A schematic diagram of the apparatus is shown in Fig. 1. An effusive beam of benzene through a multichannel array A with a pushing pressure of 2—3 Torr (1 Torr=133.322 Pa) was excited by electron impact (2—20 eV) to the T_1 state [5]. The electron gun and the excitation region was magnetically shielded with μ-metal. Either biacetyl or benzophenone was deposited continuously on an alumimum surface cooled at 77 K from nozzle B. The metastable benzene molecules were allowed to collide on the phosphor surface after traveling 17 cm. The emission from the surface was detected through an interference filter having a band-pass of 10 nm. The filter was so chosen that the wavelength of the maximum transmittance of the filter coincided with that of the maximum intensity of the resulting emission, *i.e.*, band pass filters of 520-nm (Toshiba KL-52) and 440-nm (Toshiba KL-44) for biacetyl and benzophenone, respectively. Charged species produced concurrently were removed by an electrostatic deflector (see Fig. 1).

For measurement of the time dependence of the emission intensity, the molecular beam was excited by a pulsed electron beam with a pulse width of 70 μs and a repetition rate of 10 ms. The data were accumulated in a Hewlett-Packard 5480A multichannel analyzer for 2 h. For measurement of the excitation function, the emission intensity was recorded as a function of electron impact energy, where the electron beam was not pulsed. A part of the fluorescence from the benzene molecules produced in the excitation region was estimated and eliminated from the observed emission; for the purpose a quartz window, shown in Fig. 1, was placed on the beam path.

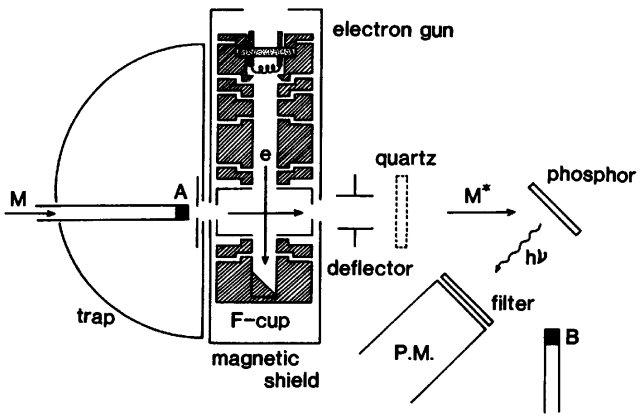

Fig. 1. A schematic diagram of the apparatus. A and B are multichannel slits for introducing benzene (M) and phosphor molecules, respectively, into the chamber. The emission from the phosphor surface is detected by a photomultiplier tube, PM. A quartz window is placed on the beam path when the contribution of stray light from the excitation region is estimated.

The signals at each impact energy were collected for 200 s, so that statistical errors were reduced to less than 6%. The absolute scale of the impact energy was calibrated by the threshold energy of the $N_2(C—B)$ transition [6].

Results and Discussion

The time-dependence curve of the emission from biacetyl surface is made of one sharp peak at $t\simeq 0$ ms and one broad peak at $t\simeq 0.6$ ms. The sharp peak arises from the photons produced in the excitation region, because (1) the peak appears at a time much shorter than the time of flight of the metastable molecules, and (2) only this peak is observed when no phosphor is deposited on the surface. Almost identical time dependence was obtained when benzophenone was used as a phosphor.

The emission forming the broad peak has maximum intensity at 520 nm for biacetyl and at 440 nm for benzophenone. Each wavelength coincides with that of the intensity maximum in the phosphorescence spectrum of the corresponding phosphor. Furthermore, the time of flight of the metastable benzene molecule agrees approximately with the time corresponding to the maximum intensity of the broad peak. These results indicate that the impinging metastable molecules to the target surface excite the phosphor by the $T—T$ energy transfer, which arises the broad peak, *i.e.*, the phosphorescence.

The shape of the broad peak is reproduced by

†Present address: Department of Chemistry, Faculty of Science, Toho University, Funabashi, Chiba 274.

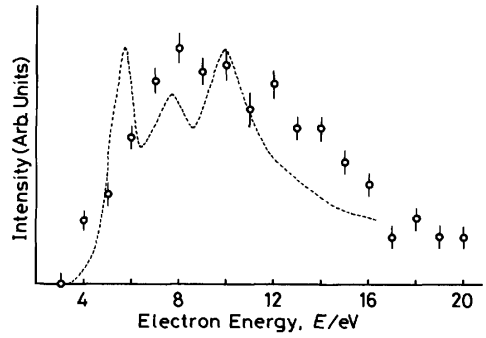

Fig. 2. Intensity of the phosphorescence (open circles) produced by collision of metastable benzene molecules on benzophenone surface (77 K) as a function of electron-impact energy. The broken line is the excitation function measured by Auger electron emission from sodium surface [7]. The ordinate is in arbitrary units.

assuming the velocity distribution of the metastable benzene molecules as

$$N(v) \propto v^4 \exp[-Mv^2/2kT], \quad (1)$$

where v and M are the velocity and the mass of benzene molecule, respectively. In addition, the phosphorescence is assumed to decay exponentially with a lifetime τ. The lifetime thus estimated, 1.0±0.2 ms, is much shorter than that for polycrystalline biacetyl (about 2 ms [2]). By optical excitation of polycrystalline biacetyl the excitation occurs in the bulk so that the measured lifetime corresponds to that of the phosphor molecules in the bulk. In contrast, the lifetime, τ, determined in the present measurement corresponds to that of the phosphor molecules on the surface, because the excitation energy of the T_1 state is transmitted directly to the phosphor surface.

Figure 2 shows the excitation function of the emission obtained by using benzophenone deposited on aluminum at 77 K. The excitation function rises in the vicinity of 3—4 eV, makes a broad maximum at 8—12 eV and falls off. This excitation function agrees qualitatively with that measured by Smyth *et al.* [7] by detecting Auger electron emission from sodium surface. In spite of the limited resolution ($\Delta E \simeq$ 2 eV) of the electron-impact energy in the present measurement, the general shape of the present excitation function provides another support that collision of the metastable benzene molecules is the main origin of the emission from the phosphor surface. A similar excitation function was obtained when biacetyl was used as a phosphor, where the signals were about 25% of those from benzophenone. The less intense signals from biacetyl is probably an indication that the phosphorescence quantum yield from biacetyl is about 25% of that from benzophenone [3,4]. On the basis of the reported cross sections for the formation of metastable benzene and $N_2(A^3\Sigma_u^+)$ molecules [8,9] and a comparison of the measured phosphorescence from metastable benzene molecules with that from the $N_2(A^3\Sigma_u^+)$ molecules, the phosphorescence yield from biacetyl surface is estimated to be on the order of 10^{-3}—10^{-4}. A more detailed study using a supersonic nozzle beam of metastable molecules is in progress [10].

We are indebted to Mr. H. Kume for his assistance in the estimation of the phosphorescence quantum yield. This work was supported by a Grant-in-Aid from the Ministry of Education, Science and Culture.

Synthesis and Magnetism of Trinuclear Copper(II) Complexes with a Salen-like Schiff Base and a Tertiary Diamine

Makoto HANDA, Hisashi ŌKAWA,* and Sigeo KIDA
Department of Chemistry, Faculty of Science, Kyushu University 33, Hakozaki, Higashiku, Fukuoka 812
(Received November 28, 1984)

Synopsis. Trinuclear Copper(II) complexes [{Cu(sb)}$_2$Cu(da)](ClO$_4$)$_2$ have been synthesized by the use of a copper(II) complex with a salen analog ([Cu(sb)]) and a diamine (da) such as bpy or phen. Cryomagnetic investigations revealed the operation of an antiferromagnetic spin-exchange interaction ($-J$=26—78 cm^{-1}) between the adjacent copper ions.

Binuclear copper(II) complexes of the type [Cu(sb)CuX$_2$] (H$_2$sb denotes salen-like Schiff bases; H$_2$salen=*N*,*N*′-di-salicylideneethylenediamine) have been synthesized and magnetically studied by Gruber *et al.*[1] Recently Patel and Bhattacharya[2] have reported the synthesis of binuclear copper(II) complexes of the type [Cu(sb)Cu(da)](ClO$_4$)$_2$ by the use of a diamine (da) such as 2,2′-bipyridyl (bpy) or 1,10-phenanthroline (phen). According to them, the magnetic moments of the complexes at room temperature fall in the range 0.83—1.19 BM†, which are considerably lower than the moments of [Cu(sb)CuX$_2$].[1] The configuration around the copper coordinated by [Cu(sb)] and da must be much distorted to tetrahedron because of a steric hinderance between these ligands.[1] Since antiferromagnetic spin-exchange interaction generally becomes weaker when the >Cu<$\overset{O}{\underset{O}{}}$>Cu< configuration is distorted from a coplane,[3] such low magnetic moments (which suggest a fairly strong antiferromagnetic spin-exchange interaction) observed for [Cu(sb)Cu(da)](ClO$_4$)$_2$ seem quite unusual. In this study we have reinvestigated the synthesis of the complexes by the use of [Cu(salen)], *N*,*N*′-disalicylidene-1,2-propanediaminatocopper(II) ([Cu(salpn)]), or *N*,*N*′-bis(5-methylsalicylidene)ethylene-diaminatocopper(II) ([Cu(5-Mesalen)]) as [Cu(sb)] and bpy or phen as da. Contrary to the Patel and Bhattacharya's result,[2] we have obtained the complexes of the type [{Cu(sb)}$_2$Cu(da)](ClO$_4$)$_2$. The characterization and the magnetism of the complexes have been reported in this paper.

Experimental

Syntheses. The synthesis of the complexes was carried out in nearly the same way as that of the literature.[2] However, the products obtained by the method often contaminated with some impurities. It was found in this study that the same complexes were obtained without the contamination of impurities when [Cu(sb)], [Cu(H$_2$O)$_6$](ClO$_4$)$_2$, and da were reacted in the 2:1:1 mole ratio.

Magnetic Measurements. Magnetic susceptibilities were measured by the Faraday method in the temperature range 80—300 K. The apparatus was calibrated by the use of [Ni(en)$_3$]S$_2$O$_3$.[4]

Results and Discussion

The elemental analyses were invariably consistent with the formulation of [{Cu(sb)}$_2$Cu(da)](ClO$_4$)$_2$ (see Table 1). No complexes of the stoichiometry [Cu(sb)Cu(da)](ClO$_4$)$_2$ as reported in the literature[2] were obtained in spite of our all efforts. We believe that [{Cu(sb)}$_2$Cu(da)](ClO$_4$)$_2$ is the most stable among possible oligonuclear complexes when [Cu(sb)] and da are utilized as the ligands. It is to be noted that tetranuclear complexes [Cu(sb)Cu(ta)]$_2$(ClO$_4$)$_4$ are obtainable when a triamine (ta) is utilized instead of a diamine.[5]

The sketetal band near 1525 cm^{-1} of [Cu(sb)] shifted to 1540 cm^{-1} in [{Cu(sb)}$_2$Cu(da)](ClO$_4$)$_2$, suggesting that the phenolic oxygens are acting as the bridges in the present complexes.[6] Magnetic moments (per copper atom) at room temperature are lower than the spin-only value, implying an operation of antiferromagnetic spin-exchange interaction. The plausible structure is supposed to be trinuclear as shown in Fig. 1, since such a structure has been demonstrated for [{Cu(sb)}$_2$M(H$_2$O)$_2$](ClO$_4$)$_2$.[7]

TABLE 1. ELEMENTAL ANALYSES, MAGNETIC MOMENTS AT ROOM TEMPERATURE, AND MAGNETIC PARAMETERS OF COMPLEXES

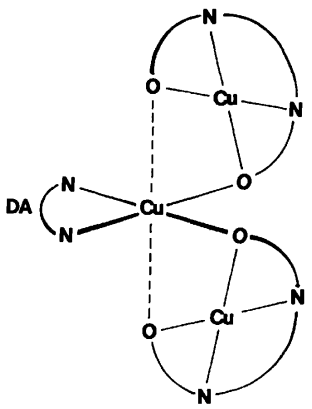

Fig. 1. Schematic representation of trinuclear structure for $[\{Cu(sb)\}_2Cu(da)]^{2+}$.

The magnetic susceptibilities of the complexes were examined in the temperature range 80—300 K. Based on the spin Hamiltonian, $\mathcal{H}=-2J(\hat{S}_1\cdot\hat{S}_2+\hat{S}_2\cdot\hat{S}_3)$, the susceptibility equation for the linear trinuclear system is given by

$$\chi_A=\frac{Ng^2\beta^2}{12kT}\times\frac{\exp(2J/kT)+10\exp(3J/kT)+1}{\exp(2J/kT)+2\exp(3J/kT)+1}+N\alpha,$$

where J is the exchange integral between the adjacent copper ions and other symbols have their conventional meanings. As exemplified in Fig. 2, the magnetisms of the complexes can be well explained with this equation. The magnetic parameters determined by the best-fit technique are given in Table 1, together with the moments at room temperature. Thus, the magnetical investigations clearly demonstrate the trinuclear structure for the present complexes.

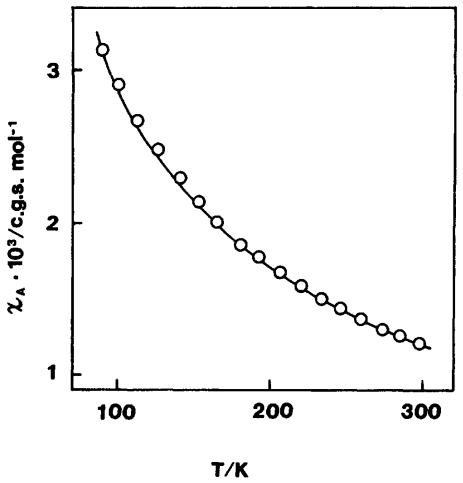

Fig. 2. Temperature variation of magnetic susceptibility of $[\{Cu(salen)\}_2Cu(bpy)](ClO_4)_2\cdot H_2O$. Solid curve is drawn on the basis of the expression in the text using the parameters, $J=-30\,cm^{-1}$, g=2.07, and $N\alpha=0$.

A Fairly Effective Environment Substance $[Co(sep)]^{3+}$ Ion in the Pfeiffer Effect of Some Oxalato Complexes of Chromium(III)

Katsuhiko MIYOSHI, Yukio SAKAMOTO, Yoshihisa TODA, and Hayami YONEDA*

Department of Chemistry, Faculty of Science, Hiroshima University, Higashi-senda-machi, Naka-ku, Hiroshima 730

(Received December 27, 1984)

Synopsis. A chiral complex ion $[Co(sep)]^{3+}$ (sep= 1,3,6,8,10,13,16,19-octaazabicyclo[6.6.6]eicosane) was found to displace the chiral equilibrium between Δ and Λ enantiomers greatly for moderately optically labile metal complexes $[Cr(ox)_2(acac)]^{2-}$ and $[Cr(ox)_2(gly)]^{2-}$ in dioxane-water mixtures.

When an optically labile and racemic complex is mixed with a certain chiral compound (called an environment substance hereafter) in solution, new optical activity due to the initially racemic complex is sometimes induced. This phenomenon is referred to as the Pfeiffer effect,[1] and has been ascribed to a shift in a chiral equilibrium between two enantiomers of the racemic complex. Several organic compounds have been so far reported to induce the equilibrium shift. Nordquist[2] was probably the first to study the Pfeiffer effect in which a dissymmetric metal complex, *e.g.*, resolved $[Co(en)_3]^{3+}$(en=ethylenediamine), was used as an environment substance. Pollock *et al.*[3] have also examined this complex as an environment substance to $[Ni(acac)_3]^-$ (acac=acetylacetonate ion) in water. However, the above two studies did not afford direct evidence that the chiral equilibrium was actually displaced by chiral $[Co(en)_3]^{3+}$ ion.[4a] Subsequently, Yoneda and coworkers[4,5] unambiguously demonstrated that one enantiomer of $[Cr(ox)_3]^{3-}$ (ox=oxalate dianion) was enriched at a rate comparable to its racemization rate in the presence of resolved *cis*-$[Co(X)(Y)(en)_2]^{n+}$-type complexes (X and/or Y=anionic unidentate ligand) as well as $[Co(phen)_3]^{3+}$ (phen= 1,10-phenanthroline). The enantiomeric excess (ee) attained with these chiral complexes, however, amounts to only a few per cent, despite the expectation that these cationic complexes associate with $[Cr(ox)_3]^{3-}$ more strongly than do usual organic environment substances such as *d*-cinchoninium ion. We report herein that an optically active cation complex $[Co(sep)]^{3+}$ (sep=1,3,6,8,10,13,16,19-octaazabicyclo[6.6.6]eicosane) derived from resolved $[Co(en)_3]^{3+}$ serves as a fairly effective environment substance to some oxalato complexes of Cr(III) in dioxane-water mixtures.

Experimental

Preparation of Complexes. Perchlorate salts of Λ-$[Co(en)_3]^{3+}$, Λ-$[Co(d\text{-pn})_3]^{3+}$ (*d*-pn=(S)-propylenediamine), and Λ-$[Co(sep)]^{3+}$ employed as an environment substance were available from our previous works.[6] Λ-$[Co(phen)_3]^{3+}$ was obtained as a chloride salt as before.[4a] Racemic complexes $K_2[Cr(ox)_2(acac)]$ and $K_2[Cr(ox)_2(gly)]$ (gly=glycinate anion) were prepared as described in the literature,[7,8] and their purity was checked by ion-exchange chromatography and/or their absorption spectra. They were resolved by the methods applied to the corresponding Co(III) complexes.[9,10] The $\Delta\varepsilon$ values of -3.40 mol^{-1} dm^3 cm^{-1} (at 545 nm) and $+1.23$ mol^{-1} dm^3 cm^{-1} (at 533 nm) were obtained for Δ-$[Cr(ox)_2(acac)]^{2-}$ and Λ-$[Cr(ox)_2(gly)]^{2-}$, respectively. Since these complexes were moderately optically labile, their recrystallization did not lead to improved optical purity, and hence no further attempt was made to obtain correct $\Delta\varepsilon$ values. The correct $\Delta\varepsilon$ value for the gly complex must be much higher than was obtained above. Absolute configurations were assigned to these complexes on the criterion that the Λ enantiomers have a positive main CD component at the first d-d transition region.[11]

Detection of the Pfeiffer Effect. The degree and direction of the equilibrium shift attained in the racemic Cr(III) complexes were determined in exactly the same manner as in the previous studies.[4a,12] Sample solutions were prepared in volumetric flasks (10 cm^3) to which 3 cm^3 of dioxane had been added, so that they contained the racemic Cr(III) complex in 8 mmol dm^{-3} and the chiral environment substance in 30 mmol dm^{-3}. CD spectra of these solutions were recorded as quickly as possible after the environment substance was removed by passing them through a cation-exchange column.

Results and Dicussion

Figure 1 shows the CD spectra recorded for initially racemic complexes $[Cr(ox)_2(acac)]^{2-}$ and $[Cr(ox)_2(gly)]^{2-}$ after they had been mixed with Λ-$[Co(sep)]^{3+}$ in dioxane-water mixtures. These spectra are the same in pattern as those of the respective complexes resolved separately. Thus, it is evident that the Δ enantiomer is enriched for both complexes in the presence of Λ-$[Co(sep)]^{3+}$. If the $\Delta\varepsilon$ of -3.40 mol^{-1} dm^3 cm^{-1} at 545 nm is adopted for the pure Δ-$[Cr(ox)_2(acac)]^{2-}$, the ee is estimated to be 10.9%, which is fairly high. A high ee is probably attained for the gly complex also, though a correct CD intensity for its pure enantiomer is not known. On the other hand, when Λ-$[Co(en)_3]^{3+}$ from which Λ-$[Co(sep)]^{3+}$ is derived is employed as an environment substance, the Δ enantiomer is similarly enriched for both complexes,[13] but the ee's are very low; an ee of 0.4% is estimated for the acac complex.

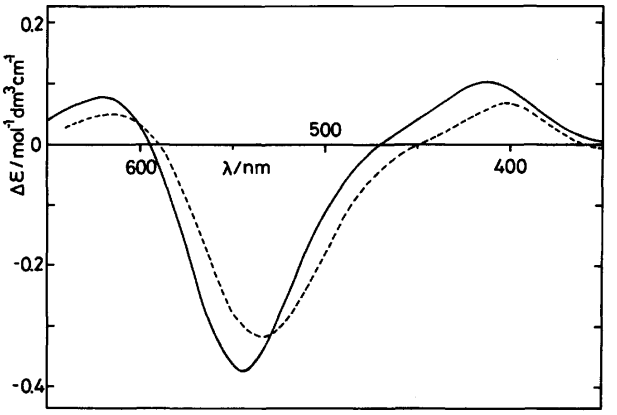

Fig. 1. CD spectra induced for $[Cr(ox)_2(acac)]^{2-}$ (solid curve) and $[Cr(ox)_2(gly)]^{2-}$ (dotted curve) with Λ-$[Co(sep)]^{3+}$ as an environment substance.

TABLE 1. ABSOLUTE CONFIGURATIONS OF ENANTIOMERS ENRICHED BY THE PFEIFFER EFFECT

Environment[a] Substance	Racemic Complex $[Cr(ox)_2(acac)]^{2-}$	$[Cr(ox)_2(gly)]^{2-}$
$[Co(sep)]^{3+}$	Δ	Δ
$[Co(en)_3]^{3+}$	Δ	Δ
$[Co(d\text{-pn})_3]^{3+}$[b]	Λ	Λ
$[Co(phen)_3]^{3+}$	Λ	Λ

a) All have a Λ configuration. b) A mixture of *fac-lel*$_3$ and *mer-lel*$_3$ isomers.

Since the ee's attained with Λ-$[Co(d\text{-pn})_3]^{3+}$ and Λ-$[Co(phen)_3]^{3+}$ were also low (at most 1.4%), only the direction of the equilibrium shift was determined. In Table 1 are listed absolute configurations of the enantiomers of the two Cr(III) complexes enriched by the Pfeiffer effect. Table 1 indicates that Λ-$[Co(en)_3]^{3+}$ and Λ-$[Co(sep)]^{3+}$ interact with the Δ enantiomer more favorably than with the Λ enantiomer for the two Cr(III) complexes. This is consistent with the earlier observation that the Δ enantiomers of $[Co(ox)_2(acac)]^{2-}$ and $[Co(ox)_2(gly)]^{2-}$ are eluted faster on usual ion-exchange chromatography with Λ-$[Co(en)_3]^{3+}$ or Λ-$[Co(sep)]^{3+}$ as an eluent.[14,15] On the other hand, the Λ enantiomers of the two Cr(III) complexes are favored by Λ-$[Co(d\text{-pn})_3]^{3+}$ and Λ-$[Co(phen)_3]^{3+}$ (Table 1), suggesting that the mode of chiral discrimination is different at least between the former two environment substances and the latter two.

In our previous work,[14] it was proposed that both chiral $[Co(en)_3]^{3+}$ and $[Co(sep)]^{3+}$ ions discriminate between Λ and Δ enantiomers of a usual complex anion with the C_2 axis directed to the anion to form hydrogen bonds to the anion (C_2 access). If the Δ anion is favored by Λ-$[Co(en)_3]^{3+}$ or Λ-$[Co(sep)]^{3+}$ in the C_2 access, it is a reasonable observation that the Λ anion is favored by Λ-$[Co(d\text{-pn})_3]^{3+}$ which "uses" the C_3 axis predominantly owing to the steric hindrance due to methyl groups.[16] The interaction mode of $[Co(phen)_3]^{3+}$ seems complicated,[17] since it has no hydrogen atom available for the interaction with the anion complex.[18]

Finally, it is noteworthy that the efficiency of chiral discrimination is surprisingly enhanced when the environment substance $[Co(en)_3]^{3+}$ is capped covalently with alkyl groups along its C_3 axis to form $[Co(sep)]^{3+}$. This may be partly attributed to the resulting conformational rigidity of the environment substance[19] and/or to a greater affinity of the anion complex for $[Co(sep)]^{3+}$ than for $[Co(en)_3]^{3+}$, as exemplified by their association constants with *d*-tartrate and bis(μ-*d*-tartrato)-diantimonate(III) anions in water.[6] However, it is more tempting to suppose that chiral $[Co(en)_3]^{3+}$ can also "use" the C_3 axis to favor the enantiomer opposite to that favored by it in the C_2 access, its discrimination efficiency being thereby extremely low. By contrast, since $[Co(sep)]^{3+}$ is forced to "use" the C_2 axis only, it serves not only as an effective environment substance in the Pfeiffer effect, but also as an effective eluent in the chromatographic resolution of several anion complexes.[20]

19) It is informative to note that all the racemic complexes for which the equilibrium shifts have been confirmed are with no exception composed of planar ligands such as ox^{2-}, gly^{-}, $acac^{-}$, phen, 2,2′-bipyridine, 8-hydroxy-5-quinolinesulfonate^{2-}, and 2,6-pyridinedicarboxylate^{2-}. The ligand rigidity might be a necessary condition for the development of the Pfeiffer effect.

The Crystal Structures of a Dicopper(II) Complex Containing Two N_4-Macrocyclic Rings Connected with an Ethylene Chain

Masahiro MIKURIYA, Kosuke HAMADA, Sigeo KIDA,* and Ichiro MURASE†

Department of Chemistry, Faculty of Science, Kyushu University 33, Hakozaki, Higashi-ku, Fukuoka 812

†*Laboratory of Chemistry, College of General Education, Kyushu University 01, Ropponmatsu, Chuo-ku, Fukuoka 810*

(Received January 17, 1985)

Synopsis. The crystal structure of diaqua {7,7′-ethylenebis[2,12-dimethyl-3,7,11,17-tetraazabicyclo[11.3.1]-heptadeca-1(17),2,11,13,15-pentaene]}dicopper(II) perchlorate dihydrate was determined by a single-crystal X-ray diffraction method. The complex assumes an extended conformation with the intramolecular Cu···Cu separation 7.081(2) or 6.985(2) Å.

Recently, Murase *et al.* reported the synthesis and characterization of a binuclear copper(II) complex with bis(macrocycle), $Cu_2(dap)(ClO_4)_4$ (dap=7,7′-ethylenebis[2,12-dimethyl-3,7,11,17-tetraazabicyclo[11.3.1]-heptadeca-1(17),2,11,13,15-pentaene]), as shown in Fig. 1.[1] Molecular models showed many structural possibilities between two extremes of open(extended) conformation and closed(bent) conformation. The ESR spectra in DMF frozen solution suggested that the two copper(II) ions are located in a proximity and the two coordination planes are of a face-to-face or half-opened clam shell structure. The present X-ray study was undertaken to reveal the structure of this complex in crystal.

Experimental

The $Cu_2(dap)(ClO_4)_4$ complex was prepared by the method previously reported.[1] Crystals suitable for an X-ray study were obtained from a dilute aqueous solution after standing one year. The unit-cell parameters and intensities were measured on a Rigaku AFC-5 automated four-circle diffractometer with graphite-monochromated Mo$K\alpha$ radiation (λ=0.71069 Å) at 21±1 °C.

Crystal Data: $Cu_2(C_{32}H_{46}N_8)(ClO_4)_4\cdot 4H_2O$, FW=1139.72; triclinic; $P\bar{1}$; a=14.894(2), b=15.144(2), c=10.734(1) Å; α=91.04(1), β=108.80(1), γ=87.22(1)°; D_m=1.64, D_c=1.65 g cm^{-3}; Z=2; μ(Mo$K\alpha$)=12.4 cm^{-1}, crystal dimensions: 0.23×0.28×0.50 mm^3.

The intensity data were collected by the 2θ—ω scan technique with a scan rate of 2° min^{-1}. A total of 15954 reflections with $2\theta<62°$ were collected. The intensity data were corrected for the Lorentz and the polarization effects, but not for absorption. Independent 6564 reflections with $|F_o|>3\sigma(|F_o|)$ were considered as "observed" and were used for the structure analysis. The structure was solved by the direct methods and refined by the block-diagonal least-squares method. In the course of refinement, it became apparent that the oxygen atom of the perchlorate ion, O(4A), is subjected to disorder. The oxygen atom was divided between two positions with an occupancy factor 0.5 on the basis of a difference Fourier map. Hydrogen atoms were inserted in their calculated positions and included in the refinement. In the least-squares refinement the weighting scheme, $w=(8.82+|F_o|+0.0086|F_o|^2)^{-1}$ was employed. The final discrepancy factors were $R_1=\sum||F_o|-|F_c||/\sum|F_o|=0.081$ and $R_2=[\sum w(|F_o|-|F_c|)^2/\sum w|F_o|^2]^{1/2}=0.123$.

The atomic scattering factors and the anomalous dispersion corrections were taken from the International Tables for X-Ray Crystallography.[2] All the calculations were carried out on the FACOM M-200 computer at the Computer Center of Kyushu University by the use of a local version of the UNICS-III programs.[3] The final positional and thermal parameter with their estimated standard deviations are given in Table 1. The atomic coordinates, the thermal parameters and the F_o-F_c tables have been deposited as a Document No. 8531 at the Office of the Editor.

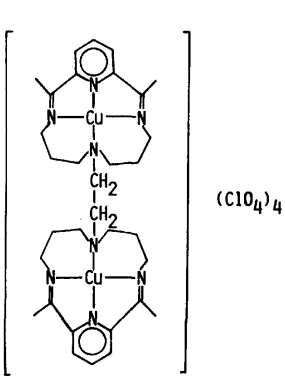

Fig. 1. Chemical structure of $Cu_2(dap)(ClO_4)_4$.

Results and Discussion

The crystal contains two crystallographically inde-

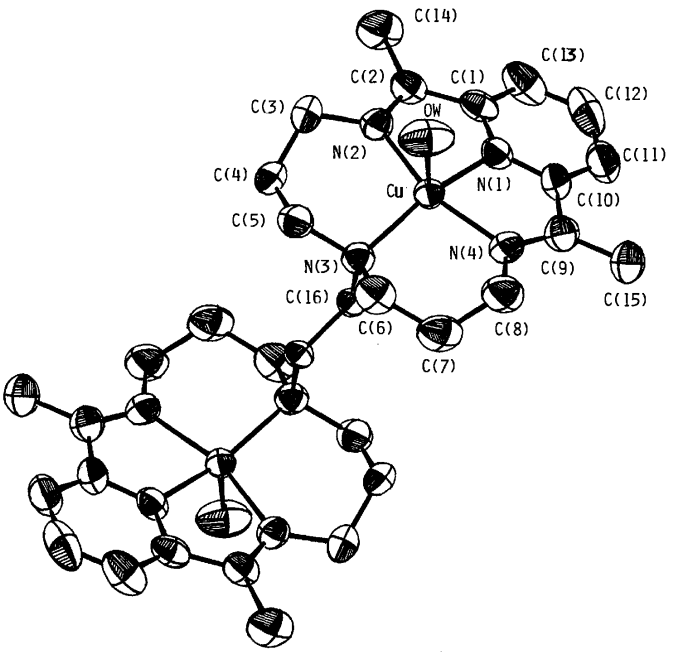

Fig. 2. Molecular structure of $[(Cu_2(dap)(H_2O)_2]^{4+}$ with thermal ellipsoids. Distances (l/Å): Cu-N(1) 1.915(6), 1.904(7); Cu-N(2) 2.013(6), 2.023(10); Cu-N(3) 2.010(7), 1.988(6); Cu-N(4) 2.003(8), 2.001(7); Cu-OW 2.255(8), 2.237(8). Angles (ϕ/°): N(1)-Cu-N(2) 79.7(3), 80.3(4); N(1)-Cu-N(4) 80.2(3), 79.7(3); N(2)-Cu-N(3) 100.4(3), 99.1(3); N(3)-Cu-N(4) 98.1(3), 99.0(3) for molecules A and B, respectively.

pendent binuclear molecules; they are denoted by A and B. Their structures are essentially the same. Both molecules are centrosymmetric about the mid-point of the central ethylene group connecting the two macrocyclic rings. The molecular structure is shown in Fig. 2. The coordination geometry of each copper atom is a distorted square pyramid. Each basal plane is formed by four nitrogen atoms, which are coordinated to Cu with Cu–N bond lengths, 1.904—2.023 Å, of the macrocyclic ring. The fifth coordination site is occupied by a water oxygen atom with Cu–O distance of 2.255(8) or 2.237(8) Å. The basal atoms around each copper atom deviate from the mean plane within ±0.2 Å and Cu(A) and Cu(B) are displaced by 0.23 Å and 0.24 Å, respectively, from the basal-mean planes toward water molecules.

The structures of the macrocyclic moieties are similar to that of the analogous mononuclear copper(II) complex, $Cu(CR)Cl(NO_3)\cdot 2H_2O$ (CR=2,7,12-trimethyl-3,7,11,17-tetraazabicyclo[11.3.1]heptadeca-1(17),2,11,-13,15-pentaene).[4]

Both binuclear molecules assume an extended conformation and the intramolecular Cu···Cu distances are 7.081(2) Å and 6.985(2) Å for molecules A and B, respectively. The shortest intermolecular Cu···Cu distance is 8.059(2) Å (Cu(A)···Cu(B)($x, y-1, z$)). The water molecules (two per complex molecule) are trapped in the space of the crystal lattice. The perchlorate ions are hydrogen bonded with the coordinated or crystal water molecules.

This structure dose not accord with that presumed from the ESR spectra. But, this is not surprising, because in solution, free rotation about the central ethylene group is possible and may give rise to the closed conformation allowing the two copper atoms to array close to each other.

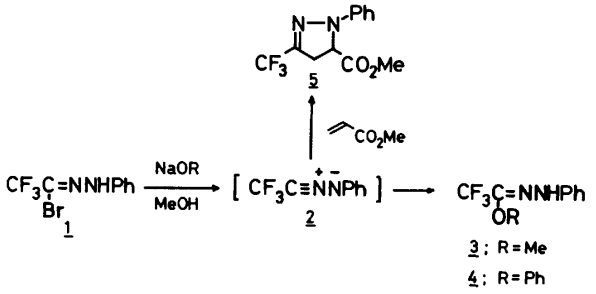
Behavior of Trifluoroacetohydrazonoyl Bromide in Basic Media

Kiyoshi TANAKA,* Seiji MAENO, and Keiryo MITSUHASHI
Department of Industrial Chemistry, Seikei University, Musashino-shi, Tokyo 180
(Received September 11, 1984)

Synopsis. The bromide **1** was treated with sodium methoxide or phenoxide to give exclusively the corresponding substituted product. The predominant formation of the substituted products was also recognized with regard to various amines. However, the reaction with triethylamine proceeded more complicatedly to give the products *via* reduction process together with a trace amount of the dimer of *N*-phenyl-*C*-(trifluoromethyl)nitrilimine.

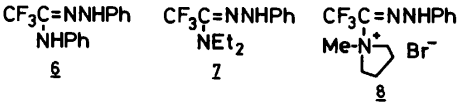
It is well known that hydrazonoyl halides, when treated with a base such as triethylamine or alkoxide, are converted into the corresponding nitrilimines which, in the absence of a reactive dipolarophile, result in the head-to-tail dimerizations to the corresponding tetrazines.[1] And only when treated with soft nucleophiles such as thiolates, hydrazonoyl halides are known to undergo the substitutions.[2-4] As a part of studies on the fluorinated nitrilimines,[5,6] we now wish to report the behavior of *N*-phenyltrifluoroacetohydrazonoyl bromide (**1**) toward bases such as alkoxides and amines.[7]

The bromide **1** was treated with sodium methoxide or phenoxide in methanol to give the corresponding substituted product **3** or **4** in 64 or 36% yield, respectively (Scheme 1). The reaction with sodium methoxide was next carried out in the presence of excess methyl acrylate to give a 56% yield of the 1,3-dipolar cycloadduct, 5-methoxycarbonyl-1-phenyl-3-trifluoromethyl-2-pyrazoline (**5**), as well as a 38% yield of **3**. These results indicate that the nitrilimine **2** is generated on treatment of **1** with sodium methoxide. Therefore, the substituted product **3** is thought to be formed entirely or partially *via* **2**. In this case, the usually observed dimerization of **2** was not detected at all.

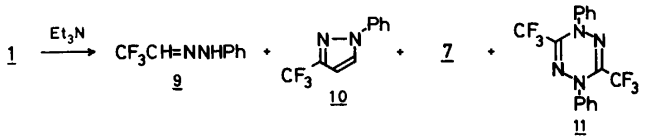


Scheme 1.

The predominant formation of the substituted products was also recognized with regard to amines. Aniline or diethylamine was allowed to react with **1** to afford *N*-phenyl- or *N,N*-diethyltrifluoroacetamide phenylhydrazone (**6** or **7**) in 49 or 89% yield, respectively. Similarly, the reaction with *N*-methylpyrrolidine proceeded smoothly to give the pyrrolidinium salt **8** in 79% yield. The IR spectrum of **8** shows the band at 1614 cm^{-1} due to the C=N group, no absorption owing to the ammonium salt (–$\overset{|}{N}H^+$) being observed.[8] The salt is relatively unstable and gradually decomposes on storing for several weeks.



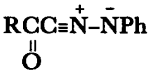
On the other hand, the reaction with triethylamine was found to be more complicated to give trifluoroacetaldehyde phenylhydrazone (**9**) (16%), 1-phenyl-3-(trifluoromethyl)pyrazole (**10**) (16%), and the acetamide **7** (7%) together with a trace amount of 1,4-diphenyl-3,6-bis(trifluoromethyl)-1,4-dihydro-1,2,4,5-tetrazine (**11**) (Scheme 2). The products **7**, **9**, and **10** were identified by



Scheme 2.

comparing their physical and spectral data with those of the authentic samples. Regarding the structure of **11**, the MS spectrum and elemental analysis indicate the dimer of **2** and the UV spectrum (λ_{max} 267 nm, log ε=4.23; 275 nm(sh), log ε=4.22) supports the 1,2,4,5-tetrazine ring.[9] The formation of **7**, **9**, and **10** is quite curious. However, a similar reduction is reported by Knunyants and his co-workers in the reaction of trifluoroacetyl chloride with triethylamine which affords trifluoroacetaldehyde and 4-diethylamino-1,1,1-trifluoro-3-buten-2-one derived from once formed *N,N*-diethylvinylamine.[10] The products **7**, **9**, and **10** may be formed through a similar reduction. That is, **1** is reduced with triethylamine to give **9** and *N,N*-diethylvinylamine. *N,N*-Diethylvinylamine is trapped with **2** to produce the unstable 5-diethylamino-1-phenyl-3-trifluoromethyl-2-pyrazoline which undergoes breakdown to **10** and diethylamine.[11] Diethylamine thus formed reacts with **1** to give **7**, as shown above.

In summary, it is found that the nucleophilic substitution of the bromide **1** is predominant over the dimerization of the nitrilimine **2** *in situ* formed. It should be also noted that the nitrilimine **2** dimerizing with great difficulty is in sharp contrast to the nitrilimine **12** with a similar electron-withdrawing group such as benzoyl[12] or ethoxycarbonyl group[9] which easily dimerize to the corresponding tetrazines.



12

Experimental

The IR spectra were recorded on a JASCO IRA-1 spec-

trometer and ^{1}H NMR spectra were measured with a JEOL JNM-PMX 60 spectrometer using tetramethylsilane as an internal standard, the chemical shifts being given in δ ppm downfield. The MS spectra were obtained on a Finnigan 4023 GC-MS DS spectrometer. The UV spectra were observed with a Hitachi 340 spectrometer. The bromide **1** was prepared by the method reported in our previous papers.[5,7]

Reaction of 1 with Sodium Methoxide. A solution of 1.00 g (3.7 mmol) of **1** in 10 cm^3 of methanol was added dropwise to a solution of 0.61 g (11.3 mmol) of sodium methoxide in 20 cm^3 of methanol. After stirring at room temperature for 0.5 h, the solvent was removed. To the residue was added 100 cm^3 of ethyl ether and the mixture was washed with water and brine, dried over magnesium sulfate, and evaporated to leave crude **3** which was purified by distillation to give 0.52g (64%) of pure **3**, bp 80°C/2mmHg (1mmHg=133.322 Pa), ^{1}H NMR (CCl_4) δ=3.96 (q, J=2 Hz, 3H), 6.6—7.4 (m, 5H), and 7.6 (br.s, 1H), IR (neat) 1643 (C=N) and 1115 cm^{-1} (CF_3).

Found: C, 49.37; H, 3.98; N, 12.75%. Calcd for $C_9H_9F_3N_2O$: C, 49.55; H, 4.16; N, 12.84%.

In a similar manner, the reaction of **1** (1.00 g) with sodium phenoxide (1.30 g, 11.2 mmol) in methanol (30 cm^3) was carried out to give a mixture of **4** and **3**. The mixture was submitted to column chromatography (silica gel, hexane–chloroform; 8:1) to give 0.38 g (36%) of **4** and 40 mg (5%) of **3**. The hydrazonate **4** was further purified by bulb-to-bulb distillation (bath temperature 123—125°C, 1 mmHg), ^{1}H NMR (CCl_4) δ=6.6—7.5 (m, 10H) and 7.6 (br.s, 1H), IR (neat) 3330 (NH), 1638 (C=N), and 1159, 1125 cm^{-1} (CF_3).

Found: C, 60.11; H, 3.71; N, 9.77%. Calcd for $C_{14}H_{11}F_3N_2O$: C, 60.00; H, 3.96; N, 10.00%.

Reaction of 1 with Sodium Methoxide in the Presence of Methyl Acrylate. A solution of **1** (1.00 g, 3.7 mmol) in 10 cm^3 of methanol was added dropwise to a mixture of methyl acrylate (0.97 g, 11.3 mmol) and sodium methoxide (0.40 g, 7.4 mmol) in 20 cm^3 of methanol and the mixture was stirred at room temperature for 24 h. The usual workup gave 0.57 g (56%) of **5** and 0.31 g (38%) of **3**. **5**, mp 60—61°C (lit,[5] mp 60—61.5°C). Spectral data are consistent with those of our authentic sample.

Reaction of 1 with Diethylamine. A mixture of diethylamine (3 cm^3) and **1** (1.00 g) in 10 cm^3 of toluene was stirred at room temperature for 4 h. The residue obtained by the usual workup was chromatographed over silica gel (hexane–chloroform; 4:1) to give 0.86 g (89%) of **7** which was further purified by distillation, bp 103—104°C/4 mmHg, ^{1}H NMR (CCl_4) δ=1.13 (t, 6H), 2.96 (q, 4H), 6.6—7.4 (m, 5H), and 8.5 (br.s, 1H), IR (neat) 3290 (NH), 1602 (Ph and C=N), and 1139, 1109 cm^{-1} (CF_3).

Found: C, 55.68; H, 6.26; N, 16.03%. Calcd for $C_{12}H_{16}F_3N_3$: C, 55.59; H, 6.22; N, 16.21%.

The reaction with aniline was similarly performed at 100°C for 7 h to give **6** in 49% yield, mp 66.5—67.5°C (hexane) (lit,[6] mp 66.5—67.5°C).

Reaction of 1 with N-Methylpyrrolidine. *N*-Methylpyrrolidine (3 cm^3) was added dropwise to a solution of 2.00 g (7.5 mmol) of **1** in 10 cm^3 of toluene holding the temperature below 20°C. After stirring for 2 h, the deposited white crystals were collected on a filter, washed with hexane, and dried to give 2.09 g (79%) of **8**, mp 72°C (dec.), ^{1}H NMR ($CDCl_3$) δ=1.84 (m, 4H), 2.46 (s, 3H), 2.62 (m, 4H), 6.9—7.5 (m, 5H), and 8.0 (br.s, 1H), IR (KBr) 3355 (NH), 1614 (C=N), and 1179, 1129 cm^{-1} (CF_3).

Found: C, 44.08; H, 4.66; N, 11.84%. Calcd for $C_{13}H_{17}BrF_3N_3$: C, 44.33; H, 4.86; N, 11.93%.

Reaction of 1 with Triethylamine. A mixture of 2.00 g (7.5 mmol) of **1** and 6 cm^3 of triethylamine in 10 cm^3 of toluene was stirred at room temperature for 23 h. To the reaction mixture was added 100 cm^3 of ethyl ether and the mixture was washed with water and brine, dried over magnesium sulfate, and evaporated. The residue was chromatographed over silica gel (hexane–chloroform; 7:1) to give 0.22 g (16%) of **9**, 0.25 g (16%) of **10**, 0.13 g (7%) of **7**, and 30 mg (2%) of **11**. Spectral data of **7** are consistent with those obtained above. **9**, mp 69—71°C (lit,[5] mp 69—73°C), ^{1}H NMR (CCl_4) δ=6.5—7.3 (m, 6H) and 7.6 (br.s, 1H).

10, ^{1}H NMR (CCl_4) δ=6.60 (d, J=2.5 Hz, 1H), 7.2—7.8 (m, 5H), and 7.83 (d, J=2.5 Hz, 1H), IR (neat) 3135 (=CH), 1605 (Ph and C=N), and 1166, 1130 cm^{-1} (CF_3).

Found: C, 56.36; H, 3.27; N, 13.15%. Calcd for $C_{10}H_7F_3N_2$: C, 56.61; H, 3.33; N, 13.20%.

11, mp 118—120°C (hexane), ^{1}H NMR ($CDCl_3$) δ=7.37 (s), IR (KBr) 1612 (C=N) and 1138, 1104 cm^{-1} (CF_3), MS (CI, m/z) 372 $(M)^+$ and 401 $(M+C_2H_5)^+$, UV λ_{max}^{EtOH} (log ε) 267 (4.23) and 275 nm (sh, 4.22).

Found: C, 51.47; H, 2.69; N, 15.25%. Calcd for $C_{16}H_{10}F_6N_4$: C, 51.62; H, 2.71; N, 15.05%.

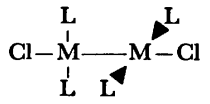
Dichlorotetrakis(isocyanide)dipalladium(I) Containing a Metal-Metal Bond[1)]

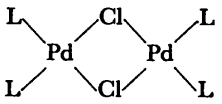
Yasuhiro YAMAMOTO* and Hiroshi YAMAZAKI
The Institute of Physical and Chemical Research, Wako, Saitama 351-01
(Received November 21, 1984)

Synopsis. The structure of $[\{PdCl(t\text{-}BuNC)_2\}_2]$ has been determined by X-ray diffraction. A metal-metal bond joins two Pd atoms, each of which possesses an essentially square-planar coordinate site. The photochemical reaction of $[\{PdCl(RNC)_2\}_2]$ in CH_2Cl_2 led to a cleavage of the metal-metal bond to give *trans*-$[PdCl_2(t\text{-}BuNC)_2]$.

Metal clusters attract considerable attention as plausible models of surfaces in heterogeneous catalysts.[2)] Binuclear complexes are the simplest units which can provide information on the metal-metal interactions. Previously we reported that the electrochemical reductions of *cis*-$[PtCl_2(RNC)_2]$ gave $[\{PtCl(RNC)_2\}_2]$ **1** containing a metal-metal bond.[3)] This finding prompted us to reexamine the structure of $[\{PdCl(t\text{-}BuNC)_2\}_2]$, assigned to chloride bridged structure.[4)]



1: M = Pt
2X: M = Pd



2

When we were preparing the paper on the X-ray crystallographic analysis of $[\{PdCl(t\text{-}BuNC)_2\}_2]$ **2a**, we knew of the study on crystal structure of $[\{PdI(MeNC)_2\}_2]$ **3** described by Balch and his co-workers.[5)] We report here the X-ray analysis of **2a** and the characterization of related complexes having aromatic isocyanides as ligands.

Experimental

The isocyanides,[6)] $PdCl_2(RNC)_2$,[7)] and $[\{PdCl(RNC)_2\}_2]$[7)] were prepared according to the literature.

$PdCl_2(2,6\text{-}Me_2C_6H_3NC)_2$: IR (Nujol): 2205, 2172 cm^{-1} (N≡C). Found: C, 49.15; H, 4.18; N, 6.37%. Calcd for $C_{18}H_{18}N_2Cl_2Pd$: C, 49.17; H, 4.13, N, 6.37%.

$PdCl_2(2,6\text{-}Me_2\text{-}4\text{-}BrC_6H_2NC)_2$. IR (Nujol): 2224, 2205 cm^{-1} (N≡C). Found: C, 36.17; H, 2.73; N, 4.59%. Calcd for $C_{18}H_{16}N_2Cl_2Br_2Pd$: C, 36.19; H, 2.70; N, 4.69%.

$[\{PdCl(2,6\text{-}Me_2C_6H_3NC)_2\}_2]$ **2b**. IR (Nujol): 2155 cm^{-1}. (N≡C). ^1H NMR($CDCl_3$): δ=2.53 (s, CH_3), 7.2 (aromatic protons). Found: C, 53.50; H, 4.46; N, 6.84%. Calcd for $C_{36}H_{36}N_4Cl_2Pd_2$: C, 53.49; H, 4.49; N, 6.93%.

$[\{PdCl(2,6\text{-}Me_2\text{-}4\text{-}BrC_6H_2NC)_2\}_2]$ **2c**. IR (Nujol): 2154 cm^{-1} (N≡C). ^1H NMR ($CDCl_3$): δ=2.50 (s, CH_3), 7.31 (aromatic protons). Found: C, 38.19; H, 2.95; N, 4.92%. Calcd for $C_{36}H_{32}N_4Br_4Cl_2Pd_2$: C, 38.47; H, 2.87; N, 4.98%.

$[Pd_2(2,6\text{-}Me_2C_6H_3NC)_6](PF_6)_2(2C_6H_6)$ **4b**. IR (Nujol): 2194, 2173 cm^{-1}. UV (CH_2Cl_2): λ 264 (49230), 325 sh nm. Found: C, 54.78; H, 4.40; N, 5.74%. Calcd for $C_{66}H_{66}N_6P_2F_{12}Pd_2$: C, 54.82; H, 4.60; N, 5.81%.

X-Ray Data and Structure Determination. Crystal data: space group C_c. a=12.665(2), b=14.449(2), c=18.402(3) Å, β=102.94(1)°, V=3282(9) Å^3. Z=4. R=0.060 for 2588 reflections. The choice of the space group C_c was justified on the basis of the successful refinement of the struture. Intensity data were collected with the crystals mounted in a nitrogen filled capillary. The positions of the palladium atoms were determined from Patterson maps. Subsequent difference Fourier maps and cycles of block-diagonal least-squares refinement revealed the positions of the remaining nonhydrogen atoms. The scattering factors were taken from "International Table for X-Ray Crystallography" (1974). The two *t*-butyl groups displayed disorder. The Pd and Cl, and C-N-C groups were refined anisotropically and other nonhydrogen atoms isotropically. The final difference synthesis showed no peaks higher than 0.4 e Å^{-3}.

Results and Discussion

The dimeric complexes $[\{PdCl(RNC)_2\}_2]$ (**2a**: R=*t*-Bu; **2b**: R=2,6-$Me_2C_6H_3$; **2c**: R=2,6-Me_2-4-BrC_6H_2) were prepared by the reaction of $Pd_2(dba)_3(CHCl_3)$, isocyanide and dichlorobis(isocyanide)palladium(II) in a 1:4:2 ratio. They are yellow and stable. The IR spectra showed a peak near 2155 cm^{-1} due to terminal isocyanide groups. The reaction of **2b** with 2,6-xylyl isocyanide in the presence of NH_4PF_6 took place readily to give $[Pd_2(2,6\text{-}Me_2C_6H_3NC)_6](PF_6)_2$ **4b** quantitatively.

The photochemical reaction of **2a** in CH_2Cl_2 was monitored by the electronic spectra. The band at 307 nm in **2a** decreased with the photolysis time and finally the spectrum was in good agreement with that of *trans*-$[PdCl_2(t\text{-}BuNC)_2]$, indicating a cleavage of a metal-metal bond. The band at 307 nm was assigned as a σ-σ^* transition.

$$[\{PdCl(t\text{-}BuNC)_2\}_2] \xrightarrow[CH_2Cl_2]{h\nu} \textit{trans}\text{-}[PdCl_2(t\text{-}BuNC)_2]$$

Similar σ-σ^* transitions connected with metal-metal bonds have also been observed in the same range with $[\{PtCl(2,4\text{-}t\text{-}Bu_2\text{-}6\text{-}MeC_6H_2NC)_2\}_2]$ **1d**[3)] [324 nm(CH_2Cl_2)] and $[Pd_2(MeNC)_6](PF_6)_2$ **5** [302 nm(CH_2Cl_2)].[8)]

Crystal Structure of **2a**.[9)] The crystal structure is shown in Fig. 2. Typical bond lengths and angles are given in Table 1. A metal-metal bond joins the two Pd atoms, each of which possesses essentially a square-planar coordinate geometry with the Pd-Pd bond occupying one of the coordination sites. The overall geometry is nearly D_{2d} symmetry. The Pd(1)-Pd(2) bond length of 2.532(2) Å is similar to those [2.533(1) and 2.531(9) Å] found in **3** and **5**, and somewhat shorter than those [2.563(2) and 2.561(2) Å] found in **1d**. The dihedral angle between the two $PdClC_2$ coordination planes is 82.7°, compared with those (85.3 and 86.4°) in **3** and **5**. The Cl-Pd-Pd-Cl unit is nearly linear. The Pd-Pd-Cl angles are 176.7

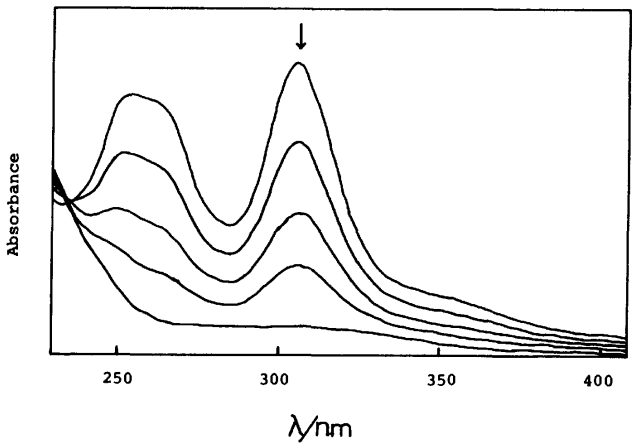

Fig. 1. Electronic spectrum of $[PdCl(t\text{-}BuNC)_2]_2$ in CH_2Cl_2 as a fnction of photolysis time.

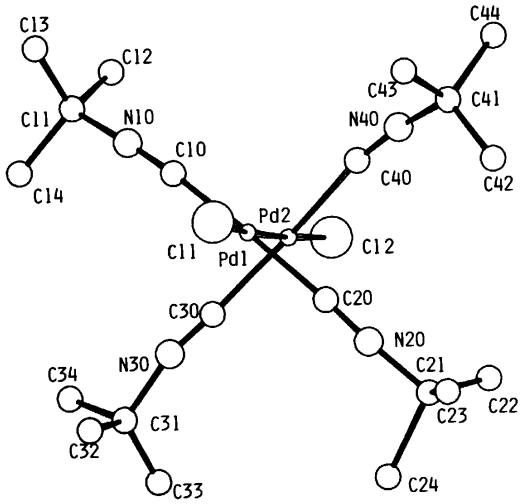

Fig. 2. A perspective drawing of $[PdCl(t\text{-}BuNC)_2]_2$ with the numbering scheme.

(2) and 177.4(2)°. The Pd-Cl bond lengths of 2.403 (9) and 2.416(9)Å, are longer than those [2.300(2) and 2.302(2)Å] of *cis*-$[PdCl_2(c\text{-}C_6H_{11}NC)_2]$.[10] This arises from the high trans effect of Pd-Pd bond. Similar behavior of terminal halide-metal bonds trans to metal-metal bonds has been noted in **3**.[5] The equatrial isocyanide ligands bend away from the axial Cl ligand giving rise to values of 97.2° for the mean C-Pd-Cl angle and 83.0° for the mean C-Pd-Pd angle. A similar distortion has been observed in **1d**, **3**, and **5**, where the averages of C-M-Cl (or equatrial C) angles are 93.8, 95.2, and 95.0°, the averages of C-M-M angles are 85.5, 84.7, and 85.0°, respectively. Thus, the type of the complexes $[\{PdCl(RNC)_2\}_2]$ was revised to the structure **2a** involving terminal halogens and a metal-metal bond.

A list of the final F_o—F_c table, bond lengths and angles (Table 1), and temperature factors are deposited as Document No. 8523 at the office of Bull. Chem. Soc. Jpn.

A Facile Synthesis of 3-(1-Benzyloxymethyl-3-hydroxypropyl)-2,5-piperazinedione

Masanori YAMAURA, Khalid Khan SADOZAI, and Juji YOSHIMURA*
Laboratory of Chemistry for Natural Products, Faculty of Science, Tokyo Institute of Technology, Nagatsuta, Midori-ku, Yokohama 227
(Received January 7, 1985)

Synopsis. The title compound, a key intermediate for a total synthesis of bicyclomycin, was obtained from γ-butyrolactone through eight steps in *ca.* 4.4% overall yield.

Bicyclomycin,[1] an antibiotic having unique structure[2] and biological activity, was recently synthesized in racemic[3] and optically active[4] forms. In these syntheses, the pathway in which the carbon-substituent is introduced into the 2,5-piperazinedione ring was adopted for the construction of racemic bicyclic skeleton. However, another pathway in which a precursor having a suitable carbon chain is cyclized into 2,5-piperazinedione[5] should be used for the synthesis of optically active skeleton, though many reaction steps are necessary. This paper describes a synthesis of racemic title compound (**12**) from γ-butyrolactone as an attempt of the latter pathway.

γ-Butyrolactone was converted into the racemic mixture of 2-methoxy-3-methoxycarbonyltetrahydrofuran (**1**) by the known method[6] in 82% yield. Reduction of **1** with lithium aluminum hydride (LAH) gave quantitatively the corresponding alcohol (**2**), which was converted into 3-benzyloxymethyl-2-hydroxytetrahydrofuran (**4**) in a good yield, by successive *O*-benzylation (**3**) and partial hydrolysis with 0.1 M (M=mol dm^{-3}) hydrochloric acid–dioxane (1:1) at room temperature.

Reaction of **4** in methanol with ammonia and hydrogen cyanide gave the corresponding amino nitrile (**5**) in 72% yield, and that with *p*-methoxybenzylamine instead of ammonia gave **6** in 85% yield. The structures of **5** and **6** were confirmed by ^{1}H NMR after conversion into acetates (**7** and **8**), respectively. While, the reaction of **4** with ammonium carbonate and sodium cyanide gave the corresponding hydantoin (**9**). However, the hydantoin ring could not be opened by refluxing with barium hydroxide for a long period. Hydrolysis of **5** in aqueous methanol with hydrochloric acid, and *N*-chloroacetylation of the product gave the expected product (**10**) and a lactone (**11**) in 23 and 31% yields, respectively. Successive treatment of **10** with sodium iodide for halogen exchange and with methanolic ammonia gave one of the two possible racemates of the corresponding 2,5-piperazinedione (**12**) as crystals in 24% yield. A similar treatment of **11** gave also **12** in 9% yield. The structure of **12** was confirmed by ^{1}H and ^{13}C NMR, after conversion into the corresponding *N,N',O*-triacetyl derivative (**13**).

Experimental

Melting points were determined with a Yanagimoto micro melting-point apparatus, and were not corrected. ^{1}H and ^{13}C NMR spectra were recorded with a JEOL JMN PS-100 and a JEOL FX-90Q spectrometers, respectively, in $CDCl_3$ with tetramethylsilane as the internal standard.

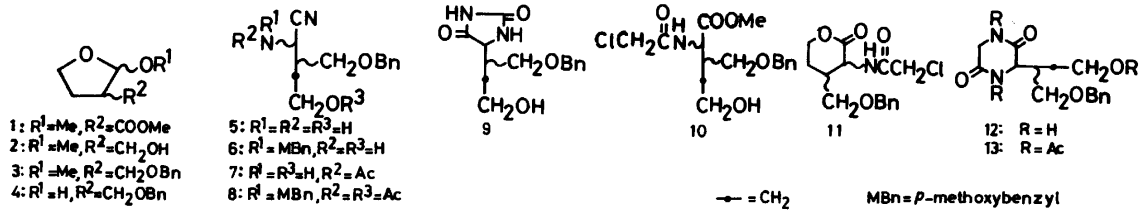
3-Hydroxymethyl-2-methoxytetrahydrofuran (2). Reduction of **1** (5.8 g, 39 mmol) in dry ether with LAH (3.0 g, 79 mmol) by the usual manner, and purification of the product on a column of silica gel (chloroform–hexane 3:1) gave **2** (5.1 g, 99%) as a syrup. ^{1}H NMR: δ 4.94 and 4.86 (each d, 1H, $J_{2,3}$=5.0 and 2.0 Hz, H-2), 4.05—3.65 (m, 2H, H-5), 3.54 (d, 2H, $J_{3,1'}$=8.0 Hz, CH_2OH), 3.36 (s, 3H, OMe), 2.7—1.8 (m, 4H, H-3,4 and OH). Anal. ($C_6H_{12}O_3$) C, H.

3-Benzyloxymethyl-2-methoxytetrahydrofuran (3). Benzylation of **2** (47.0 g, 350 mmol) in dry DMF with sodium hydride (18.8 g, 390 mmol) and benzylchloride (47.3 g, 370 mmol) by the usuel manner, and distillation of the product gave oily **3** (73.5 g) in 95% yield. Bp 119—125 °C/1 Torr (1 Torr=133.322 Pa). Anal. ($C_{13}H_{18}O_3$) C, H.

3-Benzyloxymethyl-2-hydroxytetrahydrofuran (4). Partial hydrolysis of **3** (5.0 g, 23 mmol) in dioxane (100 cm^3) with 0.1 M hydrochloric acid (100 cm^3) at room temperature for 2 days, and purification of the product on a silica-gel column (hexane–ethyl acetate 7:3) gave syrupy **4** (4.5 g, 96%). Anal. ($C_{12}H_{16}O_3$) C, H.

2-Amino-3-benzyloxymethyl-5-hydroxypentanenitrile (5). To a solution of **4** (10.0 g, 48 mmol) in abs methanol (80 cm^3) saturated with ammonia at 0 °C was added hydrogen cyanide (3.9 g, 144 mmol), the mixture was kept at room temperature for 72 h, and then evaporated. The residue was purified on a silica-gel column (chloroform–methanol 5:1) to give **5** (8.1 g, 72%) as a colorless syrup. The usual *N*-acetylation of **5** in methanol with acetic anhydride, and purification of the product on a preparative TLC (chloroform–ethyl acetate 1:1) gave syrupy 2-scetamido-3-benzyloxymethyl-5-hydroxypentanenitrile (**7**) in 89% yield. ^{1}H NMR: δ 7.35 (s, 6H, Ph and NH), 5.3—5.0 (m, 1H, H-2), 4.55 (s, 2H, CH_2Ph), 3.9—3.5 (m, 4H, H-5 and CH_2OBn), 2.70 (bs, 1H, OH), 2.45—2.15 (m, 1H, H-3), 1.93 and 1.87 [each s (1:1), 3H, Ac)], 1.9—1.5 (m, 2H, H-4). Anal. ($C_{15}H_{20}N_2O_3$) C, H, N.

3-Benzyloxymethyl-5-hydroxy-2-(p-methoxybenzylamino)pentanenitrile (6). A similar treatment of **4** (2.3 g, 11 mmol) with hydrogen cyanide (0.90 g, 33 mmol) and *p*-methoxybenzylamine (1.7 g, 12 mmol) to **5**, and purification of the product on a silica-gel column (chloroform–methanol



7:1) gave **6** (3.3 g, 85%) as a colorless syrup. The usual acetylation of **6** in pyridine with acetic anhydride, and purification of the product on a preparative TLC (hexane–ethyl acetate 3:2) gave syrupy 5-acetoxy-3-benzyloxymethyl-2-[*N*-(*p*-methoxybenzyl)acetamido]pentanenitrile (**8**) in 65% yield. ^{1}H NMR: δ 7.42 and 7.39 (each s, 5H, Ph), 7.24, 7.16, 6.95 and 6.93 (each d, 4H, J=8.5 Hz, MBn), 5.45—5.15 (m, 1H, H-2), 4.9—3.4 (m, 6H, H-5, CH_2OBn and CH_2 in MBn), 4.54 and 4.52 (each s, 2H, CH_2Ph), 2.2—1.6 (m, 3H, H-3 and 4), 2.19 and 2.13 (each s, 3H, OAc), 2.04 and 2.01 (each s, 3H, NAc). Anal. ($C_{25}H_{30}N_2O_5$) C, H, N.

*5-(1-Benzyloxymethyl-3-hydroxypropyl)-2,4-imidazolidinedione (**9**).* A mixed solution of **4** (1.0 g, 4.8 mmol) in ethanol (40 cm^3), ammonium carbonate (4.3 g, 44.7 mmol) and sodium cyanide (0.48 g, 9.8 mmol) in water (40 cm^3), was heated for 5 h at 60 °C, poured into ice–water, and extracted with chloroform. The usual processing of the extract gave a crude syrup, which was purified on a column of silica gel (chloroform–methanol 9:1) to give **9** (540 mg) in 41% yield. ^{1}H NMR: δ 7.38 and 7.34 (each s, 5H, Ph), 4.78 (bs, 2H, NH and OH), 4.59 and 4.48 (each s, 2H, CH_2Ph), 4.28 and 4.40 (each d, 1H, $J_{3,1'}$=2.5 and 3.0 Hz, H-3), 3.8—3.5 (m, 2H, H-3′), 3.32 and 3.28 (each d, 2H, J=3.0 Hz, CH_2OBn), 2.6—2.2 (m, 1H, H-1′), 1.7—1.4 (m, 2H, H-2′). Anal. ($C_{14}H_{18}N_2O_4$) C, H, N.

*Methyl 3-Benzyloxymethyl-2-chloracetemido-5-hydroxypentanoate (**10**) and 3-Benzyloxymethyl-2-chloroacetamido-5-pentanolide (**11**).* A mixed solution of **5** (16.0 g, 68 mmol) in methanol (40 cm^3), methanol (40 cm^3) saturated at 0 °C with hydrogen chloride and water (2.4 g, 130 mmol) was kept at room temperature for 48 h, filtered, and the filtrate was evaporated to one third volume, again filtered, and the filtrate was evaporated. The usual *N*-chloroacetylation of the residue in benzene (120 cm^3) and ether (40 cm^3) with potassium carbonate (28.0 g, 203 mmol) in water (200 cm^3) and chloroacetyl chloride (15.4 g, 136 mmol) in benzene (20 cm^3) at 0 °C, and separation of the products on a column of silica gel (benzene–ethyl acetate 7:3) gave **11** (6.5 g, 31%) and **10** (5.5 g, 23%) as colorless syrups.

11: ^{1}H NMR: δ 7.56 and 7.16 (each d, 1H, $J_{2,NH}$=7.0 and 8.0 Hz, NH), 7.40 (s, 5H, Ph), 4.9—4.6 (m, 1H, H-2), 4.52 and 4.49 (each s, 2H, CH_2Ph), 4.45—4.25 (m, 2H, H-5), 4.07 and 3.97 (each s, 2H, CH_2Cl), 3.6—3.3 (m, 2H, CH_2OBn), 3.1—2.7 (m, 1H, H-3), 2.4—1.9 (m, 2H, H-4). Anal. ($C_{15}O_{18}O_4NCl$) C, H, N.

10: ^{1}H NMR: δ 7.86 and 7.75 (each bd, 1H, $J_{2,NH}$=8.0 and 7.0 Hz, NH) 7.35 (s, 5H, Ph), 4.9—4.7 (m, 1H, H-2), 4.44 (s, 2H, CH_2Ph), 4.27 and 4.25 (each t, 2H, $J_{4,5}$=6.5 Hz, H-5), 4.07 and 4.04 (each s, 2H, CH_2Cl), 4.05 (bs, 1H, OH), 3.71 (s, 3H, OMe), 3.6—3.3 (m, 2H, CH_2OBn), 2.6—2.2 (m, 1H, H-3), 2.0—1.7 (m, 2H, H-4). Anal. ($C_{16}H_{22}O_5NCl$) C, H, N.

*3-(1-Benzyloxymethyl-3-hydroxypropyl)-2,5-piperazinedione (**12**).* A solution of **10** (700 mg, 2.0 mmol) and 3 equimolar sodium iodide in acetone (20 cm^3) was refluxed for 3 h, evaporated to a half volume, poured into water, and then extracted with ethyl acetate. The usual processing of the extract gave a crude syrup, which was treated for 12 h at room temperature with methanol (10 cm^3) saturated with ammonia to give crude **12**. It was crystallized from methanol-ether and recrystallized from methanol–water. Yield, 24% (140 mg), mp 204—205 °C. Anal. ($C_{15}H_{20}N_2O_4$) C, H, N.

*3-[3-Acetoxy-1-(benzyloxymethyl)propyl]-1,4-diacetyl-2,5-piperazinedione (**13**).* The usual acetylation of **12** (100 mg, 0.34 mmol) in DMF (20 cm^3) with acetic anhydride (2 cm^3) and catalytic amount of 4-(dimethylamino)pyridine, and purification of the product on a column of silica gel (hexane–ethyl acetate 7:3) gave syrupy **13** (62 mg, 43%). ^{1}H NMR: δ 7.28 (s, 5H, Ph), 5.32 (d, 1H, $J_{3,1'}$=7.5 Hz, H-3), 4.97 (d, 1H, $J_{6a,6b}$=18.0 Hz, H-6a), 4.73 (s, 2H, CH_2Ph), 4.3—3.9 (m, 3H, H-6b and 3′), 3.6—3.35 (m, 2H, CH_2OBn), 2.54 and 2.51 (each s, 6H, NAc×2), 2.01 (s, 3H, OAc), 2.2—1.5 (m, 3H, H-1′ and 2′); ^{13}C NMR: 171.3s, 171.1s and 170.0s (C=O×3), 167.8s and 166.9s (C-2 and 5), 137.0s, 128.4d, 127.9d and 127.7d (aromatic), 73.4t, 69.5t and 61.4t (CH_2Ph, CH_2OBn and C-3′), 58.9d (C-3), 47.1t (C-6), 39.3d (C-1′), 28.3t (C-2′), 26.4q, 26.7q and 20.8q (Ac×3). Anal. ($C_{21}H_{26}N_2O_7$) C, H, N.

NAD(P)$^+$-NAD(P)H Model. 54. Free Radical Mechanism for the Reductive Debromination of *vic*-Dibromides to Alkenes

Shinro YASUI,* Kaoru NAKAMURA,† and Atsuyoshi OHNO†
Tezukayama Junior College, Gakuen-Minami, Nara 631
†*Institute for Chemical Research, Kyoto University, Uji, Kyoto 611*
(Received January 30, 1985)

Synopsis. *vic*-Dibromides undergo reductive debromination with a model of NAD(P)H, *N*-benzyl-1,4-dihydronicotinamide, to afford the corresponding alkenes quantitatively. Stereochemistry of the reduction suggests that the reaction involves a free radical intermediacy.

Whether the reduction with NAD(P)H or its model compounds proceeds through a multi-step (electron-transfer) mechanism or through a one-step (hydride-transfer) mechanism has been a subject of current discussion.[1] There are several reports on reactions in which a model of NAD(P)H acts as a one-electron donor; it acts even as a radical-chain initiator in the reaction of bromotrichloromethane to chloroform,[2a] radical polymerization of acrylamide,[2b] and dediazoniation of arene diazonium salts.[2c] These reactions have been invoked to support the multi-step mechanism which involves initial one-electron transfer process. Nevertheless, since these reactions are not initiated by any provocations other than one-electron transfer onto the substrates, the models may be compelled to act as a one-electron donor in these reactions. Therefore, in order to obtain the definitive proof for the intrinsic ability of dihydropyridine derivatives as a one-electron donor, an alternative reaction system that is known to be susceptible both for one-electron and two-electron reductions should be taken.

A variety of reductants[3-5] as well as electrochemical reduction[6] convert *vic*-dibromide into the corresponding alkene by reductive debromination. Studies on the stereochemistry of these reductions have demonstrated that two-electron reductants such as iodide and hydride ions mainly give rise to concerted *anti*-elimination resulting in stereoselective formations of *trans*- and *cis*-alkenes from *meso*- (or *erythro*)- and *dl*- (or *threo*)-isomers, respectively. On the other hand, one-electron reductants such as copper(I) and iron(II) generate free radical species, which then give thermodynamically more stable alkenes predominantly[7,8] Thus, the reductive debromination of *vic*-dibromide is supposed to be an useful tool to diagnose whether a model of NAD(P)H acts as a one-electron donor or a hydride donor.

Results and Discussion

The results from the reactions of *vic*-dibromides **1a—c** with a model of NAD(P)H, *N*-benzyl-1,4-dihydronicotinamide (BNAH), are summarized in the Table. The table shows that *meso*- (or *erythro*)-bromide gave the *trans*-alkene (*trans*-**2**) quantitatively under anaerobic conditions with excess BNAH. On the other hand, the alkene from the *dl*-bromide is contaminated by a small amount of the *cis*-isomer (*cis*-**2**) under the same conditions. The results can be interpreted in terms of a free radical intermediacy in the course of the reaction. That is, **1** accepts one electron from BNAH and eliminates a bromide ion, and thus generated free radical species **3** can rotate around the central C–C bond to afford thermodynamically more stable isomer of the alkene predominantly.[8] A plausible reaction path is illustrated in the Scheme.

It has been reported that triphenylphosphine generates a carbanion from 1,2-dibromo-1-nitro-2-phenylethane (**5**) on its 1-position through the abstraction of a bromonium ion, which may afford the isomerized product.[9] However, the situation is not applicable to the present system, because BNAH is not a so strong nucleophile as triphenylphosphine and the substrates employed presently are not so electron deficient as **5**. Interestingly, an amine such as triethylamine gave rise to β-elimination of hydrogen bromide instead of reductive debromination.

Reductions under aerobic conditions also supports

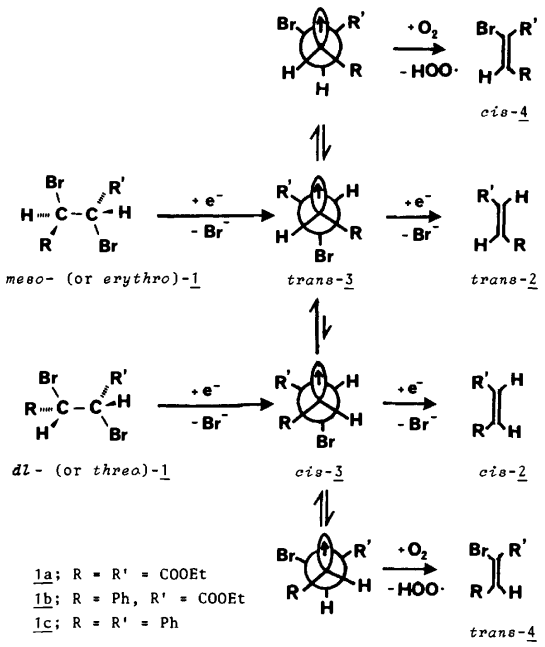

Scheme 1.

the participation of a free radical intermediacy: an oxygen molecule, which is an effective free radical scavenger, suppresses the debromination and β-elimination of hydrogen bromide predominates. Thus, as illustrated in the scheme, a free radical **3** generated is immediately trapped by an oxygen molecule to form a peroxide, which subsequently undergoes β-elimination of hydrogen peroxide in *anti*-direction to give the corresponding bromoalkene (**4**) without isomerization.[10]

BNAH promoted neither interconversion between *trans*-**2** and *cis*-**2** nor between *meso*- (or *erythro*)-**1** and *dl*-**1** under the reaction conditions. It was also confirmed that BNAH does not convert **4** to **2**.

Stoichiometry of the present reduction is noteworthy. The completion of the reduction requires more than two equivalents of BNAH against **1**, which excludes the possibility that BNAH releases a hydride ion in one step. Unfortunately, the fate of the cation radical produced from BNAH is not clear at present.

In conclusion, BNAH acts as a one-electron reductant in the reductive debromination of *vic*-dibromides even though it has a potential to behave as a hydride-ion donor. The present finding supports our previous proposal that the reduction with NAD(P)H-models involves initial one-electron transfer process.

In addition, the reductive debromination of *vic*-dibromides is an useful procedure for the purification of alkenes or the protection of alkenyl groups. The present reaction system is available for these procedures, since the conversion of the reaction and the yields of the products are satisfactory under anaerobic conditions with a little excess of BNAH. The process is much simpler than those so far reported.[4,5]

Experimental

Materials. Diethyl *dl*-dibromosuccinate (*dl*-**1a**)[11] and *dl*-1,2-dibromo-1,2-diphenylethane (*dl*-**1c**)[12] were prepared by bromination of diethyl maleate and *cis*-stilbene, respectively. Diethyl *meso*-dibromosuccinate was prepared by esterification of the corresponding acid. Ethyl *erythro*-α,β-dibromohydrocinnamate (*erythro*-**1b**) and *meso*-**1c** were commercially available (Tokyo chemical industry Co., Ltd.). NMR, IR, and GC-MS spectra of these compounds were satisfactory.

General Procedure. To a solution of 5.0×10^{-2} mmol of **1** in 0.5 cm³ of acetonitrile was added, using a syringe, a solution of 1.5×10^{-1} mmol of BNAH in 0.5 cm³ of acetonitrile through a silicone-rubber stopper. The mixture was left at 323 K in the dark for an appropriate time: then a 0.20-cm³ aliquot of the mixture was quenched with 1 cm³ of water. The aliquot was extracted with 1 cm³ of benzene containing *p*-diethoxybenzene as an internal standard for VPC analysis. The organic layer was analyzed on a Yanaco G-180 gas chromatograph (OV-17 column). Identification of products was done by comparison of IR, NMR, and GC-MS spectra of isolated products with those of the corresponding authentic smaples.

8) It may be claimed that the cis/trans ratio of the product, alkene, is determined also by relative stabilities of rotamers of the intermediate, property of the leaving atom (group), or bulkiness and charge of counter cation(s). Although such a point is not investigated in detail in the present study, this does not interfere our present discussion. It is important for the present study to point out that the intermediate has a chance to change its conformation.

Effects of Reduction Conditions on the Catalytic Activity of Rhodium Supported on TiO_2 for the Hydrogenation of Carbon Monoxide: Favorable Metal-Support Interaction

Hiroshi FUJITSU,* Nobuhide IKEYAMA,† Yasunobu SHIGAKI,† and Isao MOCHIDA

Research Institute of Industrial Science,

(Received November 16, 1984)

Synopsis. Catalytic activity of Rh/TiO_2 was influenced significantly by reduction conditions, the maximum activity per weight being obtained by reduction at 400°C for 2 h, in spite of limited adsorption abilities against reactant gases. The nature of Rh/TiO_2 is sensitively modified to develop the most favorable metal-support interaction.

Designs of novel catalysts for $CO-H_2$ reaction have been extensively investigated for these years.[1] The roles of support and additive may be one of the most influential factors to be considered for this purpose. Titania is one of the most interesting supports to modify the catalytic activity and selectivity,[2-5] since Tauster *et al.*[6] reported SMSI as for the reduced adsorption abilities of group VIII metals supported on the oxide after the reduction at higher temperatures (above 500°C). Vannice *et al.*[7] claimed that the turnover frequency on such catalysts was enhanced by the higher reduction temperatures because of SMSI, however the activity per weight was rather similar to that reduced at lower temperature.[8] It has been scarecely attempted yet to find catalysts of better practical performance in spite of a number of studies on SMSI concept.[5,7] Kikuchi *et al.*[9] reported recently that Ru supported on rutile of large surface area showed the larger activity per weight at the SMSI than that at the non-SMSI state.

The present authors are going to report significant effects of the reduction temperature and time on the catalytic activity of Rh on TiO_2 for the $CO-H_2$ reaction to find the most active catalyst.

The most favorable extent of the reduction for the highest catalytic activity per weight must exist, since electron transfer from the support is profoundly influenced by the reductive heat-treatment.[10]

Experimental

Rh/TiO_2 was prepared by the impregnation of $RhCl_3-3H_2O$ on TiO_2 (Aerosil Inc, P-25, 50 m^2/g) using a methanol solution (Rh: 4.6 wt%). The catalytic reaction was carried out at 200 and 250°C, using a circulating reactor (vol. 800 ml) with a fixed catalyst bed (0.5 g cat, diluted with 5 g SiC), through which a reactant gas of CO and H_2 (their partial pressures were 26.7 and 53.3 KPa, respectively) flowed. Before the reaction, the catalyst was reduced in situ, and evacuated at 200°C for 1 h. During the reaction, products except for methane were trapped at liquid nitrogen temperature. The reactant gases and methane were analyzed with a gas chromatograph (Molecular Sieve 13 X, 1m) by the sampling at proper intervals during the reaction. Other trapped products were analyzed after the reaction with a gas chromatograph (Porapack Q, 1m, for CO_2; VZ-10, 2m, for hydrocarbons).

Reaction rates were calculated from the conversion of CO. The catalytic reacation was repeated three time at least giving well-reproduced rates and product distributions.

Adsorption of CO, H_2 and O_2 on the catalyst was measured volumetrically using the same reactor.

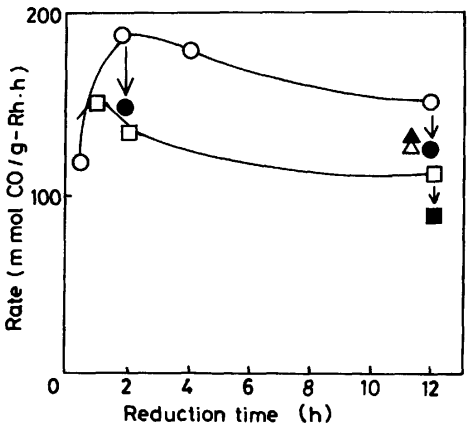

Fig. 1. Effects of reduction conditions and oxygen preadsorption on the catalytic activity of Rh/TiO_2. cat: 0.5 g/5 g SiC, P_{H_2}/P_{CO}=26.7/53.3(KPa), reaction temp: 200°C, reduction temp: 200°C (△,▲), 400°C (○,●), 500°C (□,■), open: without oxygen preadsorption, colsed: after the oxygen pre-adsorption.

Results and Discussion

Catalytic activities at 200°C depended very much on the reduction conditions, both temperature and time, as shown in Fig. 1. The reduction at 400°C for 2 h (catalyst-400) provided the highest activity per weight among the reduction conditions examined. Longer time at the same temperature decreased the rate considerably. The catalyst reduced at 500°C (catalyst-500) showed the maximum activity by the reduction for 1 h and gradual decreases of activity with longer times to give the lowest activity by 12 h. In contrast, the reduction at 200°C (catalyst-200) provided constant activities independent on the reduction time. Such activity differences due to the reduction conditions were more marked in the reaction at 250°C (Table 1).

More long-chain hydrocarbons ($>C_5$) were obtained over the catalysts reduced at both 400 and 500°C when the product distributions were compared.

Table 2 summarized the effects of reduction conditions on the adsorption abilities against H_2, CO and O_2 at room temperature. The reduction at 200°C provided *ca.* 0.5 of both H/Rh and CO/Rh atomic ratios regardless the reduction time. These ratios decreased markedly by increasing the reduction temperature. The smallest values on the catalyst-500 indicate the definite SMSI as reported in the literature.[6] In contrast, adsorption ability of the catalyst against O_2

was not influenced by the reduction conditions to show almost constant values of O/Rh ratio as reported by Meriaudeau *et al.*[11]

The oxygen adsorption at room temperature provided remarkable effects on the catalytic activity, depending strongly on the reduction temperatures of the catalysts as shown in Fig. 1 and Table 1. The reaction rates over the catalysts-400 and -500 at 200 and 250 °C were decreased by the oxygen adsorption by *ca.* 20 and 30%, respectively, whereas no retardation was observable with the catalyst-200. The product distribution was not effected by the oxygen adsorption.

It may be the most significant observation in the present study that the catalyst reduced at 400 °C for 2 h exhibited the highest catalytic activity per g-Rh. The interaction between Rh and TiO_2 which allowed the maximum activity per g-Rh can be defined as FMSI (Favorable Metal Support Interaction), its search being a practical target in the catalyst design. The reduction at 400 °C for 2 h may compromise most favorably the extents of reduction and dispersion of Rh as well as electron-donating ability of supporting TiO_2.[10] The hydrogenation activity of such a catalyst was rather low to increase the yields of longchain hydrocarbons.

The activity per g-catalyst is the product of the activity of an active site and its number on the catalyst surface. The latter has been proposed to be estimated from the amounts of hydrogen adsorption (H/Rh ratio).[5,7,8] However, it is suspicious that the ratio reflects its accurate number. The nature of the metal catalyst is suggested to be modified significantly by the support according to the pretreatment conditions.

The balanced activation abilities against H_2 and CO of Rh modified through FMSI may provide the maximum activity where the number of the active sites is rather unchanged. Such a FMSI may be possible between Rh metal and properly reduced titania by dehydration and hydrotreatment.

Rate Coefficient for $H+C_2H_2 \rightleftarrows C_2H+H_2$

William GARDINER,* Tsuneo TANZAWA, Tohru KOIKE,† and Kihei MORINAGA†
Department of Chemistry, University of Texas, Austin, Texas 78712 U. S. A.
†*Department of Chemistry, National Defense Academy, Hashirimizu, Yokosuka 239*
(Received November 27, 1984)

Synopsis. The rate coefficient expressions $k=10^{13.78}$ exp(−99 kJ/RT) cm^3 mol^{-1}s^{-1} for $H+C_2H_2 \rightarrow C_2H+H_2$ and $k=10^{13.05}$ exp(−12 kJ/RT) cm^3 mol^{-1} s^{-1} for $C_2H+H_2 \rightarrow H+C_2H_2$ were proposed after correcting for errors in previously reported data analyses of shock tube data on C_2H_2 pyrolysis.

The homogeneous thermal decomposition of C_2H_2 proceeds by chain reactions in which one of the important elementary reactions is

$$H + C_2H_2 \longrightarrow C_2H + H_2. \quad (1)$$

Rate coefficients for this reaction can be derived by analysing C_2H_2 decomposition rate data with the aid of computer modeling. In one of such studies, Tanzawa and Gardiner[1] (TG1) fitted laser-schlieren profiles of the density gradients in C_2H_2–Ar mixtures heated by incident shock waves to temperatures in the range 1700—3400 K. In another, Koike and Morinaga[2] (KM) fitted 216 nm absorption profiles of C_4H_2 appearance from C_2H_2–Ar mixtures heated to temperatures in the range 1800—2600 K in incident shock waves. In a modeling study in which a number of experiments were interpreted with a single mechanism[3] (TG2), a temperature-independent value for the rate coefficient of the reverse reaction $k_{-1}=10^{13.54}$ cm^3 mol^{-1}s^{-1} was reported to fit the experimental results. This value is higher than the k_{-1} value $10^{12.4}$ cm^3 mol^{-1}s^{-1} of KM by a factor much larger than the anticipated experimental error bounds. In order to discover the source of this difference, the procedures used in both data analyses were reexamined. As described below, the apparent discrepancy resulted from transcriptional errors in manuscript preparation and in an incorrect thermochemical data record for C_2H. When these corrections were made, it became clear that the KM and TG1 experiments are in close agreement about the rate of Reaction (1).

For the conditions of C_2H_2 decomposition in shock waves, Reaction (1) proceeds in the forward direction during the time of rate measurements. In the data analysis of TG2, the forward rate coefficient k_1 was input as an Arrhenius expression for the computer modeling. As it was noticed that this expression implied fairly constant values of the reverse rate coefficient k_{-1}, it was decided to report a temperature-independent k_{-1} valid for the range of the TG1 experiments rather than the Arrhenius expression of k_1. (The computer programs used in all studies discussed here used essentially identical mathematical procedures and include both the forward and reverse directions of all reactions, the reverse reaction rate coefficients being computed from the forward reaction rate coefficients using the equilibrium constant implied by the thermochemical properties of the reacting species.) Unfortunately, in preparing the TG2 manuscript for publication, the preexponential factor of the k_1 expression $10^{13.54}$ cm^3 mol^{-1} s^{-1} was assigned to k_{-1} instead of the value $10^{12.75}$ cm^3 mol^{-1} s^{-1} that was actually found to be typical of the k_{-1} values implied by k_1 expressions that provided good fits to the TG1 data.

In analysing their data, KM adopted the more convenient reverse reaction $C_2H+H_2 \rightarrow H+C_2H_2$ as input even though the direction in which reaction proceeded during their measurements was $H+C_2H_2 \rightarrow C_2H+H_2$ as in the TG1 experiments. By adjusting k_{-1} to fit their data, the value $k_{-1}=10^{12.4}$ cm^3 mol^{-1} s^{-1} was found to be optimal, still a factor of two smaller than the corrected TG2 value and still outside the error limits of both studies. The source of the remaining discrepancy was found on investigation to be a faulty thermochemical data record for the species C_2H. While this record was faulty at first in both the TG2 and KM computer programs, it affected the data analysis only through computing the value of k_1 from k_{-1}, and thus distorted only the KM computations. When the correct C_2H thermochemistry was used, it was found that the optimal k_{-1} values for fitting the KM data became quite close to the corrected TG2 result. Over 2000 K, $k_{-1}=10^{12.88}$ cm^3 mol^{-1} s^{-1} gave very close match to the KM data, while at lower temperatures $k_{-1}=10^{10.18}$ exp(115 kJ/RT) was required. A comparison with the KM data is shown in Fig. 1. It can be seen that the inconsistent k_{-1} expression for lower temperatures is actually very close to higher-temperature result; There seems to be some unappreciated systematic error at lower temperatures, which has no effect upon the analysis presented here. Arrhenius expressions can be derived for k_1 and k_{-1} by combining room temperature

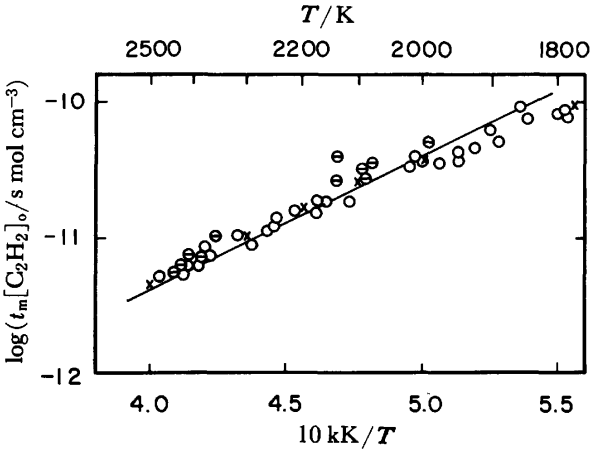

Fig. 1. Comparison of computed and measured rate parameters for 216 nm absorption change. For definition of t_m, see Ref. 2.
○: C_2H_2/Ar=3.2/96.8, ⊖: C_2H_2/H_2/Ar=2.0/2.2/95.8, and ×: computed for C_2H_2/Ar=3.2/96.8. All data points are from Ref. 2.

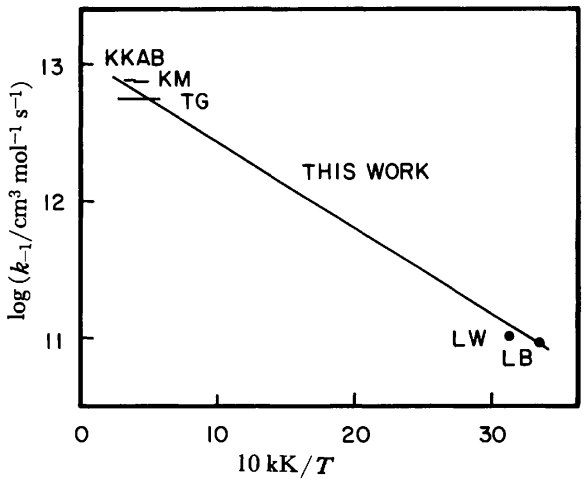

Fig. 2. Arrhenius graph for $C_2H+H_2 \rightarrow C_2H_2+H$. KKAB=Ref. 11, KM=Ref. 2, TG=Ref. 1, LW=Ref. 4, LB=Ref. 5, and THIS WORK=$10^{13.05}$ exp(−12 kJ/RT) $cm^3 mol^{-1} s^{-1}$.

measurements of k_{-1} with a representative value for k_{-1} at 2800 K of $10^{12.75}$ $cm^3 mol^{-1} s^{-1}$. Lange and Wagner[4] reported $k_{-1}=10^{11}$ $cm^3 mol^{-1} s^{-1}$ at 320 K, while Laufer and Bass[5] reported $10^{10.96}$ $cm^3 mol^{-1} s^{-1}$ at 298 K. The Arrhenius expression $k_{-1}=10^{13.05}$ exp(−12 kJ/RT) $cm^3 mol^{-1} s^{-1}$ accounts for the 50-fold increase in rate coefficient between 300 and 2800 K. (Fig. 2) The corresponding expression for k_1 is $10^{13.78}$ exp(−99 kJ/RT) $cm^3 mol^{-1} s^{-1}$. These two expressions are thermochemically compatible with one another providing that JANAF[6] thermochemistry is used for all species except that $\Delta H^\circ_{f0}(C_2H)=531$ kJ/mol as derived by Okabe and Dibeler.[7]

The only other study known to us in which fairly direct determination of k_1 or k_{-1} is asserted is that of Yampol'skii *et al.*[8] Their expessions, however, are more than an order of magnitude higher than the consensus of the 5 studies shown in Fig. 2, and apparently result from contamination by unidentified catalytic pathways for isotope exchange.

Aside from Reaction (1), the reaction mechanisms used by KM and TG2 differ in that TG2 included the reaction

$$H + C_2H_2 \longrightarrow C_2H_3 \qquad (2)$$

using a rate coefficient reported by Payne and Stief,[9] while KM used instead the M-dependent form for the reverse reaction

$$C_2H_3 + M \longrightarrow C_2H_2 + H + M \qquad (-2)$$

and a theoretical rate coefficient derived by Benson and Haugen.[10] While reactions of C_2H_3 become important in C_2H_2 thermal decomposition only at temperatures well below those of the TG1 and KM experiments, we nonetheless repeated the TG2 computations using Reaction (−2) and the Benson and Haugen rate coefficient expression. No significant differences were seen. We note, however, that while the rate of Reaction (2) is predicted to be more or less the same by both the Payne and Stief and the Benson and Haugen expressions for the conditions of the TG1 and KM experiments, they do diverge for other conditions and must be adopted with care for simulation purposes.

Subsequent to the TG2 and KM publications, the thermal decomposition of C_2H_2 produced from thermal decomposition of C_2H_4 was studied by Kiefer *et al.*[11] For their conditions, Reaction (1) proceeds predominantly in the reverse direction, and the laser-schlieren gradients they measured proved to be sensitive to k_{-1}. Their result $k_{-1}=10^{12.87}$ $cm^3 mol^{-1} s^{-1}$, for the temperature range 2600—3000 K, is seen to be in good agreement with the expression derived here. Reference is made to their paper for extensive discussion of the effect of subsequent reactions for their and the TG1 experimental conditions.

Our reexamination of the rate coefficient for this important reaction was stimulated by discussions with J. H. Kiefer and J. Warnatz. Finantial support was provided by the U. S. Army Research Office and the Robert A. Welch Foundation.

Measurement of Ultralow Interfacial Tension in the Vicinity of Critical Solution Temperature

Makoto ARATONO* and Kinsi MOTOMURA
Department of Chemistry, Faculty of Science, Kyushu University 33, Fukuoka 812
(Received January 24, 1985)

Synopsis. A new apparatus adopting the sessile drop technique has been designed to measure the ultralow interfacial tension between two liquids of a binary mixture. The equilibrium interfacial tension of the mixture of isobutyric acid and water has been determined near its upper critical solution temperature up to the value of 0.02 $\mu N\,m^{-1}$.

When two liquids are practically immiscible with each other, the properties and structure of the interface between the liquids have been clarified by measuring the dependence of interfacial tension on temperature and pressure and evaluating the thermodynamic quantities of interface formation.[1-3] When two liquids are practically miscible and have the critical solution temperature, however, thermodynamic investigations of the interface are scarce.[4-9] This may be attributable to the difficulty of the precise measurement of ultralow interfacial tension at temperatures near the critical solution temperature. In the present study, we made an apparatus for measuring the ultralow interfacial tension and determined the equilibrium interfacial tension values near the critical solution temperature.

Experimental

Materials. Isobutyric acid (Nakarai's guaranteed reagent) was distilled fractionally at atmospheric pressure and the middle fraction was used for the experiments. The sample was found to be 99.9% pure by gas-liquid chromatography with a 3 m long and 3 mm in diameter column packed with Unisole 400 (Gaskuro Kogyo Inc.). The doubly distilled water was further distilled after refluxing with alkaline permanganate.

Interfacial Tension Measurement. The measurements of the interfacial tension between the two phases in equilibrium near the upper critical solution temperature T_c of binary liquid mixture under atmospheric pressure were carried out by a new sessile drop method. Figure 1 shows the sessile drop cell which was mounted in the jacketed vessel made of acrylate resin. The temperature control of the cell is an important matter in the present study. To minimize a fluctuation in temperature, the whole system was placed in the air thermostat. In result, the temperature of the cell measured by the Beckmann thermometer was found to be constant within ±0.002 K. The sessile drop was formed in the following way. The binary mixture (80—100 ml) having a composition close to the critical one in the cell was vigorously stirred by a rotor (a) for about 30 min at the desired temperature and permitted to stand for from 1 to 7 h to separate completely into the water-rich (b) and acid-rich (c) phases. Then a part of the upper layer solution was sucked up into the syringe (d) by the plunger (e) and then the optical flat (f) attached to the bottom of syringe was dipped into the lower layer solution. At this stage, the sessile drop (g) was formed on the surface of the optical flat by pushing the plunger by rotating micrometer (h) and located by the level adjuster in the position which permits to take its photograph. By the use of the camera with the bellows of about five magnification and the light ray parallel to the optical axis, we could have a clear, enlarged, and undistorted profile.

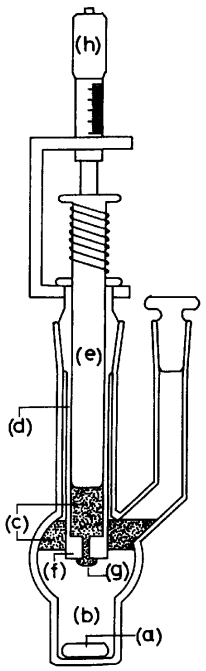

Fig. 1. Cross sectional view of a quartz sessile drop cell. (a): Rotor, (b): water-rich phase, (c): acid-rich phase, (d): syringe, (e): plunger, (f): optical flat, (g): sessile drop, (h): micrometer.

The interfacial tension γ was calculated by making use of the following equation[10,11]

$$\gamma = (1/2)g\Delta d a^2 \quad (1)$$

where g is the acceleration of gravity and Δd the density difference between two conjugate solutions. The values of Δd were available from the literature.[12] The capillary constant a^2 is correlated to the dimensions of the image on the negative film by the relation

$$a^2 = r^2 f(h/r), \quad (2)$$

where r is the radius of the drop in the equatorial plane, h the distance from the apex to the plane, and $f(h/r)$ the function of h/r. The values of h and r were determined by Nikon measurescope (model II) with the precision of ±1 μm. The experimental error of the interfacial tension did not exceed two percent of the obtained value.

Figure 2 shows the time dependence of interfacial tension. It can be seen that the equilibrium value can be obtained within a few minutes. Therefore, the drop was stood for about 15 min and photographed.

Results and Discussion

The γ *vs.* $T-T_c$ curves are shown in Fig. 3; the value of T_c determined by making use of the mutual solubility curve[13] has been used. It is seen from Fig. 3 that the value of γ decreases monotonously with rising

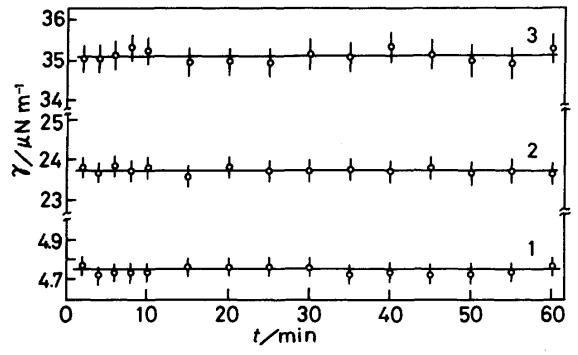

Fig. 2. Interfacial tension *vs.* time curves. 1: $T-T_c$=−0.708 K, 2: −2.365, 3: −3.175.

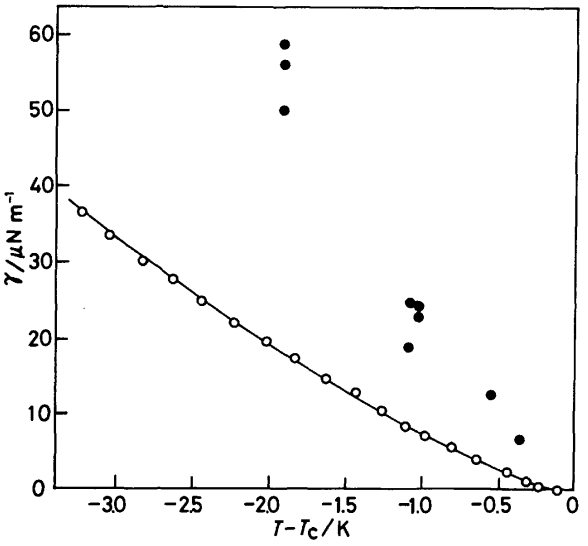

Fig. 3. Interfacial tension *vs.* temperature curve. (○): Present study, (●): data from reference 9.

temperature and approaches zero at the critical solution temperature. This is the behavior expected for the binary liquid mixture which has the upper critical solution temperature. Further it is worth noting that the value varies from 35 to 0.02 μN m^{-1} in the narrow temperature range in $T-T_c$ from −3.2 to −0.1 K. The closed symbols in Fig. 3, the γ values of Howland *et al.*,[9] are larger than ours and show considerable scatter. In addition, the lowest value of the former is found to be significantly high compared to the one of the latter. Taking into account that the capillary rise method employed by Howland *et al.* is unsuitable in principle for measuring the ultralow interfacial tension, the above results may indicate that the sessile drop method of the present study provides the ultralow interfacial tension values accurate enough to consider the behavior of the interface between the two phases of binary liquid mixture near the critical solution temperature.

It has been shown that the dependence of γ on temperature at constant pressure gives useful information regarding the entropy of interface formation.[1,4] It is supposed, therefore, that the formation of the interface from the two phases of binary liquid mixture in equilibrium near the upper critical solution temperature is attended by an increase in entropy and the entropy of interface formation is reduced to zero at the upper critical solution temperature. Further discussion will be made in the separate paper.[13]

Determination of the Stability Constants of Crown Ether Complexes with Protonated Amines by Solvent Extraction

Hideyuki NOGUCHI,* Masatoshi NAGAMATSU, and Masaki YOSHIO
Department of Industrial Chemistry, Faculty of Science and Engineering, Saga University, Honjyo, Saga 840
(Received September 27, 1984)

Synopsis. Stability constants of crown ether complexes with protonated primary amines were determined by the solvent extraction method. Stability constants between protonated amines(AH^+) and 18-crown-6(L), log K_{AHL}, were found to be 0.4, 0.15, 0.1, −0.05, and −0.1 for protonated methylamine, ethylamine, propylamine, butylamine, and *iso*-propylamine at 25.0 °C, respectively.

Accurate determination of stability constants of small values are more difficult than those of higher values.[1] Here, we propose a method for the determination of stability constants. The method has been successfully applied to determing especially small values of stability constants between 18-crown-6 and protonated primary amine. Crown ether in an organic phase is extracted by complexation with primary amine hydrochloride (or sodium chloride etc.) in the aqueous phase, which can not be extracted into the organic phase. So, stability constants of crown ether with protonated primary amines can be determined by the analysis of the extraction equilibria.

In this paper, we describe the method for the determination of stability constant by back extraction, and discuss the results with data obtained in other literature.[3-5]

Theory

The following equations may be written for the extraction system composed of crown ether, water, organic solvent, and salts, such as potassium chloride, sodium chloride and ammonium chloride, which can not be extracted into the organic phase at the limited pH range.

$$L \rightleftharpoons L_o \qquad K_{d,L} = [L]_o/[L] \tag{1}$$

$$M^+ + L \rightleftharpoons ML^+ \qquad K_{ML^+} = [ML^+]/([M^+][L]) \tag{2}$$

$$C_{M^+} = [M^+] + [ML^+] \tag{3}$$

$$C_L = [L] + (V_o/V)[L]_o + [ML^+] \tag{4}$$

where subscript "o" denotes the organic phase, $K_{d,L}$, K_{ML^+}, C_{M^+}, C_L, V_o, and V show the distribution coefficient of the crown ether, stability constant of crown ether complex (ML^+) in the aqueous phase, total concentration of M^+ and L, volume of organic and aqueous phase, respectively. In the case of protonated amines, the symbol AH^+ is used instead of M^+. Eq. 5 can be obtained when C_{M^+} is much larger than C_L.

$$\log C_L = \log [L]_o + \log (V_o/V + K_{d,L}^{-1}(1 + K_{ML^+}C_{M^+})) \tag{5}$$

Log C_L against log $[L]_o$ plot should show a straight line of slope 1. Therefore, K_{ML^+} can be calculated from the value at the intercept of the log C_L axis. Thus, the stability constants can be determined under constant ionic strength by the method.

Experimental

A typical procedure was as follows. 25 ml of aqueous solution containing 0.5 mol dm^{-3} primary amine hydrochloride and 18-crown-6(5×10^{-5}—2×10^{-3} mol dm^{-3}) was mixed with 10 ml of 1,2-dichloroethane and shaken for 1 day in a thermostated bath at 25.0 °C. The concentration of alkali metal chloride or ammonium chloride were the same as in the above case except for the potassium ion, which was 0.1 mol dm^{-3}. The concentration of the 18-crown-6 in the organic phase was measured spectrophotometrically after extraction with potassium picrate.[2] The adjustment of the pH was made with dilute hydrochloric acid and lithium hydroxide solution. No other reagents and buffers were used during the experimental runs.

Results and Discussion

In order to check the validity of the Eq. 5, 18-crown-6, water, 1,2-dichloroethane and metal salt (KCl, NaCl, or NH_4Cl) system was chosen. It was found that cations (K^+, Na^+, NH_4^+) and anion(Cl^-) are not extracted into the 1,2-dichloroethane phase at least over the pH range of 3.5—6.0.

Distribution coefficient of 18-crown-6($K_{d,L}$) was determined to be 1.12 at 25.0 °C.

Plots of C_L against log $[L]_o$ are shown in Fig. 1. Linear relationships were obtained as expected from Eq. 5. The calculated values of log K_{ML^+} are found to be 2.08, 0.63, and 0.97 for potassium, sodium, and ammonium complexes with 18-crown-6 under the ionic strength 0.5 (0.1 in the case of KCl). These values agreed very closely with those in the literature,[3,4] in which 2.03, 0.8, and 1.23 were reported for the values of the respective complexes.

●: methylamine, □: ethylamine, ◐: propylamine, ■: buthylamine, ○: isopropylamine

Methods for the determination of accurate stability constants having small values are very limited and such small values of stability constants sometimes contain errors.

Our method proposed here would, especially, be valid for the determination of stability constants of small values, because the concentration of crown ether in the organic phase can be determined accurately. The accuracy increases when the crown ether distributes more equally between both phases. The determination of stability constants of 18-crown-6 complexes with several protonated amines were then attempted. The experimental conditions are the same as those described before. Plots of log C_L against log $[L]_o$ are shown in Fig. 2a for protonated primary amines. Each plot has a straight line with a slope of 1. The result shows that the extraction system can be expressed by Eqs. 1—4.

The log K_{AHL} values obtained are 0.4, 0.15, 0.1, −0.05, and −0.1 for protonated methylamine, ethylamine, propylamine, butylamine, and isopropylamine at a constant ionic strength (0.5).

The values obtained by Larson *et al.*[5] for protonated amine–18-crown-6 are obviously higher than the data obtained by us. Their values obtained by the glass electrode measurement may contain some errors. They determined the stability constants by the measurement of the pH difference before and after adding 18-crown-6 to the system containing an amine and the corresponding amine hydrochloride. For example, the pH difference for the trimethylamine system is only 0.074 pH units according to our calculation by using the stability constant 5.5 (log $K_{AHL}=0.74$) given by them. They reported that the uncertainties are equivalent to an error in pH of about ±0.02 pH units. This means that the stability constants especially for weak complexes such as 18-crown-6-protonated trimethylamine, contains about ±30% errors.

Another approach for the determination of stability constants is as follows. Equation 6 can be obtained by using Eqs. 1—4 and distribution ratio of crown ether, ($D_L=[L]_o/([L]+[AHL^+])$).

$$\frac{1}{D_L}=\frac{1}{K_{d,L}}+\frac{K_{AHL}C_{AH^+}}{K_{d,L}} \qquad (6)$$

Plot of $1/D_L$ against C_{AH^+} should show a straight line and the intercept at $C_{AH^+}=0$ should show the value of $K_{d,L}^{-1}(=0.89)$. Hence, K_{AHL} can be also calculated from the slope analysis. The plot of $1/D_L$ *vs.* C_{AH^+} for protonated primary amines at fixed C_L (2.4×10^{-4} mol dm^{-3}) is shown in Fig. 2b. The extrapolation to $C_{AH^+}=0$ shows $1/K_{d,L}$, then the extraction mechanism could be expressed by Eqs. 1—4. Log K_{AHL} values obtained from this method agreed well with those obtained (deviations are within ±0.03) by the method under constant ionic strength.

Crystal and Molecular Structure of a Triply-thiolate-bridged Binuclear Cobalt(III) Complex, $[Co_2\{SCH(CH_2CH_2NH_2)_2\}_3](ClO_4)_3 \cdot H_2O$

Masahiro MIKURIYA,* Sigeo KIDA, Shigehiro UENO, and Ichiro MURASE†

Department of Chemistry, Faculty of Science, Kyushu University 33, Hakozaki, Higashi-ku, Fukuoka 812

†*Laboratory of Chemistry, College of General Education, Kyushu University 01, Chuo-ku, Fukuoka 810*

(Received February 8, 1985)

Synopsis. The crystal structure of tris[μ-(1,5-diamino-3-pentanethiolato)-*N*,*N*′, μ-*S*]-dicobalt(III) perchlorate monohydrate was determined by the single-crystal X-ray diffraction method. The binuclear complex has a novel type of binuclear structure in which the two cobalt atoms are bridged by three thiolate sulfur atoms forming a face-shared bioctahedron.

Metal compounds with thiolate ligands are now regarded as an important class of complex in the field of bioinorganic chemistry.[1] A number of compounds containing metal atoms bridged by thiolate sulfur have been reported, but little effort has been devoted toward the isolation of discrete binuclear metal complexes as yet.[2] Recently, Murase *et al.* reported the synthesis of binucleating ligand, 1,5-diamino-3-pentanethiol (Hdpet), and its binuclear complexes, $[M_2(dpet)_2](ClO_4)_2$ (M=Ni, Pd) and $[Co_2(dpet)_3](ClO_4)_3$.[3] Based on the analytical, spectral and magnetic data, they concluded that the cobalt(III) complex possesses a binuclear structure in which the two cobalt atoms are bridged by three thiolate sulfur atoms forming a face-shared bioctahedron. To our knowledge, this is the first example of a triply-thiolate-bridged binuclear cobalt(III) complex. In this study, we have confirmed the structure of $[Co_2(dpet)_3](ClO_4)_3$ by the single-crystal X-ray diffraction method.

Experimental

Black crystals of $[Co_2(dpet)_3](ClO_4)_3 \cdot H_2O$ were prepared by method previously reported.[3] A crystal with dimensions of 0.20×0.40×0.42 mm was used for the X-ray analysis. The unit-cell parameters and intensities were measured on a Rigaku AFC-5 automated four-circle diffractometer with graphite-monochromated Mo$K\alpha$ radiation (λ=0.71069 Å) at 23±1 °C.

Crystal Data: $Co_2(C_5H_{13}N_2S)_3(ClO_4)_3 \cdot H_2O$, F.W.=833.93, monoclinic; $P2_1/c$; a=11.101(4), b=28.619(6), and c=10.692(2) Å; β=113.66(2)°; V=3111(1) Å^3; D_m=1.78, D_c=1.78 g cm^{-3}; Z=4.

The intensity data were collected by the 2θ—ω scan technique with a scan rate of 4° min^{-1}. Three standard reflections were monitored every 100 reflections, and their intensities showed a good stability. A total of 5960 reflections with 2θ<50° were collected. The intensity data were corrected for the Lorentz and the polarization effects, but not for absorption. Independent 4439 reflections with $|F_o| \geq 3\sigma(F_o)$ were considered as "observed" and were used for the structure analysis.

The structure was solved by the direct method. Refinement was carried out by the block-diagonal least-squares method. Hydrogen atoms were inserted in their calculated positions and included in the refinement. The final R value was $R=\sum||F_o|-|F_c||/\sum|F_o|=0.071$. Final difference Fourier map was featureless except for three peaks of 1.26—1.78 e/Å^3 in the vicinity of the sulfur atoms, S(A), S(B), and S(C). All the calculations were carried out on the FACOM M-200 computer in the Computer Center of Kyushu University by the use of a local version[4] of the UNICS-III and the ORTEP programs. The final positional and thermal parameters with their estimated standard deviations are given in Table 1. The coordinates and isotropic temperature factors of the hydrogen atoms, the anisotropic thermal parameters of the non-hydrogen atoms, bond lengths and bond angles, and the F_o—F_c tables have been deposited as a Document No. 8528 at the Office of the Editor.

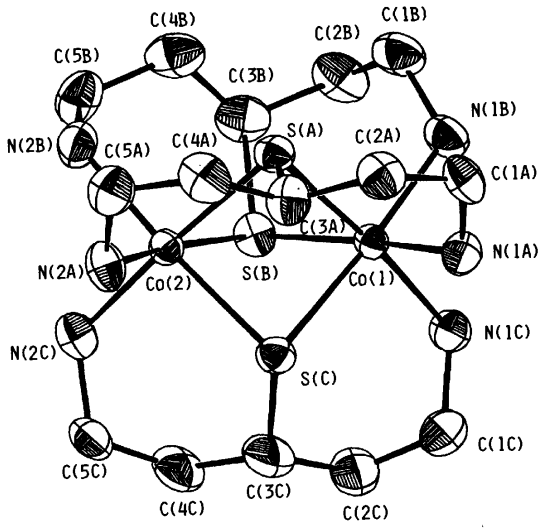

Fig. 1. A perspective view of $[Co_2(dpet)_3]^{3+}$ ion. Selected bond lengths (l/Å) and angles (ϕ/°) are: Co(1)-Co(2) 2.955(2), Co(1)-S(A) 2.229(3), Co(1)-S(B) 2.247(3), Co(1)-S(C) 2.257(3), Co(2)-S(A) 2.229(3), Co(2)-S(B) 2.256(3), Co(2)-S(C) 2.243(3), Co(1)-N(1A) 2.013(8), Co(1)-N(1B) 2.000(8), Co(1)-N(1C) 2.003(8), Co(2)-N(2A) 2.008(8), Co(2)-N(2B) 1.997(8), Co(2)-N(2C) 1.996(10); Co(1)-S(A)-Co(2) 83.04(9), Co(1)-S(B)-Co(2) 82.03(8), Co(1)-S(C)-Co(2) 82.09(8).

Results and Discussion

The crystal structure consists of discrete binuclear clusters, $[Co_2(dpet)_3]^{3+}$, perchlorate ions and crystal water molecules. A perspective view of the complex ion, $[Co_2(dpet)_3]^{3+}$, is shown in Fig. 1. As has been anticipated, the complex ion consists of two distorted octahedra sharing the face formed by the three thiolate sulfurs.

The Co-S bond lengths (2.229—2.257 Å) fall in the range of those of other cobalt(III)-mercaptide complexes.[5] The Co-N bond lengths (1.996—2.013 Å) are significantly longer than those of ordinary cobalt(III)-amine complexes. The observed lengthening seems to be due to the trans influence of the thiolate sulfur coordination as was observed for cobalt(III) complexes containing 2-aminoethanethiol.[5]

The Co-Co distance is 2.955(2) Å and the Co-S-Co angle 82.0—83.1°. For some tri(μ-hydroxo)dicobalt(III) complexes Co-Co distances of 2.55—2.58 Å, and Co-O-Co angles of 81—86° were reported.[6] Thus, the substitution of the thiolate sulfur for the hydroxo oxygen leads to an appreciable lengthening of the metal-metal separation.

The water molecules and perchlorate ions are in the vicinity of the amino groups of the dpet ligands by hydrogen bonds.

Electrogenerated Acid-catalyzed Cyclization of Isoprenoids

Kenji UNEYAMA, Akihiro ISIMURA, and Sigeru TORII*
Department of Industrial Chemistry, School of Engineering, Okayama University, Okayama 700
(Received January 24, 1985)

Synopsis. Biogenetic-type cyclization of some isoprenoids (geranyl phenyl sulfone, methyl geranate, pseudoionone, and 6,10-dimethyl-2,5,9-undecatrien-4-one) has been performed by use of an electrogenerated acid in 1,2-dichloroethane.

The biogenetic cyclization of polyisoprenoids to cyclic terpenoids has been performed by the action of strong acids such as boron trifluoride, tin(IV) chloride, and concentrated sulfuric acid.[1] For instance, pseudoionone is converted into ionone in concentrated sulfuric acid[2] and geranyl phenyl sulfone in concentrated sulfuric acid–acetic acid[3] or stannic tetrachloride in dichloromethane.[4] The requirement of a large amount of bases to neutralize the strong acid is unfavorable for the practical process.

Recently, the electrogenerated acid (EGA) has been recognized as a powerful acid-catalyst for epoxide ring opening,[5] acetalization[6] cyanation,[7] and conversion of nerolidol to bisaborol.[8] We describe an EGA-catalyzed cyclization of polyisoprenoids, demonstrating that a very small quantity of the EGA does promote the cyclization and the neutralization is easy for workup.

The electrolysis of **1a** (500 mg) in a distilled 1,2-dichloroethane (DCE) in the presence of lithium perchlorate (50 mg) and tetraethylammonium perchlorate (50 mg) was performed by use of platinum foil electrodes in an undivided cell. Constant current (1.7 mA/cm^2) was passed for 25 min (0.04 F/mol). If it is assumed that a proton of EGA is produced by one-electron oxidation of a trace amount of water existed in the solvent employed,[9] the amount of the EGA must be very small since 0.04 F/mol of electricity is enough to complete the cyclization. Therefore, a few drops of pyridine can neutralize the solution. The yield (95%) is comparable to that (87—94%) obtained in concentrated sulfuric scid.[3]

Lithium perchlorate is an essential electrolyte for generation of EGA, but tetraethylammonium perchlorate was employed as a coelectrolyte so as to get an enough conductivity of the solution. The use of tetraethylammonium perchlorate or tetraethylammonium tosylate alone is less effective for the purpose. 1,2-Dichloroethane is highly effective solvent while mixing of about 7% of more polar solvent such as ethyl acetate (81%, 0.8 F/mol), acetone (73%, 1.0 F/mol), and THF (42%, 2.1 F/mol) as a cosolvent resulted in decrease of both yield and reaction rate.

In order to elucidate the behavior of the EGA in this cyclization, two types of electrolysis procedure were examined. On electrolyzing the solution in the absence of **1a** (0.5 F/mol), and then adding **1a** in the pre-electrolyzed solution and allowing to react at 55 °C for 20 min, **2a** was obtained in almost the same yield (92%) as compared with that (95%) obtained in the electrolysis in the presence of **1a**. However, at the lower temperature (20 °C), both electrolysis procedures revealed a marked difference as shown in Table 1 (entry 5 and 7), clearly demonstrating that the cyclization proceeds faster on electrolyzing in the presence of a substrate. The EGA would be concentrated during the electrolysis at the anode surface to make the proximity of the anode extremely acidic so that the cyclization proceeds even with a small amount of EGA.[9]

TABLE 1. EGA CATALYZED CYCLIZATION OF **1a**[a]

Entry	Electrolyte[b]	Temp °C	F/mol	**2a** %	**1a** %
1	$LiClO_4$–Et_4NClO_4	55	0.04	95	0
2	Et_4NClO_4	55	1.6	15	38
3	Et_4NOTs	55	2.0	trace	71
4	$LiBF_4$–Et_4NClO_4[e]	55	1.0	54	15
5	$LiClO_4$–Et_4NClO_4	20	2.1	60	0
6[c]	$LiClO_4$–Et_4NClO_4	55	0.5	92	0
7[d]	$LiClO_4$–Et_4NClO_4	20	2.1	12	80

a) Substrate (0.36 mmol) in 8 ml of DCE. b) Electrolyte (50 mg for each). c) Pre-electrolyzed conditions (0.5 F/mol). d) Pre-electrolyzed conditions (2.1 F/mol). e) Because of the low solubility of $LiBF_4$ in DCE, Et_4NClO_4 was employed as a coelectrolyte.

The cyclization of **1a** and **1b**[10] proceeds successfully by the EGA catalysis [95% (α:β:γ=86:9:5) and 88% (α:γ=89:11)], respectively. Also pseudoionone **1c** afforded ionone in 57% yield. α-Damascone **2d**[11] was prepared in 30% yield from **1d**. In contrast, geraniol **1e** behaved somewhat differently and dehydrative cyclization occurred exclusively rather than the desired cyclization leading to the formation of a mixture of limonene and terpinolene (78%, limonene:terpinolene =36:64). And cyclization of **3** provided **4** (72%, α-H$_9$:β-H$_9$=34:64).[12]

Experimental

Boiling points are indicated by an air bath temperature and uncorrected. The IR spectra were obtained with a JASCO IRA-1 spectrometer. ^{1}H-NMR spectra were measured with a JNM FX-100 spectrometer at 100 MHz in $CDCl_3$ using Me_4Si as an internal standard. Substrates **1a**,[13] **1b**,[10] **1d**,[11] and **3**[12] were prepared as reported in the literatures. Geraniol and pseudoionone were the samples which were manufactured in Kuraray Co. Ltd., to which the authors are grateful. 1,2-Dichloroethane and ethyl acetate were refluxed over P_2O_5 and distilled. THF was refluxed over NaOH and then $LiAlH_4$, and finally distilled from a sodium-benzophenone drying system. Acetone was stirred over dry $MgSO_4$ for overnight, filtered, and distilled. Electrolytes, $LiClO_4$, Et_4NClO_4, $LiBF_4$, and Et_4NOTs were commercially available and dried under the reduced pressure. A typical electrolysis is described below and the products, **2a**,[2,3] **2b**,[10] **2c**, **2d**,[11] and **4**[12] were idientified in comparison with the authentic samples.

Electrolysis of ***1a*** *in a 1,2-Dichloroethane-$LiClO_4$-Et_4NClO_4 system.* A solution of **1a** (500 mg, 1.8 mmol) $LiClO_4$ (50 mg), and Et_4NClO_4 (50 mg) dissolved in 1,2-dichloroethane (8 ml) was added in a beaker-type (10 cm in height and 3 cm in diameter) undivided cell settled with two platinum foil electrodes (2×1.5 cm^2) and electrolyzed at 55 °C under a constant current (1.7 mA/cm^2) for 25 min (0.04 F/mol). Saturated $NaHCO_3$ was added to the electrolysis mixture. After evaporation of the solvent under reduced pressure, the residue was extracted with ether three times. The combined extracts were washed with brine, dried (Na_2SO_4), and concentrated *in vacuo*. The residue was chromatographed (SiO_2, hexane:AcOEt=20:1) to give **2a** as a mixture (476 mg, 95%, isomer ratio α:β:γ=86:9:5). The pure γ-isomer of **2a** was obtained by column chromatography, and β-isomer was recrystallized from a mixture of α- and β-isomers. The structures of α- and β-isomers were identified in comparison with the authentic samples.[2,3]

*1,1-Dimethyl-3-methylene-2-(phenylsulfonylmethyl)cyclohexane (γ-**2a**)*: bp 113—115 °C/1.9 Pa; IR (neat) 3060, 2930, 2860, 1645 (C=C), 1443, 1300 (SO_2), 1136 (SO_2), 910, 730 cm^{-1}; ^{1}H NMR ($CDCl_3$) δ 0.80 (s, 3H, CH_3), 0.92 (s, 3H, CH_3), 1.20—1.70 (m, 4H, CH_2), 2.02 (t, J=6 Hz, 2H, CH_2), 2.45 (dd, J_1=8.3 Hz, J_2=3.6 Hz, 1H, CH), 3.24 (dd, J_1=14.6 Hz, J_2=3.7 Hz, 1H, CH_2), 3.42 (dd, J_1=14.6 Hz, J_2=8.3 Hz, CH_2), 4.60 (br s, 1H, =CH_2), 4.77 (br s, 1H, CH_2), 7.50—8.10 (m, 5H, ArH). Found: C, 69.25; H, 8.13%. Calcd for $C_{16}H_{22}O_2S$: C, 69.03; H, 7.96%.

The authors are grateful to the Ministry of Education, Science, and Culture for a financial support by a Grant-in-Aid (No 57118002 and 59550596).

Reactions of Aromatic Azido, Azo, Azoxy, and Hydrazo Compounds with Diphosphorus Tetraiodide

Hitomi SUZUKI,* Hiroyuki TANI, and Shigeko ISHIDA
Department of Chemistry, Faculty of Science, Ehime University, Bunkyo-cho, Matsuyama 790
(Received February 16, 1985)

Synopsis. On treatment with diphosphorus tetraiodide in boiling benzene followed by aqueous work-up, the title nitrogen-containing compounds undergo a reductive cleavage of the nitrogen–nitrogen bond, giving the corresponding amines in low to good yields.

Diphosphorus tetraiodide (P_2I_4) is a long-known halogen derivative of diphosphine, but its potential as a reagent for organic synthesis has received attention only recently. It possesses a high affinity for oxygen and exhibits a unique ability to deoxygenate and dehydrate a variety of oxygen-containing functionalities.[1] As for the reaction of P_2I_4 with nitrogen-containing compounds, we have already reported the dehydration of aldoximes[2] and amides[3] to nitriles, coupling of carboxylic acids and amines into amides,[4] and dehydrative cyclization of 2-amino alcohols to aziridines.[5] In the present paper, we wish to report a new feature of this reagent to cleave the nitrogen–nitrogen bond of aromatic azido, azo, azoxy, and hydrazo compounds in a reductive way, giving the corresponding amines in various yields.

When heated with P_2I_4 in dry benzene for several hours under nitrogen, aryl azides lost a molecule of nitrogen and aqueous work-up of the reaction mixture afforded the corresponding aromatic amines in low to good yields. Aroyl and arenesulfonyl azides reacted similarly to give the respective amides. The results are summarized in Table 1.

$$\begin{matrix} ArN_3 \\ ArCON_3 \\ ArSO_2N_3 \end{matrix} \xrightarrow[2.\ H_2O]{1.\ P_2I_4/C_6H_6,\ \Delta} \begin{matrix} ArNH_2 \\ ArCONH_2 \\ ArSO_2NH_2 \end{matrix}$$

While aryl azides were smoothly converted to aromatic amines within a short reaction time under mild conditions, aroyl azides needed more time for complete conversion. 4-Methylbenzenesulfonyl azide was quite slow to be transformed into sulfonamide; even after 50 h refluxing in benzene, appreciable amounts of the substrate remained unchanged. In these reactions, hindered as well as functionalized azides could be reduced cleanly with moderate ease.

On a similar treatment with diphosphorus tetraiodide, azobenzene, azoxybenzene, and hydrazobenzene underwent a reductive cleavage of the nitrogen–nitrogen bond, giving aniline in *ca.* 30—40% yields. The reaction was accompanied by the extensive formation of as yet unidentified, powder-like substance of pale yellow color as a common by-product. The typical results are summarized in Table 1.

$$\begin{matrix} ArN{=}NAr \\ ArN{=}NAr \\ \downarrow O \\ ArNHNHAr \end{matrix} \xrightarrow[2.\ H_2O]{1.\ P_2I_4/C_6H_6,\ \Delta} ArNH_2$$

When these reactions were carried out in the presence of 4-methoxybenzoic acid or benzyl alcohol, the major products obtained were 4-methoxybenzanilide and *N*-benzylated aniline respectively.

$$C_6H_5N{=}NC_6H_5 + 4\text{-}CH_3OC_6H_4CO_2H \xrightarrow[2.\ H_2O]{1.\ P_2I_4/C_6H_6,\ \Delta,\ 5h} 4\text{-}CH_3OC_6H_4CONHPh \quad 56\%$$

$$C_6H_5N_3 + C_6H_5CH_2OH \xrightarrow[2.\ H_2O]{1.\ P_2I_4/C_6H_6,\ \Delta,\ 6h} C_6H_5NHCH_2C_6H_5 + C_6H_5N(CH_2C_6H_5)_2 \quad 54\% \quad 9\%$$

TABLE 1. REACTION OF AROMATIC AZIDO, AZO, AZOXY, AND HYDRAZO COMPOUNDS WITH DIPHOSPHORUS TETRAIODIDE

Substrate	Reaction time/h	Product	Yield/%[a]
Phenyl azide	5	Aniline	86[b]
4-Chlorophenyl azide	7	4-Chloroaniline	75
4-Methoxyphenyl azide	4	4-Methoxyaniline	13
4-Nitrophenyl azide	8	4-Nitroaniline	63
2-Methylphenyl azide	6	2-Methylaniline	45
4-Azidobiphenyl	10	4-Aminobiphenyl	53
2,6-Dimethylphenyl azide	11	2,6-Dimethylaniline	40
Benzoyl azide	4	Benzamide	61
4-Methoxybenzoyl azide	4	4-Methoxybenzamide	20
4-Nitrobenzoyl azide	6	4-Nitrobenzamide	53
4-Methylbenzenesulfonyl azide	50	4-Methylbenzenesulfonamide	57
Azobenzene	2	Aniline	27[b]
4,4'-Dichloroazobenzene	2	4-Chloroaniline	31[b]
Azoxybenzene	2	Aniline	28[b]
Hydrazobenzene	2	Aniline	41[b]

a) Yields were based on the isolated compounds and not optimized. All products are known and identified by comparison with authentic specimens. b) Yields were determined by GLC using $C_{14}H_{30}$ as internal standard.

The transformation of the title nitrogen-containing compounds into the corresponding amines may be easily accomplished by conventional methods based on the reduction with hydride reagents or catalytic hydrogenolysis. However, most of these methods are not compatible with compounds containing activated carbon–carbon multiple bond, carbonyl, ester, nitro, or cyano groups, to which P_2I_4 is known to be inert.

Although nothing can be said as yet about the scope and synthetic utility of the present reaction, one may expect its potential as a means for the selective reduction of azido, azo, azoxy, and hydrazo groups in the presence of other reducible functionalities. Reaction with aliphatic analogues has not been studied yet.

Experimental

Materials. Solvents were dried and distilled under nitrogen before use. Diphosphorus tetraiodide (P_2I_4) was prepared according to the previously reported procedure.[2,6] Thin layer chromatography was performed using Kieselgel 60 HF_{254} (Merck).

Reaction of Azides with P_2I_4. To a solution of aryl azide (aroyl azide or arenesulfonyl azide) (2.0 mmol) in dry benzene (20 ml) was added P_2I_4 (1.2 mmol) in one portion under nitrogen and the mixture was heated with stirring under a gentle reflux. The progress of the reaction was monitored by GLC. After appropriate hours, the reaction mixture was allowed to cool and 10% sodium carbonate solution was added. The organic phase was extracted with ether, dried over sodium sulfate, and evaporated to give the corresponding amine or amide.

Reaction of Azo, Azoxy, and Hydrazo Compounds with P_2I_4. Each of the above nitrogen-containing compounds (1.0 mmol) was dissolved in dry benzene (10 ml) containing tetradecane (1.0 mmol) as internal standard. P_2I_4 (1.2 mmol) was added to the solution and the resulting mixture was stirred under reflux for 2 h. As the reaction went on, a pale yellow powder-like substance gradually deposited on the wall of reaction vessel. It was almost insoluble in ordinary solvents. The reaction was quenched by the addition of 10% sodium carbonate solution and the organic phase was extracted with ether, dried over sodium sulfate and evaporated. The product yields were determined by GLC.

Reaction of P_2I_4 with Azobenzene and Aryl Azide in the Presence of Benzoic Acid or Benzyl Alcohol. To a solution of one of the above nitrogen-containing compounds (1.0 mmol) in dry benzene (10 ml) was added 4-methoxybenzoic acid (1.0 mmol) or benzyl alcohol (1.0 mmol) followed by P_2I_4 (1.2 mmol) and the resulting mixture was heated to reflux with stirring under nitrogen. After appropriate hours, the reaction was quenched by the addition of water and the reaction mixture was worked up as described above. Products were recrystallized from aqueous ethanol and identified by comparison with authentic samples.

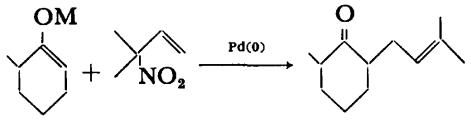
Regioselective Monoalkylation of Ketones with Allylic Nitro Compounds

Noboru ONO,* Isami HAMAMOTO, and Aritsune KAJI*
Department of Chemistry, Faculty of Science, Kyoto University, Kyoto 606
(Received February 18, 1985)

Synopsis. Lithium enolates from 2-methylcyclohexanone and *p*-methylacetophenone react with allylic nitro compounds in the presence of triethylborane (2 equiv) and $Pd(PPh_3)_4$ (5 mol%) to give monoallylated compounds regioselectively.

Palladium-catalyzed allylic alkylations are extremely useful synthetic reactions, with allylic acetates being among the most commonly used allylic compounds.[1] Recently, allylic nitro compounds have been demonstrated to react with stabilized nucleophiles such as carbanions from active methylene compounds, amines or sulfinate ions in a similar way.[2,3] In this paper we wish to report the allylic alkylation of allylic nitro compounds with the less stabilized nucleophiles such as enolates from ketones, which will expand the scope of the allylic alkylation.

The reaction of various enolates (**1**) from 2-methylcyclohexanone with 3-methyl-3-nitro-1-butene (**2**) was carried out under the conditions summarized in Table 1. The results are also summarized in this table.



(1)

1 **2** **3**

M = Li, Li + $2BEt_3$, ZnCl, MgCl, CdCl, $SnBu_3$, $SiMe_3$

The reaction of the lithium enolate with **2** did not give the allylated compound (**3**) in good yield even if a catalytic system [bis(dibenzylideneacetonato)palladium+1, 2-bis(diphenylphosphino)ethane, $Pd(dba)_2$-dppe] which allowed the alkylation of allylic acetates with lithium enolates[4] was used. However conversion of the counter cation from lithium to boron or zinc enhanced the reactivity of the present reaction.[5] Thus, 6-methyl-2-prenylcyclohexanone (**3**) was prepared in 62% or 45% yield by the reaction with the boron or zinc enolate, respectively, where the regiochemistry of the enolate was preserved and the nucleophile attacked at the less hindered site predominantly.[6] Although enol stannates are reported to be reactive to palladium-catalyzed reaction of allylic acetates,[7] they are inert to **2**.[8] *p*-Methylacetophenone (**4**) was also monoalkylated to give **5** and **5'** in the similar way. (Eq. 2).

a) A: $Pd(PPh_3)_4$ (5 mol%) B: $Pd(dba)_2$+dppe (3 mol%). b) Yields were determined by GLC. c) Isolated yields.
All reactions were carried out at room temperature for 20 h in dry THF.

Although compounds **3** and **5** can be prepared by the reaction of the corresponding acetate, the use of allylic nitro compounds as allylic electrophiles has also its own merits over the conventional alkylating agents. Allylic nitro compounds can be prepared by different methods from those for preparation of other alkylating agents.[2,3] Furthermore, electrophiles can be introduced regioselectively at the α-position of the nitro compounds. For example, 2-nitro-2-butene (**5**) was readily converted into allylic nitro compound (**6**) by very simple procedures as shown in Eq. 3, where the isomerization of **5** and the Michael addition of the resultant allylic nitro compound to methyl acrylate took place simultaneously. Alkylation of **1** with **6** gave the monoalkylated product, **7**, in good yield.[9]

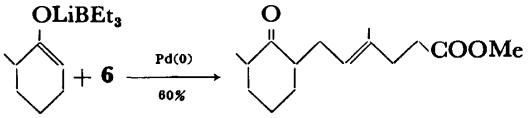
5 **6**



(4)

7

Introduction of a vinyl group to nitroalkanes also provides a useful method for the preparation of allylic nitro compounds.[2] Ethyl 2-methyl-2-nitro-3-butenoate (**9**) was prepared by this procedure. Alkylation of **4** with **9** gave the monoalkylated compound, **10**, in 65% yield with high regio-and stereoselectivity. The products **5** and **10** are good precursors of terpenoids such as curcumene and dehydrolancenol, respectively.

Experimental

Preparation of Allylic Nitro Compounds. Allylic nitro compounds, **2**[9] and **9** were prepared by the Michael addition of the corresponding nitro compounds to phenyl vinyl sulfoxide and the subsequent termolysis.[2,10] **9**: IR (neat) 1340, 1540, 1730 cm^{-1}, NMR ($CDCl_3$) δ 1.36 (3H, t, J=8 Hz), 1.84 (3H, s), 4.22 (2H, q, J=8 Hz), 5.30 (1H, d, J=10 Hz), 6.28 (1H, dd, J=10 and 17 Hz). 4-Methyl-4-nitro-5-hexenoate (**6**) was prepared as follows: A solution of 2-nitro-2-butene (**5**, 1.01 g, 10 mmol), methyl acrylate (1.03 g, 12 mmol) and tetramethylguanidine (0.233 g, 2 mmol) in 10 ml of acetonitrile was kept at room temperature for 24 h. The reaction mixture was poured into water and extracted with diethyl ether. The usual work-up followed by distillation with Kugelrohr gave **6**, 1.31 g (70%), bp 150 °C/1 mmHg (1 mmHg=133.322 Pa). IR (neat) 1370, 1535, 1720 cm^{-1}, NMR ($CDCl_3$) δ 1.64 (3H, s), 2.26 (4H, m), 3.60 (3H, s), 5.20 (1H, d, J=17 Hz), 5.24 (1H, d, J=10 Hz), 6.12 (1H, dd, J=17 and 10 Hz). Found: C, 51.28; H, 6.99; N, 7.48. Calcd for $C_8H_{13}NO_4$: C, 51.32; H, 6.94; N, 7.48.

Reaction of 2-Methylcyclohexanone with 2. Preparation of 3: The lithium enolate of 2-methylcyclohexanone was prepared according to the literature[5] by using *n*-BuLi (1.6 M (1 M=1 mol dm^{-3}) in hexane, 0.683 ml, 1.1 mmol), diisopropylamine (0.11 g, 1.1 mmol) and THF (3 ml). Triethylborane (1 M in hexane, 2 ml) was added to the lithium enolate at −75 °C and stirred for 35 min at this temperature. To the above solution was added a solution of **2** (0.115 g, 1 mmol) and $Pd(PPh_3)_4$ (0.058 g, 0.05 mmol) in THF (1 ml). The reaction mixture was warmed to room temperature and stirred for 20 h, then worked up in the usual way after destroying Et_3B by adding 3 M NaOH (1 ml) and H_2O_2 (30%, 0.5 ml). Pure **3** was isolated by column chromatography (silica gel/benzene–hexane), 0.11 g (62%). IR (neat) 1700 cm^{-1}, NMR ($CDCl_3$) δ 0.98, 1.05 (3H, d, J=7 Hz), 1.2—1.6 (10H, m), 1.60 (3H, s), 1.68 (3H, s), 4.9—5.2 (m, 1H). The ratio of **3**/other isomers was determined by GLC to be 98/2. The spectral data were in good agreement with those of the literature.[5] Other metal enolates were preapard according to the literature[5] and the reaction of them with **2** was carried out in the same way. The yield of **3** was determined by GLC or isolation of pure product. Following compounds were prepared by this procedure.

5: The reaction starting from *p*-methylacetophenone (0.403 g, 3 mmol) gave the mixture of **5** and **5′** (0.35 g, 58%), bp 120—130 °C/1 mmHg. IR (neat) 1700 cm^{-1}, NMR ($CDCl_3$) δ 1.60 (3H, s), 1.64 (3H, s), 2.36 (3H, s), 2.42 (2H, t, J=8 Hz), 2.92 (2H, m), 5.0—5.3 (1H, m), 7.2 (2H, m), 7.8 (2H, m). The regio isomer **5′**; NMR ($CDCl_3$) δ 1.16 (6H, s), 2.36 (3H, s), 2.4 (2H, s), 4.8—5.1 (2H, m), 5.8—6.2 (1H, m), 7.2 (2H, m), 7.8 (2H, m). MS of **5**+**5′**, Found: m/z 202.1348. Calcd for $C_{14}H_{18}O$: M, 202.1295.

7: The reaction using 2-methylcyclohexanone (0.336 g, 3 mmol) gave **7**, 0.455 g (60%). IR (neat) 1710, 1720 cm^{-1}, NMR ($CDCl_3$) δ 0.98, 1.04 (3H, d, J=8 Hz), 1.60, 1.64 (3H, s), 1.2—2.6 (14H, m), 3.65, 3.67 (3H, s), 5.0—5.4 (1H, m). This is the mixture of the cis and trans 2,6-isomers whose ratio is about 65/35 by GLC and NMR. Although exact ratio of *E/Z* was not determined, the *E*-isomer was predominant. Found: 252.1712. Calcd for $C_{15}H_{24}O_3$: M, 252.1724.

10: The reaction in 3 mmol scale gave **10**, 0.51 g (65%). IR (neat) 1690, 1710 cm^{-1}, NMR ($CDCl_3$) δ 1.22 (3H, t, J=8 Hz), 1.85 (3H, s), 2.38 (3H, s), 2.46 (2H, q, J=8 Hz), 3.00 (2H, t, J=8 Hz), 4.20 (2H, q, J=8 Hz), 6.82 (1H, t, J=8 Hz), 7.22 (2H, m), 7.80 (2H, m). Found: 260.1423. Calcd for $C_{16}H_{20}O_3$: 260.1411.

The *E/Z* ratio was determined by GLC and NMR to be 95/5.

5) E. Negishi and R. A. John, *J. Org. Chem.*, **48**, 4098 (1983), in which similar tendency of the rate enhancement of the reaction with allylic acetates was reported. It is not clear about the structure of the enolate formed by the addition of triethylborane to the lithium enolate, but transmetallation from lithium to boron should occur to some extent.

6) The regiochemistry of the present reaction is affected by mainly two factors, steric and electronic effects. Secondary ketones gave only γ-substitition product as in Eq. 1 and primary ketones gave some amounts of α-substitution product as in Eq 2. This selectivity in the present reaction is higher than that in the reaction with stabilized nucleophiles.[2,3]

7) B. M. Trost and E. Keinan, *Tetrahedron Lett.*, **21**, 2591 (1980).

8) This difference may be due to the difference of catalytic spieces between the reaction of allylic nitro coompounds and allylic acetates. The catalysis in the former reaction involves the nitro group which deactivates the reaction with enol stannates.

9) Allylic alkylation of allylic nitro compounds with enolates of ketones is limited to tretiary nitro compounds. For example, the reaction of **1** with primary or secondary allylic nitro compounds resulted in recovery of 2-methylcyclohexanone.

Abnormal Methyl Radicals on Alumina Surfaces

John David BARNES, Mahendra Aruind TRIVEDI, Duro Abimbola ODUWOLE, and Barrie WISEALL
Department of Chemistry, City of London Polytechnic, Jewry Street, London EC3N 2EY.
†*Department of Chemistry, Queen Mary College, Mile End Road, London El 4NS.*
(Received April 17, 1984)

Synopsis. The ESR spectrum of abnormal methyl radicals on alumina surfaces is found to be symmetrical at low surface coverages. Possible mechanisms for the formation of these radicals are presented.

Fujieda *et al.*[1] have interpreted the ESR spectra of methyl radicals produced by the photolysis of methane adsorbed on alumina surfaces as indicating that the three methyl protons are not equivalent and that one is interacting more strongly with the surface than the other two. In an earlier paper[2] concerned with the stabilisation of abnormal methyl radicals (Me_{ab}) on silica gel surfaces we suggested that this observation was due to concentration effects arising from the relatively high surface coverages employed and that strongly caged adsorbate molecules are precursors of the abnormal radical. The present study examines this problem in more detail and suggests a possible mechanism for the production of Me_{ab}.

Chromatographic grade neutral activated alumina powder, Brockmann grade 1, was obtained from British Drug House (BDH). Prior to sample preparation, alumina powder was heated in air at 537 K to oxidize and remove any organic impurities; it was then dehydrated at a predetermined temperature (T_d) for 4 h *in vacuo*. Excess iodomethane was adsorbed onto the surface at room temperature and the sample pumped off for 1 h. The samples were sealed in Vitreosil/Pyrex ESR cells as previously described.[3-6] Methyl radicals were produced by UV photolysis at 77 K using a medium pressure Hanovia lamp. ESR measurements were made on a Decca X-3 spectrometer employing a microwave frequency of 9270.28±0.01 MHz with a reflection cavity fitted with a proton resonance probe for field determination and modulated at 100 kHz.

A preliminary study showed that Me_{ab} radicals could be obtained only from strongly pumped off alumina samples prepared above a T_d of 673 K and were not stable above 77 K. Contrary to the observation of Fujieda, the Me_{ab} radical ESR spectrum was found to be symmetrical with approximate line intensities of 1:5:5.5:1 and line widths of 0.211, 0.143, 0.132, and 0.198 mT respectively from low to high field. The Me_{ab} radical concentration at first increased with photolysis time but eventually attained a steady state. The yield as a function of T_d is shown in Fig. 1 and confirms that these radicals are not produced on samples prepared below a T_d of 673 K even after prolonged photolysis. Their absence may be attributed either to the lack of sites of stabilization for the radicals and/or to the lack of sites of absorption for the iodmethane. Since molecular water remains strongly adsorbed onto alumina surfaces up to 573 K,[7,8] it is possible that at the lower temperature iodomethane molecules cannot be strongly adsorbed in the first step and are completely removed in the pump-off process. The Me_{ab} radical

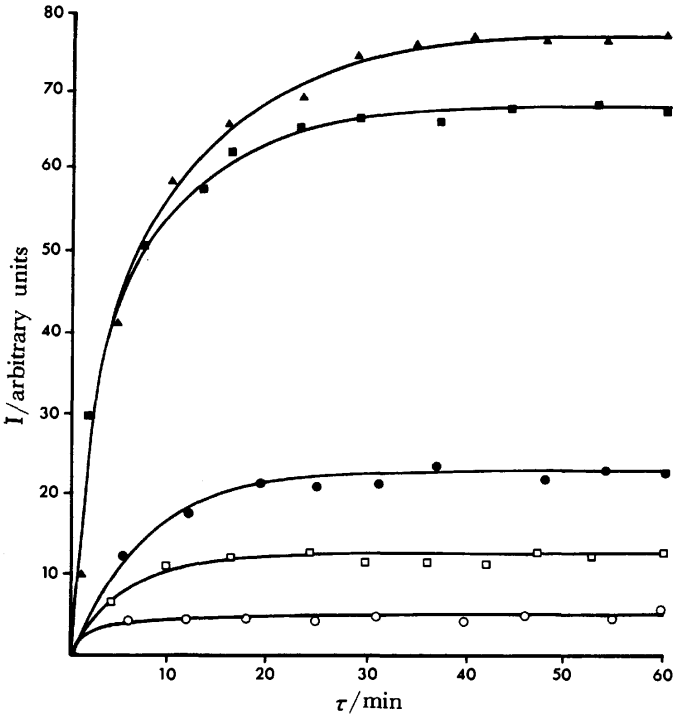

Fig. 1. The yield of abnormal methyl radicals at 77 K on alumina surfaces pretreated at various temperatures. I is the integrated signal intensity of the low field line in the methyl radical spectrum and τ is the photlysis time.
T_d; ■: 1173 K, ▲: 1073 K, ●: 973 K, □: 873 K, ○: 773 K.

yield increased with T_d from 673 K to 1073 K and then decreased at 1173 K. On increasing the T_d abve 673 K, although the surface hydroxyls which are thought to be the sites of adsorption may decrease[9] the surface sites of stabilisation would increase and result in a higher concentration of Me_{ab} radicals. However, at 1173 K, bulk movement in the alumina matrix may result in the sintering of pore walls, a reduction in pore volume and a large reduction in surface area which must reduce the number of sites of stabilization.

The formation of Me_{ab} radicals on alumina surfaces can be accounted for in two ways. The first involves the sites of adsorption and it is suggested that iodomethane is more strongly adsorbed by those surface hydroxyls remaining on the surface. The stronger adsorption may result in a change of planar methyl in iodomethane to nonplanar methyl, which on UV photolysis yields Me_{ab} radicals. If this was true, then since alumina surfaces have at least 5 different types of surface hydroxyl group[7] it should be possible to observe 5 different types of Me_{ab} radical and to vary their relative concentrations with T_d.

The second and more likely possibility involves the sites of stabilization of the radical once formed. Normal methyl radicals (Me_n, a=2.3 mT) produced

during photolysis stabilise upon electron deficient aluminium ions exposed during dehydration of the surface to exhibit a single Me_{ab} radical spectrum (a =2.08 mT). The attraction of the unpaired electron of the Me_n radical closer to the site of stabilisation, effectively changes the ESR characteristics of the methyl radical spectrum. Support for this mechanism is found in the work of Fujita *et al.*[10] who suggest that a reduction in the hyperfine splitting constant indicates charge transfer to the environment.

The production of Me_{ab} may be represented schematically as:

Preparation of Hexafluorodisilane and Reactions of Hexafluorodisilane and Hexachlorodisilane with Sulfur Trioxide

Bettadapura Srinivasaiah SURESH and Doddaballapur Krishnamurthy PADMA*

Department of Inorganic and Physical Chemistry, Indian Institute of Science, Bangalore 5600 12, India

(Received July 15, 1983)

Synopsis. Hexafluorodisilane has been prepared by the fluorination of hexachlorodisilane or hexabromodisilane by potassium fluoride in boiling acetonitrile, in yields approximating 45 and 60% respectively. Hexafluorodisilane has been characterised by infrared spectral data, vapour density measurements and analytical data. Both hexafluorodisilane and hexachlorodisilane are found to react with sulfur trioxide when heated to 400 °C for 12 h. The products of reaction are silicon tetrafluoride, silica and sulfur dioxide with hexafluorodisilane while hexachlorodisilane in addition gives rise to hexachlorodisiloxane.

The chemistry of hexahalodisilanes is interesting because of the presence of Si–Si bond and Si–X (halogen) bond which can undergo oxidation and cleavage. The bond energy of Si–Si bond is relatively weak when compared to C–C bond and therefore it undergoes homolytic cleavage on application of thermal energy. However, the Si–Si bond is thermodynamically favoured to undergo oxidation and this happens in reactions involving phosphine and phosphetane oxides[1,2] as well as phosphine sulfides.[3] In these cases, the hexachlorodisilane gets oxidised to hexachlorodisiloxane in the case of the oxides and to hexachlorodisilathiane with the sulfides. Therefore, it was of interest to see the action of sulfur trioxide on hexafluorodisilane and hexachlorodisilane.

In the reported methods for the preparation of Si_2F_6[4,5] disproportionation occurs and the product is contaminated with mixed halide fluorides. In the present modified procedure, based on the synthetic procedures evolved in this laboratory,[6,7] wherein the hexachlorodisilane or hexabromodisilane is treated with potassium fluoride in boiling acetonitrile, considerable improvement in the yields and purity are noted. Hexachlorodisilane and hexabromodisilane are prepared by standard methods.[8,9] The procedural details of preparation of Si_2F_6 and the reaction of sulphur trioxide on these hexahalodisilanes are given below.

Experimental

A Preparation of Hexafluorodisilane (Si_2F_6). Hexachlorodisilane (≈12.0 g) or hexabromodisilane (≈24 g), prepared and purified by standard methods,[8,9] is dissolved in 1,2-dichloroethane (20 ml) and added dropwise to a suspension of potassium fluoride (finely ground and dried at 110 °C in vacuum for 20 h) in boiling acetonitrile held in a three necked flask provided with a dropper, reflux condenser (with an outlet for the evolved gas) and a nitrogen inlet. The exit of the condenser is connected to two traps T_1 and T_2 maintained at −40 °C and liquid nitrogen temperature respectively. The addition is done slowly (about 2 h) and then the contents of the flask are allowed to reflux for a further period of 30 min in a slow stream of nitrogen. At the end of this period, heating and nitrogen flow are stopped, trap T_2 containing the solidified product gas is disconnected from the assembly. The uncondensable gases are removed at the pump and the solid is then allowed to sublime into a previously evacuated dry glass globe.

The infrared spectrum of the gaseous sample was recorded and the impurities SiF_4 and HCl were removed by low temperature fractional distillation (sublimation point of SiF_4=−95.7 °C, boiling point of HCl=−85 °C and of Si_2F_6=−18.4 °C). The infrared spectrum of the purified sample exhibits all the reported bands[10] of Si_2F_6 along with an absorption band at 1030 cm^{-1} characteristic of SiF_4, is as following, Observed: 420 (s), 440 (m), 520 (w), 740 (w), 840 (s), 850 (vs), 860 (s), 875 (m), 910 (w), 975—1010 (vvs, br) 1030 (SiF_4), 1060 (w), 1180 (m). (The intensities of the absorption bands are given in parentheses; vvs=very very strong, vs=very strong, s=strong, m=medium, w=weak and br=broad). The sample is found to contain more than 90% of Si_2F_6, remaining being SiF_4 as impurity as seen from the gas density measurements and chemical analysis. The compound; preparation mode (a) Si_2Cl_6 (b) Si_2Br_6; vapour density (reported, found); chemical analysis (Si(%): calcd, found, F(%): calcd, found); purity and yields are given below. a) Si_2F_6; Si_2Cl_6 and KF; (7.74,[4] 7.30); (33.01, 32.41; 66.99, 67.59),>90%; ≈45%. b) Si_2F_6; Si_2Br_6 and KF; (7.75,[4] 7.39); (33.01, 32.59, 66.99, 67.40); >93%; ≈60%. The yield of hexafluorodisilane is found to be approximately 45% with hexachlorodisilane and 60% with hexabromodisilane. This increase in yield can be attributed to the decreased bond energy of Si–Br bond compared to Si–Cl bond.

B. Reaction of Hexafluorodisilane with Sulfur Trioxide. Hexafluorodisilane (≈0.200 g, ≈1.1 m moles) containing some silicon tetrafluoride (≈10%) is condensed in a reaction vessel cooled by liquid nitrogen. Sulfur trioxide (≈0.240 g, 3.0 m moles) is condensed on to this and the reactant gases allowed to attain room temperature by withdrawing the coolant. At room temperature for 12 h no reaction occurred. Even at 300 °C the infrared spectrum shows only the reactants. The contents of the reaction vessel are then heated to 400 °C for 12 h. A white solid deposit is observed at the bottom and sides of the reaction vessel. The gas-phase infrared spectrum shows complete absence of the absorption bands of hexafluorodisilane and presence of enhanced absorption bands of SO_2,[11] 520 (s), 1150 (s), 1360 (vs), and SiF_4,[12] 1030 (s). The spectrum also shows the absence of any other compound such as hexafluorodisiloxane and sulfuryl fluoride.

The white solid in the reaction vessel is found to be silica by infrared spectroscopy. This is further confirmed by chemical tests. The solid dissolves rapidly in aqueous hydrofluoric acid to give fluorosilicic acid. The latter is identified by the formation of a white precipitate (K_2SiF_6) when potassium chloride solution is added.

C. Reaction of Hexachlorodisilane with Sulfur Trioxide. Sulfur trioxide (≈0.240 g; ≈3.0 m mole) is taken in an evacuated reaction vessel. Into this hexachlorodisilane (≈0.538 g, ≈2.0 m moles) is condensed and then the reactants are brought to room temperature. As the condensed hexachlorodisilane melts it dissolves in sulfur trioxide to form a clear colourless liquid. This is kept for 12 h at room temperature and the gas phase infrared spectrum is taken

which shows unreacted hexachlorodisilane. This is the case up to 300 °C. The reactants are then heated at 400 °C for 12 h. The infrared spectrum of the gaseous products now show the presence of hexachlorodisiloxane, sulfur dioxide and silicon tetrachloride. Sulfur dioxide and silicon tetrachloride are removed from the reaction mixture by low temperature fractional distillation. The gas phase infrared spectrum of the remaining products in the reaction vessel show the presence of only hexachlorodisiloxane,[13] 480 (s), 640 (vs), 1130 (vs), and complete absence of hexachlorodisilane.[14] The volatile hexachlorodisiloxane is removed from the reaction vessel by slow pumping till the gas phase does not show any absorption bands. It is observed that no other nonvolatile higher polychlorosiloxanes are present in the reaction vessel, except a white solid deposit at the bottom of the reaction vessel. The solid is found to be silica.

It is important to mention that these compounds are moisture sensitive and strictly anhydrous conditions have to be maintained.

The experimental results indicate that Si_2F_6 has been prepared in improved yields and greater purity. Mixed halides of silicon are not produced.

Both hexafluoro- and hexachloro-disilane have been found to undergo complete reaction with sulfur trioxide at 400 °C in 12 h. The products of reaction with Si_2F_6 are silicon tetrafluoride, sulfur dioxide and silica while hexachlorodisilane in addition gives rise to hexachlorosiloxane. With hexachlorodisilane some oxidation of the Si–Si bond occurs to form siloxane (Si–O–Si) linkage. However, with hexafluorodisilane no such oxidation is observed possibly because the nucleophilic attack on silicon by oxygen through a barrier of highly electronegative fluorine atoms occurs less predominantly at 400 °C and cleavage takes an upper hand. It has also been shown in the present investigation that higher molecular weight polysiloxanes, whose formation requires radical type cleavage and recombination, are not formed. This observation suggests the formation of the products *via* cleavage and disproportionation in both the cases.

Interaction between 1,1′-Biacenaphthene-2,2′-diyl and Dibromomethane. Decay Kinetics in Mixed Solvents

Harumichi KOBASHI* and Hiroshi MASAMOTO
Department of Chemistry, Faculty of Engineering Gunma University, Kiryu, Gunma 376
(Received December 17, 1984)

Interaction of the triplet biradical, 1,1′-biacenaphthene-2,2′-diyl (BR) with dibromomethane has been examined by means of transient absorption measurements and kinetic analysis. The absorption spectrum of BR in CH_2Br_2 shows a red shift compared with those in other solvents with various polarities. The spectral result indicates that the red shift is not due to effect of solvent polarity but due to existence of weak electronic interaction acting directly between BR and CH_2Br_2. The nonlinear dependence of decay rates of BR upon $[CH_2Br_2]$ is interpreted in terms of a simple kinetic model of solvation based on solvent replacement between cage and bulk.

In a previous paper, it was reported that BR interacts with halogenated compounds to cause intersystem crossing (ISC) through spin-orbit (SO) interaction enhanced by heavy atoms, prior to chemical reactions.[1] At the same time, a complex formation

BR

between BR and the quencher C_2H_5I was suggested from a result of only kinetic analysis for decay rates of BR as a function of $[C_2H_5I]$. However, no spectroscopic evidence for the complex formation was obtained, because the intensity of BR absorption became too weak to observe the spectrum of the complex with increasing the quencher concentration. For the type II biradicals, on the other hand, it has been considered that a complex formation does not contribute to the enhancement of ISC induced by di-*t*-butyl nitroxide or oxygen through spin-spin interaction.[2] BR has two aromatic rings which are apt to form electron donor-acceptor (EDA) complexes with several quenchers. Therefore, in order to elucidate the decay behavior of BR, it will be important to examine whether direct electronic interaction concerns the biradical decay or not.

In this paper we examine in detail the interaction between BR and CH_2Br_2 in the wide range of $[CH_2Br_2]$, since the decay time of BR lies in a measurable time range of our experimental apparatus even in neat solvent of CH_2Br_2. Results give spectral evidence for the existence of an electronic interaction different from solvent polarity effect. In addition, a simple solvation model is proposed for interpreting the decay rates as a function of $[CH_2Br_2]$.

Experimental

The transient absorption spectra were observed by means of a 347 nm ruby-laser photolysis at room temperature.[3] For kinetic analysis, the decay times of BR were measured at several temperatures controlled by circulating thermostated water into a cell holder.

trans-Dimer of acenaphthylene (t-D) as a source material of BR was synthesized and purified by the same methods as described before.[3] Commercially available dibromomethane (Wako, GR grade) was taken out from an ampoule and immediately used without further purification. Zone-refined benzophenone (BP) was used as a triplet sensitizer. The concentrations of t-D and BP were both *ca.* 4×10^{-3} M (1 M=1 mol dm^{-3}). All solutions were degassed by the freeze-pump-thaw method.

Results and Discussion

Figure 1 shows time-resolved absorption spectra obtained for the BP-t-D system in several solvents, where the absorbances in the wavelength region $\leq$400 nm observed at the earlier time after excitation are omitted for simplicity. The initially observed absorptions at 530 nm and around 450 nm are due to ^{3}BP and ^{3}t-D, respectively.[3] After disappearance of ^{3}BP and ^{3}t-D, BR exhibits characteristic absorption bands at 379±1 nm in toluene (dielectric constant at 20 °C: ε=2.38), pyridine (ε=13.23), chlorobenzene (ε=5.71), and dichloromethane (ε=9.14) as well as in benzene (ε=2.28), dichloromethane, and 1,4-dioxane (ε=2.29) reported previously.[1,3] Although no spectra are given here, BR also shows the absorption maxima at 379±1 nm both in 1,2-dichloroethane (ε=10.66) and bromobenzene (ε=5.39). In dibromomethane solvent (ε=7.04), however, the absorption of BR is red-shifted by *ca.* 5 nm (Fig. 1(5)). Then, it is clear that the red shift is not due to the effect of solvent polarity but due to a weak electronic interaction between BR and CH_2Br_2. An origin of the interaction is probably charge-transfer (CT) interaction as in the systems of anthracene–CCl_4 and *etc.*[4] The quenching of BR by CH_2Br_2 in both CH_2Cl_2 and C_6H_6 were followed by lifetime measurements at 380 nm over the wide range of $[CH_2Br_2]$. Figure 2 shows the Stern-Volmer plots in C_6H_6. Each quenching curve bends downward similar to that by C_2H_5I in C_6H_6 but the deviation from a straight line is remarkable only in

much higher concentration region for the quencher CH_2Br_2 than for C_2H_5I. In the present case, therefore, an influence of change of medium properties by the addition of CH_2Br_2 could not be neglected for analyzing the quenching curve. Then, it is supposed that a complex formation is unrealistic, although the curvatures fit fairly well to Eq. 4 in Ref. 1 based on the complex formation mechanism. In order to obtain a more precise information about this circumstance, highly resolved absorption spectra around 380 nm were measured in mixed solvents of CH_2Cl_2 plus CH_2Br_2 and C_6H_6 plus CH_2Br_2 as well as in CH_2Cl_2, C_6H_6, and CH_2Br_2. The results are given in Fig. 3. The spectrum of BR shows gradual red-shift with increasing $[CH_2Br_2]$ in each solvent system (CH_2Cl_2 or C_6H_6). But, no spectrum with two absorption peaks indicating firmly the simultaneous existence of both free and complexed BR was observed in the mixed solvents of any composition of CH_2Br_2 so far as we examined (at 3, 5, and 10 M of CH_2Br_2). Hence, it seems plausible to consider that the red shift and nonlinear quenching curves are due to a

continuous change of properties of medium surrounding BR but not due to formation of a complex with fixed geometry and stoichiometry.

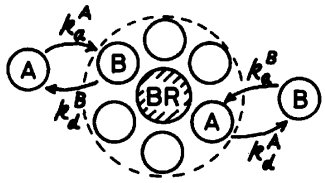
Then, we employ a simple solvation model developed below for analyzing the decay behavior of BR in the mixed solvents. We assume the following conditions in the model: (i) The decay rate constant of BR (τ^{-1}) is determined by the composition of a solvent cage surrounding BR, as expressed by Eq. 1.

$$\tau^{-1} = \theta_A\tau_A^{-1} + \theta_B\tau_B^{-1} \quad (1)$$

where τ_A and τ_B are the lifetimes of BR in neat solvent A and B, respectively and θ_A and θ_B denote the mole fractions of component solvents A and B, respectively, in the solvent cage. Namely, Eq. 1 indicates the additivity between τ_A^{-1} and τ_B^{-1}. (ii) The solvent composition of the cage is proportional to that of the bulk solution in an equilibrium state of solvation;

$$\theta_A/\theta_B = K(\chi_A/\chi_B), \quad (2)$$

where χ_A and χ_B are the mole fractions of A and B, respectively, in the bulk solution and K is the proportionality constant. Equation 2 can be derived by assuming a solvent replacement between one component molecule (A or B) in the solvent cage and another component one (B or A) in the bulk. This situation is schematically shown as follows:



where k_a^i and k_d^i are the rate constants of solvation (or association) to BR and escape (or dissociation) from the cage, respectively, for i-th component molecule. When the equilibrium as to the solvent replacement is attained, the rate of solvation will be equal to the rate of escape for each component under the given conditions; *i.e.*, $k_a^A\theta_B[A]=k_d^A\theta_A[B]$ or $k_d^B\theta_B[A]=k_a^B\theta_A[B]$. These two equations are rearranged to Eq. 3;

$$\frac{\theta_A}{\theta_B} = \frac{k_a^A}{k_d^A}\cdot\frac{\chi_A}{\chi_B} = \frac{k_d^B}{k_a^B}\cdot\frac{\chi_A}{\chi_B}. \quad (3)$$

Therefore, K in Eq. 2 is equal to k_a^A/k_d^A or k_d^B/k_a^B. By combining Eq. 1 with Eq. 2 using the relations $\theta_A+\theta_B=1$ and $\chi_A+\chi_B=1$, one can obtain Eq. 4,

$$\frac{1}{\tau} = \frac{1}{\tau_B} + \frac{K\chi_A}{1+(K-1)\chi_A}\left(\frac{1}{\tau_A}-\frac{1}{\tau_B}\right). \quad (4)$$

Equation 4 shows that τ^{-1} is a nonlinear function of χ_A, involving only one unknown parameter K if τ_A and τ_B values are known. Rearrangement of Eq. 4 yields the following linear expressions with respect to $X(\equiv\chi_A/\chi_B)$, which are mathematically equivalent to one another.

$$(\tau^{-1}-\tau_B^{-1})^{-1} = (\tau_A^{-1}-\tau_B^{-1})^{-1}\{1+(KX)^{-1}\} \quad (5)$$

$$X^{-1}(\tau^{-1}-\tau_B^{-1}) = K(\tau_A^{-1}-\tau^{-1}) \quad (6)$$

$$X(\tau^{-1}-\tau_B^{-1})^{-1} = (\tau_A^{-1}-\tau_B^{-1})^{-1}(X+K^{-1}) \quad (7)$$

Equation 5 is identical in form to those derived by Ketelaar *et al.* for analyzing EDA complex formation[5] and by Ware *et al.* for exciplex formation.[6] Equation 6 is formally identical to those employed by Foster *et al.* for EDA complex systems[7] and by Rayner and Wyatt for an acid-base equilibrium in the excited state.[8] Equation 7 has also the same form as that described by Scott for EDA complexes.[9] These equations are very useful, since they do not need the knowledge about τ_A value.

Here, we analyze the decay times of BR using Eqs. 5, 6, and 7, because we can estimate the lifetime of BR in neat CH_2Br_2 simultaneously with K.[10] It was found that the observed lifetimes (τ) in the solvent systems of CH_2Br_2 (component A)/C_6H_6 (component B) and CH_2Br_2 (A)/CH_2Cl_2 (B) follow the relations, Eqs. 5, 6, and 7 with correlation factors better than those in the complex formation model. The results obtained for the CH_2Br_2/C_6H_6 mixture are shown in Fig. 4. By using the method of weighted least square,[11] each K and τ_A values obtained from these plots are, as a matter of course, in agreement with one another. Table 1 lists the parameter values obtained at several temperatures. According to the van't Hoff equation, the temperature dependence of K yields ΔH (-6.4 ± 1.1 kJ mol^{-1}) and ΔS (-14 ± 4 J mol^{-1} K^{-1}) for the solvation of CH_2Br_2 in the place of C_6H_6. In the CH_2Br_2 (A)/CH_2Cl_2 (B) mixture, K and τ_A values were also estimated to be 2.5 ± 0.2 and 70 ± 6 ns respectively at 20 °C.

The estimated τ_A values for both solvent systems agree with each other and are in fair agreement with the observed τ_A (84 ± 3 ns at 25 °C).[12] Therefore, the kinetic model used here is consistent. The small values of ΔH and ΔS seem to support that this model is more appropriate than the (1:1) complex forma-

Table 1. K and τ_A (in ns) values in the CH_2Br_2(A)/C_6H_6(B) system at several temperatures (t in °C)

t	K	τ_A
15	2.6 ± 0.3	71 ± 8
25	2.6 ± 0.5	64 ± 10
35	2.2 ± 0.5	62 ± 11
45	2.0 ± 0.5	60 ± 10
55	1.9 ± 0.5	58 ± 13

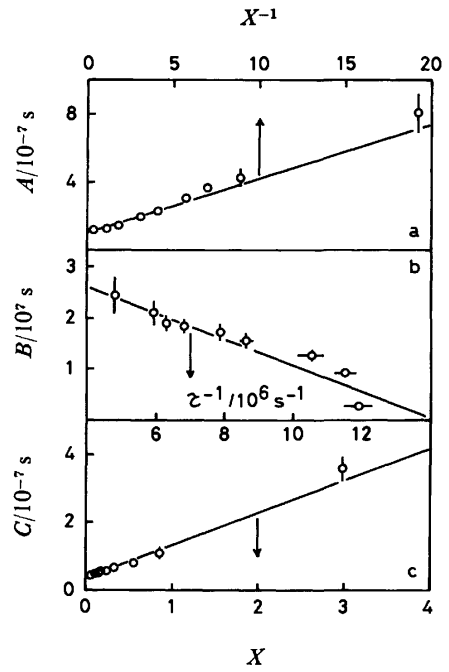


Fig. 4. Plots of the relations corresponding to Eqs. 5, 6, and 7 for the CH_2Br_2/C_6H_6 system at 15 °C. The abbreviated functions in the ordinate:
(a) $A=(\tau^{-1}-\tau_0^{-1})^{-1}$; (b) $B=X^{-1}(\tau^{-1}-\tau_0^{-1})$;
(c) $C=X(\tau^{-1}-\tau_0^{-1})^{-1}$.

tion model which, in most cases, accompanies rather large values of ΔH(*ca.* 20 kJ mol^{-1}) and ΔS(*ca.* 40 J K^{-1} mol^{-1}).[7] It is then implied that BR is likely to be solvated by CH_2Br_2 approximately 2.5 times stronger than by C_6H_6 or CH_2Cl_2, since K is *ca.* 2.5 in both solvent systems at ordinary temperatures. A different approach to solvation has been done for fluorescence frequency shift and quenching in mixed solvents by Lippert and Moll[13] and Kokubun[14] based on the Langmuir adsorption isotherm. They derived a kinetic equation which has also the same form as the present Eq. 5, if ψ or [Q] in their expression is replaced by X.

It should be noted further that a change in hydrodynamic properties of solvent mixtures is not negligible when the viscosity and molecular volume of A are largely different from those of B. If K is replaced by $(\eta_A V_A/\eta_B V_B)\exp \gamma_A$, Eq. 4 becomes identical to the expression derived by Stevens *et al.* based on the cage displacement model.[15] Here, η_i and V_i are the viscosity coefficient and the molecular volume of i-th component solvent, respectively, and γ_A is the index of preferential solvation of A in place of B. In the present cases, $\eta_A V_A/\eta_B V_B=1.26$ for A=CH_2Br_2 and B=C_6H_6 at 25 °C and $\eta_A V_A/\eta_B V_B=2.53$ for A=CH_2Br_2 and B=CH_2Cl_2 at 20 °C. By using these values, $\gamma_A=0.72$ for the CH_2Br_2/C_6H_6 system and $\gamma_A=-0.011$ for the CH_2Br_2/CH_2Cl_2 system are obtained. Accordingly, the preferential solvation by CH_2Br_2 should be taken into account for the BR quenching in the CH_2Br_2/C_6H_6 system and need not almost completely for that in the CH_2Br_2/CH_2Cl_2 system, in addition to the change of hydrodynamic properties.

As for BR decay, an important fact is that there exists the direct electronic interaction between BR and CH_2Br_2, which is able to cause the red shift of the BR spectrum but not so strong as a complex formation is confirmed spectroscopically. In conclusion, it is considered that the BR quenching is enhanced by SO interaction[1] perturbed by the weak electronic interaction, probably CT interaction, between BR and CH_2Br_2 in the solvent cage.

One of the authors (H.K.) expresses his thanks to Prof. Hiroshi Kokubun at Tohoku University for valuable suggestions in setting the kinetic model and to Prof. Haruo Shizuka at this laboratory for kind advice.

X-Ray Photoelectron Diffraction (XPED) Studies on Metal Oxide Surfaces. (I) Analysis of the XPED Patterns from TiO_2(001) and α-Al_2O_3(0001) by the Single Scattering Calculation

Koji TAMURA,* Masanori OWARI, Masahiro KUDO, and Yoshimasa NIHEI
Institute of Industrial Science, University of Tokyo,

(Received January 5, 1985)

X-Ray photoelectron diffraction (XPED) measurements were applied to the (001) surface of TiO_2 rutile and the (0001) surface of α-Al_2O_3 in order to examine the applicability of XPED to metal oxides. Obtained XPED patterns were compared with the results of theoretical calculations based on a single scattering model. The calculated patterns from both oxides agreed with the experimental patterns. It was revealed from theoretical calculations that the four oxygen atoms in the unit cell of TiO_2 made different contributions to the XPED pattern which reflected different atomic environments. The same calculation was also made on titanium in TiO_2, and on aluminum and oxygen in Al_2O_3. This clarified the contributions of nonequivalent sites of emitter atoms to the main peaks in the experimental XPED patterns. In comparison with the crystal structures, some peaks could be attributed to some specific emitters or specific emitter-scatterer pairs. This analysis was found to be useful to interpret experimental XPED patterns, and is expected to be applied to the analysis of the structures of surfaces or interfaces related to such phenomena as selective desorption or substitution of specific site of atoms.

It is known that angular distributions of XPS intensities from single crystals exhibit fine structures [1—4]. This modulation of photoelectron intensities is caused by the diffraction effect of photoelectrons excited in a single crystal by X-ray radiation, and is called X-ray photoelectron diffraction (XPED). Since XPED patterns reflect atomic arrangements, structural information regarding material can be obtained from an XPED measurement. The information derived from an XPED measurement can be summarized as 1) symmetry and orientation of the crystal surface [5,6], 2) atomic sites in the crystal [7—12], 3) crystal regularity [5,13], and 4) adsorption structure [14—16]. The influence of crystal symmetry and orientation on the XPED patterns have been investigated in detail by the present authors using GaAs(110) and Ge(110) [6]. The knowledge obtained in that study was then used to characterize such systems as the epitaxially grown Au overlayers on the GaAs(110) surface [5].

The XPED studies on a compound mixed crystal $Ga_{1-x}Al_xAs$ [9] showed correspondence between XPED patterns and the sites of photoelectron emitter atoms in the crystal, which indicated that XPED patterns can be regarded as finger prints of atomic sites. This method, therefore, can be used to determine the atomic sites of the foreign atoms in the crystal surface layers [11,12]. In the case of Au/GaSb interface [7], it was concluded that gold atoms occupy the equivalent atomic sites to gallium atoms.

XPED can further be used to estimate the crystal structural regularity. For example, measurements on the ion-bombarded GaAs(110) surface [5] made it possible to evaluate the crystal regularity and the thickness of the disordered layers in the surface region.

XPED can also provide information about the adsorption structure on the surface. The adsorption site of oxygen on the O/c(2×2)Cu(001) [14,15] and the bond orientation of adsorbed CO on the CO/Ni-(001) [16] have been reported.

The purpose of this study is to apply XPED to metal oxides and to investigate their surface structures. Metal oxides are used in many fields as solar cells, sensors, electronic devices, catalysts, absorbents and substrates for crystal growth. It is, therefore, very important to sufficiently characterize the surface structure and the chemical state of the oxide in order to control and reproduce their properties.

In general, in order to obtain structural information regarding the crystal surface, low energy electron diffraction (LEED) or reflection high energy electron diffraction (RHEED) have been used. However, in the case of the metal oxide, these conventional diffraction methods cannot be effectively used due to several reasons. First, they cannot distinguish the contribution from each component. This means that they are not suitable for the analysis of the complicated changes which occur on such samples as metal oxides. Secondly, these metal oxides suffer from severe charge-up problems because of irradiation of high-density primary electron beams. Thirdly, they generally require rather long-range ordering to obtain explicit diffraction patterns.

On the other hand, XPED does not have these drawbacks. Therefore, it can be expected that by using this new method, useful information can be provided regarding the surface structures of metal oxides.

In this study, the XPED patterns for metal oxides were obtained and compared with the results of theoretical calculations. The metal oxides selected for this study were the (001) surface of TiO_2 rutile and the (0001) surface of α-Al_2O_3, which are of great importance in connection with catalysts and have been investigated by many other methods [17—19].

Experimental

Apparatus. All experiments were performed with an angle-resolved X-ray photoelectron spectrometer [6,20] with an aperture in front of the entrance lens of the hemispherical analyzer in order to restrict the solid angle of photoelectron detection. The position-sensitive detection system compensates for the reduced photoelectron intensity due to the restriction of the solid angle. The angular scans were automatically performed using a two-axis sample rotation manipulator. The direction of the normal of the surface was defined as a polar angle of θ=0°, and the direction parallel to the surface was θ=90° [10]. The mean divergence of the acceptance angle was 1.3° along the polar-angle scan and 2.0° perpendicular to the polar-angle scan. The pressure during all measurements was kept below 5×10^{-9} Torr†. Al $K\alpha$ radiation was used to excite photoelectrons.

Samples. A (001) oriented TiO_2 single crystal (10×10×1 mm; Murakami Engineering Co. Ltd) was mechanically polished using a diamond polishing powder. A (0001) oriented Al_2O_3 single crystal (8×9×0.5 mm; Kyoto Ceramic Co. Ltd) had been polished beforehand. Both samples were chemically etched in HCl and in NaOH, and were thoroughly rinsed with distilled water. Before measurements, both samples were annealed in vacuum at 773 K for 50 min and at 823 K for 20 min, respectively, to reduce contaminations. It was confirmed by XPS that there were no carbon nor other impurities after the surface cleaning. Although a slight charge-up effect was observed on both samples, it did not cause any problems on the XPS spectrum shape and intensity.

Results and Discussion

TiO_2(001). (a) XPED Patterns from Oxygen Atoms: The azimuthal dependences of Ols emission from TiO_2(001) are shown in Fig. 1(a). The crystal structure of TiO_2 rutile [21] is also shown as the inset in Fig. 1. The polar angle θ=39° was chosen since the preliminary polar dependence measurement at ϕ=45° showed an intensity maximum at around θ=39°. As for the azimuthal angle, ϕ=0° is defined on the (010) plane and was determined by considering the symmetry property of the crystal. As can be seen in this XPED pattern, the photoelectron intensity maxima were observed at ϕ=0° (This angle is equivalent to 90° by the symmetry of the crystal.) and at ϕ=45°. The peaks at ϕ=45° are relatively sharp, whereas the peaks at ϕ=0° and 90° are broad. The results of the theoretical calculations based on the single scattering model [22] are also shown in Fig. 1(b) as a comparison with those obtained from the experiments. Although the relative intensities of peaks are somewhat different, the calculated XPED pattern reproduces the features of the experimental XPED pattern very well.

