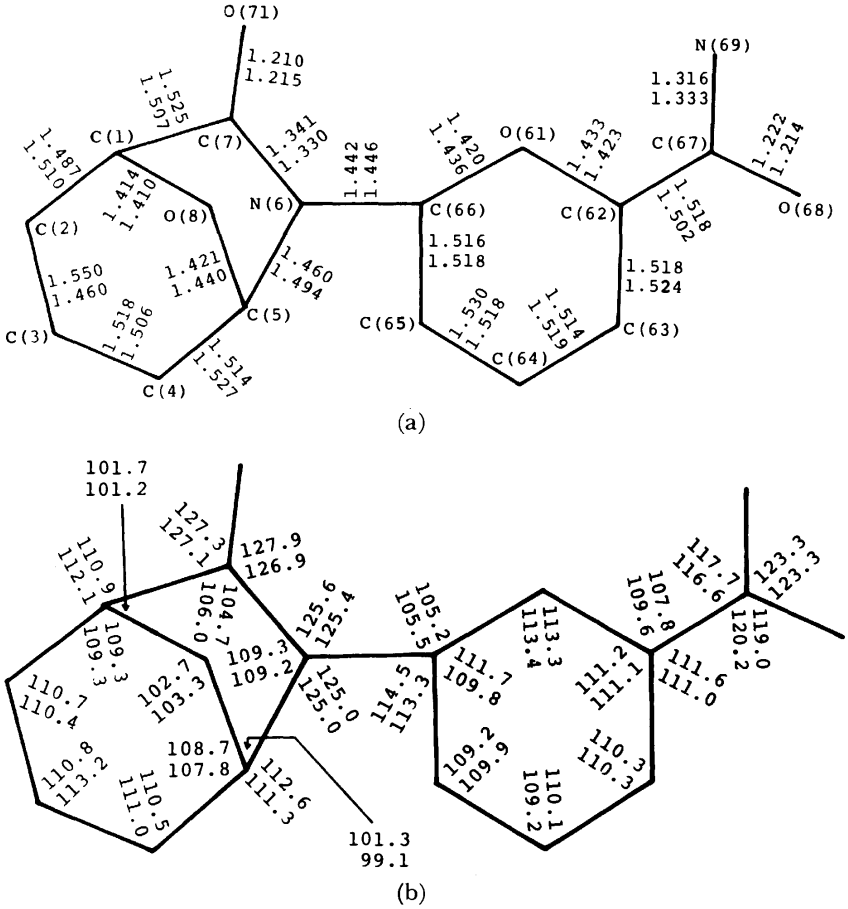

Fig. 1. (a) Bond distances (l/Å), (b) bond angles (ϕ/°) for molecule **A** (upper) and molecule **B** (lower). The estimated standard deviations are 0.005—0.007 Å for bond distances and 0.3—0.4° for bond angles.

with the numbering scheme of the atoms. Two independent molecules, **A** and **B**, are included in the asymmetric unit. The overall structure of the two molecules are almost the same. However, the thermal motion of molecule **B** is slightly larger than that of molecule **A**, as a whole. The bond distances and angles between the two molecules are in good agreement with each other, except for the C(2)–C(3) distance. An *ORTEP II*[6] drawing of molecule **A** is shown in Fig. 2. This shows that the tetrahydopyran ring takes a chair conformation, and ascertains that both the amide and the BOL moiety are equatorial with respect to the tetrahydropyran ring. This structure confirms the anticipated structure, and supports the presumed reaction mechanism of Eq. 1 that the cationic oligomerization of BOL proceeds through the C^5–N^6 scission of the oxaamide unit.

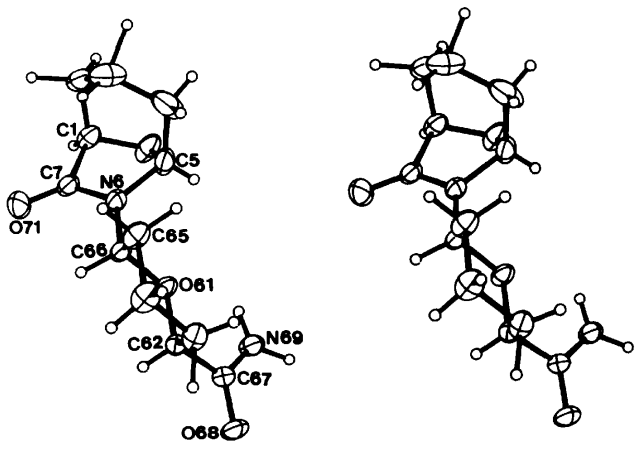

Fig. 2. Stereodrawing of molecule **A**. Atoms are drawn with 50% probability thermal ellipsoids.

The most interesting conformational feature of the molecule is the anticlinal conformation (ac^+) around the N(6)–C(66) bond. From the spectral data, the C(7)–N(6) bond was speculated to take g^- conformation to the C(66)–O(61) bond, leading to the formation of the intramolecular hydrogen bond between N(69) and O(71). However, the torsion angle of C(7)–N(6)–C(66)–O(61) is 118.4(3)° for **A** and 104.8(4)° for **B**, and the intramolecular hydrogen bond is not made. In this structure the C(5) is g^- to the O(61) and g^+ to the C(65) around the N(6)–C(66) bond. The torsion angles of the main skeleton which is of interest in consider-

TABLE 2. HYDROGEN BONDS(THE ESTIMATED STANDARD DEVIATIONS ARE IN PARENTHESES)

D*	A*	D···A	<D—H···A	Symmetry code of A

	O(61)**A**	2.588(4)	107(2)	—
N(69)**B**	O(8)**B**	2.940(6)	165(2)	$-x,-0.5+y,2-z$
N(69)**B**	O(68)**B**	2.930(5)	121(2)	$-x,0.5+y,2-z$
	O(61)**B**	2.581(4)	115(2)	—

* D means a protan donor and A a proton acceptor.

ing the model structure of the polymer of BOL synthesized by the anion polymerization are: C(1)-C(7)-N(6)-C(66), −173.5(3)° for **A** and −171.0(3)° for **B**; N(6)-C(66)-O(61)-C(62), −176.8(2)° for **A** and −177.6 (3)° for **B**; C(66)-O(61)-C(62)-C(67), −179.8(2)° for **A** and 178.6(3)° for **B**; O(61)-C(62)-C(67)-N(69), 11.5 (4)° for **A** and 2.8 (5)° for **B**. Therefore the conformation around the N(6)-C(66), C(66)-O(61) and O(61)-C(62) bonds can be described as an ac^{+}-*t*-*t* conformation.

Hydrogen bonds are listed in Table 2. The fairly distorted bifurcated hydrogen bonds are observed between N(69) and O(61), and between N(69) and O(68). The former is intramolecular and the latter is intermolecular. One of the reasons for the distorsions is considered to be the formation of the five-membered ring by the N(69)···O(61) hydrogen bond.

The authors would like to thank Toyota Physical and Chemical Research Institute for financial support.

Photocatalytic Isomerization of Butenes over ZnO and SnO_2

Sukeya KODAMA,* Masaaki YABUTA, Masakazu ANPO, and Yutaka KUBOKAWA
Department of Applied Chemistry, University of Osaka Prefecture, Sakai, Osaka 591
(Received April 1, 1985)

It has been found with ZnO as well as TiO_2 that 2-butene is much more reactive than 1-butene for their photocatalytic isomerization. Although both *cis-trans* and double bond isomerizations take place on ZnO, only *cis-trans* isomerization occurs over SnO_2. The photocatalytic isomerizations were suppressed drastically in the presence of NO. From those results together with the ESR studies the following conclusions emerge: a butene molecule interacts with the photoformed O^- to form a radical species as a result of fission of the C=C bond; the photocatalytic isomerization proceeds *via* such a radical intermediate; the lack of the reactivity of 1-butene appears to be explicable on such basis.

In order to understand the photocatalysis of metal oxides, it seems necessary to investigate on a wide range of the photocatalytic reactions, other than the oxidation and reduction reactions. From such standpoint we have investigated the photocatalytic isomerization of butenes over TiO_2 and ZnO with the result that in the case of TiO_2 2-butene is more reactive than 1-butene.[1] A continued study concerning the isomerization over ZnO has revealed that it is unnecessary to propose an intermediate different from that for the isomerization over TiO_2. Essentially the same features have been observed with both ZnO and TiO_2. Similar works have been extended to SnO_2.[2] In addition to those results, the present paper deals with the ESR studies which provide information on the active species as well as an intermediate in the photocatalytic isomerization of butenes. Furthermore, its mechanism has been worked out.

Experimental

All the butenes used in the present work as well as NO were of extrapure grade from the Takachiho Kagakukogyo Co. ZnO (Kadox 25, 10 m^2g^{-1}) was obtained from New Jersey Zinc Co. SnO_2 (8.6 m^2g^{-1}) was prepared from hydrolysis of $SnCl_2$ with aqueous ammonia. Both ZnO and SnO_2 were subjected to oxygen treatment for one hour at 560°C followed by evacuation at the same temperature. Butenes of about 4.0 kPa were introduced over the catalysts (ZnO 0.6 g, SnO_2 2.0 g) which had been spread on the quartz cell window, having a surface area of *ca.* 32 cm^2. The photoisomerization was carried out by UV irradiation from a high pressure mercury lamp (Toshiba, SHL-100UV) with and without a filter (Toshiba, UV-D33S) shading the visible and infrared regions. Gas samples were taken at definite intervals and analyzed gas chromatographically using a dimethylsulfolane column. ESR measurements were carried out with JES-ME-1 (X-band). Mn^{2+} ions in MgO powder were used for *g* value and sweep calibration.

Results

Continued work concerning the isomerization of 1-butene over ZnO at 0°C was carried out in the dark and under UV irradiation with and without the filter with the results shown in Fig. 1. No enhancement of the isomerization by UV irradiation was found. Figure 2 shows the results on the isomerization of *trans*-2-butene over ZnO at 0°C. It is found that both isomerizations to *cis*-2-butene and 1-butene are enhanced by UV irradiation. From those results the following conclusions emerge: the enhancement of the isomerizations of 2-butene under UV irradiation arises from photocatalytic effects and not thermal effects by the radiation from the lamp; 1-butene is unreactive for

photocatalytic isomerization. Thus, the conclusion obtained with TiO_2 that 2-butene is much more reactive than 1-butene holds for ZnO. Its general applicability is confirmed. As shown in Fig. 3, the photocatalytic isomerization of *cis*-2-butene is suppressed by the presence of NO.

Similar studies have been extended to SnO_2. The results are shown in Fig. 4. It should be noted that only *cis-trans* isomerization proceeds, without double bond migration. The isomerization is again restrained in the presence of NO.

When NO molecules were adsorbed onto the catalyst, which had been treated in vacuum, the ESR spectrum due to the adsorbed NO molecules was observed at 77 K.[3] UV irradiation of the catalyst in the presence of NO at 77 K led to the appearance of a new signal shown in Fig. 5, which was thermally unstable and it disappeared completely on raising the temperature up to 300 K. This new spectrum is characterized by *g* value of 2.002 with hyperfine splitting of *ca.* 35 G† for N^{14}.

† 1 G≈10^{-4}T.

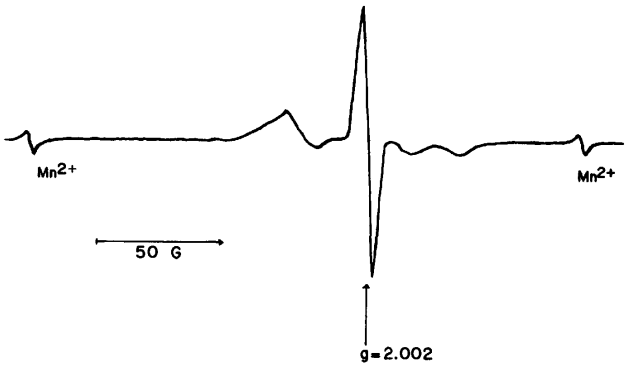

Fig. 5. ESR spectrum of photoformed NO_2^{2-} anion radicals adsorbed on ZnO (0.20 g) at 77 K. Amount of photoformed NO_2^{2-} is 8.6×10^{-7} mol.

These values are similar to those for NO_2^{2-} species adsorbed on the surface of ZnO, though the hyperfine splitting of 35 G is slightly smaller.[3b] As described previously,[4] UV irradiation of ZnO at 77 K *in vacuo* leads the formation of O^- anion radicals. Accordingly, it is expected that the photoformed O^- species reacts with NO to produce NO_2^-, which is transformed to NO_2^{2-} by electron trapping. This assumption is strongly supported from the results of ESR measurements. From these results, it is concluded that the spectrum shown in Fig. 5 can be assigned to NO_2^{2-}. Thus, the reaction of photoformed O^- with NO is confirmed. Since the photocatalytic isomerization is suppressed by the presence of NO as described above, it is suggested that interaction of butene molecules with photoformed O^- is involved in its photocatalytic isomerization.

The catalyst exhibited the ESR spectrum due to the presence of Zn^+ and bulk O^- species after the pretreatment in vacuum.[5] When 1-butene was admitted onto the catalyst, a new ESR spectrum was observed neither at 77 K nor at room temperature, except for a slight weakening of the signal due to O^- species. On UV irradiation of the catalyst in the presence of butene at 77 K, a new ESR signal appears as shown in Fig. 6. It shows a doublet hyperfine splitting separated by *ca.* 22 G. This splitting is comparable to the 17—22 G splitting due to one β-hydrogen in alkyl or alkene radicals.[6] Further triplet hyperfine splitting with *ca.* 7 G is similar to that for two α-hydrogens in alkene cation radicals adsorbed on zeolite surfaces.[7] When the temperature was raised up to around 300 K, this signal disappeared irreversibly without appearance of any new signals. In addition to such hyperfine splitting, the number of hyperfine components, *i.e.*, a doublet of triplet and their intensity ratio together with a *g* value of 2.0014 suggest that a radical species, $CH_2\dot{-}CH-CH_2-CH_3$, is formed on ZnO under UV irradiation.

Discussion

The fact that 2-butene is much more reactive than

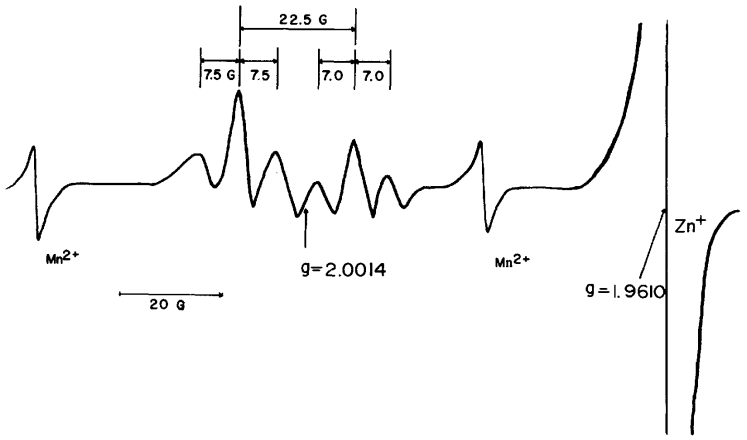

Fig. 6. ESR spectrum of photoformed butene radicals at 77 K.
Amount of 1-butene adsorbed on ZnO (0.20 g) is 1.2×10^{-5} mol g^{-1}.

1-butene is unexplicable by π-allyl intermediates, which has been proposed for the isomerization of butenes over ZnO and Al_2O_3.[8] This suggests that an intermediate different from π-allyl species is involved in the photocatalytic isomerization. In the previous works[9] it has been shown that fission of the C=C bond of alkenes is induced by its interaction of photoformed O^- or $[M^{(n-1)+}—O^-]$ pairs. Furthermore, the ESR studies described above demonstrate clearly that the photoformed O^- species interacts with a butene molecule to form a radical species. Accordingly, it might be concluded that a radical species is involved as the intermediate in the photocatalytic isomerization. Thus, the following reaction scheme is proposed for the 2-butene isomerization:

$$\begin{array}{l} CH_3\text{-}CH{=}CH\text{-}CH_3 \xrightarrow{h\nu} CH_3\text{-}CH{=}CH\text{-}CH_3 \longrightarrow \\ O^{2-}\ M^{2+}\ OH^- \qquad\quad O^-\ M^+\ OH^- \end{array}$$

$$\begin{array}{l} \overset{1}{CH_3}\text{-}\overset{2}{CH}\text{-}\overset{3}{CH}\text{-}\overset{4}{CH_3} \xrightarrow{[I]} CH_3\text{-}CH\text{-}CH_2\text{-}CH_3 \longrightarrow \\ \quad\vdots\ \cdot \qquad\qquad\qquad\quad \vdots \\ O^-\ M^+\ OH^- \qquad\quad O^-\ M^{2+}\ O^{2-} \end{array}$$

$$\begin{array}{l} CH_2\text{-}CH\text{-}CH_2\text{-}CH_3 \longrightarrow CH_2{=}CH\text{-}CH_2\text{-}CH_3 \\ \quad\vdots \qquad\qquad\qquad\quad \\ OH^-M^{2+}\ O^{2-} \qquad OH^-\ M^{2+}\ O^{2-} \end{array}$$

The photoformed O^- or $[M^{(n-1)+}—O^-]$ pairs interact with a butene molecule to form the radical [I] as a result of opening of the C=C bond. When the radical reverts to butene, the *cis-trans* isomerization is expected to occur. In fact, Morikawa *et al.*[10] have proposed that such radical species adsorbed on porous Vycor glass play a significant role in the photocatalytic *cis-trans* isomerization of butenes on it.

In case where the double bond migration proceeds *via* a radical intermediate, the presence of hydrogen atoms appears to be the prerequisite for its occurrence. If H atoms are present on the surface, H atom addition to C atom at the position 3 of the radical [I] will occur. This will be followed by removal of H atom from CH_3 group by the O^- species because of its high efficiency for hydrogen abstraction. Thus, 1-butene is formed. In the above reaction scheme it is assumed that H atoms are supplied from the surface OH groups, although there is no evidence for this postulate. In this case the acidity of the OH groups as well as the concentration of electrons available for the neutralization of protons would determine to what extent the double bond migration occurs. The photoformed electrons trapped as M^+ ions are used for the neutralization of protons. At present it is unclear whether or not the difference in the selectivity of the isomerization between ZnO and SnO_2 described above is explicable on the basis of such a concept. A further study is necessary to settle this problem. It is to be noted that trace amounts of the OH groups are enough to bring about the isomerization in the case of a concerted mechanism where the removal and addition of H atom proceed with a similar rate.

In the case of the isomerization of 1-butene, in contrast to the case of 2-butene where opening of the C=C bond brings about only one type of the adsorbed radical, two types of the adsorbed radicals may be expected to be formed:

$$\begin{array}{ll} \dot{C}H_2\text{-}CH\text{-}CH_2\text{-}CH_3 & CH_2\text{-}\dot{C}H\text{-}CH_2\text{-}CH_3 \\ \quad\vdots & \quad\vdots \\ \quad M^+ & \quad M^+ \\ \text{(primary radical)} & \text{(secondary radical)} \end{array}$$

Although for the primary radical the removal and addition of H atom may be possible, for the secondary radical only regeneration of 1-butene may take place. Since it is well-known that the secondary radical is more stable than the primary one, the secondary radical is expected to participate in the reaction. Accordingly, in the case of 1-butene occurrence of the isomerization is not expected, in agreement with the experimental results. Finally it should be noted that the unusual feature of the photocatalytic isomerization, *i.e.*, the lack of the reactivity of 1-butene is explicable on the basis of

the concept that an intermediate where one unpaired electron remains uninteracted with the surface is involved in the reaction.

Polarization in Light-scattering by Aerosol

Akiyoshi MATSUZAKI
The Institute of Space and Astronautical Science, Komaba 4-6-1, Meguro-ku, Tokyo 153
(Received April 5, 1985)

The polarization of the light scattered by aerosol has been studied by the theoretical calculation based on the Mie scattering theory. The present calculation obtains the polarization of the light scattered by aerosol as a function of size parameter, *i.e.* $x=2\pi r/\lambda$, where r and λ are the radius of aerosol and the wavelength of the scattered light, respectively, for various refractive indexes. These results give the useful informations for the experimental study on the size-growth in aerosol formation by the measurement of the scattered light polarization. The characteristic of the scattered light intensity, which is usually used as a kind of concentration parameter in the study on aerosol formation, is also discussed.

The investigation on aerosols, which are small particles floating in the atmosphere, is of great importance in view of chemical reaction and environmental science. For example, aerosol formation includes heterogeneous reactions, *i.e.*, gaseous molecules and solid, gas and liquid, or liquid and solid. On the other hand, in view of environmental science, the stratospheric aerosol is known to affect the radiation balance in the atmosphere. Consequently, it is very important with the relevance to the climate problem. Its property and formation mechanism are the up-to-date targets.

In the study on aerosol, the scattered light intensity is usually used as a kind of concentration parameter. Namely, the property of aerosol, *e.g.* the size, the refractive index, *etc.*, has been studied by the measurement of the polarization and the angular distribution of the scattered light. However, in fact, these show the complex dependence on the size and the refractive index of aerosol and the wavelength of the scattered light. In this situation, the present work made the theoretical calculation of the polarization of the scattered light for some typical aerosol models with the aid of the Mie scattering theory.[1] The property of the scattered light intensity is also discussed with the experimental and theoretical results.

Experimental

The experimental system is schematically shown in Fig. 1. The N_2 laser with 25 Hz of repetition causes aerosol formation in the reaction cell (sphere glass with 25 cmϕ), which is filled with approx. fifty Torr† of carbon disulfide vapor. The polarized radiation of a He-Ne laser is introduced coaxially with the N_2 laser radiation, and the light scattered by the aerosol formed and the carbon disulfide vapor was measured in the direction perpendicular to the He-Ne

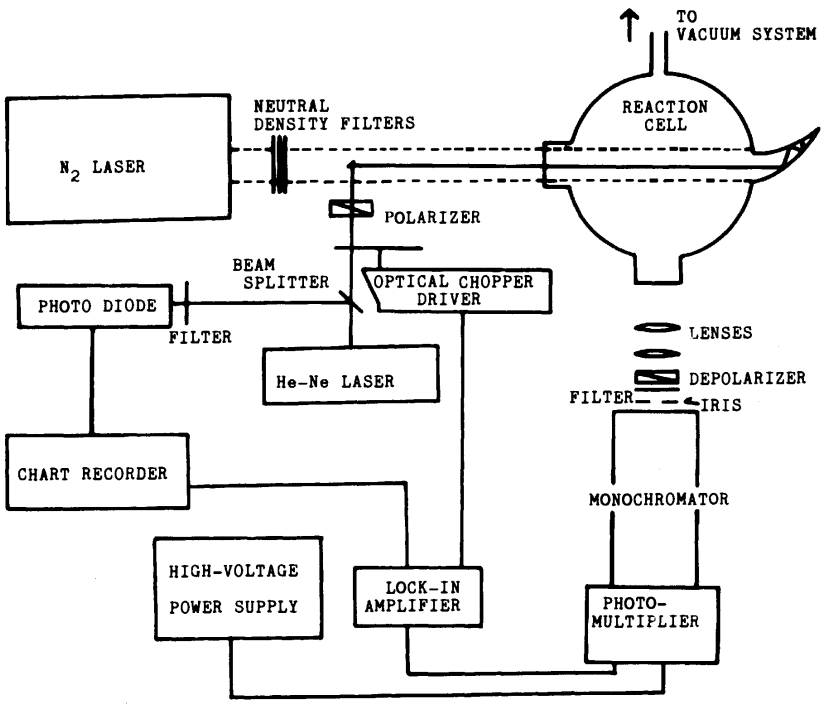

Fig. 1. Block diagram of experimental apparatus.

† 1 Torr=133.322 Pa.

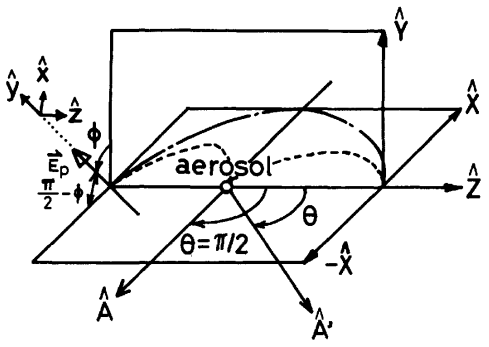

Fig. 2. Definition of the laboratory coordinate $(\hat{X},\hat{Y},\hat{Z})$ and the electric vector coordinate $(\hat{x},\hat{y},\hat{z})$. The angle between $\hat{Y}$ and $\hat{y}$ is ϕ. $\hat{A}$ and $\hat{A}'$ have the angles of $(\pi/2)$ and θ with the $\hat{Z}$-axis, respectively.

laser beam. Namely, lenses and an iris introduce the scattered light into a monochromator (f=200 mm) after the depolarization, then a photomultiplier detects it. The modulation of the He–Ne laser radiation with an optical chopper allows the measurement with a good signal-to-noise ratio by using a lock-in-amplifier detecting system. Carbon disulfide (Wako reagent grade) was used after the vacuum distillation.

Method of Theoretical Calculation

Definitions of Axes. For the convenience to describe these theoretical and experimental examinations, Figure 2 defines the laboratory-fixed axes $(\hat{X},\hat{Y},\hat{Z})$, the electric-vector-fixed axes $(\hat{x},\hat{y},\hat{z})$ and the angular parameters. The $\hat{Z}$-axis is coincident with the incident laser-beam axis. The directions of observation, *i.e.* $\hat{A}$ and $\hat{A}'$, are on the $\hat{X}$–$\hat{Z}$ plane and have the angles of $(\pi/2)$ and θ with the $\hat{Z}$-axis, respectively. The electric vector $\vec{E}_p$ of the incident laser beam is expressed in term of the $\vec{E}_p$-fixed axes $(\hat{x},\hat{y},\hat{z})$. The $\hat{z}$-axis is in the same direction as the $\hat{Z}$-axis. The angle between the $\hat{y}$-axis and the $\hat{Y}$-axis is ϕ. For example, the Rayleigh-scattering angular distributions for the incident light polarized with ϕ=0° and 90° are shown by the dashed-solid line and the dashed line, respectively, in Fig. 2.

Outline of the Mie Scattering Theory. The exact solution to the scattering problem for a sphere radius r at wavelength λ was given by Mie in 1908,[1] elaborated by Debye,[2] and thereafter arranged by van de Hulst.[3] The problem is to obtain three dimensional solutions for Maxwell's equations for the electric and magnetic fields inside and outside a spherical region of radius r and the refractive index m at the frequency ω. By seperating the variables, solutions of the scalar wave equation $\nabla^2\psi+k^2m^2\psi=0$, where k is the wavenumber $(2\pi/\lambda)$, can be written in the spherical coordinates as:

$$\psi_{l,n} = \begin{cases}\cos l\phi \\ \sin l\phi\end{cases} P_n^l(\cos\theta)\left\{\sqrt{\frac{\pi}{2mkr}}\,Z_{n+1/2}(mkr)\right\}, \tag{1}$$

where Z represents either J- or H-solutions of Bessel's equation, P_n^l Legendre polynominals. A plane-incident scalar wave can be written:

$$u_0 = \exp(i\omega t)\cos\phi\sum_1^\infty(-)^n\frac{2n+1}{n(n+1)}P_n^1(\cos\theta)j_n(kr), \tag{2}$$

$$v_0 = \exp(i\omega t)\sin\phi\sum_1^\infty(-)^n\frac{2n+1}{n(n+1)}P_n^1(\cos\theta)j_n(kr). \tag{2'}$$

The corresponding spherical Bessel functions are written by j_n and h_n. The scattered wave therefore contains only terms with l=1 and the scalar functions u and v can be written as:

$$u = \exp(i\omega t)\cos\phi\sum_{n=1}^\infty(-a_n)(-i)^n\frac{2n+1}{n(n+1)}P_n^1(\cos\theta)h_n(kr), \tag{3}$$

$$v = \exp(i\omega t)\sin\phi\sum_{n=1}^\infty(-b_n)(-i)^n\frac{2n+1}{n(n+1)}P_n^1(\cos\theta)h_n(kr). \tag{3'}$$

The Mie solution process is one of finding a set of complex numbers a_n and b_n (Mie coefficients):

$$a_n = \frac{S_n'(y)S_n(x)-mS_n(y)S_n'(x)}{S_n'(y)[S_n(x)+iC_n(x)]-mS_n(y)[S_n'(x)+iC_n'(x)]}, \tag{4}$$

$$b_n = \frac{mS_n'(y)S_n(x)-S_n(y)S_n'(x)}{mS_n'(y)[S_n(x)+iC_n(x)]-S_n(y)[S_n'(x)+iC_n'(x)]}. \tag{4'}$$

These complex-valued coefficients, functions of the refractive index m, $x=2\pi r/\lambda$ and $y=mx$ provide the full solution to the scattering problem. Here, S_n and C_n can be represented, as follows, with the Bessel functions $J_{n+1/2}(\rho)$ and the Neumann functions $N_{n+1/2}(\rho)$:

$$S_n(\rho) = \sqrt{\pi\rho/2}J_{n+1/2}(\rho), \tag{5}$$

$$C_n(\rho) = -\sqrt{\pi\rho/2}N_{n+1/2}(\rho). \tag{5'}$$

The prime denotes differentiation with respect to the argument. The Mie coefficients give directly some important integrated quantities: The excitation, scattering and absorption efficiencies. The efficiency factors are defined as follows: The energy removed from an incident wave with energy flux density I_0 is $\pi r^2Q_eI_0$, Q_e being the extinction efficiency; the energy which reappears as scattered energy is $\pi r^2Q_sI_0$, Q_s being the scattering efficiency; the energy absorbed is $\pi r^2Q_aI_0$, Q_a being the absorption efficiency. These all can be written in terms of the Mie coefficients:

Extinction efficiency

$$Q_e = (2/x^2)\sum_1^\infty(2n+1)\mathrm{Re}(a_n+b_n), \tag{6}$$

Scattering efficiency

$$Q_s = (2/x^2)\sum_1^\infty(2n+1)\{|a_n|^2+|b_n|^2\}, \tag{7}$$

Absorption efficiency $Q_a = Q_e - Q_s$. (8)

Results and Discussion

The relationships between Q_s and the size of the aerosol particle are calculated for several refractive indices $1.5+im_{IM}$, m_{IM}=0, 0.01, 0.1, 1, 10, as shown in Fig. 3. Since x is the size parameter defined by $x=2\pi r/\lambda$ with an aerosol radius r and wavelength λ, x is proportional to r for a constant wavelength. Figures 4(a)—(f) show the angular distributions, *i.e.* θ-dependence, for x=0.01, 0.1, 1, 1.5, 2, 2.5 with m=1.55+0i. These figures indicate that, with the increase of x, (1) the forward scattering becomes predominant, (2) the perpendicular and parallel components of the scattered light intensities against the electric vector of the incident light, *i.e.* $I_\perp$ and $I_{/\!/}$, respectively, become greater and greater, (3) there is the intensity inversion between $I_\perp$ and $I_{/\!/}$ for the large x range, while $I_{/\!/}$ is always equal to or smaller than $I_\perp$ for $x\leq 1.5$, and (4) $I_\perp$ and $I_{/\!/}$ becomes oscillatory. The intensity inversion between $I_\perp$ and $I_{/\!/}$ causes the large variation of the polarization. The polarization is defined by $P=(I_\perp-I_{/\!/})/(I_\perp+I_{/\!/})$. Figure 5 shows the plot of P as a function of x. The polarization is nearly constant, *i.e.* approx. 1, for the range $x\leq 1.2$, then decreases steeply and gets to approx. −0.6 for

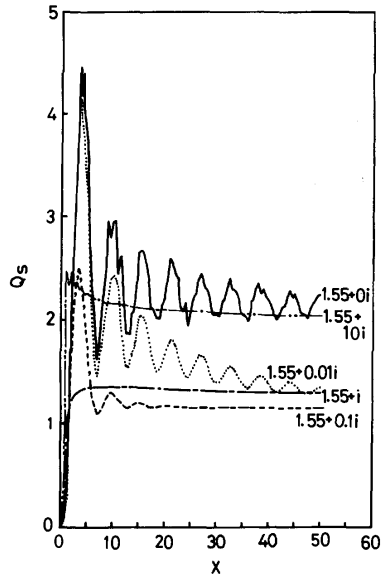

Fig. 3. The scattered light intensity Q_s versus the size-parameter x for $m=1.55+im_{IM}$, where m_{IM}=0, 0.01, 0.1, 1, 10.

$1.2 \leq x \leq 2.3$, and oscillates with the periods of $1 \leq x \leq 2$ and the amplitudes of $0.3 \leq P_{\text{peak-to-peak}} \leq 1.5$ for the range of $x \geq 2.3$. Therefore, as a function of the angle ($\phi - 90°$), the scattered light intensity in the direction of $\theta = 90°$

can be theoretically estimated as shown in Fig. 6.

Furthermore, the scattering cross section Q_s and

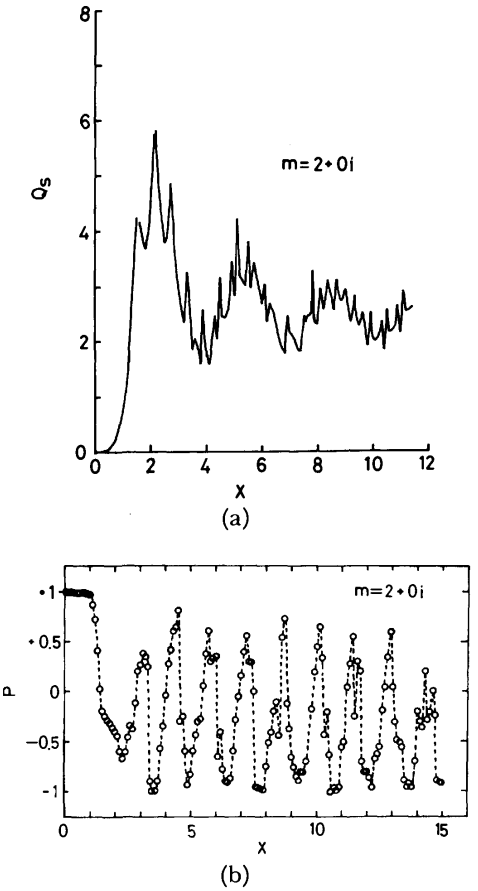

Fig. 8. (a) Scattered light intensity Q_s as a function of size parameter x, (b) Polarization P as a function of size parameter x, for $m=2.0+0i$.

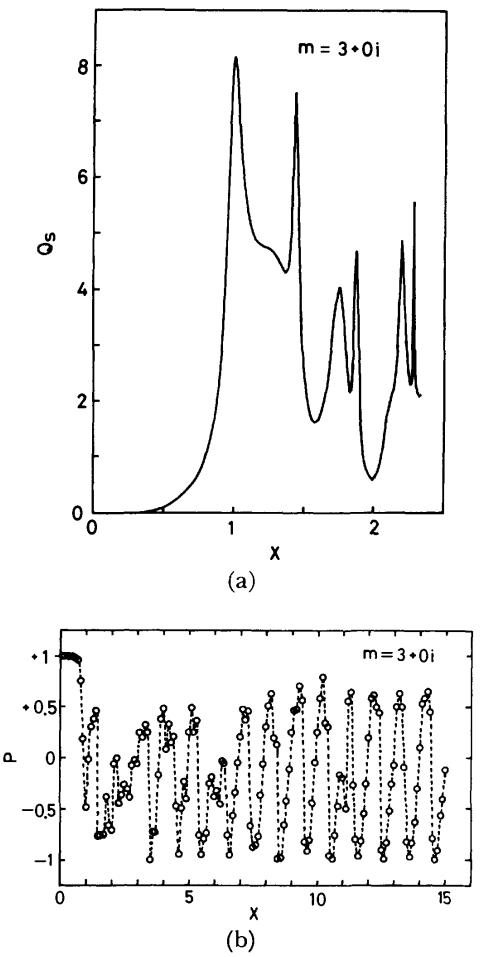

Fig. 9. (a) Scattered light intensity Q_s as a function of size parameter x, (b) Polarization P as a function of size parameter x, for $m=3.0+0i$.

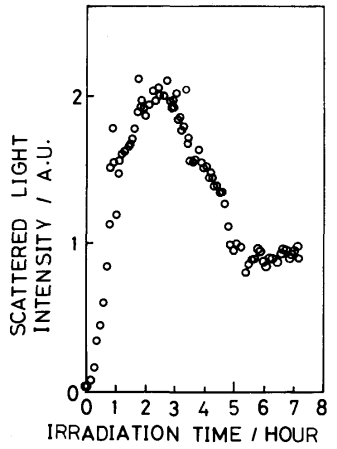
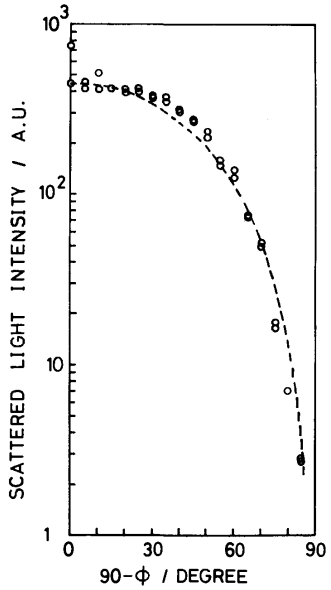
the polarization P were also calculated for various indices, *i.e.* $m=1.3+im_{IM}$ ($m_{IM}=0$, 0.01, 1, and 10), $m=2+0i$, and $3+0i$, as shown in Figs. 7(a) and (b), 8(a) and (b), and 9(a) and (b), respectively. The essential shapes of the scattering extinction coefficients Q_s are similar for 1.3—2.0 of the real refractive index m_R, but Q_s becomes oscillatory with the increase in the real refractivity. The period becomes shorter. On the other hand, Q_s for $m_R=3$ has the different shape from those of $m_R=1.3$, 1.5, and 2. We can recognize the consistent characteristics of the polarizations for $m_R=1.3$, 1.5, 2, and 3. Namely, the steep decreasing of the polarization appears at smaller values of the size-parameter with the increase of the real refractive index. Furthermore, the polarization becomes oscillatory with the increase in the real refractive index.

The measurement of polarization has been used for experimental study on the size-growth in photoexcitation-induced aerosol formation.[4] However, the present study strongly suggests the caution for using this technique. Namely, since the polarization oscillates and becomes the same value for various size parameters, we cannot in general determine the size parameter from the polarization. In this view, the measurement of the angular distribution, *i.e.* θ-dependence, can be accounted much better for the study on the size-distribution of aerosol, as inferred from Figs. 4(a)—(f). Nevertheless, the polarization will be very useful for the judgement whether the scattering by the aerosol can be approximately expressed by the Rayleigh scattering[5] or not, *i.e.* the polarization is equal to 1 or not. As the application of it, this paper describes the experiments of the scattered-light polarization in laser-induced aerosol formation from gaseous CS_2.

In laser-induced aerosol formation, the light intensity scattered by the aerosol formed varies with time. The time evolution of the scattered light intensity in Fig. 10(a) is typical.[6] The scattered light intensity for the incident light polarized by the angle of $(90°-\phi)$ varies as a function of the angle $(90°-\phi)$, as shown by the open circles in Fig. 10(b). This ϕ-dependence was invariant for this time range. The dashed line in Fig. 10(b) is the curve of $\cos^2(90°-\phi)$, whose intensity is normalized to be 450 at $\phi=90°$. The experimental results agree well with the $\cos^2(90°-\phi)$ curve. By the comparison with the theoretical result shown in Fig. 6, the scattered light by the aerosol formed under the present experimental condition can be approximately expressed by the Rayleigh scattering theory. On the



(a)



(b)

Fig. 10. (a) Scattered light intensity as a function of N_2-laser irradiation time. The CS_2 pressure is 50 Torr. The intensity of the N_2-laser beam was reduced by nuetral density filters. (b) Scattered light intensity as a function of $(90°-\phi)$. The dashed line is the curve of $\cos^2(90°-\phi)$.

other hand, the scattered light shows different behavior for the experiment with much more intense excitation N_2-laser beam, as shown in Fig. 11. In this case, the time-evolution of the scattered light intensity is quite different from that shown in Fig. 10(a). The polarization is less than 1 and varies with time. Therefore, in Fig. 11, the radius of the aerosol particle is large and the scattered light behavior cannot be expressed by the Rayleigh scattering theory.

The scattered light intensity has been extensively used as a kind of concentration variable. Since the scattered light intensity can be expressed by $\pi I_0 \int_{-\infty}^{+\infty} r^2 Q_s N(r) dr$, it depends upon the radius and concentration of aerosol. If the aerosol is small enough, the scattering intensity behavior is in the Rayleigh scattering range, *i.e.* it can be expressed as:

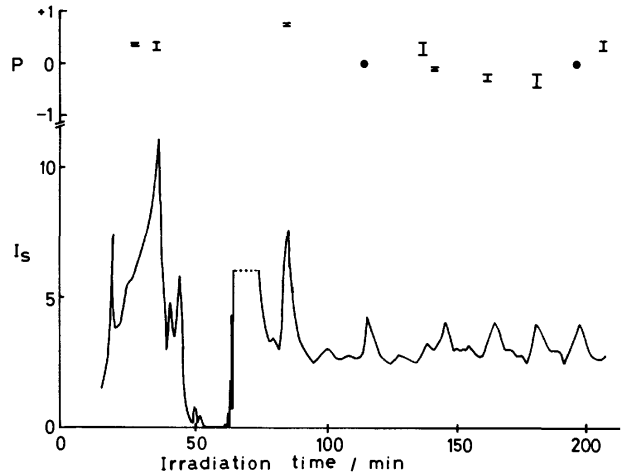


Fig. 11. The polarization P and scattered light intensity I_s as a function of N_2-laser irradiation time.

$$I = \frac{\omega^4}{c^4 R^2} \alpha^2 (1+\cos^2\theta) N(r) I_0, \tag{9}$$

$$I = \frac{\omega^4 r^6}{c^4 R^2} \left(\frac{m^2-1}{m^2+2}\right)^2 (1+\cos^2\theta) N(r) I_0, \tag{9'}$$

where R is the distance from the aerosol, ω the frequency of the scattered light, and c the light velocity. The polarizability α can be expressed by

$$\alpha = \frac{3}{4\pi N_s}\left(\frac{m^2-1}{m^2+2}\right), \tag{10}$$

where N_s is the total number of molecules per volume, and m is the nondimensional refractive index of molecules. Equation 9′ suggests that the scattered light intensity is proportional to the number of aerosol, $N(r)$, and the sixth power of the aerosol radius. Therefore, for the Rayleigh scattering range, the scattered light intensity can be expressed by $I=c_1 r^6 N(r)=c_2 v^2 N(r)$, where c_1 and c_2 are constants, $N(r)$ the number density, v the volume of aerosol, as a kind of extensive variable. Since the total number of molecules in the aerosol, N_m, can be considered proportional to the volume v, the scattered light intensity can also be expressed by $I=c_3 N_m^2 N(r)$, where c_3 is a constant. Thus the *trajectory tracing approach*[6] is applicable by using the scattered light intensity for the Rayleigh scattering range. On the other hand, more complicated process will be required for the case shown in Fig. 11. Nevertheless, since the maximum entropy method used in the *trajectory tracing approach*[6] is a kind of nonlinear spectrum analysis, it can make the analysis of the oscillatory behavior of the scattered light intensity for the size-parameter range, where Q_s increases with the size-parameter, even if it is out of the Rayleigh scattering range.

(Received April 15, 1985)

The ^{127}I NQR spectra of 1,4-dithiane-2I_2, thiane-I_2, 1,4-thioxane-I_2, and 1,3,5-trithiane-I_2 are reported. Two distinct iodine atoms are observed in the former three complexes, whereas only one iodine atom is present in the last-named complex. The charge densities on the donors and the iodine atoms are obtained according to the Townes-Dailey approximation. The order of donor strength toward the iodine molecule is: thiane>1,4-thioxane>1,4-dithiane≫1,3,5-trithiane. The thioethers can compete with amines in terms of the donor strength to iodine molecules. The no-bond ionic structure of the ground state is less important in the thioether–iodine complexes than in amine–iodine complexes. The positive temperature coefficients found previously in a few similar complexes of amines are observed for the terminal iodine atoms of 1,4-dithiane-2I_2, thiane-I_2, and 1,4-thioxane-I_2. This phenomenon is ascribed to the increasing shift of the dative structure to the no-bond covalent structure with the rise in the temperature.

Many n-σ-type charge-transfer (CT) complexes, such as amine–halogen and amine–interhalogen, have been successfully investigated by means of the halogen[1-4] and the nitrogen[4,5] nuclear quadrupole resonance (NQR). This method makes it possible to estimate the charge distribution on the atom related directly to the CT interaction from the quadrupole coupling constant ($e^2q_{zz}Q/h$). It has been indicated that, for strong n-σ complexes, 0.2—0.3 electrons transfer from the amine to the halogen molecule; further, the bridging halogen atom bonded to a nitrogen atom is charged positively, while the terminal halogen atom, on which the transferred charges mostly exist, is charged negatively.

Sulfur-containing organic molecules (thioethers) also can act as electron donors to iodine molecules. X-Ray-crystal-structure investigations were carried out for 1,4-dithiane-2I_2[6] and dibenzyl sulfide-I_2.[7] In each structure, a strong n-σ CT bond is found between the donor S atom and the iodine molecule; *i.e.*, one atom of each iodine molecule is bonded to the sulfur atom, while the remaining one is free from the intermolecular bonding, and the S···I_A–I_B arrangement is almost linear. The S···I bond is shorter than the sum of the respective van der Waals radii, while the I_A–I_B bond is longer than the I–I bond in solid I_2.

It is of interest to compare the CT interaction in intermolecular S···I bonds with that in N···I bonds on the basis of the charge distribution. We tried to observe the ^{127}I NQR for several thioether–iodine complexes: 1,4-dithiane–iodine (1:2) (DT-2I_2), thiane–iodine (1:1) (TH-I_2), and 1,4-thioxane–iodine (1:1) (TO-I_2), and 1,3,5-trithiane–iodine (1:1) (TT-I_2).

The most interesting feature of the halogen NQR in the amine–halogen complexes is the positive temperature coefficient found for terminal halogen atoms;[1,2,4] it has been suggested that this is due to a vibronic coupling effect.[2] The temperature dependence of the ^{127}I (1/2—3/2) transition frequency is precisely measured to investigate whether or not the same phenomenon is observed in the present compounds.

Experimental

Preparation of the Samples. All the chemicals were obtained commercially and were used without further purification. The TH-I_2 complex was prepared by mixing approximately stoichiometric amounts of the components in chloroform. The dark brown crystalline product was precipitated by then concentrating and cooling the solution. The product was filtered, washed, and dried in air. The product decomposed slowly in air. The iodine content was analyzed by means of iodimetry. (Found: I, 70.5%. Calcd for $C_5H_{10}S$-I_2: I, 71.5%). The orange-red TO-I_2 was prepared in hexane in the same manner. The stoichiometry was determined by means of elemental analysis. (Found: C, 13.2; H, 2.4; I, 67.5%. Calcd for C_4H_8OS-I_2: C, 13.4; H, 2.3; I, 70.9%). The purple crystalline complex of DT-2I_2 was obtained by adding a saturated iodine solution of carbon tetrachloride to a dithiane solution of the same solvent. (Found: C, 7.7; H, 1.4; I, 80.8%. Calcd for $C_4H_8S_2$-2I_2: C, 7.7; H, 1.3; I, 80.8%). The red crystalline complex of TT-I_2 was prepared in chloroform by a procedure similar to that used for the TH-I_2 complex. The complex easily decomposed to its components within 10—15 min in air at room temperature. (Found: I, 64.0%. Calcd for $C_3H_6S_3$-I_2: I, 64.7%).

NQR Measurement. The NQR spectra were observed on an oscilloscope using an externally quenched superregenerative Lecher-line oscillator similar to that described by Schawlow,[8] but incorporating minor changes. Temperature variation was attained by immersing the sample tube in a copper container, placed in a Dewar vessel filled with petroleum ether, and by then cooling the petroleum ether with dry ice or liq. N_2. The accuracy of the measurements was estimated to be within ±0.01 MHz in frequency and ±1 K in temperature.

Results and Discussion

Table 1 lists the resonance frequencies observed at 77 and 298 K, with the signal-to-noise ratios shown in parentheses. These are assigned to the ^{127}I (1/2—3/2)

TABLE 1. ^{127}I NQR FREQUENCIES IN IODINE-SULFUR-CONTAINING ORGANIC MOLECULE COMPLEXES[a)]

Compound	Frequency/MHz		$(d\nu/dT)_{T=273\,K}$	Assignment
	77K	298K	KHz/K	
1,4-Dithiane-2I_2	377.81(6)	374.83(3)	−16.5	I_A(1/2—3/2)
	233.37(2.5)	238.02(2)	+25.4	I_B(1/2—3/2)
Thiane-I_2	377.82(10)	373.69(1.5)	−23.4	I_A(1/2—3/2)
	197.22(10)[b)]	200.99(2)[b)]	+24.2	I_B(1/2—3/2)
	394.43(4)[b)]	401.98(1.5)[b)]	—	I_B(3/2—5/2)
1,4-Thioxane-I_2	374.78(2.5)	370.46(1.5)	−23.4	I_A(1/2—3/2)
	220.58(5)	226.01(1.5)	+30.0	I_B(1/2—3/2)
1,3,5-Trithiane-I_2	322.14(10)	320.39(1.5)	−9.8	I(1/2—3/2)

a) The numbers in parentheses are the signal-to-noise ratios as measured on an oscilloscope. b) $e^2q_{zz}Q/h$ and η are 1314.8 MHz and 0.004 at 77 K, and 1339.9 MHz and 0.000 at 298 K.

transitions except for the resonance line with the highest frequency in TH-I_2, corresponding to the ^{127}I (3/2—5/2) transition. The existence of two resonance lines in DT-2I_2, separated in frequency by about 140 MHz, is consistent with its crystal structure, which has the S···I_A-I_B arrangement.[6)] Since it is well established that the terminal iodine atom I_B is negatively charged compared to the bridging iodine atom I_A, the lower frequency line can be assigned to the I_B atom, and the higher line, to the I_A atom. The similarity of the NQR spectrum in TH-I_2 or TO-I_2 to that in DT-2I_2 suggests that the S···I_A-I_B arrangement also exists in both complexes. The O atom as well as the S atom in the TO molecule can act as the donor atom, though no solid complexes with the O···I_A-I_B arrangement have yet been observed. However, the proximity of the ^{127}I NQR frequencies of TO-I_2 to those of DT-I_2 and TH-I_2 may show that not the O atom, but the S atom, acts as the donor atom toward the iodine molecule in TO-I_2.

On the other hand, only a single line is observed in TT-I_2; this suggests that all I atoms are equivalent in their crystals. This fact and the molar ratio of its component molecules (1:1) predict the existence of endless chains consisting of alternating TT and iodine molecules in the solid state of TT-I_2. Probably, the CT interaction is of a weak n-σ type. The resonance frequency in TT-I_2 is close to the 332 MHz[3)] of the ^{127}I (1/2—3/2) transition observed for the phenazine-I_2 complex, which contains a N···I-I···N bridge in its structure.[9)]

It has previously been pointed out that a three-center four-electron bonding scheme[1,10–13)] gives a good approximation for describing the bonding in trihalide anions, amine-halogen complexes, and bis(amine)-halogen cations. Therefore, we consider only the pure p_σ bond orbitals for the bonding of I atoms in the present compounds. Then we can estimate the charge density on the iodine atoms and, hence the transferred charges from the donor to the acceptor, according to the Townes-Dailey approximation:[14)]

$$\rho = 1 - (e^2q_{zz}Q/h)/(e^2q_{at}Q/h), \quad (1)$$

TABLE 2. CHARGE DISTRIBUTIONS IN SEVERAL CT COMPLEXES OF IODINE WITH SULFUR-CONTAINING ORGANIC MOLECULES

Complex	Charge on I_A	Charge on I_B	Charge on S
1,4-Dithiane-2I_2	+0.10	−0.32	+0.22
Thiane-I_2	+0.10	−0.43	+0.33
1,4-Thioxane-I_2	+0.09	−0.36	+0.27
1,3,5-Trithiane-I_2	−0.06		+0.06

where $e^2q_{zz}Q/h$ is the observed quadrupole coupling constant, where $e^2q_{at}Q/h$ is the atomic quadrupole coupling constant, which equals the value of 2292.7 MHz for ^{127}I, and where ρ stands for the charge density localized on the iodine atom.

When the frequencies attributable to both the ^{127}I (1/2—3/2) and ^{127}I (3/2—5/2) transitions are obtained, the exact values of the $e^2q_{zz}Q/h$ and the asymmetry parameter (η) are derived from the eigen-value table for a nuclear spin, I=5/2. The $e^2q_{zz}Q/h$ and η values are given in the margin of Table 1 for the I_B atom of TH-I_2. In the other cases, where only the ^{127}I(1/2—3/2) transition is observed, we obtain the $e^2q_{zz}Q/h$ value by putting η=0 into the following relation, which holds for $\eta \leq 0.1$:

$$\nu(1/2-3/2) = \frac{3}{20}(e^2q_{zz}Q/h)\left(1+\frac{5}{54}\eta^2\right) \quad (2)$$

It is safe to neglect η in Eq. 2 for the purposes of the present calculation because of the expected small η value and the much smaller contribution to the resonance frequency of the second term than the first. Obviously, the η value is very small for the I_B atom of TH-I_2, and also for the iodine atoms of the amine-iodine complexes,[3,15–17)] corresponding to the present type of complexes.

The charge densities on the iodine and sulfur atoms, as calculated from the values of $e^2q_{zz}Q/h$ at 77 K, are listed in Table 2. In accordance with the prediction from the delocalized three-center bonding, the terminal iodine I_B has negative charges, and the bridging iodine I_A, small positive charges. The small negative charge on the iodine atom of TT-I_2 indicates a weak CT interaction. We may estimate the order of donor

strengths toward the iodine molecule from the amounts of the positive charges localized on the donors:

$$TH > TO > DT \gg TT.$$

The bonding of the complexes is alternatively described in terms of Mulliken's valence-bond expression[18] of a charge-transfer model. As is well known, the ground-state wave function is written as:

$$\Psi_N = a\Psi(D,X_2) + b\Psi(D^+-X_2^-). \quad (3)$$

This equation is satisfactory for a weak CT complex. Bowmaker and Hacobian[1] expanded Eq. 3 in the following form for the strong n-σ complex by considering that the two X atoms in D-X_2 are in inequivalent positions:

$$\Psi_N = a\Psi(D,X_2) + b\alpha\Psi(D^+-XX^-) + b\beta\Psi(D^+X^-X) + c\Psi(DX^+X^-) \quad (4)$$

where the first and fourth terms refer to the no-bond structures, and the second and third, to the dative structures. The fourth structure, regarded as a resonance hybrid with the second structure, is introduced into Eq. 4 because the D^+-X bond must have a partial ionic character if D^+ has a greater affinity than the X atom. This term is more important than the third because the bridging halogen atoms of the complexes have positive charges.

For further discussion, we plot the charges on the I atoms against those on the S donors in Fig. 1. The results of several amine-iodine complexes are also shown in this figure. Unfortunately, the ^{127}I NQR results for the strong n-σ type of amine-iodine complexes have been obtained imperfectly; the frequencies of only the bridging iodine atom are observed, mainly because of the weakness of the resonance intensities of the terminal halogen atoms. However, a few data on the amine-iodine complexes obtained from the ^{129}I Mössbauer-effect measurements[15-17] are available for this purpose.

Though the quantity of data is restricted, it is found from the charges on the donors that the S donor is almost as strong as the N donor in its donor strength toward the iodine molecule. When the donor strength increases in each set of the S···I_A-I_B and N···I_A-I_B complexes, the negative charge on the I_B atoms increases linearly, whereas the charge on the I_A atoms is maintained at an almost constant value. It is, therefore, obvious that transferred charges from the donor are mostly localized on the terminal iodine atom. This shows that the weight of the fourth term in Eq. 4 is maintained to about a constant value from complex to complex in each set of complexes, while the third term is practically negligible. Thus, we can calculate the weight of each structure in Eq. 4 from the charge densities, neglecting the third structure. The weights

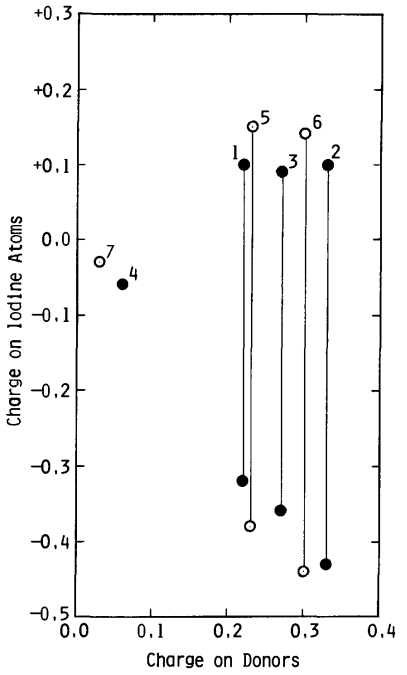

Fig. 1. Plot of the charges on I atoms *vs.* the charges on donors. ●: S donor; ○: N donor. 1) 1,4-Dithiane-$2I_2$, 2) Thiane-I_2, 3) 1,4-Thioxane-I_2, 4) 1,3,5-Trithiane-I_2, 5) Pyridine-I_2,[15,17] 6) Triethylamine-I_2,[17] 7) Phenazine-I_2.[3,16]

of the first (no-bond covalent), the second (dative), and the fourth (no-bond ionic) structures are 68, 22, and 10% for DT-$2I_2$, 57, 33, and 10% for TH-I_2, and 64, 27, and 9% for TO-I_2, respectively. Both positive charges on I_A and negative ones on I_B are larger in their absolute values for the N-atom donors than for the S-atom donors when the donor strengths are about the same. Those results indicate that the contribution of the fourth term in Eq. 4 is smaller for the S-atom donor-iodine complexes than for the N-atom donor-iodine complexes. The ionic structure of the ground state is less important in the former than in the latter. This is reasonable, because the N^+ has a larger electron affinity than the S^+.

The temperature dependence of the resonance frequency due to the ^{127}I (1/2—3/2) transition was observed in the range of from the temperature of liquid N_2 to room temperature. The results for the present complexes are shown in Figs. 2 and 3, while the temperature coefficients at 273 K of the frequency curves are listed in the fourth column of Table 1. It is found that all terminal iodine atoms of DT-$2I_2$, TH-I_2, and TO-I_2 have positive temperature coefficients; this is in accordance with the results previously reported for the terminal halogens of pyridine-ICl,[2] 4-methylpyridine-ICl,[2] and 3,5-dibromopyridine-Br_2.[1]

This tendency can be qualitatively realized from Eq. 4. As the temperature is raised, the increasing excitation of molecular vibrations will weaken the weaker intermolecular CT-bond rather than the intramolecular I-I bond; the contribution of the dative

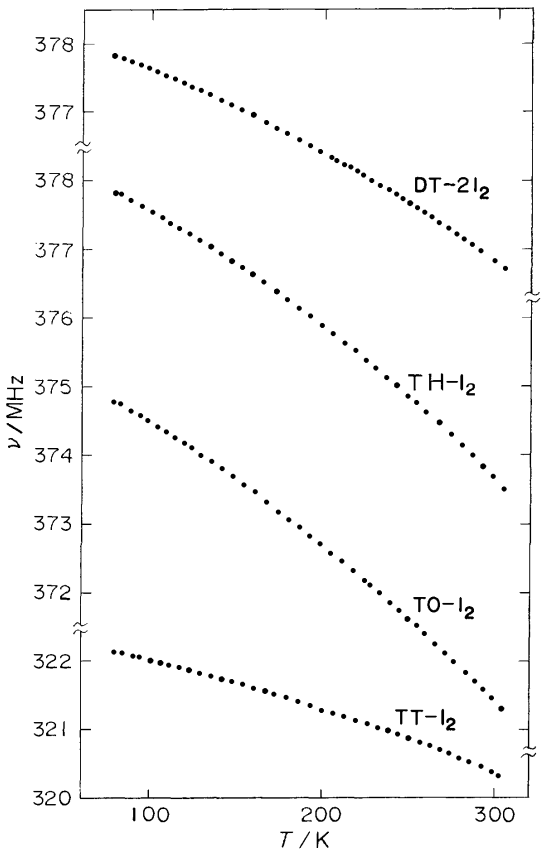

Fig. 2. Temperature dependence of the ^{127}I(1/2—3/2) NQR frequencies of the bridging iodine atoms. DT: 1,4-dithiane, TH: Thiane, TO: 1,4-thioxane, TT: 1,3,5-trithiane.

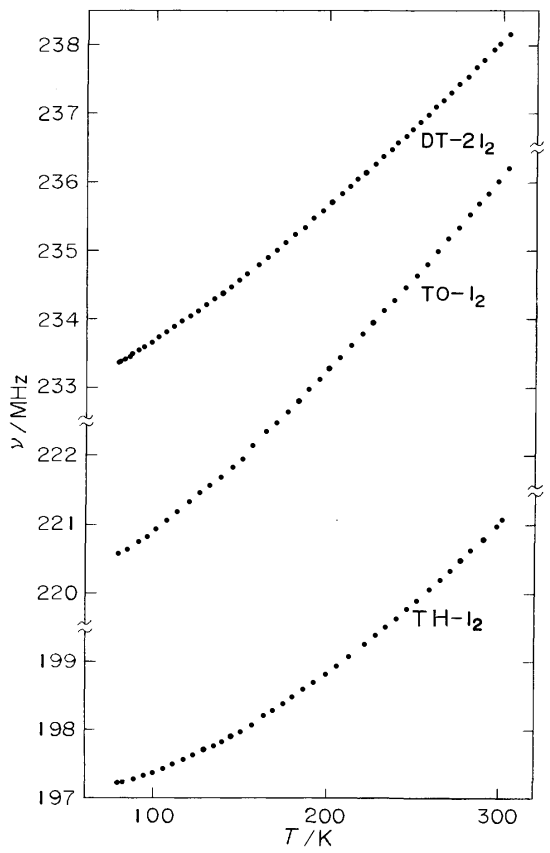

Fig. 3. Temperature dependence of the ^{127}I(1/2—3/2) NQR frequencies of the terminal iodine atoms. DT: 1,4-dithiane, TH: Thiane, TO: 1,4-thioxane.

structure will, consequently, decrease with the increase in the temperature. As has been seen previously, the dative structure is approximated by the second structure in Eq. 4, while neglecting the third structure. The contribution of the no-bond covalent structure is larger than that of the no-bond ionic one. Further, the contribution of the no-bond ionic structure is kept at about a constant value even if the donor strength is changed. Accordingly, it is mainly the no-bond covalent structure that increases its contribution with an increase in the temperature. The conversion of the second structure to the first one reduces the negative charge (and hence the p_z-electron populations) of the I_B atom, holding the charge density of the I_A atom constant. Since the decrease of p_z-electron populations of the iodine atom results in the increase of the value of its electric-field gradient (eq_{zz}), the resonance frequency increases from Eq. 2. The frequency of the I_B atom thus increases with the temperature, as in the present case, if the frequency increase due to the decrease of the dative structure described above overcomes the normal decrease in frequency[19] which is caused by the averaging of eq_{zz} following the increasing molecular vibrations.

The authors wish to express their thanks to Dr. Tsutomu Okuda of Hiroshima University for his helpful suggestions.

Voltammetric Studies of the Metal-Ligand Interaction in Low-valent Metal-Olefin π-Complexes. II. Palladium(0) and Platinum(0) Complexes with Olefin-Diimine Mixed Ligands

Naoyuki Ito, Tetsuo Saji,* and Shigeru Aoyagui
Department of Chemical Engineering, Tokyo Institute of Technology, Ohokayama, Meguro-ku, Tokyo 152
(Received February 4, 1985)

Cyclic voltammograms for the reduction of Pd^0 and Pt^0 complexes with mixed ligands of diimine and olefin exhibit, respectively, two or four reversible one-electron steps. The half-wave potentials of each step give a straight line with a slope of 1.0, when plotted against the half-wave potentials of diimine ligands, and a slope smaller than 0.2, when plotted aganist the half-wave potentials of olefinic ligands. The half-wave potentials of the complexes are affected only a little by the difference in the central metal. These findings lead to the conclusion that each LUMO of these complexes is dominated by the diimine π*-orbital, though it is higher-lying than the olefinic π*-orbital in free ligands.

The changes in the molecular structure and electronic state that olefinic compounds may suffer when they are coordinated to transition metals may be worthy of note in connection with their reactions catalyzed by these metals. Usually, the former change can be detected by X-ray diffraction and the latter by absorption spectroscopy. Besides these, the specific contribution of voltammetry to the latter purpose is promising because it provides information on the ionization potential and the electron affinity, *viz.* the HOMO and LUMO energies, in contrast to absorption spectroscopy which provides information on the intramolecular relative energy levels. Knowledge of the HOMO and LUMO energies will make it possible to determine the behaviour of the frontier electron which has a dominant effect on the chemical reactivity.

Voltammetric and IR studies of $[M(0)_2(dibenzylideneacetone)_3]$(M=Pd and Pt; dibenzylideneacetone= 1,5-diphenyl-1,4-pentadien-3-one) in Part I of this seires have led to the conclusion that each LUMO of these complexes is twofold degenerate and delocalized over a π-framework composed of a metal and three phenyl-substituted olefinic moieties.[1] This paper deals with the voltammetry of mixed ligand complexes, [M(0)LoLc] (M=Pd and Pt; Lo=olefinic ligand; Lc=diimine ligand), with a hope that we can discuss the change of LUMO of Lo caused by coordination.

Experimental

Ethenetetracarbonitrile (tcne), (*E*)-2-butenedinitrile (fn), dimethyl fumarate (dmf), dimethyl maleate (dmm), diethyl fumarate (def), 1,10-phenanthroline (phen) and 2,2′-bipyridine (bpy) were supplied by Tokyo Chemical Industries, maleic anhydride (ma) by Wako Pure Chemical Industries and 4,7-diphenyl-1,10-phenanthroline (dφphen) by Kanto Chemical Industries. 4,4′-Dimethyl-2,2′-bipyridine (4-dmbpy), 5,5′-dimethyl-2,2′-bipyridine (5-dmbpy), and 4,4′,5,5′-tetramethyl-2,2′-bipyridine (tmbpy) were gifts of Dr. Y. Ohsawa who prepared them by the literature method.[2]

[Pd(0)Lo(bpy)] (Lo=ma, dmf, and dmm) were prepared by methods found in the literature,[3] and other palladium complexes by similar methods. Platinum complexes were prepared by the same methods as the corresponding palladium complexes, except that the reaction mixtures were slightly heated until their colors turned yellow. The complexes were characterized by elemental analyses on C, H, and N.

The half-wave potential was identified with the midpoint of the cathodic peak potential (E_{pc}) and the anodic one (E_{pa}) of a cyclic voltammogram. The reversibilities of redox steps were judged on the basis of the separation (ΔE_p) beween the E_{pc} and the E_{pa} and the ratio of the anodic peak current to the cathodic one. The base solution was 0.2 M (1M=1 mol dm^{-3}) tetrabutylammonium perchlorate (TBAP) in ethylene glycol dimethyl ether (DMeE). Neutral alumina (ICN W200) was added to the test solutions except for tcne, ma, and dφphen, which are strongly adsorbed on alumina. Voltammetric measurements were carried out at −30±2 °C with a scan rate of 0.1 V s^{-1}, unless otherwise noted. Other experimental procedures have been previously described.[4] IR spectra were recorded with KBr plates on a Hitachi 295 IR spectrometer operated at 25 °C.

Results and Discussion

The ν(C-N) frequencies for [Pd(0)LoLc] with Lo= tcne and fn, and Lc=bpy and dφphen, and [Pt(0)Lo-(dφphen)] with Lo=tcne and fn fall within 2100—2240 cm^{-1}, as those of other complexes of similar structure generally do.[5,6] They are lower than the ν(C-N)

frequencies of free olefin ligands, *i.e.* 2262 cm^{-1} for tcne and 2246 cm^{-1} for fn. The same lowering has been reported concerning the ν(C=O) frequencies of [Pd(0)LoLc] with Lo=dmm and dmf, and Lc=bpy and phen.[3] These findings may be evidence for the metal-to-olefin charge transfer and/or the back-donating bond operating in these complexes.

Cyclic voltammograms for the reduction of free ligands (L) exhibited, respectively, one or two one-electron steps judged on the basis of ΔE_p. Some of these steps were reversible and others irreversible, in the sense that they had no current peaks in reversal scans. Table 1 lists the reversible half-wave potentials of $L^{0/-}$ ($E^{0/-}_{1/2,L}$) and $L^{-/2-}$ ($E^{-/2-}_{1/2,L}$). For irreversible steps, E_{pc} values are shown instead of $E_{1/2,L}$ values. All of the ligands studied gave no oxidation steps within the available potential range.

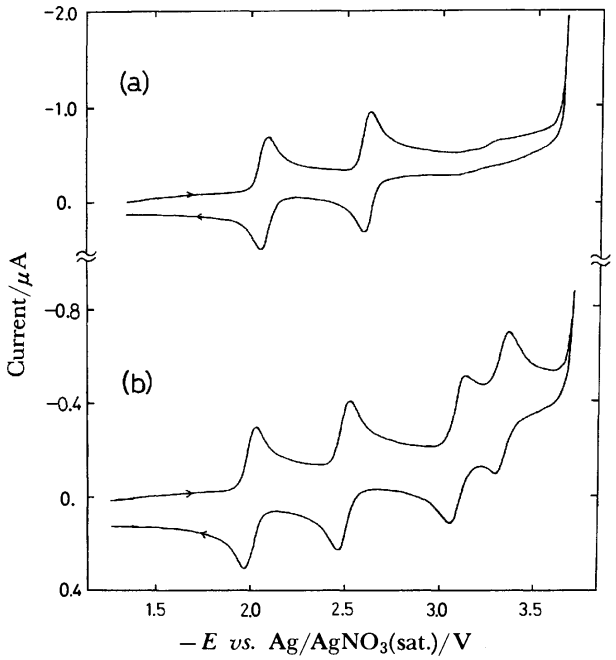

Fig. 1. Cyclic voltammograms for 0.3 mM of (a) [Pd(fn)(bpy)] and (b) [Pd(fn)(dφphen)] in 0.2 M TBAP-DMeE at −30 °C, scan rate 0.1 V s^{-1}.

Cyclic voltammograms for the reduction of complexes (C) gave four one-electron steps for complexes with dφphen as Lc. Otherwise, two are given as shown in Fig. 1. The reversible steps may be tentatively assigned to $C^{0/-}$, $C^{-/2-}$, $C^{2-/3-}$, and $C^{3-/4-}$. No oxidation steps were observed. Table 2 summarizes the voltammetric results on complexes.

The characteristic features of Tables 1 and 2 are follows:

(1) Each $E^{0/-}_{1/2,C}$ is by 0.4—0.9 V more positive than the corresponding $E^{0/-}_{1/2,L}$ of Lc ($E^{0/-}_{1/2,Lc}$), and by 0.1—1.5 V more negative than the $E_{1/2,L}$ of Lo ($E^{0/-}_{1/2,Lo}$).

(2) The $E^{0/-}_{1/2,C}$ and $E^{-/2-}_{1/2,C}$ for the Pt complexes are by 0.1 V more positive than the corresponding Pd complexes.

(3) The $E^{2-/3-}_{1/2,C}$ and $E^{3-/4-}_{1/2,C}$ of dφphen complexes are independent of type of metal.

(4) The $E^{0/-}_{1/2,C}-E^{-/2-}_{1/2,C}$ values are nearly identical with the $E^{0/-}_{1/2,Lc}-E^{-/2-}_{1/2,Lc}$ values, which suggests that the coordinated Lc in a C^{2-} should be of the form Lc^{2-}.[7]

Figure 2 shows $E^{red}_{1/2,C}$ *vs.* $E^{0/-}_{1/2,L}$ plots for [M(0)-(dmf)Lc] (M=Pd and Pt) with Lc=tmbpy, 5-dmbpy, 4-dmbpy, and bpy. The straight lines were drawn in accordance with the following equation:[8]

$$E_{1/2,C} = E_{1/2,L} + \text{const.}, \quad (1)$$

Experimental points with horizontal and vertical arrows are plotted with cathodic peak potentials for olefinic ligands and complexes, respectively. The arrows show the direction in which reversible half-wave potentials are located.

which was derived by assuming that the redox orbital is a ligand π*-orbital. Figure 3 shows $E^{red}_{1/2,C}$ *vs.* $E^{0/-}_{1/2,Lo}$ plots for [M(0)Lo(dφphen)] and [Pd(0)Lo(bpy)] with Lo=tcne, dmf, and def. The experimental points of Fig. 2 obey Eq. 1. The straight lines of Fig. 3, however, are only tentative, because experimental points for appropriate $E^{0/-}_{1/2,Lo}$ values are lacking. However, it is evident that $E^{red}_{1/2,C}$ *vs.* $E^{0/-}_{1/2,Lo}$ has a positive slope of 0.1—0.2, when the experimental points for the irreversible $Lo^{0/-}$ steps of ma, fn, and dmm are taken into consideration. These findings, together with features (2) and (4) of Tables 1 and 2, lead to the conclusion that the two electrons added to [M(0)LoLc] occupy the LUMO of this complex, which is dominated by a diimine ligand π*-orbital. Unfortunately, the lack of data on reversible $E^{red}_{1/2,Lo}$ makes it difficult to assign the third and fourth steps of [M(0)Lo(dφphen)] which molecular orbital an electron occupies a molecular orbital mainly of an olefinic orbital character or a diimine orbital one. However, taking into account $E^{0/-}_{1/2,Lo}$ values of ma, fn and dmm, the coordination of tri and tetra-anions of dφphen can be concluded for the following reasons: First, the third and fourth steps cannot be ascribed to the reduction of coordinated Lo's because [M(0)(dmf)(bpy)] and [M(0)(dmf)(phen)] exhibit no such steps. Secondly, $E^{2-/3-}_{1/2,C}$ and $E^{3-/4-}_{1/2,C}$ do not depend on $E^{0/-}_{1/2,Lo}$ or the type of metal at all. This suggests that the redox orbital in these steps should be localized on the coordinated dφphen molecules.

Strikingly, the excess electrons of [M(0)LoLc] occupy the Lc π*-orbitals inspite of the fact that they are higher-lying than the Lo π*-orbitals in a free ligand, *e.g.* the $E^{0/-}_{1/2,Lo}$ of tcne is by 2.4 V more positive than the $E^{0/-}_{1/2,Lc}$ of bpy. One of the probable reasons may be the stabilization of the diimine π*-orbitals caused by coordination, and the instabilization of the olefin π*-orbitals. Although the same stabilization is seen in [M(0)(bpy)$_3$] (M=Cr and Mo),[8] the stabilization energy is considerably greater in [M(0)LoLc] than in [M(0)(bpy)$_3$]. This may be due to the coexistance of Lo operating as an electron acceptor. This is suggested by the finding that the IR spectra of the Lo is shifted to lower frequencies upon coordination. The instabilization of the olefin π*-orbital, on the other hand, can be ascribed to the structural change of the olefin ligand caused by coordination. Such a change is suggested by the experimental finding that the olefin C-C bond distance is longer in the complex than in the free ligand, probably due to a decrease in π-conjugation caused by the metal-to-ligand back donation.[9] A similar π-conjugation decrease in [M(0)$_2$(dibenzylideneacetone)$_3$] (M=Pd and Pt) was discussed in Part I.[1] Also, X-ray and neutron diffraction studies of [Pt(0)(tcne)(PPh$_3$)$_2$] show that the configuration around the ethylene carbons is essentially tetrahedral. Consequently, the ligand-metal bond is equivalent to that of the two metal-alkyl σ-bonds.[10]

The Viscosities and Molal Volumes of *t*-Butyl Alcohol in Metal Chelate Electrolyte Solutions

Kouzou Yoshitani
Faculty of General Education, Gifu University, Yanagido, Gifu 501-11
(Received February 23, 1985)

The Viscosities and molal volumes of *t*-butyl alcohol (*t*-BuOH) in aqueous solutions of $[Fe(phen)_3]Cl_2$, $[Co(phen)_3]Cl_3$ (phen=1,10-phenanthroline), $[Co(en)_3]Cl_3$ (en=ethylenediamine), tetraphenylphosphonium chloride ($(C_6H_5)_4PCl$), tetramethylammonium chloride (Me_4NCl), tetraethylammonium chloride (Et_4NCl), and tetra-*n*-butylammonium bromide ($(n\text{-}Bu)_4NBr$) were measured at 25 °C, and solute–solvent interactions characteristic of the metal chelate cations were investigated. The apparent molal volumes of *t*-BuOH in the solutions of $[Fe(phen)_3]^{2+}$ are larger than those in the $(n\text{-}Bu)_4N^+$ and $[Co(phen)_3]^{3+}$ solutions. The hydrophobicity of $[Fe(phen)_3]^{2+}$ is not so strong because of the aromaticity of the ligand. The same can be said for $[Co(phen)_3]^{3+}$. However, on the interaction between $[Co(phen)_3]^{3+}$ and *t*-BuOH, the charge-dipole interaction and hydrophobic interaction act cooperatively to stabilize this pair through the overlap of the solvation spheres.

The solute–solvent interactions of such metal chelate ions as $[Fe(phen)_3]^{2+}$ have been studied by means of their thermodynamic,[1–4] transport,[5–6] and kinetic[7] properties. From the viscosity study, $[Fe(phen)_3]^{2+}$ and $[Fe(bpy)_3]^{2+}$ (bpy=2,2′-bipyridine) were found to be hydrophobic-structure-making ions, though their hydrophobicity is weaker than that of the tetraalkylammonium ions at the equivalent level of the partial molal volumes.[5] $[Fe(phen)_3]^{2+}$ was found to show a large salting-in effect through hydrophobic interaction on the nonelectrolytes, such as nitrobenzene, toluene, benzene, and $[Co(acac)_3]$ (Hacac=2,4-pentanedione).[2–4] It was also found that the racemization rate of the trivalent metal chelate cation, $[Co(phen)_3]^{3+}$, by the electron-transfer mechanism is strongly affected by the structural change of water on the addition of *t*-BuOH.[7] In the present study, solute–solvent and solute–solute interactions of the metal chelates were examined through the viscosities and the apparent molal volumes of *t*-BuOH in aqueous solutions of these metal chelate electrolytes.

Experimental

The metal chelate electrolytes, $[Fe(phen)_3]Cl_2 \cdot 7H_2O$,[5] $[Co(phen)_3]Cl_3 \cdot 6H_2O$,[8] and $[Co(en)_3]Cl_3 \cdot H_2O$[9] were prepared by the literature methods and recrystallized twice from water. The tetraalkylammonium salts (Tokyo Kasei Kogyo Co., Ltd.) were purified by the methods described in the literature.[10] The tetraphenylphosphonium chloride (Merck) was used without further purification. The purities of the salts were checked by analysis. The *t*-BuOH was reagent grade (Nakarai Chemicals, Ltd.) and was used without further purification. The water was distilled from an alkaline permanganate solution. The concentrations of the electrolytes were determined by potentiometric titrations of the halide ions with $AgNO_3$ standard solutions just prior to use.

Ubbelohde viscometers with flow times for water at 25 °C of about 590 and 690 s were used. The kinetic-energy corrections for the viscometers were found to be negligible within the limits of experimental error. All the viscosity measurements were carried out in a 25.00±0.03 °C constant-temperature water bath controlled to ±0.005 °C. The flow times were measured with a stop watch and were reproducible to ±0.1 s.

The densities were measured with a digital densimeter (Anton Paar, Model DMA-02D). The thermostated bath was kept at 25.00±0.03 °C and controlled to ±0.002 °C. The densimeter was calibrated by the use of dry air and distilled water, and checked by measuring the densities of the aqueous *t*-BuOH solutions.[11] The errors in the density measurements were estimated to be within $\pm 2 \times 10^{-6}$ g cm^{-3}.

Results

The relative viscosities, η_r, of the aqueous solutions of *t*-BuOH in the presence of the electrolytes could be represented by the following equation over the range of *t*-BuOH concentrations from 0.2 to 1.5 mol dm^{-3}:

$$\eta_r = \eta/\eta^\circ = 1 + BC + DC^2, \quad (1)$$

where η_r represents the relative viscosity of the ternary solution (*t*-BuOH–electrolyte–water) with respect to the electrolyte solution used as the solvent, where η and η° are the viscosities of the ternary solution and the solvent respectively, and where C is the molar concentration of *t*-BuOH. The B coefficient is a function of the solute–solvent interaction, and the D coefficient represents the contribution of the solute–solute interaction to the relative viscosity.

Taking pure water as the reference solvent, the relative viscosity can be represented as follows:

$$\eta/\eta_w = \eta^\circ/\eta_w + B'C + D'C^2, \quad (2)$$

where η_w is the viscosity of pure water, and where B' and D' are $B\eta^\circ/\eta_w$ and $D\eta^\circ/\eta_w$ respectively. These equations differ in their reference states. In the present study, Eq. 2 was used, because B' reflects the differences more clearly than B. The B' and D' coefficients obtained by the least-squares method are given in Table 1. The B coefficient of *t*-BuOH in pure water at 25 °C is in good agreement with the literature value.[12]

The apparent molal volumes, ϕ_v, of *t*-BuOH in the electrolyte solutions were calculated from the density data.[11] The partial molal volumes at infinite dilution in aqueous electrolyte solutions, V^∞, were obtained by

fitting the apparent molal volumes to this equation:

$$\phi_v = V^\infty + A_v C + B_v C^2, \quad (3)$$

where C is the molar concentration of t-BuOH and where A_v and B_v are the fitting parameters. The V^∞ and fitting parameters, A_v and B_v, were obtained by the least-squares method and are given in Table 2.

Discussion

In the presence of the electrolyte, the viscosity B' coefficient of t-BuOH increases with an increase in the concentration of the electrolyte, as is shown in Fig. 1. The increase in the B', coefficient can be attributed to the t-BuOH–electrolyte interaction and the obstruction effect.[13] Of course, it is difficult to evaluate these two effects separately, but it can be assumed that it is proportional to the volume fraction and, therefore, to the partial molal volume of the electrolyte, by analogy with the obstruction effect in conductance and diffusion.[13] Therefore, the B' coefficients in various electrolyte solutions at 0.1 mol dm^{-3} are plotted against the partial molal volumes of the electrolytes in Fig. 2, which shows that the B' coefficients increase with an increase in the partial molal volumes of electrolytes in pure water. The plot for $(C_6H_5)_4PCl$ falls on the line connecting plots for pure water, NaCl, Me_4NCl, and $[Co(en)_3]Cl_3$. The plot for $[Fe(phen)_3]Cl_2$ does not deviate markedly from the line.

Here, the B' coefficients can not be divided into the

contributions of the cation and the anion, but it may be safely assumed that the cationic contributions are the main factor in the large difference of the B' coefficients between the solutions of $(n\text{-Bu})_4NBr$ and $(C_6H_5)_4PCl$, or $[Fe(phen)_3]Cl_2$ and $[Co(phen)_3]Cl_3$.

The larger B', coefficient of *t*-BuOH in the $(n\text{-Bu})_4N^+$ solution was attributed to the strongly hydrophobic interaction.[11,14–16] The smaller B' value for $(C_6H_5)_4P^+$ means that the hydrophobicity becomes weak upon the introduction of the aromatic character.[5,17] The same can be said for the hydrophobicity of $[Fe(phen)_3]^{2+}$.

The large B' coefficient in the solution of $[Co(phen)_3]^{3+}$ compared with that in the $[Fe(phen)_3]^{2+}$ solution needs to be explained other than in terms of the hydrophobicity, because the hydrophobicity of $[Co(phen)_3]^{3+}$ should be weaker than $[Fe(phen)_3]^{2+}$ because of its trivalent charge. On the other hand, it seems that the ion-dipole interaction by the trivalent

charge of the ion can not cause the large B' coefficient by itself, because the B' coefficient is not so large in the solution of the trivalent ion with much smaller volumes of $[Co(en)_3]^{3+}$.

As is shown in Fig. 3, the ϕ_v of *t*-BuOH decreases with an increase in the concentration of *t*-BuOH and reaches a minimum at about 1.9 mol dm^{-3} in pure water. This minimum corresponds to the composition of the maximum structure of the solution.[11] For the case of ϕ_v in the $(n\text{-}Bu)_4N^+$ solution the minimum in ϕ_v shifts to a lower concentration as a result of the cooperative effect of *t*-BuOH and $(n\text{-}Bu)_4N^+$. In the solution of $[Fe(phen)_3]^{2+}$, the minimum shifts only a little, which indicates that such a cooperative action does not occur for the pairs of $[Fe(phen)_3]^{2+}$ and *t*-BuOH.

When the V^∞ values of *t*-BuOH in electrolyte solutions of about 0.1 mol dm^{-3} in Table 2 are compared, the V^∞ values are nearly equal in alkali halide solutions, slightly smaller in Me_4N^+, and smallest in $(n\text{-}Bu)_4N^+$, compared with the V^∞ value in pure water. Such a trend can be expected from the effects of these ions on the water structure, but the fairly small V^∞ value in $[Co(phen)_3]^{3+}$ can not be explained from the structural property. The most probable explanation for the V^∞ and B' values of *t*-BuOH in $[Co(phen)_3]^{3+}$ is that $[Co(phen)_3]^{3+}$ attracts *t*-BuOH in the vicinity of the hydrophobic ligands by means of such long-range forces as the charge-dipole interaction.[3] After that, the van der Waals interaction between *t*-BuOH and $[Co(phen)_3]^{3+}$ becomes effective and the overlap of the hydration sphere occurs.[3] This also causes the large B' coefficient of *t*-BuOH in the solution of $[Co(phen)_3]^{3+}$.

From the above observations, it may be concluded that the hydrophobic interaction between the $[Fe(phen)_3]^{2+}$ ion and the aliphatic solute of *t*-BuOH is weak because of the aromatic character of the ligands. However, for the pair of the $[Co(phen)_3]^{3+}$ ion and *t*-BuOH, the cooperative action of ion-dipole and hydrophobic interaction is very effective in stabilizing the water structure.

The author wishes to thank Professor Yuroku Yamamoto and Dr. Manabu Yamamoto of Hiroshima University for their helpful discussions.

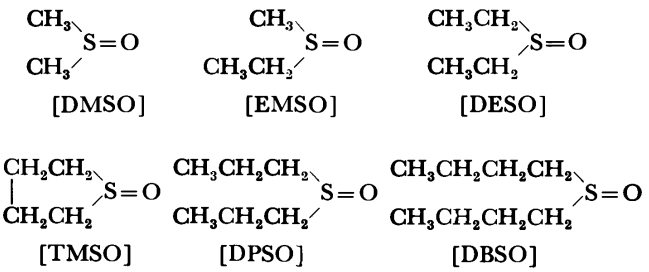
The Solution Chemistry of Organotin Compounds. IV. Thermodynamic Parameters of the Complex Formation between $MeSnCl_3$ and Alkyl Sulfoxides Determined from Titration Calorimetry

Hideaki FUJIWARA,* Fumihiko SAKAI, Akio KAWAMURA, Naoto SHIMIZU, and Yoshio SASAKI
Faculty of Pharmaceutical Sciences, Osaka University, 1-6 Yamada-Oka, Suita, Osaka 565
(Received March 11, 1985)

Calorimetric titration data have been analyzed to determine thermodynamic parameters of the interacting system. The system studied is $MeSnCl_3$ plus dialkyl sulfoxide in CH_2Cl_2 and a nonlinear least squares method is utilized to simulate the titration curve. The 1:1 and 1(acid):2(base) complexes are found to coexist in solution, and the effect of alkyl chain length on the complex formation is examined. The complex formation proceeds most favorably under the total carbon number of four, and inductive and steric effects are considered to operate in a compensating way. Entropy changes on the reactions are discussed with the aid of molecular theory of thermodynamic functions, and a new method is suggested that affords the number of solvent molecules released on the complex formation.

Thermodynamic parameters are essential for the discussion of molecular interactions such as complex formation between acids and bases. These parameters are most often determined from the van't Hoff plot after measuring equilibrium constants at different temperatures.[1] However, titration calorimetry may be best suited for such studies, because those parameters are determined precisely and readily from the direct observation of the heat evolved or absorbed on reaction. For the analysis of such titration data it is frequently encountered that more than one type of reaction needs be dealt with concurrently.[2] This arises from the fact that concentration of solute studied is relatively high and the infinite dilution approximation is not applicable. This seems to be a main reason of rather small number of reports regarding the titration calorimetry. Hitherto, a trial and error method has been reported[3] and applied[4] to the complex formation of several organometallic compounds with bases. The authors have established a simulation program for the analysis of concentration dependence of NMR parameters, which optimizes adjustable parameters by means of a nonlinear least squares method under the several types of equilibrium.[5-7] This program is extended in this paper to apply to the titration calorimetry and the complex formation of $MeSnCl_3$ with dialkyl sulfoxides is examined. The sulfoxides used are as follows:



Experimental

An isothermal isoperibol titration calorimeter Model 550 (Tronac Inc.) was used under the isothermal mode at 25 °C. Calibration of the energy equivalent of the reaction solution is unnecessary under this mode. Total sample volume was 50.0 ml and about 2 ml of titrant was added in increment of 0.1315 ml. Solution of the base was added titrimetrically to the solution in vessel containing the tin compound by *ca.* 0.05 mol dm^{-3}. Heat necessary to compensate for the reaction enthalpy was measured in 15 s. after an addition of the titrant. Titration and the subsequent data collection were controlled by the Programmer C-930. Heat of solution of the base was also measured by adding the titrant to the solvent without tin compound in the same manner. Differential heat of these two runs was set to the effective heat of complex formation and analyzed by the computer program. Errors were also estimated in the program for each parameter as equal to the 95% confidence range which makes the σ^2(see Eq. 4 below) larger by 1.96 times, and they were also tested by repeated experiments (more than 3 runs).

$MeSnCl_3$ was synthesized from Me_2SnCl_2 using catalytic reagents[8] and sublimed at *ca.* 30 °C after distillation. EMSO, DESO, and DPSO were synthesized from the corresponding sulfides according to a scheme:[9]

$$R_1R_2S + NaIO_4 \longrightarrow R_1R_2SO + NaIO_3$$

Sulfoxides were dried over BaO and distilled under reduced pressure after decantation. All operations of the purification and sample preparation were done in dry boxes.

Analysis of Calorimetric Titration Data

Effective heat of the complex formation determined experimentally q_{expt} is expressed as the differential heat between the titration q_{titrn} and the dilution q_{diln} (Fig. 1): $q_{expt}=q_{titrn}-q_{diln}$. The heat q in each incremental step in the succesive titration experiment can be integrated to give the integrated heat Q, for which following eq holds after i-th step of titration.

$$Q_{expt,i} = Q_{titrn,i} - Q_{diln,i} \quad (1)$$

On the other hand, integrated heat of the complex formation such as in Eq. 2 is calculated according to Eq. 3:

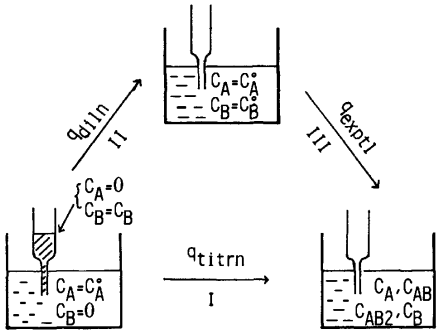


Fig. 1. Heat of titration (step I) can be divided into two parts, *i.e.*, heat of dilution q_{diln} in step II and heat of complex formation q_{exptl} in step III: $q_{titrn}=q_{diln}+q_{exptl}$.

$$\left.\begin{array}{ll} A + B = AB & K_1, \Delta H_1^\circ \\ AB + B = AB_2 & K_2, \Delta H_2^\circ \end{array}\right\}, \quad (2)$$

$$Q_{calcd,i} = (\Delta H_1^\circ \cdot C_{AB} + \Delta H_2^\circ \cdot C_{AB_2}) \cdot V_i, \quad (3)$$

where ΔH_1° and ΔH_2° are the molar enthalpies for the reactions in Eq. 2, and V_i is the volume of solution, *i.e.*, $V_i=V_0+i\cdot\Delta V$, V_0 being the initial volume of the titrated solution and ΔV the incremental volume added in each step. Molarity of the complexes AB and AB_2, C_{AB} and C_{AB_2}, are obtained by solving Eqs. of the chemical equilibrium. In this way, the problem is how to reproduce well the experimental data (Eq. 1) by adjusting K_1, K_2, ΔH_1°, and ΔH_2° in Eq. 2. For this purpose, standard deviation σ as expressed by Eq. 4 needs be minimized by optimizing the four parameters, and to this end a least squares method is surely superior than a trial and error method.

$$\sigma = [\sum_{i=1}^{n} (Q_{expt.i} - Q_{calcd,i})^2/(n-p)]^{1/2} \quad (4)$$

In above equation n is the total number of titration steps and p is the number of adjustable parameters. In our previous case of NMR titration experiments,[5-7] chemical shift or coupling constant (ϕ) is expressed as $\phi_{calcd}=(\phi_A\cdot C_A+\phi_B\cdot C_B+\phi_{AB_2}\cdot C_{AB_2})/C_A^\circ$ instead of Eq. 3 in the present case. Therefore, the method is easily modified to the present case.[10]

Among various kinds of nonlinear least squares analysis, we have adopted a version of so-called DFP (Davidon-Fletcher-Powell) method, which belongs to a variable metric method. This algorithm is widely accepted as one of the most sophisticated search technique, and it appears to be independent of the number of variables involved.[11] The superiority of the DFP method itself is also approved in the MO calculation with geometrical optimization[12] where a large number of variables are usually included but the derivatives of the minimized function are available. However, when we utilized a version of this algorithm, some drawbacks were encountered. A search process failed frequently in improving the variable parameters when started from initial values far from the final ones under the three- or four-parameter simulation. In the original DFP algorithm, an updating formula 5 is used to find a Hessian matrix

$$H_{j+1} = H_j + \delta\cdot\delta^T/\delta^T\cdot\gamma - H_j\gamma\cdot\gamma^T H_j/\gamma^T H_j\gamma, \quad (5)$$

appropriate for the next step. Fletcher[13] demonstrated that use of this equation together with the linear search is unsuccessful in special circumstances and proposed an improved algorithm where the updating formula is switched appropriately between Eq. 5 and the complementary one:

$$H_{j+1} = (I-\delta\gamma^T/\delta^T\gamma)H_j(I-\gamma\delta^T/\delta^T\gamma) + \delta\delta^T/\delta^T\gamma. \quad (6)$$

In the present study the improved algorithm is incorporated and the failure of improving parameters stated above is circumvented.

Results and Discussion

Calorimetric titration curves are depicted in Fig. 2

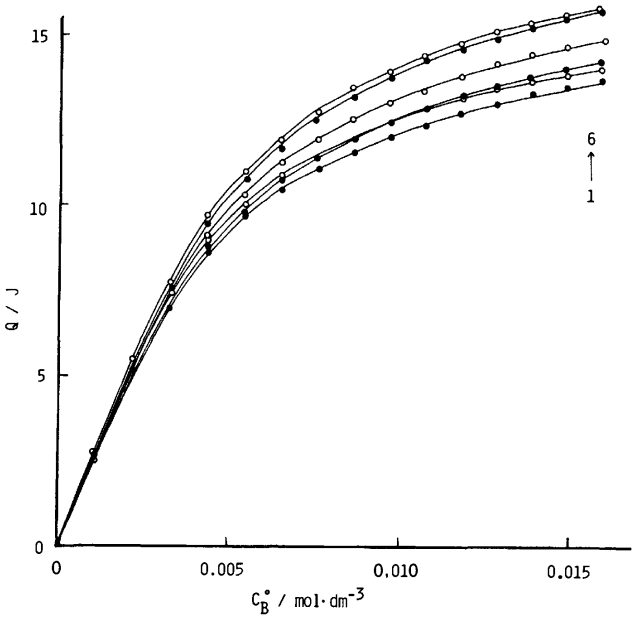

Fig. 2. Calorimetric titration curves for the $MeSnCl_3$ plus alkyl sulfoxide systems in CH_2Cl_2.
Solution of sulfoxide is added titrimetrically into that of $MeSnCl_3$ at 25 °C. Sulfoxides used are: DMSO(1), EMSO(3), DESO(5), TMSO(6), DPSO(4), DBSO(2). C_B° is the initial concentration of sulfoxide and Q the integrated heat of complex formation.

Table 1. Analysis of calorimetric titration data of $MeSnCl_3$ plus DMSO system under some models of chemical equilibrium

compared in Table 1 for the DMSO system typically. It is clear that 1:1 and 1(acid):2(base) complexes are formed in solution. Analysis under the model III in Table 1 is summarized in Table 2 for all the systems studied here, including error limit estimated from the program and repeated runs whichever is larger. Equilibrium constants, enthalpies, and entropies are plotted in Fig. 3 to 5 against the total number of carbon atoms in the alkyl groups in sulfoxide. It is interesting to note that the complexes AB and AB_2 are most stable for the sulfoxide with the carbon number of four (Fig. 3). For the 2nd step of the complex formation, $-\Delta H^\circ$ and $-\Delta S^\circ$ also show the similar dependency on the carbon number (Figs. 4 and 5). This means that the enthalpy term contributes positively but the entropy term negatively in the 2nd step. That is, the dependency comes out of the enthalpy term. Introduction of a methylene group into the substituent of the functional

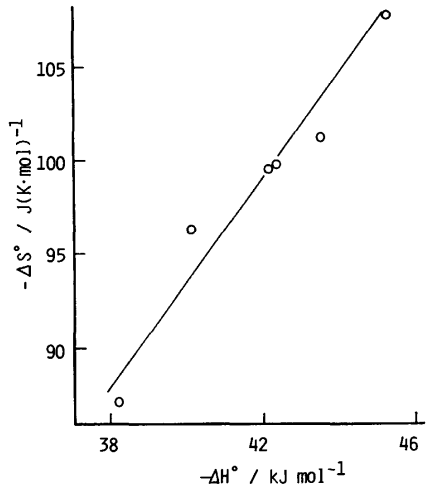

Fig. 6. Enthalpy-entropy compensation relation for the reaction of AB+B=AB_2. A=$MeSnCl_3$ and B=alkyl sulfoxide.

S=O group will increase the electron-donating ability of the functional group through an effect such as called "hyperconjugation." On the contrary, increase in the number of methylene groups will induce the steric hindrance, weakening the chemical bond between Sn and S=O.[14] This steric effect is, however, not such a strong and specific one as to disturb the enthalpy-entropy compensation relation as revealed in Fig. 6 for the 2nd step.

In contrast to the 2nd step of the complex formation, the results are not straightforwardly explained in the 1st step. That is, the entropy change is oppositely dependent on the carbon number (Fig. 5), and the enthalpy change is not clearly dependent on this number (Fig.4).[15] The 1st step of the complex formation is considered entropy-dependent, because the trend in reactivity in Fig. 3 is consistent with that in the entropy term and because difference in the enthalpy term is small among the sulfoxides listed in Fig. 4. Only an exception is TMSO, for which enhanced reactivity surely comes from the enthalpy term.

Entropy change on the complex formation is generally expressed by the difference in standard entropies of the components, *e. g.*, $\Delta S^\circ_{calcd}=S^\circ_{AB}-(S^\circ_A+S^\circ_B)$ for A+B=AB. The entropies can be calculated from molecular theory of thermodynamic functions, and it is composed of several contributions of translational, rotational, vibrational, and internal rotational parts, *i.e.*, $S^\circ=S^\circ_{tr}+S^\circ_r+S^\circ_v+S^\circ_{fir}-(S_f-S)$.[16] This value of ΔS°_{calcd} is considered to correspond to the gas-phase value of ΔS°. Such calculations have been applied precisely to various chemical reactions and equilibria to approve the third-law of thermodynamics, and the results are also useful for the discussion of internal motions in the relevant substances.[17] Although similar discussion should be applicable to the case of complex formation,

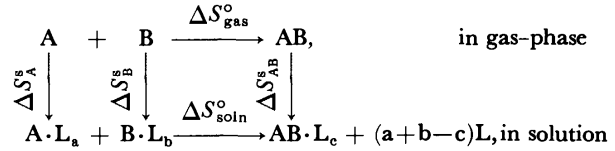

Fig. 7. Entropy changes related to the complex formation in gas phase and in solution.
The species A, B, and AB are assumed solvated weakly by the solvent L, and the numbers of solvation are a, b, and c, respectively, the related entropies of solution being denoted by ΔS^s's.

those studies are very limited in number.[18] This is probably because only the enthalpy change is interested and the entropy one is overlooked. However, if the entropy is measured carefully in gas phase, the result can be compared with the calculation. As an example, $\Delta S^\circ=-166.9$ J K^{-1} mol^{-1} determined for the complex formation of $B(CH_3)_3$ with NH_3 in gas phase at 100° C[19] can be interpreted by the moment of inertia and vibration-spectral data of each species, calculated value being -168.9 J K^{-1} mol^{-1}.[20]

For the present case of $MeSnCl_3$ plus sulfoxides, experimental values of ΔS° are measured in solution and the values will not correspond with the calculated ones, and also exact calculations of the vibrational and the internal rotational entropies are prevented by a lack of necessary physicochemical constants. However, it is interested to compare the experimental values with the calculated ones which include predominant parts, *i.e.*, translational and rotational ones, of the entropies. The calculated value is -253.1 J K^{-1} mol^{-1} against the observed one of -87.7 for A+B=AB, and is -259.8 against -96.2 for AB+B=AB_2 when B is DMSO. Since the vibrational and the internal rotational contributions are very small for the simple molecule such as DMSO, the entropy changes observed in CH_2Cl_2 are said to be about 1/3 of the net entropy changes in gas phase. If, as in a model calculation described in the previous paper,[21] DMSO is assumed to be solvated by one molecule of CH_2Cl_2 and the latter be released on the complex formation, the entropy changes are reduced in absolute value to -19.2 for A+BS=AB+S and -25.5 for AB+BS=AB_2+S. Therefore, experimental entropies can be said to indicate the solvation number of 0.7 or the release of solvent molecules by 0.7 mol on the complex formation of both A+B=AB and AB+B=AB_2. In these calculations entropies are also estimated by assuming different geometries of the complexes as well as the solvated species, but the result does not change considerably. This situation may be discussed more precisely by a thermodynamic cycle as shown in Fig. 7. The entropy change in solution ΔS°_{soln} is expressed as follows:

$$\Delta S^\circ_{soln} = \Delta S^\circ_{gas} + (\Delta S^s_{AB} - \Delta S^s_A - \Delta S^s_B) + (a+b-c)S^\circ_L \quad (7)$$

where S°_L means the entropy of solvent.[22] Therefore,

a+b−c, the number of solvent molecules released on the complex formation, is seen to be obtained from the Eq.:

$$a+b-c = \{\Delta S^{\circ}_{soln} - \Delta S^{\circ}_{gas} - (\Delta S^{s}_{AB} - \Delta S^{s}_{A} - \Delta S^{s}_{B})\}/S^{\circ}_{L}. \quad (8)$$

This number may be interpreted as reflect the solvation number judged from the entropy effect. It is, however, not easy to estimate exactly the entropy of solution for the complex, *i. e.*, ΔS^{s}_{AB}. Usually ΔS°_{gas} is more negative than ΔS°_{soln} as is shown in above case. Therefore, if the entropies of solution ΔS^{s}'s are smaller than ΔS°_{gas} in absolute value or if ΔS^{s}_{AB} almost cancells out with $\Delta S^{s}_{A}+\Delta S^{s}_{B}$, above equation is simplified as:

$$a+b-c = (\Delta S^{\circ}_{soln} - \Delta S^{\circ}_{gas})/S^{\circ}_{L}. \quad (9)$$

From this equation and by putting ΔS°_{calcd} in place of ΔS°_{gas}, a+b−c is calculated as 0.6 for $MeSnCl_3$ plus DMSO in CH_2Cl_2, in consistent with above preliminary calculations. In this way, entropy changes in the complex formation is expected to give a number of solvent molecules released on the reaction. Further study is under way including other systems.

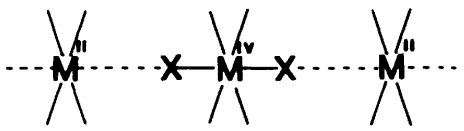
(Received April 13, 1985)

The X-ray photoelectron spectra have been measured for the one-dimensional halogen-bridged metal-alternated mixed-valence complexes, $[Pd^{II}(en)_2][Pt^{IV}X_2(en)_2](ClO_4)_4$ (X=Cl, Br, and I) and $[Ni^{II}(en)_2][Pt^{IV}X_2(en)_2](ClO_4)_4$(X=Cl and Br), along with their parent complexes, $[Pd(en)_2]Cl_2$, $Ni(en)_2Cl_2$, and $[PtCl_2(en)_2]Cl_2$. As the bridging halogen changes from Cl to I, the binding energies of the Pt(IV)4f levels become lower while those of M(II) (M=Pd and Ni) levels become higher, each gradually approaching to the M(III) binding energies (M=Pt, Pd, or Ni), respectively. Comparing the binding energies of the Pt(IV)4f levels in these hetero-metal mixed-valence complexes with those previously reported for the homo-metal halogen-bridged Pt(II)-Pt(IV) mixed-valence complexes having the same bridging halogens, the reductive trend of the oxidation states of Pt(IV) is found to be significantly suppressed by the metal alternation. In accord with this result, the activation energies obtained from the electrical conductivities are fairly larger than those of the homo-metal Pt(II)-Pt(IV) mixed-valence complexes. Their magnitudes are in the order of Pd^{II}-Pt^{IV}>Ni^{II}-Pt^{IV}>Pt^{II}-Pt^{IV}, suggesting that the electron-electron repulsion energy on M(II) ions plays an important role in mixed-valence states.

Various kinds of halogen-bridged one-dimensional M(II)-M(IV) mixed-valence complexes of Pt, Pd, and Ni have created a greater current interest in the field of low-dimensional chemistry and physics.[1-4] So far, we have prepared about one hundred compounds with a general formula of $[M^{II}(AA)_2][M^{IV}X_2(AA)_2]Y_4$ (M=Pt, Pd and Ni; X=Cl, Br and I; $(AA)_2$=(diamines)$_2$, linear-tetramines, and tetraaza-macrocycles; Y=ClO_4, BF_4 *etc.*).[5-9] Although these complexes exhibit a considerable variety of semiconducting properties, they can be well characterized by a common feature; the electrical,[10-12] optical,[13-15] and vibrational properties[16-18] are closely correlated with the degree of the oxidation states of the M(II) and M(IV) ions. This has been clearly demonstrated by the X-ray photoelectron spectra[19-22] and XANES.[23] From the results of the X-ray diffraction measurements,[24-31] the oxidation states of metal ions were found to be systematically dependent on the ratio between M(IV)-X and M(II)···X distances, which is influenced by the kinds of metals, bridging halogens, counter ions, and in-plane ligands.



For example, as the bridging halogen ions change from Cl to I, the ratio between M(IV)-X and M(II)···X distances approaches unity.[31] At the same time, the oxidation states of the M(II) and M(IV) metal ions almost become tervalent states. These characteristic behaviors have been theoretically elucidated by energy-band calculations by Whangbo and Foshee[32] using the extended Hückel method and recently by Nasu[33-35] on the basis of an extended Peierls-Hubbard model. According to Nasu's model, the oxidation states of metal ions are determined by three physical parameters: the distortion energy due to the displacement of a halogen ion from the midpoint between adjacent metal ions, the transfer energy between metal ions, and the electron-electron (e-e) repulsion energy on metal ions. In a preceding paper,[36] it has been confirmed that the metal (M) and halogen ions (X) dependences on intervalence charge transfer transitions along the chains can be interpreted in terms of these parameters, including the e-e repulsion energy on the adjacent metal ions.

In order to obtain more detailed information regarding the mixed-valence states in one-dimensional complexes of this type, we have measured the X-ray photoelectron spectra and single-crystal electrical conductivities of the hetero-metal mixed-valence complexes, $[Pd(en)_2][PtX_2(en)_2](ClO_4)_4$(X=Cl, Br, and I) and $[Ni(en)_2][PtX_2(en)_2](ClO_4)_4$ (X=Cl and Br) (hereafter, they are abbreviated to Pd(II)-X-Pt(IV) and Ni(II)-X-Pt(IV)). The X-ray photoelectron spectra of their parent complexes, $[Pd(en)_2]Cl_2$, $Ni(en)_2Cl_2$[37] and $[PtCl_2(en)_2]Cl_2$ have also been measured as references. The metal alternation is expected to add two different types of energy to the one-dimensional M-X-M system. One is due to the alternating ionization energies and the other is due to the alternating electron-electron repulsive energies on metal sites.

Experimental

Materials. The M(II)-X-Pt(IV) complexes were synthesized by methods previously described.[5,8,38] Single crystals of the Pd(II)-X-Pt(IV) complexes were grown from dilute perchloric acid solutions, while those of the Ni(II)-X-Pt(IV) complexes were obtained from aqueous solutions containing $NaClO_4$.

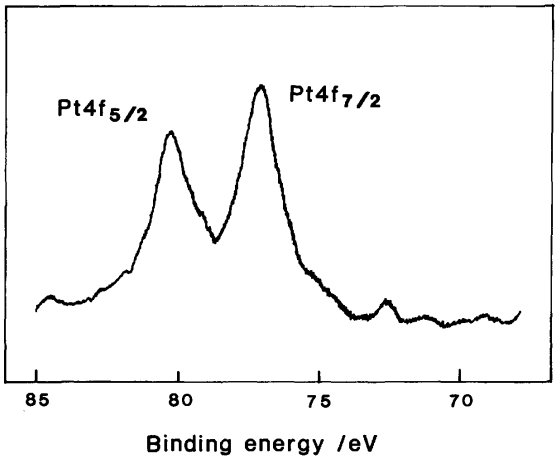


Fig. 1. X-Ray photoelectron spectra of Pt4f in [Pd(en)$_2$][PtCl$_2$(en)$_2$](ClO$_4$)$_4$.

X-Ray Photoelectron Spectra. The X-ray photoelectron spectra were obtained on a SHIMADZU ESCA 750 using Mg$K\alpha$ exciting radiation at room temperature, the source vacuum being $\approx 10^{-7}$ Torr.† The spectra were calibrated by the emission from the Cls line (285.0 eV). The absolute energy of emitted electrons, however, may not be so meaningful in the present study because it is not free from possible systematic errors due to charging-up. Thus, in this paper, we will refer only to a relative energy with respect to the reference signals for the parent complexes.

Electrical Conductivities. Single-crystal d.c. conductivities along the needle axis were measured in a temperature range below 100°C by the two-probe method. Silver paste was used as the electrode material.

Results and Discussion

As a probe for an examination of the oxidation states of metal ions in metal-alternated mixed-valence complexes, we measured the binding energies of Pt(IV)4f, Pd(II)3d, and Ni(II)2p levels in the Pd(II)-X-Pt(IV), Ni(II)-X-Pt(IV) and their parent complexes. In Fig. 1, the X-ray photoelectron spectrum of Pt(IV)4f levels in the Pd(II)-Cl-Pt(IV) complex is shown as an example. The peak energies of the doublet correspond to the binding energies of the 4f$_{7/2}$ and 4f$_{5/2}$ levels of Pt(IV). All the Pt(IV)4f spectra observed in the metal-alternated mixed-valence complexes, including the reference complexes, are quite similar, but the magnitudes of their binding energies show a characteristic dependence on the kind of the constituent metal and halogen ions. The observed binding energies of the Pt(IV)4f$_{7/2}$ and Pd(II)3d$_{5/2}$ levels for the Pd(II)-X-Pt(IV) complexes and for the Pt(IV)4f$_{7/2}$ and Ni(II)2P$_{3/2}$ levels of the Ni(II)-X-Pt(IV) complexes are listed in Table 1, along with those for reference states of the parent complexes.

In this table, it is immediately noticed that the binding energy of the Pt(IV)4f$_{7/2}$ level shifts to a lower

† 1 Torr≈133.322 Pa.

energy while those of the Pd(II)3d$_{5/2}$ and Ni(II)2p$_{3/2}$ levels shift to higher energies by changing halogen ions in order of X=Cl, Br, and I. Such a trend is the same as that previously observed for homo-metal M(II)-M(IV) mixed-valence complexes.[19-22] This can be interpreted in terms of the difference of magnitudes of the charge-transfer dependence on the ionic radius of the bridging halogens.[36] The energy shifts of the Pt(IV)4f$_{7/2}$ level in the metal-alternated Pd(II)-X-Pt(IV) complexes from the reference energy of [Pt^{IV}Cl$_2$(en)$_2$]Cl$_2$ yield 0.0, −0.2, and −0.4 eV for X=Cl, Br, and I, respectively. These values are remarkably smaller than −0.3, −0.7, and −1.0 eV for the Pt(IV)4f$_{7/2}$ level in the homo-metal Pt(II)-X-Pt(IV) complexes.[19] Such a suppression of the reductive trend of the Pt(IV)4f binding energy due to the alternated substitution of Pd ions indicates that the alternated core-potentials in the Pd-X-Pt chain structure give a fairly large effect on the mixed-valence states constituted by the metal d electron. Since there is a considerable energy difference between the Pd-4d and Pt-5d levels, the 4d-5d

charge transfer in the Pd(II)-X-Pt(IV) complexes is thought to be considerably smaller compared with the resonance 5d-5d charge transfer in the Pt(II)-X-Pt(IV) complexes. The decrease in the charge transfer, therefore, provides for the smaller energy shift of the Pt(IV)$4f_{7/2}$ level, indicating that the oxidation state of the Pt(IV) species remains close to the quadrivalent state. A similar interpretation can hold for the change in the Pt(IV)$4f_{7/2}$ binding energy in the Ni(II)-X-Pt(IV) complexes. Thus, it may be concluded that the metal alternation in the mixed-valence complexes leads to a suppression of the mixing of d_{z^2} orbitals between adjacent metal ions.

The metal alternation effect is expected to cause a change in the semiconducting properties of the mixed-valence complexes. The experimental results of the electrical conductivities of M(II)-X-Pt(IV) complexes along the chain are presented as a function of temperature in Fig. 2. Their behaviors suggest a hopping-type of electron-conduction with a thermal-activation energy ΔE. Upon assuming this conduction mechanism, estimated activation energies can be determined as summarized in Table 2, together with conductivities at room temperature. For complexes indicated by an * mark, we used room-temperature conductivities obtained by extrapolation. In this table, for comparison, we also list data concerning the homo-metal M(II)-M(IV) mixed-valence complexes of Pt, Pd, and Ni.

It is found that the activation energies decrease in the order of Cl>Br>I for X in both Pd(II)-X-Pt(IV) and Ni(II)-X-Pt(IV) complexes. This tendency is also coincident with those observed in homo-metal mixed-valence complexes. Such a ΔE behavior can be qualitatively interpreted in terms of a small polaron model,[39] whose activation energy is closely correlated with the degree of the charge transfer between M(II) and M(IV) ions; the smaller the charge transfer, the larger the binding energy of the polaron. This may be the reason why the activation energies are in the order of Cl>Br>I.

It is interesting to note that the activation energies in changing metal ions increase in the order of Pd(II)-Pt(IV)>Ni(II)-Pt(IV)>Pt(II)-Pt(IV) for the same bridging halogen ions. The relation, M(II)-X-Pt(IV)>Pt(II)-X-Pt(IV) (M=Pd and Ni), that is, the activation energies of the metal-alternated complexes are larger than those of the regular Pt(II)-Pt(IV) mixed-valence complexes, may be naturally understood assuming a smaller charge-transfer energy in the metal-alternated complexes, as described before regarding the M-dependence of the Pt(IV)$4f_{7/2}$ binding energy. However, the order of Pd(II)-X-Pt(IV)> Ni(II)-X-Pt(IV) is rather peculiar because the ionization energy of a Ni ion is much larger than that of a Pd ion and, thereby, it gives a smaller charge transfer, suggesting an opposite relation regarding the activation energy to the experimental results. In order to interpret such a characteristic nature of the metal-alternated complexes, we have to take into account another contribution arising from metal alternation. In the M(II) species of M(II)-X-M(IV) complexes, electron-electron (e-e) repulsion energy is much larger for M= Ni(II) than for M=Pd(II). This surpassed the effect brought about by a change in the ionization energy, resulting in the observed relation concerning ΔE, Pd-(II)-X-Pt(IV)>Ni(II)-X-Pt(IV). Such an important role of the e-e repulsive energy in mixed-valence complexes has been emphasized in a previous paper.[36] For a more concrete discussion, we need information regarding the crystal structures of alternated-metal complexes, which is now under investigation. The optical results will be reported elsewhere.

Photoregulated Ion-binding to Azobenzene-linked Ethylenediamines and Iminodiacetic Acids[1)]

Seiji SHINKAI,* Shinichiro NAKAMURA, Mikio NAKASHIMA, Osamu MANABE,* and Masakazu IWAMOTO

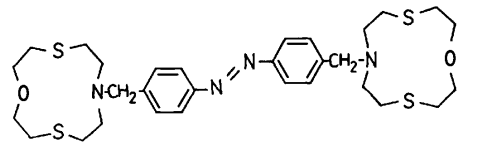
Department of Industrial Chemistry, Faculty of Engineering, Nagasaki University, Nagasaki 852

(Received November 21, 1984)

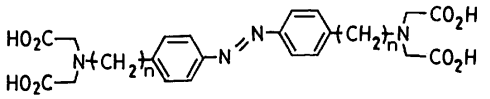
New photoresponsive complexones bearing two iminodiacetic acid units or ethylenediamine units at the two sides of an azobenzene through CH_2 or $(CH_2)_2$ (AzoIDA(n=1,2) and AzoED(n=1,2), respectively) have been synthesized. The CH_2 and $(CH_2)_2$ spacers were selected in order to examine the influence of the spacer length on the intramolecular cooperativity for the two ligands in the cis-isomers to coordinate to one metal ion. The thermal cis-to-trans isomerization of AzoIDA was efficiently suppressed by Zn(II) and Cu(II) while that of AzoED was suppressed only by Cu(II). The rate suppression supports the formation of the intramolecular chelate complexes with the metal ion. The measurements of ESR spectra of the cis-isomer·Cu(II) complexes indicated that the square-planar structure of the complexes is somewhat distorted and probably close to a lozenge. The stability constants (K_s) were determined by a displacement method. The K_s values for the cis-isomers were generally greater than those for the trans-isomers, and the K_s for n=2 series increased more clearly. In particular, the K_s for *cis*-AzoED(n=2)+Cu(II) was improved by 43.8 fold. The photoresponsive change in the stability constants suggests a possible application of the present system as light-driven ion pumps for heavy metal ions.

Azobenzene derivatives which exhibit photoinduced reversible cis-trans isomerism have frequently been employed as a photoantenna to control physical and chemical functions of membranes,[2-5)] microemulsions,[6)] synthetic polymers,[7-9)] polypeptide chains,[10,11)] cyclodextrins,[12,13)] and crown ethers.[14-18)] The ideas are all associated with the photoresponsive, large geometrical change between *trans*- and *cis*-azobenzene. These systems are interesting not only as candidates for the storage of light energy but also as models of natural photoresponsive systems mediating the conversion of light into other forms of energy.

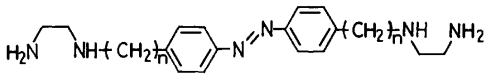
The purpose of our investigation has been to control the functions of a crown ether family by light, which would lead to photoresponsive ion extraction and light-driven ion-transport across membranes.[18)] We and others have synthesized several photoresponsive crown ethers, but the research effort has mainly been devoted toward photoresponsive binding of alkali and alkaline earth metal ions.[14-20)] In contrast, very few precedents exist for photoresponsive binding of heavy metal ions. Irie *et al.*[21)] synthesized a thioindigo derivative with ethylene glycol chains which exhibits photoresponsive affinity with Ag(I), Hg(II), Cu(II), *etc.* We synthesized azobenzene-capped and azopyridine-capped thiacrown ethers which exhibit affinity with Cu(II) and Hg(II).[22)] Blank *et al.*[23)] extended this concept to a complexone, 4,4′-bis[bis(carboxymethyl)-aminomethyl]azobenzene(AzoIDA(n=1)). It is known that the stability constants (K_s) of complexones are efficiently increased through cooperative binding of plural ligand groups.[24-26)] Thus, the *cis*-isomer of AzoIDA(n=1) (*i.e.*, *cis*-AzoIDA(n=1)) which can form an intramolecular complex with a single metal ion gives the K_s greater than the trans-isomer of AzoIDA-(n=1) (*i.e.*, *trans*-AzoIDA(n=1)). Blank *et al.*[23)] established on the basis of a polarographic method that *cis*-AzoIDA(n=1) forms a 1:1 metal/AzoIDA complex with Zn(II). On the other hand, we recently studied the photoresponsive behavior of a copper complex of 4,4′-bis(1-oxa-4,10-dithia-7-azacyclododec-7-ylmethyl)azobenzene (**1**).[27)] The most noteworthy result in this paper is that the Cu(I) complex is capable of binding O_2 in a partially reversible manner only when **1** is photoisomerized to the *cis*-form. Therein, we found that both *trans*- and *cis*-**1** bind two copper ions to form the 1:1 copper/crown complex. The finding suggests that the two crown ether rings act quite independently and that most probably, two nitrilo nitrogens of *cis*-AzoIDA(n=1) are too far to bind intramolecularly to one metal ion.



1



trans-AzoIDA(n=1,2)



trans-AzoED(n=1,2)

It occurred to us that if appropriate spacers are inserted between azobenzene and iminodiacetic acid, two nitrilo nitrogens may be able to coordinate intramolecularly to one metal ion. Examination of Corey-Pauling-Koltun (CPK) molecular models of AzoIDA-(n=1,2) suggests that (i) four carboxy groups in *cis*-AzoIDA(n=1) favorably occupy the tetrahedral coordination sites and it is fairly difficult for two nitrilo

nitrogens to coordinate to one metal ion and (ii) four carboxy groups in *cis*-AzoIDA(n=2) possibly be placed in either (tetrahedral and planar) coordination structure and two nitrilo nitrogens can interact with one metal ion. We thus synthesized AzoIDA(n=1,2) and AzoED(n=1,2) and examined whether or not metal affinities of these azobenzene-linked ligands change in response to photoinduced trans-cis isomerization. We employed Zn(II) and Cu(II) as metal ions, because Zn(II) is classified as a relatively "hard" metal ion and adopts the tetrahedral coordination, whereas Cu(II) is a "soft" metal ion and favors the square-planar coordination.

Experimental

Materials. *trans*-AzoIDA(n=1) and *trans*-AzoIDA(n=2) were synthesized by the reaction of iminodiacetic acid with 4,4′-bis(chloromethyl)azobenzene and 4,4′-bis(2-chloroethyl)azobenzene, respectively.

trans-*4,4′-Bis[bis(carboxymethyl)aminomethyl]azobenzene-(*trans-*AzoIDA*(n=*1*)).* 4,4′-Bis(chloromethyl)azobenzene (0.28 g; 1.0 mmol) in 40 ml of methanol and iminodiacetic acid (0.54 g; 4.1 mmol) in 50 ml of water containing K_2CO_3 (0.80 g; 5.79 mmol) were mixed and refluxed for 21 h. The progress of the reaction was followed by TLC. Methanol was removed from the reaction mixture by evaporation under reduced pressure. The residual solution was turbid (probably owing to monosubstituted compound). It was filtered after treatment with active charcoal, and orange crystals precipitated from the filtrate on the addition of NaCl were recovered by filtration. The crystals were dissolved in water and reprecipitated by adding concd HCl; mp 225.5—226.5 °C (lit,[23] 208—209 °C), yield 38%. Found: C, 55.03; H, 5.06; N, 11.67%. Calcd for $C_{22}H_{24}N_4O_8$: C, 55.93; H, 5.12; N, 11.86%. IR (KBr): ν_{OH} 3000 cm^{-1}, $\nu_{C=O}$ 1725 cm^{-1}, $\nu_{N=N}$ 1635 cm^{-1}. NMR (Me_2SO-d_6): NCH_2CO, δ=3.50, 8H; $ArCH_2N$, 3.99, 4H; aromatic protons, 7.63 and 7.91, 4H each.

trans-*4,4′-Bis[2-[bis(carboxymethyl)amino]ethyl]azobenzene-(*trans-*AzoIDA*(n=*2*)).* First, *trans*-4,4′-bis(2-hydroxyethyl)azobenezene was prepared from 1-(2-hydroxyethyl)-4-nitrobenzene. 1-(2-Hydroxyethyl)-4-nitrobenzene (5.0 g; 29.9 mmol) in 30 ml of ethanol and NaOH (1.3 g; 32.5 mmol) in 6 ml of water were mixed in a 100 ml flask, and zinc powder (16.1 g; 0.246 mol) was added to the stirred solution. The reaction mixture was refluxed for 1 h. The hot solution was filtered and the solid was washed with ethanol. To the combined solution air was introduced for 2 h. After filtration, ethanol in the filtrate was removed under reduced pressure, and the residual solution was diluted with water. The precipitate was recovered by filtration and recrystallized from ethanol; mp 140.5—142.5 °C, yield 75%. Found: C, 70.84; H, 6.80; N, 10.34%. Calcd for $C_{16}H_{18}N_2O_2$: C, 71.09; H, 6.71; N, 10.36%. IR(KBr): ν_{OH} 3240—3340 cm^{-1}, $\nu_{N=N}$ 1580 cm^{-1}. NMR (Me_2SO-d_6): Ar-CH_2, δ=2.82, 4H; CH_2O, 3.68, 4H; OH, 4.69, 2H; aromatic protons, 7.41 and 7.79, 4H each.

trans-4,4′-Bis(2-hydroxyethyl)azobenzene was converted to *trans*-4,4′-bis(2-chloroethyl)azobenzene by treatment with thionyl chloride. *trans*-4,4′-Bis(2-hydroxyethyl)azobenzene (3.0 g; 11.1 mmol) was heated in 30 ml of thionyl chloride for 4 h in the presence of one drop of *N,N*-dimethylformamide. The progress of the reaction was followed by TLC. The hot solution was filtered using a glass filter and evaporated to dryness *in vacuo*. The residual crystals were recrystallized from benzene; mp 120—121 °C, yield 91%. Found: C, 62.22; H, 5.23; N, 9.03%. Calcd for $C_{16}H_{16}N_2Cl_2$: C, 62.55; H, 5.25; N, 9.12%.

trans-AzoIDA(n=2) was synthesized in a manner similar to *trans*-AzoIDA(n=1); mp 215 °C (dec), yield 35%. Found: C, 57.76; H, 5.75; N, 10.98%. Calcd for $C_{24}H_{28}N_4O_8$: C, 57.59; H, 5.64; N, 11.19%. IR(KBr): ν_{OH} 2960—3020 cm^{-1}, $\nu_{C=O}$ 1725 cm^{-1}, $\nu_{N=N}$ 1630 cm^{-1}. NMR(Me_2SO-d_6): $ArCH_2$ and NCH_2, δ=2.92 and 2.94, 4H each; NCH_2CO, 3.55, 8H; aromatic protons, 7.49 and 7.86, 4H each.

trans-*4,4′-Bis[(2-aminoethyl)aminomethyl]azobenzene(*trans-*AzoED* (n=*1*)).* 4,4′-Bis(chloromethyl)azobenzene (1.00 g; 3.58 mmol) in 100 ml of acetonitrile was added slowly (for 75 min) into stirred acetonitrile solution (200 ml) of ethylenediamine (4.31 g; 7.17 mmol) containing finely powdered K_2CO_3 (9.90 g; 71.6 mmol). The mixture was refluxed for 2 h and the completion of the reaction was confirmed by TLC. The hot solution was filtered to remove KCl and K_2CO_3, the filtrate being evaporated to dryness. The residue was crystallized by benzene-diisopropyl ether. The crystals were dissolved in hot water, the insoluble material removed by filtration, and the filtrate was acidified by concd HCl. On cooling, *trans*-AzoED(n=1) was recovered as its tetrahydrochloride salt; mp>300 °C, yield 35%. Found: C, 45.21; H, 6.36; N, 17.93%. Calcd for $C_{18}H_{30}N_6Cl_4$: C, 45.78; H, 6.40; N, 17.79%. IR(KBr): ν_{NH} 2890—3030 and 2735—2770 cm^{-1}, $\nu_{N=N}$ 1585 cm^{-1}.

trans-*4,4′-Bis[2-[(2-aminoethyl)amino]ethyl]azobenzene(*trans-*AzoED*(n=*2*)).* This compound was synthesized from *trans*-4,4′-bis(2-chloroethyl)azobenzene and ethylenediamine in a manner similar to *trans*-AzoED(n=1) and isolated at its tetrahydrochloride; mp 279—281 °C, yield 63%. Found: C, 46.89; H, 6.88; N, 16.40%. Calcd for $C_{20}H_{34}N_6Cl_4 \cdot 0.66H_2O$: C, 46.89; H, 6.95; N, 16.40%. IR(KBr): ν_{NH} 2735—2770 and 2890—3030 cm^{-1}, $\nu_{N=N}$ 1560 cm^{-1}.

Measurements of ESR Spectra. The ligand (1.00×10^{-3}M[†]) in the buffer solution (pH 9.02) was irradiated by UV light and then mixed with an equal amount of the buffer solution containing $CuSO_4$(1.00×10^{-3} M). ESR spectra were measured at −50 °C with JEOL-JES-FE-1X and simulated by using a computer program made by Dr. M. Iwamoto. The ligand after photoirradiation was a mixture of trans- and cis-isomer (see Table 1). We first made a simulation of the ESR spectra of trans-isomer·Cu(II) complexes and reduced these spectra from the observed ESR spectra. The remaining spectra thus obtained were regarded to be those of "pure" cis-isomer·Cu(II) complexes and analyzed by computer simulation.

Photoisomerization and Kinetic Measurements. A 100-W high-pressure Hg-lamp with a color glass filter ($330<\lambda<380$ nm) was used for the trans-to-cis photoisomerization. The thermal cis-to-trans isomerization was followed spectrophotometrically at 30 °C by monitoring the appearance of the absorption maximum of trans-isomers. The details of the method have been described.[16,17] The thermal isomerization of *cis*-AzoIDA(n=1) in the presence of metal ions was very slow. At [Zn(II)]/[AzoIDA(n=1)]=1.0, for example, the $(A_\infty-A_0)/(A_\infty-A_t)$ after 48 h was only 1.014. We

[†] 1 M=1 mol dm^{-3}.

thus calculated the first-order rate constant (k) for this system from about 2% change in the optical density. Other systems gave much greater spectral changes, so that the k values could be determined by a usual first-order rate equation.

Estimation of Stability Constants. A displacement method was employed to estimate the stability constants of AzoIDA(n=1,2) and AzoED(n=1,2).[28] Eriochrome Black T (EBT) and 1-(2-pyridylazo)-2-naphthol (PAN) were used as indicators for Zn(II)- and Cu(II)-complexes, respectively: log K_{EBT}=10.4 for Zn(II) and log K_{PAN}=12.6 for Cu(II).[29,30] The employed wavelengths were 650 nm for EBT-Zn(II) and 550 nm for PAN-Cu(II). For an equilibrium in Eq. 1, one can derive Eq. 2 where K_e is the displacement equilibrium constant and K_I and K_s are the stability constants of I (indicator) and L (ligand), respectively.[28]

$$\text{I}\cdot\text{M(II)} + \text{L} \overset{K_e}{\rightleftharpoons} \text{I} + \text{L}\cdot\text{M(II)} \quad (1)$$

$$K_s = K_e \cdot K_I \quad (2)$$

As the indicators have the stability constants greater than 10^{10} M^{-1}, one can consider that the indicator and the metal ion (added in a 1:1 mole ratio) totally exist as the complex form. Thus, the degree of the spectral change induced by ligand addition is readily ascribed to the production of the free indicator. From this spectral change one can estimate the K_e for trans-isomers.[28] In the present system, however, one should pay attention to the possibility that AzoIDA and AzoED may form L·M(II)$_2$ in addition to L·M(II). In order to obviate this problem we employed excess L over M(II) (see Tables 4 and 5).

The analysis of the spectral change induced by the addition of the cis/trans mixture is more complex. The magnitude of the spectral change (ΔOD_{photo}) can be regarded as the sum of ΔOD_{trans} and ΔOD_{cis}. That is,

$$\Delta OD_{photo} = \frac{\text{trans}\%}{100}\cdot\Delta OD_{trans} + \frac{\text{cis}\%}{100}\cdot\Delta OD_{cis} \quad (3)$$

Since trans%, cis%, and ΔOD_{trans} are known, one can estimate ΔOD_{cis} which corresponds to hypothetical ΔOD induced by the "pure" cis-isomer. By using ΔOD_{cis} thus estimated, we calculated K_e and K_s for cis-isomers.

In a separate study, we determined the K_s for iminodiacetic acid and ethylenediamine by a titration method and a displacement method.[28,31] The K_s values determined by two different methods agreed with the satisfactory accuracy (see Tables 4 and 5). The K_s values determined by the displacement method are therefore reliable.

Results and Discussion

Effects of Metal Ions on Photo and Thermal Isomerization. The spectroscopic properties of AzoIDA and AzoED are summarized in Table 1. These compounds gave two absorption bands at around 330 nm and 427 nm, which are attributed to π-π* and n-π* transition, respectively. The photoisomerization was carried out using a 100-W high-pressure Hg-lamp equipped with a colored glass filter (330<λ<380 nm). In aqueous solution buffered to pH 9.02, the isomerization reached a photostationary state after 5 min.

Table 1. Spectroscopic properties and photoisomerization of AzoIDA and AzoED[a]

Ligand	λ_{max}/nm		ε_{max} of π-π*	*cis/trans*
	π-π*	n-π*	/cm^{-1}M^{-1}	
trans-AzoIDA(n=1)	329	428	25200	61/39
trans-AzoIDA(n=2)	332	426	24000	63/37
trans-AzoED(n=1)	333	427	19400	66/34
trans-AzoED(n=2)	333	426	19300	67/33

a) pH 9.02 with 0.01 M NH_3 buffer, μ=0.10 with KCl.

The cis/trans ratios are collected in Table 1. The cis concentration at the photostationary was not affected in the presence of an equimolar amount of $ZnSO_4$. In the dark in the absence of metal ions, the cis-isomers isomerized, although very slowly, to the corresponding trans-isomers and the initial spectra of the trans-isomers were regenerated. The appearance of the absorption maximum of the trans-isomers satisfied a first-order rate equation for up to three-half lives. The first-order rate constants (k) were obtained by analyzing the time-dependence.

We previously investigated the metal effect on the photoresponsive behaviors of azobis(benzocrown ether)s.[17,32] It has been found that in the presence of metal ions which can form intramolecular 1:2 metal/crown sandwich-type complexes with cis-isomers, the rate of the thermal cis-to-trans isomerization is suppressed. This novel phenomenon is attributed to the "lock-in" effect of metal ions flanked by two crown rings. That is, an additional free energy of activation is required for the cis-to-trans isomerization process, which reflects the need to disrupt favorable interactions between the metal ion and the crown ethers. In contrast, such an inhibitory effect was not seen for an analogous photoresponsive crown ether in which crown ether groups are linked to the two sides of an azobenzene *via* methylene spacers (*i.e.*, CrCH_2-*p*-C_6H_4-N=NC_6H_4-*p*-CH_2Cr where Cr denotes monoaza-15-crown-5).[33] Probably, free-rotating methylene spacers act as an absorber of the geometrical change occurring at the N=N bond. One may conclude, therefore, that the "lock-in" effect is operative only in fairly rigid molecules.

In AzoIDA and AzoED, ligand groups are linked to an azobenzene *via* methylene or ethylene spacers. Nevertheless, we observed that the rates of thermal cis-to-trans isomerization are efficiently inhibited by Zn(II) and Cu(II). The inhibitory effect of Zn(II) is illustrated in Fig. 1. The rates for AzoIDA were strongly inhibited by Zn(II) and the plots provided a minimum at [Zn(II)]/[AzoIDA]=1.0. This may be taken as evidence that both *cis*-AzoIDA(n=1) and *cis*-AzoIDA(n=2) form intramolecular 1:1 metal/ligand complexes: that is, two intramolecular iminodiacetate moieties coordinate to one Zn(II) ion. This finding is in agreement with the conclusion obtained from a polarographic study.[23] The slight rate increase at

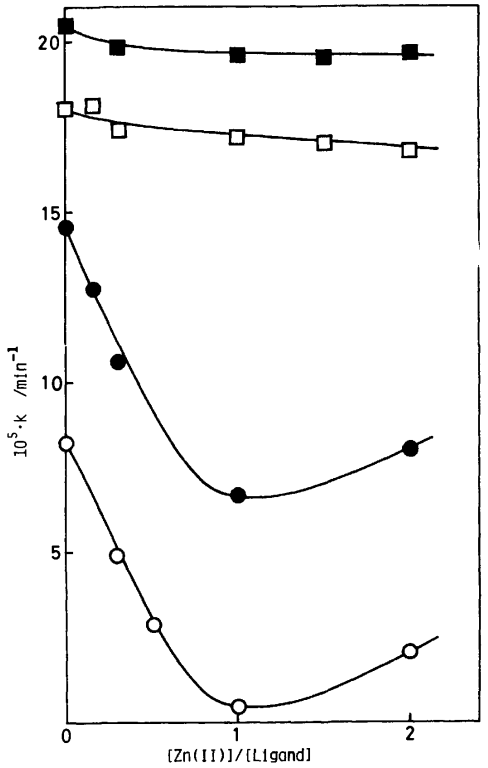


Fig. 1. Influence of added $ZnSO_4$ on the first-order rate constants for the thermal cis-to-trans isomerization. 30 °C, pH 9.02 with 0.01 M NH_3 buffer, μ= 0.10 with KCl, [ligand]=1.67×10^{-5} M.
○: AzoIDA(n=1), ●: AzoIDA(n=2), □: AzoED(n= 1), ■: AzoED(n=2).

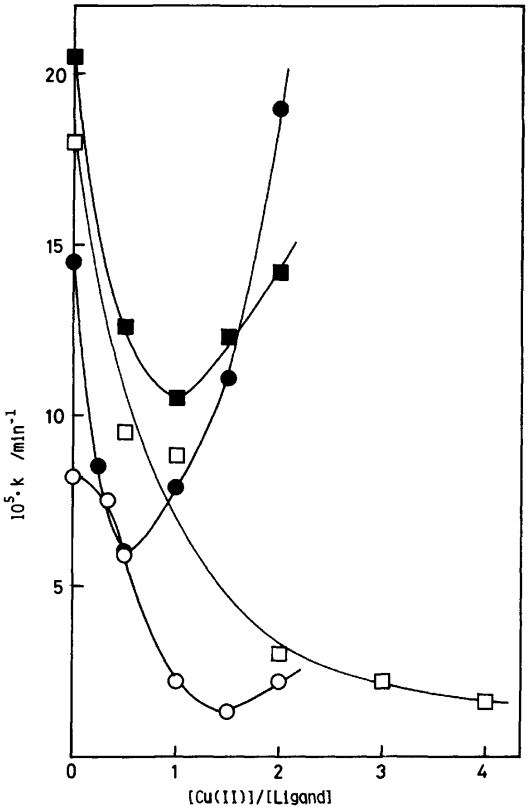

Fig. 2. Influence of added $CuSO_4$ on the first-order rate constants for the thermal cis-to-trans isomerization. The reaction conditions and symbols are identical to those in Fig. 1.

TABLE 2. PSEUDO-FIRST-ORDER RATE CONSTANTS(k) FOR THE THERMAL CIS-TO-TRANS ISOMERIZATION[a]

Ligand	$10^5 \cdot k$/min^{-1}		
	No metal	Zn(II)[b]	Cu(II)[b]
AzoIDA(n=1)	8.2	0.5	2.2
AzoIDA(n=2)	14.5	6.7	7.9
AzoED(n=1)	18.0	17.2	8.8
AzoED(n=2)	20.5	19.6	10.5

a) 30 °C, pH 9.02 with 0.01 M NH_3 buffer, μ=0.1 with KCl, [ligand]=1.67×10^{-5} M. b) [Zn(II) or Cu(II)] /[ligand]=1.00.

[Zn(II)]/[AzoIDA]>1 may be attributed either to the catalytic effect of Zn(II) on the thermal isomerization through the Zn(II)-azo interaction[27,35] or to the electrostatic repulsion between two Zn(II) ions[32] if *cis*-AzoIDA·$Zn(II)_2$ is formed at [Zn(II)]>[AzoIDA]. In contrast, the rates of AzoED were scarcely affected by Zn(II). The marked difference between AzoIDA and AzoED is probably rationalized in terms of low affinity of "soft" ethylenediamines with "hard" Zn(II) ion. In fact, AzoED gave the K_s much smaller than AzoIDA (*vide post*).

The k values at [Zn(II)]/[ligand]=1.0 are summarized in Table 2. The k observed for *cis*-AzoIDA(n=1)+ Zn(II)(5×10^{-6} min^{-1}) is the smallest rate constant we have ever observed: thus, extra free energy of activation ($\Delta\Delta G^{\ddagger}=\Delta G^{\ddagger}_{\text{no metal}}-\Delta G^{\ddagger}_{\text{Zn(II)}}$) required to disrupt the interaction between Zn(II) and the iminodiacetate moieties is roughly estimated to be 7.1 kJ mol^{-1}. This value is comparable with those required to disrupt the interaction between *cis*-azobis(benzocrown ether)s and alkali metal ions (2.5—7.1 kJ mol^{-1}).[17,32] The fact that the thermal isomerization of *cis*-AzoIDA is efficiently inhibited in spite of the presence of the spacers suggests that the Zn(II)iminodiacetate interaction should be stronger than the alkali metal-crown interaction, because the inhibitory effect in the latter system has disappeared in the presence of the spacers.[33]

The effect of Cu(II) on the thermal cis-to-trans isomerization is illustrated in Fig. 2. The most distinct difference from Fig. 1 is that Cu(II) can suppress not only the thermal isomerization of *cis*-AzoIDA but also that of *cis*-AzoED. Conceivably, "soft" Cu(II) can interact with the ethylenediamine moieties more strongly. However, the k values for *cis*-AzoIDA are still smaller than those for *cis*-AzoED. It is interesting to note that the ligand which has the relatively small rate constant gives the large K_s (see Table 5).

Here, one may notice that the plots in Fig. 2 are more complex than those in Fig. 1 and the rate minimum does not always appear at [Cu(II)]/[ligand]=1.0. The complexity is associated with overlapping of two

contrasting effects of Cu(II): that is, an inhibitory effect due to intramolecular chelation and an accelerative effect due to interaction between Cu(II) and the azo linkage.[27,34] We have examined the catalytic effect of various metal ions on the thermal cis-to-trans isomerization of *cis*-azobenzene derivatives.[27,35] Among metal ions tested therein, Cu(II) exerted the greatest accelerative effect while Zn(II) acted as very weak catalyst.

The plots of k *vs.* [Cu(II)]/[ligand] for *cis*-AzoIDA-(n=1), *cis*-AzoIDA(n=2), and *cis*-ED(n=2) provided a minimum, whereas the plot for *cis*-AzoED(n=1) decreased monotonously with increasing Cu(II) concentration. It is also seen from Fig. 2 that after experiencing a minimum, the rate constants for n=2 series are enhanced at high Cu(II) concentrations. In contrast, the accelerative effect of Cu(II) ion is scarcely operative on n=1 series. Examination of CPK models suggests that the intramolecular complexes with the n=1 cis-isomers are more rigid than the corresponding complexs with the n=2 cis-isomers. In fact, the complexes of n=2 series showed a considerable flexibility due to ethylene spacers. The absence of the accelerative effect on n=1 series implies, therefore, that in *cis*-azobenzenes rigidified through metal complexation, the thermal isomerization is rather insusceptible to the metal catalysis.

ESR Spectra of cis-Isomer·Cu(II) Complexes. Subsequently, we measured the ESR spectra of *cis*-isomer·Cu(II) complexes in order to obtain a further insight into the coordination structure. Practically, the ESR spectra were measured for the mixture of trans- and cis-isomers. The process we obtained the spectra of "pure" cis-isomer·Cu(II) complexes is following (Fig. 3): first, we measured the ESR spectra of trans-isomer·Cu(II) complexes and then eliminated this spectra from the observed spectra taking trans% at the photostationary state (see Table 1) into account. The remaining spectra which can be regarded as those of "pure" cis-isomer·Cu(II) complexes were analyzed by computer simulation. The results are summarized in Table 3 and Fig. 4.

Examination of Table 3 and Fig. 4 reveals that basically, all Cu(II) complexes adopt square-planar or octahedral coordination, but the xy planes are somewhat distorted from a neat square-planar structure because the third g value is required in order to fully simulate the spectra. Probably, the xy planes of the cis-isomer·Cu(II) complexes are more or less close to a lozenge.

With respect to g_1 in *cis*-AzoIDA, the g_1 for n=1 is somewhat greater than that for n=2, while the reverse is true in *cis*-AzoED. This difference may be rationalized in connection with the spacer effect. Provided that the nitrilo nitrogens in *cis*-AzoIDA(n=1) cannot coordinate to central Cu(II) because of steric hindrance, it serves as a tetradentate ligand. In this case, the g_1 for *cis*-AzoIDA(n=1) reflects the axial coordination of solvent or buffer base(NH_3). On the other hand, *cis*-AzoIDA(n=2) possibly serves as a hexadentante ligand owing to the flexibility increased by the ethylene spacers, and the g_1 would reflect the axial coordination of intramolecular ligand groups. In fact, *cis*-AzoIDA(n=1) shows an ESR pattern characteristic of square-planar coordination, whereas that of *cis*-AzoIDA(n=2) is rather close to octahedral coordination. It is very likely, therefore, that the distance from central Cu(II) to the intermolecular ligand is longer than that to the intramolecular one. On the other hand, *cis*-AzoED(n=2) has the g_1 greater than *cis*-AzoED(n=1). Since *cis*-AzoED series act as tetradentate ligands, the g_1 values are definitely governed by

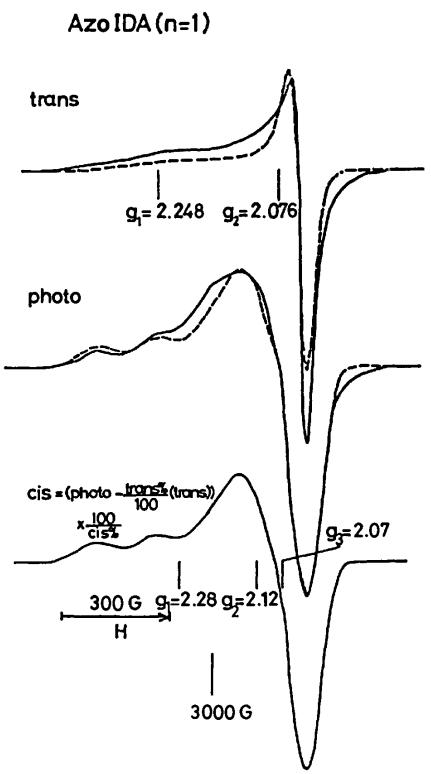

Fig. 3. ESR simulation of the "pure" *cis*-AzoIDA(n=1)·Cu(II) complex. The spectrum of *trans*-AzoIDA(n=1)·Cu(II) could be simulated by using two g values. The spectrum of *cis*-AzoIDA-(n=1)·Cu(II) was obtained by subtracting this spectrum from photo spectrum observed under photoirradiation.

TABLE 3. ESR PARAMETERS FOR THE cis-isomer·Cu(II) COMPLEXES[a]

Ligand	g value		
	g_1	g_2	g_3
cis-AzoIDA(n=1)	2.28	2.12	2.07
cis-AzoIDA(n=2)	2.23	2.15	2.06_5
cis-AzoED(n=1)	2.20	2.10	2.05_5
cis-AzoED(n=2)	2.34	2.10	2.05_2

a) −50 °C, [ligand]=5.00×10^{-4} M, [$CuSO_4$]=5.00×10^{-4} M, pH 9.02 with 0.01 M NH_3 buffer, μ=0.1(KCl).

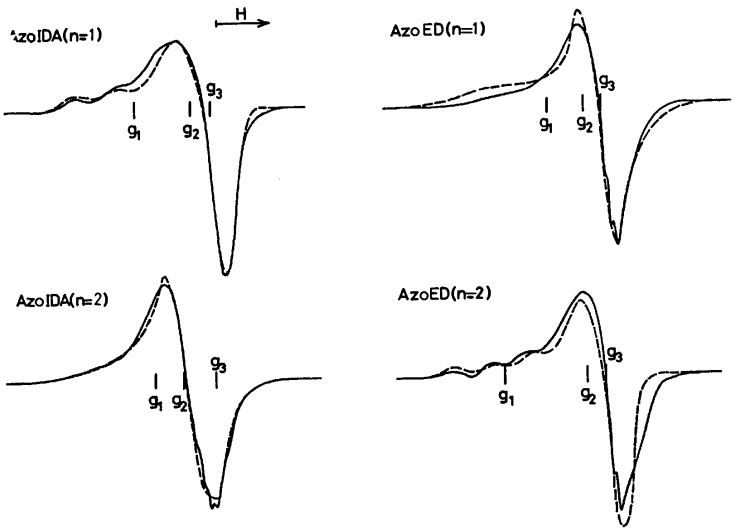

Fig. 4. ESR spectra (solid line) and simulated spectra (dotted line) of the Cu(II) complexes with the photoirradiated ligands. The g values inserted in the figure are those determined for the "pure" cis-isomer·Cu(II) complexes. −50 °C, [ligand]=5.00× 10^{-4} M, pH 9.02 with 0.01 M NH_3 buffer, μ=0.1(KCl).

Table 4. Displacement equilibrium constants (K_e) and stability constants (K_s) of AzoIDA and AzoED for Zn(II)[a]

Ligand	K_e		$10^{-8}\cdot K_s/M^{-1}$	
	dark or trans-isomer	cis-isomer	dark or trans-isomer	cis-isomer
$HN(CH_2COOH)_2$	1.71×10^{-3}	—	0.43[b]	—
AzoIDA(n=1)	0.230	0.327	57.8	82.1
AzoIDA(n=2)	1.86	3.30	467	829
$H_2N(CH_2)_2NH_2$	8.36×10^{-5}	—	0.021[c]	—
AzoED(n=1)	1.10×10^{-3}	1.95×10^{-3}	0.28	0.49
AzoED(n=2)	4.00×10^{-3}	0.0188	1.00	4.72

a) pH 9.02 with 0.01 M NH_3 buffer, μ=0.10 with KCl, [EBT]=[$ZnSO_4$]=3.00×10^{-6} M, [ligand]=1.50×10^{-5} M. b) K_s=2.75×10^7 M^{-1} from titration. c) K_s=1.26×10^6 M^{-1} from titration.

Table 5. Displacement equilibrium constants (K_e) and stability constants (K_s) of AzoIDA and AzoED for Cu(II)[a]

Ligand	K_e		$10^{-9}\cdot K_s/M^{-1}$	
	dark or trans-isomer	cis-isomer	dark or trans-isomer	cis-isomer
$HN(CH_2COOH)_2$	7.32×10^{-4}	—	2.91[b]	—
AzoIDA(n=1)	0.0163	0.0226	64.9	89.9
AzoIDA(n=2)	0.0180	0.0376	71.7	150
AzoED(n=1)	1.18×10^{-4}	7.70×10^{-4}	0.47	3.06
AzoED(n=2)	3.02×10^{-4}	0.0132	1.20	52.5

a) pH 9.02 with 0.01 M NH_3 buffer, μ=0.10 with KCl, [PAN]=[$CuSO_4$]=3.14×10^{-6} M, [ligand]=3.05×10^{-4} M. b) K_s=4.79×10^9 M^{-1} from titration.

the axial coordination of solvent or buffer base. The g_1(=2.34) for *cis*-AzoED(n=2) much greater than others is characterized by the elongation of the distance from Cu(II) to the axial ligand. This may be induced by the stable coordination of the ethylenediamine moieties in the xy plane which is brought forth by the ethylene spacers. In fact, the K_s for *cis*-AzoED(n=2) was much greater than that for *cis*-AzoED(n=1) (*vide post*).

These findings consistently suggest that the structure of the cis-isomer·Cu(II) complexes is significantly affected by the spacer length.

Photoresponsiveness of Stability Constants. The stability constants (K_s) were determined according to a displacement method[28] and are summarized in Tables 4 and 5 together with the displacement equilibrium constants (K_e). Since one of our objects is to

specify whether or not the amine nitrogens in AzoIDA can contribute to the complex formation, we evaluated the K_s at pH 9.02 where they are mostly dissociated.[31] As reference ligands, we employed Eriochrome Black T (EBT) and 1-(2-pyridylazo)-2-naphthol(PAN) for Zn(II) and Cu(II), respectively. Further details of the experimental methods and measurement conditions are described in Experimental and footnotes to Tables 4 and 5. In order to give full assurance to this method, we determined the K_s for iminodiacetic acid and ethylenediamine by a titration method.[28,31] The K_s values determined by two different methods agreed within the allowable error (see Tables 4 and 5). Therefore, the displacement method with EBT and PAN is reliable enough to make discussions on the photoirradiation effect. Here, note that we have defined K_s= [M(II)·AzoIDA(or AzoED)]/[M(II)][AzoIDA(or AzoED)].

Blank *et al.*[23] who first synthesized AzoIDA(n=1) reported that (i) *cis*-AzoIDA(n=1) forms an intramolecular 1:1 metal/ligand complex with Zn(II), (ii) the K_s for *cis*-AzoIDA(n=1)+$ZnSO_4$ determined in aqueous solution (no buffer) is $1.1\times10^5\,M^{-1}$, and (iii) *trans*-AzoIDA (n=1) scarcely interacts with Zn(II). The last conclusion sounds a little strange, because it has been established that iminodiacetic acid and its derivatives usually have the K_s of 10^7—$10^9\,M^{-1}$.[31] As shown in Table 4, the K_s values for AzoIDA+Zn(II) determined in buffered (pH 9. 02) aqueous solution lie between 8.13×10^9—$1.16\times10^{11}\,M^{-1}$ and those for AzoED+Zn(II) between 3.0×10^7—$4.64\times10^8\,M^{-1}$.[36] As for the association with Zn(II), the marked photoresponsive difference reported by Blank *et al.*[23] could not be realized under the present conditions. Detailed examination of Table 4 indicates, however, that the K_s values for AzoIDA(n=1), AzoIDA(n=2), and AzoED(n=1) are enhanced by 1.4—1.8 fold by photoirradiation, and that for AzoED(n=2) is further enhanced (4.7 fold). The slight but perceptible improvement in *cis*-AzoED(n=2) may be ascribed to superiority of the ethylene spacer over the methylene spacer to form the intramolecular complexes.

It is known that Zn(II) absolutely favors the tetrahedral coordination. On the other hand, the ESR studies established that all Cu(II) complexes tested herein adopt the planar coordination. Examination of CPK models suggests that one can easily make the molecuar models of either tetrahedral or planar coordination from n=2 series, whereas it is pretty difficult to make the molecular models of planar coordination from n=1 series without any steric distortion. One may expect, therefore, that the effect of the spacer length appears more clearly in the association with Cu(II). As recorded in Table 5, the photoinduced K_s increases are relatively small for AzoIDA(1.4-fold for n=1 and 2.1-fold for n=2). The lack of the spacer effect is probably rationalized as follows: the K_s values for *cis*-AzoIDA are primarily governed by the interaction with four carboxyl groups and the interaction with the amines exerts only the additional stabilization effect. Thus, the K_s values are scarcely changed by the spacer length. In contrast, the distinct spacer effect was observed for AzoED: the photoirradiation increases the K_s values for AzoED(n=1) and AzoED(n=2) by factors of 6.5 and 43.8, respectively, and the K_s for *cis*-AzoED-(n=2) is 17 times greater than that for *cis*-AzoED(n=1). The K_s for *cis*-AzoED is crucially governed by whether or not the four nitrogens can coordinate intramolecularly to one Cu(II) ion. In other words, when the coordination of two nitrogens close to the benzene ring accompanies some steric distortion (probably, *cis*-AzoED(n=1) is the case), it directly leads to the lowering of K_s. Consequently, *cis*-AzoED(n=2) having the longer spacer becomes more advantageous in the intramolecular complexation to one Cu(II) ion. These findings suggest that in order to realize the large spacer effect, the heteroatom which has a straightforward influence on the complex formation should be placed next to the spacer moiety.

Conclusion. The present study has demonstrated that the stability constants for typical complexones such as iminodiacetic acid and ethylenediamine can be photocontrolled by means of induced structural changes arising from the photoisomerization of azobenzene. Although several examples for photoresponsive binding of alkali and alkaline earth metal ions have been reported, few examples ever exist for photoresponsive binding of heavy metal ions. This study newly suggests, although the reversibility of the photoinduced isomerization in the presence of metal ions is not fully studied in this paper, possible applications of photoresponsive complexones to ion-extraction, ion transport, light-driven ion pumps, *etc.*

We thank Mr. Yoshihiro Honda and Miss K. Ueda for technical assistance. This work was supported by the Grant-in-Aid for the Special Project Research on the Properties of Molecular Assemblies (No. 59212033) from the Ministry of Education, Science and Culture.

36) These K_s values are somewhat greater than those determined for iminodiacetic acid and ethylenediamine. The reason is not clear at the present time but a similar trend was observed for analogous ligands:[37] that is, the K_s values of 1,3- and 1,4-bis[bis(carboxymethyl)amino]cyclohexane for Mg(II) and Ca(II) are greater by 10—10^2 fold than those of iminodiacetic acid. One possible rationale is that these *trans*-isomers may form the polymeric, intermolecular complexes.

The Crystal and Molecular Structure of *syn*-[2.2](1,4)-Anthracenophane and Its Photoisomer

Toshihiro TOYODA, Nobutami KASAI,*,† and Soichi MISUMI*

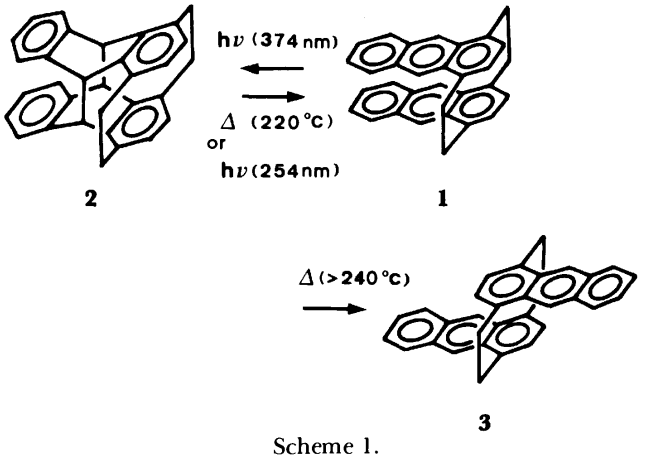
The Institute of Scientific and Industrial Research, Osaka University, Ibaraki, Osaka 567

†*Department of Applied Chemistry, Faculty of Engineering, Osaka University, Suita, Osaka 565*

(Received March 18, 1985)

Molecular structure of *syn*-[2.2](1,4)anthracenophane (**1**) and its photoisomer (**2**) have been determined by means of X-ray diffraction; **1**, monoclinic, space group A2, a=25.539(2), b=8.152(1), c=20.561(3) Å, β=106.03(1)° (−149 °C), Z=8; **2**, monoclinic, space group $P2_1/c$, a=8.065(6), b=12.963(9), c=19.580(5) Å, β=91.46(5)°, Z=4. The structure of **1** was solved by the vector search method and **2** by the direct method. Both structures were refined including all hydrogen atoms by the block-diagonal least-squares procedure: R=0.053 and 0.043 for 4413 and 2003 observed reflections for **1** and **2**, respectively. Two anthracene nuclei, connected by ethylene bridges at the 1 and 4 positions, in each of the two independent molecules (A and B) of **1** are approximately parallel. However, their overlappings differ slightly. In the photoisomer **2** the two anthracene nuclei are bound by newly formed bonds at the 9 and 10 positions: bond distances are 1.628(5) and 1.637(5) Å whereas the corresponding nonbonded distance in **1** are 3.312(6) and 3.301(6) Å (A molecule) and 3.357(6) and 3.366(6) Å (B molecule).

Previously, the preparation of *syn*-[2.2](1,4)anthracenophane (**1**), its photoisomer (**2**), and *anti*-[2.2](1,4)-anthracenophane (**3**) by pyrolysis of ammonium base and interesting photochemical interconversion of **1** and **2** have been reported.[1]



Scheme 1.

Each of the anthracenophane isomers contains anthracene nuclei with ethylene bridges at their 1- and 4-carbon atoms. They are of special interest for studying transannular electronic interaction and steric effect. Spectral properties of these isomers have been studied. The *syn*-[2.2](1,4)anthracenophane, **1**, shows an excimer fluorescence spectrum, with shorter life time, in longer wavelength region than the other anthracenophane, *anti*-[2.2](1,4)anthracenophane, **3** and [2.2](1,4)-(9,10)anthracenophane, and anthracene excimer.[2] On the other hand, [2.2](9,10)anthracenophane gives no fluorescence spectrum. The comparison of these fluorescence spectra indicates distinctly that the nonbonded distance between the active sites, 9- and 10-positions, of two anthracene nuclei is the most important factor to solve a relationship between the excimer structure and fluorescence spectrum.

As the structure difference of the molecules before and after the photoisomerization is also of much interest, this paper deals with the X-ray crystal structure analysis of *syn*-[2.2](1,4)anthracenophane†† and its photoisomer.††† A brief account of the *syn*-anthracenophane structure[3] and a profile of both structures[4] have been reported.

Experimental

Crystal Data. (**1**) *syn*-Anthracenophane, $C_{32}H_{24}$, M=408.5, monoclinic, space group A2, a=25.344(5), b=8.1340(2), c=20.743(4) Å, β=104.80(15)°, V=4238.9(15) Å^3, D_m=1.29 g cm^{-3}, D_c=1.280 g cm^{-3} for Z=8 (room temperature); a=25.539(2), b=8.152(1), c=20.561(3) Å, β=106.03(1)°, V=4114.3(9) Å^3, D_c=1.319 g cm^{-3} for Z=8 (−149 °C). (**2**) Photoisomer, $C_{32}H_{24}$, M=408.5, monoclinic, space group $P2_1/c$, a=8.065(5), b=12.963(9), c=19.580(5) Å, β=91.46(5)°, V=2046.3(12) Å^3, D_m=1.32 g cm^{-3}, D_c=1.323 g cm^{-3} for Z=4 (room temperature).

Oscillation and Weissenberg photographs determined the possible space group for *syn*-anthracenophane as A2 (No. 5), Am (No. 8), or A2/m (No. 12) (absent reflections; hkl: $k+l=2n+1$) and that for photoisomer as $P2_1/c$ (No. 14) (absent reflections; $h0l$: $l=2n+1$, $0k0$: $k=2n+1$). Unit-cell dimensions and reflection intensities were measured on a Rigaku automated four-circle diffractometer using Mo $K\alpha$ radiation (λ=0.71069 Å).

The θ—2θ scan technique was employed for the intensity data collection at a 2θ rate of 2° min^{-1}. The scan width was from $\{2\theta(\alpha_1)-0.7\}$ to $\{2\theta(\alpha_2)+0.7\}$°. Backgrounds were measured for 10 s at both ends of a scan. Three standard reflections measured after every 50 reflections to monitor the stability and orientation of the crystal showed no significant decay throughout the data collection.

syn-Anthracenophane: The intensity measurement was first carried out at room temperature, but later at −149 °C, in a dark room in order to avoid the photochemical cycloaddition of the present compound. The low temperature data were used for the structure analysis. In total 4477 independent

††Called as *syn*-anthracenophane hereafter.

†††Called as photoisomer hereafter.

reflection data were collected ($2\theta \leqq 100°$), of which 4413 could be observed ($|F_o| \leqq 3\sigma(F_o)$). Low temperature was attained by the gas flow method of liquid nitrogen.

Photoisomer: A total of 3740 independent reflections was measured at room temperature($2\theta \leqq 100°$), of which 2003 were non-zero reflections.

Intensity data of both crystals were corrected for usual Lorents and polarization effects but not for absorption [μ(Mo $K\alpha$)=0.767 and 0.785 cm^{-1} for *syn*-anthracenophane and photoisomer, respectively.]

Structure Solution and Refinement

The structures of *syn*-anthracenophane and photoisomer were solved by the Patterson function and direct method, respectively. Both structures were refined anisotropically by the block-diagonal least-squares procedure (*HBLS* V).[5]

syn-*Anthracenophane*: The unit-cell has a short b axis and contains eight molecules. Of the three possible space groups, Am and A2/m could be excluded by considering the packing of molecules with expected dimensions. The structure was then solved by assuming the space group as A2, which was later proved correct by the structure determined. Trials to establish the structure by the *MULTAN* program[6] were not successful. The deduction of the structure was then carried out by translational and rotational operations in the Patterson function with the idealized model structure constructed by referencing the structure of a similar compound, [2.2](9,10)anthracenophane.[7] The position of one of the two independent molecules (A molecule) in an asymmetric unit could be deduced. The other molecule (B molecule) was located on the Fourier map computed by using atomic parameters of carbon atoms of the A molecule. Hydrogen atoms of the two molecules were located by geometrical consideration, and they were refined isotropically. Final R index was 0.053 for observed reflections. The weighting scheme used at the final stage of the refinement was $w=\{\sigma^2(F_o)+0.04756|F_o|+0.00017|F_o|^2\}^{-1}$, where σ is the standard deviation obtained from the counting statics. The final atomic parameters are listed in Table.††††

Photoisomer: From the Wilson plot average temperature factor and scale factor were obtained. The $\sum_2$ formula was applied to 795 normalized structure factor magnitudes $|E|$'s($|E| \leqq 1.2$) in order to establish the phase relationship by the symbolic addition method.[9] One of the two E maps, respectively synthesized by two possible sets of signs of 277 reflections, could locate the 32 carbon atoms. The structure was first refined isotropically. Anisotropic temperature factors were then assigned for the carbon atoms, and the structure was refined with unit weight. Hydrogen atoms located on the difference Fourier map was in-

††††Tables of observed and calculated structure factors and anisotropic thermal parameters are kept at the Chemical Society of Japan, Document No. 8541.

cluded in the refinement with isotropic temperature factors. Finally, the refinement converged with R= 0.043 for non-zero reflections. The atomic parameters are given in Table 2.††††

Atomic scattering factors for the carbon and hydrogen atoms were first taken from those of T. Suzuki[10] and at the final stage from International Tables for X-Ray Crystallography.[11] Computations were done mainly on a NEAC2200-700 computer at the Computation Center, Osaka University. At the final stage, an ACOS 850 computer was used at the Crystallographic

Results and Discussion

Molecular Structure. Perspective views (*ORTEP* drawing)[12] of *syn*-anthracenophane and photoisomer molecules with atom labelling, are shown in Figs. 1 and 2, respectively. Bond distances and bond angles of both compounds are listed in Table 3.

syn-*Anthracenophane*: As seen in Fig. 1, the feature of the molecular structure is that two anthracene nuclei are closely placed in nearly parallel. All of the four anthracene nuclei in two crystallographically independent A and B molecules have normal bond distances and bond angles. However, each of the ethylene-bridged benzene rings is boat-shaped as those in [2.2]paracyclophane[13] and layered paracyclophanes.[14]

The four C_{sp^3}–C_{sp^3} bonds of ethylene bridges, 1Cl–2Cl [1.588(6)Å], 1C6–2C6[1.597(6)Å], 3Cl–4Cl[1.585(5)Å], and 3C6–4C6[1.598(5)Å] are elongated by 0.02 to 0.04Å than the corresponding bonds of [2.2](9,10)anthracenophane[7] and [2.2]paracyclophane.[13]

As side view of each molecule is presented in Fig. 3, in which nonbonded intramolecular atomic distances between anthracene nuclei are given. As shown in Figs. 1 and 3 the structure of the present compound demonstrates that all the anthracene nuclei are approximately in parallel position suitable for forming an excimer and that two anthracene nuclei are mutually overlapped well in the A molecule whereas less in the B molecule. The nonbonded interatomic distances between the two pairs of active sites, C8 and C15 in the largely overlapped A molecule [1C8···2C8= 3.312(6) and 1C15···2C15=3.301(6)Å] are shorter than the van der Waals contact. On the other hand, the less overlapped B molecule shows slightly longer interatomic distances between the corresponding carbon atoms, 3C8···4C8[3.357(6)Å] and 3C15···4C15[3.366(5)Å], which are longer than the 3C7···4C8[3.302(5)Å] and 3C16···4C15[3.256(5)Å], owing to larger mutual displacement of the two anthracene nuclei along their longer axis. However, all of them are longer than the corresponding ones of [2.2](9,10)anthracenophane [both 2.772(3)Å][7] but shorter than that of anthracenophane excimer [~3.5Å].[2] These nonbonded distances between two sp^2 carbon atoms are relatively shorter than the van der Waals distance, which shows considerable overlap between the two $2p_x$ orbitals easy to form a covalent bond. It can be said that the *syn*-anthracenophane molecule has the structure ready for the isomerization to their photoisomers, and *vice versa*.

Photoisomer: The feature of the structure is that, in addition to the ethylene bridge, the 1C8–2C8 and 1C15–2C15 bonds connect the upper and lower dihydroanthracene nuclei tightly, and the end benzene rings are not in parallel (Fig. 4). The 1C8–2C8 and

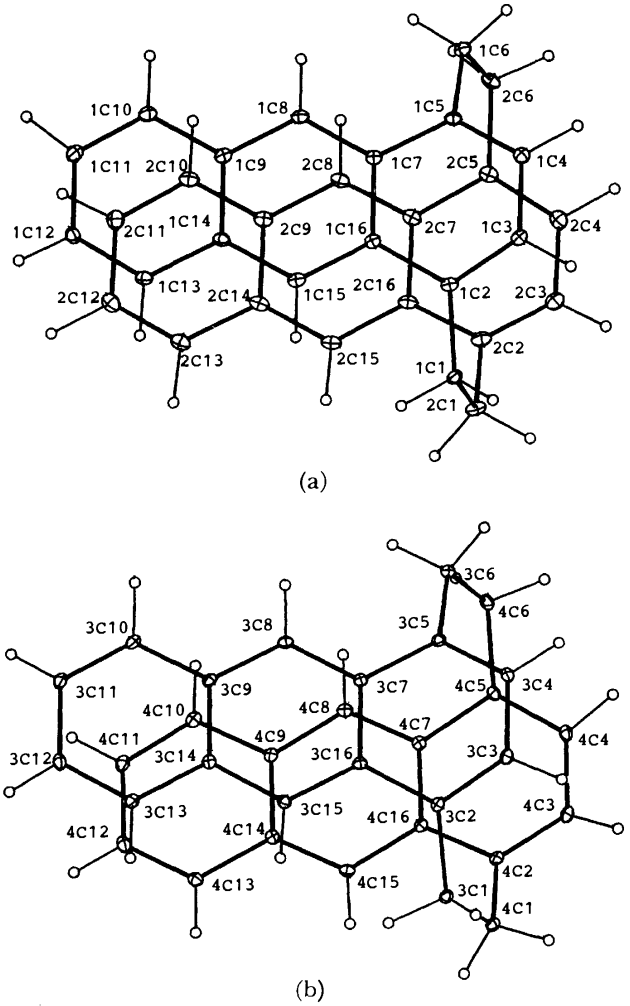

Fig. 1. A. perspective view(*ORTEP* drawing)[12] of *syn*-[2.2](1,4) anthracenophane molecules.
(a): A molecule, (b): B molecule
Non-hydrogen atoms are expressed by thermal ellipsoids with 10% probability level. Hydrogen atoms are drawn as spheres with B=1 Å^2.

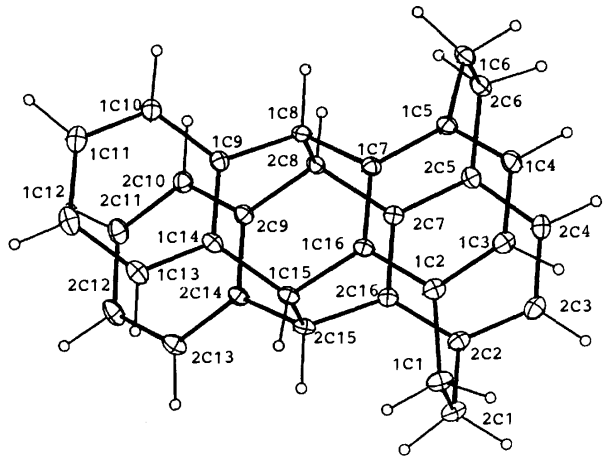

Fig. 2. A perspective view[12] of *syn*-[2.2](1,4) anthracenophane photoisomer molecule.
Non-hydrogen atoms are expressed by thermal ellipsoids with 10% probability level. Hydrogen atoms are drawn as spheres with B=1 Å^2.

1C15-2C15 bond distances are 1.628(4) and 1.637(5) Å, which are very long and comparable to that in [9′,10′]-dihydroanthraceno[9,10]dihydroanthracene[1.61(2) Å].[14]

In the [2.2]paracyclophane moiety at one end of the molecule, the C2-C16[1.404(5) and 1.394(5) Å], C5-C7[1.389(5) and 1.396(5) Å], and C7-C16[1.400(5) and 1.412(5) Å] bond distances are clearly shorter than those in *syn*-anthracenophane. Two benzene rings in this moiety deformed in boat form as in *syn*-anthracenophane and other related compounds. The central C_{sp^3}-C_{sp^3} bonds of the ethylene bridges are equal to those in *syn*-anthracenophane.

In the third benzene rings of the dihydroanthracene nuclei, the C9-C10, C11-C12, C13-C14, and C9-C14 bond distances are respectively shorter, whereas the C10-C11 and C12-C13 distances are longer, than the corresponding distances in *syn*-anthracenophane (Table 3). The bond distances [av. 1.387 and 1.384 Å] and bond angles [av. 120 and 120°] in the third benzene rings are contracted to normal values of the benzene molecule by the photoisomerization.

A side view of the molecule, which can be compared with those of *syn*-anthracenophane (Fig. 3), is depicted in Fig. 4 with nonbonded intramolecular atomic distances. The left half of the present molecule, namely the [2.2]orthocyclophane skeleton, has a similar structure as a half of the [9′,10′]dihydroanthraceno-[9,10] dihydroanthracene. The dihedral angle formed by the end benzene rings is 46.6°, which is equal to that of [9′,10′]dihydroanthraceno[9,10]dihydroanthracene [46°]. In the right half of the molecule, namely the tetra-bridged cyclophane skeleton, the nonbonded 1C7····2C[2.580(4) Å] and 1C16····2C16[2.581(4) Å] distances are shorter by about 0.04 Å than that between the upper and lower benzene rings in [2.2.2.2.2.2](1,2,3,4,5,6)cyclophane[2.624 Å], the closest

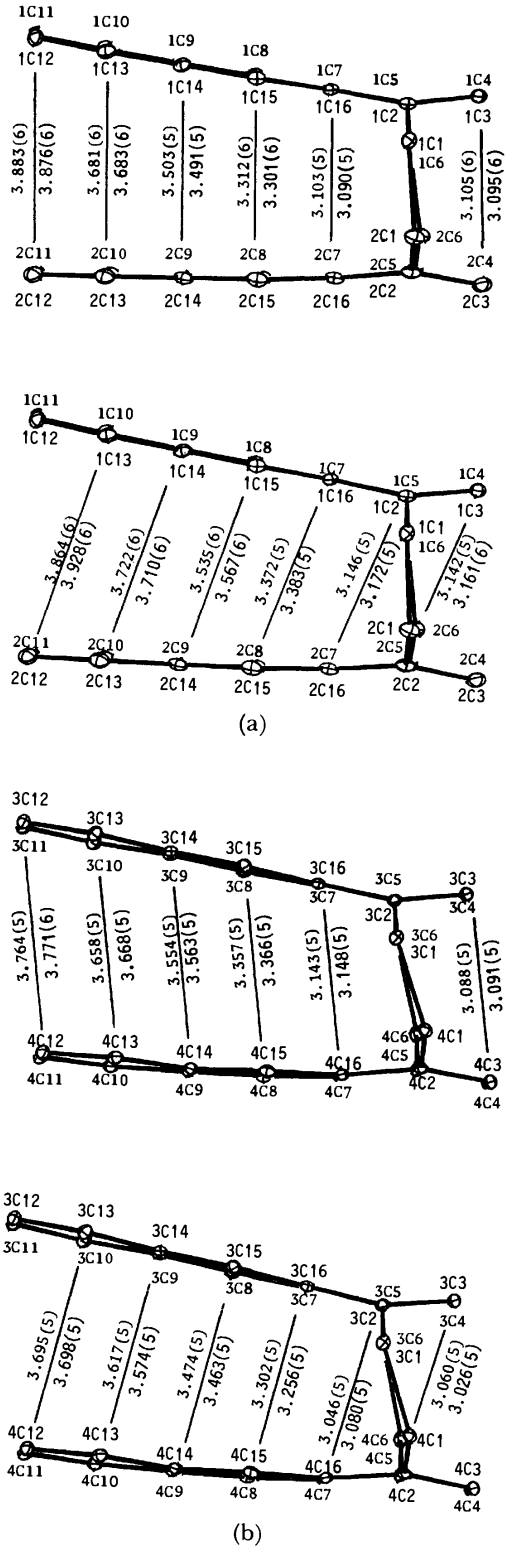

Fig. 3. A side view of *syn*-anthracenophane molecules.[12]

Hydrogen atoms are omitted for clarity. Nonbonded atomic distances(l/Å) are given with their estimated standard deviations in parentheses.

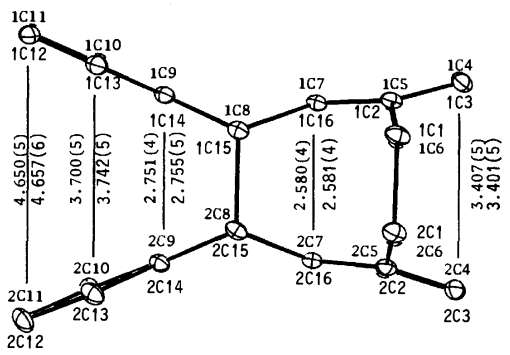

Fig. 4. A side view of *syn*-anthracenophane photoisomer molecules.[12]
Hydrogen atoms are omitted for clarity. Nonbonded atomic distances(l/Å) are given with their estimated standard deviations in parentheses.

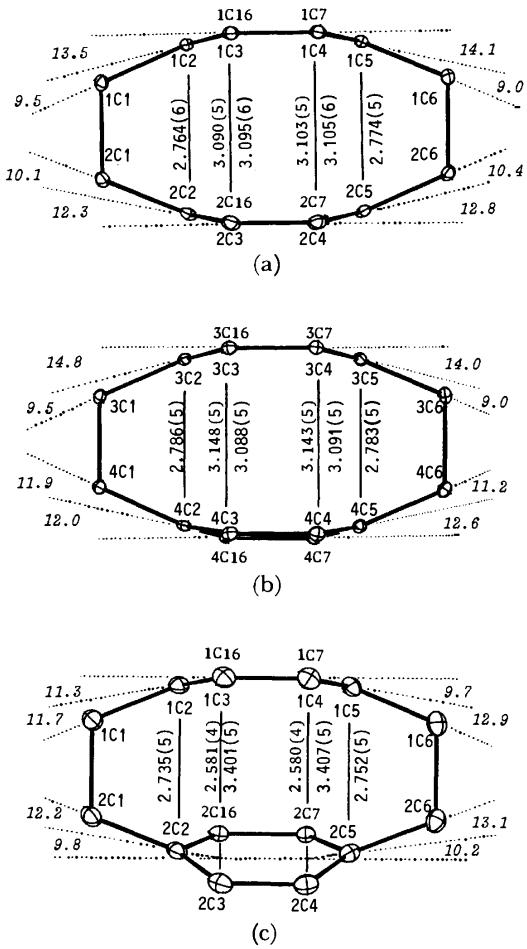

Fig. 5. A comparison of [2.2]paracyclophane moieties in *syn*-anthracenophane and its photoisomer.[12]
Selected interatomic distances [l/Å] are given with their estimated standard deviations in parentheses.
(a): *syn*-Anthracenophane, A molecule, (b): *syn*-Anthracenophane, B molecule, (c): Photoisomer.

distance reported so far. This fact suggests an existence of large strain in the present molecule. One of the chemical proof is that, against the Woodward-Hoffmann rule, by thermal fission of the 1C8–2C8

and 1C15–2C15 bonds the present compound is easily isomerized to *syn*-anthracenophane.

A side view of the [2.2]paracyclophane moiety in the present photoisomer is compared with those of *syn*-anthracenophane in Fig. 5. In the *syn*-anthracenophane the upper and lower benzene rings of this part of the A molecule are parallel and mutually overlapped well (Figs. 3a and 5a), while those of the B molecule not so parallel and not so overlapped well (Figs. 3b and 5b); this difference is caused by a conformational change at ethylene bridges as seen in Fig. 3. Whereas, the [2.2]paracyclophane moiety in the photoisomer shows a large distortion due to the 1C8–2C8 and 1C15–2C15 bonds formation (Figs. 4 and 5c).

Crystal Structure: The packing of molecules in crystals of *syn*-anthracenophane and its photoisomer are respectively given in Figs. 6 and 7 (*ORTEP* drawing).[12] Close intermolecular atomic contacts in these crystals are listed in Table 4.

syn-*Anthracenophane*: Molecules are packed densely. The closest distance between A molecules is 3.400(6) Å and that between B molecules 3.399(5)Å. However, the shortest contact between A and B molecules is 3.539(6)Å, which is slightly longer than the former two.

Photoisomer: A comparatively loose packing of molecules is observed. The closest intermolecular atomic contact is 3.563(7)Å.

The authors are grateful to Miss Nobuko Kanehisa who helped them at the final stage of the computation and for *ORTEP* drawing.

Bitter Principles of *Ailanthus altissima* Swingle. Conversion of Ailanthone into Shinjulactone C[1)]

Masami Ishibashi, Takahiko Tsuyuki,* and Takeyoshi Takahashi*
Department of Chemistry, Faculty of Science, The University of Tokyo, Hongo, Bunkyo-ku, Tokyo 113
(Received April 13, 1985)

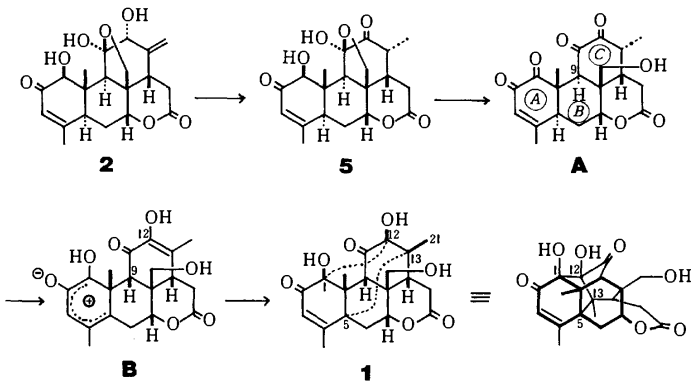
Ailanthone was converted into shinjulactone C with a hexacyclic 1α,12α:5α,13α-dicyclo-9β*H*-picrasane skeleton. The key reaction consists of an intramolecular ionic [4+2] cycloaddition between a pentadienyl cation and an olefin.

In the course of studies on the bitter principles of Simaroubaceous plants, we obtained three new compounds possessing modified picrasane skeletons, shinjudilactone,[2)] shinjulactone B,[3)] and shinjulactone C (**1**),[2)] from *Ailanthus altissima* Swingle (Japanese name: Shinju or Niwaurushi). Structures of these new quassinoids were determined by single crystal X-ray diffraction analyses. These migrated picrasane skeletons are very interesting from the biogenetical view points and stimulated us to study on the backbone-rearrangement reactions leading to the modified picrasanes. Since it seems possible that these migrated quassinoids are biogenetically derived from ailanthone (**2**),[4)] a main quassinoid of this plant, chemical conversions of ailanthone (**2**) into the migrated picrasanes were investigated. In previous papers[2,5)] we have reported a transformation of ailanthone (**2**) into shinjudilactone through benzilic acid rearrangement. This paper deals with chemical conversion of ailanthone (**2**) into shinjulactone C (**1**) with a novel 1α,12α:5α,13α-dicyclo-9β*H*-picrasane skeleton.

A conceivable biogenetic pathway from ailanthone (**2**) to shinjulactone C (**1**) *via* intermediates **A** and **B** is shown in Scheme 1. An inversion of a chiral center at C-9 position must occur prior to the cycloaddition of $\Delta^{12(13)}$-double bond in ring C with a pentadienyl cation in ring A. If the inversion of 9α-H into 9β-H occurs and both B and C rings adopt boat forms, the rings A and C would be sterically very close to each other enough to overlap π-orbitals.

According to these considerations, chemical conversion of ailanthone (**2**) into shinjulactone C (**1**) was investigated. Prior to the intramolecular cycloaddition, the compound which corresponds to the hypothetical intermediate **A** or **B** has to be prepared from ailanthone (**2**). For this purpose there seem to be three problems to be examined; i) an isomerization of $\Delta^{13(21)}$-exocyclic double bond into $\Delta^{12(13)}$ endocyclic double bond, ii) a selective oxidation of the hydroxyl group at C-1 position, and iii) an inversion of the stereochemistry of the hydrogen atom at C-9 position.

In regard to the third problem J. Polonsky *et al.* described that when glaucanol (**3**) was heated in pyridine, the inversion of 9α-H occurred to afford a 9β-H derivative (**4**).[6)] According to this procedure, an isomerization of ailanthone (**2**) was examined. But on heating in pyridine under reflux for 10 h, **2** produced isoailanthone (**5**) in 67% yield.[2)] Though it was shown that the isomerization proceeded without an inversion of the C-9 position, this experiment corresponds to giving a solution to the problem i discussed above. However the heating of ailanthone (**2**) in pyridine was continued for longer time to furnish a complex mixture, from which shinjulactone C (**1**) was obtained in 5—8% yield together with isoailanthone (**5**; 30—40% yield) and many unidentified by-products. Since the reaction was carried out in atmosphere, isoailanthone (**5**) or other intermediates must suffer autoxidation, which was supported by the following experiment; neither ailanthone (**2**) nor isoailanthone (**5**), on heating in argon atmosphere, yielded shinjulactone C (**1**). The reaction carried out in atmosphere was shown to yield so many by-products by HPLC examination and the separation of them was



Scheme 1.

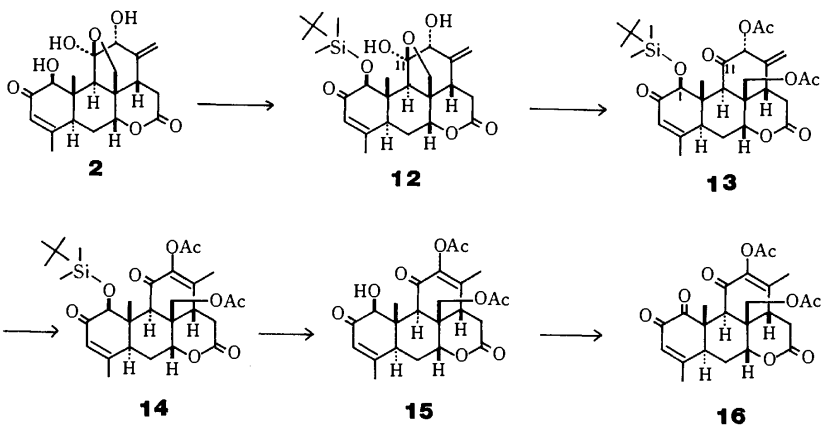
found to be so difficult that any attempts to isolate intermediates corresponding to **A** or **B** were not successful.

Instead of the isolation of intermediates, a stepwise conversion from ailanthone (**2**) into shinjulactone C (**1**) was then investigated. First examination concerned a direct oxidation of the hydroxyl group at C-1 of ailanthone (**2**). But oxidation of **2** with Jones reagent afforded unidentified polar products, while oxidation of ailanthone (**2**) with lead tetraacetate or manganese dioxide gave an 11,12-seco aldehyde (**6**);[4] this suggested that the protection of hydroxyl groups in C ring was required.

On heating in pyridine ailanthone triacetate (**7**)[7] isomerized to enol acetate (**8**), which was also obtained by acetylation of isoailanthone (**5**). Partial hydrolysis of the acetates (**7** and **8**) was examined under several conditions, but it was found that the selective removal of the acetyl group at C-1 was not easy. Under alkaline conditions ($NaHCO_3$, NH_3, *etc.*) the hydrolysis reactions did not proceed cleanly, probably owing to the opening of δ-lactone in D ring and an isomerization to α-diketone (**C**-type) in A ring, the latter being proposed in the case of 6-acetoxyisophorone (**9**).[8] Heating might cause a backbone rearrangement in C ring.[2,5] Acidic hydrolysis of the triacetate (**7**) afforded 1,12-di-*O*-acetylailanthone (**10**) and 12-*O*-acetylailanthone (**11**), but the 1-hydroxy-12,20-di-*O*-acetyl derivative was not obtained.

Discrimination of the hydroxyl group at C-1 from those in C ring was accomplished as follows (Scheme 2). Treatment of ailanthone (**2**) with *t*-butyldimethylsilyl chloride in the presence of imidazole in *N,N*-dimethylformamide[9] afforded a monosilyl derivative (**12**; 91% yield), which underwent acetylation to give a monosilyl diacetate (**13**; 92% yield). On heating in pyridine, **13** isomerized to a monosilyl enol acetate (**14**; 95% yield). ^{1}H NMR spectrum of **14** showed a signal due to vinyl methyl protons (δ 1.79, 3H, s; $C_{(13)}$-CH_3) instead of signals due to *exo*-methylene (δ 5.14 and 5.20, each 1H, s; $C_{(21)}$-H) and a proton (δ 5.45, 1H, s; $C_{(12)}$-H) attached to a carbon atom with an acetoxyl group for **13**. Signals due to a proton attached to a carbon atom with a siloxyl group appeared at δ 3.97 (1H, s; $C_{(1)}$-H) in ^{1}H NMR spectra of both **13** and **14**. ^{13}C NMR spectrum of **13** showed a signal at δ 198.9 due to a carbonyl carbon atom at C-11 position, while a signal due to a hemiacetal carbon atom was observed at δ 108.5 for **12**. From these results the structure of the monosilyl diacetate (**13**) was firmly established. Then the deprotection of the monosilyl enol acetate (**14**) was carried out by a treatment with AcOH–H_2O–THF (2:1:1) at room temperature to afford 1-hydroxy enol acetate (**15**; 85% yield based on the consumed **14**). Jones oxidation of **15** gave an α-diketone (**16**; 80% yield). This compound corresponds to a diacetate of the intermediate **A** shown in Scheme 1.

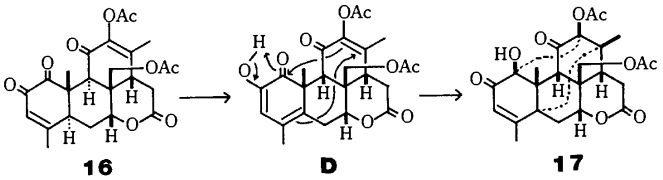
Now the α-diketone (**16**) in hand was transformed into 12,20-di-*O*-acetylshinjulactone C (**17**) by heating in pyridine under reflux for 9 h in 22% yield, which was shown to be completely identical with a specimen (**17**) derived from natural shinjulactone C (**1**). Alkaline hydrolysis of **17** afforded shinjulactone C (**1**) in *ca.*



Scheme 2.

90% yield.

The reaction from the α-diketone (**16**) to the diacetate (**17**) could be explained by an inionic [4+2] cycloaddition of class B,[10] which was proposed for a transformation from perezon (**18**) to pipitzol (**19**).[11] The reaction process from **16** to **17** through an intermediate **D** is depicted in Scheme 3.



16 **D** **17**

Experimental[12]

Reaction of Ailanthone (2) with Pyridine. Ailanthone (**2**; 60 mg) was heated in pyridine (5 ml) under reflux for 19 h. After evaporation under reduced pressure, the reaction mixture was separated by preparative TLC developed with 10% methanol-chloroform to give isoailanthone (**5**; 30—40%) and shinjulactone C (**1**; 5—8%) together with many unidentified by-products. After recrystallization from acetone, **1** was identified with a natural specimen by mp, TLC, HPLC, ^{1}H NMR, and IR. The yields were estimated by HPLC examination (column: Nucleosil 10-CN; solvent system: hexane-THF, 3:2; flow rate: 0.8 ml/min; retention times were 11.5, 13.2, and 23.1 min for **1**, **2**, and **5**, respectively).

Oxidation of Ailanthone (2) with Manganese Dioxide. A solution of ailanthone (**2**; 19 mg) in ethyl acetate (20 ml) was treated with manganese dioxide (120 mg) for 3 d at room temperature. After the usual work-up, the reaction mixture was subjected to a separation by preparative TLC developed with methanol-chloroform (1:19) to afford a mixture (13 mg) of an aldehyde (**6**) and a hemiacetal (**20**) in *ca.* 1:1 ratio.[4]

1β,12,20-Triacetoxypicrasa-3,12-diene-2,11,16-trione (8). i) Ailanthone triacetate (**7**; 497 mg) in pyridine (10 ml) was heated under reflux for 10 h. After evaporation of the solvent under reduced pressure, the reaction mixture was purified by a column chromatography eluted with 3% methanol-chloroform to give an enol acetate (**8**; 369 mg). ii) Ailanthone (**2**; 26 mg) in pyridine (5 ml) was heated under reflux for 11 h. After cooling, acetic anhydride (5 ml) and a catalytic amount of 4-dimethylaminopyridine were added to the reaction mixture. Standing at room temperature for 6 d followed by the usual work-up afforded the enol acetate (**8**; 23 mg), mp 153—156 °C (acetone-hexane); IR (Nujol) 1745, 1705, 1685, 1230, and 1140 cm^{-1}; UV (EtOH) 240 nm (ε 17000); ^{1}H NMR (400 MHz; $CDCl_3$) δ=1.33 (3H, s; $C_{(10)}$-CH_3), 1.82 (3H, s; $C_{(13)}$-CH_3), 1.98 (3H, br s; $C_{(4)}$-CH_3), 2.07, 2.09, and 2.23 (each 3H, s; CH_3CO-), 3.25 (1H, s; $C_{(9)}$-H), 4.13, and 4.59 (each 1H, d, J=12.5 Hz; $C_{(20)}$-H), 4.61 (1H, br s; $C_{(7)}$-H), 5.25 (1H, s; $C_{(1)}$-H), and 6.08 (1H, br s; $C_{(3)}$-H); MS *m/z* (%) 502 (M^+; 2), 460 (30), 418 (100), and 400 (20); Found: *m/z* 502.1807. Calcd for $C_{26}H_{30}O_{10}$: M, 502.1837.

Acidic Hydrolysis of Ailanthone Triacetate (7). A solution of the triacetate (**7**; 590 mg) in 1.5 M (1 M=1 mol dm^{-3}) sulfuric acid-THF (each 10 ml) was refluxed for 5 h. After extraction with dichloromethane, the organic layer was dried over magnesium sulfate and evaporated to give a residue. Purification by a silica-gel column chromatography eluted 3% methanol-chloroform afforded 1,12-di-*O*-acetylailanthone (**10**; *ca.* 120 mg), 12-*O*-acetylailanthone (**11**; *ca.* 120 mg), and ailanthone (**2**; 155 mg) in succession. **10**: Mp 266—268 °C (chloroform-acetone); IR (Nujol) 3420, 1735, 1705, and 1675 cm^{-1}; ^{1}H NMR ($CDCl_3$) δ=1.35 (3H, s), 2.04 (6H, s), 2.24 (3H, s), 3.55 and 3.93 (each 1H, d, J=8 Hz), 4.49 (1H, t, J=3 Hz), 5.25 (1H, s), 5.32 (1H, s), 5.38 (1H, s), 5.49 (1H, s), and 6.10 (1H, m); MS *m/z* (%) 460 (M^+; 2), 418 (88), 358 (94), 247 (63), 151 (100), and 60 (86); Found: *m/z* 460.1768. Calcd for $C_{24}H_{28}O_9$: M, 460.1733. **11**: Mp 221—224 °C (acetone); IR (Nujol) 3200, 1730, 1670, and 1240 cm^{-1}; ^{1}H NMR ($CDCl_3$) δ=1.20 (3H, s), 2.03 (3H, br s), 2.07 (3H, s), 3.56 and 3.94 (each 1H, d, J=8 Hz), 4.07 (1H, br s), 4.52 (1H, *t*, J=3 Hz), 5.10 (1H, br s), 5.30 (2H, s), 5.51 (1H, s), 6.15 (1H, m), and 7.66 (1H, s); MS *m/z* (%) 418 (M^+; 24), 358 (14), 328 (23), 313 (18), 247 (22), 151 (32), and 60 (100); Found: *m/z* 418.1632. Calcd for $C_{22}H_{26}O_8$: M, 418.1627.

1-O-t-Butyldimethylsilylailanthone (12). Ailanthone (**2**; 402 mg) was treated with *t*-butyldimethylsilyl chloride (806 mg; 5.0 equiv) in the presence of imidazole (950 mg; 13 equiv) in DMF (12 ml) at room temperature for 18 h. After addition of water, the reaction mixture was extracted with dichloromethane. The organic layer was washed with 2 M hydrochloric acid and then with a saturated solution of sodium hydrogencarbonate, dried over magnesium sulfate, and evaporated under reduced pressure. The residue was subjected to separation by a silica-gel column chromatography eluted with 15—30% ethyl acetate-ether to give the starting ailanthone (**2**; 12 mg) and a monosilyl derivative (**12**; 480 mg), mp 234—236 °C; IR (KBr) 3450, 3250, 1730, 1685, 1660, and 840 cm^{-1}. ^{1}H NMR ($CDCl_3$) δ=0.15 and 0.16 (each 3H, s), 1.05 (9H, s), 1.25 (3H, s), 1.95 (3H, br s), 3.52 and 3.90 (each 1H, d, J=8 Hz), 4.01 (1H, s), 4.26 (1H, s), 4.50 (1H, t, J=2.5 Hz), 5.22 and 5.31 (each 1H, br s), 5.99 (1H, m); ^{13}C NMR ($CDCl_3$) δ=−4.1q, −2.5q, 10.1q, 19.1s, 22.4q, 25.7t, 26.7q, 26.7q, 26.7q, 34.5t, 43.0d, 43.5d, 45.2s, 45.6s, 47.2d, 71.6t, 78.0d, 79.3d, 86.0d, 108.5s, 120.7t, 126.3d, 143.4s, 159.4s, 169.3s, and 195.1s; MS *m/z* (%) 490 (M^+; 3), 475 (3), 433 (55), and 57 (100); Found: *m/z* 490.2383. Calcd for $C_{26}H_{38}O_7Si$: M, 490.2385.

1β-t-Butyldimethylsiloxy-12α,20-diacetoxypicrasa-3,13(21)-diene-2,11,16-trione (13). The monosilyl derivative (**12**; 480 mg) was acetylated with acetic anhydride (5 ml) and pyridine (15 ml) at 70 °C for 18 h. After the usual work-up, purification with a silica-gel column chromatography eluted with ethyl acetate-ether (1:3) afforded a monosilyl diacetate (**13**; 519 mg), mp 182—184 °C (ether-hexane); IR (Nujol) 1750, 1690, 1230, and 845 cm^{-1}; ^{1}H NMR ($CDCl_3$) δ=−0.14, −0.10 (each 3H, s), 0.84 (9H, s), 1.14 (3H, s), 1.83 (3H, br s), 2.00 and 2.07 (each 3H, s), 3.97 (1H, s), 3.80 and 4.31 (each 1H, d, J=12 Hz), 4.57 (1H, br s), 5.14 and 5.20 (each 1H, s), 5.45 (1H, s), and 5.85 (1H, br s); ^{13}C NMR ($CDCl_3$) δ=−3.7, −3.3,

10.6, 18.8, 20.6, 21.0, 21.9, 25.9, 26.5, 26.5, 26.5, 30.7, 40.1, 41.6, 42.6, 46.4, 51.1, 65.0, 76.0, 77.9, 86.9, 114.5, 126.9, 140.5, 158.3, 168.9, 169.9, 170.1, 196.5, 198.9; MS *m/z* (%) 574 (M^+; 0.3), 559 (5), 517 (100), 475 (10), 457 (10), 415 (15), and 207 (8); Found: *m/z* 574.2618. Calcd for $C_{30}H_{42}O_9Si$: M, 574.2598.

1β-t-Butyldimethylsiloxy-12,20-diacetoxypicrasa-3,12-diene-2,11,16-trione (14). The monosilyl diacetate (**13**; 75 mg) was heated in pyridine (5 ml) under reflux for 11 h. After evaporation under reduced pressure, the reaction mixture was purified by a silica-gel column chromatography eluted with ethyl acetate-ether (1:3) to give a monosilyl enol acetate (**14**; 71.5 mg), mp 210—213 °C (ether-hexane); IR (Nujol) 1740, 1710, 1690, 1240, and 845 cm^{-1}; ^1H NMR ($CDCl_3$) δ=−0.12 and 0.07 (each 3H, s), 0.90 (9H, s), 1.24 (3H, s), 1.79 (3H, s), 1.93 (3H, br s), 2.08 and 2.20 (each 3H, s), 3.97 (1H, s), 4.60 (1H, t, J=2.5 Hz), 4.19 and 4.68 (each 1H, d, J=12 Hz), and 5.98 (1H, m); MS *m/z* (%) 574 (M^+; 0.1), 559 (3), 517 (100), 475 (10), 457 (18), and 207 (18); Found: *m/z* 574.2648. Calcd for $C_{30}H_{42}O_9Si$: M, 574.2598.

12,20-Diacetoxy-1β-hydroxypicrasa-3,12-diene-2,11,16-trione (15). The monosilyl enol acetate (**14**; 457 mg) was treated with AcOH (10 ml), H_2O (5 ml), and THF (5 ml) at room temperature for 22 h. The reaction mixture was evaporated and separated by a silica-gel column chromatography eluted with 30—80% ethyl acetate-ether to give the starting monosilyl enol acetate (**14**; 147 mg) and 1-hydroxy enol acetate (**15**; 210 mg), mp 173—175 °C (acetone); IR (KBr) 3430, 1740, 1675, 1220, and 1030 cm^{-1}; ^1H NMR ($CDCl_3$) δ=1.16 (3H, s), 1.86 (3H, s), 1.97 (3H, br s), 2.11 and 2.26 (each 3H, s), 3.30 (1H, s), 3.97 (1H, d, J=3.5 Hz), 4.47 (1H, d, J=3.5 Hz), 4.21 and 4.61 (each 1H, d, J=12 Hz), 4.59 (1H, br s), and 6.07 (1H, br s); MS *m/z* (%) 460 (M^+; 3), 418 (18), 400 (23), 358 (40), 151 (90), and 60 (100); Found: *m/z* 460.1741. Calcd for $C_{24}H_{28}O_9$: M, 460.1734.

12,20-Diacetoxypicrasa-3,12-diene-1,2,11,16-tetrone (16). 1-Hydroxy enol acetate (**15**; 210 mg) was treated with Jones reagent (in excess) in acetone (30 ml) at 0 °C for 30 min. After addition of 2-propanol (*ca.* 3 ml) and sodium hydrogencarbonate (*ca.* 1 g), the reaction mixture was filtered through Florisil (Wako, 100—200 mesh; *ca.* 5 g) and evaporated to a concentrated solution, to which brine and dichloromethane were added. After extraction with dichloromethane, the organic layer was subjected to purification by a silica-gel column chromatography eluted with 3% methanol-chloroform to afford an α-diketone (**16**; 167 mg), mp 160—164 °C (dichloromethane-hexane); IR (KBr) 2910, 1740, 1695, 1220, and 1040 cm^{-1}; UV (EtOH) 245 nm (ε 9100); ^1H NMR ($CDCl_3$) δ=1.41 (3H, s), 1.89 (3H, s), 2.04 (3H, br s), 2.11 and 2.25 (each 3H, s), 3.52 (1H, s), 4.25 and 4.65 (each 1H, d, J=12 Hz), 4.56 (1H, t, J=2.5 Hz), and 6.23 (1H, m); ^{13}C NMR ($CDCl_3$) δ=14.2, 16.0, 20.0, 20.6, 22.4, 25.6, 30.3, 38.5, 41.0, 43.1, 44.8, 51.5, 61.9, 76.9, 129.0, 141.4, 143.2, 164.1, 167.9, 168.5, 170.2, 185.5, 187.5, and 198.5; MS *m/z* (%) 458 (M^+; 60), 430 (12), 416 (100), 398 (30), 356 (45), 151 (70); Found: *m/z* 458.1586. Calcd for $C_{24}H_{26}O_9$: M, 458.1576.

12,20-Di-O-acetylshinjulactone C (17). The α-diketone (**16**; 51 mg) was heated in pyridine (5 ml) under reflux for 9 h. After evaporation, the reaction mixture was separated by preparative TLC developed with ethyl acetate-ether (1:1) to give 12,20-diacetylshinjulactone C (**17**; 11 mg), whose ^1H NMR, IR, and mass spectra and optical rotation were completely identical with those of a specimen (**17**) obtained by acetylation of natural shinjulactone C (**1**).

Hydrolysis of 12,20-Di-O-acetylshinjulactone C (17). To a solution of the diacetate (**17**; 2.8 mg) in methanol (2 ml), 0.24 M potassium methoxide-methanol solution (0.1 ml) was added and the reaction mixture was stirred at room temperature for 1 h. After addition of 2 M hydrochloric acid (*ca.* 1 ml), the reaction mixture was evaporated to give a residue, which was subjected to purification by preparative TLC developed by 10% methanol-chloroform to afford shinjulactone C (**1**; 2.1 mg).

The authors wish to thank Mr. Kazuhiro Matsushita of JEOL Co., Ltd. for measurement of ^1H NMR spectrum at 400 MHz.

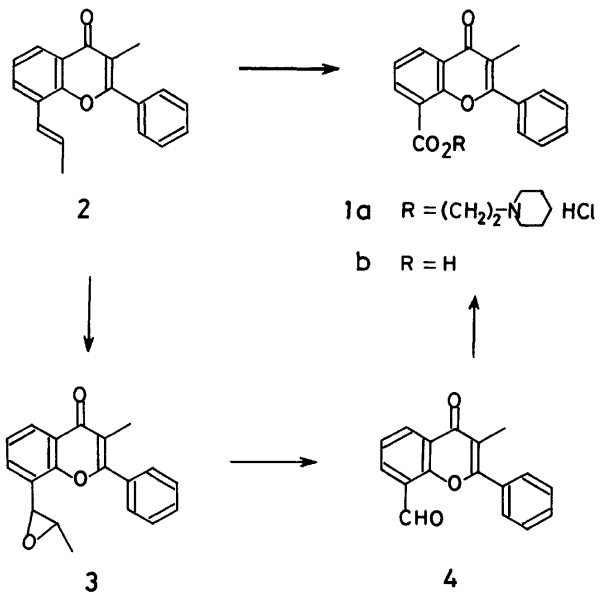
(Received April 15, 1985)

Electrooxidative carbon-carbon bond cleavage is useful for the preparation of 3-methyl-4-oxo-2-phenyl-4*H*-1-benzopyran-8-carboxylic acid (**1b**) from 3-methyl-2-phenyl-8-(1-propenyl)-4*H*-1-benzopyran-4-one (**2**). Olefin **2** was transformed into 3-methyl-8-(1,2-epoxypropyl)-3-methyl-2-phenyl-4*H*-1-benzopyran-4-one (**3**) by the electrochemical bromohydrination in an MeCN–H_2O–H_2SO_4–NaBr–(Pt) system followed by treatment of aqueous sodium hydroxide (94%). The epoxide **3** was electrooxidized in an MeOH–H_2SO_4–(C) system, affording 8-formyl-3-methyl-2-phenyl-4*H*-1-benzopyran-4-one (**4**) in 83% yield. Hydrogen peroxide oxidation of **4** in refluxing 2-butanone gave **1b** in 86% yield.

Among the flavone derivatives, 2-piperidinoethyl 3-methyl-4-oxo-2-phenyl-4*H*-1-benzopyran-8-carboxylate (**1a**) has been used as a drug for prostatitis.[1] Several syntheses have been proposed where carboxyl group of salicylic acid was employed as a source of 8-carboxyl group of **1b**.[2] Carbon-carbon bond cleavage methods of propenyl group of 3-methyl-2-phenyl-8-(1-propenyl)-4*H*-1-benzopyran-4-one (**2**)[3] and 1-(3-propenyl-2-hydroxyphenyl)propanone with potassium permanganate and dichromate[4,5] are also known. Unfeasibility of the waste heavy metal in industry prompted us to study non-heavy metal oxidation method.

Chemoselective electrooxidative cleavage of a carbon-carbon double bond of the propenyl group would be promising. However, very few example has been known so far on one-step carbon-carbon double bond cleavage. Electrooxidation of stilbene[6] in an MeOH–NH_4Cl–(Pt) system and isoeugenol[7] in an H_2O–KOH–(PbO_2) system give the corresponding aromatic aldehyde in 45 and 77% yield, respectively. Yield of the reaction is not satisfactory and alkaline media are not usable for the present purpose because of instability of **2** in the media. Oxygenation of carbon-carbon double bond followed by carbon-carbon bond cleavage leading to aldehyde is an alternative method. Dimethoxy compounds[8] and α-hydroxy ketones[9] are electrochemically cleaved but their preparation from olefins is not accessible. 1,2-Diols and epoxides are promising precursors of the desired aldehydes and can be prepared from the corresponding halohydrins whose electrochemical preparations are intensively studied. On this basis, we have studied an electrochemical preparation and carbon-carbon bond cleavage of epoxide **3** and glycol **6a**, as precursors of **1b**. (Scheme 1).



Scheme 1.

Electrooxidation of 2. The olefin **2** was prepared as described in literatures.[10] Aqueous acetonitrile containing sodium bromide was found to be an excellent medium for the epoxidation of isoprenoids,[11] cyclohexene,[12] and isosafrole.[13] Because of the low solubility of **2** in aqueous acetonitrile, tetrahydrofuran was employed as a cosolvent. In an MeCN–THF–H_2O (5:2:2)–NaBr–(Pt) system, a constant-current-density electrolysis (3.3 mA cm^{-2}) was conducted at room temperature in an undivided cell, affording **3** in 48% yield along with the dibromide **5a** in 9% yield. When 5—10 F mol^{-1} of electricity were passed, the starting material **2** was consumed completely but the material balance was poor due to the formation of the unidentified products. The reactivity of the double bond of propenyl group of **2** was found to be lower than those of isoprenoids and isosafrole due to meta-carbonyl group. Therefore, pH of the electrolysis solution was kept at an acidic side to affect bromohydrination. The result is shown in Fig. 1.

Electrochemical bromohydrination occurs chemoselectively at the double bond of propenyl group. Yield of **5b** increased sharply and reached to an maximum value (88%) and the amount of electricity required for the conversion of **2** was saved as increase of the concentration of sulfuric acid. Interestingly, the formation of **5a** could be suppressed in a higher concentration of sulfuric acid. [Yield % **3**, **5a**, and **5b** (con-

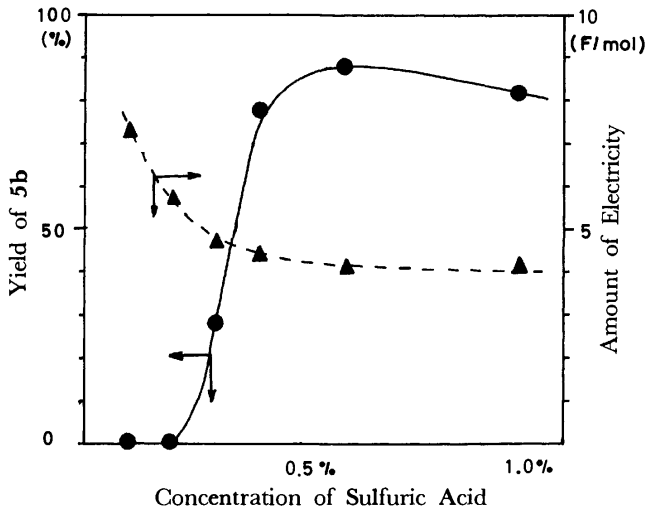


Fig. 1. Effect of the concentration of sulfuric acid for the yield of 5b and the amount of electricity in bromohydrination of **2** in an MeCN-THF-aq H_2SO_4-NaBr-(Pt) system.

centration of sulfuric acid %), 40, 32, 0 (0.1), and 0, 10, 88 (0.6)]. At 45 °C, **2** was soluble in MeCN-aq H_2SO_4 and converted to **5b** effectively in the highest chemical yield and current efficiency (93%, 2.9 F mol^{-1}).

Concentration of sodium bromide is also important. In the epoxidation of isoprenoids, bromide ion is regenerated in situ after epoxidation and thus 0.1—0.5 molar equivalent of sodium bromide to olefin is suitable so as to suppress the formation of the dibromides.[11] On the contrary to this, isosafrole **7** was efficiently electroepoxidized in the presence of 3—4 molar equivalent of sodium bromide because the dibromide **8a** was spontaneously hydrolyzed to the bromohydrin **8b** and finally converted to the epoxide *in situ* under the electrolysis conditions.[13] Hydrolysis of **5a** to **5b** was slow under the electrolysis conditions and therefore, the use of excess amount of sodium bromide should be avoided to minimize dibromination.

The base-catalyzed ring closure of **5b** to **3** proceeded smoothly. Thus, after electrochemical bromohydrination the electrolysis mixture was alkalined with 1 ml of 1 M sodium hydroxide and stirred at room temperature for 1 h, affording **3** in 94% yield.

Electrolysis of 3 and 6a. Glycol **6a** was obtained in 94% yield by the acidcatalyzed ring opening of **3** in THF-10% aq H_2SO_4 at room temperature for 11 h. The electrooxidative carbon-carbon bond cleavage of glycols has been examined in MeOH-Et_4NOTs for cyclic glycols,[14] in MeOH-NaOH for 1,1,2,2-tetraphenyl-1,2-ethanediol,[15] and in H_2O-$NaIO_4$-H_2SO_4 for 2,3-butanediol.[16] At first, electrooxidation of **6a** was examined in an MeCN-aq H_2SO_4-(Pt) system. But, unfortunately the electrooxidative cleavage of **6a** gave **4** in only 60—70% yield. Meanwhile, electrolysis in an MeOH-H_2SO_4-(C) system, the yield of **4** was improved to 91%. At 60 °C with a lower sulfuric acid concentration in MeOH, acetal **9** was formed exclusively (97%). The acetal **9** can be hydrolyzed to **4** in THF-aq H_2SO_4 almost quantitatively.

Comparison of the electrooxidative cleavage of **6a** with the chemical oxidant induced cleavage is shown in Table 1, which clearly reveals the prominent aspect of the electrolysis. Oxidation with sodium periodate proceeds smoothly under very mild conditions. However, the use of the expensive reagent is not economically feasible. Cobalt(II) acetate-catalyzed air oxidation[17] and calcium hypochlorite oxidation[18] under neutral conditions resulted in a disappointed yield.

Next, a direct cleavage of carbon-carbon bond of epoxide **3** was studied. Epoxide **3** was readily and quantitatively transformed into methoxy alcohol **6b** in MeOH-aq H_2SO_4 which was then electrolyzed *in situ*. Acetal **9** was a major product (83%) and **10b** was produced as a side product (8%). Comparison between entries 3 and 4, and entries 6 and 7 (Table 1) indicates that methoxylation on 3-methyl group took place partially at a higher current density. Presumably, electrooxidation of 2-phenyl group would compete with

Table 1. Electrochemical and chemical oxidative transformation of **6a** and **3** into **4** or **9**

Entry	Substrate	Oxidation Methods and Conditions	F/mol	mA/cm²	Product/%[a]

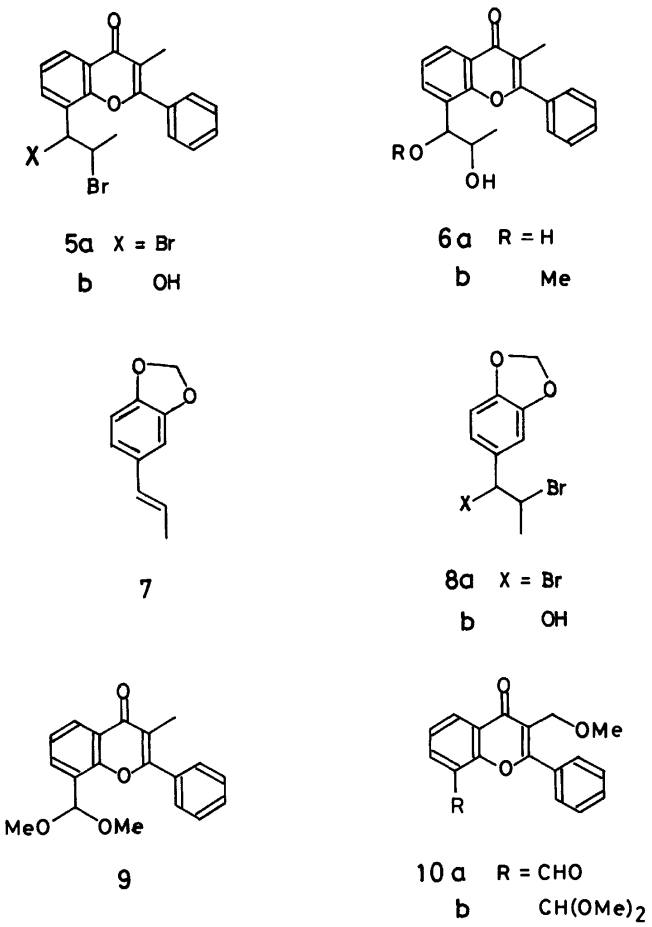
9		$Co(OAc)_2$-O_2, DMF (110 °C)[f]			69			
10		$Ca(ClO)_2$, MeOH-H_2O (65 °C)[g]			27			

a) Isolated yield. b) The mixture was worked up without neutralization. c) After electrolysis, the mixture was neutralized with aq $NaHCO_3$. d) Mole equivalent of H_2SO_4 to substrate. e) 2 eq of $NaIO_4$ to **6a** for 1.5 h. f) 0.3 mole eq of $Co(OAc)_2$ to **6a** for 26 h. g) 4 mole eq of $Ca(ClO)_2$ to **6a** for 7 h.

that of the glycol moiety. Current efficiency of the conversion of **6b** to **9** is lower than that of **6a** to **9**, suggesting the lower reactivity of **6b** than **6a** (entries 5 and 6). In fact, when a 1:1 mixture of **6a** and **6b** was electrolyzed in an MeOH–aq H_2SO_4–(Pt) system (2 mA for 2 d, 3 F mol^{-1} on the basis of a total amount of **6a** and **6b**, **6a** was smoothly converted to **9** in 84% yield, while **6b** was recovered intact (98%).

Oxidation of Aldehyde 4 to Carboxylic Acid 1b. Although electrooxidation of benzaldehyde provides benzoic acid, oxidation of **4** in an MeOH–aq H_2SO_4–(C) system failed and methoxylation at 3-methyl group exclusively occurred leading to the formation of **10b** in 52% yield. In the electrolysis system, the initial electron transfer from 2-phenyl group rather than the trisubstituted aromatic nucleus and the following deprotonation from 3-methyl group would generate a conjugated methyl radical, which suffers methoxylation leading to **10b** by the further one-electron oxidation. Therefore, any oxidations where an initial step occurs on the formyl group rather than aromatic nucleus must be chosen for the present purpose and also because of the instability of **4** in alkaline media, oxidation conditions must be neutral or acidic. Oxidation of **4** with hydrogen peroxide in refluxing 2-butanone proceeded slowly and gave **1b** in 86% yield where supply of hydrogen peroxide at regular time intervals was useful. Nitric acid oxidation of **4** in refluxing benzene also provided **1b** in 85% yield in which concentration of nitric acid plays an important role [Yield (molar concentration of nitric acid); 77% (2 M), 68% (3 M), 85% (4 M), and 59% (6 M)]. Meanwhile, oxidation of **3** with ammonium vanadate–nitric acid[19] in refluxing benzene yielded a mixture of **1b** and **4** (35%).



Scheme 2.

Experimental

Melting points and boiling point are uncorrected. The IR spectra were obtained with a JASCO IRA-1 spectrometer. ^{1}H NMR were measured with a JNM FX-100 spectrometer at 100 MHz or Hitachi R-24 spectrometer at 60 MHz in $CDCl_3$ using Me_4Si as an internal standard. Elemental analysis was performed using a Yanaco Model MC-2 micro-determining apparatus. Substrate **2** were supplied from Shiono Koryo Kaisha Ltd., to which the authors are grateful. A regulated DC power was supplied by a Metronix 543B instrument for electrolysis.

8-(1,2-Epoxypropyl)-3-methyl-2-phenyl-4H-1-benzopyran-4-one (3). A mixture of **2** (100 mg, 0.36 mmol) and NaBr (41 mg, 0.4 mmol) dissolved in MeCN (7 ml)–H_2O (1.7 ml) and 1% aq H_2SO_4 (0.3 ml) was electrolyzed in a beaker type undivided cell. A constant current (10 mA, 2.92 F mol^{-1}) was passed at 45 °C for 2 h and 50 min using platinum foils (1.5×2 cm^2) as an electrode. After electrolysis, 1 M NaOH (1 ml) was added to the mixture, which was stirred at room temperature for 1 h. After evaporation of MeCN, the mixture was extracted with AcOEt. The extracts were washed with brine, dried (Na_2SO_4), and concentrated *in vacuo*. The residue was chromatographed (Wako-gel C200, benzene/AcOEt=15/1) to give **3** (99.3 mg, 94%): mp 157.4—159 °C (ether); IR (Nujol) 1632, 1600, 1590, 1136, 761,700 cm^{-1}; ^{1}H NMR ($CDCl_3$) δ=1.48 (3H, d, J=5 Hz, CH_3), 2.18 (3H, s, CH_3), 3.40 (1H, dq, J=5 Hz and 2 Hz, CH), 4.06 (1H, d, J=2 Hz, CH), 7.17—7.80 (7H, m, ArH), 8.15 (1H, dd, J= 8 Hz and 2 Hz, ArH). Found: C, 78.02; H, 5.67. Calcd for $C_{19}H_{16}O_3$: C, 78.07: H, 5.52.

8-(2-Bromo-1-hydroxypropyl)-3-methyl-2-phenyl-4H-1-benzopyran-4-one (5b). Electrolysis of **2** was conducted in the same manner as described for **3** and the mixture was worked up as usual, affording **5b** (125.2 mg, 93%): decomposed at around 160 °C; IR (Nujol) 3300 (OH), 1614, 1595, 1395, 764, 696, 657 cm^{-1}; ^{1}H NMR ($CDCl_3$) δ=1.58 (3H, d, J=7 Hz, CH_3), 2.15 (3H, s, CH_3), 3.00—3.42 (1H, br s, OH), 4.40—4.70 (1H, m, CH), 5.56 (1H, d, J=4 Hz, CH), 7.10—7.75 (6H, m, ArH), 7.85 (1H, dd, J=8 Hz and 2 Hz, ArH), 8.12 (1H, dd, J=8 Hz and 2 Hz, ArH). Found: C, 61.02; H, 4.57. Calcd for $C_{19}H_{17}O_3Br$: C, 61.14; H, 4.59.

8-(1,2-Dibromopropyl)-3-methyl-2-phenyl-4H-1-benzopyran-4-one (5a); mp 128—129.4 °C (ether): IR ($CHCl_3$) 1630, 1607, 1590, 1485, 1450, 1400, 1140 cm^{-1}: ^{1}H NMR ($CDCl_3$) δ=1.79 and 2.05 (3H, d, J=7 Hz, CH_3, a ratio of diastereoisomer= 2:9), 2.20 (3H, s, CH_3), 4.50—5.10 (1H, m, CH), 5.50—5.90 (1H, m, CH), 7.20—7.95 (7H, m, ArH), 8.29 (1H, J=8 Hz and 2 Hz, ArH). Found: C, 52.39; H, 3.74. Calcd for $C_{19}H_{16}O_2Br_2$: C, 52.33; H, 3.70.

8-(1,2-Dihydroxypropyl)-3-methyl-2-phenyl-4H-1-benzopyran-4-one (6a). To a solution of **3** (708.1 mg, 2.42 mmol) in distilled THF (10 ml) was added 10% aq H_2SO_4 (4 ml) at

room temperature and the mixture was stirred for 11 h. The mixture was concentrated *in vacuo* and insoluble materials were removed by filtration. The crystals on filter were washed with water and benzene, dried *in vacuo* to give **6a** (703 mg, 94%): mp 192—193 °C (AcOEt); IR (Nujol) 3400 (OH), 1620, 1605, 1125, 1067, 1025, 763, 700, 660 cm^{-1}; ^1H NMR ($CDCl_3$) δ=1.08 (3H, d, J=8 Hz, CH_3), 2.16 (3H, s, CH_3), 4.08 (1H, m, CH), 5.36 (1H, d, J=4 Hz, CH), 7.20—7.84 (6H, m, ArH), 7.96 (1H, dd, J=8 Hz and 2 Hz, ArH), 8.22 (1H, dd, J=8 Hz and 2 Hz, ArH). Found: C, 73.55; H, 6.00. Calcd for $C_{19}H_{18}O_4$: C, 73.54; H, 5.85.

8-Formyl-3-methyl-2-phenyl-4H-1-benzopyran-4-one (4) and 8-Dimethoxymethyl-3-methyl-2-phenyl-4H-1-benzopyran-4-one (9): Electrolysis of 6a. A solution of **6a** (100 mg, 0.32 mmol) dissolved in H_2SO_4–MeOH solution (25 mM, 10 ml) was electrolyzed in a beaker-type undivided cell. A constant current (5 mA, 3.86 F mol^{-1}) was passed at room temperature for 6 h and 40 min with glassy carbon electrodes (1.21×2.7 cm^2). After evaporation of MeOH under reduced pressure, the residue was dissolved in AcOEt, and the solution was washed with sat. $NaHCO_3$ and brine, dried (Na_2SO_4), and concentrated *in vacuo*. The residue was chromatographed over silica-gel (Wako-gel C200, benzene/AcOEt=11/1) to give **4** (77.7 mg, 91%): mp 119—121.5 °C; IR (Nujol) 1684, 1655, 1623, 1405, 1122, 761, 698, 660 cm^{-1}; ^1H NMR ($CDCl_3$) δ=2.22 (3H, s, CH_3), 7.17—7.87 (6H, m, ArH), 8.20 (1H, dd, J=8 Hz and 2 Hz, ArH), 8.49 (1H, dd, J=8 Hz and 2 Hz, ArH), 10.64 (1H, s, CHO). Found: C, 77.18; H, 4.52. Calcd for $C_{17}H_{12}O_3$: C, 77.26; H, 4.58.

On the other hand, **6a** was electrolyzed in H_2SO_4–MeOH solution (5 mM, 10 ml) under a constant current of 0.67 mA cm^{-2} at 60 °C for 24 h (5.6 F mol^{-1}) using glassy carbon electrodes (1.2×2.5 cm^2). After electrolysis, the reaction solution was neutralized with sat. $NaHCO_3$. The usual workup provided **9** (96.7 mg, 97%): mp 136.5—137.5 °C (ether); IR (Nujol) 1644, 1486, 1404, 1115, 1060, 770, 703, 660 cm^{-1}; ^1H NMR ($CDCl_3$) δ=2.20 (3H, s, CH_3), 3.39 (6H, s, OCH_3), 5.84 (1H, s, ArCH), 7.20—7.80 (6H, s, ArH), 7.90 (1H, dd, J=8 Hz and 2 Hz, ArH), 8.24 (1H, dd, J=8 Hz and 2 Hz, ArH). Found: C, 73.38: H, 5.93. Calcd for $C_{19}H_{18}O_4$: C, 73.54; H, 5.85.

Oxidation of 6a with $NaIO_4$. A solution of $NaIO_4$ (96 mg, 0.45 mmol) in H_2O (3 ml) was dropped to **6a** (70 mg, 0.23 mmol) dissolved in MeOH (4 ml) at 0—3 °C and the mixture was stirred at the temperature for 1.5 h. Ethyl acetate extraction followed by chromatography (Wako-gel C200, benzene/AcOEt=10/1) provided **4** (49.4 mg, 82%).

Oxidation of 6a with $Co(OAc)_2$–O_2. A mixture of **6a** (100 mg, 0.32 mmol) and $Co(OAc)_2$ (17 mg, 0.096 mmol) dissolved in DMF (6 ml) was stirred under oxygen atmosphere at 110—115 °C for 26 h. After addition of water, the organic substance was extracted with AcOEt. The usual workup provided **4** (58.9 mg, 69%).

Oxidation of 6a with $Ca(OCl)_2$. A suspension of $Ca(OCl)_2$ (23 mg, 0.1 mmol) in MeCN (2 ml)–H_2O (1 ml) was added to a solution of **6a** (60 mg, 0.19 mmol) dissolved in MeCN (4 ml)–H_2O (2 ml). After vigorous stirring at 65 °C for 1 h, $Ca(OCl)_2$ (70 mg, 0.3 mmol) suspended in MeCN (2 ml)–H_2O (1 ml) was added again and the mixture was stirred for 2 h. In the same way, $Ca(OCl)_2$ (52 mg, 0.22 mmol) suspended in MeCN (1 ml)–H_2O (1 ml) was added additionally twice and the mixture was stirred for 2 h in each addition. Organic substances were extracted with AcOEt and the usual workup provided **4** (14 mg, 27%) after chromatography.

Electrolysis of 3. A solution of **3** (100 mg, 0.34 mmol) dissolved in H_2SO_4–MeOH solution (5 mM, 10 ml) was stirred at 60 °C for 40 min. And the mixture was electrolyzed under a constant current of 0.67 mA cm^{-2} at 60 °C for 48 h (10.5 F mol^{-1}) using glassy carbon electrodes. After evaporation of MeOH, the residue was dissolved in THF (3 ml). The mixture was added 10% aq H_2SO_4 (2 ml) and stirred at room temperature for 1 h, concentrated *in vacuo*, and extracted with AcOEt. The extracts were washed with sat. $NaHCO_3$ and brine, dried (Na_2SO_4), and concentrated *in vacuo*. The residue was chromatographed (Wako-gel C200, benzene/AcOEt=15/1) to give **4** (75.7 mg, 84%).

8-(2-Hydroxy-1-methoxypropyl)-3-methyl-2-phenyl-4H-1-benzopyran-4-one (6b). The acid-catalyzed ring opening of **3** as described above and the usual workup gave **6b** (quantitatively): mp 151—152 °C (ether); IR (Nujol) 3350 (OH), 1626, 1585, 1397, 1114, 763, 695, 660 cm^{-1}; ^1H NHR ($CDCl_3$) δ=1.14 (3H, d, J=6 Hz, CH_3), 2.13 (3H, s, CH_3), 2.92 (1H, br s, OH), 3.30 (3H, s, OCH_3), 3.95—4.35 (1H, m, CH), 4.85 (1H, d, J=5 Hz, ArCH), 7.20—7.90 (7H, m, ArH), 8.10 (1H, dd, J=8 Hz and 2 Hz, ArH). Found: C, 74.09: H, 6.27. Calcd for $C_{20}H_{20}O_4$: C, 74.06: H, 6.21.

After electrolysis, the reaction mixture was neutralized with sat. $NaHCO_3$. The usual workup and chromatography gave **9** (83%).

3-Methyl-4-oxo-2-phenyl-4H-1-benzopyran-8-carboxylic Acid (1b). Oxidation of 4 with Hydrogen Peroxide: To a solution of **4** (80 mg, 0.30 mmol) in 2-butanone heated to 90—95 °C, 31% of H_2O_2 (1 ml) was added four times at every 10 h intervals. After being stirred for 44 h, H_2O_2 was quenched with $NaHSO_3$. The reaction mixture was acidified with 10% HCl and extracted with AcOEt. The extracts were concentrated *in vacuo*. The residue was dissolved in sat. $NaHCO_3$ and extracted with AcOEt. The aqueous layer was acidified with 10% HCl and extracted with AcOEt. The extracts were dried (Na_2SO_4) and concentrated *in vacuo*. The residue was chromatographed over short silica-gel column (Wako-gel C200, AcOEt/benzene=3/1) to give **1b** (72.4 mg, 85%): mp 226.5—228 °C (AcOEt)(lit,[3a] 227—229 °C); IR (Nujol) 3160 (OH), 1734, 1620, 1218, 1180, 1134, 1025, 785, 763, 700, 678, 664 cm^{-1}; ^1H NMR ($CDCl_3$+CD_3OD=1:2) δ=2.23 (3H, s, CH_3), 7.30—7.65 (5H, m, ArH), 7.70—7.95 (1H, m, ArH), 8.15—8.55 (2H, m, ArH).

Oxidation of 4 with Nitric Acid. A solution of **4** (80 mg, 0.30 mmol) in benzene (2 ml) was added to 4 M HNO_3 (6 ml) and stirred vigorously at 90 °C for 49 h. The reaction mixture was extracted with AcOEt. The extracts were concentrated *in vacuo*. The residue was dissolved in sat. $NaHCO_3$ and extracted with AcOEt. The aqueous layer was acidified with 10% HCl and extracted with AcOEt. The extracts were dried (Na_2SO_4) and concentrated *in vacuo*. The residue was chromatographed over short column (Wako-gel C200, AcOEt/benzene=3/1) to give **1b** (72 mg, 85%).

8-Formyl-3-methoxymethyl-2-phenyl-4H-1-benzopyran-4-one (10a). Mp 146.7—148 °C (ether); IR (Nujol) 1690, 1660, 1623, 1090, 760, 690, 656 cm^{-1}: ^1H NMR ($CDCl_3$) δ=3.50 (3H, s, OMe), 4.37 (2H, s, CH_2), 7.10—8.00 (6H, m, ArH), 8.17 (1H, dd, J=8 Hz and 2 Hz, ArH), 8.45 (1H, dd, J=8 Hz and 2 Hz, ArH), 10.64 (1H, s, CHO). Found: C, 73.71; H, 4.90. Calcd for $C_{18}H_{14}O_4$: C, 73.46; H, 4.79.

8-Dimethoxymethyl-3-methoxymethyl-2-phenyl-4H-1-benzo-

pyran-4-one (10b). Bp 185—186 °C (6.92×10^{-1} Pa): IR(Neat 2950, 1740, 1715, 1650, 1490, 778, 705, 665 cm^{-1}; ^1H NMR ($CDCl_3$) δ=3.37 (6H, s, OMe), 3.50 (3H, s, OMe), 4.36 (2H, s, CH_2), 5.85 (1H, s, CH), 7.25—8.10 (7H, m, ArH), 8.25 (1H, dd, J=8 Hz and 2 Hz, ArH). Found: C, 73.89; H, 6.43. Calcd for $C_{20}H_{20}O_4$: C, 74.06; H, 6.21.

A Highly Selective Transannular Route to *trans-trans*-1,2,3,3a,4,-5,9,10,10a,10b-Decahydropyrenes from [2.2]Metacyclophanes

Takeo SATO,* Kozaburo NISHIYAMA, Akira MORITA, and Yoichi IITAKA†

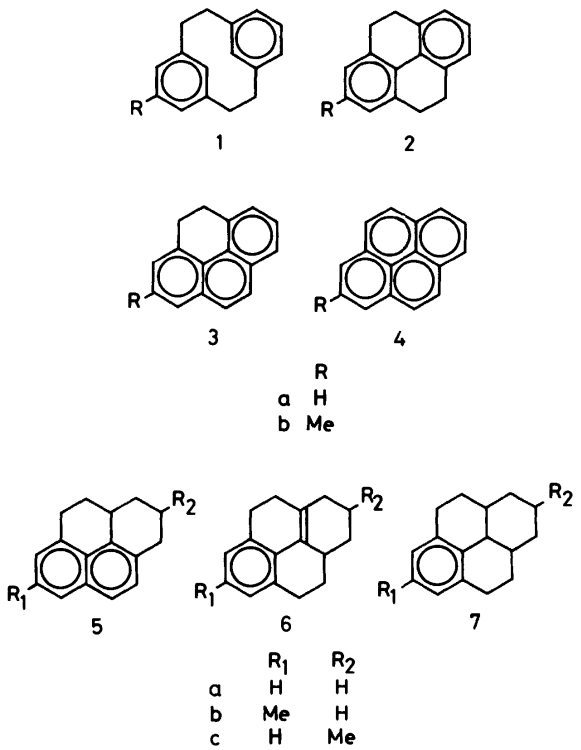
(Received April 23, 1985)

The treatment of [2.2]metacyclophanes with aluminum chloride gave a variety of hydropyrenes as the results of dehydrogenation, cycloisomerization, and disproportionation reactions. With ethylaluminum dichloride, however, a highly selective reaction occurred to give *trans-trans*-1,2,3,3a,4,5,9,10,10a,10b-decahydropyrene. Revised structures were presented for *cis-cis*- and *trans-trans*-decahydropyrenes based on ^{13}C NMR and X-ray crystallographic analyses.

We have reported[1] that the treatment of [2.2]-metacyclophane (**1a**) with aluminum chloride in carbon disulfide gives a variety of hydropyrenes, arising from three types of transannular reactions; 1) dehydrogenation (**2a**, **3a**, and **4a**), 2) cycloisomerization (**5a**), and 3) hydrogenation *via* disproportionation (**6a** and **7a**). The type-1 reaction occurred quite readily



due to an anomalously low anodic potential of **1a**[2] by the action of various one-electron oxidants and other electron-transfer conditions.[3] The selective formation of **5a** through the type-2 reaction was best achieved by the reaction of **1a** with iodine.[4]

In this paper we describe the selective formation of the type-3 products, especially decahydropyrene (*cf.* **7a**) by using ethylaluminum dichloride. We also report the stereochemistry of the decahydropyrene studied by the NMR spectrometry and by the X-ray crystallographic analysis.

The Reaction of [2.2]Metacyclophane with Aluminum Chloride. Baker and co-workers[5] have reported the formation of 1,2,3,3a,4,5-hexahydropyrene (**5a**) by the reaction of **1a** with aluminum chloride in carbon disulfide. When we repeated the reaction we obtained a complex mixture of products, **2a**, **3a**, **4a**, **5a**, **6a**, and **7a**. By carrying out the reaction under various conditions[1] we have shown that the initial products are 1,2,3,3a,4,5,9,10-octahydropyrene (**6a**), **5a**, and 4,5,9,10-tetrahydropyrene (**2a**). Upon further contact with aluminum chloride, 1,2,3,3a,4,5,9,10,10a,10b-decahydropyrene (**7a**) was formed by the disproportionation of **6a**.

Table 1 shows the product ratio obtained from the transannular reaction of **1a** and **1b** with 4 equiv aluminum chloride in carbon disulfide for 3 h at room temperature. The analyses of the products were performed by GC–MS by using an OV-1 column for gas chromatography. When hydrogen chloride was passed through the mixture, the cycloisomerization product **5a** became the major product.

The effect of a substituent at C-5 was then investigated. Under similar conditions as above, 5-methyl-[2.2]metacyclophane (**1b**) also gave a complexed mixture. Compared with **1a**, the yields of **6** and **7** decreased while the yields of **2** and **5** increased marked-

a) Ref. 1. b) $AlCl_3$–HCl reflux. c) $AlCl_3$–HCl room temperature.

ly. For **5**, **6**, and **7**, two isomeric products are possible, namely the b or c types according to the direction of reaction. The ^{1}H NMR of the products showed the presence of an aromatic methyl resonance at around δ 2.2—2.5 and, hence, these were **5b**, **6b**, and **7b** but not **5c**, **6c**, and **7c**. When hydrogen chloride was passed through the mixture the major product was **5b**.

Selective Formation of Decahydropyrene. The Lewis acid strength of ethylaluminum compounds were found to be as follows:[6]

$$AlCl_3 > EtAlCl_2 > Et_2AlCl, Et_3Al$$

While aluminum chloride was too reactive for **1a** to induce a selective disproportionation reaction, **1a** was inert toward triethylaluminum as well as diethylaluminum chloride.

Ethylaluminum dichloride has been generated *in situ* using the following scheme:[7]

$$Et_2AlCl + TiCl_4 \longrightarrow EtAlCl_2 + EtTiCl_3$$

Ethyltitanium trichloride formed was unstable and the evolution of ethylene among others was noticed.[8] As a control experiment, compound **1a** was found to be stable toward titanium tetrachloride.

When compound **1a** was treated with the reagent formed from 3 equiv each of diethylaluminum chloride and titanium tetrachloride in benzene under reflux for 3 h, nearly equal amounts of **2a** and **7a** were produced. Compound **7a** was found to be a single stereoisomer by the ^{13}C NMR spectrum and gas chromatography using an SE-30 column. The stoichiometric consideration requires a hydrogen donor other than **1a** to give **7a** since only two hydrogens are evolved to form **2a** while the formation of **7a** requires four. Presumably, the ethylaluminum reagent is responsible for the hydrogen source to form highly hydrogenated **7a**.

The directional selectivity on the formation of isomeric decahydropyrenes was tested using methyl-substituted [2.2]metacyclophanes, **1b**, **8**, and **9**. It has been found[1,9] that an alkyl substituent on [2.2]metacyclophane exerts different effects according to the position of substitution. With cycloisomerization, for example, a C-5 alkyl group as in **1b** directs the hexahydropyrene formation while preserving a substituted aryl ring. The C-4 and 6 alkyl groups as in **8** and **9** lead the hydrogenation of a substituted aryl ring, presumably through the additional strain effect of the methyl group on the bridging methylene group.[1,9]

	R_1	R_2
a	Me	H
b	Me	Me

5-Methyl derivative **1b**, upon treatment with 3 equiv diethylaluminum chloride and titanium tetrachloride in benzene, gave an exclusive formation of **7b**, no isomeric **7c** being detected. 4-Methyl derivative **8**, on the other hand, gave a mixture of products **10a** and **11a** in a ratio of 4:6 as analyzed by gas chromatography and ^{1}H NMR. 4,6-Dimethyl derivative **9** gave, under similar conditions, a mixture of **10b** (75%) and **11b** (25%). Here again, the methyl group next to the bridging methylene group forced the formation of the product with a hydrogenated substituted aryl ring similar to the case of cycloisomerization.

In addition to decahydropyrenes, these reactions afforded approximately equal amounts of the corresponding tetrahydropyrenes, **2b**[10] from **1b**, 1-methyl- and 1,3-dimethyl-4,5,9,10-tetrahydropyrenes[10] from **8** and **9**, respectively.

Isomeric structures between **7b** and **7c**, and also **10** and **11**, could be assigned based on both ^{1}H NMR and mass spectrometry. Aromatic methyl compounds, **7b**, **10a**, and **10b** showed singlets around δ 2.2, while aliphatic methyl derivatives **7c**, **11a**, and **11b** showed doublets in the expected region. A base peak in mass spectrometry also gives the difference; namely, base peaks for aromatic methyl and aliphatic methyl compounds were found to be M-15 and M-28, respectively (Table 3).

Stereochemistry of Decahydropyrene. The decahydropyrene **7a** can exist in three stereoisomers, namely *cis-cis*-compound **12a**, *trans-trans*-compound **13a**, and *cis-trans*-**14**. Compounds **12a** and **13a** are *meso* type while **14a** is a *dl*-type.

a) Ref. 1. b) Mp of the mixture, **12d** and **13d**.

hydropyrene, mp 53.5—54.5 °C, by the disproportionation of **1a**. It was also a *meso*-type compound similar to that of Lehner, as examined by ^{13}C NMR. In view of Lehner's results, we tentatively assigned a *cis-cis*-structure **12a**.[1] Later, Hansen *et al.* obtained[12] both of these by the cathodic reduction of tetrahydropyrene **2a** in DMF in the presence of a proton donor. The *dl*-type compound **14** was also reported by Hansen *et al.*[12]

Table 2 summerizes the ^{13}C NMR data for isomeric decahydropyrenes obtained by Lehner *et al.* and by us. The assignment was achieved by an intensity consideration, the off-resonance spectrum, and by a comparison with reported data. Compared with our product, Lehner's decahydropyrene showed a general upfield shift of corresponding resonances. For example, two quaternary carbon resonaces and three out of four methylene carbon resonances showed upfield shifts of 2—8 ppm while aromatic signals were almost similar. The upfield shift of the 10b carbon amounted to almost 8 ppm. This was taken as evidence that Lehner's product had a more congested structure compared to our decahydropyrene.[13] Our product showed a clear triplet in the ^1H NMR spectra, determined at 500 MHz at 1.845 ppm with J=11.3 Hz. This was assigned to the 10b proton which had antiperiplaner vicinal protons (possible only for **13a**, but not for **12a**). From this evidence, we concluded that the assignment must be revised. The Lehner's product was **12a** not **13a**, and our product was **13a** but not **12a**. This assignment appeared to be consistent with the hydrogenation experiment carried out by Lehner for **1a**. They obtained[14] a perhydropyrene possessing *cis-cis*-structure as the partial structure expected from one-sided hydrogenation.

Our decahydropyrenes **7b** and **10a** are best represented by **13b** and **13c**, respectively. The ^{13}C resonances of the 10b carbon for **13b** and **13c** were δ 47.93 and 48.24, respectively, expected from a *trans-trans*-structure. Decahydropyrene **10b**, obtained from **9**, was found to be a mixture of both **12d** and **13d** (mp 75—85 °C as a mixture), almost in equal amounts. These were separated by repeated chromatography on alumina containing silver nitrate. This separated **13d** (mp 97—98 °C) as a fast eluting fraction which was followed by *cis-cis*-compound **12d**. By gas chromatography on OV-1, the elution order was reversed and **12d** became the fast moving fraction. Compound **12d** showed an upfield shift of the 10b carbon resonance by about 8 ppm compared with **13d**. Also, **12d** showed a high-field multiplet in the ^1H NMR at 0.80—1.40 ppm, which in the case of **13d** occurred at 1.05—1.50 ppm. Axial protons Ha in 12′ must be responsible for the upfield shift due to a ring-current

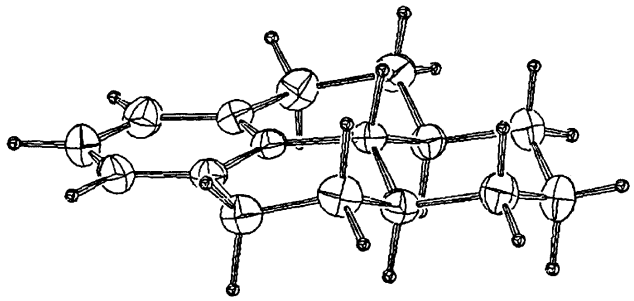

Fig. 1. ORTEP drawing of the structure of **13a**, thermal ellipsoid of 30% probability.

effect.

Conclusive evidence was obtained by the X-ray crystallographic analysis of **13a**. The crystal data for **13a** are as follows: $C_{16}H_{20}$, M=212.32, monoclinic, space group C2/c, a=19.139(15), b=9.970(8), c=15.311(10)Å, β=123.34(9)°, U=2440.8Å^3, Z=8, D_c=1.155 g cm^{-3}. The structure was solved by the direct method. Least-squares refinement of the atomic positional and thermal parameters converged at R=0.06 using 2467 refractions. A view of the molecular structure is shown in Fig. 1.

Experimental

[2.2]Metacyclophane Derivatives. Compounds **1a**,[1] **1b**,[10] and **9**[10] were prepared as described in the literature.

2,11-Dithia-5-methyl[3.3]metacyclophane. α,α'-Dibromo-*m*-xylene was treated with thiourea in ethanol and then with a potassium hydroxide solution to give *m*-xylene-α,α'-dithiol. Benzene solution (600 cm^3) of 4-methyl-α,α'-dichloro-*m*-xylene (17.8 g, 94 mmol), prepared by bischloromethylation of toluene, was dropped slowly into a solution of the dithiol (16 g, 94 mmol) and sodium hydroxide (8 g, 0.2 mol) in benzene (400 cm^3)-ethanol (1000 cm^3) during 72 h under reflux. The solvent was then evaporated, and washed dichloromethane extracts were passed through a silica-gel column. The bis(sulfide) was thus obtained in a 52% yield: pale yellow needles from ethanol-water-hexane, mp 86—88°C: NMR ($CDCl_3$) δ=2.15 (3H, s, Me), 3.6 (8H, m, CH_2), and 6.5—6.9 (7H, m, ArH).

Found: C, 71.24; H, 6.41; S, 22.13%. Calcd for $C_{17}H_{18}S_2$: C, 71.28; H, 6.33; S, 22.39%.

4-Methyl[2.2]metacyclophane (8). The above bis(sulfide) was converted to bis(sulfone), 2,11-dithia-5-methyl[3.3]-metacyclophane 2,2,11,11-tetraoxide, by oxidation with 30% hydrogen peroxide in benzene-acetic acid at room temperature. The pyrolysis of bis(sulfone) at 550°C gave **8** (mp 70—72°C) after chromatography on silica gel: NMR ($CDCl_3$) δ=2.35 (3H, s, Me), 2.05 and 3.07 (8H, m, CH_2), 4.2—4.3 (2H, m, C-8H and C-16H), and 6.9—7.4 (7H, m, ArH).

Found: C, 91.81; H, 8.15%. Calcd for $C_{17}H_{18}$: C, 91.84; H, 8.16%.

The Reaction of 5-Methyl[2.2]metacyclophane (1b) with Aluminum Chloride. The reaction was carried out at room temperature according to the reported method.[1] Analyses of products were carried out by GC-MS using OV-1 (1 m) column. The results are summerized in Table 1.

The Reaction of [2.2]Metacyclophanes with Ethylaluminum Dichloride. a) 1,2,3,3a,4,5,9,10,10a,10b-Decahydropyrenes: As an example the reaction of **1a** with ethylaluminum dichloride is shown. A solution of **1a** (104 mg, 0.5 mmol), diethylaluminum chloride (180 mg, 1.5 mmol), and titanium tetrachloride (285 mg, 1.5 mmol) in benzene (5 cm^3) was stirred at room temperature for 3 h. Column chromatography on alumina eluted with hexane gave **13a** (45 mg, 42%) and **2a** (46 mg, 45%).

Compounds **1b**, **8**, and **9** were treated in a similar manner. Melting points, mass spectra, analytical data, and ^{13}C NMR of decahydropyrenes are shown in Tables 2 and 3.

b) 1-Methyl-4,5,9,10-tetrahydropyrene: The compound was obtained from **8** as an oily material. ^{1}H NMR ($CDCl_3$) δ=2.30 (3H, s, Me), 2.82 (8H, s, CH_2), 6.97 (2H, s, ArH), and 7.05 (3H, s, ArH). Mass spectrum, *m/z* 226.

Found: C, 92.25; H, 7.65%. Calcd for $C_{17}H_{16}$: C, 92.68; H, 7.32%.

Other hydropyrenes were characterized by comparing with the authentic materials reported before.[2,10]

Measurements. ^{1}H NMR spectra were determined on a JEOL GX-500 spectrometer and ^{13}C NMR spectra were measured on a JEOL GX-400 or on a Varian XL-300 spectrometers. X-ray crystallographic analysis was carried out on a Philips automated difractometer (graphite monochromated Cu $K\alpha$ radiation, λ=1.5418Å; θ—2θ scan method, θ_{max} 78°).

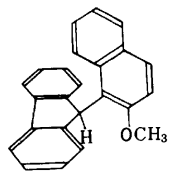
(Received April 23, 1985)

The title compounds of which substituents carry atoms with lone-pair electrons have been prepared and their rotamers isolated as stable entities at room temperature. Deprotonation rates of these rotamers with butyllithium in benzene–hexane solution show a striking difference depending upon the substituents and the rotamers. In both *sp* and *ap* series, compounds with a methoxyl group exhibit the largest rate constants, while those with a sulfur substituent show the smallest reactivity. The difference is explained in terms of coordination ability of the heteroatoms toward butyllithium and by taking advantage of the entropy effect at the transition state of lithiation. The difference in reactivities between rotamers is further striking in a sense that the reactions differ in the order; *sp* rotamers show the first-order kinetics while *ap* rotamers obey the second-order kinetics in the substrate. By assuming that the observed rates are the sum of the first-order and the second-order contributions, we estimate the minimum ratios of the first-order rate constants between *sp* and *ap* rotamers, k_1^{sp}/k_1^{ap}, to be >2300 in the methoxyl and dimethylamino derivatives and >240 in the methylthio derivatives.

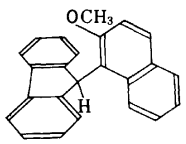
Understanding of the reactivities of rotational isomers is essential for the improvement of selectivity of a reaction. The estimation of the intrinsic reactivity of a rotamer is, however, hampered by the fact that the fast interconversion among rotamers takes place. Some years ago, we were able to isolate stable rotamers of 9-arylfluorene derivatives at room temperature[2)] and have made it possible to investigate the reactivities of rotational isomers.

Fluorene is an acidic compound because, if it is derpotonated at the 9-position, the 6 π electron system develops which should be stabilized due to the aromaticity.[3)] Thus we first selected the deprotonation of 9-arylfluorene derivatives when we launched the project of the work on reactivity of conformational isomers.

In 9-(2-methoxy-1-naphthyl)fluorene (**1**) the difference in deprotonation rates between the *sp* and *ap* rotamers reached the order of 10^3.[4)] The large difference in reactivities observed in this system attracted our attention. Thus, in a previous paper of this series, we



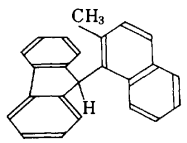
sp-**1**



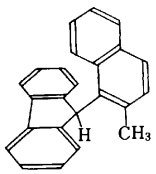
ap-**1**

reported the lithiation of a pair of 9-arylfluorene rotamers which consist of carbon and hydrogen only: The ratio of lithiation rates in the case of 9-(2-methyl-1-naphthyl)fluorene (**2**) was only 7.0 in favor of the *sp* form. The difference can solely be ascribed to the steric effects.[5)] Thus the large difference in lithiation rates in the rotamers of **1** must be ascribed to the existence of the coordinating methoxyl group in a suitable position.

Then it became of interest to see whether a hetero



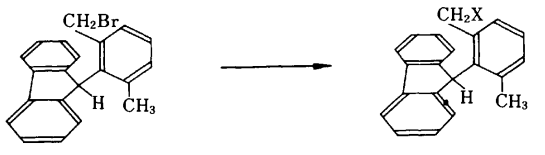
sp-**2**



ap-**2**

atom located remotely from the site of the deprotonation can assist the reaction. Thus in order to investigate the effect of the heteroatoms, we have prepared 9-[2-(substituted methyl)-6-methylphenyl]fluorene derivatives. *sp*-Rotamers of compounds **4**, **5**, and **6** were prepared by the nucleophilic substitution reactions of *sp*-**3** with dimethylamine, methanol, or sodium methanethiolate, respectively. *ap*-Rotamers were also prepared from *ap*-**3** in a similar way.

sp-**3** *sp*



ap-**3** *ap*

4: X = $N(CH_3)_2$
5: X = OCH_3
6: X = SCH_3

In this paper, we wish to report and to discuss the results on deprotonation rates of these rotamers, which showed striking differences from a rotamer to another.

Experimental

9-[2-(Dimethylaminomethyl)-6-methylphenyl]fluorene (4). To a solution of 320 mg of *sp*-**3**[6] in 50 mL of tetrahydrofuran was added 10 mL of 50% aqueous dimethylamine. The mixture was stirred at room temperature for 3 h and then the solvents were evaporated *in vacuo*. The residue was dissolved in 20 mL of ether and dried over sodium sulfate. After evaporation of the solvent, the residue was submitted to silica-gel TLC. Elution with dichloromethane–ethanol (10:1) gave 208 mg (72%) of *sp*-**4**. Recrystallization from hexane–tetrahydrofuran afforded a pure material, mp 87—88 °C. Found: C, 87.89; H, 7.33; N, 4.30%. Calcd for $C_{23}H_{23}N$: C, 88.13; H, 7.40; N, 4.47%. ^{1}H NMR($CDCl_3$) δ=1.10 (3H, s), 2.32 (6H, s), 3.69 (2H, s), 6.02 (1H, s), 6.8—7.5 (9H, m), 7.7—7.9 (2H, m).

To a solution of 130 mg (0.37 mmol) of *ap*-**3** in 50 mL of benzene was added 5 mL of aqueous dimethylamine and 120 mg (0.58 mmol) of silver perchlorate. The mixture was stirred for 20 h at room temperature and then the organic layer was separated. After drying over sodium sulfate, the solvent was evaporated and the residue was submitted to silica-gel TLC (dichloromethane–ethanol (10:1)) to give 52 mg or 44% of *ap*-**4**, mp 90—91 °C, as colorless crystals. Found: C, 87.83; H, 7.15; N, 4.47%. Calcd for $C_{23}H_{23}N$: C, 88.13, H, 7.40; N, 4.47%. ^{1}H NMR ($CDCl_3$) δ=1.51 (6H, s), 2.11 (2H, s), 2.70 (3H, s), 5.44 (1H, s), 7.2—7.5 (9H, m), 7.7—7.9 (2H, m).

9-(2-Methoxymethyl-6-methylphenyl)fluorene (5). Both *sp* and *ap* rotamers were obtained by the treatment of *sp*-**3** and *ap*-**3** with methanol, respectively, as reported previously.[6] mp: *sp* 65—67 °C; *ap* 118 °C.

9-[2-(Methylthiomethyl)-6-methylphenyl]fluorene (6). To a solution of 253 mg (0.72 mmol) of *sp*-**3** in 50 mL of tetrahydrofuran was added 5 mL (11 mmol) of *ca.* 15% aqueous sodium methanethiolate. The mixture was stirred at room temperature for 2 h. After evaporation of the solvent, the residue was dissolved in 20 mL of ether and the solution was dried over sodium sulfate. The ether was evaporated and the resulting oil was submitted to silica-gel TLC. Elution with benzene–hexane (1:1) gave 203 mg (88%) of *sp*-**6**, mp 66—67 °C, as colorless crystals. Found: C, 83.39; H, 6.09; S, 10.41%. Calcd for $C_{22}H_{20}S$: C, 83.50; H, 6.37; S, 10.13%. ^{1}H NMR ($CDCl_3$) δ=1.08 (3H, s), 2.12 (3H, s), 4.00 (2H, s), 5.63 (1H, s), 6.7—7.6 (9H, m), 7.7—7.9 (2H, m).

The *ap*-rotamer of **6** was similarly prepared from *ap*-**3** and sodium methanethiolate in tetrahydrofuran–water solution in 80% yield and was obtained as colorless crystals, mp 76—79 °C. Found: C, 83.52; H, 6.28; S, 10.04%. Calcd for $C_{22}H_{20}S$: C, 83.50; H, 6.37; S, 10.13%. ^{1}H NMR ($CDCl_3$) δ=1.28 (3H, s), 2.45 (2H, s), 2.67 (3H, s), 5.47 (1H, s), 6.7—7.5 (9H, m), 7.7—7.9 (2H, m).

Kinetic Measurement. Following is a typical procedure. A solution of 99.9 mg of *sp*-**4** in 900 μL of benzene-d_6 was prepared. By the use of a microsyringe, 200 μL of this solution (7.08×10^{-5} mol of the substrate) was taken into an NMR sample tube. To each of the 4 samples thus prepared, 300 μL of *ca.* 15% butyllithium in hexane solution was added at −78 °C under a nitrogen atmosphere. These samples were gradually warmed with stirring to make homogeneous solutions. The quantity of butyllithium was determined to be 7.1×10^{-4} mol from the integrated intensity of the signal due to methylene protons alpha to lithium in ^{1}H NMR spectra. Thus the concentration of butyllithium was found to be 10 times as much as that of the substrate. The rates of reactions were determined by monitoring the proton signals due to 4-H and 5-H of the fluorene ring. These protons gave a multiplet signal at δ 8.0—8.2 in the lithiated compound. In each set of the data obtained at 4 different temperatures, a plot of log $(1-x/a)$ *vs.* t gave a good straight line, where a is the initial amount of the substrate and x the amount of the product at time t. The pseudo-first-order rate constants were then obtained by the usual way.

The deprotonation reactions of the other rotamers also obeyed the pseudo-first-order kinetics. The rate constants were similarly obtained at 4 different temperatures. By putting these rate constants into Eyring equation, we obtained the activation parameters for lithiation.

The rates of reactions in the *ap*-rotamers could be followed as in the cases of the *sp*-rotamers. In these cases, however, the treatment of the data assuming the pseudo-first-order kinetics did not give a straight line, but that assuming the rates of second order in the substrate did a straight line.

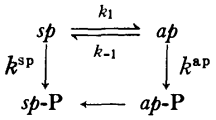
In all of these reactions, the initial amount of butyllithium was kept constant at 7.1×10^{-4} mol. The reaction temperatures were determined from the difference in chemical shifts between the OH and the methyl signals of methanol in ^{1}H NMR spectra.

Results and Discussion

Rotational Barriers and Rates of Lithiation. Barriers to rotation about C_9–C_{aryl} bond in compounds **4**, **5**, and **6** are expected to be similar to that of compound **3** for the process *sp*→*ap*, since the effect of substituent X in the types, $-CH_2X$,[7] $-COX$,[8] and $-OCOX$,[9] on the barrier to rotation is known to be negligible in the 9-arylfluorene system regardless of the kinds of the substituent X. The barrier to rotation for the process *ap*→*sp* can vary especially when attractive or repulsive interactions are present in the *ap* form between X and fluorene ring.[8,9] Since such effects are not expected in the *ap* forms of the compounds examined in this work, the barriers to rotation are estimated to be E_a=27.1±1.0 kcal mol^{-1} (1 cal=4.18 J) or $\Delta G^{\ddagger}$=28.0±1.0 kcal mol^{-1} at 31.5 °C on the basis of the results reported for compound **3**.

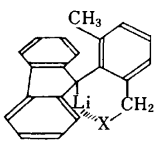
If we take the minimum values of the barrier to rotation, 27 kcal mol^{-1}, the rate constants of interconversion, k_1 and k_{-1}, are calculated to be 3.3×10^{-7} s^{-1}. Since the pseudo-first-order rate constant of lithiation is at least 2×10^{-4} s^{-1} (*sp*-**6**) at 31.5 °C, isomerization of the *sp* rotamer to the *ap* during the lithiation needs not be considered. In the case of *ap* rotamers, however, the rate of isomerization of the *ap* to the *sp* isomer and that of lithiation are comparable and are not very much different from each other especially in the case of *ap*-**6**: the initial rate of lithiation is given by $k^{ap}[ap]_0^2=8.0\times10^{-8}$ mol L^{-1} s^{-1}, which is only 2.4 times larger than the isomerization rate, $k_{-1}[ap]_0=3.3\times10^{-8}$ mol L^{-1} s^{-1}, if the concentration

of the substrate is 0.10 mol L^{-1}. Therefore, partial isomerization of *ap*-**6** to *sp*-**6** may take place under the conditions, which will be followed by the fast lithiation to the product. Raising the temperature increases both k_{-1} and k^{ap}, making the analysis difficult. Thus the rates of lithiation were measured at 31.5 °C only.

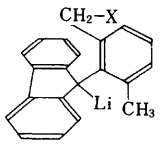


Structure of Lithiated Product. Both *sp* and *ap* rotamers gave identical spectra by lithiation. The structure of the lithiated compound is thought to be **7** where the heteroatom can coordinate to lithium at position 9 to stabilize this form. Such a stabilization is not expected in **8** because of the unfavorable distance between the methoxyl oxygen and the lithium. A piece of experimental evidence supporting this structure is the chemical shifts of the methylene and methyl protons which are connected to the heteroatom. In the lithiated compound derived from **5**, methylene and methyl protons gave broad signals at δ 4.6 and 3.0, respectively, in benzene–hexane (2:3) solutions. These chemical shifts resemble those of the corresponding protons of *sp*-**5**, δ 4.6 and 3.1, in the same solvent system but differ greatly from these of *ap*-**5**, δ 3.3 and 2.6. The results suggest that the methylene and methyl groups in question are located nearly in the plane of the fluorene ring. Although we failed to detect the methyl signals in the NMR spectra of lithiated compounds derived from **4** and **6** owing to the interference of the huge peaks due to solvents, we could find the methylene signals appearing at similar positions as those of the starting *sp* rotamers.

Another piece of evidence for the structure of the lithiated product came from the quenching experiment of it with hydrochloric acid at 0 °C. After the work up procedure as usual, ^{1}H NMR spectrum showed the for-



7



8

mation of the *sp* rotamer as a sole product. Since it is well known that the electrophilic substitution of lithiated compounds in nonpolar solvents such as benzene or hexane proceeds with retention of configuration,[10] the formation of the *sp* rotamer is the direct indication that **7** is the correct structure for the product.

It is difficult to assume that the lithiated structure **7** is directly formed from the *ap* isomers. Instead, the structure **8** will be formed at the first stage and will isomerize to **7** because of the thermal stability of **7**. The barrier to isomerization is expected not prohibitively high in rotation mechanism: The barrier to rotation is known to be reduced as a bulky substituent is introduced to the 9-position of 9-arylfluorenes.[11]

Table 1. Pseudo-first-order rate constants ($\times 10^4$ s^{-1}) of lithiation with temperature (°C) in parentheses of *sp* rotamers[a]

sp-**4**	1.95 (−20.5), 2.93 (−16.2), 12.0 (0.7), 18.8 (4.8)
sp-**5**	1.50 (−24.0), 2.37 (−19.3), 4.96 (−13.7), 7.97 (−9.0)
sp-**6**	2.28 (32.8), 3.29 (37.0), 5.94 (42.6), 10.5 (48.6)

a) Initial concentrations of butyllithium and the substrate were 1.42 and 0.14 mol L^{-1}, respectively.

Table 2. Activation parameters for lithiation of *sp* rotamers

Compound	$\Delta H^{\ddagger}$	$\Delta S^{\ddagger}$

sp-**5**	14.6±0.9	−17.1±3.4
sp-**6**	18.5±1.6	−14.8±5.1

a) 1 e.u.=4.18 J K^{-1} mol^{-1}.

Kinetics. Deprotonation reactions were carried out by the addition of a hexane solution of butyllithium into a benzene solution of the substrate. The reaction rates were followed by monitoring ^{1}H NMR signals at low fields. The starting material possessed a multiplet signal at δ 7.7—7.9 due to 4-H and 5-H of the fluorene ring, whereas the product exhibited a doublet signal at δ 8.0—8.2, thanks to the aromatic character of the product anion.

Analysis of the data for the *sp* series of compounds conformed with the pseudo-first-order kinetics. In Table 1 are listed the pseudo-first-order rate constants thus obtained. Putting these rate constants into the Eyring equation afforded the activation parameters for the reaction, which are shown in Table 2.

By contrast, for the *ap*-rotamers, the reaction rates did not obey the pseudo-first-order kinetics but were second order in the substrate. The second order kinetics in the substrate was further confirmed by the change in the initial concentration. Thus the half-life of *ap*-**5** became longer when the less amount of the substrate was used than the original case. Since the rates of lithiation of *ap*-rotamers were very low even at ambient temperature in the concentration range examined, measurement of the rates at higher temperatures is required to obtain the activation parameters. Raising the temperature, however, may cause the isomerization of the *ap* rotamer to the *sp* which will be deprotonated rapidly. Thus the pseudo-second order rate constants were obtained at 31.5 °C only which are listed in Table 3 together with the concentration of the substrates and the relative rates.

Reaction Mechanisms. Before discussing the difference in reactivities among compounds or between rotamers, the reaction mechanisms of each rotamer

TABLE 3. PSEUDO-SECOND-ORDER RATE CONSTANTS OF LITHIATION OF *ap* ROTAMERS AT 31.5 °C AND RELATED DATA[a)]

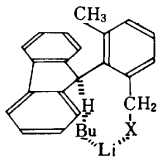
Compound	Rate Constants	Concentration	Relative Rates
	$mol^{-1}Ls^{-1}$	$mol\ L^{-1}$	
ap-**4**	5.34×10^{-5}	0.10	6.7
ap-**5**	3.20×10^{-4}	0.051	40
	3.38×10^{-4}	0.084	42
ap-**6**	7.98×10^{-6}	0.10	1.0

a) Initial concentration of butyllithium was 1.42 mol L^{-1}.

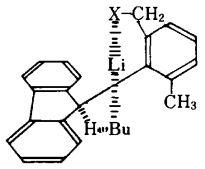
must be considered. In nonpolar solvents, such as benzene or cyclohexane, butyllithium exists as a hexamer[12] and carbon–lithium bond is mainly covalent. As a result, butyllithium behaves as a bulky reagent. In more polar solvents than hydrocarbons, such as ether or tetrahydrofuran, however, coordination of solvent molecules toward lithium occurs to result in the deaggregation of butyllithium.[12,13] The deaggregation together with the increase in ionic nature of the carbon–lithium bond in the polar solvents makes butyllithium a more reactive species. In fact, a parent hydrocarbon, 9-(2,6-xylyl)fluorene, did not react with butyllithium at 31.5 °C in a benzene–hexane solution even after several days, while it did react instantaneously in tetrahydrofuran solutions at the same temperature.[5] Thus the reaction of *sp* and *ap* rotamers with butyllithium, which occured even in nonpolar solvents is ascribed to the coordination effect of the substituent to the butyllithium and the reaction mechanism must be considered accordingly.

The large negative values of entropy of activation for the reactions of the *sp* series shown in Table 2 suggest that the reactions proceed at least bimolecularly. Deaggregation of butyllithium will take place, when the substrate and butyllithium collide, to form an active species responsible for deprotonation by the assistance of the heteroatom in the substituent. There may be several active species, which differ in the degree of aggregation and are differently contributing to the total reaction. In the second step, the active species deprotonates from the 9-position of the same complex. A plausible structure of the transition state is given by **9** in the case where butyllithium exists as a monomer.

In the case of *ap* rotamers, the reaction path must be different from that of *sp* rotamers because the rates of deprotonation of the *ap* rotamers obeyed the second-order rate law in the substrate. Thus the direct abstraction of 9-H by butyllithium spanning between the substituent and the 9-H as shown by **10** is neglected, since the rate should be first order in the substrate, if it were the case. Inspection of the molecular model also revealed that the distance between the coordinating butyllithium and the 9-H is unfavorable for the reaction to occur, especially when the butyllithium is a monomer. It is, therefore, more reasonable to consider an intermolecular reaction: Coordinated butyllithium



9



10

abstracts the 9-H of another molecule in the rate-determining step.

Comparison of Reactivities among Compounds. *a)* sp-*Rotamers*: As discussed in the previous section, coordination of the substituent to lithium is very important for the reaction to occur. Then the rate of the reaction of the *sp* rotamer is affected both by the rate constant of deprotonation and the equilibrium constant of deaggregation. If a strong coordination of the heteroatom toward the aggregated butyllithium takes place, it will increase the concentration of active species as well as the ionic character of the lithium–carbon bond: It results in the increase in the rate of deprotonation as well as the equilibrium constant. It is, therefore, reasonable to state that the compound which has a substituent of stronger coordinating ability to lithium ion is much more reactive than the compound carrying a less coordinating substituent.

The rate constants in Table 1 indicate that the oxygen-containing **5** showed the highest reactivity toward butyllithium among the compounds examined at ambient temperature. Nitrogen substitution similarly accelerated the reaction but the sulfur substitution was not so effective as those of the former two compounds. The high reactivities observed in *sp*-**4** and *sp*-**5** relative to that in *sp*-**6** seem to correspond to the generally accepted coordination ability of the heteroatoms concerned toward lithium ions: lithium ions are classified as a typical hard acid[14] and thus tend to make a stronger bond with a hard base such as a nitrogen- or oxygen-containing substituent than a soft base such as a sulfur-containing group.

The recent thermodynamic study by Xu and Smid showed that polyamines such as penta-*N*-methyldiethylenetriamine and hexa-*N*-methyltriethylenetetramine have a higher affinity toward lithium ions than the corresponding oxygen analogs, di- and triethylene glycol dimethyl ether, respectively.[15] These results suggest that the nitrogen-containing substituent has a stronger coordination ability toward lithium ions than the oxygen-containing group and thus are against the order of the reactivities that we observed.

Further inspection of the data in Table 2, however, reveals that *sp*-**4** has the smallest activation enthalpy and the largest negative value of entropy of activation among the compounds examined. The former is ascribed to the strong coordination of the dimethylamino group to butyllithium in the transition state of reaction, being consistent with the thermodynamic

data. The latter could be explained in terms of the orientation of the reactants required in the transition state. Since a dimethylamino group has only one lone pair of electrons, the direction of the lone-pair electrons is important for the effective coordination. Existence of two methyl groups also prohibits certain conformations for steric reasons. As a result, only a limited number of conformations is possible for the dimethylamino group to coordinate to butyllithium. These factors are considered to decrease the entropy of activation. In the case of *sp*-**5**, such a restriction of conformations may not be severe since the methoxyl group has two pairs of electrons and only one methyl group. Thus the apparent reversal in the order of reactivities between **4** and **5** is ascribed to the entropy effect. The activation parameters in Table 2 suggest that the rate constants of *sp*-**4** become larger than those of *sp*-**5** at temperature below −28 °C, where the molecular motion slows down and the rates are controlled mainly by the enthalpy of activation.

b) ap-*Rotamers.* Reactivities of *ap* rotamers are quite similar to those of *sp* rotamers in a sense that *ap*-**5** and *ap*-**6** showed the largest and smallest rate constants, respectively, among the compounds examined at 31.5 °C. The data in Table 3 also showed that the ratio of rate constants, *k*(*ap*-**5**)/*k*(*ap*-**4**), is *ca.* 6.0 which is twice as large as the corresponding ratio in the *sp* series. The difference in the ratio can be explained in terms of the entropy effect as well. The number of conformations possible for the *ap*-form of **4** is more limited than *sp*-**4** because of the presence of the fluorene ring in proximity. As to the C(aryl)-to-C_α(substituent) bond rotation, no conformation is possible in which the C–N bond directs toward the fluorene ring. In addition, any invertomers about the nitrogen atom, in which one or two of the methyl groups directs toward the fluorene moiety may be unstable for the steric reasons. These factors all act to decrease the entropy when lithium ions coordinate to the amino-nitrogen.

Comparison of Reactivities between Rotamers. The most striking feature in the reactivities of rotamers is that they showed different mechanism in the lithiation. Thus the direct comparison of the rate constants between *sp* and *ap* rotamers may be meaningless. For the comparison, let us assume that the observed rate is given by the sum of the first-order and the second-order contributions as described by equations 1 and 2 for the cases of *sp* and *ap* series, respectively. Although it is possible to state that various kinds of reactions, those of butyllithiums of different degrees of aggregation and those of the higher order than the second, can take place, as a rule of thumb, the assumption may be justified.

$$\text{Rate}(sp) = k_1^{sp}[sp] + k_2^{sp}[sp]^2 \quad (1)$$

$$\text{Rate}(ap) = k_1^{ap}[ap] + k_2^{ap}[ap]^2 \quad (2)$$

TABLE 4. PSEUDO-FIRST-ORDER RATE CONSTANTS OF *sp* AND *ap* ROTAMERS AT 31.5 °C

Compound	k_1^{sp} / s^{-1}	k_1^{ap} / s^{-1}	k_1^{sp}/k_1^{ap}
4	1.25×10^{-2}	$<5.3\times10^{-6}$	>2300
5	3.80×10^{-2}	$<1.6\times10^{-5}$	>2300
6	1.95×10^{-4}	$<8.0\times10^{-7}$	>240

where k_1 and k_2 are rate constants of first and second order reactions in the substrate, respectively.

In these equations, the concentration of butyllithium is included in the constants, k_1 and k_2, since it is at least 10 times as much as the concentration of the substrate. In the case of *sp* rotamers, the observed rate obeyed the first-order kinetics, meaning that the first term predominates over the second term in Eq. 1. In the case of *ap* rotamers, in contrast, second term becomes predominant in Eq. 2. Thus we concluded the following two relations, 3 and 4:

$$k_1^{sp} \gg k_2^{sp}[sp] \quad (3)$$

$$k_1^{ap} \ll k_2^{ap}[ap] \quad (4)$$

By considering the data in Table 2 with respect to these relations, we can calculate the maximum values of k_1^{ap} for each *ap* rotamer. In Table 4 are listed these values together with the rate constants of the reaction of the *ap* form at 31.5 °C and the minimum ratios of k_1^{sp}/k_1^{ap}.

It may be possible to obtain the intrinsic k_1 values for *ap* rotamers by measuring the rates at the low concentration range of the substrates, where the second term of Eq. 2 is negligibly small. Present method, which consists of the monitoring of the signals by ^{1}H NMR spectroscopy, however, makes it very difficult to obtain reasonably good results in such a low concentration range. In addition, the reaction of the *ap* form under such conditions may be too slow to be practicable for the measurement, even if we assume that a suitable methodology is found.

This work was supported by a Grant-in-Aid for Scientific Research of the Ministry of Education, Science and Culture, to which our thanks are due.

Studies with Inorganic Ion-exchange Membranes. I. Effect of Binding Material on the Permeation of Electrolyte Solutions across Titanium Tungstoarsenate Membranes

S. K. SRIVASTAVA,* Satish KUMAR,† and Surendra KUMAR
Department of Chemistry, University of Roorkee, Roorkee-247 667, India
(Received March 19, 1984)

A comparative study of permeability for various electrolytes is made on parchment-, polystyrene-, and Araldite based membranes of titanium tungstoarsenate at 20, 25, 30, and 35 °C. At any given temperature the order of permeability increase is $K^+ > Na^+ > Li^+$ for 1:1 electrolytes and $Ba^{2+} > Ca^{2+} > Mg^{2+}$ for 2:1 electrolytes. Permeability values are higher for parchment-based than polystyrene-based membranes. The diffusion of these electrolyte solutions across Araldite based membrane is almost negligible. Thermodynamic parameters of diffusion process, *viz.*, $\Delta H^{\neq}$, $\Delta S^{\neq}$, $\Delta F^{\neq}$ have been evaluated at 25 °C by applying the theory of absolute reaction rates. $\Delta S^{\neq}$ values are negative for all the cations for both the membranes except that of Li^+ which is positive for parchment-based membranes. $\Delta F^{\neq}$ values are higher for the polystyrene-based than parchment-based membranes.

Inorganic ion-exchange membranes are of vital importance in analytical chemistry[1-6] and also as the models for biological membranes. Literature survey on this topic reveals that a lot of work has been done in the last two decades on the characterization and membrane properties of this class of membranes by various research groups.[7-13] Most of the reports made in this direction deal with the membranes prepared by keeping the same binder but different membrane materials and almost no attempt has been made so far to investigate the effect of binding material on membrane properties by selecting the same membrane material but different binding materials.

We have also been working on the electrochemical properties of inorganic ion-exchange membranes and their possible applications as ion-selective electrode.[14-16] In this communication we report the effect of binding material on the permeability and thermodynamic parameters of the diffusion process, *viz.* ΔS^{*}, ΔH^{*}, ΔF^{*}, across titanium tungstoarsenate membranes with parchment, polystyrene and Araldite as binding material for their preparation.

Experimental

Titanium(IV) chloride (B.D.H), sodium arsenate heptahydrate (E. Merck) and sodium tungstate (AnalR) were used as such. The specimen of Araldite was obtained from Cibatul Limited, India (composition not known). All other chemicals used in this investigation were also of A.R. grade.

Preparation of Titanium Tungstoarsenate. Titanium tungstoarsenate is prepared by adding 0.25 M (1 M=1 mol dm^{-3}) titanium(IV) chloride solution to a mixture of 0.25 M sodium arsenate and 0.25 M sodium tungstate in the volume ratio 2:1:1. The pH of the mixture and titanium(IV) chloride solution was adjusted to one. The precipitate thus obtained was allowed to stand for 24 h at room temperature. It was then washed by decantation with distilled water and afterwards with 2 M nitric acid. The gel, dried at 50 °C, broke down to small particles when immersed in distilled water. The conditions mentioned above are optimum one for the preparation of a stable gel showing good sorption property.

† Institute of Paper Technology, Saharanpur.

A 0.2 g amount of the exchanger material was dissolved in concentrated sodium hydroxide solution and filtered. The residue, titanium hydroxide was dissolved in sulfuric acid and titanium was determined by hydrogen peroxide method, In the filtrate, arsenic was estimated by Volhard's thiocyanate method and tungsten by gravimetry as barium tungstate. The values obtained are Ti=9.51%, W=40.03%, and As=19.98% (the ratio Ti:W:As=1:4:2). The exchange capacity of the material is 0.86 meq g^{-1} (univalent ion) as reported earlier.[17]

Preparation of Membranes Using Different Binding Materials. The homogeneous membranes of titanium tungstoarsenate could not be prepared. Heterogeneous membranes of these compounds employing three different support materials (*i.e.* parchment paper, polysterene and Araldite) were prepared and found to be quite satisfactory.

(i) Preparation of Parchment Paper Impregnated Membrane: The membrane was prepared by impregnated parchment paper with titanium tungstoarsenate. The paper was first soaked in distilled water and then tied carefully on an open glass cylinder. A 0.25 M titanium(IV) chloride (pH=1) solution was filled inside the paper container which was then suspended in a beaker containing a mixture of sodium arsenate and sodium tungstate (prepared by mixing 0.25 M solution each in volume ratio 1:1 at pH=1) for 12 h. The parchment was then taken out and washed repeatedly with distilled water to remove the adsorbed electrolytes. The solutions of titanium(IV) chloride and mixture of sodium arsenate and sodium tungstate were then interchanged and paper was immersed again for another 12 h. The white membrane thus obtained was repeatedly washed with distilled water for complete removal of adsorbed electrolytes.

(ii) Preparation of Polystyrene-based Membrane: Polystyrene granules were heated in a glass tube in a concentrated sulfuric acid bath at 200 °C. The molten mass was allowed to cool down to room temperature and the polystyrene rod, thus obtained was ground to a 50 mesh sieve product. Membranes were obtained by mixing polystyrene and exchanger material in the ratio 1:5 by weight and heating the mass in a die kept in a metallurgical specimen mount press at 110 °C under a pressure of 6000—7000 psi. The optimum quantity of polystyrene to be added was determined by trial. Membranes with 20% polystyrene content were quite stable and did not show any dispersion in salt solutions.

(iii) Preparation of Araldite-based Membranes: A homogeneous mixture of 0.6 g titanium tungstoarsenate and 0.4 g

of Araldite (minimum amount of binder necessary for a stable membrane) was uniformly spread over a piece of filter paper, which was then pressed gently with the help of a glass plate and left to dry overnight. After drying, the membrane of 1.5 cm in diameter was cut manually with the help of a razor and filter paper was also removed from the membrane surface. A large number of membranes were thus prepared and the one which did not have any cracks and was quite smooth and had a thickness of 2 mm was selected for subsequent investigations.

Determination of Permeability. The constant flow method, recommended by Willis,[18] was emplyed for permeability measurements. All experiments were performed with 0.05 M metal chloride solutions and the flow of water as well as solution was maintained at 50 $ml\,h^{-1}$. The conductivity of the lower half cell solution was measured at various time intervals. An increase in initial stages and then a constant value of conductance were observed in almost one hour time. The equilibrium conductance was corrected for conductance of water flowing through the lower half cell.

The concentration of the solution flowing through the lower half cell was computed from calibration curves drawn for this purpose by plotting conductance against concentration. For the evaluation of thermodynamic parameters of diffusion process, the permeability of salt solutions was determined at four tempertures, *viz.* 20, 25, 30, and 35 °C.

Results and Discussion

Permeability of a membrane may be defined as the amount of solute diffusing across it in unit time and unit concentration gradient. The data on permeability of various electrolyte solutions at different temperatures across the parchment- and polystyrene-based membranes are given in Table 1. The permeability across Araldite-based membrane of this compound was found to be negligible and no diffusion of the electrolyte was observed even when the experiments were performed with salt solutions tagged with radioactive isotopes. Thermodynamic parametres for the diffusion process across the membranes, as computed from permeation data at 25 °C, are given in Table 2.

Permeabilities of various electrolytes across the membranes having different binders show the following order:

Parchment-based membranes > Polystyrene-based membranes > Araldite-based membranes.

The diffusion of various salt solutions across the parchment- and polystyrene-based membranes follow the order:

$$K^+ > Na^+ > Li^+ \text{ and } Ba^{2+} > Ca^{2+} > Mg^{2+}$$

The permeation of an electrolyte through a membrane depends upon the charge and size of the diffusing ion, charge on the membrane matrix and its porosity. Over and above this, another factor of prime importance is the exchange capacity of the membrane material and the nature of binder used (in the case of heterogeneous membranes).

The fixed charge on the membrane matrix acts in two ways, firstly it excludes the co-ions from the membrane phase due to electrostatic repulsion and secondly it increases the mobility of counter ions in the membrane phase. Thus the fast moving chloride ions would be exluded from the membrane phase whereas the slow moving cations such as Li^+, Na^+, and Ca^{2+} *etc.* would be attracted towards it. The next two steps in the process of diffusion are the entry of cations into the membrane phase by ion exchange and their diffusion to the other side, through the pores of the membrane.

Table 1. Permeability of univalent and bivalent metal chlorides through titanium tungstoarsenate membranes at different temperatures

Electrolyte	Parchment-based TWA membrane Permeability/$\mu mol\,h^{-1}$				Polystyrene-based TWA membrane Permeability/$\mu mol\,h^{-1}$			
	20 °C	25 °C	30 °C	35 °C	20 °C	25 °C	30 °C	35 °C
LiCl	23.20	30.35	41.50	58.30	1.30	1.70	1.84	2.32
NaCl	38.20	46.25	55.00	62.75	1.64	1.99	2.23	2.50
KCl	82.00	89.00	103.50	121.00	1.99	2.32	2.81	3.27
$BaCl_2$	36.10	42.20	47.75	53.00	0.43	0.45	0.51	0.55
$CaCl_2$	23.10	27.60	31.15	36.20	0.15	0.20	0.24	0.29
$MgCl_2$	8.25	11.15	14.10	17.75	0.05	0.07	0.08	0.99

Table 2. Activation energy and other thermodynamic parameters for electrolyte diffusion through titanium tungstoarsenate membranes at 25 °C

Electrolyte	Parchment-based TWA membrane				Polystyrene-based TWA membrane			
	E_a	ΔH^*	ΔF^*	ΔS^*	E_a	ΔH^*	ΔF^*	ΔS^*
	$kJ\,mol^{-1}$	$kJ\,mol^{-1}$	$kJ\,mol^{-1}$	$J\,mol^{-1}\,K^{-1}$	$kJ\,mol^{-1}$	$kJ\,mol^{-1}$	$kJ\,mol^{-1}$	$J\,mol^{-1}\,K^{-1}$
LiCl	44.98	42.50	37.73	16.00	25.01	22.53	40.46	−60.16
NaCl	23.96	21.48	36.67	−50.97	19.55	11.07	40.07	−77.18
KCl	19.49	17.01	35.00	−60.37	25.53	23.05	39.69	−55.84
$BaCl_2$	19.40	16.92	36.90	−67.05	12.31	9.83	43.72	−113.72
$CaCl_2$	21.13	18.65	37.99	−64.89	31.53	29.05	44.60	−58.18
$MgCl_2$	36.76	34.28	40.24	−20.00	36.47	33.99	48.35	−48.18

This eventually leads to the setting up of an electrical double layer across the membrane and gives rise to equilibrium conditions.

The passage of ions through membranes also depends on the charge and hydration of ions. Multivalent ions will experience a greater electrostatic force than the univalent one. Ions undergoing hydration would affect the permeability in two ways: Firstly by virtue of their size and secondly due to the extent to which the electrical forces of the membrane can pierce through the hydration shell. The position of ions in Holfmeister series should therefore influence the diffusion process and the order of diffusion should be:

$$Cs^+ > Rb^+ > K^+ > Na^+ > Li^+ \text{ and } Ba^{2+} > Ca^{2+} > Mg^{2+}$$

The order of permeability observed with the membranes under discussion, is in agreement with the sequence mentioned above.

It is observed that permeability increases with temperature. Applying Boltzmann distribution law to hydration-dehydration dynamic equilibrium, it can be concluded that at higher temperature considerably higher fraction of the total number of ions would be dehydrated and would possess the excess energy E_a required for permeation. The slope of log P *vs.* $1/T$ (Figs. 1 and 2) gives the activation energy E_a for the process of diffusion and the values obtained for these membranes are listed in Tables 1 and 2.

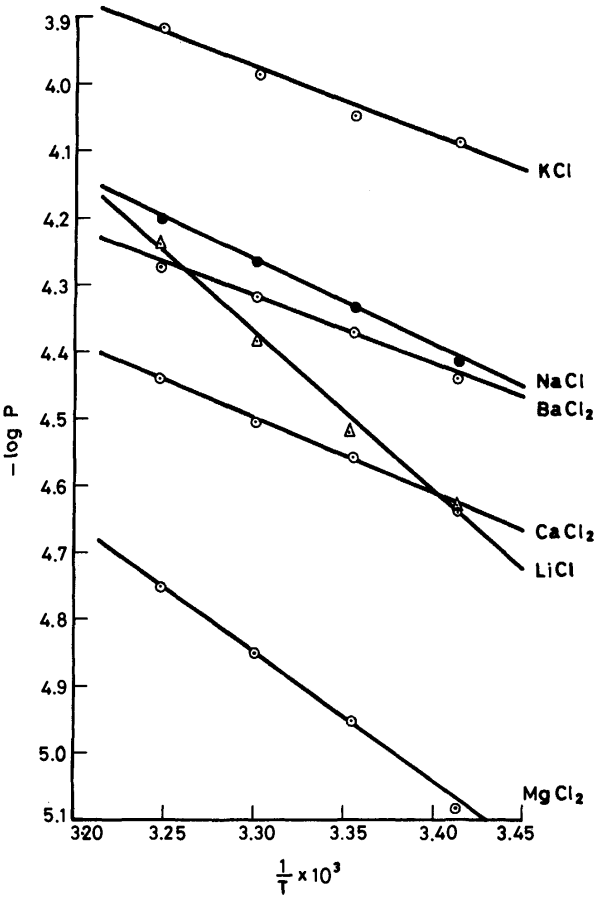

Fig. 1. Plots of log P *vs.* $1/T$ for parchment-based TWA membrane.

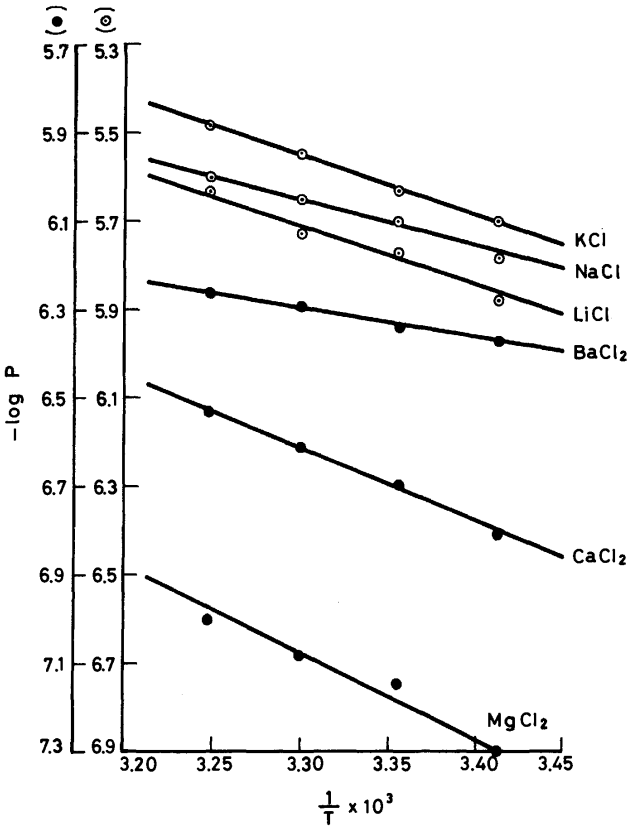

Fig. 2. Plots of log P *vs.* $1/T$ for polystyrene-based TWA membrane.

The theory of absolute reaction rate has been applied to diffusion processes in membranes by several investigators.[19-21] According to Zwolinski *et al.*[19] the permeability P' (cm s^{-1}) is given by the expression

$$P' = \left(\frac{\lambda^2 kT}{\delta h}\right)\exp(-\Delta F^*/RT)$$

where λ is the average distance between two equilibrium positions during the diffusion process, δ is the thickness of the membrane, while other symbols have their usual thermodynamic meanings. The value of free energy of activation can be calculated provided λ is known. This distance can be taken to be the same as the hopping distance, (3×10^{-8} cm) determined by Lai and Mortland.[22]

The ΔH^*, enthalpy of activation is related to E_a by the equation:

$$\Delta H^* = E_a + RT$$

and ΔS^*, the entropy of activation, can be calculated by Gibbs-Helmholtz equation:

$$\Delta F^* = \Delta H^* - T\Delta S^*$$

The values of ΔS^*, ΔF^*, and ΔH^* calculated on the basis of expressions given above are tabulated in Table 2.

It is observed that the values of entropy of activation

are generally negative except for lithium in the case of parchment-based membrane of this compound which exhibits a positive entropy of activation. Similar observations have also been reported by other workers in the case of parchment based ion-exchange membranes.[23] According to Zwolinski *et al.*[19] the values of ΔS^* indicate the mechanism of flow and a large positive ΔS^* is interpreted to reflect the breakage of bonds while low and negative values of entropy of activation indicate that activation is accompanied by a decrease in entropy and this would be possible only if the activated state involved formation of some bonds between the diffusing ion and the membrane material.

According to zone activation theory of Barrer and coworkers[24,25] for permeation of gases through polymer membranes, a high entropy value means either the existence of a large zone of activation or the reversible loosening of ordered segments of the membrane structure on permeation.

The positive value of ΔS^* obtained for Li^+ in the case of parchment-based membrane of this compound indicates that the diffusion of this ion across the membrane generates a greater region of disorder. The negative ΔS^* for other species imply two things:

(i) The permeating ions are partially immobilized in the membrane structure or interfacial region as the activated state involves in the formation of a bond between the diffusing ion and membrane material.

(ii) Permeation across membrane is not the only step which guides the rate, besides other factors are also operative.

A perusal of Table 2 reveals that the energy of activation (E_a) and enthalpy of activation (ΔH^*) values for the diffusion of cations are higher in the case of parchment based membrane except for K^+ and Ca^{2+} ions. The values of ΔF^* are higher for polystyrene-based than the parchment-based membranes for all the cations. ΔF^* may be interpreted as the work involved for the permeating species in overcoming the energy barrier during diffusion. Thus the values (Table 2) reveal that diffusion across polystyrene-based membrane involves more work than the parchment-based membrane of this exchanger material. The data on ΔS^* is higher for parchment-based membrane than polystyrene-based membrane. Higher values of permeability observed across the parchment-based membrane also support the above view-points.

One of authors (S. Kumar) is grateful to Council of Scientific and Industrial Research, India for providing financial assistance for carrying out these investigations.

Tin(IV) selenophosphate has been synthesized by mixing 0.05 mol dm^{-3} aqueous solutions of tin(IV) chloride, sodium selenite and sodium dihydrogenphosphate in 1:1:2 ratio at pH=0. The chemical and thermal stabilities are investigated. A tentative formula has been proposed for tin(IV) selenophosphate on the basis of chemical composition, pH titration, IR spectrum and thermogravimetric anslysis. The distribution coefficients of metal ions have been determined in DMF, DMSO, DMF-HNO_3, and DMSO-HNO_3 media. A number of binary, ternary, and quaternary separations of metal ions have been achieved on the columns of tin(IV) selenophosphate.

Studies on amorphous tin(IV) selenophosphate have been reported.[1] Crystalline products as an ion exchanger are being developed because of its many advantages over amorphous products.[2] Recently semicrystalline tin(IV) selenophosphate has been synthesized in our laboratory.[3] The present paper deals with the studies on semicrystalline tin(IV) selenophosphate beyond its synthesis.

Experimental

Reagents. Tin(IV) chloride (Baker Analyzed; USA), dihydrogenphosphate (BDH, England) and sodium dihydrogenphosphate (BDH, India) were used for the synthesis of tin(IV) selenophosphate. Other chemicals were of analytical reagent grade.

Apparatus. The spectrophotometry and pH measurements were performed using EC spectrophotometer GS 866D and Elico LI-10 pH-meter respectively. Perkin Elmer model 137 spectrophotometer and stanton thermobalance type H_4 were used for Infrared and thermogravimetric analyses.

Synthesis. Two samples of tin(IV) selenophosphate were prepared by earlier method.[3] The condition of synthesis and their few properties are shown in Table 1.

Ion Exchange Capacity. The hydrogen libration capacities of sample P_2 and R_3 with potassium ions were determined by column operations as reported earlier.[3]

Chemical Stability. The chemical stabilities of samples

P_2 and R_3 were determined in several solvents at room temperature. A 0.5 g of the material was equilibrated with 50 cm^3 of the solvent and kept for 24 h with intermittent shaking. Tin(IV), selenium and phosphate ion released in the solution were then determined by standard spectrophotometric methods.[4-6] The results are summarized in Table 2.

Composition. For determination of chemical composition of tin(IV) selenophosphate, 0.5 g of the sample was dissolved in hot concentrated hydrochloric acid. Tin(IV) and selenium were determined spectrophotometrically using hematoxylin and potassium iodide reagents.[4,5] Phosphate ion was determined titrimetrically.[7]

pH-Titrations. pH Titrations for NaCl-NaOH system have been performed on sample R_3. A 0.25 g of the exchanger in hydrogen form was equilibrated with 25 cm^3 of the solution at room temperature. pH-titration curve is shown in Fig. 1.

Thermal Treatment. Thermogravimetric analysis (Fig. 2) of the sample R_3 in hydrogen form was performed at a heating rate of 10 °C min^{-1}. To examine the effect of temperature on the ion-exchange capacity, the material (Sample R_3) was heated at different temperatures in a muffle furnace for 1 h. The results are reported in Table 3.

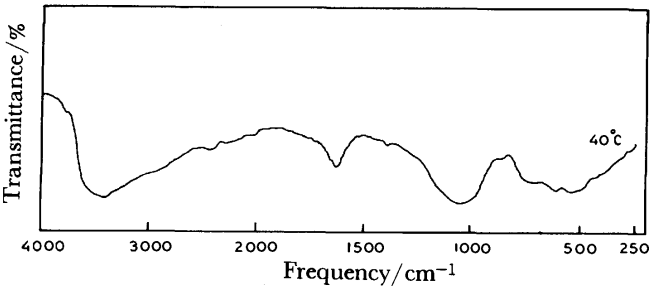

Fig. 3. Infrared spectrum of tin(IV) selenophosphate-(in H^+ form).

IR Analysis. The IR spectrum of sample R_3 dried at 40 °C was obtained by KBr disc method (Fig. 3).

Distribution Coefficients. Distribution coefficients (K_d) of some important metal ions were determined in *N,N*-dimethylformamide (DMF), dimethyl sulfoxide (DMSO) and in mixtures of nitric acid-DMF and nitric acid-DMSO systems as described earlier.[9] The K_d value is defined as following,

$$K_d = \frac{I-F}{F \times W} \times 50$$

where, I is the volume of EDTA consumed by the original solution, F is the volume of EDTA consumed after equilibrium and W is the weight of ion-exchanger in g. The ionic strengths of various metal ion solutions lies between 0.0006 to 0.02. Four mol dm^{-3} DMSO, 4 mol dm^{-3} DMF, and 0.5 mol dm^{-3} HNO_3 were used for distribution studies. The results are given in Tables 4 and 5.

Quantitative Separations. The ion-exchange column was prepared using an earlier method.[10] A 2.0 g of the exchanger (50—100 mesh size) in hydrogen form was taken into a glass column of internal diameter 0.60 cm. Mixture of metal ions was then applied and allowed to pass through the column with a slow rate. The metal ions adsorbed on the exchanger were then eluted with suitable eluting reagent. The flow rate of the effluent was maintained 1 cm^3 min^{-1}, until the metal ions were completely eluted from the column. The metal ions in 10 cm^3 fractions of the effluent were collected and determined either titrimetrically or by standard photometric method.[8] Table 6 describes the separations of metal ions which have been actually achieved on tin(IV) selenophosphate columns.

Results and Discussion

The results of Table 2 show that the samples of

tin(IV) selenophosphate prepared by these methods are more chemically stable than those prepared earlier.[1] The material becomes more stable when it was refluxed in a mixture of phosphoric acid and selenious acid (sample R_3). Tin (IV) selenophosphate is not affected at all by DMSO and DMF. The pH titration curve however shows bifunctional behaviour of tin(IV) selenophosphate.

A comparison of the ion-exchange capacities of tin(IV) selenophosphate, tin(IV) selenite[11] and tin(IV) phosphate[12] after drying the material at different temperatures are shown in Table 3. Tin(IV) selenophosphate appears to be thermally more stable than tin(IV) phosphate and tin(IV) selenite as it retains reasonable capacity (0.38 meq g^{-1}) upto 600 °C.

The molar composition of tin(IV) selenophosphate shows that tin(IV), selenium and phosphate ion are present in the ratio of 4:1:6.

The thermogram of tin(IV) selenophosphate (Fig. 2) in H^+ form shows continuous loss in weight upto 350 °C. The weight loss upto 200 °C (5%) may be due to the loss of external water molecules. The weight loss from 200 to 350 °C may be due to the loss of water molecules by condensation of OH groups and the conversion of phosphate into pyrophosphate. This process is completed at 450 °C and the ion-exchange capacity of the material coincides with the ion-exchange capacity of tin(IV) selenite (0.70 meq g^{-1}) dried at 500 °C (Table 3). The ion exchange capacity of tin(IV) phosphate is completely lost at this temperature (Table 3). The loss in weight is again observed at about 450 °C. This loss may be referred to the loss of water molecules by condensation of more OH groups and the ion-exchange capacity gradually decreases. After 600 °C the weigt becomes constant due to the formation of oxides and the ion-exchange capacity drops to a negligible value at 800 °C.

IR spectrum of sample R_3 (Fig. 3) in H^+ form shows three strong peaks in the regions of 3500—3000 cm^{-1}, 1700—1500 cm^{-1}, and 1100—900 cm^{-1}. The broad peak in the region 3500—3000 cm^{-1} may be due to presence of water molecules and OH groups. A sharp peak in the region 1700—1500 cm^{-1} with a maximum at 1650 cm^{-1} is characteristics of interstitial water molecules. A third broad peak in the region 1100—900 cm^{-1} may be attributed to HPO_4^{2-} ion.

On the basis of the ion-exchange capacity, pH titration curve, chemical composition and thermogravimetric analysis, the following tentative formula for the tin(IV) selenophosphate may be proposed.

$$[(SnO)_4(OH)(HSeO_3)(H_2PO_4)_6]_n \cdot 4nH_2O \quad (1)$$

If it is assumed that the weight loss (5%) upto 200 °C is due to the removal of external water molecules then the number of water molecules per molecule of exchanger, calculated from the formula given by Alberti[13] are 4. If two hydrogen ions are exchanged at pH 6.5, the ion-exchange capacity calculated from the above formula is 1.48 meq g^{-1} which is in good agreement with the experimental value (1.60 meq g^{-1}). The weight in the temperature range 350—450 °C remains constant (Fig. 2) which is supposed to be due to the conversion of hydrogen phosphate to pyrophosphate. The above formula then can be modified to

$$(SnO)_4(HSeO_3)(P_2O_7)_3 \quad (2)$$

The transformation in this temperature range corresponds to 13.4% loss in weight of the sample. This theoretical value is very close to the weight loss calculated from TGA curve (13% at 400 °C). The ion-exchange capacity therefore at 400 °C should only be due to $HSeO_3$ group of the material. The ion-exchange capacity calculated from formula 2 is 0.80 meq g^{-1} which resembles the experimental ion-exchange capacity (0.70 meq g^{-1} at 400 °C).

The potentiality of tin(IV) selenophosphate has been further investigated for the separation of metal ions. The distribution coefficients (K_d) for some important metal ions have been determined in nitric acid and in some more prospective solvents such as DMF, DMSO, DMF-HNO_3, and DMSO-HNO_3 media. It has been observed that these organic solvents have pronounced effect on the adsorption ability of the material. It is observed that the adsorption of almost all metal ions is very low in DMF and DMSO as compared to water. The K_d values increases as the nitric acid concentration increases in the mixture of DMF and DMSO (Tables 4 and 5). However this effect is more pronounced in the cases of Ni^{2+}, Cu^{2+}, and Mn^{2+}. K_d values become almost negligible with the increased concentration of nitric acid in the mixture. However Pb^{2+} has been found to behave in different manner. The metal ion is strongly adsorbed on tin(IV) selenophosphate in DMSO-HNO_3 and DMF-HNO_3 mixtures. In 0.5 mol dm^{-3} HNO_3 solution the K_d value drops to a negligible value. The peculiar behaviour of Pb^{2+} permits the selective separations of Pb^{2+} from other metal ions in a mixture. A very unique feature which has been noticed regarding this exchanger is that the adsorptions of Cr^{VI} is very low in almost all these media as compared to Cr^{III}. The differential uptake of metal ions in these solvents have been utilized for the separations of some important and valuable metal ions. A number of binary, ternary and quaternary separations have been achieved on the columns of tin(IV) selenophosphate (Table 6).

Tin(IV) selenophosphate may be utilized in the determination of Cr^{VI}/Cr^{III} ratio in sea water which is one of the most important subjects in chemical oceanography.[14] The separations of chromium, nickel, manganese, copper, and iron from one another on columns of tin(IV) selenophosphate suggest the possibility of determination and separation of metal ions in steel, alloys, ores, rocks, and related materials.

Crystal Structure of Potassium Dithizonate†,††

Hiroshi NODA,[1] Lutz Meinhardt ENGELHARDT, Jack MacBean HARROWFIELD, Chaveng PAKAWATCHAI, Jennifer Mary PATRICK, and Allan Henry WHITE*

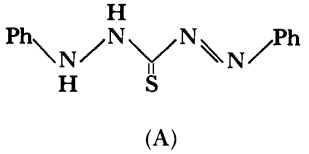
Department of Physical and Inorganic Chemistry, University of Western Australia, Nedlands, W.A. 6009, Australia

(Received May 14, 1984)

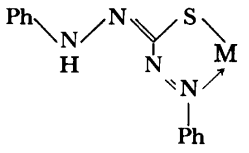
The crystal structure of potassium dithizonate, $K^+[C_6H_5\cdot NH\cdot N\cdot CS\cdot N:NC_6H_5]^-$, has been determined by single crystal X-ray diffraction methods at 295 K and refined by full matrix least squares to a residual of 0.045 for 1101 independent "observed" reflections. Crystals are orthorhombic, Pbca, a=28.942(9), b=13.247(4), c=7.163(3) Å, Z=8. The structure determination is the first carried out on a salt rather than a complex of the anion. The pseudo-planar anion stacks parallel to the ab face of the cell with considerable delocalization evident; as indicated by the above formula, the remaining acidic hydrogen atom is associated with one of the nitrogen atoms.

The well-known analytical reagent dithizone, H_2dz, (A), undergoes both single and double deprotonation, but is best known by way of the numerous, highly-coloured, solvent extractable complexes of the mono-anion, simply referred to usually as the dithizonate anion, Hdz^-.[2]

For such complexes, a variety of linkage isomers is possible and establishment of the coordination mode has demanded the application of X-ray crystallography. In this way, the bidentate N, S chelating form (B) has been established as "usual," though unidentate coordination through sulfur has also been characterized recently in indium(III) dithizonate,[3] in which two bidentate (N,S) and one monodentate (S) ligands are found. All known structures have



(A)



(B)

been determined on compounds of metals which show strong coordinating tendencies and no data has been available for dithizonates which might be regarded as essentially ionic. Accordingly, we have prepared the potassium salt of the monoanion, (1), and report its crystal structure hereunder. Because of its ease of preparation and high solubility in many solvents, it is anticipated that this salt should be of some utility in the preparation of other metal dithizonates.

Synthesis

Because of the ease of oxidation of the ligand, as a routine precaution, all manipulations were carried out under nitrogen using deoxygenated solvents.

Dithizone (2.5 g) was added to a solution of KOH (0.70 g, ≈5% excess assuming 85% purity) in water (3 mL) and the mixture stirred to give a deep orange solution and then a paste as KHdz precipitated. Ethanol (25 mL) was added to dissolve the paste and the solution filtered to remove a small amount of insoluble material. Addition of ether (≈100 mL) to the point of turbidity and standing at room temperature caused the precipitation of clusters of thin, metallic-brown crystals of KHdz. Crystals suitable for X-ray diffraction were obtained from this material, though it could also be recrystallized from ethanol by the addition of ether.

Crystallography

Crystal Data. $C_{13}H_{11}N_4SK$, M=294.4, Orthorhombic, space group Pbca (D_{2h}^{15}, No. 61), a=28.942 (9), b=13.247 (4), c=7.163 (3) Å, U=2746 (2) Å^3. D_c(Z=8)=1.42 g cm^{-3}. F(000)=1216. Monochromatic Mo $K\alpha$ radiation, λ=0.7106$_9$ Å, μ_{Mo}=5.2 cm^{-1}. Specimen: right prism, 0.20×0.40×0.20 mm. T=295 K.

Structure Determination. A unique data set was measured to $2\theta_{max}$=50° using a Syntex P$\bar{1}$ four-circle diffractometer in conventional $2\theta/\theta$ scan mode. 2869 independent reflections were obtained, 1101 with $I>3\sigma(I)$ being considered "observed" and used in the full matrix least squares refinement after analytical absorption correction and solution of the structure by direct methods. Anisotropic thermal parameters were refined; (x, y, z, U_{iso})$_H$ were included constrained at idealized geometries (Exception: the NH hydrogen which was located in a difference map and refined in (x, y, z). Residuals at convergence R, R' (on $|F|$) were 0.045, 0.052, reflections weights being $(\sigma^2(F_0)+0.0005(F_0)^2)^{-1}$. Neutral atom complex scattering factors[4] were used; computation used the X-RAY 76 program system[5] implemented on a Perkin-Elmer 3240 computer by S. R. Hall. Results are presented in the Tables and Figure; atom coordinates for all atoms are given in Table 1, and atom labelling in the Figures.

The lists of structure factors, anisotropic thermal parameters, and non-hydrogen interanion contacts are deposited at the office of the Chemical Society of Japan as Document No. 8504.

Discussion

The result of the structure determination is consistent with the stoichiometry expected for K^+Hdz^-, the

†Material deposited with the editor comprises structure factor amplitudes, thermal parameters and inter-anion contacts.

††Systematic name: Potassium 1,5-Diphenyl-3-mercapto-formazanate.

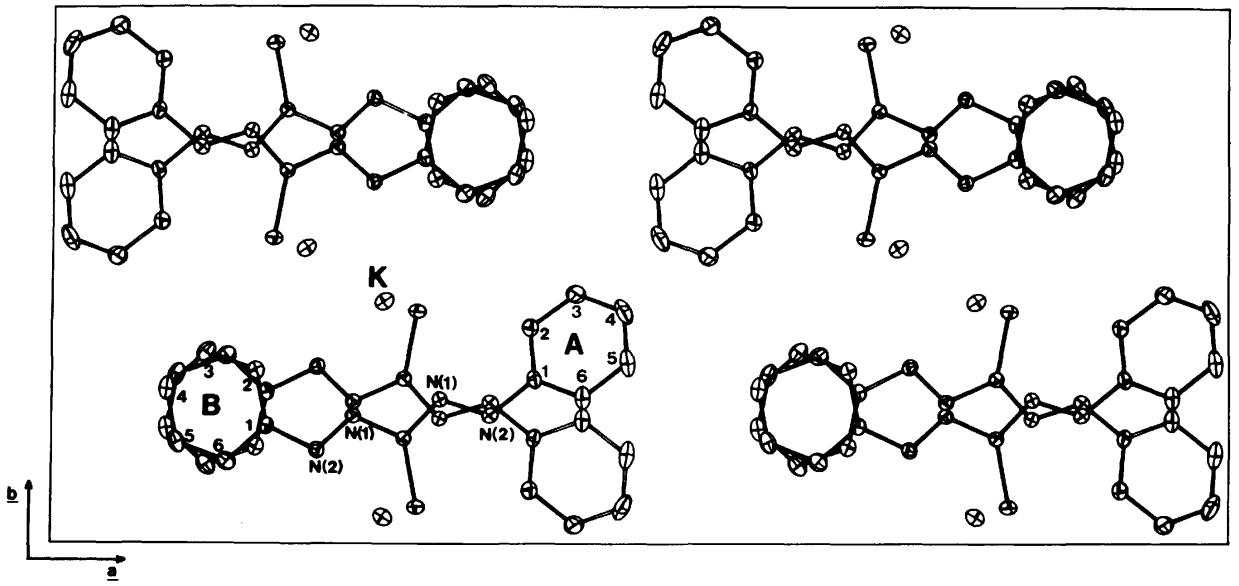
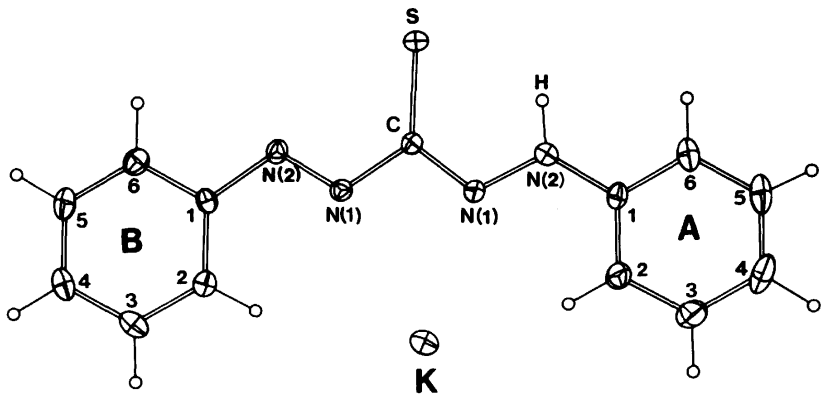
asymmetric unit of the structure comprising one formula unit. The anion is pseudo-planar and approximately parallel to the *ab* face of the cell (Fig. 1(a)); although as discussed below, the central fragment dimensions are indicative of the presence of conjugation, the deviations of the anion from planarity are not confined to the molecular periphery. The plane defined by the $N_2 \cdot CS \cdot N_2$ fragment has σ (defining atoms), 0.047 Å; atom deviations δ N(A2,A1)·CS·N(B1, B2) respectively are 0.041, −0.006, −0.022, −0.021, −0.060, 0.068 Å, with the phenyl ring planes ($\sigma(C_6)$, 0.006, 0.004 Å) having dihedral angles of 14.8, 7.3°





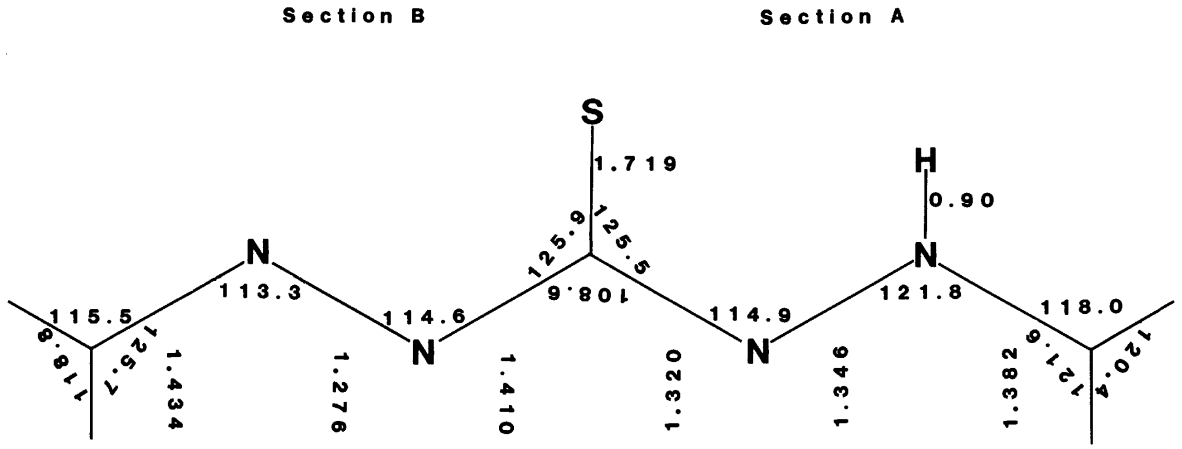


Fig. 1. (a) Unit cell contents, projected down c; 20% thermal ellipsoids are shown for the non-hydrogen atoms.

(b) The asymmetric unit, showing the interaction of the anion with the potassium ion and the location of the acidic hydrogen. Non-hydrogen atom numbering is given, and hydrogen atoms are given arbitrary radii of 0.1 Å.

(c) Non-phenyl anion geometry; distances are in Å and angles in degrees.

Table 2. Potassium environment[a)]

	r	N(B1)	S^{i}	$N(B2^{i})$	S^{ii}	$N(B2^{ii})$

S^{i}	3.150(2)			55.7(1)	108.7(1)	82.9(1)
$N(B2^{i})$	3.196(5)				116.9(1)	133.0(1)
S^{ii}	3.426(3)					52.2(1)
$N(B2^{ii})$	3.305(5)					

a) r is the potassium–ligand atom distance (Å); the other entries are the angles (degrees) subtended by the relevant atoms at the metal.
Transformations of the asymmetric unit: i: (1/2−x, 1/2+y,z), ii: (x, 1/2−y, z−1/2).

respectively to the central plane. For the anion non-hydrogen skeletal plane overall, σ is 0.177 Å, with the potassium ion of the asymmetric unit deviating by 1.274 Å; its deviation from the $N_2 \cdot CS \cdot N_2$ plane is −0.906 Å.

The potassium ion environment is sparse (Table 2); an interesting feature is the disposition within the defined asymmetric unit of the two shortest contacts relative to the anion to N(A1,B1), and, because of anion "planarity," the associated contacts to H(A2,B2) of 2.8_8, 2.9_9 Å. Phenyl ring "B," with the smaller dihedral angle to the $N_2 \cdot CS \cdot N_2$ plane, is reasonably coplanar with the associated NN·CS fragment (deviations, 0.01_8, 0.03_8, 0.077, −0.095, although it is clear that there is a twist about the $CS \cdot N_2$ linkage), and the potassium ion deviation is −0.428 Å. Phenyl ring "A"'s association with its NN·CS fragment is less equable (deviations 0.006, −0.191, 0.003, 0.442 Å) and indicative of considerable torsion within the string; the potassium deviation is considerable, being −1.703 Å. It may therefore be assumed that the closeness of the association of the potassium with N(A1), in the situation of a planar anion, results in too close an association with H(A2), with the associated strain being relieved by distortion of the ligand plane. Although the other

C-N-N(H)	114.6(4)	114.8(6)	119.5(6),	117.6(6)	115	117.3(6),	116.9(6)	117.2(7)	114.9(4)
N-N(H)-C(aryl)	113.4(4)	112.9(6)	116.0(6),	114.6(6)	122	117.4(6),	122.5(7)	120.6(8)	121.8(5)

Species compared are: (1)(A) Unprotonated section of the present dithizonate anion. (3)(A′) Unprotonated section of the S-coordinated ligand of indium(III) dithizonate. (3)(A) Coordinated sections of the chelate ligands of indium(III) dithizonate. (2) The mean of both (protonated) sections of the parent dithizone molecule. (3)(B) Uncoordinated sections of the chelate ligands of indium(III) dithizonate. (3)(B′) Protonated section of the S-coordinated ligand of indium(III) dithizonate. (1)(B) Protonated section of the present dithizonate anion.

four contacts to the potassium ion are also two pairs of "chelate" type interactions, originating in S,N(B2) combinations, the associated K···H(B6) distances are longer (greater than 3.1 Å) and less relevant. About the sulfur atom, a pair of symmetry related potassium ions is found (S···K(1/2−x, y−1/2, z), (x, 1/2−y, 1/2+z), 3.150 (2), 3.426 (3) Å), with the angle subtended at the sulfur being 80.83 (5)° and K···K, 4.268 (2) Å).

The "acidic" hydrogen atom of the anion is clearly associated with N(A2); as refined, the angles H-N(A2)-N(A1), C(A1) may be slightly unsymmetrical (113(3), 125(3)°) with H···S, 2.34 (5), and H···H(A6), 2.4 Å. The *cis* angles at N(A1) and C(A1) are 114.9 (4), 118.0 (5), slightly greater than their counterparts in section B (114.6(4); 115.5(5)°), with the presence of H presumably a contributing factor, as it also presumably is to the distortions noted above in section A.

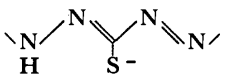
In considering geometry and bonding within the ligand, (Table 3), the closest analogues with which comparison might usefully be made appear to be (i) the protonated ligand (2),[6] with a pair of similar halves (average geometry quoted), and (ii) the five-coordinate indium(III) complex, (3),[3] in which a pair of chelating ligands are found with distinctly different geometries for the chelating segment, denoted (A) and the non-chelating (B), and a third ligand which is monodentate S-coordinated, with a protonated section (denoted (B)) and an unprotonated section (A). The geometries of these species are compared in Table 4 with those of sections A and B of the present anion. With certain dimensional exceptions, the present values are comparable with others expected to lie at the extremes of the range. The exceptions are:

(i) The carbon-sulfur distance, comparable with that in the free ligand, but shorter than that in the S-coordinated monodentate ligand of the indium complex (3), and, in parallel, because of electron-pair repulsion effects

(ii) The N-C-N angle again resembles more nearly the value of the free ligand, rather than that of the S-coordinated monodentate ligand;

(iii) The C-N-NH angle in the present complex is less than its counterpart in the protonated section of the monodentate ligand of the indium complex, and nearer the value of the free ligand, presumably assisted by the incorporation of the potassium ion on its opposite side.

The two halves of the ligand suggest a considerable contribution of the resonance form



The length of certain bonds, in particular, C-S, (1.719(5) Å) and N(A2)-C(A1), 1.382(7) Å, are indicative of more extensive delocalization, however. A number of non-hydrogen interanion contacts, generated in the stacking apparent in Fig. 1(a) by (x, 1/2−y, 1/2+z), approach 3.3 Å as a lower limit and are suggestive of the possibility of charge-transfer interactions.

We gratefully acknowledge support of this work by a grant from the Australian Research Grant Scheme.

Kinetics and Mechanisms of Oxidations by Metal Ions. V. Oxidation of 4-Oxopentanoic Acid by the Aquavanadium(V) Ion†

Raj Narain MEHROTRA
Department of Chemistry, University of Jodhpur, Jodhpur 342 001, India
(Received January 5, 1984)

The outer sphere oxidation of 4-oxopentanoic acid(4-OPA), studied at 50 °C by aquavanadium(V) ion, is H^+-catalyzed reaction. The reaction has a first-order dependence on each of [V^V], [4-OPA], and [H^+]. The H^+ catalysis can not be ascribed to keto⇌enol equilibrium because of the knowledge that a γ-keto acid is the least enolized amongst keto acids. Hence $V(OH)_3^{2+}$ (aq) ion is the active oxidant. The proposed mechanism, assumed to involve the initial decarboxylation, is supported by the spot test characterization of acetoin as the intermediate oxidation product. Acetoin is further oxidized to two moles of acetic acid which is the final oxidation product. The overall energy of activation($\Delta H_1=26\pm3$ kJ mol^{-1}) is lower than the normal value(84 kJ mol^{-1}) and therefore the highly negative value of the overall entropy of activation($\Delta S_1=-268\pm8$ J K^{-1} mol^{-1}) is considered to be responsible for the observed slowrate of oxidation.

Aquavanadium(V) ions in acid perchlorate solution are milder oxidants in comparison to the other aquametal ions such as Ce^{IV}, Mn^{III}, Co^{III}, Ag^{II} *etc.* However, the redox potential of V^V/V^{IV} couple in acidic solution[1] is about 1 volt and is sufficient for the oxidation of a variety of organic compounds with ease. The subject matter has been reviewed.[2-4]

The equilibrium 1 is considered for explaining the acid catalysis having a first-order dependence in [H^+] in the oxidations by vanadium(V). The protonation equilibrium constant K_1 has been not as yet estimated by physical methods though several studies[5,6] on redox kinetics have consistently suggested that $1 \gg K_1[H^+]$ in solutions of 1—5 mol dm^{-3} perchloric acid.[6]

$$VO_2^+ + H_3O^+ \overset{K_1}{\rightleftharpoons} V(OH)_3^{2+}. \quad (1)$$

Recently, that $K_1=3.4$ dm^3 mol^{-1} at 30 °C was estimated in the oxidation of pyruvic acid.[7] Since this value is of such a magnitude that would render the assumption[5,6] that $1 \gg K_1[H^+]$ erroneous even in dilute acid solutions ≥0.1 mol dm^{-3}. Hence a necessity was felt to have a recheck on this value of K_1. It was only obvious to have a similar substrate and the choice of 4-oxopentanoic acid (here in after abbreviated as 4-OPA) was also motivated by the fact that γ-keto acid is least enolized in comparison to α- and β-keto acids.[8] The choice thus eliminated the complexity of the effect of enolization of the >CO group in the interpretation of the results.

Experimental

Reagents. Stock solution of vanadium(V) was prepared by dissolving ammonium metavanadate (Hopkin & Williams, G. R.) in twice distilled water. To the clear yellow solution was slowly added a calculated amount of standard perchloric acid to have a vanadium(V) solution having 2 mol dm^{-3} perchloric acid. In calculating the amount of perchloric acid, extra amount needed for the protonation reaction 2 was also considered.

$$VO_3^- + 2H^+ \longrightarrow VO_2^+ + H_2O. \quad (2)$$

†Reprints are not available.

The stock vanadium(V) solution was standardised titrimetrically[9] with a standard Fe(II) solution using *N,N*-diphenylsulfamate of barium as the indicator in presence of phosphoric acid.

Solutions of 4-oxopentanoic (E. Merck) and perchloric (E. Merck) acids were prepared by suitable dilutions and standardized against a standard alkali. Solutions of 4-oxopentanoic acid of long standing were discarded.

The stock solution of sodium perchlorate was prepared by neutralising sodium carbonate (BDH, AnalaR) with perchloric acid. The neutralized solution was later boiled to eliminate dissolved carbon dioxide. The solution was standardized gravimetrically.

All other reagents used were of analytical grade and distilled water was once again distilled from an all glass still.

Rate Measurements. The kinetics was studied at constant ionic strength (3 mol dm^{-3}) maintained with sodium perchlorate. Reactant solutions of suitable strength were separately thermostatted in a water bath maintained at the desired temperature (±0.1 °C). The reaction was generally initiated by the quick addition of 4-oxopentanoic acid. However, the rate was not affected when the reaction was initiated with vanadium(V). In all experiments, [4-OPA] ≫[V^V] was used which ensured that k_{obsd}, the pseudo first-order rate constant with respect to vanadium(V), was not affected by any reactive intermediate produced during the course of the reaction.

The disappearance of vanadium(V) was followed with a Beckman DU 2 spectrophtometer at 350 nm.[5,6,10] Absorbance due to vanadium(IV) was negligible at this wave length ($\varepsilon_{350}=1.0$ dm^3 mol^{-1} cm^{-1}).[11]

The values of the pseudo first-order rate constant k_{obsd} were obtained by least square analysis of the slopes of the linear plots of ln (A_t-A_∞) against time where A_t and A_∞ are the absorbance at any time t and at infinite time, respectively. The plots were linear ($r>0.998$) beyond three half-lives. Few runs were repeated in presence of an inert nitrogen atmosphere and the k_{obsd} values so obtained were within the limits of experimental agreement (±3%) with those obtained in the presence of air, and the rate was not affected by the presence of vanadium(IV).

Stoichiometry. The stoichiometry of the complete oxidation reaction was determined under different acidity and atmospheric conditions as are detailed in Table 1. The [V^V] was present in excess and the reaction mixtures were left at 35 °C in a thermostatted water bath till $\Delta[V^V]/\Delta$[4-OPA]

					Means: 4.1±0.1

assumed a constant value (6.0±0.1).

Product Analysis. The oxidation products were repeatedly extracted with ether from the reaction mixtures once $\Delta[V^v]/\Delta$[4-OPA] was constant. The ether solution was slowly evaporated and the liquid left behind was found to smell like acetic acid. The presence of acetic acid was characterized by its usual test with neutral Fe(III) chloride and the spot test with lanthanum nitrate and iodine.[12] Hence the stoichiometry of the reaction is expressed by Eq. 3.

$$CH_3CO(CH_2)_2CO_2H + 6V^v + 3H_2O \longrightarrow 2CH_3CO_2H + CO_2 + 6V^{IV} + 6H^+. \quad (3)$$

Reactive Intermediates. In another series of experiments the reaction mixtures were so prepared as to have large excess of 4-OPA over vanadium(V). The reaction products were repeatedly extracted from the partially oxidized reaction mixtures with ether. In this case acetoin was found to be the product and its presence was confirmed with the specific spot test.[12b] Acetoin is reported to be oxidized to acetic acid *via* biacetyl as the reactive intermediate requiring four equivalents of vanadium(V) per mole of acetoin.[13] The presence of biacetyl as the reactive intermediate could not be confirmed, perhaps, for the reason that it is oxidized at a much faster rate.

In view of the above it is clear that the keto acid is first oxidized to acetoin needing only two equivalents of vanadium(V) per mole. The formation of acetoin could be expressed by Eq. 4.

$$CH_3CO(CH_2)_2CO_2H + 2V^v + H_2O \longrightarrow CH_3COCH(OH)CH_3 + 2V^{IV} + CO_2 + 2H^+. \quad (4)$$

Test for Free Radical. Partially oxidized reaction mixtures which were previously flushed with nitrogen and maintained under nitrogen atmosphere produced polyacrylonitrile upon the addition of monomer acrylonitrile indicating the presence of free radical in the reaction mixtures. The blank experiments in which the monomer was separately added to the solutions of vanadium(V) and the keto acid did not show the formation of polyacrylonitrile. While these experiments are not helpful in identifying the actual free radical species, they did indicate the formation of free radicals during the progress of the reaction.

Results

Dependence on [4-OPA]. A twelve fold variation in the initial [4-OPA] was effected to investigate its effect on the k_{obsd}; the results are reported in Table 2. It was found that the plot of k_{obsd} against [4-OPA] was linear with zero intercept indicating that the order with respect to 4-oxopentanoic acid is unity.

Dependence on [H^+]. The effect of initial [H^+] on k_{obsd} was investigated at five different temperatures in the range 0.5—2.5 mol dm^{-3} perchloric acid at a constant ionic strength adjusted with sodium perchlorate to 3.0 mol dm^{-3}. The rate measurements in solutions with [$HClO_4$]<0.5 mol dm^{-3} were not attempted because of the rate of reaction was found to be very slow. The results are reported in Table 3. The plot of k_{obsd} against [H^+] was linear at all temperatures with zero intercept on the rate ordinate as is shown in Fig. 1. Similarly, the plot between k_{obsd} and $-H_0$, the Hammett acidity function,[14] was linear at all the temperatures as is illustrated in Fig. 2. These plots, which are parallel to each other, indicated that slope of plot, 0.84, is independent of temperature. Thus the slope value is nearer to the ideal value of unity expected in this correlation.[15] The H_0 values reported by Day and Wyatt[16] were used.

Effect of Ionic Strength. The effect of ionic

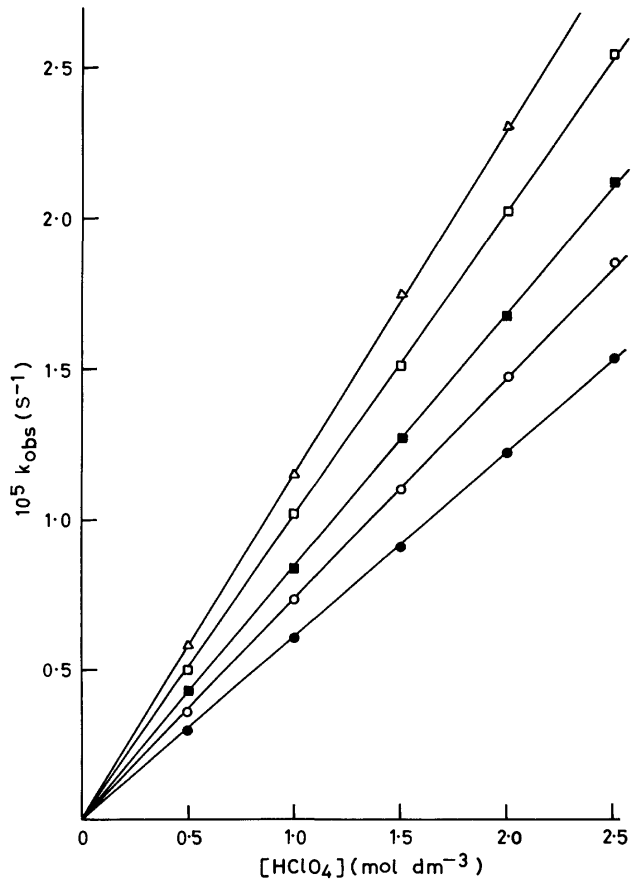

Fig. 1. The linear plots between k_{obsd} and [$HClO_4$] with zero intercepts in solutions of constant ionic strength (3.0 mol dm^{-3}) at 45° (●), 50° (○), 55°(■), 60° (□), and 65° (△). [Vanadium(V)]=0.02 mol dm^{-3} and [4-Oxopentanoic acid]=0.36 mol dm^{-3}.

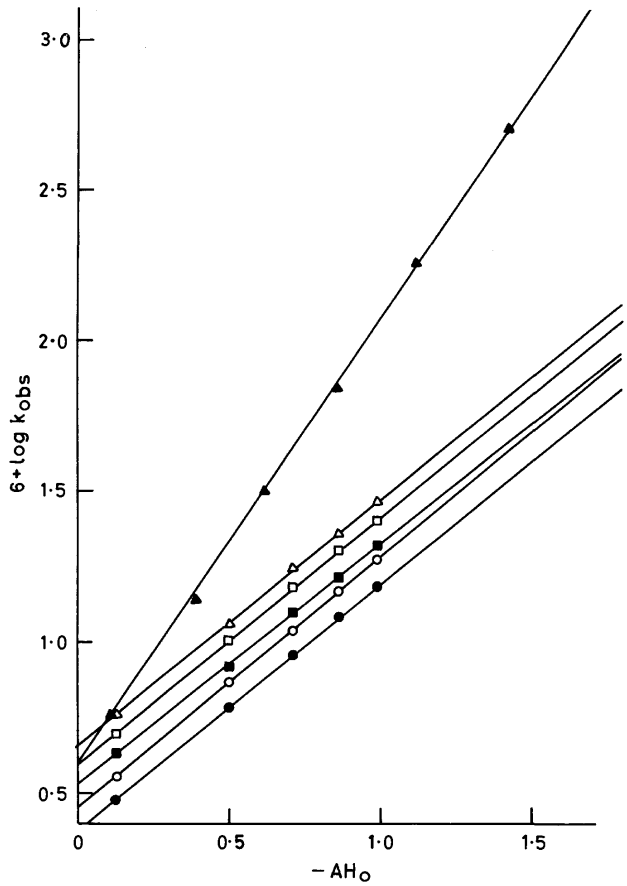

Fig. 2. The linear plots between log k_{obsd} and $-H_0$, the Hammett acidity function, for perchloric acid solutions of a constant ionic strength (3.0 mol dm^{-3}) at 45° (●), 50° (○), 55° (■), 60° (□), and 65° (△) with A=1, and for perchloric acid solution of varying ionic strength at 50° (▲) with A=0.5 [Vanadium(V)]=0.02 mol dm^{-3} and [4-Oxopentanoic acid]=0.36 mol dm^{-3}.

strength on k_{obsd} was investigated by varying the [$NaClO_4$] in the range 0.1—1.0 mol dm^{-3} at a fixed [H^+](2.0 mol dm^{-3}) and [4-OPA] (0.36 mol dm^{-3}) at 50°C. The k_{obsd} was almost independent of ionic strength (10^5 k_{obsd}=1.5±0.1 s^{-1}) indicating that one of the reactants is not charged. Since vanadium(V) species are positively charged[17] in acid solutions>0.1 mol dm^{-3} it is obvious that 4-oxopentanoic acid reacted in the unionized state. A similar conclusion was also derived by considering its pK_a value of 4.5 at 25 °C.[18] The pK_a value indicated that the keto acid is a weak acid and therefore it would largely exist in its undissociated state under the [H^+] used. Moreover, had the anion of the keto acid been reactive a retardation in the rate with increasing [H^+] was expected and was not found.

Discussion

The spectrum of 4-oxopentanoic acid has indicated that any lactol contribution is very small and the keto-form predominates,[19] a fact in conformity with the observation that γ-keto acids are least enolized.[8] Although the formation of enol-lactones is more readily effected in the presence of acid catalysts yet these are less stable,[19] and therefore are not considered to be a major reactive entity. Similarly the keto⇌enol equilibrium has also been excluded from the proposed mechanism because (i) if the rate of keto→enol transformation was rate controlling then the order of the reaction with respect to the oxidant was expected to be zero, and (ii) the very slow nature of the reaction ($10^5 k_{obsd}$/[4-OPA]=4.1±0.1 dm^3 mol^{-1} s^{-1} at 50°C and [$HClO_4$]=2.0 mol dm^{-3}) did not indicate any possibility of the enol as being the reactive entity.

The cationic species of vanadium(V) in acidic aqueous solution are VO_2^+(aq)[20,21] and $V(OH)_4^+$/(aq).[22,23] The existence of $V(OH)_4^+$ as $(VO_2 \cdot H_2O)^+$ has been suggested.[24] The equilibrium between $(VO_2 \cdot 2H_2O)^+$ and its protonated species $V(OH)_3^{2+}$ is shown in equilibrium 5.

In view of the kinetics which has indicated a first-order dependence in each of [V^V], [4-OPA], and [H^+], the following reactions are considered part of the mechanism which is based on the assumption that decarboxylation of the keto acid is the rate determining reaction. The exclusion of the possibility of

the oxidant attacking the >CO group is explained at a later stage of discussion.

$$(VO_2\cdot 2H_2O)^+ + H^+ \overset{K_1}{\rightleftharpoons} V(OH)_3^{2+} + H_2O \quad (5)$$

$$(VO_2\cdot 2H_2O)^+ + CH_3CO(CH_2)_2CO_2H \xrightarrow{k} V^{IV} + CH_3COCH_2\dot{C}H_2 + CO_2 + H^+ \quad (6)$$

$$V(OH)_3^{2+} + CH_3CO(CH_2)_2CO_2H \xrightarrow{k_1} V^{IV} + CH_3COCH_2\dot{C}H_2 + CO_2 + H^+ \quad (7)$$

$$CH_3COCH_2\dot{C}H_2 \xrightarrow{fast} CH_3CO\dot{C}HCH_3 \quad (8)$$

$$CH_3CO\dot{C}HCH_3 + V^V + H_2O \xrightarrow{fast} CH_3COCH(OH)CH_3 + V^{IV} + H^+ \quad (9)$$

$$CH_3COCH(OH)CH_3 + 2V^V \xrightarrow{fast} CH_3COCOCH_3 + 2V^{IV} + 2H^+ \quad (10)$$

$$CH_3COCOCH_3 + 2V^V + 2H_2O \xrightarrow{fast} 2CH_3CO_2H + 2V^{IV} + 2H^+ \quad (11)$$

where reactions 6 and 7 are rate determining, all other reactions are fast. The inclusion of reaction 9 is based on the belief that hydroxylation of free radicals in presence of an oxidant is always a fast process.

The oxidation of acetoin in reaction 10 as a fast one is based on the comparison of the rate constant k_1K_1 with $k_3(=k_{obsd}/4[H^+][\text{acetoin}])$. The value of k_3 is[13] 8.0×10^{-3} $dm^6\,mol^{-2}\,s^{-1}$ compared to k_1K_1 which is 1.32×10^{-6} $dm^6\,mol^{-2}\,s^{-1}$ in solutions of 1.5 mol dm^{-3} perchloric acid and 3 mol dm^{-3} ionic strength at 25 °C. Hence it is seen that the oxidation of acetoin is somewhat 6×10^3 times faster than the rate of oxidation of the keto acid. The inclusion of reaction 10 as the fast one is thus justified. The value of k_1K_1 at 25 °C was obtained by extrapolating the linear plot of ln k_1K_1 and $1/T$. The values of k_1K_1 at different temperatures, Table 4, were obtained by the relation described latter. The actual rate measurements on the oxidation of biacetyl (2,3-butanedione) have as yet not been carried out but it is reported[13] to be much faster than that of acetoin.[13]

The rate of disappearance of $[V^V]$ in terms of reactions 5—11 is given by Eq. 12 which could also be written as Eq. 13.

$$\frac{-d[V^V]}{dt} = \frac{6(k+k_1K_1[H^+])[V^V][\text{4-OPA}]}{1+K_1[H^+]} \quad (12)$$

$$k_{obsd}(1+K_1[H^+]) = 6(k+k_1K_1[H^+])[\text{4-OPA}] \quad (13)$$

Now if it is assumed that $K_1=3.4$ $dm^3\,mol^{-1}$, reported by Sengupta and coworkers in the oxidation of

TABLE 4. VALUES OF k_1K_1 AT DIFFERENT TEMPERATURES AND THE VALUES OF THE ENTHALPY AND ENTROPY OF ACTIVATION

(°C)	45	50	55	60	65
$10^6k_1K_1$ / $dm^6\,mol^{-2}\,s^{-1}$	2.80	3.40	3.89	4.63	5.37

$\Delta H_1=26\pm3$ kJ mol^{-1}
$\Delta S_1=-268\pm8$ J $K^{-1}\,mol^{-1}$

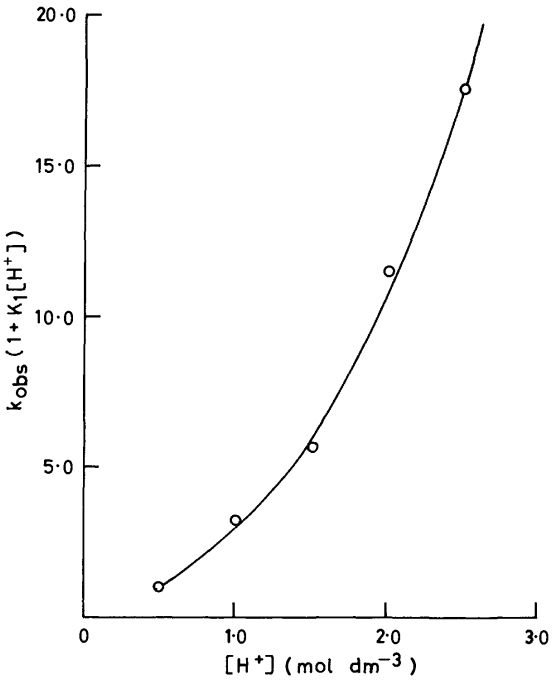

Fig. 3. The plot between k_{obsd} $(1+K_1[H^+])$ and $[H^+]$ at 50 °C with $K_1=3.4\,dm^3\,mol^{-1}$ for perchloric acid solution of constant ionic strength (3.0 mol dm^{-3}). Similar plots were obtained at other temperatures too. [Vanadium(V)]=0.02 mol dm^{-3} and [4-Oxopentanoic acid]=0.36 mol dm^{-3}.

pyruvic acid,[7] then the plot of k_{obsd} $(1+K_1[H^+])$ against $[H^+]$ should be linear with a positive intercept on the rate ordinate. However, when this plot was constructed, Fig. 3, it was found that the plot is not linear indicating that the assumption of the high value of K_1 is at least not correct in the present case.

Next, the application of the assumption[5,6] that $1 \gg K_1[H^+]$ resulted in the linear correlation between k_{obsd} and $[H^+]$ as is shown in Fig. 1. The plot, however, has a zero intercept indicating that $k \ll k_1K_1[H^+]$ *i.e.* $V(OH)_3^{2+}$ is more reactive than VO_2^+ which is rationalized by the assumption that an increase in the effective charge on metal ion increases its oxidizing capability.

The values of $k_1K_1(=k_{obsd}/6[H^+][\text{4-OPA}])$ at different temperatures were calculated from the data given in Table 3. The values so obtained are in Table 4 wherein are also reported the values of the thermodynamic parameters.

Alternate Mechanism. The following sequence of reactions are based on the probability of the initial electron transfer to vanadium(V) from the >CO group of the keto acid.

$$(VO_2\cdot 2H_2O)^+ + H^+ \overset{K_1}{\rightleftharpoons} V(OH)_3^{2+}(aq) + H_2O \quad (5)$$

$$V(OH)_3^{2+} + CH_3CO(CH_2)_2CO_2H \xrightarrow{k_1} CH_3\dot{C}O + \overset{+}{C}H_2CH_2CO_2H + V^{IV} \quad (14)$$

$$CH_3\dot{C}O + V^V + H_2O \longrightarrow CH_3CO_2H + V^{IV} + H^+ \quad (15)$$

$$\overset{+}{C}H_2CH_2CO_2H \longrightarrow CH_3\overset{+}{C}HCO_2H \quad (16)$$

$$CH_3\overset{+}{C}HCO_2H + V^V + H_2O \longrightarrow CH_3CH(OH)CO_2H + V^{IV} + H^+ \quad (17)$$

$$CH_3CH(OH)CO_2H + 2V^V \longrightarrow CH_3CHO + CO_2 + 2V^{IV} + 2H^+ \quad (18)$$

$$CH_3CHO + 2V^V + 2H_2O \longrightarrow CH_3CO_2H + 2V^{IV} + 2H^+ \quad (19)$$

where reaction 14 is the rate determining and the corresponding reaction with VO_2^+(aq) is not included because of the knowledge that VO_2^+(aq) species are not effective oxidant species as had been discussed earlier. The reaction 19 may also not be very correct representation of the oxidation of acetaldehyde because it is just probable that its enol form might be undergoing oxidation as is the case with the oxidation of other aldehydes.[25] Acetaldehyde is the first oxidation product of lactic acid in the oxidation by vanadium(V).[26] The inclusion of fast oxidation of lactic acid in 18 is based on the comparison of k_1K_1 and k_4 ($=k_{obsd}/4[H^+][CH_3CH(OH)CO_2H]$). The value of k_4 is 2.95×10^{-4} dm^6 mol^{-2} s^{-1} against a value of 1.41×10^{-6} dm^6 mol^{-2} s^{-1} for k_1K_1 both at $[HClO_4]=1.0$ mol dm^{-3} at 25 °C.

The rate of disappearance of $[V^V]$ in terms of reactions 5 and 14—19 of course will be given by Eq. 12 and as such the two mechanisms become indistinguishable. However, this alternate mechanism is not well supported by the initial oxidation product detected in the oxidation of the keto acid. Lactic acid, as required by the above mechanism was not the initial oxidation product which was acetoin. Moreover there is no similarity between the observed rate law in Eq. 12 and the one obtained in the oxidation of lactic acid[26] and $Me_2C(OH)COMe$[13] which involved C-C fission similar to reaction 14. Both lactic acid and $Me_2C(OH)COMe$ were oxidized by a path independent of $[H^+]$.

Activation Parameters. The observed enthalpy (ΔH_1) and entropy (ΔS_1) of activation are in Table 4. The ΔH_1 value for the reaction is low compared with the value reported in the oxidation of other organic compounds.[3] Similarly ΔS_1 is highly negative compared to the values obtained in various redox reactions.[3] Since ΔH and ΔS are extensive properties, it is therefore clear that $\Delta H_1=\Delta H°+\Delta H^{\neq}$, and $\Delta S_1=\Delta S°+\Delta S^{\neq}$ where $\Delta H°$, $\Delta S°$, and $\Delta H^{\neq}$, $\Delta S^{\neq}$ are the enthalpy and entropy of activation for reactions 5 and 7 respectively. A negative $\Delta S°$ for the reaction 5 is expected because there is a net increase in the charge on the reactive vanadium(V) species. Similary a negative $\Delta S^{\neq}$ for the reaction 7 is expected because it involves the reaction between polyatomic molecules. Hence the high negative value of ΔS_1 for the combined reactions 5 and 7 is understandable.

The low value of ΔH_1 is probably due to the negative value of either $\Delta H°$ or $\Delta H^{\neq}$. It is also clear that $\Delta H^{\neq}$ cannot be negative hence $\Delta H°$ must be negative which is consistent with the views available in the literature.[27] The negative $\Delta H°$ means that there would be less formation of $V(OH)_3^{2+}$ with increasing temperature, a fact well supported by the report[28] that a 0.2 mol dm^{-3} vanadium(V) solution in 4.4 mol dm^{-3} perchloric acid precipitated vanadium pentaoxide when warmed above 60 °C.

Conclusion. The keto acid is oxidized by the primary attack of the V^V on carboxylic group. That the keto acid is not oxidized at >CO group is concluded on the basis that k_{obsd} is at least one order less than the k_{obsd} value obtained in the oxidation of cyclohexanone under similar conditions of acidity and temperature and concentrations of the substrates. The carboxylic acids, except formic acid,[3] are resistant to the oxidation by vanadium(V) under conditions used in the present study. Thus the relatively easier yet slow oxidation of the keto acid could be ascribed to the presence of >CO group which is apparently not involved in the initial transfer of electron to the oxidant. Whether the >CO group remains in the keto form or is transformed to enol prior to the oxidation is not clear, yet certain conclusions can be derived from certain known facts.

Since the γ-keto acid is least enolised[8] it is suggested that 4-OPA is mainly oxidized in its keto form. The oxidation at >CO group site has been eliminated on the basis of magnitude of k_{obsd} value. A partial order with respect to 4-OPA was expected if the oxidation involved the enol form. However, this would be true only if the equilibrium constant K_e for keto⇌enol equilibrium has a significant value so that $1 \gg K_e$[4-OPA]. Since a strict first-order dependence in 4-OPA is observed, it is clear that K_e has no signifant value and therfore the concentration of the enol form is considered to be kinetically insignificant. The emphasis that 4-OPA is oxidized in the keto form (where keto group remains unreactive) stems out from the fact that one equivalent oxidants generally oxidize a ketone by attacking the >CO group. That the >CO group is not attacked in the present case is another matter.

Thanks are due to Prof. R. C. Kapoor for his interest and encouragement, and to CSIR and UGC for the financial support.

Mono(cyclopentadienyl)titanium(IV) Derivatives with Heterocyclic Thioketones

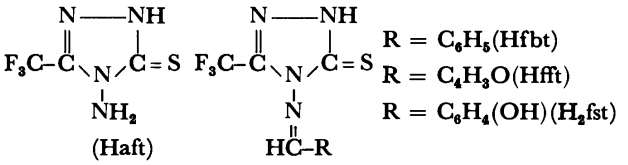
Om Prakash PANDEY, Soumitra Kumar SENGUPTA,* and Satish Chandra TRIPATHI
Department of Chemistry, University of Gorakhpur, Gorakhpur-273001, India
(Received February 23, 1984)

The reactions of mono(cyclopentadienyl)titanium(IV) trichloride with three important series of heterocyclic thioketones, *viz.*, triazolinethiones 4-amino-, 4-benzylideneamino-, 4-furfurylideneamino-, and 4-salicylideneamino-5-trifluoromethyl-1,2,4-triazoline-3-thiones, thioxoquinazolones (3-methyl-, 3-phenyl-, and 3-(*o*-tolyl)-2-thioxo-4-quinazolones), and oxadiazolethiones (5-phenyl-, 5-(*p*-nitrophenyl), and 5-(*p*-chlorophenyl)-1,3,4-oxadiazole-2-thiones, have been studied in anhydrous dichloromethane. The reaction products have been characterized on the basis of elemental analyses, electrical conductance, magnetic susceptibility and spectral (electronic, infrared, and ^{1}H NMR) data. Proton NMR spectra indicate that there is rapid rotation of the cyclopentadienyl ring around the metal ring axis on the NMR time scale at 28 °C.

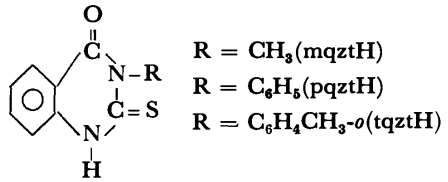
Although the preparation of mono(cyclopentadienyl)titanium(IV) trichloride was reported[1] by Gorsich as early as 1960, its coordination behaviour with chelating agents is still practically unknown. Some papers have appeared on mono(cyclopentadienyl)titanium(IV) compounds containing carboxylic acids,[2,3] dithiocarbamates,[4] thiols[5] or β-diketones[6,7] as ligands but they are mostly derived by the oxidation of $cpTiCl_2$ or removal of one cyclopentadienyl moiety from cp_2TiCl_2 derivatives. Recently, some papers appeared dealing with the reactions of $cpTiCl_3$ with dithiocarbamates,[8] Schiff bases,[9] 1,10-phenanthroline,[10] *o*-phenylenebis(dimethylarsine) and 2,2′-bipyridyl.[11] In this paper, we report the syntheses and characterization of mono(cyclopentadienyl)titanium(IV) derivatives containing heterocyclic thioketones as chelating agents. These ligands, containing thioamide bond and capable of undergoing thione-enethiol (HN–C=S⇌N=C–SH) tautomerism, can coordinate to a metal atom through nitrogen or through sulfur or simultaneously through nitrogen and sulfur. The chemistry of transition metal complexes with heterocyclic thioketones continues to be of unabated interest on account of the striking structural features presented by this class of compounds and also due to their biological importance.[12–16]

The structures of the ligands are given below:

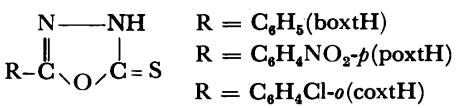
(a) Triazolinethione



(b) Thioxoquinazolone



(c) Oxadiazolethione



Experimental

The ligands triazolinethiones, thioxoquinazolones, and oxadiazolethiones were prepared as mentioned in literature.[17–19] Mono(cyclopentadienyl)titanium(IV) trichloride was prepared from $(cp)_2TiCl_2$ and $TiCl_4$ in *p*-xylene.[1] Dichloromethane was dried by refluxing it for 30 h over calcium hydride.

Most of derivatives prepared and studied are susceptible to hydrolysis. Hence, all operations were carried out under strictly anhydrous conditions and glass apparatus with standard interchangeable joints was used throughout the work.

Titanium was determined gravimetrically as TiO_2 and chloride as AgCl. Sulphur was estimated as $BaSO_4$. The carbon and hydrogen analyses were carried out at Central Drug and Research Institute, Lucknow.

The details of physical measurements are same as described earlier.[20]

Preparation of Complexes. All these complexes were prepared by taking mono(cyclopentadienyl)titanium(IV) trichloride and respective ligand in appropriate molar ratios and adding about 60 ml of dichloromethane followed by a reflux time of 20—50 h. The solutions were then filtered and their volume reduced to about 20 ml. Further, addition of dry petroleum ether (60—80 °C, ≈20 ml) to the above solution and allowing them to stand for overnight resulted yellow to brown crystals of the products which were filtered and dried in oven at 80 °C.

The details of the amounts of reactants taken for the preparation of complexes, refluxing time, yield and colour of the products are given in Table 1.

Results and Discussion

The analytical data of the complexes are given in Table 1. The methods used for preparation and isolation of these compounds give materials of good purity as supported by their analyses and TLC. All these complexes are coloured. They are thermally stable but decompose above ≈150 °C without melting. They are quite stable in air but their solutions are hydrolyzed on standing. Conductance measurements reveal that they are essentially nonelectrolytes. Magnetic susceptibility values at room temperature show the diamagnetic nature of the complexes. The electronic spectra of all these complexes show a

band in the region 23500—24400 cm^{-1}, which can be assigned[20] to the charge transfer band and is in accordance with the $(n-1)$ d^0 ns^0 electronic configuration of titanium. In additon, the ligands and the complexes show bands around 32000 cm^{-1} which are assigned to $\pi \rightarrow \pi^*$ transition of the azomethine linkages.

Infrared Spectra. *(a) Triazolinethione Derivatives*: The assignments of infrared spectral bands of the ligands and the complexes are based on an earlier study of similar ligands.[21] Organic compounds having a thioamide group (H-N-C=S) give rise to four thio-

amide bands in the IR spectra.[22] These are thioamide band I at about 1500 cm^{-1}, band II at about 1300—1400 cm^{-1}, band III at about 1000 cm^{-1} and band IV at about 700—850 cm^{-1}. These bands have contributions from δ(C-H)+δ(N-H), ν(C=S)+ν(C=N)+ δ(C-H), ν(C-N)+ν(C-S), and ν(C=S) modes of vibrations respectively. In our ligands, these bands appear in the region 1560—1550, 1250, 1090—1080, and 790—780 cm^{-1}. These bands are expected to be affected differently by different modes of coordination after complexation with the metal ions.[21,23,24] However, in our complexes, these bands disappear indicating that mixing of ν(C-N), δ(N-H), and ν(C=S) vibrations may be absent and ligand is coordinating to the metal atom through a deprotonated thiol sulfur atom. A weak band at ≈2550 —2480 cm^{-1} in the spectra of the ligands due to the -SH group vibration, further suggests the thione⇌enethiol tautomerism. However, in the spectra of the complexes, this band disappears indicating the coordination through sulfur after deprotonation. This is further confirmed by the appearance of new band in the far IR region 380—340 cm^{-1} which can be assigned to the ν(Ti-S) vibration.[25]

The bands observed around 3250—3150 (in Haft), 1630 in (Hfbt, Hfft, and H_2fst), 1580—1565 and 1500 cm^{-1} in the spectra of the ligands may be assigned[21] to ν(N-H), ν(C=N) (N-N=C-), ν(C=N) (ring) and ν(C=C) (phenyl) vibrations, respectively. Strong vibrations in the region 1600—1550 cm^{-1} are usually associated with phenyl and C=N groups and it is not usually possible to identify such bands with particular C=C or C=N linkage. However, a stringent assignment of the C=N group can be made by comparing the spectrum of the ligand Haft containing N-NH_2 group with that of the ligands Hfbt, Hfft, and H_2fst in which it is replaced by N-N=CH group. Following this method, the strong band observed around 1630 cm^{-1} is assigned to the ν(C=N) vibration. However, the spectra of the complexes show the shifting of this band to lower frequency (≈25 cm^{-1}) indicating the coordination of the azomethine nitrogen to metal atom. The IR band in the region 3250—3200 cm^{-1} in the ligand Hfat due to ν(NH) of the amino group is shifted towards the lower wave number (≈50 cm^{-1}) in its complexes which indicate[26] the coordination of the amino nitrogen to the metal atom. The bands observed in the region 450—430 cm^{-1} may be assigned[25] to ν(Ti-N).

The ligand H_2fst shows one band at ≈3400 cm^{-1} which may be assigned[26] to ν(OH) of phenolic hydroxyl group. However, in its complex, this band disappears indicating the coordination of phenolic oxygen to the metal atom through deprotonation. The bands at 500 cm^{-1} in the complex can be assigned to ν(Ti-O).[20]

Thus, the infrared spectra reflect that the ligand Haft acts as monobasic bidentate ligand having coordination sites at thiol sulfur and amino nitrogen, the ligands Hfbt and Hfft coordinate through thiol sulfur and azomethine nitrogen and the ligand H_2fst behaves as dibasic tridentate ligand coordinating through thiol sulfur, phenolic oxygen, and azomethine nitrogen.

(b) Thioxoquinazolone Derivatives: The IR spectra of the ligands, 3-substituted 2-thioxo-4-quinazolones, show one sharp band at 3400 cm^{-1} which may be assigned[26] to ν(NH). The δ(NH) mode is observed at 1650 cm^{-1}. However, in the spectra of complexes, these bands disappear indicating the displacement of N-H hydrogen by metal ion. This is further confirmed by the appearance of new bands around 470—440 cm^{-1}, assignable[25] to ν(Ti-N). A sharp band appearing at 1720—1700 cm^{-1} in the ligands may be assigned to ν(C=O) which appears at the same place in the spectra of the complexes, ruling out the possibility of coordination through carbonyl group. The ligands 2-thioxo-4-quinazol-one contains a thioamide group. The four thioamide bands, I, II, III, and IV typical of molecules containing H-N-C=S skeleton are found at ≈1500, 1400—1300, 1000, and 850—700 cm^{-1}, respectively. The appearance of four thioamide bands and the absence of any band near 2500 cm^{-1} (due to ν(S-H)), indicates[16] the existence of the ligands in the thione form. The thioamide III and IV bands, having main contribution from ν(C=S), are shifted towards lower energies in the complexes indicating[21] the coordination of thioxo sulfur to titanium atom. The ν(Ti-S) vibrations appear at 390—360 cm^{-1}. Thus, it becomes evident that the ligands, 3-substituted 2-thioxo-4-quinazolone, act as bidentate chelating agents, coordinating through thione sulfur and amino nitrogen (through deprotonation).

(c) Oxadiazolethione Derivatives: The ligands, 5-substituted 1,3,4-oxadiazole-2-thione, have one phenyl, one oxadiazole rings and >C=S group resulting in the presence of four donor sites (two nitrogen atoms, one oxygen atom and one sulfur atom). Its infrared spectra should, therefore, show characteristic bands of phenyl, oxadiazole rings and of >C=S groups. Although the spectra of the ligand and the complexes are quite complicated owing to the overlap of various bands and the coupling of various modes of vibrations. However, the systematic shifts in the positions of a few bands relative to those present in the spectrum of the ligand, give clue to the mode of bonding in the complexes.

The ν(NH) and δ(NH) vibration bands, which appear in the region 3350 and 1630 cm^{-1} in the ligands, disappear in the complexes indicating[26] the coordination of amino nitrogen to the titanium atom through deprotonation. This is confirmed by the appearance of new bands at about 480—440 cm^{-1}, assignable[25] to ν(Ti-N). The thioamide III and IV vibrations, which have largest contribution from ν(C=S), undergo a red shift in the complexes suggesting the coordination of sulfur atom to the titanium atom in the thione form.[21] The ν(Ti-S) vibrations appear at 400—370 cm^{-1}. The position of IR bands due to phenyl and oxadiazolyl group

(C-O-C)[22] do not change in the complexes indicating the non-coordination of oxygen atom. The above observations indicate that possibly the bonding in titanium complexes is through amino nitrogen and thioxo sulfur.

In addition, absorption bands occurring at ≈3000 cm^{-1} ν(C-H), ≈1430 cm^{-1} ν(C-C), and 1020 cm^{-1} ν(C-H) in all the complexes indicate the presence of cyclopentadienyl ring. All these bands are similar to those of mono(cyclopentadienyl) titanium(IV).[27] Davison and Rakita have pointed out[28] that at 3000 cm^{-1}, η'-C_5H_5 should show four bands whereas η^5-C_5H_5 should show only one. In the complexes, reported in this paper, only one band at 3000 cm^{-1} indicate the pentahapto nature of cyclopentadienyl ring.

^1H NMR Spectra. The proton NMR spectra of some of these complexes have been recorded in deuterated chloroform and *N,N*-dimethyl-formamide. The intensities of all the resonance lines were determined by planimetric integration. The following conclusions can be derived by comparing the spectra of ligands and their corresponding complexes:

(i) A signal in all derivatives at δ≈6.5—6.8 ppm may be assigned to the protons of cyclopentadienyl ring. The value is in the range reported[2] for other (C_5H_5)Ti^{IV} complexes with chelating ligands and is significantly separated from the position of (C_5H_5)$TiCl_3$ (≈7.07 ppm). The appearance of a single, sharp cyclopentadienyl resonance is attributed to rapid rotation of the ring around the metal-ring axis.

(ii) The two kinetic possibilities, *viz.*, metal-centered rearrangement is slow or fast, can be distinguished by the analysis of NMR spectra. In the spectra of 1:3 complexes, (cp)Ti(L)$_3$, two distinct resonance lines for the protons of the ligands are observed which must result from the nonequivalent environments for the different ligands. However in the 1:2 derivatives, (cp)Ti(L)$_2$Cl, the ligand groups are equivalent since one signal have been observed for ligand proton groups.

(iii) In NMR spectra of mercaptotriazoles, the signal due to -SH proton appears at about δ=4.4 ppm which disappears in the corresponding complexes indicating the deprotonation of thiol proton. Further, the ligand H_2fst shows one signal at δ=9.8 ppm due to phenolic proton. This signal disappears in its complex indicating the deprotonation of the phenolic hydroxyl group.

(iv) The spectra of thioxoquinazolone and oxadiazolethione show one sharp signal at δ=4.8—4.9 ppm due to -NH proton which disappear in their corresponding complexes suggesting the coordination of amino nitrogen to titanium atom through deprotonation.

Cyclizations of Dianions from 2-Imino-1,2-diphenylethanone to Oxazolines, Oxazocines, and Oxazonines

Kailash Nath MEHROTRA,* Indra Sen SINGH, and Jalpana ROY
Department of Chemistry, Faculty of Science, Banaras Hindu University, Varanasi-221 005, India
(Received April 16, 1984)

The reaction of 2-imino-1,2-diphenylethanone with sodium in ether and subsequent addition of carbon disulfide or ethyl chloroformate resulted in the formation of 3,4,5-trisubstituted 4-oxazoline-2-thiones and 2-ones, respectively. 1,4-Oxazonines and 1,4-oxazocines were also synthesised from the reaction of 2-imino-1,2-diphenylethanone with sodium in THF followed by addition of dihaloalkanes.

The reported cyclization reactions of anils and dianils leading to the imidazolidine,[1,2] imidazoline,[3] diazocine and diazonine[4] derivatives prompted us to investigate the reactions of dianions from α-imino ketones. This study has led to new, convenient and general synthetic routes to oxazolines, oxazocines and oxazonines. These five-, eight-, and nine-membered heterocycles each containing one oxygen and one nitrogen atoms draw a special attention as potential biologically active compounds.

Results and Discussion

The reaction of (±)-2-(α-phenylethylimino)-1,2-diphenylethanone (**1a**) with sodium in dry ether followed by addition of carbon disulfide gave (±)-3-(α-phenylethyl)-4,5-diphenyl-4-oxazoline-2-thione (**2a**, 49%). The structural assignment of **2a** was made on the basis of its analytical and spectral data. In the above reaction replacing carbon disulfide by ethyl chloroformate gave (±)-3-(α-phenylethyl)-4,5-diphenyl-4-oxazolin-2-one (**3a**, 35%) identified by its analytical and spectral data. Similar treatment of the dianions from 2-imino-1,2-diphenylethanone **1b**—f with carbon disulfide and ethyl chloroformate gave 3-substituted 4,5-diphenyl-4-oxazoline-2-thiones **2b**—**f** and -2-ones **3b**—**f**, respectively. The products have been characterized on the basis of their analytical and spectral data.

Treatment of 2-imino-1,2-diphenylethanone **1d**—**e** with sodium in dry THF and subsequent addition of 1,4-dichlorobutane gave 2,3,4-triaryl-5,6,7,8-tetrahydro-4*H*-1,4-oxazocines **4d**—**e** which were crystallized from hexane.

Similar treatment of the dianions from imino ketones **1d**—**e** with 1,5-dichloropentane gave 2,3,4-triaryl-4,5,6,7,8,9-hexahydro-1,4-oxazonines **5d**—**e** which were recrystallized from hexane. The structural assignments of the products **4d**—**e** and **5d**—**e** were made on the basis of their analytical and spectral data.

When the dianions from imino ketones **1d**—**e** were similarly treated with 1,3-dibromopropane the expected cyclization products 1,4-oxazepines were not obtained and 2-anilino-1,2-diphenyl-4-penten-1-ones (**6d**—**e**) were formed. The products **6d**—**e** have been identified by their analytical and spectral data. One of the three vinyl protons (H_A) appeared downfield as compared to others. An inspection of the models of compounds **6d**—**e** reveals that this proton would be deshielded by the carbonyl group and the nitrogen lone pair. The formation of diazepine derivatives from the reactions of the dianion from benzil dianils with 1,3-dibromopropane and 1,3-diiodopropane,[5] in low yields have been observed due to the steric factors. It has been reported earlier that in the reaction of benzil dianil with sodium in ether followed by addition of 1,3-dichloropropane no diazepine derivative was obtained.[6]

The formation of products **2a**—**f**, **3a**—**f**, **4d**—**e**, **5d**—**e**, **6d**—**e** from 2-imino-1,2-diphenylethanone **1a**—**f** is depicted in the following scheme:

The above reactions involve the initial formation of dianions, by the electron transfer from sodium to 2-imino-1,2-diphenylethanone, which attack carbon disulfide, ethyl chloroformate, 1,3-, 1,4-, and 1,5-dihaloalkanes with elimination of sulfide ions (detected by the formation of lead(II) sulfide with aq lead(II) acetate) or halide ions (detected by the formation of silver halide with aq silver nitrate) or/and ethoxide ions to give rise to the observed products. These reactions provide new, convenient one-pot syntheses of heterocycles which would be difficult to prepare otherwise.

Experimental

Instrumentation. Melting points have been determined in capillaries on Büchi melting point apparatus and are uncorrected. The NMR spectra in $CDCl_3$ were recorded on Varian A-60D and VN 1009 (S-60T) spectrometers with TMS as an internal standard. The IR spectra were measured on a Perkin Elmer 720 spectrophotometer and UV spectra on a Beckman DB-G spectrophotometer.

Materials The 1,2-diketones, amines and dihaloalkanes were obtained from Ega, Chemie, West Germany.

Preparation of 2-Imino-1,2-diphenylethanone 1a—f.
General Procedure From Alkylamines: The starting α-imino ketones **1a**—**c** and **1f** were obtained by keeping an equimolar mixture of benzil and alkylamine in 95% ethanol at room temperature for a week, following the reported method[7] and purified by fractional crystallization from ethanol (78—88%).

From Arylamines. The starting 2-imino-1,2-diphenylethanones **1d**—**e** were obtained by heating an equimolar mixture of benzil and aromatic amine at 150°C for 2—3 h following the reported method[8] and purified by fractional crystallization from ethanol (75—78%).

Preparation of 3-Substituted 4,5-Diphenyl-4-oxazoline-2-thiones 2a—f. *General Procedure*: Sodium pieces (**1g**) were slowly added to dry ether (60 ml) in a three-necked round-

	R	Yield(%) 2	3
a	-CH(CH3)C6H5	49	35
b	-CH2CH2CH3	35	33
c	-CH2CH2CH2CH3	36	35
d	-C6H5	48	45
e	-C6H4CH3(p-)	50	55
f	-CH(CH3)CH3	32	35

Scheme

bottomed flask, fitted with a condenser, a mercury trap and a pressure-equalizing addition funnel, with stirring under a nitrogen atmosphere. A solution of imino ketone (**2g**) in dry ether (10 ml) was added dropwise. Stirring at reflux temperature was continued for 4 h and the contents were allowed to cool. Unreacted sodium pieces were removed by filtration. Dry carbon disulfide (2 ml) was slowly added and the mixture was heated under reflux for 1 h. The ethereal suspension was washed 2—3 times with water and dried over sodium sulfate. The solvent was removed on a rotary evaporator and the residual material was purified by column (neutral alumina, hexane/benzene: 90/10).

*3-(α-Phenylethyl)-4,5-diphenyl-4-oxazoline-2-thione (**2a**).* A yield of 49% was obtained, mp 135—137 °C. UV (Ethanol): 310 (ε 21100) and 223 (22600) nm; IR (Nujol, cm^{-1}): 1165 (ν C=S); NMR ($CDCl_3$, δ): 7.20 (m, 15H, aromatic protons); 6.40 (m, 1H, CH) and 1.70 (bd, 3H, CH_3, J=7 Hz). Found: C, 77.35; H, 5.38; N, 4.21%. Calcd for $C_{23}H_{19}NOS$: C, 77.31; H, 5.32; N, 3.92%.

*4,5-Diphenyl-3-propyl-4-oxazoline-2-thione (**2b**).* A yield of 35% was obtained, mp 128—129 °C. UV (Ethanol): 310 (ε 9740) and 275 (19800) nm; IR (Nujol, cm^{-1}): 1160 (ν C=S); NMR ($CDCl_3$, δ): 7.42 (m, 10H, aromatic protons); 3.80 (t, 2H, N-CH_2, J=7 Hz): 1.60 (m, 2H, C-CH_2); 0.82 (t, 3H, methyl, J=7 Hz). Found: C, 73.55; H, 5.61; N, 4.61%. Calcd for $C_{18}H_{17}NOS$: C, 73.22; H, 5.76; N, 4.74%.

*3-Butyl-4,5-diphenyl-4-oxazoline-2-thione (**2c**).* A yield of 36% was obtained, mp 133—134 °C. UV (Ethanol): 310 nm; IR (Nujol, cm^{-1}): 1180 (ν C=S); NMR ($CDCl_3$, δ): 7.40 (m, 10H, aromatic protons); 3.80 (t, 2H, N-CH_2, J=7 Hz); 1.50 (m, 4H, C-CH_2); 0.80 (t, 3H, methyl, J=7 Hz). Found: C, 73.71; H, 6.10; N, 4.32%. Calcd for $C_{19}H_{19}NOS$: C, 73.78; H, 6.14; N, 4.53%.

*3,4,5-Triphenyl-4-oxazoline-2-thione (**2d**).* A yield of 48% was obtained, mp 228—229 °C (lit,[9] 229 °C). UV (Ethanol): 308 (ε 15700) and 226 (17500) (lit,[10] 308, 225) nm; IR (Nujol, cm^{-1}): 1162 (lit,[11] 1161) (ν C=S); NMR ($CDCl_3$, δ): 7.40 (m, aromatic protons). Found: C, 76.40; H, 4.73; N, 4.51%. Calcd for $C_{21}H_{15}NOS$: C, 76.59; H, 4.55; N, 4.25%.

*4,5-Diphenyl-3-(p-tolyl)-4-oxazoline-2-thione (**2e**).* A yield of 50% was obtained, mp 235—237 °C. UV (Ethanol): 310 (ε 16000) and 225 (22500) nm; IR (Nujol, cm^{-1}): 1162 (ν C=S); NMR ($CDCl_3$, δ): 7.30 (m, 14H, aromatic protons); 2.30 (s, 3H, methyl). Found: C, 76.64; H, 4.65; N, 4.31%. Calcd for $C_{22}H_{17}NOS$: C, 76.96; H, 4.95; N, 4.08%.

*4,5-Diphenyl-3-isopropyl-4-oxazoline-2-thione (**2f**).* A yield

of 32% was obtained, mp 172—173 °C. UV (Ethanol): 310 (ε 18000) and 225 (14300) nm; IR (Nujol, cm^{-1}): 1161 (ν C=S); NMR ($CDCl_3$, δ): 7.51 (m, 10H, aromatic protons); 4.80 (sept, 1H, methine, J=7 Hz); 1.40 (d, 6H, methyl, J=7 Hz). Found: C, 73.60; H, 6.00; N, 5.01%. Calcd for $C_{18}H_{17}NOS$; C, 73.22; H, 5.76; N, 4.74%.

Preparation of 3-Substituted 4,5-Diphenyl-4-oxazolin-2-ones ***3a—f.*** *General Procedure*: In place of carbon disulfide in the above method dry ethyl chloroformate (2 ml) was slowly added and the product was purified by column chromatography as mentioned above.

*3-(α-Phenylethyl)-4,5-diphenyl-4-oxazolin-2-one (**3a**).* A yield of 35% was obtained, mp 155—157 °C. IR (Nujol, cm^{-1}): 1600 (ν C=C), 1750 (ν C=O); NMR ($CDCl_3$, δ): 7.30 (m, 15H, aromatic protons); 4.30 (m, 1H, CH) and 1.40 (bd, 3H, methyl, J=7 Hz). Found: C, 80.65; H, 5.62; N, 4.30%. Calcd for $C_{23}H_{19}NO_2$: C, 80.92; H, 5.61; N, 4.01%.

*4,5-Diphenyl-3-propyl-4-oxazolin-2-one (**3b**).* A yield of 33% was obtained, mp 92—93 °C. UV (Ethanol): 282 (ε 22100) and 221 (29100) nm; IR (Nujol, cm^{-1}): 1610 (ν C=C) and 1745 (ν C=O); NMR ($CDCl_3$, δ): 7.60 (m, 10H, aromatic protons); 3.50 (t, 2H, N-CH_2, J=7 Hz); 1.60 (m, 2H, C-CH_2); 0.80 (t, 3H, methyl, J=7 Hz). Found: C, 77.45; H, 6.20; N, 5.25%. Calcd for $C_{18}H_{17}NO_2$: C, 77.40; H, 6.13; N, 5.01%.

*3-Butyl-4,5-diphenyl-4-oxazolin-2-one (**3c**).* A yield of 35% was obtained, mp 73—75 °C. UV (Ethanol): 286 (ε 17700) and 217 (4350) nm; IR (Nujol, cm^{-1}): 1610 (ν C=C) and 1740 (ν C=O); NMR ($CDCl_3$, δ): 7.50 (m, 10H, aromatic protons); 3.50 (t, 2H, N-CH_2, J=7 Hz); 1.40 (m, 4H, C-CH_2); 0.84 (t, 3H, methyl, J=7 Hz). Found: C, 77.90; H, 6.50; N, 4.63%. Calcd for $C_{19}H_{19}NO_2$: C, 77.79; H, 6.53; N, 4.77%.

*3,4,5-Triphenyl-4-oxazolin-2-one (**3d**).* A yield of 45% was obtained, mp 215—217 °C (lit,[12] 211 °C). UV (Ethanol): 293 (ε 18900) and 226 (14700) (lit,[10] 225, 291.5) nm; IR (Nujol, cm^{-1}); 1600 (ν C=C) and 1750 (lit, [11] 1750) (ν C=O); NMR ($CDCl_3$, δ): 7.40 (m, aromatic protons). Found: C, 80.50; H, 4.62; N, 4.35%. Calcd for $C_{21}H_{15}NO_2$: C, 80.49; H, 4.82; N, 4.47%.

*4,5-Diphenyl-3-(p-tolyl)-4-oxazolin-2-one (**3e**).* A yield of 55% was obtained, mp 224—226 °C. UV (Ethanol): 294 (ε 18900) nm; IR (Nujol, cm^{-1}): 1600 (ν C=C) and 1750 (ν C=O); NMR ($CDCl_3$, δ): 7.42 (m, 14H, aromatic protons); 2.33 (s, 3H, methyl). Mass (m/z): 327. Found: C, 80.75; H, 5.40; N, 4.32%. Calcd for $C_{22}H_{17}NO_2$: C, 80.71; H, 5.23; N, 4.28%.

*3-Isopropyl-4,5-diphenyl-4-oxazolin-2-one (**3f**).* A yield of 35% was obtained, mp 120—124 °C. UV (Ethanol): 286 (ε 15100) and 220 (15400) nm; IR (Nujol, cm^{-1}): 1600 (ν C=C) and 1750 (ν C=O); NMR ($CDCl_3$, δ): 7.50 (m, 10H, aromatic protons); 4.80 (sept, 1H, methine, J=7 Hz); 1.40 (d, 6H, methyl, J=7 Hz). Found: C, 77.80; H, 6.00; N, 5.20%. Calcd for $C_{18}H_{17}NO_2$: C, 77.40; H, 6.13; N, 5.01%.

Preparation of 2,3,4-Trisubstituted-5,6,7,8-tetrahydro-4H-1,4-oxazocines ***4d—e.*** *General Procedure*: A solution containing 2 g of imino ketone (**1d—e**) in dry THF (30 ml) was added dropwise to 2 g of sodium pieces in 30 ml of dry THF under a nitrogen atmosphere and the mixture was stirred for 5—6 h at refluxing temperature. The reaction mixture was allowed to stand at room temperature for 1/2 h. Sodium pieces were removed by filtration. Dry 1,4-dichlorobutane (2 ml) was slowly added and the mixture was heated to reflux for 10—12 h. The excess of THF was removed under reduced pressure and the residual matter was extracted with ether. The ethereal layer was washed 2—3 times with water, dried over sodium sulfate. The solvent was removed on a rotary evaporator and the residual material was purified by column (neutral alumina, hexane) chromatography.

*2,3,4-Triphenyl-5,6,7,8-tetrahydro-4H-1,4-oxazocine (**4d**).* A yield of 33% was obtained, mp 125—126 °C. UV (Ethanol): 352 (ε 10500) and 273 (11500) nm; IR (Nujol, cm^{-1}): 1605 (ν C=C); NMR ($CDCl_3$, δ): 6.90 (m, 15H, aromatic protons); 4.10 (m, 4H, N-CH_2 and O-CH_2); 1.90 (m, 4H, C-CH_2). Mass (m/z): 341. Found: C, 84.10; H, 6.85; N, 3.95%. Calcd for $C_{24}H_{23}NO$: C, 84.42; H, 6.79; N, 4.10%.

*2,3-Diphenyl-4-(p-tolyl)-5,6,7,8-tetrahydro-4H-1,4-oxazocine (**4e**).* A yield of 35% was obtained, mp 128—129 °C. UV (Ethanol): 356 (ε 12000) and 273 (12200) nm; IR (Nujol, cm^{-1}): 1605 (ν C=C); NMR ($CDCl_3$, δ): 7.00 (m, 14H, aromatic protons); 4.00 (m, 4H, N-CH_2 and O-CH_2); 2.20 (s, 3H, methyl); 1.90 (m, 4H, C-CH_2). Mass (m/z): 355. Found: C, 84.20; H, 6.91; N, 4.10%. Calcd for $C_{25}H_{25}NO$: C, 84.47; H, 7.09; N, 3.94%.

Preparation of 2,3,4-Trisubstituted-4,5,6,7,8,9-hexahydro-1,4-oxazonines ***5d—e.*** *General Procedure*: In place of 1,4-dichlorobutane in the above procedure dry 1,5-dichloropentane was slowly added and the product was purified by column chromatography as mentioned above.

*2,3,4-Triphenyl-4,5,6,7,8,9-hexahydro-1,4-oxazonine (**5d**).* A yield of 31% was obtained, mp 141—143 °C. UV (Ethanol): 350 (ε 2370) and 265 (3760) nm; IR (Nujol, cm^{-1}): 1605 (ν C=C); NMR ($CDCl_3$, δ): 6.90 (m, 15H, aromatic protons); 4.00 (m, 4H, N-CH_2 and O-CH_2); 1.80 (m, 6H, C-CH_2). Mass (m/z): 355. Found: C, 84.15; H, 6.95; N, 3.64%. Calcd for $C_{25}H_{25}NO$: C, 84.47; H, 7.09; N, 3.94%.

*2,3-Diphenyl-4-(p-tolyl)-4,5,6,7,8,9-hexahydro-1,4-oxazonine (**5e**).* A yield of 28% was obtained, mp 142—144 °C. UV (Ethanol): 265 and 350 nm; IR (Nujol, cm^{-1}): 1615 (ν C=C); NMR ($CDCl_3$, δ): 7.00 (m, 14H, aromatic protons); 4.00 (m, 4H, N-CH_2 and O-CH_2); 2.20 (s, 3H, methyl); 1.80 (m, 6H, C-CH_2). Found: C, 84.24; H, 7.26; N, 3.90%. Calcd for $C_{26}H_{27}NO$: C, 84.55; H, 7.31; N, 3.79%.

Preparation of 2-Arylamino-1,2-diphenyl-4-penten-1-ones ***6d—e.*** *General Procedure*: In place of 1,4-dichlorobutane, 1,3-dibromopropane was slowly added and the same procedure for purification was followed as described above.

*2-Anilino-1,2-diphenyl-4-penten-1-one (**6d**).* A yield of 45% was obtained, mp 102—104 °C. UV (Ethanol): 250 (ε 25200) nm; IR (Nujol, cm^{-1}): 3370 (N-H) and 1660 (C=O); NMR ($CDCl_3$, δ): 7.00 (m, 16H, aromatic and CH); 5.70 (bs, 1H, NH, D_2O exchangeable); 4.80 (m, 2H, =CH_2); 3.30 (m, 2H, -CH_2). Mass (m/z): 327. Found: C, 84.60; H, 6.41; N, 3.95%. Calcd for $C_{23}H_{21}NO$: C, 84.37; H, 6.46; N, 4.28%.

*1,2-Diphenyl-2-(p-toluidino)-4-penten-1-one (**6e**).* A yield of 48% was obtained, mp 109—110 °C. UV (Ethanol): 250 (ε 23000) nm; IR (Nujol, cm^{-1}): 3355 (NH) and 1660 (ν C=O); NMR ($CDCl_3$, δ): 7.00 (m, 15H, aromatic and CH); 5.50 (bs, 1H, NH, D_2O exchangeable); 4.80 (m, 2H, =CH_2); 3.30 (m, 2H, -CH_2); 2.25 (s, 3H, CH_3). Found: C, 84.10; H, 6.65; N, 3.90%. Calcd for $C_{24}H_{23}NO$: C, 84.42; H, 6.79; N, 4.10%.

We are thankful to professor R. C. Aggarwal for providing the facilities and to C. S. I. R., New Delhi, India for appointing Dr. (Mrs.) Jalpana Roy as Pool Officer under the Scientists' Pool.

Spectroscopic Studies of Photochemical Reactions in Organic Solids. Photodimerization of *p*-Formylcinnamic Acid

Urmi GHOSH and Tridibendra Narayan MISRA*

Optics Department, Indian Association for the Cultivation of Science, Jadavpur, Calcutta-700 032, India

(Received May 22, 1984)

Raman phonon spectroscopy and electronic absorption and emission spectroscopy have been used to study the mechanism of reaction and the role of electron–phonon coupling in determining the photoreactivity of *p*-formylcinnamic acid (*p*-FCA) in the crystalline state. Raman and infrared spectroscopy in the internal vibration region have been used to characterize the reactant *p*-FCA and the dimeric product *t*-3,*t*-4-bis(*p*-formylphenyl)-*r*-1,*c*-2-cyclobutanedicarboxylic acid. Phonon spectroscopy reveals that the reaction proceeds principally by a heterogeneous mechanism though a homogeneous mechanism in the initial stage of short time domain can not be ruled out. The electronic spectroscopy suggests a strong electron-phonon coupling in the monomer crystal.

Recently Raman phonon spectroscopy has been successfully used to study the mechanism and the kinetics of solid state photoreaction in organic crystals.[1–4] Phonon participation and strong electron–phonon coupling have been shown to be involved in solid state photodimerization reaction of 2,6-dimethyl-*p*-benzoquinone.[3] The study revealed that the reaction is homogeneous in the initial stage but becomes heterogeneous in the later stage.

A new type of crystalline state photodimerization has recently been reported by Nakanishi *et al.*[5,6] in case of some cinnamic acid derivatives. In *p*-FCA, for example, it has been shown that a molecule of water is incorporated in dimer during the photodimerization process. We have used the phonon spectra, sampled as a function of reaction progress, to study this photoreaction to see if the reaction is homogeneous or heterogeneous in the molecular level. The electronic absorption and emission spectroscopy on dimerization reaction progress have been studied. The electronic absorption spectroscopy has also been used to determine the extent of reaction progress. The laser Raman spectroscopy and infrared spectroscopy have been used to obtain intramolecular vibrations of the reactants and the products as well as the partially converted samples. These intramolecular

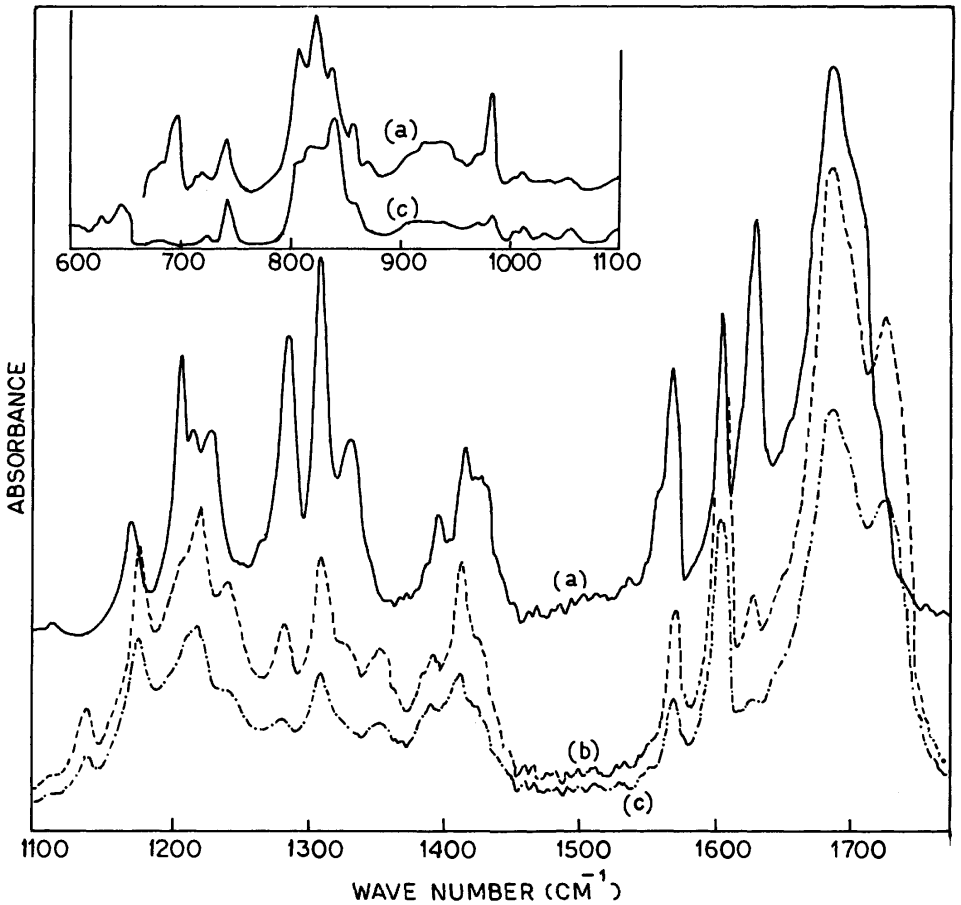

Fig. 1. Infrared absorption spectra of *p*-FCA crystals in KBr pellet as a function of photoreaction progress (a) monomer, (b) exposed for 30 min (c) exposed for 1 h.

vibrations have also been used to characterize the materials as well as to study the mechanism of the reaction. In this paper we report our results.

Experimental

p-FCA prepared as described earlier[6] was further purified by repeated crystallization from ethanol. Crystals were finally grown from ethanol and acetone. Photodimerization was carried out by using a 750 W Xe lamp with the *p*-FCA crystallites dispersed in water in a quartz vessel at room temperature. For the specific set up, almost complete photodimerization was obtained in one hour. The experimental set up was the same as reported earlier.[3] The electronic absorption spectra were run in Shimadzu UV-Vis 210A Spectrophotometer. The emission spectra were run in Perkin-Elmer MPF 44A Spectrofluorimeter. The infrared spectra were run in a KBr pellet on a Beckman Spectrophotometer (Model 4240).

Results and Discussion

Two crystalline modifications of *p*-FCA crystals are known. Crystals grown from ethanol solution are photoreactive and belong to the β-form while γ-form of crystals, obtained from acetone solution, are photostable. The phonon spectra of the two forms are distinctly different as are their reported X-ray diffraction patterns.[6] Nakanishi[6] *et al.* have not observed any phase transition point.

The extent of photodimerization has been monitored by studying the electronic absorption spectra. Monomer *p*-FCA has its absorption maximum at 295 nm in ethanol solution at room temperature whereas the photodimer under similar condition has its maximum at 257 nm.

Characterization of the Reactant and the Product by Infrared and Raman Spectroscopy. The infrared spectra of *p*-FCA crystal before and after photodimerization to different extent are shown in Fig. 1 and the results are summarized in Table 1. The infrared bands observed in partially dimerized crystals were attributed to the monomer if it appeared relatively weaker. Bands present in monomer if appeared in the partially dimerized crystal without losing intensity were attributed to the dimer as existence of some dimer in the monomer crystal can not be ruled out. New bands, of course, were the dimer bands. In monomer crystal, the band at 1624 cm^{-1} which is due to the aliphatic C=C stretching mode is very intense but decreases with the increase of the extent of photodimerization and almost disappears in near complete photodimer crystal. This, indeed, suggests cyclobutane ring formation. The cyclobutane ring breathing vibration around 1000 cm^{-1}, however, has not been observed in the Raman spectrum. Observation of such a Raman active mode has usually been attributed to the confirmation of four center type photopolymerization with cyclobutane ring formation.[4] Absence of such a vibration in the Raman spectrum is however consistent with the structure of the dimer as suggested by Hasegawa *et al.*[6] which is trans, head to head type like β-truxinic acid.

TABLE 1. INFRARED BANDS (IN KBr) OF *p*-FCA CRYSTAL BEFORE AND AFTER PHOTODIMERIZATION

Monomer bands/cm^{-1}	Dimer bands/cm^{-1} (After extensive dimerization)[a]	Inference
698 (ms)		
	720 (w)	D: cyclobutane ring deformation
738 (w)	738 (m)	D
808 (ms)	808 (vw)	M
825 (s)	825 (vw)	M
	843 (s)	D: C-C Skeletal stretch
860 (mw)	860 (vw)	M
875 (w)		M
941 (s, br)	941 (w, vbr)	M
986 (s)	986 (w)	M
1015 (w)	1015 (w)	D
	1036 (w)	D: cyclobutane ring deformation
	1052 (w)	D
1111 (w)		M
	1135 (m)	D
1167 (m)		M
	1170 (m)	D
1202 (s)		M
1214 (ms)		M
	1216 (s)	D
1225 (ms)		M
	1240 (ms)	D: O-H in-plane bending
1282 (vs)	1282 (w)	M
1305 (vs)	1305 (s)	M
1329 (s)		M
	1355 (ms)	D: aliphatic C-H deformation
1393 (s)	1393 (w)	M
	1410 (s)	D
1424 (ms)		M
1564 (vs)	1564 (ms)	M
1599 (ms)	1599 (s)	D
1624 (vvs)		M: aliphatic C=C stretch
1682 (vvs)	1685 (vvs)	D: C=O carboxylic
	1722 (s)	D: C=O formyl

a) m: medium, s: strong, ms: medium strong, w: weak, vw: very weak, vs: very strong, br: broad, mw: medium weak, vbr: very broad, vvs: very very strong. b) M: monomer, D: dimer.

The other infrared features also suggest such a structure of four center type photodimerization in the crystalline state. The bands observed in the dimer at 720, 1035, and 1052 cm^{-1} are possibly the ring deformation vibrations. In such structure of the dimer, the C=O stretching frequency in the carboxyl group and in the formyl group are distinctly resolved, the former possibly is 1722 cm^{-1} and the latter 1685 cm^{-1}. Due to the loss of conjugation through the aliphatic C=C bond, some of the bands are shifted on dimerization. C-C skeletal stretching mode at 825 cm^{-1}, O-H in-plane bending at 1225 cm^{-1} and aliphatic

C-H deformation at 1329 cm^{-1} in monomer shift to 843, 1240, and 1355 cm^{-1} respectively in the dimer.

The Raman spectrum of the dimer is very weak, possibly due to the low value of the polarizability tensor. Intense Raman bands of the monomer are only observed in the partially dimerized sample without any significant change in the band positions.

Electronic Spectral Change on Dimerization Reaction Progress. *p*-FCA in the polycrystalline film at 25 °C show a broad absorption band with λ_{max} at 300 nm. Another band is also observed with λ_{max} at 200 nm. On photoreaction the product dimer in the solid film at 25 °C also shows two broad absorption bands, the 300 nm band is now shifted to 260 nm, the second band at λ_{max} 200 nm does not show any appreciable shift. This band shows a red shift to 210 nm on cooling at 77 K, 260 nm band, however, does not show any appreciable shift on cooling. The solid state absorption spectra are shown in Fig. 2.

Cinnamic acid molecule like benzoic acid is non-fluorescent and only strong phosphorescence emission is observed[7] which, as in benzoic acid, is possibly a $^3\pi,\pi^* \rightarrow S_0$ transition. *p*-Formylcinnamic acid in ethanol solution, on the other hand, is only fluorescent and no phosphorescence emission is observed. The emission spectra of *p*-FCA are shown in Fig. 3, (solid film). In monomer crystal a strong broad fluorescence emission in the 430—550 nm region with λ_{max} at 470 nm is observed at 77 K. This emissive property of *p*-FCA molecule evidently arises because the carbonyl oxygen in the formyl group contributes an additional set of $n\pi^*$ states. Relative energetic position of such states may make the singlet triplet intersystem crossing inefficient. The broad structureless absorption and emission spectra in the crystal at 77 K and the large Stokes' shift (12057 cm^{-1}) between the absorption and emission maxima provide a clear evidence for a strong lattice distortion in the excited state and thus a strong electron phonon coupling. On dimerization reaction progress, the monomer emission

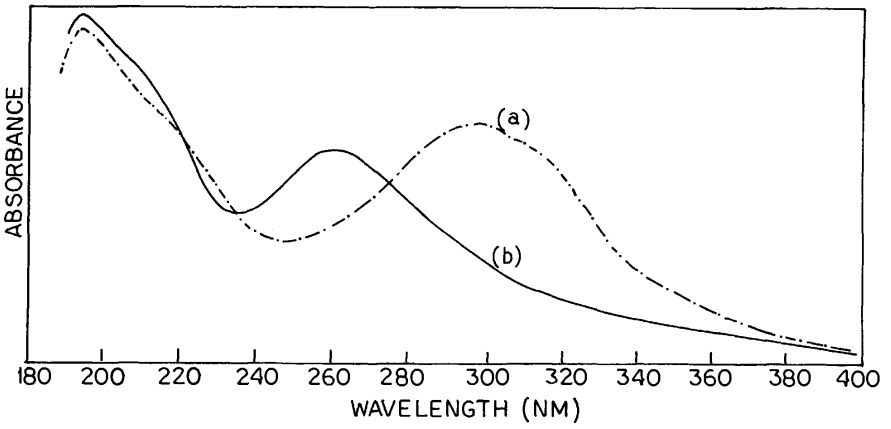

Fig. 2. Solid state absorption spectra at room temperature (a) monomer (b) dimer.

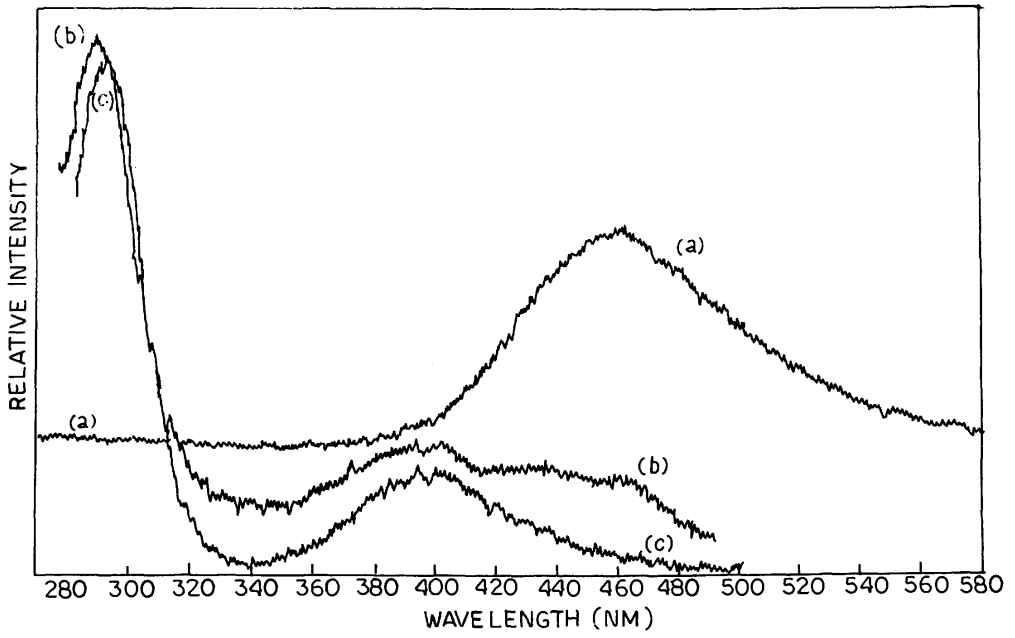

Fig. 3. Emission spectra of solid film of *p*-FCA at 77 K (a) monomer (b) partially dimerized (c) dimer.

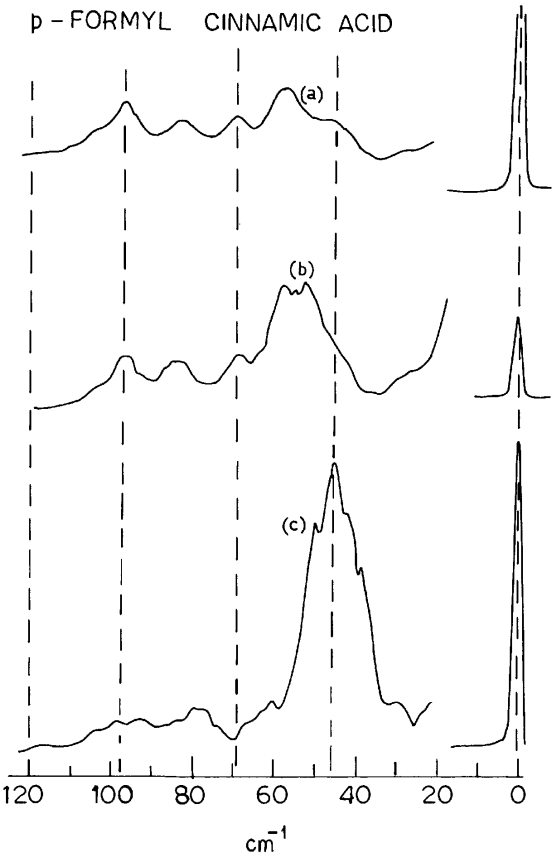

Fig. 4. Raman phonon spectra of *p*-FCA crystal monitored as a function of the photoreaction progress in order of a→c, a being the phonon spectra of the monomer and c that of an extensively dimerized crystal.

intensity decreases and a new emission band system appears on the higher energy side of the monomer crystal emission. This structureless emission band has its λ_{max} at 390 nm. On complete dimerization, only the new emission band, characteristic of the dimer is observed. One interesting feature of the photoproduct emission is that in addition to the emission discussed above another prompt high energy emission is observed with λ_{max} at 290 nm. At this point it is not certain if this double emission arises from the product *t*-3,*t*-4-bis(*p*-formylphenyl)-*r*-1,c-2-cyclobutanedicarboxylic acid molecule or it is some other secondary photoproduct emission.

Phonon Spectral Change on Dimerization Reaction Progress. β-Form of the *p*-FCA crystal is photoreactive. The change in the phonon spectra as the dimerization reaction progress is shown in Fig. 4. The phonon spectrum of the monomer crystal of the β-form obtained from ethanol solution (top) show five distinct phonon bands at 45, 57, 69, 83, and 98 cm^{-1}. In addition two weak phonon bands are observed at 29 and 104 cm^{-1}. On photoirradiation for few minutes slight photodimerization occurs and the phonon spectrum of such crystal (middle) shows some new phonon bands at 31, 52, 55, 63, 87, and 92 cm^{-1}. The monomer phonon bands appear more broad and their intensity is slightly diminished. The broadening of monomer phonon bands may indicate slight shift in frequency of monomer phonons suggesting an amalgamation of phonons in this initial stage of reaction. Appearence of new phonon bands indicates initiation of seggregation of the reaction product. On extensive photodimerization (bottom), the monomer phonon bands appear very weak and new phonon spectrum arise with phonon bands at 29, 39, 43, 45, 50, 60, 63, 67, 74, 77, 87, 92, and 117 cm^{-1}, the 45 cm^{-1} phonon band being most intense in the dimer lattice. Thus the phonon spectrum of the dimerized crystal shows seggregated phonon spectra of the monomer and the dimer lattice. These results suggest that the solid state photoreaction in this crystal is homogeneous in the initial stage but becomes heterogeneous as the concentration of the product increases with reaction progress. The lattice distortion introduced by the product becomes too strong and the product seggregates out, the reactant and the product form their own lattices and no solid solution results.[1,8,9] Further, the existence of the 45 cm^{-1} monomer lattice phonon throughout the reaction progress and its enhanced intensity in the photodimer lattice suggests thet the lattice topology along this phonon coordinate is preserved during the reaction.

This work was partly done in the Chemistry Department, State University of New York at Buffalo. One of the authors (TNM) expresses his thanks to Prof. P. N. Prasad for his kind hospitality and for many valuable discussion. Thanks are also due to Professor M. Hasegawa for a generous gift of the *p*-formylcinnamic acid sample.

The Fluorescence Lifetimes of Jet-cooled Alkylnaphthalenes

Teijiro ICHIMURA,* Andrew R. AUTY,† Anita C. JONES,† and David PHILLIPS†
Department of Chemistry, Tokyo Institute of Technology, Ohokayama, Meguro-ku, Tokyo 152
†*The Royal Institution, Albemarle St., London, W1X 4BS, U. K.*
(Received February 22, 1985)

Synopsis. The measured fluorescence lifetime of the origin of jet-cooled 1-methylnaphthalene is close to that of naphthalene, whereas the corresponding lifetimes of the 2-substituted are longer. The fluorescence lifetime decreased with increasing excitation energy; this can be attributed to an increase in the rate of intersystem crossing with vibrational excitation.

Supersonic free jet experiments have been extensively applied to investigate the spectroscopic and molecular dynamical aspects of various size molecules. The supersonic molecular beam prepares isolated gas molecules of low internal temperature, which makes feasible the study of the dynamical behaviour of state selected single vibronic level.

The naphthalene molecule in jet-cooled conditions has recently been investigated by Smalley *et al.*[1] and Rice's group.[2] Many vibronic bands up to about 4000 cm^{-1} from the origin are assigned and intramolecular vibrational relaxation processes have an onset at about 2500 cm^{-1} above the origin. Measurements of fluorescence lifetime and quantum yield led to the radiationless decay rate and the radiationless process is postulated to be intersystem crossing to triplet manifolds, a similar process to that of benzene.

On the other hand, naphthalene derivatives have not been studied well in the jet. Very recently Small's group[3] has observed laser induced fluorescence of jet-cooled 1-methyl- and 2-methylnaphthalene derivatives. They suggested that in the first excited singlet state of 2-methylnaphthalene symmetry reduction-vibronically induced mode mixing should occur.

A previous paper[4] has demonstrated jet-cooled fluorescence excitation spectra associated with 1-methyl-, 2-methyl- and 2-ethylnaphthalene derivatives by monochromatized xenon lamp irradiation. In this paper fluorescence lifetimes were first measured for the origin bands and vibronic bands up to excess vibrational energy of 700 cm^{-1} to study substitution effect on radiative and nonradiative transitions in jet-cooled alkylnaphthalenes.

Experimental

The supersonic free-jet apparatus used in this experiment has been described elsewhere,[5] therefore only a brief description is given here.

The free-jet portion of the apparatus consists of a 50 cm diameter vacuum chamber, through one side of which is inserted a continuously operated supersonic nozzle. A large slit nozzle, 4 mm long and 380 μm wide, was used for these experiments. Back ground pressure in the expansion chamber was maintained in the region of 10^{-3} Torr (1 Torr= 133.322 Pa) by evacuation with a vapour booster (pumping speed 4000 l s^{-1}) backed by a rotary pump. The expansion mixture is argon, at a typical stagnation pressure of 50 Torr. Naphthalene derivatives were seeded into the argon by placing a sample tube heated at 75 °C in the argon feed line to the nozzle, giving a concentration of 2—4 mole%.

Fluorescence excitation spectra were measured by crossing the free jet at 90° with the light of a 450 W Xe lamp, dispersed by a 1 m monochromator with resolution 10 cm^{-1} FWHM. The excitation beam was mildly focused and crossed the jet 5 mm downstream from the slit nozzle. The crossing position is varied by the movement of a lens. Fluorescence was collected, at right angles to the free jet and the excitation beam, by an f/1 lens and focussed *via* a band pass filter (340±20 nm), onto a photomultiplier tube. The signal from the photomultiplier was processed by the photon counting technique. The fluorescence excitation spectrum was corrected for the spectral intensity distribution of the xenon lamp.

Fluorescence lifetimes were determined for each peak of the excitation spectra by the time correlated single photon counting techniques. The excitation source used was the frequency doubled output of a cavity dumped dye laser synchronously pumped by a mode-locked argon ion laser with resolution 3 cm^{-1} FWHM.

Samples of 1-methyl-, 2-methyl-, and 2-ethylnaphthalene were obtained from Aldrich and used without further purification. Stated purities of these samples ranged from 95% to 99%.

Results and Discussion

The positions of the observed origins for π-π^* electronic transitions of 1-methyl-, 2-methyl-, and 2-ethylnaphthalene are 31773, 31705, and 31749 cm^{-1}, respectively.[4] Relative frequencies of some vibronic bands <1000 cm^{-1} are listed in Table 1, together with frequencies and assignments of pertinent naphthalene transitions. Assignments of these naphthalene derivatives are tentative since we do not have reliable information on the vibrational structures of the methyl- and ethylnaphthalene molecules. The prominent Herzberg-Teller origin band 8 ($^1b_{1g}$) at 437 cm^{-1} for naphthalene[1,2] was observed at 422 cm^{-1} in the 1-methylnaphthalene spectrum with slight shift; for the 2-methyl and 2-ethyl derivatives only very weak features were observed at 429 and 421 cm^{-1}, respectively, which are tentatively assigned as the band. Assignments for 1-methylnaphthalene in Table 1 is based on the assumption that relative intensity of the vibronic bands are similar to that of naphthalene. For 2-methyl- and 2-ethylnaphthalene derivatives the frequency change of these vibronic bands is assumed to be small and hence similar to the frequency of 1-methylnaphthalene vibronic bands though relative intensity of the vibronic bands are drastically changed due to mode-mixing.[3,4] The fact that replacement of the 2-methyl group with an ethyl group produces only a minor change in the excitation spectrum is in agreement with the observations of Hopkins *et al.*[6] for jet-cooled alkylbenzenes.

a) Reproduced from Ref. 2). b) Assignments for alkylnaphthalenes are tentative.

The results of fluorescence lifetime measurements are also shown in Table 1. The fluorescence lifetime of the origin of 1-methylnaphthalene is close to that of naphthalene, whereas the corresponding lifetimes of the 2-substituted are longer. The increase in transition moment of the origin resulting from alkyl substitution is accompanied by an increase in the radiative decay rate of S_1. The observed decrease in the fluorescence decay rate must therefore be due to a decrease in the rate of intersystem crossing in the alkyl substituted naphthalenes. Nonradiative transition in 0-0 bands of the alkylnaphthalenes can not be internal conversion in analogy to naphthalene[2] though the frequency of these 0-0 bands is slightly red-shifted ($\approx$300 cm^{-1}) compared with that of naphthalene.

Reiser and Wright[7] have theoretically predicted that the radiative decay rate increases by a factor of $\approx$2 for 1-methylnaphthalene and $\approx$3 for 2-methylnaphthalene, relative to naphthalene. They have shown these values to be consistent with radiative lifetimes measured in solution. Behlen and Rice[2] have estimated the rate coefficient for radiative decay (k_r) of the S_1 origin of jet-cooled naphthalene to be 9.4×10^5 s^{-1}, and that for intersystem crossing (k_{isc}) to be 2.4×10^6 s^{-1}. On this basis the following values can be predicted: $k_r\approx2\times10^6$ s^{-1}, $k_{isc}\approx1\times10^6$ s^{-1} for the origin of jet-cooled 1-methylnaphthalene and $k_r\approx3\times10^6$ s^{-1}, $k_{isc}\approx1\times10^5$ s^{-1} for 2-methylnaphthalene. The implication is thus that 2-methyl substitution leads to an order of magnitude decrease in the rate of intersystem crossing from the origin level, giving a fluorescence quantum yield of $\approx$1. The effect of 2-ethyl substitution is expected to be similar, and the measured fluorescence lifetime indicates the upper limit for k_r to be 3×10^6 s^{-1} in this case.

For both of the 2-substituted naphthalenes studied, the fluorescence lifetime decreases with increasing excitation energy; this can be attributed to be an increase in the rate of intersystem crossing with vibrational excitation. The marked dependence of decay rate on population of particular vibrational modes which was observed in naphthalene[2] (*e.g.* the sharp increase in k_{isc} on population of the $2(b_{2g})$ mode) was not observed for the 2-substituted molecules, presumably as a result of the mode-mixing which is induced by alkyl substitution.

(Received March 8, 1985)

Synopsis. An excimer-like fluorescence band at 470 nm was observed for anthracene liquid. A distinct shoulder at 414 nm was recognized in the absorption spectrum of anthracene liquid. These results suggest the existence of dimeric aggregates in this liquid.

Optical properties of pure organic liquids have been studied in only a very few cases compared with corresponding solids, gases or solutions. Experimental and theoretical difficulties may partly be responsible for this fact. Only benzene and substituted benzenes have been rather extensively studied on the absorption or fluorescence spectra of the liquids.[1]

On the other hand, optical properties of amorphous organic films, which may be regarded as a somewhat frozen-liquid in structure, have recently been studied by several workers, and many interesting characteristics have been revealed.[2] Most prominent features of such amorphous solids are broadening of bands and/or disappearance of Davydov splitting in the absorption spectra[3] and appearance of strong excimer-like emission in the fluorescence spectra.[4,5] The existence of excimer-like fluorescence which is absent in the crystals means that there are significant numbers of dimeric molecular aggregates in these amorphous solids which are more strongly interacting with each other than in the corresponding crystalline solids. The concentration of the dimeric molecular pairs has been tentatively estimated to be 10^{-3} mol/mol or more in an amorphous anthracene film.[5] However, considering the facts that the red-shift and/or the enhancement of long wavelength tail of the lowest absorption band are usually observed in such amorphous films,[6] the dimeric molecular pairs might occur in higher concentrations in a more disordered state, such as a liquid state. In fact, an amorphous anthracene film is colored slightly yellow, although its crystallized film by annealing is colorless in spite of the larger grain size in the latter.

A colorless anthracene crystal turns to yellow liquid on melting in an inactive gas atmosphere, and returns to colorless again on solidifying. This coloration on melting has usually been ascribed to a vibrational hot-band effect[7] or an impurity effect. However, if sufficient numbers of dimeric molecular pairs are prevailing in the liquid, they may contribute to make the color of the liquid yellow, and thus excimer-like emissions could be observed for the liquid anthracene. This point is our main motivation for the present work. Ferguson *et al.* observed the excimer emission from sandwich dimers of anthracene by the photolysis of photodimers of anthracene, and he also proposed the existence of 55° dimers of anthracene.[8] Excimer fluorescence of anthracene has also been observed in amorphous films, in a deformed crystal under high pressure[9] and also in a saturated $CHCl_3$ solution.[10] Pyrene and naphthalene excimer emissions in the liquid state has been reported by Birks.[11] In this note, we report the fluorescence spectra of liquid anthracene and discuss the possibility of the exsistence of the dimeric molecular aggregates as the structural units in such an organic liquid.

Experimental

Anthracene used was purified by recrystallization, sublimation and zone melting. A single crystal was grown with the Bridgman method in a quartz tube sealed off with 0.5 atm He gas and directly used for optical measurements. A larger diameter quartz tube wound by a wire heater was coaxially set with the sample tube for melting. Optical spectra were measured by a conventional technique for stationary fluorescence detection. Light from a 500 W xenon lamp was fed to a monochromator (Bosch-Lomb 1200 G/mm), of which output, 300 nm light, was used for excitation. Fluorescence was detected with a HT VR376 photomultiplier tube through a TEC G-250CT monochromator. Front surface excitation and viewing geometry was mainly used except for the case of meniscus viewing. Other geometries were carefully tested to check the reabsorption effect.

Results and Discussion

Fluorescence intensity of an anthracene crystal gradually decreased with increasing temperature and the total intensity became very low when it was melted. The reducing ratios were different from band to band. Especially, 470 nm band of the crystal most slowly decreased its intensity. A typical fluorescence spectrum of a single crystal at 300 K is shown in Fig. 1(b).

When a crystal in a quartz tube was melted and irradiated by 300 nm exciting light, bluish green fluorescence was emitted from the meniscus which was about 10 mm apart from the irradiated point in the liquid, and it was carried there by total-internal-reflection effects. Its spectrum at 493 K is shown as curve I in Fig. 1(a). The most intense emission in this spectrum is the band around 470 nm which is corresponding to the excimerlike band in the emission spectrum of an amorphous anthracene solid.[4,5] Intensities of monomer emission bands were rather weak in this spectrum because of reabsorption effect. The bulk of the liquid faintly fluoresced in nearly the same color as in the meniscus, but the spectral distribution of the intensity was rather different. Monomer emission bands were rather intensified in the fluorescence spectrum just from the excited region as shown by curve II in Fig. 1. The 386 nm (25906 cm^{-1}) band in this spectrum may be assigned to the 0-0 fluorescence band which corresponds to the 396 nm (25252 cm^{-1}) 0-0 absorption band in the crystalline

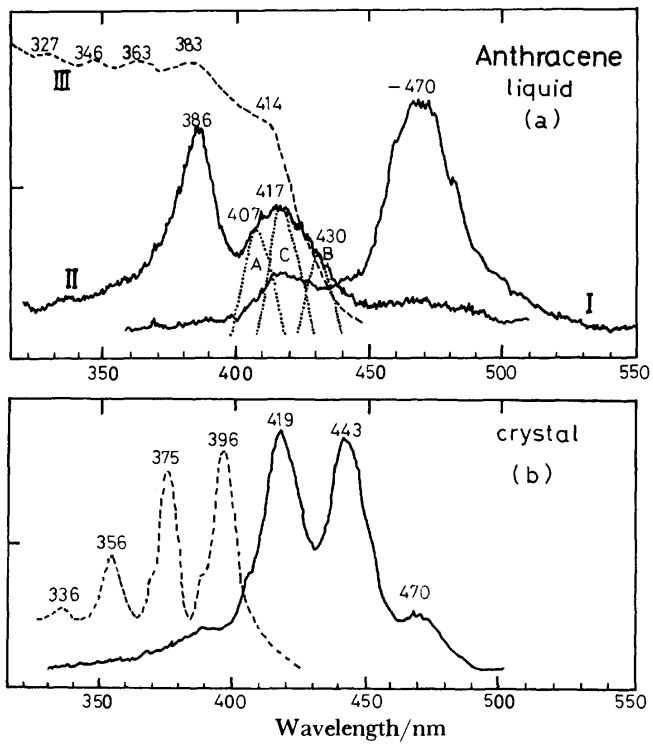

Fig. 1. (a) Fluorescence (full lines I and II) and absorption (in absorbance; dashed line III) spectra of anthracene liquid. Dotted lines show the resolved bands (see the text). (b) Fluorescence (full line) and absorption (in absorbance; dashed line) spectra of anthracne crystal. The absorption sepctrum is of a thin film deposited *in vacuo*.[6]

state. The second band around 417 nm is rather so broad that it could be resolved into three components. A possible procedure for resolving of this band was as follows; assuming the similar vibrational progression in the liquid state as in the crystalline state, the first and second vibronic band peaks could be 407 nm (24570 cm^{-1}) (A) and 430 nm (23256 cm^{-1}) (B) referring to the 386 nm (25907 cm^{-1}) 0-0 band. The halfwidths of these bands were also assumed to be proportional to that of the 386 nm band and the subtraction of these two bands from the observed broad band resulted in the band (C) around 417 nm, as shown in Fig. 1(a).

In order to pursue the origin of the 417 nm band and also to confirm the assignment mentioned above, we tried to observe an absorption spectrum of liquid anthracene, using a ≈50μm thick Pyrex glass cell. This absorption spectrum is shown in Fig. 1(a) together with the fluorescence spectra for convenience of comparison with each other. The 383, 363, 346, and 327 nm absorption bands are recognized to be monomeric vibronic bands. However, the remarkable extra absorption shoulder at 414 nm may be assigned to the dimeric molecular aggregates origin, since it is separated by much larger energy, 1955 cm^{-1}, than the monomer vibrational progression (1450 cm^{-1}) mentioned above. Although the monomer-monomer interactions in a sandwich type geometry in the ground state are usually considered to be repulsive, some configurations might be favourable for attractive interactions because of the reported cluster formation in some molecular beams.[12] Thus, the 417 nm fluorescence band could be assigned to the dimer emission which comes directly from the 414 nm absorption. Then, the 470 nm fluorescence band in the liquid state may be an excimer band which is emitted from the more strongly interacting excimeric molecules in the excited state.

In conclusion, all these observed facts suggest that the existence of fair amounts of dimeric molecular aggregates in the liquid anthracene and these units may also be responsible for the yellow coloration of the liquid, since it has the 414 nm absorption band which is never regarded as a hot band. Further confirmation by the use of time-resolved spectroscopy will appear elsewhere soon.

Reactions of Ketene, Methylketene, Ethylketene, and Dimethylketene with Ozone in Air

Shiro HATAKEYAMA,* Shigeo HONDA,† and Hajime AKIMOTO
Division of Atmospheric Environment, The National Institute for Environmental Studies, P.O. Tsukuba-gakuen, Ibaraki 305
(Received March 9, 1985)

Synopsis. Rate constants for reactions with ozone were measured for four kinds of simple ketenes (ketene, methylketene, ethylketene and dimethylketene) in 1 atm of air. The rate constants were obtained as upper limits; $<1\times10^{-21}$, 7×10^{-19}, 1×10^{-18}, and 4×10^{-17} cm^3 molecule^{-1} s^{-1}, respectively. The mechanism of the reactions was proposed to be similar to that for the liquid-phase reaction.

Formation and loss process of oxygen-containing secondary pollutants in the atmosphere is of great interest in the area of atmospheric chemistry. In addition to the well-known oxygen-containing secondary pollutants such as aldehydes, ketones, and carboxylic acids, α-dicarbonyl compounds, ketenes, and peroxides are also observed in the atmosphere. Among these compounds ketenes are known as products of ozone–alkene reactions.[1]

As to the homogeneous loss processes of ketenes in the atmosphere, photolysis and reactions with OH, ozone, and O(^{3}P) should be important. Recently, we reported the reaction of ketenes with O(^{3}P),[2] and with OH.[3] However, little is known about the kinetics of the reactions of ketenes with ozone. To our knowledge, mechanisms of the ozone reactions of ketenes in the gas phase have not been studied so far. For the liquid phase several investigations[4–7] were reported.

In this paper we report the measurement of rate constants for the reactions of ketenes with ozone. The reaction mechanism is also discussed.

Experimental

Ketene, methylketene (MK), ethylketene (EK), and dimethylketene (DMK) were prepared in the same manner as reported before.[2] $^{18}O_2$ (99%) was obtained from Nippon Sanso.

Kinetic measurements were performed both in an 11 L cylindrical quartz vessel (120 mm i.d., 1000 mm long), and in a large volume (6 m^3) smog chamber,[8] whose inner surface is coated with Teflon. The change in the concentration of reactants and products was monitored by means of long-path Fourier transform infrared spectroscopy (LP-FTIR). Path length is 40 m and 221.5 m for the quartz cell and the smog chamber, respectively. Absorptivities used are reported in the previous paper.[3] All the IR spectra were taken at 1 cm^{-1} of resolution. Scans accumulated were 32 times (≈1 min) and 128 times (≈4 min) in the quartz cell runs and in the smog chamber runs, respectively.

Measurements of the rate constant for the reaction of ketene with ozone were performed in the 11 L quartz cell with 2.8 mTorr (1 Torr=133.322 Pa) of ketene and 24—100 mTorr of ozone or with 5.8 mTorr of ozone and 58 mTorr of ketene at room temperature. Those for other ketenes were performed in the smog chamber with ≈0.2 mTorr of ketenes and 1—6 mTorr of ozone at 30±1 °C in the presence of ≈15 mTorr of CH_3CHO as a scavenger of free radicals.

Results and Discussion

Even in the presence of a large excess of ketene (58 mTorr), the decay of ozone (5.8 mTorr) was under detection limit. In the presence of a large excess of ozone (24—100 mTorr), the decay rate of ketene (initial concentration 2.8 mTorr) did not show any dependence on the concentration of ozone as shown in Fig. 1. Thus, the reaction of unsubstituted ketene with ozone is concluded to be very slow. Ketene decay observed in Fig. 1 should be attributed to wall decay of ketene. Decay rate shown in Fig. 1 is three to four times as high as that in the absence of ozone, so it seems that excess ozone enhances the wall decay of ketene. From the results obtained above the upper limit of the rate constant was estimated to be $<1\times10^{-21}$ cm^3 molecule^{-1} s^{-1}. The other ketenes were found to react with ozone more than 100 times faster than ketene. Therefore, the 6 m^3 smog chamber was used as the reactor in order to use much lower concentration of ketenes. Decay of ketenes (initial concentration is about 0.2 mTorr) in the presence of excess ozone (1—6 mTorr) and CH_3CHO (≈15 mTorr) as a scavenger of free radicals was first order. From the dependence of the decay rates on the initial concentrations of ozone as shown in Fig. 2, second order rate constants were calculated to be $(6.7\pm1.9)\times10^{-19}$, $(9.8\pm3.4)\times10^{-19}$, and $(3.7\pm0.5)\times10^{-17}$ cm^3 molecule^{-1} s^{-1} for MK, EK, and DMK respectively. In these plots the intercepts are in good agreement with the wall decay rates of ketenes (filled circles in Fig. 2).

However, stoichiometry of the reaction for three kinds of ketenes are not unity: consumption of ozone is always smaller than that of ketenes in a factor of about 0.7 under the conditions employed for the smog chamber runs and the discrepancy of stoichiometry

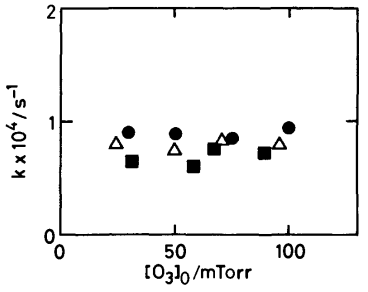

Fig. 1. Dependence of decay rate of ketene on the concentration of ozone. [Ketene]$_0$≅2.8 mTorr.

†On study leave from the University of Tsukuba, Sakura, Ibaraki 305.

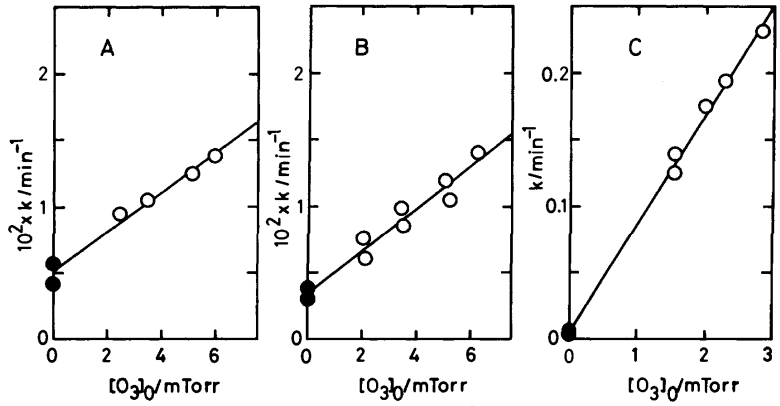

Fig. 2. Dependence of decay rates of MK, EK, and DMK on the concentration of ozone. Solid circles indicate the wall decay. $[Ketene]_0 \cong 0.2$ mTorr.

becomes larger when the concentration of reactants is higher. In the runs with low concentration of ozone and excess ketenes first order decay of ozone was not observed. These facts indicate the contribution of secondary reactions which cannot be prohibited even in the presence of excess CH_3CHO. Thus, the rate constants obtained here may be also regarded as upper limits.

To our knowledge, the gas phase reaction of ozone with ketenes has never been investigated. As for the liquid phase reaction of ozone with ketenes, several reports have been presented.[4,7] In these papers the reaction mechanism is described as follows:

$$RR'C{=}C{=}O + O_3 \longrightarrow RR'\overset{O\diagup\ \diagdown O}{C}\!\!-\!\!\!-\!C{=}O \longrightarrow RR'COO + CO_2 \quad (1)$$

$$RR'COO + RR'C{=}C{=}O \longrightarrow RR'CO + RR'C(\diagup O\diagdown)\!\!-\!\!\!-C{=}O \quad (2)$$

$$RR'C(\diagup O\diagdown)\!\!-\!\!\!-C{=}O \longrightarrow RR'CO + CO \quad (3)$$

In the present study formation of CO, CO_2, and RR'CO (CH_3CHO, C_2H_5CHO, and CH_3COCH_3 from MK, EK and DMK, respectively) was observed, but the stoichiometry of the reaction is not so good enough to discuss the product yields quantitatively. However, the formation of methane, formaldehyde and a small amount of ketene in MK ozone reactions strongly indicates the existence of CH_3CHOO biradical when the mechanism of the decomposition of this biradical,[9] as depicted by following equations, is taken into account.

$$CH_3CHOO \longrightarrow CH_3 + H + CO_2 \quad (4)$$

$$\longrightarrow CH_4 + CO_2 \quad (5)$$

$$\longrightarrow CH_3 + CO + OH \quad (6)$$

$$\longrightarrow CH_2C{=}O + H_2O \quad (7)$$

Radical species formed by the reactions 4 and 6 can consume ketenes, which results in the poor stoichiometry.

An interesting result was obtained in the experiments using $^{18}O_3$ as a reactant. Produced CO_2 mainly consists of $C^{16}O^{18}O$, which supports the occurrence of reaction 1. However, since even a large excess of acetaldehyde cannot trap the biradical (ozonides were not detected), the biradical seems to decompose very quickly and the reaction 2 does not take place in the gas phase.

The authors are grateful to Mr. H. Takagi for his help to conduct experiments using the smog chamber.

Remarkable Isotope Effect on the Hydrogen-atom Reaction in the Photolysis of D_2-H_2-HI Mixtures at 4 K. A Quantum-mechanical Tunneling Effect

Tetsuo MIYAZAKI
Department of Synthetic Chemistry, Faculty of Engineering, Nagoya University, Chikusa-ku, Nagoya 464
(Received March 22, 1985)

Synopsis. The photolysis of D_2-H_2-HI (0.05 mol%) mixtures has been studied at 4 K by means of ESR spectroscopy. The yield of D atoms decreases sharply upon the addition of a small amount of H_2, while the yield of H atoms increases. The results of the photolysis are similar to those in the radiolysis of D_2-H_2 mixtures at 4 K. The preferential formation of H atoms in the photolysis and radiolysis of the D_2-H_2 mixtures is due to the selective H-atom-abstraction reaction from H_2 by D atoms by means of a quantum mechanical tunneling.

Basic to any theory of the chemical kinetics of elementary reactions is an understanding of the simplest atom-diatomic exchange reaction. A number of experimental and theoretical studies of the reaction of H (or D) with $H_2(D_2)$ in the gas phase have been reported previously.[1] The previous studies, however, have been undertaken above room temperature. Thus, it was difficult to discriminate between the reaction caused by a quantum mechanical tunneling effect and the reaction which proceeds by passing over a potential energy barrier. In order to clarify the tunneling effect, the present author and his colleagues have recently studied the $H_2(D_2)$+H(D) reaction at extremely low temperatures, such as 4.2 and 1.9 K.[2,3]

When solid D_2-H_2 mixtures are irradiated by γ-rays at 4 K, the yields of the trapped D atoms in the radiolysis of D_2 decrease drastically upon the addition of a small amount of H_2, while the yields of trapped H atoms increase.[2] It has been suggested that the remarkable isotope effect on the formation of the D and H atom is to be ascribed to a selective hydrogen-atom reaction caused by a quantum-mechanical tunneling.[2] Since γ-irradiation produces different active species, the selective formation of H atoms in the γ-radiolysis of the D_2-H_2 mixtures may also be explained in terms of activation transfer, such as excitation, charge, and proton transfers, from D_2 to H_2.

In order to verify the remarkable isotope effect on the hydrogen-atom reaction, the reaction of hydrogen atoms produced by the photolysis of HI has been studied here in D_2-H_2 mixtures at 4 K.

Experimental

The H_2 was more than 99.999 mol% pure. The D_2 was more than 99.5 mol% pure. An aqueous solution of HI was vaporized and passed through P_2O_5 to prepare hydrogen iodide. Then, the hydrogen iodide was subjected to trap-to-trap sublimation on a vacuum line several times. The solid sample was made by the rapid cooling of gaseous hydrogen-hydrogen iodide mixtures in a sample tube from room temperature to 4 K. UV illumination was performed at 4 K with a low-pressure mercury lamp. The trapped hydrogen atoms in the irradiated samples were measured at 4 K with a JES-3BX ESR spectrometer at a microwave power level which does not result in the saturation of the signals of the atoms. The relative yields of the H and D atoms were obtained by double integration of the signals, which was performed with a personal computer system. The details of the experimental procedure and the power saturation of the ESR signals had been described in a previous paper.[4]

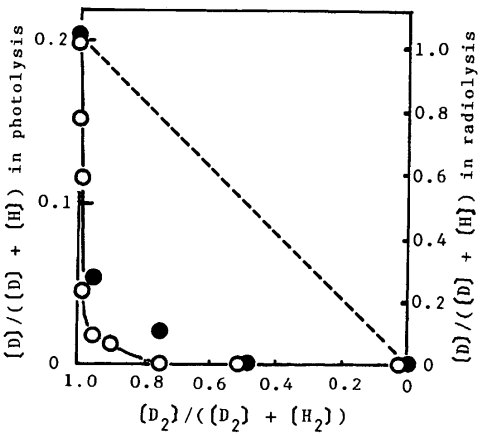

Fig. 1. Fractions of D atom yield in total hydrogen atom yield against fractions of D_2 in D_2-H_2 mixtures at 4 K: (●) D atoms in the UV photolysis of a D_2-H_2-HI(0.05 mol%) mixtures; (○) D atoms in the γ-radiolysis of the D_2-H_2 mixtures.

Results and Discussion

When pure D_2, pure H_2, and D_2-H_2 mixtures containing 0.05 mol% HI are UV-irradiated at 4 K, trapped D and/or H atoms can be observed by means of ESR spectroscopy at 4 K. Figure 1 shows the fraction of the trapped-D-atom yield in the total trapped-hydrogen-atom yield, denoted by closed circles, against a fraction of D_2 in the photolysis of the D_2-H_2-HI (0.05 mol%) mixtures at 4 K. The fraction of the trapped-D-atom yield in the radiolysis of the D_2-H_2 mixtures at 4 K is also shown by open circles. Since the total yields of the trapped D and H atoms are approximately constant over the whole range of D_2 fraction;[5] the D yields decrease sharply upon the addition of H_2, while the H yields increase complementarily. The results in the photolysis are roughly similar to those in the radiolysis. Since the ultraviolet light can be absorbed only by hydrogen iodide in the D_2-H_2-HI mixtures, the possibilities of the excitation, charge, and proton transfers from D_2 to H_2 can be discarded in the photolysis. Thus, the preferential formation

of H atoms in the photolysis can be described by the following schemes of hydrogen-atom reactions:

$$HI \xrightarrow{h\nu} H^* + I \quad (1)$$

$$H^* + D_2(H_2) \longrightarrow HD(H_2) + D(H) \quad (2)$$

$$\searrow H \quad (3)$$

$$D + D_2 \longrightarrow D_2 + D \quad (4)$$

$$D + H_2 \longrightarrow HD + H \quad (5)$$

$$H + D_2 \longrightarrow HD + D \quad (6)$$

$$H + H_2 \longrightarrow H_2 + H \quad (7)$$

Hot H atoms (H*) are produced initially by the photolysis of HI. The hot atoms abstract hydrogen atoms from D_2(or H_2) to produce thermal D(or H) atoms (Reaction 2) or are thermalized to become H atoms (Reaction 3).[4] If the thermal D and H atoms do not react further at 4 K, and if the isotope effect on the hot-atom reaction (Reaction 2) is small, the fraction of the D-atom yields ([D]/([D]+[H])) may be represented by the dotted line in Fig. 1. The large isotope effect on the formation of D and H atoms in the photolysis indicates the secondary reactions of thermal D or H atoms in the D_2–H_2 mixtures at 4 K. All possible reactions of D(H) and D_2(H_2) are represented in Reactions 4—7. Though these reactions have activation energies, the reaction may take place even at 4 K by means of quantum mechanical tunneling reaction.[2,3] Since Reactions 4 and 7 give the same products as the reactants, the large isotope effect is caused by the difference in rate constants between Reactions 5 and 6. Since Reaction 6 is slightly endothermic, the rate of this reaction may be very slow at 4 K.[2] D atoms produced by Reaction 2 react fast with H_2 to form H atoms, as was previously suggested by a theoretical calculation of a tunneling reaction.[3] Thus, it may be concluded that the preferential formation of H atoms in the photolysis and radiolysis of the D_2–H_2 mixtures is due to a selective H-atom-abstraction reaction from H_2 by D atoms.

The author wishes to thank Professor Kenji Fueki at Nagoya University for his encouragement throughout the work. This work was supported in part by a Grant-in-Aid for Scientific Research from the Ministry of Education, Science, and Culture.

4) T. Miyazaki, H. Tsuruta, and K. Fueki, *J. Phys. Chem.*, **87**, 1611 (1983).

5) Though the total yields of hydrogen atoms are approximately constant in the radiolysis of the D_2–H_2 mixtures, the yields in the photolysis are affected by the experimental conditions, such as the cooling process, the sample preparation, and the UV irradiation conditions. Thus, the constancy of the total yields in the photolysis is poorer than that in the radiolysis.

The Determination of the Dissociation Constants of Picric Acid and 2,2′,4,4′,6,6′-Hexanitrodiphenylamine in Ketone-Water Mixtures

Tadashi IWACHIDO,* Shinji OOSAWA,†,†† and Kyoji TÔEI†
College of Liberal Arts, Okayama University, Tsushima, Okayama 700
†*Department of Chemistry, Faculty of Science, Okayama University, Tsushima, Okayama 700*
(Received March 4, 1985)

Synopsis. The acid dissociation constants, K_a, of picric acid and 2,2′,4,4′,6,6′-hexanitrodiphenylamine in acetone, ethyl methyl ketone, and isobutyl methyl ketone were determined in the presence of water. The pK_a values increased remarkably with a decrease in the water content. The pK_a values in water-free ketones were estimated.

Picric acid (HPic) and 2,2′,4,4′,6,6′-hexanitrodiphenylamine (HND) have widely been used as soft acids in the field of analytical chemistry. However, the reported acid dissociation constant values for these substances in ketones lack consistency.[1-5] The aim of the present paper is to determine the dissociation constant values, K_a, of HPic and HND in acetone, ethyl methyl ketone (EMK), and isobutyl methyl ketone (IBMK) as a function of the concentration of water in these solvents, and to show that small quantities of water play a decisive role in acid dissociation. The dissociation constants were determined by means of the spectrophotometric and vapor-pressure osmometric methods.

Experimental

Commercial HND and HPic were recrystallized from acetone and water respectively. The acetone was dried over anhydrous calcium sulfate. The EMK and IBMK were treated with potassium permanganate, washed with a concentrated aqueous potassium carbonate solution and then with water, and dried over anhydrous sodium sulfate for a week or more. These solvents were distilled just before use. The water concentration of the solutions was determined from the absorbances at 1.9 μm. The absorbances of the HND (3×10^{-5} mol dm^{-3}) and HPic (5×10^{-5} mol dm^{-3}) solutions were measured at 430 and 400 nm respectively. The absorbances of the undissociated acid species were evaluated by extrapolating the absorbance-water concentration curves to zero water concentration. The absorbances of the completely dissociated species were approximated by those of the corresponding potassium salts.

Vapor-pressure osmometric measurements of the solutions ($(3-24)\times10^{-2}$ mol dm^{-3}) were done on a Hitachi-Perkin-Elmer Model 115 vapor-pressure osmometer calibrated with 1,2-diphenylethanedione solutions. All the measurements were carried out at 25 °C.

Results and Discussion

The dissociation constant of a weak acid, HA, can be written as:

$$HA \rightleftharpoons H^+ + A^-, \quad (1)$$

$$K_a = [H^+][A^-]/[HA] = C\alpha^2/(1-\alpha), \quad (2)$$

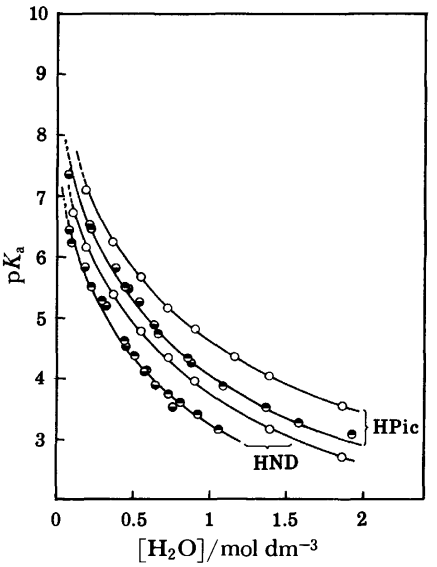

Fig. 1. pK_a *vs.* [H_2O] plots. ○: Acetone, ◓: EMK, ◒: IBMK.

where the brackets denote the molar concentration; C, the total molar concentration of the acid; and α, the degree of dissociation. The absorbance, E, of HA can be expressed as:

$$E = E_{HA}(1-\alpha) + E_A\alpha, \quad (3)$$

where E_{HA} and E_A designate the absorbances of HA and A^- respectively. Taking into account the fact that $[H^+]=[A^-]$, we obtain Eq. 4:

$$K_a = C(E-E_{HA})^2/((E_A-E)(E_A-E_{HA})). \quad (4)$$

In Fig. 1, the pK_a values calculated from E by means of Eq. 4 are plotted against the water concentration. The pK_a values increased markedly with a decrease in the water concentration.

The dissociation constant values in the water-free ketones were determined from pK_a *vs.* $[H_2O]^{1/2}$ plots (Fig. 2) to be pK_a (HPic)=9.3 (acetone), 8.8 (EMK), and 8.8 (IBMK) and pK_a (HND)=8.4 (acetone), 8.0 (EMK), and 8.0 (IBMK). The pK_a value of 9.3 for HPic in acetone is in good agreement with Foltin's value (pK_a=9.2).[1] However, it must be noted that the pK_a values reported by others are much smaller than the present values; Moor reported pK_a values of 3.86 (acetone) and 3.70 (EMK) for HPic;[2] Glover, a pK_a value of 3.3 for HND in acetone;[3] Majersky, pK_a values of 6.04 for HPic in acetone (0.09% water) and 6.54 in EMK (0.16% water);[4] and Majer, a pK_a value of 7.2 for HPic in acetone with a known content of water.[5]

††Present address: Kagawa Prefectural Government, Takamatsu, Kagawa, 761.

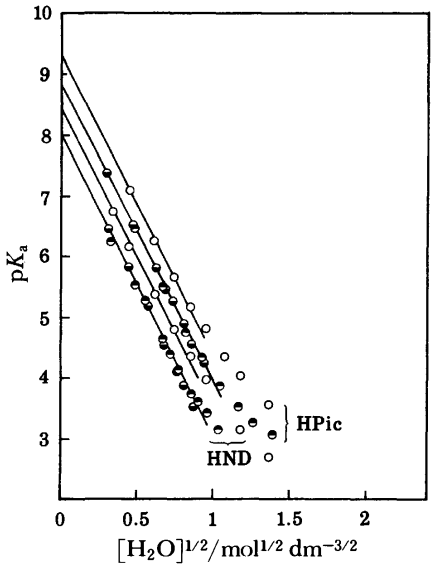

Fig. 2. pK_a *vs.* $[H_2O]^{1/2}$ plots. Symbols: see Fig. 1.

Taking into account the hydration of the solutes, the dissociation of HA can be expressed as:

$$HA_{x(H_2O)} + nH_2O \rightleftharpoons H^+_{y(H_2O)} + A^-_{z(H_2O)}, \quad (5)$$

where $n=x+y+z$. The equilibrium expression is given by:

$$K = [H^+][A^-]/([HA][H_2O]^n), \quad (6)$$

where K refers to the equilibrium constant; the symbols which denote hydration are omitted. Equation 6 can be rearranged as:

$$K_a = [H^+][A^-]/[HA] = K[H_2O]^n. \quad (7)$$

pK_a *vs.* log[H_2O] plots gave straight lines, as is shown in Fig. 3. From the slopes of the lines, the n values were determined to be 4.0±0.1 for all the acid-solvent systems. Since HA and A^- are bulky and hydrophobic in nature, the extent of their hydration is presumably very small or negligible as compared with that of the protons; this leads to the conclusion that the protons exist as $(H_9O_4)^+$ in ketonerich media, as observed in aqueous media.[6]

The dissociation constants can also be determined by means of vapor-pressure osmometry. When a solution and a solvent are placed together in a closed small room, the solvent vapor condenses on the solution, causing a rise in the temperature of the solution. The temperature difference, ΔT, is related to C as follows:

$$\Delta T = K_s(C+b_2C^2 + b_3C^3 + \cdots\cdots), \quad (8)$$

where K_s and b are constants, the values being calibrated with 1,2-diphenylethanedione as a reference substance.

For a dilute solution of electrolytes, Eq. 8 is approximated as:

$$\Delta T = K_s((1+\alpha)C + b_2(1+\alpha)^2C^2). \quad (9)$$

The pK_a values can thus be calculated from ΔT based on Eqs. 2 and 9. The dissociation constants of the potassium salts can also be determined in the same way.

Table 1 summarizes the dissociation constants. In the vapor-pressure osmometric method, the pK_a measurements of weak acids ($pK_a>6$) were unsuccessful because of the limited accuracy of the ΔT of the apparatus. The pK_a values in Table 1 agreed very closely with those obtained by means of the spectrophotometric method (*cf.* Fig. 3). Figures 1—3 and Table 1 show that HND is a stronger acid than HPic in ketone-water media, unlike as in aqueous media (pK_a(HND)= 2.75,[7] pK_a(HPic)=0.29[8]). The dissociation constants of the potassium salts also agreed well with those obtained conductometrically.[9,10]

Electrochemical Reductive Acylation of 2,3-Disubstituted 1-Indenones

Nobuhiro TAKANO,* Noboru TAKENO, Mutsuo MORITA, and Yoshio OTSUJI†
Department of Industrial Chemistry, Muroran Institute of Technology, Mizumoto-cho, Muroran 050
†*Department of Applied Chemistry, College of Engineering, University of Osaka Prefecture, Mozu-Umemachi, Sakai, Osaka 591*
(Received February 8, 1985)

Synopsis. The electrochemical reductive acylation of 2,3-disubstituted 1-indenones in the presence of acetic anhydride in aprotic media such as DMF, DMSO, and acetonitrile gave 2,3-disubstituted 1-acetoxy-1*H*-indenes (**2**) and 1,2-disubstituted 3-acetoxy-1*H*-indenes (**3**) in good yields. The ratios of **2** to **3** in the products were affected by the substituents.

The synthesis of organic compounds using electrochemically generated intermediates is a current topic in synthetic organic chemistry.[1] Previously, we have reported that two reductive acylation products, **2a** and **3a**, are obtained in good yields by the cathodic reduction of 2,3-diphenyl-1-indenone (**1a**) in the presence of acetic anhydride (Scheme 1).[2] As an extension of this synthetically useful reaction, we now wish to report an efficient, one-step synthesis of 2,3-disubstituted 1-acetoxy-1*H*-indenes (**2a—m**) and 1,2-disubstituted 3-acetoxy-1*H*-indenes (**3a—m**) by the cathodic reduction of 1-indenone derivatives (**1a—m**) in the presence of acetic anhydride and discuss the substituent effect on this reaction.

Scheme 1.

Experimental

The electrolyses were performed in a double cylindrical cell which was divided into the cathode and anode compartments with a sintered glass diaphragm. The working electrode (cathode) was a mercury pool and the auxiliary electrode (anode) was a platinum plate. A 0.1 mol dm^{-3} solution of *n*-Bu_4NBF_4 in DMF was used as both catholyte and anolyte. Acetic anhydride (20 g) and an indenone derivative (0.5 g) were added to the catholyte (100 cm^3). The solution was deoxygenated by bubbling purified N_2 and stirred with a magnetic stirrer. The electrolysis was then carried out at room temperature under controlled potential using a potentiostat and continued until the current dropped to the initial background current. The total electricity passed was measured by use of an integrator. Upon completion of the electrolysis, the catholyte was diluted with water and extracted several times with ether. The combined ether extracts were washed with a saturated $NaHCO_3$ solution and water, dried over Na_2SO_4, and evaporated. The crude products were separated and purified by column chromatography on silica gel using benzene-hexane (1:5) as eluent. The structures of products were confirmed by their IR and NMR spectral data (Table 1).

Results and Discussion

The results of the electrolyses are summarized in Table 2. Only the *O*-acylation products, **2a—m** and **3a—m**, were obtained in good yields under the conditions shown in Table 2. Curphy and co-workers have reported that in the electrochemical reductive acylation of benzophenone under similar conditions, acylation takes place on both carbonyl carbon and carbonyl oxygen atoms.[3] However, in the case of indenone derivatives, *C*-acylation products were not detected at all.

We have shown that the reductive acylation of **1a** to

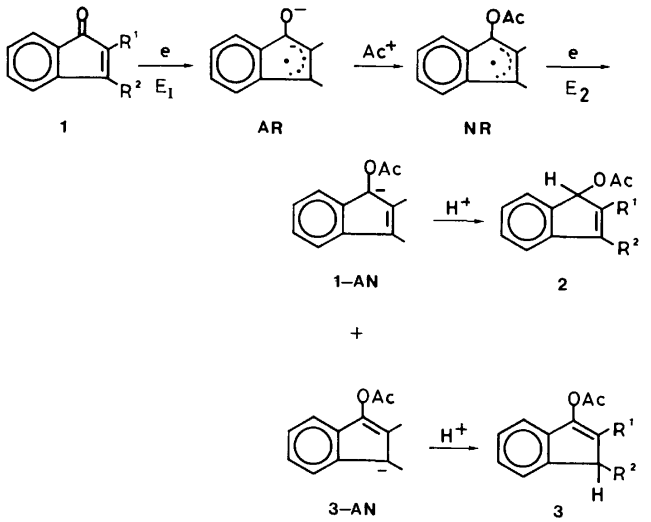
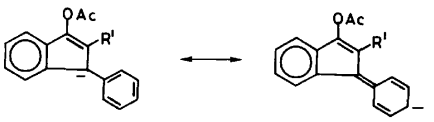
2a and **3a** is achieved by way of the reaction of the electrogenerated anion radical (**AR**) with acetyl cation and proceeds *via* the ECE mechanism as shown in



Scheme 2.

Scheme 2.[2] The same mechanism presumably operates for the reductive acylation of the compounds studied in this paper. Support for this mechanism was obtained by observing the voltammetric behavior of the substrates[4] and also by the coulometric analyses of the reactions which showed that the electricity (n) passed during each reaction was very close to two electrons for all the compounds studied (Table 2). Furthermore, the product ratio of **2a** to **3a** in the electrolysis of **1a** at −1.80V where the formation of the dianion of **1a** should predominate was virtually the same as that in the electrolysis at −1.20V where the formation of the anion radical of **1a** should predominate. This result suggests that disproportionation occurs rapidly between the substrate indenone and its electrogenerated dianion if formed, to produce two molecules of the anion radical (**AR**) which is converted into the final products by the reaction with acetyl cation *via* the path way shown in Scheme 2.

The substituent effect on the product ratios in the electrolyses of indenone derivatives is noteworthy. When 3-substituted 2-aryl-1-indenones were used as substrates, alkyl, benzyl, and cyclohexyl substituents at C-3 lowered the ratios of 2,3-disubstituted 1-acetoxy- (**2**) to 1,2-disubstituted 3-acetoxy-1*H*-indenes (**3**) in the products, compared with aryl substituents at the same position (Table 2). This tendency may be explained on the basis of the mechanism of Scheme 2. In this scheme, the second one-electron reduction stage (**NR**→ **1-AN** and/or **3-AN**) is faster than the first one-electron reduction stage (**1**→**AR**), since **NR** is more readily reducible than the starting substrate; $E_1 < E_2$.[5] As a result, the product distribution is most probably considered to be determined at the final protonation stage which depends on the relative electron densities on the reaction centers of **1-AN** and **3-AN**. The inductively electron-donative alkyl substituents at C-3 favor the formation of **3** particularly by increasing the electron density on the reaction center of **3-AN**. On the other hand, the aryl substituents at C-3 favor the formation of **2** particularly by decreasing the electron density on the reaction center of **3-AN**. This is due to the resonance of the aryl groups (Eq. 1).



(1)

For **1m** whose substituents at C-2 and C-3 are the electron-donative alkyl groups, the formation of **2** is favored by increasing the electron density on the reaction center of **1-AN**.

Reaction of Trimethylsilyl Azide with C=N-O Bond

Kozaburo NISHIYAMA* and Izumi MIYATA
Department of Chemistry, Tokyo Metropolitan University, 2-1-1, Fukasawa, Setagaya, Tokyo 158
(Received March 12, 1985)

Synopsis. Trimethylsilyl azide (TMSA) was reacted with an oxime ester or a Reissert salt in the presence of trimethylsilyl trifluoromethanesulfonate to give tetrazole derivative. The details of these reactions are examined.

Trimethylsilyl azide (TMSA) has a high potential in the synthetic chemistry of heterocycles and azido compounds.[1] We have reported that the decomposition reaction of *gem*-diazidoalkane, which was obtained by a reaction of ketone with TMSA, gave tetrazole derivatives in excellent yields and, therein, imidoyl azide was postulated as a reaction intermediate.[2] As a part of the investigations concerning the reactivities and synthetic utilities of TMSA, we would now like to describe reactions of TMSA with oxime esters or *N*-acyloxy(or *N*-sulfonyloxy)pyridinium(or quinolinium) chloride, which possess C=N-O bonding.

Results and Discussion

When a solution of acetone oxime methanesulfonate (**1a**) and TMSA in acetonitrile was heated to reflux for 24 h, 43% of 1,5-dimethyltetrazole (**2a**), along with trimethylsilyl methanesulfonate, was obtained by the usual work-up of the reaction mixture followed by column chromatography on silica gel. Oxime esters (**1a—g**) with TMSA were treated under various conditions and the results are summarized in the Table 1. From acetone oxime esters (**1a**—c), 1,5-dimethyltetrazole (**2a**) was yielded as the sole product. Acetophenone oxime esters (**1d** and **1e**) and cyclohexanone oxime esters (**1f** and **1g**) were similarly transformed to 5-methyl-1-phenyltetrazole (**2b**) as a major product (a regioisomer, 1-methyl-5-phenyltetrazole (**2c**), was also obtained less than 5%) and 6,7,8,9-tetrahydro-5*H*-tetrazolo[1,5-*a*]azepine (**2d**), respectively. However, the yield of tetrazole **2** obtained from oxime carboxylates with TMSA was not so good, compared with those of oxime sulfonates and TMSA. Even with oxime sulfonates, the addition of trimethylsilyl trifluoromethanesulfonate (TMSOTf) as a catalyst markedly improve the yields of tetrazoles **2** (*vide* Runs 2, 4, and 6). Especially, as shown in runs 3 and 4, such a tendency was more remarkable in benzene. In refluxing dichloromethane, only trace amounts of **2** were obtained, even if TMSOTf was added.

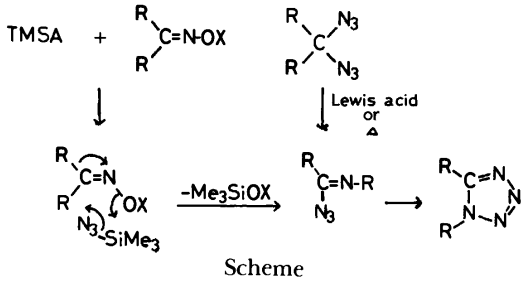
a) The reactions were carried out at refluxing temperature of the employed solvents for 24 h. b) TMSOTf was used as a catalyst. c) Regioisomer **2c** was contained less than 5%.

In a mechanistic consideration, we assume that the reaction of oxime esters with TMSA takes place *via* a pathway as shown in the Scheme; the Beckmann rearrangement of the oxime esters in the presence of TMSA gives the imidoyl azides, followed by cyclization to tetrazoles **2**. As for the Beckmann rearrangement, a similar reaction in which oxime esters and iodotrimethylsilane afforded imidoyl iodides, has been reported by Yamamoto *et al.*[3] The equilibrium



Scheme

between imidoyl azide and tetrazole was well established.[4] According to these investigations, tetrazole form, in most cases, exists predominantly at a low temperature (around room temperature). Thus, 1,5-disubstituted tetrazoles (but not imidoyl azides) were obtained in the reaction of oxime esters with TMSA.

The treatment of *N*-(methylsulfonyloxy)pyridinium chloride, which was prepared from pyridine *N*-oxide and methanesulfonyl chloride *in situ*, with TMSA gave tetrazolo[1,5-*a*]pyridine (**3**) in 29% yield. When acyl chloride instead of sulfonyl chloride was employed, the reaction did not occur. Pyridine *N*-oxide (itself with TMSA) did not give **3**, in contrast to the reaction of pyridine *N*-oxide and sulfonyl azide.[5] Similarly, *N*-(methylsulfonyloxy)quinolinium chloride and TMSA gave tetrazolo[1,5-*a*]quinoline (**4**) in 64% yield. These reactions seem to be modified Reissert reactions.[6,7] The difference in the yields between **3** and **4** may be due to the considerable loss of resonance energy caused by the formation of dihydro intermediates in monocyclic compounds.[8]

In conclusion, TMSA readily reacted with oxime esters or Reissert salts to give tetrazoles (**2**, **3**, and **4**). In these reactions, the sulfonyloxy group was better than an acyloxy group as the leaving group. The temperature dependence, solvent effect, and catalytic effect of TMSOTf were distinctly observed.

Experimental

Melting points are uncorrected. ^{1}H NMR were determined with a Hitachi R-600, Varian XL-100 or XL-300 spectrometer using tetramethylsilane as an internal standard. IR spectra were taken on a Hitachi 260-10 infrared spectrometer and the MS spectra were measured with a JEOL DX-300 spectrometer.

Materials. Trimethylsilyl azide was prepared from chlorotrimethylsilane and sodium azide in dibutyl ether,[1] bp 95—96 °C. Oxime esters (**1a—g**) were synthesized by a reaction of the corresponding oximes with sulfonyl (or acyl) chlorides in the presence of triethylamine or pyridine in benzene according to the reported methods.[9,10] **1a**, mp 46—47 °C (lit,[11] 45—46 °C); **1b**, mp 86—87 °C (lit,[12] 87—88 °C); **1d**, mp 63—64 °C (lit,[9] 64—65 °C); **1e**, mp 98—100 °C (lit,[10] 100—102 °C); **1f**, mp 43—45 °C (lit,[9] 43—45 °C); **1g**, mp 57—58 °C (lit,[13] 58 °C). In addition, these compounds were confirmed by spectroscopic analyses (IR, ^{1}H NMR, and MS). Acetone oxime benzoate (**1c**), pyridine *N*-oxide, quinoline *N*-oxide, and TMSOTf were commercial products and were purified if necessary.

Reaction of Oxime Ester (1a—g) with TMSA. A solution of acetone oxime methanesulfonate (**1a**, 2 g, 13 mmol) and TMSA (2.3 g, 19 mmol) in anhydrous acetonitrile (20 cm^3) was refluxed for 24 h with stirring. After a careful removal of low-boiling substances followed by distillation of trimethylsilyl methanesulfonate (570 mg, 26%), bp 54 °C/3 mmHg (1 mmHg=133.322 Pa), the residue was chromatographed on silica gel using various mixtures of benzene–chloroform and chloroform. Elution with a mixture of benzene–chloroform (1:2) afforded 0.56 g of 1,5-dimethyltetrazole (**2a**, 43%), which was recrystallized from hexane to give colorless needles, mp 72—73 °C (lit,[2] 72—73 °C); ^{1}H NMR ($CDCl_3$) δ=2.50 (s, 3H) and 4.00 (s, 3H); MS, *m/z* 98 (M^+). Elution with chloroform gave the starting sulfonate **1a**. Other oxime esters were treated in a similar manner. The yields of tetrazoles are shown in Table. TMSOTf was used in a range of 0.05—0.1 equiv of oxime esters. From acetophenone oxime ester (**1d**), 5-methyl-1-phenyl- (**2b**) and 1-methyl-5-phenyltetrazole (**2c**), of which ratio was 95:5 from ^{1}H NMR spectrum, δ=2.60 (s, *C*-Me), 4.10 (s, *N*-Me), 7.40 (s), and 7.50 (s), were obtained. After recrystallization from benzene–hexane, only **2b** was isolated, as colorless needles, mp 97—98 °C (lit,[14] 98—99 °C); ^{1}H NMR ($CDCl_3$) δ=2.60 (s, 3H) and 7.50 (s, 5H); MS, *m/z* 161 (M+1). From cyclohexanone oxime esters **1f** and **1g**, 6,7,8,9-tetrahydro-5*H*-tetrazolo[1,5-*a*]azepine (**2d**), recrystallized from hexane, colorless needles, mp 57—58 °C (lit,[2] 57—58 °C); MS, *m/z* 138 (M^+), was obtained.