There are four kinds of atomic sites which are occupied by oxygen atoms in the unit cell of the TiO_2 crystal, as is shown in Fig. 1. Generally, the atomic arrangements surrounding these oxygen atoms are not equivalent to each other on the occasion of the photoelectron diffraction, though

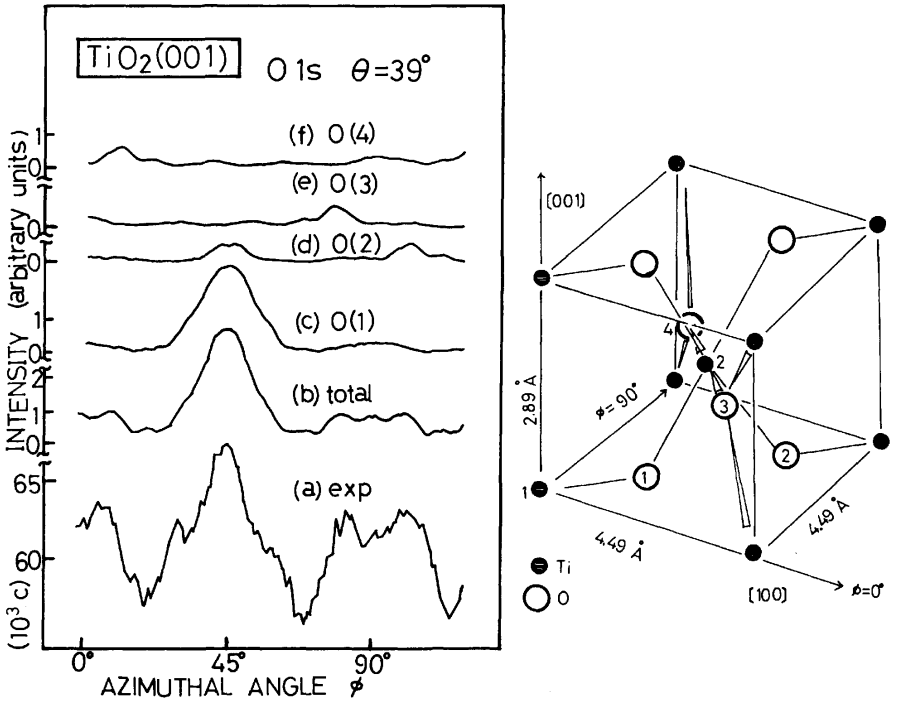

Fig. 1. XPED patterns of Ols from TiO_2(001) and crystal structure. (a) Experimental pattern. (b) Total calculated pattern. (c)—(f) Calculated patterns for each site of oxygen atom.

† 1 Torr ≈ 133.322 Pa.

these four sites become equivalent by rotating the arrangements by some multiples of 90°. As an XPED pattern is known to vary according to the environment of the photoelectron emitter atom, each XPED pattern from nonequivalent atomic sites should be different. An experimentally observed pattern is regarded as the sum of each pattern, and the contribution of each site can not be decomposed. On the other hand, in the theoretical calculation, XPED patterns from these four atomic sites can be individually obtained. The calculated XPED patterns from oxygen atoms in the different sites are shown in Fig. 1 (c—f). The four oxygen atomic sites O(1)—O(4) indicated for each pattern correspond to those shown in the crystal structure.

By comparing the individual calculated patterns with the total calculated pattern (b), it is easily understood that the peak at an azimuthal angle ϕ=45° is mainly due to the photoelectrons from oxygen atom O(1) and slightly to those from the oxygen atom O(2), and also understood that no contribution is made by the oxygen atom O(3) or O(4) at this angle. A similar comparison is also possible for other peaks. The peak at ϕ=12° was revealed to be constructed due to the contribution of oxygen atom O(4), and the peak at ϕ=78° by oxygen atom O(3).

The peak at ϕ=45° will be discussed in more detail in order to understand the origin of this peak. It is known that strongly peaked forward scattering is dominant in the scattering of electrons in metals with kinetic energies about 1000 eV [23,24]. The cause for this effect is that the magnitude of the atomic-scattering factor $f_j(\theta_j)$ is very strongly peaked in the forward direction, and that in this direction the scattering phase shift is rather small. The calculated polar dependence of Ols emission from oxygen atom O(1) at ϕ=45° showed an intensity maximum at θ=39°. This direction (θ,ϕ)=(39°,45°) is almost the same as that of the vector O(1)→Ti(2) in TiO_2. Taking all these facts into account, it is concluded that the experimental peak at ϕ=45° in the azimuthal pattern (Fig. 1(a)) originates mainly from the forward scattering of photoelectrons from the oxygen atom O(1) by the titanium atom Ti(2).

(b) XPED Patterns from Titanium Atoms: In Fig. 2 the azimuthal dependences of Ti2p emission at polar angle θ=39° are shown for TiO_2(001). As is seen in the experimentally obtained XPED pattern (Fig. 2 (a)), there are sharp and strong peaks at ϕ=0° and ϕ=±45°. The results of calculations are also shown in Fig. 2 (b) and they reproduce the features and the relative intensities of the experimental XPED patterns very well. In a TiO_2 crystal, these are two nonequivalent Ti atomic sites as are shown in Fig. 1. The calculated XPED patterns for each site of titanium atom are also shown in Fig. 2 (c—d). It is evident from these results that both emitter atoms Ti(1) and Ti(2) significantly contribute to all of the main peaks at ϕ=0° and ϕ=±45°, which is different

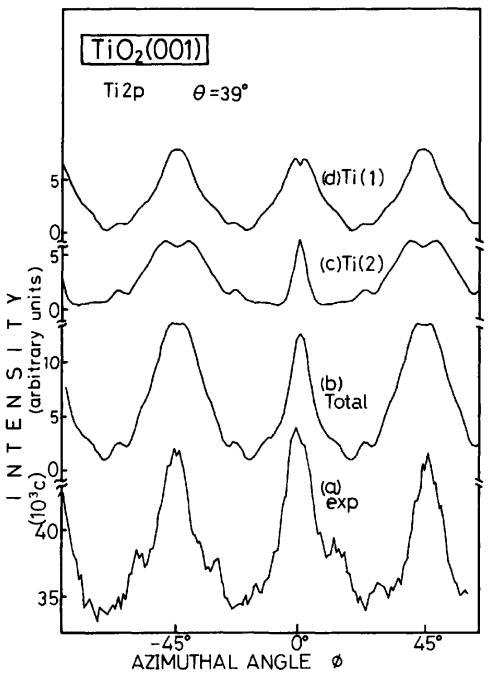

Fig. 2. XPED patterns of Ti2p from TiO_2(001). (a) Experimental pattern. (b) Total calculated pattern. (c), (d) Calculated patterns for each site of titanium atom.

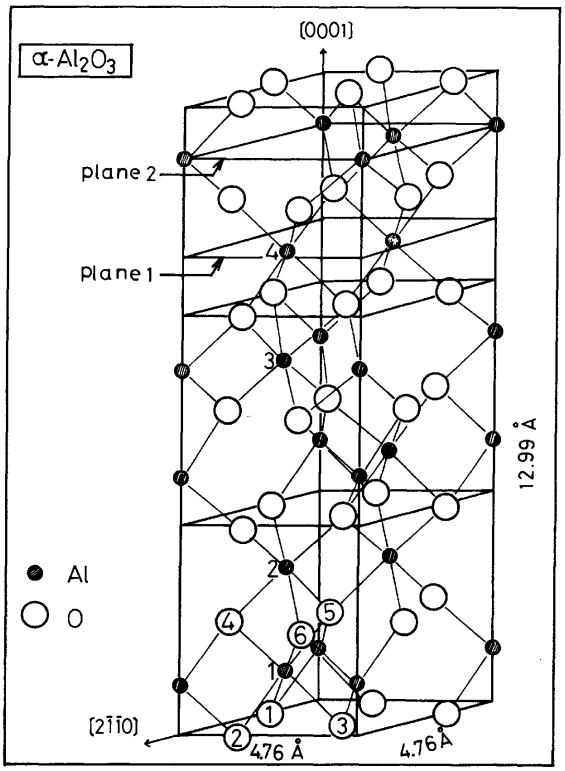

Fig. 3. Crystal structure model of α-Al_2O_3.

from the case of oxygen.

$Al_2O_3(0001)$. (a) XPED Patterns from Aluminum Atoms: The crystal structure of α-Al_2O_3 is shown in Fig. 3. The atomic positions of aluminum atoms and oxygen atoms in the hexagonal unit cell of α-Al_2O_3 were calculated from the results of X-ray diffraction measurement [25]. In an α-Al_2O_3 crystal, aluminum atoms are displaced about 0.2 Å upward or downward from the ideal plane along the c-axis. This displacement was taken into account in the theoretical calculation. On the other hand, the displacement of oxygen atoms in the c-plane was neglected. The azimuthal dependences of Al2s emission at polar angle θ=50° relative to surface normal are shown in Fig. 4. In the experimental XPED pattern (a), there are six peaks at −90°, −60°, −30°, 0°, 30°, 60°, whose shapes and relative intensities are not equal each other. Because of the symmetry of the crystal, ϕ=−90° is equivalent to ϕ=30°. In this figure, azimuthal angle ϕ=0° was on the (01$\bar{1}$0) plane of the hexagonal system. The result of the theoretical calculations is also shown in Fig. 4 (b). Though only single scattering was taken into account, the calculated results agreed well with the experimental results.

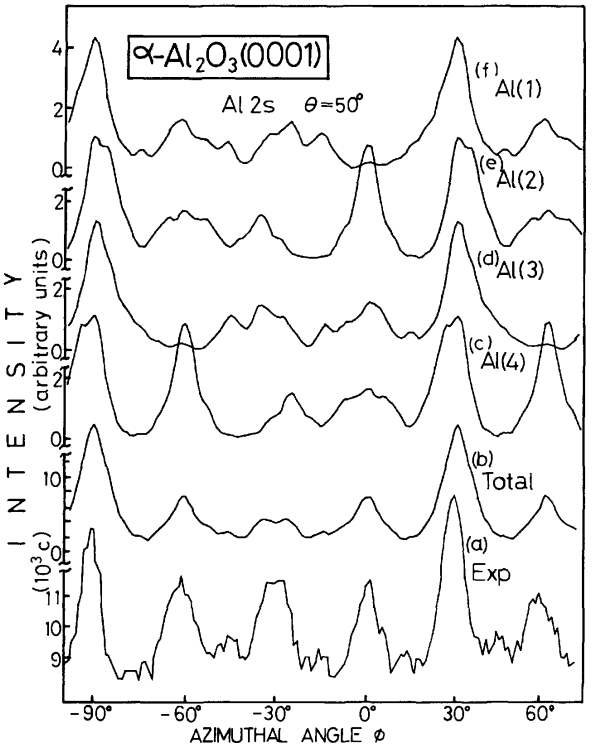

Fig. 4. XPED patterns of Al2s from α-Al_2O_3(0001). (a) Experimental pattern. (b) Total calculated pattern. (c)—(f) Calculated patterns for each site of aluminum atom.

There are four nonequivalent Al atomic sites in an α-Al_2O_3 crystal which are denoted as Al(1)—Al(4) as are shown in Fig. 3. Calculated XPED patterns for these four aluminum atoms are shown as Fig. 4(c)—(f), respectively. By comparing these calculated XPED patterns with the experimental pattern, it is easily seen how each peak in the experimental XPED pattern is constructed. The peak at ϕ=30° is constructed by the contribution of all four emitter atoms and this peak becomes rather a strong one. On the other hand, the peak at ϕ=0° is constructed mainly by the contribution of emitter atom Al(2) and the peak at ϕ=−60° is constructed mainly by the contribution of emitter atom Al(4), and these two peaks become relatively weak.

It is interesting to note the peak at ϕ=−30°. The

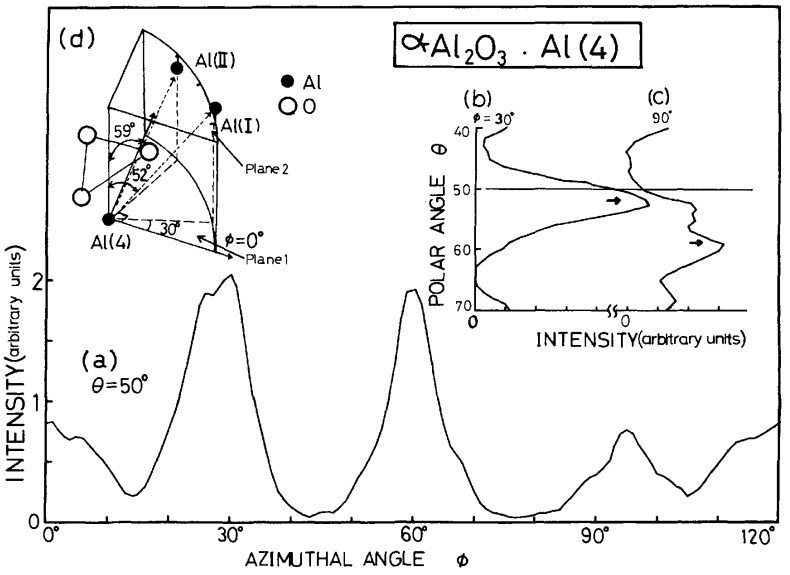

Fig. 5. XPED patterns calculated for aluminum atom Al(4) in α-Al_2O_3. (a) Azimuthal dependences. (b), (c) Polar dependences. (d) Atomic arrangement.

experimentally obtained peak is symmetrical and the top of the peak is flat. The comparison with each calculated pattern revealed that all four emitter atoms contribute to this peak and that the peak positions of each pattern deviated from $\phi=-30°$ to a higher or lower azimuthal angle. The peak shapes of patterns due to aluminum atoms Al(1) and Al(3) or due to aluminum atoms Al(2) and Al(4) are in the relation of a mirror symmetry about $\phi=-30°$. Thus, the total shape of these four patterns becomes a symmetrical one.

The relation between the direction from the emitter atom to the scatterer atom and the XPED pattern is discussed below by use of aluminum atom Al(4) (as an example). Figure 5 shows the calculated results for aluminum atom Al(4) and its atomic environment. The bottom curve (a) shows the azimuthal dependence at $\theta=50°$, and in the upper right, the polar dependences at some azimuthal angles are shown (b—c). In the same figure, some of the surrounding atoms of the emitter atom are also illustrated (d) where the emitter atom Al(4) is on a plane 1, and the scatterer atoms Al(I) and Al(II) are located almost on a plane 2. More strictly, the aluminum atom Al(I) displaces upward and Al(II) downward from a plane 2, as was mentioned before (also see Fig. 3). In the azimuthal dependence (a), there is a strong peak at $\phi=30°$, and this azimuthal

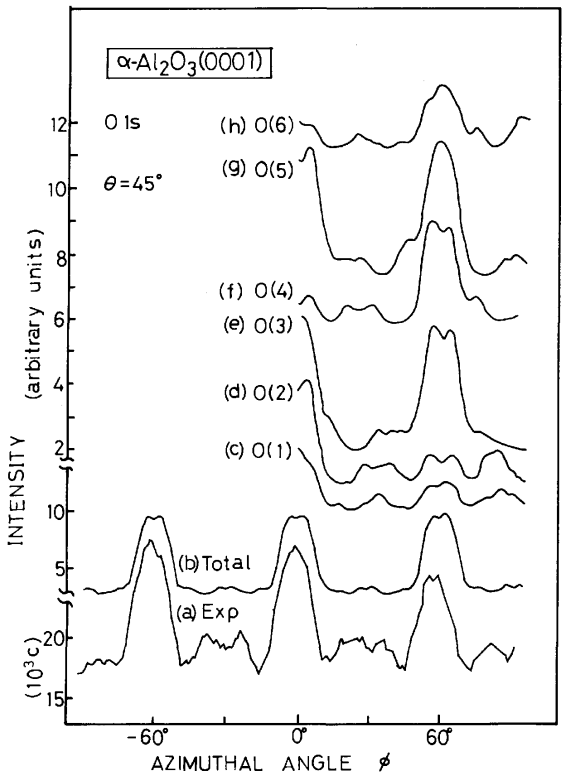

Fig. 6. XPED patterns of O1s from α-Al_2O_3 (0001). (a) Experimental pattern. (b) Total calculated pattern. (c)—(h) Calculated patterns for each site of oxygen atom.

direction is the direction from emitter atom Al(4) to the scatterer atom Al(I). The polar dependence at $\phi=30°$ (Fig. 5(b)) shows the peak at $\theta=52°$. This direction $(\theta,\phi)=(52°,30°)$ coincides with the direction from emitter Al(4) to scatterer Al(I). From this fact, the peak in curve (a) at $\phi=30°$ can be attributed to the forward-scattering peak by the emitter Al(4) and the scatterer Al(I).

On the other hand the shoulder at $\phi=90°$ in curve (a) has a different character. As shown in (d), the azimuthal angle $\phi=90°$ corresponds to the direction from Al(4) to Al(II). The polar angle of this direction is 59°, which leads to the appearance of a peak at $\theta=59°$ in the polar dependence curve (c). From this analysis it is understood that the small hump at $\phi=90°$ in the curve (a) at $\theta=50°$ is just the skirt of the forward-scattering peak which arises from the combination of the emitter Al(4) and the scatterer Al(II).

(b) XPED Patterns from Oxygen Atoms: Azimuthal dependences of O1s emission from α-Al_2O(0001) at polar angle $\theta=45°$ are shown in Fig. 6. As seen in this figure, strong peaks were found at $\phi=0°$, and $\phi=\pm60°$. The results of the theoretical calculations are also shown in Fig. 6(b). The comparison between these results showed that each main peak in the experimental pattern was reproduced by theoretical calculations. For the oxygen atoms in an α-Al_2O_3 crystal, there are six nonequivalent atomic sites, and these six atomic sites O(1)—O(6) correspond to those shown in Fig. 3. The calculated patterns obtained from each emitter atom O(1)—O(6) are shown in Fig. 6(c—h). It is evident that the main peaks in the experimental pattern are constructed by the contributions of some specific emitters.

As shown above, clear XPED patterns for the constituent elements on the metal oxide surfaces were obtained on which structural analysis is generally not easy because of the charge-up problem. A calculation based on the single scattering model explains the experimental results. It is found that the comparison of the total XPED pattern with each pattern from nonequivalent sites of atoms clarified the origin of XPED patterns. Therefore, such a comparison is useful in interpreting the experimental XPED patterns, and some main peaks were, for example, interpreted as the forward-scattering peaks from a specific emitter atoms by the surrounding scatterer atoms. When selective substitution or desorption takes place, some of the peaks in the experimental XPED patterns which are related to the specific sites of atoms appear and/or disappear. It is expected that the XPED analysis can be applied to the characterization of the surface or interface resulting from the reaction on the metal oxide surface. This is very difficult or impossible to be analyzed by other techniques.

The Curve Fitting Analysis of D.c. and A.c. Voltammograms of a Two-step Surface-redox Reaction. The Application to the Surface-redox System of Adriamycin Adsorbed on a Pyrolytic Graphite Electrode

Kenji KANO, Tomonori KONSE, and Tanekazu KUBOTA*
Gifu Pharmaceutical University, 6-1 Mitahora-higashi 5-Chome, Gifu 502
(Received February 21, 1985)

A theoretical study of the two-step surface-redox reaction ($O_{ad}+n_1e \rightleftharpoons S_{ad}$, $S_{ad}+n_2e \rightleftharpoons R_{ad}$) was performed using d.c. voltammetry. A new method based on a non-linear least-squares curve fitting of cyclic d.c. and a.c. voltammograms was proposed for determining electrochemical parameters and was successfully applied to the surface-redox system of the quinone moiety of adriamycin adsorbed on a pyrolytic graphite electrode.

Recently, research regarding redox modified electrodes has been a very active field in electrochemistry and a wealth of reports have been published concerning applications to electroanalysis, electrocatalysis, and electrochromic devices (for reviews, see Refs. 1—3). In order to analyze the electrochemical behavior of surface-attached redox materials associated with biological, pharmaceutical, and chemical fields, a two-step electron-transfer surface-redox reaction mechanism seems to be very important. Numerous studies have been carried out regarding this type of electrode reaction.[4-8] However, there is little literature pertinent to the kinetic treatment of this mechanism. Kakutani and Senda have recently reported a theory of the a.c. polarization and a.c. voltammetry of the mechanism[7] and showed that a.c. voltammetry is a powerful technique for determining electrochemical kinetic parameters.[8] Alternatively, cyclic d.c. voltammetry has been widely used for the characterization of the electrochemical behavior of a modified electrode.[1-3] Analyses regarding cyclic d.c. voltammetry are, thus, very important. As far as we know, however, theoretical studies of cyclic d.c. voltammetry regarding two-step surface-redox reactions are limited to an electrochemically reversible system[4,6,7] and also to a reversible electrochemical reactions coupled with irreversible chemical reactions.[4]

In this paper, we report on a theoretical study regarding a two-step surface-redox reaction in d.c. voltammetry and also a useful method for the analysis of cyclic d.c. and a.c. voltammograms by means of non-linear least-squares curve fitting for determining the electrochemical kinetic parameters. The application of our methods to a surface-redox system of adriamycin (antitumor anthracycline antibiotics) adsorbed on a pyrolytic graphite electrode is discussed in detail.

Theoretical Treatment of D.c. Voltammetry for the Case of Two-step Surface-redox Reaction

Let us now consider a two-step surface-redox reaction:

$$\begin{aligned} O_{ad} + n_1e &\rightleftharpoons S_{ad} \quad \text{(1st step)} \\ S_{ad} + n_2e &\rightleftharpoons R_{ad} \quad \text{(2nd step)}, \end{aligned} \tag{1}$$

where all the electrochemical species (O, S, and R) are strongly adsorbed on the electrode surface. The quantities of O, S, and R due to a mass transfer from (to) the electrode surface to (from) the solution are negligibly small compared with those of the adsorbed reactants. Thus,

$$\Gamma_o + \Gamma_s + \Gamma_r = \Gamma_t = \text{const.} \tag{2}$$

Here Γ_j (j=o, s, or r) is the surface concentration of the adsorbed reactant j per unit area, and Γ_t is the total surface concentration. For the above system, theoretical studies of the reversible d.c.[4,6,7] and a.c.[7] voltammetries have already been reported. Our formulation for Scheme (1) is therefore for the d.c. voltammogram of a quasi-reversible case.

Assuming that the surface-redox reaction occurs only among the adsorbed reactants, the faradaic current, i, is given by

$$i = i(1) + i(2) \tag{3a}$$

$$i(1) = n_1FA\,d\Gamma_o/dt \tag{3b}$$

$$i(2) = -n_2FA\,d\Gamma_r/dt, \tag{3c}$$

where $i(1)$ and $i(2)$ are the faradaic currents of the first and second electron-transfer steps, respectively, and A is the electrode area. The electrode potential, E, can now be written as

$$E = E_i + vt, \tag{4}$$

E_i and v being the initial potential and the sweep rate, respectively. The current-potential-surface

concentration characteristics can, thus, be expressed by the Butler-Volmer equation:[1,7,9]

$$i(1) = n_1FAk_{sap}(1)\{\Gamma_s \exp[(1-\alpha_1)n_1F(E-E'_{o1})/RT] - \Gamma_o \exp[-\alpha_1 n_1F(E-E'_{o1})/RT]\} \quad (5a)$$

$$i(2) = n_2FAk_{sap}(2)\{\Gamma_r \exp[(1-\alpha_2)n_2F(E-E'_{o2})/RT] - \Gamma_s \exp[-\alpha_2 n_2F(E-E'_{o2})/RT]\}. \quad (5b)$$

In these equations, $k_{sap}(1)$ and $k_{sap}(2)$ are, respectively, the apparent rate constants of the first and second steps at the formal standard redox potentials, E'_{o1} and E'_{o2}, corresponding to the redox couples O_{ad}/S_{ad} and S_{ad}/R_{ad}. The transfer coefficient with regard to the (cathodic) electron-transfer of the j-th step is expressed by α_j (j=1 or 2).

Combination of Eqs. 2 to 5 may lead to current potential characteristics for linear potential sweep voltammetry. Assuming $n_1=n_2=n$ (for convenience), we define the semiquinone formation constant, K, as follows:

$$K = [S_{ad}]^2/[O_{ad}][R_{ad}] = \exp[nF(E'_{o1}-E'_{o2})/RT]. \quad (6)$$

Differential equations (as dimensionless functions) are easily written as Eqs. 7a and 7b using the above equations,

$$\psi(1) = i(1)RT/n^2F^2vA\Gamma_t = m(1)[(1-f_o-f_r)(\rho/\sqrt{K})^{1-\alpha_1} - f_o(\rho/\sqrt{K})^{-\alpha_1}] = df_o/d\rho \quad (7a)$$

$$\psi(2) = i(2)RT/n^2F^2vA\Gamma_t = m(2)[f_r(\rho\sqrt{K})^{1-\alpha_2} - (1-f_o-f_r)(\rho\sqrt{K})^{-\alpha_2}] = -df_r/d\rho, \quad (7b)$$

the current being defined by

$$\psi = iRT/n^2F^2vA\Gamma_t = \psi(1) + \psi(2), \quad (7c)$$

where

$$f_j = \Gamma_j/\Gamma_t \quad (j=o, r) \quad (8a)$$

$$m(j) = k_{sap}(j)RT/nFv \quad (j=1, 2) \quad (8b)$$

$$\rho = \exp[nF(E-E'_o)/RT]. \quad (8c)$$

Here $E'_o(=(E'_{o1}+E'_{o2})/2)$ is the formal standard redox potential of the redox couple O_{ad}/R_{ad}. Other symbols have their usual meanings. Solving Eqs. 7a and 7b, we obtain values for f_o and f_r. Thus, ψ can be calculated using Eq. 7c where $\psi(1)$ and $\psi(2)$ are easily evaluated by introducing f_o and f_r into the original Eqs. 7a and 7b.

Two sets of the differential Eqs. 7a and 7b were solved using a standard fourth-order Runge-Kutta method.[10] The initial conditions are $f_o=0$ and $f_r=1$ at $\rho\to 0$ for the anodic curve, and $f_o=1$ and $f_r=0$ at $\rho\to\infty$ for the cathodic curve. The calculation was carried out with an NEC 8001 personal computer.[11]

Let us also assume that the adsorbed reactants undergo homogeneous intermolecular interactions (written by Frumkin's a-parameter[12]). Thus, E'_{o1}, E'_{o2}, $k_{sap}(1)$, and $k_{sap}(2)$ are now given by[7]

$$E'_{o1} = E_{o1} + (RT/n_1F)\ln[B_s(1)/B_o(1)] \quad (9a)$$

$$E'_{o2} = E_{o2} + (RT/n_2F)\ln[B_r(2)/B_s(2)] \quad (9b)$$

$$k_{sap}(1) = k_s(1)B_o(1)^{\alpha_1-1}B_s(1)^{-\alpha_1}\exp(-a\theta) \quad (10a)$$

$$k_{sap}(2) = k_s(2)B_s(2)^{\alpha_2-1}B_r(2)^{-\alpha_2}\exp(-a\theta). \quad (10b)$$

In these equations, $B_j(1)$ and $B_j(2)$ (j=o, s, or r) are the adsorption coefficients of the species j at E_{o1} and E_{o2}, respectively. The E_{o1} and E_{o2} stand for the standard redox potentials of the redox couples O/S and S/R in the bulk solution, respectively, θ being the total surface coverage (Γ_t/Γ_t^{max}; Γ_t^{max} is the maximum value of the total surface concentration). Note that when $k_{sap}(1)=k_{sap}(2)=k_{sap}$, the k_{sap} dependence on θ is given by

$$k_{sap} = k_{sap}(\theta\to 0)\exp(-a\theta), \quad (10c)$$

where $k_{sap}(\theta\to 0)$ means k_{sap} at $\theta\to 0$.

Figure 1 shows the m ($=m(1)=m(2)$) dependence of the normalized anodic voltammograms at K=1 and α ($=\alpha_1=\alpha_2$)=0.5. There is a positive shift of the peak potential, $E_{p,a}$, with decreasing m. Figure 2 depicts the K dependence of the normalized voltammograms under the conditions of m=0.5 and α=0.5. As in the case of a reversible system[4,7] there is only one peak

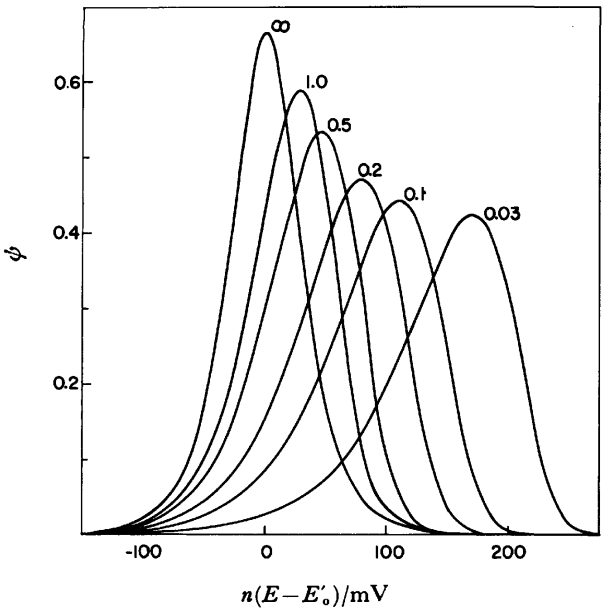

Fig. 1. The dependence of m on the normarized d.c. anodic voltammograms at K=1.0 and α=0.5. The m value is indicated on each curve.

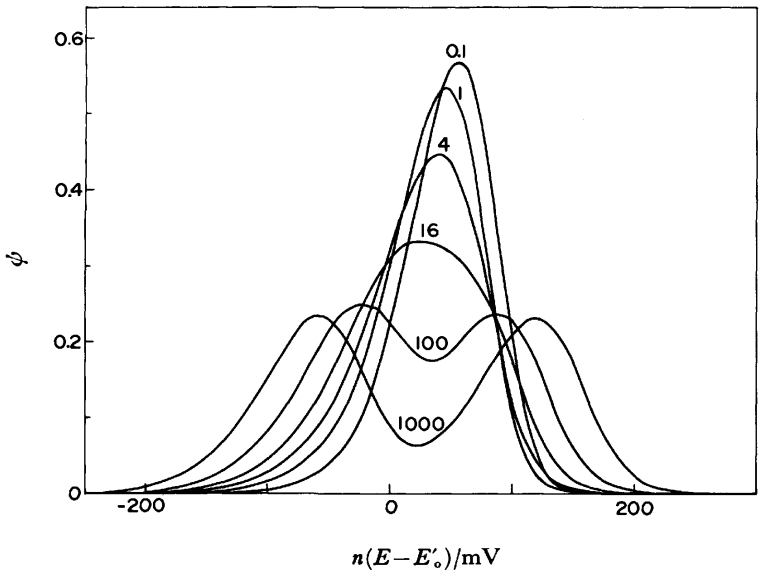

Fig. 2. The dependence of K on the normarized d.c. anodic voltammograms at $m=0.5$ and $\alpha=0.5$. The K value is indicated on each curve.

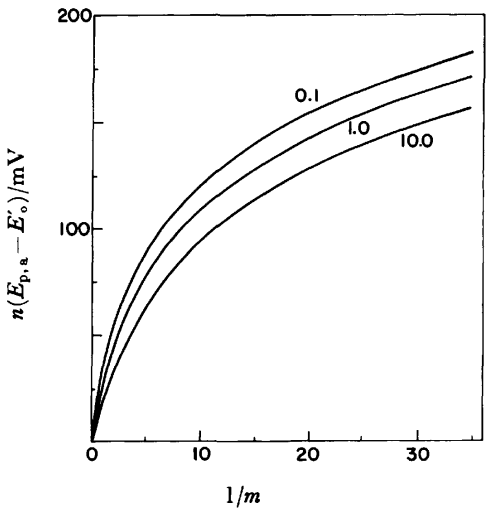

Fig. 3. Variation of $n(E_{p,a}-E'_o)$ with $1/m$ for $\alpha=0.5$ and $K=0.1$, 1.0, and 10.0. The value of K is indicated on each curve.

for $K\leq16$, but two peaks are obtained for $K>16$. Also, Eqs. 7a to 7c indicate that the cathodic curve, having $m(1)=a$, $m(2)=b$, $K=c$, and $\alpha=d$, and the anodic curve, having $m(1)=b$, $m(2)=a$, $K=c$, and $\alpha=1-d$, are symmetrical about the C_2 axis which is vertical to the curve plane and goes through the point of $\rho=1$ ($E=E'_o$) and $\psi=0$ ($i=0$). Accordingly, when $m(1)=m(2)$ and $\alpha=0.5$ (conditions necessary to experimentally obtain cathodic and anodic voltammograms in a C_{2h} symmetry) both the waves are symmetrical about the point of $E=E'_o$ and $i=0$.

The change of $n(E_{p,a}-E'_o)$ with m is shown in Fig. 3 for various K's at $\alpha=0.5$. Using the working curves like those in Fig. 3, k_{sap} can be estimated from the observed $E_{p,a}-E'_o$ value[13], provided that n and K can be obtained by the other methods, and that $k_{sap}(1)=k_{sap}(2)=k_{sap}$ and of $\alpha_1=\alpha_2=0.5$ are kept. The latter situation can be verified by checking whether or not the average of the cathodic and anodic peak potentials, $(E_{p,a}+E_{p,c})/2$, is independent of v and Γ_t and equal to E'_o,[13] and also whether the peak currents, the half-peak widths, and the electricities of the cathodic and anodic waves coincide with each other. Needless to say, the K as well as E'_o can be estimated from the reversible d.c. voltammogram.[4,7]

The above method is, however, only based on information regarding peak potentials. Furthermore, if an estimation of K is difficult, the above method can not be used. Thus, we propose here a non-linear least-squares analysis of the d.c. voltammograms for the determination of kinetic parameters.[14,15] In the following section we will discuss the results concerning the characterization of the electrochemical behavior of adriamycin adsorbed on a pyrolitic graphite electrode.

Experimental

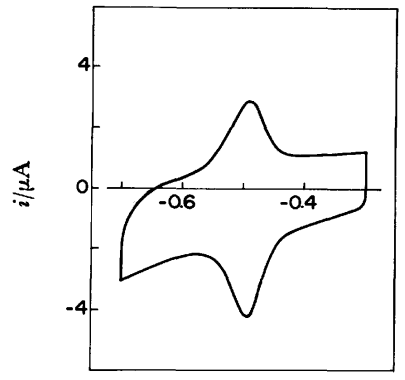
Adriamycin hydrochloride and all other chemicals used have been described elsewhere.[16] The electrochemical measurements were performed mostly as described in previous papers.[16,17] Positive feedback circuits were used for ohmic drop compensation. Electrodes, used as working electrodes, were fabricated using cylindrical rods of pyrolytic graphite carbon (Tomoe Co., Osaka), and were sealed onto glass tubing by heat-shrinkable Teflon tubing. The pyrolytic graphite electrode was cleaved with a razor blade to produce a basal-plane surface and was first polished with silicon carbide paper (No. 1000) and then with a diamond paste in order to prepare a smooth shiny surface. The electrode was ultrasonically cleaned in ethanol. The geometrical area of the electrodes were

0.126 cm^2. The freshly prepared pyrolytic graphite electrode was immersed into an electrolysis solution containing adriamycin for 1—3 min under stirring at an initial potential, E_i. After standing for 0.5—2 min, a d.c. voltage scan was started from E_i, a saturated calomel electrode (SCE) being used as a reference electrode. A sodium acetate (0.2 mol dm^{-3})-nitric acid buffer (pH 4.54, ionic strength 0.5 with potassium nitrate) was used as the base solution. Most experiments were performed in solutions containing $2—6\times10^{-6}$ mol dm^{-3} of adriamycin.

The electrode surface was cleaned after several potential scans because of an aging effect which may have some relation to the stability of the reduced adriamycin[16,17] as well as the electrode.

Results and Discussion

Cyclic D.c. Voltammetry. Figure 4 shows the cyclic d.c. voltammogram of adriamycin adsorbed on a pyrolytic graphite electrode (recorded from $E_i=-0.30$ V at $v=10$ mV s^{-1}). A symmetric pair of cathodic and anodic waves was observed at −0.5 V. This wave is ascribed to the redox reaction of the quinone moiety of the adsorbed adriamycin.[16] When the voltammograms were recorded at $v\leq50$ m V s^{-1}, the peak heights of cathodic and anodic waves, $i_{p,c}$ and $i_{p,a}$, coincided with each other and were proportional to v at a given Γ_t.[18] The electricities of cathodic and anodic waves, Q_c and Q_a, also agree well with each other within the experimental error. The peak potentials ($E_{p,c}$ and $E_{p,a}$) and the half-peak widths ($\Delta E_{p/2,c}$ and $\Delta E_{p/2,a}$) are −0.498 V and 54—55 mV, respectively, for both the cathodic and anodic waves, and are independent of v and Γ_t. This electrochemical behavior should be interpreted in terms of a d.c. reversible two-step surface-redox reaction as shown in Scheme (1), where $n_1=n_2=1$.[8,16] According to the theory of a reversible two-step surface-redox reaction, we have estimated the K value to be 0.244±0.085 from the half-peak widths.[19]



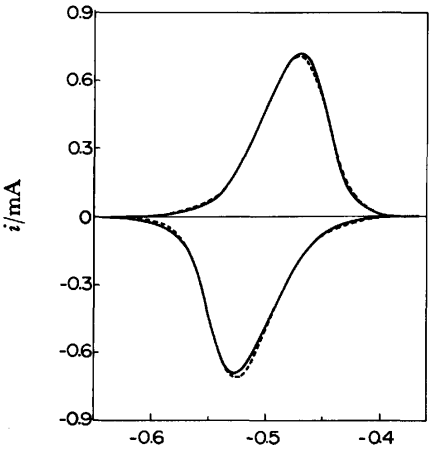
E/V *vs.* SCE

Fig. 4. Cyclic d.c. voltammogram of adriamycin adsorbed on a pyrolytic graphite electrode. Voltage scanning was done with $v=10$ mV s^{-1} after stirring for 1 min at $E_i=-0.3$ V in 5.52×10^{-6} mol dm^{-3} adriamycin solution.

Under the conditions of $v>100$ mV s^{-1}, a discrepancy occurs between $E_{p,a}$ and $E_{p,c}$, and the ΔE_p ($=E_{p,a}-E_{p,c}$) becomes larger with an increase in v. Figure 5 shows the cyclic d.c. voltammogram recorded at $v=9000$ mV s^{-1}, the current being corrected for the base. This is a typical quasi-reversible voltammogram: ΔE_p comes out 59 mV. Nevertheless, the same values between $i_{p,a}$ and $i_{p,c}$, and also between $\Delta E_{p/2,a}$ and $\Delta E_{p/2,c}$ can be within the experimental error at a given v and Γ_t. The $(E_{p,a}+E_{p,c})/2$ value is independent of v and Γ_t and agrees well with E_o', which is equal to $E_{p,a}$ or $E_{p,c}$ of the reversible waves. These facts suggest that $k_{sap}(1)=k_{sap}(2)=k_{sap}$, and $\alpha_1=\alpha_2=\alpha=0.5$.

Based on the above consideration, we analyzed the voltammogram shown in Fig. 5 by means of a non-linear least-squares analysis using two parameters, k_{sap} and K, at $E_o'=-0.498$ V, $Q=5.94$ μC[20] ($\Gamma_t=2.44\times10^{-10}$ mol cm^{-2}),[18] and $\alpha=0.5$.[21] The refined parameters are $k_{sap}=503\pm19$ s^{-1} and $K=0.229\pm0.023$. The resultant regression curve is depicted in Fig. 5 as a broken curve. Table 1 gives the regression results of the voltammograms at various Γ_t and v. We can see that although k_{sap} decreases with an increase in Γ_t, K is almost independent of Γ_t and stays within 0.211±0.099. This is in good agreement with the K estimated from the reversible voltammograms. This indicates the effectiveness of the non-linear least-squares curve fitting analysis of d.c. voltammograms.

In addition, a one-parameter curve fitting was also



E/V *vs.* SCE

Fig. 5. Cyclic d.c. voltammogram of adriamycin adsorbed on a pyrolytic graphite electrode. Voltage was scanned with $v=9000$ mV s^{-1} after stirring for 1 min at $E_i=-0.3$ V in 1.84×10^{-6} mol dm^{-3} adriamycin solution. The current is corrected for the base current. The broken line represents the regression curve calculated under the conditions of $k_{sap}=503$ s^{-1}, $K=0.229$, $\alpha=0.5$, $E_o'=-0.498$ V *vs.* SCE, and $Q=5.94$ μC.

TABLE 1. k_{sap} AND K VALUES OF ADRIAMYCIN ADSORBED ON A PYROLYTIC GRAPHITE ELECTRODE ESTIMATED BY MEANS OF CYCLIC D.C. VOLTAMMETRY

Γ_t / 10^{-10} mol cm^{-2}	v / V s^{-1}	k_{sap} / s^{-1}	K
1.72	4.0	532	0.104

3.33	9.0	358	0.187
4.20	4.0	239	0.290
6.30	4.0	167	0.325

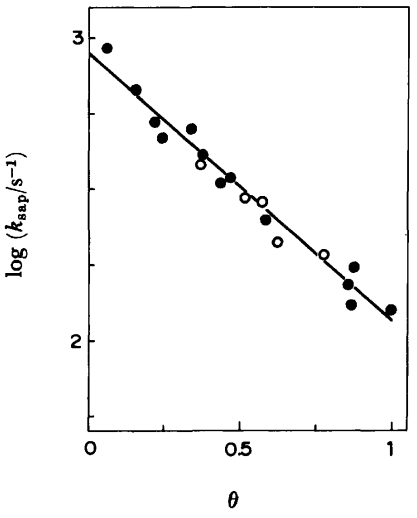

Fig. 6. Surface coverage dependence of the log k_{sap} values estimated by one-parameter curve fitting (K= 0.211) of cyclic d.c. (●) and of a.c. (○) voltammograms. The solid line represents the regression result; *i.e.* log k_{sap}[=log $k_{sap}(\theta\rightarrow 0)-a\theta/2.303$]=2.94−0.882$\theta$ (r=0.983).

carried out using a constant K value of 0.211 (the average value obtained by two-parameter fitting). A linear log k_{sap} *vs.* θ (surface coverage) plot for the refined k_{sap} is depicted in Fig. 6 (closed circles); the linearity seems to be quite good. These results prove the adequacy of Eq. 10c for the adsorbed adriamycin; *viz.* the interaction among the adsorbed reactants is homogeneous, and the reactants obey Frumkin's adsorption isotherm. The negative log k_{sap} *vs.* θ plot indicates an attractive interaction.

A.c. Voltammetry. Figure 7 shows the real and imaginary components of the a.c. voltammogram of the adsorbed adriamycin, recorded at 100 Hz (a.c. frequency, f). The imaginary component is less than the real component and has two peaks. The peak potential of the real component and the valley potential between the two imaginary component peaks coincide with each other and also with the E_o'

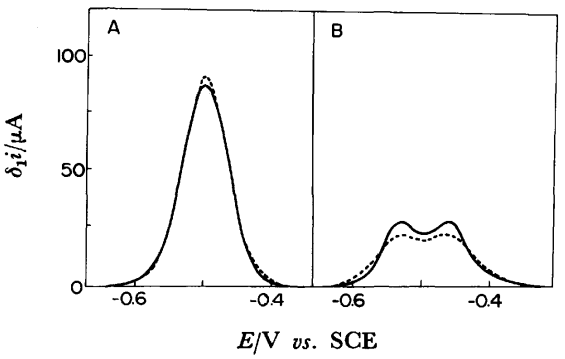

Fig. 7. (A) Real component and (B) imaginary component of a.c. voltammograms of adriamycin adsorbed on a pyrolytic graphite electrode. D.c. voltage sweep was done with v=20 mV s^{-1} after stirring 3 min at E_i=−0.3 V in 1.84×10^{-6} mol dm^{-3} adriamycin solution. Amplitude of the superimposed a.c. voltage was 10 mV peak-to-peak and the a.c. frequency was 100 Hz. The current is corrected for the base current. The broken lines represent the regression curves calculated under the conditions of k_{sap}=194 s^{-1}, K=0.199, α=0.5, E_o'=−0.498 V *vs.* SCE, and Q=13.37 μC.

TABLE 2. k_{sap} AND K VALUES OF ADRIAMYCIN ADSORBED ON A PYROLYTIC GRAPHITE ELECTRODE ESTIMATED BY MEANS OF A.C. VOLTAMMETRY

Γ_t / 10^{-10} mol cm^{-2}	f / Hz	k_{sap} / s^{-1}	K
2.63	100	415	0.135
3.69	100	238	0.217
4.12	200	311	0.137
4.48	100	225	0.156
5.50	100	194	0.199

estimated from d.c. voltammetry. This result makes it possible to set $k_{sap}(1)=k_{sap}(2)=k_{sap}$ and α=0.5, and agrees well with the situation derived from the d.c. voltammetry (previously described). The theory of a.c. voltammetry[7] tells us that the a.c. frequency dependence of the current ratio of the real and imaginary components at the E_o' and a constant Γ_t leads to information regarding kinetic parameters. In case of solid electrodes, however, it is a quite difficult matter to always obtain a constant Γ_t. This renders the experiment regarding the frequency dependence of a.c. voltammograms at a given Γ_t difficult. Here, we have analyzed the a.c. voltammogram by a direct non-linear least-squares analysis[15] according to the theory of a.c. voltammetry.[7,22] Using the same procedure as that regarding an analysis of the d.c. voltammograms, we have used two parameters, k_{sap} and K, for the simulation. The analysis of the voltammograms (Fig. 7) results in k_{sap}=194±12 s^{-1} and K=0.199± 0.028, at E_o'=−0.498 V, Q=13.37 μC[20] (Γ_t= 5.50×10^{-10} mol cm^{-2}),[18] and α=0.5.[23] The broken lines in Fig. 7 represent regression curves. The

a) This work. b) Ref. 16.

refined parameters, thus obtained, are shown in Table 2. It was found that an increasing Γ_t becomes a decreasing k_{sap}; however, K is almost independent of Γ_t. The average value of K (0.169±0.037) agrees with that estimated by d.c. voltammetry. We have also simulated a.c. voltammograms with only one parameter, k_{sap}, by setting K=0.211. In Fig. 6, a linear graph of log k_{sap} *vs.* θ (open circles) for the refined k_{sap} is given. The agreement between the k_{sap} values obtained by d.c. and a.c. voltammetries is quite good. The results now verify that the curve fitting analysis of d.c. and a.c. voltammograms is a useful technique for determining electrochemical kinetic parameters.

Table 3 summerizes the electrochemical data regarding the adriamycin adsorbed on a pyrolytic graphite electrode as well as that regarding a hanging mercury drop electrode (HMDE), reported in a previous paper.[16] The E'_o value at a pyrolytic graphite electrode is more negative by 48 mV than at an HMDE. This difference can be attributed to a disagreement in the adsorption energies on the electrodes, as predicted by Eqs. 9a and 9b. Nevertheless, the K's obtained for the two electrodes are almost the same, and less than unity, indicating the semiquinone formation reaction to be unfavorable thermodynamically at pH 4.54.[17] Note that the Γ_t^{max} value at a graphite electrode is almost 7 times as large as that at an HMDE, the former being determined by using the geometrical surface area. The "effective" surface area of the pyrolytic graphite electrode, however, is postulated to be no more than tenfold the geometrically calculated surface area. This assumption causes us to believe that the adsorption state of adriamycin on a pyrolytic graphite electrode is essentially the same as that on an HMDE; that is, the aromatic ring of the adsorbed adriamycin must be oriented parallel to the basal-plane of a pyrolytic graphite electrode. The agreement of the values of the Frumkin's α-parameter derived from the two electrodes may support the above consideration. In turn, it was also found that the $k_{sap}(\theta\rightarrow 0)$ value, *i.e.* extrapolated k_{sap} value at $\theta\rightarrow 0$, evaluated using a pyrolytic graphite electrode is markedly small compared with that at an HMDE. Similar results were observed for flavin-adenine dinucleotide adsorbed on a graphite electrode[5b,24] and on an HMDE.[8c]

As a conclusion we may say that the thermodynamic and kinetic informations concerning a two-step surface-redox reaction system can be successfully evaluated by means of a direct non-linear least-squares analysis of d.c. as well as a.c. voltammograms. Particularly, note that in these analyses we do not need (necessarily) information regarding K values, since K can be treated as one of the parameters. The viewpoint that a cyclic d.c. voltammetry has been widely used for the study of the surface-redox reaction would make it noteworthy that the kinetic information can be obtained from the theoretical analysis of the d.c. voltammetry.

The authors wish to express their sincere thanks to professor Mitsugi Senda and Dr. Tadaaki Kakutani, Kyoto University, for their valuable advice and discussion on this study. This work was supported in part by a Grant-in-Aid for Scientific Research (No. 59390012) from the Ministry of Education, Science and Culture.

18) The value of Γ_t was estimated from the electricity, Q, using the relation, $Q=(n_1+n_2)FA\Gamma_t$, where $n_1=n_2=1$ for the redox of the quinone moiety and A is the "geometric" surface area of a pyrolytic graphite electrode.

19) Equation 40 in Ref. 7 was used for the estimation of K, where $\alpha+\beta=1$ and $n=1$.

20) The Q value is the average of Q_a and Q_c of the d.c. voltammogram.

21) In curve-fitting analysis of the voltammogram in Fig. 5, the observed currents were measured at every 10 mV from -0.600 V to -0.380 V from the anodic wave (23 points) and from -0.410 V to -0.650 V for the cathodic wave (25 points). The initial conditions for numerical solution were set as $f_o=0$ and $f_r=1$ at -0.650 V for the anodic wave and $f_o=1$ and $f_r=0$ at -0.360 V for the cathodic wave. The initial parameters were roughly estimated as follows: K was evaluated from the $\Delta E_{p/2}$ of the reversible d.c. wave[19] and k_{sap} was estimated from the ΔE_p by using the working curves like those in Fig. 3 (see text). In a simulation of these voltammograms, the parameters set under the above conditions usually converged at an iteration of no more than 5 cycles.

22) See Eqs. 34a and 34b in Ref. 7 for the analytical solutions of the real and imaginary components of the a.c. voltammograms.

23) In a simulation of the voltammograms in Fig. 7, the observed currents of the real and imaginary components were measured at every 10 mV from -0.360 V to -0.620V (27 points for each component). The initial parameters were estimated as follows: K was the value (0.211) obtained by d.c. voltammetry (see text), and k_{sap} was estimated (to be 234 s^{-1}) using the ratio of the real component current to the imaginary one at $E=E_o'$, according to Eq. 37 in Ref. 7 under the assumpsion of $K=0.211$. In a simulation of these voltammograms, the parameters converged at an iteration of no more than 5 cycles.

24) The authors of Ref. 5b have treated this system as a "one-step" surface-redox reaction and reported the standard electron-transfer rate constant to be about 1 s^{-1}. A reanalysis of the cyclic d.c. voltammograms of Fig. 1 in Ref. 5b by the curve-fitting method proposed in this paper has revealed that $k_{sap}=1.8\ s^{-1}$ and $K=7.6$, under the assumption that $k_{sap}(1)=k_{sap}(2)=k_{sap}$ and $\alpha_1=\alpha_2=0.5$.

Electric and Magnetic Properties of a Neutral Radical, 2-Cyano-10-methyl-5-phenazinyl

Kunio AWAGA, Tadashi SUGANO, and Minoru KINOSHITA*
The Institute for Solid State Physics, The University of Tokyo, Roppongi, Minato-ku, Tokyo 106
(Received March 8, 1985)

The temperature dependence of electric conductivity, static magnetic susceptibility and ESR absorption, and electronic absorption spectra at room temperature have been measured on an organic neutral radical, 2-cyano-10-methyl-5-phenazinyl (NMPN). NMPN is found to be more conductive than the neutral radicals studied previously. The room temperature conductivity of powder NMPN is of the order of $10^{-7}\,\Omega^{-1}\,cm^{-1}$ and the activation energy is 0.36 eV. The absorption spectra and the magnetic susceptibility measurements indicate that the NMPN molecules form pairing array with considerably large interpair interaction in the solid state. The absence of the triplet fine structure in the ESR spectrum also suggests the existence of the interpair interaction. From these, the magnetic behavior of NMPN is interpreted in terms of the alternating antiferromagnetic Heisenberg model with temperature dependent alternation.

The electrical conduction of organic solids has been a matter of concern for long time and the efforts to find out highly conducting materials among the organic solids composed of one kind of molecules have been continued. Especially, the conduction of aromatic hydrocarbons represented by anthracene has been studied in detail.[1] However, it is known that most of them show the conductivity of less than $10^{-10}\,\Omega^{-1}\,cm^{-1}$ at room temperature and the activation energy of several eV (1 eV/molecule≒96.48 kJ mol^{-1}). One of the reasons for poor conductivity is that in the ground state no carriers can exist because the component molecules take the closed shell structure.

In this regards, the electrical conduction of a neutral free radical, which has intrinsically one unpaired electron giving the expectancy of becoming a carrier, has been interested in. Table 1 (a)—(c) shows the electric conductivities of the neutral radicals studied previously.[2-4] Contrary to expectation, they exhibit poor conductivity in spite of the presence of unpaired electrons. The reason for this is considered to be as follows. These radicals are characterized commonly by having protective substituents to stabilize the unpaired electron.[5,6] The protective substituents must obstruct the interactions between the unpaired electrons and therefore the unpaired electrons would be localized on each site of radical molecules. Above consideration is supported by the fact that the magnetic behavior of these radicals follow the Curie-Weiss law with small Weiss constants, representing the localized character of spins. Taking it the other way round, it would be predicted that using a planar radical molecule leads to increase of the interactions and to improvement of the conductivity.

To confirm this prediction, we have chosen 2-cyano-10-methyl-5-phenazinyl(commonly called *N*-methylphenazyl-2-nitrile; abbreviated as NMPN hereafter) shown in Fig. 1 as an experimental sample, which has planar molecular structure and is stabilized mainly by the intramolecular delocalization of the unpaired electron. We have investigated the electric conductivity and further, to make the properties of NMPN clearer, the temperature dependence of the magnetic susceptibility and the electron spin resonance signals, and the absorption spectra at room temperature have been measured.

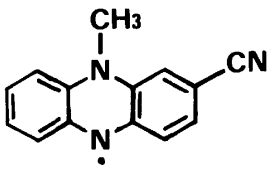

Fig. 1. The molecular structure of NMPN (2-cyano-10-methyl-5-phenazinyl).

In this paper, we characterize the electric and magnetic properties of NMPN using the results of the above experiments and discuss the electric conductivity of NMPN. From these, we suggest the way to improve the electric conductivity of a neutral free radical.

Experimental

NMPN was prepared by the method of McIlwain.[7] The crude NMPN obtained was purified by recrystallization from chloroform or a mixture of chloroform and diethyl ether, followed by washing with diethyl ether continuously (Found: C, 76.36; H, 4.36 N, 19.31%, Calcd for $C_{14}H_{10}N_3$: C, 76.35; H, 4.58; N, 19.08%). The purified samples were kept in a freezer, because they were gradually damaged when kept at room temperature.

The d.c. electric conductivity of compressed polycrystals was measured in a vacuum using the standard two-probe technique with the aid of Ag paint for electrodes.

The magnetic susceptibility was measured by using a Faraday balance on a powder sample of about 50 mg. The details of the apparatus have been described previously.[8] The measurement was taken over the con-

tinuous temperature range of 4—295 K.

A Cary model 14 spectrophotometer was used for measurements of the electronic absorption spectra of an ethanol solution and a solid sample suspended in liquid paraffin. The spectra were measured at room temperature in the range of 5000—30000 cm^{-1}.

Temperature dependence of X-band electron spin resonance (ESR) spectra from 10 to 300 K were performed on a JES-FE1X spectrometer with an Oxford Instruments ESR-900 variable temperature helium gas flow cryostat. In every measurement the modulation width was kept within 0.1 G (1 G=10^{-4}T) in order to prevent lineshape distortion due to over modulation.

Electrical and Magnetic Properties

Electric Conductivity. Figure 2 shows a plot of logarithm of the conductivity at absolute temperature T *vs.* $1/T$ for two specimens which were prepared in different butches. The discrepancy between the temperature dependence of the two specimens is within the experimental error. The conductivity at room temperature is of the order of $10^{-7}\,\Omega^{-1}\,cm^{-1}$. Below 350 K, the linear relation between logarithm of the conductivity and $1/T$ is established well. Above 350 K, the conductivity decreases abruptly. After keeping the samples above this temperature, the intensity of ESR signals vanishes almost completely. Therefore, the decrease of conductivity would be ascribed to the decomposition of radical molecules. In other words, the relatively high conductivity of NMPN observed below 350 K is attributable to the existence of an unpaired electron on each molecule.

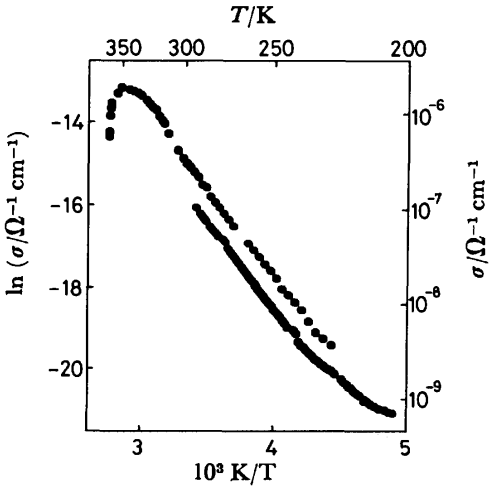

Fig. 2. Specific conductivity of NMPN for two specimens.

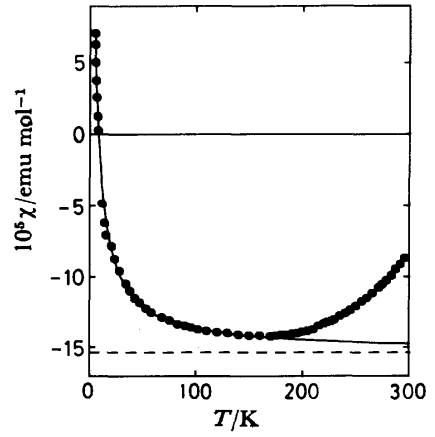

Fig. 3. Temperature dependence of total magnetic susceptibility of NMPN. The dashed line represents the diamagnetic susceptibility. The solid curve represents the paramagnetic one due to impurities.

The activation energy is computed from the change of conductivity as a function of temperature using the equation

$$\sigma = \sigma_0 \exp(-\Delta/k_B T), \quad (1)$$

where σ is the specific conductivity at T, σ_0 is a constant, k_B is the Boltzmann constant and Δ is the activation energy. The slope below 350 K corresponds to the activation energy of 0.36 eV. NMPN shows relatively high conductivity and low activation energy among the organic solids composed of one kind of molecules.

Table 1 shows the comparison of the electric conductivity of NMPN and that of the neutral free radicals investigated previously.[2-4] The latter radicals are stabilized by the protective substituents.[5,6] The conductivity of NMPN is higher than that of the other radicals by more than three orders of magnitude. The activation energy of NMPN is about a half as large as the others. The prediction made in the introductory section thus seems to be fulfilled.

Magnetic Susceptibility. Temperature dependence of the molar magnetic susceptibility of NMPN is shown in Fig. 3. In the high temperature region, the susceptibility decreases with decreasing temperature, and after passing a minimum it increases in the low temperature region. The diamagnetic contribution is evaluated by assuming that the susceptibility change in the low temperature region is dominated by the paramagnetic susceptibility due to impurities

Table 1. The comparison of the electric conductivity of the neutral radicals

		$\sigma_{25\,°C}$ / $\Omega^{-1}\,cm^{-1}$	Δ / eV	σ_0 / $\Omega^{-1}\,cm^{-1}$
(a)	DPPH (single crystal)	2×10^{-10}	0.75	10^{3}
(b)	Galvinoxyl	4×10^{-14}	0.72	0.07
(c)	Banfield and Kenyon's radical	3×10^{-15}	1.2	10^{5}
(d)	NMPN	3×10^{-7}	0.36	0.35

(a) in Ref. 4. (b), (c) in Ref. 3. (d) This work.

and/or defects which follows the Curie-Weiss law. The diamagnetic susceptibility thus obtained is -153×10^{-6} emu mol^{-1} [9] which is indicated by the dashed line in Fig. 3. The Curie-Weiss susceptibility with the Curie constant of 1.70×10^{-3} emu K mol^{-1}, corresponding to a spin concentration ($S=1/2$) of 0.45%, and with the Weiss constant of -2.66 K, is shown in Fig. 3 by the solid curve.

The intrinsic paramagnetic susceptibility χ_P, after correction for the diamagnetic and the Curie-Weiss parts have been made, is plotted as a function of temperature in Fig. 4. χ_P appears to increase exponentially from about 150 K. This shows existence of relatively strong antiferromagnetic interactions between the unpaired electrons and of the thermally accessible magnetic excitation state. By assuming that the antiferromagnetic interactions are limited only within a pair of spins, the temperature dependence of χ_P may be analyzed by the singlet-triplet model. The temperature dependence of the singlet-triplet susceptibility χ_{st} is given by

$$\chi_{st} = \frac{N_A g^2 \mu_B^2}{k_B T} \frac{1}{3+\exp(J/k_B T)}, \qquad (2)$$

where N_A is the Avogadro constant, μ_B is the Bohr magneton, g is the g-value and J is the energy separation between the ground singlet state and the excited triplet state. The solid curves (a), (b), and (c) in Fig. 4 are theoretical curves of the singlet-triplet model for $J=0.11$, 0.12, and 0.13 eV, respectively. The temperature dependence of magnetic susceptibility of NMPN is found to fit only qualitatively to the singlet-triplet susceptibility, but does not fit quantitatively for any value of J. Such discrepancy between χ_P and χ_{st} has also been observed in various charge transfer complexes and the following explanations have been suggested.

1) The change in the intermolecular distance by thermal expansion.[10]

2) The phonon induced interaction between magnetic excitons.[11,12]

3) The existence of interpair interaction (*i.e.*, alternating antiferromagnetic chain).[13–17]

Further discussion will be given below by taking account of the results of the absorption spectra and the ESR measurements.

Electronic and ESR Spectra

Absorption Spectra. The temperature dependence of χ_P suggests that, within the first approximation, NMPN molecules exist in the solid as what is called "radical pair" formed by the charge transfer interaction.[18] In order to confirm the existence of the charge transfer interaction, absorption spectra were measured for an ethanol solution and a solid sample at room temperature. The comparison is shown in Fig. 5. The broad band at about 9000 cm^{-1} in the solid spectrum is much enhanced in comparison with that of the solution spectrum. Therefore, we could attribute this band to the charge transfer band. A weak absorption appears like shoulder at about 12000 cm^{-1}. Such a structure of a CT-band is also observed in Würster's blue perchlorate and alkali metal-TCNQ(7,7,8,8-tetracyano-*p*-quinodimethan) which are known as Mott insulators. Lyo has given two explanations for this phenomenon.

1) The effect of long-range Coulomb interaction.[19]

2) The charge transfer between pairs.[20]

On the basis of the experimental results of susceptibility and ESR, we will take the latter explanation in the later sections.

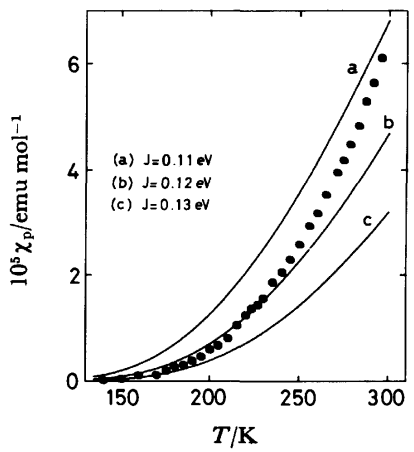

Fig. 4. Intrinsic paramagnetic susceptibility of NMPN. The solid curves are theoretical fits as explained in the text.

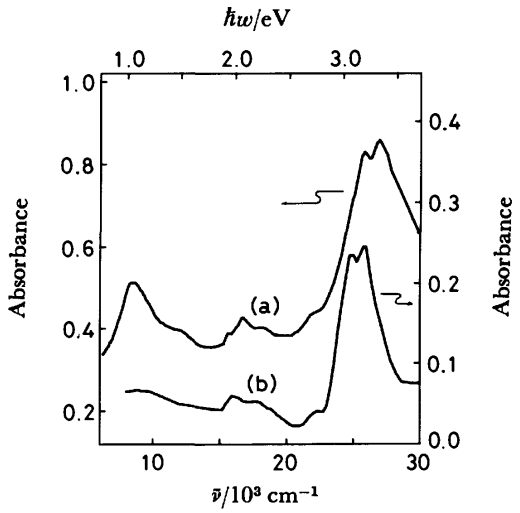

Fig. 5. Absorption spectra of NMPN at room temperature. (a): Powder sample suspended in liquid paraffin, (b): solution in ethanol.

The other absorption bands of solid NMPN correspond well to those of the solution spectrum except for blue shift of the strong absorption at about 27000 cm^{-1}. This blue shift would be explained by either the solvent effect or the coupling of CT and LE transitions.[21]

ESR Absorption. The ESR spectra observed on the powder sample at various temperatures are shown in Fig. 6, in which the three signals at lower temperatures are magnified by ten times. Asymmetric lineshape of the spectra in the high temperature region is due to g-value anisotropy. The g-value anisotropy disappears with broadening of the linewidth at low temperatures. Temperature dependence of the peak-to-peak linewidth ΔH_{pp} is shown in Fig. 7. Below 140 K, ΔH_{pp} increases abruptly with decrease of temperature and becomes constant at 80 K. Thus,

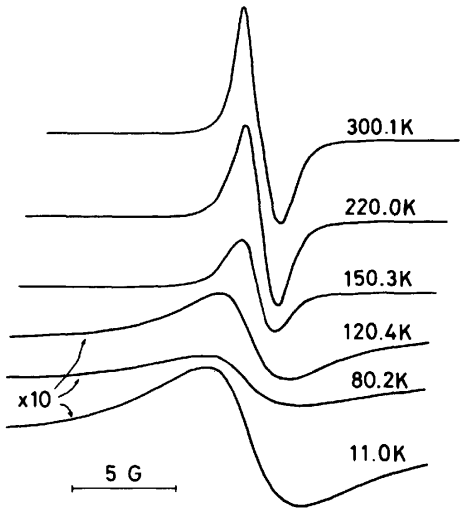

Fig. 6. ESR signals on powder sample at various temperatures.

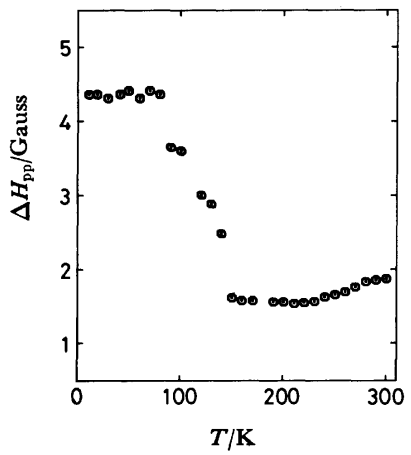

Fig. 7. Temperature dependence of ESR peak-to-peak linewidth, ΔH_{pp}.

the temperature dependence of ΔH_{pp} may be separated into the following three temperature regions.

In the high temperature region ($T>140$ K), the narrow linewidth signal, which increases in intensity with increasing temperature, is dominant. From the results of the static magnetic susceptibility, the observed ESR signals in this region should represent the spins excited thermally across the magnetic gap. The g-value anisotropy stands up with increasing temperature. Because the peak-to-peak linewidth in Fig. 7 is affected by the g-value anisotropy, we cannot place much significance on the variation of the linewidth in this temperature region. However, the true linewidth seems to depend little on temperature or to become narrower a little with increasing temperature.

In the low temperature region ($T<90$ K), the broad linewidth signal without g-value anisotropy, which increase in intensity with decreasing temperature, is dominant. These signals represent paramagnetic impurities observed in the susceptibility measurements. Their temperature independent linewidth suggests that the spins on the impurities are localized. The fact that the two kinds of signals observed in the high and low temperature regions have the same g-value suggests that the paramagnetic impurities are the localized spins on the monomer radicals, which have failed to form a pair structure during crystallization.

In the middle temperature region, the observed signals result from the two kinds of signals being piled up and therefore originate from the two kinds of spins discussed above. With decreasing temperature the linewidth increases abruptly and main contribution to the observed signals varies from the narrower signal to the broader one.

In order to examine whether or not the magnetic excited state is described by the triplet spin Hamiltonian:

$$\mathscr{H} = D\left(S_z^2 - \frac{2}{3}\right) + E(S_x^2 - S_y^2), \tag{3}$$

which represents the dipolar interaction in an isolated spin pair, we have tried to find out fine structure signals and $\Delta m = \pm 2$ transitions. The measurements were carefully done on the powder samples over the range of 90—300 K, but we could not find out both of them. This fact indicates that the spin system in NMPN is not simply described by an assembly of noninteracting spin pairs of Hamiltonian (3).

Analysis of Magnetic Susceptibility

The Model to be Used. From the experimental results described in the preceding sections, the

NMPN molecules are considered to be paired off, within the first approximation, by the charge transfer interaction in the solid state. Because this interaction needs the overlapping of the molecules and NMPN exhibits relatively high conductivity, it is reasonable to assume that the NMPN molecules form linearly stacking columns in the solid. The results of the ESR experiments suggest the existence of the interpair interaction. The discrepancy between the temperature dependence of the magnetic susceptibility observed and the singlet-triplet statistics would also be attributed to the interpair interactions as mentioned above. As a matter of course, this interpair interaction is weaker than the intrapair one, but seems to be so strong that the spin system in NMPN is not represented by the spin Hamiltonian (3). Therefore, the spins on the NMPN molecules are to be interpreted by a linear alternating antiferromagnetic Heisenberg model. As mentioned in a previous section, one of the explanations for the side band in the CT absorption region is also due to the coexistence of the intra- and interpair charge transfer interactions. The interpair charge transfer makes the two pair spins singlet just like the intrapair interaction.

Analysis. The Hamiltonian of the linear alternating antiferromagnetic Heisenberg model is given by

$$\mathscr{H} = \sum_{i=1}^{N/2} (J_1 \boldsymbol{S}_{2j}\boldsymbol{S}_{2j+1} + J_2 \boldsymbol{S}_{2j-1}\boldsymbol{S}_{2j}) = J_1 \sum_{i=1}^{N/2} (\boldsymbol{S}_{2j}\boldsymbol{S}_{2j+1} + \gamma \boldsymbol{S}_{2j-1}\boldsymbol{S}_{2j}) \quad (4)$$

where J_1 and J_2 are the alternating interactions along the chain (assumed as $J_1 > J_2 > 0$) and $\gamma = J_2/J_1$ is a parameter which conveniently measures the degree of alternation. When $\gamma=1$, the linear Heisenberg model is obtained, whereas when $\gamma=0$ the system breaks up into an assembly of noninteracting spin pairs.

Bulaevskii calculated the spectrum of triplet excitations of alternating chain of spins with the above Hamiltonian (4), by using the Hartree-Fock approximation.[13,14] His model has been used frequently in approximate theoretical treatments of a variety of phenomena. For example, it has been applied to charge-transfer salts,[22-24] to spin dynamics,[25] and to the uniform Heisenberg chain.[26]

On the other hand, Duffy and Barr[16] and Bonner *et al.*[17] have made exact calculations of the susceptibility on finite alternating antiferromagnetic Heisenberg spin-1/2 chains. The extrapolation of their results to $N \to \infty$ shows a good numerical agreement with the corresponding curves calculated from the model of Bulaevskii, especially at low temperatures.

In our case, the temperature region examined falls into the low temperature regions of these models. Therefore, we use the results of Bulaevskii for the analysis of the temperature dependence of the intrinsic paramagnetic susceptibility in Fig. 4. Bulaevskii has derived the following approximate equation at low temperatures ($0.033 < k_B T/J_1 < 0.25$)

$$\chi = \frac{N_A g^2 \mu_B^2 a(\gamma)}{k_B T} \exp\left(\frac{-J_1 \Delta(\gamma)}{k_B T}\right), \quad (5)$$

where $a(\gamma)$ and $\Delta(\gamma)$ are γ dependent parameters whose values are given by him.[14] For any value of γ, the relations of $0 < a(\gamma) < 1$, $0 < \Delta(\gamma) < 1$ are to be satisfied. Although the plot of $\log(\chi_P T)$ *vs.* $1/T$ (not shown) gives rise to a linear relation between them, the regression yields contradictory values of $a(\gamma)$ and $J_1\Delta(\gamma)$ as follows

$$a(\gamma) = 3.8, \quad J_1\Delta(\gamma) = 0.15\,\text{eV}.$$

This contradiction could originate in the temperature dependence of the alternation parameters, J_1 and/or γ. When both J_1 and γ are temperature dependent, each of J_1 and γ cannot be determined uniquely from our susceptibility measurements, but the possible combinations of (J_1, γ) can be determined so as to reproduce the observed value of χ_P at T by using Eq. 5. In Fig. 8, the determined combinations are plotted as a function of temperature over the range of J_1 from 0.10 to 0.16 eV. A curved plane is obtained for the possible set of parameters (J_1, γ, T). When J_1 is assumed to be constant, γ increases with increasing temperature. Such behavior of γ means that the spin system varies from the singlet-triplet model to Heisenberg one with increasing temperature. When γ is assumed to be constant contrariwise, J_1 decreases with increasing temperature. Thus, the

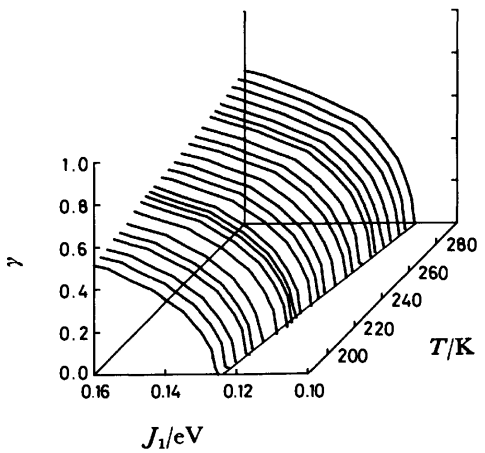

Fig. 8. Temperature variation of possible combination of (J_1, γ). The curves are not smooth, because the numerical values of $a(\gamma)$ and $\Delta(\gamma)$ in Eq. 5 are given for the values of γ in every 0.1 step.[14]

curved plane in Fig. 8. seems to be reasonable phenomenologically. In other words, the observed temperature dependence of χ_p could be explained by the linear alternating antiferromagnetic Heisenberg model with the rational temperature dependence of the alternation parameters. We expect the value of γ to be somewhat large (*e.g.*, 0.3—0.5) in NMPN on the basis of the absence of the fine structure and the transitions of $\Delta m=\pm 2$ in the ESR measurements.

Such temperature dependence of the alternation parameters resembles the prediction made by the theoretical studies of the spin-Peierls transition. It is known from these studies that the presence of the spin-lattice[24,27,28] or spin-phonon[22,27,28] interactions in an uniform chain system results in a phase transition to an alternating chain, indicating temperature dependence of alternation parameters. This predicted temperature dependence is similar to that observed in our material. The decompositions of the radical molecules above room temperature prevent us from getting the information about the phase transition and therefore we cannot apply the theory of the spin-Peierls transition to our problem at present. However, we preferably think that the spin-lattice or spin-phonon interaction plays an important role in the magnetic behavior of our material.

Comparison of NMPN and NEP

The comparison of properties of organic solids whose components have similar molecular structure is important in chemistry, especially for molecular designing. 10-Ethyl-5-phenazinyl (NEP) is a member of the phenazinyl family and has well been studied. Therefore NMPN and NEP are compared with each other below.

NEP was investigated by Hausser[31] and Hausser and Murrell[32] first. They discovered the charge transfer absorption in the near IR region. Sakata and Nagakura[33] measured the temperature dependence of the CT-band intensity and of the magnetic properties in detail. They found that the properties of NEP were explained as the isolated spin pairs almost quantitatively. The existence of the charge transfer interactions is thus common to the two radicals. In ESR studies of NEP, however, the fine structure and the transitions of $\Delta m=\pm 2$ are found[33] and therefore its magnetic excited state is described by the spin Hamiltonian (3). The comparison of the two radicals is summarized in Table 2.

Table 2. The comparison of NMPN and NEP

	NMPN	NEP[a]
$h\nu_{CT}$/eV	1.08	1.38
J/eV	0.11[b]	0.04
Fine structure and transition of $\Delta m=\pm 2$	not observed	observed

a) in Ref. 33. b) The magnetic excitation gap at room temperature calculated from Eq. 2.

The most remarkable difference is the magnitude of the interpair interactions. The ESR behaviour of NEP is described by the spin Hamiltonian of noninteracting pair, whereas that of NMPN is not. This difference would arise from the steric factor. The steric hindrance due to the ethyl group in NEP seems to be so large that the interpair interactions are prevented. This difference has something in common with that of the crystal structures of *N*-methylphenazinium(NMP)-TCNQ and other *N*-alkylphenazinium-TCNQ complexes. NMP-TCNQ is a famous organic conductor and forms segregated columns in the crystal. NMP molecules in the columns stack uniformly.[34] On the other hand, NEP_2-$TCNQ_2$ crystallizes in mixed stacks with σ-bonded dimers of $(TCNQ)_2^{2-}$.[35] *N*-butylphenazinium (NBP)-TCNQ[36] and NBP-F_4TCNQ[37] comprise -AADD- type mixed stacks. Replacement of the methyl group of NMP by a larger alkyl group therefore seems to hinder the interactions beyond the intradimer ones.

The maximum position of the CT-band of NMPN is lower than that of NEP by about 0.30 eV. In terms of the Hubbard model,[38] it is known that when the on-site Coulomb repulsion U is much larger than the transfer integral t the position of the CT-band maximum is almot determined only by U.[39] Therefore, the relation of the on-site Coulomb repulsion of the two radicals is established as;

$$U_{NMPN} < U_{NEP}.$$

It is likely that the nitrile group in NMPN extends the conjugation system of the phenazinyl frame and the extention decreases the on-site repulsion.

The magnetic excitation gap J of NMPN is about three times as large as that of NEP at room temperature. This gap is approximated by the equation $J=(1/2)(U^2+16t^2)^{1/2}-U/2$. The difference of U is not so large that the following relation of the intrapair hopping integrals would be established;

$$t_{NMPN} > t_{NEP}.$$

The Electric Conductivity of Neutral Radicals

Finally, we discuss the way to obtain more conductive neutral radicals by referring to the electric conductivity of NMPN. As described in a previous section, NMPN is much more conductive than the other neutral radicals which are thought to be stabilized by the protective subtituents and is placed in the most conductive class of organic solids

composed of one kind of molecules. In comparison with recent "organic metals", however, the conductivity of NMPN is still much poor.

The factors which raise the conductivity of NMPN are summarized as follows.

1) The existence of the unpaired electron on the each molecule.

2) The planar molecular structure giving the expectancy of large molecular overlaps.

3) The small substituent.

It is clear from our studies that the second and the third factors are necessary conditions to give neutral radicals higher conductivity. These factors mean that the neutral radical should be stabilized not by the protective substituents, but by the intramolecular delocalization energy of unpaired electron.

On the other hand, the conductivity of NMPN would be suppressed by the following factors.

1) The nonuniform interactions between unpaired electrons which are localized, to some extent, within a pair.

2) The electron localization due to the fully-occupied Hubbard band with large U (Mott insulator).

In order to produce new neutral radicals having higher conductivity than that of NMPN, these factors should be improved. One of the possibilities for improvement is to find neutral radicals containing heavy atoms that are expected to have interactions comparable with or beyond the intrapair ones. In this case, we could further expect the effect of interchain interaction, if the heavy atoms are properly chosen. The problem of electron localization would also be relaxed, to some extent, by introducing heavy atoms with large polarizability and large van der Waals radius, because such heavy atoms would reduce the magnitude of U and increase the transfer integral. Another way to reduce the electron localization is to make a mixed crystal of a neutral radical and a closed shell compound, which has molecular structure similar to the radical molecule and has HOMO or LUMO of energy nearly equivalent to the nonbonding molecular orbital of the neutral radical. In such a crystal, if exist, it would be possible that the nonbonding MO of the neutral radicals and HOMO or LUMO of the closed shell molecules make the band partially filled, in which electrons or holes are delocalized. In the case of NMPN, the mixed crystal of NMPN and phenazine or 5,10-dialkyl-5,10-dihydrophenazine could be a possible candidate.

The authors are thankful to Professor Kazuo Morigaki and Dr. Izumi Hirabayashi of Institute for Solid State Physics for the kindness in putting the ESR spectrometer at their disposal. This work was in part supported by the Grant-in-Aid for Scientific Research (Nos. 58118003, 58470003, and 59112003) from the Ministry of Education, Science and Culture.

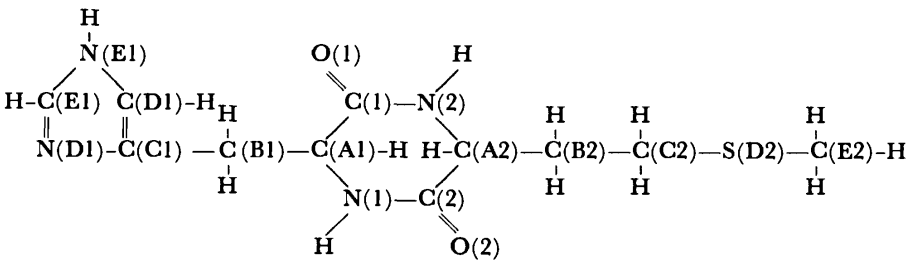
Conformation and Coordination Behavior of Zinc(II) Complex with Cyclo(L-methionyl-L-histidyl)

Yoshitane KOJIMA,* Ken HIROTSU,* Tetsushi YAMASHITA, and Toshio MIWA
Department of Chemistry, Faculty of Science, Osaka City University, Sugimoto, Sumiyoshi-ku, Osaka 558
(Received December 3, 1984)

The crystal structure of a zinc(II) complex with cyclo(L-methionyl-L-histidyl) shows that all four ligands coordinated tetrahedrally to a Zn^{2+} ion have a folded conformation, with the imidazole ring facing the piperazine ring in each ligand. The calculation from α-β coupling constant data (obtained by ^1H NMR measurement) of the histidyl residue of cyclo(L-methionyl-L-histidyl) linked to a Zn^{2+} ion shows that the ratio of a folded conformation to an unfolded one is 61:39 in D_2O.

Several metal complexes with cyclic dipeptides[1] have been used as simple model compounds for studying metallo-proteins and -enzymes, in which metal ions link to the functional groups in the side chains of the peptides, but not to the amide groups in the main chain. Especially, the limited conformations[2] of the peptides with the imidazole rings show the important effects on the formations and conformations of the metal complexes.

In this paper, the conformation and coordination behavior of the $[Zn(CMH)_4]^{2+}$ [abbreviated as CMH for cyclo(L-methionyl-L-histidyl)] ion are examined using X-ray structure analysis, NMR (^1H and ^{13}C) and molecular-weight measurements. A preliminary communication on the structure of this zinc(II) complex with CMH has already been published.[1b] The numbering scheme of a CMH moiety is given below:



Experimental

Materials. CMH was prepared according to the methods reported earlier.[1a] Zinc(II) sulfate (obtained commercially) was used without further purification.

Preparations of Zinc(II) Complexes. A mixture of CMH (1.40 mmol) and zinc(II) sulfate (0.35 mmol) was completely dissolved in hot water (5 ml) with stirring. After standing at room temperature for a few days, a formed precipitate was filtered off. mp; 232—234°dec., Yield; 63%. Found: C, 41.51; H, 5.22; N, 17.49%. Calcd for $Zn(C_{11}H_{16}N_4O_2S)_4SO_4 \cdot 2H_2O$: C, 41.65; H, 5.24; N, 17.66%.

X-Ray Measurement. X-Ray analysis: $Zn(C_{11}H_{16}N_4O_2S)_4 \cdot SO_4 \cdot 10H_2O$, M=1414.9, monoclinic, space group $P2_1$, a=15.143(2), b=20.586(4), c=11.007(2) Å, β=97.89(1)°. Z=2.

With the use of 2692 uniquely observed reflections, the structure was solved by MULTAN[3a] and refined anisotropically to R=0.062 (R_w=0.071).[3b] The absolute configuration was determined by reference to the known configuration of L-histidine moiety. Fractional atomic coordinates and B_{eq} values are listed in Table 1. Tables of observed and calculated structure factors, bond distances and angles, anisotropic temperature factors, atomic parameters of hydrogen atoms, and hydrogen bonds are kept at the chemical society of Japan. (Document No. 8526)

Other Measurements. ^1H and ^{13}C NMR data were obtained in D_2O at 50°, using sodium 3-trimethylsilyl-1-propanesulfonate as an internal reference. The ^1H NMR investigation of CMH were carried out with the aid of spin decoupling methods. The amide protons were replaced by deuterium in D_2O. The molecular weights of zinc(II) complexes with CMH were measured in H_2O at 42°, using urea as a standard material. A JEOL FX-100 (for ^1H and ^{13}C NMR spectra), a PS-100 (for ^1H NMR spectra), and a Knauer Vapor-Pressure Osmometer (for molecular weight) were used for the measurements of the samples.

Results and Discussion

A Zn^{2+} ion is coordinated tetrahedrally by four N (E1) atoms of the imidazolyl groups of the histidyl residues of peptides exclusively (see Fig. 1). The N-Zn-N angles are all within 3.5° from 109.5° and the average distance of four independent Zn-N bonds is 2.01(1) Å, which is comparable to the values found

in other tetrahedral complexes.[4] The complex ion, except for the terminal $-CH_2SCH_3$ groups, has an approximate D_2 symmetry since three pseudo two-fold axes bisect the N-Zn-N angles.

Selected dihedral angles of the CMH moieties of the complex and the free CMH molecule are given in Table 2.[5] The orientation of imidazole rings to the piperazine rings is determined by the dihedral angles around C(A1)-C(B1) and C(B1)-C(C1) bonds. The values of χ_1^1 and χ_1^2 show that all CMH moieties have a same conformation concerning the piperazine and imidazole rings. The imidazole rings are folded back over the piperazine rings to have the intimate contacts between these two rings. Recent X-ray crystallographic studies of cyclic dipeptides such as cyclo(L-histidyl-L-histidyl),[6] CMH,[5] and cyclo(L-

leucyl-L-histidyl)[7] with at least one histidyl residue indicate that these dimers also have the folded conformation, although the χ_1^2 values are nearly +90° and are different by about 180° from those in the $[Zn(CMH)_4]^{2+}$ ion.

The piperazine rings (A and B) are intramolecularly connected to the C and D piperazines through two -NH···O=C hydrogen bonds, respectively, to give the hydrogen-bonded dimers which may behave like bidentate ligands. The formation of these dimers forces χ_1^2 to have nearly −90° when the folded conformations between the imidazole and the piperazine rings are maintained, since χ_1^2=+90° causes a large conformational change of the complex ion, which make the intramolecular hydrogen bonds between the piperazine rings impossible. Interestingly, the conformations of the $-CH_2-CH_2-S-CH_3$ groups are not only different from each other but also different from that of free CMH as given in Table 2, reflecting a large conformational flexibility of this group.

The crystal structure of $[Zn(CMH)_4]\ SO_4 \cdot 10H_2O$ is shown in Fig. 1. The complexes are linked by a complex system of many hydrogen bonds. There is no hydrogen bond which directly connects the complex ions. All of N(1), N(2), N(D1), O(1), and O(2) atoms except O(2)A and O(2)D participate in hydrogen bonds as donors or acceptors. There are two >C-H···O=C< type short contacts other than typical hydrogen bonds described above: C(E1)B···O(2)D of

a) $\Delta\delta=\delta$[zinc(II) complex ion]$-\delta$(free ligand). b) C(B1)-H(β-protons) and C(A1)-H(α-proton) fragments of histidyl residues exhibit an ABX spin system, in which A and B are the β-protons and X is the α-proton. c) Complex and unresolved signals were given for C(B2)-H at this region. d) $Zn(CMH)_4SO_4\cdot 2H_2O$ was used for the measurement.

2.97(2) Å and C(E1)D···O(2)A of 3.08(2) Å.[8] It is noticeable that O(2)A and O(2)D atoms free from hydrogen bonds take part in this interaction as proton acceptors.

Table 3 shows the proton chemical shifts of CMH and its zinc(II) complex ion. β-Methylene protons [C(B2)-H; δ=1.11—1.84] of the methionyl residue of CMH absorbs at higher fields than those (δ= 2.10—3.00) of cyclo(L-methionyl-L-methionyl)[1a] because of the magnetic anisotropy of imidazole ring, suggesting that CMH prefers a folded form.[2a] Although the peaks of β-methylene protons [C(B2)-H] of CMH and $[Zn(CMH)_4]^{2+}$ ion are complex and unresolved, the values of the chemical shifts are used for explaining the conformation of $[Zn(CMH)_4]^{2+}$ ion. The small difference between the chemical shift (δ=1.11—1.84) of β-methylene protons [C(B2)-H] of CMH and those (δ=1.30—1.85) of $[Zn(CMH)_4]^{2+}$ ion suggests a possibility for the complex ion to have a folded form.

Table 4 shows α-β coupling constants and side-chain conformations for CMH and its zinc(II) complex in D_2O. These data indicate that the side-chain conformations of CMH and its zinc(II) complex are 67 and 61% for a folded form, respectively, showing the preference of a folded one in aqueous solution.

$Zn(CMH)_4^{2+}$[b]	4.9	4.6	61	18	21

a) Expressed in %; for notations see Ref. 2. b) $Zn(CMH)_4SO_4\cdot 2H_2O$ was used for the measurement.

Also, Table 3 indicates the downfield shift ($\Delta\delta$= 0.09 and 0.33) for C(D1)-H and C(E1)-H of $[Zn(CMH)_4]^{2+}$ ion from those of CMH, respectively. Table 5 shows the up- or down-field shifts ($\Delta\delta$=−1.4, −2.1, 3.4, and 1.0) for C(B1), C(C1), C(D1), and C(E1) carbons of $[Zn(CMH)_4]^{2+}$ ion from those of CMH, respectively. Moreover, Tables 3 and 5 show no distinct shifts for the methine protons [C(A1)-H and C(A2)-H], the methionyl residue protons [C(B2)-H, C(C2)-H, and C(E2)-H], the piperazine ring carbons [C(A1), C(A2), C(1), and C(2)], and the methionyl residue carbons [C(B2), C(C2), and C(E2)] of zinc(II) complex ion from those of CMH. These results reveal that the Zn^{2+} ion links exclusively to the imidazolyl groups of the histidyl residues.

We would also like to infer which N(D1 or E1) atom of the imidazolyl group coordinates to the Zn^{2+} ion in aqueous solution. Iyer *et al.*[9] previously reported that the N(D1) atom of the imidazolyl group coordinates to the Zn^{2+} ion in DMSO-d_6 from their NMR studies of the zinc(II) complexes with cyclohepta- and cyclooctapeptides though their results are similar to those for our zinc(II) complex. As shown in Fig. 1, the X-ray structure of the $[Zn(CMH)_4]^{2+}$ ion indicates that the N(E1) atom of the imidazolyl group of CMH links to the Zn^{2+} ion. Speculation regarding the CPK model also supports a possibility for the N(E1) atom of imidazolyl groups to coordinate to the Zn^{2+} ion. These results introduce a conclusion that the N(E1) atom of CMH coordinates to the Zn^{2+} ion in an aqueous solution (as

a) $\Delta\delta=\delta$[zinc(II) complex ion]$-\delta$(free ligand). b) $Zn(CMH)_4SO_4\cdot 2H_2O$ was used for the measurement.

opposed to that of Iyer *et al.*). However, further studies of similar complexes are necessary for determining which N(D1 or E1) atom of the imidazolyl group coordinates to the Zn^{2+} ion in an aqueous solution.

The values (381 and 412 for 0.0246 and 0.0591M, respectively) of the molecular weight obtained for $[Zn(CMH)_4]SO_4 \cdot 2H_2O$ are smaller than the theoretical value (1233/2=617) given in the dissociation of this complex to a monomeric complex ion and a sulfate one. These results suggest that the above complex ion has the following dissociative equilibrium;

$$[Zn(CMH)_4]^{2+} \rightleftharpoons [Zn(CMH)_3]^{2+} + CMH \rightleftharpoons [Zn(CMH)_2]^{2+} + 2CMH \text{ } etc.$$

The authors wish to thank Mr. Junichi Gohda for the measurements of the elemental analyses. We are also indebted to the Crystallographic Research Center, Institute for Protein Research, Osaka University, for computer calculations.

Differential Pulse Polarographic Determination of Lead Using Coprecipitation with Hafnium Hydroxide

Joichi UEDA* and Chikako KITA

Department of Chemistry, Faculty of Education, Kanazawa University, Marunouchi, Kanazawa 920

(Received January 28, 1985)

A differential-pulse polarographic determination of trace amounts of lead using coprecipitation with hafnium hydroxide has been studied. Hafnium hydroxide is effective as a collector of lead and makes 2.5 to at least 1250 μg of lead coprecipitate quantitatively from 100—500 cm^3 of sample solution. The formed precipitate is easily dissolved with hydrochloric acid and the presence of hafnium does not affect to the polarogram of lead. The effects of twenty-three diverse ions such as aluminium, zinc, cadmium, chromium(III), manganese(II), cobalt, and nickel were examined, and it was found that the presence of tin(IV), copper, and iron(III) interfered with the determination, even in small amounts. The recommended procedure for the determination is as follows. To a sample solution containing lead, 5 mg of hafnium is added and the pH is adjusted to about 10 with 1:1 aqueous ammonia. Then, the precipitate is filtered with a glass filter and dissolved with 2 cm^3 of concd hydrochloric acid. After the solution is diluted to 25 cm^3 with distilled water and deaerated with pure nitrogen for 5 min, lead is determined by the current peak height at −0.41 V.

The methods for the determination of trace amounts of lead by a combined coprecipitation-polarography have frequently been studied, and several coprecipitants such as hydroxides of beryllium,[1] aluminium,[2,3] iron(III),[4,5] thorium,[6] and zirconium,[7] or carbonates of calcium[8] and strontium[9] or sulfides of nickel,[10] copper,[11] and zinc[12] or barium chromate[13] have been proposed for a concentration of trace amounts of lead. The majority of these coprecipitants except hydroxides of zirconium and thorium, however, have more or less their individual disadvantages: It is difficult to dissolve the precipitates, the recovery of lead is not so good or the polarogram of lead is affected by the presence of the coprecipitants. This time, we have investigated a new collector of lead, and have found that hafnium hydroxide is excellent. That is, hafnium hydroxide can not only quantitatively collect lead as well as zirconium hydroxide,[7] but it can also quantitatively coprecipitate lead from a wider pH range than zirconium. Furthermore, it dissolves easier than zirconium hydroxide. In this work, we have also tried to filter the precipitate by means of suction with a glass filter and have obtained good results; shortening of the filtration time without the loss of the precipitate and simplifying the filtration procedure. This paper describes the fundamental conditions for the collection of trace amounts of lead by coprecipitation with hafnium hydroxide and a differential pulse polarographic determination of lead.

Experimental

Apparatus. A Yanagimoto model p-1000 polarograph was used for the differential-pulse polarographic measurements. It was operated in a three-electrode configuration with a dropping-mercury electrode, a saturated calomel reference electrode and a platinum counter electrode. A Hitachi-Horiba model M-5 glass electrode pH meter was used for the pH measurements.

All measurements were carried out at 25.0±0.1 °C and the solutions were deaerated with pure nitrogen for 5 min before the polarographic analysis. Voltage scans were made from −0.25 to −0.65 V at a rate of 10 mV s^{-1}, a modulation amplitude of 100 mV and a drop time of 1 second.

Reagents. *Standard Lead Solution*: A solution containing about 1 mg cm^{-3} of lead was prepared by dissolving guaranteed reagent-grade lead nitrate in a small amount of nitric acid and diluting with distilled water. The solution was standardized by the complexometric titration using Xylenol Orange as an indicator. This solution was diluted as required.

Hafnium Solution: A solution containing about 5 mg of hafnium was prepared by dissolving hafnium chloride (Nakarai Chemicals Co.) in 2 mol dm^{-3} hydrochloric acid. The solution was standardized by the complexometric back titration with a standard solution of thorium using Xylenol Orange as an indicator.

1:1 aqueous ammonia and 1 mol dm^{-3} hydrochloric acid were used for pH adjustments.

All the other reagents used were of guaranteed reagent grade.

Recommended Procedure. To a sample solution (100—500 cm^3) containing 2.5—1250 μg of lead, 5 mg of hafnium is added and the pH is adjusted to about 10 with 1:1 aqueous ammonia. Then, this solution is allowed to stand for more than 10 min. The precipitate is filtered by suction using a 3G4 glass filter, washed with aqueous ammonia of pH 10, and dissolved with 2 cm^3 of concd hydrochloric acid (with two 1 cm^3 portions of concd hydrochloric acid in about 5 min intervals). After the solution is diluted to 25 cm^3 with distilled water and deaerated with pure nitrogen for 5 min, the polarogram is recorded from −0.25 to −0.65 V. Lead is determined by the current peak height at −0.41 V.

Results and Discussion

Supporting Electrolyte. As a result of the investigation of various acids (such as hydrochloric, nitric, sulfuric, and perchloric acid), the most

suitable supporting electrolyte was found to be hydrochloric acid in respect to the shape of the polarograms of lead and the ease of dissolution of hafnium hydroxide. So, hydrochloric acid was chosen as the supporting electrolyte for further studies. Then, the effect of the concentration of this acid on the current peak height was studied. As shown in Fig. 1, the current peak height was gradually decreased with increasing amounts of hydrochloric acid; however, a maximum and almost constant value was obtained over a concentration range from 0.5 to 2 mol dm^{-3} of hydrochloric acid. Accordingly, an acidity of 1 mol dm^{-3} was used in this experiment and obtained the highest current peak height.

In Table 1, the relation between the concentration of hydrochloric acid and the time required for the dissolution of hafnium hydroxide is also shown. From this, it can be seen that hafnium hydroxide is dissolved easily by the use of hydrochloric acid whose concentration is more than 3 mol dm^{-3}. In this Table, the results of experiments with zirconium hydroxide is also appended.

Effect of pH on Coprecipitation. The effect of the pH on the coprecipitation of lead with hafnium hydroxide was studied for a solution (100 cm^3) containing 20 μg of lead. The pH values were adjusted with 1:1 aqueous ammonia and 1 mol dm^{-3} hydrochloric acid. The results are shown in Fig. 2. The pH range in which about 100% recovery of lead was observed was found to be 7.0—11.5, which was wider by about 4 times than that of zirconium hydroxide.[7] In this experiment, a pH of about 10 was adopted for the coprecipitation with hafnium hydroxide.

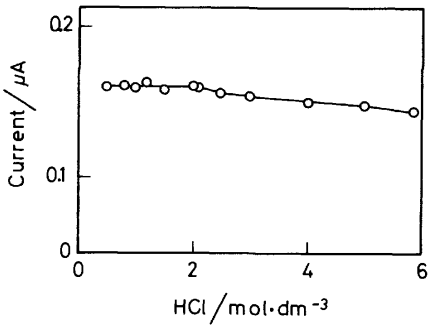

Fig. 1. Effect of the concentration of supporting electrolyte.
Pb: 20 μg/25 cm^3, Hf: 5 mg/25 cm^3, temperature: 25.0±0.1 °C.

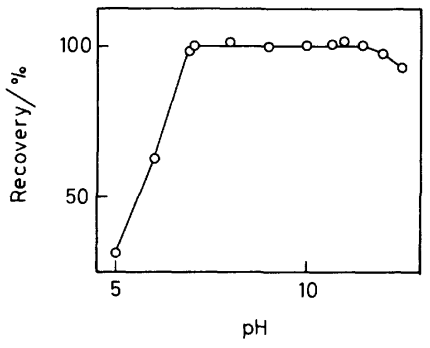

Fig. 2. Effect of pH on coprecipitation.
Pb: 20 μg/25 cm^3, Hf: 5 mg/25 cm^3, supporting electrolyte: 1 mol dm^{-3} HCl, temperature: 25.0±0.1 °C.

Effect of the Amount of the Coprecipitant. The effect of the hafnium concentration on the coprecipitation was studied with a solution (100 cm^3) containing 20 μg of lead and various amounts of hafnium. As the result, lead could be quantitatively collected by adding from 2 mg to at least 20 mg of hafnium.

Effect of Volume of Sample Solution. The relation between the recovery percentage of lead and the volume of the sample solution was studied by the recommended procedure, using various volumes (100—900 cm^3) of sample solutions which contain 20 μg of lead. The recovery percentage was approximately 100% when volumes from 100 to 500 cm^3 were used. However, in the case of using a volume of more than 500 cm^3, the percentage decreased considerably.

Effect of Aging of Precipitate on Lead Recovery. The relation between the recovery of lead and the aging time of the precipitate was investigated. The results indicated that the recovery of lead reached almost 100% at about 10 min after the precipitate was formed. After that, this percentage remained almost constant for at least 10 h. Then, the effect of the aging temperature of precipitate on the recovery of lead was also studied. It was found that almost a 100% recovery was always obtained within a temperature range from room temperature to 90 °C. In this experiment, therefore, the aging of the precipitate was carried out for more than 10 min at room temperature.

TABLE 1. RELATION BETWEEN CONCENTRATION OF HYDROCHLORIC ACID AND DISSOLUTION TIME OF PRECIPITATES

Concentration of HCl/mol dm^{-3}	$Hf(OH)_4$ min	$Zr(OH)_4$ min
1	*ca.* 2.5	*ca.* 50
2	*ca.* 1	*ca.* 12
3	*ca.* 10 s	*ca.* 3
6	*ca.* 5 s	*ca.* 1
9	(A)	*ca.* 1
12	(A)	*ca.* 0.5

10 mg of hafnium or zirconium was taken and 1 cm^3 of hydrochloric acid was used. (A): Precipitate dissolved instantaneously.

Filtration of Precipitate. In this experiment, we tried to filter the precipitate by means of suction using a glass filter and were able to considerably shorten the filtration time without any loss of precipitate. Also, the filtration and dissolution procedures of the precipitate were simplified. Whether the loss occurs or not by suction was examined by a comparison of the recovery of lead obtained by suction with that obtained by natural filtration (using Toyoroshi No. 5A filter paper). It was confirmed that almost the same recoveries were obtained for the both cases.

Calibration Curves. The calibration curves which were prepared by the recommended procedure were shown in Fig. 3. A linear relationship between the current peak height and the concentration was maintained over the range of 0.1—50 μg cm^{-3} for lead. In the absence of 5 mg of hafnium, the calibration curves were also prepared. It was recognized that the obtained curves were the same as the one which was prepared in the presence of hafnium. The reproducibility of the method, expressed by the relative standard deviation of the current peak heights which were obtained from ten repeated determinations, was 1.2% for 20 μg in 100 cm^3 sample solution. In order to investigate the temperature effect on the current peak height, a series of polarograms were also recorded at different temperatures. With a rise of temperature, the potential of the current peak shifted to more negative values and the current peak height increased. In this case, the temperature coefficient was calculated as 1.0%.

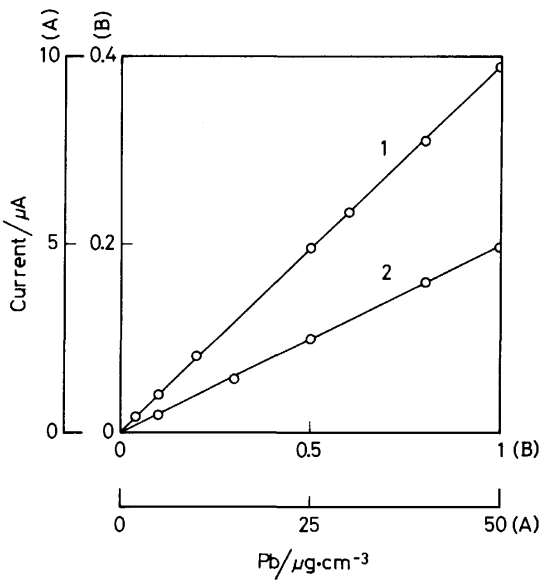

Fig. 3. Calibration curves.
Supporting electrolyte: 1 mol dm^{-3} HCl, Hf: 5 mg/25 cm^3, temperature: 25.0±0.1 °C, 1: utilize scale (A), 2: utilize scale (B).

Effect of Diverse Ions. The effect of twenty-three diverse ions on the determination of 20 μg of lead were examined by the application of the recommended procedure. The results are summarized in Table 2. Lead could be determined within a 5% error in the presence of 5 mg each of 8 cations, such as alkali metals, alkaline earth metals, aluminium, lanthanum, and molybdenum(VI), 0.5 mg each of 3 cations such as zinc, manganese(II), and nickel, and 0.1 mg each of 5 cations such as antimony(III), bismuth(III), cadmium, chromium(III), and cobalt. Tin(IV), copper, and iron(III), however, interfered with the determination even if they were present in a small amounts.

Gas Chromatography-Mass Spectrometry of Trimethylsilylated Imino Derivatives of Alanine

Katsuhiro KAWASHIRO,* Shiro MORIMOTO, and Hideyuki YOSHIDA
Department of Chemical Engineering, Faculty of Engineering, Tokushima University, Minamijosanjima, Tokushima 770
(Received December 4, 1984)

Trimethylsilylation of seven imino derivatives of alanine with *N,O*-bis(trimethylsilyl)trifluoroacetamide in acetonitrile was studied. The imino derivatives include 2,2′-iminodipropionitrile (**1**), 2,2′-iminodipropionamide (**2**), 2,2′-iminodipropionic acid (**3**), 2-(1-cyanoethylamino)propionamide (**4**), 2-(1-cyanoethylamino)-propionic acid (**5**), 2-(1-carbamoylethylamino)propionic acid (**6**), and 3,5-dimethyl-2,6-piperazinedione (**7**). The reaction products were identified by gas chromatography–mass spectrometry. Under the present reaction conditions (at 100 °C for 30 min), hydrogen atoms of carboxyl and carbamoyl groups and an imide hydrogen were readily replaced by the trimethylsilyl (TMS) group, but imino hydrogens were not replaced because of the steric hindrance of *N*-substituent group. For the carbamoyl group, only one hydrogen was replaced. Consequently, **1** was not trimethylsilylated. Furthermore, no definite trimethylsilylation products were obtained for **4**. Upon electron impact at 70 eV, **2**, **3**, and **5**—**7** gave rather simple spectra with molecular (M^+) and M −15 (loss of CH_3) ions characteristic of TMS derivatives. A fragment, M−117 (loss of COOTMS) or M −116 (loss of CONHTMS), was very prominent for **2**, **3**, **5**, and **6**. Other important ions such as *m/z* 70 were noted. Preparations and properties of some of the imino derivatives are also described.

In recent years, gas chromatography–mass spectrometry (GC–MS) has become a useful method for unequivocal identification of nonvolatile compounds such as amino acids and related compounds after their conversion into suitable volatile derivatives. Of numbers of such volatile derivatives,[1] the trimethylsilyl (TMS) derivative has received great interest because of its simple preparation and both good gas chromatographic and mass spectral properties.

In our previous paper[2] the presence of certain imino derivatives of alanine (Ala) in the polymerization product of 2-aminopropionitrile (2-APN) was suggested by ion-exchange chromatography. Ion-exchange retention data, however, are generally not sufficient to identify unequivocally amino acids and related compounds present in complex reaction mixtures. This has led us to study the GC–MS of the imino derivatives of Ala as shown in Fig. 1, after conversion into their TMS derivatives. The main reason for choosing the TMS derivative is that TMS groups can be readily introduced into functional groups such as carboxyl, hydroxyl, amino, carbamoyl groups, *etc.* with an easily available reagent such as *N,O*-bis(trimethylsilyl)trifluoroacetamide (BSTFA). Because of the absence of an acid or a base no hydrolysis takes place during trimethylsilylation; this makes it possible to distinguish, for example, between acid and amide groups present in the molecules. In this respect the TMS derivative has an advantage over the *N*-trifluoroacetyl alkyl ester derivative, preparations of which generally involve an esterification catalyzed by HCl.

Leimer *et al.*[3] have reported a comprehensive study of the complete mass spectra (electron impact at 70 eV), and the general fragmentation pathways for TMS derivatives of protein amino acids. The GC–MS of TMS derivatives of nonprotein amino acids such as

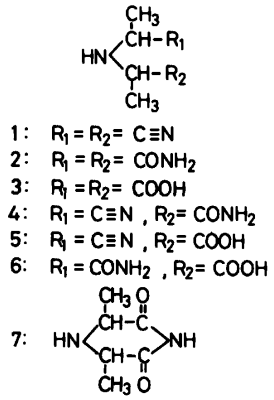

Fig. 1. Imino derivatives of Ala.

N-substituted amino acids, however, has far less been studied. In the previous paper,[4] we have reported GC–MS of TMS derivatives of some iminodicarboxylic acids including 2,2′-iminodipropionic acid (**3**).

This paper describes trimethylsilylation of imino derivatives of Ala as shown in Fig. 1 with BSTFA, and mass spectra of the resultant TMS derivatives upon electron impact at 70 eV. The imino derivatives include 2,2′-iminodipropionitrile (**1**), 2,2′-iminodipropionamide (**2**), (**3**), 2-(1-cyanoethylamino)propionamide (**4**), 2-(1-cyanoethylamino)propionic acid (**5**), 2-(1-carbamoylethylamino)propionic acid (**6**), and 3,5-dimethyl-2,6-piperazinedione (**7**). The structures of **1**—**7** are shown in Fig. 1. Preparations, ion-exchange chromatography, and lability in aqueous solutions are also described for **1**—**7**.

Results and Discussion

Preparations and Properties of 1—7. Of **1**—**7**, symmetrical compounds such as **1**—**3** were easily pre-

pared according to the method of Dubsky.[5] Compound **4** was prepared for the first time in a 40% yield in the following way:[6]

$$CH_3CHO\cdot NaHSO_3 + H_2NCH(CH_3)CONH_2 + NaCN \xrightarrow{0\,^\circ C} \mathbf{4}$$

However, preparations of unsymmetrical compounds such as **5** and **6**, were rather difficult.[7]

Karrer *et al.*[8] have reported preparation of **5**, which involved partial hydrolysis of **1** *via* an imidate derivative. In the present study, a product of mp 188—189 °C was obtained according to their method. Although the results of elemental analysis suggested the formation of **5**, spectral data were not consistent with the structure of **5**. IR spectrum showed no C≡N absorption near at 2250 cm^{-1}, but two strong absorptions due to $\nu_{C=O}$ were observed at 1680 and 1710 cm^{-1}, characteristic positions of an imide structure. The ^1H NMR spectrum of the product is rather simple, and equivalence of both two methyl (δ=1.20) and methine (3.45) protons suggests a cyclized imide structure as shown in Fig. 2. On the basis of these spectral data, the product was determined to be not **5**, but its isomer **7**. Repeated preparations gave the same product. Although the mechanism of the formation of **7** from **1** is not well understood, this reaction may be speculated as shown in Scheme 1.[9] A longer elution time of the product on ion-exchange chromatography

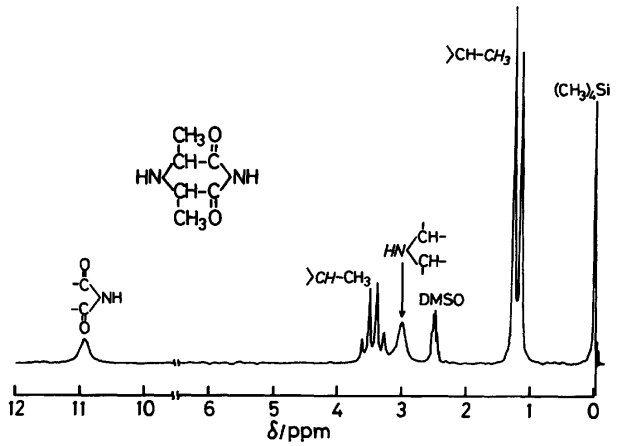

Fig. 2. ^1H NMR spectrum of the product obtained from **1** (DMSO-d_6).

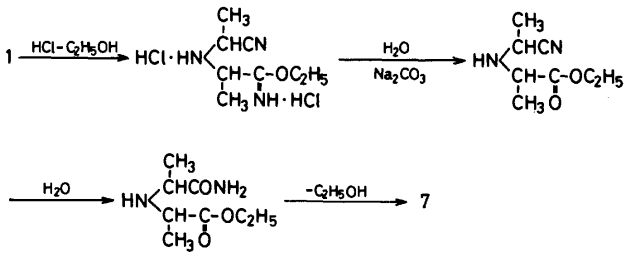
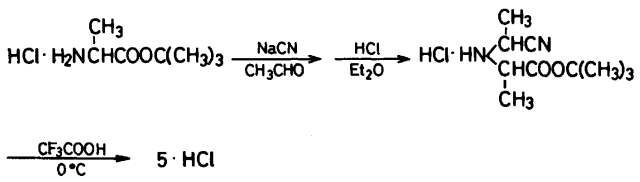


Scheme 1. Possible route for the formation of **7** from **1**.



Scheme 2. Synthetic route for **5**.

(158 min, Table 1) revealed that it was of a basic nature rather than of an acidic nature. This is an additional evidence for the imide structure.

Compound **5** was successfully synthesized by the Strecker reaction and subsequent removal of the *t*-butyl group as shown in Scheme 2. An intermediate, *t*-butyl 2-(1-cyanoethylamino)propionate, was isolated as its hydrochloride (mp 120—122 °C), which was characterized by ^1H NMR spectrum and elemental analysis. Addition of CF_3COOH (TFA) to it gave a very hygroscopic hydrochloride of **5** with removal of the *t*-butyl group.[10] On ion-exchange chromatography, the product exhibited a single peak with a very short elution time (57 min, Table 1); the elution behavior was consistent with an acidic nature of **5**. After conversion into the TMS derivative, the product was further characterized by GC-MS which revealed the presence of both M^+ (*m/z* 214) and M−15 (*m/z* 199) ions corresponding to the mono-TMS derivative (Table 3).

Although two methods[5,11] have been reported for the preparation of **6**, they have individual disadvantages.[12] In the present study, **6** was prepared by partial hydrolysis of **2**. Compound **2** was found to be hydrolyzed to give **3** *via* an intermediate **6** in a hot dilute aqueous solution. The yield of **6** reached a maximum after 1 d at 100 °C, when starting compound **2** disappeared almost completely. After separation by ion-exchange chromatography, **6** was obtained as the monohydrate.

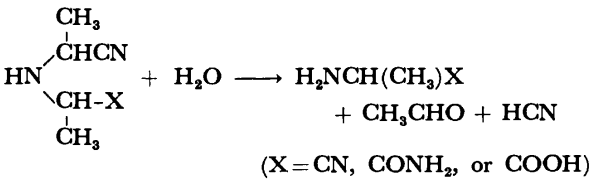
Table 1 gives elution times and color constants of **1**—**7** except **3** on ion-exchange chromatography using an amino acid analyzer. Compound **3** is known to be ninhydrin-negative.[8,13,14] Data of some related compounds such as Ala, alaninamide (Ala-NH_2), and 2-APN are also included. With buffer system A (pH 3.25—pH 5.28, buffer change of 30 min), elution orders of imino derivatives of Ala were similar to those of imino derivatives of glycine (Gly) reported previously.[6] With buffer system B (pH 3.25 alone), elution of basic components was retarded significantly, and **7** was found not to be eluted as a peak. The elution order of 2-APN and Ala-NH_2 reversed with the two buffer systems. As shown in Table 1,[15] **2a** and **6a** exhibited a single peak. On the other hand, the separation between diastereomers was observed for both **2b** and **6b**. It is noted that the peaks of **2a** and **6a** corresponded to the second peaks of **2b** and **6b**, respectively.

Table 1. Elution times and color constants of imino derivatives of Ala and related compounds on ion-exchange chromatography[a)]

Imino derivative	Elution time/min[b,c)] A	B	Relative color constant[d)]
1	54		1.03
5	57		0.65
6	60, 66		0.095
Ala	98		1.00
4[e)]	112, 131		0.63
7	158	—	0.17
2	206, 240	294, 363	0.70
2-APN	221	390	1.05
NH_3	249	348	0.96
Ala-NH_2	276	379	1.05

a) Column: 0.25ϕ×50 cm (Aminex A-4). Conditions of chromatography are shown in the Experimental section. b) Buffer systems A and B refer to pH 3.25—5.28 buffer with buffer change of 30 min, and to pH 3.25 buffer alone, respectively. c) In the cases of **2** and **6**, the separation between diastereomers was observed for **2b** and **6b**, whereas **2a** and **6a** gave a single peak. The peaks of **2a** and **6a** corresponded to the second peaks of **2b** and **6b**, respectively. d) Color constant of Ala: 124.9 μmol^{-1}. In the cases of **2** and **6**, color constants were calculated for **2a** and **6a**, respectively. e) The separation between diastereomers was observed.

Lability of α-amino nitriles in dilute aqueous solutions is well known.[6,16,17] Figure 3 shows the time course of decomposition of **1**, **4**, and **5** in both H_2O and the buffer solutions of pH 3.25 at room temperature. Lability increased in the order of **4**, **1**, and **5** in both solutions and the decomposition was more rapid in the buffers (pH 3.25) than in aqueous solutions. α-Aminonitriles **1**, **4**, and **5** decomposed with the formation of 2-APN, Ala-NH_2, and Ala, respectively. Consequently, the decomposition may be explained in terms of the reverse Strecker reaction as follows:[6]



On decomposition, **4** and **5** gave almost stoichiometric amounts of Ala-NH_2 and Ala, respectively, and no other ninhydrin-positive products were found. In contrast, a significant amount of NH_3 was released in the case of **1** as shown Fig. 4. The formation of NH_3 can be explained in terms of the decomposition of the unstable intermediate, 2-APN, as follows:

$$H_2NCH(CH_3)CN + H_2O \longrightarrow NH_3 + CH_3CHO + HCN$$

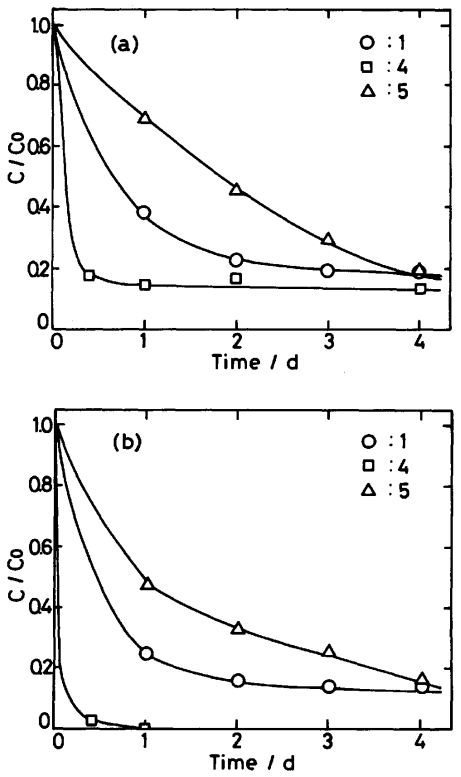


Fig. 3. The time course of decomposition of **1**, **4**, and **5** in aqueous solutions at room temperature. Initial concentration (C_0) is 1 mM (1 M = 1 mol dm^{-3}) for **4** and **5**, but 0.5 mM for **1**. a: H_2O. b: Citrate buffer solution of pH 3.25.

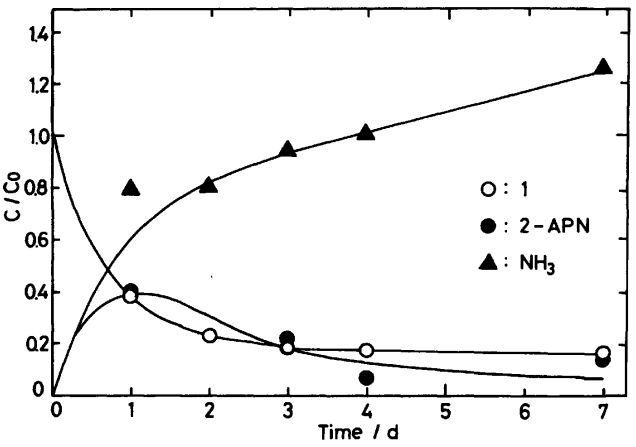

Fig. 4. The time course of decomposition of **1** in aqueous solution at room temperature. C_0: 0.5 mM.

There were some differences in decomposition of **1**, **4**, and **5**. As shown in Fig. 3a, **5** decomposed irreversibly according to the pseude first-order kinetics,[18] whereas **1** and **4** appeared to reach equilibria after 2 and 1 d, respectively. In the buffer solution of pH 3.25, **4** decomposed completely after 1 d (Fig. 3b); this fact indicates that the equilibrium was shifted greatly to the decomposition-product side with a decrease in

pH. In aqueous solutions, α-amino nitriles **1**, **4**, and **5** were found to be more labile than the corresponding imino derivatives of Gly reported previously.[6] Therefore, when these α-amino nitriles are to be analyzed with an amino acid analyzer, freshly prepared aqueous sample solutions should be charged on the analyzer as promptly as possible.

Trimethylsilylation and Gas Chromatography. When trimethylsilylation was performed in BSTFA-CH_3CN (1:1, v/v)[19] at 100 °C for 30 min, completely clear solutions were obtained for **1**—**7**. This observation suggests the formation of the corresponding TMS derivatives. In general, active hydrogens such as NH (imino), COOH, $CONH_2$, and NH (imide), were expected to be replaced by TMS groups. The GC-MS of the derivatized products revealed that among the active hydrogens, the imino NH could not be trimethylsilylated under the present conditions because of the steric hindrance of the *N*-substituent group.[4] Consequently, **1** having only imino NH as an active hydrogen was not trimethylsilylated. Nevertheless, free **1** was eluted most rapidly on GC because of its high volatility (Table 2). In contrast, some GC peaks were observed for **4**, but any definite trimethylsilylation products could not be identified, suggesting the decomposition of **4** during derivatization.

Table 2 gives retention times of trimethylsilylated imino derivatives of Ala on GC and the number of TMS groups introduced into them. A fused silica capillary column (OV-101 FS-WCOT, 0.35 mmφ×25 m) had advantages over a packed column (3 mmφ×1 m, 1.5% OV-101 on Chromosorb G HP) in terms of the good separation and the absence of decomposition of TMS derivatives. As shown in Table 2, separation between diastereomers of **3** was rather poor as compared with those of **2** and **6**. However, almost base line separation between the diastereomers was achieved when an SE-30 fused silica capillary column (FS-WCOT, 0.35 mmφ×25 m) was used.

Table 2. Retention times of trimethylsilylated imino derivatives of Ala on GC[a]

Parent compound	Number of TMS group	Retention time/min[b]
1	0	6.6
2	2	23.7, 24.7
3	2	16.8, 17.0
4[c]	—	—
5	1	11.1
6	2	20.1, 20.9
7	1	14.6

a) Initial temp: 100 °C. Initial hold: 5 min. Program rate: 5 °C/min. Final temp: 250 °C. Injector temp: 250 °C. Column: OV-101 fused silica capillary (0.35 mmφ×25 m). Retention time of phenanthrene: 25.9 min. b) In the cases of **2**, **3**, and **6**, the separation between diastereomers was observed for **2b**, **3b**, and **6b**, whereas **2a**, **3a**, and **6a** gave a single peak. The peak of **3a** corresponded to the first peak of **3b**. On the other hand, the peaks of **2a** and **6a** corresponded to the second peaks of **2b** and **6b**, respectively. c) No definite trimethylsilylation products were detected.

There was a difference in the elution behavior between **3a** and **3b**. Two GC peaks were eluted for **3b**, indicating separation between the diastereomers, which were proved on the basis of mass spectral data. On the other hand, a single peak was observed for **3a**, which corresponded to the first peak of **3b**. From these findings, it is evident that **3b** is a mixture of the diastereomers whereas **3a** is a racemate (*R,R*-+*S,S*-) or meso-form (*R,S*-). Similarly, two peaks were eluted for **2b**, while a single peak was observed for **2a**. It is noted, however, that the peak of **2a** corresponded to the second peak of **2b**. The reversed elution order of the diastereomers may be attributable to the nature of the carbamoyl groups, because it seems reasonable to assume no inversion of the two asymmetric centers during the preparation of **2a** from **3a**. Similar elution behavior of diastereomers was also found for **6a** and **6b**. For **2** and **6**, their elution behavior was well consistent with that on ion-exchange chromatography (Tables 1 and 2). Karrer and Appenzeller have reported that 2,2′-iminodipropionic acid (mp 233 °C) prepared by acid hydrolysis of **1**, was not a racemate, but a meso-form or a mixture of these two forms, by comparing its melting point with those of authentic samples.[13,20] The fact that **6a** prepared from **3a** as the starting material exhibited a single GC peak in the present study,[21] is not consistent with the results obtained by Karrer and Appenzeller. If **3a** is a meso-form, **6a** must become a mixture of the diastereomers. This discrepancy needs to be investigated further.

Figure 5 shows the time course of trimethylsilylation of **2b** at 100 °C, as a typical example. The peak area ratio of the di-TMS derivative to an internal standard (phenanthrene) becomes almost constant after 20 min, and its conversion into a more highly

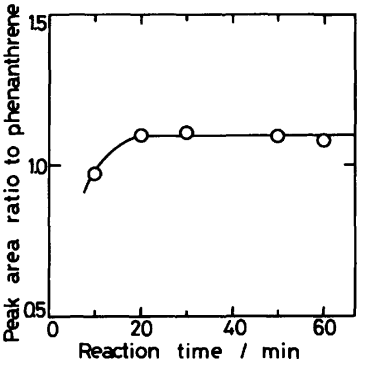

Fig. 5. The time course of trimethylsilylation of **2b** at 100 °C (**2b**: 50 μmol, BSTFA: 0.25 ml, CH_3CN: 0.25 ml, phenanthrene: 3.0 mg).

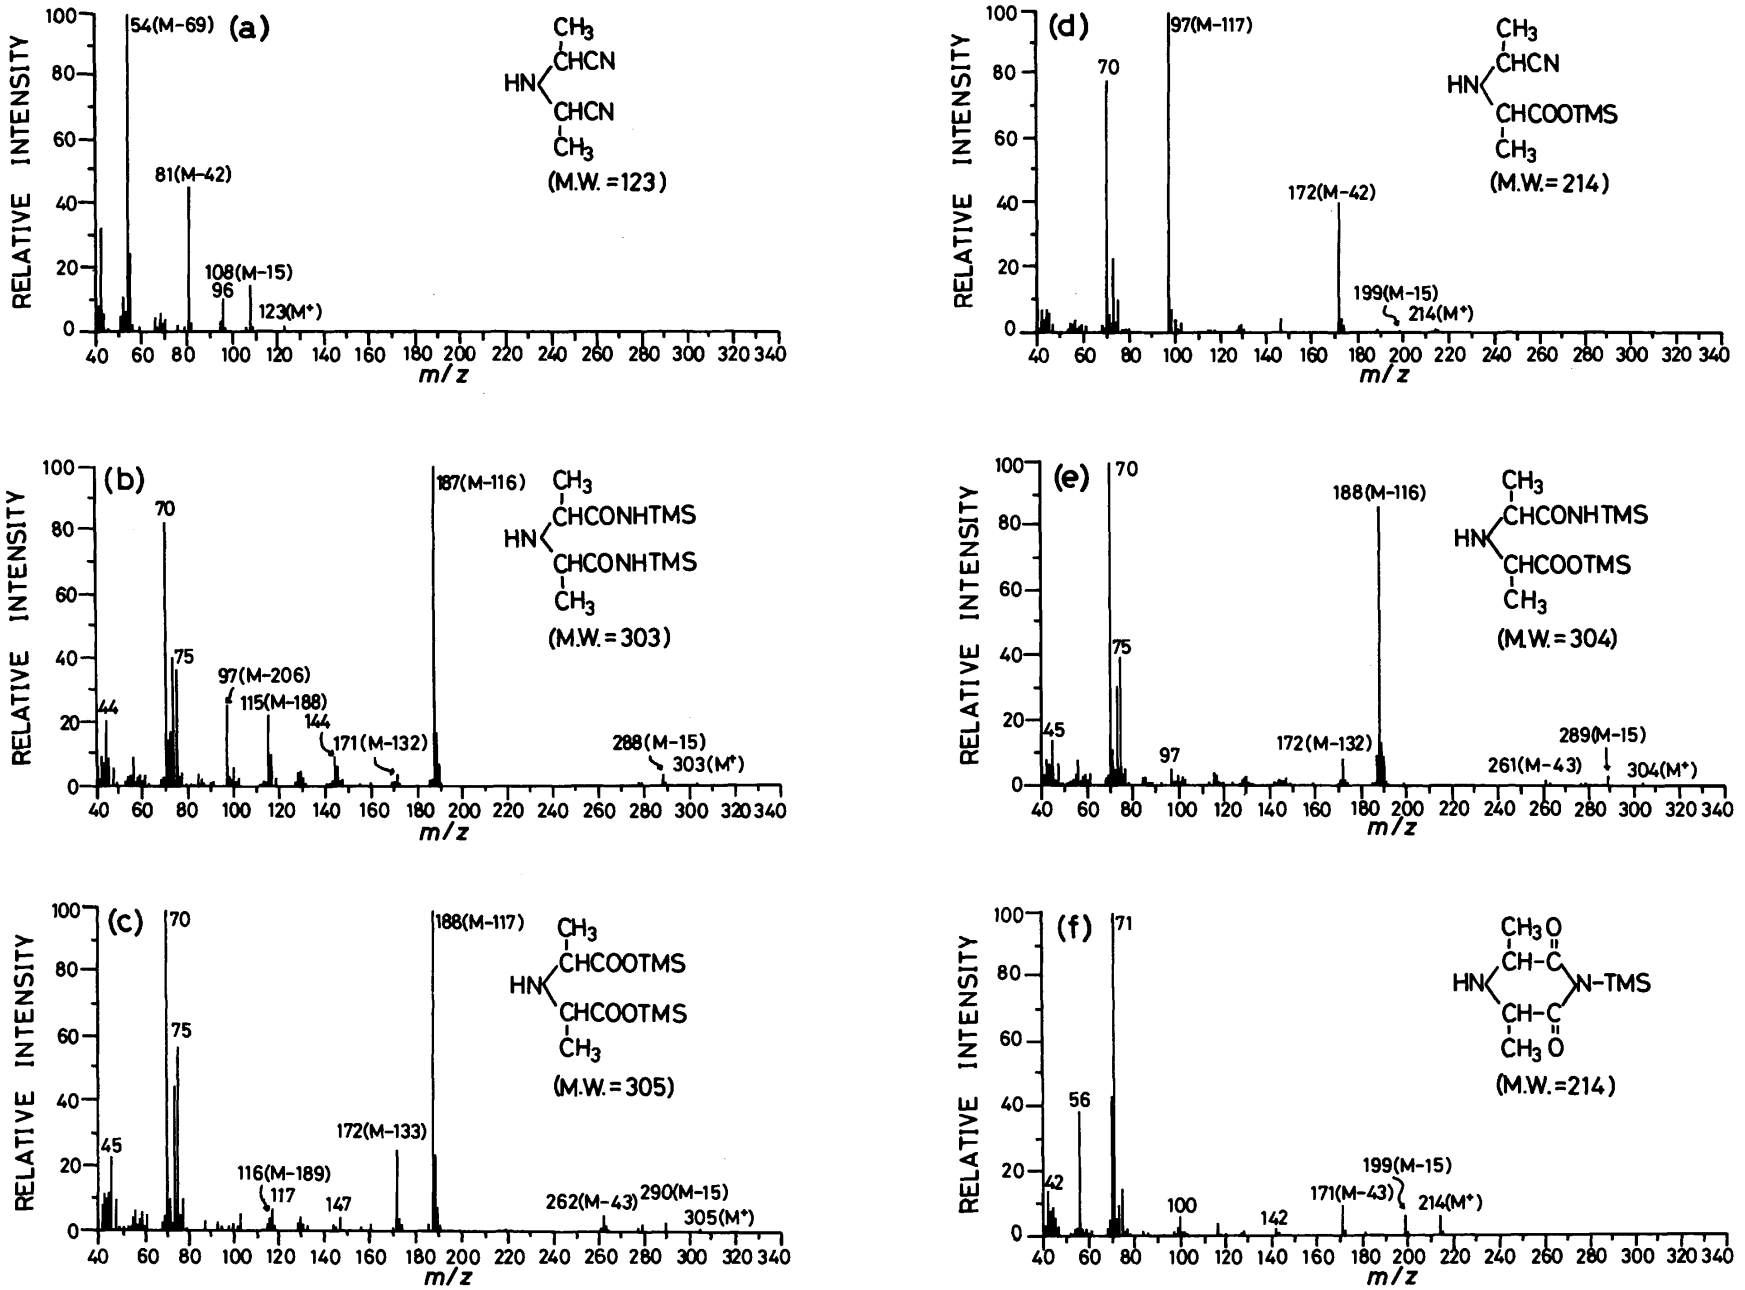

Fig. 6. Mass spectra of trimethylsilylated imino derivatives of Ala. a: **1**, b: **2**, c: **3**, d: **5**, e: **6**, and f: **7**.

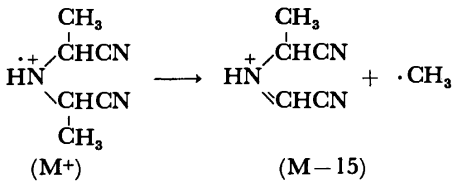
trimethylsilylated derivative was not observed under the present conditions. Compound **7** having an imide NH also exhibited similar behavior on derivatization. Trimethylsilylation of **3b** was found to be more facile than **2b**. Therefore, derivatization of the functional groups present in the imino derivatives of Ala (except the imino NH) may be taken as completed under the present conditions (at 100 °C for 30 min).

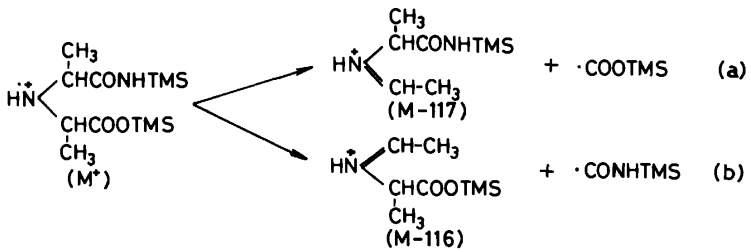
Mass Spectra. Figures 6a—f present mass spectra of trimethylsilylated products for **1**—**3** and **5**—**7**. No TMS groups were introduced into **1**, as described above. Some characteristic ions are listed in Table 3. Both M^+ and M−15 ions are present in all the spectra.

For **2**, **3**, and **5** which have either a carboxyl or carbamoyl group, the most important ions arise from the M^+ by the loss of a COOTMS or CONHTMS group (α-cleavage to the imino nitrogen) with charge retention on the amine fragments. That the carbon-carbon bond adjacent to the nitrogen is preferentially cleaved is well known for amino acids and related compounds.[3,4] Thus both **3** and **5**, and **2** are characterized by the prominent M−117 (COOTMS) and M−116 (CONHTMS) ions, respectively. These fragments resulted from the α-cleavage constitute base peaks. The predominance of the fragments can be explained in terms of their stabilization due to resonance. There are two possibilities of α-cleavage for **6**, which has both carboxyl and carbamoyl groups (Scheme 3). As shown in Table 3, the M−116 ion is about 10 times abundant than the M−117 ion. This fact indicates that the CONHTMS group is more preferentially split off from the M^+ than the COOTMS. The elementary compositions of both the M−116 and M−117 ions were confirmed by hgh-resolution mass measurement.

For **5**, there are also two possibilities of α-cleavage, the loss of COOTMS and CN, with charge retention on the amine fragment. As shown in Fig. 6d, the M−117 (COOTMS) ion at m/z 97 constitutes a base peak, whereas the M−26 (CN) ion at m/z 188 has a relative intensity of less than 1%. This fact indicates that the cleavage of the carbon-carbon bond adjacent to the cyano group is very difficult. The increased stability of the bond compared with those adjacent to electron-withdrawing functional groups such as carbonyl, has been explained by McLafferty.[22]

As is expected, for **1** having two cyano groups no cleavage of the carbon-carbon bond adjacent to the cyano group, is observed. However, instead of the cleavage, the following fragmentation becomes significant, which accounts for the presence of a rather intense M−15 ion (rel. intensity, 14.2%) for **1** without





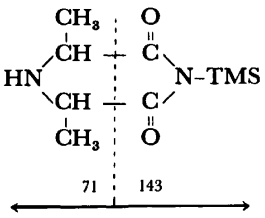
Scheme 3. Two possible α-cleavages for **6**.

TABLE 3. CHARACTERISTIC IONS OF TRIMETHYLSILYLATED IMINO DERIVATIVES OF Ala

Parent compound	Number of TMS group	m/z[a]						
		M^+	M−15	M−42	M−43	M−116	M−117	Others
1	0	123 (1.3)	108 (14.2)	81 (45.0)	—	—	—	54 (100)
2	2	303 (0.4)	288 (3.4)	261 (0.3)	—	187 (100)	186 (0.4)	115[M−118], (22.0) 97[M−206], (25.2) 70 (82.3)
3	2	305 (1.3)	290 (3.0)	—	262 (5.0)	189 (23.2)	188 (100)	172[M−133], (25.0) 116[M−189], (3.1) 70 (99.3)
5	1	214 (0.7)	199 (0.3)	172 (30.0)	—	98 (7.4)	97 (100)	70 (70.2)
6	2	304 (0.3)	289 (2.4)	—	261 (1.1)	188 (86.7)	187 (9.1)	172[M−132], (8.2) 97[M−207], (4.8) 70 (100)
7	1	214 (6.2)	199 (6.1)	—	171 (9.5)	98 (0.5)	97 (1.1)	71, 70 (100) (43.8)

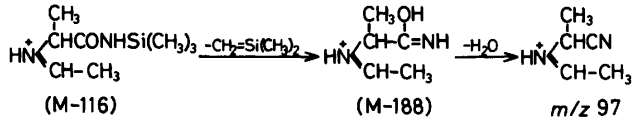
a) Values in parentheses indicate relative intensity.

TMS groups. A base peak at *m/z* 54 corresponds to M−69 (NHCH(CH$_3$)CN), indicating that the N-C bond between the imino nitrogen and methine carbon is cleaved with charge retention on the 1-cyanoethyl fragment. Two ions characteristic of the nitrile, the M−27 (HCN) at *m/z* 96 and M−42 (CH$_3$+HCN) at *m/z* 81, are observed. The latter ion also appears at *m/z* 172 for **5**, indicating the presence of a -CH(CH$_3$)-CN group in the molecule. For **7**, the M$^+$ ion is rather intense because of its cyclic structure. An ion at *m/z* 71 constitutes a base peak, which may result from the following cleavage:

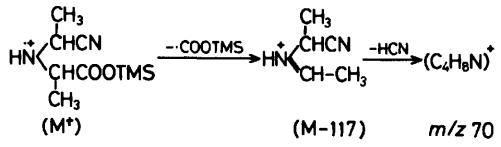


As is expected, the 70 eV spectrum of **3** becomes slightly complicated as compared with the corresponding 20 eV spectrum reported previously,[4] although similar characteristic ions are present. In the 70 eV spectrum, ions in the low mass region such as *m/z* 70, 73, and 75, become significant, whereas the M+1 ion which was larger than the M$^+$ in the 20 eV spectrum is not seen.

As shown in Fig. 6c, **3** having two carboxyl groups gives characteristic ions such as M−43 (CH$_3$+CO), M−133 (CH$_3$+CO+(CH$_3$)$_3$SiOH), and M−189 (COOTMS+CH$_2$=Si(CH$_3$)$_2$). Analogous characteristic ions are observed for **2**, which has two carbamoyl groups (Fig. 6b). Ions at *m/z* 261 and 171 were determined to be M−42 (CH$_3$+CNH) and M−132 (CH$_3$+CNH+(CH$_3$)$_3$SiOH), respectively. Although an ion at *m/z* 170 corresponds to M−131 (CH$_3$+CNH+(CH$_3$)$_3$SiNH$_2$), this is far less significant than the M−132 ion. A prominent ion at *m/z* 115 was determined to be M−188 (CONHTMS+CH$_2$=Si(CH$_3$)$_2$). This fact indicates that the ion results from the α-cleavage fragment (M−116) by the loss of a neutral species, CH$_2$=Si(CH$_3$)$_2$. The elementary composition of an ion at *m/z* 97 was determined to be C$_5$H$_9$N$_2$, which corresponds to M−206 (CONHTMS+CH$_2$=Si(CH$_3$)$_2$+H$_2$O). Consequently, this ion arises most likely from the M−188 ion by the loss of H$_2$O. The fragmentation may be depicted as shown in Scheme 4.



Scheme 4. Proposed fragmentation to the *m/z* 97 for **2**.



Scheme 5. Proposed fragmentation to the *m/z* 70 for **5**.

As is expected, the ions characteristic of both **2** and **3** (except M−42 and M−133) are observed for **6**, which has both carboxyl and carbamoyl groups. In this case, ions at *m/z* 116 and 115 were determined to be M−188 (CONHTMS+CH$_2$=Si(CH$_3$)$_2$) and M−189 (COOTMS+CH$_2$=Si(CH$_3$)$_2$), respectively. The ion *m/z* 97 corresponds to M−207 (COOTMS+CH$_2$=Si(CH$_3$)$_2$+H$_2$O) and, therefore, results from the M−189 by the loss of H$_2$O. Most of the characteristic ions described above were confirmed by high-resolution mass measurement.

In the low mass region, a very prominent ion at *m/z* 70 appears in most of the spectra (except **1**); this is a base peak for **6**. Generally, this unusual ion is not found for the TMS derivatives of common amino acids. High-resolution mass measurement revealed that it had an elementary composition of C$_4$H$_8$N without a silicon atom. Since the *m/z* 70 ion corresponds to M−144 (COOTMS+HCN) for **5**, its formation may be depicted as shown in Scheme 5. Similarly, for **2** and **3**, the *m/z* 70 ion arises most likely from the *m/z* 97 (M−206) and *m/z* 116 (M−189) by the loss of neutral species, HCN and HCOOH, respectively. For **6**, both the two fragmentations are possible for the formation of the *m/z* 70 ion.

In the previous paper,[4] tri-TMS derivative of **3** exhibited an abundant ion at *m/z* 70. In the present study, under forced derivatization conditions, **6** was found to give a small amount of the tri-TMS derivative along with the di-TMS derivative. The tri-TMS derivative also gave a prominent *m/z* 70 ion upon electron impact.[23] These observations indicate that imino derivatives of Ala (except **1**) generally exhibit a very prominent ion at *m/z* 70, whether their imino NHs are trimethylsilylated or not. Consequently, the presence of this ion can be used as a method of detecting them by GC-MS.

Experimental

All the melting points were determined with a Yanagimoto micro melting point apparatus and were not corrected. ^{1}H NMR spectra were measured with a Hitachi R-24B spectrometer using tetramethylsilane or sodium 2,2-dimethyl-2-silapentane-5-sulfonate as an internal standard. IR spectra were taken with a Hitachi 285 infrared spectrophotometer. Ala and 2-bromopropionic acid used as starting materials were of (*RS*)-form.

2,2'-Iminodipropionitrile (1). Compound **1** was prepared by the method of Dubsky.[5] Yield, 13%; mp, 65—

66 °C (lit,[5] 68 °C). Found: C, 58.29; H, 7.31; N, 34.14%. Calcd for $C_6H_9N_3$: C, 58.52; H, 7.37; N, 34.12%.

2,2'-Iminodipropionic Acid (3). ***3a***: Compound **1** was hydrolyzed with 6 M† HCl (at 100 °C for 6 h)[5] and then the product was isolated as a zinc salt to remove Ala produced by a side reaction. The free acid was obtained by decomposition of the salt with H_2S in aq solution. Yield, 25%; mp (dec), 239—241 °C (lit,[5] 233—235 °C). Found: C, 44.81; H, 6.96; N, 8.68%. Calcd for $C_6H_{11}NO_4$: C, 44.72; H, 6.88; N, 8.69%.

3b: Compound **3b** was prepared by the reaction of Ala and 2-bromopropionic acid in the presence of NaOH.[14] Yield 32%; mp (dec), 256—258 °C (lit,[14] 250—252 °C). Found: C, 44.56; H, 6.62; N, 8.48%.

2,2'-Iminodipropionamide (2). Compounds **2a** and **2b** were prepared from **3a** and **3b**, respectively, by the method of Dubsky,[5] which involves esterification with methanol and subsequent ammonolysis.

2a: Yield 20%; mp, 133—136 °C (lit,[5] 127 °C). Found: C, 45.11; H, 8.41; N, 26.09%. Calcd for $C_6H_{13}N_3O_2$: C, 45.27; H, 8.23; N, 26.40%.

2b: Yield 41%; mp 135—138 °C. Found: C, 45.01; H, 8.45; N, 26.56%.

2-(1-Cyanoethylamino)propionamide (4). A mixture of acetaldehyde-sodium hydrogensulfite[24] (6.67 g) and H_2O (5 ml) was cooled below 0 °C with stirring, to which was added dropwise a solution of NaOH (1.2 g, 30 mmol) and Ala-NH_2·AcOH[25] (4.45 g, 30 mmol) dissolved in a small amount of H_2O. After the addition was complete, the mixture was stirred for 2h at 0 °C and further for 30 min at room temperature. A solution of NaCN (1.60 g, 33 mmol) in a minimum amount of H_2O was added to it under cooling. After being left overnight at room temperature, the solution was extracted with ethyl acetate (AcOEt) (40 ml×4) and the extract was dried (Na_2SO_4), filtered and then evaporated to give a pale yellowish oil, which solidified on the addition of diethyl ether (Et_2O). Recrystallization was performed from AcOEt–petroleum ether; yield 1.70 g (40%); mp 92—95 °C; IR (KBr) 3410 (NH), 2210 (C≡N), and 1670 cm^{-1} (amide I); ^1H NMR (DMSO-d_6) δ=1.18 (3H, d, J=7.0 Hz, CH_3), 1.47 (3H, d, J=7.0 Hz, CH_3), 2.80—3.92 (2H, m, 2CH), 3.30 (1H, s, NH), and 7.01, 7.27 (2H, br, $CONH_2$). Found: C, 50.91; H, 8.10; N, 29.80%. Calcd for $C_6H_{11}N_3O$: C, 51.05; H, 7.85; N, 29.76%.

As an alternative approach, ammonolysis of methyl 2-(1-cyanoethylamino)propionate was attempted, which was prepared from acetaldehyde-sodium hydrogensulfite, methyl alaninate, and NaCN in a similar manner. However, the product was found to contain a considerable amount of a by-product (Ala-NH_2), which could not be removed by repeated recrystallizations.

2-(1-Cyanoethylamino)propionic Acid (5). *t-Butyl 2-(1-Cyanoethylamino)propionate Hydrochloride*: *t*-Butyl alaninate hydrochloride (mp 143—145 °C; lit,[26] 139—140.5 °C) was prepared by the reaction of *N*-benzyloxycarbonyl-Ala[27] and 2-methylpropene in the presence of H_2SO_4, and subsequent hydrogenation[10] and introduction of dry HCl gas. A mixture of *t*-butyl alaninate hydrochloride (1.0 g, 5.5 mmol), acetaldehyde (0.43 g, 9.8 mmol), and Et_2O (20 ml) was cooled below 0 °C with stirring, to which was added a solution of NaCN (0.49 g, 10 mmol) in a small amount of H_2O. After the addition was complete, stirring was continued for 4 h. The Et_2O layer was separated and then the aq layer was extracted with Et_2O (50 ml×3). The combined Et_2O layer was dried (Na_2SO_4) and filtered. Introduction of dry HCl gas into the Et_2O layer caused crystallization of the hydrochloride, which was recrystallized from ethanol–Et_2O; yield 0.60 g (46%); mp 120—122 °C; ^1H NMR (DMSO-d_6) δ=1.47 (9H, s, $C(CH_3)_3$), 1.54 (3H, d, J=7.1 Hz, CH_3CHCO), 1.65 (3H, d, J=7.1 Hz, CH_3CHCN), 3.93 (1H, q, J=7.1 Hz, CHCO), 4.57 (1H, q, J=7.1 Hz, CHCN), and 7.58 (2H, br, NH_2^+). Found: C, 51.08; H, 8.25; N, 11.94%. Calcd for $C_{10}H_{19}N_2O_2Cl$: C, 51.17; H, 8.16; N, 11.93%.

Removal of the t-Butyl Group: The removal of the *t*-butyl group was carried out with TFA, giving a very hygroscopic product (**5**·HCl). A typical example was as follows. *t*-Butyl 2-(1-cyanoethylamino)propionate·HCl (50 μmol) was dissolved in TFA (0.5 ml) below 0 °C. After being kept for 10 min, the solution was allowed to stand at room temperature for 1 h. Evaporation of the TFA in vacuum gave the product. When a portion of an aq solution of the product was analyzed with the amino acid analyzer, only one peak was eluted (elution time, 57 min; Table 1). The product was also trimethylsilylated with BSTFA–CH_3CN (1:1, v/v) (at 100 °C for 30 min) for GC–MS. GC of the derivatized solution exhibited only one peak with a retention time of 3.1 min (column, 3 mmϕ× 1 m packed with 1.5% OV-101 on Chromosorb G HP; temperature, 100 °C). Its mass spectrum contained both M^+ (m/z 214) and M−15 (m/z 199) ions, indicating the formation of a mono-TMS derivative (mol wt=214) (Table 3).

2-(1-Carbamoylethylamino)propionic Acid (6). Compounds **6a** and **6b** were obtained as monohydrates by partial hydrolysis of **2a** and **2b**, respectively.

6a: A solution of **2a** (0.25 g, 1.6 mmol) in H_2O (45 ml) was heated on a sand bath at 100 °C for 24 h. After evaporation, the residue was extracted with hot methanol (15 ml) to remove **3a**. The methanol was evaporated and then the residue was dissolved in H_2O (3 ml). The solution was charged on a column (2.0 ϕ×5 cm) packed with Amberlite CG-120 (H form). After the column was washed with H_2O, the product was eluted with 1% aq pyridine; yield 0.11 g (38%); mp (dec) 208—209 °C (lit,[5] 210 °C (as **6**·1.5H_2O)). Found: C, 40.68; H, 8.00; N, 15.39%. Calcd for $C_6H_{12}N_2O_3$·H_2O: C, 40.44; H, 7.92; N, 15.72%.

6b: Yield 42%; mp (dec) 196—199 °C; ^1H NMR (TFA) δ=1.87 (6H, d, J=7.2 Hz, $2CH_3$), 4.14—4.73 (2H, m, 2CH), 7.34 and 7.44 (2H, br, $CONH_2$), and 7.82 (2H, br, NH_2^+). Found: C, 40.54; H, 7.61; N, 15.69%.

3,5-Dimethyl-2,6-piperazinedione (7). Into a solution of **1** (1.0 g, 8.1 mmol) in anhydrous ethanol (20 ml) was introduced dry HCl gas under cooling until first-formed white precipitates dissolved completely. The introduction of HCl was continued further for 30 min. The solution was stored in a refrigerator overnight, and then filtered into a flask containing Et_2O (200 ml). The resultant hygroscopic precipitates were collected by filtration, washed with Et_2O, and then dried in vacuum, which were dissolved in H_2O (5 ml). After the addition of Na_2CO_3 (0.86 g, 8.1 mmol), the solution was extracted with Et_2O (30 ml×10). The extract was dried (Na_2SO_4), filtered and then evaporated to give crystals which were recrystallized from AcOEt–petroleum ether; yield 0.21 g (18%); mp 188—189 °C (lit,[5]

† 1 M=1 mol dm^{-3}.

186 °C); IR (KBr) 3250 (imino NH), and 1710 and 1680 cm^{-1} (imide C=O); ^1H NMR (DMSO-d_6) δ=1.20 (6H, d, J=7.2 Hz, $2CH_3$), 3.00 (1H, br, imino NH), 3.45 (2H, q, J=7.2 Hz, 2CH), and 10.92 (1H, br, imide NH). Found: C, 50.42; H, 7.06; N, 19.63%. Calcd for $C_6H_{10}N_2O_2$: C, 50.69; N, 7.09; N, 19.71%.

It is well known that a C≡N group can be easily converted into an amide in hydrobromic acid-acetic acid (HBr-AcOH).[6,17] Treatment of this product with 25% HBr-AcOH (Protein Research Foundation), however, resulted merely in the formation of HBr salt of **7**, which was confirmed by elemental analysis and ^1H NMR spectrum. This is an additional evidence for the absence of a C≡N group in the product.

Ion-exchange Chromatography. Ion-exchange chromatography was carried out with a Sibata amino acid analyzer AA-600 under the following conditions: Column 0.25 ϕ×50 cm packed with Aminex A-4 (Bio-Rad); flow rate of an eluent, 6 ml/h; flow rate of a ninhydrin solution, 3 ml/h; jacket temp, 30 °C. Absorbance at 570 nm was measured by continuous photometry. Sodium citrate buffers of pH 3.25 (0.2 M Na^+) and 5.28 (0.35 M Na^+) were used as eluents (Wako Pure Chemical Industries, Ltd.). Each of imino derivatives of Ala and related compounds was chromatographed separately and its color constant was calculated according to the common H×W method. Ala-NH_2 and 2-APN were prepared as Ala-NH_2·AcOH[25] and 2-APN·1/2 H_2SO_4,[28] respectively, according to the reported methods.

Decomposition of 1, 4, and 5 in Aqueous Media. Both H_2O and pH 3.25 citrate buffer solutions were prepared for **1**, **4**, and **5**. Compound **5**·HCl was obtained from a known amount of *t*-butyl 2-(1-cyanoethylamino)propionate hydrochloride by the treatment of TFA. The concentration of the solutions was 1 mM for **4** and **5**, but 0.5 mM for **1**. The solutions were allowed to stand at room temperature. Portions (0.1 ml) of the solutions were analyzed with the amino acid analyzer (buffer system A) at appropriate time intervals. The reason why the concentration of 0.5 mM was chosen for **1** is that the calibration curve of **1** does not follow Beer's law at a concentration higher than this. Decomposition products were identified by comparing elution times with those of the authentic samples. The other imino derivatives of Ala were stable under the conditions.

Trimethylsilylation. About 25 μmol of each imino derivative was weighed into a 1 ml screw vial. Then, 0.25 ml of BSTFA (Nakarai Chemicals, Ltd.) and 0.25 ml of CH_3CN (Wako Pure Chemical Industries, Ltd., S grade reagent) were added to the vial. It was closed tight with a silicone cap and then heated at 100 °C for 30 min in a Reacti-Therm (Pierce Chemical Company) or in a constant-temperature air bath (Yamato Drying-Oven, DX-58). For the experiments of the time course of trimethylsilylation, the latter was used because of its constant temperature. The derivatized solutions were usually clear, 0.5—1 μl portions of which were injected into a GC column. For GC-MS, about 50 μmol of each imino derivative was trimethylsilylated with 0.4 ml of BSTFA and 0.4 ml of CH_3CN.

GC. GC was carried out with a Hitachi 163 gas chromatograph equipped with a flame ionization detector. The conditions were as follows: Column, 3 mmϕ×1 m (glass) packed with 1.5% OV-101 on Chromosorb G HP (100/120 mesh) (Shimadzu); injector temp, 230 °C. Flow rates of carrier gas (N_2), H_2, and air were 30, 35, and 920 ml/min, respectively. The column oven was operated isothermally at 100 °C for 5 min after injection and then programmed to be heated up to 230 °C at a rate of 5 °C/min. A fused silica capillary column (FS-WCOT, 0.35 mmϕ×25 m, OV-101 or SE-30) (Gasukuro Kogyo Co. Ltd.) was also used instead of the packed column under the following conditions: Flow rate of carrier gas (N_2). 1 ml/min; split ratio, 1:50. Peak area ratios were calculated by a Chromatogram Processor 7000B (System Instrument Corporation).

GC-MS. Mass spectra were obtained with a Varian MAT 312 mass spectrometer which was connected with a Varian 3700 gas chromatograph. Each volatile derivative was chromatographed on a glass column (1.6 mmϕ×1 m) packed with 3% OV-101 on Gas Chrom Q (80/100 mesh) by the use of He as the carrier gas (flow rate, 15 ml/min). The column oven was operated isothermally at 70 °C for 5 min after injection (injector temp, 230 °C) and then programmed to be heated up to 230 °C. The GC-MS combination was operated under the following conditions: Separator temp, 240 °C; energy of electron, 70 eV; accelerating voltage, 3.0 kV; ion source temp, 300 °C. The spectrometer was continuously scanned.

High-Resolution Mass Measurement. High-resolution mass spectra (70 ev) of selected samples were obtained with a JEOL JMS-D 300 mass spectrometer by the use of perfluorokerosene as an internal standard.

We wish to thank Mr. Hideo Mori, Otsuka Pharmaceuticals Co. Ltd., Tokushima Factory, for obtaining low-resolution mass spectra by GC-MS.

7) In the previous paper (Ref. 6), 2-(cyanomethylamino)acetic acid and 2-(carbamoylmethylamino)acetic acid were prepared by deprotection of *N*-(*p*-methoxybenzyloxycarbonyl)(Z(OMe))-2-(cyanomethylamino)acetic acid with TFA and HBr-AcOH, respectively. The *N*-protected 2-(cyanomethylamino)acetic acid was obtained by introduction of Z(OMe) to the imino nitrogen of ethyl 2-(cyanomethyl)-acetate with *S*-(*p*-methoxybenzyloxycarbonyl)-4,6-dimethyl-2-pyrimidinethiol followed by saponification with aq NaOH. In the present study, attempted preparations of **5** and **6** according to this method were unsuccessful, because introduction of Z(OMe) to the imino nitrogen of ethyl 2-(1-cyanoethylamino)propionate did not take place under the same conditions. This is due to the steric hindrance of the

N-substituent group.

The Nature of the Cosolvent Effects of Sugars on the Aqueous Solubilities of Hydrocarbons

Masanobu JANADO* and Yuki YANO†
Department of Food Science, Kyoto Women's University, Kyoto 605
(Received December 19, 1984)

Pentoses (D-arabinose, D-xylose, and D-ribose) and hexoses (D-glucose, D-galactose, and D-mannose) increased appreciably the aqueous solubilities of naphthalene and biphenyl, but all the sugars except ribose caused solubility depression of 1-octanol. Ribose increased most effectively the hydrocarbon solubilities while glucose showed the least effect. Deoxy sugars and methyl glycosides were more effective than the corresponding unsubstituted sugars. As to maltodextrins the solubility-increasing effect per glucose unit is cooperatively enhanced as the number of glucose residue increases. On the basis of these data, it was concluded that the cosolvent effects of the sugars are primarily brought about by their nonpolar interactions with hydrocarbons that occur at the structure-breaking sites of the sugar molecules.

We have previously reported that hexoses decreased to widely different extents the aqueous solubility of 1-octanol.[1] It was also shown that maltose, maltotriose and dextran, but not cellobiose and sucrose, caused solubility increases of 1-octanol and 1-heptanol particularly at high concentrations and that this effect was markedly enhanced as the temperature increased. These results apparently indicate that the cosolvent effects of sugars depend on the configurations of CH and OH groups in the monosaccharide molecules, the type of glycosidic linkages and the molecular size of the oligomers. Inspection of the relevant thermodynamic parameters suggested the presence of the hydrophobic interactions between the solute molecules and the hydrophobic surfaces[2,3] of sugars. We now report the effect of pentoses, hexoses, deoxy sugars, methyl glycosides and maltodextrins on the aqueous solubilities of 1-octanol, benzene, naphthalene and biphenyl, to look further into the nature of the cosolvent effect of sugars.

Experimental

Materials. Hexoses, pentoses and maltose of analytical reagent grade were purchased from Nakarai Chemical Ltd. (Kyoto, Japan) and were used as supplied. Maltotriose and maltopentaose (Nakarai Chemical Ltd.) and maltotetraose and maltohexaose (Seishin Pharm. Ltd., Chiba, Japan) were all analytical reagent grade. All other reagents used including benzene, naphthalene, biphenyl, 1-octanol, 1-butanol, and hexane were analytical reagent grade and were used as supplied.

Solubility Measurement of Aromatic Hydrocarbons and 1-Octanol. The solubilities of benzene, naphthalene, biphenyl and 1-octanol were measured in sugar solutions in the concentration range of 0—50%. As previously pointed out,[4] these aromatic hydrocarbons evaporated rapidly from their saturated aqueous solutions even in tightly closed vials with some air spaces. As a consequence, significantly lower apparent solubilities were often obtained from the solutions which stood for some time after separation from the excess hydrocarbons. This evaporation effect, which is the main source of error, could be practically eliminated by employing the following procedure: An appropriate amount (approximately 10 g) of a sugar solution plus an excess amount of a hydrocarbon was stirred for 6 h and gently shaken for another 18 h in a chamber thermostated within ±0.05°C. After removing a large part of the excess hydrocarbon using a transfer pipet, the mixture was allowed to stand without agitation for 6 h in the thermostated chamber. A portion of clear solution was taken up by a transfer pipet and immediately placed in a 15 ml vial containing a weighed amount of hexane with extreme care being taken not to touch the floating or sedimented residual hydrocarbon. The solubility measurements were made after extracting the solutes into hexane. Benzene, naphthalene and biphenyl were determined by spectrophotometry and 1-octanol by gas chromatography. The average percentage of deviation from the mean never exceeded 2%.

† Present address: Department of Education, Kōgakukan University, Ise 516.

Results

The Cosolvent Effects of Monosaccharides. Figure 1 shows solubilities of 1-octanol, benzene, naphthalene and biphenyl in sugar solutions plotted against the sugar concentrations. The temperature dependence of the cosolvent effects of sugars is summarized in Table 1 for the aromatic hydrocarbons. The results obtained for 1-octanol were omitted here since the relevant data for this solute have been reported elsewhere.[1]

The Cosolvent Effects of Deoxy Sugars and Methyl Glycosides. To examine the effect of OH–H and OH–OCH_3 substitutions and the anomer effect, solubilities of the hydrocarbons were measured in the solutions of fucose, deoxy ribose and α- and β-methyl glycosides. The results are given in Table 2. It is clear that the substitution of one OH group with H and OCH_3 resulted in marked increase in the cosolvent effect, particularly for the large aromatic hydrocarbons. As to the methyl glycosides, β-anomers appear to be more effective than the α-

anomers.

The Cosolvent Effects of Maltodextrins. To examine the effect of molecular size of maltodextrins on their cosolvent effects, solubility of naphthalene was measured in maltodextrin solutions of an identical glucose residue concentration (0.55 M†). Accordingly, the data given in Table 3 represent the cosolvent effect of glucose residue but not that of maltodextrin molecules. The results clearly show that the effect of glucose residue cooperatively increases as the degree of polymerization increases.

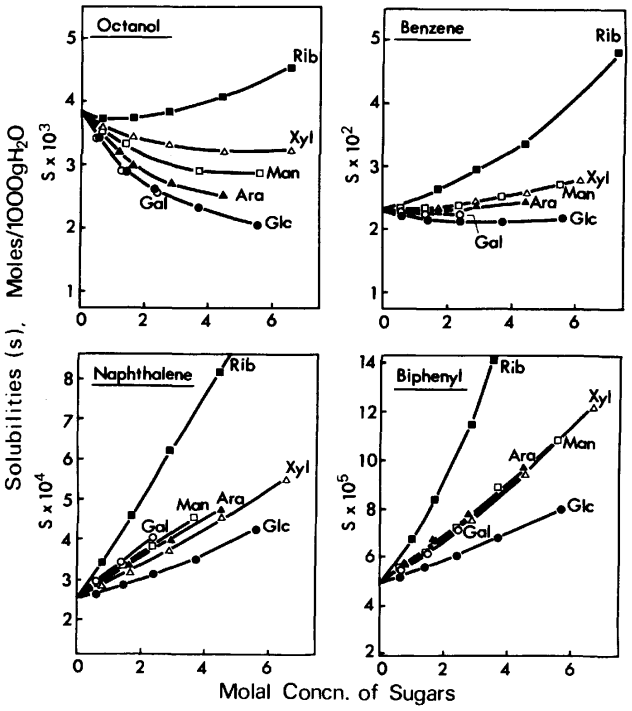

Fig. 1. Solubilities of 1-octanol, benzene, naphthalene, and biphenyl in sugar solutions at 25 °C.

Discussion

The Factors Determining the Cosolvent Effects of Sugars. The solubility plots of 1-octanol and benzene reveal that at low sugar concentrations the solubility-decreasing effect (the negative cosolvent effect) predominates but as the sugar concentration increases it is countervailed by the opposing effect (the positive cosolvent effect) resulting in leveling off or upward curvature of the solubility curves (Fig. 1). In solution of naphthalene and biphenyl the positive cosolvent effect prevails throughout the entire concentration range of sugars. We shall examine the nature of the cosolvent effects of sugars in the light of a current theory put forward by Roseman and Jencks.[5] According to their theory, the cosolvent effect or the transfer free energy of a nonpolar solute from water to a water-cosolvent mixture (ΔF_t) can be written as a sum of the free energy differences of the cavity formation (ΔF^{cav}), of the nonpolar solvent-solute interactions (ΔF_{np}^{int}), and of the polar interactions involving primarily solvent-solute hydrogen bonding (ΔF_p^{int}), in the two solvents. That is,

$$\Delta F_t = \Delta F^{cav} + \Delta F_{np}^{int} + \Delta F_p^{int}. \quad (1)$$

On the basis of extensive data on the cosolvent effects, they concluded that ΔF_t is largely determined by the first two terms, $\Delta F^{cav}+\Delta F_{np}^{int}$, the last term ($\Delta F_p^{int}$) playing a minor role in solution of nonpolar solutes. The important part of their theory is that the primary effect of almost all organic cosolvents is to increase solubilities of nonpolar solutes by making ($\Delta F^{cav}+\Delta F_{np}^{int}$) more favorable. The relative

† 1 M=1 mol dm^{-3}.

magnitude of ΔF^{cav} and ΔF_{np}^{int}, however, has not been evaluated. In the discussion that follows, the cosolvent effects of sugars will be examined in terms of ΔF^{cav} and ΔF_{np}^{int}.

As previously noted,[1] the negative part of the cosolvent effect evident in the solubility plots of 1-octanol and benzene but obscured by the opposing effect in the plots of naphthalene and biphenyl may largely be attributed to the reduction of water activity caused by sugar hydration. One prominent feature of the solubility curves is their remarkable solute-dependence, *e.g.*, while the molar volumes of biphenyl and 1-octanol are comparable, their solubility curves are totally different. This indicates that ΔF_{np}^{int} rather than ΔF^{cav} predominates in the cosolvent effects of sugars. The decrement of the activity coefficients (see Eq. 5) of the solutes on transfer from water to sugar solutions increases in the order, 1-octanol<benzene<naphthalene<biphenyl, indicating that the nonpolar interactions of the hydrocarbons with the sugars are enhanced by the high polarizability and planarity of aromatic rings.[5] The effective nonpolar interactions through Van der Waals' forces can be achieved only when water molecules are excluded and the sugar and hydrocarbon molecules come close to each other. That is, for the effective interaction the water structure around the specific interaction sites of the sugar molecules, presumably the sites where CH density is relatively high, needs to be loose. This contention is consistent with the increased positive-cosolvent effect brought about by the OH-H and OH-OCH_3 substitutions (Table 2). The cooperative effect of glucose residues of maltodextrins (Table 3) may reflect that they form curved nonpolar surfaces, similar to the internal surfaces of the cyclodextrin cavities, that strongly interact with the hydrocarbons.[6]

Relative Magnitude of ΔF_{np}^{int} of Each Sugar. The foregoing evidence indicates that ΔF^{cav} is an important component of ΔF_t and a favorable ΔF^{cav} is prerequisite to the effective nonpolar interaction (ΔF_{np}^{int}) but that the negativity of ΔF_t is largely attributed to the negativity of ΔF_{np}^{int}. If the stoichiometric complex formations between the sugars (S) and biphenyl (B) are assumed, it is possible to estimate the relevant association constants. (Biphenyl was chosen because its ΔF_t values are all negative (Fig. 1)). Let us consider an equilibrium dialysis system in which an aqueous solution of sugar and biphenyl in dialysis bag permeable to water and biphenyl, but not to sugar, is in equilibrium with the external saturated aqueous solution of biphenyl. The equilibrium system can be described by

$$B + \nu S = BS_\nu, \tag{2}$$

where ν is the average number of bound sugar molecules per biphenyl. Provided that ν does not fluctuate greatly,[7] the apparent association constant (K^{app}) can be written as

$$K^{app} = \frac{[BS_\nu]}{[B][S]^\nu}, \tag{3}$$

where [B], [S], and [BS_ν] are the equilibrium molar concentrations. Since [B]=C^o (the molar solubility of biphenyl in the external solvent water) and hence

a) mol kg^{-1} H_2O.

$[BS_\nu]=C-C^\circ$ where C refers to the molar solubility of biphenyl in the sugar solution contained in the dialysis bag, Eq. 3 can be rewritten as

$$\frac{C^\circ}{C}=\frac{1}{1+K^{app}[S]^\nu}. \quad (4)$$

Assuming the activity coefficient of biphenyl in the saturated water solution to be unity,[8] the activity coefficient (f) in a sugar solution is given by

$$f=C^\circ/C. \quad (5)$$

Eq. 4 and Eq. 5 may be combined to yield

$$(1-f)/f=K^{app}[S]^\nu. \quad (6)$$

The term $(1-f)/f$ represents a relative decrement of the activity coefficient of biphenyl upon transfer from water to the sugar solutions. Since the concentration of the added sugar $[S_o]$ is much greater than that of biphenyl (C°), [S] may be replaced by $[S_o]$, and Eq. 6 can be rewritten as

$$\ln[f/(1-f)]=\ln(1/K^{app})-\nu\ln[S_o]. \quad (7)$$

Such an approach can only provide the rough estimates of the interaction parameters (K^{app} and ν), but these values are still quite informative.[9,10] Figure 2 shows the plots of $\ln[f/(1-f)]$ *vs.* $\ln[S_o]$ for all the monosaccharides except glucose for which f is nearly 1 thereby yielding an infinite value of $f/(1-f)$. The values of K^{app} and ν evaluated from Fig. 2 are summarized in Table 4. The results show that each sugar forms 1 to 1 stoichiometric complex with biphenyl and the association constant increases in the order of glucose≪galactose<mannose<xylose<arabinose≪ribose. The difference in K^{app} may reflect the difference in the total surface area of CH group of sugars accessible to water molecule.[11] However, the cooperative enhancement of the positive cosolvent effect of glucose residues of maltodextrins, but not of cellobiose,[1] indicates the importance of the "CH-dense surface," a specific site of sugar molecule where the CH density is the highest, rather than the total CH-surface area.[6]

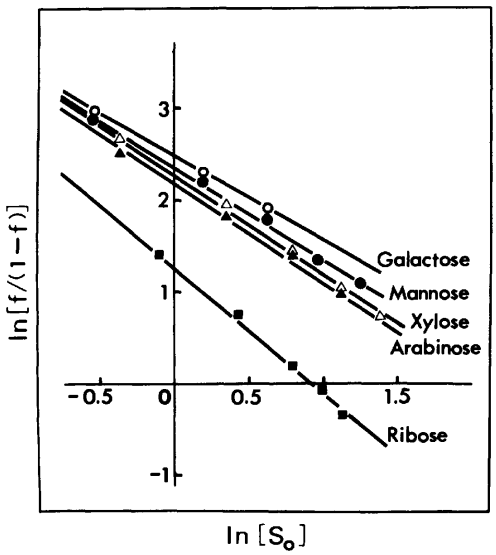

Fig. 2. The plot of Eq. 7.

The Specific Interaction Sites of the Sugar Molecules. The free energy for transfering one mole of the solutes (naphthalene and biphenyl) from pure water to the sugar solutions was calculated from Eq. 8 and summarized in Table 5.

$$\Delta F_t=RT\ln f. \quad (8)$$

The temperature dependence of ΔF_t of the two solutes is negative indicating that their spontaneous transfer from water to the sugar solutions is endothermic and hence entropic in nature. These thermodynamic parameter changes may be interpreted in terms of the "structured water" hypothesis.[12-14] On the other hand, Howarth[15] showed by ^{13}C relaxation time measurements that water is unique in its ability to restrict the motion of hydrophobic part of solute molecules and that the motional restriction accounts for most part of the entropy change on solution.

TABLE 4. THE ASSOCIATION PARAMETERS PERTAINING TO THE SUGAR-BIPHENYL INTERACTIONS

a) cal mol^{-1}.

And according to Roseman and Jencks,[5] the presence of almost all organic cosolvents in water results in a decrease in the number density of hydrogen bonds. Accordingly, it is also possible to attribute the observed positive entropy of the transfer to the increased motional freedom in the sugar solutions relative to that in water. There will be a negative entropy contribution from the nonpolar sugar-aromatic hydrocarbon interaction, but its magnitude is expected to be relatively small. The water structure around the interaction sites of sugar molecules is presumably loose allowing easy access of the hydrocarbons.

It is generally accepted that sugars are structure maker[16-22] with a few exceptions, *e.g.* ribose,[20] and that the extent of hydration depends on the spatial orientations of the individual OH groups.[17,20,21] According to the "specific hydration model"[20] the spacing of equatorial OH groups in a pyranose ring is compatible with the ice-like structure of water thereby enhancing structure of surrounding water. However, ^{17}O NMR study could not distinguish between the hydration properties of glucose, galactose and mannose.[20] It seems that the solubility-increasing effect of the three hexoses as well as their significant differences in the effectivity are not readily explainable in terms of the "specific hydration model" alone. Furtheremore, the structure promoting effect of sugars has been questioned by several authors[23-25] and recently, Miyajima *et al.*[26,27] reported some notable hydration properties of mono- and oligosaccharides which are contrary to what would be expected from the "specific hydration model." Sugar molecules possess many CH groups which will not be compatibly caged in the preexisting network of water without causing serious entropy disadvantage. Recently, the direct evidence for the CH surface-sugar hydrophobicity correlation has been provided by Miyajima *et al.*[11] They showed that the CH and CH_2 surface area of sugars accessible to water molecule is closely correlated with their differential affinity for polystyrene gel.[6] On the basis of the proceeding arguments, we are inclined to conclude that the hydration shell around sugar molecule is quite loose at the vicinity of the "CH-dense surfaces" where the nonpolar sugar-hydrocarbon interactions occur through Van der Waals' forces.

The authors are grateful to Dr. K. Miyajima of Kyoto University for his useful discussions on the stereochemical basis of the hydrophobicity of sugars. This study was supported in part by a Grant-in-Aid for Scientific Research from Ministry of Education, Science and Culture.

Reactions of Trimethylsilyl Cyanide with Tropone, 2-Phenyltropone, and 2-Methoxytropone. Formations of 2-Cyano-1-hydroxytropylidene Derivatives

Katsuhiro SAITO* and Hisashi KOJIMA†

Department of Chemistry, Nagoya Institute of Technology, Gokiso-cho, Showa-ku, Nagoya 466

(Received January 10, 1985)

Reaction of trimethylsilyl cyanide (TMSCN) with tropone and 2-phenyltropone in the presence of a catalytic amount of zinc iodide in dichloromethane afforded silyl ethers of 7-cyano-1,3,5-cycloheptatriene-1-ol (**2a**) and 2-phenyl-7-cyano-1,3,5-cycloheptatriene-1-ol (**2b**), respectively. On the other hand, reaction of TMSCN with 2-methoxytropone gave 2-cyanotropone. Upon hydrolysis, **2a**, and **2b** yielded 2-cyano-1,3,5-cycloheptatrien-1-ol (**3a**) and a tautomeric mixture of 2-cyano-7-phenyl-1,3,5-cycloheptatrien-1-ol (**3b**) and 2-cyano-7-phenyl-3,5-cycloheptadien-1-one (**4b**). Oxidation of **3a** and the tautomeric mixture of **3b** and **4b** with selenium dioxide in dioxane afforded 2-cyanotropone and 2-cyano-7-phenyltropone, respectively.

Reactions of trimethylsilyl cyanide (TMSCN) with carbonyl compounds have attracted much attention from chemists because of their utility in the synthesis of cyanohydrin derivatives and of various compounds which can be derived from the cyanohydrins.[1] TMSCN is known to react with isolated and conjugated carbonyl groups to give 1,2-addition products[1a-e] and 1,4- or 1,6-addition products,[1f] respectively. Tropone derivatives are cyclic conjugated carbonyl compounds with aromaticity and their reactions with organometallic compounds such as Grignard reagents have attracted considerable attention from chemists,[2] however the reported examples of reactions of tropone derivatives with organosilane compounds are relatively few in number.[3] We reacted some tropone derivatives with TMSCN in the presence of a catalytic amount of zinc iodide. Here, we wish to report the result of these reactions.

Results and Discussion

When tropone (**1a**) and 2-phenyltropone (**1b**) were allowed to react with TMSCN in anhydrous dichloromethane in the presence of a catalytic amount of zinc iodide at room temperature for 5 d, silyl ethers of 7-cyano-1,3,5-cycloheptatrien-1-ol (**2a**)

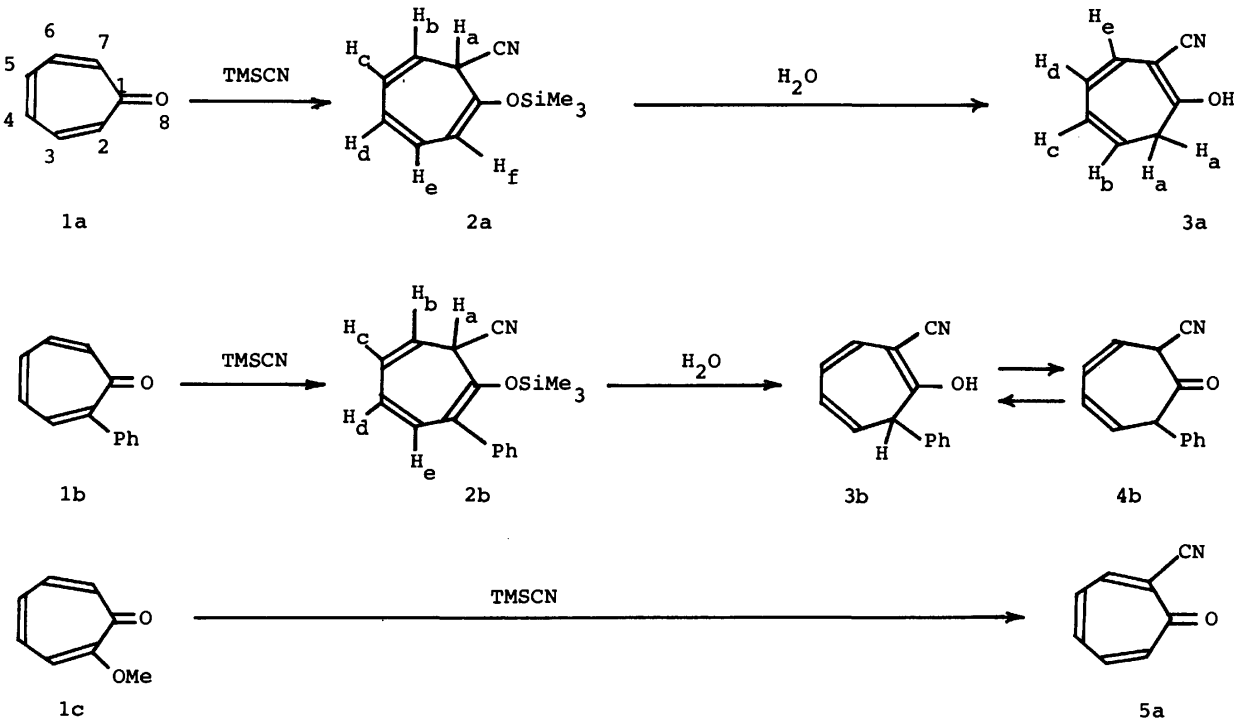

Fig. 1.

† Present address: Okazaki National Research Institutes, National Institute for Basic Biology, Myodaiji-cho, Okazaki 444.

and 2-phenyl-7-cyano-1,3,5-cycloheptatrien-1-ol (**2b**) were obtained in 54 and 59% yields, respectively. On the other hand, the reaction of TMSCN with 2-methoxytropone (**1c**) under the same conditions as above afforded 2-cyanotropone (**5a**) in 84% yield. Upon hydrolysis, **2a** and **2b** gave 2-cyanocycloheptatrien-1-ol (**3a**) and a tautomeric mixture of 2-cyano-7-phenyl-1,3,5-cycloheptatrien-1-ol (**3b**) and 2-cyano-7-phenyl-3,5-cycloheptadien-1-one (**4b**) in 84 and 93% yields, respectively. Oxidation of **3a** and the tautomeric mixture of **3b** and **4b** in dioxane with selenium dioxide afforded 2-cyanotropone (**5a**) and 2-cyano-7-phenyltropone (**5b**) in 54 and 67% yields, respectively.