Reaction of Pyridine (or Quinoline) N-Oxide with TMSA. A mixture of pyridine *N*-oxide (1.0 g, 11 mmol) and methanesulfonyl chloride (1.2 g, 11 mmol) in anhydrous acetonitrile (20 cm^3) was stirred for 3 h at room temperature. TMSA (2.4 g, 11 mmol) was added to the suspension and then the mixture was heated to reflux for 24 h. The dried dichloromethane extract was evaporated and chromatographed on silica gel. Elution with chloroform gave 0.36 g of tetrazolo[1,5-*a*]pyridine (**3**, 29%), recrystallized from ethanol, colorless needles, mp 156—157 °C (lit,[15] 156—158 °C); ^{1}H NMR ($CDCl_3$) δ=7.30 (m, 1H), 7.76 (m, 1H), 8.12 (d, *J*=9.2 Hz, 1H), and 8.92 (d, *J*=6.7 Hz, 1H); MS, *m/z* 120 (M^+). When a reaction of quinoline salt, which was prepared from quinoline *N*-oxide (6 g, 41 mmol) and methanesulfonyl chloride (5.2 g, 45 mmol), was similarly performed for 24 h, the precipitated solid was filtered and the filtrate was concentrated to dryness. Recrystallization of the combined solid gave 4.5 g of tetrazolo[1,5-*a*]quinoline (**4**, 64%) as colorless needles from ethanol, mp 153—155 °C (lit,[16] 155 °C); MS, *m/z* 170 (M^+). ^{1}H NMR ($CDCl_3$) δ=7.73 (m, 1H), 7.88 (d, *J*=9.4 Hz, 1H) 7.90 (m, 1H), 7.97 (m, 1H), and 8.72 (d, *J*=8.0 Hz, 1H).

Desulfurization of Thioketones and Thioamides with Diphosphorus Tetraiodide

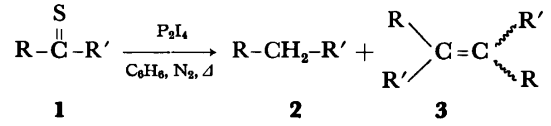
Hitomi SUZUKI,* Hiroyuki TANI, and Setsuko TAKEUCHI
Department of Chemistry, Faculty of Science, Ehime University, Bunkyo-cho, Matsuyama 790
(Received March 22, 1985)

Synopsis. On heating with diphosphorus tetraiodide in benzene, thioketones undergo reductive desulfurization to afford parent hydrocarbons, while thioamides are slowly converted into nitriles.

Diphosphorus tetraiodide (P_2I_4) exhibits a high affinity for oxygen and thus acts as an excellent deoxygenating and dehydrating agent for various oxygen-containing compounds.[1] However, its ability as a desulfurizing agent has been little studied yet. Only recently, the desulfurization of episulfides to olefins has been reported.[2] In the present paper, we describe the reaction of P_2I_4 with thioketones and thioamides.

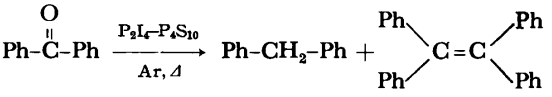
Ketones are inert to P_2I_4 in boiling benzene and only in combination with lithium aluminum hydride they are reducible to hydrocarbons.[3] In contrast, thioketones **1** have been found to be moderately reactive and on heating with P_2I_4 in boiling benzene followed by aqueous work-up, they were converted to parent hydrocarbons **2** in good to moderate yields (Table 1). The origin of protons may be sought to a trace of water which is normally present in commercial solvent employed, since the use of less amounts of solvent or thorough drying of solvent led to significantly reduced yields of the reduction products. In some cases, especially when the reactions were performed in a concentrated solution, the desulfurative dimerization of thioketones was found to compete with the reduction, giving olefins **3** as a side product. Geometry of these olefinic products was not determined.

Conventional synthesis of aromatic thioketones involves treatment of the corresponding ketones with



1 **2** **3**

tetraphosphorus decasulfide (P_4S_{10}). When this reaction was carried out in the presence of equimolar amounts of P_2I_4, ketones underwent reduction and reductive dimerization in parallel to give mixtures of hydrocarbons **2** and olefins **3**, usually the latter being predominant. Thus, by this treatment benzophenone was converted into diphenylmethane and tetraphenylethylene in 21 and 35% isolated yields, respectively.



Amides are smoothly dehydrated to nitriles by P_2I_4.[4] In contrast, dehydrosulfurization of thioamides **4** with P_2I_4 proceeded quite slowly in a benzene/triethylamine mixture (10:1) under refluxing conditions, but nitriles **5** were in most cases obtained in high state of purity (Table 2). In the absence of triethylamine, little or no nitriles were formed. Uses of other solvent systems such as DMF, carbon tetrachloride, and heptane in combination with triethylamine or pyridine gave poor results. Aliphatic thioamides were more easily dehydrosulfurized as compared to aromatic ones.

TABLE 1. REDUCTIVE DESULFURIZATION OF THIOKETONES WITH P_2I_4[a]

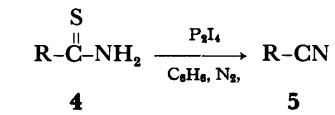
Thioketone **1**		Reaction time/h	Hydrocarbon **2**	Yield/%[b]
	X=H	6		85[c]
	Me	5		52
	Me	5[d]		26[e]
	MeO	7		34
	Cl	4		74
		5		79
		9		56

a) All reactions were carried out according to the procedure described in Experimental section, except for the case d) where the reaction was conducted in a more concentrated solution. b) Yields refer to the isolated compounds and are not optimized. All products are known and identified by comparison with authentic specimens. c) GLC yield. d) Amount of benzene as solvent was reduced to 5 ml. e) Accompanied by 16% yield of 1,2-diphenyl-1,2-bis(4-methylphenyl)ethylene.

Table 2. Dehydrosulfurization of thioamides to nitriles with P_2I_4

Thioketone **4**		Reaction time/h	Nitrile **5**	Yield/%[a]
	X=H	16		35
	MeO	12		53
	Cl	14		42
		13		56
		14		88
$Ph-CH_2-C(=S)-NH_2$		10	$Ph-CH_2-CN$	59
$Ph-CH_2CH_2-C(=S)-NH_2$		10	$Ph-CH_2CH_2-CN$	71

a) Yields refer to the isolated compounds and are not optimized. All products are known and identified by comparison with authentic specimens.



4 **5**

We may conclude that P_2I_4 is not so effective as a desulfurizing agent for thiocarbonyl compounds. However, it exhibits an interesting mode of reductive dimerization with some substrates which, depending on circumstances, may find utility for synthetic purposes.

Experimental

Materials. Thioketones were prepared from ketones and tetraphosphorus decasulfide according to the literature procedure.[5,6] Thioamides were obtained by adding hydrogen sulfide to nitriles in pyridine in the presence of triethylamine, as described in Ref. 7. Products were identified by mass, IR, and ^{1}H-NMR spectra as well as by direct comparison with authentic specimens. All products are known. Separation of hydrocarbon mixture was performed on a fraction preparative liquid chromatograph (Japan Analytical Industry Co, LC-08) using chloroform as solvent.

Reaction of Thioketones 1 with P_2I_4. To a solution of thioketone (1.0 mmol) in benzene (20 ml) was added P_2I_4 (1.0 mmol) and the resulting mixture was heated under reflux for appropriate hours under argon. Then the reaction was quenched by the addition of aqueous sodium hydrogensulfite and the organic phase was separated, washed with water, and dried over sodium sulfate. Removal of the solvent under reduced pressure yielded corresponding product or products, which were purified either by chromatography over silica gel or by recrystallization.

Reaction of Ketones with P_2I_4 in the Presence of P_4S_{10}. A mixture of aromatic ketone (1.0 mmol), P_2I_4 (1.0 mmol), and P_4S_{10} (1.0 mmol) was heated in an oil bath at around 130 °C for 3 h. After cooling the dark brown reaction mixture was extracted with ether and the extract was washed with 10% aqueous sodium sulfite and water, dried over sodium sulfate, and evaporated under reduced pressure. The residue was subjected to preparative liquid chromatography to obtain hydrocarbon component.

Reaction of Thioamides 4 with P_2I_4. To a solution of thioamide (1.0 mmol) in benzene–triethylamine mixture (10:1, 10 ml) was added P_2I_4 (1.0—1.5 mmol) and the resulting mixture was heated under gentle reflux for appropriate hours under nitrogen. After cooling the mixture was washed with 10% aqueous ammonium chloride, the organic phase was extracted with ether, dried over sodium sulfate, and evaporated to leave a residue, which was chromatographed over silica gel, distilled *in vacuo*, or recrystallized from appropriate solvent.

Absolute Configuration of Platyphylloside and (−)-Centrolobol

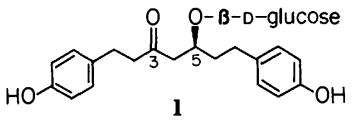
Shinji OHTA, Mika KOYAMA, Tadashi AOKI, and Takayuki SUGA*
Department of Chemistry, Faculty of Science, Hiroshima University, Higashisenda-machi, Naka-ku, Hiroshima 730
(Received March 25, 1985)

Synopsis. The absolute configuration of platyphylloside was established to be *S* by ^{13}C NMR spectroscopy. On the basis of this establishment, the *S*-configuration previously assigned to the chirality at C-3 of (−)-centrolobol was revised to the *R*-configuration.

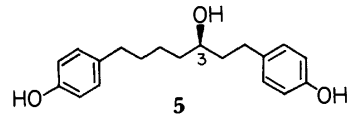
The absolute configuration of platyphylloside, isolated from the green inner-bark of *Betula platyphylla* Sukatchev var. *japonica* (Japanese name: Shirakamba),[1] has not been assigned yet. In addition, the absolute configuration of (−)-centrolobol ($[\alpha]_D^{25}$ −8.6°) isolated from the heartwoods of *Centrolobium robustum* Mart. is assigned to be *S*[2] on the basis of the empirical rule.[3] However, this rule is not described to be applicable to the compound possessing a phenyl group. This suspicious point necessitated the reexamination of the absolute configuration of (−)-centrolobol, 1,7-bis(4-hydroxyphenyl)-3-heptanol (**5**). We now have established the absolute configuration of platyphylloside by ^{13}C NMR spectroscopy, and this establishment has resulted in the revision of the absolute configuration previously assigned to the (−)-centrolobol.

Results and Discussion

A diarylheptanoid glycoside (**1**) was isolated from the green bark of *B. platyphylla* var. *japonica*. Hydrolysis of **1** with Taka-diastase[4] gave its aglycone (**2**) and glucose. Not only the mp and spectral data (UV, IR, and ^{1}H NMR) of **1** and **2** but also the chemical behaviors of **1** and the EI-MS spectral data of **2** were identical with those reported for platyphylloside and its aglycone, respectively.[1] The glycoside (**1**) was thus confirmed to be platyphylloside, *i.e.*, 1,7-bis(4-hydroxyphenyl)-5-(β-D-glucopyranosyloxy)-3-heptanone. Although the platyphylloside has an asymmetric carbon, however, even the optical rotation, needless to mention the absolute configuration, is not been given in Ref. 1.



1



5

The absolute configuration of **1** was established by ^{13}C NMR spectroscopy. On comparison of the ^{13}C NMR chemical shifts of **1** with those of **2**, the larger glycosidation shift (−2.9 ppm) at C-4 than that (−2.3 ppm) at C-6 was observed, as shown in Table 1. Application of the glycosidation shift rule[5] to these shifts indicated the configuration at C-5 of **1** and **2** to be *S*. The validity of this application has been recently confirmed for diarylheptanoid analogs.[6] The similar glycosidation shifts (Table 1) were further observed in comparison of the chemical shifts at C-4 and C-6 of the dimethyl ether (**3**) of **1** with the shifts at those of its aglycone (**4**). This observation supports the *S*-configuration at C-5 of **1** and **2**.

a) These values in any vertical column may be reversed although those given here are preferred.

Compound (**5**), 1,7-bis(4-hydroxyphenyl)-3-heptanol ($[\alpha]_D^{25}$ −8.3°±0.6°), was derived from **2** by conversion of the carbonyl group into the methylene. Thus, the configuration at C-3 of **5** should be *R*. This was supported by the fact that (*R*)-1,7-bis(3,4-dimethoxyphenyl)-3-heptanol (**6**) and (*R*)-1,7-diphenyl-3-heptanol (**7**) were all levorotatory. The physical (mp and $[\alpha]_D$) and spectral (UV, IR, ^{1}H NMR, and EI-MS) data of **5** were identical with those given for (−)-centrolobol,[2] except for the assignment of absolute configuration. Consequently, the *S*-configuration previously assigned to (−)-centrolobol[2] should be revised to the *R*-configuration.

Experimental

The ^{1}H NMR spectra were taken on Hitachi R-600 FT and R-24B NMR spectrometers using TMS as an internal standard. The ^{13}C NMR spectra were obtained on a Hitachi R-42 FT NMR spectrometer (22.6 MHz; δ_{TMS}=0). The EI-MS were obtained on a Shimadzu QP-1000 mass spectrometer at 70 eV. The FD-MS was taken on a JEOL JMS-D 300 mass spectrometer equipped with a silicone emitter; the emitter current was 0—25 mA. The optical rotations were measured on a JASCO DIP-360 Digital Polarimeter using 1-dm cell. Preparative TLC was carried out on a silica-gel plate (Merck 60 GF_{254}; 0.75 mm thick).

Isolation of Diarylheptanoid Glycoside (1). According to the method described in the literature,[1] the glycoside (**1**) (1.624 g) was isolated from the green bark (10.0 kg) of *B. platyphylla* var. *japonica* and it showed the following physical and spectral data: mp 62—64°C (an amorphous solid) (lit,[1] an amorphous solid,* mp 65°C); $[\alpha]_D^{25}$ −14.3°±0.1° (*c* 2.30, MeOH); UV (EtOH) 224 (log ε 4.15), 279 nm (3.54); IR (KBr) ν_{max} 3400 (OH), 1700 (C=O), 1612, 1592, 1515 cm^{-1} (aromatic ring); ^{1}H NMR (CD_3OD) δ=1.57—2.00 (2H, m, -CH_2-), 2.43—2.80 (8H, m, -CH_2-×4), 4.31 (1H, d, *J*=7 Hz, anomeric H), 6.59—7.06 (8H, AA'BB'-type, *J*=8 and 2 Hz, aromatic H); FD-MS *m/z* 499 (M^++Na), 477 (M^++H), 476 (M^+), 296 (M^+−180).

Hydrolysis of 1 with Taka-diastase. To a solution of **1** (191 mg) in H_2O (7.5 cm^3), Taka-diastase (Sankyo Co. Ltd.,[4] 600 mg) dissolved in H_2O (15 cm^3) and then toluene (0.5 cm^3) were added. The reaction mixture was incubated at 33°C for 2 d and extracted with *n*-BuOH. An extract, after removal of the solvent, was purified by preparative TLC with a MeOH-$CHCl_3$-H_2O (10:40:1 v/v) mixture to give 1,7-bis(4-hydroxyphenyl)-5-hydroxy-3-heptanone (**2**) (55 mg): mp 127—129°C (lit,[1] 125—127°C); $[\alpha]_D^{25}$ −1.8°±0.2° (*c* 1.02, MeOH); UV (EtOH) 225 (log ε 4.13), 279 nm (3.52); IR (KBr) ν_{max} 3450, 3340 (OH), 1692 cm^{-1} (C=O); ^{1}H NMR (CD_3OD) δ=3.99 (1H, quin, *J*=6 Hz, >C<u>H</u>OH); EI-MS *m/z* 314 (M^+), 296 (M^+-H_2O). The aqueous liquor obtained in the hydrolysis was lyophilized. A residual substance obtained was acetylated with acetic anhydride-pyridine to give penta-*O*-acetylglucopyranose, which was identified by co-TLC with an authentic sample.

Methylation of 1 and Hydrolysis of Its Dimethyl Ether (3). Methylation of **1** (1.114 g) in MeOH with CH_2N_2 at 0°C gave 1,7-bis(4-methoxyphenyl)-5-(β-D-glucopyranosyloxy)-3-heptanone (**3**) (380 mg): $[\alpha]_D^{25}$ −7.4°±0.1° (*c* 1.57, MeOH). Hydrolysis of **3** (145 mg) with Taka-diastase (900 mg) in the same way as in the case of **1** gave the aglycone (**4**) (26 mg): mp 77—78°C; $[\alpha]_D^{25}$ −7.6°±0.7° (*c* 0.28, MeOH); IR (KBr) ν_{max} 3420 (OH), 1700 cm^{-1} (C=O); ^{1}H NMR ($CDCl_3$) δ=3.77 (6H, s, -OCH_3×2), 4.03 (1H, quin, *J*=6 Hz, >C<u>H</u>OH).

Conversion of 2 to Diarylheptanol (5). Following the method described in the literature,[7] reduction of the carbonyl group of **2** (24 mg) with $TsNHNH_2$ (15 mg) and $NaBH_4$ (100 mg) in MeOH gave compound (**5**) (9 mg): mp 125—126°C (lit,[2] mp 128—130°C); $[\alpha]_D^{25}$ −8.3°±0.6° (*c* 0.34, MeOH); UV (MeOH) 224 (log ε 4.15), 279 (3.59), 285 nm (sh, 3.52); IR (KBr) ν_{max} 3545—3200 (OH), 1615, 1597, 1512 cm^{-1} (aromatic ring); ^{1}H NMR (($CD_3)_2CO$) δ=1.29—1.76 (8H, m, -CH_2-×4), 2.29—2.72 (4H, m, -CH_2-×2), 3.31 (1H, brs, OH), 3.52 (1H, m, >C<u>H</u>OH), 6.66—7.11 (8H, AA'BB'-type, *J*=8 and 2 Hz, aromatic H), 7.92 (2H, brs, Ar-OH×2); EI-MS *m/z* 300 (M^+), 282 (M^+-H_2O). Found: C, 76.11; H, 8.12%. Calcd for $C_{19}H_{24}O_3$: C, 75.97; H, 8.05%.

Preparation of Diarylheptanols (6 and 7). (*S*)-1,7-bis(3,4-Dimethoxyphenyl)-5-hydroxy-3-heptanone (**8**)[6] and (*S*)-1,7-diphenyl-5-hydroxy-3-heptanone (**9**)[8] were converted to their corresponding diarylheptanols (**6** and **7**) in the same way as in the case of **2**. The structures of **6** [mp 63—65°C; $[\alpha]_D^{25}$ −6.0°±2.0° (*c* 0.20, MeOH)] and **7** [mp 44—46°C; $[\alpha]_D^{25}$ −5.7°±2.9° (*c* 0.14, MeOH)] were confirmed by their IR, ^{1}H NMR, and EI-MS spectra.

*It is described[1] that recrystallization of this amorphous solid from EtOH-H_2O gave crystals with mp 189—190°C. However, our attempt at recrystallization failed.

The authors thank Professor Kazumasa Wakabayashi of Shinshu University for his kind arrangement to obtain the green bark of *B. platyphylla* var. *japonica*. They are also grateful to Dr. Teruo Yasui and Mr. Masaya Oka of Kuraray Co. Ltd. for measurement of the FD-MS spectrum.

Palladium-catalyzed Ketone Synthesis from Acyl Chloride and Organoaluminum Reagents

Kuni WAKAMATSU, Yasuhiro OKUDA, Koichiro OSHIMA,* and Hitosi NOZAKI
Department of Industrial Chemistry, Faculty of Engineering, Kyoto University, Yoshida, Kyoto 606
(Received April 26, 1985)

Synopsis. The reaction of organoaluminum reagents with acyl chloride catalyzed by $Pd(PPh_3)_4$ in tetrahydrofuran provides ketones in fair yields.

During the past decade, a wide variety of organometallics are examined to react with acyl halides to give ketones. Among them, those containing Mg,[1] Mn,[2] Zn,[3] and Cu[4] have been widely used. The transformation of R^1COCl into R^1COR fails, however, by means of plain R_3Al, because they react easily with the resulting ketones. Several attempts have been made to overcome this difficulty. A ketone synthesis reported previously[5] is based on the organometallic reagent generated from trialkylaluminum, bis(acetylacetonato)-copper(II), and triphenylphosphine in 2:1:2 molar ratio. Here we wish to report another effective method for the preparation of ketones from acyl chlorides with organoaluminum reagents in the presence of Pd(0) catalyst.[6]

$$R^1COCl + R_3Al \xrightarrow[THF]{Pd(PPh_3)_4} R^1COR$$

Treatment of benzoyl chloride with triethylaluminum in tetrahydrofuran in the presence of a catalytic amount of $Pd(PPh_3)_4$ gave propiophenone in 70% yield. The uncatalyzed reaction gave <5% yield of propiophenone under the same reaction conditions. Palladium catalyst generated *in situ* from $Pd(OAc)_2$ and triphenylphosphine (1:2) was also efficient for the transformation.[7] Other catalysts such as $RuCl_2(PPh_3)_3$, $NiCl_2(PPh_3)_2$, and $RhCl(PPh_3)_3$ were not effective for this ketone synthesis. The use of tetrahydrofuran as a solvent is critical. In benzen or dichloromethane, the complex mixture was obtained since the resulting ketones were attacked by organoaluminum reagents. The results are summarized in Table 1. Alkynyl and alkenyl groups were introduced selectively in preference to the ubiquitous alkyl substituents on aluminum to give ynones and enones, respectively.

Experimental

The IR spectra were determined on a Shimadzu IR-27-G spectrometer; the mass spectra, on a Hitachi X-80 machine. The NMR spectra were recorded on a Varian EM-390H spectrometer, using TMS as an internal standard. The analyses were performed at the Elemental Analyses Center of Kyoto University. Tetrahydrofuran was dried in benzophenone ketyl and distilled. All the experiments were carried out under an argon atmosphere. Purification of the product was performed by preparative thin-layer chromatography (TLC) or column chromatography on silica gel

a) The reactions were performed in THF at 0—25 °C. Organoaluminum reagent (1.0—2.0 mmol), acid chloride (1.0 mmol), and $Pd(PPh_3)_4$ (0.05 mmol) were employed. b) Isolated yields unless otherwise stated. c) GLPC yield.

(Merck Kiesel gel 60).

General Procedure for the Preparation of Ketones with Trialkylaluminum: The reaction of benzoyl chloride with triethylaluminum is representative. Triethylaluminum (1.0 M† hexane solution, 2.0 ml, 2.0 mmol) was added to a tetrahydrofuran solution of benzoyl chloride (0.14 g, 1.0 mmol) and $Pd(PPh_3)_4$ (58 mg, 0.05 mmol) at 0 °C under an argon atomosphere. The whole was stirred at 25 °C for 4 h. The resulting mixture was poured into 1 M HCl and extracted with ethyl acetate. The combined organic layer was dried (Na_2SO_4) and concentrated *in vacuo*. Purification by preparative TLC on silica gel (hexane:ethyl acetate=10:1) gave propiophenone (90 mg, 70% yield) as an oil which was identical with the authentic sample.

1-Trimethylsilyl-12-tridecen-1-yn-3-one: Butyllithium (1.6 M hexane solution, 1.3 ml, 2.0 mmol) was added to a solution of trimethylsilylacetylene (0.25 g, 2.5 mmol) in hexane (2.0 ml) at 0 °C. After stirring for 15 min at 0 °C, diethylaluminum chloride (1.0 M hexane solution, 2.0 ml, 2.0 mmol) was added and the resulting mixture was stirred for 15 min at 0 °C. Tetrahydrofuran (3.0 ml), $Pd(PPh_3)_4$ (46 mg, 0.04 mmol), and 10-undecenoyl chloride (0.14 g, 0.7 mmol) were added successively and the whole was stirred for additional 60 min at 25 °C. Workup and purification by silica gel column chromatography gave the desired ketone in 51% yield: Bp 100 °C (bath temp, 2 Torr††); IR (neat) 3080, 2930, 2860, 2150, 2100, 1680, 1640, 1460, 1250, 850, 760 cm^{-1}; NMR (CCl_4) δ=0.25 (s, 9H), 1.08—1.77 (m, 12H), 1.77—2.13 (m, 2H), 2.27—2.57 (m, 2H), 4.83 (d, J=11 Hz, 1H), 4.87 (d, J=18 Hz, 1H), 5.67 (ddt, J=18, 11, 7.5 Hz, 1H). Found: m/z 249.1699. Calcd for $C_{15}H_{25}OSi$: M−CH_3, 249.1678.

18-Nonadecen-7-yn-9-one: Bp 115—120 °C (bath temp, 2 Torr); IR (neat) 3080, 2930, 2850, 2210, 1740, 1680, 1640, 1460, 1160, 1000, 910 cm^{-1}; NMR (CCl_4) δ=0.88 (m, 3H), 1.17—1.80 (m, 23H), 1.80—2.17 (m, 2H), 2.17—2.53 (m, 4H), 4.88 (d, J=12 Hz, 1H), 4.93 (d, J=18 Hz, 1H), 5.73 (ddt, J=18, 12, 7 Hz, 1H). Found: m/z 276.2444. Calcd for $C_{19}H_{32}O$: M, 276.2451.

(Z)-12-Trimethylsilyl-1,12-nonadecadien-11-one: Diisobutylaluminum hydride (1.5 M hexane solution, 1.3 ml, 2.0 mmol) was added to a solution of 1-trimethylsilyl-1-octyne (0.37 g, 2.0 mmol) in hexane (3.0 ml) and ether (1.5 ml) at 25 °C under an argon atmosphere.[8] After stirring for 40 min, tetrahydrofuran (4.0 ml) was added, then $Pd(PPh_3)_4$ (0.04 g, 0.05 mmol) and a solution of 10-undecenoyl chloride (0.14 g, 0.7 mmol) in tetrahydrofuran (3.0 ml) was added. The resulting mixture was stirred for 1.5 h. Workup (1 M HCl, ethyl acetate) and purification by preparative TLC on silica gel (hexane:ethyl acetate=10:1) provided the title compound (0.13 g, 53% yield) as an oil: Bp 115—120 °C (bath temp, 2 Torr); IR (neat) 3080, 2940, 2860, 1675, 1600, 1465, 1250, 850, 760 cm^{-1}; NMR (CCl_4) δ=0.01 (s, 9H), 0.68—0.93 (m, 3H), 0.97—1.67 (m, 20H), 1.70—2.43 (m, 6H), 4.70 (d, J=11 Hz, 1H), 4.75 (d, J=18 Hz, 1H), 5.55 (ddt, J=18, 11, 7 Hz, 1H), 6.5 (t, J=7.5 Hz, 1H). Found: C,75.28; H, 12.09%. Calcd for $C_{22}H_{42}OSi$: C, 75.36; H, 12.07%.

(Z)-1-Trimethylsilyl-1-hexenyl Phenyl Ketone: Bp 110 °C (bath temp, 2 Torr); IR (neat) 2960, 2860, 1655, 1600, 1450, 1250, 840, 710 cm^{-1}; NMR (CCl_4) δ=0.20 (s, 9H), 0.83—1.05 (m, 3H), 1.17—1.55 (m, 4H), 2.17—2.45 (m, 2H), 6.28 (t, J=7.5 Hz, 1H), 7.30—7.93 (m, 5H). Found: m/z 260.1602. Calcd for $C_{16}H_{24}OSi$: M, 260.1595.

New Crossed Aldol Reaction. Reaction of Enamines with Aldehydes Activated by Lewis Acids

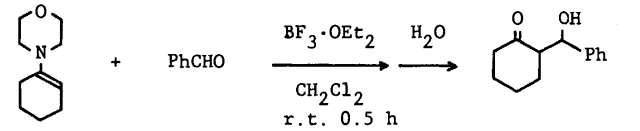
Osamu TAKAZAWA,* Kunio KOGAMI, and Kazuo HAYASHI
Kawasaki Research Laboratories, T. Hasegawa Co., Ltd., 335 Kariyado, Nakahara-ku, Kawasaki 211
(Received February 20, 1985)

Synopsis. Enamines react with aldehydes in the presence of Lewis acids such as $BF_3 \cdot OEt_2$ to give the corresponding crossed aldol products in good yields. Reaction of dienamines with aldehydes gives the corresponding β,γ-unsaturated α-(1-hydroxyalkyl) carbonyl compounds.

The aldol reaction is one of the most versatile methods in organic synthesis.[1] In recent years, various useful direct aldol reactions have been reported, most of them being carried out under basic conditions;[2] Mukaiyama and coworkers[3] reported that enol silyl ethers, enol ethers, or enol esters react with carbonyl compounds in the presence of $TiCl_4$ under acidic conditions to give crossed aldol products.

Generally, it is known that the reaction of enamines with aldehydes gives α,β-unsaturated ketones, but that aldols cannot be obtained in this reaction except for some special substances such as chloral.[4] In contrast, we found that a use of Lewis acids allows enamines to react smoothly with aldehydes to give the corresponding aldols in good yields under acidic conditions, as with enol silyl ethers.

In our preceding papers,[5] we reported that enamines react with acetals or trialkyl orthoformates activated by Lewis acids to give the corresponding β-alkoxy or α-dialkoxymethyl carbonyl compounds, respectively. We considered that enamines also would react with aldehydes to afford the corresponding aldols. The reaction of 1-morpholino-1-cyclohexene (**1**) with benzaldehyde (**2**) was first tried. To a dichloromethane solution of a 1.2 molar amount of **2** was added a 1.3 molar amount of $BF_3 \cdot OEt_2$ at −40 °C. Then **1** was added and the reaction mixture was stirred for 0.5 h at room temperature. The aldol product, 2-(α-hydroxybenzyl)-1-cyclohexanone (**3**), was obtained in 92% yield.



1 **2** **3** 92% (threo/erythro=78/22)

Scheme

The effect of the amount of $BF_3 \cdot OEt_2$ upon the yield of **3** was investigated by using the reaction between **1** and **2** under similar conditions as described above. It was found that the product **3** was obtained in the highest yield when a 1.3 molar amount of $BF_3 \cdot OEt_2$ was applied (Table 1).

TABLE 1. EFFECT OF THE AMOUNT OF $BF_3 \cdot OEt_2$ ON THE YIELD

mentioned above (Table 2). The results described in Table 2 demonstrate that, of the Lewis acids examined, $BF_3 \cdot OEt_2$ exhibits a remarkable effect as compared with the others in respect of the yield of **3**. It is noteworthy that the reaction gave predominantly the *threo*-isomer when $AlCl_3$, $FeCl_3$, or $ZnCl_2$ was used.

Furthermore, the effect of the structure of the amine moiety in the enamines was studied by treating enamines with **2** and $BF_3 \cdot OEt_2$. It was found that **1** realizes an excellent yield (Table 3).

Since it was noted that the combination of morpholine enamine (**1**) and $BF_3 \cdot OEt_2$ is significantly better than other possible combinations (Tables 2 and 3), reactions of morpholine enamines, such as **1**, 2-methyl-5-morpholino-2,4-hexadiene (**6**), or 1-morpholino-1-hexene (**7**), with various aldehydes were tried in the presence of $BF_3 \cdot OEt_2$, and the corresponding aldols were obtained in good yields as shown in Table 4.

In the present reaction, the reverse reaction or the dehydration of aldol would be impossible because of the formation of a stable iminium salt as an intermediate. Furthermore, the acidic reaction medium makes the method useful for compounds that have base-sensitive functional groups. On the other hand, it is known that the reaction of dienoxysilanes with aldehydes in the presence of $TiCl_4$ gives α,β-unsaturated γ-(1-hydroxyalkyl) carbonyl compounds.[3g,6] In contrast to this reaction, the present reaction of a dienamine **6** with **2** in the presence of $BF_3 \cdot OEt_2$ regioselectively afforded β,γ-unsaturated α-(1-hydroxyalkyl) carbonyl compound **10**.

Experimental

Reaction of 1-Morpholino-1-cyclohexene (1) with Benzaldehyde (2) in the Presence of $BF_3 \cdot OEt_2$. To a dichloromethane (20 ml) solution of 1.27 g (12 mmol) of **2** was added 1.85 g (13 mmol) of $BF_3 \cdot OEt_2$ at −40 °C under an argon atmosphere. Then 1.67 g (10 mmol) of **1** was added immediately and the reaction mixture was stirred for 0.5 h at room temperature. The mixture was quenched with water and stirred for 1 h at room temperature. After hydrolysis, the organic layer was separated, washed with a saturated solution of $NaHCO_3$, and dried over $MgSO_4$. After removal of the solvent, the residue was purified by silica-gel column chromatography. Elution with hexane–ether afforded 0.418 g (20%) of *erythro*-2-(α-hydroxybenzyl)-1-cyclohexanone (**3**) and 1.46 g (72%) of *threo*-**3**.

Reactions of a variety of enamines with various aldehydes in the presence of Lewis acids were carried out according to the same procedure, and the yields of the corresponding aldols are listed in Tables 1, 2, 3, and 4. The physical properties and analytical data of the products are shown in Table 5.

The authors wish to express their thanks to Professor Teruaki Mukaiyama, The University of Tokyo for his helpful discussions.

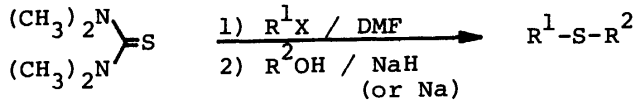
A Facile One-pot Synthesis of Sulfides from Alkyl Halides and Alcohols Using Tetramethylthiourea

Shizuo FUJISAKI, Isamu FUJIWARA, Yasumasa NORISUE, and Shoji KAJIGAESHI*
Department of Industrial Chemistry, Faculty of Engineering, Yamaguchi University, Tokiwadai, Ube 755
(Received February 23, 1985)

Synopsis. Sulfides can be readily prepared under mild conditions by a reaction of tetramethylthiourea with alkyl halides and alcohols in the presence of sodium hydride in satisfactory yields. The scope and limitation of this method are also presented.

The reaction of alkyl halides with Na_2S, leading to symmetrical sulfides, is well known. And, unsymmetrical sulfides are widely synthesized by neucleophilic substitution reaction of alkyl and aryl halides with thiols under basic conditions.[1] Recently, some convenient methods for the preparation of sulfides by the reaction of 2-alkylthio-1,3-benzoxazoles with sodium alkoxide,[2] and 2-alkoxy-1-methylpyridinium salt with thiol in the presence of triethylamine,[3] have been reported.

In the course of our investigation of the reaction of thiocarbamoyl derivatives, we have now found a convenient one-pot preparative method of sulfides (**2**) under mild conditions from alkyl halides and alcohols using tetramethylthiourea (**1**) as starting material which is easily available.



1 **2**

Results and Discussion

The reaction of **1** with alkyl halides in *N,N*-dimethylformamide (or acetonitrile) for 1 h followed by treatment of alcohols in the presence of sodium hydride for 10 min at room temperature gave readily dialkyl sulfides (**2**) in satisfactory yields.

In the case of synthesis of methyl or ethyl sulfide (R^1SCH_3 or $R^2SC_2H_5$), the reagent methanol or ethanol was employed also as a solvent instead of *N,N*-dimethylformamide or acetonitrile, and sodium metal was used instead of sodium hydride. The results are summarized in the Table 1.

The postulated reaction mechanism is shown in the Scheme. Actually, intermediate *S*-alkyltetramethylthiouronium salt (**3**) was obtained as a crystals by the treatment of **1** with alkyl halide in acetone at room temperature for several days in good yield, and then the reaction of **3** with alcohol using sodium hydride in *N,N*-dimethylformamide gave the sulfide **2**. In this reaction, unstable *O*-alkyltetramethyluronium salt (**5**), derived from **3** *via* intermediate **4**, may be undergone nucleophilic attack by alkanethiolate ion to give sulfide **2** and tetramethylurea (**6**).

Scheme

These our methods do not use ill-smelling thiols and are applicable to the syntheses of various dialkyl sulfides under mild conditions. Dialkyl sulfides containing heterocyclic moiety, *e.g.*, furfuryl methyl sulfide (**2j**), was also obtained. However, our methods were unsuitable for the syntheses of aryl sulfides and dialkyl sulfides having branched-chain alkyl moiety such as *t*-butyl or isopropyl group because of instability of crowded intermediate **4**. Thiourea could not be used as the reagent instead of tetramethylthiourea since inert imines ($HN{=}C(NH_2){-}SR$) was only obtained from thiourea with alkyl halides.

Experimental

*Typical Procedure for the Syntheses of Sulfides (**2a—2j**) by Use of Sodium Hydride in* N,N-*Dimethylformamide or Acetonitrile. Benzyl Methyl Sulfide (**2c**)*: A solution of **1** (1.0 g, 7.6 mmol) and methyl iodide (1.4 g, 10 mmol) in *N,N*-dimethylformamide (10 ml) was stirred at room temperature for 1 h, and then benzyl alcohol (0.84 g, 7.8 mmol) was added. To the solution was added dropwise sodium hydride (0.5 g, 21 mmol) dispersed in hexane (5 ml) under stirring at room temperature, then the reaction mixture was further stirred for 10 min, and quenched with water. The organic layer was extracted with hexane (3×15 ml), dried with magnesium sulfate, concentrated in a rotatory evaporator and distilled to give benzyl methyl sulfide (**2c**) as colorless oil. Yield 0.68 g (65%); bp 199—201 °C/760 Torr[†] (lit,[6] 195—198 °C/760 Torr).

*Allyl Benzyl Sulfide (**2h**).* Compound **2h** was prepared similarly. ^{1}H NMR (CCl_4) δ=2.92 (2H, d, J=8 Hz, SCH_2-CH=), 3.56 (2H, s, Ph-CH_2S), 5.00, 5.05 (two br. d, J=18 Hz, J=9 Hz, CH=CH_2), 5.50—6.00 (1H, m, CH=CH_2), and 7.22 (5H, br. s, C_6H_5). Found: C, 72.86; H, 7.44%. Calcd for $C_{10}H_{12}S$: C, 73.12; H, 7.36%.

*2-Furfuryl Methyl Sulfide (**2j**).* Compound **2j** was prepared similarly. ^{1}H NMR (CCl_4) δ=2.01 (3H, s, CH_3), 3.55 (2H, s, CH_2), 6.02 (1H, d, J=3 Hz, CH=C-O), 6.16 (1H, dd, J=3 and 2 Hz, CH=CH-O), 7.20 (1H, d, J=2 Hz, =CH-O). Found: C, 56.02; H, 6.39%. Calcd for C_6H_8OS: C, 56.22; H, 6.29%.

*Typical Procedure for the Syntheses of Sulfides (**2c** and **2d**) by Use of Sodium Alkoxide in Alcohol. Benzyl Ethyl Sulfide (**2d**).* A solution of **1** (1.5 g, 11 mmol) and benzyl chloride (1.4 g, 11.1 mmol) in ethanol (10 ml) was refluxed for 4 h. After cooling the solution to room temperature, sodium metal (0.3 g, 13 mmol) was added and the reaction mixture was stirred for 10 min, and then quenched with water. The mixture obtained was worked up as described above **2c** to give **2d** as colorless oil. Yield 1.1 g (63%); bp 223—224 °C/760 Torr (lit,[4] bp 103 °C/16 Torr).

*S-Methyl Tetramethylthiouronium Iodide (**3a**).* Preparation of **3a** was described below as an example of synthetic procedure of **3**. A solution of **1** (4.0 g, 30 mmol) and methyl iodide (4.6 g, 32 mmol) in acetone (50 ml) was allowed to stand for 1 d at room temperature, and then the precipitate deposited was filtered off, washed with acetone (2×5 ml) and dried *in vacuo* to give **3a** as colorless crystals. Yield 7.9 g (96%); mp 177—180 °C (Mp was not given in the literature[7] because of its hygroscopicity).

*Benzyl Methyl Sulfide (**2c**) from **3a** and Benzyl Alcohol.* Preparation of **2c** was described below as an example of synthetic procedure of **2** from **3** and alcohol. To a solution of **3a** (1.0 g, 3.7 mmol) and benzyl alcohol (0.34 g, 3.7 mmol) in *N,N*-dimethylformamide (10 ml) was added dropwise sodium hydride (0.5 g, 21 mmol) dispersed in hexane (5 ml), and then the reaction mixture was stirred at room temperature for 10 min, and quenched with water. The organic layer was extracted with hexane (3×15 ml), dried with magnesium sulfate, concentrated in a rotatory evaporator and distilled to give **2c** as colorless oil. Yield 0.3 g (60%); bp 199—201 °C/760 Torr.

[†]1 Torr=133.322 Pa.

Rates of Thermal Decomposition of *t*-Butyl Peroxypivalate

Takeshi KOMAI,* Hideyo ISHIGAKI, and Kazuo MATSUYAMA
Chemicals and Explosives Research Laboratory, Nippon Oil & Fats Co., Ltd., Taketoyo, Chita-gun, Aichi 470-23
(Received February 25, 1985)

Synopsis. The kinetics of decomposition of *t*-butyl peroxypivalate in benzene, hexane and mineral spirits were determined iodometrically in the temperature range 50—75°. The decomposition in benzene indicated smaller rate constants and activation parameters than those in hexane or mineral spirits. The solvated transition state in aromatic solvent is discussed on the basis of these results and the previously published data.

The rate constants of decomposition of *t*-butyl peroxypivalate which decomposes with a concerted mechanism have been used as standard of those of other peroxyesters.[1)]

$$(CH_3)_3CC(=O)\text{-}OO\text{-}C(CH_3)_3 \longrightarrow (CH_3)_3C\cdot + CO_2 + \cdot OC(CH_3)_3 \quad (1)$$

However, different values of the activation parameter in the decomposition have been reported by several investigators.[2)] For instance, Lorand and coworkers[2a)] obtained $\Delta H^{\ddagger}=115\,kJ\,mol^{-1}$ and $\Delta S^{\ddagger}=15\,JK^{-1}mol^{-1}$ in cumene, but Fort and Franklin[2b)] reported $\Delta H^{\ddagger}=107\,kJ\,mol^{-1}$ and $\Delta S^{\ddagger}=-11\,JK^{-1}mol^{-1}$ in the same solvent. These conflicting values give rise to some difficulty on studying the decomposition mechanism of peroxyesters.

We measured the rates of the decomposition of *t*-butyl peroxypivalate in benzene, hexane and mineral spirits, and also reevaluated the previously published data.

TABLE 1. RATES OF DECOMPOSITION OF *t*-BUTYL PEROXYPIVALATE

Initial concentration M†	Temperature °C	Rate constant $k\times10^5/s^{-1}$

0.10	65	3.39
0.10	70	6.19
Solvent: Mineral spirits		
0.10	55	1.01
0.10	60	2.15
0.10	65	4.14
0.10	70	7.58
0.10	75	14.7

† 1M=1 mol dm^{-3}.

Results and Discussion

The rates of the decomposition of *t*-butyl peroxypivalate were determined by following the disappearance of the peroxide with iodometric titration. The results yielded good first order kinetics and were independent of initial peroxide concentration. These ruled

TABLE 2. ACTIVATION PARAMETERS FOR THE DECOMPOSITION OF *t*-BUTYL PEROXYPIVALATE

Benzene	115±1	14± 3	3.82	2.1

a) See Ref. 2a. b) Reevaluated from published data (See Fig. 1.).

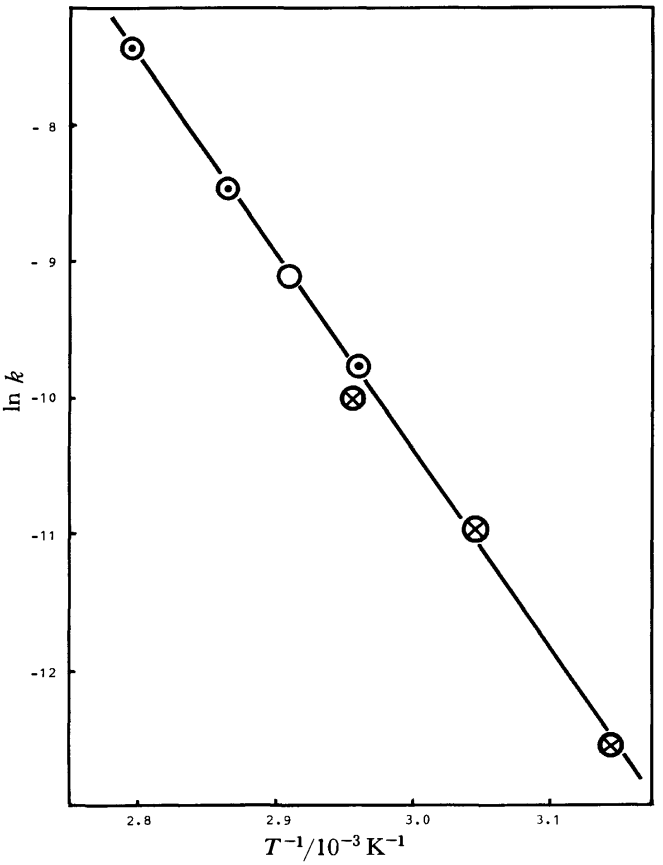

Fig. 1. Arrhenius plot of published data on thermal decomposition of *t*-butyl peroxypivalate in cumene: (⊙) data points of Lorand *et al.*[2a)] (○) data points of Fort *et al.*[2b)] (○) data point of Ernst *et al.*[2c)]

out radical induced decomposition under our experimental conditions. Table 1 shows the obtained data. The activation parameters were calculated from the data of the table and given in Table 2.

We also reevaluated the decomposition rates in cumene using the early published data. The data were plotted in Fig. 1 and the activation parameters were recalculated to be also shown in Table 2. A remarkable good Arrhenius plot in the figure shows that the differences between the activation parameters in each report are due to small systematic errors occurring within each set of experiments.

The rates of homolytic decomposition of *t*-butyl peroxypivalate were affected by solvents. It decomposes about twice faster in polarizable solvents such as benzene and cumene than aliphatic hydrocarbons having low polarizability. This could be explained by strong interactions of the aromatic solvent with *t*-butyl peroxypivalate at the transition state.[3] The observed decreases of the $\Delta H^{\ddagger}$ and $\Delta S^{\ddagger}$ in the aromatic solvents relative to those in the aliphatic hydrocarbons support this solvated transition state. Similar results have been reported in the thermal decomposition of diacyl peroxides,[4] di-*t*-butyl peroxide and *t*-butyl α-(*p*-substituted phenyl) peroxyisobutyrate.[6]

Experimental

t-Butyl peroxypivalate, benzene, hexane and mineral spirits were commercial materials. The rates of decomposition were measured by monitoring the undecomposed peroxyester with iodometric titration. A weighed amount of the peroxyester solution was added to glacial acetic acid solution containing saturated aquous sodium iodide solution and a small amount of iron(III) chloride, and allowed to stand at room temperature for 15 min. Then the iodide liberated was titrated with aquous sodium thiosulfate solution.

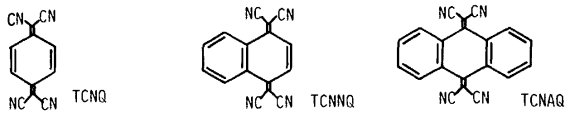
Charge-transfer Complexes of 11,11,12,12-Tetracyanoanthraquinodimethans with Various Donors

Toshio MUKAI,* Takanori SUZUKI, and Yoshiro YAMASHITA
Department of Chemistry, Faculty of Science, Tohoku University, Aramaki, Sendai 980
(Received February 27, 1985)

Synopsis. Titled compounds were found to form charge-transfer (CT) complexes with aromatic hydrocarbons or tetrathiafulvalene (TTF) and the molecular complexes could be isolated.

Since the high electrical conductivity was discovered in the charge-transfer (CT) complex of tetracyanoquinodimethan (TCNQ) and tetrathiafulvalene (TTF),[1] much attention has been paid to CT complexes of electron donors and acceptors such as tetracyano-1,4-naphthoquinodimethan (TCNNQ).[2,3] Recently four groups found facile synthetic methods of 11,11,12,12-tetracyanoanthraquinodimethan (TCNAQ) and its derivatives [4-7] which are dibenzo analogues of TCNQ and promising electron acceptors to form conductive complexes. However, it was reported that TCNAQ failed to form charge-transfer complexes because it is nonplanar due to a steric hindrance between the dicyanomethylene and the hydrogens at C_1, C_4, C_5, and C_8-positions.[5,8] As the first example we report here CT complexes of TCNAQs with various donors.



Scheme 1.

When naphthalene, phenanthrene, fluorene, and chrysene were used as donors, only shoulders or end absorptions due to the CT transition were observed. When pyrene, anthracene, perylene, and TTF were used as donors, however, the CT absorption maxima could be observed in the longer wavelength region since they have lower oxidation potentials.[9] These data are summarized in Table 1 together with reduction potentials. Linear correlation is observed between the CT transition energies and reduction potentials except for 1-chloro derivative **1d**, confirming that the absorptions are assigned to the CT transition. The deviation of **1d** from the line can be explained in terms of the larger steric hindrance of the substituent.[7]

In addition to the formation of the CT complexes in solution as described above, TCNAQs were found to form stable molecular complexes in solid state. They were obtained by dissolving TCNAQs and excess donors in dichloromethane. The melting points and colors of the complexes are shown in Table 2. According to elemental analyses, the mole ratio of acceptor to donor was determined to be 1:1 for benzene and diaminodurene, while that for naphthalene, anthracene, phenanthrene, pyrene, and TTF was 2:1. X-Ray analyses of **1e**-benzene complex and **1e**-pyrene complex also support that they are a 1:1 complex and a 2:1 complex, respectively.[10] This ratio is different from that of TCNNQ which is 1:2 for anthracene, phenanthrene, and pyrene.[2] This result may be attributed to the difference of the molecular sizes. Another interesting feature in the formation of the molecular complexes is that TCNAQs form complexes with benzene, while there is no report on the formation of the molecular complexes of TCNQ and TCNNQ with benzene. It should be noted that TCNAQs favorably form molecular complexes in spite of their nonplanar structures. Electical resistivities of complexes of TCNAQs **1b**, e, f, **g** with TTF show that they are insulators.[11] The high resistivities are mainly attributed to the nonplanar structures of TCNAQs.

Experimental

Materials. TCNAQ **1a** and substituted TCNAQs **1b—k** were prepared by our method[7] or Hünig's method.[4] Donors which were commercially available were purified by recrystallization or column chromatography.

Spectra. UV spectra were measured using a Hitachi 340 spectrophotometer. The charge-transfer maxima were measured at room temperature in spectrophotometric grade dichloromethane. The concentration of TCNAQs was ad-

a) These complexes could not be obtained.

justed to 6.67×10^{-3} mol dm^{-3}, and that of donors to 6.67×10^{-2} mol dm^{-3} except perylene in which case a saturated solution of perylene (1.67×10^{-2} mol dm^{-3}) was used because of its low solubility.

Complex Formation. The following is a general procedure to prepare complexes of TCNAQs with donors except benzene.[12] A TCNAQ derivative and an excess donor are dissolved in dichloromethane, and carbon tetrachloride or ethanol is added in order to precipitate a complex and prevent isolation of the excess donor. Concentration of the solvent is needed if crystals do not appear. For example, **1g**-pyrene complex was prepared by the following method. **1g** 100 mg and pyrene 61 mg were dissolved in hot dichloromethane 3 ml and the solution was concentrated to 1 ml. Ethanol 0.5 ml was added and the solution was allowed to stand. Separated red micro-crystals were filtered and washed with hot ethanol.

Analytical data are as follows.[13] Bz: benzene, Nap: naphthalene, Ant: anthracene, Phen: phenanthrene, Pyr: pyrene, DAD: diaminodurene. Found, % (Calcd,† %). **1a**-DAD, C, 76.86; H, 5.07; N, 18.13 (C, 76.90; H, 5.16; N, 17.94). **1b**-Bz, C, 81.98; H, 4.35; N, 14.29 (C, 81.80; H, 4.07; N, 14.13). **1b**-Phen, C, 82.71; H, 3.95; N, 14.02 (C, 82.54; H, 3.71; N, 13.75). **1b**-Pyr, C, 83.19; H, 3.85; N, 13.49 (C, 83.40; H, 3.60; N, 13.36). **1b**-TTF,C, 68.24; H, 3.05; N, 13.22; S, 15.17 (C, 68.55; H, 2.88; N, 13.32; S, 15.25). **1b**-DAD, C, 76.53; H, 5.46; N, 17.23 (C, 77.15; H, 5.43; N, 17.41). **1b**-Pyr, C, 76.59; H, 2.98; N, 11.82; Cl, 8.47 (C, 76.45; H, 2.75; N, 12.74; Cl, 8.06). **1e**-Bz, C, 74.81; H, 3.14; N, 13.44; Cl, 8.50 (C, 74.91; H, 3.17; N, 13.78; Cl, 8.64). **1e**-Nap, C, 74.54; H, 2.97; N, 13.75; Cl, 9.08 (C, 74.54; H, 2.75; N, 13.91; Cl, 8.80). **1e**-Ant, C, 75.59; H, 3.01; N, 13.11, Cl, 8.60 (C, 75.79; H, 2.83; N, 13.09; Cl, 8.28). **1e**-Phen, C, 75.51; H, 2.93; N, 13.12; Cl, 8.47 (C, 75.79; H, 2.83; N, 13.09; Cl, 8.28). **1e**-Pyr, C, 76.29; H, 2.91; N, 12.70; Cl, 8.36 (C, 76.45; H, 2.75, N, 12.74; Cl, 8.06). **1e**-TTF, C, 63.01; H, 2.30; N, 12.71; Cl, 8.36; S, 14.59 (C, 62.65; H, 2.06; N, 12.71; Cl, 8.04; S, 14.54). **1e**-DAD, C, 71.48; H, 4.41; N, 16.69; Cl, 7.45 (C, 71.63; H, 4.61; N, 16.70; Cl, 7.05). **1f**-Pyr, C, 77.30; H, 3.28; N, 12.07 (C, 77.75; H, 3.26; N, 12.09). **1f**-TTF, C, 64.54; H, 2.73; N, 12.05; S, 13.85 (C, 64.64; H, 2.60; N, 12.06; S, 13.81). **1g**-Bz, C, 79.59; H, 3.19; N, 17.21 (C, 79.59; H, 3.22; N, 17.19). **1g**-Phen, C, 80.64; H, 2.92; N, 16.82 (C, 80.37; H, 2.89; N, 16.74). **1g**-Pyr, C, 81.18; H, 2.98; N, 16.26 (C, 80.92; H, 2.81; N, 16.27). **1g**-TTF, C, 66.24; H, 2.14; N. 16.30; S, 13.58 (C, 66.81; H, 2.10; N, 16.23; S, 14.86). **1h**-Phen, C, 74.17; H, 2.50; N, 15.45 (C, 73.97; H, 2.76; N, 15.79), **1h**-Pyr, C, 74.49; H, 2.53; N, 14.69 (C, 74.66; H, 2.69; N, 15.55).

†These values are calculated assuming that the mole ratio of the TCNAQ to donor is 1:1 for Bz, DAD complexes, and is 2:1 for other complexes.

11) Electrical resistivities were measured as compacted samples at room temperature. **1b**-TTF;$<10^{13}$ Ωcm, **1e**-TTF; 8.2×10^{10} Ωcm, **1f**-TTF; 2.7×10^{13} Ωcm, **1g**-TTF; 5.7×10^{10} Ωcm. We thank Dr. Gunzi Saito at The University of Tokyo for providing the measurement of the resistivities.

12) The benzene complexes were obtained just by recrystallization of TCNAQs from benzene.

13) All of the complexes could not be recrystallized since they easily dissociate into indivisual components by dissolution in solvent. Therefore, some complexes showed unsatisfactory elemental analyses which still establish the mole ratio of the TCNAQs to donors.

Structures of Two New Halochamigrene Derivatives from the Red Alga *Laurencia nipponica* Yamada[1)]

Department of Chemistry, Faculty of Science, Hokkaido University, Sapporo 060
(Received March 8, 1985)

Synopsis. The structures of two new halochamigrene derivatives isolated from the title alga were determined by chemical and spectral methods.

We have previously reported the structures of the halogenated chamigrene derivatives which have been isolated from the red alga *Laurencia nipponica* Yamada, collected at Soya point, Hokkaido.[2)] Further investigation of this alga has yielded two new metabolites, a halogenated sesquiterpene alcohol **1** and a ketone **2**. We wish to describe herein the structures of these metabolites.

The sesquiterpene alcohol **1**, $C_{15}H_{21}OBr_2Cl$, oil, $[\alpha]_D^{20}$ −24.2° ($CHCl_3$), showed in its ^1H NMR spectrum broad signals at δ 0.99 (3H), 1.17 (3H), 4.27 (1H, m), 4.60 (1H, m), 5.06 (1H), 5.67 (1H), and 6.07 (1H), and a sharp singlet at δ 1.71 (3H). The ^{13}C NMR spectrum revealed no other double bonds, apart from those of an *exo*-methylene group at δ 144.4 (s) and 111.8 (t) and a trisubstituted double bond at 137.2 (s) and 130.9 (d), and hence **1** had to be a bicyclic alcohol. Acetylation of **1** with acetic anhydride and pyridine gave the corresponding acetate **3**, $C_{17}H_{23}O_2Br_2Cl$. Oxidation of **1** with pyridinium chlorochromate in CH_2Cl_2 afforded an α,β-unsaturated ketone which was identical with the natural ketone **2**, $C_{15}H_{19}OBr_2Cl$. The ^1H NMR spectrum of **2** exhibited pairs of signals very similar to those of the dienone **4**,[2)] derived from 2,10-dibromo-3-chlorochamigra-7(14)-en-8-ol (**5**). However, these pairs of signals, when the spectrum was measured at 100°C (in toluene-d_8), collapsed into singlets and the spectral change with temperature variation was reproducible. This fact suggests that the ketone **2** exists as two conformers equilibrated slowly at room temperature. Treatment of **1** with zinc and AcOH in MeOH yielded a monobromo alcohol **6**, $C_{15}H_{21}OBr$, which gave the acetate **7**, $C_{17}H_{23}O_2Br$. The ^1H NMR spectrum of **6** showed the presence of two quaternary methyl groups at δ 0.92 and 1.16 (each 3H, s), a vinyl methyl group at δ 1.60 (3H, br s), an *exo*-methylene group at δ 5.08 and 5.30 (each 1H, s), two olefinic protons at δ 5.38 (1H, m) and 6.17 (1H, d, J=4.5 Hz), and a proton α to hydroxyl group at δ 4.48 (1H, dd, J=4.5, 4.5 Hz), thus indicating that the vicinal bromine and chlorine atoms in **1** were eliminated to form an additional trisubstituted double bond bearing a methyl group. Spin decoupling experiments on the ^1H NMR spectrum of **6** showed the presence of $CH_2{=}\underset{|}{C}{-}CH(OH){-}CH{=}\underset{|}{C}-$ and $-CH_2{-}CH{=}C(CH_3)-$ moieties in the molecule. Comparison of the ^1H NMR spectra of **6** and **7** with those of previously described halochamigrene derivatives coupled with detailed analysis of the spectral data of **2** and **4** allowed us to propose formulae **1** and **2** for the sesquiterpene alcohol and the ketone, respectively. Confirmation of the structures **1** and **2** was obtained by the following chemical correlation with 2,10-dibromo-3-chloro-7,8-epoxychamigrane (**8**), the major metabolite of Atsuta's *L. nipponica*.[3)] Treatment of **8** with zinc and AcOH in MeOH gave three products, **9**, **10**, and **11**. The product **9**, $C_{15}H_{24}OBrCl$, revealed ^1H NMR spectrum very similar to that of **8** except for the chemical shifts of the *gem*-dimethyls and lack of the signal corresponding to the bromomethine proton at δ 4.10. The two signals due to the *gem*-dimethyl group (δ 0.84 and 0.88) in **9** were observed at higher magnetic field region than that (δ 0.96 and 1.10) in **8**, thus indicating that the bromine atom at C-10 of **8** was reduced in a way similar to the case of glanduliferol.[4)] The acid-catalyzed isomerization of **9** with *p*-toluenesulfonic acid in warm benzene gave an alcohol **12**, $C_{15}H_{24}OBrCl$; ν_{max} 3630, 1640, and 910 cm^{-1}. On the other hand, hydrogenation of **1** with PtO_2 in EtOAc gave the hydrogenated product, with evolution of hydrogen bromide, which was identical with **12** in all respects. Consequently, the structures of **1** and **2** were established as (2*S*,3*S*,8*R*)-2,10-dibromo-3-chlorochamigra-7(14),9-dien-8-ol and (2*S*,3*S*)-2,10-dibromo-3-chlorochamigra-7(14),9-dien-8-one, respectively. Conformational analyses of **1** and **2** are in progress.

Experimental

The melting points were uncorrected. The IR spectra were measured on a JASCO A-102 spectrometer and the UV spectra on a Shimadzu UV-240 spectrometer. The ^1H and ^{13}C NMR spectra were recorded on a JEOL JNM-FX 100 spectrometer. TMS was used as an internal reference in $CDCl_3$. The low and

high resolution mass spectra were obtained at 70 eV with a JEOL JMS-D300 spectrometer. The optical rotations were measured on a JASCO DIP-140 polarimeter in $CHCl_3$.

Isolation. The detail of the separation of the extracts has been described in the previous paper.[2] The ethyl acetate fraction obtained by alumina column chromatography of the extracts was repeatedly chromatographed on silica-gel column to yield **1** (4% of the extracts) along with two halochamigrene derivatives[2] and *trans*-deacetylkumausyne.[5] From the benzene fraction **2** was isolated in 1.5% yield by repeated silica-gel column chromatography together with kumausallene[6] and *trans*-kumausyne.[5]

1: Colorless oil; $[\alpha]_D^{20}$ −24.2° (*c* 1.88); UV (EtOH), λ_{max} 203 nm (ε 8500); IR (film), ν_{max} 3350, 1640, 1390, 1380, 1367, 1300, 1100, 1045, 990, 910, 860, 810, and 750 cm^{-1}; ^1H NMR, in the text; ^{13}C NMR (25.0 MHz), δ=23.0 (q), 23.5 (q), 24.0 (q), 25.9 (t), 38.6 (t×2), 47.0 (s), 50.1 (s), 60.6 (d), 69.0 (d), 71.7 (s), 111.8 (t), 130.9 (d), 137.2 (s), and 144.4 (s); MS, *m/z* (rel. intensity) 416, 414, 412, 410 (0.2:1:1.5:0.5; M^+), 335, 333, 331 (13:48:37; M^+−Br), 297, 295 (16:17; M^+−Br-HCl), 215 (40; M^+−Br-HCl-HBr), 147 (32), 119 (50), 97 (51), 91 (48), 81 (48), 69 (69), 57 (77), 55 (79), 43 (78), and 41 (100). Found: *m/z* 333.0445. Calcd for $C_{15}H_{21}O^{81}Br^{35}Cl$: M−Br, 333.0445.

2; Pale yellow oil; $[\alpha]_D^{22}$+1.95° (*c* 1.59); UV (EtOH), λ_{max} 262 (ε 9700) and 202 (6200) nm; IR (film), ν_{max} 1670, 1620, 1595, 1390, 1380, 1370, 1320, 1290, 1260, 1220, 1180, 1150, 1100, 1065, 950, 890, 870, and 760 cm^{-1}; ^1H NMR, δ=1.11, 1.14 (total 3H, s), 1.37 (3H, s), 1.69 (3H, s), 4.21 (0.4H, dd, *J*=12, 5 Hz), 4.64 (0.6H, dd, *J*=13, 5 Hz), 5.45 (1H, s), 6.21 (1H, s), 6.52 (0.6H, s), and 6.54 (0.4 H, s); MS, *m/z* 414, 412, 410, 408 (3:16:22:10; M^+), 377, 375, 373 (0.9:2:1; M^+−Cl), 333, 331, 329 (26:100:78; M^+−Br), 296, 294 (9:11; M^+−Br-Cl), 295, 293 (52:53; M^+−Br-HCl), 252, 250 (10:30; M^+−Br-Br), 251, 249 (12:20; M^+−Br-HBr), 215 (41; M^+−Br-Br-Cl), 214 (63; M^+−Br-Br-HCl), 213 (71; M^+−Br-HBr-HCl), 149 (61), 95 (66), 67 (68), and 41 (78). Found: *m/z* 409.9470. Calcd for $C_{15}H_{19}O^{79}Br^{81}Br^{35}Cl$: M, 409.9472.

Acetylation of 1. Acetylation of **1** (19 mg) was carried out with acetic anhydride (0.3 ml) and pyridine (0.3 ml) in the usual manner. The acetylated product was purified by a silica-gel plate to give **3** (17 mg); oil; $[\alpha]_D^{20}$−71.7° (*c* 0.53); IR (film), ν_{max} 1740, 1640, 1230, 1100, 1040, 1010, 990, 930, 920, and 900 cm^{-1}; ^1H NMR, broad and complex signals; MS, *m/z* 458, 456, 454, 452 (0.3:1.1:1.3:0.6; M^+) and 416, 414, 412, 410 (5:25:35:16; M^+−CH_2CO). Saponification of **3** with K_2CO_3 in MeOH gave the original alcohol **1** in quantitative yield.

PCC Oxidation of 1. To a suspended solution of pyridinium chlorochromate (10 mg) in CH_2Cl_2 (0.5 ml) was added a solution of **1** (12 mg) in CH_2Cl_2 (0.5 ml). The mixture was stirred for 40 min at room temperature and then worked up in the usual manner. The resulting oil was chromatographed on a silica-gel plate to afford **2** (10 mg); pale yellow oil; $[\alpha]_D^{23}$ +1.68° (*c* 1.28); whose spectral data were consistent with those of the natural ketone **2**.

Treatment of 1 with Zn-dust-AcOH. To a solution of **1** (10 mg) in MeOH (0.4 ml) was added activated Zn-dust (50 mg) and AcOH (0.04 ml). The mixture was stirred for 70 h at room temperature and then filtered to remove the Zn-dust. The filtrate was extracted with ether. The ethereal solution was successively washed with water, 5% aqueous $NaHCO_3$, and water, and dried over Na_2SO_4. The subsequent removal of the solvent gave a residual oil, which was chromatographed on a silica-gel plate to give **6** (4 mg); crystals; mp 58—59 °C; $[\alpha]_D^{20}$ −95.8° (*c* 0.45); IR ($CHCl_3$), ν_{max} 3600, 3400, 1640, 1010, 990, 915, and 895 cm^{-1}; ^1H NMR, in the text; MS, *m/z* 298, 296 (3:3; M^+) and 280, 278 (56:58; M^+−H_2O).

Acetylation of 6. Acetylation of **6** (3 mg) was carried out with acetic anhydride (0.15 ml) and pyridine (0.15 ml) at room temperature by the usual method to give **7** (3 mg); oil; $[\alpha]_D^{25}$ −103° (*c* 0.25); IR ($CHCl_3$), ν_{max} 1730, 1640, 1230, 1015, 973, and 915 cm^{-1}; ^1H NMR, δ=0.92 (3H, s), 1.18 (3H, s), 1.59 (3H, br s), 2.04 (3H, s), 5.14 (1H, s), 5.30 (1H, m), 5.49 (1H, s), 5.61 (1H, d, *J*=5 Hz), and 6.12 (1H, d, *J*=5 Hz); MS, *m/z* 340, 338 (0.3:0.3; M^+) and 280, 278 (41:42; M^+−CH_3COOH).

Treatment of 8 with Zn-dust-AcOH. To a solution of **8** (46 mg) in MeOH (1.5 ml) was added activated Zn-dust (200 mg) and AcOH (0.15 ml). The mixture was stirred for 6 h at room temperature and then worked up in a manner similar to the case of **1**. The resulting oil was chromatographed on a silica-gel column to give **9** (6 mg); crystals; mp 114—115 °C; $[\alpha]_D^{21}$ +16.8° (*c* 0.46); IR ($CHCl_3$), ν_{max} 1150, 1105, 1090, and 1055 cm^{-1}; ^1H NMR, δ=0.84 (3H, s), 0.88 (3H, s), 1.54 (3H, s), 1.71 (3H, s), 2.97 (1H, dd, *J*=2, 2 Hz), and 4.90 (1H, dd, *J*=12, 6 Hz); MS, *m/z* 338, 336, 334 (0.2:1:0.9; M^+) and 257, 255 (3:13; M^+−Br); **10** (9 mg); oil; $[\alpha]_D^{18}$−81.1° (*c* 0.76); ^1H NMR, δ=0.93 (3H, s), 0.99 (3H, s), 1.31 (3H, s), 1.67 (3H, br s), 2.88 (1H, dd, *J*=2, 2 Hz), 4.38 (1H, dd, *J*=12, 6 Hz), and 5.42 (1H, m); MS, *m/z* 300, 298 (0.7: 0.8; M^+) and 219 (28; M^+−Br); **11** (6 mg); oil; $[\alpha]_D^{21}$−77.5° (*c* 0.46); ^1H NMR, δ=0.76 (3H, s), 0.81 (3H, s), 1.29 (3H, s), 1.67 (3H, br s), 2.89 (1H, dd, *J*=2, 2 Hz), and 5.43 (1H, m); MS, *m/z* 220 (4; M^+).

Isomerization of 9. To a solution of **9** (4 mg) in benzene (0.5 ml) was added a piece of TsOH, and the mixture was stirred for 35 min at 60 °C, cooled, and extracted with ether. The ethereal solution was washed with 5% aqueous $NaHCO_3$ and water, dried over Na_2SO_4, and then evaporated to leave a residual oil, which was chromatographed on a silica-gel plate to give **12** (2 mg); oil; $[\alpha]_D^{18}$−29.4° (*c* 0.19); IR ($CHCl_3$), ν_{max} 3630, 1640, 1300, 1100, and 910 cm^{-1}; ^1H NMR, δ=0.82, 0.94, 1.70 (each 3H, s), 4.32 (1H, m), 4.37 (1H, dd, *J*=13, 4 Hz), 4.93 (1H, s), and 5.59 (1H, s); MS, *m/z* 338, 336, 334 (0.2:0.8:1; M^+) and 320, 318, 316 (0.8:1.3:1; M^+−H_2O).

Hydrogenation of 1. Hyrogenation of **1** (8 mg) was performed in EtOAc over PtO_2-catalyst. After removal of the catalyst and the solvent, the residual oil was chromatographed on a silica-gel plate to give **12** (3 mg); oil; $[\alpha]_D^{23}$−31.9° (*c* 0.31); the spectral data were identical with those of **12** derived from **9**.

A New Chamigrane-type Bromo Diether from the Red Alga *Laurencia nipponica* Yamada[1)]

Hajime KIKUCHI,† Teruaki SUZUKI, Minoru SUZUKI, and Etsuro KUROSAWA*
Department of Chemistry, Faculty of Science, Hokkaido University, Sapporo 060
(Received March 8, 1985)

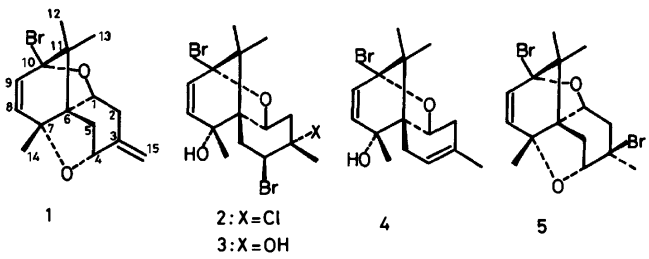
Synopsis. A new halogenated sesquiterpene diether has been isolated from the title alga and its structure was established on the basis of the spectral and chemical evidence.

As part of our studies on the constituents of the red alga *Laurencia nipponica* Yamada ("Ura-sozo") grown in Northern Hokkaido,[2,3)] belonging to the warm current region, we have collected in two locations at Teuri island and Hamamasu. Both specimens displayed the presence of laureatin[4)] (25% and 20% of the extracts) and isolaureatin[4)] (10% and 8%) as the major metabolites. In this paper we report the isolation and the structural determination of a new sesquiterpene bromo diether **1**, which has been obtained as the minor metabolite (0.6%) from the Hamamasu's specimen.

Compound **1**, mp 78—79 °C, $[\alpha]_D^{21}$ −54.8° ($CHCl_3$), was found to have a molecular formula of $C_{15}H_{19}O_2Br$ by high resolution mass spectrometry. The IR spectrum of **1** showed no hydroxyl and carbonyl absorptions, thus indicating that two oxygen atoms in **1** were involved in ether linkages. The ^{13}C NMR spectrum indicated the presence of an *exo*-methylene group at δ 144.2 and 114.6 and a disubstituted vinyl group at 133.9 and 130.1. Tetracyclic nature, including two ether rings, of **1** was demonstrated from the absence of further unsaturation besides the two double bonds. The ^1H NMR spectrum revealed signals at δ 1.02 and 1.14 (each 3H, s) due to two quaternary methyl groups, at 1.24 (3H, s) due to a CH_3–$\overset{|}{C}$–O– grouping, at 4.95 and 5.07 (each 1H, br s) due to an *exo*-methylene group, and at 5.82 (2H, br s) due to a disubstituted vinyl group. Furthermore, the spin decoupling studies indicated the presence of ■–$\underset{|}{\overset{}{CH}}$–$CH_2$–■ grouping at
O–
δ 1.71 (1H, d, J=12 Hz), 2.20 (1H, dd, J=12, 6 Hz), and 4.45 (1H, d, J=6 Hz) and ■–$\underset{|}{\overset{}{CH}}$–$CH_2$–$\overset{|}{C}$=$CH_2$
O–
grouping at 2.39 (1H, dddd, J=14, 14, 2, 2 Hz), 2.66 (1H, dd, J=14, 5 Hz), and 4.06 (1H, dd, J=14, 5 Hz) (■; quaternary carbon).

In view of the above-mentioned partial structural units coupled with comparisons of the spectral data with those of various chamigrane-type sesquiterpenoids, *e.g.* **2** (pacifenol)[5)] and **3**,[6)] which co-occurred in the same alga, it is suggested that formula **1** would be proposed as possible structure for this bromo diether. The structure **1** was confirmed by the following chemical derivation from the known bromo alcohol **4**,[6)] which has also been isolated from *L. nipponica*.

Treatment of **4** with *N*-bromosuccimide in *t*-BuOH and H_2O at room temperature afforded a dibromo compound **5**, $C_{15}H_{20}O_2Br_2$ (*m/z* 394, 392, and 390; M^+), in 90% yield. The IR and ^1H NMR spectra of **5** indicated that the hydroxyl and trisubstituted vinyl groups in **4** disappeared and that an additional ether ring was formed. The formation of the expected diether **5** (not 4-bromo-3,7-epoxy derivative) in the bromonium ion induced cyclization[7)] was supported by the presence of the CH_3–$\overset{|}{C}$(Br)– moiety at δ 1.80 (3H, s) in the ^1H NMR spectrum of **5**. Treatment of **5** with 1 mol dm^{-3} ethanolic potassium hydroxide gave a dehydrobromination product (20% yield) which was identical with natural bromo diether **1** in all respects (IR, ^1H NMR, and MS spectra and undepressed mixed mp). Thus the structure, including the absolute configuration, of the bromo diether is represented by formula **1**.



Experimental

All the mps were uncorrected. The IR spectra were measured on a JASCO A-102 spectrophotometer. The ^1H and ^{13}C NMR spectra were recorded on a JEOL JNM-PS-100 and JEOL JNM-FX200 spectrometer, respectively, using tetramethylsilane as an internal reference in $CDCl_3$. The low and high resolution mass spectra were taken at 70 eV with a JEOL JMS-D300 spectrometer. Optical rotations were determined on a JASCO DIP-140 polarimeter in $CHCl_3$. Aluminium oxide (Merck, activity II-III) and silica gel (Merck, Kieselgel 60, 70—230 mesh) were used for column chromatography.

Collection. Algae were collected at Teuri island (Haboro) and Hamamasu (*ca.* 40 km southwest of Rumoi[3)]) early in August 1980.

Isolation. The neutral MeOH extracts (5 g; *ca.* 2% of the half-dried alga), obtained from the Hamamasu's specimen in the usual manner, was fractionated by column chromatography on alumina. The fraction eluted with hexane–benzene (1:1) was rechromatographed on silica-gel column to yield laureatin[4)] (1 g) and isolaureatin[4)] (400 mg) together with deoxyprepacifenol[8)] (25 mg), (3*Z*)-isoprelaurefucin[9)] (170 mg), and spirolaurenone[10)] (40 mg). The fraction eluted with benzene was further submitted to column chromatography on silica gel to give **1** (30 mg) as a crystalline material along with cycloeudesmol[11)] (65 mg). The fraction eluted with benzene–ethyl acetate (10:1) was repeatedly chromato-

†Present address: Tobishi Pharmaceutical Co. Ltd., Koganei 184.

graphed over silica gel to yield pacifenol[5] (100 mg), 2,10-dibromo-3-chloro-α-chamigren-9-ol[12] (10 mg), and laureacetal-A[13] (10 mg). The following fraction eluted with ethyl acetate was submitted to repeated silica-gel column chromatography to afford laureacetal-B[14] (60 mg), 4,10-dibromo-1,10-epoxychamigra-8-ene-3,7-diol[6] (10 mg), and 10-bromo-1,10-epoxychamigra-2,8-diene-4,7-diol[15] (65 mg).

1: Mp 78—79 °C (hexane–diisopropyl ether); $[\alpha]_D^{21}$ −54.8° (*c* 1.43); IR, ν_{max} (Nujol) 1160, 1090, 1050, 1030, 1020, 985, 935, 915, and 865 cm^{-1}; ^1H NMR (100 MHz), in the text; ^{13}C NMR (50.1 MHz), δ=144.2 (s, C3), 133.9 (d, C8 or C9), 130.1 (d, C9 or C8), 114.6 (t, C15), 98.8 (s, C10), 84.7 (s, C7), 81.2 (d, C4), 78.0 (d, C1), 55.5 (s, C6), 47.7 (s, C11), 31.1 (t, C2), 26.9 (t, C5), 23.9 (q, C14 or C13), 23.3 (q, C13 or C14), and 20.1 (q, C12); MS, *m/z* (rel intensity) 312, 310 (0.2; M^+), 297, 295 (1; M^+-CH_3), 231 (9; M^+-Br), 200, 198 (32), 171 (40), 133 (88), 121 (100), 119 (37), 91 (36), 57 (42), 43 (77), and 41 (71). Found: *m/z* 295.0333. Calcd for $C_{14}H_{16}O_2{}^{79}Br$: $M-CH_3$, 295.0333.

Treatment of 4 with NBS in t-BuOH–H_2O. To a soln of **4**[6] (30 mg) in *t*-BuOH (1 ml) and H_2O (1 ml) was gradually added recrystallized NBS (19 mg) at 0 °C. After the mixture had been stirred for 1 h at room temperature, water was added, and the mixture was extracted with ether. The ethereal soln was washed with saturated brine, dried over anhydrous Na_2SO_4, and evaporated to leave an oily substance, which was purified by column chromatography over silica gel to give **5** (34 mg); mp 97—98 °C (hexane–diisopropyl ether); $[\alpha]_D^{23}$ −29.4° (*c* 1.49); IR, ν_{max} (Nujol) 1265, 1160, 1105, 1050, 1040, 1030, 1015, 1005, 982, 958, 950, 935, 925, 910, 880, 865, 815, 765, and 743 cm^{-1}; ^1H NMR (100 MHz), δ=1.03, 1.14, 1.25, 1.80 (each 3H, s), 2.13 (2H, m), 2.33 (1H, br s), 2.43 (1H, s), 3.74 (1H, dd, *J*=10, 9 Hz), 4.26 (1H, dd, *J*=4, 2 Hz), and 5.84 (2H, br s); MS, *m/z* 394, 392, 390 (0.3:0.5:0.3; M^+), 379, 377, 375 (0.3:0.5:0.3; M^+-CH_3), 313, 311 (40; M^+-Br), 231 (5; $M^+-Br-HBr$), 199 (20), 162 (20), 133 (85), 121 (100), 113 (34), 71 (37), 43 (69), and 41 (48).

Conversion of 5 into 1. A soln of **5** (30 mg) in 1 mol dm^{-3} ethanolic KOH (1.5 ml) was refluxed for 2 h and then worked up in the usual way to give an oily product which was further purified by silica-gel column chromatography to yield a crystalline substance (5 mg) (20 mg of **5** was recovered), mp 77—78 °C, $[\alpha]_D^{22}$ −51.0° (*c* 1.21), whose spectral data were consistent with those of natural **1**.

Irreversible Conformational Change of the Complex of Poly(L-lysine) with Methyl Orange upon Irradiation of Light

Hiroyuki YAMAMOTO
Institute of High Polymer Research, Faculty of Textile Science and Technology, Shinshu University, Ueda 386
(Received March 11, 1985)

Synopsis. The effect of light on the chiral complex of poly(L-lysine) (PLL) with Methyl Orange (MO) was studied by means of absorption and circular dichroism (CD) measurements. Upon irradiation, the magnitude of the induced CD of the PLL-MO complex decreased together with a decrease in dimeric dye species. The change was irreversible under dark or visible-light conditions.

Reversible conformational changes induced by light in azobenzene-containing polypeptides in organic solvents have been studied by different groups.[1-3] Conformational changes induced by light in water-soluble poly(L-glutamic acid) (PLG) with photochromic side chains have also been studied by Pieroni *et al.*[4,5] Though a *trans* to *cis* photoconversion in an aqueous solution was lower than in an organic solvent, the photochemical reactions in both solvents were entirely reversible.[4,5]

We have investigated the induced CD of cationic polypeptides and azo dyes[6-9] and wish to report here the effect of light irradiation on the PLL-MO complex in water.

Experimental

The PLL HBr sample used had a polymerization degree of 3260. 4-(4-Dimethylaminophenylazo)benzenesulfonic acid sodium salt (Methyl Orange, MO) was a guaranteed reagent (Wako). A MO solution was prepared in red light and kept in the dark. The final concentrations of MO were 2×10^{-5} mol dm^{-3}, and the ratio of lysyl residues to dye molecules (R/D) was 5. The absorption and CD spectra were measured with a Jasco UVIDEC-1 and a CD J-40A spectrometer. All the following data were reduced to the molar basis of the total dye concentration or the lysyl residue concentration, and were expressed in terms of the ellipticity $[\theta]$ (degree cm^{2}dmol^{-1}) and molar extinction coefficient ε (dm^{3}mol^{-1}cm^{-1}).

Irradiations of the sample solutions were carried out with a mercury lamp (400 W) filtered with narrow-band interference filters (UV-D36A for 360 nm and B-46 for 460 nm) from Toshiba. The light intensity was measured by actinometry.[10]

Results and Discussion

The MO showed a single visible absorption band at 467 nm with ε_{467}=25600 in water (at a neutral pH). Upon complexation with PLL, an additional blue-shifted band was observed at 367 nm due to the dimeric dye species,[11,12] exhibiting an induced CD. The magnitudes of the induced CD of the PLL HBr-MO complex were −128000 (371 nm) and 129000 (359 nm) at pH 6 and R/D=5. Figure 1 shows the time dependence of the absorption spectra of the PLL HBr-MO complex upon irradiation at 360 nm (2.7×10^{19} photons cm^{-2}s^{-1}).[10] The intensity of the absorption band at 367 nm decreased and a new broad band appeared at around 400 nm, together with an increase in the monomeric MO band. The band at around 400 nm has been considered to be due to aggregated MO molecules bound to PLL.[13] After 800 min, the dimeric dye species at 367 nm almost disappeared. Figure 2 shows the time dependence of the CD spectra of the PLL HBr-MO complex under the same experimental conditions. Upon irradiation at 360 nm, the magnitudes of the induced CD in the 300—450 nm region decreased, and the extrema and crossover wave lengths shifted to the shorter wave length region. In agreement with the results of the absorption spectra described above, the induced CD of the PLL HBr-MO complex almost completely disappeared after 800 min. Non-filtered light (1.3×10^{20} photons cm^{-2}s^{-1}) from a mercury lamp caused much faster spectral changes than those of a filtered light and the induced CD disappeared after 10 min. Filtered ultraviolet light (360 nm) caused similar changes after 800 min and visible light (460 nm, 2.1×10^{19} photons cm^{-2}s^{-1}) after 1000 min.

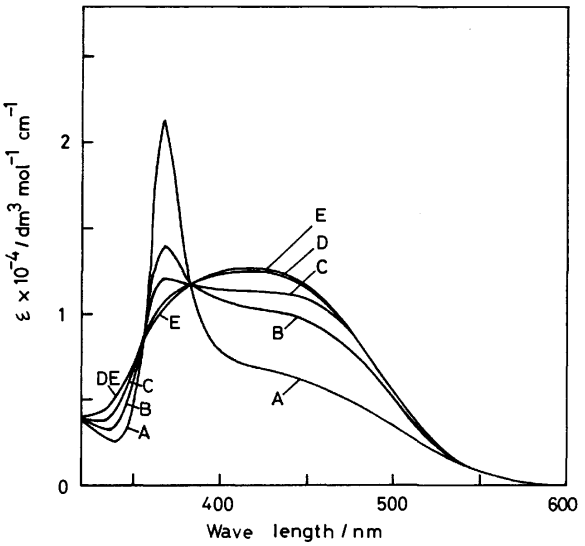

Fig. 1. Absorption spectra of the PLL HBr-MO complex in water at pH 6 and R/D=5 upon irradiation at 360 nm. A: At 0 min, B: after 200 min, C: after 400 min, D: after 600 min, E: after 800 min.

The inherent n-π^* peptide transition of an extended random coiled PLL HBr-MO complex gave an ellipticity value of $[\theta]_{217}$=2500 (based on lysyl residues) at pH 6 and R/D=5 before irradiation. The value decreased to 1000 after irradiation at 360 nm for 800 min. The decrease of the induced CD and n-π^* peptide transition was almost parallel as can be seen from Fig. 2. This observation is the same as for the CD results of water-soluble PLG with azobenzene side chains.[4,5]

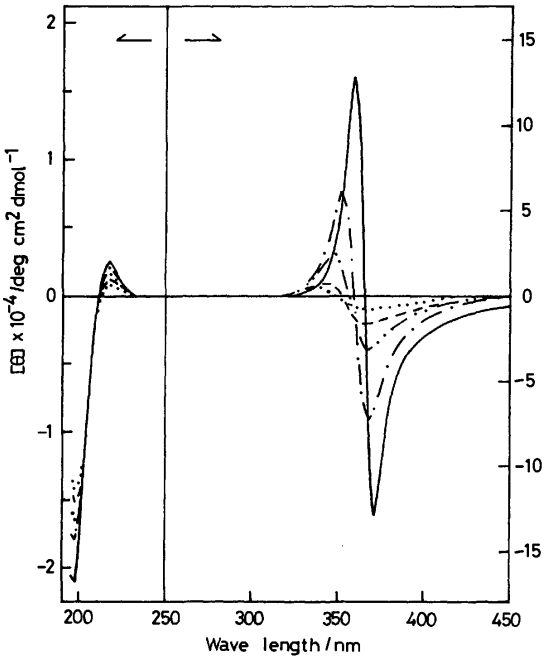

Fig. 2. CD spectra of the PLL HBr-MO complex in water at pH 6 and R/D=5 upon irradiation at 360 nm. ——: At 0 min, —·—: after 200 min, —··—: after 400 min, – – –: after 600 min, ·····: after 800 min.

MO in water does not cause an isomerization from *trans* to *cis* upon irradiation of light.[14] The reason for the spectral changes in Figs. 1 and 2 is due to the change in the interaction mode of the bound dye on the PLL, that is, from dimeric to aggregated and monomeric states. The irradiated sample (at 360 nm) left in the dark or upon re-irradiation by the visible light did not return to its original absorption and CD spectra. Thus, the change in the induced CD spectrum by light is irreversible within several days.

The author wishes to thank Professor Tadao Hayakawa for his encouragement and Miss Ayako Nakazawa for her skillful assistance.

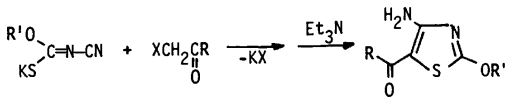
Synopsis. Various kinds of α-halo ketones readily reacted with sodium cyanophenyldithioacetate to provide 2-acyl-3-amino-5-phenacylthio-4-phenylthiophenes in good yields.

In the course of our intensive synthetic studies of heterocyclic compounds,[1,2] we found that 5-acyl-2-alkoxy-4-aminothiazoles were easily prepared by the reaction of potassium (alkoxythiocarbonyl)cyanamide with α-halo ketones (Scheme 1).[1] We have tried to



Scheme 1.

extend this process to a facile synthesis of 2-acyl-3-amino-5-mercapto-4-phenylthiophenes (**5**) using α-halo ketones (**2**) and sodium cyanophenyldithioaceate (**1**) instead of (alkoxythiocarbonyl)cyanamide salts as shown in Scheme 2. The starting material **1** was easily prepared from carbon disulfide and phenylacetonitrile in the presence of sodium hydride[3] and without purification the crude **1** was used for the synthesis of **5**.

At first, in a procedure similar to the preparation of 2-acyl-3-aminothiazoles,[1] the reaction was carried out at room temperature using equimolar **1** and phenacyl bromide **2a** and subsequent cyclization was attempted by treatment with triethylamine under slightly warming. The product was not the desired compound **5a** but **6a**.

Since **6a** should be stoichiometrically formed from one mole of **1** and two moles of **2a**, the first condensation reaction was carried out using 2 equiv of **2a** in the presence of an equiv of triethylamine as a dehydrobrominating reagent,[4] and then base-catalyzed cyclization with additional triethylamine was performed. In this case, the thiophene **6a** could be obtained in an excellent yield. The structure of **6a** was confirmed by elemental analysis and spectral studies as follows: The parent peak (*m/z* 429) was observed in MS, and the IR absorption band of a cyano group in the starting **1** disappeared after the reaction, while that of an amino group newly appeared. In addition, the bands of two carbonyl groups (1700 and 1600 cm^{-1}) were also observed.

Thiophenes (**6b—g**) were prepared in good or excellent yields by the similar one-pot reaction from substituted phenacyl halides as shown in Table 1. In this reaction, any aldol condensation to form **7** did not occur and **6** was always a sole product.

Since the reaction proceeds selectively under quite mild conditions, it seems to be useful for the preparation of aminothiophenes having unstable substituents. Although a number of sydnone compounds have been prepared because of their unique electronic structure and biological activities,[5] few works[1b,6] dealing with the successful synthesis of sydnones having heterocyclic substituents have been reported because of the instability of a sydnone ring. From this aspect, the reaction of **1** with 3-aryl-4-(bromoacetyl)sydnone was successfully tried under such mild conditions and pure aminothiophenes (**6h**, **6i**) having a sydnone ring were directly obtained in good yields without purification. In a similar manner, a thiophene derivative (**6j**) having an antipyrine ring was also prepared from the viewpoint of biological activity.

Although our attempts to prepare 3-amino-2-acetylthiophene derivative from α-chloroacetone (**2l**) and **1** failed, the reaction was successfully carried out using 3-chloro-2,4-pentanedione instead of **2l** to provide **6k** in a moderate yield. The product **6k** seemed to be formed by elimination of ketene from the cyclized

Experimental

Typical Procedure for the Preparation of Thiophenes. Preparation of 3-Amino-2-benzoyl-5-phenacylthio-4-phenylthiophene (6a): To a stirred suspension of 2.15 g (10 mmol) of sodium cyanophenyldithioacetate (**1**)[3] and 1.4 ml (10 mmol) of triethylamine in 30 ml of ethanol was gradually added a solution of 4.00 g (20 mmol) of phenacyl bromide in 20 ml of ethanol at room temperature. After about 2 h of stirring, additional triethylamine (1.4 ml) was added and the reaction mixture was refluxed for 1 h or stirred for 10 h at room temperature. The reaction mixture was evaporated to dryness under reduced pressure. The residue was mixed with water, and insoluble solid was collected by filtration. 4.29 g (quant). Recrystallization from DMF-ethanol provided pure **6a** as light yellow needles. Mp 164—165 °C. IR (KBr) 3500, 3400 (ν_{NH}), 1700, and 1600 cm^{-1} ($\nu_{C=O}$). ^{1}H NMR (DMSO-d_6) δ= 3.27 (s, 2H, SC$\underline{H}_2$), 4.70 (s, 2H, N$\underline{H}_2$), and 7.10—8.07 (m, 15H, $C_6\underline{H}_5$). MS: *m/z* 429 (M^+). Found: C, 69.79; H, 4.28; N, 3.27%. Calcd for $C_{25}H_{19}NO_2S_2$: C, 69.90; H, 4.46; N, 3.26%.

Preparation of 2-Acetyl-3-amino-4-phenyl-5-(diacetylmethylthio)thiophene (6k): In a similar manner, **6k** was obtained from 3-chloro-2,4-pentanedione and **1** in 57% yield. Recrystallization from aq ethanol provided pure **6k** as yellow needles. Mp 125 °C. IR (KBr) 3390, 3280, 3200 (ν_{NH}), 1605, 1590 cm^{-1} ($\nu_{C=O}$). ^{1}H NMR (DMSO-d_6) δ=2.22 (s, 3H, C$\underline{H}_3$), 2.40 (s, 6H, C$\underline{H}_3$COCH), 3.44 (broad s, 1H, SC$\underline{H}$), 6.90 (broad s, 2H, N$\underline{H}_2$), and 7.38—7.80 (m, 5H, $C_6\underline{H}_5$). MS: *m/z* 347 (M^+). Found: C, 58.60; H, 4.79; N, 4.14%. Calcd for $C_{17}H_{17}NO_3S_2$: C, 58.77; H, 4.93; N, 4.03%.

We are grateful for valuable discussion with Profs. H.-J. Tien and M.-Y. Yeh of National Cheng Kung University (Republic of China, Taiwan), and thank Mr. C.-S. Chen for doing part of the experiments.

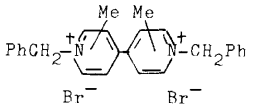
Photochromism of Benzylviologens Containing Methyl Groups on Pyridinium Rings and Embedded in Solid Poly(*N*-vinyl-2-pyrrolidone) Matrix

Hiroyoshi KAMOGAWA* and Masashi SUGIYAMA
Department of Applied Chemistry, Yamanashi University, Takeda 4, Kofu 400
(Received March 18, 1985)

Synopsis. Benzylviologens with 2,2′- and 3,3′-dimethyl groups embedded in poly (*N*-vinyl-2-pyrrolidone) matrix indicate reversible photochromisms with absorption maxima at 605 and 775 nm under light, respectively, which are different from those (610, 570 nm) of conventional benzylviologens.

It is known that viologens embedded in solid poly (*N*-vinyl-2-pyrrolidone)(PVP) matrix undergo rapid reversible photoreductions in the air, which are clearly recognized by a deep color development ascribable to the formation of viologen radical cations (photochromism).[1,2]

The effect of the introduction of the methyl group in 2,2′- and 3,3′-positions of the pyridinium rings on the photochromic behavior of benzylviologens is the object of the present study.



2, 2′-Me **1**
3, 3′-Me **2**

Compounds **1** and **2** were prepared from 2,2′- and 3,3′-dimethyl-4,4′-bipyridyls, respectively, by the Menschutkin Reaction.

Figure 1 indicates the absorption spectra of PVP films containing viologens under exposure to UV light. Table 1 also gives data for photochromic behaviors of these films. Two remarkable features are recognized from these results. The absorption maximum for the colored form of **1**, *i.e.* radical cations, in Fig. 1 is located at 605 nm, which is almost the same as those for conventional viologen radical cations without ring substituents,[3] whereas that for **2** is remarkably red-shifted (775 nm) and the photosensitivity of **2** is lower than **1** (Table 1). This may indicate that the methyl substituents at 3 and 3′ positions of **2** hinder sterically the overlappings of the π-orbitals of the pyridine rings of viologen. The reason of the red-shift is unknown at present time, although the shape of curve III in Fig. 1 is somewhat different from II, which is a typical curve for viologen radical cation.[3] Another feature is that, in the absorption spectrum of the colored form of **1** (II in Fig. 1), no peaks for aggregated forms are recognized, whereas for conventional benzyl viologen dibromide (I) a distinct peak for the aggregated forms (570 nm)[3] is seen under the same film-forming conditions, there by indicating that the presence of 2,2′-methyl groups hinders the aggregation of viologen radical cations to a significant extent.

Accordingly, it is concluded that the introduction of simple methyl groups on the pyridinium rings of viologen dications brings about marked effects on the photochromic behavior in PVP matrix.

TABLE 1. PHOTOCHROMIC BEHAVIORS OF COMPOUNDS **1** AND **2** IN PVP MATRIX

Viologen	Irradiation[a] time/s	Absorption peak/nm	Absorbance[b] /mm^{-1}	Half-recovery[c] /min
Benzyl viologen dibromide	30	610	4.82	30

a) At a distance of 10 cm from a 75W Hg lamp. b) Reduced to 1 mm of film thickness. c) Recoveries in the dark were complete for all films. d) Peak for aggregate.

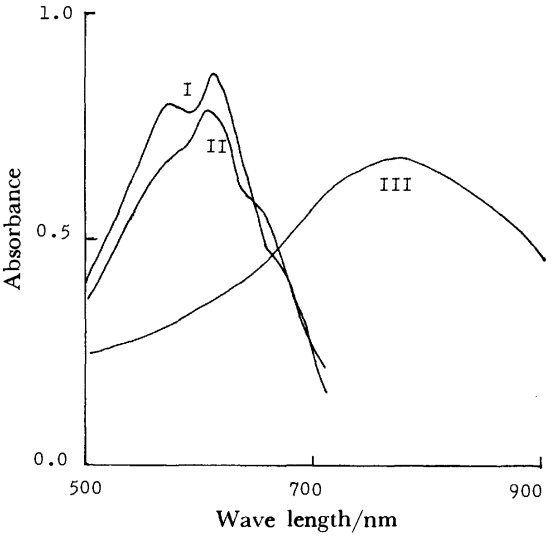

Fig. 1. Color development of viologens in PVP matrix under exposure to UV light.
I: Benzyl viologen dibromide, II: compound **1**, III: compound **2**.
Irradiations of films were carried out at a distance of 10 cm from a 75W Hg lamp. Irradiation times were 30, 30, and 60 s for I, II, and III, respectively.

Experimental

Infrared, ^{1}H NMR, and mass spectra were recorded on a Hitachi 215 spectrophotometer, a JNM-PMX 60 spectrometer, and Hitachi RMU-6 spectrometer, respectively, under standard conditions. Elemental analyses were carried out with a Perkin-Elmer 250 instrument.

2,2′-Dimethyl-4,4′-bipyridyl. A mixture of α-picoline (81 g, 0.87 mol) and sodium metal (1.0 g, 0.043 mol) was first stirred at 20 °C for 48 h with exclusion of moisture and then

kept at 115 °C for 16 h. Oxygen was then bubbled through the mixture kept at 90 °C until the initial dark color disappeared (15 h). The reaction mixture was distilled to remove excess picoline, the residue was crushed to powder with addition of ether (50 ml), and water (2 ml) was added, followed by stirring for 10 min. Ether extraction was then made and the organic layer was dried over anhydrous sodium sulfate, followed by evaporation *in vacuo*. An excess of concd hydrochloric acid was added, the mixture was evaporated, and an equal volume of ethanol was added to the residue. Upon cooling in a refrigerator overnight, the resulting precipitate was filtered and washed with ethanol. Isolation of the product was done by dissolving the precipitate in water (10 ml) and then adding 1 M sodium hydroxide (1 M=1 mol dm^{-3}) solution (10 ml) and ether (50 ml) to effect extraction. The organic layer was washed with water, dried over anhydrous sodium sulfate, and evaporated *in vacuo*. The residue was recrystallized from benzene–hexane to afford crystals of mp 74—75 °C in 2% yield: Found: C, 78.24; H, 6.69; H, 15.07%. Calcd for $C_{12}H_{12}N_2$: C, 78.23; H, 6.57; N, 15.20%. IR (KBr) 3050 (aromatic), 3000—2900 (Me) cm^{-1}. NMR ($CDCl_3$) δ=2.6 (s, 6H, Me), 7.4 (d, 4H, pyridyl), 8.6 (d, 2H, pyridyl). MS (rel. intensity) 185 (M^+, 100).

3,3′-Dimethyl-4,4′-bipyridyl. The same procedure as that for the 2,2′-isomer was employed using β-picoline instead of the α-isomer to afford crystals of mp 120—122 °C in 2% yield: Found: C, 78.17; H, 6.63; N, 15.19%. Calcd for $C_{12}H_{12}N_2$: C, 78.23; H, 6.57; N, 15.20%. IR (KBr) 3050 (aromatic), 3000—2900 (Me) cm^{-1}. NMR ($CDCl_3$) δ=2.1 (s, 6H, Me), 7.0 (d, 2H, pyridyl), 8.6 (d, 4H, pyridyl). MS (rel. intensity) 185 (M^+, 100).

1,1′-Dibenzyl-2,2′-dimethyl-4,4′-bipyridylium Dibromide (1). A solution of 2,2′-dimethyl-4,4′-bipyridyl (2.0 g, 13 mmol) and benzyl bromide (3.9 g, 26 mmol) in anhydrous acetonitrile (40 ml) was heated under reflux for 15 h. The resulting precipitate was filtered and recrystallized from methanol–ether to afford a pale yellow crystals in 87% yield. Found: C, 59.46; H, 4.95; N, 5.20%. Calcd for $C_{26}H_{26}N_2Br_2$: C, 59.33; H, 4.98; N, 5.32%. IR (KBr) 3050 (aromatic), 3000—2900 (CH_3, CH_2) cm^{-1}. NMR (D_2O) δ=3.0 (s, 6H, Me), 6.0 (4H, CH_2), 7.6 (m, 10H, Ph), 8.5 (t, 4H, pyridylium), 9.1 (d, 2H, pyridylium).

1,1′-Dibenzyl-3,3′-dimethyl-4,4′-bipyridylium Dibromide (2). The same procedure as that for **1** was employed using 3,3′-dimethyl-4,4′-bipyridyl instead of the 2,2′-isomer to afford a colorless crystalline powder in 87% yield. Found: C, 59.38; H, 4.89; N, 5.34%. Calcd for $C_{26}H_{26}N_2Br_2$: C, 59.33; H, 4.98; N, 5.32%. IR (KBr) 3050 (aromatic), 3000—2900 (CH_3, CH_2) cm^{-1}. NMR (D_2O) δ=2.3 (s, 6H, Me), 5.9 (s, 4H, CH_2), 7.6 (s, 10H, Ph), 8.1 (m, 2H, pyridylium), 9.0 (d, 4H, pyridylium).

Measurement of Photochromism. *(1) Film Preparation*: A solution of viologen (20 mg) and PVP (500 mg; MW 10000) in water (5 ml) was spread over a glass plate so as to cover an area of 1.2×2 cm. The glass plate was then stored in a desiccator ($CaCl_2$) overnight to make a transparent and almost colorless film. The films thus prepared were stored in a desiccator over saturated aqueous NaBr (RH, 58% at 20 °C) except for exposure to light and measurements of absorption spectra.

(2) UV-irradiation: Films were exposed to light at a distance of 10 cm from a 75 W mercury lamp (Toshiba SHL-100UV-2). Absorption spectra of the irradiated films were measured with a Hitachi 200-10 spectrophotometer. The absorbances thus obtained were reduced to values for 1 mm of film thickness.

The Reaction of Cyclopropenethione with Carbonyl-stabilized Phosphonium Methylides to Yield 2*H*-Pyran-2-thione

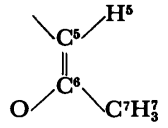
Hiroshi YOSHIDA,* Jyun SHIMIZU, Tsuyoshi OGATA, and Kiyoshi MATSUMOTO†
Department of Applied Chemistry, Faculty of Engineering, Shizuoka University, Hamamatsu 432
†*College of Liberal Arts and Sciences, Kyoto University, Kyoto 606*
(Received April 10, 1985)

Synopsis. The reaction of diphenylcyclopropenethione with carbonyl-stabilized triphenylphosphonium methylides (**2**) to yield 2*H*-pyran-2-thiones was studied. It was clarified that electron-releasing substituents increased the reactivity of **2**.

The reactions of carbonyl-stabilized pyridinium and sulfonium methylides with cyclopropenone or cyclopropenethione to yield 2-pyrone derivatives[1,2] are well known. On the other hand the reaction of diphenylcyclopropenone with acyl- or alkoxycarbonyl-stabilized phosphonium methylides yields either 2-pyrone or methylenecyclopropene *via* (3+3)-cycloaddition or Wittig reaction.[1,2] However to our knowledge none of the reaction of diphenylcyclopropenethione (**1**) with carbonyl-stabilized phosphonium methylides (**2**) has been investigated.

In the continuation of our studies on the reaction of cyclopropenone with S-, N-, and P-ylides and imides,[3] we extended our attention to the use of carbonyl-stabilized phosphonium methylides (**2**) which are stable to air and moisture.

Methylides **2** were prepared according to the known methods.[4] Since **1** dimerizes on irradiation,[5] it was treated in the dark. Although a benzene solution of **1** and 1-(triphenylphosphoranylidene)-2-propanone **2a** at reflux gave only a tarry mixture, the reaction at room temperature for 3 d yielded a brown crystalline mass (51%) together with triphenylphosphine in 84% yield after TLC purification. The structure of the product was confirmed to be 3,4-diphenyl-6-methyl-2*H*-pyran-2-thione **3a** on the basis of IR ($\nu_{C=S}$ 1130 cm^{-1}) and NMR spectroscopic studies. The ^{13}C-NMR spectrum of **3a** gave a doublet at δ=111.1 (C^5, $J_{C^5H^5}$=170 Hz) and a quartet at δ=20.2 (C^7, $J_{C^7H^7}$=140 Hz) with long range couplings $J_{C^7H^5}$=3, $J_{C^5H^7}$=4, and $J_{C^5H^5 \text{ and } H^7}$=6 Hz), indicating the presence of the framework:



A similar treatment of the carbonyl-stabilized methylides **2b—d** with **1** afforded 2*H*-pyran-2-thiones **3b—d**. The methylides substituted with aroyl groups **2e—i** were less reactive toward **1** than **2a—d**. Thus, the ylides **2e—i** reacted with **1** at toluene reflux to give **3e—i** in moderate yields (Table 1 and 2). The known 2*H*-pyron-2-thione **3f** was obtained in a higher yield than the previously reported (71%).[2] Physical properties are collected in Table 2.

As is evident from the Table 1, increasing the electron releasing power of the substituent R increases the reactivity of **2**. The result correlates well with the reported mechanism for the reaction of cyclopropenone with S- and P-ylides.[1] Thus, the formation of 2*H*-pyran-2-thiones can be explained either by an initial attack on the thiocarbonyl group of **1** by the betaine oxygen atom of **2** or a Michael type addition of the methine of **2** to the C=C bond of **1** followed by isomerization to yield the product.

In conclusion, phosphonium methylides **2** have proven to be convenient reagents for the preparation of 2*H*-pyran-2-thiones in moderate yields.

2 were obtained by the known methods.[4]

Reaction of 1 with 2. An equimolar mixture of **1** and **2** (**2a—d** in benzene at room temperature and **2e—i** in toluene at reflux temperature) was allowed to react in the dark. The disappearance of **1** was checked by TLC at suitable time intervals. Then, the solvent was removed *in vacuo* to give a crystalline mass. TLC separation over silica gel afforded **3** and triphenylphosphine. Yields and physical properties of **3a—i** are summarized in Tables 1 and 2.

^{13}C-NMR spectroscopic data. **3a**($CDCl_3$) δ=20.2 (q, Me), 111.1 (d, C^5), 127.5 (d), 127.9 (d), 128.0 (d), 128.4 (d), 128.7 (d), 130.6 (d), 136.1 (s), 136.8 (s), 137.0 (s), 147.9 (s), 165.8 (s, C^6), and 198.0 (s, C^2). **3f** ($CDCl_3$) δ=108.5 (d, C^5), 125.7 (d), 127.5 (d), 127.9 (d), 128.1 (s), 128.4 (d), 128.7 (d), 129.0 (d), 130.4 (s), 130.6 (d), 131.3 (d), 136.8 (s), 137.0 (s), 137.4 (s), 147.7 (s), 164.4 (s, C^6), and 196.9 (s, C^2).

Rapid Spectrophotometric Determination of Chromium(III) with 1-(2-Thiazolylazo)-2-naphthol in Presence of Surfactant

Gogineni V. RATHAIAH and Muppalla C. ESHWAR*
Department of Chemistry, Indian Institute of Technology, Bombay-400 076, India
(Received May 7, 1984)

Synopsis. Chromium(III) reacts with 1-(2-thiazolylazo)-2-naphthol at 80—95 °C in acid media (pH 5.7), in presence of benzoate and sodium dodecyl sulfate. Presence of surfactant increases sensitivity of the complex and reduces heating time to 5 min, thus giving rise to perhaps the most rapid method for absorptiometric determination of chromium(III). The 1:1 complex obeys Beer's law for 0.2 to 2.4 μg of Cr(III) per ml, has molar absorptivity and Sandell sensitivity of 1.46×10^4 dm^3 mol^{-1} cm^{-1} and 3.5 ng cm^{-2} respectively, at 575 nm.

Among various pyridylazo and thiazolylazo derivatives, 1-(2-pyridylazo)-2-naphthol (PAN),[1] 4-(2-pyridylazo)resorcinol (PAR),[2] 4-(2-thiazolylazo)resorcinol (TAR)[3] have been reported for spectrophotometric determination of chromium(III). These methods require 45, 35, and 45 min of heating time respectively, at elevated temperatures. The methods reported by Yotsuyanagi *et al.*[4] Yamamoto[5] with PAR require 130 and 20 min of heating respectively, and the latter method employs hydrogen peroxide to oxidise Cr(III) to Cr(VI). Sodium benzoate has been reported to exert catalytic influence in reducing the heating time for chromium(III)-EDTA reaction.[6] Surfactants find increased application in studies of metal-ligand complexes due to enhanced sensitivity obtained. Hence, the reaction between chromium(III) and 1-(2-thiazolylazo)-2-naphthol (TAN) has been studied in presence of surfactants and benzoate.

Experimental

Apparatus and Reagents. A Spectromom 204 spectrophotometer with matched 10 mm cells was used for all absorbance measurements. The absorption spectra were recorded on a Varian Superscan 3 UV-Visible spectrophotometer. For pH measurements an EC-pH meter (Model 822) was used.

1.923 g of chromium nitrate was dissolved in 250 ml of 2% nitric acid, the solution standardised titrimetrically[7] and diluted as required. A 0.2% (w/v) methanolic solution of TAN was prepared from 1-(2-thiazolylazo)-2-naphthol (Fluka A.G. purum). A buffer solution of pH 5.7 was prepared from 0.5 mol dm^{-3} solutions of sodium benzoate (dissolved in warm water and cooled) and benzoic acid. A 5% (w/v) solution of sodium dodecyl sulfate was prepared with hot water and cooled to room temperature.

General Procedure. An aliquot of solution containing <60 μg of chromium(III) was taken in a 25 ml volumetric flask, added 5 ml of buffer solution, 4 ml of SDS solution and 3 ml of TAN solution. The reaction mixture was heated on a water bath for 5 min around 90 °C, flask cooled to room temperature and contents diluted to 25 ml. The absorbance of the complex was measured at 575 nm against a reagent blank, prepared under identical conditions.

Results and Discussion

Due to inert nature of $[Cr(H_2O)_6]^{3+}$, the reaction between chromium(III) and TAN at room temperature required 24 and 4 h in presence of acetate and benzoate respectively, maximum absorbance being attained in 50% solutions of methanol or *t*-butyl alcohol. Eventhough ionic surfactants dissolved the sparingly soluble complex, it was still necessary to wait for very long intervals of time. For example, in presence of SDS, maximum absorbance was reached only after 38 and 8 h in presence of acetate and benzoate respectively. Hence, the reaction was studied at elevated temperatures in presence of SDS, acetate and benzoate.

Effect of Heating. When the reaction mixture was heated to different temperatures, from 40 to 100 °C, maximum absorbance was observed on heating at ≥80 °C. Hence, reaction mixture was heated at 90 °C.

Complications arose when the time of heating was varied. When the reaction was carried out with 1 ml of 0.1% TAN, time required for complexation was reduced to 30 and 10 min in presence of acetate and benzoate respectively, the resulting complex requiring 50% methanol or *t*-butyl alcohol for dissolution. On further addition of TAN, the complex did not dissolve in any of the water-miscible solvents, but was soluble in some immiscible solvents (max. absorbance in 1-butanol). In latter case, complexation required heating for 60 and 40 min in presence of acetate and benzoate respectively and even then results were not satisfactorily reproducible. However, addition of SDS resulted, besides dissolution of the complex, in a further decrease in reaction time to 4 min at 90 °C both in presence and absence of acetate or benzoate. Hence, reactants were heated for 5 min at 90 °C.

Effect of Sodium Dodecyl Sulfate. On addition of 1 to 8 ml of 5% SDS at least 2 ml of SDS was required for dissolution of the complex, and absorbance remained uneffected with higher volumes. Hence, 4 ml of SDS solution was employed in all studies.

Effect of pH and Benzoate. pH of the solution containing 40 μg of Cr(III) and 4 ml of SDS was varied from 3.0 to 8.0, and maximum absorbance was observed in the pH range 5.4 to 6.2 (Fig. 1, curve a). Hense, pH of 5.7 was maintained in all studies. When attempts were made to maintain the pH with various buffers, only acetate and benzoate buffers were found to be satisfactory and an increase in their concentration resulted in an increase in absorbance of the complex. Maximum absorbance was observed on addition of 1 to 8 ml of 0.5 mol dm^{-3} solutions of benzoate, while further addition of benzoate resulted in a decrease in absorbance. Studies with acetate of different concentrations resulted in lower absorbance. Hence, 5 ml of benzoate buffer was employed in all studies. The increase in sensitivity caused by benzoate may be seen from Fig. 1, curve b, which shows the effect of pH on absorbance in presence of 5 ml of 0.5 mol

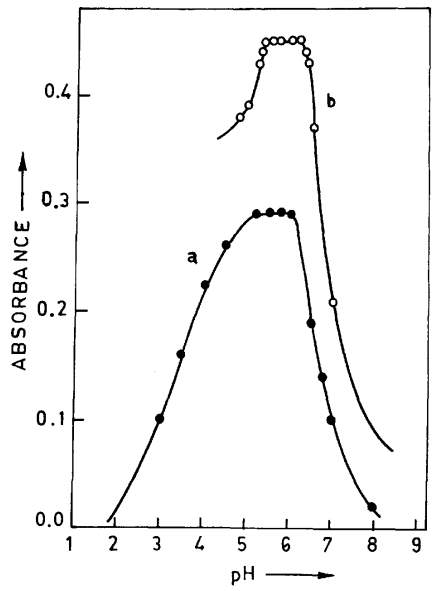

Fig. 1. Effect of pH on Absorbance. See the text for a and b.

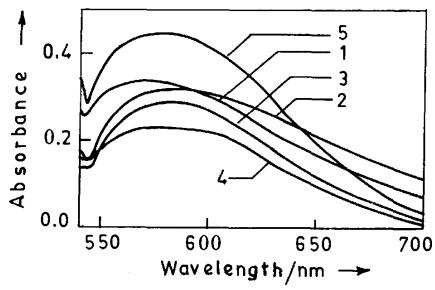

Fig. 2. Absorptin Spectra.
Curves 1, 2, 3, 4, and 5 are as in Table 1 [Cr(III)]=3.077×10 mol dm^{-3}; [TAN]=9.4×10^{-4} mol dm^{-3}; SDS=0.8%; [Benzoate]=[Acetate]=0.1 mol dm^{-3}.

dm^{-3} benzoate.

Effect of Reagent Concentration. Amount of reagent (0.1% TAN) was varied from 0.25 to 8 ml and maximum absorbance observed with ≥5.0 ml. Hence, 3.0 ml of 0.2% TAN was employed for all studies.

Absorption Spectra. Figure 2 gives absorption spectra of different systems *vs.* appropriate reagent blank. Since the complex formed in presence of SDS and benzoate exhibited maximum sensitivity (Table 1) at 575—580 nm, all measurements were made at 575 nm. Reagent blank for all systems exhibited maxium absorbance at 490 nm. All systems were heated for 5 min.

Composition. Composition of the complex established by Job's continuous variation method and mole ratio method, was found to be 1:1, metal to ligand.

Beer's Law, Sensitivity, and Stability. The Cr(III)-TAN-benzoate-SDS complex obeyed Beer's law in the concentration range 5 to 60 μg of chromium(III) per 25 ml. The apparent molar absorptivity of the complex, calculated from Beer's law plot, was 1.46×10^4 dm^3 mol^{-1} cm^{-1} and Sandell sensitivity 3.5 ng cm^{-2}. Table 1 presents sensitivity of complexes obtained by various systems. The complex was found to be stable for 24 h.

Table 1. Sensitivity of the complexes

Sr. No.	Complex	λ_{max}/nm	Sensitivity ng cm^{-2}	ε 10^4 dm^3 mol^{-1} cm^{-1}
1	Cr(III)+TAN+ acetate[a)]	565	4.7	1.09
2	Cr(III)+TAN+ benzoate[a)]	580—590	5.0	1.04
3	Cr(III)+TAN+ SDS	580	5.5	0.95
4	Cr(III)+TAN+ SDS+acetate	580	6.9	0.75
5	Cr(III)+TAN+ SDS+benzoate	575—580	3.5	1.46

a) In 50% *t*-butyl alcohol.

Effect of Diverse Ions. Effect of various ions, usually associated with chromium(III), was studied in the determination of 40 μg of Cr(III) per 25 ml. $EDTA^{4-}$ caused negative interference, while positive interference was shown by Fe(II), Ni(II), Zn(II), and Bi(III) in all proportions. Tolerance limits (in μg) of various ions are: Cl^- Br^-, I^-, 10000; Mg(II) 2500; Ca(II), thiourea, $NH_2OH \cdot HCl$, $N_2H_4H_2SO_4$ 2000; Pt(IV) 1500; Sr(II), Ba(II), Th(IV), CN^- 1000; SCN^- 750; Be(II), Mo(VI), $S_2O_3^{2-}$ 500; Au(III), W(VI), PO_4^{3-} 250; Mn(II), V(V) 200; tartrate, oxalate, Ag(I), Hg(II), Sc(III), Zr(IV), Cr(VI) 100; Pd(II), Ru(III), V(IV) 50; citrate, Co(II), Pb(II), Fe(III), Y(III), Ce(III), Ga(III), Hf(IV), Sb(III), U(VI) 25; In(III) Rh(III) 10. Fluoride was employed to mask Be(II), Sc(III), Zr(IV), and Th(IV), whereas CN^- was employed to mask Mn(II), Co(II), Cu(II), Hg(II), and Fe(III).

Precision and Accuracy. Relative standard deivation and relative mean error, calculated from ten repeat determinations, were found to be ±0.41% and ±0.72% respectively.

Application to Analysis of High Speed Steel. 0.2 g of high speed steel was treated with 15 ml of concd HCl and 5 ml of concd HNO_3, the precipitated tungstic acid filtered off, and filtrate diluted to 100 ml. An aliquot of this was acidified with HCl to 3.5 mol dm^{-3} and iron removed by extraction with mesityl oxide.[8)] Aqueous layer was evaporated to dryness, dissolved in water, pH adjusted to 5.7 and chromium content determined as described in general procedure. From duplicate analysis, amount of chromium was found to be 3.9 and 3.94% against theoretical value of 4.0%. Other constituents of alloy are W=18%, V=1.0% and rest iron.

Synthesis of New Heterocycles: Condensation of 2-Methyl-4*H*-naphth-[1,2-*d*][1,3]oxazin-4-one with Schiff Bases and Formation of 3-Aryl-2-styrylbenzo[*h*]quinazolin-4(3*H*)-ones

Mandala Satyanarayana REDDY and Chengalvala Venkata RATNAM*
Department of Chemistry, Osmania University, Hyderabad 500 007, India
(Received April 2, 1984)

Synopsis. Condensation of 2-Methyl-4*H*-naphth[1,2-*d*][1,3]oxazin-4-one (**2**) with Schiff bases (**3**) in acetic acid has resulted in 3-aryl-2-styrylbenzo[*h*]quinazolin-4(3*H*)-ones (**4**), characterized by spectral and analytical methods.

As a part of our work on the role of Schiff bases in heterocyclizations[1-8] and with a view to prepare hitherto unreported benzo[*h*]quinazolinones, the condensation of 2-methyl-4*H*-naphth[1,2-*d*][1,3]-oxazin-4-one with Schiff bases has been undertaken and the results are presented below.

The reaction of 1-amino-2-naphthalenecarboxylic acid (**1**)[9] with acetic anhydride under refluxing conditions yielded a colourless crystalline compound with mp 178°, identified as 2-methyl-4*H*-naphth[1,2-*d*][1,3]-oxazin-4-one on the basis of spectral and analytical values. Unlike the lactone bond of 2-methyl-3,1-benzoxazin-4-one,[10] which is vulnerable and is readily hydrolyzed to *N*-acetylanthranilic acid in contact with traces of moisture or on prolonged exposure to atmosphere, the lactone bond of **2** was found to be quite stable.

Condensation of compound **2** with an equimolar proportion of *N*-(*p*-methoxybenzylidene)aniline (**3**, Ar=*p*-methoxyphenyl; Ar′=phenyl) in acetic acid medium at steam bath temperature resulted in a yellow crystalline compound, mp 186° in high yield, characterized on the basis of its microanalytical, mass, IR, and ^{1}H-NMR spectral data as 2-(*p*-methoxystyryl)-3-phenylbenzo[*h*]quinazolin-4(3*H*)-one [**4b**; MS: M^+ at *m/z* 404, IR (KBr): $\nu_{C=O}$ at 1670 cm^{-1}, ^{1}H-NMR ($CDCl_3$): δ 3.7 (*s*, 3H, OCH_3) 6.3 (*d*, 1H, H-7, $J_{7,8}$=15 Hz), 6.7—8.0 (*m*, 14H, H-2 to H-6, H-9 to H-12 and five protons of 3-phenyl), 8.2 (*d*, 1H, H-8, $J_{8,7}$=15 Hz) and 9.1—9.3 (*m*, 1H, H-1)]. The *J* value (15 Hz) of the two olefinic protons (H-7 and H-8) suggested the preferred trans-geometry of the exocyclic double bond. Thus, it is apparent that **4b** is formed by styrylation of 2-methyl group and replacement of ring oxygen in **2** by *N*-phenyl moiety in one step.

This reaction has been extended to eleven other Schiff bases and the product obtained in each case has been characterized as corresponding 3-aryl-2-styrylbenzo[*h*]-quinazolin-4(3*H*)-one (**4a**—l, Scheme 1, Table 1) by analogy, spectral and microanalytical data.

To understand the mechanism of formation of **4**, the reactions of **2** with *p*-methoxybenzaldehyde and separately with aniline have been carried out under identical conditions of the Schiff base reaction. The former reaction resulted in the formation of 1-acetamido-2-naphthalenecarboxylic acid (**5**)[11] characterized by comparing with an authentic sample prepared from 1-amino-2-naphthalenecarboxylic acid and acetic anhydride and spectral data. Compound **5** must have been formed by the addition of elements of water obviously from solvent to the oxazinone ring followed by ring opening.

Oxazinone **2** with aniline gave a compound with mp 192°, characterized as 2-methyl-3-phenylbenzo[*h*]-quinazolin-4(3*H*)-one(**6**) by spectral data [MS: M^+ at *m/z* 286; IR (KBr): $\nu_{C=O}$ at 1675 cm^{-1}, ^{1}H-NMR ($CDCl_3$+DMSO-d_6): δ 2.3 (*s*, 3H, CH_3), 7.4—8.2 (*m*, 9H, aromatic) and 9.0 (*m*, 1H, H_a)] and microanalytical data. Reaction of **6** with *p*-methoxybenzaldehyde in hot acetic acid did not result in the styrylated product **4b**. However, **6** could be converted into **4b** on treatment with **3** (Ar=*p*-methoxyphenyl, Ar′=phenyl) under identical conditions. This result emphasises the superiority of Schiff bases over aldehydes in the styrylation of an active methyl group. Facile styrylation with Schiff base may be possibly due to better leaving ability of the arylamino moiety compared to hydroxyl, from the possible 2-[2-aryl-2-(arylamino)-ethyl]-3-phenyl benzo[*h*]quinazolin-4(3*H*)-one intermediate (**7**).

Based on these results, the formation of **4** from **2** and Schiff base (**3**) is explained on the basis of initial nucleophilic attack by active methyl group through the enamine tautomer. Its attack on the electrophilic carbon of azomethine function and subsequent transformations were described earlier.[7]

4h, **4j**, and **4k**; MS: M^+ at *m/z*: 408, 418, and 402 respectively.

Experimental

Melting points are uncorrected. IR spectra were recorded on a Perkin-Elmer infracord 377 Spectrophotometer, ^{1}H-NMR spectra on Varian A-60D instrument using TMS as internal standard and mass spectra on a Perkin-Elmer Hitachi RMU-6L instrument.

1-Amino-2-naphthalenecarboxylic Acid (1): An ethanolic solution of potassium hydroxide (0.5 mol in 56 ml) was added to a boiling solution of 2-methyl-1-nitronaphthalene[12] (0.21 mol in 100 ml) during a period of 6 h and the resulting solution heated under reflux for a further period of 6 h. The mixture was steam-distilled to remove ethanol and then filtered. The filtrate was brought to the neutralization point first with strong acetic acid and then with dilute acetic acid. At first there comes down brown, flocculent precipitates which was discarded. The filtrate on further acidification gave light brown precipitates which was filtered after 2 h. The crude amino acid was purified by repeated dissolution in sodium hydroxide and precipitation with acetic acid, mp 198—199°, yield 10.4 g (26%).

2-Methyl-4H-naphth[1,2-d][1,3]oxazin-4-one (2): A mixture of 1-amino-2-naphthalenecarboxylic acid (3.74 g, 0.02 mol) and acetic anhydride (10 ml) was refluxed for 4 h, the resulting solution concentrated to one third and allowed to stand. The compound that separated was filtered, treated with charcoal and recrystallized from pet. ether (60—80°)-benzene, mp 178°, [MS: M^+ at *m/e* 211, IR (KBr): $\nu_{C=O}$ at 1745 cm^{-1}, ^{1}H-NMR ($CDCl_3$): δ 2.55 (*s*, 3H, CH_3) 7.5—8.2 (*m*, 5H, aromatic) and 8.7—8.9 (*m*, 1H, H_a); Found: C, 73.25; H, 4.32; N, 6.68%; $C_{13}H_9NO_2$ requires C, 73.93; H, 4.26; N, 6.64%].

Condensation of 2 with Schiff Bases (3): *General Procedure.* To a solution of **2** (2 m mol) in acetic acid (2 ml) was added the required Schiff base (**3**; 2 m mol) and the reaction mixture heated on a steam bath for half an hour and left aside for few minutes. The crystalline compound that separated in each case was filtered, washed with a few drops of methanol and recrystallized from appropriate solvent. The characterization data of benzo[*h*]quinazolinones (**4**) thus prepared are given in Table 1.

The acetic acid filtrate on dilution with water and processing the resulting solid gave additional quantities of **4**.

One of the authors (MSR) is thankful to the UGC, New Delhi, India for the award of a teacher fellowship.

Triplet-Triplet Energy Transfer between the Same Molecular Species

Kunio MASUMO† and Nozomu EBARA*
Department of Chemistry, College of Arts and Sciences, The University of Tokyo, Komaba, Meguro-ku, Tokyo 153
(Received January 14, 1985)

A method for obtaining the rate constants for triplet-triplet energy transfer between the same molecular species is presented. It is an improvement on a previously proposed method and comprises an analysis of the phosphorescence decay curve of a mixture of an organic substance and its deuterated homolog. It has been found that the new method gives a good fit to experimental decay curves at 77 and 4.2 K. It was also found that the critical transfer distance between similar molecules is usually smaller than that between differrent molecules.

So far, very few investigations have been reported on the triplet-triplet energy transfer between the same molecular species. Photoselection[1] (or magneto-photoselection[2]), which consists of the measurement of the concentration depolarization of phosphorescence, has been the only investigative method until 1975. These methods, however, had a fatal drawback in that results could not evade the effect of a singlet-singlet transfer whenever it took place.[3]

The isotopic mixture method[4,5] and the ODMR method[6] were developed by one of the authors. The former method was based on the fact that some kinds of organic molecules (H) and their deuterated homologs (D) are quite similar in electronic structures, but are quite different regarding their phosphorescence lifetimes. It consists of analyzing the phosphorescence decay profile of a mixed solution of H and D, where the decay form tends to deviate from a mere superposition of each decay curve when an energy transfer takes place. This method is almost free from the effects of a singlet-singlet transfer since the extent of the initial triplet population is not important in the treatment. However, the analysis is inevitably crude due to the presence of a back transfer which precludes an exact statistical treatment. The latter method makes use of the fact that spin angular momentum must be conserved during an energy transfer. However, the spin-lattice relaxation taking place in a glassy solvent greatly affected the population of each spin sublevel, making a quantitative discussion almost impossible.

The present paper concerns an improvement in the isotopic-mixture method. First, in order to completely exclude any effect due to a singlet-singlet transfer, benzophenone was used as a sensitizer for initial pumping. Second, the experimental decay curves were analyzed by a computer-simulation method, rather than by seeking a solution to the rate equations in a closed form. Thus a more exact statistical treatment is now possible. Moreover, we have taken into account not only the D→H and H→D energy transfers, but also the D→D transfer. The last process may increase the possibility that the exitation on D happens to encounter an H molecule[7,8]. Inhomogeneous widths of the T_1 levels were also taken into consideration in order to account for the temperature dependence of energy-transfer efficiency.

Experimental

The samples used were naphthalene, phenanthrene, and biphenyl (H) together with their perdeuterated homologs (D). Equal molar amounts of H and D were dissolved in methyl methacrylate and deoxygenated by several freeze-thaw cycles. The sample solutions were polymerized at 100 °C for 48 h without an initiator and then annealed at 40 °C for 24 h. The initial concentration was 0.20, 0.15, 0.10 or 0.075 mol dm^{-3} for each component. In each case, benzophenone (0.20 mol dm^{-3}) was added as a sensitizer. The volume contraction according to polymerization was 1/1.27 and contraction by cooling was only a few percent; hence the latter effect was disregarded.

Samples were irradiated at 340 or 350 nm for 20 s using two shutters to excite only the benzophenone, and the total decays of the ensuing phosphorescence, containing H and D components simultaneously, were observed at 77 and 4.2 K. The output signals were accumulated 10—20 times to improve the S/N ratio.

Simulation

Simulation was carried out upon the following assumptions.

1) Solute molecules are randomly distributed in poly(methyl methacrylate) (PMMA); thus, the distribution of the nearest-neighbor distance (R) is[9]

$$\rho(R) = \rho(R, C) = 4\pi CR^2 \exp(-4\pi CR^3/3), \quad (1)$$

where C is the concentration of the solute.

2) The distribution of the mutual orientation is also random; thus, the effect of the orientation on the transfer rate can be ignored.

3) Energy is transferred only to the nearest-neighbor molecule.

4) The sensitization efficiency of benzophenone is the same for H and D.

5) The environment of each molecule was assumed

† Present adress: Asahi Glass Co., Ltd., Research and Development Division; Kanagawa-ku, Yokohama 221.

to be statistically equivalent; that is, a correlation of environments for donor and acceptor molecules was disregarded.[7]

6) The rate constant for energy transfer can be expressed as a product of two terms,

$$k_{ET}(R,\ \Delta E) = k_1(R)\cdot k_2(\Delta E) \tag{2}$$

$k_1(R)$ is approximated[10] as

$$k_1(R) = k_D\exp(\gamma(1-R/R_0)), \tag{3}$$

where k_D is the phosphorescence decay constant of D and γ and R_0 (critical transfer distance) are parameters to be determined. The use of k_D is perfectly arbitrary. k_H (decay constant of H) or any other reference value may be employed instead, whereupon the critical distance changes according to the reference value. However, because of the strong R-dependent nature of the transfer rate, the obtained values of γ and R_0 are not very sensitive to the reference value. $k_2(\Delta E)$ is a function of the triplet energy difference in a donor (excited molecule)-acceptor (nearest-neighbor molecule) pair, $\Delta E=E_{donor}-E_{acceptor}$. It does not depend on whether the molecules are H or D, and can be expressed as

$$\begin{aligned} k_2(\Delta E) &= \exp(\Delta E/kT) && \text{if } \Delta E\leq 0,\\ &1 && \text{if } \Delta E\geq 0. \end{aligned} \tag{4}$$

7) The triplet energy of the solute molecule differs from site to site. Its distribution, $\sigma(E)$, is assumed to follow the spectral form of the 0-0 phosphorescence band (*vide infra*).

Since energy is transferred from molecule to molecule while being dissipated by intramolecular processes, the decay of a D molecule is expressed as

$$f_D(t,\ R,\ \Delta E) = \exp[-(k_D+k_{ET}(R,\ \Delta E))t]. \tag{5}$$

Similarly, the decay of an H molecule is given by

$$f_H(t,\ R,\ \Delta E) = \exp[-(k_H+k_{ET}(R,\ \Delta E))t]. \tag{6}$$

In the following, superfix 0 stands for a group of molecules which are excited by a transfer from benzophenone. Superfix n is for those molecules which are excited by a transfer from group $n-1$.

Decay of the group 0 is

$$f_D^0(t) = \int dR\rho(R) \times \int d\Delta E[\xi_{DD}(\Delta E)+\xi_{DH}(\Delta E)]f_D(t,\ R,\ \Delta E)/2, \tag{7}$$

$$f_H^0(t) = \int dR\rho_D(R)\int d\Delta E\xi_{HD}(\Delta E)f_H(t,\ R,\ \Delta E), \tag{8}$$

where $\xi_{DD}(\Delta E)$, $\xi_{DH}(\Delta E)$, and $\xi_{HD}(\Delta E)$ are the distributions of ΔE for D→D, D→H, and H→D donor-acceptor pairs, respectively, and are

$$\xi_{AB}(\Delta E) = \int \sigma_A(E)\sigma_B(E-\Delta E)dE. \tag{9}$$

$\rho(R)$ is the distribution of the distance to the nearest-neighbor molecule, irrespective of whether it is H or D. $\rho_D(R)$ is the distribution of the distance to the nearest-neighbor D molecule, so that

$$\left.\begin{aligned} \rho(R) &= \rho(R,\ C)\\ \rho_D(R) &= \rho(R,\ C/2) \end{aligned}\right\}, \tag{10}$$

where C is the total concentration. The transfer H→H is disregarded, since the lifetime of H is short; however, it is partly taken into account by using the above ρ_D expression rather than $\rho_D=\rho/2$. We took the arithmetic mean of ξ_{DD} and ξ_{DH} because the probability that the nearest-neighbor molecule is H or D is the same.

Let A^0 be the amount of energy transferred to other molecules in the course of decay (7) and (8), so that

$$A_{DD}^0(t) = \int dR\rho(R) \times \int d\Delta E\xi_{DD}(\Delta E)k_{ET}(R,\ \Delta E)f_D(t,\ R,\ \Delta E)/2, \tag{11}$$

$$A_{DH}^0(t) = \int dR\rho(R) \times \int d\Delta E\xi_{DH}(\Delta E)k_{ET}(R,\ \Delta E)f_D(t,\ R,\ \Delta E)/2, \tag{12}$$

$$A_{HD}^0(t) = \int dR\rho_D(R) \times \int d\Delta E\xi_{HD}(\Delta E)k_{ET}(R,\ \Delta E)f_H(t,\ R,\ \Delta E). \tag{13}$$

In the course of a successive transfer of energy, the decay of group n becomes,

$$f_D^n(t) = [A_{DD}^{n-1}(t) + A_{HD}^{n-1}(t)]*f_D^0(t), \tag{14}$$

$$f_H^n(t) = A_{DH}^{n-1}(t)*f_H^0(t), \tag{15}$$

where

$$A_{DD}^n(t) = [A_{DD}^{n-1}(t) + A_{HD}^{n-1}(t)]*A_{DD}^0(t), \tag{16}$$

$$A_{DH}^n(t) = [A_{DD}^{n-1}(t) + A_{HD}^{n-1}(t)]*A_{DH}^0(t), \tag{17}$$

$$A_{HD}^n(t) = A_{DH}^{n-1}(t)*A_{HD}^0(t). \tag{18}$$

The asterisk * denotes a convolution. The total phosphorescence decay is, then,

$$F(t) = \sum_{n=0}^{\infty}[k_D^r f_D^n(t) + k_H^r f_H^n(t)], \tag{19}$$

where k_D^r and k_H^r are the radiative rate constants of D and H, respectively. Finally, we convolute $F(t)$ with the 20 s square form of the light-sourse intensity $I(t)$

$$G(t) = I(t)*F(t) \tag{20}$$

and then normalize $G(t)$ with respect to the integrated area.

For naphthalene and phenanthrene, the values of

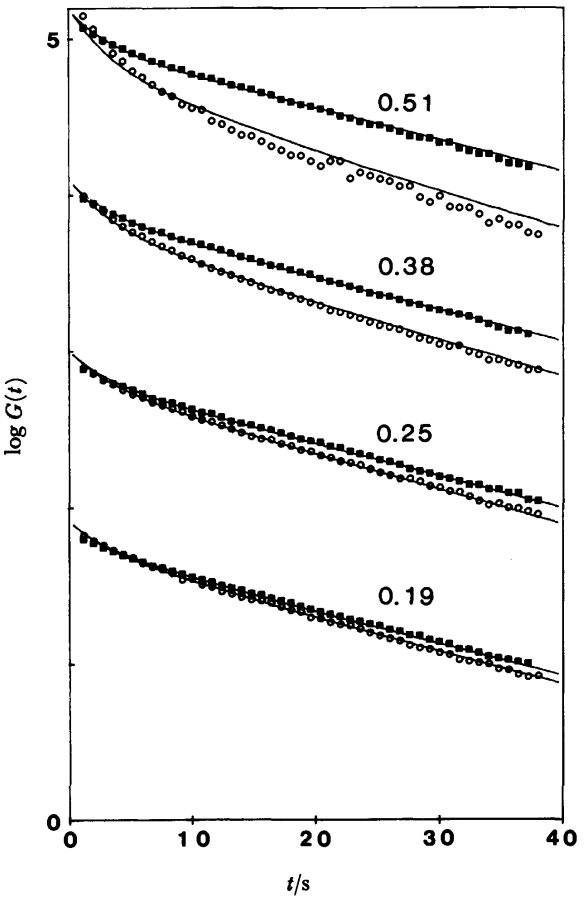

Fig. 1. Decay of naphthalene phosphorescence at 77 K (lower curves) and 4.2 K (upper curves). Total concentrations (mol dm^{-3}) are indicated. Solid lines: calculated ($\gamma=15$, $R_0=13.0$ Å); ○ and ■: experimental.

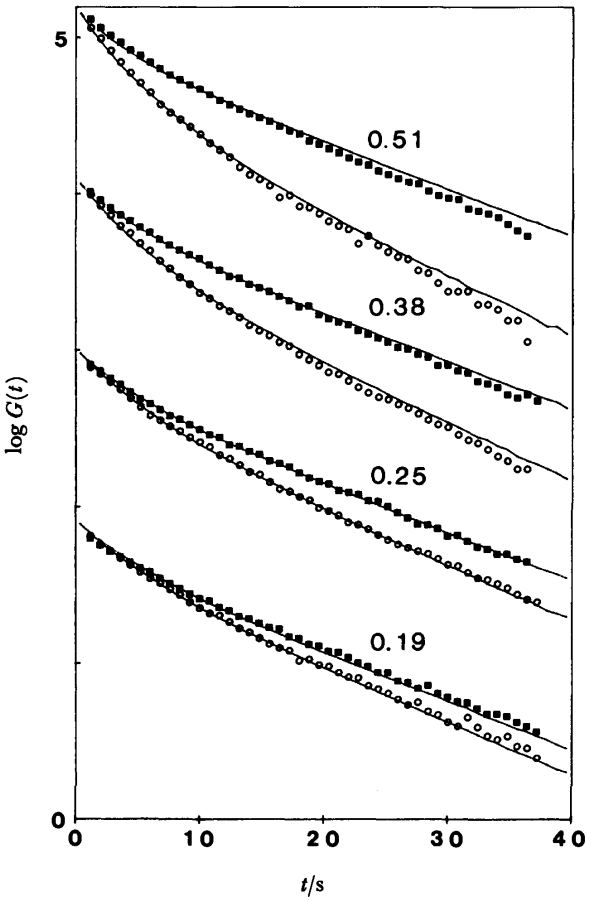

Fig. 2. Decay of phenanthrene phosphorescence at 77 K (lower curves) and 4.2 K (upper curves). Total concentrations (mol dm^{-3}) are indicated. Solid lines: calculated ($\gamma=10$, $R_0=14.5$ Å); ○ and ■: experimental.

Table 1. Phosphorescence lifetimes (s)

Sample	77 K	4.2 K
Naphthalene-d_0	2.3	2.4
Naphthalene-d_8	21.0	21.5
Phenanthrene-d_0	3.3	3.4
Phenanthrene-d_{10}	14.5	14.5
Biphenyl-d_0	3.7	4.4
Biphenyl-d_{10}	10.0	11.2

k_D^r and k_H^r were borrowed from the results of Fischer and Lim[11] (0.0163 s^{-1} and 0.0276 s^{-1} for naphthalene and 0.0215 s^{-1} and 0.0311 s^{-1} for phenanthrene, respectively). Since the values for biphenyl H and D were not available, they were assumed to be equal to each other.

Values of k_H and k_D were measured separately, as displayed in Table 1. They were constant over the whole range of concentrations. For naphthalene and phenanthrene, they were essentially unaffected by the temperature. For biphenyl, on the contrary, both of them increased when the temperature was lowered.

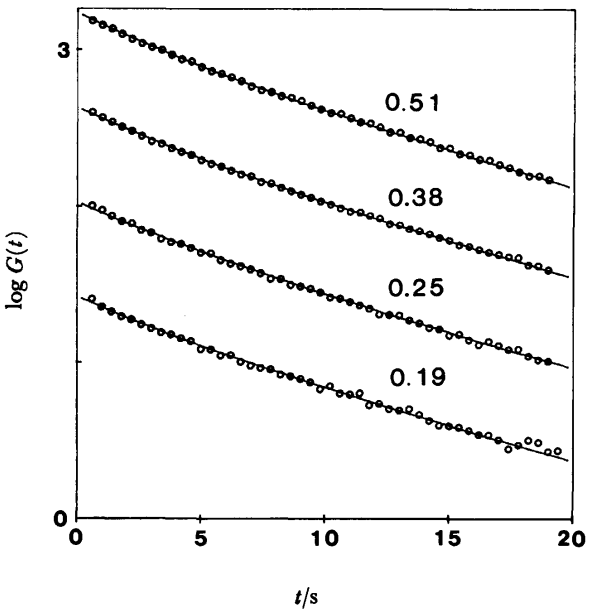

Fig. 3. Decay of biphenyl phosphorescence at 77 K. Total concentrations (mol dm^{-3}) are indicated. Solid lines: calculated ($\gamma=25$, $R_0=8.5$ Å); ○: experimental.

This may be attributed to the structural change which often takes place in labile molecules. Hence, only the curves at 77 K were simulated.

Calculations were carried out up to n=20. The inclusion of higher terms was found to be unnecessary. The results are compared with experiments in Figs. 1—3.

Results and Discussion

Calculations were carrried out by changing γ and R_0 to seek for the best fits to the experimental curves at 77 K. The best fits were obtained by minimizing the square sums of the residuals and, also, by inspecting the uniformity of the distribution of the residuals. Optimal R_0 values are not very sensitive to γ. Changing the latter from 25 to 10 causes a change in the former by only 1.0 Å for naphthalene and no change for phenanthrene (Table 2). A calculation was also carried out by taking account of the exclusion volume for the neighboring molecule within the van der Waals radii, with essentially no effect. This is reasonable since the distribution of R falls off rapidly with decreasing R, whereas the effect of γ has just the reverse trend. However, the distribution of residuals is fairly sensitive to γ; thus, the best values of γ could be obtained and are displayed in Figs. 1—3 and in Table 2.[12]

R_0 of biphenyl is very small. We also measured several donor-acceptor systems, such as carbazole-naphthalene, carbazole-quinoline and carbazole-biphenyl. The values of R_0 were determined to be 16.5, 15.5, and 13.0 Å, respectively. We see that the value for biphenyl is also very small compared to the first two, which are in good agreement with those by Strambini and Galley[13] and by Oginets.[14] Thus, the acceptor property of biphenyl seems to be always poor. Gustav *et al.*[15] have calculated the structure of biphenyl by geometry optimization and have claimed that the molecule is twisted in the ground state by 22.9° about the central bond and is coplanar in the excited singlet and triplet states. If this is the case, the relaxed (planar) triplet biphenyl molecule must transfer its energy to the twisted acceptor molecule in the ground state. This requires an excess energy and renders the transfer less efficient. This may account for the small R_0 value.

It is interesting that the R_0 values for similar molecules are smaller than for different molecules.

Table 2. Values of R_0 (Å)

Sample	γ= 10	15	25	35
Naphthalene	12.5	<u>13.0</u>	13.5	14.0
Phenanthrene	<u>14.5</u>	14.5	14.5	15.0
Biphenyl	8.0	8.5	<u>8.5</u>	9.0

The best values are underlined.

This may reflect a possible requirement that the sum of the Franck-Condon products, corresponding, apart from normalization factors, to the overlap of the S-T absorption spectrum of the acceptor and phosphorescence spectrum of the donor in the treatment of Dexter,[16] should be small due to the small energy difference between the donor molecule and the acceptor molecule.

The fit is somewhat bad for curves of higher concentrations. This may be due to a failure of the assumptions, especially for 5, to hold at high concentrations.

In previous papers,[4,5] the triplet energy difference of H and D had been taken to be equal to the difference of the peak positions of their phosphorescence 0-0 bands; thus only the H→D back transfer had been assumed to be phonon-assisted. If this is true, the phosphorescence decay curves of the mixtures should be steeper at 4.2 K than at 77 K, since transfers to molecules with longer lifetime tend to be inhibited. This contradicted the present experiments and, thus, we have been forced to assume that the phonon-assisted energy transfer takes place in either direction. The phosphorescence spectra of the solutes in PMMA were broad and their band widths did not change even when the temperature was lowered to 4.2 K. Therefore, the widths of the 0-0 bands could be regarded as the inhomogeneous widths of the T_1 levels due to solvation. The Gaussian forms of the bands were regarded to be the distributions functions $\sigma(E)$ of T_1 energies in PMMA. Differences in the peak positions of H and D (that of D is always higher) is 110 cm^{-1} for naphthalene, 60 cm^{-1} for phenanthrene and 110 cm^{-1} for biphenyl. These are smaller than their widths; thus the signs and the values of ΔE differ from site to site and do not depend much on the types of molecules. At 4.2 K, the energy is transferred mainly to sites with lower energies and the effect of temperature is to scramble the transfer sequences. The importance of the energy distribution has recently been stressed with regard to somewhat different aspects of the energy transfer.[17-19]

The values of γ and R_0 obtained from curves at 77 K were used to reproduce curves at 4.2 K. The fits are good, as can be seen from Figs. 1—2; thus, the present method has proven to be of use. In the above-metioned donor-acceptor systems of carbazole-naphthalene, carbazole-quinoline and carbazole-biphenyl, of which the energy differences were larger than their spectral widths, no change was observed in the donor phosphorescence decay curves when the temperature was changed from 77 to 4.2 K. This fact might strongly support our mechanism.

Studies of Collectors. VI.[1] Application of β-Diketone-type Surfactants to Ion Flotation

Yoshifumi KOIDE,* Shuichi KITAOKA, and Kimiho YAMADA
Department of Synthetic Chemistry, Faculty of Engineering, Kumamoto University, Kurokami, Kumamoto 860
(Received February 12, 1985)

β-Diketone-type surfactants(2,4-alkanedione, R_nA) were applied as ion-flotation collectors and as extraction reagents. Fe^{3+}, Ga^{3+}, and Cu^{2+} were floated effectively with R_nA as a 1:1 complex from an acidic solution. From a mixture of metal ions(Fe^{3+}, Ga^{3+}, Cu^{2+}, Zn^{2+}, Pb^{2+}, Cd^{2+}, and Ca^{2+}), the Cu^{2+} was floated selectively at pH 6 by R_8A or $R_{12}A$. Then, the metal ions were extracted with R_nA into a benzene layer as coordination-saturated species at regions of a neutral pH. The order of selectivity at pH 6.0 was $Fe^{3+}>Cu^{2+}>\cdots$. The difference between the properties of R_nA as an ion-flotation collector and as an extraction reagent was explained using the HLB value and the surface activity based on the composition of R_nA-metal complexes. The metal ions and R_nA could be recovered from the scum.

Ion flotation has been examined as a method of collecting specific metal ions.[2] However, there are few ion-flotation collectors which exert the flotation effect by adding a small amount. In a previous paper[3] it was shown that complexane-type surfactants formed floatable complexes with heavy metal ions when the HLB(hydrophilic-liphophilic balance) values of the complexes were 4—14. Also, only a trace amount of surfactants remained in the residual solution. Consequently, the mechanism regarding ion flotation might be the complex formation (stability constant) and the flotation of the complex(HLB). Even if a surfactant shows a similar stability constant, the selective removal of a specific metal ion may be achieved using a chelating agent bearing a long alkyl group to regulate its HLB. However, there are few reports concerning flotation using such a chelating agent (surfactant) and the floatability of surfactant-metal complexes. Therefore, the HLB values of floatable complexes must be confirmed using various surfactants. Surfactants are considered to be excellent extraction reagents since their distribution coefficients are large due to a long alkyl group.[4-6]

The enol form of acetylacetone, known as an extraction reagent, behaves as a bidentate univalent anion and forms a stable metal chelate.[6] In this study, in order to obtain further information about the HLB effects on floatability and selectivity, and to clarify the characteristic properties of ion-flotation collectors and extraction reagents, β-diketone-type surfactants(2,4-alkanediones,R_nA) were prepared and applied to an ion-flotion collector and compared with other extraction reagents.

Experimental

Materials. R_nA was prepared by the Claisen condensation of methyl alkanoate with acetone in the presence of a sodium hydride.[7] The crude R_nA was purified by the recrystallization of their copper complexes from 50% of a DMF-water solution and by fractionation at reduced pressure after a decomposition process using 20% sulfuric acid. Abbreviations for various forms of R_nA are R_8A(for 2,4-undecanedione), $R_{12}A$(for 2,4-pentadecanedione) and $R_{18}A$(for 2,4-henicosanedione). A further purification of R_nA gave rather low yields (R_8A 24%, $R_{12}A$ 35%, $R_{18}A$ 48%). The structures of the synthesized R_nA were confirmed by means of their melting points,[7] IR spectra (Shimadzu IR-408), NMR spectra (JEOL JMN-MH-100), and elementary analyses(Yanaco CHN Corder MT-3). Mp: $R_{12}A$, 31.5—33.0 °C (lit,[7] 31—32 °C); $R_{18}A$, 56.0—58.0 °C (lit,[8] 52.5 °C). IR(KBr): ν_{CH} 2920 cm^{-1}, $\nu_{C=O}$ 1640 cm^{-1}. NMR (CCl_4) δ=0.9 (3H, t, CH_3-C-C-), 1.3 (methylene in alkane), 2.0 (3H, CH_3COC-), 2.2 (2H, t, -C-C-CH_2COC-), 3.4 (2H, -CCOCH_2COC-), 5.4 (H, -CC(-O-)=CHCOC-). R_8A Found: C, 70.82; H, 10.84%; Calcd for $C_{11}H_{20}O_2$: C, 71.70; H, 10.94%. $R_{12}A$ Found: C, 74.67; H, 11.82% Calcd for $C_{15}H_{28}O_2$: C, 74.95; H, 11.74%. $R_{18}A$ Found: C,77.63; H, 12.59% Calcd for $C_{21}H_{40}O_2$: C, 77.72; H, 12.42%. Acetylacetone(AA) and dibenzoylmethane(DBM) were obtained from Wako Pure Chemical Industries, Ltd., and benzoylacetone(BzA) was obtained from Kishida Chemical Co., Ltd.

The surface tensions of R_nA solutions were measured on a Du nouy surface-tension balance. R_nA in an alkaline solution lowered the surface tension: 46 dyn (10^{-5}N) cm^{-1} for 10^{-3} mol dm^{-3} of R_8A[critical micelle concentration (cmc) was not observed at below 10^{-3} mol dm^{-3}], 36 dyn cm^{-1} for $R_{12}A$(cmc 5×10^{-4} mol dm^{-3}), and 47 dyn cm^{-1} for $R_{18}A$(cmc 3×10^{-4} mol dm^{-3}). BzA and DBM, known as extraction reagents, scarcely lowered the surface tension. Therefore, the concentration of R_nA in the following ion flotations were always kept below their cmc.

Apparatus and Procedures. The removal of eight kinds of metal ions (Fe^{3+}, Ga^{3+}, Al^{3+}, Cu^{2+}, Zn^{2+}, Pb^{2+}, Cd^{2+}, and Ca^{2+}) was examined by the method of ion flotation and extraction. The concentrations of these metal ions were determined using an atomic absorption spectrophotometer (Hitachi 170—30). The flotation apparatus and procedures were the same as that previously reported.[1] The floatability(%) of a metal ion was calculated using:

$$F = \frac{a_0 - a_1}{a_0} \times 100$$

where a_0 and a_1 denote the initial and final metal-ion concentrations in solution. Extraction was carried out

using a general operation; 100 cm^3 of benzene was added to the 100 cm^3 of metal solution in a separating funnel, and the funnel was shaken for 30 min. The extractability was calculated using the same formula as that regarding floatability.

Results and Discussion

Ion Flotation. The eight kinds of metal ions dissolved in 300 cm^3 of water were floated with a small amount of R_nA, especially $R_{12}A$. The floatable pH ranges for a 10^{-5} mol dm^{-3} solution of specific metal ions using 3×10^{-5} mol dm^{-3} of aqueous $R_{12}A$ were as follows: for Fe^{3+}, pH 4—8; for Ga^{3+}, 4—8; for Al^{3+}, 7—9; for Cu^{2+}, 4—8; for Zn^{2+}, 7—9; for Pb^{2+}, 6—11; for Cd^{2+}, 10—13; and for Ca^{2+}, 12—13. The flotation data for Fe^{3+}, Ga^{3+}, and Cu^{2+} are shown in Fig. 1. The optimum pH for the Cu^{2+} and Fe^{3+} flotations shifted to a lower pH with an increase in the length of the alkyl group, and $R_{12}A$ showed the highest floatability in the series of R_nA. However, DBM(having two phenyl groups) was not so effective and AA(having no long alkyl group) was wholly ineffective. The HLB value of the metal complex is affected by pH since the composition varies with pH.

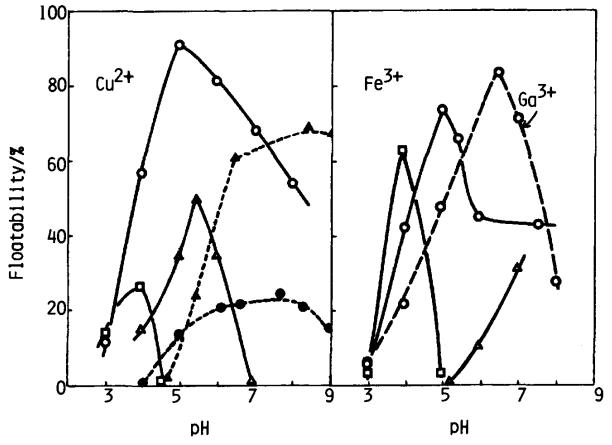

Fig. 1. Flotations for Cu^{2+}, Fe^{3+}, and Ga^{3+}.
Cu^{2+}: 10^{-5} mol dm^{-3}; Fe^{3+}: 10^{-5} mol dm^{-3}; Ga^{3+}: 2.87×10^{-4} mol dm^{-3}; $[R_nA]/[M]=3$. △: R_8A, ○: $R_{12}A$, □: $R_{18}A$, ▲: BzA, ●: DBM.

Then, the metal-ligand ratio of a $R_{12}A$-copper complex was examined. The scum(resulting at pH 5.0 upon adding $R_{12}A$) decomposed with 10% sulfuric acid and the resulting $R_{12}A$ was extracted using chloroform. The amount of $R_{12}A$ was determined by spectrophotometry{Hitachi model 101; ε^{276}, 8360 M^{-1} cm^{-1} (1 M=1 mol dm^{-3}); λ, 276 nm in chloroform}. The mole ratio of $R_{12}A$ and Cu^{2+} was 1:1. The obtained ratio was equal to that obtained by conductometry(Toa CM-7B). For R_nA-copper complex, a 1:1 complex would be present at a lower pH and the complex would be hydrolyzed above pH 5—6 since the hydrolysis constant of a copper(II) ion (pK_1, $I>0$) is 5.4 to 5.8.[9] The HLB values of these complexes calculated using the Oda equation[3,10] are shown in Table 1. High floatabilities were observed over a pH range of 3—4 for hydrophobic $R_{18}A$, 4—6 for less hydrophobic $R_{12}A$, and 5—6 for least hyrophobic R_8A. From these data, it is considered that the floatable complexes are R_8A-CuOH, $R_{12}A$-Cu^+, $R_{12}A$-CuOH, and $R_{18}A$-Cu^+. Their HLB values are in a range of 4—8. Furthermore, the relation between floatability and surface activity at pH 5 is shown in Table 2. The surface tension of 10^{-4} mol dm^{-3} $R_{12}A$ solution was 54 dyn cm^{-1}, and the value in the presence of 3×10^{-4} mol dm^{-3} Cu^{2+}, Fe^{3+}, or Ca^{2+} ion was 65 dyn cm^{-1}, 61 dyn cm^{-1}, or

a) Collector 3×10^{-5} mol dm^{-3}, metal ion 10^{-5} mol dm^{-3}. b) Collector 10^{-4} mol dm^{-3}, metal ion 3×10^{-4} mol dm^{-3}. c) Calculated by the Oda equation.[10] * Hydroxo-metal complex.

54 dyn cm^{-1}, respectively. The copper and iron complexes were considered to be weakly surface-active, and the copper complex would be more hydrophobic than the other. However, the floatability of copper using DBM(having a suitable HLB value) was not so high. The surface tension of a 10^{-4} mol dm^{-3} DBM solution was 68 dyn cm^{-1} and this value was not altered even if metal ions were added. DBM and its complex are presumably surface inactive because of their structural characteristics.

The floatability varies with the concentration of metal ions and the collector. The floatabilities at pH 6.5 for a 2.8×10^{-4} mol dm^{-3} Ga^{3+} solution changed as a function of the $R_{12}A$ concentration and were as follows: 38% with 2.8×10^{-4}mol dm^{-3} $R_{12}A$, 60% with 5.7×10^{-4} mol $dm^{-3}$$R_{12}A$, 82% with 8.2×10^{-4} mol dm^{-3} $R_{12}A$, and 64% with 14.3×10^{-4} mol dm^{-3} $R_{12}A$, respectively.

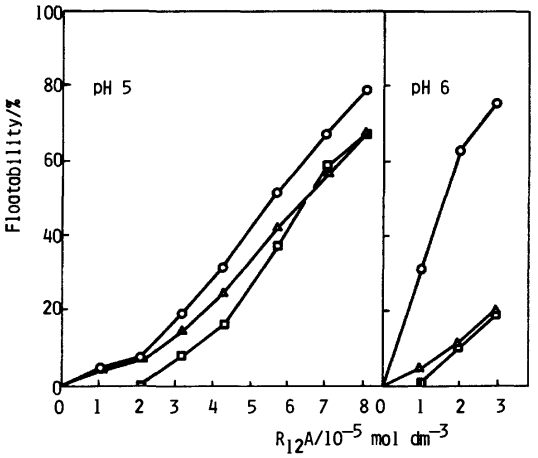

Fig. 2. Selectivity to metal ions.
Mixture of metal ions(Fe^{3+}, Ga^{3+}, Cu^{2+}, Pb^{2+}, Zn^{2+}, Cd^{2+}, and Ca^{2+}: 10^{-5} mol dm^{-3}, respectively). ○: Cu^{2+}, △: Fe^{3+}, □: Ga^{3+}.

The selectivity of these agents to metal ions was examined at pH 5 and 6. A Cu^{2+} ion could be selectively floated with $R_{12}A$ from a mixture of Fe^{3+}, Ga^{3+}, Cu^{2+}, Zn^{2+}, Pb^{2+}, Cd^{2+}, and Ca^{2+}(each a_0 was 10^{-5} mol dm^{-3}) at pH 6.0 as indicated in Fig. 2. However, the selectivity was not obtained at pH 5.0. Moreover, the selectivity was also examined using a 3×10^{-5} mol dm^{-3} solution of BzA, R_8A, $R_{12}A$, $R_{18}A$, and DBM. The floatabilities for Fe^{3+} and Cu^{2+} are indicated in Fig. 3. The Cu^{2+} ion could be selectively floated with R_8A and $R_{12}A$ at pH 6 (floatabilities were 70% and 75%, respectively). However the Cu^{2+} couldn't be floated with the others. The concentration of R_nA was smaller than that of the total metal ions. Therefore, the mole ratio of a R_nA-metal or a R_nA-hydroxo metal complex must be 1:1 at pH 6.0. The HLB values calculated for $R_{12}A$-Cu^+ and $R_{12}A$-CuOH were 8 and 4, as indicated in Table 1. Regarding the complexes of $R_{12}A$-Fe^{2+}, $R_{12}A$-$FeOH^+$, and $R_{12}A$-$Fe(OH)_2$, they were 10, 9, and 8, respectively. Consequently, the more hydrophobic copper complex would be floated selectively.[3] However, the floatabilities of Cu^{2+} using BzA and $R_{18}A$ were very low. The calculated HLB values for the complexes of BzA-Cu^+ and BzA-CuOH were 12 and 7, and for the complexes of $R_{18}A$-Cu^+ and $R_{18}A$-CuOH were 6 and 3 (Table 1), respectively. The BzA complex would be too hydrophilic, while the $R_{18}A$ complex would be too hydrophobic to be floated selectively.

Extraction. Extractability is greatly affected by the distribution coefficient of the extraction reagent corresponding to the HLB value.[4,5] R_nA is expected to be an excellent extraction reagent due to its large distribution coefficent related to its long alkyl group.[4-6] Therefore, extractions for eight kinds of metal ions were examined. The metal ions and the pH range when extracted by benzene (a_0 for 10^{-5} mol dm^{-3} metal ion and 10^{-4}mol dm^{-3} $R_{12}A$) were as follows: for Fe^{3+}, 5.5—11; for Ga^{3+}, 6—8; for

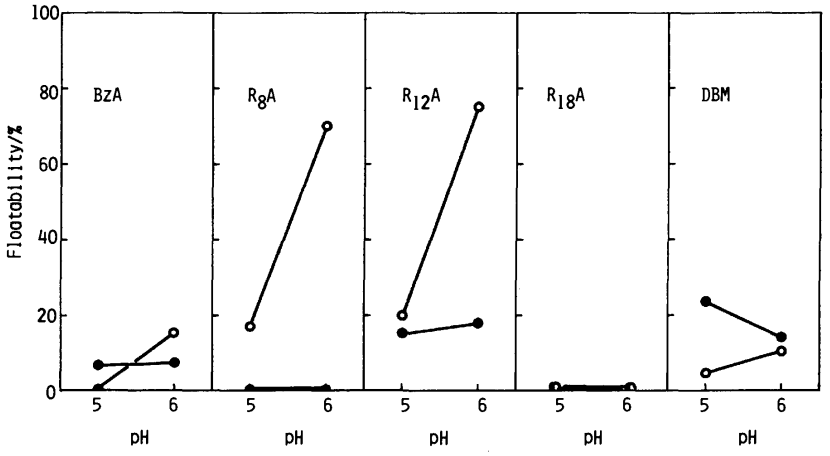

Fig. 3. Selectivity in ion flotation.
Mixture of metal ions(Fe^{3+}, Ga^{3+}, Cu^{2+}, Pb^{2+}, Zn^{2+}, Cd^{2+}, and Ca^{2+}: 10^{-5} mol dm^{-3}, respectively); R_nA: 3×10^{-5} mol dm^{-3}; BzA: 3×10^{-5} mol dm^{-3}; DBM: 3×10^{-5} mol dm^{-3}. ○: Cu^{2+}, ●: Fe^{3+}.

Cu^{2+}, 5.5—11; for Zn^{2+}, 8—12; for Pb^{2+}, 6—11; for Cd^{2+}, 9—13; and for Ca^{2+}, 11—13. Extractions for Cu^{2+} and Ga^{3+} ions are shown in Fig. 4. The extraction efficiencies with R_nA and BzA were more effective than that with AA. Furthermore, the highest extractability was obtained by DBM. The HLB values calculated for DBM, $R_{18}A$, $R_{12}A$, R_8A, BzA, and AA were 5, 3, 4, 6, 7, and 13, respectively. However, the distribution coefficient of DBM must be the largest value in these agents.

The selectivity regarding an extraction was examined using $R_{12}A$. The stability constants of the metal acetylacetone complexes (log K_{MA} and log K_{MA_2}) are arranged in the following order: Fe^{3+}> Ga^{3+}>Cu^{2+}>Zn^{2+}>Pb^{2+}>Cd^{2+}>Ca^{2+}.[11] The selectivity order regarding an extraction from a mixture of seven metal ions at pH 6.0 was the same as the order regarding their stability constants (Fig. 5). A more selective removal of Fe^{3+} was obtained at pH 5 when DBM was employed. The formed metal complex is thought to be uncharged(neutral) because the complex is soluble in benzene. Furthermore, the concentration effect of $R_{12}A$ on the extraction of a Cu^{2+} ion suggested that the mole ratio of R_nA to copper is 2:1. The calculated HLB value for both the complexes{$(R_{12}A)_2Cu$ and $(R_{12}A)_3Fe$} was 1. Therefore, the selectivity is presumably controlled by the stability constant.

Comparison. Ion flotation by using R_8A or $R_{12}A$ was superior to extraction at a lower pH region and inferior around neutral regarding the separation of Cu^{2+}, Fe^{3+}, or Ga^{3+} ion(Fig. 6). The R_nA-metal complex at a lower pH was a 1:1-complex and the ratio of R_nA to metal ions became maximum around a neutral pH. The 1:1-complex must be slightly hydrophilic(HLB, 4—14) and the 2:1- and 3:1-complexes must be more hydrophobic(HLB, 1). The 1:1-complex(which shows a surface-active property) is presumably suitable for ion flotation. Also, coordination-saturated and uncharged complexes of 2:1 and 3:1 are presumably suitable for extraction.

Especially the selective removal for Cu^{2+} ion by the ion-flotation method using R_nA was superior to that by extraction, in spite of a smaller stability constant compared to Fe^{3+} and Ga^{3+} ions.

Recovery. The ion-flotation collector should be recovered almost completely from the residual solution. The residual concentration of $R_{12}A$ was 0.2 ppm after the flotation of Cu^{2+} ions at pH 5, and was below 0.2 ppm after selective removal by the successive addition of $R_{12}A$ at pH 6. Therefore, the additive, $R_{12}A$, remained in an aqueous solution very little and was floated as a scum. The scum was dispersed in benzene; then, the benzene solution was shaken with a 2 mol dm^{-3} solution of mineral acid.

Breathing Vibration of Cyclohexane Ring in Cyclohexanol

Yoshiko TAKEOKA

Department of Chemistry, Otsuma Women's University, Sanban-cho, Chiyoda-ku, Tokyo 102

(Received March 8, 1985)

It was found that the wave numbers of the bands due to the breathing vibration of the cyclohexane ring in the e-conformer are higher than 802 cm^{-1} in the monosubstituted cyclohexane-derivatives having substituents Cl, Br, I, SH, SD and SCH_3, while lower than 802 cm^{-1} in cyclohexanol and fluorocyclohexane. The effect of introducing OH group to the cyclohexane ring upon this band was studied.

The Raman band of cyclohexane due to the breathing vibration of the cyclohexane ring, namely A_{1g} C-C stretching vibration, has been found at 802 cm^{-1} by the studies of fundamental vibration.[1,2] In the Raman spectrum of cyclohexane-derivatives, we can assign a strong band near 800 cm^{-1} to the breathing vibration of the cyclohexane ring, because the Raman band of this vibration is expected to possess the lowest wave number among C-C stretching vibrations and also the strong intensity due to the highest symmetry of this vibration mode. By studying several halogen-derivatives of cyclohexane, it has been found that the wave numbers of the breathing vibration of the ring having substituents in the a-position or the a,a-positions do not remarkably shift from that of cyclohexane, namely, 802 cm^{-1}, and are always lower than that having substituents in the e-position or the e,e-position.[3] This fact could be explained by considering that, in the a- or the a,a-conformer, the carbon-halogen bond is situated nearly vertically to the cyclohexane ring and contributes slightly to the breathing vibration; on the other hand that, in the e- or the e,e-conformer, the carbon-halogen bond is located almost in the same plane as the cyclohexane ring and possesses an important effect upon the breathing vibration.

We have made conformational studies on cyclohexanol,[4] *trans*-2-halocyclohexanols[5] and *trans*-4-halocyclohexanols[6] by infrared spectroscopy. The existence of two mutually convertible isomers, namely the e- and the a-conformers, was found in these molecules as in halogen derivatives of cyclohexane. However, the bands of the breathing vibration for the cyclohexane ring in these molecules were not assigned except *trans*-4-chlorocyclohexanol. It would be interesting to find the bands of the breathing vibration of the ring in these molecules having OH group.

Experimental

The infrared spectra were measured by JASCO model A-302 and Perkin-Elmer model 112 spectrometers. Commercial cyclohexanol was purified by desiccation with calcium oxide and subsequent distillation.

The sample of cyclohexanol was cooled with the mixture of Dry Ice and ethanol. The supercooled solid (phase I) in a cell with potassium bromide windows changed gradually to the ordered solid (phase III) by cooling for about three hours.

Results and Discussion

We have studied the conformational isomers of cyclohexanethiol[7] which is structurally similar to cyclohexanol. It is known that the bands of C-SH stretching vibration have similar wave numbers to those of C-Cl stretching vibration, because of their similar mass. We found that only the e-conformer exists in the true solid of cyclohexanethiol as in that of chlorocyclohexane.

As shown in Table 1, some cyclohexane derivatives having monosubstituent Cl, Br, I, SH, SD and SCH_3

TABLE 1. BANDS OF THE BREATHING VIBRATION IN THE MONOSUBSTITUTED CYCLOHEXANE-DERIVATIVES (cm^{-1})

	Substituente	a-Conformer	e-Conformer	Ref.

Cyclohexanol	OH		789 *	
Fluorocyclohexane	F		793 *	10

* This band remained in the true solid.

possess the bands of the breathing vibration in the similar wave number region.

The F atom of fluorocyclohexane has a mass similar to OH of cyclohexanol, and the C-F stretching vibration have the bands in the similar region to those of the C-OH stretching vibration. Christian *et al.* showed by the infrared spectra that fluorocyclohexane possesses the e- and the a-conformers in the liquid, while almost only the e-conformer in the true solid (ordered anisotropic phase).[10]

As for cyclohexanol, many studies have been made.[4,9,12,13] It has been known that cyclohexanol has a supercooled plastic solid (disordered phase, phase I) and two true solids (ordered phases, phase II has the transition point at −7.9 °C and the phase III at −28.4 °C).[11]

It is very probable, in view of the results on fluorocyclohexane and cyclohexanethiol, that only or almost only the e-conformer exist in the true solid. However it seems that there is not yet conclusive evidence whether the true solid of cyclohexanol has only one conformer or two conformers. The infrared spectra of cyclohexanol has the very strong bands at 968 cm^{-1} and 1068 cm^{-1} in the true solid (phase II and phase III) and it has been pointed out that the C-O stretching bands for the a- and the e-conformer appear near 960 cm^{-1} and 1060 cm^{-1} respectively in the derivatives of cyclohexanol.[11,13]

The a- and the e-conformers of cyclohexanol exist in the phase I as in the liquid. There are many differences between the infrared spectra of the phase III and that of the phase I.

As shown in Table 2, the infrared spectra of cyclohexanol and fluorocyclohexane have the similarity in the 780 cm^{-1}—1070 cm^{-1} region. Around the 800 cm^{-1} region of the infrared spectra, cyclohexanol has the bands at 789 (m) cm^{-1}, 835 (w) cm^{-1}, 844 (m) cm^{-1}, and 863 (w) cm^{-1} in the liquid, while in the true solid (phase III and according to Ref. 13 also phase II) the bands at 835 cm^{-1} and 863 cm^{-1} disappear, the bands at 789 cm^{-1} and 844 cm^{-1} persist.

TABLE 2. THE SIMILARITY IN THE INFRARED SPECTRA OF CYCLOHEXANOL AND FLUOROCYCLOHEXANE (cm^{-1})

Cyclohexanol		Fluorocyclohexane (Data of Ref. 10)
Liquid	Solid (phase III)	Liquid
789 (m)	787 (m)	793 (m)
835 (w) *		830 (m) *
844 (m)	845 (m)	844 (m)
863 (w) *		865 (m) *
889 (s)	888 (s)	892 (m)

	1049 (w)	
1068 (vs)	1067 (vs)	1049 (vs)

* This band disappeared in the true solid.

According to Ref. 10, in the same region of the infrared spectra, fluorocyclohexane has the bands at 793 (m) cm^{-1}, 830 (m) cm^{-1}, 844 (m) cm^{-1}, and 865 (m) cm^{-1} in the liquid, however in the true solid the bands at 830 cm^{-1} and 865 cm^{-1} disappear, the bands at 793 cm^{-1} and 844 cm^{-1} persist like in cyclohexanol. In the true solid of fluorocyclohexane almost only the e-conformer exists as mentioned above, the bands at 793 cm^{-1} and 844 cm^{-1} are assigned to the e-conformer and the bands at 830 cm^{-1} and 865 cm^{-1} to the a-conformer.

By the similarity of the infrared spectra in near 800 cm^{-1} region for cyclohexanol and fluorocyclohexane, the bands at 789 cm^{-1} and 844 cm^{-1} which exist in the true solid of cyclohexanol may belong to the e-conformer and the bands at 835 cm^{-1} and 863 cm^{-1} which disappear in the true solid to the a-conformer. It is very probable that only the e-conformer exists in the true solid of cyclohexanol.

Near 960 cm^{-1} cyclohexanol has one infrared band at 968 (vs) cm^{-1} in the liquid, but according to Ref. 10, fluorocyclohexane has three bands at 962 (vs) cm^{-1}, 948 (sh) cm^{-1}, and 938 (vs) cm^{-1} in the liquid, and only the 938 cm^{-1} band disappears in the true solid. As shown in Fig. 1, the shape of the 968 cm^{-1} band in the liquid cyclohexanol is largely changed in the CS_2 solution from that in the true solid. According to the similarity of the infrared spectra of cyclohexanol to that of fluorocyclohexane, it is very probable that the 968 cm^{-1} band of cyclohexanol consists of three bands in the CS_2 solution and in the liquid, while two bands in the true solid. The 968 cm^{-1} band in the liquid splits in the CS_2 solution and the lower wave number band probably consists of two bands, one of them disappear in the true solid (phase III). Then the band disappearing in the true solid may be assigned to the C-O stretching vibration for the a-conformer of cyclohexanol.

The 789 cm^{-1} band of cyclohexanol and the 793 cm^{-1} band of fluorocyclohexane in the infrared spectra have the very strong intensities in the Raman liquid spectra[10,12] and their intensities are the most strong in each near 800 cm^{-1} region. Therefore the bands at 789 cm^{-1} and 793 cm^{-1} may be assigned to the breathing vibration of cyclohexane ring in the e-conformers of cyclohexanol and fluorocyclohexne respectively.

As shown in Table 1, the wave numbers of the bands due to the breathing vibration of the e-conformer are higher than 802 cm^{-1} in the mono-substituted cyclohexane-derivatives having substituente Cl, Br, I, SH, SD and SCH_3, while lower

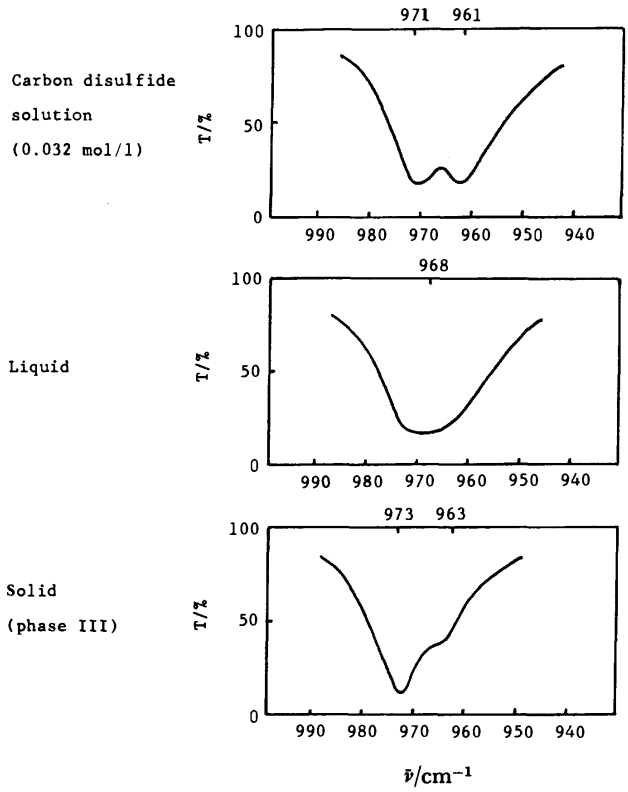

Fig. 1. Change of the 968 cm^{-1} band shape in the infrared spectra of cyclohexanol.

than 802 cm^{-1} in cyclohexanol and fluorocyclohexane. This difference may be due to the fact that the wave numbers for the bands of the C–O and C–F stretching vibrations are higher than 802 cm^{-1}, namely the band of the C–O stretching vibration at 1068 cm^{-1} and the C–F stretching vibration probably at 1049 cm^{-1} in the e-conformer, on the other hand those of the bands of C–Cl, C–Br, C–I, and C–S stretching vibrations are lower than 802 cm^{-1}, namely C–Cl at 733 cm^{-1}, C–Br at 688 cm^{-1}, C–I at 655 cm^{-1}, and C–SD at 757 cm^{-1} in the e-conformers.

As for the breathing vibration, the wave numbers of the bands for the e-conformer differ from those of the band for the a-conformer by about 5—15 cm^{-1} as shown in Table 1. However in the infrared spectra of the liquid, near the 789 cm^{-1} band of cyclohexanol and near the 793 cm^{-1} band of fluorocyclohexane, there are no bands which may be assigned to the breathing vibration for the a-conformers. In these moleculs, the bands at 793 cm^{-1} and 789 cm^{-1} may belong to both the e- and the a-conformer because of the small difference of the wave numbers in the a- and the e-band.

Molecular Deformation Caused by Hydrogen Bonding and Resonance. 1,3-Dimethyl-2-imidazolidinone

Kunio FUKUSHIMA and Takashi HARAOKA
Department of Chemistry, Faculty of Science, Shizuoka University 836, Oya, Shizuoka 422
(Received March 13, 1985)

The Raman spectra of 1,3-dimethyl-2-imidazolidinone were found to change due to a hydrogen bonding to its nitrogen atoms, especially at low temperatures. The change in the spectra included the unusual change for CH_2 bending vibrations, suggesting that the deformation of the ring of the molecule takes place by hydrogen bonding.

In a preceding paper,[1] one of the present authors reported a remarkable change in the spectra of *N,N'*-dimethylurea in hydrogen-bonding solvents. This change was attributed to the molecular deformation by hydrogen bonding to nitrogen atoms. Further measurements regarding the temperature dependence of the spectra of the substance and an estimation of the enthalpy change of hydrogen bonding supported the idea of molecular deformation.[2] However, in this substance, other probable cause for the change (existence of cis and trans conformers due to an internal rotation around its CO–N axes) is present. In the present study, 1,3-dimethyl-2-imidazolidinone, which has no possibility of cis or trans conformations with respect to its CO–N axes, was adopted. Thus, measurements of Raman spectra were made in the hope of finding some change of the spectra (due to a molecular deformation caused by hydrogen bonding to nitrogen atoms).

Experimental

1,3-Dimethyl-2-imidazolidinone was a commercial product from Tokyo Kasei Co. (grade GR). The Raman

spectra were recorded on a Model R-800T Raman spectrometer (Japan Spectroscopic Co.) with an excitation effected by use of a Spectra Physics argon ion laser (Model 165) at 514.5 nm (300 mW). The depolarization ratio was measured with a system consisting of a half-wave plate, a lens, and a polarizer. Room-temperature liquid samples were measured using 0.3-ml Raman cells and crystals, solutions and pure liquids at lower temperatures were measured using an Oxford-type cryostat and liquid nitrogen. Experimental results are shown in Tables 1 and 2 and Figs. 1 and 2.

Results and Discussion

An 1,3-dimethyl-2-imidazolidinone molecule is expected to undergo a molecular deformation due to a deformation of its five-membered ring or the internal rotation of its methyl groups around the N–C axes. The vibrational frequencies of conformers (arising from the internal rotation of methyl groups) do not show any remarkable dependence on the

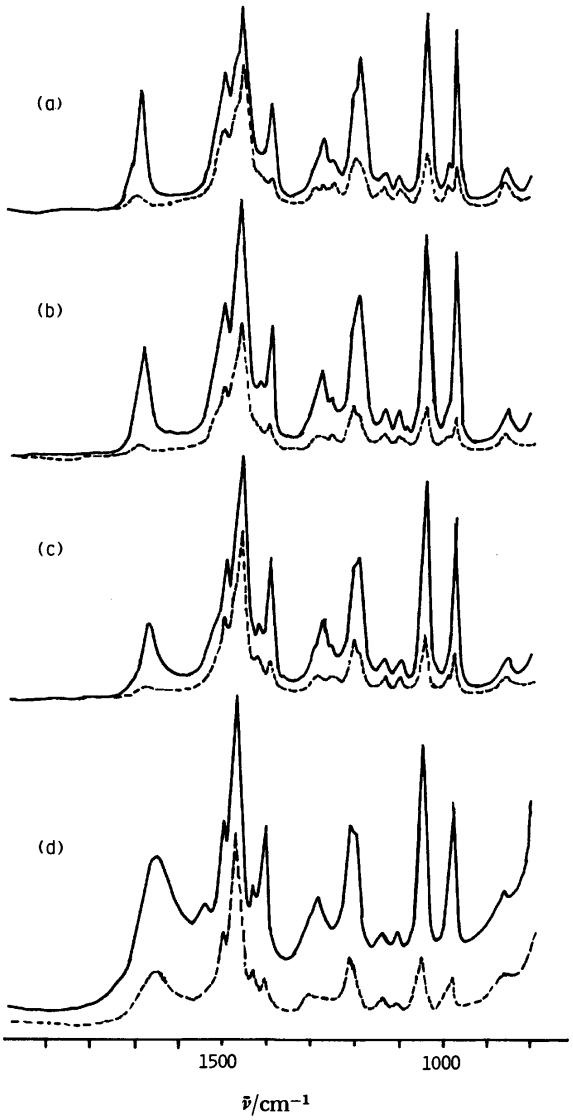

Fig. 2. Raman spectra of aqueous solutions of 1,3-dimethyl-2-imidazolidinone: mixing mol ratio of solute to solvent: (a) 1 : 0.21 (b) 1 : 0.99 (c) 1 : 3.00 (d) 1 : 71.

conformation of the methyl groups. Therefore, a difference among the spectra of the conformers is not expected. On the other hand, the effects of the deformation of the five-membered ring on the vibrational spectra are expected to be very remarkable. The probable causes of the deformation of the ring are the conformational changes due to the internal rotation around the bonds in the ring and that due to a change in the valence angle around the nitrogen atoms. Assuming the above-mentioned conformational change arising from a deformation of the ring, the observed spectral change associated with the state change was interpreted.

(a) Comparison of Liquid Spectra with Those of Solid: As shown in Table 1, there are two groups of bands. One group (1070 cm^{-1}, 1170 cm^{-1}, 1280 cm^{-1}, 1406 cm^{-1}, 1473 cm^{-1}, 1513 cm^{-1}, bands below 235 cm^{-1}) exists in the solid spectra but does not in the liquid spectra. The other (1201 cm^{-1}, 1695 cm^{-1}) exists in the liquid spectra but does not in the solid spectra. In the case of the former, although those below 235 cm^{-1} can be interpreted as due to lattice modes, which are characteristic to crystalline state, the existence of others suggests that a conformation of molecules in the solid state is a little different from that of molecules in a liquid state. The existence of bands of the latter group also supports this interpretation.

(b) Comparison of Liquid Spectra with Those of Solutions of Hydrogen-bonding Solvents: The following frequency shifts were observed to be associated with state changes from pure liquids to aqueous solutions (refer to Table 1 and Fig. 1); 1031 cm^{-1}→1040 cm^{-1}, 1184 cm^{-1}→1195 cm^{-1}, 1384 cm^{-1}→1394 cm^{-1}. The concentration dependency of relative intensities was determined (refer to Fig. 2). In addition, there are Raman bands of pure liquid (1201 cm^{-1} and 1451 cm^{-1}) which increase in intensity in the spectra of aqueous solutions. The 1420-cm^{-1} band appears only for aqueous solutions and the band for a pure liquid (523 cm^{-1}) decreases in intensity for the spectra of aqueous solutions. Similar changes are observed for methanol solutions. The above-mentioned changes do not occur for solutions of non-hydrogen-bonding solvents, of which a few examples (acetonitrile and carbon tetrachloride) are shown in Table 1. The changes are, therefore, considered to be characteristic of solutions of hydrogen-bonding solvents and are interpreted to be caused by the generation of hydrogen-bonded conformers. These arise from the deformation of the conformer which is stable in pure liquid as a result of hydrogen bonding. The Raman bands which appear at the higher frequency side of the pure-liquid bands for solutions of hydrogen-bonding solvents and the bands which appear only in the spectra of solutions of hydrogen-bonding solvents are due to the above-mentioned deformed conformers.

There are two types of hydrogen bonding to 1,3-dimethyl-2-imidazolidinone: Hydrogen bonding to its oxygen atom and that to its nitrogen atoms. In the former, the planarity of the $CH_2(CH_3)NCON$ skeleton by an increase of the double-bond character of the NC bond is expected, while in the latter, a tetrahedral configuration around the nitrogen atom is probable. In solutions of 1,3-dimethyl-2-imidazolidinone dissolved in hydrogen-bonding solvents, the latter situation is considered to be present because the spectra of 1,3-dimethyl-2-imidazolidinone in a hydrochloric acid solution, in which a species having a hydrogen ion attached to its nitrogen and having a tetrahedral configuration around the nitrogen atom is expected to occur, are almost similar to those of 1,3-dimethyl-2-imidazolidinone in an aqueous solution, as shown in Table 2. In connection with this, the remarkable increase in the intensity

of the band at 1460 cm^{-1} (CH_2 bending vibration band) in the spectra of aqueous solutions, (whose frequency is different from those of conformers in pure liquid), is interpreted to be due to a valence change of the CH_2 group due to a deformation of the molecular ring caused by a configuration change around the nitrogen atom due to hydrogen bonding.

(c) Spectrum Change Due to Temperature Change: The change in the relative intensity of the bands of a methanol solution at 1195 and 1203 cm^{-1} were observed in a temperature range between −65 °C and room temperature. The former band increased in intensity, while the intensity of the latter decreased. Assuming a Lorentzian curve for the two bands, the overlapping bands were decomposed into two bands by a computer calculation. The enthalpy stabilization about 2 KJ mol^{-1}, of a hydrogen-bonded conformer relative to a non-hydrogen-bonded conformer was obtained. The obtained lower stabilization-enthalpy suggests that the stabilization enthalpy regarding hydrogen bonding is somewhat cancelled by the enthalpy loss due to a deformation around the nitrogern atom.

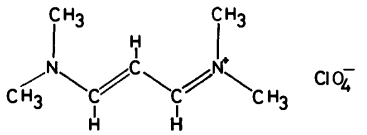
Electronic Spectra of a Simple Trimethine Cyanine Dye Crystal. (3-Dimethylamino-2-propenylidene)dimethylammonium Perchlorate

Masakazu OTSU and Jiro TANAKA*
Department of Chemistry, Faculty of Science, Nagoya University, Chikusa-ku, Nagoya 464
(Received March 25, 1985)

The electronic spectra of the simplest polymethine cyanine dye crystal were studied by measuring the reflection spectra of (3-dimethylamino-2-propenylidene)dimethylammonium perchlorate. The spectra consist of a single peak situated at 32400 cm^{-1} in solution. Davydov splitting is observed in the crystal spectra and it is explained by calculating the dipole-dipole interaction energy and the interaction energy between the transition densities with the Ewald sum method.

(3-Dimethylamino-2-propenylidene)dimethylammonium perchlorate (3-DMP) is the simplest polymethine cyanine dye so far studied. The spectral features and the crystal structure of 3-DMP were studied by Johnson *et al.*[1] and Matthews *et al.*[2] to investigate the orientation of the molecules in a crystal. In our laboratory we continued the study of the reflection spectra and the crystal structures of (5-dimethylamino-2,4-pentadienylidene)dimethylammonium perchlorate.[3,4] A comparative study regarding 3-DMP will be quite interesting.

The reflection spectra of 3-DMP were measured with several crystal faces and the absorption spectra and the optical constant of the crystals were obtained by Kramers-Kronig transformation of the reflectivity. The observed Davydov splitting can be explained by the dipole-dipole interaction energy calculated with the dipole approximation and the Ewald sum of the transition density. The results showed reasonable agreement between theory and experiment.



3-Dimethylaminopropenylidenedimethylammonium perchlorate (3-DMP)

Experimental

The material, 3-DMP, was synthesized from propalgyl alcohol. Propynal was obtained by the oxidation of the alcohol with CrO_3 and H_2SO_4.[5] Dimethylamine and the aldehyde reacted to form an adduct[6] and the obtained 3-dimethylamino-2-propenal was refluxed with dimethylammonium perchlorate to give 3-DMP.

Single crystals were obtained from a hot acetic anhydride solution under slow cooling. The crystalline faces are illustrated in Fig. 1. The reflection spectra of the crystals were measured with the (010), ($1\bar{1}0$), and ($11\bar{1}$) faces by a microspectrophotometer developed in this laboratory.

Results and Discussion

The absorption spectrum of 3-DMP measured in an aqueous solution is shown in Fig.2. It consists of a single peak centered at 32400 cm^{-1}. Its origin is considered to be a $\pi\pi^*$ transition of the polymethine chain. From the oscillator strength (f=0.97), the transition moment length is estimated as 1.66 Å. The f value given by Johnson *et al.*[1] is larger by a factor of 3 because of a difference in formulation.

On the (010) face shown in Fig. 3(a), all molecules are aligned along the same direction, and only a single excited state may be found if an intermolecular interaction such as a charge transfer is not concerned.

The reflection spectra were recorded along the

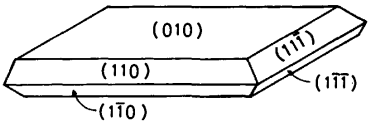


Fig. 1. Crystal habit of 3-DMP.

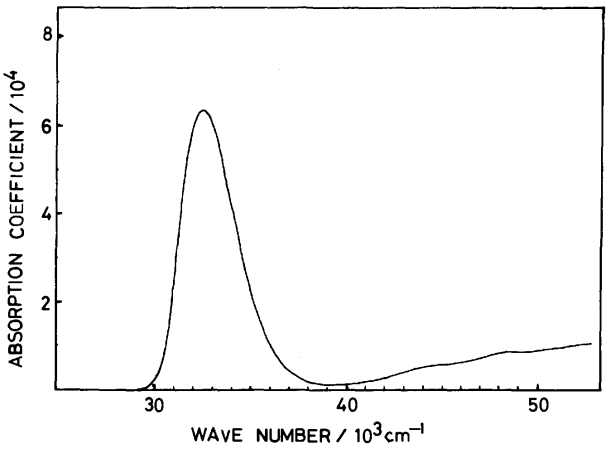

Fig. 2. Electronic absorption spectrum of 3-DMP in aqueous solution.

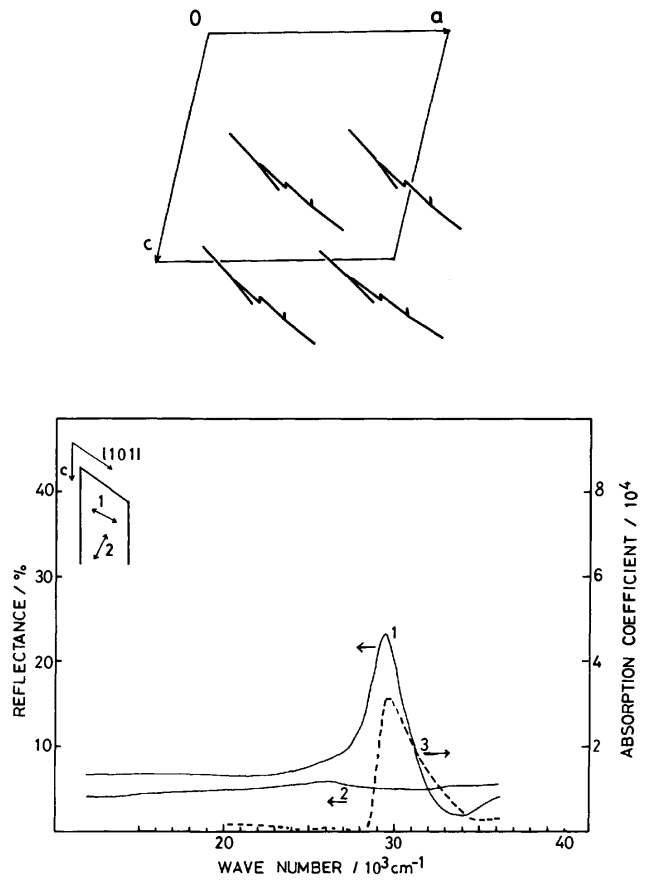

Fig. 3. (a): Projection of molecules onto the (010) face. (b): Crystal reflection spectra parallel to the [101] axis (1) and perpendicular to it (2) and absorption spectrum obtained by K-K transformation for the [101] direction with the (010) face (3).

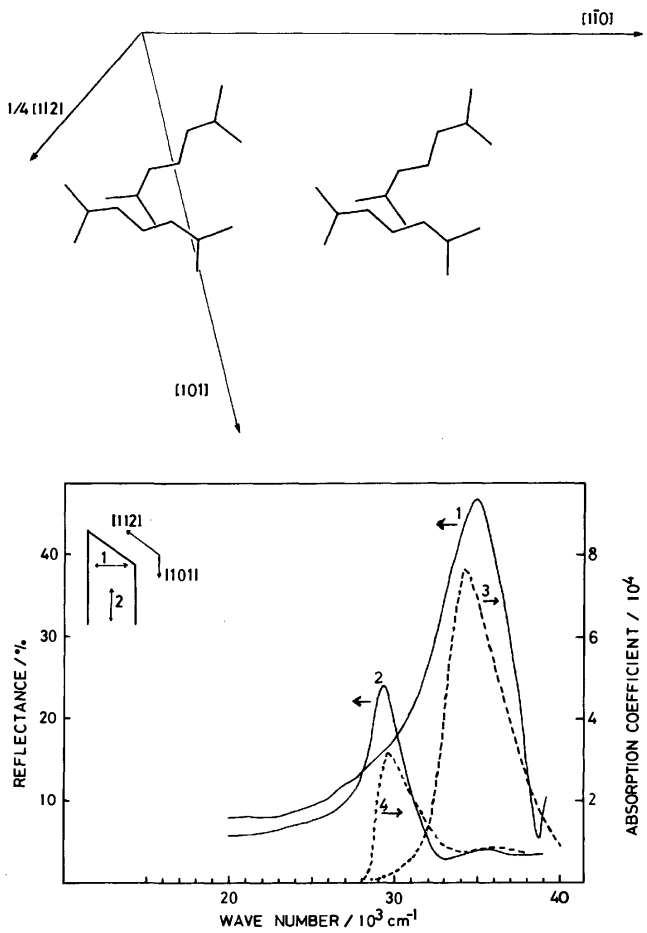

Fig. 4. (a): Projection of molecules onto the (11$\bar{1}$) face. (b): Crystal reflection spectra measured for perpendicular (1) and parallel (2) direction to the [101] axis and absorption spectra obtained by K-K transformation for perpendicular (3) and parallel (4) direction to the [101] axis with the (11$\bar{1}$) face.

molecular axis and perpendicular to it (Fig. 3(b)). A strong peak was found at 29000 cm^{-1} but nothing was found along the perpendicular direction. The K-K transformation gives a single peak situated at 29600 cm^{-1} (Fig. 3(b)).

A projection of the dye molecules onto the (11$\bar{1}$) face is shown in Fig. 4(a). The reflection spectra were measured along the directions parallel and perpendicular to the [101] zone axis. The [101] direction is perpendicular to the b axis, and it has only an ac component. Therefore, a Davydov splitting between the [101] direction and the direction perpendicular to it is expected, and it was actually found. Along the [101] zone axis, a peak was found at 29200 cm^{-1} that is almost coincident with the peak found with the (010) face at 29000 cm^{-1}. A very strong reflection peak was found for the direction perpendicular to the [101] direction at 34800 cm^{-1}. The K-K transformation of the reflectance shows an absorption peak at 34500 cm^{-1} for the perpendicular to the [101] direction which includes the b-axis transition and 29500 cm^{-1} for the [101] zone axis. A large Davydov splitting of 5000 cm^{-1} was found between the ac and b axes components.

The projection of the molecules onto the (1$\bar{1}$0) face is shown in Fig. 5(a). The reflection spectra were measured along the c axis and perpendicular to it parallel to the [110] direction. Along the c axis, no strong peak was detected since the transition moment on the molecule is almost perpendicular to this axis. For the [110] zone axis, both the b and ac axes components were expected and were clearly found at 35300 cm^{-1} and 30200 cm^{-1}. The K-K transformation of these spectra gives absorption maxima at 34600 cm^{-1} and 30000 cm^{-1}.

Using the K-K transformation, the real and imaginary parts of the dielectric constants were estimated (Fig. 6) for the [101] direction and its perpendicular. Large dispersions of the real and imaginary parts were found in the region of a strong absorption band.

The transition moments on the respective faces

were estimated from the intensities of these absorption bands. (Table 1)

A crystal of 3-DMP has four molecules in a unit cell; the crystal symmetry is Cc[2] and the coordinates of these molecules are given by (x,y,z), $(x, -y, 1/2+z)$, $(1/2+x, 1/2+y,z)$ and $(1/2+x, 1/2-y, 1/2+z)$. The molecular exciton state of the crystal is considered to have symmetry of A′ or A″ in the irreducible representation of Cs group. The A′ state is allowed for the ac axis, and the A″ state is active for the b axis direction.

$$\text{A}' \quad \Psi(ac)=\frac{1}{\sqrt{N}}\sum_{i=1}^{n}(\phi_{1i}+\phi_{2i}+\phi_{3i}+\phi_{4i})e^{i\boldsymbol{K}\cdot\boldsymbol{R}_i}$$

$$\text{A}'' \quad \Psi(b)=\frac{1}{\sqrt{N}}\sum_{i=1}^{n}(\phi_{1i}-\phi_{2i}+\phi_{3i}-\phi_{4i})e^{i\boldsymbol{K}\cdot\boldsymbol{R}_i}$$

where ϕ_{1i} represents the molecule in the 1-st site of the i-th unit cell being excited while all other molecules are in the ground state. The summation over i is extended ideally to all N molecules in a cell; however, it is limited in order to give a convergent result. Here $\boldsymbol{R}_i$ is the lattice vector and $\boldsymbol{K}$ is the reciprocal lattice vector.

The calculation of the Davydov splitting was performed using two methods. One was a dipole-dipole approximation to calculate the interaction energy on a particular crystalline surface for molecules with a limited depth and area; namely the summation is taken for molecules within a 20-Å depth and a 100-Å radius. The calculated splitting is shown in Table 1, where the calculated values are compared with the observed ones. Tendencies in the calculated shift are in good agreement with the observed

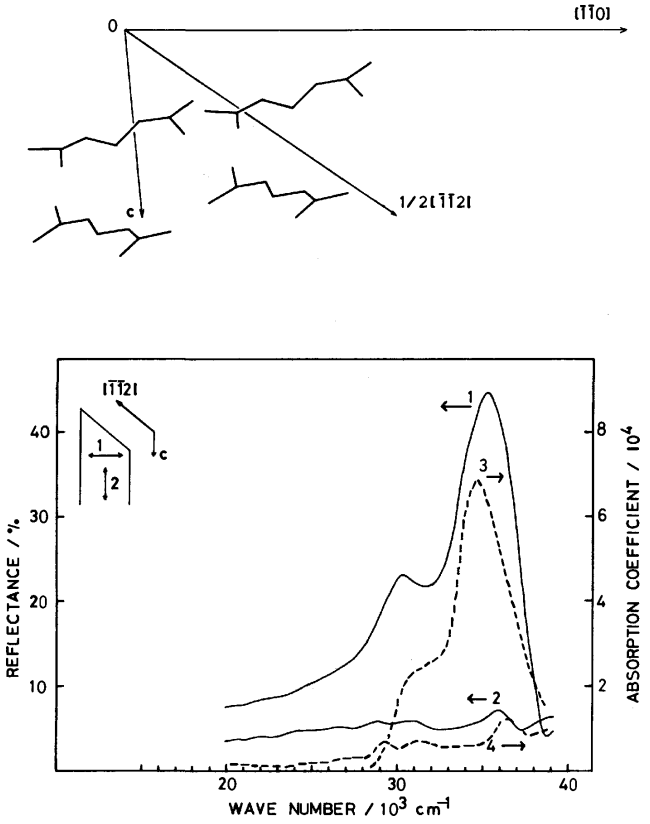

Fig. 5. (a): Projection of molecules onto the (1$\bar{1}$0) face. (b): Crystal reflection spectra measured for perpendicular (1) and parallel (2) to the c axis and absorption spectra obtained by K-K transformation for perpendicular (3) and parallel (4) to the c axis with the (1$\bar{1}$0) face.

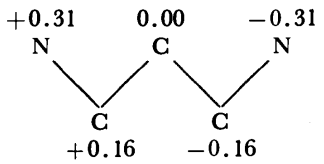
values; however, the magnitude is larger by a factor of 1.5~2.3.

It is well known that the dipole approximation exagerates the electrostatic Coulomb interaction, particularly at short distance. In order to more accurately estimate the interaction, the Ewald sum of the Coulomb energies for the transition densities on a molecule was calculated using a program written by Mrs. S. Akhtar of our laboratory. The molecular orbitals concerning the electronic transition were calculated by the Pariser-Parr-Pople method, and the transition densities estimated for a one-electron transition was multiplied by a factor of $\sqrt{2}$ as shown below,



This was because the excited state is described by a linear combination of two one-electron excited configurations. Moreover, these values were multiplied by a factor of 1.12 in order to scale the observed transition moment with the observed value in for a solution. The calculation was performed at the Nogoya University computation center. The result gives a much smaller value compared to the dipole-dipole approximation; the splitting being 3000 cm^{-1} as compared to the observed value of 5000 cm^{-1}.

The oscillator strengths for these crystal transitions were calculated by the oriented gas model and compared with observed values (Table 1). The agreement between theory and experiment is quite reasonable in spite of the simple approach.

The crystal reflection spectra of 3-DMP are characterizad by a single band and its behavior on several crystalline surfaces can be explained well by the excited state of the crystal; the selection rule, the energy shift and the intensities are all explained by the oriented gas model interacting through the electrostatic interaction in the excited state. The results provide a simple example of crystal excited state where no other complication due to a charge transfer or mixing with other highly excited states is significant.

The authors thank to Mrs. S. Akhtar of our laboratory for the help of the calculation. This research was supported by the grant in aid of the special research project on the properties of molecular assemblies (No. 59112003) from the Ministry of Education, Science and Culture.

A New Theorem on an Internal Balance in the State Energy

Makoto Isihara
Department of General Education, Shotoku-Gakuen Women's Junior College, Nakauzura 1-38, Gifu 500
(Received April 17, 1985)

A theorem useful for checking the accuracy of the wave function is presented, which is especially valid and significant for open-shell systems. The theorem connects the kinetic and potential energies of electrons in the up- and down-spin states with one another through an antisymmetric quantity concerned with the spin polarization. Two mutually related derivations of the theorem are shown for the atomic system: One from the hypervirial theorem sets forth the general applicability and the other by the spin-dependent scaling clarifies the variational aspect. The numerical application to restricted and unrestricted analytic self-consistent field wave functions illustrates the sound nature of the theorem. Possibilities of its extension and generalization are touched upon briefly.

The state energy is undoubtedly a quantity of primary importance in the nonempirical calculation of electronic wave functions, not only because the quantity itself is the most fundamental that concerns many physical and chemical properties, but also because the approximate wave function is almost always calculated through the variation principle with the expectation value of the state energy as an indicator of accuracy. However, since the state energy given as an expectation value is of an extremely global character, the accuracy of the wave function cannot be checked enough if one concentrates exclusively on the lowering of the state energy expectation value.

It is, accordingly, quite reasonable to examine an expectation value of some physical quantity other than the state energy, provided that the "exact" value of the quantity is known. This way of checking may work effectively for specific problems under the appropriate choice of the quantity for examination, but it hardly seems to give any feeling for the general situation over various approximate wave functions of different systems.

One can also utilize relations between physical quantities which hold for the exact wave function or in the limit of a specific approximation. Although such relations can be often paraphrased into the form that the expectation value of a relevant composite quantity vanishes, there is qualitative difference between the use of a physical quantity with a known value and that of a physical relation, which is inherently nonempirical and commonly applicable. One of the most typical and important examples is the virial theorem[1-4] which has been frequently used in terms of the virial ratio check.

The virial ratio is, as a matter of course from its global character, not very sensitive in the high stage of approximation. It is true, however, that the virial theorem necessarily holds for the well-optimized wave function even without the gross scaling which forces the approximate wave function to satisfy the theorem. So is that the approximate wave function violating the theorem is more or less ill-behaved.

The usefulness of the virial theorem is mainly due to its intimate association with the state energy. Two dominant constituents of the state energy, the kinetic and potential energies, are subjected to a definite interrelation by the theorem, which is thus regarded as acquanting us with some detail of the state energy, an internal balance therein. Then, is there any other profitable theorem on another internal balance in the state energy?

In this paper we give an affirmative answer to this. The key observation is that a simple expression analogous with the virial relation is to be obtained separately for electrons in the up- and down-spin states. The expression is ready to lead us to a new theorem besides the virial theorem. The constituents participating in the new theorem are the kinetic and potential energies of electrons in the up- and down-spin states. They are connected with one another through an antisymmetric quantity concerned with the spin polarization. The theorem is, therefore, expected to be especially valid and significant in dealing with open-shell systems.

In the subsequent two sections, confining ourselves to the atomic system, we describe the derivation from the hypervirial theorem[5-8] and the derivation by the scaling dependent on the spin. The former is very transparent and clearly sets forth the applicability of the theorem, the latter clarifying the variational aspect. Next, a simple illustrative application is presented to restricted and unrestricted analytic self-consistent field (SCF) wave functions. After short concluding remarks, three appendices follow.

Derivation from the Hypervirial Theorem

Let $\{\phi_{j\sigma}(\boldsymbol{r})\xi_\sigma\}$ be a complete set of orthonormal spin orbitals, ξ_σ being the one-electron spin eigenfunction; σ stands for the one-electron spin state, taking $\uparrow$ (up) or $\downarrow$ (down), and $\boldsymbol{r}$ symbolizes the spatial coordinates with the origin at the atomic center. The notation $\bar{\sigma}$ is used to indicate the spin state opposite to σ in the following. Each of $\{\phi_{j\uparrow}(\boldsymbol{r})\}$ and $\{\phi_{j\downarrow}(\boldsymbol{r})\}$ are assumed to form a complete set of orthonormal spatial orbitals,

though $\phi_{j\sigma}(\boldsymbol{r})$ is not necessarily identical with $\phi_{j\bar{\sigma}}(\boldsymbol{r})$.

Denoting the creation and annihilation operators for the spin orbital $\phi_{j\sigma}(\boldsymbol{r})\xi_\sigma$, respectively, by $a_{j\sigma}^\dagger$ and $a_{j\sigma}$, we can write the atomic electronic Hamiltonian in the second quantized form as

$$H = \sum_\sigma (T_\sigma + V_\sigma + W_{\sigma\sigma} + W_{\sigma\bar{\sigma}}) \tag{1}$$

with

$$T_\sigma = \sum_{jk} t_{jk\sigma} a_{j\sigma}^\dagger a_{k\sigma}, \tag{2}$$

$$V_\sigma = \sum_{jk} v_{jk\sigma} a_{j\sigma}^\dagger a_{k\sigma}, \tag{3}$$

and

$$W_{\sigma\tau} = \frac{1}{2} \sum_{jklm} w_{lm\tau}^{jk\sigma} a_{j\sigma}^\dagger a_{l\tau}^\dagger a_{m\tau} a_{k\sigma}, \tag{4}$$

where

$$t_{jk\sigma} = \int \phi_{j\sigma}^*(\boldsymbol{r})(-\nabla^2/2)\phi_{k\sigma}(\boldsymbol{r})\mathrm{d}v, \tag{5}$$

$$v_{jk\sigma} = \int \phi_{j\sigma}^*(\boldsymbol{r})(-Z/r)\phi_{k\sigma}(\boldsymbol{r})\mathrm{d}v, \tag{6}$$

and

$$w_{lm\tau}^{jk\sigma} = \iint \phi_{j\sigma}^*(\boldsymbol{r}_1)\phi_{l\tau}^*(\boldsymbol{r}_2)(1/r_{12})\phi_{m\tau}(\boldsymbol{r}_2)\phi_{k\sigma}(\boldsymbol{r}_1)\mathrm{d}v_2\mathrm{d}v_1. \tag{7}$$

We abbreviate $|\boldsymbol{r}|$ to r and $|\boldsymbol{r}_1-\boldsymbol{r}_2|$ to r_{12} as usual; $\mathrm{d}v$ stands for the spatial volume element and Z for the atomic number. It holds that

$$W_{\sigma\tau} = W_{\tau\sigma} \tag{8}$$

as a direct consequence of $w_{lm\tau}^{jk\sigma} = w_{jk\sigma}^{lm\tau}$.

Now the hypervirial theorem asserts that an exact stationary state fulfils

$$\langle [H, F] \rangle = 0 \tag{9}$$

for arbitrary choice of an operator F of the system considered.[5-8] The pure bracket means the expectation value in the exact stationary state. Introducing the virial operator for the spin state σ

$$G_\sigma = \sum_{jk} g_{jk\sigma} a_{j\sigma}^\dagger a_{k\sigma} \tag{10}$$

with

$$g_{jk\sigma} = -\frac{\mathrm{i}}{2} \int \phi_{j\sigma}^*(\boldsymbol{r})(\boldsymbol{r}\cdot\nabla + \nabla\cdot\boldsymbol{r})\phi_{k\sigma}(\boldsymbol{r})\mathrm{d}v, \tag{11}$$

we adopt this (or $G_\uparrow \pm G_\downarrow$) as F in the hypervirial theorem. Since $\nabla\cdot\boldsymbol{r}$ is converted into $\boldsymbol{r}\cdot\nabla$ plus a constant, the use of the non-hermitian virial operator containing only $\boldsymbol{r}\cdot\nabla$ is tantamount to that of the present operator under the Hamiltonian which conserves both the numbers of electrons in the up- and down-spin states. We prefer the hermitian form; it just fits the unitary transformation formalism. (See the next section and Appendix II.)

Because G_σ is commutative with $T_{\bar{\sigma}}$, $V_{\bar{\sigma}}$, and $W_{\bar{\sigma}\bar{\sigma}}$, we have only to calculate the commutators of G_σ with T_σ, V_σ, $W_{\sigma\sigma}$, and $W_{\sigma\bar{\sigma}}$. The one-electron commutators are readily found to be

$$[T_\sigma, G_\sigma] = -2\mathrm{i}T_\sigma \tag{12}$$

and

$$[V_\sigma, G_\sigma] = -\mathrm{i}V_\sigma. \tag{13}$$

For the two-electron commutators we have

$$[W_{\sigma\tau}, G_\sigma] = -\mathrm{i}(1+\delta_{\sigma\tau})(W_{\sigma\tau} + X_{\sigma\tau})/2 \tag{14}$$

with

$$X_{\sigma\tau} = \frac{1}{2} \sum_{jklm} x_{lm\tau}^{jk\sigma} a_{j\sigma}^\dagger a_{l\tau}^\dagger a_{m\tau} a_{k\sigma}, \tag{15}$$

where

$$x_{lm\tau}^{jk\sigma} = \iint \phi_{j\sigma}^*(\boldsymbol{r}_1)\phi_{l\tau}^*(\boldsymbol{r}_2)(1/\tilde{r}_{12})\phi_{m\tau}(\boldsymbol{r}_2)\phi_{k\sigma}(\boldsymbol{r}_1)\mathrm{d}v_2\mathrm{d}v_1 \tag{16}$$

with

$$\tilde{r}_{12} = r_{12}^3/(r_1^2 - r_2^2). \tag{17}$$

The property that $x_{lm\tau}^{jk\sigma} = -x_{jk\sigma}^{lm\tau}$ leads to

$$X_{\sigma\tau} = -X_{\tau\sigma} \tag{18}$$

in sharp contrast to $W_{\sigma\tau}$. Because of this antisymmetry it follows that

$$[W_{\sigma\sigma}, G_\sigma] = -\mathrm{i}W_{\sigma\sigma}, \tag{19}$$

but

$$[W_{\sigma\bar{\sigma}}, G_\sigma] = -\mathrm{i}(W_{\sigma\bar{\sigma}} + X_{\sigma\bar{\sigma}})/2. \tag{20}$$

The quantity $X_{\sigma\bar{\sigma}}$ is considered to represent the electronic repulsion potential "filtered" with the factor $(r_1^2 - r_2^2)/r_{12}^2$. It seems proper to refer to this quantity as the spin polarization potential. The point of calculation of the above commutators is given in Appendix I.

It is convenient to define the potential energy operator for the spin state σ as

$$U_\sigma = V_\sigma + W_{\sigma\sigma} + W_{\sigma\bar{\sigma}}. \tag{21}$$

The commutators in the preceding paragraph suffice to give

$$[H, G_\sigma] = -\mathrm{i}(2T_\sigma + U_\sigma + X_{\sigma\bar{\sigma}}), \tag{22}$$

which results in

$$2\langle T_\sigma \rangle + \langle U_\sigma \rangle + \langle X_{\sigma\bar{\sigma}} \rangle = 0 \qquad (\sigma = \uparrow, \downarrow) \tag{23}$$

by virtue of the hypervirial theorem. By the relevant recombination in this set of equations, which is equivalent to using

$$\langle [H, G_\uparrow \pm G_\downarrow] \rangle = 0, \tag{24}$$

we obtain the virial theorem

$$2\langle T\rangle+\langle U\rangle = 0, \tag{25}$$

where

$$T = T_\uparrow + T_\downarrow \tag{26}$$

and

$$U = U_\uparrow + U_\downarrow = V_\uparrow + V_\downarrow + W_{\uparrow\uparrow} + W_{\downarrow\downarrow} + 2W_{\uparrow\downarrow}, \tag{27}$$

and the following theorem independent of the virial one.

$$2\langle \Delta T\rangle + \langle \Delta U\rangle + \langle \Delta X\rangle = 0 \tag{28}$$

with

$$\Delta T = T_\uparrow - T_\downarrow, \tag{29}$$

$$\Delta U = U_\uparrow - U_\downarrow = V_\uparrow - V_\downarrow + W_{\uparrow\uparrow} - W_{\downarrow\downarrow}, \tag{30}$$

and

$$\Delta X = X_{\uparrow\downarrow} - X_{\downarrow\uparrow} = 2X_{\uparrow\downarrow}. \tag{31}$$

We provisionally call this the spin virial theorem for the sake of convenience.

It is evident that the spin virial theorem as well as the virial theorem still holds even if the exact stationary state is replaced with any approximate state $|\Phi\rangle$that satisfies the one-electron hypervirial theorem[9]

$$\langle\Phi|[H,\ a_{j\sigma}^\dagger a_{k\sigma}]|\Phi\rangle = 0 \quad (\text{any } j\sigma, k\sigma). \tag{32}$$

The most representative example is the unrestricted Hartree-Fock (HF) state and the restricted HF state for the closed-shell system. The restricted HF state for the open-shell system, however, does not satisfy the one-electron hypervirial theorem in general, even though it does

$$\langle\Phi|[H,\ a_{j\uparrow}^\dagger a_{k\uparrow}+a_{j\downarrow}^\dagger a_{k\downarrow}]|\Phi\rangle = 0 \quad (\text{any } j,\ k), \tag{33}$$

which is enough for the virial theorem to hold. The application to the approximate state with a specified form is thus often to be considered with respect to the exact limit of the approximation.

Scaling Dependent on the Spin

It is well known the close relation between the virial theorem and the positive gross scaling in the wave function, which can be worded in various manner.[4] The essential point is still the equivalence of the virial theorem to the variational condition upon the scale factor incorporated into the wave function.[2] The corresponding equivalence can be obtained also for the spin virial theorem. Here, in favor of naivety, we show a pedestrian approach starting with the explicit introduction of the spin-dependent scaling in orbitals, though the objective can be reached elegantly with the unitary transformation formalism,[6,8] which is outlined in Appendix II for reference.

Now incorporating the spin-dependent scale factor into orbitals, we define the scaled orbitals as

$$\phi_{j\sigma}(\boldsymbol{r};\ \lambda_\sigma) = \lambda_\sigma^{3/2}\phi_{j\sigma}(\lambda_\sigma \boldsymbol{r}). \tag{34}$$

The orthonormality is preserved;

$$\int \phi_{j\sigma}^*(\boldsymbol{r};\ \lambda_\sigma)\phi_{k\sigma}(\boldsymbol{r};\ \lambda_\sigma)\mathrm{d}v = \delta_{jk}. \tag{35}$$

Soon it is seen to be suitable for our purpose to use the following parameters η and θ instead of $\lambda_\uparrow$ and $\lambda_\downarrow$.

$$\lambda_\sigma = \exp(\eta+\kappa_\sigma\theta) \tag{36}$$

with

$$\kappa_\sigma = \begin{cases} 1 & (\sigma=\uparrow) \\ -1 & (\sigma=\downarrow). \end{cases} \tag{37}$$

The creation and annihilation operators corresponding to the scaled spin orbital $\phi_{j\sigma}^\eta(\boldsymbol{r})\xi_\sigma \equiv \phi_{j\sigma}(\boldsymbol{r};\lambda_\sigma)\xi_\sigma$ are denoted by $a_{j\sigma}^{\eta\theta\dagger}$ and $a_{j\sigma}^{\eta\theta}$, respectively.

We can rewrite T_σ, V_σ, and $W_{\sigma\sigma}$ in the scaled representation simply as

$$T_\sigma = \exp(2(\eta+\kappa_\sigma\theta))\sum_{jk} t_{jk\sigma}a_{j\sigma}^{\eta\theta\dagger}a_{k\sigma}^{\eta\theta}, \tag{38}$$

$$V_\sigma = \exp(\eta+\kappa_\sigma\theta)\sum_{jk} v_{jk\sigma}a_{j\sigma}^{\eta\theta\dagger}a_{k\sigma}^{\eta\theta}, \tag{39}$$

and

$$W_{\sigma\sigma} = \exp(\eta+\kappa_\sigma\theta)\frac{1}{2}\sum_{jklm} w_{lm\sigma}^{jk\sigma}a_{j\sigma}^{\eta\theta\dagger}a_{l\sigma}^{\eta\theta\dagger}a_{m\sigma}^{\eta\theta}a_{k\sigma}^{\eta\theta}, \tag{40}$$

whereas we have

$$W_{\sigma\bar\sigma} = \exp(\eta)\frac{1}{2}\sum_{jklm} w_{lm\bar\sigma}^{jk\sigma}(\theta)a_{j\sigma}^{\eta\theta\dagger}a_{l\bar\sigma}^{\eta\theta\dagger}a_{m\bar\sigma}^{\eta\theta}a_{k\sigma}^{\eta\theta}, \tag{41}$$

where

$$w_{lm\bar\sigma}^{jk\sigma}(\theta) = \iint \phi_{j\sigma}^*(\boldsymbol{r}_1)\phi_{l\bar\sigma}^*(\boldsymbol{r}_2)(1/r_{12}^{\sigma\bar\sigma}(\theta))\phi_{m\bar\sigma}(\boldsymbol{r}_2)\phi_{k\sigma}(\boldsymbol{r}_1)\mathrm{d}v_2\mathrm{d}v_1 \tag{42}$$

with

$$r_{12}^{\sigma\bar\sigma}(\theta) = |\exp(\kappa_{\bar\sigma}\theta)\boldsymbol{r}_1 - \exp(\kappa_\sigma\theta)\boldsymbol{r}_2|. \tag{43}$$

As is implied by the notation, $w_{lm\bar\sigma}^{jk\sigma}(\theta)$ is independent of η, the η-dependence of the matrix element of $W_{\sigma\bar\sigma}$ being completely put into $\exp(\eta)$.

The expansion theorem[10] allows us, without loss of generality, to write the exact or approximate state $|\mathrm{O}\rangle$ as

$$|\mathrm{O}\rangle = \sum_M C_M|M\rangle, \tag{44}$$

where C_M is a numerical coefficient and $|M\rangle$ is a single configuration state

$$|M\rangle = \prod_{j^\sigma\in M} a_{j\sigma}^\dagger|\text{vacuum}\rangle \tag{45}$$

which is characterized by a set M of relevant spin orbital indices. The scaled state is obtained by replacing $a_{j\sigma}^{\eta\theta\dagger}$ with $a_{j\sigma}^{\dagger}$ in the original state;

$$|\eta\theta\rangle = \sum_M C_M |M\eta\theta\rangle \tag{46}$$

with

$$|M\eta\theta\rangle = \prod_{j^\sigma\in M} a_{j^\sigma}^{\eta\theta\dagger}|\text{vacuum}\rangle. \tag{47}$$

The density matrices, $\gamma_{jk\sigma}$ and $\Gamma_{lm\tau}^{jk\sigma}$, are consequently kept unchanged;

$$\gamma_{jk\sigma} = \langle a_{j\sigma}^{\dagger}a_{k\sigma}\rangle_0 = \langle a_{j\sigma}^{\eta\theta\dagger}a_{k\sigma}^{\eta\theta}\rangle_{\eta\theta} \tag{48}$$

and

$$\Gamma_{lm\tau}^{jk\sigma} = \langle a_{j\sigma}^{\dagger}a_{l\tau}^{\dagger}a_{m\tau}a_{k\sigma}\rangle_0 = \langle a_{j\sigma}^{\eta\theta\dagger}a_{l\tau}^{\eta\theta\dagger}a_{m\tau}^{\eta\theta}a_{k\sigma}^{\eta\theta}\rangle_{\eta\theta}, \tag{49}$$

where $\langle\cdots\rangle_0$ and $\langle\cdots\rangle_{\eta\theta}$ are short for the expectation value in $|O\rangle$ and that in $|\eta\theta\rangle$. Thus it follows that

$$\langle T_\sigma\rangle_{\eta\theta} = \exp(2(\eta+\kappa_\sigma\theta))\langle T_\sigma\rangle_0, \tag{50}$$

$$\langle V_\sigma + W_{\sigma\sigma}\rangle_{\eta\theta} = \exp(\eta+\kappa_\sigma\theta)\langle V_\sigma + W_{\sigma\sigma}\rangle_0, \tag{51}$$

and

$$\langle W_{\sigma\bar{\sigma}}\rangle_{\eta\theta} = \exp(\eta)\frac{1}{2}\sum_{jklm} w_{lm\bar{\sigma}}^{jk\sigma}(\theta)\Gamma_{lm\bar{\sigma}}^{jk\sigma} \tag{52}$$

rather straightforwardly.

The differentiation of the above expectation values with respect to η and θ is trivial except that of $\langle W_{\sigma\bar{\sigma}}\rangle_{\eta\theta}$ with respect to θ. Going through

$$\frac{\partial}{\partial\theta}w_{lm\bar{\sigma}}^{jk\sigma}(\theta) = \kappa_\sigma x_{lm\bar{\sigma}}^{jk\sigma}(\theta), \tag{53}$$

where

$$x_{lm\bar{\sigma}}^{jk\sigma}(\theta) = \iint \phi_{j\sigma}^{*}(\boldsymbol{r}_1)\phi_{l\bar{\sigma}}^{*}(\boldsymbol{r}_2)(1/\tilde{r}_{12}^{\sigma\bar{\sigma}}(\theta))\phi_{m\bar{\sigma}}(\boldsymbol{r}_2)\phi_{k\sigma}(\boldsymbol{r}_1)\mathrm{d}v_2\mathrm{d}v_1 \tag{54}$$

with

$$\tilde{r}_{12}^{\sigma\bar{\sigma}}(\theta) = r_{12}^{\sigma\bar{\sigma}}(\theta)^3/(\exp(2\kappa_{\bar{\sigma}}\theta)r_1^2 - \exp(2\kappa_\sigma\theta)r_2^2), \tag{55}$$

we arrive at

$$\frac{\partial}{\partial\theta}\langle W_{\sigma\bar{\sigma}}\rangle_{\eta\theta} = \kappa_\sigma\langle X_{\sigma\bar{\sigma}}\rangle_{\eta\theta}, \tag{56}$$

since $\exp(\eta)x_{lm\bar{\sigma}}^{jk\sigma}(\theta)$ is just the matrix element of $X_{\sigma\bar{\sigma}}$ in the scaled representation;

$$X_{\sigma\bar{\sigma}} = \exp(\eta)\frac{1}{2}\sum_{jklm} x_{lm\bar{\sigma}}^{jk\sigma}(\theta)a_{j\sigma}^{\eta\theta\dagger}a_{l\bar{\sigma}}^{\eta\theta\dagger}a_{m\bar{\sigma}}^{\eta\theta}a_{k\sigma}^{\eta\theta}. \tag{57}$$

After all, we have

$$\frac{\partial}{\partial\eta}\langle T_\sigma\rangle_{\eta\theta} = 2\langle T_\sigma\rangle_{\eta\theta}, \tag{58}$$

$$\frac{\partial}{\partial\theta}\langle T_\sigma\rangle_{\eta\theta} = 2\kappa_\sigma\langle T_\sigma\rangle_{\eta\theta}, \tag{59}$$

$$\frac{\partial}{\partial\eta}\langle V_\sigma + W_{\sigma\sigma} + W_{\sigma\bar{\sigma}}\rangle_{\eta\theta} = \langle V_\sigma + W_{\sigma\sigma} + W_{\sigma\bar{\sigma}}\rangle_{\eta\theta}, \tag{60}$$

and

$$\frac{\partial}{\partial\theta}\langle V_\sigma + W_{\sigma\sigma} + W_{\sigma\bar{\sigma}}\rangle_{\eta\theta} = \kappa_\sigma(\langle V_\sigma + W_{\sigma\sigma}\rangle_{\eta\theta} + \langle X_{\sigma\bar{\sigma}}\rangle_{\eta\theta}). \tag{61}$$

Complete parallelism between the present treatment and the preceding one is quite clear in this step.

Using the above result with the notation defined before, we immediately obtain

$$\frac{\partial}{\partial\eta}\langle H\rangle_{\eta\theta} = 2\langle T\rangle_{\eta\theta} + \langle U\rangle_{\eta\theta} \tag{62}$$

and

$$\frac{\partial}{\partial\theta}\langle H\rangle_{\eta\theta} = 2\langle \Delta T\rangle_{\eta\theta} + \langle \Delta U\rangle_{\eta\theta} + \langle \Delta X\rangle_{\eta\theta}, \tag{63}$$

which show that the variational condition

$$\frac{\partial}{\partial\eta}\langle H\rangle_{\eta\theta} = 0 \tag{64}$$

and

$$\frac{\partial}{\partial\theta}\langle H\rangle_{\eta\theta} = 0 \tag{65}$$

are equivalent to the virial theorem and the spin virial theorem. The exact wave function evidently lets these theorems hold. If θ is excluded out or fixed at zero throughout the treatment, the virial theorem results alone.[11]

Now suppose that one has an approximate wave function violating both or either of the virial theorem and the spin virial theorem. The relevant scaling may be thought to improve the approximate wave function, making it satisfy the theorems; yet, aside from the case that the violation is conspicuous, the approximate wave function will not be improved genuinely with the sole use of the scaling. Here note that the completeness of a set of spin orbitals is assumed in the above, or else the Hamiltonian in the scaled representation inevitably differs from that in the original representation. Therefore, if one starts with an approximate wave function determined with some physical (presumably variational) condition in an incomplete space built of finite spin orbitals, then the scaled wave function may not fulfil the condition with respect to the "scaled" Hamiltonian.

Even in such a case, it is possible to invoke a practical iterative procedure: After the scaling process, calculate a wave function in the space built of the scaled spin orbitals with the predesignated condition, and go back to the scaling process with the calculated wave function as a new nonscaled wave function. This procedure is, however, not recommended as a general way of improving an

approximate wave function in an incomplete space. The determination of η and θ is considerably laborious compared with that of the gross scale factor. It is rather important that the well-optimized, refined wave function is to fulfil the theorems without any scaling treatment. Here we only add that the spin-dependent scaling in a finite basis space necessarily leads us to "different bases for different spins,"[12] which does not match the spin restricted picture.

Illustrative Application

Here we apply the spin virial theorem to several restricted and unrestricted SCF wave functions obtained by the analytic expansion method,[13,14] using the spin virial ratio

$$\Omega_s = -(\overline{\Delta V}+\overline{\Delta W}+\overline{\Delta X})/(2\overline{\Delta T}), \tag{66}$$

where ΔV and ΔW are, respectively, the one- and two-electron components of ΔU. The upper bar means the expectation value for the wave function under consideration. Of course, the spin virial ratio takes unity if the theorem is satisfied. Our aim now is to realize the nature of the theorem rather than to test those wave functions.

For the present application, the above expectation values are reduced to the orbital integrals $t_{jj\sigma}$, $v_{jj\sigma}$, $w^{jj\sigma}_{kk\sigma}$, $w^{jk\sigma}_{kj\sigma}$, and $x^{jj\sigma}_{kk\sigma}$. Further, for the restricted case, we have only to take account of those integrals with which the singly occupied orbital is concerned. The integral of the spin polarization potential can be calculated analytically as well as the others. A few details of the integration are put in Appendix III.

The results are summarized in Tables 1—4. The state considered is ^2S for Li and Na, ^2P for B, and ^4S for N. The basis sets are from Clementi and Roetti's table,[15] unless otherwise specified. For the restricted case, we used the data of expansion coefficients in the published tables[15-17] directly with no SCF recalculation. Hence, the accuracy of the obtained values is a little degraded. The calculated values of the state energy

$$E = \overline{T} + \overline{U} \tag{67}$$

coincide with the published ones in five figures, and the virial ratio

$$\Omega_v = -\overline{U}/(2\overline{T}) \tag{68}$$

remains 1.0000 with the deviation about ± 0.00001, being omitted in Tables 1 and 2. On the other hand, for the unrestricted case, we started with the SCF calculation using Clementi and Roetti's[15] and Weiss'[16] basis sets. Proper accuracy was sustained consistently.

Table 1 shows how the spin virial ratio varies with basis sets for the restricted case. The calculations for B, N, and Na exemplify the varying with the size of a basis set. We see a distinct gap between the single- and double-zeta results, the change being small beyond the double-zeta calculation. As the SCF wave function approaches the HF limit, the spin virial ratio appears to converge to the limit characteristic of the system. This is ascertained by the calculation for Li with different basis sets of fairly large size; the values of Ω_s are almost identical. As mentioned before, the open-shell HF wave function inherently violates the spin virial theorem,[18] so that the limit of convergence is not unity in general. Although the double-zeta results for B and N may look somewhat

strange at first sight, it is easily understood that such results are quite probable and no strange. The spin virial ratio need not to vary in parallel with the state energy and further it now tends to the limit other than unity.

In Table 2 we inquire into the behavior of the spin virial ratio in different systems and in their isoelectronic sequences for the restricted case. The most remarkable feature is that the ratio has comparatively small deviation from unity in the isoelectronic systems of N and B. This is reasonably ascribed to the fact that the influence of the spin restriction is indirect in these systems, the p-symmetry orbital being purely singly occupied. In the Li-isoelectronic sequence we see that the spin virial ratio becomes close to unity as the nuclear charge increases, but this inclination is not general in the results for the other isoelectronic sequences. We should not make such a hasty deduction as "the tighter is the electronic cloud, the less effective is the spin polarization." The change of Ω_s in the isoelectronic sequences is complicatedly affected by the quality of the basis set and the constraint of the spin restriction.

Turning to the unrestricted case, we examine the spin virial ratio in different systems with the variation of the basis set size in Table 3. Again a gap is observed between the single- and double-zeta results. Here, as expected, the limit of convergence is certainly unity. Generally speaking, the unrestricted

SCF wave function fulfils the spin virial theorem much more well than the restricted one. It may be interpretable as a reflex of this that the unrestricted calculation often gives excellent estimates for spin-related quantities. As another overall feature we should point out that the unrestricted wave function gives larger $\overline{\Delta T}$ and smaller $\overline{\Delta V}$ than the corresponding restricted one almost exclusively.

Table 4 presents the results for the unrestricted wave functions of the isoelectronic systems of Li, B, N, and Na, complementing Table 2. Though the values of Ω_s in the Na-isoelectronic systems have a little large deviation from unity in comparison with the others, we can say that all the members fulfil the spin virial theorem fairly well, taking it into consideration that the basis set used are optimized for the restricted calculation. Comparison between Tables 2 and 4 manifests that the spin restriction is surly a severe constraint.

Concluding Remarks

The spin virial theorem is thought to have both the practical and conceptual significance. The former results from the validity for examining approximate wave functions, being accorded with our original motivation, and the latter consists in the clear recognition of the fact that the motion of electrons in the different spin state is regulated in the stationary state so as to maintain the specific balance represented by the theorem. This recognition is quite fundamental and no less important than the practicability. It is also to be emphasized that the spin virial theorem as well as the spin polarization potential, which is indispensable for the theorem, is not an artificial but natural conception describing a leading feature of the electronic structure.

The idea of specifying the spin state of an operator in the hypervirial theorem seems to be fruitful. We would like to regard the present theorem as the inception of the spin-related theorems derivable from the hypervirial theorem. Moreover, noting that the virial and the spin virial theorems correspond to the Pauli matrices σ_0 and σ_z, respectively, we have certain possibilities of generalization to the other Pauli matrices with appropriate choice of an operator, provided that the Hamiltonian is not spin-conservative.

An extension of the present theorem to the molecular system is conceptually straightforward, and indeed no essential difficulty is met in the formulation using the hypervirial theorem. Nevertheless, we have much to be considered: There are some nuclear-coordinate derivatives that do not vanish even in an equilibrium position. The actual calculation of the spin polarization potential is, of course, very troublesome.

Finally, we would like to add that the spin virial theorem is completely quantum-mechanical, having no classical counterpart, in striking contrast to the virial theorem.

Appendix I

What is to be noted is that the spin state is specified but that we still have the completeness

$$\sum_j \phi_{j\sigma}(\boldsymbol{r}_1)\phi^*_{j\sigma}(\boldsymbol{r}_2) = \delta(\boldsymbol{r}_1-\boldsymbol{r}_2). \tag{69}$$

By virtue of this, for example, it is found that

$$[T_\sigma,\ G_\sigma] = \sum_{jkl}(t_{jl\sigma}g_{lk\sigma} - g_{jl\sigma}t_{lk\sigma})a^\dagger_{j\sigma}a_{k\sigma}$$
$$= -\frac{i}{2}\sum_{jk}\int \phi^*_{j\sigma}(\boldsymbol{r})[\nabla^2,\ \boldsymbol{r}\cdot\nabla]\phi_{k\sigma}(\boldsymbol{r})dv\, a^\dagger_{j\sigma}a_{k\sigma}. \tag{70}$$

Hence we have only to use the well-known relation

$$[\nabla^2,\ \boldsymbol{r}\cdot\nabla] = 2\nabla^2. \tag{71}$$

Likewise

$$[1/r,\ \boldsymbol{r}\cdot\nabla] = 1/r \tag{72}$$

suffices for the case of V_σ. For the two-electron operator, again by virtue of the above completeness, we have

$$[W_{\sigma\tau},\ G_\sigma] = (1+\delta_{\sigma\tau})\frac{1}{2}$$
$$\times \sum_{jklmn}(w^{jn\sigma}_{lm\tau}g_{nk\sigma} - g_{jn\sigma}w^{nk\sigma}_{lm\tau})a^\dagger_{j\sigma}a^\dagger_{l\tau}a_{m\tau}a_{k\sigma}$$
$$= -(1+\delta_{\sigma\tau})\frac{i}{2}\sum_{jklm}\iint \phi^*_{j\sigma}(\boldsymbol{r}_1)\phi^*_{l\tau}(\boldsymbol{r}_2)[1/r_{12},\ \boldsymbol{r}_1\cdot\nabla_1]$$
$$\times \phi_{m\tau}(\boldsymbol{r}_2)\phi_{k\sigma}(\boldsymbol{r}_1)dv_2dv_1\, a^\dagger_{j\sigma}a^\dagger_{l\tau}a_{m\tau}a_{k\sigma}. \tag{73}$$

Calculating the commutator in the integrand as

$$[1/r_{12},\ \boldsymbol{r}_1\cdot\nabla_1] = (r_1^2 - \boldsymbol{r}_1\cdot\boldsymbol{r}_2)/r_{12}^3$$
$$= (1/r_{12} + (r_1^2 - r_2^2)/r_{12}^3)/2, \tag{74}$$

we reach the resultant.

Appendix II

The crucial point is that the definition of the scaled state with the unitary transformation[6,8]

$$|\eta\theta\rangle = \exp(-i(G_\uparrow + G_\downarrow)\eta - i(G_\uparrow - G_\downarrow)\theta)|O\rangle \tag{75}$$

immediately leads to

$$\frac{\partial}{\partial\eta}\langle\eta\theta|H|\eta\theta\rangle = -i\langle\eta\theta|[H,\ G_\uparrow + G_\downarrow]|\eta\theta\rangle \tag{76}$$

and

$$\frac{\partial}{\partial\theta}\langle\eta\theta|H|\eta\theta\rangle = -i\langle\eta\theta|[H,\ G_\uparrow - G_\downarrow]|\eta\theta\rangle. \tag{77}$$

If the unscaled state $|O\rangle$ is written in the expanded form (Eqs. 44 and 45), we have

$$|\eta\theta\rangle = \sum_M C_M \prod_{j^\sigma\in M} a^\dagger_{j\sigma}(\mu_\sigma)|\text{vacuum}\rangle, \tag{78}$$

where

$$a^\dagger_{j\sigma}(\mu_\sigma) = \exp(-iG_\sigma\mu_\sigma)a^\dagger_{j\sigma}\exp(iG_\sigma\mu_\sigma) \tag{79}$$

with

$$\mu_\sigma = \eta + \kappa_\sigma\theta, \tag{80}$$

because $a^\dagger_{j\sigma}$ is commutative with $G_{\bar\sigma}$ and because

$$\exp(-iG_\sigma\mu_\sigma)|\text{vacuum}\rangle = |\text{vacuum}\rangle. \tag{81}$$

The unitarity allows us to put

$$a_{j\sigma}(\mu_\sigma) = \sum_k u_{jk\sigma}(\mu_\sigma)a_{k\sigma} \tag{82}$$

with

$$u_{jk\sigma}(\mu_\sigma) = \int \phi^*_{j\sigma}(\boldsymbol{r})\phi_{k\sigma}(\boldsymbol{r}:\mu_\sigma)dv, \tag{83}$$

where $\phi_{j\sigma}(\boldsymbol{r}:\mu_\sigma)$ is the spatial orbital associated with $a^\dagger_{j\sigma}(\mu_\sigma)$ and $a_{j\sigma}(\mu_\sigma)$. From the differential equation

$$\frac{\partial}{\partial\mu_\sigma}a_{j\sigma}(\mu_\sigma) = -i[G_\sigma,\ a_{j\sigma}(\mu_\sigma)]$$
$$= i\sum_k g_{jk\sigma}a_{k\sigma}(\mu_\sigma) \tag{84}$$

we can extract the equation for the orbital

$$\frac{\partial}{\partial\mu_\sigma}\phi_{j\sigma}(\boldsymbol{r}:\mu_\sigma) = \frac{1}{2}(\boldsymbol{r}\cdot\nabla + \nabla\cdot\boldsymbol{r})\phi_{j\sigma}(\boldsymbol{r}:\mu_\sigma). \tag{85}$$

It follows immediately that

$$\phi_{j\sigma}(\boldsymbol{r}:\mu_\sigma) = \exp(3\mu_\sigma/2 + \mu_\sigma\boldsymbol{r}\cdot\nabla)\phi_{j\sigma}(\boldsymbol{r}), \tag{86}$$

which is readily proved to be identical with our scaled orbitals.

Appendix III

We can analytically integrate the matrix element of the spin polarization potential

$$P = \iint \rho_1(\boldsymbol{r}_1)\rho_2(\boldsymbol{r}_2)((r_1^2 - r_2^2)/r_{12}^3)dv_2dv_1 \tag{87}$$

rather easily when one of ρ_1 and ρ_2 is spherically symmetric. The analytic integration is not only useful in actual calculation but also instructive because it reveals a latent characteristic of the spin polarization potential. Now we assume ρ_2 is spherically symmetric; $\rho_2(\boldsymbol{r}_2)=\rho_2(r_2)$. Letting the direction of z axis of the second coordinates coincide with that of $\boldsymbol{r}_1$, we change the integration variable θ_2 with r_{12}. Then we have

$$P = 2\pi\int dv_1\int_0^\infty dr_2\rho_1(\boldsymbol{r}_1)\rho_2(r_2)r_1^{-1}r_2(r_1^2 - r_2^2)\int_{|r_1-r_2|}^{r_1+r_2} dr_{12}r_{12}^{-2}$$
$$= I_{r_1>r_2} - I_{r_2>r_1} \tag{88}$$

with

$$I_{r_1>r_2} = 4\pi\int dv_1\rho_1(\boldsymbol{r}_1)r_1^{-1}\int_0^{r_1} dr_2\rho_2(r_2)r_2^2 \tag{89}$$

and

$$I_{r_2>r_1} = 4\pi\int dv_1\rho_1(\boldsymbol{r}_1)\int_{r_1}^\infty dr_2\rho_2(r_2)r_2. \tag{90}$$

These integrals are already familiar. They appear in the calculation of the matrix element of the Coulomb-type electron repulsion integral

$$I = \iint \rho_1(\boldsymbol{r}_1)\rho_2(\boldsymbol{r}_2)(1/r_{12})dv_2dv_1, \tag{91}$$

which can be arranged as

$$I = 2\pi \int dv_1 \int_0^\infty dr_2 \rho_1(r_1)\rho_2(r_2) r_1^{-1} r_2 \int_{|r_1-r_2|}^{r_1+r_2} dr_{12}$$
$$= I_{r_1>r_2} + I_{r_2>r_1} \quad (92)$$

to clarify an intimate connection between P and $I_{..}$ Besides the density built of s-symmetry orbitals we have a few types of spherically symmetric densities, say, the sum like $p_x^2+p_y^2+p_z^2$; the above treatment is widely practical.

Studies on the Hydrous Niobium(V) Oxide Ion Exchanger. I. A Method for Synthesis and Some Properties

Yasushi INOUE,* Hiromichi YAMAZAKI, and Yasuyuki KIMURA
Department of Nuclear Engineering, Faculty of Engineering, Tohoku University, Aramaki, Sendai 980
(Received January 9, 1985)

A comprehensive study of the preparation of hydrous niobium(V) oxide ion exchangers was made using three kinds of niobium solutions: (1) HCl, (2) C_2H_5OH, and (3) H_2SO_4. From a detailed examination of the dependency of the yield, the ion-exchange behavior toward Na^+, the chemical stability, and some other properties, regarding the method for precipitation, it was found that the pyrohydrolysis of the $NbCl_5$ solution was the best method, since the procedure was simple, rapid and reproducible, and the product had a comparatively good ion-exchange property. The product obtained from the H_2SO_4 solution had the largest ion-exchange capacity and was most stable in highly alkaline solutions, but the whole procedure was very tedious. The exchanger prepared from the ethanolic solution had a smaller ion-exchange capacity in a pH region higher than 8. The materials, thus obtained, had at least two kinds of weakly dissociable ion-exchange sites, and the ion-exchange capacity for alkali metal ions decreased in the order of $Li^+>Na^+>K^+$. The aging effect and the chemical stability were also examined.

As has been previously pointed out,[2] hydrous oxide ion exchangers based on various polyvalent metal ions have the serious disadvantage of giving inconsistent results to different investigators, because of the irreproducibility of the synthesis. With this point in mind, the present authours previously studied hydrous titanium(IV) oxide and hydrous tin(IV) oxide for establishing satisfactory synthesis methods.[1,2] Hydrous niobium(V) oxide is expected to have a large ion-exchange capacity (3.2 mequiv/g at pH 12) and to be stable in highly acidic or alkaline solutions.[3] Its ion-exchange properties, however, have not yet been investigated in detail. This material has been prepared using the following methods: (1) the neutralization of the acidic solutions of niobium salts, such as sulfate, chloride, and fluoride,[3-5] (2) the pyrohydrolysis of an $NbCl_5$ solution[6] and, (3) the hydrolysis of a potassium fluoroniobate solution or niobium(V) alkoxide solution.[7,8] These methods, however, are not always suited for synthesizing a large amount of a hydrous niobium(V) oxide. A detailed comparison of these methods must be experimentally made in order to choose the best method since a detailed description of the experimental conditions is lacking in the literature.

The present paper will describe the results of an investigation undertaken to establish the best conditions for the synthesis of the hydrous niobium(V) oxide ion exchanger, together with some of its properties, particularly those with direct bearing on the conditions of the synthesis.

Experimental

Reagents and Apparatus. Niobium(V) chloride and niobium(V) oxide, respectively, were supplied from Mitsuwa Kagaku Yakuhin Kaisha, Ltd. and Shinetsu Kagaku Kogyo Kaisha, Ltd. Hydrofluoric acid was obtained from Hirota Kagaku Kogyo Kaisha, Ltd., and sulfochlorophenol S from Dojindo laboratories. The other chemicals were of the highest purity grades supplied by Wako Pure Chemical Industries, Ltd.

The pH values were measured with a Toa Dempa model HM-6A pH meter. A thermogravimetric analysis was undertaken with a Shimadzu model DT-20B micro thermal analyzer, connected to a Shimadzu model TGC-20H thermal balance. The absorbance was measured with a Hitachi model 124 double-beam spectrophotometer with a 1-cm glass cell.

Synthesis of Hydrous Niobium(V) Oxide. A synthesis was tried for three systems: (a) $NbCl_5$–HCl, (b) $NbCl_5$–C_2H_5OH, and (c) Nb_2O_5–H_2SO_4, as shown in Fig. 1. The concentration of niobium was held constant for each system because of a technical difficulty to make a meaningful variation in the concentration of the niobium from the respective starting materials. In the HCl-system, the starting solution was produced by dissolving 25 g of niobium(V) chloride in 50 cm^3 of concentrated hydrochloric acid, followed by dilution to 1 dm^3 with distilled water. The niobium(V) ethoxide solution was produced by dissolving 25 g of niobium(V) chloride into 200 cm^3 of 99.5% ethanol, followed by dilution to 3 dm^3 with distilled water. In the H_2SO_4-system, the starting solution was obtained by fuming the hydrochloric acid solution or the hydrofluoric acid solution of niobium with 40 cm^3 of concentrated sulfuric acid; the hydrofluoric acid solution was made by dissolving 5 g of niobium(V) oxide in 50 cm^3 of hot 7 mol dm^{-3} hydrofluoric acid.

In the methods from (1) through (6), hydrous niobium(V) oxide was precipitated by pyrohydrolyzing the $NbCl_5$ solution, while in the methods from (7) through (11), the precipitate was obtained by hydrolyzing the $NbCl_5$ solution by the addition of alkaline solutions. In methods (8),(9), and (11), the obtained slurries were refluxed with the mother liquor. In the methods from (12) through (14), the hydrous oxide was precipitated by the dilution of the respective starting solution with distilled water.

After being separated from the mother liquor by a

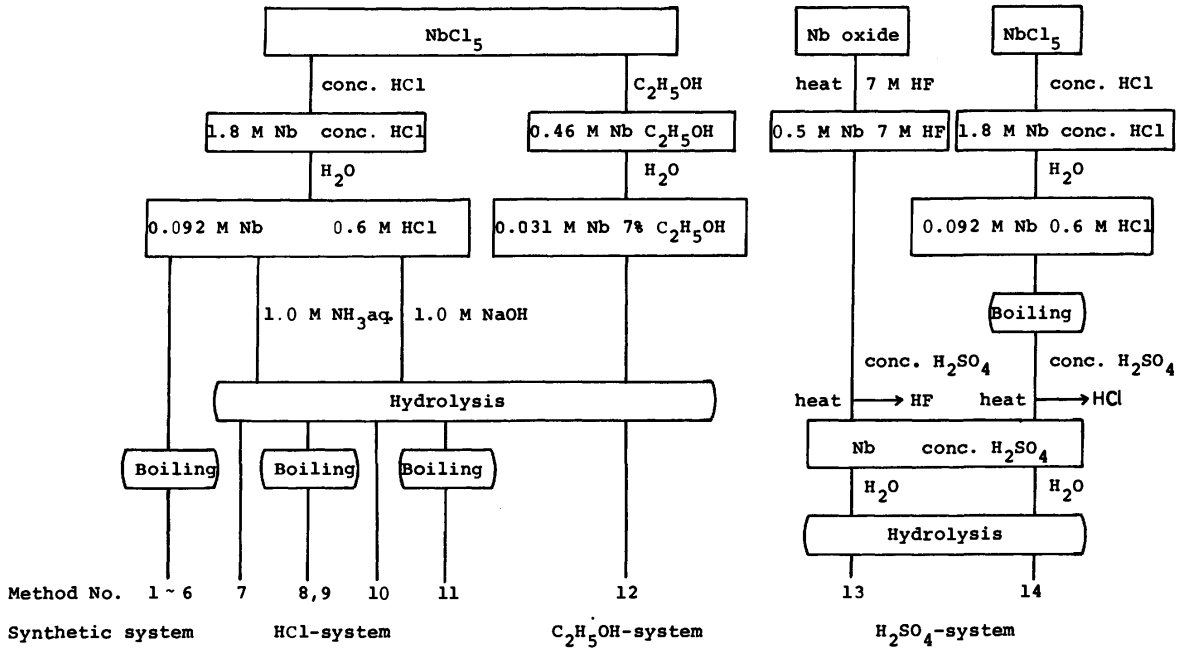

Fig. 1. Scheme of synthesis. (1 M = 1 mol dm^{-3})

combination of decantation and filtration through Toyo No. 1 filter paper under suction, the precipitate was uniformly dispersed into distilled water and filtered again after being completely sedimentated. This procedure was repeated until no chloride or sulfate ion was detected in the filtrate. Then, the precipitate was air-dried at room temperature. The resulting product was then immersed in distilled water to break it down into fine particles, which were subsequently dried again at room temperature. Particles were then ground in a porcelain mortar and sieved to obtain the required particle sizes.

Conditioning. The exchanger of a desired particle size (100—200 mesh) was washed with distilled water to remove any adherent powder. The slurry was poured into a glass tube with glass-wool plugging for column support, and then 0.1 mol dm^{-3} HCl was passed through the column until the pH of the effluent approached that of the influent. Then the column was washed with distilled water until the pH of the effluent became constant. The exchanger in the H^+ form thus prepared was air-dried and stored in a desiccator containing a saturated NaCl solution (relative humidity; 75% at 25 °C). The exchangers were used within 30 d after preparation, unless otherwise noted.

Specific Ion-exchange Capacity and Uptake Curves for Metal Ions. The exchanger (0.5 g) in the H^+ form was immersed into 50 cm^3 of different solutions, prepared by the desired mixed ratio of 0.1 mol dm^{-3} NaCl and 0.1 mol dm^{-3} NaOH, for 7 d at room temperature with intermittent shaking. This was followed by pH measurements and by the determination of the sodium ions. The sodium ions were converted to pure sodium chloride and indirectly determined by titrating the chloride ions. The amount of the ions taken up by the exchanger was evaluated from the difference between the initial and the final concentrations of the ions present in the solutions. The dissolved amount of the exchanger was evaluated from the amount of niobium in the supernatant solution which was determined spectrophotometrically by the sulfochlorophenol S method.[9] The limit of detection was 0.1 wt% of the exchanger used.

Analysis of Cl^- in the Exchanger. A sample of 0.5 g was dissolved by heating with 100 cm^3 of 9 mol dm^{-3} H_2SO_4 in a 500-cm^3 distilling flask, and the HCl evolving therefrom, carried by steam, was absorbed in a slightly alkaline solution and then determined spectrophotometrically using mercury(II) thiocyanate and ammonium iron(III) sulfate as coloring reagents. The limit of detection was 0.01 wt%.

Analysis of Water in the Exchanger. The water content was calculated from the weight loss at 850 °C in the TGA curves which were measured with 5 mg of sample in air at a heating rate of 10 °C min^{-1}.

Density. The apparent density of the exchangers was measured in the usual manner using a 25-cm^3 pycnometer.

Yield of the Exchangers. The yield was calculated on the basis of the recovery of niobium used.

Results and Discussion

Preparation of Hydrous Niobium(V) Oxide as an Ion Exchanger. The conditions for the precipitation, compositions and properties of the hydrous niobium(V) oxides are summarized in Table 1.

(I) Pyrohydrolysis of the Chloride Solution (the methods (1)—(6)): The semitransparent and gelatinous hydrous niobium(V) oxide was precipitated by heating 1 dm^3 of the hydrochloric acid solution of

Table 1. Comparison of various exchangers

niobium in a 3-dm^3 round-bottom flask, equipped with a reflux condenser, for 0.1—24 h. When the precipitate was air-dried at room temperature, it turned into a light-creamy solid.

(II) Neutralization of the Chloride Solution (the methods (7)—(11)): The precipitate was made by hydrolyzing niobium ions in the hydrochloric acid solution with either a 1-mol dm^{-3} NaOH solution or 1-mol dm^{-3} NH_3 aq without refluxing the slurry (the methods (7) and (10)), the precipitate formed at a pH lower than 2.0 was partially lost during washing because of incomplete sedimentation. When the pH at the time of precipitation was higher than 5.0, the yield decreased due to the peptization during washing. When a NaOH solution was used for neutralization, a marked peptization occurred at a pH higher than 6.0 and, then, the yield fell to around zero at a pH higher than 9.0. On the other hand, when NH_3 aq was used, the yield always exceeded 50 per cent at any realizable pH value since the degree of peptization was slight. It can be concluded from the above observations that the desirable pH range at precipitation is 2.5 to 4.0. When the slurries were refluxed (the methods (8), (9), and (11)), the precipitate obtained at a pH as low as 1.0 to 2.0 did not peptize during washing, and the yield exceeded 80 per cent. The air-dried products obtained by the neutralization with NH_3 aq solution were the semitransparent and glassy solid, while those produced by the neutralization with NaOH solution were white, opaque, and brittle like chalk.

(III) Precipitation from Ethanolic Solution of $NbCl_5$: Three cubic decimetres of the starting solution were diluted with distilled water to make total volume 5 dm^3, and it was allowed to stand for 2 d at room temperature. Then, the gelation of the solution took place and, when the precipitate was air-dried, the glassy and semitransparent solid was obtained.

The amount of chloride ions included in the exchanger in the H^+ form synthesized from the HCl-system was below the detection limit (0.01 wt%).

(IV) Precipitation from Sulfuric Acid Solution: The sulfuric solution of niobium was diluted with distilled water to make a total volume of 2 dm^3 and stood for 1 d at room temperature to complete precipitation. The precipitate (air-dried at room temperature) was glassy solid; the solids obtained from methods (13) and (14) were pale purple and light brown, respectivery, in color. The yield in the H_2SO_4-system was appreciably lower than that in the other systems. This is attributable to the lengthy washing of the precipitate due to the difficulty to remove the sulfate ions included in the precipitate.

Ion-exchange Properties. Figure 2 shows the uptake curves for Na^+ of the exchangers prepared by the neutralization of $NbCl_5$ with alkaline solutions (the methods (7), (8), (10), and (11)). These materials were weakly acidic ion exchangers having at least two kinds of dissociable hydrogen atoms, since the inflection points existed in the curves at around pH 8. In the extremely high pH region, the specific ion-exchange capacity decreased with the pH. As will be shown later, this is attributed to the dissolution of a part of the exchanger. This observation was common to all exchangers prepared by any methods except those prepared from the H_2SO_4-system. The uptake curves of the exchangers prepared from methods (8) and (11) indicated that the boiling procedure reduced the ion-exchange capacity in the

whole pH range by a total amount of 0.4 mmol Na^+ g^{-1}, instead, it stabilized the exchanger in alkaline solutions. The stabilization by aging, therefore, is accompanied by the degradation of some of the ion-exchange sites. Figure 3 compares the uptake curves of the exchangers obtained without using alkaline solutions. The ion-exchange capacities of the materials prepared by the pyrohydrolysis of the $NbCl_5$ solution (the methods (1), (3), and (6)) gradually decreased with the length of the boiling period and were slightly smaller than those of the exchangers prepared by the hydrolysis of the $NbCl_5$ solution with alkaline solutions. Furthermore, when the slurries were boiled for longer than 1 h, the degree of the decrease in the ion-exchange capacity in the highly alkaline region became very small, probably due to the stabilization of the exchanger in alkaline solutions. This figure also shown that the exchanger prepared from the H_2SO_4-system had the largest ion-exchange capacity throughout the pH range examined, and that it was most stable in alkaline solutions, since the ion-exchange capacity did not decrease in highly alkaline solutions. The ion-exchange capacities at a pH higher than 9 were appreciably smaller for the exchanger precipitated from the ethanolic solution of $NbCl_5$ than for the materials prepared by the pyrohydrolysis of $NbCl_5$ solution.

Water Content. The water contents in the exchangers are summarized in Table 1. It should be noted that the values in the table are not precise enough to determine the stoichiometry of the compounds since they were obtained during thermal nonequilibrium, the TGA method. However, they are useful for comparative purposes. Table 1 indicates that the water content differs greatly with the synthesis method, that is, 4.5—6.7 mol H_2O per mol Nb_2O_5. As a definite correlation between the water content and the ion-exchange capacity was not observed, it may be considered that a large part of the water does not take part in the ion-exchange reaction.

The exchangers prepared from the H_2SO_4-system have the best property as an ion exchanger, that is, they have the largest ion-exchange capacity and are most stable in alkaline solutions. The method, however, has a serious disadvantage due to a very complicated and lengthy procedure, whereas the synthesis by pyrohydrolysis is very simple. From a practical point of view, the advantages due to the simplicity and rapidity of the procedure in the latter method more than offset the demerits of smaller ion-exchange capacity. Efforts were then concentrated on determining the properties of the exchangers prepared from this system.

Physical Properties. Table 2 shows examples of the size distribution of the particles formed when a gel prepared from method (4) was immersed in water. It is evident from this table that a large part of the exchanger invariably possesses particles large enough for use in column operation. The density of the exchanger in the H^+ form was 2.46±0.01 g cm^{-3}.

Chemical Stability. To examine the chemical stability of the exchanger, the amount of niobium dissolved in various reagents was measured using the exchangers prepared by methods (3) and (14). The amount of niobium dissolved in the MOH-MCl solution (M=Li, Na, K) of ionic strength 0.1 is shown in Fig. 4, where the dotted line indicates the detection limit (0.1 wt%). The exchanger prepared from method (3) was stable up to a pH of 10.0, 10.5, or 10.8, respectively, for M=Li^+, Na^+, and K^+. This indicates that the kind of alkali metals in the solution greatly affects the stability of the exchanger. On the other hand, the exchanger prepared from method (14) was fairly stable in an alkaline solution; even at a pH as high as 11.9. Only 0.2 wt% of the exchanger was dissolved. As is shown in Table 3, the exchangers prepared from any method were unstable in a 0.1 mol dm^{-3} NaOH solution, but fairly stable in a 1 mol dm^{-3} NH_3 aq solution. To further examine the stability in various acids, measurements were made of the amount of niobium in typical mineral and organic acids. The results, also shown in Table 3, indicate that both exchangers were very stable against 1 mol dm^{-3} mineral acids but dissolved appreciably into organic acids, particularly into oxalic acid. This fact shows that the exchanger is easily attacked by acids with a strong tendency to complex Nb(V).

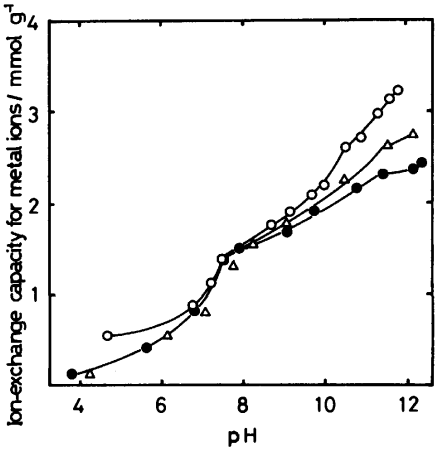

Fig. 5. Uptake curves for various alkali metal ions. Cation; ○: Li^+, △: Na^+, ●: K^+. Exchanger: The method (4) in Fig. 1.

Uptake Curves for Various Alkali Metal Ions. In order to compare the ion-exchange behavior of alkali metal ions, uptake curves were obtained for Li^+ and K^+, as is shown in Fig. 5. The ion-exchange capacities for these cations decreased in the order of $Li^+ > Na^+ > K^+$. This figure also shows that the pH of the inflection point in the curves was independent of the kinds of the exchanging cations and the difference of the ion-exchange capacities was mainly brought about in the pH range higher than that point. This observation can be understood by considering that the weakly dissociable sites are the hydroxyl groups which form olation bonds in the exchanger. When anhydrated cations are exchanged with H^+ from these hydroxyl groups, some of the olation bonds are severed, enhancing the tendency to dissolve into the solution; this tendency is compatible with the order of the ability of alkali metal ions to dissolve the exchanger.

Change in Capacities During Storage. As the hydrous oxide is thermodynamically metastable, the ion-exchange capacity is expected to decrease during storage; in fact hydrous titanium(IV) oxide in the H^+ form was reported to lose its cation-exchange capacity appreciably during storage in air.[10] Figure 6 shows the result for material prepared from method (4), which was stored for 300 d over a saturated NaCl

Table 3. Chemical stability at room temperature[a)]

solution. This figure reveals that the ion-exchange capacity in a pH region lower than the inflection point decreased a little during storage. The stability in alkaline solutions was improved slightly. The storage, however, did not affect at all the stabilities of the exchanger in other reagents.

Recommended Synthetic Method. It is concluded that the exchanger precipitated from the concentrated sulfuric acid solution of niobium is best with respect to the ion-exchange capacity and the chemical stability. This method, however, is of no use in preparing a hydrous niobium(V) oxide as an ion exchanger because of the tedious procedure (due to the difficulty in preparing a sulfuric acid solution of niobium in high concentration and the lengthy washing of the precipitate). The method for the pyrohydrolysis of a $NbCl_5$ solution is considered practical since a large amount of pure hydrous niobium(V) oxide can be easily prepared without suffering much from the defects of low ion-exchange capacity and chemical unstability.

In the method regarding pyrohydrolysis, an increase in the boiling period improves the stability for highly alkaline solutions, but reduces the ion-exchange capacity of the product; hence, by a mutual concession between them, method (4), where the $NbCl_5$ solution was thermally hydrolyzed by boiling for 2 h, was chosen as the recommended procedure for synthesizing a hydrous niobium(V) oxide ion exchanger. Table 4 shows the reproducibility of the synthesis by this method. The variation of the water content may be ascribed to the sensitivity of the amount of occluded water to the conditions of the work environment (such as temperature and humidity) since the same water content was observed for exchangers prepared in different batches at a same time. The fluctuation in the yield is a natural consequence of the irregularity in the recovery of a precipitate at the time of repeated washing. As the ion-exchange capacities of the products agree well with each other, a synthesis using method (4) can be regarded as reproducible.

Glass Formation Study of Aqueous HX Solutions (X=F, Cl, and Br)

Hitoshi KANNO* and Kenji SATOH
Department of Chemistry, Meisei University, Hino, Tokyo 191
(Received May 2, 1985)

Glass-forming composition regions of aqueous HX solutions (X=F, Cl, and Br) were determined. It was found that oxonium ions play an important role in glass-forming behavior of these solutions. Including the results for HI solution previously reported,[1] the general trends of glass-formation behavior of aqueous HX solutions are summarized.

As an extension of the previous work,[1] we measured the glass-transition temperatures (T_g's) of aqueous HX solutions (X=F, Cl, and Br) as a function of the HX concentration.

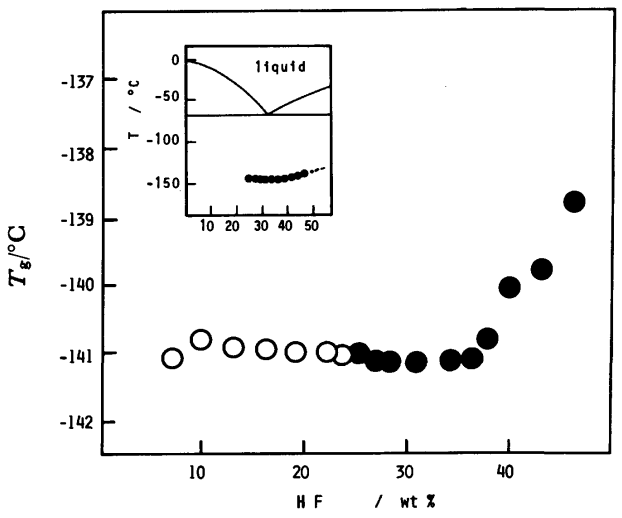
The object of this work is two-fold: (1) to see the general trends of glass-formation behavior of aqueous HX solutions, and (2) to find out the reason why the extrapolation of the T_g data of the HI-water system to pure water predicts the glass-transition temperature of glassy bulk water to be around −177 °C, far below the value (−135~−140 °C) expected from the T_g data for other aqueous electrolyte solutions.[2,3]

Experimental

Each sample solution was prepared by simple mixing concentrated HX acid and distilled water by weight. The T_g measurements were carried out in the same way as previously described.[1] Glass formation of the quenched sample solution was visually checked. The abrupt shift of T_g is a good indicator for crystallization or partial crystallization of a quenched sample and therefore can be used for checking glass-formation (crystallization). The upper limit of the glass forming composition range was not established because of the difficulty of obtaining higher concentrated HX solutions (HF>46 wt%, HCl>35 wt%, HBr> 47 wt%).

Results and Discussion

The T_g results for each HX solutions are shown in Figs. 1—3 together with the phase diagrams. Among HX solutions, glass formation of HCl solution has been well studied[4,5] and our results are in good agreement with previous reports.[4,5] Including the results for HI solution which was already reported,[1] we summarized the general trends as follows; (1) except the HF solution, T_g increases almost linearly



Glass forming region of the HF–H_2O system

with HX (in wt%) concentration, (2) the lowest T_g value for each glassy HX solution is about −141 °C, and (3) the first eutectic composition is glass-forming for all HX solutions (X=F, Cl, Br, and I).

Among these trends, the last one is generally observed for most glass forming aqueous solutions.[3] In fact, a binary solution of the eutectic composition is most prone to be glass forming if it has any glass forming composition range.[6]

Glass formation of the HF solution begins from the concentration of about 25 wt% up to ≈46 wt%HF (above which experiment was not made in this study). An interesting point is that T_g is nearly invariant in the concentration range from ≈25 wt% to ≈40 wt% HF and then rises up at higher HF concentrations. Similar behavior has been observed for aqueous LiCl and $MnCl_2$ solutions.[2,7] In these solutions, T_g decreases with water content, then tends to level off at a certain salt concentration and becomes concentration independent of further increase in water content.[2,7,8] There are two possible causes: One is a precursor phenomenon of a phase-separation (liquid–liquid immiscibility)[9,10] and the other the partial crystallization of the solution in the quenching process. In the former case, a homogeneous solution splits into two phases (one is a water-rich phase and the other is a salt-rich one) as the temperature of the solution is lowered.[10] Due to the large thermal instability of the water-rich phase in a high-degree supercooled state, the water-rich liquid phase (possibly dispersed as fine micro-droplets in the solution) crystallizes in the quenching process and only the salt-rich phase is quenched to a vitreous state. In the latter case, the partial crystallization of the solution occurs in the quenching process. As water content increases in the solution, the energy barrier for ice nucleation becomes very low due to the very low stability of bulk supercooled water against ice crystallization.[11] At present it is difficult to determine which is the cause for the observed T_g behavior of the HF solution.

Comparing the solution compositions at which the HX solution becomes glass-forming with the cooling rate of about 600 K min^{-1}, we immediately know that the order of the HX concentration is HF>HBr>HCl>HI, indicating that the HX solution tends to be glass forming with a lower concentration of HX when X^- is a stronger structure breaker: A HI solution is glass-forming at R≃10.2 or less but a HF solution can be vitrified only at R≃3.3 or less (R=moles of water/moles of HX). This glass-forming feature is opposite to the trend for other aqueous electrolyte solutions, which are tend to be glass forming when containing small structure-making ions as a component (or components) of an electrolyte in the solutions.[2] Therefore, we consider that the glass forming ability of aqueous HX solutions should be relevant to oxonium ions in the solutions.

It is now established that oxonium ions in aqueous HX solutions (except X=F) are mostly preserved from a liquid state at room temperatures to a glassy state.[12] On the other hand, ionic dissociations of HNO_3, H_2SO_4, and H_3PO_4 in concentrated aqueous solutions are greatly reduced at low temperatures.[13] In these solutions, Raman bands arising from neutral acid molecules increase in their intensities at low temperatures.[13] Glass formation of aqueous HNO_3 solution begins from 35 wt% HNO_3 (R=6.5) to higher HNO_3 concentrations.[14] The need of higher acid concentration for glass forming of the HNO_3 solution as compared with HX solutions (X=Cl, Br, and I) should be partly due to the decrease of ionization of HNO_3 at low temperatures.

From X-ray and neutron diffraction studies,[15,16] it is concluded that the structure of hydrated oxonium ions in aqueous HCl solutions is trigonal pyramid $OH_3^+(OH_2)_3\cdots(HOH)$, in which three water molecules combine with a H_3O^+ ion through rather strong hydrogen bonds and one water molecule lies at the apex of the $OH_3^+(OH_2)_3$ pyramid. The existence of strong hydrogen bonds between oxonium ions and water molecules is considered to be a good inhibitor to ice nucleation.

The formation of oxonium ions should also be a major cause of the anomalous low T_g prediction for pure bulk water in the T_g data of aqueous HI

solution. When a pure liquid is not glass -forming, estimation of its T_g is made successfully by the extrapolation of the T_g data of binary solution.[2,3,17] Though there have recently been a few reports[18,19] claiming that bulk water can be vitrified, at least partially, by ejecting highly compressed water into cryogenic solvents held at very low temperatures, there has been no reliable T_g datum for bulk glassy water. The estimated T_g for bulk water from the T_g data for binary aqueous solutions is around −138 °C.[2,3] In the cases of HCl and HBr solutions, least-square-curve-fitting calculations give the following formulae:

$T_g = 0.43Y - 150$(°C) for aqueous HCl solution, and

$T_g = 0.37Y - 158$(°C) for aqueous HBr solution,

where Y is wt% of HX. As previously reported,[1] the HI solution predicts T_g for a bulk glassy water to be around −177 °C. Acid strength increases in the order HF>HCl>HBr>HI,[20] and the strength of hydrogen bonds between X^- ions and water molecules is in the order HI>HBr>HCl>HF.[21] In acid solutions, protons move about between water molecules very rapidly.[22] It is well known that the ionic mobility of protons in aqueous solution is about nine times larger than that of lithium ions at 18 °C though the data are at infinite dilution.[23] Thus, knowing that glass transition occurs when diffusion is almost suppressed in a liquid[24] and that ionization of HX in aqueous HX solution is very high even at low temperatures,[12] we expect that the predicted T_g for pure water should reflect the high mobility of protons in the HX solutions. If the expectation is the case, the low T_g for bulk water predicted from the T_g data of aqueous HX solutions is reasonable. The fact that the stronger the HX acid is the lower the predicted T_g for pure water becomes can be taken as a validity of the above explanation. One supporting experimental evidence comes from the observation that the glass transition in a glassy ice crystal, which is claimed to be related to proton movements, occurs at −173 °C.[25] Another, though indirect, evidence is that the T_g data of HNO_3 solution predicts the T_g of pure water to be −144 °C,[14] in parallel with the observation that ionization of concentrated HNO_3 solution is much reduced at low temperatures.[13] However, these data are not so conclusive to warrant our conclusion definitely. Therefore, further experiments are needed before the anomalously low T_g prediction from aqueous HX solutions is fully clarified.

This work was in part assisted by a Grant-in-Aid for Scientific Research from the Ministry of Education, Science and Culture.

Kinetic Analysis of the High-pressure Diels-Alder Reactions of Tropone with Maleic Anhydride and Norbornene[1)]

Hitoshi TAKESHITA,* Shigeru SUGIYAMA, and Toshihide HATSUI
Research Institute of Industrial Science, 86, Kyushu University, Kasuga-koen, Kasuga, Fukuoka 816
(Received March 12, 1985)

The kinetics of Diels-Alder reactions of tropone with maleic anhydride and norbornene were studied at pressures up to 2000 bar. The activation volumes, obtained from the former at 378.2 K in isopropylbenzene (IPB) and *N,N*-dimethylformamide (DMF), were $\Delta V^{\neq}$(IPB)=−21.4 cm³/mol and $\Delta V^{\neq}$(DMP)=−16.8 cm³/mol. Those from the latter (at 408.2 K) were $\Delta V^{\neq}$(IPB)=−30.0 cm³/mol and $\Delta V^{\neq}$(DMF)=−27.8 cm³/mol. These $\Delta V^{\neq}$ and ΔV showed a large deviation from those of the (6+4)π process of tropone with cyclopentadiene (by le Noble) and a small deviation from those of other typical Diels-Alder reactions to support the concerted cycloaddition mechanism which has been established by the kinetic analysis at atmospheric pressure.

In the field of high pressure organic chemistry, electrocyclic reactions, *e.g.*, Diels-Alder reaction, have been intensively investigated in the last two decades, and the reaction mechanism has been interpreted in terms of the activation parameters obtained by this method.[2,3)] According to general knowledge regarding the activation volume ($\Delta V^{\neq}$) and the reaction volume (ΔV), the concerted reactions show large negative values for their activation volumes; −25 to −35 cm³/mol for Diels-Alder reactions and −18 to −24 cm³/mol for 1,3-dipolar cycloaddition reactions.[3)] $\Delta V^{\neq}/\Delta V$ is in a range between 0.5 and 1.[4)] These values are in contrast to those of a two-step reaction *via* a zwitterionic intermediate in which, $\Delta V^{\neq}/\Delta V$ exceeds unity and $\Delta V^{\neq}$ might be larger than −50 cm³/mol.

Since there should not be much difference in the nature of bond formation among various concerted cycloadditions, such reaction features may be universally recognized in the concerted reactions. However, a remarkable exception has been noticed in a cycloaddition reaction involving tropone (**1**) with cyclopentadiene (CP) in dioxane.[5)] This has been the sole (6+4)π cycloaddition reaction ever studied by means of high-pressure kinetics, from which, a very small $\Delta V^{\neq}$ and ΔV (−7.5 and −4.3 cm³/mol) with a remarkably large $\Delta V^{\neq}/\Delta V$ (1.7) was obtained.[5)] Generally, when $\Delta V^{\neq}$ shows such a small negative value, $\Delta S^{\neq}$ must also be small and negative. However, as far as a kinetic analysis at atmospheric pressure shows, the $\Delta S^{\neq}$ is large and negative.[6)] This result is similar to that obtained in typical concerted Diels-Alder reactions.

These small activation and reaction volumes were interpreted on the basis of an unusually small partial molar volume of **1** which might be attributable to its highly polar structure.

It is true that the chemical properties of **1**, one of the most basic nonbenzenoid aromatic compounds, have been interpreted in terms of a contribution of a delocalized limiting structure (**1a**) with a delocalized 6π structure. Thus, **1** has a large dipole moment. On the other hand, **1** is known to undergo various types of pericycloadditions, such as (2+4)π-,[7)] (4+2)π-,[8)] (4+6)π-,[9)] (6+4)π-,[10)] and (8+2)π cycloaddition[11)] reactions. The concerted nature of its cycloaddition reactions has been accepted after a product analysis and kinetic investigations. Taking these into account, the above-mentioned results regarding (6+4)π cycloaddition of **1** with CP called our attention to whether the extraordinary figures which were obtained should be attributable to the characteristics of **1**, itself, as interpreted by le Noble, or to the special feature of the (6+4)π pericycloaddition of **1**. If the anomalies are due to the observed molar volume of **1** (85.6 cm³/mol; smaller than that calculated from the parachor listings (by 20 cm³/mol), as has been explained),[5)] this might be a good reason for the large dipole moment of **1** (4.17 D[12)]; 4.30 D[13)]). Then, this feature should always be observed in the cycloadditions of tropones.

To verify this point, we carried out Diels-Alder reactions of **1** with two kind of dienophiles: i) polar-, electron-deficient maleic anhydride (**2**) and ii) non-polar-, a strained and rigid bicyclic compound, norbornene (**3**). Each is known to give a single product.[8,14)] Particularly, the selection of the hydrocarbon, **3**, should provide reliable data for comparisons with the le Noble's experiment.

Experimental

Materials. Tropone (**1**) was prepared using Nozoe's procedure,[15)] purified by silica-gel chromatography, and distilled using a Kugelrohr tube *in vacuo*.. The purity was over 99.0%. Maleic anhydride (**2**) was sublimed *in vacuo* to show a mp of 53.5—54.0 °C. Norbornene (**3**) was used without further purification (a commercial Extra-Pure brand of Tokyo Kasei Co.). The adducts, **4** and **5**, were purified by repeated recrystallizations from acetone and pentane, respectively. They showed pertinent melting points, elemental analyses, and IR, NMR, and mass spectra. Isopropylbenzene (IPB) was distilled over Na and *N,N*-

dimethylformamide (DMF) was dried on CaH_2 and distilled *in vacuo*. Both solvents were gas-liquid chromatographically pure.

Kinetic Measurements. All kinetic runs, including the atmospheric runs, were carried out in a pressure vessel with an outlet valve for sampling. The temperature was controlled within 0.5 K and the pressure was measured using a Heise-Bourdon gauge. The initial concentrations of the reactants were *ca.* 0.007 mol/kg for **1** and 0.14 for **2** or **3**. The progress of the reactions was gas-liquid chromatographically monitored with a JEOL JGC-20KFP model gas chromatograph (column: 10%-Silicone XE 60 on Chromosorb W-DMCS) connected to a digital integrator, by observing the change of **1** (in the reaction with **2**) or **5** (in the reaction with **3**). Reliable data were collected after at least 1 h when thermal and pressure equilibrums were achieved. An analysis was performed as a *pseudo*-first-order reaction for **1**. Each reaction was repeated at least three times and second-order rate constants (k) were obtained from the observed rate constants (calculated by least-squares method).

Measurements of the Partial Molar Volumes. The partial molar volume of each substrate (V_i) was determined by an extrapolation of the apparent molar volume (ϕ_i) to infinite dilution (obtained by a measurement of the density with Ostwald's pycnometer at 333.15±0.01 K). For each substrate, ϕ_i was almost constant for the same solvent.

$$\Phi_i = [(1000+M_im_i)/d_{mi}-1000/d]/m_i \quad (1)$$

where the subscript i represents the solute and M the molecular weight. d_{mi} and d are the densities of the solution and a pure solvent, respectively, and m_i is the molality. V_4 in IPB could not be obtained due to the insolubility of **4**.

Results and Discussion

Activation Volume. The rate constants for reactions of **1** with **2** and **3** at various pressures in IPB and in DMF are listed in Table 1. There are good linear correlations between ln k and the pressure in the range of 1 to 2000 bar, exhibited in Fig. 1 (correlation coefficient r: 0.998 and 0.992 for the reactions of **1** with **2** in IPB and in DMF, respectively; 0.997 and 0.999 for **1** with **3** in IPB and DMF, respectively). From Eq. 2 (derived from transition-state theory), $\Delta V^{\neq}$ was obtained and is listed in Table 2, together with the V_i for each compound and the volume profile ($\Delta V^{\neq}/\Delta V$).

$$\Delta V^{\neq} = -RT(\partial \ln k/\partial p)_T \quad (2)$$

The values of $\Delta V^{\neq}$ in Table 2 are large negative figures and (especially for the reaction with **3**) are typical values for Diels-Alder reactions.[2] Therefore, as far as the activation volume is concerned, the

Table 2. Partial molar volumes (V_1), activation volumes ($\Delta V^{\neq}$), and reaction volumes (ΔV) for the reaction of **1** with **2** and **3** (in cm^3/mol)

Reactants	Solvent	V_1	V_2 or V_3	V_4 or V_5	ΔV	$\Delta V^{\neq}$	$\Delta V^{\neq}/\Delta V$
1+**2**	IPB	99.8	75.0	—	—	−21.4	—
	DMF	97.0	72.6	144.1	−25.5	−16.8	0.66
1+**3**	IPB	99.8	106.8	173.1	−33.5	−30.0	0.90
	DMF	97.0	106.0	170.9	−32.1	−27.8	0.87

V_1 and ΔV are obtained at 333.15 K, and $\Delta V^{\neq}$ at 378.2 K for **1** and **2**, and at 408.2 K for **1** and **3**.

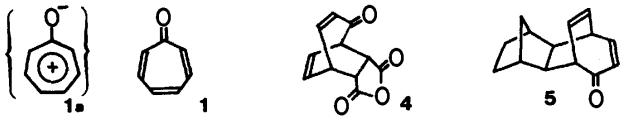

Chart 1

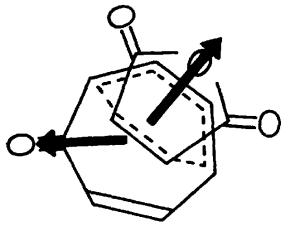

Fig. 2. Schematic Model of Dipoles in the Transition States.

Diels-Alder reaction of **1** clearly falls into a category of the concerted reaction. If one trusts the present results, the electrostriction of **1** must not be as large as has been suggested.

Nevertheless, the negative values for the activation volumes of reaction of **1** with **2** were slightly small. In this case, should the difference in the size of molecule be negligible, it is important that both reactants are equally polar molecules (dipole moments: 4.17 D for **1**[12] and 3.95 D for **2**[16]). In the initial state, **1** and **2** contract due to their high polarity. The polarity should decrease during the transition state, but should not cause a reduction in the volume if one considers a geometry in which the dipole moments of the two components are oriented at large angles with each other (θ=130 to 140°, Fig. 2) in the transition state. In other words, the contracted volumes of the two components are responsible for the small $\Delta V^{\neq}$ in the reaction of **1** with **2**. This conclusion is supported by the observed difference in the activation volumes in the two solvents. The value $\Delta V^{\neq}$(IPB)−$\Delta V^{\neq}$(DMF)=−4.6 cm^3/mol is quite similar to the difference between the sums of the volumes of the reactants in the two solvents ($\Sigma[V_i$(IPB)−V_i(DMF)]=5.2 cm^3/mol). Therefore, the volumes of the transition state are almost same in the two solvents. As the solvent effect on the partial molar volume (V_i) is parallel to the polarity of the reactant and the solvent,[17] the transition state is, therefore, less polar than the initial state.

Reaction Volume and Volume Profile. An analysis of ΔV and $\Delta V^{\neq}/\Delta V$ led to the same conclusion as above. The volume changes and the volume profiles for the reaction of **1** with **3** were the same as those for ordinary Diels-Alder reactions. We also obtained small values for ΔV and $\Delta V^{\neq}/\Delta V$ during the reaction of **1** with **2**. The former can be attributable to the polarity of the reactants and the latter represents a smaller polar transition state than for the product, **4**, as discussed above. Since the dipole moments of **1** and **2** are almost the same, we can assume that the volume reduction of **1** due to polarity is just as large as that of **2**. In this respect, the value of the previously reported partial molar volume of **1** in dioxane[5,18] is too small unless there are some unusual solvent-solute interactions.

Solvent Effect. The reaction rates of **1** with **2** or **3** in solvents having different polarities were slightly different from ordinary Diels-Alder reactions due to an increase in the dielectric constant (36.7 (DMF) from 2.4 (IPB)). The rates changed by only a factor of 1.1 (for the reaction with **3**) and 0.67 (with **2**) at atmospheric pressure. This means: i) the change of polarization is small during the rate-determination step in both reactions, and ii) in the reaction with **2**, the polarity of solvent decreases the rate; *i.e.*, the transition state should be less polar than the initial state. The former (i) seems to conflict with the above discussion concerning volumes, but it does not. Because that depends on the total dipole moment during the transition state. This means that the conclusion regarding the solvent effect is in accord with that for the activation volume.

Activation Energy and Entropy of the Reaction of 1 with 2. For a further determination of the transition state of the cycloaddition of **1** with **2**, atmospheric reactions were examined in IPB and DMF (the rate constants are summarized in Table 3). Arrhenius plots gave good linear correlations (r: 0.997 in IPB and 0.998 in DMF). The activation energy (E_a), activation entropy ($\Delta S^{\neq}$) and activation free energy ($\Delta G^{\neq}$) at 378.2 K are shown in Table 4. The remarkably large negative $\Delta S^{\neq}$ undoubtedly in-

Table 3. The rate constants of the Diels-Alder reaction of **1** with **2** at atmospheric pressure (10^5 k/kg mol^{-1} s^{-1})

Solvent	Temperature/K			
	378.2	388.2	398.2	408.2
IPB	2.32±0.02	3.66±0.08	5.50±0.18	7.36±0.15
DMF	1.56±0.09	2.51±0.01	3.96±0.16	5.54±0.12

Table 4. The activation paraneters for the Diels-Alder reaction of **1** with **2** at 378.2 K

Solvent	E_a/kJ mol^{-1}	$\Delta S^{\neq}$/J mol^{-1} K^{-1}	$\Delta G^{\neq}$/kJ mol^{-1}
IPB	49.7±3.3	−229±9	133±7
DMF	54.8±2.5	−219±7	134±5

dicates a concerted character regarding the reaction. This is parallel to kinetic studies of other Diels-Alder reactions,[19] including those of troponoids.[14,20] In addition, the E_a values, larger in DMF than in IPB, support the proposal that the initial state is more stabilized than the transition state in DMF, *i.e.*, the transition state is less polar than the initial state.

In conclusion, from the reactions with **2** and **3**, it was clarified that in the Diels-Alder reaction of **1**, the activation and reaction volumes are affected by the polarities of the initial state and the transition state. However, they are not negatively small as reported for the reaction of **1** with CP. We will report on studies regarding the (6+4)π cycloaddition of **1** with dienes in order to understand the thermal reactions of tropones.

Critical Peptide Size for Insolubility Caused by a β-Sheet Aggregation and Solubility Improvement in Hydrophobic Peptides by Replacement of Alanine Residues with α-Aminoisobutyric Acid Residues[1)]

Mitsuaki NARITA,* Junn-Yann CHEN, Hiroyuki SATO, and Yukio KIM
Department of Industrial Chemistry, Faculty of Technology, Tokyo University of Agriculture and Technology, Koganei, Tokyo 184
(Received March 19, 1985)

In order to demonstrate an important role of a β-sheet aggregation on insolubility of peptides, hydrophobic peptides having partial amino acid sequences found in natural proteins have been prepared by the stepwise elongation and fragment condensation methods. In conformity with the solubility prediction for protected peptides in our previous paper, solubility data indicate that insolubility of peptides appears to begin at octa- or nonapeptide levels. In hydrophobic sequences found in proteins, the structure of peptide backbones, namely, the β-structure clearly plays an important role on insolubility of peptides, but the composition of peptides does not. Solubility improvement in hydrophobic peptides included in α-helical regions of proteins is easily achieved by replacement of Ala residues with Aib residues. High solubility of the peptides containing Aib residues is clearly explained by the observation that replacement of C^{α} hydrogen atoms with methyl groups greatly disturbs β-sheet structures, promoting helical folding in peptides. The great ability of an Aib residue to promote helical folding is distinctly revealed in the peptide fragments included in α-helical regions of proteins as demonstrated before in model oligo(Leu)s.

Peptide fragments having only hydrophobic amino acid residues are often found in signal peptides[2)] and hydrophobic regions of intrinsic membrane proteins.[3)] On the basis of our solubility prediction method in a previous paper,[4)] they are predicted to be extraordinarily less soluble in the solvents used in peptide syntheses and to be less amenable to further elongation of peptide chains. For solubility prediction in the paper,[4)] the peptides **1**—**5** in Fig. 1 were used as representative examples of hydrophobic peptide fragments contained in natural proteins and, as expected, actually found to be extraordinarily less soluble due to their β-sheet aggregations. In Fig. 1, the peptides **1**—**5** have the amino acid sequences corresponding to murine H-2K^{b} [287—294], murine H-2K^{b} [291—298], murine H-2K^{b} [287—298], subtilisin BPN′ [227—235], and T24 human bladder carcinoma oncogene [6—15], respectively.[5-7)] The numbers in brackets in the following trivial names represent the positions of the first and last amino acids from the N-terminals in the intact proteins.[8)]

In this paper, we describe syntheses and IR absorption conformational analyses of the peptides in Fig. 1 and investigate critical chain length for

Fig. 1. The amino acid sequences of the peptides **1**—**18** used in this study.

insolubility of hydrophobic peptides caused by the β-sheet aggregation since we postulated that peptides smaller than heptapeptides are readily soluble in the solvents used in peptide syntheses.[4] The peptide **6** in Fig. 1 is further presented as an interesting example to have high solubility in spite of having the β-structure in solution. It has the amino acid sequence corresponding to bacteriorhodopsin [217—224].[9] The peptides **7—13** in Fig. 1 are also presented to investigate the critical chain length for insolubility. They have partial sequences of the peptides **1—5**. Recently, we also demonstrated that replacement of Ala residues with Aib residues in peptides constrained helical folding in the peptides, and that a dramatic change took place in solubility.[10,11] The implications of the strategy of solubility improvement for the chemistry of peptides and proteins were also discussed. The peptides **14—18** in Fig. 1 are presented to demonstrate the usefulness of replacement of Ala residues with Aib residues for solubility improvement in hydrophobic peptides included in α-helical regions of proteins. They have the amino acid sequences in which Ala residues in the peptides **2** and **4** and in their fragments are replaced by Aib residues.

Experimental

General. The uncorrected capillary melting points will be reported. Analytical instruments and conditions were described in the previous paper.[10] The solubility (c=1.0 g/dl) was divided into the following four classes: (A) completely soluble at room temperature, (B) completely soluble at 80 °C or refluxing temperature, (C) partially soluble at 80 °C or refluxing temperature, and (D) nearly insoluble at 80 °C or refluxing temperature.

General Procedure for the Coupling Reaction Using DCC Activation in the Presence or in the Absence of HOBt. DCC (1.1 equiv) was added to an ice-chilled, stirred mixture of a carboxyl component (1.1 equiv) and an amino component (10 mmol) in dichloromethane or DMF (100 ml). The amino components were obtained from a TosOH salt or HCl salt with an equivalent of NMM. When the carboxyl component was a peptide, HOBt (1.2 equiv) was added before the addition of DCC. Peptide chain elongation of lower peptides was performed in dichloromethane, and fragment condensation for the peptides **1—6** and **9—13** was carried out in DMF. The reaction mixture was stirred in an ice-chilled bath for 3 h, at room temperature overnight, and then filtered. The filtrate was concentrated *in vacuo*. The subsequent work-up procedure was essentially the same as those described before.[10,11]

General Procedure for Removal of the Boc Group. Boc-peptide benzyl esters (10 mmol) in 3 M† HCl/AcOEt (40 ml) were stirred in an ice-chilled bath for 1.5 h. Removal of the Boc group from the peptide **2** was carried out in TFA/dichloromethane (1/2, v/v) at room temperature for 1 h. Then, the mixture was concentrated *in vacuo*, followed by the repetition of the addition and removal *in vacuo* of dichloromethane. The residue was used for a subsequent coupling reaction without further purification.

General Procedure for Removal of the Bzl Group. Boc-peptide benzyl esters (7 mmol) were hydrogenated overnight at atmospheric pressure in a mixture of AcOH/MeOH (1/4, v/v) (100 ml) using 5% Pd/C (10 wt%) as a catalyst. After the removal of Pd/C, the filtrate was concentrated *in vacuo*. The residue was washed with water and recrystallized from appropriate solvents.

Results

Syntheses and Solubilities of Hydrophobic Oligopeptides. The typical synthetic procedures are summarized in Scheme. Starting with amino acid benzyl esters as amino components, di- to pentapeptides were prepared by usual stepwise elongation of the peptide chains using DCC activation[12] in dichloromethane. Further chain elongations were performed mainly in DMF by fragment condensation with least danger of racemization using DCC activation in the presence of HOBt.[13] Liberation of the amino group from Boc-peptide benzyl esters was carried out by treatment with 3 M HCl/AcOEt followed by treatment with NMM. Removal of the benzyl group from Boc-peptide benzyl esters was performed by hydrogenolysis using Pd/C as a catalyst in a mixture of MeOH and AcOH. All the soluble peptides were purified by repeated recrystallization, and, as a result of this purification process, each peptide gave a single peak on HPLC. Insoluble peptides were purified by repeated washing with hot MeOH. Synthetic and analytical results of the peptides **1—18** are assembled in Tables 1—3. The amino acid and elemental analyses of the peptides shown in Tables 2 and 3 are in good agreement with the calculated values. Solubility of the peptides **1—18** is also summarized in Table 4. Solubility of the peptides **1—5** was previously examined and found to be extraordinarily less soluble in such solvents as DMSO, NMP, DMA, DMF, and MeOH (Table 4). For these peptides HMPA turned out to be a better solvent than the above (Table 4). On the other hand, the lower oligopeptides **7—11** are easily soluble in these solvents. The peptides **17** and **18**, which are obtained by replacement of Ala residues with Aib residues in the peptides **2** and **4**, respectively, have also high solubility in moderately and highly polar organic solvents. This is in remarkable contrast with the result that the original peptides **2** and **4** are barely soluble in these solvents.

IR Absorption Conformational Analyses of Hydrophobic Peptides in the Solid State and in Dichloromethane. Conformational analyses of hydrophobic peptides in the solid state are interesting for the purpose of elucidating the relationship between

† 1 M=1 mol dm^{-3}.

the conformation and solubility of hydrophobic peptides. Figure 2 shows the IR absorption spectra of the peptides **1**—**6** in the solid state in the most significant spectral regions for the conformational assignments (3600—3200 cm^{-1}, amide A; 1700—1600 cm^{-1}, amide I). As representative examples of the tetra- to hexapeptides, the IR absorption spectra of the peptides **7**—**9** in the solid state are also depicted in Fig. 3. All the peptides show strong bands at 3290—3270 cm^{-1} and 1635—1625 cm^{-1}, assigned to a typical β-sheet structure.[14-16] On the other hand, the IR absorption spectra (Fig. 4) of the peptides **14**—**18** in the solid state, which are obtained by replacement of Ala residues with Aib residues in the peptides **2** and **4** and in their fragments, have shoulder bands at about 3340 cm^{-1} and 1660—

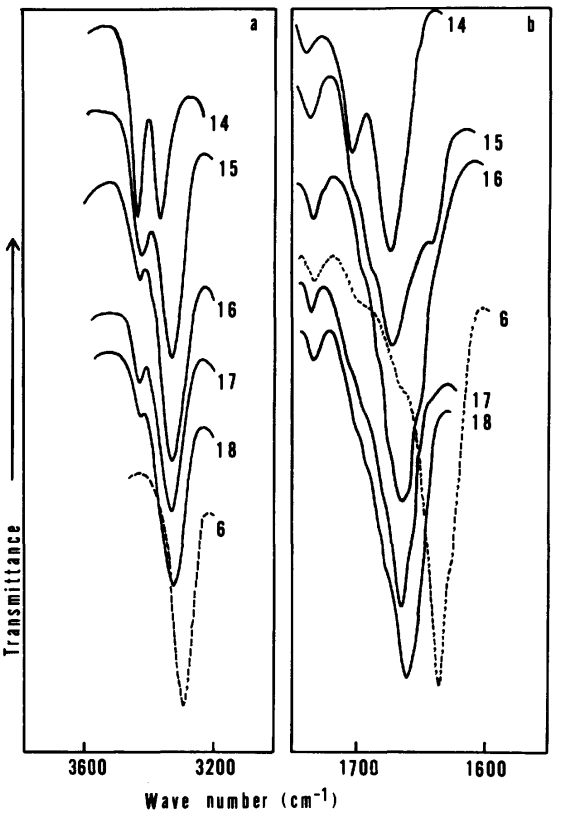

Fig. 5. IR absorption spectra of the peptides **6** and **14**—**18** in dichloromethane.

1650 cm^{-1}, indicating that β-structures are distorted on the Aib residues.

The peptides **6** and **14**—**18** are soluble in dichloromethane and their IR absorption spectra in dichloromethane are presented in Fig. 5. The spectral pattern of the peptide **6** in dichloromethane is essentially the same as that in the solid state. The peptides **14**—**18** in solution, as expected from solubility data and the nature of Aib residues, show no band at about 3280 cm^{-1} and 1630 cm^{-1}, indicating that the restriction of the values of the backbone dihedral angles ϕ and ψ of the Aib residues within the values in the helical regions ($\phi=\pm60\pm20$ and $\psi=\pm40\pm20$)[17] efficiently hinders development of the β-sheet structure. The IR absorption spectrum of the tetrapeptide **14** has two strong bands at 3430 cm^{-1} and 3350 cm^{-1} in the amide A region, indicating the existence of both the nonhydrogen bonding NH and hydrogen bonding NH bonds.[10,11,18] The IR spectrum of the peptide **14** has also a medium-intensity shoulder band at 1708 cm^{-1} and a strong band at 1672 cm^{-1} in the amide I region, assigned to the hydrogen-bonded urethane and free amide carbonyl groups, respectively.[10,11,18] Owing to a strong preference of the Aib residues to form a helical conformation (3_{10}- or α-helix), the peptides **15**—**18** show strong intensity bands at 3325—3320 cm^{-1} and 1672—1660 cm^{-1}, indicating a helical structure (3_{10}- or α-helix), although the frequencies of the amide I region are rather high.[14] Weak or medium intensity bands at 3430—3420 cm^{-1} of the peptides **15**—**18** are also assigned to the nonhydrogen bonding NH bonds, which are attributed to the NH bonds of two or three amino acid residues at the N-terminal portions.

Discussion

Preparation of the peptides **1**—**18** were performed without difficulty by the usual stepwise elongation and fragment condensation methods. The amino component peptide having the Aib residue at the N-terminal, H-Aib-Ala-Ile-Val-OBzl, reacted smoothly with the carboxyl component peptide, Boc-Val_2-Leu-Gly-OH, to produce the peptide **17** in a high yield and the carboxyl component peptide having the Aib residue at the C-terminal, Boc-Val-Ala-Gly-Ala-Aib-OH, also reacted with the amino component peptide, H-Ala-Leu-Ile-Leu-OBzl, to produce the peptide **18** in a high yield, in spite of the fact that the N- and C-terminal Aib residues were sterically hindered.[19] In conformity with the solubility prediction for protected peptides,[4] the β-sheet aggregation caused insolubility in polar solvents of hydrophobic peptides larger than octa- or nonapeptides and, in their preparation, gelation took place along with the reaction. In hydrophobic sequences found in

proteins, the structure of peptide backbones, namely, the β-structure apparently plays an important role on insolubility of peptides, but the structure of peptide side chains, namely, the composition does not.

With respect to the critical chain length for insolubility caused by the β-sheet aggregation, solubility data of the peptides **1**—**13** (Table 4) indicate that insolubility in highly polar solvents of hydrophobic peptides appears to begin at the octa- or nonapeptide levels. Solubility of the octapeptide **6** is rather high in spite of having the β-sheet structure in the solid state (Fig. 3) and 1.0 g of the peptide **6** is easily soluble at room temperature in 100 ml of such solvents as DMSO, HMPA, DMA, DMF, MeOH, and THF. The spectral pattern of the peptide **6** in dichloromethane (Fig. 5) and THF (not shown) is essentially the same as that in the solid state and indicates that the peptide **6** in both solutions exists in the β-sheet aggregation form as reported for a homohexapeptide of Glu(OBzl) in 1,2-dichloroethane.[20] Further development of interpeptide-chain interactions through hydrogen bonding will give rise to severe insolubility as pointed out for model peptides in our previous paper.[21]

Hydrophobic sequences found in natural proteins are expected to be highly organized since hydrophobic amino acid residues have high potentials for the formation of helix- and β-structures.[22] The peptides **1**—**3** are thought to be the partial sequences of a membrane-binding subregion of the murine H-2K^b molecule and the subregion is practically considered to be in the conformation of an α-helix.[23] The peptide **4** is also known to be included in an α-helical region of subtilisin BPN′.[24] On the other hand, the preferred structure, predicted by the Chou-Fasman method,[22] is the β-structure and α-helix for the peptides **1**—**3**, **5**, and **6** and for the peptide **4**, respectively (Table 5). In spite of the disparity between observed and predicted of the conformation, a conformational preference for β-structure formation in the solid state is experimentally demonstrated for the peptides **1**—**6** (Fig. 1). The result is illustrated by the observation that secondary structure formation is dependent on peptide chain length and that critical peptide size for development of the α-helix in the solid state is among decapeptide and pentadecapeptide levels.[25] Therefore, in protein syntheses by fragment condensation methods, the peptide fragments included in α-helical regions of proteins have the β-sheet structure and low solubility before they give rise to helical folding.

Table 5. The preferred structure of the peptides **1**—**6** predicted by the Chou-Fasman method

Compound	P_α	P_β	Preferred structure
1	1.15	1.35	β
2	1.15	1.32	β
3	1.19	1.33	β
4	1.24	1.15	helix
5	1.01	1.29	β
6	1.04	1.23	β

Solubility improvement in hydrophobic peptides included in α-helical regions of proteins is easily achieved by the strategy of replacement of Ala residues with Aib residues.[10,11] The strategy for solubility improvement is based on the restriction of the values of the backbone dihedral angles ϕ and ψ of Aib residues within the values in the region of α- and 3_{10}-helices ($\phi=\pm60\pm20$ and $\psi=\pm40\pm20$). In fact, high solubility of the peptides containing Aib residue is clearly explained by the observation that replacement of C^α hydrogen atoms with methyl groups greatly disturbs β-sheet structures, promoting helical folding in the peptides **14**—**18** (Figs. 4 and 5). The IR spectral patterns of the peptides **14**—**18** in the solid state and in dichloromethane are nearly equivalent to those of the corresponding oligo(Leu)s containing an Aib residue described before.[11] The great ability of an Aib residue to promote helical folding is distinctly revealed in the peptide fragments included in α-helical regions of proteins as demonstrated before in the study of model oligo(Leu)s.[10,11] These results indicate that replacement of a few Ala residues with Aib residues in helical regions of proteins offers the prospect for creating novel proteins in ways not possible by any other method as mentioned previously.[10,11]

Functionalized Dithia(2,5)pyridinophanes as Vitamin B_6 Analogues. Synthesis, Properties, and Catalytic Activity for Racemization Reaction

Masaaki IWATA* and Hiroyoshi KUZUHARA
Riken (The Institute of Physical and Chemical Research), Wako, Saitama 351-01
(Received February 6, 1985)

Exploration of synthetic routes to achieve designed vitamin B_6 models on the structural basis of functionalized dithia(2,5)pyridinophanes from pyridoxine hydrochloride was undertaken and the catalyst potency for a racemization reaction was examined in comparison with that of pyridoxal. By the reaction of 3,4′-*O*-isopropylidenepyridoxine 2′,5′-dichloride with α,ω-dithiols, dithia(2,5)pyridinophanes were synthesized in good yields. For dithia[3]paracyclo[3](2,5)pyridinophanes, juncture sulfur atoms were extruded photochemically, whereas 2,(n+3)-dithia[m](2,5)pyridinophanes incompletely extruded sulfur atoms under various conditions. Because of instability and low preparative yield of 15-hydroxy-16-formyl[2]paracyclo[2](2,5)pyridinophane, dithia-containing phanes, (n+9)-hydroxy-(n+10)-formyl-2,(n+3)-dithia[m](2,5)pyridinophanes [**26a** (n=4), **26b** (n=6), **26c** (n=8); m=n+4], 17-hydroxy-18-formyl-2,11-dithia[3]paracyclo[3](2,5)pyridinophane (**27**), and an acyclic congener for **26a**, 5′-deoxy-2′,5′-bis(ethylthio)pyridoxal (**28**), were eventually prepared in high yields by use of manganese dioxide in the presence of a primary amine. It was found on the basis of ^{1}H-NMR spectral analyses that the rotations of pyridine rings in some molecules, **26a**, **26b**, and **27** with ring sizes equal to or less than fourteen were restricted. The racemization potency of **26a—c**, **27**, and **28** for sodium hydrogen L-glutamate demonstrated that these are 1.4- to 1.7-fold more potent than pyridoxal itself under certain conditions (pH 10.0, 25±0.5 °C) until *ca.* 80% completion of the racemization reaction. **26a** was found to be quite stable (no decomposition), but the others, **26b**, **26c**, and **28**, indicated 14, 8, and 12% decomposition, respectively. **27** was so unstable that a 63% decomposition was marked at the time of 56% completion of the racemization reacion.

Racemization, transamination, decarboxylation, replacement, condensation, and elimination of amino acids (depending on the system requirements in the biological systems) are mediated by coenzyme B_6 through a common intermediate, the Schiff base (**1a**).[1] Various chemical model systems for this coenzyme have been devised so far to elucidate the coenzyme function. It is convinced that (a) **1b** mimics all types of reactions *via* **1a**,[2-7] (b) 3-hydroxy-4-pyridinecarbaldehyde[8] and salicylaldehydes[9] may be pyridoxal substitutes, and (c) most of the nonenzymic reactions are catalyzed by metal ions[3c,4,9] and imidazole,[8] or in a cationic micelle without metal ions.[10] The distinct difference between the enzymic and nonenzymic reactions investigated so far is that the former proceeds in a stereospecific manner regarding amino acids (assisted by the protein backbone of the enzyme)[1b-f] and that a stereospecific catalyst is lacking in the latter.[11]

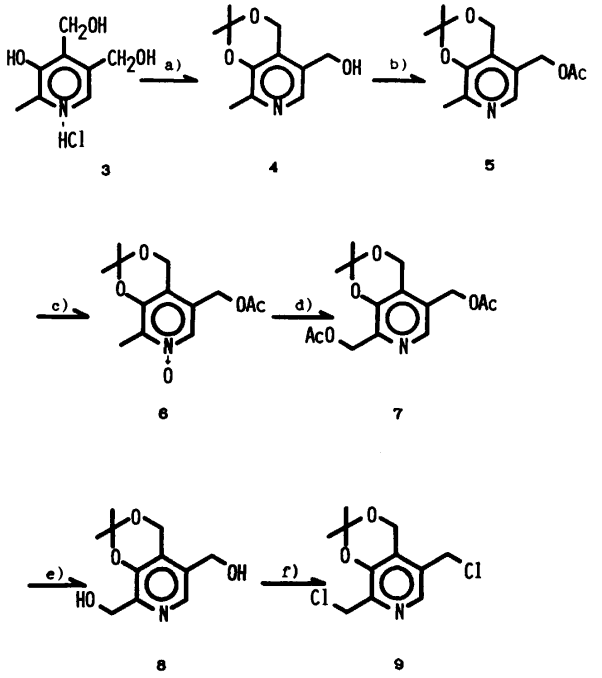
2

Along the line of our continuing interest in chemical congeners to B_6-coenzymes,[9c,12] we started to construct functionalized dithia(2,5)pyridinophanes **2** nearly a decade ago, which were expected to function as a stereospecific vitamin B_6-like catalyst through a mechanism. This includes a bridged chain with a specified length to provide a restricted rotation of the molecule (inducing planar chirality) and functional groups to act in the same way that the catalytic sites of vitamin B_6 do in biological systems. Through a series of experiments since then, this type of molecular design has been found to be very promising regarding alternative enantioselective catalysts. Evidence has been produced in successful studies concerning the optical resolution,[13a-d] the stereoselective racemization of α-amino acids,[13a] enantioselective transamination to α-keto acids,[13e-g] and the stereospecific α-deuteration of α-amino acids.[13h] The present report deals with a synthetic elaboration regarding the exploration of prototypes of pyridoxal-like (dithia)(2,5)pyridinophanes (which are routinely employed now). Also, the properties of the pyridinophanes have been scrutinized and an examination of catalytic activities for the racemization reaction of L-glutamate in terms of racemate catalysts (including the details of preliminary reports)[13a,i,j] was carried out.

Results and Discussion

Synthesis. Syntheses of the target molecules, **21**, **26**, and **27**, were achieved through sequences of



Scheme 1. Modification of C_2- and C_5-Positions of Pyridoxine; (a) i) acetone/HCl, ii) $NaHCO_3$ (Yield of **4**, 95%). (b) Ac_2O–Pyridine (**5**, 93%). (c) *m*-CPBA (**6**, 98%). (d) Ac_2O at 80—90 °C. (e) i) $NaOCH_3$/MeOH, ii) CO_2 (**8**, 83%). (f) i) $SOCl_2$, ii) $NaHCO_3$ (**9**, 98%).

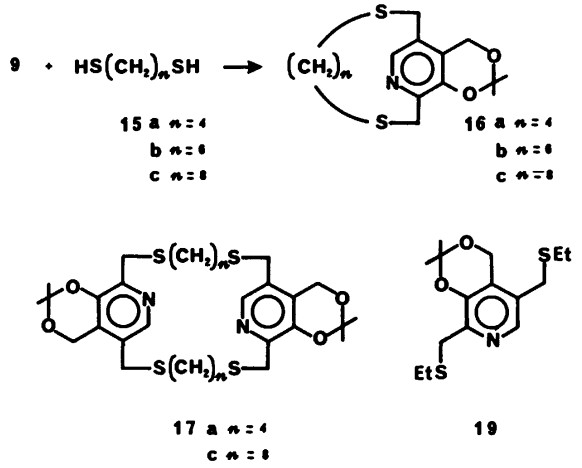
reactions which will be described in the following order; (1) modification of the C_2- and C_5-positions of pyridoxine (Scheme 1), (2) the coupling reaction of the modified pyridoxine with α,ω-dithiol (Scheme 3), taking into account preliminary attempts (Scheme 2), (3) the photochemical extrusion of sulfur atoms from the coupling product (Scheme 4) and (4) oxidation with manganese dioxide (Scheme 5).

Modification of the C_2- and C_5-positions of pyridoxine to give the first stable key intermediate (**8**) was attained by a different route from that reported.[14] Pyridoxine hydrochloride (**3**) was treated with dry acetone–hydrogen chloride followed by neutralization with sodium hydrogencarbonate to yield 3,4′-*O*-isopropylidenepyridoxine (**4**)[15] which was converted by acetylation to 5′-acetyl-3,4′-*O*-isopropylidenepyridoxine (**5**) (Scheme 1). Oxidation of **5** with *m*-chloroperbenzoic acid (*m*-CPBA) gave the corresponding *N*-oxide (**6**) in high yield. This was rearranged in a mixture of chloroform and acetic anhydride to 2′-acetoxy-5′-acetyl-3,4′-*O*-isopropylidenepyridoxine (**7**). A hydrolysis of **7** with sodium methoxide in methanol was accomplished to afford a key intermediate, 2′-hydroxy-3,4′-*O*-isopropylidenepyridoxine (**8**)[14] in 70% total yield based on **3**. Another key intermediate **9** was quantitatively obtained by the direct chlorination of **8** with thionyl chloride, after several unsatisfactory attempts with triphenylphosphine–carbon tetrachloride[16] or with thionyl chloride–pyridine. Unfortunately, however, **9** was relatively unstable ($t_{1/2}$ *ca.* 1 d), and, thus, the next coupling reaction had to be executed soon after its preparation.



Scheme 3. The Coupling Reaction of the Modified Pyridoxine with α,ω-Dithiol.

In order to prepare bridged compounds connected by heteroatoms from **8** or **9** in good yield, several attempts using *p*-xylene derivatives as model compounds were performed (Scheme 2). The coupling trial employing **8** and α,α'-dichloro-*p*-xylene (**10**) mediated by sodium hydride as a base trigger in dioxane was quite unsuccessful under any condition. Then, in an effort to seek out the appropriate counterparts for the bridge resulted in finding efficient conditions to couple *p*-xylene-α,α'-dithiol (**11**)[17] with **10**. A mixture of **10** and **11** in ethanol was added to sodium ethylate in an ethanol solution (highly diluted).[18] The resulting 2,11-dithia[3.3]-paracyclophane (**12**)[19] had a sulfur atom juncture which may benefit the preparation of [2.2]paracyclophane (**13**) through a photochemical extrusion of the sulfur atoms.[20] Practically, **12** was photochemically desulfurized to **13** by triethyl phosphite in benzene with a high-pressure mercury lamp in 55% yield.

These perspectives through model reactions were put into practice by use of the dichlorides, **9** and **11**, which were successfully coupled to afford 17,18′-*O*-isopropylidene-17-hydroxy-18-hydroxymethyl-2,11-di-

thia[3]paracyclo[3](2,5)pyridinophane (**14**) by a high-dilution method. Likewise, **9** was condensed with α,ω-alkanedithiol (**15**) to give 2,(n+3)-dithia[m](2,5)-pyridinophane (n=4, 6, 8; m=n+4) (**16**) in fairly good yields, with the concomitant formation of the corresponding dimer **17**. The susceptibility of a reactive intermediate **9** to a nucleophilic attack was further exemplified in a condensation with ethanethiol (**18**) to yield 5′-deoxy-2′,5′-bis(ethylthio)-3,4′-*O*-isopropylidenepyridoxine (**19**) (95% based on **8**). This can be a reference open-chain compound relevant to **16a** for a comparison of the catalytic potency.

A photochemical extrusion of the juncture sulfur atoms from **14** yielded **20** (83%) under conditions similar to those aforementioned for **12**. The acetate derivative (**23**) which was obtained through the hydrolysis of **14** was likewise desulfurized to **24** (59%, based on **23**) (Scheme 4). However, this extrusion method regarding the sulfur atom was not satisfactorily applicable to cyclophanes, **16a** and **16b**, and their acetate derivatives **29b**,c (see Experimental). In addition, although the sulfur-extruded cyclophane (**20**) was directly oxidized to the corresponding aldehyde (**21**) by means of a reagent, triphenylmethylium tetrafluoroborate,[21] we had to abandon this type of paracyclophane as a target molecule because of the low yield of **21** (only 7%, based on **20**) and with an unexpected instability ($t_{1/2}$ *ca.* 15d). Therefore, we had to change our tentative target toward direct functionalization as embodied in pyridoxal without desulfurization and with the alternative oxidation method.

Manganese dioxide seemed promising as an alternative oxidant since numerous examples exemplified so far had shown the practical usefulness of this oxidant for the oxidation of α,β-unsaturated alcohols,[22] including pyridoxine derivatives.[23] Therefore, newly prepared active manganese dioxide[24] was applied to the oxidation of the acid-hydrolyzed products of the isopropylidene derivatives (**16b** and **16c**) which are potentially pyridoxine-like. Unfortunately, however, the product yields of **26b** and **26c** remained less than 18 and 16%, respectively. The reason for such low yields might be due to an inadequate preparation of the active manganese dioxide and/or chosen reaction conditions referring to those reported, and/or due to the substrate selectivity of manganese dioxide. A number of trials were carried out which resulted in the conclusion that all these possible causes operated together. The requisite construction of the tentative target encouraged us to develop a new preparative oxidation system.

Recently, we have reported that pyridoxine is oxidized in practical synthetic yield with commercially available manganese dioxide in the presence of a primary amine. We proposed that the oxidation proceeds on the amine-manganese dioxide complex[25] through a probable bimolecular oxidation mechanism.[26,27] The product prepared through the amine-mediated oxidation is the corresponding Schiff base

of the pyridoxal. In addition, we have found that Schiff bases prepared from amines with strong basicity can transfer the methylene moiety to amines with relatively weaker basicity.[25] The trend of this transimination is, in principle, compatible to those found by Jencks[28a] and Leussing.[28b] The "basicity-dependent transimination" has been successfully applied to the direct *in situ* resolution of phanes in the treatment of a Schiff base prepared from phane and 3-(dimethylamino)propylamine (DAPA) with an amino sugar.[13a]

These findings made it possible to overcome synthetic problems in the oxidation of the present compounds. The pertinent results are given in Table 1, in which the same remarkable trend as found regarding the oxidation of pyridoxine[25] (that the product yields are increased 4—5 fold in the presence of a primary amine) is substantiated. Likewise, strained compounds like **14** and **16a** and an unstrained molecule **19** (*vide infra*) (**S**) were satisfactorily oxidized (Scheme 5) to corresponding pyridoxal-type compounds (**P**), **26a**—c, **27**, and **28**, by use of DAPA as a coexisting amine (Table 2). It is noteworthy that the juncture sulfur atoms were unaffected during the oxidation process.

Properties. It is of special interest to scan the properties in the light of the determination of the possible upper-limit length for the restricted rotation depending on the length of the bridged chain and of the general catalytic activity of such modified pyridoxal compounds with heteraphane structures.

In contrast to carba(2,5)pyridinophanes,[29] dithia-(2,5)pyridinophanes offer certain advantages for ^{1}H-NMR spectral studies regarding the restricted rotation as well as the sulfur analogues of metacyclophane.[30] The incorporation of a sulfur atom into the β-position of the benzene ring not only simplified the methylene signals at the α-position by eliminating the complex spin-spin coupling with the other methylene groups, but also shifted them to a sufficiently lower field, allowing them to be observed separately from the other methylene signals.[30] Therefore, the existence of a restricted rotation can be simply judged from an observation of whether or not the proton signal of the α-methylene group of the pyridine ring is split into an AB quartet.

The chemical shifts and coupling constants of the focused α-methylene, formyl, and hydroxyl protons for the final products, **26a**—c and **27**, are summarized in Table 3, and refer to the related simpler compounds, **12**, **13**, and **28**. Chemical shifts of the signals with AB spin systems in Table 3 were adjusted, according to the general method of NMR analysis,[31] based on those observed on the spectral chart. Additionally, signal assignments were elaborated on the basis of numerous reference compounds synthesized through the present study. In Fig. 1, the representative spectral aspect of the methylene proton signals contiguous to heteroatoms and to the pyridine ring is illustrated for the isopropylidene derivatives, **14** and **16a**—c.

The appearance of the spin-spin couplings of the α-methylene protons of **26a,b**, and **27** split into AB quartets is a measure of the restricted rotation of the bridge chain due to an unsymmetrical magnetic field effect on those nuclei. As for the chemical shifts of formyl and hydroxyl protons, it was indicated that the greater conformational strain becomes, the more

364 (3800)	361.5 (3700)		

The investigation of the temperature dependence of the spin-spin interaction is a subject related to the practical optical resolution of enantiomers. For this purpose, the ^{1}H-NMR spectra of **14**, **16a**,**b**, and **26b** were recorded in $CDBr_3$ at 10°C intervals up to 120°C while monitoring the AB quartets as markers. Within the temperature range examined, all the AB quartets of the α-methylene protons remained uncolapsed together with unchanged chemical shift differences while participating in the spin-spin interaction. Thus, the conformation of the compounds with the AB quartet signals is found to be fairly rigid and the energy barrier for free rotation is estimated to be more than 15 kcal† mol^{-1}.[30] This suggests that these compounds could be resolved into each enantiomer by appropriate means. A congener of **26** has actually been resolved with an amino sugar.[13a,d]

The UV-VIS spectra of **26a**—c and **27** in ethanol are characterized by a ring strain (Table 4) as well as ^{1}H-NMR spectra. The absorption maxima appear-

† 1 cal_{th}=4.184 J.

a) λ_{max} used for O.D. change measurement. b) Estimated values, based on the plot.

ing at the longest wavelength show distinct red shifts with an augmentation of the extinction coefficient when the ring strain is increased. The red shifts are directly related to the sterically induced nonplanarity of the pyridine ring.[32] The tendency to increase the extinction coefficient with a shortening of the length of the carbon chain, may reflect the increment of the electron density around the formyl chromophore, which, in turn, may positively enforce the catalytic potency of these model compounds.

Catalytic Potency. The catalytic activities of the synthesized pyridinophanes, **26a—c** and **27**, were examined by a measure of the racemization ability for sodium hydrogen L-glutamate as a representative amino acid (chosen for its large rotatory power as in previous work).[9] These were referred to the less modified derivative **28** and pyridoxal as a standard reference. The reaction conditions were set, taking into account the catalyst solubility and those reported[9] (see Experimental). The analyzed results are collected in Table 5 and as a relative measure of catalytic activity, the times for 50% racemization completion are also listed. In addition, the evaluated apparent rate constants for **26b** and **28** are shown on the basis of less-scattered values of k_{obsd} (see Experimental). The results clearly reveal that **26a** is the best catalyst among those investigated. This showed superior properties to those of pyridoxal, with respect to catalytic activity (1.5 fold more active) and to stability (no decomposition) in contrast to an open-chain congener **28**. This compound is highly strained, as shown in ^{1}H-NMR and UV-VIS spectra and, thus, is a promising enantioselective catalyst. Structurally, the same is embodied in **26b** and **27**, but **27** is less active than pyridoxal and outstandingly labile, on one hand. On the other hand, **26b** might have a complex reaction mechanism (suggested by an observation of a nonlinear optical rotation change with considerable catalyst instability). It is of interest to note that less-strained or unstrained compounds, **26c** and **28**, are even more active than pyridoxal with a comparable decomposition each other.

In conclusion, the present results demonstrate that (a) the bridging between C_2- and C_5-positions by suitable chains afforded many advantages over natural vitamin B_6, especially, with respect to catalyst stability and catalytic effectiveness, (b) the π-donor-acceptor interaction between the bridged chain and the pyridine ring decreases the catalytic activity and catalyst stability, and (c) the torsion of the pyridine ring working as an electron sink has no effect on rate enhancement. It would be of interest to extend the present investigation to the construction of better model compounds which might intramolecularly provide suitable groups to efficiently affect the proton abstraction-addition process on the α-carbon of α-amino acid in a transition state.

Experimental

Apparatus. The IR spectra were obtained with a Shimadzu IR-27 spectrophotometer, the UV-VIS measurements (λ_{max}) with a Hitachi 124 spectrophotometer, ^{1}H-NMR spectra with a Varian HA-100D instrument, using TMS as an internal standard, and the optical-rotation measurements with a Perkin-Elmer 241MC polarimeter. The mass spectra (MS) and the exact mass measurements were obtained with a Japan Electron Optics Lab. Model JMS-OISG instrument. The melting points were recorded with a micro-melting apparatus, Yanagimoto Seisakusho, ser. No. 2647. The photochemical reaction was carried out with a high-pressure mercury lamp, UVL-100p (100 W), Rikoh Kagaku Co., Ltd. The elemental analyses were performed by the staff of the Organic Microanalysis Lab. in this Institute.

Materials. Pyridoxine hydrochloride, *m*-chloroperbenzoic acid, thionyl chloride, α,α'-dichloro-*p*-xylene (**10**), triphenylmethylium tetrafluoroborate, triethyl phosphite, 3-(dimethylamino)propylamine (DAPA), α,ω-alkanedithiols (**15a—c**) and ethanethiol were obtained commercially. The preparation of *p*-xylene-α,α'-dithiol (**11**) was performed according to a reported method;[17] 90% yield, colorless crystals, mp 42—44 °C (lit,[33] 46—47 °C). Pyridoxine was prepared by neutralization of the corresponding commercial hydrochloride with sodium hydrogencarbonate followed by azeotropic distillation of water with 1-propanol and by trituration into pyridine. For a separation of the products using column chromatography, Merck Art 7734 (E. Merck,

Darmstadt) silicagel was used. For the detection of the product and for monitoring the reaction by thin-layer chromatography (TLC), a Wakogel B-5 FM (Wako Pure Chem. Ind.) was employed. The following solvent systems were used for column chromatography and TLC unless otherwise stated; benzene:acetone=10:1 v/v (solvent BA1), 9:1 v/v (solvent BA2), 5:1 v/v (solvent BA3), 4:1 v/v (solvent BA4), 5:2 v/v (solvent BA5); chloroform:methanol=95:5 v/v (solvent CM1), 9:1 v/v (solvent CM2). Chemical shift (δ) and coupling constants (J) in ^{1}H-NMR spectrum (in $CDCl_3$) are shown in ppm and Hz, respectively.

Synthesis of 8 from 3 (Scheme 1). The acetonation of pyridoxine hydrochloride (**3**) was achieved by a method reported by Korytnyk and Ikawa[34] in 92% yield. The subsequent treatment of a suspended mixture of 55.1 g of 3,4′-*O*-isopropylidenepyridoxine hydrochloride, colorless crystals, mp 216—217 °C (dec) (lit,[15] 210—212 °C (dec). 217—218 °C (dec)[35]), in water with sodium hydrogencarbonate yielded 45.1 g (96%) of HCl free **4**, mp 118—120 °C (lit, 111—112 °C,[15] 113—115 °C,[35] 108—109 °C[36]), which, in turn, was acetylated by acetic anhydride–pyridine (1:1 v/v) at ambient temperature to give 5′-acetyl-3,4′-*O*-isopropylidenepyridoxine (**5**) in 93% yield, after a usual work-up; colorless liquid, R_f 0.5 (solvent BA3), IR (neat) $\nu_{C=O}$ 1740 cm^{-1}. The corresponding *N*-oxide (**6**) was obtained in 98% yield upon treatment of **5** with a slight molar excess of *m*-chloroperbenzoic acid in chloroform at ambient temperature. This was followed by neutralization with sodium acetate; colorless crystals, recryst, from diisopropyl ether, R_f 0.2 (benzene:acetone 2:1 v/v). In the mixed solution of chloroform and acetic anhydride (4:1 v/v) at *ca.* 50 °C, **6** was rearranged to 2′-acetoxy-5′-acetyl-3,4′-*O*-isopropylidenepyridoxine (**7**), R_f 0.8 (solvent CM1), in 98% yield with column chromatographic separation; colorless viscous liquid (R_f 0.5; chloroform:acetone 93:7 v/v), IR (neat) $\nu_{C=O}$ 1740 and ν_{st} 1420, 1380, 1365, 1220, 1060, 1025, and 855 cm^{-1}. At this stage, it was noted that the lower the reaction temperature was upon mixing an organic solvent such as $CHCl_3$, the better was the product yield and the darkening was less. The hydrolysis of **7** (3.05 g) with sodium (0.6 g) in methanol (40 ml) was followed by neutralization with solid carbon dioxide, then by the evaporation of the solvent and, subsequently, by filtration of the acetone solution, yielded 1.8 g (83%) of 2′-hydroxy-3,4′-*O*-isopropylidenepyridoxine (**8**), R_f 0.3 (solvent CM1); recryst. from acetone–diisopropyl ether, colorless needles, mp 119—122 °C (lit,[15] 110 °C); λ_{max} (EtOH) 281.5 nm; IR (KBr) ν_{OH} 3430, ν_{st} 1420, 1385, 1375, 1290, 1060, 1020, 1010, 900, 860, and 790 cm^{-1}.

Chlorination of 8. Chlorination with triphenylphosphine–carbon tetrachloride[16a] or DMF[16b] was unsuccessful. Then, several trials employing thionyl chloride–pyridine, changing the mole ratio 1:1 to 1:12, suggested that the greater the ratio becomes, the less the product yield of 5′-deoxy-2′,5′-dichloro-3,4′-*O*-isopropylidenepyridoxine (**9**). The reaction was monitored by TLC (R_f of **9**, 0.7 (solvent BA3)). Thus, it was eventually found that when 10—12 ml of thionyl chloride (cooled to 0 °C) was added all at once to 4.5 g of **8** (while being magnetically stirred in an iced-water bath). Stirring was continued for 30 min. The system was then equipped with a drying tube containing anhydrous calcium chloride and any excess of thionyl chloride was removed under reduced pressure. The mixture was neutralized by the addition of sodium hydrogencarbonate solution until no more carbon dioxide was generated and then extracted with ether. After a usual work-up, **9** was obtained in 91% yield (4.78 g) as yellow crystals; mp 89—91 °C. IR (KBr) ν_{st} 1415, 1385, 1380, 1305, 1280, 1250, 1205, 1135, 1060, 855, 760, and 715 cm^{-1}. On a smaller scale, the product yield became quantitative, by supressing decomposition during the work-up. However, **9** seemed to be not so stable that the next reaction was executed immediately after the preparation of **9**.

Attempts of Coupling and Photochemical Extrusion of Sulfur Atom (Scheme 2). Since the condensation of diol (**8**) with α,α'-dichloro-*p*-xylene (**10**) mediated by sodium hydride was unsuccessful in dioxane under any condition, the coupling of **10** with *p*-xylene-α,α'-dithiol (**11**) was examined under basic conditions. After 1.7 g (0.01 mol) of hot **10** in 20 ml of ethanol was rapidly added to a sodium ethylate solution prepared by 0.5 g (0.02 mol) of sodium in 50 ml of ethanol, containing 1.7 g (0.01 mol) of **11** the mixture was warmed for 3 h with stirring and precipitated a white solid (2.6 g) which was not the intended product. After it was filtered off, the filtrate contained a small amount of 2,11-dithia[3.3]paracyclophane (**12**), detected on TLC (R_f 0.6, benzene:cyclohexane 3:2 v/v). Thus, a 16-fold dilution[18] of the above reaction was carried out at ambient temperature to give 0.6 g (22%) of **12**, after chromatography with benzene; recryst. from benzene, mp 236.5—237.5 °C. Calcd for $C_{16}H_{16}S_2$: C, 70.54; H, 5.92; S, 23.54%. Found: C, 70.53; H, 5.70; S, 23.42%. MS *m/z* 272 (M^+) (base peak). ^{1}H-NMR ($CDCl_3$) δ=6.86 (8H, aromatic protons) and 3.82 (8H, $-CH_2-$). IR (KBr) ν_{S-CH} 1423; ν_{st} 1105, 850, 806, 758, 715, and 536 cm^{-1}. λ_{max} (EtOH) 255.5 nm.

According to a reported method,[20] a solution of 0.19 g of **12** and 20 ml of triethyl phosphite in 35 ml of benzene was irradiated using a high-pressure mercury lamp for 6 h while bubbling dry nitrogen gas. After the evaporation of the solvents *in vacuo*, the residue was recrystallized from ethanol to yield 80 mg (55%) of [2.2]paracyclophane (**13**) as colorless fine needles; mp 218—220 °C (lit,[37] 285—287 °C); MS *m/z* 208 (M^+) and 104 (base peak); λ_{max} (EtOH) 225 nm; R_f 0.8 (benzene:cyclohexane 3:2 v/v).

Coupling 9 with α,ω-Dithiols (Scheme 2). In a typical procedure, a mixture of 0.37 g (1.4 mol) of dichloride (**9**) and 0.3 g (1.76 mol) of dithiol (**11**) in 100 ml of ethanol was added (dropwise) over a period of 2.5 h to a 300-ml ethanol solution containing 0.1 g (4 mmol) of sodium in an ice-water bath while bubbling dry nitrogen gas. The mixture was then stirred overnight. After evaporating the ethanol, the residue was triturated with benzene and filtered. The filtrate was chromatographed on a silica-gel column eluted with benzene–acetone (7:2 v/v) then (5:2 v/v) to give 17-hydroxy-18-hydroxymethyl-17,18′-*O*-isopropylidene-2,11-dithia[3]paracyclo[3](2,5)pyridinophane (**14**) as colorless crystals; mp 194—196 °C. Calcd for $C_{19}H_{21}O_2S_2N$: C, 63.48; H, 5.89; S, 17.84; N, 3.90%. Found: C, 63.36; H, 5.92; S, 17.63; N, 3.75%. IR (KBr) ν_{st} 1423, 1406, 1383, 1372, 1295, 1244, 1200, 1135, 1059, 1049, 860, 725, and 543 cm^{-1}. λ_{max} (EtOH) (relative O.D. to the maximum absorption) 258—268 (broad, 0.95), 271.5 (0.97), 281 (1.0), and 306.5 (0.84) nm. ^{1}H-NMR ($CDCl_3$) δ=1.55 and 1.75 (3H each, s,

$C(CH_3)_2$) 3.51 and 3.75 (1H each, AB-q, J=14.9, $-CH_2-S$), 3.75, and 4.05 (1H each, AB-q, J=14.0, $-CH_2-S$), 4.53 and 5.24 (1H each, AB-q, J=16.5, $-CH_2-O$), 3.88 (4H, broad s, $-SCH_2-C_6H_4-CH_2S$), 6.95 (2H, broad d, J=8.0, Ar-H), 7.10 (2H, broad d, J=8.0, Ar-H), and 7.14 (1H, s, Ar_{py}-H). The spectral aspect of the methylene groups is depicted in Fig. 1. MS, metastable peaks appeared at m/z 138.2 for the fragmentation of m/z 197 to m/z 165 and at m/z 113.1 for m/z 166 to m/z 137.

The dropwise addition (3.5 h) of 1.9 g (7.3 mmol) of **9** and 0.82 g (6.6 mmol) of 1,4-butanedithiol (**15a**) in 100 ml of benzene to 400 ml of an ethanol solution containing 0.4 g (14 mmol) of sodium yielded 0.57 g (27% based on **8**) of **16a** and 0.68 g (19%, based on **8**) of the dimer of **16a**, (**17a**), after a similar work-up to the above was eluted with the solvent BA1 for column chromatography.

13-Hydroxy-14-hydroxymethyl-13,14′-*O*-isopropylidene-2,7-dithia[8](2,5)pyridinophane (**16a**); recryst. from diisopropyl ether as colorless crystals; mp 144.5—145.5 °C. R_f 0.55 (solvent BA1). Calcd for $C_{15}H_{21}O_2NS_2$: C, 57.84; H, 6.80; N, 4.50; S, 20.59%. Found: C, 57.59; H, 6.53; N, 4.50; S, 20.62%. IR (KBr) ν_{st} 1408, 1375, 1354, 1295, 1275, 1255, 1235, 1210, 1145, 1130, 1118, 1060, 1050, 855, 780, 730, 685, 665, and 565 cm^{-1}. λ_{max} (EtOH) (M^{-1} cm^{-1}); 211.5 (18900), 235sh (8100), and 303 (7700) nm. ^{1}H-NMR ($CDCl_3$); δ=1.61 (6H, s, $C(CH_3)_2$), 0.6—1.4 (4H, m, $-CH_2-$), 1.8—2.7 (4H, m, $-CH_2-$), 3.51 and 3.68 (1H each, AB-q, J=13.0, $-CH_2S$), 3.62 and 4.05 (1H each, AB-q, J=12.5, $-CH_2S$), 4.85 and 5.21 (1H each, AB-q, J=16.5, $-CH_2O$), and 7.81 (1H, s, Ar-H). The spectral aspect of the methylene signals is shown in Fig. 1. MS; m/z 311 (M+).

The corresponding dimer (**17a**), recryst. from benzene (minor) and diisopropyl ether (major); mp 149.5—150.5 °C. R_f 0.3 (solvent BA1). Calcd for $C_{30}H_{42}O_4N_2S_4$: C, 57.84; H, 6.80; N, 4.50; S, 20.59%. Found: C, 58.12; H, 6.68; N, 4.49; S, 20.59%. IR (KBr) ν_{st} 1410, 1375, 1293, 1250, 1200, 1135, 1063, 1050, and 845 cm^{-1}. λ_{max} (EtOH) (M^{-1} cm^{-1}), 209 (34200), 227.5sh (19000), and 290 (17200) nm. ^{1}H-NMR ($CDCl_3$) δ=1.55 (12H, s, $-C(CH_3)_2$), 1.4—1.6 (8H, m, $-CH_2-$), 2.2—2.6 (8H, m, $-CH_2-$), 3.51 (4H, s, $-CH_2S$), 3.75 (4H. s, $-CH_2S$), 4.95 (4H. s, $-CH_2O$), and 7.88 (2H, s, Ar-H). No signal shift or intensity change was observed until −30 °C in $CDCl_3$. MS: m/z 622 (M^+).

In a similar way, the reaction of 1.325 g (4.8 mmol) of 9 and 0.66 g (4.5 mmol) of 1,6-hexanedithiol (**15b**) in 100 ml of benzene with 400 ml of an ethanol solution containing two molar equiv. of sodium yielded 1.37 g (91%, based on **8**) of 2,9-dithia[10](2,5)pyridinophane (**16b**). This was isolated by silica-gel chromatography eluted with a solvent (BA1) as colorless crystals; R_f 0.5 (solvent BA1). mp 168—170 °C. Calcd for $C_{17}H_{25}O_2NS_2$: C, 60.14; H, 7.42; N, 4.13; S, 18.89%. Found: C, 59.88; H, 7.32; N, 3.86; S, 18.90%. IR (KBr) ν_{st} 1413, 1385, 1377, 1297, 1262, 1242, 1202, 1135, 1065, 1045, and 853 cm^{-1}. λ_{max} (EtOH) (M^{-1} cm^{-1}); 208 (19200), 228sh (8800), and 293 (8300) nm. ^{1}H-NMR ($CDCl_3$) δ=1.57 and 1.63 (3H each, s, $-C(CH_3)_2$), 0.4—1.4 (8H, m, $-CH_2-$), 1.8—2.7 (4H, m, $-CH_2-$), 3.50 and 3.73 (1H each, AB-q, J=13.5, $-CH_2S$), 3.66 and 4.04 (1H each, AB-q, J=12.5, $-CH_2S$), 4.77 and 5.29 (1H each, AB-q, J=16.5, $-CH_2O$), and 7.85 (1H, s, Ar-H). The spectral aspect of the methylene signals is depicted in Fig. 1.

Likewise, the reaction of 1.17 g (4.5 mmol) of **9** and 0.8 g (4.8 mmol) of 1,8-octanedithiol (**15c**) in 100 ml of benzene with 400 ml of an ethanol solution containing 0.21 g (8.96 mmol) of sodium yielded 1.27 g (78%, based on **8**) of 2,11-dithia[12](2,5)pyridinophane (**16c**), 0.26 g (8%, based on **8**) of the dimer of **16c**, **17c** (as colorless crystals), and a pale-yellow viscous liquid. They were isolated by silica-gel column chromatography eluted with a solvent (BA1).

16c showed R_f 0.4 (solvent BA1); mp 68.5—70 °C. Calcd for $C_{19}H_{29}O_2NS_2$: C, 62.09; H, 7.95; N, 3.81; S, 17.44%. Found: C, 62.08; H, 7.82; N, 3.82; S, 17.48%. IR (neat) ν_{st} 1410, 1385, 1875, 1296, 1275, 1240, 1200, 1140, 1062, 1049, and 860 cm^{-1}. λ_{max} (EtOH) (M^{-1} cm^{-1}); 208.5 (18800), 226sh (9700), and 292 (8400) nm. ^{1}H-NMR ($CDCl_3$) δ=1.57 (6H, s, $-C(CH_3)_2$), 0.95—1.5 (12H, m, $-(CH_2)_6-$), 2.40 (2H, t, J=6.5, CH_2-CH_2S), 2.60 (2H, t, J=6.5, CH_2-CH_2S), 3.59 (2H, s, $Ar-CH_2S$), 3.78 (2H, s, $Ar-CH_2S$), 5.01 (2H, s, CH_2O), and 7.92 (1H. s, Ar-H). The spectral aspect of the methylene signals is depicted in Fig. 1.

17c revealed R_f 0.25 (solvent BA1); Calcd for $C_{38}H_{58}O_4N_2S_4$: C, 62.09; H, 7.95; N, 3.81; S, 17.44%. Found: C, 62.80; H, 7.93; N, 3.62; S, 16.36%. IR (neat) ν_{st} 1410, 1385, 1375, 1295, 1275, 1240, 1200, 1138, 1062, 1047, and 856 cm^{-1}. λ_{max} (EtOH) (M^{-1} cm^{-1}); 208.5 (33700), 224.5sh (18400), and 291 (16000) nm. ^{1}H-NMR ($CDCl_3$) δ=1.56 (12H, s, $C(CH_3)_2$), 1.0—1.6 (24H, m, $-(CH_2)_6-$), 2.38 (4H, t, J=7.0, CH_2-CH_2S), 2.52 (4H, t, J=7.0, CH_2-CH_2S), 3.56 (4H, s, $Ar-CH_2S$), 3.79 (4H, s, $Ar-CH_2S$), 4.98 (4H, s, $Ar-CH_2O$), and 7.89 (2H. s. Ar-H).

In a similar treatment of the dichloride (**9**), prepared from 1.0 g (4.45 mmol) of **8**, and 0.9 g (8.9 mmol) of ethanethiol (**18**) in 50 ml of benzene with 200 ml of ethanol solution containing 0.21 g (8.9 mmol) of sodium for 1 h, 5′-deoxy-2′,5′-bis(ethylthio)-3,4′-*O*-isopropylidenepyridoxine (**19**) was prepared in 95% (1.35 g) yield, based on **8**; R_f 0.75 (solvent BA2), as a pale-yellow viscous liquid. Calcd for $C_{15}H_{23}O_2NS_2$: C, 57.47; H, 7.40; N, 4.47; S, 20.45%. Found: C, 57.44; H, 7.33; N, 4.47 S, 20.14%. IR (neat) ν_{st} 1410, 1380, 1370, 1292, 1270, 1236, 1197, 1135, 1055, and 852 cm^{-1}. ^{1}H-NMR ($CDCl_3$) δ=1.22 (3H, t, J=7.3, SCH_2CH_3), 1.25 (3H, t. J=7.3, SCH_2CH_3), 1.54 (6H, s, $C(CH_3)_2$), 2.45 (2H. q, J=7.3, SCH_2CH_3), 2.57 (2H, q, J=7.3, SCH_2CH_3), 3.55 (2H, s, $Ar-CH_2S$), 3.79 (2H, s, $Ar-CH_2$), 4.95 (2H, s, $Ar-CH_2O$), and 7.89 (1H, s, Ar-H).

Photochemical Extrusion of Juncture Sulfur Atoms (Scheme 4). The irradiation of 1.93 g (5.37 mmol) of **14** in a mixture of 350 ml of triethyl phosphite and 150 ml of benzene in an inlet-jacket with a high-pressure mercury lamp at tap-water temperature for 17 h (bubbling dry nitrogen gas throughout) yielded 1.31 g (83%, based on **14**) of [2]paracyclo[2](2,5)pyridinophane (**20**). This was isolated upon evaporation of solvents from the reaction mixture, silica-gel column chromatography eluted with a solvent (BA2). This resulted in a pale-yellow liquid; R_f 0.35 (solvent BA5). MS m/z 295 (M^+) and base peaks at m/z 155 and 182. Exact mass measurement; Calcd for $C_{19}H_{21}O_2N$, 295.157; Found 295.151. IR (neat) ν_{st} 1407, 1383, 1372, 1281, 1242, 1200, 1137, 1058, 1043, 1024, and 858 cm^{-1}. λ_{max} (EtOH) (O.D.); 252sh (0.884); 280sh (0.411), 290 (0.525), and 313.5 (0.515) nm. ^{1}H-NMR ($CDCl_3$) δ=1.32 and 1.68 (3H each, s, $C(CH_3)_2$), 3.00 (center) (8H, AA′BB′-m, $Ar-CH_2-CH_2-Ar$), 4.43 and 4.62 (1H each AB-q, J=16.0, $Ar-CH_2O$), 6.74 (center) (4H, AA′BB′-m, Ar-H),

and 7.39 (1H, s, Ar_{py}-H).

To obtain 17-acetoxy-18-acetoxymethyl-2,11-dithia[3]-paracyclo[3](2,5)pyridinophane (**23**), 0.5 g (1.39 mmol) of **14** was heated at 50 °C for 30 min with 24 ml of 2M-HCl(1 M=1 mol dm^{-3}), followed by neutralization by the addition of sodium hydrogencarbonate after cooling. The precipitate (**22**) was collected by filtration, washed several times with water and dried *in vacuo* over Drierite. The solid was treated with 10 ml of acetic anhydride in 30 ml of pyridine at the ambient temperature for 30 min, followed by evaporation under reduced pressure. After silica-gel chromatography eluted with benzene–acetone (85:15 v/v), the result was 0.45 g (80%, based on **14**) of **23**, as colorless viscous liquid which, then, became crystals by scrubbing; mp 115—116 °C, R_f 0.8 (solvent BA5). Calcd for $C_{20}H_{21}O_4S_2N$: C, 59.53; H, 5.25; N, 3.47; S, 15.89%. Found: C, 59.65; H, 5.29; N, 3.44; S, 15.71%. IR (neat) $\nu_{C=O}$ 1765 and 1740, ν_{st} 1425, 1407, 1370, 1220, 1185, 1027, and 680 cm^{-1}. λ_{max} (EtOH) (M^{-1} cm^{-1}); 207.5 (17800), 215sh (16400), 234sh (8100), 275 (3700), and 297.5sh (2200) nm. ^{1}H-NMR ($CDCl_3$) δ=1.95 (3H, s, $COCH_3$), 2.37 (3H, s, Ar-$OCOCH_3$), 3.81 and 4.09 (1H each, AB-q, J=16.1, Ar_{py}-CH_2-S), 3.83 (2H, s, Ar_{py}-CH_2S), 3.85 (2H, s, Ar-CH_2S), 3.89 (2H, s, Ar-CH_2S), 5.06 and 5.34 (1H each, AB-q, J=12.5, -CH_2O), 7.65 (1H, s, Ar_{py}-H), 6.93 (2H, broad d, J=8.0, Ar-H), and 7.07 (2H, broad d, Ar-H).

23 (0.4 g) in 250 ml of triethyl phosphite was irradiated at tap-water temperature (*ca.* 20 °C) for 9.5 h with a high-pressure mercury lamp. Dry nitrogen was bubbled throughout. After the removal of the solvent *in vacuo*, the residue was chromatographed on a silica-gel column eluted with a solvent (BA5) to give 0.2 g (59%, based on **23**) of 15-acetoxy-16-acetoxymethyl[2]paracyclo[2](2,5)pyridinophane (**24**) as colorless viscous liquid. MS; m/z 339 (M^+) and a base peak at m/z 155. Exact mass measurement; Calcd for $C_{20}H_{21}O_4N$, 339.147. Found, 339.151. IR (neat) $\nu_{C=O}$ 1765 and 1743, ν_{st} 1370, 1226, 1182, 1025, 970, 795, and 720 cm^{-1} λ_{max} (EtOH) (O. D.); 222 (2.73), 287 (0.437), and 307 (0.263) nm. ^{1}H-NMR ($CDCl_3$) δ=1.95 (3H s, $COCH_3$), 2.32 (3H, s, Ar-$OCOCH_3$), 3.09 (center) (8H, AA'BB'-m, -CH_2-CH_2-), 4.83 and 4.91 (1H each, AB-q, J=12.0, CH_2O), 6.71 (center) (4H, AA'BB'-m, Ar-H), and 7.75 (1H, s, Ar_{py}-H).

Photochemical reactions of **16a** (0.2 g) or **16b** (0.5 g) in a solution comprised of 50 ml of benzene and 200 ml of triethyl phosphite at *ca.* 20 °C (by circulating tap-water) under a nitrogen atmosphere for 4 h or 16 h, respectively, resulted in a slight disappearance of the starting materials (R_f 0.55 and 0.5, respectively) on TLC (solvent BA1). However, sulfur-extruded products are unisolable as a result of careful silica-gel chromatography. Then, both isopropylidene-cyclophanes (**16b,c**) were converted to the corresponding acetates **29b,c** in order to examine any alternative possibility regarding the photochemical extrusion of a sulfur atom.

16b (1.6 g, 4.7 mmol) was subjected to the same sequence of procedures as those for the preparation of **23** from **14** to yield 1.8 g (99%, based on **16b**) of 15-acetoxy-16-acetoxymethyl-2,9-dithia[10](2,5)pyridinophane (**29b**) as colorless crystals. These were recryst. from diisopropyl ether after a chromatographic separation by silica gel; R_f 0.6 (solvent BA1), mp 121—122 °C. Calcd for $C_{18}H_{25}O_4NS_2$: C,. 56.37; H, 6.57; N, 3.65; S, 16.72%. Found: C, 56.43; H, 6.54; N, 3.55; S, 16.72%. IR (KBr) $\nu_{C=O}$ 1770 and 1745, ν_{st} 1440, 1405, 1377, 1362, 1301, 1215, 1178, 1153, 1055, 1034, 1010, and 830 cm^{-1}. λ_{max} (EtOH) (M^{-1} cm^{-1}); 205.5 (14400), 221sh (10300), 240sh (5400), and 285 (6100) nm. ^{1}H-NMR ($CDCl_3$) δ=0.4—1.4 (8H, m, -(CH_2)$_4$-), 1.8—2.7 (4H, m, -CH_2CH_2S), 2.03 (3H, s, CH_2OCOCH_3), 2.40 (3H, s, Ar-$OCOCH_3$), 3.79 and 4.11 (1H each, AB-q, J=14.0, Ar-CH_2S), 3.82 (2H, s, Ar-H), 5.22 and 5.41 (1H each, AB-q, J=13.0, Ar-CH_2O), and 8.22 (1H, s, Ar-H).

29b (1.0 g) was irradiated in a solution comprising 50 ml of benzene and 200 ml of triethyl phosphite for 9 h. Dry nitrogen was bubbled throughout. However, the obtained product still included one sulfur atom. 0.15 g of **29b** was recovered by silica-gel chromatography.

16c (0.75 g, 2 mmol) was acetylated by a sequence of procedures similar to those for **23** from **14** to afford 0.79 g (94%, based on **16c**) of 17-acetoxy-18-acetoxymethyl-2,11-dithia[12](2,5)pyridinophane (**29c**) as a pale-yellow viscous liquid. This was isolated by silica-gel column chromatography eluted with a solvent (BA1) (R_f 0.5). Calcd for $C_{20}H_{29}O_4NS_2$: C, 58.37; H, 7.10; N, 3.40%. Found: C, 58.88; H, 6.77; N, 3.41%. IR (neat) $\nu_{C=O}$ 1775 and 1745, ν_{st} 1370, 1220, 1180, and 1028 cm^{-1}. λ_{max} (EtOH) (O.D.); 220sh (0.642), 241sh (0.30), and 283.5 (0.374) nm. ^{1}H-NMR ($CDCl_3$) δ=0.8—1.5 (12H, m, -(CH_2)$_6$-), 2.01 (3H, s, CH_2OCOCH_3), 2.37 (2H, t, J=6.5, CH_2CH_2S), 2.50 (2H, t, J=6.5 CH_2CH_2S), 2.38 (3H, s, Ar-$OCOCH_3$), 3.76 (2H, s, Ar-CH_2S), 3.90 (2H, s, Ar-CH_4S), 5.27 (2H, s, Ar-CH_2O), and 8.33 (1H, s, Ar-H).

29c (0.55 g, 1.3 mmol) in 200 ml of triethyl phosphite was irradiated for 28 h and monitored by TLC. After a work-up followed by a careful silica-gel chromatography eluted with the solvent BA1 (R_f 0.5). gave 80 mg (16%) of a product (R_f 0.45) with a concomitant recovery of the starting material **29c** (50 mg). The product showed MS, m/z 379 (M^+). Exact mass measurement; Calcd for $C_{20}H_{29}O_4NS$, 379.181. Found, 379.188. IR (neat) $\nu_{C=O}$ 1775 and 1750, ν_{st} 1224, 1188, and 930 cm^{-1}. λ_{max} (EtOH) (O.D.); 238sh (0.4) and 277 (0.52) nm. These spectral data suggest that only one sulfur atom is extruded from the starting diacetate **29c**.

Attempts at the oxidation of **20** with triphenylmethylium tetrafluoroborate was carried out as follows:[21] a mixture of 0.95 g (1.2 mmol) of **20** and 3.2 g (3 mol equiv) of triphenylmethylium tetrafluoroborate in 100 ml of dichloromethane was stirred at the ambient temperature under a nitrogen atmosphere for 18 h. This was followed by hydrolysis with a saturated sodium hydrogencarbonate solution. The organic layer was separated, dried over anhydrous magnesium sulfate, filtered through Celite (No. 545) and evaporated to dryness. The residue was chromatographed on a silica-gel column eluted with the solvent BA3 to yield 60 mg (7.4% based on **20**) of 15-hydroxy-16-formyl[2]paracyclo[2](2,5)pyridinophane (**21**) as yellow liquid; R_f 0.9 (benzene–acetone 3:2 v/v) and 0.8 (chloroform). MS; m/z 253 (M^+), 237 (M^+—16), and 225 (M^+—28) and base peaks at m/z 91 and 77. Exact mass measurement; Calcd for $C_{16}H_{15}O_2N$, 253.110. Found, 253.114. ^{1}H-NMR ($CDCl_3$) δ=9.94 (1H, s, CHO).

Oxidation with (Active) Manganese Dioxide (Scheme 5). General Procedure Prior to Oxidation. All the

pyridoxine-type cyclophanediols and related compounds were prepared from corresponding isopropylidene derivatives using acid hydrolysis as follows; the isopropylidene derivatives were heated at *ca.* 70 °C for 1—2 h with 2M-HCl (*ca.* 30 ml/g of the acetal) while being magnetically stirred. The reaction mixture, in which mostly diol hydrochloride was crystallized out as a white solid when the hydrolysis came closer to the terminal point (monitored by TLC), was neutralized with sodium hydrogencarbonate after cooling, followed by the evaporation of any water. The residue was triturated with ethanol and/or pyridine and filtered through Celite (No. 545). The filtrate was evaporated to dryness under reduced pressure to give a colorless solid which was subjected to manganese dioxide oxidation in the presence or absence of amine.

i) *Direct Oxidation with Active Manganese Dioxide.* Newly prepared active manganese dioxide (MnO_2*) (according to the method described by Attenburrow *et al.*)[24] was employed.

When the hydrolyzed product of **16b** (0.4 g, 1.18 mmol) was refluxed with MnO_2* (2.0 g) in chloroform (50 ml) for 23 h, followed by filtration through Celite (No. 545) on 3G sintered-glass filter, washed several times with hot ethanol and pyridine, the combined filtrate was evaporated to dryness and then chromatographed on a silica-gel column eluted with the solvent BA3 to yield 50 mg (14%, based on **16b**) of 16-formyl-15-hydroxy-2,9-dithia[10](2,5)pyridinophane (**26b**) with concomitant recovery of 40 mg (11%) of the starting diol. Obtained **26b** was recrystallized from acetone; R_f 0.75 (solvent BA5), mp 128—130 °C. Calcd for $C_{14}H_{19}O_2NS_2$: C, 56.53; H, 6.44; N, 4.71; S, 21.56%. Found: C, 56.64 H, 6.42; N, 4.39; S, 21.32%. IR (neat) $\nu_{C=O}$ 1653, ν_{st} 2930, 1375, 1295, 1240, 1195, 964, 728, 697, and 670 cm^{-1}. The UV-VIS data are shown in Table 4. ^{1}H-NMR data except for those listed in Table 3; 0.2—1.65 (8H, m, $-(CH_2)_4-$), 1.95—2.75 (4H, m, $-CH_2CH_2S$), and 7.95 (1H, s, Ar-H).

When a mixture of the hydrolyzed product from **16b** (0.4 g, 1.18 mmol) and MnO_2* (1.6 g) in benzene (50 ml) was refluxed with an azeotropic removal of the resulting water using Dean-Stark apparatus for 39 h, followed by filtration and washing as mentioned above, **26b** was obtained by silica-gel chromatography in 18% (50 mg) yield, based on **16b**. with a recovery of 70 mg (20%) of the diol.

After the diol obtained from the hydrolysis of **16c** (0.43 g) was oxidized with MnO_2* (1.5 g) in a mixed solvent of pyridine (5 ml) and chloroform (50 ml) and refluxed for 71 h, the reaction mixture was treated as mentioned above and chromatographed on a silica-gel column eluted with the solvent BA2 to yield 60 mg (16%, based on **16c**) of 18-formyl-17-hydroxy-2,11-dithia[12](2,5)pyridinophane (**26c**) as a pale-yellow liquid. This was crystallized spontanously at the ambient temperature; R_f 0.65 (solvent BA2), mp 68.0—69.5 °C. Calcd for $C_{16}H_{23}O_2NS_2$: C, 59.04; H, 7.12; N, 4.30; S, 19.70%. Found: C, 59.05; H, 7.12; N, 3.90; S, 19.67%. IR (neat) $\nu_{C=O}$ 1655, ν_{st} 2930, 1380, 1248, 1234, and 870 cm^{-1}. The UV-VIS data are listed in Table 4. ^{1}H-NMR data except for those shown in Table 3 are 0.8—1.7 (12H, m, $-(CH_2)_6-$), 2.40 (2H, t, J=7.5, CH_2CH_2S), and 8.04 (1H, s, Ar-H).

ii) *MnO_2* Oxidation in the Presence of* p-*Phenetidine Hydrochloride.* After the diol prepared by the hydrolysis of **16b** (0.3 g, 0.88 mmol) was refluxed with *p*-phenetidine hydrochloride ($ArNH_2$) (0.3 g, 1.6 mmol) and MnO_2* (1.5 g) in a mixed solvent of pyridine (10 ml) and chloroform (40 ml) for 64 h, filtered cooled, through Celite (No. 545) mounted on a 3G sintered-glass filter (the filtrate was evaporated), the residue was chromatographed on a silica-gel column eluted with a solvent BA3 to give 160 mg (39%, based on **16b**) of the Schiff base (**30b**). It comprised **26b** and $ArNH_2$ as red brown crystals, recryst. from benzene-diisopropyl ether; R_f 0.65 (solvent BA3), mp 173—174 °C. Calcd for $C_{22}H_{28}O_2N_2S_2$: C, 63.43; H, 6.77; N, 6.72; S, 15.39%. Found: C, 63.43 H, 6.74; N, 6.66; S, 15.20%. IR (KBr) $\nu_{C=N}$ 1615, ν_{st} 2920, 1510, 1390, 1305, 1292, 1250, 1043, and 836 cm^{-1}. λ_{max} (EtOH) (M^{-1} cm^{-1}); 204 (16200), 228 (15800), 295 (4200), 340sh (10900), 361 (13200), 373 (13300), and 390sh (11000) nm. ^{1}H-NMR ($CDCl_3$) δ=0.55—1.4 (8H, m, $-(CH_2)_4-$), 1.45 (3H t, J=6.95, $-CH_2CH_3$), 2.0—2.7 (4H, m, CH_2CH_2S), 3.80 and 4.25 (1H each, AB-q, J=12.78, $Ar_{py}-CH_2S$), 3.82 and 4.04 (1H each, AB-q, J=14.03, $Ar-CH_2S$), 4.10 (2H, q, J=6.95, OCH_2CH_3), 6.99 (2H, d, J=8.9, Ar-H), 7.40 (2H, d, J=8.9, Ar-H), 7.88 (1H, s, Ar_{py}-H), and 14.45 (1H, s, -OH).

Diol (0.05 g, 0.167 mmol), prepared by the hydrolysis of **16b**, was oxidized with MnO_2* (0.5 g) in the presence of $ArNH_2$ (0.1 g, 0.53 mmol) in a mixed solvent of pyridine (5 ml) and benzene (20 ml) while removing the resulting water (using a the Dean-Stark tube), and gave **30b** (70 mg, 99% yield based on the diol).

Diol (**22**) (0.1 g, 0.313 mmol), prepared by the hydrolysis of **14**, was oxidized with MnO_2* (0.7 g) in the presence of $ArNH_2$ (0.1 g, 0.53 mmol) in benzene (30 ml), refluxed for 12 h while removing the resulting water (using a Dean-Stark tube). The residue, after a work-up as mentioned above, was chromatographed on a silica-gel column eluted with a solvent (BA3) to give 55 mg (40%, based on **22**) of the Schiff base (**31**) composed of **27** and $ArNH_2$, as yellow-red fine needles, recryst. from benzene-diisopropyl ether; R_f 0.6 (solvent BA3), mp 243.5—244.5 °C (dec). Calcd for $C_{24}H_{24}O_2N_2S_2$: C, 66.03; H, 5.54; N, 6.42; S, 14.69%. Found: C, 66.11; H, 5.59; N, 6.27; S, 14.63%. IR (KBr) $\nu_{C=N}$ 1615, ν_{st} 1510, 1390, 1300, 1255, and 820 cm^{-1}. λ_{max} (EtOH) (O.D.); 240sh (0.597), 295sh (0.205), 350sh (0.497), 364 (0.525), and 400sh (0.330) nm. ^{1}H-NMR ($CDCl_3$) δ=1.46 (3H, t, J=7.1, OCH_2CH_3), 3.91 (2H, s, $Ar-CH_2S$), 4.97 (2H, s, $Ar-CH_2S$), 4.12 (2H, q, J=7.1, OCH_2CH_3), 3.85 and 4.08 (1H each, AB-q, J=14.56, $Ar_{py}-CH_2S$), 3.78 and 4.35 (1H each, AB-q, J=14.0, $Ar_{py}-CH_2S$), 6.86—7.46 (8H, m, Ar-H), 7.36 (1H, s, Ar_{py}-H), 9.04 (1H, s, -CH=N), and 14.13 (1H, s, -OH).

iii) *Oxidation with Commercial MnO_2 in the Presence of Amines.* The hydrolysis of each acetal was performed under the conditions mentioned above. The oxidation was carried out under the similar conditions to those described in a previous report,[25] unless otherwise noted. When $ArNH_2$ was used as a coexisting amine, the product was isolated in the form of the corresponding Schiff base (**M** in Scheme 5) by means of silica-gel chromatography. When 3-(dimethylamino)propylamine (DAPA) was employed as a coexistent amine, the resulting Schiff base (**M** in Scheme 5) was hydrolyzed with 0.3 M-HCl, monitored by TLC, followed by extraction with benzene-ethyl acetate. It was then isolated in the form of the corresponding pyridoxal-

type compound (**P** in Scheme 5) by means of silica-gel chromatography.

Diol (**22**), prepared by the hydrolysis of **14** (0.85 g, 2.36 mmol), was oxidized for 3 h with commercial MnO_2[38] (5 g) in the presence of DAPA (1.5 ml) in a mixed solvent of benzene (50 ml) and pyridine (20 ml). This was followed by filtration through Celite (No. 545), washing with hot pyridine, and evaporation of the filtrate. The residue was hydrolyzed with 0.3 M-HCl (40 ml) in benzene–ethyl acetate (1:1 v/v) (20 ml) for 40 min, carefully monitored by TLC (solvent BA2, R_f 0.4 for **27**, and solvent CM2, R_f 0.4 for the Schiff base **M**). The organic layer was separated and passed through a short column to remove the amine and residual water eluted with a solvent (BA2). The eluate was further chromatographed on a silica-gel column to yield 0.31 g (41%, based on **14**) of 18-formyl-17-hydroxy-2,11-dithia-[3]paracyclo[3](2,5)pyridinophane (**27**) as pale-yellow crystals; mp 218—219 °C (start browning near at 204 °C and then decomposed). Calcd for $C_{16}H_{15}O_2NS_2$: C, 60.54; H, 4.76; N, 4.41; S, 20.20%. Found: C, 60.43; H, 4.82; N, 4.39; S, 20.12%. IR (KBr) $\nu_{C=O}$ 1645, ν_{st} 1423, 1410, 1377, 1250, 970, and 723 cm^{-1}. The UV-VIS data are listed in Table 4. ^{1}H-NMR data except for those collected in Table 3 are 3.84 (2H, s, Ar-C$\underline{H}_2$S), 6.84—7.16 (4H, m, Ar-$\underline{H}$), and 7.42 (1H, s, Ar_{py}-$\underline{H}$).

Diol, prepared by the hydrolysis of **16a** (1.1 g, 3.54 mmol), was oxidized with MnO_2 (7.0 g) in the presence of DAPA in a mixed solvent of benzene (50 ml) and pyridine (20 ml) for 1.5 h, followed by filtration, washing with hot pyridine, and an evaporation of the filtrate. The residue in the benzene–ethyl acetate (1:1 v/v) (20 ml) was hydrolyzed with 0.3 M-HCl (60 ml), carefully monitored by TLC (solvent BA2, R_f 0.6 for **26a** and solvent CM2, R_f 0.4 for the Schiff base **M**). The organic layer was treated using the method mentioned above and by a chromatographic separation with silica gel eluted with a solvent (BA4), 0.4 g (42%, based on **16a**) of 14-formyl-13-hydroxy-2,7-dithia-[8](2,5)pyridinophane (**26a**) was obtained as pale-yellow crystals. These were spontaneously crystallized; mp 118—119.5 °C. Calcd for $C_{12}H_{15}O_2NS_2$: C, 53.51; H, 5.61; N, 5.20; S, 23.80%. Found: C, 53.74; H, 5.64; N, 5.03; S, 23.37%. IR (neat) $\nu_{C=O}$ 1655, ν_{st} 1385, 1297, 1240, 1223, 1110, 967, 755, 695, and 675 cm^{-1}. The UV-VIS data are listed in Table 4. ^{1}H-NMR data except for those listed in Table 3; 0.7—1.4 (4H, m, -(C$\underline{H}_2$)$_2$-), 1.6—2.8 (4H, m, SC$\underline{H}_2$C$\underline{H}_2$), and 7.87 (1H, s, Ar_{py}-$\underline{H}$).

Diol, prepared by the hydrolysis of **16b** (1.09 g, 3.22 mmol), in the mixed solvent of benzene (50 ml) and pyridine (20 ml) was oxidized with MnO_2 (7.0 g) in the presence of DAPA (2 ml) for 1 h. This was followed by the hydrolysis of the Schiff base (**M**) with 0.3 M-HCl and a similar work-up to that described above. This yielded 0.68 g (71%, based on **16b**) of **26b**; physical data and elemental analyses are described in section i) of this section.

Diol, propared by the hydrolysis of **16c** (1.14 g, 3.1 mmol), in the mixed olvent of benzene (50 ml) and pyridine (18 ml) was oxidized with MnO_2 (3.5 g) in the presence of DAPA (1.0 ml) for 2 h. This was followed by a similar work-up to that described above and yielded 0.48 g (51%, based on **16c**) of **26c**; physical data and elemental analyses are described in section i) of this section.

Diol, prepared by the hydrolysis of **16c** (0.27 g, 0.825 mmol), in benzene (30 ml), was oxidized with MnO_2 (0.72 g) in the presence of $ArNH_2$ (0.31 g, 1.65 mmol) for 1 h. This produced 0.14 g (38%, based on **16c**) of a Schiff base (**M**) composed of **26c** and $ArNH_2$. This was chromatographically isolated with eluting a solvent (BA3); R_f 0.7 (solvent BA3).

The oxidation of the diol, prepared by the hydrolysis of **16b** (1.33 g, 4.48 mmol), in benzene (100 ml) with MnO_2 (4.6 g) in the presence of $ArNH_2$ (1.7 g, 8.89 mmol) yielded 0.9 g (49%, based on **16b**) of the Schiff base (**M**) comprising **26b** and $ArNH_2$; physical data and elemental analyses are described in section ii) of this section.

The oxidation of the diol, prepared by the hydrolysis of **19** (1.26 g, 4 mmol), with MnO_2 (7 g) in the presence of DAPA (2 ml) in the mixed solvent of benzene (50 ml) and pyridine (20 ml) for 1.2 h, followed by the hydrolysis of the Schiff base (**M**) with 0.3 M-HCl and a similar work-up to that described for the preparation of **26a**. This yielded 0.85 g (78%, based on **19**) of 5′-deoxy-2′,5′-bis(ethylthio)pyridoxal (**28**), as yellow viscous liquid, after chromatography; R_f 0.8 (solvent BA2). Calcd for $C_{12}H_{17}O_2NS_2$: C, 53.11; H, 6.31; N, 5.16; S, 23.63%. Found: C, 53.22; H, 6.24; N, 5.14; S, 23.23%. ^{1}H-NMR ($CDCl_3$) δ=1.25 (6H, t, J=7.5, $SCH_2C\underline{H}_3$), 2.51 (2H, q, J=7.5, $SC\underline{H}_2CH_3$), 2.60 (2H, q, J=7.5, $SC\underline{H}_2CH_3$), 3.90 (2H, s, Ar_{py}-C$\underline{H}_2$S), 3.92 (2H, s, Ar_{py}-C$\underline{H}_2$S), 7.98 (1H, s, Ar_{py}-$\underline{H}$), 10.50 (1H, s, -C$\underline{H}$O), and 11.53 (1H, s, -O$\underline{H}$). IR (neat) $\nu_{C=O}$ 1655, ν_{st} 1380, 1243, and 968 cm^{-1}.

Racemization Reaction. A 0.03 M-borate buffer (pH 10.0) was prapared as follows; 5.73 g (15 mmol) of sodium borate·10H_2O was dissolved in 300 ml of water. A part (60 ml) of the solution was made to be pH 10.0 by adding *ca.* 35 ml of a 0.1 M-NaOH solution and allowed to stand overnight. Then, the pH was readjusted to be 10.0 by adding a 0.1 M-NaOH solution (to become 100 ml).

Sodium hydrogen L-glutamate (18.7 g, 0.1 mol) and 0.5 g (2 mmol) of copper(II) sulfate·5H_2O was mixed in a small amount of water. Then 2 M-NaOH was added to produce a pH of 10. This was then allowed to stand overnight. Then, total volume of the solution was made to be 100 ml by the addition of water and 2 M-NaOH (readjusting the pH to 10.0).

A catalyst solution was prepared as follows; 0.5 mmol of a catalyst was dissolved into a 0.03 M-borate buffer (50 ml) and the pH was readjusted to be 10.0 by adding 2 M-NaOH. Then, the mixture was made to be 100 ml by the addition of *ca.* 50 ml of ethanol.

In a thermostated water bath at 25±0.5 °C, a 2 ml aliquot of an amino acid solution containing copper(II) sulfate (a.a. 1 M, Cu^{+2}, 2×10^{-2} M, pH 10 (NaOH), 25 °C) and a 5 ml aliquot of a catalyst solution (5×10^{-3} M, pH 10 (0.03 M borate buffer), 25 °C) was withdrawn from each stock solution using a pipet. These were mixed in a test tube equipped with a glass stopper and sealed (final molar ratio; a.a.:Cu^{+2}:catalyst=80:1.6:1). The degree of the optical rotation (α_t) was recorded in a standard cell with sodium D-line (589 nm) when the racemization reaction was terminated (every 8 h by the addition of 6 M-HCl all at once). In cases where we found precipitate in a terminated solution, it was filtered through Celite (No. 545) mounted on a 3G4 sintered-glass filter. The filtrate was used for an optical-rotation measurement. The measurement of α_t

continued until the racemization yield (calculated using 100 $(\alpha_0-\alpha_t)/\alpha_0$) became 56—84% (in ten to seventeen aliquots). α_0 is the average magnitude of the initial and the final optical rotation of the amino acid solution in the absence of catalyst. This showed almost no observable difference. The apparent rate constants (k_{obsd}) were calculated (using $2.30(\log \alpha_0-\log \alpha_t)/60t$). It was assumed that the reaction obeys first-order kinetics. The catalyst stability (decomposition percent) was checked by measuring the optical-density change at several specific absorption maxima for a 25-fold diluted aliquot of the reaction mixture terminated by the addition of 6 M-HCl (in the range of 210—450 nm).

In the case of pyridoxal, a plot of $(\log \alpha_0-\log \alpha_t)$ *vs.* time was linearly correlated for 56 h (50% racemization completion). Then the slope was decreased slowly with a linear correlation for 188 h (84% completion, 6.6% decomposition of catalyst at 288 nm). In the case of **27**, the same plot showed a linear relationship for up to 64 h (43% completion) and then leveled off (linearly) for 96 h (56% completion, 42 and 63% decomposition at 243 and 396 nm, respectively). The same plot for **26** was linearly correlated perfectly through measurements lasting 96 h (80% completion, zero percent decomposition at 325 nm). However, **26c** showed the same propensity as that of pyridoxal with a linear relation for 56 h (62% completion). Then it showed a decreased slope until an elapsed time of 188 h (83% completion, 8% decomposition at 305 nm). Additionally, the same plot of **26b** and **28** partly showed a linear correlation (but totally nonlinear) until 96 h (70 and 76% completion respectively, 14 and 26% decomposition at 307 and 385 nm for **26b**, and 12% decomposition at 304.5 nm for **28**, respectively). The reaction of **26c**, **27**, and **28** proceeded with the formation of a preciptate which could be dissolved by the final addition of 6 M-HCl.

We would like to express our thanks to Dr. Haruo Homma and his staff in this Institute for elemental analyses. Dr. Jun Uzawa and Mrs. Tamiko Chijimatsu are greatly appreciated for measurement of ^{1}H-NMR spectra, and Mr. Yasuaki Ezumi, for measurement of mass spectra. We are grateful to Dr. Makoto Ando and Dr. Sakae Emoto for useful discussion.

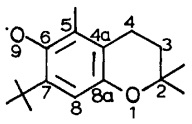
ENDOR Studies of Vitamin E Model Radical. The Solution Structure and Dynamic Behavior of Chromanyloxyl Ring

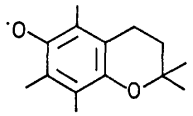
Kazuo MUKAI,* Kimiko TAKAMATSU, and Kazuhiko ISHIZU
Department of Chemistry, Faculty of Science, Ehime University, Matsuyama 790
(Received March 7, 1985)

ENDOR technique has been used to elucidate the solution structure and dynamic behavior of chromanyloxyl ring in vitamin E radical. We have measured the ENDOR spectrum of a stable vitamin E model radical (7-*t*-butyl-2,2,5-trimethyl-6-chromanyloxyl (**1**)) in toluene in the temperature range −30°—−100 °C. From detailed analysis of the temperature dependence of hyperfine coupling of β-methylene protons in the heterocyclic ring, the equilibrium conformation of the β-methylene group and activation energy, enthalpy and entropy for the conformational interconversion of the heterocyclic ring have been determined. The observed positive temperature dependence of the hyperfine coupling constants ($a_5^{CH_3}$ and a_8^H) may be explained as a consequence of the restricted motion about the C_{8a}–O_1 bond in the chromanyloxyl ring, based on the McLachlan MO calculation.

Tocopherols (vitamin E) are well known as scavengers of lipid peroxide radicals generated in biological membranes.[1,2] The ESR studies of the tocopheroxyl radicals obtained by the oxidation of tocopherols are of biological interest since they are involved in radical-scavenging reactions of tocopherols.[3–6] In a previous paper, we reported the ESR spectra of α-, β-, γ-, and δ-tocopheroxyl and their model compounds in toluene at 20 °C, and found that all the two β-methylene protons at C-4 position are magnetically equivalent.[4] Further, from the results of the ENDOR measurements of α-tocopheroxyl and its model, it was observed that each of the two β- and γ-methylene protons in the heterocyclic ring shows an equivalent hyperfine coupling.[7] This suggests that the two carbon atoms C-4 and C-3 in the heterocyclic ring are coplanar with the aromatic ring. The result is inconsistent with the X-ray structure of α-tocopherol model,[8,9] which shows that the dihedral angle, θ_γ, between the C_3–C_4 bond and the aromatic ring is 11.1° and 11.9° (see Fig. 3).[10] However, in a previous paper, the clear ENDOR spectra of the α-tocopheroxyl and its model radicals were observed in the comparatively high and narrow temperature range (from −25° to −35 °C for α-tocopheroxyl and from −40° to −55 °C for α-tocopheroxyl model), because these radicals are not so stable and dimerize at low temperature region.[7]



Tocopheroxyl **1**



α-Tocopheroxyl model

In the present work, we have measured the ENDOR spectrum of stable vitamin E model radical (7-*t*-butyl-2,2,5-trimethyl-6-chromanyloxyl, hereafter called tocopheroxyl **1**) in toluene in the temperature range −30°—−100 °C. From detailed analysis of the temperature dependence of the hyperfine coupling constants, the conformation and dynamic behavior of the heterocyclic ring in tocopherol in solution have been discussed.

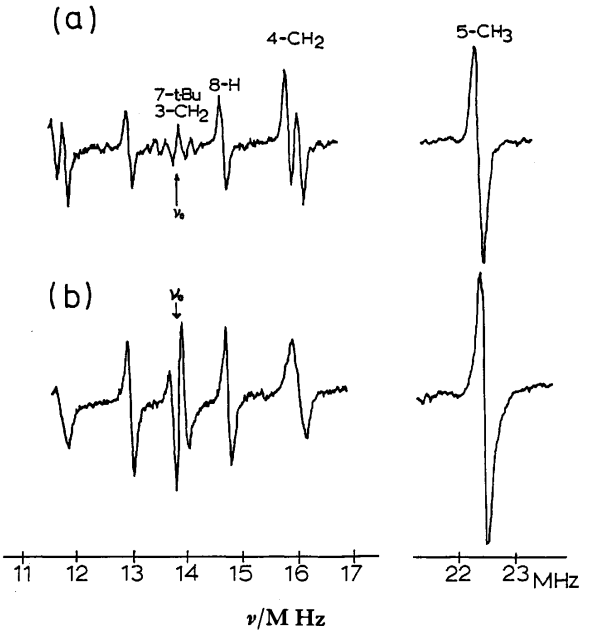
Experimental

The preparation of tocopherol model compound (7-*t*-butyl-2,2,5-trimethyl-6-chromanol) was reported in a previous paper.[11] The tocopheroxyl **1** was obtained by the PbO_2 oxidation of the above tocopherol model compound in toluene under vacuum.

The ENDOR spectra were recorded by a JES-EDX-1 spectrometer, operated with 80 Hz magnetic field modulation.

Results

The ENDOR spectrum of tocopheroxyl **1** was observed in the temperature range −30° to −100 °C. As shown in Fig. 1 and 2, notable temperature effects



ν/M Hz

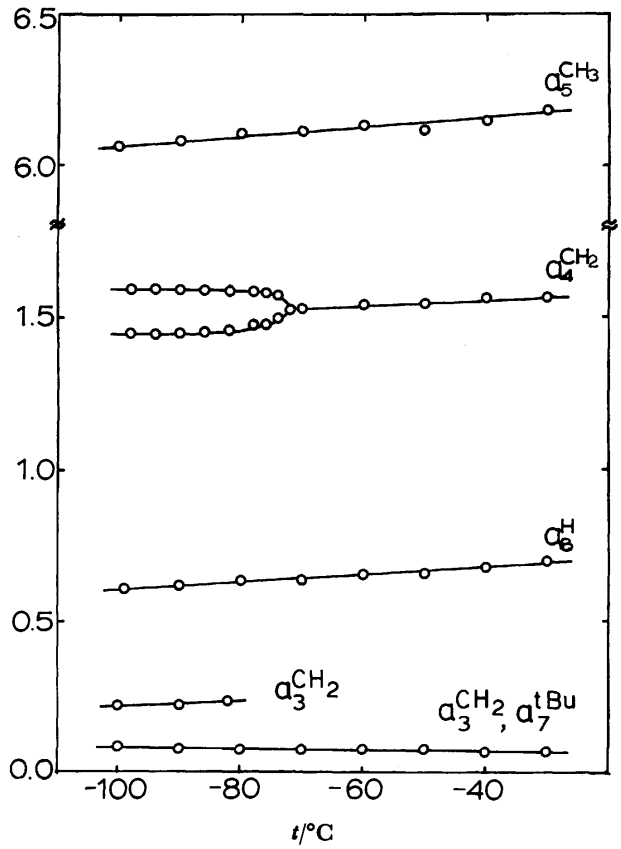

Fig. 2. Temperature dependence of the hyperfine couplings of tocopheroxyl **1** in toluene.

were observed. The ENDOR spectrum at −94 °C (see Fig. 1(a)) clearly shows six different proton hyperfine couplings (6.074, 1.592, 1.448, 0.608, 0.234, and 0.076 G). The larger four hyperfine couplings (6.074, 1.592, 1.448, and 0.608 G) are easily assigned to the protons at C-5, C-4, C-4, and C-8 positions, respectively, taking its ESR hyperfine couplings (see Table 1) into account.[11] By comparing the ENDOR spectrum of **1** with that of α-tocopheroxyl model,[7] the smallest hyperfine coupling of 0.076 G, which has never been observed in the ESR spectrum of **1**, will be assigned to the γ-methylene proton hyperfine coupling at C-3 position and/or *t*-butyl proton at C-7 position. The hyperfine coupling of 0.234 G was tentatively assigned to the γ-methylene proton at C-3. The ENDOR spectrum of **1** remains essentially unchanged upon warming from −100° to −80 °C except for small changes of the hyperfine couplings. When the temperature is increased further, the weak absorption due to γ-methylene proton ($a_3^{CH_2}$=0.234 G) has disappeared at −81 °C, and the two lines of alkyl β-protons ($a_4^{CH_2}$) were gradually merged into a single line at −72 °C, as is shown in Fig. 1(b) and Fig. 2. The values of the hyperfine couplings observed at −72 °C are $a_5^{CH_3}$=6.086, $a_4^{CH_2}$=1.525, a_8^H=0.635, and a_7^{tBu} and/or $a_3^{CH_2}$=0.073 G. These values are listed in Table 1, together with the values of the experimental spin densities (ρ_i) calculated from the hyperfine coupling.[4,11]

Discussion

Conformation of β-Methylene Group in Tocopheroxyl 1. As described in a previous section, in the ENDOR spectrum for the tocopheroxyl **1** in toluene, two signals attributable to the inequivalent splittings ($a_{4A}^{CH_2}$=1.592 G and $a_{4B}^{CH_2}$=1.448 G) of the β-methylene protons were recorded at −94 °C. The inequivalent β-methylene proton splittings have been understood by assuming a tightly rocking model of the methylene group, based on the Heller-McConnell relationship (Eq. 1).[12] In these cases, the sum of the two dihedral angles (θ_A, θ_B) of the inequivalent β-protons is about $\pi/3$. A similar situation probably exists in the present case.

$$a_4^{CH_2} = \langle Q(\theta)\rangle \rho_{4a}, \quad Q(\theta) = B_0 + B_2 \cos^2\theta \qquad (1)$$

where B_0 and B_2 are empirical parameters, and θ is the dihedral angle between the axis of the $2p_z$ orbital and the C–H bond of the β-methylene group. B_0 and B_2 were taken to be 0 and 54 G, respectively, in Eq. 1. Consequently, based on the observed β-methylene proton couplings, and assuming the sum of the two dihedral angles of the inequivalent β-protons is $\pi/3$, the values of the dihedral angles, θ_A and θ_B, were calculated to be 27.6° and 32.4° for **1**, respectively. These values show that the dihedral angle, θ_γ, between the C_3–C_4 bond and the aromatic ring is 2.4° (see Fig. 3). From the results of the estimated dihedral angles, a preferable equilibrium conforma-

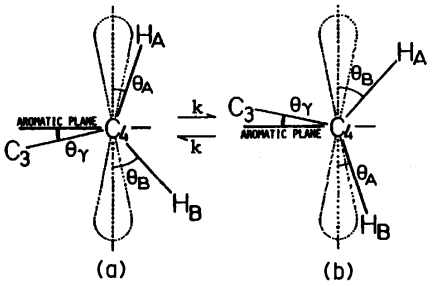

Fig. 3. Possible equilibrium conformations of the β-methylene group in tocopheroxyl **1** in toluene.

tion of C-H and C_3-C_4 bonds was assumed as illustrated in Fig. 3.

On the other hand, as the result of the analysis of the ENDOR spectrum indicates, the two β-methylene protons of **1** show an equivalent hyperfine splitting at higher temperatures. Therefore, the spin density (ρ_{4a}) at the C-4a position was tentatively calculated from $a_4^{CH_2}$=1.525 G at −72 °C, assuming θ=30° for two β-methylene protons in Eq. 1.[7] Using this spin density (ρ_{4a}), the splittings of $a_{4A}^{CH_2}$=1.592 and $a_{4B}^{CH_2}$=1.448 G are found to correspond respectively to angles of θ_A=27.8° and θ_B=32.5°, which add up very nearly to $\pi/3$. These values (θ_A and θ_B) are very similar to those (θ_A=27.6° and θ_B=32.4°) calculated above assuming $\theta_A+\theta_B=\pi/3$.

Very recently, we have succeeded in measuring the ENDOR spectrum of cation radical obtained by the oxidation of benzo[1,2-*b*:4,5-*b*']dipyran, which has heterocyclic ring common to that of tocopherols, in $AlCl_3$-CH_2Cl_2 mixtures.[13] In the cation radical, it was found that the two β-methylene protons in the heterocyclic ring become magnetically inequivalent at low temperature, showing two kinds of hyperfine couplings. The observed dihedral angles are θ_A=28.9° and θ_B=31.1°, and θ_γ is calculated to be 1.1°. These values are very similar to those of the tocopheroxyl **1**, because the steric repulsion force between the β-methylene protons at C-4 and the neighboring methyl protons is equivalent in **1** and the above cation radical. On the other hand, the values of the dihedral angle, θ_γ, (2.4° in **1** and 1.1° in cation radical) in solution are different from those (θ_γ=11.1° and 11.9° in α-tocopherol model[8,9]) in the crystal. The result suggests that the crystal and solution conformations of the heterocyclic ring attached to the aromatic ring in α-tocopherol are different.

Dynamic Behavior of Heterocyclic Ring. In the ENDOR spectra for the **1** in toluene, two signals due to the inequivalent splittings of the β-methylene protons were recorded at −100 °C. The β-methylene proton hyperfine coupling constants remain almost unchanged upon warming from −100° to −90 °C. They collapsed into a single line as the temperature

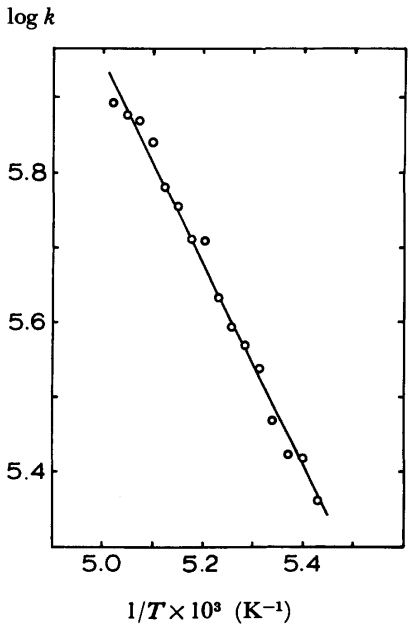

Fig. 4. The Arrhenius plot of the rate constant for the conformational interconversion process of the heterocyclic ring of tocopheroxyl **1** in toluene.

was raised to −72 °C (see Fig. 1 and 2). In such a case, we can calculate the activation energy (E_{act}) for the conformational interconversion of the heterocyclic ring, applying the Gutowsky-Holm equation.[14-16]

In a two-jump dynamic process, in which two nuclear spins of I=1/2 exchange their different hyperfine couplings, the observed separation $\Delta\omega$ of the two ENDOR lines is given by

$$\Delta\omega = (\Delta\omega_{max}^2 - 2k^2)^{1/2} \quad (2)$$

where $\Delta\omega_{max}$ is $\gamma_e|(a_{4A}^{CH_2}-a_{4B}^{CH_2})/2|$, and $a_{4A}^{CH_2}$ and $a_{4B}^{CH_2}$ (measured in Gauss) are the hyperfine coupling constants for the two β-methylene protons observed at −94 °C, and $k=1/\tau$. Here, τ is the mean lifetime of each conformation. We obtained k values as a function of the temperature between −89° and −74 °C.

Dynamic processes of this type can be described by the well-established theories of activated chemical reactions. Empirically the temperature dependence of the rate constant k for such an interconversion is given by the Arrhenius equation.

$$k = A_0 \exp(-E_{act}/RT) \quad (3)$$

where k is the jump rate of Eq. 2. Figure 4 shows the Arrhenius plots of log k *vs.* 1/T for tocopheroxyl **1** from which E_{act} and A_o were determined. The obtained values are E_{act}=25.9±1.7 kJ mol^{-1} and A_o=$5.6\times10^{12\pm0.4}$ s^{-1}. It may be seen that the activation energy, E_{act}, obtained in the present work for **1** is similar to that (29.9 kJ mol^{-1}) reported for such an interconversion in 1,2,3,6,7,8-hexahydropyrene anion radical.[16] From the Eyring theory of the activated

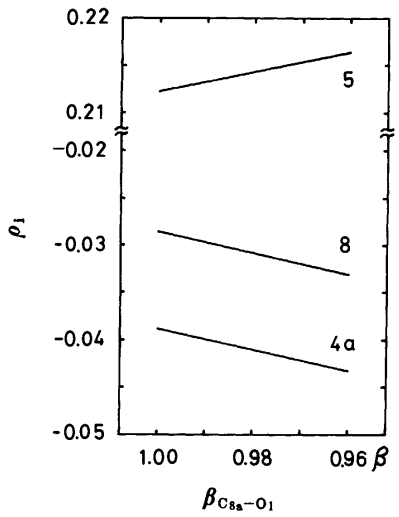

Fig. 5. The variation of the McLachlan spin densities (ρ_i) in tocopheroxyl **1** as a function of the resonance integral $\beta_{C_{8a}-O_1}(=\beta\cos\theta_{CO})$ between O_1 and C_{8a} atoms.

transition state, on the other hand, one obtains

$$k = (kT/h)\cdot\exp(\Delta S^*/R)\cdot\exp(-\Delta H^*/RT) \quad (4)$$

where ΔH^* is the activation enthalpy and ΔS^* is the activation entropy.[15] The thermodynamic quantities ΔH^* and ΔS^* were deduced from plots of ln k/T *vs.* 1/T which yielded straight lines according to Eq. 4. The obtained values are $\Delta H^*=24.2\pm1.7$ kJ mol^{-1} and $\Delta S^*=-5.4\pm3.4$ J mol^{-1} K^{-1}.

Temperature Dependence of the Proton Hyperfine Couplings of the Tocopheroxyl 1. As is shown in Fig. 2, the proton hyperfine couplings, $a_5^{CH_3}$, $a_4^{CH_2}$, and a_8^H, of the tocopheroxyl radical **1** are temperature dependent. These effects are considered to be the restricted motion about the C_{8a}–O_1 bond which causes changes in the unpaired spin density (ρ_i) throughout the radical.[17,18] McLachlan MO calculations successfully predict the changes in the above proton hyperfine couplings from −100° to −30 °C. Following Stone and Carrington,[17] we have used the resonance integral, $\beta_{C_{8a}-O_1}=\beta\cos\theta_{CO}$, as an adjustable parameter to account quantitatively for the changes in the average dihedral angle (θ_{CO}) of the C_{8a} carbon $2p_z$ orbital with respect to the C_{8a}–O_1–C_2 plane. The other Coulomb and resonance integrals employed in the calculations are as follows: $\alpha_{O_1}=\alpha+2.0\beta$, $\alpha_{O_9}=\alpha+1.3\beta$, $\alpha_{C_6}=\alpha-0.1\beta$, $\alpha_{C_{4a}}=\alpha-0.06\beta$, $\alpha_{C_7}=\alpha-0.04\beta$, $\beta_{C_6-O_9}=1.5\beta$, and $\lambda=1.2$, where α and β are, respectively, the standard carbon Coulomb and resonance integrals. These parameters are the same as those used previously for the α-tocopheroxyl radical.[7]

The McLachlan spin densities (ρ_5, ρ_{4a}, and ρ_8) calculated for the tocopheroxyl **1** are plotted against $\beta_{C_{8a}-O_1}$ in Fig. 5. The result indicates that the absolute values of ρ_i increase linearly with increasing the value of $\beta_{C_{8a}-O_1}$. The observed temperature dependence of the hyperfine couplings may be reconciled with the variation of calculated hyperfine couplings since $\beta_{C_{8a}-O_1}$ is expected to decrease with increasing temperature due to increased torsional amplitudes.[17,18] For instance, the change of $\beta_{C_{8a}-O_1}$ required to explain the change (0.118 G) of the methyl hyperfine couplings ($a_5^{CH_3}$) observed between −100° and −30 °C is 0.04 β. Recently, the result of the X-ray analysis of α-tocopherol model was reported by Burton *et al.*; an X-ray structure for α-tocopherol model gives the dihedral angle θ_{CO}= 18.5° and 15.2°.[8–10] Therefore, if we assume that the tocopheroxyl **1** has θ_{CO}=16.9° at −100 °C, the average dihedral angle θ_{CO} at −30 °C is calculated to be 23.5°.

We are very grateful to Mr. Yuichi Uemoto for his kind help in the preparation of 7-*t*-butyl-2,2,5-trimethyl-6-chromanol.

A New Synthetic Method of Alkyl Carbonocyanidate *N*-Oxides

Tomio SHIMIZU,* Yoshiyuki HAYASHI, and Kazuhiro TERAMURA
Department of Color Chemistry and Technology, Faculty of Engineering and Design, Kyoto Institute of Technology, Matsugasaki, Sakyo-ku, Kyoto 606
(Received April 17, 1985)

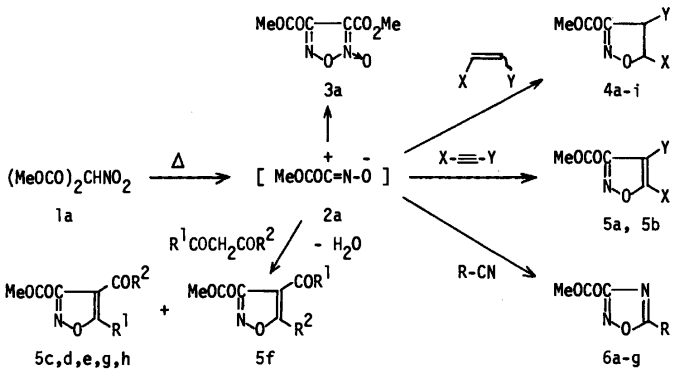
A thermal decomposition of dimethyl nitromalonate to bis(carbomethoxy)furoxan was observed at about 170 °C. In the presence of dipolarophiles, an intermediate, methyl carbonocyanidate *N*-oxide MeOCOC≡N→O, could be trapped as cycloadducts in good yields by the 1,3-dipolar cycloaddition. Treatment of dimethyl nitromalonate in mesitylene at the refluxing temperature resulted in a formation of methyl 2-(hydroxyimino)-2-(2,4,6-trimethylphenyl)acetate.

1,3-Dipolar cycloaddition reactions using nitrile oxides were one of the versatile methods for the preparation of five-membered heterocycles. Many preparative methods of nitrile oxides have been known so far,[1-8] but each of these methods suffers from some disadvantages; for example, i) many troublesome steps are required for the preparation of a precursor of nitrile oxides, ii) formation of by-products, and iii) a poor yield of the cycloadducts in the reaction with dipolarophiles. The present paper describes a new effective and simple method for the generation of alkyl carbonocyanidate *N*-oxides, ROCOC≡N→O, by a thermal decomposition of dialkyl nitromalonates and the trapping of the intermediate in the presence of dipolarophiles as cycloadducts. Nitromalonates (**1**) can be prepared quantitatively by the nitration of malonates with nitric acid under mild conditions.[9] Dimethyl nitromalonate (**1a**) and diethyl nitromalonate (**1b**) are known to be thermally stable (bp 124 °C/16 mmHg and 134 °C/14 mmHg, respectively).[9]

Results and Discussion

Thermal decomposition of **1** into distinct products is unprecedented to our knowledge, but we found that the thermolysis of **1a** in neat or in decalin at about 170 °C for several hours gave bis(methoxycarbonyl)furazan oxide (furoxan)(**3a**) in 70—75% yields with evolution of CO_2 and methanol. The isolation of the furoxan suggests that methyl carbonocyanidate *N*-oxide (**2a**) is first formed and then is converted into the dimer, **3a**. In the presence of dipolarophiles such as olefins, acetylenes, and nitriles, **2a** could be trapped as 2-isoxazolines (**4a—i**), isoxazoles (**5a** and **5b**), and 1,2,4-oxadiazoles (**6a—g**) respectively in the yields shown in Table 1 (also see Scheme 1). The structures of the products were assigned on the basis of elemental and spectral analyses and comparison of their physical properties with those of authentic specimens. β-Keto esters and 1,3-diketones are known to behave as dipolarophiles *via* a tautomerization into the enol forms.[10] Isoxazoles (**5c—h**) were thus obtained from the reaction of **1a** with several 1,3-dicarbonyl compounds *via* a dehydration of the initial cycloadducts, 5-hydroxy-2-isoxazolines.

A probable mechanism of the formation of **2a** in these reactions would be as follows; **1a** equilibrates with the nitronic acid (**7**), which undergoes an intramolecular substitution with loss of methanol followed by decomposition to give **2a**.



Scheme 1.

TABLE 1. 1,3-DIPOLAR CYCLOADDUCTS FROM THE REACTION OF **1a** WITH DIPOLAROPHILES

Dipolarophile	Reaction[a] condition	Product	Yield %	Mp(Bp) °C
1-Tetradecene	A	**4a** (X=$C_{12}H_{25}$, Y=H)	68	66—68[b]
Allyl *p*-nitrophenyl ether	A	**4b** (X=$CH_2OC_6H_4NO_2$, Y=H)	100	142—143[b]

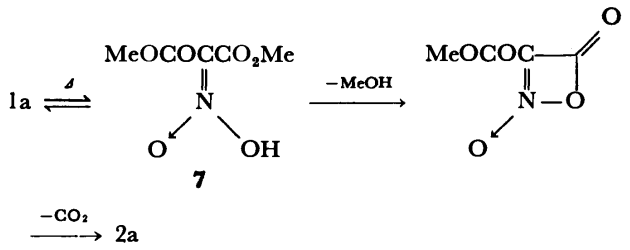
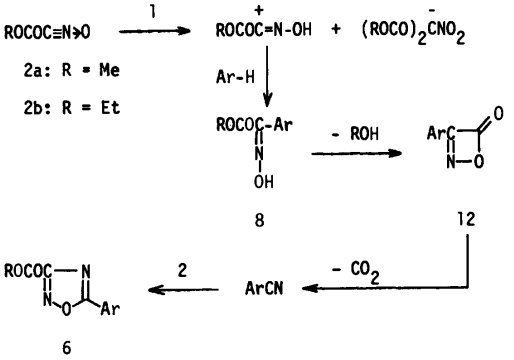
DMAD[c]	A	**5b** (X=Y=CO_2Me)	80	97—98[b]
Acetylacetone	B	**5c** (R^1=R^2=Me)	30	(95—100/1.5)
Dibenzoylmethane	C	**5d** (R^1=R^2=Ph)	28	111—112
Benzoylacetone	B	**5e** (R^1=Ph, R^2=Me)	43	62—64
		5f (R^1=Me, R^2=Ph)	29	82—85
Ethyl acetoacetate	B	**5g** (R^1=Me, R^2=OEt)	25	(100—120/2)
Ethyl benzoylacetate	C	**5h** (R^1=Ph, R^2=OEt)	20	(150—152/1)
Benzonitrile	C	**6a** (R=Ph)	31	107—108
2,4,6-Trimethylbenzonitrile	C	**6b** (R=C_9H_{11})	15	75—85
4-Methoxybenzonitrile	C	**6c** (R=C_6H_4OMe)	42	156—157
1-Naphthonitrile	C	**6d** (R=$C_{10}H_7$)	12	109—111
Phenylacetonitrile	C	**6e** (R=$CH_2C_6H_5$)	26	75—76
Dodecanenitrile	B	**6f** (R=$C_{11}H_{23}$)	16	50—51
Nonanenitrile	B	**6g** (R=C_8H_{17})	16	35—39

a) A: Refluxing the mesitylene solution of an equimolar mixture of **1a** and dipolarophiles for 20 h; B: Heating the mixture of **1a** and excess amount of dipolarophiles at about 170 °C for 8 h; C: Heating the decalin solution of an equimolar amount of **1a** and dipolarophiles at 170 °C for 20 h. b) **4a**: Lit,[8] mp 66—68 °C; **4b**: lit,[8] mp 142—143 °C; **4c**: lit,[8] mp 60—61 °C; **4h**: lit,[8] mp 223—225 °C; **5b**: lit,[6a] mp 101—102 °C. c) DMAD: Dimethyl acetylenedicarboxylate.



Although the yields of the cycloadducts were not highly dependent on solvents (neat, mesitylene, or decalin), we found that some of aromatic compounds bearing electron-releasing substituents were another acceptor of nitrile oxides. Refluxing a solution of **1a** in mesitylene for 20 h evolved CO_2 and methanol, and methyl 2-(hydroxyimino)-2-(2,4,6-trimethylphenyl)acetate (**8a**) was isolated in 27% yield. Furoxan (**3a**) was not detected in the solution. The structure of **8a** was confirmed by the agreement of the physical properties of **8a** with those of the specimen prepared from the reaction of methyl chloro(hydroxyimino)-acetate (**9**) with mesitylene. Though similar compounds (**8b—f**) were obtained from the reaction of **1a—b** with mesitylene, 1,2,4,5-tetramethylbenzene, pentamethylbenzene, and 3,5-dimethylanisole (see Table 2), 5-(*p*-methoxyphenyl)-3-methoxycarbonyl-1,2,4-oxadiazole (**6c**) or 3-methoxycarbonyl-5-(1,2,3,4-tetramethylphenyl)-1,2,4-oxadiazole (**6h**) was the only isolable compound from the reaction mixture of **1a** and anisole or 1,2,3,4-tetramethylbenzene, respectively.



Scheme 2.

The mechanism of the formation of these products can be explained in a fashion as shown in Scheme 2. Nitromalonates are known to be strong carbon-acids.

Protonation of the nitrile oxides (**2**) by nitromalonates would give a carbonium ion followed by electrophilic aromatic substitution to afford **8**. So far only an example of aromatic substitution has been reported using nitrile oxides, although a completely different mechanism of the substitution was suggested.[11] The aromatic substitution described here would provide new aspect of the chemistry of nitrile oxides.

In conclusion, our new reaction provides a simple and useful means of syntheses of isoxazolines, because of economical starting materials, easiness of the removal of by-products (MeOH and CO_2), and high yields of cycloadducts. On the other hand, the less reactive dipolarophiles such as nitriles and 1,3-dicarbonyl compounds gave poor yields of the cycloadducts.

Experimental

Measurements. All melting and boiling points are uncorrected. The ^1H NMR were measured on a Valian T-60A instrument with Me_4Si as an internal standard; chemical shifts are given in δ units and coupling constants (J) are in herz units: s=singlet; d=doublet; t=triplet; q=quartet; m=multiplet; br=broad singlet. All new

Table 2. Reactions of **1a—b** with aromatic compounds

Nitro Malonate	Aromatic Compound	Product	Yield %	Mp θ_m/°C
1a	Mesitylene	**8a** (R=Me, Ar=2,4,6-tetramethylphenyl)	27	131—132
1b	Mesitylene	**8b** (R=Et, Ar=2,4,6-tetramethylphenyl)	20	112—114

* Dissolved in DMSO-d_6.

products gave satisfactory elemental analyses (±0.3% for C, H, and N).

Materials. Dimethyl and diethyl nitromalonate (**1a** and **1b**),[9] and methyl chloro(hydroxyimino)acetate (**9**),[12] were prepared according to the methods described in the literature. Mesitonitrile [mp 49—50 °C (lit,[13] 50 °C)] was prepared in 75% yield from the reaction of mesitaldehyde with hydroxylamine hydrochloride in refluxing ethanol for 10 h. The other chemicals were of commercial origin and used without further purification.

*Thermal Decomposition of **1a—b** to Furoxan.* A decalin solution (10 ml) of **1b** (4.1 g, 20 mmol) was heated in an oil bath (about 170 °C) for several minutes. Gradual evolution of CO_2 (trapped as $CaCO_3$) and ethanol was observed in the course of the reaction. After the mixture was kept at the temperature for 20 h, the solvent was removed from the reaction mixture by distillation. Further distillation under reduced pressure gave a colorless oil (2.2 g yield, bp 110—130 °C/2 mmHg). The oil was found to be a mixture of **1b** and bis(ethoxycarbonyl)furoxan (**3b**) (molar ratio: *ca.* 1:4; yield of **3b**: 78%). Separation of **3b** and **1b** could be accomplished by passing the oil through an alumina column with chloroform. Evaporation of the chloroform eluents gave pure **3b** in 75% yield (1.68 g). **3a** was obtained similarly in 70% yield by decomposition of **1a**.

*Reaction of **1a** with Olefins or Acetylenes. Method A.* A mixture of **1a** (1.77 g, 10 mmol) and a dipolarophile (10 mmol) was refluxed in mesitylene (20 ml) at 160—170 °C for 20 h. Evaporation of the solvent and other low-boiling products from the reaction mixture in a rotary evaporator gave crude product. Crystalline crude products (**4a—e**, **4h**, **5a**, and **5b**) obtained by this method were recrystallized from appropriate solvents (**4a**, **4b**, and **5a** from ethanol; **4c** and **5b** from ethanol–hexane; **4d** from hexane; **4e** from methanol). Oily crude products (**4f**, **4g**, and **4i**) were distilled *in vacuo* to give pure cycloadducts.

*Reaction of **1a** with Nitriles or 1,3-Dicarbonyl Compounds. Method B.* A mixture of **1a** (1.77 g, 10 mmol) and an excess amount of a dipolarophile (*ca.* 20—30 mmol) was heated at about 170 °C for 8 h. The excess dipolarophile was distilled off from the reaction mixture. Crystalline residue was recrystallized from an appropriate solvent: **5e** and **5f** could be separated by fractional recrystallization from ethanol, **6f** from ethanol, and **6g** from hexane. Oily residue was further distilled *in vacuo* and the distillate was passed through an alumina column with chloroform. After evaporation of the chloroform eluent, the fractional distillation of the residue gave pure cycloadducts (**5c** and **5g**).

Method C. An equimolar amount (10 mmol) of **1a** and dipolarophile was heated at about 170 °C in decalin (20 ml) for 20 h. Upon cooling to room temperature, the reaction mixture separated into two layers. After removing a large portion of upper decalin layer by decantation, the residue was distilled *in vacuo* to remove decalin, furoxan **3a**, and the dipolarophile unchanged. Crystalline residue thus obtained was recrystallized from an appropriate solvent (**5d**, **6a**, **6d**, and **6e** from ethanol; **6b** from methanol; **6c** from ethanol–hexane). The oily residue obtained from the reaction with ethyl benzoylacetate was treated similarly as shown in Method B to give pure **5h**.

*Thermal Decomposition of **1a—b** in Aromatic Compounds.* A mixture of **1a** or **1b** (10 mmol) and an aromatic compound (20—30 mmol) was heated in an oil bath at 170 °C for 20 h. Unreacted **1** and aromatic compound were recovered by distillation of the reaction mixture. Crystalline residues obtained from the reactions with 1,2,4,5-tetramethylbenzene, pentamethylbenzene, 3,5-dimethylanisole, and 1,2,3,4-tetramethylbenzene were recrystallized from ethanol (**8e**, **8f**, and **6h**) or carbon tetrachloride (**8c** and **8d**). Oily residues obtained from the reactions with mesitylene and anisole were further distilled *in vacuo* to give viscous oils. The viscous oils were solidified by scraching in hexane to give crystals (**8a**, **8b**, and **6c**).

*Reaction of **8a** with **1a**.* A mixture of **8a** (800 mg, 3.6 mmol) and **1a** (2.0 g, 11 mmol) was heated at 170 °C for 20 h. 1.2 g of **1a** was recovered by distillation of the reaction mixture. Residual oil was passed through an alumina column with chloroform to give crystals, which were recrystallized from methanol to give **6b** in 25% yield (220 mg).

*Reaction of Mesitylene with Methyl Chloro(hydroxyimino)-acetate (**9**).* A mesitylene solution (20 ml) of **9** (1.8 g, 13 mmol) was refluxed untill the evolution of HCl had ceased (after *ca.* 10 h) and removal of excess amount of mesitylene from the reaction mixture afforded reddish oil. The oil was distilled and a viscous fraction (bp 130—150 °C/0.3 mmHg†) was collected, which crystallized partially in a condenser. The fraction was crystallized by scraching in hexane and the crystals were filtered to yield **8a** in 40% yield (1.15 g).

Hydroxylation of Cedrol by *m*-Chloroperbenzoic Acid. Synthesis of an Epimer of the Alleged "Senoxydene"

Motoo Tori, Reiko Matsuda, and Yoshinori Asakawa*

Faculty of Pharmaceutical Sciences, Tokushima Bunri University, Yamashiro Cho, Tokushima 770

(Received April 24, 1985)

Cedrol was hydroxylated by *m*-chloroperbenzoic acid to give four tertiary alcohols and two secondary alcohols, one of which was converted into an epimer of "senoxydene" in four steps.

The hydroxylation of natural products at unactivated positions has been effected by dry ozonization,[1] remote oxidation,[2] the Barton reaction,[3] microbial oxidation,[4] and mammalian metabolism.[5] In 1979, Deno and Meyer reported a method of hydroxylation of the 25-position of a steroidal side chain using hydrogen peroxide and trifluoroacetic acid.[6] Schneider described a practical method of hydroxylation of polycyclic hydrocarbons by *m*-chloroperbenzoic acid (*m*CPBA) yielding tertiary alcohols.[7] However, no examples of the use of *m*CPBA as a reagent for the hydroxylation of natural products have been reported.

We have been studying the oxidation of natural products by not only biological but also chemical methods. The hydroxylation of terpenoids in rabbits has been investigated in these laboratories.[8] We have recently applied *m*CPBA to the hydroxylation of unactivated carbon atoms of triterpenes belonging to the dammarane,[9] lupane,[10] and friedelane[10] classes.

Cedrol(**1**) is a sesquiterpene found in cedar wood. Ourisson and co-workers[11] subjected **1** to dry ozonization which afforded cedrane-2α,8β-diol (**5**) in 79% yield (50% conversion). Moreover, it has been reported by Wang *et al.*[12] that microbial oxidation of **1** produced cedrane-3α,8β-diol (**6**), 8β-hydroxycedran-3-one, and cedrane-3β,8β-diol (**7**).

We became interested in the structure of **1** which is very similar to an epimer of "senoxydene." If we could hydroxylate the 7-position of cedrol (**1**), oxidative bond cleavage and intramolecular aldol condensation would lead to a triquinane skeleton.

In a continuation of our work, the hydroxylation of natural products using *m*CPBA, we have examined the reaction of cedrol (**1**) with this reagent. We now report the products of this reaction as well as the conversion of one of these to an epimer[13] of the alleged "senoxydene."[14]

Cedrol (**1**, 2.2 g) was treated with *m*CPBA (1.2 equiv) in chloroform (75 ml) under reflux for 6 h. The usual work-up and chromatographic separation (see Experimental) afforded three novel compounds (**2**, **3**, and **4**) in addition to the previously known cedrane-2α,8β-diol (**5**),[11] cedrane-3α,8β-diol (**6**),[12,15,16] and cedrane-3β,8β-diol (**7**).[12,15,16] The least polar compound, the diol **2** [IR($CHCl_3$) 3570 and 3450 cm^{-1}; *m/z* 238 (M^+)] had signals characteristic of three tertiary methyl groups [δ 1.35, 1.21, and 0.97 (each s)] and a secondary methyl group [δ 0.87 (d, J=7 Hz)] in its ^1H NMR spectrum. As no resonance due to an oxygenated methine group was observed, it followed that the compound was either cedrane-7β,8β-diol (**2**) or cedrane-5β,8β-diol (**3**). The correctness of the former structure was demonstrated by ^{13}C NMR spectroscopy and $Pb(OAc)_4$ cleavage to the diketone (**8**) [IR($CHCl_3$) 1730 and 1715 cm^{-1}; *m/z* 236 (M^+)].

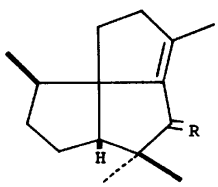
10 R=O
14 $R=H_2$



11 R=O
12 $R=H_2$

An analogous argument based on spectroscopic data led to the assignment of structure **3** [IR($CHCl_3$) 3600 and 3550 cm^{-1}; *m/z* 238 (M^+)] to a further product of cedrol oxidation. The ^1H NMR spectrum of the final product, a diol **4** [mp 114 °C; $[\alpha]_D$ +14.1 ° (*c*, 0.28 in $CHCl_3$); IR ($CHCl_3$) 3600 and 3400 cm^{-1}] indicated the presence of four tertiary methyl groups which led directly to structure **4**, cedrane-2β,8β-diol. Dehydration (HCOOH) of **4** gave cedra-2,8-diene,[11] which was obtained by a similar reaction of **5**.[11]

In order to demonstrate the synthetic utility of this method, the diol **2** was transformed into an epimer of the alleged "senoxydene." The glycol **2** was converted to the diketone (**8**) (*vide supra*) which, on treatment with methanolic sodium methoxide, underwent an intramolecular aldol condensation to afford the hydroxy ketone (**9**) [IR(CCl_4) 3600, 3400, and 1720 cm^{-1}; *m/z* 236 (M^+)] in 63% yield. Subsequent dehydration [$SOCl_2$/Py/0 °C] gave an equimolar mixture of enones **10** and **11**, separation of which was effected by column chromatography over silica-gel (EtOAc–hexane gradient as eluent). Upon Huang-Minlon reduction (KOH/NH_2NH_2/diethylene glycol) of **10**, a mixture of olefin **12** and bicyclic hydrocarbon **13** (presumably arising *via* a retro-aldol reaction) was obtained. However, when the preformed hydrazone (NH_2NH_2/diethylene glycol/180 °C/3 h) was subjected to base treatment (KOH/240 °C/9 h/Ar atmosphere) the desired olefin (**14**) ($[\alpha]_D$ −42.5° (*c*, 0.17 in $CHCl_3$)) was isolated in 27% yield after purification. The spectral data were in accord with those reported by Tsunoda *et al.*[13]

In conclusion, cedrol was hydroxylated by *m*CPBA to give cedrane-7β,8β-diol and the transformation of this diol into the optically active triquinane type hydrocarbon, which is the C-2 epimer of "senoxydene," was achieved in four steps.

Experimental

General Procedures. Melting points were determined on a Yanaco Micro Melting Point apparatus (Yanagimoto) and are uncorrected. IR spectra were taken on a Shimadzu IR-27G infrared spectrophotometer. ^1H and ^{13}C NMR spectra were determined on a JEOL JNM GX 400 (400 MHz for ^1H and 100 MHz for ^{13}C) spectrometer in $CDCl_3$ with TMS as internal standard. Low and high resolution mass spectra were obtained on a Shimadzu LKB-9000B and JEOL HX-100 spectrometer, respectively. Precoated silica gel 60 F_{254} (E. Merck) glass supported plates were used for the purposes of analytical (0.25 mm) and preparative (0.5 mm) thin-layer chromatography.

Oxidation of Cedrol (1) by mCPBA. *m*CPBA (2.7 g, 1.2 equiv) was added to a solution of cedrol (**1**, 2.2 g) in chloroform (75 ml) and the mixture was refluxed for 6 h. The cooled solution was washed succesively with 5% Na_2SO_3, 5% $NaHCO_3$, and brine, dried over $MgSO_4$ and the solvent removed to give a residue (2.5 g). Column chromatography over silica gel (155 g, EtOAc–PhH gradient as eluant) gave cedrane-7β,8β-diol (**2**, 36 mg), a mixture of cedrane-3α,8β-diol (**6**), cedrane-3β,8β-diol (**7**), and cedrane-5β,8β-diol (**3**), cedrane-2β,8β-diol (**4**, 49 mg), and cedrane-2α,8β-diol (**5**, 193 mg) as well as unchanged cedrol (**1**, 1.8 g). The mixture of **6**, **7**, and **3** was separated by HPLC (TSK gel; MeOH–H_2O 7:3, 1.2 ml/min) to give **6** (2.5 mg), **7** (1.5 mg), and **3** (33 mg). **2**: mp 95—97 °C (sublime); Found: *m/z* 238.1938. Calcd for $C_{15}H_{26}O_2$: M 238.1933; $[\alpha]_D$=+14.1 ° ($CHCl_3$); IR ($CHCl_3$) 3570—3450 cm^{-1}; ^1H NMR ($CDCl_3$) δ=1.35 (3H, s), 1.21 (3H, s), 0.97 (3H, s), and 0.87 (3H, d, *J*=7 Hz); ^{13}C NMR ($CDCl_3$) δ=85.3 (s), 77.9 (s), 57.3 (d), 49.3 (s), 45.6 (s), 45.5 (t), 42.3 (d), 36.4 (t), 34.8 (t), 31.3 (t), 26.5 (t), 26.1 (q), 25.4 (q), 24.7 (q), and 15.2 (q); MS *m/z* 238 (M^+), 220, 193 (base), 165, 121, 109, and 43. **3**: oil; Found: *m/z* 238.1945. Oxidation of Cedrane-7β,8β-diol (2). The diol (**2**, 10 mg) was treated with $Pb(OAc)_4$ (18 mg) in benzene (5 ml) at rt for 2 h and worked up as usual to give 4,4,8-trimethyl-1-(3-oxobutyl)bicyclo[3.3.0]octan-3-one (**8**, 9.3 mg) as an oil. Found: *m/z* 236.1799. Calcd for $C_{15}H_{24}O_2$: M 236.1776; IR ($CHCl_3$) 1730 and 1715 cm^{-1}; ^1H NMR ($CDCl_3$) δ=2.18 (3H, s), 1.09 (3H, s), 0.99 (3H, s), and 0.95 (3H, d, *J*=7 Hz); ^{13}C NMR ($CDCl_3$) δ=223.1 (s), 208.4 (s), 55.4 (d), 48.4 (s), 48.3 (s), 45.9 (t), 44.9 (d), 39.7 (t), 32.8 (t), 30.2 (q), 28.6 (q), 27.6 (t), 25.1 (t), 22.0 (q), and 14.0 (q); MS *m/z* 236 (M^+), 221, 193, 165, 81, and 43.

Intramolecular Aldol Condensation of the Diketone (8). The diketone (**8**, 25 mg) was treated with NaOMe in MeOH [prepared from Na (*ca.* 0.1 g) and MeOH (4.5 ml)] at rt for 3 h. The usual work up and chromatography over silica gel (elution with hexane–EtOAc) afforded 4-hydroxy-4,7,7,11β-tetramethyl-(5α,8β)-tricyclo[6.3.0.0^{1,5}]undecan-6-one (**9**, 16 mg) as an oil. Found: *m/z* 236.1751. Calcd for $C_{15}H_{24}O_2$: M 236.1776; IR ($CHCl_3$) 3600, 3400, and 1720 cm^{-1}; ^1H NMR δ=2.34 (1H, s), 2.22 (1H, dd, *J*=9.5 and 5.5 Hz), 1.45 (3H, s), 1.06 (3H, s), 0.98 (3H, d, *J*=6.5 Hz), and 0.95 (3H, s). ^{13}C NMR δ=226.0 (s), 80.2 (s), 66.2 (d), 59.3 (d), 58.8 (s), 50.8 (s), 43.6 (d), 42.1 (t), 34.3 (t), 32.9 (t), 29.1 (q), 26.0 (q), 23.8 (t), 23.1 (q), and 13.8 (q); MS *m/z* 236 (M^+), 221, 193 (base), 178, 165, and 43.

Dehydration of the Ketol (9). The ketol (**9**, 2.3 mg) was treated with $SOCl_2$ (3 drops) in pyridine (0.6 ml) at 0 °C for 30 min. The usual work up and prep. TLC gave 4,7,7,11β-tetramethyl-(5α,8β)-tricyclo[6.3.0.0^{1,5}]undec-3-en-6-one (**10**, 0.5 mg) [oil; Found: *m/z* 218.1655. Calcd for $C_{15}H_{22}O$:M 218.1671; IR ($CHCl_3$) 1720 cm^{-1}; ^1H NMR δ= 5.33 (1H, brs), 2.84 (1H, brs), 2.71 and 2.12 (each 1H, d, *J*=19.5 Hz), 2.22 (1H, dd, *J*=9 and 6 Hz), 1.75 (3H, s), 1.06 (3H, s), 0.98 (3H, s) and 0.97 (3H, d, *J*=7 Hz); MS *m/z* 218 (M^+), 190, 175, 147 (base), 120, 108, 91, and 55] and

4,7,7,11β-tetramethyl-(8β)-tricyclo[6.3.0.0^{1,5}]undec-4-en-6-one (**11**, 0.6 mg) [oil; IR ($CHCl_3$) 1725 cm^{-1}; ^{1}H NMR δ= 2.05 (3H, brs), 1.04 (6H, s), and 0.94 (3H, d, J=6.6 Hz); MS m/z 218 (M^+), 203, 193 (base), 175, 121, and 43].

Reduction of the Enone (10). The enone (**10**, 18 mg) was heated with hydrazine (0.3 ml) in diethylene glycol (2 ml) at 180 °C for 3h under Ar. After removal of water and excess of hydrazine, the mixture was heated with KOH (50 mg) at 220—240 °C for 9h. The usual work up and chromatography over silica gel afforded 4,7,7,11β-tetramethyl-(5α,8β)-tricyclo[6.3.0.0^{1,5}]undec-3-ene (**14**, 4.7 mg) as an oil. Found: m/z 204.1878. Calcd for $C_{15}H_{24}$: M 204.1878; $[\alpha]_D$=−42.5° ($CHCl_3$, c=0.17); IR ($CHCl_3$) 1460, 1380, 1365 cm^{-1}; ^{1}H NMR ($CDCl_3$) δ=5.09 (1H, brs), 2.59 (1H, brd, J=16.8 Hz), 2.45 (1H, m), 2.02 (1H, brd, J=16.8 Hz), 1.89 (1H, t, J=8.1 Hz), 1.72 (1H, dd, J=13 and 8.5 Hz), 1.65 (3H, brs), 1.43 (1H, dd, J=13 and 4.6 Hz), 0.96 (3H, s), 0.92 (3H, s), and 0.90 (3H, d, J=6.5 Hz); MS m/z 204 (M^+), 189, 161, 147, 133, 123 (base), 105, and 91.

We thank Professor Shô Itô, Tohoku University, for his generous gift of cedrol and Professor Mitsuaki Kodama, of this university, for providing the spectra of the hydrocarbon **14** and helpful discussions. We are also indebted to Dr. Leslie J. Harrison for reading the manuscript. This work was supported in part by a Grant-in-Aid from the Ministry of Health and Welfare.

16) We found that the previous assignments[12,15] of these compounds are contrary to each other. Therefore, we have carried out difference NOE experiments for these compounds. When the 3β-proton of **6** was irradiated, an NOE upon the 2β-methyl group was observed. However, no NOE appeared in the case of the 2β-methyl group of **7**, when the 3α-proton was saturated. From these results, **6** was determined to be cedrane-3α,8β-diol and **7** to be cedrane-3β,8β-diol, which is in agreement with Ourisson's results.[15]

Reactions of Ozone with 1-(*m*-Substituted phenylazo)-2-naphthol-6-sulfonic Acids in Aqueous Solutions

Yasuo ONARI
Mie Industrial Research Institute, Takajayakomori-cho, Tsu 514
(Received March 15, 1985)

The substituent effect on the ozone decoloration reactions of 1-(*m*-substituted phenylazo)-2-naphthol-6-sulfonic acids (PANSA) in aqueous solutions was investigated. Both the acidities of PANSA and the variation of the ozone decoloration rates of them increased compared to those of the corresponding 1-(*m*-substituted phenylazo)-2-naphthol-3,6-disulfonic acids (PANDSA). The relationships between the decoloration rates and the indexes(pK_{OH} and σ_m values) of the basicities of the dyes, however, indicated nearly the same characteristics between the data of these two series of dyes, and the ozone decoloration reactions of PANSA appeared to proceed by nearly the same mechanism as those of PANDSA. The changes of the keto–enol ratios of the dyes with their ozone decolorations suggested that the decoloration rates might rise as the reduction rates of their keto–enol ratios increased. It seems likely that the chief organic product that was finally produced in these reactions is oxalic acid.

Because of the toxicity of dye waste, the biological treatment of it is very difficult. Ozone decoloration reactions of dyes have already been applied for the removal of the organic color of the waste water from dyeing industries. However, little is known about the ozonation mechanism of dyes and about the ozone reactivities of them in aqueous media. Ikehata and co-workers[1] have investigated the ozone oxidation products of some azo dyes in water. Matsui *et al.*[2] reported on the ozonation of *p*-aminoazobenzene in aqueous solution. In the previous papers,[3,4] some phenylazonaphthols and naphthylazonaphthols were taken up, and the ozone decoloration reactions of them were investigated. The ozone decoloration rates of these dyes showed the tendency to increase with increasing the electron-withdrawing powers of their substituents. It was also proved that the ozone decolorations of the dyes were accelerated with their substituent sulfo groups. On the basis of these results, the selectivity of the ozone decoloration reactions of a series of phenylazonaphthol dyes was expected to increase with decreasing the number of sulfo groups in their naphthol moieties. Therefore, a series of dyes bearing only one sulfo substituent on each of their naphthol moieties was desired to be taken up for the purpose of the further investigations on the mechanism of the ozone decoloration reactions of azo dyes. The ozone reactivities of seven 1-(*m*-substituted phenylazo)-2-naphthol-6-sulfonic acids(PANSA) were previously investigated using ^{1}H-NMR spectra.[5] In the present work, eight PANSA were examined similarly to eight 1-(*m*-substituted phenylazo)-2-naphthol-3,6-disulfonic acids(PANDSA)[4] so as to throw light mainly on the polar effect of the ozone decoloration rates of them in aqueous media. These observations induce us to know the reaction mechanism more precisely and to see what the difference in the reactivity is between the ozone decoloration of PANSA and that of the corresponding PANDSA.

Experimental

Preparations of the Dyes. The dyes were prepared by the diazotizated-coupling reactions of *m*-substituted anilines with Schaeffer's acid(2-naphthol-6-sulfonic acid) in the ordinary way. They were extracted with 1-butanol from the resulting reaction mixtures followed by purification on a cellulose column using a 2 mol dm^{-3} NH_3 solution saturated with 1-butanol as eluent. And then they were recrystallized from suitable organic solvents for a few times. The properties of the dyes are shown in Table 1.

Measurements. Equipments and measuring methods were the same as those shown in the previous paper.[3] All the chemicals employed for the experiment were special reagent grade. A solution of dye(4×10^{-5} mol dm^{-3}) in 0.5 dm^3 distilled water, the pH and the ionic strength (μ: 0.2) of which were controlled with the Sörensen buffer solution and KNO_3 respectively, was employed for the ozone decoloration reaction. The prepared solution was placed in a 0.5 dm^3 Pyrex gas-washing bottle having a G-2 sintered-glass filter at the bottom of it as a diffuser. Ozonized air(O_3 concn: 1.94 mg dm^{-3}) was continuously supplied into the bottle at a constant flow rate of 2.7 dm^3 min^{-1} through the sintered-glass filter. A part(3.5 cm^3) of the solution was circulated through micro flow-cell of the spectrophotometer with a micropump, and the ozone decoloration of the dye was continuously recorded. Ozonized air was obtained using a Nihon Ozon 0-3-3 electric discharge ozone generator. A Nihon Bunko UVIDEC-1 digital doublebeam spectrophotometer was used for the measurements of the decoloration rates. The visible absorption spectra and the acid dissociation constants of the dyes were obtained on a Hitachi 323 spectrophotometer. Elemental analysis was performed on a Yanaco MT-3 CHN Corder. Fatty acids were measured with a Nihon Bunko FLC 350 high-performance liquid chromatograph equipped with a UVIDEC-100 UV spectrometer as a detector.

Results and Discussion

Acid Dissociation Constants of the Dyes. The acid dissociation constants(pK_{OH}) of the dyes were

Table 1. Properties of the dyes

No.	Constitution	Anal (C/N) Found (Calcd)	λ_{max} (nm)(ε_{max})[a]	pK_{OH}[b]	Keto–enol[c] ratio
1		6.99 (6.86)	474 (1.58×10^4)	10.27	2.14
2		7.00 (6.86)	473 (1.59×10^4)	10.30	2.10
3		7.37 (7.29)	482 (1.50×10^4)	10.39	2.28

determined spectrophotometrically at 21 °C (μ: 0.2 (KNO_3)) in the same manner as that was shown in the previous report.[3] The result is shown in Fig. 1.

The relationship between the pK_{OH} values of PANSA and the Hammett's σ_m values of their substituent groups is shown in Fig. 2. The pK_{OH} values of the dyes showed the tendency to decrease with increasing σ_m values of their substituents, and the regression equation was calculated as follows: $pK_{OH}=10.51-0.62\,\sigma_m$. The result indicated nearly the same tendency as that shown in the pK_{OH} values of PANDSA: $pK_{OH}=10.80-0.91\,\sigma_m$. However, the p$K_{OH}$ values of PANSA were smaller than those of the corresponding PANDSA in contrast to the expectation that was produced from the reduction of the inductive effect of the sulfo substituent in the *ortho*-position to OH. This seemed to be based on the disappearance of another influence (for example, the effect of the negative charge) of the substituent.

The pH Dependence of the Ozone Decoloration Rates of the Dyes. Because of the electrophilic nature of ozone, the ozone decoloration rates of PANSA can be estimated to be accelerated with their proton dissociations. The relationship between the logarithms of pseudo-first-order rate constants($\log k_{obsd}$)

Number attached to each point is the same as that given in Table 1.

and pH for the ozone decolorations of the dyes is shown in Fig. 3. The log k_{obsd} values of these reactions increased linearly with increasing pH of the solutions in the pH ranges of about the half-neutralization points of the hydroxyl groups of the dyes to 6.0. The slopes of these regression lines were 0.039(NO. 6)—0.171(NO. 4), and the average value of them was 0.119. This average value of the slopes showed nearly the same as those: 0.13 and 0.116 of the results that had been shown in Refs. 3 and 4 respectively. These results suggested that the pH dependence of the decoloration rates was scarcely variable in all the ozone decoloration reactions of those monoazo dyes.

The Relationship between the Basicities of the Dyes and the Ozone Reactivities of Them. In order to reveal the mechanism of these ozone decoloration reactions, the investigation on the pK_{OH} dependence of the decoloration rates was also made in this work. The relationship between log k_{obsd} and pK_{OH} of PANSA is shown in Fig. 4. It showed a good linearity with the exception of 4, 5, and 6(log k_{obsd}=13.77−1.333 pK_{OH}(n=5, γ=−0.997)). The negative slope of this regression line suggested the global process to be nucleophilic. In this case, the variation of log k_{obsd} with pK_{OH} was larger than that shown in the ozone decolorations of the monoazo dyes bearing only sulfo substituents(pH 7.0, log k_{obsd}= 1.955−0.207 pK_{OH})[3] and larger than that shown in the ozone decolorations of PANDSA(pH 7.0, log

k_{obsd}=0.937−0.0911 pK_{OH})[4] as expected.

The relationship between the Hammett's σ_m values and log k_{obsd} for the ozone decolorations of the dyes is shown in Fig. 5. The obtained ρ values were: 0.42(ρ_1) for the dyes bearing the electron-withdrawing groups and 11.2(ρ_2) for those bearing the electron-releasing groups. The positive ρ values indicated that the global process of these reactions was nucleophilic in nature, but $\rho_1<\rho_2$ and the discontinuity in the relationship showed that the electrophilic process played an important role in these ozone decoloration reactions. In the ozone decoloration reactions of these dyes, the variation of the decoloration rates was larger than, but the characteristic of the Hammett plot was similar to, those shown in the ozone decoloration reactions of PANDSA. From these results, the ozone decoloration reactions of these dyes appeared to proceed by nearly the same mechanism as those of PANDSA.

The Changes of the Keto-Enol Ratios of the Dyes with Their Ozone Decoloration Reactions. These dyes exist as the hydroxy azo-keto hydrazo tautomeric equilibria in aqueous solutions. In this work, the effect of the tautomeric equilibria of the dyes on their ozone decoloration rates was investigated. Burawoy and Thompson[6] examined the tautomeric equilibria of arylazonaphthols using electronic spectra, and indicated that the absorption maxima near 480 and 420 nm were due to the keto hydrazo form and the hydroxy azo form respectively. As an index of the tautomeric equilibria, the ratio(A_{CO}/A_{OH}, keto-enol ratio) of the absorbance at the absorption maximum appeared near 480 nm (A_{CO}) to that at the shoulder near 420 nm (A_{OH}) was taken up. The changes of the keto-enol ratios with the ozone decolorations of these dyes are shown in Fig. 6. In the case of the ozone decolorations of PANDSA,[4] the percent residual values of the keto-enol raios after the ozone treatments of PANDSA for 60 s were 50.7—63.4% (average value: 56.3%). The values obtained in this work were 66.9—87.9% (average value: 73.3%). The two couples of dyes; 2, 4 and 5, 7, the initial values of the keto-enol ratios for two dyes of each couple were nearly the same, suggested that the ozone decoloration rates of the dyes increased with increasing the reduction rates of their keto-enol ratios. Therefore, the unexpected behavior of 5 in the Hammett plot (Fig. 5) seemed to be mainly based on the low reduction rate of its keto-enol ratio compared with the reduction rates of those of the others in these ozone decoloration reactions. From these results, initial attack of ozone on the dye molecule was anticipated to take place at the

NC double bond of its keto hydrazo form in a similar manner as described in the ozonolysis of PANDSA.[4]

Oxidation Products of the Dyes. Initial ozone oxidation products of phenylazonaphthol dyes had already been reported in the previous paper.[3] In the present work, fatty acids from the ozonations of these dyes were analyzed by the high-performance liquid chromatograph using a Shodex Ionpak C-811 column (50 cm 8 cm i.d, Showadenko Co., Ltd.) and 0.1% H_3PO_4 as eluent. The typical chromatogram is presented in Fig. 7. In all these reactions, the formations of maleic acid, glyoxylic acid, and oxalic acid were confirmed. Maleic acid seems to be the precursor for glyoxylic acid and oxalic acid, and glyoxylic acid seems to be that for oxalic acid. Consequently, it seems likely that the main organic product that was finally produced in these ozone oxidizing reactions is oxalic acid. Nitrate ion was also detected in the resulting reaction mixtures. This indicates that a part of the azo group of the dye appeared to oxidized to nitrate.

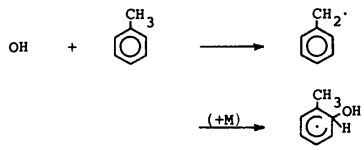
Ring-cleavage Reactions of Aromatic Hydrocarbons Studied by FT-IR Spectroscopy. I. Photooxidation of Toluene and Benzene in the NO_x-Air System

Hiroshi BANDOW,* Nobuaki WASHIDA, and Hajime AKIMOTO
Division of Atmospheric Environment, The National Institute for Environmental Studies, P.O. Tsukuba-gakuen, Ibaraki 305
(Received February 12, 1985)

The products of the atmospheric photooxidation reactions of toluene and benzene were analyzed quantitatively using long-path FT-IR spectroscopy. Methylglyoxal (only in the case of toluene), glyoxal and maleic anhydride were observed as aromatic ring-cleavage products. In the toluene photooxidation, yields of methylglyoxal, glyoxal, and maleic anhydride were 14±4, 15±4, and 4.0±0.4% (mole/mole), respectively. The formation of small molecules, formaldehyde and formic acid, was observed. It is suggested that the precursor of the ring-cleavage reaction is OH-aromatics-O_2 adducts, and that the α-dicarbonyls and unsaturated γ-dicarbonyls are produced by ring cleavage after cyclization of the OH-aromatics-O_2 adduct. The observation of maleic anhydride is considered as an evidence of the aromatic ring cleavage into C_2 and C_4 fragments. The fraction of the ring cleavage process in the total reaction is 29 and 15—20% in the cases of toluene and benzene, respectively.

Oxidation processes of aromatic hydrocarbons initiated by the reaction of hydroxyl radicals are of fundamental interest in physical chemistry of organic compounds as well as in the development of chemical models of photochemical air pollution.[1-3] For the reactions of OH radicals with an aromatic hydrocarbon such as toluene, the initial reaction can be either abstraction (Reaction 1a) or addition to the aromatic ring (Reaction 1b).

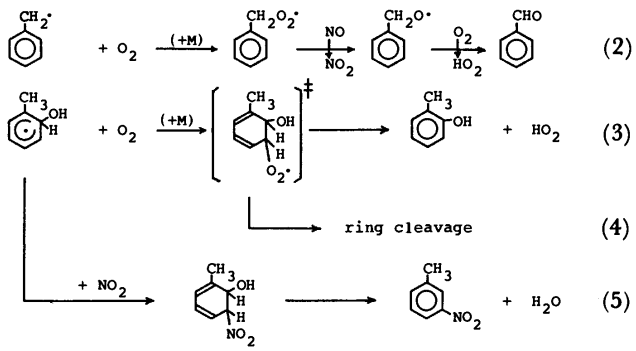


(1a)

(1b)

Studies both by measurements of the rate constant[4-12] and by analysis of reaction products[13-19] indicate that electrophilic addition of the OH radical to the aromatic ring is the dominant reactive pathway (80—93% in the case of toluene) at room temperature over the pressure range from several hundred Pa to 101 kPa (1 atm) total pressure, that side-chain hydrogen abstraction channel is small but significant (7—20% in the case of toluene), and that ring-hydrogen abstraction is a negligible channel. In the presence of O_2 and NO, aromatic aldehydes are produced from radicals obtained by side-chain hydrogen abstraction.[3,13-15,17-19] Under these conditions some of the OH-aromatics adducts yield stable products retaining the aromatic ring[3,14,15,17-19] (including phenols and aromatic nitro compounds) competing with the ring cleavage.[3,17,19-25]

The formation of α-dicarbonyls[17,19,23,24] (glyoxal, methylglyoxal, and biacetyl) in addition to small fragment molecules[3,20-22] (CO, CO_2, formaldehyde, and formic acid) has been reported. These dicarbonyls are typical reaction products caused by the



(2)

(3)

ring cleavage (4)

(5)

ring cleavage of cyclic organic compounds as suggested in the oxidation of cycloalkanes.[26,27] Although the importance of ring-cleavage processes in the oxidation of aromatic hydrocarbons has been suggested,[3,17,24] yields and the formation mechanism of dicarbonyls are not clear.

It is well known that aromatic hydrocarbons are important constitutents in polluted atmospheres.[28] The concentration of the total aromatic hydrocarbons is often close to and sometimes higher than that of the total olefins. Recent measurements on the rate constants[4-12,29] for the reaction of hydroxyl radicals with aromatic hydrocarbons indicate that most of aromatic hydrocarbons react with OH faster than paraffins and that highly-alkyl-substituted benzenes are comparable to olefins. Therefore, the elucidation of photooxidation processes of the aromatic hydrocarbons is important to the development of chemical models of photochemical air pollution.[3,30]

In the present study, observations of the reaction products in the photooxidation of aromatic hydrocarbons in the NO_x-air system were carried out using long-path Fourier transform infrared absorption spectroscopy (LP FT-IR), in which products are observed directly without the sampling and preconcentration needed in the GC (gas chromato-

graphy) and GC/MS (gas chromatography/mass spectroscopy) analysis. The major goal of this study is the quantitative analysis of the α-dicarbonyls and unsaturated γ-dicarbonyls to elucidate the mechanism of the ring-cleavage reactions.

In this paper, the reactions of toluene and benzene are reported. Toluene is important as a prototype of the oxidation process of alkylbenzenes.

Experimental

Toluene or benzene, NO, and NO_2 diluted in 1 atm air were irradiated in a reaction chamber and reaction products were measured by LP FT-IR directly. A schematic diagram of the reaction chamber and the LP FT-IR system is shown in Fig. 1. The chamber is a stainless-steel cylinder, 0.5 m inner diameter and 3.55 m long with a volume of 0.79 m^3. Its inner wall is coated by FEP-teflon to minimize wall effects. The chamber is bakable up to 80 °C by circulating hot water through the wall, and evacuable below 1×10^{-6} Torr by an oil-diffusion pump (1500 l s^{-1}) and an oil-rotary pump (950 l min^{-1}). Fourteen

black light lamps (40W, Toshiba FL40S BLB) on the inner wall of the chamber were used as a light source. The wavelength distribution of the lamp ranges from 300 to 430 nm with an intensity maximum at about 350 nm. The effective light intensity as measured by the primary photodecomposition rate of NO_2[31] was 0.22 min^{-1}.

An eight-mirror multireflection system (a White cell) is set in the chamber and connected to a Nicolet 7199 FT-IR spectrometer as shown in Fig. 1. The base path between multireflection mirrors is 3.0 m and the number of reflections is 69, giving a total path length of 210.8 m. A liquid nitrogen cooled MCT (Hg-Cd-Te semiconductor) detector was used as an IR detector. The spectral resolution used in the present study was 1 cm^{-1}. IR spectra were recorded by accumulating 128 scans with 3.8 min scanning time.

The air used was supplied by an air purifier (Standard Technology Inc., model SGPU-21), in which hydrocarbons and NO in source air are converted to CO_2, H_2O, and NO_2 by a Pt/Al_2O_3 catalyst at 450 °C and CO_2, H_2O, and NO_2 are removed by a molecular sieves adsorbent. Impurities in the purified air were typically NO_x ($\approx$2 ppb), hydrocarbons (<100 ppbC), CO_2 (<1 ppm), CO (<10 ppb), and H_2O (<10 ppm). Research grade benzene and toluene were used without further purification except degassing. NO and NO_2 (both Research grade, Matheson) were used also without further purification. Standard samples of formaldehyde, formic acid, dimethylglyoxal (biacetyl), and maleic anhydride were prepared by freeze-pump-thaw cycles. Methylglyoxal and glyoxal were desiccated by molecular sieves and P_2O_5, respectively.[32,33] The chemicals used were all from Wako Pure Chemical Ind. except NO and NO_2.

The reaction mixtures were prepared as follows: The amounts of reactant gases were measured by an MKS Baratron capacitance manometer in a known volume in a gas-handling line and the gases were flushed separately by pressurized nitrogen gas into the chamber which was first filled with the matrix air. The total pressure of the reaction mixture thus obtained was 101 kPa (1 atm). The air was stirred by two mixing fans in the chamber during the irradiation.

All runs were made at the temperature 22.5±1 °C controlled by the water circulation system.

Results

A. Photooxidation of Toluene. Formation of formaldehyde, formic acid, glyoxal, methylglyoxal, peroxyacetyl nitrate (PAN), maleic anhydride, and benzaldehyde was observed in the photooxidation of the toluene (4 ppm)-NO (0.17—1.50 ppm)-NO_2 (0.50—1.51 ppm)-air (1 atm) system. These products were identified by using the standard IR absorption spectra of authentic samples as listed in Table 1.

Figure 2 shows an example of the subtraction of spectra in the frequency region of 3000—2700 cm^{-1}. Figure 2a shows the absorption spectrum of products produced in the toluene (4 ppm)-NO (0.17 ppm)-NO_2 (0.50 ppm)-air (1 atm) mixture after 217 min

Table 1. The characteristic band of each product used to determine the concentration

Product		Absorption band	Wavenumber / cm^{-1}
Formaldehyde	HCHO	ν_{C-H}	2781.0, 2778.5
Formic acid	HCOOH	ν_{C-O}	1105.2
Peroxyacetyl nitrate (PAN)	$CH_3C(O)OONO_2$	ν_{C-O}	1160[a]
Glyoxal	$(CHO)_2$	ν_{C-H}	2900—2750
Methylglyoxal	CH_3COCHO	ν_{C-H} in -CHO	2860—2800
Maleic anhydride (MAH)	$\begin{matrix}-CO\\ \|\|\\ -CO\end{matrix}>O$	$\nu_{C=O}$	1805.3, 840.6
Benzaldehyde	C_6H_5CHO	ν_{C-H} in -CHO	2750—2710

a) The standard spectrum of PAN was obtained by the reaction of $CH_3CHO+N_2O_5(NO_3)$ in 101 kPa (1 atm) air.[34] The absolute concentration of PAN was determined by using the reported absorption coefficient.[35]

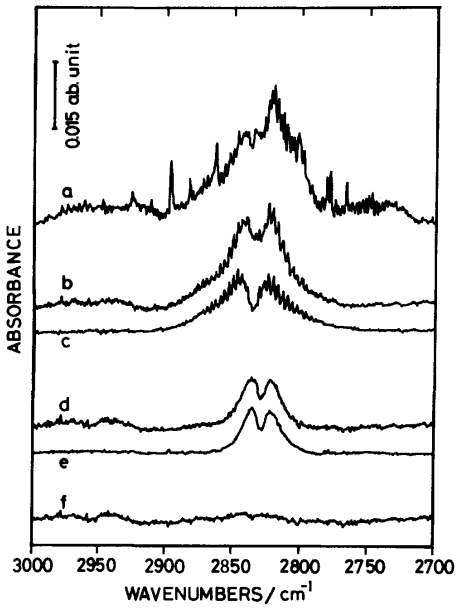

Fig. 2. Typical IR absorption spectrum of the products and spectral subtractions in the frequency region of 2700—3000 cm^{-1} (the region of the C-H stretching). a: Product spectrum from the photooxidation of the toluene (4.00 ppm)-NO(0.17 ppm)-NO_2(0.50 ppm)-air(101 kPa=1 atm) system, after 217 min irradiation. b: Spectrum after subtraction of HCHO, HCOOH, PAN, and benzaldehyde from spectrum (a). C: Spectrum of $(CHO)_2$. d: Difference spectrum, (b) −(c). e: Spectrum of CH_3COCHO. f: Difference spectrum, (d)−(e).

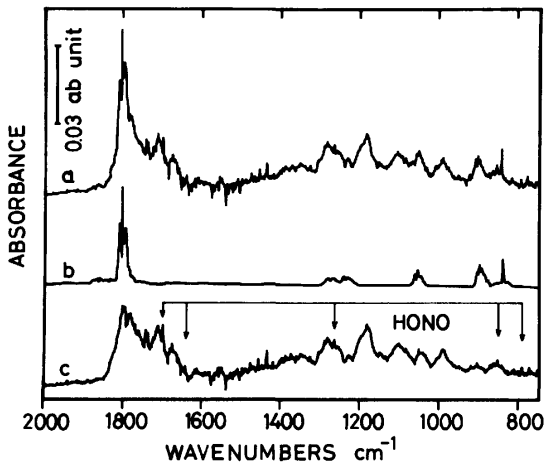

Fig. 3. Absorption spectrum of the products in the frequency region of 800—2000 cm^{-1}. a: Product spectrum under the same condition as in Fig. 2f. b: Spectrum of maleic anhydride. c: Difference spectrum, (a)—(b).

irradiation. In this case, absorption spectra of reactants and H_2O are subtracted. Rotational structure of formaldehyde (2950—2730 cm^{-1}) and broad absorption of benzaldehyde (around 2730 cm^{-1}) are apparent. Subtracting the spectra of formaldehyde, formic acid, benzaldehyde, and PAN from the spectrum (a), the spectrum (b) was obtained. The fine structure in the spectrum (b) corresponds to the absorption of glyoxal whose standard spectrum is shown in spectrum (c). Subtraction of the spectrum of glyoxal from the spectrum (b) gives the spectrum (d) which coincides with the standard spectrum of methylglyoxal, spectrum (e). Spectrum (f) shows the difference spectrum of (d)−(e). No significant absorption remained in the region from 3000 to 2700 cm^{-1} (the frequency region of the C-H stretching mode).

After these spectral manipulations, some absorption bands remained in the frequency region of 2000—800 cm^{-1} as shown in spectrum (a) in Fig. 3. Characteristic bands at 1800 and 900 cm^{-1} and sharp absorption at 840 cm^{-1} are in agreement with the standard spectrum of maleic anhydride (spectrum (b)). Subtraction of spectrum (b) from spectrum (a) gives spectrum (c) shown in Fig. 3. Several bands

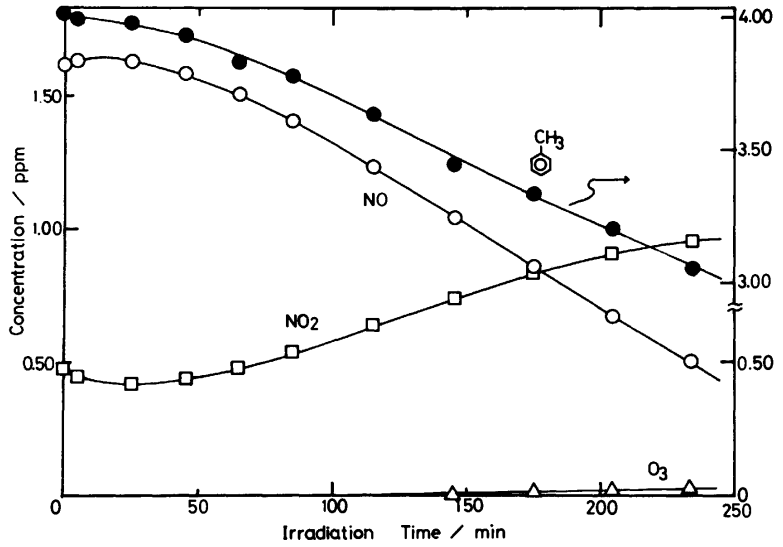

Fig. 4. Concentrations of toluene, NO, NO_2, and O_3 are plotted against the irradiation time. Initial conditions; toluene=4.01 ppm, NO=1.50 ppm, NO_2=0.50 ppm, and air=101 kPa (=1 atm).

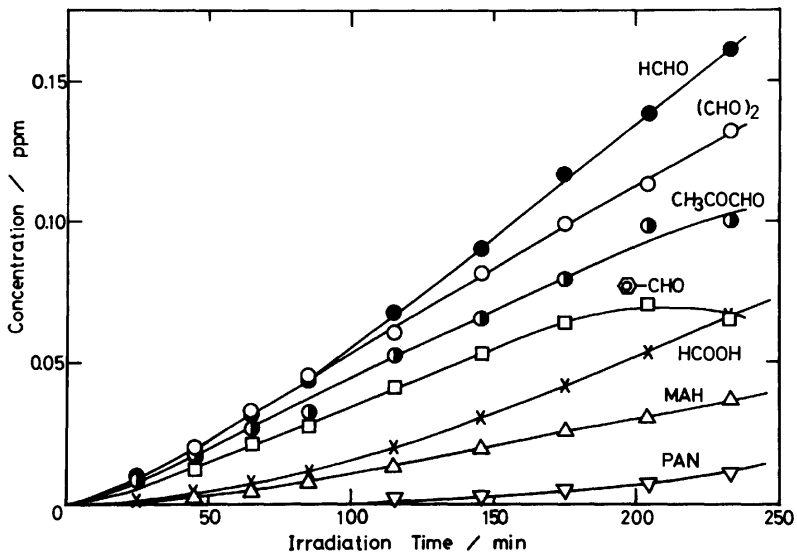

Fig. 5. Dependence of the absolute concentrations of the reaction products on irradiation time. The experimental conditions are the same as the conditions in Fig. 4. MAH: maleic anhydride. PAN: Peroxyacetyl nitrate.

in spectrum (c) can be identified to be HONO,[36] as indicated by the arrows. The remaining spectrum shows intense absorptions at 1800 and 1700 cm^{-1}, which are characteristic of the C=O stretching in carbonyl compounds. The strong absorption around 1800 cm^{-1} is attributable[37] to C=O stretching vibration in a carboxylic acid (not hydrogen-bonded), an anhydride, or a peroxyacyl nitrate. The absorption around 1700 cm^{-1} corresponds[38] to C=O stretching in aldehydes, ketones, dialdehydes, and diketones. However, the spectrum shown in Fig. 3c could not be uniquely identified in the present study.

Figure 4 shows the concentration of reactants (NO, NO_2, O_3, and toluene) plotted against the irradiation time for the photooxidation of the toluene (4.01 ppm), NO (1.50 ppm), NO_2 (0.50 ppm), and air (1 atm) mixture. Change of the concentration of products on the irradiation time is shown in Fig. 5. All these products except PAN are observed from the beginning of the irradiation.

In Fig. 6, the amounts of each product formed are plotted against the amount of toluene consumed.

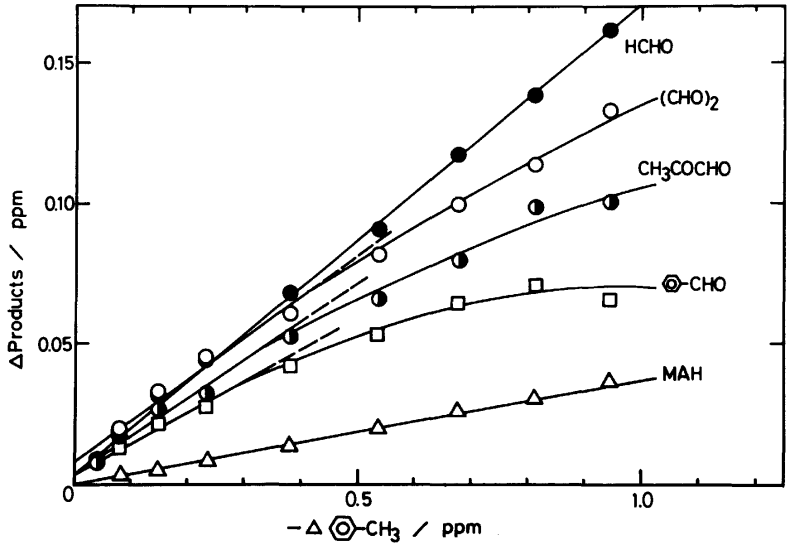

Fig. 6. Concentrations of products are plotted against the toluene consumed.

Table 2. Yields of the primary products in the photooxidation of the toluene-NO_x-air system under three different experimental conditions

	Run No.			
	1	2	3	average[c]
Initial concentration (ppm in 1 atm air)				
Toluene	4.00	4.01	4.00	
NO	0.17	1.50	0.51	
NO_2	0.50	0.50	1.51	
Yield of product[a]				
HCHO	0.15	0.17	0.16	0.16 ± 0.01
$(CHO)_2$	0.20	0.15	0.11	0.15 ± 0.04
CH_3COCHO	0.18	0.14	0.11	0.14 ± 0.04
MAH[b]	0.044	0.039	0.037	0.040±0.004
C_6H_5CHO	0.12	0.11	0.10	0.11 ± 0.01

a) Values were calculated by the least-square fit of four initial points of each run as shown in Fig. 6. b) MAH: maleic anhydride. c) The indicated errors are one standard deviation of three runs.

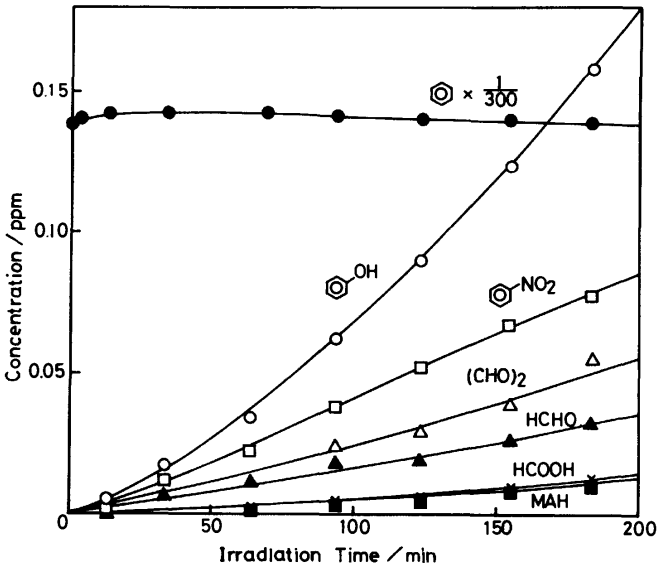

Fig. 7. Concentrations of benzene and reaction products are plotted against the irradiation time. Initial conditions; benzene = 42.65 ppm, NO_2 = 1.50 ppm, and air = 101 kPa (= 1 atm).

Formaldehyde and maleic anhydride increase linearly against toluene consumed, and glyoxal, methylglyoxal, and benzaldehyde show linear increase at the initial stage where toluene consumed is less than 10% of the initial concentration. The plots of formic acid and PAN (not shown) were not straight lines, indicating that both are not primary products. The initial slopes of the products shown in Fig. 6 give the formation yield of each product. Yields of products calculated under three different experimental conditions are listed in Table 2. Values shown in each run were obtained by the least-square fit of four initial points of each run as shown in Fig. 6. The indicated errors are one standard deviation of three runs.

B. Photooxidation of Benzene. In the case of benzene, formation of formaldehyde, formic acid, glyoxal, maleic anhydride, phenol, and nitrobenzene was observed. Since the rate constant for the reaction of OH+benzene is about one-fifth[5,8,11] of that for OH+toluene, this experiment was carried out with a high concentration of benzene. The concentrations of reaction products as a function of irradiation time are shown in Fig. 7. In this case the mixture of 42.7 ppm of benzene, 1.5 ppm of NO_2 in 1 atm air was photolyzed. Since the amount of benzene

consumed was too small to measure, yields of each product could not be determined exactly.

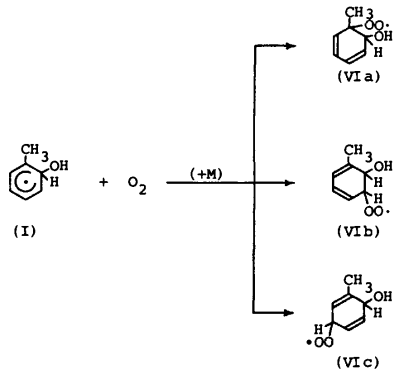
Discussion

A. Photooxidation of Toluene. In the NO–NO_2–air system, the reaction of aromatic hydrocarbon is initiated mainly by OH radicals formed by the photodecomposition of HONO[39] produced in both homogeneous[36] and heterogeneous[40] reactions among NO, NO_2, and H_2O. Further, OH radicals can be produced in a long chain mechanism[41] involving the reaction of HO_2+NO. The effect of the reaction of toluene with oxygen atoms must be considered. $O(^3P)$ is produced in the photodecomposition of NO_2 with the photolysis rate constant of 0.22 min^{-1} in the present chamber, and is readily removed by O_2 under 1 atmospheric air with the rate of 7.4×10^4 s^{-1}.[42a] Using steady state approximation for oxygen atoms, we can roughly estimate the oxygen atom concentration to be at most 2.5×10^6 molecule cm^{-3} under the present experimental conditions. OH radical concentration is in the range of $(1—5)\times10^6$ molecule cm^{-3} under the similar conditions of smog chamber experiments.[40b] Since the rate constant of toluene with OH radicals under 1 atmospheric air is about 6×10^{-12} molecule^{-1} cm^3 s^{-1} [4-12] which is 10^2 times larger than that with $O(^3P)$,[42b-d] the contribution of the reaction of toluene with oxygen atoms can be neglected in the present study.

OH radicals react with toluene by both abstraction (Reaction 1a) and addition (Reaction 1b) reactions. O_2 adds to the benzyl radical produced in Reaction 1a and the peroxyl radical product reacts with NO, and benzaldehyde and benzyl nitrate are eventually produced. The OH-toluene adduct produced in Reaction 1b yields cresols and *m*-nitrotoluene by subsequent reactions. Details of yields and reaction mechanisms for the formation of these high-boiling-point products were reported and discussed previously.[3,14,15,18,19] The addition of OH radicals to toluene is predominantly at the 2-position since *o*-cresol was produced predominantly.[14,15,18]

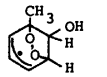
The low-boiling-point products measured previously are CO, CO_2, formaldehyde, formic acid,[3,20-22] glyoxal, and methylglyoxal.[23,24] Recently C_4 and C_5 compounds and substituted furans were detected in the toluene photooxidation products.[24c,d] In the present study, the formation of maleic anhydride was observed and analyzed quantitatively in addition to these products. Systematic analysis of these low-boiling-point products from various methylbenzenes is crucial to elucidate the mechanisms of ring-cleavage reaction.

Atkinson *et al.*[3] suggested that the OH-toluene adduct produced in Reaction 1b is the precursor of the ring-cleavage reaction. In air, addition of O_2 to the adduct can occur at the 1-, 3-, or 5-position[3] as shown in Reaction 6. According to Atkinson *et al.*,



O_2 addition at the 5 position should be the least thermochemically favored, since the double bonds are unconjugated.