The structures of **5a**[4a] and **5b**[4b] were confirmed by comparison of their physical properties with the literature values. The structures of the new compounds were deduced on the basis of their physical properties and confirmed by comparison of the physical properties to those of the analogous tropylidene derivatives.[5] The formation of **5a** and **5b** by the oxidation of **3a** and the tautomeric mixture of **3b** and **4b**, respectively, also supports the structures of **3a**, **3b**, and **4b**.

The reaction of **1a** and **1b** with TMSCN can be explained as shown in Fig. 3. The addition reaction of TMSCN to 2- and 8-positions of **1a** and to 7- and 8-positions of **1b** gives the corresponding silyl ethers **2**. It is known that nucleophilic reagents attack the carbon atom at the 2- or 7- position of the tropone moieties.[2] The hydrolysis of **2** affords 7-cyano-1,3,5-cycloheptatrien-1-ol derivatives (**6**), which tautomerize to the corresponding keto-forms **4**, which further tautomerize to **3**. The preferential formations of 1,3,5-cycloheptatrien-1-ol of the type **3** as opposed to the type **6** can be explained by the strong acidity of the methine proton attached to the carbon atom, which has the electron-withdrawing cyano group in **6** compared to that of the methine proton of **3**.

Two possible mechanisms may be considered for

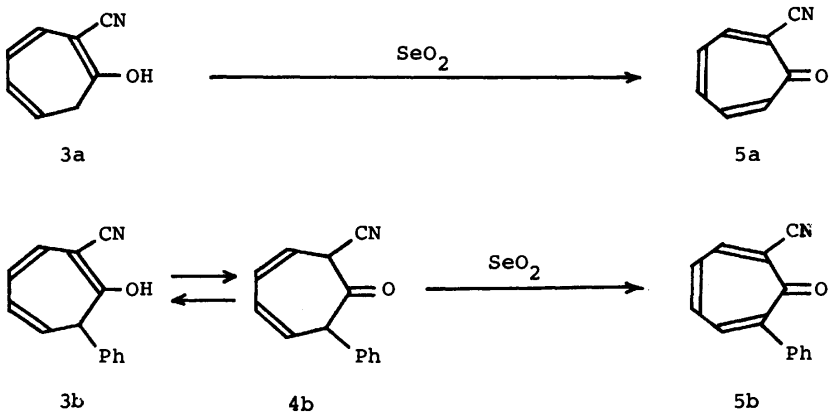

Fig. 2.

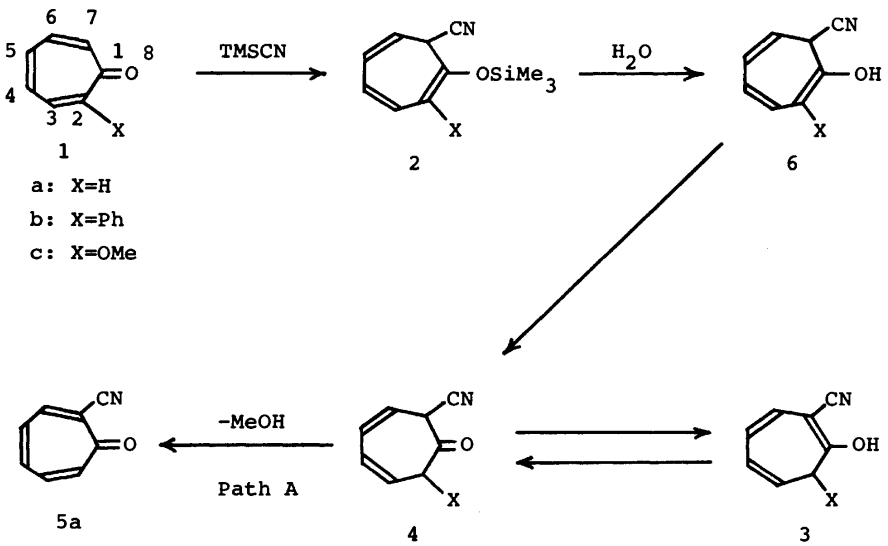

Fig. 3.

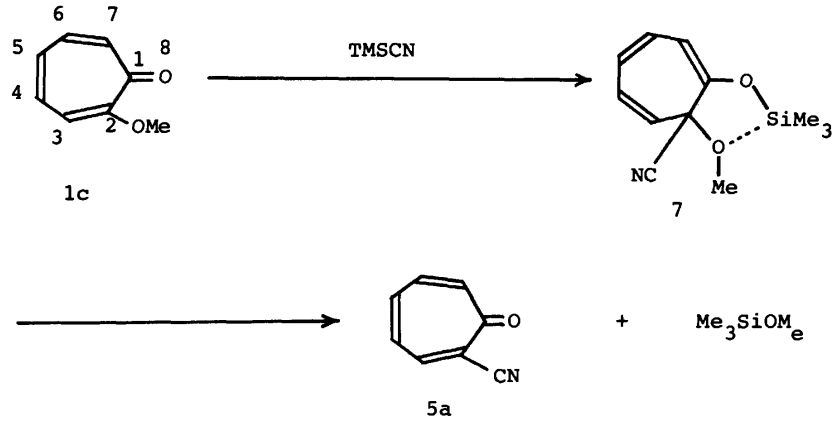

Fig. 4.

the formation of 2-cyanotropone (**5a**) by the reaction of TMSCN with 2-methoxytropone (**1c**). Pathway A involves 2-cyano-7-methoxycyclohepta-3,5-dien-1-one (**4c**) as an intermediate, which is formed through the same reaction path as that described above *via* the silyl ether derivative (**2c**) and the 1,3,5-cycloheptatrien-1-ol derivative (**6c**). Elimination of methanol from **4c** affords **5a**. Pathway B involves the intermediate **7**, which is formed *via* 2,8-addition of TMSCN to **1c**. Elimination of trimethylsilyl methoxide from the intermediate **7** leads to the formation of 2-cyanotropone (**5a**).* Pathway B does not need the existence of water for the formation of **5a**. The fact that despite the same anhydrous reaction conditions as those of the reactions of **1a** and **1b** with TMSCN, the silyl ether **2c** could not be detected seems to support pathway B.

Experimental

All the melting points are uncorrected. IR, UV, Mass, and high resolution Mass spectra were measured with DS-701G, Hitachi 220A, Hitachi M-52, and JMS-DX 300 spectrometers, respectively. NMR spectra were recorded with Hitachi R-20B spectrometer with tetramethylsilane as an internal standard. Wakogel C-200 and Wakogel B5F were used for column and thinlayer chromatography, respectively.

Reaction of ***1a*** *with TMSCN.* A mixture of **1a** (1.60 g, 15 mmol), TMSCN (2.97 g, 30 mmol), zinc iodide (100 mg), and anhydrous methylene chloride (20 ml) was stirred at room temperature for 5 d. After filtration, the solvent was evaporated on a rotary evaporator to yield a yellow oil, which was distilled under reduced pressure to yield a colorless oil of **2a** (690 mg, 54%, 0.2 Torr,† 85—90 °C).

2a: Found *m/z*: 205.09393. Calcd for $C_{11}H_{15}NOSi$: 205.09377. Mass *m/z* (rel intensity): 205 (M^+, 9), 190 (34), 131 (42), 103 (100). UV (EtOH): 280 nm (log ε, 3.49). IR (neat): 3030, 2960, 2240, 1620 cm^{-1}. NMR ($CDCl_3$) δ=0.3 (9H, s), 3.41 (H_a, d, *J*=7 Hz), 5.25 (H_b, dd, *J*=7 and 8 Hz), 5.7 (H_c, m), 6.2—6.6 (3H, m, H_d-H_f).

Reaction of ***1b*** *with TMSCN.* A mixture of **1b** (1.82 g, 10 mmol), TMSCN (1.98 g, 20 mmol), zinc iodide (100 mg), and anhydrous methylene chloride (20 ml) was stirred at room temperature for 5 d. After filtration, the solvent was removed on a rotary evaporator to yield a yellow oil, which was chromatographed on silica gel to yield a colorless oil of **2b** (1.65 g, 59%) by pet ether–benzene 1:1.

2b: Found *m/z*: 281.12362. Calcd for $C_{17}H_{19}NOSi$: 281.12362. Mass *m/z* (rel intensity): 281 (M^+, 57), 266 (100), 211 (60). UV (EtOH): 280 nm (log ε, 3.60). IR (neat): 3020, 2960, 2240, 1605 cm^{-1}. NMR ($CDCl_3$) δ=0.0 (9H, s), 4.05 (H_a, d, *J*=7 Hz), 5.57 (H_b, dd, *J*=7 and 8 Hz), 6.28 (H_c, m), 6.61 (2H, m, H_d, H_e), 7.3 (5H, m).

Reaction of ***1c*** *with TMSCN.* A mixture of **1c** (1.36 g, 10 mmol), TMSCN (1.98 g, 20 mmol), zinc iodide (100 mg), and anhydrous dichloromethane (20 ml) was stirred at room temperature for 5 d. The usual treatment of the reaction mixture gave a yellow oil, which was chromatographed on silica gel to yield crystals of **5a** (1.10 g, 84%, mp 139—140 °C, lit,[4a] 138—139 °C) by benzene–ether 1:1.

Hydrolysis of ***2a***. A mixture of **2a** (410 mg, 2 mmol), water (1 ml), and dioxane (5 ml) was stirred at room temperature for 20h. The reaction mixture was extracted with ether and dried over anhydrous sodium sulfate. After filtration, the solvent was removed on a rotary evaporator to yield a colorless crystals of **3a** (220 mg, 83%). Recrystallization from chloroform gave pure crystals of **3a**.

3a: Mp 127—128 °C. Found *m/z*: 133.04879. Calcd for C_8H_7NO: 133.04916. Mass *m/z* (rel intensity): 133 (M^+, 100), 115 (6), 104 (56). UV (EtOH): 283 nm (log ε, 3.67). IR (KBr): 3100, 2220, 1610 cm^{-1}. NMR ($CDCl_3$) δ=2.65 (2H, H_a, d, *J*=7 Hz), 5.40 (H_b, ddd, *J*=2, 7, and 8 Hz), 6.10 (H_c, m), 6.28 (2H, m, H_d, H_e), 6.50 (1H, bs, OH).

Hydrolysis of ***2b***. A mixture of **2b** (850 mg, 3 mmol), water (5 ml), and dioxane (10 ml) was stirred at room temperature for 20h. The reaction mixture was extracted with ether, and dried over anhydrous sodium sulfate. After

†1 Torr≈133.322 Pa.

filtration, the solvent was removed on a rotary evaporator to yield a yellow oil, which was chromatographed on silica gel to give a colorless oil of the tautomeric mixture of **3b** and **4b** (590 mg, 93%).

Tautomeric mixture of **3b** and **4b**: Found *m/z*: 209.08268. Calcd for $C_{14}H_{11}NO$: 209.08281. Mass *m/z* (rel intensity): 209 (95), 208 (42), 181 (96), 180 (100). UV (EtOH): 245 nm (log ε, 3.88). IR (neat): 3360, 3040, 2240 2220, 1723, 1600 cm^{-1}. NMR ($CDCl_3$) δ=2.69 (d, J=8 Hz), 3.31 (d, J=7 Hz), 4.35 (bs, OH), 5.8—6.5 (m), 6.9—7.5 (m).

Oxidation of ***3a***. A mixture of **3a** (265 mg, 2 mmol), selenium dioxide (270 mg, 2.4 mmol), and dioxane (5 ml) was refluxed for 30 min. After filtration, the solvent was removed on a rotary evaporator to yield a black tarry material, which was disolved in ethyl acetate, washed with aqueous saturated sodium hydrogencarbonate and water, and dried over anhydrous sodium sulfate. After filtration, the solvent was removed on a rotary evaporator to yield a brown solid, which was thin-layer chromatographed on silica gel using benzene–ether 1:1 as a developing solvent to give crystals of **5a** (R_f=0.45, 125 mg, 54%).

Oxidation of the Tautomeric Mixture of ***3b*** *and* ***4b***. A mixture of the tautomeric mixture of **3b** and **4b** (315 mg, 1.5 mmol), selenium dioxide (200 mg, 1.8 mmol), and dioxane (10 ml) was refluxed for 40 min. The reaction mixture was treated as usual to give a black tarry material, which was thin-layer chromatographed on silica gel using benzene–ether 8:2 as a developing solvent to give crystals of **5b** (R_f=0.40, 210 mg, 67%, mp 134—135 °C, lit,[4b] 134—135 °C).

The authors are indebted to Professor Paul G. Gassman of University of Minnesota, Professor Toshio Mukai of Tohoku University, and Professor Takashi Toda of Utsunomiya University for their fruitful suggestions.

The Facile Synthesis of Dihydrofurans by the Oxidation of Olefins with Tris(2,4-pentanedionato)manganese(III)

Hiroshi NISHINO
Department of Chemistry, Faculty of Science, Kumamoto University, Kurokami, Kumamoto 860
(Received January 21, 1985)

Eleven olefins were oxidized with tris(2,4-pentanedionato)manganese(III) at the reflux temperature to give the corresponding 3-acetyl-2-methyl-4,5-dihydrofurans in good yields. The oxidation of 9-benzylidene-9,10-dihydroanthracene under the same reaction conditions did not produce the corresponding dihydrofuran, but 9-[α-(1-acetyl-2-hydroxy-1-propenyl)benzylidene]-9,10-dihydroanthracene. When 1,1-diphenylethene was oxidized at room temperature, 3-acetyl-2-hydroperoxy-2-methyl-5,5-diphenyltetrahydrofuran was obtained in a high yield. The effects of the solvent and the additives on the yield of dihydrofuran, the comparable reactivities of other (2,4-pentanedionato)metal complexes, such as Co(III), Cr(III), Fe(III), and Cu(II), and the reaction mechanism are discussed.

In previous papers it was reported that the reaction of malonic acid with olefins in the presence of manganese(III) acetate, $Mn(OAc)_3$, gave spirobi-γ-lactones,[1] while a similar reaction of malonamide yielded 2-buten-4-olides and/or 1*H*-pyrrol-2(5*H*)-ones.[2] The formation of these lactones and lactams can be explained by a proposed mechanism based on the generation of radicals from malonic acid and malonamide.[2] The reactions of β-dicarbonyl compound with olefins in the presence of $Tl(OAc)_3$,[3] $Pb(OAc)_4$,[4] $Mn(OAc)_3$,[5] AgO, and PbO_2[6] have also been reported to give dihydrofurans. The yields of dihydrofurans, however, were not always satisfactory, and it seems possible to improve the yields by using tris(2,4-pentanedionato)manganese(III), $Mn(acac)_3$, in a donor solvent such as acetic acid, which can complex manganese(III) ions. This is because Mn(III) complexes generally tend to undergo a rapid exchange of ligands (ligand-exchange reaction),[7] and hence $Mn(acac)_3$ will be easily decomposed in the donor solvent to form $\cdot CH(COCH_3)_2$ radicals directly. This radical should react with olefins in the reaction mixture to produce the corresponding dihydrofurans. The present author was interested in this active property of Mn(III) complexes and investigated the title reaction. It is known in general that $Mn(acac)_3$ can be used as a catalyst in a polymerization reaction[8] and as one-electron-transfer oxidant in coupling reactions of phenols[9] or thiophenols.[10]

Results and Discussion

When 1,1-diphenylethene (**1a**) was oxidized with $Mn(acac)_3$ in acetic acid at the reflux temperature, it gave 3-acetyl-2-methyl-5,5-diphenyl-4,5-dihydrofuran (**2a**), together with a small amount of benzophenone (**3a**). The reaction was repeated in various solvents, but it was found that acetic acid was the best of all, as is shown in Table 1. The effects of various additives were then examined. The addition of acetic anhydride to the reaction mixture decreased the yield of **2a**, but the reaction time was shortened considerably (Table 2, Entry 2). When β-dicarbonyl compounds were added to the reaction mixture, they still gave **2a** predominantly, thus proving that $Mn(acac)_3$ is a more active species than the $\cdot CH(CO_2H)_2$, $\cdot CH(CONH_2)_2$, and $\cdot CH(CO_2Et)_2$ radicals (Table 2, Entries 3—5).[1,2]

When **1a** was oxidized with $Mn(acac)_3$ at room temperature for 12 h, **2a** (6%) and 3-acetyl-2-hydroperoxy-2-methyl-5,5-diphenyltetrahydrofuran (**8**; 89%) were isolated from the reaction mixture. The structure of **8** was determined on the basis of its spectral data. The treatment of **8** with acetic anhydride gave the corresponding (acetyldioxy)tetrahydrofuran **9**. The same oxidation under a nitrogen atmosphere

Table 1. Oxidation of 1,1-diphenylethene (**1a**) with $Mn(acac)_3$ in various solvents[a,b]

Entry	Solvent	Reaction time / h	Recovery / %	Product/yield/%[c] **2a**	**3a**

7	Benzene	24	53	16	15

a) The reaction was carried out at the reflux temperature. b) **1a** (1 mmol) and $Mn(acac)_3$ (2 mmol) were employed. c) The yields are based on the amount of **1a** used. d) Minutes.

Table 2. Oxidation of 1,1-diphenylethene (**1a**) with $Mn(acac)_3$ in the presence of some additives in boiling acetic acid

Entry	Additive	Molar ratio of **1a**: additive: $Mn(acac)_3$	Time / s	Recovery / %	Product/yield/%[a]		
					2a	**12**[b]	**13**[c]
1	None	1 : 0 : 2	150	3	89		
2	Ac_2O	1 : 20 : 2	10	17	73		
3	$CH_2(CO_2H)_2$	1 : 1 : 2	10	14	75	2	
4	$CH_2(CONH_2)_2$	1 : 4 : 2	10	22	50		9
5	$CH_2(CO_2Et)_2$	1 : 4 : 2	10	9	90		

a) The yields are based on the **1a** used. b) 3,3,8,8-Tetraphenyl-2,7-dioxaspiro[4.4]nonane-1,6-dione.[1] c) 2-Carbamoyl-4,4-diphenyl-2-buten-4-olide.[2]

for 27 h yielded **2a** (27%) and **8** (67%).

Similar reactions of **1a** were carried out by using $Co(acac)_3$, $Cr(acac)_3$, $Fe(acac)_3$, and $Cu(acac)_2$ instead of $Mn(acac)_3$. In the case of $Co(acac)_3$, the reaction gave **2a** (66%), but the reaction took more than 1 h. The reaction with the other oxidants did not occur in boiling acetic acid. It seems that these complexes are stable under the present reaction conditions.

The reactions of 1,1-bis(4-methoxyphenyl)ethene (**1b**), 2-phenylpropene (**1c**), styrene (**1d**), acenaphthylene (**1e**), 1,1,2-triphenylethene (**1f**), 1,1-bis(4-methoxyphenyl)-2-phenylethene (**1g**), 1,1,2-tris(4-methoxyphenyl)ethene (**1h**), 9-benzylidene-9*H*-xanthene (**1i**), 9-benzylidene-9,10-dihydroanthracene (**1j**), and 1-heptene (**1k**) with $Mn(acac)_3$ were also carried out in acetic acid to yield the corresponding dihydrofurans **2b—i** and **2k**, except for **1j** (Fig. 1 and Table 3). In the cases of **1g** and **1h**, acetoxyethenes **4g** and **4h** were mainly produced rather than the dihydrofurans **2g** and **2h**. For the reaction of **1j** with $Mn(acac)_3$, the corresponding dihydrofuran was not isolated, but 9-[α-(1-acetyl-2-hydroxy-1-propenyl)benzylidene]-9,10-dihydroanthracene (**7j**) was obtained. The dienone **7j** was heated with $Mn(OAc)_3$ in acetic acid in the hope obtaining the corresponding dihydrofuran.[11] However, this was not formed, and the products were found to be **10** and **11** (Scheme 1). The absorption bands at 395, 374, 355, and 338 nm in the UV spectrum of **10** are similar to those of anthracene, and the ^{1}H-NMR and the IR spectrum showed that a 1-acetyl-2-hydroxy-1-propenyl group remained intact. Thus, the structure of **10** was determined to be 9-(1-acetoxy-2-acetyl-3-hydroxy-1-phenyl-2-butenyl) anthracene. The ^{13}C-NMR spectrum of **11** (R=Ac) indicated the structure of 9-acetoxy-9-(2-acetyl-3-oxo-1-phenyl-1-butenyl)-9,10-dihydroanthracene.

The mechanism for the formation of the dihydrofurans can be depicted as involving the α,α′-diketo radical, which is generated directly by the thermolysis of $Mn(acac)_3$ (Scheme 2).[5] It appears that acetic acid as a donor solvent facilitates the ligand-exchange reaction of $Mn(acac)_3$, while the addition of acetic

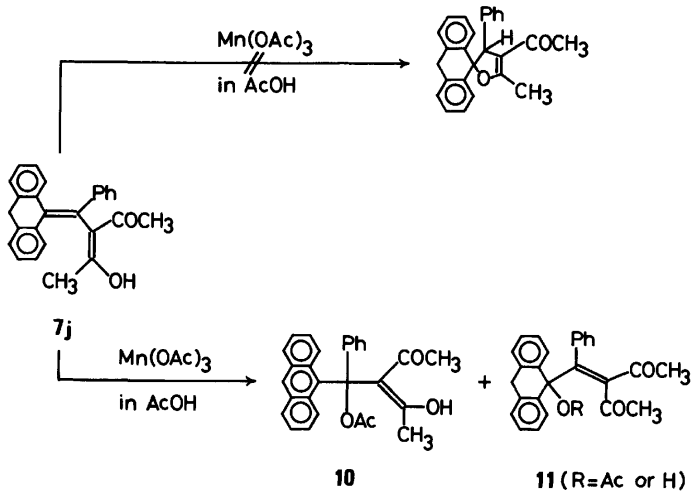
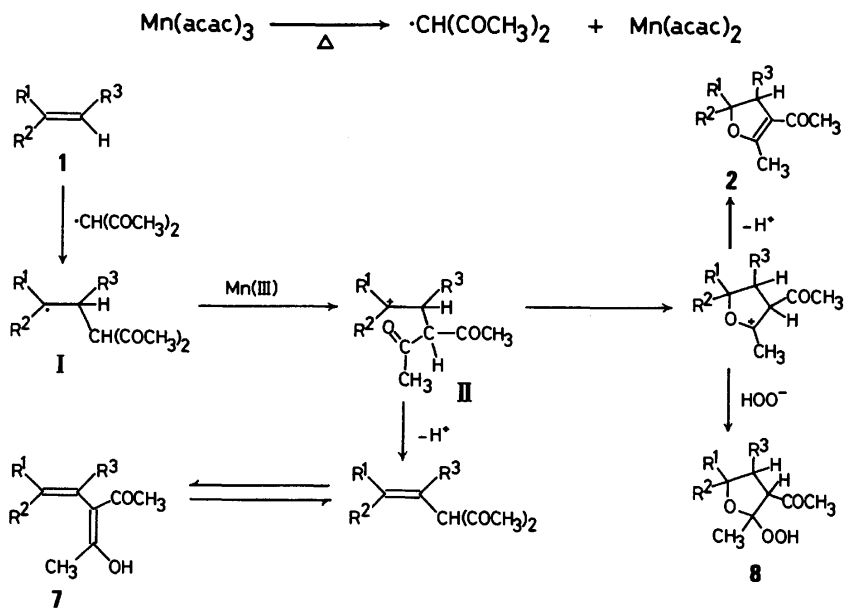


Scheme 1.



Scheme 2.

anhydride or β-dicarbonyl compounds accelerates the thermolysis of $Mn(acac)_3$, as in the oxidation of olefins with $Mn(OAc)_3$ in the presence of acetic anhydride.[12] The reason for the failure to cyclize **7j** to the corresponding dihydrofuran is not evident. However, it could be pointed out that the cyclization may occur at the stage of the carbonium ion **II** and that one of the oxygen functions and the C-1 in **7j** are too far apart to ring-closure.

The reaction of olefins with acetylacetone in the presence of $Mn(OAc)_3$ by the method of Heiba and Dessau[5] gave dihydrofurans in similar yields. In their method, an excess of acetylacetone was needed, and the reaction took more than 10 min. In the present author's method, however, only a stoichiometrical amount of $Mn(acac)_3$ was required for the synthesis of dihydrofurans, except in the case of trisubstituted olefins **1f—i**. Moreover, the oxidation with $Mn(acac)_3$ was completed within 3 min.

The reaction of $Mn(acac)_3$ with olefins is most successful when ethenes containing an aryl group are used. This is primarily due to the electronic effect of the aryl group, which could stabilize the intermediate radical **I** and the cation **II**. Alkyl-substituted olefin **1k** gave the lowest yield. The yields of dihydrofurans from trisubstituted olefins **1f—i** range from moderate to poor. It should be pointed out that the furans are always formed by the attack of the α,α′-diketo radical on the less substituted carbon in ethenes. This is probably attributable to steric reasons.

Thus, it has been shown that the reaction of $Mn(acac)_3$ with aryl-substituted olefins is a useful method for the preparation of substituted dihydrofurans.

Experimental

Measurements. The melting points are uncorrected. The IR spectra were taken on a JASCO A-102 infrared spectrometer, and the IR spectral data are expressed in cm^{-1}. The ^1H- and ^{13}C-NMR spectra were recorded on a Hitachi Perkin-Elmer R-24 spectrometer and a JEOL FX-100 spectrometer at room temperature. The chemical shifts are recorded in the δ scale, relative to TMS as an internal standard. The mass spectra were obtained with a JEOL JMS-DX-300 mass spectrometer using a direct-insertion probe at an ionizing voltage of 70 eV. The UV spectrum is measured on a Hitachi 220A spectrophotometer in a methanol solution.

Materials. The $Mn(acac)_3$ and olefins (**1a—c, f—j**) were prepared according to the method described in the literature.[2,13] The $Co(acac)_3$, $Cr(acac)_3$, $Fe(acac)_3$, $Cu(acac)_2$, and olefins (**1d, e,** and **k**) were obtained from commercial samples of the Wako Pure Chemical Industries, Ltd.

Oxidation of Olefins with $Mn(acac)_3$. A typical procedure for the oxidation of olefins with $Mn(acac)_3$ was as follows. To a heated solution of olefin (1 mmol) in acetic acid (25 cm^3), the amount of $Mn(acac)_3$ shown in Table 3 was added. The solution was then heated under reflux until the brown color of the Mn(III) ion disappeared (within 3 min). The solvent was removed *in vacuo*, and the residue was triturated with 2 M (1 M=1 mol dm^{-3}) hydrochloric acid and then extracted with chloroform. The products were separated on TLC (Kieselgel 60G), with chloroform as the developing solvent. The yields are summarized in Table 3.

Oxidation Products. 3-Acetyl-2-methyl-5,5-diphenyl-4,5-dihydrofuran (2a): Yellow liquid; bp 180—185 °C/133 Pa (bath temperature); IR ($CHCl_3$) 1667 (C=O) and 1620 (C=C); ^1H-NMR ($CDCl_3$) δ=2.13 (3H, s, $COCH_3$), 2.32 (3H, t, J=1.2 Hz, CH_3), 3.61 (2H, q, J=1.2 Hz, CH_2), and 7.13—7.50 (10H, m, ArH). Found: *m/z* 278.12918. Calcd for $C_{19}H_{18}O_2$: M, 278.13068.

3-Acetyl-5,5-bis(4-methoxyphenyl)-2-methyl-4,5-dihydrofuran (2b): Colorless needles (from benzene/light petroleum); mp 96.0—96.5 °C; IR ($CHCl_3$) 1664 (C=O); ^1H-NMR ($CDCl_3$) δ=2.28 (3H, s, $COCH_3$), 2.30 (3H, t, J=1.2 Hz, CH_3), 3.55 (2H, q, J=1.2 Hz, CH_2), 3.73 (6H, s, 2×OCH_3), and 6.69—7.27 (8H, m, ArH). Found: C, 74.24; H, 6.49%. Calcd for $C_{21}H_{22}O_4$: C, 74.55; H, 6.55%.

In the oxidation of **1a** and **1b**, small amounts of benzophenone (**3a**) and 4,4′-dimethoxybenzophenone (**3b**) were also obtained.

3-Acetyl-2,5-dimethyl-5-phenyl-4,5-dihydrofuran (2c): Yellow liquid; bp 160—165 °C/133 Pa (bath temperature).[6]

3-Acetyl-2-methyl-5-phenyl-4,5-dihydrofuran (2d): Yellow liquid; bp 140 °C/133 Pa (bath temperature).[4]

7-Acetyl-8-methyl-cis-6b,9a-dihydroacenaphtho[1,2-b]furan (2e): Pale orange needles (from benzene/hexane); mp 149.7—150.2 °C; IR ($CHCl_3$) 1660 (C=O) and 1622 (C=C); ^1H-NMR ($CDCl_3$) δ=2.07 (3H, d, J=1.2 Hz, CH_3), 2.26 (3H, s, $COCH_3$), 5.12 (1H, br. d, J=7.8 Hz, H-6b), 6.20 (1H, d, J=7.8 Hz, H-9a), and 7.15—7.80 (6H, m, ArH). Found: C, 81.35; H, 5.67%. Calcd for $C_{17}H_{14}O_2$: C, 81.58; H, 5.64%.

3-Acetyl-2-methyl-4,5,5-triphenyl-4,5-dihydrofuran (2f): Colorless microcrystals (from benzene/light petroleum); mp 139.5—140.5 °C; IR ($CHCl_3$) 1665 (C=O) and 1622 (C=C); ^1H-NMR (CCl_4) δ=1.80 (3H, s, $COCH_3$), 2.40 (3H, d, J=1.2 Hz, CH_3), 4.98 (1H, q, J=1.2 Hz, >CH-), and 6.70—7.69 (15H, m, ArH). Found: C, 84.65; H, 6.33%. Calcd for $C_{25}H_{22}O_2$: C, 84.71; H, 6.26%.

Oxidation Products of 1g. 3-Acetyl-5,5-bis(4-methoxyphenyl)-2-methyl-4-phenyl-4,5-dihydrofuran (2g): Colorless liquid; IR ($CHCl_3$) 1664 (C=O); ^1H-NMR ($CDCl_3$) δ=1.89 (3H, s, $COCH_3$), 2.42 (3H, d, J=1.2 Hz, CH_3), 3.47 (3H, s, OCH_3), 3.66 (3H, s, OCH_3), 4.97 (1H, q, J=1.2 Hz, >CH-), and 6.36—7.60 (13H, m, ArH). Found: *m/z* 414.18228. Calcd for $C_{27}H_{26}O_4$: M, 414.18311.

1-Acetoxy-2,2-bis(4-methoxyphenyl)-1-phenylethene (4g): Colorless microcrystals (from ethanol); mp 103.0—103.5 °C (lit,[2] mp 101—102 °C).

2-Hydroxy-2,2-bis(4-methoxyphenyl)-1-phenylethanone (5g): The ^1H-NMR and IR spectral data were in agreement with those of an authentic sample.[2]

Oxidation Products of 1h. 3-Acetyl-4,5,5-tris(4-methoxyphenyl)-2-methyl-4,5-dihydrofuran (2h): Colorless liquid; IR ($CHCl_3$) 1664 (C=O); ^1H-NMR ($CDCl_3$) δ=1.90 (3H, s, $COCH_3$), 2.45 (3H, d, J=1.2 Hz, CH_3), 3.57 (3H, s, OCH_3), 3.61 (3H, s, OCH_3), 3.73 (3H, s, OCH_3), 4.94 1H, q, J=1.2 Hz, >CH-), and 6.41—7.55 (12H, m, ArH).

Found: *m/z* 444.19165. Calcd for $C_{28}H_{28}O_5$: M, 444.19368.

1-Acetoxy-1,2,2-tris(4-methoxyphenyl)ethene (4h) and 2-Hydroxy-1,2,2-tris(4-methoxyphenyl)-1-ethanone (5h): These ^{1}H-NMR and IR spectral data were compatible with those of authentic samples.[2]

Oxidation Products of 1i. 4-Acetyl-5-methyl-3-phenylspiro[furan-2(3H), 9'-xanthene] (2i): Colorless prisms (from aqueous ethanol); mp 141 °C; IR ($CHCl_3$) 1665 (C=O); ^{1}H-NMR ($CDCl_3$) δ=1.74 (3H, s, $COCH_3$), 2.68 (3H, d, J=1.2 Hz, CH_3), 4.44 (1H, q, J=1.2 Hz, >CH-), and 6.57—7.57 (13H, m, ArH). Found: C, 81.56; H, 5.59%. Calcd for $C_{25}H_{20}O_3$: C, 81.50; H, 5.47%.

9-(α-Acetoxybenzylidene)-9H-xanthene (4i): Colorless plates (from ethanol); mp 156—157 °C; IR ($CHCl_3$) 1758 (OAc); ^{1}H-NMR ($CDCl_3$) δ=2.04 (3H, s, OAc) and 6.49—8.00 (13H, m, ArH). Found: C, 80.26; H, 4.95%. Calcd for $C_{22}H_{16}O_3$: C, 80.47; H, 4.91%.

9-(α-Acetoxybenzyl)-9-xanthenol (6): The ^{1}H-NMR and IR spectra were identical with those of an authentic sample.[2]

Oxidation Product of 1j. 9-[α-(1-Acetyl-2-hydroxy-1-propenyl)benzylidene]-9,10-dihydroanthracene (7j): Colorless microcrystals (from ethanol); mp 181.3—181.8 °C; IR ($CHCl_3$) 3600—3200 (OH) and 1600 (C=O); ^{1}H-NMR ($CDCl_3$) δ=1.64 (6H, s, 2×CH_3), 5.09 (2H, s, CH_2), 7.20 (5H, s, Ph), 7.40—8.38 (8H, m, ArH), and 17.02 (1H, s, OH). Found: C, 85.09; H, 6.12%. Calcd for $C_{26}H_{22}O_2$: C, 85.21; H, 6.05%.

Oxidation of 1a with Mn(acac)$_3$ in the Presence of Additives. To a heated solution of **1a** and an additive in acetic acid (25 cm^3), Mn(acac)$_3$ was added (see Table 2). The mixture was then heated under reflux and worked-up according to the procedure previously described.

When malonic acid was used in the reaction mixture, 3,3,8,8-tetraphenyl-2,7-dioxaspiro[4.4]nonane-1,6-dione (**12**)[10] was formed as a by-product. The reaction using malonamide gave **2a**, together with 2-carbamoyl-4,4-diphenyl-2-buten-4-olide (**13**).[2]

Oxidation of 1a with Mn(acac)$_3$ at Room Temperature. The olefin **1a** (1 mmol) and Mn(acac)$_3$ (2 mmol) were stirred in acetic acid (25 cm^3) at room temperature for 12 h. The subsequent treatment of the reaction mixture by the above method yielded **2a** (6%) and **8** (89%).

3-Acetyl-2-hydroperoxy-2-methyl-5,5-diphenyltetrahydrofuran (8): Colorless prisms (from ethanol); mp 161—162 °C; IR ($CHCl_3$) 3600—3200 (OH) and 1696 (C=O); ^{1}H-NMR ($CDCl_3$) δ=1.26 (3H, s, CH_3), 2.28 (3H, s, $COCH_3$), 2.81 (3H, m, $-CH_2-CH<$), 4.20 (1H, s, OH), 7.28 (5H, s, Ph), and 7.26—7.70 (5H, m, Ph); ^{13}C-NMR ($CDCl_3$) δ=209.244 (s, C=O), 143.047 (s, ArC), 140.520 (s, ArC), 128.515 (d, ArC), 128.308 (d, ArC), 128.017 (d, ArC), 127.401 (d, ArC), 126.697 (d, ArC), 125.814 (d, ArC), 98.131 (s, C-2), 85.158 (s, C-5), 52.487 (d, C-3), 32.143 (t, C-4), 29.736 (q, $CO\underline{C}H_3$), and 24.687 (q, CH_3); MS *m/z* (rel intensity), 312 (M^+, 1), 279 (65), 182 (60), 105 (100), 77 (100), and 43 (100). Found: C, 72.93; H, 6.39%. Calcd for $C_{19}H_{20}O_4$: C, 73.06; H, 6.45%.

Reaction of 8 with Acetic Anhydride. The product **8** (101.4 mg) was heated under reflux in acetic anhydride (20 cm^3) for 4 h. The solvent was then removed under reduced pressure, and the residue was triturated with 2 M HCl (20 cm^3). The aqueous solution was extracted with chloroform, and the products were separated on TLC.

2-Acetyldioxy-3-acetyl-2-methyl-5,5-diphenyltetrahydrofuran (9): 57.7 mg, 50%; colorless needles (from ethanol); mp 117.5—118.0 °C; IR ($CHCl_3$) 1754 (OAc) and 1701 ($COCH_3$); ^{1}H-NMR ($CDCl_3$) δ=1.70 (3H, s, CH_3), 2.11 (3H, s, OAc), 2.25 (3H, s, $COCH_3$), 2.73—3.06 (3H, m, $-CH_2-CH<$), 7.22 (5H, s, Ph), and 7.15—7.65 (5H, m, Ph); MS *m/z* (rel intensity), 354 (M^+, 10), 279 (73), 180 (100), 105 (100), and 43 (100). Found: C, 71.00; H, 6.31%. Calcd for $C_{21}H_{22}O_5$: C, 71.17; H, 6.26%.

Oxidation of 1a with (2,4-Pentanedionato) Metal Complexes. The olefin **1a** (1 mmol) and Co(acac)$_3$ (2 mmol) were heated under reflux in acetic acid (25 cm^3) until the dark green color of the Co(III) ion turned to the pink color of the Co(II) ion (for 1 h). The change in the color of the reaction mixture was monitored by means of TLC. The mixture was then treated by the procedure described above, and **1a** (13% recovered) and **2a** (66%) were obtained. The reaction of **1a** (1 mmol) with Cr(acac)$_3$, Fe(acac)$_3$, and Cu(acac)$_2$, respectively (2 mmol of each), under reflux for 4 h in acetic acid, did not give **2a** (**1a** was recovered in 92, 89, and 85% yields, respectively).

The Attempt of Cyclization of 7j with Mn(OAc)$_3$. The **7j** compound (0.5 mmol) was oxidized with Mn(OAc)$_3$ (2 mmol) in acetic acid (25 cm^3). The mixture was heated under reflux for 10 min and then treated by the above method. However, the cyclization reaction did not occur (**7j** was recovered in a 3% yield), and **10** and **11** were obtained instead of the corresponding dihydrofuran.

9-(1-Acetoxy-2-acetyl-3-hydroxy-1-phenyl-2-butenyl)anthracene (10): 45%; colorless microcrystals (from benzene/ethanol); mp 245.5—246.5 °C; UV(MeOH) λ_{max}nm (log ε), 338 (3.59), 355 (3.89), 374 (4.10), and 395 (4.12); IR ($CHCl_3$) 3600—3200 (OH), 1728 (OAc), and 1600 (C=O); ^{1}H-NMR ($CDCl_3$) δ=1.64 (6H, s, 2×CH_3), 2.17 (3H, s, OAc), 7.27 (5H, s, Ph), 7.44—8.65 (9H, m, ArH), and 17.05 (1H, s, OH). Found: C, 79.05; H, 5.85%. Calcd for $C_{28}H_{24}O_4$: C, 79.22; H, 5.70%.

9-Acetoxy-9-(2-acetyl-3-oxo-1-phenyl-1-butenyl)-9,10-dihydroanthracene (11; R=Ac): 29%; colorless needles (from benzene/hexane); mp 152—153 °C; IR ($CHCl_3$) 1747 (OAc) and 1680 ($COCH_3$); ^{1}H-NMR ($CDCl_3$) δ=2.13 (9H, s, OAc and 2×$COCH_3$), 3.24 (2H, s, CH_2), 6.8—7.5 (13H, m, ArH); ^{13}C-NMR ($CDCl_3$) δ=200.875 (s, $\underline{C}OCH_3$), 167.996 (s, $O\underline{C}OCH_3$), 144.338 (s, C=C), 138.937 (s, ArC), 136.560 (s, ArC), 134.621 (s, ArC), 131.187 (d, ArC), 130.102 (s, C=C), 128.721 (d, ArC), 127.636 (d, ArC), 127.167 (d, ArC), 126.814 (d, ArC), 126.697 (d, ArC), 124.316 (d, ArC), 81.372 (s, $-\underset{|}{\overset{|}{\underline{C}}}-$), 49.520 (t, CH_2), 31.292 (q, $CO\underline{C}H_3$), and 21.722 (q, $OCO\underline{C}H_3$); MS *m/z* (rel intensity), 424 (M^+, 7), 366 (5), 333 (8), 291 (100), 273 (27), and 249 (25). Found: C, 79.05; H, 5.87%; *m/z* 424.16835. Calcd for $C_{28}H_{24}O_4$: C, 79.22; H, 5.70%; M, 424.16746.

9-(2-Acetyl-3-oxo-1-phenyl-1-butenyl)-9,10-dihydro-9-anthrol 11; R=H): 14%; liquid; IR ($CHCl_3$) 3600—3100 (OH) and 1680 (C=O); ^{1}H-NMR ($CDCl_3$) δ=2.21 (6H, s, 2×$COCH_3$), 2.53 (1H, br. s, OH), 3.08 (2H, s, CH_2), 6.75—7.55 (13H, m, ArH).

Reaction of Olefins with Acetylacetone in the Presence of Manganese(III) Acetate (Heiba's Method).[9] To a heated solution of olefin (1 mmol) and acetylacetone (4 mmol) in acetic acid (25 cm^3), Mn(OAc)$_3$ (4 mmol) was added. The solution was heated under reflux until the brown color of the Mn(III) ion disappeared. The reaction mixture was then treated by the procedure described above. The prod-

ucts were separated on TLC, and the structure of the compound was determined by means of the ^{1}H-NMR and IR spectra. **2a** (88%) and **3a** (2%) from **1a** (10% recovered); **2b** (89%) from **1b**; **2c** (69%) from **1c**; **2d** (36%) from **1d**; **2e** (55%) from **1e**; **2f** (39%) and **6f** (2%) from **1f** (50% recovered); **2g** (22%), **4g** (38%), and **5g** (10%) from **1g**; **4h** (28%), **5h** (15%), **6h** (2%), and 2,3,3-tris(4-methoxyphenyl)-2-propenal (6%)[2] from **1h**; **2i** (25%) and **6i** (18%) from **1i**; **7j** (67%) from **1j**.

The author would like to thank Mr. Hiromichi Matsuura of the Wakunaga Pharmaceutical Co., Ltd., Hiroshima, for his measurements of the mass spectra. Thanks are also due to Mr. Teruyoshi Marunaka and Mr. Yasunori Sudo of the Taiho Pharmaceutical Co., Ltd., Tokushima, for their measurements of the mass and ^{13}C-NMR spectra.

ESR and ENDOR Studies of Cation Radicals Derived from Benzodipyran Compounds. Structure and Dynamic Behavior of Heterocyclic Ring in Tocopherol (Vitamin E)

Kazuo MUKAI,* Yuichi UEMOTO, and Kazuhiko ISHIZU
Department of Chemistry, Faculty of Science, Ehime University, Matsuyama 790
(Received February 8, 1985)

ESR and ENDOR spectra of cation radicals of benzodipyran compounds were measured in CH_2Cl_2, and the proton hyperfine coupling constants were correctly determined for each radical. From detailed analysis of the temperature dependence of hyperfine coupling of β- and γ-methylene protons in the heterocyclic ring, the equilibrium conformation of the β-methylene group and activation energy for the conformational interconversion have been determined. The structure of the heterocyclic ring was compared with those of α-tocopherol (vitamin E) model previously obtained by X-ray analysis. The result suggests that the solution and crystal conformations of the heterocyclic ring are distinctly different.

It is well recognized that tocopherols (vitamin E) are localized in cellular membranes and have function as an antioxidant by protecting unsaturated lipids from peroxidation.[1,2] The ESR studies of the "tocopheroxyl" neutral radicals (6-chromanyloxyl radicals from tocopherol) are biologically interesting since they are involved in antioxidant action of vitamin E. Therefore, in recent years, several investigators including present authors have studied the ESR spectra of α-, β-, γ-, and δ-tocopheroxyl radicals and their model compounds in detail.[3-9] The proton hyperfine coupling constants were determined correctly, and the methyl-substitution effects on the unpaired spin distribution and radical stability of the tocopheroxyl radicals have been discussed.[7,9]

Recently, Ingold *et al.* have reported absolute rate constants, k_1, for the reaction of α-tocopherol and some related phenols (for example, 4-methoxy-2,3,5,6-tetramethylphenol) with peroxyl radicals (ROO·).[11-14] By comparing the k_1 value for α-tocopherol with those found for structually related phenols that lacked the 6-membered heterocyclic ring, they suggested that the structure of this ring was largely responsible for the high reactivity of α-tocopherol. In a previous paper, from the results of the ENDOR measurements of α-tocopheroxyl and its model, we reported that each of the two β- and γ-methylene protons in the heterocyclic ring shows an equivalent hyperfine coupling (see Fig. 1).[6] This suggests that the two carbon atoms C-4 and C-3 in the heterocyclic ring are coplanar with the aromatic ring. The result is inconsistent with the X-ray structure of α-tocopherol model, which shows that the dihedral angle, θ_γ, between the C_3–C_4 bond and the aromatic ring is 11.1 and 11.9°.[11,13] However, in a previous work, the clear ENDOR spectra of the α-tocopheroxyl and its model radicals were observable in the comparatively high and narrow temperature range (from −25 to −35 °C for α-tocopheroxyl and from −40 to −55 °C for α-tocopheroxyl model), because these radicals are not so stable and dimerize at low temperature region.

In the present paper, we have succeeded in measuring ESR and ENDOR spectra of cation radicals obtained by the oxidation of benzo[1,2-*b*:4,3-*b*′] and [1,2-*b*:4,5-*b*′]dipyran compounds **1** and **2** (see Fig. 1), which have heterocyclic ring common to that of tocopherols, in $AlCl_3$–CH_2Cl_2 mixtures. The proton hyperfine coupling constants were correctly determined for each radical, and further the temperature dependence of the hyperfine coupling constants has been studied in detail. From the results, the electronic structure of the cation radicals and the conformation and dynamic behavior of the heterocyclic ring have been discussed.

α -Toc. model

Fig. 1. Molecular structures of benzo[1,2-*b*:4,3-*b*′] and [1,2-*b*:4,5-*b*′]dipyran cation radicals **1** and **2** and α-tocopherol model, and the atomic numbering system.

Experimental

Preparation of Specimens. 2,3- and 2,5-dimethylhydroquinones were prepared according to the method of Nilsson *et al.*[15] Benzo[1,2-*b*:4,3-*b'*] and [1,2-*b*:4,5-*b'*]dipyran compounds (**1**; mp 101—102 °C and **2**; mp 196—197 °C) were synthesized by condensation of 2-methyl-3-buten-2-ol to the corresponding alkylhydroquinone, according to the method of Nilsson *et al.*[16]

Measurements. The ESR measurements were carried out using a JES-FE-2XG spectrometer equipped with a Takeda-Riken microwave frequency counter. The *g*-values were measured relative to the value of Li-TCNQ powder, calibrated with $(KSO_3)_2NO$ (g=2.0054).[17] The ENDOR spectra were recorded by a JES-EDX-1 spectrometer, operated with 80 Hz magnetic field modulation. All the ESR and ENDOR spectra have been measured in a sealed, degassed system.

Results and Discussion

ESR and ENDOR Spectra of Benzodipyran Cation Radicals 1 and 2. The cation radicals **1** and **2** were prepared by the oxidation of the corresponding benzodipyran compounds in an $AlCl_3$–CH_2Cl_2 solution. The ESR spectra of the **1** and **2** are shown in Figs. 2 and 3, respectively. The ESR spectra are complex and exhibit line-width alternation phenomena. This is due to the hindered rotation of the heterocyclic ring in radicals **1** and **2**. The g_{iso}-values of these cation radicals observed in CH_2Cl_2 at −105 °C are given in Table 1.

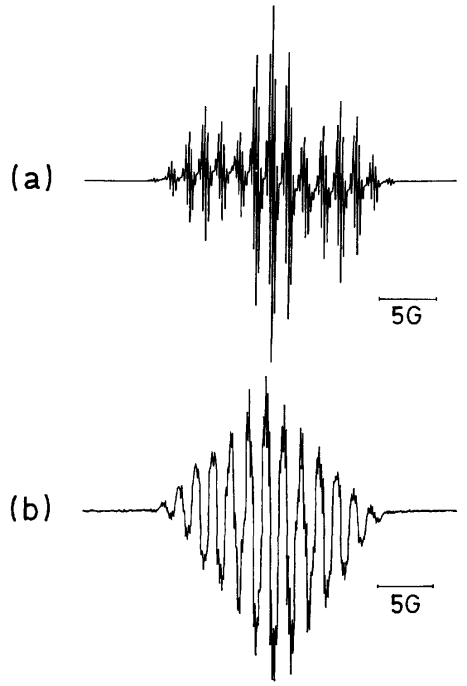

Fig. 2. ESR spectrum of cation radical **1** in CH_2Cl_2 at (a) 20 °C and (b) −100 °C.

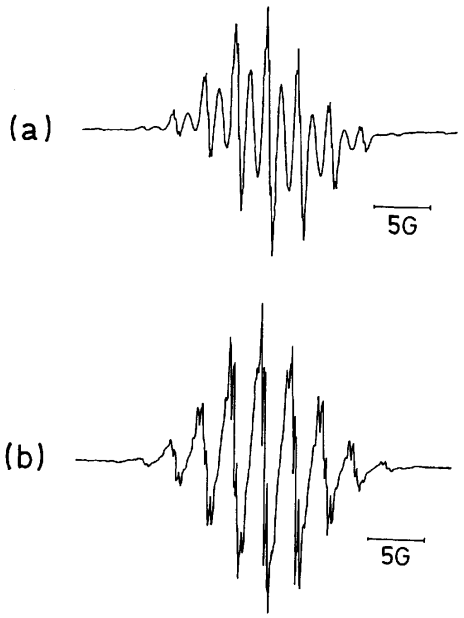

Fig. 3. ESR spectrum of cation radical **2** in CH_2Cl_2 at (a) 20 °C and (b) −100 °C.

a) Experimental errors ±0.010 G. 1 G = 10^{-4} T. b) Spin densities at C-4a,4'a. c) It is not clear at present whether the smallest hyperfine coupling $a_{2,2'}^{CH_3}$ is due to two or four methyl groups at C-2,2'. d) Experimental errors ±0.00005.

ENDOR measurements of the cation radicals were performed on several samples under slightly different conditions of oxidation, varying the concentration of the benzodipyran precursors and the amount of $AlCl_3$. The ENDOR spectra of the cation radicals were observed in the broad temperature range −105 to −40 °C. Figures 4 and 5 show ENDOR spectra of cation radicals **1** and **2** in CH_2Cl_2, respectively, where the free proton frequency ν_0 (13.8 MHz) is shown by an arrowhead in the diagram.

The ENDOR spectrum of **1** clearly shows six different proton hyperfine splittings at −105 °C, as shown in Fig. 4(b). The spectrum changed explicitly by increasing temperature, and showed four different hyperfine splittings at −55 °C (see Fig. 4(a)). The cation radical **2** also shows notable temperature dependence of the ENDOR spectrum. The temperature dependence of the hyperfine couplings observed for the cation radicals **1** and **2** is shown in Figs. 6 and 7, respectively, and the hyperfine coupling constants obtained at −105 and −40 °C are summarized in Table 1.

If all the proton hyperfine couplings due to 5-CH_3, 4-CH_2, 3-CH_2, 2-$(CH_3)_2$ are different from each other, we can expect seven different hyperfine couplings for both the cation radicals **1** and **2**, as a maximum, assuming the free rotation of CH_3 groups. In our ENDOR measurements, we could resolve six different hyperfine splittings for both the

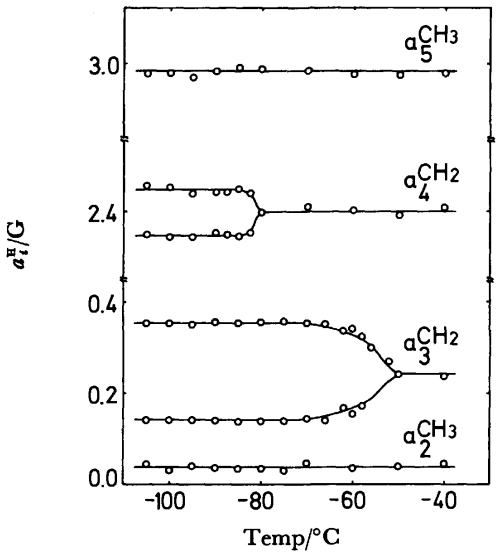

Fig. 7. Temperature dependence of the hyperfine couplings of cation radical **2** in CH_2Cl_2.

cation radicals **1** and **2**. Assignments of the hyperfine couplings have been performed, taking the temperature dependence of the hyperfine couplings (see Figs. 6 and 7) and the result of the McLachlan MO calculations (see Table 1), as described in the following section, into account.

McLachlan Molecular Orbital Calculations. McLachlan spin densities (ρ_i^π) of benzodipyran cation radicals were calculated, using the same parameters for the oxygen atom and methyl group ($\alpha_{O_1}=\alpha_{O_{1'}}=\alpha+2.0\beta$, $\beta_{C_{3a}-O_1}=\beta_{C_{3'a}-O_{1'}}=1.0\beta$, $\alpha_{C_{4a}}=\alpha_{C_{4'a}}=\alpha-0.06\beta$, $\alpha_{C_5}=\alpha_{C_{5'}}=\alpha-0.1\beta$, $\lambda=1.2$) as those used for the vitamin E radical (α-tocopheroxyl).[6] The results of McLachlan MO calculations (see Table 1) were found to be in satisfactory agreement with the "experimental" spin densities evaluated from the hyperfine coupling constants.

Conformation of β-Methylene Group in Benzodipyran Cation Radicals 1 and 2. The magnitude of the β-proton hyperfine coupling can often be calculated using Heller-McConnell's equation.[18]

$$a_\beta^H = \langle B_0 + B_2 \cos^2\theta \rangle \rho_i^\pi , \quad (1)$$

where ρ_i^π is the spin density on the carbon atom to which an alkyl group is attached and θ is the dihedral angle between the axis of the $2p_z$ orbital and the aliphatic C–H bond of the alkyl group. B_0 and B_2 are empirical parameters and were taken to be 0 and 54 G respectively, in Eq. 1. Consequently, the experimental values of the spin densities at C-5 and C-5′ carbon atoms were estimated from the methyl proton coupling, assuming the free rotation of the methyl group, $\langle\cos^2\theta\rangle=1/2$. On the other hand, in the ENDOR spectra for the cation radical **2** in CH_2Cl_2, two kinds of hyperfine couplings ($a_4^{CH_2}=2.452$ G and $a_4^{CH_2}=2.349$ G) (1 G=10^{-4} T) attributable to the magnetically inequivalent β-methylene protons were recorded at −105 °C. They collapsed into a single line as the temperature was raised to −80 °C (see Fig. 7). Therefore, in the case of the present cation radical **2**, one may expect that a rotation of the β-methylene residue would be tightly rocked at low temperatures. This is indeed true, because the temperature dependence of the β-proton coupling constant has been found to be negligible for the above cation radical **2** in the temperature range from −105 to −90 °C, as shown in Fig. 7. Consequently, the dihedral angles, θ_A and θ_B, of the inequivalent β-protons, were calculated to be 28.9 and 31.1° for **2**, respectively, assuming the sum of the two dihedral angles is $\pi/3$. The result suggests that the dihedral angle, θ_γ, between the C_3–C_4 bond and the aromatic ring is 1.1° (see Fig. 8). The experimental values of the spin densities at C-4a and C-4′a carbon atoms were estimated using Eq. 1.

Similarly, the dihedral angles (θ_A and θ_B) and the experimental spin densities of the cation radical **1** were calculated from the observed β-methylene hyperfine splittings (5.024 and 1.444 G) at −105 °C, assuming $\theta_A+\theta_B=\pi/3$. These values are listed in Tables 1 and 2.

As listed in Table 2, the values of dihedral angles (θ_A and θ_B) observed for **1** are very different from those observed for **2**. The above change in dihedral angles will be due to the difference in the steric repulsion forces between the β-methylene protons at C-4 and at C-4′ in **1** and between the β-methylene protons at C-4 and neighboring methyl protons

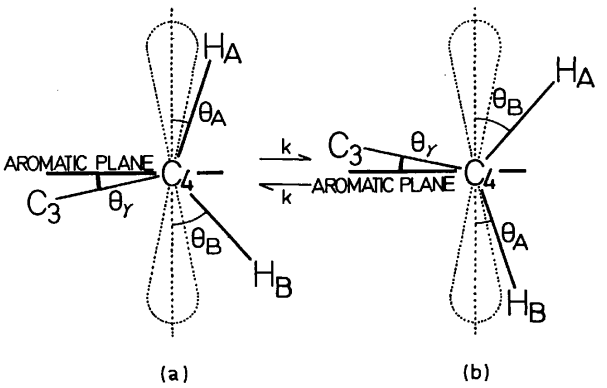

Fig. 8. Possible equilibrium conformations of the β-methylene group in cation radicals **1** and **2** in CH_2Cl_2.

at C-5′ in **2**.

As described in a previous section, Burton and Ingold have reported that the dihedral angle, θ_γ, between the aromatic ring and the C_3–C_4 bond is 11.1 and 11.9°, from an X-ray crystallographic analysis of α-tocopherol model.[13] In the α-tocopherol model and the above cation radical **2**, the steric repulsion force between the β-methylene protons at C-4 and the neighboring methyl protons (at C-5 in α-tocopherol model and at C-5′ in **2**) will be similar to each other, and thus the conformation of the heterocyclic ring in **2** is considered to be similar to that of the α-tocopherol model. However, the value of the dihedral angle (θ_γ=1.1°) in **2** is different from those (θ_γ=11.1 and 11.9°) in α-tocopherol model. On the other hand, very recently, we have succeeded in measuring the ENDOR spectrum of a new stable tocopheroxyl radical **3** (7-*t*-butyl-2,2,5-trimethyl-6-chromanyloxyl) (see Table 2) in toluene.[19] It was found that the two β-methylene protons in the heterocyclic ring become magnetically inequivalent at low temperature (<−72 °C). The observed dihedral angles are θ_A=27.6° and θ_B=32.4°, and θ_γ is calculated to be 2.4°. These values are very similar to those of the cation radical **2**, because the steric repulsion force between the β-methylene protons at C-4 and the neighboring methyl protons is equivalent in **2** and **3**. These results suggest that the solution structure of the heterocyclic ring attached to the aromatic ring is similar to each other and the crystal and solution conformations of the heterocyclic ring are distinctly different.

Dynamic Behavior of Heterocyclic Ring. As described in a previous section, in the ENDOR spectra of the cation radical **2** in CH_2Cl_2, two signals attributable to the two inequivalent splittings of the β-methylene protons ($a_4^{CH_2}$=2.452 G and $a_4^{CH_2}$=2.349 G) were recorded at −105 °C. The β-methylene proton hyperfine coupling constants remain almost unchanged upon warming from −105 to −85 °C. They collapsed into a single line ($a_4^{CH_2}$=2.401 G) as the temperature was raised to −80 °C (see Fig. 7). Similar behavior has been observed for γ-methylene protons.

In such a case, we can calculate the activation energy E_{act} for the conformational interconversion of the heterocyclic ring, applying the Gutowsky-Holm equation.[20–22] In a four-jump dynamic process, the separation $\Delta\omega$ on the two ENDOR lines at T K due to β- or γ-methylene protons is given by

$$\Delta\omega = (\Delta w_{max}^2 - 8k^2)^{1/2} \quad (2)$$

where $\Delta\omega_{max}$ is the two limiting values of the splitting constants of β- or γ-methylene protons and equals to $\gamma_e|(a_A^{CH_2}-a_B^{CH_2})/2|$, and $k=1/2\tau$. Here, τ is the mean life time of each conformation.

With the aid of this relation we have obtained k at different temperatures for cation radical **2** in CH_2Cl_2. However, in the case of the β-methylene protons, the value of $\Delta\omega_{max}$(=0.103 G=0.289 MHz) is very small and thus the change of the $a_4^{CH_2}$ values occurs in the narrow temperature range (−85—−80 °C). Therefore, the E_{act} value was obtained from the temperature dependence of γ-methylene proton hyperfine couplings ($a_3^{CH_2}$). Figure 9 shows the Arrhenius plots of $\log k$ *vs.* $1/T$ for **2** from which E_{act} was determined. The observed activation energy E_{act}=32.8±4.6 kJ mol^{-1}. On the other hand, in the case of cation radical **1**, the value of $\Delta\omega_{max}$(=3.580 G=10.033 MHz) for β-methylene hyperfine coupling is very large and the coalescence temperature is higher than the temperature where the ENDOR observation is possible. Therefore, the E_{act} was calculated from the temperature dependence of γ-methylene proton hyperfine couplings, as performed for cation radical **2**. The activation energy obtained is E_{act}=19.0±2.7 kJ mol^{-1}. As described in a previous section, in the cation radical **2** and the tocopheroxyl radical **3** (7-*t*-butyl-2,2,5-trimethyl-6-chromanyloxyl), the steric repulsion force between the β-methylene protons at C-4 and the neighboring methyl protons will be similar to each other, and thus we can expect similar E_{act} values for **2** and **3**. However, the activation energy, E_{act} obtained in the present work for **2** is slightly larger than that (25.9±1.7 kJ mol^{-1}) reported for such an interconversion in **3**.[19]

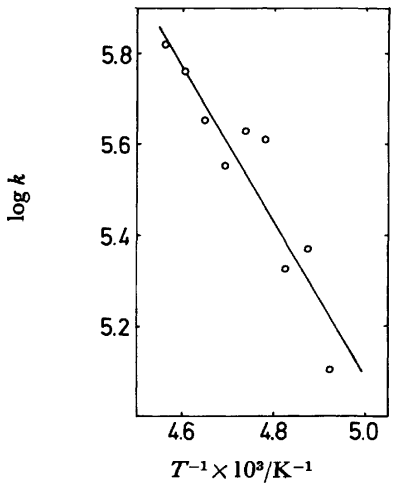

Fig. 9. The Arrhenius plot of the rate constant for the conformational interconversion process of the heterocyclic ring of cation radical **2** in CH_2Cl_2.

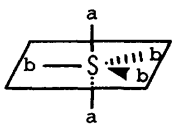
Nucleophilic Substitution of Tricoordinate Sulfur Atom of Sulfonium Salt with Retention of Configuration.[1] Different Stereochemistry of Substitution by Amidate Anions

Katsuaki KIKUCHI, Naomichi FURUKAWA,* Masaru MORIYAMA,† and Shigeru OAE*,††
Department of Chemistry, The University of Tsukuba, Sakura-mura, Niihari-gun, Ibaraki 305
(Received February 12, 1985)

Optically active *N*-substituted *S*-(*o*-methoxyphenyl)-*S*-phenylsulfilimines were obtained in moderate yields upon simple treatment of a mixture of *o*-methoxyphenyl phenyl sulfide and *t*-butyl hypochlorite in the presence of *l*-menthol and followed by amidate anions. Although some sulfilimines (*N*-tosyl-, *N*-benzoyl-, and *N*-(chloroacetyl)sulfilimines) were found to be rich in *S*-configuration around the sulfur atom, the others (*N*-(dichloroacetyl)-, *N*-(trichloroacetyl)-, and *N*-(trifluoroacetyl)sulfilimines) were found to be rich in *R*-configuration around the sulfur atom. In the displacement of *l*-menthyloxy group on the sulfur atom of the incipiently formed *l*-menthyloxysulfonium salt with *p*-toluenesulfonamidate, benzamidate, and chloroacetamidate anions, the respective *N*-acylsulfilimines of *S*-configuration were obtained by substitution with inversion of configuration, while *N*-acylsulfilimines having *R*-configuration were obtained by substitution of the same *l*-menthyloxysulfonium salt by polyhaloacetamidate anions such as dichloroacetamidate, trichloroacetamidate, and trifluoroacetamidate anions, with retention of configuration.

The mechanism of nucleophilic substitution reaction at the tricoordinate sulfur atom has been a subject of considerable interest.[2] One of the important problems is the structure of the transition state or the intermediate and the stereochemical course of the nucleophilic substitution on the sulfur atom. The nucleophilic substitution of the tricoordinate sulfur atom has been suggested to proceed *via* formation of a sulfurane type intermediate of trigonal bipyramidal structure shown below, and the stereochemistry of the substitution which involves the initial formation of a σ-sulfurane is believed to be determined by the relative orientation of the attacking nucleophile and the leaving group. In the hypervalent σ-sulfurane, the apical bond is presumed to be made up with a *p*-orbital, and hence is longer and more polar than the basal bond which is composed mainly of sp^2 hybrid.



NUCLEOPHILE	LEAVING GROUP	STEREOCHEMISTRY
a	a	INVERSION
b	b	INVERSION
a	b	RETENTION
b	a	RETENTION

Fig. 1. The relation between the stereochemistry and the orientation of the nucleophile and the leaving group.

Therefore both the entering nucleophile and the leaving group are considered to be placed at apical positions in the nucleophilic substitution on the tricoordinate sulfur atom. When there is no special interaction between the entering nucleophile and the leaving group, both groups will be placed at the apical positions of opposite directions, inversion of configuration on the sulfur atom will be the rational course.

Inversion of configuration would also be resulted, if both entering and leaving groups would occupy the basal positions.

However, this orientation is quite unlikely, since both entering and leaving groups are relatively more polar and their bonds are longer than others and hence should be placed at the apical rather than at the basal positions at the transition state of the nucleophilic substitution on the tricoordinate sulfur atom. Meanwhile, if there is any special interaction between the entering nucleophile and the leaving group, in the resulted sulfurane type intermediate, the nucleophile which enters from the apical position and the leaving group at the basal position may turn their positions by pseudorotation before placing the entering nucleophile at a basal position and extruding the leaving group from an apical position, retention of configuration is expected to be observed (Fig. 1).

Since the first example of inversion at the sulfur atom was found in the transesterification of a chiral sulfite,[3] numerous instances of nucleophilic substitution reaction have been demonstrated to occur with inversion of configuration on the sulfur,[4] and this is

believed to be the most common stereochemical course for the nucleophilic substitution (ligand exchange) on the sulfur atom. However, there have been a few cases in which retention of configuration has been observed in the nucleophilic substitution on the tricoordinate sulfur atom. Oae *et al.* were the first who observed that optically active methyl *p*-tolyl sulfoxide labeled with ^{18}O undergoes the oxygen exchange with that of dimethyl sulfoxide without any loss of optical activity, *i.e.*, the retention of configuration on the sulfur atom.[5] In this case a dipole-dipole interaction between the two sulfoxide linkages is considered to keep the two ligands at nearly 90° angle throughout the ligand exchange. Since then the retention of configuration in nucleophilic substitution has also been observed in the several reactions, such as in the conversion of chiral sulfoxides into the corresponding sulfilimines in the reactions with *N*-sulfinyl-*p*-toluenesulfonamide,[6] *N,N'*-ditosylsulfur diimide,[7] and *p*-toluenesulfinylnitrene[8] as reagents. Moreover, the reaction of an optically active amidothiosulfite with mercury(II) chloride leading to the optically active aminosulfinyl chloride was shown to proceed with retention of configuration at the sulfur center.[9]

Recently, a few other reactions also have been reported to proceed with retention of configuration on the sulfur atom.[10]

In all these reactions involving the trigonal bipyramidal intermediates, formation of four-membered ring by a special interaction between leaving and entering groups at the apical and basal positions is generally believed to be the main factor responsible for the retention mechanism.

Recently, we have reported that optically active (*S*)-(−)-*S*-(*o*-methoxyphenyl) (or *o*-methylphenyl)-*S*-phenyl-*N*-tosylsulfilimine was obtained by simple treatment of an equimolar mixture of *l*-menthol and the corresponding sulfide at first with *t*-butyl hypochlorite and subsequent addition of sodium *N*-*p*-toluenesulfonamidate at a low temperature, as shown in Fig. 2. When we used some other nucleophiles instead of the amidate anion, we were able to obtain other optically active diaryl tricoordinate sulfur compounds; namely, when hydroxide anion was used, the corresponding (*S*)-(−)-sulfoxide of inverted configuration was obtained whereas in the teatment of malonate anion, the corresponding inverted (+)-sulfonium ylide was also obtained.[11] In all these reactions, optically active *l*-menthyloxysulfonium chloride is presumed to be formed as the incipient intermediate (Fig. 2). This method has now become a simple and hence the most general preparative method to synthesize optically active (*o*-substituted aryl) phenyl tricoordinate sulfur compounds. However, when such polyhaloacetamidates such as dichloro-, trichloro-, and trifluoroacetamidate anions were used instead of *p*-toluenesulfonamidate anion, we have obtained unexpectedly the corresponding sulfilimines each having excess of the R-configuration in good yields.[1] In this papar we wish to report this new type of nucleophilic substitution at the tricoordinate sulfur atom and the mechanism of this unusual stereochemistry.

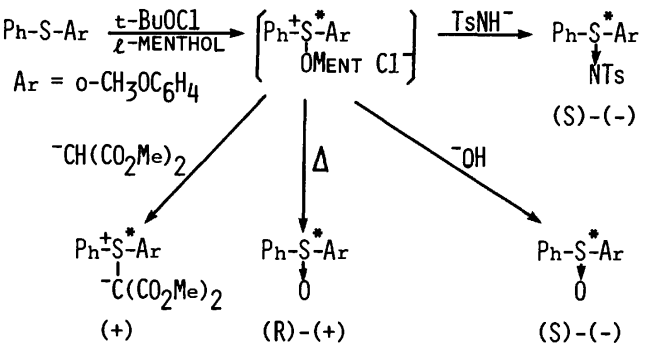

Fig. 2. Asymmetric syntheses of some optically active tricoordinate sulfur compounds.

Results and Discussion

Unsymmetrical *S,S*-diarylsulfilimines were obtained in moderate yields by treating an equimolar mixture of *l*-menthol and the corresponding sulfide first with *t*-butyl hypochlorite and subsequently with amidate anions as shown in Scheme 1.

The *N*-tosylsulfilimines (**3a** and **g**), *N*-benzoylsulfilimine (**3b**), and *N*-(chloroacetyl)sulfilimine (**3c**) thus obtained showed minus sign of optical rotation, and *N*-(polyhaloacetyl)sulfilimines such as *N*-(dichloroacetyl)-(**3d**), *N*-(trichloroacetyl)-(**3e**), and *N*-

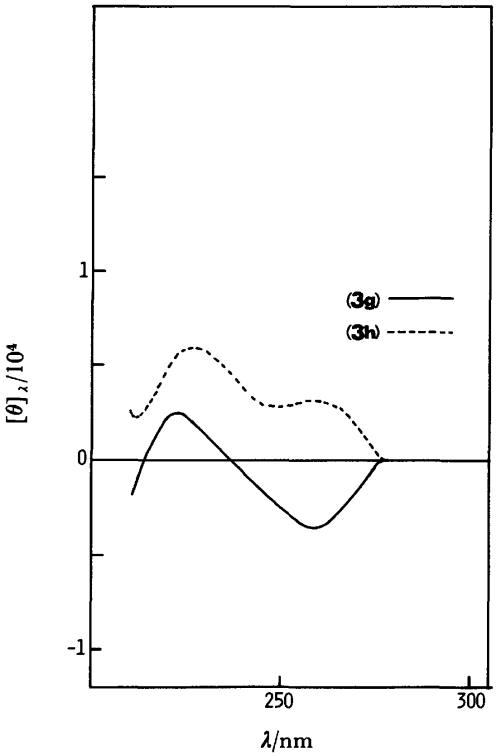

Fig. 3c. CD spectra of (*S*)-(−)-*S*-(*o*-methylphenyl)-*S*-phenyl-*N*-tosylsulfilimine (**3g**) and (*R*)-(+)-*N*-(trifluoroacetyl)sulfilimine (**3h**).

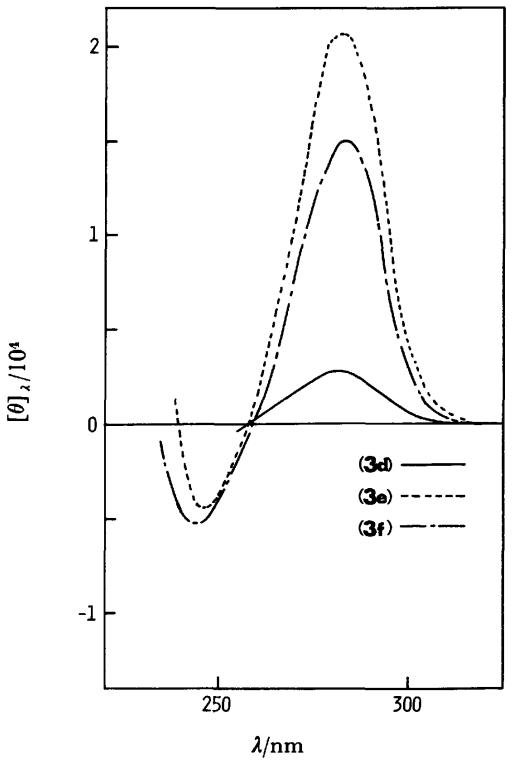

Fig. 3b. CD spectra of (*R*)-(+)-*S*-(*o*-methoxyphenyl)-*S*-phenyl-*N*-(dichloroacetyl)-(**3d**), *N*-(trichloroacetyl)-, (**3e**), and *N*-(trifluoroacetyl)-(**3f**) sulfilimines.

(trifluoroacetyl)sulfilimines (**3f** and **h**) showed plus sign of optical rotation. The configurations of these sulfilimines were determined by comparing their circular dichroism (CD) spectra with that of (−)-**3a** which was determined to be of *S*-configuration by X-ray crystallographic analysis.[12] The CD spectra of these sulfilimines, thus obtained, are shown in Fig. 3. Meanwhile, the configurations of sulfilimines (**3b—f**) were also determined by comparing the optical rotations with those of the authentic samples. The authentic samples were prepared by acylating of optically active (*S*)-(−)-S-(*o*-methoxyphenyl)-*S*-phenylsulfilimine formed upon treatment of (*S*)-(−)-*S*-(*o*-methoxyphenyl)-*S*-phenyl-*N*-tosylsulfilimine with concd sulfuric acid, as shown in Scheme 2. The sulfilimines thus obtained are listed in Table 2. The assignment of the configuration of each of these sulfilimines (**3b—f**) determined by the CD spectrum was in good agreement with the result obtained by comparison with the optical rotation of the authentic sample.

Based on these observations the sulfilimines having minus optical rotations (**3a—c** and **g**) obtained in this reaction, are considered to have the *S*-configuration, while those having plus optical rotations (**3d—f** and **h**) are determined to have the *R*-configuration. Thus, the sulfilimines prepared by treatment of the *l*-menthyloxysulfonium salt (**2**) with such amidate

anions as *p*-toluenesulfonamidate, benzamidate, and chloroacetamidate have in excess of those of the *S*-configuration, while the sulfilimines prepared by the reaction of **2** with amidate anions having highly electron-withdrawing acyl groups such as dichloroacetamidate, trichloroacetamidate, and trifluoroacetamidate have in excess of those of the *R*-configuration. In order to scrutinize the stereochemistry of these substitutions, we have made an attempt to isolate the key intermediate, namely *o*-methoxyphenylphenyl-*l*-menthyloxysulfonium salt and investigated the stereochemical course of the nucleophilic substitution of the sulfonium salt with various amidate anions. *o*-Methoxyphenylphenyl-*l*-menthyloxysulfonium salt was obtained as perchlorate (**2**) by treating an equimolar mixture of *o*-methoxyphenyl phenyl sulfide and *l*-menthol, at first with *t*-butyl hypochlorite and subsequent addition of silver perchlorate as shown in Scheme 3. The sulfonium salt (**2**) thus obtained was found to be a mixture of two

a) Reaction temperature was −35 °C.

diastereomers, since the sulfonium salt (**2**) has two chiral centers, namely the sulfonium sulfur atom and the carbon atom of *l*-menthyloxy group attached to the oxygen atom. The ratio of the two diastereomers thus obtained was determined by the ^{1}H NMR integration of the peaks of *o*-methoxyl groups appeared at δ 3.93 for the major diastereomer and δ 4.01 for the minor one. However, the diastereomeric ratio of 2 was found to change with the change of solvent and reaction temperature in the treatment with *t*-butyl hypochlorite as shown in Table 3. When an amidate anion was added into the acetonitrile solution of the sulfonium salt (**2**), the corresponding sulfilimine was obtained as summarized in Table 4. Their optical yields are rather low, however, the stereochemical course for the substitution is in good agreement with the result obtained from the direct asymmetric induction shown in Table 1; namely, the corresponding *N*-tosyl-(**3a**) and *N*-(chloroacetyl)sulfilimine (**3c**) have the *S*-configuration, and *N*-(dichloroacetyl)-(**3d**), *N*-(trichloroacetyl)-(**3e**), and *N*-(trifluoroacetyl)sulfilimines (**3f**) show the *R*-configuration. These observations clearly indicate that the *l*-menthyloxysulfonium salt (**2**) is the key intermediate in the asymmetric reaction as shown in Scheme 1.

3f	$COCF_3$	47.2	94

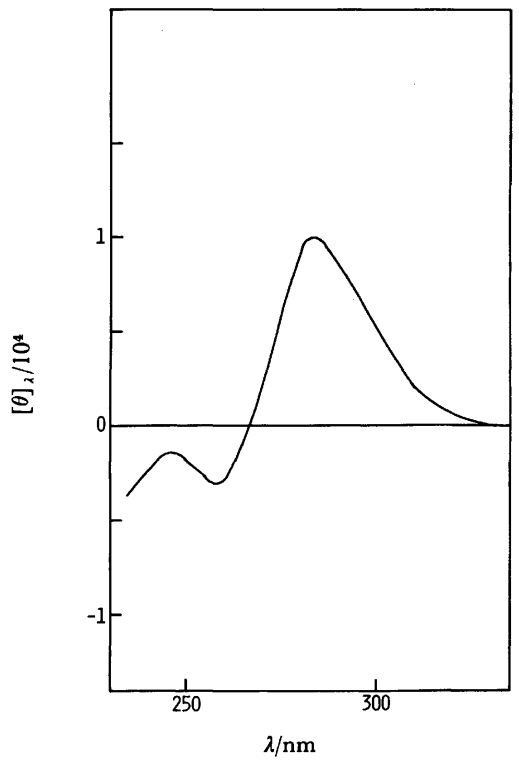

Fig. 4. CD spectra of (*l*-menthyloxy)(*o*-methoxyphenyl)phenylsulfonium perchlorate (**2**).

When *t*-butyl hypochlorite was added at −40°C into the acetonitrile solution of the equimolar mixture of sulfide (**1**) and *l*-menthol, namely under the same conditions as the results shown in Table 1 and the ratio of the two diastereomers was found to be 75 : 25. Thus, the optical yields in the asymmetric syntheses of these sulfilimines shown in Table 1 have been determined and the results are summarized in Table 5. The CD spectrum of *l*-menthyloxysulfonium perchlorate (**2**) is shown in Fig. 4. From the CD curve, the configuration around the sulfur atom of the *l*-menthyloxysulfonium perchlorate (**2**) was determined to be excess of the *R*-configuration, in accordance with the result reported previously by us.[11a] Therefore, the sulfilimines having the opposite sign of the Cotton effect to that of the sulfonium perchlorate (**2**), namely, *N*-tosyl-(**3a**), *N*-benzoyl-(**3b**), and *N*-(chloroacetyl)sulfilimines (**3c**) are undoubtedly obtained through the inversion process. When the sulfilimines showing the same sign of the Cotton effect to that of the sulfonium perchlorate (**2**), namely *N*-(dichloroacetyl)-, (**3d**), *N*-(trichloroacetyl)-(**3e**), and *N*-(trifluoroacetyl)-sulfilimines (**3f**) are obviously formed through the retention process stereochemically. Thus, it appears that the retention process predominates over the inversion process when the more acidic amidate anion is used. Accordingly, some reported pK_a values for the conjugated acids of amides which were used in this experiment have been sought out, as shown in the following, namely $PhCONH_3^+$=−1.55,[13] $ClCH_2CONH_3^+$−3.21,[14] *p*-$TolSO_2$ NH_3^+=−3.3,[15] $Cl_2CHCONH_3^+$<−6.4.[14]

These data sugggest that the stereochemistry of substitution of the *l*-menthyloxysulfonium salt with the amidate anion seems to be related to the acidity of the amide. Namely, the ordinary amidate anion seems to substitute *l*-menthyloxy group of *l*-menthyloxysulfonium salt with inversion of the configuration, while the more acidic amidate anion seems to undergo substitution with retention of the configuration.

The effect of temperature on the stereochemistry of the reaction was also examined. In order to fix the *R*/*S* ratio of the intermediate, *i.e.*, the *l*-menthyloxysulfonium ion, *t*-butyl hypochlorite was added under a certain fixed conditions. Then, after changing the temperature of the whole mixture,

sodium trifluoroacetamidate was added into the system as shown in Scheme 4. The enantiomeric excess of the *N*-(trifluoroacetyl)sulfilimine thus obtained has been found to decrease with the increase of the reaction temperature as shown in Table 6. The decrease of *R/S* ratio with the increase of temperature could be resulted by the thermal racemization of the intermediate sulfonium salt. However, since the *R/S* ratio was found not to change from −30 °C to 42 °C, the thermal racemization cannot be responsible (Table 7). Furthermore, the sulfonium salt (**2**) did not undergo any racemization even under keeping at 61.5 °C for 1 h.

Only at a somewhat higher temperature (80.1°C,1 h), it decomposed completely to form the corresponding sulfoxide but no thermal racemization was observed. Another possibility is the intervention of the concurrent inversion process.

At a low temperature (−40°C), trifluoroacetamidate anion may attack the sulfur atom of the sulfonium salt (**2**) interacting with a basal ligand to offer the sulfilimine (**3f**) of only the retained configuration (stereoselectivity is over 94%), and at a higher temperature (22°C), the ratio (*R/S*) of retention to inversion path decreased to roughly 75 : 25.

This result suggests that the substitution with retention of configuration is more sensitive to the effect of temperature than that with inversion. This would mean that the substitution with retention proceeds through a more rigid transition state than the inversion process. Indeed the plots of *R/S* ratio against the reaction temperature, gave a value of energy difference between the retention and the inversion process for trifluoroacetamidate anion as $\Delta\Delta G^{\ddagger}=4.9$ KJ mol^{-1} (Fig. 5).

Temp/°C	R_S-R_C/S_S-R_C[a)]
−30±2	75/25
0±2	75/25
+20±2	75/25

a) Diastereomer ratio was determined by ^{1}H NMR in $CDCl_3$.

Mechanism. It has become quite clear from all the observations that the retention process is the main path of the nucleophilic substitution when the nucleophile used is the amidate anion bearing an acidic proton, and proceeds through a more rigid transition state than the inversion process. The most plausible mechanism for this process is as shown in Fig. 6. When *t*-butyl hypochlorite is added to an equimolar mixture of *l*-menthol and *o*-methoxyphenyl (or *o*-methylphenyl) phenyl sulfide, the corresponding *l*-menthyloxysulfonium ion is obtained. This sulfonium ion is a mixture of two diastereomers, *i.e.*, R_S—R_C and S_S—R_C, however in excess of the kinetically favored R_S—R_C conformer. When the ordinary amidate anion such as *p*-toluenesulfonamiate, benzamidate, or chloroacetamidate, attacks the sulfur atom along an apical direction, *i.e.*, the back side of the leaving group, namely *l*-menthyloxy group of the sulfonium ion at another apical direction, the reaction proceeds *via* formation of a σ-sulfurane as the key intermediate, in which both attacking and leaving groups are placed

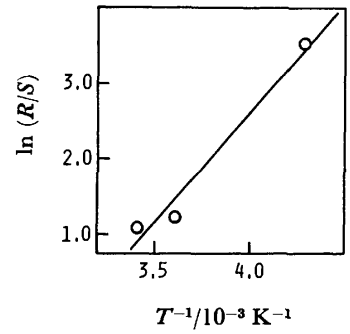

Fig. 5. The retention/inversion plots against the reaction temperature.

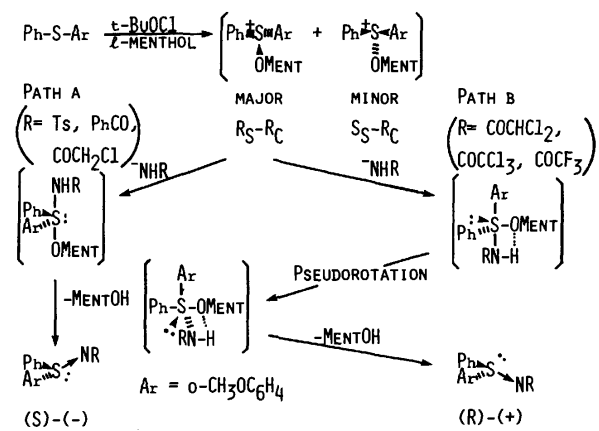

Fig. 6. Reaction mechanisms.

at apical-apical positions respectively, to result in the formation of the sulfilimine of inverted configuration on the sulfur, (path a). However, when the amidate anion, which has an acidic proton such as in dichloro, trichloro-, or trifluoroacetamidate anion, attacks the sulfur atom along an apical direction, there would be a substantial interaction between the amidate and the leaving group, *i.e.*, *l*-menthyloxy group of the sulfonium ion, and even during and after pseudorotation, the interaction would hold both groups at nearly perpendicular around the sulfur atom till the final release of *l*-menthyloxy group from the apical direction.

Thus the retention of configuration on the sulfur is resulted. This study has thus revealed that hydrogen bonding plays an important part in fixing the geometry of the entering nucleophile and the leaving group in the incipiently formed σ-sulfurane and leads the nucleophilic substitution on tricoordinate sulfur to proceed with retention of configuration.

Experimental

General. All melting points were uncorrected. IR spectra were recorded on a JASCO A-3 spectrometer. ^{1}H NMR spectra were recorded on a Hitachi Perkin-Elmer R-20 and R-600 spectrometers. Optical rotations were measured by a JASCO DIP-140 spectrometer. Circular dichroism spectra were recorded on a JASCO J-20 spectrometer.

Elemental analyses were carried out at the Chemical Analysis Center of this University.

Sulfides. The sulfides were prepared by decomposition of the diazonium salt of *o*-substituted anilines in the presence of thiophenol, as described previously.[16] Their boiling points were 146 °C (399 Pa) for *o*-methoxyphenyl sulfide (lit,[11a] 130—135 °C (266 Pa)) and 117—118 °C (399 Pa) for *o*-methylphenyl phenyl sulfide (lit,[11a] 120—125 °C (266 Pa)).

t-Butyl Hypochlorite. *t*-Butyl hypochlorite was prepared by chlorination of *t*-butyl alcohol by aqueous sodium hypochlorite in the presence of acetic acid as described before.[17]

(R)-(+)-S-(o-Methoxyphenyl)-S-phenyl-N-(trifluoroacetyl)-sulfilimine (3f). A mixture of *o*-methoxyphenyl phenyl sulfide (0.66 g, 3.05 mmol), *l*-menthol (0.559 g, 3.58 mmol), and dry pyridine (0.227 g, 3.50 mmol) was dissolved in 20 ml of dry acetonitrile. Into the well-stirred solution kept at −40 °C, at first *t*-butyl hypochlorite (0.388 g, 3.57 mmol) in 4 ml of dry acetonitrile and then sodium trifluoroacetamidate (prepared by treating trifluoroacetamide (0.511 g, 4.52 mmol) with 60% sodium hydride (0.18 g, 4.51 mmol)) was added. After the whole mixture was strirred at the temperature for 2 h, it was warmed up to room temperature.

Then into the reaction mixture was added aqueous dil. $Na_2S_2O_3$ and the aqueous solution was extracted with chloroform.

The residue was chromatographed on silica gel by elution with hexane–ethyl acetate (7:3). Yield was 0.527 g (53%); colorless crystals; mp 109—114 °C; $[\alpha]_D^{20}$=+35.4° ($CHCl_3$, c=1.06). The enantiomeric excess of the sulfilimine was determined by NMR using Eu(hfc) as shift reagent to be 47±5%; IR (KBr) 1630 (C=O); ^{1}H NMR ($CDCl_3$) δ=3.83 (3H,s,*o*-CH_3O-), 6.8—8.2 (9H,m, aromatic protons); Found; C, 54.45; H, 3.65; N, 4.24%. Calcd for $C_{15}H_{12}F_3NO_2S$; C, 55.04; H, 3.70; N, 4.28%.

Other optically active sulfilimines (**3a—h**) were obtained by the same procedure as described above.

(S)-(−)-S-(o-Methoxyphenyl)-S-phenyl-N-tosylsulfilimine (3a). Optically active **3a** was prepared by a similar method as described above except for using sodium *p*-toluenesulfonamidate (prepared by treating *p*-toluenesulfonamide with sodium methoxide and recrystallized from ethanol-methanol) instead of sodium trifluoroacetamidate. Yield was 47%; colorless crystals; mp 156—158 °C; $[\alpha]_D^{20}$=−40° C ($CHCl_3$, c=1.00); 41% o.p.;[11a] IR (KBr), 995(S-N); ^{1}H NMR ($CDCl_3$) δ=2.32 (3H, *p*-CH_3-), 3.70 (3H,s,*o*-CH_3O-), 6.78-8.20 (13H,m, aromatic protons).

(S)-(−)-S-(o-Methoxyphenyl)-S-phenyl-N-benzoylsulfilimine (3b). Yield was 40%; colorless crystals; mp 115.5—118 °C; $[\alpha]_D^{25}$=−17° ($CHCl_3$, c=1.03); 27±5% e.e; IR (KBr), 1590 (C=O); ^{1}H NMR ($CDCl_3$) δ=3.80 (3H,s,*o*-CH_3O-), 6.82—8.47 (14H,m, aromatic protons).

(S)-(−)-S-(o-Methoxyphenyl)-S-phenyl-N-(chloroacetyl)sulfilimine (3c). Yield was 47%; colorless crystals; mp 122—125 °C; $[\alpha]_D^{20}$=−45.5° ($CHCl_3$, c=0.994); 35±5% e.e; IR (KBr), 1590 (C=O); ^{1}H NMR ($CDCl_3$) δ=3.88 (3H,s,*o*-CH_3O-), 4.24 (2H,s,$ClCH_2$-), 6.84—8.13 (9H,m, aromatic protons); Found; C, 58.48; H, 4.49; N, 4.51%. Calcd for $C_{15}H_{14}ClNO_2S$; C, 58.53; H, 4.58; N, 4.55%.

(R)-(+)-S-(o-Methoxyphenyl)-S-phenyl-N-(dichloroacetyl)-sulfilimine (3d). Yield was 34%; colorless crystals; mp 116.5—120 °C; $[\alpha]_D^{20}$=−11.7° ($CHCl_3$, c=3.78 (3H, s,*o*- IR (KBr) 1600 (C=O); ^{1}H NMR ($CDCl_3$) δ=3.78 (3H,s,*o*-CH_3O-), 6.25 (1H,s,Cl_2CH-), 6.83—8.17 (9H,m, aromatic protons); Found; C, 52.60; H, 3.78; N, 4.09%. Calcd for $C_{15}H_{13}Cl_2NO_2S$; C, 52.64; H, 3.82; N, 4.09%.

(R)-(+)-S-(o-Methoxyphenyl)-S-phenyl-N-(trichloroacetyl) sulfilimine (3e). Yield was 72%; colorless crystals; mp 121—122 °C; $[\alpha]_D^{20}$=+26.4° ($CHCl_3$, c=0.85); 47±5% e.e.; IR (KBr) 1625 (C=O); ^{1}H NMR ($CDCl_3$) δ=3.90 (3H,s,*o*-CH_3O-), 6.85—8.23 (9H,m, aromatic protons); Found; C, 47.80; H, 3.14; N. 3.77%. Calcd for $C_{15}H_{12}Cl_3NO_2S$; C, 47.82; H, 3.21; N, 3.71%.

(S)-(−)-S-(o-Methylphenyl)-S-phenyl-N-tosylsulfilimine (3g). Yield was 72% (2.8 ml of *N,N*-dimethylformamide was added to 28 ml of acetonitrile solution as reaction solvent); colorless crystals; mp 102—103 °C; $[\alpha]_D^{25}$=−14.4° ($CHCl_3$, c=2.07); 35%o.p.[11a]; IR (KBr), 955 (S-N); ^{1}H NMR ($CDCl_3$) δ=2.36 (6H,s,*o*-CH_3- and *p*-CH_3-), 7.02—8.04 (13H,m, aromatic protons)

(R)-(+)-S-(o-Methylphenyl)-S-phenyl-N-(trifluoroacetyl) sulfilimine (3h). Yield was 96%; colorless crystals; mp 64—65°C; $[\alpha]_D^{25}$=+21° ($CHCl_3$, c=1.32); 26±5%e.e.; IR (KBr), 1640 (C=O); ^{1}H NMR ($CDCl_3$) δ=2.66 (3H,s,*o*-CH_3O-), 7.25—8.04 (9H,m, aromatic protons); Found; C, 57.91; H, 3.92; N, 4.46%. Calcd for $C_{15}H_{12}F_3NOS$; C, 57.87; H, 3.88; N, 4.49%.

Circular Dichroism Spectra. CD spectra shown in Fig. 3a, 3b, and 3c were all recorded in methanol solution.

Sulfilimines of which CD spectra were measured, have following optical rotations. (**3a**), $[\alpha]_D^{20}$=−25.5° ($CHCl_3$)

c=1.19); (**3b**), $[\alpha]_D^{20}$=−17.3° ($CHCl_3$, c=1.03); (**3c**), $[\alpha]_D^{20}$=−43.6° ($CHCl_3$, c=2.34); (**3d**), $[\alpha]_D^{20}$=+4.8° ($CHCl_3$, c=2.34); (**3e**), $[\alpha]_D^{20}$=+26.4° ($CHCl_3$, c=0.85); (**3f**), $[\alpha]_D^{20}$=+35.4° ($CHCl_3$, c=1.06); (**3g**), $[\alpha]_D^{25}$=−14.4° ($CHCl_3$, c=2.07); (**3h**), $[\alpha]_D^{25}$=+20.9° ($CHCl_3$, c=1.32).

Syntheses of Authentic Samples. *(S)-(−)-S-(o-Methoxyphenyl)-S-phenyl-N-(trifluoroacetyl)sulfilimine (3f) from (S)-(−)-S-(o-Methoxyphenyl)-S-phenylsulfilimine.* To a benzene solution (10 ml) of (*S*)-(−)-S-(*o*-methoxyphenyl)-S-phenylsulfilimine[11a] $[\alpha]_D^{25}$=−187° (96%o.p) (0.253 g 1.09 mmol) and dry pyridine (0.088 g, 1.12 mmol) stirred in an ice bath, trifluoroacetic anhydride (0.258 g, 1.23 mmol) was added slowly. After stirring the mixture for 1 h, the solution was washed with 10% aqueous NaOH, water, dried ($MgSO_4$), and evaporated under vacuum. The remained oily product was chromatographed on silica gel eluted with benzene: ethyl acetate=2 : 1. Yield was 0.263 g (75%); colorless oil; $[\alpha]_D^{25}$=−13.1° ($CHCl_3$, c=1.02). The IR spectrum and the ^1H NMR spectrum are identical to those of the sulfilimine obtained previously.

Other authentic sulfilimines were obtained by similar methods as described above. The acylating reagents and the results are summarized in Table 2.

(1-Methyloxy)(o-methoxyphenyl)phenylsulfonium perchlorate (2). A mixture of *o*-methoxyphenyl phenyl sulfide (0.228 g, 1.05 mmol) and *l*-menthol (0.194 g, 1.24 mmol) was dissolved in 25 ml of dry acetonitrile. Into the well-stirred solution kept at −40°C, at first *t*-butyl hypochlorite (0.125 ml, 1.05 mmol) and then silver perchlorate (0.228 g, 1.10 mmol) were added. After colorless precipitates (silver chloride) appeared, $Na_2S_2O_3$ and water were added and the solution was filterd. The filterate extracted with chloroform, was washed with water, dried ($MgSO_4$). The chloroform solution was poured into a large amount of ether. Oily product was precipitated and the ethereal layer was removed by decantation. After reprecipitation several times, the oily product was evaporated under reduced pressure. Yield was 0.153 g (31%); colorless oil; R_S-R_C: S_S-R_C=75:25. IR (NaCl), 1070 (ClO_4); ^1H NMR ($CDCl_3$) δ=0.46—2.00 (m, menthyl group protons), 3.93 (s,*o*-CH_3O-(R_S-R_C)), 4.01 (s,*o*-CH_3O-(S_S-R_C)), 6.92—8.15 (m, aromatic protons); Found; C, 58.65; H, 6.74%. Calcd for $C_{23}H_{31}ClO_6S$; C, 58.65; H, 6.63%.

Reactions of Sodium Amides with (1-Methyloxy)(o-methoxyphenyl)phenylsulfonium Perchlorate (2). Typical procedure is as following: The sulfonium salt (**2**) (0.239 g, 0.506 mmol) (*R*/*S*=83/17) was dissolved in 10 ml of dry acetonitrile and strirred at −35 °C. Into the well-stirred solution, sodium trichloroacetamidate (prepared from trichloroacetamide (0.168 g, 1.04 mmol) and 60% sodium hydride (0.041 g, 1.03 mmol)) was added at the temperature. After stirring for 20 min, water was added and extracted with chloroform. The extract was dried and evaporated under vacuum. The oily product was chromatographed on silica gel by elution with benzene-ethyl acetate (2:1). Yield was 0.028 g (39%); colorless crystals; $[\alpha]_D^{19}$=+16° ($CHCl_3$, c=1.1); 44%e.e.; 66% optical yield. The IR and the ^1H NMR spectra of sulfilimines obtained by above method are identical to those of the sulfilimines obtained previously.

Temperature Effect. A mixture of *o*-methoxyphenyl phenyl sulfide (0.215 g, 0.993 mmol) and *l*-menthol (0.195 g, 1.25 mmol) was dissolved in dry acetonitrile (15 ml).

Into the well-stirred solution kept at −40 °C, *t*-butyl hypochlorite (0.125 ml, 1.05 mmol) was added. The reaction mixture was allowed to be set at a certain temperature (−40°, +2, or +22 °C) and then sodium trifluoroacetamidate (prepared as described before) was added. Further work up procedure was the same as described before.

A Convenient Route to 2-Lithio-1,3-butadiene from Chloroprene *via* 2-Stannyl-1,3-butadiene

Eiji WADA, Shuji KANEMASA, Isamu FUJIWARA, and Otohiko TSUGE*
Research Institute of Industrial Science, and Department of Molecular Science and Technology, Interdisciplinary Graduate School of Engineering Sciences, Kyushu University, Kasugakoen, Kasuga 816
(Received February 22, 1985)

A convenient route to 2-lithio-1,3-butadiene from chloroprene *via* a 2-stannyl-1,3-butadiene is presented, and the regioselective additions to a variety of carbonyl groups are demonstrated.

Introduction of a 1,3-butadienyl unit to a molecule is important in organic synthesis as the diene moiety can be used usefully to construct a stereochemically defined six-membered ring. One of the most useful reagents along this purpose is 1-methylene-2-propenylmagnesium chloride which is easily accessible in a large quantity from an industrial material, chloroprene.[1] However, a serious disadvantage is a poor regioselectivity in the additions to carbonyl groups. In most reported cases, it reacts at both the α- and γ-positions and major products are usually the γ-adducts,[2] while its cross coupling reactions with alkyl halides[3] and the Michael reactions take place in a highly regioselective manner at the α-position.[4]

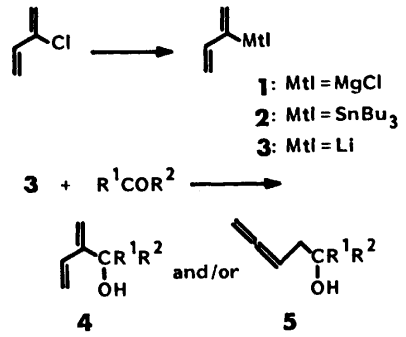
Recently it has been reported that 2-lithio-1,3-butadiene reacts with several aldehydes mainly at the α-position.[5] However, this reagent was prepared only in a fair yield from the Shapiro reaction of trisylhydrazone (2,4,6-triisopropylphenylsulfonylhydrazone) of methyl vinyl ketone, its use in organic synthesis having been quite limited.

The present work aims at opening a more convenient and efficient route to 2-lithio-1,3-butadiene from chloroprene, and also knowing the degree of α-regioselectivity of this reagent in the reactions with some other types of carbonyl compounds.

Results and Discussion

The Grignard reagent **1**, prepared from chloroprene and metal magnesium in the presence of zinc chloride in dry tetrahydrofuran (THF) was transmetalated with chlorotributyltin affording an excellent yield of 2-(tributylstannyl)-1,3-butadiene **2**, which had been previously synthesized from the Grignard reagent of 4-chloro-1,2-butadiene with the stannyl reagent.[6] The tin-lithium exchange reaction was examined in dry THF at −78 °C using butyllithium, and 2-lithio-1,3-butadiene **3** generated was allowed to react with a variety of carbonyl compounds as shown in Scheme 1.

Treatment of **2** with an equivalent of butyllithium in dry THF, at −78 °C for 0.5 h, provided a deep red-colored solution of **3** to which was then



Scheme 1.

added an equivalent of benzaldehyde in THF. The mixture was quenched, after 0.5 h at the same temperature, with an ice-cold ammonium chloride solution. The crude product which was obtained in 80% yield by the filtration through a short column over silica gel was found to be a mixture of two isomeric alcohols, the 2-methylene-3-buten-1-ol **4a** as an α-adduct and the 3,4-pentadien-1-ol **5a** as a γ-adduct, in 9:1 ratio.

Table 1 summarizes the results obtained from the reactions of **3** with other carbonyl compounds under similar conditions. Aliphatic aldehydes, whichever with a straight alkyl chain or a bulky substituent, α,β-unsaturated aldehydes carrying a variety of substituents at the β-position, and acetophenones all smoothly reacted with **3** providing the corresponding alcohols **4b**—**4i** and/or **5b**—**5i** in satisfied yields. The α-selectivity was found excellent in all cases, no γ-adducts being even detected by GLC or ^{1}H-NMR analyses in some cases (the reactions leading to exclusive formation of **4b**, **4c**, **4e**, and **4g**). To be noteworthy is the high α-selectivity toward acetophenones because the Grignard reaction of **1** has shown a very poor afinity at the α-position to this aromatic ketone (**4h**:**5h**=12~19:88~81). Even benzophenone which is known to afford only the γ-adduct **5j** in the Grignard reaction produced a mixture of comparable amounts of **4j** and **5j**, while their separation was unsuccessful.

The present method offers an alternative for the preparation of **3** and seems more convenient and effi-

cient than the Shapiro procedure. It is certain that this method stimulates the wide applications of the industrial material, chloroprene, in organic synthesis. We have recently developed a new [6.6] annelation method by the diene-transmissive Diels-Alder reaction equivalent of 2-methylene-3-buten-1-ols which were prepared by the Grignard reactions of chloroprene.[2b)] These carbinols are now being employed in a research directed toward the [6.5] annelation processes by the sequence of Diels-Alder reaction and Nazarov cyclization or Diels-Alder cycloaddition and electrocyclic reaction.

Experimental

General. IR spectra were recorded on a JASCO IRA-1 or a JASCO A-102 IR spectrometer. ^{1}H-NMR spectra were taken with a Hitachi R-40 (90 MHz) or a JEOL FX-100 instrument (100 MHz) and ^{13}C-NMR spectra on a JEOL FX-100 spectrometer at 25.04 MHz. Chemical shifts are expressed in part per million downfield from tetramethylsilane as an internal standard. Mass spectra were measured with a JEOL JMS-01SG-2 mass spectrometer at 70 or 40 eV of ionization energy. Elemental analyses were obtained with a Hitachi 026 CHN micro analyzer. GPLC analysis was performed on a Yanagimoto gas chromatograph YANACO G-2800 model equipped with a hydrogen flame ionization detector (column: SE 30, 3 mm×2 m). Micro vacuum distillation was carried out with a Shibata GTO-250R Kugelrohr distilling apparatus, and boiling points are all uncorrected. For preparative column chromatography, either of Wakogel C 300 or Silicagel 60 (Merck, 70—230 mesh) was used. Solvents were evaporated with a Tokyo Rikakikai rotary evaporator type V at 0 °C to room temperature unless otherwise stated.

Materials. Tetrahydrofuran as a reaction solvent was distilled over lithium aluminum hydride prior to its use. Chloroprene was purified by distillation under nitrogen stream from the xylene solution also immediately before it was used. Anhydrous zinc chloride was obtained by the crystallization of commercial material from dioxane containing a small amount of zinc powder. Metal magnesium (turning), chlorotributyltin, and butyllitium (15% in hexane) are commercially available and were used without further purification. The carbonyl compounds which are also all commercially available were purified by distillation or crystallization.

2-(Tributylstannyl)-1,3-butadiene **2**. To a solution of **1**, prepared from chloroprene (21 g, 0.187 mol), magnesium (5 g, 0.206 g atom), anhydrous zinc chloride (1.2 g) in dry tetrahydrofuran (80 ml) according to the reported method,[1)] was added dropwise a solution of chlorotributyltin (55.3 g, 0.17 mol) in tetrahydrofuran (80 ml) at −12 to −10 °C. After heated under reflux for 0.5 h, the mixture was treated with aqueous solution of ammonium chloride at 0 °C. The tetrahydrofuran was condensed *in vacuo*, the residue extracted with ether, the ether dried over anhydrous magnesium sulfate, and finally evaporated *in vacuo*. The liquid obtained was distilled under vacuum giving 51.6 g (89%) of pure **2** as a colorless liquid: bp 92—95 °C (93 Pa) (lit,[6)] bp 80—90 °C (53 Pa)).

General Procedure for the Preparation of 2-Lithio-1,3-butadiene **3** *and its Reactions with Carbonyl Compounds.* To a solution of **2** (1.25 g, 3.64 mmol) in dry tetrahydrofuran (9 ml), was added butyllithium (2.25 ml, 3.6 mmol) at −78 °C under nitrogen and then the mixture was stirred for 0.5 h during which time the color of solution gradually turned deep red. When carbonyl compounds (3.6 mmol) in tetrahydrofuran (2 ml) was added by the use of a syringe, the red color immediately faded away. The mixture was stirred for 0.5 h at the same temperature and treated with ice-cold ammonium chloride solution. Organic products were extracted with ether (20 ml×2), the ether dried over magnesium sulfate, and then evaporated *in vacuo*. The residue was chromatographed through a short column packed with silica gel. The first fraction containing tetrabutyltin as an undesired product was eluted with hexane and disregarded. After all the tin compound was removed out, the second fraction was collected using hexane–ether (3:1) for the low-boiling products or hexane–

ethyl acetate (9:1) for the nonvolatile products. At this moment, the isomer ratios between **4** and **5** were determined by GPLC and/or ^{1}H-NMR analyses. The combined yields as well as the isomer ratios for **4** and **5** are given in Table 1.

Although the 2-methylene-3-buten-1-ols **4a** to **4i** could be separated and purified through repeated chromatographic operations over silica gel in a long column (15 mm×400 mm) using hexane–ether (20:1) or hexane–ethyl acetate (9:1) as an eluent, no authentic samples of allenic alcohols **5** were obtained because of the too poor formation and the contamination by the major products **5**. The formation of **5** was, however, confirmed on the basis of the analysis of ^{1}H-NMR spectra for the crude reaction mixtures. The separation of either **4j** or **5j** which was yielded from benzophenone was unsuccessful.

The spectral data and elemental analyses for the products are given below. Some of the products were transformed to their derivatives which were then submitted for elemental analyses.

2-Methylene-1-phenyl-3-buten-1-ol ***4a***: Colorless viscous oil; IR (neat) 3350 cm^{-1} (OH); ^{1}H-NMR ($CDCl_3$) δ=2.82 (1H, br. s, OH), 4.97 (1H, d, $J_{4-3\,(cis)}$=11.2 Hz, one of 4-H), 5.11 (1H, d, $J_{4-3\,(trans)}$=17.8 Hz, the other of 4-H), 5.22 (1H, s, 1-H), 5.30 (2H, s, 2-(CH_2=)), 6.23 (1H, dd, J_{3-4}=17.8 and 11.2 Hz, 3-H), and 7.23 ppm (5H, m, Ph); ^{13}C-NMR ($CDCl_3$) δ=73.78 (d, 1-C), 115.25, 115.49 (each t, 4-C and 2-($\underline{C}H_2$=)), 126.89, 127.62, 128.31 (each d, *o*-, *m*-, and *p*-C of Ph), 135.81 (d, 3-C), 142.00 (s, 1-C of Ph), and 147.56 ppm (s, 2-C); MS *m/z* (rel. intensity, %) 160 (M^+, 33), 142 (16), 129 (10), 115 (11), 107 (83), 105 (28), 91 (18), 79 (base peak), 78 (18), and 77 (64).

Found: *m/z* 160.0880. Calcd for $C_{11}H_{12}O$: M, 160.0888. ^{1}H-NMR ($CDCl_3$) of the isomeric alcohol **5a**: δ=2.36 (m, CH_2) and 4.60 ppm (m, =CH_2). The ratio of **4a**:**5a**=9:1.

3-Methylene-1-decen-4-ol ***4b***: Colorless oil; IR (neat) 3330 cm^{-1} (OH); ^{1}H-NMR ($CDCl_3$) δ=0.87 (3H, t, Me), 1.05—1.80 (10H, m, CH_2), 2.47 (1H, br. s, OH), 4.37 (1H, t, J_{4-5}=5.7 Hz, 4-H), 5.04 (1H, d, $J_{1-2\,(cis)}$=11.0 Hz, one of 1-H), 5.10, 5.18 (each 1H, s, 3-(CH_2=)), 5.29 (1H, d, $J_{1-2\,(trans)}$=17.9 Hz, the other of 1-H), and 6.31 ppm (1H, dd, J_{2-1}=17.9 and 11.0 Hz, 2-H); ^{13}C-NMR ($CDCl_3$) δ=14.13 (q, 10-C), 22.71, 25.88, 29.34, 31.92, 36.50 (each t, 5-, 6-, 7-, 8-, and 9-C), 71.63 (d, 4-C), 113.78 (t, 3-($\underline{C}H_2$=)), 114.08 (t, 1-C), 136.30 (d, 2-C), and 149.40 ppm (s, 3-C); MS *m/z* (rel. intensity, %) 168 (M^+, 5), 151 (9), 97 (29), 84 (98), and 83 (base peak).

Elemental analysis was carried out with an authentic sample of the *p*-nitrobenzoate of **4b** (pale yellow oil).

Found: C, 67.98; H, 7.35; N, 4.57%. Calcd for $C_{18}H_{23}NO_4$: C, 68.12; H, 7.31; N, 4.41%.

2,2-Dimethyl-4-methylene-5-hexen-3-ol ***4c***: Colorless viscous oil; IR (neat) 3450 cm^{-1} (OH); ^{1}H-NMR ($CDCl_3$) δ=0.90 (9H, s, *t*-Bu), 2.10 (1H, br. s, OH), 4.10 (1H, s, 3-H), 4.99 (1H, dd, $J_{6-5\,(cis)}$=11.2 and J_{gem}=1.2 Hz, one of 6-H), 5.10, 5.27 (each 1H, br. s, 4-(CH_2=)), 5.34 (1H, dd, $J_{6-5\,(trans)}$=17.6 and J_{gem}=1.2 Hz, the other of 6-H), and 6.34 ppm (1H, br. dd, J_{5-6}=17.6 and 11.2 Hz, 2-H); ^{13}C-NMR ($CDCl_3$) δ=26.46 (q, Me of *t*-Bu), 35.50 (s, 2-C), 78.86 (d, 3-C), 113.82 (t, 4-($\underline{C}H_2$=)), 115.67 (t, 6-C), 138.28 (d, 5-C), and 148.58 ppm (s, 4-C).

Elementary analysis was performed with an authentic sample of the *p*-nitrobenzoate of **4c** (pale yellow prisms from hexane, mp 46—47 °C).

Found: C, 66.64; H, 6.66; N, 4.90%. Calcd for $C_{16}H_{19}NO_4$: C, 66.42; H, 6.62; N, 4.84%.

4-Methylene-1,5-hexadien-3-ol ***4d***: Colorless viscous oil; bp 75 °C (439 Pa); IR (neat) 3500 cm^{-1} (OH); ^{1}H-NMR ($CDCl_3$) δ=2.48 (1H, br. s, OH), 4.86 (1H, d, J_{3-2}=5.5 Hz, 3-H), 4.96—5.50 (6H, m, 1-H (2H), 6-H (2H), and 4-(CH_2=) (2H)), 5.93 (1H, ddd, J_{2-1}=17.5 and 10.0 and J_{2-3}=5.5 Hz, 2-H), and 6.32 ppm (1H, dd, $J_{5-6\,(trans)}$=17.5 and $J_{5-6\,(cis)}$=11.0 Hz, 5-H); ^{13}C-NMR ($CDCl_3$) δ=72.32 (d, 3-C), 114.91 (t, 4-($\underline{C}H_2$=)), 115.10, 115.64 (each t, 1- and 6-C), 135.86 (d, 5-C), 139.03 (d, 2-C), and 147.21 ppm (s, 4-C).

This compound **4d** polymerized in the oven of mass spectrometer, showing some higher fragment peaks than that for the parent ion.

The elemental analysis was carried out with an authentic sample of the *p*-nitrobenzoate of **4d** (pale yellow viscous oil).

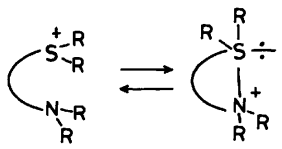
Alkylation and Oxidation of 6,7-Dihydro-6-methyl-5*H*-dibenzo-[*b*,*g*][1,5]thiazocine. Selective Oxidation of the Sulfide Moiety by Transannular Participation of the Amino Group

Katsuo OHKATA, Kohichi TAKEE, and Kin-ya AKIBA*
Department of Chemistry, Faculty of Science, Hiroshima University
Higashisenda-machi, Naka-ku, Hiroshima 730
(Received February 23, 1985)

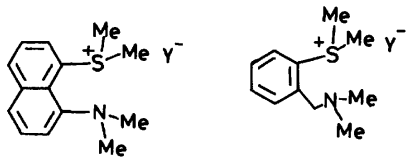
6,7-Dihydro-6-methyl-5*H*-dibenzo[*b*,*g*][1,5]thiazocine (**7**) was prepared by cyclization of the corresponding amino alcohol using thionyl chloride in acetonitrile. Methylation of **7** gave *N*,*N*-dimethyl derivative (**8**) as the sole product. Treatment of **7** with various oxidizing reagents, however, afforded the corresponding sulfoxide (**9**) and/or *N*-oxide (**13**), and sulfone (**14**) depending on the kind of reagent. Oxidation of **7** with sodium periodate furnished *N*-oxide (**13**) in 72% yield as a major product along with sulfoxide (**9**) in 12% yield, while **9** was obtained as a major product (76%) by oxidation with sodium hypochlorite together with a small amount of methoxysulfonium derivative (**15**) in aqueous methanol. The acceleration in oxidation of **7** compared with diphenyl sulfide as well as production of **15** is ascribed to the transannular participation of the amino group with the chlorosulfonio group or intermediacy of a sulfurane. In addition, structural features of **9** and **15** have been investigated by means of ^{1}H NMR and evidence for the transannular interaction between the two heteroatoms is presented.

Previously, one of us reported that the selectivity of alkylation of compounds containing both sulfur and nitrogen atoms is dependent upon the structure of the compounds and also the properties of reagents.[1] During the investigation, we invoked the presence of equilibrium between the sulfonioamine (**1**) and the ammoniosulfurane (**2**) or the formation of the latter (Eq. 1). No positive evidence for Eq. 1, however, could be obtained by ^{1}H NMR and UV spectroscopy even for **3** and **4**, where the two heteroatoms are designed to come closely. This was ascribed to the congestion among methyl groups.[1a]



(1)

1 **2**



3 **4**

On the other hand, Young and Hsieh proposed that a sulfurane intermediate with S–N bonding was required to account for the kinetic behavior in oxidation of methionine.[2] Moreover, Musker *et al.* also invoked such a sulfurane intermediate in the iodine oxidation of 5-methyl-1-thia-5-azacyclooctane on the basis of their kinetic investigation.[3]

In this paper, we wish to describe selective methylation and oxidation of 6,7-dihydro-6-methyl-5*H*-dibenzo[*b*,*g*][1,5]thiazocine (**7**) in which frontal congestion between the two heteroatoms can be got around. The corresponding ammonium salt (**8**) was obtained exclusively in the methylation and the oxidation took place predominantly on the sulfur where transannular participation of the amino group is proposed.

Results and Discussion

6,7-Dihydro-6-methyl-5*H*-dibenzo[*b*,*g*][1,5]thiazocine (**7**) and its ammonium salt (**8**) were prepared by a suitable modification of the procedure developed by Mehta and his coworkers[4] as illustrated in path A and the sulfoxide (**9**) in path B by Tanaka *et al.*[5] (Scheme 1). These contain the sulfide, the sulfoxide, and the amino groups, which are susceptible to electrophilic reactions.

Methylation of the Title Compound (7). Methylation of **7** with various reagents (MeI, MeI/HgI_2, $Me_3O^+BF_4^-$, MeI/$AgBF_4$, and FSO_3Me) gave the ammonium salt (**8**) as the sole product, which was identified on the basis of spectral comparisons with an authentic sample.[4] The spectral data and the reaction conditions are summarized in Table 1. The results are, on the whole, independent of the method of methylation and are contrary to those obtained for other substrates, where selective methylation took place on the amino and the sulfide groups according to the kind of reagent.[1] The observed spectra result from two kinds of conformer (BC and TB) in every case as reported by Mehta and coworkers.[4,6] Furthermore, reaction of the ammonium sulfide (**10**) with Meerwein's reagent ($Me_3O^+BF_4^-$) does not proceed, whereas *o*-(methylthio)benzylammonium salt (**12**) is smoothly converted into the corresponding sulfonium salt (**4**) under the same conditions (Scheme 2).[1a] The results indicate that the reactivity at the

sulfide function in **7** is extremely decreased due to the delocalization of a lone-pair electrons over two benzene rings.

Oxidation of the Title Compound (7). Due to relatively small difference between the oxidation potentials of sulfide and amine, considerable difficulty was expected for selective oxidation of the title compound (**7**), *i.e.*, oxidation potential in cyclic voltammetry is +1.81 V ($Ag/AgNO_3$) for diphenyl sulfide and +1.92 V ($Ag/AgNO_3$) for *N*,*N*-dibenzylmethylamine.[7] The results of oxidation of **7** with some reagents are illustrated in Scheme 3.

The reactive position clearly depends on the kind of oxidizing reagent. Oxidation of **7** with sodium periodate afforded a mixture of sulfoxide (**9**: 12%) and *N*-oxide (**13**: 72%), the latter is very polar with a low R_f value on silica gel and is an extremely hygroscopic compound. In the oxidation of **7** with hydrogen peroxide in refluxing acetic acid, sulfoxide (**9**) was not obtained but sulfone (**14**) was a sole product. Reaction of **7** with aqueous sodium hypochlorite at −78 °C in methanol solution afforded sulfoxide (**9**) in 76% yield. It is noteworthy that the oxidation at room temperature furnished methoxysulfonium derivative (**15a**) in a very small amount besides the major product (**9**: 47%). The structure of **9** was confirmed by an alternative synthesis developed by Tanaka *et al.* as shown in path B of Scheme 1.[5a] Structural assignment to **13** and **14** is based upon the spectral data and their chemical behavior in comparison with **9**.

It is noteworthy that the amino sulfide (**7**) was oxidized to **9** accompanied with a small amount of methoxysulfonium derivative (**15a**) smoothly with aqueous hypochlorite in methanol under the same conditions where diphenyl sulfide was inert. The structure of **15a** was assigned as methoxyammoniosulfurane on the basis of spectral analogy to that of **15b** obtained by methylation of **9**.[8a,c] Both the acceleration in oxidation of **7** and the formation of **15a** are understandable in terms of the intermediacy of ammoniochlorosulfurane such as **16a**. A similar chloride (**16b**) was obtained by treatment of **9** with thionyl chloride in benzene solution as a stable species in quantitative yield, and **16b** was converted to **16c** as relatively nonhygroscopic crystals by exchange of the counter anion using ammonium hexafluorophosphate.[8a] The S-chloro derivaives (**16b,c**) were easily hydrolyzed to give protonated amino sulfoxide which was converted back to **9** by neutralization.

It is therefore reasonable to consider that the S-chloro intermediate (**16a**) may react with water or methanol competitively to produce the final products in the aqueous methanol solution. The acceleration of the oxidation of 1,5-thiazocine with iodine has been ascribed to the presence of an analogous sulfurane, but such an intermediate has not been

isolated so far.[3]

Structural Considerations of 9 and 15. There are some structural problems of **9** concerning the conformation of eight-membered ring and the relative stereochemistry around the sulfur atom. From theoretical and experimental investigations on conformational properties of 1,4-cyclooctadiene systems, it was concluded that the boat-chair (BC) conformer is significantly more stable than the twist-boat (TB) and boat-boat (BB) conformers,[9] but the TB conformer is of considerable importance in the heteroatom containing systems.[10] In the present system, sulfoxide (**9**) does not show any temperature dependence in ^{1}H NMR spectrum from −75 to 110 °C which indicates that only a single conformer is present for **9**, while both conformers exist for amino sulfide (**7**) and also for dimethylammonio sulfide (**8**) as reported by Tanaka *et al.* and Mehta *et al.*, respectively.[4,5] In the ^{1}H NMR spectrum of **9**, benzyl protons appear as a broad singlet at δ 3.88 in $CDCl_3$ solution but as a distinct AB quartet (J=15 Hz) at δ 3.18, 3.42 in benzene-d_6 solution. The proton-decoupled carbon spectrum features only eight lines, which reveals the presence of a single conformer for **9**. This spectral feature of **9** in solution is consistent with TB or BB conformer according to the criticism for such a conformer which was investigated in detail by Ollis *et al.*[10a] and Renaud *et al.*[10b] However the relative stereochemistry at the sulfur atom could not be completely determined by such a spectral consideration.

The unambiguous structure of **9** and **15b** in the solid state was determined by X-ray analysis on a single crystal (Fig. 1).[8a,c] The sulfur has distorted trigonal bipyramidal configuration and O, S, and N atoms are colinear with the angle of 179.5 and 175.0 ° for **9** and **15b**, respectively. The N···S distances are 2.593 and 2.207 Å for **9** and **15b** respectively and are very much shorter than the sum of van der Waals radii (3.35 Å) and longer than that of covalent radii (1.74 Å). It is concluded that there is a weak but definite attractive interaction between the electron-deficient sulfur and the donating amino group, which is strong enough to keep **9** and **15** in the unfavorable distorted BB conformation with TBP

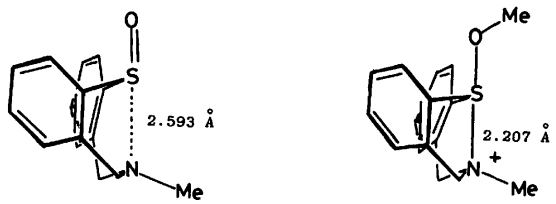

Fig. 1. Structure of **9** and **15**.

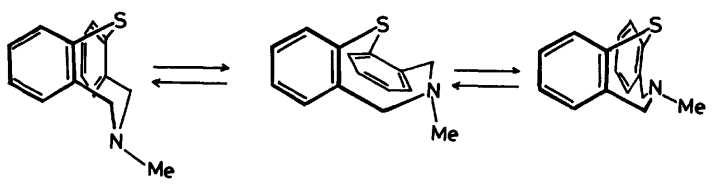

configuration at the sulfur. This is maintained also in solution as was exemplified by ^{1}H NMR study.[8,11,12]

In conclusion, the present investigation offers strong evidence for the formation of ammoniosulfuranes as intermediates in the oxidation of the sulfur of **7**, methionine, and 5-methyl-1-thia-5-azacyclooctane.[2,3]

Experimental

All the melting points are uncorrected. IR spectra were obtained with a Hitachi 215 grating IR spectrophotometer. ^{1}H NMR measurements were carried out on a Varian T-60 instrument and a Hitachi R-90H FT instrument, using tetramethylsilane as the internal reference. Mass spectra were measured with Hitachi RMU-6L spectrometer.

2-(Methoxycarbonyl)phenyl 2-(Methylcarbamoyl)phenyl Sulfide (5). Treatment of 2-(methoxycarbonyl)phenyl 2-carboxyphenyl sulfide (1.98 g, 6.88 mmol), which was prepared according to the literature,[4] with excess thionyl chloride (10 ml) gave a yellowish oil under refluxing for *ca.* 2 h. To a solution of the oil in 30 ml of ether was added an aqueous methylamine solution (in excess). The reaction mixture was poured into water after stirring for 2 h and extracted with dichloromethane. The organic layers were dried ($MgSO_4$) and concentrated to yield 1.41 g (68%) of the amide ester (**5**), mp 125—126 °C (hexane–dichloromethane); ν_{max} (KBr) 3260, 1705, and 1630 cm^{-1} ; ^{1}H NMR ($CDCl_3$) δ=2.78 (d, J=5 Hz, 3H), 3.92 (s, 3H), 6.70—7.62 (m, 7H), and 7.63—8.08 (m, 2H).

Found: C, 63.70; H, 4.94; N, 4.78%. Calcd for $C_{16}H_{15}NO_3S$: C, 63.77; H, 5.02; N, 4.65%.

2-(Hydroxymethyl)phenyl 2-(Methylaminomethyl)phenyl Sulfide (6). To a solution of 2.23 g (7.41 mmol) of **5** in benzene (20 ml) was added phosphorus pentachloride (1.55 g, 7.43 mmol) and the mixture was heated at reflux for 1 h. After removal of benzene, the residue was dissolved in THF (30 ml) and added to a suspension of lithium aluminium hydride (1.6 g, 41 mmol) in the same solvent (20 ml). The mixture was stirred at 0 °C for 30 min and at room temperature for 35 h before the excess hydride was carefully decomposed with water. The solution was filtered and the filtrate was concentrated to yield 1.61 g (84%) of amino alcohol (**6**) as a colorless oil; ^{1}H NMR (CCl_4) δ=2.17 (s, 3H), 3.64 (s, 2H), 3.72 (s, 2H), 4.52 (s, 2H), and 6.65—7.80 (m, 8H). The product was crystallized as a hydrochloride; mp 221—223 °C (lit,[4] mp 216—219 °C); ν_{max} (KBr) 3360, 2920, 2760, and 1035 cm^{-1}; ^{1}H NMR (CD_3OD) δ=2.85 (s, 3H), 4.33 (s, 2H), 4.70 (s, 2H), 4.76 (s, 2H), and 6.90—7.74 (m, 8H).

*6,7-Dihydro-6-methyl-5*H*-dibenzo*[b,g]*[1,5]thiazocine (7).* To a solution of amino alcohol (**6**) (1.0 g, 3.86 mmol) in 100 ml of benzene was added 10 ml of thionyl chloride and the mixture was heated at reflux for 2.5 h. After concentration of the reaction mixture, the residue was dissolved in 50 ml of ethanol and treated with potassium hydroxide (2.2 g) in 50 ml of the same solvent for 1 h at reflux temperature. Workup in the ordinary manner gave 0.77 g (83%) of a yellow oil. A pure sample of **7** was isolated by preparative TLC (silica gel; benzene–ethyl acetate (1:1)). Recrystallization from petroleum ether afforded a colorless solid of **7**, mp 65—66 °C (lit,[5] mp 68—69 °C); ν_{max} (KBr) 2875 cm^{-1}; ^{1}H NMR ($CDCl_3$, at 35 °C) δ=2.11 (s, 3H), 3.31—5.07 (br s, 4H), 6.90—7.30 (m, 6H), and 7.41—7.72 (m, 2H); ^{1}H NMR (CD_3OD, at −49.5 °C) δ=1.92 (s, Me for BC form), 2.23 (s, Me for TB form), 3.84 and 5.02 (ABq, J=14 Hz, CH_2 for BC form), 3.67 (br s, CH_2 for TB form), 7.08—7.49 (m, 6H), and 7.60—7.84 (m, 2H). BC/TB=2/1 at 49.1 °C.

*6,7-Dihydro-6,6-dimethyl-5*H*-dibenzo*[b,g]*[1,5]thiazocinium Salt (8).* To a solution of amino sulfide (**7**) (50 mg, 0.21 mmol) in acetonitrile (1 ml) was added 40 mg (0.28 mmol) of methyl iodide dissolved in the same solvent (1.5 ml). The mixture was stirred at room temperature for 24 h. After evaporation of the solvent, a yellow solid (40 mg, 63%) of **8a** was obtained. By using different solvents and methylating reagents under the same procedure, the other salts (**8b—e**) were obtained. The ^{1}H NMR spectral data and reaction conditions are collected in Table 1.

Oxidation of Amino Sulfide (7) with Sodium Periodate.

*6,7-Dihydro-6-methyl-5*H*-dibenzo*[b,g]*[1,5]thiazocine 6-Oxide (13).* A solution of **7** (224 mg, 0.93 mmol) in methanol (25 ml) was treated with sodium periodate (248 mg, 1.16 mmol) in water (5 ml) for 10 d. After ordinary workup, 219 mg of yellow residue was obtained. Thin layer chromatography of the residue on silica gel (ethyl acetate) gave 13.5 mg (12%) of **9** and 82.5 mg (72%) of **13** as a colorless solid. Recrystallization of **13** from dichloromethane–hexane afforded a pure sample, mp 175—177 °C (hygroscopic); ν_{max} (KBr) 905 cm^{-1}; ^{1}H NMR ($CDCl_3$) BC/TB=1/2.8, for BC form: δ=2.80 (s, 3H), 3.79 and 5.74 (ABq, J=14 Hz, 4H), and 7.00—8.00 (m, 8H); for TB form: 3.20 (s, 3H), 4.46 and 4.93 (ABq, J=16 Hz, 4H), and 7.00—8.00 (m, 8H); Mass (m/z) 257 (M^+), 241 (M^+−16), and 211 (M^+−46).

Found: C, 66.82; H, 6.15; N, 5.11%. Calcd for $C_{15}H_{15}NSO+0.7H_2O$: C, 66.77; H, 6.08; N, 5.19%.

Oxidation of Amino Sulfide (7) with Hydrogen Peroxide.

*6,7-Dihydro-6-methyl-5*H*-dibenzo*[b,g]*[1,5]thiazocine 12,12-Dioxide (14).* A mixture of **7** (209 mg, 0.87 mmol) and 30% hydrogen peroxide (2.5 ml) in acetic acid (5 ml) was heated at reflux for 1.5 h. After ordinary workup and recrystallization from hexane–dichloromethane, 159.6 mg (68%) of **14** was obtained as a colorless solid; mp 170—174 °C: ν_{max} (KBr) 1305 and 1125 cm^{-1}; ^{1}H NMR ($CDCl_3$) δ=1.97 (s, 3H), 3.95 and 5.62 (ABq, J=15 Hz, 4H), 7.06—7.71 (m, 6H), and 7.87—8.28 (m, 2H).

Found: C, 65.68; H, 5.52; N, 4.97%. Calcd for $C_{15}H_{15}NSO_2$: C, 65.91; H, 5.53; N, 5.12%.

*Oxidation of Amino Sulfide (7) with Sodium Hypochlorite. 6,7-Dihydro-6-methyl-5*H*-dibenzo*[b,g]*[1,5]thiazocine 12-Oxide (9).* To a solution of **7** (352 mg, 1.46 mmol) in 7 ml of methanol was added 10% aqueous sodium hypochlorite (2.72 g, 3.65 mmol) at −78 °C. The mixture was stirred for 1 h at the same temperature before the mixture was poured onto ice and extracted with dichloromethane. The organic layers were washed with water, dried, and evaporated to yield yellow solids. Recrystallization of the solids from benzene–hexane gave **9** (284 mg, 76%) as colorless crystals, mp 113—115 °C; ν_{max} (KBr) 1065 and 1015 cm^{-1}; ^{1}H NMR ($CDCl_3$) δ=2.56 (s,

3H), 3.88 (s, 4H), 6.98—7.67 (m, 6H), and 8.08—8.35 (m, 2H); ^{1}H NMR (C_6D_6) δ=2.02 (s, 3H), 3.18 and 3.42 (ABq, J= 15 Hz, 4H), 6.58—7.32 (m, 6H), and 8.50—8.67 (m, 2H); ^{13}C NMR (CD_3CN) δ=41.9 (q), 58.6 (t), 125.3 (d), 127.3 (d), 129.4 (d), 130.4 (d), 140.2 (s), and 145.8 (s); Mass (*m/z*) 257 (M^+), 241 (M^+ −16), 226 (M^+ −31), and 197 (M^+−60).

Found: C, 69.82; H, 5.91; N, 5.50%. Calcd for $C_{15}H_{15}NOS$: C, 70.01; H, 5.88; N, 5.44%.

Oxidation of **7** with sodium hypochlorite at room temperature for 15.5 h afforded sulfoxide (**9**) (47%) as a major product together with a small amount of methoxysulfonium salt (**15a**). The latter was isolated in 4% yield by evaporation of the filtrate followed by trituration of the residue twice with benzene. The structure was assigned by spectral comparison with an analogous sample (**15b**) obtained by methylation of **9** as described below.

*6,7-Dihydro-6-methyl-12-methoxy-5*H*-dibenzo*[b,g]*[1,5]-thiazocinium Hexachlorantimonate (15b).* A mixture of sulfoxide (**9**) (512 mg, 1.99 mmol) and trimethyloxonium hexachloroantimonate (787 mg, 1.99 mmol) in dichloromethane (10 ml) was stirred at room temperature for 15 h under argon atmosphere. The mixture was filtered and the filtrate was concentrated to furnish 588 mg (49%) of **15b**. A pure sample of the salt (**15b**) was obtained by recrystallization from acetonitrile–ether: mp 148—151 °C: ν_{max} (KBr) 1445 and 993 cm^{-1}, ^{1}H NMR (CD_3CN) δ=2.77 (s, 3H), 3.92 (s, 3H), 4.25 (s, 4H), 7.35—7.80 (m, 6H), and 7.92—8.15 (m, 2H).

Found: C, 31.82; H, 2.98; N, 2.30%. Calcd for $C_{16}H_{18}NSOSbCl_6$: C, 31.67; H, 2.99; N, 2.31%.

*12-Chloro-6,7-dihydro-6-methyl-5*H*-dibenzo*[b,g]*[1,5]thiazocinium Chloride (16b).* To a solution of **9** (639 mg, 2.49 mmol) in dry benzene (14 ml) was added dropwise a solution of thionyl chloride (1 ml) in the same solvent (2 ml) under nitrogen atmosphere. The mixture was stirred at room temperature for 2.5 h and filtered. The yellowish solids were washed with dry benzene and ether successively before drying under an inert gas. There was obtained a colorless hygroscopic chloride (**16b**, 739 mg, 95%). ^{1}H NMR ($CDCl_3$) δ=3.13 (s, 3H), 4.70 (s, 4H), 7.22—8.02 (m, 6H), and 8.23—8.63 (m, 2H).

*12-Chloro-6,7-dihydro-6-methyl-5*H*-dibenzo*[b,g]*[1,5]thiazocinium Hexafluorophosphate (16c).* To a stirred suspension of **16b** in anhydrous dichloromethane (10 ml) prepared from **9** (517 mg, 2.01 mmol) was added ammonium hexafluorophosphate (1.31 g, 8.04 mmol). The mixture was stirred at room temperature for 17 h prior to filtration. The filtrate was diluted with dry ether to afford 288 mg (34%) of **16c** as a colorless solid: mp 145—155 °C (dec); ν_{max} 1470 and 820 cm^{-1}; ^{1}H NMR (CD_3CN) δ=3.13 (s, 3H), 4.59 and 4.72 (ABq, J=15.6 Hz, 4H), 7.30—8.05 (m, 6H), and 8.27—8.65 (m, 2H).

Found: C, 42.82; H, 3.62; N, 3.59; Cl, 8.65%. Calcd for $C_{15}H_{15}NSClPF_6$: C, 42.72; H, 3.58; N, 3.32; Cl, 8.41%.

Hydrolysis of **16b** or **16c**, followed by neutralization with sodium hydrogencarbonate, reverted back to amino sulfoxide (**7**) in quntitative yield.

N,N-Dimethyl-2-(methylthio)benzylamine (11). To a stirred suspension of lithium aluminium hydride (2.93 g, 75 mmol) in anhydrous tetrahydrofuran (100 ml) was added dropwise a solution of *N,N*-dimethyl-2-(methylthio)-benzamide[13] (4.88 g, 25 mmol) in the same solvent (50 ml). The mixture was stirred at 0 °C for 1 h and at room temperature for 6 d before the excess hydride was carefully decomposed with water. Workup in the predescribed manner gave 3.72 g (**11**, 82%) of a colorless oil:[1a] ν_{max} (neat) 1465 cm^{-1}; ^{1}H NMR ($CDCl_3$) δ=2.22 (s, 6H), 2.40 (s, 3H), 3.45 (s, 2H), and 6.87—7.40 (m, 4H); Mass (*m/z*) 181 (M^+) and 166 (M^+−15).

Dimethyl[2-(dimethylaminomethyl)phenyl]sulfonium Hexafluorophosphate (4). Treatment of **11** (1.03 g, 5.70 mmol) with 42% aqueous tetrafluoroboric acid (1.9 ml, 9.3 mmol) in acetonitrile (25 ml) gave 1.03 g (71%) of *N,N*-dimethyl-2-(methylthio)benzylammonium salt (**12**) as colorless crystals, mp 122—125 °C: ν_{max} (KBr) 1443 and 1068 cm^{-1}; ^{1}H NMR (CD_3CN) δ=2.54 (s, 3H), 2.84 (s, 6H), 4.38 (s, 2H), and 7.23—7.67 (m, 4H).

Treatment of **12** (1.03 g, 4.05 mmol) with methyl iodide (1.73 g, 12 mmol) and silver tetrafluoroborate (2.34 g, 12 mmol) in acetonitrile (10 ml) afforded 2.77 g of the sulfonium salt as yellow crystals: ^{1}H NMR (CD_3CN) δ=2.98 (d, J=5 Hz, 6H), 3.25 (s, 6H), 4.70 (d, J=5 Hz, 2H), 7.77—8.12 (m, 3H), and 8.12—8.50 (m, 1H).

The salt was neutralized with aqueous sodium hydrogen carbonate to give a colorless precipitate. The mixture was treated with an aqueous solution (10 ml) of potassium hexafluorophospate (10 g) and ammonium chloride (2 g) at room temperature for 1 h. After the usual workup, 742 mg (57%) of **4** was obtained as a colorless oil: ^{1}H NMR ($CDCl_3$) δ=2.23 (s, 6H), 3.10 (s, 6H), 3.63 (s, 2H), 7.27—7.82 (m, 3H), and 7.84—8.20 (m, 1H).

Found: C, 38.95; H, 5.52; N, 4.31%. Calcd for $C_{11}H_{18}NSPF_6$: C, 38.71; H, 5.32; N, 4.10%.

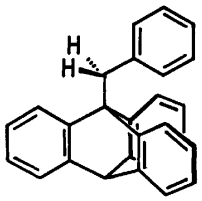
Restricted Rotation Involving the Tetrahedral Carbon. LVII. Stereodynamics of 9-(2-Alkylphenoxy)-1,4-dimethyltriptycenes[1)]

Gaku YAMAMOTO* and Michinori ŌKI
Department of Chemistry, Faculty of Science, The University of Tokyo, Bunkyo-ku, Tokyo 113
(Received February 26, 1985)

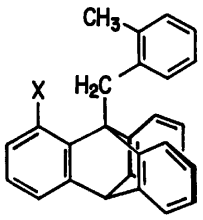
1,4-Dimethyl-9-phenoxytriptycene and its derivatives carrying a methyl, isopropyl, or *t*-butyl group in the *o*-position of the phenoxyl moiety were synthesized and their dynamic NMR behavior was studied. These molecules are considered to constitute a bevel gear system with a two-toothed and a three-toothed wheels and the dynamic NMR behavior is best explained in terms of gear rotation. The *o*-isopropyl derivative, for example, shows the energy barriers of 17.2 and 10.8 kcal† mol^{-1} for the $ap \rightleftarrows \pm sc$ and $+sc \rightleftarrows -sc$ gearing processes, respectively. The population of the $\pm sc$ rotamer increases with the bulkiness of the *o*-alkyl group: The steric congestion among the *o*-alkyl group, the oxygen atom, and the *peri*-methyl group is severer in *ap* than in $\pm sc$. Results of molecular mechanics calculations on these molecules are discussed.

In the course of our studies on restricted rotation about the bridgehead-to-substituent bond in 9-substituted triptycene derivatives,[2)] we have been interested in the stereodynamics of 9-benzyltriptycene (**1**) and its various derivatives.[3–7)]

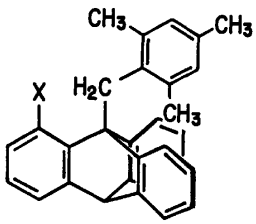


1

Compound **1** adopts a conformation in which the plane of the phenyl group is coplanar with the bridgehead-to-methylene bond and thus constitutes a meshed bevel gear with a two-toothed and a three-toothed wheels. Dynamic NMR studies of singly *peri*-substituted 9-(2-methylbenzyl)triptycenes (**2**)[6)] and 9-(2,4,6-trimethylbenzyl)triptycenes (**3**)[7)] revealed that these molecules behave as dynamic gears: Gear rotation is the lowest energy process and gear slippage has a higher barrier. Mislow *et al.*[8)] made detailed molecular mechanics studies on the stereodynamics of **1**, 9-(2,6-dimethylbenzyl)triptycene, and its 1-methyl derivative, which are complementary to our results.



2



3

† 1 cal=4.184 J.

It was reasonably expected that observation of gear rotation could be extended to systems where the methylene group in 9-(arylmethyl)triptycenes is replaced by a heteroatom group such as O, NH, and so on, and that it would be of interest to see how the stereodynamics of these compounds differs from that of the carbon analogs. We report here NMR studies on the stereodynamics of 1,4-dimethyl-9-phenoxytriptycene (**4**) and its derivatives (**5**—**7**) carrying an alkyl group in the *o*-position of the phenoxyl moiety.[9)] We discuss also the results of molecular mechanics calculations on these molecules.

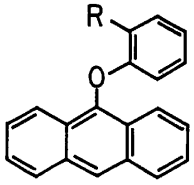
Results and Discussion

Syntheses. The triptycenes **4**—**7** were synthesized by reactions of 9-aryloxyanthracenes (**8**—**11**) with 3,6-dimethylbenzyne. The anthracenes were obtained by Ullmann reactions from 9-bromoanthracene and appropriate phenols[10)] (Method A). Compounds **9** and **10** were prepared also by



8: R=H
9: R=CH_3
10: R=$CH(CH_3)_2$
11: R=$C(CH_3)_3$

condensation of anthrone with the corresponding phenols in the presence of acid catalyst by the analogy of the recent report on the syntheses of 9-alkoxyanthracenes from anthrone and alcohols[11] (Method B). An attempt at the synthesis of **11** by the second method was not successful probably because of partial dealkylation under the reaction conditions.

NMR Spectral Studies. On the analogy of the behavior observed in 9-(2-methylbenzyl)triptycenes (**2**),[6] the stereodynamic behavior of **5—7** is expected to be explained in terms of the gear rotational circuit shown in Fig. 1.

Molecules of **5—7** exist as one of the three stable conformers, *ap*, $+sc$, and $-sc$, in which the *o*-alkyl group points toward outside of the triptycene skeleton. Conformers with the *o*-alkyl group pointing inwards, *ap'*, $+sc'$, and $-sc'$, are very unstable and populated too little to be detected, but serve as intermediates in the interconversion among the stable conformers by gear rotation (GR). The $+sc$ rotamer changes to *ap'* by a GR step in which the aryl group passes over a *peri*-hydrogen. We refer to this step as GR(H). As *ap'* is unstable, the molecule immediately changes to $-sc$ by further GR(H). Thus $+sc$ and $-sc$ interconvert by two successive GR(H) steps. In order for the $+sc$ rotamer to convert to *ap*, it should first change to $-sc'$ by passing of the aryl group over the *peri*-methyl group, which we refer to as GR(CH_3), and then to *ap* by GR(H). GR(CH_3) should naturally have a higher energy barrier than GR(H) and therefore the $ap \rightleftharpoons \pm sc$ process should show a higher overall barrier than the $+sc \rightleftharpoons -sc$ process.

From the discussion above, the following behavior is expected in the dynamic NMR spectra. At low temperatures where both processes are frozen on the NMR time scale, the *ap* and $\pm sc$ rotamers are separately observed, and the chiral nature of the $\pm sc$ rotamer is proved by the diastereotopicity of a prochiral group such as $-CX_2Y$, if the molecule carries such a group. At an intermediate temperature range, the situation is realized where the $+sc \rightleftharpoons ap' \rightleftharpoons -sc$ occurs fast on the NMR time scale but the $+sc \rightleftharpoons -sc' \rightleftharpoons ap$ (and $-sc \rightleftharpoons +sc' \rightleftharpoons ap$) process is still slow.[12] In such circumstances, two rotamers are separately observed but the $\pm sc$ rotamer appears achiral in the NMR spectra. At higher temperatures where both processes occur fast on the NMR time scale, identity of the rotamers is lost and a coalesced signal is observed.

The 2'-isopropyl derivative (**6**) serves as a typical example. In the ^1H NMR spectrum at ambient temperature, two sets of signals are observed in an intensity ratio of *ca.* 1:2 corresponding to the presence of two types of rotamers, *ap* and $\pm sc$ (Table 1). Among the four singlets due to the aromatic methyl groups appearing at δ 2.0—3.0, the highest-field one is reasonably assigned to the 1-methyl group of the $\pm sc$ rotamer because this methyl group is susceptible to the diamagnetic ring current of the benzene ring in the aryloxyl moiety. Then the other signals can be uniquely assigned as shown in Table 1 on the basis of the relative intensities and the coalescence behavior observed upon raising the temperature: The major isomer is assigned to $\pm sc$. Validity of the rotamer assignment in **6** is further confirmed by the low temperature NMR behavior of **6** described below. The isopropyl-methyl signals consist of two doublets, one from *ap* and the other from $\pm sc$, indicating that the *gem*-dimethyl groups

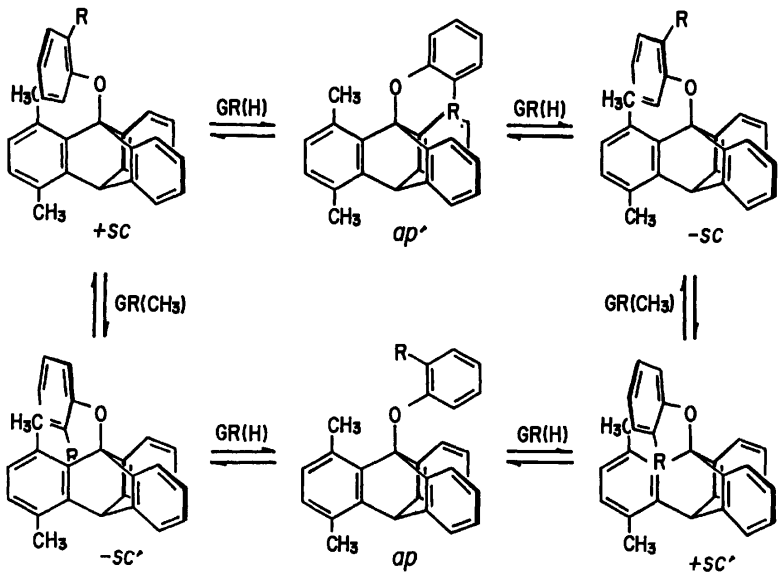


Fig. 1. Gear rotational circuit for 9-(2-alkylphenoxy)-1,4-dimethyltriptycenes.

are isochronous not only in *ap* but also in ±*sc*.

These spectral features are just those expected at intermediate temperatures mentioned above. Upon raising the temperature, the two sets of signals coalesce into an averaged set of signals, reflecting the increase of the interconversion rate between the *ap* and ±*sc* rotamers. Lineshape analysis of the 1- and 4-methyl proton signals obtained at 60 MHz in a chlorobenzene solution at five temperatures between 51 and 80 °C gave the rate constants for the process. The kinetic parameters obtained therefrom are shown in Table 2.

Meanwhile, upon lowering the temperature, the doublet signal assigned to the isopropyl-methyl group of the ±*sc* rotamer splits into two equally intense doublets, the other nonaromatic signals remaining intact. This feature suggests the slow-down of the $+sc \rightleftarrows -sc$ process. The spectral change was studied at 400 MHz because no explicit splitting was observed at 60 MHz. At −81 °C in dichloromethane-d_2, the isopropyl-methyl signals appeared as three doublets at δ=1.52, 1.48, and 1.46 with an intensity ratio of 29:29:42 indicating the presence of ±*sc* and *ap* in a ratio of 58:42.[13] Lineshape analysis of these signals in the temperature range of −60 to −25 °C afforded the rate con-

stants for the $+sc \rightleftarrows -sc$ interconversion and the Eyring parameters therefrom (Table 2).

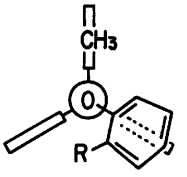
The 2′-methyl compound (**5**) shows a similar spectral feature as **6** does. Each of the 1- and 4-methyl groups gives rise to two singlets with an intensity ratio of 56:44 at ambient temperature. From the chemical shift criteria mentioned above, the major isomer is assigned to *ap* (Table 1). These signals coalesce on raising the temperature and lineshape analysis of the spectra at six temperatures between 39 and 73 °C affords the kinetic parameters for the $ap \rightleftarrows \pm sc$ process in **5** as shown in Table 2.

As compound **5** has no NMR sensor groups which would definitely detect the $+sc \rightleftarrows -sc$ process, no clear information is easily obtained for the process in **5**. The spectra of the aromatic protons give some information on this point, which is described later.

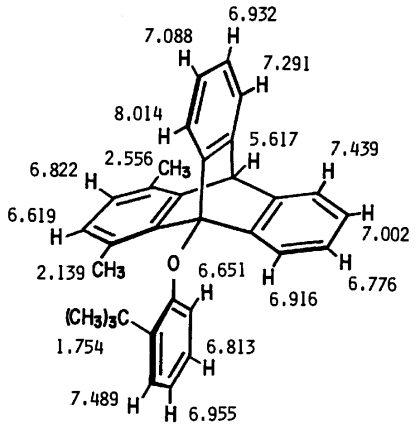
In the ^{1}H NMR spectrum of the 2′-*t*-butyl derivative (**7**) at ambient temperature, a single peak is observed for each of the 1-methyl, 4-methyl, and 2′-*t*-butyl groups. The chemical shifts of the signals due to the 1- and 4-methyl groups are very similar to those of the corresponding signals in the $\pm sc$ rotamers of **5** and **6**.[14] This strongly suggests that **7** exists almost exclusively as the $\pm sc$ rotamer. The 400 MHz spectrum of the aromatic proton region is rather simple and is easily analyzed: The spectrum consists of three sets of ABCD four-spin systems and one AB-quartet, indicating that the two unsubstituted *o*-benzeno bridges are not equivalent. This clearly confirms that **7** exists solely as $\pm sc$ rotamer and further that the $+sc \rightleftarrows -sc$ process is frozen at ambient temperature. The spectrum was completely analyzed by use of the double resonance technique and the signals were assigned as shown in Scheme 1 by assuming that the lowest-field signal should derive from 13-H and the highest-field one from 6′-H. No significant change in the lineshape was observed up to 60 °C and thus the energy barrier to the $+sc \rightleftarrows -sc$ gearing, *i.e.* GR(H), in **7** is concluded to be considerably higher than 16 kcal mol^{-1}. The value is still conservative. In the 60 MHz spectra, the doublet at δ 8.01 assigned to 13-H appears clearly separated from the other aromatic signals, and shows no significant change of its appearance up to 120 °C, indicating that the energy barrier to GR(H) is higher than 19.5 kcal mol^{-1}.

The aromatic proton spectra of **5** and **6** are far more complex than that of **7**, because **5** and **6** consist of two types of rotamers, *ap* and $\pm sc$. In these compounds, change in the lineshape in the aromatic region owing to the $+sc \rightleftarrows -sc$ process was observed over a wide range of temperature, from −60 °C up to room temperature. Signals ascribed to 8-H and 13-H of the $\pm sc$ rotamer of **6** appearing at δ 7.90 and *ca.* 6.9 at −81 °C broadened on raising the temperature and coalesced at about −10 °C. The free energy of activation is roughly estimated to be 11.8±0.5 kcal mol^{-1} using the approximate equation.[15] The value is consistent with the kinetic data obtained from the lineshape analysis of the isopropyl-methyl signals. The 2′-methyl compound (**5**) shows a similar signal broadening at somewhat lower temperatures than **6** does. The *peri*-protons coalesce at about −30 °C, which gives a rough ΔG^* value of 10.5±0.5 kcal mol^{-1} for the $+sc \rightleftarrows -sc$ process.

The transition state for the GR(H) step in the $+sc \rightleftarrows -sc$ process would be represented by **12**. The severest steric interaction occurs between the face of the aryl group and the opposing *peri*-hydrogen. The



12a : R = CH_3
12b : R = $CH(CH_3)_2$
12c : R = $C(CH_3)_3$

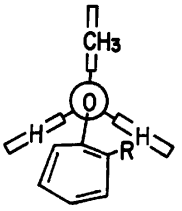


Scheme 1.

energies of **12a** and **12b** will be similar because the *o*-substituent R can adopt a conformation in which an α-hydrogen directs towards the triptycene skeleton, but the energy of **12c** will be considerably higher than those of **12a** and **12b**, because R has no α-hydrogen in **12c**. Therefore it may be reasonable that the energy barriers to the $+sc \rightleftarrows -sc$ process are similar for **5** and **6** but that for **7** is higher than those for **5** and **6**. Similarity of the GR(CH_3) barriers between **5** and **6** may be similarly understood.

It should be pointed out that the interconversion between *ap* and $\pm sc$ in **5** and **6** can occur by several other pathways. One group of such pathways involves an "isolated rotation" (IR) of the aryl group, which corresponds to slippage of the gear[4]: *ap*

changes to *ap'* by IR and then to $+sc$ (or $-sc$) by GR(H), or *ap* changes first to $+sc'$ (or $-sc'$) by GR(H) and then to $+sc$ (or $-sc$) by IR. In both pathways, IR is rate-determining. Inspection of molecular models, however, immediately suggests that the energy barrier to IR would be far higher than that to GR(CH_3) because the steric hindrance during the process is far larger. The transition state



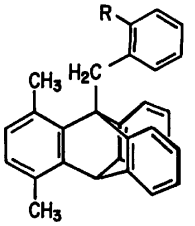
13

for IR seems something like **13** (the one for $ap \rightleftarrows ap'$ is illustrated), in which the severest interactions occur between the *o*-groups (R or H) and the *peri*-hydrogens. The congestion around the *o*-substituent is far severer than that in the transition state for GR(H) or GR(CH_3), and thus the energy barrier to IR should be significantly dependent on the bulkiness of the *o*-substituent R. The similar barrier heights observed in **5** and **6** therefore strengthen the impression from the molecular model considerations that the pathways involving IR are not the lowest energy process for the $ap \rightleftarrows \pm sc$ interconversion.[16]

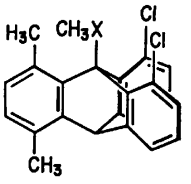
The possibility that any process involving the configurational inversion of the oxygen atom might be responsible for the dynamic NMR behavior is rejected by the facts that the $+sc \rightleftarrows -sc$ and $ap \rightleftarrows \pm sc$ processes are separately observed and that the energy barrier to the former process is far lower than that to the latter.[17]

Temperature dependence of the ^1H NMR spectra of the 9-phenoxy compound (**4**) was studied as well at 400 MHz. In this molecule, the interconversion between *ap* and $\pm sc$ is attained by a single GR(H) step. At ambient temperature, one singlet is observed for each of the methyl groups, suggesting that the interconversion among rotamers is fast on the NMR time scale. The singlet at δ 2.44 is unambiguously assigned to the 4-methyl group by nuclear Overhauser effect (NOE) experiments: Upon irradiation of this signal, the bridgehead proton signal at δ 5.63 enhances its intensity by *ca.* 20%, while it remains intact on irradiation of the signal at δ 2.78. Even at -101 °C either of the methyl signals remains a singlet though somewhat broadened because of the slow-down of the process. Broadening of the 1-methyl signal is considerably larger than the 4-methyl signal and the peak height of the former is about a half of that of the latter at -101 °C. The larger broadening of the 1-methyl signal is reasonable because it should split into two peaks with a larger chemical shift difference than the 4-methyl signal on the analogy of the behavior found in **5** and **6**. Energy barrier to this process is estimated to be less than 8 kcal mol^{-1}.

Close inspection of the aromatic proton region of the spectra of **4** reveals an interesting phenomenon. Signals ascribed to two *o*-protons of the phenoxyl moiety appear as two multiplets at δ 6.32 snd 7.52 at -101 °C. The anisochrony of the *o*-protons remains even at room temperature, although the signals show considerable broadening. This means that any



14 : R = H
15 : R = CH_3



16 : X = O
17 : X = CH_2

process which exchanges the magnetic environments of the two protons has a considerably high energy barrier of more than 15 kcal mol^{-1}. The to-and-fro gearing process ($+sc \rightleftarrows ap' \rightleftarrows -sc$) by two GR(H) does not average out the chemical shifts of the two protons. Either of two processes, GR(CH_3) and IR, can explain the observed dynamic NMR behavior. Differentiation between the two as the lower energy process is not possible at the present stage. Detailed studies along this line are in progress.

In Table 2 are included the data for 1,4-dimethyl-9-(2-methylbenzyl)triptycene (**15**).[6] The rather small difference in the energy barriers between **5** and **15**, in both of those for GR(CH_3) and GR(H), is intriguing when one considers the large difference in the barriers to rotation about the triptycyl-X bond found in compounds **16** and **17**, where X is O and CH_2, respectively. The energy barriers to the $ap \rightleftarrows \pm sc$ process, in which the methyl group in the 9-substituent eclipses one of the *peri*-chlorines in the transition state, were 11.8 and 20.2 kcal mol^{-1} for **16** and **17**, respectively.[1,18]

As discussed in detail in the previous paper,[1] two main factors should be considered which govern the difference in rotational barriers between C–C and C–O bonds: (1) Three pairs of eclipsing interactions in the transition state for C–C rotation *vs.* one pair for C–O rotation, and (2) the difference in

TABLE 3. ROTAMER EQUILIBRIA OF 5 AND 6

a) [±*sc*]/[*ap*].

bond length between C–C and C–O. The former factor operates to lower the C–O barrier. In the 9-CH_3X system (**16** and **17**), the former factor contributes more strongly than the latter, resulting in the large barrier difference. In the aryl-X compounds (**5** and **15**), the latter factor would act to raise the C–O barrier, because the shorter C–X bonds increase the steric interaction between the face of the aryl group and the opposing *peri*-group (H or CH_3) in the transition state, while the effect would be less important in the ground state. Thus the second factor partly compensates the former factor to result in the small difference in the barriers.

Rotamer Equilibria. As shown in Table 1, the rotamer distribution is highly dependent on the *o*-alkyl group. Population of the *ap* rotamer steeply decreases as the *o*-alkyl group becomes bulkier. The van't Hoff parameters for **5** and **6** are given in Table 3.

Inspection of molecular models of 9-phenoxytriptycene indicates that the inner *o*-hydrogen in the phenoxyl moiety locates very closely to and thus strongly interacts with the triptycene skeleton. When a methyl group is present at a *peri*-position of the triptycene skeleton, it sterically interacts with the oxygen atom at the bridgehead. In the *ap* rotamer, the aryl group is pushed down into the notch made by the two *o*-benzeno bridges due to the buttressing effect of the *peri*-methyl group, which results in the destabilization of this isomer, but such an effect does not work in the ±*sc* rotamer. Presence of an alkyl group in the *o*-position increases the congestion and enhances the destabilization. Therefore, as the bulkiness of the *o*-alkyl group increases, the *ap* rotamer would be steeply destabilized, resulting in the increase in the population of the ±*sc* rotamer.

These situations seem to be reflected in ^{1}H NMR spectra (Table 1). In the spectra of **5** and **6**, a doublet signal ascribed to 6′-H appears at the highest-field part of the aromatic proton region (*ca.* δ 6.2). No such signal is observed in the spectrum of **7**, in accordance with the absence of *ap* in **7**. The corresponding proton in the ±*sc* rotamer appears at a lower field of *ca.* δ 6.6 in **5**—**7**. The buttressing effect should push the proton into the shielding region of the flanking benzene rings in the *ap* rotamer.

Although the rotamers of **4** are not separately observed at room temperature or even at the lowest temperature examined (−101 °C), the populations can be roughly estimated from the averaged chemical shift of the 1-methyl signal. If it is assumed that the chemical shift of the 1-methyl protons for each rotamer is the same as that in **5**, *i.e.* δ 2.04 for ±*sc* and δ 2.90 for *ap*, the averaged value of δ 2.78 observed at 24 °C predicts the population of *ap*-**4** to be about 85% at this temperature. Predominance of the *ap* rotamer in **4** may be consistent with the extrapolation of the tendency observed in **5**—**7**, though the value seems somewhat larger than expected judging from the fact that, in the carbon analogs **14** and **15**, the population of *ap* decreases only slightly on going from **14** to **15** (54% in **14** at −50 °C in $CDCl_3$–CS_2 (2:3)[3a] and 50% in **15** at −33 °C in $CDCl_3$[6]).

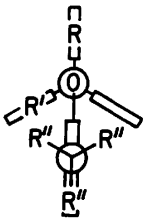
Molecular Mechanics Calculations. In order to understand the dependence of rotamer equilibria upon the *o*-alkyl group in more detail, we performed molecular mechanics calculations on **4**—**7** using the MM2 force field.[19] Relative steric energies of conformers are compiled in Table 4.

In any of the stable rotamers of **4**—**7**, the plane of the aryl moiety is coplanar with the C_9–O bond: The dihedral angles C(9)–O–C(1′)–C(6′) are less than ±3°, except for +*sc*-**7** where it is −6.6°. Two *o*-benzeno

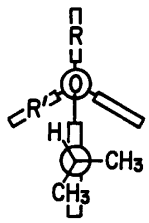
bridges flanking the aryl group bend away from each other, the dihedral angle C(1′)-O-C(9)-C being *ca.* 65°. The C(9)-O-C(1′) angles are around 121°, widening by about 10° from the standard C(sp^3)-O-C(sp^2) angle of 110.8°.

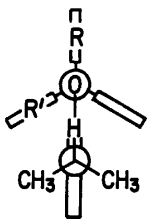
As for the conformation of the *o*-alkyl group, the conformation **18** in which a hydrogen or a methyl

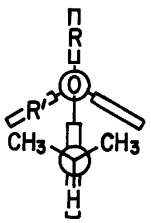


R or R′ = CH_3
R″ = H or CH_3

18







19 **20** **21**

a : R = CH_3, R′ = H
b : R = H, R′ = CH_3

group eclipses 3′-C was calculated to be the most stable in either rotamer of **5** and **7**. In *ap*-**6**, the lowest-energy conformation is **19a** in which one of the methyl group is perpendicular to the plane of the benzene ring. Conformation **20a** is slightly less stable than **19a**. **21a** in which the methine hydrogen eclipses 3′-C is far less stable, because the *gem*-dimethyl groups are very close to the *peri*-methyl group. In +*sc*-**6**, on the other hand, **19b**, **20b**, and **21b** have almost the same energy.[20]

Steric energies of the unstable rotamers with the *o*-alkyl group pointing inwards, *ap′* and ±*sc′*, were calculated for **5**. *ap′*-**5** was shown to be less stable by 9.08 kcal mol^{-1} than *ap*-**5**, and ±*sc′*-**5** less stable by 8.18 kcal mol^{-1} than ±*sc*-**5**.

As is evident from Table 4, the steric energy of the ±*sc* rotamer relative to the corresponding *ap* one decreases on going from **5** to **6**, and in the *t*-butyl derivative **7**, ±*sc* is more stable than *ap*. The tendency that the ±*sc* rotamer becomes more and more populous as the *o*-substituent becomes bulkier is reproduced by calculation, but the quantitative agreement between the experiment and the calculation is very poor.

These discrepancies might be partly ascribed to solvent effects and/or some other factors which affect the relative energies of rotamers but are not reproduced by molecular mechanics calculations. One of such possibilities is the C-H···π attractive interaction, which might operate between the *peri*-methyl and the aryl groups in the ±*sc* rotamer.[21] However, most of the discrepancies should be attributed to the intrinsic properties of the force field used. Overestimation of the steric energies of the ±*sc* rotamers, especially by overestimating the repulsive interaction between the *peri*-methyl group and the flanking aryl group in ±*sc*, seems to be the most probable origin. Similar situations were encountered by Mislow *et al.* in their molecular mechanics studies on the stereodynamics of 9-(arylmethyl)triptycenes.[8] They found that the repulsive interaction between a benzene ring and a hydrogen which protrudes into the π-cloud of the benzene ring is overestimated in the calculations of the transition states for GR in 9-(arylmethyl)triptycenes and also for the ring flipping in [2.2]metaparacyclophane. Such overestimation seems to operate in the calculations of conformational equilibria as well.[8]

It has become evident that the MM2 force field does not satisfactorily reproduce the conformational equilibria in our present compounds. Improvement of the force field and/or the calculation methodology is necessary to obtain satisfactory results on the ground states and to further extend the calculations to the energy surfaces of the dynamic processes, and is under investigation.[22]

Experimental

Materials. Yields, melting points, and the analytical data are compiled in Table 5. Melting points are not corrected.

General Procedure for the Synthesis of 9-Aryloxyanthracenes. Method A. A mixture of 2.57 g (10 mmol) of 9-bromoanthracene and 30 mmol of an appropriate phenol was heated at 220—230 °C for 4 h together with 1.0 g of potassium hydroxide and 0.3 g of copper powder. The reaction mixture was extracted with dichloromethane and the extract was washed with aqueous sodium hydroxide to remove the unreacted phenol and then with water, dried over magnesium sulfate and concentrated. The residue was chromatographed on silica gel with benzene-hexane as the eluent. Recrystallization of the eluate from tetrahydrofuran-hexane gave pure compounds. ^1H NMR data of the anthracenes are given in Table 6.

Method B. A mixture of 3.88 g (20 mmol) of anthrone and 100 mmol of a phenol in 100 mL of toluene containing 1.0 mL of concentrated sulfuric acid was heated under reflux for 150—180 h using a Dean-Stark water collector. The reaction mixture was washed with aqueous sodium hydroxide and then with water, dried over magnesium sulfate, and concentrated. Chromatography on silica gel followed by recrystallization gave the anthracenes as above.

General Procedure for the Synthesis of 9-Aryloxy-1,4-dimethyltriptycenes. A solution of 830 mg (5 mmol) of 3,6-dimethylanthranilic acid[23] in 20 mL of 1,2-dimethoxyethane (DME) and a solution of 1.0 mL (*ca.* 7.5 mmol) of isopentyl nitrite in 10 mL of DME were added dropwise during the course of 1 h to a boiling solution of 2.0 mmol of 9-aryloxyanthracene in 20 mL of DME so that an excess of isopentyl nitrite was always present in the reaction mixture. The reaction mixture was heated under reflux for further 30 min and concentrated. Chromatography of the residue on silica gel with hexane as the eluent followed by recrystallization from tetrahydrofuran-hexane gave the desired triptycene as colorless crystals.

Spectral Measurements. ^{1}H NMR spectra at ambient temperature and below were obtained on a JEOL GX-400 spectrometer operating at 399.65 MHz in the pulse FT mode. Temperatures were read as digital outputs from the variable temperature accessory and are not corrected. Dynamic NMR spectra above room temperature were obtained on a Hitachi R-20B spectrometer at 60.0 MHz in the CW mode, and temperatures were calibrated using ethylene glycol.[24] Measurements of some of the spectra at ambient temperature as well as the nuclear Overhauser effect experiments were made on a Varian EM-390 spectrometer at 90.0 MHz in the CW mode.

Computer Simulations. Theoretical spectra were obtained on a HITAC M-280H computer system at the Computer Center of The University of Tokyo (CCUT) using a modified version of the DNMR3 program by Binsch.[25] Temperature dependence of the isopropyl-methyl signals of **6** was analyzed as a 3-spin 3-site system (ABX $\rightleftarrows$ BAX $\rightleftarrows$ C_2Y) instead of a 7-spin 3-site system ($A_3B_3X \rightleftarrows B_3A_3X \rightleftarrows C_6Y$), regarding a methyl group as a single nucleus. In this case, the rate constant for the $\pm sc \rightarrow ap$ process, *i.e.* ABX$\rightarrow C_2Y$ and BAX$\rightarrow C_2Y$, was assumed to be 0.001 s^{-1} throughout the temperature range of −60 to −25 °C (see Ref 13). The spectra of the 1- and 4-methyl groups in **5** and **6** were simulated as a 2-spin 2-site system (AB $\rightleftarrows$ CD), regarding again a methyl group as a single nucleus.

Molecular Mechanics Calculations. Calculations were performed on the HITAC M-280H computer system using the MM2 program in the CCUT Program Library. Original parameters in the program were used as they were except for the bond length and the stretching force constant for C(sp^2)-C(sp^2), which were modified so that they represented aromatic carbons (l_o=1.3937 Å, k_s=8.067 mdyn[††] $Å^{-1}$). Only one set of torsional parameters were newly added: $V_1=V_2=V_4=0$, V_3=0.403 kcal mol^{-1} for C(sp^2)-C(sp^3)-O-C(sp^2).

The authors are grateful to Professors N. L. Allinger and E. Ōsawa for their helpful discussion, and to Dr. G. Izumi of Nippon Kayaku Co., Ltd. and Mr. S. Murata of Institute for Molecular Science for the measurements of the 400 MHz ^{1}H NMR spectra.

12) In this temperature range, the *ap* rotamer may be in dynamic equilibrium with $\pm sc'$ although the situation is not detected by NMR because the population of $\pm sc'$ is extremely low. Similarly, the GR(H) barrier in $ap \rightleftarrows \pm sc'$ is not obtained experimentally.

13) The ratio does not necessarily represent the equilibrium populations at −81 °C: The data in Table 3 indicate that the value corresponds to the equilibrium populations at about −30 °C. The $ap \rightleftarrows \pm sc$ process is very slow in this temperature range and the equilibrium might not have been attained during the NMR measurements. The nonequilibrium state, however, does not affect the analysis of the $+sc \rightleftarrows -sc$ process.

14) Nuclear Overhauser effect experiments confirmed that the low-field signal at δ 2.56 derives from 4-CH_3: irradiation of this signal enhances the intensity of the 10-H signal at δ 5.62 by *ca.* 20% while irradiation at δ 2.14 does not change the 10-H signal intensity.

22) For example, the use of smaller values for the van der Waals radius (r^*) of an sp^2-carbon was found to improve the situation. When the radius of 1.50 Å was used instead of the original value of 1.94 Å, the energy difference between *ap*-**5** and $\pm sc$-**5** was 1.45 kcal mol^{-1} favoring *ap*-**5**. It is however uncertain whether the single change of $r^*(sp^2\text{-C})$ gives the totally consistent results not only for the energy differences of rotamers but also for the molecular geometries.

Hydrogenation of Pyrene and Catalytic Interconversion of Hydropyrenes

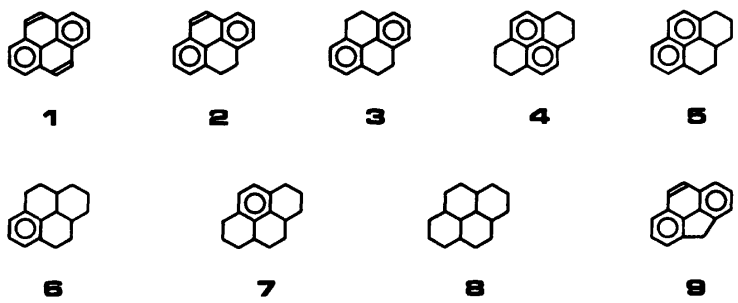
Masahiro MINABE* and Katsuko NAKADA
Department of Industrial Chemistry, Faculty of Engineering, Utsunomiya University, Ishiicho, Utsunomiya 321
(Received December 10, 1984)

Reexamination on the hydrogenation of pyrene (**1**) with Raney nickel catalyst under atmospheric pressure afforded a mixture of 4,5-di- (**2**), 4,5,9,10-tetra- (**3**), 1,2,3,6,7,8-hexa- (**4**), and 1,2,3,3a,4,5-hexahydropyrene (**5**). The relative amount of each product at the initial reaction stage was determined by time–yield relation of the products. The formation sequence of the products is discussed with reference to the hydrogenations of **2**—**5**: **4** may be formed independent of **2**, and **2** is converted to **3**. Hydropyrene **5** may be produced from **1** mainly through the same σ-adsorbed species which also leads to **2**. The hydrogenation of **1** with palladium and platinum catalysts gave similar results as with nickel. With nickel and palladium catalysts the hydrogenation of **1** was faster than that of 4*H*-cyclopenta[*def*]phenanthrene (**9**). However, with platinum the hydrogenation of **1** was slower than that of **9**. Catalytic interconversion of **2**—**5** was examined at 240 °C under an argon pressure of 90 kg cm^{-2}. Hydroarene **2** was easily dehydrogenated, and **3** and **5** were interconverted to a fair extent. Therefore, **2**, **3**, and **5** may be good hydrogen donor solvents for coal liquefaction.

The catalytic hydrogenation of polycyclic aromatic hydrocarbons (PAHs) has been investigated extensively from both stereochemical and mechanistic standpoints.[1,2] The products are of interest both as synthetic intermediates,[1] and because of their carcinogenic properties.[1,3,4] In addition, partially hydrogenated PAHs have recently been used as hydrogen donor solvents in coal liquefaction.[5] For our continuing study of PAHs having active methylene such as fluorene,[6] we have compared the reactivity of hydrogenation of PAHs possessing active methylene with that of PAHs possessing no active methylene such as pyrene (**1**). The hydrogenation of **1** is of interest in particular from the following three viewpoints. One of those is the hydrogenation sequence. It has been known that the hydrogenation of **1** gives 4,5-di- (**2**),[7] 4,5,9,10-tetra- (**3**),[8] 1,2,3,6,7,8-hexa- (**4**),[9] 1,2,3,3a,4,5-hexa- (**5**),[9] isomeric deca- (**6**, **7**),[10] and perhydropyrenes (**8**)[11] under various reaction conditions (Scheme 1).[12] Although the previous papers have studied the function of temperature and pressure in addition to catalysts, the hydrogenation sequence was not so clear.[10] This is because the change of the yield of each product has not yet been examined as a function of reaction time. The study of the hydrogenation of **1** with respect to the reaction time may shed light on the reaction pathway and be useful to uncover the reaction conditions to obtain specific hydroarenes.

A second consideration is the relative reactivity of **1** among PAHs. For example, the rate of hydrogenation of **1** to **2** with palladium-on-carbon catalyst has been reported to be comparable to the rate of the hydrogenation at the 8,9-double bond of 4*H*-cyclopenta[*def*]phenanthrene (**9**).[13] We have recognized in the study of the hydrogenation of **9**[14] that the reduction of **1** is slower than that of **9** when platinum oxide is used as catalyst. The abnormality of palladium as a catalyst in the platinum group metals has been pointed out in the hydrogenation of aromatic compounds[15,16] and cycloolefins.[17] The abnormality may be caused by the fact that palladium in particular adsorbs reactants very weakly[18] and the rate- and product-controlling steps of hydrogenation with palladium may differ from that of hydrogenation with platinum.[19]

The third interest concerns the ability of **2**—**5** as hydrogen donor solvents in coal liquefaction. Mochida *et al.* have reported the effectiveness of hydrogenated pyrene mixture as the solvent.[20] The direct coal liquefaction occurs mainly by radical hydrogen transfer, and hence, the ability of hydrogen transfer of the solvent may play an important role in the coal liquefaction process. The hydrogen donat-



Scheme 1.

ing property of partially hydrogenated aromatics has been determined by disproportionation of the substrate or by the reaction of substrate with hydrogen acceptor as the cases of cyclohexene,[21] naphthalene,[22] phenanthrene,[23] and anthracene[12] derivatives. With regard to the partially hydrogenated pyrenes, no reports describing such reactions are limited to a few examples.[24]

The present paper deals with the hydrogenation of **1** under mild conditions to indicate the reaction pathway of **1**. Also, it examines the competitive hydrogenation of **1** and **9**. Finally, it considers the catalytic interconversion of hydropyrenes, **2**—**5** to clarify the ability of these compounds as hydrogen donors.

Results and Discussion

Hydrogenation of **1** in the presence of Raney nickel (W-7) was carried out in ethanol at room temperature under atmospheric pressure of hydrogen to afford **2**, **3**, **4**, and **5** as illustrated in Fig. 1. In addition, more highly hydrogenated arenes, **6**—**8**, were detected in small amounts, but they were not further studied. Also, the hydrogenations of **2**—**5** were examined under similar conditions. The relative amount of each product at the initial reaction stage was determined by a known procedure[15,25] (Table 1). The rate constant of the conversion of each substrate was roughly estimated from time-conversion relation, based on the assumption that the reaction followed zero-order kinetics in reactant till its complete conversion.

The results suggest that **2** and **4** are mainly formed from **1**, and the main portion of **2** is converted gradually into **3**. Hydroarene **4** is formed independent of the formation of **2**. The interconversion of hydropyrenes except **3** may be negligible under these conditions as is explained later. Therefore, the adsorption of the planar molecule **1** onto the catalyst surface (A) could take place in two different manners; namely at the C_4–C_5 bond (B) and at the biphenyl ring system (C)[26] (Scheme 2). Either the half-hydrogenated state (D) at the C_4 atom may undergo desorption to give **2**, or may be converted to the adsorption state (E)[19] at the biphenyl ring moiety to afford **5** by subsequent hydrogenation. In a similar manner, **2** can give **3** *via* (F) and **3** may be hydrogenated slowly to **4** and **5** through hydrogen transfer. Absorbate (C) may yield **4** and **5** *via* (G) and (H), respectively. The process to **5** through (H) may be a minor route in the hydrogenation of **1** because **5** is thermodynamically less stable than **4** as is explained later.[26]

The hydrogenation of **1** was also carried out in

Table 1. Relative amount of **2**—**7** formed in the hydrogenation of pyrene and hydropyrenes with Raney nickel at initial stage

Reactant	Relative amount/mol%				Rate constant

the presence of palladium-on-carbon or platinum catalyst at 50 °C under a hydrogen pressure of 5 kg cm^{-2} (1 kg cm^{-2}=98066.5 N m^{-2}) to afford **2**—**8**. Table 2 shows the product distribution at about 50% conversion of **1**. The distribution with Mo-Co catalyst was estimated by comparison of the NMR data described elsewhere[27] with the NMR spectra of an authentic mixture of pure **1**—**5**. Since the overall trend of the yield is similar to the case of Raney nickel, the reaction sequence in the presence of palladium or platinum catalyst may be explained as in the case of the nickel catalyst. The palladium catalyst in particular gives **2** in relatively high yield (Table 1). On the contrary, significant amounts of **6**—**8** are formed with the platinum catalyst in analogy with the example of **9**.[14]

The relative reactivity of **1** and **9** was examined by a competitive method. The hydrogen pressure was maintained as constant as possible during the reaction in order to remove the factor of hydrogen pressure.[16,28,29] The reactions followed zero-order kinetics in reactants till about half-conversion of reactants. Table 2 shows that **1** is more reactive than **9** over the nickel and palladium catalysts, in contrast to hydrogenation using platinum.

The ratio of conversion of **1** and **9** may be regarded as the overall results of two factors. One is the adsorption equilibrium of each reactant and the other is the rate factor of each adsorbed species. If the adsorbed species of one reactant disturbs the adsorption of the other reactant, the rate of the latter reactant estimated by the competitive method may be less than that determined independently. Therefore, the ratio of conversion in Table 2 may differ from that obtained independent hydrogenations of **1** and **9**. Nevertheless, the difference of the ratio due to the catalyst is thought in some degree to indicate the difference of reactivities of each component. The real reason could be complex, but **9** is presumed to be more reactive than **1**, because **9** is strained owing to the five-membered ring. In fact, **9** is known to give an 8,9-dihydro derivative by treatment with sodium in ethanol[13] and to give 8,9-dibromide by the action of bromine.[30]

TABLE 3. CATALYTIC INTERCONVERSION OF HYDROPYRENES[a]

Reactant	Product distribution/%				
	1	**2**	**3**	**4**	**5**
1	99	1			
2	70	25	2	2	1
3	48	18	4	20	8
3[b]	97	3	*	*	*
3[c]	*	1	99	*	*
4	20	9	1	58	9
5	19	7	1	21	48

a) Reaction was carried out with platinum at 240 °C under an argon pressure of 90 kg cm^{-2} for 10 h. The asterisk shows that trace amount (<0.4%) was detected by GLPC. b) 240 °C, 9 kg cm^{-2}, 3 h. c) 50 °C, 90 kg cm^{-2}, 50 h.