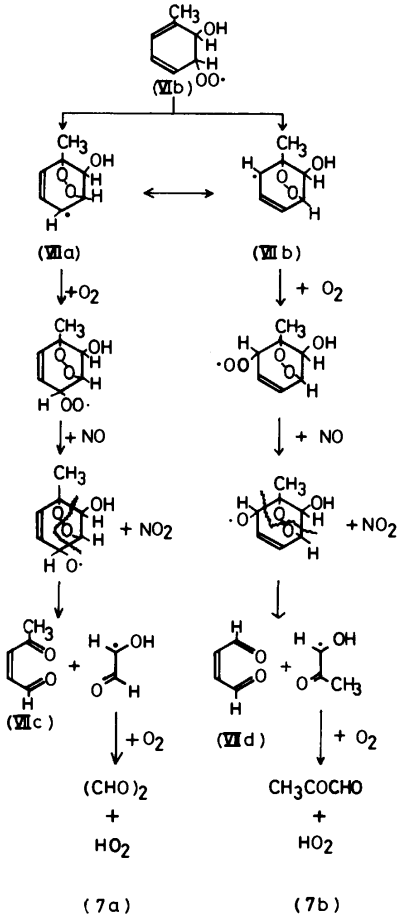
Two types of ring-cleavage mechanisms are considered for the OH–toluene–O_2 adduct. The first is a cyclization type of reaction suggested by Atkinson *et al.*[3] For example, in the case of the compound **VIb**, bicyclo[3.2.1] cyclization gives allyl-type radicals, 6,7-dioxabicyclo[3.2.1]octane compounds (DBO[3.2.1]), and both glyoxal and methyl-



glyoxal can be produced from DBO[3.2.1]. Scheme 1 depicts the reactions which lead to formation of both glyoxals from **VIb** (DBO[3.2.1] is represented formally as **VIIa**↔**VIIb** by its resonance structures). In this scheme glyoxal and methylglyoxal are produced exclusively in Reactions 7a and 7b, respectively. As for the compound **VIa**, the other possible OH–toulene–O_2 adduct, bicyclo[3.2.1] cyclization gives the same allyl radical compound, DBO[3.2.1], as from **VIb**. Therefore, in the bicyclo[3.2.1] cyclization mechanism, the formation ratio of glyoxal to methylglyoxal is governed by the ratio of Reaction 7a to 7b, in other words, the relative probability of oxygen-molecule addition to the alternate radical points (shown as **VIIa** and **VIIb**) in DBO[3.2.1]. When the OH-aromatics–O_2 adducts undergo bicyclo[2.2.2] cyclization process, glyoxal and methylglyoxal can be produced from compounds **VIa** and **VIb**, respectively, as suggested by Atkinson *et al.*[19] In this case, the ratio of glyoxal and methylglyoxal is governed by the ratio of compound **VIa** and **VIb**; *i.e.* position of the O_2 addition in Reaction 6. The bicyclo[2.2.2] intermediate, 2,3-dioxabicyclo[2.2.2]octane compounds (DBO[2.2.2]), might have a lower ring strain energy than the DBO[3.2.1] intermediate, but a radical point and a double bond are isolated. These are conjugated to make an allyl-type radical in the DBO[3.2.1] intermediate. Thus, so far, it is not evident that

either of the DBO[2.2.2] or the DBO[3.2.1] intermediate is more stable.

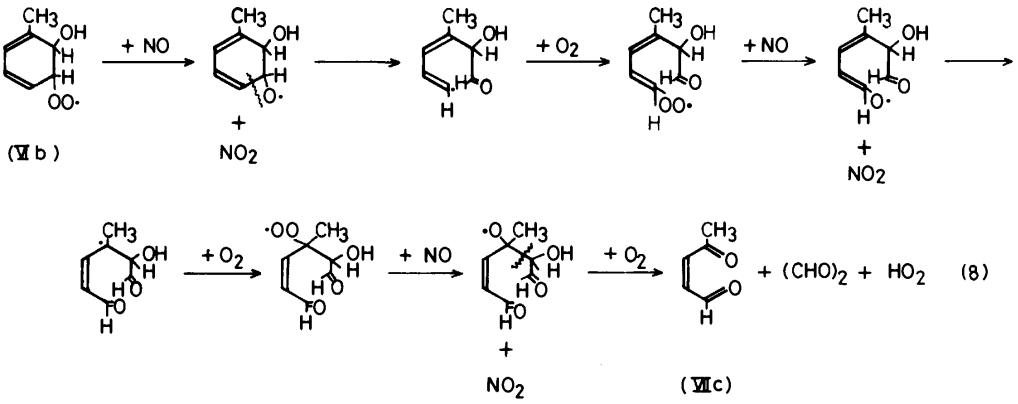
Another possible ring-cleavage mechanism is a ring opening type of reaction shown in Scheme 2, Reaction 8. For example, glyoxal and compound **VIIc** are produced from compound **VIb** by the mechanism shown in Scheme 2. When the reaction starts from compound **VIa**, methylglyoxal and compound **VIId** are produced. In this case, the ratio of glyoxal and methylglyoxal is governed by the ratio of compounds **VIb** and **VIa**.



Scheme 1.

As shown in Table 2, the formation ratio of glyoxal to methylglyoxal seems one to one. Recently two groups have reported the yield of these compounds in the toluene photooxidation. Shepson *et al.*[24c] have reported 8.0 and 7.5% yield for glyoxal and methylglyoxal, respectively. The values reported by Tuazon *et al.*[24b] are 0.111±0.013 and 0.146±0.014 for glyoxal and methylglyoxal, respectively. The present result and these recent data clearly show that the formation ratio of glyoxal and methylglyoxal in the toluene photooxidation is almost one to one, although the yield obtained by Shepson *et al.* are little bit smaller than the others. The formation ratio of glyoxal to methylglyoxal, 1:1, can be explained from both the cyclization, Scheme 1, and the ring opening, Scheme 2, mechanisms. In the case of Scheme 1, the probability of O_2 addition to the resonance structures **VIIa** and **VIIb** should be the same in order to explain the formation ratio. While in the case of Scheme 2, the formation ratio of **VIb** to **VIa** in Reaction 6 is to be 1:1.

If glyoxal and methylglyoxal are produced, unsaturated γ-dicarbonyls, compound **VIIc** (*cis*-4-oxo-2-pentenal) and **VIId** (*cis*-2-butenedial), are expected to form as counterparts of ring-cleavage products against glyoxal and methylglyoxal, respectively. In their extensive study of identifying the ring fragmentation products on the photooxidation of toluene, Shepson *et al.*[24c] were successful to detect the compounds **VIIc** and **VIId** using GC/MS, although the apparent yields of these products were quite small, one eighth or less than those of glyoxals. These products might have absorptions in the aldehydic C–H stretching frequency region (2850—2700 cm^{-1}). However, as shown in spectrum (f) in Fig. 2, no significant absorption was observed in this region. This indicates that these products are probably very unstable in the gas phase due to a wall

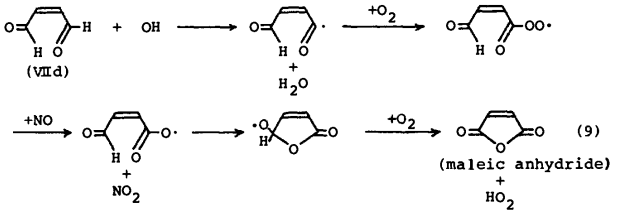


Scheme 2.

loss and also partly due to a photolysis and a reaction with OH radicals.

Maleic anhydride was observed in the present study, and seems a primary product apparently from Fig. 6. However, since the two hydrogen atoms originally attached to the carbons which become carbonyl carbons in maleic anhydride should be removed to form maleic anhydride, it seems unlikely to yield maleic anhydride as a primary product according to the mechanism generally applied to the photooxidation of hydrocarbons.

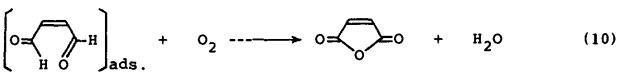
Maleic anhydride can be produced by the following reactions from *cis*-2-butenedial (compound **VIId**) which is expected to be produced as a counterpart of methylglyoxal. Rate determining step for Reaction 9



(9)

is considered to be the first step under atmospheric air. The rate constant for the step has been estimated[3] under the assumption that the aldehydic hydrogen in compound **VIId** has a similar reactivity to OH radicals as other aldehydes. The estimated value is 3×10^{-11} molecule^{-1} cm^3 s^{-1}, while the rate constant for the reaction of toluene with OH radicals which would be expected as the rate determining step to produce **VIId** has been measured to be about 6×10^{-12} molecule^{-1} cm^3 s^{-1} [4-12] under 1 atmospheric air. Therefore, only Reaction 9 can not explain the observed linear increase of maleic anhydride against toluene consumption.

Another possible route of the formation of maleic anhydride is the oxidation of *cis*-2-butenedial on the wall surface of the reaction chamber. Recently,



(10)

Dumdei, and O'Brien[24d] reported the observation of 2-butenedial and 4-oxo-2-pentenal among various compounds recovered by solvent extraction from the reaction vessel walls in which the photooxidation of toluene was performed. In the present study, since the gas in the reaction chamber was stirred by fans, *cis*-2-butenedial can collide with the wall in about one minute. Although both Reactions 9 and 10 are probable, at present the mechanism to form maleic anhydride is not clear. A similar reaction mechanism can be considered for *cis*-4-oxo-2-pentenal (compound **VIIc**), with maleic anhydride production by the release of a methyl radical. However, as will be described in a subsequent paper II, maleic anhydride is not produced from *cis*-4-oxo-2-pentenal. As shown in Table 2, the yield of maleic anhydride is about one fourth of yields of both glyoxal and methylglyoxal. This implys that most of the unsaturated γ-dicarbonyls are photodecomposed or consumed by other reactions including adsorption on the reactor surface. In any case, the observation of maleic anhydride suggests the occurrence of the aromatic ring cleavage of toluene into C_2+C_4 fragments.

If the fragmentation of methyl radicals from *cis*-4-oxo-2-pentenal occurs, formaldehyde can be produced as follows:

$$CH_3 + O_2 + M \longrightarrow CH_3O_2 \quad (11)$$

$$CH_3O_2 + NO \longrightarrow CH_3O + NO_2 \quad (12)$$

$$CH_3O + O_2 \longrightarrow CH_2O + HO_2 \quad (13)$$

The formation mechanism of formic acid is not clear although there might be many possible formation routes in secondary reactions involving *cis*-2-butenedial and *cis*-4-oxo-2-pentenal, particularly, in surface reactions. According to Su *et al.*,[43] formic acid can be produced by the photooxidation of formaldehyde. Formic acid might also be produced by the reaction of OH radicals with glyoxal and methylglyoxal.

$$OH + (CHO)_2 \longrightarrow HCO + HCOOH \quad (14)$$

$$OH + CH_3COCHO \longrightarrow CH_3CO + HCOOH \quad (15)$$

Recently, Plum *et al.*[44] reported that the rates of reactions of OH+glyoxal and methylglyoxal are very fast. PAN may be formed from the acetyl radical produced by the photodecomposition of methylglyoxal as suggested by Darnall *et al.*[24a]

In the previous studies,[13-15,18,19] high-boiling-point products formed in the photooxidation or the OH radical reaction with toluene were analyzed. The major products were benzaldehyde and *o*-cresol. The benzaldehyde yield from toluene of 0.11 obtained in the present study is in reasonable agreement with yields obtained previously by the GC analysis.[45] On the other hand, the yield of cresols reported in the previous studies was scattered from 13 to 68%.[46] In the present study, high-boiling-point products except benzaldehyde could not be identified. It is suggested that the fraction of the ring-cleavage process is 29% of toluene consumed and that 71% of total products may be high-boiling-point compounds retaining the aromatic ring[47] (benzaldehyde is 11% and other products including cresols are 60%).

Two possible mechanisms, Scheme 1 and 2, were suggested as the ring-cleavage reaction. In these reactions, the number of NO molecules which are converted to NO_2 when one toluene molecule is consumed are two and four in the cases of Scheme 1 and 2, respectively, including the reaction of $HO_2+NO\rightarrow OH+NO_2$. This number for the pho-

tooxidation of toluene obtained in the previous studies[48,49] are scattered from 1.2 to 2.3 depending upon the experimental conditions. A determination of this number was made in the present reaction chamber. Three measurements were carried out in the toluene (4 ppm) and NO (2 ppm) system.[50] The number obtained from the ratio of toluene consumed to NO consumed in the initial stage (<100 min) were 1.5, 1.5, and 1.6 in these measurements with an average value of 1.5. The number of 1.5 consists of three types of reactions: (1) Formation of benzaldehyde from benzyl radicals produced by the side-chain-hydrogen abstraction (in this case the number is two:[51] (2) Formation of cresols from OH-aromatics adducts (in this case the number is one:[51] (3) Ring cleavage as discussed in the present study. Assuming the fraction of these three types of reactions, (1), (2), and (3), are 11, 60, and 29% of total reaction, respectively, the number in the ring-cleavage reaction can be estimated[52] to be 2.4—2.6. In the ring-cleavage reaction, both α-dicarbonyls and unsaturated γ-dicarbonyls are produced when one toluene molecule is consumed. A part of the unsaturated γ-dicarbonyls is converted to maleic anhydride, and another part of them may be decomposed (including the release of methyl radicals). Therefore, some additional NO should be converted to NO_2 by reaction related to unsaturated γ-dicarbonlys (including the formation of formaldehyde *via* Reactions 11—13). In order to satisfy the estimated number of 2.4—2.6, the preferred number is two rather than four in the reaction related to α-dicarbonyls. Thus, the cyclization mechanism, Reaction 7 is preferred over Reaction 8 as the ring-cleavage mechanism.

B. Photooxidation of Benzene. In the previous work on the photooxidation of benzene, the formation of phenol and nitrobenzene[14,18] and glyoxal[23] were reported as products. In the present study, the formation of formaldehyde, formic acid, and maleic anhydride were observed in addition to the products previously identified. It has been suggested,[14,18] that both phenol and nitrobenzene are produced from the same precursor, OH-benzene adduct.

If phenol and nitrobenzene are the high-boiling-point products and glyoxal is produced by the ring cleavage reaction, the ratio of the high-boiling-point products to the ring-cleavage product can be calculated from the concentration of products shown in Fig. 7. The yields calculated are 80—85% (high-boiling-point products) and 15—20% (ring-cleavage products).

Formaldehyde was detected in the photooxidation of benzene, although the yield is smaller than in the case of toluene. One possible formation route of formaldehyde is the photodecomposition of glyoxal as suggested by Plum *et al.*[44]

$$(CHO)_2 + h\nu \longrightarrow H_2CO + CO \quad (16)$$

The heterogeneous reaction of *cis*-2-butenedial produced as a counterpart of glyoxal might be possible to produce formaldehyde.

45) Yields obtained in the previous studies are 0.073 (Ref. 19), 0.12 (Ref. 3), and 0.15 (Ref. 18).

46) Yields reported are 0.131 (Ref. 19), 0.21 (Ref. 3), and 0.68 (Ref. 18).

47) The ratios of the *o*-cresol/benzaldehyde yields reported previously are 1.8 (Refs. 19 and 3), 2.1 (Ref. 14), and 4.5 (Ref. 18). If these values are used to the estimation of the yield of cresols in the present study, the yields are 20, 23, and 50% of toluene consumed, respectively. The ratio of [benzaldehyde]/[total high-boiling-point products] obtained under the conditions of high NO_2 concentrations (Ref. 15) was about 0.16. Total high-boiling-point products were mostly cresols, nitrocresols, and *m*-nitrotoluene. If this value, 0.16, is used, the yield of total high-boiling-point products can be estimated to be 68% of toluene consumed. This value is in excellent agreement with the value of 71% estimated in the present study.

48) N. Washida, G. Inoue, H. Akimoto, and M. Okuada, *Bull. Chem. Soc. Jpn.*, **51**, 2215 (1978).

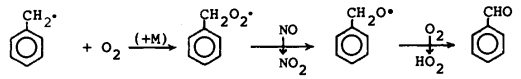
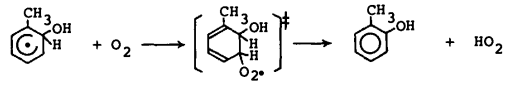
50) For the determination of this number, the conditions in the absence of NO_2 was desired, because the photodecomposition of NO_2 ($NO_2 \rightarrow NO+O$) disturbs the measurement.

51) The formation mechanisms of benzaldehyde (A) and *o*-cresol (B) suggested (Refs. 14, 15, and 48) are



(A)



(B)

52) The number, n=2.4 is obtained from the equation; $0.11\times2+0.60\times1+0.29n=1.5$. This number is a lower limit, because in the presence of NO_2, formation of some benzyl nitrate and *m*-nitrotoluene at the expense of benzaldehyde and cresols, observed. Therefore, effective numbers slightly less than 1 and 2 should be used in the above equation. However, even when the photooxidation was carried out in the NO_2–toluene system,[15] yields of benzyl nitrate and *m* nitrotoluene were always less than 10% of benzaldehyde and cresols, respectively. Therefore, the value can be estimated to be 2.4—2.6.

Ring-cleavage Reactions of Aromatic Hydrocarbons Studied by FT-IR Spectroscopy. II. Photooxidation of *o*-, *m*-, and *p*-Xylenes in the NO_x-Air System

Hiroshi BANDOW and Nobuaki WASHIDA

Division of Atmospheric Environment, The National Institute for Environmental Studies, P. O. Tsukuba-gakuen, Tsukuba, Ibaraki 305

(Received February 12, 1985)

α-Dicarbonyl compounds produced in the photooxidation of *o*-, *m*-, and *p*-xylenes were analyzed quantitatively using long-path FT-IR spectroscopy. Glyoxal, methylglyoxal, and biacetyl were observed in the case of *o*-xylene, and glyoxal and methylglyoxal were observed in cases of *m*- and *p*-xylenes. Yields of glyoxal, methylglyoxal, and biacetyl were 8, 23, and 10% (mole/mole) of *o*-xylene consumed, respectively. Yields of glyoxal and methylglyoxal were 13 and 42% in the case of *m*-xylene, and 24 and 12% in the case of *p*-xylene. These yields could be explained by the ring cleavage of 6,7-dioxabicyclo[3.2.1]octane compounds of OH-aromatics-O_2 adduct. Formations of maleic anhydride was observed in the case of *o*-xylene and it is suggested that maleic anhydride is produced from *cis*-2-butenedial. Formation of 3-hexene-2,5-dione (unsaturated γ-dicarbonyl) was observed from *p*-xylene. The ring-cleavage process accounts for 41, 55, and 36% of the total reaction in *o*-, *m*-, and *p*-xylenes, respectively.

The studies of the mechanism of the ring-cleavage reactions in the photooxidation of benzene and toluene described in part I, are extended to *o*-, *m*-, and *p*-xylenes in the present work. The initial reaction of OH with xylenes also proceeds mainly by addition to aromatic ring (80—98% of the total reaction).[1-4] Also *m*-xylene reacts faster[1,4,5] than either *p*- or *o*-xylene with OH at 298K since meta substitution of the ring enhances electrophilic addition. The formation of α-dicarbonyls, glyoxal, methylglyoxal, and biacetyl (only in the case of *o*-xylene), by xylene-ring-cleavage reaction has been reported.[2,6,7] However, the yields of α-dicarbonyls reported are scattered. For example, in the case of *o*-xylene, the yields of glyoxal, methylglyoxal, and biacetyl per *o*-xylene consumed reported by Nojima *et al.*[6] are 0.2, 4.0, and 1.2%, respectively, the values by Takagi *et al.*[2] are 85, 14, and 26%, respectively, and those by Shepson *et al.*[7c] are 3.4, 11.6, and 8.5%, respectively. Darnall *et al.*[7a] measured only the yield of biacetyl and reported it to be 18% of *o*-xylene consumed. Very large spread of these results might be mainly due to difficulty of handling of α-dicarbonyls. In the previous studies, GC analyses were carried out after a pre-collection of gas-phase products in a solution[6,7c] or by combining with a photoionization mass spectrometer as a detector.[2] The former represents a rather complicated procedure, while the latter requires concentration of a large amount of products, in compensation for the low detectivity of the compounds. Therefore, the direct observation of gaseous products by FT-IR should provide more reliable data on the yield and the ring-cleavage-reaction mechanisms of xylenes.

Experimental

The apparatus and experimental procedures were the same as those mentioned in part I.[8] The experimental conditions were xylene(4 ppm), NO(1.5 ppm), NO_2(0.5 ppm), and air (1 atm=101 kPa) system. Three experiments were carried out for each xylene isomer.

Results

Formaldehyde, formic acid, glyoxal, methylglyoxal, PAN, and tolualdehydes were observed as reaction products in the photooxidation of *o*-, *m*-, and *p*-xylenes. Formation of biacetyl and maleic anhydride was observed only from *o*-xylene. Product spectra (spectra, from which spectra of reactants, xylenes, NO, NO_2, and H_2O were subtracted) and residual spectra (spectra, from which spectra of products mentioned above were subtracted) are shown in Fig. 1 for each of *o*-, *m*-, and *p*-xylenes. Product spectra shown in Fig. 1, (a), (c), and (e), were obtained under the same conversion of xylenes (xylene consumed was about 20%).

Concentrations of each product from *o*-xylene as a function of irradiation time are shown in Fig. 2. Characteristic absorption bands used to determine the absolute concentrations of products are the same as for toluene (Table 1 in part I). The concentration of biacetyl was determined by absorption at 1120 cm^{-1} (in the region of skeletal vibrations), and that of tolualdehydes by absorption at 2730 cm^{-1} which corresponds to the C-H stretching mode of -CHO. The time profiles of formic acid and PAN show that both molecules are secondary products as in the case of toluene. From the slopes of the plots of the concentrations of products formed *versus* *o*-xylene consumed, shown in Fig. 3, yields of products listed in Table 1 were calculated. Yields shown in each run are obtained by the least-square fit of five initial points of each run (as shown in Fig. 3) except the case of tolualdehydes. For tolualdehydes, the least-square fit was done for three initial points. The indicated errors are one standard deviation of three runs.

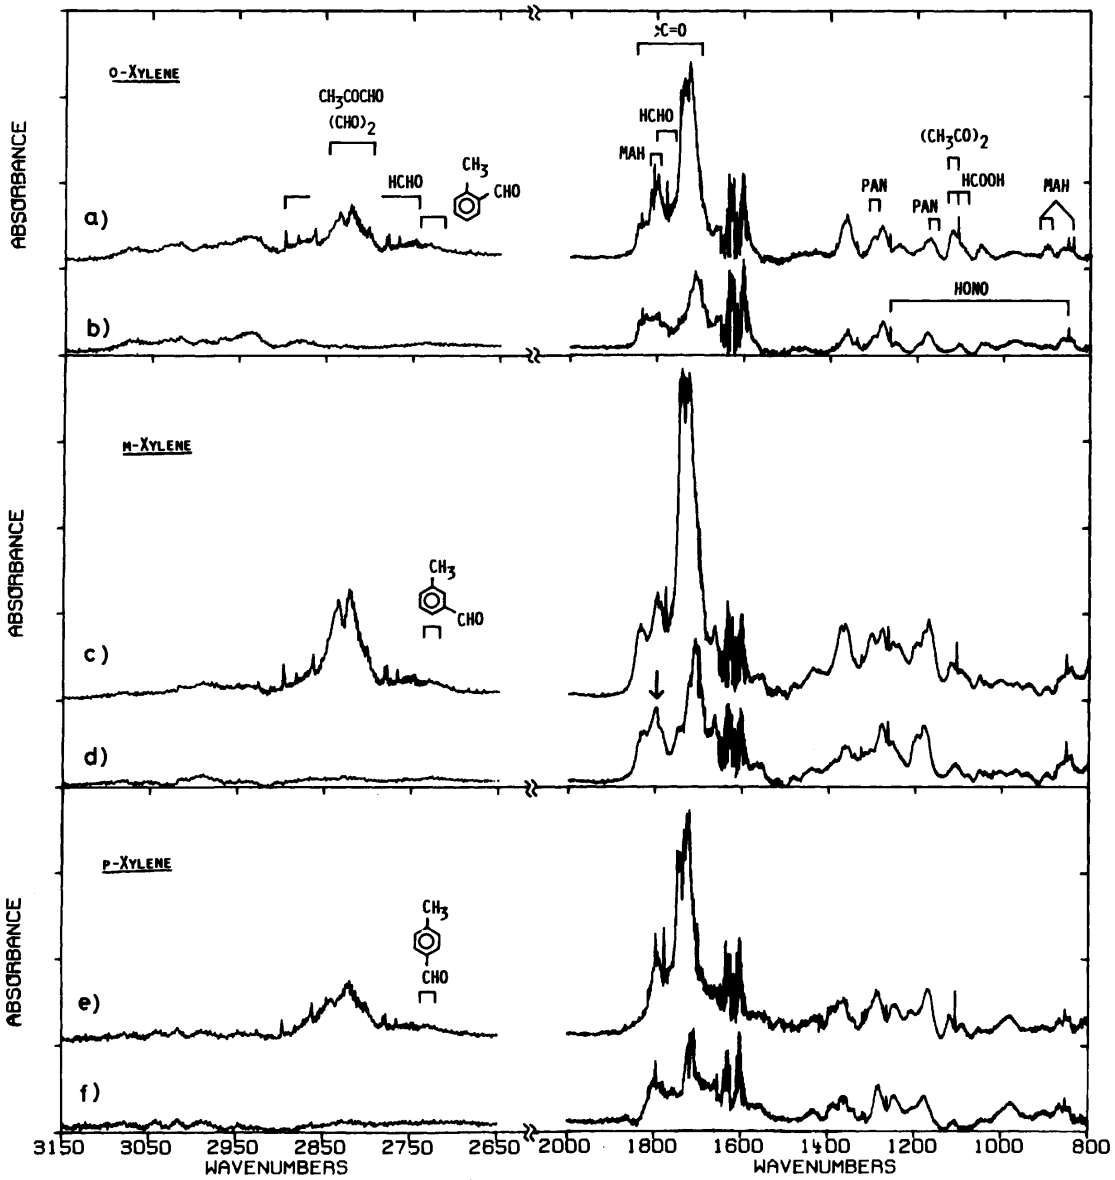

Fig. 1. Product spectra (spectra, from which spectra of xylene, NO, NO_2, and H_2O were subtracted) and residual spectra (spectra, from which spectra of products identified were subtracted).
a) Product spectra in the photooxidation of the *o*-xylene(4 ppm), NO(1.5 ppm), NO_2(0.5 ppm) diluted in 1 atm (=101 kPa) air system. Conversion of *o*-xylene is about 20%. b) Residual spectra after subtraction of products identified (H_2CO, HCOOH, $(CHO)_2$, CH_3COCHO, $(CH_3CO)_2$, maleic anhydride, PAN, and *o*-tolualdehyde). c) Product spectra in the photooxidation of the *m*-xylene(4 ppm), NO(1.5 ppm), NO_2(0.5 ppm) diluted in 1 atm air system. Conversion of *m*-xylene is about 20%. d) Residual spectra after subtraction of products identified (H_2CO, HCOOH, $(CHO)_2$, CH_3COCHO, PAN, and *m*-tolualdehyde). ↓ : See text. e) Product spectra in the photooxidation of *p*-xylene (4 ppm), NO(1.5 ppm), NO_2(0.5 ppm) diluted in 1 atm air system. Conversion of *p*-xylene is about 20%. f) Residual spectra after subtraction of products identified (H_2CO, HCOOH, $(CHO)_2$, CH_3COCHO, PAN, and *p*-tolualdehyde).

Discussion

A. Yields of α-Dicarbonyls and Reaction Mechanism of Ring-cleavage Reaction. As shown in Table 1, product yields of each α-dicarbonyl are varying among the xylenes. For example, the yield of methylglyoxal is the largest for *o*- and *m*-xylene, and that of glyoxal is the largest in the case of *p*-xylene. It is very interesting if the significant variations in yield of α-dicarbonyls among the xylenes can be explained by a unique and simple ring-cleavage mechanism. If such a mechanism will be proved to be applicable as a general rule to other aromatic compounds, it would be very useful for modeling

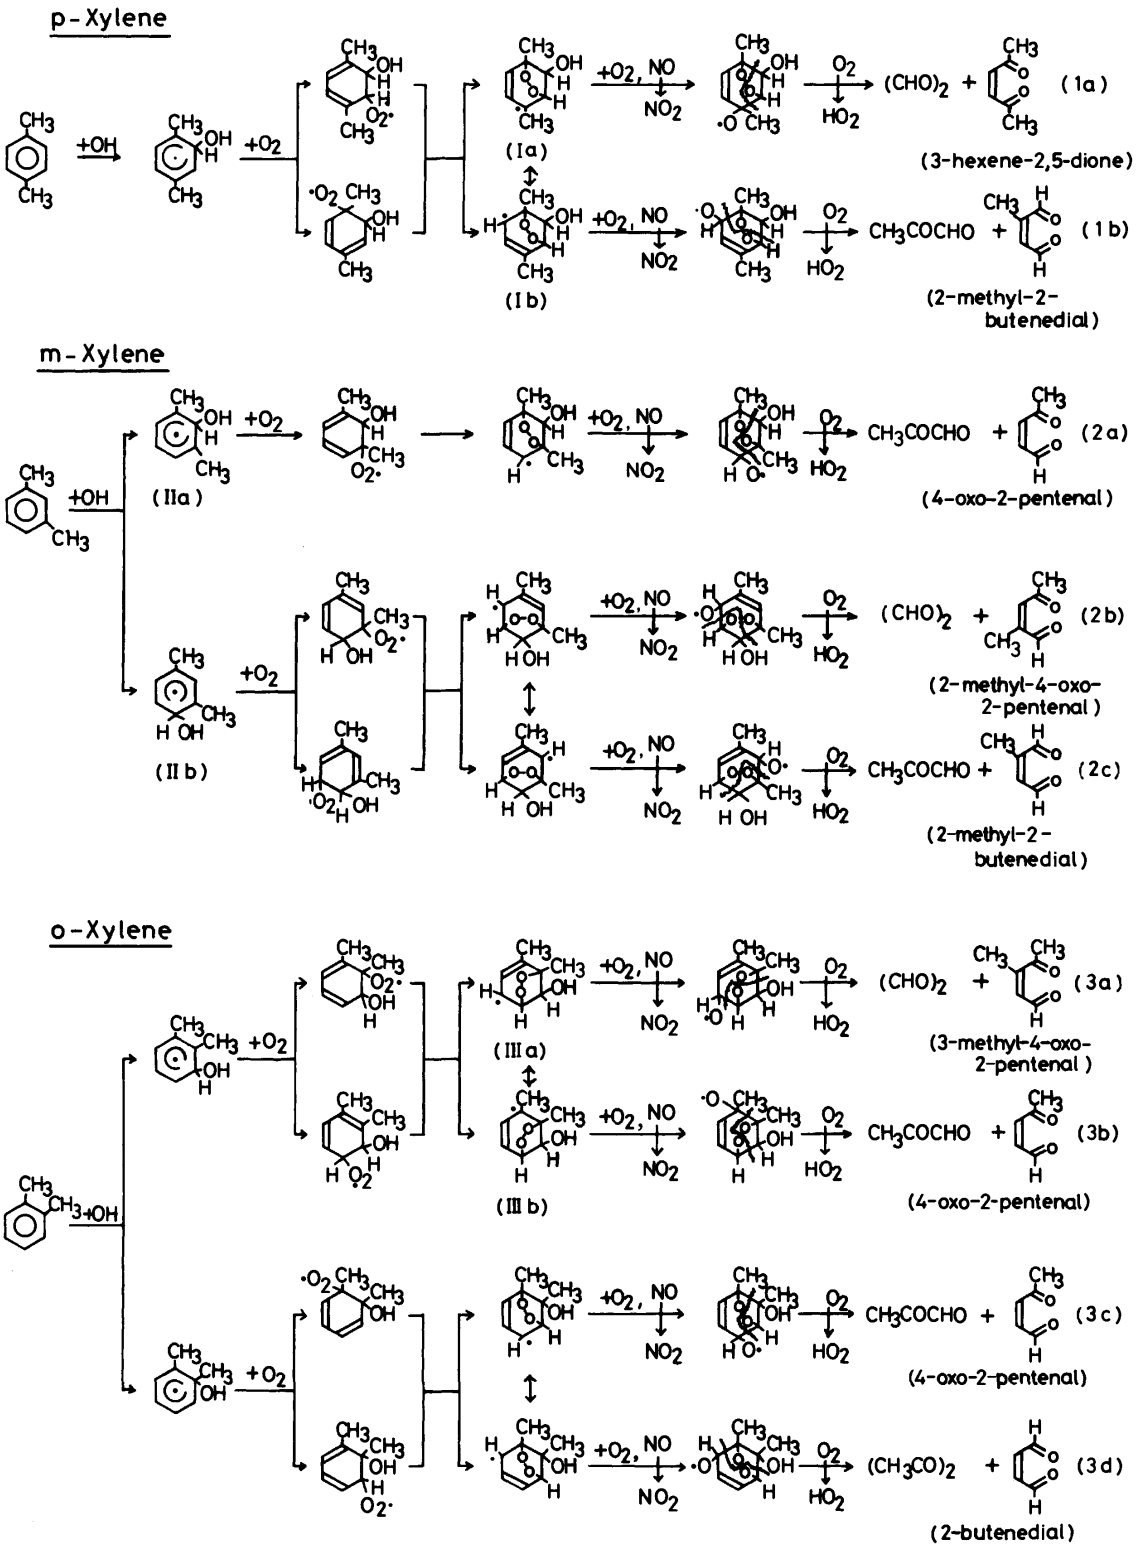
studies of the photooxidation of aromatic compounds.

First, we assume [Assumption I] that the addition of OH to xylene is predominantly at the ortho position.[9] According to the cyclization mechanism described for the ring-cleavage reaction of toluene,[8] the reactions of xylenes are considered to proceed as shown in Scheme 1. In this scheme, allyl-type radicals, 6,7-dioxabicyclo[3.2.1]octane compounds which are produced by bicyclo[3.2.1] cyclization from OH–aromatics–O_2 adducts, are represented by their resonance structures, for example, **Ia**↔**Ib** in the case of *p*-xylene. We consider the example of *p*-xylene first since it is the simplest to follow. Glyoxal and methylglyoxal can be produced with 3-hexene-2,5-dione and 2-methyl-2-butenedial, respectively, and the ratio of the formation of glyoxal and methylglyoxal is governed by the ratio between Reactions 1a and 1b. In the case of *p*-xylene, the formation ratio of glyoxal to methylglyoxal obtained by experiment (see Table 1) is two to one. Therefore, if one takes the bicyclo[3.2.1] cyclization mechanism as the reaction path to yield α-dicarbonyls, the branching ratio of Reaction 1a to 1b should be two to one, that is, the probability of O_2 addition to **Ia** (resonance structure with tertiary radical) and **Ib** (that with secondary radical) of the allyl radicals should be



Scheme 1.

two to one. On the other hand, when the resonance structures of the allyl radicals are both secondary radicals, the probability of O_2 addition to the alternate radical points is expected to be the same judging from the case of toluene.[8] This consideration leads us to the second assumption [Assumption II] that the probability of O_2 addition to the resonance structure with tertiary radical is twice as that with secondary radical when the resonance structures of 6,7-dioxabicyclo[3.2.1]octane com-

pounds consist of both secondary and tertiary radicals, otherwise the probability is the same.

In the case of *m*-xylene, the formation mechanism of glyoxal and methylglyoxal according to Assumption I is also shown in Scheme 1. In the OH-aromatics adducts, **IIa** and **IIb**, the compound **IIa** is produced by the addition of OH to *m*-xylene at the 2-position. The compound **IIb** can be produced by the addition of OH at either the 4- or the 6-position of *m*-xylene. Therefore, if the addition of OH occurs with equal probability, the formation ratio of the compounds **IIa** and **IIb** is one to two. With the assumption of the equal probability of Reactions 2b and 2c under Assumption II the formation ratio of glyoxal to methylglyoxal can be calculated to be 0.33 to 0.67. The experimentally observed formation ratio of glyoxal to methylglyoxal, 0.23 to 0.77, can be explained by introducing the third assumption [Assumption III]: the probability of addition of OH at the 2-position is two times larger than at the other ortho position when the aromatics have methyl groups at 1- and 3-positions simultaneously (*e.g.* *m*-xylene, 1,2,3- and 1,3,4(=1,2,4)-trimethylbenzenes), otherwise the probability is the same. According to Assumption III, the formation ratio of compound **IIa** to **IIb** is one to one and the formation ratio of glyoxal and methylglyoxal was calculated to be 0.25 to 0.75. The value obtained including Assumption III is much closer to the experimental results and assumption III is important to explain the results in cases of trimethylbenzenes as will be described in part III. The formation ratio of α-dicarbonyls obtained by experiments and estimated from Assumptions I—III are listed in Table 2 with estimated yields of unsaturated γ-dicarbonyls.

Reaction mechanisms for the ring-cleavage processes for *o*-xylene are shown also in Scheme 1, and the formation ratios of dicarbonyls obtained by experiments and calculations are listed in Table 2. In the case of *o*-xylene, Assumption II was used to determine the branching ratio of Reactions 3a and 3b (1:2). Table 2 clearly shows that using the same reaction mechanism and the same assumptions which have been introduced to explain the formation ratio of α-dicarbonyls from toluene and *m*- and *p*-xylenes, the ratio from *o*-xylene can be also reproduced well.

The fractions of the ring-cleavage process in the total reaction were 41, 55, and 36% in cases of *o*-, *m*-, and *p*-xylenes, respectively. These values are larger than those of toluene and benzene. The largest fraction from *m*-xylene is reasonable because the addition reaction of OH to the ring is enhanced. This is also evident from the fact that the yields of tolualdehydes which are produced *via* competitive reaction, H-atom abstraction from methyl side chain, are in the reverse order, *i.e.* *p*->*o*->*m*-, as will be discussed later. The reason for the yield of the ring cleavage being larger in *o*-xylene than in *p*-xylene is not clear. However, if the cleavage of the ring occurs in the 6,7-dioxabicyclo[3.2.1]octyloxyl radicals, the distortion energy of the rings should have an effect on the ring cleavage as demonstrated in the photooxidation of C_5–C_7 cycloalkanes.[11] In those molecules, the ring rupture in the vibrationally hot cycloalkyloxyl radicals occurs in order of $C_5>C_7>C_6$ following the order of the strain energy of rings. It is very probable that the distortion energy of the bicyclo compound is larger in the case of *o*-xylene which has adjacent methyl side groups, than in the case of *p*-xylene. Discussions on the distortion energy are given again in paper III.

Yields of α-dicarbonyls obtained in the present study disagree with those obtained in the previous studies by GC analysis.[2,6,7a] In *o*-xylene, for example, reported yields of glyoxal, methylglyoxal and biacetyl by Takagi *et al.*[2] are 0.85, 0.14, and 0.26, respectively. Calculated values from the data by

Nojima *et al.*[6] are 0.002, 0.040, and 0.012, respectively. These data showed quite poor agreement in the yield. Recently, Shepson *et al.*[7c] have carried out an extensive analysis of ring-cleavage products in toluene and *o*-xylene photooxidation. Their reported yields of glyoxal, methylglyoxal and biacetyl are 0.034, 0.116, and 0.085, respectively. Also, Atkinson *et al.*[12] reported the yield of biacetyl (0.137 at 740 torr of air) formed in the NO_x photooxidation of *o*-xylene. The values obtained in the present study (0.08±0.01, 0.23±0.03, and 0.10±0.02 for glyoxal, methylglyoxal and biacetyl, respectively) are in good agreement with those of Shepson *et al.*[7c] and Atkinson *et al.*[12] We believe the direct measurement such as in the present study gives more reliable data of the yield. In *m*- and *p*-xylenes, very low yields of glyoxal, one tenth and one fifth of methylglyoxal, respectively, and the very low absolute yields , only a few percent of the xylene consumed, were reported by Nojima *et al.*[6]

The yield of the high-boiling-point products has been reported only for the photooxidation of *o*-xylene by the use of the GC analysis.[2] The yield of the total high-boiling-point products analyzed was about 17% of *o*-xylene consumed. Therefore, 58% of the total products were accounted for in the case of *o*-xylene; total high-boiling-point products (17%), glyoxal (8%), methylglyoxal (23%), and biacetyl (10%).

B. Residual Spectra of Products and Unsaturated γ-Dicarbonyls. The spectra of unidentified products are shown in the residual spectra (b, d, and f) in Fig. 1. In these, absorptions appearing in the frequency region of 2850—3010 cm^{-1} are due to C–H stretching of hydrocarbons. The absorptions around 1800 cm^{-1} corresponds to the C=O stretching of carboxylic acids, anhydrides, and peroxyacyl nitrates as described in paper I. Formation of maleic anhydride was observed in the case of *o*-xylene. Although Fig. 2 shows a linear increase of maleic anhydride to *o*-xylene consumption, maleic anhydride is considered to be a secondary product produced from *cis*-2-butenedial as proposed in the case of toluene.[8] Under the reaction mechanism mentioned above, only *o*-xylene can yield *cis*-2-butenedial (see Table 2). This also suggests that maleic anhydride is produced from *cis*-2-butenedial. If maleic anhydride is produced from *cis*-2-butenedial, methylmaleic anhydride can be produced from 2-methyl-2-butenedial. However, no significant IR absorption[13] of methylmaleic anhydride was observed. In *m*-xylene, a strong absorption (shown by an arrow) appears at the low frequency side of the absorption around 1800 cm^{-1}. This absorption was always prominent in cases of *m*-xylene and 1,3,5-trimethylbenzene (will be described in part III), and increases strongly upon prolonged irradiation. Although the compounds for this absorption were not identified, it is suggested that more carboxylic acids and/or anhydrides are produced in the photooxidation of *m*-xylene and 1,3,5-trimethylbenzene.

A strong absorption in the frequency region of 1700—1750 cm^{-1} corresponds to the C=O stretching of aldehyde, ketone, dialdehyde, and diketone. If unsaturated γ-dicarbonyls shown in Scheme 1 are present, these compounds should have strong absorption in this region. The noise appearing in the region of 1600—1650 cm^{-1} is caused by the subtraction of the absorption of NO_2. Organic nitrates, which should absorb around 1670, 1280, and 850 cm^{-1}, were not observed as major products.

Absorptions appearing in the frequency region of 1400—800 cm^{-1} are attributable to skeletal vibrations. As described in paper I, absorptions by HONO can also be seen. Spectra in the frequency region of 1400—900 cm^{-1} are expanded and shown in Fig. 4. Spectra (a), (b), and (c) in Fig. 4 are residual spectra of *o*-, *m*-, and *p*-xylene, respectively. In these, the absorption spectrum of HONO was subtracted. Among unsaturated γ-dicarbonyls shown in Scheme 1

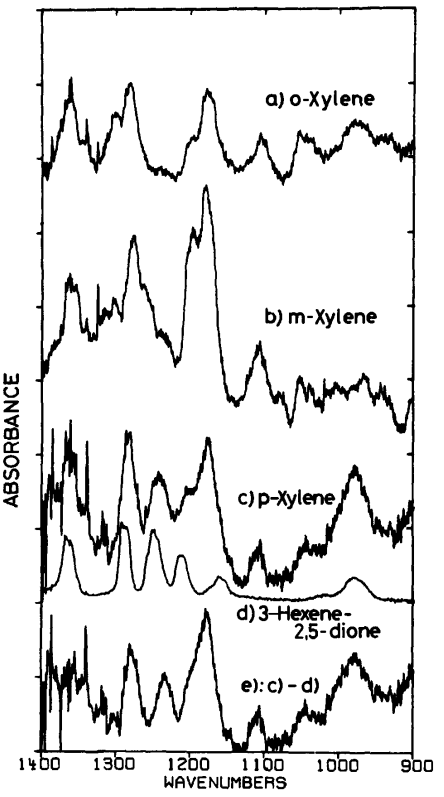

Fig. 4. Residual spectra in the frequency region of 1400—900 cm^{-1}. Conditions are the same as the case in Fig. 1.
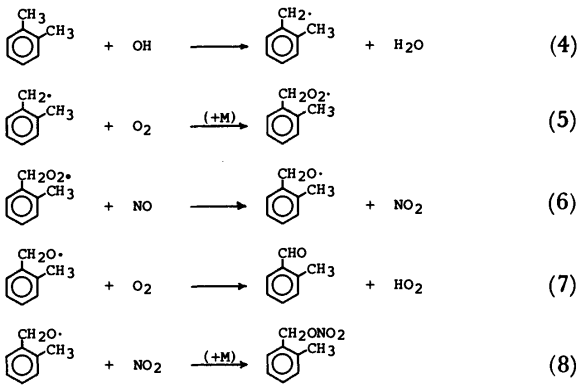
a), b), and c) are residual spectra in cases of *o*-, *m*-, *p*-xylenes, respectively. d) Standard spectrum of *trans*-3-hexene-2,5-dione. e) Difference spectrum of c)—d).

and Table 2, 3-hexene-2,5-dione is expected to be the least reactive against OH attack because of an absence of aldehydic hydrogens, taking into account that the loss of unsaturated γ-dicarbonyls is partly due to hydrogen-atom abstraction from -CHO by OH radicals. Takagi *et al.*[14] reported the observation of 3-hexene-2,5-dione by GC/MS method among the compounds collected in a trap at liquid nitrogen temperature from gaseous mixtures of both 1,2,4-trimenthylbenzene and *p*-xylene photooxidation. Thus, in the present study, *in-situ* observation of 3-hexene-2,5-dione was attemped. The standard spectrum of 3-hexene-2,5-dione synthesized by the reaction of acetonylacetone with selenious acid[14,15] is shown in Fig.4(d). Only in the *p*-xylene, spectrum(c), the absorption by 3-hexene-2,5-dione was apparent. Spectrum (e) shows the (c)—(d) difference spectrum. By substraction of the spectrum of 3-hexene-2,5-dione, the yield of 3-hexene-2,5-dione was estimated to be about 8% of the *p*-xylene consumed. The uncertainty of the value is ±100% because of ambiguity of the subtraction. Recently, Tuazon *et al.*[16] investigated the atmospheric chemistry of *cis*- and *trans*-3-hexene-2,5-dione. They report the existence of photoisomerization between the two isomers, and the isomerization was found to account for ≥80% of the total photolysis rate with a photoequilibrium [trans]/[cis] ratio of 0.55±0.05 under their irradiation conditions (25-kW xenon arc solar simulator, NO_2-photolysis rate of 2.1×10^{-3} s^{-1}). According to the vapor-phase IR spectra of the two isomers reported in their study, the spectrum shown in Fig. 4 (d) is *trans*-3-hexene-2,5-dione. In the ring cleavage of *p*-xylene formation of cis isomer is expected primarily, and the cis isomer shows only one strong IR absorption at around 1160 cm^{-1} [16] in the skeletal vibration region. Unfortunately the existence of *cis*-3-hexene-2,5-dione can not be confirmed from Fig. 4(e). It can be, however, assumed that in the present study light intensity is strong enough to establish the photoequilibrium of [trans]/[cis]≃0.5 in 3-hexene-2,5-dione within a few tens min, judging from their data[16] and the NO_2 photodecomposition rate of the present study (3.7×10^{-3} s^{-1}) although the dependence of the photoisomerization rate on wavelength is uncertain. If we take the photoequilibrium into account, the total yield of 3-hexene-2,5-diones should be about three times larger than that of the trans isomer. The yield thus estimated is comparable to that of glyoxal (24±2%), which is a counterpart of 3-hexene-2,5-dione in the ring cleavage of *p*-xylene in Scheme 1.

Syntheses of other unsaturated γ-dicarbonyls, *e.g.* 2-butenedial[17] and 4-oxo-2-pentenal,[18] were attempted. However these compounds were glassy and easily polymerized. Since the purification of these compounds was very difficult, standard spectra of these compounds were not obtained although the residual spectra show the possibility of the presence of unsaturated γ-dicarbonyls.

C. Yields of Tolualdehydes. The formation of *o*-, *m*-, and *p*-tolualdehydes was observed in the photooxidation of *o*-, *m*-, and *p*-xylene, respectively. Since *o*-, *m*-, and *p*-tolualdehydes are formed from *o*-, *m*-, and *p*-methylbenzyl radicals produced by the side-chain hydrogen abstracion by OH radicals, Reactions 4—7, the fractions of the side-chain abstraction channel in the total reaction can be estimated from the yields of tolualdehydes.



Results are listed in Table 3 together with literature values. The values in the present study were obtained from the yields of tolualdehydes only, and are therefore lower limit, because the amount of other products produced from methylbenzyl radicals such as *o*-, *m*-, *p*-methylbenzyl nitrates (Reaction 8) should account for up to 10%[2] of tolualdehydes produced.

D. Atmospheric Implication. From the photochemical reactivity point of view, ring-cleavage products are important among the compounds produced in the photooxidation of aromatic hydrocarbon. The ring-cleavage products are produced through rather long sequences of reactions involving organic radicals and are often more reactive against photolysis and OH radical attack, which bring forth other radical reaction sequences, than the parent aromatic hydrocarbons. Therefore, the yield of ring-cleavage products such as α-dicarbonyls and unsaturated γ-dicarbonyls is a key for atmospheric photooxidation of aromatic hydrocarbons. Nevertheless, there have been few systematic studies[6,7b] on the yield of α-dicarbonyls from alkylbenzenes, and there is no generalized mechanism for the ring-cleavage reactions so far. This has enforced one to include many branches of reactions and thus to introduce many parameters in model simulation studies of aromatic hydrocarbon photooxidation.

The yield of α-dicarbonyls has been determined systematically for toluene and xylenes in paper I and

the present study, and the observed data could be explained by the mechanism depicted as Scheme 1 with Assumptions I—III. Although it is extremely simplified and its validity is still uncertain, the authors believe that it is very useful for predicting the product distribution of the ring-cleavage products and it can provide the most appropriate basis at present of the complex ring-cleavage processes for modeling studies. Indeed, the mechanism seems applicable to other aromatic hydrocarbons as will be demonstrated in the following report, paper III. However, in order to establish more realistic reaction mechanism for the ring-cleavage reactions, extensive analysis of ring-cleavage products is needed including unsaturated γ-dicarbonyls. Further the thermochemical information of the radicals which might involve in the photooxidation of aromatic compounds, such as 6,7-dioxabicyclo[3.2.1]octane and 2,3-dioxabicyclo[2.2.2]octane compounds and their oxygenated radicals, is also needed.

Ring-cleavage Reactions of Aromatic Hydrocarbons Studied by FT-IR Spectroscopy. III. Photooxidation of 1,2,3-, 1,2,4-, and 1,3,5-Trimethylbenzenes in the NO_x-Air System

Hiroshi Bandow and Nobuaki Washida
Division of Atmospheric Environment, The National Institute for Environmental Studies, P.O. Tsukuba-gakuen, Ibaraki 305
(Received February 12, 1985)

Photooxidation of 1,2,3-, 1,2,4-, and 1,3,5-trimethylbenzenes was carried out in the NO_x-air system. Formation of glyoxal, methylglyoxal and biacetyl was observed in the cases of 1,2,3- and 1,2,4-trimethylbenzenes, and only methylglyoxal was observed from 1,3,5-trimethylbenzene. Yields of glyoxal, methylglyoxal and biacetyl were 7, 18, and 45% and 8, 37, and 11% of trimethylbenzene consumed in cases of 1,2,3- and 1,2,4-trimethylbenzenes, respectively. The reaction mechanism which was used to explain the yields of α-dicarbonyl compounds from toluene and *o*-, *m*-, *p*-xylenes in the preceding paper (part II) has been applied to explain these yields, and has been found to reproduce these yields well. Formation of 3-hexene-2,5-dione was observed only from 1,2,4-trimethylbenzene. The fractions of the ring-cleavage process in the total reaction were 70, 56, and 64% in cases of 1,2,3-, 1,2,4-, and 1,3,5-trimethylbenzenes, respectively. The yields of the ring-cleavage process are discussed.

In the final paper of this series,[1,2] quantitative analysis of ring-cleavage products in the photooxidation of 1,2,3-, 1,2,4-, and 1,3,5-trimethylbenzenes is reported. The rate constants for the reactions of OH+trimethylbenzenes are reported to be very large[3,4,5] (as large as OH+butenes), and the branching ratios for side-chain hydrogen abstractions (estimated to be 2—3% of total reaction[4,6]) are much smaller than in the cases of toluene and xylenes.

The questions addressed in this study are as follows: (1) How large is the fraction of the ring-cleavage process in the total reaction of trimethylbenzenes? (As described in papers I and II, fractions of the ring-cleavage process were in order of *m*-xylene (55%)>*o*-xylene (41%)>*p*-xylene (36%)>toluene (29%)>benzene (15—20%)): (2) Can the formation ratio of α-dicarbonyls (glyoxal, methylglyoxal, and biacetyl) be explained by the cyclization mechanism with three assumptions used in cases of toluene and *o*-, *m*-, *p*-xylenes?: (3) Can formation of unsaturated γ-dicarbonyls be observed? (In the case of 1,2,4-trimethylbenzene, formation of 3-hexene-2,5-dione has been observed by the GC analysis[7]): (4) Are there new specific ring-cleavage products in the photooxidation of trimethylbenzenes?: (5) How consistent are the results for the photooxidation of aromatic hydrocarbons (from benzene to trimethylbenzenes)?

Results

A mixture of trimethylbenzene (4 ppm), NO (1.5 ppm), and NO_2 (0.5 ppm), diluted in 1 atm (=101 kPa) air was irradiated in the reaction chamber as described in paper I.[1] Three experiments were carried out for each 1,2,3-, 1,2,4-, and 1,3,5-trimethylbenzenes.

Product spectra (spectra of reactants and H_2O were subtracted) of each trimethylbenzene are shown by spectrum (a), (c), and (e) in Fig. 1. Residual spectra (spectra of identified products were subtracted from spectrum (a), (c), and (e)) of each trimethylbenzene are shown by spectrum (b), (d), and (f) in Fig. 1. These spectra were obtained under nearly equal (about 20%) conversions of trimethylbenzenes. In all cases, formation of formaldehyde, formic acid, and PAN was observed. α-Dicarbonyls observed are

a) Values were calculated by the least-square fit of six initial points of each run. b) Initial concentrations of reactants were 4 ppm trimethylbenzene, 1.5 ppm NO, and 0.5 ppm NO_2 in 1 atm (=101 kPa) air in all runs. c) The indicated errors are one standard deviation of three runs.

glyoxal, methylglyoxal, and biacetyl in cases of 1,2,3- and 1,2,4-trimethylbenzenes, and only methylglyoxal is produced from 1,3,5-trimethylbenzene. Maleic anhydride, which is produced in the reactions of benzene, toluene, and *o*-xylene, was not observed as products of the trimethylbenzenes in significant amounts. Dimethylbenzaldehydes are probably produced, but were not analyzed because of too small yields.

The profile of the product concentrations *versus* irradiation time in the case of 1,2,4-trimethylbenzene is shown in Fig. 2 as an example. Among the products identified, formic acid and PAN were found to be secondary products, like in the cases of toluene and xylenes. As described in paper I,[1] amounts of products formed were plotted against trimethylbenzene consumed. From the slopes of these plots, the yield of each product was determined. Yields of products except formic acid and PAN (secondary products) are listed in Table 1. Values of yield were

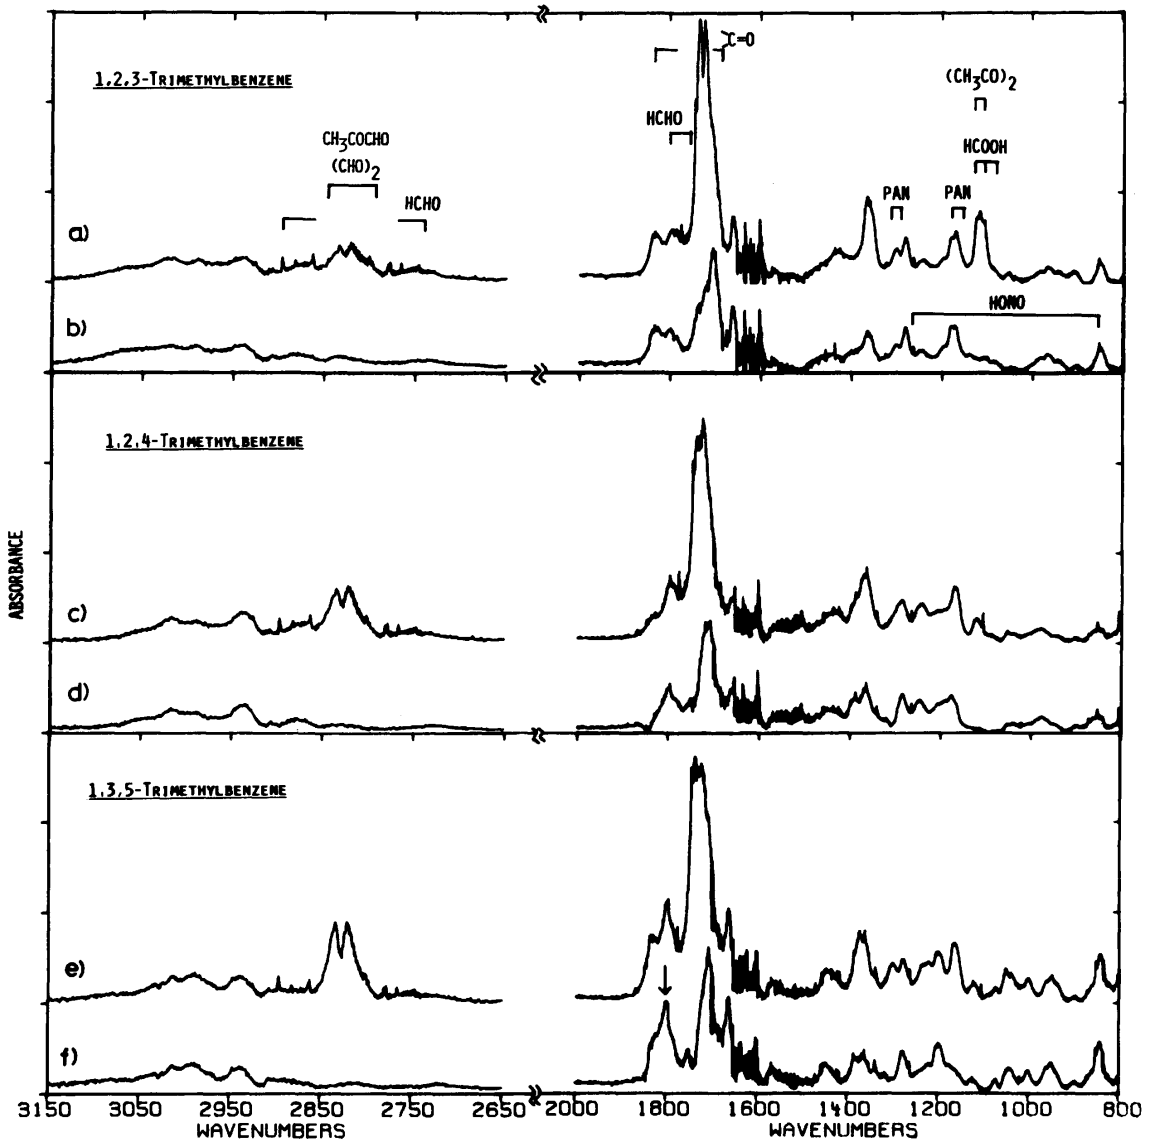

Fig. 1. Product spectra (spectra of reactants were subtracted) and residual spectra (spectra of products identified were subtracted). The initial conditions: [trimethylbenzene]=4 ppm, [NO]=1.5 ppm, and [NO_2]=0.5 ppm in 1 atm (=101 kPa) air.

a) Product spectra in the photooxidation of 1,2,3-trimethylbenzene after 80 min irradiation. Conversion of 1,2,3-trimethylbenzene is 19%. b) Residual spectra after subtraction of products identified (H_2CO, $(CHO)_2$, CH_3COCHO, $(CH_3CO)_2$, PAN, and HCOOH). c) Product spectra in the photooxidation of 1,2,4-trimethylbenzene after 66 min irradiation. Conversion of 1,2,4-trimethylbenzene is 19%. d) Residual spectra after subtraction of products identified (H_2CO, $(CHO)_2$, CH_3COCHO, $(CH_3CO)_2$, PAN, and HCOOH). e) Product spectra in the photooxidation of 1,3,5-trimethylbenzene after 50 min irradiation. Conversion of 1,3,5-trimethylbenzene is 18%. f) Residual spectra after subtraction of products identified (H_2CO, CH_3COCHO, PAN, and HCOOH). ↓: See text.

calculated by the least-square fit of six initial points of each run. The indicated errors are one standard deviation of three runs. Yields of α-dicarbonyls are fairly large in cases of 1,2,3- and 1,3,5-trimethylbenzenes compared with those of xylenes.

Discussion

A. Yields of α-Dicarbonyls and Reaction Mechanisms. It should be examined whether the yields of α-dicarbonyls shown in Table 1 can be explained by the cyclization mechanism with the assumptions used in cases of toluene and xylenes, as described in paper II.[2] The rules in the reaction mechanism used in paper II are as follows: (1) OH radicals add primarily to the ortho position of each side chain ([Assumption I] in paper II): (2) When the aromatics have side chains ($-CH_3$) at 1- and 3-positions (*e.g.* in *m*-xylene, 1,2,3- and 1,3,4(=1,2,4)-trimethylbenzenes), the probability of OH addition at the 2-position is two times larger than at other ortho position, otherwise the probability is the same ([Assumption III] in paper II): (3) Addition of O_2 to the OH-aromatics adduct occurs predominantly at a position which yields conjugated double bonds (see Reactions 6a and 6b in paper I[1]): (4) The OH-aromatics-O_2 adduct primarily undergoes a cyclization reaction forming a bicyclo-(-O-O-bridge) compound. In this case, formation of 6,7-dioxabicyclo[3.2.1]octane compound (allyl-type radical) is dominant. (In the case of 2,3-dioxabicyclo[2.2.2]octane compound, a radical point and a double bond are not conjugated): (5) The probability of O_2 addition to resonance structure with tertiary radical is two times larger than that to resonance structure with secondary radical when the resonance structures of the allyl-type radical consist of both secondary and tertiary radicals, otherwise the probability of O_2 addition to resonance structures of allyl-type radical is the same ([Assumption II] in paper II): (6) After addition of O_2 to the bicyclo[3.2.1] radical, an alkoxyl-type radical is produced by the abstraction of an O atom by NO: (7) The resulting alkoxyl-type radical undergoes cleavage of the ring, and a 1-hydroxyl-2-oxoalkyl radical (R-C(OH)-CR′=O) and an unsaturated γ-dicarbonyl are produced: (8) The 1-hydroxy-2-oxoalkyl radical undergoes hydrogen abstraction by O_2, and an α-dicarbonyl is produced.

Ring-cleavage reactions of the trimethylbenzenes according to the above rules are shown in Scheme 1. The process of O_2 addition to the OH-aromatics adduct and the formation of 6,7-dioxabicyclo[3.2.1]-octane compound are excluded just for avoiding complication. Formation ratios of α-dicarbonyls obtained by experiments and of α- and unsaturated γ-dicarbonyls calculated using the above rules are listed in Table 2. Branching ratios used in the calculations are as follows: Compound **Ia**:**Ib**:**Ic**= 1:1:1 and **IIa**:**IIb**:**IIc**:**IId**:**IIe**=2:1:1:1:1, according to the number of equivalent positions and Assumptions I and III: Compound **Id**:**Ie**=2:1, **If**:**Ig**=2:1, **IIf**:**IIg**=2:1, **IIh**:**IIi**=2:1, and **IIj**:**IIk**=2:1, according to Assumption II in paper II: One to one is used for all other branching ratios. Yields of α-dicarbonyls obtained by the calculations are in excellent agreement with experimentally observed values. In the

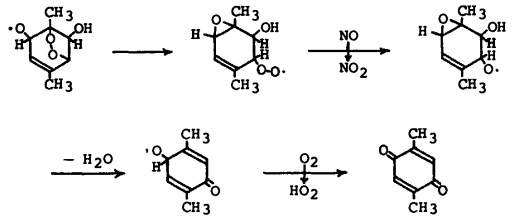
calculations, Assumption III in paper II is crucial. Without this assumption less satisfactory agreement of calculations with experimental values was obtained.[8]

B. Yield of the Ring-cleavage Process. The fractions of the ring-cleavage process in the total reaction are 70, 56, and 64% in cases of 1,2,3-, 1,2,4-, and 1,3,5-trimethylbenzenes, respectively. The percentages in 1,2,3- and 1,3,5-trimethylbenzenes are larger than in the cases of benzene, toluene and xylenes. The value of 56% in 1,2,4-trimethylbenzene is close to 55% in the case of *m*-xylene which shows the largest value of all xylenes. Factors governing the extent of ring cleavage are as follows: 1) The branching ratio between OH addition to the aromatic ring and side-chain hydrogen abstraction: 2) The branching ratio between cyclization of the OH-aromatics-O_2 adduct and the formation of phenols by hydrogen abstraction from the ring by O_2, and the formation of aromatic nitro compounds by the addition of NO_2:[9] 3) The distortion energy of 6,7-dioxabicyclo[3.2.1]octane compound (the alkoxyl-type radical).

As to factor 1, 100%, 85—90%, 90—95%, and 97—98% of total reactions are estimated to proceed through addition in the cases of benzene (no side chain), toluene, xylenes, and trimethylbenzenes, respectively.[4] Therefore, side-chain abstraction might have a slight effect on the yield of ring cleavage, except the case of benzene. Factor 1 alone seems not to explain the large variations of the ring-cleavage yields (15—20% in benzene, 29% in toluene, 36% in *p*-xylene, 41% in *o*-xylene, 55% in *m*-xylene, 56% in 1,2,4-trimethylbenzene, 64% in 1,3,5-trimethylbenzene, and 70% in 1,2,3-trimethylbenzene).

Factor 2 is likely to be important. The probability of cyclization might be governed by the reactivity to electrophilic attack of the carbon with which the end oxygen of the OH-aromatics-O_2 adduct forms a bond. Presumably increase of the number of methyl side chains enhances the probability of cyclization, meta substitution being particularly favorable for electrophilic attack leading to cyclization. The increasing extent of ring cleavage in the order of benzene<toluene<xylenes<trimethylbenzenes, and the large extent of ring cleavage in the cases of *m*-xylene and 1,3,5-trimethylbenzene, might reflect the reactivity of the aromatic ring to electrophilic attack.[10]

After the formation of the 6,7-dioxabicyclo[3.2.1]-octane compound, the distortion energy of this compound would affect the occurrence of the ring cleavage as mentioned in paper II.[2] Although distortion energies of the bicyclo[3.2.1] compounds are not known, the distortion energy is probably larger in the case that the side chains are located adjacent to each other than in the case that side chains are located separately in good symmetry. The larger extent of the ring-cleavage process in the case of 1,2,3-trimethylbenzene as compared with 1,3,5-trimethylbenzene and also in the case of *o*-xylene as compared with *p*-xylene, might be partly due to differences in distortion energy. The fate of the bicyclo compounds when the ring cleavage does not occur is not clear. One possible route is the formation of quinones after rupture of the -O-O- bridge in 6,7-dioxabicyclo[3.2.1]octyloxyl radicals. For example, in the case of *p*-xylene:



(4)

Formation of small amounts of dimethyl-*p*-benzoquinones have been reported in the photooxidation of *o*-, *m*-, and *p*-xylenes.[11,12] The relative yield of dimethyl-*p*-benzoquinone is the largest for *p*-xylene.[12]

As discussed above, the yield of the ring-cleavage process and the ratio of the α-dicarbonyls formed are governed by several factors. Some features of the ring-cleavage reaction can be explained, although a quantitative evaluation of all factors is not possible at present.

C. Residual Spectra of Products and Unsaturated γ-Dicarbonyls. The spectra of unidentified products are shown in the residual spectra (b,d, and f) in Fig. 1. Absorptions appearing in the frequency region of 2850—3010 cm^{-1} (C-H stretching of hydrocarbons) are stronger than in the case of xylenes. This is probably due to larger yields of unsaturated γ-dicarbonyls (*cf.* Table 2 and Scheme 1) which have more methyl groups.

Residual absorption around 1800 cm^{-1} can be accounted for by C=O stretching of carboxylic acids, anhydrides, and peroxyacyl nitrates. A sharp absorption at 1800 cm^{-1} observed in the case of *m*-xylene is also apparent for 1,3,5-trimethylbenzene (marked by an arrow). No absorptions of maleic anhydride, methylmaleic anhydride, and dimethylmaleic anhydride were observed in this frequency region. Absorption around 1700 cm^{-1} (C=O stretching of aldehyde, ketone, dialdehyde, and diketone) is also present. The large number of overlapping bands in the frequency region of 1700—1850 cm^{-1} shows that there should be a variety of carbonyls present. Sharp absorption at 1670 cm^{-1} is due to organic nitrates which have accompanying bands at 1280 and 850 cm^{-1}.

Absorptions in the region of skeletal vibrations (1400—900 cm^{-1}) are shown on an expanded scale in

Fig. 3. The spectra shown in Fig. 3 are arranged in order of 1,2,3-, 1,3,5-, and 1,2,4-trimethylbenzene: (Note that the order differs from the order in Fig. 1). Spectrum (d) in Fig. 3 shows a standard spectrum of *trans*-3-hexene-2,5-dione. Formation of 3-hexene-2,5-dione in the photooxidation of 1,2,4-trimethylbenzene has been reported in the previous work using the method of GC/MS analysis.[7] In this study, also the formation of 3-hexene-2,5-dione was observed in the case of 1,2,4-trimethylbenzene (spectrum (c) in Fig. 3). Subtraction of the spectrum of *trans*-3-hexene-2,5-dione from spectrum (c) led to an estimated yield of 6% for *trans*-3-hexene-2,5-dione to 1,2,4-trimethylbenzene consumed. According to the study on atmospheric chemistry of *cis*- and *trans*-3-hexene-2,5-dione by Tuazon *et al.*[13] cis and trans isomers of the compound is expected to establish a photoequilibrium with the ratio of [trans]/[cis]≈0.5 under the present experimental conditions.[2] The estimated total yield of 3-hexene-2,5-diones is thus about 18%. The uncertainty of this estimate is ±100% because of the ambiguity of the subtraction. Spectrum (e) shows the difference spectrum (c)—(d).

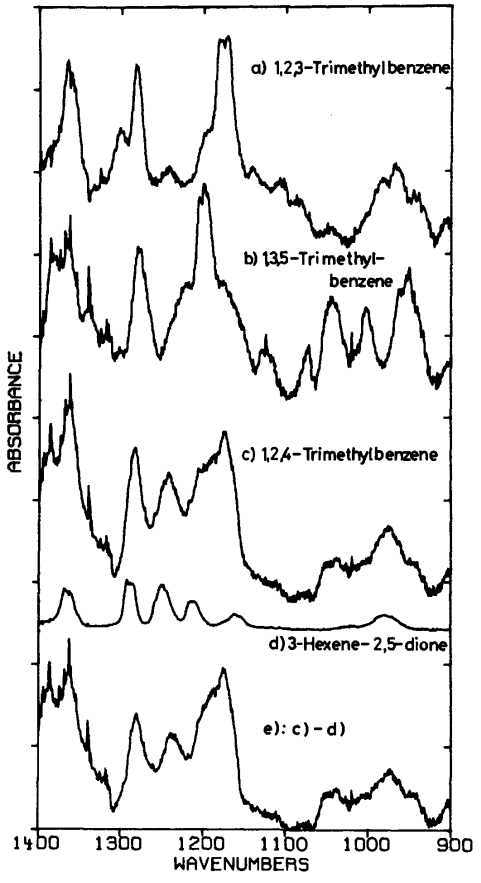


Fig. 3. Residual spectra in the frequency region of 1400—900 cm^{-1}. Conditions are the same as in Fig. 1. a), b), and c) are residual spectra in the cases of 1,2,3-, 1,3,5-, and 1,2,4-trimethylbenzenes, respectively. d) Standard spectrum of *trans*-3-hexene-2,5-dione. e) Difference spectrum of c)−d).

Although no further products except 3-hexene-2,5-dione could be identified in the residual spectra, remaining of C-H stretching vibrations (2850—3010 cm^{-1}), strong absorption around 1700 cm^{-1}, and numerous bands in the region of skeletal vibrations (800—1400 cm^{-1}), suggests the presence of unsaturated γ-dicarbonyls (shown in Table 2 and Scheme 1) in considerable amounts. No unique products of the trimethylbenzenes could be identified.

D. General Conclusions: The Photooxidations of Aromatic Hydrocarbons. This study of eight aromatic hydrocarbons (benzene, toluene, *o*-, *m*-, and *p*-xylenes, 1,2,3-, 1,2,4-, and 1,3,5-trimethylbenzenes) and the conclusions drawn from it may be summarized as follows:

1) Products formed by the ring-cleavage reaction in the photooxidation of aromatic hydrocarbons were analyzed by long-path FT-IR spectroscopy. The advantage of this technique is that products can be observed *in situ*, without the sampling and preconcentration processes which are needed generally in GC and GC/MS analysis. The FT-IR is particularly useful for the quantitative analysis of α-dicarbonyls which cannot be analyzed with reasonable sensitivity by GC even with flame ionization detection.[11] Therefore, reliable yields of α-dicarbonyls were determined for the first time in the present study.

2) The α-dicarbonyls observed in the photooxidation of aromatic hydrocarbons are glyoxal, methylglyoxal, and biacetyl. The relative yields of these products can be explained by a cyclization mechanism of OH-aromatics-O_2 adducts, and cleavage of 6,7-dioxabicyclo[3.2.1]octane compounds. It is suggested that an α-dicarbonyl and an unsaturated γ-dicarbonyl are produced in this process.

3) 3-Hexene-2,5-dione was observed as an unsaturated γ-dicarbonyl in the photooxidation of *p*-xylene and 1,2,4-trimethylbenzene. Formation of maleic anhydride observed in the photooxidation of benzene, toluene, and *o*-xylene is considered as an indirect evidence of the formation of *cis*-2-butenedial (an unsaturated γ-dicarbonyl). Other unsaturated γ-dicarbonyls could not be identified.

4) The fractions of the ring-cleavage process are: 15—20% (benzene); 29% (toluene); 36% (*p*-xylene); 41% (*o*-xylene); 55% (*m*-xylene); 56% (1,2,4-trimethylbenzene); 64% (1,3,5-trimethylbenzene); and 70% (1,2,3-trimethylbenzene). It is suggested that the extent of ring cleavage is governed by the reactivity to electrophilic attack of the OH-aromatics-O_2 adduct, and by the distortion energy of the resulting 6,7-dioxabicyclo[3.2.1]octane compound.

5) Since the formation of fairly large amounts of α- and unsaturated γ-dicarbonyls are expected in the urban atmosphere, studies of the mechanisms of both photolysis and photooxidation of α- and γ-dicar-

bonyls are necessary to develop the chemical models of photochemical air pollution, although the rate constants of the photolysis and OH radical reactions of α-dicarbonyls[14] and 3-hexene-2,5-diones[13] were reported recently.

Throughout this series of investigations, the authors wish to thank Prof. U. Schurath of University of Bonn in Germany and Dr. C. J. Howard of National Oceanic and Atmospheric Administration for helpful suggestions and discussions. We also thank Dr. S. Hatakeyama in our laboratory for helpful discussions. The assistance of H. Takagi in the early stage of this work is gratefully acknowledged.

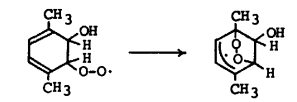
10) Assuming that the probability of forming the 6,7-dioxabicyclo[3.2.1]octane compound increases when the -O-O· attacks the carbon at the ipso position [Assumption IV], the yield of the bicyclo[3.2.1] compound should increase in the cases of *m*-xylene and 1,3,5-trimethylbenzene. For example, in the cases of *o*-, *m*-, and *p*-xylene, the total yield of α-dicarbonyls can be explained if the ratio of the rate of Reactions A to B is 8:1. In the case of *p*-xylene:



ipso attack (A)

(B)

On this assumption (A:B=8:1), the ratio of the calculated yield of each α-dicarbonyl (Table 2 in paper II and Table 2 in paper III) according to the ring-cleavage mechanism shown in Scheme 1 in paper II and III would vary not more than 10—20%.

Effect of Methyl Substitution in 1,2-Ethanediaminenickel(II) Complexes upon Their Thermal Stabilities

Ryokichi Tsuchiya,† Akira Uehara,* Masatatsu Suzuki, and Akira Matsuda
Department of Chemistry, Faculty of Science, Kanazawa University, Kanazawa 920
†*Kanazawa Women's Junior College, Kanazawa 920*
(Received November 10, 1984)

The enthalpy changes (ΔH) in the reaction of three types of the nickel(II) complexes, $[Ni(AA)_2(H_2O)_2]X_2 \cdot nH_2O$, $[NiX_2(AA)_2]$, and $[Ni(AA)_2]X_2$, with aqueous potassium cyanide solution were calorimetrically measured at 25 °C, where AA denotes a diamine selected from 1,2-ethanediamine (en), *N*-methyl-1,2-ethanediamine (*N*-men), *N,N*-dimethyl-1,2-ethanediamine (*NN*-dmen), *N,N'*-dimethyl-1,2-ethanediamine (*NN'*-dmen), and *N,N,N'*-trimethyl-1,2-ethanediamine (*NNN'*-tmen); X is Cl, Br, I, NO_3, or ClO_4; n=0, 2, or 3. The thermal stabilities of the complexes in the solid state defined by the enthalpy changes (not by the free energy changes) were compared with one another, so that the thermal stabilities of the complexes are highly dependent on numbers and/or positions of *N*-methyl groups on diamines. In the series of $[NiX_2(AA)_2]$ and $[Ni(AA)_2]X_2$ type complexes, the *NN'*-dmen complexes are the most stable. Except for the *NN'*-dmen complexes, as the numbers of *N*-methyl group(s) contained in the diamines increase, the complexes have the tendency to become less stable. The relative thermal stabilities of the present complexes were discussed in terms of the basicities of diamines and steric effect of *N*-methyl groups.

We have systematically studied the structural and thermochemical changes in the course of the solid phase thermal reactions of the nickel(II) complexes containing a variety of diamines.[1] In the preceding paper, the relative thermal stabilites of the octahedral and square planar nickel(II) complexes containing *N,N*- and *N,N'*-diethyl-1,2-ethanediamines were discussed on the basis of their calorimetric data.[2]

In the present study, our interest is focused on the information on the relative thermal stabilities of the nickel(II) complexes containing *N*-methyl, *N,N*(or *N,N'*)-dimethyl, and *N,N,N'*-trimethyl substituted diamines. The diamines selected are 1,2-ethanediamine (en), *N*-methyl-1,2-ethanediamine (*N*-men), *N,N*-dimethyl-1,2-ethanediamine (*NN*-dmen), *N,N'*-dimethyl-1,2-ethanediamine (*NN'*-dmen), and *N,N,N'*-trimethyl-1,2-ethanediamine (*NNN'*-tmen). The enthalpy changes for the following reactions were also estimated; the dehydration ($[Ni(AA)_2(H_2O)_2]X_2 \cdot nH_2O \rightarrow [Ni(AA)_2(H_2O)_2]X_2 + nH_2O$), the dissociation ($[Ni(AA)_2(H_2O)_2]X_2 \rightarrow [Ni(AA)_2]X_2 + 2H_2O$), and the deaquation anation ($[Ni(AA)_2(H_2O)_2]X_2 \rightarrow [NiX_2(AA)_2] + 2H_2O$).

Experimental

Preparation of Complexes. The en,[3] *N*-men, *NN*-dmen, *NN'*-dmen and *NNN'*-tmen[4] complexes were prepared by the known methods or a slight modification thereof, if necessary.

Calorimetric Measurements. In order to discuss the difference in the thermal stabilities of these complexes, the enthalpy changes (ΔH) for the reactions of the accurately weighed complexes in the range of order of 1×10^{-4} mol in the powder state with 100 dm^{-3} of aqueous potassium cyanide solution of 6×10^{-2} mol dm^{-3} were measured with Tokyo Riko TIC-2S isoperibol calorimeter at 25 °C. Three or more measurements were carried out every one sample, and three values within ±0.5 kJ mol^{-1} were averaged. In these reactions, $[Ni(CN)_4]^{2-}$ is formed. The formation constant of $[Ni(CN)_4]^{2-}$(aq) is 31.3 (25 °C)[5], the concentration of Ni^{2+}(aq) remained being calculated to be in the order of 10^{-27} mol dm^{-3}, so that the reactions were concluded to take place completely.

Results and Discussion

Thermal Stability in the en Complexes. Table 1 summarizes the enthalpy changes for the bis(en), bis(*N*-men), bis(*NN*-dmen), bis(*NN'*-dmen) and bis(*NNN'*-tmen) nickel(II) complexes measured. The enthalpy changes for the reaction of $[Ni(en)_2(H_2O)_2]X_2$ (X=NO_3, I, and ClO_4) with aqueous potassium cyanide solution are given as below,

$$[Ni(en)_2(H_2O)_2]X_2(s) + 4CN^-(aq) = Ni(CN)_4^{2-}(aq) + 2en(aq) + 2X^-(aq) + 2H_2O(l),$$

where ΔH=−58.6 kJ mol^{-1} for X=NO_3, ΔH=−60.8 kJ mol^{-1} for X=I and ΔH=−63.4 kJ mol^{-1} for X=ClO_4. By combining the above values with the hydration enthalpies of the respective anions, ΔH_x for the reactions of $X^-(g)=X^-(aq)$ (Table 2),[6] the enthalpy changes for the exchange reaction of anions,

$$[Ni(en)_2(H_2O)_2](NO_3)_2(s) + 2X^-(g) = [Ni(en)_2(H_2O)_2]X_2(s) + 2NO_3^-(g),$$

are calculated. The values thus obtained are 61 kJ mol^{-1} for $X^-=I^-$ and 172 kJ mol^{-1} for $X^-=ClO_4^-$. As was mentioned before, the above enthalpy changes correspond to the difference in the lattice energy between the nitrate and iodide, and between the nitrate and perchlorate, respectively. These results reflect that the iodide and perchlorate are thermally less stable than the nitrate.

The enthalpy changes for the substitution reaction

of the dianiono complexes,

$$[Ni(en)_2Cl_2](s) + 2X^-(g) = [NiX_2(en)_2](s) + 2Cl^-(g),$$

were obtained as ΔH=58 kJ mol^{-1} for X^-=Br^-, ΔH=60 kJ mol^{-1} for X^-=NO_3^-, and ΔH=110 kJ mol^{-1} for X^-=I^-, by using the enthalpy data measured (Table 1) for the octahedral dianiono complexes, $[NiX_2(en)_2]$, where X^- is Cl^-, Br^-, NO_3^-, or I^-, and the ΔH_x values listed in Table 2. These values correspond to the decrements in lattice energies of the dibromo, dinitrato, and diiodo complexes as compared with that of dichloro complex.

From the above enthalpy data, the diagram of enthalpy level for the en complexes can be illustrated as seen in Fig. 1. It is obvious from the figure that the thermal stability decreases in the order, nitrate> iodide>perchlorate in the diaqua series, and dichloro> dibromo>dinitrato>diiodo in the aniono series.

The enthalpy changes for the deaquation-anation,

$$[Ni(en)_2(H_2O)_2]X_2(s) = [NiX_2(en)_2](s) + 2H_2O(g),$$

are also given in Fig. 1. The values were estimated to be ΔH=112 kJ mol^{-1} for X=NO_3 and ΔH=101 kJ mol^{-1} for X=I by combining the heat of vaporization

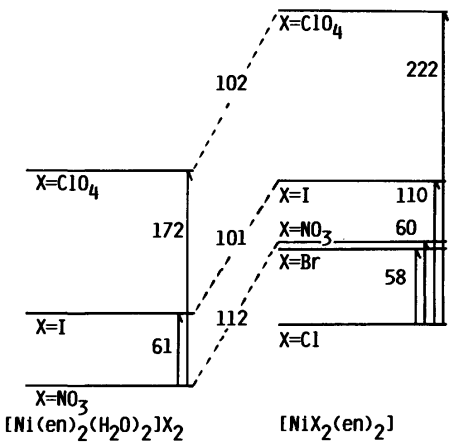

Fig. 1. Enthalpy level diagram for Ni(II)–en complexes (kJ mol^{-1}).

of water, ΔH=44.2 kJ mol^{-1}[17] with the enthalpy data concerned (Table 1). The dissociation enthalpy for the reaction,

$$[Ni(en)_2(H_2O)_2](ClO_4)_2(s) = [Ni(en)_2](ClO_4)_2(s) + 2H_2O(g), \quad \Delta H = 102 \text{ kJ mol}^{-1}$$

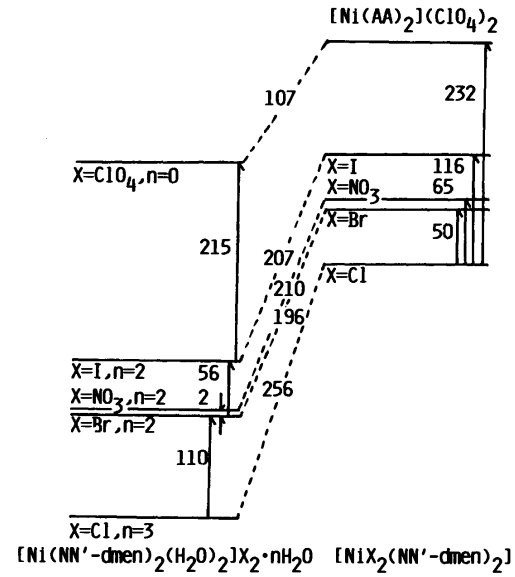

Fig. 4. Enthalpy level diagram for Ni(II)–*NN'*-dmen complexes (kJ mol^{-1}).

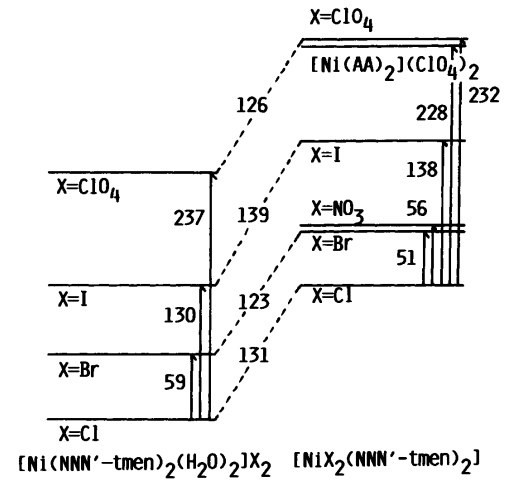

Fig. 5. Enthalpy level diagram for Ni(II)–*NNN'*-tmen complexes (kJ mol^{-1}).

is also shown in Fig. 1.

Thermal Stability in the N-*men Complexes.* The enthalpy changes for the substitutions of counter anion and of aniono ligand, the dehydration, the deaquation-anation, and the dissociation of the *N*-men complexes were calculated in a manner similar to that carried out for the en complexes. The enthalpy level diagram thus obtained is represented in Fig. 2. The figure exhibits that [Ni(*N*-men)$_2$(H$_2$O)$_2$]X$_2$·*n*H$_2$O become thermally less stable in the order, chloride dihydrate>bromide dihydrate (*n*=2), and chloride>bromide>nitrate>iodide> perchlorate (*n*=0); the thermal stabilities of [Ni(*N*-men)$_2$X$_2$] decrease in the order, dichloro>dibromo >dinitrato>diiodo complexes.

Thermal Stability in the NN-*dmen,* NN'-*dmen, and* NNN'-*tmen Complexes.* In the same way as that shown in the *N*-men complexes, the enthalpy level diagrams of the *NN*- and *NN'*-dmen, and *NNN'*-tmen complexes are obtained, which are represented in Figs. 3, 4, and 5, respectively. These figures indicate that the thermal stabilities decrease in the order, chloride>bromide>nitrate>iodide in the diaqua series, and dichloro>dibromo>dinitrato>diiodo in the aniono series except for *NN*-dmen complexes, which are consistent with the orders of the stability

appearing in the *N*-men complexes. The orders of decrement in lattice energy observed in the diaqua and dianiono complexes are parallel to the increasing order of the anionic radii.[8]

Influence of Numbers of N-*Methyl Groups upon Thermal Stability.* The relative thermal stabilities of a series of $[Ni(AA)_2(H_2O)_2]X_2$ can be estimated by comparing the enthalpy changes for the following substitution reaction of diamines:

$$[Ni(AA)_2(H_2O)_2]X_2(s) + 2AA'(g) = [Ni(AA')_2(H_2O)_2]X_2(s) + 2AA(g)$$

For example, the enthalpy change (ΔH) for the reaction,

$$[Ni(en)_2(H_2O)_2](NO_3)_2(s) + 2N\text{-men}(g) = [Ni(N\text{-men})_2(H_2O)_2](NO_3)_2(s) + 2en(g)$$

Table 3. The heats of dissolution of the diamines in aqueous potassium cyanide solution (/kJ mol^{-1})

en	*N*-men	*NN'*-dmen	*NN*-dmen	*NNN'*-tmen
−30.4	−32.9	−45.0	−40.6	−43.8

was calculated as -0.3 kJ mol^{-1} by using the following equation,

$$\Delta H = \Delta H_1 - \Delta H_2 - \Delta H_{en} + \Delta H_{N\text{-men}},$$

where ΔH_1 and ΔH_2 are the enthalpy changes for the following reactions, respectively (Table 1):

$$[Ni(en)_2(H_2O)_2](NO_3)_2(s) + 4CN^-(aq) = Ni(CN)_4^{2-}(aq) + 2en(aq) + 2NO_3^-(aq) + 2H_2O(l) \cdots \Delta H_1$$

$$[Ni(N\text{-men})_2(H_2O)_2](NO_3)_2(s) + 4CN^-(aq) = Ni(CN)_4^{2-}(aq) + 2N\text{-men}(aq) + 2NO_3^-(aq) + 2H_2O(l) \cdots \Delta H_2,$$

and ΔH_{en} and $\Delta H_{N\text{-men}}$ are the heats for the reactions of en(g)=en(aq) and *N*-men(g)=*N*-men(aq), respectively (Table 2). The same procedures as those described above were employed for the calculation of the corresponding enthalpy changes for the reactions of the *NN*-dmen, *NN'*-dmen and *NNN'*-tmen complexes. In these calculations, the enthalpy changes for the reaction of AA(g)=AA(aq) in the various diamine systems should be referred. These values were calculated from the heats of vaporization and the heats of solution. The former heats were estimated from the Trouton's constant and the

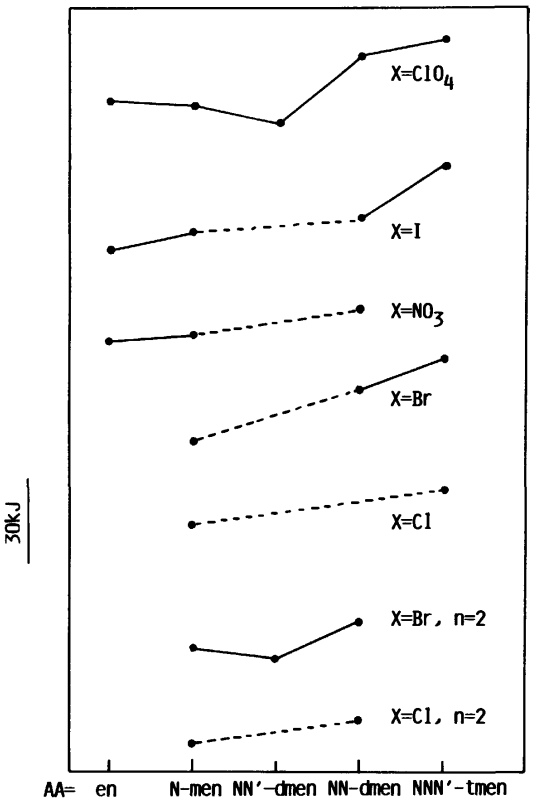

Fig. 6. Enthalpy change diagrams depending upon the displacement of diamines for $[Ni(AA)_2(H_2O)_2]X_2 \cdot nH_2O$ type complexes. The lines to which *n* values are not given are referred to the anhydrates.

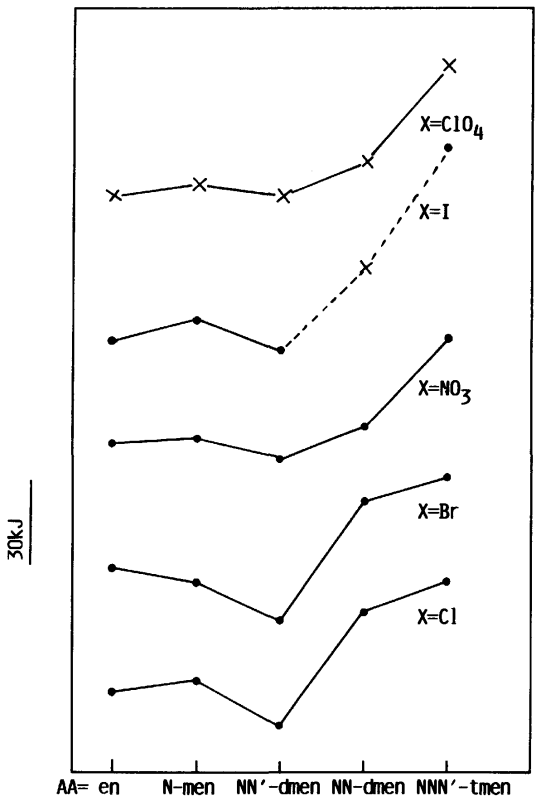

Fig. 7. Enthalpy change diagrams depending upon the displacement of diamines for $[NiX_2(AA)_2]$ (--●--) and $[Ni(AA)_2]X_2$ (--×--) type complexes.

boiling points of diamines within about 5% errors. The latter heats were measured in the concentration of diamine similar to that liberated by the reaction of complexes with CN^- solution. These data measured are listed in Table 3.

Additionally, the enthalpy changes for the substitution reactions of diamines in $[NiX_2(AA)_2]$ and $[Ni(AA)_2]X_2$ were estimated from the data obtained above. The enthalpy change diagrams for $[Ni(AA)_2(H_2O)_2]X_2 \cdot nH_2O$ are depicted in Fig. 6, and those for $[NiX_2(AA)_2]$ and $[Ni(AA)_2]X_2$, in Fig. 7.

The most striking feature is that, in the series of $[NiX_2(AA)_2]$ and $[Ni(AA)_2]X_2$ type complexes, the *NN'*-dmen complexes are the most stable as can be seen in Fig. 7. Except for the *NN'*-dmen complexes, as the number of *N*-methyl groups on diamines increases, the relative thermal stabilities of the complexes generally decrease: namely the complexes become unstable in the order of the en, *N*-men, *NN*-dmen, *NNN'*-tmen complexes (Figs. 6 and 7). This may be partly attributable to an increase of steric repulsion between *N*-methyl groups and the ligands in the apical positions. In the *N*-methyl substituted en complexes, the orientation of methyl group(s) is expected to have an significant influence on the thermal stability of the complexes. In the *NN'*-dmen complexes, two methyl groups are equatorial with respect to the N_4 plane. On the other hand, the *NN*-dmen and *NNN'*-tmen complexes have at least one axial methyl group, which causes a stronger steric repulsion with the ligands in the apical positions than equatorial methyl group and makes the complexes less stable.

The stability of the complexes in the solid state would be mainly dependent not only on the steric interaction but also on the size and shape of the complex cation and the basicity of diamines. In fact, as the numbers of *N*-methyl groups increase, the size of complex cations becomes larger, leading the complexes less stable in the order, en>*N*-men *NN*-dmen>*NNN'*-tmen complexes. This is in line with the results observed in the effect arising from variation of anion size.

So far as the order of the thermal stability between *N*-men and *NN'*-dmen complexes is concerned, however, the interpretation is not so clear only from the steric factor. It has been shown that the formation constant of nickel(II)-*N*-men complex in aqueous solution is larger than that of nickel(II)-*NN'*-dmen complex.[9] In general, the stronger the basicity of the ligand is, the more stable the complex becomes, if no steric hindrance is present within the complex, and the basicity of *N*-men is known to be larger than that of *NN'*-dmen.[10] The observed order of the stabilities between *N*-men and *NN'*-dmen complexes, therefore, is not in harmony with that expected from the formation constant and basicity arguments. In spite of the above discussions, the interpretation on the difference of the thermal stabilities between *N*-men and *NN'*-dmen complexes is not so clear.

The Stereochemistry of the Six Geometrical Isomers of the Bis(ethylenediamine-*N*-acetato)cobalt(III) Ion, $[Co(edma)_2]^{+}$[1)]

Tomoharu AMA,* Hiroshi KAWAGUCHI, Takaji YASUI, Keiji MATSUMOTO,† and Shun'ichiro OOI†

Department of Chemistry, Faculty of Science, Kochi University, Akebono-cho, Kochi 780
†*Department of Chemistry, Faculty of Science, Osaka City University, Sumiyoshi-ku, Osaka 558*
(Received December 19, 1984)

All of the six geometrical isomers possible in $[Co(edma)_2]^+$ (edma: ethylenediamine-*N*-acetate) were isolated, and the five chiral isomers were resolved into optically active isomers by a column-chromatographic method. Their structures were determined on the basis of the X-ray analysis and the visible absorption, ^1H NMR, and CD spectral data. One of the methylene protons in the glycinate-ring of the facially coordinating edma is stereospecifically exchanged by a deuteron in the basic D_2O solution, and its deuteration rate is influenced by the ligating atoms in the *trans* position. A ^1H NMR method to determine the absolute configurations of the optically active isomers, which contain the stereospecifically deuterated edma, is reported and applied to the $[Co(edma)_2]^+$ systems. The relationship between the absolute configurations and the CD spectral behaviors of these complexes is also discussed.

The ethylenediamine-*N*-acetate anion ($NH_2CH_2CH_2NHCH_2COO^-$: edma) is a terdentate ligand of the N-N-O type. The [Co(N-N-O)$_2$]-type complex provides six geometrical isomers (Fig. 1). Although there have been several reports on this type of complex,[2-7] there have been only a few reports which have dealt with all of the six isomers.[1] In a previous letter[1] we reported the preparation and tentative assignments of the six geometrical isomers for the [Co(edma)$_2$]X complex. In order to confirm these assignments, we have now determined the structure (and the absolute configuration) of one of the isomers by means of X-ray analysis.

It was found that one of the methylene protons in the glycinate-ring of the facially coordinating edma was stereospecifically deuterated in a basic D_2O solution. Optically active edma ($NH_2CH_2CH_2NHC^*HDCOO^-$) was obtained from a stereospecifically deuterated, optically active $[Co(edma)_2]^+$. Further, the isomers of $[Co(edma)_2]^+$, which contain this deuterated edma, were used to determine the absolute configurations on the basis of the ^1H NMR data. In the present paper, this ^1H NMR method to determine the absolute configuration of the complex will be discussed in detail. In addition, the relationship between the absolute configuration and the CD spectral behavior will be discussed.

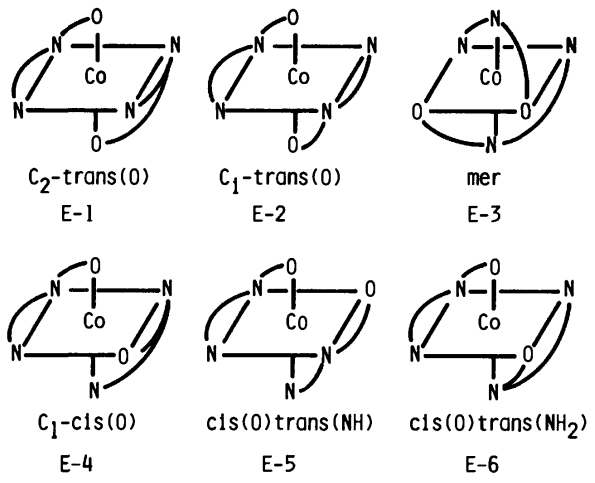

Fig. 1. The six geometrical isomers of the $[Co(edma)_2]^+$ ion.

Experimental

Preparation and Separation of the Isomers of the $[Co(edma)_2]^+$ Ion. The previously reported method[1] was modified for the preparation of the complexes. A solution containing 10 g of ethylenediamine-*N*-acetic acid dihydrochloride dihydrate (Hedma·2HCl·2H$_2$O) in 50 ml of water and solution containing 4.75 g of $CoCl_2 \cdot 6H_2O$ in 30 ml of water were separately passed through an anion-exchange resin (Dowex 1×8, ClO_4^- form) column to convert the chloride ions to perchlorate ions, and then the two solutions were combined. The pH of the combined solution was adjusted to 6—7 with 1 mol dm^{-3} NaOH solution. Lead dioxide (9.0 g) was stirred into the solution in small portions at 50 °C over a 1-h period, the pH of the solution being held at about 6.5. After the insoluble material had then been removed by filtration, the filtrate was charged on an SP-Sephadex column (K^+ form). The adsorbed band was developed by the method described in the previous paper[1] (eluent: 0.1 mol dm^{-3} KCl solution).

The method of preparing the [Co(edma)$_2$]Cl described above (PbO_2-oxidation in a weakly acidic solution) gave better overall yields, especially for E-5 and -6, than the method using $Na_3[Co(CO_3)_3] \cdot 3H_2O$[8] as the starting material (carbonato method[1]). (Under basic conditions, the PbO_2-oxidation method gave low yields for E-3, -5, and -6.)

All of the isomers except for E-2 (the achiral isomer) were optically resolved by the chromatographic method described in the previous paper[1] (eluent: 0.05 mol dm^{-3} K_2Sb_2-(d-tart)$_2$ aqueous solution). The formulas of the optically active complexes (faster eluted isomers) finally obtained are

as follows: $(-)^{CD}_{543}$E-1: $[Co(edma)_2]ClO_4$; $(-)^{CD}_{504}$E-3: $[Co(edma)_2]$-Br; $(+)^{CD}_{534}$E-4: $[Co(edma)_2]Cl\cdot 2H_2O$; $(-)^{CD}_{521}$E-5: $[Co(edma)_2]$-Br; $(+)^{CD}_{509}$E-6: $[Co(edma)_2]Cl\cdot 1.5H_2O$.

The $(-)^{CD}_{521}$E-5 (bromide salt) isomer was converted to a perchlorate salt using QAE-Sephadex (ClO_4^- form) to obtain single crystals suitable for X-ray analysis.

X-Ray Analysis of $(-)^{CD}_{521}$*-[Co(edma)$_2$]ClO$_4\cdot 2H_2O$ (E-5).* *Crystal Data*: Monoclinic, space group $P2_1$, a=11.530(2), b=11.157(2), c=6.489(1) Å, β=96.83(1)°, D_m=1.70 g cm^{-3}, Z=2, D_c=1.72 g cm^{-3}, μ(Mo $K\alpha$)=13.0 cm^{-1}. The unit-cell dimensions were determined from a least-squares analysis of 24 θ values of higher angle reflections (θ=8—14°), as measured on an automated diffractometer by the use of graphite-monochromated Mo $K\alpha$ radiation.

The intensity data ($2\theta<50°$) were collected on the diffractometer by means of the ω-scan method with Mo $K\alpha$ radiation (scan speed, 0.033° s^{-1}; scan width, (1.0+0.4 tan θ)°; background measurement, 10 s at each end of the scan; crystal size, 0.15×0.17×0.15 mm). Of the 1552 independent reflections measured, 1371 with $I>3\sigma(I)$ were used for the structure analysis. No correction was made for absorption.

The crystal structure was solved by the heavy-atom technique. The positional and thermal parameters were refined by the block-diagonal-matrix least-squares method. The minimized function was $\sum w(|F_o|-|F_c|)^2$, where $w=\sigma(F_o)^{-2}$. The large temperature factors found for the O atoms of the ClO_4^- ion were indicative of a disorder of the ion; therefore, the 4 O atoms were treated, in the subsequent least-squares calculation, as a rigid group in which the O atoms lie at the apices of the regular tetrahedron, with a Cl···O distance of 1.426 Å.[9] The parameters of the Cl atom were allowed to vary independently from those of the 4 O atoms.

The atomic scattering factors, with correction for the anomalous dispersion effect for Co and Cl atoms, were taken from Ref. 10. The convergence was attained with R 0.071 and R' ($=[\sum w\Delta F^2/\sum wF_o^2]^{1/2}$) 0.100, whereas R and R' at convergence were 0.070 and 0.098 respectively for the inverted structure. All the parameter shifts in the final cycle of the refinement for either structure were $<0.2\sigma$. The absolute crystal structure was determined by means of the Bijvoet method. Table 1 shows several Bijvoet pairs, which showed a remarkable intensity difference on the Weissenberg photographs taken with Cu $K\alpha$ radiation. The inequality relationship between the intensities of the Bijvoet pair agrees well with that between $|F_c(hkl)|^2$ and $|F_c(h\bar{k}l)|^2$ calculated on the basis of the atomic coordinates (the inverted structure) listed in Table 2. The observed and calculated structure factors, thermal parameters, bond lengths and angles (Table 3), and the projection of the crystal structure along the b axis are preserved by the Chemical Society of Japan (Document No. 8532). The computation was carried out on an ACOS 900 computer at the Crystallographic Research Center, Institute of Protein Research, Osaka University, and a FACOM M180 computer at Osaka City University. The computer programs used were as follows: UNICS,[11] ORTEP,[12] and ORFLS.[13]

Spectral Measurements. The ^{1}H NMR spectra were recorded on a JEOL MH-100 spectrometer, with DSS as the internal standard in D_2O. The visible and UV absorption spectra were recorded on a HITACHI 557 spectrophotometer, while the circular dichroism (CD) spectra were recorded on a JASCO J-22 spectropolarimeter in an aqueous solution.

Measurements of the Deuteration Rate of the G-ring. In order to measure the H-D exchange rate (deuteration rate) of the glycinate-ring (G-ring) $-CH_2-$ in the coordinating

Bond lengths and angles in the ClO_4^-:
Cl–O = 1.38 – 1.43(2) Å
O–Cl–O = 106 – 112(2)°

edma, an equivolume mixture of 0.1 mol dm^{-3} Na_2CO_3–D_2O and 0.1 mol dm^{-3} $NaDCO_3$–D_2O was used as the solvent; the $-CH_2-$ signals were recorded at prescribed intervals on a ^{1}H NMR spectrometer at 40 °C.

Determination of the Absolute Configuration of the Complexes by ^{1}H NMR. A buffer solution (pH 10) was prepared by adding proper amount of 2 mol dm^{-3} DCl–D_2O to a solution containing 106 mg Na_2CO_3 in 10 cm^3 of D_2O. About 100 mg of $(+)^{CD}_{521}$E-5 was dissolved into the buffer solution, and the temperature of the solution was kept at 40 °C. The deuteration of the G-ring $-CH_2-$ was checked by means of ^{1}H NMR measurements. When the singlet peak arising from the G-ring $-C\underline{H}D-$ increased in intensity in comparison with the AB quartet arising from the G-ring $-CH_2-$ (about 4 h), the solution was acidified to pH 6 with 1 mol dm^{-3} HCl to stop the deuteration reaction. The volume of the solution was adjusted to 20 cm^3 with water, and zinc powder (2 g) was added to the solution. After stirring for 5 min at room temperature, the excess of zinc was filtered off. To the filtrate, 1.5 g of PbO_2 was added, and then the mixture was stirred for 15 min at room temperature. After the solution had been filtered, the filtrate was poured into an SP-Sephadex column (Na^+ form, 2.7 cm×50 cm); then the adsorbed complexes were eluted with a 0.2 mol dm^{-3} NaCl solution. The earlier-eluted band (E-1 and -2) was transferred to another SP-Sephadex column (Na^+ form, 2.7 cm×60 cm) and developed with a 0.1 mol dm^{-3} Na_2Sb_2(d-tart)$_2$ solution by the recycle chromatographic method. The band separated into three bands: red ($(-)^{CD}_{543}$E-1), orange (E-2), and red ($(+)^{CD}_{543}$E-1). Each band of the E-1 enantiomers was once more transferred to another SP-Sephadex column, washed with 1 dm^3 of water, and then eluted out with a 0.2 mol dm^{-3} $NaClO_4$ solution. The eluate was evaporated almost to dryness under reduced pressure, and then 50 cm^3 of ethanol was added to the concentrate to obtain red-orange crystals. The ^{1}H NMR spectra of the E-1 enantiomers are illustrated in Fig. 2.

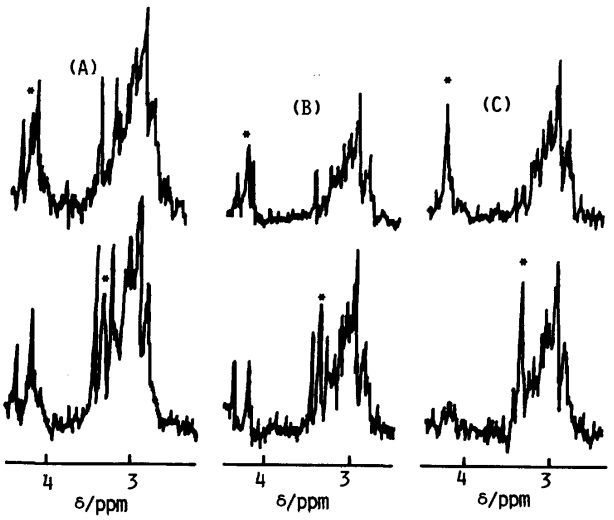

Fig. 2. ^{1}H NMR spectra of $(-)^{CD}_{543}$ and $(+)^{CD}_{543}$E-1 obtained from the deuterated $(+)^{CD}_{534}$E-4, $(+)^{CD}_{521}$E-5, and $(+)^{CD}_{509}$E-6 isomers. Upper: $(-)^{CD}_{543}$E-1. Lower: $(+)^{CD}_{543}$E-1. (A) from $(+)^{CD}_{534}$E-4, (B) from $(+)^{CD}_{521}$E-5, and (C) from $(+)^{CD}_{509}$E-6. (Asterisked peaks: G-ring $-C\underline{H}D-$).

Similarly, the deuterated E-1 enantiomers were obtained from the optically active deuterated E-4 and E-6 isomers. Their ^{1}H NMR spectra are also shown in Fig. 2.

Results and Discussion

Assignments of the Geometrical Isomers. The structural assignments for the six isomers, given in our previous report,[1] are shown in Fig. 1. Although the structures of E-1, -2, -3, and -4 were assigned on the basis of unambiguous evidence, some uncertainty remained as to the tentative assignments for E-5 and -6; E-5 is either *cis*(O)*trans*(NH_2) or *cis*(O)*trans*(NH). The X-ray study which will be shown below revealed that E-5 is *cis*(O)*trans*(NH). (Consequently, E-6 is assigned to *cis*(O)*trans*(NH_2)).

Crystal Structure of $(-)^{CD}_{521}$-[Co(edma)$_2$]$ClO_4 \cdot 2H_2O$ (E-5). Figure 3 shows the absolute configuration of the $(-)^{CD}_{521}$-isomer of E-5. This complex has a distorted octahedral coordination, with two O atoms in the *cis* positions and two secondary N atoms in the *trans* positions: *cis*(O)*trans*(NH). The complex cation has an approximate two-fold axis running through the Co atom and the mid point of the O···O edge. Each coordinating edma contains an asymmet-

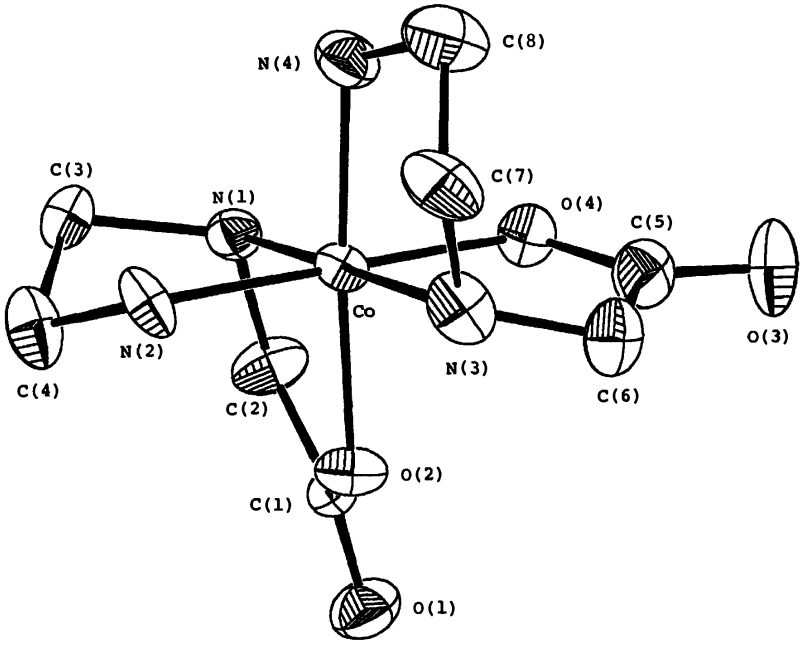

Fig. 3. The structure and absolute configuration of $(-)^{CD}_{\delta\lambda\delta}$E-5 $[Co(edma)_2]^+$ ion in its perchlorate dihydrate crystal.

ric nitrogen whose chirality is *R*. The conformation of the ethylenediamine ring is δ. By modifying the conventional nomenclature,[14] the absolute configuration of this isomer is represented as $\Delta(GG)\Lambda(EE)$ in this paper, where G and E represent the glycinate-ring and the ethylenediamine-ring respectively.

The average Co-N (primary N) and Co-N (secondary N) bond lengths are nearly equal to those found in *u-fac* and *s-fac* $[Co(dien)_2]^{3+}$,[15,16] while the average Co-O bond length is nearly equal to that in $[Co(ida)_2]^-$.[17]

^1H NMR. Table 4 shows the ^1H NMR data of the glycinate methylene protons in the six isomers of the $[Co(edma)_2]^+$ ion. The methylene protons of the G-rings in E-1, -2, -4, -5, and -6, which contain the facially coordinating edma's, appeared as the AB quartet signals. On the other hand, those in E-3 with the meridionally coordinating edma's appeared as a singlet-like signal (slightly splitting) because of a slight difference in chemical shift between the two methylene protons. Such a singlet-like signal has also been observed for the meridionally chelated ring (in-plane G-ring methylenes) of edda in the β-$[Co(edda)(ch)]^{\pm}$ (where ch is ox, mal, or en) ions.[18] The coupling constant of the glycinate geminal protons in the meridionally coordinating edma is 16 Hz, and those in the facially coordinating edma are 18 Hz (Table 4); these findings are consistent with the results of the previous papers.[19-22]

The ^1H-NMR spectra of the facial isomers (E-1, -2, -4, -5, and -6) were measured in 0.5 mol dm^{-3} DCl-D_2O solutions. The ^1H NMR signal of each G-ring in these isomers splits into eight peaks as a result of the $J_{Ha,Hb}$, $J_{N-H,Ha}$, and $J_{N-H,Hb}$ couplings (Fig. 4(A)). The $J_{N-H,Hb}$ and $J_{N-H,Ha}$ values are *ca.* 8 Hz's (lower fields) and 1 Hz's (higher fields) respectively. On the basis of the Karplus equation,[23] the following assignments are possible: the dihedral angles of the protons resonating at higher fields (H-C-N-H) are about 90°, and the protons can be assigned to H_a (inside; Fig. 4 (A)). The angles of the protons (which are assigned to H_b (outside)) resonating at lower fields are about 30°. Similar assignments for the G-ring methylene protons have been made by Legg and Cooke[27] and Schoenberg *et al.*[28] for the edda-Co(III) complexes.

It is known that the methylene protons of the

(A): undeuterated, (B): deuterated, and (C) and (C'): reprepared by oxidizing the reduction product of (B) (See Experimental).

chelating glycinate are deuterated in a basic D_2O solution.[18,21-26] The G-ring methylene protons in the facially coordinated edma are also deuterated; this fact is confirmed from the intensity loss of the AB quartet peaks (Fig. 5). The deuteration occurs stereospecifically in all of the facial isomers; a new singlet appeared between the two higher-field peaks of the AB quartet, with an intensity loss of the AB quartet. In other words, the deuteration rates are different between the two protons; the deuteration of the higher-field proton is much slower than that of the lower-field one. (The new singlet signal disappeared after a long period). Sudmeier and Occupati[26] pointed out that the rate of the deuteration of the inside proton of the facial G-ring is slower than that of the outside proton for the edda-Co(III) complexes. The application of this result to the *fac*-$[Co(edma)_2]^+$ system leads to the conclusion that the two lower-field peaks of the AB quartet arise from the outside proton, which is easily deuterated, while the two higher-field peaks arise from the inside proton (Fig. 4 (B)). These assignments are consistent with those made by the Karplus equation mentioned above.

In a previous paper,[29] we reported that the deuteration rate of the G-ring methylene protons out of the O-Co-O plane which is present in C_1- or C_2-*cis*(*O*)-$[Co(gly)_2(en)]^+$ is smaller than that of the G-ring methylene protons in the O-Co-O plane which is present in C_1-*cis*(*O*)-$[Co(gly)_2(en)]^+$ and that of the G-ring methylene in *trans*(*O*)-$[Co(gly)_2(en)]^+$.

The deuteration rates of the six isomers were measured under the same conditions (40 °C; dissolved in an equivolume mixture of 0.1 mol dm^{-3} Na_2CO_3-D_2O and 0.1 mol dm^{-3} $NaDCO_3$-D_2O). The

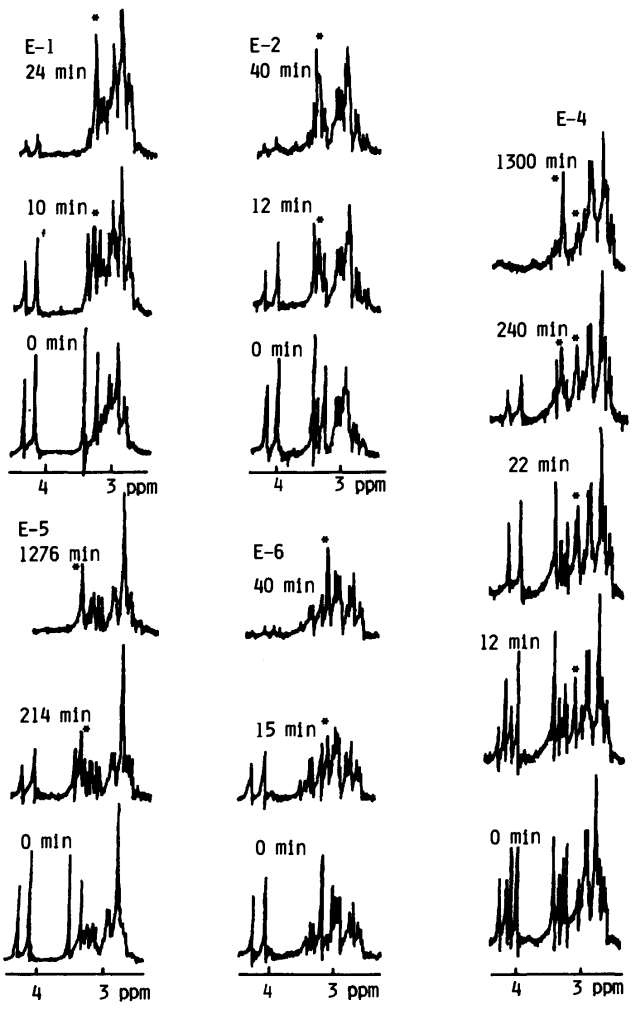

Fig. 5. Changes in ^1H NMR spectra of $[Co(edma)_2]^+$ in basic D_2O solutions. (Asterisked peaks: G-ring -CHD-).

order of the deuteration rates are as follows: C_2-*trans*(O) (E-1)(half-life: *ca.* 15 min)≃*cis*(O)*trans*(NH_2) (E-6)≃C_1-*cis*(O) (E-4; in-plane)≃C_i-*trans*(O) (E-2)≫*cis*-(O)*trans*(NH) (E-5)(*ca.* 190 min)>C_1-*cis*(O) (E-4; out-of-plane) (*ca.* 230 min). This result corresponds well with that obtained for the $[Co(gly)_2(en)]^+$ ion.

The G-ring methylene protons of E-3 (*mer*) are deuterated very slowly; this slow deuteration may arise from the following two effects: (1) from the meridional form (Coleman *et al.*[18] pointed out, for the $[Co(edta)]^-$ ion, that the more strained glycinate-ring meridional to the back-bone ethylenediamine-ring does not prefer to remove one of the methylene protons) and (2) the methylene protons are not situated on the O-Co-O plane.

Determination of Absolute Configurations by ^1H NMR. When the edma ligand coordinates to a cobalt(III) ion in the facial form, the secondary nitrogen (C-NH-C) becomes asymmetric (*R* or *S*) (Fig 4 (A)). Although each isomer of $[Co(edma)_2]^+$ may be expected to provide four diastereomers (*R,R*, *R,S*, *S,R*, and *S,S*), some of them do not exist because of the structural restrictions. For example, the nitrogen atoms in the E-1 isomer can take only the *S,S*(*ΔΔΔ*) or *R,R*(*ΔΔΔ*) chiral configuration. The possible configurations for each geometrical isomer are listed in Table 5.

The $(-)^{CD}_{521}$E-5 isomer, whose structure was determined by the X-ray analysis in this work, has the configuration of *Δ*(GG)*Δ*(EE)(*R,R*). As has been mentioned, one of the G-ring $-CH_2-$ protons in $(+)^{CD}_{521}$E-5 (*Δ*(GG)*Δ*(EE)(*S,S*)) is stereospecifically deuterated in basic D_2O. When the outside proton (H_b in Fig. 4(A)) of $(+)^{CD}_{521}$E-5 is deuterated, the G-ring -CHD- carbon in the facial edma becomes an asymmetric center with the *R* chirality (Fig 4 (B)). It is noteworthy that, when the nitrogen atom of the facially coordinated edma which contains *R* carbon takes the *S* chirality, the undeuterated proton (-CHD-) occupies the inside position (Fig 4 (C)). Using this deuterated edma (containing *R* carbon), the E-1 isomer was prepared and optically resolved (See Experimental section). In the ^1H NMR spectrum of the deuterated $(-)^{CD}_{543}$E-1, a singlet peak due to the G-ring -CHD- appeared between the two lower-field peaks of the AB quartet due to the G-ring $-CH_2-$ (Fig. 2). On the contrary, in the spectrum of the $(+)^{CD}_{543}$E-1, a singlet peak appeared between the two higher-field peaks of the AB quartet. As the chiralities of the asymmetric carbon and nitrogen atoms in the starting material ($(+)^{CD}_{521}$E-5) are *R* and *S* respectively, it is concluded that the asymmetric nitrogens of the coordinating edma's in $(-)^{CD}_{543}$E-1 and $(+)^{CD}_{543}$E-1 should have *R* and *S* chiralities respectively (Fig 4.); the absolute configurations of the $(-)^{CD}_{543}$E-1 and $(+)^{CD}_{543}$E-1 isomers are *ΔΔΔ*(*R,R*) and *ΛΛΛ*(*S,S*) respectively.

TABLE 5. POSSIBLE CONFIGURATIONS AND CD SIGNS OF THE $[Co(edma)_2]^+$ ION

Geometrical isomers	Possible configuration and CD signs	
E-1 C_2-*trans*(O)	*ΔΔΔ*(*R,R*)$(-)^{CD}_{543}$	*ΛΛΛ*(*S,S*)$(+)^{CD}_{543}$
E-2 C_i-*trans*(O)	(*R,S*) (achiral isomer)	
E-4 C_1-*cis*(O)	*ΛΔΔ*(*S*,R*)$(+)^{CD}_{534}$	*ΔΛΔ*(*R*,S*)$(-)^{CD}_{534}$
E-5 *cis*(O)*trans*(NH)	*Δ*(GG)*Δ*(EE)-(*R,R*)$(-)^{CD}_{521}$	*Λ*(GG)*Λ*(EE)-(*S,S*)$(+)^{CD}_{521}$
E-6 *cis*(O)*trans*(NH_2)	*ΔΔΔ*(*R,R*)$(-)^{CD}_{509}$	*ΛΛΛ*(*S,S*)$(+)^{CD}_{509}$

R or *S*: Chirality around the asymmetric nitrogen. *R** or *S**: The asymmetric nitrogen being present on the in-plane (O-Co-O plane) G-ring.

By using the stereospecifically deuterated $(+)^{CD}_{509}$E-6 as a starting material, the $(+)^{CD}_{543}$ and $(-)^{CD}_{543}$E-1 isomers were also obtained, as has been shown in the Experimental section. The ^1H NMR spectra of the $(-)^{CD}_{543}$E-1 and $(+)^{CD}_{543}$E-1 isomers showed a singlet signal due to -CHD- in the lower and higher fields respectively. These signal patterns suggest that the edma ligand contains the *R* asymmetric carbon. Accordingly, the configuration of $(+)^{CD}_{509}$E-6 can be assigned to *ΔΔΔ*(*S,S*) ($(-)^{CD}_{509}$E-6: *ΔΔΔ*(*R,R*)).

Although the *ΛΔΔ*(*S*,R*)E-4 isomer contains both the *R* and *S* asymmetric nitrogens, the in-plane G-ring which contains *S* nitrogen (*S**) is more rapidly deuterated than the out-of-plane G-ring which contains *R* nitrogen, as has been mentioned above. The deuteration was quenched at the time the G-ring containing *S** nitrogen was stereospecifically deuterated. By employing the same method as has been described for the determination of the absolute configuration of E-6, the configurations of the $(+)^{CD}_{534}$E-4 and $(-)^{CD}_{534}$E-4 isomers can be identified as *ΛΔΔ*(*S*,R*) and *ΔΛΔ*(*R*,S*) respectively. The absolute configurations of the facial complexes are summarized in Table 5.

CD Spectra. The CD data of the isomers are summarized in Table 6.

The $E_g(D_{4h})$ component in the first absorption band of E-1 (*trans*-$[Co(N)_4(O)_2]$-type complex) is on a lower-energy side than the $A_{2g}(D_{4h})$.[30] According to the method of ring-pairing proposed by Legg *et al.*[32], the (+) CD component which is related to the E_g transition is assigned to the net *Λ* configuration. Based on the above recognition, Igi and Douglas[3] assigned $(+)^{CD}_{543}$E-1 to the *ΛΔΔ*(net *Λ*) configuration, which is consistent with the result described in our ^1H NMR section. However, the $(+)^{CD}_{534}$E-4 (*cis*-$[Co(N)_4(O)_2]$-type complex) shows (−) CD band in the region related to the $E_g(D_{4h}$: holohedrized symmetry) component (which is at a higher-energy side than the $A_{2g}(D_{4h})$ in the *cis*-$[Co(N)_4(O)_2]$-type), while $(+)^{CD}_{521}$ *Λ*(GG)*Λ*(EE) E-5 shows a CD pattern similar to that of $(+)^{CD}_{534}$E-4.

Complex	First Band Region[a]	Second Band Region[a]	Charge-transfer Band Region[a]
E-1	18.87(1.963)	27.86(2.125)	45.46(4.35)
	22.14(1.60)[sh]		
E-2	19.80(1.585)	28.90(1.769)	45.66(4.40)
	21.93(1.56)[sh]		
E-3	21.01(2.279)	28.24(2.240)	45.05(4.31)
E-4	19.96(2.002)	28.01(2.047)	45.46(4.36)
E-5	20.92(1.794)	28.56(1.932)	46.30(4.36)
E-6	20.00(2.061)	28.25(1.855)	45.46(4.33)

a) Wave numbers and log ε values (in parentheses) are given in 10^3 cm^{-1} and mol^{-1} dm^3 cm^{-1} respectively. sh) Shoulder bands.

Although the CD intensity of E-6 in the d-d absorption-band region is very small, the CD band in *ca.* 45000 cm^{-1} is stronger than in the other isomers examined. The low CD intensity in the d-d region probably arises from the counteraction of the vicinal effects due to asymmetric nitrogens against the configurational effect.

The relationship between the CD pattern and the absolute configuration is difficult to account for by the method of ring-pairing for the E-4, -5, and -6 isomers. This is true for the following reasons: (1) The difference in the numbers of the Δ and Λ ring pairs is very small in the present systems (the same as in E-5). (2) The effect of the vicinal CD of asymmetric nitrogen is not negligible compared with that of the configurational CD, though it is difficult to separate the vicinal CD curves from the observed CD. This difficulty results from the geometrical structures of the complexes containing unsymmetrical terdentates.

Absorption Spectra. The absorption spectral data of the six geometrical isomers are listed in Table 7. The first absorption bands of E-1 and -2 show a marked split,[1] which is characteristic of the *trans*(*O*)-$[Co(N)_4(O)_2]$-type,[30,31] and the molar-absorption coefficient of the lower-energy component is larger in E-1 than in E-2. E-1 lacks the center of symmetry, which would give a more intense spectrum than E-2.[32]

The *cis*(*O*)-$[Co(N)_4(O)_2]$-type isomers, E-3, -4, -5, and -6, do not show such a marked split in the first-absorption-band region as the *trans*(O)-type isomers do. The molar-absorption coefficient of the first absorption band is larger in E-3 than in the other five isomers. By stereochemistry, the *mer* isomer is more distorted from a regular octahedron than are the other five isomers, which contains the facially coordinating edma's. The strained structure will give the more intense spectrum.[32,33] An analogous situation is observed for the geometrical isomers of $[Co(ida)_2]^-$[34] and $[Co(ida)(dien)]^+$.[32]

Of the *cis*(O)-type isomers, E-3 exhibits the first absorption maximum in the highest energy region, though the E-3 is the more distorted isomer. This fact may arise from the fact that the molar-absorption coefficient of the $E_g(D_{4h})$ component (on the higher-energy side) is much larger than the $A_{2g}(D_{4h})$ component (on the lower-energy side). In the other *cis*(O) isomers, the $E_g(D_{4h})$ component is not so intense that the absorption maximum may be pulled down to the lower-energy side by the A_{2g} component.

Class Separation of Higher Hydrocarbons by Thin-Layer Chromatography with Flame Ionization Detection

Yojiro YAMAMOTO
Research Center, Maruzen Oil Co., Ltd. 1134-2, Gongendo Satte-cho, Saitama 340-01
(Received March 29, 1985)

3-Aminopropyl or 3-cyanopropyl-bonded silica-gel thin-layer rods (Chromarod NH_2-SII or CN-SII) were prepared and a hydrocarbon class separation of higher hydrocarbons has been investigated by flame ionization detection-thin-layer chromatography (FID-TLC) with those rods as the stationary phase. The resolutions (*Rs*) of the class separation with Chromarod NH_2-SII and CN-SII were compared with those with conventional rods on the market, which were silica-gel-sintered (Chromarod S and SII) and alumina-gel-sintered (Chromarod A) thin-layer rods. An adequate class separation of higher hydrocarbons into Saturates (Sa), Monoaromatics (M-Ar), Diaromatics (D-Ar) and Triaromatics (T-Ar) could be performed by FID-TLC with Chromarod NH_2-SII or CN-SII.

Since heavy oil comprises many kinds of compounds with complicated structures, the isolation of these compounds is impossible. A compositional analysis to determine the content of fractions with similar chemical properties in heavy oil provides an important characterization.

Adsorption column chromatography with silica gel[1] or alumina gel[2] has been generally used for analyzing the composition of heavy oil. Since these methods have, however, such shortcomings as long times for determination and a large quantities of required solvents, high performance liquid chromatography (HPLC) has been recently tried regarding many applications.[3-10] Since Wise *et al.*[5] discovered that alkylamine-bonded silica gels had an advantage for the separation of aromatic ring compounds, these have been widely used for various hydrocarbon class analyses.[8-10] However, this method has not been put to practical use yet due to poor quantitativeness although HPLC has advantages such as a high separating power, and a simple and rapid procedure.

Thin-layer chromatography has a drawback regarding quantitation, although it has such advantages as high separating power, a simple and rapid procedure, and a small quantity of required sample. Recently, this drawback has been corrected due to the development of thin-layer chromatography with flame ionization detection (FID-TLC). This has been widely used for compositional analysis of heavy oil.[11-17] However, a detailed hydrocarbon class separation can not be carried out by FID-TLC, since a stationary phase is limited to silica gel or alumina gel.

In this study, 3-aminopropyl or 3-cyanopropyl bonded silica gel thin layer rods were prepared and the hydrocarbon class separation of higher hydrocarbons has been investigated by FID-TLC with those rods as the stationary phase.

Experimental

Materials. For standard samples, pentacosane, dodecylbenzene, octadecylbenzene, 2,6-dimethylnaphthalene, 1-ethylnaphthalene, acenaphthene, anthracene, phenanthrene, 9,10-dimethylanthracene and chrysene (guaranteed or extra pure reagents obtained from Tokyo Kasei Kogyo) were used. Hexane (chromatographic grade from Wako Pure Chemical Industries) was used as a developing solvent for FID-TLC.

FID-TLC. Iatroscan TH-10 (Iatron Labolatories Inc.) was used for an FID-TLC analysis. Chromarod S and SII (silica-gel-sintered thin-layer rod) and Chromarod A (alumina-gel-sintered thin layer rod) were used as the stationary phase. A chromatopak C-R1A data processor (Shimadzu) was used for FID data collection and treatment. Analytical conditions, such as the weight of a sample loaded in TLC and the combustion in FID were set according to the optimun conditions described in a previous paper.[14] The FID-TLC procedure is described below.

(1) A 1 μl spot of the toluene solution sample (adjusted

(a): Quartz rod, (b): Thin layer of silica gel, (c): Thin layer of alkyl bonded silica gel, (F): Front, (O): Origin.

to a concentration of 5—10 wt%) is placed on the TLC rod with a 1 μl glass capillary.

(2) The rod is developed to 10 cm after it is suspended in a developing tank containing hexane for 5 min.

(3) The rod is dried at room temperature.

(4) The components are determined as the peak area in FID chromatogram.

Preparation of Thin-Layer Rods of Alkyl Bonded Silica-gel. The constructions of the 3-aminopropyl and 3-cyanopropyl bonded silica gel thin-layer rods (Chromarod NH_2-SII and Chromarod CN-SII, respectively) are shown in Fig. 1. These were prepared by the following procedure.[18] Chromarod SII was treated with (3-aminopropyl)triethoxysilane or (3-cyanapropyl)trichlorosilane according to a procedure that is the most popular and convenient for the preparation of bonded phases. It is described in literature.[19,20] The upper portion of the rod was then passed through a hydrogen flame to reform the silica gel layer for detection by FID, as shown in Fig. 1.

Results and Discussion

The characteristics for the hydrocarbon class separation of higher hydrocarbons by FID-TLC with various Chromarods (Chromarod S, SII, A, NH_2-SII, and CN-SII) were examined.

Table 1 shows the R_f values of various standard samples developed with hexane on each Chromarod, and an FID-TLC chromatogram for a standard mixture prepared from pentacosane, octadecylbenzene, 2,6-dimethylnaphthalene and 9,10-dimethylanthracene, which are selected as representatives of Saturates (Sa), Monoaromatics (M-Ar), Diaromatics (D-Ar), Triaromatics (T-Ar), respectively, are shown in Figs. 2 and 3.

From the R_f values of the various standard samples, it is suggested that Sa, M-Ar, D-Ar, and T-Ar can be classified by FID-TLC with every Chromarod. However, Fig. 2 reveals that the separation of Sa, M-Ar, and D-Ar can hardly be carried out with Chromarod A, and that the adequate separation of D-Ar and T-Ar from each other can not be performed even with Chromarod S and SII. On the other hand, an improved separation of these can be carried out by FID-TLC with both Chromarod NH_2-SII and CN-SII, as shown in Fig. 3.

The resolution (Rs) between adjacent peaks in TLC can be calculated using the following equation,

$$Rs = \frac{|(Zx)_2 - (Zx)_1|}{(b_2 + b_1)}$$

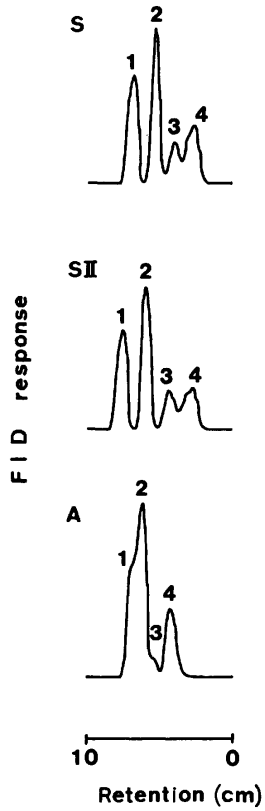

Fig. 2. FID-TLC chromatogram of standard mixture by using Chromarod S, SII, and A.

1,2,3,4: Described in Fig. 2.

Table 1. R_f Values of standard samples on Chromarods

Sample	Hydrocarbon class	S	SII	A	NH_2-SII	CN-SII
Pentacosane	Sa	0.74	0.80	0.76	0.84	0.85
Dodecylbenzene	M-Ar	0.57	0.62	0.66	0.70	0.75
Octadecylbenzene	M-Ar	0.57	0.64	0.68	0.71	0.75
1-Ethylnaphthalene	D-Ar	0.45	0.46	0.57	0.62	0.61
2,6-Dimethylnaphthalene	D-Ar	0.40	0.43	0.59	0.58	0.59
Acenaphthene	D-Ar	0.45	0.41	0.57	0.56	0.62
Anthracene	T-Ar	0.29	0.32	0.42	0.47	0.52
Phenanthrene	T-Ar	0.30	0.36	0.48	0.51	0.52
9,10-Dimethylanthracene	T-Ar	0.26	0.28	0.43	0.44	0.53
Chrysene	P-Ar	0.05	0.06	0.05	<0.4	<0.4

Table 2. Comparison of various Chromarods for resolutions(Rsi) of hydrocarbons

Rsi*	S	SII	NH_2-SII	CN-SII
$Rs1$	1.07	1.09	1.07	1.06
$Rs2$	0.80	0.98	1.00	1.01
$Rs3$	0.56	0.78	1.04	0.89

* The resolution between Sa and M-Ar($Rs1$) M-Ar and D-Ar($Rs2$), and D-Ar and T-Ar($Rs3$).

where $(Zx)_1$ and $(Zx)_2$ are the moved distances of peaks for component-1 and 2, and b_1, b_2 are the half widths of those peaks, respectively.

Following this, the characteristics of the various Chromarods used in this study for the hydrocarbon class separation of higher hydrocarbons by FID-TLC were studied using Rs values as indices. Table 2 gives the results. Rs1, Rs2, Rs3 are the resolutions between Sa and M-Ar, M-Ar and D-Ar, D-Ar and T-Ar, respectively. Since the separation of Sa, M-Ar, and D-Ar could not be carried out with Chromarod A, Chromarod A could not be compared.

Though $Rs1$ values for both Chromarod S and SII are large (1.07 and 1.09, respectively), both the $Rs2$ and $Rs3$ values are small. Especially, the $Rs3$ values for these Chromarods are very small (0.56 and 0.78, respectively). Thus, the Rs values had a tendency to decrease when the number of hydrocarbon aromatic rings increase. That is, it was found that the greater the number of aromatic rings, the more difficult it was to separate the hydrocarbons. On the other hand, the values of $Rs1$, $Rs2$, and $Rs3$ for Chromarod NH_2-SII (1.07, 1.00, and 1.04, respectively) are larger than those for both Chromarod S and SII. This suggests that a more clear separation of each class with Chromarod NH_2-SII can be carried out than with both Chromarod S and SII. The Rs values for Chromarod CN-SII are also larger than those for Chromarod S and SII, though the $Rs3$ value (0.89) is somewhat small compared to that for Chromarod NH_2-SII. Thus, it was found that a clear class separation of hydrocarbon with Chromarod CN-SII could be carried out as well as with Chromarod NH_2-SII.

Consequently, it was proved that an adequate class separation of the higher hydrocarbons into Sa, M-Ar, D-Ar, and T-Ar could be performed by FID-TLC with Chromarod NH_2-SII or CN-SII, which possesed 3-aminopropyl or 3-cyanopropyl-bonded phase.

Magnetic and Spectral Properties of Dimeric Copper(II) Phenylpropynoate Complexes

Yoneichiro MUTO,* Ayako SASAKI, Tadashi TOKII, and Michio NAKASHIMA
Department of Chemistry, Faculty of Science and Engineering, Saga University, Saga 840
(Received May 14, 1985)

Dimeric copper(II) phenylpropynoate adducts $[Cu(Ph\text{-}C{\equiv}C\text{-}COO)_2 \cdot L]_2$, where L=benzonitrile, 3,5-dichloropyridine, dimethyl sulfoxide and triphenylphosphine oxide, have been synthesized in order to study the influence of the C≡C group linked to the COO group upon the extent of antiferromagnetic interaction between the two metal ions. Magnetic susceptibility measurements between 80 and 300 K show that the singlet-triplet separation ($-2J$) ranges from 283 to 318 cm^{-1}. The magnetic behavior of the non-adduct compound $Cu(Ph\text{-}C{\equiv}C\text{-}COO)_2$ is interpreted by taking an inter-dimer interaction into consideration.

The relation between the magnetism of copper(II) carboxylate dimers, $[Cu(RCOO)_2 \cdot L]_2$, and their structures or the physicochemical nature of R is still subject to much disputation.[1,2] It was previously shown that the antiferromagnetic interaction in $[Cu(RCOO)_2 \cdot L]_2$ complexes tends to increase as the group R becomes a stronger electron donor.[3,4] Thus, in a number of series of dimeric copper(II) carboxylates, the singlet-triplet separation ($-2J$, a measure of the magnetic interaction) increases as the pK_a of the parent acid RCOOH increases.[3,4] However, there exist a few exceptions to the postulated dependence of $-2J$ upon pK_a; for example, while pK_a of trifluoroacetic acid is lower than that of trichloroacetic acid, the $-2J$ found for $[Cu(F_3CCOO)_2(quinoline)]_2$ (310 cm^{-1})[5] is much higher than that found for $[Cu(Cl_3CCOO)_2(2\text{-chloropyridine})]_2$ (217 cm^{-1}).[6] Recently, Doedens *et al.*[7] have pointed out that, in the series of dimeric copper(II) carboxylate adducts with R=H, CH_3, CF_3, CCl_3, and CBr_3, the $-2J$ decreases as the polarizability of the group R increases. However, recent finding of a very large antiferromagnetic interaction, more than 1000 cm^{-1} in $-2J$, in $[Cu(Ph_3MCOO)_2 \cdot L]_2$ (Ph=phenyl and M=Si and Ge) with the very large polarizability of Ph_3M does not stand for the Doedens' indication.[8] These facts suggest the importance of studying the influence of R on the magnetism of $[Cu(RCOO)_2 \cdot L]_2$ from a variety of viewpoints. Under the situation, we have decided to see the influence of unsaturated systems directly linked to the COO group on magnetism in dimeric copper(II) carboxylates. There are three types of such unsaturated systems: (A)  , (B) >C=C<, (C) -C≡C-. Copper(II) carboxylate dimers containing the unsaturated group of type A, *i.e.*, copper(II) arenecarboxylate dimers tend to show lower values of $-2J$ than the related copper(II) alkanoate dimers.[4] Magnetic studies on dimeric copper(II) carboxylates with the unsaturated systems of type B are limited at present. A typical structural and magnetic study in this series is on $[Cu(CH_3CH{=}CHCOO)_2(quinoline)]_2$ which showed a normal value of $-2J$ (333 cm^{-1}).[9] For copper(II) carboxylate dimers with the unsaturated system of type C, no magnetic study has appeared up to date. Based on such a situation, in the present study, six copper(II) phenylpropynoate complexes, $Cu(Ph\text{-}C{\equiv}C\text{-}COO)_2 \cdot 3H_2O$, $Cu(Ph\text{-}C{\equiv}C\text{-}COO)_2$, and $Cu(Ph\text{-}C{\equiv}C\text{-}COO)_2 \cdot L$, where L=benzonitrile (PhCN), 3,5-dichloropyridine (3,5-Cl_2py), dimethyl sulfoxide (DMSO) and triphenylphosphine oxide (Ph_3PO), were prepared and characterized by means of magnetic susceptibility and electronic spectrum measurements. The magnetic properties of $Cu(Ph\text{-}C{\equiv}C\text{-}COO)_2 \cdot L$ complexes were compared with those reported for several other dimeric copper(II) carboxylates. For the sake of discussion, the dimethyl sulfoxide adduct of copper(II) acetate, $Cu(CH_3COO)_2(DMSO)$, was also prepared and investigated.

Experimental

Syntheses. $Cu(Ph\text{-}C{\equiv}C\text{-}COO)_2 \cdot 3H_2O$: Phenylpropynoic acid (12 mmol) was dissolved in 0.25 M sodium hydroxide (100 ml) and the resulting solution was filtered. The solution was neutralized with dilute nitric acid using phenolphthalein as an indicator. When a solution of copper(II) nitrate trihydrate (6 mmol) in water (25 ml) was added to the above solution with stirring, blue crystals precipitated. The crystals were collected, washed repeatedly with water and air-dried at room temperature.

$Cu(Ph\text{-}C{\equiv}C\text{-}COO)_2 \cdot L$: L=PhCN or DMSO: The mixture of $Cu(Ph\text{-}C{\equiv}C\text{-}COO)_2 \cdot 3H_2O$ (1 mmol) and L (5 mmol) in chloroform (60 ml) was stirred for *ca.* 1/2 h at room temperature. The resulting solution was filtered and then concentrated to one-third of its volume. When petroleum ether was added to the solution, green crystals precipitated. The crystals were collected, washed with petroleum ether and dried *in vacuo* at room temperature. L=3,5-Cl_2py or Ph_3PO: A solution of L (1 mmol) in acetone (10 ml) was added to a solution of $Cu(Ph\text{-}C{\equiv}C\text{-}COO)_2 \cdot 3H_2O$ (1 mmol) in acetone (30 ml). The separated green crystals were collected, washed with a 1:2 acetone-petroleum ether mixture and dried *in vacuo* at room temperature.

$Cu(Ph\text{-}C{\equiv}C\text{-}COO)_2$: This non-adduct compound was obtained by dehydrating the hydrate complex at *ca.* 80 °C.

$Cu(CH_3COO)_2(DMSO)$: The mixture of anhydrous copper(II) acetate (5 mmol) and DMSO (13 mmol) in ehanol (70 ml) was heated with stirring for *ca.* 6 h. The

resulting solution was filtered and then allowed to stand overnight at *ca.* 5 °C in a refrigerator. The separated green crystals were collected, washed with benzene and dried *in vacuo* at room temperature.

The results of the elemental analyses are given in Table 1.

Physical Measurements. Magnetic susceptibilities in the temperature range of 80—300 K were determined by the Faraday method. Pascal's constants[10] were used for diamagnetic corrections. The value of 60×10^{-6} cgs emu mol^{-1} (1 cgs emu mol^{-1}=$4\pi\times10^{-6}$ m^3 mol^{-1}) for the temperature-independent paramagnetism ($N\alpha$) per gram ion of copper(II) was used throughout the present study. The cryomagnetic data of Cu(Ph-C≡C-COO)$_2$·3H$_2$O were analyzed in terms of Curie-Weiss law of the form,

$$\chi_A = \frac{Ng^2\beta^2}{4k(T-\theta)} + N\alpha, \quad (1)$$

where θ is Weiss constant and the other symbols have their usual meanings. Plots of χ_A *vs.* T and of $(\chi_A-N\alpha)^{-1}$ *vs.* T are shown in Fig. 1. The cryomagnetic data of the adduct complexes, Cu(Ph-C≡C-COO)$_2$·L, were fitted to the modified Bleaney-Bowers equation (2),

$$\chi_A = \frac{Ng^2\beta^2}{3k(T-\theta')}\left[1+\frac{1}{3}\exp\left(\frac{-2J}{kT}\right)\right]^{-1}\cdot(1-P) + \frac{Ng_i^2\beta^2}{4kT}\cdot P + N\alpha, \quad (2)$$

where P is the mole fraction of the noncoupled copper(II) impurity, g_i is the average g factor for the impurity and θ' represents the Weiss constant for inter-cluster interaction. A fixed value of 2.2 was used for g_i throughout this study. The best-fit parameters, $-2J$, g, P, and θ', were obtained by a nonlinear least-squares fitting procedure. The quality of fit was estimated by means of a discrepancy index, σ_{dis},

$$\sigma_{dis} = \left[\frac{\Sigma(\chi_{obsd}-\chi_{calcd})^2}{\Sigma\chi_{obsd}^2}\right]^{1/2}. \quad (3)$$

The thermal magnetic data are shown in Figs. 2 and 3 as plots of χ_A *vs.* T. The values of $-2J$, g, P, θ', and σ_{dis} are summarized in Table 2.

IR spectra were recorded on a Hitachi 260-10 IR Spectrophotometer as Nujol mulls.

Reflectance spectra were recorded on a Hitachi Recording Spectrophotometer 323.

Results and Discussion

The magnetic susceptibility data of Cu(Ph-C≡C-

$COO)_2\cdot3H_2O$ follow the Curie-Weiss law. The best fit of the experimental data to Eq. 1 yields the values of $g=2.19_9$ and $\theta/K=+2.0$ with $\sigma_{dis}=8.55\times10^{-3}$. The effective magnetic moment at 10 °C calculated from the equation, $\mu_{eff}=2.83[(\chi_A-N\alpha)\cdot T]^{1/2}$, is 1.91 BM (1 BM=$9.27\times10^{-24}$ A m^2). These results indicate that this compound does not have a dimeric structure but may have a monomeric structure, as has copper(II) 2-carboxybenzoate dihydrate[11] (μ_{eff}=1.95 BM at 297 K and $\theta/K=-0.6\pm3.3$),[12] or a polymeric structure, as has copper(II) benzoate trihydrate[13] (μ_{eff}=1.97 BM at 293.4 K and $\theta/K=+40$).[14]

The cryomagnetic data observed for the adducts of copper(II) phenylpropynoate prepared in the present study are well represented by Eq. 2 (*cf.* Figs. 2 and 3 and Table 2), indicating that all these adducts have a dimeric structure similar to that found for copper(II) acetate monohydrate.[15] The $-2J$ values of these adducts and those of the corresponding adducts of other dimeric copper(II) carboxylates studied in our laboratory are given in Table 3 along with the pK_a values of their parent carboxylic acids. From Table 3, it can be seen that, in each series of the complexes with the same L, the $-2J$ value decreases as the pK_a value of the parent carboxylic acid becomes smaller. This fact suggests that, in the present phenylpropynoate adducts, the electron-withdrawing nature of the Ph-C≡C group predominantly affects the magnetic interaction. On the other hand, in the present study, the influence of the highly unsaturated

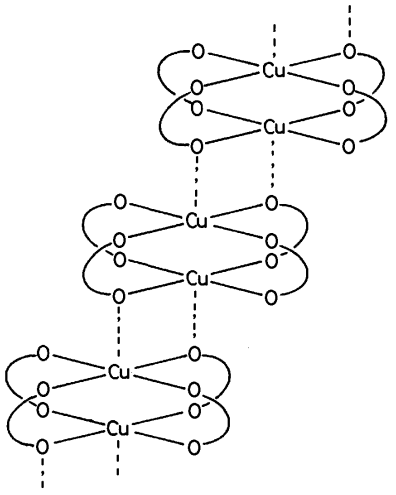

Fig. 4. Schematic representation of polymeric chain structure of copper(II) propionate.[19]

property of the C≡C group directly linked to the COO group on the magnetic interaction could not be detected.

For the non-adduct compound, Cu(Ph-C≡C-COO)$_2$, the best fit of the thermal magnetic data to Eq. 2 gave the value of $-2J$=213 cm^{-1}, a value much lower than those found for the adduct complexes, 283—318 cm^{-1} (*cf.* Table 2 and Fig. 3). Such magnetochemical behavior is in accord with the general trend that, in many dimeric copper(II) carboxylates, the values of $-2J$ for the non-adduct complexes are often lower than those for the corresponding adduct complexes,[4,16] as seen in the case, Cu(C$_2$H$_5$COO)$_2$ (300 cm^{-1})[17]<Cu(C$_2$H$_5$COO)$_2$(py) (350 cm^{-1}).[18] The crystal structure of Cu(C$_2$H$_5$COO)$_2$ is composed of carboxylato-bridged dimers which are linked into one-dimensional polymeric chains by apical Cu-O interaction (*cf.* Fig. 4).[19] Such an apical Cu-O interaction will disturb the superexchange interaction through the carboxylato bridges,[20] leading to the lower value of $-2J$. The low $-2J$ value found for Cu(Ph-C≡C-COO)$_2$, therefore, suggests the presence of apical-to-basal Cu-O-Cu linkages similar to Cu(C$_2$H$_5$COO)$_2$ in this compound. This deduction is further supported by the fact that, among the dimeric compounds in the present study, only the non-adduct compound, Cu(Ph-C≡C-COO)$_2$, showed an appreciably large positive value of θ', θ'/K=+6.86 (*cf.* Table 2). The positive value of θ' is considered to arise from the presence of ferromagnetic spin-spin interaction through the apical-to-basal Cu-O-Cu bonds shown in Fig. 4.

The C≡C stretching vibrations for the non-adduct

a) Shoulder.

compound (2223 cm^{-1}) and the adduct compounds (2221—2223 cm^{-1}) are almost the same as those for free phenylpropynoic acid (2235, 2200 cm^{-1}). This fact indicates the absence of coordination through the C≡C π system in these dimeric copper(II) compounds.

The reflectance spectra of the present adduct complexes in the range 5000—29400 cm^{-1} show three bands having maxima at 28000—29000 cm^{-1} (so-called Band II), 24000—25000 cm^{-1}, and 13000—14000 cm^{-1} (so-called Band I) with a shoulder at *ca.* 8000 cm^{-1}. The wave numbers of the band maxima ($\tilde{\nu}_{max}$) are listed in Table 4 and their spectral curves are shown in Fig. 5. A remarkable feature of the spectra of these complexes is the appearance of a new band in the range 24000—25000 cm^{-1} which is absent in dimeric copper(II) alkanoate and arenecarboxylate complexes. For comparison, the reflectance spectrum of $Cu(CH_3COO)_2(DMSO)$ ($-2J$=326 cm^{-1}) is given in Fig. 5, which has no such absorption in the 24000—25000 cm^{-1} region. Such a new band has been recently observed for $[Cu(Ph_3GeCOO)_2(DMSO)]_2$ and $[Cu(Me_2PhSiCOO)_2(DMSO)]_2$, where Me=methyl.[8] Since the assignment of d-d bands for dimeric copper(II) carboxylates is still in dispute,[21] finding of such a new band is hoped to serve to elucidate the electronic state of the copper(II) ion in these dimeric systems. From Table 4 and Fig. 5, we can also see that the $\tilde{\nu}_{max}$ value of Band I decreases in the order: PhCN adduct>3,5-Cl_2py adduct>DMSO adduct>Ph_3PO adduct, the order of which is the same as that of the $-2J$ value (*cf.* Table 2). A parallelism exists between the $\tilde{\nu}_{max}$ and $-2J$ values (higher $\tilde{\nu}_{max}$-higher $-2J$). A similar parallelism was previously observed for a series of $[Cu(RCOO)_2\cdot L]_2$ complexes, where R=CH_3, $ClCH_2$, and Cl_2CH, and L=pyridine analogues, and the parallelism was interpreted in terms of the electroneutrality principle.[22]

Reduction of Aromatic Ketones or Thioketones with Phenylphosphine

Michiko TAMANO and Jugo KOKETSU*
Department of Industrial Chemistry, College of Engineering, Chubu University, 1200 Matsumoto, Kasugai, Aichi 487
(Received February 7, 1985)

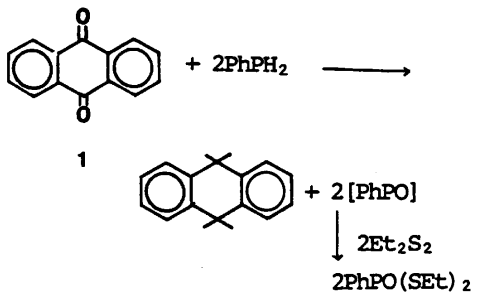
Reactions of certain aromatic ketones or thioketones with phenylphosphine and subsequent addition of diethyl disulfide gave the reduction products of the ketones and *S,S*-diethyl phenylphosphonodithioate or *S,S*-diethyl phenylphosphonotrithioate. A possible intermediate of the phosphine moiety was suggested to be phenylphosphinylidene [PhP=O] or phenylphosphinothioylidene [PhP=S]. The reduction of 10,10′-bianthrone and $\Delta^{10,10'}$-bianthrone resulted in the cleavage of the carbon–carbon single and double bonds and the reduction of the carbonyl groups, respectively.

The reducing properties of the compounds which contain a trivalent phosphorus atom have attracted little attention so far. Because of the affinity of a phosphorus atom for a oxygen atom and its ability to donate hydrogen atoms, primary phosphine is expected to behave as a reducing reagent.

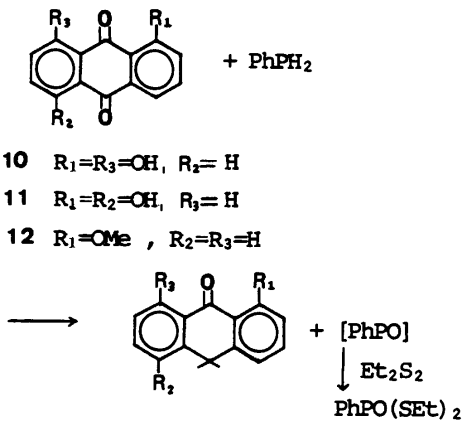
The successful reductions of *N*-chloro-*p*-toluenesulfonamide to *p*-toluenesulfonamide,[1] 1-naphthol to naphthalene,[2] arenesulfonyl chloride to disulfide,[3] and nitro compounds with phosphine to azoxy derivatives[3] and amines[4] have been reported. However, there is no report concerning the reduction of carbonyl or thiocarbonyl compounds with phosphine. The reductions of the carbonyl compounds to alcohols can be achieved by using various reducing reagents such as metal hydrides and dissolving metals, and by catalytic hydrogenations.[5] The complete removal of the oxygen atom from a carbonyl group to give methylene group can be accomplished by well-known Wolf-Kishner[6] and Clemmensen reductions.[7] These methods involve alkaline (Wolf-Kishner) or acidic (Clemmensen) conditions and need drastic heating. The thiocarbonyl groups are also readily reduced with various reducing reagents.[8] Especially, diaryl thioketones are known to be reduced with Zn/HCl to give diarylmethylene.[9] This paper describes our finding about the reduction of aromatic ketones or thioketones with phenylphosphine under mild and neutral conditions.

Results and Discussion

Reduction of anthraquinone (**1**) with $LiAlH_4$[10,11] or $NaBH_4$[12] gives 9,10-dihydro-9,10-anthracenediol, and reduction with Sn/HCl[13] or $SnCl_2$/HCl[14] gives mainly anthrone. Also anthracene was obtained by the reduction of anthraquinone with triphenylsilane,[15] zinc dust/HCl,[16] and HI/AcOH.[17] The conversion of anthraquinone to 9,10-dihydroanthracene was realized by Clemmensen reduction,[18] and reduction with hydriodic acid-phosphorus-iodine[19] and reduction with tetralin in molten $SbCl_3$.[20] Reaction of anthraquinone with two equivalents of phenylphosphine in a sealed ampoule at 140 °C for 3 d and subsequent addition of excess amount of diethyl disulfide gave 91% yield of 9,10-dihydroanthracene and 65% yield of *S,S*-diethyl phenylphosphonodithioate.

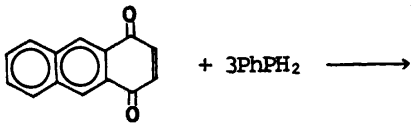


The reduction of this type was carried out successfully with a number of aryl ketones such as 5,12-naphthacenequinone (**2**) and 6,13-pentacenequinone (**3**). By the reaction with equimolar amounts of phenylphosphine, the carbonyl groups of fluorenone (**4**), xanthone (**5**), thioxanthone (**6**), acridinone (**7**), 10-methyl-9(10*H*)-acridone (**8**), and 7*H*-benz[*de*]-anthracen-7-one (**9**) were easily converted to the methylene groups in high yields. Chrysazin(1,8-dihydroxyanthraquinone) (**10**) and anthrarufin(1,5-dihydroxyanthraquinone) (**11**) gave the corresponding anthrones, *i.e.*, 1,8-dihydroxy-9(10*H*)-anthracenone and 1,5-dihydroxy-9(10*H*)-anthracenone, respectively, upon reduction with excess amounts of phenylphosphine.

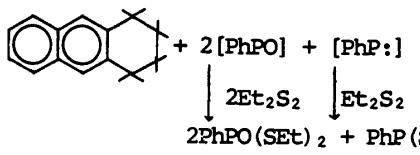


Also, 1-methoxyanthraquinone (**12**) gave 1-methoxy-9(10*H*)-anthracenone. These anthraquinones, in which one or both of the carbonyl groups were protected by hydrogen bonding or by steric hindrance, show strong resistance to the complete removal of the oxygen atoms.

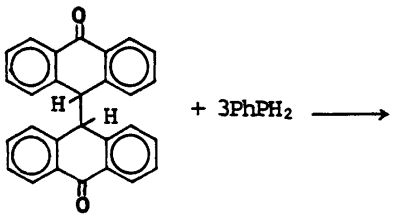
The reduction of 1,4-anthraquinone (**13**) with three molar excess of phenylphosphine and subsequent treatment with excess amounts of diethyl disulfide gave 1,2,3,4-tetrahydroanthracene. *S,S*-Diethyl phenylphosphonodithioate and *S,S*-diethyl phenylphosphonodithioite were separated from the phosphine moiety in 2:1 molar ratio.



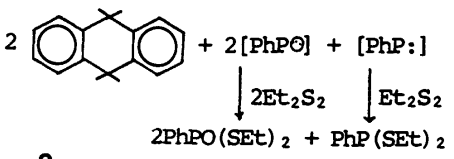
13

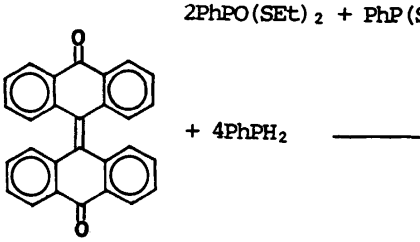


10,10′-Bianthrone (**14**) and $\Delta^{10,10'}$-bianthrone (**15**) were reduced with three and four molar amounts of phenylphosphine to gave 9,10-dihydroanthracene. Also, *S,S*-diethyl phenylphosphonodithioate and *S,S*-diethyl phenylphosphonodithioite were obtained in 2:1 and 1:1 molar ratios, respectively.

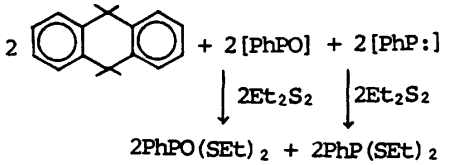


14





15



In these reductions, the carbon–carbon single and double bonds were cleaved in addition to the removal of the oxygen atoms from the carbonyl groups.

The reduction of benzophenone (**16**) and acetophenone (**17**) with phenylphosphine gave diphenylmethane and ethylbenzene, respectively. However, the yield of the reduction of acetophenone was very low, and aliphatic ketones could not be reduced with this reagent. Therefore, the intermediate of this reduction must have two aryl rings for stabilization.

Thiocarbonyl groups of 9*H*-xanthenethione (**18**), 9*H*-thioxanthenethione (**19**), 9(10*H*)-acridinethione (**20**), and 10-methyl-9(10*H*)-acridinethione (**21**) were rapidly converted to the methylene groups to give 9*H*-xanthene, 9*H*-thioxanthene, 9,10-dihydroacridine, and 10-methyl-9,10-dihydroacridine, respectively.

With regard to the mechanism of this reduction, a carbonyl or thiocarbonyl group will undergo insertion into the P–H bond of the phenylphosphine to form >CH–XPHPh (X=O or S) as an intermediate. The C–X bond in this intermediate would be cleaved and the hydrogen atom on the phosphorus atom would migrate to the carbonyl carbon atom. Therefore, phenylphosphine would accept an oxygen or a sulfur atom and donate two hydrogen atoms suggesting the intermediary of phenylphosphinylidene [PhP=O] or phenylphosphinothioylidene [PhP=S].

$$>C{=}X + PhPH_2 \longrightarrow >CH{-}XPHPh \longrightarrow >CH_2 + PhP{=}X \quad (X{=}O \text{ or } S)$$

By subsequent addition of diethyl disulfide, these phosphine moieties were trapped as *S,S*-diethyl phenylphosphonodithioate and *S,S*-diethyl phenylphosphonotrithioate.

In the cases of the reduction of 1,4-anthraquinone, 10,10′-bianthrone and $\Delta^{10,10'}$-bianthrone, some part of phenylphosphine acts as a hydrogen donor only and gives phenylphosphinidene [PhP:] as an intermediate, which is converted to *S,S*-diethyl phenylphosphonodithioite by the reaction with diethyl disulfide.

Experimental

General. All the reactions were carried out under an argon atmosphere. Melting points determined with a Yanagimoto micro-melting point apparatus were uncorrected. IR spectra were taken with a Shimadzu IR-430 spectrometer, UV spectra on a Hitachi 200-10 spectrophotometer, ^1H and ^{13}C NMR spectra on a JEOL JNM-FX 60 spectrometer in $CDCl_3$ with tetramethylsilane as an internal standard. MS spectra were recorded on a Hitachi RMU-6L spectrometer. Commercially available carbonyl compounds were used without further purification. 1-Methoxyanthraquinone was prepared from 1-chloroanthra-

quinone according to the method as that reported by Cook and Pauson.[21] 1,4-Anthraquinone was obtained by the reduction of quinizarin with $NaBH_4$ and purified by sublimation.[22] 9*H*-Xanthenethione, 9*H*-thioxanthene-9-thione, 9(10*H*)-aoacridinethione, and 10-methyl-9(10*H*)-acridinethione were prepared by treatment of the corresponding carbonyl compounds with phosphorus pentasulfide.[8] Phenylphosphine was obtained by the reduction of dichlorophenylphosphine with $LiAlH_4$ according to the method described by Pass and Schindlbauer.[23]

Reduction Procedure. A mixture of an aromatic ketone (10 mmol) with phenylphosphine (molar amount used is specified in Table 1) was placed in a sealed ampoule under argon atmosphere, and heated at 140 °C for periods shown in Table 1. The reaction mixture turned into homogeneous pale orange paste. Subsequently, an excess amount (50 mmol) of diethyl disulfide was added to the ampoule, which was resealed and heated at 140 °C for another 24 h. After removal of excess diethyl disulfide, the reduction products were obtained by sublimation under reduced pressure (13.33 Pa/120 °C). From the sublimation residue, *S,S*-diethyl phenylphosphonodithioate or *S,S*-diethyl phenylphosphonotrithioate were distilled. In the reduction of 1,4-anthraquinone, 10,10′-bianthrone, and $\Delta^{10,10'}$-bianthrone. *S,S*-diethyl phenylphosphonodithioate and *S,S*-diethyl phenylphosphonodithioite were separated by column chromatography (silica gel–$CHCl_3$ as eluent) of the distillation mixture. The structures of the reduction products were deduced based on the following analytical and spectroscopic data.

9,10-Dihydroanthracene: White crystals; mp 70—72 °C (lit,[19] 108—110 °C). Spectra data(IR,[24] ^1H,[25] and ^{13}C[26] NMR) matched with the reported data.

5,12-Dihydronaphthacene: Pale yellow needles; mp 210—211 °C; IR (KBr-disk) 3030(w), 2880(w), 1501(w), 1492(w), 1477(m), 1438(w), 767(vs), and 755(vs) cm^{-1}; ^1H NMR ($CDCl_3$) δ=7.24—7.72 (m, 10H), and 4.06 (s, 2H); ^{13}C NMR δ=137.16, 135.73, 132.48, 127.28, 126.31, 125.33, 125.20, and 36.84; UV_{max} (C_2H_5OH) 228 (ε 56200), 260 (ε 2300), 271 (ε 3200), 280 (ε 3020), and 291 nm (ε 2290); MS (70 eV), *m/z* (rel intensity), 230 (M^+, 100), 229 (94), 228 (26), 110 (26), and 109 (90). Found: C, 93.51; H, 6.50%. Calcd for $C_{18}H_{14}$: C, 93.87; H, 6.13%.

6,13-Dihydropentacene: White needles; mp 265—268 °C; IR (KBr-disk) 3055—2750(w), 1595(w), 1485(w), 1440(w), 750(vs), and 740(vs) cm^{-1}; ^1H NMR ($CDCl_3$) δ=7.16—7.78 (m, 12H) and 4.24 (s, 2H); ^{13}C NMR δ=135.93, 133.72, 127.28, 125.33, 125.14, and 37.36; UV_{max} (C_2H_5OH) 234 (ε 105000), 260 (ε 8900), 272 (ε 10200), 281 (ε 9330), and 292 nm (ε 6300); MS (70 eV), *m/z* (rel intensity), 280 (M^+, 100), 270 (72), 278 (56), 140 (33), 79 (39), and 78 (28). Found: C, 93.88; H, 5.62%. Calcd for $C_{22}H_{16}$: C, 94.25; H, 5.75%.

Fluorene: White plate; mp 117—118 °C. All spectroscopic data were identical with those of commercially available sample.

Xanthene: White crystals; mp 98—100 °C (lit,[27] 100.5 °C). All spectroscopic data were identical with those of commercially available sample.

Thioxanthene: White crystals; mp 126—127 °C (lit,[15] 128 °C). IR and ^1H NMR spectra data matched with reported data (IR; Aldrich 627F, ^1H NMR; Aldrich 5, 533 A).

9,10-Dihydroacridine: White crystals; mp 165—167 °C; IR Aldrich 695E.

10-Methyl-9,10-dihydroacridine: White crystals; mp 85—88 °C; IR (KBr-disk) 2960(w), 1585(s), 1460(s), 1152(m), 1110(m), 1032(m), and 742(vs) cm^{-1}; ^1H NMR δ=7.19—6.58

Kinetic Studies of Fast Equilibrium by Means of High-performance Liquid Chromatography. X. Separation of Rotamers of Acetanilides

Masataka MORIYASU,* Kazuko KAWANISHI, Atsushi KATO, Yohei HASHIMOTO, and Makiko SUGIURA

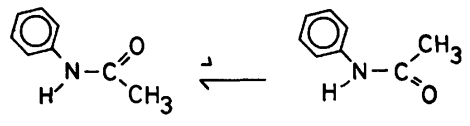
Kobe Women's College of Pharmacy, Motoyamakita-machi, Higashinada-ku, Kobe 658

(Received December 6, 1984)

The restricted rotation about the carbonyl-nitrogen bonds of acetanilides has been investigated by means of high-performance liquid chromatography. The separation of two rotamers (*E*- and *Z*-forms) of acetanilides has been achieved at low temperatures. The presence of a very small amount of the *E*-form has been confirmed for 3-, 4-, and non-substituted acetanilides. The ratios of the *E*- and *Z*-forms in different solvents have also been determined. By combining the HPLC and NMR results, it has been elucidated that the molecular structure of acetanilide in solution can be described in terms of an equilibrium between a large amount of the nearly planar *Z*-form and a small amount of the twisted *E*-form.

In a series of papers,[1-5] we have previously demonstrated that considerably fast equilibria in solutions can be examined by means of high-performance liquid chromatography (HPLC) based on conventional principles. We have entitled the HPLC method "dynamic HPLC"[3] in imitation of "dynamic NMR." We have already separated two rotamers of formanilide at low temperatures and shown that the ratios of rotamers are affected by the solvent composition as well as by the concentration. The present report deals with the separation of various acetanilide derivatives.

Several reports have appeared[6-8] on the NMR study of acetanilides in order to elucidate the conformation, and these results may be summarized as follows. Acetanilide exists as a nearly planar structure, and π-electrons of the benzene ring may be partially delocalized onto the $>N^{+}=C<^{O^{-}}$ moiety, consequently forming an extended partially-conjugated system. The steric hindrance between the benzene ring and the methyl group is so large that acetanilide exists exclusively as the *Z*-form; the presence of the *E*-form has not hitherto been confirmed by NMR. The replacement of *m*-(3-) or *p*-(4-) hydrogen in the benzene ring by a bulky substituent does not bring about any remarkable change in the molecular structure. Contrary to this, when an *o*-(2-) hydrogen is substituted, a drastic change in the molecular structure results. The steric hindrance between the *o*-substituted benzene ring and the carbonyl group is so large that the planar structure is no longer maintained even in the *E*-form rotamer, and eventually the benzene ring deviates from the amide plane and a twisted structure results.[8]



Z-form E-form

Experimental

Reagents. The following acetanilide derivatives were obtained from the market; acetanilide, 2-hydroxyacetanilide, 3-hydroxyacetanilide, 4-hydroxyacetanilide (acetaminophene), 4-ethoxyacetanilide (phenacetin), 2-nitroacetanilide, 3-nitroacetanilide, 4-nitroacetanilide, and *N*-methylacetanilide. The other acetanilides were synthesized by usual procedures from the corresponding aromatic amines and acetic anhydride;[9] 2-methylacetanilide, 3-methylacetanilide, 4-methylacetanilide, 2-ethylacetanilide, 2-isopropylacetanilide, 2,4-dimethylacetanilide, 2,6-dimethylacetanilide, and 2,4,6-trimethylacetanilide.

Apparatus. The HPLC apparatus used in this study is similar to the one described previously.[3] In order to determine the precise ratios of the two rotamers, some modification of the apparatus was made as follows: A column effluent was passed through a narrow stainless-steel tube (0.5 mm in diameter and 10—20 m in length) which was thermostated at 50—100 °C in an air bath (Model ASB-200, Japan Spectroscopic Co., Ltd.) prior to detection by means of a UV detector. This treatment promptly facilitated the attainment of an equilibrium between the two rotamers in the effluent. When the equilibrium is attained in the effluent, the ratio of the two peak areas should reflect the population ratio of the rotamers, irrespective of their absorption coefficients.

The proton NMR spectra of several acetanilides were measured on a Varian XL-200 spectrometer (200.06 MHz) in $CDCl_3$ from 25 to −10 °C.

Results

HPLC of o-Substituted Acetanilides. Various acetanilides were dissolved in chloroform (0.5%), and these sample solutions were submitted to HPLC at different column temperatures. Figure 1 exemplifies the chromatograms of 2-methylacetanilide. A sharp

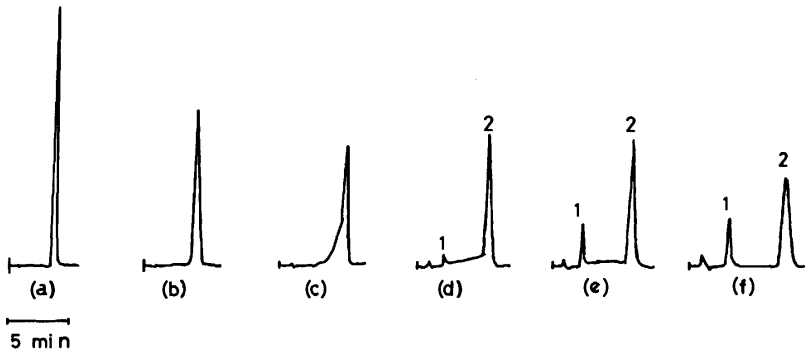


Fig. 1. HPLC chromatograms of 2-methylacetanilide at various temperatures.
Column: Polygosil 60–5 (4.6 mm × 15 cm). Eluent: hexane : 1-propanol : acetic acid = 100 : 10 : 3. Flow rate: 2.0 cm³/min. Detector: UV 254 nm. (a): 20 °C, (b): 0 °C, (c): −20 °C, (d): −30 °C, (e): −40 °C, (f): −50 °C. 1: *E*-form, 2: *Z*-form.

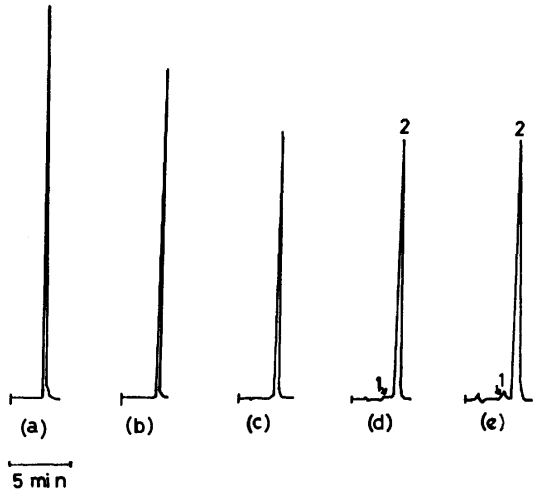

Fig. 2. HPLC chromatograms of 3-methylacetanilide at various temperatures.
For chromatographic conditions, see Fig. 1.

peak at room temperature splits into two peaks at low temperatures. The complete baseline separation of the two peaks at −50 °C suggests that interconversion between two rotamers does not take place during chromatography at this temperature. The former and the latter peak in Fig. 1 are attributed to the *E*- and *Z*-forms respectively by comparing the present HPLC results with the NMR data[8] reported by Kessler and Rieker. Other *o*-substituted acetanilides, such as 2-ethylacetanilide and 2-isopropylacetanilide, gave similar chromatographic patterns.

HPLC of Acetanilide, 3-Methylacetanilide, and 4-Methylacetanilide. Figure 2 shows chromatograms of 3-methylacetanilide at various column temperatures. Two rotamers of 3-methylacetanilide were separated by HPLC below −50 °C. The small peak in Fig. 2(e) is not due to impurity but is attributed to the *E*-form for the following reason: When the fraction corresponding to the small peak in Fig. 2(e) was collected and rechromatographed after having been kept at room temperature for some time, equilibrated chromatograms were obtained again. Quite similar chromatograms were obtained when 4-methylacetanilide and acetanilide were chromatographed. Thus, the presence of a very small amount of the *E*-form isomer was confirmed for these acetanilides.

HPLC of Other Acetanilides. When two or more hydrogens of the benzene ring are replaced by bulky substituents, the chromatographic patterns might vary. 2,4-Dimethylacetanilide gave chromatograms quite similar to 2-methylacetanilide. Thus, the equilibrium between *E*- and *Z*-rotamers is determined by the *o*-methyl group, and the *p*-methyl group seems to have little effect on the ratio. 2,6-Dimethylacetanilide and 2,4,6-trimethylacetanilide gave chromatograms similar to 2-methylacetanilide, though the complete separation of two rotamers was achieved at rather higher column temperatures. These results suggest that internal rotation about the carbonyl–nitrogen bond is seriously restricted when both *o*-positions of the benzene ring are occupied by bulky substituents.

Among the various acetanilides tested, only the following did not give the separation of the two rotamers; 2-nitroacetanilide, 3-nitroacetanilide, 4-nitroacetanilide, and *N*-methylacetanilide. This does not necessary mean that the content of the *E*-form is too small to be detected by HPLC, and the following alternative explanations are also possible. (1) The retention times of the two rotamers may happen to be quite similar for these acetanilides under the present HPLC conditions. (2) If the rate of interconversion between the two rotamers is much faster than the rate of separation by HPLC, the two rotamers will not be

separated. This phenomenon may occur especially in nitro-substituted acetanilides because the strongly electron-withdrawing nitro group in the benzene ring should reduce the double-bond character of the carbonyl-nitrogen bond. Actually, a decrease in the rotational energy barrier was observed for nitro-substituted formanilides.[10]

The Ratios of the Two Rotamers. Various acetanilides were dissolved in chloroform (0.5%, 25 °C), and the ratios of the two rotamers were determined under the conditions where the complete separation is achieved. The results are summarized in Table 1. The content of the *E*-form was found to increase as the *o*-alkyl group becomes bulkier for *o*-alkyl-substituted acetanilides.

In order to examine the effect of the solvent on the ratios of the two rotamers, 2-methylacetanilide, 3-methylacetanilide, 4-methylacetanilide, and acetanilide were dissolved in a variety of solvents, and the ratios of the two rotamers were determined; the results are shown in Table 2. The population of the *E*-form was found to decrease in the following order; 2-methylacetanilide>4-methylacetanilide>3-methylacetanilide>acetanilide. Table 2 also shows that the population of the *E*-form is high when acetanilides are dissolved in nonpolar solvents, such as chloroform and hexane.

The effect of the concentration was examined on 2-methylacetanilide in chloroform. In contrast to formanilide,[3] the percentage of the *E*-form is insensitive to the concentration. The contents of the *E*-form were calculated to be 18.0, 18.1, and 18.4% at 0.27, 1.1, and 8.6% in molar ratio, respectively.

NMR Measurements. The Proton NMR data hitherto reported have shown that a small amount of the *E*-form exists in the equilibrium state for *o*-substituted acetanilides, while for other acetanilides the presence of the *E*-form has not been confirmed by NMR. When we measured the ^{1}H-NMR spectra of 2-methylacetanilide, 3-methylacetanilide, 4-methylacetanilide, 2-ethylacetanilide, 2-isopropylacetanilide, and acetanilide carefully on a high-field NMR instrument, the following facts were found. A couple of signals corresponding to the *E*- and *Z*-rotamers

appeared for *o*-substituted acetanilides at room temperature. For 4-methylacetanilide, two broad signals were observed at 10 °C; the larger one, at δ 2.15, should be assigned to the acetyl protons of the *Z*-form while the smaller one, at δ 2.05, should possibly corresponds to those of the *E*-form. The decrease in the temperature sharpened both signals (Fig. 3). On the other hand, when the temperature was increased, these signals were broadened; indeed, the smaller one was not recognized at 25 °C. At this temperature, these two signals probably coalesce. Thus, this phenomenon may be interpreted in terms of the interconversion between *E*- and *Z*-forms. 3-Methylacetanilide and acetanilide gave similar results. The percentage of the *E*-form of these acetanilides amounts to only 1—3%. These results are summarized in Table 3, together with the data obtained by HPLC. The two sets of results agree quite well. The NMR data hitherto reported by other authors,[7,8] however, give a smaller content of the *E*-form. We consider that the discrepancy between those results and ours may be interpreted in terms of the low sensitivity of the earlier, relatively low-field NMR instruments, for example, 60 MHz for ^{1}H. When NMR signals are broad and when, in addition, the signal-to-noise ratio is not good, the minor components are apt to be overlooked or sometimes estimated to be too small.

Discussion

The following facts seem noteworthy in considering the rotamer equilibrium of acetanilides in solution: (1) The presence of a considerable amount of the *E*-form in *o*-substituted acetanilides was confirmed by HPLC; this finding was in good agreement with the NMR data hitherto reported. (2) The presence of a very small amount of the *E*-form in several *o*-unsubstituted acetanilides was confirmed for the first time by HPLC. We examined the ^{1}H-NMR spectra of these anilides carefully and found small peaks which were attributable to the *E*-form. Since the content of *E*-form of acetanilide is very low, its detection has not been possible by several spectroscopic methods including NMR. Thus, the studies carried out hitherto by means of ^{1}H-NMR,[8] ^{13}C-NMR,[11] and photoelectron spectroscopy,[12] which has been considered to be a powerful tool for investigating labile equilibria in recent years, have failed to detect the *E*-form. (3) When a hydroxyl group was introduced into the benzene ring, the ratios of the *E*- and *Z*-rotamers were found to be different from those for the corresponding methyl-substituted acetanilides. The following sequence was found for increasing percentages of the *E*-form; 3-hydroxyacetanilide<2-hydroxyacetanilide<4-hydroxyacetanilide. The low percentage of the *E*-form of 2-hydroxyacetanilide may be explained in terms of some intramolecular hydrogen bonding in the *Z*-form.[13-15] (4) The ratios of the *E*- to the *Z*-form are somewhat dependent on the solvents. The percentage of the *E*-form is slightly higher in less polar solvents, although the effect is not so remarkable as that found for formanilide.[3] Furthermore, contrary to formanilide, the ratios of the two forms of 2-methylacetanilide in chloroform were almost unaffected by the concentration. Thus, the ring-dimer formation[16,17] attributable to intermolecular hydrogen bonding does not occur for acetanilides.

The acetyl protons of the *E*-rotamer appear at a higher field than those of the *Z*-rotamer (Table 4) in the ^{1}H-NMR spectra of not only *o*-substituted acetanilides, but also of other acetanilides. These high-field shifts may be due to the ring-current effect of the benzene ring, which suggests a twisted structure of the *E*-rotamer of these acetanilides. A previous ^{1}H-NMR study showed[8] that the *Z*-form of

Table 4. ^{1}H-NMR chemical shifts of the acetyl protons

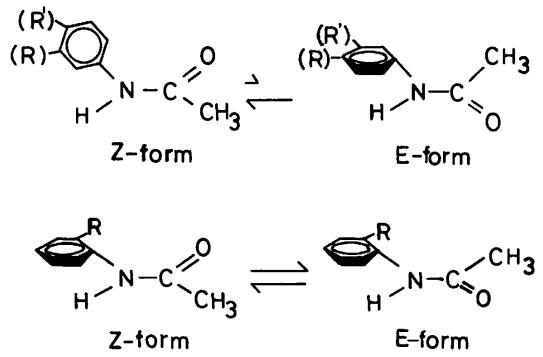
2% solution. a) 10 °C, b) 0 °C.

o-substituted acetanilides has a twisted structure. Contrary to this, the *Z*-forms of the non-*o*-substituted acetanilides have an almost planar structure,[8,18] although the X-ray data of acetanilide indicated[19] that, in the crystalline state, the plane of the aromatic ring deviates slightly from that of the amide group. On the base of these results, the rotamer equilibrium of acetanilides may be described as follows:



Both *E*- and *Z*-forms of *o*-substituted acetanilides have a twisted structure, because the *o*-substituted benzene ring causes a large steric hindrance if it is located coplanar with the amide plane. Contrary to this, the benzene ring of *o*-unsubstituted acetanilides will cause less steric hindrance. Thus, the *Z*-forms of these acetanilides may allowed to have an almost planar structure. The *E*-forms of these acetanilides, however, cannot have a planar structure, for a methyl group is bulkier than a carbonyl oxygen and the *E*-form will be more crowded than the *Z*-form. In the planar structure of the *Z*-form, since π-electrons in the benzene ring will get delocalized to some extent, a partially extended conjugated system will be formed. Thus, the *Z*-form will be more favoured energetically than the twisted *E*-form. The differences in free energies between the two rotamers ($\Delta G°=-RT\ln K$, K=[*Z*-form]/[*E*-form]) are calculated to be −3.8 and −7.9 kJmol^{-1} for 2-methylacetanilide and 4-methylacetanilide respectively, both in 0.5% solutions in chloroform at 25 °C. The difference between the two $\Delta G°$ values (=4.1 kJmol^{-1}) might be attributed to the difference in resonance energy between the *Z*-forms of the two acetanilides, provided that there is little difference in steric hindrance between the *E*-forms of these two acetanilides.

The authors wish to express their gratitude to Dr. Usha Shome, National Botanical Research Institute, Lucknow, India, who kindly corrects the English description of this paper.

Volatility of Low-Henry's Constant Contaminants in Water

Shoichi Okouchi* and Sokichi Sasaki
Chemical Laboratory, College of Engineering, Hosei University, Koganei, Tokyo 184
(Received January 10, 1985)

The volatilization rate of low-Henry's constant contaminants (less than about 2 m^3 Pa/mol) from water to the atmosphere was studied, together with the water volatilization rate, using tracer compounds under various mixing conditions. 1-Butanol, 1-pentanol, 1-hexanol, and 1-heptanol were used as the tracer compounds. The volatilization rates of these compounds and water were controlled by a mass-transfer process in the gas phase. The measured parameter was the ratio of the volatilization rate constant of a tracer(i) to that of water, $K_v^{(i)}/K_v^{(H_2O)}$. The obtained ratios agreed with those estimated theoretically. The volatilization rate constant of low-Henry's constant contaminant(i) in environmental water, $K_{v(env)}^{(i)}$, can be estimated by multiplying the ratio, $K_v^{(i)}/K_v^{(H_2O)}$, by the environmental value of $K_{v(env)}^{(H_2O)}$.

The volatilization of contaminants (such as pesticides) from water bodies to the atmosphere can be an important environmental pathway for certain contaminants. The rate equation for the volatilization of a contaminant, i, in water to the atmosphere is given by Eq. 1:

$$-dC_L^{(1)}/dt = K_v^{(1)}(C_L^{(1)} - p^{(1)}/H^{(1)}), \quad (1)$$

where C_L is the concentration of the contaminant in water; t is the time; K_v is the volatilization rate constant; p is the partial pressure of the contaminant in the atmosphere; and H is Henry's constant. The ratio of the volatilization rate constant of a contaminant(i) to the oxygen-reaeration rate constant, $K_v^{(i)}/K_v^{(O_2)}$, has been experimentally determined[1-10] as a parameter for the volatility of contaminants in water. Mackay and Leinonen[11] suggested that the volatilization rate of the volatilized compound is controlled by a mass transfer in the aqueous phase when Henry's constant is greater than about 400 m^3 Pa/mol. However, it is controlled by a mass transfer in the gas phase when Henry's constant is less than about 2 m^3 Pa/mol. In the former case ($H \geq 400$ m^3 Pa/mol), the ratio $K_v^{(i)}/K_v^{(O_2)}$ remains constant, independent of the mixing conditions and the temperature. If the ratio is available, the volatilization rate constant of the contaminant in environmental water, $K_{v(env)}^{(i)}$, can be estimated by multiplying the ratio by the environmental value of $K_{v(env)}^{(O_2)}$. However, the parameter for the volatility in the latter case ($H \leq 2$ m^3 Pa/mol) has been little investigated. Pesticides such as DDT, dieldrin, lindane, parathion, and chlordane correspond to a low-Henry's constant contaminant as an environmental interest, and their pesticide volatilizations from water to the atmosphere have been reported.[9,12-15]

In this work, the volatilization rate of the contaminant which is controlled by a mass transfer in the gas phase was simultaneously measured along with the water volatilization rate, instead of the oxygen reaeration rate. The ratio $K_v^{(i)}/K_v^{(H_2O)}$ was investigated as the parameter for the volatility of low-Henry's constant contaminants in water. As the tracer compounds for the low-Henry's constant contaminants, 1-butanol (H=0.84 m^3 Pa/mol at 298 K), 1-pentanol (H=1.0), 1-hexanol (H=1.3), and 1-heptanol (H=1.6)[16] were used since the concentrations of these compounds and water could be continuously monitored.

Experimental

A schematic diagram of the experimental apparatus is shown in Fig. 1. A dilute aqueous solution of 1-butanol (the tracer for volatilization) which was dissolved into distilled water was prepared in a volatilization vessel (V in Fig. 1), and was then stirred at a constant agitation speed by means of a magnetic stirrer. The vessel was maintained at a constant temperature using the outside-jacket of the vessel. Nitrogen was made to flow through the space above the aqueous solution at a constant rate. The dissolved 1-butanol was volatilized together with the water into the flowing nitrogen as a vapor. The 1-butanol and water concentrations vaporized in the nitrogen were continuously measured by means of a photo-ionization detector (PID in Fig. 1, model PI-101, HNU System, INC., U. S. A.) and a humidity meter (HD in Fig. 1), respectively. The volatilization-rate constant of 1-butanol, $K_v^{(BuOH)}$, was

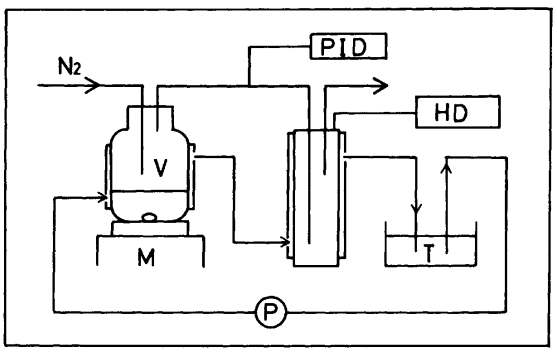

Fig. 1. Schematic diagram of experimental apparatus. V: Volatilization vessel, M: magnetic stirrer, P: pump, T: thermostat, PID: photo-ionization detector, HD: humidity meter.

determined by fitting the concentration data to an integral form of Eq. 1 as $p^{(i)}=0$. That of water, $K_v^{(H_2O)}$, was determined from Eq. 2 using the volatilization rate of water vapor, $F^{(H_2O)}$.

$$K_v^{(H_2O)} = F^{(H_2O)}/(C_{SG}-C_G)V_L, \quad (2)$$

where C_{SG} is the saturated water concentration at the water surface; C_G is the water-vapor concentration in the gas phase; and V_L is the volume of the aqueous solution (0.10 dm^3 in this work).

The same techniques were also used to determine the volatilization-rate constant for 1-pentanol, 1-hexanol, and 1-heptanol with that of water at 298 K.

Results and Discussion

The volatilization-rate constant of 1-butanol, $K_v^{(BuOH)}$, was not affected by the concentration over a range from 0.01 to 0.1 mol dm^{-3}, as was to be expected from Eq. 1. The effects of turbulence in the aqueous phase, which depends on the agitation speed, on $K_v^{(BuOH)}$ and $K_v^{(H_2O)}$ were negligibly small (Fig. 2). On the other hand, both volatilizationrate constants increased with an increase of turbulence in the gas phase, which depends on the nitrogen flow rate, as shown in Fig. 3. In Fig. 4, the values of $K_v^{(BuOH)}$ and $K_v^{(H_2O)}$ are linearly related with a slope of 1.1×10^{-4} ($=K_v^{(BuOH)}/K_v^{(H_2O)}$) at 298 K. Fig. 5 shows the temperature effect on the ratio, $K_v^{(BuOH)}/K_v^{(H_2O)}$, in a temperature range from 288 to 303 K.

From the above data it can be seen that the volatilization rates of both 1-butanol and water were much more affected by turbulence in the gas phase than by that in the aqueous phase. Also, the ratio is highly dependent on temperature. Consequently, the results indicate that the volatilization rates of 1-butanol and water are controlled by a mass-transfer

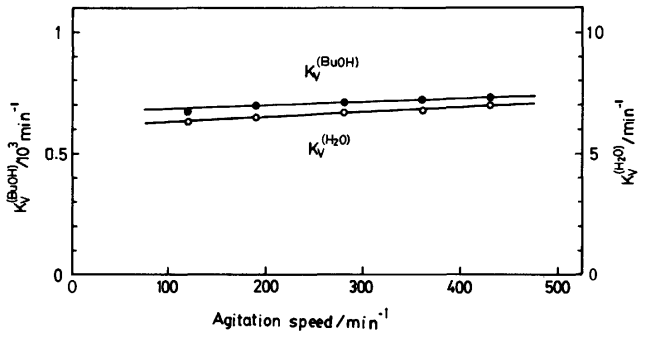

Fig. 2. Effects of turbulence in the aqueous phase (the agitation speed) on $K_v^{(BuOH)}$ and $K_v^{(H_2O)}$ at 298 K. Nitrogen flow rate: 2.0 dm^3 min^{-1}, 1-butanol concentration: 0.05 mol dm^{-3}.

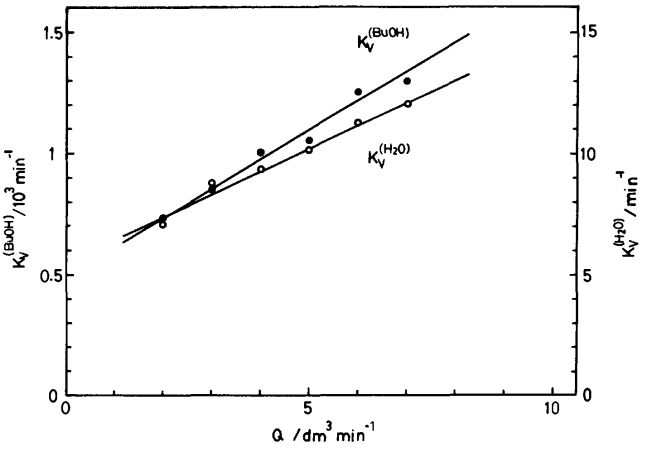

Fig. 3. Effects of turbulence in the gas phase (the nitrogen flow rate) on $K_v^{(BuOH)}$ and $K_v^{(H_2O)}$ at 298 K. Agitation speed: 430 min^{-1}, 1-butanol concentration: 0.05 mol dm^{-1}.

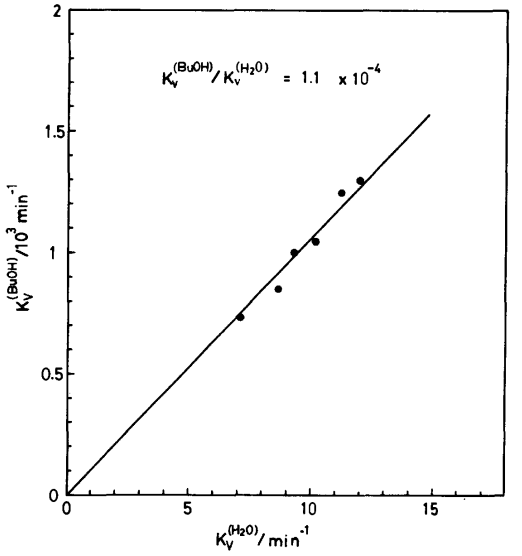

Fig. 4. Relationship between $K_v^{(BuOH)}$ and $K_v^{(H_2O)}$ at 298 K.

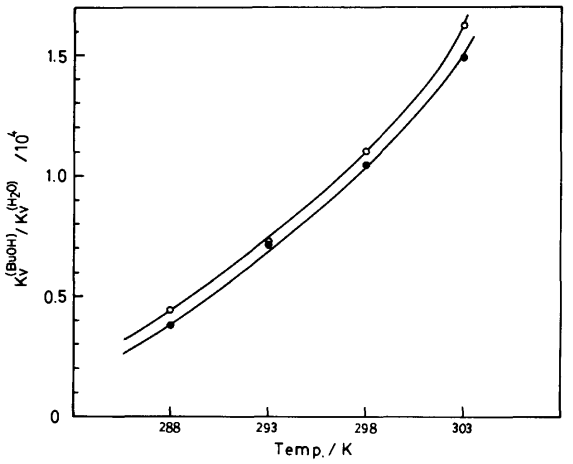

Fig. 5. Effect of temperature on $K_v^{(BuOH)}/K_v^{(H_2O)}$. 1-Butanol concentration: 0.05 mol dm^{-3}, ●: measured, ○: estimated.

in the gas phase, supporting the suggestion of Mackay and Leinonen.[11] Therefore, it is concluded that most of the resistance to these mass-transfer rates lies in the gas-phase boundary layer; thus, the ratio can be theoretically estimated from Eq. 3 since the resistance in the aqueous phase can be neglected.

$$K_v^{(1)}/K_v^{(H_2O)} = (H^{(1)}/RT)k_G^{(1)}a/k_G^{(H_2O)}a = (H^{(1)}/RT)(D_G^{(1)}/D_G^{(H_2O)})^n \quad (3)$$

where k_G is the mass-transfer coefficient in the gas phase; a is the interfacial contact area per liquid volume which corresponds to the reciprocal of the depth of water;[3] D_G is the diffusivity in the gas phase; R is the gas constant; and T is the absolute temperature. The value of n is suggested to be 1 and 2/3 according to the classical theory of the two-film mass-transfer model[17] and the analogy of Chilton and Colburn[18,19] ((Sherwood numbers)$\propto$(Schmidt numbers)$^{1/3}$), respectively. Experimentally, the values of n so far reported are in the range from 0.5 to 1.[20] Using Eq. 3, the ratio $K_v^{(BuOH)}/K_v^{(H_2O)}$ is estimated to be 1.2×10^{-4} for n=1 or 2.0×10^{-4} for n=0.5 at 298 K. In Fig. 5, the estimated ratios were obtained for n=1 in the temperature range 288 to 303 K. The diffusivities in the gas phase in Eq. 3 were calculated from the equation of Fuller *et al.*,[21] suggesting that the diffusivity is proportional to $T^{1.75}$. The good agreement of the measured values with the estimated values indicated that the estimated values for n=1 were better than those for n=0.5.

Table 1. The values of $K_v^{(1)}/K_v^{(H_2O)}$ measured and estimated, and of $D_G^{(1)}$ at 298 K

Tracer (i)	$D_G^{(1)}$/cm^2 s^{-1}	$K_v^{(1)}/K_v^{(H_2O)}\times10^4$	
		Measured	Estimated (n=1—0.5)
1-Butanol	0.0899	1.1±0.2	1.2—2.0
1-Pentanol	0.0807	1.6±0.2	1.3—2.3
1-Hexanol	0.0739	2.0±0.2	1.6—2.9
1-Heptanol	0.0684	1.9±0.2	1.8—3.4

Table 1 shows the measured and estimated ratios, $K_v^{(j)}/K_v^{(H_2O)}$, for 1-pentanol, 1-hexanol, and 1-heptanol with 1-butanol at 298 K. These results indicate the effective estimation of Eq. 3 in the n value range from 0.5 to 1. Therefore, Eq. 3 would give an "order of magnitude" estimation for the volatility of low-Henry's constant contaminants such as the pesticides. Table 2 shows the volatilization-rate constants, $K_{v(ocean)}^{(i)}$, and half-lives, $\tau^{(i)}$, of low- and high-Henry's constant contaminants in the ocean. The mass-transfer rates between the ocean and the atomosphere were reviewed in terms of the gas- and liquid-phase mass-transfer coefficients by Liss and Slater.[22] They suggested that the values of the gas- and liquid-phase mass-transfer coefficients were typically 30 m/h ($=k_{G(ocean)}^{(H_2O)}$) for water and 0.2 m/h ($=k_{L(ocean)}^{(O_2)}$) for oxygen, respectively. Hence, the relations of $K_{v(ocean)}^{(H_2O)}=k_{G(ocean)}^{(H_2O)}/L$ and $K_{v(ocean)}^{(O_2)}=k_{L(ocean)}^{(O_2)}/L$ in the ocean are held for the volatilization and reaeration rate constants, respectively, where L is the water depth. In Table 2, the volatilization-rate constant of the contaminant (i) in the ocean, $K_{v(ocean)}^{(i)}$, is estimated from Eq. 4 as the water depth L=1 m.

$$K_{v(ocean)}^{(1)} = K_{v(ocean)}^{(J)} \times (K_v^{(1)}/K_v^{(J)}) \quad (4)$$

where j refers to water (H_2O) or oxygen (O_2). While, the half-life of the contaminant in the ocean, $\tau^{(i)}$, is given by Eq. 5.

$$\tau^{(1)} = 0.693/K_{v(ocean)}^{(1)} \quad (5)$$

The values of $K_v^{(i)}/K_v^{(H_2O)}$ for DDT, dieldrin, α-HCH (α-hexachloro-cyclohexane), and DBP (dibutyl phthalate) in Table 2 were calculated from Eq. 3 using $H^{(i)}$ from the EPA compilation,[10] whereas the values of $K_v^{(i)}/K_v^{(O_2)}$ were experimentally obtained by Smith *et al.*[3] and Okouchi *et al.*[2] The volatilization rate of low-Henry's constant contaminants was very slow, compared with that of high-Henry's constant contaminants. However, the worldwide atmospheric distribution of pesticides such as DDT clearly indicates that the volatilization of pesticides from

aquatic systems or soils (or both) is an important process because of their toxicities and persistences. The ratio, $K_v^{(i)}/K_v^{(H_2O)}$, suggested in this work would be used to estimate the volatilization rate of low-Henry's constant contaminants ($H \leq 2$ m^3 Pa/mol) from environmental water bodies and wastewater treatment facilities to the atmosphere.

A Temperature Dependence Study of ^{35}Cl NQR Frequencies in Dimethylammonium Hexachlorostannate(IV), Hexachlorotellurate(IV), and Hexachloroplatinate(IV)

Keizo HORIUCHI, Hiroyuki ISHIDA, and Daiyu NAKAMURA*
Department of Chemistry, Faculty of Science, Nagoya University, Chikusa-ku, Nagoya 464
(Received February 14, 1985)

The temperature dependence of ^{35}Cl NQR frequencies was observed for $[(CH_3)_2NH_2]_2SnCl_6$, $[(CH_3)_2NH_2]_2TeCl_6$, and $[(CH_3)_2NH_2]_2PtCl_6$. Two ^{35}Cl NQR frequencies were recorded for the tin complex between 77 and *ca.* 260 K, the intensity ratio of which was 2:1 for the high- to the low-frequency line. An unusual temperature variation of both frequencies attributable to the motion of the cation was observed, and the existence of a phase transition was suggested. For the tellurium complex, the NQR frequencies were observed below *ca.* 240 K. At higher temperatures, two signals having the same intensity ratio as that of the tin complex were detected as expected from the isomorphous relation between both complexes proved at room temperature. A phase transition was newly located for this complex at 98 K in addition to another one at 171 K previously reported. The intermediate phase yielded three broad signals having equal intensity, whereas four broad lines could be detected in the low-temperature phase where more than four lines may be expected by referring to the temperature-dependence curves of the NQR lines.

Recently, we studied the differential thermal analysis (DTA) of dimethylammonium (hereafter abbreviated as diMA) hexachlorotellurate(IV) and found a phase transition at 169 K.[1] Knop *et al.*[2] reported the occurrence of a phase transition in $(diMA)_2SnCl_6$ at 100 K from the study of IR absorptions. Dillon *et al.*[3] revealed a phase transition at 253 K in $(diMA)_2SnBr_6$ isomorphous with $(diMA)_2SnCl_6$ from the temperature dependence study of ^{79}Br NQR frequencies. For these hexachloro complexes, we also studied the ^1H NMR spin-lattice relaxation time, T_1, and the second moment of ^1H NMR absorptions at various temperatures in a fairly wide range of temperature.[1] This reveals the occurrence of the usual C_3 reorientation of the methyl groups of the cation and the 180° flip motion of the whole cation about its twofold pseudo-symmetry axis. However, no anomaly indicating the existence of phase transition was observed from these NMR measurements of both complexes.

Since NQR frequencies are very sensitive to a change in the structure of ionic crystals involving resonant nuclei, the NQR spectroscopy is a powerful means for the detection of phase transition and also for the precise location of the transition temperature, T_{tr}. The present investigation of the temperature dependence of ^{35}Cl NQR frequencies in $(diMA)_2SnCl_6$, $(diMA)_2TeCl_6$, and $(diMA)_2PtCl_6$ has been undertaken in order to confirm the existence of phase transitions for the former two complexes and to clarify the participation of the cationic motions in the temperature dependence of the ^{35}Cl NQR frequencies of these complexes.

Experimental

A modified Dean-type superregenerative spectrometer[4] was employed for the observation of chlorine NQR frequencies. The rf coil of the spectrometer including the sample sealed in a glass ampoule was placed in a Dewar vessel filled with petroleum ether. The sample temperature wanted was obtained by adding Dry-Ice or liquid nitrogen to petroleum ether. A chromel-alumel thermocouple was used for the determination of temperature. The sample temperature determined was estimated to be accurate within ±1 K. A homemade apparatus was employed for the experiments of DTA.[5] Copper-constantan thermocouples were used for the detection of heat anomalies and also for the determination of the sample temperature which was measured to be accurate within ±1 K.

The samples, $(diMA)_2SnCl_6$ and $(diMA)_2TeCl_6$, prepared for the previous NMR experiments were used for the present investigation. The platinum complex was synthesized in a method similar to that used in the preparation of $(diMA)_2SnCl_6$[1] from hexachloroplatinic acid and dimethylammonium chloride. Found: Cl, 42.55; N, 5.61; C, 9.63; H, 3.25%. Calcd for $[(CH_3)_2NH_2]_2PtCl_6$: Cl, 42.55; N, 5.60; C, 9.61; H, 3.23%.

Results

$[(CH_3)_2NH_2]_2SnCl_6$. The temperature variation of ^{35}Cl NQR frequencies observed for this complex is shown in Fig. 1. The resonance frequencies determined at various temperatures are given in Table 1 along with those of the other complexes.

At 196 K (Dry-Ice temperature), two ^{35}Cl NQR frequencies which were confirmed by observing the corresponding ^{37}Cl NQR signals were recorded. The high-frequency ($S/N \approx 100$) line was about twice as strong as that of the low-frequency one. With increasing temperature, the resonance frequency of the two lines decreased smoothly and the intensity of both lines became weak above *ca.* 250 K until they disappeared in the noise level at *ca.* 270 K, although the weak low-frequency line faded out at a slightly lower temperature. The DTA experiments carried

* Two lines observed for this complex may be assigned to different crystalline modifications.

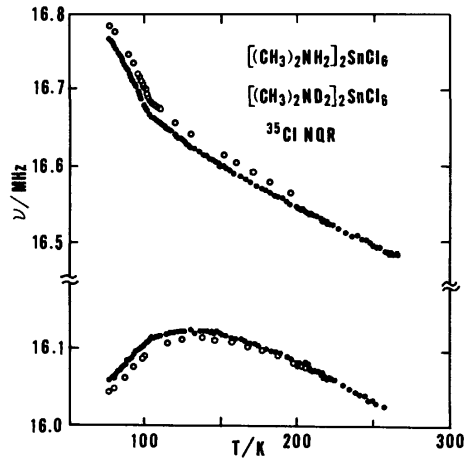

Fig. 1. Temperature dependences of ^{35}Cl NQR frequencies in dimethylammonium hexachlorostannate(IV). Dots and Circls indicate the resonance frequencies of $[(CH_3)_2NH_2]_2SnCl_6$ and $[(CH_3)_2ND_2]_2SnCl_6$, respectively.

out previously showed no heat anomaly up to 420 K.[1]

From the X-ray analysis of this complex,[2,6] it is known that the all complex anions in the crystal are crystallographically equivalent and there exist two nonequivalent chlorine atoms in the anion, *i.e.* two axially elongated chlorine atoms and four equatorial ones. Accordingly, the high- and low-frequency lines, respectively, can be unequivocally assigned to the equatorial and axial chlorine atoms of the hexachlorostannate(IV) anion by referring to the intensity ratio of the observed signals. It is quite reasonable that the axial chlorine atoms having a Sn–Cl bond longer than that of the equatorial ones yield a lower NQR frequency at a given temperature, because chlorine atoms having a longer metal-ligand bond is expected to be more ionic and to give a lower-frequency NQR line.

When the temperature decreased from 196 K, both lines of $(diMA)_2SnCl_6$ decreased their intensity gradually although the intensity ratio remained unchanged. The high-frequency line increased its frequency almost linearly with decreasing temperature down to 102 K, where the temperature coefficient, $d\nu/dT$, was changed discontinuously. Below this temperature, the absolute value of $d\nu/dT$ became larger as can be seen in Fig. 1. On the other hand, the low-frequency line exhibits quite unusual temperature variation. When the temperature increased from 77 K, the resonance frequency of the line increased almost linearly and fairly steeply up to *ca.* 100 K, indicating that the line has an unusual positive temperature coefficient. Above *ca.* 100 K, the temperature gradient of the line became discontinuously gentle and the ν *vs.* T curve yielded a broad maximum around 140 K. With increasing the temperature furthermore, the frequency of the line decreased monotonously.

Knop *et al.*[2] studied the temperature variation of the IR spectra of $(diMA)_2SnCl_6$ and concluded the

occurrence of a phase transition near 100 K by observing the splitting of the N–H stretching band of the NHD^+ group into a doublet below 100 K. They attributed the splitting of the IR band to the appearance of nonequivalent NH hydrogen atoms in the $(diMA)_2SnCl_6$ crystal. The present NQR investigation revealed a discontinuous change at 102 K in the gradient of both ν *vs.* T curves observed. This strongly suggests the existence of a higher-order phase transition in this crystal although no heat anomaly could be detected near 100 K on the DTA measurements repeatedly and carefully carried out.

To obtain further information about the phase transition suggested above, we prepared a partially deuterated analog, $[(CH_3)_2ND_2]_2SnCl_6$, and observed the temperature dependence of ^{35}Cl NQR frequencies. The results are also shown in Fig. 1. The temperature dependence curves obtained are very similar to those of the undeuterated analog. The curve of the high-frequency line shifts by *ca.* 20 kHz to the high-frequency side by *N*-deuteration whereas the curve of the low-frequency line moves to the low-frequency side by *N*-deuteration although the separation of the two curves increases gradually with decreasing temperature.

$[(CH_3)_2NH_2]_2TeCl_6$. The temperature dependence of ^{35}Cl NQR frequencies observed for this complex is exhibited in Fig. 2.

At 196 K, two fairly sharp ^{35}Cl NQR frequencies were observed having the intensity ratio approximately equal to 2:1 for the high- to the low-frequency line ($S/N\approx8$). With increasing temperature, the resonance frequency of both lines lowered almost linearly and the high- and low-frequency lines disappeared in the noise level at *ca.* 240 and 230 K, respectively. The disagreement of the fade-out temperatures is thought as arising from the unequal intensity of both lines. With increasing temperature, each line gradually weakened from the temperature which was lower than each fade-out temperature by *ca.* 10 K. These results are very similar to those of $(diMA)_2SnCl_6$. This is a reasonable consequence because $(diMA)_2TeCl_6$ is isomorphous with $(diMA)_2SnCl_6$ as confirmed already by X-ray powder patterns taken at room temperature.[1] No heat anomaly, of course, was detected above 196 K for $(diMA)_2TeCl_6$ in the DTA experiments performed previously.

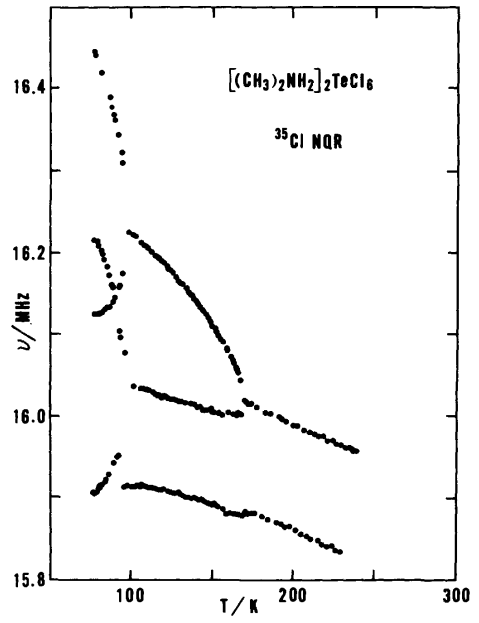

Fig. 2. Temperature dependences of ^{35}Cl NQR frequencies in $[(CH_3)_2NH_2]_2TeCl_6$.

When the temperature decreased from 196 K, the high-frequency line gradually broadened and suddenly disappeared at 171 K and two broad new lines having equal intensity ($S/N\approx3$) appeared at a slightly lower temperature. This indicates the existence of a phase transition as revealed previously.[1] The two new frequencies were observed above and below the resonance frequency of the high-frequency line of the high-temperature phase observed immediately above 171 K. The frequency of the broad high-frequency line newly recorded increased fairly sharply with decreasing temperature down to 98 K, where the signal disappeared. The broad low-frequency line increased its frequency almost linearly with decreasing temperature showing a mild gradient and also disappeared at 98 K. The low-frequency line of the high-temperature phase lowered its frequency slightly and discontinuously at 171 K and increased its frequency gently with decreasing temperature down to 98 K where the signal also disappeared. In the temperature range between 98 and 171 K, the lowest-frequency signal was also broad and the signal intensity was almost unchanged immediately above and below 171 K. Accordingly, three resonance lines having nearly the same intensity were observed in this temperature range. With increasing temperature, the same process of the temperature dependence of ^{35}Cl NQR frequencies could be followed exactly for this complex, indicating that the previously reported T_{tr}[1] of 169 K should be revised as 171 K.

At 77 K, four ^{35}Cl NQR frequencies having nearly equal intensity ($S/N\approx4$) to each other could be clearly observed. A very weak ($S/N\approx2$) and also very broad signal could be barely recorded near 15.95 MHz. However, the temperature dependence of this line could not be determined partly because this signal was too weak and broad to be measured accurately and partly because this line and another strong line with many side bands overlapped each other with increasing temperature. Two of the four lines lowered their frequencies very steeply with increasing temperature whereas the remaining two

lines showed unusual positive temperature coefficients. The four lines disappeared just below 98 K, at which temperature three fairly strong signals appeared.

From the above observation of the temperature dependence of ^{35}Cl NQR frequencies, one can conclude that $(diMA)_2TeCl_6$ undergoes structural phase transitions at 98 and 171 K and two and three crystallographically nonequivalent chlorine atoms exist in the high and intermediate phases, respectively. The two and three nonequivalent chlorine atoms can be assigned to the single $[TeCl_6]^{2-}$ ion in the crystal by comparing these results with those of $(diMA)_2SnCl_6$ and by referring to the fact that the doubly strong line of the high-temperature phase is split into two with equal intensity. In the low-temperature phase, there exist at least five nonequivalent chlorine atoms. To confirm the existence of the phase transition at 98 K, we undertook the experiments of DTA. However, no heat anomaly could be observed. This may be due to the low sensitivity of our apparatus at lower temperatures and also possibly due to the small heat anomaly of this phase transition.

$[(CH_3)_2NH_2]_2PtCl_6$. At 77 K, two ^{35}Cl NQR frequencies were observed for this complex. The high-frequency line was moderately strong and also broad whereas the low-frequency line was weak and fairly sharp. With increasing temperature, the resonance frequency of both lines decreased almost linearly although the low-frequency curve was very slightly convex. The high-frequency line became gradually sharp and weak with increasing temperature, although it could be clearly observed even at room temperature. On the other hand, the low-frequency line decreased its intensity until it disappeared below room temperature. At 196 K, the intensity ratio of the high- to the low-frequency line was approximately 7:1.

Discussion

According to the X-ray analysis recently carried out,[2,6] $(diMA)_2SnCl_6$ forms orthorhombic crystals belonging to the space group Pnnm with Z=2. The structure consists of parallel sheets of almost regular $[SnCl_6]^{2-}$ octahedra held together by hydrogen bonds formed between cationic NH_2^+ groups and chlorine atoms. Each NH_2^+ group is symmetrically H-bonded to the two nearest neighbor complex anions in a sheet and each complex anion is the recipient of H-bonds from four cations. Each N-H vector lies nearly along the pseudo-threefold axis of the anion but it deviates in such a way that the N-H···Cl H-bonds are described as asymmetrically trifurcated or close to out-of-plane bifurcated. Short H-bonds having the distance of 2.6 Å are formed between N-H hydrogen and equatorial chlorine atoms which have a shorter Sn-Cl bond distance, while the axial chlorine atoms form longer H-bonds (3.0 Å). Accordingly, each chlorine atom has N-H···Cl type H-bonds, the hydrogen atom of which exists nearly on the plane including the chlorine atom and perpendicular to the Sn-Cl bond axis.

The present NQR results completely agree with the above crystal structure especially in the features that the tin complex yields two ^{35}Cl NQR lines attributable to two nonequivalent chlorine atoms in the single anion and that the high- and low-frequency lines are assignable to the equatorial and axial chlorine atoms, respectively. This assignment is compatible with the foregoing Sn-Cl bond distance discussion.

By referring to the above X-ray results, the unusual temperature dependence of the ^{35}Cl NQR frequencies observed particularly for the low-frequency line and the phase transition suggested can be explained as follows.[7] Let an Sn-Cl bond axis be the z axis of the chlorine atom. Then, two hydrogen atoms forming H-bonds with the chlorine atom lie nearly along the x- and y-axes of the chlorine atom. This suggests that the p_x and p_y electrons of the chlorine atom are polarized and that the population of these electrons decreases to some extent. This results in a decrease in the ^{35}Cl NQR frequency.[7-9]

Here, we assume that the H···Cl distances involving the equatorial and the axial chlorine atoms are longer and shorter, respectively, at 77 K than the corresponding values determined at room temperature. This is achieved by widening the H-N-H angle which is reported to be 84° at room temperature although this value is exceptionally small. With increasing temperature, the equilibrium position of the hydrogen atoms moves to that determined at room temperature through the excitation of unharmonic deformation vibrations of NH_2^+ groups. This may result in an increase and a sharp decrease in the ^{35}Cl NQR frequencies of the low- and high-frequency lines, respectively. In this phase, two slightly nonequivalent NH groups, as pointed out its existence by Knop *et al.*[2] from the IR study of the stretching vibration of partially deuterated NHD^+ groups in the cation, can be allowed to exist in the crystal without changing the number of nonequivalent chlorine atoms in each complex anion. At 102 K, the slightly nonequivalent NH groups become equivalent forming symmetrical NH_2^+ groups in the crystal. However, the equilibrium positions of the H atoms are still near those of the low-temperature phase. With increasing temperature furthermore, the equilibrium positions move slightly and gradually to those determined at room temperature. The high-frequency line of the partially deuterated analog $[(CH_3)_2ND_2]_2SnCl_6$ also shows a discontinuous change in the temperature coefficient

of ^{35}Cl NQR frequencies near 102 K. This provides strong evidence for the existence of the phase transition suggested.

The NQR results of the high-temperature phase of $(diMA)_2TeCl_6$ can be explained along the same line as those obtained for $(diMA)_2SnCl_6$ at higher temperatures. In the intermediate phase, three broad NQR lines were observed suggesting the existence of strong dipolar interactions through N-H···Cl type H-bonding and/or the presence of some slight disorder in the position of CH_3 groups. In the low-temperature phase, more than four crystallographically nonequivalent chlorine atoms which presumably belong to the same complex anion exist, suggesting the presence of nonequivalent cations in the crystal in agreement with the results of our previous ^1H T_1 study.[1]

For $(diMA)_2PtCl_6$, two ^{35}Cl NQR lines having signal intensity greatly different from each other were observed. According to Ries,[10] this complex shows polymorphism and crystallizes in two morphologically different forms. In fact, the complex prepared in the present investigation yielded complicated X-ray powder patterns which are completely different from those of $(diMA)_2SnCl_6$ and $(diMA)_2TeCl_6$. The elementary analysis of the complex prepared exhibits perfect agreement with the theoretical value for $(diMA)_2PtCl_6$. Therefore, the two lines observed can be assigned to two different crystal forms. Although both forms have the same point-group symmetry D_{2h}, one form is easily crystallized with the bigger abundance ratio. Accordingly, the high-frequency line may be attributed to this crystalline form. No further discussion can be made of this complex because of the above ambiguity in the crystals prepared.

The ^{35}Cl NQR frequencies of $(diMA)_2SnCl_6$ and $(diMA)_2TeCl_6$ disappear in the noise level around 270 and 240 K, respectively. Each signal loses its intensity fairly quickly from the temperature lower by *ca.* 15 K than each fade-out temperature. The characteristic appearance of these temperature dependence curves below each fade-out temperature is that each ν *vs.* T curve decreases almost linearly with increasing temperature.

The fade-out phenomenon of NQR signals is usually interpreted in terms of a large fluctuation of the electric field gradient (EFG) produced at resonant nuclei by appropriate molecular motions such as molecular reorientation and molecular self-diffusion.[11] Brown *et al.*[12] observed the nuclear quadrupole relaxation time T_1 in $CaSnCl_6 \cdot 6H_2O$ and found a fairly sharp decrease in T_1 above 250 K, which was attributed to the reorientational motions of the complex anions. However, the ^{35}Cl NQR frequency could be observed up to 390 K. This suggests that the reorientational motion of the anions does not affect drastically the EFG of the chlorine atoms. Furthermore, the reorientation of octahedral hexachloro complex anions in various K_2PtCl_6 type complexes including $(NH_4)_2MCl_6$ is known usually to start far above room temperature.[13–15] Therefore, the fade-out of ^{35}Cl NQR signals in $(diMA)_2SnCl_6$ and $(diMA)_2TeCl_6$ which was observed below room temperature may not be explained by the fluctuation of EFG due to the motion of the complex anions.

From our ^1H NMR measurements previously carried out,[1] the 180° flip motion of the whole cation about its twofold pseudo-symmetry axis accompanying a large amplitude libration or small angle reorientation of the cation was detected above *ca.* 300 and 260 K for $(diMA)_2SnCl_6$ and $(diMA)_2TeCl_6$, respectively. These motions of the cations are expected to generate a large fluctuation of EFG produced at the chlorine nuclei of these complex anions, because the cation has two nonequivalent CH_3 groups and each chlorine atom has two H-bonded hydrogen atoms carrying a partial positive charge. The 180° flip motion of the cation results in a positional disorder of the CH_3 groups and the slow motion of NH_2^+ hydrogen atoms will disturb EFG at the chlorine nuclei and broaden the NQR signals. Therefore, one can conclude that the disappearance of the ^{35}Cl NQR signals of these complexes below room temperature is solely attributable to the motion of the cation as a whole.

Hydrophobic Indexes for Various Monosaccharides

Koichiro MIYAJIMA,* Katsunosuke MACHIDA, and Masayuki NAKAGAKI
Faculty of Pharmaceutical Sciences, Kyoto University Yoshida Shimoadachi-cho, Sakyo-ku, Kyoto 606
(Received February 21, 1985)

The hydrophobic and the hydrophilic surface areas of seven kinds of monosaccharide molecules were calculated by using Hermann's method. The hydrophobic indexes (Index A and Index B) which are defined as the ratio of the hydrophobic and the hydrophilic surface areas of the molecule are clearly correlated with the partition coefficient of monosaccharide between polystyrene gel and water, and the free energy change of transfer of monosaccharide from water to 1-butanol, indicating that the fraction of the hydrophobic surface area plays an important role in the interaction of monosaccharides and hydrophobic solutes in water.

Sugar has so far been regarded as a typical hydrophilic nonelectrolyte like urea. Generally sugars have nearly the same numbers of CH groups as OH groups in a molecule, and the hydration behavior of monosaccharide has been discussed in terms of the orientation of OH groups of hexopyranose ring.[1]

Recently several evidences have been revealed on the hydrophobic character of saccharides. Various saccharides are partitioned to polystyrene gel from aqueous phase.[2-4] The partition coefficients obtained from the gel chromatography using polystyrene gel as a stationary phase are different from each other irrespective of the same molecular formula and the same configuration (Cl), *i.e.* D-glucose, D-galactose, and D-mannose. The partition coefficients increase with the concentration of structure making salts such as NaCl, and decrease with increase of the concentration of structure breaking salt, NaSCN.[3] Inversely, cyclohexane is adsorbed by Sephadex gel, which is the polymer of D-glucose.[5]

On the other hand, the condensed ring compounds of D-glucose, such as cyclodextrins, include the hydrophobic solute in their cavities and the inner wall of the cavity has been regarded as hydrophobic.[6]

These experimental results seem to indicate that the saccharide molecule has the hydrophobic character even if it is considerably weak, because the interactions mentioned above may be hydrophobic.

In order to confirm that the nature of interactions mentioned above are hydrophobic, we investigated the correlation between the partition coefficients[3] and the surface area ratio of hydrophobic and hydrophilic groups for various monosaccharides molecules. For the partitioning of saccharide to polystyrene gel phase from aqueous phase may be mainly based on the adsorption of saccharide molecules onto the phenyl groups of polystyrene through hydrophobic interaction and the hydrophobic character of saccharides may possibly originate from the hydrophobic surface formed by the CH and CH_2 groups of monosaccharide molecules.[3,4] From these viewpoints, we calculated the hydrophobic and hydrophilic surface areas of seven kinds of monosaccharide molecules, on the assumption that the hydrophobic surface area is the area occupied by CH and CH_2 groups at a distance of 1.4 Å above the atom surface. Combining this area with the total surface area, the hydrophilic surface area is also obtained. Good correlations between the surface area ratio of hydrophobic and hydrophilic groups and the partition coefficients or the free energy of transfer were obtained.

Experimental

Calculation of Surface Area: Surface area of monosaccharides was calculated basically by the computer program QCPE 225 MOLAREA developed by Hermann.[7] The atomic coordinates mainly obtained from the X-ray data except for ribofuranose were used in the calculation. For the furanose-type saccharides, furanose ring was assumed to be planar and the atomic coordinates were obtained from usual bond lengths and bond angles. The van der Waals radii were used as the radii of the atoms. The surface area at a distance of 1.4 Å above the spherical atom surface was calculated on the assumption that the radius of water molecule is 1.4 Å. Since the OH groups of monosaccharide molecule rotate around the C-O axis, the OH group was approximated to the sphere with the radius of 1.72 Å.

Definition of Hydrophobic Area: Total hydrophobic surface area was defined as the area occupied by CH and CH_2 groups of monosaccharide. The hydrophilic surface area is the area occupied by OH and -O- groups and corresponds to the difference between total surface area and hydrophobic surface area.

Monosaccharide molecule is approximated to a disk which has two surfaces. The two surfaces of monosaccharide molecule are in general not equivalent in their hydrophobic areas, the one is richer in CH and CH_2 groups than the other.

For the calculation of the hydrophobic surface area of CH-rich surface (specified hydrophobic surface area), we first selected the CH and CH_2-rich surface from the molecular model and specified hydrophobic surface area occupied by the specified carbon and hydrogen atoms was calculated under the following conditions.

1) For the β-axial CH and CH_2 groups, the specified hydrophobic surface area is equal to the calculated area.

2) For the α-axial and α-equatorial CH and CH_2 groups, the specified hydrophobic surface area is zero.

3) For β-equatorial CH and CH_2 groups, the specified hydrophobic surface area is half the calculated area.

4) The specified hydrophobic surface area of monosaccharide molecule is the sum of the area obtained from 1) and 3).

For the calculation of the surface area of ribofuranose, we assumed that the five membered ring of furanose is planar. Therefore, every OH group attached to furanose ring belongs to either α- or β- type. In this case, the specified hydrophobic surface area of β-CH or CH_2 group was assumed to be the calculated area and that of α-CH or CH_2 group zero. The same criterion was applied to the calculation of the specified hydrophobic surface area of 2-deoxy-D-ribofuranose. Definition of the hydrophobic index: As an expression of hydrophobicity of a compound, the value of hydrophile-lipophile balance(HLB) is frequently used in the physical chemistry of surfactants. HLB value is originally the mass ratio of the hydrophilic and the lipophilic groups. In the similar manner, we defined the hydrophobic index (Index) as the surface area ratio instead of the mass ratio, because aldohexopyranoses, *i.e.* glucose, galactose and mannose, have the same mass ratio of hydrophobic and hydrophilic groups in this treatment.

The hydrophobicity of α- and β-anomers of monosaccharide A, index A_α and A_β, are defined by Eqs. 1 and 2, respectively. The index of monosaccharide A is the sum of indexes of each anomer.

$$\text{Index } A_\alpha = \frac{\text{Total hydrophobic surface area } (\alpha)}{\text{Total hydrophilic surface area } (\alpha)} \times \alpha\text{-anomer } \% \quad (1)$$

$$\text{Index } A_\beta = \frac{\text{Total hydrophobic surface area } (\beta)}{\text{Total hydrophilic surface area } (\beta)} \times \beta\text{-anomer } \% \quad (2)$$

$$\text{Index A} = \text{Index } A_\alpha + \text{Index } A_\beta \quad (3)$$

Since D-ribose and 2-D-deoxyribose have six and four isomers, respectively, indexes of these saccharides were calculated by the extention of the above treatment.

The indexes B_α and B_β were calculated by the similar equations to those of index A_α and A_β using the specified hydrophobic surface area instead of total hydrophobic surface area. Index B was defined as the sum of index B_α and B_β.

Results and Discussion

The results are shown in Tables 1 and 2. Funasaki *et al.*[8] correlated the hydrophobic surface area with hydrophobic interaction for oligoethylene glycol diethers and diesters. First we investigated the correlation between the average total hydrophobic surface area (=Σ hydrophobic surface area×anomer fraction) and the partition coefficients of monosaccharides (K_{av}) obtained from the polystyrene gel-water chromatography by Janado.[3] The magnitude of K_{av} increases in the order galactose<glucose<mannose<arabinose<xylose<ribose<deoxyribose. However the magnitude of the average total hydrophobic surface area calculated from the data of Table 1 lies in the order xylose<arabinose<glucose<mannose<galactose<ribose<deoxyribose, which is quite different from the order of magnitude of K_{av}.

On the other hand, the mangitude of average specified hydrophobic surface area (=Σ specified hydrophobic surface area×anomer fraction) lies in the order arabinose<xylose<mannose<galactose<glucose<ribose<deoxyribose. This order is also different from that of K_{av}. These results would be reasonable, because the hydrophobicity of the molecule depends on both the sizes of hydrophobic and the hydrophilic groups of the molecule as seen in the HLB values of the surfactants. It is reasonable to assume as a first approximation that the strength of hydrophobicity and hydrophilicity of a saccharide molecule depends on the dimensions of the surface area of hydrophobic and hydrophilic groups, respectively, because the hydrophilic groups are mainly OH groups except an ether oxygen group and hydrophobic groups are aliphatic CH or CH_2 groups.

Based on this idea, we calculated the hydrophobic index A (Index A) as shown in Table 1. From the definition of index, the larger the index is the stronger the hydrophobicity. Therefore, the order of hydrophobicity lies in the order, glucose<galactose<mannose<xylose<arabinose<ribose<deoxyribose. The reversing of the order is observed at glucose-galactose and arabinose-xylose as compared with the order of K_{av}. The dependences of K_{av} and log K_{av} on index A are shown in Figs. 1 and 2, respectively. Almost a linear relation is observed between index A and K_{av}. But a nonlinear relation is obtained between index A and log K_{av}. However index A increases with K_{av}. The relation between index A and the relative free energy of transfer of monosaccharide from water to 1-butanol, ΔG^{tr}[4] (galactose as a standard), is shown in Fig. 3. The negative value of ΔG^{tr} increases nonlinearly with index A. From Figs. 2 and 3, free energy of interaction of monosaccharide with hydrophobic compound is correlated nonlinearly with index A, because RT log K_{av} (R: the gas constant, T: absolute temperature) gives the energy dimension.

Based on the idea that the CH-rich surface interacts with hydrophobic solute, we calculated the index B by using the specified hydrophobic surface area instead of the total hydrophobic surface area. Therefore the index B refers to the preferential interaction of the CH-rich surface and hydrophobic solute. As seen in Table 2, index B lies in the order galactose<glucose<arabinose<mannose<xylose<ribose<deoxyribose. As compared with the order of K_{av}, the position of mannose is replaced by arabinose.

*: Integer means the position of carbon atom.

As shown in Fig. 4, an almost linear relation is obtained between index B and K_{av}. The order of K_{av} is better correlated to that of index B than that of index A. As shown in Figs. 5 and 6, index B is nonlinearly correlated with log K_{av} and ΔG^{tr}.

We cannot judge from the above results which index is more closely correlated to the thermodynamic data. Judging from the fact that monosaccharide molecule rotates at considerably fast rate in aqueous solution, index A may be more plausible than index B.

The partition coefficients of monosaccharides between active charcoal and water[9] were not correlated to these indexes, indicating that the negatively charged surface of active charcoal may

influence the interaction of monosaccharide molecule with charcoal surface.

An important problem of this treatment is related to the evaluation of hydrophilicity of the monosaccharide molecule, that is, the validity of the relation of hydrophilicity and the hydrophilic surface area. The hydrophilic character of saccharide molecule comes from the hydrogen bonding of OH groups with water molecules, which is stabilized by the suitable orientation of OH group of monosaccharide molecule. Water molecules form tridymite-like structure in liquid state.[1] Based on the special hydration model originally proposed by Kabayama and Patterson,[10] an equatorial OH group of pyranose ring is more favorable than an axial OH group on the formation of hydrogen bonding with water molecule in aqueous solution. In this calculation, the hydrophilic surface area occupied by equatorial OH group is larger than that of axial OH group at anomer carbon atom. But this relation does not always hold at another carbon atoms. Therefore, we cannot comment whether the difference of orientation of OH group reflects the surface area of hydrophilic group of monosaccharide at the present stage. We did not take into account the presence of monosaccharide of straight chain form throughout the discussion, because of its low amount in aqueous solution of equilibrium state.

In conclusion, it was revealed that the fraction of hydrophobic surface area is primarily important factor on the interaction of monosaccharides with hydrophobic compounds in water.

The authors express their sincere gratitude to Dr. T. Taga for his useful discussion of the conformation of monosaccharides and also to Dr. M. Janado for the presentation of thermodynamic data and fruitful discussion.

(Received March 13, 1985)

The photoreactions of 2,4,6-triphenyl- (TPP), 2-*t*-butyl-4,6-diphenylpyrylium (2BDPP) and 2,4,6-triphenylthiopyrylium (TPTP) salts in tetrahydrofuran (THF) and/or 1,2-dimethoxyethane were investigated. Photoproducts were identified to be pyranyl radicals on the basis of photochemical behavior and ESR spectra. Quantum yields of one-electron reduction reactions of TPP, 2BDPP, and TPTP were obtained to be 0.21, 0.047, and 0.53, respectively. The hf coupling constants of protons in the radicals were determined by simulation. The photoillumination of TPP in THF at low temperatures revealed that a certain intermediate radical species was involved in this one-electron photoreduction.

Pyrylium salts are present as natural products in pigments named anthocyanin. They have a six-membered ring containing an oxygen atom of the oxonium type. Thus, the ring has a benzenoid structure and has almost the same stability as that of aromatic rings. The compound which has a sulfur atom instead of an oxygen is called a thiopyrylium salt. As the pyrylium ring has a positive charge, it exhibits a high reactivity to nucleophilic reagents. Further, it is expected that the salt can be easily reduced to neutral radical, which may be stable in a rather nonpolar media.

Among several kinds of derivatives of pyrylium and thiopyrylium tetrafluoroborate, 2,4,6-triphenyl- (TPP), 2-*t*-butyl-4,6-diphenylpyrylium (2BDPP) and 2,4,6-triphenylthiopyrylium (TPTP) salts were found to be subject to a one-electron photoreduction with high quantum yields. They can be converted into stable radical species in such nonpolar solvents as tetrahydrofuran (THF) and 1,2-dimethoxyethane (DME). Fundamental data concerning a photoreaction by steady light illumination at room temperature, the behavior of radicals produced by a short period of illumination at low temperatures and the results on an ESR spectra analysis of the photoproduct radicals are reported.

Experimental

Materials. All the pyrylium salts used have the form of tetrafluoroborate and were synthesized by the ordinary method.[1] 4,4′-Bi(2,4,6-triphenyl-4*H*-pyran-4-yl) (BTPP) was synthesized by reducing a TPP salt with zinc in a mixture of acetic acid–benzene–water after Panov *et al.*[2] THF and DME as solvents were distilled immediately after a few hours of refluxing on metallic sodium and then stocked on a sodium–potassium alloy in an ampoule connected to a vacuum line. Potassium trisoxalato ferrate (III) for the chemical actinometer was newly synthesized by the usual way before use.

Procedures. The device for illuminating the steady light and following the reaction is the same one as reported previously.[3] The light source was a Toshiba high-pressure mercury lamp USH-100UV with a suitable filter system (Toshiba UV-D36C and SL-1A for 365 nm, and Toshiba C-39B and L-42/Y-43 for 436 nm illumination). The light intensity was measured with a potassium trisoxalato ferrate (III) actinometer at each wavelength.[4] The electronic absorption spectra were taken with a Hitachi 228-type double-beam spectrophotometer. ESR spectra were recorded with a JEOL PE-1X-type ESR spectrometer. The simulation of ESR spectra was performed with the use of an NEC PC-9801 microcomputer and on-line Watanabe WX-4675 plotter. ENDOR spectra were taken with a Varian E-1700 ENDOR spectrometer.

Results and Discussion

General Aspects of Photoreactions and Identification of Photoproducts. The absorption spectrum of a TPP salt in THF is shown in Fig. 1-a. The solution was yellowish green and the absorption maxima were located at 278, 363, and 409 nm. When a solution was illuminated with 436-nm light, the spectrum changed with some isosbestic points and the color changed to pink. The photoproduct (which had absorption maxima at 515 and 555 nm in THF) was found to be a radical species since the solution exhibited a strong ESR signal. When the solution was kept in the dark, the absorption of the starting substance was gradually recovered and at the same time the pink color faded and the ESR signal diminished. By the introduction of air into the pink solution, a quarter of the absorption of the starting substance was recovered. The recovered product was again converted into the pink species and exhibited an ESR signal upon illumination. This indicates

that the pyrylium skeleton was retained in the photoproduct molecule. The reactant emitted blue fluorescence[5] in THF and DME but the photoproduct had no emission. The introduction of air into the photoproduct solution caused the emission.

On the basis of the electronic absorption spectrum, the photochemical behavior (mentioned above) and the results of an ESR analysis (see below), the photoproduct of which the electronic spectrum is given by the line (----) in Fig. 1-a is safely identified to be a neutral radical species, or pyranyl, which was formed by one-electron reduction of the pyrylium salt. The reductant is considered to be the solvent.

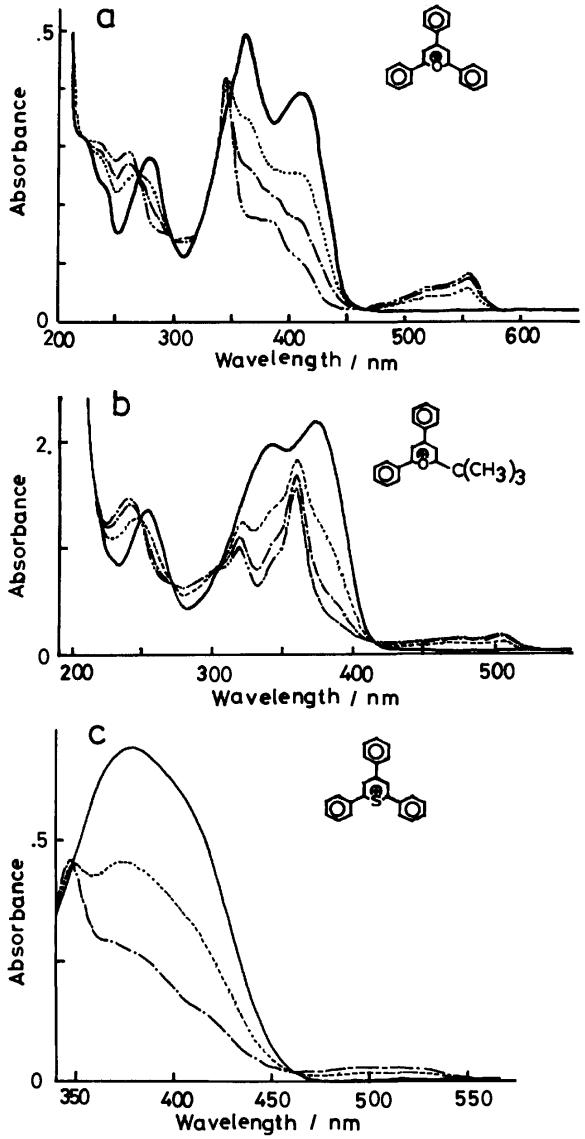

Fig. 1. Absorption spectra in THF and thier change with photoillumination a) of 436 nm light for 0 s(——), 30 s(·····), 1 min(– – –) and 3 min(– – – –), b) of 365 nm light for 0 s(——), 5 min(·····), 11 min (– – –) and 20 min(– – – –) and c) of 436 nm light for 0 s (——), 40 s(·····), and 2 min(– – –).

The spectral change of 2BDPP and TPTP salts upon illumination is shown in Figs. 1-b and c, respectively. Again, the photoproducts exhibited strong ESR signals, indicating that they were neutral radicals. Their electronic spectra are represented by the line (– – – –) in Fig. 1-b and the line (– – –) in Fig. 1-c, respectively.

Reaction Kinetics by Steady Light Illumination. The quantum yields of the photoreactions of the three salts mentioned above were examined as follows: The solutions were illuminated by an exciting light and the intensities of transmitted light were measured with a phototube-amplifier system. As the reaction rate is considered to be proportional to the amount of absorbed light, equation (1) holds.[3]

$$\ln (e^{2.303\varepsilon cd} - 1) = \text{const} - 2.303 \times 10^3 \phi \varepsilon I_0 t \qquad (1)$$

Here, ε, c, d, I_0, and t denote the extinction coefficient of the solute at the observing wavelength, the concentration of the solution, the optical-path length, the incident-light intensity and the time, respectively. ϕ represents the quantum yield of the reaction and is calculated from the slope of the straight line obtained by plotting $\ln(e^{2.303\varepsilon cd}-1)$ against t. ϕ values are listed in Table 1 as well as the ε values used for their calculation. The correction of ϕ for the inner filter effect was carried out in the case that the absorption wavelength of the photoproduct overlapped with that of the excitation wavelength. In Table 1, data on the 4-*t*-butyl-2,6-diphenylpyrylium (4BDPP) salt are added for comparison. The quantum yield for molecules with a higher symmetry tends to be higher. The fact that a higher quantum yield is observed when the ring O atom was replaced by an S atom is in line with the fact that the rate of a one-electron reduction of phenyl(thioxanthone) by Cr^{2+} ion is larger than that of phenyl xanthone.[6]

The effect of the light intensity on the reaction rate was examined about TPP and 4BDPP salts. A linear relation between them was obtained for both salts.

Table 1. Quantum yield of photoreduction ϕ and ε value in THF

Compound		TPP	2BDPP	4BDPP[a)]	TPTP
ε[b)]	365 nm	24500	20300	13300	23400
	436 nm	7690		830	8560
ϕ	365 nm[c)]	0.11[d)]	0.047[d)]		
	436 nm[c)]	0.21[e)]		0.23[e)]	0.53[d)]

a) Irreversible photoreaction. b) In 10^{-3} mol^{-1} cm^2. c) Irradiation wavelength. d) The value obtained by the correction of inner filter effect. e) The reaction rate was proportional to light intensity.

Thus, the photoreaction proceeds with a one-photon process.

An effect of the excitation wavelength on the quantum yield of pyrylium consumption was found to exist in the case of a TPP salt. The quantum yield for 365 nm illumination was about half that for 436 nm illumination, as given in Table 1. The spectral change with 365 nm illumination shows the occurrence of a decomposition reaction of pyrylium ring.

ESR Spectra of Photoproducts. The ESR spectrum of the neutral radical produced by the photoillumination of TPP salts and its temperature dependence are shown in Fig. 2. Simulated spectra are also given in the same figure. All the spectra at different temperatures could be simulated by using a single set of proton hf coupling constants. The spectrum at −10 °C had the smallest linewidth, 48 mG (1 G=10^{-4} T). It increased both at higher and lower temperatures. This implies that the main factor which contributes to the ESR linewidth switches at this temperature. It might represent, for example, a predomination of the spin-rotational interaction (T/η dependence) at the higher-temperature region and of an anisotropy of the Zeeman interaction between the spin and the external magnetic field (η/T dependence) at the lower region. The coupling constants determined by simulation are listed in Table 2 along with those from an ENDOR measurement. The unpaired spin density in the table was calculated using McLachlan's method based on a simple LCAO-MC method. Parameters used in the calculation are also given in the table. From the relation between the hf coupling constants *vs.* the absolute value of the spin densities, 37 G was obtained as McConnell's Q value. Such a large Q value was reported for *o*-semiquinones.[7] Q values for positive ions of aromatic hydrocarbons were also reported to be 36 G.[8] The cited values of the hf coupling constants in the table were those obtained from the radicals produced by zinc powder or other metal reduction in cyclohexane[9,10] and were in good accord with ours.

The ESR spectra of the photochemically produced radical from a 2BDPP salt in THF and their simulation are given in Fig. 3. Although a

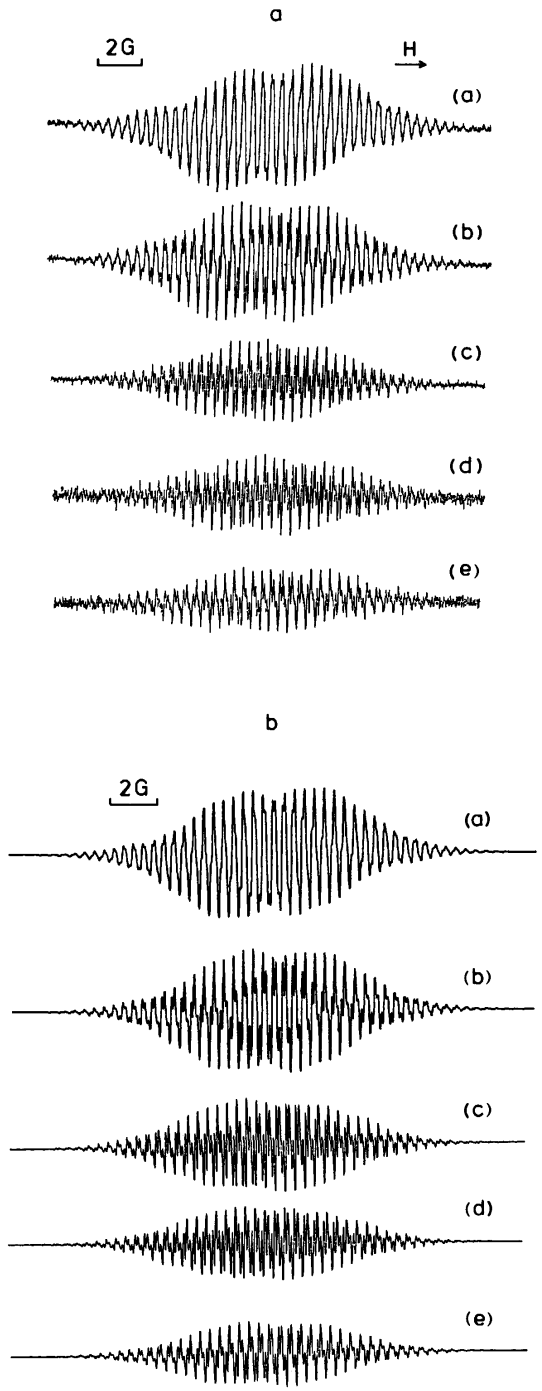

Fig. 2. a: ESR spectra of the radical produced from TPP by the irradiation of 436 nm for 4 min at 23 °C (a) in THF and at 23 °C (b), 0 °C (c), −10 °C (d), and −20 °C (e) in DME. b: Simulated spectra. The linewidths (ΔH_{msl}) used in simulation are 110 mG (a), 80 mG (b), 53 mG (c), 48 mG (d), and 64 mG (e).

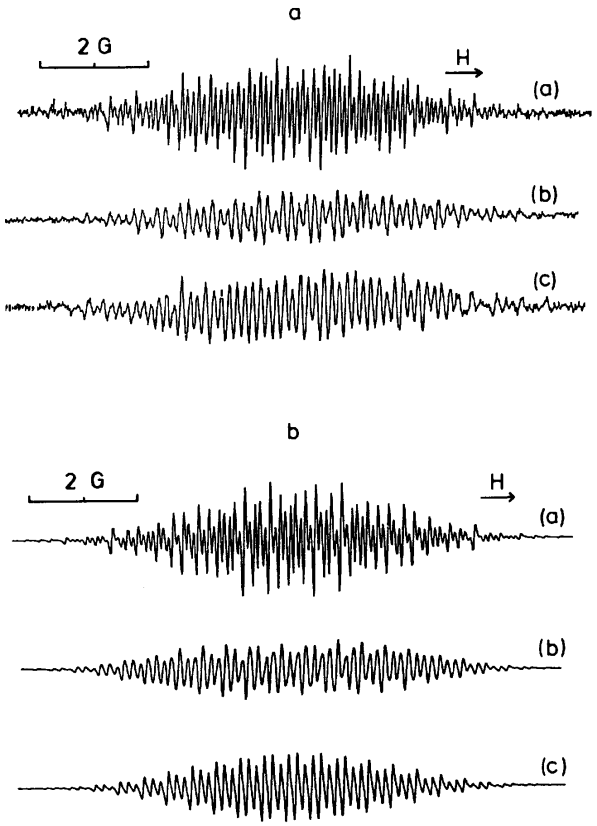

Fig. 3. a: ESR spectra of the radical produced from 2BDPP by the irradiation of 365 nm light for 4 min in THF at 25 °C (a), −30 °C (b), and −50 °C (c). b: Simulated spectra. Marks (a)—(c) correspond to those in ESR spectra.

remarkable change in the spectral shape with temperature change was observed, the simulation parameters were not appreciably different. A slight change in the rotation energy of the *t*-butyl group with temperature may lead to a slight change in the angles between the pyran ring and the two phenyl planes. This may cause a small change in the spin distribution in the molecule.

Figure 4 shows ESR spectra and their simulation for a 2,4,6-triphenyl-4*H*-thiopyran-4-yl radical. A slight variation in the hf coupling constants with temperature may be attributed to a variation in the rotation angle of the three phenyl groups to the thiopyryl ring.

The hf coupling constants of the three radical species were examined by ENDOR. The results coincided with those by the ESR method within the experimental errors and are given in Table 2. Thus, the electronic and steric structures of these radicals were very stable against a temperature change.

The Behavior of Radical at Low Temperatures. The ESR signal intensity of the photochemically produced radical from TPP in THF decreased reversibly with decreasing temperature. This may be due to the occurrence of the following dimerization equilibrium which has been reported for a chemically produced BTPP;[2]

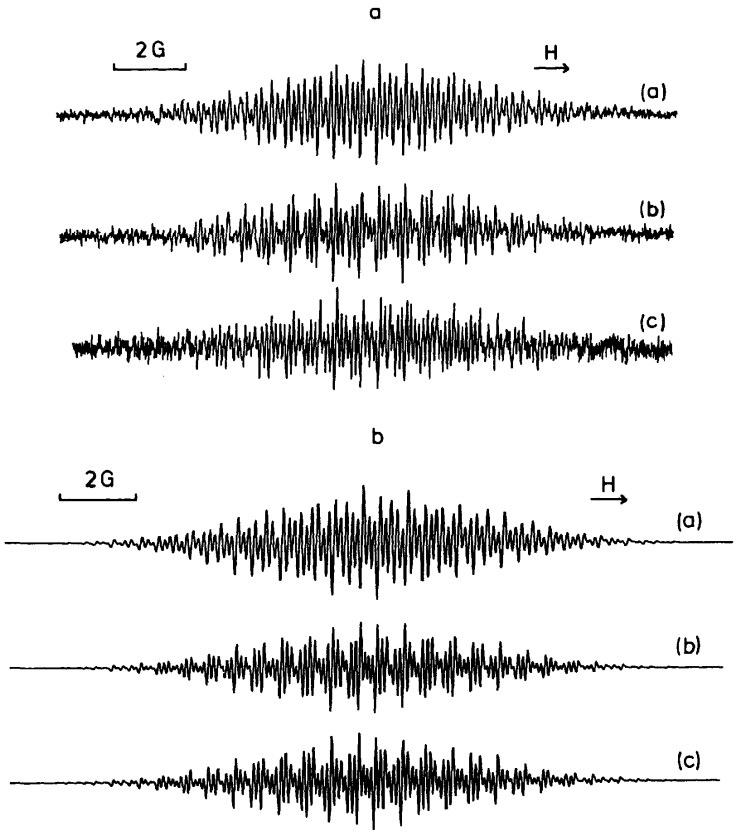

Fig. 4. a: ESR spectra of the radical produced from TPTP by the irradiation of 365 nm light for 4 min in DME at 23 °C (a), −9 °C (b), and −20 °C (c). b: Simulated spectra. Marks (a)—(c) correspond to those in ESR spectra.

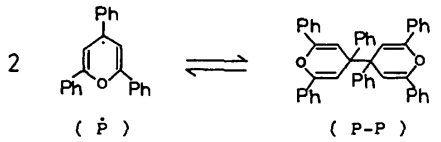

(-Ph=phenyl group)

If we estimate the signal intensity at an infinite temperature, I_∞, by extrapolation, the relative dissociation constant, K_d', can be calculated by Eq. 2;

$$K_d' = \frac{I^2}{I_\infty - I} \tag{2}$$

Here I is the signal inteinsity at temperature T. The plot of logalithm of K_d' against the reciprocal of the absolute temperature was found to be linear over a range from 10 to −60 °C, as shown in Fig. 5. From the slope of this straight line, the enthalpy of dissociation was obtained to be 43.1 kJ mol^{-1}. This value is in good atreement with 44.4 kJ mol^{-1} which we also obtained by the electronic absorption method for a system of chemically produced BTPP (P-P) in THF.

It was confirmed that chemically produced BTPP was quite stable against illumination. It is noteworthy that BTPP is partially converted into pyranyl radical only by thermal process.

Photoillumination at Low Temperature. It seems to be interesting to know whether a radical is formed by photoillumination at low temperatures or not. Indeed a radical was formed by a 436-nm illumination of the TPP salt in THF, even at low temperatures (−40—−100 °C). With an illumination time as short as three or four seconds, the ESR signal at a fixed magnetic field rose up first abruptly, attained a photostationary state and then started to decay immediately after the illumination terminated. It was difficult to observe the hf structure of its ESR signal even during photoillumination because of line broadening. At temperatures higher than −70 °C, the decay curve approached asymptotically not to zero level but to a constant level. We examined this phenomenon at ten-degree intervals between −30—−70 °C. The higher the temperature was, the higher this constant level was. A typical example is shown in Fig. 6. These stable signals showed the same hf pattern as those given in Fig. 2-a at room temperature. The decay rate increased as the temperature rose. The decay curve was successfully analyzed by a first-order reaction-rate equation. On

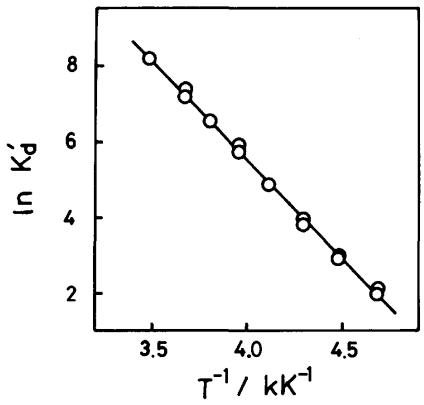

Fig. 5. The temperature dependence of the relative dissociation constant of photochemically produced BTPP in THF.

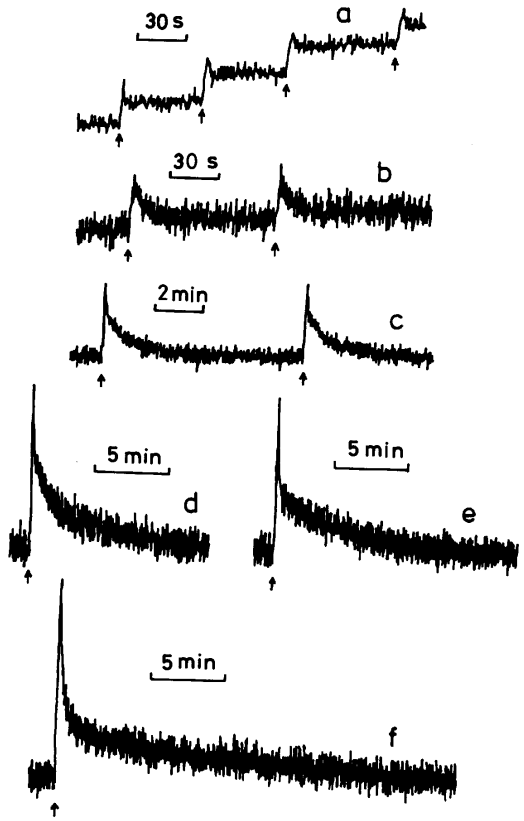

Fig. 6. The time profile of ESR signal intensity at the fixed magnetic field at −30 °C (a), −50 °C (b), −70 °C (c), −80 °C (d), −90 °C (e), and −100 °C (f). 3 to 4 second illumination of 436 nm light was performed at the time point of arrow mark.

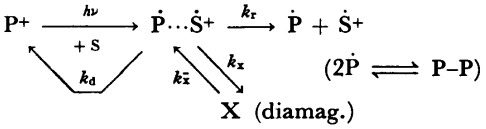
the other hand, no permanent formation of the radical was observed at temperatures lower than −70 °C. Between −80—−100 °C, the decay curves were found to comprise two exponential decays, fast and slow ones, as shown in Fig. 6.

This phenomenon may be explained by the following simple scheme;



where P^+ is the TPP cation and S is the solvent molecule, which serves as an electron donor. As no similar reaction was observed in DME, the counter ion, BF_4^-, can not be the electron donor. We propose the very loosely complexed radical pair, $\dot{P}\cdots\dot{S}^+$, as an unstable species which showed a first-order decay at all the temperatures studied. This species may be trapped in a solvent cage with some lifetime. To explain the two-step decay at lower temperatures, a certain diamagnetic species X was postulated to be in equilibrium with the radical pair. It might be a spin-paired complex or a compound between pyrylium cation and THF molecule. Processes k_x and $k_{\bar{x}}$ express the faster decay and processes k_d and k_r the solwer one. At temperatures higher than −70 °C, k_x and $k_{\bar{x}}$ are so large that the faster decay does not appear explicitly. Below −70 °C, k_r becomes practically zero and the $\dot{P}\cdots\dot{S}^+$ species are considered to relax through process k_d into the original P^+ and S.

Since there is no reliable data regarding k_r for an analysis, we hereafter treat only decay at temperatures lower than −70 °C. If we neglect the process k_d at the initial stage of decay, $[\dot{P}\cdots\dot{S}^+]_0=[\dot{P}\cdots\dot{S}^+]+[X]$ holds. Starting with the first-order decay equation, $-d[\dot{P}\cdots\dot{S}^+]/dt=k_x[\dot{P}\cdots\dot{S}^+]-k_{\bar{x}}[X]$, we readily obtain Eq. 3.

$$\ln\left(\frac{[\dot{P}\cdots\dot{S}^+]}{[\dot{P}\cdots\dot{S}^+]_0}-\frac{k_{\bar{x}}\cdot}{k_x+k_{\bar{x}}}\right)=-(k_x+k_{\bar{x}})t+\text{const} \qquad (3)$$

Here, $[\dot{P}\cdots\dot{S}^+]$ is the radical concentration and $[P\cdots S^+]_0$ is the same quantity immediately after the light is turned off. In the later stage of a decay, the equilibrium $\dot{P}\cdots\dot{S}^+\rightleftharpoons X$ is considered to be achieved. Then, the decay curve can be represented by Eq. 4.

$$[P\cdots S^+]=[P\cdots S^+]_e\exp(-k_d t) \qquad (4)$$

Here, $[\dot{P}\cdots\dot{S}^+]_e$ is the radical concentration just after equilibrium is achieved. Plots of Eqs. 3 and 4 at various temperatures are shown in Fig. 7-a and b where ESR signal intensities, $(SI)_i$, were used instead of radical concentrations, $[\dot{P}\cdots\dot{S}^+]_i$. The equilibrium constant $K_x=k_x/k_{\bar{x}}$ is represented by $[\dot{P}\cdots\dot{S}^+]_e/([\dot{P}\cdots\dot{S}^+]_0-[\dot{P}\cdots\dot{S}^+]_e)$. k_x and $k_{\bar{x}}$ values were calculated separately from the slope of the lines in Fig. 7-a and the K_x values. They are listed in Table 3.

The Arrhenius plots of k_x, $k_{\bar{x}}$, and k_d are given in Fig. 8-a and b. The activation energies for the processes k_x, $k_{\bar{x}}$, and k_d were calculated (from the

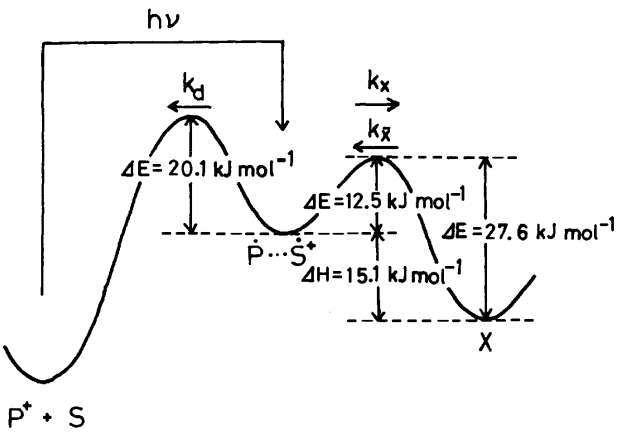

Fig. 9. Potential energy diagram among three systems; $P^+ + S$, $\dot{P}\cdots\dot{S}^+$ and X.
ΔE: Activation energy, ΔH: Enthalpy change.

slope of the lines in the figures) to be 12.5, 27.6, and 20.1 k J mol^{-1}, respectively. The enthalpy change of the reaction $\dot{P}\cdots\dot{S}^+ \rightarrow X$ was calculated to be −15.1 kJ mol^{-1}, the difference between the activation energies for the k_x and $k_{\bar{x}}$ processes. This quantity was also estimated from the temperature dependence of K_x (Table 3) to be −15.5 kJ mol^{-1}. This is in good

agreement with the above mentioned value.

A potential-energy diagram concerning the three systems is depicted in Fig. 9. In view of the relatively high activation energy, a certain modification of the molecular structure (for example, the transfer of a hydrogen atom) might be involved in the process k_x. Thus, it is also plausible that the back reaction to the original P^+ and S occurs from $\dot{P}\cdots\dot{S}^+$, which is formed only by an electron transfer.

The authors wish to thank Professor Masamoto Iwaizumi of Tohoku University for his help in taking ENDOR spectra. One of authors (S.N.) is indebted to the Japan Association of Chemistry for financial support.

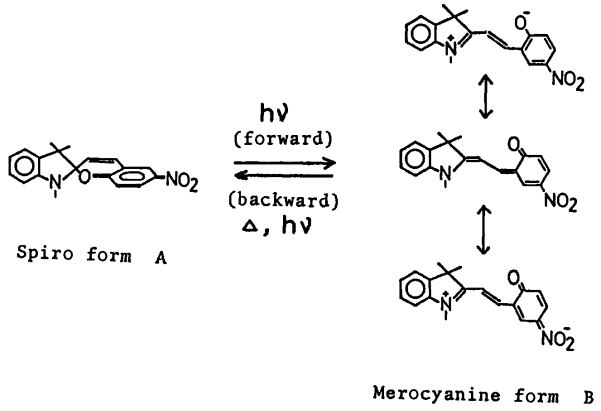
Kinetic Studies of Solvent and Pressure Effects on Thermochromic Behavior of 6-Nitrospiropyran

Yoshimi Sueishi,* Masanobu Ohcho, and Norio Nishimura
Department of Chemistry, School of Science, Okayama University, Okayama 700
(Received March 13, 1985)

The thermal conversion of 6-nitrospiropyran from a merocyanine form to a spiro form was studied in various solvents and under high pressures. The rates of the thermal conversions were remarkably retarded in polar solvents, and a Kirkwood plot of the rate constants showed a large downward deviation as the solvent polarity increased. The rate constants (on a logarithmic scale) were linearly related to Kosower's *Z*-values. The values of the activation volumes were positive and divided into two groups: $\Delta V^{\neq} \approx 10$ cm^3 mol^{-1} (in nonpolar solvents) and $\Delta V^{\neq} \approx 20$ cm^3 mol^{-1} (in polar solvents). These findings suggest that for the reaction in polar solvents, specific interactions are operating and that the thermal conversion proceeds *via* a transition state which is much less polar than the initial state.

The photochromism and thermochromism of 1′,3′,3′-trimethyl-6-nitrospiro[2*H*-1-benzopyran-2,2′-indoline] (6-nitrospiropyran) have been recognized as the equilibrium between stable colorless and metastable colored forms (Scheme 1).[1]



Scheme 1.

The absorption of light transforms the colorless form **A** having reciprocally orthogonal indoline and pyran rings into the colored form **B** having the structure of a merocyanine dye. This merocyanine form is considered as characterized by the coplanarity of the molecular skeleton. In the dark, form **B** thermally isomerizes to form **A**.[1] However, in spite of the fact that there have been some studies regarding the thermochromism of 6-nitrospiropyran, the mechanism of the thermal conversion (**B**→**A**) in relation to the polarity of the transition state has not been well established yet.

Very recently, we reported[2] that in the isomerization of 4-dimethylamino-4′-nitroazobenzene (NDAAB), the activation volumes ($\Delta V^{\neq} < 0$) tend to negatively increase with an increase in the solvent polarity. This trend regarding the pressure effect is just the reverse of that for some ionic reactions such as Menschutkin reactions.[3] We suggested, therefore, that this might be due to the dipole induced by polar solvents. Form **B** in Scheme 1 is electronically similar to *trans*-push-pull azobenzenes in the sense that the conjugation band shows remarkable shifts.[4] Therefore, it is of great interest to investigate the kinetic solvent effects of 6-nitrospiropyran and to compare these with those of push-pull azobenzenes such as NDAAB.

This work has been undertaken from such a point of view and a discussion regarding the electronic structure of the transition state is presented.

Experimental

Reagent. 1′,3′,3′-Trimethyl-6-nitrospiro[2*H*-1-benzopyran-2,2′-indoline] (6-nitrospiropyran) was purchased from Tokyo Chemical Industry Co. and was used as received; mp 179—180 °C (lit,[5] 179—180 °C).

Solvents. All the chemicals were of reagent grade. Hexane, cyclohexane, dioxane, and benzene were purified by drying over sodium wire and distillation. Chloroform, acetone, and acetonitrile were dried over calcium chloride, calcium sulfate, and calcium hydride, respectively, and distilled. *N*,*N*-Dimethylformamide (DMF) and dimethyl sulfoxide (DMSO) were dried over molecular sieves (Type 4A) and calcium hydride, respectively, and distilled under reduced pressure.

Apparatus and Procedure. The high-pressure techniques and procedures for kinetic measurements were the same as those described elsewhere.[2] The sample solution (*ca.* 10^{-4} mol dm^{-3}) was irradiated with a Toshiba H400-P mercury arc through an interference filter (Toshiba UV-D33D) to produce **B**. The thermal return was monitored by the change in the maximum absorption in the vicinity of 600 nm (**B**) by means of a Hitachi 139 spectrophotometer.

Results

The wavelengths at the maximum absorption of **B** of 6-nitrospiropyran and first-order rate constants in various solvents are given in Table 1, together with the activation parameters. The pressure dependence of the rate constants was treated by a quadratic equation (Eq. 1). The rate constants under high pressures and the activation volumes ($\Delta V^{\neq}$) at atmospheric pressure were estimated according to Eq. 2 and are given in Table 2.

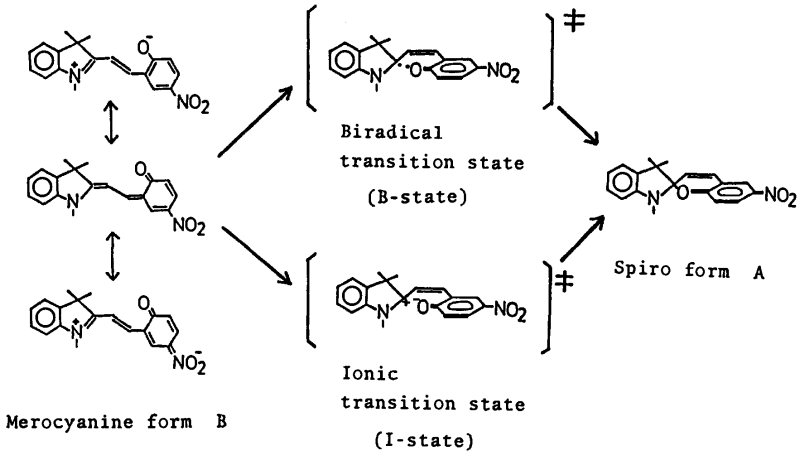
Discussion

Regarding the thermal conversion (**B**→**A**) of 6-nitrospiropyran, there are a few reports.[1] For example, Metras *et al.*[6] reported that the competitive ring-closure reaction takes place *via* either of the two conformational isomers. Meanwhile, Arnaud *et al.*[7] inferred the existence of four conformational isomers, and pointed out that a rapid equilibrium is established among them at room temperature and that the thermal conversion from **B** to **A** proceeds from one of them. A similar discussion has been presented by Tamagake *et al.*[8] who suggested eight possible conformational isomers. On the other hand, Flannery, Jr.[9] suggested that a rate-determining step (in polar solvents) is the dissociation of a dimer or of



Scheme 2.

a solute-solvent complex.

As far as we examined the electronic spectrum and the time-dependence of its intensity in the dark, any evidence to support the above suggestions has not been found. The visible absorption spectra in alkanes consist of two bands (Table 1). From the temperature dependence of the intensities of these bands, Heiligman-Rim *et al.*[10] concluded that the bands could be ascribed to two different conformational isomers, not to the vibrational structure for a single species. In fact, the relative rate of the disappearance of these bands at any time was constant, indicating that a rapid equilibration between the two isomers had been attained before the ring-closure reaction (**B**→**A**) occured. Judging from the spectral shifts of merocyanine dyes,[11] the band in the vicinity of 620 nm in alkanes could be ascribed to the conformational isomer that dominantly exists in polar solvents (the structure has not been clarified yet). However, even if the reaction proceeds from one of the conformational isomers, there are two possible routes (Scheme 2): One involves the homolytic fission of the bond between the spiro C atom and the pyran oxygen to produce a biradical transition state (B-state) and the other involves a heterolytic fission to produce an ionic transition state (I-state). Since the thermal conversion from **B** to **A** is a Cyclization reaction, it is natural to assume these cyclic transition tates. In the transition state, the delocalization of the π-electrons, substantiated in form **B**, becomes impossible since the indoline and pyran parts of the molecule are reciprocally orthogonal. Accordingly, the I-state must be zwitterionic such as the products of the Menschutkin reaction.[3] In order to clarify which of these routes is more consistent with the experimental observations, we have examined the kinetic solvent and pressure effects regarding the thermal conversion.

Solvent Effects. Figure 1 shows an *Ea vs.* $\Delta S^{\neq}$ plot. Though *Ea* and $\Delta S^{\neq}$ do not necessarily line up in the order of the dielectric constants of the solvents and a scatter is observed, it could be said that the linear free energy relationship[12] roughly holds. If the reaction of this system proceeds by a competitive mechanism[6] and the mechanism continuously varies with solvent polarities,[9] the Ea-$\Delta S^{\neq}$ plot might be curved. From the plots, such an indication is not observed.

On the basis of the Kirkwood treatment,[13] the dielectric influence of solvents on the rate constants for unimolecular reactions is given by

$$\ln k = \ln k_0 + \frac{N}{RT}\left(\frac{\mu_{\neq}^2}{r_{\neq}^3} - \frac{\mu^2}{r^3}\right)\left(\frac{\varepsilon-1}{2\varepsilon+1}\right), \qquad (3)$$

where notations have their usual meanings. If the $(\mu_{\neq}^2/r_{\neq}^3 - \mu^2/r^3)$-term is independent of the solvent polarity, a linearity between ln k and $(\varepsilon-1)/(2\varepsilon+1)$ is expected and the slope can be regarded as a measure of the change in the dipole moment upon activation. As shown in Fig. 2, the linearity is poor. Very recently, a similar nonlinear behavior of the Kirkwood plot was reported by Asano and Okada[14] for the thermal *cis*-to-*trans* isomerization of NDAAB: The plot becomes nonlinear when the points for all polar solvents are included. Asano and Okada interpreted this in terms of a mechanism change from inversion to rotation. According to our view,[2] however, such a behavior is not due to the intervention of a competitive reaction but arises due to the neglect of the induced dipole in the polar solvents. The solvent-induced dipole moment is not involved in the Kirkwood treatment.

Recently, ^{1}H- and ^{13}C-NMR spectroscopy have been applied to the problem of the electronic structure of the molecules having a conjugation system. For instance, on the basis of the ^{1}H-NMR spectral shifts in various solvents, Mottaleb and Kader[15] interpreted their shifts as an indication of a solvent-induced change in the electronic structure. Moreover, in a

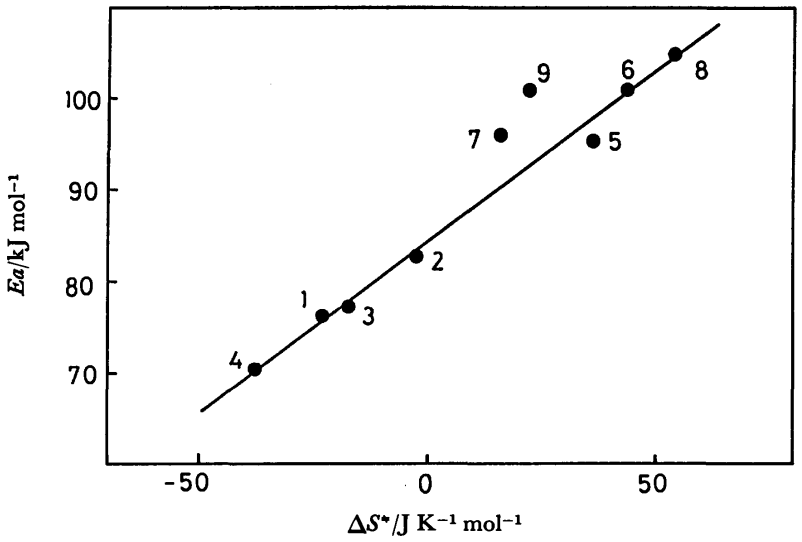


Fig. 1. Ea-ΔS^* relationship for the thermal conversion of 6-nitrospiropyran at 30 °C; correlation coefficient r 0.964.

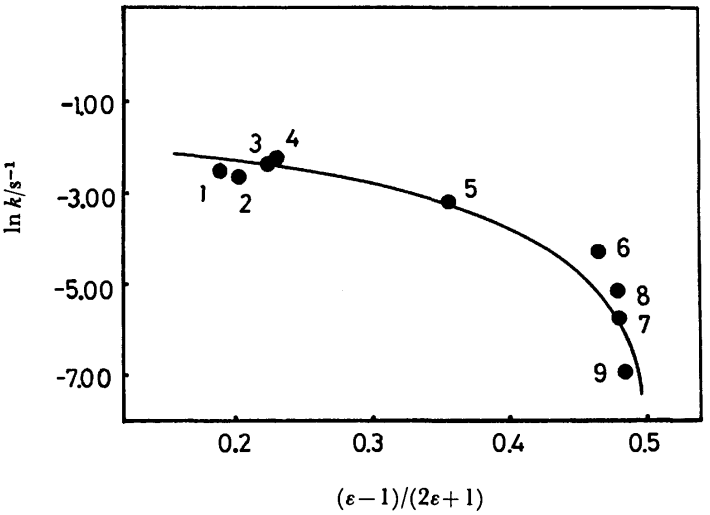

Fig. 2. The Kirkwood plot for the thermal conversion of 6-nitrospiropyran at 30 °C; correlation coefficient r −0.909.

theoretical investigation through the CNDO/S-CI method (including solvation for 4-[2-(1-methyl-4-pyridinio)ethenyl]phenolate which has a large π-electron system) Botrel *et al.*[16] showed a significant increase in the dipole moment with an increasing solvent polarity, and pointed out that it is important to take account of the change in the dipole moment induced by surrounding solvents. These are in accordance with our view.

In this connection, we considered that scales involving solute-solvent interactions at molecular levels would be better than a macroscopic dielectric constant in order to analyze the reaction-rate data. Whitten *et al.*[17] examined the relationship between the activation parameter $\Delta G^{\neq}$ of the thermal *cis*-to-*trans* isomerization of 4-diethylamino-4′-nitroazobenzene and the empirical scales (Koswer's Z-values, the Taft π^* parameter *etc.*), and have shown that they are linearly related (as a whole). We also have tentatively plotted ln k against Kosower's Z-values[18] (Fig. 3). Although a considerable scatter is observed (as in the case of azobenzenes shown in Ref. 17) the linearity is much improved over the Kirkwood plot. We could say, therefore, that for reactions where the change in the delocalization of π-electrons upon activation plays an important role, these empirical scales are better than the macroscopic ε-scale, although the choice of those scales is somewhat arbitrary.

In any case, the reaction rates were remarkably retarded in polar solvents (Table 1). If a biradical mechanism (Scheme 2) is assumed for the reaction, the transition state may be less polar than the initial one. This accounts for the above observations. On the contrary, if the reaction proceeds *via* the I-state,

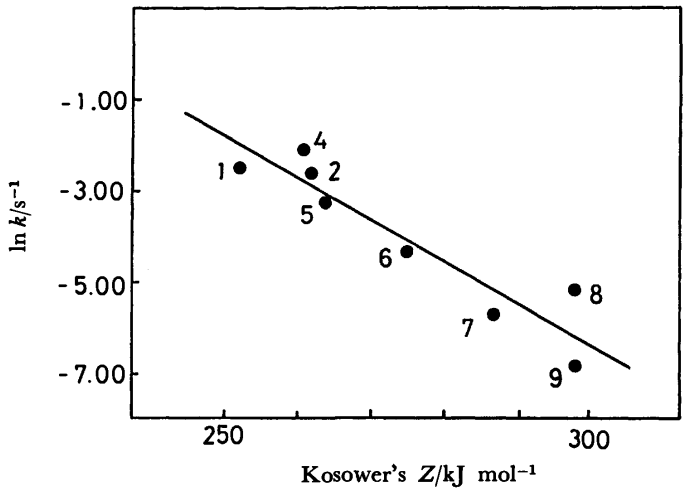

Fig. 3. $\ln k$ (at 30 °C) *vs.* Kosower's Z-values; correlation coefficient r −0.931.

an acceleration of the reaction rate is expected in analogy with the case of the Menschutkin reaction.[3] This is against the experimental observations.

Pressure Effects. The activation volume ($\Delta V^{\neq}$) is given (after differentiating Eq. 1 with respect to pressure) by,

$$\Delta V^{*} = \Delta V_0^{*} - N\left(\frac{\mu_{*}^{2}}{r_{*}^{3}} - \frac{\mu^{2}}{r^{3}}\right)\frac{3}{(2\varepsilon+1)^{2}}\left(\frac{\partial\varepsilon}{\partial p}\right)_T \quad (4)$$

where $\Delta V_0^{\neq}$ is the difference in the intrinsic volume of a reaction molecule between the initial and the transition states. The second term represents the change in volume due to solvation or electrostriction. In our case, if the thermal conversion (**B**→**A**) proceeds *via* the cyclic transition state, it may safely be considered that the change in the intrinsic volume ($\Delta V_0^{\neq}$) accompanying cyclization upon activation is similar to the activation volume of the Claisen rearrangement reaction,[19] which is considered not to involve a volume change due to electrostriction. The reported activation volumes are about −15 cm^3 mol^{-1} for the Claisen rearrangement reaction.[19] If the reaction proceeds *via* the zwitterionic transition state, solvent may be constricted upon activation, as exemplified by the Menschutkin reaction.[3] Accordingly, the value for the activation volume ($\Delta V^{\neq}$) is large and negative, as expected from Eq. 4. On the contrary, if the biradical mechanism is assumed for the reaction, a positive activation volume is expected due to the release of electrostricted solvent molecules, as Stwart and Weale[20] reported for the reverse Menschutkin reaction ($\Delta V^{\neq}$=45 cm^3 mol^{-1}). As can be seen in Table 2, the activation volumes obtained are all positive and divided roughly into two groups: $\Delta V^{\neq}\approx$10 cm^3 mol^{-1} (in nonpolar solvents) and $\Delta V^{\neq}\approx$20 cm^3 mol^{-1} (in polar solvents). Therefore, the biradical mechanism is more favorable than the ionic one.

On the assumptions of the biradical mechanism and $\Delta V_0^{\neq}\approx$−15 cm^3 mol^{-1}, the activation volume can be estimated according to Eq. 4. In benzene, by substituting the numerical values (μ=12.7 Debye,[21] $\mu_{\neq}\approx$0 Debye, r=4 Å (the distance between >N- and the nitro group), and $[3/(2\varepsilon+1)^2](\partial\varepsilon/\partial p)_T$=15×10^{-11} Pa^{-1} at 30 °C[22]) into Eq. 4, the change in volume due to desolvation is calculated to be 23 cm^3 mol^{-1}. Therefore, the total volume change ($\Delta V^{\neq}$) is calculated to be 8 cm^3 mol^{-1}. Similarly, the activation volume in hexane ($[3/(2\varepsilon+1)^2](\partial\varepsilon/\partial p)_T$=19.4×10^{-11} Pa^{-1} at 30 °C[22]) is estimated to be 14 cm^3 mol^{-1}. As may be seen in Table 2, these estimated values are approximately in accordance with the experimental ones. Similarly, the activation volume in acetone can be estimated as −7.7 cm^3 mol^{-1} ($[3/(2\varepsilon+1)^2](\partial\varepsilon/\partial p)_T$= 4.82×10^{-11} Pa^{-1} at 30 °C[22]). This value is extremely small compared with the observed one. The large discrepancy between the calculated and observed $\Delta V^{\neq}$-values in acetone may be ascribed to a change in the μ-term in Eq. 4 upon increasing the polarity of the solvent. In a previous section, we considered that the B-state is plausible and the extra dipole moment of form B with an ionic resonance structure is induced in polar solvents. The large positive $\Delta V^{\neq}$-value in acetone may be resposible for the increase in the dipole moment. The same trend has been observed for the thermal *cis*-to-*trans* isomerization of push-pull azobenzenes. The common situation is that a remarkable polarization through the delocalization of the π-electrons is considered to be substantiated both in the ground state (present case) and in the transition state (case of push-pull azobenzenes), and that the contribution of the polarized canonical resonance form is reinforced by polar solvents, in agreement with other evidence.[15,16] The large $\Delta V^{\neq}$-values in polar solvents can be qualitatively explained by this reasoning.

In conclusion, the kinetic solvent and pressure

effects are in favor of the biradical mechanism *via* the less-polar transition state for the thermal conversion (**B**→**A**) of 6-nitrospiropyran and against the ionic one *via* the polar transition state.

NQR Study of Phase Transitions in $SbCl_3 \cdot (C_6H_5)_2NH_2^+Cl^-$ and $2SbCl_3 \cdot C_6H_5OCH_3$

Hideta ISHIHARA,* Tsutomu OKUDA,† Koji YAMADA,† and Hisao NEGITA†
Department of Chemistry, Faculty of Education, Saga University, Honjo-machi, Saga 840
†*Department of Chemistry, Faculty of Science, Hiroshima University, Naka-ku, Hiroshima 730*
(Received March 29, 1985)

The temperature dependence of ^{35}Cl and $^{121,123}Sb$ NQR frequencies was measured in $SbCl_3 \cdot (C_6H_5)_2NH_2^+Cl^-$ between 77 and 300 K. A phase transition takes place at 108 K and ^{35}Cl NQR lines disappeared above about 275 K. Possible mechanisms of the phase transition and of the disappearance of ^{35}Cl NQR lines were suggested. The phase transition in $2SbCl_3 \cdot C_6H_5OCH_3$ was investigated by the NQR technique. The temperature dependence of the splitting of the $^{121}Sb(\nu_1)$ NQR lines in the low-temperature phase gave a critical exponent of $\beta=1/2$ near the transition point T_c. A Zeeman-effect experiment revealed that the crystals in both low- and high-temperature phases were monoclinic.

In the course of the study regarding the bond character in $SbCl_3$ molecular complexes[1,2] we have observed the phase transition and the disappearance of ^{35}Cl NQR lines in $SbCl_3 \cdot (C_6H_5)_2NH_2^+Cl^-$. A possible mechanism for the phase transition could be inferred on the basis of the crystal structure.[3] Kyuntsel' and Rosenberg reported a phase transition at 141 K in $2SbCl_3 \cdot C_6H_5OCH_3$ and suggested that the change of the relative position of $SbCl_3$ and methoxybenzene molecules took part in the phase transition.[4] We carried out a Zeeman-effect experiment on this compound in order to obtain information regarding the crystal structure.

Experimental

The compounds were prepared by melting and mixing $SbCl_3$ with diphenylammonium chloride and methoxybenzene in a molar ratio of 1:1 and 2:1, respectively. A single crystal of $2SbCl_3 \cdot C_6H_5OCH_3$ was prepared by the Bridgman method. NQR lines were displayed on an oscilloscope using a supperregenerative oscillator with the frequency modulation or recorded on a pen-recorder using an oscillator with the Zeeman modulation and a lock-in amplifier.

Results and Discussion

The results of the NQR measurement are listed in Table 1. The values for $2SbCl_3 \cdot C_6H_5OCH_3$ at 77 K are comparable to those already reported.[5]

$SbCl_3 \cdot (C_6H_5)_2NH_2^+Cl^-$. Figure 1 shows the temperature dependence of ^{35}Cl and $^{123}Sb(\nu_1)$ NQR frequencies between 77 and 300 K. The frequency-temperature curves of ^{35}Cl NQR lines showed a discontinuity at 108 K. The $^{121,123}Sb$ NQR lines were not observed below 108 K. We intended to search for the Sb NQR lines at 77 K between 6 and 48 MHz.

TABLE 1. NQR PARAMETERS FOR $SbCl_3 \cdot (C_6H_5)_2NH_2^+Cl^-$ AND $2SbCl_3 \cdot C_6H_5OCH_3$

Compound	T/K	Assignment		ν/MHz	
$SbCl_3 \cdot (C_6H_5)_2NH_2^+Cl^-$	77	^{35}Cl		20.39, 18.03, 17.32	
	109	^{123}Sb	ν_1[a]	29.96	$e^2Qq/h(^{121}Sb)=308.9$ MHz[b]
		^{121}Sb	ν_1	47.27	$\eta=0.136$
	263	^{35}Cl		19.91, 17.85, 17.10	
		^{123}Sb	ν_1	28.06	$e^2Qq/h(^{121}Sb)=294.4$ MHz[b]
		^{121}Sb	ν_1	44.85	$\eta=0.119$
$2SbCl_3 \cdot C_6H_5OCH_3$	77	^{35}Cl		20.82, 20.50, 20.42, 20.19, 19.14, 19.12	
		^{121}Sb	ν_1	63.12	$e^2Qq/h(^{121}Sb)=411.9$ MHz[c]
		^{121}Sb	ν_2[a]	123.09	$\eta=0.141$
		^{121}Sb	ν_1	61.19	$e^2Qq/h(^{121}Sb)=401.1$ MHz[c]
		^{121}Sb	ν_2	119.97	$\eta=0.125$
	R.T.[d]	^{35}Cl		19.81, 19.72, 18.80	
	298	^{121}Sb	ν_1	59.41	$e^2Qq/h(^{121}Sb)=389.1$ MHz[c]
		^{121}Sb	ν_2	116.38	$\eta=0.130$

a) ν_1 and ν_2 are frequencies corresponding to the transitions $\pm1/2 \leftrightarrow \pm3/2$ and $\pm3/2 \leftrightarrow \pm5/2$, respectively. b) The values of e^2Qq/h and η were derived from the frequency ratio of $\nu_1(^{121}Sb)/\nu_1(^{123}Sb)$. c) The values of e^2Qq/h and η were derived from the frequency ratio of ν_1/ν_2 for ^{121}Sb. d) R.T. signifies room temperature.

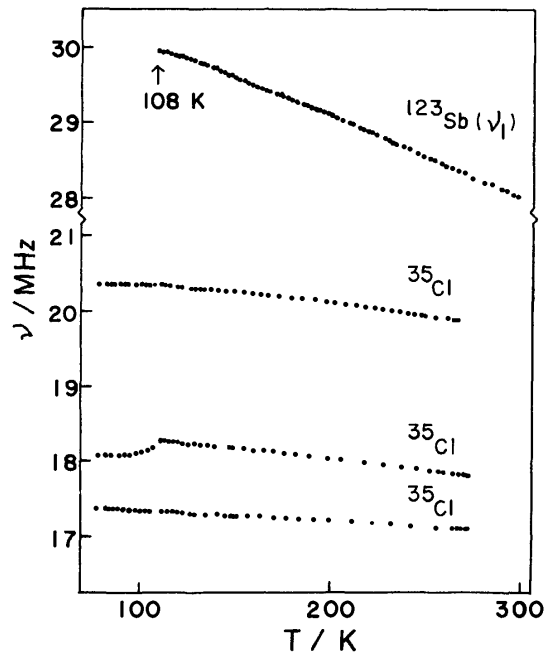

Fig. 1. Temperature dependence of $^{123}Sb(\nu_1)$ and ^{35}Cl NQR frequencies in $SbCl_3 \cdot (C_6H_5)NH_2{}^+Cl^-$.

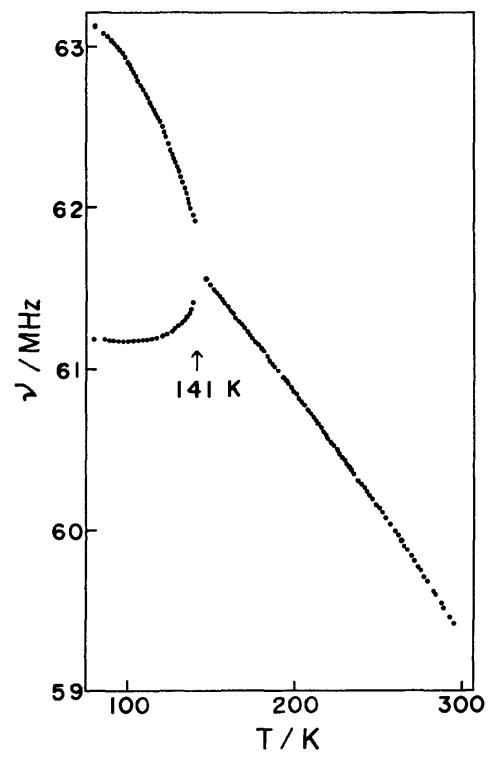

Fig. 2. Temperature dependence of $^{121}Sb(\nu_1)$ NQR frequencies in $2SbCl_3 \cdot C_6H_5OCH_3$.

One weak NQR line was recorded at 20.52 MHz and this line could not be assigned because the NQR line due to the corresponding isotope was not observed. One ^{35}Cl NQR line shows a greater frequency shift than the other two lines in the low-temperature phase. An assignment of the ^{35}Cl NQR lines to each chlorine atom in a crystal can be made on the basis of the relation between the Sb-Cl bond length and the ^{35}Cl NQR frequency,[2] *i.e.*, the NQR frequency generally decreases with an increasing bond length. Accordingly, this line is assigned to the chlorine atom in a position *trans* to the chloride ion situated at a distance of 3.130 Å from the Sb atom.[3] This chloride ion also forms a N-H···Cl^- hydrogen bond with the diphenylammonium cation.[3] We consider that in the low-temperature phase the N-H bond length becomes short and this results in the weakning of the H···Cl^- interaction and the approach of the chloride ion to the Sb atom. Therefore, below the transition point the coordination state about the Sb atom changes and then the Sb NQR frequencies change greatly. In addition, a ^{35}Cl NQR line due to a chlorine atom in the Sb-Cl bond *trans* to this chloride ion shows a decreased frequency since the Sb-Cl bond is weakened by the *trans* influence. This could be seen in some other $SbCl_3$ complexes.[1,2]

The ^{35}Cl NQR lines disappeared above about 275 K, but the Sb NQR lines were observed at room temperature. From the results of a ^1H NMR measurement, the second moment decreased from 9 G^2 at 270 K to 5 G^2 at 300 K. In addition, the thermal parameters of the carbon atoms in the diphenylammonium cation have large values according to an X-ray crystal-structure analysis.[3] These facts show that some motions of the cation take place at room temperature. We consider that these cation motions and/or the reorientation of the $SbCl_3$ molecule as is seen in $SbCl_3 \cdot C_8H_{10}$[2] cause the disappearance of the ^{35}Cl NQR lines. We could not observe the thermal anomaly around the transition point by a differential thermal analysis.

$2SbCl_3 \cdot C_6H_5OCH_3$. Figure 2 shows the temperature dependence of $^{121}Sb(\nu_1)$ NQR frequencies between 77 and 300 K. Below the transition point, the resonance line splits into two lines with equal intensity. The frequency difference Δ in the low-temperature phase serves as a measure of the order parameter.[6,7] It could be seen from the plot of Δ^2 as a function of temperature that Δ^2 was a linear function between 123 and 138 K. Then, the transition point T_c was obtained by a best-fit procedure and it gave T_c=141.3±0.8 K. Using this value, it was also possible to fit Δ to the function[6]

$$\Delta = D\varepsilon^{\beta}, \tag{1}$$

where $\varepsilon = |T_c - T|/T_c$ and β is the critical exponent. The values of D and β were obtained by the best fit of a log-log plot and it gave D=3.2±0.2 MHz and β=0.50±0.01 between $\varepsilon = 2.1\times10^{-2}$ and $\varepsilon = 1.2\times10^{-1}$. In

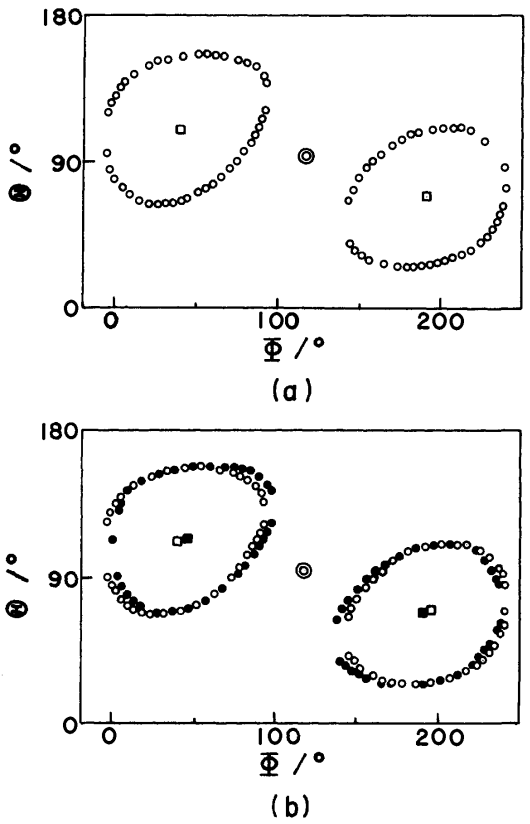

Fig. 3. Zero-splitting loci for $^{121}Sb(\nu_1)$ NQR lines in $2SbCl_3 \cdot C_6H_5OCH_3$.
(a) Zero-splitting loci at room temperature.
(b) Zero-splitting loci at liquid-nitrogen temperature, ● for the 63-MHz line and ○ for the 61-MHz line. ■ and □: principal z-axes of EFG tensors; ◎: two-fold axis.

addition, the average frequency of the two split lines in the low-temperature phase was not continuously connected with the extraporation of the high-temperature curve. These experimental results confirm that β=0.5. This value is consistent with what the usual molecular field theory predicts.[6,7]

Figure 3 shows the zero-splitting loci at room temperature and liquid-nitrogen temperature. The single crystal for the Zeeman experiment was not broken by repeated heating and cooling cycles through the transition point. The measured points were fitted to the equation of a quadratic cone by the least-squares method in order to obtain the direction of the principal axes of the electric field gradient (EFG) tensor and the asymmetry parameter η. The obtained values of η were 0.142±0.007 for the 63-MHz line and 0.130±0.003 for the 61-MHz line at liquid-nitrogen temperature and 0.138±0.005 for the line at room temperature, respectively. The polar coordinates (Φ, Θ) for the principal z-axes of the EFG tensors in both phases are listed in Table 2 with respect to an orthogonal-axis system fixed to a

Table 2. Polar coordinates of the principal z-axes of EFG tensors

Temperature	Resonance line	(Φ, Θ)/° [a]	
ca. 300 K		(39.0, 112.1)	(192.6, 70.2)
ca. 77 K	63-MHz	(42.1, 113.8)	(189.0, 69.4)
	61-MHz	(36.9, 111.8)	(194.3, 70.3)

a) The standard deviations of the directions of the magnetic field for zero-splitting from the leat-squares method are 0.2° at room temperature and 0.5° at liquid-nitrogen temperature.

crystal. The four zero-splitting loci which showed a Laue symmetry $2/m$ were obtained for each line in both phases. Only a pair of cones related to each other by the two-fold axis are represented in Fig. 3. The polar coordinates for the two-fold axis were obtained from the symmetry among the zero-splitting loci, *i.e.*, (117.7, 95.1) for the high-temperature phase and (117.6, 95.3) for the low-temperature phase. The Laue symmetry shows that the crystal in each phase belongs to a monoclinic system considering a number of ^{35}Cl and $^{121,123}Sb$ NQR lines. It is also apparent that two $SbCl_3$ molecules represented by the chemical formula are crystallographically equivalent in the high-temperature phase. We consider that the crystal in the high-temperature phase has two types of symmetry elements, *i.e.*, a two-fold screw axis and a center of symmetry by which two $SbCl_3$ molecules are related to each other and that the crystal loses its center of symmetry in the low-temperature phase. A phenomenon like this has been actually observed in $NH_4H(ClCH_2COO)_2$.[8] In addition, we suggest that the loss of the center of symmetry arises from the displacement of a methoxybenzene molecule. This suggestion could be derived from the results of an observation of the ^{35}Cl NQR lines.

In the 2:1 $SbCl_3$ molecular complexes with aromatic compounds, the lowest NQR line is generally assigned to the chlorine atom in the Sb–Cl bond perpendicular to the aromatic ring and the other chlorine atoms in the Sb–Cl bonds parallel to the ring give the higher NQR lines.[2] On the basis of the NQR frequencies for $2SbCl_3 \cdot C_6H_5OCH_3$ at room temperature, two resonance lines around 19 MHz were assigned to the chlorine atoms in the parallel Sb–Cl bonds and the line around 18 MHz to the one in the perpendicular Sb–Cl bond. Although each resonance line splits into two lines and, therefore, six resonance lines are observed in the low-temperature phase, we could distinguish three pairs of lines and also assigned them to individual lines in the high-temperature phase on the basis of the intensity ratio of the resonance lines for a single crystal. The magnitudes of the splittings at 77 K are 400 and 310 KHz for the chlorine atoms in the parallel Sb–Cl

bonds and 20 KHz for the one in the perpendicular Sb–Cl bond. The change of the crystal field which arises from the displacement of the methoxybenzene molecule must largely affect the chlorine atoms in the parallel Sb–Cl bonds near the ring. This is consistent with a suggestion by Kyuntsel' and Rosenberg.[4] For a more detailed discussion, a crystal-structure analysis is necessary. A differential thermal analysis shows that there is a small shift of the base line at the transition point and it is considered that a discontinuous change in the specific heat takes place.

Studies of Polystyrene-based Ion-exchange Fiber. III. A Novel Fiber-form Chelating Exchanger and Its Adsorption Properties for Heavy-metal Ions†

Toshio YOSHIOKA
Fibers Research Laboratories, Toray Industries, Inc., Sonoyama, Otsu 520
(Received May 4, 1985)

Fibrous chelating exchangers with $-N(CH_2COOH)_2$ and $-N(CH_2CH_2COOH)_2$ groups have been prepared for the first time by using a polystyrene–polypropylene composite fiber as the starting material. They have large surface areas per unit of weight and can be utilized in various forms. The properties of adsorbing Cu^{2+} are compared between these chelating fibers and an ordinary chelating resin. The former groups form more stable complexes with Cu^{2+} than the latter, probably because of their different chelating structure. The rate of the adsorption of Cu^{2+} to the fibers is dependent upon their water content and is from ten to fifty times as high as that to the resin. These results are explained by assuming that the diffusion within the exchangers is the major rate-controlling step in the adsorption process. The diffusion equation of isotopic ion exchange for a cylindrical endless fiber was solved in the case of ideal particle-diffusion control by modifying the method used for a spherical resin. The experimental data are interpreted in terms of their theoretical solutions. For practical application, the removal of Cu^{2+} and Mn^{2+} from various solutions was also carried out by using fixed-beds of these chelating fibers.

The preparation methods, fundamental characteristics, and acid-base catalytic properties of a polystyrene-based ion-exchange fiber (IONEX) have already been reported by the present author and his co-worker.[1,2] This ion-exchanger based on a polystyrene–polypropylene composite fiber has high mechanical strengths and can be used in various forms. The ion-exchange fiber also has two fundamental characteristics because of its larger surface areas; the ion exchange rate for metal ions is extremely high, and the capacity for adsorbing the macromolecular ionic substances is exceedingly large, compared with ordinary ion-exchange resins. Taking the latter characteristic into account, we have also studied the adsorption or immobilization to IONEX of biologically-active substances, such as enzyme, protein, and microorganism cell. These results have been published in preliminary reports.[3] Polystyrene is suitable for the addition not only of ionic groups, but also of various functional groups. The introduction of special functional groups to crosslinked polystyrene–polypropylene composite fibers is of especial interest. The quaternary phosphonium ions and crown ethers supported on the polystyrene–polypropylene composite fiber have been investigated as phase-transfer catalysts for numerous organic reactions by Tomoi and Kakiuchi.[4]

Recently selective chelating resins based on a styrene–divinylbenzene polymer have been intensively studied[5–8] and used for the separation, removal, and recovery of heavy-metal ions in the fields of waste-fluid treatment, the atomic-power industry, the food industry, and analytical chemistry. The use of chelating resins, however, has the disadvantage that the adsorption rate is very low because of their small ion dissociation in comparison with strong cation- and anion-exchange resins.[9–13] Although the adsorption rate is enhanced by using fine or crushed resins, the treatment of such resins becomes difficult.[11,13] It is also well-known that adsorption properties are affected by the physical structure of polymers supporting chelating groups.

In order to enhance the adsorption rate and to make the treatment easier, we have undertaken an investigation of fibrous chelating exchangers, which have large surface areas per unit of weight and which can be used in various forms. An iminodicarboxylic-acid-type chelating fiber has been prepared, for the first time, by using the polystyrene–polypropylene composite fiber as the starting material; it has then been used in the adsorption of Cu^{2+}.[14] In this paper the author would like to report on this chelating fiber and its ability to adsorb Cu^{2+}. The results of the adsorption rate will be discussed in terms of the kinetic theory of isotopic ion exchange for fiber systems, which is introduced in detail here. The results of removing Cu^{2+} and Mn^{2+} from various solutions by fixed-beds of the chelating fiber will also be described.

Experimental

Polystyrene–Polypropylene Composite Fiber. Forty-nine parts of polystyrene and 12 parts of polypropylene as the *sea* ingredient and 39 parts of polypropylene as the *island* ingredient were melt-spun at 255 °C into composite filaments with an *islands-in-a-sea* type sectional structure, as is shown in Fig. 1. The composite filaments were drawn five times as long as their original length in a conventional manner. The diameters of the *sea* and the *islands* of the resulting filaments were 20 and 3.1 μm respectively. Their tensile strength was 2.5 g d^{-1}.[14]

Crosslinked Polystyrene–Polypropylene Composite Fiber. Ten grams of the fiber were high-(or low-) crosslinked in 100 ml of a solution consisting of 5 wt% paraformaldehyde, 25 (45) wt% acetic acid, and 70 (50) wt% concd sulfuric acid

† A preliminary report of this work was presented in *Polym. Prepr. Jpn.*, **33**, 1615 (1984).

at 80 °C for 2 h.[14]

Iminodiacetic-acid(IDA)-type Chelating Fiber. Ten grams of the crosslinked fiber were acrylamidomethylated in a solution comprising 20 g of bis(acrylamidomethyl) ether, 200 ml of nitrobenzene, and 140 g of concd sulfuric acid at room temperature for 20 h. After being extracted with methanol, the fiber was treated in 450 ml of concd hydrochloric acid at 105 °C for 20 h; it was thus hydrolyzed into an aminomethylated fiber.[15] The IDA-type chelating IONEX was obtained by treating the aminomethylated fiber (10 g) with a solution consisting of 27 g of chloroacetic acid, 11 g of sodium hydroxide, 19 g of sodium carbonate, and 130 g of water at 100 °C for 8 h.[14] The structure of the IDA chelating group is shown in Fig. 2.

Iminodipropionic-acid(IDP)-type Chelating Fiber. Ten grams of the crosslinked fiber were chloromethylated in a solution comprising 100 ml of chloromethyl methyl ether and 10 ml of tin(IV) chloride at 30 °C for 1 h. Ten grams of the chloromethylated fiber were treated in a solution consisting of 160 g of *N, N, N″, N″*-tetrakis(2-cyanoethyl)diethylenetriamine and 350 ml of dioxane at 70 °C for 6 h. The IDP-type chelating IONEX was obtained by treating the fiber with 450 ml of concd hydrochloric acid at 60 °C for 6 h.[14,16] The structure of the IDP chelating group is also shown in Fig. 2.

Adsorption Capacity of Cu^{2+}. A chelating IONEX (0.25 g in the Na form) was added to 100 ml of a 0.013 M†† Cu^{2+} solution containing 0.5 M NaCl and a Clark Lubs buffer of pH 6.0, and then the mixture was strongly shaken at 20 °C for 24 h. The adsorption capacity of Cu^{2+} to the fiber was evaluated by measuring the concentration of Cu^{2+} in the solution before and after the adsorption treatment.

Water Content. A chelating IONEX in the Na form was immersed in a bath of deionized water at room temperature for a sufficient period of time to reach saturation. The fiber was then centrifugally dehydrated at 3000 r.p.m. for 5 min. Immediately thereafter, the wet weight (W) of the fiber was measured. The water content of the fiber was determined from the following equation:

$$\text{Water content} = (W - W_0)/W_0,$$

where W_0 is the absolutely dry weight of the fiber.

Chelating Resin and Measurements. The bead chelating resin (Diaion CR-10, IDA-type resin based on styrene-divinylbenzene copolymer) with a diameter of *ca.* 400 μm and a water content of 1.7 was obtained from the Mitsubishi Kasei Kogyo Co., Ltd. (Japan). The concentrations of Cu^{2+} and Mn^{2+} were determined by using an atomic absorption photometer.

Results and Discussion

Fibrous Chelating Exchanger. The process of preparing the chelating fiber is shown in Fig. 3. The chelating fiber in various forms, such as filament, cut fiber, knitted fabric, woven fabric, braid, felt, nonwoven fabric, chip, and paper, can be obtained by processing the polystyrene-polypropylene composite fiber before crosslinking reactions, as the fiber reinforced with polypropylene has high mechanical strengths. Figure 4 shows the polystyrene-poly-

Fig. 3. Process of preparing the polystyrene-based chelating fiber.

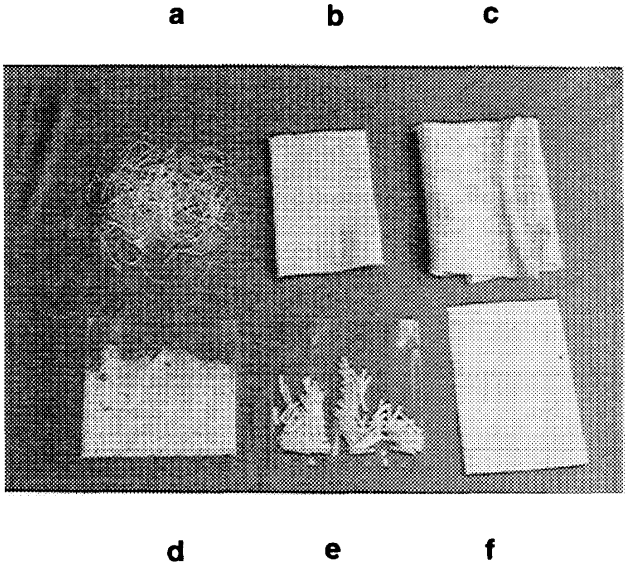

Fig. 4. Polystyrene-polypropylene composite fiber in various forms of filament (a), needle punched felt (b), knitted fabric (c), cut fiber (d), chip (e), and paper (f).

propylene composite fiber in the various forms. The characteristic data of the chelating IONEX are summarized in Table 1. The chelating filaments had a diameter of *ca.* 30 μm and exhibited a tensile strength of *ca.* 1.0 g d^{-1}. It was found that the low-crosslinked fibers have larger adsorption capacities and water contents than the high-crosslinked ones. The former result is explained by the fact that the amount of the aminomethyl or chloromethyl group introduced in the synthetic process is larger in the case of the low-crosslinked fiber because of its high reactivity.

Equilibrium Adsorption. The correlation between the adsorption capacity of Cu^{2+} and the pH in the solution for various chelating exchangers is shown in Fig. 5. The IDA-type fiber exhibits the same pH dependence as the CR-10 resin. The half-pH, where the adsorption capacity becomes half of pH 5.2, is 1.7. On the other hand, the IDP-type fiber exhibits a different pH dependence from the IDA-type; here, the half-pH is 2.9. These results indicate that the IDA type forms more stable complexes with Cu^{2+} than the IDP type.[7] This fact can be explained by assuming that the former coordinates to Cu^{2+} by forming five-members rings while the latter does so by forming six-members rings.

Adsorption Rate Ion exchange between the Na form of a chelating exchanger (0.25 g) and a 0.013 M Cu^{2+} solution containing 0.5 M NaCl and a Clark Lubs buffer of pH 6.0 (100 ml) was examined. Figure 6 displays the fractional attainment of the equilibrium as a function of the time. The fibers do not require ten minutes to attain 50% of equilibrium, whereas the resin requires more than one hour. Besides, the exchange rate becomes higher as the water content of the fibers increases, that is, as the degree of crosslinking is lowered. This means that the diffusion within the exchangers is the major rate-controlling step in the adsorption process. The plots of t_R/t_F *vs.* the water content of the fibers is given in Fig. 7, where t_R and t_F are the half-times of ion exchange for the resin and the fiber respectively. It can be seen from Fig. 7 that the exchange rate of the fiber is forty times higher than that of the resin when

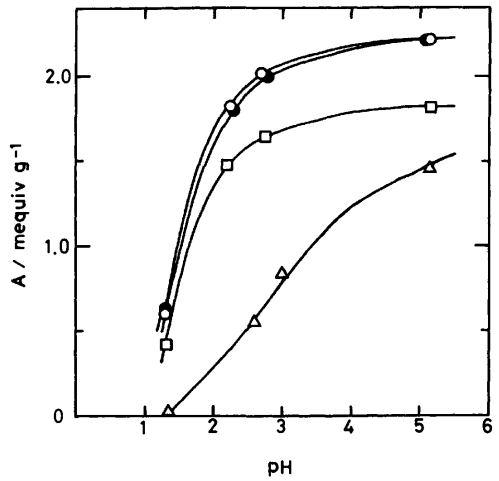

Fig. 5. Effect of pH in solution on adsorption capacity of Cu^{2+}. Adsorption to Na form of chelating exchanger (0.25 g) was carried out with 100 ml of 0.013 M Cu^{2+} solution containing 0.5 M NaCl and Clark Lubs buffer (20 °C, 24 h).

Table 1. Characteristic data of chelating IONEX

No.	Chelating group	Fiber form[a]	Degree of crosslinking	Capacity[b] / mequiv g^{-1}	Water[c] content
1	IDA-Na	filament	low	2.2	2.6
2		filament	high	1.8	1.4
3		felt	high	1.8	—
4	IDP-Na	filament	low	1.5	1.7
5		filament	high	1.4	1.0

a) Diameter and composition of original fiber: 20 μm, *Sea*(PSt//PP)/*Islands*(PP) = (49//12)/39. b) Adsorption capacity for Cu^{2+}. c) $(W-W_0)/W_0$. W: wet weight, W_0: dry weight.

the fiber has the same water content (1.7) as the resin and that the exchange rate is independent of the structure of the chelating groups because of the diffusion control.

Theoretical Considerations. The theoretical solution of ion exchange[1,6,9] in a simple system (isotopic exchange) can be applied to our experimental results as a first-order approximation. We solve the diffusion equation in the case of an endless fiber with a radius of r_f and a length of l ($l \gg r_f$) by modifying the method used for a spherical resin.[1] The diffusion equation for the fiber systems in the case of an ideal particle-diffusion control is given by:

$$\frac{\partial \bar{C}_A}{\partial t} = \bar{D}_f\left(\frac{\partial^2 \bar{C}_A}{\partial r^2} + \frac{1}{r}\frac{\partial \bar{C}_A}{\partial r}\right), \tag{1}$$

where r is the radial coordinate of the fiber; t, the time; $\bar{C}_A$, the concentration of the A ion at r and t, and $\bar{D}_f$, the interdiffusion coefficient in the fiber. Hereafter, quantities with bars will refer to the interior of the fiber. A schematic drawing of the fiber systems is shown in Fig. 8. The general solution of Eq. 1 can be described as follows:

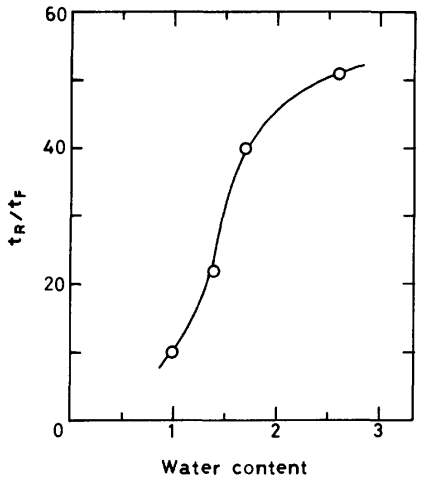

Fig. 7. t_R/t_F *vs.* water content of chelating IONEX. t_R: The half-time of ion exchange with Diaion CR-10, t_F: the half-time of ion exchange with chelating IONEX.

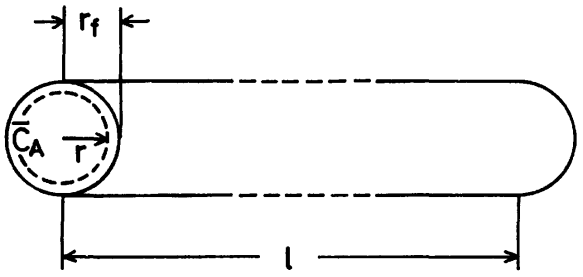

Fig. 8. Schematic drawing of fiber systems (Eq. 1).

$$\bar{C}_A = \sum_{n=1}^{\infty} A_n J_0(a_n r) \exp(-\bar{D}_f a_n^2 t), \tag{2}$$

where A_n is derived as:

$$A_n = \frac{2}{x_0^2[J_{i+1}(a_n x_0)]^2}\int_0^{x_0} x J_i(a_n x) f(x)\mathrm{d}x,$$

when $f(x)=\sum_{n=1}^{\infty} A_n J_i(a_n x)$ and $J_i(a_n x_0)=0$, in which $J_i(x)$ is the ith-order Bessel function.

The simple initial conditions are assumed to be:

$$\begin{aligned} &r > r_f,\ t = 0 && \bar{C}_A(r) = 0, \\ &0 \leqq r \leqq r_f,\ t=0 && \bar{C}_A(r) = \bar{C}_A{}^0 = \text{const.} \end{aligned} \tag{3}$$

Secondly we assume that the concentrations at the fiber surface are the same as in the bulk solution. The infinite solution volume condition is then postulated as:

$$r = r_f,\ t > 0 \qquad \bar{C}_A(t) = 0. \tag{4}$$

The conditions of Eqs. 3 and 4 give, respectively:

$$\bar{C}_A{}^0 = \sum_{n=1}^{\infty} A_n J_0(a_n r), \tag{5}$$

$$J_0(a_n r_f) = 0. \tag{6}$$

The A_n coefficients can, therefore, be determined from Eqs. 5 and 6 as follows:

$$\begin{aligned} A_n &= \frac{2}{r_f^2[J_1(a_n r_f)]^2}\int_0^{r_f} \bar{C}_A{}^0 r J_0(a_n r)\mathrm{d}r \\ &= \frac{2\bar{C}_A{}^0}{a_n r_f J_1(a_n r_f)}. \end{aligned} \tag{7}$$

The fractional attainment of the equilibrium, $U(t)$, is obtained from the integration of the solution $\bar{C}_A(r,t)$ throughout the fiber as:

$$U(t) = 1 - \frac{\int_0^{r_f} 2\pi r l \bar{C}_A \mathrm{d}r}{\pi r_f^2 l \bar{C}_A{}^0}. \tag{8}$$

By substituting Eqs. 2 and 7, Eq. 8 is finally reduced to:

$$\begin{aligned} U(t) &= 1 - \sum_{n=1}^{\infty}\frac{4}{a_n^2 r_f^2}\exp(-\bar{D}_f a_n^2 t) \\ &= 1 - \sum_{n=1}^{\infty}\frac{4}{x_n^2}\exp\left(-\frac{\bar{D}_f x_n^2 t}{r_f^2}\right), \end{aligned} \tag{9}$$

where the x_n quantities are the roots of the equation $J_0(x)=0$, as was preliminarily described in Ref. 1. From this equation, $U(t)$ is found to depend only on the magnitude of the dimensionless time parameter, $\bar{D}_f t/r_f^2$, which is plotted in Fig. 9 as a function of the parameter. The numerical values are tabulated in Table 2. The half-time of ion exchange is also

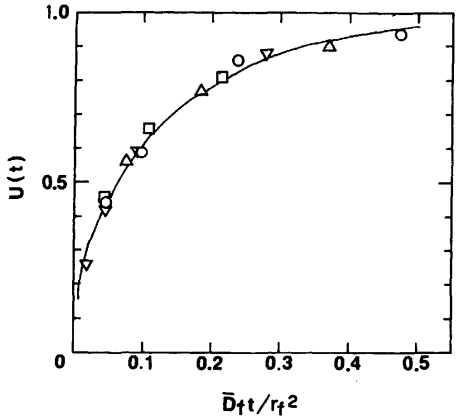

Fig. 9. Fractional attainment of equilibrium as a function of $\bar{D}_f t/r_f^2$. The solid line represents the theoretical curve for particle-diffusion controlled isotopic exchange in the case of cylindrical endless fiber (Eq. 9). Experimental points are plotted by use of empirical $\bar{D}_f$ obtained from Eq. 13. The notations for the points are used in the same meanings as Fig. 6.

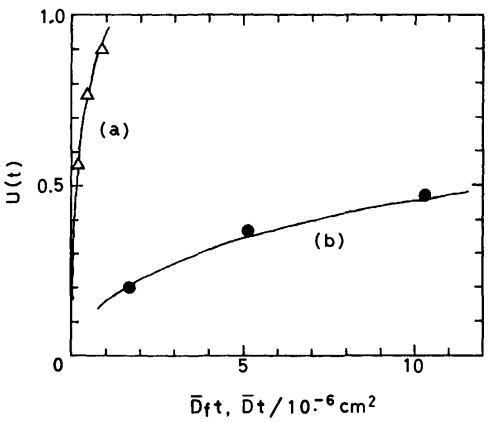

Fig. 10. Fractional attainment of equilibrium as a function of $\bar{D}_f t$ and $\bar{D}t$. The solid lines represent the theoretical curves for particle-diffusion controlled isotopic exchange. (a) Fiber with r_f=0.0015 cm and l=4.74 cm (Eq. 9), and (b) resin with r_0=0.02 cm (Eq. 11). Experimental points are plotted by use of empirical $\bar{D}_f$ and $\bar{D}$ obtained from Eqs. 13 and 14 respectively. The notations for the points are used in the same meanings as Fig. 6.

Table 2. Numerical values of

$$U(\tau) = 1 - \sum_{n=1}^{\infty} \frac{4}{x_n^2} \exp(-x_n^2\tau) \quad \text{(Eq. 9)}$$

τ	$U(\tau)$	τ	$U(\tau)$	τ	$U(\tau)$
0.005	0.155	0.05	0.452	0.20	0.782
0.01	0.215	0.06	0.489	0.25	0.837
0.02	0.299	0.08	0.553	0.30	0.878
0.03	0.360	0.10	0.606	0.40	0.932
0.04	0.410	0.15	0.708	0.50	0.962

readily derived from Eq. 9 as follows:

$$t_F = 0.065 r_f^2/\bar{D}_f. \tag{10}$$

The fractional attainment of the equilibrium, $U(t)$, within a spherical resin with a radius of r_0 has been described in the case of ideal particle-diffusion control by the following equation:

$$U(t) = 1 - \sum_{n=1}^{\infty} \frac{6}{X_n^2} \exp\left(-\frac{\bar{D}X_n^2 t}{r_0^2}\right) = 1 - \frac{6}{\pi^2} \sum_{n=1}^{\infty} \frac{1}{n^2} \exp\left(-\frac{\bar{D}\pi^2 n^2 t}{r_0^2}\right), \tag{11}$$

where $\bar{D}$ is the interdiffusion coefficient in the resin and where the quantities $X_n=\pi n$, the roots of the equation $J_{1/2}(x)=0$. The half-time of ion exchange has been calculated from Eq. 11 as follows:

$$t_R = 0.030 r_0^2/\bar{D} \tag{12}$$

The equations derived for the fractional attainments and the half-times do not involve $\bar{C}_A$ and remain unchanged under our experimental conditions.[6] Now, let us theoretically compare the ion-exchange rate of our fibers with that of the CR-10 resin, assuming that no polymer for the reinforcement in our fibers exists. The volume of the resin with r_0=0.02 cm corresponds to that of the fiber with r_f=0.0015 cm and l=4.74 cm. The theoretical $U(t)$ for the fiber and resin can be plotted as a function of the time parameter ($\bar{D}_f t$ and $\bar{D}t$) in Fig. 10 by using Eqs. 9 and 11 respectively. The half-times of ion exchange can also be obtained from Eqs. 10 and 12 respectively as:

$$t_F = 1.46 \times 10^{-9}/\bar{D}_f \tag{13}$$

$$t_R = 120 \times 10^{-9}/\bar{D}. \tag{14}$$

The ratio of the half-time of the resin to that of the fiber can be calculated to be 82 from Eqs. 13 and 14, as $\bar{D}_f=\bar{D}$ can be expected when the water contents are the same, that is, when there are the same degrees of crosslinking. The ratio obtained from the experimental data is, however, 40, about half the calculated ratio. This discrepancy can be interpreted on the assumption that the interdiffusion coefficients in our fibers are lowered because the polymer for reinforcement disturbs the diffusion of ions. The apparent $\bar{D}_f$ values for the fibers with the water contents of 1.0, 1.4, 1.7, and 2.6 can be directly evaluated from Eq. 13 to be 0.35, 0.80, 1.39, and 1.78×10^{-9} cm^2 s^{-1} respectively by using the half-times obtained from the experimental curves. Similarly, the apparent $\bar{D}$ value for the resin with the water content of 1.7 can be evaluated to be 2.86×10^{-9} cm^2 s^{-1} from Eq. 14. In Fig. 9, the experimental $U(t)$–$\bar{D}_f t/r_f^2$ data obtained by the use of these empirical interdiffusion coefficients are given, together with the theoretical curve. The experimental $U(t)$–$\bar{D}_f t$ and $-\bar{D}t$ data

obtained by the use of $\bar{D}_f=1.39\times10^{-9}$ cm^2 s^{-1} and $\bar{D}=2.86\times10^{-9}$ cm^2 s^{-1} are also compared with the theoretical curves in Fig. 10. Although the interpretation does not include direct comparisons of the observed rates with the results of calculations based on independent measurements, the experimental results are in fairly good agreement with the theoretical curves.

Practical Applications

Removal of Cu^{2+} from a Solution by Fix-bed Methods. A 830 mg dm^{-3} Cu^{2+} solution containing 0.5 M NaCl was passed through a column packed with a chelating exchanger at a space velocity (S. V.) of 10 h^{-1}. The breakthrough curves of the filamentary IONEX No. 4 and Diaion CR-10 columns are given in Fig. 11. The ion leaks through the resin column in the early stage, while the fiber column represents the breakthrough curve of a roughly *S* form. From this curve, the band length and utilization of the ion exchange can be evaluated to be 7.8 cm and 0.71 respectively. The band length for the resin column is estimated to be more than 30 cm. These results show that the utilization of the fiber is high, since the band length is short because of its rapid adsorption properties, even if the Cu^{2+} concentration is high.

The breakthrough volume of a cylindrical module made of the felt IONEX No. 3 was examined by using a feed solution of 100 mg dm^{-3} Cu^{2+} and compared with those of the felt IONEX No. 3 and filamentary IONEX No. 2 columns. The felt column is superior to the others, as is shown in Fig. 12. The breakthrough volume of the module, which has seventy times as large a filtrating area as the felt column, is 30% lower than that of the felt column. From the observation of the module colored with Cu^{2+}, it was found that some of its parts are not utilized because of an irregular flow. The breakthrough volume of the module is, however, almost equal to that of the filamentary column. It can be concluded that the cylindrical module is a suitable one for a rapid fluid treatment since it has a large filtrating area and a low pressure drop.

Removal of Mn^{2+} from a Solution by Fix-bed Methods. A 100 mg dm^{-3} Mn^{2+} solution containing 0.5 M NaCl was passed through columns of various chelating exchangers. The results are shown in Fig. 13. The breakthrough volume of the felt column is superior to that of the filamentary column, as was found in the case of Cu^{2+}. The minimum Mn^{2+} concentrations in the effluent for the resin columns are 0.2 mg dm^{-3} at S. V. 20 h^{-1} and 0.1 mg dm^{-3} at S. V. 10 h^{-1}, while those for the fiber columns are below 0.02 mg dm^{-3} at S. V. 20 h^{-1}.

Next, a 137.5 mg dm^{-3} Mn^{2+} solution containing 30 wt/vol% lysine was passed through the felt and resin columns at various space velocities. Figure 14 presents the space velocity dependence of the breakthrough volume. The minimum concentrations for the resin and felt columns are 0.05 mg dm^{-3} and below 0.02 mg dm^{-3} respectively at S. V. 5 h^{-1}. In the case of the resin column, the breakthrough volume decreases rapidly as the space velocity is raised, and the ion leak takes place in the early stage at S. V. 20 h^{-1}. On the other hand, even at S. V. 80 h^{-1}, the felt column gives 72% as large a

breakthrough volume as at S. V. 5 h^{-1}, and its minimum concentration is still below 0.02 mg dm^{-3}. These results indicate that the chelating fiber can be utilized in various fields which require a rapid treatment or a high removal ratio, since it has such a high adsorption rate.

Conclusion

1. A fibrous chelating exchanger based on polystyrene has been prepared by using an *islands-in-a-sea* type composite fiber as the starting material. This fibrous chelating exchanger can be used in various forms because of its high mechanical strength.

2. This chelating fiber has from ten to forty times as high an adsorption rate for Cu^{2+} as the ordinary chelating resin. These results are interpreted in terms of the rate laws of ion exchange for the limiting case of ideal particle-diffusion control in a simple system.

3. A column packed with this chelating fiber has excellent removal properties for heavy-metal ions. A cylindrical module made of felt is a suitable one for a rapid fluid treatment.

The author is grateful to Professor Noboru Hirota and Dr. Hiroaki Ohya-Nishiguchi of Kyoto University for their kind advice and valuable discussions. He would also like to express his appreciation to Dr. Masaharu Shimamura for his helpful advice and illuminating discussions. He is also deeply indebted to Dr. Tatsuro Kawaguchi, Mr. Michihiko Tanaka, and Dr. Masaki Nishino for their continuous encouragement throughout this work. He is also much obliged to Mr. Kazuo Teramoto for his advice on the chemical treatments and to Mr. Seiichi Yoshikawa and other collaborators for the preparation of the composite fibers. The author also wishes to thank Toray Industries, Inc., for making this study possible.

Kinetics of the Transfer of Picrate Ion at the Water/Nitrobenzene Interface

Toshiyuki OSAKAI, Tadaaki KAKUTANI, and Mitsugi SENDA*
Department of Agricultural Chemistry, Faculty of Agriculture, Kyoto University, Sakyo-ku, Kyoto 606
(Received February 12, 1985)

Kinetics of the transfer of picrate (Pic^-) ion at the interface between an aqueous solution of lithium chloride (LiCl) and a nitrobenzene solution of tetrabutylammonium tetraphenylborate (TBATPB) has been studied by phase-selective a.c. polarography with a two-electrode cell system. By assuming Butler-Volmer type equations for the rate constants, the kinetic parameters of the Pic^--ion transfer have been determined at various concentrations of LiCl (0.02—1.0 mol dm^{-3}) and TBATPB (0.05—0.17 mol dm^{-3}). The rate constants virtually do not change with the electrolyte concentrations. Frumkin correction for the double-layer effect of the rate constants has been examined. The result seems to indicate that the observed potential dependence of the rate constants obtained in moderately concentrated electrolyte solutions may reflect the real potential dependence of the rate constants.

In a previous paper[1] we have shown that the phase-selective a.c. polarographic method is useful for accurate measurement of the rate of ion (tetramethylammonium ion) transfer at the interface between two immiscible electrolyte solutions (water/nitrobenzene interface). In this study, we have applied this technique to determine the rate constants of the transfer of picrate (Pic^-) ion at the interface between an aqueous solution of lithium chloride (LiCl) and a nitrobenzene solution of tetrabutylammonium tetraphenylborate (TBATPB).

Dependence of the rate constants of ion transfer on the potential difference across the interface between two immiscible electrolyte solutions has been a subject of theoretical[2,3] and experimental[4-7] studies; with tetraalkylammonium ions at water/nitrobenzene[4] and water/1,2-dichloroethane[5] interfaces, and with cesium ion[6] and choline and acetylcholine ions[7] at the water/nitrobenzene interface. According to Samec *et al.*,[6,7] the observed potential dependence of the rate constants for the transfer of cesium, choline, and acetylcholine ions arises largely from the effect of the potential on the concentration of the transferred ions at the reaction planes, which are supposed to be located at the outer Helmholtz planes (OHP's) on each side of the interface. In this study we have determined the rate constants of the Pic^--ion transfer at the interface between aqueous and nitrobenzene solutions containing various concentrations of LiCl (0.02—1.0 mol dm^{-3}) and TBATPB (0.05—0.17 mol dm^{-3}), respectively. The observed rate constants were corrected for the double-layer effect (so called Frumkin correction) using the capacity data and the Gouy-Chapman theory. The results indicate that the formalism of Frumkin correction with the reaction planes being located at the OHP's to obtain the "true" rate constants is probably not valid for the Pic^--ion transfer across the water/nitrobenzene interface.

Experimental

The electrochemical cell employed in this study is represented by

	I	II		
Ag | AgCl	0.1 mol dm^{-3} TBACl (W)	x mol dm^{-3} TBATPB (N)		
	III			
	y mol dm^{-3} LiCl, c mol dm^{-3} LiPic (W)	AgCl	Ag,	(A)

where (W) and (N) stand for the aqueous and the nitrobenzene phases, respectively. The interface between phases II and III is the test interface at which the Pic^--ion transfer takes place. The left-hand reference electrode Ag/AgCl/0.1 mol dm^{-3} TBACl(W) was connected to the nitrobenzene phase (II) through sintered glass.[1] The potential drop across the interface between phases I and II is determined by the distribution potential of TBA^+ ion in the two phases.[8,9] In electrochemical measurements, a two-electrode cell system[1] was used. The solution resistance between the two reference electrodes, R_u, was measured with a laboratory-made linear bridge[1] with a 10 kHz a.c. generator and the ohmic drop due to R_u was compensated for by positive feedback.[1] The observed values of R_u were in the range between 0.96 and 3.27 kΩ. The details of electrochemical measurements have been described elsewhere.[1] The electrolytic cell was thermostated at 25±0.1 °C.

Lithium picrate (LiPic) was prepared by the reported method.[10] The other chemicals and the preparation of electrolyte solutions have been described elsewhere.[1]

Results

In the following, the potential E applied to Cell A is defined by the potential of the right-hand reference

electrode, E_{right}, referred to the potential of the left-hand reference electrode, E_{left}, that is, $E=E_{right}-E_{left}$. The flow of the positive charge from the aqueous to the nitrobenzene phase is taken as the positive current.

Cyclic Voltammetry. Cyclic voltammograms for the Pic^--ion transfer at the interface between aqueous solution of LiCl and nitrobenzene solution of TBATPB at various concentrations of the electrolytes as listed in Tables 1—3 were recorded at the voltage scan rate of 5 mV s^{-1}. At all concentrations used, well-defined reversible cyclic voltammograms were obtained at the scan rate of 5 mV s^{-1} (Fig. 1). The peak separation was 63±2 mV being close to the theoretical value of 60 mV for the reversible cyclic voltammogram. The midpoint potential, E_{mid}, which is considered to be equal to the reversible half-wave potential, agreed with the summit potential, E_s, of the admittance curves in a.c. polarography (see Figs. 2 and 3 and Tables 1—3) within the experimental errors (±4 mV). Figure 2 shows the dependence of E_{mid} and E_s on the logarithm of the mean activity of LiCl, $a^{\pm,w}_{LiCl}$, in the aqueous solution (phase III in Cell A). The experimental points in Fig. 2 lie on a straight line with the slope of −58 mV which is close to $-2.30RT/F$=−59 mV at 25 °C. Similarly, the change of E_{mid} and E_s with the change of TBATPB concentration was close to −59 mV per decade (Table 3). These results indicate that the ion-pair formation of Pic^--ion with Li^+ and TBA^+ ions is negligibly small in the concentration range studied (see Discussion).

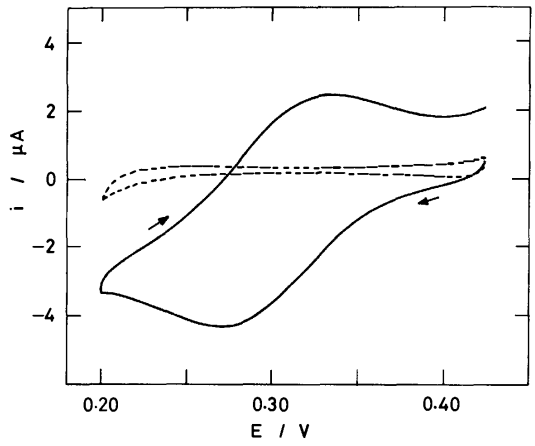

Fig. 1. A cyclic voltammogram for the transfer of 0.5 10^{-3} mol dm^{-3} Pic^- ion from a 0.1 mol dm^{-3} LiCl aqueous solution to a 0.1 mol dm^{-3} TBATPB nitrobenzene solution at the voltage scan rate of 5 mV s^{-1}. Dashed line shows a cyclic voltammogram in the absence of Pic^- ion.

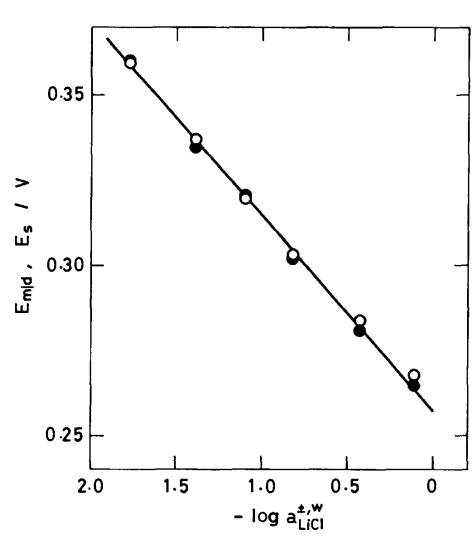

Fig. 2. Dependence of the midpoint potential (○) and the summit potential (●) on the logarithm of mean activity of LiCl in the aqueous phase when the concentration of TBATPB is 0.1 mol dm^{-3}. The slope of the straight line is −58 mV.

A.c. Polarography. In a.c. polarography, a small a.c. voltage (usually 5 mV peak to peak) was superimposed on the d.c. applied potential E_{dc} (usually at the scan rate of 5 mV s^{-1}), and the real (Y'_t) and the imaginary (Y''_t) components of the admittance, $Y_t=Y'_t+jY''_t$($j=(-1)^{-1/2}$), of the test interface in Cell A were measured at seven frequencies from 10 to 100 Hz. Curves a in Fig. 3 show representative plots of Y'_t and Y''_t against E_{dc}. Also plotted in Fig. 3 (curves b) are the real (Y'_B) and the imaginary (Y''_B) components of the admittance of the base aqueous solution/base nitrobenzene solution interface, $Y_B=Y'_B+jY''_B$. Thus, the ion-transfer admittance, $Y_F=Y'_F+jY''_F$, is determined by subtraction of Y_B from Y_t[1]:

$$Y'_F = Y'_t - Y'_B, \quad (1)$$

$$Y''_F = Y''_t - Y''_B. \quad (2)$$

Y'_F and Y''_F are plotted against E_{dc} in Fig. 3 (curves c). The summit potentials of the Y'_F and Y''_F *vs.* E_{dc} curves coincided with each other and were virtually equal to the corresponding reversibe half-wave potentials obtained from cyclic voltammetry, irrespective of the frequency, the Pic^--ion concentration, and the supporting-electrolyte concentrations. The summit potentials are summarized in Tables 1—3.

From the ion-transfer admittance, the ion-transfer impedance, Z_F, which is expressed by a series combination of resistance (r_s) and capacitance (c_s), *i.e.* $Z_F=r_s-j(1/\omega c_s)$, was calculated:

$$r_s = Y'_F/(Y'^2_F+Y''^2_F), \quad (3)$$

$$1/\omega c_s = Y''_F/(Y'^2_F+Y''^2_F), \quad (4)$$

where ω is the angular frequency of the a.c. signal

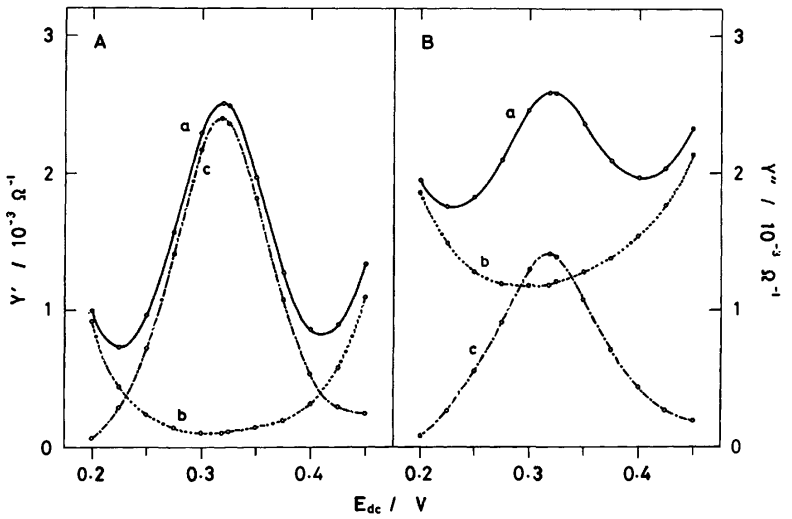

Fig. 3. Real (A) and imaginary (B) components of the admittance of the interface between a 0.1 mol dm^{-3} LiCl aqueous solution and a 0.1 mol dm^{-3} TBATPB nitrobenzene solution, at f=50 Hz, in the presence (a) and absence (b) of 0.5×10^{-3} mol dm^{-3} Pic$^-$ ion in the aqueous phase. Curve c shows the ion-transfer admittance, Y_F' and Y_F'', for the Pic$^-$ ion transfer corrected for the base admittance.

($\omega=2\pi f$, f being the frequency).

Determination of the Kinetic Parameters. For the sake of simplicity, we assume a linear kinetic equation:

$$I = I(E, C^W, C^N) = zFA[\vec{k}(E)C^W - \overleftarrow{k}(E)C^N], \quad (5)$$

for the ion-transfer current I, which is a function of the potential, E, and the surface concentrations of the transferred ion in the aqueous and nitrobenzene phases, C^W and C^N, respectively. Here, z is the ionic valence of the transferred ion ($z=-1$ for Pic$^-$ ion), F the Faraday constant, A the surface area of the interface, and $\vec{k}(E)$ and $\overleftarrow{k}(E)$ are the rate constants of ion transfer from the aqueous to the nitrobenzene phase and from the nitrobenzene to the aqueous phase, respectively, both being considered to be functions of the potential E. On the basis of the information obtained by cyclic voltammetry, we assume that the mass transfer of the ion is due to semi-infinite linear diffusion and that the ion-transfer reaction at the interface is d.c. reversible at the d.c. voltage scan rate of 5 mV s^{-1}, that is, the Nernst equation is valid for the mean surface concentrations or the d.c. components of the surface concentration of the transferred ion in both sides of the interface, $\overline{C}^W$ and $\overline{C}^N$:

$$E_{dc} = E^{\oplus} + (RT/zF)\ln(\overline{C}^N/\overline{C}^W), \quad (6)$$

where $E^{\ominus}$ is the standard ion-transfer potential (with respect to the reference electrodes in Cell A), R the gas constant, and T the absolute temperature. We also assume that the ion-pair formation of the transferred ion is negligibly small in both phases.

On the above assumptions, the ion-transfer impedance can be expressed, by analogy with the faradaic impedance theory of electrode reaction, by[1]

$$r_s = (\sigma/\omega^{1/2})[1+(2\omega)^{1/2}\lambda^{-1}], \quad (7)$$

$$1/\omega c_s = \sigma/\omega^{1/2}, \quad (8)$$

with

$$\sigma = \frac{4RT\cosh^2(\xi/2)}{z^2F^2A(2D^W)^{1/2}C^{W,\circ}}, \quad (9)$$

$$\lambda = \frac{\vec{k}}{(D^W)^{1/2}} + \frac{\overleftarrow{k}}{(D^N)^{1/2}}, \quad (10)$$

$$\xi = zF(E_{dc}-E^r_{1/4})/RT, \quad (11)$$

$$E^r_{1/4} = E^{\oplus} + (RT/zF)\ln(D^W/D^N)^{1/2}, \quad (12)$$

where $\vec{k}$ and $\overleftarrow{k}$ are the ion-transfer rate constants defined by $\vec{k}=\vec{k}(E=E_{dc})$ and $\overleftarrow{k}=\overleftarrow{k}(E=E_{dc})$ (see Eq. 5), respectively, and D^W and D^N are the diffusion coefficients of the transferred ion in the aqueous and nitrobenzene phases, respectively; $C^{W,\circ}$ is the bulk concentration of the ion in the aqueous phase (the bulk concentration in the nitrobenzene phase is assumed to be zero). When the ion-transfer reaction is d.c. reversible, we have $k\overline{C}^W=k\overline{C}^N$ from Eq 5. Using Eqs. 6, 11, and 12, we then have $\vec{k}=(D^W/D^N)^{1/2}\overleftarrow{k}\exp(\xi)$. Consequently, Eq. 10 can be rewritten as

$$\ln[\vec{k}/(D^W)^{1/2}] = \ln[\lambda/(1+\exp(-\xi))], \quad (13)$$

or

$$\ln[\overleftarrow{k}/(D^N)^{1/2}] = \ln[\lambda/(1+\exp(\xi))]. \quad (14)$$

Here λ can be obtained by Eqs. 7 and 8 as

$$\lambda = (2\omega)^{1/2}/(r_s c_s \omega - 1). \quad (15)$$

Thus these relationships enable us to determine the ion-transfer rate constants from the ion-transfer impedance.

We assume Butler-Volmer type equations for the potential dependence of the rate constants:

$$\vec{k} = k_s \exp[\vec{\alpha} z F(E_{dc} - E^{\bullet})/RT], \quad (16)$$

$$\overleftarrow{k} = k_s \exp[-\overleftarrow{\alpha} z F(E_{dc} - E^{\bullet})/RT], \quad (17)$$

where k_s is the standard rate constant, $\vec{\alpha}$ and $\overleftarrow{\alpha}$ ($\vec{\alpha} + \overleftarrow{\alpha} = 1$) are the transfer coefficients. Then, using Eqs. 10—12, Eqs. 13 and 14 can be rewritten as

$$\ln[\vec{k}/(D^W)^{1/2}] = \ln \Lambda + \vec{\alpha}\xi, \quad (18)$$

$$\ln[\overleftarrow{k}/(D^N)^{1/2}] = \ln \Lambda - \overleftarrow{\alpha}\xi, \quad (19)$$

with

$$\Lambda = k_s \left(\frac{1}{(D^W)^{1/2}}\right)^{\overleftarrow{\alpha}} \left(\frac{1}{(D^N)^{1/2}}\right)^{\vec{\alpha}}. \quad (20)$$

In Fig. 4, r_s and $1/\omega c_s$ at the summit potential are plotted against $\omega^{-1/2}$ for x=0.1 mol dm^{-3}, y=0.1 mol dm^{-3}, and c=0.5×10^{-3} mol dm^{-3} in Cell A. According to Eqs. 7 and 8, both plots gave straight lines with a common slope giving the diffusion coefficient of Pic$^-$ ion in the aqueous phase, D^W_{Pic}=8.8×10^{-6} cm^2 s^{-1} by Eqs. 9 and 11. For all compositions of the solution measured in this study (Tables 1—3) similar linear plots were obtained for the ion-transfer impedance in the d.c. potential range of $|E_{dc} - E_s| < 80$ mV. The D^W_{Pic} values obtained at various compositions of the solutions are summarized in Tables 1—3.

The potential dependence of the rate constants

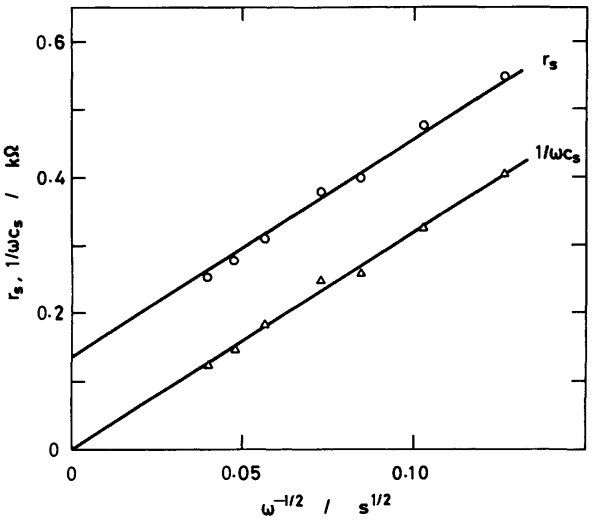

Fig. 4. Plot of the real (r_s) and imaginary ($1/\omega c_s$) components of ion-transfer impedance at the summit potential against $\omega^{-1/2}$ for the transfer of 0.5×10^{-3} Pic$^-$ ion at the interface between a 0.1 mol dm^{-3} LiCl aqueous solution and a 0.1 mol dm^{-3} TBATPB nitrobenzene solution.

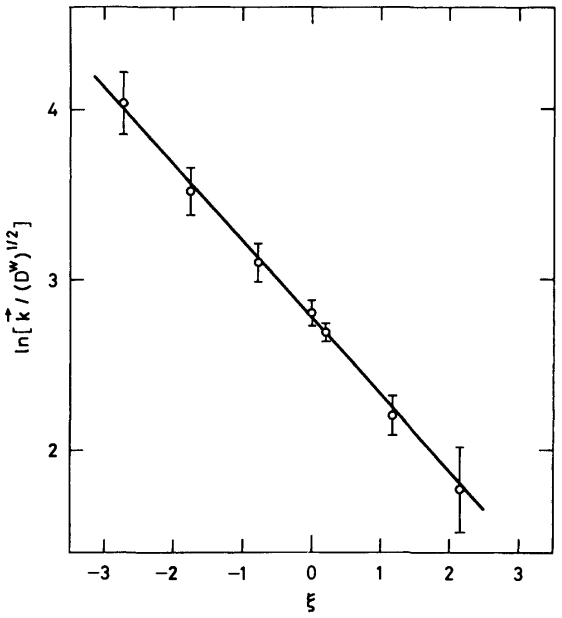

Fig. 5. Plot of $\ln[\vec{k}/(D^W)^{1/2}]$ *vs.* $\xi(=zF(E_{dc} - E^r_{1/2})/RT)$ for the transfer of 0.5×10^{-3} mol dm^{-3} Pic$^-$ ion at the interface between a 0.1 mol dm^{-3} LiCl aqueous solution and a 0.1 mol dm^{-3} TBATPB nitrobenzene solution. Vertical bars indicate the standard deviations.

Table 1. Kinetic parameters of Pic$^-$-ion transfer at the interface between a 0.1 mol dm^{-3} LiCl aqueous solution and a 0.1 mol dm^{-3} TBATPB nitrobenzene solution, determined at various concentrations of Pic$^-$ ion in the aqueous phase

C^W_{Pic} / 10^{-3} mol dm^{-3}	E_s / mV	ln Λ	k_s / 10^{-2} cm s^{-1}	$\vec{\alpha}$	D^W_{Pic} / 10^{-6} cm^2 s^{-1}

were analysed using Eqs. 13—15. A typical plot of $\ln[\vec{k}/(D^{W})^{1/2}]$ against ξ for $x=0.1$ mol dm^{-3}, $y=0.1$ mol dm^{-3}, and $c=0.5\times10^{-3}$ mol dm^{-3} in Cell A is shown in Fig. 5. Similar linear plots were obtained for all compositions of the solutions examined in this study. By fitting the $\ln[\vec{k}/(D^{W})^{1/2}]$ *vs.* ξ plot to Eq. 18, Λ and $\vec{\alpha}$ were determined. Then k_s was determined from Λ using Eq. 20 with $D^{W}_{Pic}=7.46\times10^{-6}$ cm^2 s^{-1} and $D^{N}_{Pic}=D^{W}_{Pic}/2.07$[11]$=3.60\times10^{-6}$ cm^2 s^{-1}. The kinetic parameters of Pic$^-$-ion transfer obtained at various Pic$^-$-ion concentrations at the interface between 0.1 mol dm^{-3} LiCl aqueous solution and 0.1 mol dm^{-3} TBATPB nitrobenzene solution are shown in Table 1. Also, the kinetic parameters of Pic$^-$-ion transfer obtained at various concentrations of LiCl in the aqueous solution and TBATPB in the nitrobenzene solution are shown in Tables 2 and 3.

Discussion

The cyclic voltammetric measurements show that the Pic$^-$-ion transfer at the water/nitrobenzene interface is d.c. reversible (nernstian) at the scan rate of 5 mV s^{-1}. This experimental finding ensures the validity of the Nernst equation for the mean surface concentration (Eq. 6) in a.c. polarography with the d.c. voltage scan rate of 5 mV s^{-1}. The d.c. reversibility of Pic$^-$-ion transfer at the water/nitrobenzene interface has been described also by Homolka and Marečcek.[12] Thus the mid-point potential, E_{mid}, can be equated to the reversible half-wave potential, $E^{I}_{1/2}$, which is related to the standard ion-transfer potential, $E^{\ominus}$, by Eq. 12. The standard ion-transfer potential of Pic$^-$-ion $E^{\ominus}_{Pic}$, observed with Cell A is expressed by

$$E^{\ominus}_{Pic} = \Delta\phi^{\ominus}_{Pic} + \Delta E^{A}_{ref}, \tag{21}$$

where $\Delta\phi^{\ominus}_{Pic}$ is the standard ion-transfer potential of Pic$^-$ ion at the water/nitrobenzene interface, and ΔE^{A}_{ref} is the constant determined solely by the left- and right-hand reference electrodes in Cell A. In the present case the left- and right-hand reference electrodes are reversible to TBA$^+$ and Cl$^-$ ions, respectively, and ΔE^{A}_{ref} is given as a function of the activities of TBA$^+$ and Cl$^-$ ions, a^{N}_{TBA} and a^{W}_{Cl}, in the nitrobenzene (II) and aqueous (III) solutions, respectively, by

$$\Delta E^{A}_{ref} = \text{constant} - (2.30RT/F)\log(a^{N}_{TBA}a^{W}_{Cl}). \tag{22}$$

Furthermore, if the ion-pair formation of Pic$^-$-ion with Li$^+$ and TBA$^+$ ions is appreciable, $\Delta\phi^{\ominus}_{Pic}$ in Eq. 21 should be replaced by $\Delta\phi^{\ominus'}_{Pic}$:

$$\Delta\phi^{\ominus'}_{Pic} = \Delta\phi^{\ominus}_{Pic} + \frac{RT}{F}\ln\frac{1+K^{N}_{LiPic}K^{N/W,\Delta\phi}_{Li}a^{W}_{Li}+K^{N}_{TBAPic}a^{N}_{TBA}}{1+K^{W}_{LiPic}a^{W}_{Li}+K^{W}_{TBAPic}(K^{N/W,\Delta\phi}_{TBA})^{-1}a^{N}_{TBA}}, \tag{23}$$

where K^{α}_{LiPic} and K^{α}_{TBAPic} (α=N and W) are the association constants of the ion pairs Li$^+$Pic$^-$ and TBA$^+$Pic$^-$ in the α phases, respectively, whereas $K^{N/W,\Delta\phi}_{TBA}$ and $K^{N/W,\Delta\phi}_{Li}$ are the ionic distribution co-

efficients of TBA^+ and Li^+ ions, respectively, between nitrobenzene and water when the interfacial potential difference is $\Delta\phi$, and are given by

$$K_j^{N/W,\Delta\phi} = \exp[z_jF(\Delta\phi-\Delta\phi_j^*)/RT], \quad j = Li^+ \text{ and } TBA^+ \text{ and } z_j = +1. \tag{24}$$

The change in the effective diffusion coefficients caused by the ion-pair formation in this case hardly affects the $E_{1/2}^t$ values (see Eq. 12). The experimental results (Fig. 2 and Tables 2 and 3) show that the change of $E_{1/2}^t$ ($\approx E_{Pic}^{\circ}$) with Cl^- or TBA^+ activity is close to $-2.30RT/F = -59$ mV per decade, indicating that the variation in $\Delta\phi_{Pic}^{\circ\prime}$ with Li^+ and TBA^+ activities is negligibly small. Therefore the ion-pair formation of Pic^--ion with Li^+ and TBA^+ ions should be negligible in the concentration range of the electrolytes used in this study.

The plot of $\ln[\vec{k}/(D^W)^{1/2}]$ against ξ for the Pic^--ion transfer generally gave a straight line (Fig. 5). This is in contrast to the tetramethylammonium-ion transfer, in which the plot gave an appreciably upward convex curve (see Fig. 12 in Ref. 1). Thus we applied the Butler-Volmer type equations (Eqs. 16 and 17) to the rate constants of Pic^--ion transfer to determine the kinetic parameters Λ, k_s, and $\vec{\alpha}$. The results are summarized in Tables 1—3. Table 1 shows that the observed kinetic parameters are hardly dependent on Pic^--ion concentration in the range from 0.3×10^{-3} to 1.0×10^{-3} mol dm^{-3} indicating the validity of assuming the linear kinetic equation for the ion transfer (Eq. 5). As seen in Tables 2 and 3, the kinetic parameters, except the transfer coefficients, were virtually independent of the concentrations of LiCl and TBATPB in the aqueous and nitrobenzene solutions, respectively.

The electrical double layer of the interface between aqueous solution of LiCl and nitrobenzene solution of TBATPB consists of the inner layer which is sandwiched by the two diffuse double layers on the aqueous and nitrobenzene solution sides.[13] Accordingly, when an ion is transferred from one solvent to the other, the ion is transferred through the three layers, *i.e.* the diffuse double layer in one phase, the inner layer, and the other diffuse double layer in the other in series. The effect of the potential of the diffuse double layer on the concentrations of transferred ion at the reaction planes where the transfer of ion from one solvent to the other will take place can be expressed, in the first approximation, by the Frumkin equation for the double-layer correction:

$$C_2^W = C^W \exp[zF(\phi^W-\phi_2^W)/RT], \tag{25}$$

$$C_2^N = C^N \exp[zF(\phi^O-\phi_2^O)/RT], \tag{26}$$

where C_2^α (α=W or N) is the concentration of the transferred ion at the reaction plane on the aqueous (α=W) or nitrobenzene (α=N) solution side and C^α (α=W or N) is the surface concentration, *i.e.* the concentration of the transferred ion just outside the diffuse double layer. ϕ^W and ϕ^O are the inner potentials in the bulk of the aqueous and nitrobenzene solutions, respectively, and ϕ_2^W and ϕ_2^O are the potentials of the reaction planes on the respective solution sides. Consequently, Eq. 5 can be rewritten as

$$I = zFA(\vec{k}_{corr}C_2^W - \overleftarrow{k}_{corr}C_2^N), \tag{27}$$

with

$$\vec{k}_{corr} = \vec{k}\exp[-zF(\phi^W-\phi_2^W)/RT], \tag{28}$$

$$\overleftarrow{k}_{corr} = \overleftarrow{k}\exp[-zF(\phi^O-\phi_2^O)/RT], \tag{29}$$

where $\vec{k}_{corr}$ and $\overleftarrow{k}_{corr}$ are the "true" rate constants or the rate constants for the ion-transfer reaction taking place from the reaction plane on one solvent side to the reaction plane on the other. Upon assuming that the reaction planes are located on the OHP's on each solution side, the values of $\phi^W-\phi_2^W$ and $\phi^O-\phi_2^O$ can be calculated (in the absence of specific adsorption) by the Gouy-Chapman theory by knowing the surface charge density which was calculated from the double-

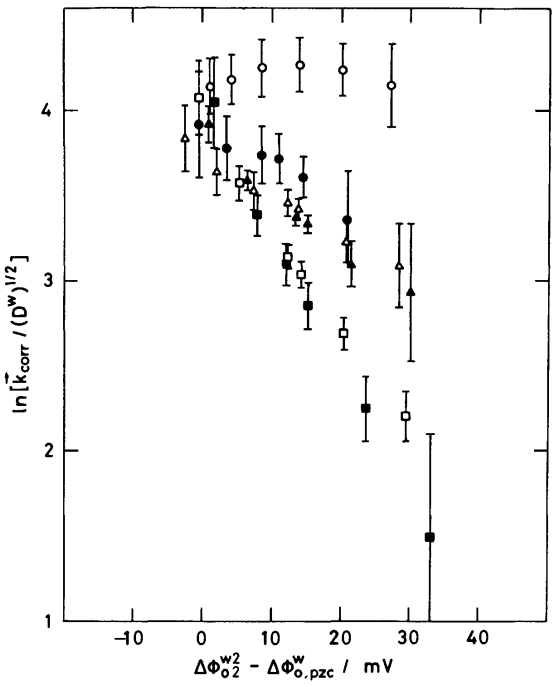

Fig. 6. Plot of $\ln[\vec{k}_{corr}/(D^W)^{1/2}]$ *vs.* $\Delta\phi_{o2}^{W2}-\Delta\phi_{o,pzc}^{W}$ for the Pic^--ion transfer at the interface between a nitrobenzene solution of 0.1 mol dm^{-3} TBATPB and an aqueous solution of (○) 0.02, (●) 0.05, (△) 0.10, (▲) 0.20, (□) 0.50, and (■) 1.0 mol dm^{-3} LiCl. Vertical bars indicate the standard deviations.

layer capacity data[14] and the potential of zero charge (pzc) data.[13] In Fig. 6, the values of $\ln[\vec{k}_{corr}/(D^W)^{1/2}]$ thus obtained for various concentrations of LiCl in the aqueous solution are plotted against the potential drop across the inner layer, $\Delta\phi_{O2}^{W2}=\phi_2^W-\phi_2^O$, referred to the potential drop across the inner layer at the pzc, $\Delta\phi_{O,pzc}^{W}=\phi_{pzc}^{W}-\phi_{pzc}^{O}$.[14] It has been shown[13,14] that the inner layer capacity of the interface between an aqueous solution of LiCl and a nitrobenzene solution of TBATPB depends only on the surface charge density (or the inner layer potential difference) and not on the concentration of LiCl in the aqueous solution. Therefore it is expected that the corrected rate constants obtained at various LiCl concentrations lie on a single curve representing the dependence of $\vec{k}_{corr}$ on $\Delta\phi_{O2}^{W2}$. In contrast to this expectation, the $\ln[\vec{k}_{corr}/(D^W)^{1/2}]$ *vs.* $\Delta\phi_{O2}^{W2}-\Delta\phi_{O,pzc}^{W}$ plots varies considerably with the concentration of LiCl in the aqueous solution (Fig. 6). Considerable variation of the $\ln[\overleftarrow{k}_{corr}/(D^N)^{1/2}]$ *vs.* $\Delta\phi_{O2}^{W2}-\Delta\phi_{O,pzc}^{W}$ plots with the change of TBATPB concentration in the nitrobenzene solution was also found for the corrected rate constants obtained at various TBATPB concentrations (data not shown). These results (Fig. 6) suggest that the formalism of Frumkin correction based on the assumption that the reaction planes are located on the OHP's on respective solution sides is not valid for this case, especially in moderately concentrated supporting electrolyte solutions.

In the above discussion, the potentials of OHP's were estimated by the basic Gouy-Chapman theory. Modifications of the basic Gouy-Chapman theory have been described.[16] In view of the smallness of the surface charge density (less than 4 μC cm^{-2}) and the moderate concentration of the electrolytes (less than 0.20 mol dm^{-3} except in a few extreme cases), however, we may conclude that the error caused by applying the basic Gouy-Chapman theory to the present system is probably small.

In the above discussion it is also assumed that the ion-pair formation of Pic$^-$ ion is negligible which is in harmony with the d.c. voltammetric data on Pic$^-$ ion. Available data on the ion-pair formation of Pic$^-$ ion in water and nitrobenzene are limited. However, according to Poonia *et al.*[15] $K_{LiPic}^{W}=12.8$, which suggests that the ion-pair formation of Pic$^-$ ion would be appreciable in concentrated LiCl aqueous solution. Accordingly, it is worth while discussing the possible effect of the ion-pair formation on the kinetic parameters of the ion transfer at the water/nitrobenzene interface. If the rate constants of the association and dissociation of the ion-pair are sufficiently large (*e.g.*(the first order rate constant)/$\omega \gg 1$), the a.c. faradaic impedance theory predicts that $\vec{k}$ and $\overleftarrow{k}$ in Eqs. 10, 13, 14 and the following equations should be replaced, respectively, by

$$\vec{k}' = \frac{\vec{k}}{1+K_{LiPic}^{W}a_{Li}^{W}+K_{TBAPic}^{W}(K_{TBA}^{N/W},\Delta\phi)^{-1}a_{TBA}^{N}} \tag{30}$$

and

$$\overleftarrow{k}' = \frac{\overleftarrow{k}}{1+K_{LiPic}^{N}K_{Li}^{N/W},\Delta\phi a_{Li}^{W}+K_{TBAPic}^{W}a_{TBA}^{N}}. \tag{31}$$

Thus, the $\ln[\vec{k}_{corr}/(D^W)^{1/2}]$ *vs.* $\Delta\phi_{O2}^{W2}-\Delta\phi_{O,pzc}^{W}$ plots, such as those in Fig. 6 should be also corrected by Eq. 30. However, it is clear that such a correction will not modify the scattered plots to align them on a single curve. Therefore we may conclude that the ion-pair formation of Pic$^-$ ion with TBA$^+$ and/or Li$^+$ ion, if any, would not seriously affect the above discussion.

The ion transfer from one solvent to the other should consist of desolvation of one solvent and resolvation with the other and could take place in the reaction layer of a certain thickness, possibly extending beyond the inner layer into the diffuse double layers (or even beyond the diffuse double layers in concentrated electrolyte solutions). The Frumkin correction, if any, should be applied to the concentrations of the transferred ion at the reaction planes which are supposed to be located distant from the OHP's toward the bulk of respective solutions. Samec and his coworkers, using relatively dilute LiCl solutions (0.05 and 0.01 mol dm^{-3}), found that the corrected rate constants of the transfer of Cs$^+$ [6] and choline and acetylcholine ions[7] at the aqueous solution of LiCl/nitrobenzene solution of TBATPB interface change little with the potential across the interface. This result led these authors to conclude that the observed potential dependence of the "apparent" rate constants arises largely from the effect of the porential on the concentration of the transferred ions at the reaction planes which are located at the OHP's. Actually, the potential dependence of the "corrected" rate constants in 0.02 mol dm^{-3} LiCl aqueous solution was relatively small (see Fig. 6). However, as discussed above, the strong potential dependence of the "corrected" rate constants of Pic$^-$-ion transfer observed in moderately concentrated electrolyte solutions seems to indicate that the observed potential dependence may reflect the real potantial dependence of the Pic$^-$-ion transfer rate constants at the water/nitrobenzene interface.

The photoelectrochemical behavior of p-type boron phosphide (p-BP) in acidic solution was investigated. The p-BP photocathode was stable in sulfuric acid solution under irradiation, and the band gap deduced from the photocurrent action spectrum in acidic solution was 2.0 eV. The gas evolved from p-BP photocathode was hydrogen which was obtained with a current efficiency of *ca.* 100%. The photocurrent was markedly increased by suitable ruthenium treatment of the BP. A photoelectrochemical cell (PEC), Pt(H_2)/0.5 M H_2SO_4(1 M=1 mol dm^{-3})//0.5 M H_2SO_4/p-BP, was shown to have an open-circuit photovoltage of 0.45 V and a fill factor of 0.25.

The photoassisted electrolysis of water using semiconductor electrodes has been studied extensively in the last few years.[1-7] One of the major requirements in any practical application is that the semiconductor be stable. Because it is very difficult to find intrinsically stable materials, considerable effort has been expended on electrode modifications to improve stability and charge transfer properties. Some of the methods employed or suggested includes the use of stabilizing redox couples in the electrolyte,[8-10] overcoating of unstable semiconductors with noble metals,[11] stable semiconductors,[12,13] and conductive polymers.[14-18]

Although much work has been done on semiconductors, hardly any has been reported on boron phosphide (BP) behavior after Ginley *et al.*[13] reported that BP stabilized n-Si, n-GaAs photoanodes, and after Grantham's patent[19]. In this paper, we report the attainment of quite stable photocurrents resulting in hydrogen production that were obtained from a p-BP electrode in acidic solution. Also, we report a detailed study of the effects of ruthenium treatment of a p-BP electrode surface.

Experimental

A BP single crystal was prepared by a flux method[20] under high pressure either at 10 or 18 atms. The BP crystal was etched for 10 min in fused sodium hydroxide at 420 °C and then washed with distilled water. After an ohmic contact was made with an indium-gallium alloy, a copper wire was connected with silver paste, and then all surfaces except one side were covered with an epoxy resin.

The same cell was used for photoelectrolysis and for measurement of current-potential curves. This cell consisted of two compartments separated by a cation

exchange membrane (Selemion CMV, Asahi Chem. Co.) and a 2 ml burette in the catholyte chamber, as shown in Fig. 1. The volumes of catholyte and anolyte chamber were 100 and 80 ml, respectively. Another cell was used for mass spectrometric analysis, the volume of the catholyte of which was 1 ml, as shown in Fig. 2. These cells were equipped with the p-BP working electrode (av. surface area≈0.12 cm^2), a platinum wire counter electrode (dia. 1.0 mm × length 10 mm), and a saturated calomel electrode (SCE) as a reference electrode.

The light source was a 500W xenon lamp (Ushio Electric Inc.), and the light path included an infrared cut filter and quartz lens. Current-potential curves were taken by using a potentiostat/galvanostat system (Hokuto Denko Co.) in cojunction with an X–Y recorder. The hydrogen evolved was analyzed by means of a gas chromatograph (Hitachi model 163) and mass spectrometer (Ulvac YTP-150). The packing material of the column was molecular sieve 5A and the carrier gas for the gas chromatography was argon gas. Scanning electron microscopic and surface analyses were performed by means of a scanning electron microscope (Hitachi type S 550), X-ray detector (Kevex Co. type 7000-75), and a computer system (DEC Co. PDP 11/34). Ruthenium was applied to the BP surface by dipping the BP into ruthenium chloride solution [0.5—10% $RuCl_3$–methanolic solution (CH_3OH:H_2O=1:1)] and irradiating with 500W xenon lamp.

All chemicals were of reagent grade. Before all experiments, the electrolytic solutions were purged with nitrogen gas for more than 30 min.

Results and Discussion

Current-potential Characteristics. The effect of irradiation on the current-potential curves for an etched p-BP photocathode in 0.5M H_2SO_4 is shown in Fig. 3 for samples prepared at 10 and 18 atm pressure. The photocurrent was shifted about 0.9V in the anodic direction compared to the dark current value. Since the optical to electrical conversion efficiency was reported to be increased by applying ruthenium on semiconductor surfaces[21,22] we determined the effect of ruthenium concentration on the photocurrent-potential curves for the BP treated with ruthenium(III) chloride in 0.5M H_2SO_4, shown in Fig. 4. Increasing the concentration of ruthenium(III) chloride solution increased the photocurrent. In the case of treating the BP surface with concentrated ruthenium chloride solution or of long-term irradiation of the BP surface in diluted ruthenium solution, the photocurrent was markedly shifted in the cathodic direction. This phenomenon of cathodic shift can be explained by a decrease of characterization of semiconductor to be covered with ruthenium metal or ruthenium oxide.

Dependence of Photocurrent on Wavelength and the Stability of a BP Cathode. The wavelength dependence of the photocurrent for p-BP prepared under 18 atm pressure is shown in Fig. 5. The quantum yield was calculated by dividing the photocurrent at a certain wavelength by the number of photons incident on the BP electrode. The threshold of the photocurrent response was about

600 nm (2.0 eV), in agreement with the direct band gap calculation. As is evident from Fig. 5, the p-BP photocathode will respond to sunlight of wavelength shorter than 600 nm.

Figure 6 shows the photocurrent-irradiation time profile for a p-BP photocathode with and without a ruthenium treatment. As shown for a cell where the photocathode process was according to hydrogen evolution, there was no evidence that the photocathode deteriorated.

Hydrogen Evolution. The hydrogen evolution produced by the BP and the Ru-treated BP photocathodes during electrolysis was determined by measuring the quantity of electricity under constant set potential, and the results are shown in Table 1. For the purpose of calculating the current efficiency, the volume of gas evolved from the BP photoelectrolytic cell of Fig. 1 was compared with the volume of hydrogen evolved from the cathode of the Pt cathode/Pt anode electrolytic cell in 0.5M H_2SO_4. These two cells were connected in series with each other. The results in Table 1 show that the photoreaction on the BP photocathode in an acidic solution produced hydrogen, and the current efficiency of the process was almost 100% by comparison with the Pt cathode.

p-BP/H_2SO_4 Photoelectrochemical (PEC) Cell.

1: Bare etched BP, 2: BP etched and treated with 3% $RuCl_3$ solution.

A PEC cell was made by connecting the p-BP semiconductor to a counter electrode by means of a variable resistive load in the external circuit. Schematic diagram of PEC cell is shown in Fig. 7. Figure 8 shows the power characteristic in the acidic

solution obtained with and without ruthenium treatment on the BP electrode using light from a 500W xenon lamp. From curve 2 in Fig. 8, we estimate that the open circuit photovoltage was 0.45 V, the short-circuit photocurrent density was 2.4 mA cm^{-2}, and the fill factor was 0.25. The overall conversion efficiency of optical to electrical energy for the PEC photovoltaic cell was much increased by the ruthenium treated BP but it was still low with respect to the case of InP.

Examination of Surface State of BP. The surfaces of different BP specimens after etching and treating with ruthenium were observed by scanning electron micrographs. It was found that the p-BP surface without etching had a very smooth surface while the surface of etched p-BP had many blisters. The surface of etched BP, which had been treated by dipping in methonolic ruthenium(III) chloride solution for 1 min, washing with water, and irradiating for 1 min with the 500W xenon lamp, observed the white and black areas by the scanning electron microscope.

Analytical results of X-ray fluoresence of the average area have indicated, for example, that weight percents of each component were Si 3.09%, P 87.97%, and Ru 8.94%, where Si was surface impurities on the BP semiconductor. The amount of ruthenium was greater in the white areas than the black areas. Therefore, the surface layer was not a homogeneous coating, but rather there were islands of ruthenium on the BP. By dipping the BP in the ruthenium solution for 5 min a thick ruthenium covered the BP surface, not only in the white areas but also in the black areas. The thicker, homogeneous ruthenium layer on the p-BP is undesirable because the deposited ruthenium would absorb and reflect photons before they could reach the semiconductor, thereby decreasing the cell efficiency. Therefore, it is necessary that the surface treatment is carried out with a suitable concentration of ruthenium and treatment time.

Conclusion

The p-BP photocathode has a good wavelength response (E_g=2.0 eV), and is stable in an acidic solution under irradiation. The gas evolved from this BP photocathode under irradiation was hydrogen which was produced with a current efficiency of about 100%. The photocurrent was markedly increased by a suitable surface ruthenium treatment of the BP.

The overall conversion efficiency of optical to electrical energy for the PEC photovoltaic cell was low, that was, the open-circuit photovoltage was 0.45V, the short-circuit photocurrent density was 2.4 mA cm^{-2}, and the fill factor was 0.25. Therefore, to make a more practical device it is necessary to improve this conversion efficiency.

Surface Treatment of *meso*-Carbon Microbeads by Oxygen Plasma

Masaaki SUGIURA, Kunio ESUMI,* Kenjiro MEGURO, and Hidemasa HONDA
Department of Applied Chemistry, Institute of Colloid and Interface Science, Science University of Tokyo, Kagurazaka, Shinjuku-ku, Tokyo 162
(Received March 23, 1985)

A surface treatment of *meso*-carbon microbeads was carried out using an oxygen plasma to improve the wettability in aqueous solution. The surface acidity of *meso*-carbon microbeads increased with treating time and the pH of the aqueous dispersion shifted to lower values. The zeta potential varied with treating time from a positive to a negative value. Further, the turbidity behavior of aqueous dispersion with treating time was similar to that of surface acidity. From these results, it was found that the surfaces of *meso*-carbon microbeads were oxidized by oxygen plasma, resulting in an enhancement of wettability of *meso*-carbon microbeads in an aqueous solution.

It is well known[1] that a mesophase transformation takes place in graphitizable organic materials (such as pitches) during pyrolysis at temperatures between 350 and 500 °C. During the heat treatment of pitches, mesophase spherule is formed due to an accumulation of oriented polycondensed aromatic hydrocarbons. The mesophase spherules that separated as quinoline insolubles from the mesophase pitches are called *meso*-carbon microbeads.

These do not melt or fuse upon a heat treatment and do not dissolve at room temperature in organic solvents such as quinoline, pyridine and benzene. From the chemical reactivity,[2] the pore structure,[3] the adsorption-desorption isotherms, and the heat-of-immersion,[4] of the *meso*-carbon microbeads, it has been recognized that the constituent unit of *meso*-carbon microbeads is a micelle composed of the molecules and that the micelles lie perpendicular to a pole of the sphere, as in the Taylor model.[5] The exteriors of *meso*-carbon microbeads melt in a medium of polynuclear aromatic hydrocarbons or pitch materials during a heat treatment. The *meso*-carbon microbeads in liquids similar to pitch under heat treatment behave in a similar manner as mesophase spherules produced in pitch during a heating.

In polycyclic aromatics, the reactivity of the edge carbon atoms at the periphery is very high, as is well known. Therefore, the surfaces of *meso*-carbon microbeads are interesting from the view point of the surface chemistry of solids. Hagiwara *et al.*[6] examined the possibility of using *meso*-carbon microbeads as a chromatographic filler. They confirmed that benzene derivatives could be separated using *meso*-carbon microbeads treated with a Friedel-Crafts reaction. When *meso*-carbon microbeads are used in an aqueous solution, there is a wetting problem since *meso*-carbon microbeads exhibit hydrophobic properties.

Recently, as one method for surface treatment, a plasma treatment[7] has become attractive, probably due to it being a dry process at low temperatures with a relatively low-pressure gas.

In this work, changes in the surface properties of *meso*-carbon microbeads upon a treatment of oxygen plasma were examined by measuring the surface acidity, surface charge, turbidity, and pH of *meso*-carbon microbeads in an aqueous solution.

Experimental

Materials. *Meso*-carbon microbeads were obtained through a separation from heat-treated quinoline soluble coal-tar pitch. The physical properties of the obtained *meso*-carbon microbeads were as follows: quinoline insoluble, 92.3%; benzene insoluble, 97.0%; volatile matter, 17.3%; ash, 0.3%; C/H=2.314; diameter, 2-15 μm.

Procedure. About 3 grams of *meso*-carbon microbeads were charged into a reactant vessel, followed by degassing down to 1.5 Torr. Then, oxygen gas was flowed at a rate of 100 ml/min into the vessel while evacuated *meso*-carbon microbeads were being treated with an oxygen plasma under various high-frequency powers and treating times. The pressure during the treatment was kept at about 3 Torr†. The high-frequency power used in this study was 25, 50, and 100 W, and the treating times were 1, 2, 3, and 4 h, respectively.

Measurements. About 0.1 grams of *meso*-carbon microbeads were put into 50 ml of deionized water, boiled for 15 min, then allowed to stand for 2 d. The, thus obtained, suspension's pH was measured with a pH meter (Denki Kagaku Keiki Co. Ltd.).

The zeta potential of the suspension used for the pH measurement was determined by an electrophoresis apparatus (Laser-Zee Model 500, Pen Kem.).

About 0.1 grams of *meso*-carbon microbeads were put into a sedimentation tube and 30 ml of deionized water was added. Then the solution was dispersed by supersonic waves for half an hour and the turbidity of the dispersion was measured after 1 d of standing.

The acidity of surface functional groups of *meso*-carbon microbeads was determined by a titration method which was the same as that Boehm[8] used. About 1 gram of *meso*-carbon microbeads and a 50-ml aqueous solution of 50 ml ($NaHCO_3$, Na_2CO_3, NaOH, and $NaOC_2H_5$) of 0.05

† 1 Torr=133.322 Pa.

to 0.1 M†† were placed in an Erlenmeyer flask. After shaking for 1 d at 25 °C, it was allowed to stand for 4 d; then, after centrifuging, 20 ml of the supernatant solution was titrated with 0.1 M HCl. At the same time, a blank test was carried out. From the difference in the titrations, the acidity of *meso*-carbon microbeads was evaluated.

Results and Discussion

The *meso*-carbon microbeads were treated with the oxygen plasma under conditions such as high-frequency power (25, 50, and 100 W) and an oxygen-flow rate of 100 ml min^{-1}. The plasma-treated samples were used for measuring the turbidity in an aqueous solution. The result is given in Fig. 1. The turbidity of the samples increased with an increased treating time. A maximum value appeared at 3 h; then, it decreased slightly for three different high-frequency powers. Further, the turbidity of the treated *meso*-carbon microbeads decreased upon increasing the high-frequency power. Thus, from the turbidity results, it is apparent that the *meso*-carbon microbeads become wettable in an aqueous solution upon treatment with an oxygen plasma.

To elucidate the surface charge of *meso*-carbon microbeads treated with the oxygen plasma, the zeta potential of treated samples in an aqueous solution was measured. At the same time, the pH of the dispersion was also measured. As shown in Fig. 2, the zeta potential of the untreated sample was positive. After the plasma treatment, the zeta potential became negative and reached a constant value after 1 h. It should be noted that the magnitude of zeta potential of the sample treated with the oxygen plasma increased upon decreasing the high-frequency power. From the facts that the pH of the aqueous dispersion of the plasma-treated samples was at around 5—4.5 and their zeta potential values were negative, the surface functional groups formed by the oxygen plasma treatment were acidic groups. Indeed, Ihara *et al.*[9] examined the surface functional groups of carbon black treated with oxygen plasma and they found that these groups were carboxyl, phenolic, and carbonyl groups and the concentrations of these groups varied with the

	2	50	45	0	95
	3	100	30	0	130
	4	62.5	30	35	127.5

high-frequency power and treating time. In this work, the concentrations of surface functional groups were also determined by titration. The results are shown in Table 1 and Fig. 3. These functional groups(-COOH, -OH, C=O) were formed by the oxidation of *meso*-carbon microbeads as the oxygen plasma and the concentrations of these groups increased with the treating time, reached a maximum and then decreased. At each treating time, the order in the total concentrations of these groups was as follows: 25 W>50 W>100 W. This decrement in the total concentration of functional groups with longer treating times is probably due to a burn-off of the functional groups by a further oxygen plasma. Accordingly, in order to attain a maximum concentration of functional groups, a proper condition should be selected. It is noteworthy that even after the oxygen-plasma treatment, the surface area of the *meso*-carbon microbeads determined by nitrogen gas adsorption changed only a little compared with that for an untreated sample.

Compared with carbon black,[9] the *meso*-carbon microbeads were less oxidized due to the oxygen plasma. A maximum concentration of functional groups for *meso*-carbon microbeads was obtained at a treating time of 3 h. However, the concentrations of functional groups for carbon black[9] increased linearly with the treating time.

From the above results, it is concluded that the surfaces of *meso*-carbon microbeads become oxidized through the oxygen plasma, resulting in the formation of surface functional groups such as -COOH, -OH. Also, the wettability of *meso*-carbon microbeads treated with oxygen plasma in an aqueous solution is improved. Therefore, it is anticipated that the adsorption capacity for water-soluble materials would be enhanced upon using the *meso*-carbon microbeads treated with an oxygen plasma as the adsorbent.

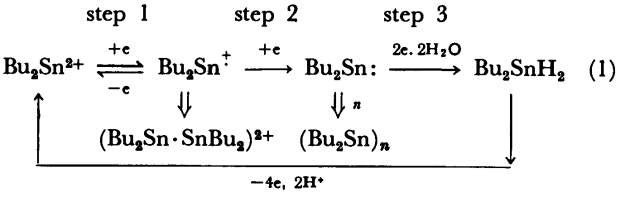
Electrochemical Behavior of Dibutyltin(IV) Compounds and Their Determination at ppb Levels by Differential Pulse Anodic Stripping Voltammetry

Hideki KITAMURA,* Akiyoshi SUGIMAE, and Masao NAKAMOTO
Environmental Pollution Control Center, Osaka Prefectural Government, 1-3-62 Nakamichi, Higashinari-ku, Osaka 537
(Received September 14, 1984)

The electrochemical behavior of dibutyltin(IV) compounds (Bu_2SnX_2) (X=chloride, laurate (L), and 6-methylheptyl maleate (MHM)) in 50% (v/v) and 80% (v/v) ethanol-water media (apparent pH 7.3) containing 0.002% Triton X-100 has been investigated by polarography and cyclic voltammetry. It has been found that Bu_2SnX_2 gives a two-electron transfer step at about −0.8 V *vs.* SCE, which consists of very close two one-electron steps, and a two-electron step at about −1.4 V in both media. Over the potential range of either side of the first reduction wave, both Bu_2SnX_2 and their reduction products are significantly adsorbed on the surface of a mercury electrode in 50% (v/v) ethanol, but not in 80% (v/v) ethanol. The adsorbed reduction products are readily re-oxidized at the mercury electrode in 50% ethanol. The re-oxidation peak was successfully utilized for the determination of traces of Bu_2SnCl_2 by means of the differential pulse anodic stripping voltammetry (DPASV) over the concentration range of 3—50 ppb (μg dm^{-3}) at the deposition time of 60 s. The DPASV behavior of Bu_2SnX_2 (X=chloride, L, MHM, and 1-dodecanethiolate) has been investigated in a 50% ethanol medium in detail. Further, a procedure has been developed for determining Bu_2SnX_2 in natural water down to ppb levels.

In recent years, organotin compounds attained rapidly commercial importance. Dibutyltin compounds are widely used as stabilizers for PVC plastics and as the control of helminthic and protozoal infections in poultry.[1] Various methods have been proposed for the determination of organotin compounds, *e.g.* atomic absorption spectrophotometry,[2,3] and fluorometry.[4] As the organotin compounds are reduced at a dropping mercury electrode (DME), this offers the possibility of direct determination.[5–14] Triphenyltin chloride (Ph_3SnCl)[5] and tributyltin compounds[6] are strongly adsorbed onto the electrode surface when reduced at the mercury electrode to the corresponding radicals. This property has been utilized for the determination of traces of Ph_3SnCl and tributyltin compounds by anodic stripping voltammetry (ASV).[5,7,8] Polarographic behavior of dialkyl- and diaryltin(IV) compounds (R_2SnX_2)(R= methyl, ethyl, butyl, phenyl, and X=anion) was also investigated in acids, ethanol-water, *etc.*[9–14] Fleet and Fouzder[11] showed that dibutyltin compounds (Bu_2SnX_2)(X=laurate (L) and maleate (M)) in the 80% (v/v) ethanol-water medium (pH 7.0) gave three reduction waves and proposed the following mechanism.



In this mechanism they, however, claimed that no adsorption of both depolarizers and their reduction products occurred at the surface of a mercury electrode. Morris[9] studied the polarographic behavior of diethyltin compounds (Et_2SnX_2) in aqueous acid solutions and claimed that a reversible two-electron step distorted by the formation of insoluble polymer products $(Et_2Sn)_n$ was observed on the electrode surface. We have investigated the polarographic behavior of Bu_2SnCl_2 in the 50% (v/v) ethanol-water medium (pH 7.3) containing 0.002% Triton X-100, a surface-active agent, as a maximum suppressor. Contrary to the previous work by Fleet and Fouzder[11] described above, significant adsorption has been found of both depolarizer and its reduction product(s) onto the mercury electrode, and the adsorbed reduction product(s) is readily re-oxidized. These findings has been successfully utilized for the determination of traces of Bu_2SnCl_2 by differential pulse anodic stripping voltammetry (DPASV) which is one of the most sensitive electrochemical techniques for trace analysis. Meanwhile there have been few reports on the ASV of dibutyltin compounds.

In this paper, we present a more detailed electrochemical behavior of Bu_2SnX_2 (X=chloride, L, and 6-methylheptyl maleate (MHM)) at the mercury electrode in the same medium as described above, primarily with the aim of developing a more sensitive method, *i.e.* DPASV, of Bu_2SnX_2 (X=chloride, L, MHM, and 1-dodecanethiolate (DT)).

Experimental

Materials. The following tin compounds were used in this study: Bu_2SnCl_2, Ph_3SnCl (Tokyo Kasei Kogyo, Tokyo, Japan), Bu_2SnL_2, Bu_2SnMHM_2, Bu_2SnDT_2, $(Bu_3Sn)_2O$ (ICN Pharmaceuticals, Inc., Life Sci. Group, Plainview, N. Y., USA). The purities of these compounds were higher than 95%. The stock solutions of tin compounds were prepared by dissolving them in 99.5%

ethanol (Wako Pure Chem., Osaka, Japan; Pesticide Analytical Grade). All reagents were analytical reagent grade. The cation-exchange resin for column chromatography (Amberlite CG-120, chromatographic grade, 200 mesh) was pre-washed in the usual manner, and conditioned with ethanol.[22]

Apparatus. Normal, reverse and differential pulse polarograms and cyclic voltammograms were measured on a Yanagimoto Voltammetric Analyzer (model P-1000) using a three-electrode cell. Throughout this study an aqueous saturated calomel electrode (SCE) and a spiral platinum electrode were used as a reference electrode and as a counter electrode, respectively. Cyclic voltammograms were measured with a hanging mercury drop electrode (HMDE) (Metrohm, Type EA290, electrode surface area 1.39±0.03 mm^2).

For DPASV, Yanagimoto Voltammetric Analyzer (P-1000) was used to supply both the applied potential for the pre-electrolysis and the voltage sweep for the stripping process. During pre-electrolysis the solution was constantly stirred by a Metrohm model E549 magnetic stirrer. The working electrode used was the same HMDE as that used in the measurement of cyclic voltammograms. The polarographic cell employed was Princeton Applied Research model K64.

The apparent pH values of ethanolic solutions were measured with a Hitachi pH meter molel F-7AD.

Procedure. Working solutions for all voltammetry were made up in constant ionic strength buffer medium (0.1 M in acetic acid and ammonia) at apparent pH 7.3. Unless otherwise stated, the solutions contained 50% ethanol and 0.002% Triton X-100.[5,9,11] Solutions were deoxygenated with a steam of purified nitrogen gas for 10 min prior to measurement, which was presaturated with ethanol–water (1:1) vapor.

For DPASV, after deaeration of the solution, a drop at the HMDE was formed and a constant voltage (−1.0 V for Bu_2SnX_2 and Ph_3SnCl, and −1.3 V for $(Bu_3Sn)_2O$) was applied for a given interval (60 s). The deposition proceeded in a stirred solution. After a quiescent period of 10 s, the electrode was polarized from the deposition potential to more positive values and the stripping peak was recorded. For every measurement the solution was deoxygenated for 2 min and a new drop was formed at the HMDE.

Results and Discussion

General Voltammetric Behavior. In order to develop a sensitive method for determining Bu_2SnX_2 (X=chloride, L, MHM, and DT), its voltammetric behavior, especially Bu_2SnCl_2, was investigated. Since Bu_2SnDT_2 is sparingly soluble in 50% (v/v) ethanol–water medium, it was not investigated.

Normal pulse polarograms (NPP) for Bu_2SnCl_2 in 50% (v/v) and 80% (v/v) ethanol–water media (apparent pH 7.3) are shown in Fig. 1. In both media, Bu_2SnCl_2 gives three reduction waves (I—III).[11] At 1×10^{-4} M (1 M=1 mol dm^{-3}) of Bu_2SnCl_2 in 50% ethanol, distortion is present at more negative potentials than −1.0 V (Fig. 1, curve 1), where the waves appear to split into several steps[9] which were ascertained from cyclic voltammetry. Compared with the respective potentials of three reduction waves of Bu_2SnX_2 (X=L and M) at −0.8, −1.0, and −1.4 V *vs.* SCE according to Scheme (1),[11] the first wave (I) in both media is probably attributed to a two-overlapped wave corresponding to the first and second steps, *i.e.* the formation of Bu_2Sn: which is polymerized to $(Bu_2Sn)_n$.[11] This is also confirmed by the fact that in tast polarography of Bu_2SnCl_2 the limiting current of the first wave (I) in 50% ethanol is the same as that in 80% ethanol. Further, the second wave (II) is probably due to a two-electron reduction of Bu_2Sn: to the hydride Bu_2SnH_2 (third step in Scheme 1).

There is significant adsorption of both Bu_2SnX_2 (X=chloride, L, and MHM) and their reduction products in 50% ethanol, as demonstrated by the appearance of a maximum at the first wave in normal[15] and reverse pulse polarograms, and the depression of electrocapillary curves of Bu_2SnX_2 at both sides of the maximum (Fig. 1). On the other hand, the first wave is accompanied with no maximum in 80% ethanol, indicating that there is no adsorption of the depolarizers and their reduction products in 80% ethanol, as was observed by Fleet and

Fouzder.[11]

Differential pulse polarograms (DPP) of Bu_2SnCl_2 show one distinct peak in both 80 and 50% ethanol-water media as shown in Fig. 2. A similar DPP was obtained for Bu_2SnL_2 in 50% ethanol. The peak in 50% ethanol (curve 1) is narrower and higher than that in 80% ethanol (curve 2) at the same concentration (1×10^{-4} M) of Bu_2SnCl_2. The half-widths ($W_{1/2}$) of Bu_2SnCl_2 in 50 and 80% ethanol and

Compounds (Bu_2SnX_2)	$E_{p,c}$ [a] (V)	$E_{p,a}$ [b] (V)
Bu_2SnCl_2	−0.90	−0.72
Bu_2SnL_2	−0.83	−0.65
Bu_2SnMHM_2	−0.77	−0.60

Conditions of cyclic voltammograms are the same as those in Fig. 3.
a) Peak potential of the cathodic peak. b) Peak potential of the anodic peak.

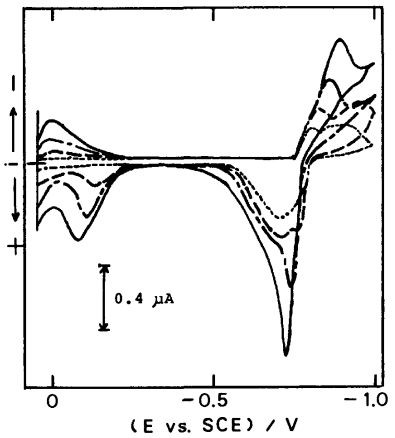

Fig. 4. Effect of scan rate on cyclic voltammograms of Bu_2SnCl_2. $[Bu_2SnCl_2] = 1 \times 10^{-4}$ M; scan rate/mV s^{-1} = ---- 20, —— 50, ---- 100, —— 200.

Bu_2SnL_2[11] in 80% ethanol without surface-active agents at the modulation amplitude (ΔE) of 50 mV are 57, 88, and 90 mV, respectively. The smaller $W_{1/2}$ in 50% ethanol than those in 80% ethanol probably depends partially on the adsorption of the depolarizer and its reduction product(s) in 50% ethanol.

Cyclic voltammograms of Bu_2SnX_2 (X=chloride, L, and MHM) in 50% ethanol are shown in Fig. 3, and the peak potentials on the forward and reverse scans are also shown in Table 1. Peaks (A) for Bu_2SnX_2 occur on the forward or cathodic scan corresponding to the reduction of Bu_2SnX_2. Peaks (B) for Bu_2SnX_2 on the reverse or anodic scan are observed corresponding to the re-oxidation or "stripping" of the products of (A) from the electrode.[16] This finding suggests that the reduction products of Bu_2SnX_2 accumulated on the electrode are readily re-oxidized. The current-voltage curve for the re-oxidation or "stripping" can be utilized for the determination of traces of Bu_2SnX_2 by ASV.

In cyclic voltammetry, scan rate is probably most important experimental parameter for studying the adsorption of reactants or products at the electrode.[17] The dependence of the scan rate on the cyclic voltammetric curve for 1×10^{-4} M Bu_2SnCl_2 in 50%

ethanol is shown in Fig. 4. At the relatively lower scan rate, two cathodic and two corresponding anodic peaks were observed, one of the latter being a shoulder. As the scan rate increases, the respective cathodic and anodic peak currents increase. With further increase of the scan rate above 100 mV s^{-1}, the cathodic and anodic peaks are reduced to one peak, and respective peak currents increase. This cyclic voltammetric behavior described above is analogous to the case, where the reduction product is strongly adsorbed on the stationary electrode,[17] as demonstrated by pulse polarography and electrocapillary curves.

Fleet and Fouzder[11] stated that in Scheme (1) Bu_2Sn^+ ion radical is stable in 80% (v/v) ethanol, but is unstable in <50% (v/v) ethanol as is shown by disappearance of the second wave in 50% ethanol. However, various electrochemical behavior of Bu_2SnX_2 as described above probably indicates that the first and second steps in Scheme (1) proceed at the very close potentials in 50% ethanol, and the reduction products are significantly adsorbed at the mercury electrode. The cause of this difference between both studies is not clear, but is presumably due to the presence or absence of Triton X-100 in ethanolic solutions.

DPASV. Since the voltammetric studies described above suggest the possibility of determining Bu_2SnX_2 by ASV in 50% ethanol, the detailed DPASV behavior of Bu_2SnX_2 (X=chloride, L, MHM, and DT), especially that of Bu_2SnCl_2, was investigated in 50% ethanol in order to develop a more sensitive method, and the DPASV behavior of Bu_2SnX_2 was partly compared to those of tributyltin compounds and Ph_3SnCl.

Typical differential pulse anodic stripping voltammograms for Bu_2SnCl_2, $(Bu_3Sn)_2O$, and Ph_3SnCl obtained in 50% ethanol are shown in Fig. 5. Similar voltammograms were obtained for the other Bu_2SnX_2 in question. The half-widths for the stripping peaks of Bu_2SnCl_2, $(Bu_3Sn)_2O$, and Ph_3SnCl are 30, 107 and 95 mV, respectively.

The variation of the stripping peak current with the mass concentration of Bu_2SnCl_2 was examined. The peak current rises linearly with the concentration of Bu_2SnCl_2 in the range of 3 to 50 ppb (1 ppb=1 μg dm^{-3}) at the deposition time of 60 s. It is to be stressed here that this linear range is a function

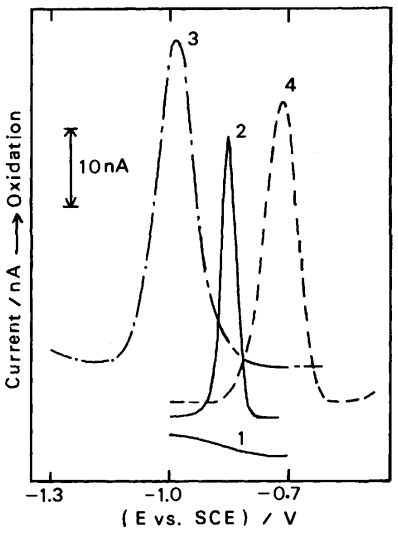

Fig. 5. Typical differential pulse anodic stripping voltammograms of Bu_2SnCl_2, Ph_3SnCl, and $(Bu_3Sn)_2O$ in 50% (v/v) ethanol–water medium of the same composition as in Fig. 1. Pulse repetition time, 0.1 s; modulation amplitude, 50 mV; scan rate 20 mV s^{-1}; deposition potential, (1) −1.0 V, (2) −1.0 V, (3) −1.3 V, and (4) −1.0 V; deposition time, 60 s (stirred); equilibration period, 10 s (unstirred). $[Bu_2SnCl_2]$/ppb=(1) 0 (blank), (2) 24.9; $[(Bu_3Sn)_2O]$/ppb=(3) 129; $[Ph_3SnCl]$/ppb=(4) 115.

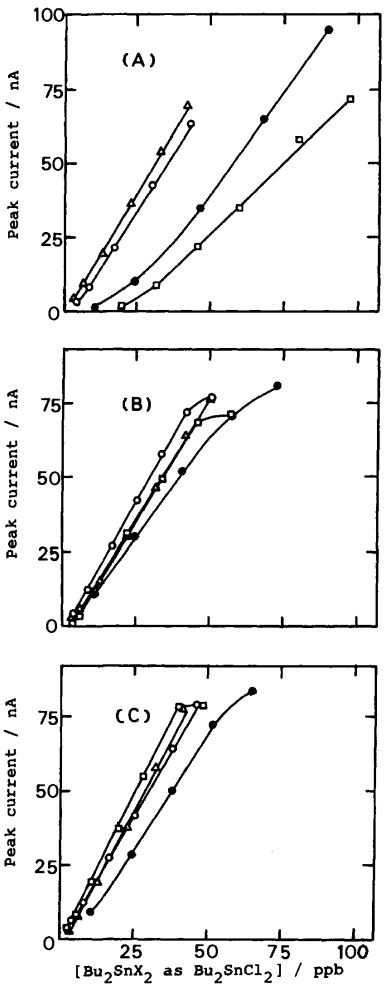

Fig. 6. Effect of potassium chloride on calibration curves of Bu_2SnX_2 in 50% (v/v) ethanol–water medium. [KCl]/M=(A) 0, (B) 0.1, and (C) 0.5, Species of Bu_2SnX_2; -○- Bu_2SnCl_2, -△- Bu_2SnDT_2, -●- Bu_2SnMHM_2, -□- Bu_2SnL_2.

of deposition time, stirring rate, *etc.*, and is not always valid under various conditions. Further, the rise is smaller than the linear value up to 70 ppb and the decrease occurs gradually again. This behavior is expected when a film of insulating material is formed as the reduction product.[9] Beyond a certain critical concentration, at which point the electrode is completely covered with the film, the stripping peak current increases slowly, if at all, with increasing depolarizer concentration. These findings indicate that, in the DPASV steps, the reduction of Bu_2SnCl_2 and the re-oxidation of its reduction product(s), which is only stabilized by the adsorption onto the mercury electrode,[9,11] should occur on the electrode surface.

The lower limits of detection of Bu_2SnCl_2, $(Bu_3Sn)_2O$, and Ph_3SnCl are 3, 2.5, and 7 ppb, respectively. The relative standard deviation at 8.4 ppb of Bu_2SnCl_2 (eight runs) was 3.1%.

The comparison of calibration curves of the respective Bu_2SnX_2 is of interest in connection with its chemical property. Each Bu_2SnX_2 in 50% ethanol–water medium gives a different calibration curve and further each calibration curve varies with the concentration of potassium chloride added in 50% ethanol–water medium (Fig. 6), where all concentrations of Bu_2SnX_2 are represented as that of Bu_2SnCl_2. Without potassium chloride (Fig. 6 A), the slopes of calibration curves giving straight lines increase in the following order: $Bu_2SnL_2 < Bu_2SnMHM_2 < Bu_2SnCl_2 — Bu_2SnDT_2$. Moreover, the intercepts at zero peak current of these straight lines decrease in the above order. These findings indicate that the DPASV steps of Bu_2SnX_2 occur readily in the above order. With increasing concentration of potassium chloride, the calibration curves of Bu_2SnL_2 and Bu_2SnMHM_2 approach gradually to that of Bu_2SnCl_2, but the calibration curve of Bu_2SnMHM_2 does not overlap even at 0.5 M potassium chloride. It was also observed that the stripping peak potential (E_p) of Bu_2SnMHM_2 is more positive than those of others in a medium without potassium chloride, and E_p of Bu_2SnMHM_2 approaches to those of others with increasing concentration of potassium chloride. These facts indicate that L and MHM of Bu_2SnX_2 are gradually replaced by chloride, and the replacement of MHM by chloride is not so easy as L. Further, the different DPASV behavior of Bu_2SnMHM_2 from others is probably ascribed to the effect of an olefinic double bond of Bu_2SnMHM_2.[11] On the other hand, the fact that the calibration curve of Bu_2SnDT_2 is very close to that of Bu_2SnCl_2 even in a medium without potassium chloride is presumably attributed to a strong and stable adsorption of Bu_2SnDT_2 and its reduction product(s) at the HMDE. This may be the result of the interaction between mercury and sulfur, as was observed for dioctyltin bis(mercaptoacetate) in 80% ethanol.[12] From the results described above, the bond between tin atom and X in Bu_2SnX_2 seems to possess a covalent property enhancing in the reverse order as mentioned above.

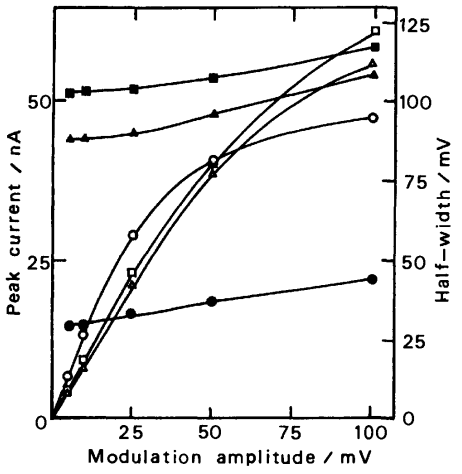

Fig. 7. Effects of modulation amplitude on peak current and half-width. -○-, -●- [Bu_2SnCl_2] = 25.2 ppb; -△-, -▲- [Ph_3SnCl] = 115 ppb; -□-, -■- [$(Bu_3Sn)_2O$] = 129 ppb. Peak current, -○-, -△-, -□-; half-width, -●-, -▲-, -■-.

Optimization of Instrumental Parameters: The effects of various instrumental parameters on the stripping peak current are shown below.

The effects of the ΔE on the peak current and the $W_{1/2}$ for Bu_2SnCl_2, $(Bu_3Sn)_2O$, and Ph_3SnCl are shown in Fig. 7. The peak currents of these compounds are proportional to the ΔE up to 25 mV. The $W_{1/2}$ for these compounds also increase with an increase in ΔE. These findings are generally observed in DPASV.[18–20] On the grounds of sensitivity and selectivity the modulation amplitude of 50 mV was chosen for this study.

The peak current is proportional to the deposition time up to 2 min. Hence, the deposition time of 1 min was chosen throughout this study.

The effect of the scan rate on the peak current of Bu_2SnCl_2 was examined over the scan rate of 5 to 100 mV s^{-1}. The peak current increased steeply with increasing scan rate in the range of 5—20 mV s^{-1} and increased gradually above 20 mV s^{-1}.

The plots of the deposition potential (E_{dep}) *vs.* peak current for Bu_2SnCl_2, $(Bu_3Sn)_2O$, and Ph_3SnCl are shown in Fig. 8. The plots for the other Bu_2SnX_2 were similar to that of Bu_2SnCl_2. The maximum peak current for each compound was observed in the narrow range. When deposited at −1.0 V, Bu_2SnCl_2 is co-deposited considerably with Ph_3SnCl, but scarcely with $(Bu_3Sn)_2O$.

Several DPASV behavior of Bu_3SnCl was also investigated and the DPASV behavior obtained for Bu_3SnCl was the same as that of $(Bu_3Sn)_2O$ described above.

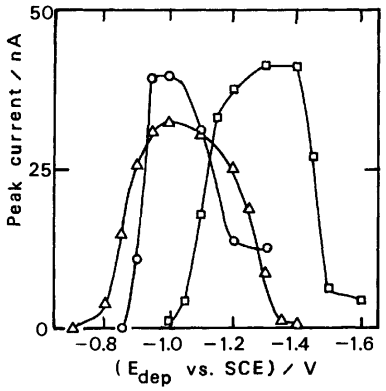

Fig. 8. Effect of deposition potential on peak current.
-○- $[Bu_2SnCl_2]=25.2$ ppb; -△- $[Ph_3SnCl]=100$ ppb;
-□- $[(Bu_3Sn)_2O]=129$ ppb.

On the grounds of the results described above, the instrumental parameters were chosen for the conditions shown in Fig. 5.

Stability of Stripping Peak Current of Bu_2SnX_2: Fleet and Fouzder[11] claimed that Bu_2Sn^+ ion radical is unstable in <50% (v/v) ethanol as described above. However, each stripping peak current of Bu_2SnX_2 in 50% ethanol was constant over the standing time at least up to 180 min under the stream of nitrogen gas.

Effect of Coexisting Substances: As can be seen in Fig. 6, the peak current of Bu_2SnCl_2 increased slightly with increasing concentration of potassium chloride added in 50% ethanol-water medium.

The effects of Ph_3SnCl and Bu_3SnCl on the determination of Bu_2SnCl_2 was also examined. As described above, Bu_2SnCl_2 is co-deposited with Ph_3SnCl, but scarcely with Bu_3SnCl when deposited at −1.0 V (Fig. 8). The presence of Ph_3SnCl in the concentration above 4 ppb depressed the peak current of Bu_2SnCl_2 (25.2 ppb). The presence of Bu_3SnCl at *ca.* 30 ppb scarcely affected the peak current of Bu_2SnCl_2 (25.2 ppb).

Determination of Bu_2SnX_2. On the basis of the above detailed study, an analytical method for the determination of Bu_2SnX_2 in natural water was developed. The proposed method involves extraction[21] and cleaning up by chromatography on a cation-exchange resin[22] in order to avoid interferences from heavy metals and organic materials in the measurement of DPASV.

To 250 ml of natural water was added 10 grams of sodium chloride (except for sea water) and 2 ml of hydrochloric acid (36%), and then Bu_2SnX_2 was extracted twice with 25 ml of 50% ethyl acetate-hexane. The extract was dried over anhydrous sodium sulfate, concentrated to about 5 ml by use of Kuderna-Danish concentrator and then evaporated to near dryness under the stream of nitrogen gas. The concentrate was dissolved in 10 ml of ethanol. The ethanolic solution was passed through a cation-exchange resin column (2×5 cm). After washing the column with 20 ml of ethanol and 10 ml of 5% (v/v) water-ethanol, Bu_2SnCl_2 was eluted with 13 ml of 5% (v/v) hydrochloric acid-ethanol. During extraction and cleaning up by chromatography, Bu_2SnX_2 will be converted to Bu_2SnCl_2. The eluate was neutralized to approximately pH 7.0 with ammonia and acetic acid. After adding buffer (pH 7.0) and Triton X-100 the solution was diluted to 25 ml with water, whereupon the final concentration of ethanol became 50% (v/v). Then, Bu_2SnCl_2 was determined by DPASV by use of the standard addition method.

Recovery tests of Bu_2SnCl_2 (1 μg) from river water and sea water were carried out, and the recovery percentages were 67 and 91%, respectively. The lower recovery percentage from river water is probably ascribed to the lower extractability of Bu_2SnCl_2 due to the absence of ions such as bromide.[23]

We wish to express our hearty thanks to Professor Toyokichi Kitagawa and Dr. Akio Ichimura of the Faculty of Science, Osaka City University for their helpful discussion and encouragement. We also wish to thank Mr. Yoshio Kuge of the Environmental Pollution Control Center, Osaka Prefectural Government for his encouragement, and Yanagimoto Mfg. Co. Ltd. for lending a polarographic instrument.

This study is partially supported by the Environmental Agency.

A Nuclear Magnetic Resonance Study of the Exchange Reaction of Dimethyl Sulfoxide in Pentakis(dimethyl sulfoxide)oxovanadium(IV) Ions

Kiyoshi KAYA, Yasuhisa IKEDA, and Hiroshi FUKUTOMI*
Research Laboratory for Nuclear Reactors, Tokyo Institute of Technology, O-okayama, Meguro-ku, Tokyo 152
(Received March 19, 1985)

The dmso exchange reaction in $[VO(dmso)_5]^{2+}$ has been studied in the mixture of CD_3NO_2 and DMSO by means of ^1H NMR. The exchange rate is independent of the free DMSO concentration and the kinetic parameters are as follows: $k_{ex}(25\,^\circ C)=1.76\times10^3\ s^{-1}$, $\Delta H^*=60.1\pm4.3$ kJ mol^{-1}, and $\Delta S^*=18.5\pm12.9$ JK^{-1} mol^{-1}.

Ligand-exchange reactions in several oxovanadium (IV) complexes have been studied by using the NMR line-broadening method,[1-4] but the mechanisms for these reactions have not been proposed in detail. On the other hand, Lincoln[5] has shown that the plot of ΔH^* *vs.* ΔS^* for ligand-exchange reactions in oxovanadium(IV) complexes is linear and consistent with that for the ligand-exchange reactions in various uranyl(VI) complexes in which the reactions proceed dissociatively. Such an isokinetic relationship suggests that the reactivity of oxovanadium(IV) ions is very similar to that of uranyl(VI) ions, and that the ligand-exchange reactions in oxovanadium(IV) complexes seem to proceed dissociatively. However, the associative mechanism has been proposed for some complex-formation reactions in oxovanadium(IV) ions.[6-8] From this point of view, further studies for the ligand-exchange reactions in oxovanadium(IV) complexes are necessary to understand the mechanisms in detail. This paper reports the exchange of dmso (dimethyl sulfoxide) in the $[VO(dmso)_5]^{2+}$ ion. This reaction has already been studied by Angerman and Jordan with the NMR line-broadening method,[3] but no accurate kinetic parameters have been determined, because the slow exchange region, where the relaxation time is controlled by the chemical exchange rate,[9] was not observed in the temperature range above the freezing point of DMSO. In the present study, CD_3NO_2 was used as a diluent in order to extend the lower limit of temperature range. As a result, it became possible to observe the slow exchange region and to determine the kinetic parameters.

Experimental

The $[VO(dmso)_5](ClO_4)_2$ complex was synthesized by the same method as described in a previous paper.[10] Anal. Calcd for $[VO(dmso)_5](ClO_4)_2$: C, 18.30; H, 4.61; S, 24.42. Found: C, 18.28; H, 4.56; S, 24.38. Dimethyl sulfoxide (Wako Pure Chemical Ind. Ltd.) was distilled *in vacuo*, followed by distillation with 3A molecular sieves (Wako), and stored over 3A molecular sieves. Nitromethane-d_3 (CD_3NO_2, Merck 99%), which was used as a diluent and an NMR lock reagent, was dried over 3A molecular sieves. The UV and visible spectra of the $[VO(dmso)_5]^{2+}$ ion in DMSO and in the mixture of CD_3NO_2 and DMSO were measured on a Shimadzu UV-210A double-beam spectrophotometer. Sample solutions for NMR measurements were prepared by weighing $[VO(dmso)_5](ClO_4)_2$, DMSO, and CD_3NO_2 in a 1 cm^3 volumetric flask and were placed in NMR sample tubes and sealed under vacuum. All samples were prepared in a glove-box filled with dried nitrogen. ^1H NMR spectra of bulk DMSO were measured at 100 MHz on a JEOL JNM-FX 100 FT-NMR spectrometer equipped with a JNM-VT-3B temperature controller. Typical spectral settings are as follows: data points, 8K; spectral width, 1000 Hz; pulse width, 14 μs; pulse delay time, 2.5 s; number of scan, 4.

Results and Discussion

The absorption spectrum of the $[VO(dmso)_5]^{2+}$ ion in DMSO was measured, and the two absorption bands at 820 and 690 nm were assigned to the $^2B_2\rightarrow{}^2E(I)$ and $^2B_2\rightarrow{}^2B_1$ (10 Dq) transitions, respectively, from the molecular orbital diagram of Ballhausen and Gray.[11] Based on this assignment, Dq is calculated to be 1450 cm^{-1} and is consistent with that obtained by Angerman and Jordan.[3] The absorption spectrum of the $[VO(dmso)_5]^{2+}$ ion in the mixture of CD_3NO_2 and DMSO was compatible with that in DMSO. This fact indicates that the $[VO(dmso)_5]^{2+}$ ion has the same solvation structure in both solvents, DMSO and the mixture of CD_3NO_2 and DMSO.

On the basis of the spectrophotometric results, the dmso exchange in the $[VO(dmso)_5]^{2+}$ ion was measured in the mixture of CD_3NO_2 and DMSO by using the NMR line-broadening method. The line-width and chemical shift of the methyl proton signal of bulk DMSO in the presence and absence of the $[VO(dmso)_5]^{2+}$ ion were measured by varying temperature from −45 to 70 °C. In this temperature range, the line-width of methyl proton signal of DMSO changed with temperature, while no change was observed in chemical shift of the corresponding signal. In this case, the transverse relaxation time (T_2) is expressed as follows:[9]

$$\frac{1}{T_2}=\frac{1-p_m}{p_m}\left(\frac{1}{T_{2p}}-\frac{1}{T_{2a}}\right)=\frac{1}{T_{2m}+\tau_m}+\frac{1}{T_{2o}}, \quad (1)$$

where T_{2p} and T_{2a} are the transverse relaxation times of nuclei in the bulk solvent in the presence and absence of the paramagnetic metal ion, respectively, and are related with the full line-width ($\Delta\nu$) at half-height as $1/T_{2p}=\pi\Delta\nu_p$ and $1/T_{2a}=\pi\Delta\nu_a$, p_m is the ratio of the concentration of solvent bound to the paramagnetic metal ion to the concentration of free solvent, τ_m is the solvent exchange lifetime, T_{2m} is the transverse relaxation time of the coordinated solvent, and T_{2o} is the relaxation time of solvent outside the first-coordination sphere of the paramagnetic metal ion. The ralationship between τ_m and the first-order rate constant (k_{ex}) with temperature is as follows:

$$1/\tau_m = k_{ex} = (kT/h)\exp(-\Delta H^*/RT)\exp(\Delta S^*/R), \quad (2)$$

and the temperature dependence of T_{2m} and T_{2o} is assumed to be given by Eqs. 3 and 4, respectively.[12]

$$\frac{1}{T_{2m}} = C_m \exp\left(\frac{E_m}{RT}\right) \quad (3)$$

$$\frac{1}{T_{2o}} = C_o \exp\left(\frac{E_o}{RT}\right) \quad (4)$$

The values of T_2 were calculated based on the equatorial coordination number of four and from the assumption that the dmso exchange in the axial site is very faster than that in the equatorial site,[2,3] and hence only the dmso exchange in the equatorial site contributes to the line-broadening in the present temperature range. Figure 1 shows the typical plot of $\ln(1/T_2)$ *vs.* the reciprocal temperature. This figure indicates that T_2 is controlled by T_{2m}, τ_m, and T_{2o} successively as the temperature decreases, and that the above assumption is reasonable. If the dmso exchange in the axial site is not much faster than that in the equatorial site in the present temperature range, the value of $1/T_2$ should decrease again in the low temperature range as observed in the dmf (*N*,*N*-dimethylformamide) exchange in $[VO(dmf)_5]^{2+}$ ions.[4] Kinetic parameters were determined by a nonlinear least-squares fit of $1/T_2$ data to the equation obtained by substitution of Eqs. 2, 3, and 4 into Eq. 1. Kinetic parameters for solutions with various compositions were determined by the same manner and are listed in Table 1. The table shows that the exchange rate is independent of the concentration of DMSO and the ΔS^* values are positive. These results suggest that the dmso exchange in the equatorial site of the $[VO(dmso)_5]^{2+}$ ion proceeds through either the D or I_d mechanism. On the other hand, the activation volume (ΔV^*) for the dmso exchange reaction was determined to be $-5.3\pm0.4\,cm^3\,mol^{-1}$ in our recent study,[10] and suggested that the reaction proceeded associatively. Since the ΔS^* value is in conflict with the ΔV^* value, it is difficult to infer the mechanism of dmso exchange reaction. However, the A mechanism is excluded because the rate of dmso exchange is independent of [DMSO]. Furthermore, the D mechanism also seems to be unlikely from the following reasons. It was proposed that the solvent exchange reactions proceeding through the D mechanism have the positive ΔV^* value, because no net change occurs before and after the exchange reaction, so that negligible solvational change is expected and the observed ΔV^* value reflects the intrinsic volume change.[13,14] In addition, it was suggested that the

ΔS^* value does not necessarily reflect the activated state owing to the contribution of the solvent rearrangement around the metal complexes, especially in mixed solvents.[15]

In the I mechanism, the exchange process in the equatorial site is expressed as follows:

$$[VO(dmso)_5]^{2+} + DMSO^* \overset{K_{os}}{\rightleftharpoons} [VO(dmso)_4(dmso)_{ax}]^{2+}\cdots DMSO^*$$
$$\xrightarrow[\text{slow}]{k_I} [VO(dmso)_3(dmso^*)(dmso)_{ax}]^{2+}\cdots DMSO$$
$$\xrightarrow[\text{fast}]{} [VO(dmso)_3(dmso^*)(dmso)_{ax}]^{2+} + DMSO,$$

where an asterisk is used to denote the exchanging species, $(dmso)_{ax}$ represents the coordinated dmso to the axial site, K_{os} is the formation constant of the outer-sphere complex, $[VO(dmso)_4(dmso)_{ax}]^{2+}\cdots DMSO^*$, and k_I is the dmso interchange rate constant between the dmso molecules in the equatorial sites and those in the second-coordination sphere above the triangular faces of the octahedral $[VO(dmso)_5]^{2+}$ ion[7,16] or the rate constant for a process involving intramolecular rearrangement of the coordinated dmso from the axial to the equatorial sites in $[VO(dmso)_4(dmso)_{ax}]^{2+}$.[17,18] For this mechanism, k_{ex} is given by

$$k_{ex} = k_I K_{os}[DMSO]/(1+K_{os}[DMSO]). \quad (5)$$

If $K_{os}[DMSO] \gg 1$, Eq. 5 can be simplified as $k_{ex}=k_I$ and gives the independence of the exchange rate from the DMSO concentration. In the present study, it is suggested that DMSO molecules may preferentially solvate around the $[VO(dmso)_5]^{2+}$ ion from the spectrophotometric results. This preferential solvation is due to the fact that the basity of DMSO is larger than that of CD_3NO_2 on the basis of Gutmann's donor number (DN).[19] In a previous paper[20] dealing with the dmso exchange of $UO_2(acac)_2dmso$ in CD_2Cl_2, the K_{os} value for the formation of $UO_2(acac)_2dmso\cdots DMSO$ was found to be *ca.* 5 M^{-1}(M=mol dm^{-3}). The K_{os} value for the present study is expected to be larger than 5 M^{-1} in spite of the fact that the dielectric constant of CD_3NO_2(35.94) is larger than that of CD_2Cl_2(8.93), because the positively charged $[VO(dmso)_5]^{2+}$ ion has a stronger affinity for DMSO than does the neutral $UO_2(acac)_2dmso$ complex. Therefore, it seems reasonable to consider that the condition, $K_{os}[DMSO] \gg 1$, is satisfied in the present study, and that the dmso exchange proceeds through the I mechanism. Especially, the I_a mechanism seems more likely because of the negative ΔV^* value. Nishizawa and Saito have proposed that the rate constant for the intramolecular rearrangement from the axial to the equatorial site is$\simeq 10^3$ s^{-1} at 25 °C. Since this value is comparable to the value for k_{ex}(1.8×10^3 s^{-1} at 25 °C) in our study, the possibility exists that the k_I pathway might be the intramolecular rearrangement proposed by Nishizawa and Saito.

The kinetic parameters for the present and previous studies on the ligand-exchange reactions in oxovanadium(IV) complexes are summarized in Table 2. For the ligand-exchange reactions in oxovanadium(IV) complexes with the ligands coordinated through oxygen, the values of exchange rate constants are almost identical with each other within a factor of 23, and the differences in ΔH^* value are also small in spite of the large differences in basicity and size of ligands. These facts suggest that the ligand-exchange reactions in oxovanadium(IV) complexes may not proceed dissociatively because the ligand basicity is one of the dominant kinetic factors in the dissociative process. On the other hand, Caldin and Bennetto proposed that the substitution reactions proceeding dissociatively exhibit an isokinetic relationship between ΔH^* and ΔS^* values.[15] Figure 2 shows the plot of ΔH^* *vs.* ΔS^* for the ligand exchange reactions in the equatorial site of oxovanadium(IV) complexes and reveals that the isokinetic

relationship is satisfied. Hence, if the proposal by Caldin and Bennetto is acceptable, the possibility still remains, in which the ligand-exchange reactions in oxovanadium(IV) complexes proceed dissociatively. Further studies for the activation volume and anation reactions in oxovanadium(IV) complexes are necessary to clarify the mechanism of the ligand exchange in the present complex.

Hydrophobic Vitamin B_{12}. IV. Addition Reactions of Alcohols to Olefins as Catalyzed by Hydrophobic Vitamin B_{12} Derivatives†

Yukito MURAKAMI* and Yoshio HISAEDA
Department of Organic Synthesis, Faculty of Engineering, Kyushu University, Hakozaki, Higashi-ku, Fukuoka 812
(Received March 26, 1985)

Addition reactions of alcohols to olefins were catalyzed by hydrophobic vitamin B_{12} derivatives under aerobic irradiation conditions at the room temperature range. Ethyl vinyl ether, 1-pentene, and cyclohexene were adopted as olefins, while heptamethyl methylaquacobyrinate perchlorate and heptamethyl cyanoaquacobyrinate perchlorate were used as the starting complexes. Heptamethyl cobyrinate, which was generated from heptamethyl methylaquacobyrinate perchlorate by aerobic photolysis, is an appropriate catalyst for investigation of the reaction mechanism because the alkylated complex having the cobalt–carbon σ-bond, the reaction intermediate, has a long lifetime sufficient for its identification in the dark. On the other hand, heptamethyl cyanocobyrinate, which was derived from heptamethyl cyanoaquacobyrinate, is superior to heptamethyl cobyrinate as the catalyst for the addition reaction. The reaction proceeds *via* light-promoted decomposition of the alkylated complex, and the catalyst is regenerated upon autoxidation by air. These hydrophobic vitamin B_{12} derivatives are particularly effective homogeneous catalysts for the addition of an alcohol to an electron-rich olefin. Plausible reaction schemes for the catalytic cycle have been presented on the basis of experimental findings.

Recently, reactions of olefins catalyzed by vitamin B_{12} and its model complexes have been studied rather extensively,[1] but most of these studies deal with reduction of substrates as caused by the nucleophilic reactivity of the univalent cobalt species. On the other hand, the electrophilic reactivity of the tervalent cobalt species toward olefins has been scarcely examined. In this regard, Dolphin *et al.* reported that bromo(pyridine)cobaloxime and hydroxocobalamin undergo reaction with an electron-rich olefin such as ethyl vinyl ether in the presence of an alcohol to afford the corresponding alkylated complex, having the cobalt–carbon σ-bond, with the acetal moiety as the axial ligand under anaerobic conditions in the dark.[2] Cobalamin and cobaloxime are not efficient catalysts for the reaction in the light of the following observations: (i) the reaction between the catalyst and ethyl vinyl ether proceeds extremely slowly; (ii) an electron-rich olefin such as ethyl vinyl ether undergoes reaction, while other ordinary olefins such as ethylene, 2-methyl-1-butene, 2-ethyl-1-butene, 3,3-dimethyl-1-butene, and ethyl acrylate are unreactive. In addition, cobalamin is soluble in water, methanol, and ethanol, which exercise large solvation effects, while apolar organic solvents can not be used as reaction media because of insolubility of the complex.

We have been dealing with hydrophobic vitamin B_{12} derivatives which have ester groups in place of the peripheral amide moieties of the naturally occurring vitamin B_{12}.[3] These modified cobalt complexes are readily soluble in a wide range of organic solvents and expected to be utilized as homogeneous catalysts in such media. In this regard, we have carried out in this work the reactions of an electron-rich olefin, ethyl vinyl ether, and ordinary olefins, 1-pentene and cyclohexene, with alcohols, methanol and ethanol, in the presence of either heptamethyl methylaquacobyrinate perchlorate, $[(CH_3)(H_2O)Cob(III)7C_1ester]ClO_4$, or heptamethyl cyanoaquacobyrinate perchlorate, $[(CN)(H_2O)Cob(III)7C_1ester]ClO_4$, as the catalyst under aerobic irradiation conditions. The catalytic schemes are to be discussed on the basis of experimental findings obtained under various conditions.

Experimental

Materials. Cyanocobalamin was purchased from Nakarai Chemicals and used without further purification. Heptamethyl dicyanocobyrinate, $(CN)_2Cob(III)7C_1ester$, was derived from cyanocobalamin after the method of Werthemann *et al.*[4] Preparation of heptamethyl cobyrinate perchlorate, $[Cob(II)7C_1ester]ClO_4$, has been described previously.[3a] Ethyl vinyl ether, 1-pentene, cyclohexene, acrylonitrile, methanol, ethanol, and dichloromethane were purified and dried according to the standard procedures[5] and confirmed to be sufficiently pure by GLC.

† Contribution No. 770 from this Department.

Heptamethyl Cyanoaquacobyrinate Perchlorate, [(CN)(H$_2$O)-Cob(III)7C$_1$ester]ClO$_4$. $(CN)_2$Cob(III)7C$_1$ester (50 mg, 4.6×10^{-5} mol) was dissolved in 40 mL of dichloromethane, and the resulting purple solution was treated with 25 mL of 30% aqueous perchloric acid at room temperature. The orange dichloromethane layer was separated from the acidic aqueous layer and washed with distilled water. After being dried over sodium sulfate, the orange layer was evaporated to dryness *in vacuo* at room temperature. The residue was reprecipitated from benzene upon addition of hexane to afford fine red crystals: yield 50 mg (92%); UV_{max} (C_6H_6) 325 (ε 1.79×10^4), 356 (2.75×10^4), 406 (0.79×10^4), 490 (1.15×10^4), and 520 nm (0.91×10^4); IR (KBr) 2150 (C≡N), 1730 (ester C=O), and 1100 and 620 cm^{-1} (ClO_4^-).

Found: C, 53.75; H, 6.40; N, 6.03. Calcd for $C_{53}H_{75}ClCoN_5O_{19}$: C, 53.92; H, 6.40; N, 5.93.

Heptamethyl Methylaquacobyrinate Perchlorate, [(CH$_3$)(H$_2$O)-Cob(III)7C$_1$ester]ClO$_4$. [Cob(II)7C$_1$ester]ClO$_4$ (50 mg, 4.4×10^{-5} mol) was mixed with 600 mg of zinc powder dispersed in 30 mL of acetic acid, and the mixture was stirred for 10 min at room temperature under nitrogen atmosphere. All the following treatments were performed under subdued light. After the mixture turned dark green, it was stirred for 5 min upon addition of 1.0 g of methyl iodide. The residual zinc powder was removed by filtration, and 50 mL of 15%(w/w) aqueous sodium perchlorate was added to the filtrate. The reaction mixture was extracted with dichloromethane (50 mL×3), and the extract was washed with 5%(w/w) aqueous sodium hydrogencarbonate (50 mL) and distilled water (50 mL). After being dried over sodium sulfate, the yellow dichloromethane solution was evaporated to dryness *in vacuo* at room temperature. The residue was reprecipitated from benzene upon addition of hexane to afford brown powder: yield 43 mg (84%); UV_{max} (CH_2Cl_2) 264 (ε 2.14×10^4), 305 (2.36×10^4), 373 (0.85×10^4), and 457 nm (1.03×10^4); CD (CH_3OH) 260 ($\Delta\varepsilon$ −18.6), 323 (+13.7), 356 (−1.71), 378 (+1.38), 462 (−4.82), 508 (+2.87), and 550 nm (+1.69); IR (KBr) 1730 (ester C=O), and 1100 and 620 cm^{-1} (ClO_4^-); ^{1}H-NMR (CD_3OD, TMS) δ=−0.18 (3H, s, CH_3-Co), 1.02, 1.14, 1.40, 1.45, 1.62, 1.80, 2.35, and 2.40 (24H, each s, CH_3), 3.65 (21H, m, CO_2CH_3), and 6.65 (1H, s, H at C-10).

Found: C, 54.49; H, 6.61; N, 4.96. Calcd for $C_{53}H_{78}ClCoN_4O_{19}$: C, 54.43; H, 6.72; N, 4.80.

Although both Coα- and Coβ-methyl isomers are generally expected to be formed, the methylated complex prepared by the present method is regarded as the Coβ-methyl isomer in the light of UV, CD, and ^{1}H-NMR data.[6]

Spectroscopic Measurements. Electronic absorption spectra were recorded on a Hitachi 340 or a Hitachi 220A spectrophotometer. ^{1}H-NMR spectra were taken on a Hitachi R-24B spectrometer. ESR spectra were obtained with a JEOL JES-ME-3 X-band spectrometer equipped with a 100-kHz field modulation unit; a standard MgO/Mn^{II} sample calibrated with a NMR magnetometer was employed for calibration of the magnetic field.

Kinetic Measurements. Pseudo-first-order rate constants for the alkylation of heptamethyl cobyrinate, [(ROH)$_2$Cob(III)7C$_1$ester]$^{2+}$ (R=H and/or CH_3), with ethyl vinyl ether and methanol in dichloromethane were determined spectrophotometrically. A mixture of [(CH_3)-(H_2O)Cob(III)7C$_1$ester]ClO_4 (5.0×10^{-5} mol dm^{-3}), ethyl vinyl ether, methanol, and dichloromethane was placed in a spectrophotometric cell of 1-cm path length which was thermostated at 21.5±0.1 °C. The solution was irradiated with a conventional 500-W tungsten lamp from a distance of 20 cm for 1 min. [(CH_3)(H_2O)Cob(III)7C$_1$ester]ClO_4 was converted completely into [(ROH)$_2$Cob(III)7C$_1$ester]$^{2+}$ upon aerobic irradiation. Then, the complex thus formed was subjected to alkylation in the dark. Under the present experimental conditions, clear isosbestic points were observed in the course of alkylation along with absorbance decay of the 335-nm band which is characteristic of the dicationic cobalt complex. All the kinetic runs provided linear correlations for plots of $\ln(OD_t-OD_\infty)$ *vs.* time, where OD_t and OD_∞ stand for optical densities at time t and after completion of the reaction, respectively.

Catalytic Reactions. [(CN)(H_2O)Cob(III)7C$_1$ester]-ClO_4 was dissolved in a solution composed of ethyl vinyl ether and ethanol, and the mixture was placed in a Pyrex ampule (ϕ 20 mm). The reaction mixture was stirred and irradiated with a conventional 500-W tungsten lamp from a distance of 10 cm at 20±1 °C. As for the reaction carried out in the dark, the ampule was covered with aluminum foil. After an appropriate time interval, the reaction mixture was distilled *in vacuo* at room temperature and analyzed by means of GLC on a Shimadzu GC-4C apparatus with helium as a carrier gas. Identification of the reaction products was performed by coinjection of the distilled fraction with authentic samples into columns of Polyethylene Glycol 600, Silicone DC-550, and Silicone SE-30. A turnover number for the catalyst was calculated after correction for the blank reaction, if any, in the absence of the catalyst.

Results and Discussion

Reactions with [(CH$_3$)(H$_2$O)Cob(III)7C$_1$ester]ClO$_4$. When [(CH_3)(H_2O)Cob(III)7C$_1$ester]ClO_4 dissolved in a solution of ethyl vinyl ether and methanol was irradiated with the visible light for a short period of time under aerobic conditions, the complex was transformed into [(ROH)$_2$Cob(III)7C$_1$ester]$^{2+}$ which shows absorption maxima at 335, 490, and 510 nm (Fig. 1).[7] Then, the mixture was allowed to stand in the dark to afford an alkylated complex having the cobalt–carbon bond, which shows absorption maxima at 303 and 464 nm (Fig. 2); clear isosbestic points being observed along the progress of the reaction. When the starting complex was replaced with another alkylated complex such as [(C_2H_5)(H_2O)Cob-(III)7C$_1$ester]ClO_4 or [((CH_3O)$_2$$CHCH_2$)($H_2O$)Cob-(III)7C$_1$ester]$ClO_4$, the spectral changes identical with those shown in Figs. 1 and 2 were observed. Irradiation of [(CH_3)(H_2O)Cob(III)7C$_1$ester]ClO_4 with the visible light in methanol without ethyl vinyl ether under aerobic conditions resulted in the formation of [(ROH)$_2$Cob(III)7C$_1$ester]$^{2+}$, which was then converted into [Cob(II)7C$_1$ester]$^+$ in the dark, showing absorption maxima at 317 and 470 nm (Fig. 3). On the other hand, the anaerobic photolysis of [(CH_3)(H_2O)Cob(III)7C$_1$ester]ClO_4 in a solution of

ethyl vinyl ether and methanol gave [Cob(II)-7C$_1$ester]$^+$ as shown in Fig. 4, and the alkylated complex was not detected in a short period of time while the solution was allowed to stand further in the dark.

The ^{1}H-NMR spectra for [(CH$_3$)(H$_2$O)Cob(III)-7C$_1$ester]ClO$_4$ and the alkylated complex, which was obtained under the conditions described above, are shown in Fig. 5. The spectrum for the latter does not show the proton signal at $\delta=-0.18$ attributable to the cobalt-bound methyl group and is consistent with the structural formula, [((C$_2$H$_5$O)(CH$_3$O)CHCH$_2$)(H$_2$O)-Cob(III)7C$_1$ester]$^+$.

In the light of the above observations, [(CH$_3$)(H$_2$O)-Cob(III)7C$_1$ester]ClO$_4$ is apparently converted into [(ROH)$_2$Cob(III)7C$_1$ester]$^{2+}$ by the aerobic photolysis, and the latter complex undergoes alkylation with

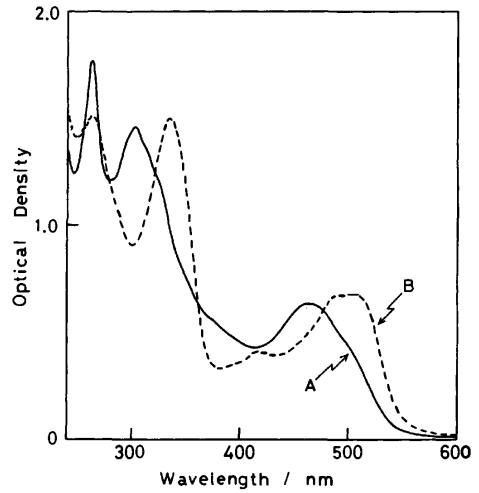

Fig. 1. Electronic spectra for the aerobic photolysis of [(CH$_3$)(H$_2$O)Cob(III)7C$_1$ester]ClO$_4$ in ethyl vinyl ether–methanol (1 : 1 v/v) at 21.5±0.1 °C: A, [(CH$_3$)-(H$_2$O)Cob(III)7C$_1$ester]ClO$_4$ (7.6×10^{-5} mol dm^{-3})before photolysis; B, irradiation with a 500-W tungsten lamp from a distance of 30 cm for 5 min to afford [(ROH)$_2$Cob(III)7C$_1$ester]$^{2+}$.

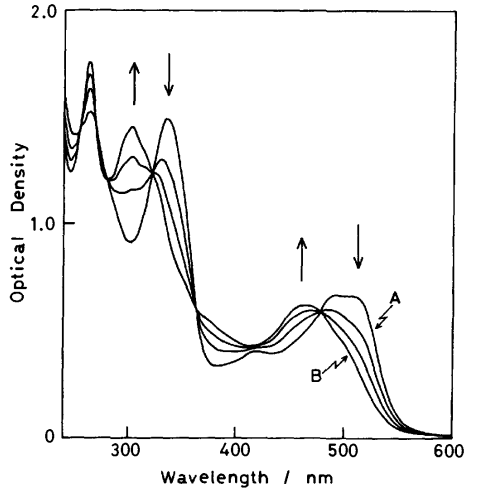

Fig. 2. Spectral change for formation of the cobalt–carbon bond derived from the aerobic photolysis product in the dark at 21.5±0.1 °C. Trends of spectral change with time are shown by arrows: A, the aerobic photolysis product, [(ROH)$_2$Cob(III)7C$_1$ester]$^{2+}$; B, the final product, [(C$_2$H$_5$O)(CH$_3$O)CHCH$_2$-Cob-(III)7C$_1$ester]$^+$. As for the amounts of reacting species, see Fig. 1.

ethyl vinyl ether and methanol in the dark. Pseudo-first-order rate constants for the alkylation in various solutions were evaluated on the basis of spectral change typically shown in Fig. 2 and summarized in Table 1. The alkylation rate was found to increase as the concentration of ethyl vinyl ether was increased on one hand and to be reduced as the quantity of methanol was increased on the other. This result indicates that the reaction rate is controlled by the complex formation (*vide infra*) between ethyl vinyl ether and $[(ROH)_2Cob(III)7C_1ester]^{2+}$, which is enhanced as the solvent polarity is reduced: solvent polarity parmeters ($E_T(30)$) methanol, 55.5; dichloromethane, 41.1; ethyl vinyl ether, 35.1 kcal mol^{-1}.[8]

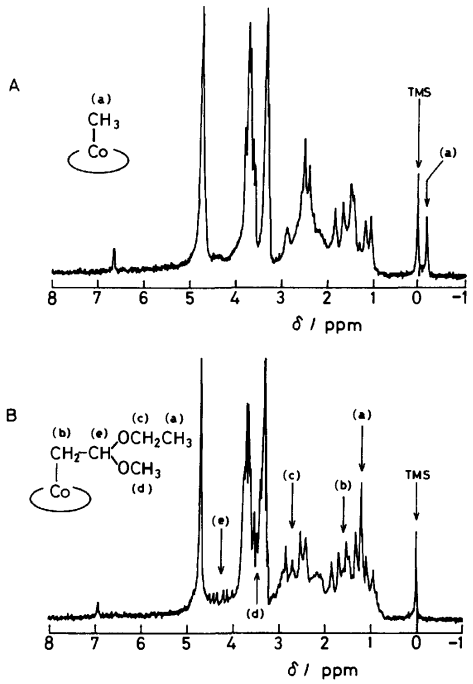

Fig. 5. ^{1}H-NMR (60 MHz) spectra of alkylated hydrophobic vitamin B_{12}'s in CD_3OD: A, $[(CH_3)(H_2O)$-$Cob(III)7C_1ester]ClO_4$; B, $[(CH_3)(H_2O)Cob(III)7C_1$-$ester]ClO_4$ (20 mg) in ethyl vinyl ether–methanol (1 : 1 v/v, 10 mL) being irradiated with a 500-W tungsten lamp from a distance of 30 cm for 3 h, allowed to stand in the dark for 24 h, and evaporated to dryness *in vacuo*.

Table 1. Pseudo-first-order rate constants for alkylation of hydrophobic vitamin B_{12}[a] at 21.5±0.1 °C under aerobic conditions in the dark

Entry	Medium (mL)			$k_{obsd} \times 10^5/s^{-1}$	k_{rel}[c]

a) $[(ROH)_2Cob(III)7C_1ester]^{2+}$ (R=H and/or CH_3), 5.0×10^{-5} mol dm^{-3}. b) Ethyl vinyl ether. c) Relative rate; k_{obsd} for entry 1 as a reference.

Reactions with [(CN)(H₂O)Cob(III)7C₁ester]ClO₄. When $[(CN)(H_2O)Cob(III)7C_1ester]ClO_4$ dissolved in a solution of ethyl vinyl ether and methanol was irradiated with the visible light under aerobic conditions and subsequently allowed to stand in the dark, the electronic spectrum did not undergo significant change; different from the spectral behavior of $[(CH_3)(H_2O)Cob(III)7C_1ester]ClO_4$ under comparable conditions. This does not mean, however, that the reaction does not take place. $[(CN)(H_2O)Cob$-$(III)7C_1ester]ClO_4$ shows no ESR signal in a solution of ethyl vinyl ether and methanol before irradiation (Fig. 6A), but characteristic signals due to the Co^{II} species[3a] were detected upon irradiation with the visible light under anaerobic conditions (Fig. 6B).

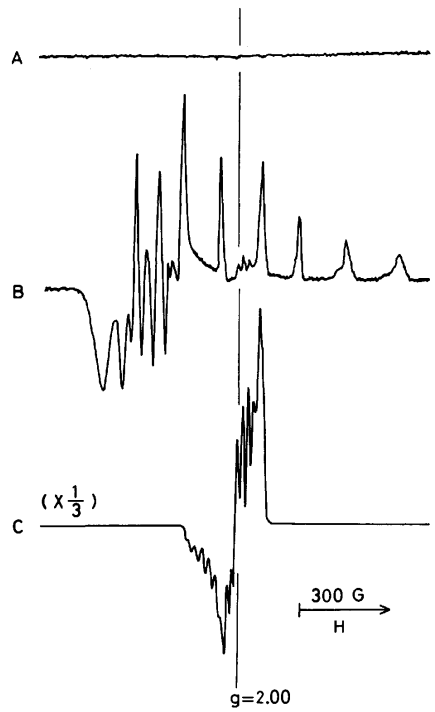

Fig. 6. ESR spectra for the following samples at 77 K: A, $[(CN)(H_2O)Cob(III)7C_1ester]ClO_4$ (2.7×10^{-3} mol dm^{-3}) in ethyl vinyl ether–methanol (3 : 1 v/v) in the dark under anaerobic conditions; B, sample A being irradiated with a 300-W tungsten lamp from a distance of 20 cm for 2 h at room temperature under anaerobic conditions; C, sample B being exposed to the open air.

Since such an ESR spectral change caused by the irradiation was insignificant for the cyanoaqua complex dissolved in diethyl ether and methanol under anaerobic conditions, a photosensitive alkylated complex was undoubtedly produced by the reaction of the complex with ethyl vinyl ether and methanol. Immediately after the reaction system was exposed to the open air, the ESR signals characteristic of the Co^{II} species were replaced with the ones due to the superoxo complex Co^{III}–O_2^-, the unpaired spin density being largely localized at the coordinated O_2^- group,[9] as shown in Fig. 6C. Since the superoxo complex was eventually converted into the original cyano complex[10] under irradiation conditions as confirmed by ESR and electronic spectroscopy, the Co^{II} species generated by the photolysis was readily oxidized to afford the Co^{III} species *via* formation of the superoxo complex under aerobic conditions.

The axial ligation constant (K) for [(CN)(H_2O)Cob(III)7C$_1$ester]ClO_4 with ethyl vinyl ether in dichloromethane was evaluated according to the method described previously;[3a] log K=−2. Even though the ligation constant was not evaluated because of its much smaller value in a polar medium used in the present reaction, such complex formation must take place so that the olefin is activated prior to the attack by methanol.

It is now clear that the alkylated complex is produced as the reaction intermediate in the course of the reaction with [(CN)(H_2O)Cob(III)7C$_1$ester]ClO_4 as the starting catalyst in a manner as observed for the reaction with [(CH_3)(H_2O)Cob(III)7C$_1$ester]ClO_4 (*vide supra*). In the light of the observation by electronic spectroscopy, the alkylated complex derived from [(CN)(ROH)Cob(III)7C$_1$ester]ClO_4 is decomposed by the trans effect provided by the axial cyano ligand much more readily than the one derived from [(ROH)$_2$Cob(III)7C$_1$ester]$^{2+}$.

When ethyl vinyl ether was used as an olefin, any oxygenation product was not detected by GLC. However, small amounts of cyclohexene oxide and 2-cyclohexen-1-ol (the total quantity, *ca.* 10 mole% of an amount of the alcohol adduct of cyclohexene produced) were obtained under the conditions described below by the reaction of cyclohexene with the superoxo complex. This result provides another evidence for the formation of the superoxo complex.

Catalytic Reactions and Turnover Behavior. The addition of an alcohol to ethyl vinyl ether took place by the catalysis of either [(ROH)$_2$Cob(III)-7C$_1$ester]$^{2+}$ or [(CN)(ROH)Cob(III)7C$_1$ester]$^+$ under aerobic irradiation conditions. Acetaldehyde ethyl methyl acetal and acetaldehyde diethyl acetal were the major products when methanol and ethanol were used, respectively. When a mixture of ethyl vinyl ether (1.9 g, 2.6×10^{-2} mol), ethanol (0.39 g, 8.6×10^{-3} mol), and [(CH_3)(H_2O)Cob(III)7C$_1$ester]ClO_4 (3.0 mg, 2.6×10^{-6} mol) was irradiated aerobically at 20±1 °C for 50 h with a 500-W tungsten lamp from a distance of 30 cm, acetaldehyde diethyl acetal was obtained in a yield, 10±2 times as much as the molar quantity of the hydrophobic vitamin B_{12} (refer to Eq. 1). In the

$$CH_2{=}CH{-}OC_2H_5 \xrightarrow[\substack{[(CH_3)(H_2O)Cob(III)7C_1ester]ClO_4 \\ \text{or} \\ [(CN)(H_2O)Cob(III)7C_1ester]ClO_4}]{C_2H_5OH,\ O_2,\ h\nu} CH_3{-}CH(OC_2H_5)_2 + CH_3CHO \quad (1)$$

course of the reaction, both alkylated and alkyl-free complexes, [((C$_2$H$_5$O)$_2$CHCH$_2$)(ROH)Cob(III)7C$_1$-ester]$^+$ and [(ROH)$_2$Cob(III)7C$_1$ester]$^{2+}$, respectively, were observed by means of electronic spectroscopy.

In the case that [(CN)(H_2O)Cob(III)7C$_1$ester]ClO_4 was used in place of the methylaqua complex otherwise under the same conditions, acetaldehyde diethyl acetal was obtained in a yield, 60±10 times as much as the molar quantity of the catalyst. This result indicates that the cyano complex is superior to the cyano-free complex as the catalyst for addition of an alcohol to the olefin. Time courses for the formation of acetaldehyde diethyl acetal as catalyzed by the former complex at 20±1 °C under aerobic conditions are shown in Fig. 7. The formation of the acetal was detected to a minor extent in the dark because the alkylated complex is thermally de-

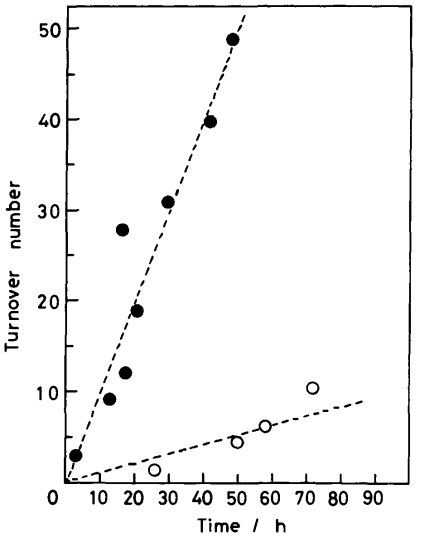

Fig. 7. Time courses for formation of acetaldehyde diethyl acetal as catalyzed by [(CN)(H_2O)Cob(III)-7C$_1$ester]ClO_4 under aerobic conditions at 20±1 °C. Composition of the initial reaction mixture: [(CN)-(H_2O)Cob(III)7C$_1$ester]ClO_4, 6.0 mg (5.1×10^{-6} mol); ethyl vinyl ether, 2.5 mL (1.9 g, 2.6×10^{-2} mol); ethanol, 0.50 mL (0.39 g, 8.6×10^{-3} mol). Turnover numbers for [(CN)(H_2O)Cob(III)7C$_1$ester]ClO_4 were calculated after correction for the blank reaction in the absence of the catalyst: ●, irradiated with a 500-W tungsten lamp from a distance of 10 cm; ○, in the dark.

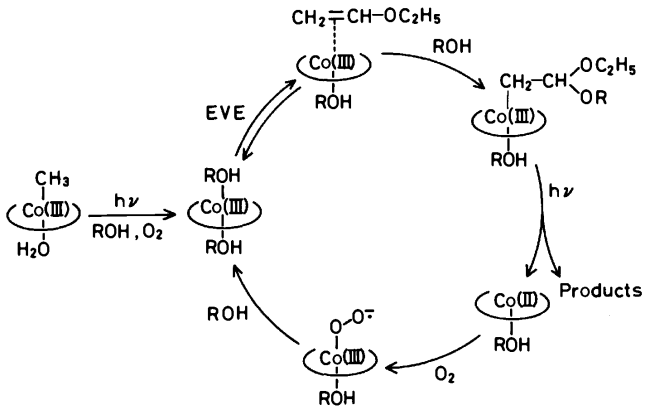
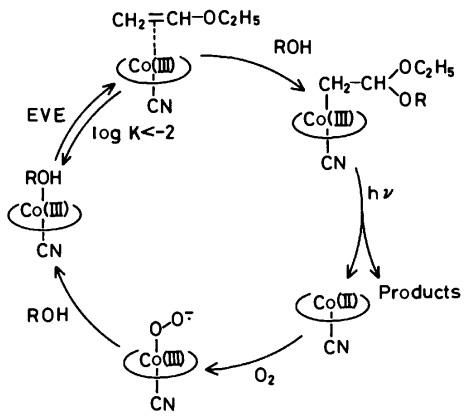
composed by the trans effect originated from the axial cyano ligand. The acetal products, obtained by the reactions with C_2D_5OD and C_2H_5OD as alcohol components, were identified by NMR spectroscopy. A mixture of [(CN)(H_2O)Cob(III)7C_1ester]ClO_4 (10 mg, 8.5×10^{-6} mol), ethyl vinyl ether (2.25 g, 3.1×10^{-2} mol), and a deuterated ethanol (C_2H_5OD or C_2D_5OD, 0.48 g) was irradiated for 200 h, and the products were recovered in a manner as described in the experimental section. The major products were $CH_2DCH(OC_2H_5)(OC_2D_5)$ and $CH_3CH(OC_2H_5)_2$ when C_2D_5OD and C_2H_5OD were used, respectively; splitting patterns of the CH signal at δ=4.7 being a triplet and a quartet, respectively. This clearly indicates that the hydrogen atom is abstracted from the ethyl group of ethanol.

Judging from the spectral measurements and the product analyses, the catalytic reactions with the use of [(CH_3)(H_2O)Cob(III)7C_1ester]ClO_4 and [(CN)(H_2O)-Cob(III)7C_1ester]ClO_4 plausibly proceed *via* reaction cycles shown in Schemes 1 and 2, respectively. When the former complex is used as the starting one for example, the complex is first converted into the methyl-free complex by the aerobic photolysis. Ethyl vinyl ether, which is activated upon complex formation with the methyl-free complex in the second place, is subjected to the nucleophilic attack of an alcohol to afford an alkylated complex as the intermediate. The alkylated complex is then decomposed by the visible light to give the Co^{II} species and an acetal. [$(ROH)_2$Cob(III)7C_1ester]$^{2+}$ is regenerated by autoxidation of the Co^{II} species *via* formation of the superoxo-Co^{III} complex under aerobic conditions (see Scheme 1). It needs to be noted that the present reaction sequence is apparently similar to that of the coenzyme B_{12}-dependent enzymatic reaction, in which an alkylated complex is repeatedly produced and a product is obtained upon homolytic cleavage of the cobalt-carbon bond.[11]

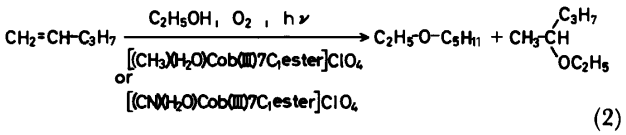


Scheme 1.



Scheme 2.

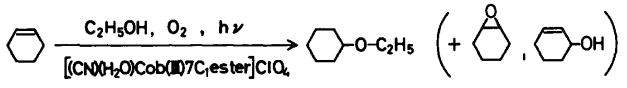
In order to make further clarification on the catalytic performance of the hydrophobic vitamin B_{12}, other olefins were also used in place of ethyl vinyl ether. Firstly, 1-pentene was used as a typical straight-chain olefin. The methyl-free Co^{III} complex, generated by the aerobic photolysis of [(CH_3)-(H_2O)Cob(III)7C_1ester]ClO_4 in 1-pentene and methanol, was transformed into the corresponding alkylated complex in the dark along with the spectral change similar to that shown in Fig. 2. However, the alkylation rate is extremely slow (*ca.* 1/50 of the rate with ethyl vinyl ether), while the alkylated complex is quite photo-labile and readily decomposed even under room light. When a mixture of 1-pentene (0.96 g, 1.4×10^{-2} mol), ethanol (1.2 g, 2.6×10^{-2} mol), and [(CN)(H_2O)Cob(III)7C_1ester]ClO_4 (3.9 mg, 3.3×10^{-6} mol) was irradiated at 20±1 °C for 150 h with a 500-W tungsten lamp from a distance of 10 cm under aerobic conditions, ethyl pentyl ether and ethyl 1-methylbutyl ether were obtained in the following yields; 15±5 and *ca.* 2 times, respectively, as much as the molar quantity of the hydrophobic vitamin B_{12} (refer to Eq. 2). Meanwhile, the reaction with



(2)

[(CH_3)(H_2O)Cob(III)7C_1ester]ClO_4 in place of the cyanoaqua complex otherwise under the same conditions afforded the former and latter ethers in the following respective yields; 3±1 and *ca.* 0.5 times as much as the molar quantity of the catalyst.

Secondly, cyclohexene was employed as a typical cyclic olefin. A mixture of cyclohexene (1.2 g, 1.5×10^{-2} mol), ethanol (1.2 g, 2.6×10^{-2} mol), and [(CN)(H_2O)Cob(III)7C_1ester]ClO_4 (9.7 mg, 8.2×10^{-6} mol) was irradiated at 20±1 °C for 150 h with a 500-W tungsten lamp from a distance of 10 cm under aerobic conditions, and cyclohexyl ethyl ether was obtained in a yield, 2±1 times as much as the molar quantity of the catalyst (refer to Eq. 3). The



(3)

extremely low reactivity of cyclohexene may be partly attributed to a significant steric hindrance between the olefin and the catalyst against the formation of the corresponding complex.

Thirdly, acrylonitrile was used as a typical electron-deficient olefin. $[(ROH)_2Cob(III)7C_1ester]^{2+}$ was slowly converted into $[Cob(II)7C_1ester]^+$ in acrylonitrile and methanol under aerobic conditions in the dark without forming the corresponding alkylated complex. When a mixture of acrylonitrile (2.0 g, 3.8×10^{-2} mol), ethanol (0.39 g, 8.6×10^{-3} mol), and $[(CN)(H_2O)Cob(III)7C_1ester]ClO_4$ (10 mg, 8.5×10^{-6} mol) was aerobically irradiated for 100 h under conditions identical with those described above, any ethanol adduct (*e.g.*, 3-ethoxypropionitrile or 2-ethoxypropionitrile) was not detected by GLC.

In conclusion, it became apparent that the hydrophobic vitamin B_{12} catalyzes the nucleophilic attack of an alcohol on an olefin under mild conditions, aerobic irradiation with the visible light at the room temperature range. As for the substrate selectivity, an electron-rich olefin is more reactive with the present catalysts than ordinary olefins. $[(ROH)_2Cob(III)7C_1ester]^{2+}$ is an appropriate catalyst for investigation of the reaction mechanism because the alkylated intermediate complex has a long lifetime enough for its identification in the dark. On the other hand, $[(CN)(ROH)Cob(III)7C_1ester]^+$ is superior to the cyano-free Co^{III} complex as the catalyst for the addition reaction due to the trans effect exercised by the axial cyano ligand for the cleavage of the cobalt-carbon bond.

Preparation of Michael Adducts of Isobutyraldehyde and Acetylenecarboxylic Esters *via* *N*-Isobutylidene-*t*-butylamine

Shingo MIYAJIMA* and Kunio ITO

Department of Applied Chemistry, Faculty of Engineering, Toyo University, Kawagoe, Saitama 350

(Received March 16, 1985)

N-Isobutylidene-*t*-butylamine reacted with methyl propiolate or dimethyl acetylenedicarboxylate to afford the Michael adducts predominantly. The adducts were converted to the corresponding formyl esters.

No Michael addition of isobutyraldehyde to acetylenecarboxylic esters has been reported, presumably because both the aldehyde and the acetylenes[1] undergo self-condensation in the presence of a strong base catalyst. The enamines derived from isobutyraldehyde react with electrophilic olefins to give 1,2- or 1,4-cycloaddition products,[2] which on hydrolytic ring opening yield Michael adducts. With acetylenecarboxylic esters, spontaneous rearrangement of initially formed cyclobutenes takes place and leads to dienamino esters.[3] Schiff's bases of α,α-disubstituted acetaldehydes are excellent complementary reagents to the enamines for the Michael addition to electrophilic olefins.[2a,4] With acetylenecarboxylic esters, however, only the formation of compounds resulting from *N*-alkenylation has been reported;[5] *N*-isobutylidenemethylamine, for example, reacts with two equivalents of dimethyl acetylenedicarboxylate to give a dihydropyridine derivative, a product of the reaction classified by Huisgen and Herbig[6] as a 1,4-dipolar cycloaddition.

We have investigated the reaction of *N*-isobutylidene-*t*-butylamine (**1**) with methyl propiolate (**2a**) or dimethyl acetylenedicarboxylate (**2b**) and found that the *t*-butyl group effectively prevents *N*-alkenylation, allowing the Michael addition to take place predominantly.

A solution of **2a** in tetrahydrofuran (THF) was gradually added to a stirred solution of **1** in THF heated at a bath temperature of 80 °C, and the heating was continued for an additional period of time. Fractional distillation afforded three isomeric products, the Michael adducts **3a** and **4a** and the enamino ester **5a**, in 45, 17, and 12% yields,

Fig. 3.

respectively (Fig. 1). These isomers were identified by their IR and ^{1}H NMR spectra and elemental analyses.

Reaction of **1** with **2b** was carried out in a similar manner. Distillation gave a mixture of the Michael adducts **3b** and **4b**, as judged by its ^{1}H NMR spectrum. When the mixture was heated at 160 °C for 2 h, isomerization took place and **3b** was obtained in 82% overall yield after distillation. The configuration of **3b** was further ascertained by its conversion to the maleic anhydride derivative **14**.

Apparently, the tautomeric enamine in equilibrium with the Schiff's base acts as a reacting species,[7] although the imino form is the only detectable form. The presumed pathways leading to the products are shown in Fig. 1.

The (*E*)-Michael adduct **3a**, on treatment with 1 M (1 M=1 mol dm^{-3}) HCl at room temperature, gave methyl (*E*)-4,4-dimethyl-5-oxo-2-pentenoate (**6**) in 94% yield.