Catalytic interconversion of hydropyrenes, **2**—**5**, was examined at 240°C under an argon pressure of 90 kg cm^{-2} with platinum catalyst (Table 3). Dehydrogenation takes place due to increase of the resonance stability by aromatization. Easily dehydrogenated reactants such as **2** or **3** may be good hydrogen donors. The thermodynamical stability

of **4** compared with that of **5** would be supported by the fact that **4** was easily formed from **5**, as contrasted with the yield of **5** from **4**. Consequently, the interconversions of **3** and **5** occur easily. This is the reason why **2**, **3**, and **5** may be good hydrogen donors for coal liquefaction solvent.

Experimental

All melting points are uncorrected. The ^{1}H NMR (in CCl_4), IR (KBr-disk), UV (in cyclohexane), and mass spectra were recorded using the same apparatus as described elsewhere.[14]

The distribution of products was examined by GLPC with a GC-8A gas chromatograph (Shimadzu) equipped with a column (3 mmϕ, 1 m) containing Dexsil 300GC (5%) on Chromosorb WAW (80—100 mesh) at 195 °C under 1 kg cm^{-2} of nitrogen. Each peak area of **1** (retention time; 9.5 min), **2** (7.2 min), **3** (4.6 min), **4** (6.3 min), **5** (5.8 min), **6** (3.4 min), and **7** (3.8 min) was compared using TR-2217 integrator (Takeda Riken). The competitive hydrogenation of **1** and **9** was also examined by the same gas chromatograph containing Silicone OV-17 (5%) as liquid phase at 165 °C. Each peak area of **1** (8.8 min) and **9** (3.8 min) was compared with that of tetracosane (13.5 min) as an internal reference.

The catalysts used in this experiment were the same as those described elsewhere.[14]

Hydrogenation of 1 over Palladium-on-Carbon. 400-mg of Pd-C (10%) suspended in AcOEt (5 ml) was pretreated at 50±1 °C under hydrogen pressure of 5 kg cm^{-2} for 1 h. A solution of **1** (202 mg, 1 mmol) in AcOEt (25 ml) was added to the suspension. After 4 purges with hydrogen, the mixture was stirred at 50 °C and 5 kg cm^{-2}. A small amount (*ca.* 0.2 ml) of the mixture was taken out, filtered, and submitted to GLPC after 30 min, 1 h, and additionally every 1 h.

After 7 h, the test portion showed the proportion to be **1** (46%), **2** (33%), **3** (4%), **4** (11%), **5** (5%), and others (1%). All the mixtures were filtered and evaporated to dryness, and the residues chromatographed on an alumina column (200 g, 16 mmϕ, 120 cm) with hexane. The rate of effusion was 1.2 min ml^{-1}, and the eluate was collected as 10-ml units. Fraction from 840 to 1140 ml gave 21.4 mg (10%) of **4**: mp 131—132 °C (from hexane) (lit,[9] mp 132—134 °C); NMR, δ=1.99 (4H, q, J=6.5 Hz), 3.02 (8H, t), and 6.95 (4H, s); UV, λ_{max} 235 (log ε 4.81), 286 (3.87), 309 (4.15), 315 (3.71), 323 (3.32), and 330 nm (3.49). Fraction between 1240 and 1490 ml afforded 5.8 mg (3%) of **3**: mp 135—137 °C (hexane) (lit,[8] mp 135—136 °C); NMR,[26] δ=2.85 (8H, s) and 6.96 (6H, s); UV, λ_{max} 215 (log ε 4.59), 270 (4.18), and 280 nm (4.27). Fraction at 1490—2050 ml gave 11.0 mg (5%) of **5**: mp 104—106 °C (hexane) (lit,[9] mp 105 °C); NMR, δ=1.25—3.26 (11H, m) and 6.89—7.46 (5H, m); UV, λ_{max} 227 (log ε 4.78), 233 (4.93), 285 (3.80), 294 (3.70), 311 (3.17), and 325 nm (3.21). Fraction between 2130 and 3640 ml afforded 52.6 mg (26%) of **2**: mp 131—132 °C (hexane) (lit,[7] mp 132 °C); NMR,[26] δ=3.24 (4H, s) and 7.23—7.67 (8H, m); UV,[7] λ_{max} 217 (log ε 4.63), 260 (4.67), 282 (4.17), 287 (4.13), 299 (4.00), 319 (3.03), and 335 nm (3.19). Fraction at 3830—4440 ml gave 90.0 mg (45%) of **1**, mp 149 °C.

In addition, fraction ranging from 540 to 840 ml afforded an oil (9.9 mg) which was determined as a mixture of **4**, **6**, **7**, and **8** by means of GC-MS.

Hydrogenation of 1 over Platinum. A 50.2-mg portion of platinum oxide in AcOEt (5 ml) was treated with hydrogen for 1 h at 5 kg cm^{-2}. A solution of **1** (101 mg, 0.5 mmol) in AcOEt (20 ml) was added to the vessel and the mixture was stirred at 50 °C under hydrogen pressure of 5 kg cm^{-2}.

Hydrogenation of 1 over Raney Nickel. A mixture of **1** (202 mg, 1 mmol) in HOEt (40 ml) was shaken with Raney nickel catalyst (W-7, 0.4 g as alloy) at room temperature under hydrogen at atmospheric pressure. The composition of the mixture was determined by GLPC as is shown in Fig. 1.

Hydrogenation of 2. Compound **2** (40.8 mg, 0.2 mmol) in HOEt (15 ml) was shaken with Raney nickel (W-7, 0.2 g) in a similar manner to **1**. The distribution of the test portion was **2** (trace), **3** (76%), **4** (9%), and **5** (6%) after 3 h and was **3** (74%), **4** (11%), and **5** (6%) after 10 h.

Hydrogenation of 3. A solution of **3** (41.2 mg, 0.2 mmol) in HOEt (15 ml) was allowed to react in the presence of Raney nickel (W-7, 0.75 g). The test portion showed the proportion to be a mixture of **3** (86%), **4** (8%), **5** (4%), **6** (1%), and **7** (1%) after 3 h and to be **3** (42%), **4** (33%), **5** (trace), **6** (7%), and **7** (11%) after 23 h.

Hydrogenation of 4. A mixture of **4** (41.6 mg, 0.2 mmol) in HOEt (15 ml) was treated with Raney nickel (W-7, 1 g) in a similar manner to **1**. The distribution of the mixture was as follows: **4** (89%), **6** (1%), and **7** (7%) after 3 h and **4** (62%), **6** (2%), and **7** (32%) after 27 h.

Hydrogenation of 5. Compound **5** (41.6 mg, 0.2 mmol) in HOEt (15 ml) was shaken with Raney nickel (W-7, 1 g) as above. The proportion of the mixture was **5** (72%), **6** (12%), and **7** (15%) after 3 h and **5** (5%), **6** (40%), and **7** (49%) after 19 h.

Competitive Hydrogenation of 1 and 9. Over Raney Nickel. A mixture of **1** (51.1 mg, 0.26 mmol), **9** (45.1 mg, 0.24 mmol), and tetracosane (31.0 mg) in HOEt (30 ml) was shaken with Raney nickel (W-7, 0.6 g) at room temperature under hydrogen at atmospheric pressure. Every 15 min, a small portion was taken out and submitted to GLPC.

Over Palladium-on-Carbon. A mixture of **1** (50.5 mg, 0.25 mmol), **9** (50.3 mg, 0.27 mmol), tetracosane (35.5 mg), and Pd-C catalyst (10%, 600 mg, pretreated with hydrogen at 50 °C under 5 kg cm^{-2} for 1 h) in EtOAc (30 ml) was stirred at 50 °C and 5 kg cm^{-2} of hydrogen.

Over Platinum Catalyst. Platinum oxide (50.1 mg) in AcOEt (5 ml) was pretreated with hydrogen at 50 °C for 1 h under 5 kg cm^{-2}. A mixture of **1** (50.8 mg, 0.25 mmol), **9** (47.5 mg, 0.25 mmol), and tetracosane (34.5 mg) in AcOEt (25 ml) was poured into the solution, and all was stirred at 50 °C under a hydrogen atmosphere of 5 kg cm^{-2}.

Catalytic Interconversion of Hydropyrenes. General Procedure. About 1-mg portion of platinum oxide (1.0—1.5 mg) was placed in a tube (0.5 mmϕ, 6 cm), cyclohexane (0.1 ml) was added, and it was stirred at 50 °C under 5 kg cm^{-2} of hydrogen pressure for 1 h. Reactant (0.05 mmol per 1 mg of PtO_2) was added with cyclohexane (0.4 ml). After purge by argon, the top of the tube was extended to 12 cm in length with a diameter of *ca.* 0.1 mm. The reaction tube was placed in an autoclave which contained hexane

(20 ml), and it was maintained at 240—250 °C under an argon pressure of 85—95 kg cm^{-2} during 10 h. Upon cooling the mixture, the content was submitted to GLPC. A part (<3%) of the reaction mixture flowed out into outer hexane; the proportion of the hexane solution was similar to that of the reaction mixture.

We wish to thank Professor Takashi Toda and Mr. Masaaki Yoshida, Utsunomiya University for their valuable discussion.

Rotational Isomerism in Fluorene Derivatives. IX. Restricted Rotation about the C(9)-C(9′) Bonds in 9(or 9′)-Substituted 2-Methyl-9,9′-bifluorenyls[1]

Shoji KAJIGAESHI,* Akiko NISHIDA, and Shizuo FUJISAKI
Department of Industrial Chemistry, Faculty of Engineering, Yamaguchi University, Tokiwadai, Ube 755
(Received December 24, 1984)

Several 9(or 9′)-substituted 2-methyl-9,9′-bifluorenyls were prepared and the restricted rotation about the C_{sp^3}–C_{sp^3} bonds in these compounds were investigated by DNMR. In these cases, nonequivalent gauche conformers were observed at low temperatures. Barriers (ΔG^*) for the forward and backward interconversions were slightly increased in agreement with the bulkiness of the 9(or 9′)-substitutents.

Previously, we have discussed the conformations of 9-(9-fluorenyl)-9-(2-substituted 9-fluorenyl)fluorene derivatives[2] (**1**) and 9-aryl-9-(2-methyl-9-fluorenyl)-fluorene derivatives[3] (**2**) concerning the restricted rotation about the C_{sp^3}–C_{sp^3} bonds on the basis of their DNMR behavior.

This work was undertaken to examine the restricted rotation about the C_{sp^3}–C_{sp^3} bonds in 9(or 9′)-substituted 2-methyl-9,9′-bifluorenyl derivatives (**3**). These compounds have a simpler skeleton than **1** or **2**, such as 9,9′-unsubstituted[4] (**3a**), 9-bromo-[4] (**3b**), 9′-hydroxy-[4] (**3c**), 9-methoxy-[4] (**3d**), 9′-methoxy- (**3e**), 9-ethoxy-[4] (**3f**), 9′-ethoxy[4] (**3g**), 9-propoxy- (**3h**) and 9-isopropoxy-2-methyl-9,9′-bifluorenyl (**3i**).

3d:	OCH_3	H	**3i**:	$OCH(CH_3)_2$	H
3e:	H	OCH_3			

Results and Discussion

The compounds **3h** and **3i** were prepared by refluxing **3b** with 1-propanol and 2-propanol, respectively. The ^{1}H-NMR data of **3** at room temperature are shown in Table 1.

It has been noted that bifluorenyl has a gauche geometry in the solid state, and the same gauche conformation prevails in solution judging from the magnitude of the H(9)–H(9′) vicinal coupling constant in its ^{1}H-NMR spectrum.[5] We have also reported that rotational isomerization in **1** or **2** may occur by interconversion between two stable gauche conformers of these compounds.[2,3]

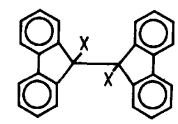
Recently, Olah *et al.*[6] have determined the energy barriers for the interconversion of the equivalent gauche conformers of the symmetrical 9,9′-disubstituted 9,9′-bifluorenyl derivatives (**4**) by complete line-shape analysis of the DNMR spectra of the protons in aromatic regions. We have now obtained the energy barriers for the rotation about the C_{sp^3}–C_{sp^3} bonds in **3** from the line-shape analysis of their DNMR spectra due to the protons of the 2-methyl group; this does not directly hinder rotation about the central bonds. The observed and simulated ^{1}H-NMR spectra of **3c** are shown in Fig. 1 as a typical example.



X=H, Me, Cl, Br

4

In Fig. 1, the 2-methyl signal (δ=2.21) which is observed as a singlet at room temperature gradually broadens when the temperature is lowered, and is completely split into two nonequivalent singlets (δ=2.56 and 1.84) at −75 °C. That is, two different conformers which are caused by restricted rotation about the C(9)–C(9′) bond can be observed at low

temperature.

Figure 2 shows the conformations concerned with rotation about the C(9)–C(9′) bond in **3c**, and their interconversion processes by Newman projection formulas. The conformation B (+*ac*), D(*sp*), and F(−*ac*) should be unstable forms because of their eclipsed geometries. An examination of the molecular model suggests that anti conformation E(−*sc*) is also unstable on account of the steric interaction between the 1- and 1′-protons as well as the 8- and 8′-protons in the two fluorene moieties. Consequently, the observed conformations at low temperature are attributed to the gauche forms A(*ap*) and C(+*sc*). In this case, it is reasonable to assume that the methyl group in conformation A which is located in a shielding zone of the other

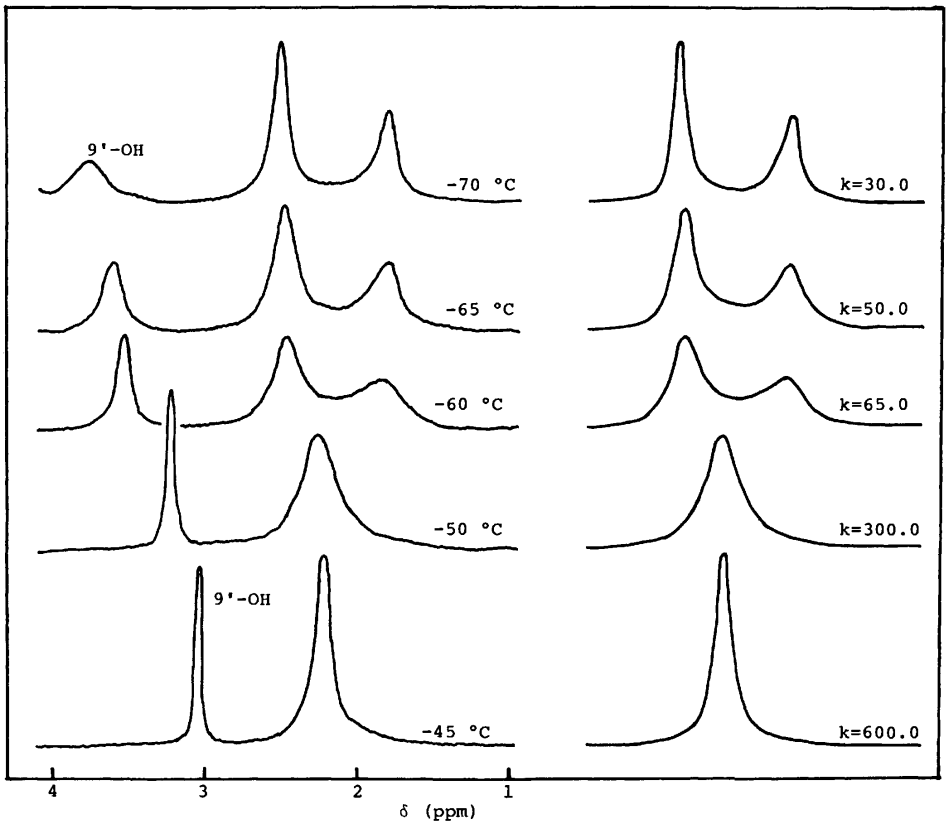


Fig. 1. Obserbed (left) and calculated (right) spectra of 2-CH_3 in **3c** at various temperature.

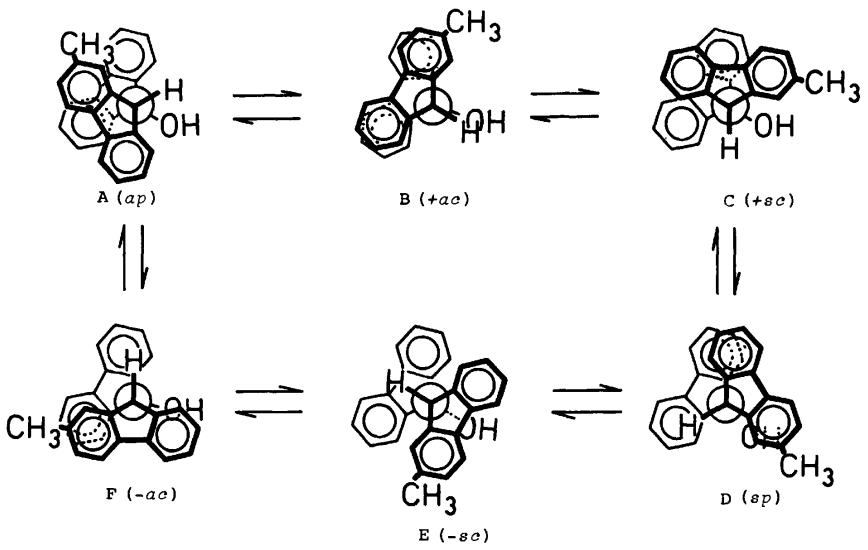

Fig. 2. Stereoisomerization process of **3c** by rotation about the C(9)–C(9′) bond.

fluorene moiety gives ^{1}H-NMR signal at a high field, and the methyl group in C located in a deshielding zone of the other's gives the signal at low field. Thus, the singlet at δ=1.82 is assigned to the methyl signal of A and the singlet at δ=2.52 is assigned to that of C. Furthermore, the equilibrium constant $K(N_A/N_C)$ for the equilibria C$\rightleftharpoons$A was found to be 0.54—0.73 from the intensity ratio of the two methyl signals.

Interconversion between the two gauche conformers, A and C, can occur by two different pathways, *via* the fully eclipsed form B, or *via* the anti form E. But irrespective of the pathways, the observed dynamic behavior can be viewed as a rocking motion from one gauche form to the other. The rotational energy profile for **3c** is illustrated graphically in Fig. 3. The same convincing argument is applicable to the other deirvatives in the series of **3**.

In the ^{1}H-NMR spectra of the derivatives **3** at low temperature, signal intensities of the methyl groups observed at the higher magnetic field were always smaller than that observed at the lower magnetic field. As shown in Fig. 2, it turned out that the conformer A in which the 2-methyl group of **3** is located above the other fluorene moiety is less stable than the conformer C, and the conformational equilibrium between A and C favors C. Therefore, it can be expected that there would be appreciable π-π repulsive interaction between the phenyl moiety with an electron-donating methyl group and the other fluorene moiety.

The activation parameters for internal rotation in **3** obtained from the line-shape analysis of their DNMR spectra due to the methyl groups are listed in Table 2, together with the equilibrium constants between the two rotamers at low temperature.

Steric interactions are obviously responsible for the observed barriers. In fact, as shown in Table 2, the free energies of activation ($\Delta G^{\ddagger}$) for rotation about the C(9)-C(9′) bonds in **3** were slightly increased as the size of 9- or 9′-substituents (X or Y) increased, except for the OH in **3c**. Particularly, 9-alkoxy-2-methyl 9,9′-bifluorenyls gave the magnitudes of the rotational barriers (A→C and/or C→A) in the following order, $\Delta G^{\ddagger}_{3i} > \Delta G^{\ddagger}_{3h} \approx \Delta G^{\ddagger}_{3f} > \Delta G^{\ddagger}_{3d}$.

Experimental

The ^{1}H-NMR spectra were recorded on a JEOL-MH-100 spectrometer with a JEOL model JES-VT-3 variable temperature controller. The chemical shifts are expressed in ppm, with tetramethylsilane as the internal standard. Dynamic NMR spectra were analyzed by using a modified version of the computer program DNMR3.[7] The melting points of the compounds obtained are uncorrected.

*2-Methyl-9-propoxy-9,9'-bifluorenyl (**3h**).* A solution of **3b** (0.21 g, 0.5 mmol) in 1-propanol (3 ml) was refluxed for 30 min. Solvent was distilled off and the residue was chromatographed on alumina using benzene as eluent. The crude product was recrystallized from acetone to give **3h** (0.16 g, 80%) as slight yellow crystals; mp 135—136 °C. ^{1}H-NMR ($CDCl_3$) δ=0.91 (3H, t, J=7 Hz, $(CH_2)_2C\underline{H}_3$), 1.4—1.79 (2H, m, $CH_2C\underline{H}_2CH_3$), 2.31 (3H, s, CH_3), 2.88, 2.90 (2H, two t, J=7 Hz, $C\underline{H}_2CH_2CH_3$), 4.78 (1H, s, CH), 6.67—7.63 (15H, m, aromatic protons).

Found: C, 89.69; H, 6.63%. Cacld for $C_{30}H_{26}O$: C, 89.51; H, 6.51%.

*9-Isopropoxy-2-methyl-9,9'-bifluorenyl (**3i**).* A solution of **3b** (0.21 g, 0.5 mmol) in 2-propanol (3 ml) was refluxed for 30 min. After the same procedure as above, **3i** (0.15 g, 75%) was obtained as slight yellow crystals; mp 141—142 °C. ^{1}H-NMR ($CDCl_3$) δ=0.94, 0.96 (6H, two d, J=6 Hz, $CH(C\underline{H}_3)_2$), 2.22 (3H, s, CH_3), 3.10 (1H, m, J=6 Hz, $C\underline{H}(CH_3)_2$), 4.64 (1H, s, CH), 6.62—7.50 (15H, m, aromatic protons).

Found: C, 89.54; H, 6.52%. Calcd for $C_{30}H_{26}O$: C, 89.51; H, 6.51%.

(Received January 23, 1985)

Vitamin E acted as an efficient antioxidant in the oxidation of soybean phosphatidylcholine liposome in an aqueous dispersion initiated by free radicals generated initially either in the aqueous phase or in the lipid phase. Vitamin E decayed linearly with time, and when it was exhausted, the oxidation proceeded rapidly at a similar rate to that in the absence of vitamin E. Vitamin C was also effective by itself in scavenging radicals in an aqueous phase, but it could not scavenge the radicals efficiently in a lipid bilayer. However, when vitamin E was located in phosphatidylcholine bilayer, the addition of vitamin C into an aqueous phase prolonged the period of suppression of oxidation and vitamin C reduced the rate of decay of vitamin E markedly even when the radicals were generated initially in the lipid region. Vitamin C was predominantly consumed linearly at first and vitamin E began to decay after vitamin C was exhausted. It was suggested that vitamin C could regenerate vitamin E by reacting with vitamin E radical during the oxidation of phosphatidylcholine liposome in an aqueous dispersion as observed in a homogeneous solution.

Vitamin E is now accepted to function as a chain-breaking antioxidant during the non-enzymatic oxidation of lipids *in vivo*.[1-5] It scavenges the chain-carrying peroxyl radicals very quickly[6-12] and a small concentration of vitamin E protects the biomembranes from peroxidation efficiently. Vitamin E is also popular as a natural and safe antioxidant for foods. A synergistic inhibition of oxidation by the combination of vitamin E and vitamin C has long been suggested[10,13-22] and it has been found experimentally that vitamin E radical reacts with vitamin C,[21,22] glutathione,[22,23] and cysteine.[23] We have recently found[10] that, when both vitamin E and vitamin C are present, the oxidation of methyl linoleate solution is suppressed quite efficiently and that vitamin E remains almost unchanged while only vitamin C is consumed at the initial stage and vitamin E is consumed after vitamin C is exhausted. A question still remains whether vitamin C which resides largely in an aqueous phase can interact with vitamin E radical that must be located in a lipid phase in heterogeneous liposome system or *in vivo*. We wish to report here the evidence that shows the synergistic inhibition of oxidation by vitamin E and vitamin C in the oxidation of soybean phosphatidylcholine (PC) as a bilayer liposome in an aqueous dispersion.

Experimental

Commercial soybean PC purchased from Daigo Chemicals Co. (Osaka) was purified with alumina and silica-gel columns. The purified PC gave only one spot on thin-layer chromatography and no conjugated diene was observed before oxidation. The composition of fatty acids in PC measured by gas-liquid chromatography after hydrolysis and esterification with HCl-methanol was as follows: palmitic acid 12.1, stearic acid 1.6, oleic acid 9.6, linoleic acid 69.6, and linolenic acid 7.1 mol%. Dimyristoyl PC was purchased from Sigma Chemical Co. 2,2′-Azobis(2-amidinopropane) dihydrochloride (AAPH) and 2,2′-azobis(2,4-dimethylvaleronitrile) (AMVN) were used as a water-soluble and oil-soluble radical initiator respectively. Both AAPH and AMVN were provided by Wako Chemicals (Tokyo) and used as received. These water-soluble and lipid-soluble initiators enable us to generate radicals initially outside or within the bilayer as requested and initiate free radical chain oxidation at a constant rate, which is essential for the fundamental and quantitative study.

Vitamin E (*d*-α-tocopherol) was kindly supplied from Eisai Co. (Tokyo) and commercial vitamin C (L-ascorbic acid) was used as received.

The liposome was prepared as follows as reported previously.[11] PC and oil-soluble additives such as AMVN and vitamin E were dissolved in chloroform and the solution was taken into a small flask. Chloroform was removed by evacuation on a water aspirator using a rotary vacuum evaporator to obtain a thin film on a flask wall. Appropriate amount of 0.1 M (M=mol dm^{-3}) NaCl aqueous solution was added and the film was slowly peeled off by shaking to obtain a white and milky liposome solution. It must be noted that the liposome we have prepared in this study is a multilamellar vesicles.

The oxidation was carried out at either 37 or 50 °C under air in a Pyrex glass ampoule. The reaction conditions such as temperature and concentrations of substrate, initiator, and additives were determined so as to obtain appropriate rates of oxidation and disappearance of reactants. The reaction mixture was agitated with a magnetic stirrer. The rate of oxygen uptake was measured continuously in an automatic recording gas absorption apparatus with a pressure transducer.[10] In some oxidations, the rate of build-up of conjugated diene was followed spectrometrically at 233 nm. Since linoleic acid is the major fatty acid in soybean PC and its oxidation gives conjugated diene hydroperoxides quantitatively,[24-29]

this spectrometric analysis should give a good measure of the rate of oxidation. Since the extinction coefficient of conjugated diene is large, $\varepsilon=28000\ M^{-1}\,cm^{-1}$, the rate of oxidation can be followed at very early stages.

The rates of consumption of vitamin E and vitamin C were followed by high performance liquid chromatography (HPLC).[10] A Finepak SIL C18 column was used and methanol was delivered as an eluent at 1 $cm^3\ min^{-1}$. Vitamin C (eluted at 2.7 min) was measured at 275 nm and vitamin E (eluted at 7.7 min) was measured at 290 nm.

Results

When water soluble AAPH is used as a radical initiator, the radicals are formed initially in an aqueous phase, whereas water-insoluble and oil-soluble AMVN incorporated into PC bilayers generates free radicals within the lipid region. In both cases, the soybean PC liposome was oxidized smoothly at a constant rate without any noticeable induction period with long kinetic chain length, suggesting that the free radicals initially formed either in aqueous phase or in lipid phase induce the autoxidation of liposome similarly as observed previously.[11] In the absence of radical initiator, the rates of oxygen uptake and conjugated diene formation and that of vitamin E disappearance were negligibly small. Figure 1 illustrates the profile of oxygen uptake during the oxidations of soybean PC

liposome initiated with AAPH and AMVN.

Oxidations Initiated with AAPH. When vitamin E or vitamin C was added in the oxidation of PC liposome initiated with AAPH, the rate of oxygen uptake was suppressed markedly as observed in the oxidation of methyl linoleate in homogeneous solution[10] or in water dispersion.[9,11] As shown in Fig. 2, vitamin E was consumed linearly with time and after all of vitamin E was consumed the oxidation proceeded rapidly at a similar rate to that in the absence of vitamin E. Figure 3 shows that, when both vitamin E and vitamin C were present, vitamin C was consumed first linearly with time but vitamin E remained almost constant at the initial stage and then it was consumed after vitamin C was exhausted.

Oxidations Initiated with AMVN. When oil-soluble AMVN was incorporated into liposome and the initiating radicals were generated within the liposomal lipid region, the oxidation of PC liposome proceeded smoothly at a constant rate and oxygen uptake was suppressed efficiently by a small amount of vitamin E which was also incorporated into lipid bilayer (Fig.1b). Vitamin E decayed linearly with time as shown in Fig. 4 (Line A). However, although vitamin C alone added to an aqueous phase retarded the oxidation, it did not produce a clear induction period (Fig. 1b) which was observed when the oxidation was initiated with water-soluble AAPH (Fig. 1a). As shown in Fig. 5, similar results were observed when the rate of oxidation was followed by the formation of conjugated diene. These results show that, as observed previously in the oxidation of methyl linoleate micelle in aqueous dispersions,[9] vitamin C can not scavenge the radicals in the bilayer as efficiently as it scavenges radicals in aqueous phase.

When vitamin E and vitamin C were located in bilayer and in aqueous phase, respectively, the induction period was lengthened markedly as shown in Figs. 1b and 5. Furthermore, it must be pointed out that the rate of oxidation during the induction period was much smaller than that in the presence of vitamin C alone. Figure 4 shows how vitamin E and vitamin C decayed with time when both vitamins were present in the oxidation of PC liposome initiated with AMVN. Interestingly, the rate of consumption of vitamin E in liposome was reduced markedly by vitamin C in an aqueous phase even though the radicals were generated initially in the lipid region. When all of vitamin C was consumed, vitamin E began to decrease at a similar rate to that in the absence of vitamin C.

Discussion

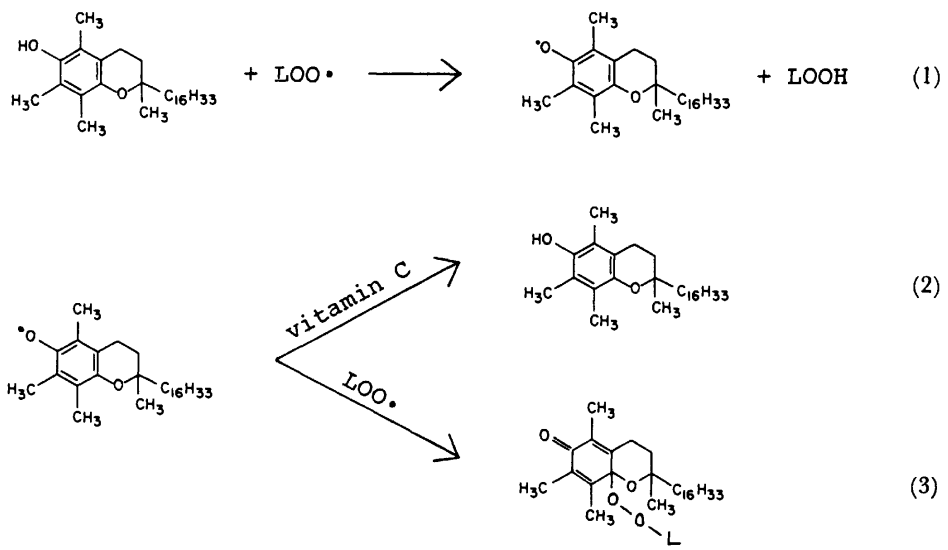
Both vitamin E and vitamin C can scavenge peroxyl radicals when they are accessible and interact.[10] However, Fig. 1b indicates that vitamin C can not efficiently scavenge peroxyl radicals formed from AMVN and PC within liposomal lipid region, probably because AMVN is buried in the bilayer and the peroxyl radicals from both AMVN and PC are not accessible to vitamin C.

The results shown in Fig. 3 that vitamin C retards the rate of consumption of vitamin E during the

oxidation of PC liposome initiated with AAPH suggest that vitamin C scavenges the initiating radicals from AAPH in an aqueous phase directly before they attack liposome or that vitamin C regenerates vitamin E by reacting with vitamin E radical as observed in homogeneous solution.[10] Probably some combination of these reactions may be involved. The use of water soluble initiator AAPH does not permit us to differentiate which reaction is more important.

On the other hand, the results of oxidation initiated with lipid soluble AMVN give us more information concerning the cooperative and synergistic inhibition of oxidation by vitamins E and C. The results in Figs. 1 and 5 show that, although vitamin C can not scavenge chain-carrying peroxyl radicals within liposomal lipid region efficiently, vitamin C can prolong the induction period in the presence of vitamin E. This strongly supports the interaction of vitamin C in an aqueous phase and vitamin E radical in the lipid region. Apparently, vitamin C is more accessible to vitamin E radical than to peroxyl radicals in the lipid region, since the phytyl side chain of vitamin E must be buried in the lipid region and polar chromanyloxyl head group must be located near the membrane surface.

In contrast to the oxidation initiated with AAPH (Fig. 3), vitamin E did not remain constant but it was consumed gradually (Fig. 4) even though some vitamin C was present in an aqueous phase. This may imply that vitamin C in an aqueous region can not react with vitamin E radical in the lipid layer as efficiently as in the homogeneous system and/or that vitamin E radical reacts with another peroxyl radical (Reaction 3)[30] faster than it reacts with vitamin C (Reaction 2).



Furthermore, the synergistic inhibition of oxidation of methyl linoleate micelle by the combination of vitamin C and 2,2,5,7,8-pentamethyl-6-chromanol (PMC, a vitamin E model) observed previously[32] supports the interaction of vitamin E radical with vitamin C. Vitamin C acts as an efficient antioxidant for the oxidation of methyl linoleate micelle in 0.01 M Triton X-100 aqueous dispersion initiated with AAPH. On the other hand, when AMVN was used as an initiator and the radicals were generated initially in the oil region, vitamin C could not act as an antioxidant. However, even in this case, vitamin C was found to lengthen the suppression period when PMC was located in the methyl linoleate micelle.

It must be also noteworthy that ESR spectrum of vitamin E radical disappeared quite rapidly when it reacted with vitamin C.[22] It was also found by ESR study and absorption spectroscopy that galvinoxyl, a stable phenoxyl radical, which was incorporated into dimyristoyl PC liposome could react with vitamin C in an aqueous phase.[23]

The results and discussion given above strongly suggest that vitamin C can contribute to the synergistic inhibition of oxidation and to the regeneration of vitamin E by reacting with vitamin E radical during the oxidation of PC liposome in an aqueous dispersion as well as in the homogeneous solution.

As shown in Figs. 1b and 5, vitamin C could retard, although slightly, the oxidation of soybean

PC liposome initiated with AMVN. This probably indicates that vitamin C could interact with peroxyl radicals at the membrane surface and/or that vitamin C could penetrate into the membrane slowly. It must be noteworthy that the liposome prepared in this study by soybean PC alone without choresterol may be more leaky than real biomembranes. In biological systems, the oxygen radicals generated in a lipid region must be scavenged by vitamin E while those present in an aqueous region must be scavenged by water soluble antioxidants such as vitamin C, uric acid, and cysteine, and the synergistic inhibition by vitamin E and vitamin C must contribute to maintaining the vitamin E level and also its antioxidant activity in biological membranes.

Studies of Unusual Amino Acids and Their Peptides. XVII.[1,2] The Synthesis of Peptides Containing *N*-Carboxymethyl Amino Acids. II[3,4]

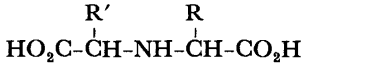
Toshifumi MIYAZAWA,* Shin'ichi HIRAMATSU, Yasuhiro TSUBOI, Takashi YAMADA, and Shigeru KUWATA

Department of Chemistry, Faculty of Science, Konan University, Okamoto, Higashinada-ku, Kobe 658

(Received February 23, 1985)

The synthetic routes were investigated to four kinds of tetrapeptides made up of three usual amino acid residues and one *N*-carboxymethyl (Cm-) amino acid residue. The application of vacuum distillation made the isolation of a Cm-amino acid diester more convenient and efficient compared with the chromatographic methods which had been used previously. The efficiency of peptide bond formation at the imino group of a Cm-amino acid by the acid chloride method was remarkably improved under suitable reaction conditions. In the elongation of the peptide chain from a peptide containing a Cm-amino acid at the C-terminal position, the coupling efficiency was usually poorer than that in the case of the corresponding peptide composed only of the usual amino acid residues, and it depended greatly on the coupling methods, the 1-ethyl-3-(3-dimethylaminopropyl)carbodiimide–1-hydroxybenzotriazole method being generally the most desirable.

In our previous publications,[3,5,6] we have reported on the preparation of *N*-carboxymethyl (Cm-) amino acids (**I**, R′=H) and their derivatives using the corresponding usual amino acids as the starting materials. Cm-amino acids are simple-structured members of a group of unusual amino acids represented by the general structural formula of **I**.



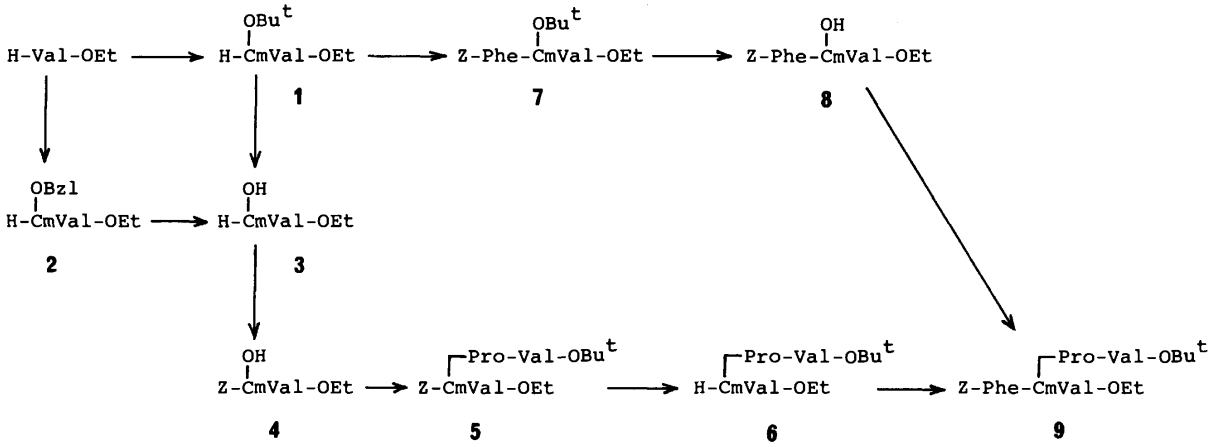
I

These amino acids (**I**) have been found in increasing numbers in nature, *e.g.*, in many marine animals and in crown gall tumors, and have recently been receiving more attention.[7,8] Furthermore, a series of synthetic peptides containing substituted Cm-amino acids have recently been demonstrated to be active as inhibitors of angiotensin-converting enzyme,[9] thermolysin,[10] enkephalinase,[11] and malate dehydrogenase.[12]

In Part I[3] of this series, we dealt with some basic problems in the synthesis of peptides containing Cm-amino acids, *e.g.*, the protection of the carboxyl and the imino groups of a Cm-amino acid, and the peptide bond formation at its carboxyl groups and imino group. As an extension of this work, the present paper will deal with the synthetic routes to four kinds of tetrapeptides (**9**, **15**, **19**, and **20**) made up of three usual amino acid residues (Pro, Val, and Phe) and one Cm-amino acid residue (CmVal),[13] the latter occupying four different positions in the peptide chains. These tetrapeptides were intended as the starting materials for a cyclic peptide model containing a Cm-amino acid.[14] The peptide chains were lengthened mainly from the dipeptide (**7**), which contained the Cm-amino acid at the C-terminal position and was protected by three kinds of selectively removable groups. Such a way of peptide chain elongation has not yet been attempted, and it has often been demonstrated that the efficiency of peptide bond elongation from a peptide containing a Cm-amino acid residue as either the amino or the carboxyl component is much poorer than that in the case of the corresponding usual peptide.

Preparation of Tetrapeptide **9**. According to the route adopted in the previous study,[3] Z-CmVal-OEt (**4**) was coupled with H-Pro-Val-OBu^t by the DCC, DCC-HOBt, or EDC method, to afford the tripeptide **5** (Scheme 1). For this purpose, **4** was prepared first *via* the H-Val-OEt→**2**→**3**→**4** route,[3] and later *via* a new route, H-Val-OEt→**1**→**3**→**4**. The debenzyloxycarbonylation of **5** was accomplished by hydrogenation, using Pd on carbon as the catalyst in the absence of any acid. It is noteworthy that the resulting product, **6**, though having a free imino group, was stable at room temperature for a long period of time, like the diesters of Cm-amino acids.[5] Then, **6** was coupled with Z-Phe-OH by the acid chloride method. Though the coupling efficiency by this method had generally been far from satisfactory,[3] the improvement of the procedure described below gave the tetrapeptide **9** in a fairly good yield (60%).

As an alternative to the desired tetrapeptide (**9**), the route *via* the dipeptide **7**, which contains CmVal as the C-terminal residue and is useful as a key compound for the preparation of two other tetrapeptides (**15** and **19**) as well, was examined next. For



Scheme 1.

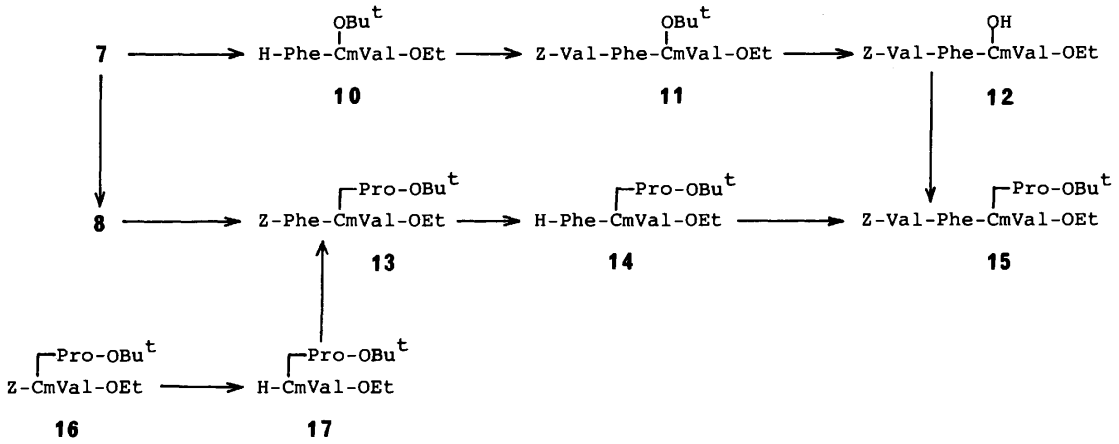
that purpose, the Cm-valine ethyl *t*-butyl ester **1** was prepared according to the general procedure described previously,[5] using ethyl valinate and *t*-butyl bromoacetate in the presence of triethylamine (TEA). Though the purification of Cm-amino acid diesters had hitherto been carried out by silica-gel column chromatography or TLC,[5] **1** was found to be isolable by means of vacuum distillation, thus making it possible to prepare such Cm-amino acid diesters as **1** more conveniently and in quantity.

As stated in the previous papers[3,5] the imino group of a Cm-amino acid has a remarkably poor reactivity, showing that the attempted couplings of Z-Phe-OH with a diester of Cm-valine by several conventional condensation methods all ended in failure, except by the acid chloride method. The coupling efficiency by the last method, however, was rather poor (*ca.* 40%). Recently we have attempted to overcome this difficulty by the use of the high pressure technique in the couplings of Z-amino acids with Cm-amino acid diesters by means of the *N*-hydroxysuccinimide ester method.[16] The application of high pressure (10 kbar) enabled some of the coupling reactions to be carried out so as to give much higher yields than at atmospheric pressure, while the coupling yields remained low in some reactions between relatively bulky amino acid residues. Moreover, a large-scale preparation at high pressure must be attended with some difficulties under the present conditions. Accordingly, the optimum reaction conditions for the coupling by the acid chloride method was investigated in the reaction of Z-Phe-Cl with the Cm-valine diester **1**; it was revealed that the best yield of **7** (84%) was obtained by the use of 2 to 3 equivalents of Z-Phe-Cl and by conducting the reaction at 0 °C from beginning to end instead of at 0 °C for several hours and thereafter at room temperature.[3]

The removal of the *t*-butyl group from **7** was carried out by treating **7** with hydrogen chloride in ethyl acetate for a few hours, without causing any damage to the coexistent Z group. Then, as an attempt to elongate the peptide chain from a C-terminal Cm-amino acid residue, the de-*t*-butylated product **8** was coupled with H-Pro-Val-OBu^t by means of the EDC or EDC–HOBt method. The yield of the reaction, **8**→**9**, (45%) as conducted according to the EDC method, was poorer than that of the corresponding reaction, **4**→**5**, (66%) under comparable conditions. This illustrates the large steric hindrance of a peptide containing a Cm-amino acid compared with that of a Cm-amino acid itself. On the other hand, the application of the EDC–HOBt method to the present coupling gave **9** in a good yield (80%). The superiority of this coupling method seems to be a general trend in the preparation of peptides containing Cm-amino acids, as will be indicated below by several examples.

The optical rotation of the product (**9**) obtained from **8** and H-Pro-Val-OBu^t by the EDC or EDC–HOBt method was identical with that of the product obtained *via* the first-mentioned route (**4**→**5**→**6**→**9**). No racemization occurs during the segment coupling at the carboxyl group in the glycine moiety of a Cm-amino acid residue, as might be expected. On the other hand, when we compare the overall yields of the tetrapeptide **9** starting from ethyl valinate *via* the two routes mentioned above, it is apparent that the route *via* the dipeptide **7** is more desirable, so much the more because the route *via* Z-CmVal-OEt (**4**) contains more steps (H-Val-OEt→**2**→**3**→**4** or H-Val-OEt→**1**→**3**→**4**).

Preparation of Tetrapeptide 15. For the preparation of the tetrapeptide **15**, the following two routes were examined starting from the dipeptide **7** mentioned above: (i) **7**→**10**→**11**→**12**→**15** and (ii)



Scheme 2.

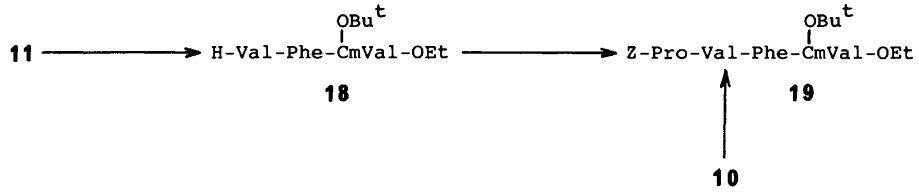
7→8→13→14→15 (Scheme 2). The elongation of the peptide chain at the N-terminal residue of a peptide containing a C-terminal Cm-amino acid residue has not previously been attempted. In the (i) route, the Z group of **7** was first removed, and the resulting product (**10**) was coupled with Z-Val-OH by several methods. Generally, the coupling efficiency was less satisfactory than that of the corresponding coupling, Z-Val-OH+H-Phe-Val-OBu^t, under comparable conditions (see Experimental). This presumably indicates the extention of the influence of the bulkiness of the Cm-amino acid to the amino group of the adjacent amino acid residue. Thus, the coupling method and conditions had a profound influence on the coupling efficiency. The *N*-hydroxysuccinimide ester method in dioxane gave only a 25% yield after 3 d, while it gave a 46% yield in dichloromethane. The mixed anhydride method and the EDC method gave better yields (45 and 54% respectively). The best yield (70%) was obtained by the EDC-HOBt method. The comparison of the yields of the couplings of Z-Val-OSu and Z-Ala-OSu with **10** in dichloromethane under comparable reaction conditions (46 and 65% respectively) also reveals the influence of the steric hindrance. Then the removal of the *t*-butyl group from **11** was attained as in the **7→8** step to give **12**. The coupling of **12** with H-Pro-OBu^t was carried out by the EDC-HOBt method, thus obtaining the desired tetrapeptide **15** in a 61% yield.

On the other hand, in the (ii) route, **8** was first coupled with H-Pro-OBu^t by means of the EDC-HOBt method to give the tripeptide **13** in a 65% yield. This yield was somewhat better than that of the corresponding coupling of the tripeptide **12** with H-Pro-OBu^t described above. The tripeptide **13** was also prepared *via* another route. The dipeptide **16**[3] was debenzyloxycarbonylated by hydrogenation as usual to give **17**, and this was then coupled with Z-Phe-Cl by the improved procedure described above (77% yield). The product thus obtained was identical with that obtained by the (ii) route. Then the tripeptide **13** was debenzyloxycarbonylated by hydrogenation, and the resulting **14** was coupled with Z-Val-OH by several methods. The yields were 34% for the *N*-hydroxysuccinimide ester method, 41% for the mixed anhydride method, and 51% for the EDC-HOBt method. These yields were rather poor compared with those of the corresponding coupling of Z-Val-OH with **10**. This presumably reflects the difference in the bulkiness of the two amino components containing the Cm-amino acid (**14** *vs.* **10**).

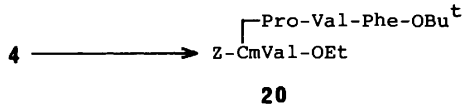
The final products (**15**) obtained *via* the two routes, (i) and (ii), were identical. On the other hand, a comparison of the overall yields (from the dipeptide **7**) of the tetrapeptide **15** obtained by the EDC-HOBt method *via* Routes (i) and (ii) revealed that the (i) route (43%) was somewhat better than the (ii) route (33%).

Preparation of Tetrapeptides 19 and 20. As is shown in Scheme 3, the tripeptide **11** was debenzyloxycarbonylated by hydrogenation to give **18**, which was then coupled with Z-Pro-OH by several different methods. The yields were 26% for the *N*-hydroxysuccinimide ester method, 44% for the mixed anhydride method, and 77% for the EDC-HOBt method. In this case also, the last method was the most desirable one. The yields were generally comparable with those of the preceeding step, **7→10→11**. Moreover, there was a close resemblance in the relationship between the coupling method and the coupling efficiency in both cases.

The tetrapeptide **19** was also prepared in a 59%



Scheme 3.



Scheme 4.

yield by the coupling of Z-Pro-Val-OH with **10** by the EDC-HOBt method. This yield was poorer than that of the corresponding coupling of Z-Val-OH with **10**, but the overall yield *via* the **7**→**10**→**19** route (segment coupling) was somewhat better than that *via* the **7**→**10**→**11**→**18**→**19** route (stepwise elongation). The optical rotation of the product obtained by the segment coupling was identical with that of the product obtained by the stepwise elongation, indicating that no racemization occurred.

The EDC coupling of Z-CmVal-OEt (**4**) with H-Pro-Val-Phe-OBu^t, which had been prepared by the stepwise elongation starting from the C-terminal phenylalanine, gave the tetrapeptide **20** in a 55% yield (Scheme 4). This yield was better than that reported previously[3] of the corresponding coupling of **4** with H-Pro-Val-Val-OBzl by the DCC method (37%).

In conclusion, the results obtained in the present work indicate that, in the elongation of the peptide chain from a peptide containing a Cm-amino acid residue, the coupling efficiency is generally poor compared with that in the case of the corresponding peptide composed only of usual amino acid residues, and depends largely on the coupling methods. The EDC-HOBt method is the method of choice.

Experimental

All the melting points are uncorrected. The optical rotations were measured with a JASCO DIP-4 polarimeter. The TLC and preparative TLC were performed on Merck Kieselgel 60 F_{254} and Kieselgel GF_{254} (Type 60) respectively. Merck Kieselgel 60 was used for the column chromatography. The ^{1}H NMR spectra were recorded on a Hitachi R-24B spectrometer.

H-CmVal-OEt (1). To a stirred mixture of H-Val-OEt·TosOH (59.10 g) and TEA (37.96 g) in THF (180 ml) we added, drop by drop, a solution of *t*-butyl bromoacetate[17] (43.58 g) in THF (10 ml) over a period of 2 h. The reaction mixture was then stirred at room temperature for 10 d. The precipitates were subsequently filtered off, and the filtrate was evaporated under reduced pressure. The residue was dissolved in EtOAc, washed with water, and dried over Na_2SO_4. After the solvent had been removed, the residue was distilled under reduced pressure; yield, 29.22 g (61%); oil, bp 85 °C/0.7 Torr (1 Torr=133.322 Pa); $[\alpha]_D^{25}$ −18.0° (*c* 1.0, MeOH); n_D^{22} 1.4345. ^{1}H NMR ($CDCl_3$) δ= 0.96 (6H, d, *J*=6 Hz, $CH(C\underline{H}_3)_2$), 1.26 (3H, t, *J*=7 Hz, $CH_2C\underline{H}_3$), 1.44 (9H, s, $C(C\underline{H}_3)_3$), 1.7—2.2 (1H, m, $C\underline{H}(CH_3)_2$), 2.27 (1H, s, NH), 3.00 (1H, d, *J*=5.5 Hz, $NHC\underline{H}(C_3H_7)CO$), 3.22 (2H, s, $NHC\underline{H}_2CO$), and 4.14 (2H, q, *J*=7 Hz, $C\underline{H}_2CH_3$).

Picrolonate: mp 136.5—138 °C (EtOH); $[\alpha]_D^{25}$ +1.0° (*c* 1.0, MeOH). Found: C, 52.79; H, 6.43; N, 13.35. Calcd for $C_{23}H_{33}N_5O_9$: C, 52.77; H, 6.35; N, 13.38.

DCHA Salt of Z-CmVal-OEt (4). The diester **1** (1.56 g) was treated with 4 M HCl (1 M=1 mol dm^{-3}) in EtOAc (30 ml) at room temperature for 3 h. After the solvent had been removed under reduced pressure, the residue (**3**·HCl) was dissolved in water (11 ml) with $NaHCO_3$ (1.76 g). To the resulting solution, we added a solution of Z-Cl (1.13 g) in ether (2 ml) in 8 portions over a period of 3.5 h. Then the mixture was stirred below 5 °C overnight. After the usual work-up, the raw product was mixed with DCHA (1.09 g) to afford the corresponding salt, which was then recrystallized from hexane; yield, 2.14 g (69%); mp 109.5—110 °C; $[\alpha]_D^{25}$ −40.1° (*c* 1.0, $CHCl_3$). [lit,[3] mp 109.5—110 °C, $[\alpha]_D^{25}$ −39.8° (*c* 1.0, MeOH).]

Z-Pro-Val-OBu^t. This was prepared from Z-Pro-OH and H-Val-OBu^t by the mixed anhydride method using isobutoxycarbonyl chloride in THF; yield, 79%; mp 111—113 °C (EtOAc-petroleum ether); $[\alpha]_D^{23}$ −32.8° (*c* 1.0, DMF). This compound had previously been prepared by the DCC-HOBt method;[18] mp 114—115 °C, $[\alpha]_D^{23}$ −34.3° (*c* 1.0, DMF).

Tripeptide 5. This was prepared from Z-CmVal-OEt (**4**) (recovered from the DCHA salt by treatment in EtOAc with 1 M HCl as usual) and H-Pro-Val-OBu^t (prepared through the debenzyloxycarbonylation of Z-Pro-Val-OBu^t by catalytic hydrogenation in MeOH) by the three different methods described below, according to a previous report.[3] The final purification was performed by preparative TLC on silica gel with benzene-EtOAc (3:1), while recrystallization was done from cyclohexane;

mp 96—97 °C; $[\alpha]_D^{25}$ −107.4° (*c* 1.0, MeOH). Found: C, 63.22; H, 8.23; N, 7.16. Calcd for $C_{31}H_{47}N_3O_8$: C, 63.14; H, 8.03; N, 7.13.

The yields were 54% by the DCC method, 59% by the DCC–HOBt method, and 66% by the EDC method.

Dipeptide **7**. To a stirred solution of **1** (3.65 g) and TEA (1.57 g) in THF (10 ml), we added a solution of Z-Phe-Cl (freshly prepared by the reaction of Z-Phe-OH (10.48 g) with PCl_5 (7.29 g) in ether according to the literature[19]) in THF (20 ml) at 0 °C over a period of 20 min. The mixture was stirred overnight in a thermostatted bath at 0 °C. The precipitates were then filtered off, and the filtrate was evaporated under reduced pressure. The residue was distributed between EtOAc and water, and the separated organic layer was washed successively with 10% citric acid, water, 4% $NaHCO_3$, and water, and dried over Na_2SO_4. After the solvent had been removed under reduced pressure, the residue was purified on a silica-gel column, with hexane–EtOAc (3:1) as the eluent; yield, 6.42 g (84%); syrup, $[\alpha]_D^{25}$ −52.1° (*c* 1.0, MeOH). Found: C, 66.77; H, 7.72; N, 5.05. Calcd for $C_{30}H_{40}N_2O_7$: C, 66.65; H, 7.46; N, 5.18.

De-t-butylation of **7**. **7** (3.81 g) was treated with 4.5 M HCl (9.5 ml) in EtOAc at room temperature for 3.5 h. The oily residue (**8**) obtained after the removal of the solvent under reduced pressure was used for the next reaction without any further purification. On the other hand, a part of this product was converted to the DCHA salt in the usual manner; mp 125—127 °C (EtOAc–hexane); $[\alpha]_D^{25}$ −47.2° (*c* 1.0, MeOH). Found: C, 68.03; H, 8.34; N, 6.30. Calcd for $C_{38}H_{55}N_3O_7$: C, 68.54; H, 8.33; N, 6.31.

Tetrapeptide **9**. a) Into a solution of **8** (prepared from **7** (3.35 g) as described above) and HOBt (0.98 g) in THF (10 ml), we stirred EDC·HCl (1.44 g) at 0 °C. After 15 min, a solution of H-Pro-Val-OBu^t (prepared from Z-Pro-Val-OBu^t (3.00 g) by catalytic hydrogenation) in THF (10 ml) was added, and the reaction mixture was stirred at 0 °C for several hours and then at room temperature overnight. After the mixture had been evaporated under reduced pressure, the residue was dissolved in EtOAc, washed successively with water, 10% citric acid, water, 4% $NaHCO_3$, and water, and dried over Na_2SO_4. The subsequent removal of the solvent afforded a syrup, which was purified on a silica-gel column, with hexane–EtOAc (1:1) as the eluent; yield, 3.63 g (80%); syrup, $[\alpha]_D^{25}$ −76.8° (*c* 1.0, MeOH). Found: C, 64.91; H, 7.91; N, 7.50. Calcd for $C_{40}H_{56}N_4O_9$: C, 65.20; H, 7.66; N, 7.60.

The EDC method in acetonitrile gave the desired compound (**9**) in a 45% yield.

b) The tripeptide **5** (617 mg) was hydrogenated in THF in the presence of 5% Pd-C (150 mg). After the filtration of the catalyst and the removal of the solvent, the residue (**6**) was treated with Z-Phe-Cl (freshly prepared from Z-Phe-OH (877 mg) and PCl_5 (677 mg)) in the presence of TEA (110 mg) in a manner similar to that described for the preparation of the dipeptide **7**. The final purification was performed by preparative TLC on silica gel with benzene–EtOAc (3:2); yield, 466 mg (60%); $[\alpha]_D^{25}$ −76.9° (*c* 1.0, MeOH).

Tripeptide **11**. To a solution of Z-Val-OH (2.26 g) in THF (15 ml), we added EDC·HCl (1.73 g) and HOBt (1.22 g) at 0 °C. After 30 min, a solution of **10** (prepared through the debenzyloxycarbonylation of **7** (4.05 g) by catalytic hydrogenation) in THF (5 ml) was added, after which the reaction mixture was stirred at 0 °C for several hours and then at room temperature overnight. After a work-up similar to that described for the preparation of **9** (Method (a)), the residual syrup was purified on a silica-gel column, with hexane–EtOAc (1:1) as the eluent; yield, 3.37 g (70%); syrup, $[\alpha]_D^{25}$ −55.0° (*c* 1.0, MeOH). Found: C, 65.76; H, 7.85; N, 6.62. Calcd for $C_{35}H_{49}N_3O_8$: C, 65.71; H, 7.72; N, 6.57.

The *N*-hydroxysuccinimide ester method gave a 25% yield in dioxane and a 46% yield in CH_2Cl_2 after 3 d at room temperature. The mixed anhydride method using isobutoxycarbonyl chloride in THF gave a 45% yield, and the EDC method in acetonitrile, a 54% yield.

Z-Val-Phe-Val-OBu^t. Z-Val-OH (1.26 g) and H-Phe-Val-OBu^t (prepared through the debenzyloxycarbonylation of Z-Phe-Val-OBu^t[20] (2.27 g) by catalytic hydrogenation) were reacted in THF (11 ml) by the EDC–HOBt method in the same manner as has been described for the preparation of **11**. The raw product was recrystallized from EtOAc–petroleum ether; yield, 2.52 g (91%); mp 178–179 °C; $[\alpha]_D^{25}$ −46.2° (*c* 1.0, MeOH). [lit,[21] mp 178 °C, $[\alpha]_D$ −45.5° (*c* 1, MeOH).]

The *N*-hydroxysuccinimide ester method in dioxane gave a 72% yield, the mixed anhydride method using isobutoxycarbonyl chloride in THF gave a 78% yield, and the EDC method in acetonitrile gave a 84% yield, under the same reaction conditions as were used for the preparation of **11**.

Z-Ala-Phe-CmVal(OBu^t)-OEt. A sloution of Z-Ala-OSu (222 mg) and **10** (prepared from **7** (308 mg) by catalytic hydrogenation) in CH_2Cl_2 (2 ml) was stirred at room temperature for 3 d. 1-(2-Aminoethyl)piperazine (30 mg) was then added, and the mixture was stirred for an additional hour. After the solvent had been removed under reduced pressure, the residue was dissolved in EtOAc and washed as usual. The final purification was performed by preparative TLC on silica gel with benzene–EtOAc (3:1); yield, 228 mg (65%); syrup, $[\alpha]_D^{25}$ −65.4° (*c* 0.51, MeOH). Found: C, 65.04; H, 7.52; N, 6.80. Calcd for $C_{33}H_{45}N_3O_8$: C, 64.79; H, 7.41; N, 6.87.

Tripeptide **13**. a) **8** (prepared through the de-*t*-butylation of **7** (1.62 g) with HCl in EtOAc as described above) and H-Pro-OBu^t (prepared from Z-Pro-OBu^t (1.01 g) by catalytic hydrogenation) were coupled by the EDC–HOBt method in a manner similar to that described for the preparation of **9** (Method (a)). The final purification was performed on a silica-gel column, with hexane–EtOAc (1:1) as the eluent; yield, 1.24 g (65%); syrup, $[\alpha]_D^{25}$ −64.9° (*c* 1.0, MeOH). Found: C, 65.86; H, 7.56; N, 6.45. Calcd for $C_{35}H_{47}N_3O_8$: C, 65.91; H, 7.43; N, 6.59.

b) The dipeptide **16**[3] (250 mg) was hydrogenated in THF in the presence of 5% Pd-C (55 mg). After the filtration of the catalyst and the removal of the solvent, the residue was treated with Z-Phe-Cl (freshly prepared from Z-Phe-OH (460 mg) and PCl_5 (320 mg)) in the presence of TEA (57 mg) in a manner similar to that described for the preparation of the dipeptide **7**. The final purification was performed by preparative TLC on silica gel with

benzene–EtOAc (3:1); yield, 251 mg (77%); syrup, $[\alpha]_D^{25}$ −64.6° (*c* 1.0, MeOH).

Tetrapeptide 15. a) The tripeptide **11** (3.19 g) was treated with 4 M HCl in EtOAc (15 ml) at room temperature for 1.5 h. After the solvent had been removed under reduced pressure, the oily residue (**12**) was coupled with H-Pro-OBu^t (prepared from Z-Pro-OBu^t (1.67 g)) in THF by the EDC–HOBt method in a manner similar to that described for the preparation of **9** (Method (a)). The final purification was performed on a silica-gel column, with hexane–EtOAc (1:1) as the eluent; yield, 2.23 g (61%); syrup, $[\alpha]_D^{25}$ −78.8° (*c* 1.0, MeOH). Found: C, 65.00; H, 7.91; N, 7.38. Calcd for $C_{40}H_{56}N_4O_9$: C, 65.20; H, 7.66; N, 7.60.

b) The tripeptide **13** (322 mg) was hydrogenated in MeOH in the presence of 5% Pd-C (200 mg). After the filtration of the catalyst and the removal of the solvent, the oily residue (**14**) was coupled with Z-Val-OH (152 mg) in THF (2 ml) by the EDC–HOBt method in a manner similar to that described for the preparation of **9** (Method (a)). The final purification was performed by preparative TLC on silica gel with benzene–EtOAc (3:1); yield, 196 mg (51%); $[\alpha]_D^{25}$ −78.1° (*c* 1.0, MeOH).

The *N*-hydroxysuccinimide ester method in CH_2Cl_2 gave a 34% yield after 3 d at 30 °C, while the mixed anhydride method using isobutoxycarbonyl chloride in THF gave a 41% yield.

Tetrapeptide 19. a) The tripeptide **11** (570 mg) was hydrogenated in MeOH in the presence of 5% Pd-C (400 mg). After the filtration of the catalyst and the removal of the solvent, the oily residue (**18**) was coupled with Z-Pro-OH (266 mg) in THF (3 ml) by the EDC–HOBt method in a manner similar to that described for the preparation of **9** (Method (a)). The raw product was purified by recrystallization from EtOAc–petroleum ether; yield, 506 mg (77%); mp 108—110 °C; $[\alpha]_D^{25}$ −84.1° (*c* 1.0, MeOH). Found: C, 64.98; H, 7.71; N, 7.54. Calcd for $C_{40}H_{56}N_4O_9$: C, 65.20; H, 7.66; N, 7.60.

The *N*-hydroxysuccinimide ester method in CH_2Cl_2 (reactant concentration, 0.34 M) gave a 26% yield after 3 d at room temperature. The mixed anhydride method, using isobutoxycarbonyl chloride in THF, gave a 44% yield (duration and temperature, 3 h at 0 °C and then overnight at 25 °C).

b) Z-Pro-Val-OBu^t (140 mg) was treated with 4 M HCl in EtOAc (2 ml) at room temperature for 1.5 h. After the solvent had been removed under reduced pressure, the residue was coupled with **10** (prepared from **7** (185 mg) by catalytic hydrogenation) in THF (2 ml) by the EDC–HOBt method in a manner similar to that described for the preparation of **9** (Method (a)). Subsequent recrystallization from EtOAc–petroleum ether afforded a pure product; yield, 149 mg (59%); mp 108.5—110 °C; $[\alpha]_D^{25}$ −84.4° (*c* 1.0, MeOH).

Z-Val-Phe-OBu^t. This was prepared from Z-Val-OH and H-Phe-OBu^t by the mixed anhydride method, using isobutoxycarbonyl chloride in THF; yield, 72%; mp 102—103 °C (ether–petroleum ether); $[\alpha]_D^{25}$ −32.5° (*c* 1.0, MeOH). Found: C, 68.79; H, 7.60; N, 6.17. Calcd for $C_{26}H_{34}N_2O_5$: C, 68.70; H, 7.54; N, 6.16.

Z-Pro-Val-Phe-OBu^t. This was prepared from Z-Pro-OH and H-Val-Phe-OBu^t (prepared through the debenzyloxycarbonylation of Z-Val-Phe-OBu^t by catalytic hydrogenation) by means of the EDC–HOBt method in THF; yield, 73%; mp 164—166 °C (EtOAc–petroleum ether); $[\alpha]_D^{25}$ −78.5° (*c* 1.0, MeOH). Found: C, 67.34; H, 7.39; N, 7.74. Calcd for $C_{31}H_{41}N_3O_6$: C, 67.49; H, 7.49; N, 7.62.

Tetrapeptide 20. To a solution of **4** (0.69 g) in THF (5 ml), we added EDC·HCl (0.41 g) at 0 °C. After 20 min, a solution of H-Pro-Val-Phe-OBu^t (prepared through the debenzyloxycarbonylation of Z-Pro-Val-Phe-OBu^t (1.01 g) by catalytic hydrogenation with 5% Pd-C (0.28 g) in THF) in THF (5 ml) was added. After the resulting mixture had been stirred at 0 °C overnight, it was evaporated under reduced pressure. The residue was dissolved in EtOAc, washed successively with water, 10% citric acid, water, 4% $NaHCO_3$ and water, and dried over Na_2SO_4. The subsequent removal of the solvent afforded a syrup (1.19 g). A part of this raw product was chromatographed on preparative layers of silica gel with benzene–EtOAc (1:1); yield, 55% (based on Z-Pro-Val-Phe-OBu^t used); syrup, $[\alpha]_D^{25}$ −101.3° (*c* 0.94, MeOH). Found: C, 65.11; H, 7.77; N, 7.60. Calcd for $C_{40}H_{56}N_4O_9$: C, 65.20; H, 7.66; N, 7.60.

α,β-Epoxy Sulfoxides as Useful Intermediates in Organic Synthesis. I. A Novel Synthesis of Dialkyl Ketones and a Synthesis of Aldehydes from Ketones by One Carbon Elongation

Tsuyoshi SATOH, Youhei KANEKO, Takao IZAWA, Kiichi SAKATA, and Koji YAMAKAWA*

Faculty of Pharmaceutical Sciences, Science University of Tokyo, Ichigaya-funagawara-machi, Shinjuku-ku, Tokyo 162

(Received March 12, 1985)

Treatment of α,β-epoxy sulfoxides, prepared from 1-chloroalkyl phenyl sulfoxides with ketones or aldehydes, with sodium benzeneselenolate gives dialkyl ketones or aldehydes in good yields under mild conditions. The mechanism of this reaction and an application of this process to a formal total synthesis of dihydrojasmone are described.

Carbonyl compounds are obviously of most important in synthetic organic chemistry. In the synthesis of ketones with the construction of carbon skeleton, reactions of carboxylic acid or acid halide with organometallic compounds[1] or acid halide with organocopper reagents[2] have extensively been used. Recent years, methods by using organotransition metal catalyst such as palladium are also actively studied.[3] On the other hand, reaction of the "umpolung" reagents involving sulfur compounds acting acyl anion equivalent with alkyl halides or carbonyl compounds is another good method for preparation of carbonyl compounds (Scheme 1).[4] This process, however, has some drawbacks. For example, this reaction usually gives good yields only when primary alkyl halides or active alkyl halides, such as benzyl or allyl halides, are used.

α,β-Epoxy sulfoxides (**4**) were initially reported by Durst in 1969.[5] They are very easily prepared from 1-chloroalkyl phenyl sulfoxide (**1**)[6] and carbonyl compounds (**2**) *via* chlorohydrin (**3**). A few studies on the synthesis of α,β-unsaturated ketones or aldehydes from α,β-epoxy sulfoxides are reported[7] but these interesting compounds have received a scant attention. On the other hand, synthetic methods for a synthesis of α-substituted ketones or aldehydes *via* α,β-epoxy sulfones were reported by Durst[8] and Watt.[9]

Recently, we have found that the β-carbon of α,β-epoxy sulfoxides (**4**) is very reactive to benzeneselenolate to give dialkyl ketones (**5**) or aldehydes (**6**) in excellent yields as shown in Scheme 2.[10] In this paper we describe, in detail, the synthesis of dialkyl ketones and the synthesis of aldehydes from ketones by one carbon elongation through the reaction of α,β-epoxy sulfoxides with sodium benzeneselenolate and an application of this method to a formal total synthesis of dihydrojasmone.

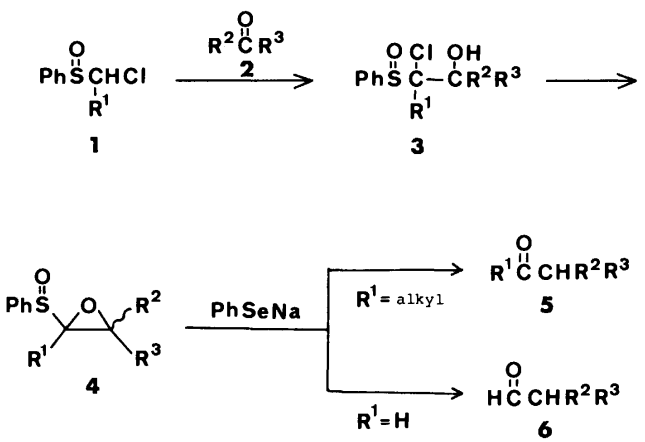
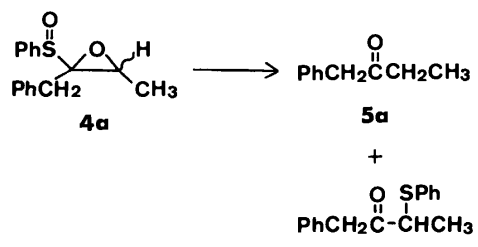


Scheme 2.

Results and Discussion

A Synthesis of Dialkyl Ketones from α,β-Epoxy Sulfoxides. The α,β-epoxy sulfoxide (**4a**) prepared from 1-chloro-2-phenylethyl phenyl sulfoxide and acetaldehyde was treated with three mol equivalents[11] of sodium benzeneselenolate[12] in ethanol under nitrogen for 20 min to give two ketones, 1-phenyl-2-butanone (**5a**) and 1-phenyl-3-phenylthio-2-butanone, in 73 and 18% yields, respectively. The



Scheme 3.

mechanism of this reaction is of some interest. The observation that the α,β-epoxy sulfoxide (**4a**) rapidly yields α-sulfenylated carbonyl compounds (1-phenyl-3-phenylthio-2-butanone) along with the desired 1-phenyl-2-butanone (**5a**) implies that the reaction takes place on the pathway as shown in Scheme 4. Benzeneselenolate attacks the β-carbon of **4a** to give 1-phenyl-3-phenylseleno-2-butanone and benzenesulfenate. The α-phenylseleno ketone was attacked by benzeneselenolate to afford 1-phenyl-2-butanone (**5a**) and diphenyl diselenide.[13] On the other hand, the liberated benzenesulfenate is reduced with benzeneselenol to afford benzenethiolate, which attacks the β-carbon of **4a** competitively with benzeneselenolate to give 1-phenyl-3-phenylthio-2-butanone. As the nucleophilicity of selenolate is known to be higher than that of thiolate and the generated thiolate is less than one equivalent, it is thought that the excess

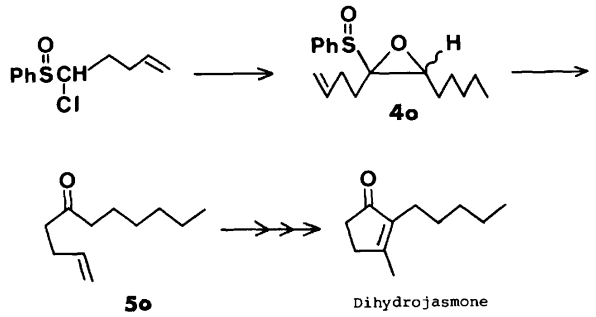
a) Isolated yield after silica-gel column chromatography.

benzeneselenolate exclusively gives the desired ketone with little sulfenylated carbonyl compound. Actually treatment of **4a** with six mol equivalents of sodium benzeneselenolate gave 92% yield of 1-phenyl-2-butanone (**5a**) along with almost no sulfenylated carbonyl compound.

The results of the reaction of various α,β-epoxy sulfoxides (**4**) with excess sodium benzeneselenolate are summarized in Table 1. As shown in Table 1, various kinds of dialkyl ketones were synthesized in good yields under mild conditions. Di-(secondary alkyl) ketones were also synthesized with no problem though at a higher temperature, a larger amount of sodium benzeneselenolate, and a longer period of reaction time were required. It is worth noting that the unreacted sodium benzeneselenolate is recovered as diphenyl diselenide, which was given by oxidation of benzeneselenolate by air, in nearly quantitative yield.



Scheme 5.

This procedure was applied to a formal total synthesis of dihydrojasmone as shown in Scheme 5. Alkylation of chloromethyl phenyl sulfoxide with 4-bromo-1-butene gave 1-chloro-4-pentenyl phenyl sulfoxide in 61% yield. Treatment of this chloride with lithium diisopropylamide followed by hexanal afforded chlorohydrin in 89% yield, which was treated with aqueous potassium hydroxide in methanol to give α,β-epoxy sulfoxide (**4o**) in good yield. The epoxy sulfoxide (**4o**) was treated with six mol equivalents of sodium benzeneselenolate in ethanol at room temperature for 10 min to afford 1-undecen-5-one (**5o**)[14] in 91% yield. This ketone was already converted to dihydrojasmone.[14]

Synthesis of Aldehydes from Ketones by One Carbon Elongation. Many synthetic methods for aldehydes from ketones by one carbon homologation have already been known[15] but they have some advantages and at the same time disadvantages. We have found that the α,β-epoxy sulfoxides (**4**) having hydrogen for R^1 gave aldehydes in excellent yields by the present method. This result means a synthesis of aldehydes (**6**) from ketones (**2**) by one carbon elongation (see Scheme 2). The results of the reaction of α,β-epoxy sulfoxides (**4p—4s**) with sodium benzeneselenolate are summarized in Table 2.

The reaction of **4s** with sodium benzeneselenolate gave 2-methyl-3-phenylthiopropanal (**6s**). This fact may be interpreted as shown in Scheme 6: The α,β-

Table 2. Preparation of aldehydes from ketones via α,β-epoxy sulfoxides

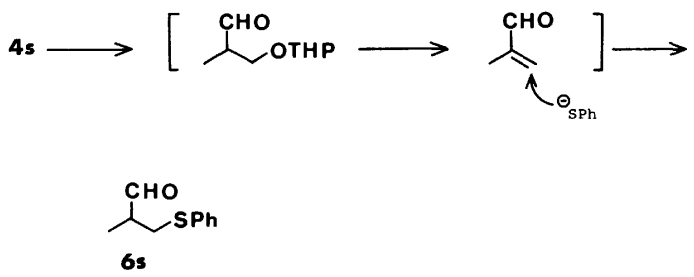

Scheme 6.

epoxy sulfoxide (**4s**) initially gave the aldehyde having tetrahydropyranyloxyl group, which underwent β elimination to afford an enal. Michael addition of benzenethiolate generated from benzenesulfenate (see Scheme 4) to the enal gave the aldehyde having phenylthio group (**6s**).

In conclusion, a novel and versatile procedure for a synthesis of dialkyl ketones and aldehydes has been developed from α,β-epoxy sulfoxides. In regard to the accessibility of the starting material, the simplicity and mildness of the operation, and high yield of the products, the present procedure offers a simple and useful approach to ketones and aldehydes.

Experimental

General. All melting points and boiling points are uncorrected. A Shibata GTO-250 glass tube oven was used for bulb-to-bulb distillation and boiling points are given as the temperature of the heating bath. Infrared (IR) spectra were measured directly on an NaCl plate or in KBr disks with a Hitachi 215 spectrometer. ^{1}H NMR spectra were measured in $CDCl_3$ solution with a JEOL FX-100 puls Fourier-transform spectrometer using Me_4Si as an internal standard. Electron impact mass spectra (MS) were obtained on a Hitachi M-80 double focusing spectrometer at 70 ev by direct insertion. Wako silica gel c-200 containing 2% fluorescence reagent 254 and quartz column were used for column chromatography and the products having UV absorption were detected by ultraviolet irradiation. In experiments requiring dry solvent, THF or ether was distilled from benzophenone ketyl and amines were from calcium hydride.

Preparation of 1-Chloroalkyl Phenyl Sulfoxide. Method A: Alkylation of chloromethyl phenyl sulfoxide with primary alkyl halides (benzyl bromide and 1-iodohexane) was carried out according to Wemple's procedure[6a] to give almost quantitative yield of 1-chloro-2-phenylethyl phenyl sulfoxide [diastereomeric mixture; colorless oil; NMR: δ=2.74 (dd, J=10, 14 Hz), 3.18 (dd, J=10, 14 Hz), 3.58 (dd, J=3, 14 Hz), 3.63 (dd, J=5, 14 Hz), 4.53 (dd, J=3, 10 Hz), 4.67 (dd, J=5, 10 Hz), 7.23 (s), 7.1—7.8 (m)] and 1-chloroheptyl phenyl sulfoxide [diastereomeric mixture; bp 185 °C/1 mmHg†; NMR: δ=0.87 (t, J=6 Hz), 4.39 (dd, J=3.5, 9 Hz), 4.51 (dd, J=3.5, 9 Hz), 7.4—7.8 (m)]. *Method B*: As the alkylation of chloromethyl phenyl sulfoxide with 2-iodopropane or cyclohexyl iodide gave almost no product 1-chloro-2-methylpropyl phenyl sulfoxide and 1-chloro-1-cyclohexylmethyl phenyl sulfoxide were prepared as follows: To a solution of EtONa (55 mmol) in 30 ml of dry EtOH was added thiophenol (50 mmol) followed by isobutyl bromide or cyclohexylmethyl bromide (50 mmol) and the mixture was stirred at room temperature for 3 h. The EtOH was evaporated and the residue was extracted with benzene. The product was distilled to give isobutyl phenyl sulfide (bp 110—114 °C/19 mmHg; 94%) or cyclohexylmethyl phenyl sulfide (bp 117 °C/2 mmHg; 92%). Isobutyl phenyl sulfide (10 mmol) was added to a suspension of *N*-chlorosuccinimide (10.5 mmol) in 30 ml of CCl_4 and the reaction mixture was stirred at room temperature for 2.5 h. The reaction mixture was filtered and the CCl_4 was evaporated. The residue was dissolved with 20 ml of CH_2Cl_2 and cooled to −60 °C. To this solution was added *m*-chloroperbenzoic acid (10 mmol) and the temperature of the reaction mixture was allowed to warm to −40 °C. The reaction mixture was diluted with CH_2Cl_2 and was washed with 10% NaOH followed by sat. aq NH_4Cl. The sulfoxides were separated by flash column chromatography to give 1-chloro-2-methylpropyl phenyl sulfoxide as two diastereomers. Main isomer (a colorless oil; 60%): IR (neat): 1055 (SO) cm^{-1}; NMR: δ=1.14, 1.20 (each 3H, d, J=7 Hz), 2.88 (1H, double septet, J=2, 7 Hz), 4.30 (d, J=2 Hz), 7.4-7.8 (5H, m). Minor isomer (a colorless oil; 25%): IR (neat): 1060 (SO) cm^{-1}; NMR: δ=1.20, 1.24 (each 3H, d, J=7 Hz), 2.40 (1H, octet, J=7 Hz), 4.24 (d, J=7 Hz), 7.4—7.7 (5H, m). Cyclohexylchloromethyl phenyl sulfoxide was synthesized from cyclohexylmethyl phenyl sulfide as similar procedure described above. Main isomer (70% yield): Colorless prisms; mp 86—87 °C; IR (KBr): 1055 (SO) cm^{-1}; NMR: δ=1.0—2.7 (11H, m), 4.31 (1H, d, J=3 Hz), 7.5—7.9 (5H, m). Minor isomer (22% yield): Colorless needles; mp 127—128 °C; IR (KBr): 1060, 1055 (SO) cm^{-1}; NMR: δ=1.0—2.3 (11H, m), 4.24 (1H, d, J=7 Hz), 7.5—7.7 (5H, m). The main isomers were used in this study.

General Procedure for the Preparation of α,β-Epoxy Sulfoxide (4): A synthesis of 2,3-epoxy-1-phenyl-2-phenylsulfinylbutane (**4a**) is described. To a solution of lithium diisopropylamide (3.45 mmol) in dry THF (8 ml) at −70 °C under N_2 was added a solution of 1-chloro-2-phenylethyl phenyl sulfoxide (3 mmol) in 2 ml of dry THF dropwise with stirring. The solution was stirred at −70 °C for 20 min and then acetaldehyde (6 mmol) was added through a syringe and the reaction mixture was stirred for additional 10 min. The reaction was quenched with sat. aq NH_4Cl and the whole was extracted with ether. The products were separated by silica-gel column chromatography (hexane: AcOEt=5:1) to give chlorohydrins (**3a-L**)[24] and (**3a-P**).[24] **3a-L** (40% yield): mp 89—91 °C; IR (KBr): 3360 (OH), 1030 (SO) cm^{-1}; NMR: δ=1.26 (3H, d, J=7 Hz), 3.41, 4.18 (each 1H, d, J=15 Hz), 4.17 (1H, q, J=7 Hz), 7.2—7.8 (5H, m); MS m/z (%): 182 ([M−PhSOH]$^+$, 7), 165 (14), 147 (29), 126 (100), 91 (81). **3a-P** (54% yield): mp 113-115 °C; IR (KBr): 3375 (OH), 1025 (SO) cm^{-1}; NMR: δ=1.40 (3H, d, J=6 Hz), 3.29, 3.42 (each 1H, d, J=15 Hz), 3.83 (1H, q, J=15 Hz), 3.83 (1H, q, J=6 Hz), 7.2—7.8 (5H, m); MS m/z (%): 182 ([M−PhSOH]$^+$, 20), 147 (55), 126 (100), 91 (79); Found: C, 62.21; H, 5.48; S, 10.37; Cl, 11.24%. Calcd for $C_{16}H_{17}SO_2Cl$: C, 62.23; H, 5.55; S,

10.38; Cl, 11.48%. To a solution of **3a-L** (1 mmol) in 12 ml of MeOH was added 30% aq KOH (2.5 ml) dropwise with stirring and the mixture was stirred at room temperature for 1 h. The solution was neutralized by adding NH_4Cl and the MeOH was evaporated. The residue was extracted with ether and the product was purified by silica-gel column chromatography to give 2,3-epoxy-1-phenyl-2-phenylsulfinylbutane (**4a-L**)[25] as colorless oil in 95% yield. IR (neat): 1095, 1055 (SO) cm^{-1}; NMR: δ=1.34 (3H, d, J=6 Hz), 3.05, 3.10 (each 1H, d, J=16 Hz), 3.79 (1H, q, J=6 Hz), 6.9—7.7 (10H, m); MS m/z (%): 272 (M^+, 2), 147 ([M−PhSO]$^+$, 18), 126 (39), 105 (38), 91 (100). Epoxy sulfoxide (**4a-P**)[25] was synthesized from **3a-P** by the similar procedure described above in 98% yield. **4a-P**: IR (neat): 1095, 1055 (SO) cm^{-1}; NMR: δ=1.62 (3H, d, J=6 Hz), 2.45, 3.55 (each 1H, d, J=15 Hz), 2.75 (1H, q, J=6 Hz), 6.9—7.8 (10H, m); MS m/z (%): 272 (M^+, 1.5), 147 ([M−PhSO]$^+$, 20), 126 (49), 105 (40), 91, (100).

2,3-Epoxy-1-phenyl-2-phenylsulfinyloctane (4b). Chlorohydrin **3b-L** (37% yield): Colorless oil; IR (neat): 3375 (OH), 1075, 1020 (SO) cm^{-1}; NMR: δ=0.83 (3H, t, J=6 Hz), 3.38, 4.14 (each 1H, d, J=15 Hz), 3.90 (1H, m), 7.2—7.8 (10H, m). **3b-P** (47% yield): Colorless oil; IR (neat): 3390 (OH), 1075, 1040 (SO) cm^{-1}; NMR: δ=0.87 (3H, t, J=6 Hz), 3.36, 3.50 (each 1H, d, J=14 Hz), 3.52 (1H, m), 7.2—7.9 (10H, m). Epoxy sulfoxide **4b-L** (65% yield): Colorless oil; IR (neat): 1090, 1055 (SO) cm^{-1}; NMR: δ=0.86 (3H, t, J=6 Hz), 1.0—1.7 (8H, m), 3.00, 3.05 (each 1H, d, J=16 Hz), 3.71 (1H, t, J=6 Hz), 7.0—7.7 (10H, m); MS m/z (%): 328 (M^+, trace), 203 (7), 126 (11), 91 (100). **4b-P** (69% yield): Colorless oil; IR (neat): 1090, 1050 (SO) cm^{-1}. NMR: δ=0.89 (3H, t, J=6 Hz), 1.1—2.1 (8H, m), 1.96 (2H, m), 2.54, 3.54 (each 1H, d, J=14 Hz), 2.63 (1H, t, J=6 Hz), 6.8—7.8 (10H, m); MS m/z (%): 328 (M^+, trace), 203 (7), 126 (11), 91 (100).

1,2-Epoxy-1,3-diphenyl-2-phenylsulfinylpropane (4c). Chlorohydrin **3c-L** (37% yield): mp 158—160 °C; IR (KBr): 3320 (OH), 1015 (SO) cm^{-1}; NMR: δ=3.16 4.40 (each 1H, d, J=15 Hz), 5.07 (1H, s), 7.2—8.0 (15H, m); MS m/z (%): 250 (1), 241 (1), 233 (3), 207 (3), 126 (100). **3c-P** (45% yield): Colorless oil; IR (neat): 3350 (OH), 1040 (SO) cm^{-1}; NMR: δ=2.55, 3.30 (each 1H, d, J=15 Hz), 5.41 (1H, s), 7.2—7.8 (15H, m); MS m/z (%): 244 ([M−PhSO]$^+$, 13), 209 (29), 186 (17), 125 (86), 77 (100). Epoxy sulfoxide **4c-L** (50% yield): mp 135.5—136 °C; IR (KBr): 1060 (SO) cm^{-1}; NMR: δ=2.76 (2H, s), 4.87 (1H, s), 7.0—7.7 (15H, m); MS m/z (%): 209 ([M−OhSO]$^+$, 18), 181 (25), 91 (100). **4c-P** (71% yield): mp 112—113 °C; IR (KBr): 1040 (SO) cm^{-1}; NMR: δ=2.66, 3.71 (each 1H, d, J=15 Hz), 3.79 (1H, s), 7.0—7.8 (15H, m); MS m/z (%): 209 ([M−PhSO]$^+$, 19), 181 (28), 91 (100); Found: C, 75.45; H, 5.26; S, 9.69%. Epoxy sulfoxide **4e** (86% yield): mp 61—62 °C; IR (KBr): 1055 (SO) cm^{-1}; NMR: δ=1.2—2.3 (10H, m), 3.24 (2H, s), 6.7—7.7 (10H, m); MS m/z (%): 201 ([M−PhSO]$^+$, 18), 91 (100); Found: C, 73.37; H, 6,76; S, 9.92%. Calcd for $C_{20}H_{22}O_2S$: C, 73.58; H, 6.79; S, 9.82%.

2,3-Epoxy-3-phenylsulfinylnonane (4f). Chlorohydrin **3f-L** (37% yield): mp 62—64 °C; IR (KBr): 3375 (OH), 1085, 1025 (SO) cm^{-1}; NMR: δ=0.93 (3H, t, J=6 Hz), 1.19 (3H, d, J=6 Hz), 1.1—3.0 (10H, m), 4.08 (1H, q, J=6 Hz), 7.5—7.9 (5H, m); MS m/z (%): 250 (2), 126 (100). **3f-P** (52% yield): mp 67—69 °C; IR (KBr): 3360 (OH), 1080, 1035, 1020 (SO) cm^{-1}; NMR: δ=0.89 (3H, t, J=6 Hz), 1.1—2.2 (10H, m), 1.37 (3H, d, J=6 Hz), 4.10 (1H, q, J=6 Hz), 7.4—7.8 (5H, m); MS m/z (%): 241 (1), 126 (100). Epoxy sulfoxide **4f-L** (90% yield): Colorless oil; IR (neat): 1090, 1055 (SO) cm^{-1}; NMR: δ=0.83 (3H, t, J=6 Hz), 0.9—2.0 (10H, m), 1.37 (3H, d, J=6 Hz), 3.73 (1H, q, J=6 Hz), 7.4-7.7 (5H, m); MS m/z (%): 266 (M^+, 4), 141 (12), 126 (29), 57 (100); Found: m/z 266.1353. Calcd for $C_{15}H_{22}O_2S$: M, 266.1339. **4f-P** (92% yield): Colorless oil; IR (neat): 1090, 1050 (SO) cm^{-1}; NMR: δ=0.81 (3H, t, J=6 Hz), 0.9—2.3 (10H, m), 1.77 (3H, d, J=6 Hz), 3.39 (1H, q,J=6 Hz), 7.4—7.7 (5H, m); MS m/z (%): 266 (M^+, 3), 141 (10), 126 (23), 57 (100); Found: m/z 266.1325. Calcd for $C_{15}H_{22}O_2S$: M, 266.1339.

6,7-Epoxy-7-phenylsulfinyltridecane (4g). Chlorohydrin **3g-L** (39% yield): Colorless oil; IR (neat): 3350 (OH), 1075, 1035 (SO) cm^{-1}; NMR: δ=0.83, 0.93 (each 3H, t, J=6 Hz), 3.82 (1H, dd, J=4, 8 Hz), 7.4—7.9 (5H, m); MS m/z (%): 306 (1), 233 (9), 161 (34), 126 (100). **3g-P** (61% yield): Colorless oil; IR (neat): 3375 (OH), 1075, 1035 (SO) cm^{-1}; NMR: δ=0.95 (6H, t, J=6 Hz), 3.70 (1H, dd, J=2, 9 Hz), 7.4-7.8 (5H, m); MS m/z (%): 306 (1), 197 (7), 161 (62), 41 (100). Epoxy sulfoxide **4g-L** (93% yield): Colorless oil; IR (neat): 1090, 1055 (SO) cm^{-1}; NMR: δ=0.84, 0.88 (each 3H, t, J=6 Hz), 3.63 (1H, t, J=6 Hz), 7.4—7.7 (5H, m); MS m/z (%): 322 (M^+, 0.5), 197 (12), 113 (77), 43 (100). **4g-P** (87% yield): Colorless oil; IR (neat): 1090, 1050 (SO) cm^{-1}; NMR: δ=0.81, 0.94 (each 3H, t, J=6 Hz), 3.25 (1H, t, J=6 Hz), 7.4—7.7 (5H, m); MS m/z (%): 322 (M^+, 0.5), 197 (16), 113 (100).

1,2-Epoxy-1-phenyl-2-phenylsulfinyloctane (4h). Chlorohydrin **3h-L** (45% yield): mp 133—134 °C; IR (KBr): 3325 (OH), 1035 (SO) cm^{-1}; NMR: δ=0.89 (3H, t, J=6 Hz), 1.1—2.1 (10H, m), 4.92 (1H, s), 7.24 (5H, s), 7.5—8.0 (5H, m); MS m/z (%)+ 238 ([M−PhSOH]$^+$, 9), 203 (17), 126 (69), 105 (100). **3h-P** (34% yield): mp 99—100 °C; IR (KBr): 3350 (OH), 1035 (SO) cm^{-1}; NMR: δ=0.83 (3H, t, J=6 Hz), 0.9—2.0 (10H, m), 5.29 (1H, s), 7.2—7.9 (10H, m); MS m/z (%): 238 ([M−PhSOH]$^+$, 11), 203 (25), 133 (22), 126 (33), 107 (100). Epoxy sulfoxide **4h-L** (99% yield): mp 55—56 °C; IR (KBr): 1085 1055 (SO) cm^{-1}; NMR: δ=0.80 (3H, t, J=6 Hz), 0.8—1.7 (10H, m), 4.78 (1H, s), 7.1—7.8 (10H, m); MS m/z (%): 328 (M^+, 0.4), 203 ([M−PhSO]$^+$, 14), 91 (100); Found: C, 73.02; H, 7.36; S, 10.00%; M^+, 328.1500. Calcd for $C_{20}H_{24}O_2S$: C, 73.13; H, 7.36; S, 9.76%; M, 328.1496. **4h-P** (95% yield): mp 38—39 °C; IR (KBr): 1085, 1045 (SO) cm^{-1}; NMR: δ=0.84 (3H, t, J=6 Hz), 1.0—2.4 (10H, m), 4.41 (1H, s), 7.3—7.8 (10H, m); MS m/z (%): 328 (M^+, trace), 203 ([M−

PhSO]$^+$, 15), 91 (100); Found: *m/z* 328.1507. Calcd for $C_{20}H_{24}O_2S$: M, 328.1495.

1,2-Epoxy-1-(4-chlorophenyl)-2-phenylsulfinyloctane (4i). Chlorohydrin **3i-L** (41% yield): mp 67—69 °C; IR (KBr): 3230, 1040 (SO) cm^{-1}; NMR: δ=0.90 (3H, t, J=6 Hz), 4.93 (1H, s), 7.28 (4H, s), 7.6—8.0 (5H, m); MS *m/z* (%): 398 (M$^+$, trace), 272 (5), 237 (7), 141 (33), 139 (31), 126 (100). **3i-P** (49% yield): Colorless crystals; mp 114—115 °C; IR (KBr): 3330 (OH), 1045 (SO) cm^{-1}; NMR: δ=0.85 (3H, t, J=6 Hz), 5.43 (1H, d, J=2.5 Hz), 7.2—7.9 (9H, m); MS *m/z* (%): 272 ([M−PhSOH]$^+$, 16), 237 (36), 167 (42), 141 (100). Epoxy sulfoxide **4i-L** (93% yield): Colorless oil; IR (neat): 1090, 1060 (SO) cm^{-1}; NMR: δ=0.81 (3H, t, J=6 Hz), 4.74 (1H, s), 7.0—7.8 (9H, m); MS *m/z* (%): 362 (M$^+$, trace), 237 (14), 125 (100). **4i-P** (90% yield): Colorless crystals; mp 76—77 °C; IR (KBr): 1090, 1050 (SO) cm^{-1}; NMR: δ=0.84 (3H, t, J=6 Hz), 4.38 (1H, s), 7.3—7.8 (9H, m); MS *m/z* (%): 362 (M$^+$, trace), 237 ([M−PhSO]$^+$, 18), 125 (100); Found: C, 66.13; H, 6.32; Cl, 9.89; S, 8.81%. Calcd for $C_{20}H_{23}ClO_2S$: C, 66.19; H, 6.39, Cl, 9.77; S, 9.08%.

2'-Hexyl-2'-phenylsulfinylspiro[cyclohexane-1,1'-oxirane] (4j). Chlorohydrin **3j** (99% yield): Colorless crystrals; mp 73—74 °C; IR (neat): 3345 (OH), 1035 (SO) cm^{-1}; NMR: δ=0.84 (3H, t, J=6 Hz), 7.3—7.8 (5H, m). Epoxy sulfoxide **4j** (76% yield): Colorless oil; IR (neat): 1080, 1045 (SO) cm^{-1}; NMR: δ=0.78 (3H, t, J=6 Hz), 7.4—7.7 (5H, m); MS *m/z* (%): 195 ([M−PhSO]$^+$, 57), 126 (10), 113 (100).

2'-Isopropyl-2'-phenylsulfinylspiro[cyclohexane-1,1'-oxirane] (4k). Colorless crystals; mp 84—85 °C; 94% yield from 1-chloro-2-methylethyl phenyl sulfoxide *via* chlorohydrin (**3k**); IR (KBr): 1050 (SO) cm^{-1}; NMR: δ=0.59, 1.17 (each 3H, d, J=7 Hz), 1.4—2.3 (10H, m), 2.66 (1H, septet, J=7 Hz), 7.3—7.7 (5H, m); MS *m/z* (%): 278 (M$^+$, trace), 262 (1.2), 218 (8), 191 (16), 43 (100); Found: C, 68.89; H, 8.02; S, 11.57%. Calcd for $C_{16}H_{22}O_2S$: C, 69.03; H, 7.97; S, 11.52%.

2''-Isopropyl-2''-phenylsulfinyldispiro[1,3-dioxolane-2,1'-cyclohexane-4',1''-oxirane] (4l). Chlorohydrin **3l** (97% yield): Colorless oil; IR (neat): 3400 (OH), 1040 (SO) cm^{-1}; NMR: δ=1.37, 1.42 (each 3H, d, J=6 Hz), 3.88 (4H, s), 7.3—7.8 (5H, m). Epoxy sulfoxide **4l** (92% yield): Colorless crystals; mp 73—76 °C; IR (KBr): 1090, 1050, 1040 (SO) cm^{-1}; NMR: δ=0.59, 1.16 (3H, d, J=7 Hz), 1.6—2.5 (4H, m), 2.68 (1H, septet, J=7 Hz), 4.01 (4H, s), 7.4—7.7 (5H, m); MS *m/z* (%): 336 (M$^+$, trace), 249 (trace), 211 (55), 99 (100); Found: C, 64.27; H, 7.26; S, 9.60%; M$^+$, 336.1383. Calcd for $C_{18}H_{24}O_4S$: C, 64.26; H, 7.19; S, 9.53%; M, 336.1393.

1,2-Epoxy-2-(4-chlorophenyl)-1-cyclohexyl-1-phenylsulfinylethane (4m). Chlorohydrin **3m-L** (46% yield): Colorless crystals; mp 165—167 °C; IR (KBr): 3350 (OH), 1045 (SO) cm^{-1}; NMR: δ=1.0—2.9 (11H, m), 5.17 (1H, s), 7.2—8.1 (9H, m); MS *m/z* (%): 270 (4), 139 (100). **3m-P** (51% yield): Colorless crystals; mp 164—166 °C; IR (KBr): 3175 (OH), 1015 (SO) cm^{-1}; NMR: δ=0.9—2.6 (11H, m), 5.78 (1H, s), 7.3—7.8 (9H, m); MS *m/z* (%): 270 (10), 252 (15), 217 (63), 78 (100). Epoxy sulfoxide **4m-L** (95% yield): Colorless crystals; mp 131—132 °C; IR (KBr): 1090, 1050 (SO) cm^{-1}; NMR: δ=0.6—1.9 (11H, m), 4.63 (1H, s), 7.2—7.5 (4H, m), 7.5—8.0 (5H, m); MS *m/z* (%): 360 (M$^+$, 0.6), 344 (2), 125 (88), 83 (100); Found: C, 66.43; H, 5.70; Cl, 9.89; S, 8.98%. Calcd for $C_{20}H_{21}ClO_2S$: C, 66.56; H, 5.86; Cl, 9.82; S, 8.88%. **4m-P** (80% yield): Colorless crystals; mp 137—138 °C; IR (KBr): 1090, 1040 (SO) cm^{-1}; NMR: δ=0.6—2.4 (11H, m), 4.42 (1H, s), 7.44 (4H, m), 7.4—7.8 (5H, m); MS *m/z* (%): 344 (trace), 235 (14), 207 (4), 125 (100).

2'-Cyclohexyl-2'-phenylsulfinylspiro[cyclohexane-1,1'-oxirane] (4n). 32% overall yiels from 1-chloro-1-cyclohexylmethyl phenyl sulfoxide and cyclohexanone *via* chlorohydrin (**3n**): Colorless crystals; mp 104—105.5 °C; IR (KBr): 1090, 1055 (SO) cm^{-1}; NMR: δ=0.5—2.5 (methylene-H), 7.3—7.8 (5H, m); MS *m/z* (%): 193 ([M−PhSO]$^+$, 29), 126 (11), 111 (41), 83 (100); Found: C, 71.40; H, 8.15%. Calcd for $C_{19}H_{26}O_2S$: C, 71.66; H, 8.23%.

2'-Phenylsulfinylspiro[5α-cholestane-3,1'-oxirane] (4q). Chlorohydrin **3q-L** (55% yield): Colorless oil; IR (neat): 3430 (OH), 1060 (SO) cm^{-1}; NMR: δ=0.66 (3H, s), 0.89 (6H, d, J=7 Hz), 0.91 (3H, d, J=7 Hz), 0.99 (3H, s), 4.79 (1H, s), 7.62 (5H, s). **3q-P** (39% yield): Colorless oil; IR (neat): 3400 (OH), 1050 (SO) cm^{-1}; NMR: δ=0.66 (3H, s), 0.88 (6H, d, J=7 Hz), 0.91 (3H, d, J=7 Hz), 1.01 (3H, s), 4.30 (1H, s), 7.60 (5H, m). Epoxy sulfoxide **4q-L** (96% yield): Colorless crystals; mp 142—143 °C; IR (KBr): 1050 (SO) cm^{-1}; NMR: δ=0.67 (3H, s), 0.88 (6H, d, J=7 Hz), 0.92 (3H, d, J=7 Hz), 1.04 (3H, s), 3.68 (1H, s), 7.5—7.9 (5H, m); Found: C, 78.03; H, 10.07%. Calcd for $C_{34}H_{52}O_2S$: C, 77.81; H, 9.99%. **4q-P** (94% yield): Colorless crystals; mp 137—140 °C; IR (KBr): 1055 (SO) cm^{-1}; NMR: δ=0.67 (3H, s), 0.89 (6H, d, J=7 Hz), 0.92 (3H, d, J=7 Hz), 1.02 (3H, s), 3.74 (1H, s), 7.5—7.9 (5H, m); Found: C, 77.87; H, 10.03%. Calcd for $C_{34}H_{52}O_2S$: C, 77.81; H, 9.99%.

2'-Phenylsulfinylspiro[indan-2,1'-oxirane] (4r). Chlorohydrin **3r** (86% yield): Colorless crystals; mp 193—195 °C; IR (KBr): 3420 (OH), 1050 (SO) cm^{-1}. Epoxy sulfoxide **4r** (85% yield): Colorless crystals; mp 77—78 °C; IR (KBr): 1060 (SO) cm^{-1}; NMR: δ=3.07, 3.36, 3.52, 3.94 (each 1H, d, J=18 Hz), 4.08 (1H, s), 7.28 (4H, m), 7.5—7.9 (5H, m); MS *m/z* (%): 193 ([M−C_6H_5]$^+$, 0.3), 145 (10), 117 (100); Found: C, 70.93; H, 5.17%. Calcd for $C_{16}H_{14}O_2S$: C, 71.08; H, 5.22%.

1,2-Epoxy-2-methyl-1-phenylsulfinyl-3-(tetrahydropyranyloxy)propane (4s). Chlorohydrin **3s** (99% yield): Colorless oil (about 2:1 diastereomeric mixture); IR (neat); 3340 (OH), 1040 (SO) cm^{-1}. Epoxy sulfoxide **4s** (94% yield): Colorless oil (diastereomeric mixture); IR (neat): 1020 (SO) cm^{-1}; NMR: δ=1.51, 1.76 (s, CH_3).

General Procedure for the Preparation of Dialkyl Ketones (5) or Aldehydes (6) from *α,β-Epoxy Sulfoxides (4)*: A synthesis of 1-phenyl-2-butanone (**5a**) is described. Note that both isomers of the *α,β*-epoxy sulfoxides (**4**) shows almost the same reactivity toward benzeneselenolate. $NaBH_4$(34 mg; 0.9 mmol) was added to a suspension of diphenyl diselenide (140 mg; 0.45 mmol) in 2 ml of EtOH by portions with stirring. After vigorous hydrogen gas evolution ceased, a solution of **4a** (41 mg; 0.15 mmol) in small amount of EtOH was added to the selenolate solution through a syringe under nitrogen. The reaction mixture was stirred at room temperature for 20 min. The reaction mixture was neutralized by NH_4Cl and the EtOH was evaporated. The residue was extracted with ether and, after usual work-up, the product was purified by silica-gel column chromatography followed by bulb-to-bulb distillation (150 °C/15 mmHg) to give 20.5 mg (92%) of 1-phenyl-2-butanone (**5a**). When this reaction was carried out with 3 mol equivalents of sodium benzeneselenolate, 1-phenyl-3-phenylthio-2-butanone (18%) was obtained with 73% of **5a**. 1-Phenyl-3-phenylthio-2-butanone: Colorless oil; IR (neat): 1720 (CO) cm^{-1}; NMR: δ=1.37 (3H, d, J=7 Hz), 3.83 (1H, q, J=7 Hz), 3.92 (2H, s), 7.0—7.5 (10H, m); MS *m/z* (%): 256

(M^+, 18), 147 (19), 137 (100); Found: *m/z* 256.0922. Calcd for $C_{16}H_{16}OS$: M, 256.0921.

1-Phenyl-2-octanone (5b). Colorless oil; IR (neat): 1710 (CO) cm^{-1}; NMR: δ=0.85 (3H, t, J=6 Hz), 2.43 (2H, t, J=6.5 Hz), 3.66 (2H, s), 7.24 (5H, m); MS *m/z* (%): 204 (M^+, 2), 113 (100), 91 (49); Found: *m/z* 204.1512. Calcd for $C_{14}H_{20}O$: M, 204.1513.

1-Cyclohexyl-2-phenylethanone (5e). Bp 135 °C/2.5 mmHg; IR (neat): 1720 (CO) cm^{-1}; NMR: δ=1.0—2.0 (10H, m), 2.44 (1H, m), 3.72 (2H, s), 7.22 (5H, m).

1-(4-Chlorophenyl)-2-octanone (5i). Colorless oil; IR (neat): 1715 (CO) cm^{-1}; NMR; δ=0.86 (3H, t, J=6 Hz), 1.1—1.7 (8H, m), 2.44 (2H, t, J=7 Hz), 3.64 (2H, s), 7.0—7.3 (4H, m); MS *m/z* (%): 238 (M^+, 3), 125 (29), 113 (100); Found: *m/z* 238.1111. Calcd for $C_{14}H_{19}ClO$: M, 238.1122.

1-(4,4-Ethylenedioxycyclohexyl)-2-methyl-1-propanone (5l). Bp 115 °C/3 mmHg; IR (neat): 1715 (CO) cm^{-1}; NMR: δ=1.09 (6H, d, J=7 Hz), 2.50 (1H, m), 2.79 (1H, septet, J=7 Hz), 3.95 (4H, s); MS *m/z* (%): 212 (M^+, 12), 169 (3), 141 (15), 99 (100), 86 (66); Found: *m/z* 212.1387. Calcd for $C_{12}H_{20}O_3$: M, 212.1400.

2-(4-Chlorophenyl)-1-cyclohexylethanone (5m). Mp 97—98 °C; IR (KBr): 1700 (CO) cm^{-1}; NMR: δ=1.0—2.0 (10H, m), 2.42 (1H, m), 3.69 (2H, s), 6.98—7.32 (4H, m); MS *m/z* (%): 236 (M^+, 2), 125 (16), 111 (32), 83 (100); Found: *m/z* 236.0954. Calcd for $C_{14}H_{17}ClO$: M, 236.0967.

3-Formyl-5α-cholestane (6q). Colorless oil; IR (neat): 2720 (CHO), 1740 (CO) cm^{-1}; NMR: δ=0.64 (3H, s), 0.87 (6H, d, J=7 Hz), 0.90 (3H, d, J=7 Hz), 0.96 (3H, s), 9.67 (1H, d, J=2 Hz); MS *m/z* (%): 400 (M^+, 61), 385 (31), 382 (61), 245 (100).

2-Methyl-3-phenylthiopropanal (6s). Colorless oil; IR (neat): 2740 (CHO), 1735 (CO) cm^{-1}; NMR: δ=1.24 (3H, d, J=7 Hz), 2.63 (1H, m), 2.93, 3.33 (each 1H, dd, J=7, 14 Hz), 7.33 (5H, m), 9.71 (1H, d, J=1 Hz); MS *m/z* (%): 180 (M^+, 16), 158 (16), 123 (13), 110 ([M−C_4H_6O]$^+$, 100).

A Formal Total Synthesis of Dihydrojasmone: Alkylation of chloromethyl phenyl sulfoxide with 4-bromo-1-butene in the Method A afforded 61% yield of 1-chloro-4-pentenyl phenyl sulfoxide as an oil; IR (neat): 1640 (C=C), 1085, 1055 (SO) cm^{-1}; NMR: δ=1.6—2.5 (4H, m), 4.50 (dd, J=3, 14 Hz), 4.59 (dd, J=3, 10 Hz), 4.98—5.21 (2H, m), 5.55—5.97 (1H, m), 7.4—7.9 (5H, m); MS *m/z* (%): 228 (M^+, 1), 126 (100). This was treated with LDA in THF at −50 °C for 15 min followed by slight excess hexanal to give chlorohydrins (**3o-L**) and (**3o-P**) in 60 and 29% yield, respectively. **3o-L**: Colorless oil; IR (neat): 3350 (OH), 1080, 1040 (SO) cm^{-1}; NMR: δ=0.83 (3H, t, J=6 Hz), 3.88 (1H, dd, J=3, 7.5 Hz), 4.97—5.24 (2H, m), 5.84 (1H, ddt, J=6, 10, 17 Hz), 7.4—7.9 (5H, m); MS *m/z* (%): 259 ([M−C_4H_9]$^+$, 3), 203 (6), 126 (100). **3o-P**: Colorless oil; IR (neat): 3380 (OH), 1080, 1050 (SO) cm^{-1}; NMR: δ=0.88 (3H, t, J=6 Hz), 3.67 (1H, dd, J=2.5, 9 Hz), 4.88—5.16 (2H, m), 5.74 (1H, ddt, J=6, 10, 17 Hz), 7.4—7.8 (5H, m); MS *m/z* (%): 259 ([M−C_4H_9]$^+$, 1), 203 (5), 126 (100).

These chlorohydrins were treated with aq KOH in MeOH at room temperature for 2 h to give α,β-epoxy sulfoxide (**4o-L**) and (**4o-P**) in 56 and 99% yield, respectively. **4o-L**: Colorless oil; IR (neat): 1090, 1055 (SO) cm^{-1}; NMR: δ=0.89 (3H, t, J=6 Hz), 3.68 (1H, t, J=6 Hz), 4.8—5.0 (2H, m), 5.62 (1H, ddt, J=6, 10, 17 Hz), 7.5—7.8 (5H, m); MS *m/z* (%): 292 (M^+, trace), 167 (5), 126 (11), 83 (48), 55 (100). **4o-P**: Colorless oil; IR (neat): 1090, 1055 (SO) cm^{-1}; NMR: δ=0.94 (3H, t, J=6 Hz), 3.27 (1H, t, J=6 Hz), 4.74—5.02 (2H, m), 5.58 (1H, ddt, J=6, 10, 17 Hz), 7.4—7.7 (5H, m); MS *m/z* (%): 292 (M^+, trace), 167 (4), 126 (11), 83 (55), 55 (100).

The α,β-epoxy sulfoxide (**4o-P**) or (**4o-L**) was treated with 6 mol equivalents of sodium benzeneselenolate in EtOH at room temperature for 10 min. The reaction mixture was neutralized by NH_4Cl and the EtOH was evaporated. After usual work-up, the product was purified by silica-gel column chromatography to give 91% yield of 1-undecene-5-one as an oil. Bp 95 °C/16 mmHg; IR (neat): 1715 (CO), 1645 (C=C) cm^{-1}; NMR: δ=0.88 (3H, t, J=6 Hz), 4.84—5.12 (2H, m), 5.56—6.00 (1H, m); MS *m/z* (%): 168 (M^+, 6), 113 ([M−C_4H_7]$^+$, 86), 83 ([M−C_6H_{13}]$^+$, 50), 43 (100).

Nucleophilic Aminomethylation of Aldehydes with α-Amino Alkylsilanes

Otohiko TSUGE,* Junji TANAKA, and Shuji KANEMASA
Research Institute of Industrial Science, and Department of Molecular Science and Technology, Interdisciplinary Graduate School of Engineering Sciences, Kyushu University, Kasugakoen, Kasuga 816
(Received March 14, 1985)

Fluoride-induced desilylation of (α-phthalimido-, α-morpholino-, and α-acetamidobenzyl)silanes and a (phthalimidomethyl)silane generates the corresponding α-amino carbanions which add to a variety of aldehydes. The conversion of phthalimido group of the adducts into amino moiety leads to β-amino alcohols. This simple reaction sequence offers a new and general method of nucleophilic aminomethylation.

Removal of a proton from a carbon adjacent to nitrogen leads to an α-amino carbanion synthon which is important for nucleophilic aminomethylation. However, deprotonation at the α-position of amines is generally quite difficult since the α-hydrogen is not highly acidic.[1] When the nitrogen bears a strongly electron-withdrawing substituent or the nitrogen is incorporated in a system in which an anion formed can be stabilized by delocalization, some successful deprotonation has been achieved.[2] Thus, such dipole-stabilized α-amino carbanions[3,4] as α-metalated amides, *N*-nitrosoamines, amidines, amine oxides and such resonance-stabilized α-amino carbanions[5,6] as α-metalated imines, isocyanides are now available and have found wide applications in organic synthesis.

Although not widely developed so far, the use of isolable organometallic compounds with an amino moiety at the α-position offers a fascinating access to the α-amino carbanions. One example is the transmetalation reaction of (α-amino alkyl)tins with alkyllithiums leading to α-amino carbanions of nonstabilized type.[7,8] This method would be useful in organic synthesis if the starting α-amino organometallic compounds are readily available, because the regioselective carbanion generation that is difficult at the α-position of amino substituent could be possible even if some other more acidic hydrogens are present in the same molecule.[9]

It has been recently reported that (α-alkoxybenzyl)-silanes are smoothly desilylated by the action of a fluoride ion forming α-alkoxy carbanions which react with a variety of carbonyl compounds as a useful synthon for nucleophilic hydroxymethylation.[10] As this method has an advantage of regioselective carbanion formation under nearly neutral conditions, its extention to other hetero-substituted silanes has been investigated.

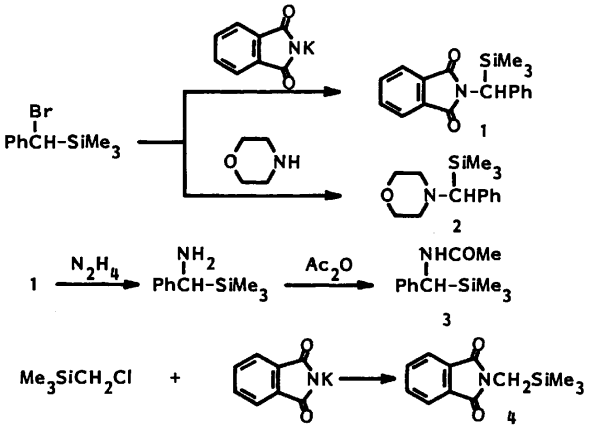
The present paper describes a new approach to nucleophilic aminomethylation using α-aminobenzylsilanes and an aminomethylsilane which carry phthalimido, morpholino, and acetamido moieties as amino substituents.

Results and Discussion

(α-Amino alkyl)silanes were synthesized by the reactions of readily available (α-halo alkyl)silanes with amines as shown in Scheme 1. Thus, (α-phthalimidobenzyl)trimethylsilane **1** and (α-morpholinobenzyl)trimethylsilane **2** were obtained in excellent yields in the reactions of (α-bromobenzyl)trimethylsilane, prepared by the bromination of benzyltrimethylsilane with *N*-bromosuccinimide,[11] with potassium phthalimide and morpholine, respectively. Hydrazinolysis of **1** provided (α-aminobenzyl)trimethylsilane which was then acetylated to give (α-acetamidobenzyl)trimethylsilane **3**. Phthalimidomethyltrimethylsilane **4** was obtained from the reaction of potassium phthalimide with (chloromethyl)trimethylsilane which was commercially available.

α-Amino carbanion formation from the α-aminobenzylsilanes **1**, **2**, and **3** was accomplished by the action of a fluoride ion in such aprotic polar solvents as *N*,*N*-dimethylformamide (DMF) and hexamethylphosphoric triamide (HMPA) at room temperature, and the carbanions generated were attempted to capture with aldehydes as β-amino alcohols.

The reaction of **1** with benzaldehyde (1 equiv) in the presence of cesium fluoride (1 equiv) in dry DMF,



Scheme 1.

at room temperature under nitrogen, furnished a mixture of erythro and threo isomers (1:1) of 1,2-diphenyl-2-phthalimidoethanol **5a** as shown in Scheme 2 and Table 1. Each isomer of **5a** was separable from the other through a flash chromatography over silica gel, their structures being confirmed by their conversion into the known erythro and threo isomers of 2-amino-1,2-diphenylethanol as mentioned later.

The same reaction was carried out as well by the use of a catalytic amount of tetrabutylamonium fluoride (TBAF) under similar conditions. As a solvent, HMPA could be effectively employed, but separation of the solvent from the crude reaction mixture was rather annoying. The reaction in tetrahydrofuran (THF) was found not practical because only a very sluggish reaction occurred in this solvent.

Other aldehydes such as *p*-substituted benzaldehydes (*p*-methyl- and *p*-methoxybenzaldehyde), a heteroaromatic aldehyde (2-furancarbaldehyde), and an α,β-unsaturated aldehyde (cinnamaldehyde) also successfully reacted with **1** under similar conditions giving good to fair yields of the corresponding β-phthalimido-β-phenyl alcohols **5b** to **5e**. In all cases, the ratios of erythro and threo isomers were found to be 1:1, and their separation was carried out without any difficulty through a flash chromatography over silica gel. In the reaction of **1** with an aliphatic aldehyde (butanal), comparable amounts of the desired adduct **5f** and *N*-benzylphthalimide **9** were obtained. The formation of **9** as a protodesilylated product of **1** might be because the aldehyde carries acidic α-hydrogens which could protonate the carbanion species generated from **1** resulting in the formation of **9** and also the decrease of the yield of **5f**. The erythro/threo ratio in this case was 1/2, their separation being easy.

Trapping the α-amino carbanion of **1** with ketones (cyclohexanone and acetophenone), an imine (*N*-benzylideneaniline), and an α,β-unsaturated ester (methyl crotonate) was all unsuccessful. The only

4	Me_3CCHO	TBAF (0.05×2)	100	2+2	**8g**	Me_3C	28	**10** (39)

a) In the reactions of **4**, TBAF was added in two portions at the time intervals shown in Table. b) Isolated yields as mixtures of erythro and threo isomers with the ratio of 1:1 in all cases of **5** to **7** except for **5f** which is composed of 1:2 erythro/threo isomers.

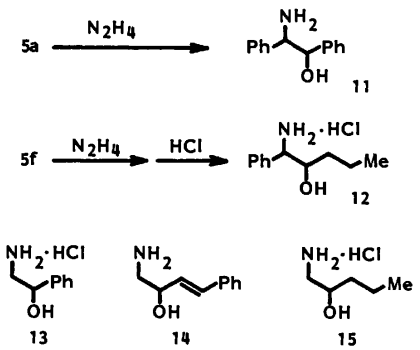
isolated product from **1** was **9** in each case.

The phthalimido moiety as an amino substituent could be replaced with others such as a morpholino and an acetamido moiety as well. Thus, the reactions of (α-morpholinobenzyl)- **2** and (α-acetamidobenzyl)-trimethylsilane **3** with benzaldehyde under similar conditions gave satisfied yields of 2-aminoethanols **6** and **7**, respectively, which were unseparable mixtures of erythro and threo isomers (1:1). From these results, it is easily indicated that other dialkylamino substituents might be able to use in the present reaction since the easiness of desilylation of (α-amino-substituted benzyl)silanes seems independent upon the carbanion-stabilizing ability of the amino substituents. Surprising was that even a secondary amide group with a highly acidic NH hydrogen has led to the smooth generation and longtime survival of the α-acetamido carbanion which reacted with the aldehyde leading to **7** with no trace of the corresponding protodesilylated product.

The phthalimidomethylsilane **4**, carrying no anion-stabilizing substituent such as a phenyl in **1**, was only desilylated very slowly at room temperature as shown in Table 2. In addition, the α-amino carbanion generated from **4** showed the preference for the proton abstraction from somewhere forming *N*-methylphthalimide **10** rather than the addition to benzaldehyde giving the 2-aminoethanol **8a**. Although it was certain that the reaction using a catalytic amount of fluoride was more favored for the formation of **8a**, a trouble was that some of the starting **4** remained unchanged even if the reaction time was prolonged. This problem was resolved by the addition of another portion of fresh catalyst (fluoride) sometime in the course of reaction. In this way the yield of **8a** increased up to 60% and that of the undesired product **10** was suppressed down to 16% (Table 2). As the formyl hydrogen in DMF which was used as a solvent was suspected to be a possible proton source for the formation of side-product **10**,[12] a similar reaction in dry HMPA was carried out. However, only nearly identical results were obtained providing no solution to our concern on the proton source.

Table 1 shows the results of reactions of **4** with a variety of aldehydes. Every reaction was performed at 100 °C using two portions of catalytic amounts of TBAF which were added in the intervals of reaction times shown in Table 1. The α-phthalimido carbanion generated from **4** was found also unreactive toward ketones, α,β-unsaturated esters, and imines.

The removal of the phthalimido protecting group of **5** and **8** permits the establishment of a synthetic route of β-amino alcohols *via* a nucleophilic aminoalkylation onto aldehydes. In fact it was found easy to convert the phthalimido group into amino moiety through a hydrazinolysis using hydrazine hydrate. Thus, some of the 2-phthalimidoethanols **5** and **8** that were listed in Table 1 were subjected to the hydrazynolysis (Scheme 3 and Table 3). Both erythro and threo isomers of **5a** and **5f** were separately deprotected giving the erythro and threo isomers of β-amino alcohols **11** and **12**, respectively, in almost quantitative yields. The structures of *erythro*-**11** and *threo*-**11** were confirmed by the comparison of the spectral data and physical properties with those of the authentic samples.



Scheme 3.

Table 2. Reactions of **4** with benzaldehyde under various conditions

Reaction conditions[a]				Products (yield/%)[b]

a) **4**: benzaldehyde = 1:1.5 in 2 ml of solvents per 1 mmol of **4**. b) All isolated yields.

Similarly other 2-phthalimidoethanols **8a**, **8e**, and **8f** were treated with hydrazine hydrate under reflux in ethanol giving excellent yields of **13**, **14**, and **15**, respectively.

As mentioned above, the reactions of **1** with a variety of aldehydes gave mixtures of comparable amounts of erythro and threo isomers of **5** and these isomers were readily separable by a flash chromatography. The only remarkable difference in the spectral data of *erythro*-**5a** and *threo*-**5a**, whose structures were confirmed by their derivation to the known β-amino alcohols, *erythro*-**11** and *threo*-**11**, is that the hydroxyl proton appears considerably lower in *erythro*-**5a** than in *threo*-**5a** (Table 4).

Table 3. Hydrazinolysis of 2-phthalimidoethanols **5** and **8**

2-Phthalimido-ethanols	Reaction time/h[a]	Products	Yield[b] %

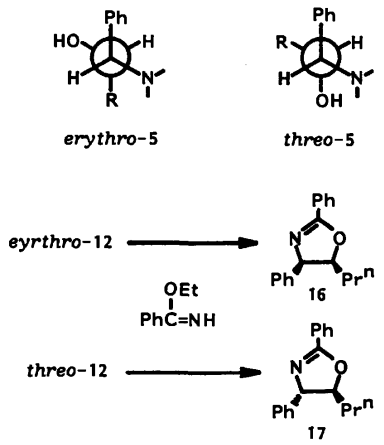
8a	4	**13**	82
8e	4	**14**	97
8f	2	**15**	99

a) The time for hydrazinolysis under reflux in ethanol. b) All isolated yields.



Scheme 4.

In Scheme 4, the most stable conformers for *erythro*-**5** and *threo*-**5** were illustrated. These models show that both the methine hydrogens α and β to the hydroxyl group of *erythro*-**5** look magnetically almost equivalent to those of *threo*-**5**. However, the hydroxyl proton of *threo*-**5** is located close to the adjacent phthalimido moiety so that it may be deshielded to some extent. This is the case observed for *erythro*-**5a** and *threo*-**5a** (R=Ph). Other erythro and threo structures for the similar products **5b** to **5e** were tentatively assigned on the basis of the ^{1}H-NMR spectral data shown in Table 4.

The possibility for intramolecular hydrogen bonding in *threo*-**5a** was confirmed on the basis of the IR spectra taken as the solution in chloroform. For *threo*-**5a**, no essential change of OH stretching vibration was observed between two kinds of solutions of different concentrations: for the solution containing 30 mg of *threo*-**5a** in 1 ml of chloroform, 3728, 3704 (free OH), 3604, and 3464 cm^{-1} (hydrogen-bonded OH); for the solution containing 0.6 mg in 1 ml, 3728, 3705 (free OH), 3516, and 3448 cm^{-1} (hydrogen-bonded OH). However, the last two of four OH absorptions which were observed in the solution containing 30 mg of *erythro*-**5a** in 1 ml of chloroform (3728, 3705 (free OH), 3602, and 3466 cm^{-1} (hydrogen-bonded OH) dissapeared in the spectrum of a diluted solution (0.3 mg in 1 ml, 3730 and 3705 cm^{-1}).

As the ^{1}H-NMR spectra for the two isomers of **5f** were found too close each other, it was impossible to determine the stereostructures only on the basis of the spectral data. Therefore each isomer of **5f** was first converted into **12** (Scheme 3 and Table 3) and then cyclized into each isomeric 2-oxazoline **16** or **17** by the reaction with an imino ether. The isomer **16** showed a coupling constant of 9.7 Hz for J_{4-5} and the other **17** 7.2 Hz, **16** and **17** being assigned as cis and trans isomers, respectively. The propyl hydrogens

at the 5-position of **16** as well as the methine hydrogen at the 5-position of **17** are both suffering from shielding from the adjacent phenyl plane. As it is known that 2-oxazoline formation from β-amino alcohols and imidic esters takes place with the retention of stereochemistry of the alcohols,[13] one isomer of **5f** which provided **16** can be assigned as *erythro*-**12**, and hence the other of **5f** leading to **17** is *threo*-**12**.

Experimental

General. Melting points were determined on a Yanagimoto micro melting point apparatus and uncorrected. IR spectra were taken with a JASCO A-702 or a JEOL JIR-100 spectrometer. ^{1}H-NMR spectra were recorded on a Hitachi R-40 or a JEOL FX-100 instrument and ^{13}C-NMR spectra were obtained on a JEOL FX-100 spectrometer at 25.05 MHz. Chemical shifts are expressed in parts per million downfield from tetramethylsilane. Mass spectra were measured with a JEOL JMS-01SG-2 spectrometer at 70 eV of ionization energy. Elementary analyses were performed on a Hitachi 026 CHN analyzer. Thin-layer chromatography (TLC) was accomplished on 0.2 mm precoated plates of silica gel 60 F-254 (Merck). Visualization was with ultraviolet light (254 and 365 nm) and iodine. Wakogel C 300 (Wako) and Silicagel 60 (Merck, size: 0.063—0.200 mm) were used for preparative column chromatography. Flash chromatography was carried out on an EYELA EF-10 apparatus using a column (20×180 mm) packed with Silicagel 60 (Merck, size: 0.040—0.063 mm). Micro vacuum distillation was accomplished with a Sibata GTO-250R Kugelrohr distilling apparatus. Solvents were evaporated with a Tokyo Rikakikai rotary evaporator type V.

DMF was purified by a vacuum distillation over alumina under nitrogen and stored on molecular sieves MS-5A. HMPA was also distilled *in vacuo* over calcium hydride under nitrogen and stored on molecular sieves MS-13X. THF was distilled over lithium aluminum hydride immediately prior to its use. Other solvents for reactions as well as for chromatography were used without further purification.

Materials. (α-Bromobenzyl)trimethylsilane (bp 88—92 °C (266 Pa), lit,[11] bp 98—99 °C (532 Pa)) was prepared by the reaction of benzyltrimethylsilane[14] with *N*-bromosuccinimide according to the reported method.[11] (Phthalimidomethyl)trimethylsilane **4** (bp 95—97 °C (100 Pa), lit,[15] bp 117 °C (266 Pa)) was synthesized from both commercially available (chloromethyl)trimethylsilane and potassium phthalimide. Morpholine was used without further purification. Commercial cesium fluoride was dried in a reaction flask under vacuum by heating at about 100 °C. TBAF solution in THF (1 mol dm^{-3}) was dried over molecular sieves MS-5A under nitrogen. Benzaldehyde, butanal, and cinnamaldehyde were purified by distillation. 2-Furancarbaldehyde was passed through a short column packed with alumina immediately before use. Other aldehydes were all used without further purification.

(α-Phthalimidobenzyl)trimethylsilane 1. A mixture of (α-bromobenzyl)trimethylsilane (12.15 g, 0.05 mol) and potassium phthalimide (10.2 g, 0.055 mol) in dry DMF (50 ml) was heated at 140 °C for 3 h. After cooled to room temperature, the reaction mixture was poured into ice-water and extracted with ether (50 ml×2). The ether was dried over magnesium sulfate and evaporated *in vacuo*. The residue was chromatographed over silica gel using hexane–benzene (2:1) as an eluent to give 12.96 g (84%) of **1**: Colorless prisms from hexane; mp 106—107 °C; IR (KBr) 1768, 1712 (CO), 1252, and 845 cm^{-1} (TMS); ^{1}H-NMR ($CDCl_3$) δ=0.15 (9H, s, Me_3Si), 4.66 (1H, s, CH), 7.08—7.30 (5H, m, Ph), and 7.53—7.85 (4H, m, Ar); MS *m/z* (rel. intensity, %) 309 (M^+, 44) and 73 (base peak).

Found: C, 70.04; H, 6.21; N, 4.46%. Calcd for $C_{18}H_{19}NO_2Si$: C, 69.86; H, 6.12; N, 4.53%.

(α-Morpholinobenzyl)trimethylsilane 2. A mixture of (α-bromobenzyl)trimethylsilane (1.2 g, 4.9 mmol) and morpholine (1.3 g, 14.9 mmol) was heated under reflux for 6 h. After cooled to room temperature, the reaction mixture was poured into aqueous potassium hydroxide solution and extracted with ether (10 ml×2). The ether was dried and evaporated *in vacuo*. The residue was distilled on a micro distilling apparatus to give 0.932 g (76%) of **2**: Pale yellow oil; bp 210—215 °C (3325 Pa) (bulb-to-bulb); IR (neat) 1250, 858, and 841 cm^{-1} (TMS); ^{1}H-NMR ($CDCl_3$) δ=−0.09 (9H, s, Me_3Si), 2.35—2.64 (4H, m, CH_2N), 2.79 (1H, s, CH), 3.53—3.78 (4H, m, OCH_2), and 7.01—7.32 (5H, m, Ph); ^{13}C-NMR ($CDCl_3$) δ=−1.17 (q, Me_3Si), 54.82 (t, CH_2N), 66.71 (d, CH), 67.25 (t, NCH_2), 125.58, 127.96 (each d, *o*-, *m*-, and *p*-C of Ph), and 142.00 (s, 1-C of Ph); MS *m/z* (rel. intensity, %) 249 (M^+, 8) and 176 (base peak).

The elementary analysis was carried out with an authentic sample of hydrochloride of **2** (mp 211—212 °C).

Found: C, 58.87; H, 8.70; N, 4.93%. Calcd for $C_{14}H_{24}NOClSi$: C, 58.82; H, 8.46; N, 4.90%.

(α-Acetamidobenzyl)trimethylsilane 3. A mixture of **1** (8.3 g, 0.027 mol) and hydrazine hydrate (100%, 1.5 g, 0.03 mol) in ethanol (100 ml) was heated under reflux for 3 h. Concd hydrochloric acid (3 ml) was added and the resulting mixture was again refluxed for 1 h. After cooled to room temperature, the precipitate separated was removed by filtration and the filtrate was evaporated *in vacuo*. The residue was treated with water, the insoluble material was removed off by filtration, the filtrate was made alkaline with aqueous potassium hydroxide solution, and extracted with dichloromethane (25 ml×2). The dichloromethane was dried and evaporated *in vacuo*. The residue was distilled under vacuum to give 2.9 g (61%) of (α-aminobenzyl)trimethylsilane: Pale yellow oil; bp 114—117 °C (2660 Pa) (bulb-to-bulb); IR (neat) 3380 (NH), 1250, and 840 cm^{-1} (TMS); ^{1}H-NMR ($CDCl_3$) δ=0.03 (9H, s, Me_3Si), 1.56 (2H, br. s, NH_2), 3.52 (1H, s, CH), and 7.04—7.38 (5H, m, Ph); MS *m/z* (rel. intensity, %) 179 (M^+, 22), 106 (98), 105 (62), and 73 (base peak).

The elementary analysis was performed with an authentic sample of hydrochloride of the amine (mp 239—241 °C).

Found: C, 55.87; H, 8.66; N, 6.56%. Calcd for $C_{10}H_{18}NClSi$: C, 55.66; H, 8.41; N, 6.49%.

A mixture of the above amine (0.5 g, 2.8 mmol), triethylamine (0.5 ml), and acetic anhydride (0.5 ml) in dichloromethane (5 ml) was stirred overnight at room temperature and poured into water. The organic material was extracted with dichloromethane (25 ml), the dichloromethane was dried, and evaporated *in vacuo*. The residue

was chromatographed over silica gel using hexane-ethyl acetate (2:1) as an eluent to give 0.41 g (66%) of **3**: Colorless needles from benzene-hexane; mp 137.5—139 °C; IR (KBr) 3270 (NH), 1633 (CO), 1250, 865, and 840 cm^{-1} (TMS); ^{1}H-NMR ($CDCl_3$) δ=0.02 (9H, s, Me_3Si), 2.00 (3H, s, MeCO), 3.60 (1H, d, J=9.0 Hz, CH), 6.00 (1H, br. d, NH), and 6.97—7.32 (5H, m, Ph); MS m/z (rel. intensity, %) 221 (M^+, 30), 178 (20), 106 (41), 104 (19), 79 (20), 77 (21), and 73 (base peak).

Found: C, 65.29; H, 8.61; N, 6.40%. Calcd for $C_{12}H_{19}NOSi$: C, 65.10; H, 8.65; N, 6.33%.

General Procedure for the Reactions of 1 with Aldehydes. The reagents were charged in a reaction flask in the following manner: When cesium fluoride was used, a weighed quantity of cesium fluoride (1—0.1 mmol) was placed in a reaction flask and dried at 100 °C under vacuum. After it was cooled to room temperature, dry DMF (2 ml), aldehydes (1—1.4 mmol), and then **1** (1 mmol) were added. When TBAF was used as a catalyst, to a mixture of **1** (1 mmol) and aldehydes (1—1.4 mmol) in dry DMF (2 ml) was added TBAF (0.05 ml, 0.05 mmol). The resulting mixture was stirred at room temperature under nitrogen for the period of time shown in Table 1. The solvents were all evaporated to dryness under vacuum. The residue was filtered through a short column packed with silica gel using hexane-ethyl acetate (2:1) to give a mixture of two isomeric 2-aminoethanols **5a** to **5f**. The yields as well as the erythro/threo ratios were measured at this stage, the formers of which were listed in Table 1. The separation of isomers was carried out by a flash chromatography over silica gel using hexane-ethyl acetate (5:1) as an eluent.

1,2-Diphenyl-2-phthalimidoethanol **5a**. *erythro*-**5a**: Colorless leaflets from benzene-hexane; mp 184—186 °C; IR (KBr) 3523, 3469, 3425 (OH), and 1708 cm^{-1} (CO); ^{1}H-NMR ($CDCl_3$) δ=2.77 (1H, br. s, OH), 5.49 (1H, d, J_{2-1}=9.0 Hz, 2-CH), 5.92 (1H, d, J_{1-2}=9.0 Hz, 1-CH), and 7.10—7.71 (14H, m, Ph and Ar); MS m/z (rel. intensity, %) 237 (43), 236 (40), 130 (30), 104 (21), 79 (55), and 77 (base peak).

Found: C, 77.05, H; 5.06; N, 4.26%. Calcd for $C_{22}H_{17}NO_3$: C, 76.94; H, 4.99; N, 4.08%.

threo-**5a**: Colorless needles from benzene-hexane; mp 182—184 °C; IR (KBr) 3425 (OH), 1709, and 1697 cm^{-1} (CO); ^{1}H-NMR ($CDCl_3$) δ=3.29 (1H, m, OH), 5.55 (1H, d, J_{2-1}=9.0 Hz, 2-CH), 5.75—5.90 (1H, m, 1-CH), and 7.04—7.90 (14H, m, Ph and Ar); MS m/z (rel. intensity, %) 237 (17), 236 (29), 130 (26), 107 (38), 105 (32), 104 (31), 79 (74), and 77 (base peak).

Found: C, 77.17; H, 4.89; N, 4.11%. Calcd for $C_{22}H_{17}NO_3$: C, 76.94; H, 4.99; N, 4.08%.

^{13}C-NMR ($CDCl_3$) of the mixture of *erythro*-**5a** and *threo*-**5a**: δ=60.86, 62.63 (each d, 2-C), 72.60, and 73.00 (each d, 1-C).

1-(p-Methylphenyl)-2-phenyl-2-phthalimidoethanol **5b**. *erythro*-**5b**: Colorless prisms from benzene-hexane; mp 163—164 °C; IR (KBr) 3545 (OH) and 1709 cm^{-1} (CO); ^{1}H-NMR ($CDCl_3$) δ=2.21 (3H, s, Me), 2.69 (1H, d, J=2.5 Hz, OH), 5.29 (1H, d, J_{2-1}=9.0 Hz, 2-CH), 5.92 (1H, dd, J_{1-2}=9.0 and J_{1-OH}=2.5 Hz, 1-CH), and 6.91—7.74 (13H, m, Ar); MS m/z (rel. intensity, %) 357 (M^+, 5), 238 (17), 237 (base peak), 236 (19), 219 (17), 209 (12), 130 (9), 121 (14), 119 (12), 105 (19), 104 (48), and 91 (38).

Found: C, 77.39; H, 5.39; N, 3.91%. Calcd for $C_{23}H_{19}NO_3$: C, 77.29; H, 5.36; N, 3.92%.

threo-**5b**: Colorless leaflets from benzene-hexane; mp 161—162 °C; IR (KBr) 3450 (OH), 1711, and 1699 cm^{-1} (CO); ^{1}H-NMR ($CDCl_3$) δ=2.21 (3H, s, Me), 3.32 (1H, m, OH), 5.53 (1H, d, J_{2-1}=9.0 Hz, 2-CH), 5.73—5.98 (1H, m, 1-CH), and 6.88—7.82 (13H, m, Ar); MS m/z (rel. intensity, %) 357 (M^+, 4), 238 (17), 237 (base peak), 236 (23), 219 (18), 209 (13), 208 (10), 133 (11), 130 (29), 121 (18), 105 (19), 104 (46), 93 (16), and 91 (25).

Found: C, 77.33; H, 5.38; N, 3.91%. Calcd for $C_{23}H_{19}NO_3$: C, 77.29; H, 5.36; N, 3.92%.

1-(p-Methoxyphenyl)-2-phenyl-2-phthalimidoethanol **5c**. *erythro*-**5c**: Colorless prisms from benzene-hexane; mp 147.5—148.5 °C; IR (KBr) 3460 (OH), 1767, and 1705 cm^{-1}; ^{1}H-NMR ($CDCl_3$) δ=2.64 (1H, br. s, OH), 3.64 (3H, s, MeO), 5.49 (1H, d, J_{2-1}=9.3 Hz, 2-CH), 5.95 (1H, d, J_{1-2}=9.3 Hz, 1-CH), 6.65—6.85, and 7.20—7.78 (13H, m, Ar); MS m/z (rel. intensity, %) 373 (M^+, 4), 356 (13), 238 (15), 237 (89), 236 (17), 219 (22), 209 (13), 137 (base peak), 130 (18), 109 (20), 104 (24), and 94 (14).

Found: C, 74.27; H, 5.17; N, 3.86%. Calcd for $C_{23}H_{19}NO_4$: C, 73.98; H, 5.13; N, 3.75%.

threo-**5c**: Colorless leaflets from benzene-hexane; mp 151—152.5 °C; IR (KBr) 3430 (OH), 1765, and 1700 cm^{-1} (CO); ^{1}H-NMR ($CDCl_3$) δ=3.18 (1H, d, J=6.0 Hz, OH), 3.70 (3H, s, OMe), 5.55 (1H, d, J_{2-1}=8.7 Hz, 2-CH), 5.87 (1H, dd, J_{1-2}=8.7 and J_{1-OH}=6.0 Hz, 1-CH), 6.65—6.81, 7.10—7.43, and 7.56—7.85 (13 H, m, Ar); MS m/z (rel. intensity, %) 373 (M^+, 4), 238 (11), 237 (69), 236 (32), 219 (18), 209 (13), 208 (11), 152 (10), 137 (base peak), 135 (12), 133 (12), 130 (36), 109 (31), 105 (20), 104 (45), and 94 (32).

Found: C, 74.15; H, 5.21; N, 4.01%. Calcd for $C_{23}H_{19}NO_4$: C, 73.98; H, 5.13; N, 3.75%.

1-(2-Furyl)-2-phenyl-2-phthalimidoethanol **5d**. *erythro*-**5d**: Colorless prisms from benzene-hexane; mp 133—134 °C; IR (KBr) 3510 (OH), 1765, and 1708 cm^{-1} (CO); ^{1}H-NMR ($CDCl_3$) δ=2.80 (1H, d, J=4.8 Hz, OH), 5.70 (1H, d, J_{2-1}=9.3 Hz, 2-CH), 6.06 (1H, dd, J_{1-2}=9.3 and J_{1-OH}=4.8 Hz, 1-CH), 6.18 (1H, dd, J=3.6 and 2.2 Hz, 4-H of furyl), 6.31 (1H, br. d, J=3.6 Hz, 3-H of furyl), and 7.20—7.80 (10H, m, Ar and 5-H of furyl); MS m/z (rel. intensity, %) 333 (M^+, 3), 238 (17), 237 (base peak), 236 (40), 219 (14), 130 (16), 104 (16), and 77 (14).

Reaction of **2** *with Benzaldehyde.* Cesium fluoride (152 mg, 1 mmol) was dried in a reaction flask under vacuum at 100 °C. To the falsk, after cooled to room temperature, were added dry DMF (2 ml), **2** (249 mg, 1 mmol), and then benzaldehyde (106 mg, 1 mmol). The mixture was stirred under nitrogen at room temperature for 24 h and then poured into ice-water. The products were extracted with ether (25 ml×2), the ether was dried over magnesium sulfate, and finally evaporated *in vacuo*. The residue was chromatographed over silica gel using hexane-ethyl acetate (3:1) as an eluent to give 190 mg (67%) of the erythro and threo mixture of 2-morpholino-1,2-diphenylethanol **6**, whose separation by a flash chromatography was unsuccessful. The following data were given for the mixture of *erythro*-**6** and *threo*-**6** (1:1) Colorless prisms from benzene-hexane; mp 110—118 °C; IR (KBr) 3500, 3380 (OH), 3100—2800 (CH), 1126, 882, and 712 cm^{-1}; ^{1}H-NMR ($CDCl_3$) δ=2.19—2.80 (4H, m, CH_2N), 4.32 (0.5H, d, J_{2-1}=2.5 Hz, 2-CH), 4.52 (0.5 H, d, J_{2-1}=5.2 Hz, 2-CH), 4.40—4.80 (5H, m, CH_2O and OH), 5.02 (0.5 H, d, J_{1-2}=5.2 Hz, 1-CH), 5.30 (0.5 H, d, J_{1-2}=2.5 Hz, 1-CH), and 6.80—7.38 (10H, m, Ph); ^{13}C-NMR ($CDCl_3$) δ=49.32, 51.90 (each t, CH_2N), 67.00, 67.15 (each t, CH_2O), 70.27, 71.19 (each d, 2-C), 76.46, 76.70 (each d, 1-C), 126.11, 127.28, 127.47, 129.52, 129.61, 132.59, 135.61, and 141.02; MS *m/z* (rel. intensity, %) 177 (13), 176 (base peak), 105 (12), and 91 (13).

Found: C, 76.57; H, 7.47; N, 4.98%. Calcd for $C_{18}H_{21}NO_2$: C, 76.29; H, 7.47; N, 4.94%.

Reaction of **3** *with Benzaldehyde.* To a mixture of **3** (130 mg, 0.59 mmol) and benzaldehyde (70 mg, 0.66 mmol) in dry DMF (1 ml) was added TBAF (0.6 ml, 0.6 mmol). The mixture was stirred under nitrogen at room temperature for 16 h and then poured into ice-water. The products were extracted with ether (25 ml×2), the ether was dried, and evaporated *in vacuo* to give a viscous oily material which solidified on trituration with ether-hexane. Thus obtained colorless solid was found to be the mixture of erythro and threo isomers (1:1) of 2-acetamido-1,2-diphenylethanol **7** (86 mg, 57%), which could not be separated by a flash chromatography. The following data were given for the mixture of *erythro*-**7** and *threo*-**7** (1:1): Colorless solid; IR (KBr) 3360 (OH) and 1650 cm^{-1} (CO); ^{1}H-NMR ($CDCl_3$) δ=1.89, 1.95 (each 0.5×3H, s, COMe), 3.19 (1H, br. s, OH), 4.85—5.30 (2H, m, 1- and 2-CH), 6.42 (1H, br. s, NH), and 6.88—7.32 (10H, m, Ph); MS *m/z* (rel. intensity, %) 149 (83), 148 (18), 107 (22), 106 (base peak), 104 (10), 79 (27), and 77 (25).

Found: C, 75.24; H, 6.73; N, 5.49%. Calcd for $C_{16}H_{17}NO_2$: C, 75.26; H, 6.71; N, 5.49%.

General Procedure for the Reactions of **4** *with Aldehydes.* To a mixture of **4** (1 mmol) and aldehydes (1.5 mmol) in dry DMF (1 ml) was added TBAF (0.05ml, 0.05 mmol) by use of a syringe. The mixture was heated at 100 °C under nitrogen for the time period shown in Table 1 and cooled to room temperature. Another portion of TBAF (0.05 ml) was added and this mixture was again heated under the conditions listed in Table 1. After cooled to room temperature, ice-cold water was added to the mixture which was then extracted with ether (25 ml×2), the ether was dried, and evaporated *in vacuo*. The residue obtained was dissolved in benzene (5 ml) to separate the precipitation of *N*-benzylphthalimide **10** which was filtered off. The filtrate was condensed *in vacuo* and chromatographed over silica gel using hexane-ethyl acetate (2:1) to give 1-substituted 2-phthalimidoethanol **8a** to **8g**. The yields of **8** as well as **10** are listed in Table 1.

1-Phenyl-2-phthalimidoethanol **8a**: Colorless leaflets from benzene-hexane; mp 166—168 °C (lit,[16] mp 164—165 °C); IR (KBr) 3467 (OH) and 1701 cm^{-1} (CO); ^{1}H-NMR ($CDCl_3$) δ=2.92 (1H, d, *J*=5.1 Hz, OH), 3.89 (1H, dd, J_{2-1}=5.0 and J_{gem}=14.0 Hz, one of 2-CH_2), 4.05 (1H, dd, J_{2-1}=7.1 and J_{gem}=14.0 Hz, the other of 2-CH_2), 5.04 (1H, ddd, J_{1-2}=5.0, 7.1 and J_{1-OH}=5.1 Hz, 1-CH), and 7.20—7.92 (9H, m, Ph and Ar).

1-(p-Methylphenyl)-2-phthalimidoethanol **8b**: Colorless needles from benzene-hexane; mp 155—156.5 °C; IR (KBr) 3379 (OH), 1768 and 1711 cm^{-1} (CO); ^{1}H-NMR ($CDCl_3$) δ=2.33 (3H, s, Me), 2.82 (1H, d, *J*=5.0 Hz, OH), 3.85 (1H, dd, J_{2-1}=5.0 and J_{gem}=14.0 Hz, one of 2-CH_2), 4.02 (1H dd, J_{2-1}=7.5 and J_{gem}=14.0 Hz, the other of 2-CH_2), 5.02 (1H, dt, J_{1-2}=5.0, 7.5 and J_{1-OH}=5.0 Hz, 1-CH), 7.04—7.40, and 7.60—7.92 (each 4H, m, Ar); MS *m/z* (rel. intensity, %) 281 (M^+, 7), 190 (15), 162 (15), 161 (base peak), 160 (14), 133 (10), 121 (28), 117 (15), 105 (13), 104 (19), and 91 (15).

Found: C, 72.75; H, 5.46; N, 5.06%. Calcd for $C_{17}H_{15}NO_3$: C, 72.58; H, 5.38; N, 4.98%.

1-(p-Methoxyphenyl)-2-phthalimidoethanol **8c**: Colorless leaflets from benzene-hexane; mp 172—174 °C; IR (KBr) 3470 (OH), 1770, and 1695 cm^{-1} (CO); ^{1}H-NMR ($CDCl_3$)

δ=2.77 (1H, d, J=5.0 Hz, OH), 3.78 (3 H, s, OMe), 3.86 (1H, dd, J_{2-1}=5.0 and J_{gem}=14.5 Hz, one of 2-CH_2), 4.03 (1H, dd, J_{2-1}=7.6 and J_{gem}=14.5 Hz, the other of 2-CH_2), 6.02 (1H, dt, J_{1-2}=5.0, 7.6 and J_{1-OH}=5.0 Hz, 1-CH), 6.85, 7.36 (each 2H, d, J=9.5 Hz, p-$MeOC_6H_4$), and 7.63—7.90 (4H, m, Ar); MS m/z (rel. intensity, %) 297 (M^+, 4), 161 (18), 160 (68), 137 (base peak), 135 (17), 133 (18), 117 (18), 109 (60), 105 (24), 104 (34), and 94 (46).

Found: C, 68.88; H, 5.16; N, 4.96%. Calcd for $C_{17}H_{15}NO_4$: C, 68.68; H, 5.09; N, 4.71%.

1-(2-Furyl)-2-phthalimidoethanol ***8d***: Colorless prisms from benzene-hexane; mp 86—87 °C; IR (KBr) 3400 (OH), 1775, and 1708 cm^{-1} (CO); ^{1}H-NMR ($CDCl_3$) δ=2.80 (1H, d, J=7.0 Hz, OH), 4.00 (1H, dd, J_{2-1}=5.3 and J_{gem}=14.2 Hz, one of 2-CH_2), 4.18 (1H, dd, J_{2-1}=7.6 and J_{gem}=14.2 Hz, the other of 2-CH_2), 5.05 (1H, ddd, J_{1-2}=5.3, 7.6 and J_{1-OH}=7.0 Hz, 1-CH), 6.32 (2H, m, 3- and 4-H of furyl), 7.37 (1H, dd, J=1.8 and 1.2 Hz, 5-H of furyl), and 7.62—7.95 (4H, m, Ar); MS m/z (rel. intensity, %) 257 (M^+, 13), 162 (13), 161 (base peak), 160 (50), 133 (43), 132 (23), 117 (42), 110 (83), 105 (29), 104 (48), and 97 (84).

Found: C, 65.16; H, 4.51; N, 5.62%. Calcd for $C_{14}H_{11}NO_4$: C, 65.36; H, 4.31; N, 5.45%.

(E)-4-Phenyl-1-phthalimido-3-buten-2-ol ***8e***: Pale yellow needles from benzene-hexane; mp 184—186 °C; IR (KBr) 3454 (OH) and 1701 cm^{-1} (CO); ^{1}H-NMR ($CDCl_3$) δ=2.63 (1H, d, J=5.3 Hz, OH), 3.91 (2H, d, J_{1-2}=5.8 Hz, 1-CH_2), 4.65 (1H, dddt, J_{2-1}=5.8, J_{2-3}=6.0, J_{2-OH}=5.3, and J_{2-4}=1.2 Hz, 2-CH), 6.21 (1H, dd, J_{3-2}=6.0 and J_{3-4}=15.8 Hz, 3-CH), 6.68 (1H, dd, J_{4-3}=15.8 and J_{4-2}=1.2 Hz, 4-H), 7.10—7.42 (5H, m, Ph), and 7.58—7.92 (4H, m, Ar); MS m/z (rel. intensity, %) 293 (M^+, 12) 161 (34), 160 (20), 146 (24), 134 (12), 133 (base peak), 115 (14), 105 (12), 104 (12), and 77 (22).

Found: C, 73.56; H, 5.18; N, 4.93%. Calcd for $C_{18}H_{15}NO_3$: C, 73.70; H, 5.16; N, 4.78%.

1-Phthalimido-2-pentanol ***8f***: Colorless prisms from benzene-hexane; mp 86—87.5 °C; IR (KBr) 3508 (OH), 1774, and 1711 cm^{-1} (CO); ^{1}H-NMR ($CDCl_3$) δ=0.76—1.08 (3H, m, Me), 1.21—1.70 (4H, m, 3- and 4-CH_2), 2.52 (1H, br. s, OH), 3.61—4.02 (3H, m, 1-CH_2 and 2-CH), and 7.48—7.83 (4H, m, Ar); MS m/z (rel. intensity, %) 233 (M^+, 2), 190 (14), 162 (11), 161 (base peak), 160 (22), 133 (30), 132 (15), 117 (30), 105 (33), 104 (46), and 77 (36).

Found: C, 67.08; H, 6.39; N, 6.14%. Calcd for $C_{13}H_{15}NO_3$: C, 66.93; H, 6.48; N, 6.00%.

3,3-Dimethyl-1-phthalimido-2-butanol ***8g***: Colorless needles from benzene-hexane; mp 94-95.5 °C; IR (KBr) 3400 (OH), 1770, and 1713 cm^{-1} (OH); ^{1}H-NMR ($CDCl_3$) δ=1.01 (9H, s, Me), 2.47 (1H, d, J=5.8 Hz, OH), 3.46—4.02 (3H, m, 1-CH_2 and 2-CH), and 7.62—7.90 (4H, m, Ar); MS m/z (rel. intensity, %) 247 (M^+, 1), 190 (58), 162 (14), 161 (base peak), 160 (20), 133 (23), 132 (13), 104 (25), and 77 (23).

Found: C, 68.02; H, 6.93; N, 5.78%. Calcd for $C_{14}H_{17}NO_3$: C, 67.99; H, 6.93; N, 5.66%.

General Procedure for the Hydrazinolysis of 5 and 8. A mixture of **5** or **8** (1 mmol) and hydrazine hydrate (100%, 1.5 mmol) in 4 ml of ethanol was heated unnder reflux for a few hours. After a slight excess of concd hydrochloric acid was added, the resulting mixture was again heated under reflux for 0.5 h and then cooled to room temperature. The precipitate separated was filtered off and the filtrate was evaporated *in vacuo*. The residue was dissolved in water (5 ml) to separate some insoluble material which was removed by filtration. Evaporation of the filtrate *in vacuo* gave the hydrochloride of 2-aminoethanols (*erythro*-**12**, *threo*-**12**, **13**, and **15**). Treatment of the filtrate with aqueous potassium hydroxide afforded the free bases (*erythro*-**11**, *threo*-**11**, and **14**). The reaction times and the yields were listed in Table 3.

Identification of the products was accomplished by the comparison of the melting points with those of authentic samples or on the basis of the spectral data of 2-oxazoline derivatives.

erythro-*2-Amino-1,2-diphenylethanol.* erythro-***11***: Colorless needles from ethanol; mp 166.5—168 °C (lit,[17] mp 163 °C); IR (KBr) 3365 and 3298 cm^{-1} (NH and OH); ^{1}H-NMR ($CDCl_3$) δ=1.70 (3H, br. s, NH_2 and OH), 4.15 (1H, d, J_{1-2}=6.2 Hz, 1-H), 4.73 (1H, d, J_{2-1}=6.2 Hz, 2-H), and 7.05—7.20 (10H, m, Ph).

threo-*2-Amino-1,2-diphenylethanol.* threo-***11***: Colorless needles from benzene-hexane; mp 129—131 °C (lit,[17] mp 129 °C); IR (KBr) 3363, 3302, and 3159 cm^{-1} (NH and OH); ^{1}H-NMR ($CDCl_3$) δ=2.00 (3H, br. s, NH_2 and OH), 3.97 (1H, d, J_{1-2}=6.5 Hz, 1-H), 4.63 (1H, d, J_{2-1}=6.5 Hz, 2-H), and 7.00—7.30 (10H, m, Ph).

2-Amino-1-phenylethanol Hydrochloride ***13***: Colorless prisms from ethanol-ether; mp 179—181 °C (lit,[18] mp 176—177 °C); IR (KBr) 3350 and 3000 cm^{-1} (NH and OH); ^{1}H-NMR (DMSO-d_6) δ=2.86 (2H, br. s, CH_2), 4.30 (1H, br. s, OH), 4.63—4.92 (1H, m, 1-H), 7.21 (5H, br. s, Ph), and 8.15 (3H, br. s, NH_3^+).

(E)-1-Amino-4-phenyl-3-buten-2-ol ***14***: This compound **14** was converted into the oxalate whose appearance and melting point are given as follows: colorless prisms from ethanol; mp 235—238 °C (lit,[19] mp 238 °C). The IR and ^{1}H-NMR spectral data are shown for the free base: IR (KBr) 3360 cm^{-1} (NH and OH); ^{1}H-NMR ($CDCl_3$) δ=2.67 (5H, br. s, $C\underline{H}_2N\underline{H}_2$ and OH), 3.95—4.28 (1H, m, 2-H), 6.02 (1H, dd, J_{3-2}=6.0 and J_{3-4}=15.0 Hz, 3-H), 6.50 (1H, d, J_{4-3}=15.0 Hz, 4-H), and 6.95—7.40 (5H, m, Ph).

1-Amino-2-pentanol Hydrochloride ***15***: This compound **15** was converted into 1-benzamido-2-pentanol by the reaction of **15** with benzoyl chloride in the presence of triethylamine. The following data are for the *N*-benzoyl derivative. Colorless leaflets from benzene; mp 111—113 °C (lit,[20] mp 112—113.5 °C); IR (KBr) 3373, 3329 (NH and OH), and 1633 cm^{-1} (CO); ^{1}H-NMR ($CDCl_3$) δ=0.80—1.08 (3H, m, Me), 1.22—1.64 (4H, m, 3- and 4-CH_2), 2.65 (1H, d, J_{OH-2}=4.7 Hz, OH), 3.25 (1H, ddd, J_{1-NH}=4.8, J_{1-2}=8.0, and J_{gem}=13.8 Hz, one of 1-H), 3.70 (1H, ddd, J_{1-NH}=6.5, J_{1-2}=2.7, and J_{gem}=13.8 Hz, the other of 1-H), 3.70—3.95 (1H, m, 2-H), 6.66 (1H, br. s, NH), and 7.26—7.84 (5H, m, Ph).

cis-*2,4-Diphenyl-5-propyl-2-oxazoline* ***16***: The hydrochloride *erythro*-**12** which was obtained according to the general procedure described above was converted into **16** by the following reaction. A mixture of *erythro*-**12** (38 mg, (0.18mmol) and ethyl benzimidate[21] (70 mg, 0.46 mmol) was heated under reflux in 1,2-dichloroethane (5 ml) for 24 h. After cooled to room temperature, the mixture was washed with water twice and the organic layer was dried over magnesium sulfate. The residue which was given by the evaporation of the solution was chromatographed over silica gel using hexane-ethyl acetate (5:1) as an eluent. Colorless oil of **16** (46 mg, 94%) gave the following spectral

data: IR (neat) 1647 cm^{-1} (C=N); ^{1}H-NMR ($CDCl_3$) δ=0.83 (3H, t, J=7.0 Hz, Me), 0.90—1.68 (4H, m, $MeCH_2CH_2$), 4.88 (1H, ddd, J_{5-4}=9.7, J_{5-CH_2}=4.3, and J_{5-CH_2}=9.7 Hz, 5-H), 5.20 (1H, d, J_{4-5}=9.7 Hz, 4-H), and 7.06—7.92 (10H, m, Ph); MS m/z (rel. intensity, %) 265 (M^+, 4), 194 (19), 193 (base peak), 90 (18), 89 (17), and 77 (11).

Found: m/z 265.1466. Calcd for $C_{18}H_{19}NO$: M, 265.1466.

trans-*2,4-Diphenyl-5-propyl-2-oxazoline* **17**: According to the similar procedure mentioned above, colorless oil of **17** was obtained in 92% yield: IR (neat) 1647 cm^{-1} (C=N); ^{1}H-NMR ($CDCl_3$) δ=0.98 (3H, t, J=7.0 Hz, Me), 1.30—2.03 (4H, m, $MeCH_2CH_2$), 4.48 (1H, ddd, J_{5-4}=7.2, J_{5-CH_2}=5.1, and J_{5-CH_2}=7.2 Hz, 5-H), 4.88 (1H, d, J_{4-5}=7.2 Hz, 4-H), and 7.15—8.12 (10H, m, Ph); MS m/z (rel. intensity, %) 265 (M^+, 9), 194 (14), and 193 (base peak).

Found: C, 81.69; H, 7.29; N, 5.52%. Calcd for $C_{18}H_{19}NO$: C, 81.47; H 7.22; N, 5.28%.

Vibrational Analysis of Tangled Spectra. I. The Crystal Phase T←S Spectra of Acetophenone[1)]

Kenichi NAKASHIMA† and Motohiko KOYANAGI*
Department of Chemistry, Faculty of Science, Kyushu University 33, Hakozaki Higashi-ku, Fukuoka 812
(Received May 7, 1984)

The $T_{1,2}$←S_0 phosphorescence excitation spectrum of acetophenone has been observed in a crystal at 4.2 K. The observed tangled vibronic structure is a manifestation that two states of different orbital types, $^3\pi\pi^*$ and $^3n\pi^*$, lie close to each other. For the first time, the spectrum has been vibrationally analyzed in terms of the crude adiabatic Born-Oppenheimer vibronic states. The calculation is advanced *via* the following steps: (1) to assume appropriate zero-order vibronic level functions of both electronic excited states in the energy region 0—1000 cm^{-1} above the T_1 phosphorescent origin level, (2) to take into account two different perturbations of vibronic and environmental interactions, (3) to establish a secular equation with two adjustable parameters for the evaluation of the off-diagonal matrix elements, (4) to diagonalize the equation after allocating appropriate values to the parameters, (5) to simulate the T←S spectrum, (6) to compare the simulation spectrum with the observed, (7) to revise several diagonal elements and the parameters if the comparison is not satisfied, and (8) to proceed with steps (1)—(7) until the simulation spectra accord with the observed. The results establish that the lowest excited triplet state of acetophenone in the crystal is $\pi\pi^*$, and that the next one is $n\pi^*$ whose zero-order vibrationless level is postulated to lie at $\approx$400 cm^{-1} higher than $T_1^0(0)$.

Aromatic carbonyls have been very attractive for molecular spectroscopists and photochemists because of the dynamical characteristics in the excited triplet states. There are reported many thereof,[2-21)] and it has generally been accepted that the photochemical reactivity of such a molecule depends strongly upon whether its lowest triplet state is $\pi\pi^*$ or $n\pi^*$ and upon how large the energy separation is.[22,23)] For the state assignments, of course, it is still valuable to vibrationally analyze the T→S emission and, especially, the T←S absorption spectra. Such T←S spectra, however, sometimes become very tangled, reflecting a heavy overlap of different electronic transition absorptions. As regards the tangled spectra of organic molecules, Wessel and McClure have done pioneering (and beautiful) work on the $S_{1,2}$←S_0 absorption spectra of naphthalene,[24)] and their work has been developed by several theoretical investigators.[25-27)] Recently we have also been engaged in analyzing the tangled T←S spectra of benzaldehydes.[28,29)]

Concerning the phosphorescent state of acetophenone in the crystal, there exists a serious discrepancy. On the basis of the intensity of the longest wavelength band (at 382.8 nm) and on the basis of an energy correlation between this and other related molecules, Dym and Hochstrasser concluded that the lowest excited triplet state is $n\pi^*$.[30)] From a study of the polarization and Zeeman effects on the origin band, Tanimoto *et al.* also came to the same conclusion[31)] although they never rejected the alternative $\pi\pi^*$ assignment which has been suggested from a study on dynamical properties of the triplet state by Hirota *et al.*[15)] From the polarization data, on the other hand, Case and Kearns assigned the longest wavelength band as $^3L_a(\pi\pi^*)$←S_0, and the 280 cm^{-1} band as the origin of $^3U(n\pi^*)$←S_0,[32)] reversing the suggestion of Dym and Hochstrasser. A series of works on the zero field magnetic substates of acetophenone by Hirota *et al.* supported this assignment[15,16)] although environments employed were different. On the basis of a study on the phosphorescence of 1% acetophenone in acetophenone-*phenyl-d*$_5$, Koyanagi *et al.* concluded that the phosphorescent state of crystal phase acetophenone is $\pi\pi^*$.[7)] Recently, Souto and Lin have observed the phosphorescence spectra of acetophenone and its derivatives in *p*-dimethoxybenzene[33)] and suggested that the phosphorescent state is $n\pi^*$, preferring Dym and Hochstrasser's assignment[30)] to Case and Kearns'.[32)]

The purpose of this paper is to analyze this tangled spectrum both experimentally and theoretically; and to give a clearcut answer to the controversial issue. The calculation method is based on making up secular equations with many crude BO vibronic state functions. The validity of the treatment will be manifested in comparison with the observed spectra.

Theoretical

The present treatment is, in principle, very simple and essentially the same as that reported elsewhere.[28,29)] Here let us outline the major aspects and show a schematic block diagram of the calculation process (see Fig. 1).

We start with the assumptions that two excited electronic levels T_1^0 and T_2^0 lie close to each other and that there are vibronic and environmental interactions between them. For this system it is no longer

† Present address: Department of Food Science, Nishikyushu University, Kanzaki, Kanzaki-gun, Saga Prefecture 842.

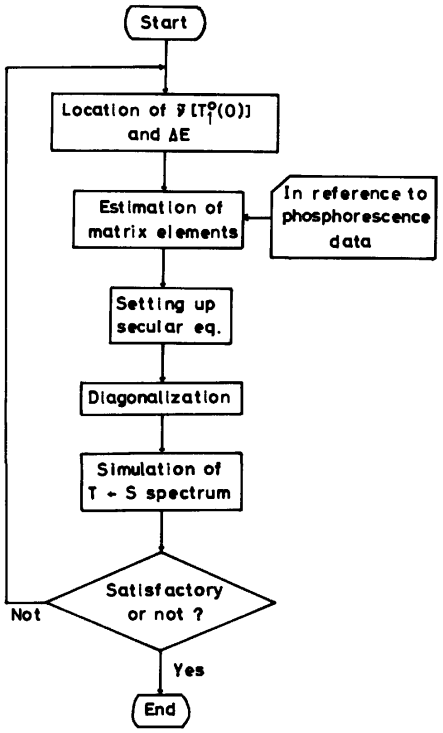

Fig. 1. Block diagram of the calculation process. ΔE is the energy separation between $T_1^0(0)$ and $T_2^0(0)$.

legitimate to use the general perturbation theory. The energies of the perturbed vibronic levels are then obtained by a direct diagonalization of the corresponding part of the energy matrix corrected to the first (or second) order, *i. e.*, by solution of the secular equation:

$$\begin{vmatrix} H_{11}-E & H_{12} & \cdots & H_{1m} & \cdots & H_{1n} \\ \cdot & H_{22}-E & \cdots & \cdot & & \cdot \\ \cdot & \cdots & \cdot & \cdots & & \cdot \\ H_{l1} & \cdots & H_{ll}-E & H_{lm} & \cdots & \cdot \\ \cdot & \cdots & \cdot & \cdots & & \cdot \\ H_{n1} & \cdots & & & & H_{nn}-E \end{vmatrix} = 0, \quad (1)$$

where

$$H_{lm} = \langle l|H_0+H'|m\rangle = \langle l|H_0|m\rangle\delta_{lm} + \langle l|H'|m\rangle(1-\delta_{lm}), \quad (2)$$

and n is the number of vibronic levels considered. H_0 is the Hamiltonian of an idealized problem which can be solved exactly, while H' is the perturbation operator, *i. e.*, vibronic and environmental interactions.

$$H' = H_{\text{vib}} + H_{\text{environment}}. \quad (3)$$

Now, we need to evaluate the matrix elements of the coupling perturbation. If there is no vibronic level degeneracy and the vibronic levels are described by a set of harmonic oscillator wavefunctions, it seems that the calculation is, in principle, straightforward. The zero-order eigenfunctions are given as the crude adiabatic wavefunctions of states T_1^0 and T_2^0. Vibronic interactions, H_{vib}, are in general described as follows:[34]

$$H_{\text{vib}} = \sum_a [\partial V(q, Q)/\partial Q_a]_0 Q_a + 1/2 \sum_a \sum_b [\partial^2 V(q, Q)/\partial Q_a \partial Q_b]_0 Q_a Q_b + \cdots = H_{\text{vib}}(q, Q). \quad (4)$$

Here Q_a and Q_b denote the ath and bth vibrational normal coordinates, respectively. On the other hand, $H_{\text{environment}}$ is given in the point-dipole approximation by[35]

$$H_{\text{environment}} = -(e^2/R_{uv}^3) \sum_r \sum_{f,s} (2Z_r z_{f,s} - X_r x_{f,s} - Y_r y_{f,s}) - (1/2)(e^2/R_{vv}^3) \sum_{f,s} \sum_{g,t} (2z_{f,s} z_{g,t} - x_{f,s} x_{g,t} - y_{f,s} y_{g,t}) = H_{\text{environment}}(q, Q; \xi_1, \Xi_1; \xi_2, \Xi_2; \cdots), \quad (5)$$

where (X_r, Y_r, Z_r) denotes the coordinates of the rth electron of the solute molecule in question, $(x_{f,s}, y_{f,s}, z_{f,s})$ the coordinates of the sth electron of the fth environmental molecule.

For the evaluation of these two types of off-diagonal matrix elements in the acetophenone crystal, we prefer empirical methods to direct calculation. One of the methods is to find other suitable guest/host systems where the energy separation between T_1^0 and T_2^0 is very large. Optical data, if obtainable, will be useful for the evaluation of H_{lm} ($l \neq m$). If there is found no suitable guest/host system, another method is to utilize the spectral data of emissions which originate at the levels in "off-resonance region" and to take several practical assumptions. In the present work we employed this approach because of a failure in finding a suitable host system.

As shown in Eq. 5, $H_{\text{environment}}$ contains a number of solvent (environment) coordinates (ξ_f, Ξ_f) together with the guest molecular coordinates (q, Q). However, we treat this as an "averaged, static" perturbation on the "guest" molecule in question. In other words, we still consider the condensed phase problem in terms of the modulated electronic structure of the one guest molecule:

$$H_{\text{environment}} = H_{\text{environment}}(q, Q) \quad (6)$$

Similar treatments were reported elesewhere.[35,36] This type of perturbation may generally be taken into account for the spectra of molecules in

condensed media with poor site symmetry, and will allow the electrostatic couplings between intramolecular electronic states,[35,37] *e. g.*, direct couplings between T_1 and T_2 zero-point levels of aromatic carbonyls in rigid crystals as has been suggested by Hirota *et al.*[15-17] and Koyanagi *et al.*[38]

Several calculations were carried out for the following two cases: (1) $T_1={}^3\pi\pi^*$ and $T_2={}^3n\pi^*$; and (2) $T_1={}^3n\pi^*$ and $T_2={}^3\pi\pi^*$. Here, let us describe the detailed calculation method for case (1). Similar calculations are possible for case (2) (see the last subsection in "Results and Discussion"). For case (1) the secular determinant was made up using thirty-six crude adiabatic Born-Oppenheimer product functions, of which twenty-seven concern the $T_1(\pi\pi^*)$ electronic state and the others the $T_2(n\pi^*)$ state. For the $T_1(\pi\pi^*)$ state, we took into account eleven nontotally symmetric vibrations with low frequencies, *i. e.*, ν_{45}—ν_{35}; three phosphorescence-active totally symmetric vibrations, *i.e.*, ν_{30}, ν_{29}, ν_{27}, and their combination vibrations.[39] The zero-order vibronic levels of $T_2(n\pi^*)$, are the vibrationless level, three in-plane vibrations (ν_{30}, ν_{29}, ν_{27}), and five low frequency out-of-plane vibrations (ν_{45}—ν_{41}). Several important vibrational modes are listed in Table 1.

Vibronic interaction matrix elements are given assuming Herzberg-Teller couplings.

$$\begin{aligned}&\langle T_1^0(0+\nu_i)|H_{vib}|T_2^0(0+\nu_j)\rangle_{(i\neq j)}\\&=\langle {}^3\pi\pi^*|(\partial V/\partial Q_i)_0|{}^3n\pi^*\rangle\langle i_1|Q_i|i_2\rangle\langle j_1|j_2\rangle\prod_{k\neq i,j}\langle k_1|k_2\rangle\\&+\langle {}^3\pi\pi^*|(\partial V/\partial Q_j)_0|{}^3n\pi^*\rangle\langle j_1|Q_j|j_2\rangle\langle i_1|i_2\rangle\prod_{k\neq i,j}\langle k_1|k_2\rangle\\&=\langle T_1^0(0+\nu_j)|H_{vib}|T_2^0(0+\nu_i)\rangle.\end{aligned}\tag{7}$$

Here $|T_1^0(0+\nu_i)\rangle$, for example, is the eigenstate function for the ν_i vibronic level of $T_1^0(\pi\pi^*)$ and $|k_2\rangle$ is that for the k-normal mode of $T_2^0(n\pi^*)$. The integrals, $\langle i_1|Q_i|i_2\rangle$ and $\langle j_1|Q_j|j_2\rangle$, yield a number of zero-valued matrix elements on the assumption of a set of harmonic oscillators. The overlap integrals, *e. g.*, $\langle i_1|i_2\rangle$ and $\langle j_1|j_2\rangle$, are related to the Franck-Condon factor in the transition $T_2\leftarrow T_1$ (and that in the transition $T_2\leftarrow S_0$ if the molecular structure is assumed to be identical both in the ground and first excited ${}^3\pi\pi^*$ state). The first order perturbation theory for a [weak vibronic coupling/large ΔE] system gives

$$\langle T_1^0(0+\nu_i)|H_{vib}|T_2^0(0)\rangle \propto I(i\leftarrow 0)^{1/2}\Delta E \propto I(0\rightarrow i)^{1/2}\Delta E,\tag{8}$$

where ΔE is the energy separation between $T_1^0(0)$ and $T_2^0(0)$; $I(i\leftarrow 0)$ and $I(0\rightarrow i)$ are the relative intensities of $T_1(0+\nu_i)\leftarrow S_0(0)$ absorption and $T_1(0)\rightarrow S_0(0+\nu_i)$ phosphorescence bands, respectively. Similarly,

$$\begin{aligned}&\langle T_1^0(0+\nu_i)|H_{vib}|T_2^0(0+\nu_j)\rangle_{(i_1\in a'',\ j_2\in a')}\\&\propto I(i\leftarrow 0)^{1/2}\Delta E\langle 0_1|j_2\rangle \propto I(0\rightarrow i)^{1/2}\Delta E\langle 0_1|j_2\rangle,\end{aligned}\tag{9}$$

and so on.

Next let us write more practical assumptions. Two parameters were introduced for the evaluation of the off-diagonal matrix elements. They are f_v and F_e, where the former concerns the vibronic couplings and the latter the environmental couplings. These parameters were then refined in comparison with the simulated and observed spectra. Interaction matrix elements were evaluated from the relative intensity of the corresponding band of the $T_1\rightarrow S_0$ phosphorescence spectrum[7] on the assumption of $\langle T_1^0(0)|H'|T_2^0(0+\nu_i)\rangle=\langle T_1^0(0+\nu_i)|H'|T_2^0(0)\rangle$ (see Eq. 7 for H_{vib}-terms); where H' is given by Eq. 3. The matrix elements $\langle T_1^0(0+\nu_i)|H_{vib}|T_2^0(0)\rangle$ were given as $f_v\times$[the relative intensity of the corresponding vibronic band in the phosphorescence]$^{1/2}$ (see Eqs. 8 and 9); the matrix elements $\langle T_1^0(0+\nu_i)|H_{environment}|T_2^0(0)\rangle$ were given as $F_e\times$[Franck-Condon factor for the phosphorescence band $0\rightarrow\nu_i$]$^{1/2}$. The parameter f_v is common to all the vibronic couplings and the successive quantity in brackets is uniquely determined from the phosphorescence intensity data. This leads to a considerable reduction from a tedious labor of fixing off-diagonal terms in a trial and error method. Similar simplification was carried out for $\langle T_1^0(0+\nu_i)|H_{environment}|T_2^0(0)\rangle$ by using the other parameter F_e.