The (*Z*)-adduct **4a**, on the other hand, was much less reactive under similar reaction conditions and both the imino and ester groups were slowly hydrolyzed to form the hydroxy lactone **9** (Fig. 2). Interestingly, when **4a** was stirred with water (50 times the weight of **4a**) at room temperature for 20 min, it went into solution and gave the carboxylate **10**. This rapid hydrolysis of the ester group of **4a** under such mild conditions can be explained in terms of intramolecular participation of the anion of the *gem*-diol in hydrolysis of **8**. The resulting hydroxy lactone **9**, which is in tautomeric equilibrium with the chain form,[8] combines with the initially liberated *t*-butylamine to afford **10**. Compound **9** was regenerated by acidification (85% yield based on **4a**).

When **9** was allowed to react with diazomethane, the (*Z*)-formyl ester **7** was obtained in 86% yield. Treatment of **9** with methanol containing H_2SO_4, on the other hand, gave the thermodynamically stabler[9] methoxy lactone **11** in a yield of 68%.

Similarly to **4a**, **3b** on treatment with water afforded the carboxylate **12**, which on acidification gave the hydroxy lactone **13** in 90% yield (Fig. 3). The formyl diester **15** was obtained by hydrolysis of **3b** with 1 M HCl in 79% yield. Alternatively, treatment of **13** with diazomethane gave a 92% yield of **15**. With methanol containing H_2SO_4 **13** yielded the methoxy lactone **16** (64%) along with a small amount of **15** (6%).

Experimental

Melting and boiling points are uncorrected. GLPC analyses were carried out with a Hitachi 163 instrument using an SE-30 or a PEG-20 M column. IR spectra were recorded on a Hitachi 285 or 260-50 spectrometer; absorptions are given in cm^{-1} in what follows. ^{1}H NMR data were obtained with a Hitachi R-24B spectrometer; chemical shifts are reported in δ relative to TMS or DSS and coupling constants (J) in Hz in what follows. Microanalyses were performed at the Microanalysis Laboratory, Department of Chemistry, Faculty of Science, the University of Tokyo. The Schiff's base **1** was prepared according to the procedure of Tiollais.[10] Compound **2a** was obtained by the method of Ingold[11] using commercial potassium hydrogen acetylenedicarboxylate as a starting material. **2b** of commercial grade was used without further purification. THF was dried with 4A Molecular Sieve.

Reaction of 1 with 2a. To a stirred solution of **1** (63.6 g, 0.500 mol) in THF (60 ml) heated at a bath temperature of 80 °C was added a solution of **2a** (46.2 g, 0.550 mol) in THF (50 ml) over a period of 1 h. Stirring and heating were continued for an additional 10 h. Removal of the solvent *in vacuo* and distillation of the residue gave an isomeric mixture of methyl (*E*)-(**3a**), methyl (*Z*)-5-(*t*-butylimino)-4,4-dimethyl-2-pentenoate (**4a**), and methyl 2-(*t*-butylaminomethylene)-4-methyl-3-pentenoate (**5a**) in a ratio of 61:23:16 (determined by GLPC): bp 56.0—92.0 °C/0.90 mmHg (1 mmHg=133.322 Pa); 87.9 g (83% based on **1**). Each isomer was isolated by redistillation through a 50 cm spinning band column; 47.5 g (45%) of **3a**, 18.0 g (17%) of **4a**, and 12.6 g (12%) of **5a** were obtained.

3a: bp 70.0—72.0 °C/0.90 mmHg; IR (neat) 1724 (C=O), 1670 (C=N), 1645 (C=C), and 977 ($^{H}\!>\!C\!=\!C\!<^{H}$); ^{1}H NMR ($CDCl_3$) 1.15 (s, 9H, $C(CH_3)_3$), 1.23 (s, 6H, $C(CH_3)_2$), 3.71 (s, 3H, CO_2CH_3), 5.76 (d, J=16, 1H, CH=C<u>H</u>CO_2Me), 7.00 (d, J=16, 1H, C<u>H</u>=CHCO_2Me), and 7.44 (s, 1H, CH=N). Found: C, 68.50; H, 10.18; N, 6.60%. Calcd for $C_{12}H_{21}NO_2$: C, 68.21; H, 10.02; N, 6.63%.

4a: bp 56.5—57.5 °C/0.90 mmHg; IR (neat) 1727 (C=O), 1663 (C=N), and 1637 (C=C); ^{1}H NMR ($CDCl_3$) 1.12 (s, 9H, $C(CH_3)_3$), 1.31 (s, 6H, $C(CH_3)_2$), 3.62 (s, 3H, CO_2CH_3), 5.77 (d, J=12, 1H, CH=C<u>H</u>CO_2Me), 6.28 (d, J=12, 1H, C<u>H</u>=CHCO_2Me), and 7.63 (s, 1H, CH=N). Found: C, 68.44; H, 9.78; N, 6.68%. Calcd for $C_{12}H_{21}NO_2$: C, 68.21; H, 10.02; N, 6.63%.

5a: bp 87.0—90.0 °C/0.90 mmHg; IR (neat) 3285 (NH), 1665 (C=O), and 1604 (C=C); ^{1}H NMR ($CDCl_3$) 1.28 (s, 9H, $C(CH_3)_3$), 1.68 (d, J=1.5, 3H, $C(CH_3)_2$), 1.76 (d, J=1.5, 3H, $C(CH_3)_2$), 3.63 (s, 3H, CO_2CH_3), 5.81 (m, 1H, C<u>H</u>=$C(CH_3)_2$), 6.76 (d, J=14, 1H, =C<u>H</u>NH), and 8.23 (br d, J=14, 1H, NH). Addition of CD_3OD containing a trace of HCl resulted in loss of the signal at 8.23 and collapse of the signal at 6.76 to a singlet. Found: C, 68.04; H, 10.15; N, 6.56%. Calcd for $C_{12}H_{21}NO_2$: C, 68.21; H, 10.02; N, 6.63%.

Reaction of 1 with 2b. To a stirred solution of **1** (127.2 g, 1.00 mol) in THF (260 ml) heated at a bath temperature of 70 °C was added a solution of **2b** (142.1 g, 1.00 mol) in THF (280 ml) during 1 h. Stirring and heating were continued for an additional 1 h. The solvent was removed *in vacuo* and the residue was distilled to give 222.7 g of the main fraction boiling at 107.0—111.0 °C (0.60 mmHg). GLPC on an SE-30 or a PEG-20 M column showed virtually a single peak. ^{1}H NMR analysis, however, indicated a mixture of the geometrical isomers, dimethyl [2-(*t*-butylimino)-1,1-dimethylethyl]maleate (**3b**) and dimethyl [2-(*t*-butylimino)-1,1-dimethylethyl]fumarate

(**4b**), in a ratio of *ca.* 70:30; besides the signals due to **3b**, which will be shown below, those attributable to **4b** were observed: 1.11 (s, 9H, $C(CH_3)_3$), 1.40 (s, 6H, $C(CH_3)_2$), 3.73 (s, 3H, CO_2CH_3), 3.81 (s, 3H, CO_2CH_3), 6.49 (s, 1H, C=CH), and 7.58 (s, 1H, CH=N).

The mixture was heated at 160 °C for 2 h and distillation gave 219.7 g (82% based on **1**) of **3b**: bp 88.5—89.0 °C/0.15 mmHg; IR (neat) 1732 (C=O), 1655 (C=N), and 1639 (C=C); ^{1}H NMR ($CDCl_3$) 1.16 (s, 9H, $C(CH_3)_3$), 1.30 (s, 6H, $C(CH_3)_2$), 3.73 (s, 3H, CO_2CH_3), 3.81 (s, 3H, CO_2CH_3), 5.86 (s, 1H, C=CH), and 7.51 (s, 1H, CH=N). Found: C, 62.34; H, 8.90; N, 5.05%. Calcd for $C_{14}H_{23}NO_4$: C, 62.43; H, 8.61; N, 5.20%.

Methyl (E)-4,4-Dimethyl-5-oxo-2-pentenoate (6). A mixture of **3a** (30.0 g, 0.142 mol) and 1 M HCl (220 ml) was stirred for 1 h at room temperature. The reaction mixture was extracted with ether (3×150 ml). The ethereal extract was washed with aq $NaHCO_3$, dried (Na_2SO_4), concentrated, and distilled, giving 20.9 g (94%) of **6**: bp 64.5—65.0 °C/0.75 mmHg; IR (neat) 1725 (C=O), 1650 (C=C), and 982 ($H>C=C<H$); ^{1}H NMR ($CDCl_3$) 1.26 (s, 6H, $C(CH_3)_2$), 3.71 (s, 3H, CO_2CH_3), 5.88 (d, J=16, 1H, CH=C<u>H</u>CO_2Me), 6.91 (d, J=16, 1H, C<u>H</u>=CHCO_2Me), and 9.41 (s, 1H, CHO). Found: C, 61.46; H, 7.90%. Calcd for $C_8H_{12}O_3$: C, 61.52; H, 7.74%. 2,4-Dinitrophenylhydrazone, mp 124.0—124.4 °C (from methanol). Found: C, 50.18; H, 4.64; N, 16.83%. Calcd for $C_{14}H_{16}N_4O_6$: C, 50.00; H, 4.80; N, 16.66%.

6-Hydroxy-5,5-dimethyl-5,6-dihydro-2H-pyran-2-one (9). The (*Z*)-imino ester **4a** (12.7 g, 0.0601 mol) was stirred with water (640 ml) at room temperature. After 20 min, it went into solution. The solution was washed with ether (100 ml) and concentrated with a rotary evaporator below 55 °C *in vacuo* until some crystals began to separate out. To the residue, 4 M HCl (18 ml) was added, and the resulting solution was extracted with ether (3×50 ml). The ethereal extract was dried (Na_2SO_4) and evaporated, leaving 7.22 g (85%) of **9**[12] as a crystalline solid, mp 62.0—64.0 °C. A sample was recrystallized from ether–hexane for analysis: mp 65.0—65.8 °C; IR (KBr) 3270 (OH) and 1670 (C=O); ^{1}H NMR ($CDCl_3$) 1.17 (s, 6H, $C(CH_3)_2$), 5.38 (d, J=1, 1H, CH), 5.81 (br s, 1H, OH, caused to disappear by adding D_2O), 5.88 (d, J=9.5, 1H, CH=C<u>H</u>CO), and 6.59 (dd, J=9.5, 1, 1H, C<u>H</u>=CHCO). (Found: C, 59.29; H, 7.38%)

t-Butylammonium (Z)-4,4-Dimethyl-5-oxo-2-pentenoate (10). A mixture of **4a** (18.5 mg) and D_2O (0.93 ml) was shaken at room temperature for 20 min. The ^{1}H NMR spectrum of the resulting solution was identical with that of **10** prepared as follows.

t-Butylamine (0.397 g, 5.43 mmol) was added dropwise to a solution of **9** (0.712 g, 5.01 mmol) in water (1.0 ml). The reaction mixture was cooled, and the precipitated crystals were collected and dried with KOH pellets *in vacuo* (0.785 g, 73%): mp 111.5—113.0 °C; IR (KBr) 3000—2800 ($\overset{+}{N}H_3$), 1726 (C=O), 1637 (C=C), 1540 ($\overset{+}{N}H_3$), and 1416 (COO^-); ^{1}H NMR (D_2O) 1.20 (s, 6H, $C(CH_3)_2$), 1.34 (s, 9H, $C(CH_3)_3$), 5.82 (d, J=12, 1H, CH=C<u>H</u>COO^-), 5.85 (d, J=12, 1H, C<u>H</u>=CHCOO^-), and 9.23 (s, 1H, CHO). Found: C, 61.51; H, 9.83; N, 6.49%. Calcd for $C_{11}H_{21}NO_3$: C, 61.37; H, 9.83; N, 6.51%.

Acid-catalyzed Hydrolysis of 4a. To 86.5 mg (0.409 mmol) of **4a** was added 0.60 ml of 1 M HCl in D_2O. The ^{1}H NMR spectrum of the resulting iminium salt showed signals at 1.46 (s, 9H, $C(CH_3)_3$), 1.55 (s, 6H, $C(CH_3)_2$), 3.76 (s, 3H, CO_2CH_3), 6.12 (d, J=12, 1H, CH=C<u>H</u>CO_2Me), 6.57 (d, J=12, 1H, C<u>H</u>=CHCO_2Me), and 8.72 (s, 1H, CH=$\overset{+}{N}$H). With the salt kept standing at room temperature for 1 d, the peak areas of the CO_2CH_3 protons and the CH=$\overset{+}{N}$H proton decreased to 25 and 24% of their initial areas, respectively, relative to the total area of the olefinic protons. After 2 d, the spectrum indicated the completion of reaction, *i.e.*, an approximately equimolar mixture of **9**, CH_3OD, and *t*-butylammonium chloride.

Methyl (Z)-4,4-Dimethyl-5-oxo-2-pentenoate (7). Diazomethane was fed into a stirred solution of **9** (5.80 g, 40.8 mmol) in ether (100 ml) with N_2 as a carrier gas until a yellow color persisted for several min. An air condenser was attached and the solution was refluxed to remove the excess of diazomethane. Evaporation and distillation gave 5.45 g (86%) of **7**:[12] bp 49.0—49.3 °C/0.80 mmHg; IR (neat) 1722 (C=O) and 1637 (C=C); ^{1}H NMR ($CDCl_3$) 1.30 (s, 6H, $C(CH_3)_2$), 3.67 (s, 3H, CO_2CH_3), 5.93 (d, J=12, 1H, CH=C<u>H</u>CO_2Me), 6.18 (d, J=12, 1H, C<u>H</u>=CHCO_2Me), and 9.46 (s, 1H, CHO). (Found: C, 61.32; H, 7.97%) 2,4-Dinitrophenylhydrazone, mp 119.8—120.2 °C (from methanol). Found: C, 50.16; H, 4.65; N, 16.53%. Calcd for $C_{14}H_{16}N_4O_6$: C, 50.00; H, 4.80; N, 16.66%.

6-Methoxy-5,5-dimethyl-5,6-dihydro-2H-pyran-2-one (11). A solution of **9** (2.00 g, 14.1 mmol) in methanol (40 ml) containing concd H_2SO_4 (0.078 g) was allowed to stand at room temperature for 3 h. The solution was poured into satd aq NaCl (120 ml) and the mixture was extracted with ether (3×60 ml). The ethereal extract was dried (Na_2SO_4), concentrated, and distilled to afford 1.49 g (68%) of **11**: bp 71.0—72.0 °C/1.0 mmHg; IR (neat) 1723 (C=O); ^{1}H NMR ($CDCl_3$) 1.11 (s, 3H, CCH_3), 1.18 (s, 3H, CCH_3), 3.54 (s, 3H, CO_2CH_3), 4.85 (d, J=1, 1H, CH), 5.86 (d, J=9.5, 1H, CH=C<u>H</u>CO), and 6.53 (dd, J=9.5, 1, 1H, C<u>H</u>=CHCO). Found: C, 61.28; H, 7.88%. Calcd for $C_8H_{12}O_3$: C, 61.52; H, 7.74%.

Methyl (Z)-5-Hydroxy-4,4-dimethyl-2-oxotetrahydrofuran-$\Delta^{3,\alpha}$-acetate (13). A mixture of **3b** (80.8 g, 0.300 mol) and water (4000 ml) was stirred at room temperature for 2.5 h. The resulting solution was washed with ether (2×400 ml) and concentrated on a rotary evaporator below 55 °C *in vacuo* until some crystals began to separate out. To the residue was added 80 ml of 4 M HCl, and the resulting solution was extracted with ether (3×150 ml). The ethereal extract was dried (Na_2SO_4) and evaporated, leaving 54.3 g (90%) of **13** as a crystalline solid; mp 71.0—75.0 °C. A sample was recrystallized from ether–hexane for analysis: mp 77.1—77.5 °C; IR (KBr) 3295 (OH), 1775, 1710 (C=O), and 1670 (C=C); ^{1}H NMR ($CDCl_3$) 1.25 (s, 6H, $C(CH_3)_2$), 3.82 (s, 3H, CO_2CH_3), 5.60 (s, 1H, CH), 5.72 (br s, 1H, OH, caused to disappear by adding D_2O), and 6.25 (s, 1H, C=CH). Found: C, 54.24; H, 6.26%. Calcd for $C_9H_{12}O_5$: C, 54.00; H, 6.04%.

t-Butylammonium (Z)-2-(1,1-Dimethyl-2-oxoethyl)-3-methoxycarbonylacrylate (12). A mixture of **3b** (28.0 mg) and D_2O (1.40 ml) was stirred at room temperature for 2.5 h. The ^{1}H NMR spectrum of the resulting solution was identical with that of **12** prepared as follows.

To a suspension of **13** (0.807 g, 4.03 mmol) in water (1.0 ml) warmed to 50 °C was added *t*-butylamine (0.298 g,

4.07 mmol). The resulting solution was cooled, and the precipitated crystals were collected and dried with KOH pellets *in vacuo* (0.548 g, 50%): mp 113.5—114.5 °C; IR (KBr) 3000—2800 ($\overset{+}{N}H_3$), 1720 (C=O), 1634 (C=C), 1540 ($\overset{+}{N}H_3$), and 1400 (COO^-); ^{1}H NMR (D_2O) 1.25 (s, 6H, $C(CH_3)_2$), 1.36 (s, 9H, $C(CH_3)_3$), 3.70 (s, 3H, CO_2CH_3), 5.69 (s, 1H, C=CH), and 9.33 (s, 1H, CHO). Found: C, 57.29; H, 8.77; N, 5.07%. Calcd for $C_{13}H_{23}NO_5$: C, 57.13; H, 8.48; N, 5.12%.

(1,1-Dimethyl-2-oxoethyl)maleic Anhydride (14). Compound **13** (40.0 g, 0.200 mol) was heated at 140 °C for 2 h under reduced pressure (20 mmHg). Distillation afforded 32.7 g (97%) of **14**: bp 103.0—106.0 °C/0.25 mmHg; mp 31.0—31.9 °C; IR (KBr) 1835, 1766, 1716 (C=O), and 1628 (C=C); ^{1}H NMR ($CDCl_3$) 1.51 (s, 6H, $C(CH_3)_2$), 6.76 (s, 1H, C=CH), and 9.50 (s, 1H, CHO). Found: C, 57.21; H, 4.78%. Calcd for $C_8H_8O_4$: C, 57.14; H, 4.80%.

Dimethyl (1,1-Dimethyl-2-oxoethyl)maleate (15).

Acidcatalyzed Hydrolysis of 3b: A mixture of **3b** (40.0 g, 0.149 mol) and 1 M HCl (300 ml) was stirred at room temperature for 10 min. Ether (200 ml) was added and stirring was continued for an additional 2 h. The ether layer was separated and the aq layer was extracted with ether (3×150 ml). The combined extracts were washed with a small amount of water, dried (Na_2SO_4), concentrated, and distilled, giving 25.0 g (79%) of **15**: bp 100.0—101.0 °C/0.50 mmHg; IR (neat) 1735, 1725 (C=O), and 1641 (C=C); ^{1}H NMR ($CDCl_3$) 1.28 (s, 6H, $C(CH_3)_2$), 3.70 (s, 3H, CO_2CH_3), 3.79 (s, 3H, CO_2CH_3), 5.91 (s, 1H, C=CH), and 9.38 (s, 1H, CHO). Found: C, 56.08; H, 6.88%. Calcd for $C_{10}H_{14}O_5$: C, 56.07; H, 6.59%. 2,4-Dinitrophenylhydrazone, mp 145.9—146.1 °C (from methanol). Found: C, 48.71; H, 4.47; N, 14.31%. Calcd for $C_{16}H_{18}N_4O_8$: C, 48.73; H, 4.60; N, 14.21%.

Formyl Diester 15 from 13: Treatment of **13** (16.0 g, 79.9 mmol) in ether (200 ml) with diazomethane and working up in the same manner as employed in the preparation of **7** yielded 15.8 g (92%) of a material boiling at 102.0—103.5 °C (0.65 mmHg), whose IR and ^{1}H NMR spectra were identical with those of **15** prepared as described above.

Methyl (Z)-5-Methoxy-4,4-dimethyl-2-oxotetrahydrofuran-$\Delta^{3,\alpha}$-acetate (16). A solution of **13** (3.01 g, 15.0 mmol) in methanol (60 ml) containing concd H_2SO_4 (0.11 g) was allowed to stand at room temperature for 4 h. The solution was poured into 180 ml of satd aq NaCl and the mixture was extracted with ether (2×90 ml). The ethereal extract was dried (Na_2SO_4), concentrated, and distilled with a 15 cm concentric column, giving 0.20 g (6%) of **15** (bp 99.0—101.5 °C/0.50 mmHg) and 2.05 g (64%) of **16** (bp 109.0—110.0 °C/0.50 mmHg, mp 68.0—69.6 °C). A sample of **16** was recrystallized from hexane-CCl_4 for analysis: mp 70.6—71.3 °C; IR (KBr) 1761, 1728 (C=O), and 1672 (C=C); ^{1}H NMR (CCl_4) 1.19 (s, 3H, CCH_3), 1.22 (s, 3H, CCH_3), 3.48 (s, 3H, OCH_3), 3.73 (s, 3H, CO_2CH_3), 4.95 (s, 1H, CH), and 6.08 (s, 1H, C=CH). Found: C, 56.02; H, 6.68%. Calcd for $C_{10}H_{14}O_5$: C, 56.07; H, 6.59%.

The authors thank Messrs. Hirofumi Yasuda and Kazuhiro Tatsuo for their experimental assistance.

Decompositions of Tropone Tosylhydrazone Sodium Salt in the Presence of Cyclopentadienone Derivatives. [4+2]-Type Cycloaddition Reactions of Cycloheptatrienylidene or 1,2,4,6-Cycloheptatetraene with Cyclopentadienone Derivatives

Katsuhiro SAITO* and Hiraku ISHIHARA
Department of Chemistry, Nagoya Institute of Technology, Gokiso-cho, Showa-ku, Nagoya 466
(Received April 19, 1985)

Tropone tosylhydrazone sodium salt, the precursor of the cyclic conjugated carbene (cycloheptatrienylidene), was decomposed in the presence of various cyclopentadienone derivatives to give endo- and exo-[4+2]-type adducts and benzotropylidene derivatives. The product ratios between the endo-[4+2]-type adducts and the exo-[4+2]-type adducts are considered to suggest that these addition reactions proceed *via* a cyclic conjugated allene (1,2,4,6-cycloheptatetraene), which is a valence-bond isomer of cycloheptatrienylidene. Upon heating, the [4+2]-type adducts gave the benzotropylidene derivatives *via* decarbonylation reactions followed by 1,5-hydrogen shifts.

Recently, medium-sized ring-conjugated allenes are attracting the attention of chemists from the viewpoint of the addition reactions and the molecular rearrangements of the allenes.[1] Allenes are twisted molecules with rectlinear three-carbon atoms. Consequently, medium-sized ring allenes are considered to have a considerable amount of strain energy. It is known that three-membered ring-cyclic carbenes, cyclopropylidenes, rearrange to allenes *via* ring-opening processes.[2]

Cycloheptatrienylidene (**2**), which is generated by the thermolysis of a tropone tosylhydrazone sodium salt (**1**) (accompanied by nitrogen gas and sodium *p*-toluenesulfinate (**3**)), is known to be a nucleophilic singlet carbene because of a contribution of the 6 π-electrons aromatic structure (**2b**).[3] Actually, **2**, preferentially reacts with electron-deficient double bonds,[3c] and adds to maleonitrile and fumalonitrile with stereospecificity.[3d]

Recently, a possibility of an isomerization of the carbene (2) and a medium-sized ring-conjugated allene, 1,2,4,6-cycloheptatetraene (4), was pointed out and a number of reports have been published concerning this isomerization.[3,4]

As a part of our research on the reactivity of **2**,[3f] we studied addition reactions of **2** with various cyclopentadienone derivatives and obtained a result which suggests that **2** is rearranged to 4. Here we wish to report on this result.

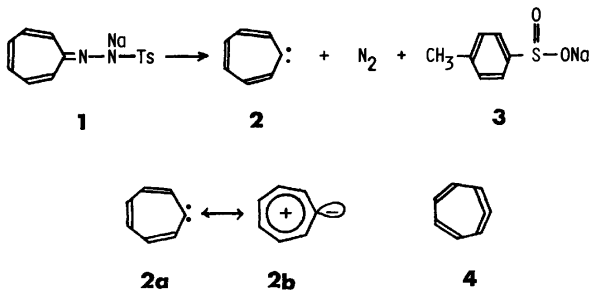

Fig. 1.

Results and Discussion

When tropone tosylhydrazone sodium salt (**1**) was allowed to decompose in anhydrous diglyme at 95 °C for 3 h in the presence of 2 mole equivalents of 2,5-dimethyl-3,4-diphenylcyclopentadienone (**5**), an endo-[4+2]-type adduct (**6**), exo-[4+2]-type adduct (**7**), and a benzotropylidene derivative (**8**) were afforded in 16, 2, and 9% yields, respectively. Under similar conditions, **1** was allowed to decompose in the presence of tetracyclone (**9**) to give an exo-[4+2]-type adduct (**10**) and two kinds of benzotropylidene derivatives (**11** and **12**)[3c] in 8, 6, and 10% yields, respectively. The same type of reaction of **1** with phencyclone (**13**) afforded an endo-[4+2]-type adduct (**14**) in a 17% yield. The analogous reaction of **1** with a cyclopentadienone derivative (**15**) gave a benzo-tropylidene derivative (**16**) in a 24% yield.

The endo- and exo-[4+2]-type adducts (**6** and **7**) gave the benzotropylidene derivative (**8**) in 79 and 80% yields upon heating at 105 °C for 180 h and 120 h, respectively. No interconversion between **6** and **7** was observed. The two kinds of benzotropylidene derivatives **11** and **12** were afforded by pyrolysis of exo-[4+2]-type adduct (**10**) at 100 °C for 80 h in 17 and 69% yields, respectively. On the other hand, upon heating at 100 °C for 2h, endo-[4+2]-type adduct (**14**) rearranged in a 80% yield to exo-[4+2]-type adduct (**17**), which gave a benzotropylidene derivative (**18**) in a 85% yield upon heating at 150 °C for 100 h. Considering this thermal isomerization of **14** to **17**, it seems not to be unreasonable to think that the exo-[4+2]-type adduct (**10**) is afforded by a thermal isomerization of the initially formed endo-[4+2]-type adduct, which corresponds to the endo-[4+2]-type adduct **6**.

The structures of the products were determined on

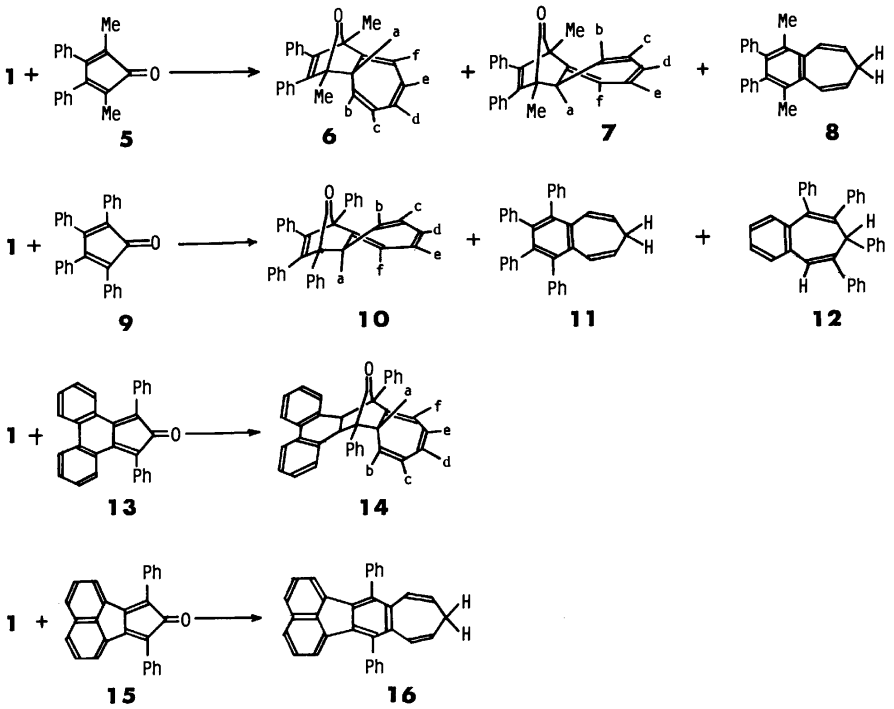

Fig. 2.

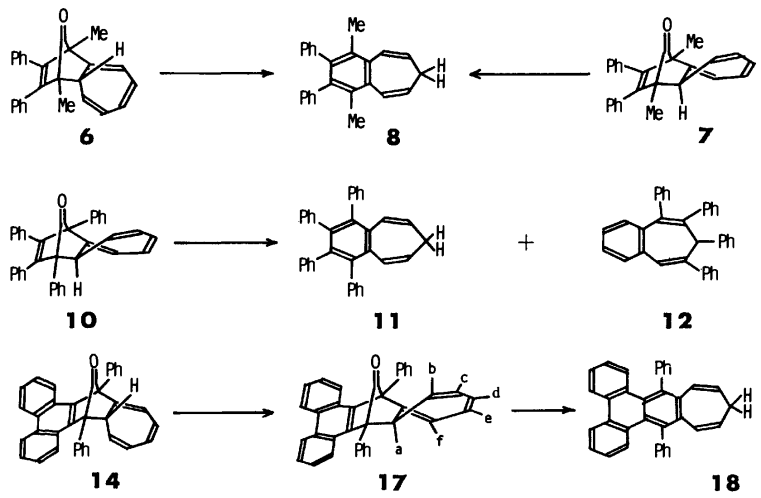

Fig. 3.

Table. NMR Data of the [4+2]-type adducts

Adducts		Chemical shifts (δ, ppm) in $CDCl_3$						Coupling constants (Hz)	
		H_a (d)	H_b (dd)	H_c (m)	H_d, H_e, H_f (m)	Me (s)	Ph (m)	J_{ab}	J_{ac}
Endo	6	3.12	4.91		6.1—6.7 (4H)	1.30, 1.48	7.0—7.5 (10H)	4	10
	14	4.35	4.73	5.70	6.3—6.7 (3H)		7.0—8.7 (18H)	4	10
	20[3f)]	3.68	4.75	5.85	6.1—6.5 (3H)		7.0—7.8 (14H)	4	10
Exo	7	2.30	5.21		6.2—6.9 (4H)		7.0—7.5 (10H)	4	10
	10	2.63	5.12		6.2—6.8 (4H)		7.0—7.8 (20H)	4	10
	17	2.30	5.43		6.2—6.9 (4H)		7.0—8.7 (18H)	4	10
	21[3f)]	2.60	5.15	6.05	6.3—6.7 (3H)		7.0—7.8 (14H)	4	10
	22[3f)]	2.46	4.63	5.86	6.2—6.5 (3H)		7.0—7.5 (8H)	4	10

the basis of their physical properties and confirmed by comparisons of these properties to those of the analogous compounds, such as **19**, **20**, and **21**.[3f,5,6] The stereochemistries of the endo- and exo-[4+2]-type adducts were determined by comparisons of the chemical shifts of the methine protons (H_a) of the adducts to those of the corresponding methine protons (H_a) of the endo-compound (**19**), exo-compound (**20**), and the compound **21**, whose methine proton corresponds to the methine proton of the exo-[4+2]-type adducts. The NMR signal of the methine proton (H_a) of **14** appears at a low field (4.35 ppm) compairing to that of **6** (3.12 ppm) because of a paramagnetic anisotropic effect of the phenyl group attached to the carbon atom adjacent to the carbon atom bearing the methine proton (H_a). The benzo-tropylidene derivatives **11** and **12** are compounds from the literature.[3e]

The formation mechanism of the [4+2]-type adducts (**6**, **7**, **10**, and **14**) via the carbene, cycloheptatrienylidene (**2**), requires a multistep reaction through the tropylium cation intermediate (**22**) (Path A). According to the Dreiding model there is no obvious difference between the steric repulsions in the formations of the endo-[4+2]-type adducts (**6** and **14**) and the exo-[4+2]-type adducts (**7** and **10**) from the corresponding intermediates (**22**). The fairly large difference between the yields of the endo-[4+2]-type adduct (**6**, 16%) and the exo-[4+2]-type adduct (**7**, 2%), and the preferential formation of the endo-[4+2]-type adduct (**14**, 17%) would suggest that the reaction does not proceed via the intermediate (**22**).[7]

The major formation of the endo-[4+2]-type adducts, which contain no less strain energies than those of the exo-[4+2]-type adducts suggests the contribution of a stabilization effect of a secondary orbital interaction in the transition state of Diels-Alder type addition reaction *via* the allene, 1,2,4,6-cycloheptatetraene (**4**) (Path B).[8] Cyclopentadienone derivatives are well known to be reactive enophiles in Diels-Alder type addition reactions.[5d,9] Oda has reported that a cyclic conjugated allene derivative reacted with an enophile, diphenylisobenzofuran, to give endo- and exo-[4+2]-type adducts in a yield ratio of 5:1, though without defining the stereochemistry of the adducts.[10]

As mentioned above, it is hard to conclude whether cycloheptatrienylidene (**2**) or 1,2,4,6-cycloheptatetraene (**4**) is involved in the reactions, but the allene mechanism (Path B), which indicates the isomerization of **2** to **4** seems to be plausible.

The benzotropylidene derivative (**8**, **11**, **16**, and **18**) are considered to be formed by the thermally allowed 1,5-hydrogen shift[7] of the intermediate (**23**), which is afforded by a decarbonylation reactions of the corresponding [4+2]-type adducts (**6**, **7**, **10**, and **17**).

Experimental

All the melting points are uncorrected. Mass, UV, and IR spectra were measured with the Hitachi M-52, Hitachi 220A, and DS 701 G spectrometers, respectively. NMR spectra were measured with a Hitachi R-20B or a Varian XL 200 spectrometers with tetramethylsilane as an internal standard. Wako gel C-200 and Wako gel B-5F were used for column and thin-layer chromatography, respectively. Diglyme was dried over Molecular Sieves 3A 1/16.

Reaction of 1 with 5. A mixture of **1** (23.84 g, 80 mmol), dimer of **5** (41.60 g, 160 mmol), and anhydrous diglyme (400 ml) was heated at 95 °C for 3 h. After evolution of nitrogen gas had ceased (1800 ml, *ca.* 100%), the gray powder of **3** (14.30 g, *ca.* 100%) was removed by filtration. The filtrate was extracted with ether, washed with water and brine, and dried over anhydrous sodium sulfate. After filtration, the solvent was removed on a rotary evaporator to give a mixture of crystals and an oil, which was chromatographed on silica gel to yield colorless crystals of **8** (2.45 g, 9%) by pet ether–benzene 9:1, colorless crystals of **6** (4.50 g, 16%) by pet ether–benzene 8:2, a colorless oil of **7** (0.64 g, 2%) by pet ether–benzene 7:3, and crystals of recovered dimer of **5** (3.91 g) by pet ether–benzene 3:7. The crystals of **6** and **8** were purified by

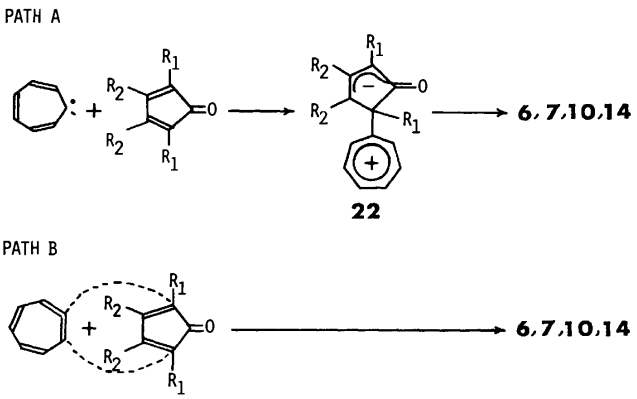

Fig. 5.

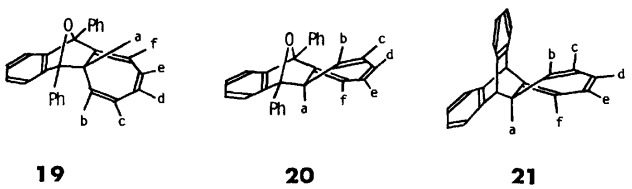

Fig. 4.

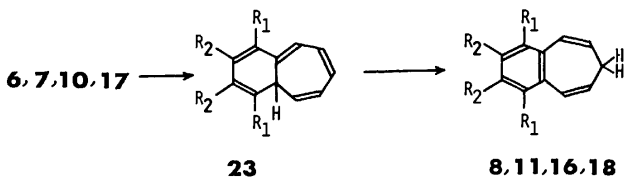

Fig. 6.

recrystallization from benzene and ethanol, respectively, and the oil of **7** was purified by thin-layer chromatography on silica gel using pet ether-benzene 9:1 as a developing solvent (R_f=0.61). **6**: Mp; 158—159 °C. Found: C, 89.37; H, 6.55%. Calcd for $C_{26}H_{22}O$: C, 89.11; H, 6.33%. Mass *m/z* (rel intensity): 350 (M^+, 4), 323 (50), 308 (100), 246 (10). UV (EtOH): 260 nm (log ε, 4.27). IR (KBr): 3030, 1780, 1600 cm^{-1}. **7**: Found: C, 88.08; H, 6.25%. Calcd for $C_{26}H_{22}O$: C, 89.11; H, 6.33%. Mass *m/z* (rel intensity): 350 (M^+, 11), 307 (100), 229 (11), 215 (6). UV (EtOH): 257 nm (log ε, 4.24). IR (neat): 3030, 1780, 1600 cm^{-1}. **8**: Mp 223—224 °C. Found: C, 92.90; H, 6.73%. Calcd for $C_{25}H_{22}$: C, 93.12; H, 6.88%. Mass *m/z* (rel intensity): 322 (M^+, 28), 321 (100), 308 (52), 293 (9). UV (EtOH): 253 nm (log ε, 4.36). IR (KBr): 3030, 1600 cm^{-1}. NMR ($CDCl_3$) δ (ppm)=2.12 (s, 6H), 2.32 (t, 2H, *J*=7 Hz), 6.02 (m, 2H), 6.51 (m, 2H), 7.0—7.5 (m, 10H).

Reaction of 1 with 9. A mixture of **1** (23.84 g, 80 mmol), **9** (51.52 g, 160 mmol) and anhydrous diglyme (400 ml) was heated at 95 °C for 3 h to evolve nitrogen gas (1800 ml, *ca.* 100%). After separation of the gray powder of **3** (14.30 g, *ca.* 100%) by filtration, the filtrate was treated as usual to give a mixture of crystals and an oil. The crystals of recovered **9** (37.11 g) were separated by filtration, and the filtrate was chromatographed on silica gel to yield colorless crystals of **12** (3.46 g, 10%), **11** (1.97 g, 6%), and **10** (2.34 g, 8%), in this order by pet ether-benzene 8:2. The crystals of **10** were further purified by recrystallization from benzene. **10**: Mp 190—191 °C. Found: C, 90.92; H, 5.41%. Calcd for $C_{36}H_{26}O$: C, 91.11; H, 5.52%. Mass *m/z* (rel intensity): 446 (M^+, 100), 369 (20), 291 (21). UV (EtOH): 253 nm (log ε, 4.18). IR (KBr): 3030, 1790, 1600 cm^{-1}.

Reaction of 1 with 13. A mixture of **1** (8.88 g, 30 mmol), **13**, (22.92 g, 60 mmol) and anhydrous diglyme (150 ml) was heated at 95 °C for 2 h to evolve nitrogen gas (600 ml, 90%). After separation of the gray powder of **3** (4.65 g, 87%) by filtration, the filtrate was treated as usual to yield a mixture of crystals and an oil. The crystals of recovered **13** (19.56 g) were separated by filtration and the filtrate was chromatographed on silica gel to give colorless crystals of **14** (2.41 g, 17%) by pet ether-benzene 5:5. The crystals of **14** were further purified by recrystallization from ethyl acetate. **14**: Mp 216—217 °C. Found: C, 91.21; H, 5.06%. Calcd for $C_{36}H_{24}O$: C, 91.27; H, 5.25%. Mass *m/z* (rel intensity): 472 (M^+, 20), 444 (100), 377 (25), 353 (15). UV (EtOH): 257 nm (log ε, 4.57). IR (KBr): 3030, 1785, 1600 cm^{-1}.

Reaction of 1 with 15. A mixture of **1** (8.88 g, 30 mmol), **15** (21.26 g, 60 mmol) and anhydrous diglyme (150 ml) was heated at 95 °C for 2 h to evolve nitrogen gas (650 ml, 97%). After separation of the gray powder of **3** (5.07 g, 95%) by filtration, the filtrate was treated as usual to give a mixture of crystals and an oil. The crystals of recovered **15** (19.89 g) were separated by filtration and the filtrate was chromatographed on silica gel to yield colorless crystals of **16** (1.57 g, 24%) by pet ether-benzene 1:1. Recrystallization from ethyl acetate gave pure crystals of **16**. **16**: Mp 254—256 °C. Found: C, 94.37; H, 5.03%. Calcd for $C_{33}H_{22}$: C, 94.70; H, 5.30%. Mass *m/z* (rel intensity): 418 (M^+, 100), 341 (22), 326 (18). UV (EtOH): 247 nm (log ε, 4.28). IR (KBr): 3030, 1600 cm^{-1}. NMR ($CDCl_3$) δ (ppm)=2.40(t, 2H, *J*=7 Hz), 5.81 (m, 2H), 6.43 (m, 2H), 7.1—7.9 (m, 16H).

Thermal Reaction of 6 to Form 8. A solution of **6** (760 mg) in toluene (7.5 ml) was heated at 105 °C for 180 h. After evaporation of the solvent on a rotary evaporator, the residue was thin-layer chromatographed on silica gel using pet ether-benzene 8:2 as a developing solvent to give colorless crystals of **8** (550 mg, 79%, R_f=0.78).

Thermal Reaction of 7 to Form 8. A solution of **7** (50 mg) in toluene (1 ml) was heated at 105 °C for 120 h. After evaporation of the solvent, the residue was thin-layer chromatographed on silica gel using pet ether-benzene 8:2 as a developing solvent to give a colorless crystals of **8** (40 mg, 80%).

Thermal Reaction of 10 to Form 11 and 12. A solution of **10** (128 mg) in toluene (3 ml) was heated at 100 °C for 80 h. After evaporation of the solvent, the residue was thin-layer chromatographed on silica gel using pet ether-benzene 8:2 as a developing solvent to give colorless crystals of **12** (90 mg, 69%, R_f=0.81) and colorless crystals of **11** (27 mg, 17%, R_f=0.68).

Thermal Isomerization of 14 to 17. A solution of **14** (40 mg) in deuteriochloroform (0.5 ml) was heated at 100 °C for 2 h in a sealed ampoul. After evaporation of the solvent, the residue was thin-layer chromatographed on silica gel using pet ether-benzene 7:3 as a developing solvent to give a colorless oil of **17** (32 mg, 80%, R_f=0.53). In spite of repeated purification by thin-layer chromatography on silica gel, the analytically pure sample of **17** could not be obtained. **17**: Mass *m/z* (rel intensity): 472 (M^+, 21), 444 (100), 377 (33), 353 (33). UV (EtOH): 254 nm (log ε, 4.50). IR (neat): 3030, 1790, 1605 cm^{-1}.

Thermal Reaction of 17 to Form 18. A solution of **17** (200 mg) in chloroform (5 ml) was heated at 150 °C for 100 h in a sealed ampoul. After evaporation of the solvent, the residue was thin-layer chromatographed on silica gel using pet ether-benzene 1:1 as a developing solvent to give a colorless oil of **18** (170 mg, 85%, R_f=0.83). **18**: Found: C, 94.38; H, 5.43%. Calcd for $C_{35}H_{24}$: C, 94.56; H, 5.44%. Mass *m/z* (rel intensity): 444 (M^+, 100), 367 (46), 352 (18). UV (EtOH): 293 nm (log ε, 4.05). IR (neat): 3030, 1600 cm^{-1}. NMR ($CDCl_3$) δ (ppm)=2.41 (t, 2H, *J*=7 Hz), 5.73 (m, 2H), 6.42 (m, 2H), 7.0—7.9 (m, 18H).

The authors are indebted to Professor Toshio Mukai of Tohoku University for his fruitfull suggestions.

Hydroxylation of Aliphatic Compounds with *m*-Chloroperbenzoic Acid. Synthesis of Hydroxylated Vitamin K_1 Analogues

Motoo Tori, Masakazu Sono, and Yoshinori Asakawa*
Faculty of Pharmaceutical Sciences, Tokushima Bunri University, Yamashiro-cho, Tokushima 770
(Received April 30, 1985)

Pristane and 1,5,9,13-tetramethyltetradecyl acetate were treated with *m*-chloroperbenzoic acid in chloroform under reflux to afford hydroxylated derivatives, respectively. The products, 13- and 9-hydroxy-1,5,9,13-tetramethyltetradecyl acetates, were converted to hydroxylated vitamin K_1 analogues *via* the corresponding hydroxyphytols.

We have been studying the biotransformation of terpenoids in rabbits.[1] Compounds administered to mammals are often hydroxylated prior to excretion, a process which is related to detoxification.[2] We are interested in *in vitro* reactions which simulate this biological phenomenon. In 1979 Müller and Schneider reported that alicyclic compounds could be hydroxylated using *m*-chloroperbenzoic acid (*m*-CPBA).[3] Recently we have applied this reaction to dammarane,[4] lupane,[5] and friedelane[5] triterpenoids and have demonstrated the formation of tertiary and secondary alcohols. As a continuation of this work we have investigated the reactions of pristane and phytane derivatives with *m*CPBA and have applied the products of the reaction to the synthesis of vitamin K analogues.

Pristane (**1**) was treated with *m*CPBA in refluxing chloroform for 22 h, after which work-up and chromatography over silica-gel afforded two monohydric tertiary alcohols. ^{1}H NMR spectroscopy indicated that whilst the less polar alcohol, **2** (43% yield[6])[7] [IR 3350 cm^{-1}, δ=72.8 (s)] possessed only one tertiary methyl group [δ=1.15 (3H, s)], the more polar product, **3** (36% yield[6]) [IR 3350 cm^{-1}, δ=71.1 (s)][8] contained a 1-hydroxy-1-methylethyl group [δ=1.21 (6H, s)]. These observations led to structures **2** and **3**, 2,6,10,14-tetramethyl-6-pentadecanol (**2**) and 2,6,10,14-tetramethyl-2-pentadecanol (**3**), respectively. Further support for these structures was furnished by mass spectroscopy. The major peaks in the mass spectrum of **2** occurred at *m/z* 199 and 129 and resulted from bond fission α to the hydroxyl group (Fig. 1). An analogous fragmentation gave rise to the predominant ion with *m/z* 59 in the spectrum of **3**. As the tertiary alcohols are formed in relatively good yield, we examined the reactions of phytane derivatives with *m*CPBA.

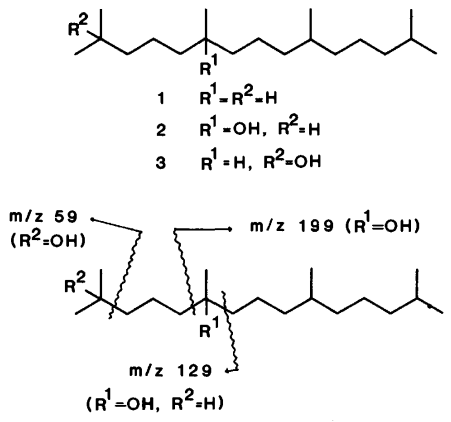

Fig. 1.

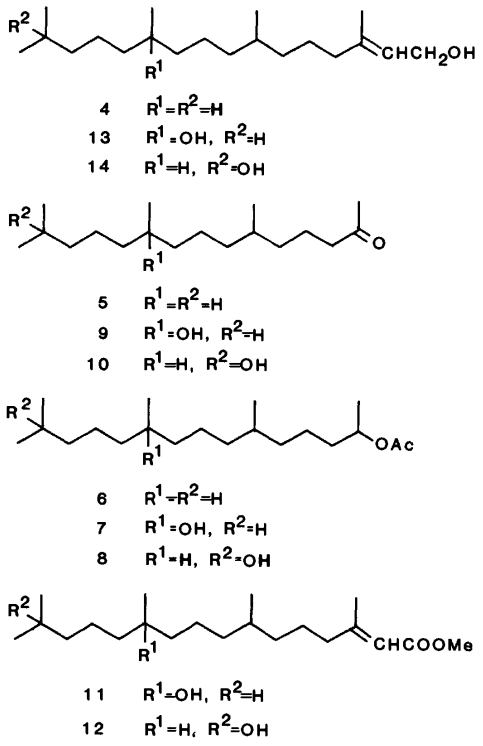
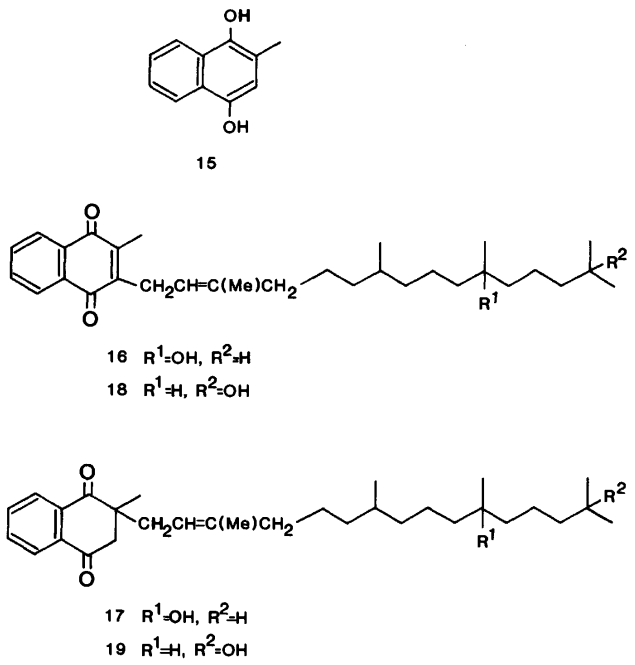
Since *m*CPBA reacts with the double bond of phytol (**4**), it was first of all necessary to protect the olefin. However, a simple protecting group was unavailable and we therefore planned to remove the allylic alcohol by ozonolysis; regeneration would be effected by a Wittig reaction at a later stage. The resulting ketone should be more readily protected.

Ozonolysis of phytol (**4**) in methanol at −18 °C followed by zinc/acetic acid reduction gave 6,10,14-trimethyl-2-pentadecanone (**5**)[8,9] in 91% yield after chromatographic purification over silica-gel. When the ethylene acetal of **5** was treated with *m*CPBA in $CHCl_3$ under reflux, many spots on TLC were observed due to the lability of the acetal to the acid formed in the reaction mixture. Therefore, the ketone **5** was reduced by $NaBH_4$ in MeOH followed by acetylation to **6**.[7] The acetate (**6**)[7] was then treated with *m*CPBA in $CHCl_3$ under reflux for 24 h to afford two hydroxylated derivatives after column chromatography over silica-gel. The spectral data of the less polar product (**7**)[7] [IR 3430, 1730, and 1240 cm^{-1}; *m/z* 243; δ=1.15 (3H, s), 1.20 (3H, d, *J*=6.4 Hz), 2.02 (3H, s), and 4.89 (1H, m)] indicated that **7** was 9-hydroxy-1,5,9,13-tetramethyltetradecyl acetate and those of the more polar product (**8**)[7] [IR 3420, 1730, and 1240 cm^{-1}; *m/z* 59; δ=1.21 (6H, s), 2.03 (3H, s), and 4.89 (1H, m)] suggested that **8** was 13-hydroxy-1,5,9,13-tetramethyltetradecyl acetate. The fact that 5-position was not hydroxylated is presumably due to the electrophilic nature of the reagent as described by Deno and Messer.[10] The hydroxy acetates, **7** and **8**, were hydrolyzed by methanolic KOH followed by Jones oxidation to give the corresponding hydroxy ketones, **9**[7] [IR 3450 and 1715 cm^{-1}; *m/z* 199; δ=1.16 (3H, s) and 2.13 (3H, s)] and **10** [IR 3430 and 1715 cm^{-1}; *m/z* 59; δ=1.21 (6H, s) and 2.14 (3H, s)], respectively. The ketone **9** was





allowed to react with the anion prepared from methyl dimethoxyphosphorylacetate with sodium hydride in dry 1,2-dimethoxyethane at rt to yield methyl 11-hydroxy-3,7,11,15-tetramethyl-2-hexadecenoate (**11**)[7] [IR 3410, 1720, and 1645 cm^{-1}; *m/z* 322 $(M-18)^+$; δ=5.66 (bs)] in 49% yield after chromatographic purification. Methyl 15-hydroxy-3,7,11,15-tetramethyl-2-hexadecenoate (**12**) [IR 3400, 1715, and 1645 cm^{-1}; *m/z* 322 $(M-18)^+$ and 59; δ=5.67 (bs)] was prepared in the same manner in 64% yield. Although analysis by GC showed that **11** and **12** were *ca.* 1:1 mixtures of the geometric isomers, further separation was not attempted. Reduction of the methyl esters, **11** and **12**, using $LiAlH_4$ in dry ether gave the desired hydroxylated phytol derivatives, **13**[7] [IR 3310 cm^{-1}; *m/z* 294 $(M-18)^+$; δ=5.40 (m)] and **14** [IR 3330 cm^{-1}; *m/z* 294 $(M-18)^+$ and 59; δ=5.40 (m)], respectively. The structures were fully characterized by IR, NMR, and mass spectra.

The chemistry of vitamin K has been studied extensively[11] and synthesis[11] and biological studies[12] of its derivatives are still undertaken. Several works[12] on the preparation and estimation of hydroxylated vitamin K_1 derivatives have been reported, although the compounds are less active than vitamin K_1 itself. As a demonstration of the synthetic utility of the compounds obtained here, we next carried out the reaction of 2-methyl-1,4-naphthalenediol with the hydroxyphytols.

A mixture of the diol **13** and 2-methyl-1,4-naphthalenediol (**15**) in dioxane was treated with $KHSO_4$ at 40—50 °C for 4 h followed by Ag_2O oxidation. After the usual work-up, the residue was separated by prep TLC (AcOEt–PhH 1:4) to afford the desired 11′-hydroxyvitamin K_1 (**16**)[7] [IR 3580—3250, 1650, and 1610 cm^{-1}; *m/z* 466 (M^+); δ=5.00 (m)] in 17% yield in addition to the by-product, 2-methyl-2-(11-hydroxy-3,7,11,15-tetramethyl-2-hexadecenyl)-2,3-dihydro-1,4-naphthoquinone (**17**)[7] [IR 3580—3310 cm^{-1}; *m/z* 453 $(M-15)^+$; δ=5.03 (m)] in 18% yield. The diol (**14**) was next subjected to a condensation reaction with **15** and oxidation (Ag_2O) in the same manner to yield 15′-hydroxyvitamin K_1 (**18**) [IR 3580—3280 cm^{-1}; *m/z* 466 (M^+), 225 (base peak), and 59; δ=5.00 (m)] in 19% yield and 2-methyl-2-(15-hydroxy-3,7,11,15-tetramethyl-2-hexadecenyl)-2,3-dihydro-1,4-naphthoquinone (**19**) [IR 3580—3300 cm^{-1}; *m/z* 468 (M^+), 174 (base peak), and 59; δ=5.04 (m)] in 20% yield. The structures are consistent with the spectral data. In these reactions dehydration of the newly attached hydroxyl groups was not observed.

In conclusion, we have carried out the hydroxylation of the aliphatic compounds, pristane (**1**) and 1,5,9,13-tetramethyltetradecyl acetate (**6**) using *m*CPBA. In both cases hydroxylation occurred at the tertiary positions. Furthermore we have applied the products to the synthesis of vitamin K analogues. Although the biological activity of these analogues is still undetermined, the methodology may be applicable to other classes of natural products.

Experimental

General Procedures. Infrared (IR) spectra were recorded on a Shimadzu IR-408 infrared spectrometer.

Mass spectra were measured using a Shimadzu LKB-9000B, JEOL D-300, or JEOL HX-100 mass spectrometer operating at 70 eV. GC/MS was operated using PEG-20M (15%) or OV-17 (5%) columns (2 m each) with increasing temperature program (from 80 °C—220 °C, rate: 5 °C/min). ^{1}H and ^{13}C NMR spectra were measured in $CDCl_3$ using a JEOL JNM GX-400 (400 MHz for ^{1}H and 100 MHz for ^{13}C) spectrometer. High performance liquid chromatography (HPLC) analysis was determined on a JASCO liquid chromatograph model TRI ROTAR-V. Analytical and preparative thin layer chromatographies (TLC) were carried out on Kieselgel $60F_{254}$ 0.25 mm and 0.5 mm, respectively. Column chromatography was carried out on Kieselgel 60 (70—230 mesh, Merck).

Reactions of each substrate with *m*-chloroperbenzoic acid (*m*CPBA) were performed by addition of *m*CPBA (1—2 equiv) into a solution of the substrate in chloroform (*ca.* 35 mg/mL) and heating under reflux for 20—30 h. Successive washing of the reaction mixture with aq Na_2SO_3, aq $NaHCO_3$, and brine and evaporation of solvents after drying with $MgSO_4$ gave a residue.

Reaction of Pristane (1) with m*CPBA.* Pristane (**1**; 1.0 g) was treated with *m*CPBA (964 mg) in $CHCl_3$ (30 ml) under reflux for 22 h to afford a residue (1.3 g) after work-up. The residue was subjected to column chromatography on silica gel (120 g). Elution with 20% hexane–AcOEt gave 2,6,10,14-tetramethyl-6-pentadecanol (**2**) (289 mg) as an oil: Found: *m/z* 269.2844. Calcd for $C_{18}H_{37}O$: M 269.2844; IR (film) 3350 cm^{-1}; ^{1}H NMR δ=0.86 (3H, d, J=6.6 Hz), 0.87 (6H, d, J=6.6 Hz), 0.88 (6H, d, J=6.8 Hz), and 1.15 (3H, s); MS *m/z* 269 $(M-15)^+$, 199, 129, 111, 69, and 43; ^{13}C NMR δ=19.7 (q), 21.3 (t), 21.7 (t), 22.6 (3×q), 22.7 (q), 24.8 (t), 27.0 (q), 27.9 (d), 28.0 (d), 32.7 (d), 37.3 (t), 37.7 (t), 39.3 (t), 39.6 (t), 42.1 (t), 42.2 (t), and 72.8 (s); and 2,6,10,14-tetramethyl-2-pentadecanol (**3**)[8] (240 mg) as an oil: IR (film) 3350 cm^{-1}; ^{1}H NMR δ=0.85 (3H, d, J=6.3 Hz), 0.86 (3H, d, J=6.4 Hz), 0.87 (6H, d, J=6.6 Hz), and 1.21 (6H, s); MS *m/z* 269 $(M-15)^+$ and 59; ^{13}C NMR δ=19.7 (q), 19.7 (q), 21.8 (t), 22.6 (q), 22.7 (q), 24.5 (t), 24.8 (t), 28.0 (d), 29.2 (2×q), 32.8 (2×d), 37.3 (t), 37.4 (2×t), 37.6 (t), 39.4 (t) 44.3 (t), and 71.1 (s).

Preparation of 6,10,14-Trimethyl-2-pentadecanone (5). Ozone was bubbled through a solution of phytol (**4**; 679 mg) in MeOH (20 mL) at −18 °C for 20 min. Acetic acid (5 mL) was added and the solution was treated with Zn (*ca.* 10 mg) to afford 6,10,14-trimethyl-2-pentadecanone (**5**; 563 mg).[8,9]

Acetalization of 6,10,14-Trimethyl-2-pentadecanone (5). A mixture of the ketone (**5**; 184 mg), ethylene glycol (110 mg), *p*-toluenesulfonic acid (25 mg), and benzene (30 mL) was heated using a Dean-Stark water separator for 5 h yielding the ethylene acetal (55 mg) after work up and prep TLC: ^{1}H NMR δ=0.83—0.87 (m), 1.32 (s), 1.57 (s), and 3.94, (m); MS *m/z* 297 $(M-15)^+$, 87, and 43.

Preparation of 1,5,9,13-Tetramethyltetradecyl Acetate (6). A solution of the ketone (**5**; 2.1 g) in MeOH (10 mL) was treated with $NaBH_4$ (390 mg) at rt for 12 h to afford 6,10,14-trimethyl-2-pentadecanol, which was directly treated with Ac_2O in Py yielding 1,5,9,13-tetramethyltetradecyl acetate (**6**; 2 g) as an oil after usual work-up: Found: *m/z* 252.2787 $(M-CH_3COOH)^+$. Calcd for $C_{18}H_{36}$: M 252.2815; IR (film) 1730 and 1240 cm^{-1}; ^{1}H NMR δ=0.84 (6H, d, J=6.6 Hz), 0.87 (6H, d, J=6.6 Hz), 1.20 (3H, d, J=6.3 Hz), 2.03 (3H, s), and 4.89 (1H, m); MS *m/z* 252 $(M-CH_3COOH)^+$, 126, and 97.

Reaction of 1,5,9,13-Tetramethyltetradecyl Acetate (6) with m*CPBA.* A mixture of the acetate (**6**; 3.2 g), *m*CPBA (2.8 g), and $CHCl_3$ (90 mL) was heated under reflux for 24 h. Work-up and column chromatography (elution with hexane–AcOEt) gave 9-hydroxy-1,5,9,13-tetramethyltetradecyl acetate (**7**; 280 mg): oil; Found: *m/z* 310.2873 $(M-H_2O)^+$. Calcd for $C_{20}H_{38}O_2$: M 310.2872; IR (film) 3430, 1730, and 1240 cm^{-1}; ^{1}H NMR δ=0.86 (3H, d, J=6.6 Hz), 0.88 (6H, d, J=6.8 Hz), 1.15 (3H, s), and 1.20 (3H, d, J=6.4 Hz); MS *m/z* 268 $(M-CH_3COOH)^+$, 253, 243, 129, 69, and 43: and 13-hydroxy-1,5,9,13-tetramethyltetradecyl acetate (**8**) (350 mg): oil; Found: *m/z* 313.2790 $(M-CH_3)^+$. Calcd for $C_{19}H_{37}O_3$: M 313.2743; IR (film) 3420, 1730, and 1240 cm^{-1}; ^{1}H NMR δ=0.85 (3H, d, J=6.4 Hz), 0.86 (3H, d, J=6.6 Hz), 1.21 (6H, s), 2.03 (3H, s), and 4.89 (1H, m); MS *m/z* 253, 210, 59, and 43.

Preparation of 10-Hydroxy-6,10,14-trimethyl-2-pentadecanone (9). 9-Hydroxy-1,5,9,13-tetramethyltetradecyl acetate (**7**; 170 mg) was treated with 5% KOH–MeOH at rt for 12 h to yield 10-hydroxy-6,10,14-trimethyl-2-pentadecanol (148 mg), which was oxidized with Jones reagent (4 drops) to 10-hydroxy-6,10,14-trimethyl-2-pentadecanone (**9**; 105 mg) after purification by column chromatography on silica gel (15 g): oil; Found: *m/z* 302.3016 $(M+NH_4)^+$. Calcd for $C_{18}H_{40}O_2N$: M 302.3059; IR (film) 3450 and 1715 cm^{-1}; ^{1}H NMR δ=0.87 (3H, d, J=6.6 Hz), 0.88 (6H, d, J=6.6 Hz), 1.16 (3H, s), 2.13 (3H, s), and 2.41 (2H, t, J=7.6 Hz); MS *m/z* 269 $(M-CH_3)^+$, 199, 181, 69, and 43. ^{13}C NMR δ=19.3 (q), 21.1 (t), 21.2 (t), 21.5 (t), 22.5 (2×q), 26.8 (q), 27.7 (d), 29.6 (q), 32.4 (d), 36.2 (t), 37.3 (t), 39.4 (t), 41.9 (2×t), 43.9 (t), 72.5 (s), and 209.1 (s).

Preparation of 14-Hydroxy-6,10,14-trimethyl-2-pentadecanone (10). 13-Hydroxy-1,5,9,13-tetramethyltetradecyl acetate (**8**; 215 mg) was hydrolyzed and oxidized successively as before to afford 14-hydroxy-6,10,14-trimethyl-2-pentadecanone (**10**; 100 mg) as an oil: Found: *m/z* 302.3010 $(M+NH_4)^+$. Calcd for $C_{18}H_{40}O_2N$: M 302.3059; IR (film) 3430 and 1715 cm^{-1}; ^{1}H NMR δ=0.86 (6H, d, J=6.6 Hz), 1.21 (6H, s), 2.14 (3H, s), and 2.41 (2H, t, J=7.6 Hz); MS *m/z* 269 $(M-CH_3)^+$, 59, and 43; ^{13}C NMR δ=19.5 (q), 19.7 (q), 21.4 (t), 21.7 (t), 24.3 (t), 29.2 (2×q), 29.8 (q), 32.6 (d), 32.7 (d), 36.4 (t), 37.1 (t), 37.3 (t), 37.5 (t), 44.1 (t), 44.2 (t), 71.0 (s), and 209.4 (s).

Preparation of Methyl 11-Hydroxy-3,7,11,15-tetramethyl-2-hexadecenoate (11). To a stirred mixture of sodium hydride (58 mg) and methyl dimethoxyphosphorylacetate (143 mg) in dry DME (3 mL) was added a solution of 10-hydroxy-6,10,14-trimethyl-2-pentadecanone (**9**; 105 mg) in dry DME (2 mL) at rt under an Ar atmosphere. The reaction mixture was stirred overnight. Work-up as usual and column chromatography afforded recovered **9** (30 mg) and methyl 11-hydroxy-3,7,11,15-tetramethyl-2-hexadecenoate (**11**; 62 mg): oil; Found: *m/z* 327.2866 $(M-H_2O)^+$. Calcd for $C_{21}H_{38}O_2$; M 322.2871; IR (film) 3410, 1720, and 1645 cm^{-1}; ^{1}H NMR δ=0.86—0.89 (9H, m), 1.15 (3H, s), 1.88 (d, J=1.2 Hz), 2.15 (d, J=1.2 Hz), 3.67 (s), 3.68 (s), and 5.66 (bs); MS *m/z* 322 $(M-H_2O)^+$, 223, 114, and 69.

Preparation of Methyl 15-Hydroxy-3,7,11,15-tetramethyl-2-hexadecenoate (12). 14-Hydroxy-6,10,14-trimethyl-2-

pentadecanone (**10**; 101 mg) was reacted with the phosphonate reagent as before to afford the starting **10** (34 mg) and methyl 15-hydroxy-3,7,11,15-tetramethyl-2-hexadecenoate (**12**; 77 mg): oil; Found: *m/z* 322.2864 $(M-H_2O)^+$. Calcd for $C_{21}H_{38}O_2$: M 322.2870; IR (film) 3400, 1715, and 1645 cm^{-1}; ^1H NMR δ=0.85—0.89 (6H, m), 1.21 (6H, s), 1.88 (d, *J*=1.2 Hz), 2.15 (d, *J*=1.2 Hz), 3.67 (s), 3.68 (s), and 5.67 (bs); MS *m/z* 332, 293, 114, and 59.

*Preparation of 3,7,11,15-Tetramethyl-2-hexadecene-1,11-diol (**13**).* To a stirred solution of methyl 11-hydroxy-3,7,11,15-tetramethyl-2-hexadecenoate (**11**; 26 mg) in dry Et_2O (2 mL) was added $LiAlH_4$ (*ca.* 10 mg) at rt. After 2 h, the reaction mixture was worked up as usual to afford 3,7,11,15-tetramethyl-2-hexadecene-1,11-diol (**13**; 23 mg): oil; Found: *m/z* 330.3362 $(M+NH_4)^+$. Calcd for $C_{20}H_{44}O_2N$: M 330.3372; IR (film) 3310 cm^{-1}; ^1H NMR δ=0.84—0.89 (9H, m), 1.15 (3H, s), 1.66 (s), 1.73 (s), 1.97—2.06 (m), 4.11—4.15 (m), and 5.40 (m); MS *m/z* 294 $(M-H_2O)^+$, 276, 209, 191, 69, 55, and 43.

*Preparation of 3,7,11,15-Tetramethyl-2-hexadecene-1,15-diol (**14**).* Methyl 15-hydroxy-3,7,11,15-tetramethyl-2-hexadecenoate (**12**; 17 mg) was reduced with $LiAlH_4$ (*ca.* 10 mg) in dry Et_2O (2 mL) as before to give 3,7,11,15-tetramethyl-2-hexadecene-1,15-diol (**14**; 16 mg): oil; Found: *m/z* 330.3373 $(M+NH_4)^+$ (CI-MS). Calcd for $C_{20}H_{44}O_2N$: M 330.3372; IR (film) 3330 cm^{-1}; ^1H NMR δ=0.84—0.89 (m), 1.21 (s), 1.66 (s), 1.73 (s), 1.99 (m), 4.13 (m), and 5.40 (m); MS *m/z* 294 $(M-H_2O)^+$, 276, 191, 69, and 59.

*Preparation of 11′-Hydroxyvitamin K_1 (**16**).* A mixture of 3,7,11,15-tetramethyl-2-hexadecene-1,11-diol (**13**; 11 mg), 2-methyl-1,4-naphthalenediol (64 mg), $KHSO_4$ (42 mg), and dioxane (0.3 mL) was heated at 40—50 °C under Ar for 4 h and worked up as usual. After stirring with Ag_2O in dry Et_2O at rt, prep TLC afforded 11′-hydroxyvitamin K_1 (**16**; 3 mg): oil; Found: *m/z* 466.3400. Calcd for $C_{31}H_{46}O_3$: M 466.3445; IR ($CHCl_3$) 3580—3250, 1650, 1610, 1590, and 1455 cm^{-1}; ^1H NMR δ=0.82—0.90 (m), 1.14 (s), 1.16 (s), 2.19 (s), 3.37 (d, *J*=6.9 Hz), 5.00 (m), 7.68—7.70 (m), and 8.07—8.09 (m); MS *m/z* 466 (M^+), 448, 225, 69, 55, and 43: ^{13}C NMR δ=185.5 (s), 184.6 (s), and 72.9 (s): and 2-methyl-2-(11-hydroxy-3,7,11,15-tetramethyl-2-hexadecenyl)-2,3-dihydro-1,4-naphthoquinone (**17**; 3 mg): oil; Found: *m/z* 453.3356 $(M-CH_3)^+$. Calcd for $C_{30}H_{45}O_3$: M 453.3366; IR ($CHCl_3$) 3580—3310, 1690, 1590, and 1455 cm^{-1}, ^1H NMR δ=0.82—0.88 (m), 1.15 (s), 1.16 (s), 1.29 (s), 1.48 (s), 1.87—1.89 (m), 2.28—2.45 (m), 2.82—3.05 (m), 5.03 (m), 7.71—7.76 (m), and 8.00—8.09 (m); MS *m/z* 453 $(M-CH_3)^+$, 451, 383, 174, 69, 55, and 43.

*Preparation of 15′-Hydroxyvitamin K_1 (**18**).* 3,7,11,15-Tetramethyl-2-haxadecene-1,15-diol (**14**; 11 mg) was allowed to react with 2-methyl-1,4-naphthalenediol (63 mg) in dioxane (0.5 mL) using $KHSO_4$ (26 mg) as before to give 15′-hydroxyvitamin K_1 (**18**; 3 mg): oil; Found: *m/z* 466.3452. Calcd for $C_{31}H_{46}O_3$: M 466.3447; IR ($CHCl_3$) 3580—3280, 1650, 1610, 1590, and 1455 cm^{-1}; ^1H NMR δ=0.81—0.88 (m), 1.21 (s), 1.68 (s), 1.77 (s), 2.19 (s), 3.37 (d, *J*=6.8 Hz), 5.00 (m), and 7.68—7.70 (m); MS *m/z* 466 (M^+), 448, 433, 408, 225, 59, and 43; ^{13}C NMR δ=185.5 (s), 184.6 (s), and 71.1 (s): and 2-methyl-2-(15-hydroxy-3,7,11,15-tetramethyl-2-hexadecenyl)-2,3-dihydro-1,4-naphthoquinone (**19**; 4 mg): oil; Found: *m/z* 453.3379 $(M-CH_3)^+$. Calcd for $C_{30}H_{45}O_3$: M 453.3369; IR ($CHCl_3$) 3580—3300, 1690, 1590, 1455, and 1370 cm^{-1}; ^1H NMR δ=0.81—0.87 (m), 1.21 (s), 1.29 (s), 1.48 (s), 1.88 (m), 2.29—2.45 (m), 2.82—3.04 (m), 5.04 (m), 7.72—7.74 (m), and 8.02—8.08 (m); MS *m/z* 468 (M^+), 453, 451, 174, 69, 59, and 43.

We thank Dr. Hiroshi Hirota, The University of Tokyo, for measuring the high resolution mass spectra and Dr. Leslie J. Harrison for reading the manuscript prior to submission. This work is supported in part by a Grant-in-Aid for Cancer Research from the Ministry of Health and Welfare.

(Received April 16, 1985)

Three new quassinoids and four new quassinoid glycosides were isolated from water-soluble fraction of methanol extract of seeds of *Brucea javanica* (L.) MERR, known as "Ya-dan-zi" in Chinese folklore and their structures were determined by spectral and chemical means. Yadanziosides F, I, J, and L were demonstrated to have antileukemic activity.

Quassinoids, bitter principles of Simaroubaceous plants have been extensively investigated from the interest in antileukemic activity and structure determination,[3] and some of them have been shown to exhibit useful biological activities.[4] In connection with our studies on bitter principles of *Picrasma ailanthoides* PLANCHON and *Ailanthus altissima* SWINGLE,[5] constituents of seeds of *Brucea javanica* (L.) MERR were examined and several new bitter principles were reported.[1,2] Seeds of *B. javanica* are known as "Ya-dan-zi" in Chinese folklore and have been used as a Chinese medicine for cancer. The main active compounds of the plant have been extensively investigated by Polonsky,[6] Geissman,[7] and Lee.[8] We examined minor components in the polar fraction. This paper deals with isolation and structure elucidation of new bitter quassinoids, yadanziolides A, B, and C (**1**, **2**, and **3**) and bitter quassinoid glycosides, yadanziosides F, I, J, and L (**4**, **5**, **6**, and **7**).

The methanol extract of defatted seeds of *B. javanica* was partitioned between dichloromethane and water. The aqueous layer was separated by silica-gel column chromatography eluted with a lower layer of chloroform–methanol–water. Each fraction was further purified by gel chromatography on Toyopearl HW-40S eluted with methanol and then a reversed phase chromatography on Lobar column Lichroprep RP-8 eluted with methanol–water. These isolation procedures afforded several new bitter principles together with known compounds, bruceosides A (**8**), B (**9**),[8] bruceins D (**10**), E (**11**),[8,9] and F (**12**).[10]

Yadanziolide A (**1**; *ca.* 0.01% yield) crystallized from methanol as colorless needles, mp 283—285 °C (decomp) and $[\alpha]_D^{28}$ −10.5° (pyridine). Elemental analysis indicates the formula $C_{20}H_{26}O_{10}$. The IR and UV spectra showed the presence of hydroxyl(s), a δ-lactone and an α,β-unsaturated carbonyl groups. Comparison of ^{1}H and ^{13}C NMR spectra of **1** with those of brucein F (**12**)[10] could lead to the structure (**1**) for yadanziolide A, which is a conjugated ketone corresponding to an oxidation product of brucein F (**12**). Brucein F (**12**) was treated with manganese dioxide in *N,N*-dimethylformamide to give the oxidation product, which was identical with **1** in respect to mp, IR, ^{1}H NMR, and TLC. Thus the structure of yadanziolide A (**1**) was determined to be 13β,20-epoxy-1β,11β,12α,14,15β,21-hexahydroxypicras-3-ene-2,16-dione.

When treated with acetic anhydride in pyridine at room temperature for 48 h, **1** give a tetraacetyl derivative (**13**), mp 202—203 °C. The ^{1}H NMR spectrum of **13** indicates that **13** is 1,12,15,21-tetra-*O*-acetylyadanziolide A.

Yadanziolide B (**2**; *ca.* 0.002% yield), mp 279—282 °C (decomp), was shown by elemental analysis to have the molecular formula, $C_{20}H_{26}O_{11}$, which possesses one more oxygen atom than **1**. The IR and UV spectra showed the presence of hydroxyl(s), a δ-lactone, and an α,β-unsaturated carbonyl groups. In the 400 MHz ^{1}H NMR and COSY spectra, all protons were assigned unambiguously (Table 1). A doublet signal at δ 5.70 (J=1.5 Hz) due to H-7 and a double-doublet signal at δ 4.24 (J=11.5 Hz) due to H-6 are shifted to a lower field than those of yadanziolide A (**1**). These observations suggest that the structure of yadanziolide B (**2**) is 6-hydroxy-substituted yadanziolide A (**1**). The coupling constants, $J_{5,6}$=11.5 Hz and $J_{6,7}$=1.5 Hz, suggest a trans-relationship between H-6 and an α(axial)-proton on C-5, and therefore the hydroxyl group on C-6 was determined to be in 6α(equatorial)-configuration. This assignment is firmly established by the fact that the NOE was observed between H-6 and $C_{(10)}$-CH_3 in the NOESY spectrum.

Yadanziolide B (**2**) was acetylated with acetic anhydride in pyridine to afford a pentaacetate (**14**), mp 278—283 °C (decomp). The ^{1}H NMR spectrum showed two methyl signals at δ 1.52 (s, 10-CH_3) and 2.03 (br s, 4-CH_3) together with signals due to acetoxyl groups at δ 1.96 (3H, s), 2.09 (6H, s), and 2.22 (6H, s). Thus the structure of yadanziolide B (**2**) was concluded to be 13β,20-epoxy-1β,6α,11β,12α,14,

15β,21-heptahydroxypicras-3-ene-2,16-dione.

Yadanziolide C (**3**; *ca.* 0.001% yield) crystallized from methanol–diethyl ether as colorless prisms, mp 292—297 °C (decomp). The elemental analysis indicates the molecular formula, $C_{20}H_{26}O_9$, which is the same as that of brucein D (**10**).[8,9] The IR and UV spectra showed the presence of hydroxyl(s), a δ-lactone, and an α,β-unsaturated carbonyl groups. The ^{1}H NMR spectrum revealed that the signals of H-1, H-5, and H-9 of yadanziolide C (**3**) shifted to a lower field than those of brucein D (**10**; see Table 2). Comparison of ^{13}C NMR spectra showed that the signals of C-5 and C-9 of **3** (δ 37.7 and 38.3, respectively) shifted to a higher field than those of **10** (δ 43.6 and 45.8, respectively).

When treated with acetic anhydride in pyridine at room temperature for 1 week, **3** gave 1,15-di-*O*-acetyl derivative (**15**; 35% yield) and 1,12,15-tri-*O*-acetyl derivative (**16**; 52% yield). Under the same conditions, brucein D (**10**) gave 1,12,15-tri-*O*-acetyl derivative in 96% yield.

These evidences suggest that the configuration of C-1, C-5, or C-9 might be defferent from that of brucein D (**10**). The extensive double resonance experiments at 400 MHz led to an unambiguous assignment of all protons for **3** (Table 2). Two broad doublet signals due to H-1 and H-12 were assigned as follows. Two signals at δ 4.46 and δ 4.66 were changed into broad singlets on addition of D_2O. Irradiation at δ 1.63 due to $C_{(10)}$-CH_3 resulted in a slight sharpening of the broad doublet at δ 4.66, while the signal at δ 4.46 remained unchanged. Therefore, the broad doublet signals at δ 4.66 and δ 4.46 are assigned to H-1 and H-12, respectively.

The coupling constants, $J_{5,6\alpha}$=3 Hz and $J_{5,6\beta}$=13.5 Hz, being the same as those of other picrasane derivatives, the proton at C-5 was determined to be in α(axial)-configuration.

The configurations at $C_{(1)}$-H and $C_{(9)}$-H were determined by differential NOE measurement. On saturation of the signal due to $C_{(10)}$-CH_3, increases in area of signals due to $C_{(1)}$-H and one of $C_{(20)}$-H_2 were observed, while an increase in area of the signal due to $C_{(9)}$-H was not detected, indicating $C_{(1\beta)}$-H and $C_{(9\alpha)}$-H orientations.

Thus the structure of yadanziolide C (**3**) was established to be 13β,20-epoxy-1α,11β,12α,14,15β-pentahydroxypicras-3-ene-2,16-dione, which corresponds to 1-epibrucein D.

Yadanzioside F (**4**; *ca.* 0.03% yield), a bitter glycoside, mp 202—207 °C, showed the presence of a secondary methyl, a tertiary methyl, an acetoxyl, and a methoxycarbonyl groups in 90 MHz ^{1}H NMR spectrum. The ^{13}C NMR spectrum and a peak observed at *m/z* 643 in the secondary ion mass spectrometry (SIMS) suggested the molecular formula, $C_{29}H_{38}O_{16}$, for **4**, which was supported by the following observations. In the EI mass spectrum, an abundant fragment ion at *m/z* 480 (M^+—162) indicated the presence of a hexose moiety. Yadanzioside F (**4**) was hydrolyzed with β-glucosidase to give brucein B (**17**).[10,11] Since a doublet signal due to $C_{(4)}$-CH_3 of the aglycone part of **4** was observed at δ 1.15 (*J*=5 Hz), it is indicated that the brucein B moiety isomerizes into a 3-keto-1-ene structure and the glycoside linkage is formed through an oxygen atom on C-2. The structure of yadanzioside F (**4**) was therefore formulated as 2-*O*-(β-D-glucosyl)brucein B.

Yadanzioside I (**5**; *ca.* 0.02% yield) crystallized from ethanol as colorless needles, mp 287—290 °C (decomp). The molecular formula, $C_{29}H_{38}O_{16}$, was inferred by a peak at m/z 643 in the SIMS together with the ^{13}C NMR spectrum and hydrolysis with β-glucosidase giving brucein B (**17**). In the ^{1}H NMR spectrum, the $C_{(4)}$-CH_3 was observed at δ 2.04 as a singlet. In ^{13}C NMR spectrum, glycosylation shifts (see Table 3) of the signals due to C-3 and C-4 were observed, respectively, indicating that D-glucose is attached at C-3 of the aglycone. Thus the structure of yadanzioside I (**5**) was determined to be 3-*O*-(β-D-glucosyl)brucein B.

Yadanzioside J (**6**; *ca.* 0.002% yield), mp 198—202 °C, was suggested to have a molecular formula, $C_{32}H_{44}O_{17}$ by SIMS and ^{13}C NMR spectrum. The IR and UV spectra showed the presence of hydroxyl(s), a δ-lactone, and an α,β-unsaturated carbonyl groups. In the ^{1}H NMR spectrum, a doublet signal due to $C_{(4)}$-CH_3 of the aglycone part was observed at δ 1.16 (J=6.6 Hz), and a doublet signal due to the anomeric proton of the sugar part was observed at δ 5.35 (J=7.3 Hz). In the ^{13}C NMR spectrum, all of carbons were assigned (see Table 3). These indicate that the structure of **6** must be a 2-β-D-glucoside like bruceoside A or yadanzioside F and the aglycone must be 15-*O*-(3-hydroxy-3-methylbutanoyl)bruceolide.

On hydrolysis with 1.5 M sulfuric acid (1 M=1 mol dm^{-3})-methanol (1:2), **6** gave the aglycone (**18**) and D-glucose. The latter was identified as its trimethylsilyl derivative by GLC. The aglycone (**18**) was shown to have the molecular formula, $C_{26}H_{34}O_{12}$ by high-resolution mass spectrum. By comparison of the ^{1}H and ^{13}C NMR spectra with those of known bruceolides, the signals δ 1,34 (6H, s) and 2.43 (2H, s) in the ^{1}H NMR, and δ 170.7s, 48.6t, 69.2s, 29.8s, and 29.9s in the ^{13}C NMR (see Table 3) were well assigned to 3-hydroxy-3-methylbutanoate moiety. Thus the structure of **18** was determined to be 15-*O*-(3-hydroxy-3-methylbutanoyl)bruceolide, which is corresponding to 3′-hydroxybrucein A. From these evidences, the structure (**6**) is proposed for yadanzioside J.

Yadanzioside L (**7**; *ca.* 0.01% yield), mp 199—204 °C, was suggested to have a molecular formula, $C_{34}H_{46}O_{17}$, by a peak observed at m/z 727 in the SIMS and the ^{13}C NMR spectrum. On hydrolysis with 1.5 M sulfuric acid-methanol, **7** afford brucein C (**19**)[6,11,12] and D-glucose. The former was identified in respect to mp, IR, and ^{1}H NMR, and the latter was identified as its trimethylsilyl derivative by GLC examination. Glycosylation shifts of the signals due to C-3 and C-4 were observed in ^{13}C NMR, respectively, (see Table 3) which implies that D-glucose is attached at C-3 of the aglycone. An anomeric proton was observed at δ 5.40 as a doublet (J=7 Hz) in the ^{1}H NMR spectrum. Thus the structure of yadanzioside L (**7**) was determined to be 3-*O*-(β-D-glucosyl)-brucein C.

Yadanziosides F (**4**), I (**5**), J (**6**), and L (**7**) were demonstrated to have *in vivo* antileukemic activity against the murine P-388 lymphocytic leukemia at same strength as bruceoside A (**8**).

Experimental

General Procedures. All melting points were measured

a) Measured in C_5D_5N at 22.5 MHz. b) Measured in $(CD_3)_2SO$. c) Measured in $CDCl_3$. d, e) Signals within any vertical column may be reversed.

on a Mel-temp capillary melting point apparatus (Laboratory Devices) and uncorrected. Optical rotations were determined on a JASCO polarimeter DIP-181. Infrared (IR) spectra were measured on a Hitachi 260-30 spectrometer. Ultraviolet absorption (UV) spectra were measured on a Hitachi 340 spectrometer. Low and high resolution mass spectra (MS and HRMS, respectively) were run on a JEOL JMS-D300 mass spectrometer operating at 70 eV and secondary ion mass spectra (SIMS) on a Hitachi M-80 mass spectrometer. Proton nuclear magnetic resonance (^1H NMR) spectra (90 MHz) were taken using a Varian EM390 and carbon-13 nuclear magnetic resonance (^{13}C NMR) spectra (22.5 MHz) JEOL FX 90Q. Measurement of ^1H NMR spectra at 400 MHz was carried out on a JNM GX 400 (JEOL) spectrometer. Chemical shifts were expressed in δ-value (ppm downfield from tetramethylsilane as an internal standard) and coupling constants in Hz. Thin-layer chromatography (TLC) was carried out on Kieselgel 60 GF_{254} or Kieselgel 60 HF_{254} silasiert coated in 0.25 mm or on TLC plates Kieselgel 60/Kieselgur F_{254} (E. Merck). Wakogel C-200 (Wako), TSK-gel Toyopearl HW-40S (Toyo Soda), or Lobar column Lichroprep RP-8 size B (E. Merck) was used for column chromatography. Commercialized β-glucosidase available from Sigma Chemical Company was used.

Plant Material. Seeds of *Brucea javanica* (L.) Merr as Chinese medicine, "Ya-dan-zi", were ground to afford 60 kg of materials.

Extraction and Separation. Seeds (60 kg) were defatted with haxane (*ca.* 100 l) twice, and then extracted with methanol (*ca.* 100 l) twice. The extract was concentrated to give a syrup, to which the same volume of water was added, and defatted with hexane (*ca.* 7 l) four times. The aqueous layer was extracted five times with dichloromethane. The aqueous layer, on evaporation, gave a bitter residue (*ca.* 1 kg). A part of the residue (53 g) was absorbed on silica gel

(60 g), placed on a top of a silica-gel (1.2 kg) column, and eluted with a lower layer of chloroform-methanol-water (50:12:3; *ca.* 9 l, 65:35:10; *ca.* 9 l, 50:50:18; *ca.* 12 l), and 40 fractions (each 700 ml) were collected (Column A).

The each fraction was further separated by the following procedures.

Procedure A: Gel chromatography using Toyopearl HW-40S (2.4×100 cm). Elution was performed with methanol, and fractions (each 10 g) were collected by an automatic fraction collector. Flow rate was about 0.2 ml/min.

Procedure B: Reversed phase chromatography using Lobar column Lichroprep RP-8 size B. Elution was performed with methanol-water, and fractions were collected by an automatic fraction collector. Flow rate was about 1 ml/min. The ratio in volume of methanol-water is given in each chromatographic procedure.

Fractions 8 and 9 (1.02 g) of Column A were combined and separated by Procedure A. Fractions 44—52 (730 mg; Fraction A) and fractions 59—65 (Fraction B; 149 mg) were combined respectively on the basis of TLC examination. Recrystallization of Fraction B from methanol gave brucein D (**10**).

Fractions 10 and 11 (1.24 g) of Column A were combined together and separated by Procedure A. On the basis of TLC, fractions 32—36 (467 mg; Fraction C), fractions 37—41 (193 mg; Fraction D), fractions 42—49 (193 mg; Fraction E), and fractions 50—55 (241 mg; Fraction F) were combined, respectively.

Fraction A and Fraction C were combined and separated by Procedure B (methanol-water, 1:1). Fractions 13—25 (790 mg) were combined and identified to be bruceoside A (**8**).[7] Fractions 26—35 (138 mg) were combined and evaporated to give yadanzioside A (**20**).[2]

Fraction D was separated by Procedure B (methanol-water, 3:7). Fractions 18—23 and fractions 24—45 were identified to be yadanziolide C (**3**; 20 mg) and yadanzioside F (**4**; 58 mg), respectively.

Fraction E was recrystallized from methanol to give brucein D (**10**; 150 mg).

Fraction 12 and 13 (1.63 g) of Column A were separated by Procedure A. Fractions 38—47 (1.18 g; Fraction G) and fractions 52—57 (243 mg; Fraction H) were collected.

Fraction G was separated by Procedure B (methanol-water, 1:1). Fractions 17—23 were combined to give yadanziolide C (**3**; 59 mg). Fractions 24—36 (960 mg) were combined and further separated by Procedure B (methanol-water, 3:7). Fractions 24—51 were combined and evaporated to give yadanzioside F (**4**; 534 mg), and fractions 52—80 were combined and identified to be bruceoside B (**9**; 85 mg).[8]

Fraction F and Fraction H were combined and recrystallized from methanol to afford yadanziolide A (**1**; 410 mg).

Fractions 14 and 15 (1.98 g) of Column A were separated by Procedure A. Fractions 38—47 (1.57 g) were further sepatated by Procedure B (methanol-water, 3:7). Fractions 24—45 (419 mg) were ascertained to be a mixture of yadanzioside F (**4**), brucein E (**11**), and yadanzioside D (**21**)[2] by TLC examination (Kieselgel 60 HF_{254} silasiert, methanol-water, 4:6). Fractions 46—90 (761 mg) were also identified to be a mixture of yadanzioside D (**21**) and bruceoside B (**9**).

Fraction 16 of Column A was crystallized from methanol to give crystalline brucein E (**11**; 1.2 g). The mother liquor (1.16 g) was separated by Procedure A. Fractions 33—38 (372 mg; Fraction I) and fractions 39—43 (353 mg; Fraction J) were combined, respectively. Fraction I was further separated by Procedure B (methanol-water, 3:7). Fractions 44—46 were combined to give yadanzioside J (**6**; 50 mg) and fractions 47—53 were identified to be yadanzioside C (**22**; 200 mg). Fraction J was also separated by Procedure B (methanol-water, 3:7). Fractions 15—23 were combined to give yadanzioside I (**5** 178 mg) and fractions 24—50 were combined and evaporated to give brucein E (**11**; 150 mg).

Fractions 17 and 18 of Column A were crystallized from methanol to give crystalline brucein E (**11**; 450 mg). The mother liquor (2.7 g) was separated by Procedure A. Fractions 35—40 (935 mg; Fraction K), fractions 41—48 (526 mg; Fraction L) and fractions 52—56 (71 mg; Fraction M) were combined, respectively, on the basis of TLC examination. Fraction K was separated by Procedure B (methanol-water, 3:7). Yadanzioside **I** (**5**; 79 mg) was given from fractions 16—21, brucein E (**11**; 273 mg) from fractions 22—42, and yadanzioside L (**7**; 192 mg) from fractions 43—56. Fraction L was separated by Procedure B (methanol-water, 3:7). Fractions 15—23 were combined to give yadanzioside I (**5**; 178 mg) and fractions 24—50 gave brucein E (**11**; 220 mg).

Fractions 19 and 20 (2.36 g) of Column A were separated by Procedure A. Fractions 43—50 (880 mg; Fraction N) and fractions 51—70 (220 mg; Fraction O) were combined, respectively. Fraction N was crystallized from methanol to give brucein F (**12**).[10] Fraction M and Fraction O were combined and separated by procedure B (methanol-water, 1:1) to give yadanziolide B (**2**; 70 mg) from fractions 12—15.

Yadanziolide A (1). Colorless needles crystallized from methanol, mp 283—285 °C (decomn); $[\alpha]_D^{28}$ −10.5° (*c* 1.7, pyridine); IR (KBr) 3430, 1700, 1645, 1620, and 1025 cm^{-1}; UV (methanol) 240 nm (ε 9300); ^1H NMR (Table 1); ^{13}C NMR (C_5D_5N, 22.5 MHz) δ=11.5q, 22.2q, 28.0t, 43.6d, 45.7d, 48.6s, 50.7s, 64.7t, 70.6t, 70.7d, 75.4d, 78.3d, 79.1d, 83.0d, 83.8s, 84.6s, 124.9d, 163.5s, 174.9s, and 198.4s; MS (EI) *m/z* (%) 426 (M^+; 0.4), 408 (2), 390 (34), 372 (16), 151 (100), and 135 (88); Found: C, 56.04; H, 6.16%. Calcd for $C_{20}H_{26}O_{10}$: C, 56.33; H, 6.15%.

Oxidation of Brucein F (12) with Manganese Dioxide. A solution of brucein F (**12**; 52.6 mg) in *N,N*-dimethylformamide (10 ml) was treated with manganese dioxide (1 g, prepared by Attenburrow's procedure[13]) for 24 h at room temperature. After the usual work-up, the reaction mixture was separated by silica-gel column chromatography (C-200, 12 g) eluted with a lower layer of chloroform-methanol-water (50:12:3). The oxidation product, yadanziolide A (**1**; 9.2 mg) was identified by mp, IR, ^1H NMR, and TLC, and the starting material, brucein F (**12**; 11 mg) was recovered.

1,12,15,21-Tetra-O-acetylyadanziolide A (13). Yadanziolide A (**1**; 25 mg) was acetylated with acetic anhydride (1.5 ml) in pyridine (1.5 ml) at room temperature for 64 h. Addition of methanol and the usual work-up afforded a reaction mixture, which was purified by silica-gel column chromatography (C-200, 10 g) eluted with dichloromethane-ethyl acetate (2:1) to give 1,12,15,21-tetra-*O*-acetylyadanzi-

olide A (**13**; 34 mg), mp 202—203 °C (colorless prisms crystallized from methanol–diethyl ether); IR (KBr) 3430, 1750, 1685, 1630, 1380, 1245, and 1055 cm^{-1}; UV (ethanol) 239 nm (ε 9000); ^1H NMR ($CDCl_3$ 90 MHz) δ=1.38 (3H, s, 10-CH_3), 1.97 (6H, s, 4-CH_3 and OAc), 2.09 (3H, s, OAc), 2.18 (3H, s, OAc), 2.34 (1H, d, J=5 Hz, 9-H), 3.04 (1H, br d, J=11 Hz, 5-H), 4.00 (1H, d, J=5 Hz, 11-H), 4.02, 4.68 (each 1H, d, J=8 Hz, 20-H), 4.30, 4.49 (each 1H, d, J=13 Hz, 21-H), 5.04 (1H, s, 12-H), 5.16 (1H, br s, 7-H), 5.40 (1H, s, 1-H), 6.02 (1H, br s, 3-H), and 6.09 (1H, s, 15-H); MS (EI) m/z (%) 594 (M^+, 1), 576 (0.6), 552 (2), 534 (10), 492 (10), 474 (22), 432 (100), 267 (25), 151 f(25), 135 (26), and 60 (28); Found: m/z 594.1953. Calcd for $C_{28}H_{34}O_{14}$: M, 594.1948.

Yadanziolide A Monohydrate. Colorless prisms crystallized from aqueous methanol, mp 310—314 °C (decomp), IR (KBr) 3540, 3440, 1750, 1665, 1625, 1160, and 1075 cm^{-1}; Found: C, 53.78; H, 6.38%. Calcd for $C_{20}H_{26}O_{10}\cdot H_2O$: C, 54.05; H, 6.34%.

Yadanziolide B (2). Colorless needles crystallized from ethanol–diethyl ether, mp 279—282 °C (decomp); $[\alpha]_D^{23}$ +83° (c 4.3, methanol); IR (KBr) 3500, 3360, 1710, 1645, 1630 (sh), 1255, 1125, and 1070 cm^{-1}; UV (methanol) 244 nm (ε 10000); ^1H NMR (Table 1); ^{13}C NMR (C_5D_5N, 22.5 MHz) δ=12.5q, 27.1q, 44.6d, 49.2d, 51.1s, 51.2s, 64.6t, 68.2d, 70.0t, 70.9d, 75.5d, 78.6d, 83.3d, 83.8s, 83.8d, 84.3s, 126.9d, 166.4s, 174.7s, and 198.2s; MS (EI) m/z (%) 442 (M^+, 0.8), 424 (12), 406 (28), 388 (10), 378 (36), 360 (12), and 111 (100); Found: C, 54.11; H, 5.77%. Calcd for $C_{20}H_{26}O_{11}$: C, 54.30; H, 5.92%.

1,6,12,15,21-Penta-O-acetylyadanziolide B (14). Yadanziolide B (**2**; 27 mg) was acetylated with acetic anhydride (1.5 ml) in pyridine (1.5 ml) at room temperature for 5 d. The usual work-up and silica-gel column chromatography (dichloromethane–ethyl acetate, 2:1) yielded, after crystallization from methanol–diethyl ether, a pentaacetate (**14**; 28 mg), as colorless needless, mp 278—283 °C (decomp); IR (KBr) 3460, 1740, 1680, 1640, 1375, 1240, and 1030 cm^{-1}; UV (ethanol) 239 nm (ε 10000); ^1H NMR ($CDCl_3$, 90 MHz) δ=1.52 (3H, s, 10-CH_3), 1.96 (3H, s, OAc), 2.03 (3H, br s, 4-CH_3, 2.09 (6H, s, OAc), 2.22 (6H, s, OAc), 2.37 (1H, d, J=6 Hz, 9-H), 3.10 (1H, br d, J=11 Hz, 5-H),4.07 (1H, d, J=6 Hz, 11-H), 4.15, 4.70 (each 1H, d, J=8 Hz, 20-H), 4.27, 4.50 (each 1H, d, J=12 Hz, 21-H), 5.03 (1H, s, 12-H), 5.08 (1H, dd, J=11, 2 Hz, 6-H), 5.10 (1H, d, J=2 Hz, 7-H), 5.45 (1H, s, 1-H), 6.07 (1H, br s, 3-H), and 6.12 (1H, s, 15-H); MS (EI) m/z (%) 652 (M^+, 0.8), 634 (0.8), 610 (1.2), 592 (6), 567 (8), 550 (14), 532 (13), 490 (22), 472 (10), 430 (18), and 60 (100); Found: m/z 652.2031. Calcd for $C_{30}H_{36}O_{16}$: M, 652.2004.

Yadanziolide C (3). Colorless prisms crystallized from methanol–diethyl ether, mp 292—297 °C (decomp); $[\alpha]_D^{23}$ +29° (c 1.2, MeOH); IR (KBr) 3575, 3550, 3500, 3420, 1705, 1675, 1620, 1160, and 1060 cm^{-1}; UV (methanol) 244 nm (ε 11000); ^1H NMR (Table 2); ^{13}C NMR (C_5D_5N, 22.5 MHz) δ=15.0q, 19.5q, 22.0q, 28.0t, 37.7d, 38.3d, 44.6s, 49.7s, 70.5d, 70.5t, 73.2d, 76.2d, 79.7d, 82.0s, 82.6s, 85.5s, 125.0d, 161.6s, 174.9s, and 198.4s; MS (EI) m/z (%) 410 (M^+, 4), 392 (64), 374 (32), 151 (60), and 135 (100); Found: C, 58.27; H, 6.36%. Calcd for $C_{20}H_{26}O_9$: C, 58.53; H, 6.39%.

Acetylation of Yadanziolide C (3). Yadanziolide C (**3**; 21 mg) was treated with acetic anhydride (1 ml) and pyridine (1 ml) at room temperature for 1 week. After the usual work-up, the reaction mixture was separated by silica-gel column chromatography (C-200, 10 g) eluted with dichloromethane–ethyl acetate (2:1) to give the diacetate (**15**; 8.8 mg) and the triacetate (**16**; 14.2 mg). 1,15-Di-*O*-acetylyadanziolide C (**15**): mp 299—303 °C (colorles prisms from methanol–diethyl ether); IR (KBr) 3600, 3500, 1740, 1725, 1660, 1620, 1235, and 1075 cm^{-1}; UV (methanol) 246 nm (ε 10000); ^1H NMR ($CDCl_3$, 90 MHz) δ=1.37 (3H, s, 10-CH_3), 1.47 (3H, s, 13-CH_3), 1.97 (3H, br s, 4-CH_3), 2.14 (3H, s, OAc), 2.21 (3H, s, OAc), 2.42 (1H, br d, J=12 Hz, 6α-H), 2.50 (1H, 9-H), 3.11 (1H, br d, J=12 Hz, 5-H), 3.9—4.1 (3H, 11-H, 12-H, and 20-H), 4.51 (1H, d, J=8 Hz, 20-H′), 5.10 (1H, br s, 7-H), 5.15 (1H, s, 1-H), 5.92 (1H, br s, 3-H), and 6.40 (1H, s, 15-H); MS (EI) m/z (%) 494 (M^+, 0.4), 476 (0.8), 434 (3), 416 (3), 392 (2), 374 (15), 356 (5), 135 (100), and 60 (100); Found: m/z 494.1776. Calcd for $C_{24}H_{30}O_{11}$: M, 494.1787. 1,12,15-Tri-*O*-acetylyadanziolide C (**16**): mp 183—188 °C (powder); IR (KBr) 3450, 1750, 1680, 1640, 1380, 1235, 1070, and 1040 cm^{-1}; UV (methanol) 246 nm (ε 10000); ^1H NMR ($CDCl_3$, 90 MHz) δ=1.30 (3H, s, 10-CH_3), 1.41 (3H, s, 13-CH_3), 1.97 (3H, br s, 4-CH_3), 2.00 (3H, s, OAc), 2.11 (3H, s, OAc), 2.23 (3H, s, OAc), 2.45 (1H, br d, J=12 Hz, 6α-H), 3.05 (1H, br d, J=12 Hz, 5-H), 3.97, 4.55 (each 1H, d, J=8 Hz, 20-H), 4.10 (1H, d, J=5 Hz, 11-H), 4.89 (1H, d, J=1.5 Hz, 12-H), 5.18 (1H, br s, 7-H), 5.27 (1H, s, 1-H), 5.95 (1H, br s, 3-H), and 6.13 (1H, s, 15-H); MS (EI) m/z (%), 536 (M^+, 2), 494 (3), 476 (5), 458 (1), and 135 (100); Found: m/z 536.1917. Calcd for $C_{26}H_{32}O_{12}$: M, 536.1894.

Yadanzioside F (4). Amorphous solid, mp 202—207 °C; $[\alpha]_D^{23}$ +10° (c 4.1, ethanol); IR (KBr) 3450, 1740, 1680, 1630, and 1065 cm^{-1}; UV (ethanol) 256 nm (ε 6500); ^1H NMR (C_5D_5N, 90 MHz) δ=1.15 (3H, s, J=5 Hz, 4-CH_3), 1.63 (3H, s, 10-CH_3), 2.10 (3H, s, 15-OAc), 3.81 (3H, s, $COOCH_3$), 6.76 (1H, d, J=13 Hz, 15-H), and 7.22 (1H, s, 1-H); ^{13}C NMR (Table 3); MS (SIMS) 643 (MH^+), 481, and 439; Found m/z 480.1614. Calcd for $C_{23}H_{28}O_{11}$ (M−$C_6H_{10}O_5$): m/z 480.1629.

Enzymatic Hydrolysis of Yadanzioside F (4). A mixture of yadanzioside F (**4**; 143 mg) and β-glucosidase (41 mg) in water (10 ml) was allowed to stand for 2 weeks at 37 °C. Methanol (5 ml) was added and the mixture was heated at boiling-water temperature for 10 min. After being cooled, the mixture was filtered and the filtrate was evaporated *in vacuo*. The residue was separated by silica-gel column chromatography (chloroform–methanol, 9:1) to yield a pure compound (**17**; 37 mg). The physical and spectral data of **17** (IR, ^1H NMR, MS) are in agreement with literature[11] for brucein B (**17**). Found: m/z 480.1618. (M−$C_6H_{10}O_5$): m/z 480.1629.

Yadanzioside I (5). Colorless needles crystallized from ethanol, mp 287—290 °C (decomp); $[\alpha]_D^{28}$ −21° (c 1.0, methanol); IR (KBr) 3450, 1755, 1650, 1620 (sh), and 1065 cm^{-1}; UV (ethanol) 254 nm (ε 9700); ^1H NMR (C_5D_5N, 90 MHz) δ=1.69 (3H, s, 10-CH_3), 2.04 (3H, s, 4-CH_3), 2.10 (3H, s, 15-OAc), 3.81 (3H, s, $COOCH_3$), and 6.80 (1H, d, J=13 Hz, 15-H); ^{13}C NMR (Table 3); MS (SIMS) m/z 643 (MH^+) and 481; Found: m/z 480.1646. Calcd for $C_{23}H_{28}O_{11}$ (M—$C_6H_{10}O_5$): m/z 480.1629.

Enzymatic Hydrolysis of Yadanzioside I (5). A mixture of yadanzioside I (47 mg) and β-glucosidase (23 mg) in water (5 ml) was treated by the same procedure

as before. Brucein B (**17**; 11 mg) was isolated and identified as the sole aglycone.

Yadanzioside J (6). Amorphous solid, mp 198—202 °C; $[\alpha]_D^{22}$ −6.4° (*c* 2.8, methanol); IR (KBr) 3430, 1740, 1680, 1640, and 1075 cm^{-1}; UV (methanol) 254 nm (ε 8000); ^1H NMR (C_5D_5N, 400 MHz) δ=1.16 (3H, d, *J*=6.6 Hz, 4-CH_3), 1.61 (6H, s, 3′-CH_3×2), 1,64 (3H, s, 10-CH_3), 2.01 (1H, br d, *J*=15.0 Hz, 5-H), 2.52 (1H, d, *J*=5.1 Hz, 9-H), 2.88, 2.94 (each 1H, d, *J*=13.7 Hz, 2′-H), 3.80 (3H, s, $COOCH_3$), 3.90, 5.07 (each 1H, d, *J*=7.7 Hz, 20-H), 4.48 (1H, br d, *J*=10.3 Hz, 6″-H), 4.94 (1H, br s, 11-H), 5.13 (1H, br s, 12-H), 5.18 (1H, br s, 7-H), 5.35 (1H, d, *J*=7.3 Hz, 1″-H), and 7.27 (1H, s, 1-H); ^{13}C NMR (Table 3); MS (SIMS) *m/z* 701 (MH^+), 683, 539, 521, and 439; Found: *m/z* 538.2068. Calcd for $C_{26}H_{34}O_{12}$ (M−$C_6H_{10}O_5$): *m/z* 538.2051.

Acid Hydrolysis of Yadanzioside J (5). A solution of **5** (42 mg) in 1.5 M sulfuric acid-methanol (1:2, 6 ml) was refluxed for 5 h. The reaction mixture was concentrated *in vacuo* and extracted with dichloromethane four times. The combined dichloromethane layers were dried over anhydrous magnesium sulfate and evaporated under reduced pressure to give a product (21 mg) which was separated by silica-gel column chromatography (C-200, 10 g) eluted with methanol–chloroform (1:9) to give a pure compound (20 mg). This compound crystallized from methanol–diethyl ether to afford 15-*O*-(3-hydroxy-3-methylbutanoyl)-bruceolide (**18**) as colorless prisms: mp 251—254 °C (decomp); $[\alpha]_D^{19}$ +13° (*c* 1.4, methanol); IR (KBr) 3575, 3460, 1745, 1730, 1675, 1650, 1195, 1150, and 1070 cm^{-1}; UV (methanol) 278 nm (ε 8000); ^1H NMR ($CDCl_3$, 90 MHz) δ=1.34 (6H, s, 3′-CH_3×2), 1.39 (3H, s, 10-CH_3), 1.84 (3H, d, *J*=2 Hz, 4-CH_3), 2.40, 2.95 (each 1H, d, *J*=18 Hz, 1-H), 2.43 (2H, s, 2′-H_2), 3.13 (1H, d, *J*=13 Hz, 14-H), 3.75, 4.73 (each 1H, d, *J*=7 Hz, 20-H), 3.82 (3H, s, $COOCH_3$), 4.23 (2H, br s, 11-H and 12-H), 5.77 (1H, br s, 7-H), and 6.38 (1H, d, *J*=13 Hz, 15-H); ^{13}C NMR (Table 3); MS (EI) *m/z* (%) 538 (M^+, 1.5), 520 (12), 480 (26), 438 (50), 420 (20), 402 (20), 392 (28), 297 (46), 151 (74), and 83 (100); Found: *m/z* 538.2048. Calcd for $C_{23}H_{34}O_{12}$: M, 538.2051.

The aqueous layer, obtained from the acid hydrolysis of **5**, was passed through a short column of anion-exchange resin (Amberlite IRA-400, hydroxide form) and the eluate was evaporated under reduced pressure to give a residue which was identified as D-glucose (as trimethylsilyl derivative) by gas-liquid chromatography.

Yadanzioside L (7). Colorless needles crystallized from methanol–diethyl ether, mp 199—204 °C; $[\alpha]_D^{26}$ −0.7° (*c* 6.2, methanol); IR (KBr) 3420, 1735, 1640, and 1060 cm^{-1}; UV (methanol) 220 nm (ε 14000) and 254 nm (ε 9000); ^1H NMR (C_5D_5N, 90 MHz) δ=1.43 (6H, s, 4′-CH_3×2), 1.69 (3H, s, 3′-CH_3) 2.03 (3H, s, 4-CH_3), 2.38 (3H, s, 10-CH_3), 3.0—3.3 (2H, 1-H, and 14-H), 3.71 (3H, s, $COOCH_3$), 5.40 (1H, d, *J*=7 Hz, anomeric-H), 6.70 (1H, s, 2′-H), and 6.85 (1H,d, *J*=13 Hz, 15-H); ^{13}C NMR (Table 3); MS (SIMS) *m/z* 727 (MH^+) and 565; Found *m/z* 564.2182. Calcd for $C_{28}H_{36}O_{12}$ (M−$C_6H_{10}O_5$): *m/z* 564.2205.

Acid Hydrolysis of Yadanzioside L (7). The same treatment of a solution of **7** (94 mg) in 1.5 M sulfuric acid–methanol (1:2, 10 ml) as that described above led to the isolation of an aglycone (**19**; 47 mg). The physical and spectral data of **19** are in agreement with those[11] for brucein C (**19**). Found: *m/z* 564.2230. Calcd for $C_{28}H_{36}O_{12}$: M, 564.2205.

D-Glucose was also identified from aqueous layer by the same procedure described above.

The authors wish to thank Mr. Kazuhiro Matsushita of JEOL Co. Ltd. for the measurement of 400 MHz ^1H NMR spectra. They also thank Mr. Hideo Naoki of Suntory Institute for Bioorganic Research for the measurement of SIMS.

(Received April 16, 1985)

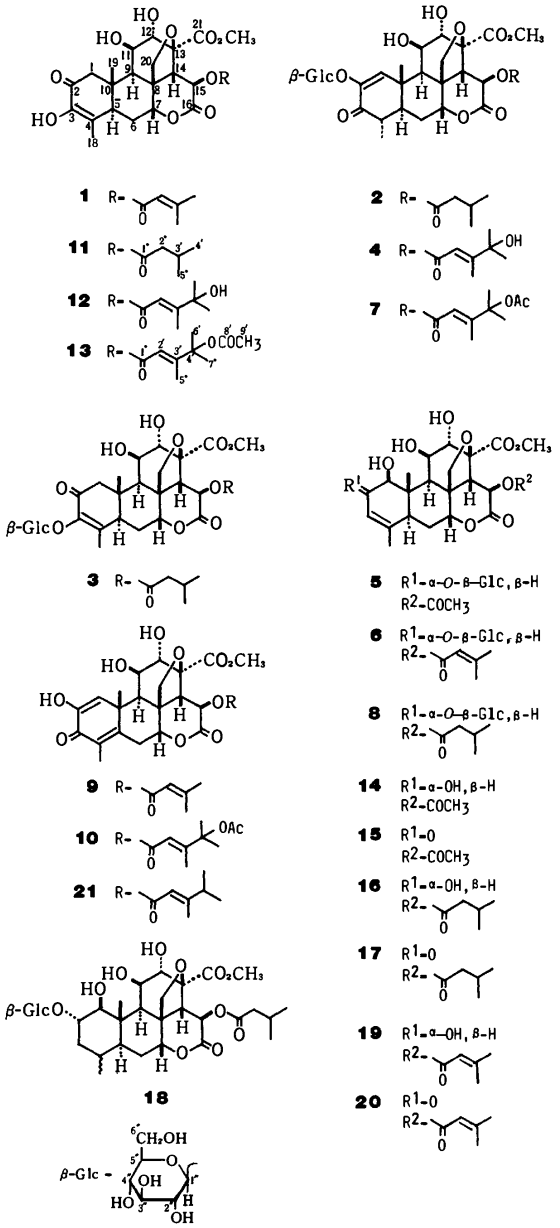
Quassinoid glycosides, yadanziosides A, B, C, D, E, G, and H, and two quassinoids, dehydrobrusatol and dehydrobruceantinol were isolated from seeds of *Brucea javanica*, and their structures were determined. These glycosides showed bitter taste and were demonstrated to have antileukemic activity.

In the preceding paper,[2)] the structure determination of three new quassinoids, yadanziolides A, B, and C, isolated from "Ya-dan-zi", seeds of *Brucea javanica* (L.) MERR was reported. As a continuation of studies on bitter principles of "Ya-dan-zi", quassinoid glycosides were examined, since our preliminary examination revealed the presence of many glycosides in the polar fraction of the methanol extract. Three quassinoid glycosides, bruceoside-A and -B[3)] and bruceantinoside A[4)] have been isolated from the same source as antileukemic constituents.

The methanol extract was subjected to separation to give seven new glycosides, yadanziosides A (**2**; 0.01%), B (**3**; 0.002%), C (**4**; 0.001%), D (**5**; 0.001%), E (**6**; 0.002%), G (**7**; 0.01%), and H (**8**; 0.001%), and two new quassinoids, dehydrobrusatol (**9**; 0.0002%) and dehydrobruceantinol (**10**; 0.0001%) together with brusatol(**1**),[5)] dehydrobrucein-A,[6)] brucein D,[7)] brucein E,[7)] bruceoside-A,[3)] bruceoside-B,[3)] bruceantinoside A,[4)] yadanziolide A,[2)] and yadanzioside F.[2)]

Yadanzioside B (**3**), mp 189—195 °C, showed a peak at *m/z* 707 due to $[M+Na]^+$ in SIMS, from which the molecular formula, $C_{32}H_{44}O_{16}$, was deduced. Its IR and UV spectra showed the presence of hydroxyl, δ-lactone, and conjugated enone moieties. An appearance of a peak at *m/z* 522.2082 ($[M-C_6H_{10}O_5]^+$) in the EI-high-resolution mass spectrum and the presence of a doublet signal (J=7.3 Hz) at δ 5.46 due to an anomeric proton in the ^{1}H NMR spectrum suggested that **3** should be a β-D-glucopyranoside. ^{1}H and ^{13}C NMR spectra (Tables 1 and 2) of **3** revealed that the aglycone must be brucein A (**11**)[6,8)] and glycosylation shifts of signals due to C-3 and C-4 were Δδ +1.9 and +18.1 ppm,[9,10)] respectively, in ^{13}C NMR spectra of **3** and **11**, leading to the structure assignment of yadanzioside B as 3-*O*-(β-D-glucopyranosyl)brucein A (**3**).

This assignment was supported by hydrolysis of **3**; treatment with 1.5 M (1 M=1 mol dm^{-3}) sulfuric acid afforded brucein A (**11**) and hydrolysis with hydrogen chloride in methanol yielded methyl D-glucoside, which was identified as its trimethylsilyl derivative by GLC.



Carbon numbers of picrasane skeleton refer to those described in Chemical Abstracts and numbers of carbon atoms in the side-chain at C-15 are given conventionally.

Yadanzioside A (**2**), mp 200—204 °C, was shown to be a glucoside with the same molecular formula as that of **3** by SIMS. On hydrolysis with β-glucosidase, **2** afforded brucein A (**11**) as the major aglycone. The ^{1}H NMR spectrum of **2** showed the presence of a doublet signal (J=6 Hz) due to $C_{(4)}$-CH_3 at δ 1.13. This fact implies the brucein A moiety isomerizes into a 3-keto-1-ene structure, which forms the β-D-glucoside linkage through an oxygen atom on C-2 of the aglycone. The configuration of the $C_{(4)}$-CH_3 of **2** was assigned as β-equatorial on the basis of the structural similarity to bruceoside-A.[3] Thus the structure of yadanzioside A was determined to be 2-*O*-(β-D-glucosyl)brucein A (**2**).

Yadanzioside C (**4**), mp 204—209 °C, gave a peak at m/z 749 due to $[M+Na]^+$ in the SIMS, which corresponds to the molecular formula $C_{34}H_{46}O_{17}$ and a peak at m/z 564.2230 ($[M-C_6H_{10}O_5]^+$) in the EI-high-resolution mass spectrum. Acid hydrolysis of **3** with 1.5 M sulfuric acid in methanol gave brucein C (**12**)[6,8,11] as the aglycone. On treatment with hydrogen chloride in methanol yielded methyl D-glucoside. The ^{1}H NMR spectrum of **4** showed a doublet signal (J=7.0 Hz) at δ 5.37 due to an anomeric proton and a doublet signal (J=6.7 Hz) due to $C_{(4)}$-CH_3 at δ 1.19. These observations led to the structure, 2-*O*-(β-D-glucopyranosyl)brucein C (**4**) for yadanzioside C.

Yadanzioside G (**7**), mp 180—185 °C, showed the presence of three tertiary methyl groups, one secondary methyl, one olefinic methyl, one acetoxyl, and one methoxycarbonyl groups in the ^{1}H NMR spectrum. The molecular formula, $C_{36}H_{48}O_{18}$, was suggested by a peak at m/z 791 due to $[M+Na]^+$ in the SIMS. On hydrolysis with β-glucosidase, **7** afforded bruceantinol (**13**).[6,11] A doublet signal (J=6 Hz) due to $C_{(4)}$-CH_3 at δ 1.17 indicates the sugar moiety in yadanzioside G (**7**) was linked to C-2 of bruceantinol (**13**). Therefore, the structure of yadanzioside G is formulated as 2-*O*-(β-D-glucopyranosyl)bruceantinol (**7**).

Yadanzioside D (**5**), mp 207—212 °C, exhibited the IR-absorption bands due to hydroxyl and δ-lactone moieties, but no UV-absorption maximum characteristic of a conjugated enone moiety. In the EI-mass spectrum of **5**, a peak at m/z 480 derived from an aglycone was observed and the ^{1}H NMR spectrum suggests the presence of an acetoxyl group. Yadanzioside D (**5**) was hydrolyzed with β-glucosidase to yield the aglycone (**14**), whose molecular formula, $C_{23}H_{30}O_{11}$, was given by the high-resolution mass spectrum. The structure of **14** was determined by oxidation with manganese dioxide in *N*,*N*-dimethylformamide (DMF) leading to isobrucein B (**15**).[12,13] In the ^{1}H NMR spectrum of **14**, the signal due to $C_{(1)}$-H appeared at δ 4.01 as a doublet and its coupling constant between $C_{(1)}$-H and $C_{(2)}$-H was 8 Hz. A glycosylation shift (Δδ +11.0 ppm) due to

a) Measured in $CDCl_3$ at 22.5 MHz. b) Measured in $CDCl_3$ at 100 MHz. c) The assignments of these signals may be reversed in each column. d), e), and f) are the same as c).

C-2 was observed in the ^{13}C NMR spectra of **5** and **14**. These observations suggest that the configuration of $C_{(2)}$-OH of **14** is α-equatorial and the glycoside linkage forms through the C-2 oxygen atom, leading to the structure, 2-β-D-glucoside of the allylic alcohol (**14**) derived from isobrucein B (**15**) for yadanzioside D (**5**).

Yadanzioside H (**8**), mp 180—185 °C, showed a peak at *m/z* 709 due to $[M+Na]^+$ in the SIMS, indicating the molecular formula, $C_{32}H_{46}O_{16}$, and was hydrolyzed with β-glucosidase to give an aglycone (**16**). The aglycone (**16**) showed a similar ^1H NMR spectrum to that of **14**, except for the presence of an isopropyl group (δ 0.94 and 0.97, each d, J=6 Hz) instead of the acetyl group (δ 2.09, s) for **14**. Therefore, the structure (**16**) was deduced for the aglycone and the proposed structure was confirmed by oxidation with manganese dioxide yielding isobrucein A (**17**).[14]

In the ^{13}C NMR spectra of **8** and **16**, a glycosylation shift ($\Delta\delta$ +11.0 ppm) was observed at C-2, indicating the structure of yadanzioside H (**8**) should be assigned as a 2β-D-glucoside of the aglycone (**16**) derived from isobrucein A (**17**).

On hydrogenation, yadanzioside H (**8**) yielded a dihydro derivative (**18**), $C_{32}H_{48}O_{16}$, as the sole product judging from ^{13}C NMR, although the configuration of $C_{(4)}$-CH_3 could not be assigned.

Yadanzioside E (**6**), mp 190—195 °C, was inferred to be a 2′,3′-dehydro derivative of yadanzioside H (**8**) from the following observations. The molecular formula, $C_{32}H_{44}O_{16}$, was determined by the peak at *m/z* 707 due to $[M+Na]^+$ in the SIMS and the presence of $(CH_3)_2C$=CH- grouping (δ 1.67 (3H, s), 2.14 (3H, s), and 5.82 (1H, brs)) was revealed by the ^1H NMR spectrum.

On hydrolysis with β-glycosidase, yadanzioside E (**6**) afforded an aglycone (**19**), the ^1H NMR spectrum being compatible with the proposed structure. The aglycone (**19**) was oxidized with manganese dioxide in DMF to give a keto alcohol (**20**). The molecular formula, $C_{26}H_{32}O_{11}$, of **20** was determined by high-resolution mass spectrum and the presence of the $(CH_3)_2C$=CH- grouping was confirmed by a peak at *m/z* 83 characteristic of $[(CH_3)_2C=CH-C^+=O]$ together with ^1H NMR spectrum. Thus the structure of yadanzioside E (**6**) was proposed to be a 2β-D-glucoside of the aglycone (**19**). The proposed structure was firmly established as follows. Yadanzioside E (**6**) was hydrogenated over 10% palladium on carbon in ethanol to give a tetrahydro derivative, which was completely identical with the dihydro derivative (**18**) obtained from yadanzioside H (**8**).

Prior to yadanziosides, a fraction containing new quassinoids was eluted from the silica-gel column chromatography of the filtrate obtained by the separation of brusatol (**1**) (*loc. cit.*). The fraction was further subjected to separation by silica-gel column chromatography and then by reversed-phase preparative TLC to give new quassinoids, dehydrobrusatol (**9**) and dehydrobruceantinol (**10**).

Dehydrobrusatol (**9**), mp 157—160 °C, gave the molecular formula, $C_{26}H_{30}O_{11}$, in EI-high-resolution mass spectrum, which is two hydrogen atoms less than that of brusatol (**1**). The mass spectrum also showed prominent peaks at *m/z* 436 ($[M-82]^+$), and *m/z* 83, which indicate the presence of $(CH_3)_2C$=CH-CO- grouping. Dehydrobrusatol (**9**) exhibited the UV absorption maximum at 256 nm, which shifted to 340 and 262 nm on addition of alkali. This behavior is characteristic of dehydro-type quassinoids, such as dehydrobruceantin (**21**),[12] which shows the UV maxima at 259 and 225 nm and the former absorption shifts to 340 and 263 nm on addition of alkali. The ^1H NMR spectrum of **9** is similar to that of dehydrobruceantin (**21**) except for the side chain. These observations led to the structure (**9**) for dehydrobrusatol and the structure was supported by chemical transformation; brusatol (**1**) was treated with 2,3-dichloro-5,6-dicyano-*p*-benzoquinone (DDQ) in boiling benzene to give a dehydro product in 64% yield, which was identical with dehydrobrusatol (**9**).

Dehydrobruceantinol (**10**), mp 152—154 °C, showed the peak at *m/z* 627 due to $[M+Na]^+$ in the SIMS, which corresponds to the molecular formula, $C_{30}H_{36}O_{13}$. The EI-high-resolution mass spectrum gave a dehydration peak at *m/z* 586.2064. The ^1H NMR spectrum of **10** measured at 400 MHz was given in Table 1. Comparison with dehydrobrusatol (**9**) as to the skeletal structure and with bruceantinol (**13**) as to the side chain led to the construction of the structure (**10**) for dehydrobruceantinol.

Yadanziosides A, B, C, D, E, and G showed antileukemic activities against the murine P388 lymphocytic leukemia at a 10 mg/kg dose level and their ILS values[15] were 7.1, 4.1, 2.0, 9.2, 7.1, and 4.1%, respectively. These activities were found to be slightly stronger than that (ILS value; 2.0%) of bruceoside A.

Experimental[16]

Extraction and Separation. Pulverized seeds (60 kg) of *B. javanica* were defatted with hexane (100 l) twice and then extracted with methanol (100 l) twice. The methanol extract was concentrated *in vacuo* to give a syrup, to which the equal volume of water was added. The aqueous solution was completely defatted with hexane (7 l) three times and extracted with dichloromethane five times. The organic layer was concentrated to give a residue, which was dissolved in methanol kept at *ca.* 60 °C. The methanolic solution was allowed to stand at room temperature to afford brusatol (**1**) as crystals, which was filtered off. The filtrate was evaporated to give an oily residue (160 g), a part (36 g) of which was separated by the following procedures.

Column A. The oily residue (36 g) was subjected to separation by silica-gel (575 g) column chromatography.

Elution (each fraction 1 l) with PhH–AcOEt (2:1) gave fractions 1—7, PhH–AcOEt (1:1) fractions 8—16, AcOEt fractions 17—22, and AcOEt–MeOH fractions 23—32. Fraction 20 afforded brucein D (736 mg).

Column **B**. The fraction 9 of Column **A** yielded brusatol (**1**; 4.1 g) as crystals on standing, which was filtered off. The mother liquor, on evaporation, gave a residue (980 mg), which was chromatographed on silica gel (150 g) eluted with 5% MeOH in $CHCl_3$ (each fraction 30 ml). The fraction 20 (56 mg) was further separated by preparative TLC (RP-2, developed with H_2O–MeOH (6:4) twice) to give dehydrobrusatol (**9**; 13.6 mg), dehydrobrucein A (7.5 mg), and dehydrobruceantinol (**10**; 5.5 mg).

Column **C**. The fractions 23 and 24 of Column **A** were combined and evaporated to afford a residue (17.6 g), a part (10.7 g) of which was chromatographed on silica gel (865 g). Low layers of the following solvent-ratios of $CHCl_3$–MeOH–H_2O were used for elution (each fraction 400 ml): fractions 1—6; 25:4:1, fractions 7—10; 20:4:1, and fractions 11—24; 16:4:1.

Column **D**. The fractions 12 and 13 (1.5 g) of Column C were subjected to separation by a Lobar column (RP-8) eluted with MeOH–H_2O (4:6) and a total of 142 fractions (each 10 g) were collected. Fractions 30—63 gave bruceoside A (792 mg). Yadanziosides A (**2**; 151 mg) and G (**7**; 300 mg) were obtained from fractions 75—86 and 88—111, respectively. Fractions 113—125 afforded bruceantinoside A (24 mg).

Column **E**. The fraction 14 (932 mg) of Column C was purified by partition chromatography on silicic acid (400 g) absorbed with water (270 ml). Elution (each fraction 250 ml) was performed with 0, 3, 6,···24% EtOH in $CHCl_3$ (each 1 l).

Column **F**. The fractions 16 and 17 of Column **E** were combined (524 mg) and chromatographed using a Lobar column (RP-8). Elution was carried out with MeOH–H_2O and 28 fractions (each 10 g) were collected.

Column **G**. The fractions 17—24 (291 mg) of Column **F** were chromatographed on Toyopearl HW-40S eluted with MeOH (each 10 g). Fractions 37—39 (207 mg) were further purified by silica-gel (30 g) column chromatography eluted with a low layer of $CHCl_3$–MeOH–H_2O (16:4:1) to give yadanzioside E (**6**; 123 mg).

Column **H**. The fractions 25—28 (47 mg) of Column **F** were chromatographed using Toyopearl HW-40S. Elution with MeOH afforded yadanzioside H (**8**; 32 mg).

Column **I**. The fractions 16 (958 mg) of Column C was subjected to separation by partition chromatography on silicic acid (400 g) absorbed with water (270 ml). Elution (each 250 ml) was performed with 0, 3, 6, 9,···24% EtOH in $CHCl_3$ (each 1 l). Fractions 26—29 and 32—34 afforded yadanzioside D (**5**; 68 mg) and brucein E (35 mg), respectively.

Column **J**. The fractions 17—20 (681 mg) of Column **I** were chromatographed on a Lobar column (RP-8). Elution with MeOH–H_2O (1:1, each fraction 10 g) afforded bruceoside B (147 mg) from fractions 11—13. Fractions 18 and 19 were combined (62 mg) and further purified using Toyopearl HW-40S eluted with MeOH to give yadanzioside B (**3**; 52 mg).

Column **K**. The fractions 22—24 (128 mg) of Column **I** were chromatographed using Toyopearl HW-40S. Elution with MeOH afforded yadanzioside C (**4**; 86 mg).

Yadanzioside B (3). Amorphous solid, mp 189—195 °C (decomp), $[\alpha]_D^{26}$ −8.1° (*c* 0.84, EtOH); IR (KBr) 3425, 1735, 1635, and 1050 cm^{-1}; UV (ethanol) 255 nm (ε 8300); MS (SIMS) *m/z* 707 ($[M+Na]^+$), 523, and 439; High-resolution MS (EI) *m/z* 522.2082. Calcd for $C_{26}H_{34}O_{11}$ ($M-C_6H_{10}O_5$): *m/z* 522.2099.

Acid Hydrolysis of 3. Yadanzioside B (**3**; 36 mg) was treated with 1.5 M sulfuric acid (7 ml) and methanol (7 ml) at reflux temperature for 5 h. The usual work-up gave brucein A (**11**; 6 mg).

A solution of **3** (>1 mg) in a mixture of acetyl chloride (0.05 ml) and dry methanol (0.5 ml) was refluxed for 16 h. The reaction mixture was concentrated *in vacuo* to yield methyl D-glucoside, which was treated with trimethylsilyl chloride (10 μl) in pyridine (50 μl) and hexamethyldisilazane (5 μl). The trimethylsilylated product was identified by GLC retention time (9.4 min) by comparison with an authentic sample.

Yadanzioside A (2). Amorphous solid, mp 200—204 °C (decomp): $[\alpha]_D^{26}$ +3° (*c* 1.8, ethanol); IR (KBr) *ca.* 3400, 1740, 1675, 1625, and 1040 cm^{-1}; UV (ethanol) 256 nm (ε 5900); MS (SIMS) *m/z* 707 ($[M+Na]^+$), 523, 439, 421, and 403; High-resolution MS (EI) *m/z* 522.2127. Calcd for $C_{26}H_{34}O_{11}$ ($M-C_6H_{10}O_5$): *m/z* 522.2099.

Enzymatic Hydrolysis of 2. A mixture of yadanzioside A (**2**; 43 mg) and β-glucosidase (23 mg, Product of Sigma Chemical Company) in water (5 ml) was kept 2 weeks at 37 °C. The mixture was added to ethanol and heated at 80 °C for 10 min. After being cooled, the mixture was filtered and the filtrate was evaporated to dryness *in vacuo*. The residue was subjected to purification by column chromatography (C-200, 10 g) eluted with 10% MeOH in $CHCl_3$ to yield brucein A (**11**; 13 mg) as the aglycone and the starting material (20 mg). The aglycone, brucein A, was completely identical with an authentic sample.

Yadanzioside C (4). Amorphous solid, mp 204—209 °C (decomp); $[\alpha]_D^{26}$ +20° (*c* 0.92, ethanol); IR (KBr) 3445, 1740, 1680, 1640, and 1070 cm^{-1}; UV (ethanol) 221 nm (ε 14800) and 254 nm (ε 7800); MS (SIMS) *m/z* 749 ($[M+Na]^+$), 709, 673, 565, 547, 521, 439, 185, and 127; High-resolution MS (EI) *m/z* 564.2230. Calcd for $C_{28}H_{36}O_{12}$ ($M-C_6H_{10}O_5$): *m/z* 564.2207.

Acid Hydrolysis of 4. A solution of yadanzioside C (**4**; 38 mg) in 1.5 M sulfuric acid (10 ml) and methanol (10 ml) was refluxed for 5 h. The usual work-up gave brucein C (**12**; 13 mg), which was identical with an authentic sample.

A solution of **4** (>1 mg) in a mixture of dry methanol (0.5 ml) and acetyl chloride (0.05 ml) was refluxed for 16 h and the usual work-up afforded methyl D-glucoside.

Yadanzioside G (7). Amorphous solid, mp 180—185 °C (decomp); $[\alpha]_D^{22}$ +19° (*c* 1.2, ethanol); IR (KBr) 3450, 1740, 1685, 1645, 1075, 1050, and 1025 cm^{-1}; UV (ethanol) 222 nm (ε 16000) and 253 nm (ε 7800); MS (SIMS) *m/z* 791 ($[M+Na]^+$), 547, 127, and 109; High-resolution MS (EI) *m/z* 546.2103. Calcd for $C_{28}H_{34}O_{11}$ ($M-C_6H_{10}O_5-C_2H_4O_2$): *m/z* 546.2101.

Enzymatic Hydrolysis of 7. A solution of **7** (66 mg) and β-glucosidase (23 mg) in water (8 ml) was kept at 37 °C for 2 weeks and worked up as before to give bruceantinol

(**13**; 14 mg) and the starting material (31 mg).

Yadanzioside D (5). Amorphous soilid, mp 207—212 °C (decomp); $[\alpha]_D^{20}$ +38° (*c* 0.98, ethanol); IR (KBr) 3430, 1745, 1640, 1065, and 1040 cm^{-1}; MS (EI) *m/z* (%) 480 (0.8), 464 (1.5), 446 (1.4), 438 (1), 169 (27), 73 (100), 60 (72), and 57 (72); High-resolution MS (EI) *m/z* 480.1610. Calcd for $C_{23}H_{28}O_{11}$ ($M-C_6H_{12}O_5$): *m/z* 480.1630.

Enzymatic Hydrolysis of 5. Yadanzioside D (**5**; 29 mg) was hydrolyzed with β-glucosidase (10 mg) for 2 weeks at 37 °C to give an aglycone (**14**; 8 mg) and the starting material (**5**; 7 mg). **14**: mp 218—219 °C (from acetone-hexane); $[\alpha]_D^{26}$ +16° (*c* 0.63, pyridine); IR (KBr) 3450, 1745, 1640, 1060, and 1035 cm^{-1}; ^1H NMR (pyr-d_5, 90 MHz) δ=1.52 (3H, s; 10-Me), 1.55 (3H, brs; 4-Me), 2.09 (3H, s; 15-OAc), 2.60 (2H. br; 5- and 9-H), 3.78 (3H, s; CO_2Me), 3.85 (1H, d, *J*=8 Hz; 20-H), 3.90 (1H, br; 14-H), 4.01 (1H, d, *J*=8 Hz; 1-H), 4.50 (1H, m; 2-H),4.91 (1H, t-like; 7-H), 5.05 (1H, br; 12-H), 5.20 (1H, d, *J*=7 Hz; 20-H), 5.50 (1H, d, *J*=6 Hz; 11-H), 5.71 (1H, br; 3-H), and 6.76 (1H, d, *J*=13 Hz; 15-H); MS (EI) *m/z* (%) 482 (M^+; 2), 464 (6), 446 (8), 422 (5), 404 (7), 60 (100), and 57 (80); High-resolution MS (EI) *m/z* 482.1764. Calcd for $C_{23}H_{30}O_{11}$: *m/z* 482.1786.

Oxidation of 14 with Manganese Dioxide. The aglycone (**14**; 7 mg) was stirred with manganese dioxide (115 mg, preheated at 110 °C) in DMF (3 ml) for 6 h. The reaction mixture was filtered and the residue was washed with methanol. The filtrate and washings were combined and evaporated. The residue was purified by column chromatography on silica gel (C-200, 3 g). Elution with chloroform-methanol-water (16:4:1) gave isobrucein B (**15**; 5 mg), which was identified by comparison with an authentic specimen.

Yadanzioside H (8). Amorphous solid, mp 180—185 °C (decomp); $[\alpha]_D^{24}$ +33° (*c* 1.03, ethanol); IR (KBr) 3450, 1750, 1640, 1065, and 1040 cm^{-1}; MS (SIMS) *m/z* 709 ($[M+Na]^+$), 523, 507, and 439; MS (EI) *m/z* (%) 522 (0.6), 506 (0.6), 488 (2.7), 474 (2.2), 456 (3.8), 438 (4.2), 169 (26), 85 (59), and 57 (100); High-resolution MS (EI) *m/z* 522.2091. Calcd for $C_{26}H_{34}O_{11}$ ($M-C_6H_{12}O_5$): *m/z* 522.2099.

Enzymatic Hydrolysis of 8. Yadanzioside H (**8**; 43 mg) was hydrolyzed with β-glucosidase (15 mg) in water (5 ml) at 37 °C for 2 weeks to give an aglycone (**16**; 15 mg) and the starting material (**8**; 17 mg). **16**: mp 162—165 °C (from acetone-hexane); IR (KBr) 3455, 1750, 1640, 1060, and 1040 cm^{-1}; $[\alpha]_D^{26}$ +10° (*c* 1.0, pyridine); ^1H NMR (pyr-d_5, 90 MHz) δ=0.94 and 0.97 (each 3H, d, *J*=7 Hz; 3′-Me), 1.52 (3H, s; 10-Me), 1.53 (3H, brs; 4-Me), 2.60 (2H, br; 5- and 9-H), 3.80 (3H, s; CO_2Me), 3.85 (1H, d, *J*=8 Hz; 20-H), 3.98 (1H, d, *J*=7 Hz; 1-H), 4.50 (1H, m; 2-H), 4.87 (1H, brs; 7-H), 5.05 (1H, br; 12-H), 5.19 (1H, d, *J*=8 Hz; 20-H), 5.48 (1H, brd, *J*=5 Hz; 11-H), 5.70 (1H, br; 3-H), and 6.82 (1H, d, *J*=13 Hz; 15-H); MS (EI) *m/z* (%) 524 (M^+; 0.1), 506 (1), 85 (60), and 57 (100); Found: *m/z* 524.2279. Calcd for $C_{26}H_{36}O_{11}$: M, 524.2257.

Oxidation of 16 with Manganese Dioxide. The aglycone (**16**; 14 mg) was treated with manganese dioxide (230 mg) in DMF (4 ml) for 6 h. The same work-up as before afforded isobrucein A (**17**; 3 mg), which was identical with an authentic sample.

Hydrogenation of Yadanzioside H (8). A solution of yadanzioside H (**8**; 20 mg) in ethanol (3 ml) was hydrogenated in the presence of 10% palladium on carbon (10 mg) for 10 h. The usual work-up and separation by silica-gel chromatography afforded a dihydro derivative (**18**; 18 mg), mp 201—205 °C (from acetone-hexane); ^1H NMR (pyr-d_5, 90 MHz) δ=0.65 (3H, brs; 4-Me), 0.94 and 0.96 (each 3H, d, *J*=7; 3′-Me), 2.31 (2H, s; 2′-H), 3.80 (3H, s; CO_2Me), and 6.84 (1H, d, *J*=13 Hz; 15-H); ^{13}C NMR (pyr-d_5, 22.5 MHz) δ=12.9, 19.5, 22.5, 22.5, 25.8, 28.7, 29.2, 41.5, 43.4, 44.1, 44.6, 45.9, 46.9, 50.7, 52.3, 62.8, 68.4, 71.6, 73.6, 75.7, 75.9, 76.0, 78.6, 78.7, 82.4, 82.5, 83.5, 84.2, 106.9, 168.3, 171.5, and 171.6; MS (EI) *m/z* (%) 526 (0.2), 508 (0.6), 490 (0.7), 476 (0.7), 442 (0.6), 424 (1.5), 407 (1.7), 406 (2.4), 392 (1.9), 388 (1.6), 376 (1.5), 374 (1.5), 358 (1.6), 348 (2.4), 318 (2.8), 126 (17), 85 (50), 73 (24), 69 (32), 60 (100), and 57 (72).

Yadanzioside E (6). Amorphous solid, mp 190—195 °C (decomp); $[\alpha]_D^{23}$ +59° (*c* 1.6, ethanol); IR (KBr) 3450, 1740, 1645, 1080, 1060, and 1040 cm^{-1}; MS (SIMS) *m/z* 707 ($[M+Na]^+$), 519, 505, and 439; High-resolution MS (EI) *m/z* 520.1928. Calcd for $C_{26}H_{32}O_{11}$ ($M-C_6H_{12}O_5$): *m/z* 520.1943.

Enzymatic Hydrolysis of 6. Yadanzioside E (**6**; 39 mg) in water (5 ml) was enzymatically hydrolyzed with β-glucosidase (17 mg) at 37 °C for 2 weeks. The usual work-up and separation afforded an aglycone (**19**; 18 mg), mp 162—164 °C (from acetone-hexane); IR (KBr) 3450, 1740, 1645, 1055, and 1035 cm^{-1}; ^1H NMR (pyr-d_5, 90 MHz) δ=1.54 (6H, brs; 4- and 10-Me), 1.66 and 2.14 (each 3H, s; 3′-Me), 2.60 (2H, br; 5- and 9-H), 3.74 (3H, s; CO_2Me), 4.02 (1H, d, *J*=8 Hz; 1-H), 4.50 (1H, m; 2-H), 4.94 (1H, br; 7-H), 5.08 (1H, br: 12-H), 5.21 (1H, d, *J*=8 Hz; 20-H), 5.51 (1H, m; 11-H), 5.71 (1H, br; 3-H), 5.80 (1H, brs; 2′-H), and 6.75 (1H, d, *J*=13 Hz; 15-H); MS (EI) *m/z* (%) 522 (M^+; 0.1), 504 (0.4), 486 (3), and 83 (100); Found: *m/z* 522.2108. Calcd for $C_{26}H_{34}O_{11}$: M, 522.2102.

Oxidation of 19 with Manganese Dioxide. Oxidation of the aglycone (**19**; 15 mg) with manganese dioxide (245 mg) in DMF (3 ml) for 6 h gave a keto alcohol (**20**; 3 mg) after purification by silica-gel (5 g) column chromatography eluted with 10% MeOH in $CHCl_3$ **20**: Amorphous, mp 162—164 °C (from acetone-hexane); IR (KBr) 3460, 1750, 1675, 1660, 1085, 1065, and 1040 cm^{-1}; UV (ethanol) 222 nm (ε 17600); ^1H NMR ($CDCl_3$, 90 MHz) δ=1.19 (3H, s; 10-Me), 1.94 (3H, d, *J*=1 Hz; 3′-Me), 1.96 (3H, s; 4-Me), 2.19 (3H, brs; 3′-Me), 3.78 (3H, s; CO_2Me), 4.16 (1H, s; 1-H or 12-H), 4.29 (1H, brs; 12-H or 1-H), 4.77 (1H, br; 7-H), 4.82 (1H, d, *J*=6 Hz; 20-H), 5.64 (1H, brs; 2′-H), 6.12 (1H, brs; 3-H), and 6.23 (1H, d, *J*=14 Hz; 15-H); MS (EI) *m/z* (%) 520 (M^+; 0.7), 502 (1.5), and 83 (100); Found: *m/z* 520.1968. Calcd for $C_{26}H_{32}O_{11}$: M, 520.1943.

Hydrogenation of Yadanzioside E (6). Yadanzioside E (**6**; 46 mg) in ethanol (6 ml) was hydrogenated in the presence of 10% palladium on carbon (30 mg) for 4 h. The reaction product was worked up as usual to give a tetrahydro derivative (46 mg). The physical and spectral data were completely identical with those of **18**, obtained by the hydrogenation of yadanzioside H (**8**).

Dehydrobrusatol (9). Amorphous solid, mp 157—160 °C (from acetone-hexane); $[\alpha]_D^{22}$ +57° (*c* 1.4, ethanol); IR (KBr) 3440, 1740, 1635, 1140, 1080, and 1060 cm^{-1}; UV (ethanol) 256 nm (ε 7500); (ethanol+KOH) 340 nm and 262 nm; MS (EI) *m/z* (%) 518 (M^+; 1), 436 (>0.1), and 83 (100); Found: *m/z* 518.1784. Calcd for $C_{26}H_{30}O_{11}$: M, 518.1787.

Dehydrogenation of Brusatol (1). A solution of brusatol (**1**; 20 mg) in benzene (2 ml) was refluxed with DDQ (12 mg) for 6 h under nitrogen atmosphere. The reaction product was subjected to separation by silica-gel column chromatography. Elution with 3% 2-propanol in dichloromethane gave crude dehydrobrusatol (**9**; 16 mg), which was further chromatographed on silica gel. Elution with 1% methanol in chloroform afforded dehydrobrusatol (**9**; 13 mg), whose physical and spectral data were identical with those of the natural dehydrobrusatol (**9**).

Dehydrobruceantinol (10). Amorphous solid, mp 152—154 °C (from acetone-hexane); $[\alpha]_D^{22}$ +39° (*c* 0.45, ethanol); IR (KBr) 3445, 1740, 1635, 1260, 1165, and 1060 cm^{-1}; UV (ethanol) 255 nm (ε 8400); (ethanol+KOH) 336—340, 262, and 229 nm; MS (SIMS) *m/z* 627([M+Na]$^+$) and 567; High-resolution MS (EI) *m/z* 586.2064 and *m/z* 526.1866. Calcd for $C_{30}H_{34}O_{12}$ (M−H_2O): *m/z* 586.2051 and $C_{28}H_{30}O_{10}$ (M−H_2O−AcOH): *m/z* 526.1839, respectively.

The authors wish to thank Mr. Hideo Naoki of Suntory Institute for Bioorganic Research for measurement of SIMS.

(Received May 24, 1985)

13β,18β-Epoxybaccharan-3β-yl acetate was treated with boron trifluoride etherate in acetic anhydride to afford a complex mixture, in which a formation of backbone rearrangement products, *D*:*C*-friedobacchar-9(11)-en- and -7-en-3β-yl acetates together with 3β-acetoxy-*D*-friedo-13,18-secobacchar-13-en-18-ylidene diacetate was observed. The *D*:*C*-friedobacchar-9(11)-ene derivative is the first example of the backbone rearrangement product formed by a sequential migration of two methyl groups and a hydride towards the biogenetic direction in baccharene-shionene series.

In biogenetic processes of triterpenes, some proceed enzymatically in direction to produce thermodynamically unstable products.[2)] A biogenesis of friedelin from oleanene-type precursor is known as a typical example of such energetically unfavorable processes.

Owing to the greater thermodynamic stability of the oleanene skeleton, most of the chemically-induced backbone rearrangement in oleanene-friedelene series proceed in the opposite direction from the biogenesis. On treatment with acid, for example, fridel-3-ene affords an equilibrium mixture of olean-13(18)-ene and 18α-olean-12-ene.[2)] Besides oleanene-friedelene series, the reactions of ursene-, lupene-, and baccharene-type triterpenes with acid do not give friedo-type triterpenes which would be produced by the biogenetic-like backbone rearrangement. However, it is possible to bring about the energetically unfavorable rearrangement in the biogenetic direction by combination with a free-energy releasing reaction which provides the thermodynamic driving force. Corey *et al.*[3)] reported backbone rearrangements of oleanene derivatives in the biogenetic direction under oxidative conditions. Paryzek[4)] and Baddeley *et al.*[5)] described the acid-catalyzed reaction of 9(11)-epoxylanostane derivatives in order to effect $C_{10}\rightarrow C_9$ methyl rearrangement. In these reactions, however, only one methyl group shifted towards biogenetic-like direction. Occurrence of a sequential multigroup rearrangement has never been observed so far.

The thermodynamic stability of baccharane skeleton was demonstrated by the following evidence. Treatment of bacchar-13(18)-en-3β-yl acetate (**1**)[6)] with hydrogen chloride in chloroform was found to yield a 1:1 mixture of bacchar-12-en-3β-yl acetate (**2**) and the starting material (**1**) by GLC examination; no skeletal rearrangement occurred. On the other hand, it has been shown that shiona-3,21-diene (**3**) is rearranged on treatment with boron trifluoride etherate ($BF_3\cdot OEt_2$) to give *D*:*C*-friedobaccharа-9(11),21-diene (**4**) and bacchara-12,21-diene (**5**),[7)] Therefore the baccharane skeleton was proved to be thermodynamically the most stable skeleton in the baccharene-shionene series.

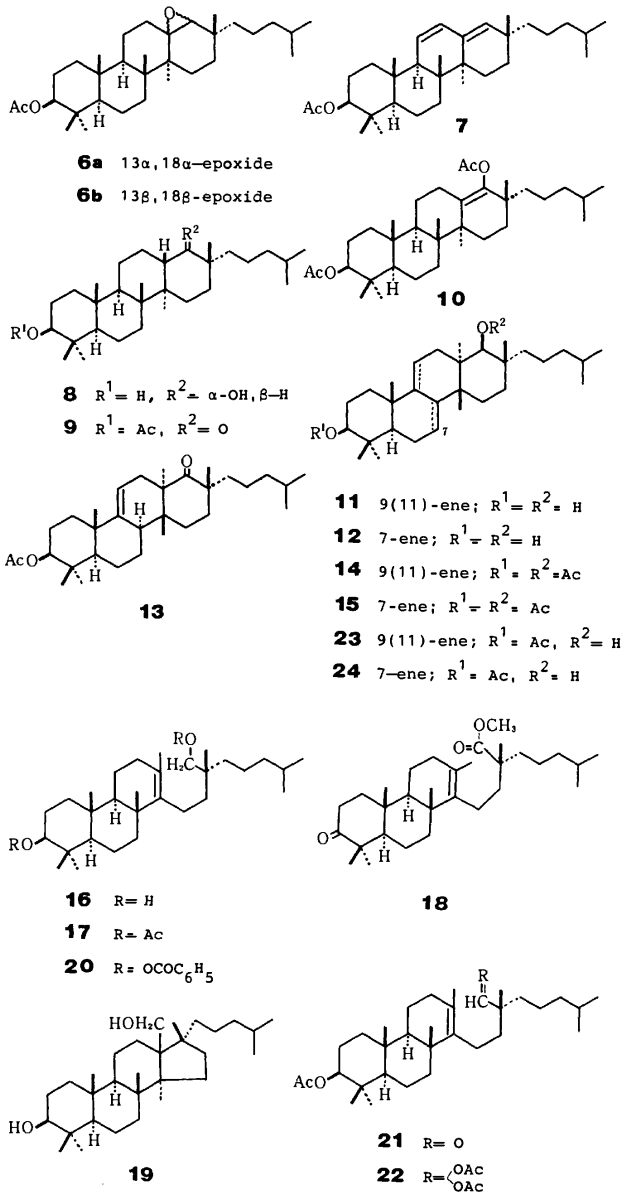
5

Paryzek[4b)] recommended the use of acetic anhydride as a solvent in a $BF_3\cdot OEt_2$-catalyzed backbone rearrangement, because BF_3–Ac_2O system is expected to be a useful reagent in which efficient skeletal rearrangements induced by an epoxide cleavage may proceed. Therefore, backbone rearrangement of 13β,18β-epoxybaccharan-3β-yl acetate (**6b**) in acetic anhydride was first examined.

13β,18β-Epoxybaccharan-3β-yl acetate (**6b**) was prepared by epoxidation of bacchar-13(18)-en-3β-yl acetate (**1**)[6,8)] with *m*-chloroperbenzoic acid (MCPBA). The epoxidation product was a mixture of α- and β-epoxides (**6a** and **6b**) in a ratio of 1:9, which was separated by silica-gel column chromatography. The

configuration of the epoxy ring was easily assignable from the ^{1}H NMR spectra.

13β,18β-Epoxybaccharan-3β-yl acetate (**6b**) was treated with $BF_3 \cdot OEt_2$ in acetic anhydride at 0 °C. The reaction product was separated by silica-gel column chromatography into three fractions, **A**, **B**, and **C**.



The fraction **A** was found to be bacchara-11,13(18)-dien-3β-yl acetate (**7**)[6] from the spectral data. The fraction **B** and **C** were shown to be mixtures by ^{1}H NMR spectral measurement, but each could not be separated by silica-gel column chromatography. The fraction **B** gave complicated signals appearing at δ 2.03, 2.07 (each *ca.* 3H, s), 4.45 (1H, dd), 4.90 and 4.92 (total *ca.* 0.7H, each s), and *ca.* 5.3 (*ca.* 0.5H, m). The fraction **C** showed complex signals appearing at δ 2.04, 2.06, 2.09, and 2.20 (each s), 3.35 (0.3—0.4H, m), *ca.* 4.45 (1H, m), 4.87 (0.3—0.4H, s), *ca.* 5.3 (0.1—0.2H, m), 6.69 and 6.71 (total *ca.* 0.4H, each s). On treatment with lithium aluminium hydride, the fraction **B** could be separated into three compounds, $\mathbf{B_1}$, $\mathbf{B_2}$, and $\mathbf{B_3}$ and the fraction **C** three compounds, $\mathbf{C_1}$, $\mathbf{C_2}$, and $\mathbf{C_3}$ by silica-gel column chromatography, respectively.

The compound $\mathbf{B_1}$ was identical with an authentic baccharane-3β,18α-diol (**8**).[8] Therefore the initial rearranged product is deduced to be bacchar-13(18)-ene-3β,18-diyl diacetate (**10**), which was formed directly by abstraction of the hydrogen or *via* 18-oxobaccharan-3β-yl acetate (**9**)[9] followed by acetylation under the reaction conditions (Scheme 1 [**A**]-*b*). The formation of **9** was supported by the rearrangement of **6b** in benzene (*vide infra*).

The compound $\mathbf{B_2}$, $C_{30}H_{52}O_2$, was a diol with a trisubstituted double bond, which was proved from the presence of a multiplet signal due to an olefinic proton at δ 5.38 in the ^{1}H NMR spectrum and characteristic fragment ion peaks at *m/z* 259 and *m/z* 247 in the mass spectrum. Comparison with olefinic signals of friedo-type triterpenes (see Table 1) revealed that the olefinic proton observed at δ 5.38 is corresponding to that of either 7-ene, 9(11)-ene, or 14-ene. A formation of the fragment ions at *m/z* 259 and *m/z* 247 is indicative of the presence of either 7-ene, 8-ene, or 9(11)-ene.[13] From these observations, the compound $\mathbf{B_2}$ was inferred to be either *D:C*-friedobacchar-9(11)-ene-3β,18β-diol (**11**) or a 7-ene isomer (**12**). On acetylation followed by oxidation, the compound $\mathbf{B_2}$ afforded a keto acetate (**13**), which showed a multiplet signal due to the olefinic proton at δ 5.38 in the ^{1}H NMR spectrum and fragment ion peaks at *m/z* 343 and *m/z* 344 in the mass spectrum. However, since further information concerning the exact position of the double bond could not be obtained from the spectral inspection for compound $\mathbf{B_2}$ and its derivative (**13**), X-ray single crystal analysis was carried out for the keto acetate (**13**). The crystals of **13** belong to a monoclinic, space group $P2_1$, and the lattice parameters are a=17.273(9), b=11.981(5), and c=7.323(3) Å, β=99.13(3)°, and D_c=1.08 g·cm^{-3} with two molecules in a unit cell. Intensity data were measured on a Philips PW1100 automatic four-circle diffractometer using monochromated Cu $K\alpha$ radiation. A total of 2349 non-zero, independent reflections with $3° \leq \theta \leq 78°$ were obtained by 2θ—θ scanning mode. The structure was solved by the direct method using MULTAN program and was refined by the block-diagonal least-squares method. All hydrogen atoms were located on a difference electron density map. The final R value was 0.056 assuming the anisotropic temperature factors for non-hydrogen atoms and the isotropic ones for the hydrogen atoms. The final atomic coordinates are listed in Table 2 and bond lengths and bond angles

are listed in Tables 3 and 4.[14] Figure 1 is a computer-generated perspective drawing of the molecule of the keto acetate (**13**).

Thus the structure of the keto acetate was determined to be 18-oxo-*D*:*C*-friedobacchar-9(11)-en-3β-yl aceteate (**13**) and therefore the compound **B**$_2$ is formulated as *D*:*C*-friedobacchar-9(11)ene-3β,18β-diol (**11**). This conclusion implies that the reaction product obtained by the backbone rearrangement of **6b** was *D*:*C*-friedobacchar-9(11)-ene-3β,18β-diyl diacetate (**14**).

The compound **B**$_3$, $C_{30}H_{52}O_2$, was shown to be a double-bond isomer of **B**$_2$ from the spectral data; it showed a multiplet signal at δ 5.35 in the ^{1}H NMR spectrum and fragment ion peaks at *m/z* 259 and *m/z* 247 in the mass spectrum. These spectral data lead to the conclusion that the compound **B**$_3$ is formulated as *D*:*C*-friedobacchar-7-ene-3β,18β-diol (**12**) and therefore the rearranged product is *D*:*C*-friedobacchar-7-ene-3β,18β-diyl diacetate (**15**).

The compound **C**$_1$ (**16**) showed the molecular formula, $C_{30}H_{54}O_2$ by the high-resolution mass spectrum and the ^{1}H NMR spectrum revealed the presence of two hydroxyl groups; one is secondary (δ 3.17, 1H, dd) and the other primary (δ 3.36, 2H, s). Since no signal due to unsaturation was observed in the ^{1}H NMR spectrum, the compound **C**$_1$ was inferred to be either a tetracyclic saturated diol or a tricyclic diol with a tetrasubstituted double bond. On acetylation, the compound **C**$_1$ afforded a diacetate (**17**), $C_{34}H_{58}O_4$, whose ^{1}H NMR spectrum showed the presence of an acetoxymethyl group (δ 3.82, 2H, s and δ 2.04, 3H, s) together with a secondary acetoxyl group (δ 4.46, 1H, dd and δ 2.04, 3H, s).

The presence of the hydroxymethyl group in the compound **C**$_1$ was confirmed by the following chemical conversion. The compound **C**$_1$ was oxidized with Jones reagent to give a keto carboxylic acid, which, without purification, was treated with diazomethane. The reaction product (**18**) showed the molecular ion at *m/z* 472 ($C_{31}H_{52}O_3$) and the presence of $COOCH_3$ group (δ 3.67, 3H,s; 1730 cm^{-1}) together with a carbonyl group (1705 cm^{-1}). From these evidence and mechanistic consideration, the structure of the compound **C**$_1$ was inferred first to be 17(18→13)*abeo*-baccharane-3β,18-diol (**19**). However, this structure assignment was found to be erroneous by X-ray diffraction analysis of the dibenzoate (**20**). Crystals of the dibenzoate (**20**) belong to orthorhombic, space group $P2_12_12_1$, and the lattice parameters are a=17.071(5), b=21.191(6), and c=10.870(3) Å and D_c=1.10 g·cm^{-3}. Four molecules are contained in the unit cell. Intensity data were measured by the same procedure as before and a total of 3173 non-zero, independent reflections with $3°\leq\theta\leq78°$ were obtained by 2θ—θ scanning mode. The structure was solved and refined by the same procedure as before. The final R value was 0.066

Table 1. δ-Values of olefinic protons of friedo-type triterpenes

Compound	δ-Value	Lit,
Bacchar-5-en-3β-ol	5.62 m (6-H)	10)

a) $B_{eq}=8\pi^2(u_1^2+u_2^2+u_3^2)/3$.

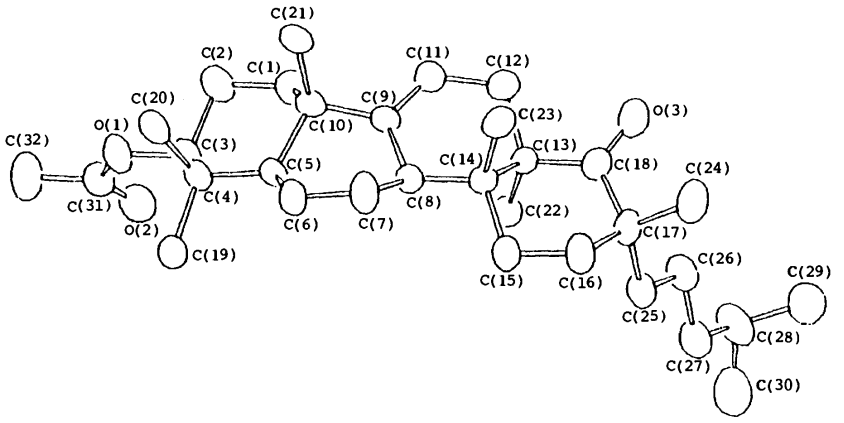

Fig. 1. Perspective view of 18-oxo-*D* : *C*-friedobacchar-9(11)-en-3β-yl acetate (**13**).

assuming the anisotropic temperature factors for non-hydrogen atoms and the isotropic ones for hydrogen atoms. The final atomic coordinates are listed in Table 5 and bond lengths and bond angles are listed in Tables 6 and 7.[14] Figure 2 is a computer-generated perspective drawing of the molecule of the dibenzoate (**20**), the structure being formulated as *D*-friedo-13,18-secobacchar-13-ene-3β, 18-diyl dibenzoate (**20**). Therefore, it is concluded that the initial rearranged product had been 3β-acetoxy-*D*-friedo-13,18-secobacchar-13-en-18-al (**21**), which was converted into its acylal (**22**) in the reaction conditions. This conclusion is supported by the presence of a singlet signal due to the acylal proton at δ 6.71 or δ 6.69 in the ^{1}H NMR spectrum of the fraction **C** (*loc. cit.*).

The compound **C$_3$** showed a molecular ion peak at *m/z* 488, which indicates an increment corresponding to a substituent, CH_3-CH(OH)-, compared with those of the olefinic diols **B$_2$** (**11**) and **B$_3$** (**12**). Therefore, the initial reaction product of the backbone rearrangement was deduced to possess an additional acetyl group. It is conceivable that the olefin, such as **14** or **15**, which had been produced by the rearrangement was subjected to acetylation, because the rearrangement conditions could bring about Friedel-Crafts reaction. However, further investigation on the structure of **C$_3$** could not carried out because of a paucity of the material.

Since the compound **C$_2$** was found to be a complex mixture of compounds derived from acetylated products by the ^{1}H NMR spectrum, this fraction was not further examined.

On treatment with $BF_3 \cdot OEt_2$ in acetic anhydride, 13β,18β-epoxybaccharan-3β-yl acetate (**6b**) has been shown to afford backbone rearrangement products, *D*:*C*-friedobacchar-9(11)- and -7-ene-3β,18β-diyl diacetates (**14** and **15**), 3β-acetoxy-*D*-friedo-13,18-secobacchar-13-en-18-ylidene diacetate (**22**), and many unidentified acetylated products. Formation of these reaction products can be reasonably explained by the reaction pathway depicted as in Scheme 1. The epoxide ring of **6b** was cleaved by the attack of $BF_3 \cdot Et_2O$ to give a carbonium ion [**A**] at C-13. Deprotonations, *a* and *b*, would produce **7** and **10**, respectively, while a consecutive 1,2-methyl migration (pathways *c* and *d*) would yield a carbonium ion [**C**] at C-8, which affords **15** and **14** by deprotonation and 1,2-hydride shift (*f*) followed by deprotonation, respectively. The formation of *D*:*C*-friedobacchar-9(11)-ene derivative (**14**) is thus demonstrated by a sequential shift of 14α-Me, 8β-Me, and 9α-H of the baccharane skeleton to 13α-Me, 14β-Me, and 8α-H, respectively. It is noteworthy that the formation of

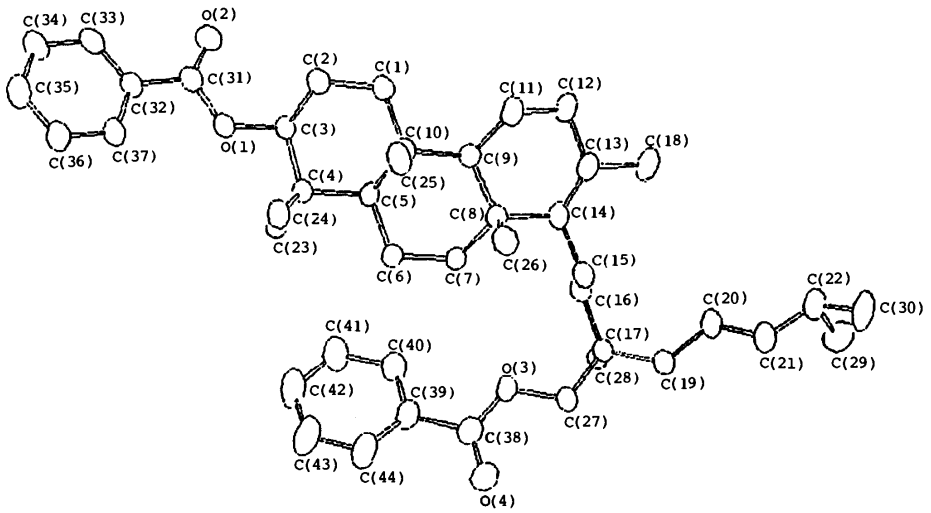

Fig. 2. Perspective view of *D*-friedo-13,18-secobacchar-13-ene-3β,18-diyl dibenzoate (**20**).

a) $B_{eq}=8\pi^2(u_1^2+u_2^2+u_3^2)/3$.

The formation of seco-acylal (**22**) is interpreted in terms of mechanism involving 1,2-alkyl migration (*c*) followed by a bond fission (*e*). These skeletal rearrangements appear often in sesquiterpene oxides such as β-patchoulene oxide[15] or cyperene oxide,[16] and they also encounter in triterpene epoxides; for example 18,19-epoxylupane derivatives are transformed into 18,19-seco-lup-13(18)-ene (=baccha-r-13(18)-ene) derivatives on treatment with $BF_3\cdot OEt_2$.[17]

In this rearrangement reaction, a formation of Friedel-Crafts type acetylation products was observed, and these products caused the complication in the separation procedure. Then the backbone rearrangement reaction was examined in benzene.

13β,18β-Epoxybaccharan-3β-yl acetate (**6b**) was treated with $BF_3\cdot OEt_2$ in benzene at room temperature for 30 min. The reaction product was separated into five compounds by silica-gel chromatography.

The first-eluted compound was shown to be bacchara-11,13(18)-dien-3β-yl acetate (**7**). The second compound was also a known 18-oxobaccharan-3β-yl acetate (**9**),[9] which was identified with an authentic sample prepared by acetylation of 18-oxobaccharan-3β-ol.[8]

The third compound showing a singlet signal at δ 9.45 (1H) in the ^{1}H NMR spectrum, was inferred to

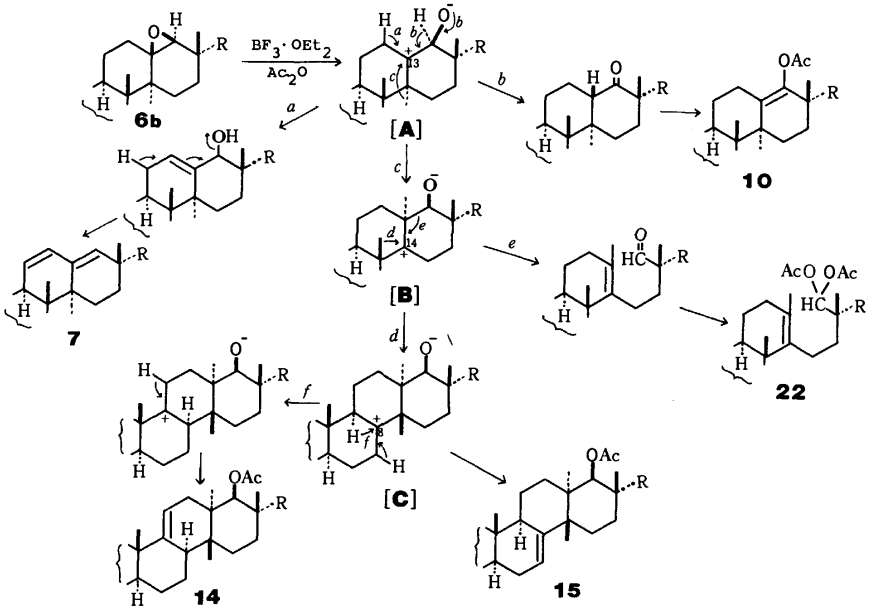
be an aldehyde (**21**) with the secobaccharene skeleton, the structure of which was confirmed by chemical conversion into *D*-friedo-13,18-secobacchar-13-ene-3β,18-diol (**16**) by lithium aluminium hydride-reduction. Therefore, the structure of the third compound was determined to be 3β-acetoxy-*D*-friedo-13,18-secobacchar-13-en-18-al (**21**).

The fourth compound (δ 3.33 (1H, s), 4.46 (1H, dd), and 5.35 (1H, m); *m/z* 486, 301, and 289) and the fifth compound (δ 3.34 (1H, s), 4.47 (1H, dd), and 5.31 (1H, m); *m/z* 486, 301, and 289) were suggested to be 18β-hydroxy-*D*:*C*-friedobacchar-9(11)- and -7-en-3β-yl acetates (**23** and **24**), respectively from the spectral data. These compounds were found to be identical with those obtained by acetylation of the corresponding diols (**11** and **12**), respectively.

Previously we reported that the $BF_3 \cdot OEt_2$-catalyzed backbone rearrangement of 3,4-epoxytriterpenes in solvents with low nucleophilicity proceeds up to C, D, or E ring to give 12-, 18-, or 19-ene derivative, while the rearrangement in solvents with high nucleophilicity, such as diethyl ether or tetrahydrofuran, is interupted in early stage to afford *D*:*A*- or *D*:*B*-friedo type triterpenes preferentially.[10,11,18-20] In order to examine the migratory aptitude, the epoxide (**6b**) was treated with $BF_3 \cdot OEt_2$ in various solvents and the results were summarized in Table 8.

In backbone rearrangement reactions in the



Scheme 1.

a) Determined by GLC. b) Calculated from isolated yield. c) The reaction products are the corresponding acetates or acylal.

energetically unfavorable direction, it is anticipated that the effects of the nucleophilicity of the solvents on the degree of the rearrangement were larger than in energetically favorable rearrangements. In fact, the table showed that relative yields of thermodynamically unfavorable products (**23** and **24**) increased in hexane and benzene, while they decreased in diethyl ether and tetrahydrofuran. Furthermore, it is also proved that acetic anhydride is a useful solvent which enables the effective backbone rearrangement.

Experimental

General Procedures. Melting points were measured on a Mel-temp capillary melting point apparatus (Laboratory Devices) and are uncorrected. IR spectra were measured with a Hitachi 260-30 spectrometer, mass spectra with a JMS-D300 (JEOL) mass spectrometer at 70 eV with a direct inlet system, and ^1H NMR spectra with a Varian EM-390 (90 MHz) spectrometer. Chemical shifts are expressed in δ (ppm downfield from TMS as an internal standard) and coupling constants in Hz. GLC analysis was carried out on a Shimadzu Gas Chromatograph GC-6A equipped with a hydrogen-flame ionization detector. Thin-layer chromatography was carried out on Kieselgel 60 GF_{254} (E. Merck) coated in 0.25 mm-thickness (for analytical) and in 0.5 mm-thickness (for preparative). Wakogel C-200 (Wako) was used for silica-gel column chromatography.

Treatment of Bacchar-13(18)-en-3β-yl Acetate (1) with Hydrogen Chloride. A solution of bacchar-13(18)-en-3β-yl acetate (**1**; 27.8 mg) in chloroform (30 ml) was saturated with dry hydrogen chloride and the solution was stirred for 22 h at room temperature. After the usual work-up, the reaction product was examined by GLC (column: Dexsil-300GC, temperature: 270—300 °C (5 °C/min), N_2: 60 ml/min) and was shown to be a 1:1 mixture of 13(18)-ene (**1**) and 12-ene (**2**). The retention times were 9.3 and 11.3 min for **1** and **2**, respectively.

Epoxyidation of Bacchar-13(18)-en-3β-yl Acetate (1). Bacchar-13(18)-en-3β-yl acetate (**1**; 114 mg) was dissolved in dichloromethane (5 ml) and the solution was stirred with

MCPBA (110 mg) and sodium hydrogencarbonate (300 mg) at room temperature. The reaction product was treated with a sodium hydrogensulfite solution, worked-up usually, and was subjected to separation by column chromatography on silica gel (120 g). Elution with hexane–ether (96:4) gave 13α,18α-epoxide (**6a**; 10 mg) and 13β,18β-epoxide (**6b**; 95 mg). **6a**: mp 182—183 °C (from $CHCl_3$–MeOH); IR (KBr) 1735 and 1255 cm^{-1}; ^1H NMR ($CDCl_3$) δ=2.0 (3H, s, Ac), 2.3 (1H, s, 18β-H), and 4.5 (1H, m, 3α-H); MS *m/z* (%) 486 (M^+; 63), 468 (21), and 383 (100); Found: *m/z* 486.4020. Calcd for $C_{32}H_{54}O_3$: M, 486.4071. **6b**: mp 130.5—131.5 °C (from $CHCl_3$–MeOH); IR (KBr) 1740 and 1255 cm^{-1}; ^1H NMR ($CDCl_3$) δ=2.0 (3H, s, Ac), 2.65 (1H, s, 18α-H), and 4.5 (1H, m, 3α-H); MS *m/z* (%) 486 (M^+, 35), 468 (92), 383 (100); Found: *m/z* 486.4046. Calcd for $C_{32}H_{54}O_3$; M, 486.4071.

Backbone Rearrangement of 13β,18β-Epoxybaccharan-3β-yl Acetate (6b) in Acetic Anhydride. 13β,18β-Epoxybaccharan-3β-yl acetate (**6b**; 230 mg) was dissolved in freshly distilled acetic anhydride (50 ml). To the solution kept at 0 °C, $BF_3 \cdot OEt_2$ (0.2 ml) was added and the stirring was continued for 2 h. The reaction product was then poured into a cold mixture of a saturated sodium hydrogencarbonate solution (50 ml) and ether (200 ml) with vigorous stirring and the ethereal layer was separated. The aqueous layer was extracted with ether and the ethereal extract was combined with the ether layer, washed with brine, and dried over sodium sulfate. The organic extract, after evaporation, was dissolved in hexane and the solution was charged on a column of silica gel (25 g) covered with Florisil (2 g). Elution was performed with 5% ethyl acetate in hexane and 19 fractions (each 50 ml) were collected. Fractions 4 and 5, fractions 6—10, and fractions 14—19 afforded, on evaporation, fractions **A** (20 mg), **B** (115 mg), and C (80 mg), respectively.

The fraction **A** was identical with an authentic baccharа-11,13(18)-dien-3β-yl acetate (**7**)[6] in every respect.

Hydrolysis and Separation of Fraction B. The fraction **B** (115 mg), dissolved in tetrahydrofuran (THF) (15 ml), was heated with lithium aluminium hydride (LAH) (25 mg) at reflux for 30 min. The reaction product was worked up as usual and subjected to separation by column chromatography on silica gel (10 g). Elution with 10% ethyl acetate in hexane gave a mixture (*ca.* 100 mg) of compound B_1 (**8**) and compound B_2 (**11**) (fractions 15—18, each 20 ml) and compound B_3 (**12**; 11.5 mg, fractions 19—22). The mixture was subjected to further separation by column chromatography on silica gel (5 g) and eluted with hexane–dichloromethane–ethyl acetate (20:20:1) to afford **8** (42 mg) and **11** (42 mg). Baccharane-3β,18α-diol (**8**): mp 164—167 °C (from Et_2O–MeOH); IR (Nujol) 3500 and 3350 cm^{-1}; ^1H NMR ($CDCl_3$) δ=3.2 (1H, m) and 3.25 (1H, br s); MS *m/z* 446 (M^+), 428, 410, and 95 (base peak); Found: *m/z* 446.4190. Calcd for $C_{30}H_{54}O_2$: M, 446.4123. *D:C*-Friedobacchar-9(11)-ene-3β,18β-diol (**11**): mp *ca.* 202 °C (decomp) (from MeOH); IR (Nujol) 3450—3400 cm^{-1}. ^1H NMR ($CDCl_3$) δ=3.21 (1H, dd, *J*=10 and 6 Hz; $C_{(3\alpha)}$-H), 3.38 (1H, s; $C_{(18\alpha)}$-H), and 5.38 (1H, m; $C_{(11)}$-H); MS *m/z* 444 (M^+), 429, 411, 408, 393 (base peak), 259, 247, 241, and 229; Found: *m/z* 444.3959. Calcd for $C_{30}H_{52}O_2$: M, 444.3967. *D:C*-Friedobacchar-7-ene-3β,18β-diol (**12**): mp 230—233 °C (from MeOH); IR (film) 3430 cm^{-1}; ^1H NMR ($CDCl_3$) δ=3.24 (1H, dd, *J*=9 and 6 Hz; $C_{(3\alpha)}$-H), 3.34 (1H, s; $C_{(18\alpha)}$-H, and 5.35 (1H, m; $C_{(7)}$-H); MS *m/z* 444 (M^+), 429, 426, 411, 408, 393, 383, 259 (base peak), 247, 241, and 229.

Hydrolysis and Separation of Fraction C. The fraction C (80 mg) was dissolved in THF (10 ml) and treated with LAH (20 mg) at reflux temperature for 30 min. The reaction product was worked up as before to afford an oily residue (70 mg), which was subjected to separation by column chromatography on silica gel (4 g). Elution with 10% ethyl acetate in hexane gave compound C_1 (**16**; 20 mg), 20% ethyl acetate in hexane a mixture C_2 (25 mg), and 33% ethyl acetate in hexane compound C_3 (16 mg), respectively.

Compound C_1, *D*-friedo-13,18-secobacchar-13-ene-3β,18-diol (**16**): mp 99—103 °C (from MeOH); IR (Nujol) 3450 cm^{-1}; ^1H NMR ($CDCl_3$) δ=1.55 (3H, s; $C_{(13)}$-CH_3), 3.17 (1H, dd, *J*=9 and 6 Hz; $C_{(3\alpha)}$-H) and 3.36 (2H, s, CH_2-OH); MS *m/z* 446 (M^+), 431, 428, 413, 275 (base peak), and 257; Found: *m/z* 446.4088. Calcd for $C_{30}H_{54}O_2$: M, 446.4121.

Since the compound C_2 was found to be a complex mixture of compounds derived from acetylated rearranged products, further examination was not carried out.

Compound C_3: IR (Nujol) 3380 cm^{-1}; ^1H NMR ($CDCl_3$) δ=3.23 (1H, dd, *J*=10 and 6 Hz; $C_{(3\alpha)}$-H), 3.32 (1H, s; $C_{(18\alpha)}$-H), and 4.20 (1H, m; -CH(OH)CH_3); MS *m/z* 488 (M^+), 443, 429, 425, 407, 397, and 223.

*18-Oxo-*D:C*-friedobacchar-9(11)-en-3β-yl Acetate (13).* *D:C*-Friedobacchar-9(11)-ene-3β,18β-diol (**11**; 43 mg) was treated with acetic anhydride and pyridine at room temperature overnight to afford a diacetate (**14**; 6.5 mg) and a monoacetate (**23**; 30 mg). Diacetate (**14**): mp 179.5—181 °C (from MeOH); IR (Nujol) 1745, 1735, and 1245 cm^{-1}. ^1H NMR ($CDCl_3$) δ=2.02 and 2.06 (each 3H, s; OAc), 4.50 (1H, m; $C_{(3\alpha)}$-H), 4.90 (1H, s; $C_{(18\alpha)}$-H), and 5.35 (1H, m; $C_{(11)}$-H); MS *m/z* 528 (M^+), 513, 468 (base peak), 453, 393, 301, and 241; Found: *m/z* 528.4124. Calcd for $C_{34}H_{56}O_4$. Monoacetate (**23**): mp 244—248 °C (from $CHCl_3$–MeOH), IR (Nujol) 3550 and 1740 cm^{-1}. ^1H NMR ($CDCl_3$) δ=3.33 (1H, s; $C_{(18\alpha)}$-H), 4.46 (1H, dd, *J*=9 and 6 Hz; $C_{(3\alpha)}$-H), and 5.35 (1H, m; $C_{(11)}$-H); MS *m/z* 486 (M^+), 471, 453, 426, 411, 393, 383, 301 (base peak), 289, 241, and 229; Found: *m/z* 486.4028. Calcd for $C_{32}H_{54}O_3$: M, 486.4073.

The monoacetate (**23**; 29 mg) in acetone (10 ml) was oxidized with Jones reagent (0.05 ml) at 0 °C for 20 min. The usual work-up and crystallization from chloroform–methanol gave a keto acetate (**13**; 9 mg), mp 115.5—117.5 °C; IR (film) 1740, 1692, and 1245 cm^{-1}; ^1H NMR ($CDCl_3$) δ=2.05 (3H, s; OAc), 4.47 (1H, dd, *J*=10 and 6 Hz; $C_{(3\alpha)}$-H), and 5.38 (1H, m; $C_{(11)}$-H); MS *m/z* 484 (M^+), 469, 409, 400, 344, and 343 (base peak); Found: *m/z* 484.3919. Calcd for $C_{32}H_{52}O_3$: M, 484.3917.

D-*Friedo-13,18-secobacchar-13-ene-3β,18-diyl Diacetate (17).* Acetylation of a diol (**16**) by the usual procedure gave a diacetate (**17**) as an oily material, IR (film) 1745 and 1250 cm^{-1}; ^1H NMR ($CDCl_3$) δ=1.53 (3H, s; $C_{(13)}$-CH_3), 2.04 (6H, s; 2×OAc), 3.82 (2H, s; -CH_2-OAc), and 4.46 (1H, dd, *J*=9 and 6 Hz; $C_{(3\alpha)}$-H); MS *m/z* 530 (M^+), 470, 455, 395, 317 (base peak), and 257; Found: *m/z* 530.4261. Calcd for $C_{34}H_{58}O_4$: M, 530.4333.

D-*Friedo-13,18-secobacchar-13-ene-3β,18-diyl Dibenzoate (20).* A diol (**16**; 5 mg) was treated with benzoyl chloride and pyridine at room temperature for 6 h. The usual work-up and crystallization from chloroform–methanol gave a dibenzoate (**20**; 2.5 mg), mp 135.5—137.5 °C; IR (film) 1715,

1280, 1120, and 720 cm^{-1}; ^1H NMR ($CDCl_3$) δ=1.53 (3H, s; $C_{(13)}$-CH_3), 4.07 (2H, brs; CH_2-OBz) 4.63 (1H, dd, J=9 and 6 Hz; $C_{(3\alpha)}$-H), and 7.9—8.1 (10H; aromatic protons); MS m/z 532 ($M-C_6H_5COOH)^+$, 517, 489, 410 ($M-2\times C_6H_5COOH)^+$, 395, 257, and 57 (base peak); High resolution MS m/z 532.4278. Calcd for $C_{37}H_{56}O_2$ ($M-C_6H_5COOH$): m/z 532.4278.

Methyl 3-Oxo-D-friedo-13,18-secobacchar-13-en-18-oate (18). A solution of a diol (**16**; 10 mg) in acetone was treated with an excess of Jones reagent. After addition of isopropyl alcohol, the reaction mixture was filtered through a column of Florisil. The filtrate gave, on evaporation, a keto carboxylic acid, which was dissolved in ether and methylated with diazomethane. The reaction product was purified by column chromatography on silica gel, eluted with 10% ethyl acetate in hexane to afford a keto methyl ester (**18**; 5 mg), IR (film) 1730 and 1705 cm^{-1}; ^1H NMR ($CDCl_3$) δ=1.53 (3H, s; $C_{(13)}$-CH_3), 2.35—2.6 (2H; $C_{(2)}$-H_2) and 3.67 (3H, s; -$COOCH_3$); MS m/z 472 (M^+), 440, 412, 384, 343, 315, 291, and 69 (base peak).

Backbone Rearrangement of 13β,18β-Epoxybaccharan-3β-yl Acetate (6b) in Benzene. A solution of 13β,18β-epoxide (**6b**; 115 mg) in dry benzene (5 ml) was treated with $BF_3\cdot OEt_2$ (0.02 ml) at room temperature for 30 min with stirring. The reaction product was worked up as before and separated by column chromatography on silica gel (4 g). Bacchara-11,13(18)-dien-3β-yl acetate (**7**; 58.5 mg) was eluted with 3% ethyl acetate in hexane. Elution with 5% ethyl acetate in hexane gave 18-oxobaccharan-3β-yl acetate (**9**; 18.8 mg) and an aldehyde (**21**; 7.3 mg), and elution with 10% ethyl acetate in hexane gave 18β-hydroxy-*D:C*-friedobacchar-9(11)-en-3β-yl acetate (**23**; 17.8 mg) and its 7-ene isomer (**24**; 11.5 mg). 18-Oxobaccharan-3β-yl acetate (**9**):[9] mp 184.5—186 °C (from $CHCl_3$-MeOH); IR (Nujol) 1725, 1700, and 1245 cm^{-1}; ^1H NMR ($CDCl_3$) δ=2.67 (1H, m; $C_{(17)}$-H) and 4.47 (1H, dd, J=10 and 6 Hz; $C_{(3\alpha)}$-H); MS m/z 486 (M^+), 468, 426, 411, 408, and 402; Found: m/z 486.4111. Calcd for $C_{32}H_{54}O_3$: M, 486.4073. Aldehyde (**21**): ^1H NMR ($CDCl_3$) δ=1.52 (3H, s; $C_{(13)}$-CH_3), 2.03 (3H, s; $C_{(3\beta)}$-OAc), 4.46 (1H, dd, J=9 and 6 Hz; $C_{(3\alpha)}$-H), and 9.45 (1H, s; $C_{(17)}$-CHO). The aldehyde (**21**; 5 mg) was converted into a diol (**16**) by reduction with LAH (5 mg). 18β-Hydroxy-*D:C*-friedobacchar-9(11)-en-3β-yl acetate (**23**): mp 244—248 °C (from $CHCl_3$-MeOH); IR (Nujol) 3350 and 1740 cm^{-1}; ^1H NMR ($CDCl_3$) δ=2.0 (3H, s; $C_{(3\beta)}$-OAc), 3.33 (1H, s, $C_{(18\alpha)}$-H), 4.46 (1H, dd, J=9 and 6 Hz; $C_{(3\alpha)}$-H), and 5.35 (1H, m; $C_{(11)}$-H); MS m/z 486 (M^+), 471, 453, 426, 411, 393, 383, 301, 289, 241 (base peak), and 229; Found: m/z 486.4028. Calcd for $C_{32}H_{54}O_3$: M, 486.4073. 18β-Hydroxy-*D:C*-friedobacchar-7-en-3β-yl acetate (**24**): mp 77—78 °C (from MeOH); IR (Nujol) 3550, 1725, and 1245 cm^{-1}; ^1H NMR ($CDCl_3$) δ=2.03 (3H, s; $C_{(3\beta)}$-OAc), 3.34 (1H, s; $C_{(18\alpha)}$-H), 4.47 (1H, m; $C_{(3\alpha)}$-H), and 5.31 (1H, m; $C_{(7)}$-H); MS m/z 486 (M^+), 471, 411, 301, 289, 241, and 229; Found: m/z 486.4084. Calcd for $C_{32}H_{54}O_3$: M, 486.4073.

Acetylation of Diols (11 and 12). Diols (**11** and **12**) were acetylated with acetic anhydride and pyridine at room temperature to afford acetates (**23** and **24**), respectively, which were identifid by ^1H NMR, MS, and TLC.

Backbone Rearrangement of 13β,18β-Epoxybaccharan-3β-yl Acetate (6b) in Diethyl Ether and in Other Solvents. 13β, 18β-Epoxide (**6b**; 30 mg) was treated with $BF_3\cdot OEt_2$ in diethyl ether and the usual work-up and separation by chromatography gave a diene (**7**; 18 mg), a ketone (**9**; 4.5 mg), an aldehyde (**21**; 1 mg), 9(11)-en (**23**; 1 mg), and 7-ene (**24**; 3 mg).

A small amount of 13β,18β-epoxide (**6b**) was treated with $BF_3\cdot OEt_2$ in hexane, dichloromethane, acetonitrile, and THF, respectively, and each reaction product, after the usual work-up, was examined by GLC (column: Dexsil-300GC, temperature: 240—290 °C (5 °C/min)). The relative yields of products were given in Table 8 and their retention times were 9.0, 10.6, 13.5, 14.1, and 14.9 min for **7**, **21**, **24**, **9**, and **23**, respectively.

X-Ray Photoelectron Spectra of Halogen-bridged One-dimensional Pd^{II}–Pd^{IV} Mixed-valence Complexes, $[Pd(en)_2][PdX_2(en)_2](ClO_4)_4$

Masahiro YAMASHITA,* Ichiro MURASE, and Isao IKEMOTO†

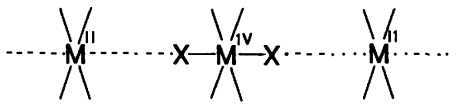
Laboratory of Chemistry, College of General Education, Kyushu University, Ropponmatsu, Fukuoka 810

†*Department of Chemistry, Faculty of Science, Tokyo Metropolitan University, Setagaya-ku 158*

(Received March 2, 1985)

Synopsis. X-Ray photoelectron spectra of $[Pd^{II}(en)_2][Pd^{IV}X_2(en)_2](ClO_4)_4$ (en=ethylenediamine, X=Cl and Br) were measured. The difference in the binding energies of Pd3d between Pd^{II} and Pd^{IV} in the bromo-bridged complex is smaller than that in the chloro-bridged complex. This result is consistent with those of the crystal structures, electrical conductivities, and electronic spectra previously reported.

Recently halogen-bridged one-dimensional M^{II}–M^{IV} mixed-valence complexes of Pt, Pd, and Ni have attracted much interest from the various viewpoints of the chemistry and physics of low-dimensional compounds.[1,2] In these complexes, the four-coordinate M^{II} and six-coordinate M^{IV} are stacked alternately with bridging halogens as shown below.[3-5] In the Pt complexes, it has been pointed out



that the ratio between the Pt^{IV}–X and Pt^{II}...X distances increases consecutively and approaches unity on going from the chloro to the iodo homologs, suggesting that the difference between the oxidation states of Pt^{II} and Pt^{IV} decreases in the order of Cl>Br>I. This was clearly verified by the X-ray photoelectron spectra and XANES.[6,7] These results coincide with those of the electrical conductivities, and electronic and emission spectra.[8,9] On the other hand, to our knowledge, X-ray photoelectron spectral studies on the Pd^{II}–Pd^{IV} mixed-valence complexes are few. In this study, the X-ray photoelectron spectra of the Pd^{II}–Pd^{IV} mixed-valence complexes, $[Pd(en)_2][PdX_2(en)_2](ClO_4)_4$ (X=Cl and Br) have been measured in order to evaluate the oxidation states of Pd atoms in the mixed-valence complexes. The results are compared with those of the crystal structures,[10,11] electronic spectra,[9] and electrical conductivities.[8]

Experimental

The Pd^{II}–Pd^{IV} mixed-valence complexes, $[Pd(en)_2][PdX_2(en)_2](ClO_4)_4$ (X=Cl and Br) were prepared by the method previously reported.[12]

The X-ray photoelectron spectra were obtained with a Mg-$K\alpha$ exciting irradiation on a SHIMADZU ESCA 750. The spectrometer was calibrated by using Cls (285.0 eV).

Results and Discussion

Figure 1 shows the X-ray photoelectron spectra of $Pd3d_{5/2}$ and $Pd3d_{3/2}$ for the $[Pd(en)_2][PdX_2(en)_2](ClO_4)_4$. These compounds were very susceptible to X-ray irradiation damage and thereby the spectra changed gradually with time during the measurements as has been experienced in the Ni^{II}–Ni^{IV} mixed-valence complexes.[13,14] Therefore, the spectral measurements were carried out as quick as possible at a lower voltage.

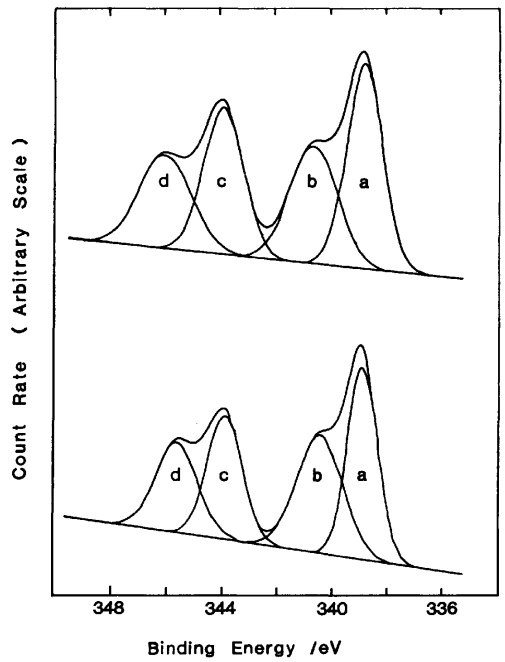


Fig. 1. X-Ray photoelectron spectra of $[Pd(en)_2][PdX_2(en)_2](ClO_4)_4$.
Top and bottom spectra are X=Cl and Br, respectively. Each spectrum is resolved into four components by simulation. a: $Pd^{II}3d_{5/2}$, b: $Pd^{IV}3d_{5/2}$, c: $Pd^{II}3d_{3/2}$, d: $Pd^{IV}3d_{3/2}$.

For the Pd^{II}–Pd^{IV} mixed-valence complexes, the spectra should be interpreted as a superposition of four bands, *i.e.*, $3d_{5/2}$ and $3d_{3/2}$ of Pd^{II} and Pd^{IV}. We have resolved the observed spectra into the Pd^{II} and Pd^{IV} components by the computer simulation. Although the intensities of Pd^{II} and Pd^{IV} components are assumed to be essentially the same as each other, the intensity of Pd^{IV} component is a little smaller than that of the Pd^{II} one. This is probably due to X-ray irradiation damage. Moreover, the intensity of the resolved Pd^{IV} spectra decreased, whereas that of the Pd^{II} spectra increased with time of X-ray irradiation. Since the spectral intensity corresponds to the number of species, it can be said from the observation that the decrease of the Pd^{IV} species were

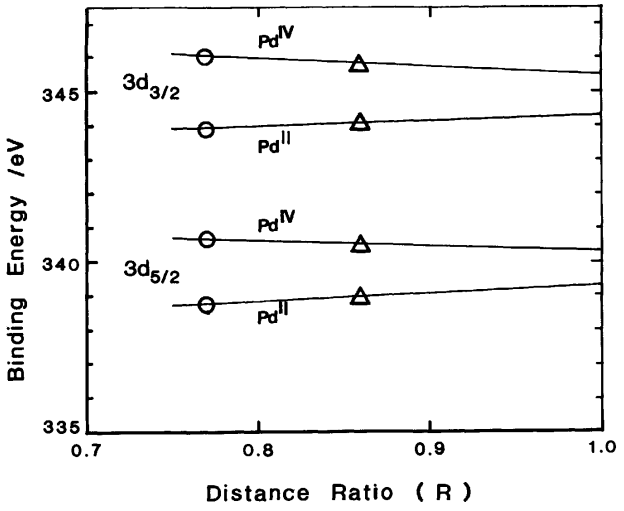

Fig. 2. Correlation between distance ratios and binding energies.
○: $[Pd(en)_2][PdCl_2(en)_2](ClO_4)_4$, △: $[Pd(en)_2][PdBr_2(en)_2](ClO_4)_4$.

roughly equal to the increase of the Pd^{II} species. This indicates that the Pd^{IV} state is decomposed to produce the Pd^{II} state. Quite a similar spectral change due to X-ray irradiation has been observed in the Ni^{II}–Ni^{IV} mixed-valence complexes.[13,14]

As the bridging halogen shifts from Cl to Br, the $Pd^{IV}3d$ binding energies become lower while those of the Pd^{II} become higher. The difference in the binding energies of $Pd3d_{5/2}$ between Pd^{II} and Pd^{IV} in the bromo-bridged complex (1.6 eV) is smaller than that in the chloro-bridged complex (1.9 eV). This result is essentially consistent with that of the crystal structures, that is, the ratio (R) between the Pd^{IV}–X and Pd^{II}...X distances in the bromo-bridged complex (0.86) is larger than that in the chloro-bridged complex (0.77) as listed in Table 1.[10,11] Therefore, we can estimate roughly the Pd^{III} binding energy as shown in Fig. 2 by the extrapolation procedure to R=1 in the correlation between the binding energies and the distance ratios.

Since the difference between the oxidation states of the Pd^{II} and Pd^{IV} in the bromo-bridged complex is smaller than that in the chloro-bridged complex as shown in the X-ray photoelectron spectra, the wave number of the intervalence charge transfer from Pd^{II} to Pd^{II} along the chain is lower in the bromo-bridged complex than in the chloro-bridged complex.[9] In the same way, the activation energy in the electrical conductivity, which is mainly concerned with the oxidation states of Pd^{II} and Pd^{IV}, is smaller in the bromo-bridged complex than in the chloro-bridged complex.[8]

Reaction Volume for the OH^- Addition to Hexafluoroacetylacetonate Ligand on Co^{III} Complex

Yoichi KITAMURA

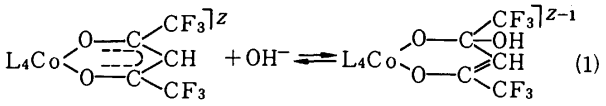
Department of Chemistry, Faculty of Science, Ehime University, Matsuyama, Ehime 790

(Received March 14, 1985)

Synopsis. For the title reaction in water: $L_4Co(hfac)^z+OH^-=L_4Co(hfacOH)^{z-1}$, reaction volumes ($\Delta V°$) at infinite dilution were obtained at 25 °C, where A_4 is $(NH_3)_4$, $(en)_2$, α-trien, β-trien, $f(N)$-*i*-dtma, α-edda, β-edda, and Hhfac stands for hexafluoroacetylacetone. The resulting $\Delta V°$ values supported the addition of OH^- to $CoA_4(hfac)^z$.

In our recent report, a unique character was clarified for the reaction between an OH^- ion and a Co^{III} complex containing a hfac ligand in water.[1] That is, the color of a $CoL_4(hfac)^z$ complex changes rapidly and reversibly upon a pH change of the solution.

This phenomenon can be explained by a shift in the following equilibrium:[1,2]



(1)

In another work, $\Delta V°$ was obtained for 19 acid-base reactions of an octahedral complex:[3]

$$MA^z + OH^- = MB^{z-1} + H_2O \quad (2)$$

In Reaction 2, MA^z is an octahedral transition-metal (Pt^{IV}, Rh^{III}, Co^{III}) complex with ligand A=H_2O, NH_3, and $C_2O_4H^-$; MB^{z-1} is the corresponding conjugate base complex with ligand B=OH^-, NH_2^-, and $C_2O_4^{2-}$, where the charge (z) on the reactant ranges from -2 to 4. The $\Delta V°$'s at 25 °C for these reactions can be summarized as:

$$\Delta V° = (-2.5\pm0.2)\Delta Z^2 + (14.5\pm0.8)\ \mathrm{cm^3\ mol^{-1}}, \quad (3)$$

where ΔZ^2=(charge of the product complex)^2−(charge of the reactant complex)^2=1−2z, and the first term in Eq. 3 corresponds to the electrostatic volume contribution due to the interaction with solvent and the second to the intrinsic volume of ions.

Interest has been developed here regarding whether the distinct difference between Reactions 1 and 2 is reflected in their reaction volumes. Thus, in the present work, $\Delta V°$ of Reaction 1 has been obtained dilatometrically for seven $CoL_4(hfac)^z$ complexes. Their magnitudes are discussed in relation to Eq. 3.

Experimental

The respective complex (perchlorate) was obtained and identified in a previous work.[1]

Dilatometry was carried out using a Carlsberg dilatometer as described before.[3] 15 cm^3 of an aqueous complex solution was mixed with 3 cm^3 of NaOH and the resulting volume change (Δv_{exptl}) was observed. Generally, two runs were performed at one condition. The correction term (Δv_{corr}) for the change in the ionic strength upon mixing was calculated as before.[3] $\Delta V°$ has been calculated from $\Delta v_o=\Delta v_{exptl}-\Delta v_{corr}$, where the degree of the completion of the neutralization process (R%) has been taken into account.

Results and Discussion

The dilatometric results and the reaction volume obtained, therefrom, are summarized in Tables 1 and 2. The experimental $\Delta V°$'s range from moderately positive to moderately negative. Thus, the main contribution to $\Delta V°$ may be ascribed to the solvational change around the complex during Reaction 1.[4]

The $\Delta V(3)$ in Table 2 is the reaction volume calculated upon inserting the relevant value of ΔZ^2 into Eq. 3. The value definitely differs from the corresponding experimental $\Delta V°$. On the other hand, assuming that the difference in the electrostriction volume for $CoL_4(hfacOH)^{z-1}$ and $CoL_4(hfac)^z$ equals (-2.5 ± 0.2) $cm^3\ mol^{-1}$, the volume change of Reaction 1 can be predicted as follows by the use of

Table 1. Dilatometric results at 25 °C

Complex[a]	C[b]/mM	NaOH/mM	$\Delta v_{exptl}/\mu l$	$\Delta v_{corr}/\mu l$	R%
$[Co(NH_3)_4hfac](ClO_4)_2$	10	50	1.55, 1.63	−0.14	100
		100	1.39	−0.20	100

b) Complex concentration.

Table 2. Volume change ($cm^3\ mol^{-1}$) for the reaction of $CoL_4(hfac)^z$ with OH^- ion in water at 25 °C

Complex	ΔZ^2	Experimental	Calculated	
		$\Delta V°$	$\Delta V(3)$	$\Delta V(4)$
$Co(NH_3)_4hfac^{2+}$	−3	11.2±0.4	22.0±1.4	6.1±2.6
$Co(en)_2hfac^{2+}$	−3	10.7±0.1	22.0±1.4	6.1±2.6
α-Co(trien)hfac^{2+}	−3	8.9±0.4	22.0±1.4	6.1±2.6
β-Co(trien)hfac^{2+}	−3	11.1±0.3	22.0±1.4	6.1±2.6
f(*N*)-Co(*i*-dtma)hfac$^+$	−1	1.6±0.5	17.0±1.0	1.1±2.2
α-Co(edda)hfac	1	−8.3±0.9	12.0±1.0	−3.9±2.2
β-Co(edda)hfac	1	−3.9±0.3	12.0±1.0	−3.9±2.2

$\overline{V}(OH^-)=1.4\pm2\ cm^3\ mol^{-1}$:[5]

$$\Delta V° = (-2.5\pm0.2)\Delta Z^2 - (1.4\pm2)\ cm^3\ mol^{-1} \quad (4)$$

The experimental $\Delta V°$'s agree fairly well with those $\Delta V(4)$ calculated using Eq. 4. Thus, the magnitudes of the experimental $\Delta V°$'s reinforce the suggestion that the origin of the rapid and reversible color change of the $CoL_4(hfac)^z$ solution is not a deprotonation from $CoL_4(hfac)^z$ but an addition of OH^- to $CoL_4(hfac)^z$. It should be noted that measurements regarding the reaction volume could, thus, become relevant tools for discriminating a reaction type.

Alternatively, a linear correlation between the experimental $\Delta V°$ and the ΔZ^2 can be obtained by a least-squares method:

$$\Delta V° = (-4.2\pm0.4)\Delta Z^2 - (2.1\pm0.8)\ cm^3\ mol^{-1} \quad (5)$$

The intercepts of Eqs. 4 and 5 coincide well, whereas the ΔZ^2 coefficients somewhat differ. According to the Drude-Nernst equation regarding electrostriction, the ΔZ^2 coefficient is inversely proportional to the assumed common ionic radius (r) of the reactant and the product.[6] Since a ΔZ^2 coefficient of $-2.5\ cm^3\ mol^{-1}$ corresponds to r=1.7 Å, that ($-4.2\ cm^3\ mol^{-1}$) of Eq. 5 corresponds to r=1.0 Å.[3] Although small, the thus-derived r is not so far from reality since the coordination bond lengths are 2.0—2.5 Å. Also, the effective charge may be fairly concentrated towards the center of the complex ion.[3] Consequently, the charge dependence of $\Delta V°$ can be consistently understood by using the Drude-Nernst equation regarding electrostriction.

The author wishes to thank Mr. Ryuichi Kume, a graduate student of Ehime University, for his co-operative work regarding the preliminary experiment.

A Raman Study of Aqueous KOH Solution in Glassy State

Hitoshi KANNO* and Jiro HIRAISHI†
Department of Chemistry, Meisei University, Hino, Tokyo 191
†*National Chemical Laboratory for Industry, 1-1 Higashi, Yatabe, Tsukubagun, Ibaraki 305*
(Received April 1, 1985)

Synopsis. Raman spectra of an aqueous KOH solution were measured in the OH stretching region and in the low frequency region (<700 cm^{-1}). Contrary to the results reported by Sharma and Kashyap,[5] only one Raman band specific to an aqueous KOH solution was observed at ≈285 cm^{-1} in the low frequency Raman spectrum.

Raman spectra of aqueous alkali hydroxide solutions have been investigated in the OH stretching frequency region by a large number of workers.[1-3] One of the notable characteristics of the OH stretching Raman spectrum is the existence of the sharp peak at 3620 cm^{-1}. This is due to the stretching vibrations of the OH^- ions in the solution.

On the other hand, it seems that there have been only two Raman studies[4,5] on the low frequency region of alkali hydroxide solutions. Sharma and Kashyap[5] observed two new bands in the low frequency Raman spectra for aqueous NaOH and KOH solutions, in addition to the two restricted translational Raman bands at ≈60 and ≈170 cm^{-1} which are common to all aqueous solutions.[4,6] However, Walrafen,[4] who measured Raman spectra of many aqueous electrolyte solutions including LiOH, NaOH, and KOH solutions, didn't mention about the new band(s) in his low frequency Raman spectra for the LiOH, NaOH, and KOH solutions.

We have recently shown that vitrification of an aqueous solution reduces the Rayleigh scattering wing in a Raman spectrum of the solution, thus permitting unequivocal detection and characterization of weak Raman bands near the exciting line.[7] Therefore, it would be interesting to see the Raman spectrum of aqueous alkali hydroxide solution in the glassy state to clarify the discrepancy of the two reports. We here report a Raman study of glassy aqueous KOH solution.

The sample solutions were prepared by dissolving the commercially obtained KOH pellets (Wako chemicals, guaranteed grade) into distilled water. Raman measurements were essentially the same as previously reported.[7] The concentration of alkali hydroxide solution was determined by titration using Methyl Orange as an indicator against a standardized 0.1 M HCl (1 M=1 mol dm^{-3}) solution. Here the KOH concentration was denoted by R (=moles of water/moles of KOH).

The obtained Raman spectra for both liquid and glassy states of a KOH solution (R=3.9) are shown in Fig. 1. Contrary to the results by Sharma and Kashyap,[5] we see only one Raman peak specific to the KOH solution in the low frequency Raman spectrum. Judging from the Raman spectra reported by Sharma and Kashyap, they devided the single broad Raman envelope into two components: One at 292 cm^{-1} and the other at 332 cm^{-1}. Depolarization measurements indicate that the band at ≈285 cm^{-1} is polarized. It must be pointed out that Raman spectra for glassy NaOH (or NaOD) solutions also gave similar results: single peak at ≈285 cm^{-1} for a $NaOH-H_2O$ solution and at ≈283 cm^{-1} for a $NaOD-D_2O$ solution (intensity is concentration dependent).[8] The two restricted translational Raman

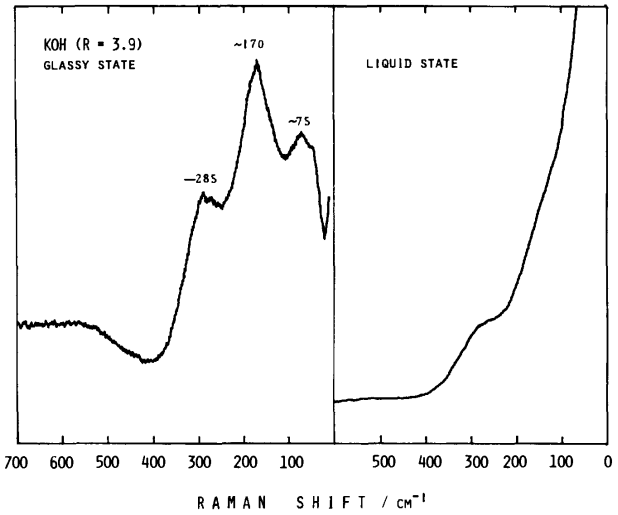

Fig. 1. Raman spectra of aqueous KOH solution (R= 3.9) in low frequency region (10~700 cm^{-1} for the glassy state, 70~600 cm^{-1} for the liquid state).

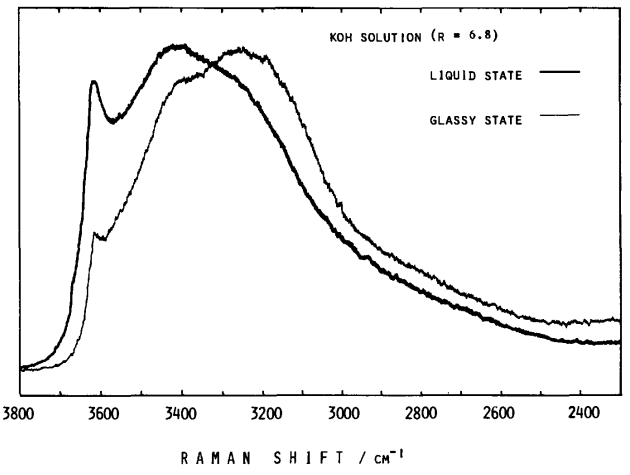

Fig. 2. Raman spectra in the OH stretching vibrational region of aqueous KOH solution (R=6.8).
Thick curve : liquid state at room temperature; thin curve: glassy state at liquid nitrogen temperature.

peaks at ≈170 and ≈75 cm^{-1} are usually assigned to the stretching ($\nu_{OH..O}$) and bending ($\delta_{OH...O}$) vibrations of the hydrogen-bonds between water molecules (and water molecules and anions).[4,6] As the peak at ≈285 cm^{-1} increases in intensity with increasing KOH concentrations and it is observed only in aqueous solutions of alkali hydroxides and ammonia, we come to conclude that it is due to the stretching vibrations of hydrogen-bonds between water molecules and OH^- ions. The fact that its frequency virtually remains unchanged with KOH concentrations also supports the assignment.

The OH stretching Raman spectra for both liquid and glassy states are shown in Fig. 2. It is observed that the relative intensity of the peak at ≈3620 cm^{-1} decreases from a liquid state to a glassy state. This arises from the decrease in ionisation of KOH at low temperatures. The most characteristic feature of the OH stretching Raman spectrum is the continuity of the spectrum down to about 2200 cm^{-1}. A similar continuum is observed in a Raman spectrum of an acid solution.[8-10] It is to be noted that the OH stretching Raman spectrum terminates at about 2900 cm^{-1} in most aqueous electrolyte solutions.[11]

The hydrogen-bonds between oxonium ions and water molecules are very strong.[12,13] Pernoll *et al.*[9] attributed the continua observed in acid solutions to the large polarizability of the hydrogen-bonds caused by protons in the hydrated oxonium ions. A similar interpretation can be invoked to explain the continuum for the KOH solution. Here the OH^- ions play the same role as oxonium ions do in an acid solution. In an aqueous acid solution, protons move around very quickly among water molecules so that each H_3O^+ ion is short-lived scarcely enough to vibrate as a distinct species.[14,15] These rapid proton movements shift and split the energy levels of the OH stretching vibrations, resulting in the continuous distribution of the OH stretching vibrations to lower frequency region.

An interesting point is that the continuum rather increases in intensity in the glassy KOH solution when the intensities are compared by making the peak heights of both states (liquid and glassy states) equal. This is mainly due to the increase in hydrogen-bond strength going from a liquid state to a glassy state, as revealed by the shift of the spectrum peak to a lower frequency side. The intensity increase in the frequency region of 3100—3300 cm^{-1} is a clear indication that strongly hydrogen-bonded structure is recovered to some extent in the glassy state. Liquid water has a strong peak near 3200 cm^{-1} whose intensity grows as the temperature approaches the freezing point of water and this feature is ascribed to the increase of strongly hydrogen-bonded water molecules in the liquid with temperature decrease.[17] The fact that amorphous solid water and polycrystalline ice, where all water molecules are strongly coupled with hydrogen-bonds, have the strongest peak at ≈3100 cm^{-1}[18,19] also substantiates the above interpretation.

On the Assignment of Band II in the Electronic Spectrum of $[Ni(H_2O)_6]^{2+}$

Hisao Ito and Kozo Sone*

Chemical Laboratory, College of General Education, Tokushima University, Minami-josanjima-cho, Tokushima 770

**Department of Chemistry, Faculty of Science, Ochanomizu University, Otsuka, Bunkyo-ku, Tokyo 112*

(Received April 10, 1985)

Synopsis. $[Ni(H_2O)_6]^{2+}$ shows two absorption maxima in the red part of the visible spectrum. The one with the lower frequency has been assigned to the $^3A_{2g}\rightarrow{}^3T_{1g}(F)$ transition, and the other to the spin-forbidden $^3A_{2g}\rightarrow{}^1E_g$ transition. A closer comparison with related spectral data, however, makes the reverse assignment more reasonable.

As is well known, high-spin octahedral Ni(II) complexes show three d-d bands in their electronic spectra if there is no other absorption (CT and/or ligand band(s)) covering some of them. These bands are denoted by I, II, and III (in the order of increasing frequency) and are assigned to transitions $^3A_{2g}\rightarrow{}^3T_{2g}(F)$, $^3A_{2g}\rightarrow{}^3T_{1g}(F)$, and $^3A_{2g}\rightarrow{}^3T_{1g}(P)$, respectively, within the $3d^8$ electronic system. The spectra of $[Ni(NH_3)_6]^{2+}$ and $[Ni(en)_3]^{2+}$ are typical examples of this spectral pattern. The spectrum of $[Ni(H_2O)_6]^{2+}$ is also very similar to these. However, its band II, which appears in the red part of the visible spectrum, is apparently composed of two maxima, *i.e.*, band IIa at 416 THz[1](721 nm) and band IIb at 457 THz(656 nm). The latter is somewhat weaker than the former.[2]

In 1950, Sone collected a number of spectral data regarding octahedral Ni(II) complexes and found that there is a reasonably good linear relationship between the frequencies of bands II and III. He also pointed out that this relation holds well in the case of $[Ni(H_2O)_6]^{2+}$, if its band IIb (and not band IIa which is apparently stronger) is identified with the band II of other complexes.[3]

In 1956, Ito measured the electronic spectra of many octahedral Ni(II) complexes with special care, and discovered that, in most cases, there is a very weak absorption band at the lower-frequency side of their band II. This band appears as a weak shoulder (or merely as a slight inflection) which often is scarcely discernible. Its position and intensity could be determined only by analyzing the whole spectrum into Gaussian-type components, which Ito carefully carried out. This band can now be assigned to the spin-forbidden $^3A_{2g}\rightarrow{}^1E_g$ transition which, according to the Tanabe-Sugano diagram, is expected to appear in the vicinity of band II. It should naturally be very weak. Figure 1 shows an example of such an analysis.[4,5]

Ito also studied the numerical relations among the ν_{max} values of the three bands, which he refined by the above-mentioned analyses. He found that a linear relationship which is similar to that found by Sone approximately holds between any two of the three ν_{max} values. These are denoted by ν_I, ν_{II}, and ν_{III}, respectively.[6] He also found another relation, $(\nu_{II})^2=\nu_I\nu_{III}$, which holds as well. He confirmed that band IIb of $[Ni(H_2O)_6]^{2+}$ satisfies these rules much better than band IIa. This shows again that the former should be taken as band II of this complex.[4]

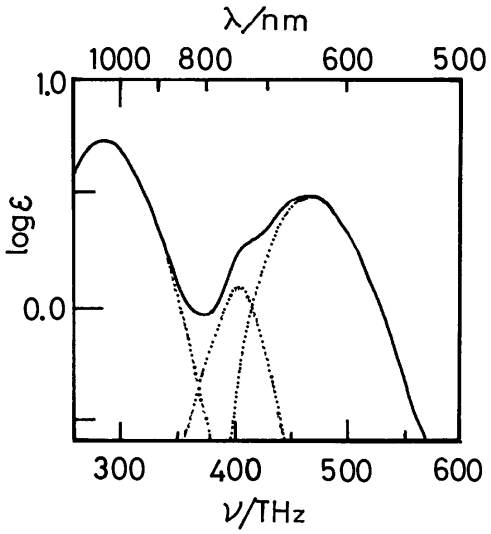

Fig. 1. Analysis of band II of $[Ni(gly)(H_2O)_4]^+$(gly= glycinate ion) in aqueous solution into two Gaussian-type components. After Ref. 4).

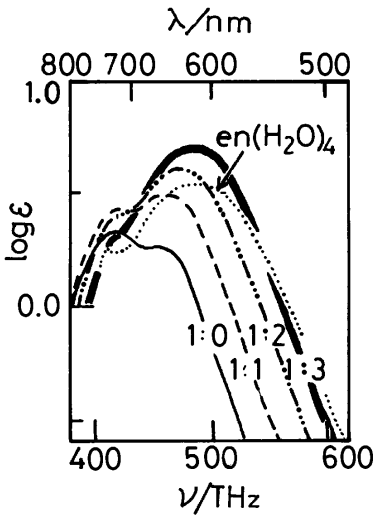

Fig. 2. Change of the absorption spectrum of $[Ni(H_2O)_6]^{2+}$ caused by the addition of NH_3. $C_{Ni^{2+}}$: 0.2 mol dm^{-3}, $C_{NH_4^+}$ (added as NH_4NO_3): 6 mol dm^{-3} The ratio Ni^{2+}: NH_3 is given on each curve. The spectrum of $[Ni(en)(H_2O)_4]^{2+}$ is also shown.

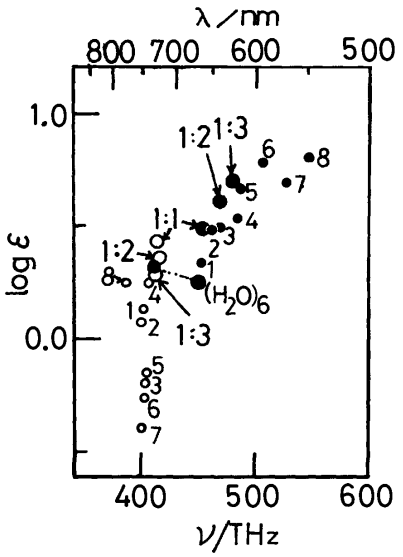

Fig. 3. The positions and intensities of band II (●) and spin-forbidden band (○) of various octahedral Ni(II) complexes in aqueous solution. Nonaqueous ligands in the coordination spheres of these complexes are: 1, asp(−I); 2, gly; 3, asp(−II); 4, en: 5, 2gly; 6, $5NH_3$; 7, $6NH_3$; 8, 3en. (asp(−I) and asp(−II) mean aspartate ions of charge −1 and −2, respectively). Apparent values taken from the curves 1 : 1 to 1 : 3 of Fig. 2 are also plotted. The points for bands IIa and IIb of $[Ni(H_2O)_6]^{2+}$ are shown by (●----●). For further details, *cf.* Refs. 4) and 10).

In spite of these early findings, later investigators generally identified band IIa of this complex with band II itself, and band IIb with the spin-forbidden band superposed on it, as may seem upon first glance.[7] There was also another explanation which denies the intervention of a spin-forbidden transition and ascribes the appearance of the two maxima to spin-orbit coupling.[8]

Recently, Ito examined the spectral data of aqueous solutions containing $[Ni(H_2O)_6]^{2+}$, NH_3, and various anions (ClO_4^-, NO_3^-, and Cl^-). Some of his curves are shown in Fig. 2. Here, one can see that, in going from a solution of $[Ni(H_2O)_6]^{2+}$ to those of Ni(II) ammine complexes, band IIa remains nearly at the same position. However, band IIb moves steadily in conformity with the spectrochemical series. This seems to be an indication that the former is the spin-forbidden band since, according to the Tanabe-Sugano diagram, its frequency should be quite insensitive to the variation in the ligand field strength. Band IIb should, thus, be identified with band II of other complexes, as was formerly pointed out by himself and Sone. A comparison with the curve of $[Ni(en)(H_2O)_4]^{2+}$, which is also shown in the same Figure, makes this view still more convincing.

On the basis of these findings, the earlier data of Ito[4] were reexamined, and the values of ν_{II} and ν_{sf} (*i.e.*, the frequency of the spin-forbidden band) of various Ni(II) complexes obtained by his curve analyses were plotted against their intensities (log ε), as shown in Fig. 3. It is now evident that the points for ν_{II} and those for ν_{sf} collect around two distinct curves. The former depend notably on the nature of the ligands and obey the spectrochemical series. However, the latter are nearly independent of the ligands, as expected from the Tanabe-Sugano diagram. Moreover, it can be observed, in general, that with the decrease of the frequency difference between band II and the spin-forbidden band, the intensity difference between them also tends to diminish (*i.e.*, band II tends to become weaker, and the spin-forbidden band stronger). This can be ascribed to an increased mixing of the nature of these transitions which occurs in the same direction.

The positions and intensities of bands IIa and IIb of $[Ni(H_2O)_6]^{2+}$, which were also refined by curve analyses, are plotted in Fig. 3. Now, it is easy to see that band IIa is better correlated with the spin-forbidden band of other complexes, and band IIb with their band II. Here, however, the two bands are so close that an exceptionally strong mixing takes place, making the former band quite spin-allowed and the latter somewhat spin-forbidden. Thus, they show a characteristic reversal of their intensities. In such a case, it may be reasonable to take the weighted mean (or center of gravity) of the two bands and assume it to be the ν_{II} of the system which should be used when the Tanabe-Sugano diagram and related formulas are applied to these data. Nephelauxetic parameters (B and β) of reasonable magnitude can be estimated in this way.[9]

Thanks of the authors are due to Prof. Hideo Yamatera for his valuable comments regarding this work.

Isomers of the (2,4-Pentanedionato)bis(*N*-phenylethylenediamine)cobalt(III) Ion

Yue OUYANG,† Masaaki KOJIMA, and Junnosuke FUJITA*
Department of Chemistry, Faculty of Science, Nagoya University, Chikusa-ku, Nagoya 464
(Received May 1, 1985)

Synopsis. By reaction of $[Co(acac)_2(Ph\text{-}en)]^+$ (acac=2,4-pentanedionate ion, Ph-en=*N*-phenylethylenediamine) with Ph-en in methanol in the presence of active charcoal, three racemic pairs of diastereomers, *Δ(SS)Λ(RR)*-, *Δ(SR)Λ(RS)*-, and *Δ(RR)Λ(SS)-trans(N*-Ph,*N*-Ph)-$[Co(acac)(Ph\text{-}en)_2]^{2+}$ were obtained. The isomers epimerize in water, methanol, and ethanol to give an equilibrium mixture of the isomers.

Cobalt(III) complexes with *N*-phenyl-substituted amines are usually unstable because of both steric and electronic reasons.[1] However, in a previous paper,[2] we reported that such amines form stable cobalt(III) complexes with two acac (acac=2,4-pentanedionate ion) ligands.

In this paper, we report the preparation and characterization of $[Co(acac)(Ph\text{-}en)_2]^{2+}$ (Ph-en=*N*-phenylethylenediamine) where only one acac ligand is contained.

Experimental

Three Isomers of trans(N-*Ph*,N-*Ph*)-$[Co(acac)(Ph\text{-}en)_2]^{2+}$. To a methanol solution (150 cm^3) of $[Co(acac)_2(Ph\text{-}en)]ClO_4$[2] (3.0 g, 5.4 mmol) were added active charcoal (0.5 g), acetic acid (1 cm^3) and a methanol solution (10 cm^3) of Ph-en (1.6 g, 11.6 mmol). The mixture was stirred for 6 d at room temperature and then filtered. The purple filtrate was diluted with 0.01 mol dm^{-3} HCl (2 dm^3) and applied on a column (ϕ4.5 cm×30 cm) of SP-Sephadex C-25. By elution with 0.3 mol dm^{-3} NaCl–0.04 mol dm^{-3} HCl, the column showed five bands; purple, red, brown, green, and brown in the order of elution. The fastest-moving purple band contained unreacted $[Co(acac)_2(Ph\text{-}en)]^+$, and the slowest-moving brown band a mixture of highly-charged species. Sodium perchlorate was added to the eluate containing the green band (G) and the mixture was cooled to yield a green precipitate. It was collected by filtration, washed with cold water, and air dried. Yield (isomer G: *Δ(SS)Λ(RR)*): 0.14 g (4%). Found: C, 39.73; H, 4.91; N, 8.63%. Calcd for $C_{21}H_{31}N_4Cl_2CoO_{10}$=$[Co(acac)(Ph\text{-}en)_2](ClO_4)_2$: C, 40.08; H, 4.97; N, 8.90%. From each of the brown (B) and the red (R) eluates, the perchlorate of the complex was obtained by the same method as that for isomer G. Each product was dissolved in acetone–0.1 mol dm^{-3} HCl, and the acetone was slowly evaporated to yield crystals. Yield (isomer B: *Δ(SR)Λ(RS)*): 0.61 g (18%). Found: C, 39.99; H, 4.96; N, 8.73%. Calcd for $C_{21}H_{31}N_4Cl_2CoO_{10}$=$[Co(acac)(Ph\text{-}en)_2](ClO_4)_2$: C, 40.08; H, 4.97; N, 8.90%. Yield (isomer R, *Δ(RR)Λ(SS)*): 0.021 g (0.6%). Found: C, 38.78; H, 5.10; N, 8.61%. Calcd for $C_{21}H_{33}N_4Cl_2CoO_{11}$=$[Co(acac)(Ph\text{-}en)_2](ClO_4)_2\cdot H_2O$: C, 38.96; H, 5.14; N, 8.66%.

Isomer Distribution at Equilibrium. Each isomer (*ca.* 0.1 g) was dissolved in water, methanol, or ethanol (5 cm^3) at 20 °C. Portions of the reaction mixture were withdrawn at timed intervals, diluted with 0.1 mol dm^{-3} HCl, and the absorption spectra were measured. The experiments were carried out until the mixture attained equilibrium and no change in the spectra was observed. The equilibrated reaction mixture was diluted with 0.04 mol dm^{-3} HCl (30 cm^3), and the solution was subjected to column chromatography on SP-Sephadex C-25 (column: ϕ 0.9 cm×25 cm; eluent: 0.3 mol dm^{-3} NaCl–0.04 mol dm^{-3} HCl) in order to examine the distribution of the isomers.

Measurements. Absorption spectra in dil $HClO_4$ solutions (pH *ca.* 1.2) were recorded on a Hitachi 323 or a JASCO 610B spectrophotometer and ^1H NMR spectra in acetone-d_6 solutions on a JEOL PMX 60 spectrometer using TMS as an internal reference.

Results and Discussion

The $[Co(acac)(Ph\text{-}en)_2]^{2+}$ complex was prepared from $[Co(acac)_2(Ph\text{-}en)]ClO_4$ and Ph-en in methanol in the presence of active charcoal. The complex was separated into three isomers (G, B, and R) by column chromatography on SP-Sephadex C-25. In the course of the separation, the complex was found to isomerize in water to give an equilibrium mixture of the three isomers. In order to avoid the isomerization, the aqueous solutions were kept acidic (pH<1.5). When isomer G is dissolved in water, the color of the solution changes from green to greenish brown, and the solution attained equilibrium in *ca.* 10 min. The rate is dependent upon pH; the lower the pH, the slower the reaction. The isomer distribution at equilibrium at 20 °C was analyzed by column chromatographic technique, the ratio being isomer R:isomer B:isomer G=5:78:17. The runs starting from any isomer gave the same result within the experimental error (*ca.* ±3%). The isomerization was also observed for methanol and ethanol solutions, and the isomer distributions at equilibrium were the same as that for the aqueous solution. In methanol the complex attained equilibrium in *ca.* 10 min. However, in 0.8 mol dm^{-3} *p*-toluenesulfonic acid–methanol, the isomers showed no detectable change in the absorption spectra over 40 h at room temperature. A rate of inversion at coordinated secondary amine nitrogen (M-NHR^1R^2; R^1,R^2: alkyl substituent) is known to be proportional to hydroxide ion concentration.[3,4] Recemization (inversion at N-CH_3) of *trans,trans*-$[Co(NO_2)_2(CH_3NHCH_2CH_2NH_2)_2]^+$ in methanol has been reported to obey a rate law of the form R=[complex]·$[CH_3O^-]$.[5] Thus the isomerization of the present complex is suggested to be epimerization caused by inversion at the chiral nitrogen atoms remaining the geometrical configuration of the donor atoms unchanged.

† Present address: Department of Chemistry, University of Hainan, Hainan Island, Kwantung Province, The People's Republic of China.

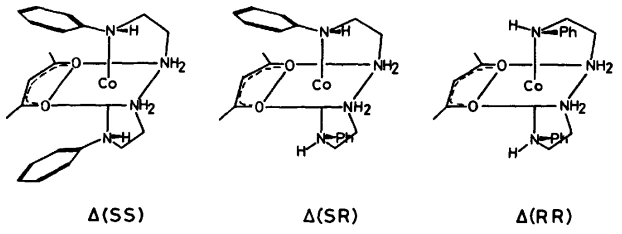

Fig. 1. Schematic structures of the three isomers of *Δ-trans(N*-Ph,*N*-Ph)-$[Co(acac)(Ph\text{-}en)_2]^{2+}$.