All the T←S transition intensities were assumed to originate in zero-order transition $T_2^0(n\pi^*;\ 0,0)$ and three Franck-Condon vibronic transitions, $T_2^0(0,0+\nu_{30})$, $T_2^0(0,0+\nu_{29})$, and $T_2^0(0,0+\nu_{27})$, since there has, in general, been accepted the following relation for halogen-free aromatic carbonyls:[8,41]

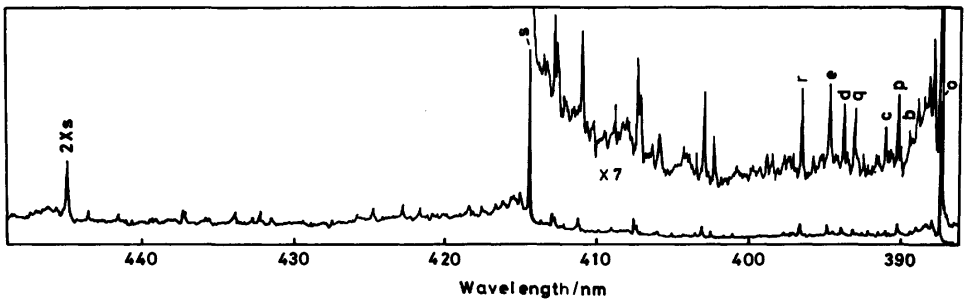

Fig. 2. Phosphorescence spectrum of $\approx 10^{-3}$ M acetophenone in *p*-dimethoxybenzene at 4.2 K. Band notations are difined in Table 1.

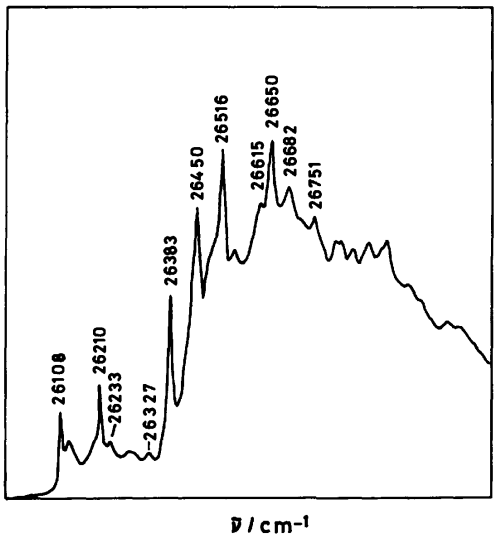

Fig. 3. $T_{1,2}\leftarrow S_0$ phosphorescence excitation spectrum of acetophenone in the crystal at 4.2 K.

$$f(^3n\pi^*\leftarrow S_0) \gg f(^3\pi\pi^*\leftarrow S_0). \quad (10)$$

Here $f(^3n\pi^*\leftarrow S_0)$ and $f(^3\pi\pi^*\leftarrow S_0)$ are the oscillator strengths of $^3n\pi^*\leftarrow S_0$ and $^3\pi\pi^*\leftarrow S_0$ transitions, respectively. The relative intensity ratios of $T_2^0(0,0)$, $T_2^0(0,0+\nu_{30})$, $T_2^0(0,0+\nu_{29})$, and $T_2^0(0,0+\nu_{27})$ were taken to be 1.000, 0.072, 0.051, and 0.086, respectively, as consulting the $T_1(n\pi^*)\rightarrow S_0$ phosphorescence spectrum of acetophenone in *p*-dimethoxybenzene at 4.2 K (Fig. 2).

For the evaluation of the diagonal matrix elements of $T_1^0(0+\nu_i)$, we started off with the same vibrational frequencies as those of the ground state (in other words, we assume almost the same molecular geometry of acetophenone in $^3\pi\pi^*$ as that in S_0),[7] while somewhat different values for the diagonal matrix elements of $T_2^0(0+\nu_i)$ in reference to the $^1n\pi^*\leftarrow S_0$ transition vibrational data in *p*-dimethoxybenzene. The two parameters f_v and F_e were taken to be close to the values employed for the benzaldehyde T←S spectra in acetophenone and methyl benzoate[28] (*e.g.*, f_v=55.0 cm^{-1} and F_e=50.0 cm^{-1} for benzaldehyde in acetophenone).

Each absorption band was assumed to be of a lorentzian with a 10 cm^{-1} full width at half maximum. Any interactions among intra- and intermolecular vibrations were ignored.

Experimental

Acetophenone (Aldrich and Wako Pure Chemical Co., Ltd.) was repeatedly distilled in vacuum. *p*-Dimethoxybenzene (Wako Pure Chemical Co., Ltd.) was purified by vacuum sublimation followed by zone-refining.

The T←S phosphorescence excitation spectrum of acetophenone was observed using crystal samples in which a small amount of benzaldehyde was doped as an effective phosphorescence emitter. The $T_1\rightarrow S_0$ phosphorescence and $S_1\leftarrow S_0$ excitation spectra of acetophenone were also studied at 4.2 K in *p*-dimethoxybenzene single crystals which were prepared by the conventional Bridgman technique (the initial concentration of acetophenone: $\approx 10^{-3}$ M). All the spectra were recorded on a 3/4 m Nalumi Spectrophotometer. Other experimental details were similar to those described previously.[42]

Results and Discussion

Phosphorescence Spectrum of Acetophenone. The phosphorescence spectrum of acetophenone in *p*-dimethoxybenzene at 4.2 K is shown in Fig. 2. The phosphorescent state of acetophenone in *p*-dimethoxybenzene has been assigned to be $n\pi^*$ by Souto and Lin.[33] We confirmed this. However, their vibrational assignment is considerably different from available normal-coordinate analysis data[7,43] and therefore seems to be erroneous especially for several out-of-plane vibrational modes. The present vibrational analysis is essentially based on the data by Koyanagi *et al.*[7] The results are shown in Fig. 2 together with alphabetical band designations whose vibrational notations are given in Table 1. Despite the propose $T_1=^3n\pi^*$ assignment,[33] it is noticeable that there appear several out-of-plane vibrational bands which are weak, but discriminating (see bands *b*—*e* in Fig. 2).

T←S Spectrum of Acetophenone in the Crystal. The T←S excitation spectrum of acetophenone in the crystal is shown in Fig. 3. Sample crystals were prepared to contain $\approx 10^{-3}$ M benzaldehyde since the dopant has been established to be an excellent triplet acceptor in the host.[6] The concentration ratios employed prove that the T←S absorption of the guest is weak enough on the present experimental conditions. Similarity of the T←S phosphorescence excitation spectrum (Fig. 3) to the direct T←S absorption spectrum (*e. g.*, Fig.2 in Ref.31) assures this is the case.

The band at 26108±2 cm^{-1} is taken to be the origin band of the $T_1 \leftarrow S_0$ transition. This assignment is supported by the fact that the band location is in good agreement with the strong phosphorescence origin peak at 26100±2 cm^{-1} which has been observed for the system of acetophenone in acetophenone-*phenyl-d*$_5$.[7] Almost all 20—60 cm^{-1} broad band features attending each prominent peak are assigned to be due to phonons. Main prominent bands are found at 26210, 26383, 26450, 26516, and 26650 cm^{-1}. The higher energy bands become the broader.

Simulated T←S Spectra of Acetophenone in the Crystal. A diagonalization of the matrix was carried out and some parameters were refined. In Tables 2 and 3 we give the final estimates to zero-

TABLE 2. ZERO-ORDER DIAGONAL MATRIX ELEMENTS EMPLOYED[a]

a) In cm^{-1} units.

order energies and interaction values on the assumption of $T_1={}^3\pi\pi^*$.[44] Figure 4(a) shows the location of zero-order levels; and the height of the solid lines represents the relative interaction energies between $T_1^0(0+\nu_i)$ and $T_2^0(0)$ and the height of dashed lines the interactions between $T_1^0(0)$ and $T_2^0(0+\nu_i)$. The longest wavelength band at 26108 cm^{-1} in the simulated T←S spectrum is assigned to the origin band of the $T_1(\pi\pi^*)\leftarrow S_0$ transition as is confirmed by analyzing the eigenvectors given in Table 4. The corresponding state is described by a large component of $|T_1^0(0)>$ and a small part of other zero-order vibronic eigenvectors:

$$\Psi_{T_1(0)} \simeq -0.95|0> + 0.20|0^*> - 0.12|44> + 0.10|42^*>, \quad (11)$$

where $|0>$ and $|0^*>$ represent $|T_1^0(0)>$ and $|T_2^0(0)>$, respectively. There is found considerable $|0^*>$ mixing with $|0>$. This will explain why the origin band of the $T_1\leftarrow S_0$ absorption appears with remarkable intensity despite the proposed $\pi\pi^*$ assignment. The major part of the state function, however, is zero-order function $|0>$. This means that many physical properties for this state are still under the control of the zero-order function $|0>$ except for several optical properties such as the absorption band intensity, polarization, and emission lifetime. The −0.12 value of the expansion coefficient for $|44>$ seems to be due to the second-order coupling through $|0^*>$ as an intermediate level.

The observed bands at 26210 cm^{-1} and 26233 cm^{-1} are assigned as $T_1(0,0+\nu_{45})$ and $T_1(0,0+\nu_{44})$, respectively, since their corresponding state functions contain a large coefficient of either $|45>$ or $|44>$. It should, however, be noted that a considerable mixing of the other zero-order function is also found (see Table 4). These mixings possibly occur *via* second-order vibronic couplings with an intermediate state, $|0^*>$, if the relevant levels (ν_{45} and ν_{44}) are lying close to each other. It is, thus, not surprizing to see that the band $T_1(0,0+\nu_{45})$ is more intense that $T_1(0,0+\nu_{44})$ despite of the reverse magnitude relation of the employed interaction matrix elements, *i.e.*, $|<45|H'$

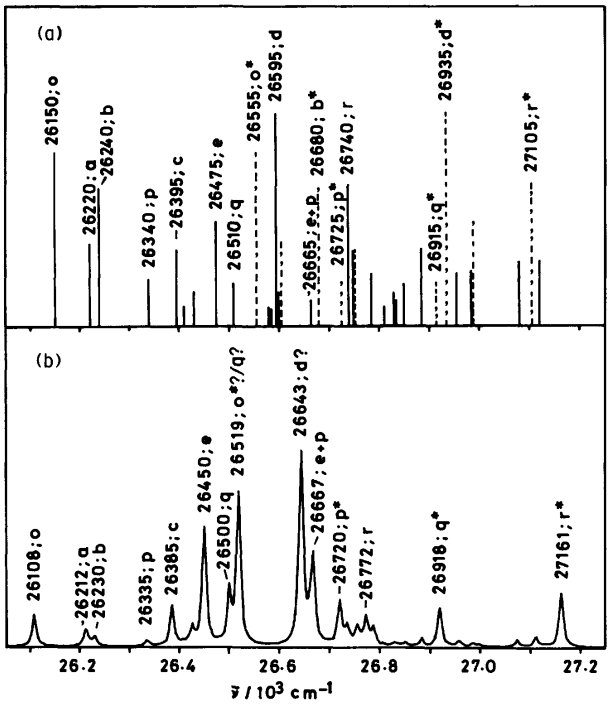

Fig. 4. (a) The zero-order vibronic levels of $T_1^0(\pi\pi^*)$ and $T_2^0(n\pi^*)$. The solid and dashed lines show the zero-order T_1^0 and T_2^0 vibronic levels, respectively. The length of each line shows the relative value of the off-diagonal matrix element between the relevant vibronic level and the zero-order vibrationless level of the counterpart electronic state. (b) Simulated $T_{1,2}\leftarrow S_0$ transition spectrum of acetophenone in the crystal. The bands are assumed to be a lorentzian, each band having a 10 cm^{-1} width.

a) Here the expansion coefficients are shown for only the major BO functions. b) The state functions are denoted by the band energies (eigenvalues). The values in parentheses are the observed data.

$|0^*>|<|<44|H'|0^*>|$. Similarly, from the coefficient analysis, the band at 26327 cm^{-1} is attributed to $T_1(0,0+\nu_{30})$.

Next, let us view the band-crowded region which starts on the lower energy tail of the 26383 cm^{-1} band (Fig. 3). At a glance, there are four prominent bands superimposed on the broadened background: the bands at 26383, 26450, 26516, and 26650 cm^{-1}. Their corresponding state functions are approximately expressed as follows:

$$|26383> \simeq 0.22|0^*> - 0.93|43> - 0.11|42> - 0.13|41> \quad (12)$$

$$|26450> \simeq -0.38|0^*> - 0.23|43> + 0.26|42> + 0.77|41> \quad (13)$$

$$|26516> \simeq 0.43|0^*> + 0.55|29> - 0.52|42> + 0.41|41> \quad (14)$$

$$|26650> \simeq 0.48|0^*> - 0.36|27> + 0.64|42> + 0.26|44^*>. \quad (15)$$

A large mix-up in these state functions is noticeable. The states corresponding to the bands at 26383 and 26450 cm^{-1} have components large enough so that they can safely be attributed to $T_1(0,0+\nu_{43})$ and $T_1(0,0+\nu_{41})$, respectively. However, the other two states do not meet our criterion[28] for unique assignment.[46]

As shown clearly in Table 4, the vibronic state functions are canonically described by a number of crude adiabatic BO state functions and there is considerable environmental mixing between $T_1^0(\pi\pi^*)$ and $T_2^0(n\pi^*)$. The environmental mixing is more prominent in this acetophenone case than in benzaldehyde case,[28] as is rationalized by the easily detectable origin band (see band at 26108 cm^{-1} in Fig. 3).

TABLE 5. VIBRATIONAL FREQUENCIES PROPOSED FOR SEVERAL IMPORTANT MODES OF ACETOPHENONE IN THE EXCITED TRIPLET STATES[a)]

Vibration	Frequency		
	S_0	T_1	T_2
ν_{45}	44	70	50
ν_{44}	125	90	125
ν_{43}	234	245	195
ν_{42}	421	445	380
ν_{41}	471	325	430
ν_{30}	204	190	170
ν_{27}	597	590	550

a) In cm^{-1} units. For comparison, the ground state frequencies taken from the observed values (Ref. 7) were given in the second column. The other frequency values cited were taken on the basis of the present calculation.

We previously gave a CNDO description of $^3n\pi^*$ and $^3\pi\pi^*$ states for benzaldehyde.[28] Similar consideration for acetophenone predicts: (i) the π and π^* orbitals are strongly bonding and antibonding in the C=O region, respectively; (ii) the expectable change in acetyl group bond order brought about by $\pi^* \leftarrow n$ promotion leads to a large reduction in C=O stretching vibrational frequency and a small reduction in C-CH_3 vibrational frequency on going from the ground state to the $n\pi^*$ excited state; and (iii) the large increase in the C-$COCH_3$ bond order is realized consequent to $\pi^* \leftarrow \pi$ promotion, while its small increase on $\pi^* \leftarrow n$ promotion. The prediction (iii) leads us to expect ν_{45} and ν_{43} frequencies increase on going from the ground to the excited states. In Table 5 are summarized several vibrational data employed for the three electronic states. Although ν_{42} essentially belongs to the ring modes, an introduction of a methyl group to the C=O group has been known to bring forth a large mode-mixing between ω(CXO) and so-called Wilson's ν_{16a} modes.[7,47] The mode frequency increase in ν_{43} and ν_{42}, thus, seems to be rationalized to a certain extent. Another notable point in Table 5 is that ν_{41} mode drastically decreases in frequency on going from S_0 to T_1. For the present we cannot explain this.

As regards off-diagonal matrix elements, the values given previously for benzaldehyde[28] are good references. For convenience sake, let us take and compare two representative off-diagonal terms with large values. The prominent values of $\langle T_1^0|H_{\text{environment}}|T_2^0\rangle$ are 36.0, 50.0, and 70.0 cm^{-1} for benzaldehyde/methyl benzoate, benzaldehyde/acetophenone, and acetophenone crystal, respectively, while the largest vibronic interaction matrix elements are 67.5 cm^{-1} (for H-wag), 55.0 cm^{-1} (for H-wag), and 85.0 cm^{-1} (for ν_{42}).

Simulation Spectra for the Reverse Case to the $T_1=^3\pi\pi^*$ Assignment loc. cit. We carried out a series of calculations on the assumption that the lowest excited triplet state of crystal phase acetophenone is of $\pi\pi^*$. Good agreement between the observed and simulated spectra seems to establish our assignment. It is, however, necessary to refer to the results of calculations which we carried out under the reverse assignment, *i.e.*, $T_1=^3n\pi^*$ and $T_2=^3\pi\pi^*$. Figure 5 shows the simulation spectrum where only the two zero-order energies are changed into: $E[T_1^0(n\pi^*;0,0)]=26150$ cm^{-1} and $E[T_2^0(\pi\pi^*;0,0)]=26555$ cm^{-1}: and where all the other parameters are the same as those *loc. cit.*[48] It should be noted that "the spectrum is characterized by the extremely intense T_1 origin band and very weak out-of-plane vibrational bands." This character is, more or less, kept for many other ΔE values except for $|\Delta E|<$ 50 cm^{-1} where the crystal field couplings between the

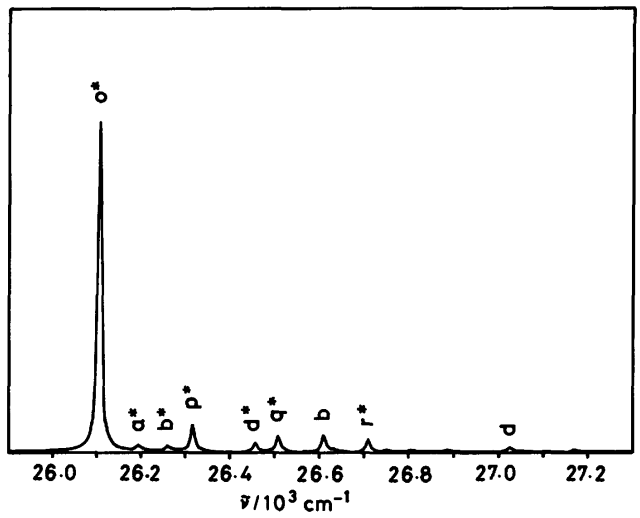

Fig. 5. Hypothetical T←S spectrum of acetophenone. Here $T_1^0 = {}^3n\pi^*$ and $T_2^0 = {}^3\pi\pi^*$ were assumed. $\Delta E = 405\ cm^{-1}$.

zero-order vibrationless levels are considerable so that there appears generally a "doublet" band structure.[50] Similar "$n\pi^*$" type band patterns have also been demonstrated for benzaldehyde T←S spectra in methylcyclohexane.[29,42] In conclusion we do not believe that T_1 is $n\pi^*$ in crystalline acetophenone.

Concluding Remarks

Two different assignments for the lowest excited triplet state of acetophenone in the crystal have been proposed.[5,7,30-32] The present treatment shows that T_1 is $\pi\pi^*$. Almost all observed T←S bands are assignable as $T_1(\pi\pi^*)$ vibronic bands which are strongly coupled with $T_2(n\pi^*)$ origin band.

Many investigators have so far searched for the $n\pi^*$-$\pi\pi^*$ criterion "measures" by which the lowest excited triplet state is discernible: *e.g.*, radiative lifetimes, deuteration shifts, zero-field splittings, spectral band patterns, Zeeman effects, Stark effects, *etc.* (for these problems, see Ref. 54). It seems, however, that there are no decisive "measures" for the criterion. We believe the present treatment could throw a light on the long-time controversial issues.

Lastly , we would like to mention phonons. We have not explicitly taken into account the role of phonon modes in the present theoretical treatment. There remains the problem of deciding whether we should take into account phonons as vibronic coupling modes or Franck-Condon modes. We will refer to this problem in the following paper.[45]

The authors acknowledge helpful discussions with Professor Donald S. McClure (Princeton University) and Professor Lionel Goodman (Rutgers University) at the earliest stage of this work on the vibronic interactions of congested electronic systems, and invaluable suggestions by referees. One of the authors (KN) wishes to express thanks to Professor R. Shimada for his warm hospitality and encouragements in Kyushu University. The calculations reported in this paper have been carried out at the Computation Center of Kyushu University.

43) A. Gambi, S. Giorgianni, A. Passerini, R. Visinoni, and S. Ghersetti, *Spectrochim. Acta*, **36A**, 871 (1980).

44) To simplify the calculation, here we neglected the following type matrix elements: $\langle T_1^0(0+\nu_i)|H_{\text{environment}}|T_2^0(0+\nu_i)\rangle$, where ν_i is an out-of-plane vibrational mode. This integral, in general, leads to minor mixing between the relevant vibronic levels. The magnitude of such mixing, in many cases, is close to that of the mixing between $T_1^0(0)$ and $T_2^0(0)$. This point will be discussed in the succeeding paper (Ref. 45).

45) K. Nakashima and M. Koyanagi, *Bull. Chem. Soc. Jpn.*, the succeeding paper.

46) It is tempting to accept a suggestion that these bands are attributed to $T_1(0,0+\nu_{29})$ and $T_1(0,0+\nu_{42})$, respectively, from the component analysis. For the former, however, we have an explicit calculation band at 26500 cm^{-1} whose state function is expressed as follows:

$$|26500> \simeq 0.25|0^*> - 0.80|29> \\ -0.25|42> + 0.43|41>.$$

47) E. B. Wilson, J. C. Decius, and P. C. Cross, "Molecular Vibration" McGraw Hill, New York (1955).

48) As for off-diagonal vibronic interaction matrix elements, we employed the same values as in case (1) where $T_1={}^3\pi\pi^*$ was assumed. Even if the phosphorescence spectrum of acetophenone in acetophenone-*phenyl*-d_5 is of $n\pi^*$ nature, no big change for the vibronic interaction matrix elements $\langle {}^3n\pi^*|H_{\text{vib}}|{}^3\pi\pi^*\rangle$ will be necessary because the phosphorescence band pattern of acetophenone in acetophenone-*phenyl*-d_5 is considerably similar to that in benzoic acid reported by Nagaoka and Hirota (Ref. 49). Without doubt the phosphorescence in benzoic acid host is of $\pi\pi^*$.

49) S. Nagaoka and N. Hirota, *Bull. Chem. Soc. Jpn.*, **56**, 3381 (1983).

50) Here we completely neglected spin-orbit couplings between ${}^3n\pi^*$ and ${}^3\pi\pi^*$. This seems to be rationalized to a great extent as long as we are concerned with optical spectra in the case of $|\Delta E| > 50\ cm^{-1}$. For $|\Delta E| < 50\ cm^{-1}$, large (8—15 cm^{-1}) spin-sublevel splitting spectra have been observed because of considerable spin-orbit couplings (see Refs. 51—53).

Adsorption of Phenol on Surface-modified Carbon Black from Its Aqueous Solution. II. Influence of Surface-chemical Structure of Carbon on Adsorption of Phenol[1)]

(Received November 10, 1984)

Samples of electronic conductive carbon black (Lion Akzo Co.) were treated with nitric acid, hydrogen peroxide, dried air, or hydrogen gas. These samples had almost the same specific surface areas and pore volumes, except for the one treated with nitric acid. Phenol gas adsorption and aqueous-phase adsorption were carried out in order to study the adsorption mechanism on these treated samples. During aqueous-phase adsorption, the amount of phenol adsorbed increased with a decrease in the number of surface oxygen compounds on the carbon sample. During gas adsorption, the amount of phenol adsorbed decreased with a decrease in the number of oxygen compounds on the carbon surface. The residual amount of phenol also decreased. In the case of gas adsorption, interactions occur not only between the hydrophobic sites on the carbon and the hydrophobic groups of phenol, but also between the surface functional groups on the carbon and the hydrophilic groups of phenol. In the case of aqueous-phase adsorption, competitive adsorption of phenol with water molecules occurs. Water molecules adsorb, selectively, the surface functional groups on the carbon. Thus, the phenol adsorption due to the hydrophobic interaction on the carbon interferes with this selective adsorption.

Municipal wastewaters and industrial wastewaters, which include various organic compounds, are sources of environmental pollution. The use of solid adsorbents as a medium for removing trace quantities of organic compounds from wastewaters is useful at the time of demanding environmental restrictions and a need for the regeneration of water.[2)]

Activated carbon which has a very large surface area has usually been used for solid adsorbents during wastewater treatment.[2-12)] The carbon produced by usual methods, contains considerable amounts of oxygen chemisorbed on the surface.[13)] It seems that the adsorptive properties of such types of carbon are affected by the amount of chemisorbed oxygen. However, the influence of oxygen compounds on the carbon surfaces regarding the adsorption of organic compounds, has not been studied in detail. In this research, a special carbon black having a very large surface area was used as an adsorbent. Using this sample, four types of surface-modified carbon black were prepared. The amount of phenol adsorbed on the modified forms of carbon black was measured in the gas state and in aqueous solution. On the base of the adsorption data, we discuss the influence of the oxygen compounds on the carbon surfaces upon the adsorption of phenol.

Experimental

Materials. The carbon black used as an adsorbent was Electronic Conductive Carbon Black supplied by Lion Akzo Company, Ltd., Tokyo, Japan. The carbon black was treated with nitric acid, hydrogen peroxide, dried air, or hydrogen gas. The modifications were carried out by a method previously reported.[1)] The modification methods and the typical properties of the modified carbon black samples are shown in Fig. 1 and Table 1.

The phenol used for the adsorption experiment was a reagent grade chemical from Wako Pure Chemical Industries Company, Ltd., Tokyo, Japan, it is more than 99% pure.

Procedures. Phenol Gas Adsorption. Prior to adsorption measurements, all samples were evacuated at 120 °C for 5 h under 1.3×10^{-3} Pa. The amount of phenol adsorbed was measured gravimetrically using a Cahn RG-type electromagnetic microbalance at 25 °C and at $P/P_0=0.080$ (where P and P_0 are equilibrium and saturated pressures respectively). After the adsorption experiment, the samples were outgassed for 12 h under 1.3×10^{-3} Pa at 25 °C and the

E	H_2	851	0.863	0.25

a) By N_2 BET method. b) Cranston-Inkley method, from 10 to 300 Å pore diameter. c) The ash content was determined with a porcelain crucible, in air.

Table 2. Adsorbed amount and residual amount of phenol on modified carbon black samples

Carbon black	Gas adsorption		Aqueous-phase adsorption
	Adsorbed amount $10^{-5} g m^{-2}$	Residual amount $10^{-5} g m^{-2}$	Freundlich const k[a] $10^{-5} g m^{-2}$
A	33.6	7.2	4.0
B	42.8	17.8	0.9
C	35.0	7.6	2.1
D	32.4	7.4	2.6
E	25.9	5.3	4.8

a) Data from the previous paper.[1]

residual amount of phenol at 25 °C was also measured gravimetrically.

The Weight Decrease of the Carbon Black Samples Heated in Vacuum. After the carbon black samples were outgassed for 18 h under 1.3×10^{-3} Pa at 120 °C, the samples were heated to 1000 °C at a heating rate of 4 °C/min in vacuum. The weight decrease of the samples was measured gravimetrically on the basis of the weight at 120 °C, using the Cahn RG-type electromagnetic microbalance.

Results and Discussion

Adsorbed amounts and residual amounts of phenol on the modified carbon blacks are shown in Table 2. The amount of phenol adsorbed on the modified carbon blacks from its aqueous solution, described in the previous paper, is also shown in Table 2. The amount of phenol adsorbed on the carbons treated with various oxidizing agents, especially with 13.2 M† HNO_3, increased, and the residual amount of phenol also increased. On the other hand, the amount of phenol adsorbed and the residual amount of phenol decreased on the carbon treated with hydrogen gas. In the previous paper it was reported that the amount of phenol adsorbed from an aqueous solution regarding the carbon treated with various oxidizing agents decreased. That regarding carbon treated with hydrogen gas, increased.

The adsorptive properties of forms of carbon are dependent on the pore structure.[6-11] However, Table 1 shows that these modified types of carbon black have almost the same specific surface areas and pore volumes, except for the carbon black treated with nitric acid.

Activated carbon and carbon black produced by the usual methods contain considerable amounts of oxygen and hydrogen chemisorbed on their surfaces.[13] The adsorptive properties of forms of carbon black are presumably affected by the amount of the oxygen and hydrogen on the surface. In order to examine the influence of chemisorbed oxygen and hydrogen on this adsorption, the carbon was evacuated and then heated from 120 to 1000 °C; this treatment decomposed the chemisorbed oxygen and hydrogen. Decomposition products during the heat/evacuation treatment were measured using mass spectrometry. Figs. 2—6 show the variations of mass spectral peaks of the desorbed gas from the modified forms of carbon black with an outgassing temperature up to 1000 °C at a heating rate of 4 °C/min in vacuum. When the samples were heated, the surface compounds decomposed into carbon dioxide, carbon monoxide, water and hydrogen. At higher temperatures, carbon monoxide is more evolved than carbon dioxide. Hydrogen is more difficult to remove than oxygen, but can be removed at very high temperatures.

† 1 M=1 mol dm^{-3}.

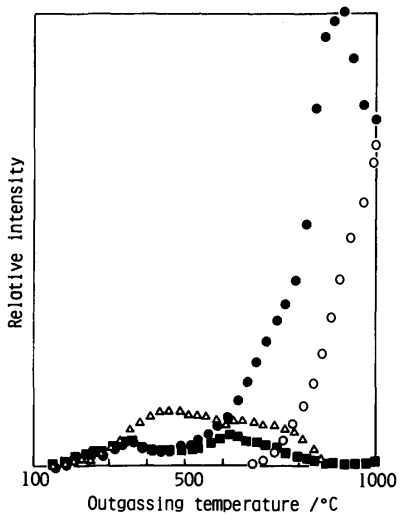

Fig. 2. Variations of mass spectral peaks of the desorbed gas on carbon black A with outgassing temperature up to 1000 °C at a heating rate of 4 °C/min in vacuum. ○: H_2, △: H_2O, ●: CO, ■: CO_2.

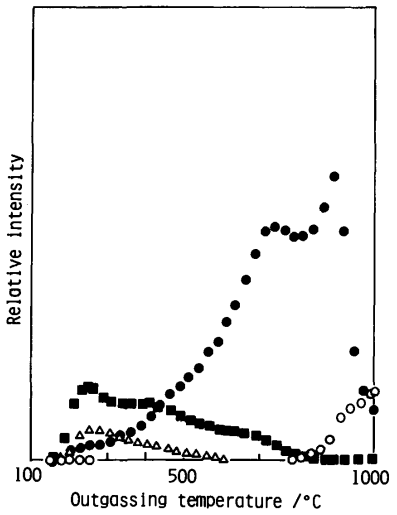

Fig. 4. Variations of mass spectral peaks of the desorbed gas on carbon black C with outgassing temperature up to 1000 °C at a heating rate of 4 °C/min in vacuum. ○: H_2, △: H_2O, ●: CO, ■: CO_2.

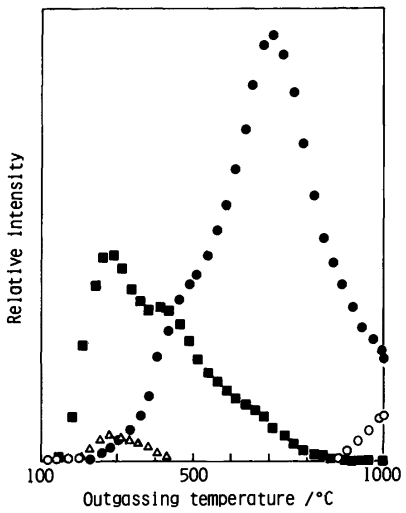

Fig. 3. Variations of mass spectral peaks of the desorbed gas on carbon black B with outgassing temperature up to 1000 °C at a heating rate of 4 °C/min in vacuum. ○: H_2, △: H_2O, ●: CO, ■: CO_2.

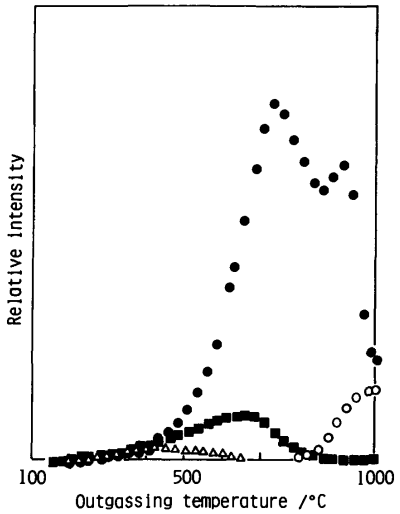

Fig. 5. Variations of mass spectral peaks of the desorbed gas on carbon black D with outgassing temperature up to 1000 °C at a heating rate of 4 °C/min in vacuum. ○: H_2, △: H_2O, ●: CO, ■: CO_2.

The mass spectral peaks of oxygen compounds such as CO and CO_2 from oxidized carbon black, especially from the carbon treated with 13.2 M HNO_3, were very large. However, the mass spectral peaks of H_2 from the oxidized forms of carbon black were low. For the carbon treated with hydrogen gas, the mass spectral peaks of oxygen compounds were very low and the mass spectral peaks of H_2 were rather large. We conclude that the hydrogen gas treatment removes the surface oxygen compounds. Mass spectroscopy showed that they were removed in the forms of H_2O, CO, and CO_2 during the hydrogen gas treatment. The weight decrease of the carbon-black samples heated in vacuum are shown in Table 3. The weight decreases of the oxidized carbon black, especially the carbon treated with 13.2 M HNO_3, were large, while that of the carbon treated with hydrogen gas was small. The weight decrease of various forms carbon, thus, increased along with the increase in the number of surface oxygen compounds.

The relationship between the amount of phenol adsorbed and the weight decrease of the carbon-black

samples during aqueous-phase adsorption is shown in Fig. 7. In aqueous-phase adsorption, the amount of phenol adsorbed decreased with increasing the amount of the surface oxygen compounds. The relationship between the amount of phenol adsorbed and the weight decrease of the carbon-black samples in gas adsorption is shown in Fig. 8. In gas adsorption, the amount of phenol adsorbed increased with increasing the number of the surface oxygen compounds, and the residual amount of phenol also increased.

From the above results, we propose a model regarding the adsorption mechanism between carbon and phenol (Fig. 9). In the case of gas adsorption, the interactions are not only between the hydrophobic sites on the carbon and the hydrophobic groups of phenol, but also between the surface functional groups on the carbon and the hydrophilic groups of phenol. In the case of aqueous-phase adsorption, there is a competitive adsorption of phenol with water molecules. The adsorption of water may commence by hydrogen bonding to surface oxygen groups.[13] It is thought that the water molecules adsorb selectively to the surface oxygen groups on the carbon because of their large polarity. The water molecules become secondary adsorption centers and retain other water molecules by means of hydrogen bonds.[12] The majority of the surface oxygen groups exist near the edges of fused hexagonal carbon rings or aromatic nuclei that make up the basis structure for carbons.[11,14] As a result, complexes of associated water form at the entrances of the pores of the carbon black. These complexes prevent the phenol adsorption due to the hydrophobic interaction on the carbon and prevent the invasion of phenol into the large surface area within the pores of the carbon. Therefore, the amount of phenol adsorbed on the carbon black in aqueous-phase adsorption decreases upon increasing the number of surface oxygen groups. However, in gas adsorption, the adsorbed amount and the residual amount of phenol on carbon black increased upon

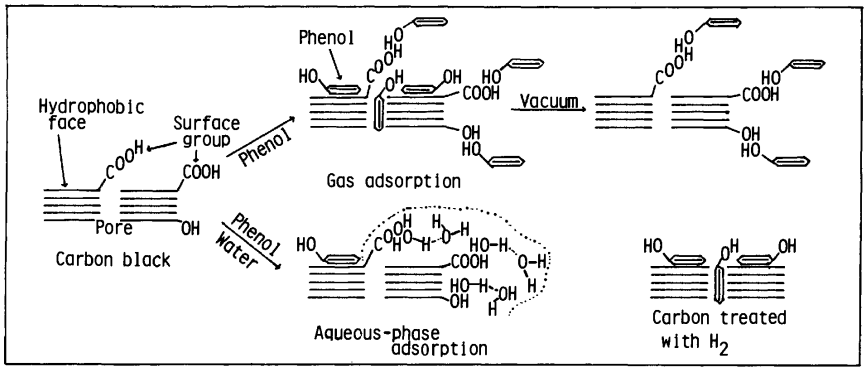

Fig. 9. The model of the adsorption mechanism between carbon and phenol.

increasing the number of surface oxygen groups, due to an interaction due to hydrogen bonding to the surface oxygen groups.

In order to investigate the influence of the forms of the surface oxygen groups on the carbon upon the adsorption of phenol, the weight decreases of the carbon for each of the desorbed gases have been evaluated using the mass spectral peaks of the desorbed gases on the modified types of carbon black shown in Figs. 2—6. These results are shown in Table 4. For carbon-black B, the weight decreases according to the desorbed gases, since CO and CO_2 are large and the total weight decrease is also large. For carbon-black C, the weight decreases are rather large for H_2 and H_2O, but the total weight decrease is little. The relationships between the amount of phenol adsorbed on the carbon and the weight decrease of the carbon for each of the desorbed gases are shown in Figs. 10 and 11. In aqueous-phase adsorption, the amount of phenol adsorbed decreased upon increasing the weight decreases based on the gases desorbed as CO and CO_2. In gas adsorption, the amount of phenol adsorbed increased upon increasing the weight decreases based on the gases desorbed as CO and CO_2.

Table 4. The weight decreases of the modified carbon black samples for each of the desorbed gases

Carbon black	Weight decrease mmol g^{-1}				
	H_2	H_2O	CO	CO_2	Total
A	0.58	0.17	0.60	0.11	1.46
B	0.14	0.08	2.82	1.75	4.79
C	0.22	0.08	1.24	0.48	2.02
D	0.33	0.07	2.11	0.38	2.89
E	0.71	0.19	0.56	0.01	1.47

The residual amount of phenol also increased. The variation of the adsorbed amounts on the modified types of carbon black is independent of the weight decreases based on the gases desorbed as H_2 and H_2O in aqueous-phase adsorption and in gas adsorption, because the variation of weight decreases based on the gases desorbed as H_2 and H_2O is little. Suzuki[15] and Walker[16] have reported on the desorbed gases of carbon during the heat/evacuation treatment. The

weight decrease based on the gas desorbed as CO_2 shows that carboxyl groups and carboxylic anhydrides exist on the carbon. The weight decrease based on the gas desorbed as CO shows that hydroxyl groups, carbonyl groups, and quinone exist on the carbon. Since the weight decrease of H_2O is independent of the variation of the amount of phenol adsorbed, it is thought that the surface oxygen groups are present as anhydrides on the carbon. The surface oxygen groups desorbed as CO and CO_2 are carboxylic anhydrides, carboxyl groups that occur as lactones, quinone, and carbonyl groups. The surface acidity of the modified carbon-black samples, which was estimated by the method of Boehm *et al.*[17,18] in the previous paper, is shown in Table 5. The surface acidity of carbon-black B, especially the surface acidity for carboxyl group, is large. The total weight decrease of carbon-black B is also large. The surface acidity of carbon-black E is less than that for the other types of carbon. The total weight decrease of carbon-black E is also less. The surface acidity of the modified types of carbon black for carbonyl group was less than that for other groups. Therefore, the surface oxygen compounds introduced with the oxidation treatments as carboxylic anhydride and as the carboxyl group that occurs as a lactone are probably dependent on the adsorption of phenol.

Consequently, the adsorption character of the various types of carbon black was found to be dependent on the surface oxygen compounds, especially on the carboxylic anhydrides and on the carboxyl groups that occur as lactones. We conclude that carbon black treated with hydrogen gas exhibits excellent adsorbability in the aqueous-phase adsorption. However, carbon black treated with stronger oxidizing agents exhibits better adsorbability regarding phenol gas adsorption.

Heterogeneous Photocatalytic Decomposition of Phenol over TiO_2 Powder

Ken-ichi Okamoto,* Yasunori Yamamoto, Hiroki Tanaka, Masashi Tanaka, and Akira Itaya†

Department of Chemical Engineering, Faculty of Engineering, Yamaguchi University, Ube 755

(Received November 28, 1984)

The photocatalytic decomposition of phenol in oxygenated aqueous suspensions of lightly-reduced anatase TiO_2, being the most satisfactory among the semiconductors investigated from the standpoint of the photocatalytic activity and stability, has been investigated at the optimum pH 3.5. The products at the initial stage of the reaction were hydroquinone, pyrocatechol, 1,2,4-benzenetriol, pyrogallol, and 2-hydroxy-1,4-benzoquinone. These intermediates underwent further photocatalytic oxidation *via* acids and/or aldehydes finally into CO_2 and H_2O. A reaction scheme involving hydroxyl radicals as real reactive species has been proposed. Although H_2O_2 was formed *via* O_2^- produced by electron trapping of adsorbed oxygen, its concentration remained constant at a low value during the reaction. About 0.7 mole of O_2 was consumed for the consumption of one mole of phenol at the initial stage of the reaction. These results indicated that hydroxyl radicals were formed not only *via* holes but also *via* H_2O_2 from O_2^-. It was interesting from the viewpoint of wastewater treatment that phenol was completely mineralized to CO_2 in the presence of TiO_2 powder under solar irradiation without both aeration and mixing of the solution.

Photocatalytic effects of semiconductors have been of much interest from the view point of solar energy utilization. They have been applied not only to produce useful chemicals,[1] but also to convert pollutants in waste streams to innocuous or less harmful form.[2-8] For example, by heterogeneous photocatalysis of some *n*-type semiconductors such as TiO_2 and ZnO, CN^-, and $Cr_2O_7^{2-}$ in aqueous solutions are converted to CNO^- and Cr^{3+}, respectively.[2,3,5,6] In dilute aqueous solutions, chlorinated hydrocarbons such as $CHCl_3$ and trichloroethylene are completely mineralized to HCl and CO_2.[8] Chlorinated aromatics such as polychlorinated biphenyls also undergo photocatalytic dechlorination to give less harmful products.[2] These facts indicate some potential for phtocatalytic treatment of wastewater utilizing sunlight.

Phenol is a refractory and common compound in industrial wastes, and there is interest in developing a new type of chemical treatment of phenol. Kawaguchi and Uejima have studied on phtocatalytic decomposition of phenol in aqueous suspensions of ZnO.[7] They observed that the decomposition process apparently obeyed the first-order reaction kinetics, and detected hydroquinone and pyrocatechol as the main products. The photocatalytic decomposition process of phenol has not, however, been clarified in detail yet.

In the present paper, the photocatalytic decomposition of phenol was studied at several semiconductor powders. For aqueous suspensions of lightly-reduced anatase, the most satisfactory photocatalyst, the dependence of the reaction rate on pH, partial pressure of O_2 and $[Cu^{2+}]$, the consumption rate of O_2, and variation of $[H_2O_2]$ during the reaction were investigated to clarify the initial steps of the photocatalysis. The intermediate products were investigated to clarify the reaction pathway. The photocatalytic decomposition under solar irradiation was also investigated. The reaction kinetics of the process will be reported elsewhere.[9]

Experimental

Materials. As photocatalysts, TiO_2 (anatase and rutile), ZnO, α-Fe_2O_3, and CdS were used as received from Wako Pure Chemical Co., except for anatase. Anatase powder was reduced in a stream of hydrogen at 520 °C for 6 h. The lightly-reduced anatase had a specific area of 38 $m^2 g^{-1}$, as determined by BET nitrogen adsorption, and was used in this paper except where noted. Cu-deposited anatase powder was prepared by UV-irradiating a deaerated suspension of lightly-reduced anatase in the presence of $CuSO_4$ (0.1 mM (1 M=1 mol dm^{-3})).[10]

All chemicals were of reagent grade (Wako Pure Chemical Co.). Solutions were prepared with distilled deionized water.

Photocatalytic Experiments. The majority of the reaction was carried out in a photochemical reactor which was fitted with a 100 W high-pressure mercury lamp (Ushio Electric Co., UM-102) surrounded by a Pyrex glass thimble. A 0.23 M solution of $CuSO_4 \cdot 5H_2O$ was circulated through the thimble to cool the reaction solution and to help filter out short-wavelength light. The 500 cm^3 reaction vessel formed a gas-tight seal around the lamp and had four ports for gas inlet and outlet, sampling, and pH measurement.

In typical experiments, 2.5 g of catalyst powder was suspended in 400 cm^3 of 1 mM phenol solution by stirring magnetically. A gas was bubbled through this solution at the rate of 220 $cm^3 min^{-1}$. In the experiments using anatase, pH of the solution was adjusted by adding an appropriate amount of a H_2SO_4 or KOH solution to the suspension. In the other experiments, it was not adjusted. During a run, the reaction solution was maintained at

† Present address: Department of Polymer Science and Engineering, Kyoto Institute of Technology, Matsugasaki, Kyoto 606.

25 °C, and *ca.* 3 cm³ samples were taken at given time intervals. After being sampled, the suspensions were centrifuged and the centrifugates were subjected to the analyses.

To measure quantum yield of phenol decomposition, the reaction was also carried out in a rectangular cell at 25 °C. With bubbling oxygen gas slowly and stirring magnetically, 15 cm³ of a 1 mM phenol solution suspended with 95 mg anatase was irradiated through a front side of the cell by a monochromatized and parallel light from a 500 W xenon lamp. The incident light intensity was measured by means of a potassium ferrioxalate actinometer.[11]

Analyses. Phenol and the reaction products were analyzed by means of a high-performance liquid chromatography (Hitachi, 635-A) with a column packed with ODS gel (Toyosoda Co., ODS-120A). An aqueous solution of 50% methanol or 0.2% acetic acid[12] was used as an eluting solvent. Products were identified by comparing both the retention times and the ratios of absorbance monitored at two different wavelengths between samples and standards. Total organic carbon (TOC) content was measured using a TOC analyzer (Shimazu, TOC-10A). COD was measured by the acidic method using a COD analyzer (Bionic Instrument Co., COD-510E). The amount of CO_2 produced was determined either from a reduction in TOC of the reaction solution or as $BaCO_3$ precipitated by passing the effluent gas into a $Ba(OH)_2$ solution. The amount of carbonyl groups produced was measured by treating the reaction solution with a 1 M aqueous HCl solution of 2,4-dinitrophenylhydrazine and following the consumption of hydrazine spectrometrically. H_2O_2 was analyzed spectrometrically using $TiOSO_4$ as the reagent.[13] Zn^{2+} and Ti^{4+} were analyzed spectrometrically using Xylenol Orange and 8-quinolinol, respectively, as the reagents.[14] The partial pressure of O_2 of a bubbled gas was measured using a gaschromatography (Shimazu, TC-4A) with a column packed with silica gel.

Adsorption. 20 cm³ of a 0.5 mM phenol solution and a certain quantity (0.1—3 g) of reduced anatase powder were added to 50 cm³ flask with a tight stopper. After the suspension was magnetically stirred for 10 h at 25 °C, the TiO_2 powder was removed by centrifugation and the absorbance of the solution was measured against a blank solution.

Solar Experiments. In the experiments using sunlight, 10 g of reduced anatase and 1.2 dm³ of 1 mM phenol solution were placed in a rectangular cell with a Pyrex glass cover. As the solution was not stirred during a run, the anatase powder covered the bottom of the cell. The deposited layer of anatase (510 cm² in the surface area) was illuminated with sunlight through the solution layer (2.3 cm in depth). Cu-deposited anatase was also used. The pH of the solution was initially set at 3.5, but it was not controlled during a run. The experiments were carried out in August in Ube located in lattitude 34° north. The temperature of the reaction solution was in the range of 30 to 55 °C. The weather was clear to partly cloudy.

Results and Discussion

Photocatalytic Activity and Stability of Semiconductors. Figure 1 shows reduction of phenol concentration

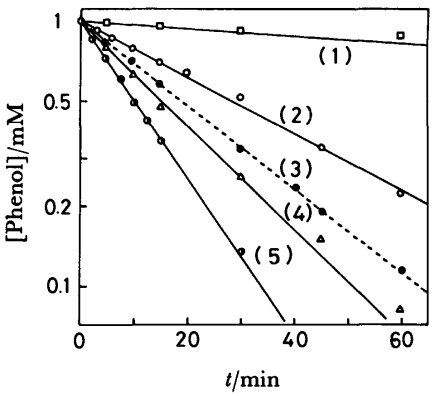

Fig. 1. Reduction of [phenol] with reaction time for the oxygenated aqueous suspensions of semiconductor powders. The ordinate is taken on a log scale.
(1) CdS, (2) anatase at pH 6.5, (3) anatase at pH 3.5, (4) ZnO, and (5) reduced anatase at pH 3.5.

Semiconductor	pH	k_{ap}[a]/10^{-4} s^{-1}
None	6.5	0
Rutile TiO_2	6.5	0
Anatase TiO_2	6.5	4.0
Anatase TiO_2	3.5	6.1
Reduced anatase	3.5	10.5—9.2[b]
CdS	—	0.7
α-Fe_2O_3	—	0
ZnO	7	≈7.5

a) $[phenol]_0 = 1.0$ mM. b) The k_{ap} values were scattered in this range between different lots of anatase samples.

with reaction time t for oxygenated aqueous suspensions of several semiconductors. As shown in Fig. 1, the reaction followed the first-order reaction kinetics (Eq. 1) concerning to [phenol].

$$\ln([phenol]/[phenol]_0) = -k_{ap}t \quad (1)$$

The photocatalytic activity of semiconductors was, therefore, compared by use of the values of the apparent rate constant, k_{ap}, shown in Table 1. It was in the order of reduced anatase>ZnO>anatase-(untreated)≫CdS. Rutile used in the present paper did not have the activity at all.

The photochemical stability of anatase and ZnO was checked by measuring the concentration of Ti^{4+} and Zn^{2+} ions dissolved out during the reaction. No trace of Ti^{4+} ions dissolved out was detected for the anatase suspensions, even after the reaction was continued till phenol disappeared completely, indicating that TiO_2 is very stable photochemically in aqueous solutions.[3] On the other hand, a significant quantity of Zn^{2+} was detected for ZnO suspensions; for example $[Zn^{2+}]$=0.93 mM, after the reaction was performed for 1 h. This quantity of Zn^{2+} corresponded to about 1% of ZnO loaded and was roughly equal to

the quantity of consumed phenol. It is known that a ZnO electrode undergoes anodic photocorrosion according to Eq. 2.

$$ZnO + 2h^+ \longrightarrow Zn^{2+} + O^* \quad (2)$$

This reaction occurs in an aqueous solution of formic acid or alchohols as well as in an inert electrolyte solution.[15] ZnO powder is, therefore, not suitable to a photocatalyst for wastewater treatment.

Among the semiconductors investigated here, lightly-reduced anatase was the most satisfactory from the standpoint of the photocatalytic activity and stability. The experiments mentioned below were, therefore, carried out using lightly-reduced anatase.

Effects of pH, Partial Pressure of O_2 and Addition of Cu^{2+}. Figure 2 shows the effect of pH on both the initial reaction rate Ω_0 and k_{ap}. It is noted that pH 3.5 is the optimum for the photocatalytic decomposition of phenol.

As shown in Fig. 3, Ω_0 depended on the partial pressure of O_2 in the bubbled gas, p_{O_2}. Under a N_2 gas bubbled, the reaction hardly occurred. The pattern of Fig. 3 suggests that the reaction rate is controlled by the quantity of O_2 adsorbed on TiO_2 surface in the Langmuir mode;

$$\Omega_0 \propto K_{O_2} p_{O_2}/(1+K_{O_2} p_{O_2}), \quad (3)$$

where K_{O_2} is the equilibrium constant of adsorption of O_2. The solid lines in Fig. 3, which were calculated from Eq. 3 with the K_{O_2} value of 0.11 kPa^{-1}, were in good agreement with the experimental results.

Figure 4 shows variation of the concentration of O_2 dissolved, $[O_2]$, with reaction time. When an anatase suspension without phenol was irradiated with UV-light, a small quantity of O_2 was consumed in the first run. After aeration, the suspension was reirradiated. O_2 was hardly consumed in the second run. After the second run, an appropriate amount of a concentrated phenol solution was added to the suspension to prepare a 1 mM phenol solution. As shown by the line (3) in Fig. 4, O_2 disappeared rapidly in this phenol solution under the UV-irradiation. In the experiments without the preirradiation in the absence of phenol, O_2 disappeared in the similar manner. About 0.7 mole of O_2 was consumed for the consumption of 1 mole of phenol at the initial stage of the reaction, as shown by the dotted lines in Fig. 4.

Table 2 shows the values of quantum yield, ϕ, of the reaction. These values were obtained in the range of the low light intensity where Ω_0 was proportional to it. The reaction proceeded only by light of wavelength shorter than 400 nm, because anatase has a band gap of 3.23 eV (corresponding to 388 nm).[16] The ϕ was almost constant for wavelength shorter than 370 nm, being in agreement with the action spectrum observed for water reduction over platinized

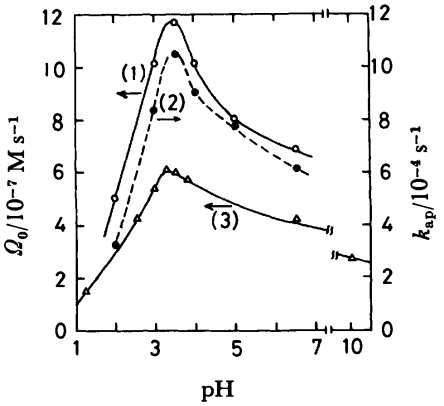

Fig. 2. Effect of pH on both Ω_0 and k_{ap}.
$[phenol]_0 = 1.0$ mM and $p_{O_2} = 101$ kPa.

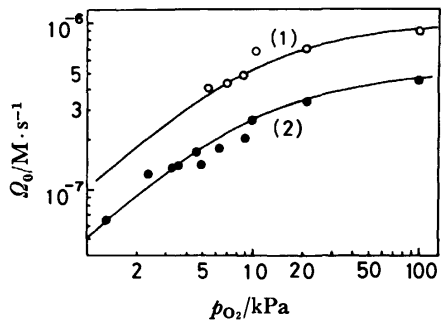

Fig. 3. Effect of p_{O_2} on Ω_0 at pH 3.5.
$[phenol]_0$: (1) 1.0 mM and (2) 0.1 mM.
The solid lines were calculated from Eq. 3 with $K_{O_2} = 0.11$ kPa^{-1}.

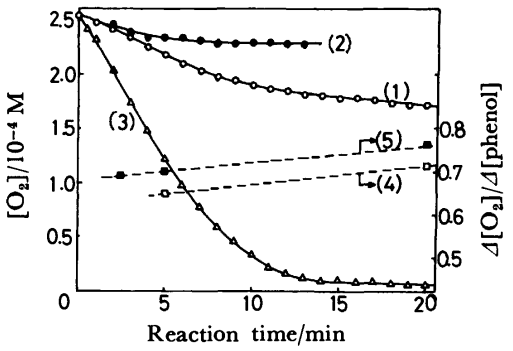

Fig. 4. Variations of $[O_2]$ with reaction time and the consumed mole ratio of O_2 to phenol, $\Delta[O_2]/\Delta[phenol]$, at pH 3.5.
$[phenol]_0 = 1.0$ mM for (3)—(5).
(1) First run in the absence of phenol; (2) second run: after the first run, the suspension was aerated for 5 min prior to the irradiation; (3) third run: after the second run, an appropriate amount of phenol was added to the suspension and it was aerated for 5 min prior to the irradiation; (4) $\Delta[O_2]/\Delta[phenol]$ for the third run; (5) $\Delta[O_2]/\Delta[phenol]$ for experiments without the pre-irradiation in the absence of phenol.

Table 2. Quantum yield of the reaction at pH 3.5[a)]

Wavelength/nm	ϕ/%
430	0
400	1.0
370	10.6
340	11.8

a) For reduced anatase, [phenol] = 1.0 mM, at 25 °C, and in the range of low light-intensity.

anatase.[17)]

For oxygenated aqueous suspensions of anatase, hydroxyl radicals have been considered to be reactive species responsible for the photocatalytic reactions of benzene,[18)] toluene,[19)] benzoic acid,[20)] and so on.[21)] They also seem reactive species responsible for the present reaction, because the photocatalytic decomposition of phenol proceeded *via* its hydroxylated compounds such as hydroquinone and pyrocatechol as will be mentioned in the following section. The initial steps of the photocatalysis are considered as follows.

Judging from the fact that Ω_0 was proportional to the square root of the incident light intensity, as will be reported elsewhere,[9)] the reaction rate was limited by the recombination of photogenerated hole-electron pairs, under the present experimental conditions. The dependence of Ω_0 on p_{O_2} expressed by Eq. 3, therefore, indicates that oxygen adsorbed on anatase surface prevents the recombination of hole-electron pairs by trapping electrons. Superoxide ions are thus formed.[18–23)]

$$O_2(a) + e^- \longrightarrow O_2^{\cdot-} \quad (4)$$

It is likely that H_2O_2 is formed from $O_2^{\cdot-}$ according to the following reactions.[20–22,24)]

$$O_2^{\cdot-} + H^+ \longrightarrow HO_2\cdot \qquad pK_a = 4.88 \quad (5)$$

$$HO_2\cdot + HO_2\cdot \longrightarrow H_2O_2 + O_2 \qquad k = 7.6\times10^5\ M^{-1}\,s^{-1} \quad (6)$$

$$O_2^{\cdot-} + HO_2\cdot \longrightarrow O_2 + HO_2^- \qquad k = 8.5\times10^7\ M^{-1}\,s^{-1} \quad (7)$$

$$HO_2^- + H^+ \longrightarrow H_2O_2 \qquad pK_a = 1.5\times10^{-12} \quad (8)$$

The values of pK_a and k were cited from Ref. 25. It has been suggested that ·OH radicals are formed from H_2O_2 by anyone of the following reactions.[19,22)]

$$H_2O_2 \xrightarrow{h\nu} 2\cdot OH \quad (9)$$

$$H_2O_2 + O_2^{\cdot-} \longrightarrow \cdot OH + OH^- + O_2 \quad (10)$$

$$H_2O_2 + e^- \longrightarrow \cdot OH + OH^- \quad (11)$$

On the other hand, holes react with either H_2O or OH^- adsorbed on anatase surface to give ·OH radicals.[16,18–22)]

$$H_2O(a) + h^+ \longrightarrow \cdot OH + H^+ \quad (12)$$

$$OH^-(a) + h^+ \longrightarrow \cdot OH + OH^- \quad (13)$$

It is ambiguous to what extent the routes of formation of ·OH *via* H_2O_2 are important as compared with ones *via* holes. Mattews has reported that the former routes are negligible as compared with the latter ones.[21)] In order to clarify this point, $[H_2O_2]$ in the reaction solutions was measured under the typical experimental conditions. It increased over first *ca.* 10 min and subsequently remained almost constant at 15 μM. The low value of $[H_2O_2]$ in the steady state suggests that formation of H_2O_2 according to Eqs. 4—8 was in a balance with its decomposition according to Eqs. 9—11. The fact that 0.7 mol of O_2 was consumed for the consumption of 1 mol of phenol is an additional support for the importance of formation of ·OH radicals *via* H_2O_2, as will be mentioned in the following section.

Figure 5 shows the effect of $[Cu^{2+}]$ on both Ω_0 and k_{ap}. A small quantity of Cu^{2+} less than 0.1 mM increased both Ω_0 and k_{ap} by a factor of *ca.* 2, suggesting that the effect is catalytic. On the other hand, a large quantity of Cu^{2+} rather reduced them. It has been observed that Cu^{2+} ions reduce the extent of hole-electron recombination by trapping photogenerated electrons;[10)]

$$Cu^{2+} + e^- \longrightarrow Cu^+ \xrightarrow{e^-} Cu \quad (14)$$

The reduced forms, in turn, prevents the recombination by trapping holes;

$$Cu + h^+ \longrightarrow Cu^+ \xrightarrow{h^+} Cu^{2+} \quad (15)$$

If a small quantity of Cu^{2+} effectively prevents hole-electron recombination even in the oxygenated suspensions, either holes or electrons escaped from the recombination produce ·OH radicals *via* the corresponding routes, resulting in the promotion of the reaction. Because a couple of Eqs. 14 and 15 is the short-circuiting reaction of Cu^{2+},[10,19)] a large quantity

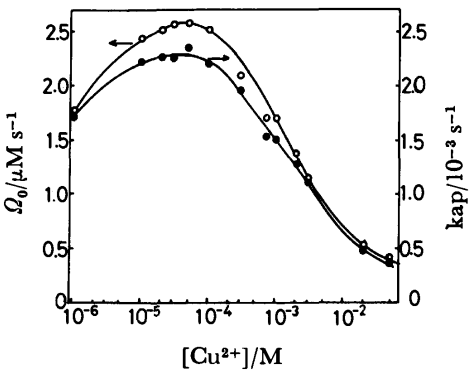

Fig. 5. Effect of $[Cu^{2+}]$ on both Ω_0 and k_{ap} at pH 3.5. $[phenol]_0 = 1.0$ mM and $p_{O_2} = 101$ kPa. With $[Cu^{2+}] = 0$, $\Omega_0 = 0.96$ μM/s and $k_{ap} = 0.92\times10^{-3}\ s^{-1}$.

of Cu^{2+} rather retards the reaction. This is the most probable explanation for the result shown in Fig. 5. An alternative explanation is based on the effect of Cu^{2+} as a catalyst for the Fenton reaction.[26]

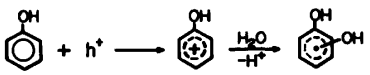
$$Cu^{+} + H_2O_2 \longrightarrow \cdot OH + OH^{-} + Cu^{2+}, \quad (16)$$

$$\cdot RHOH + Cu^{2+} \longrightarrow ROH + H^{+} + Cu^{+}, \quad (17)$$

where ·RHOH is a hydroxy adduct of a reactant RH. This effect, however, is unlikely to be significantly responsible for the promotion of the reaction, because the formation of ·OH radicals *via* H_2O_2 seems to occur sufficiently fast even in the abscence of Cu^{2+} ions as mentioned above.

In the oxygenated suspensions, oxygen acts as both a trap for a photogenerated electron and an oxidant for a hydroxy adduct of the reactant (see Eqs. 19—23). In the deaerated suspensions, Cu^{2+} ions probably act in these two modes in place of O_2 according to Eqs. 14 and 17, although formation of ·OH by the routes *via* H_2O_2 does not occur. The values of Ω_0 were 0.20 and 0.28 μM s^{-1} for the deaerated suspensions containg 50 μM and 1 mM of Cu^{2+}, respectively, while the reaction does not occur in the abscence of Cu^{2+}. These values of Ω_0 corresponded to *ca.* 20 and 30% of the value for the oxygenated suspensions without Cu^{2+}. This fact also suggests the importance of the routes of formation of ·OH *via* H_2O_2.

There remains the possibility that photogenerated holes react with phenol adsorbed on anatase to give dihydroxycyclohexadienyl radicals *via* phenol radical cations, as has been recently proposed for the photocatalytic oxidation of benzene by Hashimoto *et al.*[27]

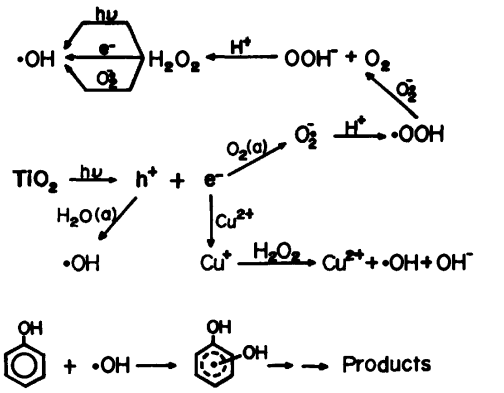


(18)

The energy of holes in the valence band of TiO_2 is about −7.5 eV and is high enough for holes to react easily with H_2O and organic compounds.[28] Therefore, the probability of the reaction of holes with phenol is considered to be roughly proportional to the surface coverage of adsorbed phenol. In the adsorption experiments, a small increase of [phenol] was observed for the solution contacted with a large amount of TiO_2 powder; for example, Δ[phenol]= 0.11 mM for [TiO_2]=50 mg cm^{-3}. This indicates that phenol was hardly adsorbed on TiO_2 powder, as compared with water. Therefore, the path expressed by Eq. 18 is not considered to be significantly responsible for the case of phenol at least.

On the bases of the above-mentioned results and discussion, a mechanism shown in Scheme 1 is proposed for the initial steps of the photocatalysis.

Intermediate Products and Reaction Pathway. The reaction products identified from liquid chromatograms were hydroquinone (abbreviated as HQ), pyrocatechol (CC), 1,2,4-benzenetriol (HHQ), pyrogallol (PG), 2-hydroxy-1,4-benzoquinone (HBQ), and 1,4-benzoquinone (BQ). Many peaks having very short retention times were enhanced with increasing reaction time. These peaks seemed to be attributed to very polar products like aldehydes and carboxylic acids, but were not analyzed in detail.



Scheme 1.

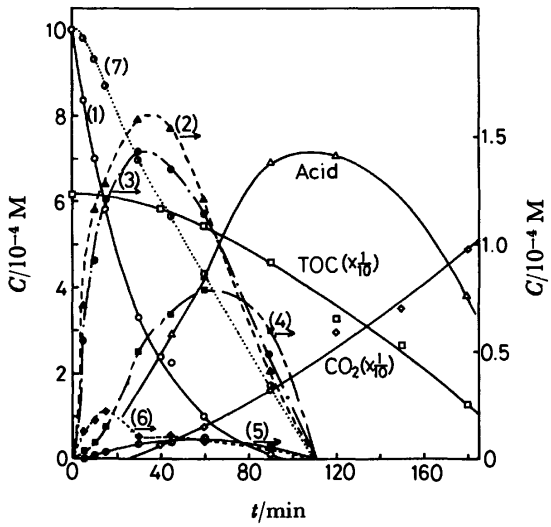


Fig. 6. Variation of concentration of the reaction products and TOC with reaction time at pH 3.5 and p_{O_2} = 101 kPa.
(1) phenol, (2) CC, (3) HQ, (4) HHQ, (5) PG, (6) HBQ and (7) total concentration of the detected aromatic compounds.

Figure 6 shows variation of the concentration of the products and TOC with reaction time. The concentration of acids was obtained from an amount of a KOH solution added to the reaction solution in order to maintain its pH at 3.5. BQ was detected by an amount less than 1 μM till phenol disappeared. At the degrees of conversion of 16, 42, and 80%, the combined amounts of HQ, CC, HHQ, PG, and HBQ corresponded to 90, 68, and 48% of consumed phenol, respectively. With a decrease of the mole ratio of the detected aromatic compounds to consumed phenol, [acids] increased rapidly. These results indicate that

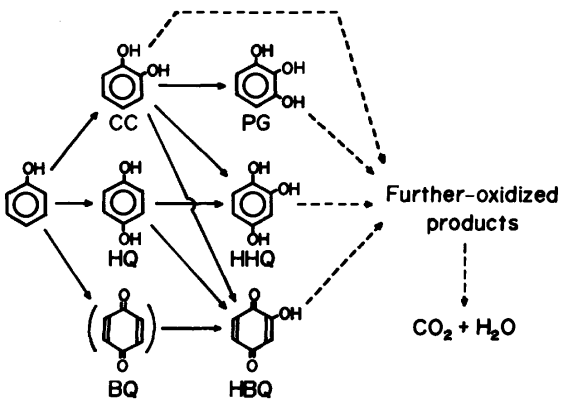
HQ, CC, HHQ, PG, and HBQ are the products at the initial stage of the reaction and undergo further photocatalytic oxidation to yield the very polar intermediate products like carboxylic acids and aldehydes. These aromatic intermediates disappeared in about ten min after disappearence of phenol. After reaching a maximum at that time, [acids] decreased with increasing reaction time. CO_2 began to be detected at the conversion of about 75%. By the reaction for 3 h, about 80% of the carbon quantity of loaded phenol was mineralized to CO_2.

Table 3 shows the distribution of the products for the photocatalytic reaction of HQ, CC, and HHQ. In spite of low conversions, about 50% of consumed pyrocatechol became undetected products having one or two carbonyl groups, suggesting that the attack of ·OH on CC brings about cleavage of benzene ring with a probability of about 50% to yield aldehydes and/or carboxylic acids. Judging from Fig. 6 and Table 3, the reaction pathway shown in Scheme 2 is the most likely. HQ and CC are the major primary products. HHQ is formed as the major secondary product *via* either HQ or CC. PG is formed *via* CC as the minor secondary one. Thus, the photocatalytic decomposition of phenol mainly proceeds *via* its hydroxylated compounds. This is very similar to the case of radiolysis of phenol in aerated aqueous solutions.[29] On the other hand, it is noted that HBQ is formed not only as the minor primary product but also as the minor secondary one *via* either HQ or CC. A possible explanation for these facts is as follows. Hydroxyl radicals react easily with phenol to yield dihydroxycyclohexadienyl radicals.[30] Most of the radicals react with O_2 according to Eqs. 19 and 20. Some of the radicals undergo the unimolecular elimination of water to yield phenoxyl radicals,[30] which react with O_2 to yield HBQ *via* BQ according to Eq. 21.

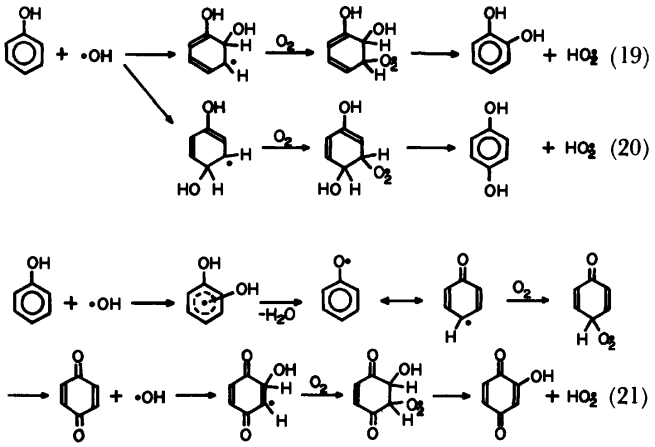
Table 3. Distribution of the products at the initial stage of the reaction[a)]

Reactant	Conversion	Yield/%					
	%	HQ	CC	HHQ	PG	HBQ	Undetected
Phenol	16.0	33.3	43.6	2.1	0.3	7.9	12.8[b)]
HQ	10.7	—	0	64.8	0	11.1	24.1[b)]
HQ	19.0	—	0	63.3	0	7.5	29.1[b)]
CC	9.8	0	—	33.7	11.8	5.8	48.7[b)]
CC	16.5	0	—	34.0	12.5	4.4	49.1[b,c)]
HHQ	6.2	0	0	—	0	0	100

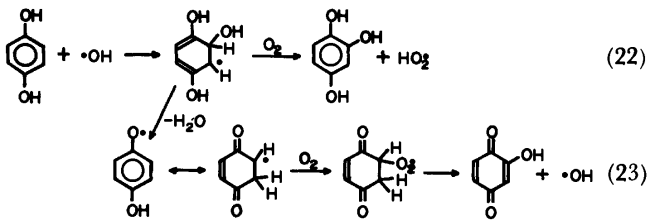
a) $[\text{reactant}]_0 = 1$ mM, $[TiO_2] = 3.0$ mg cm^{-3}, and at pH 3.5. b) In liquid chromatograms, large peaks with retention times of 5.5 and 3.3 min were observed for the reaction solutions of HQ and CC, respectively. c) The reaction solution contained 0.11 mM of carbonyl groups, which corresponded to 1.3 mole per one mole of CC changed to undetected products.



Scheme 2.



Similar reactions occur for HQ and CC. For example;



HO_2· radicals produced by Eqs. 19—21 can regenerate ·OH radicals *via* Eqs. 5—11. If the formation of ·OH *via* H_2O_2 according to Eqs. 4—11 is fully operative, 0.67 and 1.05 mole of O_2 will be necessary to consumption of one mole of phenol according to Eqs. 19 and 20 and Eq. 21, respectively. Taking the product distribution shown in Table 3 into account, it is estimated that 0.70 mol of O_2 is consumed for consumption of one mole of phenol. This estimation is in agreement with the experimental result shown in Fig. 4, indicating that the importance of formation of ·OH radicals *via* H_2O_2.

It has been reported that H_2 was not formed for photocatalytic reaction of some organic compounds

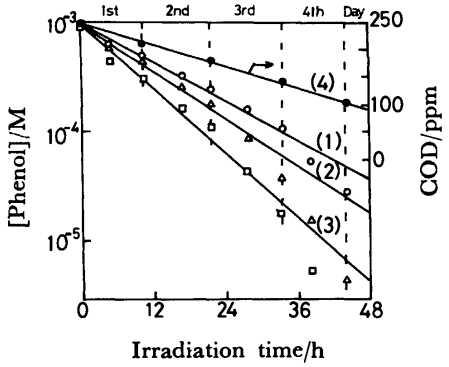


Fig. 7. Reduction of [phenol] and COD with reaction time under solar irradiation.

The experimental conditions are given in the text.

in oxygenated solutions.[8,32] Therefore, the complete decomposition of phenol seems to be expressed by Eq. 24.

$$C_6H_5OH + 7\,O_2 \longrightarrow 6\,CO_2 + 3\,H_2O \qquad (24)$$

Photocatalytic Decomposition under Solar Irradiation. Figure 7 shows reduction of [phenol] and COD under solar irradiation. Control experiments with irradiated solutions with or without Cu^{2+} (50 μM) in the abscence of anatase showed very little decomposition of phenol occurred under these conditions. In the presence of anatase covering the bottom, phenol disappeared according to Eq. 1, without the serious influence of changes in both weather and height of the sun. Phenol was decomposed by the average rate of 8.6 mmol m^{-2} d^{-1} over first two days. By using Cu-deposited anatase powder, the reduction rate was increased appreciably. This catalyst, however, was not useful for wastewater treatment, because Cu deposited were dissolved into the reaction solution according to Eq. 15.

COD was reduced linearly with irradiation time. Since the photocatalytic decomposition proceeded by hydroxylation of phenol and its intermediate products according to Scheme 2, it is reasonable that a reduction in COD is proportional to an amount of ·OH radicals produced and therefore to an irradiation time. It is interesting from the viewpoint of wastewater treatment that phenol is completely mineralized to CO_2 and H_2O in the presence of anatase powder under solar irradiation without both aeration and mixing of the solution.

The present work was partially supported by a Grant-in-Aid for Scientific Research No. 58035042 from the Ministry of Education, Science and Culture.

Kinetics of Heterogeneous Photocatalytic Decomposition of Phenol over Anatase TiO_2 Powder

Ken-ichi Okamoto,* Yasunori Yamamoto, Hiroki Tanaka, and Akira Itaya†
Department of Chemical Engineering, Faculty of Engineering, Yamaguchi University, Ube 755
(Received November 28, 1984)

The photocatalytic decomposition of phenol over anatase TiO_2 powder followed the first-order kinetics, upto high conversions, of which the apparent rate constant k_{ap} depended on initial concentration of phenol $[phenol]_0$, $[TiO_2]$, O_2 pressure p_{O_2}, and incident light intensity I. The dependence of the initial reaction rate Ω_0 on $[phenol]_0$ showed characteristic curvature convex to the concentration axis. The p_{O_2} dependence of both Ω_0 and k_{ap} was very similar each other and showed characteristic curvature to the p_{O_2} axis. The dependence of both Ω_0 and k_{ap} on $[phenol]_0$ was affected by the $[TiO_2]$ and I. Both Ω_0 and k_{ap} were proportional to I below *ca.* 1×10^{-5} mol m^{-2} s^{-1} and to $I^{1/2}$ above 2×10^{-5} mol m^{-2} s^{-1}. The activation energy was 10 kJ/mol. The results were satisfactorily explained by the equation;

$$\Omega=\phi_{\cdot OH}I_a^n\frac{K_{O_2}p_{O_2}}{1+K_{O_2}p_{O_2}}\cdot\frac{[phenol]}{[phenol]_0+\beta},$$

where Ω is the reaction rate; $\phi_{\cdot OH}I_a^n$, a parameter related to the formation rate of ·OH radicals or real reactive species; K_{O_2}, the equilibrium constant of Langmuir adsorption of O_2; β, the ratio of the combined first-order rate constant of the reaction of ·OH with species other than organic compounds to the second-order rate constant of the reaction of ·OH with phenol.

In the previous paper,[1] we have reported on the reaction pathway of the photocatalytic decomposition of phenol in oxygenated aqueous suspensions of anatase TiO_2 as follows. Hydroxyl radicals are real reactive species responsible for the reaction. They are formed not only by the reaction of holes with adsorbed H_2O or OH^{-1}, but also *via* H_2O_2 from $O_2^{\cdot-}$ formed by electron trapping of adsorbed O_2. Phenol are decomposed *via* its hydroxylated compounds into the final products of CO_2 and H_2O. It is interesting from the viewpoint of wastewater treatment that phenol is completely mineralized to CO_2 in the presence of TiO_2 powder under solar irradiation without both aeration and mixing of the solution.

In the present paper, effects of initial concentration of phenol, TiO_2 loading, partial pressure of O_2 in a gas bubbled, incident light intensity, and temperature on the reaction rate were investigated at the optimum pH 3.5. A kinetic equation was proposed to explain the experimental results satisfactorily.

Experimental

Lightly-reduced anatase TiO_2 prepared previously[1] was used as a photocatalyst. The experimental procedure was the same as mentioned in the previous paper,[1] except where noted.

The photocatalytic reaction was carried out in two types of photoreactors at pH 3.5. One (named reactor I) was the same as used previously.[1] The other (named reactor II) was a 200 cm^3 beaker with both four pieces of baffles and a water jacket. A quantity of TiO_2 was suspended in 100 cm^3 of a phenol solution by stirring magnetically. Air was bubbled through the suspension at the rate of 50 cm^3 min^{-1}. The suspension was irradiated from the upside of the beaker by a parallel UV-light, which was obtained by passing the light from a 500 W high-pressure mercury lamp (Ushio Electric Co., USH-500D) through both a $CuSO_4$ solution (0.24 M (1 M=1 mol dm^{-3}), 10 cm) and a band-pass filter (Toshiba Co., UVD-25 or UVDIC) and was substantially composed of 366, 334, and 313 nm light. The irradiated area was 27 cm^2 and the depth of the suspensions was 3.5 cm. The light intensity was adjusted by using wire meshes and/or Pyrex glass plates as neutral filters. The suspension was kept at a constant temperature (usually 25 °C) by circulating thermostated water through the jacket.

The average diameter of TiO_2 powder in the suspensions was measured by means of a highly-directional photoprobe.[2]

Results

Effects of Both Initial Concentration of Phenol and Partial Pressure of O_2. The photocatalytic decomposition of phenol followed the first-order reaction kinetics (Eq. 1) upto high conversions.[1]

$$-\ln\left(\frac{[phenol]}{[phenol]_0}\right)=k_{ap}t \qquad (1)$$

where $[phenol]_0$ is initial concentration of phenol; k_{ap}, the apparent first-order rate constant; t, the reaction time. The dependence of initial reaction rate Ω_0 and k_{ap} on $[phenol]_0$ is shown in Figs. 1 and 2, respectively. The k_{ap} depended on $[phenol]_0$, indicating that the reaction was not a simple first-

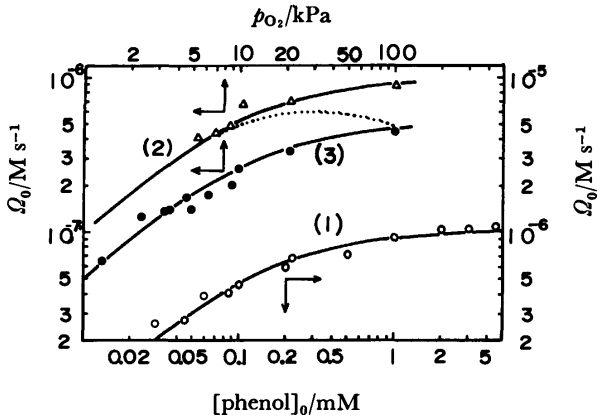

Fig. 1. Dependence of Ω_0 on both [phenol]$_0$ and p_{O_2}.
Reactor I and [TiO_2] = 6.3 mg cm^{-3}. (1) p_{O_2} = 101 kPa; (2) [phenol]$_0$ = 1 mM; (3) [phenol]$_0$ = 0.1 mM.
The solid lines were calculated from Eq. 10 with $\phi_{\cdot OH} I_a^n = 1.12$ μM s^{-1}, $\beta = 0.12$ mM, and $K_{O_2} = 0.11$ kPa^{-1}.
The dotted line was calculated from Eqs. 10 and 17 with $\phi_{\cdot OH} I_a^n = 1.12$ μM s^{-1}, $K_{O_2} = 0.11$ kPa^{-1}, and $k_d/(k_{ph}K_{ph}) = 10$ μM.

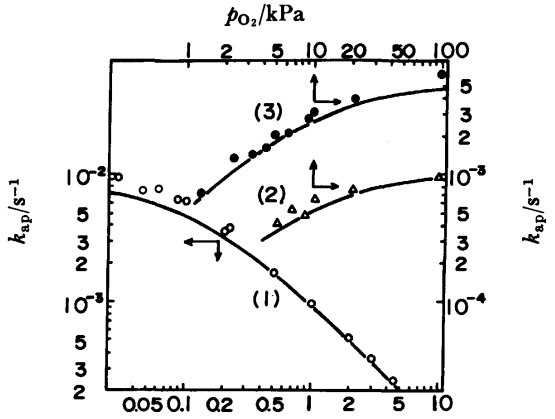

Fig. 2. Dependence of k_{ap} on both [phenol]$_0$ and p_{O_2}.
The experiments were the same as in Fig. 1.
The solid lines were calculated from Eq. 21 with the same values of the parameters as used in Fig. 1.

order one. Figures 1 and 2 also show the dependence of Ω_0 and k_{ap} on the partial pressure of O_2, p_{O_2}, in a bubbled gas, respectively. As has been reported previously,[1] the dependence of Ω_0 on p_{O_2} was represented by Eq. 2.

$$\Omega_0 \propto \frac{K_{O_2} p_{O_2}}{1 + K_{O_2} p_{O_2}} \tag{2}$$

where K_{O_2} is the equilibrium constant of Langmuir adsorption of O_2. It is noted that the dependence of k_{ap} on p_{O_2} was almost the same as that of Ω_0.

As shown in Figs. 3 and 4, the dependence of both

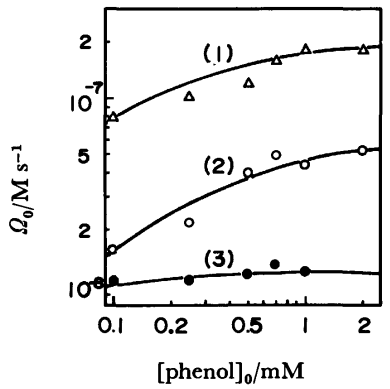

Fig. 3. Dependence of Ω_0 on [phenol]$_0$.
Reactor II and p_{O_2} = 21 kPa. (1) $I = 3.5 \times 10^{-4}$ mol m^{-2}s^{-1} and [TiO_2] = 1.2 mg cm^{-3}; (2) $I = 3.5 \times 10^{-4}$ mol m^{-2}s^{-1} and [TiO_2] = 0.15 mg cm^{-3}; (3) $I = 4.1 \times 10^{-6}$ mol m^{-2}s^{-1} and [TiO_2] = 1.2 mg cm^{-3}. The solid lines were calculated from Eq. 10 with the corresponding set of the parameter values listed in Table 2.

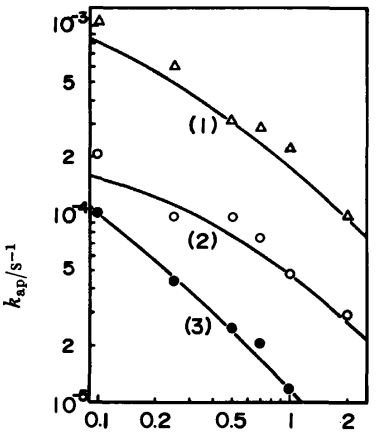

Fig. 4. Dependence of k_{ap} on [phenol]$_0$.
The experiments were the same as in Fig. 3.
The solid lines were calculated from Eq. 21 with the same values of the parameters as used in Fig. 3.

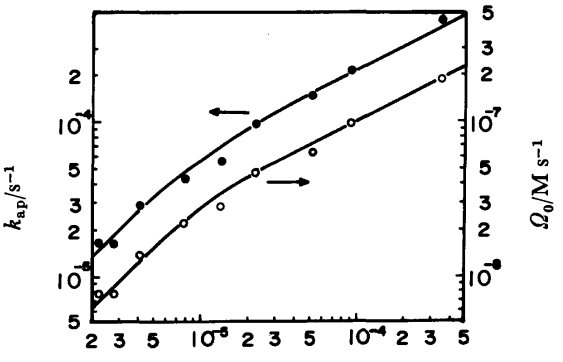

Fig. 5. Light-intensity dependence of both Ω_0 and k_{ap}.
Reactor II, p_{O_2} = 21 kPa, [phenol]$_0$ = 0.5 mM, and [TiO_2] = 2.0 mg cm^{-3}.

Ω_0 and k_{ap} on $[phenol]_0$ depended on light intensity I and $[TiO_2]$.

Effect of Light Intensity. Figure 5 shows light-intensity dependence of both Ω_0 and k_{ap}. Both Ω_0 and k_{ap} were proportional to I below *ca.* 10 μmol m^{-2} s^{-1} and to $I^{1/2}$ *ca.* above 20 μmol m^{-2} s^{-1}. The square-root dependence of Ω_0 in I indicates that the reaction was limited by the recombination of photogenerated hole-electron pairs. The experiments carried out both in the reactor I and without dense neutral filters in the reactor II were in the region of this dependence.

The effective intensity of sunlight was evaluated to be *ca.* 4 μmol m^{-2} s^{-1} from both the Ω_0 value of 1.9×10^{-8} M s^{-1} for $[phenol]_0$=1 mM and the quantum yield of 10% for 366 nm.[1] This is in the region of linear dependence of Ω_0 on I.

Effect of $[TiO_2]$. Figure 6 shows variation of [phenol] with reaction time for the suspensions with different concentrations of TiO_2. When the suspensions were stirred for only 15 min in the dark prior to the reaction, the patterns of the reaction curves observed for the dilute suspensions were quite different from that expected from Eq. 1, as shown by the solid line (3) as an example. On the other hand, when they were stirred for more than 60 min prior to the reaction, such a deviation from Eq. 1 was not observed even for the dilute suspensions, as shown by the solid line (2) as an example. This was related to a change of dispersion state of TiO_2 powder. Table 1 shows the variation of average diameter $\bar{d}_p$ of TiO_2 powder in a suspension during a run. When the suspensions were not stirred sufficiently prior to the reaction, the dispersion state of the powder was much improved by UV-irradiation, probably because of accumulation of surface charge,[3] resulting in gradual increases of the light-absorption rate and consequently of the reaction rate for the dilute suspensions. For the suspensions stirred sufficiently prior to the reaction, a decrease of $\bar{d}_p$ caused by UV-irradiation was not large and was furthermore attained in only several min after light on. Therefore, in this case it hardly affects the reaction curves.

Table 1. Variation of $\bar{d}_p$ of TiO_2 powder in a suspension during a run[a]

$\bar{d}_p$/μm	Stirring conditions
1.88	15 min in the dark
0.98	60 min in the dark
0.76	7 min under UV-irradiation[b]
0.78	20 min under UV-irradiation[b]

a) Reactor II, $[TiO_2]$=0.20 mg cm^{-3} and pH 3.5. The $\bar{d}_p$ was 0.17 μm for the suspension where TiO_2 powder was completely dispersed by use of sodium hexametaphosphate. b) The suspension was stirred for 60 min in the dark prior to UV-irradiation.

The results concerning both Ω_0 and k_{ap} mentioned here were obtained for the suspensions stirred for more than 60 min prior to the reaction.

As shown in Fig. 7, the $[TiO_2]$ dependence of both Ω_0 and k_{ap} was very similar each other. In the high concentration region above 5 mg/cm^3, both Ω_0 and k_{ap} were independent of $[TiO_2]$ at a low light intensity, while they still increased with an increase of $[TiO_2]$ at a high light intensity.

Effect of Temperature. Figure 8 shows the temperature dependence of both Ω_0 and k_{ap}. The activation energy of both Ω_0 and k_{ap} was about

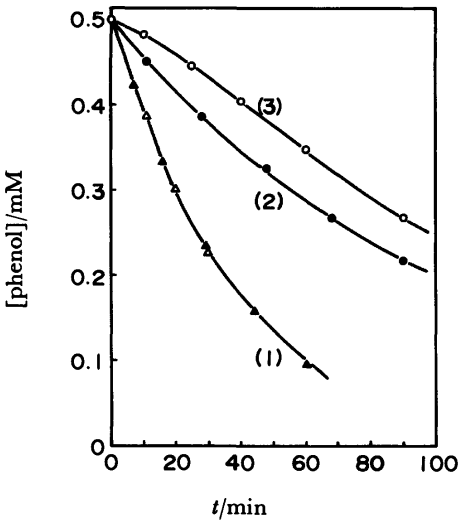

Fig. 6. Effect of stirring time prior to the reaction on the reaction curves.
Reactor II and p_{O_2}=21 kPa. The suspensions were stirred for either 15 min (○ and △) or 60 min (● and ▲) in the dark prior to the reaction.
○ and ●: $[TiO_2]$=0.3 mg cm^{-3}; △ and ▲: $[TiO_2]$ =2.0 mg/cm^3. The solid lines (1) and (2) were calculated from Eq. 1. The solid line (3) was drawn by eyes.

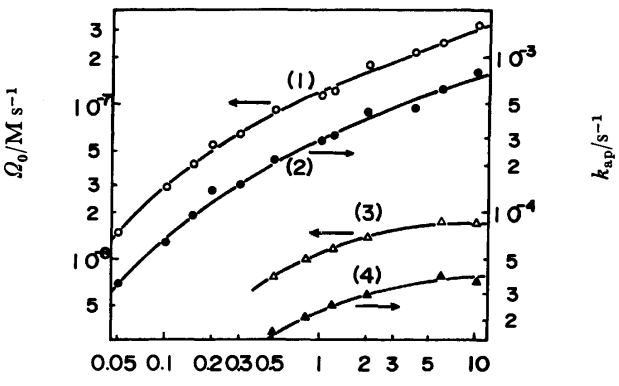

Fig. 7. Dependence of both Ω_0 and k_{ap} on $[TiO_2]$.
Reactor II, $[phenol]_0$=0.5 mM, and p_{O_2}=21 kPa.
(1) and (2): $I=3.5\times10^{-4}$ mol $m^{-2}s^{-1}$; (3) and (4): $I=4.1\times10^{-6}$ mol $m^{-2}s^{-1}$.

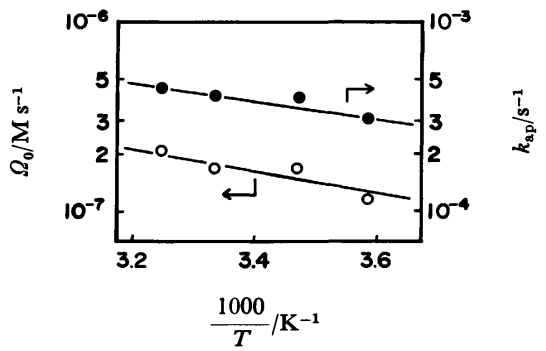

Fig. 8. Temperature dependence of both Ω_0 and k_{ap}. $[phenol]_0=0.5$ mM, $p_{O_2}=21$ kPa, $[TiO_2]=1.2$ mg/cm^3, and $I=3.5\times10^{-4}$ mol m^{-2}s^{-1}.

10 kJ/mol. This value was in the same range as those obtained for oxalic acid (13 kJ/mol)[4] and for formic acid (11 and 17 kJ/mol)[5,6], although being smaller than that obtained for 2-propanol (31 kJ/mol).[7] It was much smaller than that (48 kJ/mol) obtained for oxidation of phenol by means of Fentons' reagent.[8]

Discussion

Influence of Mass Transfer Rate on the Reaction Rate. It is clear from no influence of gas-bubbling rate on both Ω_0 and k_{ap} that mass transfer rate at gas-liquid interface did not affect the reaction rate. On the other hand, there remains the possibility that mass transfer rate at liquid-solid interface might affect the reaction rate, because both Ω_0 and k_{ap} increased with an increase of $[TiO_2]$ upto the highest concentration investigated here at a high light intensity, as shown in Fig. 7. The following consideration, however, objects this possibility.

The reaction rate Ω is expressed by Eq. 3 in terms of volumetric mass transfer coefficient k_sa.

$$\Omega = (k_sa)_A(c_{A,l}-c_{A,s}), \tag{3}$$

where $c_{A,l}$ and $c_{A,s}$ are the concentrations of species A in the bulk liquid and at the external surface of the particles, respectively. For very fine spherical particles k_sa is given by Eq. 4.[9]

$$k_sa = \frac{12\,D\,m_p}{\bar{d}_p^2\rho_p}, \tag{4}$$

where D is diffusion coefficient; m_p, mass of the particles per unit volume of a suspension; ρ_p, density of the particles. If we consider mass transfer of phenol in a dilute suspension with $[TiO_2]=0.12$ mg cm^{-3}, the value of $(k_sa)_{phenol}$ is evaluated to be 0.55 s^{-1}, using $D=8.9\times10^{-6}$ cm^2 s^{-1},[10] $\bar{d}_p=0.77$ μm, and $\rho_p=3.90$ g/cm^3. In the case of an experimental result of $\Omega_0=4\times10^{-8}$ M s^{-1} with $[phenol]_0=0.5$ mM, $I=3.5\times10^{-4}$ mol m^{-2} s^{-1}, and $[TiO_2]=0.12$ mg/cm^3, the ratio of $[phenol]_s/[phenol]_l$ is evaluated to be 0.9998. The similar values of the ratio of $c_{A,s}/c_{A,l}$ are evaluated for other species such as O_2, ·OH, and the intermediate products. This fact indicates that the results mentioned above were not affected by mass transfer rate at liquid-solid interface at all.

Chemical Kinetics. Simple Langmuir-Hinshelwood kinetics have been applied to the photocatalytic reaction of trichloroethylene,[11] chloromethanes[12], halide ions,[13] and aliphatic carboxylic acids.[4,6] In these reports, only the dependence of Ω_0 on initial concentration of the substrates has, however, been investigated. As mentioned above, the photocatalytic decomposition process of phenol had the following important characteristics. (1) Upto the high conversions, the reaction apparently proceeded according to the first-order kinetics with k_{ap} depending on $[phenol]_0$ p_{O_2}, $[TiO_2]$, and I. (2) The dependence of Ω_0 on $[phenol]_0$ showed characteristic curvature convex to the concentration axis. (3) The p_{O_2} dependence of both Ω_0 and k_{ap} was very similar each other and showed characteristic curvature convex to the p_{O_2} axis. (4) The dependence of both Ω_0 and k_{ap} on $[phenol]_0$ was affected by $[TiO_2]$ and I. A chemical kinetic model is proposed as follows, in order to explain these characteristics.

The rate determining step of the reaction is reasonably considered to be the formation of ·OH radicals or real reactive species, because they react very rapidly with phenols; for example, $k=1.4\times10^{10}$ M^{-1} s^{-1} for phenol.[14] The reaction rate is, therefore, given by the product of formation rate of ·OH, $\Omega_{\cdot OH}$, and the probability of the reaction of ·OH with phenol, P_{ph}.

$$\Omega = \frac{-d[phenol]}{dt} = \Omega_{\cdot OH}P_{ph} \tag{5}$$

Judging from the initial steps of the photocatalysis mentioned in the previous paper,[1] $\Omega_{\cdot OH}$ is proportional to the number of hole-electron pairs escaped from the recombination. O_2 adsorbed on TiO_2 surface prevents the recombination by trapping an electron. Therefore, $\Omega_{\cdot OH}$ is reasonably considered to be expressed by Eq. 6.

$$\Omega_{\cdot OH} = \frac{\phi_{\cdot OH}I_a^nK_{O_2}p_{O_2}}{1+K_{O_2}p_{O_2}}, \tag{6}$$

where $\phi_{\cdot OH}$ is a constant related to the yield of formation of ·OH; I_a, rate of light absorption; n, a constant representing the dependence of $\Omega_{\cdot OH}$ on I.

Hydroxyl radicals react with phenol and its intermediates with second-order rate constants of k_{ph} and k_I (k_{I_i} for an intermediate I_i), respectively. They also react with the other species such as electrons and

O_2^- ions[15] with a combined first-order rate constant of k_d.

$$\left.\begin{aligned} \cdot OH + e &\longrightarrow OH^- \\ \cdot OH + O_2^- &\longrightarrow O_2 + OH^- \end{aligned}\right\} \quad (7)$$

The following three cases are assumed concerning the reaction of ·OH with phenol and its intermediates.

Case I. We assume that ·OH radicals react with the species being either in bulk liquid phase or at the interface. Then, P_{ph} is given by Eq. 8.

$$P_{ph} = \frac{k_{ph}[\text{phenol}]}{k_{ph}[\text{phenol}] + \sum_i k_{I_i}[I_i] + k_d}, \quad (8)$$

where the summation of the second term of the denominator is taken over every intermediate. Moreover, we assume that Eq. 9 holds to a fairly good approximation over a long period of reaction time.

$$k_{ph}[\text{phenol}] + \sum_i k_{I_i}[I_i] = k_{ph}[\text{phenol}]_0 \quad (9)$$

Then, Ω is expressed by Eq. 10.

$$\Omega = \phi_{\cdot OH} I_a^n \frac{K_{O_2} p_{O_2}}{1 + K_{O_2} p_{O_2}} \cdot \frac{[\text{phenol}]}{[\text{phenol}]_0 + \beta}, \quad (10)$$

$$\beta = k_d / k_{ph}. \quad (11)$$

Case II. We assume that ·OH radicals react with the species adsorbed on TiO_2 surface in competition with O_2. Then, P_{ph} is given by Eq. 12.

$$P_{ph} = \frac{k_{ph}\theta_{ph}}{k_{ph}\theta_{ph} + \sum_i k_{I_i}\theta_{I_i} + k_d}, \quad (12)$$

where θ_{ph} and θ_{I_i} are the surface coverages of phenol and an intermediate I_i, respectively. Both phenol and its primary intermediates were hardly adsorbed on TiO_2 surface.[1] Moreover, the p_{O_2} dependence of both Ω_0 and k_{ap} was not affected by $[\text{phenol}]_0$. Judging from these facts, Eq. 13 holds.

$$1 + K_{O_2} p_{O_2} \gg K_{ph}[\text{phenol}] + \sum_i K_{I_i}[I_i], \quad (13)$$

where K_{ph} and K_{I_i} are the equilibrium constants of phenol and an intermediate I_i, respectively. Therefore, θ_{ph} and θ_{I_i} is given by Eqs. 14 and 15, respectively.

$$\theta_{ph} = \frac{K_{ph}[\text{phenol}]}{1 + K_{O_2} p_{O_2}} \quad (14)$$

$$\theta_{I_i} = \frac{K_{I_i}[I_i]}{1 + K_{O_2} p_{O_2}} \quad (15)$$

Moreover, we assume that Eq. 16 holds to a fairly good approximation over a long period of reaction time.

$$k_{ph}K_{ph}[\text{phenol}] + \sum_i k_{I_i}K_{I_i}[I_i] = k_{ph}K_{ph}[\text{phenol}]_0 \quad (16)$$

Then, we obtain the same equation as Eq. 10, although in this case β is expressed by Eq. 17 instead of Eq. 11.

$$\beta = \frac{k_d(1 + K_{O_2} p_{O_2})}{k_{ph}K_{ph}} \quad (17)$$

Case III. We assume that ·OH radicals react with the species adsorbed at the sites different from the adsorption sites of O_2. Then, P_{ph} is given by Eq. 12, where θ_{ph} and θ_{I_i} are expressed by Eqs. 18 and 19 instead of Eqs. 14 and 15, respectively.

$$\theta_{ph} = K_{ph}[\text{phenol}] \quad (18)$$

$$\theta_{I_i} = K_{I_i}[I_i] \quad (19)$$

Moreover, we assume Eq. 16 as in Case II. Then, we obtain the same equation as Eq. 10, although in this case β is expressed by Eq. 20.

$$\beta = \frac{k_d}{k_{ph}K_{ph}} \quad (20)$$

Concerning [phenol], Eq. 10 is a first-order kinetic equation with the rate constant k_{ap} expressed by Eq. 21.

$$k_{ap} = \frac{\phi_{\cdot OH} I_a^n K_{O_2} p_{O_2}}{(1 + K_{O_2} p_{O_2})([\text{phenol}]_0 + \beta)} \quad (21)$$

Both Eqs. 10 and 21 have three adjustable parameters of $\phi_{\cdot OH} I_a^n$, K_{O_2}, and β. The solid lines in Fig. 1 were calculated from Eq. 10 with $\phi_{\cdot OH} I_a^n = 1.12\,\mu M\,s^{-1}$, $K_{O_2} = 0.11\,kPa^{-1}$, and $\beta = 0.12\,mM$. These values were determined to give best fit of the calculated lines with the experimental results. The solid lines in Fig. 2

Table 2. Kinetic parameters obtained for various experimental conditions[a]

	Experimental conditions		Kinetic parameters		
	I / mol m^{-2} s^{-1}	$[TiO_2]$ / mg cm^{-3}	$\phi_{\cdot OH} I_a^n$ / M s^{-1}	β / mM	K_{O_2} / kPa^{-1}
(1)	$\approx 10^{-3}$	6.3	1.12×10^{-6}	0.12	0.11
(2)	3.5×10^{-4}	1.2	2.2×10^{-7}	0.15	0.11
(3)	3.5×10^{-4}	0.15	6.8×10^{-8}	0.30	0.11
(4)	4.1×10^{-6}	1.2	1.2×10^{-8}	0.02	0.11

a) (1): Reactor I and $p_{O_2} = 101$ kPa; (2)—(4): Reactor II and $p_{O_2} = 21$ kPa.

were calculated from Eq. 21 with the same values of the parameters. They were in good agreement with the experimental results.

The solid lines in Figs. 3 and 4 were calculated from Eqs. 10 and 21, respectively, with the values of the parameters listed in Table 2. They were also in good agreement with the experimental results obtained for different conditions of I and [TiO_2]. As can be seen from Table 2, there is a tendency that the β value is small for the case with both a high value of [TiO_2] and a low value of I. This is due to the dependence of k_d on both [TiO_2] and I; judging from Eq. 7, k_d is reasonably considered to be reduced with an increase of [TiO_2] and with a decrease of I. Thus, Eq. 10 satisfactorily explains the experimental results.

In Case II, β should depend on p_{O_2}, as expressed by Eq. 17. For the experiments shown in Fig. 2, the value of $k_d/(k_{ph}K_{ph})$ in Eq. 17 was evaluated to be 10 μM using the β and K_{O_2} values (0.12 mM and 0.11 kPa^{-1}, respectively) obtained with p_{O_2}=101 kPa. The relation of Ω_0 *vs.* p_{O_2} for [phenol]=0.1 mM was calculated from Eqs. 10 and 17 with $\phi_{\cdot OH}I_a^n$= 1.12 μM s^{-1}, K_{O_2}=0.11 kPa^{-1} and $k_d/(k_{ph}K_{ph})$=10 μM. As shown by the dotted line in Fig. 1, the calculated relation of Ω_0 *vs.* p_{O_2} is quite different from the experimental one, indicating that Case II is ruled out for the present reaction.

At the present, we have no idea concerning which one between Cases I and III is more appropriate for the present reaction. The Ω_0 values of hydroquinone and pyrocatechol were 70 and 65% of that of phenol observed under the same conditions, respectively, while the reaction of ·OH with phenols has been reported to be diffusion-controlled.[14] Appreciable amounts of undetected compounds having very short retention times in liquid chromatograms were produced at the initial stage of the reaction of hydroquinone and pyrocatechol.[1] Phenol, hydroquinone, and pyrocatechol were hardly adsorbed on TiO_2 powder.[1] Judging from these facts, both Eqs. 9 and 16 appear to be the resonable assumptions.

In order to discuss the dependence of both Ω_0 and k_{ap} on [TiO_2], it is necessary to know the local rate of light absorption of TiO_2 powder in the reactor. At the present, we have no information about it. The experiments are in progress.

The present work was partially supported by a Grant-in-Aid for Scientific Research No. 58035042 from the Ministry of Education, Science and Culture.

Kinetics and Mechanistic Study of the Methanol Homologation with Cobalt-Ruthenium Mixed Catalyst

Kazuhiro WATANABE,* Kiyoshi KUDO, and Nobuyuki SUGITA
Institute for Chemical Research, Kyoto University, Gokanosho Uji, Kyoto 611
(Received January 26, 1985)

The role of each catalyst was examined in detail in the methanol homologation with cobalt-ruthenium mixed catalyst. Cobalt catalyst showed much higher activity for the hydrocarbonylation of methanol than ruthenium. On the other hand, the hydrogenation of acetaldehyde proceeded much more rapidly by ruthenium catalyst. The rate of methanol homologation in 1,4-dioxane with cobalt-ruthenium mixed catalyst system was found to be of the first order with respect to the partial pressure of CO. The *in situ* IR spectra indicated that $[Co(CO)_4]^-$ was an active species for the hydrocarbonylation of methanol and that $[RuI_x(CO)_y]$ existed under the reaction conditions. On the basis of both the kinetic studies and *in situ* IR spectral observations, the reaction mechanism of methanol homologation was fully discussed.

The conversion of synthetic gas to organic chemicals has become an important problem to be solved in both fundamental and applied fields.

Methanol homologation (Eq. 1) with cobalt catalyst, which is one of the most important reactions in the so-called C_1 chemistry, was first reported by Wender and his co-workers in 1949.[1]

$$CH_3OH + CO + 2H_2 \rightarrow CH_3CH_2OH + H_2O \quad (1)$$

Berty's[2] and Mizoroki's[3] groups found independently that the addition of an iodide increased the yield of ethanol. A recent study[4] showed that the covalent CH_3I was more active than the ionic LiI, KI, and $MePBu_3I$. In order to improve the selectivity many studies have been carried out on the effect of solvents[5] and ligands,[6] and that of the addition of ruthenium[7,8] or iron[9] to cobalt catalytic system. From these results, it was revealed that the use of oxygen-containing solvent such as cyclic ether improved the selectivity of ethanol formation and that the optimum mole ratio of ruthenium to cobalt existed.

We found previously that the optimum mole ratio of ruthenium to cobalt depended on the reaction conditions such as the reaction temperature, pressure and H_2/CO.[10]

Up to now, the role of ruthenium as well as the reaction mechanism was not fully elucidated yet. Thus we investigated the mechanism of the methanol homologation with $Co_2(CO)_8$–$RuCl_3$ mixed catalyst from a kinetic study and *in situ* IR observation.

This homologation reaction was accompanied by the side reactions of methanol, as shown in Eqs. 2—4. Therefore, the kinetic experiments

$$CH_3OH + ROH \rightarrow CH_3OR + H_2O \quad (R = CH_3 \text{ or } CH_3CH_2) \quad (2)$$

$$CH_3CHO + 2\,CH_3OH \rightleftarrows CH_3CH(OCH_3)_2 + H_2O \quad (3)$$

$$CH_3OH + CO \xrightarrow{ROH} CH_3COOR \quad (R = H,\ CH_3,\ CH_3CH_2) \quad (4)$$

were carried out in 1,4-dioxane under such reaction conditions that the amounts of by-products could be minimized.

Experimental

Materials. The compounds, $Co_2(CO)_8$, $RuCl_3 \cdot nH_2O$ (Ru content: *ca.* 45 wt%), and methyl iodide were commercially obtained and used without further purification. Methanol and 1,4-dioxane were distilled over a Na-Pb alloy under nitrogen atmosphere. Hydrogen was a commercial material and its purity was above 99.9%. Carbon monoxide was prepared by decomposing formic acid in hot sulfuric acid, and its purity was above 98%.

Procedure. In all kinetic experiments, the reactions were carried out in a glass tube placed in a stainless-steel autoclave (*ca.* 200 ml) equipped with a Teflon stirrer and a Teflon sampling line.

Adequate amounts of the precatalysts ($Co_2(CO)_8$ and $RuCl_3 \cdot nH_2O$) and metyl iodide were dissolved in 1,4-dioxane and this mixture was charged in the autoclave. The air in the autoclave was purged three or four times with CO, and then the solution was pressured with CO and H_2 (total pressure: 150 kg cm^{-2} at room temperature). The vessel was heated to the reaction temperature (160 °C) for 40 min in an oil bath. After the temperature had been kept constant for 30 min, the substrate (methanol or acetaldehyde dimethyl acetal) was pumped into the autoclave with a high pressure injection pump. The mixture of CO and H_2 was introduced to the desired pressure, and stirring of the solution was started with an electromagnetic stirrer (1400 min^{-1}), this time being marked as zero time.

Stirring was stopped from time to time and an aliquot (*ca.* 0.2 ml) was withdrawn through the sampling line into a trap chilled in a dry-ice bath at interval of 10 to 30 min. To keep the pressure constant during the reaction, the consumed gas was supplied from a reservoir in which CO and H_2 had been mixed beforehand in the fixed ratio.

The IR spectra were recorded with Hitachi Model EPI-G3 spectrophotometer under a working pressure of the appropriately mixed gas of CO and H_2 and at the desired temperature (160 °C—180 °C) by using a high pressure IR cell (for *in situ* observation) designed in our laboratory. This high pressure cell consists of 60×70×80 mm block of stainless-steel through which a 30 mm diameter hole bored to form a central capacity for accommodating the window

and the spacer (0.1 mm thick). The cell has optically flat surfaces. The temperature of the cell was monitored with a thermocouple which was inserted into the cell block. Repeated registration of spectrum allowed the reaction to be followed.

Analysis. Products were indentified by comparison of their retention times in the gas-liquid chromatography (GLC) with those of authentic samples (N_2 as carrier gas). A polyethylene glycol 1000 (PEG-1000) column (1.5 m, 3 mm ϕ) was used at 90 °C for the determination of the amounts of products with *m*-xylene as an internal standard.

Results and Discussion

Preliminary Investigation. In 1,4-dioxane solvent, we have explored the optimum reaction conditions for the methanol homologation. Under the optimum reaction conditions, we obtained the high selective formation of ethanol (75 mol%) and high conversion of methanol (67 mol%) as shown in Table 1 (Run 2). The mole ratio of ruthenium to cobalt giving high selectivity of ethanol formation was revealed to be about 0.2 from Table 2. Under the optimum reaction conditions, acetaldehyde dimethyl acetal was the major by-product, and esters (methyl and ethyl acetates) and ethers (dimethyl, ethyl methyl and diethyl ethers) were merely minor by-products. Therefore, the reaction system consisting of $Co_2(CO)_8$–$RuCl_3$ mixed catalyst, methyl iodide and 1,4-dioxane as solvent was chosen for our kinetic studies.

Figure 1 shows that the total amount of acetaldehyde reaches maximum at the early stage of reaction (about 10 min), and then decreases to nearly zero. Here, the total amount of acetaldehyde is the sum of acetaldehyde and its dimethyl acetal formed by dehydration (Eq. 3), and the latter is major. This result indicates that acetaldehyde should be an intermediate for the formation of ethanol. Therefore, the methanol homologation proceeds *via* consecutive steps, that is, the hydrocarbonylation of methanol to acetaldehyde (Eq. 5) followed by the hydro-

genation to ethanol (Eq. 6).

$$CH_3OH + CO + H_2 \rightarrow CH_3CHO + H_2O \quad (5)$$

$$CH_3CHO + H_2 \rightarrow CH_3CH_2OH \quad (6)$$

Figure 2 indicates that the ruthenium catalyst has much lower reactivity for the hydrocarbonylation than the cobalt catalyst. The hydrocarbonylation of methanol seems to be principally catalyzed by the cobalt catalyst.

In order to evaluate the relative activity of the mixed catalytic system, we made three seperate studies on the hydrogenation of acetaldehyde with the cobalt catalyst, the ruthenium catalyst and the mixed catalyst. We chose acetaldehyde dimethyl acetal as the starting substrate, charged it at low concentration and added the equivalent amount of H_2O to the reaction system in order to prevent side reactions such as polymerization of acetaldehyde. Other reaction conditions such as total pressure, partial pressure of CO and H_2, reaction temperature and charged amount of CH_3I were the same as those in the present methanol homologation.

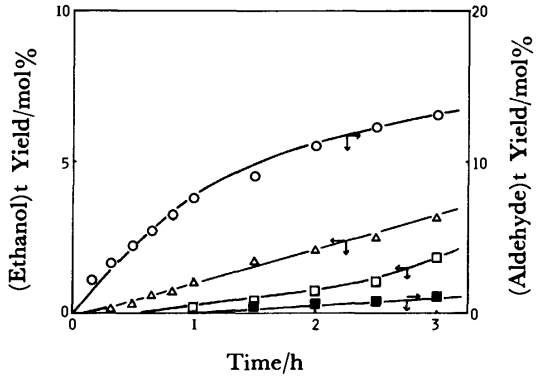

Fig. 2. Methanol homologation by cobalt catalyst and ruthenium catalyst.

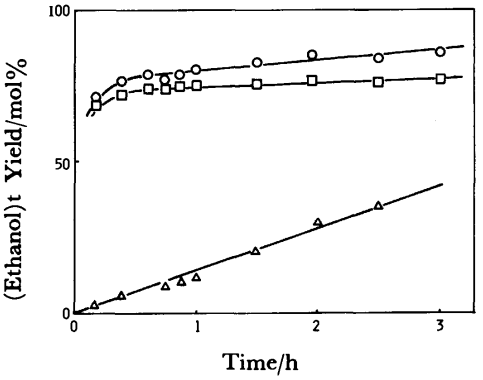

Fig. 3. The hydrogenation of acetaldehyde.
Reaction temperature: 160 °C, total pressure: 240 kg cm^{-2} at 160 °C ($H_2/CO=2/1$), solvent: 1,4-dioxane, substrate: acetaldehyde dimethyl acetal 0.7 M adding H_2O 0.8 M, total volume 70 ml, methyl iodide 0.14 M. ○: $[Co_2(CO)_8]_0=2.8\times10^{-2}$ M and $[RuCl_3]_0=1.1\times10^{-2}$ M, △: $[Co_2(CO)_8]_0=2.8\times10^{-2}$ M, □: $[RuCl_3]_0=1.1\times10^{-2}$ M.

Figure 3 shows that the ruthenium-catalyzed hydrogenation almost completed in 20 min. This rate was much faster than the rate of the cobalt-catalyzed hydrogenation. The hydrogenation rate of acetaldehyde by cobalt-ruthenium mixed catalyst was similar to that by a simple ruthenium catalyst. Hence ruthenium is considered to be the principal catalyst for the hydrogenation of acetaldehyde under the reaction conditions of methanol homologation. This fast hydrogenation should lead to the high selectivity of ethanol.

It has been reported that methyl iodide plays a part as the promoter in the formation of methylcobalt complex from methanol and the cobalt.[3,11,12] We examined the effect of methyl iodide on the hydrogenation of acetaldehyde. Figure 4 reveals that addition of methyl iodide suppresses the rate of the cobalt-catalyzed hydrogenation. We suppose that the result is due to the coordination of iodide to the vacant site

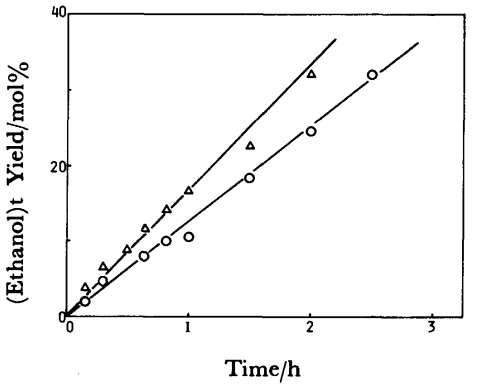

Fig. 4. The effect of methyl iodide on the hydrogenation of acetaldehyde by cobalt catalyst. ○: $[CH_3I]_0=0.14$ M, △: $[CH_3I]_0=0$.

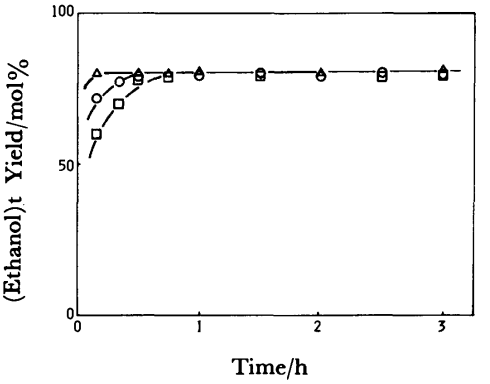

Fig. 5. The effect of methyl iodide on the hydrogenation of acetaldehyde by ruthenium catalyst. △: $[CH_3I]_0/[RuCl_3]_0=3$, ○: $[CH_3I]_0/[RuCl_3]_0=2$, □: $[CH_3I]_0=0$.

of coordinatively unsaturated [$HCo(CO)_3$], which is generally regarded as the active species for the hydrogenation of acetaldehyde. With ruthenium catalyst, the yield of ethanol at 10 min increases with the mole ratio of methyl iodide to ruthenium ([CH_3I]/[Ru]) up to [CH_3I]/[Ru]=2 (Fig. 5). The yield of ethanol becomes independent of the mole ratio when the ratio is higher than 2 (Figs. 3 and 5). This fact suggests that an iodocarbonylruthenium, [$RuI_x(CO)_y$], is an active catalyst for the hydrogenation, where x is supposed to be 2 or 3 from *in situ* IR observation. Therefore, it was found that methyl iodide gave no significant effect on the hydrogenation under the working conditions ([CH_3I]/[Ru]≧5).

Kinetic Study. As shown in Fig. 1, with the cobalt-ruthenium mixed catalyst, the time-yield plot of ethanol production is linear at the low yield of ethanol (less than 30%), and the induction period is less than 10 min. We could thus obtain the initial rate of ethanol production from the slope of the time-yield curve of ethanol. As both ethyl methyl and diethyl ethers were formed rapidly by thermal and/or acid-catalyzed dehydration of alcohols, the amounts of these ethers were included in the amount of ethanol. We investigated the effect of initial concentration of methanol, methyl iodide and ruthenium salt, and that of the partial pressure of CO and H_2 on the rate of formation of ethanol. From Figs. 6 and 7, the rate was found to be apparently of the order between the 0th and 1st in regard to the initial concentration of methyl iodide and ruthenium, and to the partial pressure of H_2. The effect of CO indicates that the insertion of CO to form acyl complex should be an important step, since the rate is of the 1st order in regard to its partial pressure. Figure 8 reveals that the rate with respect to the initial concentration of methanol is higher than the 1st order. With cobalt catalyst, the yield of ethanol at 50 min was less than 1% (Fig. 2), and that the yield of acetaldehyde (including its dimethyl acetal) was approximately proportional to the square of the initial concentration of methanol (Fig. 8). Hence, more than one molecule of methanol should take part in the hydrocarbonylation of methanol.

Determination of in situ *IR Spectra.* In order to obtain detailed information about active species involved in the catalytic cycle, IR spectra of octacarbonyldicobalt and ruthenium trichloride solution were observed under typical conditions (P_{CO}= 60 kg cm^{-2}, P_{H_2}=120 kg cm^{-2} at room temperature, and 160 °C). Since 1,4-dioxane absorbs light at 2000 cm^{-1} region, we chose methanol and hexane as the solvents for these measurements.

In the methanol solution of [$Co_2(CO)_8$], the infrared absorption at 1900 cm^{-1}, which can be ascribed to [$Co(CO)_4$]$^-$ species, was observed under high pressure of the mixture gas at 180—200 kg cm^{-2} in the range of temperature from 20 °C to 160 °C. GLC analysis revealed that the hydrocarbonylation

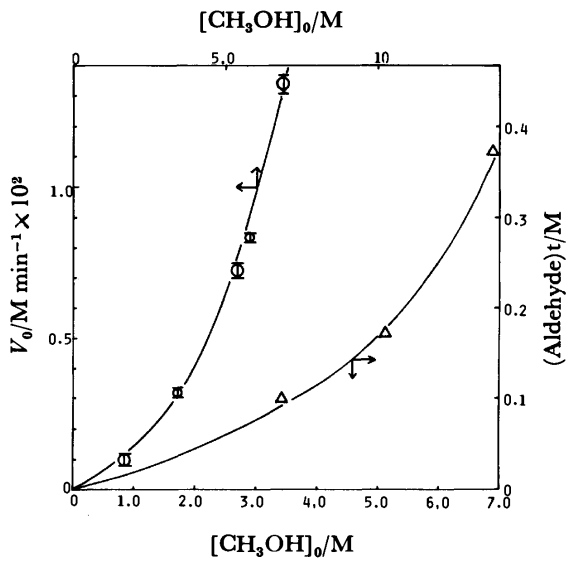

Fig. 8. The effect of the initial concentration of methanol.
◑: the rate of ethanol formation, △: the yield of acetaldehyde at 50 min.

of methanol hardly proceeded under these conditions. When CH_3I was added to this solution, a characteristic absorption at 1900 cm^{-1} was diminished as temperature raised, and ultimately disappeared at the working temperature (160 °C). GLC analysis revealed that the hydrocarbonylation proceeded. These results suggest that the steady-state concentration of $[Co(CO)_4]^-$ species becomes low with the progress of hydrocarbonylation, and that $[Co(CO)_4]^-$ is an active species in the hydrocarbonylation of methanol.

In the hexane solution of $RuCl_3$, the observation of *in situ* IR showed that two kinds of iodocarbonylruthenium species existed under the same conditions as those in the homologation and that chlorocarbonylruthenium complex did not exist. One of the two iodo species is $[RuI_2(CO)_4]$ (2126, 2107, 2096, and 2066 cm^{-1})[13] and the other $[RuI_3(CO)_3]^-$ (2120 and 2050 cm^{-1})[14]. As G. Andlich and his co-workers reported[16] the existence of these iodo species in the carbonylation of dimethyl ether to ethyl acetate, we suppose that one of these iodocarbonylruthenium species is active for the homologation of methanol.

We also prepared a cobalt-ruthenium heterometallic cluster complex ($[RuCo_3(CO)_{12}]^-$) by the reported method[7b] in order to examine the formation of this cluster in the reaction system by *in situ* IR. The results are given in Table 3. It has been known that cobalt-iron heterometallic cluster ($[FeCo_3(CO)_{12}]^-$)[9] and triruthenium cluster ($[Ru_3(CO)_{12}]$)[17] are decomposed into the respective monometallic complexes under high pressure and high temperature. From Table 3, we can conclude that under the reaction conditions a cobalt-ruthenium heterometallic cluster does not remain intact as in the original form, but is decomposed.

Mechanism and Rate Equation. Based on the above results, we propose a reaction mechanism of the homologation of methanol (Scheme 1: the hydrocarbonylation of methanol, Scheme 2: the hydrogenation of acetaldehyde).

Scheme 2.

During the heating of the reaction system to the reaction temperature, the charged methyl iodide should have reacted with $[HCo(CO)_4]$ (or $[Co(CO)_4]^-$ which is formed from the dissociation of $[HCo(CO)_4]$) to produce hydroiodic acid. The *in situ* IR spectra suggest that ruthenium chloride (precatalyst) reacts with HI and CO to form iodocarbonylruthenium species.

The disproportionation of $[Co_2(CO)_8]$ was reported[19] to produce the species $[Co(CO)_4]^-$ (Eq. 7). But this disproportionation did not

$$6\,CH_3OH + 3\,Co_2(CO)_8 \rightarrow [Co(CH_3OH)_6]^{2+}([Co(CO)_4]^-)_2 + 4\,CO \quad (7)$$

occur under the present conditions, since no libration of CO was observed in a stoichiometric reaction of methanol with $[Co_2(CO)_8]$.

The equilibrium constant K_4 was found to be 0.464 at 160 °C (calculated from a measured value at 30 °C and ΔH=1.25 kcal† mol^{-1}; ΔH was calculated from

† 1 cal_{th}=4.184 J.

the value of ΔH_f° of each substance cited in the literature).

Since the hydrocarbonylation hardly proceeded in the absence of iodide, the direct conversion of **4** to methylcobalt complex, **5**, (Eq. 8)[12] should be ruled out.

$$\mathbf{4} \longrightarrow \mathbf{5} + H_2O \tag{8}$$

As the hydrogenation of acetaldehyde with the ruthenium catalyst proceeded much more rapidly than with the cobalt catalyst, ruthenium plays a major catalytic role in the hydrogenation, and ruthenium hydride anion, **7**, in Eq. VIII is assumed to be the active species. We do not yet have any obvious evidence for the formation of this complex, but this is analogous to that suggested in a ruthenium-iodine system.[16] Although the number of iodides coordinated to ruthenium is still obscure, Dombek and his coworkers reported[15] that triiodotricarbonylruthenium was inactive for a hydrogenation of CO. Hence, diiodotetracarbonylruthenium is supposed to be the catalyst for the hydrogenation of acetaldehyde.

The initial rate of the production of ethanol, v_o, is derived as follows. Assuming the steady-state concentration for the intermediate **8**, v_o is obtained as Eq. 9. From Eqs. VIII and IX, the steady-state concentration of acetaldehyde is given as Eq. 10.

$$v_o = \frac{k_9 k_{10}[CH_3CHO][\mathbf{7}][H_2]}{k_{-9}+k_{10}[H_2]} \tag{9}$$

$$[CH_3CHO] = \frac{k_7(k_{-9}+k_{10}[H_2])[\mathbf{6}]}{k_9 k_{10}[\mathbf{7}]} \tag{10}$$

By substituting Eq. 10 into Eq. 9, v_o is represented as Eq. 11. Assuming the steady-state conditions for

$$v_o = k_7[\mathbf{6}][H_2] \tag{11}$$

acylcobalt (**6**) and alkylcobalt (**5**) intermediates, the rate equation is derived as Eq. 12, since the concentration of methanol is nearly equal to its initial concentration at the early stage of the reaction, *i.e.*, $[CH_3OH]_o \gg [CH_3I]_o$, [catalyst]$_o$ where the subscript $^\circ$ denotes the initial concentration.

$$v_o = \frac{k_5 k_6 k_7[CH_3I][\mathbf{4}][CO][H_2]}{k_{-5}(k_{-6}+k_7[H_2])[CH_3OH]_o[HI]+k_6 k_7[CO][H_2]} \tag{12}$$

From the equilibrium IV, the concentration of methyl iodide is given as:

$$[CH_3I] = K_4[CH_3OH]_o A/2, \tag{13}$$

where A is given as:

$$A = -1 + \sqrt{1+4[HI]_o/(K_4[CH_3OH]_o)}, \tag{14}$$

and $[HI]_o=[CH_3I]_o-x[RuCl_3]_o$.

The concentration of the intermediate **4**, **5**, and **6** are represented in function of [**2**] as Eq. 15 to Eq. 17 ($K_4'=K_4/2$).

$$[\mathbf{4}] = K_3[\mathbf{2}][CH_3OH]_o \tag{15}$$

$$[\mathbf{5}] = \frac{K_3 K_4' k_5(k_{-6}+k_7[H_2])[CH_3OH]_o^2 A[\mathbf{2}]}{k_{-5}(k_{-6}+k_7[H_2])([HI]_o-K_4'[CH_3OH]_o A)[CH_3OH]_o+k_6 k_7[CO][H_2]} \tag{16}$$

$$[\mathbf{6}] = \frac{K_3 K_4' k_5 k_6[CH_3OH]_o^2 A[\mathbf{2}][CO]}{k_{-5}(k_{-6}+k_7[H_2])([HI)_o-K_4'[CH_3OH]_o A)[CH_3OH]_o+k_6 k_7[CO][H_2]} \tag{17}$$

The total concentration of cobalt complexes is as follows:

$$2[\mathbf{1}]_o = 2[\mathbf{1}] + [\mathbf{2}] + [\mathbf{3}] + [\mathbf{4}] + [\mathbf{5}] + [\mathbf{6}] \tag{18}$$

Since the equilibrium II lies to the left under high pressure of CO, the concentration of **3** can be neglected. By substituting Eqs. 15, 16, and 17 in Eq. 18, the concentration of **2** is represented as the function of [**1**]$_o$ as Eq. 19 using the equilibrium relation derived from I. In Eq. 19, α_1, α_2, and α_3 are denoted as Eqs. 20 to 23.

$$[\mathbf{2}] = (1+\alpha_1+\alpha_2+\alpha_3)K_1[H_2]\{\sqrt{1+16[\mathbf{1}]_o/\{K_1[H_2](1+\alpha_1+\alpha_2+\alpha_3)^2\}}-1\}/4 \tag{19}$$

$$\alpha_1 = K_3[CH_3OH]_o \tag{20}$$

$$\alpha_2 = \frac{K_3 K_4' k_5(k_{-6}+k_7[H_2])[CH_3OH]_o^2 A}{k_{-5}(k_{-6}+k_7[H_2])([HI]_o-K_4'[CH_3OH]_o A)[CH_3OH]_o+k_6 k_7[CO][H_2]} \tag{21}$$

$$\alpha_3 = \frac{k_6[CO]\alpha_2}{k_{-6}+k_7[H_2]} \tag{22}$$

Markó and his coworkers reported[21] that K_1 was small. So, Eq. 19 can be approximately expressed as Eq. 23.

$$[\mathbf{2}] = \sqrt{K_1[H_2][\mathbf{1}]_o}-(1+\alpha_1+\alpha_2+\alpha_3)K_1[H_2]/4 \tag{23}$$

Finally, the rate equation is obtained as Eq. 24 by substituting Eqs. 15 and 23 in Eq. 12.

$$v_o = \frac{K_3K_4'k_5k_6k_7[CH_3OH]_o^2A[CO][H_2]}{k_{-5}(k_{-6}+k_7[H_2])([HI]_o-K_4'[CH_3OH]_oA)[CH_3OH]_o+k_6k_7[CO][H_2]}\{\sqrt{K_1[H_2][\mathbf{1}]_o}-(1+\alpha_1+\alpha_2+\alpha_3)K_1[H_2]/4\} \quad (24)$$

Equation 24 is rearranged as Eq. 25 by substituting Eqs. 20, 21, 22, and 23 into Eq. 24.

$$v_o = \frac{K_3K_4'K_5K_6k_7[CH_3OH]_o^2A\{\sqrt{K_1[H_2][\mathbf{1}]_o}-K_1(1+K_3[CH_3OH]_o)[H_2]/4\}[CO]}{(1+k_7[H_2]/k_{-6})([HI]_o-K_4'[CH_3OH]_oA)[CH_3OH]_o+k_6k_7[CO][H_2]/(k_{-5}k_{-6})} - \frac{K_1K_3^2K_4'^2K_5^2K_6k_7(1+k_7[H_2]/k_{-6})[CH_3OH]_o^4A^2[H_2]^2[CO]}{4\{(1+k_7[H_2]/k_{-6})([HI]_o-K_4'[CH_3OH]_oA)[CH_3OH]_o+k_6k_7[CO][H_2]/(k_{-5}k_{-6})\}^2} - \frac{K_1K_3^2K_4'^2K_5^2K_6^2k_7[CH_3OH]_o^4A^2[H_2]^2[CO]^2}{4\{(1+k_7[H_2]/k_{-6})([HI]_o-K_4'[CH_3OH]_oA)[CH_3OH]_o+k_6k_7[CO][H_2]/(k_{-5}k_{-6})\}^2} \quad (25)$$

From Fig. 7, we conclude that the last term of the right side of Eq. 25 related to the acylcobalt intermediate, **6**, can be neglected and that the rate equation is approximately expressed as Eq. 26.

$$v_o = \left\{\frac{\beta_1\beta_2[CH_3OH]_oA\sqrt{[\mathbf{1}]_o}}{[HI]_o-K_4'[CH_3OH]_oA} - \frac{\beta_2\beta_3(1+K_3[CH_3OH]_o)[CH_3OH]_oA[H_2]^{0.5}}{4([HI]_o-K_4'[CH_3OH]_oA)} - \frac{\beta_1^2\beta_2[CH_3OH]_o^2A^2[H_2]^{0.5}}{4([HI]_o-K_4'[CH_3OH]_oA)^2}\right\}[CO][H_2]^{1.5} \quad (26)$$

where $\beta_1=\sqrt{K_1}K_3K_4'K_5$, $\beta_2=K_6k_7$, $\beta_3=K_1K_3K_4'K_5$ and $[HI]_o=[CH_3I]_o-x[RuCl_3]_o$. From the slope in Fig. 7, we obtained the following value.

$$4.25\times10^4\beta_1\beta_2 - 7.91\times10^5\beta_2\beta_3(1+K_3[CH_3OH]_o) - 9.78\times10^7\beta_1\beta_2 = 1.66\times10^{-4} \quad (27)$$

With respect to $[H_2]$, the rate equation is rewritten as Eq. 28 which agrees with the experimental facts (Fig. 9).

$$v_o/[H_2]^2 = B_1/[H_2]^{0.5} - B_2 \quad (B_1,\ B_2\text{: constants}) \quad (28)$$

The slope and the intercept in Fig. 9 give:

$$\beta_1\beta_2 = 2.81\times10^{-8} \quad (29)$$

$$2.47\times10^3\beta_2\beta_3(1+K_3[CH_3OH]_o) + 3.06\times10^5\beta_1\beta_2 = 3.21\times10^{-6} \quad (30)$$

From the effect of $[CH_3I]_o$ and $[RuCl_3]_o$ (Fig. 6), a value of x to satisfy Eq. 26 is found to be 2.5 from the trial and error method. This value is consistent with the result of the *in situ* IR observation which showed the presence of both diiodo- and triiodo-carbonyl complex of ruthenium (see above). Equation 26 is rearranged as Eq. 31.

$$v_o([HI]_o - K_4'[CH_3OH]_oA)^2/A^2 = B_3([HI]_o-K_4'[CH_3OH]_oA)/4A-B_4 \quad (B_3,\ B_4\text{: constant}) \quad (31)$$

Figure 10 indicates that Eq. 26 explains the experimental results of the initial concentration of methyl iodide and ruthenium. From the slope and the intercept, the following values are obtained.

$$1.90\times10^5\beta_1\beta_2 - 3.54\times10^6\beta_2\beta_3(1+K_3[CH_3OH]_o) = (1.32\pm0.04)\times10^{-3} \quad (32)$$

$$\beta_1^2\beta_2 = (1.23\pm0.02)\times10^{-12} \quad (33)$$

By substituting the value of $\beta_1\beta_2$ and $\beta_1^2\beta_2$ in Eqs. 27, 30, and 32, the values of $\beta_2\beta_3$ $(1+K_3[CH_3OH]_o)$ are found independently from each equation to be 1.15×10^{-9} within the experimental error. The above analysis, therefore, does not conflict with each other. Equation 26 is rewritten as Eq. 34. The plot of $1/$

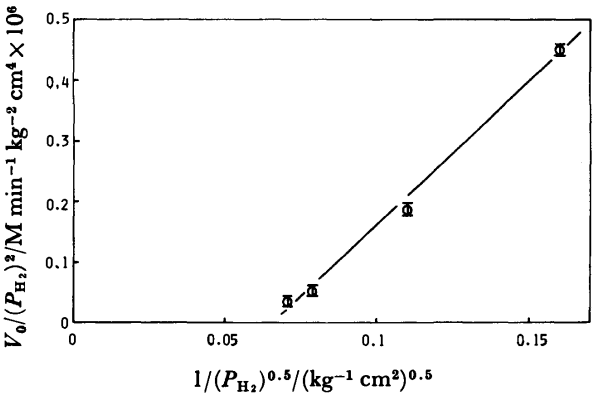

Fig. 9. Plots of $v_0/(P_{H_2})^2$ *vs.* $1/(P_{H_2})^{0.5}$.

△: $[CH_3I]_0=0.14$ M, ⓘ: $[RuCl_3]_0=1.1\times10^{-2}$ M.

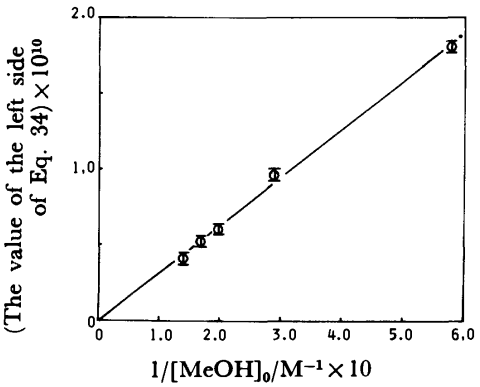

Fig. 11. Plots of the value of the left side of Eq. 34 against $1/[CH_3OH]_0$

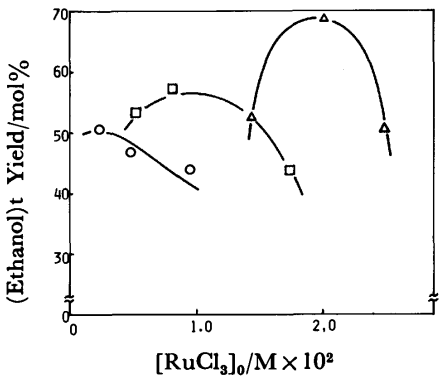

Fig. 12. The effect of the initial concentration of methyl iodide on the methanol homologation by cobalt–ruthenium mixed catalyst.
Reaction temperature: 180 °C, total pressure: 240 kg cm^{-2} at room temperature ($H_2/CO=2/1$), solvent: 1,4-dioxane 5 ml, methanol 2 ml, $[Co_2(CO)_8]_0=(2.3-2.4)\times10^{-2}$ M, Time: 3 h.
○: $[CH_3I]_0=0.07$ M, □: $[CH_3I]_0=0.14$ M, △: $[CH_3I]_0=0.28$ M.

$[CH_3OH]_0$ *vs.* the value of the left side of Eq. 34 is

$$\frac{\beta_1\beta_2B_5}{[CH_3OH]_0}-\frac{\beta_1^2\beta_2A}{4([HI]_0-K_4'[CH_3OH]_0A)}-\frac{v_0([HI]_0-K_4'[CH_3OH]_0A)B_6}{[CH_3OH]_0{}^2A}=\frac{\beta_2\beta_3}{4[CH_3OH]_0}+\frac{\beta_2\beta_3K_3}{4}\quad(B_5,\ B_6\text{: constant})\qquad(34)$$

verified as shown in Fig. 11. From the intercept, the second term of the right side in Eq. 35 related to tetracarbonylcobalt anion, **4**, is neglected. In fact, **4** was not observed by *in situ* IR during the reaction (see above). Therefore, $\beta_2\beta_3$ $(1+K_3[CH_3OH]_0)$ is nearly equal to $\beta_2\beta_3$. The slope in Fig. 11 gives the value of $\beta_2\beta_3$ as:

$$\beta_2\beta_3 = 1.25\times10^{-9} \qquad (35)$$

This value agrees with that obtained above (1.15×10^{-9}). From the above analysis, the values of constants are found as follows: $K_1=(1.83\pm0.1)\times10^{-3}$ [M/(kg cm^{-2})], $K_3K_5=(4.15\pm0.04)\times10^{-3}$ and $K_6k_7=(6.42\pm0.1)\times10^{-4}$ [(kg cm^{-2})·min^{-1}]. From the results reported by Alemdaroğlu and his coworkers,[18] K_1 at 160 °C is calculated to be 2.0×10^{-3} M/kg cm^{-2}. This value is well consistent with the value obtained from the above kinetic analysis.

The rate equation 26 also explains the reason why an optimum concentration of ruthenium exists. When ruthenium is added in excess to this system, the concentration of iodide (HI or CH_3I) is significantly decreased by the coordination of iodide to ruthenium. Consequently, the rate of hydrocarbonylation promoted by iodide is retarded. Figure 12 reveals that the optimum concentration of ruthenium increases with the initial concentration of methyl iodide and that the presence of ruthenium in excess causes the retardation of the hydrocarbonyltion of methanol, resulting in the low yield of ethanol. Thus, the mole ratio of ruthenium to iodide is important for the high yield of ethanol.

All of the above results prove that cobalt principally catalyzes the hydrocarbonylation of methanol while ruthenium only takes part in the hydrogenation of acetaldehyde.

The authors wish to thank Messers. Y. Ichikawa and M. Yasumoto for the contribution of manufacturing the *in situ* high-pressure IR cell and assembling the high-pressure experimental equipment.

Cadmium-photosensitized Reaction of γ-Valerolactone and α-Methyl-γ-butyrolactone

Shunzo YAMAMOTO,* Hiroshi TAKAHOSO, Yoshimi SUEISHI, and Norio NISHIMURA
Department of Chemistry, School of Science, Okayama University, 3-1-1, Tsushima-naka, Okayama 700
(Received January 30, 1985)

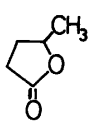
The cadmium-photosensitized reactions of γ-valerolactone and α-methyl-γ-butyrolactone have been investigated. The obtained products in both cases were carbon monoxide, ethylene, propylene, acetaldehyde, and 2-methyloxetane. The dependence of the yields of ethylene and propylene on the total pressure suggests the existence of a biradical and an energized intermediate. Possible mechanisms are discussed.

While the photochemistry of aliphatic esters and cyclic ketones has been investigated in some detail, there have been only a few quantitative studies on the photo-decomposition of simple aliphatic lactones in the gas phase.

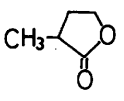
Simonaitis and Pitts[1] investigated the direct photolysis and the mercury-photosensitized decomposition of γ-butyrolactone(BL) in the gas phase and observed that lactone (1) isomerizes to succinaldehyde, (2) decomposes to ethylene, carbon monoxide, and formaldehyde, and (3) decomposes to propylene or cyclopropane and carbon dioxide. They pointed out that succinaldehyde and ethylene are probably singlet-state products, whereas cyclopropane and propylene are probably triplet-state products.

Recent work[2] in our laboratory on BL has shown that quite different products are obtained in mercury- and cadmium- photosensitized reactions. We concluded that the decomposition of lactone takes place through different intermediates, that is, a triplet state of lactone in the mercury-photosensitized reaction and an excited complex between an excited cadmium atom and a lactone molecule in the cadmium-photosensitized reaction. A rational mechanism has been proposed for the mercury-photosensitized reaction. However, the mechanism regarding the cadmium-photosensitized reaction has remained somewhat obscure.

In order to obtain further information on the cadmium-photosensitized reaction of lactone, we investigated the effect of a methyl group in the α- and γ-positions regarding primary processes, quantum yields, and rates of decomposition. In this paper we report on the cadmium-photosensitized reactions of γ-valerolactone(VL) and α-methyl-γ-butyrolactone (ML).



VL



ML

Experimental

The apparatus and techniques were similar to those used previously.[2] An analysis of products was performed using simple fractionation at 77 and 190 K, measurements with a gas burette, and gas chromatography. The light absorbed by cadmium atoms at 326.1 nm was determined by *cis*-2-butene actinometry.[3]

VL (aldrich, 98%) and ML (Tokyo Kasei Ind., E.P. grade) were used after drying using a molecular sieve (5A) and several trap-to-trap distillations. Known amounts of liquid lactone were injected into the reaction cell with a microsyringe and were fully degassed after many careful freeze-pump cycles. *cis*-2-Butene (Nihon Tokushu Gasu K.K., pure grade) snd N_2 (Takachiho Shoji., pure grade) were used as supplied.

The cadmium-photosensitized reaction was carried out at 300 °C in order to obtain a sufficient cadmium vapor pressure. A thermal decomposition occurred at this temperature and yielded carbon dioxide, methylcyclopropane and other minor products. However, the amounts of these products were very small and the influence of the thermal decomposition on the results of the cadmium-photosensitized reaction was negligible.

Results

The major observed volatile products in the cadmium-photosensitized reaction were carbon monoxide, ethylene, propylene and acetaldehyde. These products are different from those obtained during thermal decomposition. Yields of these products increased linearly with reaction time, showing that they are primary products. The quantum yields of carbon monoxide, ethylene, and propylene are shown in Fig. 1 as a function of lactone pressure. All of them decreased with an increasing lactone pressure, showing the existence of a collisional deactivation process. The amount of acetaldehyde was always roughly equal to that of ethylene.

Only small amounts of 2-methyloxetane were obtained for pure lactone systems. In the presence of a large nitrogen pressure, however, we obtained considerably more 2-methyloxetane and found that the yield increased with pressure.

When *cis*-2-butene was added to lactone, the

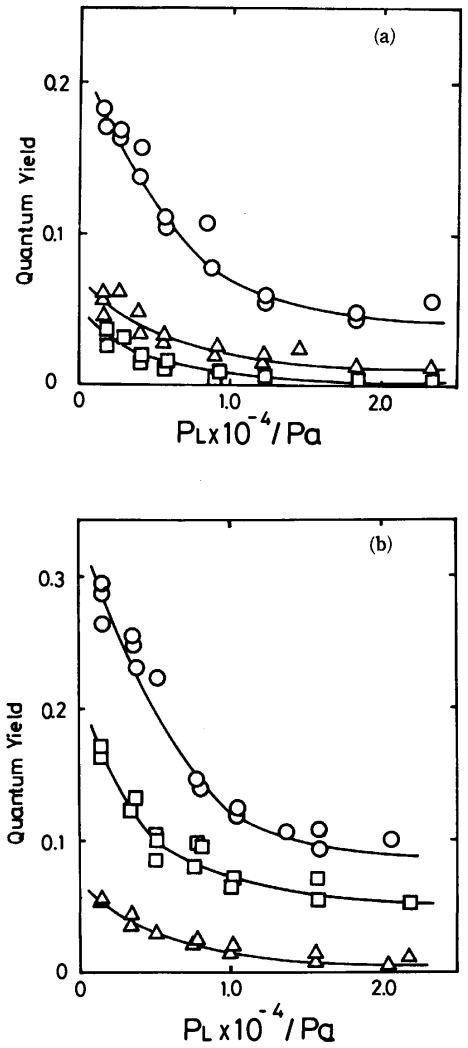


Fig. 1. Pressure dependence of quantum yields of carbon monoxide (○), ethylene (△), and propylene (□) in the cadmium-photosensitized reaction of (a) VL and (b) ML.

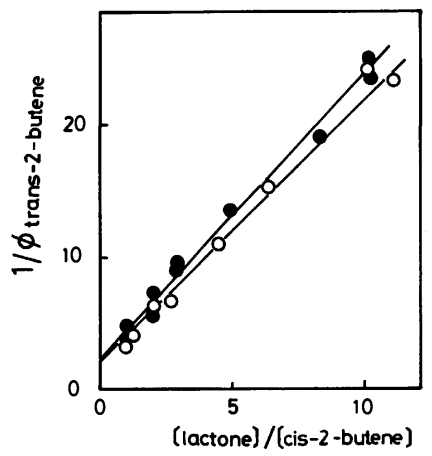

Fig. 2. Plots of the reciplocal of the quantum yield of *trans*-2-butene against the lactone/*cis*-2-butene pressure ratio for VL (●) and ML (○).

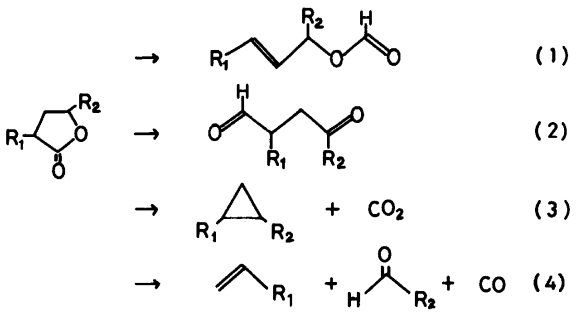
quantum yields of the decomposition products decreased as the quantum yield of *trans*-2-butene formation increased. From the slopes of the reciprocal plots of the quantum yield of *trans*-2-butene *vs.* the lactone/*cis*-2-butene ratio (Fig. 2), the quenching efficiencies of VL and ML relative to that of *cis*-2-butene were estimated to be 1.00±0.10 and 1.10±0.10. These values are close to that of BL (0.92±0.10).[2]

Discussion

Simonaitis and Pitts[4] investigated the photolysis of BL, VL, and ML in the liquid phase. They proposed primary processes (1)-(4) to explain major products.



As they pointed out, process (4) is minor regarding liquid-phase photolysis and is important for the vapor-phase photolysis of BL.[1] In the cadmium-photosensitized reactions of BL, VL, and ML, however, products considered to arise from process (4) alone were observed. This suggests the possibility that the cadmium-photosensitized reaction occurs through a different state from those for the direct photolysis.

In the photolysis of *trans*-2,3-dimethylcyclopentanone, Frey and Lister[5] obtained ethylene and butene as well as 1,2-dimethylcyclobutane as products. They pointed out that C_2+C_4 hydrocarbons and 1,2-dimethylcyclobutane are formed by independent pathways and that the former are not formed from a "hot" 1,2-dimethylcyclobutane molecule because (in the latter case) propylene must also be formed. The photolysis of cyclopentanone-2,2,5,5-d_4 gave evidence for the same conclusion.[6] In the present cases, however, ethylene and propylene were observed. Propylene (for VL) and ethylene (for ML) can not be directly formed from the biradicals produced by the elimination of carbon monoxide from VL and ML. This indicates that these products must be formed from "hot" oxetane molecules.

In order to explain the experimental results, the following set of reactions is proposed:

$$Cd(^1S_0) + h\nu(326.1\ nm) \rightarrow Cd^*(^3P_1) \qquad I_a \quad (5)$$

$$Cd^* \rightarrow Cd + h\nu(326.1\ nm) \qquad k_1 \quad (6)$$

$$Cd^* + L \rightarrow CdL^* \qquad k_1 \quad (7)$$

$$CdL^* + L \rightarrow Cd + 2L \qquad k_2 \quad (8)$$

$$CdL^* \rightarrow \alpha(CO + R_1\dot{C}HCH_2CHR_2O\text{-}Cd) \qquad k_3 \quad (9)$$

$$\rightarrow (1-\alpha)\ \text{other processes} \qquad (10)$$

$$R_1\dot{C}HCH_2CHR_2O\text{-}Cd \rightarrow R_1\underline{CHCH_2CHR_2O}^* + Cd \qquad k_4 \quad (11)$$

$$\rightarrow \gamma(R_1CH{=}CH_2 + R_2CH{=}O + Cd) \qquad k_5 \quad (12)$$

$$\rightarrow (1-\gamma)\text{other processes} \qquad (13)$$

$$R_1\underline{CHCH_2CHR_2O}^* \rightarrow R_1CH{=}CH_2 + R_2CH{=}O \qquad k_6 \quad (14)$$

$$\rightarrow R_1CH{=}O + R_2CH{=}CH_2 \qquad k_7 \quad (15)$$

$$R_1\underline{CHCH_2CHR_2O}^* + L \rightarrow R_1\underline{CHCH_2CHR_2O} + L \qquad k_8 \quad (16)$$

$$\rightarrow \text{other processes} \qquad (17)$$

VL; $R_1=H$, $R_2=CH_3$

ML; $R_1=CH_3$, $R_2=H$

Here, CdL* stands for a transient complex between the excited cadmium atom and a lactone molecule. As mentioned previously,[2] since the triplet state of BL lies at about 439 kJ/mol above the ground state, it can not be formed by a reaction of $Cd(^3P_1)$, which has an energy of only 367 kJ/mol. Therefore, we proposed that the complex is formed in the cadmium-photosensitized reaction of BL in order to explain the difference between the mercury- and cadmium-photosensitized reactions. This complex was also assumed for the present cases because the triplet energies of VL and ML are also probably larger than the excitation energy of excited cadmium atom. The formation of an O-Cd bond in Reaction (5) was assumed since the excitation energy of $Cd(^3P_1)$ alone is not sufficient to produce biradical $R_1\dot{C}HCH_2CHR_2O$, as has been shown in a previous paper.[2]

In a pure lactone system, a few minor products other than those previously mentioned were observed (some of them are the same as those observed during thermal decomposition). From their retention times, these minor products seem to be C_4- or higher compounds. Since their gas-chromatogram peaks were very small and overlapped in a complex way, we could not make assignments. In the presence of a large nitrogen pressure, a considerable amount of 2-methyloxetane was obtained (as previously mentioned). In this case, most of the peaks for minor products diminished. These findings indicate that in the presence of a large nitrogen pressure, intermediates seem to be stabilized by collisions with nitrogen molecules and give 2-methyloxetane, while in the pure lactones, most of the intermediates must react with lactone and yield other products (Reaction 17).

From the above mechanism, the following relations can be derived:

$$\frac{1}{\phi_{CO}} = \frac{1}{\alpha} + \frac{1}{\alpha}\frac{k_2}{k_3}[L] \qquad (18)$$

$$\frac{\phi_{CO}}{\phi_{R_2CH=CH_2}} = \left(1+\frac{k_5}{k_4}\right)\left(1+\frac{k_6}{k_7}\right) + \left(1+\frac{k_5}{k_4}\right)\frac{k_8}{k_7}[L] \qquad (19)$$

From plots of $1/\phi_{CO}$ *vs.* lactone pressure (Fig. 3), values of α and k_2/k_3 were obtained for VL and ML. These values are listed in Table 1, together with those for BL. The values of α for VL and ML are similar to that for BL, while the value of k_2/k_3 for VL is somewhat larger than those for ML and BL. This seems to show that the VL complex is a little less stable than those of ML and BL due to a steric hindrance of the methyl group at the γ-position, and more easily decomposes to a cadmium atom and a lactone molecule by collision with lactone molecules.

The quantum yields of carbon monoxide (extrapolated to zero pressure) were 0.31 and 0.37 for VL and ML. These small values suggest that most of the excited lactone that was formed underwent other reaction (Reaction 10). The amount of products volatile at 190 K (other than carbon monoxide, ethylene, propylene, acetaldehyde, and 2-methyloxetane) were negligibly small (see above). Therefore, isomerization to 4-oxopentanal, 2-methylsuccinaldehyde and other substances which were observed in

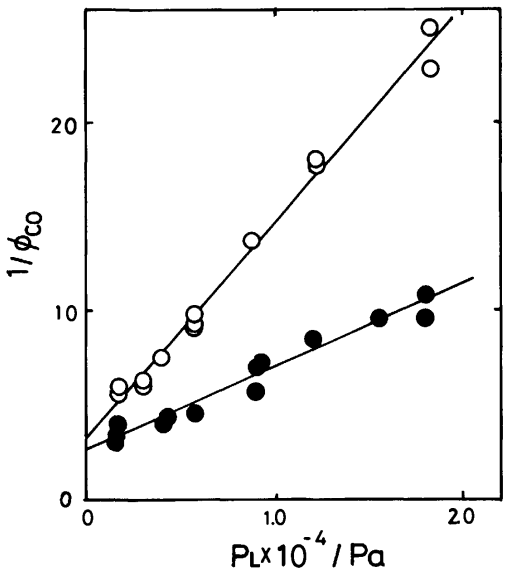


Fig. 3. Plots of $1/\phi_{CO}$ against lactone pressure for VL (○) and ML (●).

TABLE 1. CONSTANT AND RATIO OF RATE CONSTANTS INVOLVED IN Eq. 18

	BL[1]	VL	ML
α	0.27±0.02	0.31±0.02	0.37±0.02
$10^{-4}k_2/k_3$ Pa^{-1}	1.1±0.1	3.6±0.3	1.6±0.1

1) Calculated from the data shown in Ref. 2.

the photolysis of VL and ML in the liquid phase,[4] and the process in which excited lactones lose their energy without forming any products seem to be important (Reaction 10). The ratios of the other reaction (α) are almost equal for three lactones.

It was shown that in the thermal decomposition of 2-methyloxetane, both ethylene and propylene are obtained and the ratio of propylene/ethylene (1.31) is independent of temperature.[7] In our cases, $R_2CH{=}CH_2$ and a part of $R_1CH{=}CH_2$ are possibly formed from a "hot" oxetane as shown in Reactions (14) and (15). If so, the ratio of k_6/k_7 can be set at 1/1.31 for VL and 1.31 for ML. Plots of $\phi_{CO}/\phi_{R_1CH=CH_2}$ *vs.* lactone pressure are presented in Fig. 4. From the intercepts and the slopes of the straight lines, the values of k_5/k_4 and k_8/k_7 were obtained using k_6/k_7 (mentioned above). $k_8/(k_6+k_7)$ can be also calculated from the intercepts and the slopes. These values are listed in Table 2. k_5/k_4 for VL is similar to that for ML and $k_8/(k_6+k_7)$ for VL is considerably larger than for ML. The experimental values of $k_8/(k_6+k_7)$ give $k_d=k_6+k_7$ as $(5.9\pm1.6)\times10^8\ s^{-1}$ for VL and $(3.2\pm1.3)\times10^9\ s^{-1}$ for ML by adopting $8.0\times10^4\ s^{-1}$ as the kinetic collision frequency at 1 Pa and 300 °C and by assuming a collision-deactivation efficiency of unity for lactone.

The excess energy of energized 2-methyloxetane

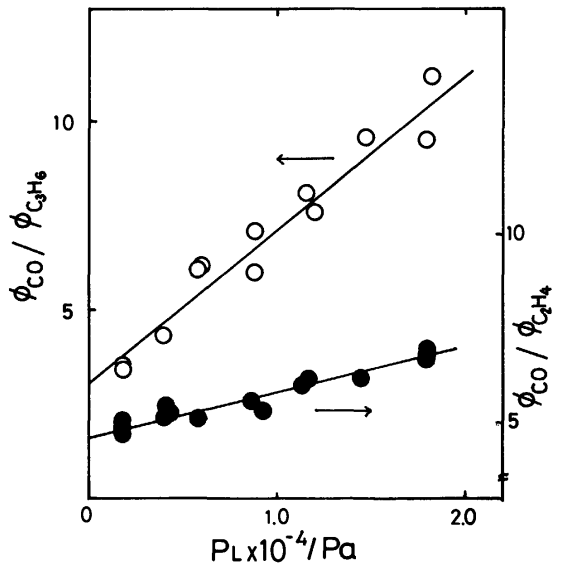

Fig. 4. Plots of $\phi_{CO}/\phi_{C_3H_6}$ (○) for VL and $\phi_{CO}/\phi_{C_2H_4}$ (●) for against lactone pressure.

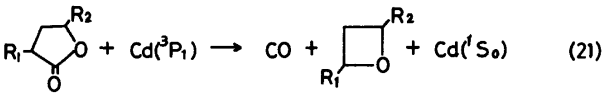
Table 2. Ratios of rate constants involved in Eq. 19

	VL	ML
k_5/k_4	0.73±0.15	1.0±0.1
$10^4\,k_8/k_7$ Pa^{-1}	2.40±0.30	0.58±0.10
$10^4\,k_8/(k_6+K_7)$ Pa^{-1}	1.36±0.30	0.25±0.10

can be estimated using

$$k_d(E) = A\left(1-\frac{E_a}{E}\right)^{s-1} \tag{20}$$

Here, $k_d(E)$ is the rate constant regarding decomposition when the excess energy is E, A is the frequency factor, E_a is the critical energy, and s is the number of effective oscillators in the molecule. Using experimental values of k_d and substituting $A=10^{14.89}\ s^{-1}$ and E_a=249.8 kJ/mol (taken from the experiment of Hammond and Holbrook[7]) and s=16 (about half of the number of the modes of vibration), the values of E were found to be (410±5) kJ/mol for VL and (444±10) kJ/mol for ML. These excess energies are much larger than the enthalpy changes for the following reaction which are estimated to be 173 and 180 kJ/mol for VL and ML according to thermochemical data given by Benson.[8]



(21)

The estimation of the excess energy is also dependent on the collision-deactivation efficiency and the value of s. For example, an efficiency of 1/10, which is an unlikely small efficiency for lactone, results in a decrease of excess energy by about 34 kJ/mol. If a value of s=14 is adopted, the value of E is found to be 377 kJ/mol for VL. Even in these cases, the excess energy is still much larger than the enthalpy change shown above. Thus, the possibility that the dissociating intermediate is an energized 2-methyloxetane must be eliminated. As has been described in a previous paper,[2] the formation of an O–Cd bond must play an important role in the cadmium-photosensitized reaction of lactone. In order to explain the large rate constant regarding the decomposition of intermediates, we proposed the following intermediate as another possibility:

The excess energy of the above intermediate must be larger than that estimated thermochemically for an energized oxetane because of the additional energy of the O–Cd bond. If this is the case, the "hot" oxetane in the above mechanism should be replaced by this intermediate. It is notable that Eq. 19 holds regarding this case. Unfortunately, since it is difficult to estimate the excess energy of the above intermediate, no quantitative conclusions can be drawn about the thermochemistry.

From the above mechanism, the following relation can be derived:

$$\frac{\phi_{R_1CH=CH_2}}{\phi_{R_2CH=CH_2}} = \frac{k_5}{k_4}\left(\frac{k_6+k_7}{k_7}\right) + \frac{k_6}{k_7} + \frac{k_5k_8}{k_4k_7}[L] \tag{22}$$

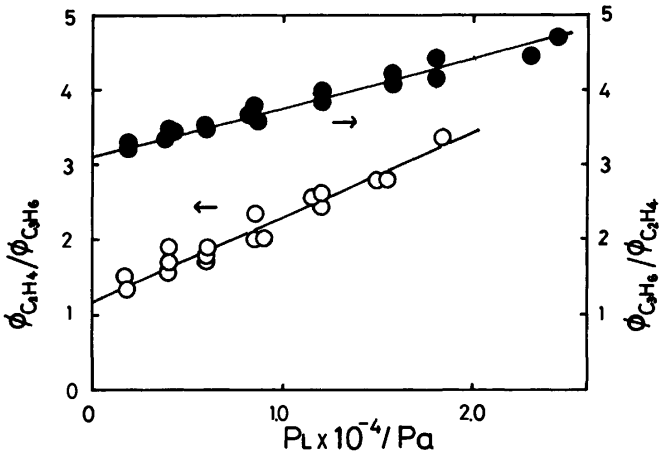


Fig. 5. Plots of $\phi_{C_2H_4}/\phi_{C_3H_6}$ (○) for VL and $\phi_{C_3H_6}/\phi_{C_2H_4}$ (●) for ML against lactone pressure.

From the intercepts and the slopes of the lines shown in Fig. 5, $k_8/(k_6+k_7)$ can be obtained using the following equation:

$$\frac{k_8}{k_6+k_7} = \frac{\text{slope}}{\text{intercept}-k_6/k_7} \tag{23}$$

The values for VL and ML obtained by using 1/1.31 and 1.31 for k_6/k_7 are $(1.79\pm0.30)\times10^{-1}$ and $(0.35\pm0.10)\times10^{-4}$ Pa^{-1}, respectively. These values are in fair agreement with those obtained from Fig. 4 (Table 2). The small discrepancy may be due to the use of these k_6/k_7 values for oxetane instead of those for the above intermediate.

In conclusion, the present results give further evidence for the formation of an O-Cd bond and the presence of an excited complex between the excited cadmium atom and the lactone molecule (discussed in a previous paper[2]).

Formaldehyde Electro-oxidation on Copper Metal and Copper-based Amorphous Alloys in Alkaline Media

Ken-ichi MACHIDA and Michio ENYO*
Research Institute for Catalysis, Hokkaido University, Sapporo 060
(Received March 6, 1985)

Copper metal and copper-based amorphous alloys, a-$Cu_{35}Ti_{65}$ and a-$Cu_{33}Zr_{67}$, exhibit a very high and stable activity for the anodic HCHO oxidation in aqueous NaOH and Na_2CO_3. The oxidation current was already observable at electrode potentials as low as 0.1 V (RHE) and, in particular, the HF-treated amorphous alloys gave high current densities around 40 mA cm^{-2} (apparent) at 0.2 V. Kinetic data, roughly first order both in HCHO and OH^- concentration, are in favour of the mechanism in which the oxidation proceeds *via* hydroxymethanolate ion ($HOCH_2O^-$) formed from HCHO and OH^-, producing $HCOO^-$ and H_2: This ion is readily oxidized on the copper metal or copper-based amorphous alloy electrodes. The Tafel slope was in general agreement with the reaction mechanism assuming a rate-determining one-electron transfer step.

Fuel cells which employ organic fuels such as methanol or its derivatives are strongly demanded, especially for uses as small scale transportable electric power sources with improved conveniences in storage and handling of the fuel as compared with hydrogen. A number of investigations on this subject have been carried out about two decades ago,[1-3] but fuel cells of this type which are economically comparable with other electric power sources have not yet been developed. A major difficulty involved in some carbonaceous fuel cells is due to sluggish rate of electro-oxidation of the fuels. Hence, a breakthrough which must be accomplished before developing such fuel cells is concerned with the fabrication of electrodes having high electrocatalytic activity towards the oxidation.

A series of precious metals generally possess high activity compared with other metals for the electro-oxidation of these fuels and most investigations carried out up to this date have been concentrated on them.[2] At the present stage, it appears that the following two directions may be sought for in order to attain fuel cells which are economically more feasible: Thus, (a) the electrocatalytic activity per unit loading of the precious metal should be improved so that its amount of use may be reduced or (b) nonprecious metal electrodes with high electrocatalytic acivity for organic fuels should be developed.

As electrode materials other than precious metals, tungsten carbides[2c] and molybdenum oxides[3c] have been noted, and some workers[4,5] have lately reported that these electrodes have excellent characteristics for the electro-oxidation of methanol or its derivatives. Among methanol derivatives, formaldehyde can readily be electro-oxidized on some nonprecious metals: The present authors have recently reported that a series of IB metals catalyze the anodic HCHO oxidation[6] in alkaline media and suggested a possible use of Cu metal or Cu-based amorphous alloys as electrocatalysts.[6c] In this paper, some further details of the anodic oxidation characteristics in both aqueous NaOH and Na_2CO_3 media are presented and then the reaction mechanism is presented.

Most amorphous alloys prepared by the rapid quench technique generally have a high strength to mechanical stresses. They are also often corrosion resistant because they are essentially in the form of homogeneous solid solutions of the alloying metals and contain no lattice defects, *e.g.* dislocation, grain boundary, *etc.* Their uses as catalysts or electrocatalysts have drawn attentions during the last several years. In the field of electrocatalysis, Kawashima and Hashimoto[7] reported electro-oxidation of methanol and its derivatives in alkaline solutions on a series of Pd-based amorphous alloys such as a-$Pd_{61}Pt_{20}P_{19}$. A number of amorphous Cu–Ti and Cu–Zr alloy specimens with compositions between 30 and 70 wt% Cu have been prepared and the hydrogen absorbability has been studied.[8] The hydrogen evolution reaction property and surface characteristics of HF-treated Cu-based amorphous alloy specimens have been reported in our previous paper.[9]

Experimental

Preparation of Electrodes. The Cu electrodes were prepared from an ordinary Cu plate (0.3 mm in thickness, 99.5% purity) in a rectangular form of 10×5 mm and their surface was etched with dilute nitric acid prior to the electrochemical measurements. The electrodes of Cu-based amorphous alloys were made from alloy ribbons (0.5—1.0 mm wide and *ca.* 20 μm in thickness)† and made porous by treatment with aq HF as described elsewhere.[9] The electrodes were clipped or spot-welded on Ta lead wires which were sealed in Pyrex glass tubings.

Roughness Factor. The roughness factor (*RF*) of the electrodes was evaluated from the double layer capacitance

† Some of these samples were provided by Prof. K. Suzuki and Dr. K. Kai of Tohoku University, to whom our thanks are due.

data measured by a galvanostatic transient method (time scale=1—5 m s) and the assumed value of 18 μF cm^{-2} (true).

Electrochemical Measurements. The cyclic voltammogram and steady-state polarization measurements were carried out in 0.03—3.0 M (M=mol dm^{-3}) NaOH or 0.5 M Na_2CO_3 solutions, which contain various amounts of HCHO (0.003—1.0 M), under a stream of purified Ar gas. The formaldehyde used (GR grade, Nakarai Chemicals, Tokyo) contained 7 wt% CH_3OH. A Ag/AgCl and a pt-Pt RHE were used as reference electrodes, but all the potential values quoted in this report are given on the RHE scale. Details of the cell and other experimental procedures were described previously.[6]

XPS Measurements. Surface analysis of the amorphous Cu-Ti and Cu-Zr alloys was performed using an ESCA apparatus (VG-III) with Mg $K\alpha$ radiation. The binding energy values recorded were calibrated using the $4f_{7/2}$ signal (83.8 eV) from a gold plate which was employed as an internal standard.

Results and Discussion

In NaOH Solutions. The electrocatalytic activity of Cu metal electrodes for the electro-oxidation of HCHO was very high. The rest (open circuit) potential of Cu metal and Cu-based amorphous alloy electrodes was usually observed to be around −50 mV (RHE). Although this value is much more positive than the theoretical oxidation potential of HCHO (−0.22 V *vs.* RHE), it is the most negative potential observed among analogous systems employing various carbonaceous fuels.

Figure 1 shows typical cyclic voltammograms obtained on a Cu plate in 1 M NaOH containing various amounts of HCHO. Even with HCHO of very low concentration (10^{-2} M), the oxidation current was quite significant and it became already noticeable at potentials around 0.1 V. The hysteresis on the cyclic voltammograms, which is very often observed in the electro-oxidation of carbonaceous fuels such as methanol, was small or almost absent in this case under the polarization between 0 and 0.5 V. The decrease of the current density above about 0.4 V observed in 0.01 M HCHO solution may perhaps be attributed, under the short HCHO supply conditions, to the formation of oxide (*e.g.* Cu_2O) on the Cu surface at that potential, which may give rise to the lowering of the electrocatalytic activity. Such a deactivation never took place in solution containing higher amounts of HCHO.

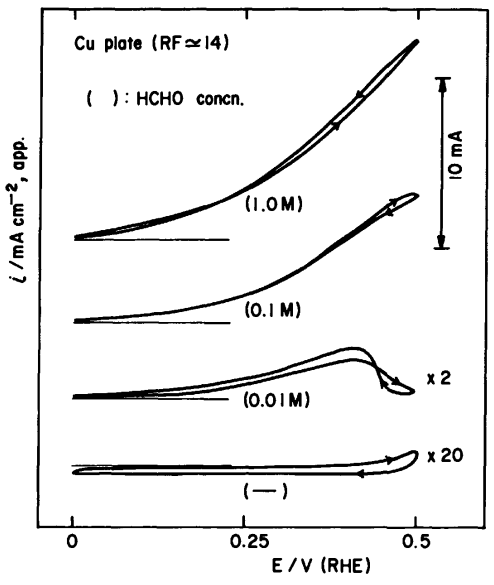

Fig. 1. Typical cyclic voltammograms observed on a Cu plate in 1 M NaOH containing 0.01—1.0 M HCHO at 303 K. Potential sweep rate: 10 mV s^{-1}.

In a previous paper,[9] we have reported that Cu-rich porous layers formed by the treatment with aq HF on the surface of the amorphous Cu-Ti and Cu-Zr alloys show a high electrocatalytic activity for the hydrogen evolution reaction as compared with usual smooth Cu electrodes. Similarly, very high HCHO electro-oxidation currents were observed on the HF-treated amorphous Cu-Ti and Cu-Zr alloy electrodes and, among them, the latter alloy showed more active and hence advantageous electrocatalytic characteristics than the former one. Meanwhile, the HCHO oxidation current on the untreated Cu-based amorphous alloys was very small: This must be due to the existence of inert oxide films, *i.e.* TiO_2 or ZrO_2, covering their surface.

Figure 2 shows cyclic voltammograms observed on the HF-treated amorphous Cu-Ti and Cu-Zr alloys with various *RF* values (given in the parentheses). On the Cu-Ti alloy electrodes, the current-voltage curves have maxima with a peak around 0.35 V in a similar manner as that of the Cu plate at the concentration of 0.01 M HCHO (see Fig 1). On the other hand, the voltammograms on the Cu-Zr alloys have no such maxima and increase monotonously with the potential sweep. In addition, the hysteresis on the voltammograms of these specimens is considerably smaller, and the catalytic activity of the electrodes with analogous *RF* values is much higher, as compared with that of the amorphous Cu-Ti alloy. These observations may suggest a difference in the surface characteristics of the porous Cu layers formed from the Cu-Ti and Cu-Zr alloys by the HF-treatments.

The surface of the Cu-based amorphous alloys was made porous by dissolving the alloy component Ti and Zr out of the alloy matrices with aq HF: It has been observed from SEM pictures that the surface indeed has a porous structure.[9] Nevertheless, the Cu-rich porous layers formed in this way contained a noticeable amount of Ti or Zr residue, as demonstrated in the XPS patterns of the Cu-Ti and Cu-Zr alloys which were observed before and after the HF-

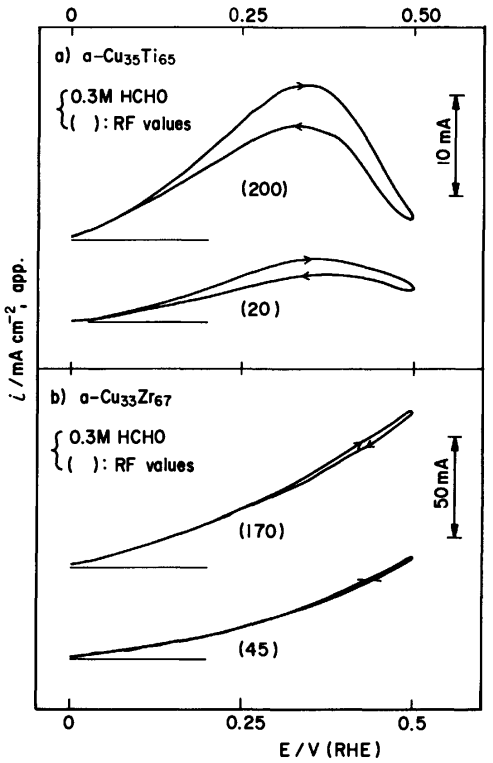

Fig. 2. Cyclic voltammograms observed on the Cu-based amorphous alloy electrodes with several *RF* values in 1 M NaOH containing 0.3 M HCHO at 303 K. Potential sweep rate: 10 mV s^{-1}.

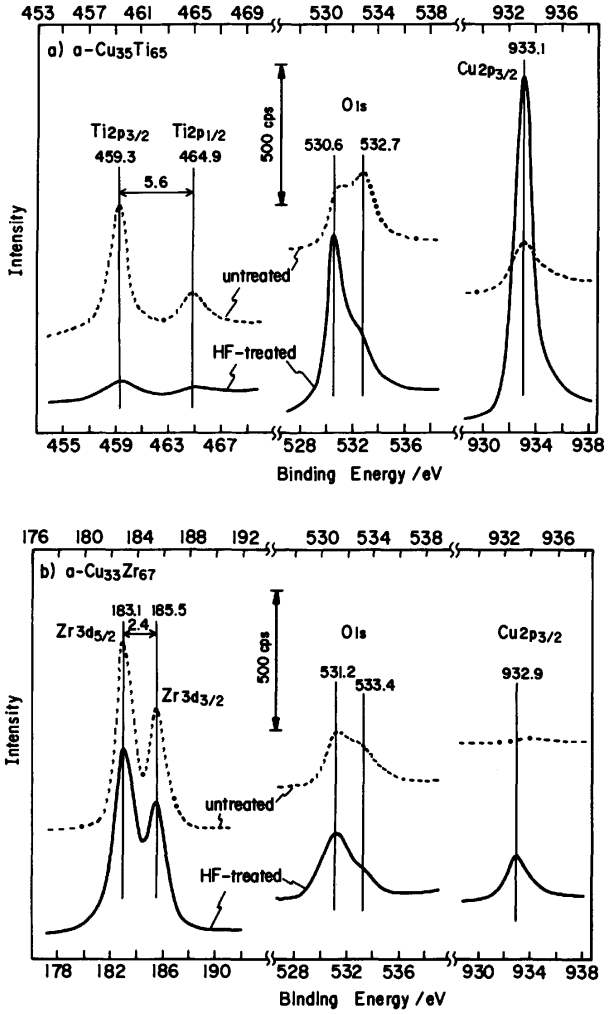

Fig. 3. XPS patterns of the Ti_{2p} (or Zr_{3d}), O_{1s}, and Cu_{2p} electrons on (a) a-$Cu_{35}Ti_{65}$ and (b) a-$Cu_{33}Zr_{67}$ alloys before (broken-lines) and after (solid-lines) the treatment with aq HF.

treatment (shown in Fig. 3).

On both the untreated and HF-treated specimens, spectra derived from strong Ti_{2p} and Zr_{3d} electrons have signals at the binding energy regions of 459—465 and 183—186 eV, respectively: These peak positions agree with those of the titanium of TiO_2 and the zirconium of ZrO_2, respectively. The O_{1s} signals consist of two bands peaking at about 530.6 and 532.7 eV which can respectively be assigned to the oxygens of oxides and hydroxyl groups. The Cu_{2p} signals are attributable to the 2p electrons of the metallic copper and/or Cu_2O. After the HF-treatments, however, the spectrum intensities from Cu_{2p} electrons are considerably increased whereas those of Ti_{2p} or Zr_{3d} electrons decreased.

It can be seen from Fig. 3 that the amounts of the Ti and Zr residue in the resulting Cu-rich layers on the HF-treated amorphous Cu-Ti and Cu-Zr alloys nevertheless differ considerably from each other: The amorphous Cu-Zr alloy gives relatively strong Zr_{3d} signals even after the HF-treatment while this was not the case for Ti in the amorphous Cu-Ti alloys. Thus, the Cu-rich layers formed on the amorphous Cu-Zr alloy still contain an appreciable amount of Zr, and the improved electrocatalytic activity of the amorphous Cu-Zr alloy may be due to this Zr residue. On the other hand, Ti was almost completely lost from the surface of the Cu-Ti alloy and this was probably the reason why the characteristics of the Cu-rich layers on this alloy was rather similar to those of usual Cu plates.

The difference between Cu-Ti and Cu-Zr alloys is again demonstrated in the relationship between the oxidation current density and *RF* values, as shown in Fig. 4 together with results obtained on the Cu metal electrodes. The current increased initially in a proportional way with the *RF* values and the highest value reached on the amorphous Cu-Zr alloy at 0.2 V was around 40 mA cm^{-2}. An analogous shape was also obtained on the Cu-Ti alloy. Although the data were rather erratic, it could be seen in general that the current density was much lower than that on the Cu-Zr alloy. In the region of still higher *RF* values, the current had a tendency to reach a saturation value. This might indicate that not all the surface area of the porous alloy electrodes was any longer used effectively in the oxidation of HCHO: The curve suggests that the electrode with the *RF* value

above 100 is quite satisfactory for the HCHO electro-oxidation.

A kind of "induction period" was seen in Fig. 4 on electrodes with low *RF* values: These were obtained on the electrode without any extensive treatment of the surface. This might indicate that the amorphous alloys became electrocatalytically active only after a significant amount of the inert oxide films (TiO_2 or ZrO_2) was lost from the surface so that their surface became sufficiently rich in Cu.

The electrocatalytic activity was very stable: Large current density values were obtained even after a prolonged time of the steady-state polarization on those electrodes, particularly on the HF-treated amorphous alloys with the porous Cu-rich layers formed on the surfaces. Figure 5 shows the stability of the electrocatalytic activity of Cu metal and Cu-based amorphous alloys at the initial period of the steady state polarization at 0.2 V. No steep decay in the anodic current density, such as those frequently observed in the methanol oxidation on platinum electrodes was recorded. In a long period (several days) polarization, however, a further amount of formaldehyde must be added to the electrolyte in order to maintain the stable current density outputs. This indicated that HCHO would have been decomposed to methanol and formate by the Cannizzaro disproportionation reaction in alkaline media.

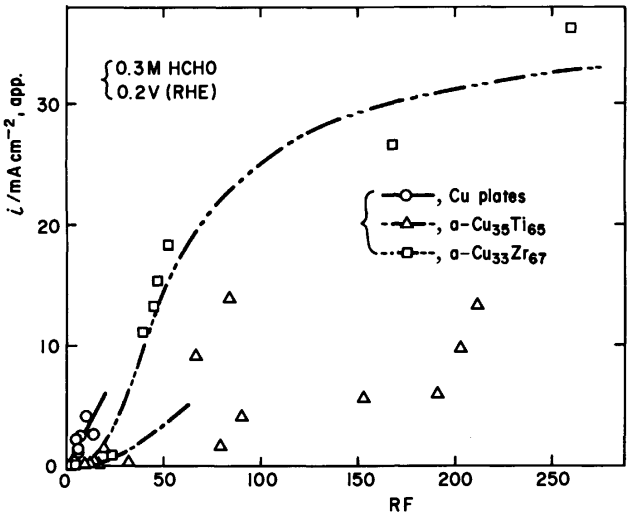

Fig. 4. *RF* value dependences of the anodic current density i on Cu metal and Cu-based amorphous alloy electrodes in 1 M NaOH containing 0.3 M HCHO at 303 K. The i values are read at 0.2 V on the cyclic voltammograms obtained with the potential sweep range of 0—0.5 V and the sweep rate of 10 mV s^{-1}.

In Na_2CO_3 Solutions. If the oxidation of HCHO in alkaline solutions such a NaOH and KOH is complete, yielding CO_2 (and H_2O), the alkali would readily take up CO_2 and form carbonate and then hydrogencarbonate. This means that the cell reaction consumes the alkali metal hydroxide rather like a part of fuels. It is then much more advantageous if the electro-oxidation of HCHO takes place with a reasonable rate in Na_2CO_3 solution. In this case, the fuel cell may be operated at relatively high temperatures so that the hydrogencarbonate is decomposed back to carbonate.

Figure 6 shows typical cyclic voltammograms observed on a Cu plate in 0.5 M Na_2CO_3 solution. As same as those obtained in NaOH solutions, the anodic oxidation current of HCHO was clearly observed at potentials lower than 0.1 V and the rest potential was again negative on the RHE scale. The hysteresis of their voltammograms are very small. The electrocatalytic activity of the Cu-based amor-

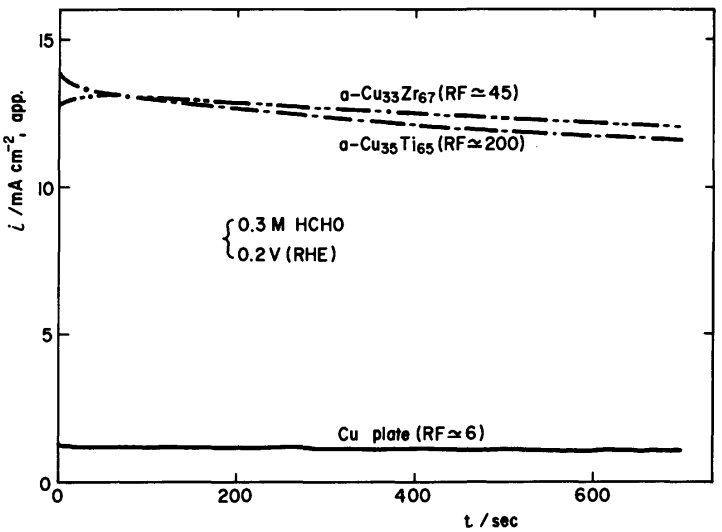

Fig. 5. Time dependences of the anodic current density i under the steady-state polarization at 0.2 V on Cu metal and Cu-based amorphous alloy electrodes in 1 M NaOH containing 0.3 M HCHO at 303 K.

phous alloys was much higher than that of the Cu metal electrodes. Nevertheless, their anodic current outputs were about one order of magnitude smaller than those obtained in NaOH solutions.

The anodic current outputs are maintained practically at constant values for a long period over several days: The Cu-based amorphous alloys with *RF* value of 110—120 constantly give the current density around 3 mA cm^{-2} (see Fig. 7), and thus these alloys are again good candidates for the electrode materials in this type of formaldehyde fuel cells.

Reaction Mechanism. Tafel plots of the anodic polarization currents on the Cu metal and Cu-based amorphous alloys are shown in Fig. 8. It is seen as mentioned already that all the rest potentials are negative to RHE and the catalytic activity is very high. The slopes of the linear portions in their Tafel plots are not much different from the ordinary behaviours of one-electron transfer kinetics, although the behaviour of the amorphous Cu-Ti alloy electrode is somewhat different from the others. The slope values would indicate that the oxidation takes place by a mechanism involving a rate-determining one-electron transfer step.

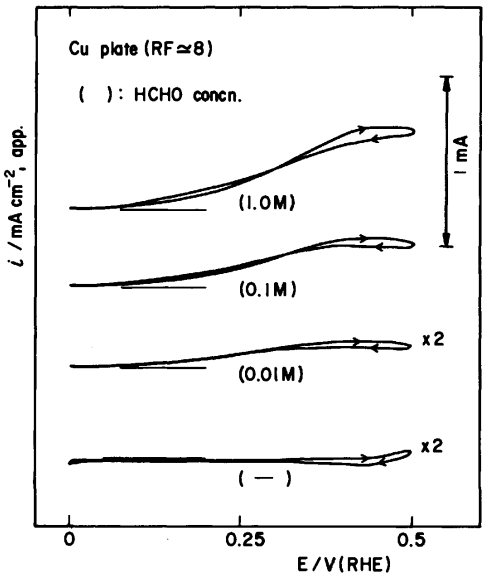

Fig. 6. Typical cyclic voltammograms observed on a Cu plate in 0.5 M Na_2CO_3 (pH=11.5) containing 0.01—1.0 M HCHO at 303 K. Potential sweep rate: 10 mV s^{-1}.

Meanwhile, evolution of hydrogen during the reaction, in spite of more positive electrode potentials than that of the RHE were involved, was reported by some investigators in experiments which are connected with the electroless plating[10c,d] of metals such as Cu: This was also confirmed in the present work.

The number of electrons involved in the electro-oxidation was evaluated from the quantity of electricity required when a given amount of HCHO was completely electro-oxidized at a constant electrode potential. Figure 9 shows a coulometric curve of the anodic HCHO oxidation on a Cu plate electrode. The number obtained was 0.97 equivalents mol^{-1} during the electrolysis at 0.23 V in 1 M NaOH solution. This observation indicates that the reaction is a partial oxidation to $HCOO^-$, along with a co-production of hydrogen.

In Fig. 10 is shown a relation between the anodic current density on the Cu metal electrode and pH of NaOH solutions, 0.03—3.0 M, which contain 0.3 M HCHO. At the lower pH region, the curve obtained was asymptotic to the line with the slope of unity (dashed line in figure): The oxidation reaction may thus be judged to be first order in OH^- in low NaOH

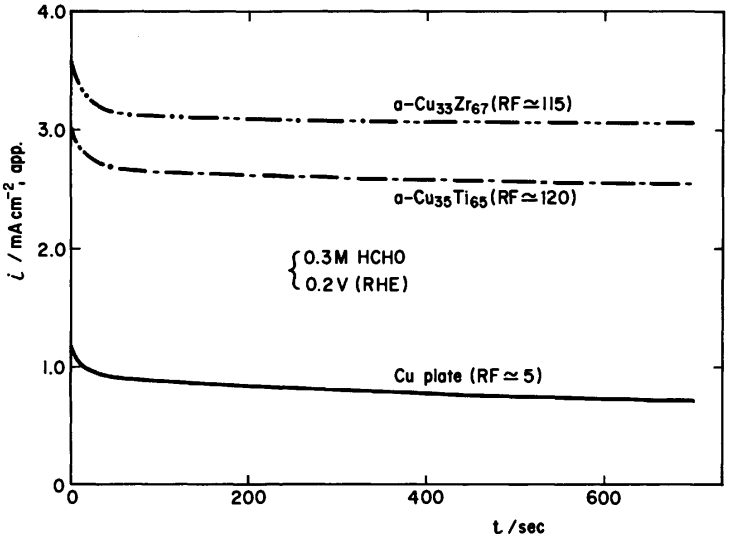

Fig. 7. Time dependences of the anodic current density i under the steady-state polarization at 0.2 V on Cu metal and Cu-based amorphous alloy electrodes in 1 M NaOH containing 0.3 M HCHO at 303 K.

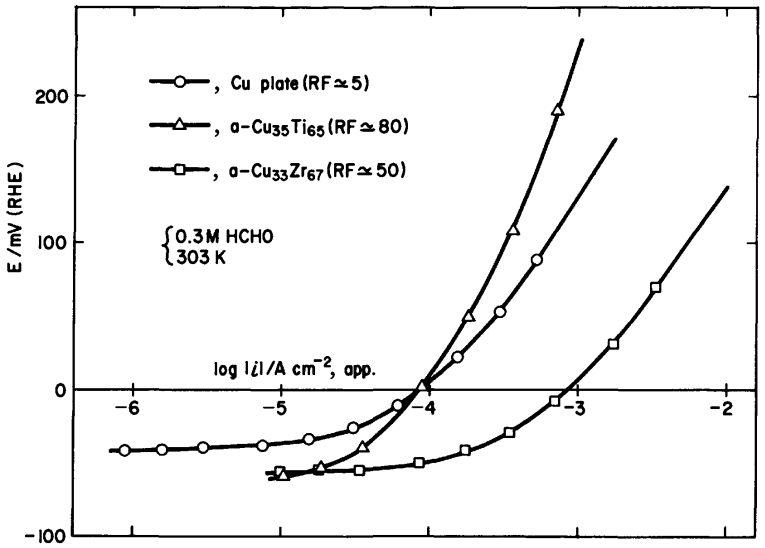

Fig. 8. Anodic polarization behaviors of Cu metal and Cu-based amorphous alloy electrodes in 1 M NaOH containing 0.3 M HCOH at 303 K.

concentration range.

The dependence of the oxidation rate on the HCHO concentration on the Cu metal electrode with a fixed NaOH concentration is shown by open circles in Fig. 11. The log-log plot again yields a smooth bending curve, but it has a general tendency to approach a line with the slope of unity at low concentrations, in a similar manner as in Fig. 10. These observations, *i.e.* the oxidation rate increases with increase both in HCHO or OH^-, are in harmony with the mechanism proposed in the literature[10] that hydroxymethanolate (methyleneglycol) ion, $HOCH_2O^-$, is formed from HCHO in aqueous alkaline solutions, and the anodic HCHO oxidation proceeds *via* this ion.

This reaction scheme means that pH of the alkaline solution should decrease by the addition of HCHO or the equilibrium constant for the formation of $HOCH_2O^-$ can be evaluated from the pH change. In Table 1, the pH values of NaOH solutions observed before and after the addition of the equimolar amounts of HCHO, and the K values thus evaluated are summarized. As an average, K=4.7 M^{-1} was obtained, although the K value at high NaOH concentration (0.298 M) was too high as compared with the other values.

Also presented in Fig. 11 (filled circles) is the relation between the oxidation current and the $HOCH_2O^-$ concentration evaluated from the reactant concentrations and the K value obtained above. It may be seen that the reaction is essentially of the first order with respect to $HOCH_2O^-$ at low concentrations. The decrease of the reaction order in the higher concentration region may require more information

a) Values obtained in the solutions containing HCHO equimolar with the amount of NaOH.

before any definite interpretations be made: It is nevertheless likely that the hydroxymethanolate ion is adsorbed on the electrode surface prior to its discharge and the adsorption gradually approaches a full coverage in this high concentration region.

On the basis of the experimental observation mentioned above, the following reaction scheme may be written:[10)]

$$HCHO + H_2O \rightleftharpoons CH_2(OH)_2 \quad (1)$$

$$CH_2(OH)_2 + OH^- \rightleftharpoons HOCH_2O^- + H_2O \quad (2)$$

$$HOCH_2O^- \xrightarrow{A} HCOOH + H(a) + e \quad (3)$$

$$HCOOH + OH^- \longrightarrow HCOO^- + H_2O \quad (4)$$

$$2H(a) \longrightarrow H_2\uparrow \quad (5)$$

where $\xrightarrow{A}$ denotes the rate-determining step. The experimental observations, namely, the first order reaction both in HCHO and OH^- at low concentrations, the Tafel line which supports rate-determining one-electron transfer step, one electron involved in the overall reaction, and the hydrogen evolution along with the electro-oxidation, may well be explained by this mechanism.

Additional Remarks. As mentioned above, HCHO is not completely oxidized on the Cu-based electrodes to CO_2 and H_2O at potentials which are desirable for practical fuel cell operations. Also, these electrodes are not good electrocatalysts for the oxidation of hydrogen and hence the hydrogen intermediate yields as gaseous H_2 by step (5). It may therefore be necessary for a complete HCHO oxidation that the Cu-based electrodes may be combined with other electrocatalysts which have a high catalytic activity for the oxidation of $HCOO^-$ and of the hydrogen intermediate,

$$HCOO^- \longrightarrow CO_2\uparrow + H^+ + e \quad (6)$$

$$H(a) \longrightarrow H^+ + e \quad (7)$$

Amorphous alloys are noteworthy in this purpose because they may be prepared in uniform solid solutions with various compositions.

In previous reports,[11)] we have reported that several Ti-and Zr-based amorphous alloys of group VIII metals are good electrocatalysts for the evolution or ionization of hydrogen (Eq 7), and also they are expected to be highly active for the oxidation of $HCOO^-$ (Eq 6). Thus, some preliminary experiments[12)] indicated that, while the electrocatalytic activity in the $HCOO^-$ electro-oxidation of Ni- and Pt-based amorphous alloys was relatively low, that of Pd-based amorphous alloys was very high. Furthermore, the electrocatalytic activity of the Pd-based electrodes was much more stable than that of the other alloys. It may be interesting to see if HCHO can be completely oxidized to CO_2 and H_2O using composite electrodes contaning Cu and Pd.

Conclusion

Cu metal and Cu-based amorphous alloy electrodes show very high electrocatalytic activity for the anodic

HCHO oxidation and the oxidation current is already significant at potentials around 0.1 V (RHE). The reaction kinetics have the characteristics such that the oxidation rate is approximately first order in HCHO and OH^-, and the Tafel line suggests a reaction mechanism involving a rate-determining one-electron transfer step. The results indicate that the oxidation proceeds *via* $HOCH_2O^-$ intermediate which is formed from HCHO and OH^-. The oxidation is, however, not of complete one to CO_2 and H_2O and hydrogen is evolved along with the electro-oxidation.

Reduction Mechanism of 2,3,5-Triphenyltetrazolium Chloride and 1,3,5-Triphenylformazan

Kisaburo UMEMOTO
Department of Pure and Applied Sciences, College of General Education, The University of Tokyo, Komaba, Meguro-ku, Tokyo 153
(Received March 14, 1985)

The reduction mechanism of 2,3,5-triphenyltetrazolium chloride(TTC) and 1,3,5-triphenylformazan was studied by electrochemical, ESR, and spectrophotometric methods. In non-aqueous aprotic solvent, 2,3,5-triphrnyltetrazolium ion was reduced to formazan anion either by two-electron reaction or by disproportionation reaction of tetrazolinyl radical generated by one-electron reduction of TTC. The same formazan anion was generated by one-electron reduction of 1,3,5-triphenylformazan. In the presence of proton donor, the formazan anion was converted to formazan by protonation reaction and cyclic regeneration of formazan was observed in the reduction of formazan. These results indicate that the quantitative determination of reducing materials by using TTC may possibly lead to erroneous evaluation of reductants unless the strength of electron donating property of reductants is established.

Tetrazolium salts have been used for demonstrating dehydrogenase activities,[1-4] for detecting hyperoxide radical,[5-7] and for determination of inorganic reducing materials.[8] Upon reduction tetrazolium salts, generally colorless, are converted to highly colored formazans.

Although tetrazolium salts have merits as qualitative indicators, their use as quantitative reagents has been less successful.[4,5] In the estimation of microbial damage by using TTC, the coloration was dependent on the quality as well as the quantity of microflora.[4] In the examination of using TTC as a quantitative reagent for the determination of hyperoxide, poor reproducibility was revealed in the intensity of the coloration of the solution.[9]

In addition to the ambiguity involved in the quantitative use of tetrazolium salts, there appeared an uncertain relationship between the color of the solution and the reaction intermediate: There has been either or not a relationship between the color of the solution and the intensity of ESR signals.[10,11] Nevertheless, there have been a few works on the systematic studies of the reduction mechanism of tetrazolium salts.[5,11-14]

The purpose of the present work is to elucidate the problem involved in the quantitative use of TTC by clarifying the stepwise reduction pathways of TTC and its formazan.

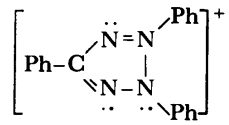
Experimental

TTC obtained from Tokyo Kasei was recrystallized from mixture of ethanol and diethyl ether and 1,3,5-triphenylformazan of the same source was recrystallized from aqueous ethanol solution under nitrogen. These materials were dried at 70 °C under vacuum. Dimethyl sulfoxide (DMSO) was treated with activated alumina and distilled twice under nitrogen at reduced pressure. Tetraethylammonium perchlorate(TEAP) was prepared according to the usual method.

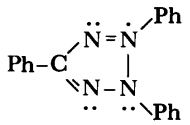
Absorption spectra were measured with a Hitachi 100-60 spectrophotometer. ESR spectra were measured by a Japan Electron Optics Lab. Co. JES-PE-3X spectrometer. Cyclic voltammograms were recorded with a laboratory made potentiostat.[15] The Pt electrode used for cyclic voltammetry was soaked in aqua regia for 30 s and heated in a blue flame.[15] Controlled potential electrolysis was carried out in an H-type cell equipped with a sintered glass separator. The cathode was a Pt net and the anode was a spiral Pt wire. Potentials were all referred to an SCE equipped with a salt bridge.[15] All experiments were carried out at room temperature (20 °C).

Results and Discussion

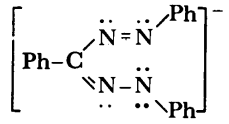
Molecular structures and abbreviations of molecular species appeared in this paper are summarized as follows:



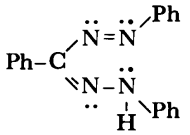
2,3,5-triphenyltetrazolium (R+)



2,3,5-triphenyltetrazolinyl (R·)



1,3,5-triphenylformazan anion (R−)



1,3,5-triphenylformazan (RH)

Reduction of TTC. A cyclic voltammogram of TTC is shown in Fig. 1. Two cathodic and two anodic waves were observed. By carrying out the potential reversal immediately after the first cathodic wave, the first redox couple was found to be A/A′.

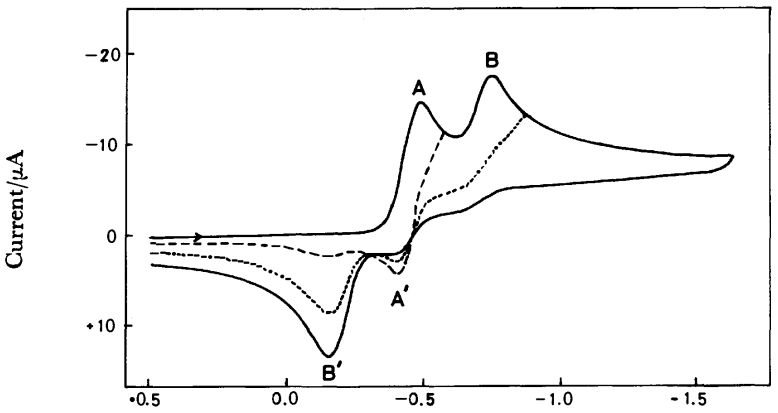


Fig. 1. Cyclic voltammogram of TTC: 1.0×10^{-3} mol dm^{-3} in DMSO containing 0.1 mol dm^{-3} TEAP. Scan rate: 0.05 Vs^{-1}.

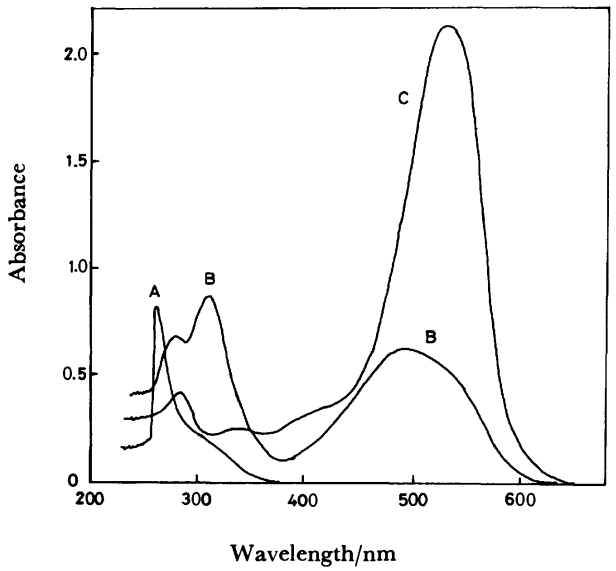

Fig. 2. Absorption spectra of (A): TTC (3.5×10^{-5} mol dm^{-3}), (B): 1,3,5-triphenylformazan (3.2×10^{-5} mol dm^{-3}), and (C): 1,3,5-triphenylformazan anion generated from (A) by controlled potential electrolysis at -1.09 V in DMSO.

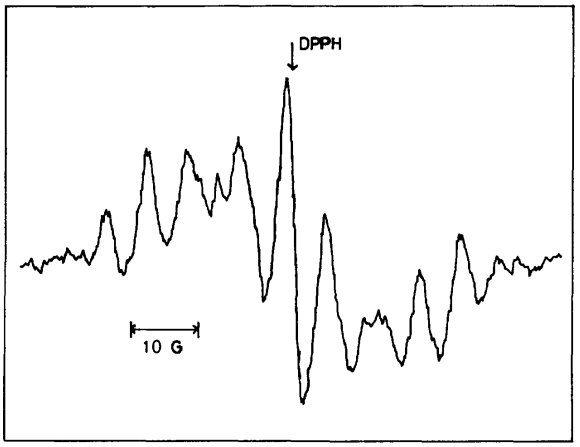

Fig. 3. ESR spectrum of tetrazolinyl radical generated by electrochemical reduction of TTC in DMSO.

The peak potential separation of the first redox couple was *ca.* 70 mV, being close to a reversible one-electron reaction. When constant potential electrolysis at -0.95 V corresponding to the second reduction step was performed to completeness, overall two electrons (1.98 electrons were found by experiment) were found to be required for each molecule of TTC and a highly red colored solution was obtained. The absorption spectrum of the solution is given in Fig. 2 along with absorption spectra of TTC and 1,3,5-triphenylformazan. The absorption band with its maximum at 538 nm was identified to that of formazan anion R^-, since an identical spectrum was obtained when R^- was liberated by adding tetraethylammonium hydroxide to the DMSO solution of 1,3,5-triphenylformazan. Taken together with these results the following stepwise electron transfer reactions are given:

$$R^+ + e \rightleftharpoons R\cdot \quad (1)$$

$$R\cdot + e \longrightarrow R^- \quad (2)$$

In order to obtain a solution of tetrazolinyl radical $R\cdot$, constant potential electrolysis was carried out at -0.55 V corresponding to the first reduction wave. For the complete electrolysis, two electrons (experimentally 1.96 electrons were found), contrary to the probable one electron, were found to be required for each molecule of TTC. The resulted solution was highly red colored and gave no ESR signal, but gave

exactly the same absorption spectrum as that of R^- shown in Fig. 2C. In contrast with the complete electrolysis, the partially electrolyzed solution gave an ESR spectrum as shown in Fig. 3 irrespective of the electrolysis potential being either −0.55 V or −0.95 V. The ESR spectrum was identified to that of 2,3,5-triphenyltetrazolinyl radical.[10,11,16] The same radical was also generated by adding TTC to the solution containing R^- alone. These results provide sufficient evidence for supporting the following equilibrium disproportionation reaction of R·.

$$R\cdot + R\cdot \rightleftharpoons R^+ + R^- \quad (3)$$

Judging from the result that the electron-transfer reaction to the radical (Eq. 2) is observable at the second cathodic wave on the cyclic voltammogram of TTC, the rate of disproportionation reaction is not very fast, since if this rate is too fast, only the first cathodic wave raised twice in height should be observed.

On the absorption spectrum of the solution containing tetrazolinyl radical, any band characteristically attributable to the radical was not observed. However, by subtracting the bands of TTC and formazan anion, a small absorption band was admitted in a range from 300 to 400 nm. Recently, by pulse radiolysis of 2-propanol solution of TTC, the absorption band of transiently lived radical was found to have its maximum at 365 nm.[14] The present observation that the absorption band of the radical was so weak indicates the equilibrium constant of disproportionation reaction (Eq. 3) being large in DMSO.

Cyclic voltammograms obtained in a series of reduction of TTC and subsequent re-oxidation of formazan anion are given in Fig. 4. The peak potentials of formazan anion (curve C) coincided with those of the second anodic wave and the two cathodic waves observed for TTC. In order to verify the probable regeneration of tetrazolium ion, constant potential electrolysis was carried out at +0.20 V. Upon completion of the electrolysis two electrons (experimentally 1.94 electrons were found) were found to be released for each formazan anion, and as shown in Fig. 4D, the original tetrazolium ion was recovered in high efficiency by the following oxidation reaction:

$$R^- - 2e \longrightarrow R^+ \quad (4)$$

In this oxidation reaction, the stepwise two one-electron reactions were not observed as shown in Fig. 4C. The large potential separation of the second redox couple observed for TTC (B/B′ in Fig. 1) indicates a large activation energy being needed for the cyclization of the open chain structure of formazan anion, bringing the potential of electron release of R^- more positive than the oxidation potential of R·. Accordingly, the second electron release would follow immediately after the first electron release of R^- and leaving no place for the accumulation of R· as a reaction intermediate.

Additional support for the reversible interconversion of R^+ and R^- was obtained in the study of absorption spectra. The absorption band of R^+ was substituted by that of R^- on completion of reduction of R^+, and on re-oxidation the absorption band of R^+ was recovered on consumption of that of R^-. The cycle of the complete reduction and oxidation was successively repeated and the interconversion of R^+ and R^- was found to be reproducible in high efficiency.

Formazan anion was stable in unhydrous DMSO, but when proton donors such as water and acids were added into the solution, the anion turned to formazan by the following protonation reaction:

$$R^- + H^+ \longrightarrow RH \quad (5)$$

The absorption spectrum obtained by addition of proton donors into the DMSO solution of R^- agreed

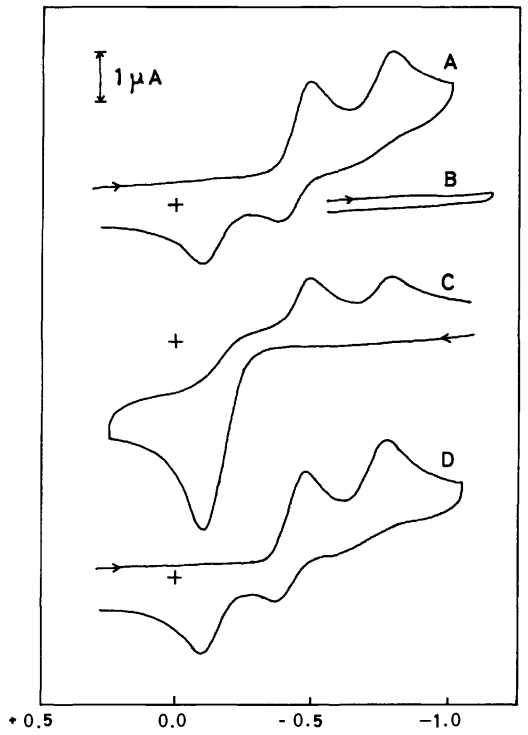

Fig. 4. Cyclic voltammogram of TTC taken (A): Before electrochemical reduction, (B) and (C): After complete electrochemical reduction, and (D): After electrochemical re-oxidation of formazan anion.

well with that of formazan shown in Fig. 2B. The rate of protonation reaction became faster with the stronger acidity of proton donors.

Reduction of 1,3,5-Triphenylformazan. The oxidation of formazan to tetrazolium salts is known to be the most characteristic property of formazan.[1,17-19] The electrochemical oxidation of formazans has been studied in acetonitrile and it was found that formazans are converted to tetrazolium salts with high efficiency.[17-19] However, the electrochemical study of reduction of formazans is quite few.[18] The reason seems to be due to the circumstances that the oxidation of formazans usually affords valuable pathways to prepare tetrazolium salts, while the reduction of formazans has not been praised for the preparative method of their decomposition products, such as hydrazine, amidrazone,amines, and aniline.

As formazan is indeed reducible, the reduction of formazan should be carefully studied, since formazan is the key substance in the analytical use of tetrazolium salt for determining reducing substances.

A cyclic voltammogram of 1,3,5-triphenylformazan is shown in Fig. 5. The first scan showed one cathodic and one anodic waves. Upon sweep reversal at *a* for the second scan additional two cathodic waves appeared at potentials where TTC gave its reduction waves. Constant potential electrolysis at −1.09 V revealed one electron (experimentally 1.06 electron was found) being required for complete electrolysis of each molecule of formazan. After the completion of the electrolysis, a highly red colored solution was obtained and the absorption spectrum as well as the cyclic voltammogram of the solution agreed well with those of formazan anion shown in Fig. 2C and in Figs. 4B and 4C, respectively. Subsequent constant potential electrolysis at +0.20 V revealed two electrons (experimentally 1.91 electrons were found) being released for the complete electrolysis of each formazan anion. After the electrolysis was completed, both the cyclic voltammogram and the absorption spectrum of the solution agreed well with those of TTC. The efficiency of conversion of 1,3,5-triphenylformazan to 2,3,5-triphenyltetrazolium ion was estimated to be over 95%. These results indicate that 1,3,5-triphenylformazan is reduced to formazan anion R^- by one-electron reaction accompanied by the elimination of hydrogen atom as shown below:

$$RH + e \longrightarrow R^- + H \qquad (6)$$

When formazan is reduced in the presence of proton donors, the regeneration of formazan is expected, since the protonation reaction shown by Eq. 5 would follow after the generation of R^-. In order to examine the probable cyclic regeneration of formazan, constant potential electrolysis at −1.09 V was carried out in an aqueous DMSO solution. Water was chosen as the proton donor, since acids were reduced at this potential, while water did not affect the electrolysis. The results are given in Fig. 6. In contrast with the asymptotic approach of the electrolysis current to the background level in unhydrous DMSO, the curent was observed to reach a stationary level in an aqueous DMSO solution, showing a stationary state being attained between the reduction and the regeneration of formazan in an aqueous DMSO solution. After 60 min of electrolysis, the peak heights of the absorption band and the reduction wave of formazan were almost the same with those recorded before the electrolysis was started, indicating that the concentration of formazan was

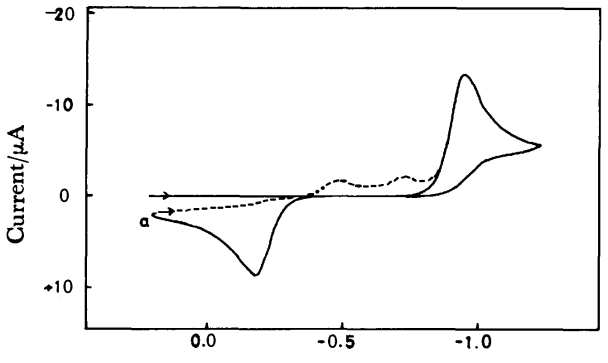

Fig. 5. Cyclic voltammogram of 1,3,5-triphenylformazan: 1.0×10^{-3} mol dm^{-3} in DMSO containing 0.1 mol dm^{-3} TEAP. Scan rate: 0.05 Vs^{-1}.

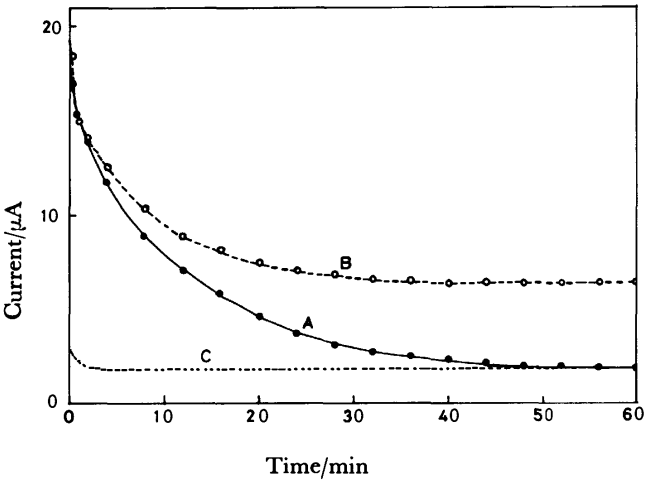

Fig. 6. Current-time curves taken in electrolysis of 1,3,5-triphenylformazan in (A): Unhydrous DMSO, (B): Aqueous DMSO (DMSO : water=92 : 8 in volume), and (C): base current (extrapolated after 10 min.). 1×10^{-7} mol of formazan was taken in *ca.* 4 dm^{-6} of solution containing 0.1 mol dm^{-3} TEAP. Potential: −1.09 V *vs.* SCE.

little affected in spite of formazan being really accepting electrons under conditions examined.

The results presented in this work provide an explanation for the problem encountered in the use of TTC as an electron acceptor. As 1,3,5-triphenylformazan is reduced at a potential (−0.95 V) not far more negative than the second reduction potential of TTC (−0.75 V), a stronger electron donor would reduce not only TTC (according to Eq. 1—4) but also formazan (according to Eqs. 5 to 6). However, the amount of electron donor used for the reduction of formazan is uncertain, since formazan is regenerated by the protonation reaction. The effect of regeneration of formazan depends both on the electron donor and the used solvent system; the stronger the electron donor and the stronger the proton donating property of the solvent system, the more effective the contribution of reduction of formazan, leading to erroneous estimation of electron donors by using TTC. In this sence, the electron donating property of reducing agents should be well established prior to the application of TTC for the particular system.

The author thanks Drs. Ryo Hirasawa and Kazuo Sakamoto for their kind permission and outstanding assistance in using their ESR spectrometer.

Adsorption Equilibria of Copper on Octadecylsilica Gel in the Presence of Acetylacetone

Masanao KATO
Department of Materials Science, Faculty of Engineering, Toyohashi University of Technology, Tempaku-cho, Toyohashi 440
(Received December 27, 1984)

The solid-liquid adsorption equilibria of copper with acetylacetone between octadecyl-bonded silica (ODS) gel and aqueous solution were investigated by a batch method at 298±1 K. It is found that a 1:1 complex of copper with acetylacetone is adsorbed on the gel surface.

Some types of chemically modified silica gels have been widely used as stationary phases for high-performance liquid chromatography. Among them, octadecylsilica (ODS) gel has been adopted for reversed phase chromatography, and the chromatographic behavior of various kinds of solute species has been studied in the system using ODS gel. They include studies using metal complexes as solute.[1-7] In these studies, it is well-known that the labile complexes introduced into the column give long tailing on the chromatograms. The phenomena have been explained as the degradation of complex molecules in the separation process; they were supressed by an addition of ligand to the eluent.

The ODS gel has also been used as a solid adsorbent for the preconcentration of trace metals in water.[8-14] In these studies, various complexing agents have been added to the sample solution as a coadsorbent. Metal ions in the samples form complexes with ligand molecules; these were considered to be adsorbed on the gel surface by a hydrophobic interaction with the long alkyl chains on the gel surface.

In these studies, however, the adsorption mechanisms underlying the separation or concentration process were not investigated for the systems containing metal complexes. They have simply been regarded as similar to those involved in the solvent extraction.

It was reported by some workers that an active site on the gel surface behaves as a cation exchanger.[15-17] Although it seems likely that the long alkyl chain on the gel surface plays an important role in the adsorption of metal complexes, these studies indicate that the roles played by the active site can not be neglected. Indeed, Mackey[16] pointed out that iron, copper, manganese, and zinc ions were adsorbed without complexing agent on the ODS gel (Waters) of low coverage.

It is also reported in the kinetic studies of liquid-liquid extraction that the 1:1 complex of copper with several kinds of ligands may be adsorbed at the liquid-liquid interface.[18-19] These studies suggest that the species adsorbed onto ODS gel follow a different mechanism from that involved in liquid-liquid extraction equilibria between two bulk phases, because the octadecyl monolayer on the ODS gel surface may behave as an interface similar to that involved in the solvent extraction or partition systems. Recently, Fardy *et al.*[14] pointed out from the calculation of the concentration of some complexes in the solution containing 8-quinolinol and some metal ions that the 1:1 complexes play dominant roles in the adsorption of copper, manganese and zinc ions on Sep-Pak C_{18} (Waters) which, according to Mackey,[16] adsorbs no metal cation except for iron.

From the above consideration, it can be supposed that the adsorbed species of metal ions on the ODS gel in the presence of some ligands would be much different from that extracted in solvent extraction or liquid-liquid partition of metal complexes. In this study, the adsorption equilibria of copper between the ODS gel and the aqueous phase were investigated in the presence of acetylacetone (2,4-pentanedione). Acetylacetone was chosen for the reasons: (1) the behavior of the ligand and its metal complexes in liquid-liquid partition has been thoroughly investigated; (2) its concentration in the adsorption systems can be changed over a wide range, since its solubility in water is relatively high; and (3) it is stable in water. The second reason aids in making the systems relatively simple, because other solvents like methanol are not required in order to dissolve the insoluble ligands such as 8-quinolinol.

Experimental

Materials. ODS gel (Unisil P-C18, Gasukuro Kogyo) was washed with diluted hydrochloric acid (Special Reagent for Trace Analysis, Kishida Chem.), ultra-pure water (obtained from Milli-Q system, Milipore Corp.), and methanol (Guaranteed reagent, Kanto Kagaku) successively, and then dried.

Acetylacetone (Guaranteed reagent, Kanto Kagaku) was used after distillation. All other reagents were commercially available guaranteed reagents, and were used without further purification.

Apparatus. The pH of the initial and final solutions were measured by a Toyo Kagaku TD-4 pH

meter. The copper concentrations in solutions were determined by atomic absorption spectrometry with a Shimadzu AA-640-12 atomic adsorption spectrometer equipped with GFA-2 graphite furnace atomizer. The concentration of acetylacetone was determined by UV absorbance at 274 nm using a Shimadzu UV-140-02 spectrometer. All the measurements were carried out in a thermostated room at 298±1 K. A box shaker (Itagaki Rika) was employed for equilibration of the adsorption mixtures.

Procedures. Twenty-five cm^3 buffer solutions of 1/15 mol dm^{-3} (CH_3COOH–CH_3COONa–NaOH or $HClO_4$–$NaClO_4$) were introduced into a 100 cm^3 vials, to which stock solution of 1.57×10^{-4} mol dm^{-3} of copper(II) sulfate, and 9.6×10^{-1} mol dm^{-3} of acetylacetone were added. They were filled up to 100 cm^3 with ultra-pure water, and the pH measured.

For the measurements of the adsorption equilibria, 20 cm^3 aliquots were introduced into 50 cm^3 glass centrifuge tubes containing 0.5 g ODS gel. The mixtures were shaken for 10 min at a shaking rate of *ca.* 300 min^{-1}. The equilibrated mixtures were allowed to stand for about 30 min in order to separate the gel from the aqueous phase. The solutions were filtered through a membrane filter of 10 μm pore to remove the gel. The pH and copper concentration of the filtrates were measured.

The ODS gels were washed with a 1 per cent solution of acetylacetone in chloroform in order to elute the adsorbed copper from the gel. Next the gel was rinsed with chloroform until no uv absorption of acetylacetone was observed in the chloroform. After the gel was successively washed with methanol, water, diluted hydrochloric acid (pH 2), and again water; it could then be reused.

The concentration of copper, C, adsorbed on the gel was calculated from the following equation

$$C_{ad} = (C_{in} - C_f)V/m, \quad (1)$$

where subscripts ad, in, and f denote the adsorbed, initial, and filtrate, respectively. V represents the volume of the aqueous phase and m is the mass of the ODS gel.

The distribution ratio, D, was defined by the following equation

$$D = C_{ad}/C_f \quad (2)$$

where the concentration of copper(II) cation in the filtrates are expressed in unit of mol cm^{-3}.

Results and Discussion

The equilibria of adsorption of copper between aqueous phase and ODS gel were attained within 5 min under these experimental conditions of the present investigation. In the measurements, the shaking time was fixed at 30 min, above which the distribution ratios were constant within experimental error.

The adsorption behavior of acetylacetone on the gel is shown in Fig. 1 as a function of initial concentration. The concentration of adsorbed acetylacetone increases linearly with the increasing concentration in the filtrates up to 0.5×10^{-2} mol dm^{-3}. In more concentrated solutions, however, another linearity appears. The distribution ratio tends to decrease with increase of acetylacetone concentration. At low concentrations, it decreases more steeply. The typical concentration of acetylacetone used in the adsorption experiments of copper(II) cation was 1×10^{-2} mol dm^{-3} and the volume of the solutions was 20 cm^3. Under these conditions, the concentration of acetylacetone on the gel is proportional to the initial concentration, and the adsorptive ability of the gel can be regarded as undersaturated.

The adsorption isotherms of acetylacetone obey the Freundlich equation (Fig. 2), but not the Langmuir equation. According to the theoretical consideration,[20] the surface of the ODS gels is not homogeneous, and it has more than two kinds of sites available

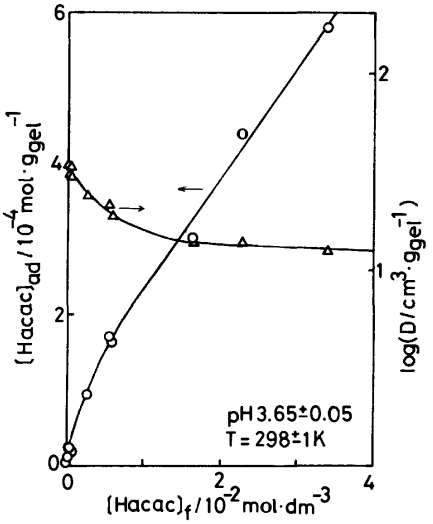

Fig. 1. Adsorption of acetylacetone onto ODS gel. ○ denotes concentration of acetylacetone on ODS gel, and △ is the distribution ratio.

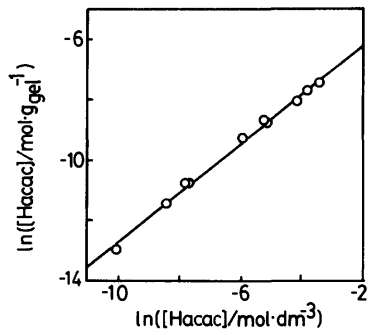

Fig. 2. Analysis of adsorption of acetylacetone by means of Freundlich equation.
$\ln[Hacac]_{ad} = 0.810 \ln[Hacac]_f - 4.60$

for adsorption of acetylacetone. This phenomenon agrees with the results that the gel has a second active site in addition to the hydrophobic site.[15-17] It is expected that these would be the remaining silanols on the surface which can interact *via* hydrogen bonding with acetylacetone, hydrophobic alkyl chains of octadecyl groups bonded on the surface, and the intermediate site among them. According to the information from the manufacturer, the gel used in the present study has uncovered surface silanols.

In Fig. 3, the pH dependence of the adsorption of acetylacetone is illustrated. The adsorption is independent of pH in the region studied. This indicates that acetylacetone is adsorbed on the gel surface as an electrically neutral species.

The dependence of adsorption of copper(II) cation upon the initial concentration is shown in Fig. 4, where the ratios of copper(II) cation concentration to that of acetylacetone are constant. The concentration of copper(II) cation on the gel increased linearly with its initial concentration in the aqueous phase up to 2×10^{-4} mol dm^{-3}, and its adsorption ratio was constant below a copper(II) cation concentration of 1.0×10^{-4} mol dm^{-3}. The ODS gel used in this study has a large ability to adsorb the copper complex, enough to permit experiments at very low copper concentrations of 1.57×10^{-5} mol dm^{-3} (this corresponds to 1 ppm Cu), or up to 3.14×10^{-5} mol dm^{-3} in the experiments of Job's continuous variation method. In this concentration range, 95 per cent of the copper(II) cation was adsorbed.

Now, consider the concentration of copper(II) cation, acetylacetone, and silanol group on the gel surface. The copper concentration on the gel is 6.3×10^{-7} mol g_{gel}^{-1} when the initial concentration is 1.57×10^{-5} mol dm^{-3} and the volume of solution is 20 cm^3, if the copper were completely adsorbed. The concentration of acetylacetone adsorbed is about 3.6×10^{-4} mol g_{gel}^{-1}, when its initial concentration in the aqueous phase is 1.0×10^{-2} mol dm^{-3} and the volume is 20 cm^3, since the adsorption rate is 90 per cent under these experimental conditions. Moreover the total concentration of residual silanol groups on the gel surface is estimated as 1.1×10^{-3} mol g_{gel}^{-1} on the basis of surface silanol concentration[21] and the information from the manufacturer. It is found from the above estimation that the concentration of copper on the gel is much smaller than those of the others, and the concentration change of acetylacetone and surface silanol caused by the adsorption of copper can be neglected. However, the concentration change of acetylacetone in solution or on the gel may significantly influence the adsorption of copper, since the concentration is comparable to that of the surface silanol.

The dependence of the distribution ratio of copper(II) cation upon the acetylacetone concentration and pH are shown in Fig 5. The pH range, in which the distribution ratio regularly increased, shifted to high pH with decrease of ligand concentration. This phenomenon is consistent with that observed in solvent extraction. However, the apparent values of the so-called extraction coefficients,

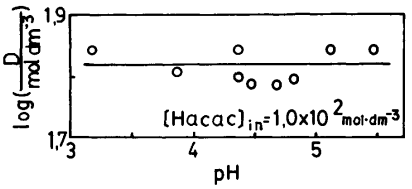

Fig. 3. pH Dependence of adsorption of aceylacetone onto ODS gel. Acetate buffer used.

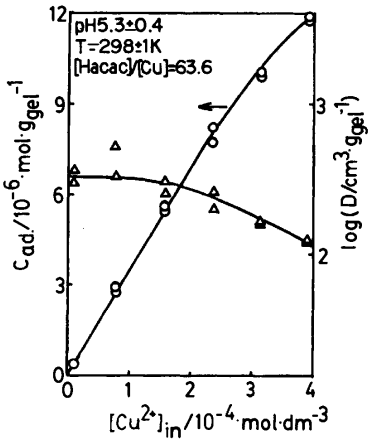

Fig. 4. Concentration dependence of adsorption of copper(II) cation with acetylacetone onto ODS gel. Concentrations of copper on gel are represented by ○, and its distribution ratio, △, respectively.

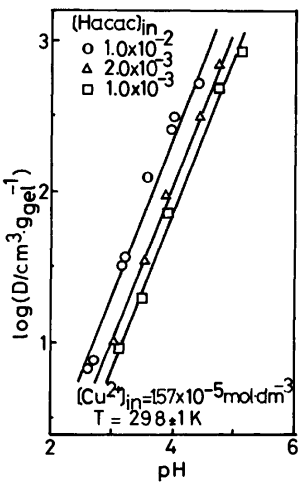

Fig. 5. pH Dependence of adsorption of copper(II) cation with acetylacetone onto ODS gel.

K_{ex}, calculated on the assumption that the ODS gel behaves as one of the phases, were not constant as tabulated in Table 1. K_{ex} is represented as the terms reciprocal to the distribution coefficient of ligand species between two phases, K_L, in the partition mechanism. As shown in Fig. 1, the apparent K_L values also decrease with increase of concentration of acetylacetone. For this reason, it is considered that the activity of the acetylacetone adsorbed on the surface is lowered in the diluted region by the adsorption to the surface silanol groups.[16]

The salt effect on the adsorption was investigated using acetic acid buffer solutions and perchlorate solution at constant pH and ionic strength in order to clarify whether the acetate anion is contained in the adsorbed species. The adsorption ratio was independent of the change of the composition of salts as shown in Fig. 6. Perchlorate anion is well known as one of the weakest ligands and forms no complexes in aqueous solution. The results in this figure suggests that acetate anion is not involved in the adsorption of copper. This fact is supported by the calculation of the degree of complex formation in these mixtures, where the concentration of acetate complex is negligibly small.

In order to determine the chemical composition of the adsorbed species, both the Job's continuous variation method and the molar ratio method were applied. In the Job's continuous varation study, the maximum adsorption was obtained for an equimolar solution. In the molar ratio study, the constant adsorptions were obtained over the equimolar solution. These results suggest that the adsorbed species are composed of one copper(II) cation and one ligand molecule.

The main driving force for the adsorption of the copper(II) cation with acetylacetone onto ODS gel from aqueous media is considered to be the hydrophobic interaction of the acetylacetonato complexes with the alkyl chain bonded on the gel. However, as mentioned above, the adsorption behavior cannot be completely interpreted only by the hydrophobic interaction. That is, it is found in this study that copper(II) cation in the aqueous media is adsorbed on the gel as the charged 1:1 complex of copper(II) cation and acetylacetone. To account for the neutralization of the electric charge of the gel adsorbing copper(II) cation, we may include another interaction of the charged complex with the ODS gel surface, *e. g.*, with residual silanol groups on it, as pointed out by Mackey.[16] At this stage it seems unlikely that the adsorbed 1:1 complexes would immediately exchange with the proton of the surface silanol groups buried under the alkyl chain. If the cation exchange occurs between the charged complex and the surface silanol, the distribution ratio is expressed as follows:

$$D = \frac{K_{ch}\beta_{n-1}K_a^{n-1}}{K_L^{n-1}}[\mathrm{HOSi}]_s\frac{[\mathrm{Hacac}]_{gel}^{n-1}}{[\mathrm{H}^+]^n}, \quad (3)$$

were K_{ch}, β_n, and K_a denote the exchange coefficient between complex and surface silanol, the formation constant of the charged complex, and the dissociation constant of acetylacetone, respectively. s and n indicate the surface and the charge on the copper(II) cation. As the concentration of copper on the gel is much smaller than that of the surface silanol, the concentration of silanol can be regarded as remaining constant. From the equation, it is concluded that if the cation exchange occurs the slope of log D *vs.* pH plot must have a value of nearly two. However, the slope obtained in the present study is close to unity. Therefore, it is reasonable to assume that the adsorption of the copper(II) cation onto the ODS gel can be explained by the partition of a 1:1 complex of copper(II) cation and acetylacetonate anion between the bulk aqueous phase and the alkyl chain layer on the ODS gel as one of the interface. The charge neutralization may be attained between ODS gel adsorbing complexes and anion in the aqueous phase in equilibrated mixtures.

The results obtained in this study may afford basic information essential to an understanding of the mechanism of separation of complexes in liquid

chromatography with ODS gel and the concentration of the metal with acetylacetone onto the gel. As mentioned above, this behavior is different from the partition mechanisms in bulk phase for liquid–liquid partition, but similar to the mechanism proposed in explaining the kinetics of partition of metal complex in the interface between two liquid phases.[18,19]

A Competition between 1,3-Dipolar Cycloaddition and Substitution of Trifluoroacetonitrile Oxide

Kiyoshi TANAKA,* Hideyuki MASUDA, and Keiryo MITSUHASHI
Department of Industrial Chemistry, Seikei University, Musashino-shi, Tokyo 180
(Received September 26, 1984)

Trifluoroacetonitrile oxide reacted with conjugated olefins such as styrenes, indenes, and acyclic conjugated dienes to give not only the cycloadduct but also its linear isomeric oxime. Methyl or phenyl group attached to the unsaturated carbon of the dipolarophiles was found to favor the formation of oxime. Such a concomitant reaction was interpreted in terms of a competition between a concerted cycloaddition and a two-step substitution through an electrophilic attack of nitrile oxide. Similar competitions were also investigated with cyclic conjugated dienes, where the competitive ratio of the products was found to depend on the ring size.

In the reactions of dipolar compounds with olefins or acetylenes, the substitution giving 1,3-addition product has been investigated in connection with the mechanism of 1,3-dipolar cycloaddition.[1,2] The reaction of benzonitrile oxide with phenylacetylene is particularly well documented,[3] and the concomitant formation of diphenylisoxazole and acetylenic oxime was interpreted by the independent two pathways, that is, a concerted cycloaddition and a substitution through an electrophilic attack of nitrile oxide on the triple bond of phenylacetylene.[1,4] As far as literatures show, however, such a substitution is limited only to rather unreactive dipolarophiles such as arylacetylenes and furan.

Previously we have reported the regio- and stereoselectivities in the conventional 1,3-dipolar cycloaddition of trifluoroacetonitrile oxide (**1**) with various olefins and acetylenes.[5] In the present paper,

$$CF_3C{\equiv}N{\rightarrow}O$$
1

we wish to demonstrate a competition between the 1,3-dipolar cycloaddition and the electrophilic substitution in the reaction of the oxide **1** with rather reactive conjugated olefins.[6]

The oxide **1**, generated from trifluoroacetohydroximoyl bromide etherate (**2**) and triethylamine,[5] reacted with styrene to give 5-phenyl-3-trifluoromethyl-2-isoxazoline (**3a**) along with a trace amount of the 1,3-addition product, 1,1,1-trifluoro-4-phenyl-3-buten-2-one oxime (**4a**). In contrast, the reaction with α-methylstyrene and α-phenylstyrene gave the corresponding oximes **4b** and **4c** in preference to the cycloadducts **3b** and **3c**, respectively (Scheme 1 and Table 1). The structures of **3a**—c and **4a**—c were determined on the basis of the elemental analyses and spectral data. Isomeric composition of **4a**—c and their steric configuration were investigated by means of ^{1}H NMR together with GLC. Thus **4a** or **4c** was deduced to be only one isomer and **4b** to consist of two geometric isomers out of four possible ones, respectively. Since **4b** could be hardly separated into

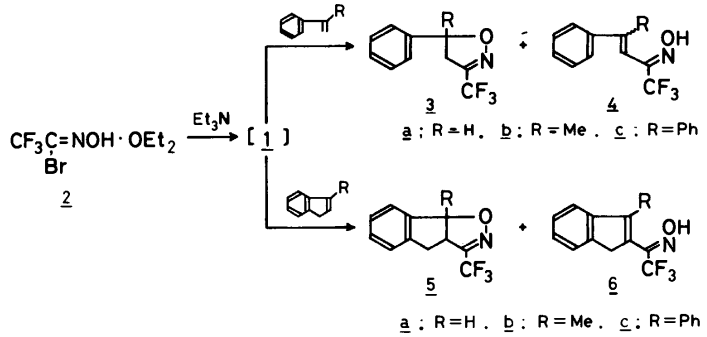
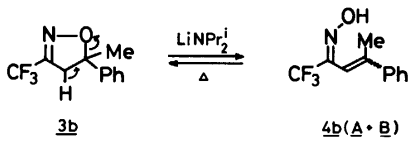


Scheme 1.

the components, its absolute configuration was ambiguous and the components are shown here as **A** and **B**. It should be noted that both the cycloadducts **3** and the oximes **4** are primary products *via* the independent pathways because they were too stable to interconvert under the reaction conditions unless the more drastic conditions were applied. The isoxazolines **3a** and **3b** were converted in high yields into the oximes **4a** and **4b**(**A** and **B**), respectively, through ring-opening by the treatment with lithium diisopropylamide[7] and, conversely, **4b** cyclized on heating at 150 °C to give **3b**. Such an interconversion



3b 4b(A + B)

might suggest the *E* configuration in respect to C–N double bond of **4**, and **4b-A** and **4b-B** could be the geometrical isomers in respect to C–C double bond. In the case with α-methylstyrene, the effect of the bases was then studied using pyridine and sodium methoxide in place of triethylamine, resulting in no appreciable changes in the ratios of **3b**/**4b** and **4b-A**/**4b-B**, as shown in Table 2.

The concomitant formation of the cycloadducts and the 1,3-addition products was also observed in the reactions of **1** with indenes (Scheme 1). Yields and ratios of these isomers are summarized in Table 1. The reaction of **2** with indene in the presence of triethylamine gave 3a,8a-dihydro-3-trifluoromethyl-4*H*-indeno[2,1-*d*]isoxazole (**5a**) and 2-[2,2,2-trifluoro-1-(hydroxyimino)ethyl]indene (**6a**) in the ratio of 79/21, where their regioisomers were not detected at all. The structure of **5a** was established by the comparable chemical shifts of two methine protons in ^{1}H NMR to those of the 3-phenyl analogue reported in the literature.[8] Singlet olefinic proton of **6a** in ^{1}H NMR supports that the trifluoro(hydroxyimino)ethyl group is attached to 2-position. In analogy with styrenes, methyl and phenyl groups on 3-position of indene ring favor the formation of the oximes. 3-Methylindene gave a mixture of **5b** and **6b** in the ratio of 37/63 and, with 3-phenylindene, the exclusive formation of the oxime **6c** was observed without any detectable amount of the cycloadduct **5c**.

Similarly with acyclic conjugated dienes, the formation of the oximes competed (Scheme 2). In the reaction with 1,3-pentadiene, only the cycloaddition occurred on the monosubstituted double bond to give exclusively **7** in 63% yield. On the other hand, with 2-methyl-1,3-butadiene, the cycloaddition took place on either double bond to afford **8** and **9**, accompanied by the oxime **10** (87% total yield, **8**/**9**/**10**; 48/40/12). The alternative oxime bearing trifluoro(hydroxyimino)ethyl group at 4-position was not detected. Similarly, the reaction with 2,3-dimethyl-1,3-butadiene gave the cycloadduct **11** and the oxime **12** in the ratio of 69/31. The oxime **12** was so unstable as to be cyclodehydrated intramolecularly during the course of isolation by column chromatography (silica gel) to give 4,5-dimethyl-2-trifluoromethylpyridine (**13**). The detailed study on the conversion to the pyridine is now under progress.

The oximes are thought to be formed *via* the addition of **1** toward the double bond giving the zwitterionic intermediate **14** followed by the intra-

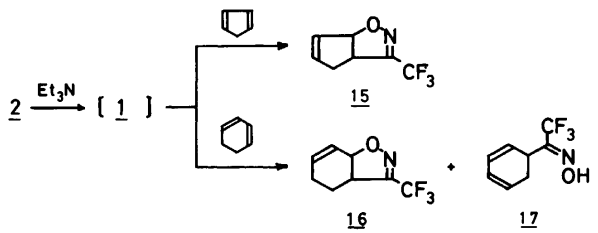
14

molecular proton shift.[9] Caramella *et al.* proposed a competing pathway stabilized by secondary orbital interactions to form oximes by the reactions of benzonitrile oxide with furan or arylacetylenes.[4] Thus the approach of the reagents with alignment, leading to a zwitterionic intermediate, is well stabilized by secondary orbital interactions between the phenyl group of benzonitrile oxide and the furan ring or the aryl group of arylacetylene. However, in the present case of trifluoroacetonitrile oxide **1**, such a stabilizing interaction is unlikely because trifluoromethyl group has no secondary interaction as reported in the Diels-Alder reactions of (trifluoromethyl)ethenes.[10] Therefore, the intermediate **14** might be formed *via* the electrophilic attack of **1** on the double bond owing to the strong electron-withdrawing effect of trifluoromethyl group.[11] The tendency of methyl or phenyl group of dipolarophiles favoring the formation of the oximes may be interpreted by both the steric hindrance which retards the concerted cycloaddition and the electronic effect which stabilizes the intermediate **14**.

A similar competition was further investigated with cyclic conjugated dienes (Scheme 3). While the reaction with cyclopentadiene gave exclusively the cycloadduct **15** in 53% yield, that with 1,3-cyclohexadiene afforded not only the cycloadduct **16** but also the 1,3-addition product **17**, in which trifluoro(hydroxyimino)ethyl group is substituted on the saturated carbon (66% total yield, **16**/**17**; 39/61). The structure of **17** was determined by its ^{1}H NMR and UV spectra. The methine proton (δ=4.07) coupled with the adjacent methylene protons and the absorption at 256 nm (ε=3393) due to conjugated diene strongly support that the trifluoro(hydroxyimino)ethyl group is attached to the saturated carbon. The concerted cycloaddition of nitrile oxide to the double bond in a six-membered ring is known to be slower than that to the one in a five-membered ring[12] and this unreactivity seems to cause the formation of the oxime **17**.



Scheme 3.

Experimental

All melting and boiling points are uncorrected. The IR spectra were recorded on a JASCO IRA-1 spectrometer. The ^{1}H and ^{13}C NMR spectra were measured with JEOL JNM-PMX 60 and -FX 60 spectrometers, respectively, using tetramethylsilane as an internal standard, the chemical shifts being given in δppm downfield. The MS spectra were obtained on a Finnigan 4023 GC-MS DS spectrometer. The UV spectra were observed with a Hitachi 340 spectrometer. The bromide **2** was prepared by the method reported in our previous paper.[5]

Reactions of 2 with Styrenes. To a mixture of **2** (2.64 g, 9.9 mmol) and α-methylstyrene (2.34 g, 19.8 mmol) in 20 cm^3 of toluene was added dropwise a solution of triethylamine (2.7 cm^3) in 10 cm^3 of toluene. The mixture was stirred at room temperature for 3 h. Then hexane was added and the salt, triethylamine hydrobromide, was collected on a filter. The filtrate was washed with water and brine and dried over magnesium sulfate. Removal of the solvent left an oily residue which was a mixture of **3b** and **4b(A+B)**. The residue was distilled (boiling range, 118—119 °C/9 mmHg (1 mmHg=133.322 Pa) to give 1.65 g (73% total yield) of a mixture of **3b** and **4b(A+B)**. The isoxazoline **3b** and **4b(A+B)** were separated by column chromatography (silica gel, hexane and chloroform) followed by preparative GLC: **3b**, ^{1}H NMR (CCl_4) δ=1.73 (s, 3H), 3.23 (q, 2H), 7.3 (s, 5H), IR (neat) 1625 (C=N), 1180 and 1131 cm^{-1} (CF_3).

Found: C, 57.75; H, 4.31; N, 5.92%. Calcd for $C_{11}H_{10}F_3NO$: C, 57.64; H, 4.40; N, 6.11%.

4b-A, ^{1}H NMR ($CDCl_3$) δ=2.29 (d, 3H), 5.87 (q, 1H), 7.2—7.6 (m, 5H), 8.6 (br.s, 1H); **4b-B**, ^{1}H NMR ($CDCl_3$) δ=2.13 (s, 3H), 6.10 (s, 1H), 7.4—7.7 (m, 5H), 8.6 (br.s, 1H).

Found: C, 57.71; H, 4.42; N, 6.05% (for a mixture of **4b(A+B)**). Calcd for $C_{11}H_{10}F_3NO$: C, 57.64; H, 4.40; N, 6.11%.

Similarly, the reactions with styrene and α-phenylstyrene were performed to give the corresponding **3** and **4**. Yields and ratios of these products are summarized in Table 1 and physical and spectral data are as follows: **3a**, bp 85—87 °C/3.5 mmHg (lit,[5] 85—87 °C/3.5 mmHg); **4a**, mp 142—143 °C (hexane-chloroform), ^{1}H NMR ($CDCl_3$) δ=7.1—7.6 (m, 7H), 9.2 (br.s, 1H), IR (KBr) 3320 (OH), 1622 (C=N, C=C), 1105 cm^{-1} (CF_3), MS (CI, *m/z*) 216 $(M+H)^+$, 244 $(M+Et)^+$, ^{13}C NMR ($CDCl_3$), δ=93.8, 112.1, 130.3, 148.6 (CF_3), 110.9 (d, HC=), 127.3, 128.6, 129.3, 135.7 (Ph), 137.3 (d, HC=), 141.5, 143.5, 145.5, 147.6 (C-CF_3).

Found: C, 55.89; H, 3.64; N, 6.45%. Calcd for $C_{10}H_8F_3NO$: C, 55.82; H, 3.75; N, 6.51%.

3c, ^{1}H NMR ($CDCl_3$) δ=3.76 (q, 2H), 7.2—7.8 (m, 10H), IR (neat) 1632 (C=N), 1190 and 1130 cm^{-1} (CF_3).

Found: C, 66.47; H, 4.15; N, 4.39%. Calcd for $C_{16}H_{12}F_3NO$: C, 65.98; H, 4.15; N, 4.81%.

4c, mp 113—114 °C (hexane-chloroform), ^{1}H NMR ($CDCl_3$) δ=6.18 (s, 1H), 7.0—7.4 (m, 10H), 8.6 (br.s, 1H), IR (KBr) 3370 (OH), 1609 (C=N), 1163 and 1093 cm^{-1} (CF_3).

Found: C, 66.12; H, 4.20; N, 4.80%. Calcd for $C_{16}H_{12}F_3NO$: C, 65.98; H, 4.15; N, 4.81%.

Conversion of 3 into 4. A 1.55 mol dm^{-3} solution of butyllithium (3.3 cm^3) in hexane was added dropwise to a solution of 1.00 g (4.7 mmol) of **3a** and 0.52 g (5.1 mmol) of

diisopropylamine in 10 cm³ of tetrahydrofuran cooled in a dry ice-acetone bath. The mixture was allowed to warm to room temperature over a period of 3 h. After stirring at room temperature for an additional 2.5 h, saturated aq ammonium chloride was added to the mixture. The solvent was removed and the resulting aqueous layer was extracted twice with diethyl ether. The ethereal extracts were washed with brine and dried over magnesium sulfate. Removal of the solvent left a residue which was submitted to column chromatography (silica gel, chloroform) to give 0.93 g (93% yield) of **4a**. Thus obtained **4a** was further purified by recrystallization from hexane–chloroform, mp 142—143 °C, ^{1}H NMR and IR spectra are consistent with those obtained above.

The similar treatment of 1.14 g (5.0 mmol) of **3b** with lithium diisopropylamide gave 0.48 g (42%) of a mixture of **4b-A** and **4b-B** in the ratio of 57/43 (^{1}H NMR analysis).

*Conversion of **4b** into **3b**.* A mixture of 1.15 g (5.0 mmol) of **4b** (**4b-A**/**4b-B**; 56/44) and 10 cm³ of chloroform in a sealed tube was stirred at 150 °C for 65 h. The similar procedure to the above afforded 0.68 g (59%) of **3b** and recovered 0.40 g (35%) of a mixture of **4b-A** and **4b-B** in the ratio of 13/87.

*Reactions of **2** with Indenes.* To a mixture of **2** (2.58 g, 9.7 mmol) and indene (3.41 g, 29.4 mmol) in 20 cm³ of toluene was added dropwise a solution of triethylamine (2.8 cm³) in 10 cm³ of toluene. After being stirred at room temperature for 3 h, hexane was added and the deposited salt was filtered out. The filtrate was washed with water and brine, dried over magnesium sulfate, and evaporated to leave an oily mixture of **5a** and **6a** (79/21 by ^{1}H NMR analysis). The oil was distilled (boiling range, 118—119 °C/6 mmHg) to give 1.17 g (53% total yield) of a mixture of **5a** and **6a**. Each isomer was separated by column chromatography (silica gel, hexane and chloroform) and further purification was carried out by recrystallization: **5a**, mp 46—46.5 °C (hexane), ^{1}H NMR ($CDCl_3$) δ=3.37 (d, 2H), 4.25 (dtq, 1H), 6.28 (d, 1H), 7.2—7.6 (m, 4H), IR (KBr) 1605 (C=N), 1160 and 1120 cm^{-1} (CF_3).

Found: C, 58.11; H, 3.54; N, 6.12%. Calcd for $C_{11}H_8F_3NO$: C, 58.16; H, 3.55; N, 6.17%.

6a, mp 170—171 °C (hexane), ^{1}H NMR ($CDCl_3$–DMSO-d_6) δ=3.94 (s, 2H), 7.2—7.5 (m, 4H), 7.64 (s, 1H), 12.6(s, 1H), IR (KBr) 3200 (OH), 1155 and 1122 cm^{-1} (CF_3), MS (CI, *m/z*) 228 $(M+H)^+$, 210 $(M-OH)^+$, 141 $(M-CF_3OH)^+$.

Found: C, 58.17; H, 3.54; N, 6.15%. Calcd for $C_{11}H_8F_3NO$: C, 58.16; H, 3.55; N, 6.17%.

In a similar manner, **5b** and **6b**-c were obtained from the reactions with 3-methyl- and 3-phenylindenes, respectively, and their spectral data are as follows: **5b**, colorless oil, ^{1}H NMR (CCl_4) δ=1.77 (s, 3H), 3.27 (d, 2H), 3.77(tm, 1H), 7.1—7.5 (m, 4H), IR (neat) 1613 (C=N), 1191 and 1131 cm^{-1} (CF_3).

Found: C, 59.49; H, 3.98; N, 5.61%. Calcd for $C_{12}H_{10}F_3NO$: C, 59.75; H, 4.18; N, 5.81%.

6b, mp 115—116 °C (hexane), ^{1}H NMR ($CDCl_3$) δ=2.16 (t, 3H), 3.60 (q, 2H), 7.2—7.6 (m, 4H), 8.9 (s, 1H), IR (KBr) 3250 (OH), 1184 and 1124 cm^{-1} (CF_3).

Found: C, 60.30; H, 3.89; N, 5.62%. Calcd for $C_{12}H_{10}F_3NO$: C, 59.75; H, 4.18; N, 5.81%.

6c, mp 168—169 °C (hexane–chloroform), ^{1}H NMR ($CDCl_3$–DMSO-d_6) δ=3.76 (s, 2H), 7.2—7.6 (m, 9H), 11.8 (s, 1H), IR (KBr) 3310 (OH), 1175 and 1123 cm^{-1} (CF_3).

Found: C, 67.48; H, 3.92; N, 4.52%. Calcd for $C_{17}H_{12}F_3NO$: C, 67.33; H, 3.99; N, 4.62%.

*Reactions of **2** with Acyclic Conjugated Dienes.* To a solution of **2** (5.21 g, 19.6 mmol) and 2,3-dimethyl-1,3-butadiene (3.21 g, 39.1 mmol) in 40 cm³ of diethyl ether was added dropwise a solution of triethylamine (5.5 cm³) in 20 cm³ of diethyl ether. The reaction mixture was stirred at room temperature for 4 h. Then diethyl ether was added and the salt was filtered out. The filtrate was washed with water and brine and dried over magnesium sulfate. The dried organic layer was evaporated to give a mixture of **11** and **12** in the ratio of 69/31 (^{1}H NMR analysis). This mixture was distilled (boiling range, 110—112 °C/40 mmHg) and chromatographed on silica gel with hexane and then chloroform to yield **11** (1.44 g, 38% yield), **12** (0.15 g, 4% yield), and **13** (0.46 g, 13% yield). Each product was further purified by preparative GLC: **11**, ^{1}H NMR (CCl_4) δ=1.53 (s, 3H), 1.81 (d, 3H), 2.87 (dq, 1H), 3.20 (dq, 1H), 4.93 (q, 1H), 5.10 (s, 1H), IR (neat) 1650 (C=C), 1625 (C=N), 1195 and 1139 cm^{-1} (CF_3).

Found: C, 49.68; H, 5.08; N, 7.12%. Calcd for $C_8H_{10}F_3NO$: C, 49.74; H, 5.22; N, 7.25%.

12, ^{1}H NMR (CCl_4) δ=1.86 (s, 3H), 2.00 (s, 3H), 5.14 (s, 1H), 5.31 (s, 1H), 5.73 (s, 1H), 8.7 (br.s, 1H), IR (neat) 3340 (OH), 1630 and 1605 (C=C, C=N), 1195 and 1140 cm^{-1} (CF_3).

Found: C, 49.28; H, 5.16; N, 7.05%. Calcd for $C_8H_{10}F_3NO$: C, 49.74; H, 5.22; N, 7.25%.

13, ^{1}H NMR (CCl_4) δ=2.37 (s, 6H), 7.40 (s, 1H), 8.40 (s, 1H), IR (neat) 1165 and 1132 cm^{-1} (CF_3).

Found: N, 8.00%. Calcd for $C_8H_8F_3N$: N, 8.00%.

In a similar manner to the above, the reactions with 1,3-pentadiene and 2-methyl-1,3-butadiene were carried out to give **7**, **8**, **9**, and **10**, respectively. Spectral data of these products are as follows: **7**, bp 89—90 °C/46 mmHg, ^{1}H NMR (CCl_4) δ=1.77 (d, 3H), 2.6—3.5 (m, 2H), 4.9—6.2 (m, 3H), IR (neat) 1680 (C=C), 1624 (C=N), 1183 and 1134 cm^{-1} (CF_3).

Found: C, 46.44; H, 4.36; N, 7.81%. Calcd for $C_7H_8F_3NO$: C, 46.93; H, 4.50; N, 7.82%.

8, ^{1}H NMR (CCl_4) δ=1.77 (d, 3H), 2.87 (ddq, 1H), 3.27(ddq, 1H), 4.9—5.3 (m, 3H), IR (neat) 1660 (C=C), 1635 (C=N), 1190 and 1140 cm^{-1} (CF_3), MS (CI, *m/z*) 180 $(M+H)^+$, 208 $(M+Et)^+$.

Found: C, 47.46; H, 4.57; N, 7.72% (for a mixture of **8** and **10**). Calcd for $C_7H_8F_3NO$: C, 46.93; H, 4.50; N, 7.82%.

9, ^{1}H NMR (CCl_4) δ=1.55 (s, 3H), 2.82 (dq, 1H), 3.08 (dq, 1H), 5.17 (dd, 1H), 5.30 (dd, 1H), 5.95 (dd, 1H), IR (neat) 1645 (C=C), 1625 (C=N), 1190 and 1140 cm^{-1} (CF_3), MS (CI, *m/z*) 180 $(M+H)^+$, 208 $(M+Et)^+$.

Found: C, 47.12; H, 4.55; N, 7.79%. Calcd for $C_7H_8F_3NO$: C, 46.93; H, 4.50; N, 7.82%.

10, ^{1}H NMR ($CDCl_3$) δ=1.83 (s, 3H), 5.28 (d, 1H), 5.45(d, 1H), 5.72 (s, 1H), 6.48 (dd, 1H), 7.1(br.s, 1H), IR (neat) 3300 (OH), 1605 (C=C, C=N), 1190 and 1140 cm^{-1} (CF_3), MS (CI, *m/z*) 180 $(M+H)^+$, 208 $(M+Et)^+$.

*Reactions of **2** with Cyclic Conjugated Dienes.* To a solution of **2** (2.36 g, 8.9 mmol) and 1,3-cyclohexadiene (2.08 g, 26.0 mmol) in 20 cm³ of toluene, a solution of triethylamine (2.4 cm³) in 10 cm³ of toluene was added. After the reaction mixture was stirred at room temperature for 3 h, hexane was added and the salt was collected on a

filter. The filtrate was washed with water and brine and dried over magnesium sulfate. Removal of the solvent left an oily mixture of **16** and **17** (39/61 by ^{1}H NMR analysis). The oil was distilled (boiling range, 104—105 °C/27 mmHg) to give 1.12 g (66% total yield) of a mixture of **16** and **17**. Each isomer was isolated by preparative GLC; **16**, ^{1}H NMR ($CDCl_3$) δ=1.4—2.3 (m, 4H), 3.3—3.7 (m, 1H), 5.03 (dd, 1H), 5.8—6.5 (m, 2H), IR (neat) 1611 (C=N), 1180 and 1130 cm^{-1} (CF_3).

Found: C, 50.65; H, 4.21; N, 6.87%. Calcd for $C_8H_8F_3NO$: C, 50.27; H, 4.22; N, 7.33%.

17, ^{1}H NMR ($CDCl_3$) δ=2.3—2.6 (m, 2H), 4.07 (ddm, 1H), 5.6—6.2 (m, 4H), 9.2 (br.s, 1H), IR (neat) 3300 (OH), 1189 and 1130 cm^{-1} (CF_3). UV, $\lambda_{max}^{EtOH}(\varepsilon)$ 256 nm (3393).

Found: C, 50.12; H, 4.25; N, 7.32%. Calcd for $C_8H_8F_3NO$: C, 50.27; H, 4.22; N, 7.33%.

Similarly, **15** was obtained from the reaction with cyclopentadiene. **15**, bp 87—89 °C/31 mmHg, ^{1}H NMR (CCl_4) δ=2.7—2.8 (m, 2H), 3.8—4.2 (m, 1H), 5.7—6.1 (m, 3H), IR (neat) 1616 (C=N), 1184 and 1131 cm^{-1} (CF_3).

Found: C, 47.44; H, 3.17; N, 7.80%. Calcd for $C_7H_6F_3NO$: C, 47.47; H, 3.41; N, 7.91%.

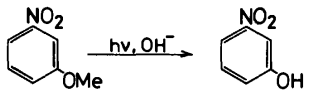
A Rationalization of Orientation in Nucleophilic Aromatic Photosubstitution[1,2]

Kiyoshi MUTAI,* Ryoichi NAKAGAKI,† and Hideyuki TUKADA
Department of Chemistry, College of Arts and Sciences, The University of Tokyo
Komaba, Meguro, Tokyo 153
†*Institute for Molecular Science, Myodaiji, Okazaki 444*
(Received December 27, 1984)

Consideration of the relationship between the mechanisms and orientation effects of the nitro group in nucleophilic photosubstitutions of nitroaromatics leads to the proposal of two rules, making use of frontier molecular orbital theory, for interpreting the regioselectivities and determining the reaction mechanisms. The first rule is a summary of previously proposed interpretations, concerning photoreactions accompanying the direct addition of a nucleophile to an excited nitroaromatic substrate. In this case, the regioselectivity is governed by the HOMO of the substrate. The second rule regards reactions involving photoinduced electron transfer, where regioselectivity is LUMO-controlled. The application of these rules is successfully demonstrated for various types of compounds.

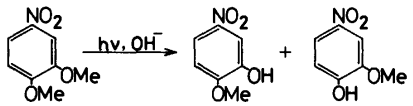
As more examples of photoinduced nucleophilic aromatic substitution accumulate, the effects of several substituents on the regioselectivity have attracted great interest.[3] Among the substituents, the nitro group is probably the most extensively studied because of its unusual *meta*-directing effect. For instance, the irradiation of *m*-nitroanisole (**1**) in aqueous organic solvents containing sodium hydroxide gives *m*-nitrophenol (**2**, Eq. 1),[4,5] and 3,4-dimethoxynitrobenzene (**3**) under similar conditions gives a mixture of 3-hydroxy-4-methoxy- (**4**) and 3-methoxy-4-hydroxynitrobenzene (**5**) with a ratio of 370:1 (Eq. 2)[6]

Compound **1** is not hydrolyzed thermally and **3** undergoes thermal



(1)

1 2

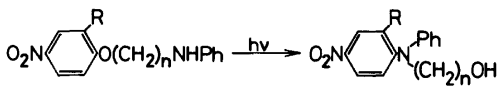


(2)

3 4 5

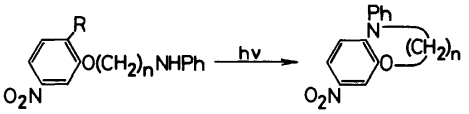
hydrolysis exclusively at C_4, affording **5** as a sole product. Thus, the orientation directing effect of the nitro group in photochemical nucleophilic substitutions is in remarkable contrast to that in corresponding thermal reactions. It is noteworthy that in such photoreactions, the presence of a good leaving group (such as methoxyl) is not a prevailing factor in the determination of the orientation, as shown in Eq. 2.

On the other hand, when a homologous series of **6** (Eq. 3, R=H or OMe) is irradiated in acetonitrile or methanol, a corresponding series of rearranged products **7** is obtained.[7,8] In these cases, the directing effect of the nitro group is clearly para, though the nitroaromatic moiety in **6** is essentially the same as in **1** or **3**. A quite similar situation is



(3)

6, R=H or OMe 7



(4)

8, R=H or OMe 9

found in **8** (Eq. 4, R=H or OMe), which gives **9** as the sole isolable product, irrespective of R.[9] Here, again, the nitro group is *para*-directing. These products, **7** and **9**, are also obtained by thermal reactions of **6** and **8** (R=OMe), respectively, catalyzed by a strong base such as sodium hydride or sodium methoxide. Thus, contrary to the cases exemplified in Eqs. 1 and 2, the photoreactions of **6** and **8** show the same regioselectivity as the thermal reactions.

Summarizing the data so far reported, it might be concluded that nitro groups exert two apparently contradicting effects, *meta*- and *para*-orientations, in photosubstitution by a nucleophile.

The present paper has three objectives: (1) to rationalize the two distinct regioselectivities observed for the nitro group; (2) to establish orientation rules based on frontier molecular orbital theory; and (3) to assess the validity of our proposed method by testing its applicability to a variety of cases.

Orientation Rules

Attempts to rationalize the *meta*-favoring regioselectivity of a nitro group have been reported by Fleming[10] using frontier molecular orbital theory and by Epiotis[11] with a more sophisticated procedure. Their conclusions regarding on nucleophilic photosubstitutions are the same in that the reactions are presumed to be HOMO-controlled. Havinga, Cornelisse, and their coworkers have also addressed this problem by attempting to correlate a number

of experimental data with MO calculations.[6,12-16] Unfortunately, according to the interpretations presented by these researchers, it is impossible to explain why apparently conflicting regioselectivities are observed in practically identical nitroaromatics (Eqs. 1—4).

We propose here a rationalization composed of two rules which are based on frontier molecular orbital theory and are applicable to a wide variety of nucleophilic aromatic photosubstitutions. Our rules are as follows;

Rule 1. *HOMO-Controlled Regioselectivity* Nucleophilic photosubstitutions which involve one-step formation of a σ-complex *via direct interaction* between an excited aromatic substrate and a nucleophile are HOMO-controlled (Eq. 5)

$$\mathrm{ArH} + :\mathrm{Nu} \xrightarrow{h\nu} \mathrm{ArH}^* + :\mathrm{Nu} \longrightarrow \sigma\text{-complex} \qquad (5)$$

Rule 2. *LUMO-Controlled Regioselectivity* Nucleophilic photosubstitutions which involve *electron transfer* from a nucleophile to a nitroaromatic substrate and subsequent recombination of the resultant radical ions are LUMO-controlled (Eq. 6).

$$\mathrm{ArH} + :\mathrm{Nu} \xrightarrow{h\nu} \mathrm{ArH}^* + :\mathrm{Nu} \longrightarrow \mathrm{ArH}^{\cdot-} + \mathrm{Nu}^{+\cdot} \longrightarrow \sigma\text{-complex} \qquad (6)$$

Rule 1 is a summary[17] of the essential parts of the conclusions obtained by Fleming,[10] Epiotis,[11] and Havinga.[6] It is based on the assumption that the lowest excited state of an aromatic molecule can be approximated by one electronic configuration in which an electron is promoted from the HOMO to the LUMO. Each level is, thus, singly occupied (Fig. 1). When a nucleophile approaches an excited aromatic substrate with two singly occupied MO's, the dominant orbital interaction is expected to be between HOMO (substrate)-HOMO (nucleophile) and not between LUMO (substrate)-HOMO (nucleophile). Thus, the direct attack of a nucleophile on an excited aromatic substrate is the key step in the reaction. As will be discussed below, the reactions shown in Eqs. 1 and 2 fall under this category.

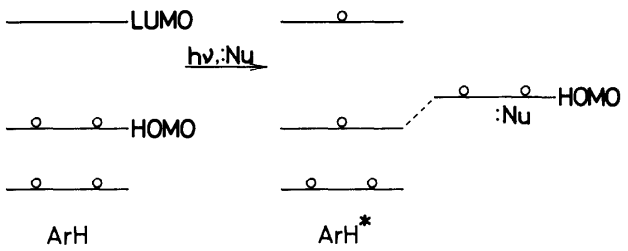


Fig. 1. Schematic illustration of the orientation-determining step, σ-complex formation *via* direct interaction of an excited molecule with a nucleophile. A brokenline denotes the orbital interaction resulting in bond formation. ArH represents an aromatic substrate and Nu a nuleophilic reagent. An asterisk refers to the excited state.

Rule 2 implies an electron-transfer process as a key step in the determination of regioselectivity. This process was originally proposed by Nagakura and Tanaka on the basis of theoretical considerations in 1959[18] regarding the thermal reaction of a nucleophile having a low ionization potential with a substrate having a high electron affinity. The reactions shown in Eqs. 3 and 4 are examples of this category; the formation of a radical ion pair composed of a nitroaryl ether radical anion and an anilino moiety radical cation and the subsequent conversion into a σ-complex (Eq. 6) have been unequivocally confirmed by laser flash photolysis.[9,19,20] As depicted in Fig. 2, in this mechanism, after an initial electron transfer, a strong interaction develops between the singly occupied MO of the nitroaromatic and the singly occupied HOMO of the nucleophile. Since the singly occupied orbital of the aromatic compound corresponds to the LUMO of the ground state, the orientation is LUMO-controlled.

Sample Applications

The rules proposed here neglect all other factors, such as leaving groups and the nature of the nucleophiles, and consider only the effective MO's to govern the regioselectivities. Of course, actual

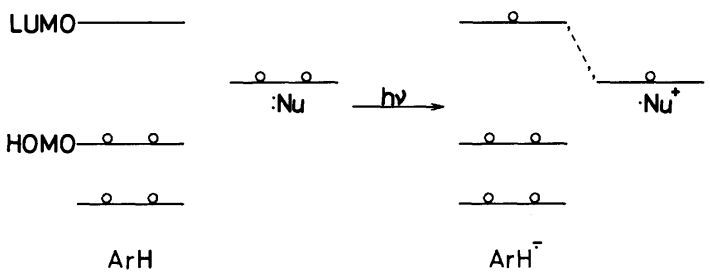

Fig. 2. Schematic illustration of the orientation-determining step, σ-complex formation after photoinduced electron transfer. A broken line denotes the orbital interaction resulting in bond fromation. ArH represents an aromatic substrate and Nu a nucleophilic reagent.

reactions cannot always be interpreted only in terms of frontier MO's; however, the rules are useful in reasoning why specific positions are subject to substitution and in determining whether the reaction mechanism is a "direct attack" or an "electron transfer". Several examples are now discussed.

According to the frontier molecular orbital theory, a nucleophile preferentially attacks the position with the highest frontier electron density (FED) in the corresponding MO's. Here, FED is defined as $FED_i=n_ic^2_{ir}$, where n_i is the number of electrons occupying the ith MO and c_{ir} the coefficient of rth atomic orbital in the ith MO. The FED shown below is calculated by the CNDO/2 approximation, for the displacement of OR with OH.

m-*Alkoxynitrobenzene.* The FED maps of the HOMO and LUMO of *m*-alkoxynitrobenzene are shown in Fig. 3. The FED's of the HOMO are in the order $C_6>C_2>C_3>C_4$. However, the first two positions are less likely to be attacked by a nucleophile on account of the absence of a good leaving group. Thus, photosubstitutions of *m*-nitroanisole have been observed to occur at C_3 with hydroxide ion[4,5] ammonia,[21] methylamine,[4] and cyanide ion[22,23] In case of the photoamination in liquid ammonia, C_6- and C_2-substituted products are minor side products,[21] consistent with the large FED's of the HOMO on these positions and also with the assumption of preferred substitution at the position with a good leaving group.

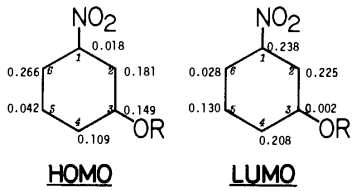

Fig. 3. FED maps of the HOMO and LUMO of *m*-alkoxynitrobenzene.

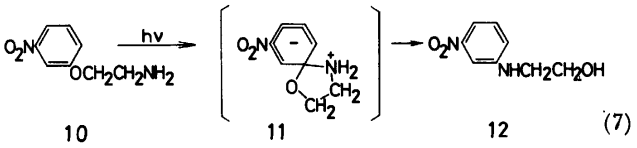
LUMO-Controlled photosubstitution in *m*-alkoxynitrobenzene analog (**8**, R=H) should occur on either C_2 or C_4 which bear much larger FED's. For steric reason the actual reaction favors the less hindered site C_4 (Eq. 4, R=H).[9] No product suggesting C_3-substitution has been detected.

In connection with the reaction of **8** (R=H), the photochemical behavior of a primary amine analog, 2-(*m*-nitrophenoxy)ethylamine (**10**), studied by Wubbels and his coworkers, is noteworthy (Eq. 7).[24] The structure of the photoproduct (**12**) reveals a *meta*-directing effect of the nitro group, suggesting that the reaction belongs to the category of rule 1, or is HOMO-controlled. Additionally, direct formation of a σ-complex (**11**) from the excited state has unambiguously been confirmed by laser flash photolysis.[25]



(7)

The significance of the findings should be emphasized because the key step of a direct attack of a nucleophile, requisite for the HOMO-controlled photosubstitutions, has rarely been confirmed spectroscopically, though the scheme itself is generally accepted. Thus, the photorearrangement of **10** is mechanistically and regioselectively in complete accord with the requirement of rule 1, providing strong supporting evidence for its validity.

Differences in the regioselectivity observed between **8** (R=H) and **10** are readily explained in terms of the ionization potential (I_p) of the nucleophilic moieties; the I_p of the primary amino group is higher than that of the anilino group (CH_3NH_2 with I_p=9.64 eV[26] and $PhNHCH_3$ with I_p=7.65 eV[27] are approximate models for nucleophilic moieties in **10** and **8**, respectively). Therefore, in **10** with the high Ip nucleophile, photoinduced electron transfer is highly unfavorable and the reaction must proceed *via* a direct addition to the *m*-nitrophenoxyl moiety, resulting in a HOMO-controlled orientation. Consequently, *m*-nitroanisole undergoes HOMO-controlled photosubstitution with methylamine to yield *N*-methyl-*m*-nitroaniline.[4]

p-*Alkoxynitrobenzene.* Nucleophilic photosubstitutions of *p*-nitroanisole reflect the trifunctional nature of this compound; *ipso* (C_1)-substitution has been observed with hydroxide ion and pyridine,[28] C_4-substitution with hydroxide ion[28] and aliphatic amines,[29] and C_3-substitution with cyanide ion[23] and cyanate ion.[30] It is interesting to note that the orientation strongly depends on the natures of the reaction media and the nucleophiles. An examination of the FED's of the HOMO of this molecule (Fig. 4) readily rationalizes the results; that is, the *ipso* carbon (C_1), *meta*-carbon (C_3), and *para*-carbon (C_4) bear fairly large FED's and, therefore, are all able to accept a nucleophile, if appropriate conditions are provided.

In the LUMO (Fig. 4), the FED's on C_1 and C_4 are the largest and the second largest, respectively. Since

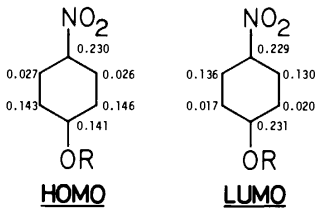


Fig. 4. FED maps of the HOMO and LUMO of *p*-alkoxynitrobenzene.

intramolecular *ipso*-substitution at the NO_2-bearing carbon is sterically inhibited in **6** (R=H), *para*-substitution predominates in its photoreaction (Eq. 3).

3,4-Dialkoxynitrobenzene and Its Isomers. As shown in Fig. 5, the FED's of the HOMO of 3,4-dialkoxynitrobenzene are in the order, $C_3>C_4>C_6>C_1$. As predicted by rule 1, photoreactions with hydroxide ion (Eq. 1),[6] aliphatic amines,[13] and cyanide ion[14] have all been observed predominantly at C_3. These reactions are accompanied by C_4-substituted products,[6,13,16] the formation of which is explained by the high FED as well as the presence of a good leaving group on C_4.

In the LUMO, the FED on the C_4-OR carbon is larger than that on the C_3-OR and photosubstitution has been observed at this position in either **6** (R=OMe)[8] or **8** (R=OMe)[9] (Eqs. 3 and 4).

Furthermore, a good correlation of the FED with experimental results is found in the HOMO-controlled photocyanation of three isomers of dimethoxynitrobenzenes;[31] as shown in Fig. 6, the reaction occurs at the positions with the largest FED in each case.

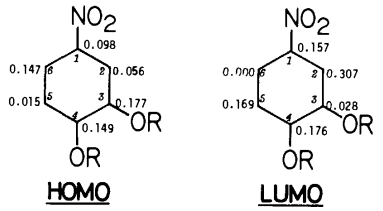

Fig. 5. FED maps of the HOMO and LUMO of 3,4-dialkoxynitrobenzene.

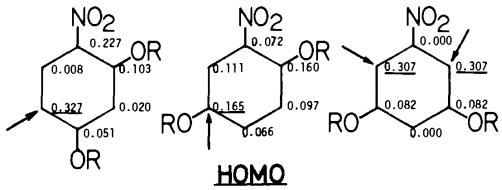

Fig. 6. FED maps of the HOMO of three dialkoxynitrobenzene isomers. The values underlined denote the largest FED's in each ring. Arrows indicate the photocyanated positions.

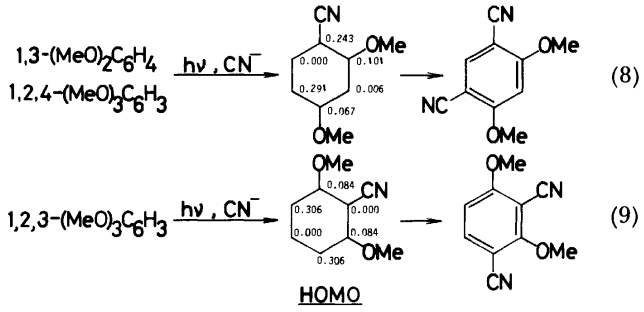
Photodicyanation of Polymethoxybenzenes. Another example is photocyanation of polymethoxybenzenes in which dicyanated products are obtained (Eqs. 8 and 9).[32] Since the yields of the dicyano derivatives are lower than those of the concomitant monocyano derivatives and the same dicyanodimethoxybenzene is obtained from 1,2,4-trimethoxybenzene as from 1,3-dimethoxybenzene, it is reasonable to suppose that the photocyanation occurs stepwise, that is, a dicyano derivative is formed by cyanation of the corresponding monocyano derivative. For the first step cyanation, an $S_R{}^+{}_N{}^1$ Ar* mechanism[33] has been proposed,[15,16] but the second step should involve direct attack of cyanide ion because of the strong electron-withdrawing nature of the cyano group. Thus, the HOMO of the predominating monocyano derivatives should determine the position of the subsequent cyanation. As illustrated in Eqs. 8 and 9, the second step takes place at the positions bearing the largest FED in each ring.



Chloronitrobenzenes. Generally, it is difficult to tell only from the structures of the starting materials and photoproducts whether a reaction belongs to rule 1 or 2, but sometimes the FED data can give a valuable clue to the reaction mechanism. Photoamination of chloronitrobenzenes is such an example.

Photoamination of the three isomers of chloronitrobenzene was carried out in liquid ammonia at −60 °C.[21] As illustrated in Fig. 7, substitution was observed in all isomers at the *para* position to the nitro group. Since the HOMO's of the *o*- and *m*-isomers show very small FED's at the *para* positions (0.012 and 0.040, respectively) and the corresponding LUMO's show the second largest values (0.246 and 0.244, respectively) at these positions the regioselectivity should be regarded as LUMO-controlled. As for the *p*-isomer, the FED on the *para*-carbon is sufficiently large in both MO's and makes it difficult

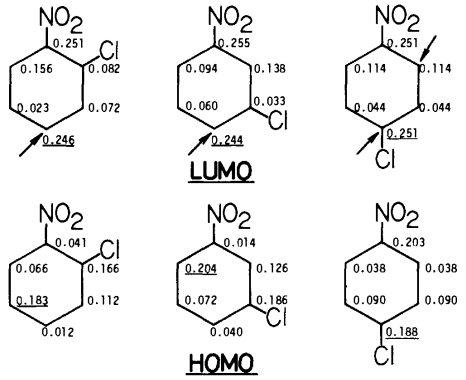


Fig. 7. FED maps of the HOMO and LUMO of chloronitrobenznes. The values underlined show the largest FED in each ring (except C-NO_2 carbons). Arrows denote the positions where photoamination is observed.

to determine which MO dominates the orientation. In this regard, it is noticeable that concurrent *o*-amination is observed as a minor pathway (affording 10% of 2-nitro-5-chloaniline) in contrast to the major pathway (producing *p*-nitroaniline in 45% yield). Examination of the FED maps of *p*-chloronitrobenzene in Fig. 7 suggests that the *o*-amination cannot be HOMO-controlled, because the FED of the HOMO on the *ortho*-carbon (0.038) is too small to allow substitution. Thus, the major part of the photoamination of the *p*-isomer is probably LUMO-controlled, though this conclusion does not completely rule out some concurrent HOMO-controlled process.

In order to obtain further supporting evidence for the electron-transfer mechanism, the key step in the LUMO-controlled reactions, we tried to detect intermediates with the aid of an ESR spectrometer, adopting *p*-chloronitrobenzene as a representative of the isomers. Upon irradiating a solution of this compound in liquid ammonia kept at −70 °C with a high-pressure Hg lamp, a rapid growth of a paramagnetic species was observed. After 10 min of irradiation, a well-defined spectrum with sufficient intensity (Fig. 8) was obtained, which showed slow decay upon cutting off the light. No signal was observed for the solution kept in the dark for the same period. Comparison of the spectral curve obtained with a simulated one, led to an identification of the paramagnetic species as the radical anion of *p*-chloronitrobenzene. Thus, a photoinduced electron transfer was confirmed to take place under similar conditions used for the photoreaction.

All these facts strongly suggest that the photoamination of all three isomers of chloronitrobenzene proceeds, partly if not wholly, *via* electron transfer, thus conforming to rule 2.

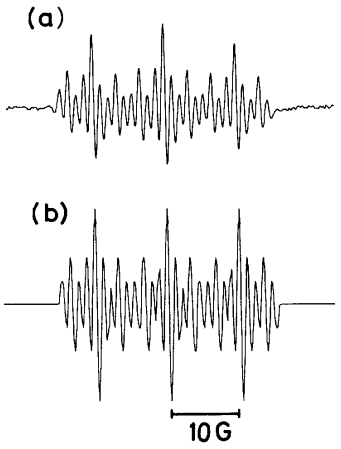

Fig. 8. (a) ESR spectrum of a paramagnetic species formed by irradiation of a solution of *p*-chloronitrobenzene in liquid ammonia. (b) Simulated spectum obtained by employing the following coupling constants; $a_N = 10.4$ G, $a_H(ortho) = 3.40$ G, and $a_H(meta) = 1.20$ G (K. Nakamura, *Bull. Chem. Soc. Jpn.*, **40**, 1 (1967)).

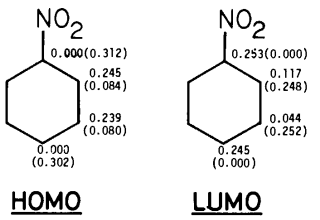

Fig. 9. FED maps of the degenerate HOMO's and LUMO's of nitrobenzene. The values in parentheses belong to nearly degenerate counterparts.

Nitrobenzene. Photoamination of nitrobenzene in liquid ammonia is an example in which the degeneracy of the MO's confuses the assignment of the regio-determining MO. The major reaction takes place at the *para* position to give *p*-nitroaniline in 25% yield.[21] The MO calculation revealed the presence of two pairs of almost degenerate π-MO's, each corresponding to HO and LU levels in energy. Comparison of the FED maps of these MO's (Fig. 9) shows that *p*-amination is explicable either as HOMO- or LUMO-controlled, depending on which HOMO–LUMO pair we choose. Fortunately, it has been reported that the nitrobenzene radical anion is formed upon irradiation of its solution in liquid ammonia,[21] suggesting the occurrence of electron transfer from the solvent to nitrobenzene. Thus, the photoamination of nitrobenzene also proceeds, at least partly, *via* electron transfer.

Concluding Remarks

Although the proposed rules should be regarded as first approximations, they find wide and successful applications to a number of aromatic nucleophilic photosubstitutions. Our present method has, thus, been shown to be useful in interpreting regioselectivities and predicting mechanisms even for polysubstituted aromatics. In addition, the present approach can provide us with a more comprehensive view of photochemical reaction mechanisms than the conventional resonance theory or empirical orientation rules.

It should be noted here that our rules are specifically concerned with the initial stage of nucleophilic photosubstitutions and give no information regarding subsequent reaction pathways. It is also noteworthy that the argument, solely based on MO calculations, does not necessarily identify the reaction mechanism.

Experimental

Calculation. The MO calculations were performed with the CNDO/2 program,[34] adapted by replacing the

original two-center electronic repulsion integrals with the Nishimoto-Mataga approximation,[35] on a Mitsubishi MELCOM COSMO 700 III computer at the University of Tokyo. For all benzene derivatives, it was assumed that the aromatic nucleus has the same structure as the unsubstituted parent,[36] regardless of the positions, numbers, or natures of the substituents. The methoxyl group was approximated by a hydroxyl for convenience of calculation. It was found for some simple anisole derivatives that no significant change in the FED distribution pattern occurred along with this treatment.

ESR Spectra. ESR Spectra were recorded on a Varian E-112 spectrometer equipped with an optical transmission cavity and a variable temperature accessory. Saturated solutions of *p*-chloronitrobenzene in liquid ammonia kept at −70 °C were irradiated with a high-pressure Hg lamp (500 W) through a Pyrex water jacket and a focusing lens.

We are grateful to Professor Koichi Ohno of the University of Tokyo for providing us with the computer program, to Dr. Akinori Inoue for his advice and help in calculation, and to Professor G. L. Closs of the University of Chicago for valuable suggestions. This work was supported by the Joint Studies Program (1984) of the Institute for Molecular Science.

The Thermal Addition Reactions of Cycloheptatriene with Aromatic *p*-Quinones[1)]

Akira MORI, Hiroaki MAMETSUKA, and Hitoshi TAKESHITA*
Research Institute of Industrial Science, 86, Kyushu University, Kasuga-koen, Kasuga, Fukuoka 816
(Received February 22, 1985)

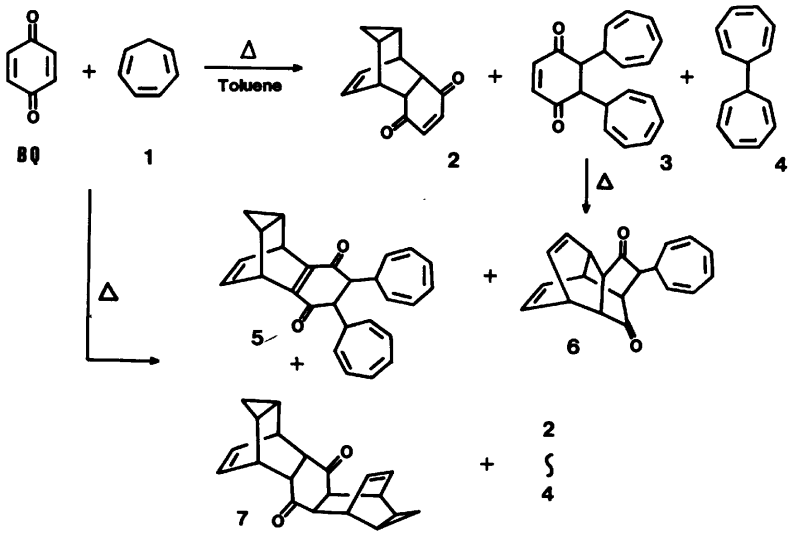
Thermal addition reactions of cycloheptatriene with several aromatic *p*-quinones gave the Diels-Alder adducts as minor products; the most characteristic feature was the formation of the *vic*-ditropylation products. The mechanism of their formation was clarified to be a sequential ene-reaction and dehydrogenation by means of chemical conversion from the isolated intermediates. Several new other additions, *e.g.*, successive Diels-Alder reactions, were also noted.

Previously, we have reported the characteristic behavior of cycloheptatriene (tropylidene, **1**) in reactions with several carbonyl compounds[2)] and aromatic quinones[3)] upon UV-light irradiations. Under these circumstances, the methylene hydrogens of **1** are extremely reactive toward the hydrogen-abstraction process because of the stability of the resultant symmetrical cycloheptatrienyl (tropyl) radical. In this connections, the thermal behavior of **1** toward aromatic quinones, which are frequently-used dienophiles[4)] and typical oxidizing agents, must also be interesting; once the stable tropyl radical is formed, it may behave differently to give products other than the Diels-Alder adducts. Herein, we wish to report our findings.

Results and Discussion

The Reaction of 1 with p-*Benzoquinone.* When a toluene solution of **1** and *p*-benzoquinone (BQ) was refluxed for 1 h, two products, 1:1-adduct (**2**) and 1:2-adduct (**3**), were isolated, along with some amounts of 1,1′-bi(cyclohepta-2,4,6-trienyl) (bitropyl, **4**)[5)] and BQ and hydroquinone (H_2BQ), which were precipitated as quinhydrone. The **2** was shown to be the ordinary Diels-Alder adduct by the appearance of four cyclopropane ring protons in the ^1H NMR spectrum. The **3** (21% yield)[6)] was shown to be a *vic*-ditropylation product; its ^1H NMR spectrum revealed a symmetrical element in its structure, showed signals ascribable to tropyl groups, and overlapped two olefinic protons. The presence of an enedione chromophore was evidenced by the IR carbonyl stretching vibration absorption peak at ν: 1685 cm^{-1}.

On the other hand, the thermal reaction of **1** and BQ without a solvent gave more complicated results. In addition to **2** (4%), **3** (6%), and **4** (15%), new products (**5**, **6**, and **7**) were isolated after repeated silica-gel column chromatography; another *vic*-ditropylation product, **5** (5%), showed its molecular



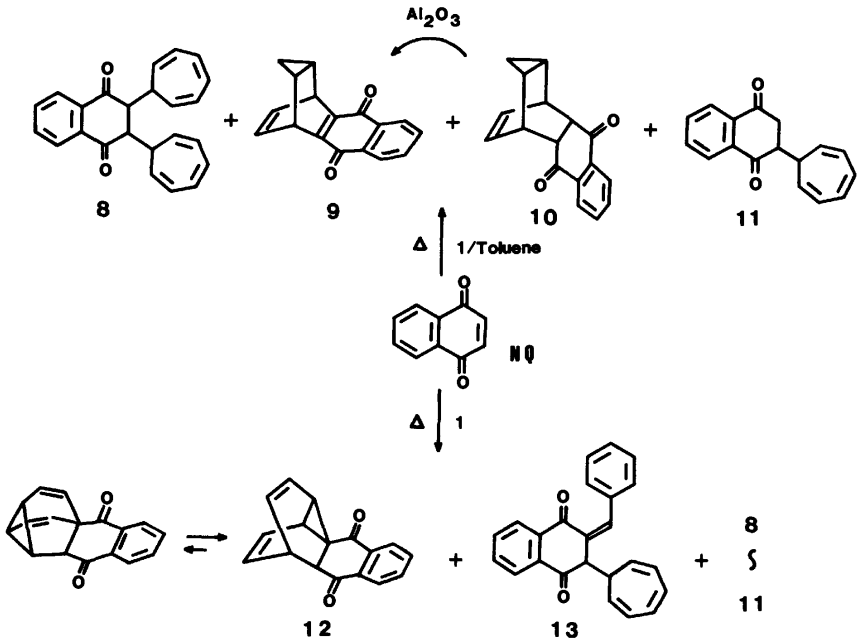
Scheme 1.

weight to be 380, and disclosed four cyclopropane ring protons and an enedione chromophore [ν: 1665, 1582 cm^{-1}]. Therefore, **5** must correspond to the ditropylation product derived from the dehydrogenation products of **2**. A cage compound, **6** (1%), revealed four olefinic protons other than those of the tropyl group in the ^1H NMR spectrum, while a carbonyl absorption at ν: 1730 cm^{-1} in the IR spectrum indicated it to be a strained cycloalkanone derivative. These feature requires the formation of two more C–C bonds. In fact, **6** could be prepared by a thermal isomerization reaction, an intramolecular Diels-Alder process, of **3** by refluxing in **1**.

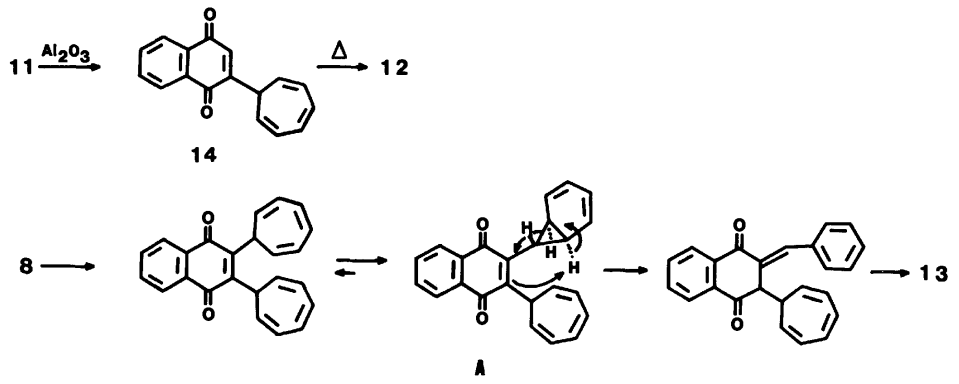
The structure of the remaining product, **7** (2%), a 1:2-adduct, showed the presence of a symmetrical element in the ^1H- and ^{13}C NMR spectra; it was deduced to be the two-fold Diels-Alder adduct of BQ with the norcaradiene form of **1**. Scheme 1 shows the deduced structures.

The Reaction of 1 with 1,4-Naphthoquinone. When a toluene solution of **1** and 1,4-naphthoquinone (NQ) was refluxed for 12 h, a complicated mixture was obtained. After repeated chromatographic work-ups, the products characterized, besides **4**, were a colorless oil (**8**, 0.6%), yellow needles (**9**, 16%), colorless plates (**10**, 22%), and a yellow oil (**11**, 5%). Their structures were unambiguously determined by NMR spectral analysis; **8** was the ditropylation product, **10** was the Diels-Alder product of NQ and the norcaradiene form of **1**, **9** was the dehydrogenation product of **10**,[7] and **11** was the monotropylated intermediate.

The reaction without any diluent yielded, together with **8** (2%), **9** (10%), **10** (7%), and **11** (1%), two more



Scheme 2.



Scheme 3.

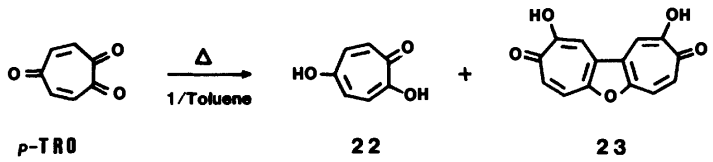
by-products, faintly brownish crystals (**12**, 3%) and a colorless oil (**13**, 6%). The **12**[8] was determined to be the intramolecular Diels-Alder product of the dehydrogenated derivative (**14**) of **11**. In fact, the heating of **14**, obtained by placing **11** in contact with a basic alumina, gave **12**. The **13** was deduced to be a benzylidene derivative derived from **8**. Its formation can be explained in terms of a sterically-favored valence tautomerization to the norcaradiene form for one of the tropyl group in dehydrogenated 2,3-ditropyl-1,4-naphthoquinone, **A**, and its isomerization *via* a $2\pi+2\sigma+2\sigma$-process.

The Reaction of 1 with p-*Toluquinone, Phenyl*-p-*benzoquinone, Chloro*-p-*benzoquinone, and 2,6-Dimethyl*-p-*benzoquinone.* When **1** was allowed to react with *p*-toluquinone (TQ) in toluene, two products, a Diels-Alder adduct (**15**, 18%) and a *vic*-ditropylation product (**16**, 14%) were obtained, while without the diluent, again, the formation of an additional compound (**17**, 6%) was observed, together with **4** (1.6%), **15** (15%), and **16** (18%). Similar products (**18**—**21**) were obtained from phenyl-*p*-benzoquinone (PQ), chloro-*p*-benzoquinone (CQ), and 2,6-dimethyl-*p*-benzoquinone (XQ). The structures of these adducts are illustrated in Chart 1.

It is also known to form cycloheptatrienium ion by the action of 2,3-dichloro-5,6-dicyano-*p*-benzoquinone (DDQ) to **1** in an acidic solution,[9] and the formation of two-electron oxidized products from **1** must be important in the organic syntheses. *p*-Tropoquinone (*p*-TRQ), whose oxidation potential is higher than those of the corresponding *p*-benzoquinones,[10] should be interesting from a comparative point of view; in fact, the reaction resulted in the reductive formation of 5-hydroxytropolone (**22**) and 2,10-dihydroxydicyclohepta[*b,d*]furan-3,9-dione (**23**),[11] showing an occurrence of the oxidation of **1** rather than of the addition reaction. On the contrary, *p*-TRQ is known to give the Diels-Alder adducts with cyclopentadiene.[12]

It is well known that **1** gives the Diels-Alder adducts, mostly having a tautomeric norcaradiene form, by reactions with many dienophiles. However, the reaction with aromatic quinones, *e.g.*, *p*-benzoquinones, under the Diels-Alder conditions predominantly yielded the hydrogen-abstraction products, as one can see from the production of quinhydrone. Moreover, the formation of the ditropylation products might also be such a case, for it requires one mole of the dehydrogenation process.

Previously, we have proven the electrocyclic formation of **8** from NQ and **4** under photochemical conditions;[13] the irradiation of NQ and **4** in benzene by means of a high-pressure mercury lamp by cutting off the light shorter in wavelength than 300 nm with a Pyrex glass filter. However, the ditropylation with **4** does not occur under thermal conditions; it merely results in the production of a complicated intractable mixture, and **8** is undetectable. Whatever the mechanisms are, the ditropylation products must be formed *via* a sequential, step-by-step mechanism. In this point, an independent addition reaction of **1** to a monotropylation product like **14** seemed worth trying. Unfortunately, such an experiment went far beyond our expectations; when **14** was heated with **1**, the only product, obtained in a 28% yield from the



Scheme 4.

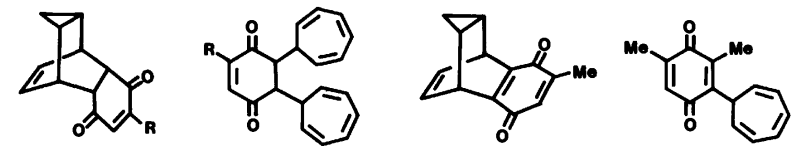


Chart 1.

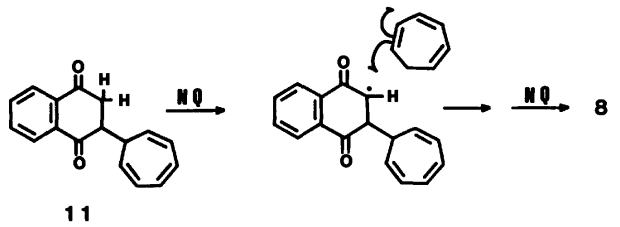

Scheme 5.

mixture, was the barbaralane derivative, **12**. Moreover, when a mixture of **1**, **11**, and NQ was heated to reflux, the products isolated were **8**, **9**, and **10**, while a similar treatment of **11** and NQ in toluene instead formed **9** and **12**; the formation of **12** from **11** and the formation of **9** and **10**, at the same time, proved it easy for NQ-dehydrogenation to occur, though the resultant dehydro intermediates were reluctant to give 1:2-products because of a competitive intramolecular reaction.

In conclusion, it is clear that the quite active methylene group of **1** determines the predominant course of the reaction depending on the nature of the other cycloaddends, *i.e.*, with quinones, the formation of the symmetrical tropyl radical *via* the abstraction of hydrogen is the primarily favored step.

Experimental

All the mps, which were measured by means of a Yanagimoto Micro-mp Apparatus, were uncorrected. The elemental analyses were performed either at the Research Institute or at the Analyses Center, Faculty of Science, Kyushu University. The NMR spectra were measured by means of a JEOL FX 100 Spectrometer in $CDCl_3$ unless otherwise specified, and the chemical shifts are expressed in δ units from the internal Me_4Si. The mass spectra were measured by means of a JEOL OISG-2 Spectrometer. The IR spectra were measured by means of a Jasco IR-A 102 Model Spectrometer. The UV spectra were measured by means of a Hitachi 124 Model Spectrophotometer in methanol. The silica-gel used in this study was Wako Gel C 300.

Thermal Reaction of 1 with BQ. *a)* A toluene solution (8 cm^3) of **1** (2 cm^3) and BQ (1.08 g) was refluxed for 1 h. The mixture was then filtered to remove the insoluble material, from which quinhydrone (375 mg) was isolated. The subsequent evaporation of the filtrate *in vacuo* left a residual mass, which was chromatographed on a silica-gel column, with benzene–ether (8:2) as the eluent, to yield colorless, crystalline **4** (mp 62.5—63.5 °C (lit, [5] 61 °C), 10.4 mg; 0.9%), pale yellow crystalline **2** (mp 113—114 °C, 150.6 mg; 11% [Found: C, 77.83; H, 6.04%. Calcd for $C_{13}H_{12}O_2$: C, 77.98; H, 6.04%. ^{1}H NMR δ=0.04 (1H, dt, J=5.5, 4 Hz), 0.14 (1H, td, J=7, 5.5 Hz), 1.12 (2H, m), 3.02 (2H, t, J=1.5 Hz), 3.48 (2H, ddm, J=4.5, 1.5 Hz), 5.76 (2H, dd, J=4.5, 3.5 Hz), and 6.62 (2H, s). ν: 1665, 1615 cm^{-1}. λ_{max}^{MeOH}: 233 nm (ε=11700)]), and pale yellow crystalline **3** (mp 112—113.5 °C; 205 mg; 21% [Found: C, 82.53; H, 6.21%. Calcd for $C_{20}H_{18}O_2$: C, 82.73; H, 6.25%. ^{1}H NMR δ=1.90 (2H, dt, J=11, 6 Hz), 3.30 (2H, d, J=11 Hz), 5.20 (2H, dd, J=9.5, 6 Hz), 5.27 (2H, dd, J=9.5, 6 Hz), 6.23 (2H, dt, J=9.5, 3 Hz), 6.32 (2H, dt, J=9.5, 3 Hz), 6.59 (2H, s), 6.70 (2H, d, J=3 Hz), and 6.73 (2H, d, J=3 Hz). ν: 1685, 1600 cm^{-1}. λ_{max}^{MeOH}: 234 nm (ε=11100), 266 (4300)]). Additional amounts of BQ (166 mg; 15%) and H_2BQ (72 mg; 7%) were then obtained from the later elutions.

b) A mixture of **1** (20 cm^3) and BQ (3.25 g) was refluxed for 5 h. The mixture was then filtered to remove polymeric materials (3.25 g), and the filtrate was chromatographed on a silica-gel column with benzene–ether (9:1), after the evaporation of the volatile material, to give **5** (pale yellow crystals; mp 161—162 °C; 199 mg; 5% [Found: M^+, 380.1790. Calcd for $C_{27}H_{24}O_2$: 380.1775. ^{1}H NMR δ=0.57 (1H, q, J=7 Hz), 0.80 (1H, dm, J=7 Hz), 1.16 (2H, m), 1.72 (2H, dt, J=10.5, 7 Hz), 3.28 (2H, ddd, J=10.5, 3, 1.5 Hz), 4.22 (2H, m), 5.22 (4H, m), 5.97 (2H, m), 6.2 (4H, m), and 6.65 (4H, m). ν: 1665, 1582 cm^{-1}. λ_{max}^{MeOH}: 257 nm (ε=10500)]), **6** (colorless crystals; mp 198—201 °C; 44 mg; 1% [Found: C, 82.51; H, 6.22%. Calcd for $C_{20}H_{18}O_2$: C, 82.73; H, 6.25%. ^{1}H NMR δ=2.21 (1H, dt, J=10, 7 Hz), 2.38 (1H, d, J=5.5 Hz), 2.79 (1H, ddd, J=9, 5.5, 3 Hz), 3.10 (5H, m), 5.22 (1H, dd, J=9, 7 Hz), 5.66 (2H, t, J=9 Hz), 6.04 (1H, t, J=9 Hz), 6.24 (2H, m), 6.44 (2H, dd, J=9, 7 Hz), and 6.64 (2H, t, J=3 Hz). ν: 1730 cm^{-1}. λ_{max}^{MeOH}: 220 nm (ε=18800), 250 (sh. 6000)]), and **7** (colorless crystals; mp 177—180 °C; 208 mg; 2% [Found: M^+, 292.1475. Calcd for $C_{20}H_{20}O_2$: 292.1462. ^{1}H NMR δ=0.0 (4H, m), 0.9 (4H, m), 2.8 (4H, br. s), 3.25 (4H, m), and 5.87 (4H, dd, J=5, 3 Hz), ν: 1690 cm^{-1}]). The later fractions, eluted with benzene–ether (8:2), contained **2** (4%), **3** (6%), and **4** (15%).

Further Conversion of 3 to 6. A mixture of **3** (107 mg) and **1** (0.7 cm^3) was heated to reflux for 2 h with an occasional check of the reaction by means of thin-layer chromatography. Subsequent silica-gel column chromatography of the mixture, with benzene as the eluent, afforded crystalline **6** (16.5 mg; 18%), whose identity with an authentic sample was established by direct comparisons, and the recovered **3** (15.3 mg; 14%).

Thermal Reaction of 1 with NQ. *a)* A toluene solution (8 cm^3) of **1** (2.1 cm^3) and NQ (1.59 g) was refluxed for 12 h. After the removal of the solvent *in vacuo*, the residue was chromatographed on a silica-gel column, with benzene–ether (9:1) as the eluent, to give **8** (colorless crystals; mp 130—132 °C; 7 mg; 0.6% [Found: C 84.27; H, 5.92%; M^+, 340.1487. Calcd for $C_{24}H_{20}O_2$: C, 84.67; H, 5.93%; M^+, 340.1462. ^{1}H NMR δ=1.88 (2H, dt, J=11, 6 Hz), 3.50 (2H, d, J=11 Hz), 5.29 (4H, m), 6.22 (4H, m), 6.62 (4H, t, J=2.5 Hz), 7.72 (2H, m), and 8.09 (2H, m). ν: 1668, 1595 cm^{-1}]), **9** (yellow needles; mp 188—189 °C; 146 mg; 16% [Found: C, 82.49; H, 4.89%. Calcd for $C_{17}H_{12}O_2$: C, 82.24; H, 4.87%. ^{1}H NMR δ=0.70 (1H, dd, J=7, 6 Hz), 0.93 (1H, dd, J=6, 3.5 Hz), 1.36 (2H, m), 4.58 (2H, m), 6.12 (2H, dd, J=5, 3.5 Hz), 7.7 (2H, m), and 8.12 (2H, m). ^{13}C NMR δ=16.2, 17.8, 35.9, 126.2, 130.0, 132.3, 133.3, 156.2, and 181.7. ν: 1658, 1593 cm^{-1}]), **10** (colorless plates; mp 165—166.5 °C; 408 mg; 22% [Found: C, 81.63; H, 5.69%. Calcd for $C_{17}H_{14}O_2$: C, 81.58; H, 5.64%. ^{1}H NMR δ=0.12 (2H, m), 1.20 (2H, m), 3.23 (2H, dm, J=1.5 Hz), 3.58 (2H, ddd, J=5, 3.5, 1.5 Hz), 5.67 (2H, dd, J=5, 3.5 Hz), 7.66 (2H, m), and

8.00 (2H, m). ν: 1670, 1596 cm^{-1}]), **11** (a yellow oil; 100 mg; 5% [Found: M^+, 250.0993. Calcd for $C_{17}H_{14}O_2$: 250.0993. ^1H NMR δ=2.24 (1H, dt, J=9, 6 Hz), 3.1—3.7 (3H, m), 5.28 (1H, dd, J=10, 6 Hz), 5.40 (1H, dd, J=10, 6 Hz), 6.23 (2H, m), 6.62 (2H, t, J=3 Hz), 7.70 (2H, m), and 8.02 (2H, m). ν: 1694, 1598 cm^{-1}]), and the recovered NQ (423 mg; 26.6%).

b) A mixture of **1** (30 cm^3) and NQ (6.37 g) was heated to reflux for 11 h. After the removal of the solvent by distillation *in vacuo*, the residue was chromatographed on a silica-gel column, with benzene–ether (9:1) as the eluent; together with the already described **8** (128 mg; 2%), **9** (508 mg; 10%), **10** (727 mg; 7%), and **11** (90 mg; 1%), two products, **12** (faintly brown crystals; mp 131—132.5 °C; 151 mg; 3% [Found: C, 82.18; H, 4.89%. Calcd for $C_{17}H_{12}O_2$: C, 82.24; H, 4.87%. ^1H NMR δ=2.48 (1H, dd, J=8.5, 6 Hz), 2.84 (1H, d, J=3 Hz), 3.54 (2H, m), 5.67 (1H, dd, J=9.5, 6 Hz), 5.80 (1H, dd, J=9.5, 6 Hz), 6.06 (2H. dd, J=9.5, 6 Hz), 7.7 (2H, m), and 8.1 (2H, m). ^{13}C NMR δ=30.2, 30.8, 33.6, 38.2, 42.0, 120.2, 121.1, 126.4, 126.6, 126.9, 128.2, 133.9, 134.1, 134.6, 135.2, 195.6, and 195.7. ν: 1700, 1670, 1595 cm^{-1}]), and **13** (a yellow oil; 250 mg; 6% [Found: M^+, 338.1302. Calcd for $C_{24}H_{18}O_2$: 338.1304. ^1H NMR δ=2.26 (2H, dt, J=12, 6 Hz), 4.73 (2H, dd, J=12, 1 Hz), 5.14 (4H, q, J=5 Hz), 6.16 (4H, m), 6.71 (4H, t, J=2.5 Hz), 6.77 (1H, d, J=1 Hz), 7.25 (5H, br. s), 7.7 (4H, m), and 8.0 (4H, m). ^{13}C NMR δ=42.0, 45.6, 123.7, 123.9, 124.9, 125.5, 125.9, 126.8, 127.2, 128.3, 128.8 (4C), 130.9, 131.2, 131.8, 132.2, 133.7, 134.6, 140.0, 151.9, 184.5, and 185.2. ν: 1659, 1596 cm^{-1}]), were isolated.

Thermal Reaction of 1 with TQ. *a)* A toluene solution (8 cm^3) of **1** (2 cm^3) and TQ (1.25 g) was refluxed for 2.5 h. The insoluble solid was then filtered off, the filtrate was evaporated *in vacuo*, and the residue was chromatographed on a silica-gel column, with benzene–ether (8:2) as the eluent, to give **15** (pale yellow needles; mp 81—82 °C; 327 mg; 18% [Found: C, 78.38; H, 6.63%. Calcd for $C_{14}H_{14}O_2$: C, 78.48; H, 6.59%. ^1H NMR δ=0.80 (2H, m), 1.08 (2H, m), 1.98 (3H, d, J=2 Hz), 2.98 (2H, t, J=2 Hz), 3.40 (2H, br. s), 5.68 (2H, dd, J=5, 4 Hz), and 6.46 (1H, q, J=2 Hz). ν: 1660 cm^{-1}. λ_{max}^{MeOH}: 239 nm (ε=8200)]) and **16** (pale yellow crystals, mp 107—108 °C; 172 mg; 14% [Found: C, 82.45; H, 6.80%. Calcd for $C_{21}H_{20}O_2$: C, 82.85; H, 6.63%. ^1H NMR δ=1.80 (2H, m), 1.92 (3H, d, J=1.5 Hz), 3.26 (1H, dt, J=11, 2 Hz), 3.32 (1H, dd, J=11, 2 Hz), 5.20 (4H, m), 6.17 (2H, dt, J=9.5, 3 Hz), 6.28 (2H, dt, J=9.5, 3 Hz), 6.42 (1H, quint, J=1.5 Hz), and 6.67 (4H, t, J=3 Hz). ν: 1680, 1618 cm^{-1}. λ_{max}^{MeOH}: 247 nm (ε=12300)]). From the more polar fractions, eluted with a benzene–ether mixture (7:3), H_2TQ (284 mg) and TQ (241 mg; 19%) were obtained.

b) A mixture of **1** (14 cm^3) and TQ (2.44 g) was heated at 120 °C for 1.5 h. The subsequent removal of the volatile material by distillation *in vacuo* and the silica-gel chromatography of the residue with benzene–ether (9:1) gave **4** (29.5 mg; 1.6%), and **17** (a faintly brown oil; 121 mg; 6% [Found: M^+, 212.0811. Calcd for $C_{14}H_{12}O_2$: 212.0837. ^1H NMR δ=0.66 (1H, q, J=7 Hz), 0.87 (1H, dt, J=7, 3 Hz), 1.24 (2H, m), 2.06 (3H, d, J=1.5 HZ), 4.36 (2H, m), 6.05 (2H, dd, J=5, 4 Hz), and 6.45 (1H, q, J=1.5 Hz). ν: 1650 cm^{-1}. λ_{max}^{MeOH}: 263 nm (ε=12100)]), together with **15** (644 mg; 15%) and **16** (541 mg; 18%). From the later eluent of the benzene–ether mixture (7:3), H_2TQ (1.04 g; 42%) was obtained.

Thermal Reaction of 1 with PQ. A mixture of **1** (3 cm^3) and PQ (416 mg) was heated at 95 °C for 1.5 h. The mixture was then filtered to remove the insoluble solid, the filtrate was evaporated *in vacuo*, and the residue was chromatographed on a silica-gel column, with benzene–ether (9:1) as the eluent, to give **18** (yellow crystals; mp 139—140.5 °C, 59.5 mg; 12.5% [Found: C, 82.20; H, 5.88%. Calcd for $C_{19}H_{16}O_2$: C, 82.58; H, 5.84%. ^1H NMR δ=0.12 (1H, tm, J=4 Hz), 0.24 (1H, tm, J=6 Hz), 1.19 (2H, ddm, J=6, 4 Hz), 3.17 (2H, t, J=3 Hz), 3.52 (2H, m), 5.82 (2H, dd, J=5, 4 Hz), 6.73 (1H, s), and 7.40 (5H, s). ν: 1664 cm^{-1}. λ_{max}^{MeOH}: 228 nm (ε=15600), 307 (7300)]) and **19** (a pale yellow oil; 56.5 mg; 18% [Found: M^+, 366.1607. Calcd for $C_{26}H_{22}O_2$: 366.1619. ^1H NMR δ=2.05 (2H, dt, J=11, 6 Hz), 3.39 (1H, t, J=11 Hz), 3.41 (1H, t, J=11 Hz), 5.70 (4H, dm, J=6 Hz), 6.27 (4H, m), 6.67 (5H, m), and 7.39 (5H, s). ν: 1690, 1595 cm^{-1}. λ_{max}^{MeOH}: 230 nm (ε=13300), 313 (5600)]). The later fractions afforded recovered PQ (99 mg; 24%).

Thermal Reaction of 1 with CQ. A mixture of **1** (5 cm^3) and CQ (1.38 g) was heated at 60 °C for 50 min. After the removal of the volatile material *in vacuo*, the residue thus obtained was chromatographed on a silica-gel column, with benzene–ether (9:1) as the eluent, to give **20** (pale yellow crystals; mp 98—98.5 °C; 368 mg; 16% [Found: C, 66.43; H, 4.76%. Calcd for $C_{13}H_{11}O_2Cl$: C, 66.53; H, 4.72%. ^1H NMR δ=0.12 (1H, tm, J=4 Hz), 0.21 (1H, tm, J=6 Hz), 1.16 (2H, ddm, J=6, 4 Hz), 3.04 (2H, t, J=2 Hz), 3.49 (2H, m), 5.80 (2H, dd, J=4, 3.5 Hz), and 6.81 (1H, s). ν: 1665 cm^{-1}. λ_{max}^{MeOH}: 254 nm (ε=8500)]) and H_2CQ (377 mg; 27%).

Thermal Reaction of 1 with XQ. A toluene solution (2 cm^3) of **1** (2 cm^3) and XQ (1.36 g) was refluxed for 1.5 h. After the subsequent evaporation of the solvent *in vacuo*, the residue was chromatographed on a silica-gel column, with benzene–ether (8:2) as the eluent, to give **4** (30 mg; 6%) and **21** (yellow crystals; mp 90—93 °C; 91 mg; 14% [Found: M^+, 226.0975. Calcd for $C_{15}H_{14}O_2$: 226.0993. ^1H NMR δ=2.05 (3H, s), 2.09 (3H, d, J=2 Hz), 3.16 (1H, t, J=6 Hz), 5.16 (2H, dd, J=9, 6 Hz), 6.17 (2H, dm, J=9 Hz), and 6.62 (3H, m). ν: 1645 cm^{-1}. λ_{max}^{MeOH}: 262 nm (ε=10600)]). Subsequently, H_2XQ (40 mg) and the recovered XQ (663 mg; 49%) were obtained from the polar fractions by elution with benzene–ether (5:5).

Dehydrogenation of 10 to 9. A benzene solution of **10** (35.6 mg) was held on an alumina column for 1 h. Subsequent elution with ether yielded **9** (22.6 mg; 67%).

Dehydrogenation of 11 to 14. The **11** (81 mg) was chromatographed on a basic alumina column with hexane–benzene (1:1) to give **14** (a colorless oil; 58.6 mg; 73% [Found: M^+, 248.0851. Calcd for $C_{17}H_{12}O_2$: 248.0837. ^1H NMR δ=3.64 (1H, td, J=7, 1.5 Hz), 5.41 (2H, dd, J=9.5, 7 Hz), 6.34 (2H, dt, J=9.5, 4 Hz), 6.64 (2H, t, J=4 Hz), 6.84 (1H, d, J=1.5 Hz), 7.75 (2H, m), and 8.1 (2H, m). ν: 1664, 1596 cm^{-1}]).

Further Conversion of 14 to 12. A mixture of **1** (0.5 cm^3) and **14** (30 mg) was heated at 100 °C for 7 h. Subsequent silica-gel column chromatography of the mixture with benzene yielded **12** (8.4 mg; 28%).

Reaction of 14 and 11. A mixture of **1** (0.5 cm^3), **11** (20.5 mg), and **14** (22.8 mg) was heated at 100 °C for 5.5 h. Subsequent silica-gel column chromatography of the mixture with benzene afforded **8** (5.5 mg; 20%) and **12**

(2.5 mg; 16%).

Further Reaction of 11 and NQ. *a)* A mixture of **1** (0.5 cm^3), **11** (16 mg), and NQ (7 mg) was heated at 110 °C for 11 h. Subsequent silica-gel column chromatography of the mixture, with benzene–ether (5:5) as the eluent, yielded **8** (0.7 mg; 6%), together with **9** (1.5 mg) and **10** (2.5 mg).

b) A toluene solution (1 cm^3) of **11** (70.4 mg) and NQ (32.2 mg) was refluxed for 13 h. Subsequent silica-gel column chromatography of the mixture, with hexane–benzene (5:5) as the eluent, yielded **9** (7.4 mg; 11%) and **12** (4.9 mg; 7%).

Thermal Reaction of 1 with p-*TRQ.* A toluene solution of **1** (0.8 cm^3) and *p*-TRQ (545 mg) was heated to reflux for 10 min. The precipitates (287 mg, 56%), removed by filtration and washed with benzene and MeOH, were identical with **23**.[11] From the MeOH washings, **22** (124 mg; 22%) was obtained. From the benzene washings, a trace of **4** was isolated.

6) The yields of the product were based on the stoichiometry of the quinones required for their formation.

7) For deduction of the stereochemistry, the argument based on the *J* values would necessarily be ambiguous in the bicyclo[2.2.2]octene system. However, the chemical shift differences of the olefinic protons, $\Delta\delta$, between the bicyclooctenes and bicyclooctadienes must provide information. Thus, $\Delta\delta$ for norbornadiene and norbornane is 6.65−5.93=0.72, which could be calculated from the figures given in the literature,[14] but our $\Delta\delta$ value for **9** and **10** is 6.12−5.67=0.45, while for **17** and **15** it is 6.05−5.68=0.37. The differences can probably be explained in terms of the induced ring current effect from the naphthoquinone moiety; therefore, the stereostructures for the products are as depicted. We admit that, in this case, there is no reason why the adducts, which are formed stereospecifically, must have an unfavorable *exo*-configuration against the secondary orbital overlappings.

8) This product is a barbaralane derivative; however, in the ^{1}H and ^{13}C NMR spectra, there is no indication of the occurrence of valence isomerization, which is well known in the case of the parent skeleton.

The Pulse-photoconductivity of Poly(*N*-vinylbenzocarbazole)s

Akira ITAYA,* Ken-ichi OKAMOTO, and Shigekazu KUSABAYASHI†
Department of Chemical Engineering, Faculty of Engineering, Yamaguchi University, Tokiwadai, Ube 755
†*Department of Applied Chemistry, Faculty of Engineering, Osaka University, Suita, Osaka 565*
(Received January 25, 1985)

The hole-drift mobility and the carrier-photogeneration efficiency of holes in poly(5-vinylbenzo[*b*]carbazole)(P5VBCz) and poly(7-vinylbenzo[*c*]carbazole)(P7VBCz) films were investigated by means of the time-of-flight method and compared with those in poly(*N*-vinylcarbazole)(PVCz) films. The mobilities of these polymers were nearly equal to each other and smaller than that of PVCz by a factor of *ca.* 1/3. The electric field and temperature dependence of the mobilities fit Gill's empirical equation. The small mobilities of both P5VBCz and P7VBCz were apparently attributable to the small values of the pre-exponential factor, μ_0. The carrier-photogeneration efficiencies, ϕ, of these polymers were larger than that of PVCz by a factor of *ca.* 10. The field dependence of ϕ of these polymers for the excitation of the ^1B_a absorption band was in good agreement with the Onsager theory of geminate recombination. These results indicate that the introduction of bulky and unsymmetric benzocarbazolyl chromophores instead of carbazolyl ones as a pendant group of vinyl polymers is a good modification from the point of view of the carrier-photogeneration, but not from the viewpoint of the carrier transport.

There have been many investigations concerning the electrical conductivity of vinyl polymers with large pendant aromatic groups. Considerable data on the photoconductivity of poly(*N*-vinylcarbazole) (PVCz) have been accumulated because of an interest in highly photoconductive polymers.[1-21] The high photoconductivity of PVCz has been reported to be attributable to both the high efficiency of carrier generation and the ease of carrier migration. The extrinsic carrier-photogeneration *via* nonrelaxed exciplexes has been reported to be predominant for all the excitation bands.[14,20] The hole-drift mobility is described by a hopping mechanism where a hole migrates among pendant chromophores of polymer chains. Therefore, it is of interest to investigate the photoconductivity of vinyl polymers with aromatic chromophores which are more bulky than a carbazolyl chromophore. We have synthesized poly(5-vinylbenzo[*b*]carbazole)(P5VBCz) and poly(7-vinylbenzo[*c*]carbazole)(P7VBCz).[22] The stereoregularity of these polymers depends on the polymerization method. They show the excimer fluorescence, while the monomeric compounds, both 5-ethylbenzo[*b*]-carbazole and 7-ethylbenzo[*c*]carbazole (7EBCz), show no excimer fluorescence in concentrated solutions. This behavior is very similar to that of PVCz.[22,23]

In the present paper, the pulse photoconductivity of P5VBCz and P7VBCz has been investigated in comparison with that of PVCz.

Experimental

The P5VBCz was prepared by the bulk polymerization of purified 5-vinylbenzo[*b*]carbazole in the presence of 2 mol% AIBN in an evacuated sealed tube at 100—105 °C for 68 h.[22] The P7VBCz was prepared by the polymerization of a 0.62 M (1 M=1 mol dm^{-3}) benzene solution of purified 7-vinylbenzo[*c*]carbazole in the presence of 1 mol% AIBN in an evacuated sealed tube at 63 °C for 7 h.[22] The polymers were reprecipitated three times from the 1,2-dichloroethane solution with methanol. The polymer samples were stored in tubes within an argon atmosphere in the dark. Gel-permeation chromatography analysis showed M_n=2.02×10^4 and M_w/M_n=3.63, and M_n=4.72×10^4 and M_w/M_n=3.35, for P5VBCz and P7VBCz respectively. Films were cast on NESA-coated quartz plates from a 1,2-dichloroethane solution and were dried *in vacuo*. A semitransparent gold electrode with a typical area of 1 cm^2 was evaporated on a film to prepare a sandwich-type cell. The film thickness was determined to be 4.3—7.2 μm from the weight and density of a film with a certain known area and/or by a capacitive method. The densities of the films were 1.21 and 1.22 g cm^{-3} for P5VBCz and P7VBCz respectively. The dielectric constants, ε, of P5VBCz and P7VBCz films were determined to be 3.61 and 3.66 respectively from capacitance measurements at the frequency of 1 kHz at 298 K.

The hole-drift mobility and the carrier-photogeneration efficiency of holes were measured with the apparatus described in a previous paper by means of a conventional time-of-flight method in a vacuum of 2.6×10^{-3} Pa.[20,21] A 3 μs light pulse from an air-gap flash was irradiated onto a sample through appropriate narrow band-pass filters. The cautions described in a previous paper[20] were taken in all the procedures in order to get reproducible results.

Results and Discussion

Hole-drift Mobility. For both P5VBCz and P7VBCz, a transient photoresponse was detected only for the illumination of a positively-biased electrode and was attributed to hole transport. It has been reported that PVCz samples with a sequence length of the *N*-vinylcarbazole(VCz) chain of more than *ca.* 10 showed a shoulder of the transient response

curve.[21] For a P5VBCz sample with a degree the polymerization($\overline{DP}$) of 80, such a shoulder was observed, and the transit time, t_r, was determined from it. For a P7VBCz sample of $\overline{DP}$=180, however, no such shoulder was observed except above 363 K. When no shoulder of the transient response curve was observed, the transit time, t_r^*, was determined from the bilogarithmic plots based on the theory of Scher and Montroll.[24] The hole-drift mobilities calculated from t_r and t_r^* were abbreviated as μ_p and μ_p^* respectively.

Figure 1 shows the absorption spectra of P5VBCz and P7VBCz thin films and the transmittance of the band-pass filters used. The hole-drift mobility was independent of the excitation bands of ^1L_b, ^1L_a, and ^1B_a. The results mentioned below concerning the hole mobility were obtained by the excitation of ^1B_a and ^1L_a absorption bands for P5VBCz and P7VBCz respectively.

The hole-drift mobilities for both polymers depended strongly on both the electric field and the temperature, as is the case with PVCz.[4,12,16,21] Figure 2 shows the electric-field dependence of the hole mobilities of both polymers at *ca.* 339 K. The result for a PVCz sample of $\overline{DP}$=1010 is also shown for the sake of comparison. Straight lines of log μ against the square root of the electric field show that the Poole-Frenkel-type relation holds for these polymers. Under this condition, the hole mobilities of P5VBCz and P7VBCz were nearly equal to each other and about one-thirds as large as that of PVCz. This is not attributable to the difference of the $\overline{DP}$ values, because the mobilities of the PVCz samples prepared by the radical polymerization were reduced by a factor of only two with a decrease in $\overline{DP}$ from 200 to 20.[21]

The electric-field and temperature dependence of the hole mobility of PVCz is expressed by Gill's empirical equation:[4]

$$\mu_p = \mu_0 \exp\{-(\Delta E_0 - \beta\sqrt{E})/kT_{eff}\} \quad (1)$$

$$1/T_{eff} = 1/T - 1/T_0, \quad (2)$$

where k is the Boltzmann constant; E, the electric field; T, the film temperature, and μ_0, ΔE_0, T_0, and β, the characteristic parameters. We have previously reported that the dependence of the mobilities of the copolymers of VCz with styrene(VCz-St copolymer) on both the electric field and the temperature also fit Gill's empirical equation.[21] Figure 3 shows the temperature dependence of the mobilities of P5VBCz and PVCz under various electric fields. The electric-field dependence of the activation energies, ΔE_a, of P5VBCz, P7VBCz, and PVCz is shown in Fig. 4. These figures indicate that the mobilities of the benzocarbazolyl polymers also follow Gill's equation, as is the case with carbazolyl polymers. The values of the parameters obtained are listed in Table 1. There was a remarkable difference in the parameter, T_0, between carbazolyl and benzocarbazolyl polymers. The glass-transition temperatures of P5VBCz and P7VBCz were higher than that of PVCz, while the T_0 values of the benzocarbazolyl polymers were much lower than those of PVCz and VCz copolymers. The T_0 values of the benzocarbazolyl polymers were close to those of polycarbonate molecularly-doped with 7EBCz (522—405 K) reported by Tsutsumi *et al.*[25] It has been suggested that T_0 was related to the freezing-in temperature of the micro motion of chromophores themselves acting as hopping sites;[21,26] their micro motion destroys some structural traps preventing the hole transport and promotes the transport. It has been suggested that the traps which control the hole

transport may be derived from structural defects such as kinks existing at joints between isotactic and syndiotactic sequences.[21] Both P5VBCz and P7VBCz consist of a syndiotactic and isotactic stereoblock structure, as is the case with PVCz.[22] Although both benzo[*b*]carbazole and benzo[*c*]carbazole are bulky compared with carbazole, they both have unsymmetric molecular structure, unlike carbazole. Therefore, the packing between chromophores around the kinks in P5VBCz and P7VBCz may be loose and the chromophores may tend to move to destroy the structural traps at low temperatures as compared with carbazolyl chromophores in PVCz.

The μ_0 values of P5VBCz and P7VBCz were much smaller than that of PVCz, as is shown in Table 1. The μ_0 value of poly(1-vinylpyrene) was close to those of P5VBCz and P7VBCz and much smaller than that of PVCz.[27] Even if a sample with a high value of T_0 tends to have a high value of μ_0, the μ_0 value of PVCz is extremely high. It has been reported that the μ_0 value is related to molecular interaction between chromophores acting as hopping sites[4] and corresponds to the trap-free drift mobility.[19] Therefore, the molecular interaction between carbazolyl chromophores in PVCz is considered to be very strong with regard to the hole transport.

The introduction of bulky and unsymmetric benzocarbazolyl chromophores instead of carbazolyl ones as a pendant group of vinyl polymers results in an increase in the exponential term related to the temperature in Eq. 1, because of the low T_0 values of P5VBCz and P7VBCz. However, the μ_0 values related to the molecular interaction ascribed to properties of the chromophores themselves are much lower for benzocarbazolyl polymers than for PVCz; consequently, the mobilities of both P5VBCz and P7VBCz are smaller than that of PVCz. Therefore, the introduction of benzocarbazolyl chromophores is not a good modification from the point of view of the carrier transport.

Carrier-photogeneration Efficiency. In order to excite the ^1L_b, ^1L_a, and ^1B_a absorption bands, narrow band-pass filters of 390, 330, and 270 nm were used for P5VBCz, and those of 370, 330, and 270 nm, for P7VBCz(Fig. 1). Figure 5 shows the field dependence of the carrier-photogeneration efficiency,ϕ, of P5VBCz and P7VBCz for the various excitation bands at 338 K, including that of PVCz for the sake of

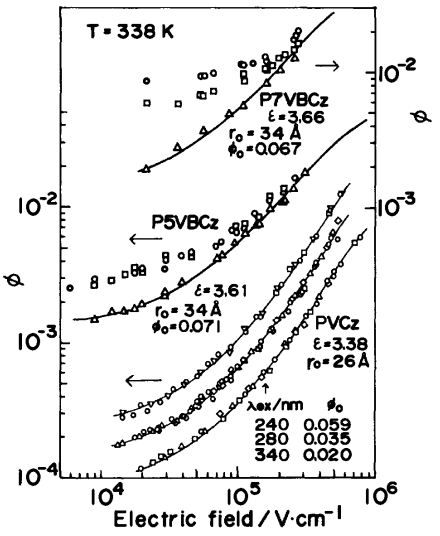

Fig. 5. Field dependence of the carrier-photogeneration efficiency in P5VBCz, P7VBCz, and PVCz films for different excitation bands. The solid lines were calculated from Eq. 1 in Ref. 20 with r_0 and ϕ_0 values presented in the figure. The keys ○, □, and △ present the ^1L_b, ^1L_a, and ^1B_a band excitation, respectively, except for PVCz.

comparison. The ϕ values of P5VBCz and P7VBCz were nearly equal to each other and were much larger than that of PVCz for all the excitation bands.

The solid lines in Fig. 5 were calculated from Eq. 1 in Ref. 20, with an interionic separation r_0 of 34 Å and with a primary yield of the electron-hole pair, ϕ_0, of 0.071 and 0.067 for P5VBCz and P7VBCz respectively; this equation is used in order to calculate the overall carrier-photogeneration efficiency, ϕ, given as the product of ϕ_0 and the dissociation probability, P(E), which is given by the Onsager theory of the geminate recombination of a bound electron-hole pair with r_0. The experimental data for the ^1B_a band were in good agreement with the lines predicted from the Onsager theory, indicating that the extrinsic carrier-photogeneration via an exciplex is predominant for the excitation of a surface layer of a film. However, the experimental data for the ^1L_b and ^1L_a bands did not fit the Onsager theory because of a contribution of another carrier-generation process, one independent of the electric field. On the other hand, the carrier-photogeneration efficiency of PVCz for all the excitation bands fit the Onsager theory, with both ϕ_0 values increasing from 0.02 to 0.059 and r_0 (=26 Å).[20] The large r_0 value of both P5VBCz and P7VBCz is probably attributable to the fact that a large excess energy must be dissipated during the thermalization process from a non-relaxed exciplex state to the ion-pair state because the ionization potential of benzocarbazolyl chromophores is smaller than that of the carbazolyl chromophores.[28]

The results described above show that the introduction of benzocarbazolyl chromophores with a small ionization potential instead of carbazolyl ones is a good modification from the point of view of the carrier-photogeneration.

Nucleophilic Photoreaction of Chlorobenzene in Methanol as Studied by Emission Spectroscopy

Shin-ichi NAGAOKA, Takeshi TAKEMURA, and Hiroaki BABA*
Division of Chemistry, Research Institute of Applied Electricity, Hokkaido University, Sapporo 060
(Received February 4, 1985)

The photoreaction of chlorobenzene in methanol has been studied by means of emission spectroscopy. Upon irradiation with UV light, chlorobenzene reacts with methanol to form anisole with a quantum yield of 0.049 at 18 °C. Contrary to the case of chlorobenzene, the photoreaction of *p*-dichlorobenzene with methanol is not observed. By combining these results with those of our recent studies on the dual phosphorescence from low-lying triplet states of halogenated benzenes, it is suggested that the photoreaction of chlorobenzene with methanol, which is a nucleophilic substitution reaction, occurs in the $^3(\pi,\sigma^*)$ state. From the temperature dependence of the quantum yield, the activation energy for the nucleophilic photoreaction is estimated to be larger by about 3—4 kcal mol^{-1} than the apparent activation energy for a combination of the nonradiative $^3(\pi,\sigma^*)\rightarrow S_0$ process and the homolytic dissociative process concerning the C–Cl bond in the $^3(\pi,\sigma^*)$ state. It is suggested that the nucleophilic photoreaction contrasts with the radical reaction leading to the dissociation of the C–Cl bond; the latter reaction occurs in the $^3(\pi,\pi^*)$ state as well as in the $^3(\pi,\sigma^*)$ state.

Halogen substitutions in benzene cause significant changes in its phosphorescence spectrum. Benzene exhibits a structured phosphorescence spectrum with a maximum near 370 nm in rigid-glass solution, while chlorobenzene (abbreviated to CB) shows a broad, structureless one with a maximum near 480 nm.[1,2] Lim and Chakrabarti assigned this phosphorescence for CB to an emission originating from a triplet excimer.[2] Recently we studied the phosphorescence emission and the dynamics in the triplet states of CB, *p*-dichlorobenzene (DCB), and *p*-dibromobenzene in 2-methylpentane in the temperature range 70 to 100 K by means of time-resolved emission spectroscopy.[1,3] From the results of these studies we concluded that CB exhibits dual phosphorescence which consists of the structureless spectrum mentioned above and a somewhat structured one with a maximum near 400 nm, and that the former spectrum is not due to the triplet excimer. The phosphorescence properties of the halogenated benzenes were explained in terms of two low-lying triplet states, $^3(\pi,\pi^*)$ and $^3(\pi,\sigma^*)$, as shown in Fig. 1.[1,3] The intersystem-crossing (ISC) quantum yields from the S_1 state to the $^3(\pi,\pi^*)$ and $^3(\pi,\sigma^*)$ states may possibly amount to 0.6 and 0.4 for CB at 77 K, respectively, while for DCB the ISC to the $^3(\pi,\pi^*)$ state predominates, to a great extent, over the ISC to the $^3(\pi,\sigma^*)$ state. The nonradiative decay rate from these triplet states is particularly large at higher temperatures (> 85 K) compared with the corresponding rate of other analogous compounds, *e.g.*, halogenated naphthalenes. Accordingly, a process peculiar to the halogenated benzenes is considered to play an important role in the relaxation from the two triplet states. We suggested that this process corresponds to homolytic dissociation of the C–Cl bond.

On the other hand, the photolysis of halogenated benzenes has been widely studied, because the halogenated compounds are often concerned with environmental pollusion.[4] It is known that the photolysis of CB generates a phenyl radical,[5] which is important as an intermediate in organic radical reactions. Ichimura and Mori suggested that the photolysis of CB in the vapor phase proceeds from the triplet state.[6] Bunce *et al.* showed that a radical reaction occurs in the triplet state of CB in cyclohexane.[7] Soumillion and De Wolf found that upon irradiation benzene and anisole are formed simultaneously in a solution of CB in methanol (MeOH), and they proposed a mechanism involving the triplet excimer for this photoreaction.[8] It is thus inferred that the photoreaction of CB is related to the nonradiative process from the triplet state.

Despite these investigations the relationships among the type of the excited state, the nonradiative

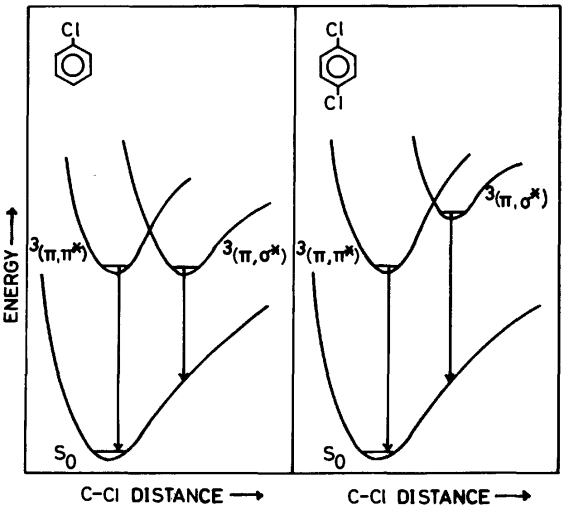

Fig. 1. Schematic sketch of potential curves of the low-lying triplet states of CB and DCB. The $^3(\pi,\sigma^*)\rightarrow S_0$ phosphorescence of DCB can be observed at temperatures higher than 85 K,[3] though it is too weak to be detected at 77 K.[1]

process, and the photoreaction have not fully been explored for halogenated benzenes, although such information is necessary for understanding the detailed mechanism of the photoreaction. Under these circumstances it would be worthwhile to examine the role of the two low-lying triplet states, $^3(\pi,\pi^*)$, and $^3(\pi,\sigma^*)$, in the photochemistry of halogenated benzenes.

From these points of view we have investigated the photoreaction of CB with MeOH by means of emission spectroscopy. One of the reaction products was found to be anisole, as shown by Soumillion and De Wolf,[8] indicating that a nucleophilic substitution reaction takes placae. The quantum yield of the nucleophilic photoreaction was determined, and the temperature dependence of the yield was examined to elucidate the reaction dynamics. The property of this reaction is compared with that of the radical photoreaction leading to the dissociation of the C–Cl bond. It is suggested that the nucleophilic reaction occurs in the $^3(\pi,\sigma^*)$ state, but that the radical reaction occurs in the $^3(\pi,\pi^*)$ state as well as in the $^3(\pi,\sigma^*)$ state. The photochemistry of DCB was also investigated for the sake of comparison.

Experimental

Materials. Chlorobenzene (CB), *p*-dichlorobenzene (DCB) (Wako Pure Chemical Co.), biacetyl, anisole, and *p*-chloroanisole (Nakarai Chemicals, Ltd.) were purified by repeated vacuum sublimation or distillation. Spectroscopic grade methanol (MeOH) and cyclohexane (Wako Pure Chemical Co.) were used without further purification. All sample solutions were degassed by the freeze-pump-thaw method prior to measurements.

Apparatus and Procedure. Unless otherwise stated, experiments were made at room temperature using a 1-cm square quartz cell. Absorption spectra were taken with a Cary 15 or a Hitachi 228A spectrophotometer. Emission and excitation spectra were measured by the photon-counting method, using a high-sensitivity emission spectrophotometer with a Hamamatsu R585 photomultiplier as detector.[9] The emission and excitation spectra were not corrected for the spectral sensitivity of the detector and the spectral intensity of the exciting light, respectively. In the photochemical experiments, unless otherwise stated, irradiation was carried out at 265 nm in the region of the $S_1 \leftarrow S_0$ transition with a bandwidth of 19 nm by the use of light from a system of a 150 W xenon arc and an *f*/4.5 monochromator.

The absolute quantum yield of the photoreaction of CB with MeOH was determined at 18 °C by means of trioxalatoferrate (III) actinometry, using a deaerated MeOH solution of 10^{-3} M (1 M=1 mol dm^{-3}) CB. Before irradiation of the solution, the intensity of fluorescence obtained by excitation at 265 nm was measured. After irradiation for 2 h, the fluorescence intensity was measured again under the same conditions as before to know the increase of the intensity resulting from the irradiation. This intensity increase was then compared with the intensity of the fluorescence from a 10^{-4} M solution of anisole in MeOH to evaluate the concentration of anisole formed by the photochemical reaction. It is to be noted here that the decrease in intensity of the fluorescence of CB need not be taken into account, because this decrease is very small compared with the intensity increase caused by anisole produced. The incident photons were counted after the method established by Hatchard and Parker.[10] These data permit determination of the quantum yield of the photoreaction. The quantum yields of photoreaction at 45, 0, −26 and −44 °C, relative to the yield at 18 °C, were also measured using three types of cryostats. By combining the results with the absolute yield at 18 °C, the absolute quantum yields were obtained for the different temperatures mentioned above.

The fluorescence decay (or the lifetime) was measured on a laser spectrophotomeric system reported previously,[11] using the time-correlated single photon counting method. The frequency of a pulsed dye laser (Molectron DL14) pumped by a nitrogen laser (Molectron UV22) was doubled by KDP crystal. The generated UV pulses, which were used for exciting the sample, have a duration of ≈3 ns. The emission was detected by a Hamamatsu R106 photomultiplier.

Results and Discussion

Photoreaction of CB with MeOH. In Fig. 2(a) the solid curves 1 and 2 represent the fluorescence and fluorescence-excitation spectra of 10^{-3} M CB in MeOH, and the broken curves 1′ and 2′ those of 10^{-3} M

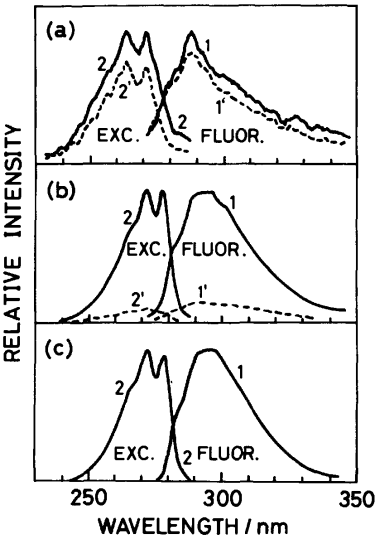

Fig. 2. (a) Fluorescence and fluorescence-excitation spectra of 10^{-3} M CB in MeOH (——) and 10^{-3} M CB in MeOH containing 10^{-2} M biacetyl (– – –). The fluorescence spectra (1 and 1′) were obtained by excitation at 265 nm and the excitation spectra (2 and 2′) by monitoring the emission at 300 nm. The spectra for the two sample solutions were recorded under the same conditions. (b) Same as (a) except that the two sample solutions were irradiated for 10 h. (c) Fluorescence spectrum (1) and fluorescence-excitation spectrum (2) of 10^{-4} M anisole in MeOH.

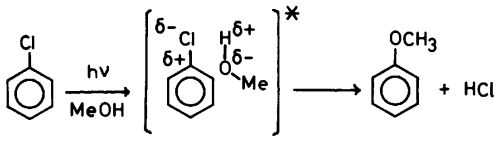
CB in MeOH containing 10^{-2} M biacetyl. Since the spectra for the two solutions were recorded under the same conditions, it is obvious that the fluorescence of CB is not quenched efficiently by biacetyl. This observation is consistent with the report that the lifetime of the S_1 state of CB is very short (80—800 ps).[12,13] On the other hand, from the latter solution containing biacetyl, strong sensitized biacetyl phosphorescence was observed, indicating that low-lying triplet states of CB are populated to a great extent.

Upon irradiation of the MeOH solution of CB alone, the fluorescence intensity increases with irradiation time, and the fluorescence spectrum undergoes a drastic change. In Fig. 2(b) the solid curves 1 and 2 represent the fluorescence and its excitation spectra for the MeOH solution of CB taken after irradiation for 10 h. These spectra are significantly different in shape and position from spectra 1 and 2 of Fig. 2(a), and are considered to originate from a photoproduct. In fact spectra 1 and 2 of Fig. 2(b) are very similar to the corresponding spectra of anisole in MeOH shown in Fig. 2(c). The fluorescence lifetime of the photoproduct (9.4 ns) also is similar to that of anisole in MeOH (9.8 ns). From these results, it is concluded that CB reacts with MeOH to form anisole upon irradiation. This photoreaction may be assumed to proceed in the excited state *via* a nucleophilic attack by MeOH on the carbon adjacent to the chlorine atom, followed by heterolysis of the C–Cl bond:



It has been found that photoreactions of alkyl halides in MeOH proceed through similar processes and generate methoxyalkanes.[14] A similar photosolvolysis was also reported for benzyl chloride in *t*-butyl alcohol.[15]

The photoreaction in the MeOH solution of CB is quenched by biacetyl. In Fig. 2(b) the broken curves 1′ and 2′ represent the fluorescence and its excitation spectra of 10^{-3} M CB in MeOH containing 10^{-2} M biacetyl after being irradiated in the same way as the MeOH solution of CB alone. These spectra were recorded under the same conditions as those for the solution without biacetyl, *i.e.*, spectra 1 and 2 of Fig. 2(b). Figure 3 shows the increase of the fluorescence intensity with irradiation time. The open and solid circles refer to the solutions of CB in MeOH in the absence and presence of biacetyl, respectively. It is seen that the efficiency of the photoreaction becomes very low when biacetyl is added to the solution. Since the photoreaction is quenched efficiently by

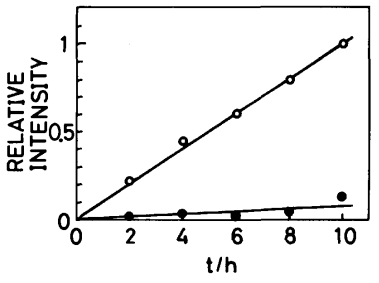


Fig. 3. Increase of the fluorescence intensity with irradiation time for 10^{-3} M CB in MeOH (○) and 10^{-3} M CB in MeOH containing 10^{-2} M biacetyl (●). The intensity was measured by excitation at 265 nm and by monitoring the emission at its intensity maximum.

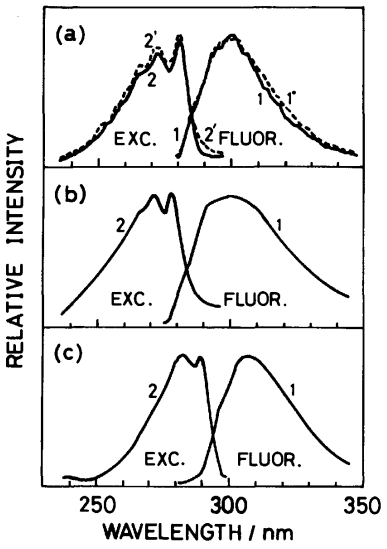

Fig. 4. (a) Fluorescence and fluorescence-excitation spectra of 10^{-3} M DCB in MeOH (——) and those of the same solution after irradiation for 10 h (- - -). The fluorescence spectra (1 and 1′) were obtained at 273 nm and the excitation spectra (2 and 2′) by monitoring the emission at 310 nm. The spectra before and after irradiation were recorded under the same conditions. (b) Fluorescence (1) and fluorescence-excitation (2) spectra of 10^{-3} M DCB in MeOH after irradiation for 3 min with intense light from a 250 W high-pressure Hg lamp. (c) Fluorescence (1) and fluorescence-excitation (2) spectra of 10^{-4} M *p*-chloroanisole in MeOH.

biacetyl in contrast to the case of the fluorescence, this reaction is considered to occur mainly in the low-lying triplet state, $^3(\pi, \pi^*)$ and/or $^3(\pi, \sigma^*)$. Tissot *et al.* also showed that the photohydrolysis of chlorobenzene in aqueous solution involves a triplet state.[16]

Contrary to the case of CB, the nucleophilic photoreaction was not observed for DCB. In Fig. 4(a) the solid curves 1 and 2 show the fluorescence and its excitation spectra of 10^{-3} M DCB in MeOH, and the broken curves 1′ and 2′ the spectra of the same solution after being irradiated under the same

experimental conditions as the solution of CB in MeOH. The solid and broken curves were recorded under the same conditions. If the nucleophilic reaction of DCB occurred in MeOH, the fluorescence and its excitation spectra of DCB should be changed to those of *p*-chloroanisole shown in Fig. 4(c). Actually the spectra of DCB remain essentially unchanged upon irradiation, as is seen in Fig. 4(a). It was found, however, that on irradiating DCB with intense light from a 250 W high-pressure Hg lamp (without being dispersed by a monochromator), the spectra were changed ultimately to those of anisole, as shown in Fig. 4(b). Moreover, during the course of the above irradiation there was no indication that *p*-chloroanisole was formed. These experimental results for DCB can be explained as follows. In the first stage of the photochemical reaction, the homolysis of DCB takes place in MeOH to form CB, as shown by Mansour *et al.*,[17] and then the CB molecule is changed to anisole by the photochemical nucleophilic reaction as described before. It is thus concluded that in the low-lying triplet states of DCB the nucleophilic reaction does not occur at all or proceeds only slowly.

The extent to which each of the $^3(\pi,\pi^*)$ and $^3(\pi,\sigma^*)$ states is involved in the nucleophilic photoreaction depends evidently upon the degree of populating the triplet state concerned. According to our recent study, the ISC quantum yield from the S_1 state to the $^3(\pi,\sigma^*)$ state may possibly amount to 0.4 for CB, but it is essentially zero for DCB in 2-methylpentane at 77 K; that is, the $^3(\pi,\sigma^*)$ state of DCB is populated from S_1 to a far smaller degree than the same state of CB. In either compound, the mutual conversion between the two low-lying triplet states $^3(\pi,\pi^*)$ and $^3(\pi,\sigma^*)$ is negligible at 77 K.[3] In DCB the $^3(\pi,\pi^*)$ state is considered to be significantly lower in energy than the $^3(\pi,\sigma^*)$ state (Fig. 1).[1,3] Accordingly, even if the conversion mentioned above occurs rapidly at high temperature, the $^3(\pi,\sigma^*)$ state of DCB will be populuated *via* $^3(\pi,\pi^*)$ only to a slight degree. It seems reasonable, therefore, to assume that the overall degree of populating the $^3(\pi,\sigma^*)$ state of DCB is much less than that of CB even under the present experimental conditions. This difference in population degree of the $^3(\pi,\sigma^*)$ state between CB and DCB may be the main factor responsible for the difference in reactivity between the two compounds. Thus, the most probable mechanism of the nucleophilic photoreaction of CB with MeOH is that the reaction proceeds from the $^3(\pi,\sigma^*)$ state. Our recent *ab initio* study on the low-lying triplet states of CB also has suggested that the $^3(\pi,\sigma^*)$ state is more favorable to the nucleophilic photoreaction than the $^3(\pi,\pi^*)$ state.[18]

From the phosphorescence and its excitation spectra of the irradiated sample solution of CB in MeOH, which were measured at 77 K after irradiation at room temperature, we noticed formation of benzene in addition to anisole. As mentioned previously, Soumillion and De Wolf also found that benzene and anisole are formed simultaneously upon irradiation of a solution of CB in MeOH, and they proposed a new mechanism which involves formation of a pair of radical ions *via* the triplet excimer.[8] Their argument is based on the suggestion by Lim and Chakrabarti[2] that the phosphorescence from CB in EPA at 77 K is due to the triplet excimer. However, we demonstrated that the phosphorescence is not attributable to the triplet excimer, but that it can be explained in terms of the two low-lying triplet states.[1] It is unlikely, therefore, that the photoreaction proceeds *via* the triplet excimer. This is consistent with the results obtained by Bunce *et al.*[7]

Reaction Quantum Yield and Its Temperature Dependence. The quantum yield of the nucleophilic photoreaction (Φ_{react}) of CB at 18 °C was determined to be 0.049 by means of actinometry. The temperature dependence of Φ_{react} of CB is shown in Fig. 5. The value of Φ_{react} decreases as the temperature is lowerd. The results were analysed under the view that the reaction proceeds from the $^3(\pi,\sigma^*)$ state.

Since the ISC in CB seems to dominate over the other deactivation processes from the S_1 state, the total ISC quantum yield is assumed to be unity. The ISC is considered to take place to both the $^3(\pi,\pi^*)$ and the (π,σ^*) states. At room temperature, the rates of the radiative decays from the two triplet states can safely be regarded as much less than those of the nonradiative decays, so that the radiative decays will be neglected in the following discussion. The rate constants for the nonradiative decay processes and the nucleophilic photoreaction are assumed to change with temperature and to be expressible in the forms of the Arrhenius equation. In order to understand the experimental results, two simple and extreme cases will be discussed. In Case 1, the mutual conversion between the $^3(\pi,\pi^*)$ and $^3(\pi,\sigma^*)$ states is regarded as much slower than the other nonradiative processes from these two triplet states. In Case 2, we assume that just the reverse is the case, namely, that a

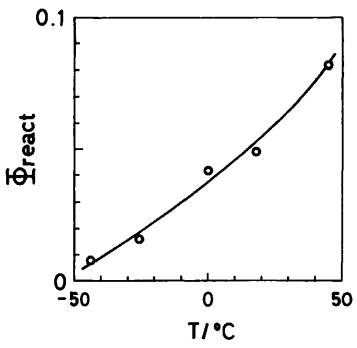

Fig. 5. Temperature dependence of Φ_{react}.

dynamic equilibrium is attained between the two triplet states.

In Case 1, we can show that the following relation holds between Φ_{react} and temperature:

$$\frac{\Phi_{ISC}^{\pi\sigma}}{\Phi_{react}} - 1 \propto \exp\left(\frac{E_r - E_\sigma}{RT}\right), \quad (1)$$

where $\Phi_{ISC}^{\pi\sigma}$ denotes the quantum yield of the ISC to the $^3(\pi,\sigma^*)$ state; E_r is the activation energy of the pseudo first order nucleophilic photoreaction from the $^3(\pi,\sigma^*)$ state, and E_σ represents the apparent activation energy associated with the total rate constant, k_σ, for a combination of the nonradiative $^3(\pi,\sigma^*)\rightarrow S_0$ process and the homolytic dissociative process concerning the C-Cl bond in the $^3(\pi,\sigma^*)$ state.

In Case 2, on some assumptions, the relation between Φ_{react} and temperature is given by

$$\frac{1}{\Phi_{react}} - 1 \propto \exp\left(\frac{E_r - E_\sigma}{RT}\right). \quad (2)$$

The assumptions which have to be introduced are described in the following.

Previously, we suggested that the homolytic dissociative process of the C-Cl bond is dominant in the decay from the two low-lying triplet states of halogenated benzenes in 2-methylpentane above 85 K.[1,3] It is not unreasonable, therefore, to assume that the rate of the homolytic dissociative process of the C-Cl bond is much greater than those of the other nonradiative processes in CB under our experimental conditions. Furthermore, the dissociation of the C-Cl bond of CB is much more likely to occur in the $^3(\pi,\sigma^*)$ state than in the $^3(\pi,\pi^*)$ state, because the C-Cl bond length in the $^3(\pi,\sigma^*)$ state is considered to be significantly longer than that in the $^3(\pi,\pi^*)$ state.[1,3,18] It is thus assumed that k_σ is far greater than the total rate constant for a combination of the nonradiative $^3(\pi,\pi^*)\rightarrow S_0$ process and the homolytic dissociative process concerning the C-Cl bond in the $^3(\pi,\pi^*)$ state. It is further assumed that for CB the ratio of the rate constant for the $^3(\pi,\sigma^*)\rightarrow{}^3(\pi,\pi^*)$ conversion process to the rate constant for the reverse process is not much larger than unity.

Equation 2 (Case 2) is the same as Eq. 1 (Case 1), except that $\Phi_{ISC}^{\pi\sigma}$ is replaced by unity. We attemped to estimate E_r-E_σ from the slopes of the plots of log $[(X/\Phi_{react})-1]$ *vs.* $1/T$ with X varying between 0.1 and 1. The plots of $\log[(X/\Phi_{react})-1]$ *vs.* $1/T$ give nearly straight lines for X between 0.2 and 1, but the plot for $X=0.1$ somewhat deviates from a straight line. Accordingly, we estimated E_r-E_σ only for $0.2 \leqq X \leqq 1$. From the slopes of the straight lines, the values of E_r-E_σ of CB were determined to be (3.9 ± 1.0) and (3.0 ± 0.7) kcal mol^{-1} (1 kcal mol^{-1}= 4.184 kJ mol^{-1}) for $X=0.2$ and 1, respectively, using the least squares method. E_r-E_σ decreases as X increases, but for $0.2 \leqq X \leqq 1$, E_r-E_σ does not depend largely on X. In other words, the two extreme cases, Case 1 and Case 2, lead to similar results for E_r-E_σ. It may thus be said that E_r is larger than E_σ by about 3—4 kcal mol^{-1} in the actual CB molecule.

Comparison between Nucleophilic and Radical Reactions. As described previously benzene as well as anisole is formed by irradiation of CB in MeOH, indicating that the radical photoreaction occurs, besides the nucleophilic one, in the sample solution. We now compare the property of the nucleophilic photoreaction of CB with that of the radical one. Bunce *et al.* showed that the radical reaction occurs in the triplet state of CB in cyclohexane.[7] Examining the photolysis of CB in cyclohexane by a method similar to the one described before, we also concluded that upon irradiation CB in cyclohexane is converted into benzene *via* the low-lying triplet states. In order to know the detailed mechanism of this radical photoreaction, we studied the photolysis of DCB in cyclohexane also.

The fluorescence and its excitation spectra of DCB in cyclohexane are shown in Fig. 6(a). As in the case of CB in MeOH, the fluorescence is not quenched efficiently by biacetyl. Upon irradiation with the intense light from the 250 W high-pressure Hg lamp mentioned previously, the spectra changed drastically. A peak to be assigned to CB was observed at 265 nm in the excitation spectrum, together with peaks of DCB and benzene (Fig. 6(b)). On further irradiation, the fluorescence and its excitation spectra

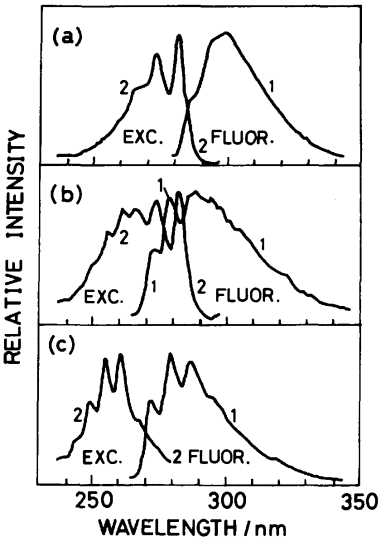

Fig. 6. (a) Fluorescence (1) and fluorescence-excitation (2) spectra of 10^{-3} M DCB in cyclohexane in a 7 mm o.d. cylindrical quartz cell. The fluorescence spectrum was obtained by excitation at 255 nm and the excitation spectrum by monitoring the emission at 310 nm. (b) Same as (a) except that the sample solution was irradiated for 10 min with intense light from a 250 W high-pressure Hg lamp. (c) Same as (b) except that the irradiation time was lengthened to 30 min.

changed finally to those of benzene alone, as may be seen from Fig. 6(c). These results indicate that the radical reaction, including the dechlorination of DCB, takes place upon irradiation. Since this photoreaction is quenched by biacetyl, it is considered to occur in the low-lying triplet states as in the case of the nucleophilic and radical photoreactions of CB. On the other hand, as has already been pointed out, the population degree of the $^3(\pi,\sigma^*)$ state of DCB is considered to be quite small. It is, therefore, reasonable to presume that the radical plotoreaction of DCB takes place in the $^3(\pi,\pi^*)$ state. The radical reaction of CB, therefore, may be supposed to occur in the $^3(\pi,\pi^*)$ state also.

From the foregoing discussion one may suppose that (1) the nucleophilic photoreaction of CB takes place in the $^3(\pi,\sigma^*)$ state, and (2) the radical photoreaction of CB leading to the dissociation of the C–Cl bond may occur both in the $^3(\pi,\pi^*)$ state and in the $^3(\pi,\sigma^*)$ state.

Kinetic Features of SERS Quenching by Underpotential Deposition (UPD) of Cd and Tl on Ag Electrodes

Tadashi WATANABE,* Osamu KAWANAMI, and Kenichi HONDA†
Institute of Industrial Science, The University of Tokyo, Roppongi, Minato-ku, Tokyo 106
†*Division of Molecular Engineering, Faculty of Engineering, Kyoto University, Yoshida, Sakyo-ku, Kyoto 606*
(Received February 4, 1985)

Surface-enhanced Raman scattering (SERS) in the Ag/pyridine system is quenched through a biphasic kinetics, after completion of submonolayer underpotential deposition (UPD) of Cd. This result is elucidated by invoking a quasi-reversible transformation of the initial SERS-active site into another by an attack, *via* surface diffusion, of deposited Cd, followed by irreversible unimolecular decomposition of the new site. From the SERS quenching data a value of about 10^{-17} cm^2 s^{-1} was derived as the surface diffusion coefficient of Cd on the Ag surface. A similar but somewhat different quenching behavior is observed by UPD of Tl.

A number of authors[1-4] have recently described the use of underpotential deposition (UPD) of foreign metals onto Ag electrodes for mechanistic investigation of the surface-enhanced Raman scattering (SERS).[5] The SERS-quenching effect observed by UPD is generally very drastic, causing nearly perfect intensity loss at metal coverages on the order of several hundredths.[1-3] Moreover, the quenching effect is usually of irreversible nature, *i.e.*, the original SERS intensity is hardly recovered upon reoxidation (stripping) of the deposited foreign metal.[1-4] Such quenching behaviors have been accounted for by invoking an attack or association of the metal atom to some special "SERS-active site," which is supposed to exist on the Ag surface sustaining the SERS effect.

In a more recent work[6] we presented evidence that the SERS-active sites consist of sparingly soluble surface Ag^+ complexes, which are removed from the surface by the action of appropriate ligands forming water-soluble Ag^+ complexes, or are disintegrated through reduction of the Ag^+ centers by application of sufficiently negative potentials. Other workers[7,8] also identify the SERS-active sites with insoluble Ag^+ salts on the electrode surface. Then, as briefly discussed previously,[6] one of the possible mechanisms for the SERS-quenching by UPD may be related to an interaction between the deposited metal atom and the surface Ag^+ complexes. This aspect has been studied in the present work by following the time courses of the UPD itself and of the SERS intensity decrease.

Experimental

A polycrystalline Ag platelet (10×10×1 mm) embedded in a Teflon holder was used as a working electrode in a base electrolyte solution containing 0.1 M KCl and 0.05 M pyridine (1 M=1 mol dm^{-3}). $CdCl_2$ or TlCl was then dissolved to give a metal ion concentration of 2.5×10^{-5} M. The pH values of the Cd^{2+} and Tl^+ solutions were 8.5 and 7.7, respectively. No turbidity was noticed in the Cd^{2+}-containing solution, in contrast to a solution with much higher Cd^{2+} concentration (5×10^{-4} M).[4] The counter and reference electrodes are a Pt wire and a saturated calomel electrode (SCE), respectively.

Stripping voltammetry was used to determine the surface coverage $\theta(E,t)$ for Cd or Tl on tha Ag electrode as functions of potential E and polarization time t in the above-specified electrolyte solution. In this measurement a mirror-finished Ag electrode was employed, the roughness factor of which was estimated to be about 1.5 as in a previous work.[1] The stripping charge Q, corrected for the roughness factor, was converted to θ assuming $\theta=1$ for $Q=420$ μC cm^{-2} (Cd) and 210 μC cm^{-2} (Tl).[9]

The pyridine SERS spectra were recorded over a wavenumber range of 985—1045 cm^{-1}, in which two major vibrational peaks are observed. A single scan required about 6 s. Other details for SERS measurements are the same as in a previous paper,[1] except that a 514.5-nm Ar^+ laser line (100 mW) was used here for excitation.

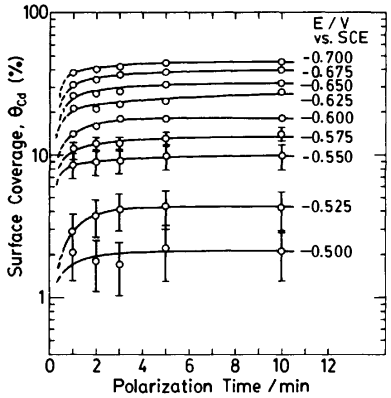

Fig. 1. Effect of electrode potential and polarization time on θ_{Cd} on the Ag electrode surface. $[Cd^{2+}]=2.5\times10^{-5}$ M.

Results and Discussion

UPD of Cd. Figure 1 shows the $\theta_{Cd}(E,t)$ characteristics obtained with a mirror-finished Ag electrode. It is seen that measurable UPD starts at a potential *ca.* 300 mV positive of the thermodynamic deposition potential for the Cd^{2+}/Cd couple (−0.78 V *vs.* SCE at $[Cd^{2+}]=2.5\times10^{-5}$ M). No significant difference was noted between the features of $\theta_{Cd}(E,t)$ in the presence and absence of 0.05 M pyridine. A similar observation is described by Kester[4] for the θ_{Tl} values in the Ag/benzotriazole system. Further, the application of an oxidation-reduction cycle (ORC), leading to roughening of the Ag surface, did not alter the essential feature of $\theta_{Cd}(E,t)$, except for some fourfold increase in the stripping charge Q due to roughening. The most important aspect in Fig. 1 is that the UPD process is practically completed in less than 100 s at each potential. A closer examination of the temporal evolution of θ_{Cd} demonstrated that the effective times for near-completion of UPD were about 40 s and 120 s for Ag electrodes before and after an ORC, respectively.