The $[Co(acac)(Ph\text{-}en)_2]^{2+}$ ion has three possible geometrical isomers with respect to the arrangement of two *N*-Ph groups. When the presence of three asymmetric centers, one at the cobalt atom and the others at the asymmetric nitrogen atoms, are taken into consideration, the number of isomers increases to ten racemic pairs. However, some of the isomers can be ruled out for steric reasons. Examination of molecular models indicates that only the *trans*(*N*-Ph,*N*-Ph) configuration can form three stable racemic pairs of diastereomers (Fig. 1). The structures of three isomers obtained in this study were assigned on the basis of the ^1H NMR and absorption spectra. In the *Δ(SS)Λ(RR)* configuration, the two phenyl groups are placed over and under the acac chelate ring and the methine proton will be strongly shielded by the phenyl groups. The resonance at a high field, δ=4.18 of isomer G can be assigned to the shielded methine proton, and the isomer is assigned to the *Δ(SS)Λ(RR)* configuration. Isomer R which exhibits the methine proton signal at a low field (δ=6.10) is assigned to the *Δ(RR)Λ(SS)* configuration in which the acac ligand is not shielded by the phenyl groups. The signal of methyl protons of isomer G (δ=1.77) is also observed at a higher field than that of isomer R (δ=2.13). Isomer B gives two methyl singlets (δ=1.88 and 1.90) and the methine singlet (δ=5.21) in the region between the corresponding signals of isomers G and R. Thus isomer B is assigned to the *Δ(SR)Λ(RS)* configuration where only one of the phenyl groups is placed over the acac chelate ring.

Figure 2 shows absorption spectra of the three isomers. All the isomers show the first absorption band, $^1A_{1g}\rightarrow{}^1T_{1g}$ (O_h) in the region of 16900 to 17950 cm^{-1} (isomer G: 16900 (2.71), isomer B: 17570 (2.56), isomer R: 17950 (2.54) in cm^{-1} (log ε)). The second absorption band, $^1A_{1g}\rightarrow{}^1T_{2g}$ (O_h) is almost hidden by strong charge-transfer bands. These first absorption bands are shifted largely to lower energy and become more intense compared to that of $[Co(acac)(NH_2CH_2CH_2NH_2)_2]^{2+}$ (20100 cm^{-1}, log ε=2.14).[6] Similar differences in absorption spectra are observed between $[Co(acac)_2(Ph\text{-}en)]^+$ and $[Co(acac)_2(NH_2CH_2CH_2NH_2)]^+$.[2] For the $[Co(acac)_2(Ph\text{-}en)]^+$[2] and $[Co(acac)_2(PhNHCH_2CH_2NH\cdot Ph)]^+$[7]

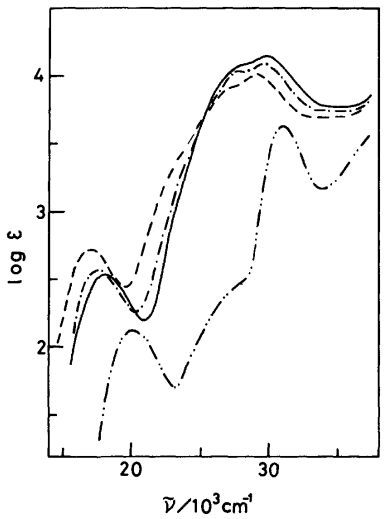

Fig. 2. Absorption spectra of isomer G *(Δ(SS)Λ-(RR))* (– –), isomer B *(Δ(SR)Λ(RS))* (–·–), and isomer R *(Δ(RR)Λ(SS))* (——) of $[Co(acac)(Ph\text{-}en)_2]^{2+}$ in dil $HClO_4$ (pH *ca.* 1.2) and of $[Co(acac)(NH_2CH_2CH_2NH_2)_2]^{2+}$ (–··–) in water.

complexes, the isomer in which the phenyl group is placed over an acac chelate ring has been observed to exhibit the first absorption band at lower energy than those of the other isomers. These observations in absorption spectra lead to the assignments that isomers G, R, and B have the *Δ(SS)Λ(RR)*, *Δ(RR)-Λ(SS)*, and *Δ(SR)Λ(RS)* configurations, respectively. These assignments are in accord with those obtained on the basis of ^1H NMR spectra.

As stated previously, the complex in solution exists in three isomers R (*Δ(RR)Λ(SS)*), B (*Δ(SR)Λ(RS)*), and G (*Δ(SS)Λ(RR)*) in the molar ratio of 5:78:17, respectively at equilibrium (20 °C). The most abundant is isomer B where only one of the phenyl groups is placed over the acac chelate ring. It is not clear whether the interaction between the phenyl and pseudoaromatic acac groups is attractive or repulsive.

Electron Transfer Initiated Replacement of Bromo and Methoxyl Groups with Aryliminodi-, Arylamino-, and Arylthiomagnesium Reagents

Masao Ōkubo,* Yasuhiro Nakagawa, Masatoshi Yoshida, and Hidenobu Yanase
Department of Chemistry, Faculty of Science and Engineering, Saga University, Honjō-machi, Saga 840
(Received November 8, 1984)

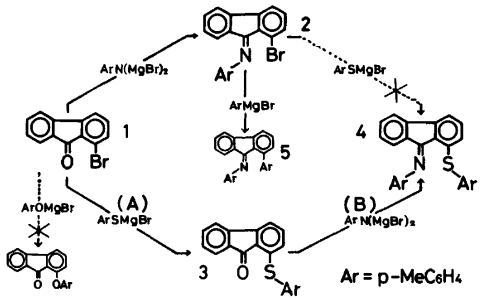
Synopsis. The replacement of bromo and methoxyl groups of fluorenone, *N*-(9-fluorenylidene)aniline, and α-benzylideneacetophenone with ArSMgBr(***S***), ArNHMgBr(***NH***), and ArN(MgBr)$_2$(***N***) were examined. The distribution of products obtained in the reactions with the reagents including ArMgBr(***C***) and ArOMgBr(***O***) were explained in terms of relative electron-donating abilities of reagents: ***C*>*S*>*NH*>*N*>*O***.

Grignard(ArMgBr, ***C***) and aryliminodimagnesium(ArN(MgBr)$_2$, aryl-IDMg, ***N***) reagents react with polar double bonds in the manners of addition and condensation, respectively.[1-4] However, the electron transfer from reagent to substrate is common to the reactions of ***C*** and ***N***, and the distribution of products is explained qualitatively in terms of the combination of relative electron-donating and -accepting abilities(EDA and EAA) of reactants.[5] The lower EDA of reagent ***N*** than that of ***C*** suggested on the basis of product distribution[5] was established by polarographic measurement of oxidation peak potentials.[6]

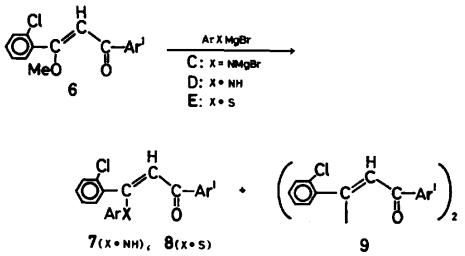
The study was thus extended to the electron transfer initiated replacement of 1-bromo substituent on fluorenone and *N*-(9-fluorenylidene)aniline[7,8] as well as that of methoxyl group on the benzylic position of α-benzylideneacetophenone[2] in the reaction with not only ***C*** and ***N*** but also with arylamino-, arylthio-, and aryloxymagnesium reagents (***NH***, ***S***, and ***O***). The product distribution will be explained in terms of relative EDA of the five magnesium reagents.

Results and Discussion

A set of reactions examined in order to convert 1-bromofluorenone (**1**) into *N*-(1-arylthio-9-fluorenylidene)aniline (**4**) and related reactions using ***C***,[7] ***N***,[7] ***S***, and ***O*** are shown in Scheme 1. Another set of reactions examined are the replacement reactions of methoxyl group of α-(α-methoxybenzylidene)acetophenone(**6a—6d**)[9] by the treatment with ***N***, ***NH***, and ***S*** shown in Scheme 2. The yields of normal and abnormal products are summarized in Table 1 (Runs A—E).



Scheme 1.



Scheme 2.

In Runs A, B, and E, the involvement of electron transfer is indicated explicitly by the formation of abnormal products due to typical radical processes: hydrogen abstraction from solvent (Run A), oxidative dimerization of reagent (Runs B_1 and B_2), reductive dimerization of substrate (Runs E_1—E_5), and radical recombination (Run A). On the treatment of **6** with ***N*** and ***NH*** having *para*- and *meta*-substituents (Runs C_1, C_2, D_1, and D_3), normal product **7** is formed in excellent yields. Abnormal product **9b**, however, is formed when the reagents have 2,6-dimethyl groups, which favor the demethoxylation followed by dimerization over the replacement (Runs C_3 and D_4) because the electron transfer is suppressed slightly and the process for the formation of **7** greatly. The latently involved electron transfer in the reactions of benzophenone with ***C*** and ***N*** is revealed similarly by use of *o*-Me-substituted reagents.[1,3] The reactivity of magnesium reagents must thus be estimated on the basis of their EDA instead of nucleophilicity.

The variation of yields of normal and abnormal products in the reactions of the same type of substrates with the different reagents is interpreted as follows. Imine **2** reacts with ***C***[7] but not with ***S*** (Scheme 1) because EDA of ***S*** is lower than that of ***C***. In the reaction with **6** (Scheme 2), ***S*** gives almost exclusively the abnormal product **9c** (Run E_1) while ***NH*** gives excellent yields of normal products **7a** and **7d** (Runs D_1 and D_3): The results are ascribed to the distinctly high EDA of ***S*** responsible for vigorous electron transfer compared with the medium EDA of ***NH*** for the mild and latent electron transfer. The low yield of **7a** obtained by use of a small excess of ***NH*** in Run D_2, in comparison with the good result of Run D_1, suggests the possibility that one mol of ***NH*** is consumed for electron transfer and another mol for product formation. Attempted variation of conditions of the reaction with ***S*** was not satisfactorily effective for improvement of the yield of **8** (Runs E_2—E_5). The substrates **1** and **6b** were recovered unchanged from the mixtures with ***O***: The red-brown coloration of the mixtures with ***O*** as well as that of ***S*** with **2** indicates that σ-complexes are formed (*vide infra*) but

Molar equivalent amount of reagents and addition manner are given in Experimental. c) Yields based on the substrates used. d) *p*-Methylphenyl 2-oxolanyl sulfide. e) 4,4'-Dimethylazobenzene. f) 2,6-Dimethyl-4-*t*-butyl. g) 2,4,6-Trimethyl.

the electron transfer is impossible because of much lower EDA's compared with the respective EAA's. Taking the polarographically determined order (***C>NH>N***)[6] into account, all the results of the reactions of Schemes 1 and 2 are interpretable in terms of the relative EDA: ArMgBr>ArSMgBr>ArNHMgBr>$ArN(MgBr)_2$>ArOMgBr.

Since magnesium has strong affinity for oxygen, the reactions are initiated with the coordination of carbonyl oxygen to Mg atom of reagent. The rate-determining nature of *σ-complex formation* in the condensation of ***N*** with diaryl ketones was proposed on the basis of the fact that electron-repelling substituents of substrate favor the product formation.[3,5] In contrast, the rate-determining nature of *electron transfer* in the reaction of ***C*** with benzophenones established by thermochemical measurement[10] was confirmed by the acceleration of ketyl formation by electron-attracting substituent of substrate.[1,11] Accordingly, the rate-determining process of the reactions with ***C***, ***S***, ***NH***, and ***N*** is localized on one of the two essentially common initial processes; subsequent ones for the product formation are not rate-determining. The dependence of product distribution on the EDA's of different types of reagent is reasonable.

The simple concept will be helpful in utilizing variuos types of magnesium reagents, and is expected to be quantified.

Experimental

The substrates **1** and **2** were prepared previously.[7] The solutions of reagents ***S***, ***NH***, ***N***, and ***O*** were prepared by the addition of calculated amount of benzenethiol, aniline, and phenol to the EtMgBr solution in tetrahydrofuran (THF).[7]

In the typical Runs, substrate(3.23 mmol) dissolved in THF(15 ml) was mixed with the THF solution(30 ml) of given amount of reagent. Molar equivalent amounts of reagents used in individual runs are: 1.5(D_2), 2.0(B_1), 2.2(E_2, E_4, and E_5), 3.0(A, C_3, D_1, D_3, D_4, E_1, and E_4), 4.0(C_1 and C_3), and 5.0(B_2). In Runs A—D and E_1, the substrates were added in normal manner at once at 0 °C(A, B_1, and B_2), at once at room temperature(C_1—C_3 and D_1—D_4), and over the period of 5 min at −78 °C(E_1). In Runs E_2—E_5, the reagent ***S*** was added in reverse manner at −78 °C over the period of 20 min(E_2, E_4, and E_5) and 60 min(E_3).

The mixtures were neated at 55 °C for 3 h (A—D) and 1 h (E). No reaction took place on the treatment of **2** with ***S*** and **1**(or **6b**) with ***O*** even by use of 8.0 mol of reagents.

The products mixtures were chromatographed on silica gel (Wako Gel, C-200 and C-300). All the ^1H-NMR spectra and elemental analyses of products were satisfactory.

The authors wish to thank Mr. Mitsunao Tokisada for the study of the reactions of runs C_3 and D_4.

Ultrasounds in Synthetic Reactions. III. Reduction of Organic Halides with Nickel(II) Chloride-Zinc-Water[1)]

Junzo YAMASHITA,* Yoshio INOUE, Takashi KONDO, and Harukichi HASHIMOTO
Department of Applied Chemistry, Faculty of Engineering, Tohoku University, Aramaki-Aoba, Sendai 980
(Received March 29, 1985)

Synopsis. The reductive dehalogenation of aryl chlorides as well as other organic halides was facilitated with nickel(II) chloride-zinc-water in hexamethylphosphoric triamide irradiated with ultrasound.

There are a number of methods for the reduction of alkyl or aryl halides using transition metals.[2)] But aryl chlorides are rather resistant to the reduction. It is known that low valent nickel complexes *in situ* generated from nickel(II) salt-zinc powder-triphenylphosphine(TPP) in *N,N*-dimethylformamide(DMF) are able to oxidatively add a large number of organic halides to yield coupling products.[3,4)] The reduction of aryl halides also proceeds with a similar reagent: zinc-water-a catalytic amount of nickel(II) chloride-TPP-sodium iodide in DMF.[5)] But the work-up procedure is frequently troublesome due to the presence of TPP. Recently Takagi and Hayama[6)] reported that the Ullmann type coupling reaction could be effectively achieved by means of *in situ*-generated nickel(0) species in hexamethylphosphoric triamide(HMPA) without TPP.

We wish to report a convenient method for the reduction of aryl halides, especially aryl chlorides, under mild conditions; aryl halides, zinc, water, nickel(II) chloride, and sodium iodide are sonicated in HMPA to yield the dehalogenated products. Ultrasound-irradiation is known to accelerate a variety of organic reactions, particularly those involving metals.[1,7)]

Experimental

Materials and Analysis. HMPA was dried over Molecular Sieves 5A, distilled under nitrogen *in vacuo*, and stored over Molecular Sieves 5A. All other reagents were used as obtained commercially. Reaction products were identified by the comparison of retention times in GLC and mass spectra (JEOL D 300 mass spectrometer) with those of the authentic samples. The yields of products were determined by GLC (Shimadzu GC 3AH using a Silicone GE SE-52 20 wt% on Chromosorb W AW, or FFAP 10 wt% on Chromosorb W AW DMCS column).

General Procedures for Reduction Reactions. To a 50 cm^3 3-necked flask, which contained 0.98 g(15 mmol) of zinc powder, 1.30 g(10 mmol) of nickel chloride, and 0.90 g(6 mmol) of chlorobenzene, 0.3 cm^3(16.7 mmol) of water, 0.200 g of toluene(an internal standard for GLC analysis) and 15 cm^3 of HMPA were added under nitrogen atmosphere and the mixture was irradiated with ultrasound(53 W, 41 kHz) at 60 °C. The yields of products were determined by GLC.

Results and Discussion

The reactions of aryl halides with zinc, nickel chloride, water and sodium iodide were carried out in HMPA at 60 °C under ultrasound-irradiation.

$$\text{R–X} \xrightarrow[\text{H}_2\text{O, NaI, HMPA, 60 °C}]{\text{NiCl}_2\text{, Zn, Ultrasound}} \text{R–H}$$

Several reaction parameters were examined and the results are shown in Table 1. The ease of reduction of halobenzenes decreased in the order: iodobenzene>bromobenzene>chlorobenzene(runs 1,2, and 4), which is consistent with the proposed oxidative addition mechanism.[4,5,6,8)] Iodobenzene and bromobenzene gave a small amount of the coupling product, biphenyl, whereas chlorobenzene and other aryl chlorides afforded only a trace amount of the coupling byproducts. Iodobenzene could be reduced without the coupling byproduct when cobalt(II) acetate or iron(II) sulfate was used instead of nickel(II) chloride(runs 12 and 13). The higher selectivity in the reduction compared with that using TPP[5)] is favorable as a synthetic method. The increasing amount of sodium iodide and nickel chloride increased the yield(runs 3—7). The role of sodium iodide is not clear, but it may promote the reduction of nickel chloride by zinc[4,5)] and/or the reduction of an arylnickel intermediate.[6)] The yield decreased when the reduction was carried out in DMF. The reduction was not observed in tetrahydro-

furan(THF), but proceeded by the addition of a small amount of HMPA to THF(runs 10 and 11). Although the reaction proceeded with ordinary stirring, the ultrasonic irradiation could increase the rate of reaction by 20—50%.

The reduction of various aryl chlorides as well as alkyl halides proceeded smoothly in rather short reaction time to give the reduction products in very high yields with the exception of *p*-chlorobenzyl alcohol and *p*-chlorobenzonitrile, where the reaction stopped within an hour and the starting materials were recovered. These results are shown in Table 2.

In conclusion, the present method is a very convenient procedure for the reduction of organic halides, especially aryl chlorides.

A part of this work was presented at the Joint Regional Meeting of Chem. Soc. Jpn. and Associated Societies of Tohoku Region, Yonezawa, October 5 (1984), Abstr. No. 1B16.

Decarboxylative Photoaddition of 3-Butenoate Anion to 1-Methyl-2-phenyl-1-pyrrolinium Perchlorate *via* Electron-transfer Reaction

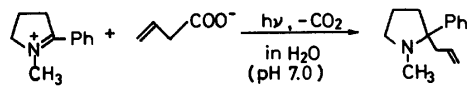
Yoshiaki KURAUCHI, Kazuya OHGA,* Hideo NOBUHARA, and Shigeru MORITA†

Department of Environmental Chemistry and Engineering, Faculty of Engineering, Oita University, Dannoharu, Oita 870-11

(Received April 11, 1985)

Synopsis. The photolysis of 1-methyl-2-phenyl-1-pyrrolinium perchlorate (**1**) with a 3-butenoate anion in an aqueous solution efficiently gives a 2-allylpyrrolidine adduct. Mechanistic studies demonstrate that the photoreaction is induced by a one-electron transfer from 3-butenoate to the singlet excited-state of **1**.

Photoinduced electron-transfer reactions of systems containing iminium cation chromophores have been extensively investigated in recent years with synthetic[1] and biological[2] interests. Mariano *et al.*[3-6] have elucidated mechanistic details regarding photoreactions of pyrrolinium cations with a variety of electron donors such as olefins, allylsilanes, allenes, and arenes. In these, electron transfers to the excited singlet states of the cations take place to give 2-pyrrolidinyl radicals. Cation radical intermediates derived from the electron donors are transformed into neutral radicals by nucleophilic capture, deprotonation or desilylation followed by radical coupling with the pyrrolidinyl radicals leading to the production of photoadducts. In this note, we show that when a 3-butenoate anion is used as an electron donor in an aqueous solution, an allylic photoaddition to 1-methyl-2-phenyl-1-pyrrolinium perchlorate (**1**) occurs to give 1-methyl-2-phenyl-2-(2-propenyl)pyrrolidine (**2**) similar to a reaction in allylsilane systems.[4]



1 **2**

Results and Discussion

1 was irradiated in an aqueous solution whose pH was adjusted to 7.0 with NaOH and contained 0.388 M (1 M=1 mol dm^{-3}) 3-butenoic acid to afford **2**. This was isolated after extraction with chloroform and was distilled under a reduced pressure in a 67.9% yield. The identification of **2** was made by a direct comparison of the ^{1}H NMR and IR spectra with those of an authentic sample[4] prepared by the photoaddition of 3-(trimethylsilyl)propene to **1**. No dark reaction to produce **2** was observed and the fluorescence and absorption spectra of **1** in aqueous solutions containing the acid revealed the absence of an excited- and ground-state complex formation. When the solution pH was not neutralized and, thus, the carboxylic acid existed predominantly in an undissociated form, the yield of **2** was reduced to about one-fortieth. This suggested that the adduct was mainly produced by a photoreaction with the carboxylate anionic form.

One of the requirements for the feasibility of an electron-transfer-initiated photoaddition in the olefin-pyrrolinium cation pairs is an efficient quenching of the fluorescences of the cations by olefins.[3,4] Certainly, the rate constant (k_q=(3.08±0.08)×10^9 M^{-1} s^{-1}) of the fluorescence quenching of 2-phenyl-1-pyrrolinium perchlorate by the undissociated form in acetonitrile (obtained from the slope of a linear Stern-Volmer plot) was comparable to those for methyl 3-methyl-2-butenoate (3.7×10^9)[3] and 3-(trimethylsilyl)propene (5.25×10^9 M^{-1} s^{-1})[4] which are able to undergo photoaddition. Furthermore, it should be noted that quenching of the fluorescence of **1** by the anionic form ($k_q\tau$=3.00±0.06 M^{-1})[7] in an aqueous solution was more efficient than that by the excellent olefin quencher, the undissociated form ($k_q\tau$=1.84±0.03 M^{-1}). Thus, the allylic photoaddition described above seems to be induced not only by an electron transfer from the vinyl group of the 3-butenoate anion to the singlet excited state of **1** (^{1}**1***), but also by an electron transfer from the carboxylato group (Scheme 1). In fact, an acetate anion quenched the fluorescence of **1**,[8] though the $k_q\tau$ value (1.14±0.07 M^{-1}) was no more than *ca.* one-third the value for the butenoate and no more than *ca.* one-half the value for the butenoic free acid. The calculated free-energy change (−1.1 eV)[9] using estimated one-electron oxidation potentials of carboxylates[10] and the reduction potential (−0.95 V *vs.* SCE in an aqueous solution) and singlet energy (3.9 eV) of **1** also suggests that a one-electron transfer from the carboxylato group should be energetically feasible.

The steady-state analysis of a sequence, analogous to that for the allylsilane systems,[4] shown in Scheme 1, gives $\phi_a^{-1}=\alpha_a^{-1}+(\alpha_a k_q\tau[\text{3-butenoate}])^{-1}$, where ϕ_a and α_a represent the quatum yield of the formation of **2** and the limiting ([3-butenoate]→∞)ϕ_a, respectively. The ratio of the intercept to slope from a linear plot of ϕ_a^{-1} *vs.* [3-butenoate]$^{-1}$ shown in Fig. 1 was 2.6±0.5 M^{-1} and closely agreed with the $k_q\tau$ value (3.00 M^{-1}) obtained from fluorescence quenching. This agreement of mathematically equivalent quantities obtained independently of one another suggests that the fluorescence quenching and photoaddition are kinetically coupled and, thus, that the photoaddition proceeds *via* the singlet excited state of **1**. In addition, the reciprocal of the intercept, α_a (0.33) and

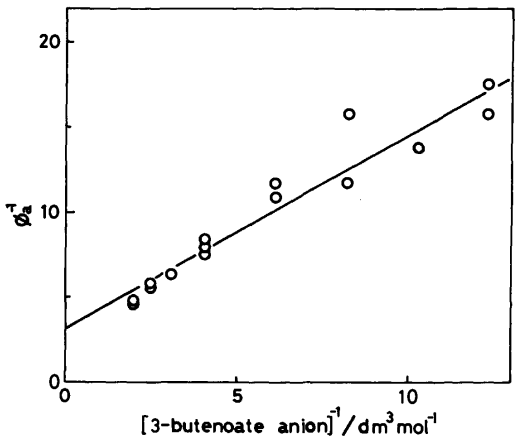

Fig. 1. Double reciprocal plot of the quantum yield for formation of **2** *vs.* the concentration of 3-butenoate anion.

the ratio (0.69) of ϕ_a (0.22±0.02) to the quantum yield for the disappearance of 1 (ϕ_{dis}=0.32±0.03) obtained at [3-butenoate] of 0.5 M had larger values than those regarding the photoaddition of 3-(trimethylsilyl)-propene (α_a=0.02 and ϕ_a/ϕ_{dis}=0.5).[4] This indicates a higher efficiency of the adduct formation with a 3-butenoate anion.

Experimental

The ^{1}H NMR, UV, and IR spectra were recorded on a Hitachi R-24B, a Shimadzu UV 202, and a Hitachi 285, respectively. The fluorescence emission was measured using a Shimadzu RF-510 spectrometer. **1** was prepared and purified according to a method from the literature:[7b] mp 117.5—119.0 °C (uncorrected). 3-Butenoic acid was commercially available and distilled *in vacuo* just before use.

Photolysis of 1 with 3-Butenoate Anion. In an aqueous solution (200 cm^3) containing 3-butenoic acid (6.67 g, 0.0776 mol) adjusted to pH 7.0 with NaOH, **1** (401 mg, 1.54 mmol) was dissolved and irradiated for 60 min. The irradiation was carried out using a 400-W high-pressure mercury lamp (Riko-Sha UVL-400HA) equipped with a Pyrex water-jacket under an atmosphere of argon. The photolysate was acidified (pH 1) with HCl and then concentrated to 5 cm^3 *in vacuo*. The acidic solution was made basic (pH 10) with NaOH, saturated with NaCl, and extracted with three 20-cm^3 portions of chloroform. The extract was dried over anhydrous Na_2SO_4 and then concentrated *in vacuo*. The resulting oily residue was purified by distillation under a reduced pressure to give 213 mg (67.9% yield) of a clear oily product **2**.

Fluorescence Quenching Experiments. The relative intensities of the fluorescence at 380 nm of **1** (1×10^{-3} M) were measured at 25±1 °C. The excitation wavelength was 305 nm and concentrations of the quenchers were in the 0.1—0.5 M ranges.

Quantum Yields. Quantum yields were measured using a linear optical-bench system equipped with a 500-W super-high-pressure mercury lamp (Ushio USH-500D) at 25±1 °C. The 280-nm band (1.54×10^{14} quanta s^{-1}) isolated with a monochrometer (Jarrel Ash JE-25E) was used to irradiate an argon-purged aqueous solution (pH 6.0, [**1**]=1.00×10^{-3} M, [3-butenoate]=0.5 M). Product analyses were performed by GLC (Shimadzu GC-3BF, 5% PEG 20M) for reaction mixtures worked up as in the preparative run. Biphenyl was used as an internal standard. The degrees of the disappearance of **1** were determined from the decrease of the absorbance at the λ_{max} of 258 nm. The conversions were not more than 10%. The relative quantum yields for the formation of **2** at different concentrations of 3-butenoate were obtained at 25±1 °C using a merry-go-round apparatus at the center of which was the 400-W high-pressure mercury lamp employed in the preparative run.

The authors wish to thank Professor Patrick S. Mariano of the University of Maryland for his helpful comments.

Preferred Conformation of 1-Phenyl-2-propanol. *Ab initio* and Molecular Mechanics Calculations with Geometry Optimization

Kazuhisa ABE,* Minoru HIROTA, and Keiji MOROKUMA†
Department of Applied Chemistry, Faculty of Engineering, Yokohama National University, Hodogaya-ku, Yokohama 240
†*Institute for Molecular Science, Myodaiji, Okazaki 444*
(Received April 19, 1985)

Synopsis. The most stable conformation of 1-phenyl-2-propanol, optimized by *ab initio* and molecular mechanics (MM2) calculations, is a phenyl-methyl anti and phenyl-OH gauche conformation with an intramolecular OH-π hydrogen bond.

Weak interactions such as OH-π hydrogen bond,[1] CH-π interaction,[2] and van der Waals interaction[3] often play an important role in determining conformations of various organic molecules. We have reported recently the stereochemistry of $C_6H_5CH_2XR$-type compounds (X=CHOH, C=O, S=O; R=CH_3, C_2H_5, *i*-C_3H_7, *t*-C_4H_9) by use of molecular mechanics (MMI) and pointed out the importance of the nonbonded weak interaction.[4] In order to understand the nature of these weak interactions in detail, we studied in this letter conformations of 1-phenyl-2-propanol with *ab initio* molecular orbital as well as molecular mechanics calculations.

Methods

We used the programs Gaussian 80[5] for *ab initio* calculation and MM2[6] for molecular mechanics calculation. The geometries of conformers were optimized with the Hartree-Fock method with the STO-3G basis set. It took about 5 h in CPU time to reach one of the local energy minima of 1-phenyl-2-propanol. At the STO-3G geometries, the energies and electron distributions were recalculated with the 4-31G basis set. Comparing with STO-3G calculations, 4-31G calculations give more reliable results about energy difference of isomers. In the case of geometry optimization by MM2, the required CPU time for this molecule was about 10—20 s.

Results and Discussion

The *ab initio* calculation showed that the most stable conformer was a phenyl-methyl anti and phenyl-OH gauche type with an intramolecular OH-π hydrogen bond (Table 1). The OH-π hydrogen bond energy was estimated to be 2.20 kcal† mol^{-1} from the energy difference between conformers **B** and **C**. From the temperature dependent IR measurement on 1-phenyl-2-propanol($\bar{\nu}_{OH}$(free)=3626 cm^{-1}, $\bar{\nu}_{OH\text{-}\pi}$= 3604 cm^{-1}), we determined experimentally this energy to be 1.0 kcal mol^{-1}. The *ab initio* calculation overestimates the hydrogen-bond interaction in this case. From the dihedral angle H(6)-C(1)-C(4)-C(9), we found that the benzene ring was twisted around the C(4)-C(1) bond in **A** and **D** conformers so as to avert the steric congestion between methyl and

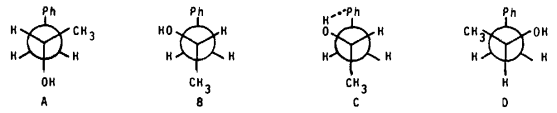
† 1 cal_{th}=4.184 J.

phenyl groups. In conformers **A** and **D**, these dihedral angles change from the normal angle(30°) to 41° and 24°, respectively.



The population analysis reveals the evidence for the intramolecular OH-π hydrogen bond as follows:

1) In conformer **C** (dihedral angle C(1)-C(2)-O(3)-H(8): −59.73°) there is a small positive sum of populations (1.62×10^{-2}) between the OH proton and the carbon atoms of the benzene ring, indicating a bonding interaction. In the other conformers, in which these dihedral angles are nearly 180° and OH proton cannot interact with benzene ring, the sums are all negative.

2) The overlap population of the OH bond in **C** (0.249) is the smallest among the conformers, indicating that the OH bond of **C** is the weakest. But the OH stretching frequencies estimated from the calculated diagonal force constant at the STO-3G level are essentially identical among these conformers (4220 cm^{-1}, which gives 3600 cm^{-1} when scaled with a factor 1.17).[7] This may be due to the neglect of off-diagonal elements.

3) Conformer **C** has the smallest atomic population on the OH proton (0.596) and the largest average atomic population on the carbon atoms of the benzene ring (6.171). These values also support the presence of OH-π interaction.

From the optimized geometry of OH-π intramolecularly hydrogen bonded form (Fig. 1) we find the fact that the OH proton(8) is interacting equally with two carbon atoms (C(4), C(9)) of the benzene nucleus and is located above the surface with an OH(8)···C(4) or C(9) distance of 2.60 Å. Ōki and Iwamura[8] reported that the OH proton and the benzene nucleus were interacting in the same form as found above based on the IR experiments on similar 2-phenylethanol.

The geometry optimized MM2 calculation revealed the same preferred conformation. The optimized geometries of conformers are quite similar to those from *ab initio* calculations. The energy difference between **B** and **C** (−0.228 kcal mol^{-1}) is thought to correspond to intramolecular OH-π hydrogen bond energy. Careful examination of the steric energy components of **B** and **C** conformers clearly indicates that the dipole energy term mainly contributes to the stabilization of OH-π hydrogen bonded form. But the hydrogen-bond energy is rather small in comparison with the experimental value (1.0 kcal mol^{-1}). Therefore the present MM2 calculation is not adequate for studying the hydrogen bond system. It is necessary to add an extra energy term corresponding to the delocalization contribution of hydrogen bond to steric energy from MM2 in order to evaluate the hydrogen bond and steric energy correctly.

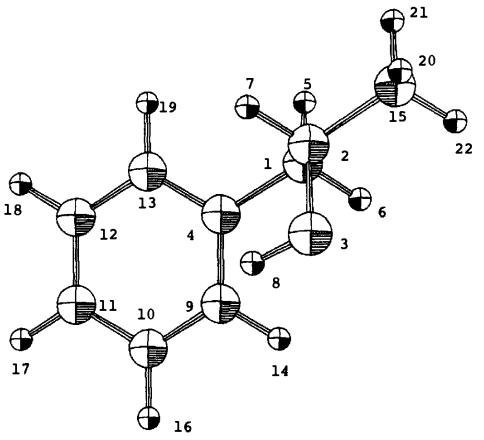


Fig. 1. Optimized Geometry of Conformer **C**.

As to the CH-π interaction, we cannot show a definitive evidence at this calculation level that CH_3 protons and the benzene nucleus are interacting. Some results may be taken to give the qualitative evidences of the CH-π interaction. In the conformer **A** and **D**, in which CH-π interaction is possible, a small positive overlap population is found (4.79×10^{-3} and 7.44×10^{-3}, respectively). This small positive bond population suggests a very small attractive interaction between CH_3 and π-electrons of the benzene ring. This suggests the presence of a delocalizative interaction between CH_3 and benzene ring. In addition, MM2 calculation estimates a considerably large attractive van der Waals interaction(−0.45 kcal mol^{-1}) between CH_3 and the benzene nucleus in conformer **A**. In other conformers, this interaction energy (CH_3-Ph) is about 0.1 kcal mol^{-1} smaller than that of **A**.

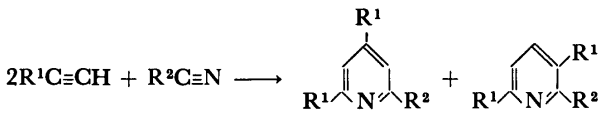
Improved Catalytic Activity of Cyclopentadienylcobalt in the Preparation of Pyridines from Acetylenes and Nitriles

Yasuo WAKATSUKI* and Hiroshi YAMAZAKI
The Institute of Physical and Chemical Research, Wako, Saitama 351
(Received April 22, 1985)

Synopsis. The catalytic activity of cyclopentadienylcobalt increases greatly upon introducing a methoxycarbonyl group into the cyclopentadienyl ring, and by carring out the reaction with a vigorous exclusion of oxygen. Among the precursors we have examined, the most active one was [Co(Cp^z)(cot)] (Cp^z=methoxycarbonyl-substituted cyclopentadienyl; cot=cyclooctatetraene) which can generate the active species at 100 °C.

In 1973, we reported that the cyclopentadienylcobalt (CpCo) species catalyzed cyclocotrimerization of alkynes with the C≡N triple bond of nitriles to give substituted pyridines (Eq. 1).[1]



$2R^1C{\equiv}CH + R^2C{\equiv}N \longrightarrow$ (substituted pyridine) + (substituted pyridine)

R^1=H, alkyl, aryl: R^2=alkyl, aryl (1)

The "CpCo" species can be generated from several precursors such as CpCo(diene),[2] Cp_2Co,[3] and $CpCo(CO)_2$.[4] Entry into the catalytic cycle is also possible by starting from cobaltacyclopentadiene complexes.[1] The mechanism of Reaction 1 (involving the metallacycle intermediate) has been fairly well understood.[5]

The catalytic activity of cobalt, in terms of pyridine moles produced per g-atom Co, has been reported to be 190,[1] 200,[4] and 400.[6] Recently, Bönnemann and coworkers have used η^6-borinato in place of the Cp ligand, thereby improving the catalytic activity to *ca.* 2100 for the cooligomerization of HC≡CH with CH_2=CHCN.[7]

We have found that the catalytic activity of cobalt with the easily available η^5-Cp ligand can be greatly enhanced by (1) the exclusion of oxygen, (2) introduction of a CO_2Me group to the Cp ligand, and (3) lowering the reaction temperature. The test reaction that we employed was the cotrimerization of methylacetylene with acetonitrile (R^1=R^2=Me in Reaction 1). In order to check the maximum activity of the catalyst, we carried out the reaction in the presence of a large amount of the reactant so that the conversions would not exceed 80%. When all three of the above conditions are satisfied, the catalytic activity reaches as high as *ca.* 4000 moles of trimethylpyridine per g-atom Co.

The effect of oxygen on the reaction is shown in Fig.1. When the reaction mixture is carefully degassed by use of a vacuum line, even the conventional CpCo(**1**,**5**-cod) exhibits high catalytic activity (*ca.* 2200 at 130 °C). However, its activity drops sharply when an increasing amount of oxygen is added to the system. A (η^5-$C_5H_4CO_2Me$)Co (abbreviated as Cp^zCo) analogue has a higher

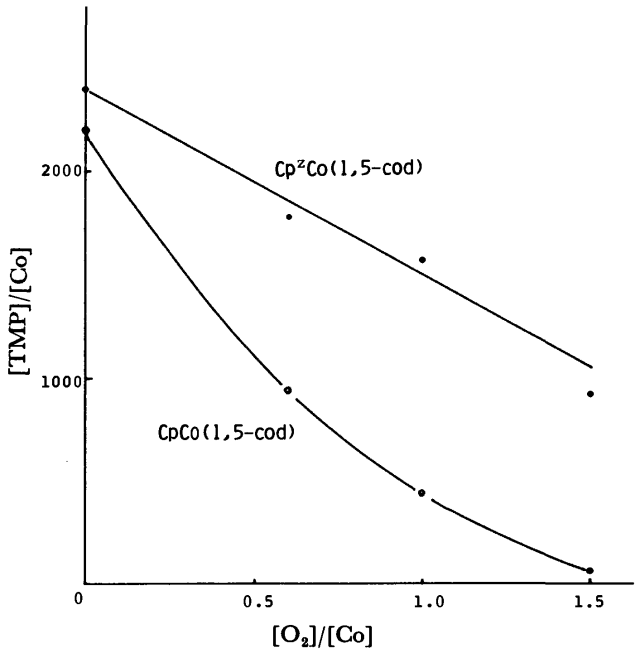


Fig. 1. Higher resistance of the Cp^zCo system towards deactivation by added oxygen.
[TMP]: amount of obtained trimethylpyridine, [Co]: amount of the catalyst used.
Reaction condition: 130 °C, 16 h.

resistance toward oxygen, and still maintains a reasonable catalytic activity (950) even in the presence of an excess amount of oxygen.

The other advantage of using Cp^zCo(**1**,**5**-cod) is that the reaction is much faster than for the case of the parent CpCo(**1**,**5**-cod), as evidenced by the time-conversion curves (A and B) in Fig. 2. A part of this phenomena must arise from an easier release of the **1**,**5**-cod ligand from Cp^zCo(**1**,**5**-cod) than from CpCo(**1**,**5**-cod), *i.e.* a faster generation of the active species in the former system. We have measured the reaction rate for the exchange of the complexed and free diene: Cp^zCo(**1**,**5**-cod) was found to release the diene 10-times faster than CpCo(**1**,**5**-cod) in an acetonitrile solution.

When the reaction temperature was lowered from 130 to 100 °C, the catalytic activity by use of Cp^zCo(**1**,**5**-cod) markedly increased while the reaction rate decreased (curve C). The reaction rate at this lower temperature can be improved by employing cyclooctatetraene (cot), an easier leaving ligand, instead of **1**,**5**-cod (curve D). In contrast, the catalytic activity of CpCo saturates at around 2000, even when CpCo(cot) is used as the precursor and the reaction is carried out at 100 °C (curve E). The difference observed in curves D and E implies that the Cp^zCo system either has a higher reactivity regarding

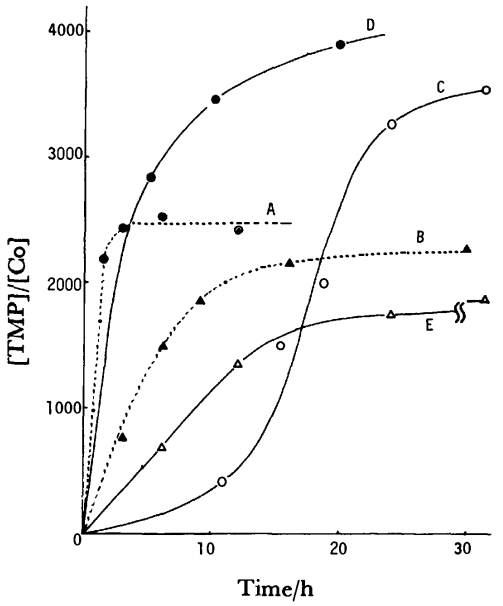

Fig. 2. Comparison of catalytic activity of CpCo and Cp^2Co systems.

cooligomerization or a higher resistance to deactivation than the parent CpCo system.

Experimental

Column chromatography was carried out using Sumitomo alumina KCG-30 under a nitogen atmosphere. GLC analyses were performed at 110 °C on a Shimadzu GC-8A equipped with a 0.3×300-cm glass column packed with 15% PEG-20M on Uniport-HP. Tetradecane was used as an inner reference to determine the amount of each product.

(η^5-Methoxycarbonylcyclopentadienyl)(η^4-1,5-cyclooctadiene)-cobalt(Cp^2Co(1,5-cod)): Sodium methoxycarbonylcyclopentadienide was prepared, according to a method from the literature,[8] (from sodium cyclopentadienide (7 mmol in 4 ml THF) and dimethyl carbonate (1 ml) by heating at reflux temperature for 1 h). Under a nitrogen atmosphere and at room temperature, the cyclopentadienide solution was transferred all at once into a flask (100 ml) containing a benzene solution (20 ml) of chlorotris(triphenylphosphine)cobalt (4.4 g, 5 mmol) and **1,5**-cyclooctadiene (2 ml). The flask was stoppered and vigorously shaken. A dark-red color immediately developed. The reaction mixture was allowed to stand overnight and was then filtered through a short column of alumina (25×25 mm) by the aid of additional benzene (10 ml). The filtrate was concentrated to *ca.* 10 ml and after the addition of hexane (20 ml), it was kept at room temperature overnight. Colorless crystals were formed and discarded, and the solution was chromatographed on alumina (deactivated by addition of 5% of H_2O, 25×200 mm). The column was washed with hexane and then with a 4/1 mixture of hexane/benzene. An orange-red band was eluted by a 1/1 mixture of hexane/benzene. The eluate was concentrated almost to dryness. The residue was dissolved in hexane (5 ml) and was kept in a refrigerator overnight to yield orange-brown crystals of the title compound. They were recrystallized from hexane; yield: 0.78 g (54%); mp 86—87 °C.

$C_{15}H_{19}O_2Co$	Calcd	C 62.07	H 6.60

IR (Nujol): ν=1720, 1700 cm^{-1} (ester). ^{1}H-NMR (CD_2Cl_2): δ=3.64 (=CH–, coordinated); 3.90 (CH_3); 4.55, 5.11 (C_5H_4); 5.56 (=CH–, uncoordinated).

Cotrimerization of Methylacetylene with Acetonitrile: Crystals of Cp^2Co(cot) (28.6 mg) were dissolved in benzene (40 ml) under argon (this solution can be stored in a refrigerator for several months without any decomposition). A portion of this solution (1 ml) was transferred by syringe to an ampule. The ampule was connected to a vacuum line. The solution was degassed by three freeze-pump-thaw cycles. In another ampule containing benzene (1.5 ml) and acetonitrile (2.5 ml), methylacetylene (*ca.* 1.3 g) was condensed by bubbling through the gas at 0 °C. The second ampule was attached to a vacuum line and the mixture was degassed by three cycles of freeze-pump-thaw. Finally it was distilled into the first ampule containing the cobalt complex. The ampule was sealed and heated to 100 °C for 20 h. Unreacted reactants and the solvent were evaporated under a reduced pressure (25 mmHg (1 mmHg=133.322 Pa)) and the oily residue (1.43 g) was subjected to an GLC analysis. The products were 1,3,5-trimethylbenzene (0.30 mmol), 1,2,4-trimethylbenzene (1.69 mmol), 2,4,6-trimethylpyridine (5.12 mmol), and 2,3,6-trimethylpyridine (4.65 mmol). Trimethylpyridine was isolated upon extracting it from an ethereal solution of the residue using an 18% HCl aquous solution. After neutralization with KOH, the pyridine was again extracted with ether. Drying of the solution with Na_2SO_4 and evaporation of the ether under a reduced pressure gave a colorless oil (1.04 g) which was a 51/46 mixture of 2,4,6- and 2,3,6-trimethylpyridine. Other runs can be performed similarly.

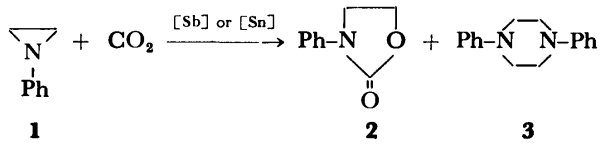
Reaction of Carbon Dioxide with 1-Phenylaziridine Catalyzed by Organo-antimony and -tin Compounds

Haruo MATSUDA, Akira NINAGAWA,* and Hiroshi HASEGAWA
Department of Applied Chemistry, Faculty of Engineering, Osaka University, Yamadaoka, Suita, Osaka 565
(Received April 23, 1985)

Synopsis. The reactions of carbon dioxide(CO_2) with 1-phenylaziridine(**1**) to afford 3-phenyl-2-oxazolidone(**2**) were carried out in the presence of organo-antimony and -tin compounds as catalysts. Tetraphenylstibonium bromide(Ph_4SbBr) and triphenyltin bromide(Ph_3SnBr) were found to be active catalysts. The use of a polar aprotic solvent, such as a HMPA, provided optimal reaction conditions.

In our previous papers,[1] we reported that organometallic compounds of group IVA, VA, and VIA are effective catalysts for the cycloaddition reaction of CO_2 to oxiranes to afford the corresponding cyclic carbonates. However, little is known about the catalysts for the syntheses of 2-oxazolidones from the reactions of CO_2 with aziridines, except for the ammonium salts[2] and iodine[3] which are effective catalysts for the reactions of CO_2 with 1-substituted phenylaziridines and 2-methylaziridine, respectively. In this study, we found that Ph_4SbBr and Ph_3SnBr were also effective catalysts for the synthesis of **2** from the reaction of CO_2 with **1**.



1 **2** **3**

Results and Discussion

The reactions of CO_2 with **1** were carried out in the presence of organo-antimony and -tin compounds. As shown in Table 1, in the case of Ph_4SbBr, **2** and 1,4-diphenylpiperazine(**3**) were obtained in 86 and 9% yields, respectively, whereas other antimony compounds show low selectivity. On the other hands, with Ph_3SnBr, **3** was obtained as a main product. On the basis of the above results, the reactions catalyzed by Ph_4SbBr and Ph_3SnBr were carried out under various conditions to survey the optimal conditions.

The yield of **2** in the reaction catalyzed by Ph_4SbBr at 80 °C increases linearly with an increase in reaction time, whereas, that of **3** increases during the first 10 min and then does not increase. In the case of Ph_3SnBr, the yields of **2** and **3** increase with an increase in the reaction time. To check the effect of reaction temperature, the reactions were carried out at temperatures from 40 °C up to 120 °C. In the case of Ph_4SbBr, **2** was selectively obtained above 60 °C. On the other hand, Ph_3SnBr did not show catalytic activity up to 60 °C, but the yields of **2** and **3** increased at higher temperature above 80 °C. In order to improve the catalytic activity of Ph_4SbBr and Ph_3SnBr, the reactions were carried out in solvents of different polarities as shown in Table 2. The solvent effect is very clear. The use of polar aprotic solvents such as HMPA and DMSO gave **2** in high yields, whereas the nonpolar solvents such as benzene and hexane gave poorer results.

Table 1. Catalytic activities of the organometallic compounds in the reaction of CO_2 with **1**[a]

Catalyst	Yield/%[b]	
	2	**3**
Ph_4SbCl	7	19

Experimental

Materials. The organometallic compounds, Ph_3SbBr_2,[1c] Ph_4SbBr,[1c] Ph_4SbCl,[4] Me_3SbCl_2,[5] Me_3SbBr_2,[5] Me_3SbI_2,[5] Ph_3SbO,[6] Ph_3SnCl,[1d] Ph_3SnBr,[1d] n-Bu_3SnBr,[7] n-Bu_2SnBr_2[7] were prepared by the reported methods and checked by elemental analysis. 1-Phenylaziridine was prepared from 2-anilinoethanol.[8] The solvents were used after rectification.

Reaction Procedure. A mixture of 3.64 cm^3 (30 mmol) of **1** and 0.257 g (0.5 mmol) of Ph_3SbBr_2 was placed into a 50 cm^3 stainless steel autoclave. CO_2 was then introduced at a pressure of *ca.* 50 atmospheres (58.8 bar). The reaction was carried out for 6 h at 80 °C. After completion of the reaction, CO_2 was allowed to escape from the autoclave and the product was separated by column chromatography on silica gel (Wako-gel C-200; chloroform as an eluent). **3** was obtained from the first fraction and **2** from the second fraction. These were recrystallized from ethanol to give pure products. **2**; 2.7 g (yield 55%), mp 115—117 °C (lit,[9] 117—119 °C). **3**; 0.9 g (yield 25%), mp 166—169 °C (lit,[10] 163—164 °C).

Analytical gas chromatography(GC) was performed on a Shimadzu GC-3BT gas chromatograph by the use of Silicone OV-1 as packing.

Synthesis of Ketazines from Dinitrogen Coordinated to Tungsten†

Masanobu HIDAI,* Masa-aki KURANO, and Yasushi MIZOBE
Engineering Research Institute, Faculty of Engineering, The University of Tokyo, Yayoi, Bunkyo-ku, Tokyo 113
(Received April 24, 1985)

Synopsis. When treated with a methanol/acetone mixture at 50 °C, the complex *trans*-$[W(N_2)_2(PPh_2Me)_4]$ gives acetone azine in moderate yield, although the yield is slightly lower than that from *cis*-$[W(N_2)_2(PMe_2Ph)_4]$. Under UV irradiation, these dinitrogen complexes produce acetone azine even at room temperature.

Direct synthesis of organonitrogen compounds from molecular nitrogen and a relatively cheap organic feedstock is an attractive field in the chemistry of nitrogen fixation. We have already reported that one dinitrogen ligand in the complex *cis*-$[W(N_2)_2(PMe_2Ph)_4]$ (**1**) is converted mainly to ammonia by reaction with alcohols at 50 °C, whereas ketazines are produced in good yields when complex **1** is treated with alcohol/ketone mixtures (ROH/$R^1R^2C{=}O$) at 50 °C.[1] The ligating dinitrogen is first protonated by alcohols to give intermediate complexes $[W(OR)_2(NNH_2)(PMe_2Ph)_3]$. In the presence of ketones, the intermediate complexes are more amenable to the condensation with ketones[2] than to the protonation at the terminal nitrogen atom. The resulting diazoalkane complexes $[W(OR)_2(NN{=}CR^1R^2)(PMe_2Ph)_3]$ react with alcohols to liberate hydrazones ($H_2NN{=}CR^1R^2$), which further condense with ketones to form ketazines as the final products. Thus, 0.88 mol of acetone azine per W atom is formed by treating complex **1** with a methanol/acetone mixture. The yield is further improved up to 0.94 mol/W atom by the addition of base to the system. Since acetone azine is easily converted to hydrazine by hydrolysis, this reaction is considered as a potential method for the synthesis of hydrazine from dinitrogen. In this paper, we wish to describe the application of this reaction system to a series of tungsten and molybdenum dinitrogen complexes $[M(N_2)_2(PR_3)_4]$ (M=W or Mo; PR_3=tertiary phosphines).

Results and Discussion

Investigations of the reactions of a series of tungsten and molybdenum dinitrogen complexes $[M(N_2)_2(PR_3)_4]$ with alcohol/ketone mixtures have disclosed that, in addition to complex **1**, *trans*-$[W(N_2)_2(PPh_2Me)_4]$ (**2**) also gives acetone azine in moderate yield by reaction with methanol/acetone mixtures at 50 °C. However, none of the other dinitrogen complexes *cis*-$[Mo(N_2)_2(PMe_2Ph)_4]$, *trans*-$[M(N_2)_2(dpe)_2]$, *trans*-$[M(N_2)(^nPrCN)(dpe)_2]$ and *trans*-$[W(N_2)_2(dpe)(PPh_2Me)_2]$(M=W or Mo; dpe=$Ph_2PCH_2CH_2PPh_2$) produces acetone azine under similar conditions.

In Table 1 is shown the yield of acetone azine obtained by treatment of complex **2** with methanol/acetone mixtures. It is to be noted that use of a methanol/acetone mixture with the volume ratio 4:1 gives only a trace amount of the azine from complex **2**, although the azine is formed in high yield from complex **1** under similar conditions. This is only because complex **2** is scarcely soluble in the mixed solvent. Therefore, if toluene or THF is added to this system to dissolve complex **2**, the yield of the azine is remarkably improved. A great difference of complex **2** from complex **1** is observed in the effect of base addition to the reaction system. For complex **1**, the yield of the azine is improved almost up to 1 mol/W atom in the presence of KOH or NaOMe.[1] However, for complex **2**, addition of base strongly supresses the formation of the azine.

The mechanism for formation of the azine from complex **2** may be essentially the same as that from complex **1** (*vide supra*). Actually, the hydrido-hydrazido(2-) complex $[WCl_3H(NNH_2)(PPh_2Me)_2]$, which is derived from complex **2** and HCl in CH_2Cl_2, reacts with methanol/acetone mixtures at 50 °C to produce acetone azine in moderate yield (0.31 mol/W atom). The azine is probably formed *via* a diazoalkane complex derived from the condensation of the hydrazido(2-) complex with acetone. Details of the condensation of hydrido-hydrazido(2-) complexes with carbonyl compounds will be reported separately.[3]

Formation of ketazines from ligating dinitrogen in complexes **1** and **2** by treatment with alcohol/ketone mixtures does not proceed at room temperature but only at an elevated temperature (50 °C). However, under irradiation by mercury lamp, the complexes give ketazines very smoothly at room temperature, although the yields of ketazines are lower than those in the reactions at 50 °C and ethanol or 2-propanol does not work as the proton source instead of methanol. Addition of NaOMe slightly increases the yield of acetone azine (Table 2). In the UV irradiated reaction, a suspension of the reaction mixture gradually turns to a dark solution within about 3 h. The yields of ketazines are no longer increased after 4 h.

Experimental

All manipurations were carried out under dinitrogen using standard Schlenk tube techniques. Complexes *cis*-$[W(N_2)_2(PMe_2Ph)_4]$,[4] *trans*-$[W(N_2)_2(PPh_2Me)_4]$,[5] and $[WCl_3H(NNH_2)(PPh_2Me)_2]$[5] were prepared according to the published methods.

Reactions of Complex 2 with Methanol/Acetone Mixtures.

† Preparation and Properties of Molybdenum and Tungsten Dinitrogen Complexes. 22.

4	2	1	Toluene, 3	—	0.64[b]
5	5	5	—	4	0
6	2	1	THF, 3	—	0.24[b]
7	2	1	THF, 3	4	0.05[b]

a) Complex **2**, 100 mg; Reaction time, 18 h; Reaction temperature, 50 °C. b) The yield of N_2H_4 after base distillation of the reaction mixture. c) 0.20 mol NH_3/W atom was also formed.

Table 2. Formation of ketazines from *cis*-$[W(N_2)_2(PMe_2Ph)_4]$ (**1**) and *trans*-$[W(N_2)_2(PPh_2Me)_4]$ (**2**) under UV irradiation[a]

Complex[b]	System			Yield of Ketazines
	Alcohol ml	Ketone ml	NaOMe mol/W atom	mol/W atom
1	MeOH, 4	Acetone, 1	—	0.46
1	MeOH, 4	Acetone, 1	4	0.66
1	MeOH, 4	Diethyl ketone, 1	—	0.40
1	EtOH, 4	Acetone, 1	—	Tr.
2	MeOH, 4	Acetone, 4	—	0.17

a) Reaction temperature, r.t.; Reaction time, 4 h. b) Complex **1**, 150 mg; Complex **2**, 100 mg.

In a typical run, complex **2** (*ca.* 100 mg) was suspended in a methanol (5 ml)/acetone (5 ml) mixture under dinitrogen and stirred for 18 h at 50 °C. The orange-red suspension was gradually converted into a dark blue solution. Acetone azine produced (0.62 mol/W atom) was quantitatively analyzed by an Ohkura Model 103 Gas Chromatograph equipped with a 5 mm×2 m stainless steel column packed with PEG 6000. When methanol/acetone/toluene and methanol/acetone/THF mixtures were used, the yield of the azine was determined by measuring the amount of hydrazine obtained by base distillation of the reaction mixture.

Reaction of Complex 2 with Methanol/Acetone/NaOMe Mixtures. Complex **2** was treated with a methanol (5 ml)/acetone (5 ml) mixture in the presence of NaOMe (4 mol/W atom) for 18 h at 50 °C. A considerable amount of unreacted complex **2** was recovered from the mixture and formation of acetone azine was not observed. When THF (3 ml) was added to a methanol (2 ml)/acetone (1 ml) mixture to dissolve complex **2**, acetone azine was formed in low yield (0.05 mol/W atom), which is much lower than that without NaOMe (0.24 mol/W atom).

Reactions of Complexes 1 and 2 with Alcohol/Ketone Mixtures under UV Irradiation. Complex **1** or **2** (100—130 mg) charged in a quartz Schlenk tube was suspended in an alcohol/ketone mixture and irradiated by Ushio 500 W mercury lamp. The reaction temperature was kept at room temperature by cooling with a fan. Acetone azine and diethyl ketone azine were analyzed by GLC as described above.

The financial support of this research by the Ministry of Education, Science and Culture of Japan (Grant-in-Aid for Developmental Scientific Research 58850181) is greatly appreciated.

Direct *N*-Allylation of Amides with 2-Allylisourea Catalyzed by Palladium(0)

Yoshio INOUE,* Masaaki TAGUCHI, and Harukichi HASHIMOTO
Department of Applied Chemistry, Faculty of Engineering, Tohoku University, Aoba, Aramaki, Sendai 980
(Received April 24, 1985)

Synopsis. Direct *N*-allylation of amides catalyzed by palladium(0) complexes took place under neutral conditions by the use of 2-allylisourea as the allylating agent.

Direct alkylation of amides using reagents such as alkyl halides or sulfonates under neutral conditions generally leads to a mixture of *O*- and *N*-alkylated product. In order to obtain pure *N*-substituted amides, it is usually necessary to generate the amide anion by the use of strong base such as sodium amide or sodium hydride before treatment with alkylating agent.[1] Recently, it was informed that alumina coated with potassium fluoride was effective in promoting *N*-alkylation of amides.[2] The alkylation of amides with alcohols in the presence of ruthenium catalyst has also been reported.[3] Very lately, palladium-catalyzed reaction of allylic substrates with sodium *p*-toluenesulfonamide was shown to afford *N*-allylic derivatives.[4] In a previous paper,[5] we have reported the palladium-catalyzed direct α-allylation of ketones with 2-allyl-1,3-dicyclohexylisourea (**1**), obtained from the reaction of allyl alcohol with dicyclohexylcarbodiimide.[6] Herein we report a novel direct *N*-allylation of amide with **1** under neutral conditions.

The *N*-allylation of amides was performed generally as follows: A solution of **1** (1 eq.), an amide (1 eq.), [Pd(dba)$_2$](2 mol%)[dba=dibenzylideneacetone], and dppe (2 mol%)[dppe=$Ph_2PCH_2CH_2PPh_2$] in dry *N*,*N*-dimethylformamide (DMF) was stirred at 60—100 °C for 1—2 h under nitrogen atmosphere. Usually the progress of the reaction was conveniently monitored

$$CH_2{=}CHCH_2OH + CyN{=}C{=}NCy \longrightarrow CH_2{=}CHCH_2OC(NCy)NHCy$$

1

$$RCNH_2 + \mathbf{1} \xrightarrow[-(NHCy)_2CO]{Pd(0)} RCNH(CH_2CH{=}CH_2) + RCN(CH_2CH{=}CH_2)_2$$

(cy=cyclohexyl)

by the deposition of 1,3-dicyclohexylurea formed. The occurrence of *N*-allylation over *O*-allylation was confirmed spectroscopically by comparing with an authentic sample. Use of [Pd(PPh$_3$)$_3$] complex as the catalyst instead of [Pd(dba)$_2$]-dppe did not give rise to the product. Results are given in Table 1. Various amides were allylated in moderate to good yields. For primary amides, mono- and diallylation took place. The sulfur counterpart of acetanilide, *i.e.*, thioacetanilide, was selectively *S*-allylated. Toluenesulfonamide (*o*- and *p*-) could be readily *N*-allylated at 25 °C by this method. In this case, exclusive diallylation occurred.

$$CH_3CONHPh + R^1OC(NCy)NHCy \xrightarrow[100\,^\circ C,\ 1\ h,\ DMF]{[Pd(dba)_2]\text{-dppe}} CH_3CONR^2Ph$$

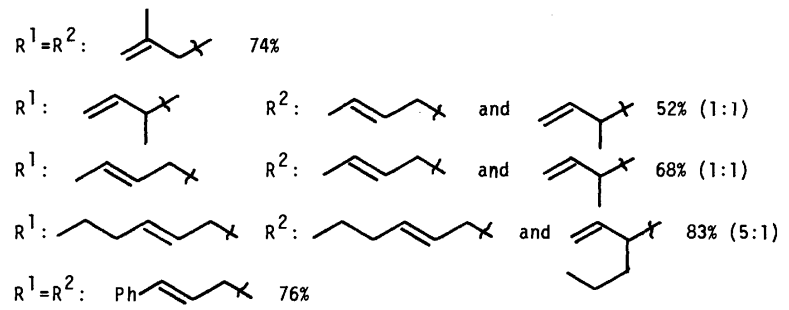
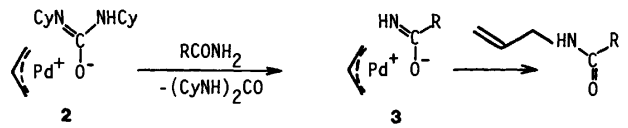
a) 2-Allylisourea (5 mmol), amide (5 mmol), [Pd(dba)$_2$] (2 mol%), dppe (2 mol%), DMF (10 cm^3); R=allyl. b) Isolated yield, based on 2-allylisourea. c) GLC yield.



The reaction of several 2-allylic-substituted isoureas with acetanilide was also investigated. For the allylic system bearing a bulky substituent, the less substituted end tended to react preferentially. Unfortunately, a γ,γ-disubstituted allyl derivative, *i.e.*, 2-prenylisourea, did not undergo the reaction. 1-Methyl-2-propenyl- and 2-butenylisourea realized the same composition of the possible two products. This may indicate that both reactions proceed *via* a same intermediate.[7] Although the mechanism of the reaction is not so clear, we propose a tentative pathway *via* (π-allyl)palladium intermediate **2**, which is derived from oxidative addition of 2-allylisourea **1** to palladium(0). The isourea anion thus formed is supposed to be basic enough to abstract an amide proton to afford imidate intermediate **3**. Then reductive coupling gives the observed product.



2 **3**

Experimental

Preparation of 2-Allylic-substituted Isoureas. They were prepred from allylic alcohols and dicyclohexylcarbodiimide in the presence of a catalytic amount of cuprous chloride according to the published method.[6]

Allylation of Amides. An amide (5 mmol) was allowed to react with 2-allyl-1,3-dicyclohexylisourea (5 mmol) in dry DMF (10 cm^3) in the presence of [Pd(dba)$_2$](0.1 mmol) and dppe (0.1 mmol) under the conditions cited in Table 1. After the reaction was complete, water was added to the mixture. The product was extracted with ether and purified by column chromatography on silica gel. Certain samples for spectroscopic analyses were obtained by preparative GLC. They were denoted by asterisk(*) in the following.

Allyl N-*Phenylthioacetimidate*: An oil. IR (neat) 1628, 1127, 980, 910, 770, and 695 cm^{-1}; ^{1}H NMR ($CDCl_3$) δ=1.84 (s, 3H), 3.61 (d, 2H), 4.81—5.32 (m, 2H), 5.51—6.22 (m, 1H), and 6.25—7.28 (m, 5H); MS (70 eV) *m/z* 191 (M^+), 176, 118, 85, 83, and 77.

N-*(2-Methyl-2-propenyl)acetanilide*: An oil. IR (neat) 1660, 1380, 1275, 900, and 700 cm^{-1}; ^{1}H NMR ($CDCl_3$) δ=1.74 (s, 3H), 1.80 (s, 3H), 4.29 (s, 2H), 4.71 (s, 1H), 4.82 (s, 1H), and 7.06—7.65 (m, 5H); MS (70 eV) *m/z* 189 (M^+), 174, 147, 146, 132, and 106.

N-*(2-Butenyl)acetanilide**: An oil. IR (CCl_4) 1660, 1370, 970, and 698 cm^{-1}; ^{1}H NMR ($CDCl_3$) δ=1.60 and 1.71 (tentatively assigned to (*Z*)- and (*E*)-CH_3C=C, respectively, d, 3H (1:2)), 1.82 (s, 3H), 4.06—4.30 (m 2H), 5.28—5.58 (m, 2H), and 6.94—7.48 (m, 5H) MS (70 eV) *m/z* 189 (M^+) 146, 132, and 93.

N-*(1-Methyl-2-propenyl)acetanilide**: An oil. IR (neat) 1660, 1495, 1385, 1000, and 920 cm^{-1}; ^{1}H NMR ($CDCl_3$) δ=1.12 (d, 3H) 1.79 (s, 3H), 4.84—5.00 (m, 1H), 5.08—5.22 (m, 1H), 5.23—6.12 (m, 2H), and 6.86—7.50 (m, 5H); MS (70 eV) *m/z* 189 (M^+), 174, 146, 132, and 93.

N-*(2-Hexenyl)acetanilide*: An oil. IR (neat) 1660, 1387, 1265, 960, and 695 cm^{-1}; ^{1}H NMR ($CDCl_3$) δ=0.80 (t, 3H), 1.00—1.60 (m, 2H), 1.80 (s, 3H), 1.80—2.15 (m, 2H), 4.25 (d, 2H), 5.35—5.60 (m, 2H), and 7.13—7.55 (m, 5H); MS (70 eV) *m/z* 217 (M^+), 174, 146, 132, and 93.

N-*(1-Propyl-2-propenyl)acetanilide**: An oil. IR (CCl_4) 1660, 1495, 1380, 995, and 925 cm^{-1}; ^{1}H NMR ($CDCl_3$) δ=0.90 (t, 3H), 1.16—1.58 (m, 4H), 1.74 (s, 3H), 4.84—5.92 (m, 4H), and 7.02—7.58 (m, 5H); MS (70 eV) *m/z* 217 (M^+), 174, 133, 132, and 93.

N-*Cinnamylacetanilide*: An oil. IR (neat) 1625, 1432, 1406, 1250, 962, and 692 cm^{-1}; ^{1}H NMR ($CDCl_3$) δ=1.76 (s, 3H), 4.35 (d, 2H), 6.13—6.37 (m, 2H), and 6.90—7.42 (m, 10H); MS (70 eV) *m/z* 251 (M^+), 208, 160, 117, and 115.

Synopsis. A new quassinoid, shinjulactone L, was isolated from *Ailanthus altissima* SWINGLE and the structure was determined to be 12β-acetoxy-2α-hydroxypicrasane-1,11,16-trione by spectral and chemical means.

In previous papers we have reported the isolation and structure elucidation of several quassinoids[1-5] and quassinoid glycosides[6] from *Ailanthus altissima* SWINGLE (Shinju or Niwaurushi in Japanese). Further investigation on bitter principles of the plant led to the isolation of a new quassinoid, shinjulactone L (**1**) from the root bark of this plant.

Shinjulactone L (**1**) crystallized from acetone–benzene as colorless prisms, mp 261—262 °C. High-resolution mass spectrum indicated the molecular formula, $C_{22}H_{30}O_7$. The ^1H and ^{13}C NMR spectra showed the presence of two secondary methyl, two tertiary methyl, two isolated carbonyl, one lactone, and one acetoxyl groups. Since six of seven oxygen atoms were thus characterized, the remaining one oxygen atom was ascribed to a hydroxyl group, the presence of which was supported by the IR absorption band at 3450 cm^{-1}.

The ^1H NMR spectrum of shinjulactone L (**1**) was very similar to that of shinjulactone H (**2**)[3] except for the presence of a signal due to an acetoxyl group and a lower field resonance of a doublet (δ 5.12) which is ascribed to a proton attached to an acetoxyl-bearing carbon atom. In the ^1H NMR of **1** a signal due to a proton attached to a hydroxyl-bearing carbon atom was observed at δ 4.70 as double-double doublets, which are very similar to the signal due to $C_{(2)}$–H (δ 4.77 ddd) observed in ^1H NMR of **2** (see Table 1). This fact suggests that the structure of the A ring of shinjulactone L (**1**) is the same as that of shinjulactone H (**2**). The presence of a carbonyl group at C-11 position and the acetoxyl group at C-12β position in the C ring was also clarified by the ^1H NMR spectrum of **1**; $C_{(9)}$–H appeared at δ 2.93 as a singlet signal and a large coupling constant (J=12.5 Hz) of the doublet signal due to $C_{(12)}$–H was observed. As a result of discussions developed above, the structure of shinjulactone L (**1**) was proposed to be 12-*O*-acetylshinjulactone H, which was finally confirmed by chemical conversion as follows. Shinjulactone L (**1**) was acetylated with acetic anhydride and pyridine to give a diacetate (**3**), which was completely identical with the diacetate (**3**) derived from shinjulactone H (**2**). Thus the structure of shinjulactone L (**1**) was determined to be 12β-acetoxy-2α-hydroxypicrasane-1,11,16-trione. This structure had been previously proposed for acetylamarolide by Casinovi *et al.*[7] but the structure of acetylamarolide was later revised to **4**.[8]

Experimental[9]

Materials and Isolation of Shinjulactone L (1). Root bark of *A. altissima* was collected at the Botanical Gardens, Faculty of Science, The University of Tokyo in August 1982. The isolation procedures are the same as described in the preceding paper.[5] The fraction containing amarolide 11-acetate (**4**)[7,8] mainly was further separated by silica-gel column chromatography eluted with ethyl acetate–chloroform (1:2) to afford shinjulactone L (**1**; *ca.* 0.0005% yield).

Shinjulactone L (1). Colorless prisms from acetone–benzene, mp 261—262 °C; $[\alpha]_D^{26}$ −41° (*c* 0.65, $CHCl_3$); IR (KBr) 3450, 1745, 1730, and 1230 cm^{-1}; ^1H NMR (Table 1); ^{13}C NMR ($CDCl_3$) δ=15.0q, 15.1q, 18.3q, 20.5q, 23.6q, 26.6t, 27.4t, 27.8d, 35.6d, 38.6s, 45.3d, 46.5t, 46.9d, 47.3d, 48.8s, 69.9d, 77.6d, 81.8d, 168.9s, 169.8s, 201.5s, and 212.4s; MS *m/z* (%) 406 (M^+; 19), 378 (13), 364 (18), 362 (19), 346 (100),

303 (36), and 206 (57); Found: *m/z* 406.1979. Calcd for $C_{22}H_{30}O_7$: M, 406.1990.

Acetylation of Shinjulactone L (1). Shinjulactone L (**1**; *ca.* 10 mg) was acetylated with acetic anhydride (2 ml) in pyridine (2 ml) at room temperature for 18 h. After addition of methanol and evaporation, the reaction mixture was purified by silica-gel column chromatography eluted with 15% acetone-benzene to afford 2-*O*-acetylshinjulactone L (**3**; 10 mg), which was identified with 2,12-di-*O*-acetylshinjulactone H (**3**) by TLC, ^{1}H NMR, IR, and mass spectra.

The authors wish to express their thanks to Mr. Eiichi Ishii of the Botanical Gardens for collection of the roots of *A. altissima.*

Synthetic Photochemistry. XXXII.[1] Structures of By-products Formed in the Photocycloaddition of Myrcene to Methyl 2,4-Dioxoalkanoates

Hitoshi TAKESHITA,* Kei KOMIYAMA,† and Koya OKAISHI†

Research Institute of Industrial Science, 86, Kyushu University, Kasuga-koen, Kasuga, Fukuoka 816

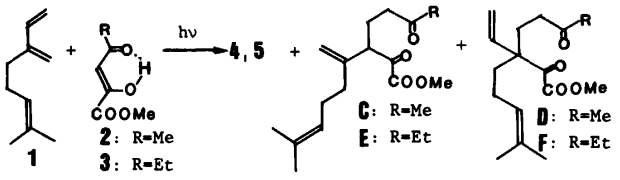
†*Graduate School of Engineering Sciences, 39, Kyushu University, Kasuga-koen, Kasuga, Fukuoka 816*

(Received April 2, 1985)

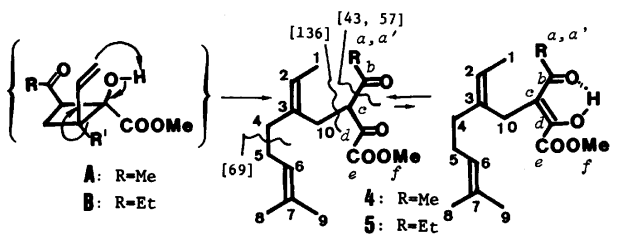
Synopsis. Structures of the by-products formed in the photocycloaddition of myrcene to methyl 2,4-dioxohexanoate and 2,4-dioxopentanoate were elucidated. They were shown to be formed by a 1,5-hydrogen shift of the intermediate (2+2)π adducts of conjugated dienes.

In the course of the photocycloaddition studies regarding myrcene (**1**), a conjugated monoterpene diene, to methyl 2,4-dioxopentanoate (**2**)[1] and to methyl 2,4-dioxohexanoate (**3**),[2] we have isolated a hitherto unknown mode of by-products which were derived from the protoadducts (**A** and **B**) of the (2+2)π adducts (**C**—**F**). This paper will describe the determination of their structures.

The reaction of **1** with **2** afforded a minor product (**4**) in a 20% yields when irradiation was performed between 0 and 5 °C. Since the photocycloaddition of **2** with olefins gives preparatively useful 1,5-diketones in good yields with a highly *regio*-selective fashion, an investigation of such by-product formation should be important. The molecular-weight determination of **4** by the mass spectrum[3] was confirmed to be a 1:1-adduct; *m/z*, 280 (M^+). Among its fragment ions, the acetyl group (*m/z*, 43), the base peak, and another prominent peak due to $C_{10}H_{16}$-moiety (*m/z*, 136) were suggestive. An alternative possibility of $C_9H_{12}O$ for the latter peak was eliminated by the appearance of the same fragment in the mass spectrum of a similar product (**5**) derived from **1** and **3**. In addition, another strong peak due to C_5H_9-ion (*m/z*, 69) ascribable to a 3-methyl-2-butenyl (prenyl) fragment appeared in both the spectra of **4** and **5**. Therefore, they are composed of two moieties, an intact C_{10}-framework of myrcene and the dioxoalkanoate group, linked with one C–C bond.



Scheme 1.



Scheme 2.

The NMR spectra[4] of **4** and **5**, respectively, exhibited not only the presence of acyl groups together with an oxalyl group [δ=2.20(3H, s) for **4** and 1.02(3H, t, J=7 Hz) and 3.83(2H, q, J=7 Hz) for **5**], but also signals ascribable to three methyl groups on the sp^2-carbons. It is certain that the signals for the two methyls are ascribable to the original isopropylidene moiety of **1**, and the third methyl signals (d, J=7 Hz), whose spin-coupling was confirmed respectively by double irradiation experiments, indicated the formation of an ethylidene group from the vinyl group in **1** (Scheme 2). Other than those mentioned, the NMR spectra of **4** and **5** resembled each other. This indicated that their structural relationships and structures could be discussed on the same ground. The NMR spectrum of **4** showed a pair of signals, 2.58(2H, d, J=7 Hz) and 4.25(1H, t, J=7 Hz), which were ascribable to the $R_2C{=}CR{-}CH_2{-}CH(CO)_2$-group. The methine signal disappeared upon a brief treatment with deuterium oxide. At the same time, the methylene signal at 2.58 changed to a singlet. As expected, the integration of the methine, the methylene, and the methoxy methyl signals were weaker than other signals; therefore, although the iron(III) chloride test was negative (as ordinary monoalkylated β-diketone), **4** should be an equilibrated keto-enol mixture. The methylene signal at 3.27 and the methyl signal at 3.84 should be attributable to the enolic tautomer. Due to this tautomerism, the ^{13}C-NMR spectrum of **4** was quite complicated, but its spectrum could, nevertheless, be analyzed with the aid of the assignment for myrcene and citronellol (Table 1). Its spectrum disclosed three carbonyl carbons, four olefinic carbons, and another ten aliphatic carbons.

Consequently, the structure of **4** could be expressed (as shown) and the other product **5** is the propionyl homolog.

The structures of **4** and **5** suggest that their formation involves a formal *retro*-Prins reaction, that is a 1,5-hydrogen shift from the *proto*-(2+2)π-adducts (**A** and **B**) to the 2-alkanoylcyclobutanols.

The yield of **4** or **5** was improved when the irradiation was carried out at low temperatures. Between 0 and 5 °C, the yield of **4** was 22%, but at an elevated temperature (25—30 °C),[5] its formation was suppressed and became practically undetectable. On the other hand, when irradiation was carried out at −35 °C, the yield of **4** was 28%. Furthermore, yields of **4** were as low as 4.8% when the irradiation was stopped immediately after a complete consumption of the starting material. Therefore, **4** and **5** are

a) This column is included as a reference.

photochemical-reaction products from the metastable *proto*-photoadducts, **A** and **B**.

The intramolecular nature of the hydrogen shift is obvious due to its occurrence in the aprotic solvent.

In the case of the photochemical reaction of **1** with 2-methyl-1,3-butadiene (isoprene, **6**),[6] none of the *retro*-Prins product were detected. The IR spectral monitoring of the reaction suggested that the *proto*-adducts from **2** and **6** are quickly dealdolized at that temperature.

In conclusion, from the required geometry for the formation of **4** or **5**, the cycloaddition of **2** or **3** has been established to proceed *via* a geometry in which the hydroxyl and the vinyl group are *cis*. The retention of the ground-state geometry of **2**, a six-membered chelation structure, has already been proven by a chemical-structure determination of the (4+2)π-adducts of **2** with cyclopentadiene.[7]

Experimental

Photocycloaddition of 1 to 2. An EtOAc solution (20 cm^3) of **1** (300 cm^3) and **2** (500 mg) was irradiated by means of a 400-W high-pressure mercury lamp through a Pyrex glass filter between 0 and 5 °C under a nitrogen atmosphere for 8 h. Any excess **1** was then collected by distillation *in vacuo*, and the residue was chromatographed on a silica-gel column. From the least polar fractions eluted by hexane–AcOEt (9:1), a colorless oil was obtained as a mixture of three compound.[1] Subsequently, the mixture was rechromatographed on a prepacked silica-gel column by use of a System 500 apparatus, Nippon Waters, Co., to give **C**,[1] **D**,[1] and **4**, a colorless oil, 215 mg (22%) [Found: C, 68.58; H, 8.67%; M$^+$, 280.1675. Calcd for $C_{16}H_{24}O_4$: C, 68.54; H, 8.63%; M$^+$, 280.1675. ^1H NMR δ=1.59(3H, s), 1.63(3H, d, J=7 Hz), 1.67(3H, s), 2.0(4H, m), 2.20(3H, s), 2.30(3H, s)*,[8] 2.57(1H, d, J=8 Hz, s by add. D_2O), 3.21(2H, s), 3.81(3H, s)*, 3.84(3H, s), 4.36(1H, t, J=8 Hz), 5.00(1H, br. s), 5.36(1H, q, J=7 Hz). IR ν: 1740, 1720, 1220 cm^{-1}].

Photocycloaddition of 1 to 3. A neat mixture of **1** (25 cm^3) and **3** (500 mg) were placed in a cylindrical vessel and irradiated by means of a high-pressure mercury lamp between 0 and 5 °C for 8 h. The mixture was then distilled *in vacuo* to recover **1**, and the residue was chromatographed on a silica-gel column to give a crude photoadduct mixture.[2] Repeated chromatography of the fractions by high-pressure liquid chromatography (HPLC) on Micro-polasil with hexane–AcOEt (95:5) afforded **E**,[2] **F**,[2] and **5**, a colorless oil, 21 mg (2%) [Found: C, 69.58; H, 8.67; M$^+$, 294.1836. Calcd for $C_{17}H_{26}O_4$: C, 69.36; H, 8.90%; M$^+$, 294.1831. ^1H NMR δ=1.06(3H, t), 1.58(6H, s), 1.62(3H, d, J=7 Hz), 1.99(4H, m), 2.58(2H, d, J=7 Hz), 2.59(2H, q, J=7 Hz), 3.27(2H, s)*,[8] 3.83(3H, s)*, 3.85(3H, s), 4.25(1H, t, J=7 Hz), 5.05(1H, m), 5.35(1H, q, J=7 Hz). IR ν: 1740, 1720, 1225 cm^{-1}], from the least polar fractions.

Photocycloaddition of 1 to 2 at Low Temperature. When a neat mixture of **1** (2.5 cm^3) and **2** (50 mg) was externally irradiated between −35 and −30 °C, after 1 h the mixture showed a formation of **4** in 4.8% yield together with **C** and **D**, in 52.4% and 42.8% yields, according to a gas-liquid chromatographic (GLC) analysis. When the irradiation was continued for another 3 h, the mixture was shown to be **C** (45%), **D** (27%), and **4** (28%), using a GLC analysis. The repeated HPLC separation of the mixture on Micro-polasil with hexane–AcOEt (95:5) furnished analytical samples of **C** (24 mg), **D** (14 mg), and **4** (19 mg).

Photocycloaddition of to 2 between 25 and 35 °C. When the same mixture of **1** (2.5 cm^3) and **2** (50 mg) was similarly irradiated between 25 and 35 °C for 2 h, the mixture became negative to the coloration with $FeCl_3$. The HPLC of a mixture on Micro-polasil with hexane–AcOEt (95:5) gave only **C** (17 mg) and **D** (33 mg).

Photochemical Reaction of 1 with 6 at Low Temperature. Attempted Preparation of the Photochemical Ene Reaction Product. An anhydrous EtOAc solution (30 cm^3) of **2** (250 mg) and **6** (*ca.* 2 g) was irradiated by means of a high-pressure mercury lamp for 6 h at −30 °C. After the evaporation of the volatile materils *in vacuo*, the residue was chromatographed on a silica-gel column to give only two previously characterized normal photoadducts.[7]

Gas Chromatography-Mass Spectrometry of *N*-Trifluoroacetyl Trimethylsilyl Esters of Some Iminodicarboxylic Acids

Katsuhiro KAWASHIRO,* Shiro MORIMOTO, and Hideyuki YOSHIDA
Department of Chemical Engineering, Faculty of Engineering, Tokushima University, Minamijosanjima, Tokushima 770
(Received April 15, 1985)

Synopsis. The simultaneous *N*-trifluoroacetylation and *O*-trimethylsilylation of some iminodicarboxylic acids were studied by the use of a mixture of α,α,α,α′,α′,α′-hexafluoro-*N*-methyldiacetamide and *N*,*O*-bis(trimethylsilyl)trifluoroacetamide, as a derivatizing reagent. The resulting *N*-trifluoroacetyl trimethylsilyl ester derivatives gave rather complicated mass spectra with molecular (M^+) and M−15 (loss of CH_3) ions upon electron impact at 20 eV.

Previously we reported EI mass spectra of *N*-trifluoroacetyl (TFA) butyl ester[1] and *N*-trimethylsilyl (TMS) TMS ester[2] derivatives of some iminodicarboxylic acids (IDCAs). It has been shown that the TMS derivatives had advantages over the *N*-TFA butyl ester derivatives in terms of the simplicity of preparation and the easily recognizable mass spectra containing both molecular (M^+) and M−15 (loss of CH_3) ions. The major drawback of the TMS derivatives is incomplete trimethylsilylation (formation of both di- and tri-TMS) due to the steric hindrance of *N*-substituent groups. This may be overcome by introducing a TFA group to the imino nitrogen instead of the TMS group, which is less bulky and also a good *N*-masking group for amino acid esters for gas chromatography. Although two groups[3-6] have reported the preparation of *N*-TFA TMS derivatives of some common amino acids, a convenient single-step derivatization has not been established yet.

We were interested in fast and convenient preparation of *N*-TFA di-TMS esters of some IDCAs on a small scale for gas chromatography-mass spectrometry (GC–MS). This paper deals with a single-step preparation of such volatile derivatives, and also with their mass spectra upon electron impact at 20 eV. The IDCAs include iminodiacetic acid (**1**), 2- and 3-(carboxymethylamino)propionic acids (**2** and **3**), and 2,2′-, 2,3′-, and 3,3′-iminodipropionic acids (**4**—**6**).

Results and Discussion

When a suspension of **3** (50 μmol) in a mixture of

equal volumes (0.20 ml) of α,α,α,α′,α′,α′-hexafluoro-*N*-methyldiacetamide (*N*-methyl-bis(trifluoroacetamide), MBTFA)[7], *N*,*O*-bis(trimethylsilyl)trifluoroacetamide (BSTFA), and acetonitrile was heated at 100 °C for 30 min, a clear solution was obtained. GC analysis showed a single peak, which was determined to be *N*-TFA di-TMS ester of **3** by GC-MS (Fig. 1). Similarly, the other IDCAs except for **4**, gave the corresponding *N*-TFA di-TMS esters on the single-step derivatization (at 100 °C for 30 min). As a typical example, the time course of derivatization of **1** at 100 °C was studied by GC. The peak area ratio of *N*-TFA di-TMS ester of **1** to an internal standard (phenanthrene) became constant after reaction time of 20 min. Although small amounts of both di- and tri-TMS derivatives were present at an early stage of the derivatization (10 min), these two disappeared completely after reaction time of 20 min. These findings indicate that **1** can be converted in a high yield into the *N*-TFA di-TMS ester under the conditions (at 100 °C for 30 min).

In the instance of **4**, however, the derivatization became complicated and gave a mixture of the corresponding *N*-TFA di-TMS ester, TMS derivatives (both di- and tri-), and an unknown by-product[8] under the conditions (at 100 °C for 30 min).

The *N*-TFA di-TMS esters exhibited sharp and symmetrical GC peaks on a packed column. There were no indications of their adsorption on solid supports because of the presence of the stable *N*-TFA group. Retention times of the *N*-TFA di-TMS esters are generally intermediate between those of the corresponding di- and tri-TMS derivatives.[2]

Figure 1 presents the mass spectrum of *N*-TFA di-TMS ester of **3**, as a typical example. Some selected ions for **1**—**6** are listed in Table 1. Both M^+ and M−15 ions characteristic of TMS derivatives are seen for **1**—**6**. These spectra were more complex than those of the corresponding di- and tri-TMS derivatives.[2]

α,α′-IDCAs (**1**, **2**, and **4**) are generally characterized by M−43 (CH_3+CO), M−44 (CO_2), M−117 (COOTMS), M−189 (COOTMS+CH_2=Si(CH_3)$_2$), and M−207 (COOTMS+CH_2=Si(CH_3)$_2$+H_2O). The M−189 and M−207 were absent for **1**. The *N*-TFA group may play an important role for the formation of the M−44 because this ion was not observed for the corresponding TMS derivatives.[2] The M−44 ion[9] can be explained by migration of a TMS group to the carbonyl oxygen of the *N*-TFA group and subsequent elimination of a neutral species CO_2 from the rearranged M^+ ion. Analogous fragmentations are known for *N*-acylglycine TMS esters.[10] The amine fragment, M−117, which constituted a base peak for the corresponding TMS derivatives (both di- and tri-)[2] becomes less abundant.

On the other hand, β,β′-IDCA (**6**) is characterized by a complex spectrum with M−43, M−117, M−118 (COOTMS+H), M−131 (CH_2COOTMS), and M−207. In addition, M−69 (CF_3) and M−97 (CF_3CO) were observed for **6**. The M−44 characteristic of α,α′-IDCAs is not seen in this instance. The structurally most important amine fragment, M−131, which constituted a base peak for the corresponding tri-TMS derivative,[2] becomes far less abundant.

Compound **3** exhibits a complicated spectrum in which both ions characteristic of α,α′- and β,β′-IDCAs are present (Fig. 1). In contrast to **3**, **5** exhibited a similar spectrum to the corresponding α,α′-IDCA, **4**. These facts indicate that either of the fragmentation characteristics of α,α′- or β,β′-IDCAs can take place predominantly depending on the structures of α,β′-IDCAs.

Experimental

Materials. MBTFA was obtained from Gasukuro Kogyo Co. Ltd. BSTFA, acetonitrile, and the IDCAs were the same as previously reported.[2]

Derivatization. About 50 μmol of each IDCA was weighed into a 1 ml mini screw vial (Maruemu MV-1). Acetonitrile (0.20 ml), MBTFA (0.20 ml), and BSTFA (0.20 ml) were added to the vial. It was closed tight with a silicone cap and then heated at 100 °C for different durations in a constant-temperature air bath (Yamato Drying-Oven, DX-58).

GC. GC was carried out with a Hitachi 163 gas chromatograph equipped with a flame ionization detector and a glass column (3 mmϕ×1 m) packed with 1.5% OV-101 on Chromosorb G HP (100/120 mesh) (Shimadzu). The temperature was programmed linearly from 100 °C (5 min hold) to 230 °C at a rate of 5 °C min^{-1}. Nitrogen was the carrier gas flowing at 30 ml min^{-1}. Retention times of the *N*-TFA di-TMS esters: **1** 11.5 min, **2** 12.3 min, **3** 14.0 min, **4** 11.8 and 12.8 min, **5** 14.8 min, **6** 17.4 min. Retention time of phenanthrene: 17.0 min.

GC-MS. GC-MS was carried out with a JEOL JMS-D 300 mass spectrometer connected with a JGC-20 KP gas chromatograph, and mass spectra upon electron impact at 20 eV were obtained. The GC-MS conditions were the same as previously reported.[1]

Solvent Effects on Absorption Spectra of Substituted Azobenzenes

Yoshimi SUEISHI,* Mari ASANO, Shunzo YAMAMOTO, and Norio NISHIMURA
Department of Chemistry, School of Science, Okayama University, Okayama 700
(Received April 17, 1985)

Synopsis. McRae's formula including the quadratic term was applied to an analysis of absorption spectra of substituted azobenzenes in various solvents. It has been suggested that the interaction between the solvent dipole and the solvent-induced solute dipole plays an important role.

Recently, we have reported[1] that the absorption maximum of *trans*-4-dimethylamino-4′-nitroazobenzene (NDAAB) and the rate of its thermal cis-to-trans isomerization are quite sensitive to solvent polarities. Influences of dipole interactions on absorption frequencies were investigated theoretically by Ooshika[2] and McRae.[3] Irick, Jr. and Pacifici[4] and Misono *et al.*[5] applied McRae's formula to absorption spectra of substituted azobenzenes. However, they neglected the quadratic Stark term which represents the contribution of the interaction between the permanent dipole of solvent molecules and the solute dipole thereby induced. Indeed, in the case of less polar solutes such as azulene, the term was reported[6] as negligibly small. McRae[3] suggested, however, that if both solute and solvent are highly polar, the Stark term would make an important contribution.

We reported[1] that solute-solvent interactions such as the dipole-induced dipole one might be operative in very polar solvents for thermal isomerization reactions of NDAAB and 4,4′-bis(diethylamino)azobenzene (BDEAAB). Thereupon, we have examined the Stark term in the McRae equation by using NDAAB and BDEAAB.

Experimental

The reagent grade solvents were used as supplied. The preparation of azobenzenes was described elsewhere.[1]

The absorption spectra were measured with a Hitachi 228 spectrophotometer. For BDEAAB, the separation of absorption spectra was made according to an attached program.

Results and Discussion

The frequencies at the absorption maxima of *trans*-NDAAB and *trans*-BDEAAB in various solvents are given in Table 1. In the case of *trans*-BDEAAB, the absorption spectra consist of three bands which are considered to arise from a normal vibrational structure, and the separation of the spectra was successful by taking their fourth-order derivative (Fig. 1). In Table 1, the lowest-frequencies (0-0 band) in various solvents are listed. As shown in Table 1, ν_{obsd} of BDEAAB is also sensitive to solvent polarity as with NDAAB. It is noteworthy that bis-BDEAAB exhibits more remarkable solvent effects on the absorption spectra than 4-dimethylaminoazo-

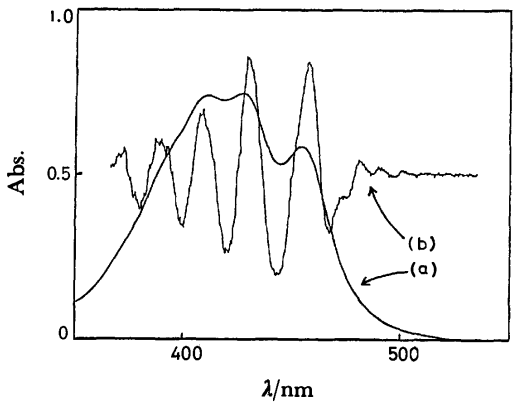

Fig. 1. Absorption spectrum of BDEAAB in hexane (a) and its fourth-order derivative (b).

benzene (DAAB).[1]

McRae[3] proposed a general expression for frequency shifts which arise from dipole interactions:

$$\Delta\nu = (AL+B)\left(\frac{n^2-1}{2n^2+1}\right) + C\left(\frac{D-1}{D+2}-\frac{n^2-1}{n^2+2}\right) + F\left(\frac{D-1}{D+2}-\frac{n^2-1}{n^2+2}\right)^2, \quad (1)$$

where $\Delta\nu$ is the difference between absorption frequencies in solution and in gas phase ($\nu_{obsd}-\nu_{gas}$). Other notations are the same as McRae's.

If the contribution of the F-term which comes from solvent dipole-solute induced dipole interaction is sufficiently small to be neglected for polar solvents, as Irick, Jr. and Pacifici[4] reported, a linear relation between $\{\Delta\nu-(AL+B)[(n^2-1)/(2n^2+1)]\}$ and $\{[(D-1)/(D+2)]-[(n^2-1)/(n^2+2)]\}$ is expected. However, as shown in Fig. 2, the upward curvature is obtained when the points for very polar solvents are included. Therefore, we have treated our data by the quadratic regression equation, and the estimated C- and F-values are given in Table 1.

It is noted that the absolute C-value of BDEAAB is considerably small compared with that of NDAAB. This can naturally be understood since the dipole moment of 4,4'-disubstituted *trans*-azobenzenes such as BDEAAB in ground state must be nearly zero. Both of the absolute F-values are considerably large compared with those reported by Robertson *et al.*[6] (*e.g.*, $|F|=12$ cm^{-1} for ^1L_b of naphthalene and $|F|=200$ cm^{-1} for ^1B_b of naphthacene). This is considered as a good indication of the change in the solute dipole moment induced by solvents. Very recently, solvent-induced changes in electronic structures of molecules having conjugation systems have been investigated with the help of ^{1}H NMR absorption spectra.[7] Moreover, Betrel *et al.*[8] have made a theoretical investigation using the CNDO/SCI method

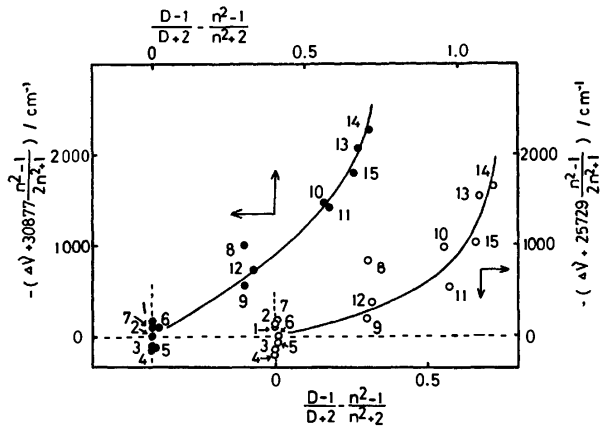

Fig. 2. Relation between $\{\Delta\nu-(AL+B)[(n^2-1)/(2n^2+1)]\}$ and $\{[(D-1)/(D+2)]-[(n^2-1)/(n^2+2)]\}$; ●: NDAAB, ○: BDEAAB. Key is shown in Table 1.

including solvation on the problem of electronic structure. They suggested a significant increase in the solute dipole moment with increasing solvent polarity. This is in accordance with the above results.

In Table 1, the ν-values calculated by using the estimated constants are also given. The standard deviation for the linear plot of ν_{calcd} against ν_{obsd} is much improved compared with the reported one (S. D. 203 cm^{-1}).[4]

Recently, we have shown that rate constants for the isomerization of NDAAB derivatives were well correlated with the absorption maxima of their *trans*-isomers, and suggested that specific solute-solvent interactions might give rise to a polarization of solute molecules enhanced by surrounding polar solvent molecules upon activation. It has been shown that the quadratic term in Eq. 1 plays an important role for the spectral shifts of the push-pull and push-push azobenzenes by polar solvents. Therefore, the present work supports our previous view just mentioned above.

^{79}Br and ^{127}I Nuclear Quadrupole Resonance of Mixed Valency Compounds Ga_2X_4(X=Br, I)

Tsutomu OKUDA,* Hiroshi HAMAMOTO, Hideta ISHIHARA, and Hisao NEGITA
Department of Chemistry, Faculty of Science, Hiroshima University, Higashisenda-machi, Naka-ku, Hiroshima 730
(Received January 14, 1985)

Synopsis. ^{79}Br and ^{127}I nuclear quadrupole resonances(NQR) were observed in α-Ga_2Br_4, β-Ga_2Br_4, and Ga_2I_4 at various temperatures. Resonance lines disappeared at 353, 335, and 448 K for α-, β-Ga_2Br_4, and Ga_2I_4 respectively. The wide separation of the ^{127}I resonance lines in Ga_2I_4 may be attributed to the interaction between the Ga^+ ions and the I atoms.

The X-ray crystal analysis has shown that Ga_2Cl_4 is a mixed valency compound with the ionic structure of $Ga^+(GaCl_4)^-$, that the Ga atom is tetrahedrally coordinated by four Cl atoms, and that the Ga^+ ion is surrounded by eight Cl atoms.[1] The Raman spectrum has revealed that Ga_2Br_4 fused at about 453 K also has the ionic structure of $Ga^+(GaBr_4)^-$.[2] Corbett and Hershaft have reported that Ga_2Br_4 exists in two crystalline forms, with melting points of 426 and 437.5 K.[3] Recently, X-ray crystal analysis has shown that Ga_2I_4 has an ionic structure similar to Ga_2Cl_4.[4]

In the present study, we observed the NQR of Ga_2X_4(X=Br, I) and examined the phase transitions and interionic interaction. The NQR of α-Ga_2Br_4 has already been investigated by Deeg and Weiss.[5]

Experimental

Ga_2Br_4 was prepared by heating equimolar amounts of Ga and $HgBr_2$ in a glass reaction tube.[6] The α-form was obtained by gradually cooling the mixture from 426 K, and the β-form, by cooling it rapidly from 438 K. Ga_2I_4 was prepared by heating equimolar amounts of Ga anf HgI_2 at 484 K in a glass tube. In each case, the compound was purified by eliminating Hg as a by-product.

NQR was measured by using superregenerative oscillators with Zeeman modulation. The temperature of the sample was determined with the aid of a copper-constantan thermocouple.

Results and Discussion

Table 1 shows the observed NQR frequencies of Ga_2X_4(X=Br, I). The ^{79}Br resonance frequencies of α-Ga_2Br_4 are in good agreement with those reported by Deeg and Weiss.[5] Two ^{79}Br resonance lines were also observed for β-Ga_2Br_4. The two lines of the β-form are widely separated, whereas those of the α-form are close to each other. The wide separation of the resonance lines suggests that the shape of the $GaBr_4^-$ ion is a distorted tetrahedron. In the case of Ga_2Cl_4, a contraction in volume has been reported by Fedrov and Lovetskaya when the α-form is transformed to the β-form.[7] This causes the intermolecular distances to shorten. Therefore, the influence of the crystal field on the electric field gradients becomes large, and the resonance lines result in a wide separation or multiple split. A similar relation can be expected to hold for Ga_2Br_4.

As the temperature was raised from 77 K, all the resonance lines in α- and β-Ga_2Br_4 decreased gradually in frequency, but the curves of the frequency *vs.* the temperature in the α-form crossed at about room temperature. The resonance lines disappeared at 353 and 335 K for the α- and β-forms respectively. When the temperature of each sample was brought back from the temperature of the line-disappearance to room temperature, however, no resonance lines could be observed. However, when each sample was once melted and then cooled to room temperature, its resonance lines could again be observed. Our differential thermal analysis measurements showed that, with an increase in the temperature from room temperature, one peak was recorded near 370 K for the α-form and two peaks were recorded near 355 and 390 K for the β-form.

	^{127}I	131.94	262.14	7.16	874.71
	^{127}I	134.27	262.61	13.24	878.46
	^{127}I	163.71	280.90	36.64	960.13

a) The experimental errors are within ±0.02 MHz for ^{79}Br and ^{127}I.

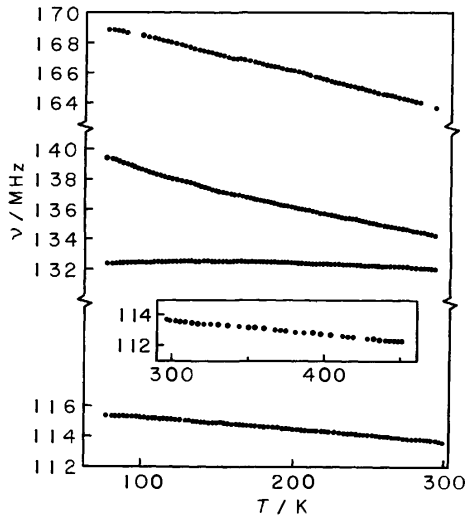

Fig. 1. Temperature dependence of ν_1 NQR frequencies of ^{127}I in Ga_2I_4.

Therefore, it seems likely that the disappearance of the resonance lines is due to the phase transition.

The eight ^{127}I resonance lines listed in Table 1 were observed for Ga_2I_4. There is an ambiguity in pairing the ^{127}I resonance lines because the pairing of these lines was done in the order of frequency. The other combination gives slightly different values for the asymmetry parameter, η, and the quadrupole coupling constant, e^2Qq/h. The four $\nu_1(\pm 1/2 \leftrightarrow \pm 3/2)$ lines of ^{127}I are so widely separated that the small distortion in the shape of the GaI_4^- ion can not be attributed to the line separation.

According to the X-ray analysis by Gerlach *et al.*,[3] the Ga–I bond lengths are 2.537(5), 2.541(4), 2.541(4), and 2.608(4)Å, and all I–Ga–I angles are within 3.1° of the tetrahedral angle. The shape of the GaI_4^- ion slightly distorted from a regular tetrahedron; therefore, the distortion of the shape of the anion can not be reasonable as the cause of the line separation. The I···I distances in the GaI_4^- ion range from 4.121 to 4.266 Å, and the I···I distances between GaI_4^- ions are equal to the sum of the van der Waals radii.[3] Accordingly, the I···I distances can not cause the resonance lines to separate widely. One Ga^+ ion is surrounded by eight I atoms at distances ranging from 3.281 to 3.820 Å, and the number of Ga^+ ions with which a given I atom interacts differs with each crystallographically nonequivalent I atom.[3] Therefore, the wide separation of the resonance lines is ascribable mainly to the Ga^+···I interaction.

Figure 1 shows the temperature dependence of the ν_1 NQR frequencies of ^{127}I in Ga_2I_4. All the resonance lines decreased in frequency with the increase in the temperature. The slopes of the curve for the higher two resonance lines are large, while those of the rest are small. In the temperature region above room temperature, the temperature dependence was observed only for the lowest resonance line, as is shown in Fig. 1. As the temperature was raised, the resonance line decreased monotonously in its frequency. The intensity of the resonance line became gradually small from about 400 K and disappeared at 451 K. When the temperature was brought back to room temperature, the resonance lines could be observed again.

The Magnetic Properties of the Copper(II) Complexes with ω-Amino Carboxylic Acids

Shuji EMORI,* Toshihiko NOGUCHI, and Yoneichiro MUTO
Department of Chemistry, Faculty of Science and Engineering, Saga University, Honjo-machi, Saga 840
(Received March 19, 1985)

Synopsis. Compounds of formula $CuX_2(OOC(CH_2)_m NH_3)_2 \cdot nH_2O$ (m=2—5 and X=Cl or Br) and $CuX_{3/2}(OOCCH_2NH_3)$ (X=Cl or Br) have been prepared and characterized by means of magnetic susceptibility and IR spectroscopy measurements. The correlation of their magnetic moments with the pK_a values of their parent carboxylic acids is discussed.

In general, α- and β-amino carboxylic acids form metal chelates in which the amino nitrogen and carboxylate oxygen atoms act as donors. However, a recent X-ray study[1] of the complex formed by the reaction between copper(II) chloride and glycine, has shown that ammonio acetate coordinates to the metal ion *via* a carboxyl group and that copper(II) acetate-type dimer units are created. This suggests that not only *N*-protected amino carboxylic acids, such as *N*-acetylglycine,[2] *N*-tosylglycine[3] and hippuric acid,[4] but amino carboxylic acids can act generally as simple carboxylic acids. The resultant copper(II) compounds seem to be appropriate to investigate the effect of the NH_3^+ group on their magnetic properties. Thus, we tried to isolate the copper(II) compounds from the acidic solutions with various ω-amino carboxylic acids.

A compound with a stoichiometry of $CuCl_2(OOC(CH_2)_mNH_3)_2 \cdot nH_2O$, where m=2—5, was precipitated in green crystals when a slight excess of amino carboxylic acid and a small amount of a 2 mol dm^{-3} HCl solution were added to a warm solution (*ca.* 40 °C) of copper(II) chloride. Then, the mixture was allowed to stand in a refrigerator overnight. The corresponding bromide salt was also obtained in a similar way. Fresh samples of the obtained compounds mostly contain water molecules (IR band at *ca.* 3450 cm^{-1}). The water was gradually lost when stored under anhydrous conditions. The corresponding glycine compound, $CuCl_2(OOCCH_2NH_3)_2 \cdot 2H_2O$, was also isolated by Castillo and Ramirez,[5] but its magnetic moment (μ_{eff}=1.81 BM at 22 °C) and IR data indicate that the compound has a monomeric structure. Since two isomers of the analogous chromium(II) bromide compound, $CrBr_2(OOCCH_2NH_3)_2 \cdot 2H_2O$, were isolated by Herzog *et al.*,[6,7] we attempted to isolate the isomeric form of $CuCl_2(OOCCH_2NH_3)_2 \cdot 2H_2O$. The mixed valence compound $CuCl_{3/2}(OOCCH_2NH_3)$, however, was isolated[1] as dark-green crystals instead of the expected isomer. This compound can be obtained more efficiently by reacting glycine with an acidic aqueous solution including equimolar amounts of copper(I) and copper(II) chlorides and allowing the solution to stand in a refrigerator overnight. The corresponding bromide salt is also obtained in a similar way.

The magnetic moments of the present compounds (Table 1) were evaluated per copper(II) ion from their susceptibilities observed at room temperature and the relevant Pascal constants.[8] The magnetic susceptibilities of the chloride salts were measured from liquid nitrogen up to room temperature (Fig. 1) and agreed well with the theoretical equation for the

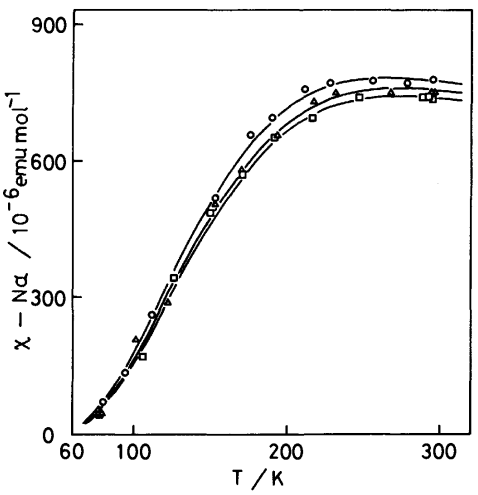

Fig. 1. Magnetic susceptibilities of the copper(II) chloride compounds with 3-aminopropionic (○), 4-aminobutyric (△) and 6-aminohexanoic (□) acids. The solid curve represents the Bleaney-Bowers equation.

susceptibility of binuclear copper(II) compounds (Bleaney-Bowers equation[9]), using the following parameters: g=2.18 and $2J$=−315 cm^{-1}, g=2.15 and $2J$=−320 cm^{-1}, and g=2.15 and $2J$=−324 cm^{-1} for the compounds with 3-aminopropionic(β-alanine), 4-aminobutyric and 6-aminohexanoic acids, respectively, and $N\alpha$=60×10^{-6} emu mol^{-1} (1 emu mol^{-1}=4π×10^{-6} m^3 mol^{-1}). IR spectra of the solid complexes show the bands near 1520 and 1580 cm^{-1} connected with NH_3^+ deformations[10] in addition to the characteristic bands in the range 1430—1450 and 1600—1660 cm^{-1} connected with symmetric and unsymmetric stretching vibrations of the carboxyl groups.[11] The obtained results show clear evidence for the presence of a dinuclear subunit, which contains four zwitterionic amino carboxylic acids bound with the copper(II) ions *via* carboxyl group like copper(II) acetate monohydrate. The axial positions seem to be occupied by halide ions, because there exists a slight difference in the magnetic moments between the chloride and bromide salts. It is consistent with the fact that the magnetic moments of the anhydrous compounds are not greatly different from those of the hydrated compounds, water being probably involved in hydrogen bonding in the packing of the molecules.

It has already been pointed out that the magnetic superexchange interaction in the dimeric carboxylates is related to the donor-acceptor character of bridging and axial ligands.[12] Although this relationship does not take into account the effect of the metal-ligand bond or steric effects in the axial ligand coordination, it has been supported experimentally[13,14] and shown to be consistent with the results of molecular orbital analyses of the bridged dimeric structure.[15] In this series of bridging ligands, the pK_a value varies from 2.36 for glycine to 3.53, 4.03, 4.27, and 4.43 for 3-aminopropionic, 4-aminobutyric, 5-aminovaleric and 6-aminohexanoic acids, respectively.[16] From Table 1, it can be seen that, except for the glycine compounds, the trend that magnetic moments in the series of the same halide salts increase as the acid strength of the ammonio carboxylic acids (pK_{a_1}) becomes stronger. This trend is consistent with the variation of singlet-triplet separation values(−2J) determined for a series of chloride salts. X-Ray and magnetic susceptibility studies of the glycine compound $CuCl_{3/2}(OOCCH_2NH_3)$ have shown that this polymeric compound is composed of cupric dimeric subunits with an exchange integral $2J$=−385 cm^{-1}.[1] Although this strong antiferromagnetic interaction was explained by the presence of an electrophilic NH_3^+ group,[1] a large number of magnetic data for copper(II) halogenoacetates[17] have shown that the σ-electron attracting effect produces a comparative decreasing magnetic interaction. The disobedience of the general trend suggests that the strong interaction in the glycine compound is attributable to steric effects or the coordination of the axial chlorine to a copper(I) ion. The fact that the magnetic moments of the chloride salts are higher than those of bromide salts indicates that the antiferromagnetic interaction in dimeric copper(II) carboxylate adducts tends to become stronger as the basicity of the added axial ligands becomes weaker.[18]

(Received March 12, 1985)

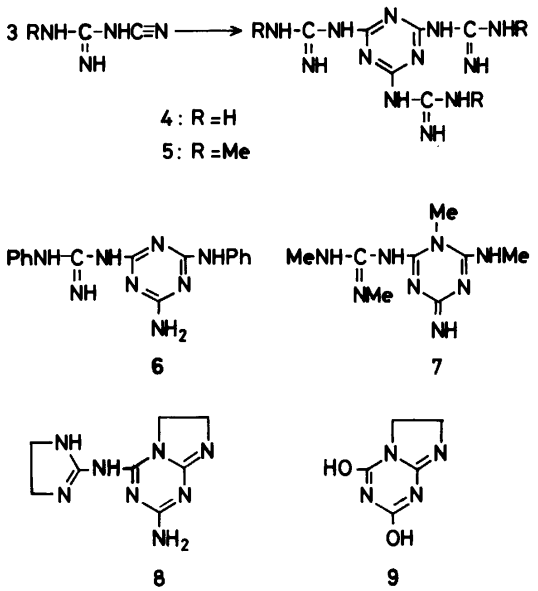
Synopsis. 2,4,6-Triguanidino-1,3,5-triazine and 2,4,6-tris(3-methylguanidino)-1,3,5-triazine were synthesized in 42 and 52% yields, respectively, by the cyclotrimerization of cyanoguanidine and 1-methyl-3-cyanoguanidine using DMF as a solvent in the presence of hydrogen chloride. 1-Phenyl-3-cyanoguanidine, 1,2-dimethyl-3-cyanoguanidine, and 2-imidazolidinylidenecyanamide, however, were cyclodimerized to the corresponding guanidino-1,3,5-triazines in a similar manner.

Our previous papers[1–3] described that 2,4-diamino-6-guanidino-1,3,5-triazine (**1**), 2-amino-4,6-diguanidino-1,3,5-triazine (**2**) and 1-amidino-2,4,6-triguanidino-dihydro-1,3,5-triazine (**3**) were prepared by a reaction of cyanoguanidine using phenol or pyridine–nitrobenzene as a solvent in the presence of hydrogen chloride. Especially 2,4,6-triguanidino-1,3,5-triazine (**4**) was not formed directly through the above reaction, but was produced quantitatively upon an elimination reaction of cyanamide from **3** in an alkaline solution.

In this paper, we wish to report a convenient method of synthesizing **4** by the cyclotrimerization of cyanoguanidine using DMF as a solvent, together with the reaction of substituted cyanoguanidines in DMF.

The reaction of cyanoguanidine in the presence of equimolar hydrogen chloride in DMF gave **4** and **1** in 42 and 8% yields, respectively. However, **2**, **3** and cyanamide were not detected in this reaction, and **3** did not release cyanamide under the conditions of this reaction. These results suggest that **4** was formed by the cyclotrimerization of cyanoguanidine.

The reaction was extended to substituted cyanoguanidines. Consequently, 2,4,6-tris(3-methylguanidino)-1,3,5-triazine (**5**) was obtained in 52% yield by the cyclotrimerization of 1-methyl-3-cyanoguanidine. The structure of **5** was established by its acid hydrolysis, which gave cyanuric acid and methylguanidine in 69 and 58% yields, respectively. The reaction of 1-phenyl-3-cyanoguanidine, however, did not afford the expected 2,4,6-tris(3-phenylguanidino)-1,3,5-triazine, and provided only the normal type of 3-phenylguanidino-1,3,5-triazines,[3] which was 2-amino-4-anilino-6-(3-phenylguanidino)-1,3,5-triazine (**6**) by the cyclodimerization of the starting material, in 21% yield. **6** was confirmed with an authentic sample.[3] In a similar manner, 1,2-dimethyl-3-cyanoguanidine and 2-imidazolidinylidenecyanamide were also cyclodimerized and deposited 1-methyl-2-methylamino-4-imino-6-(2,3-dimethylguanidino)-1,4-dihydro-1,3,5-triazine (**7**) and 2-amino-4-(4,5-dihydro-1*H*-imidazol-2-ylamino)-6,7-dihydroimidazo[1,2-*a*][1,3,5]triazine (**8**) from the DMF solution in 41 and 67% yields, respectively. **7** and **8** were also obtained in a phenol solvent in 81 and 71% yields, respectively, upon a treatment of the solution.[3] The structure of **7** was established by an elemental analysis, the mass spectrum and acid hydrolysis. This gave 1-methyl-1,3,5-triazine-2,4,6(1*H*,3*H*,5*H*)-trione, 1,3-dimethylguanidine, methylamine and ammonia. The structure of **8** was also established by an elemental analysis, its mass spectrum and acid hydrolysis, giving 6,7-dihydroimidazo[1,2-*a*][1,3,5]triazine-2,4-diol (**9**), 4,5-dihydro-1*H*-imidazol-2-amine and ammonia. These results suggest that the cyclotrimerization of cyanoguanidines using DMF has a limitation.



Experimental

2,4,6-Triguanidino-1,3,5-triazine (4). Hydrogen chloride (8.75 g, 0.24 mol) was introduced into a stirred solution of cyanoguanidine (16.81 g, 0.20 mol) in 155 ml of DMF at room temperature. The solution was stirred at 80 °C for 110 min and then evaporated under reduced pressure. 2-Propanol was added to the oily residue and the resulting precipitate was collected by filtration. The precipitate was dissolved in water. After removing the insoluble material, the solution was adjusted to pH 13.6 with an aqueous sodium hydroxide solution. Then, the precipitate, the free state of **4**, was filtered off and washed with water. The yield was 0.69 g (3%). After the filtrate was made acidic with 6 mol dm^{-3} of nitric acid, the precipitate, **4** nitrate (8.51 g, 29%), was filtered off. The filtrate was concentrated to yield **1** nitrate (6.12 g, 21%) and the nitrate of the mixture. The mixture was separated to **1** (0.54 g, 1%; insoluble to the aqueous ammonia solution) and amidinourea (2.28 g, 3%; insoluble to the acetic acid solution) as the picrates. The filtrate of 2-propanol solution was concentrated to yield

amidinourea (6.53 g, 10%) and guanidine (3.51 g, 6%) as the picrates.

In a similar manner, a cyanoguanidine–acetone adduct (hydrochloride)[4] used as a starting material gave **4** (42%) and **1** (8%) at 80 °C after 30 min, or gave **4** (40%) and **1** (1%) at room temperature after 5 d.

2,4,6-Tris(3-methylguanidino)-1,3,5-triazine (5). Hydrogen chloride (3.65 g, 0.1 mol) was introduced into a stirred solution of 1-methyl-3-cyanoguanidine[5] (9.81 g, 0.1 mol) in 70 ml of DMF below 10 °C. The solution was stirred at 80 °C for 3 h. After cooling, a precipitate was filtered off and washed with 2-butanone. The yield of **5** was 7.31 g, (52%). Recrystallization from a dilute hydrochloric acid provided pure **5** as the hydrochloride: mp 313 °C; Found: C, 25.39; H, 5.28; N, 39.39; Cl, 24.82%. Calcd for $C_9H_{18}N_{12}\cdot 3HCl\cdot H_2O$: C, 25.63; H, 5.50; N, 39.86; Cl, 25.22%. IR (KBr) 810 cm^{-1} (1,3,5-triazine ring). Recrystallization from a dilute nitric acid provided pure **5** as the nitrate: mp 265.5 °C (dec). Found: C, 21.63; H, 4.51, N. 42.25%. Calcd for $C_9H_{18}N_{12}\cdot 3HNO_3\cdot H_2O$; C, 21.56; H, 4.62; N, 41.91%. IR (KBr) 810 cm^{-1} (1,3,5-triazine ring).

2-Amino-4-anilino-6-(3-phenylguanidino)-1,3,5-triazine (6). Hydrogen chloride (18.60 g, 0.51 mol) was introduced into a stirred solution of 1-phenyl-3-cyanoguanidine[6] (80.09 g, 0.50 mol) in 386 ml of DMF at room temperature. The solution was stirred at 80 °C for 3 h, and then concentrated under reduced pressure to give *N*-(phenylamidino)urea as the picrate (76.58 g, 38%). After filtering off, the filtrate was extracted with water, and then the oily residue was dissolved in acetone. The acetone solution was evaporated to dryness and the residue was recrystallized from methanol to give 9.47 g (10%) of **6** as the hydrochloride.[3] The extracted solution was made alkaline with ammonia, and the resulting precipitate was recrystallized from a dilute nitric acid to give 11.29 g (11%) of **6** as the nitrate.[3]

1-Methyl-2-methylamino-4-imino-6-(2,3-dimethylguanidino)-1,4-dihydro-1,3,5-triazine (7). In a similar manner as for the preparation of **5**, **7** was obtained from 1,2-dimethyl-3-cyanoguanidine.[5] The yield was 41%. Recrystallization from water provided pure **7** as the hydrochloride: mp 245—246 °C; IR (KBr) 780 cm^{-1} (1,3,5-triazine ring). Found: C, 30.30; H, 7.00; N, 36.32; Cl, 11.90%. Calcd for $C_8H_{16}N_8\cdot HCl\cdot 3H_2O$: C, 30.53; H, 7.36; N, 35.60; Cl, 11.26%. MS Found: *m/z* 244. Calcd for $C_8H_{16}N_8$: M, 244.

2-Amino-4-(4,5-dihydro-1H-imidazol-2-ylamino)-6,7-dihydroimidazo[1,2-a][1,3,5]triazine (8). In a similar manner, **8** was obtained from 2-imidazolidinylidenecyanamide[7] in 64% yield. Recrystallization from 0.5 mol dm^{-3} of hydrochloric acid provided pure **8** as the hydrochloride: mp 337 °C. IR (KBr) 780 cm^{-1} (1,3,5-triazine ring). Found: C, 34.88; H, 5.35; N, 41.42; Cl, 13.11%. Calcd for $C_8H_{12}N_8\cdot HCl\cdot H_2O$: C, 34.98; H, 5.49; N, 40.79; Cl, 12.91%. MS Found: *m/z* 220. Calcd for $C_8H_{12}N_8$: M, 220.

Acid Hydrolysis. By the same procedure described in our previous paper,[8] **5** was refluxed in 6 mol dm^{-3} of hydrochloric acid for 133 h and gave unreacted **5** (6%), cyanuric acid (69%), methylguanidine as the picrate (58%). Ammonia was detected in the solution.

In a similar manner, **7** was refluxed for 10 h and gave 1-methyl-1,3,5-triazine-2,4,6(1*H*,3*H*,5*H*)-trione[9] (15%. mp 285—286 °C; MS *m/z* 143), 1,3-dimethylguanidine (96%) and methylamine (4%). Ammonia was also detected in the solution.

In a similar manner, **8** was refluxed for 48 h and gave 4,5-dihydro-1*H*-imidazol-2-amine[10] (77%) and **9**[11,12] (70%). Ammonia was also detected in the solution. By a Hinsberg test, **9** was confirmed to be the tertiary amine. Recrystallization from a dilute hydrochloric acid provided pure **9** as the hydrochloride: mp 302 °C (dec). (Found: C, 28.32; H, 4.34; N, 27.07; Cl, 16.63%. **9**: MS *m/z* 154).

A Through Space/Bond Interaction Analysis on the Shape of Band Structure of Polynitrilomethylidyne

Yuriko Aoki, Akira Imamura,* and Hiroyuki Teramae
Department of Chemistry, Faculty of Science, Hiroshima University, Hiroshima 730
Department of Hydrocarbon Chemistry, Faculty of Engineering, Kyoto University, Kyoto 606
(Received February 1, 1985)

The concept of the through space/bond interaction presented by Hoffmann *et al.* was extended to study electronic states of polymers. The band shape of lone pair orbitals was investigated by truncating converged Fock matrices and overlap integrals except for the terms corresponding to the through bond and particular through space interactions. This method was used by applying the *ab initio* tight-binding crystal orbital method to three isomers of one-dimensional polynitrilomethylidyne, for which the dependences of the lone pair orbital energy on the wave number vector differ significantly from one another. The band shape of the lone pair orbital is related intimately to the interaction with H atoms. The effect of each through space interaction on the band shape of the lone pair orbital may be reasonably interpreted in terms of the symmetry of crystal orbitals. This method seems expedient for analyzing qualitatively lone pair bands of various polymers at the *ab initio* level.

The concept of the through space/bond interaction introduced by Hoffmann *et al.* in 1968 has made a great contribution to the evaluation of the size of interaction between lone pair orbitals.[1] The through bond interaction can be quantitatively analyzed in more detail by using localized molecular orbitals transformed from canonical molecular orbitals. In the present article, an application of this through space/bond concept to one-dimensional polymer systems by using atomic orbitals was attempted in expectation of characterizing electronic states of various polymers.

In recent years a number of theoretical studies on conjugated organic polymers have been reported. We chose polynitrilomethylidyne, which possesses conjugated carbon–nitrogen double bonds, as a model polymer system for test calculation on the through space/bond interaction. This polymer has recently been synthesized, and it was found that the conductivity σ_{300K} was up to $10^{-10}\ \Omega^{-1}\mathrm{cm}^{-1}$ in spite of the possession of an even number of electrons in the unit cell.[2,3] For this reason polynitrilomethylidyne has been the object of several theoretical studies. Polynitrilomethylidyne is composed of trans-zigzag, trans-cisoid, and cis-transoid forms as shown in Fig. 1. For the trans-zigzag form, Karpfen[4,5] carried out an optimization of the geometry at the Hartree-Fock *ab initio* double zeta level by assuming that the unit cell of an infinite polymer consists of a single HCN molecule. Furthermore, the force constant, band structure, and density of state were investigated in comparison with those for polyacetylene in the literature.[6] Kertesz and co-workers[7,8] applied the restricted and unrestricted Hartree-Fock methods to studying the alternating and nonalternating structures of the trans-zigzag $(-HCN-)_x$ linear chains. Bredas *et al.*[9,10] calculated the ionization potential, band width, and band gap for the trans-zigzag polynitrilomethylidyne by using the valence effective Hamiltonian technique. For the hydrogen-bonded hydrogen cyanide polymer chain, *ab initio* studies based on crystallographic data[11,12] were previously reported in comparison with HCN molecules or their aggregates.[13,14] On the other hand, the trans-cisoid and cis-transoid forms have only rarely been studied in detail from the theoretical point of view.

In this study, *ab initio* calculations were performed on the three isomers of polynitrilomethylidyne, and by using the matrix elements obtained the through space/bond method was applied to analyzing the lone pair bands. The purpose of this study was to investigate the applicability of this method by examining the influence of the interaction between atomic orbitals on the shape of lone pair bands.

Method

The *ab initio* crystal orbital method used in this study is based on the general SCF tight-binding LCAO formalism[15] corresponding essentially to Roothaan's Hartree-Fock equation for molecules,[16] taking into account all neighbor interactions and overlap integrals. The outline of this theory is described below. A delocalized wave function of a single electron in the periodic potential of a one-dimensional crystal is represented as a linear combination of Bloch basis orbitals $\phi_i^k(r)$, which are written as periodic combinations of n atomic orbitals χ_r:

$$\phi_i^k(r_1) = (2N+1)^{-1/2}\sum_{m=-N}^{+N}\sum_{r=1}^{n}\exp(ikR_m)C_{ir}(k)\chi_r(r_1-R_m), \quad (1)$$

where k denotes a wave number vector in the first Brillouin zone, i an energy band, and i the imaginary number or the square root of -1. The term $\chi_r(r_1-R_m)$ stands for an atomic orbital localized in the m-th cell at $R_m(m=0, \pm1, \pm2, \cdots\cdots, \pm N)$, and $2N+1$ is the number of elementary cells. Applying the well known non-relativistic Hamiltonian

$$H = \sum_{\mu}\left\{-\frac{1}{2}\Delta_\mu + V(\mu)\right\} + \sum_{\mu>\nu}\frac{1}{r_{\mu\nu}} \quad (2)$$

to the antisymmetrized product of the one-electronic wave function Eq. 1 and using the orthonormality condition

$$\langle\phi_i^k(r_1)|\phi_j^k(r_1)\rangle = \delta_{ij}, \quad (3)$$

we obtain the total electronic energy as

$$E = 2\sum_{i}^{\text{occ}} H_{ii} + \sum_{i}^{\text{occ}}\sum_{j}^{\text{occ}} (2J_{ij} - K_{ij}) \tag{4}$$

where

$$H_{ij} = \int \phi_i(1)\left\{-\frac{1}{2}\Delta_1 + V(1)\right\}\phi_j(1)\,d\tau_1,$$

$$J_{ij} = \iint \phi_i(1)\,\phi_j(2)\frac{1}{r_{ij}}\phi_i(1)\phi_j(2)\,d\tau_1 d\tau_2,$$

$$K_{ij} = \iint \phi_i(1)\,\phi_j(2)\frac{1}{r_{ij}}\phi_j(1)\phi_i(2)\,d\tau_1 d\tau_2,$$

Substituting the crystal orbital Eq. 1 into Eq. 3 and using the periodic boundary condition, we obtain the corresponding total electronic energy per unit cell as

$$E = 2\sum_{i}^{\text{occ}}\sum_{k=0}^{2\pi}\sum_{r}\sum_{s} C_{ir}^{*}(k)C_{is}(k)\sum_{m=-M}^{+M}\exp(\mathbf{i}kR_m)I_{rs}^{0m}(R_m)$$
$$+ \sum_{i}^{\text{occ}}\sum_{k=0}^{2\pi}\sum_{m}\sum_{h}\sum_{l}\sum_{r}\sum_{s}\sum_{t}\sum_{u} P_{tu}^{hl}C_{ir}^{*}(k)C_{is}(k)\exp(\mathbf{i}kR_m)$$
$$\times\left\{2\left\langle {}^{0m}_{rs}\middle|{}^{hl}_{tu}\right\rangle - \left\langle {}^{0h}_{rt}\middle|{}^{ml}_{su}\right\rangle\right\}, \tag{5}$$

where M denotes the number of cells included in the summation, and

$$I_{rs}^{0m}(R_m) = \langle\chi_r(r_1)|h(1)|\chi_s(r_1-R_m)\rangle,$$

$$P_{tu}^{hl} = (2N+1)^{-1}\sum_{k'=0}^{2\pi}\sum_{j=1}^{\text{occ}}\exp\{\mathbf{i}k'(R_l-R_h)\}C_{jt}^{*}(k')C_{ju}(k'),$$

$$\left\langle {}^{0\,m}_{r\,s}\middle|{}^{h\,l}_{t\,u}\right\rangle = \langle\chi_r(r_1)\chi_s(r_1-R_m)|r_{12}^{-1}|\chi_t(r_2-R_h)\chi_u(r_2-R_l)\rangle,$$

These last three equations correspond to the one-electron core integral, the density matrix, and the two-electron integral, respectively. Symbols r, s, t, and u denote the atomic orbitals in the elementary cells characterized by symbols 0, m, h, and l, respectively. Putting the overlap integral between the r-th atomic orbital in the central cell and the s-th atomic orbital in the m-th cell as

$$S_{rs}^{0m}(R_m) = \langle\chi_r(r_1)|\chi_s(r_1-R_m)\rangle \tag{6}$$

and applying the Ritz variation method to the Eq. 5, we can obtain the eigenvalue problem

$$\sum_{s}\sum_{m=-M}^{+M}\exp(\mathbf{i}kR_m)[F_{rs}^{0m}(R_m) - S_{rs}^{0m}(R_m)E_t(k)]C_{is}(k) = 0, \tag{7}$$
$$(k=0,\ \cdots,\ 2\pi)$$

where F_{rs}^{0m} is the Fock matrix element between the r-th atomic orbital in the central segment and the s-th atomic orbital in the m-th cell and is given by

$$F_{rs}^{0m}(R_m) = I_{rs}^{0m}(R_m)$$
$$+ \sum_{h}\sum_{l}\sum_{t}\sum_{u} P_{tu}^{hl}\left\{2\left\langle {}^{0\,m}_{r\,s}\middle|{}^{h\,l}_{t\,u}\right\rangle - \left\langle {}^{0h}_{rt}\middle|{}^{m\,l}_{su}\right\rangle\right\}. \tag{8}$$

If the expression for the Fock matrix element between Bloch orbitals $F_{rs}(k)$ and that for the corresponding overlap integral $S_{rs}(k)$ are defined as

$$F_{rs}(k) = \sum_{m=-M}^{+M}\exp(\mathbf{i}kR_m)F_{rs}^{0m}(R_m), \tag{9}$$

$$S_{rs}(k) = \sum_{m=-M}^{+M}\exp(\mathbf{i}kR_m)S_{rs}^{0m}(R_m), \tag{10}$$

then the eigenvalue problem for a given value of k in the first Brillouin zone is obtained as

$$\sum_{s}F_{rs}(k)C_{is}(k) = \sum_{s}S_{rs}(k)C_{is}(k)E_i(k). \tag{11}$$

As a result the secular equation to be solved is given by

$$|F_{rs}(k) - S_{rs}(k)E_i(k)| = 0. \tag{12}$$

Based on this theory, the Polymer Gaussian 74 program has been extensively developed by Suhai[6] within the Hartree Fock scheme. *Ab initio* calculations were performed on three typical isomers of the polynitrilomethylidyne one-dimensional model polymer by using this program with an STO-3G basis set. The k-points in half the Brillouin zone were used, and the convergence criterion of 10^{-6} for the difference of density matrix elements was adopted. Twice the magnitude of the lattice vector was taken as a translational vector corresponding to the unit cell shown in Fig. 1, and the contribution up to the seventh neighbor interaction in core resonance integrals and two- electron integrals was taken into consideration. The influence of lattice sum truncation on computed total energy and energy bands for the three forms of polynitrilomethylidyne were investigated. The geometries used here are the same as those described in Refs. 17 and 18 for the CNDO/2 method.

The natural development of this study was the introduction of the through bond/space concept into polymer systems. Analysis of band shapes must be possible by neglecting Fock matrix elements and overlap integrals between particular

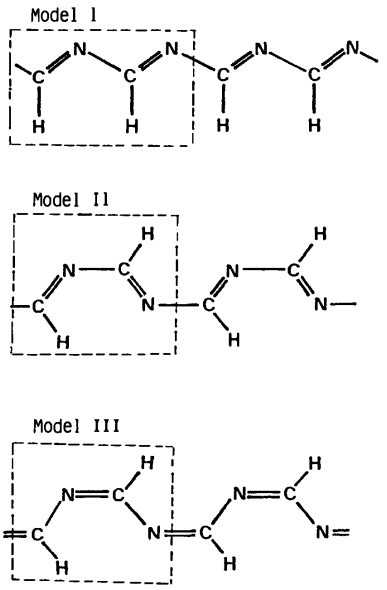

Fig. 1. Structures of the isomers of polynitrilomethylidyne: trans-zigzag (Model I), trans-cisoid (Model II) and cis-transoid (Model-III). The unit cells are surrounded with broken lines.

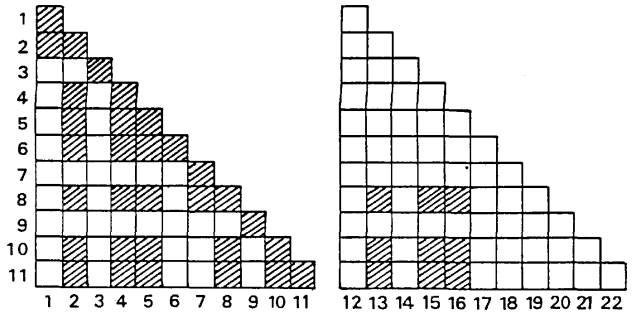

Fig. 2. Through bond interaction elements: (a) terms within a single HCN unit. (b) terms between nearest neighboring two single HCN units. 1—5: 1s, 2s, $2p_x$, $2p_y$, $2p_z$ orbitals on C atom; 6: 1s orbital on H atom; 7—11: 1s, 2s, $2p_x$, $2p_y$, $2p_z$ orbitals on N atom; 12—16: 1s, 2s, $2p_x$, $2p_y$, $2p_z$ orbitals on the neighboring C atom; 17: 1s orbital on the neighboring H atom; 18—22: 1s, 2s, $2p_x$, $2p_y$, $2p_z$ orbitals on the neighboring N atom. This polymer is on the y—z plane.

atomic orbitals. Then all Fock matrix elements and overlap integrals were classified into two kinds of interaction patterns. One type is those terms relating to the through bond interactions which include the Fock matrices given by Eq. 9 and overlap integrals given by Eq. 10 for diagonal elements and those between the 1s and 2s orbitals belonging to the same atom and between valence orbitals belonging to the nearest neighboring atoms. Here, valence orbitals mean the 2s, $2p_x$, $2p_y$, and $2p_z$ orbitals on the C and N atoms and the 1s orbitals on the H atoms. The matrix elements of the through bond interaction in the secular equation Eq. 12 for polynitrilomethylidyne are shown in Fig. 2(a) for the terms within a single HCN unit and in Fig. 2(b) for the terms between two single nearest neighbor HCN units. These elements were included for all cases of analyses. The other type is the through space interactions which include the terms except those for the through bond interaction, that is, those between particular valence orbitals belonging to different atoms. In this study three kinds of through space interactions shown in Fig. 3 were selected for the analysis of the lone pair bands. The procedure for the actual calculation was as follows:

1. The Fock matrix elements and the overlap integrals converged by usual *ab initio* calculations were stored.
2. Of the elements obtained in step 1, the through bond elements shown in Figs. 2(a) and (b), and only significant elements in the through space interactions were explicitly taken into account; the other elements were left out.
3. By using the new matrix elements retained in step 2, the eigenvalue problem given by Eq. 11 for each wave number vector was solved only once without further iterations.

The Gaussian 74 program was modified for the above-mentioned procedure. The relationship between band shapes and crystal orbitals for each through space interaction can be investigated by using the eigenvectors and energies obtained in step 3. The change in energy bands caused by increasing through space components between selected pairs of atomic orbitals, revealed a trend quantitatively consistent to the full interaction. In this process, the most significant through space interaction was found by comparing changes of band shapes.

Results and Discussion

The finite neighbor approximation is a difficult problem in the evaluation of multi-center integrals because even Fock matrix elements obtained with wrong cutoff conditions give artificially stable energy states. Suhai has reported that total energies are strongly dependent upon the number of neighbors included, and that the sphere of elementary cells within which Fock matrix elements have to be calculated is determined only by the magnitude of exchange integrals. His study for polyacetylene demonstrated that

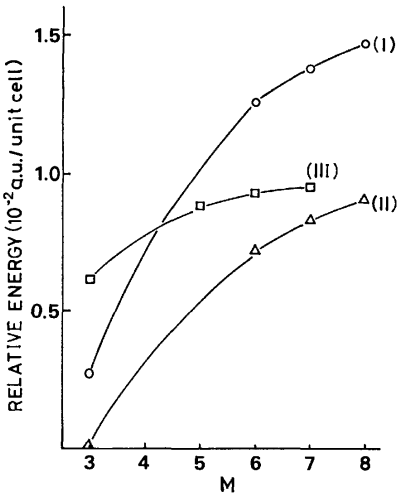

Fig. 4. Relative total energy per $\{HCN\}_2$ unit as function of the number (M) of interacting $\{HCN\}_2$ neighbors in three models of polynitrilomethylidyne Model I, Model II, and Model III.

limiting converged energies were obtained finally by taking into consideration up to the 28th neighboring C_2H_2 unit. In order to obtain some insight into convergency properties of the three forms of polynitrilomethylidyne, *ab initio* calculations were carried out for each case which includes the lattice summation up to each of the third to eighth neighbor interactions. Figure 4 shows that the third neighbor approximation is insufficient to obtain converged energy values. The total energy difference converges to a certain extent with up to eight neighbor lattice summations, but the effect of lattice truncation does not completely disappear. We did not determine for polynitrilomethylidyne how far interactions in the two-electron integrals should be taken into consideration to reach the correct limiting value, because it was not the purpose of this study.

The band structures and densities of state obtained by

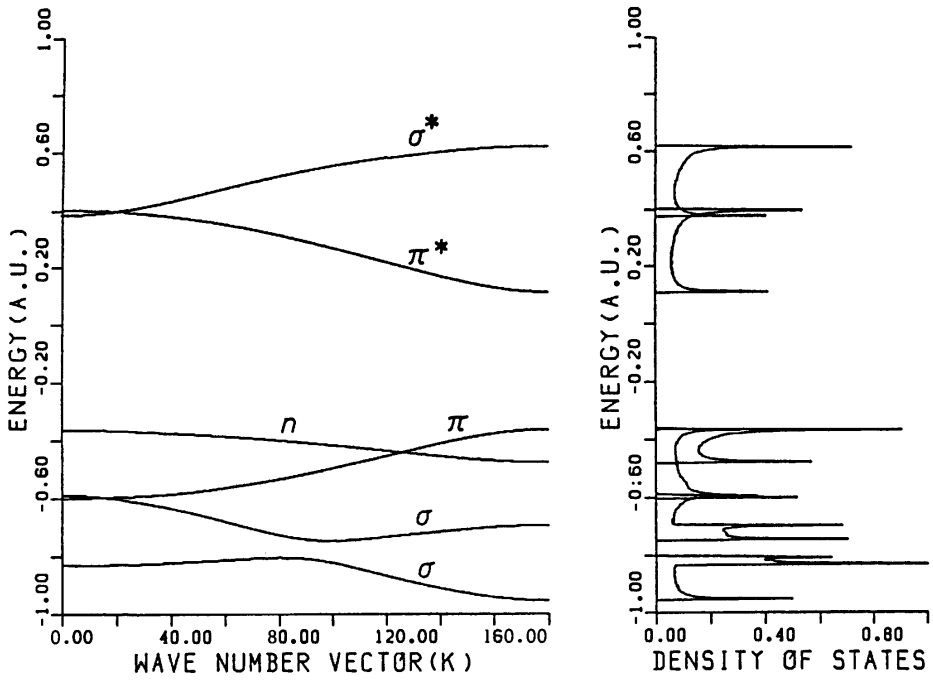

Fig. 5. Band structure and density of states of trans-zigzag polynitrilomethylidyne.

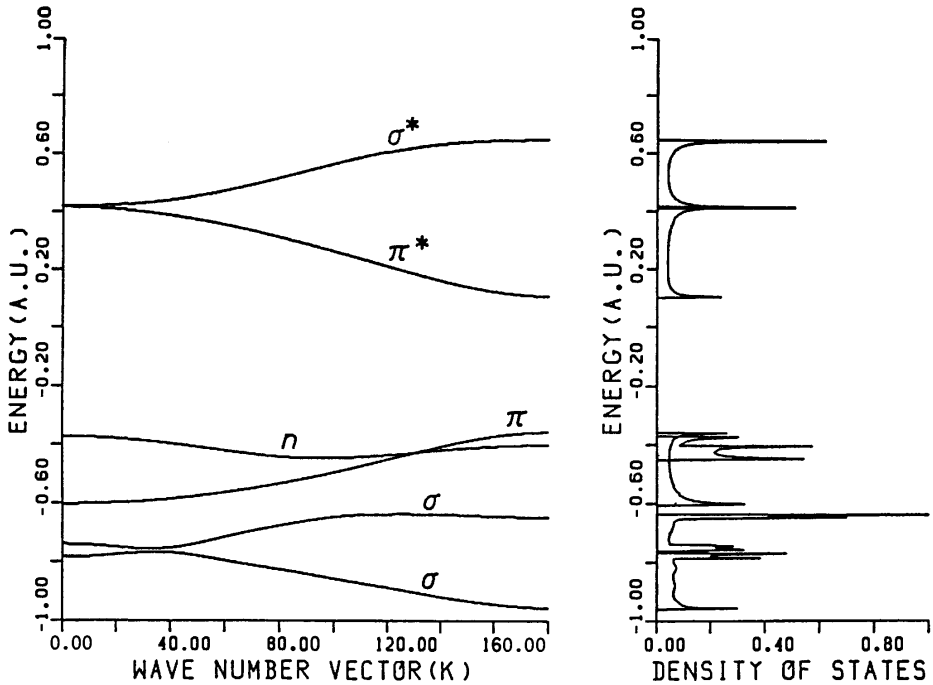

Fig. 6. Band structure and density of states of trans-cisoid polynitrilomethylidyne.

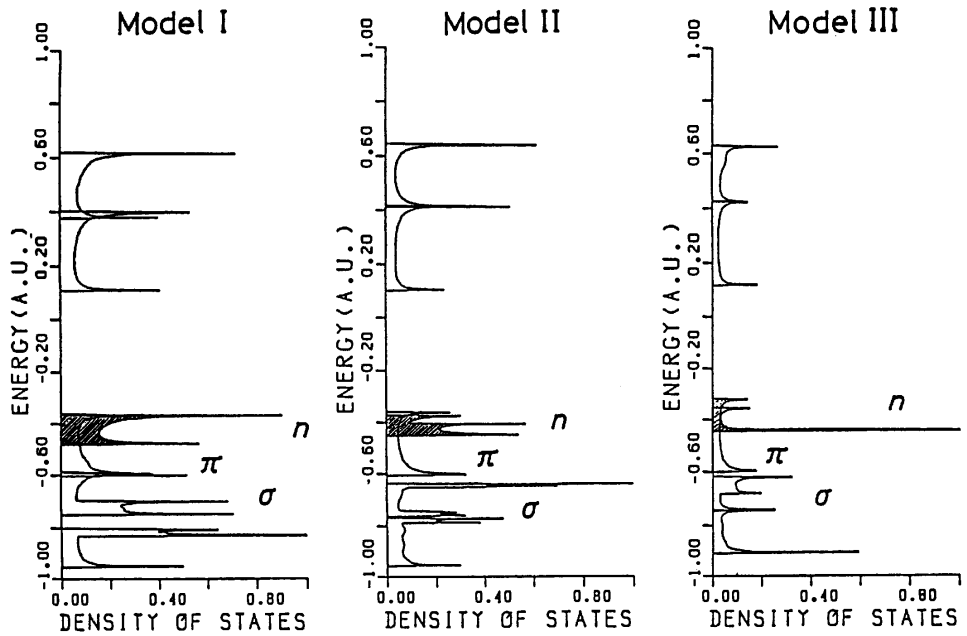

Fig. 8. Density of states for three models of polynitrilomethylidyne.

including up to the seventh neighbors are shown in Figs. 5—7 for the three forms of polynitrilomethylidyne. These polymers are insulators because the band gaps between the valence and conduction bands are as much as 12.0—12.5 eV. The energy bands obtained by these *ab initio* calculations with the STO-3G basis set indicate that the bands are correspondingly similar for the three isomers, but that the lone pair bands on the N atoms differ from one another significantly. In particular, it is noteworthy that there are three peaks in the density of state for the lone pair band of the trans-cisoid form in contrast to the other two forms, as can be seen in Fig. 8. The magnitudes of the energies for all the wave number vectors at the seventh neighbor level are larger for the three forms by about 0.01 au than those at the third neighbor level, but no effect on the band shape is caused by the increase in number of included neighbors. Therefore, the effect of the more distant neighbors on the interaction pattern between orbitals may be neglected without leading to serious errors. So the lone pair bands of the three forms were analyzed by the through space/bond method based on the matrix

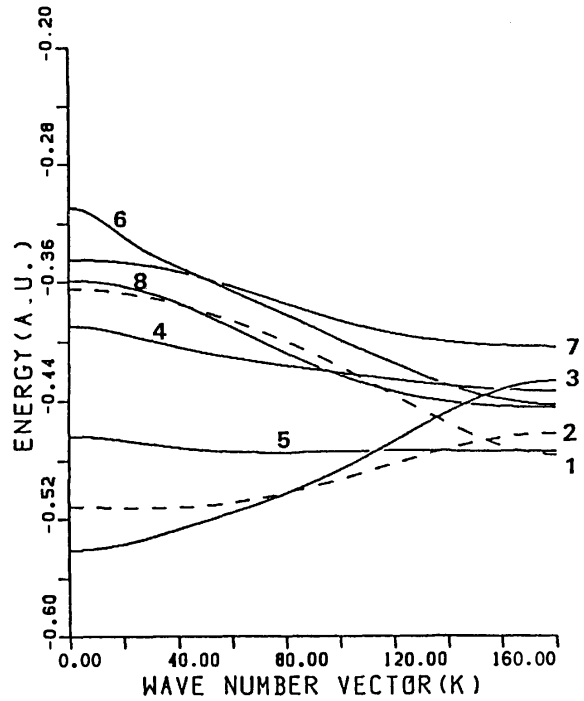

Fig. 9. The change in energy band of the lone pair orbital by analysis of the through space/bond method for Model I. 1. Full interaction, 2. Through bond interaction. elements obtained by including up to the third neighbors, in order to clarify which interaction between the atomic orbitals is most important.

The lone pair bands obtained by this through space/bond analysis are shown in Figs. 9—11 for trans-zigzag, trans-cisoid, and cis-transoid forms, respectively. The broken curve 1 refers to the full interaction including all the interactions between atomic orbitals, and the broken curve 2 to the pure through bond interaction including only the matrix elements between valence orbitals on two directly bonded atoms as shown in Fig. 2. We chose the six interactions denoted by 3—8 in Figs. 9—11 as the through space interactions to be added to the pure through bond interaction. In interactions 3—7 only the interactions between valence orbitals are included. The effect of each through space interaction on the lone pair band is discussed below for the three forms of polynitrilomethylidyne in terms of the symmetry or the phase of crystal orbitals. In crystal orbitals the range k=0°—90° belongs to the symmetric band within a unit cell and the range k=90°—180° to the antisymmetric band. The crystal orbitals at k=0° and 180° are schematically shown in Fig. 12. Furthermore, the crystal orbitals at k=0° and 180° are symmetric with respect to those of the nearest neighboring unit cells. Therefore, the crystal orbitals at k=0° are symmetric within a unit cell and symmetric to the nearest neighboring unit cells, whereas the crystal orbitals at k=180° are antisymmetric within a unit cell and symmetric to the nearest neighboring unit cells.

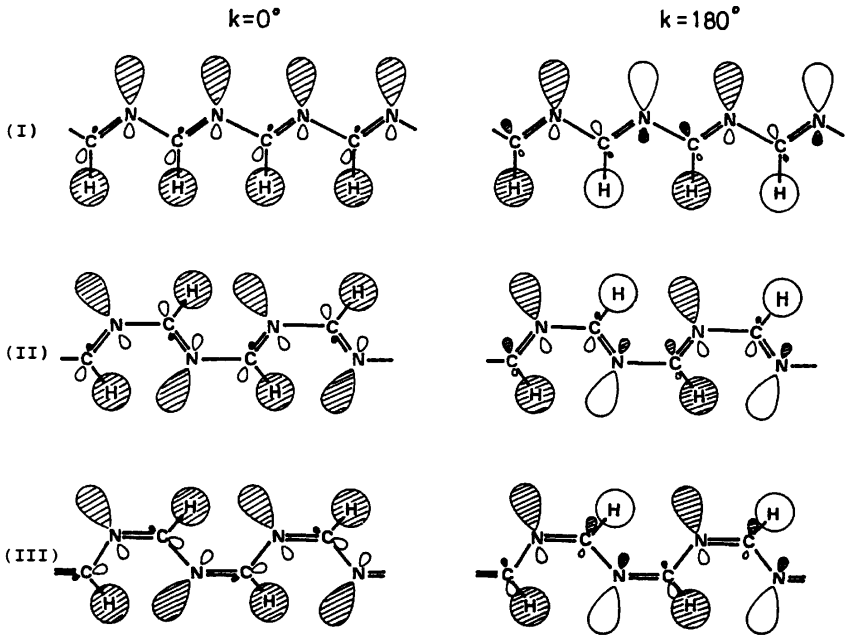

Fig. 12. Schematic representation of the magnitude of the coefficients of the atomic orbitals in the crystal orbitals in the through bond interaction for the three models of polynitrilomethylidine. Shaded areas represent positive lobes; unshaded negative.

Model I. When interaction 3 between orbitals on the neighboring N atoms (see Fig. 3) was added to the through bond interaction, the energy of the MO was lowered by 0.03 au at $k=0°$ and raised by 0.04 au at $k=180°$. As shown in the schematic orbitals (Fig. 12(I)), the lone pair orbitals belonging to N1 and N2 are symmetric at $k=0°$ and antisymmetric at $k=180°$ within a unit cell and symmetric with respect to the nearest neighboring unit cells at both the k-points; that is, all the overlap integrals between the nearest neighboring lone pair orbitals are positive at $k=0°$ and negative at $k=180°$. Therefore, it should be expected that the MO is stabilized at $k=0°$ and destabilized at $k=180°$ due to interaction 3, since the positive overlap implies bonding and the negative one anti-bonding. By interaction 4 between the lone pair orbital on N1 and the 1s orbital on H1 as well as on N2 and H2 (see Figs. 3 and 12), the MO is raised by 0.12 au in energy at $k=0°$ and by 0.03 au at $k=180°$ relative to the pure through bond interaction 2. It seems that this change relates to the antibonding properties between the orbitals on N1 and H1 or N2 and H2, because the enlarged lone pair orbital on the N atom and the 1s orbital on the H atom are out-of-phase within a single HCN molecule at all the k-points. By interaction 5 between the lone pair orbital on N1 and the 1s orbital on H2 or on N2 and H1, the MO is raised by 0.05 au in energy at $k=0°$ and lowered by 0.015 au at $k=180°$. This can be considered to be caused by the negative overlap between the lone pair orbital on N1 and the 1s orbital on H2 at $k=0°$ and the positive overlap at $k=180°$ in all the unit cells. The greater destabilization in interaction 4 than that in interaction 5 at $k=0°$ may be due to the shorter distance in interaction 4 between the N and H atoms. By interaction 6 which consists of interactions 4 and 5, the band shape is made roughly similar to that for the full interaction 1. The additivity rule holds approximately for the through bond interaction because the energy gain in interaction 6 relative to the through bond interaction 2 corresponds nearly to the sum of the increases from interactions 4 and 5 at all the k-points. By interaction 7 which is equal to the interaction 6 having the interaction between the lone pair orbitals on the neighboring N atoms added, the MO is lowered by 0.03 au in energy at $k=0°$ and raised by 0.04 au at $k=180°$. Interaction 6 is to interaction 7 what the pure through bond interaction 2 is to interaction 3. Finally by interaction 8 which is equal to interaction 7 having the interaction between the 1s orbital on the N atom and the valence orbitals (2s, $2p_x$, $2p_y$, and $2p_z$) on the C atom added, the band shape is in approximate agreement with the full interaction 1 except near $k=180°$. It was found that the effect of the interaction between the 1s orbital of N and the valence orbitals of C should not be neglected since the lone pair band is stabilized to some extent by this interaction. In conclusion, it was ascertained that interaction 6 between the lone pair orbital and the H atoms belonging to both neighboring C atoms dominates the through space interaction.

Model II. In this structure which is planar and possesses a screw axis symmetry in a unit cell, the interaction between the lone pair orbital and the 1s orbital on the H atom would be expected to be the main through space interaction, judging from the positions

of the atoms around the lone pair orbital. Similar reasoning as has been developed for the trans-zigzag form can be applied to the trans-cisoid form. By interaction 3, the MO is raised by 0.04 au in energy at $k=0°$ and is lowered by 0.01 au at $k=180°$ relative to the through bond interaction 2. As shown in the schematic orbitals (Fig. 12(II)), the overlap between the neighboring lone pair orbitals possesses antibonding properties at $k=0°$ and bonding properties at $k=180°$ over all the unit cells, since the enlarged lone pair orbitals within a unit cell are out-of-phase at $k=0°$—90° and in-phase at $k=90°$—180°. This is probably the reason for the destabilization in energy at $k=0°$ and the stabilization at $k=180°$. By interaction 4 (see Figs. 3 and 10), the MO is raised by 0.03 au in energy at $k=0°$ and by 0.14 au energy at $k=180°$. As in the trans-zigzag form, this behavior is considered to relate to the antibonding properties between the lone pair orbital on N1 and the 1 s orbital on H1 or on N2 and H2, because the lone pair orbital and the 1 s orbital on the H atom are out-of-phase within a single HCN molecule. By interaction 5, the energy level is lowered by 0.1 or 0.2 au in energy at $k=0°$ and raised by 0.05 au at $k=180°$. This may be due to the positive overlap at $k=0°$ and the negative overlap at $k=180°$ between the 1 s orbital on H1 and the lone pair orbital on N2, as can be seen from the phase of the MO. Because of this through space interaction, the band shape becomes closely similar to that for the full interaction 1, aside from the values of energy. Interaction 6, equal to the interaction 5 with interaction 4 added, has the same effect as the through bond interaction 2 has on interaction 4, that is, the MO is raised by 0.04 au in energy at $k=0°$ and by 0.16 au at $k=180°$ By interaction 7, for which interaction 3 between the nearest neighboring lone pair orbitals has been added to interaction 6, the MO is raised by 0.04 au in energy at $k=0°$ and lowered by 0.02 au at $k=180°$. As in the trans-zigzag form, the additivity rule approximately holds for interactions 3 and 6 in the through bond interaction 7. By interaction 8, the band shape is allowed to have a more consistent trend toward that for the full interaction 1. It was found that the 1 s orbital on N has a considerable contribution to the stabilization of the lone pair band in a similar manner as it has in the trans-zigzag form. The result that interaction 5 is the most important through space interaction in determining the band shape of the lone pair orbital in this trans-cisoid form, may be expected from the structure of the polymer.

Model III. By interaction 3, the energy level relative to that for interaction 2 is raised by as much as 0.09 au at $k=0°$, in contrast with little change at $k=180°$. As shown in the schematic orbitals (Fig. 12(III)), this behavior can be considered to be caused by the larger magnitude of the negative overlap at $k=0°$ than that of the positive overlap at $k=180°$ between the nearest neighboring lone pair orbitals. Otherwise, considering the shape of the wave function obtained, there may be a possibility that the difference in shape between the crystal orbitals on the C atoms is related to this behavior through a second order effect arising from this through space perturbation. By interaction 4, the MO is raised by 0.09 au at $k=180°$ due to the expected large negative overlap (see Figs. 3 and 12). On the other hand, no effect can be seen at $k=0°$, in contrast with the case of the trans-cisoid form. By interaction 5, the MO is raised by 0.01 au at $k=0°$ and by 0.075 au at $k=180°$. The destabilization at $k=180°$ can be considered to be caused by the large negative overlap, but this explanation seems inapplicable at $k=0°$. The band shape at all the k-points closely resembles that for the full interaction as with the trans-cisoid form, aside from the magnitude of energy. By interaction 6, which is equal to interaction 5 having interaction 4 added, the MO is raised by 0.09 au at $k=180°$ but not changed at $k=0°$. The additivity rule holds almost exactly since the energy gain in interaction 6 over the through bond interaction 2 corresponds to the sum of those in interactions 4 and 5 at all the k-points. By interaction 7, the MO is raised by 0.08 au at $k=0°$ and 0.01 au at $k=180°$ relative to that for interaction 6, and the additivity rule holds approximately. By interaction 8, the band shape is made still more similar to that for the full interaction as in models I and II. The result is that interaction 5 is the most important through space interaction as in the case of the trans-cisoid form. On the other hand, the energy level near $k=0°$ is hardly affected by the through space interaction between the lone pair orbitals and the 1 s orbitals on the H atoms, in contrast with the case of the trans-cisoid form. The differences between the trans-cisoid and cis-transoid forms with respect to the k-dependence of the lone pair band due to each through space interaction may result from the difference in the second order contribution of the through space perturbation. With respect to this point, more quantitative analysis is required for more detailed comparison.

Summary of the Results for Models I, II, and III. Although k-dependences of energy levels vary from model to model, they can reasonably be interpreted on the basis of the schematic orbitals shown in Fig. 12. For interaction 3, model I leads to a dependence different from those given by models II and III, in conformity with their differences in molecular structure. Of the various interactions adopted, the most important one for the determination of the curve shape is interaction 6 (composed of interactions 5 and 6) for model I and interaction 5 for models II and III. This consequence is in accord with the molecular structures of models I, II, and III. For all models I—III, interaction 8 gives curve shapes similar to those of the full interaction; that is, the interaction between the 1s orbital on the N atom and the valence orbitals on the C atom lowers the energy levels at all points of k, leading to the similar shapes. Finally, it should also be pointed out that the addi-

tivity rule for these interactions was found to hold approximately for all the three models.

Conclusion

In this paper we have developed a method for applying the through space/bond interaction to polymer systems at the *ab initio* level. As a result of applying this method to three isomers of polynitrilomethylidyne, it has been found that the interaction between the lone pair orbital and the H atoms bonded to both the neighboring C atoms governs the band shape of the lone pair orbital for the trans-zigzag form, and that the interaction between the lone pair orbital and the opposite H atoms belonging to the neighboring unit cell is most important for the trans-cisoid and cis-transoid forms. It is essentially desirable that energies of the through space interaction between pairs of localized crystal orbitals should be evaluated quantitatively. Therefore, this paper involves some obscurity in the definition of the through bond interaction because this analysis is based on atomic orbitals. However, qualitatively reasonable results on the relationship between the inter-orbital interaction pattern and the band shape have been obtained in spite of the omission of the troublesome transformation from atomic to localized orbitals. The results presented here have proved this method to be useful with the advantage of simplicity and convenience for rough estimation of the interaction between orbitals for various polymers possessing lone pair orbitals.

This work was supported in part by a Grant-in-Aid for Scientific Research from the Ministry of Education, Science and Culture. The numerical calculations were performed on the HITAC M-200H computer systems at the Information Center of Hiroshima University and the Computer Center of the Institute for Molecular Science. The authors are grateful to Dr. D. Munch for critically reading and correcting the manuscript for this paper.

Conductometric and Potentiometric Studies of the Association of α-Cyclodextrin with Ionic Surfactants and Their Homologs

Iwao SATAKE,* Tadashi IKENOUE, Tokuro TAKESHITA,
Katumitu HAYAKAWA, and Tamaki MAEDA
Department of Chemistry, Faculty of Science, Kagoshima University, Korimoto, Kagoshima 890
(Received April 11, 1985)

The conductometric determination was made of the association constants of α-cyclodextrin (αCD) with ionic surfactants and their homologs. For 1-alkanesulfonate ions with carbon atoms (n) of 5—12, the association constant was found to increase regularly with n and become abruptly constant at $n=10$. The association constants for sodium 1-dodecanesulfonate, dodecylammonium chloride, dodecyltrimethylammonium chloride, and 1-dodecylpyridinium chloride were all similar in their magnitude. The effect of complexation on the micellar properties of sodium dodecyl sulfate and dodecyltrimethylammonium chloride were also studied potentiometrically by determining the counterion activities. In both cases, the critical micelle concentration increased regularly, while the degree of counterion association to the micelle decreased almost linearly with increasing αCD concentrations. It was suggested that the αCD–surfactant ion complex is solubilized in the hydrophilic surface region of surfactant micelle to give rise to a decrease in the surface charge density.

Cyclodextrins have been well known to form inclusion compounds with a variety of small molecules by several kinds of driving forces.[1] In the complexation of bulky hydrophobic molecule such as 1-adamantanecarboxylate, the hydrophobic interaction has been found to play an important role.[2] It is thus interesting to study the interactions of cyclodextrins with the surfactant ion which has an ionic head group as well as a large hydrocarbon chain of varying hydrophobicity. In this connection, Okubo *et al.*[3] made the conductometric study of the complexations of α- and β-cyclodextrins (αCD and βCD) with sodium dodecyl sulfate (SDS) and hexadecyltrimethylammonium bromide (CTAB) in water and mixed solvents. They found that in all cases an apparent critical micelle concentration increases regularly with increasing cyclodextrin concentration. In conformity with the difference of the hydrophobicities of the surfactant ion and cyclodextrin, the association constant, K, was found to increase in the order of SDS–αCD<SDS–βCD <CTAB–αCD<CTAB–βCD. They also pointed out that the decrease in K in mixed solvents comes partly from the decrease in hydrophobic attractive interaction between cyclodextrin and surfactant ion.

These observations prompted us to study the cyclodextrin–surfactant ion interactions both from thermodynamic and colloid chemical standpoints. In this paper is described the conductometric determination of the association constants of α-cyclodextrin with various ionic surfactants and their homologs. The potentiometric study was also undertaken to obtain information about the effect of complexation on the micellar properties of sodium dodecyl sulfate and dodecyltrimethylammonium chloride.

Experimental

Materials. Sodium dodecyl sulfate (SDS, Nakarai Chemicals Ltd.) and 1-dodecylpyridinium chloride (DPC, Tokyo Kasei Kogyo Co. Ltd.) were dissolved in hot ethanol and refluxed with active carbon for 10 h, respectively. After cooling the filtrate, the precipitate was further recrystallized twice from ethanol. The purification of dodecyltrimethylammonium chloride (DTAC, Tokyo Kasei Kogyo Co. Ltd.) was the same as that described above, except that acetone was used. Dodecylammonium chloride (DAC) was prepared from dodecylamine (purity>99%, Nakarai Chemicals Ltd.).[4] Sodium *p*-dodecylbenzenesulfonate (SDBS, purity>99%, Wako Pure Chemical Industry Co. Ltd.), sodium 1-alkanesulfonates with carbon atoms (n) of 5—8, 11, and 12 (Tokyo Kasei Kogyo Co. Ltd., guaranteed grade), and α-cyclodextrin (αCD, purity>98%, Seikagaku Kogyo Co. Ltd.) were used without further purifications. Sodium 1-alkanesulfonates with n of 9 and 10 were synthesized from the alkyl bromides purified by vacuum distillation.[5]

Conductivity Measurements. The conductivity was measured with an accuracy of ±0.1 μS by using a TOA Electronics Ltd. Conductivity Meter model CM-50AT. The cell constant of the conductivity cell was estimated to be 1.005 cm^{-1} at 25 °C. In order to remove trace amounts of conducting impurities, the aqueous solution of αCD was passed through the mixed ion bed (Bio-Rad AG501-X8). The concentration of αCD was determined gravimetrically by drying aliquots of the stock solution over phosphorus pentaoxide under reduced pressure and estimating the water content of the resulting powder from elementary analysis. The conductivity was measured as a function of αCD concentration, C_h, at a constant amphiphile concentration of around 2.5 mmol dm^{-3}.

Electromotive Force Measurements. The counterion activities in SDS and DTAC solutions were measured at 25 °C by using a TOKO Ion Electrode type 1100 Na^+ and a chloride ion selective ceramic electrode, National IE-510103, respectively. The electromotive forces (EMF) of the following cells were measured with an accuracy of ±0.1 mV by using a Corning Digital 112 Research pH Meter.

Sodium ion electrode (or Chloride ion electrode)|
Sample solution|1 mol dm^{-3} NH_4NO_3 Agar bridge|
Reference electrode (Ag–AgCl)

Prior to the measurements with surfactant solutions, these electrodes were calibrated with a sodium chloride solution of known activity.[6] In both cases, the electrode showed an ideal response of 59.2 mV per decade change in measuring ion activity in the concentration range between 5×10^{-3} and 0.1 mol dm^{-3}. The counterion activity was determined as a

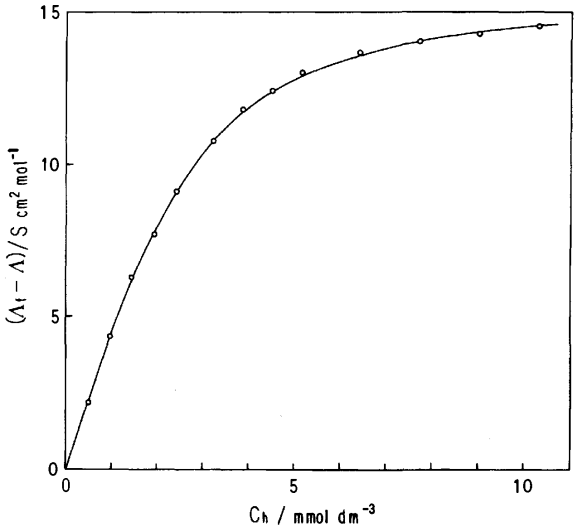

Fig. 1. Plots of $\Lambda_f - \Lambda$ *vs.* αCD concentration (C_h) for sodium 1-nonanesulfonate solution at 25 °C. C= 2.496 mmol dm^{-3}.
O, observed; solid line, calculated from Eq. 4 with K=1.49×10^3 dm^3 mol^{-1} and $\lambda_f - \lambda_a$=15.8 S cm^2 mol^{-1}.

function of the surfactant concentration, C, under the conditions where the molar ratio of αCD to surfactant, R (=C_h/C), was kept constant.

Results and Discussion

Association Constant. Figure 1 shows the typical plots of $\Lambda_f - \Lambda$ *vs.* αCD concentration for sodium 1-nonanesulfonate at 25 °C, where Λ_f and Λ represent the equivalent conductivity in the absence and presence of αCD respectively. It has been found that neither Na^+ nor Cl^- interacts appreciably with αCD.[7] Thus the successive decrease in Λ can reasonably be ascribed to the increase in the concentration of the associated 1-nonanesulfonate ion which has considerably smaller ionic equivalent conductivity than that of unassociated one. Similar results were also obtained for all of the amphiphiles studied.

In dilute electrolyte solution, which is the case for the present experiments, the activity coefficient ratio of associated and unassociated ions can safely be set equal to unity. Moreover, the activity coefficient of αCD is negligible under our experimental conditions.[8] Therefore, assuming a 1:1 reaction scheme,[3]

$$R^{\pm} + \alpha CD \rightleftharpoons \alpha CD \cdot R^{\pm}, \quad (1)$$

the association constant, K, can be written as

$$K = f/(1-f)(C_h - fC), \quad (2)$$

where $R^{\pm}$ refers to the amphiphilic ion and f to the fraction of $R^{\pm}$ associated with αCD, respectively. If we denote the ionic equivalent conductivities of $R^{\pm}$ and αCD·$R^{\pm}$ by λ_f and λ_a, we may write

$$\Lambda_f - \Lambda = f(\lambda_f - \lambda_a). \quad (3)$$

The use of Eqs. 2 and 3 for the evaluation of K requires a knowledge of λ_a. Unfortunately, however, the value of λ_a is somewhat difficult to estimate, since Λ decreases slightly but continuously even at higher αCD concentrations (see Fig. 1). This is especially true for 1-alkanesulfonate ion with shorter alkyl chain length. It follows immediately from Eqs. 2 and 3 that

$$\Lambda_f - \Lambda = \frac{\lambda_f - \lambda_a}{2KC}[K(C+C_h) + 1 - \sqrt{\{K(C+C_h)+1\}^2 - 4K^2CC_h}]. \quad (4)$$

a) ΔH°=−15.8 kJ mol^{-1}, ΔS°=29.9 J K^{-1} mol^{-1}.
b) ΔH°=−10.7 kJ mol^{-1}, ΔS°=51.7 J K^{-1} mol^{-1}.

On the basis of Eq. 4, therefore, the values of K and $\lambda_f-\lambda_a$ were all evaluated from the plots of $\Lambda_f-\Lambda$ *vs.* C_h by using the non-linear least squares method (Gauss-Newton algorithm). The results are summarized in Table 1 together with the standard free energy change of complex formation, ΔG°, estimated from K_x (=55.5 K). The solid line in Fig. 1 shows the calculated conductivity curve from Eq. 4 with parameters thus determined for sodium 1-nonanesulfonate. The agreement between experimental and calculated curves is quite satisfactory over whole range of C_h, indicating the validity of a 1:1 reaction scheme. Similar agreements were also observed for all amphiphiles studied.

The most remarkable feature of Table 1 is the regular increase in K with the number of carbon atoms (n) and the leveling-off phenomenon above n=10 for 1-alkanesulfonate ions. The corresponding chain length dependence of ΔG° is shown in Fig. 2. These results suggest that αCD cavity accomodates succesively the methylene groups of hydrocarbon tail presumably by hydrophobic interaction. It is worth noting here that αCD molecule can accommodate at most 5 methylene groups of a fully extended alkyl chain in its hydrophobic cavity of 0.67 nm[9] long. According to the geometric consideration, therefore, the leveling-off phenomenon of K or ΔG° appears to occur at $n\approx6$ even if we take into account the fact that the methylene group closest to the ionic head group shows little or no hydrophobicity.[10] As is clearly shown in Fig. 2, however, this is not the case for the present result. In an inclusion process of long hydrocarbon chain, it seems thus highly probable that the additional 4 methylene groups can still interact with other part of αCD molecule than hydrophobic cavity, presumably with the lateral hydrophilic surfaces. A similar interaction was reported by Komiyama and Bender[2] for a complexation of bulky 1-adamantanecarboxylate with αCD. In this case, the complexation was found not only to accompany large positive entropy change but to occur in such a way that the guest molecule sits on top of the cavity. In Table 1 are also given the standard enthalpy and entropy changes estimated for 1-hexane- and 1-heptanesulfonate ions from temperature dependence of K_x. In the case of 1-hexanesulfonate ion, the contribution of enthalpy term to ΔG° is larger than that of entropy term ($-T\Delta S^\circ$), while the reverse is found for 1-heptanesulfonate ion. Although the detailed mechanism remains unclear, the observed decrease in the magnitude of ΔH° and the drastic increase in ΔS° for 1-heptanesulfonate ion are supposed to arise partly from the partial breakdown of the water structure around OH groups due to the penetration of hydrocarbon tail into lateral hydrophilic surface and partly from the change in the water structure around hydrocarbon tail associated with the transfer process from bulk phase to hydrophilic surface region.

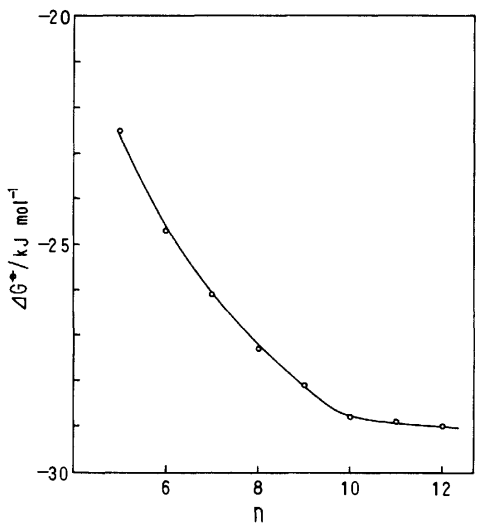

Fig. 2. The chain length dependence of ΔG° for sodium 1-alkanesulfonate at 25 °C.

The inspection of Table 1 also reveals another interesting feature that the association constants for surfactants with dodecyl chain, *i. e.*, sodium 1-dodecanesulfonate, DAC, DTAC, and DPC, are all similar in their magnitude in spite of the differences in the chemical and electrical properties of ionic head group. This fact suggests that the interaction between ionic head group and αCD molecule plays a minor role in the inclusion process of surfactant ion. An exceptional increase in K for SDBS can reasonably be ascribed to the presence of the additional aromatic ring, since a number of aromatic compounds have been found to interact strongly with αCD.[1] It should be noted that the value of K for sodium 1-dodecanesulfonate is about twice as large as that for SDS. In micelle formation of SDS, the extra oxygen atom in the sulfate group has been known to behave as an extra CH_2 group.[11] The presence of this anomalous oxygen atom may be responsible for the observed decrease in K for SDS.

Micellar Properties. In the complexation of the surfactant ion, the resulting complex is still supposed to behave like an amphiphilic ion with apparently shorter chain length. One might thus expect that the addition of αCD to surfactant solutions would affect not only the critical micelle concentration (cmc, C_o) but the micellar properties such as the degree (β) of counterion association to the micelle. Thus, we made the potentiometric determinations of β in solutions of SDS and DTAC in the presence of αCD. Figure 3 shows the typical semilogarithmic plots of the EMF (E_-) of the chloride ion electrode *vs.* DTAC concentration at varying values of R. The break point in this figure corresponds to the cmc at a given value of R. Similar behaviors were also observed for SDS solutions. In Fig. 4 are plotted the critical micelle concentrations thus determined for DTAC and SDS as a function of R. It should be noted that the cmc

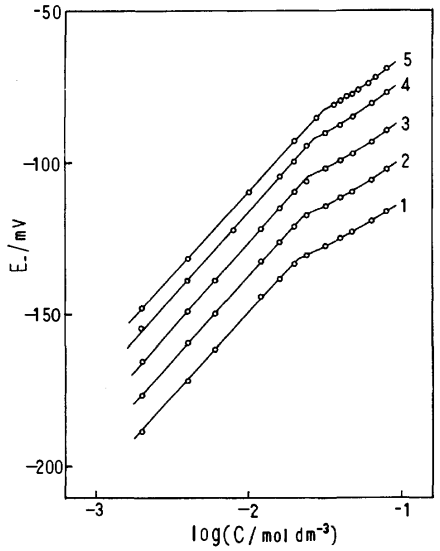

Fig. 3. The semilogarithmic plots of E_- *vs.* C for DTAC solution at 25°C. 1, $R=0$; 2, $R=0.091$; 3, $R=0.185$; 4, $R=0.275$; 5, $R=0.366$. The curves 2, 3, 4, and 5 are displaced upward by 10, 20, 30, and 40 mV, respectively.

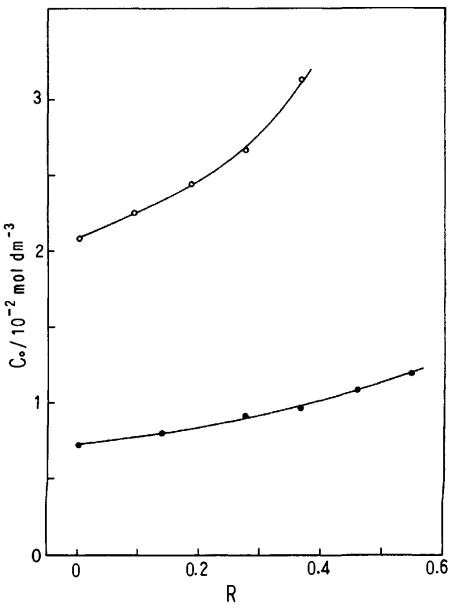

Fig. 4. Plots of C_0 *vs.* R at 25°C. ●, SDS; ○, DTAC.

becomes progressively higher as R increases and eventually disappears at R larger than 0.4 for DTAC and 0.6 for SDS respectively. Okubo *et al.*[3] assumed implicitly that the increase in an apparent cmc comes only from the increase in the concentration of the associated surfactant ion, *i.e.*, the concentration (C_m) of the monomeric surfactant ion available for the micellization process remains constant even in the presence of cyclodextrins. From the thermodynamical standpoint, however, other factors than that described above, *e.g.* the effect of the electrical potential at the micellar surface (ψ_s) on C_m can not be ignored even at the cmc,

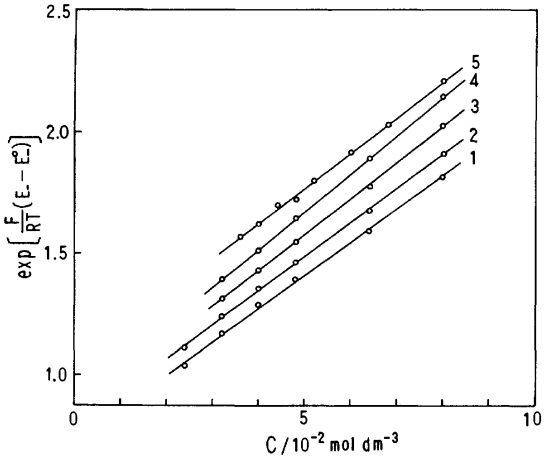

Fig. 5. Plots of the right-hand side of Eq. 6 *vs.* C for DTAC solution at 25°C. 1, $R=0$; 2, $R=0.091$; 3, $R=0.185$; 4, $R=0.275$; 5, $R=0.366$. The straight lines 2, 3, 4, and 5 are displaced upward by 0.1, 0.2, 0.3, and 0.5, respectively.

since an increase in the cmc is necessarily accompanied by the regular decrease in the magnitude of ψ_s by virtue of the increase in total counterion concentration. In fact the value of C_m calculated from Eq. 2 with K in Table 1 is not constant but decreases appreciably as R increases. For example with SDS, the value of C_m at the cmc decreases down to 6.20×10^{-3} mol dm^{-3} at $R=0.548$ (*cf.* $C_m=7.18\times10^{-3}$ mol dm^{-3} at $R=0$). If the associated surfactant ions are solubilized in the hydrophilic surface region of the micelle, the resulting depression in surface charge density will play an additional role in determining the value of ψ_s.

The EMF of the chloride ion electrode can be described as

$$E_- = E^{\circ}_- + (RT/F)\ln a_-, \tag{5}$$

where E°_- refers to the standard electrode potential and a_- to the chloride ion activity; other symbols have their usual meanings. Denoting the values of E_- and a_- at the cmc by E°_- and a°_- respectively, we immediately have

$$a_-/a^{\circ}_- = \exp\,[(F/RT)(E_- - E^{\circ}_-)]. \tag{6}$$

Figure 5 shows the plots of the right-hand side of Eq. 6 *vs.* DTAC concentration at higher concentrations than cmc. In agreement with the results[12-15] reported for counterion activities in various ionic surfactant solutions without host molecule, the chloride ion activity increases linearly with increasing DTAC concentration regardless of the value of R. This is also the case for SDS solutions containing αCD. These results allow us to estimate the degree of counterion association to the micellle at the cmc, β_o, as a function of R. If we denote the total intermicellar concentration of the associated and unassociated surfactant ions in bulk phase by C_b, and the counterion activity

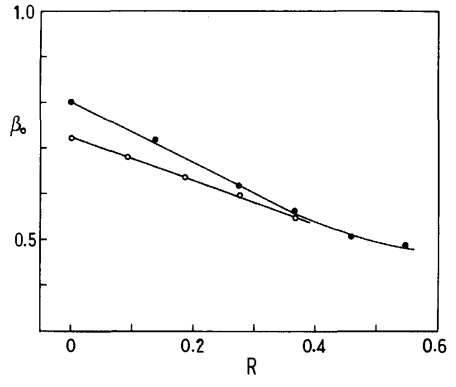

Fig. 6. Plots of β_o *vs.* R at 25 °C. ●, SDS; ○, DTAC.

coefficient by γ_-, Eq. 6 can be rewritten as

$$a_-/a^\circ_- = \gamma_-[C_b+(1-\beta)(C-C_b)]/\gamma^\circ_- C_o. \quad (7)$$

In solution of ionic surfactant alone, it is usually assumed that the values of γ_-, β, and C_b which in such case represents the concentration of the monomeric surfactant ion remain constant in the concentration range above cmc.[12-14,16] Because of the complications arising from the presence of the associated surfactant ions, it is somewhat doubtful whether the same assumption can be applicable for the present systems. Apart from the concentration dependences of γ_-, β, and C_b, however, we can easily estimate the value of β_o from the slope of the straight line in Fig. 5, since the changes in these parameters can safely be ignored at least in quite narrow concentration range above cmc. The results are shown in Fig. 6. An important feature of Fig. 6 is the regular decrease in β_o with respect to R. In their theoretical study of the counterion condensation on charged planar surface, Engström and Wennerström[17] have derived the following expression for the fraction, P_c, of counterions bound to the surface region of thickness Δ which is the order of the diameter of a hydrated counterion.

$$P_c = 1 - [1-(\sigma Ze\Delta/2\varepsilon_r\varepsilon_o kT)]^{-1} \quad (8)$$

Here, σ is the surface charge density, Ze the charge of the counterion, ε_r the relative permittivity, and ε_o the permittivity of a vacuum, respectively. In view of the fact that most of the micellar properties of ionic surfactant solutions can be interpreted in terms of the lamellar model,[18] P_c in Eq. 8 is supposed to be closely related to β_o. This in turn suggests that the observed decrease in β_o arises virtually from a decrease in the magnitude of surface charge density. It seems therefore most likely that the surfactant ion associated with bulky cyclodextrin molecule is solubilized in the hydrophilic surface region of surfactant micelle to give rise to a decrease in surface charge density.

As mentioned previously, the break point in EMF *vs.* log C plots became undetectable at R higher than 0.4 for DTAC and 0.6 for SDS, respectively. Therefore, the limiting value of β_o appears to correspond to the critical surface charge density, σ_{crit}, below which the counterion fixation no longer takes place. For example with SDS, the tentative estimation based on Eq. 8 with Δ=0.45 nm[6] leads to σ_{crit} of one unit charge per 2.1 nm^2 at R=0.548. On account of the definite size of the micellar aggregate, however, the actual value of σ_{crit} will probably be larger than that estimated above.

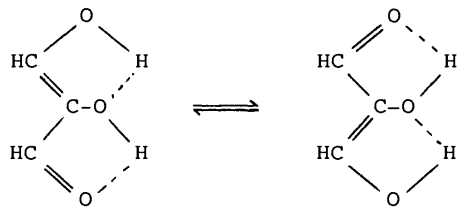
Oxidation of Triose Reductone by Oxidizing Inorganic Radicals Generated by Pulse Radiolysis

Hideo Horii,* Yasuo Abe, and Setsuo Taniguchi
Radiation Center of Osaka Prefecture, Shinke-cho, Sakai 593
(Received April 22, 1985)

Triose reductone (2,3-dihydroxy-2-propenal) was oxidized by $Cl_2^{\cdot-}$, $Br_2^{\cdot-}$, $I_2^{\cdot-}$, $(SCN)_2^{\cdot-}$, and $N_3^{\cdot}$ to produce a triose reductone radical which had an absorption maximum at 398 nm, ε=5500 $M^{-1}cm^{-1}$ (1 M=1 mol dm^{-3}) and decayed by second-order kinetics. The rate constants for the reactions of triose reductone with these oxidizing inorganic radicals were obtained. The pK_a of this radical was found to be 1.4.

Triose reductone (2,3-dihydroxy-2-propenal) was first synthesized by the decomposition of glucose in an alkaline aqueous solution and its structure was determined to be CH(OH)=C(OH)CHO by H. von Euler and C. Martius.[1] A very important characteristic of "reductone" is the strong reducing ability which is due to its enediol group, -C(OH)=C(OH)-.[2] Euler *et al.*[3] proposed that triose reductone has a double five-membered ring. Obata *et al.*[4] provided experimental proof for this by NMR and mass spectra of triose reductone and presumed the following two formulas in D_2O, $(CD_3)_2CO$, DMSO solution.



Well-known reductones, L-ascorbic acid,[5-7] adrenaline,[8] and dopamine[9] which play significant roles in biological systems, have been studied by pulse radiolysis. Thus, the oxidation of the reductones have been shown to proceed through the intermediate radicals. Furthermore, it is important and interesting to clarify the oxidation mechanisms of other enediol compounds. Triose reductone is yielded in biological systems[1,10-12] and in the process of browning reaction.[13] Also, it reacts with amino compounds to yield anil compounds[2] or causes a DNA-breaking action in the presence of Cu^{2+}.[14] The enzymatic oxidation of triose reductone has been reported to produce a free radical in the ESR study.[15] It is useful to study the oxidation mechanism of triose reductone, as it is one of the most simple reductones. We have studied the oxidations of triose reductone using oxygen and hydrogen peroxide,[16] a peroxodisulfate ion,[17] and a hexacyanoferrate(III) ion,[18] kinetically. It was found in our previous paper[19] that triose reductone is oxidized by $(SCN)_2^{\cdot-}$ and $Br_2^{\cdot-}$ to yield a one-electron oxidized radical. In this paper we studied oxidations of triose reductone by oxidizing species $Cl_2^{\cdot-}$, $I_2^{\cdot-}$, $N_3\cdot$ including $(SCN)_2^{\cdot-}$, and $Br_2^{\cdot-}$ [19] kinetically and disclosed the reaction mechanisms.

Experimental

Pulse irradiation was accomplished using the 18 Mev linac (High Voltage Engineering Co.) of the Radiation Center of Osaka Prefecture at room temperature (about 20 °C). Pulses of 10-MeV electrons of 0.5—2 μs duration were diffused by an aluminum plate (0.5—3 mm thick) for regulating the pulse dose. The dose of a pulse was monitored by the current which was collected on a brass plate located directly behind the irradiation cell. The 1.5-cm long irradiation vessel was made of thermal quartz for light path windows. The sample solution was refreshed from a Pyrex stock bottle after each pulse-irradiation by a magnetic valve under gas (N_2O or Ar) pressure. All solutions were prepared from triply distilled water. Dinitrogen monoxide (Showa Denko Co., High Purity, upper limit of O_2 content: 10 ppm) was used after the deaeration of solutions by argon (Osaka Sanso Co., Instrument Argon). The solutions were bubbled before irradiation for ≈60 min with Ar and N_2O which converts the hydrated electron into the OH radical. Triose reductone was prepared and purified by the method of Euler and Martius.[1] All other chemicals used were of analytical reagent grade. The light of a 500 W Xe lamp (Ushio Denki Co.) was focused on the irradiation cell and was detected by a photomultiplier (1P28, Hamamatsu TV) after passing through a grating monochromator (Nikon, G-250). The signals were recorded by a personal computer (YHP Co., 9815A) through a transient recorder (Riken Denshi Co., TCH-1000) and analyzed.[20] Dosimetry was performed with N_2O-saturated 0.01 M KSCN solutions taking the value of G(OH) and $\varepsilon_{472\,nm}$ for $(SCN)_2^{\cdot-}$ as 6.13 and 7580 $M^{-1}cm^{-1}$.[21] The pH of the solution was generally adjusted by an addition of appropriate amounts of $HClO_4$ or NaOH.

Results and Discussion

Rate Constants for the Oxidations of Triose Reductone with Inorganic Radicals. The rate constants for the oxidation of triose reductone with $(SCN)_2^{\cdot-}$, $Cl_2^{\cdot-}$, $Br_2^{\cdot-}$, and $I_2^{\cdot-}$ were measured by following the exponential decay of each absorbance (472, 340, 340, and 380 nm) as a function of the substrate concentration. The rate constant, in the case of $N_3\cdot$, was measured by following the first-order decay and growth of the absorbance due to triose reductone at 310 nm and the triose reductone radical at 400 nm, respectively. The rate constants were identical with each other regarding both decay and growth within experimental errors. The rate constants

of both dissociated and undissociated forms are summarized in Table 1. For the sake of a comparison, the data of L-ascorbic acid[5] are also listed in Table 1. The reactivities of triose reductone with these oxidizing species are in the order of $Cl_2^-\cdot > N_3\cdot > Br_2^-\cdot > (SCN)_2^-\cdot > I_2^-\cdot$, similar to ascorbic acid. One-electron reduction potentials[22] of the oxidizing species (Table 2) explain the reactivity order well. The rate constants for oxidation are larger in triose reductone than in ascorbic acid, except that of $I_2^-\cdot$ with undissociated ascorbic acid quoted from a reference.[5] We found from the decay of $I_2^-\cdot$ at 410 nm that the reaction rate constant of $I_2^-\cdot$ with ascorbic acid was smaller than 6×10^5 M^{-1} s^{-1}. The latter value seems more reasonable from the relation mentioned above. The stronger reducing power of triose reductone in comparison with ascorbic acid was also shown in the reductions of peroxodisulfate[17,23] and hexacyanoferrate(III).[18,24] The dependences of log k (k: rate constants for oxidation by inorganic radicals) on the reduction potential (E (ev)) in both triose reductone and ascorbic acid are presented in Fig. 1. They are almost linear except for reactions of $I_2^-\cdot$ with undissociated triose reductone and ascorbic acid. This result shows that the electron-transfer reactions that occur in these systems are as predicted from the Marcus theory.[25] Triose reductone has two dissociation constants[16] ($pK_1=5.0$, $pK_2=13.0$). Therefore, the reaction scheme can be described as follows.

$$H_2O \rightsquigarrow e_{aq}^-, H, OH, H_2O_2, H_2 \quad (1)$$

$$N_2O + e_{aq}^- \xrightarrow{H_2O} OH + OH^- + N_2 \quad (2)$$

$$X^- + OH \longrightarrow X\cdot + OH^- \quad (3)$$
(X=SCN, Cl, Br, I)

$$X^- + X\cdot \longrightarrow X_2^-\cdot \quad (4)$$

$$N_3^- + OH \longrightarrow N_3\cdot + OH^- \quad (5)$$

$$TRH_2 \overset{K_1}{\rightleftharpoons} TRH^- + H^+ \overset{K_2}{\rightleftharpoons} TR^{2-} + 2H^+ \quad (6)$$

$$TRH_2 \text{ (or } TRH^-) + X_2^-\cdot \longrightarrow TRH\cdot \text{ (or } TR^{-}\cdot) + 2X^- \quad (7)$$

$$TRH_2 \text{ (or } TRH^-) + N_3\cdot \longrightarrow TRH\cdot \text{ (or } TR^{-}\cdot) + N_3^- \quad (8)$$

Absorption Spectra. Triose reductone is oxidized with $X_2^-\cdot$ (X=SCN, Cl, Br, I) or $N_3\cdot$ radicals to generate transient species, as mentioned above. The absorption spectra observed in these systems (Fig. 2) are identical with each other within experimental errors. The absorption spectrum (Fig. 2) almost completely disappears upon the addition of 0.2 M *t*-BuOH which scavenges OH radicals. The result supports the idea that transient absorption is produced by a reaction of triose reductone with the inorganic radicals. The absorption spectrum shows a quite symmetrical (Gaussian-type) band with a maximum at 398 nm and a width at half-maximum of 71 nm. The absorption coefficient at 398 nm is 5500 $M^{-1}cm^{-1}$. The solid line in Fig. 2 represents the simulated Gaussian-curve with the deviation of 32 nm, and fits well with a observed ab-

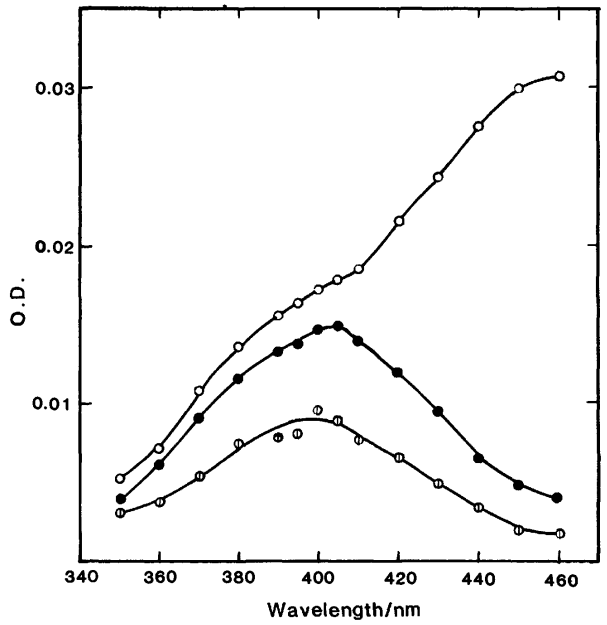

Fig. 3. Time change of transient spectrum produced by $(SCN)_2^-$ at pH 3.2. N_2O saturated 3×10^{-4}M triose reductone, 20 mM KSCN; Average dose, 536 rad; 0(○), 200(●), 900(◑), μs after the pulse.

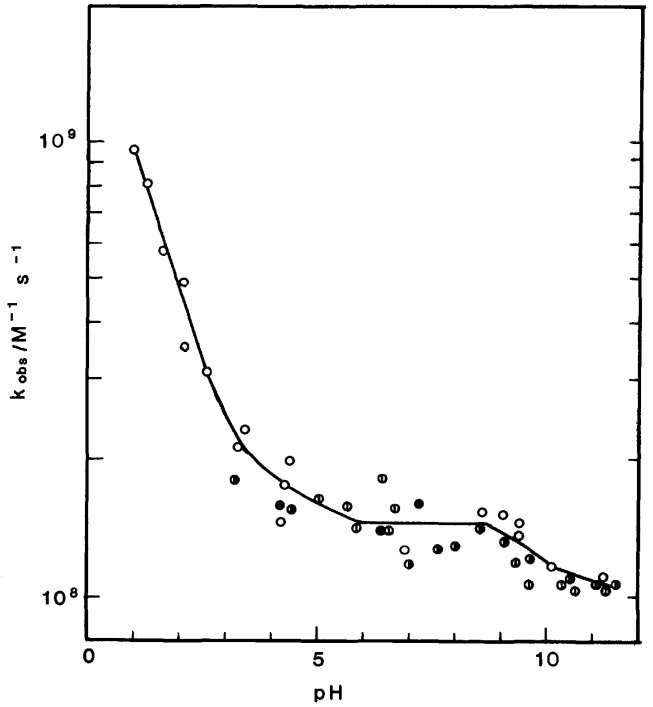

Fig. 4. Dependence of decay rate constants of the triose reductone radical corrected for ionic strength on pH. N_2O saturated solution of 2×10^{-4}, 3×10^{-4} M triose reductone; 10, 20 mM KBr (○); 5, 20 mM KSCN (◑); 5, 10, 20 mM NaN_3 (◑); 3, 20 mM KI (●).

sorption data. The ascorbic acid radical also has a very symmetric-type band with a maximum at 360 nm and a half-maximum width of 50 nm.[26] Figure 3 shows the time-changes of the transient absorption spectrum produced by $(SCN)_2^-$ radicals at pH 3.2. It indicates that the $(SCN)_2^-$ radical (λ_{max}=472 nm) is gradually converted into the triose reductone radical (reaction 7), since the rate constant for the reaction $TRH_2+(SCN)_2^-$ is rather small (2.7×10^7 $M^{-1}s^{-1}$) in comparison with that for dissociated triose reductone (9.0×10^8 $M^{-1}s^{-1}$).

Rate of Radical Decay. Triose reductone radicals including both TRH· and TR^{-}· (*vide infra*) decay by

second-order kinetics over a wide pH range (pH 1—11.5). Figure 4 shows the relationship between the second-order rate constants for the decay of the radical (TRH· and/or TR^{-}·) and the pHs of solutions, where the rate constants were corrected for ionic strength. The rate constant decreases slightly from pH 9 to 12.5 and is almost constant in the range of pH 6—9 and increases steeply from pH 4 to pH 1. The change of the rate constant around pH 10 is not at present understandable. The dependence of the decay rate of the radical on pH is probably due to H^+ as well as the ascorbate radical[5] and the decay rate may be affected by the dissociation of the radical below pH 2.5, whose pK_a is 1.4 as shown later. But, the hydrated electron reacts with H^+ competitively with N_2O to yield the H radical below pH ≈2.5. Also the transient species produced by the reaction of triose reductone with the H radical might affect the apparent rate constants. Hence, the decay mechanism of the radical is complicated below pH ≈2.5. The rate of a reaction between two ions is dependent on the ionic strength (μ), as given approximately[27] by

$$\log k/k_0 = Z_A Z_B(1.02\mu^{1/2})/(1+\mu^{1/2}) = Z_A Z_B m \qquad (I)$$

where k_0 is the value of k at zero ionic strength, and Z_A, Z_B are the charges of two ions, and μ is the total ionic strength. The effect of the ionic strength on the decay rate of the triose reductone radical was studied at pH 8.0, where the radical is presumed to be dissociated from the pK_a (1.4) as shown later, using sodium sulfate to vary μ. The results are shown in Fig. 5, where the observed values of log k are plotted as a function of m. The slope of the line in Fig. 5 is about 0.7. Hence, the oxidized intermediate can be assigned to the anion radical TR^{-}·

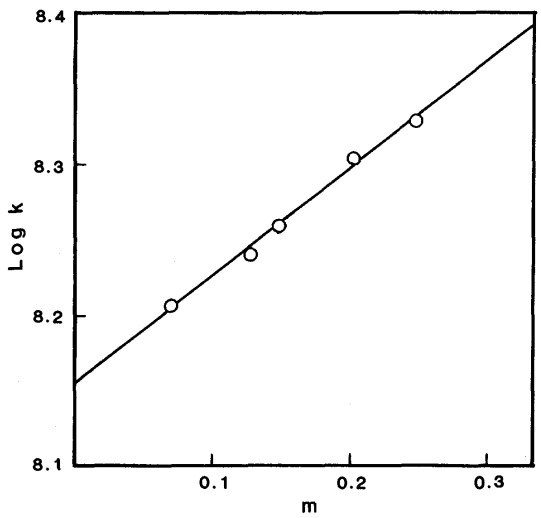

Fig. 5. Effect of ionic strength on decay rate of the triose reductone radical.
N_2O saturated solution of 3×10^{-4} M triose reductone; 5 mM KSCN; pH 8.0.

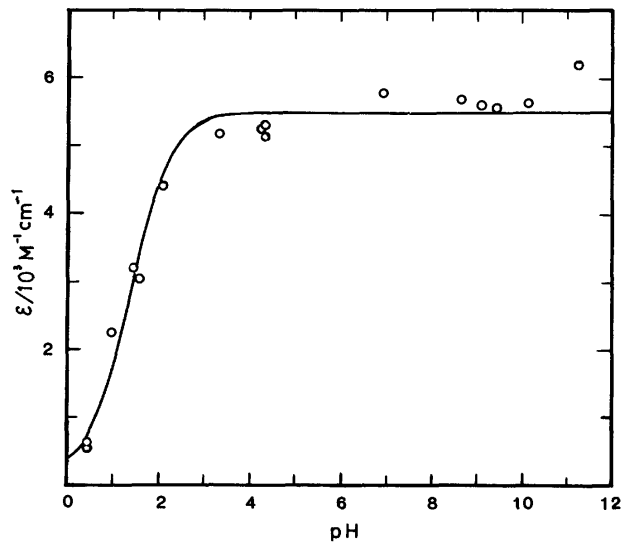

Fig. 6. Dependence of molar extinction coefficient (ε) of the triose reductone radical on pH. N_2O saturated solutions of 3×10^{-4} M triose reductone; 10, 20 mM KBr.

pK_a of the Triose Reductone Radical. The molar extinction coefficients (ε) of triose reductone radical determined at 400 nm as a function of pH are shown in Fig. 6. Below pH 3 the hydrated electron (e^-_{aq}) reacts with proton (H^+) to produce the H radical. But, the transient species which is produced by the reaction of triose reductone with the H radical has only a small extinction coefficient ($\varepsilon_{400\,nm}$=300). The extinction coefficient was obtained in the system of 1 mM TRH_2, 0.2 M *t*-BuOH, at pH 1. The numerical values of ε were corrected for the H^+ effect, as H^+ reacts with e^-_{aq} to yield the H radical. The smooth line in Fig. 6 was computed by assuming that the pH dependence of the extinction coefficient results from the acid dissociation process, using $\varepsilon^{TRH\cdot}_{400\,nm}$=200 $M^{-1}cm^{-1}$, $\varepsilon^{TR^{-}\cdot}_{400\,nm}$= 5500 $M^{-1}cm^{-1}$. The acid dissociation constant giving the best fit to the data is pK_a=1.4. In the γ-ray radiolysis of 5 mM KBr, 26 μM TRH_2, N_2O saturated solution at pH 8.5, G(-TRH_2) (the consumption G value of TRH_2) was obtained as about 3. As $G(Br_2^{-}\cdot)$ is 6.1 in the system above, the triose reductone radical is presumed to decay by disproportionation mechanism in the same way as the ascorbic acid radical.[5] Consequently, the triose reductone radical decays according to the following scheme.

$$TRH\cdot \overset{pK_a=1.4}{\rightleftharpoons} TR^{-}\cdot + H^+ \qquad (9)$$

$$TR^{-}\cdot + TR^{-}\cdot \xrightarrow{H^+} TRH_2 \text{ (or } TRH^-) + TR \qquad (10)$$

However, it is not clear in this study whether the triose reductone radical is in equilibrium with a dimer similar to the ascorbic acid radical,[7] as follows.

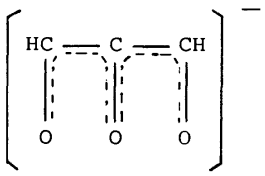
$$TR^{-}\cdot + TR^{-}\cdot \rightleftharpoons TR_2^{2-} \qquad (11)$$

Table 3. Dissociation constants for triose reductone, ascorbic acid, and their radicals

	Triose reductone	Ascorbic acid
pK_1	5.0	4.3[a]
pK_2	13.0	11.6[a]
Radical		
pK_a	1.4	−0.45[b]

a) Ref. 31. b) Ref. 28.

Fessenden, Schuler, and co-workers[28,29] showed by an ESR study that the ascorbic acid radical has a structure with an unpaired electron spread over a highly conjugated tricarbonyl system with a pK_a of −0.45. Therefore, the triose reductone radical ($TR^{-\cdot}$) probably has the following conjugated structure, as it has a similar enediol group with a carbonyl group as well ascorbic acid. In the molecular orbital calculation



study[30] of triose reductone, the result also shows that the radical is in a resonated anion form, while the spin density is localized somewhat on the central oxygen atom.

The dissociation constants of ascorbic acid, triose reductone, and their radicals are summarized in Table 3. In each case, pK_a of triose reductone and its radical is larger than that of ascorbic acid and ascorbate radical. Namely, it shows that ascorbic acid and its radical are stronger acids than those of triose reductone, respectively. The dissociation constants of the reductone radicals are greater by a factor of over 10^3 than that of the respective reductones. This fact shows that these reductone radicals are far more acidic than the corresponding reductone.

The authors wish to thank the members of the linac group for operating the linac.

Electronic Structure and Lattice Distortion of Benzene Anion

Minoru KIMURA,† Hiroyuki KAWABE, Kiyoshi NISHIKAWA, and Shigeyuki AONO*
†*Department of Physics, Faculty of Science, Kanazawa University, Marunouchi, Kanazawa 920*

(Received April 27, 1985)

Electronic structure, especially the charge density or the spin density of the benzene anion (exactly dihydrophenylide ion) is investigated by the Hubbard Hamiltonian with vibronic interaction. Two limiting cases, *i.e.*, $I/\beta \ll 1$ and $I/\beta \gg 1$ (I is the electron repulsion on site, β the absolute value of transfer integral.) are analytically examined. For whole range of this ratio, the numerical calculation has been performed. The actual system falls into the latter case, where the electron correlation produces a strong effect on the spin density distribution.

The benzene molecule is a typical subject for theories of electronic states of molecules, while the benzene anion is of interest also from physical viewpoints. In the molecular orbital theory, the benzene molecule has the unoccupied doubly degenerate orbitals. The odd electron of the benzene anion, therefore, would equally populate on these degenerate levels.

If the vibronic coupling exists, the degenerate levels are strongly coupled through an interaction with a certain mode of the vibration, and then the degeneracy is removed to lead to a distorted ground state, *i.e.*, the so-called Jahn-Teller effect arises. Almost all the studies have been made along the above-mentioned simple picture.[1-6] Even in the elaborated work,[4] the electronic state was considered within a single-particle picture for the odd electron, which neglects the role of electron repulsion.

Recently similar problems have been studied in solid state physics, *e.g.*, the study of various ordered phases in the infinite chain molecule.[7] In this decade the so-called many-body technique employed in these investigations are getting familiar also in quantum chemistry. One of the great advantages of the many-body thoery lies in making the investigating procedure systematic and pictorial. In the present work, we employ this method to study the distorted nonuniform ground state in the benzene anion, taking into account the most dominant part of the electron interaction.

Model Hamiltonian and One-electron Theory

Let us consider the system to be described by the P.P.P. Hamiltonian with terms which is responsible for lattice distortion,

$$H = \sum_{r,\sigma}\alpha_r n_{r\sigma} - \sum_{r,\sigma}(\beta_{r,r+1}a^+_{r\sigma}a_{r+1\sigma}+\text{h.c.}) + \frac{1}{2}\sum_{r,s,\sigma} I_{r,s}n_{r\sigma}n_{s-\sigma} + \frac{1}{2}M\Omega^2\sum_r Q_r^2, \quad (1)$$

where α_r is the Coulomb integral of the site r, $\beta_{r,s}$ is the resonance integral and $I_{r,s}$ the electron–electron interaction constant. The last term of Eq. 1 represents the elastic energy due to the distortion Q_r of the site r from its C_6-symmetric configuration. It includes the compressional energy of σ electrons. In the undistorted symmetric configuration, α_r and $\beta_{r,s}$ are uniform. Therefore, so long as Q_r is small, they are expanded in Q_r and can be written as

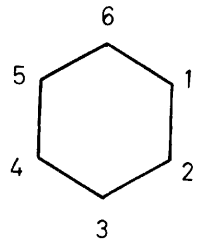

Fig. 1. Site numbers for the benzene anion.

$$a_r = \alpha_0 + gQ_r + \frac{1}{2}\Delta\alpha(\delta_{r,3}+\delta_{r,6}), \quad (2)$$

$$\beta_{r,r\pm1} = \beta + g'Q_r, \quad (3)$$

where g and g' are the expansion coefficients. The last term of Eq. 2 represents the perturbation arising from the interaction with solvent which may be added, say, at the sites r=3 and 6 (Fig. 1), which reduces the molecular symmetry from C_6 to C_2. It will be time-dependent in view of thermal motion of solvent molecules. However, if we assume that it is sufficiently slow as compared to motion of the phase of the distortion, we can consider it as a static perturbation. As will be shown below, its effect is to pin up the phase of the distortion at the particular site so as to minimize the total energy.

Equation 3 has been used to study the bond-alternation in polyene (for example the model of Su, Schriefer and Heeger in considering polyacetylene[7]), while Eq. 2 was considered by Holstein[8] to study the polaron in molecular chains. The second terms of Eqs. 2 and 3 both contribute to the change of the energy of the electrons due to the distortion. However, in the present study, they yield essentially the same physical effect except for the difference of the phases of distortion, so that we shall take only the change of α_r of Eq. 2 into account, and consider

$$\beta_{r,r\pm1} = \beta \quad (4)$$

as a constant.

The electron–electron interaction plays an important role in the electron distribution, which was not

considered in the early works.[1-7] However, the full consideration of electron interaction in Eq. 1 is so complex as to preclude physical pictures, therefore we shall consider only the on-site repulsion $I_{r,r}=I$ in order to examine the essential features qualitatively.[9-11]

Then, the Hamiltonian to be considered becomes

$$H = H_0 + H_{\rm int} + H_{\rm L}, \tag{5}$$

$$H_0 = -\beta\sum_{r,\sigma}(a^+_{r\sigma}a_{r+1\sigma}+\text{h.c.}), \tag{6}$$

$$H_{\rm int} = g\sum_{r,\sigma}Q_r n_{r\sigma} + \frac{1}{2}I\sum_{r,\sigma}n_{r\sigma}n_{r-\sigma} + \frac{1}{2}\Delta\alpha\sum_{r,\sigma}n_{r\sigma}(\delta_{r,3}+\delta_{r,6}), \tag{7}$$

$$H_{\rm L} = \frac{1}{2}M\Omega^2\sum_r Q_r^2. \tag{8}$$

Now, let us outline the one-electron theory of Jahn-Teller distortion. The molecular orbitals given by H_0 have LCAO coefficients at the atomic site r as given by,

$$C_{r,k_n} = 1/\sqrt{6}\,e^{ik_n r}, \tag{9}$$

where the periodic boundary condition for k_n imposes that

$$k_n = \frac{\pi}{3}n \quad (n=0, \pm1, \pm2, 3), \tag{10}$$

and the one-electron spectrum is given by

$$\varepsilon_n = -2\beta\cos k_n. \tag{11}$$

In the neutral benzene, the orbitals $n=0$ and ±1 are occupied. The odd electron in the benzene anion may occupy either one of the orbitals with $n=+2$ or -2, so that the state of the anion is doubly degenerate (the spin of the odd electron is fixed). Therefore, any perturbation which has the component of C_2-symmetry will remove this degeneracy, even if it may be considerably small. Indeed, if the electron-electron interaction is neglected for a time, the first order perturbation theory gives the splitting of ε_2 as

$$\tilde{\varepsilon}_\pm = \varepsilon_2 \pm \Delta. \tag{12}$$

We express the distortion of C_2-mode, which couples with the orbitals $n=\pm2$, as

$$Q_r = \frac{1}{6}Q(e^{ik_2 r+i\varphi}+e^{-ik_2 r-i\varphi}), \tag{13}$$

where Q and φ are the amplitude and the phase of distortion, respectively. Then, Δ is given by

$$\Delta = \frac{1}{6}\{(\Delta\alpha)^2 - gQ\Delta\alpha\cos\varphi + g^2Q^2\}^{1/2}. \tag{14}$$

The odd electron must occupy the level $\tilde{\varepsilon}_-$, so that the energy change caused by the distortion is

$$W = -\Delta + \frac{1}{6}M\Omega^2Q^2. \tag{15}$$

Equation 15 plays the role of adiabatic potential for the system. The ground state configuration is obtained by minimizing W with respect to Q and φ, and as optimum values we obtain

$$\varphi_0 = 0 \text{ or } \pi, \tag{16}$$

according to $\Delta\alpha<0$ or >0, respectively, and

$$Q_0 = g/(2M\Omega^2). \tag{17}$$

The minimum of W is negative, so that the Jahn-Teller distortion is stabilized. The odd electron distribution becomes nonuniform as given by

$$\Delta n_r = \frac{1}{6}(1\mp\cos\frac{2\pi}{3}r), \tag{18}$$

where the sign $\mp$ corresponds to $\Delta\alpha\gtrless0$. Within this approach the spin density distribution is the same as Eq. 18 apart from the factor 1/2 (Fig. 2). Equation 18 is the same as obtained by Hobey and McLachlan.[3]

Green's Function Theory

In benzene the electron repulsion is not considered to be small and the one-electron theory considering only the degenerate orbitals with $n=\pm2$ is too simple to explain the real system. We must consider all the seven electrons together in the framework of the many-body theory, even within the Hartree-Fock scheme. For this purpose it is convenient to introduce the Green's function defined by

$$G^\sigma_{r,s}(t) = -i\langle T[a_{r\sigma}(t)a^+_{s\sigma}(0)]\rangle. \tag{19}$$

Transforming the atomic orbitals into the molecular orbitals, Eq. 19 becomes

$$G^\sigma_{r,s}(t) = \frac{1}{6}\sum_{p,q}G^\sigma_{p,q}(t)e^{ipr-iqs}, \tag{20}$$

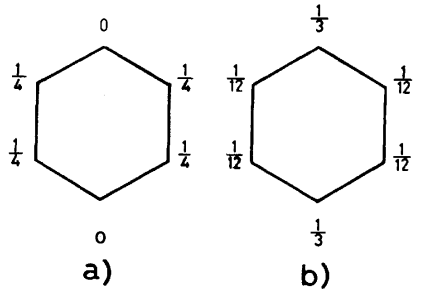

Fig. 2. The electron density distribution in the one-electron theory. a) $\Delta\alpha>0$, b) $\Delta\alpha<0$.

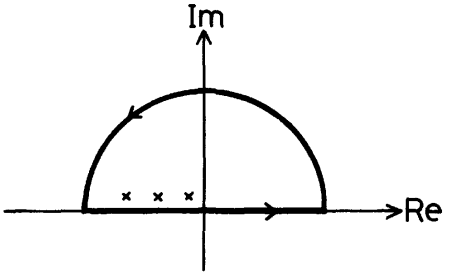

Fig. 3. Closed contour for Eq. 25. The crosses represent the singular points of the Green's function. The contour of integration in the complex plane is the real axis from $-\infty$ to ∞ and the semicircle of the upper half plane.

where

$$G^{\sigma}_{p,q}(t) = -i\langle T[a_{p\sigma}(t)a^{+}_{q\sigma}(0)]\rangle. \tag{21}$$

The Fourier transform of the Green's function is defined as

$$G^{\sigma}_{p,q}(t) = \int_{-\infty}^{\infty}\frac{d\varepsilon}{2\pi}G^{\sigma}_{p,q}(\varepsilon)e^{-i\varepsilon t}. \tag{22}$$

It can be expected that the special role played by the C_2-mode of distortion remains important so long as the electron repulsion is not too strong and we thus consider that the dominant components of the Green's function $G^{\sigma}_{p,q}(t)$ are those for $q=p$, $p\pm k$, where we denote as $k\equiv k_2=2\pi/3$, and the other components can be neglected. The electron distribution is then

$$n_{r\sigma} = n_{\sigma} + \sum_{p}(\langle a^{+}_{p+k\sigma}a_{p\sigma}\rangle e^{-ikr}+\text{c.c.}). \tag{23}$$

The first term of Eq. 23 is the uniform part of the density of the electron

$$n_{\sigma} = \frac{1}{N}\sum_{p}\langle a^{+}_{p\sigma}a_{p\sigma}\rangle = \begin{cases}4/6 \text{ for spin up}\\ 3/6 \text{ for spin down.}\end{cases} \tag{24}$$

The second term of Eq. 23 represents the non-uniform distribution. It is expressed by the Green's function as

$$\begin{aligned}\langle a^{+}_{p+k\sigma}a_{p\sigma}\rangle &= \frac{1}{i}\lim_{t\to 0-}G^{\sigma}_{p,p+k}(t)\\ &= \int_{-\infty}^{\infty}\frac{d\varepsilon}{2\pi i}G^{\sigma}_{p,p+k}(\varepsilon)e^{-i\varepsilon 0^{+}}.\end{aligned} \tag{25}$$

The ε-integral of Eq. 25 is estimated by closing the contour on the upper half plane as in Fig. 3 to be

$$\langle a^{+}_{p+k\sigma}a_{p\sigma}\rangle = \sum_{i\in\text{occ}}\text{residue of } G^{\sigma}_{p,p+k}(\varepsilon_i), \tag{26}$$

where ε_i is the i-th pole of the Green's function. The total energy can be expressed also by the Green's function as (see Appendix for details)

$$\begin{aligned}E = \frac{1}{2}\sum_{p,\sigma}\int\frac{d\varepsilon}{2\pi i}[&(\varepsilon+n_{-\sigma}I+\varepsilon_p)G^{\sigma}_{p,p}(\varepsilon)\\ &+\frac{1}{6}(gQe^{i\varphi}+\Delta\alpha)G^{\sigma}_{p,p+k}(\varepsilon)\\ &+\frac{1}{6}(gQe^{-i\varphi}+\Delta\alpha)G^{\sigma}_{p,p-k}(\varepsilon)].\end{aligned} \tag{27}$$

Equation 27 can be estimated by the sum of the residue of the occupied levels as expressed by Eq. 26.

Now, the equation of motion for the Green's function leads to[12]

$$\begin{aligned}i\frac{\partial}{\partial t}G^{\sigma}_{r,s}(t) = &\delta_{r,s}\delta(t)\\ &+\{gQ_r+\frac{1}{2}\Delta\alpha(\delta_{r,3}+\delta_{r,6})\}G^{\sigma}_{r,s}(t)\\ &-\beta\{G^{\sigma}_{r+1,s}(t)-G^{\sigma}_{r-1,s}(t)\}\\ &+I\Gamma^{\sigma}_{r,s}(t),\end{aligned} \tag{28}$$

where

$$\Gamma^{\sigma}_{r,s}(t) = -i\langle T[n_{r-\sigma}(t)a_{r\sigma}(t)a^{+}_{s\sigma}(0)]\rangle \tag{29}$$

is the higher order Green's function. Within the Hartree-Fock scheme $\Gamma^{\sigma}_{r,s}$ is approximated by decoupling as

$$\Gamma^{\sigma}_{r,s}(t) = n_{r-\sigma}G^{\sigma}_{r,s}(t). \tag{30}$$

Then, in the molecular orbital representation the equation becomes

$$\begin{aligned}(\varepsilon-\varepsilon_p-In_{-\sigma})G^{\sigma}_{p,q}(\varepsilon) - C_{\sigma}G^{\sigma}_{p+k,q}(\varepsilon)\\ - C^{*}_{\sigma}G^{\sigma}_{p-k,q}(\varepsilon) = \delta_{p,q},\end{aligned} \tag{31}$$

where

$$C_{\sigma} = \frac{1}{6}(gQe^{-i\varphi}+\Delta\alpha+D_{-\sigma}), \tag{32}$$

and

$$D_{\sigma} = I\sum_{p}\langle a^{+}_{p+k\sigma}a_{p\sigma}\rangle \tag{33}$$

is determined by Eq. 25. It is easily shown that the total energy is minimized when C_{σ} and D_{σ} are real and $\varphi=0$ or π. The system as expressed by Eq. 31 is separated into two sets of equations as illustrated in Fig. 4. Then, the equations for $G_{p,p}$ and $G_{p,p\pm k}$ are expressed as

$$\begin{bmatrix}\varepsilon-\omega_{2,\sigma} & -C_{\sigma} & -C_{\sigma}\\ -C_{\sigma} & \varepsilon-\omega_{0,\sigma} & -C_{\sigma}\\ -C_{\sigma} & -C_{\sigma} & \varepsilon-\omega_{2,\sigma}\end{bmatrix}\begin{bmatrix}G^{\sigma}_{2,q}\\ G^{\sigma}_{0,q}\\ G^{\sigma}_{-2,q}\end{bmatrix} = \begin{bmatrix}\delta_{2,q}\\ \delta_{0,q}\\ \delta_{-2,q}\end{bmatrix}, \tag{34}$$

$$\begin{bmatrix}\varepsilon-\omega_{1,\sigma} & -C_{\sigma} & -C_{\sigma}\\ -C_{\sigma} & \varepsilon-\omega_{3,\sigma} & -C_{\sigma}\\ -C_{\sigma} & -C_{\sigma} & \varepsilon-\omega_{1,\sigma}\end{bmatrix}\begin{bmatrix}G^{\sigma}_{1,q}\\ G^{\sigma}_{3,q}\\ G^{\sigma}_{-1,q}\end{bmatrix} = \begin{bmatrix}\delta_{1,q}\\ \delta_{3,q}\\ \delta_{-1,q}\end{bmatrix}, \tag{35}$$

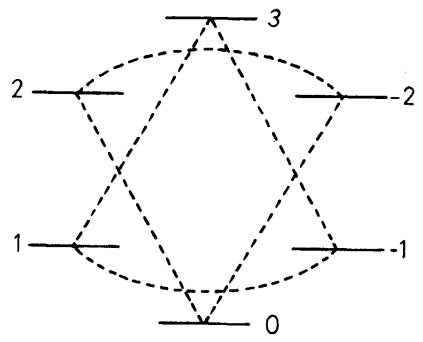

Fig. 4. The coupling of the orbitals in Eqs. 34, 35 by dashed lines.

where

$$\omega_{i,\sigma} = \varepsilon_i + n_{-\sigma}I. \tag{36}$$

The one-electron energies given by the eigenvalues of Eqs. 34 and 35 are expressed as

$$\tilde{\varepsilon}_i^\sigma = \tilde{\omega}_i^\sigma + n_{-\sigma}I, \tag{37}$$

where

$$\begin{aligned}
\tilde{\omega}_1^\sigma &= \frac{1}{2}(-\beta+C_\sigma-\gamma_+^\sigma),\\
\tilde{\omega}_2^\sigma &= -\beta - C_\sigma,\\
\tilde{\omega}_3^\sigma &= \frac{1}{2}(\beta+C_\sigma-\gamma_-^\sigma),\\
\tilde{\omega}_4^\sigma &= \beta - C_\sigma,\\
\tilde{\omega}_5^\sigma &= \frac{1}{2}(-\beta+C_\sigma+\gamma_+^\sigma),\\
\tilde{\omega}_6^\sigma &= \frac{1}{2}(\beta+C_\sigma+\gamma_-^\sigma),\\
\gamma_\pm^\sigma &= 3\sqrt{\beta^2 \pm (2/3)\beta C_\sigma + C_\sigma^2}.
\end{aligned} \tag{38}$$

Then, Green's functions are solved as

$$\begin{aligned}
G_{0,0}^\sigma(\varepsilon) &= \frac{\varepsilon-\tilde{\omega}_2^\sigma-C_\sigma}{Det_2^\sigma(\varepsilon)},\\
G_{1,1}^\sigma(\varepsilon) &= G_{-1,-1}^\sigma(\varepsilon) = \frac{1}{2}\left\{\frac{\varepsilon-\tilde{\omega}_3^\sigma}{Det_1^\sigma(\varepsilon)}+\frac{1}{\varepsilon-\tilde{\varepsilon}_2^\sigma}\right\},\\
G_{2,2}^\sigma(\varepsilon) &= G_{-2,-2}^\sigma(\varepsilon) = \frac{1}{2}\left\{\frac{\varepsilon-\tilde{\omega}_0^\sigma}{Det_2^\sigma(\varepsilon)}+\frac{1}{\varepsilon-\tilde{\varepsilon}_4^\sigma}\right\},\\
G_{3,3}^\sigma(\varepsilon) &= \frac{\varepsilon-\tilde{\omega}_1^\sigma-C_\sigma}{Det_1^\sigma(\varepsilon)},
\end{aligned} \tag{39}$$

and

$$\begin{aligned}
G_{-1,1}^\sigma(\varepsilon) &= G_{1,-1}^\sigma(\varepsilon) = \frac{1}{2}\left\{\frac{\varepsilon-\tilde{\omega}_3^\sigma}{Det_1^\sigma(\varepsilon)}-\frac{1}{\varepsilon-\tilde{\varepsilon}_2^\sigma}\right\},\\
G_{-2,2}^\sigma(\varepsilon) &= G_{2,-2}^\sigma(\varepsilon) = \frac{1}{2}\left\{\frac{\varepsilon-\tilde{\omega}_0^\sigma}{Det_2^\sigma(\varepsilon)}-\frac{1}{\varepsilon-\tilde{\varepsilon}_4^\sigma}\right\},\\
G_{3,1}^\sigma(\varepsilon) &= G_{1,3}^\sigma(\varepsilon) = G_{3,-1}^\sigma(\varepsilon) = G_{-1,3}^\sigma(\varepsilon) = \frac{C_\sigma}{Det_1^\sigma(\varepsilon)},\\
G_{0,2}^\sigma(\varepsilon) &= G_{2,0}^\sigma(\varepsilon) = G_{0,-2}^\sigma(\varepsilon) = G_{-2,0}^\sigma(\varepsilon) = \frac{C_\sigma}{Det_2^\sigma(\varepsilon)},
\end{aligned} \tag{40}$$

Table 1. The self-consistent solutions for the weak repulsion

	$\Delta\alpha>0$	$\Delta\alpha<0$
$D+$	$-1/2I$	$1/2I$
$D-$	0	0
$C+$	$1/6(gQ+\Delta\alpha)$	$-1/6(gQ+\lvert\Delta\alpha\rvert)$
$C-$	$-I/12+1/6(gQ+\Delta\alpha)$	$I/12-1/6(gQ+\lvert\Delta\alpha\rvert)$
Δn_r	$1/6(1-\cos 2\pi/3r)$	$1/6(1+\cos 2\pi/3r)$
S_r	$1/12(1-\cos 2\pi/3r)$	$1/12(1+\cos 2\pi/3r)$
φ	0	π

Δn_r is the distribution of the excess charge normalized as $\sum\Delta n_r=1$. S_r is the spin distribution.

where

$$\begin{aligned}
Det_1^\sigma(\varepsilon) &= (\varepsilon-\tilde{\varepsilon}_3^\sigma)(\varepsilon-\tilde{\varepsilon}_6^\sigma),\\
Det_2^\sigma(\varepsilon) &= (\varepsilon-\tilde{\varepsilon}_5^\sigma)(\varepsilon-\tilde{\varepsilon}_1^\sigma).
\end{aligned} \tag{41}$$

Analytic Solutions in Limiting Cases

The Green's functions, which is dependent on the potential C_σ, must be solved self-consistently with Eqs. 32 and 33. The equations are solved numerically as shown in the next section. Here we give the analytic solutions for two limiting cases of the weak and strong repulsion, as follows.

1. Weak repulsion $\beta \gg |C_\sigma|$ $(I \ll \beta)$

In this case the essential features of the one-electron theory described above are remain unchanged. The occupied levels are in ascending order

$$\begin{aligned}
&\omega_1^+, \omega_2^+, \omega_3^+, \omega_4^+, \omega_1^-, \omega_2^-, \omega_3^- \quad \text{for } \Delta\alpha > 0\\
&\omega_1^+, \omega_3^+, \omega_2^+, \omega_5^+, \omega_1^-, \omega_3^-, \omega_2^- \quad \text{for } \Delta\alpha < 0.
\end{aligned} \tag{42}$$

The self-consistent solution in the leading order in I/β are listed in Table 1. The real and small parameter of expansion is $|C_\sigma|/\beta$, but not I/β. The former is small as far as I is not too large even if it exceeds β, as will be demonstrated numerically.

The energy gain of the distortion is given by

$$\begin{aligned}
\Delta E &= E - E_0\\
&= -\frac{1}{6}(gQ+|\Delta\alpha|) + \frac{M}{6}\Omega^2Q^2,
\end{aligned} \tag{43}$$

where E_0 is the H. F. energy of undistorted configuration of the benzene anion,

$$E_0 = -7\beta + I. \tag{44}$$

The magnitude of Q for the equilibrium configuration is determined by the minimization of Eq. 43 as

$$Q_0 = g/(2M\Omega^2). \tag{45}$$

Equations 43 and 45 agree with the results in the one-electron theory.

2. Strong repulsion $\beta \ll |C_\sigma|$ $(I \gg \beta)$

The occupied levels are the same as Eq. 42. The

TABLE 2. TWO CLASSES OF THE SELF-CONSISTENT SOLUTIONS FOR THE STRONG REPULSION, ONE STABLE (A) AND ONE UNSTABLE (B)

	A (stable)	B (unstable)
$D+$	$-2I$	I
$D-$	$3/2I$	$-3/2I$
$C+$	$I/4+1/6(gQ+\Delta\alpha)$	$-I/4+1/6(gQ+\lvert\Delta\alpha\rvert)$
$C-$	$-I/3+1/6(gQ+\Delta\alpha)$	$I/6+1/6(gQ+\lvert\Delta\alpha\rvert)$
Δn_r	$1/6(1-\cos 2\pi/3r)$	$1/6(1-\cos 2\pi/3r)$
S_r	$1/12(1-7\cos 2\pi/3r)$	$1/12(1+5\cos 2\pi/3r)$
φ	0	0

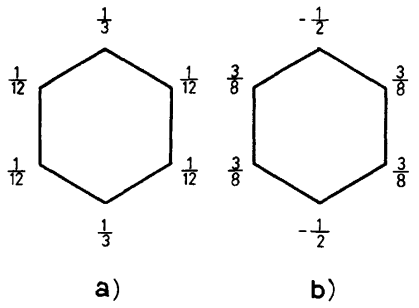

Fig. 5. a) Excess charge distribution, b) Spin distribution.

solutions are given in Table 2. In this case two classes of self-consistent solutions A and B are possible. The energy gain of A and B are, respectively

$$\Delta E_A = I + \beta - \frac{1}{6}(gQ+\Delta\alpha) + \frac{M}{6}\Omega^2Q^2, \quad (46)$$

$$\Delta E_B = -\frac{1}{2}I + \beta - \frac{1}{6}(gQ+\Delta\alpha) + \frac{M}{6}\Omega^2Q^2. \quad (47)$$