The SERS quenching effect of Cd UPD was examined as follows. After application of an ORC to a reformation charge of about 20 mC cm^{-2} in an electrolyte solution containing all the three components (pyridine, KCl, and $CdCl_2$), the potential was maintained for 1—2 min at 0.0 V *vs.* SCE to achieve a stationary SERS signal. The potential was then stepped to a negative value, ranging from −0.45 to −0.7 V, and the SERS spectra were thereafter registered every 20 s for about 40 min. Potentials negative of −0.7 V were avoided because of the occurrence of potential-induced irreversible decay of the pyridine SERS.

In a Cd^{2+}-free electrolyte solution, the pyridine SERS intensity was stable for more than 40 min at potentials from 0.0 to −0.7 V. In the presence of 2.5×10^{-5} M Cd^{2+}, a drastic decay of the intensity was observed by stepping the potential to a range of −0.48 to −0.70 V, in correspondence with the occurrence of UPD. In the initial phase of the intensity decay, a change in the SERS spectrum was also noted. These results are summarized in Fig. 2. Here the intensity is represented by the peak height of the totally symmetric vibration at 1007 cm^{-1} (I_{1007}), and the spectral shape by the intensity ratio I_{1007}/I_{1037}. The following features are noticed in this figure: (1) The intensity decay occurs essentially after the completion of Cd UPD, which takes less than 120 s as mentioned above; (2) The intensity decay apparently obeys a biphasic kinetics, with the time constant of the first phase being dependent on the potential (and hence on the θ_{Cd} value), while that of the second phase being practically potential-independent; and (3) The shape of the pyridine SERS spectrum undergoes a change exclusively during the first phase of the decay, and remains nearly unchanged throughout the second phase. The pattern of the spectral change, namely the direction of the change in the peak height ratio, is seen to depend on the potential. Besides such a peak height ratio change, some peak wavenumber shift was also noted (*e.g.*, a shift from 1007 cm^{-1} to 1009 cm^{-1} at −0.7 V within the initial 500 s). A change in the SERS spectrum as well as in the intensity has also been observed by Kester,[4] regarding the quenching of SERS in an Ag/benzotriazole (BTA) system by UPD of Tl, and was ascribed to some unknown effect of deposited Tl on the Ag–BTA interaction.

These results indicate that the SERS quenching in the Ag/pyridine system by UPD of Cd consists in the attack of deposited Cd atom to the initial "SERS-active site (A)" to produce a new site B (which is still SERS-active), followed by a unimolecular decomposition of B into a SERS-inactive site, X. Denoting the time constants of these sequential steps by τ_1 and τ_2, respectively, the quenching process could be represented by the following scheme:

$$A + Cd \xrightarrow{\tau_1} B \xrightarrow{\tau_2} X \qquad (1)$$

By assuming that the SERS activity of B is lower than that of A by a factor α ($0<\alpha<1$), a simple calculation leads to the following formula for the SERS intensity $I(t)$ at time t, normalized by the initial intensity $I(0)$:

$$I(t)/I(0) = e^{-t/\tau_1} + \frac{\alpha\tau_2}{\tau_2-\tau_1}(e^{-t/\tau_2}-e^{-t/\tau_1}) \qquad (2)$$

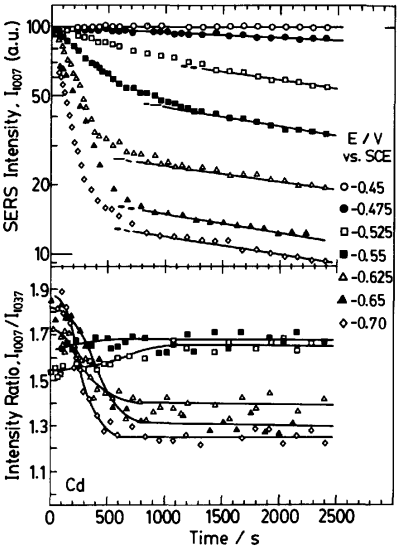

Fig. 2. Time courses of the pyridine SERS intensity (top) and its spectral shape (bottom) after potential steps from 0.0 V to a series of negative values.

Provided that the surface concentration of deposited Cd is sufficiently larger than that of the initial active site A, the first step is regarded as a pseudo-first-order process, with the time constant τ_1 inversely proportional to θ_{Cd}:

$$\tau_1 \propto \theta_{Cd}^{-1} \quad (3)$$

As an example, a result of curve fitting according to Eq. 2 is given in Fig. 3(A) for the decay profile observed at −0.55 V. The experimental points lie fairly well on the simulated curve with τ_1=370 s and τ_2=4860 s. Similar treatments have been conducted on the decay profiles at a series of potentials. In some cases, the curve fittings were not very satisfactory in the very initial phase of the decay; this is probably related to the simultaneous occurrence of spectral change in the initial phase. However, since the extent of the I_{1007}/I_{1037} ratio variation is much smaller (at most *ca.* 35% for E=−0.70 V) than that of the I_{1007} variation itself, we could obtain τ_1 values within a reasonable error range. The τ_1 and τ_2 values thus estimated are summarized in Fig. 3(B) as a function of the reciprocal of θ_{Cd}. It is evident that τ_1 changes in fair agreement with Eq. 3, and that τ_2 is practically constant around 4000—5000 s, suggestive of an intramolecular decay process.

In Fig. 2 we note that the fraction of the SERS intensity lost during the first phase of quenching depends on the electrode potential. Qualitatively this is accounted for as follows. The SERS-active sites are most probably surface Ag^+ complexes having both pyridine molecule(s) and chloride ions as ligands.[6] We could reasonably assume that the composition of

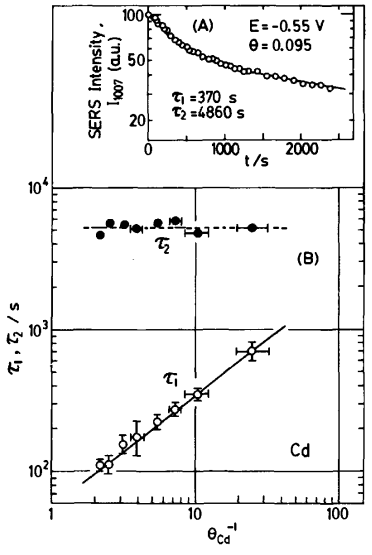

Fig. 3. (A) A typical result of analysis of the SERS intensity decay according to Eq. 2.
(B) Effect of θ_{Cd} on the values of τ_1 and τ_2.

the ligand is a function of the electrode potential, since at least the chloride ions tend to desorb from the surface by negative polarization. Thus the identities of the SERS-active sites A and B, and hence the value of α, should all vary with the electrode potential, leading to the observed potential dependence of the quenching efficiency during the first phase.

If we now assume that the first phase of quenching (interaction between A and Cd) occurs *via* surface diffusion of the deposited Cd atoms, an order-of-magnitude estimate of its diffusion coefficient can be made as follows. The average distance L (cm) between a single active site A and a nearest-neighbor Cd atom at the completion of UPD is roughly the average distance between the Cd atoms, and is thus the reciprocal of the square root of its surface concentration, C_{Cd} (atoms cm^{-2}): $L \simeq C_{Cd}^{-1/2}$. As the Cd atom moves on the surface with a diffusion coefficient D (cm^2 s^{-1}) for a period t (s), the average departure l (cm) from the origin is approximated by $(Dt)^{1/2}$. We then regard the average lifetime τ_1 (s) of the initial active site A as the value of t such that $L \simeq l$; thus $\tau_1 \simeq (DC_{Cd})^{-1}$ or $D \simeq (C_{Cd}\,\tau_1)^{-1}$. Referring to Fig. 3(A) one obtains $D \simeq 2.5\times10^{-17}$ cm^2 s^{-1} from $\tau_1 \simeq 400$ s and $C_{Cd} \simeq 10^{14}$ atoms cm^{-2}. Since several constants related to actual surface geometry have been dropped in this calculation, it would be safe to give $D \simeq 10^{-16}$—10^{-18} cm^2 s^{-1} as a rough estimate. Although there is no data available for the surface diffusion coefficient of Cd on the Ag surface, the range of D deduced above covers remarkably well the homogeneous and heterogeneous surface diffusion coefficients determined recently by field ion microscopic techniques at 25 °C (D in cm^2 s^{-1}): 7.6×10^{-19} for W atom on W(110),[10] 6.8×10^{-18} for Re on W(211),[11] 2.9×10^{-15} for Ta on W(110),[12] 6×10^{-18} for Ir on W(110),[12] and 5.1×10^{-17} for Pt on Pt(110).[13] This could be indirect evidence for the occurrence of surface diffusion of Cd in the first phase of the SERS quenching.

If the first step in Eq. 1 is a simple association between A and Cd, stripping (oxidative removal) of the latter is expected to recover the original SERS intensity. To examine this point we followed the SERS intensity at a Cd-free potential, −0.2 V, before and after the Cd UPD at −0.625 V. By controlling the holding time at −0.625 V, we were able to make the stripping of the deposited Cd either within the first phase or after the quenching had reached deep into the second phase. The results are displayed in Fig. 4. As expected, when the potential was stepped back to −0.2 V after holding it at −0.625 V for 120—600 s, which is substantially within the first phase of the quenching (Fig. 2), the SERS intensity was almost totally recovered. On the contrary, stripping after a 2400-s holding at −0.625 V regenerated the

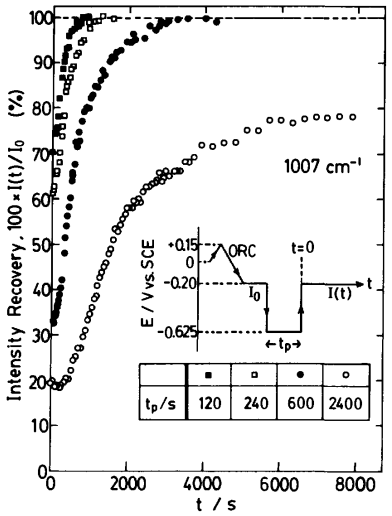

Fig. 4. Recovery of the pyridine SERS intensity observed by Cd stripping from the Ag electrode surface. The inset shows the potential programming.

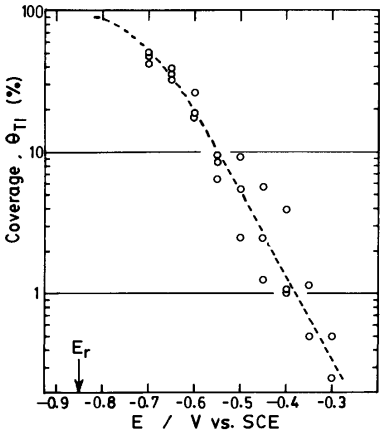

Fig. 5. Stationary Tl coverage on the electrode surface as a function of the electrode potential. $[Tl^+]=2.5\times10^{-5}$ M. E_r denotes the thermodynamic deposition potential.

original SERS intensity only to *ca.* 80%. The non-recovered fraction (20%) agrees fairly well with that calculated from Fig. 2 by means of Eqs. 1 and 2. These results indicate that the first step in Eq. 1 is of quasi-reversible nature, while the second step is an irreversible decomposition, though we are not yet sure about the actual mechanisms for these processes. Under an assumption that the initial SERS-active sites are sparingly soluble surface Ag^+ complexes having pyridine and Cl^- as ligands,[6] we tentatively propose that the second step of the quenching corresponds to an electron transfer from neutral Cd, being a reduced entity, to a surface Ag^+ center resulting in the disintegration of the Ag^+ complex. This may be in line with an observation by Kester,[4] that deposition of Tl onto the SERS-generating Ag/BTA interface leads to vanishing of BTA molecules from the surface, as evidenced by Auger spectroscopy.

The remarkable slowness of the intensity recovery noted in Fig. 4 suggests that the first phase of the quenching involves, in addition to a simple association between Cd and A, another kind of surface process. For instance, diffusion of state B toward the interior of the electrode bulk (or slight alloying), which could render the Cd atoms resistant to stripping, may be a candidate. This problem is however beyond the scope of the present paper.

The fact that Eq. 3 apparently holds fairly well at Cd surface coverages down to 0.04, or *ca.* 5×10^{13} atoms cm^{-2}, suggests, together with the assumption made in deriving Eq. 3, that the surface concentration of the initial active site A is on the order of 10^{12}—10^{13} sites cm^{-2}. Since a full coverage of pyridine on Ag corresponds to *ca.* 3×10^{14} molecules cm^{-2}, this again confirms the conclusion that the surface population of the SERS-active sites is considerably low.[1-3]

UPD of Tl. A series of similar kinetic measurements have been carried out also for the SERS-quenching effect of underpotentially deposited Tl. The potential dependence of the surface coverage, $\theta_{Tl}(E)$, determined by a procedure described above, is shown in Fig. 5. This result corresponds to a polarization time of 120 s, but we confirmed that the value of θ_{Tl} levels off within 50—100 s, as in the case of Cd UPD. Figure 5 reproduces a well-known tendency[9] that the surface coverage in the UPD region approaches unity as the potential approaches the thermodynamic deposition potential, E_r, which is −0.85 V *vs.* SCE in the present case.

Figure 6 is a counterpart of Fig. 2 (top). The pyridine SERS intensity decays again through a biphasic process, with the time constant of the first phase being dependent on the potential, while that of the second phase being nearly constant. This again

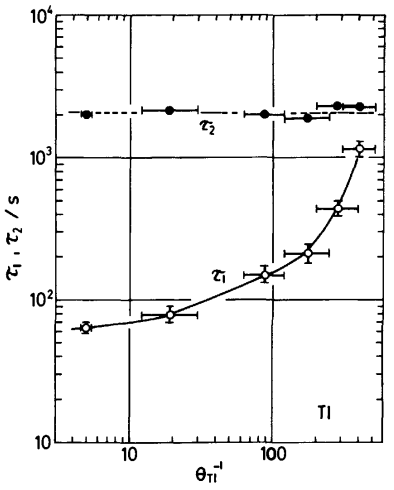

Fig. 7. Effect of θ_{Tl} on the values of τ_1 and τ_2.

suggests the occurrence of a sequential process as in Eq. 1. In comparison with the case of Cd UPD, the general quenching effect of Tl UPD is much more dramatic. For example, at E=−0.4 V, the stationary surface coverage of *ca.* 1% causes the SERS intensity loss of 93% in 2400 s (compare Figs. 5 and 6).

The biphasic decay profiles in UPD of Tl have also been successfully analyzed in terms of Eq. 2, and the τ_1 and τ_2 values thus derived are plotted in Fig. 7 against the reciprocal of θ_{Tl}. It is seen that the value of τ_2 is roughly constant at about 2000 s. The strong dependence of τ_1 on θ_{Tl} indicates that the first phase of quenching takes place *via* an interaction between the deposied Tl and the SERS-active sites. The non-linearity between τ_1 and θ_{Tl}^{-1}, however, suggests that the interaction is of more complicated nature than a simple one-to-one encounter process of the two surface species.

Two major differences were noted between deposited Cd and Tl in quenching the pyridine SERS. First, whereas the UPD of Cd caused a change in the spectrum as well as the intensity in the first phase of the quenching, such a spectral change was not observed by the UPD of Tl within experimental error. This is in contrast with the case of the SERS in the Ag/BTA system,[4] where both intensity and peak frequency underwent a change by UPD of Tl. This would probably reflect a difference in the extent of vibronic state perturbation by the attack of Tl between the two systems. Second, the SERS intensity, once quenched by the UPD of Tl, was hardly recovered by stepping the potential to a sufficiently positive value, irrespective of the holding time at the quenching potential. In the case of UPD of Cd, as stated above, the intensity could be recovered if the quenching had been limited to the first phase. This result suggests that the Tl atom, in an encounter complex such as B in Eq. 1, is bound to the initial SERS-active site so strongly that it apparently undergoes no oxidation within the time range of the present measurements (on the order of 1 h).

So far, the SERS-quenching effect of underpotentially deposited Tl has been reported on the Ag/pyridine[1,3] and Ag/BTA[4] systems. In the former system, and also in the present work, a surface Tl coverage on the order of 1% causes a drastic quenching. In contrast, the SERS signal in the latter system is affected by UPD of Tl only at relatively high surface coverages, and becomes noticeable at potentials negative of −0.5 V *vs.* SCE.[4] Such a difference could qualitatively be accounted for within the framework of the present scheme (Eq. 1), by making a reasonable assumption that there is a difference between the two systems in the stability of the SERS-active site against the attack of Tl. A significantly low value of the solubility product for the Ag^+–BTA salt ($10^{-13.6}$),[14] in comparison with that for the Ag^+–pyridine salt ($10^{-9.8}$), suggests that the strength of the Ag^+–BTA bond is higher than that of the Ag^+–pyridine bond.

The authors are grateful to Prof. Katsumi Niki, Faculty of Engineering, Yokohama National University, for his encouragements during this work, and to Mr. Hiroyuki Katoh for his participation in part of the experiments.

(Received February 5, 1985)

A stable radioactive source *in vacuo* was obtained by a modified horizontal lifting method of Langmuir-Blodgett (L/B) film. In spite of the slight consumption of the substrate solution (only 2—2.5 ml) for preparing a 15 mm×25 mm sized L/B film containing four molecular layers of ^{109}Cd icosanoate, the deposition of the film was complete. The reliability of the deposited films by this method was confirmed by their radioactivities, deposition ratios and autoradiographs. The condition to obtain a larger sized homogeneous L/B film (20—25 mm×102 mm) was also examined. Two or four molecular layers of nonradioactive Cd icosanote deposited on the L/B film of ^{109}Cd icosanoate did not influence the intensity of the γ-ray of 88.0 KeV. Concequently, it is possible to obtain the high radioactive source by the deposition of the multilayers of ^{109}Cd icosanoate. Spectra of L_2 and L_3 conversion electrons from the ^{109}Cd in its built-up film were also determined. In conclusion, the present depositing method for the L/B film is excellent for the manufacturing the radioactive source and thought to be also applicable for the deposition of other valuable materials.

A Langmuir-Blodgett (L/B) multilayer film is superior to the ordinary vacuum deposition films in the homogeneity of the lateral direction and the uniformity of the thickness together with other advantages of their easy and reliable controllability. The L/B film of soap of a radioactive metal is, therefore, expected to be an excellent radioactive source. There are, however, two problems for the preparation of a high radioactive L/B film by the commonly used depositing method, *i.e.*, the vertical dipping method.[1] One big problem is that a great amount of radioisotope is necessary by the method. Another problem is the contamination by radioactive material on the undesirable side of the substrate plate. To reduce the amount of the radioactive material and prevent the contamination of the back side of the plate in its built-up process, a modified horizontal lifting method was devised and applied to the deposition of ^{109}Cd icosanoate monolayer, combining with an extremely shallow Teflon trough whose inside was treated with oxygen plasma to be hydrophilic. To make sure the reliability of this method, the linear relationship was confirmed between the radioactivity and the deposited amount of the source, and the uniformity of the built-up films was established by the autoradiography. The stability of the source under high vacuum and the influence of the film thickness on the intensity of the γ-ray from ^{109}Cd nucleous were also examined. The built-up film of ^{109}Cd icosanoate was utilized finally as a radioactive source in vacuum.

Experimental

A sample of icosanoic acid (purity of 99.5%, Fulka AG. Swizerland) was dissolved in benzene to make a spreading solution of 1×10^{-3} mol dm^{-3}. 500μCi and 5mCi of carrier-free cadmium-109 were supplied from Amersham (Buckinghamshire, England) as $^{109}CdCl_2$ in 0.1 M HCl. After the isotopic dilution with $CdCl_2$ and the removal of the HCl by distillation from the solutions, the aqueous solutions of radioactive $CdCl_2$ (specific activity of 0.9 or 445mCi mmol^{-1}) were prepared. The pH of the solution was adjusted to be 7—7.8[2] by the addition of a small amount of the aqueous solution of NaOH (electronic grade, Kanto Chemical Co., Tokyo). Iron(III) octadecanoate (the purest grade of Tokyo Kasei Industry Co., Tokyo) was used for the pretreatment of the surfaces of aluminium plates (20 or 25 mm×102 mm×1 mm) and resistive substrate plates (15 mm×25 mm×1 mm or 40 mm×25 mm×1 mm, Japan Fine Co., Tokyo) which were made from a mixture of ruthenium oxide with glass and printed on alumina plates. Water for the underlying ^{109}Cd solution was triply distilled, the second distillation being from alkaline permanganate, and was contained in a very shallow Teflon trough (15 mm×120 mm×0.5 mm or 1mm, 40 mm×200 mm×1 mm, or 20 or 25 mm×280 mm×1 mm) whose inside was hydrophilic by the glow discharge in an oxygen atmosphere,[3] and whose rims remained hydrophobic by protective adhesive tapes. The hydrophilic property of the inside of the trough is very important because an aqueous

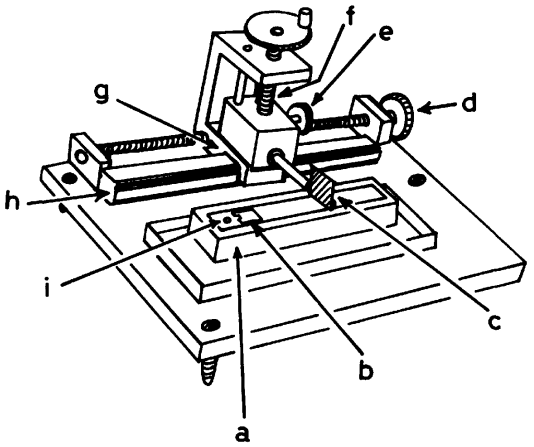

Fig. 1. Apparatus for the deposition of Langmuir-blodgett film. **a** denotes the Teflon trough whose inside is hydrophilic; **b**, Floating barrier (thin mica) coated with paraffin, having a small check at its end for the convenience of setting a small amount of piston oil; **c**, Substrate plate for built-up film; **d**, Wheel for moving the slide unit; **e**, Wheel for turning the substrate plate which was rotated by a hand or a mechanical operation with a motor and gears; **f**, Lifting screw; **g**, Slide unit; **h**, Track rail; **i**, 9-octadecenoic acid drop as a piston oil.

solution on a hydrophobic surface has a large contact angle and does not spread fully on the surface. If the inside of the shallow trough is hydrophobic, a small amount of the aqueous solution, therefore, can not fill the trough. Only 2—2.5 ml of solution was required to fill the small hydrophilic trough and 14—16 ml for the another large troughs. After sweeping the solution surface by a hydrophobic glass barrier treated with dimethyldichlorosilane,[4] a thin mica plate (13.5 mm×15 mm×0.1 mm, 38 mm×50 mm×0.1 mm, 18 mm×25 mm×0.1 mm or 23 mm×30 mm×0.1 mm) coated with paraffin[5] was placed on the surface and used as a movable barrier. As shown in the Fig. 1, the mica plate (b) had a small check at its one end for the convenience of setting a small amount of piston oil drop. The piston oil drop should not contact with the movable barrier because such a contact prevents sometimes the smooth movement of the barrier. The oil drop was set therefore in contact with the end wall of the trough. The floating barrier can move smoothly by the repulsion[6] between the hydrophilic trough and the hydrophobic ends of the movable barrier. A thin Teflon plate or a paper plate coated with paraffin was not suitable for the movable barrier in such the shallow trough because of its warping. The monolayer of ^{109}Cd icosanoate was deposited at the surface pressure of 29.5 mN m^{-1} with 9-octadecenoic acid (the purist grade of Merck AG., Darmstadt, German) using an apparatus shown in Fig. 1. After touching the substrate plate almost horizontally and gently on the monolayer surface from its one end, the plate was turned gradually by a hand or a mechanical operation with a motor and gears, lifted and removed finally from the surface (see Fig. 2). Two molecular layers of the ^{109}Cd icosanoate were deposited on the substrate plate by this process. The repetition of this process produced an additional deposition of two molecular layers. In order to achieve the

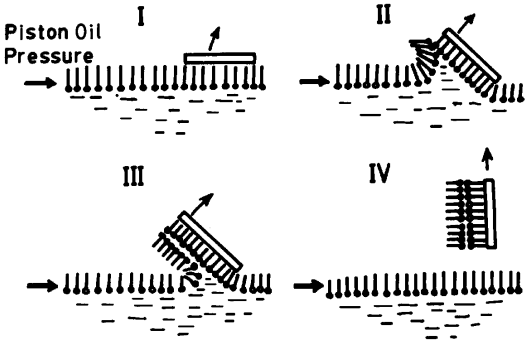

Fig. 2. Scheme of the deposition process of ^{109}Cd icosanoate monolayer on a substrate plate.

complete deposition of the rigid monolayer onto the substrate plate, we should set the plate as close as possible to the end of the floating mica plate: Its possible smallest distance from the mica plate is apparently two times of the length of the substrate plate. This depositing method giving Y-film resembles the horizontal lifting method,[7] which gives X-film, in the first contact of the plate with the monolayer and the vertical dipping method during the gradual turning and removing of the plate. The radioactivity (characteristic γ-ray of 88.032 KeV of ^{109}Cd) of the L/B film was detected with a coaxial Ge (Li) detector (ORTEC Inc. Co., Oak Ridge, USA); a known amount of ^{109}Cd sample was used for the calibration of the radioactivity. LKB2208 Biofilm (Amuko Co. Ltd, Tokyo) was used for the autoradiography of the built-up film obtained.

The stability of the L/B film *in vacuo* was confirmed by the following method. An aluminum plate was fixed in front of the L/B film of the ^{109}Cd icosanoate (the specific activity of 0.9 mCi/mmol) with a 1 mm gap; the whole source, including the plate and the ^{109}Cd film, was set in a vacuum chamber and evacuated to a pressure of 10^{-3} Pa at room temperature (*ca.* 298 K) for a week. After the experiment, the radioactivities of the L/B film and the Al plate were detected, respectively.

Spectra of L_2 and L_3 conversion electrons (84.508 and 84.681 KeV,[8] respectively) from ^{109}Cd source prepared was measured with an INS double forcusing $\pi\sqrt{2}$ air-core β-ray spectrometer[9] and a position sensitive single-wire proportional counter[10] which had the position resolution of 1.3 mm. The momentum resolution of the counter was 0.04%.

Results and Discussion

Figure 3 shows the relationship between the relative radioactivity, R_r, of the two molecular layers of ^{109}Cd icosanoate deposited on the 15 mm×25 mm sized resistive plate and the concentration of the underlying ^{109}Cd solution. The relative radioactivity is defined as the following equation,

$$R_r = \frac{R_{obs}}{R_c}, \quad (1)$$

where R_{obs} denotes the experimental value of radioactivity and R_c, the calculated value assuming the stoichiometric bonding of a ^{109}Cd ion and two icosanoic acid molecules in the deposited L/B film. The characteristic S-shaped curve was obtained and saturated to unity above at the concentration of 1×10^{-4} mol dm.$^{-3}$ The result agrees with that by Petrov *et al.*[2] using the neutron activation analysis of cadmium species. This radioactive saturation indicates that the binding between cadmium ion and the monomolecular film of the fatty acid is complete.

We used therefore the ^{109}Cd solution of 1.2×10^{-4} mol dm^{-3} as the substrate solution for the further experiment.

Figure 4 shows the relationship between the radioactivity and the number of monolayers of ^{109}Cd icosanoate deposited on the resistive plate. A good linearity was obtained. In this fugure the full diamond, whose value is calculated from the specific activity of the $^{109}CdCl_2$, the molecular area of the icosanoic acid on the $CdCl_2$ solution of 1.2×10^{-4} mol dm^{-3} at the pressure of 29.5 mN m^{-1} and the number of layers, agrees exactly with the experimental result. A simular good linearity was observed when using the large resistive plate (40 mm×25 mm),

the wide trough and the higher specific active $^{109}CdCl_2$ subsolution. These evidences suggest that the deposition of the ^{109}Cd icosanoate monolayer on the substrate plate was perfectly achieved by this method. This suggestion has been also confirmed by the facts that the trasfer ratio of the ^{109}Cd icosanoate monolayer on the substrate plate was exactly unity and that the autoradiographs taken for these built-up films (15 mm×25 mm or 40 mm×25 mm) deposited by manual operation were entirely uniform. For the larger substrate plate (102 mm in length), however, the deposited film, especially the second layer of the film, peeled off the plate (see Fig. 5) regardless of a careful turning of the plate by the manual operation. Thus we adopted a motor and gears to rotate the substrate plate with a constant angular velocity. Figure 6a shows a typical example of the relationship between a shift of the movable float, l, and an angle, θ, of the turning substrate plate (102 mm in length) to the water surface. By θ being 10° the angular velocity was regurated to be 0.33° min^{-1} and, beyond the angle, 0.7° min^{-1}. Up to 30° the most monolayer (*ca.* 90%) was transfered from water surface to the substrate plate.

A slope of the tangent to the l—θ curve is plotted against θ in Fig. 6b. We can find that the float shifts most significantly at *ca.* 3°. From the $\Delta l/\Delta\theta$ value at

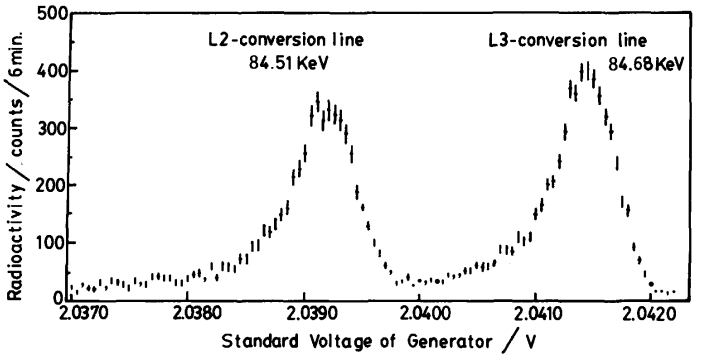

Fig. 10. A spectrum of 88 KeV-L_2 and L_3 conversion electrons (84.508 and 84.681 KeV) from ^{109}Cd source obtained. The source thickness was two-molecular layers; the source activity, 3.7 μ Ci; the source area, 40 mm × 25 mm. SVG (standard voltage of generator[9]) step: 0.00005/V.

this angle and the constant angular velocity (0.33°/min), the largest shift velocity (V_{max}) of the float was calculated to be *ca.* 10 mm min^{-1}. The V_{max} is defined in general by the length of the substrate plate and the angular velocity. The uniformity of the autoradiographs and the deposition ratios of the several built-up films were thus examined to their corresponding V_{max} values. The monolayers were deposited completely at V_{max}<10 mm min^{-1} while the deposited monolayer often peeled off the plate at V_{max}> 10 mm min^{-1}. Several examples are shown in Fig. 7.

In order to obtain a high radioactive source of the L/B film, it is necessary to deposit many number of radioactive molecular film. For such the source, the absorption of the radiation by the films themselves comes into a problem. Figure 8 shows the radioactivities of three samples of the two molecular layers of ^{109}Cd icosanoate (sp. ac. 445 mCi mmol^{-1}) deposited on 40 mm×25 mm sized resistive plate. The second (b) and the third (c) samples contain the additional two and four layers of nonradioactive Cd icosanoate monolayer on the radioactive two hayers, respectively. These three values are almost equal to each other within the experimental error. For the γ-ray of 88.0 KeV, therefore, the influence of its absorption seems to be almost negligible. In addition the result of these constant radioactivities suggests that the additional deposition of the nonradioactive Cd monolayers does not cause the isotope exchange between the ^{109}Cd in the deposited monolayers and the nonradioactive Cd ion in the subsolution in the short period of the additional depositing process (*ca.* 12—3 min).

For the application of the L/B film of ^{109}Cd icosanoate as the radioactive source, its stability *in vacuo* is essential, because the radioactive sources are often used under high vacuum. The test of the stability of the L/B film of ^{109}Cd icosanate (two-molecular layers) *in vacuo* was, threrefore, carried out. After the one week evacuation of the sample at 10^{-3} Pa any reduction of the radioactivity of the L/B film was not observed and the radioactivity was also not detected from the Al plate as shown in Fig. 9. Futhermore, the contents in a liquid nitrogen trap did not show any radioactivity of ^{109}Cd. The stability of the L/B film *in vacuo* was thus confirmed.

Figure 10 shows a spectrum of L_2 and L_3 conversion electrons from the two layers of ^{109}Cd icosanoate (40 mm×25 mm, 3.7μCi). Two peaks due to the above conversion electrons, whose energies are very close each other, were sharp and apparently distinguishable each other. The momentum resolutions obtained from the half-value widths of the peaks were 0.029 and 0.030% for the peaks of L_2 and L_3 conversion electrons, respectively.

The depositing method for the L/B film is excellent, therefore, for preparing the radioactive source and thought to be also applicable for the deposition of other valuable materials.

The authers wish to express their thanks to Prof. Kiyoshige Fukuda and Dr. Hiroo Nakahara of Saitama University for their helpful suggestions and discussions and to Mr. Masateru Kasuya and Mr. Takeo Fujino of INS workshop in The University of Tokyo for their part in constructing the apparatus for the built-up of monolayers. The present work was partially supported by a Grant-in Aid for Scientific Research No. 57460010 from the Ministry of Education, Science and Culture. We thank this supporting agency for making this study possible.

Complex Formation in Cationic Dye-Organic Anion Systems in Aqueous Solution

Sanyo HAMAI
Department of Physics, Miyazaki Medical College, Kiyotake, Miyazaki 889-16
(Received February 12, 1985)

The interaction between a cationic dye, Methylene Blue (MB), and organic anions (1-naphthalenesulfonate, 2-naphthalenesulfonate, 1-naphthaleneacetate, 2-anthracenesulfonate, 2,7-naphthalenedisulfonate, and 1,3,6-naphthalenetrisulfonate) in aqueous solution has been investigated by means of absorption and fluorescence spectra. The red shifts of the absorption and fluorescence spectra of MB caused by the addition of the organic monoanion are attributed to the 1:1 complex formation between MB and the organic anion. The thermodynamic quantities as well as the equilibrium constants for the complex formation have been determined. From the finding that the absorption spectrum of MB is not affected by the addition of ethanesulfonate, it is concluded that the complex formation is due to the interaction between the MB cation and the aromatic ring in the organic anion. The addition of polyanion (*e.g.*, 2,7-naphthalenedisulfonate) in the low-concentration range accelerates the dimerization of MB; whereas, in the high-concentration range, the formation of the 1:1 complex rather than the MB dimer is dominant. Studies on the complex formation with monoanions have also been made for Rhodamine 6G, Pyronine G, Safranin T, and Crystal Violet, and similar results to that for MB have been obtained.

Studies regarding the interaction between organic cations and organic ions are roughly divided into four categories. The first is the area related to the self-association of a dye in aqueous solution.[1-7] This association is due to an interaction between the organic ions of the same kind having a positive charge. Since the concentration ratio of the dimer to the monomer of the dye increases with an increase in the dye concentration, the electronic absorption of the dye does not follow the Beer-Lambert law.

The second is that related to the adsorption of a cationic dye on the surface of an anionic micelle, an anionic lipid membrane, or a microemulsion.[8-13] This interaction is attributed to the electrostatic attraction between the cationic dye and the anionic micelle, *etc.* Since the adsorption also induces a change in the absorption and/or fluorescence spectrum of the dye, the spectral change can be used for the determination of the critical micelle concentration.[8]

The third is related to a phenomenon known as metachromasy which is observed when an anionic polymer is added into a dye solution.[14-19] This phenomenon is accompanied by a shift of the first electronic absorption band to shorter wavelengths. Inorganic anions have also been reported to cause metachromasy.[20] Metachromasy is mainly elucidated either by the association of dye under the influence of the anionic polymer or by the interaction of dye with added anion.

The fourth is that related to a complex formation between an organic cation and an organic anion. By the addition of *N*-hexadecylpyridinium chloride (below its critical micelle concentration), a solution of 2-naphtholate becomes pale yellow and its fluorescence is quenched.[21] Both the appearance of the color and the fluorescence quenching have been explained in terms of complex formation.

Gicquel *et al.* have studied the complex formation of Crystal Violet with sulfonated azo derivatives by means of resonance Raman and electronic absorption spectra.[22] They suggested that the blue shift of the absorption band of Crystal Violet is related to the approach of the sulfonate group in the azo dye to the central carbon in Crystal Violet.

Solvent effects on the charge-transfer band energies of organic cation–organic anion complexes have been investigated by Beaumont and Davis.[23] Compared with organic cation–iodide complexes, the charge-transfer bands of organic cation–organic anion complexes are notably less solvent sensitive, this insensitivity being particularly marked in cation–neutral molecule complexes.

The pressure effect on the complex formation between 1-methyl-3-(methoxycarbonyl)pyridinium cation and 8-chlorotheophyllinate anion has been studied by Williams.[24] The complex formation of methylviologen with a porphyrin derivative has been pointed out.[25]

Organic charge-transfer salts composed of an organic cation (pyrylium or thiopyrylium) and an organic anion (1,1,3,3-tetracyanopropenide or tricyanomethanide) have been investigated by means of the absorption spectra.[26] The 1,2,3,4,5-pentakis-(methoxycarbonyl)cyclopentadienide anion is also known to form charge-transfer salts with tropylium, 2,4,6-trimethylpyrylium, *N*-methylpyridinium cations, *etc.*[27]

In spite of these studies, there is little information concerning the interaction between organic cations and organic anions. Thus, in selecting cationic dyes as organic cations, we have investigated an interaction between the dyes and the organic anions, naphthalenesulfonates, anthracenesulfonate, *etc.* in

aqueous solutions.

Experimental

Methylene Blue (MB), purchased from Wako, was recrystallized twice from water.[28] Rhodamine 6G obtained from Tokyo Kasei, Pyronine G from Chroma, and Safranin T from Tokyo Kasei were recrystallized twice from ethanol. Crystal Violet from Tokyo Kasei was recrystallized twice from water. Sodium 1-naphthalenesulfonate (1NS) from Tokyo Kasei and sodium 2-naphthalenesulfonate (2NS) from Wako were recrystallized twice from a water–ethanol mixture. Sodium 1-naphthaleneacetate (1NA) from Wako was recrystallized twice from a 1-butanol–hexane mixture. Sodium 2-anthracenesulfonate (2AS) was synthesized from sodium anthraquinone-2-sulfonate,[29] and recrystallized three times from water. Disodium 2,7-naphthalenedisulfonate (NDS) and trisodium 1,3,6-naphthalenetrisulfonate (NTS) were purchased from Tokyo kasei, and recrystallized twice from a water–ethanol mixture.

Absorption spectra were measured with a Hitachi 124 or a Shimadzu 260 spectrophotometer. The fluorescence spectra were recorded on a Shimadzu RF-501 spectrofluorometer equipped with a cooled Hamamatsu R-943 photomultiplier. The spectral response of the spectrofluorometer was determined by the previous method.[30] Measurements were made at 25 °C unless otherwise stated. In order to avoid the concentration change of a dye caused by adsorption on a glass surface, all the glass wares (volumetric flasks, pipets, *etc.*) used for sample preparations were soaked with a dye solution, and then rinsed with water immediately before use.

Results and Discussion

Complex Formation of Methylene Blue (MB) with Sodium 2-Naphthalenesulfonate (2NS). Figure 1 shows the absorption spectra of 10^{-5} M (1 M= 1 mol dm^{-3}) aqueous solutions of MB with varying concentrations of 2NS. The absorption maximum of MB shifted to the red as the concentration of 2NS increased. Below a 2NS concentration of 5×10^{-3} M, an isosbestic point is observed at 680 nm. The spectral change presented in Fig. 1 is attributed to the 1:1 complex formation between MB and 2NS. The possibility that such a spectral change is caused by a change in pH or ionic strengths of the sample solutions can be ruled out from the findings that nearly the same spectral change was observed for buffered solutions at a pH 6.7 (0.033 M potassium dihydrogenphosphate–0.033 M disodium hydrogenphosphate) or solutions containing 0.1 M NaCl. Although the MB dimer exists even at a concentration as low as 10^{-5} M, the concentration ratio of the MB dimer to the MB monomer is calculated to be only 1.5% from the data of the equilibrium constant for the dimerization of MB.[3] Therefore, the effect of the MB dimer on the concentrations of the MB monomer and the complex can be neglected under the conditions of the low concentration of the complex. This explains the appearance of the isosbestic point in the absorption spectra of the MB solutions containing 2NS below 5×10^{-3} M.

The absorption spectrum of MB did not change by the addition of sodium ethanesulfonate up to 0.1 M. This indicates that the interaction between MB and 2NS to form the complex is that between an MB cation and a naphthalene ring in 2NS rather than that between an MB cation and a sulfonate group in

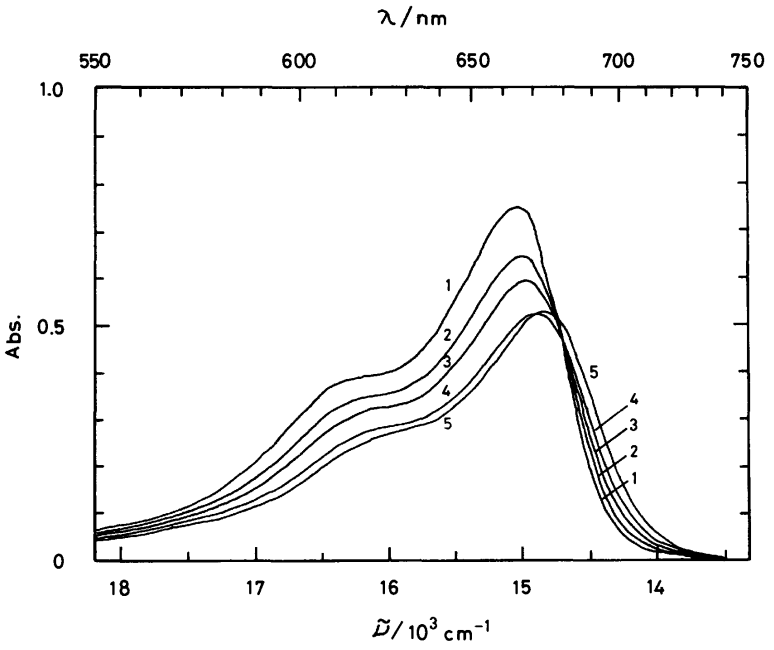

Fig. 1. Absorption spectra of MB (10^{-5} M) in aqueous solution in the presence of 2NS. Concentration of 2NS: 1, 0 M; 2, 10^{-3} M; 3, 2×10^{-3} M; 4, 5×10^{-3} M; 5, 10^{-2} M.

2NS although the attractive force between an MB cation and a sulfonate group may play an important role in the early stage of the complexation. On the other hand, for the complexes formed between Crystal Violet and sulfonated azo derivatives, it has been suggested that the central carbon in Crystal Violet interacts with the sulfonate group in the azo dye.[22] As mentioned above, the maximum of the absorption spectrum of Crystal Violet is shifted to the blue region in contrast to the red shift of the absorption maximum in the MB-2NS system.

When the existence of the dimer of MB is ignored, the absorption-spectrum change can be analyzed by the following equation:[31]

$$\frac{[MB]_0}{A-A_0} = \frac{1}{\varepsilon_1-\varepsilon_0} + \frac{1}{(\varepsilon_1-\varepsilon_0)K'}\frac{1}{[2NS]}, \quad (1)$$

where A and A_0 are the absorbances in the presence and absence of 2NS, $[MB]_0$ is the initial concentration of MB, ε_1 and ε_0 are the molar absorption coefficients of the 1:1 complex, MNS, and MB, K' is the equilibrium constant for the formation of MNS under the assumption of neglecting the MB dimer, and [2NS] is the initial concentration of 2NS. A plot of $[MB]_0/(A-A_0)$ *vs.* 1/[2NS] at 660 nm is shown in Fig. 2 (line (a)). A straight line is obtained with the equilibrium constant $K'=340\ M^{-1}$. In order to evaluate the more precise value of the equilibrium constant, we must take into account the existence of the MB dimer. When such a consideration is made, Eq. 1 becomes

$$\frac{[MB]+[MNS]}{A-A_0'} = \frac{1}{\varepsilon_1-\varepsilon_0} + \frac{1}{(\varepsilon_1-\varepsilon_0)K}\frac{1}{[2NS]}, \quad (2)$$

where [MB] and [MNS] are the concentrations of the MB monomer and MNS, A_0' is the calculated absorbance of [2NS] under the assumption that MNS thoroughly dissociates to MB and 2NS without a variation of the concentration of the MB dimer, and K is the equilibrium constant for the formation of MNS. A_0', [MB], and [MNS] were calculated using the K' value estimated from a plot of Eq. 1 and the literature value of the equilibrium constant for the dimerization of MB.[3] A plot of $([MB]+[MNS])/(A-A_0')$ *vs.* 1/[2NS] at 660 nm is shown in Fig. 2 (line (b)). The plot for Eq.2 also yields a good straight line. From the intercept and the slope, K was determined to be $400\ M^{-1}$, about 15% larger than K' ($=340\ M^{-1}$). Furthermore, we tried to construct a plot for Eq. 2 using K in place of K' for the calculations of A_0', [MB], and [MNS]. However, the new value of K, thus obtained, was identical with the previous value of K obtained by the use of K'.

In order to apply an alternate method which requires no correction for the MB dimer formation, we used a dilute MB solution containing only a negligible amount of the MB dimer, although the experimental error became larger owing to the smaller absorbance of the dilute solution. For a 2×10^{-6} M MB solution, the change in the absorp-

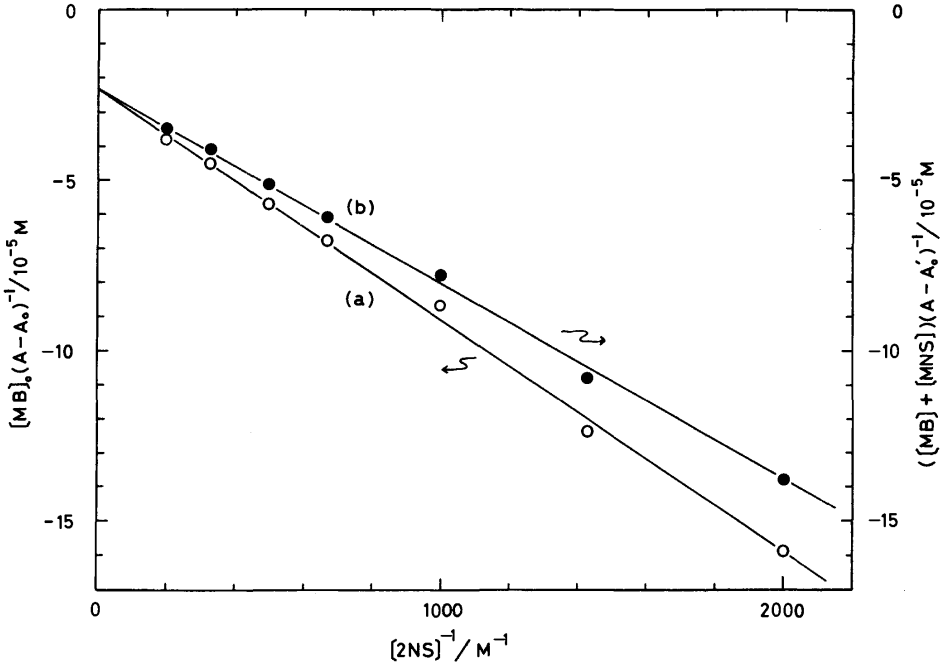

Fig. 2. (a) Plot of $[MB]_0/(A-A_0)$ *vs.* 1/[2NS] at 660 nm. (b) Plot of $([MB]+[MNS])/(A-A_0')$ *vs.* 1/[2NS] at 660 nm.

tion spectrum with the addition of 2NS was very similar to that for the 10^{-5} M MB solution. The equilibrium constant (=410 M^{-1}) evaluated from the absorption-spectrum change for the 2×10^{-6} M solutions was in excellent agreement with that of the 10^{-5} M solutions.

For the fluorescence measurements, 2×10^{-6} M solutions of MB were used to eliminate the reabsorption of fluorescence by the dye. Figure 3 shows the fluorescence spectra of MB in the absence and presence of 2NS which are normalized at the intensity maxima. With the increase in the 2NS concentration, the fluorescence intensity decreases accompanied by the red shift of the spectrum. Such changes in the fluorescence spectrum as well as the absorption spectrum are due to the complex formation between MB and 2NS. From the dependence of the fluorescence intensity on the 2NS concentration, the equilibrium constant for the complex formation was estimated by a similar method to that employed in the absorption study.[31] The equilibrium constant thus obtained is 370 M^{-1}, which agrees reasonably well with those obtained from the change in the absorbance both for the 2×10^{-6} and 10^{-5} M MB solutions. The equilibrium constants determined from the measurements of the absorbance and fluorescence intensity correspond to those in the electronic ground state and the excited state of MB, respectively. The good agreement between the equilibrium constants in the ground and excited state arises from the shortness of the fluorescence lifetime of MB.[32]

Temperature Dependence of the Equilibrium Constant. The temperature dependence of the equilibrium constants obtained from the measurements of the absorption and the fluorescence was examined over a temperature range from 3 to 43 °C. These results are shown in Fig. 4. Good straight-line relationships are obtained with the same slope and intercept for both methods. The enthalpy change ΔH and the entropy change ΔS for the complex formation are determined to be -28 kJ mol^{-1} and -46 J K^{-1} mol^{-1}, respectively.

The positive value of ΔS has been reported for the dimerization of Rhodamine B[33,34] in contrast to the negative value of ΔS usually evaluated for the aggregation of two molecules.[35-37] Generally, ΔS for the complex formation can be divided into two parts, ΔS_c and ΔS_s. Here, ΔS_c is the entropy change for the complexation which does not involve the succeeding reorientation process of solvent molecules, and ΔS_s is the entropy change for the reorientation of solvent molecules immediately after the association between two species. Because an MB cation associates with a negatively-charged 2NS molecule to form a neutral complex MNS, solvating water molecules surrounding an MNS complex may be expected to orient more randomly than those surrounding an uncomplexed, charged MB or 2NS molecule. Such a deduction leads to a positive value of ΔS_s. Our experimental result provides a negative value of ΔS for the complex formation. The implication is that the negative value of ΔS_c may prevail over the positive value of ΔS_s in the MB-2NS system, resulting in a negative value for the net ΔS.

Complex Formation of MB with Other Organic

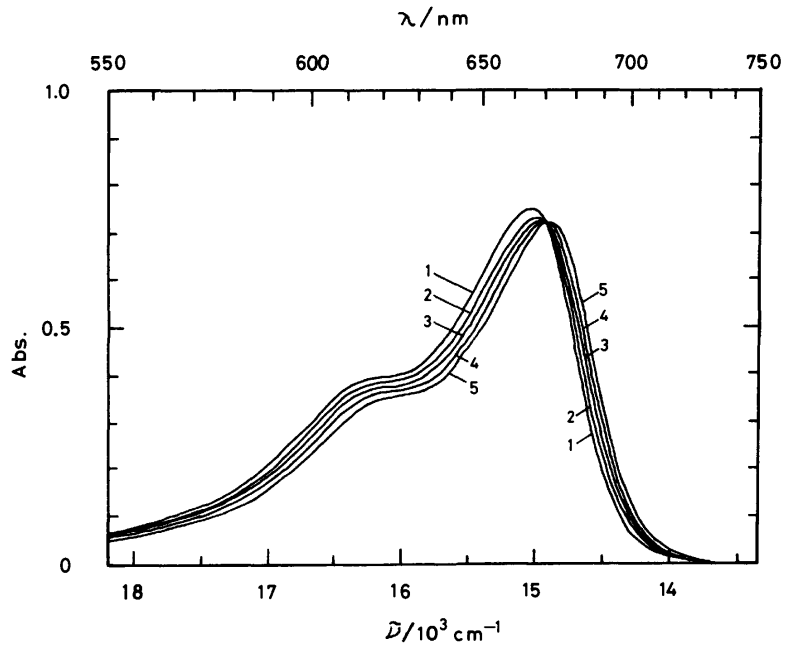

Fig. 5. Absorption spectra of MB (10^{-5} M) in aqueous solution in the presence of 1NS. Concentration of 1NS: 1, 0 M; 2, 2×10^{-3} M; 3, 5×10^{-3} M; 4, 10^{-2} M; 5, 2×10^{-2} M.

Monoanions. In addition to 2NS, the absorption and fluorescence spectra were similarly studied for other organic monoanions, 1-naphthalenesulfonate (1NS), 1-naphthaleneacetate (1NA), and 2-anthracenesulfonate (2AS). Figures 5 and 6 show the absorption spectra of MB solutions containing varying concentrations of 1NS and 2AS, respectively. As in the case for 2NS, both a red shift of an absorption maximum and an isosbestic point are observed on adding the monoanion. The 1:1 complex formation between

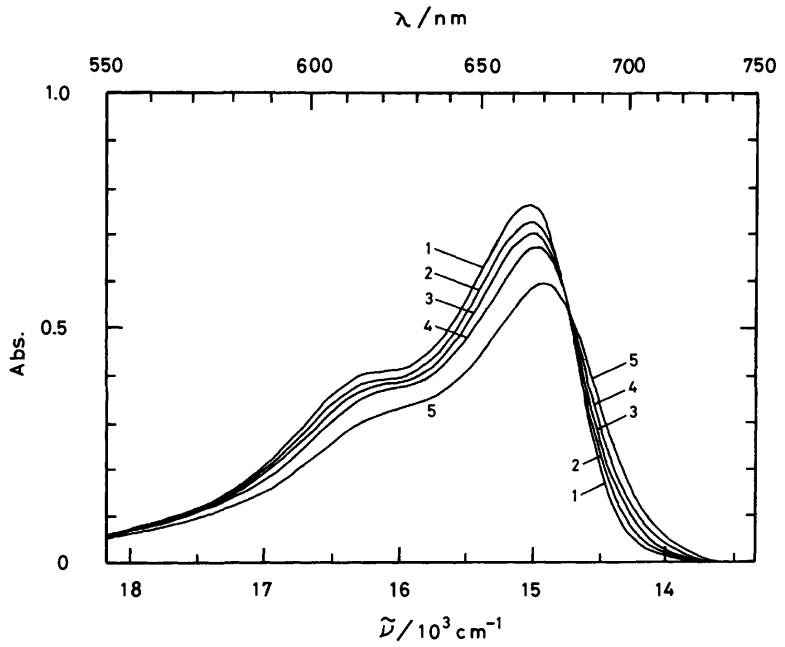

Fig. 6. Absorption spectra of MB (10^{-5} M) in aqueous solution in the presence of 2AS. Concentration of 2AS: 1, 0 M; 2, 2×10^{-5} M; 3, 5×10^{-5} M; 4, 10^{-4} M; 5, 2×10^{-4} M.

MB and the monoanion is responsible for these spectral changes. The equilibrium constants for the complex formation with 1NS, 1NA, and 2AS were determined to be 180, 240, and 7400 M^{-1}, respectively. The markedly large equilibrium constant for 2AS provides evidence that the interaction in the complex formation involves the aromatic ring in the anion.

The fluorescence spectrum of MB in the presence of 1NS is entirely similar to that in the presence of 2NS. In contrast, only the quenching of the MB fluorescence was observed for the MB-2AS system, indicating that the MB-2AS complex is nonfluorescent. The triplet state of the complex, derived primarily from the lowest triplet state of 2AS, may be assumed to lie in energy close to the lowest triplet state of anthracene (14900 cm^{-1}).[38] On the other hand, the energy of the first excited singlet state of the complex is estimated to be $\approx$14400 cm^{-1} from the maximum positions of the absorption and fluorescence of the complex. Since the maximum position of the complex fluorescence was found to be nearly constant irrespective of the kinds of anions, the peak position of the MB-2NS fluorescence was used in the above estimate. From the relationship between the energy levels of the complex, it is suggested that the nonradiative relaxation occurs with high efficiency through the triplet state derived primarily from 2AS.

The values of ΔH for the complex formation with 1NS, 1NA, and 2AS are determined to be -30, -28, and -49 kJ mol^{-1}, respectively, and the values of ΔS for 1NS, 1NA, and 2AS are -53, -47, and -92 J K^{-1} mol^{-1}, respectively. The absolute values of both thermodynamic quantities for 2AS are about two-fold larger than those for 2NS, 1NS, and 1NA. This finding also confirms a much stronger interaction of MB with 2AS possessing the anthracene ring than that with the anions possessing the naphthalene ring.

The addition of sodium benzenesulfonate to an MB solution results in no change in the absorption spectrum of MB within experimental error. The redox potential of MB in aqueous solution has been reported to be +0.011 V.[39] This value is high enough to form an electron donor-acceptor (EDA) complex with an appropriate electron donor. Whether the organic anions form EDA complexes with electron acceptors (tetracyanoethylene and chloranil) or not was not confirmed owing to the insolubility of these acceptors in water; however, the ionization potentials of the organic anions are probably not too different from the corresponding, unsubstituted aromatics which are known to form EDA complexes. In the complexes between MB and the organic anions, it seems to be reasonable that MB is an electron acceptor and the organic anions are electron donors.

Complex Formation of MB with Di- and Trianions. Spectroscopic studies were also made for a dianion, disodium 2,7-naphthalenedisulfonate (NDS) and a trianion, trisodium 1,3,6-naphthalenetrisulfonate (NTS). The absorption spectra of 10^{-5} M MB solutions with varying concentrations of NTS are

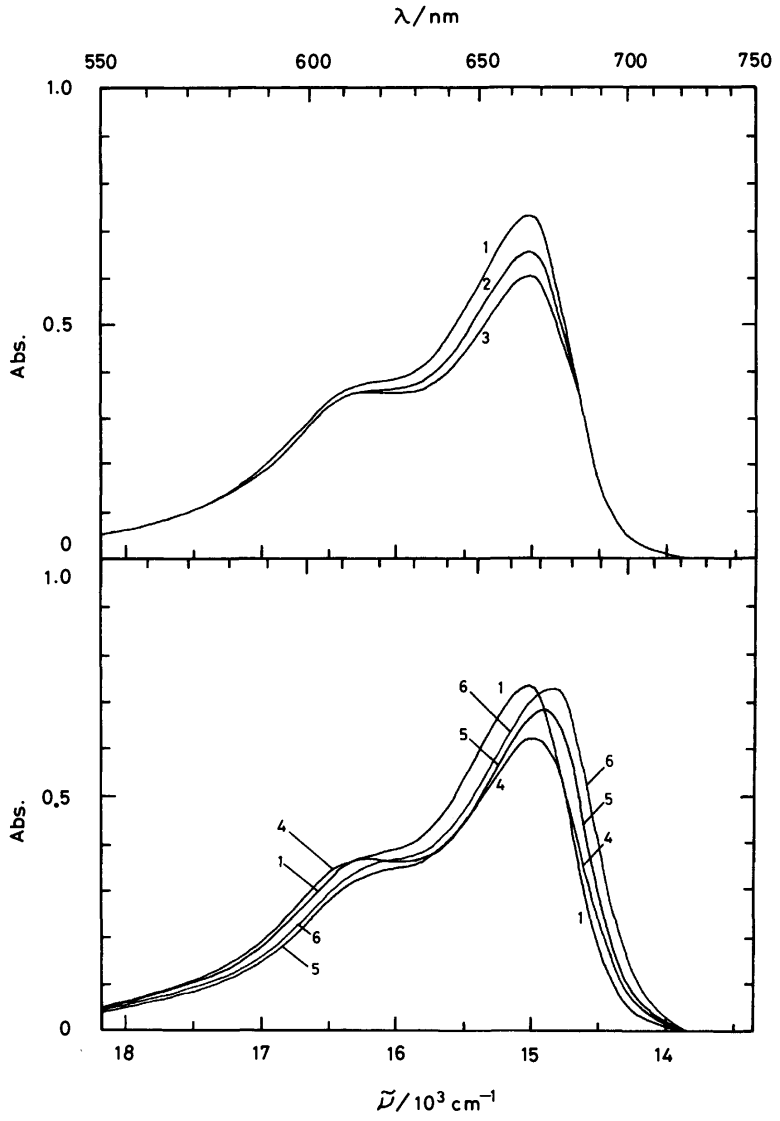

Fig. 7. Absorption spectra of MB (10^{-5} M) in aqueous solution in the presence of NTS. Concentration of NTS: 1, 0 M; 2, 5×10^{-5} M; 3, 2×10^{-4} M; 4, 10^{-3} M; 5, 10^{-2} M; 6, 5×10^{-2} M.

displayed in Fig. 7. Almost the same spectral change as in Fig. 7 was observed upon adding NDS. In contrast to the case of the monoanion (2NS, *etc.*), the absorption spectra of MB show a complicated change, exhibiting no isosbestic point. In the low-concentration range of NTS (below 10^{-3} M), the dimer peak appears at ≈610 nm and at the same time the monomer band decreases in intensity without the red shift of the monomer peak at 665 nm. However, as the concentration of NTS is increased above 10^{-2} M, the dimer peak starts to disappear accompanied by the recovery of the intensity and the red shift of the monomer band. In the low-concentration range of NTS, an MB molecule pairing with a sulfonate group substituted in an NTS molecule can easily associate with a neighboring MB molecule pairing with another sulfonate group substituted in the same NTS molecule because of the very close distance between the two MB molecules. The reason why the absorption spectra in the low-concentration range shown in Fig. 7 does not show a simple monomer-dimer equilibrium with an isosbestic point may be explained by the existence of a small amount of the 1:1 complex of MB with NTS and/or the complex of the MB dimer with NTS. Above an NTS concentration of 10^{-2} M, there is little chance that one NTS molecule is surrounded by more than one MB molecule. Under such situations, not the dimer of MB but the 1:1 complex between MB and NTS is formed. The elucidation for the absorption change shown in Fig. 7 is supported by the additional experimental result that, for a dilute (2×10^{-6} M) MB

solution with NTS, the change in the absorption spectra over the whole concentration range of NTS is similar to that of MB solution with 1NS. Nonetheless, the equilibrium constant could not be estimated both for NTS and NDS because of the absence of an isosbestic point in the absorption spectra.

The fluorescence maximum of MB was observed to be shifted to the red with an increase in the concentration of NTS (or NDS), indicating the 1:1 complex formation between MB and NTS (or NDS).

Complex Formation of Other Dyes. Other types of dyes, Rhodamine 6G, Pyronine G, Safranin T, and Crystal Violet were also studied regarding the complex formation with the organic monoanions. The spectral changes in the absorption and fluorescence for all these dyes in the presence of the monoanion are quite similar to those for MB. We ascribe the spectral changes to the 1:1 complexes between the above dyes and the monoanions. No complex formation between Crystal Violet and benzenesulfonate has been reported.[22] With respect to the complex formation with benzenesulfonate as well as with 2NS, *etc.*, the behavior of Crystal Violet resembles that of MB. Irrespective of the difference in the skeletal structure from MB, the equilibrium constants of the dyes other than Rhodamine 6G are comparable with those of MB. The values of ΔH and ΔS for the complex formation of these dyes with the anions of the naphthalene derivatives are in the range from -19 to $-29\,\mathrm{kJ\,mol^{-1}}$ and from -25 to $-57\,\mathrm{J\,K^{-1}\,mol^{-1}}$, respectively. On the other hand, ΔH and ΔS for Rhodamine 6G are in the range from -36 to $-44\,\mathrm{kJ\,mol^{-1}}$ and from -94 to $-120\,\mathrm{J\,K^{-1}\,mol^{-1}}$ respectively. The absolute values of ΔH and ΔS for Rhodamine 6G are significantly larger than those for other dyes, including MB. There still remains a question of why ΔH and ΔS for Rhodamine 6G are strikingly different from those for other dyes.

The author wishes to thank Professor Fumio Hirayama for his valuable discussion.

(Received March 15, 1985)

Proton-induced quenching in both excited singlet and triplet states of methoxynaphthalenes in H_2O–CH_3CN mixtures has been studied by means of laser flash photolysis. Inclusion effect of β-cyclodextrin (βCD) on the proton-induced quenching has been also examined. It is shown that the proton-induced quencing (the rate constant ^1k_q) of 1-methoxynaphthalene (1RH) occurs effectively in the excited singlet state, but not in the triplet state on the basis of the $T_n \leftarrow T_1$ absorption measurements. There is no enhancement of triplet formation *via* the proton-induced quenching since the ^1k_q value obtained by the $T_n \leftarrow T_1$ absorption measurements agrees with that obtained by fluorimetry. It was unsuccessful to observe a protonated σ-complex produced by the excited-state protonation to the naphthalene ring. The 1:1 inclusion complex between 1RH and βCD is produced with the association constant K_g (=27 mol^{-1} dm^3 at 300K). In the presence of βCD, the ^1L_b character of 1RH increases in the fluorescent state and the proton-induced quenching of 1RH markedly decreases, which may be due to inclusion and environmental effects of βCD upon the behavior in the excited state of 1RH. As for 2RH having little or no intramolecular CT character (^1L_a), there is no proton-induced quenching.

Proton association and dissociation in the excited state of aromatic compounds are elementary processes in chemistry. The acid-base properties in the excited state of aromatic compounds are closely related to electronic structure, which is considerably different from that in the ground state. A number of studies on the acidity constants pK_a^* in the excited state of aromatic compounds have been reported showing that the pK_a^* values are significantly different from the acidity constants in the ground state.[1-9] It is well-known that the pK_a^* values can be estimated by means of the Förster cycle,[1-3,10] the fluorescence titration curve,[2,3] and the triplet-triplet absorbance titration curve.[11] These methods involve the assumption that proton transfer in the excited state is very fast, resulting in establishment of an acid-base equilibrium during the lifetime in the excited state.

However, it has been shown recently that proton-induced quenching (^1k_q) is competitive with the proton transfer reaction in the excited state of naphthylamines (that is, simple acid-base equilibrium cannot be attained during the lifetime in the excited state of aromatic amines) and that a dynamic analysis containing the quenching process is, therefore, needed in order to obtain the accurate pK_a^* values.[12] The dynamic analyses by means of nanosecond time-resolved spectroscopy with fluorimetry have been applied to 1-pyrenyl amine,[13] 1-anthrylamine,[14] phenanthrylamines,[15] and naphthols.[16] The Stuttgart group[17] has supported our method to determine the pK_a^* values of naphthylamines. Similar experiments for excited naphthols have been reported by Harris and Selinger.[18] Establishment of prototropic equilibria at moderate acid conditions has been reported in the excited singlet state of 2-naphthol-6,8-disulfonate[19] and in the triplet states of benzophenone[20] and phenyl alkyl ketones.[21] For the triplet state, its lifetime is relatively long enough to accomplish the prototropic equilibrium.[21]

Thus, the proton-induced quenching is a very important process in the prototropic reaction in the excited state. For the quenching mechanism a complex in which a proton is shared between excited 2-naphthylamine and one water molecule[22] or a hydrated naphthylammonium cation in the ground state[23] was assumed as an intermediate for the quenching. However, it has been demonstrated that the proton-induced quenching proceeds *via* electrophilic protonation at one of carbon atoms of the aromatic ring in the excited singlet state, leading to proton exchange (or isotope exchange).[24] An intramolecular CT structure in the excited state is responsible for the quenching.[15,24,25] A linear relationship between the ^1k_q values and the charge densities in the excited state of aromatic compounds has been shown.[25]

In the course of a study on the excited-state proton transfer reaction,[26] we became interested in the proton-induced quenching of methoxynaphthalenes studied by laser flash photolysis in order to establish the proton-induced quenching mechanism. Inclusion effect of βCD on the quenching has been also examined. This work was studied to answer the following questions:
(1) Is there any enhancement of triplet formation induced by the quenching? (2) Is there any proton-induced quenching in the triplet state? (3) Is there any transient produced by protonation in the excited

state? (4) What is the relation between electronic structure and proton-induced quenching? and (5) What about the inclusion efect of βCD upon both the quenching and the fluorescent state?

Experimental

Materials. Both 1- and 2-methoxynaphthalenes were the same as those reported elsewhere.[24] β-Cyclodextrin (Wako) and H_2SO_4 (97%, Wako) were used without further purification. Deionized water was distilled. Acetonitrile (reagent grade) was purified by the usual method.[27] The actual acid contents were determined by titration. Acetonitrile and water mixtures (1:4 or 4:1 by volume) were used as solvents. All samples were thoroughly degassed by freeze-pump-thaw cycles on a high vacuum line.

Absorption and Fluorescence Measurements. Absorption and fluorescence spectra were recorded with a Hitachi 200-10 spectrophotometer and a Hitachi M850 spectrofluorimeter respectively. The spectral corrections for the emission were made.

Nanosecond Laser Flash Experiments. Laser flash photolysis studies were carried out by using a Nd^{3+}-YAG laser equipped with a forth harmonic (266 nm) generator. The duration of a laser pulse was approximately 20 ns. The detection system for measurements of transient spectra consisted of a 150 W xenon lamp (Ushio UXL 150-D) as an analyzing light source, a monochromator (Ritsu Model MC-20N), a photomultiplier (Hamamatsu R758) and a transient memory (Kawasaki Electronica, MR-50E). The analyzing light beam was intensified by a factor of *ca.* 20 during the detection of the transient spectra. The transmitted light beam through a sample cell (10 mm) was led into the entrance slit of the monochromator. The output from the photomultiplier attached to the exit slit of the monochromator was recorded on the transient memory.

Results and Discussion

Proton-induced Quenching of Methoxynaphthalenes Studied by Laser Flash Photolysis. Figure 1 shows the transient absorption spectra of (a) 1-methoxynaphthalene (1RH), (b) 1RH in the presence of acid ($[H_2SO_4]=0.5$ mol dm^{-3}), and (c) 2-methoxynaphthalene (2RH) in CH_3CN-H_2O (4:1) mixtures, obtained by laser flash photolysis at 266 nm. These spectra with peaks of 435 nm (1RH) and 430 nm (2RH) were assigned to those of $T_n \leftarrow T_1$ transitions, since they were the same as the $T_n \leftarrow T_1$ absorption spectra obtained by the triplet sensitization by acetophenone at 337 nm as can be seen in Fig. 1(d). These transient spectra were quenched effectively by dissolved oxygen. The absorbance of the $T_n \leftarrow T_1$ transient spectrum of 1RH was decreased with increasing the concentration of protons without any spectral change [*e.g.*, Fig. 1(b)]. However, for 2RH no change in the $T_n \leftarrow T_1$ absorbance dependent upon the concentration of protons was observed. The Stern-Volmer Plots of A_T^0/A_T *vs.* $[H_3O^+]$ are shown in

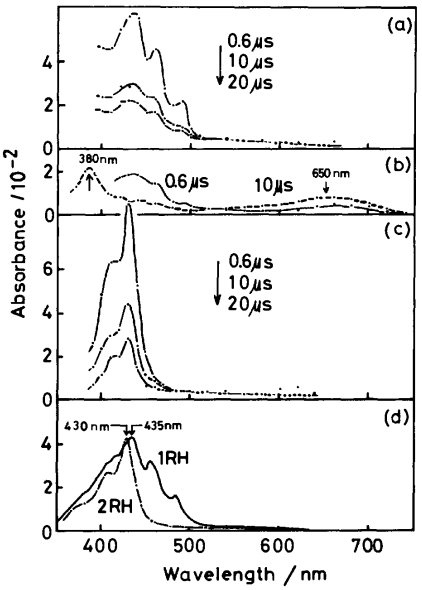

Fig. 1. Transient absorption spectra of (a) 1RH (4.4×10^{-4} mol dm^{-3}), (b) 1RH (4.4×10^{-4} mol dm^{-3}) in the presence of acid ($[H_2SO_4]=0.5$ mol dm^{-3}), and (c) 2RH (1.3×10^{-3} mol dm^{-3}) in H_2O-CH_3CN (1 : 4) mixtures obtained by laser flash photolysis at 266 nm. (d) Reference $T_n \leftarrow T_1$ transient spectra of RH's (2.5×10^{-3} mol dm^{-3}) obtained by triplet sensitization of acetophenone (3×10^{-2} mol dm^{-3}) at 1 μs after laser pulsing at 337 nm.

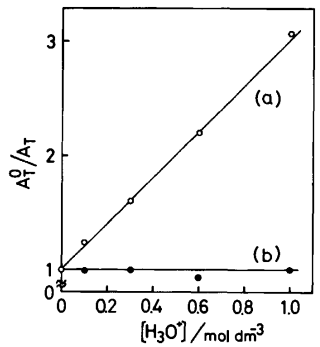

Fig. 2. Plot of A_T^0/A_T of 1RH (a) or 2RH (b) as a function of $[H_3O^+]$. For detail, see text.

Fig. 2(a) and (b) for 1RH and 2RH respectively. Straight lines are obtained indicating that Eq. 1 fairly holds.

$$\frac{A_T^0}{A_T} = 1 + {}^1k_q\tau_0[H_3O^+] \quad (1)$$

where A_T and A_T^0 denote the $T_n \leftarrow T_1$ absorbances at the transient peaks at the delay time=100 ns with and without protons respectively, ${}^1k_q$ the rate constant for the proton-induced quenching in the excited singlet state, and τ_0 the fluorescent life-time of methoxynaphthalenes. From the slope (a) in Fig. 2, the ${}^1k_q$ value is determined to be 1.5×10^8 mol^{-1} dm^3 s^{-1} for

1RH using τ_0=12.6 ns,[24] which is the same as that (1.6×10^8 mol^{-1} dm^3 s^{-1}) obtained by fluorescence intensity measurements[24] within the experimental errors. As for 2RH, the ^1k_q value is very small (less than 1×10^5 mol^{-1} dm^3 s^{-1}). The time trace of the transient $T_n\leftarrow T_1$ absorption monitored at the transient peaks are shown in Fig. 3, which decays with a single exponential function. The triplet lifetimes of 1RH and 2RH are obtained to be 10.2 (±0.4) and 10.2 (±0.2) μs, respectively. The triplet lifetimes were scarcely affected by protons, suggesting that there is little or no proton-induced quenching in the triplet state.

The introduction of electron-donating groups such as amino, hydroxyl, and methoxyl groups into the aromatic ring causes electron migration from the substituents to the ring in the excited singlet state.[28,29] This tendency is enhanced by solvation of the excited species in polar media, and the excited molecule has an intramolecular CT structure. As a result, the basicity of the aromatic ring increases appreciably in the excited state. This is the reason why the intramolecular CT structure is responsible for the proton-induced quenching.[15,24,25] The CT character in the excited species having electron-donating moieties at the α-position of the naphthalene ring is larger than that at the β-position. In contrast, there is no CT character in the lowest triplet state of 1RH, resulting in little or no proton-induced quenching.[24] Therefore, the proton-induced quenching (*i.e.*, protonation to the carbon atoms of the aromatic ring) is attributed to a typical electrophilic reaction.[24,26] A possibility of enhancement of intersystem crossing due to the proton-induced fluorescence quenching was assumed in an early stage of this study.[30] The anion-induced quenching of aromatic compounds is to be the case.[31,32] However, the possibility for enhancement of triplet formation was completely ruled out since the ^1k_q value obtained by the $T_n\leftarrow T_1$ absorbance of 1RH agrees with that fluorimetry[24] as described above. It has been pointed out that there is relatively little correlation between ^1k_q and I_P^* [the ionization potential for the excited singlet state of aromatic compounds ($^1A^*$) estimated from I_P (ionization potential for the gorund state (^1A)) minus $E_A°$ (0-0 transition energy for $^1A^*-{}^1A$)].[24] The quenching mechanism of $^1A^*$ by protons is different from that by inorganic anions X^-. The former involves a chemical interaction (protonation) at one of carbon atoms of the aromatic ring and the latter involves an electron transfer (or charge transfer).[31,32] An electronic interaction between $^1A^*$ and H^+ (or D^+) in the quenching is locally restricted to one of carbon atoms of the aromatic nucleus. This may be due to the following reasons: the radius of the proton (10^{-5} A)[33] is too small to overlap widely with the π-electronic system of $^1A^*$ compared to those of X^- (1.5—3 Å), and electrostatic and covalent interactions between H^+ [or D^+) and the proper carbon atom of $^1A^*$ become large enough to produce bond formation.[24] The experimental results can be accounted for by a schematic energy-state diagram in Fig. 4, showing that the proton-induced quenching ^1k_q occurs in the fluorescent state (^1L_a), but not in the T_1 state.

Unfortunately, the detection of a protonated σ-complex produced by electrophilic attack mainly at position 5 of the excited 1RH was unsuccessful in the present laser flash experiments. This may be due to that the transient σ-complex may have a very weak absorption in the observed wavelength region and/or that its lifetime may be too short to detect the transient absorption. Anyway, it is unknown at the

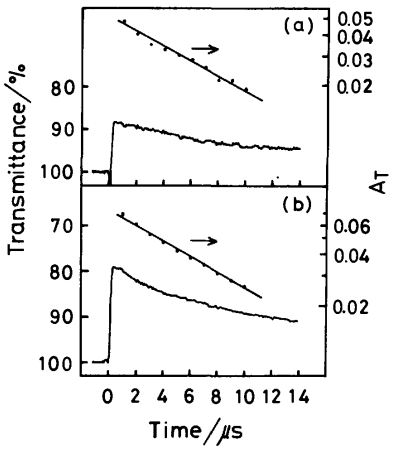

Fig. 3. Time traces of the transient $T_n\leftarrow T_1$ absorptions of 1RH (a) 2RH (b) monitored at 435 and 430 nm respectively, obtained by laser flash photolysis at 266 nm. The semilogarithmic plot of absorbance (A_T) gives a straight line, showing that the triplet species decays with a single exponential function. For the decay kinetics of 1RH, the absorbance (1.26×10^{-2}) due to a transient having a long lifetime was subtracted from the absorbance at 435 nm. Similary, for 2RH the absorbance (2.47×10^{-2}) due to a transient having a long lifetime was substracted from the absorbance at 430 nm. These absorbances may be due to photoproducts of RH.

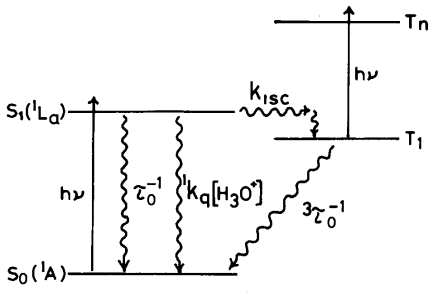

Fig. 4. A schematic energy-state diagram for the proton-induced quenching (^1k_q) of 1RH. For details, see text and Ref. (24).

present stage. A very weak absorption appeared in the longer wavelength region with a peak of 650 nm in the presence of protons, as shown in Fig. 1(b). The buildup time of the transient absorption was about 1 μs. The weak transient spectrum is very similar to that of the cation radical of 1RH.[34] It is obvious that this transient is not produced directly from the excited singlet state of 1RH because the rise (1 μs) and decay (τ_0=12.6 ns) times are different from each other. There was no 650 nm transient formation without acid. Therefore, protons should be needed for formation of the longer wavelength transient. For direct excitation of 2RH, no 650 nm transient was observed. Further investigation on the transient species will be needed in future.

Inclusion Effect of β-Cyclodextrin on Proton-induced Quenching of 1RH. It has been demonstrated that the proton-induced quenching of 1RH proceeds *via* electrophilic protonation at the proper carbon atom of the aromatic ring in the lowest excited singlet state (^1L_a) in polar media, leading to proton exchange or isotope exchange mainly at position 5 (slightly at position 8) of the naphthalene ring.[24] Therefore, it was expected that if position 5 (or position 8) of the naphthalene ring would be protected by β-cyclodextrin the proton-induced quenching might decrease significantly. It is known to produce a 1:1 inclusion complex of β-cyclodextrin (βCD) with naphthalene derivatives.[35,36]

At first, spectroscopic studies of 1RH in the presence of βCD have been carried out. Figure 5(a) shows the absorption spectra of 1RH ([1RH]=1.4×10^{-4} mol dm^{-3}) in a H_2O-CH_3CN (4:1) mixture with(1) and without(2) βCD ([βCD]=2×10^{-2} mol dm^{-3}); the differential spectrum of 1RH with and without βCD ([βCD]=2×10^{-2} mol dm^{-3}) is also depicted in Fig. 5(b). An isosbestic point was observed at 282 nm at various concentrations of βCD, reflecting an equilibrium:

$$1RH + \beta CD \rightleftharpoons (1RH-\beta CD) \quad (2)$$

The association constant in the ground state K_g (=[1RH−βCD]{[1RH][βCD]}$^{-1}$), is calculated by[35]

$$(A_\lambda - A_\lambda^0)/C_\beta = K_g(A_\lambda^\infty - A_\lambda) \quad (3)$$

where C_β represents the concentration of βCD, A_λ^0, A_λ, and A_λ^∞ stand for the absorbances of nil, C_β, and ∞, respectively. Figures 6 shows a plot of $(A_\lambda - A_\lambda^0)/C_\beta$ as a function of A_λ at λ=300 nm at 300 K. The value of K_g is determined to be 27 mol^{-1} dm^3 from the slope.

The fluorescence spectra of 1RH([1RH]=1.4×10^{-4} mol dm^{-3}) (1) with and (2) without βCD ([βCD]=2×10^{-2} mol dm^{-3}) in H_2O-CH_3CN (4:1) mixtures are also shown in Fig. 5(a). In the case of (1), the concentration of the 1RH-βCD complex is estimated to be 4.9×10^{-5} mol dm^{-3} at 300 K, which corresponds to 35% of the total concentration of 1RH

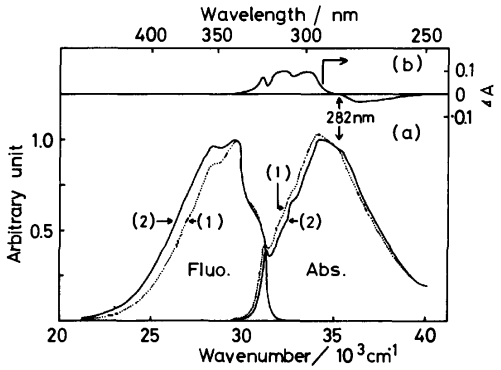

Fig. 5. (a) Absorption and fluorescence spectra of 1RH (1.4×10^{-4} mol dm^{-3}) in H_2O-CH_3CN (4 : 1) (1) with and (2) without βCD ([βCD]=2×10^{-2} mol dm^{-3}). (b) The differential absorption spectrum of 1RH between (1) and (2). For detial, see text.

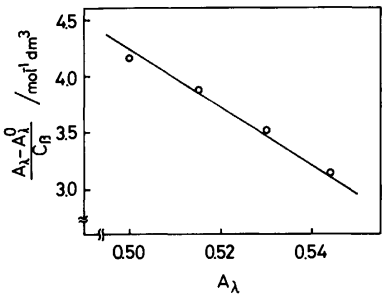

Fig. 6. Plot of $(A_\lambda - A_\lambda^0)/C_\beta$ *vs.* A_λ at 300 K, where λ is 300 nm. For detial, see text.

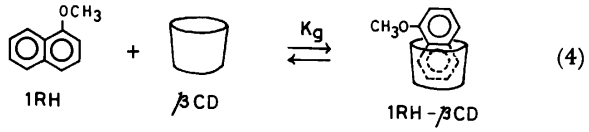
(1.4×10^{-4} mol dm^{-3}). The maximum concentration of βCD to add to the system is ≈2×10^{-2} mol dm^{-3}, since the molecular weight of βCD is extremely large (1135) and its solubility is restricted. However, the effect of βCD on the fluorescence properties and the proton-induced quenching of 1RH were distinct. The fluorescence intensity at longer wavelengths decreases when βCD is added as shown in Fig. 5. It suggests that the addition of βCD decreases intramolecular CT character (^1L_a) in the excited state. The fluorescence quantum yield and apparent lifetime of 1RH in the presence of βCD (2×10^{-2} mol dm^{-3}) in H_2O-CH_3CN (4:1) were obtained to be 0.38 and 10.6 ns at 300 K, respectively. By addition of βCD to the system, the fluorescence quantum yield slightly decreased compared to that (0.43)[24] of free 1RH, whereas the lifetime became long in comparison with that (8.9 ns)[24] of free 1RH. It is noteworthy that the fluorescence spectrnm of 1RH with βCD is similar to that of free 1RH in less polar or nonpolar media. The vibrational structures of emission from the ^1L_b state (the locally excited state) appear at the shorter wavelengths with a peak of 338 nm. This observation can be explained in terms of a model of the 1RH-βCD inclusion complex, in

which a part of the naphthalene ring of 1RH (*i.e.*, positions 5 and 8) may be included as shown in Eq. 4:



(4)

A similar Corey-Pauling-Kolton molecular model has been proposed recently by Tran and Fendler.[36]

Electron migration from the methoxy group to the naphthalene ring decreases in the excited 1RH-βCD complex, since solvation of the excited 1RH [positions 5 and 8 having large charge densities in the excited state (^1L_a)][24] with polar solvent molecules may be prevented by βCD inclusion. As a result, the 1RH-βCD complex behaves as if it were in less polar media.

The plots of I_0/I *vs.* [H_3O^+] are shown in Fig. 7, where I and I_0 are the fluorescence intensities at 338 nm with and without protons respectively and (a) and (b) denote the absence and presence of βCD ([βCD]=2×10^{-2} mol dm^{-3}) respectively. This result shows that the proton-induced fluorescence quenching of 1RH ($^1k_q=1.1\times10^9$ mol^{-1} dm^3 s^{-1}) decreases markedly in the presence of βCD. This fact shows that the reactive positions [mainly 5 and slightly 8 in the excited state (^1L_a)] of 1RH are efficiently blocked by βCD inclusion. However, the experimental results of the fluorescence and proton-induced quenching cannot be explained only by the effect of the complex formation. In addition to this, one may take into account an environmental effect of βCD upon both fluorescence properties and the proton-induced quenching rate of 1RH, since the 1RH-βCD complex formation is 35% under the experimental conditions as described above. Probably, 1RH may be surrounded by βCD molecules, resulting in that the ^1L_b character of 1RH increases in the excited state. It should be noted that the ^1L_b state (locally excited state) is not susceptible of protons, as shown previously.[24]

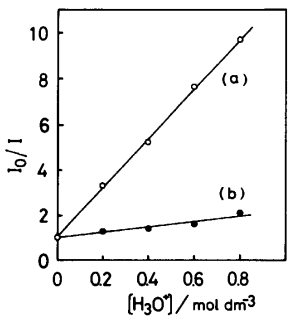


Fig. 7. Plots of I_0/I of 1RH at 338 nm *vs.* [H_3O^+] in H_2O-CH_3CN (4 : 1) (b) with and (a) without βCD ([βCD] = 2×10^{-2} mol dm^{-3}).

Summary

(1) The $T_n\leftarrow T_1$ absorbance of 1RH at 435 nm obtained by laser flash photolysis decreases considerably with increasing the concentration of protons, while its triplet lifetime (10.2 μs) is scarcely affected by protons, showing that the proton-induced quenching occurs in the excited singlet state, but not in the triplet state. There is no enhancement of triplet formation *via* the proton-induced quenching on the basis of the result that the ^1k_q value (1.5×10^8 mol^{-1} dm^3 s^{-1})in H_2O-CH_3CN (1:4) at 300 K obtained by the $T_n\leftarrow T_1$ absorption measurements is nearly equal to that (1.6×10^8 mol^{-1} dm^3 s^{-1}) obtained by fluorimetry[24] within the experimental errors. Unfortunately, the protonated σ-complex cannot be detected under the experimental conditions.

(2) The 1:1 complex between 1RH and βCD is produced with the association constant K_g (27 mol^{-1} dm^3 in H_2O-CH_3CN (4:1) at 300 K). In the presence of βCD (2×10^{-2} mol dm^{-3}) the ^1L_b character of 1RH increases in the fluorescent state and the proton-induced quenching of 1RH markedly decreases. These effects of βCD may be due to not only the inclusion effect of βCD, but also the environmental effect of βCD upon the behavior of the excited 1RH species. The intramolecular CT character (^1L_a) in the excited state of 1RH also decreases by the βCD inclusion.

(3) For 2RH, proton-induced quenching in the lowest excited singlet state is scarcely observed. The difference in the quenching between 1RH and 2RH is caused by that in electronic structures in the excited singlet state; the former has an intramolecular CT structure (^1L_a), but not for the latter (^1L_b). It is confirmed that the intramolecular CT structure in the excited state is responsible for the proton-induced quenching.

This work was supported by a Scientific Research Grant-in-Aid (No. 58470001) of the Ministry of Education. The authors are very grateful to Dr. H. Hiratsuka of Tokyo Institute of Technology for showing us the absorption spectra of the RH cation radicals.

(Received March 18, 1985)

The dopant structure in $FeCl_3$-doped polyacetylene was studied from the analysis of Fe K-edge EXAFS and XANES, measured by use of synchroton radiation. It is concluded that Fe atom is surrounded by four Cl atoms with Fe–Cl distance of 2.19—2.20 Å, and the dopant exists in the state of $[FeCl_4]^-$. The following mechanism is proposed for the doping process:

$$(CH)_x + 2yxFeCl_3 \rightarrow [CH(FeCl_4^-)_y]_x + yxFeCl_2$$

It is also shown that the chlorination of polyacetylene occurs significantly on performing a "heavy doping."

When doped with a suitable electron donor or acceptor, polyacetylene becomes metallic with an electrical conductivity more than 12 orders of magnitude higher than that of the undoped state.[1] A wide variety of dopants has been tested to see their effects on the electrical properties. However, little has been known on the electronic states and geometrical structures of dopants in the doped polyacetylenes. When a polyacetylene film is immersed into a nitromethane solution of $FeCl_3$, $FeCl_3$ is taken into the polyacetylene film to give electrical conductivity of, at most, 10^2 S cm^{-1}.[2,3] The state of the dopant in the $FeCl_3$-doped polyacetylene was studied by means of Mössbauer spectroscopy and ESR, but there were some contradictions among the conclusions given by different authors.[4–7]

The doping of polyacetylene is often compared with the formation of the graphite intercalation compound. In the case of the graphite intercalation compound with $FeCl_3$, the intercalated $FeCl_3$ layer was reported to have a structure more or less similar to that in anhydrous $FeCl_3$.[8] On the other hand, available experimental data suggest that the dopant state in $FeCl_3$-doped polyacetylene is quite different from this case.[4–7] Thus it seemed to be of great interest to elucidate the dopant structure in a $FeCl_3$-doped polyacetylene. We report here the results of the analysis of the extended X-ray absorption fine structure (EXAFS) and X-ray absorption near-edge structure (XANES) of Fe K-edge measured on $FeCl_3$-doped polyacetylene films. They provide a most direct evidence that the dopant exists in the state of $[FeCl_4]^-$. Curious behaviors were found for a heavy doping with $FeCl_3$. Namely, Fe K-edge jump decreased in spite of the increase of apparent dopant content, and the electrical conductivity of the film decreased on increasing apparent dopant content. We will also discuss the origin of this phenomenon.

Experimental

Polyacetylene films of cis-rich form were prepared by the previously reported method.[9] $FeCl_3$-doping was carried out by immersing polyacetylene films into a nitromethane solution of $FeCl_3$ as described elsewhere.[3] $FeCl_3$ had been kept *in vacuo* for several hours before use. Nitromethane was well dried over $CaCl_2$ and distilled before it was used as the solvent. Films of different dopant content were obtained by changing the immersing period and/or $FeCl_3$ concentration of the solution. The dopant contents and electrical conductivities of the prepared samples are listed in Table 1. The dopant content given there is the apparent value which is calculated from the weight uptake of a polyacetylene film in the doping process assuming that the dopant exists entirely in the form of $FeCl_3$. In reality, the dopant exists as $[FeCl_4]^-$, not as $FeCl_3$, and furthermore, the weight increase is partly due to the chlorination of polyacetylene, particularly in the case of heavy doping as we will show later. Thus the values of dopant content in Table 1 should be taken only as a measure of doping degree. Figure 1 shows the change of electrical conductivity as a function of dopant content, where the points indicated as **A**, **B**, C, and **D** correspond to Samples **A**, **B**, C, and **D**, respectively.

The specimens for the measurements of X-ray absorption spectrum were prepared in the following way. In an Ar-

Table 1. The dopant content and conductivity of $FeCl_3$-doped polyacetylene sample

Sample	Dopant concent[a] / % mol/(CH) mol	Conductivity / S/cm
Sample **A**	2.4	10—80
Sample **B**	8.7	700—800
Sample **C**	13.0	0.4—200
Sample **D**	7.4	700

a) Dopant content was calculated from the weight uptake of the polyacetylene assuming all the dopant was in the form of $FeCl_3$.

† Present address: Department of Chemistry, Faculty of Science, Tokyo Metroporitan University, Fukasawa, Setagaya-ku, Tokyo 158.

filled gloved box, a doped polyacetylene film was cut into several pieces of appropriate size and folded up several times to give a thickness suitable for X-ray absorption measurement, and then sandwiched between two pieces of adhesive tape to keep it in the folded state and, at the same time, to prevent the sample from a direct exposure to the atmosphere. The samples prepared by this way were stored in an Ar-filled Schlenk flask until just before they were used for the measurements.

Preliminary EXAFS experiments were done by use of an in-laboratory EXAFS spectrometer combined with a high-power rotating-anode X-ray generator (RIGAKU RU-1000).[10] Through these experiments, we checked the effects of sealing the sample with adhesive tapes, the appropriate sample thickness, and the homogeneity of the dopant distribution in a doped film. The final data of X-ray absorption spectrum were taken by use of synchrotron radiation emitted from the 2.5 GeV storage ring of the Photon Factory in the National Laboratory for High-energy Physics (KEK-PF), employing the EXAFS facilities at BL-10B.[11] X-Rays were monochromatized with a Si(311) channel-cut crystal. The intensity of the incident beam, I_0, and that of the transmitted beam, I, were measured with the ionization chambers which were placed before and after the sample, respectively, the gas filled in an ionization chamber being N_2 for I_0 and Ar for I. Most of X-ray absorption measurements were done at room temperature. The measurement at low temperature (10 and 80 K) was done only for Sample **D**, which was regarded to be a representative sample having a high electrical conductivity. X-Ray photoelectron spectra were taken with McPherson ESCA 36 electron spectrometer by empolying Mg $K\alpha$ (1253.6 eV) as the stimulating radiation. In order to avoid the effects of directly exposing the sample to air, a sample which has been kept in an Ar-filled vessel was transferred to the spectrometer by use of an Ar-filled gloved box which was directly connected to the spectrometer. The gases coming out from a sample were analyzed by use of JEOL JMS-D300 mass spectrometer. For the purpose to check the inhomogeneity of Fe distribution in a $FeCl_3$-doped polyacetylene film, we carried out the electron probe microanalysis by use of JEOL EPXMA TYPE JXA-5, the intensity distribution of Fe $K\alpha$ fluorescent X-ray being observed.

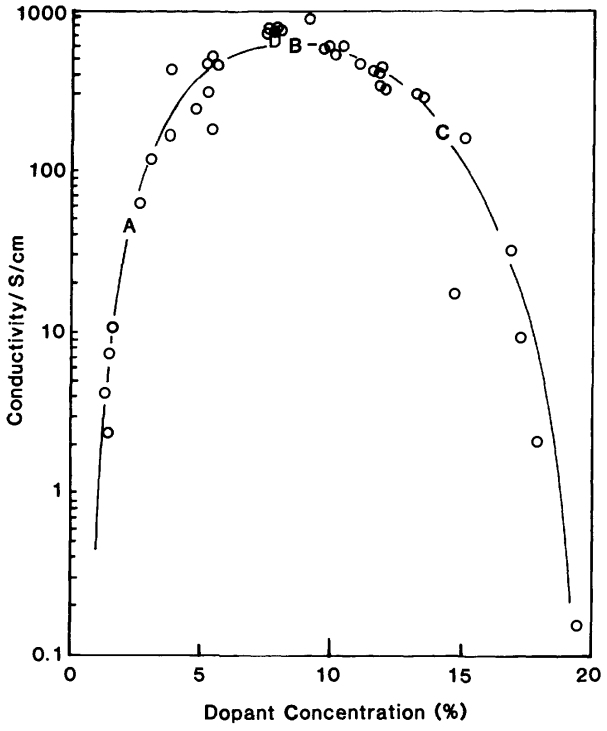

Fig. 1. Conductivity of $FeCl_3$-doped polyacetylene as a function of dopant concentration y. **A**, **B**, and **C** in the figure correspond to samples **A**, **B**, and **C**, respectively.

Results and Discussion

In the preliminary EXAFS experiments, we noted that Fe K-edge jump was significantly lower in the case of Sample **C** than what was expected from its apparent dopant content, it being even lower than those observed for Samples **A**, **B**, and **D**, and furthermore, it was found to vary as we examined different portions of Sample **C**. Since the latter fact indicated that the distribution of Fe is considerably inhomogeneous in this sample, we examined the Fe distribution in the film by use of an electron probe microanalyzer (EPMA). The image of Fe $K\alpha$ fluorescent X-ray showed that Fe distribution was indeed quite inhomogeneous, having Fe-rich regions and Fe-less regions within a film. On the other hand, the films of lower dopant content (Samples **A**, **B**, and **D**) were found to have a homogeneous Fe distribution. The reason for this anomarous behavior of Sample **C** will be discussed later.

As a typical example of the Fe K-edge absorption spectra measured by use of synchrotron radiation, the spectrum of Sample **D** at 80 K is shown in Fig. 2. The spectrum shows a sharp pre-edge peak attributable to ls-3d transition and several peaks near Fe K-edge,

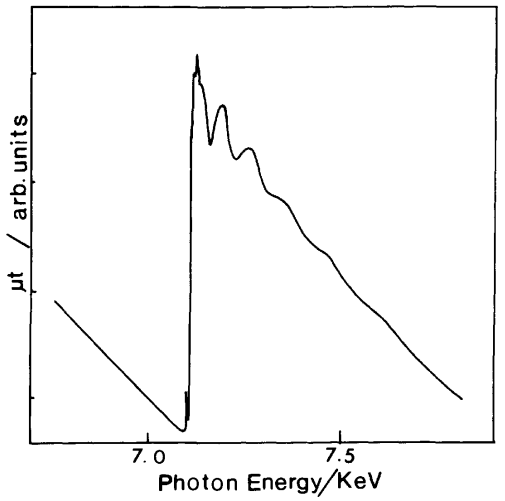

Fig. 2. Fe K absorption spectrum of Sample **D** at 80 K.

which are followed by EXAFS of a relatively simple structure. Spectral shape was found to be almost the same for all other samples of $FeCl_3$-doped polyacetylene.

We extracted EXAFS oscillation $\chi(k)$ from the observed spectra by the following method.[12] The smoothly-varying component $\mu_s(\lambda)$, was estimated by fitting an observed spectrum using the cubic spline method. The free atom absorption coefficient, $\mu_o(\lambda)$, in the region of 50—60 eV from the edge was taken to be equal to the difference between μ_s and the background absorption μ_b which was determined by a smooth extrapolation from the preedge region by use of Eq. 1.

$$\mu_b(\lambda) = \mathbf{A} + \mathbf{C}\lambda^3 + \mathbf{D}\lambda^4 \quad (1)$$

The μ_o value in other region was estimated by extrapolating the μ_o values in the above-mentioned region assuming that the wavelength dependence of μ_o was describable with the Victoreen's equation, the parameters of which were taken from the literature.[13] The photon energy E was converted to the photoelectron wave number k by Eq. 2.

$$k = \sqrt{2m(E-E_o)}/\hbar \quad (2)$$

where E_o is the ionization threshold. Then the EXAFS oscillation was calculated by using Eq. 3.

$$\chi(k) = (\mu-\mu_s)/\mu_o \quad (3)$$

Using thus extracted $\chi(k)$, we performed a Fourier transformation of $k^3\cdot\chi(k)$ over the region, $4 \leqq k \leqq 12$ Å^{-1}.

Figure 3 shows the Fourier transform of the EXAFS data of Sample **D** at 80 K. It shows only one prominent peak with the maximum at about 1.8 Å. This peak can be attributed to the nearest-neighbor Cl atoms surrounding Fe atom. No peak which is attributable to Fe-C or Fe-Fe, can be found even in the Fourier transform of the EXAFS data at 10 K. The Fourier transforms of the EXAFS data of all other samples (Samples **A**, **B**, and **C**) were also nearly the same as that of Sample **D**, exhibiting again only one prominent peak attributable to Fe-Cl.

Assuming the first shell to be due to Fe-Cl bond, we carried out the curve-fitting analysis by use of the following equation based on the single scattering theory.

$$k^3\chi(k) = (N/R^2)k^2F(k)\exp(-2k^2\sigma^2)\sin[2kR+\phi(k)] \quad (4)$$

where N is the coordination number, R the interatomic distance, $F(k)$ the back-scattering amplitude function, σ the Debye-Waller factor, $\phi(k)$ the phase shift function. The back-scattering amplitude function $F(k)$ and the phase shift function $\phi(k)$ were empirically determined from the analysis of the EXAFS data of the model compound, $[N(C_2H_5)_4][FeCl_4]$. Treating N, R, and σ as fitting parameters, their best-fit values were determined by means of the nonlinear least square technique. Figure 4 shows the calculated and observed $k^3\cdot\chi(k)$ curves for Sample **D**. The R and N values obtained by the curve-fitting analysis are listed in Table 2. For all samples of $FeCl_3$-doped polyacetylene, Fe-Cl bond length was found to be 2.19—2.20 Å. The obtained coordination numbers were somewhat different from sample to sample within the range of 3—4. But this difference is not likely to be intrinsic since a relatively large error is generally expected for a coordination number determined from the EXAFS data measured at room temperature. Because the EXAFS data obtained at lower temperature have better quality, the coordination number 3.9—4.0 obtained from the 80 K and 10 K EXAFS data of Sample **D**, is most reliable and can be taken as the actual coordination number. Thus we can conclude that, in the $FeCl_3$-doped

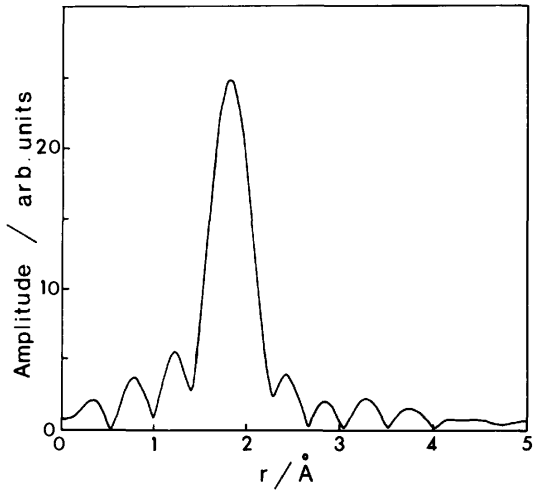

Fig. 3. Fourier transform of $k^3\cdot\chi(k)$ of the 80 K EXAFS data of Sample **D**.

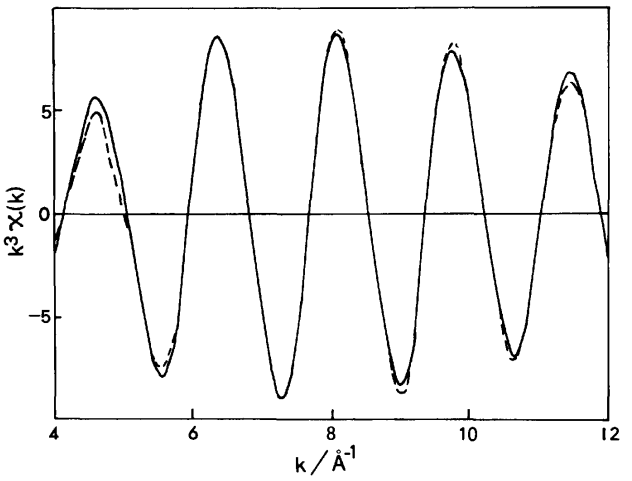

Fig. 4. The calculated (——) and observed (- - -) $k^3\cdot\chi(k)$ curves for Sample **D**.

polyacetylene, Fe atom is surrounded by four Cl atoms with Fe-Cl distance of 2.19—2.20 Å.

There are several kinds of the chemically stable ion of the type $[FeCl_x]^{y-}$, which are $[FeCl_4]^-$, $[FeCl_4]^{2-}$, $[FeCl_6]^{3-}$, and $[FeCl_6]^{4-}$. The Fe-Cl distances which have been determined from the crystal structure analysis are given in Table 3. Note that Fe-Cl distance is nearly the same for a given kind of the anion irrespective of the kind of the counter cation. In other words, it is almost determined by the valence state of Fe and the Cl coornination number. The data shown in Table 3, indicate that the Fe-Cl distance of 2.19 Å is the one characteristic of $[FeCl_4]^-$. Another ion which has the coordination number of 4, is $[FeCl_4]^{2-}$, but its average Fe-Cl distance is about 2.3 A. Therefore the results of the analysis of the Fe K-edge EXAFS data of $FeCl_3$-doped polyacetylenes indicate that the dopant is in the state of $[FeCl_4]^-$. As we have mentioned, Sample **C** has a very inhomogeneous Fe distribution. However, its Fe K-edge EXAFS data gave also the same conclusion. This means that the Fe-containing chemical species existing in the Fe-rich regions of this sample is also in the state of $[FeCl_4]^-$.

As it is known, XANES is determined by the local electronic state surrounding the X-ray absorbing atom, and reflects the valency state and the local symmetry around the X-ray absorbing atom.[23,24] Although a detailed analysis of XANES is rather complicated, one can use XANES just as a fingerprint of the local structure and electronic state. In Fig. 5, the Fe K-edge XANES spectrum of Sample **D** measured at 80 K is compared with the corresponding spectra of $[Co(NH_3)_6][FeCl_6]$, $[N(C_2H_5)_4]_2[FeCl_4]$, and $[N(C_2H_5)_4][FeCl_4]$, in which the local structure surrounding Fe is $[FeCl_6]^{3-}$, $[FeCl_4]^{2-}$, and $[FeCl_4]^-$, respectively. The sharp pre-edge peak in the spectrum of Sample **D** arises from 1a—3d transition and is characteristic of a tetrahedrally-coordinated ion like $[FeCl_4]^-$. Furthermore, the structures above the absorption edge are also similar to the ones found for $[N(C_2H_5)_4][FeCl_4]$. XANES spectra of other $FeCl_3$-doped samples are also nearly the same as that of Sample **D**. Thus the Fe K-edge XANES of $FeCl_3$-doped polyacetylene indicates that the local state surrounding Fe corresponds to $[FeCl_4]^-$ in agreement with the conclusion derived from EXAFS data. Summarizing all the results mentioned above, we can definitely conclude that, in a $FeCl_3$-doped polyacetylene, the dopant exists mainly in the state of $[FeCl_4]^-$,

Table 2. Results of the analysis of EXAFS data by using the empirical parameters[a)]

Sample	Bond length l/Å	Coordination No.
Sample **A**	2.200	2.9
Sample **B**	2.195	3.3
Sample **C**	2.195	4.2
Sample **D**	(T=300 K) 2.199	3.5
Sample **D**	(T= 80 K) 2.200	3.9
Sample **D**	(T= 10 K) 2.200	4.0

a) The phase shift and amplitude functions obtained from the analysis of the room-temperature EXAFS data of $[N(C_2H_5)_4][FeCl_4]$, assuming Fe-Cl distance as 2.18 Å and coordination number as 4, were used except for the analyses of the 80 K and 10 K EXAFS data of Sample **D**, for which the empirical parameters derived from the 80 K EXAFS data of $[N(C_2H_5)_4][FeCl_4]$.

Table 3. Fe-Cl bond lengths in $[FeCl_2]^{y-}$ ions

Type	Salt	Bond length l/Å	Ref
$[FeCl_4]^{2-}$	$(C_5H_5S_2)_2[FeCl_4]$	2.313 (av.)	14
	$(C_5H_5S_2)_2[FeCl_4]$	2.33 (av.)	15
	$\{[Fe(\eta^5\text{-}C_5H_5)(CO)_2]_3SbCl\}_2$		
	$[FeCl_4]CH_2Cl_2$	2.302 (av.)	16
	$[N(CH_3)_4]_2[FeCl_4]$	2.292	17
$[FeCl_4]^-$	$[As(C_6H_5)_4[FeCl_4]$	2.19	18
	$[FeCl_2(DMSO)_4][FeCl_4]$	2.162	19
	$Na[FeCl_4]$	2.196	20
	$[PCl_4][FeCl_4]$	2.185	21
$[FeCl_6]^{4-}$	$NaK_3[FeCl_6]$	2.5100	22
$[FeCl_6]^{3-}$	$[Co(NH_3)_6][FeCl_6]$	2.3926	22

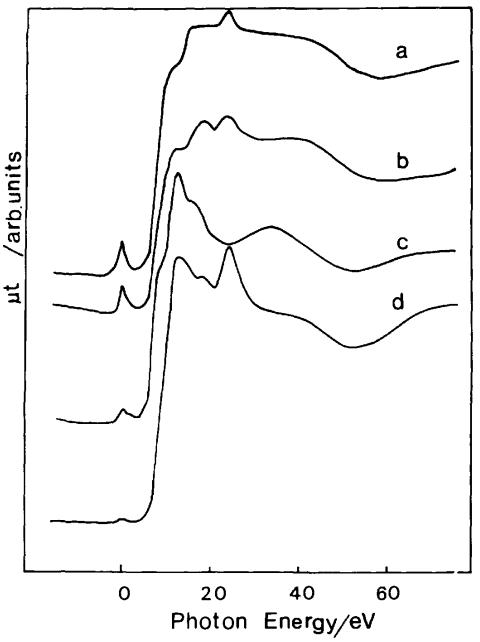

Fig. 5. XANES spectra of (a) Sample **D**, (b) $[N(C_2H_5)_4][FeCl_4]$, (c) $[N(C_2H_5)_4]_2$ $[FeCl_4]$ and (d) $[Co(NH_3)_6][FeCl_6]$. The photon energy is measured from the transition energy of the pre-edge peak E_d of each sample. The transition energies of the pre-edge peaks of Sample **D**, $[N(C_2H_5)_4][FeCl_4]$, $[N(C_2H_5)_4]_2$ $[FeCl_4]$ and $[Co(NH_3)_6]$ $[FeCl_6]$ are 7104.8, 7104.8, 7103.0, and 7104.5 eV, respectively.

not in the state of $FeCl_3$ nor in the state of $[FeCl_4]^{2-}$. This conclusion is consistent with the recent studies by Mössbauer spectroscopy.[4,5]

The dopant state revealed by the present study, is quite different from that in the graphite intercalation compound, where ther intercalated $FeCl_3$ takes a layer structure somewhat similar to the one in anhydrous $FeCl_3$, having a partial charge transfer between graphite and $FeCl_3$ layers.[8] Since the dopant exists as $[FeCl_4]^-$, we propose the following doping mechanism for the $FeCl_3$-doped polyacetylene. In a separate experiment, we have studied the solute structure in a nitromethane solution of $FeCl_3$ by use of Fe K-edge EXAFS, and found that $[FeCl_4]^-$ exists in the nitromethane solution beside another iron-containing species.[25] The latter is likely to be a solvated octahedral chloro complex,[25] which we tentatively denote as $[FeCl_2]^+$. Possibly the following electrolytic dissociation had taken place in the nitromethane solution to yield $[FeCl_4]^-$.

$$2FeCl_3 \rightarrow [FeCl_4]^- + [FeCl_2]^+ \quad (5)$$

Therefore it is most likely that, when a polyacetylene film is immersed into the nitromethane solution of $FeCl_3$, $[FeCl_2]^+$ is reduced by the electron transfer from polyacetylene to form $FeCl_2$ which might remain in the solution or precipitate from the solution, and only $[FeCl_4]^-$ ions enter into the space surrounded by positively-charged polyacetylene chains.

As shown in Fig. 1, it has been generally observed that the electrical conductivity of $FeCl_3$-doped polyacetylene initially increases with dopant content, but decreases when the apparent dopant content exceeds about 10 mol% on performing a heavy doping. Among the samples taken up in the present study, Sample **C** was the one prepared under the condition of heavy doping. In fact, the apparent dopant content of this sample was 13 mol%, which is considerably higher than that of Sample **D**. However, the magnitude of Fe K-edge jump was found to be lower in comparison with Sample **D**. As we have already mentioned, the magnitude of Fe K-edge jump varies from portion to portion on the film of Sample **C**. We confirmed also by means of electron probe microanalysis(EPMA), that Fe distribution is quite inhomogeneous in this sample. To clarify the origin of these anomalous behaviors of a heavily-doped sample, we examined the X-ray photoelectron spectra of $FeCl_3$-doped polyacetylene films. As shown in Fig. 6, Samples **A** and **B** exhibit a single C 1s peak accompanied by a high-binding-energy tail, whereas the C 1s spectrum of Sample **C** splits into two peaks, indicating the presence of two different kinds of C atom. The Cl 2p spectra of $FeCl_3$-doped polyacetylenes are shown in Fig.7 together with the corresponding spectrum of $[N(C_2H_5)_4][FeCl_4]$. Note that the Cl 2p spectrum of Sample **A** very much resembles that of $[N(C_2H_5)_4][FeCl_4]$, but the Cl 2p spectrum of Sample **C** exhibits a quite strange shape, indicating the presence of two different kinds of Cl atoms. The observed binding energies of C 1s and Cl 2p peaks are listed in Table 4. The binding energy of the main C 1s peak is 284.1 eV both for Sample **A** and Sample **B**, which is in good agreement with the C 1s binding energy of an undoped *trans*-polyacetylene. Since the C 1s spectrum of Sample **C** is clearly composed of two components, we carried out a deconvolution into two components and determined the energy splitting and the intensity ratio of the high-binding-energy com-

Sample **B**	284.1	—	—	198.2	—	—
Sample **C**	284.4	286.2	0.39	198.6	200.2	0.35

ponent to the low-binding-energy component. A deconvolution into two components was also done on the Cl 2p spectrum. The results are given in Table 4. Hereafter we denote the low-binding-energy component of the C 1s peak as C-1 and the high-binding-energy component as C-2. In the same way, we denote the low-binding-energy and high-binding-energy components of the Cl 2p spectrum as Cl-1 and Cl-2, respectively.

We noted that the shape of C 1s spectrum as well as that of Cl 2p spectum changed when Sample **C** was kept *in vacuo* for a long period (see Figs. 8 and 9). This means that the intensity ratio of the two components of each spectrum changes with time. In Fig. 10, we have plotted the intensity of each component as a function of the time for which the sample had been kept *in vacuo*. Note that the intensity of the C-2 component of the C 1s specrum decreased while that of the C-1 component increased with time, and at the same time, the intensity of the Cl-2 component of the Cl 2p spectrum showed a significant decrease with time while no appreciable

change was found for the intensity of the Cl-1 component. We examined the gases which coming from the sample during the above-mentioned process by use of mass spectroscopy and found that the main chemical species was HCl.

Summarizing the above-mentioned experimental data, we can derive the following conclusion. Since the intensities of the C-2 and Cl-2 components decrease in parallel to each other, they are likely to be associated with the same origin. The Cl $2p_{3/2}$ binding energy of the Cl-2 component, 200 eV, is the value that is usually found for a Cl atom forming C–Cl bond, and the C 1s binding energy of the C-2 component is the one that is expected for a C atom of C–Cl bond.[28] Thus the C-2 and Cl-2 components are likely to be associated with the C–Cl bond which has been formed as a result of the chlorination of polyacetylene chain. At present, we do not know about the mechamism of the chlorination taking place in the process of a heavy $FeCl_3$ doping. Possibly, when a polyacetylene film already saturated with $[FeCl_4]^-$ with apparent dopant content above 10 mol%, is further kept in a nitromethane solution of a high $FeCl_3$ concentration, the chlorination of polyacetylene chain takes place in some way within the doped region and the Fe containing species of the reaction products escapes from the polyacetylene film into the solution. Thus the weight increase in this process is not due to an increase of $[FeCl_4]^-$ content, but is mainly due to chlorination. This explains the reason why the magnitude of Fe K-edge jump is markedly smaller than what is expected from the apparent dopant content, and why the electrical conductivity decreases on a heavy doping.

The above-described phenomenon is similar in some respects to the one found for a heavy doping with bromine.[29] In this case, the addition of bromine to polyacetylene chain significantly takes place, resulting in an abrupt decrease of electrical conductivity. It is also known that HBr comes out from such a heavily Br-doped film when kept *in vacuo*.

Finally we wish to point out that, in the case of Sample **B** whose dopant content is just around 10 mol%, the shape of the Cl 2p spectrum is a little different from what is expected for $[FeCl_4]^-$. There seems to be a contribution of the component corresponding to Cl-2. In other words, the chlorination is likely to take place to a small extent even in a relatively-light $FeCl_3$ doping.

The authors would like to express their thanks for the technical advice given by Professor T. Matsushita, Dr. H. Oyanagi and Dr. M. Nomura on the measurements of EXAFS spectra at the Photon Factory. The analyses of EXAFS data were done by use of HITAC M-280H at the Computor Center, The University of Tokyo. This work was supported by the Grant-in-Aid for the Special Project Research on "the Properties of Molecular Assemblies" (No. 58118002), from the Ministry of Education, Science and Culture.

Active and Selective Transport of Alkali Metal Ions through a Polyelectrolyte Complex Membrane Consisting of Glycol Chitosan and the Sulfate of Poly(vinyl alcohol)

Yasuo KIKUCHI* and Naoji KUBOTA
Faculty of Engineering, Ōita University, 700-Dannoharu, Ōita 870
(Received December 6, 1984)

Polyelectrolyte complex (PEC) membranes consisting of glycol chitosan and the sulfate of poly(vinyl alcohol) have been prepared. The membrane of the polyelectrolyte complex under a 50% humidity prepared in a 4% hydrochloric acid solution was stable in basic and acidic solutions. The membranes of the PECs under a 90% humidity prepared at pH 1.0 were not stable in an alkaline solution. The active and selective transport of K^+ and Na^+ were observed in the PEC membrane prepared in a 4% hydrochloric acid solution. The transport behavior of alkali metal ions through this membrane was much affected by the hydrogen-ion concentration, which acted as a driving force. A proton-pump mechanism was suggested for the acive transport of Na^+ and K^+. It was also suggested that the affinity of the carrier and changes in both the chemical and physical properties of the PEC membrane with the hydrogen-ion concentration controlled the selective transport through the membrane.

The specific transport of ions is a common function of a biomembrane. An active transport process is usually defined as one that can bring about a flow of a substance against an electrochemical potential gradient of the substance; the name implies that specific biological activity is involved in the process described by Rosenberg.[1] That is to say, the dissipation function is smaller than zero. This is observed in the active and selective transport of metal ions through a protoplasmic liquid[2-4] and synthetic membranes carrying a fixed functional group.[5-7] Research into such synthetic membranes is an important objective in the field of macromolecules. Active and selective transport through a polyelectrolyte complex membrane carrying a fixed functional group has not yet been investigated. However, for several polyelectrolyte complexes[8-10] we have reported that the polyelectrolyte complex membranes consisting of [2-(diethyl-amino)ethyl]dextran hydrochloride, sodium carboxymethyl dextran, and the sulfate of poly (vinyl alcohol) were capable of the active and selective transport of alkali metal ions.[11,12] This paper will deal with the similar phenomena of membranes consisting of glycol chitosan and the sulfate of poly (vinyl alcohol).

Experimental

Glycol chitosan (GC)(nitrogen content, 4.32%; inherent viscosity, 1.79 dl/g in a 0.1 M†NaCl solution at 25 °C) and the sulfate of poly(vinyl alcohol)(PVSK)(sulfur content, 18.91%; inherent viscosity, 0.67 dl/g in a NaCl solution at 25 °C) were used.

The reaction was carried out in a hydrochloric acid solution, 4% (v/v) and pH 1.0, considering the conformational change in the materials. The polyelectrolyte complex (PEC) was not formed at hydrogen-ion concentrations above pH 4.0. The GC solution (2 g/L) or PVSK (2 g/L) solution was added dropwised to a PVSK or GC solution, and the pH values of both solutions were adjusted to that of a 4% hydrochloric acid solution, pH 1.0 at about 22 °C at a rate of 50 ml/30 min under stirring.[11] A water-insoluble PEC was thus obtained. After being left to stand for 30 min, the PEC was washed with the hydrochloric acid solution, water, and then methanol. Then it was separated by centrifugation and dried at room temperature until a constant weight was attained. The details of the expermental conditions were described in a previous paper.[11]

The PEC was dissolved in a ternary solvent mixture (HCl/1,4-dioxane/H_2O, 16:47:37 wt-%). The solution was poured onto a Teflon plate; about 2 d latter the solvent was removed at room temperature. In addition, a uniform and yellowish transparent film was obtained on the Teflon plate by further evaporating of the solvent under 50 or 90% humidity for one or 2 d. The thickness of the membrane was about 100 μm. The resistence of the membranes against acid and base were examined by immersing them in a acidic (0.1 M HCl) or an alkaline solution (0.1 M NaOH). A PMMA cell consisting of two chambers was used in the active and selective transport. The membrane, having an effective area of 4.0 cm^2,was fixed tightly with rubber between two chambers of the cell.[12] The cell was then immersed in a constant-temperature bath set at 30 °C. The concentrations of the alkali metal ions, K^+ and Na^+, in both the left and right sides of the cell (chambers) were measured by means of atomicabsorption spectrophotometer.

Results and Discussion

The experimental conditions for the PEC prepared before and after the coagulation of PEC and the mole ratio of the reactive group S(PVSK) to that of N(GC) in the mixture solution before and after the coagulation of the PEC produced are given in Table 1. The details of the experimental conditions were described

† 1 M=1 mol dm^{-3}.

TABLE 1. PREPARATION OF POLYELECTROLYTE COMPLEXES

Sample code	Concentration of hydrogen ions	Order in mixing	Molar ratio of reactive group of S(PVSK) to that of N(GC) in the mixture
1-A	4v/v% HCl	PVSK $\xrightarrow{\text{into}}$ GC solution	1.00
1-a	4v/v% HCl	PVSK $\xrightarrow{\text{into}}$ GC solution	1.57
1-B	4v/v% HCl	GC $\xrightarrow{\text{into}}$ PVSK solution	3.61
1-b	4v/v% HCl	GC $\xrightarrow{\text{into}}$ PVSK solution	2.49
2-A	pH 1.0	PVSK $\xrightarrow{\text{into}}$ GC solution	0.83
2-a	pH 1.0	PVSK $\xrightarrow{\text{into}}$ GC solution	1.30
2-B	pH 1.0	GC $\xrightarrow{\text{into}}$ PVSK solution	2.52
2-b	pH 1.0	GC $\xrightarrow{\text{into}}$ PVSK solution	1.62

The polyelectrolyte complexes (PEC) of 1-A, 1-B, 2-A, and 2-B were prepared before the starting point of coagulation. The molar ratios of S/N at the starting point of coagulation were 1.04, 3.57, 0.89, and 2.39 respectively. The PECs of 1-a, 1-b, 2-a, and 2-b were prepared after the end point of coagulation. The molar ratios of S/N at the end point of coagulation were 1.51, 2.56, 1.24, and 1.67 respectively. The concentration of glycol chitosan (GC) and that of sulfate of poly(vinyl alcohol) (PVSK) were both 2.0 g/l. GC: Nitrogen content 4.32%, inherent viscosity 1.79 dl/g, in 0.1 M NaCl solution at 25 °C. PVSK: Sulfur content 18.91%, inherent viscosity 0.67 dl/g, in 1 M NaCl solution at 25 °C.

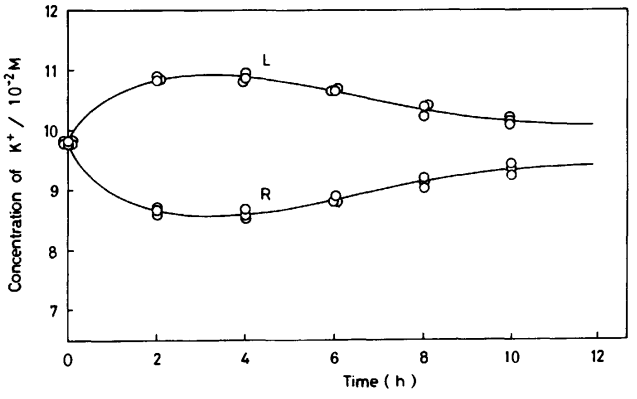

Fig. 2. Time-transport curve of K^+ of the active transport at 30 °C.

in a previous paper.[11]

The properties of the membranes in acidic and basic solutions are shown in Tables 2 and 3 respectively. The membranes formed under 50 and 90% humidity except for 2-A and 2-a, which were formed at pH 1.0, resisted an acidic solution. On the other hand, the membranes except 1-b formed in a 4% hydrochloric acid solution at 50% humidity were not resistant to a basic solution. The 1-b membrane was not damaged in either a 0.1 M NaOH or 0.1 M hydrochloric acid solution, even after 5 d. This membrane was used in the study of the transport of alkali metal ions. The sulfur and nitrogen contents in the PEC used to prepare the membrane were 9.55 and 3.73% respectively. The active-transport experiment was carried out at 30 °C. The concentration of the Na^+ or K^+ ion both the left and right sides of the cell was kept identical initially. In the left side, the cell also contained HCl, while the right-side cell contained NaOH or KOH.

Figures 1—2 show the concentration change in the Na^+ or K^+ ion against the reaction time in both cells at pH 1.0 through the membrane. The concentration of alkali metal ions in the left-side cell, which was acidic, increased up to a maximum and then decreased with the reaction time, while the change in the right-side cell was just the reverse. A back transfer of the concentrated alkali metal ions was due to the decrease in the hydrogen ion concentration on the left side. The changes in the concentration of Na^+ in the NaOH system were somewhat smaller than those of K^+ in the KOH system.

As is shown in Figs 3—4, the transport ratio[13], $([M^+]_{max}-[M^+]_o/[M^+]_o)\times 100$, of the alkali metal ions (Na^+, K^+) was proportional to the concentration of hydrogen ions in the left-side cell. Since the initial concentration of the alkali ion was originally the same in both left and right cells, the increase in the alkali concentration in the left cell suggests the active transport of the alkali metal ion through the membrane. It is of important significance in saving energy and resources that a PEC membrane carrying a fixed functional group is capable of the active transport of alkali metal ions. The difference in the transport ratios of Na^+ and K^+ against the hydrogen-ion concentration of the two systems are hardly discernible in hydrogen-ion concentrations below pH 2.0, whereas that of Na^+ is larger than that of K^+ in hydrogen-ion concentrations above pH 1.0. The transport rate,[13] $[M^+]_{max}-[M^+]_o/T_{max}$ in Mh^{-1} was proportional to the initial hydrogen-ion concentration. The pH values in the left- and right-side cells changed with the passing of time.

The change in the pH in both side cells is shown in Fig. 5. A maximum in the alkali metal-ion concentration appeared because of the neutralization of the aqueous solution in both cells. Accordingly, the driving force for transport was a gradient of the hydrogen-ion concentration. This pH change is attributed to a transfer of H^+, OH^- and alkali metal ions as well as the Cl^- ion[6] in both side cells. A proton-pump mechanism was considered for the concentration of alkali-metal ions.[5]

Selective transport from the right-side cell to the left-side cell through the membrane was observed under a 0.05 M concentration of both NaOH and KOH solutions in the right-side cell and at different hydrogen-ion concentrations in the left-side cell at 30 °C. The ratios of the transported ions the selectivity,[5,6] were calculated from the following equation:

$$\text{Selectivity} = \frac{[K^+]_{Lt}/[K^+]_{R,o}}{[Na^+]_{Lt}/[Na^+]_{R,o}}$$

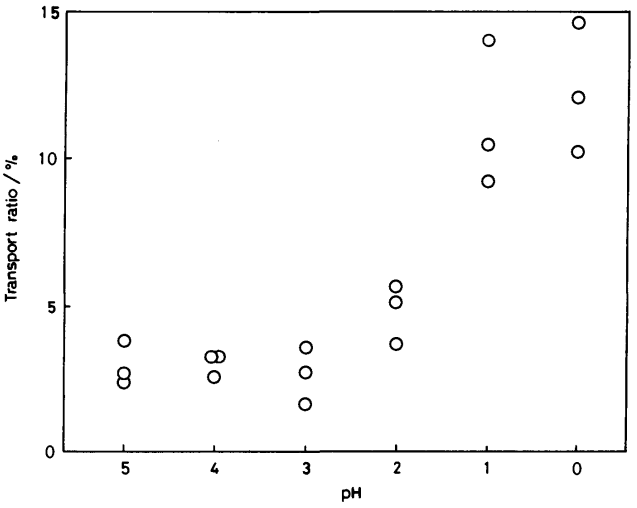

Fig. 3. Influence of hydrogen ion concentrations on the transport ratio of Na^+ ion at 30 °C.

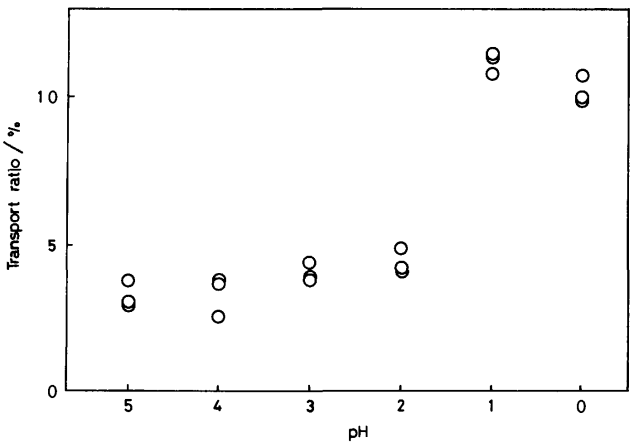

Fig. 4. Influence of hydrogen ion concentrations on the transport ratio of K^+ ion at 30 °C.

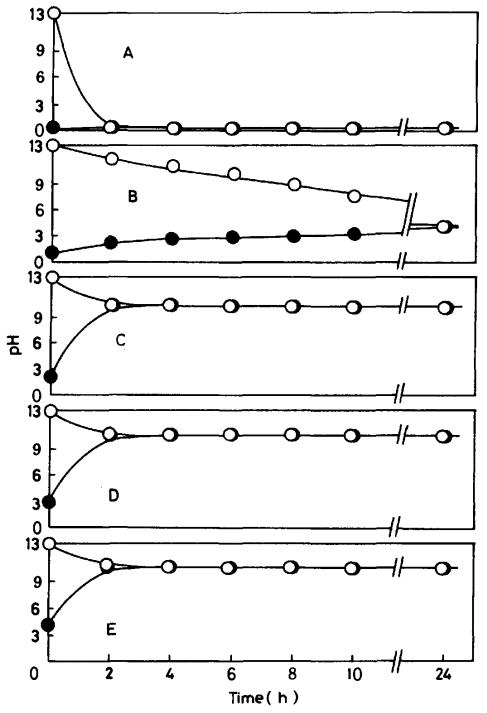

Fig. 5. Changes in hydrogen ion concentration through membrane.
A: 1 M HCl, B: 0.1 M HCl, C: 0.01 M HCl, D: 0.001 M HCl, E: 0.0001 M HCl.

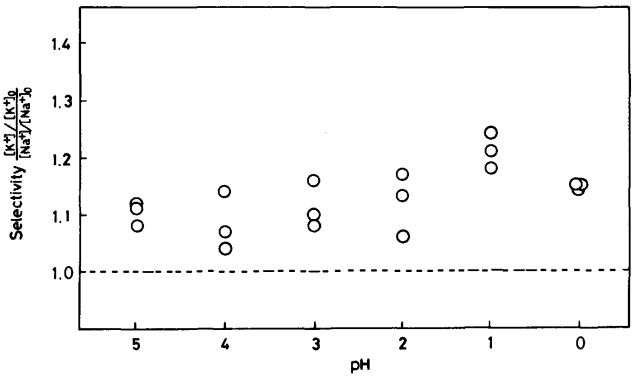

Fig. 6. Influence of hydrogen ion concentrations on selectivities in transport of Na^+ and K^+ ions after 4 h.

The selectivity of the transport through membrane after 4 h at different hydrogen-ion concentrations is shown in Fig. 6. The ratio of the permeated K^+ to the permeated Na^+ changed with the hydrogen-ion concentration. When the initial hydrogen-ion concentration was low, the selectivity was close to unity. In this region, the alkali metal ions diffused without any great or specific interaction with the membrane. In the region where the hydrogen-ion concentration was higher than 1.0×10^{-2} M, more K^+ ions permeated than Na^+ ions. The optimum hydrogen-ion concentration was 1.0×10^{-1} M with 0.05 M concentrations of NaOH and KOH solutions in the right-side cell. These results suggest that the main contributing factor in the selectivity in the transport of alkali metal ions is the hydrogen-ion concentration. The membrane prepared was throughly powdered in a agate mortar with a pestle. The pulverized membrane was then immersed in a basic or acidic solution for about 1 d. The IR spectrum of the pulverized membrane immersed in an acidic solution exhibited the medium absorption a 800—900 cm^{-1}, assigned to the $-SO_3H$ group,[14] but that immersed in a basic solution exhibited only a weak absorption. In addition, that immersed in a basic solution exhibited the medium absorption at 900—940 cm^{-1}, assigned to the $-SO_3$ group.[14] On the acidic side, this characteristic absorption band almost disappeared. From these IR spectra, therefore, it was concluded that the PEC moiety was opened on the alkaline side and closed on the acidic side. Furthermore, this conclusion has been well confirmed by the following experimental results of the lengthing or shrinkage of the membrane immersed in a basic or acidic solution. The horizontal and vertical lengthes of membrane immersed in the pH 1.0 and 13.0 solutions were 25 mm×28 mm and 33 mm×34 mm. When the above membrane, pretreated in a pH 1.0 or pH 13.0 solution, was further immersed in a pH 13.0 or pH 1.0 solution, the lengthes of the above two dimensions varied about 31 mm×34 mm and 30 mm×30 mm respectively, with an error of about 2 mm. That is, the membrane was elongated in a basic solution and shrunk in an acidic solution. In the region where the hydrogen-ion concentration was larger than 1.0×10^{-2} M in the left-side cell, the hydrated K^+ permeated faster than the hydrated Na^+ because of the radius of the hydrated K^+ was shorted than that of the hydrated Na^+ because of the formation of small holes as a result of the closing of the channel in the membrane, whereas that of the hydrogen-ion concentration was smaller. No appreciable selectivity of transport were observed because of the indiscriminate permeation of alkali metal ions owing to the formation of large holes results of the opening of the channel in the membrane. It was suggested that the affinity of the carrier fixed to the membrane, the degree of the opening and closing of the PEC moiety, and the physical properties of the PEC membrane, as well as the hydrogen bonding between -OH and $-OSO_3H$ or $-OSO_3^-Na^+$ groups with the hydrogen-ion concentration, controlled the selective transport through the membrane.[6] Therefore, on the basis of the pH change in the solution we speculate that the PEC membrane achieved the following reaction;

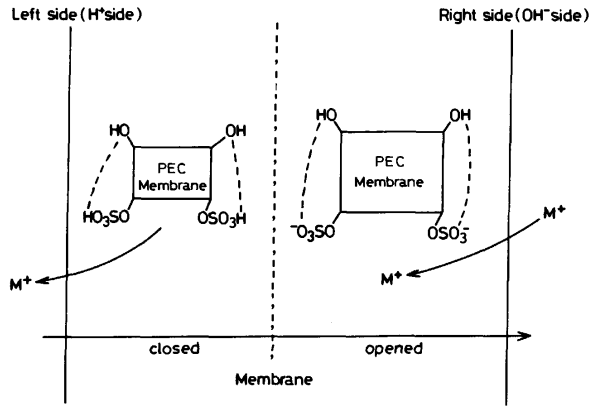

Fig. 7. Tentative mechanism of the transport of Na^+ and K^+ ions.

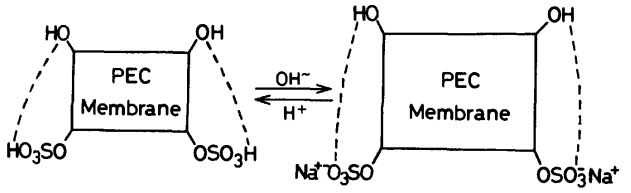

A tentative mechanism of the transport of alkali-metal ions, deduced from the results described above, is shown in Fig. 7. In this system, the hydrogen-ion concentration acted as the driving force and controlling reagent for the properties of the membrane.[5] At first, when a specific functional group, $-OSO_3^-$ in the membrane is on the right-side (OH^- side), metal ions are bound to the sulfate group in an alkaline solution with the changes in both the chemical and physical properties of the PEC membrane described above. Then, the alkali metal ions bound to the sulfate group are transferred through the membrane and are released by the hydrogen-ion or the acidic side. As a result, alkali metal ions are transported from the basic side to the acidic side. We consider that the driving force of the active transport of alkali ions is a gradient of the hydrogen-ion concentration, while the binding of the alkali metal ions to the sulfate group is attributable to the degree of the ring opening of the PEC membrane with hydrogen bonding, which affects the selectivity.[5,6]

The suitable conditions for the formation of the PEC membrane and the PEC membrane of transport for a negative ions have scarcely been elucidated at all. Therefore, further investigation must be carried out clarify the mechanism.

Studies on the Electronic Absorption Spectra of 2,2′-Bithienyl and Some of Its Derivatives. A Molecular Orbital Treatment

Rafie H. Abu-Eittah*,† and Fakhreia A. Al-Sugeir
Department of Chemistry, Faculty of Science, University of Kuwait, Kuwait
(Received March 26, 1984)

The electronic absorption spectra of 2,2′-bithienyl and a number of its derivatives have been investigated. The predominant conformer as well as the polarity of the molecule were predicted from the spectrum. Molecular orbital calculations were performed on different conformers of 5-formyl-2,2′-bithienyl and the s-*trans* geometry proved to be the predominant conformer of the molecule. A good agreement is observed between calculated and observed transition energy and intensity.

Bithienyls and their derivatives are important compounds from the biological, pharmaceutical and analytical point of view. Compounds with strong nematocidal activity are derivatives of 2,2′-bithienyl.[1] The absorption spectra of bithienyl[2-4] and substituted bithienyls have been investigated. The transitions observed in the spectra of 5- and 5,5′-substituted 2,2′-bithienyls have been assigned to intramolecular c.t., locally excited and $n\rightarrow\sigma^*$ transitions.

Molecular refraction and dipole moment measurements (in benzene at 25 °C) have shown that the s-*cis*-conformer of 2,2-bithienyl predominates.[6] On the other hand, the apparent polarization and molar Kerr constant[7] and electron diffraction[8] studies indicated that the preferred conformation is defined by an angle of twist ϕ, about the central C–C bond, of 34° from the crystal state.

The investigation of the spectra[9] of the three possible isomeric thienothiophenes as well as the CNDO/2 computations indicated that contribution of the 3d and higher orbitals of sulfur atom has negligible effect on the electronic spectra of sulfur containing composite molecules as was concluded for thiophene. Molecular orbital calculations, using the SCF–MO method, of the UV spectra of thiophene, 3,3′-, 2,3′-, and 2,2′-bithienyls have been described.[10-12] The PPP-approximation has been applied in an SCF study to investigate the barrier to internal rotation of the two isomers of bithienyl.[13] For 3,3′-bithienyl, energy minima were found at about 20° and 150° from the planar form. For the 2,2′-isomer no distinct minima were found.

In this work the electronic absorption spectra of 2,2′-bithienyl and some of its derivatives were investigated. The effect of solvent polarity and refractive index on band maxima and intensity helped in assigning the predominant conformer of the molecule. Molecular orbital calculations were carried out on 5-formyl-2,2′-bithienyl. Results obtained for the transition energies and band intensities agree satisfactorily with experimental results.

Experimental

All the solvents used were BDH-special for spectrocopy grade regents and used without further purifications.

2,2′-Bithienyl was prepared by refluxing a mixture of 2-iodothiophene, copper bronze and *N,N*-dimethylformamide for 22 h.[14] The product was recovered by steam distillation and purified by vacuum distillation (mp 34 °C).

5-Formyl-2,2′-bithienyl was prepared by stirring a mixture of bithienyl, *N,N*-dimethylformamide, dry toluene and phosphoryl chloride. The residue was recrystallized from ethanol (mp 59 °C).[15]

5,5′-Diacetyl-2,2′-bithienyl was prepared by refluxing a mixture of 85% phosphoric acid and 2,2′-bithienyl in acetic anhydride for 1 h. The mixture was cooled while stirring. The separated product was recrystallized from 1,4-dioxane, mp 235 °C (lit,[14] 233—234 °C).

5-Nitro-2,2′-bithienyl: To a solution of bithienyl and acetic anhydride at 0—5 °C fuming nitric acid in acetic anhydride was added. The nitro product was isolated by steam distillation and recrystallized from ethanol as yellow needles (mp 109 °C as reported).[16]

5,5′-Dimethyl-2,2′-bithienyl was prepared by heating a mixture of 2-iodo-5-methylthiophene and copper powder at 200—210 °C for half an hour. The mixture was colled and the product was extracted with boiling chloroform and steam-distilled. The dimethylbithienyl was recrystallized from methanol (mp 67—68 °C as reported 15—17).

5,5′-Dichloro- and 4,5,5′-Trichloro-2,2′-bithienyl: Sulfuryl chloride was added with stirring to a mixture of 2,2′-bithienyl, acetic acid, and aluminium chloride at 40 °C. The mixture was cooled and the separated solid was filtered and crystallized from chloroform (measured mp of the dichloro derivative was 109 °C, that of the trichloro was 103 °C).[18]

The absorption spectra were measured with a Pye Unicam Sp 500 spectrophotometer using 1.0 cm fused silica cells.

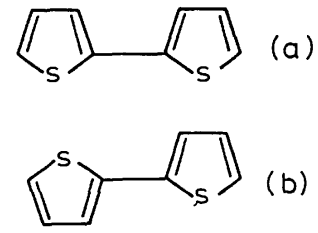
Results and Discussion

A. Electronic Absorption Spectra. (i) 2,2′-Bithienyl: The molecule, bithienyl (*R*-*S*), can be treated as a composite molecule consisting of two subsystems, each of which (*R* and *S*) is a thiophene nucleus and both are joined, apparently, by a single bond. The MO's of the composite molecule are built up from those of its subsystems and the excited states result from mutual interaction of the excited states of the subsystems. This interaction is predominant in the planar conformer of bithienyl. As the planarity is distorted, the spectrum of bithienyl will approach that of thiophene.

The calculations of the electronic spectra of sulfur

†Present address: Department of Chemistry, Faculty of Science, King Abdulaziz University, Jeddah, Saudi Arabia.

containing molecules have shown trivial dependence on the inclusion of the 3d or higher atomic orbitals of sulfur atom.[19-21] Microwave spectroscopic, electron and X-ray diffraction data[22-25] on five-membered heterocycles containing sulfur have shown that the bond angle on the sulfure atom is close to 90°, indicating that the σ-bonds result from overlap of the P_x and P_y orbitals of sulfure. Using Slater exponents for sulfur and carbon atomic orbitals, the calculated overlap integral between carbon $2P_z$ and sulfur $3P_z$ is 0.492 while that between carbon $2P_z$ and sulfur $3d_{xz,yz}$ is only 0.109.[26] Figures 1a and 1b show the electronic absorption spectra of bithienyl and that of thiophene. Thiophene spectrum consists of a singlet $\pi \rightarrow \pi^*$ transition with λ_{max} at 235 nm (log ε=4.22) in addition to a long wavelength shoulder in the region of 268 (log ε<1) nm. No discrete absorption band is observed for $n \rightarrow \pi^*$ transition and singlet→triplet transitions were assigned to very weak bands at about 5.63 eV and in the range of 3.90—3.96 eV.[27] On the other hand, the spectrum of bithienyl shows three well defined electronic transitions in the accessible UV region, none of which can be identified as the thiophene electronic transition. This result is an experimental evidence that bithienyl is a "coplanar," "rigid" or "quasi-rigid" molecule. If it were a "freerotator" the probability of getting a perpendicular conformer should be the same as that of getting a planar conformer. The electronic spectrum of the perpendicular conformer would be merely that of thiophene. As Fig. 1 shows the spectrum of bithienyl differs completely from that of thiophene. The planer conformer of bithienyl may be either the s-*cis* (a) or the s-*trans* (b)



one. The former follows the C_{2v} whereas the latter follows the C_{2h} symmetry point group. Transition probability would be different for the two conformers. The s-*cis* conformer is of much higher dipole moment than the s-*trans* conformer, consequently the electronic transitions of the former should be more affected with solvent polarity than those of the latter. Figure 1 shows a slight shift of λ_{max} with solvent polarity indicating a low polarity of both the ground and excited states.

Many physical studies concerned with the determination of the preferred conformation of 2,2′-bithienyl have been reported. In the solid state, planar *trans* configuration is favored.[28] In gaseous[29] state the angle of twist about the central C–C bond varies between 34—85° from the *cis*-conformer. In solution, the angle of twist is found to be similar to that in gaseous state.[30] However, theoretical consideration favors a near planar structure.[31,32] A molecular orbit-

al study of the barrier to internal rotation in bithienyl has shown no distinct energy minima on varying the angle of twist from 0—180°.

The observed three electronic transitions of bithienyl, Fig 1b are $\pi \rightarrow \pi^*$, none of them is localized on a subsystem of the composite molecule. The broad feature of band 1 (lowest energy) as well as the relative blurring of its vibrational components is an evidence that, in solution, bithienyl exists in a number of nearly planar conformers of comparable energy. A statistical distribution is expected to exist between the different conformers. The spectra of 2,2′-bithietyl were investigated in a wide variety of polar and nonpolar solvents (Table 1). In polar solvents, band intensity decreased with the increase of dipole moment and in non-polar solvents band intensity also decreased with the increase of refractive index. On the other hand band maxima slightly increased with the increase of both refractive index and dipole moment.

(ii) Substituted 2,2′-Bithienyl: Figure 2 shows the electronic absorption spectra of 5,5′-dimethyl-, 5,5′-dichloro-, and 4,5,5′-trichloro-2,2′- bithienyls using cyclohexane as a solvent. The features of the spectra are similar to those of the unsubstituted compound. An important observation is the broadness of the lowest energy band in addition to the blurring nature of its vibrational components.

The spectra of 5-formyl- and 5,5′-diacetyl-2,2′-bithienyl are shown in Fig. 3. A significant red shift is observed for the lowest energy transition compared to the unsubstituted compound or to the methyl or halo-substituted bithienyl. This is the result of the strong perturbing effect of the >C=O group which also incrcases the polarity of both the ground and the excited states. The lowest energy transition is apparently red shifted in polar solvent which is an indication of a large

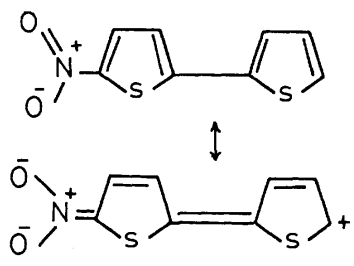
contribution of a polar configuration to the excited state.

Substitution by a nitro group in the 5-position of bithienyl will not affect the coplanarity of the molecule but will reduce its symmetry. Forms as (a) will mainly contribute to the excited states. The interaction between the nitro group and bithienyl nucleus is substantial and is reflected in the spectrum (Fig. 4). Four electronic transitions ($\pi \rightarrow \pi^*$) are observed in the 200—500 nm region. The lowest energy band is substantially red shifted in polar solvent, a characteristic of



(a)

charge transfer transitions. The highest energy band was not observed in the spectra of any of the studied

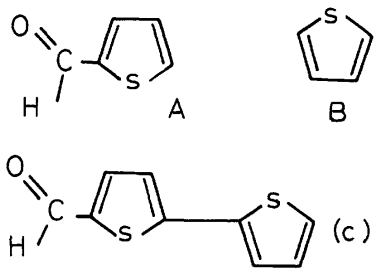
bithienyls except the diacetyl derivative. Table 2 gives the numerical values of band maxima and oscillator strength of the studied compounds.

B. Molecular Orbital Calculations. The method of molecule-in-molecule[34] has been accurately adobted to MO calculations on composite systems such as phenylthiophenes,[35] bithienyls,[32] phenylfurans,[36] and *N*-(2-furylmethylene)aniline.[37] In this work the method is applied for calculations on the different conformers of 5-formyl-2,2′-bithienyl.

The two subsystems of the composite molecule, 5-formyl-2,2′-bithienyl, are 2-thiophenecarbaldehyde (A) and thiophene (B). The molecule-in-molecule method



is based on calculating the interaction between the electronic states of subsystems (A) and (B). The SCF-CI[38] state functions were calculated for the two subsystems, results are given in Table 3. The electronic states of 5-formyl-2,2′-bithienyl were calculated for many conformers of the molecule by considering the following interactions between (i) the CI state functions of the subsystems (A) and (B); (ii) the CI state functions of the subsystems and charge-transfer configurations where an electron transfers from (A) to (B) or from (B) to (A) ; (iii) the ground state and the charge-transfer configurations. For the perpendicular conformer the resonance integral $\beta_{22'}$ is zero and interaction of the type (i) are only considered. The state functions and the corresponding energies of the s-*trans* conformer (C) and the perpendicular conformer (planes of thiophene and formylthiophene are perpendicular) are given in Table 4. The variation of transition energies with the angle of rotation around the C_2–$C_{2'}$ bond is given in Table 5.

Table 3. Configuration interaction state functions and the corresponding energies (eV) of 2-thiophenecarbaldehyde and of thiophene

2-Thiophenecarbaldehyde	eV

$\Psi_{EX,III}=0.7363Y_1-0.0942\theta_1+0.1573\theta_2+0.6421\theta_3$ $-0.0924\theta_4-0.0512\theta_6$	5.53

Γ=Ground configuration, θ_1—θ_6 excited states on subsystem A, Y_1—Y_4 excited states on subsystem B, CR's charge resonance functions.

The oscillator strength was calculated from the equation

$$f = 2.085 \times 10^{-5} M^2 \bar{\nu}$$

where M is the transition moment and $\bar{\nu}$ (cm^{-1}) is the wave number of the electronic transition. M was calculated from

$$\vec{M} = \langle \Psi_0 | \hat{M} | \Psi_E \rangle,$$

where Ψ_0 and Ψ_E are the ground and excited state wave functions, respectively. In the molecule-in-molecule procedure the wave functions have the forms:

$$\Psi_0 = {}_a\Gamma + \sum_n b_n T_n$$

$$\Psi_E = \sum_n c_n A_n + \sum_{n'} d_{n'} T_{n'} + {}_e\Gamma$$

TABLE 5. VARIATION OF TRANSITION ENERGY WITH THE ANGLE OF ROTATION ABOUT THE 2,2′-BOND

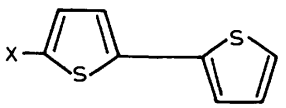
Rotation angle/deg	Transition energy/eV	Oscillator strength
30	3.72	1.00
	4.47	0.17
	5.16	0.24
60	4.06	0.51
	4.45	0.20
	5.01	0.05
90	4.19	0.39
	4.56	0.11
	5.53	0.07
120	4.15	0.28
	4.50	0.22
	4.80	0.02
180(s-*trans*)	3.72	0.85
	4.56	0.20
	5.20	0.23
Experimental	3.65	0.47
	4.68	0.22
	5.06	0.18

where A_n is the n-th excited state function and T is the charge-transfer state function. Applying the ZDO approximation

$$\langle \Psi_0|M|\Psi_E\rangle = a\sum_n \langle T|M|A\rangle + \sum_n\sum_{n'} b_n d_{n'}\langle T_n|M|T_{n'}\rangle$$

C. Comparison with Experimental Results: Table 5 gives the values of the transition energy and the oscillator strength computed as a function of the angle of rotation about the C_2–$C_{2'}$ bond together with the experimental values. The results show a good correspondence between the experimental values and the theoretical ones computed for the s-*trans* conformer. An angle of 30° between the planes of the subsystems did not lead to better results than those of the planar conformer. The electronic absorption spectra of 2,2′-bithienyl and some of its derivatives have been investigated in a wide variety of solvents. The important observation is the persistance of the features of the first band (lowest energy) in the spectra of all the studied derivatives. This band is broad, though it corresponds to one electronic transtion, intense and includes a number of blurred vibrational components, though coplanarity of the molecules is not distorted.

A simple way[5] that has been followed in interpreting the spectra of 2,2′- bithienyls is to attribute the observed transitions to: (i) locally excited on a certain subsystem of the composite molecule, (ii) charge transfer from the substituent (X) to the parent molecule or in the opposite direction and (iii) n→π* transitions.



The results of this work prove, on the contrary to what has been previously reported,[5] that the observed transitions are not localized. There is an extensive "mixing" of the state of the subsystems (Table 4) to produce the states of the composite molecule. Also, the slight shift of band maxima with solvent polarity is a proof that none of the observed transitions is a "pure" charge transfer one. The intensity and position for the observed bands indicate that none of them corresponds to n→π* transitions.

Computations on 5-formyl-2,2′-bithienyl indicated that coplanarity of the molecule is not apparently distorted and the interaction between the states of the subsystems, thiophenecarbaldehyde and thiophene, is predominant. The contribution of the charge-transfer configurations (from one subsystem to the other) is significant. The calculated parameters, transition energy and band intensity, as a function of the angle between the planes of the subsystems indicate that the s-*trans* conformer is a good representative of the geometry of the molecule in solutions. It is also evident that the height of the barrier of internal rotation is small since transition energies did not show a wide variation with the angle of rotation.

Synthesis and Structure of (Nitroacetato)((7*RS*,14*RS*)-5,5,7,12,12,14-hexamethyl-1,4,8,11-tetraazacyclotetradecane)nickel(II), [Ni(na)(Me$_6$[14]aneN$_4$)]

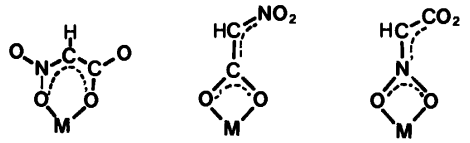
(Received February 22, 1985)

Synopsis. The title compound, [Ni(na)(Ma$_6$[14]-aneN$_4$)], has been synthesized by the reaction of α-[Ni-(Me$_6$[14]aneN$_4$)](ClO$_4$)$_2$ with potassium nitroacetate (K$_2$na) in water. X-Ray analysis shows that the complex is a *cis*-NiO$_2$N$_4$ type with the tetraazamacrocycle folded, and that a dianionic nitroacetate (na^{2-}) chelates the nickel(II) with one oxygen atom of the CO_2^- moiety and one oxygen atom of the NO_2^- moiety to form a six membered chelate ring.

Much attention has been paid to the formation of a new C–C bond using CO_2 as carbon source.[1,2] α-Nitro acids, for example, were obtained by the treatment of primary nitroparaffins with CO_2 in the presence of Mg(OCH$_3$)$_2$[3] or MgCl$_2$ and triethylamine.[4] The driving force of the reaction was attributed to the formation of a stable magnesium(II) chelate of α-nitro carboxylate ion during the reaction, since the free anion of α-nitro carboxylate is susceptible to decarboxylation. However, no direct structural evidence has been reported.

Aiming at the deeper understanding of the CO_2 uptake chemistry of this type, we intended in this study to prepare and isolate nitroacetato complex and to know its chemical properties. Another point of interest is the structure of the coordinated nitroacetate ion. There are three possible structures for the nitroacetato chelate, as shown below.



The type (a) is a six-membered chelate like the acetylacetonate. The type (b) and (c) are of four-membered chelate similar to that formed by carboxylate or nitroalkanoate ion, respectively.

The complex, [Ni(na)(Me$_6$[14]aneN$_4$)], was prepared from α-[Ni(Me$_6$[14]aneN$_4$)](ClO$_4$)$_2$[5] and K$_2$na. The complex shows three d-d bands typical of octahedral nickel(II), at 10,200 (ε=23), 17,400 (ε=13), and *ca.* 27000 (shoulder) cm^{-1}. Figure 1 shows an ORTEP view of the complex and the atom numbering system. The complex adopts *cis*-NiO$_2$N$_4$ structure with the tetraazamacrocycle folded, and the na chelate ring was found to take the type (a) structure. The atomic coordinates of non-hydrogen atoms and relevant bond distances and angles are given in Tables 1 and 2, respectively.

The N(A)O(1)O(3)C(B) and the C(A)O(2)O(4)C(B) moieties are planar within experimental errors. These two planes are not coplanar but are tilted each other by 17.3(3)°. The C(A)–C(B) distance (1.421(9)) Å is longer than C–C distances found in acetylacetonate chelates.[6] These facts indicate that the π-electrons are not fully delocalized over the six-membered ring.

The assignments of the N(A) and C(A) atoms are not unique, but they are tentatively assigned to the nitrogen (NO_2^-) and the carbon (CO_2^-) atoms, respectively, on the basis of the examination of the reliability factors and the thermal parameters.[7] No statistical disorder between NO_2^- and CO_2^- was

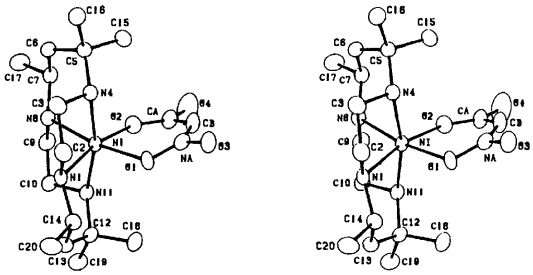


Fig. 1 ORTEP view of [Ni(na)(Me$_6$[14]aneN$_4$)] along with the atom numbering scheme.

† Present address: Department of Chemistry, Aichi Kyoiku University, Kariya, 448.

observed. The uncoordinated oxygen atom, O(3), is involved in intermolecular hydrogen bonds,[8] while the uncoordinated oxygen atom O(4) is not. There seems to be a difference in the ability of the hydrogen bond formation between the oxygen atoms of the CO_2^- and NO_2^- moieties.

The nitroacetato ligand in this complex is fairly stable toward decarboxylation, especially in methanol. The stability is attributed to the formation of the stable six-membered nitroacetato chelate, as has been postulated for the magnesium(II) complex, and to the macrocyclic effect of the ligand Me_6[14]aneN$_4$ that can fold.[9]

Experimental

Materials. α-[Ni(Me_6[14]aneN$_4$)]$(ClO_4)_2$[5] and K_2na[10] were prepared according to the literatures.

[Ni(na)(Me$_6$[14]aneN$_4$)]·CH$_3$OH·H$_2$O. To an aqueous suspension (10 cm^3) of α-[Ni(Me_6[14]aneN$_4$)]$(ClO_4)_2$ (1.08 g, 2 mmole), K_2na (0.45 g, 2.5 mmole) dissolved in a small amount of water was added. The yellow solids disappeared quickly, and blue violet solids were formed. These were filtered and extracted with methanol to remove $KClO_4$. Vacuum evaporation at 30 °C gave blue violet crystals (0.78 g). These were recrystallized from methanol. The elemental analysis was consistent with the above chemical formula. IR (KBr disk, between 1150 and 1600 cm^{-1}): 1580, 1550, 1453, 1392, 1295, and 1170 cm^{-1}.

X-Ray Analysis. A single crystal of [Ni(na)(Me_6[14]aneN$_4$)]·CH$_3$OH·H$_2$O with approximate dimension 0.56×0.42×0.38 mm was used for the X-ray study. Diffraction data were obtained on a Rigaku AFC-5 diffractometer with graphite monochromatized Mo $K\alpha$ radiation. Intensities were corrected for Lorentz and polarization factors. Crystal data are: monoclinic, $P2_1/n$, a=19.710(4), b=14.274(2), c=8.833(1) Å, β=97.13(2)°, V=2466.1(7) Å^3, Z=4, D_x=1.34 g cm^{-3}, μ(Mo $K\alpha$)=0.83 mm^{-1}. The structure was solved by the heavy atom method and refined by block-diagonal least-squares method. The weighting scheme, $w=[\sigma_{count}^2+(0.015|F_o|)^2]^{-1}$, was employed. All the hydrogen atoms except that of hydroxyl group of methanol were located by the difference Fourier syntheses and included in the final refinement with the isotropic temperature factors. The final R indices were R=0.062 and R_w=0.075 for 3344 independent reflections ($2\theta<50°$) with $|F_o|>3\sigma(|F_o|)$.[11] Calculations were carried out on the HITAC M-200H computer at the Computer Center of the Institute for Molecular Science with the Universal Crystallographic Computation Program System, UNICS III.[12]

The present study was partly supported by Grant-in-Aid for Scientific Research No. 58470039 from the Ministry of Education, Science and Culture.

Synopsis. The catalytic activity of the iron(III)-α,β,γ,δ-tetraphenylporphinetrisulfonic acid complex for the chemiluminescence reaction between luminol and H_2O_2 has been found to decrease in the presence of protein. On the basis of this phenomenon, 2×10^{-5}—2×10^{-3} g dm^{-3} bovine serum albumin was determined with the detection limit of 4 ng, lower than that in the previous paper.

It was previously reported[1] by the present authors that the catalytic activity of Cu(II) for the chemiluminescence(CL) reaction between 5-amino-2,3-dihydro-1,4-phthalazinedione(luminol) and hydrogen peroxide(H_2O_2) decreased in the presence of protein, and that the sensitive determination of protein could be carried out on the basis of this phenomenon. In order to make the method of determining protein more sensitive, the use of Co(III) instead of Cu(II) as a catalyst was attempted.[2] The results were slightly improved, but they not very satisfactory, because there was not enough bond formation between Co(III) and a protein molecule.

On the other hand, various dyestuff combination methods have been reported for the determination of a small amount of protein. The dyestuff molecule used for this method generally has several aromatic rings and sulfonic acid groups, which have a high affinity against the residues of lysine, arginine, and histidine, and the amino terminal in a protein molecule.[3] The dyestuff combination method[3,4] could be carried out only by mixing a dyestuff solution with a sample solution and by measuring the absorbance of the mixed soluion. With the object of establishing a highly sensitive method of determining protein by means of the CL method, a metal-complex compounds which had a structure similar to that of a dyestuff in the dyestuff-combination method and which had a catalytic activity for the CL reaction was used in the present study.

Several iron(III) porphine complexes have previously been reported[5] by the present authors to show a high catalytic activity for the CL reaction. Accordingly, the iron(III) α,β,γ,δ-tetraphenylporphinetrisulfonic acid complex([Fe(tpps)]), which contains aromatic rings and sulfonic acid groups in the molecule, was used for the determination of a small amount of protein by means of the CL method. This method was about 50 times as sensitive as the previous method, using the Cu(II) catalyst for the determination bovine serum albumin(BSA) as a model protein.

Experimental

The [Fe(tpps)] was prepared in accordance with Nomura's method.[6] The α,β,γ,δ-tetraphenylporphinetrisulfonic acid was purchased from Dojin Laboratories as its disulfonic acid salt. The absorption spectrum of the solution of the synthesized [Fe(tpps)] was in agreement with that reported by Nomura *et al.* The concentration of the [Fe(tpps)] stock solution was determined by means of an absorbance measurement at 395 nm.

A sample solution containing protein was diluted with a 0.01 mol dm^{-3} phosphate buffer solution(pH 7.2), and to the mixture a definite amount of [Fe(tpps)] stock solution was added to yield 5.7×10^{-9} mol dm^{-3}. The catalytic activity of the [Fe(tpps)] in the mixed solution was measured by mean of the flow-injection-analysis apparatus reported in a previous paper.[5] The ratio of the CL intensity of a protein sample solution to that of a 5.7×10^{-9} mol dm^{-3} [Fe(tpps)] solution was plotted against the amount of protein, and this graph was used as a calibration curve of the protein.

Results and Discussion

Though iron(III) porphine complexes had been reported by the previous authors to show a high catalytic activity for the CL reaction between luminol and H_2O_2, the catalytic activity of [Fe(tpps)] still remained unknown. Therefore, the catalytic activity of [Fe(tpps)] was measured; the results are shown in Fig. 1. [Fe(tpps)] was about 3 times as active as the previous iron(III) porphine complex for the CL reaction. Therefore, the effect of the protein on the catalytic activity of [Fe(tpps)] was examined. Human

serum albumin(HSA) was dissolved in a buffer solution and diluted with the same buffer solution as the preceding one, and then to it the [Fe(tpps)] stock solution was added so as to make it 5.7×10^{-9} mol dm^{-3}; this showed a CL intensity of about 10^5 cps, corresponding to the full scale of a photon counter in the absence of any protein. The mixed solution was left standing for 1 h at room temperature, and its catalytic activity was measured. This experiment was carried out at various pH values(Fig. 2). The catalytic acivity of [Fe(tpps)] for the CL reaction was found to decrease in the presence of protein. The change in the catalytic activity in the presence of protein was also found to decrease with an increase in the pH value. However, the CL intensity of a sample solution of less than pH 5 greatly decreased in the absence of protein; moreover, its CL intensity was not so reproducible. Hence, the solution containing [Fe(tpps)] and protein was adjusted to pH 7.2, and its CL intensity was measured.

The change in the catalytic activity of [Fe(tpps)] caused by HSA, BSA, human serum γ-globulin-(HγG), and bovine serum γ-globulin(BγG) was examined. HSA and BSA lowered the catalytic activity, while even 1.0×10^{-3} g dm^{-3} HγG and BγG did not affect the catalytic activiy. It is well known that Methyl Orange, Amido Black 10B, Coomassie Brilliant Blue, and so on, which are used for the dyestuff-combination method, do not react with a protein such as globulin.[3,4] Judging from the effect of the pH on the reaction between [Fe(tpps)] and protein, and the difference in reactivity with various proteins, it may be supposed that the [Fe(tpps)] binds to protein as in the above-mentioned dyestuffs.

The relationship between the reaction time of [Fe(tpps)] with protein and the catalytic activity of [Fe(tpps)] was examined. The CL intensities measured at room temperature at about 1.5 min and 1 h after mixing protein with [Fe(tpps)] were almost the same. Therefore, the CL intensity was measured immediately after a sample solution was mixed with [Fe(tpps)].

Table 1. Coefficient of variation for the determination of protein

HSA concentration/gdm⁻³	CV*/%	BSA concentration/gdm⁻³	CV*/%
0	0.54	0	0.54
2.0×10^{-5}	0.69	2.0×10^{-5}	0.79
2.0×10^{-4}	0.74	2.0×10^{-4}	0.44
2.0×10^{-3}	1.20	2.0×10^{-3}	0.73

* Coefficient of variation.

The calibration curves of HSA and BSA obtained by the present method are shown in Fig. 3, while the coefficient of variation(CV) for the determination of protein is shown in Table 1. The detection limits of HSA and BSA were 10 ng and 4 ng respectively.

In comparison with the previous method using the Cu(II) catalyst, the present method was characterized as follows: 1) about 50 times more sensitive, 2) a rapid reaction between catalyst and protein, 3) no necessity to heat the sample solution, and 4) no response for γ-globulin.

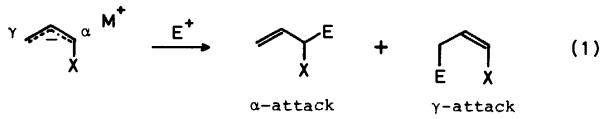
Regioselectivity of the Coupling of Phenoxyallyllithium with Allylic Electrophiles

Yasuo BUTSUGAN,* Tomokazu GOTO, and Shuki ARAKI
Department of Synthetic Chemistry, Nagoya Institute of Technology, Gokiso-cho, Showa-ku, Nagoya 466
(Received January 14, 1985)

Synopsis. The regioselectivity of the coupling of phenoxyallyllithium with allylic electrophiles was investigated. The allylation pattern corresponded with the hardness of the leaving group and the highest α-selectivity was observed in the reaction with allylic phosphate.

The reaction of heteroatom-substituted allylic anion with electrophiles can lead to two regioisomers, α-attack and γ-attack products (Eq. 1). The



(1)

regioselectivity (α/γ ratio) is a function of a number of factors including the nature of X, and the nature of other substutuents, electrophiles, solvents, and additives.[1] For example, alkyloxyallyl carbanion (X=OR) is reported to yield predominantly γ-attack product by the reaction with alkyl halides, whereas with carbonyl electrophiles α-attack product is formed selectively.[2] In order to define the effect of the leaving group of electrophiles on the α/γ ratio, we examined the reaction of phenoxyallyllithium (**1**) with a series of allylic electrophiles and it was found that the proportion of the α-product increased with increasing hardness of the electrophiles.

To a solution of phenoxyallyllithium (**1**), generated from allyl phenyl ether and butyllithium in tetrahydrofuran-*N*,*N*,*N*′,*N*′-tetramethylethylenediamine, was added allyl halides (**2a**—c), tosylate (**2d**), or phosphate (**2e**) at −78 °C, and the reaction mixture was gradually warmed to room temperature. After stirred for 1 h, the reaction was quenched and the products were extracted with ether. The separation of the α- and γ-products (**3**α and **3**γ) was easily performed by column chromatography on silica gel and the structures were deduced by their elemental and spectral data. It should be noted that the stereochemistry of **3**γ was confirmed to be *Z* by the ^{1}H NMR analysis. The yields of **3**α and **3**γ and the α/γ ratios are summarized in Table 1. The reaction of **1** with allyl iodide predominantly gave the γ-attack product (**3**α/**3**γ=28/72). The proportion of **3**α increased as the hardness of the electrophiles increased, and with allyl diphenyl phosphate the α/γ ratio was reversed (**3**α/**3**γ=53/47). These facts can be reasonably explained by the terms of HSAB principle,[3] that is, the softer halides preferentially attack the softer γ-terminus, while the harder tosylate and the phosphate attack the harder α-position. Similar tendency was also observed in the reactions with prenyl and geranyl compounds (Tables 2 and 3). By the reaction of allylic phosphates (**4**c—**e** and **6**c—**e**), the lesser amount of enol ethers (**5**γ and **7**γ) was formed compared with the reaction of the softer halides (**4a**—**b** and **6a**—**b**). Of the three allylic phosphates (diethyl, diisopropyl, and diphenyl phosphates) which were examined, diphenyl phosphates (**4e** and **6e**) gave the largest α/γ ratio. It is worthwhile to note that all the reactions of **1** with allylic electrophiles (**4** and **6**) gave the products coupled at the α-position of the allylic system, no trace of the products coupled at the γ-position being found. Although the yields of the coupling products (**3**, **5**, and **7**) are not high, considerable amounts (30—50%) of starting electrophiles were recovered in many cases. Furthermore, the coupling products are stable enough under the reaction and separation condi-

Table 1. Reaction of **1** with allyl halides tosylate, and phosphate

e	$OP(O)(OPh)_2$	29	12	70/30

tions. Therefore, the isolated yields of the α- and γ-products are considered to reflect the regioselectivity (α/γ ratio).

In summary, it is found that the regioselectivity of the coupling of **1** with allylic electrophiles largely depends on the nature of the leaving group of the electrophile and the highest α-selectivity could be attained by the use of allylic phosphate.

Experimental

General. Infrared spectra were recorded on a JASCO IRA-1 spectrometer. ^1H NMR spectra were recorded on a Hitachi R-24A spectrometer (60 MHz) in CCl_4. Chemical shifts (δ) are recorded in ppm downfield from Me_4Si. Mass spectra were determined using a Hitachi M-52 mass spectrometer at 20 eV. Elemental analyses were performed at the Elemental Analysis Center of Kyoto University.

Reaction of Phenoxyallyllithium (1) with Allylic Electrophiles (2, 4, and 6). The following reaction of **1** and allyl diphenyl phosphate (**2e**)[4] is a representative. To a solution of allyl phenyl ether (419 mg, 3.12 mmol) in THF (12 cm^3) was added a solution of *n*-BuLi in hexane [1.64 M(1 M=1 mol dm^{-3}), 1.85 cm^3, 3 mmol] and then *N,N,N',N'*-tetramethylethylenediamine (0.75 cm^3) at −78 °C. The mixture was stirred at −30——40 °C for 1.5 h. The solution of **1** thus prepared was cooled again to −78 °C and a solution of **2e** (946 mg, 3.26 mmol) in THF (6 cm^3) was added dropwise. The reaction mixture was gradually warmed to room temperature and further stirred for 1 h. After the addition of saturated aqueous ammonium chloride, the products were extracted with ether, washed with brine, and dried (Na_2SO_4). The solvent was evaporated and the residue was chromatographed on silica gel (light petroleum–benzene 10:1) to give 3-phenoxy-1,5-hexadiene (**3α**) (95 mg, 19%) and 1-phenoxy-1,5-hexadiene (**3γ**) (86 mg, 16%). The reactions with prenyl (**4**) and geranyl compounds (**6**) were similarly carried out. Results are summarized in Tables 1 to 3.

3-Phenoxy-1,5-hexadiene (3α): **IR** (neat), 3060, 2900, 1640, 1590, 1580, 1490, 1235, 1165, 980, 915, 745, and 685 cm^{-1}; ^1H NMR 7.38—6.64 (m, 5H, Ph), 6.39—5.51 (m, 2H, olefin), 5.41—4.82 (m, 4H, olefin), 4.82—4.36 (m, 1H, CH), 2.66—2.27 (m, 2H, CH_2); MS *m/z* (rel. intensity) 174 (M^+, 7.8) and 80 (100); Found: C, 82.61; H, 8.16. (Received January 24, 1985)

Synopsis. Functionalized dienes and tetraenes were synthesized in 26—63% yields by the one-pot reaction of the phosphoryl-stabilized carbanions, prepared from the Michael addition of diethyl lithiophosphonate to vinylphosphonates, with aromatic aldehydes. A similar reaction using phthalaldehyde gave 2-methylsulfonylnaphthalene (**7**) in 31% yield *via* an intramolecular double Horner-Wittig reaction.

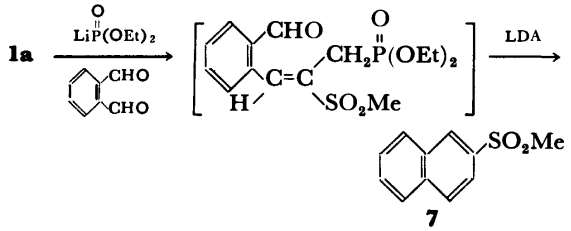
We have previously reported a new synthesis of vinylphosphonates bearing electronegative substituents such as ethoxycarbonyl and cyano groups, and their use in syntheses of functionalized heterocyclic compounds, and olefins, dienes and their analogues.[1,2] In connection with our continuing interest in the synthetic application of the vinylphosphonates, we have now developed an one-pot synthesis of unsaturated systems such as dienes and tetraenes, *etc.* having functionality.

Results and Discussion

The reaction of a phosphoryl-stabilized carbanion **2a**, generated *in-situ* from a Michael addition of diethyl lithiophosphonate to diethyl [1-(methylsulfonyl)vinyl]phosphonate (**1a**), with one equiv of benzaldehyde (**3a**) gave a mixture of 2-methylsulfonyl-1,4-diphenyl-1,3-butadiene (**4a**)(15%), diethyl (2-methylsulfonyl-3-phenyl-2-propenyl)phosphonate (**5a**)(35%), and diethyl [2-diethoxyphosphinyl-1-(methylsulfonyl)ethyl]phosphonate (**6a**)(14%). This result suggests the possibility of an one-pot synthesis of 1,3-dienes and their analogues *via* the double Horner-Wittig reaction.

Accordingly, the reaction of **2a** with an equiv of **3a**, followed by a sequential treatment with an equiv each of lithium diisopropylamide (LDA) and **3a**, afforded the expected **4a** in 63% yield. Similar reactions of **2a** with aromatic aldehydes such as *p*-chlorobenz- (**3b**), cinnam- (**3c**), and 2-thiophenecarbaldehydes (**3d**) gave the corresponding dienes and tetraenes **4b—d** in 42—53% yields. A similar treatment of [1-(ethoxycarbonyl)vinyl]phosphonate **1b** with **3a,d** produced dienes **4e,f**, albeit in low yields.

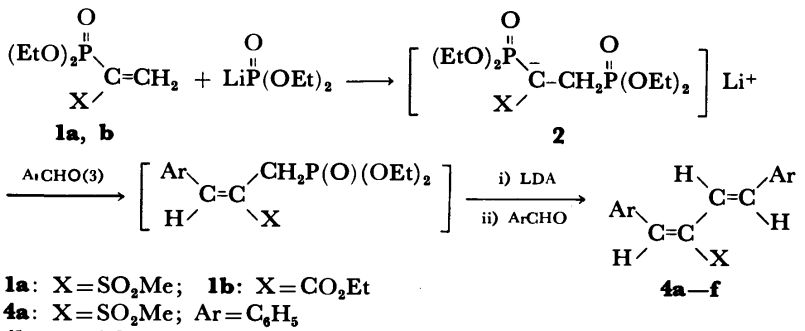
An application of similar procedures using the phosphonate **1a** to phthalaldehyde successfully gave 2-methylsulfonylnaphthalene (**7**) in 31% yield *via* an intramolecular double Horner-Wittig reaction (Eq. 1).



(1)

In contrast to aromatic aldehydes, the one-pot reaction of **1a** with butyraldehyde (**3e**) under similar conditions afforded an unexpected product, diethyl 1,3-hexadienylphosphonate (**8**) in 49% yield, whose formation can not be reasonably accounted for at present. On the other hand, a similar treatment of **1b** with **3e** produced only an 1:1 mixture of diethyl (*E*)-(**9a**) and (*Z*)-(2-ethoxycarbonyl-2-hexenyl)phosphonates (**9b**) in 40% yield.

In conclusion, vinylphosphonates serve as versatile reagents for the one-pot synthesis of dienes, tetraenes,



1a: X=SO_2Me; **1b**: X=CO_2Et

and condensed aromatic compounds, which could be useful as synthetic precursors.

Experimental

General. ^{1}H-NMR and ^{13}C-NMR spectra were taken in a $CDCl_3$ solution on a JEOL JNM-FX-60 operating at 60 and 15.04 MHz with Me_4Si as the internal standard. IR spectra were recorded with a Shimadzu IR-408 instrument. Mass spectra were taken with a JEOL DX-300 spectrometer. Melting points were measured in open capillary tubes and are uncorrected.

*Reaction of Diethyl [1-(Methylsulfonyl)vinyl]phosphonate (**1a**) with Benzaldehyde (**3a**) in the Presence of One Equiv. of Diethyl Lithiophosphonate.* To a cooled solution of diethyl lithiophosphonate, prepared from diethyl phosphonate (0.33 g, 2.39 mmol) and butyllithium (2.39 mmol), in THF (20 ml) at −75 °C was added **1a** (0.52 g, 2.15 mmol). The solution was stirred for 0.5 h at this temperature. Then **3a** (0.228 g, 2.15 mmol) was added to the solution and the mixture was stirred at room temperature for 4 h. After a conventional work-up, the residue was chromatographed on a preparative TLC with ether as the eluent to give **4a** (90 mg, 0.317 mmol, 15%), **5a** (0.25 g, 0.753 mmol, 35%), and **6a** (0.11 g, 0.289 mmol, 14%), respectively.

*2-Methylsulfonyl-1,4-diphenyl-1,3-butadiene (**4a**)*: Mp 91—93 °C; IR (KBr): 1300, 1140 cm^{-1}; ^{1}H NMR δ=3.04 (3H, s, Me), 6.70—7.90 (13H, m, olefinic and phenyl H); MS Found: *m/z* 284.0868. Calcd for $C_{17}H_{16}O_2S$: 284.0871 (M^+).

Found: C, 71.74; H, 5.80. Calcd for $C_{17}H_{16}O_2S$: C, 71.80; H, 5.67%.

*Diethyl (2-Methylsulfonyl-3-phenyl-2-propenyl)phosphonate (**5a**)*: Oil; IR (neat): 1300, 1250, 1130, 1020, 960 cm^{-1}; ^{1}H NMR δ=1.30 (6H, t, Me), 3.25 (3H, s, $SO_2\underline{Me}$), 3.40, 3.41 (2H, 2×d, 22.27, 22.12 Hz, P-CH_2), 3.80—4.50 (4H, m, $O\underline{CH_2}CH_3$), 7.10—8.00 (6H, m, olefinic and phenyl H); MS Found: *m/z* 333.0931. Calcd for $C_{14}H_{22}O_5SP$: 333.0926 (M^++1).

*Diethyl [2-Diethoxyphosphinyl-1-(methylsulfonyl)ethyl]phosphonate (**6a**)*: Mp 43—45 °C; IR (KBr): 1310, 1240,1135, 1010, 960 cm^{-1}; ^{1}H NMR δ=1.00—1.70 (12H, m, Me), 2.00—3.00 (3H, m, -$\underline{CH_2}$-$\underline{CH}$), 3.29 (3H, s, $SO_2\underline{Me}$), 3.70—4.60 (8H, m, $O\underline{CH_2}CH_3$); MS *m/z* 380 (M^+).

*General Procedure for the One-Pot Synthesis of 1,3-Dienes **4a—f**.* To a stirred solution of a phosphonate carbanion **2** (3 mmol) in THF (20 ml) at −75 °C was added an aldehyde (3 mmol). After stirring at room temperature for 4 h, the solution was cooled to −75 °C and LDA (3 mmol) in THF (5 ml) was added to the solution. After the solution was stirred at this temperature for 0.5 h, an aldehyde (3 mmol) was added to the solution. The reaction mixture was then stirred at room temperature for 10 h. After a similar work-up, a pure sample of each was obtained by preparative TLC.

*2-Methylsulfonyl-1,4-diphenyl-1,3-butadiene (**4a**)*: Yield 0.54 g (1.90 mmol, 63%).

*2-Methylsulfonyl-1,4-bis(p-chlorophenyl)-1,3-butadiene (**4b**)*: Yield 0.442 g (1.25 mmol, 42%); Mp 149—151 °C; IR (KBr): 1300, 1140 cm^{-1}; ^{1}H NMR δ=3.04 (3H, s, Me), 6.60—7.80 (11H, m, olefinic and phenyl H); MS *m/z* 352, 354, 356 (M^+).

Found: C, 57.83; H, 4.00. Calcd for $C_{17}H_{14}O_2SCl_2$: C, 57.80; H, 3.99%.

*4-Methylsulfonyl-1,8-diphenyl-1,3,5,7-octatetraene (**4c**)*: Yield 0.51 g (1.52 mmol, 51%); Mp 143—145 °C; IR (KBr): 1300, 1120 cm^{-1}; ^{1}H NMR δ=3.00 (3H, s, Me), 6.40—7.80 (17H, m, olefinic and phenyl H); MS *m/z* 336 (M^+).

Found: C, 74.89; H, 6.22. Calcd for $C_{21}H_{20}O_2S$: C, 74.97; H, 5.99%.

*2-Methylsulfonyl-1,4-di(2-thienyl)-1,3-butadiene (**4d**)*: Yield 0.47 g (1.59 mmol, 53%); Mp 123—125 °C; IR (KBr): 1290, 1130 cm^{-1}; ^{1}H NMR δ=3.03 (3H, s, Me), 6.70—8.00 (9H, m, olefinic and aromatic H); MS *m/z* 296 (M^+).

Found: C, 52.68; H, 4.02. Calcd for $C_{13}H_{12}O_2S_3$: C, 52.68; H, 4.08%.

*2-Ethoxycarbonyl-1,4-diphenyl-1,3-butadiene (**4e**)*: Yield 0.218 g (0.786 mmol, 26%); Oil; IR(neat) 1710 cm^{-1}; ^{1}H NMR δ=1.38 (3H, t, Me), 4.34 (2H, q, $\underline{CH_2}CH_3$), 6.50—7.80 (13H, m, olefinic and phenyl H); MS Found: *m/z* 278.1302. Calcd for $C_{19}H_{18}O_2$: 278.1302 (M^+).

*2-Ethoxycarbonyl-1,4-di(2-thienyl)-1,3-butadiene (**4f**)*: Yield 0.248 g (0.855 mmol, 29%); Oil; IR (neat) 1700 cm^{-1}; ^{1}H NMR δ=1.37 (3H, t, Me), 4.32 (2H, q, $\underline{CH_2}CH_3$), 6.50—7.80 (9H, m, olefinic and phenyl H); MS *m/z* 290 (M^+).

Found: C, 62.05; H, 4.88. Calcd for $C_{15}H_{14}O_2S_2$: C, 62.04; H, 4.86%.

*Synthesis of 2-Methylsulfonylnaphthalene (**7**).* The similar reaction of **1a** (2 mmol) with phthalaldehyde (0.268 g, 2 mmol) gave 0.126 g (31%) yield of **7** as white solid: Mp 138—140 °C; IR (KBr) 1290, 1120 cm^{-1}; ^{1}H NMR δ=3.12 (3H, s, Me), 7.20—8.60 (7H, m, aromatic H); MS *m/z* 206 (M^+).

Found: C, 63.64; H, 4.92. Calcd for $C_{11}H_{10}O_2S$: C, 64.06; H, 4.89%.

*One-Pot Reaction of **1a,b** with Butyraldehyd (**3e**). The Reaction Using **1a***: The reaction of **1a** (2 mmol) with **3e** (0.433 g, 6 mmol) gave 0.323 g (49%) yield of **8**: Oil: IR (neat) 1240, 1020, 960 cm^{-1}; ^{1}H NMR δ=1.04 (3H, t, J=7.03 Hz, $CH_2\underline{CH_3}$), 1.32 (6H, t, J=7.03 Hz, $OCH_2\underline{CH_3}$), 1.80—2.50 (2H, m, $\underline{CH_2}CH_3$), 3.70—4.20 (4H, m, $O\underline{CH_2}CH_3$), 5.10—7.60 (4H, m, olefinic H); ^{13}C NMR δ=12.57, 16.12 (d, $^3J_{P\text{-}C}$=6.88 Hz), 25.49, 61.27 (d, $^2J_{P\text{-}C}$=5.16 Hz), 114.34 (d, $^1J_{P\text{-}C}$=191.70Hz), 128.20 (d, $^3J_{P\text{-}C}$=27.51 Hz), 144.77, 148.92 (d, $^2J_{P\text{-}C}$=6.02 Hz). MS Found: *m/z* 218.1075. Calcd for $C_{10}H_{19}O_3P$: 218.1072.

*The Reaction Using **1b***: The reaction of **1b** (0.70 mmol) with **3e** (0.106 g, 1.47 mmol) produced 0.082 g (0.27 mmol, 40%) of an 1:1 mixture of **9a** and **9b**: Oil; IR (neat) 1710, 1250, 1030, 970 cm^{-1}; ^{1}H NMR δ=1.29 (9H, t, J=7.03 Hz, $OCH_2\underline{CH_3}$), 0.60—1.90 (5H, m, =$CHCH_2\underline{CH_2}\underline{CH_3}$), 1.90—3.30 (4H, m, PCH_2- and =$CH\underline{CH_2}CH_2CH_3$), 3.70—4.50 (6H, m, $O\underline{CH_2}CH_3$), 5.85—6.35 (0.5H, m, vinylic H), 6.70—7.15 (0.5H, m, vinylic H); MS Found: *m/z* 292.1413. Calcd for $C_{13}H_{25}O_5P$: 292.1438.

Cobalt-catalyzed Hydroesterification of Formaldehyde Dialkyl Acetals

Kazuhisa MURATA,* Akio MATSUDA, and Takashi MASUDA
National Chemical Laboratory for Industry, Tsukuba Research Center, Yatabe, Tsukuba, Ibaraki 305
(Received January 28, 1985)

Synopsis. $Co_2(CO)_8$-organic amine system was found to be an effective catalyst for the production of alkoxyacetic ester from formaldehyde dialkyl acetals and CO; this is the first example of homogeneous hydroesterification of acetal.

Alkoxyacetic ester is not only a good ether/ester type solvent, but also an important intermediate for preparing ethylene glycol by hydrolysis and hydrogenation. The ester is produced when formaldehyde dialkyl acetals(acetals) are allowed to react with CO in the presence of (solid) acid catalyst (Eq. 1).[1]

$$(RO)_2CH_2 \xrightarrow{CO} ROCH_2COOR \quad (1)$$

$$\xrightarrow{CO/H_2} \mathbf{1}\ (R=Me(\mathbf{a}),\ Et(\mathbf{b}),\ i\text{-}Pr(\mathbf{c})) \quad ROCH_2CHO \quad (2)$$

Also, the ester is obtained by the reaction of formaldehyde with alkyl formate under CO pressure using acid catalyst.[2] In the presence of cobalt catalyst, acetals react with CO/H_2 gas to give alkoxyacetaldehyde (Eq.2).[3] However, in these three processes the yields of product are low. $Co_2(CO)_8$-organic amine system is well known to catalyze the hydroesterification of olefin to give the corresponding carboxylic ester.[4] These findings prompt us to study the cobalt-catalyzed hydroesterification of acetals, yielding alkoxyacetic ester (**1**). We describe here some of our results.

As shown in Table 1, basic solutions prepared *in situ* from $Co_2(CO)_8$ were found to be active catalysts for the hydroesterification of acetals under CO pressure. The reaction proceeded smoothly with no induction period. Ethyl ethoxyacetate (**1b**) was produced from formaldehyde diethyl acetal in 91% yield (*ca.* 910% based on cobalt atom) when the reaction was carried out in dioxane in the presence of γ-picoline under CO pressure of 150 K/cm² at 160 °C (Run 6). Methyl methoxyacetate (**1a**) and isopropyl isopropoxyacetate (**1c**) were obtained from formaldehyde dimethyl acetal and formaldehyde diisopropyl acetal, respectively, in high yields (Runs 4,9). Besides γ-picoline/dioxane(solvent) system, some amine/solvent combinations are also effective (Runs 1—3). The use of γ-picoline solvent was unfavorable(11% yield (**1a**)). The use of CO/H_2 gas in place of CO reduced the yield of **1b**[5] (Run 7).

5	3-Pyridinol	65	47
6	4-Pyridinol	26	12
7	2,4-Lutidine	34	0.4
8	2,4,6-Collidine	13	1.3
9	3-Cyanopyridine	—	—

a) See footnote of Table 1.

Organic amines are essential as catalyst component;[6] the ester, **1a** was not produced at all in the absence of amine (Table 1, Run 5). Pyridine or its derivatives such as γ-picoline, 3-pyridinol are generally favorable (Table 2, Runs 1—6). The yield of ester, **1a** increased with the increase in amine concentration(pyridine 10—60 mmol, γ-picoline 10—30 mmol).

Other metal carbonyl catalysts such as $Rh_4(CO)_{12}$, $Ru_3(CO)_{12}$, $Fe(CO)_5$, $Mo(CO)_6$, and $Cr(CO)_6$ were examined for this reaction of acetals under the same conditions as that of $Co_2(CO)_8$ catalyst, but neither of these catalysts gave carbonylation products.

A possible scheme by which the production of alkoxyacetic ester can be explained, is illustrated in Fig. 1, where pyridine(Py) is used as amine. In this scheme, pyridine participates in alkoholysis step 5, as is the case of the cobalt-catalyzed hydroesterification of olefin.[4] Steps 2 and 3 have been already given in the hydroformylation of acetals (Eq. 2).[3] The absence of EtOH resulted in the appearance of induction period (*ca.* 30 min) and in the drop of **1b** yield (Table 1, Run 8), indicating that, under CO conditions, EtOH takes part in step 1. Based on the scheme, scavenging of $HCo(CO)_4$ from the reaction mixture will stop the catalytic cycle. In fact, when sodium carbonate (4 mmol) is initially added to Run 4(Table 1), the yield of **1a** was only 3%.

Experimental

Materials. Solvents and amines were obtained commercially and used with no further purification. Formaldehyde dimethyl acetal and formaldehyde diethyl acetal were purchased from Tokyo Kasei Kogyo CO., LTD. Formaldehyde diisopropyl acetal was synthesized from aqueous formalin and 2-propanol using *p*-toluenesulphonic acid as catalyst.

Reaction Procedure. A catalyst solution prepared from $Co_2(CO)_8$(2 mmol), amine(10—60 mmol), acetal(40—50 mmol), alcohol(80—100 mmol), and H_2O(5 mmol) in dioxane(15 cm³) was placed in a stainless-steel autoclave (50 cm³), which was subsequently charged with CO (150 Kg/cm²). After the reaction, the vessel was cooled to room temperature and the catalyst solution was analyzed by GLC. Satisfactory spectral data were obtained for alkoxyacetic esters.

This work was supported by National Research and Development(C_1 Chemistry project) of Ministry of International Trade and Industry.

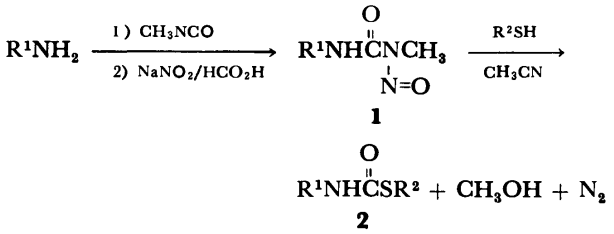
N-Nitroso Compounds. IV.[1] Reaction of *N*-Nitrosourea with Thiol. A New Synthesis of Thiocarbamic *S*-Esters

Kitaro Yoshida,* Masayoshi Isobe, Kazuyuki Yano, and Kazuo Nagamatsu
Department of Chemistry, Saitama Medical School, 981 Kawakado, Moroyama, Iruma-gun, Saitama 350-04
(Received March 1, 1985)

Synopsis. Thirteen thiocarbamic *S*-esters have been synthesized in good yield by the reaction of thiol with substituted *N*-methyl-*N*-nitrosourea in anhydrous acetonitrile.

Although several methods have been reported on the preparation of thiocarbamic *S*-esters, the most commonly used ones are those from alkylcarbamoyl chlorides with sodium alkanethiolates,[2a] alkyl thiocyanates with alcohols,[2b] or those using carbonyl sulfide with base,[2a] or carbon monoxide with selenium as a catalyst.[2c] Since the preparation of herbicidal thiocarbamic *S*-esters is of commercial importance, it is significant to explore an alternative route to this class of compounds.

Recently, we have shown that *N'*-substituted *N*-methyl-*N*-nitrosourea readily reacts with aliphatic amines to give "transaminated" urea in substantial yield.[1] Similar S_N2 reactions have also been reported for *N*-alkyl-*N*-nitroso amides with aliphatic primary amines in refluxing dichloromethane.[3] Furthermore, Challis and his co-workers observed a nucleophilic rather than a general base catalysis of imidazole in the hydrolyses of *N*-nitroso-2-pyrrolidone and related compounds in aqueous buffer solution.[4] All of these results are undoubtedly related to an enhanced leaving property of the *N*-nitrosoamino moiety of the substrates. Thus a facile reaction is also expected to occur with other nucleophiles. We have now found that *N*-nitrosourea **1** reacts with various thiols under mild conditions to give the corresponding thiocarbamic *S*-esters **2** in good yields as shown in Scheme 1.



Scheme 1.

We wish to report here a convenient method of the preparation of **2** from primary amines by the use of **1** as a key compound.

Results and Discussion

N-Methylurea ($R^1NHCONHCH_3$) was obtained conventionally[5] through the carbamoylation of starting amine with methyl isocyanate. On treatment of the urea with sodium nitrite in formic acid, an *N*-nitrosated urea **1** was produced exclusively; this was the product from the mononitrosation at the less hindered *N*-position.[6] The crude product **1** was treated with 2 equiv of thiol in anhydrous acetonitrile at 60 °C. Because of the limited solubility and to avoid the hydrolysis of **1**,[7] the use of organic solvent may be of significance. As the reaction proceeded, gas evolution was observed and in most cases, almost all quantity of **1** was consumed within several hours. However, under the same

conditions, aromatic thiol did not react with **1** even after a prolonged reaction period, so that an elevated temperature was required. After work up, the thiocarbamic *S*-ester **2** was obtained in the yields of 42—100% (39—99% based on the amine used).[8] The results are summarized in Table 1.

For synthetic purposes, the present method has some advantages in that (i) the direct reaction of **1** with alkanethiol (not sodium alkanethiolates) occurs spontaneously under rather mild conditions; (ii) by-products such as methanol and nitrogen arising from the *N*-methyl-*N*-nitrosoamino fragment can readily be eliminated, so that no tedious work up is necessary (see Experimental); (iii) in addition to the current availability of aromatic amines, it becomes possible to utilize aromatic thiols as well. Thus the present study provides an efficient new route to thiocarbamic *S*-esters.

Experimental

Mps are uncorrected. IR spectra were taken in chloroform solution by a Shimadzu IR-400 spectrophotometer. All the reagents were of commercial grade and used without further purification.

Reaction of 1 with Thiol. An *N'*-substituted *N*-methylurea was prepared in a usual fashion.[5] The urea (10 mmol) was treated by sodium nitrite (20 mmol) in formic acid (10 ml) at 0—5 °C for 1 h. The mixture was poured onto ice-water, and the precipitate formed was collected, washed with cold water, and dried under reduced pressure to yield exclusively *N*-nitrosated urea **1** (77—100% from the amine). The crude product **1** and an excess of thiol (20 mmol) were dissolved in anhydrous acetonitrile (20 ml) and the mixture was stirred at 60 °C with monitoring the reaction by TLC analysis. After **1** was consumed, evaporation of the solvent and the excess thiol under reduced pressure gave **2** in almost pure solid. When a thiol of high boiling point was used, isolation by column chromatography (silica gel, $CHCl_3$–hexane or ether–hexane) was carried out. The IR and ^1H NMR spectra of the crude solid **2** were consistent with the assigned structure. In most cases, the analytical sample was obtained by recrystallization to give a satisfactory elemental analysis within ±0.4% for C, H, N, and S. The yields and some of the physical data of **2** are summarized in Table 1.

Synthesis of Macrocarbocycles Utilizing Intramolecular 1,3-Dipolar Cycloaddition of Nitrile Oxides. Synthesis of (±)-Muscone

Morio Asaoka,* Masayoshi Abe, and Hisashi Takei
Department of Life Chemistry, Tokyo Institute of Technology, Nagatsutacho, Midori-ku, Yokohama 227
(Received March 1, 1985)

Synopsis. Intramolecular 1,3-dipolar cycloaddition of nitrile oxides generated from ω-nitro-1-alkenes gave isoxazoline-fused macrocarbocycles (ring size 12, 14, 15, and 16) in fair to good yields. The 15-membered derivative was converted into (±)-muscone.

In connection with a total synthesis of macrocyclic natural products, we examined intramolecular 1,3-dipolar cycloaddition of silyl nitronates and nitrile oxides generated from ω-nitroalkyl acrylates, and achieved the synthesis of macrolides, (±)-pyrenophorin and (±)-A26771B.[1,2] In this note we will describe intramolecular 1,3-dipolar cycloaddition of nitrile oxides generated from ω-nitro-1-alkenes.[3]

The nitro alkenes **2** were easily prepared from the corresponding aldehydes **1** by the method of Wollenberg and Mille[4] in good yields. Intramolecular 1,3-dipolar cycloaddition was carried out using dilute solution of **2** in benzene or toluene (concentration=1 mmol of **2**/400 ml of solvent) in the presence of 10 equiv of *p*-chlorophenyl isocyanate and triethylamine.[5] We examined the effects of reaction temperature and time using **2c** (Table 1, Run 4—8).

When reaction was carried out in refluxing benzene the reaction was relatively slow and after 15—25 h, desired cyclic compound **4c** was obtained in 31—44% yield (Run 4 and 5). Then the reaction was carried out in refluxing toluene for 15 h. Surprisingly the yield of **4c** dropped to 18% and a large amount (40%) of starting material (**2c**) was recovered. This result suggests that dehydration of nitro compounds with triethylamine and isocyanate is supressed at that temperature presumably because of the instability of *aci*-nitro form at high temperature (Run 6). According to this assumption, the reaction was carried out at 50 °C for 18 h in order to generate the nitrile oxide completely and then at 110 °C for 18 h to give better yield (63%) of **4c** (Run 7). However when the intramolecular addition step was carried out at higher temperature (140 °C) the yield dropped slightly, probably because of decomposition of the product at that temperature. Intramolecular 1,3-

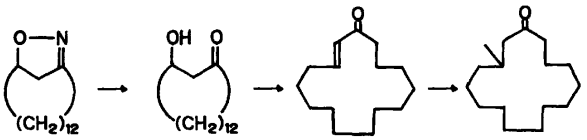
Table 2. Spectral and physical data of **4a—d**

Compound	NMR ($CDCl_3$), δ	IR (KBr), cm^{-1}	Mp, θ_m/°C
4a	1.30 (14H, broad s), 1.20—1.82 (2H, m), 2.80 (2H, t) 2.14—2.54 (2H, m), 4.26—4.85 (1H, m)	1610 (C=N)	85.5—86.5
4b	1.34 (20H, broad s), 2.26—2.70 (2H, m), 2.80 (1H, d), 2.83 (1H, d), 4.46—4.96 (1H, m)	1605 (C=N)	67.0—68.5
4c	1.43 (22H, broad s), 2.13—2.63 (2H, m), 2.63—2.97 (2H, m), 4.33—4.93 (1H, m)	1615 (C=N)	81.0—82.0
4d	1.82 (24H, broad s), 2.13—2.63 (2H, m), 2.63—2.97 (2H, m), 4.32—4.81 (1H, m)	1610 (C=N)	88.5—90.0

dipolar cycloaddition of alkenenitrile oxides having different chain length was also examined. Nitroalkenes **2b** and **2d**, gave the expected cyclic compounds **4b** and **4d** in 44 and 60% yields, respectively. In the case of **2a** however, the reaction was complex and **4a** was isolated only in 21% yield. The structures of **4a—d** were confirmed by spectral (NMR, IR, and Mass) data and elemental analyses. Their NMR and IR spectral data along with their melting points are listed in Table 2.

In the course of the synthetic studies of macrolides, we have shown that isoxazoline derivatives were easily converted to α,β-unsaturated ketones in high yields by hydrogenolysis under acidic conditions and subsequent dehydration.[1,2,6] Then transformation of the isoxazoline derivative **4c** to (±)-muscone *via* enone **6** was examined. Although hydrogenolysis of **4c** under acidic conditions in the presence of Pd–C showed formation of some by-products, use of PtO_2 as a catalyst gave better results. After hydrogenolysis of **4c** in acetic acid–water under atmospheric pressure of hydrogen at room temperature for 2 d, the resulted crude **5** was treated with methanesulfonyl chloride and triethylamine to give **6** in 45% overall yield from **4c**, which was converted to (±)-muscone **7** in 79% yield by known method.[7]



4c **5** **6** **7**

Scheme 2.

Experimental

A Typical Procedure of Intramolecular 1,3-Dipolar Cycloaddition: Nitroalkene **2c** (255 mg, 1 mmol), *p*-chlorophenyl isocyanate (1.52 g, 10 mmol), and triethyamine (4 ml, 10 mmol) were dissolved in 400 ml of dry toluene. The solution was stirred at 50 °C for 18 h and then heated under reflux for 18 h. To the reaction mixture was added isopropylamine (1 ml) at 0 °C and stirred at that temperature for 20 min. After filtration through short pad of celite, the solution was concentrated *in vacuo* and the residue was purified by column chromatography (benzene: ether=50:1) to give 149 mg of **4c**.

trans-*2-Cyclopentadecenone (6)*: A solution of **4c** (66 mg) dissolved in acetic acid (3 ml) and water (0.5 ml) was stirred under H_2 for 2 d in the presence of PtO_2. After removal of catalyst by filtration, solvent was removed under reduced pressure. To the residue dissolved in dry CH_2Cl_2 (2 ml) were added MsCl (124 mg, 1.07 mmol) and triethylamine (0.37 ml, 2.65 mmol) at 0 °C under argon. After 16 h, a small amount of MeOH was added dropwise to the reaction mixture. The mixture was diluted with ether and precipitated salt was removed by filtration. After removal of solvent, the residue was purified by column chromatography (hexane:ether=10:1) to give **6** (28 mg, 45%): IR (NaCl) 1685, 1655 cm^{-1} (C=O) and 1627 cm^{-1} (C=C); NMR (60 MHz, $CDCl_3$) δ=1.05—1.93 (20H, m), 2.07—2.70 (4H, m), 6.10 (2H, d, J=16 Hz), 6.68 (1H, dt, J=16 and 6 Hz).

(Received March 13, 1985)

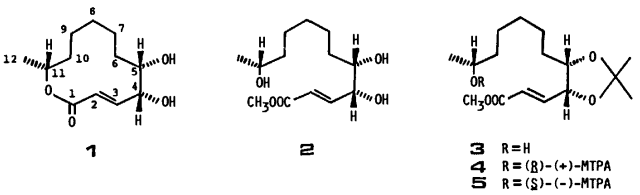
Synopsis. The absolute configuration of cladospolide A, a phytotoxic macrolide produced by a fungus *Cladosporium cladosporioides*, was determined as (4*R*,5*S*, 11*R*,2*E*)-4,5-dihydroxy-2-dodecen-11-olide by means of MTPA method.

Cladospolide A (**1**), a novel fungal metabolite, was isolated from culture filtrate of *Cladosporium cladosporioides* FI-113 and showed the inhibitory activity to lettuce seedlings. In the previous papers, we reported cladospolide A was a novel macrolide and its planar structure was shown as (*E*)-4,5-dihydroxy-2-dodecen-11-olide.[2)] The relative stereochemistry of three asymmetric centers of **1** was also established as (4*R*,5*S*,11*R*) or (4*S*,5*R*,11*S*) by X-ray single crystal structure elucidation.[1,3)] We now wish to report here the determination of the absolute configuration of cladospolide A by means of the MTPA method.[4,5)]

The lactone moiety of **1** was transformed into hydroxy ester, methyl (*E*)-4,5,11-trihydroxy-2-dodecenoate (**2**), by treatment with methanolic hydrogen chloride. Isopropylidenation of 1,2-diol part of **2** with acetone in acidic medium gave methyl (*E*)-4,5-(isopropylidenedioxy)-11-hydroxy-2-dodecenoate (**3**), which possesses an acyclic and secondary alcohol structure without steric congestion. To this alcohol (**3**), the MTPA method was applied.[4)] The alcohol (**3**) was transformed into the corresponding (*R*)-(+)-α-methoxy-α-(trifluoromethyl)phenylacetic acid [(*R*)-(+)-MTPA] ester (**4**) and (*S*)-(−)-MTPA ester (**5**) according to Mosher's method.[6)] ^{1}H NMR spectra of **4** and **5** were taken with various molar ratio (0—0.6) of Eu(fod)$_3$-d_{27} to MTPA ester in $CDCl_3$, and the magnitudes of induced chemical shifts of each signal were plotted *versus* molar ratio (Eu(fod)$_3$-d_{27}/MTPA ester). In this range the induced shifts were essentially linear with respect to molar ratio of the reagent and MTPA ester. Lanthanoid induced shift (LIS) values for the selected proton signals of **4** and **5** were given in Table 1. The ΔLIS_{OMe} value for the methoxyl group of MTPA was largely positive (+1.67), while other ΔLIS values were very small. This indicates that the chiral center at $C_{(11)}$ of **3** is in an *R*-configuration according to the generality for the MTPA method.[4)] Then, the stereostructure of cladospolide A was determined as (4*R*,5*S*,11*R*,2*E*)-4,5-dihydroxy-2-dodecen-11-olide (**1**).[7)]

Table 1. Lanthanoid induced shift (LIS) values for the selected proton signals of (*R*)-(+)-MTPA ester (**4**) and (*S*)-(−)-MTPA ester (**5**)

	LIS values of **4**	ΔLIS	LIS values of **5**
$C_{(1)}OOCH_3$	2.85	+0.17	2.68
$C_{(2)}$-H	3.08	+0.25	2.83
$C_{(3)}$-H	2.91	+0.15	2.76
$C_{(4)}$-H	0.63	+0.01	0.62
$C_{(5)}$-H	0.26	+0.05	0.21
$C_{(11)}$-H	1.17	+0.32	0.85
$C_{(11)}$-CH_3	0.63	+0.34	0.29
MTPA-OCH_3	5.05	+1.67	3.38



Experimental

General Procedures. Infrared (IR) spectra were measured on JASCO IRA-2 and Hitachi 260-30 spectrometers. Proton and carbon-13 nuclear magnetic resonance (^{1}H and ^{13}C NMR) spectra were taken using Varian EM390 (90 MHz for ^{1}H), JEOL FX-90Q (90 MHz for ^{1}H), JEOL FX-100 (100 MHz for ^{1}H and 25 MHz for ^{13}C), and JEOL MH-100 (100 MHz for ^{1}H) spectrometers. Chemical shifts were expressed in δ (ppm) downfield from tetramethylsilane as an internal standard and coupling constants in Hz. Mass (MS) spectra were run on a JEOL D-300 mass spectrometer operating at 70 eV. Wakogel C-200 (Wako) were used for column chromatography.

*Methyl (4*R*,5*S*,11*R*,2*E*)-4,5,11-Trihydroxy-2-dodecenoate (**2**).* Cladospolide A (**1**; 88 mg) was dissolved in 20 ml methanol saturated with hydrogen chloride. After standing for 1 h, the reaction mixture was concentrated *in vacuo* and extracted with ethyl acetate. The extract was subjected to separation by silica gel (20 g) column chromatography and was eluted with ethyl acetate to afford **2** as an oil (91 mg). **2**: IR (neat) 3400, 1715, and 1665 cm^{-1}; ^{1}H NMR (100 MHz; $(CD_3)_2CO$) δ=1.24 (3H, d, *J*=6 Hz), 3.75 (3H, s), 3.4—4.1 (3H including 2×—OH, m),[8)] 4.2—4.5 (3H including 1×—OH, m),[8)] 6.05 (1H, br d, *J*=15 Hz), 7.05 (1H, dd, *J*=15 and 4.5 Hz); ^{13}C NMR (25 MHz; $(CD_3)_2CO$) δ=24.42 (CH_3), 26.94 (CH_2), 27.02 (CH_2), 30.94 (CH_2), 33.96 (CH_2), 40.60 (CH_2), 52.00 (CH_3), 67.98 (CH), 75.14 (CH), 75.29 (CH), 121.62 (CH), 150.20 (CH), 167.63 (C=O);[9)] MS *m/z* 261 (M+H$^+$; 0.001),[10)] 116 (100).

*Methyl (4*R*,5*S*,11*R*,2*E*)-4,5-(Isopropylidenedioxy)-11-hydroxy-2-dodecenoate (**3**).* Trihydroxy ester (**2**; 80 mg) was

dissolved in dry acetone (20 ml) containing 0.5% 6 M* hydrochloric acid and the mixture was allowed to stand at room temperature for 45 h. The reaction mixture was neutralized with 0.1 M sodium methoxide and evaporated *in vacuo*. The residue was subjected to silica gel (20 g) column chromatographic separation and was eluted with benzene–ethyl acetate (9:1) to afford **3** as an oil (33 mg). **3**: IR (neat) 3450, 1720, 1630 cm^{-1}; ^1H NMR (100 MHz; $CDCl_3$) δ=1.16 (3H, d, J=6 Hz), 1.36 (3H, s), 1.48 (3H, s), 3.70 (3H, s), 4.16 (1H, m), 4.60 (1H, br t, J=4.5 Hz), 6.00 (1H, br d, J=15 Hz), 6.76 (1H, dd, J=15 and 4.5 Hz); ^{13}C NMR (25 MHz; $CDCl_3$) δ=23.60, 25.62, 25.62, 26.32, 28.13, 29.57, 30.53, 39.31, 51.74, 68.18, 77.48, 78.39, 108.93, 122.67, 144.23, 166.55; MS m/z 285 ($M-15^+$; 24), 193 (10), 156 (27), 125 (17), 98 (100). No molecular ion was observed.

(R)-(+)-MTPA Ester (4). A mixture of dry pyridine (0.3 ml), (*R*)-(+)-MTPA chloride (0.05 ml), the substrate alcohol (**3**; 13 mg), and carbon tetrachloride (0.3 ml) was stirred at room temperature for 3 d. Excess amount of *N,N*-dimethyl-1,3-propanediamine (*ca.* 0.1 ml) was added and the mixture allowed to stand for 10 min. It was then extracted with ether, washed (with dil. HCl ×2, saturated aqueous solution of sodium carbonate, and saturated brine ×2), and dried over magnesium sulfate. The filtered ether solution was concentrated, and the reaction product was purified by passing through a silica-gel (*ca.* 5 g) column. Elution with benzene–acetone(5:1) gave 14 mg of (*R*)-(+)-MTPA ester (**4**; 63% yield): an oil, IR (neat) 1740, 1725, and 1660 cm^{-1}; ^1H NMR (90 MHz; $CDCl_3$) δ=1.25 (3H, d, J=6 Hz), 1.38 (3H, s), 1.51 (3H, s), 3.57 (3H, s, OCH_3 at MTPA part), 3.75 (3H, s, $-COOCH_3$), 4.22 (1H, m, $C_{(5)}$-H), 4.64 (1H, td, J=6 and 1 Hz, $C_{(4)}$-H), 5.13 (br q, J=6 Hz, $C_{(11)}$-H), 6.07 (1H, dd, J=16 and 1 Hz, $C_{(2)}$-H), 6.84 (1H, dd, J=16 and 6 Hz, $C_{(3)}$-H), and 7.3—7.6 (5H, m); MS m/z 516 (M^+; 2), 501 (43), 484 (3), 225 (58), 193 (40), 189 (60), 156 (98), and 98 (100); Found: m/z 516.2352. Calcd for $C_{26}H_{35}O_7F_3$: M, 516.2334.

(S)-(−)-MTPA Ester (5). Alcohol (**3**; 14 mg) was treated with (*S*)-(−)-MTPA chloride by the same procedure as above to transform into (*S*)-(−)-MTPA ester (**5**; 15 mg; 62% yield): an oil, IR (neat) 1740, 1725, and 1660 cm^{-1}; ^1H NMR (90 MHz; $CDCl_3$) δ=1.28 (3H, diffused d), 1.38 (3H, s), 1.51 (3H, s), 3.57 (3H, s, $-OCH_3$ at MTPA part), 3.75 (3H, s, $-COOCH_3$), 4.21 (1H, m, $C_{(5)}$-H), 4.64 (1H, br t, J=6 Hz, $C_{(4)}$-H), 5.15 (1H, br q, J=6 Hz, $C_{(11)}$-H), 6.07 (1H, br d, J=15 Hz, $C_{(2)}$-H), 6.84 (1H, dd, J=15 and 6 Hz, $C_{(3)}$-H), and 7.3—7.6 (5H, m); MS m/z 516 (M^+; 2), 501 (36), 484 (6), 225 (60), 193 (38), 189 (91), 156 (96), and 98 (100). Found: m/z 516.2299. Calcd for $C_{26}H_{35}O_7F_3$: M, 516.2334.

* 1 M=1 mol dm^{-3}.

Synopsis. Correlations of ionization potentials and electrochemical oxidation potentials for group 4B dimetals were obtained.

The reactivity of the metal-metal bond of group 4B dimetals has received considerable interest in comparison with that of carbon-carbon double bond.[1,2] As electron-rich species, metal-metal bonds of group 4B dimetals are subject to cleavage by acids, halogens, metal complexes, and other electrophiles.[1] Since group 4B dimetals have rather low ionization potentials, electron-transfer process in solutions are also possible in which the rate is limited by the ionization potentials of organometals and the electron affinity of electrophiles.[3] In order to predict rates of reactions and the products for such processes, the most fundamental data are the ionization or oxidation potentials of organometals. However, there is only a paper on a correlation of organic oxidation and ionization potentials for group 4B metals.[4] Here we describe such a correlation for group 4B dimetals.

$$R_3M\text{-}M'R_3 \longrightarrow R_3M\text{-}M'R_3^{\dagger} + e \quad (1)$$
$$(M, M' = Si, Ge, Sn)$$

Results and Discussion

The anodic oxidation of group 4B dimetals was examined in acetonitrile solutions with tetraethylammonium perchlorate as a supporting electrolyte and a glassy carbon anode. The reference electrode was Ag/AgCl in acetonitrile. The anodic oxidation of each of the group 4B dimetals was found to be irreversible, suggesting that the dimetal cation radical is unstable. Equation (2) represents a probable mode of decomposition.[5]

$$R_3M\text{-}M'R_3^{\dagger} \longrightarrow R_3M\cdot + {}^{+}M'R_3 \quad (2)$$

Peak potentials (E_p) of group 4B dimetals are listed in Table 1. Since each of these oxidative processes is irreversible, the observed potentials shifted to more positive values relative to $E°$. However, the potentials listed in Table 1 reflect the relative ease of removal of a single electron from the group 4B dimetals examined in this study.

In order to determine if there is a correlation between the anodic oxidation of group 4B dimetals in solution and their ionization potentials, He (I) photoelectron spectra of group 4B dimetals were also examined.

The vapor-phase photoelectron spectra (PES) of some group 4B dimetals have been previously reported by several research groups.[6-8] The lowest-energy band is associated with ionization from the metal-metal σ bonding orbital. Semiempirical calculations for the group 4B dimetals show that a highest occupied molecular orbital (HOMO) is highly localized at the central metal-metal bond ($4a_{1g}$)[6,7] The lowest-energy bands of group 4B dimetals measured in this work are also listed in Table 1.

The threshold or adiabatic ionization energy of the lowest-energy band decreases in the order: Si-Si> Si-Ge>Ge-Ge>Si-Sn>Ge-Sn>Sn-Sn in accord with the metal-metal ionic bond dissociation energy.[9]

The vertical ionization potential correspond to the Frank-Condon transition of the ionic state. Electron detachment from group 4B dimetals in Eq. 1 under these conditions shows a relationship to the electrochemical oxidation potentials in acetonitrile solution as shown in Fig. 1.[4,10]

The plots in Fig. 1 fit the equations E_p=0.91 (IP) −6.08 for permethyl derivatives and E_p=0.78 (IP) −4.82 for perethyl derivatives. The correlation coefficents for the plots are 0.96 and 0.88, respective-

Table 1. Oxidation and ionization potentials of group 4B dimetals

Compound	IP/eV[a]	E_p/V[b]
$Me_3SiSiMe_3$	8.68, 8.69[c]	1.76
$Me_3SiMe_2SiSiMe_3$	8.19[c], 9.14[c]	1.40, 1.76
$Me_3SiGeMe_3$	8.62	1.76
$Me_3GeGeMe_3$	8.60, 8.60[d]	1.70
$Me_3SiSnMe_3$	8.39, 8.32[d]	1.60
$Me_3GeSnMe_3$	8.36, 8.33[d]	1.44
$Me_3SnSnMe_3$	8.20, 8.20[d]	1.28

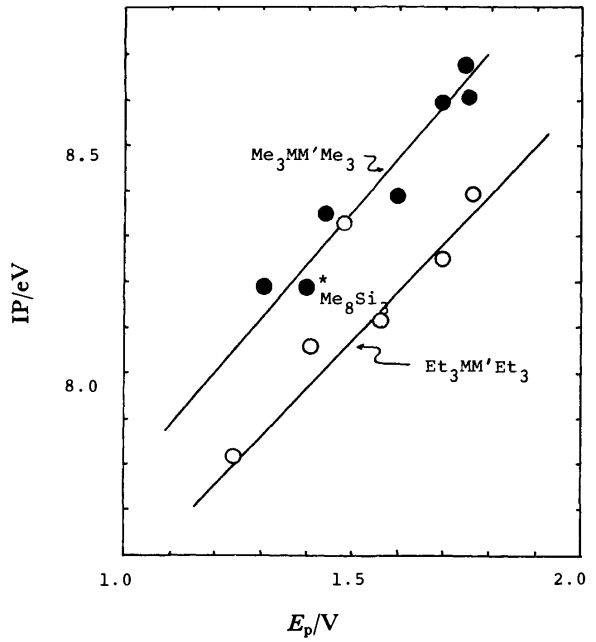

Fig. 1. Relationship between oxidation and ionization potentials of group 4B dimetals.

ly. Each slope is less than unity. It should be realized that these relations result from unstability of dimetal cation radicals and incursion of specific surface effects and solvations. Since the initially formed dimetal cation radicals may decay more rapidly than the time required for the measurement, E_p is a kinetic parameter for the overall oxidation process. The dimetal cation radicals will be strong acids stabilized by hydrogen bonding to the basic solvent, acetonitrile. This solvation will, of course, lower the E_p. These effects should be variable between permethyl derivatives and perethyl derivatives.

This correlation between anodic oxidation of group 4B dimetals in solution and their gas phase ionization potentials should provide interesting criteria for evaluating electron transfer processes involving group 4B dimetals.

Experimental

Materials. $Me_3SiSiMe_3$, bp 112 °C,[13] $Me_3SiMe_2SiSiMe_3$, bp 112 °C/106 mmHg,[14] $Me_3SiGeMe_3$, bp 122 °C,[15] $Me_3GeGeMe_3$, bp 136 °C,[16] $Me_3SiSnMe_3$, bp 144 °C,[17] $Me_3GeSnMe_3$, bp 154 °C,[17] $Me_3SnSnMe_3$, bp 182 °C,[18] $Et_3SiSiEt_3$, bp 100 °C/5.0 mmHg,[19] $Et_3SiGeEt_3$, bp 87 °C/3.0 mmHg,[20] $Et_3GeGeEt_3$, bp 73 °C/0.7 mmHg,[21] $Et_3SiSnEt_3$, bp 77 °C/0.7 mmHg,[22] $Et_3GeSnEt_3$, bp 120 °C/6 mmHg,[23] and $Et_3SnSnEt_3$, bp 160 °C/23 mmHg (1 mmHg=133.322 Pa),[24] were prepared according to the cited literatures.

Photoelectron spectra were obtained with a Perkin-Elmer PS-18 photoelectron spectrometer of Auburn University, using the He (I) resonance line at 21.22 eV as an excitation source. The spectra were calibrated with Ar and Xe as internal standards.

Electrochemical measurements were performed with Bioanalytical System Inc. CV-1B Cyclic Voltammetry Instrument under conditions similar to those described in previous works.[25] The values of E_p were measured in acetonitrile solution containing 0.1 M tetraethylammonium perchlorate (1 M=1 mol dm^{-3}) at 100 mV s^{-1}.

(Received November 26, 1984)

Synopsis. The reactions of $Si_3(PO_4)_4$ with CaO and MgO at high temperatures up to 1150 °C yielded silicon phosphate glass, $Me_3(PO_4)_2$, $Me_2P_2O_7$, and α-cristobalite, depending on the temperature, the heating time, and the $MeO/Si_3(PO_4)_4$ molar ratio (Me: Ca and Mg). These reactions were found to proceed by means of the one-way diffusion of alkaline earth metal oxides into the $Si_3(PO_4)_4$ phase.

The synthesis of SiO_2–P_2O_5 compounds was carried out by Makart[2)] and Liebau *et al.*,[3)] who reported the formations of $Si_3(PO_4)_4$ (hexagonal), SiP_2O_7 (**1**) (hexagonal), SiP_2O_7 (**2**) (monoclinic), SiP_2O_7 (**3**) (tetragonal), and SiP_2O_7 (**4**) (cubic) in the reactions of various SiO_2 compounds with phosphoric acid. However, no information is at present available on the chemical properties of these silicon phosphates. The present authors[4)] have previously prepared silicon phosphates, such as $Si_3(PO_4)_4$, and SiP_2O_7 (**1**, **2**, **3**), by means of the calcination of silica gel impregnated with a small amount of phosphoric acid at temperatures up to 1000 °C; they have thus shown that these phosphates can be used as a satisfactory hardener for silicate adhesives. A kinetic study of the hydrolysis of $Si_3(PO_4)_4$ in aqueous alkaline solutions was also carried out in this connection.[1)] Besides being useful as hardeners of silicate adhesives, silicon phosphates can also be used as binders of various ceramic materials and as raw materials for the production of glass. In this study, we investigated the reaction behaviors of $Si_3(PO_4)_4$ with CaO and MgO at high temperatures.

Experimental

Materials. $Si_3(PO_4)_4$ was prepared by the method reported previously.[1)] The particles were all disk-shaped, 2.2 μm in diameter ×0.9 μm in height. The CaO and MgO were of extra pure grade and were used after calcination at 500 °C for 1 h.

Reactions in the Powder Mixtures. The mixtures of $Si_3(PO_4)_4$ and CaO or MgO were wet with acetone and thoroughly mixed for 30 min in an agate mortar. Then, parts of the powder mixture (0.5—1.5 g) were transferred to a platinum boat, and it was heated at 940 °C in an electric furnace in air. Other parts of the powder mixtures of both systems ($MeO/Si_3(PO_4)_4$ molar ratio=3) were also heated at high temperatures up to 1150 °C with a heating rate of 10 °C min^{-1} in air using a Rigaku Denki Thermoflex TG-DTA apparatus. The reaction products in the samples were determined by means of X-ray diffraction analysis, using a Rigaku Denki Geigerflex D-2F with Ni filtered Cu $K\alpha$ radiation, with 30 kV and 10 mA.

Reactions at the Contact Surface of One-paired Tablets. The diffusion couples, *i.e.*, one-paired tablets, were prepared by a method similar to that used by Kinoshita *et al.*;[5)] about 2 g of $Si_3(PO_4)_4$ powder was pressed into a tablet 10 mm in diameter under a pressure of 640 kg cm^{-2}. A platinum tape (0.1×0.4×10 mm) was placed on the surface of the $Si_3(PO_4)_4$ tablet as a marker. Then, about 2 g of CaO or MgO powder was placed on the tablet, and it was pressed again into a double-layered tablet. After drying over P_2O_5 at room temperature, the diffusion couples were heated at 940 °C for 72 h in a manner similar to that described above. After these diffusion couples had been removed from the furnace, they were separated into two tablets from the border of a platinum marker. The reaction products in the surface layers of the tablets were examined by means of X-ray diffractometry in both the intact-tablet and powdered state.

Results and Discussion

$Si_3(PO_4)_4$–CaO System. The X-ray diffraction patterns of the products obtained in the reaction of the $Si_3(PO_4)_4$–CaO system using the TG-DTA apparatus are shown in Fig. 1. In this system, the reaction occurred at about 850 °C to yield β-$Ca_3(PO_4)_2$ and β-$Ca_2P_2O_7$ as crystalline products. As the temperature increased, the fraction of β-$Ca_2P_2O_7$ increased and that of β-$Ca_3(PO_4)_2$ decreased. At 1150 °C, β-$Ca_2P_2O_7$ and α-cristobalite were crystalline products. The X-ray diffraction lines of all the products were, on the whole, low, and a slight halation was observed in the X-ray diffraction pattern of 2θ=17—25° at 1150 °C. This means that an X-ray amorphous product such as silicon phosphate glass would be formed together with these crystalline products. In this system, no formation of crystalline

silicate compounds was observed because the acidity of P_2O_5 is higher than that of SiO_2.[6] The variation in the amounts of the crystalline product with the heating time at 940 °C is shown in Fig. 2. At the first step of the reaction, β-$Ca_3(PO_4)_2$ was formed predominantly. However, the amount of β-$Ca_3(PO_4)_2$ decreased and those of β-$Ca_2P_2O_7$ and α-cristobalite increased with the lapse of time. No changes in the fraction of each product were found after 4 h. Figure 3 shows the relation between the CaO content in the mixtures of the $Si_3(PO_4)_4$-CaO system and the X-ray diffraction intensities of the products, together with the X-ray diffraction patterns of typical products. It was found that the reaction products were also changed by the CaO content. In the region of a low CaO content, β-$Ca_2P_2O_7$ and α-cristobalite were mainly formed as crystalline products. Along with an increase in the CaO content, the fraction of β-$Ca_3(PO_4)_2$ increased and that of α-cristobalite decreased. It was also noticeable that the halation at $\theta=17—25°$ became larger with a decrease in the CaO content.

Figure 4 shows a micrograph of a cross-section of the $Si_3(PO_4)_4$-CaO diffusion couple after the reaction. It can be seen that a semitransparent layer (*E*) about 0.5 mm thick was formed on the side of the $Si_3(PO_4)_4$ phase (*C*). This means that the reactions occurred by means of the one-way diffusion of CaO into the $Si_3(PO_4)_4$ phase. X-ray diffraction revealed that the surface of the $Si_3(PO_4)_4$ tablet was a mixture of trace amounts of β-$Ca_3(PO_4)_2$ and α-cristobalite, along with a large amount of an X-ray amorphous product such as silicon phosphate glass.[6-8] The halation caused by the formation of glass was clearly observed.

$Si_3(PO_4)_4$-MgO System. The reaction behavior of the $Si_3(PO_4)_4$-MgO system was found to be similar to that of the $Si_3(PO_4)_4$-CaO system. In the $Si_3(PO_4)_4$-MgO system, $Mg_3(PO_4)_2$ was observed to be present at higher temperatures than was β-$Ca_3(PO_4)_2$ in the latter system, and the amount of α-cristobalite was lower than in the latter system. In the reaction of the $Si_3(PO_4)_4$-MgO diffusion couple, a semitransparent layer just like the layer (*E*) in Fig. 4 was also observed.

The reactions of silicon phosphates with CaO and MgO were also carried out using SiP_2O_7 (**2**) instead of $Si_3(PO_4)_4$; the results were quite similar to those described above.

The authors wish to thank Professor Taijiro Okabe of the Department of Applied Chemistry, Tohoku University, for his helpful discussion.

Facile Synthesis of 2-Phenyl-1,2-oxaphospholane and Its Related New Compounds. The Family of Deoxophostones and Deoxothiolphostones

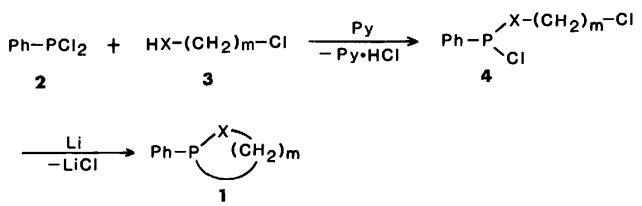
Shiro KOBAYASHI,* Masato SUZUKI, and Takeo SAEGUSA*
Department of Synthetic Chemistry, Faculty of Engineering, Kyoto University, Yoshida, Sakyo-ku, Kyoto 606
(Received February 15, 1985)

Synopsis. 2-Phenyl-1,2-oxaphospholane (**1a**), 2-phenyl-1,2-oxaphosphorinane (**1b**), 2-phenyl-1,2-thiaphospholane (**1c**), and 2-phenyl-1,2-thiaphosphorinane (**1d**) were prepared readily by the reaction of dichlorophenylphosphine with an ω-chloroalkanol or an ω-chloroalkanethiol followed by cyclization with the aid of lithium metal. Compounds **1b—d** have been obtained for the first time.

Recently, we have reported the cationic ring-opening polymerization of a five-membered deoxophostone (2-phenyl-1,2-oxaphospholane, (**1a**)) to give poly (phosphine oxide).[1] During the course of these studies we have found a new facile method to prepare **1a** and its family compounds. The present paper deals with the synthesis of five- and six-membered deoxophostones and their sulfur analogues of deoxothiolphostones,[2] *i.e.*, **1a**, 2-phenyl-1,2-oxaphosphorinane (**1b**), 2-phenyl-1,2,-thiaphospholane (**1c**), and 2-phenyl-1,2-thiaphosphorinane (**1d**).

1a **1b** **1c** **1d**

The synthetic route is given in Scheme 1.



a, X=O; *m*=3 **c**, X=S; *m*=3
b, X=O; *m*=4 **d**, X=S; *m*=4

Scheme 1.

To dichlorophenylphosphine (**2**) with pyridine in tetrahydrofuran (THF) was added an ω-chloroalkanol or ω-chloroalkanethiol **3** and refluxed for 1 h. At this time, The ^{31}P NMR spectrum of the reaction mixture showed a single peak assignable to phosphonochloridite (**4**): **4a**, 175.0 ppm; **4b**, 175.3 ppm; **4c**, 141.7 ppm; **4d**, 141.6 ppm. Without isolation, **4** in THF was reacted with lithium metal. The ^{31}P NMR spectrum of the respective reaction mixture showed many peaks. With adding diethyl ether to the mixture, precipitated insoluble parts which probably consisted of LiCl and polymeric by-products. In the ^{31}P NMR spectrum of the soluble part the peak due to **1** was main. The distillation *in vacuo* gave **1** in a moderate or low yield. ^{31}P, ^{1}H, ^{13}C NMR data as well as MS data supporting the structures of **1a—d** are given in the experimental section.

Few routes to prepare **1a** have previously been reported, which required several steps and the overall yield was lower than that of the present method.[3,5] These methods involve phosphines having a P-H bond which are very stinking and poisonous. On the other hand, the present method is more facile, not necessary to handle stinking phosphines, and more generally applicable to prepare not only **1a** but also **1b—d**. Five-membered deoxothiolphostone **1c** had been known only as a ligand of an Fe-complex.[6] Six-membered deoxophostone **1b** and deoxothiolphostone **1d** have not been known so far. Although the isolated yields are not high, the present study provides the first instance of the isolation of **1b**, **1c**, and **1d**. These new compounds are very attractive reagents which allow investigation of reactivities and stereochemical problems in phosphorus chemistry. The ring-opening polymerization of **1c** and **1d** will be reported soon.[7]

Experimental

^{1}H, ^{13}C, and ^{31}P NMR spectra were recorded on a Hitachi R-20B (^{1}H NMR) or a Hitachi R-900 (^{13}C and ^{31}P NMR) spectrometer. Mass spectra were obtained with JEOL JMS-DX300. THF, diethyl ether, and pyridine were dried respectively over $LiAlH_4$, CaH_2, or KOH, and distilled. Commercially available dichlorophenylphosphine, 3-chloro-1-propanol, and 4-chloro-1-butanol were purified by distillation. 3-Chloro-1-propanethiol was prepared according to the reported procedures.[8] 4-Chloro-1-butanethiol was prepared by the HCl-catalyzed methanolysis[8] of S-(4-chlorobutyl) thioacetate, which was obtained from the substitution reaction[9] of 4-chlorobutyl tosylate with potassium thioacetate; overall yield 38%, bp 89—95 °C (57—65 Torr, 1 Torr=133.322 Pa).

The following all operations were carried out under nitrogen atmosphere.

2-Phenyl-1,2-oxaphospholane ***1a***: To a mixture of dichlorophenylphosphine (2.01 g, 11.2 mmol), pyridine (0.95 ml, 11.8 mmol), and 10 ml of THF was added 3-chloro-1-propanol (1.06 g, 11.2 mmol) in 4 ml of THF at 0 °C. After refluxing for 1 h, the precipitate of pyridinium hydrochloride was removed by filtration. The filtrate was added to 8 ml of THF containing small pieces of lithium metal (0.172 g 24.8 mg-atom) at −78 °C and stirred overnight gradually up to room temperature. THF was evaporated *in vacuo*, and 30 ml of diethyl ether was added to the residue to extract the product. The mixture was well stirred and filtered. After concentration of the filtrate, the residue was

subjected to distillation *in vacuo* to give 0.69 g of **1a** (37% yield), bp 62—65 °C (0.13 Torr)[3]. $^{31}P\{^1H\}$NMR($CDCl_3$) +110.2 ppm (relative to 85% H_3PO_4 external standard); ^1H NMR δ($CDCl_3$) 1.4—2.5 (m, 4H, $PC\underline{H}_2C\underline{H}_2$), 3.6—4.3 (m, 2H, $OC\underline{H}_2$), and 7.1—7.4 ppm (m, 5H, $C_6\underline{H}_5$); $^{13}C\{^1H\}$NMR($CDCl_3$) 23.3 (s, $PC\underline{H}_2$), 32.2 (d, J_{CCP}=20.9 Hz, $PCH_2\underline{C}H_2$) 72.4 (d, J_{COP}=14.0 Hz, $OC\underline{H}_2$), 126.9 (s, P-Ph; δ-C) 128.0 (d, J_{CCP}=14.8 Hz, P-Ph; β-C), 128.1 (s, P-Ph; γ-C), and 144.8 ppm (d, J_{CP}=36.7 Hz, P-Ph; α-C).

These procedures for the preparation of **1a** were similarly applied to those of **1b—d**.

2-Phenyl-1,2-oxaphosphorinane ***1b***: From dichlorophenylphosphine (2.19 g, 12.2 mmol), 4-chloro-1-butanol (1.33 g, 12.2 mmol), pyridine (1.04 ml, 12.8 mmol), and lithium metal (0.186 g 26.8 mg-atom), 0.39 g of **1b** was obtained; 18% yield, bp 76—79 °C (0.55 Torr). $^{31}P\{^1H\}$NMR($CDCl_3$) +111.1 ppm; ^1H NMR δ($CDCl_3$) 1.2—2.4 (m, 6H, $PC\underline{H}_2C\underline{H}_2C\underline{H}_2$), 3.4—3.9 (m, 2H, $OC\underline{H}_2$), and 7.1—7.5 (m, 5H, $C_6\underline{H}_5$); $^{13}C\{^1H\}$NMR($CDCl_3$) 19.3 (d, J_{CP}=3.5 Hz, $PC\underline{H}_2$), 25.5 (d, J_{CCP}=22.6 HZ, $PCH_2\underline{C}H_2$), 27.6 (d, J_{CCOP}=3.5 Hz, $OCH_2\underline{C}H_2$), 63.4 (d, J_{COP}=7.8 Hz, $OC\underline{H}_2$), 127.8 (s, P-Ph; δ-C), 128.6 (d, J_{CCCP}=2.6 Hz P-Ph; γ-C), 129.0 (d, J_{CCP}=14.1 Hz, P-Ph; β-C), and 140.7 (d, J_{CP}=31.4 Hz, P-Ph; α-C); *m/z* 180 (M^+, 69%).

2-Phenyl-1,2-thiaphospholane ***1c***: From dichlophenylphosphine (48 ml, 0.355 mol), 3-chloro-1-propanethiol (39.2 g, 0.355 mol), pyridine (30 ml, 0.371 mol), and lithium metal (4.93 g, 0.710 g-atom), 6.59 g of **1c** was obtained; 10% yield, bp 102—104 °C (0.50 Torr). $^{31}P\{^1H\}$NMR($CDCl_3$) + 22.3 ppm; ^1H NMR δ($CDCl_3$) 1.1—3.1 (m, 6H, $SC\underline{H}_2C\underline{H}_2C\underline{H}_2P$) and 6.8—7.6 (m, 5H, $C_6\underline{H}_5$); $^{13}C\{^1H\}$NMR($CDCl_3$) 28.9 (d, J_{CSP}=7.3 Hz, $SC\underline{H}_2$), 35.2 (s, $PC\underline{H}_2$), 36.0 (d, J_{CCP}=23.2 Hz, $PCH_2\underline{C}H_2$), 128.1 (s, P-Ph; δ-C) 128.1 (d, J_{CCCP}=3.7 Hz, P-Ph; γ-C), 130.0 (d, J_{CCP}=17.1 Hz, P-Ph; β-C), and 140.4 (d, J_{CP}=40.3, P-Ph, α-C); *m/z* 182 (M^+, 100%).

2-Phenyl-1,2-thiaphosphorinane ***1d***: From dichlorophenylphosphine (12.65 g, 0.071 mol), 4-chloro-1-butanethiol (9.52 g, 0.071 mol), pyridine (6.0 ml, 0.074 mol), and lithium metal (0.985 g, 0.142 g-atom), 0.659 g of **1d** was obtained; 5% yield, bp 99—103 °C (0.32 Torr). $^{31}P\{^1H\}$NMR($CDCl_3$) +4.8 ppm; ^1H NMR δ($CDCl_3$) 1.0—3.0 (m, 8H, $SC\underline{H}_2C\underline{H}_2C\underline{H}_2C\underline{H}_2P$) and 6.9—7.8 (m, 5H, $C_6\underline{H}_5$); $^{13}C\{^1H\}$NMR-($CDCl_3$) 20.1 (s, $PC\underline{H}_2$ or $PCH_2CH_2\underline{C}H_2$), 23.5 (d, J_{CCP}=22.6 Hz, $PCH_2\underline{C}H_2$), 24.5 (d, J_{CSP}=10.5 Hz, $SC\underline{H}_2$), 27.8 (s, $PC\underline{H}_2$ or $PCH_2CH_2\underline{C}H_2$), 127.2 (s, P-Ph; δ-C), 128.6 (d, J_{CCCP}=3.5 Hz, P-Ph; γ-C), 130.5 (d, J_{CCP}=14.8, P-Ph; β-C), and 137.1 ppm (d, J_{CP}=32.2 Hz, P-Ph; α-C); *m/z* 196 (M^+, 100%).

Heteropoly Acids Supported on Acidic Ion-exchange Resin as Highly Active Solid-acid Catalysts

Toshihide BABA,* Yoshio ONO,† Tadao ISHIMOTO, Shun-ichi MORITAKA, and Seiichi TANOOKA

(Received December 12, 1984)

Synopsis. Heteropoly acids supported on a macroreticular acidic ion-exchange resin shows much higher activity than those supported on activated carbon for the synthesis of methyl *t*-butyl ether and the esterification of acetic acid with 1-pentanol. This high activity can plausibly be attributed to the interaction of heteropoly anions with substrates which are protonated by the protons of the acidic resin.

Heteropoly acids are very effective as catalysts for a variety of acid-catalyzed reactions.[1-4] They can be used as homogeneous as well as heterogeneous catalysts. In order to use them as solid-acids, however, it is desirable to support them on an appropriate carrier, since their surface areas are small. Izumi *at al.*[5] have reported that heteropoly acids supported on silica gel or activated carbon exhibit high catalytic activities for the alkylation of benzene with ethylene, the esterification of acetic acid with ethanol, and the dehydration of 2-propanol. It has also been reported that heteropoly acids and their salts supported on silica or activated carbon are effective in forming methyl *t*-butyl ether (MTBE) from isobutene and methanol in the vapor phase.[6-8] Here, we wish to report that heteropoly acids supported on an acidic ion-exchange resin become very active catalysts for some acid-catalyzed reactions, namely, MTBE synthesis and esterification.

The catalysts were prepared as follows. Heteropoly acid was dissolved in water, and a macroporous acidic resin, Amberlyst-15, was added to the solution. The suspension was kept overnight and then dried by evaporation. The reactions were carried out with a continuous-flow reactor operating at atmospheric pressure. The catalyst was packed in a reactor of silica tubing (10 mm i.d.) placed in a vertical furnace. Liquid reactants were delivered by means of a motor-driven syringe and vaporized in the preheating zone of the reactor containing 10 cm^3 of quartz chips. Isobutene was fed through a flowmeter. The products were analyzed by means of gas chromatography.

TABLE 1. CATALYTIC ACTIVITIES OF HETEROPOLY ACIDS SUPPORTED ON AMBERLYST-15 AND ACTIVATED CARBON

Catalyst	Isobutene conversion/%	Selectivity to MTBE/%
$H_4SiW_{12}O_{40}$/Amberlyst-15	42.0	99.7
$H_3PW_{12}O_{40}$/Amberlyst-15	38.7	99.8
$H_3PMo_{12}O_{40}$/Amberlyst-15	18.0	100
Amberlyst-15	11.0	100
$H_4SiW_{12}O_{40}$/activated carbon	2.1	100

Reaction conditions: 323 K, $W/F=0.50$ g h mol^{-1}, isobutene pressure, 25.3 kPa; methanol pressure, 25.3 kPa; 30 wt% heteropolyacids supported.

In Table 1, the catalytic activities of heteropoly acids (30 wt%) supported on Amberlyst-15 are compared with those of dodecatungstosilicate (TSA) supported on activated carbon and Amberlyst-15 itself. Every heteropoly acid supported on Amberlyst-15 was much more active than Amberlyst-15 itself, TSA supported on the resin being most active. It is also worthy of note that TSA on Amberlyst-15 is far more active than TSA on activated carbon. In all cases, the catalytic activities did not change with time on stream for at least 8 h. The selectivity to MTBE is very close to 100%. The other detectable products are isobutene dimers. No formation of dimethyl ether was observed in any case.

The dependence of the isobutene conversion and the selectivity to MTBE on the amount of supported TSA on Amberlyst-15 is illustrated in Fig. 1. The isobutene conversion increased with the increase in the supported amount and reached a maximum at 30 wt%, where the selectivity to MTBE was 99.7%. The catalysts with less activity showed a 100% selectivity.

The dependence of the isobutene conversion to MTBE on the contact time for the reaction over Amberlyst-15, TSA(30 wt%) on Amberlyst-15, and TSA(30 wt%) on activated carbon, is shown in Fig. 2. The relative activity of the three catalysts was estimated from the rate of the reaction at lower contact times as follows; TSA/activated carbon: Amberlyst-15:TSA/Amberlyst-15=1:13:33. In every case, the isobutene conversion increased with the contact time and approached to a constant value

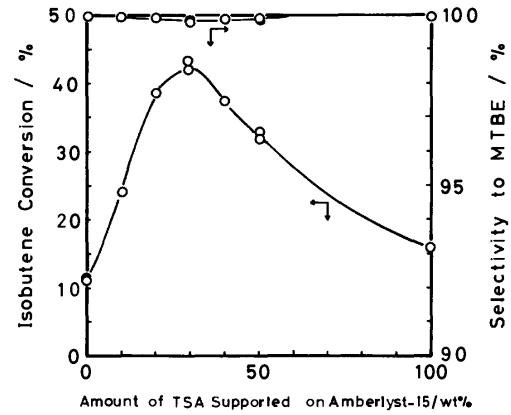

Fig. 1. Change in isobutene conversion and selectivity to MTBE with supported amount of TSA on Amberlyst-15. Reaction conditions: 323 K, $W/F=0.50$ g h mol^{-1}, isobutene pressure 25.3 kPa, methanol pressure 25.3 kPa, nitrogen pressure 50.7 kPa.

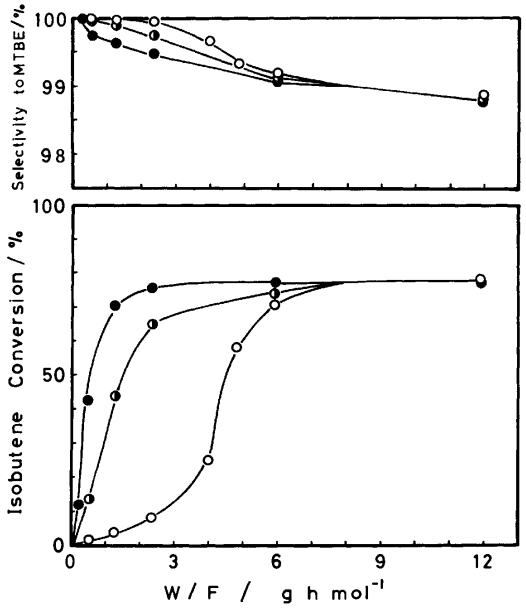

Fig. 2. Effect of contact time on isobutene conversion and selectivity to MTBE. (●): TSA (30 wt%) supported on Amberlyst-15, (○): Amberlyst-15, (◑): TSA (30 wt%) supported on activated carbon. Reaction conditions: 323 K, isobutene pressure 25.3 kPa, methanol pressure 25.3 kPa, nitrogen pressure 50.7 kPa.

because of the limitation by the thermo-dynamic equilibrium.

The reaction temperature was varied in the range of 323—373 K. The highest yield, 57%, was obtained at 333 K. The decrease in the MTBE yield at higher temperatures is due to the limitation by the thermodynamic equilibrium. The selectivity to MTBE was 100% at and below 333 K, but it dropped at higher temperatures as a result of the dimerization of isobutene.

To further test the efficiency of heteropoly acid supported on the ion-exhange resin, the esterification of acetic acid with 1-pentanol to form pentyl acetate in the vapor phase was carried out at 378 K over Amberlyst-15, TSA supported on Amberlyst-15, and TSA supported on activated carbon. As is shown in Fig. 3, the catalytic activity did not change with time on stream in any cases. Heteropoly acid supported on Amberlyst-15 showed a much higher activity for the esterification than the resin itself and also than that supported on activated carbon. Thus, the 1-pentanol conversion over Amberlyst-15 (13.6%) was increased up to 22.4% by supporting TSA(30 wt%) on the resin. The selectivity to pentyl acetate was 100% in every case.

Izumi and his coworkers[1,8] found that heteropoly acids show a much higher catalytic activity for many reactions as homogeneous catalysts than do sulfuric acid or *p*-toluenesulfonic acid and attributed the higher activity to the interaction of heteropoly anions and substrates or protonated substrates. For example, they postulated the existence of a protonated butene-heteropoly anion complex in the hydration of

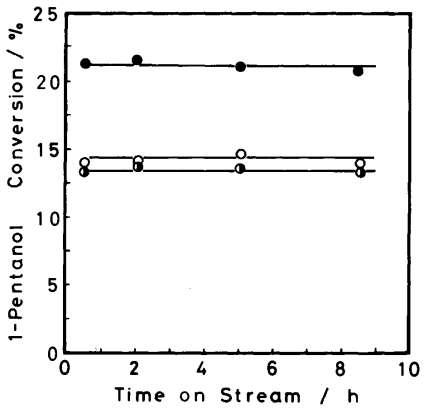

Fig. 3. Change in 1-pentanol conversion in the esterification from acetic acid and 1-pentanol. (●): TSA (30 wt%) supported on Amberlyst-15, (◑): Amberlyst-15, (○): TSA (30 wt%) supported on activated carbon. Reaction conditions: 378 K, $W/F=9.33\times10^{-2}$ g h mol^{-1}, acetic aicd pressure 15.1 kPa, pentyl alcohol pressure 15.1 kPa, nitrogen pressure 70.7 kPa.

1-butene.[1]

The interaction between the heteropoly anion and substrate (or protonated substrate) should be important also in the reactions over hereropoly acids supported on carriers. In the case of heterogeneous systems, it seems of the utmost importance that protons and heteropoly anions exist in close proximity. Protons originating from heteropoly acids naturally satisfy this condition. In addition, in the heteropoly acid/ion-exhanger system, protons originating from the ion-exchanger also can interact with supported heteropoly anions, and they exhibit a higher activity than those of the resin not supported by the anions. This may explain the high activity of heteropoly acid–acid resin composite catalysts.

Rate Constants and Mechanism for Reactions of Ketenes with OH Radicals in Air at 299 ± 2K

Shiro HATAKEYAMA,* Shigeo HONDA,† Nobuaki WASHIDA, and Hajime AKIMOTO
Division of Atmospheric Environment, The National Institute for Environmental Studies, P.O. Tsukuba-gakuen, Ibaraki 305
(Received February 26, 1985)

Rate constants for reactions of OH radicals with four kinds of simple ketenes (ketene, methylketene: MK, ethylketene: EK, and dimethylketene: DMK) were measured in 1 atm of air at 299±2 K by use of a competitive reaction method. The photolysis of CH_3ONO in air was used to generate OH radicals. The rate constants for OH reactions obtained are $(1.8\pm0.2)\times10^{-11}$, $(7.6\pm1.4)\times10^{-11}$, $(11\pm3)\times10^{-11}$ and $(10\pm3)\times10^{-11}$ cm^3 $molecule^{-1}$ s^{-1} for ketene, MK, EK, and DMK, respectively. The major product was a carbonyl compound; HCHO from ketene, CH_3CHO from MK, and CH_3COCH_3 from DMK; the yield was ≈80%, 72±17%, and 70±3%, respectively. It is proposed that the reaction proceeded mainly *via* an OH addition to the olefinic carbons of ketenes and the adduct decomposes to give a carbonyl compound and CO as final products in air.

Ketenes are known to be products of ozone-alkene reactions[1] and O(^{3}P)-alkene or alkyne reactions.[2] They are also produced during the combustion of alkynes and alkenes.[3,4] Therefore, a knowledge of oxidation rates of ketenes is significant for modeling the atmospheric life cycle and the combustion of hydrocarbons. However, there have been few reports concerning an experimental investigation of the oxidation of ketenes. Recently, we reported on the reactions of ketenes with O(^{3}P).[5]

Although the OH radical reaction plays an important role in the atmospheric oxidation and combustion processes of ketenes, little has been reported regarding the rate constants of these reactions. Faubel *et al.*[6] reported that the lower limit of the rate constant for ketene+OH is $\approx1.7\times10^{-12}$ cm^3 $molecule^{-1}$ s^{-1}. In computer-modeling studies regarding the combustion of ethylene[3] and acetylene,[4] rate constants of 1.7×10^{-11}[3] and 4.7×10^{-11} cm^3 $molecule^{-1}$ s^{-1},[4] respectively, were adopted without any experimental basis. Rate constants for other substituted ketenes have never appeared in the literature. No experimental study on the mechanism of an OH reaction with ketenes has been reported.

In the work reported here we measured the rate constants for the reactions of OH radicals with four kinds of simple ketenes (ketene, methylketene: MK, ethylketene: EK, dimethylketene: DMK) by use of CH_3ONO photolysis in air as a source of OH radicals. A competitive reaction method was employed. The mechanism for reactions of OH with the ketenes are also discussed in terms of both the linear dependence of the logarithms of the rate constants on the ionization potential and the results of product analyses.

Experimental

Ketene, MK, EK, and DMK were prepared by the pyrolysis of their corresponding dimers at 550 °C,[7] purified by repeated trap-to-trap distillation, and stored at liquid-nitrogen temperature. Dimers of ketene and DMK are commercially available (Tokyo Kasei). Those of MK and EK were prepared by the dehydrochlorination of propionyl chloride and butyryl chloride, respectively, with triethylamine.[8] UV-visible spectra were recorded using a Hitachi 220A spectrometer for given pressures of the ketenes (measured with an MKS Baratron capacitance manometer).

Kinetic measurements were performed in an 11 L cylindrical quartz vessel (120 mm i.d., 1000 mm long), and the changes in the concentration of reactants and products were monitored by means of long-path Fourier-transform infrared spectroscopy (LP-FTIR). The path length was 40 m, and 32 scans at a 1 cm^{-1} resolution were accumulated (≈1 min). The absorptivities (base 10, $Torr^{-1}$ m^{-1} at 30 °C) used were as follows: CH_2CO, 2.11 (2164 cm^{-1}); MK, 2.02 (2140 cm^{-1}); EK, 2.63 (2134 cm^{-1}); DMK, 2.60 (2134 cm^{-1}); HCHO, 0.25 (2780 cm^{-1}, peak to valley); CH_3CHO, 4.05×10^{-2} (2706 cm^{-1}); CH_3COCH_3, 0.173 (1218 cm^{-1}); cyclohexane, 3.31 (2934 cm^{-1}); propylene, 0.384 (912 cm^{-1}). The concentrations of CO and CO_2 were determined by use of calibration curves which were previously reported from this laboratory.[9]

The light source for photolysis was four 20-W black-light lamps (Toshiba FL 20S. BLB, $300<\lambda<400$ nm, $\lambda_{max}=360$ nm) which surrounded the reactor coaxially. The light intensity (measured by the NO_2 photodissociation rate, k_1) was 0.191 min^{-1}. To check for the existence of reactive intermediates such as an OH radical (which can consume ketenes during photolysis) photolyses of ketenes in the presence of 2-methylpropene were also carried out.

OH radicals were generated by the photolysis of methyl nitrite in air, as depicted by following equations.

$$CH_3ONO + h\nu \longrightarrow CH_3O + NO \quad (1)$$

$$CH_3O + O_2 \longrightarrow HO_2 + HCHO \quad (2)$$

$$HO_2 + NO \longrightarrow OH + NO_2 \quad (3)$$

CD_3ONO (in place of CH_3ONO) was also employed for ketene in order to distinguish the product formaldehyde from that produced in reaction 2.

The rate constants were measured on the basis of a competitive reaction method in the presence of cyclohexane or propylene as a reference compound. Typically, CH_3ONO (≈20 mTorr) (1 Torr=133.322 Pa)-ketenes (2—7 mTorr)-reference compound (R.C. 2—7 mTorr) in 1 atm of purified

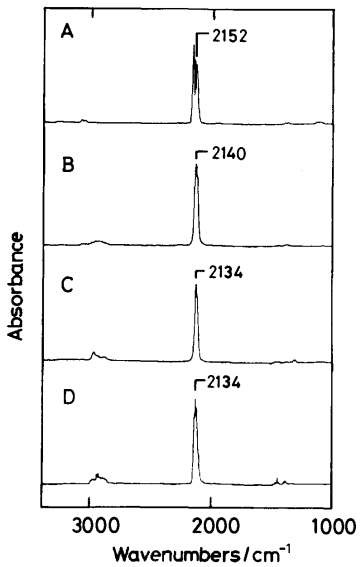

Fig. 2. IR spectra of four kinds of ketenes. A: Ketene, B: methylketene, C: ethylketene, D: dimethylketene.

air was irradiated for 10 min. IR spectra were taken at a constant interval. The reaction temperature was 299±2 K.

Results and Discussion

I. Rate Constants for OH+Ketenes. Figure 1 shows the UV-visible spectra of four kinds of ketenes. The λ_{max} and ε_{max} for ketene, MK, and DMK are in good agreement with those reported earlier.[10-12] That of EK (in a gas phase) has not been measured so far. All of the spectra show diffuse structures. Such structures have been reported for ketene.[13,14] Figure 2 shows the IR spectra of ketenes; the peaks at $\approx$2150 cm^{-1} correspond to the antisymmetric C=C=O stretching bands and were used for the concentration measurements.

An irradiation of the ketenes in 1 atm of air produced a first-order decay of each ketene. In order to check for the possibility that some reactive species, such as an OH radical which consumes ketenes, is produced in the course of photolysis, photolyses in the presence of 2-methylpropene (the rate constant for OH reaction is 5.07×10^{-11} cm^3 $molecule^{-1}$ s^{-1} [15]) were performed. No change in the concentration of 2-methylpropene was observed during 20 min of photoirradiation. Thus, it can be concluded that the decay of each ketene is solely due to photolysis. From the slope of the first-order decay of the ketenes, the photolysis rate constants in this system were calculated to be 9.5×10^{-3}, 3.5×10^{-3}, 3.0×10^{-3}, and 3.1×10^{-3} min^{-1} for ketene, MK, EK, and DMK, respectively.

The rate constants for reactions of the OH radical with ketenes were measured by use of CH_3ONO as a source of OH radicals. Thus, an irradiation of the ketenes-CH_3ONO-R.C. was carried out. The reactions which took place in the system were as follows.

$$\text{OH} + \text{ketenes} \longrightarrow \text{products} \quad (4)$$

$$\text{OH} + \text{R.C.} \longrightarrow \text{products} \quad (5)$$

$$\text{ketenes} + h\nu \longrightarrow \text{products} \quad (6)$$

The decay rate of the ketenes and R.C. are described according to the next equations.

$$-\,\mathrm{d[ketenes]}/\mathrm{d}t = k_4[\mathrm{OH}][\mathrm{ketenes}] + k_6[\mathrm{ketenes}] \quad (7)$$

$$-\,\mathrm{d[R.C.]}/\mathrm{d}t = k_5[\mathrm{OH}][\mathrm{R.C.}] \quad (8)$$

Thus,

$$\ln([\mathrm{ketenes}]_{t_0}/[\mathrm{ketenes}]_t) = k_4\int_{t_0}^{t}[\mathrm{OH}]\mathrm{d}t + k_6(t-t_0) \quad (9)$$

$$\ln([\mathrm{R.C.}]_{t_0}/[\mathrm{R.C.}]_t) = k_5\int_{t_0}^{t}[\mathrm{OH}]\mathrm{d}t \quad (10)$$

From Eqs. 9 and 10 the following equation can be derived.

$$\ln([\mathrm{ketenes}]_{t_0}/[\mathrm{ketenes}]_t) - k_6(t-t_0) = (k_4/k_5)\ln([\mathrm{R.C.}]_{t_0}/[\mathrm{R.C.}]_t) \quad (11)$$

Figure 3 shows a plot of Eq. 11 for four different ketenes. The data, which were obtained during several runs, are almost on the same straight line for each ketene. In this plot, the above photolysis rate constants were used as k_6. From the slopes of those plots and k_5 (cyclohexane: 7.85×10^{-12} cm^3 $molecule^{-1}$ s^{-1}, propylene: 2.51×10^{-11} cm^3 $molecule^{-1}$ s^{-1})[15] k_4 can be calculated. Results are listed in Table 1. The rate constant for MK was measured by use of not only cyclohexane but also propylene as a R.C. The rate constants obtained for the two R.C. agreed well (within experimental error). However, since a large difference in the rate constants between cyclohexane and MK against OH may introduce a systematic error, the rate constant obtained by use of propylene as a R.C. should be more reliable.

In the case of EK and DMK, propylene, the same compound used as the R.C., may be formed during the isomerization of the carbenes produced in the

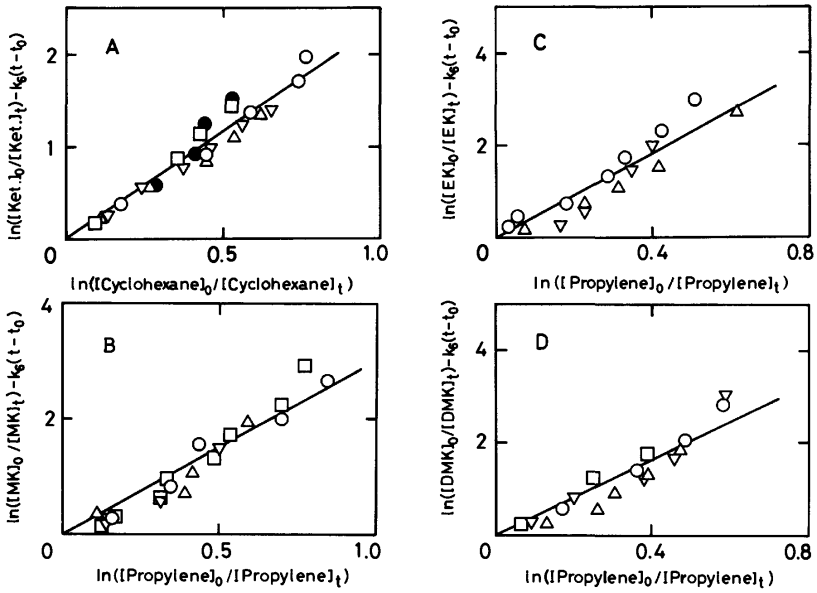

Fig. 3. Plot of Eq. 11 for four kinds of ketenes. Different symbols correspond to different runs. A: Ketene ($CH_3ONO \approx 22$ mTorr-Ketene ≈ 2 mTorr-$C_6H_{10} \approx 2$ mTorr), B: MK ($CH_3ONO \approx 22$ mTorr-MK ≈ 7 mTorr-$C_3H_6 \approx 7$ mTorr), C: EK ($CH_3ONO \approx 23$ mTorr-EK ≈ 6.5 mTorr-$C_3H_6 \approx 7.5$ mTorr), D: DMK ($CH_3ONO \approx 23$ mTorr-DMK ≈ 6.5 mTorr-$C_3H_6 \approx 7.5$ mTorr).

Table 1. Rate constants for the reaction of ketenes with OH radicals

Ketene	Reference Compound	k_4/k_5	$k_4/1\times10^{-11}$ cm^3 molecule^{-1} s^{-1}
Ketene	Cyclohexane[a)]	2.3±0.3	1.8±0.2
MK	Cyclohexane	8.0±1.7	6.4±1.4
MK	Propylene[b)]	3.0±0.5	7.6±1.4
EK	Propylene	4.5±1.1	11±3
DMK	Propylene	4.1±1.1	10±3

a) $k_5=7.95\times10^{-12}$ cm^3 molecule^{-1} s^{-1}.[15] b) $k_5=2.51\times10^{-11}$ cm^3 molecule^{-1} s^{-1}.[15] Estimated errors are 95% confidence limits.

photolysis. However, propylene was not detected during the 20-min photolysis of EK and DMK. This is, perhaps, due to the scavenging of the carbenes by O_2. Thus, the production of propylene can be neglected in our reaction system.

Only one study has previously been reported regarding the rate constants for the reaction of OH with ketene. Faubel *et al.*[6] estimated the lower limit of the rate constant for the OH+ketene reaction to be 1.7×10^{-12} cm^3 molecule^{-1} s^{-1} by means of a discharge flow-MS method in the course of their study on the C_3O_2+OH reaction. OH reactions with other ketenes have never been studied before. Our value for ketene, 1.8×10^{-11} cm^3 molecule^{-1} s^{-1}, is consistent with the lower limit given by Faubel *et al.*,[6] and is in good agreement with the value used in the numerical model study reported by Levy[3] ($\approx1.7\times10^{-11}$ cm^3 molecule^{-1} s^{-1}, no temperature dependence was assumed).

II. Reaction Mechanism of OH+Ketenes. No information is available concerning the mechanism of the reaction of ketenes with OH. In the field of combustion chemistry, the reaction of OH with ketene has been thought to proceed *via* the following reaction[3,4] without any experimental evidence.

$$CH_2CO + OH \longrightarrow HCHO + HCO \qquad (12)$$

In order to get an insight into the mechanism of the reaction, logarithms of the rate constants for OH+alkenes[15] and OH+ketenes were plotted against the ionization potential of alkenes and ketenes[16-18] (Fig. 4), as proposed by Bayes and co-workers.[19] The points for ketenes seem to fall on a straight line (the lower solid line), similar to the points for olefins (the upper solid line). This indicates that the reaction of OH with ketenes proceeds *via* a path similar to that for OH+alkenes (a reaction path on which the charge-transfer surface has an important contribution and the transition state is somewhat polarized). Thus, the reaction of OH with ketenes should proceed *via* addition.

In the reaction of OH with ketene, MK, and DMK, HCHO, CH_3CHO, and CH_3COCH_3 were detected, respectively. Figures 5 and 6 show the amount of acetaldehyde and acetone plotted against the amount of the corresponding ketenes consumed during several runs. The apparently straight lines were obtained in both systems. From the slopes of the lines shown in Figs. 5 and 6 the average ratios of the carbonyl-compounds-formed to ketenes-consumed were calculated to be 0.72±0.17 and 0.70±0.03 for acetaldehyde from MK and acetone from DMK, respectively. Since, in

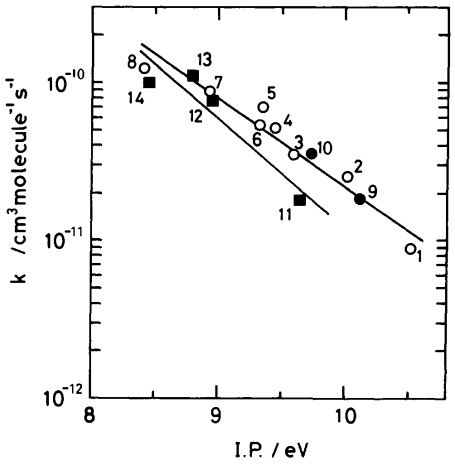

Fig. 4. Log(rate constant) *vs.* ionization potential for alkenes and ketenes. 1: Ethylene, 2: propylene, 3: 1-butene, 4: 2-methylpropene, 5: *trans*-2-butene, 6: *cis*-2-butene, 7: 2-methyl-2-butene, 8: 2,3-dimethyl-2-butene, 9: acrylaldehyde, 10: crotonaldehyde, 11: ketene, 12: methylketene, 13: ethylketene, 14: dimethylketene. Upper solid line was obtained by the least square calculation for compounds 1—10. Lower solid line was obtained by the least square calculation for ketenes.

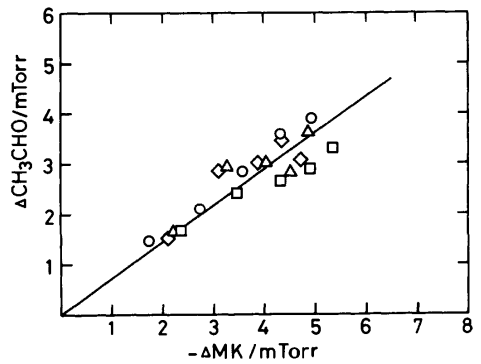

Fig. 5. Concentration of produced acetaldehyde plotted against decreased amount of methylketene. Different symbols correspond to different runs. $[MK]_0$=5.0—6.1 mTorr, $[CH_3ONO]_0$=≈22 mTorr.

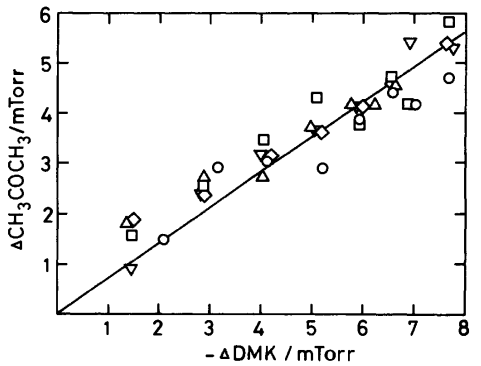

Fig. 6. Concentration of produced acetone plotted against decreased amount of dimethylketene. Different symbols correspond to different runs. $[DMK]_0$= 6.6—7.7 mTorr, $[CH_3ONO]_0$=≈23 mTorr.

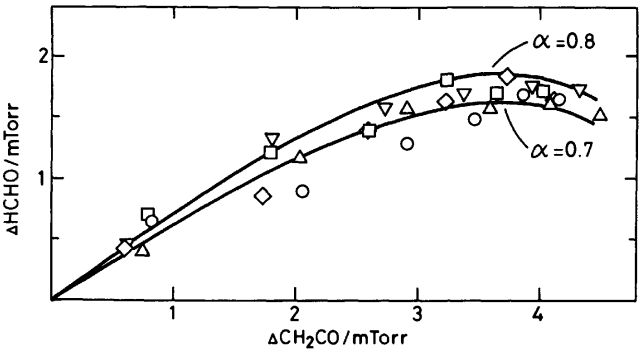

Fig. 7. Concentration of produced formaldehyde plotted against decreased amount of ketene. Different symbols correspond to different runs. $[Ketene]_0$= 4.7—5.4 mTorr, $[CD_3ONO]_0$=≈25 mTorr. Solid lines are the plot of the amount of formaldehyde formed against the amount of consumed ketene calculated by Eqs. 15 and 16 with α=0.8 and α=0.7.

each case, the photolysis of the product carbonyl compounds and the secondary OH reactions of products tend to decrease their yields, the yields estimated above should be taken as lower limits.

For ketene, the plot shows no lineality, and the final yield of formaldehyde is indicated to be much lower (Fig. 7). It is because the OH+HCHO reaction has a rate constant (1.01×10^{-11} cm³ molecule^{-1} s^{-1})[20] comparable to that for OH+ketene; the secondary reaction of OH with formaldehyde (as well as its photolysis) significantly lowers the apparent yield of formaldehyde.

In order to simulate the concentration change of ketene and formaldehyde, the following reaction scheme was used.

$$\text{ketene} + \text{OH} \xrightarrow{k_4} \alpha\text{HCHO} + \text{other products} \quad (4')$$

$$\text{ketene} + h\nu \xrightarrow{k_6} \text{products} \quad (6)$$

$$\text{HCHO} + \text{OH} \xrightarrow{k_{13}} \text{products} \quad (13)$$

$$\text{HCHO} + h\nu \xrightarrow{k_{14}} \text{products} \quad (14)$$

Here α ($\leq$1) is the yield of formaldehyde. Thus, next equations were obtained using a constant OH (OD) radical concentration (≈2×10^8 molecule cm^{-3}), which was measured[21] for about 10 min of irradiations in 5 runs.

$$[\text{ketene}] = [\text{ketene}]_0 \exp\{-(k_4[\text{OH}]+k_6)t\} \quad (15)$$

$$[\text{HCHO}] = \frac{\alpha k_4[\text{OH}][\text{ketene}]_0}{k_{13}[\text{OH}]+k_{14}-k_4[\text{OH}]-k_6} \times [\exp\{-(k_4[\text{OH}]+k_6)t\} - \exp\{-(k_{13}[\text{OH}]+k_{14})t\}] \quad (16)$$

Here $[ketene]_0$ is the initial ketene concentration. The solid lines in Fig. 7 are plots of the amounts of formaldehyde formed against the amounts of consumed ketene as calculated by Eqs. 15 and 16 with α=0.7 and α=0.8 by the use of $k_{13}=1.0\times10^{-11}$ cm³ molecule^{-1} s^{-1} and $k_{14}=2.6\times10^{-5}$ s^{-1}.[22] Most of the experimental points fall between the two lines; thus, we can assume

that the inital yield of formaldehyde in the reaction of OH (OD) with ketene was 70—80%. Therefore, it can be concluded that the reaction of OH with various ketenes at room temperature gives corresponding carbonyl compounds as the main products.

By an *a priori* consideration, the site attacked by an OH can be regarded to be the olefinic carbon of the ketenes, where the electron density is the greatest.[23] The formation of carbonyl compounds from the adduct can be explained in two ways. One is,

$$RR'C{=}C{=}O + OH \longrightarrow \left[\begin{array}{l} RR'C\text{-}C{=}O \\ \quad | \\ \quad OH \end{array}\right]^{\ddagger} \longrightarrow$$

A

$$RR'COH + CO \qquad (17)$$

$$\Delta H = -35.1 \text{ kcal mol}^{-1} \text{ for R,R}' = \text{H}^{24)}$$

Since it is known[26-28] that the RR'COH radical yields RR'CO in the presence of O_2, the formation of formaldehyde, acetaldehyde, and acetone in the reaction of ketene, MK, and DMK, respectively, can be regarded as the products of the reaction of RR'COH radicals with O_2.

The other is the hypothesized route used in the modeling studies[3,4] mentioned above

$$RR'C{=}C{=}O + OH \longrightarrow \mathbf{A} \longrightarrow RR'CO + HCO \qquad (18)$$

$$\Delta H = -31.9 \text{ kcal mol}^{-1} \text{ for R,R}' = \text{H}.^{24)}$$

HCO reacts with O_2 to give $CO+HO_2$, almost exclusively.[25] Thus, the total reaction in air is the same for both cases, as described by the following equation.

$$RR'C{=}C{=}O + OH + O_2 \longrightarrow RR'CO + CO + HO_2 \qquad (19)$$

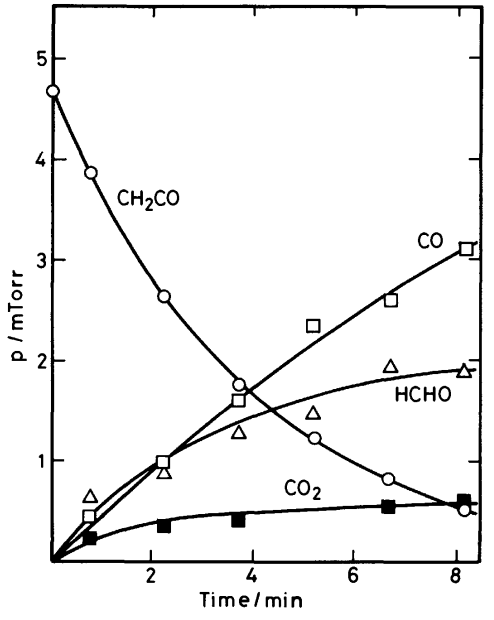

Fig. 8. Typical time profile of the concentration of the reactant and the products in CD_3ONO (22.5 mTorr)-CH_2CO (4.7 mTorr)-air-irradiation system.

The reaction paths in 17 and 18 could not be distinguished in the kinetic experiments and the product analyses performed in this study.

Since **A** is an OH-substituted acetyl radical, the formation of a PAN-type compound ($RR'C(OH)C(O)OONO_2$) can be expected if the radical is stabilized under atmospheric conditions. In the present study, however, no IR band corresponding to PAN-type compounds was detected. Thus, we can assume that the lifetime of **A** is much shorter than the collision interval, even under atmospheric conditions.

Figure 8 shows a typical time profile for the concentration of a reactant and its products in a CD_3ONO-ketene-air-irradiation system. As can be seen in this figure, the CO yield is much higher than CO_2.[29] This strongly supports the above mechanism as being the major pathway. However, the small amount of CO_2 produced may correspond to the pathway of the OH-attack on the carbonyl carbon of the ketenes.

29) Since CO and CO_2 can be produced by the photochemical reaction of RONO and photodesorption from the cell wall, the contribution of those by-products is corrected in the data shown in Fig. 8 in the following manner. Production rate of CO and CO_2 was estimated as a function of the consumption of nitrite as an average of several runs of photolysis of CH_3ONO or CD_3ONO in air. The yield of CO and CO_2 was estimated by the subtraction of the yield calculated with these functions from the apparent yield.

Preparation of Vanadium-Phosphorus Mixed Oxide (P/V=1) Catalysts and Their Application to Oxidation of Butane to Maleic Anhydride

Tomoaki SHIMODA,† Toshio OKUHARA, and Makoto MISONO*
Department of Synthetic Chemistry, Faculty of Engineering, The University of Tokyo, Hongo, Bunkyo-ku, Tokyo 113
(Received March 28, 1985)

Several vanadium-phosphorus mixed oxides with a P/V ratio=1 have been prepared and the relationships between the structure of catalyst and the catalytic function for the selective oxidation of butane to maleic anhydride were examined. As revealed from XRD, IR, XPS, and redox titration studies, five among them were presumably composed of crystalline single phases, that is, α-$VOPO_4$, β-$VOPO_4$, and $(VO)_2P_2O_7$ as well as unknown phases X_1 and X_2. The valences of the vanadium of these catalysts were close to five, except for $(VO)_2P_2O_7$ (the valence was four). These phases were prepared, respectively, by controlling the kind of precursors and the calcination conditions. The selectivity to maleic anhydride differed markedly among these catalysts, although the rate did not change much when it was normalized to surface area. The selectivity at 440 °C was less than 20% for α- and β-$VOPO_4$, 40% for X_1 and X_2, and 70% for $(VO)_2P_2O_7$. Amorphous phases having V^{4+} were much less selective than $(VO)_2P_2O_7$. No structural changes of the catalysts after use were observed in the cases of α-, β-$VOPO_4$, and $(VO)_2P_2O_7$. Therefore, the effective phase for selective oxidation of butane to maleic anhydride was speculated to be a phase like $(VO)_2P_2O_7$ in which the valence of vanadium is four and the structure is stable under the reaction conditions.

Vanadium-phosphorus mixed oxides are known as catalysts for the selective oxidation of butene to maleic anhydride.[1] Several basic studies have been reported on the active structure of the catalysts,[2] the role of phosphorus,[2-4] and the reaction mechanism.[3] The preferred atomic ratio of phosphorus to vanadium is usually in the range of 1.2 to 2.0.

Recently, certain V-P oxides with a P/V ratio of between 1.0 and 1.2 were found to be efficient catalysts for the selective oxidation of butane, a saturated hydrocarbon, to maleic anhydride.[1,5] Several studies on V-P oxide catalysts in this composition range have also been reported.[6-10] However, in most studies, the V-P oxide catalysts used had various P/V ratios, and they usually contained unknown phases or were mixtures. Therefore, the real active phase for the butane oxidation still remains unclarified, although there are many proposals in patents for the preparation of effective catalysts.[11-14]

It was recently indicated that nearly crystalline phases with P/V ratios close to unity were active and selective for the oxidation of butane.[6,7,10,14] As for V-P oxide with P/V=1, crystalline phases such as α-$VOPO_4$, β-$VOPO_4$, and $(VO)_2P_2O_7$ are known.[15-18] These facts motivated us to study these catalysts in greater detail as an extention of our studies on oxidation catalysts having well-defined bulk structures.

In the present study we attempted (i) to examine more extensively the preparation process of catalysts having single crystalline phases with P/V=1, by using well-defined precursors and (ii) to specify the phase or structure of a catalyst which is efficient for the oxidation of butane. An elucidation of the mechanism of catalytic action and the reason why that phase is effective will be the subjects of following study.

†Present address: Mitsui Petrochemical Industries, Ltd.

Experimental

1. Catalyst Preparation. 1.1. Precursors: Three kinds of V-P-O compounds (P/V=1) with well-defined structures (denoted as P-I, -II, and -III) have been prepared as precursors for catalysts.

(a) $(NH_4)_2[(VO)_2C_2O_4(HPO_4)_2]\cdot 5H_2O$ (P-I). P-I was prepared according to the literature.[19] V_2O_5 powder (0.1 mol) was added gradually with stirring into 400 ml of an aqueous solution of oxalic acid (0.75 mol l^{-1}) at 80 °C. When the solution turned to blue after a few minutes, $NH_4H_2PO_4$ (0.2 mol) was added. A green precipitate was formed while the stirring continued. The precipitate was filtrated, washed with water and acetone, and dried overnight at 100 °C. The obtained solid was confirmed to be $(NH_4)_2[(VO)_2C_2O_4(HPO_4)_2]\cdot 5H_2O$ by comparing X-ray diffraction powder patterns (XRD) with a reference.[19]

(b) NH_4HVPO_6 (P-II). This precursor (P-II) was prepared according to the literature.[15] V_2O_5 powder (0.04 mol) was added to a boiling aqueous solution of $NH_4H_2PO_4$ (0.8 mol in 600 ml H_2O), and boiling was maintained for 30 min. A yellow precipitate was formed after the solution was allowed to stand overnight. The precipitate was filtrated, washed with water and acetone, and dried overnight at 100 °C. The XRD pattern (d/Å: 8.75 (100), 4.60 (2), 4.46 (3.5), 4.41 (3), 4.09 (3), 3.17 (3), 2.95 (15), relative peak intensity in parentheses) indicated that P-II was well crystallized. However, an identification was not made because of the absence of reference data.

(c) $(VO)_2H_4P_2O_9$[20] (P-III-1, 2, and 3). P-III-1 was prepared according to the literature.[14a] V_2O_5 powder (0.1 mol) was added to an aqueous solution (200 ml) of $NH_2OH\cdot HCl$ (0.2 mol, Nakarai Chemicals) and H_3PO_4 (0.2 mol, Koso Chemicals) at 80 °C and was stirred for 1 h, in order to completely reduce V_2O_5. After the solution became a light-blue slurry of about 100 ml, it was evaporated to dryness at 130 °C overnight. A small quantity of water (100 ml) was added to the dried solid and the mixture was boiled for 10 min. A light green precipitate obtained by filtration was washed with water. The structure was confirmed by its XRD pattern with reference to the literature.[20]

P-III-2 was prepared in a similar manner as P-III-I. The

TABLE 1. STARTING MATERIALS OF PRECURSORS

Precursor		Starting Materials
P-I	$(NH_4)_2[(VO)_2C_2O_4(HPO_4)_2]$	V_2O_5, $(COOH)_2$, $NH_4H_2PO_4$
P-II	NH_4HVPO_6	V_2O_5, $NH_4H_2PO_4$
P-III-1	$(VO)_2H_4P_2O_9$	V_2O_5, $NH_2OH \cdot HCl$, H_3PO_4
P-III-2	$(VO)_2H_4P_2O_9$	V_2O_5, $NH_2OH \cdot HCl$, H_3PO_4, $C_3H_4O_3$
P-III-3	$(VO)_2H_4P_2O_9$	V_2O_4, H_3PO_4

only difference was that ethylene carbonate ($C_3H_4O_3$, Nakarai Chemicals) was added to the solution before concentration in order to eliminate Cl.[14b] The XRD pattern was very similar to that of P-III-I; however, the peaks were weaker.

P-III-3 was prepared using V_2O_4. A V_2O_4 powder (0.05 mol, Aldrich) was dissolved into an aqueous solution of H_3PO_4 (0.1 mol in 100 ml H_2O) at 80 °C. The resultant blue solution was concentrated at 80 °C with stirring into a green paste. After the green paste was dried at 100 °C, it was placed into water. A light-blue precipitate was obtained upon filtration and washing with water.

Table 1 summarizes the composition and starting materials of the precursors.

1.2 Calcination of Precursors. The precursors were calcined (a) in streams of O_2 or N_2 in a reactor or (b) in air by use of a muffle furnace.

(a) Each precursor (2—5 g) was calcined in Pyrex-tube reactors (10 or 20 mm in diameter) under the flow of oxygen or nitrogen at a prescribed temperature. The heating rate was controlled by adjusting the power, and the temperature was continuously monitored. The flow rate was 100—200 ml min^{-1}. To avoid any blockage of gas flow due to melting, the heating rate was kept low and a wide reactor diameter was adopted.

(b) In the case of any calcination in air, a muffle furnace was used. The heating rate was about 30 °C min^{-1}.

2. Characterization of Catalysts. 2.1 XRD and IR: XRD powder patterns of precursors and catalysts were recorded using a Rigaku X-ray diffractometer with Cu $K\alpha$ radiation filtered by Ni. The XRD was also measured for the catalysts after use. Infrared spectra were recorded with a spectrometer (JIR-10, FT-IR) using an KBr supporting disc.

2.2 XPS: XPS measurements of fresh and used catalysts were carried out using an ESCA Lab 5 (Vacuum Generator). The excitation was performed with the Mg $K\alpha$ line. Binding energies were referred to the C_{1s} line (285 eV). Samples were evacuated under 10^{-8} Torr (1 Torr=133.3 Pa) at 25 °C in the ESCA chamber.

2.3 Valence of Vanadium: The average oxidation state of vanadium in the catalysts was determined by redox titration.[9] About 0.1 g of each catalyst was dissolved in 100 ml of 2 M† H_2SO_4 at 80 °C. The vanadium (IV or III) content was determined by titration with a solution of $KMnO_4$ (0.1 M). The vanadium (V) content was determined by titration with a solution of a Mohr salt ($FeSO_4 \cdot (NH_4)_2SO_4 \cdot 6H_2O$, 0.1 M) using diphenylamine as an indicator.

2.4 Surface Area: The surface areas of the catalyst were measured by the BET method (N_2 adsorption).

3. Measurement of Catalytic Activity and Selectivity. The oxidation of butane was carried out using a conventional fixed-bed flow reactor at atmospheric pressure. The reactor was a Pyrex tube (10 mm in diameter) and was externally heated by an electric furnace. The feed gas consisted of 1.5 vol% butane, 17 vol% oxygen and nitrogen (balance). The reaction temperature was from 250 °C to 440 °C. Products containing carbon were maleic anhydride (MA), CO and CO_2. No other products (C_2–C_3 aldehydes and carboxylic acids) were detected (less than 1%). The carbon balance at the stationary state was always almost 95—100%. Maleic anhydride was collected by a cold trap and was determined by titration with 0.1 M NaOH.[6] Gaseous products were analyzed by a gas chromatograph. It was confirmed, in some cases, that no products other than MA were trapped.

† 1 M=1 mol dm^{-3}.

Results

1. Effects of Calcination Conditions on the Structure of V–P Oxide Catalysts. 1.1 Calcination in O_2 or Air: The structures of the catalysts obtained by calcination in an O_2 or air flow are summarized in Table 2. The results show that the kinds of precursors, the calcination temperature and the heating rate, all, greatly affect the structure of formed catalysts. For example, a high heating rate caused the formation of β-$VOPO_4$ from P-I, while α-$VOPO_4$ was formed from the same precursor using a low heating rate. At an intermediate heating rate, a mixture of α- and β-phase was obtained.

When P-II was calcined at 550 and 600 °C at a low heating rate, a new XRD pattern (d/Å: 4.72 (40), 4.11 (100), 3.15 (30), relative intensity in parentheses) different from either α-, β-$VOPO_4$ or $(VO)_2P_2O_7$ was observed. A high *S/N* ratio of the XRD peaks, together with the fact that the same XRD patterns were obtained for two samples containing this phase; indicates that this was a single phase. This will be denoted as X_1 in this paper.

The influence of the calcination temperature is seen from the results obtained at a heating rate of 30 °C min^{-1}. The calcination of P-I at 450 °C formed almost an amorphous phase (weak peaks at d/Å : 4.33, 4.17, 3.91, 3.65, 3.50, and 3.10), while after a calcination at 550 or 600 °C, the resultant catalysts were crystalline. This showed that XRD patterns are ascribable to pure β-$VOPO_4$. Changes in the phase with the calcination temperature was also found in the case of P-II. A new phase denoted by X_2 (d/Å : 4.00 (90), 3.66 (45), 3.12 (100), relative intensity in parentheses), was obtained by a low-temperature calcination. X_1 and X_2 were water-soluble and the solution was acidic (pH was 2.37 at about 2 g l^{-1} for X_1 and X_2), while α-, β-$VOPO_4$, and $(VO)_2P_2O_7$ were water-insoluble.

The calcination of P-III-1, 2, containing vanadi-

um(IV) in air or O_2 yielded mixed phases. The content of $(VO)_2P_2O_7$ tended to increase as the calcination temperature decreased or the heating rate increased.

1.2 Calcination in N_2: Table 3 shows the results for the calcination at 550°C in N_2 with a heating rate of 10°C min^{-1}. P-I and P-II were converted to amorphous phases, while P-III-1 and P-III-3 readily changed to $(VO)_2P_2O_7$. Less crystalline P-III-2 gave a phase with weak XRD peaks which are not ascribable to $(VO)_2P_2O_7$.

$(VO)_2P_2O_7$ (obtained by the calcination of P-III-1 in N_2) was insoluble in water. However, when it was heated in O_2 (500°C, 2 h), a part of the solid became soluble in the water and the solution became brown. Figure 1 shows the changes of XRD patterns of P-III-1 and P-III-2 due to these processes. After heating P-III-1 in N_2, a typical XRD pattern due to $(VO)_2P_2O_7$ was found (Fig. 1A). The subsequent treatment with O_2 at 500°C caused a partial formation of X_1. By washing with water, the intensity of the XRD peaks due to $(VO)_2P_2O_7$ increased by a factor of about 2; no peaks other than $(VO)_2P_2O_7$ appeared. The changes in the XRD peaks during this procedure were clearer in the case of P-III-2, as shown in Fig. 1B. The weight loss observed by washing with water was about 50% for the latter case.

2. Characterization of Catalyst. The surface area of catalysts and the valence state of vanadium are summarized in Table 4. The surface area decreased as follows: X_1, X_2>$(VO)_2P_2O_7$>α-$VOPO_4$>Amorphous≥β-$VOPO_4$. The oxidation states were close to five for α-, β-$VOPO_4$, X_1, and X_2 and that of $(VO)_2P_2O_7$ was essentially four. The valence was lower than four after P-I and P-II were heated in N_2 at 550°C.

Typical XRD patterns of these phases are shown

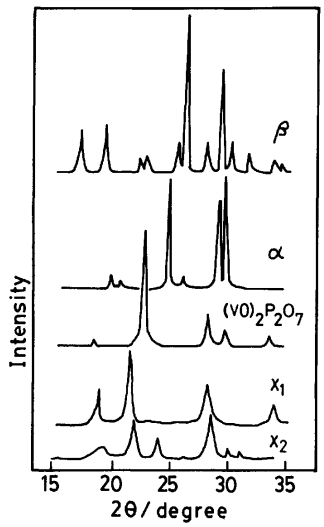

Fig. 2. Typical XRD patterns of V-P oxides prepared.

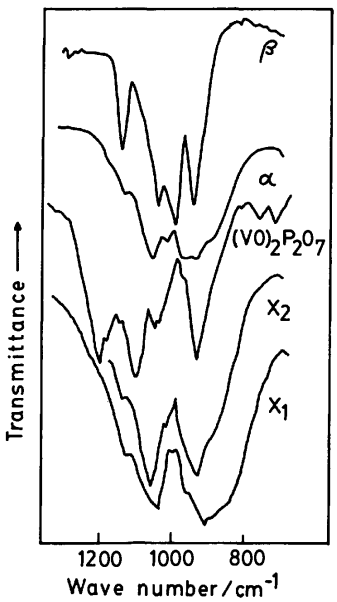

Fig. 3. Infrared spectra of V-P oxides prepared.

in Fig. 2. Figure 3 shows the infrared spectra of the catalysts in the region of 800—1200 cm^{-1}. This region corresponds to the stretching modes of P-O and V=O. The spectra for α-, β-$VOPO_4$ and $(VO)_2P_2O_7$ were in agreement with those reported in the literature.[15,21] The spectra of X_1 and X_2 (1170, 1080, and 955 cm^{-1}) were similar to each other.

XPS spectra of β-$VOPO_4$ and $(VO)_2P_2O_7$ are shown in Fig. 4. The peaks at 526.1 and 519 ev for β-$VOPO_4$ are assigned to $2p_{1/2}$ and $2p_{3/2}$ of vanadium (V) and those at 524.6 and 517.7 eV to $2p_{1/2}$ and $2p_{2/3}$ of vanadium (IV).[22] Although the surfaces of metal oxides are sometimes in more oxidized states than in the bulk, *e.g.*, Fe_2O_3 at the surface of Fe_3O_4,[23] the oxidation states of the catalysts prepared in the present study were very close to those in the bulk. Therefore, it is probable that the crystalline bulk structures were

1) showed a result similar to β-$VOPO_4$. In the case of $(VO)_2P_2O_7$, the activity and selectivity changed slightly at first, and became constant after 2 h. For X_1 and X_2, both the activity and selectivity gradually increased for an initial 3 h. Changes were also observed for amorphous catalysts.

The catalytic activity and selectivity for the oxidation of butane at 440 °C are summarized in Table 5. Data for the stationary state are given in this table. The $(VO)_2P_2O_7$ which was washed and recalcined was most active; however, the catalytic activity was more or less similar when normalized to surface area. The activity of β-$VOPO_4$ was almost proportional to the surface area of the catalysts. In contrast, the selectivity to MA greatly depended on the structure of the catalyst. It was especially high for $(VO)_2P_2O_7$ (about 70%). X_1 and X_2 showed moderate selectivity (40%), and the selectivity was low for α- and β-$VOPO_4$ (20%).

Phase and valence changes of vanadium during the reaction were determined as summarized in Table 5. The XRD patterns changed little after the reaction in the cases of α-, β-$VOPO_4$ and $(VO)_2P_2O_7$. However, X_1 and X_2 changed into mixtures of α-$VOPO_4$ and X_2, for which the compositions were similar. Amorphous phases, catalysts 7 and 8, also changed to mixed phases. The oxidation states of vanadium remained unchanged for α-, β-$VOPO_4$, X_1, X_2 and $(VO)_2P_2O_7$, but those for amorphous phases increased to about five.

Figure 6 shows the effects of W/F on the conversion and the selectivity to MA obtained for $(VO)_2P_2O_7$ and β-$VOPO_4$, where W is the weight of catalyst and F is the flow rate of butane. The selectivity was nearly constant in this range of conversion, although a slight decrease was observed at a low conversion level for $(VO)_2P_2O_7$.

The effects of the reaction temperature on the reaction rate and selectivity are shown in Fig. 7 for $(VO)_2P_2O_7$. The conversion was adjusted to about 40% in order to compare the selectivity, except for the reaction at 250 °C. The rate at 250 °C was so low that a higher conversion was not attained. The selectivity increased as the reaction temperature decreased and was about 90% at 250 °C.

Figures in parentheses are % conversions.

The effect of the valence of vanadium on the catalytic properties was examined using catalysts which were prereduced by H_2. Prior to the reaction, β-$VOPO_4$ (catalyst 3) and X_1 were reduced with H_2 in a closed circulation system (200 cm^3) at 400 °C until the average

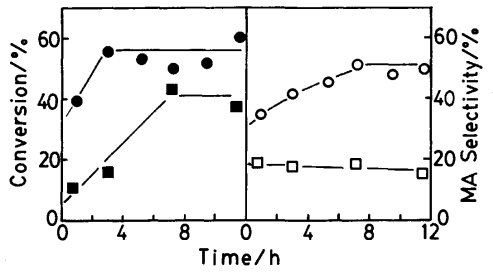

Fig. 8. Variation of activity and selectivity for oxidation of butane over reduced catalysts at 440 °C with reaction time.
Reaction conditions; butane 1.5%, O_2 17%, $W/F = 0.67 \times 10^3$ g·h·mol^{-1}.

valence of vanadium became four. After the treatment, the structure of β-$VOPO_4$ and X_1 changed to amorphous. As shown in Fig. 8, the activity increased with the reaction time for both catalysts and became constant at later stage. The rates as well as the selectivity at the steady state were comparable with those of corresponding unreduced catalysts. After the reaction, the reduced β-$VOPO_4$ showed very weak peaks corresponding to β-$VOPO_4$ and the reduced X_1 showed XRD peaks corresponding to α-$VOPO_4$ and $(VO)_2P_2O_7$.

Discussion

1. Structure of V-P Oxides with P/V=1. Several structures have been reported for crystalline phases of V-P mixed oxide catalysts with a P/V ratio close to unity. These phases have recently been reviewed by Delmon and Hodnett.[24] Among them, only α-$VOPO_4$, β-$VOPO_4$, and $(VO)_2P_2O_7$ are structures which were determined by XRD analyses of single crystals.

The phases which have been claimed to be efficient catalysts for the selective oxidation of butane to MA are, for example, phase X of ICI[12] and B phase of Chevron.[11] The XRD powder patterns of X and B closely resemble those of α-$VOPO_4$ and $(VO)_2P_2O_7$, respectively. The phases X_1 and X_2 showed XRD patterns very similar to β^* phase reported by Delmon and Hodnett[8,24,25] and to B′ phase of ICI,[26] respectively. Therefore, so far there have been reported five phases of V-P mixed oxide catalysts (P/V=1), *i. e.*, α-$VOPO_4$, β-$VOPO_4$, $(VO)_2P_2O_7$ (=B phase), X_1 (=β^* phase), and X_2 (=B′ phase). However, it must be kept in mind that catalysts showing similar XRD patterns are often different in crystallinity and purity and sometimes exhibit quite different activity and selectivity.

2. Preparation of Single Crystalline Phases. The preparation processes of the V-P oxides studied in the present work (Tables 2 and 3) are summarized in Fig. 9. As discussed below, these results demonstrate that the factors investigated, *i,e.*, the kind of precursors, the heating rate, the temperature of calcination, and the atmosphere of calcination, are all important factors in determining the resultant structure of catalysts.

2.1 Calcination in the Oxidizing Atmosphere: First of all, it is noteworthy that α- and β-$VOPO_4$ were respectively formed as single phases (judged from XRD powder patterns), by controlling the heating rate. Trifiro *et al.* reported that α-$VOPO_4$ was transformed to β-$VOPO_4$ when α-$VOPO_4$ was heated for a prolonged period at a high temperature,[21] so that β is likely the more stable phase at high temperatures. Bordes and Courtine[15] reported only the formation of β-$VOPO_4$ by the calcination of P-I in O_2. However, the present study has revealed that α-$VOPO_4$ was exclusively formed when the temperature was raised slowly. It is probable that α-$VOPO_4$ is the phase which crystallizes readily at lower temperatures and that once α-phase is formed it is not easily transformed to the β-phase.

P-I tended to melt at 400—450 °C when it was calcined in O_2; sometimes, the gas flow decreased sharply. In these cases, mixtures of α- and β-phases were often obtained. To avoid this phenomenon, we utilized a wide glass tube and raised the temperature gradually while monitoring the rate of gas flow.

Thus, it is important for the preparation of single crystalline phases to control the rate of temperature rise of the calcination process. Trifiro *et al.*[21] also indicated that the heating rate had a significant influence

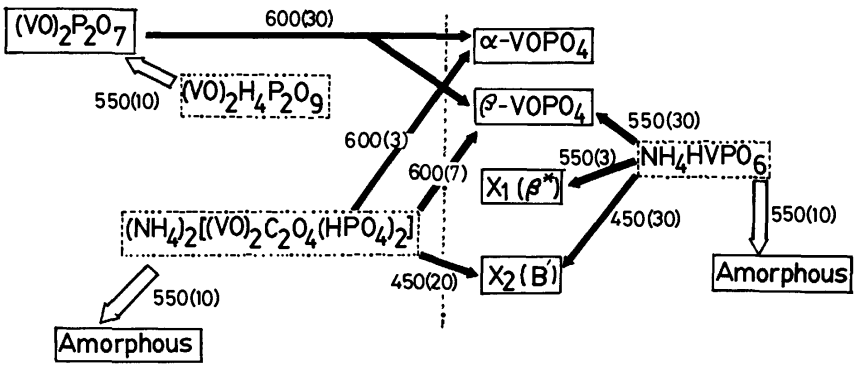

Fig. 9. Preparation processes of V-P oxides.
➡; Calcination in O_2, ⇨; Calcination in N_2.
Figures attached to arrows are calcination temperature and are heating rate (°C min^{-1}, in parentheses).

on the resultant phase.

From P-II (in which vanadium was pentavalent), β-$VOPO_4$, X_1, and X_2 were respectively obtained by controlling the calcination temperature and the heating rate (Table 2). These results are different from those of Bordes and Courtine[15] who reported the formation of α-$VOPO_4$. Probably, the detailed conditions of the preparation were different, although they are not described in their paper. X_1 and X_2 crystallized at lower temperatures and were transformed into β-$VOPO_4$ when calcined at high temperatures. As described above, the X_1 phase showed a XRD pattern similar to the β^* phase which Delmon and Hodnett obtained as mixtures with other phases. They speculated that vanadium in this phase was quadrivalent on the basis of the fact that the fraction of the β^* phase and the average valence state of vanadium changed somewhat in parallel with the calcination time. However, the X_1 phase ($=\beta^*$), which was obtained almost as a single-crystalline phase, has vanadium(V) as determined by redox titration. Although the structures of X_1 and X_2 are not known, it appears probable that they are heteropoly acids with a similar structure (if their solubility in water and the acidic nature of their solutions are considered).

P-III formed mainly $(VO)_2P_2O_7$ by calcination in air; vanadium (IV) was only partially oxidized to vanadium (V) in contrast to P-I. As described below, due to a similarity in structure, P-III is easily transformed to $(VO)_2P_2O_7$. This easy transformation may be the reason why the oxidation of vanadium(IV) took place to a much smaller extent than P-I. By calcination at high temperatures, oxidation proceeded progressively to form β-$VOPO_4$ or X_1. Therefore, it is necessary for a preparation of pure $(VO)_2P_2O_7$ to calcine P-III in the absence of O_2.

2.2 Calcination in the N_2 Flow: The average oxidation states of vanadium in the amorphous phases which were obtained by calcination in N_2 of P-I and P-III were less than four, presumably due to the reduction of catalyst by the NH_3 present in the precursors. Bordes and Courtine[15] reported the formation of $(VO)_2P_2O_7$ from P-I. As described above, the phase formed by the calcination of P-I sensitively varies depending on the calcination conditions.

P-III was transformed into $(VO)_2P_2O_7$ while keeping the valence of vanadium. This is because there was neither a reducing reagent like NH_3 nor an oxidizing reagent. As far as XRD is concerned, $(VO)_2P_2O_7$, thus formed, was pure. According to the structure of P-III determined recently by Torardi and Cababrese,[20] P-III ($(VO)_2H_4P_2O_9$) and $(VO)_2P_2O_7$ have a very similar structure (Fig. 10). This may be the reason why apparently pure $(VO)_2P_2O_7$ was rather easily obtained from P-III.

It was claimed in a patent[13] that a higher yield of MA was obtained by the recalcination of the catalyst

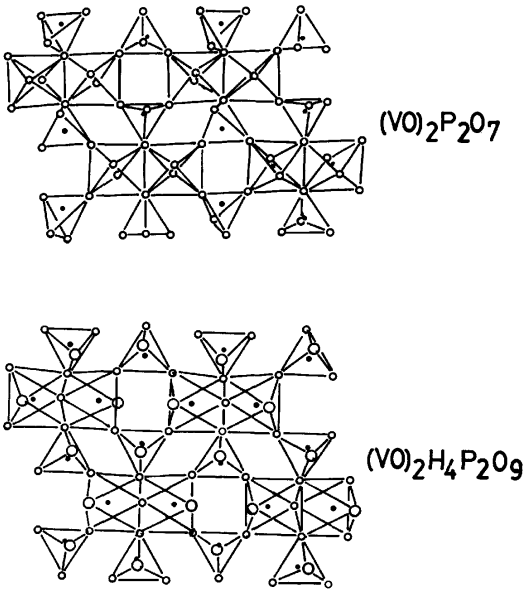

Fig. 10. Structure of $(VO)_2P_2O_7$ and $(VO)_2H_4P_2O_9$.[20]

(probably $(VO)_2P_2O_7$) in air at a high temperature followed by washing with water and calcination at a lower temperature. The present study (Fig. 1) indicates that amorphous or a less-crystalline phase, contained as an impurity, turned to the X_1 phase by calcination in O_2 and that the X_1 phase, thus formed, was washed out, resulting in a highly crystalline and pure $(VO)_2P_2O_7$.

2.3 Purity and Crystallinity: Each α- and β-$VOPO_4$, as well as $(VO)_2P_2O_7$, prepared in this work by carefully controlling the preparation conditions showed sharp XRD peaks of their corresponding structures. IR spectra also agreed with those reported in the literature. Therefore, the purity and crystallinity of all of these catalysts are considered to be of the highest level among the catalysts used in the preceding studies.

The fact that the oxidation states of vanadium were close to four for $(VO)_2P_2O_7$ and five for α- and β-$VOPO_4$ supports this consideration. X_1 and X_2 are likely to have a similar level of purity, as revealed by XRD patterns and IR spectra together with the oxidation state. Furthermore, an XPS analysis showed that the oxidation state of vanadium on the surface was not different from that in the bulk in the cases of β-$VOPO_4$ and $(VO)_2P_2O_7$.

3. Efficient Phase for Catalytic Oxidation of Butane to Maleic Anhydride (MA). The catalytic activity and selectivity to MA of each single phase will be phenomenogically discussed. Chevron found a fair correlation between the MA yield and the content of the B phase ($=(VO)_2P_2O_7$).[11] It was claimed that this phase was the efficient phase, although the highest content of the B phase was obtained at $P/V=1.2$ and the average valence of vanadium was 4.1—4.5.

Later, ICI indicated that phase X ($\fallingdotseq \alpha$-$VOPO_4$) was effective[12] and Delmon's group suggested that the β^* phase was also effective,[8] while their catalysts were

mixtures. Matsuura suggested that both α-$VOPO_4$ and $(VO)_2P_2O_7$ were good catalysts, since the reaction proceeded by the redox cycle between these two phases.[6] Recently, a patent from Mitsubishi Chemical Industry indicated that their catalysts with P/V=1 exhibited a high MA yield and had a $(VO)_2P_2O_7$ structure.[14c]

In our present study, as discussed above, catalysts contained single crystalline phases. The P/V ratios were all unity and the vanadium valences were close to four or five. Moreover, $(VO)_2P_2O_7$ was stable and changed little under the reaction conditions. Structural changes of α- and β-$VOPO_4$ were also negligible. Therefore, it is meaningful to compare the catalytic activity and selectivity of the catalysts as given in Table 5. Table 5 shows that the performance as a catalyst was in the order of $(VO)_2P_2O_7 > X_2$, $X_1 > \alpha$-, β-$VOPO_4$; the selectivity to MA was much better for $(VO)_2P_2O_7$ (catalysts 9 and 10), while the rate normalized to the surface area was more or less similar. The positions of X_1 and X_2 are not certain, since no single phase of X_1 or X_2 was observed after use for a reaction.

A possible reason for the different performances between $(VO)_2P_2O_7$ and α-, β-$VOPO_4$ is the oxidation state of vanadium. However, the prereduced catalysts showed only low selectivities (Fig. 8). Also, the selectivity increased with the reaction time when $(VO)_2P_2O_7$ was formed after reaction and it maintained a low level when β-$VOPO_4$ was formed (Fig. 8). Furthermore, amorphous catalysts having low oxidation states of vanadium also showed low selectivities (Table 5). Thus, catalysts containing vanadium(IV) are not always good catalysts. A certain well-defined structure which is stable under the reaction conditions appears to be necessary. Probably, the $(VO)_2P_2O_7$ catalyst was an efficient catalyst since it consisted of a single crystalline phase in which vanadium(IV) was stable under the reaction conditions. The very high selectivity obtained for $(VO)_2P_2O_7$ at a low temperature (Fig. 7) may be meaningful since the secondary reactions of MA are not significant in this reaction.

Matsuura suggested that the reaction proceeded by a redox cycle between $(VO)_2P_2O_7$ and α-$VOPO_4$.[6] In the present work for purified $(VO)_2P_2O_7$, such a redox cycle was not indicated. Nevertheless, the superiority of $(VO)_2P_2O_7$ is common in the two studies. While Trifiro *et al.*[9,10] also reported that the B-phase ($\fallingdotseq(VO)_2P_2O_7$) showed a good performance, our results were considerably better at high conversion levels. The purity of $(VO)_2P_2O_7$ is a possible reason of this difference. Delmon and Hodnett[8] recently indicated that the β^* phase ($=X_1$) was the efficient phase. The data obtained for the β^* phase were comparable with the X_1 phase in the present study. The X_1 phase was transformed to X_2 and α-$VOPO_4$ during the reaction (Table 5). If one considers the low selectivity of the α-phase, the pure X_2 phase itself could be a fairly good catalyst.

The variations of activity and selectivity of amorphous catalysts 7 and 8 with reaction time are consistent with the concurrent structural changes. When the amorphous catalyst 7 was used as a catalyst, the conversion increased from about 20% (at 3 h) to 60% (after 12 h), and the selectivity to MA decreased from about 30 to about 20%. The steady activity and selectivity were close to those of α-$VOPO_4$. While the conversion was less than 20% (during 15 h) over the catalyst 8, the selectivity to MA gradually increased with time from 25 to 40% (15 h). This is consistent with the result for X_2.

The authors would like to thank Prof. S. Naito and Dr. C. Egawa (The University of Tokyo) regarding the XPS measurement and Mr. M. Kojima, Mr. T. Kurokawa, and Mr. K. Shibata for experimental work at the preliminary stage of this work. A helpful discussion at this stage with Prof. I. Matsuura (presently Toyama University) is also gratefully acknowledged.

Kinetic Studies on the Oxidation of Electrogenerated Mo(V) and Stable Monomeric Mo(V) in Sulfuric Acid Solutions

Kunihiko YOKOI,* Iwao WATANABE,† and Shigero IKEDA†
Department of Chemistry, Osaka Kyoiku University, 3-1-1, Jonan, Ikeda, Osaka 563
†*Department of Chemistry, Faculty of Science, Osaka University, Toyonaka, Osaka 560*
(Received September 21, 1984)

The kinetics of polarographic catalytic reduction of nitrate and perchlorate by electrogenerated transient species of Mo(V) are investigated in 0.1M† sulfuric acid solution. Second-order rate constants for the catalytic reaction with nitrate and perchlorate obtained after Koutecky's treatment are $(2.1\pm0.4)\times10^3$ and $(1.9\pm0.1)\times10^2 M^{-1} s^{-1}$, respectively. Stable Mo(V) species in sulfuric acid solution is studied by spectrophotometry. It is concluded that there exists dimer-dimer-monomer equilibria. The oxidation of the monomer with perchlorate in 14M H_2SO_4 obeys the second-order rate law $-d[monomer]/dt=k[monomer][ClO_4^-]$, where $k=(1.59\pm0.13)\times10^{-1} M^{-1} s^{-1}$. The results indicate that electrogenerated Mo(V) in 0.1M H_2SO_4 is not the same species as the stable monomeric Mo(V) in 14M H_2SO_4.

The electrochemistry of sexivalent molybdenum ions in aqueous acidic solution has been widely investigated.[1-5] It is well known that the polarography of Mo(VI) gives catalytic waves in the presence of nitrate or perchlorate ions, and this phenomenon has been used for the quantitative analysis for Mo(VI).[3,6,7] Some conflict exists concerning the reduction mechanism of Mo(VI) and whether the catalytically active species is Mo(III) or Mo(IV).[2-5] However, recent investigations with coulometry have indicated that the catalytically active species is Mo(V).[1,8,9]

Our polarographic investigations were carried out in sulfuric acid solutions to study oxomolybdenum species. However, no quantitative investigation on the chemical equilibrium and the characteristics of Mo(V) has been reported in sulfuric acid solutions. It is not known whether the catalytically active Mo(V) species can be present as the stable species in bulk solution. The present work was carried out, (1) to obtain the rate constant for the oxidation of electrogenerated Mo(V) with nitrate or perchlorate, (2) to obtain the rate constant for the reaction of Mo(V) in bulk solution with perchlorate for comparison, and (3) to establish the equilibrium of Mo(V) in sulfuric acid solutions.

Experimental

Reagents and Apparatus. All chemicals were of reagent grade and were used without further purification. Polarographic and coulometric instruments employed in this study were the same as reported elsewhere.[10] A Hitachi 124 spectrophotometer was used for absorption measurements.

Procedure. The polarographic current values in this report were measured with RC damping, *i.e.* the average current during the drop life was measured unless otherwise noted. The catalytic current i_c was taken from the difference between the currents measured in the presence and the absence of nitrate or perchlorate at −0.36 V *vs.* SCE. The potential is 95 mV less positive than the half-wave potential of the third wave for Mo(VI) solutions without nitrate or perchlorate.[9]

The Mo(V) solutions were prepared by electrolytic reduction of $2.5-5\times10^{-3}$ M Mo(VI) in 0.1 M H_2SO_4 using a Hg-pool electrode. Oxidation of Mo(V) was initiated by mixing the Mo(V) and perchlorate solutions. Polarographic and spectrophotometric measurements were carried out at (25 ± 0.2)°C.

Results

Polarographic Catalytic Current. Polarograms and reduction mechanisms for Mo(VI) in sulfuric acid solutions were discussed earlier.[9] There are three waves corresponding to the reduction of Mo(VI) to Mo(V) in the polarogram of 0.5 mM Mo(VI) in 0.1 M H_2SO_4. The presence of nitrate or perchlorate enhances the height of the third wave only. Figure 1 shows the relationship between the height of the third wave i_3, which should be proportional to the concentration of the species giving the third wave, and the catalytic current i_c $(=i-i_3)$. When the concentration of Mo(VI) is lower than 0.5 mM, the plot is linear. At higher concentrations, it deviates from the straight line because of the adsorptive behavior of Mo(VI) or Mo(V) at higher concentration. The current amplification by catalytic reaction depends on the concentration of the oxidant as shown in Fig. 2. The ratio of i/i_3 taken at lower concentration of Mo(VI) (5×10^{-5} M) is proportional to the square root of the concentration of nitrate or perchlorate; the second-

order rate constants k_c for the catalytic reduction of nitrate and perchlorate by Mo(V) are obtained by using Koutecky's treatment.[11] Results are listed in Table 1.

Absorption Spectra. Absorption spectra of 2.5×10^{-4}M Mo(V) in various concentration of sulfuric acid solution are shown in Fig. 3. In 0.1 M H_2SO_4, absorption maxima are observed at 254 nm and 293 nm. The spectrum has already been assigned to dimeric Mo(V), $Mo_2O_4^{2+}$.[12,13] When the concentration of sulfuric acid is higher than 3 M, a peak appears at 405 nm. When $c_{H_2SO_4}$ is increased to 9 M, the absorption maxima at 254 nm and 293 nm disappear, and the absorbance of the peak (407 nm) reaches its maximum

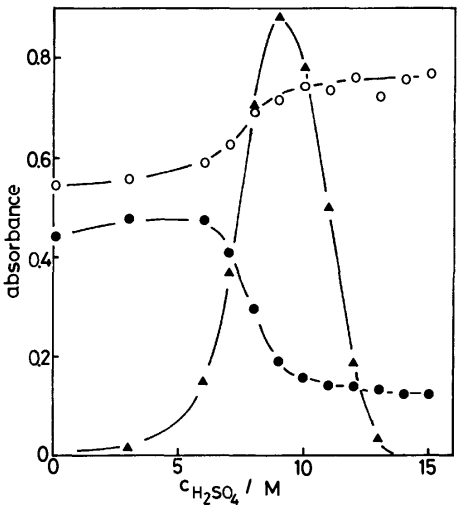

Fig. 4. Effect of the concentration of H_2SO_4 on absorbances of 2.5×10^{-4} M Mo(V) solution at 254nm (○), 293nm (●) and 407nm (▲). l=1 cm.

and the solution looks green-yellow. In 15 M H_2SO_4, there is no absorption in the visible region. The absorbances at 254 nm, 293 nm, and 407 nm vary with $c_{H_2SO_4}$ as shown in Fig. 4. The change of absorbance at 407 nm suggests that three different species of Mo(V) are present in 0.1—15 M H_2SO_4.

Dimer-dimer-monomer Equilibria of Mo(V). In hydrochloric acid solution, dimer-dimer-monomer equilibria of chloro complexes of Mo(V) have been reported.[14,15] However, few study of such equilibria in sulfuric acid solution has been known. Marov *el al.* reported ESR investigations of Mo(V) in sulfuric acid solutions but the precise equilibrium constant could not be obtained[16,17] and no spectrophotometrical investigation of such equilibria has been known. It is well known that the predominant apecies of Mo(V) in 0.1 M H_2SO_4 is dimeric, $Mo_2O_4^{2+}$.[12,13] From the analogy of the equilibria of Mo(V) in hydrochloric acid solution, we expect that the dimer($Mo_2O_4^{2+}$)-dimer-monomer equilibria of Mo(V) in sulfuric acid solution are as follows:

$$D_1 \overset{a}{\rightleftharpoons} D_2 \overset{b}{\rightleftharpoons} 2M \quad (1)$$

$$K_1 = [D_2]/[D_1] \quad (2)$$

$$K_2 = [M]^2/[D_2] \quad (3)$$

$$c_t = 2[D_1] + 2[D_2] + [M] \quad (4)$$

where D_1 means the dimer, $Mo_2O_4^{2+}$, D_2 the other dimer and M is a monomer; K_1 and K_2 are the equilibrium constants and c_t is the total concentration of Mo(V). Spectrophotometric data were treated with Haight's procedure.[14] When $c_{H_2SO_4}$ is lower than 9M, equilibrium a in Eq. 1 should predominate. From the result of Fig. 3 we conclude that only the species of D_2 absorbs at 407 nm; therefore the absorption at 407 nm is,

$$A_{407} = \varepsilon_2[D_2] \quad (5)$$

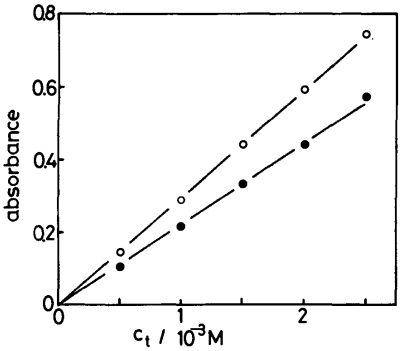

Fig. 5. Dependence of A_{407} on c_t in 7.5 M (●) and 8 M (○) H_2SO_4.

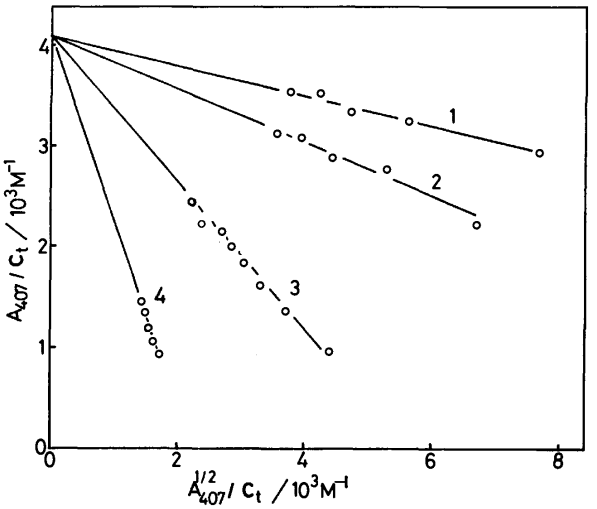

Fig. 6. Dependence of A_{407}/c_t on $A_{407}^{1/2}/c_t$ in H_2SO_4. $c_{H_2SO_4}$: (1) 9 M; (2) 10 M; (3) 11 M; (4) 12 M.

where ε_2 is the molar absorptivity of D_2. Equation 6 follows from Eqs. 2, 4 ([M]=0) and 5.

$$A_{407} = \varepsilon_2 K_1 c_t/2(1+K_1) \quad (6)$$

Therefore, if K_1 is a constant which is independent of c_t, A_{407} should be proportional to c_t when $c_{H_2SO_4}$ is lower than 9 M. The dependence of A_{407} on c_t in 7.5 M and 8 M H_2SO_4 shown in Fig. 5 indicates that D_2 is dimeric.

When $c_{H_2SO_4}$ is higher than 9 M, equilibrium b in Eq. 1 should predominate. In this case,

$$c_t = 2[D_2] + [M] \quad (7)$$

and from Eqs. 3, 5, and 7, we obtain

$$A_{407}/c_t = \varepsilon_2/2 - (\varepsilon_2 K_2/4)^{1/2} A_{407}^{1/2}/c_t. \quad (8)$$

A plot of A_{407}/c_t *vs.* $A_{407}^{1/2}/c_t$ (Fig. 6) gives a straight line with slope $-(\varepsilon_2 K_2/4)^{1/2}$ and intercept of $\varepsilon_2/2$. From the average value of ε_2 (8.17×10^3 $M^{-1}cm^{-1}$) obtained, K_1 and K_2 were calculated for various $c_{H_2SO_4}$ and are listed in Table 2. When $c_{H_2SO_4}$ is higher than 13 M, monomeric Mo(V) is a predominant species.

Oxidation of Monomeric Mo(V) by Perchlorate.

8	2.24		

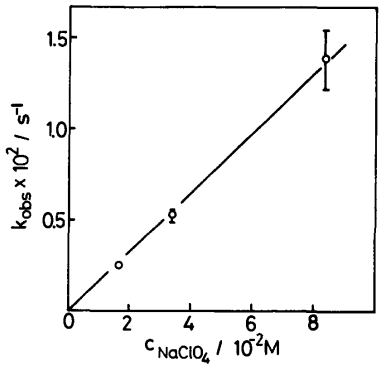

Fig. 7. Dependence of k_{obsd} on the concentration of perchlorate.

The oxidation rate of monomeric Mo(V) by perchlorate was studied by conventional spectrophotometry in the presence of excess perchlorate in 14 M H_2SO_4. The decrease in absorption at 260 nm was used to monitor the reaction. Absorbance at 260nm, A_{260}, is given by

$$A_{260} = \varepsilon_M[M] + \varepsilon_{VI}[Mo(VI)], \quad (9)$$

where ε_M and ε_{VI} are the molar absorptivities of M and Mo(VI), respectively. [M] is given by

$$[M] = (A_{260} - \varepsilon_{VI}c)/(\varepsilon_M - \varepsilon_{VI}), \quad (10)$$

where c=[M]+[Mo(VI)]. A plot of ln[M] *vs.* time was linear to >90% completion. The pseudo-first-order rate constant determined from the plot was linearly dependent on the concentration of perchlorate as shown in Fig. 7. Therefore, the rate law is expressed as

$$-d[M]/dt = k_{obsd}[M] = k[M][ClO_4^-], \quad (11)$$

where k is the second-order rate constant for oxidation of monomeric Mo(V) by perchlorate. The value for k (1.67×10^{-2}—8.33×10^{-2} M perchlorate) was $(1.59\pm0.13)\times10^{-1}M^{-1}s^{-1}$ in 14 M H_2SO_4. The corresponding oxidation by nitrate could not be studied because of the large absorbance of nitrate in the UV region. Oxidation of $Mo_2O_4^{2+}$ by perchlorate is extremely slow[18] and that of the dimer in 9 M H_2SO_4 can not be monitored precisely because the monomer is involved simultaneously. The approximate rate constant obtained is about 1000 times smaller in 9 M H_2SO_4 than in 14 M H_2SO_4.

Discussion

Recent coulometric investigations in the presence

of nitrate and perchlorate have indicated that the catalytically active species is Mo(V).[1,8,9] Paffett and Anson suggested that monomeric Mo(V), $[MoO(OH)(H_2O)_4]^{2+}$, is the catalytically active species,[1] but they did not study the kinetics of the catalytic reaction. Our data on kinetics for the catalytic reaction based on Koutecky's procedure (Table 1) might be compared with data for oxidation of monomeric Mo(V) in bulk solution. However, since such experiments have involved the presence of added ligands which form complexes with Mo(V)[17] or referred to dimeric Mo(V),[18] the direct comparison is not straightforward.

A chloromolybdenum(V) complex in hydrochloric acid solution is involved in dimer-dimer-monomer equilibria.[14,15] In the absence of other complexing ligands, the following equilibria have been considered.

$$2MoO^{3+} \overset{H_2O}{\rightleftharpoons} Mo_2O_3^{4+} + 2H^+ \overset{H_2O}{\rightleftharpoons} Mo_2O_4^{2+} + 2H^+$$

However, no quantitative experiment has been performed.[20] The existence of dimer-dimer-monomer equilibria of Mo(V) is indicated in the present work for sulfuric acid solution. It is not known whether monomeric Mo(V) in 14 M H_2SO_4 is MoO^{3+}. The existence of sulfato complex of monomeric Mo(V), $MoO(HSO_4)_5^{2-}$, has been considered,[16,17] but, detailed structural information can not be obtained at the present stage.

The rate of the reaction involving perchlorate should increase with the activity of hydrogen ion, though the second-order rate constant for oxidation of monomeric Mo(V) with perchlorate in 14 M H_2SO_4 is found to be about 1000 times smaller than that for the reaction of electrogenerated Mo(V) with perchlorate in 0.1 M H_2SO_4 (5×10^{-5}—5×10^{-4} M Mo(VI)). Therefore, monomeric Mo(V) in 14 M H_2SO_4 is not the same species as electrogenerated Mo(V) in 0.1 M H_2SO_4. It has been proposed that a monomeric cation of Mo(V), $[MoO(OH)(H_2O)_4]^{2+}$, is the catalytically active species,[1,10] and this electrogenerated monomer is more reactive than the monomer in bulk solution.

Lahr *et al.* suggested that participation of the MoO^{3+} center might be widespread in catalytic reactions of Mo(V) in aqueous media.[21] In sulfuric acid solutions, both electrogenerated Mo(V) in 0.1 M H_2SO_4 and monomeric Mo(V) in 14 M H_2SO_4 seem to have the MoO^{3+} center, and their oxidation rates with perchlorate are quite different. Thus, other structural characteristic of the catalytically active species of molybdenum having the MoO^{3+} center remains to be established.

Rate of Complex Formation of Iron(III) with Several β-Diketones in Aqueous Perchlorate Solutions Determined by Solvent Extraction Method

Kazuho INABA,† Nobuyuki ITOH, Yumi MATSUNO, and Tatsuya SEKINE*
Department of Chemistry, Science University of Tokyo, Kagurazaka, Shinjuku-ku, Tokyo 162
(Received February 25, 1985)

The rate of formation of iron(III) complexes with several β-diketones (HA) in aqueous sodium perchlorate solutions has been determined by a solvent-extraction method. The rate was found to be first order with respect to the reagent, and zero to an inverse second order with respect to the hydrogen-ion. From the results, the controlling step has been determined to be the formation of the first complex in aqueous solutions. Three types of unit reactions are suggested for this; (i) $Fe^{3+}+HA_{enol}$, which has an associative character; (ii) $Fe(OH)^{2+}+HA_{enol}$ and; (iii) $Fe(OH)^{2+}+A^-$, both of which has a dissociative character.

In previous studies,[1,2] the rate of complex formation of iron(III) with trifluoroacetylacetone (1,1,1-trifluoro-2,4-pentanedione, Htfa) in aqueous solutions was determined from kinetic data regarding solvent extraction in conjunction with equilibrium data of the complexes in a liquid–liquid system. In the present study, the rate of solvent extraction of iron(III) in aqueous 4 mol dm^{-3} sodium perchlorate solutions with several β-diketones (HA) was measured and the rates of complex formations with the reagents were calculated. Then, the effect of a nucleophilic tendency of the β-diketones on the reaction mechanism was considered. The results are compared with those from previous studies with trifluoroacetylacetone and 2-thenoyltrifluoroacetone (1-(2-thienyl-)-4,4,4-trifluoro-1,3-butanedione, Htta)[1-4] and with other β-diketones.[5]

Experimental

All the experiments were carried out at 298 K in a manner similar to that described in previous papers.[1,2,4] The β-diketones used were: acetylacetone (2,4-pentanedione, Hacac), benzoylacetone (1-phenyl-1,3-butanedione, Hbza), dibenzoylmethane (1,3-diphenyl-1,3-propanedione, Hdbm), benzoyltrifluoroacetone (1-phenyl-4,4,4-trifluoro-1,3-butanedione, Hbfa), and hexafluoroacetylacetone (1,1,1,5,5,5-hexafluoro-2,4-pentanedione, Hhfa). They were obtained from Dojindo Co., Kumamoto, Japan (Hacac, Hbfa, and Hhfa), Tokyo Kasei Co., Tokyo, Japan (Hbza), and Nakarai Chemicals Co., Kyoto, Japan (Hdbm). A portion of an aqueous 4 mol dm^{-3} (H,Na)ClO_4 solution containing iron(III) and an equal volume of carbon tetrachloride containing 5×10^{-5} to 1×10^{-3} mol dm^{-3} of one of the β-diketones were placed in a stoppered glass tube and agitated vigorously for a specific time interval and centrifuged. In some experiments, the two phases were agitated until a distribution equilibrium was established. The organic phase was washed by 4 mol dm^{-3} hydrochloric acid and any iron(III), thus back-extracted, was measured using an atomic absorption method. Any metal in an aqueous phase was also measured in a similar way. The hydrogen-ion concentrations in aqueous solutions were measured using potentiometry and a calibration curve which was obtained by measuring a set of standard perchloric acid solutions of the same ionic medium. Thus results were given in stoichiometric units. Spectrophotometric measurements were also made with acetylacetone complexes in order to determine their stability constants. An acid aqueous iron(III) solution and an aqueous Hacac solution were mixed and left standing until a complex formation equilibrium was reached. Then, the optical absorbance was measured at 440 nm to the reagent blank. The hydrogen-ion concentration was measured in a similar way.

†Present address: National Institute for Environmental Studies, 16-2 Onogawa, Yatabe-machi, Tsukuba-gun, Ibaraki 305.

Statistical

In this paper, the subscript "org" denotes a chemical species in an organic solution; a lack of it denotes species in an aqueous solution. An initial concentration is denoted by the subscript "init".

The acid-dissociation and two-phase distribution constant of a β-diketone and the stability constant of the "n-th" complex are defined as;

$$K_a = [H^+][A^-][HA]^{-1}, \quad (1)$$

$$K_d = [HA]_{org}[HA]^{-1}, \quad (2)$$

$$\beta_n = [FeA_n^{3-n}][Fe^{3+}]^{-1}[A^-]^{-n}. \quad (3)$$

The distribution ratio of metal ions when an equilibrium is established can be written as:

$$\begin{aligned} D &= [Fe(III)]_{org}[Fe(III)]^{-1} \\ &= [FeA_3]_{org}([Fe^{3+}]+\sum[FeA_n^{3-n}])^{-1} \\ &= K_{dm}\beta_3[A^-]^3(1+\sum\beta_n[A^-]^n)^{-1} \\ &= K_{ex}K_d^3K_a^{-3}[A^-]^3(1+\sum\beta_n[A^-]^n)^{-1}, \end{aligned} \quad (4)$$

where K_{dm} is the distribution constant of the tris-complex;

$$K_{dm} = [FeA_3]_{org}[FeA_3]^{-1}, \quad (5)$$

K_{ex} is the extraction constant defined by;

$$K_{ex} = [FeA_3]_{org}[H^+]^3[Fe^{3+}]^{-1}[HA]_{org}^{-3}. \quad (6)$$

From the initial concentration of HA, the hydrogen-ion concentration, and D at equilibrium, the values of β_n, K_{dm}, and K_{ex} can be obtained on the basis of Eq. 4 by a least-squares calculation.

The spectrophotometric data of the aqueous solutions obtained by the equilibrium study were treat-

ed statistically as follows. Under the experimental conditions of the present work, the molar absorption coefficient of the hydrated Fe^{3+} species is negligible and, thus, the optical absorbance can be written as;

$$E = \sum\varepsilon_n[FeA_n^{3-n}] = [Fe^{3+}]_{init} \times \sum\varepsilon_n\beta_n[A^-]^n \times (1+\sum\beta_n[A^-]^n)^{-1}, \quad (7)$$

where ε_n is the molar absorption coefficient of the "n-th" complex. From the initial concentration of HA, the hydrogen-ion concentration and E at equilibrium, β_n and ε_n can be calculated on the basis of Eq. 7.

The constant regarding the hydrolysis of Fe^{3+}, K_h, and that for the keto-enol tautomerism of a β-diketone, K_e, which are used for an analysis of the kinetic data are defined as;

$$K_h = [Fe(OH)^{2+}][H^+][Fe^{3+}]^{-1}, \quad (8)$$

$$K_e = [HA]_{enol}[HA]_{keto}^{-1}. \quad (9)$$

When the rate of complex formation is first order with respect to Fe^{3+} and when the controlling step is the formation of the first complex, the rate can be written as;

$$V = -d[Fe^{3+}]/dt = k_{obsd}[Fe^{3+}]. \quad (10)$$

The concentration of the unreacted Fe^{3+} at a certain time after the start of two-phase agitation can be calculated from the initial concentration of Fe^{3+} and that of extracted species using the following equation;[2]

$$[Fe^{3+}] = [Fe^{3+}]_{Init} - ((\beta_1\beta_3^{-1}[A^-]^{-2}+\beta_2\beta_3^{-1}[A^-]^{-1}+1) \times K_{dm}^{-1}+1) \times [FeA_3]_{org}. \quad (11)$$

Results

Equilibrium Experiments. Since the solvent extraction of iron(III) with the β-diketones proceeded rather slowly, two-phase agitation was continued for 1 h (when Hacac or Hhfa was the extractant) or for 24 h (when Hbza, Hdbm, or Hbfa was the extractant) in order to establish equilibrium. Figure 1 shows a plot of log D *vs.* log $[A^-]$ at equilibrium. The equilibrium constants in Eqs. 3, 5, and 6 were calculated from these data on the basis of Eq. 4 using a least-squares program. The values of β_n and K_{dm}, thus obtained, were somewhat erroneous since the distribution ratio of iron(III) was too high under these conditions. The relative concentrations of the aqueous complexes were too high and the extractability of the tris(β-diketonato) complexes was also too high (K_{dm} was great) to allow an accurate determination of the equilibrium constants. On the other hand, the extraction constant, K_{ex}, could be determined much more accurately. The values of the obtained constants are listed in Table 1.

Figure 2 gives the absorbance of the solutions, normalized to an iron(III) concentration as a function of the ligand anion concentration. By analysing these data on the basis of Eq. 7, β_n and ε_n were obtained (Table 1).

Rate of Complex Formation in Aqueous Solutions. It was reported in a previous paper[9] that a transient maximum appeared in the extraction of copper(II) with several β-diketones. This was explained in terms of the rate of the ketonization of the enol form β-diketones in an aqueous phase being rather low. The same type of transient maximum for extraction was observed with Hhfa in the present study. For this reason, a carbon tetrachloride solution of Hhfa was agitated with an

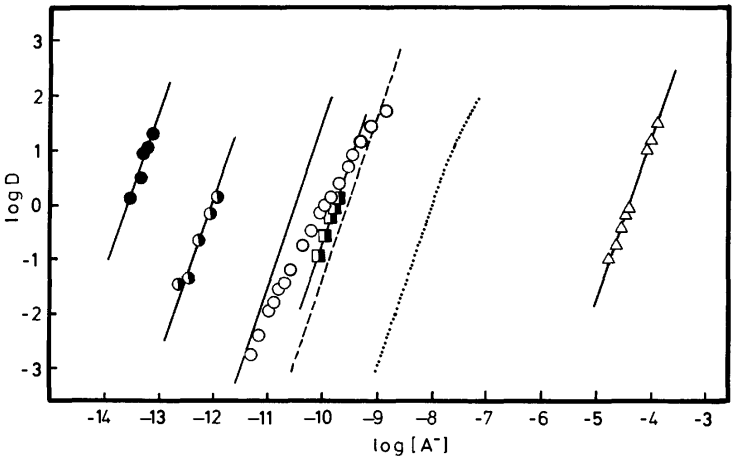

Fig. 1. Extraction curves of iron(III) with $acac^-$ (○), bza^- (◑), dbm^- (●), bfa^- (◨), and hfa^- (△) as a function of ligand concentration into carbon tetrachloride. The solid lines show the slope of +3 which are calculated by introducing the values of K_{ex} in Table 1 into Eq. 4. aqueous perchlorate solution containing no iron(III) for 10 min in order to establish the distribution and ketonization equilibria of the reagent. Then, iron(III) was added to the aqueous phase and kinetic measurements were initiated. The total amount of the iron(III) complexes formed was calculated from the amount of iron(III) extracted into an organic phase, by using Eq. 11. The rate of complex formation was found to be first order with respect to the reagent and zero to an inverse second order with respect to the hydrogen-ion. Figure 3 shows the dependence of the rate of complex formation to the β-diketone concentration; Fig. 4 gives the observed rate constants of the complex formation normalized to the β-diketone concentration in the aqueous phase as a function of the hydrogen-ion concentration. These results could be fitted to the following rate equation;

$$V = [Fe^{3+}][HA](k_A + k_B[H^+]^{-1} + k_C[H^+]^{-2}). \quad (12)$$

The values of the rate constants k_A, k_B, and k_C were obtained by introducing data into Eq. 12 (Table 2). The rate of complex formation with Hacac was too high to determine the rate constant. This is because the solubility of the ligand in an aqueous phase is high and/or the proportion of the enol from to the total amount of reagent in an aqueous phase is also high.

Discussion

In the present study, the ionic concentration in an

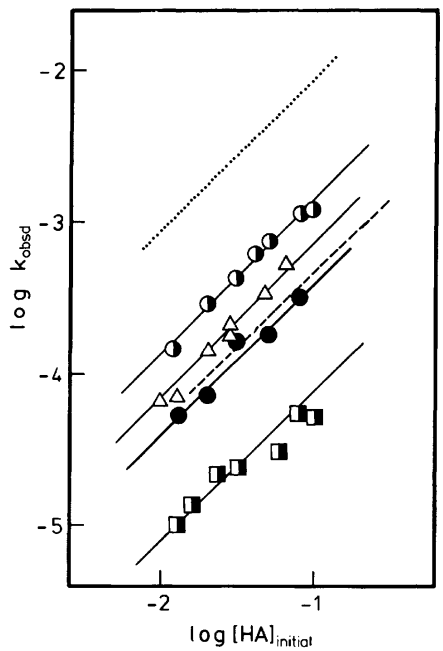

Fig. 3. Dependence of the rate of formation of iron(III) complexes with Hbza (◑), Hdbm (●), Hbfa (◨), and Hhfa (△) on the initial concentration of the reagents. The solid lines show the slope of +1. The dotted and broken lines give the results with Htfa and Htta in Refs. 2 and 4.

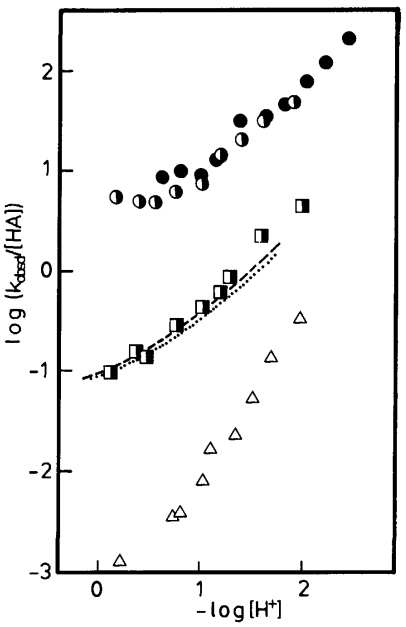

Fig. 4. Dependence of the rate of formation of iron(III) complexes (normalized to the β-diketone concentration in the aqueous phase) with Hbza (◑), Hdbm (●), Hbfa (◨), and Hhfa (△) on the hydrogen-ion concentration. The dotted and broken lines show the results with Htfa and Htta in Refs. 2 and 4.

aqueous phase was kept rather high in order to maintain the activity coefficient of the solutes constant even when for the great charge in the hydrogen-ion concentration was changed. However, the values of the stability constants for acetylacetonato complexes were not very much different from the literature at various ionic concentrations.[11,12]

The stability constants of the iron(III) complexes with bza^-, dbm^-, bfa^-, and tta^- could not be obtained for the reason already mentioned above. However, it can be reasonably assumed that the values of β_n for the bza^- and dbm^- complexes are similar to those of the $acac^-$ complexes, and those of the bfa^- and tta^- complexes to that of the tfa^- complex. In the present work, the estimated values of the stability constants of these four β-diketonato complexes on the basis of this assumption were used for an analysis of the kinetic data.

Since the data fit well with Eq. 12, it is assumed that the following reaction routes are possible.

k_A path:

$$Fe^{3+} + HA_{(enol)} \longrightarrow FeA^{2+} + H^+. \quad (13)$$

k_B path:

$$Fe^{3+} + A^- \longrightarrow FeA^{2+}, \quad (14)$$

and/or

$$[Fe(OH)]^{2+} + HA_{(enol)} \longrightarrow FeA^{2+} + H_2O. \quad (15)$$

k_C path:

$$[Fe(OH)]^{2+} + A^- \longrightarrow FeA^{2+} + OH^-, \quad (16)$$

and/or

$$[Fe(OH)_2]^+ + HA_{(enol)} \longrightarrow [FeA(OH)]^+ + H_2O. \quad (17)$$

Because of the proton ambiguity, two possible reactions are given for both of the k_B and k_C paths. However, from the magnitudes of the rate constants for complex formations, the hydrolysis constant of iron(III), the equilibrium constant for the keto–enol tautomerism, and the acid-dissociation constant of the β-diketone, it was concluded that the route in Eq. 15 was more reasonable except when the reagent was Hhfa. Since the value of K_e of Hhfa, $[Hhfa]_{enol}/[Hhfa]_{keto}$, is much smaller and the acid-dissociation constant is larger than for other β-diketones, the concentration of the ligand, $[A^-]$, in an aqueous phase with this reagent under experimental conditions should be much higher than for the other β-diketones and both the reactions in Eqs. 14 and 15 could be possible. For the k_C path, the reaction in Eq. 16 was determined to be more reasonable since the second hydrolysis constant of Fe^{3+} is very small and, thus, the amount of the $[Fe(OH)_2]^+$ species should be extremely small under the present experimental conditions.

By using K_h of iron(III), K_a and K_e of the β-diketone and k_A, k_B, and k_C in Eq. 12, the rate of each controlling reaction can be written as;

$$V_0 = k_0[Fe^{3+}][HA]_{enol} = k_A \times K_e^{-1} \times (1+K_e)[Fe^{3+}][HA], \quad (18)$$

$$V_1 = k_1[Fe(OH)^{2+}][HA]_{enol} = k_B \times K_h^{-1} \times (1+K_e) \times K_e^{-1}[Fe^{3+}][HA][H^+]^{-1}, \quad (19)$$

$$V_1' = k_1'[Fe^{3+}][A^-] = k_B \times K_a^{-1}[Fe^{3+}][HA][H^+]^{-1}, \quad (20)$$

$$V_2 = k_2[Fe(OH)^{2+}][A^-] = k_C \times K_h^{-1} \times K_a^{-1}[Fe^{3+}][HA][H^+]^{-2}. \quad (21)$$

k_0, k_1, k_1', and k_2 were calculated using the above constants (Tables 1 and 2) using Eqs. 18 to 21. They are listed in Table 3.

Ishihara, Funahashi, and Tanaka reported that the rate constant and the activation volume for the formation of iron(III) complexes in aqueous solutions with 4-isopropyltropolone, thiocyanate ion, and acetohydroxamic acid.[13,14] They concluded that a reaction of hydrated Fe^{3+} proceeded in all cases by an associative interchange mechanism. That of $[Fe(OH)]^{2+}$ proceeded by a dissociative interchange mechanism. In the present study, the values of k_1 and k_2 (Eqs. 19 and 21) for the reaction of $[Fe(OH)]^{2+}$ are about $10^{3.4}$ with all the β-diketones. These agree well with the above reported values. For this reason, it was concluded that the k_B path could be more reasonably represented by Eq. 15 and the k_C path by Eq. 16. Moreover, the values of k_1 and k_2 agree well with the literature regarding $[Fe(OH)]^{2+}$ with several ligands. Since the mechanisms for these reactions were determined previous papers to be dissociative interchanges from the activation volumes, it should be reasonable to conclude here that the reactions described by Eqs. 15 and 16 also proceed by a mechanism which has a dissociative character.

In reactions of Fe^{3+}, the value of k_0 was greater when the reagent was a weaker acid. This indicates that the rate was higher when the nucleophilic tendency of the reagent was higher and consequently the mechanism should have an associative character. Thus, the mechanism of complex formation of iron(III) with these β-diketones is different when the metal species in the controlling reaction is Fe^{3+} and when it is $[Fe(OH)]^{2+}$.

As described in a previous paper,[2] equilibrium data for complexes formed from products of the controlling reaction are often indispensable in order to make a reasonable analysis of the kinetic data regarding solvent extraction. However, in most previous work regarding the rate of solvent extraction controlled by a complex formation in an aqueous phase, this has not been considered. For example, the rates of solvent extractions and complex formations of iron(III) with β-diketones (except Hdbm) were studied,[5] but no correction was made in the previous work regarding the effect of the complexes formed in the aqueous phase when the kinetic data were analyzed. As can be seen from the previous and present paper, somewhat different conclusions can be drawn from similar experimental data.

When both of the reagents and the complexes are relatively insoluble in water, as those in the present study, the solvent extraction method should be more useful than the spectrophotometric method of the aqueous solution provided that the product is extractable into organic solvents.

The authors are grateful to Miss Akemi Saito for her experimental aid in the early stage of this work.

The Effect of α-Tocopherol on Polymerization of Methyl Methacrylate

Koe ENMANJI
The Materials Engineering Laboratory of Mitsubishi Electric Corp., Tsukaguchi-Honmachi, Amagasaki 661
(Received January 5, 1985)

Photo- and thermal polymerizations of methyl methacrylate (MMA) in the presence of α-tocopherol were investigated in air or *in vacuo*. α-Tocopherol at higher concentrations inhibits both the photopolymerization of MMA sensitized by benzoin ethyl ether and the thermal polymerization induced by benzoyl peroxide, but at lower concentrations is able to initiate photopolymerization of MMA under aerobic conditions. Spectral data indicate that a fraction of α-tocopherol is incorporated in the produced polymer chain.

α-Tocopherol (αT) (Fig. 1) is known as an oil-soluble antioxidant vitamin, whose action *in vivo* is to quench radicals produced in biological membranes, particularly multivalent unsaturated fatty acid radicals induced through decompositions, and the excited singlet oxygen $^1O_2$. A lot of literature has reported this action,[1,2] but no report is found of the effect on vinyl polymerization. Because the antioxidant property of α-tocopherol is due to the production of semiquinone radical through oxidation of the hydroxyl group having an active hydrogen,[2,3] α-tocopherol is expected to be an inhibitor for vinyl polymerization. A high resolution electron spin resonance study has shown that 6-chromanyloxyl radical is produced by photolytic oxidation of α-tocopherol,[4] but the action of this radical on vinyl monomer has not yet been investigated. The present author has studied the effect of α-tocopherol on the polymerization of methyl methacrylate (MMA) and found that α-tocopherol at high concentrations inhibits the polymerization of MMA as expected but that it is effective at low concentrations for photoinitiation of MMA polymerization in the presence of air.

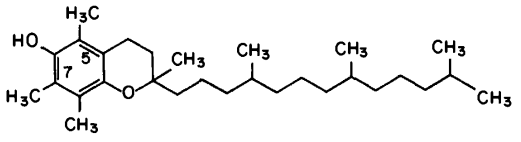

Fig. 1. Chemical structure of α-tocopherol.

Experimental

α-Tocopherol, benzoin ethyl ether (BEE), and benzoyl peroxide (BPO), all of reagent grade (Nakarai Chem. Co.), were used without further purification. MMA was distilled *in vacuo* before use. MMA was placed in a glass ampoule with or without solvent and kept at 25 °C in a thermostat for 30 min, the concentration of dissolved oxygen was confirmed to be 4.5×10^{-4} mol dm^{-3}, and then the ampoule was sealed in atomsphere.

A high pressure mercury lamp was used for photopolymerization and the lights below 300 nm wavelength were cut off with a glass filter (Toshiba, UV-30), if necessary. At a certain reaction time, the polymer solution was poured into methanol, and the conversion of polymer was estimated from the weight of the precipitant required.

Electron spectra were recorded on a Simadzu MPS-5000. Flash photolysis was conducted with a home-made apparatus consisting of a 1 cmφ×10 cm quartz sample tube, two main xenon lamps (Ushio FS-225HMA), a sub xenon flash lamp (Ushio FS-125B), and a spectroscope. The main lamps were

put parallel with the sample tube, and the sub lamp and spectroscope were put on the elongation of the center axis of sample tube. The sample was kept at room temperature. The concentration of O_2 in MMA was measured with an oxygenelectrode (Yellow Spring Instrument Co., Inc.). The viscosity of polymer acetone solution was measured with an Ubelohde viscosimeter at 30°C.

Results and Discussion

As generally known, MMA monomer is caused to polymerize *in vacuo* by a radical produced by absorption of ultraviolet light below 300 nm wavelength, but the polymerization is hard to proceed under aerobic conditions because the radical is quenched by oxygen. The results of Table 1 were obtained when MMA was photochemically or thermally polymerized in the presence of α-tocopherol under aerobic or anaerobic conditions. Table 1 indicates that α-tocopherol at higher concentrations inhibits the polymerization of MMA by quenching the initiator radical or monomer radical as expected (Nos. 8 and 15). The mechanism of inhibition is thought to be as follows:

$$C_6H_5COOOCOC_6H_5 \xrightarrow{k_d} 2C_6H_5CO_2\cdot, \quad (1)$$

$$C_6H_5CO_2\cdot + M \longrightarrow C_6H_5CO_2M\cdot, \quad (2)$$

$$M_x\cdot + M \xrightarrow{k_p} M_{x+1}\cdot, \quad (3)$$

$$2C_6H_5CO_2\cdot \xrightarrow{2k_t} \text{nonradical products}, \quad (4)$$

$$M_x\cdot + M_y\cdot \longrightarrow M_x + M_y \text{ or } M_{x+y}, \quad (5)$$

$$C_6H_5CO_2\cdot + M\cdot \longrightarrow C_6H_5CO_2M, \quad (6)$$

$$C_6H_5CO_2\cdot + \alpha T \longrightarrow C_6H_5COOH + \alpha T\cdot, \quad (7)$$

$$C_6H_5CO_2\cdot + \alpha T \xrightarrow{k_{inh}} \text{nonradical products}, \quad (8)$$

where M is the monomer and R_i is the rate of initiation. The inhibition rate is expressed by

$$R_{inh} = \frac{k_p[M]R_i}{k_{inh}[\alpha_T]}. \quad (9)$$

Plots of conversion *vs.* reaction time are shown in Fig. 2 for various α-tocopherol concentrations. The value of R_{inh} is close to zero, so that k_{inh} is much larger than k_p.

MMA does not polymerize without α-tocopherol under aerobic conditions, but MMA is photopolymerized in the presence of a small amount of α-tocopherol under an aerobic condition ($[O_2]=4.5\times10^{-4}$ mol dm^{-3}); that is to say, light and α-tocopherol are main initiators for these polymerization reactions. The effect of α-tocopherol on the conversion is shown in Fig. 3. Here, α-tocopherol inhibits to less than 10% of MMA conversion when the α-tocopherol concentration is 1.2×10^{-3} mol dm^{-3} as seen from Fig. 1 and the effect of inhibition may be ignored. The conversion increases in proportion to the square root of the amount of α-tocopherol below 5×10^{-3} mol dm^{-3}, which indicates

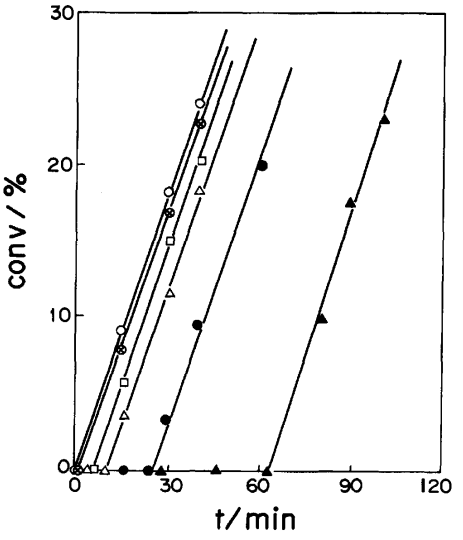

Fig. 2. The relation between conversion and reaction time, concentration of benzoyl peroxide is 2.40×10^{-2} mol dm^{-3} under anaerobic conditions, temperature is 70°C, -○-: [αT]=0, mol dm^{-3}, -×-: [αT]=3.86×10^{-5}, -□-: [αT]=2.32×10^{-4} mol dm^{-3}, -△-: [αT]=6.01×10^{-4} mol dm^{-3}, -●-: [αT]=1.5×10^{-3} mol dm^{-3}, -▲-: [αT]=4.0×10^{-3} mol dm^{-3}.

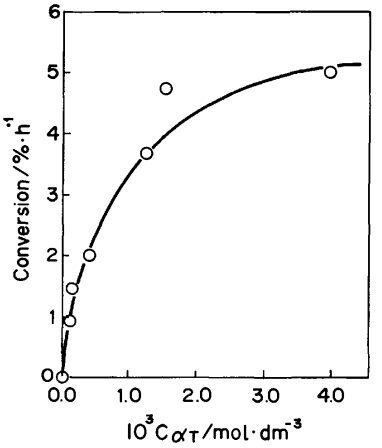

Fig. 3. The relationship between conversion and concentration of α-tocopherol at 30°C under aerobic conditions.
$I=80$ mW cm^{-2}.

that this reaction is on the bimolecular termination mechanism. The logarithm of the conversion is proportional to the logarithm of the intensity of light (the slope is 0.61 as seen from Fig. 4). This fact also supports that this reaction is on the bimolecular termination mechanism.

Next, the conversion was measured at various concentrations of monomer in benzene as a solvent. The results obtained conclude that the conversion is proportional to the concentration of monomer (the slope is 1.19 as seen from Fig. 5). This fact allows the polymerization rate R_p to be written as

$$R_p \propto I^{1/2}C_{MMA}C\alpha_T^{1/2}, \quad (10)$$

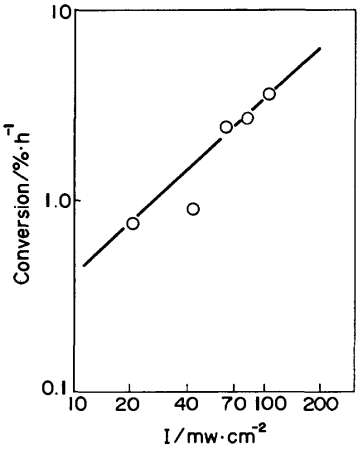

Fig. 4. Plots of conversion *vs.* intensity of light at 30.6 °C under aerobic conditions. Concentration of α-tocopherol is 6.44×10^{-4} mol dm^{-3}.

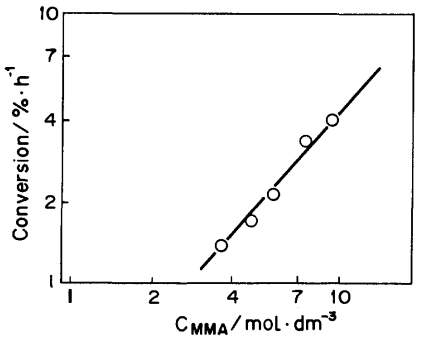

Fig. 5. Plots of conversion *vs.* monomer concentration at 30.6 °C under aerobic conditions. Concentration of α-tocopherol is 6.44×10^{-4} mol dm^{-3}. Intensity of light is 100 mW cm^{-2}.

where I is the intensity of light, C_{MMA} is the concentration of monomer, and $C\alpha_T$ is the concentration of initiator. The temperature dependence of the conversion was also examined (Fig. 6). The conversion reaches a maximum at 50 °C and decreases sharply above 50 °C. The Arrhenius relation holds in the temperature range 5 −50 °C; the activation energy ΔE is estimated as about 33.9 kJ mol^{-1}.

The effect of α-tocopherol as photoinitiator was studied under aerobic conditions. When a methanol solution of α-tocopherol was photoirradiated under aerobic conditions, the optical density at 293 nm decreased with time (Fig. 7). This reaction was found to be first order in α-tocopherol with a rate constant k of 0.024 min^{-1} at 30 °C under aerobic conditions. In contrast, k is 6.4×10^{-3} min^{-1} under anaerobic conditions and 3.9×10^{-3} min^{-1} with the light cut off below 300 nm under aerobic conditions. These results indicate that this reaction needs both oxygen and ultraviolet light. As can be seen from Fig. 6, k and the conversion of MMA decrease above 50 °C. At first glance, the decrease in the conversion might be considered to result from both the increase in the quenching rate

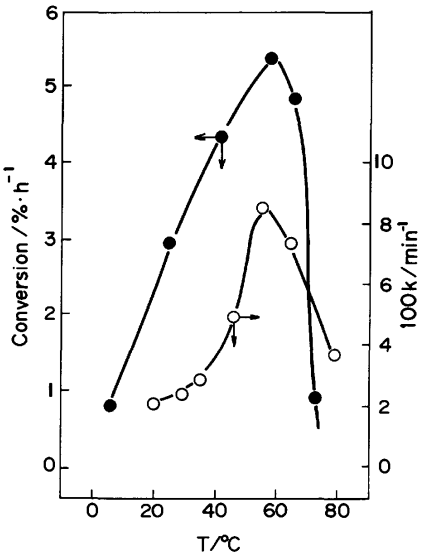

Fig. 6. Temperature dependence of conversion and the photooxidation rate constant. Concentration of α-tocopherol is 6.44×10^{-4} mol dm^{-3}, intensity of light is 100 mW cm^{-2}.
-●-: conversion of MMA, -O-: photooxidation rate of α-tocopherol.

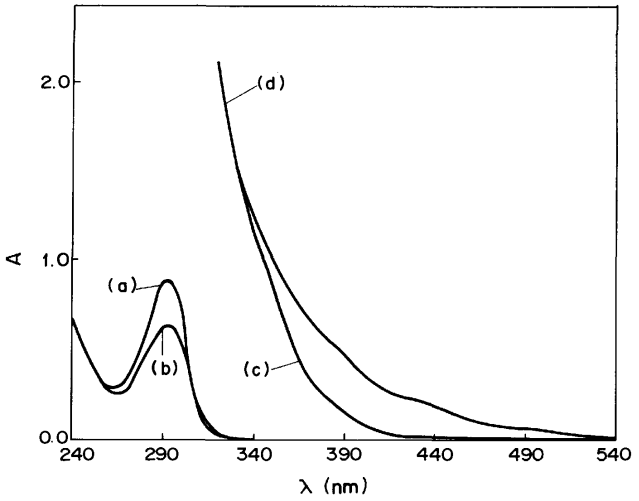

Fig. 7. Spectra of α-tocopherol and photooxidated products.
(a) 2.58×10^{-4} mol dm^{-3} α-tocopherol in methanol, (b) Photoirradiatted (a) for 1.5 h, (c) 3.63×10^{-2} mol dm^{-3} α-tocopherol in methanol, (d) Photoirradiatted (c) for 2 h.

of α-tocopherol radical with temperature and the secrease in the concentration of α-tocopherol radical which initiates the polymerization. However, this mechanism cannot interpret the decrease in the oxidation rate of α-tocopherol above 50 °C. Thus the phenomenon cannot be interpreted with our present knowledge.

Flash photolysis of an α-tocopherol solution in ethanol was examined. Transient spectra were found at 356 nm between 10 and 100 μs and the vanishing rate constant was obtained as 1.55×10^{4} s^{-1}. It may be

thought that the species concerned is the triplet state of semiquinone radical (6-chromanyloxyl radical) of α-tocopherol, because it is generally considered that even the triplet state of chlorophyll a, of which the residence time of the triplet state is the longest among popular molecules is quenched by electron acceptors to a residence time of 10^{-4} s (for example, the quenching rate constant of the triplet state of okitacene is $3.1\times10^{5}\,s^{-1}$).[5] This radical was observed by laser flash photolysis coupled with time resolved ESR.[6]

The mechanism of the photopolymerization of MMA with α-tocopherol is given as follows on the basis of the results obtained:

$$\alpha T \xrightarrow{h\nu} \alpha T\cdot, \quad (11)$$

$$\alpha T\cdot + O_2 \longrightarrow \alpha TO_2\cdot, \quad (12)$$

$$\alpha TO_2\cdot \xrightarrow{k_q} Q(\alpha T\text{-}O_2\text{-}\alpha T), \quad (13)$$

$$\alpha TO_2\cdot + MMA \xrightarrow{k_i} \alpha TO_2\text{-}MMA\cdot, \quad (14)$$

$$MMA_x\cdot + MMA \xrightarrow{k_p} MMA_{x+1}\cdot, \quad (15)$$

$$MMA_x\cdot + MMA_y\cdot \xrightarrow{k_t} MMA_{x+y} \text{ or } MMA_x + MMA_y. \quad (16)$$

The rate of initiation is expressed as

$$v_i = \frac{k_i C_{MMA}}{(k_i C_{MMA}+k_q)}\phi I[1-\exp(-\varepsilon C_{\alpha T} l)], \quad (17)$$

where ϕ is the quantum yield for producing α-tocopherol., Q is the subproduct of the reaction, l is the length of the reactor, and ε is the molecular extinction coefficient. When $C_{\alpha T}$ is small (the light is not perfectly absorbed), Eq. 17 can be reduced to

$$v_i = \frac{k_i C_{MMA}}{(k_i C_{MMA}+k_q)}\phi I\varepsilon C_{\alpha T} l. \quad (18)$$

Further, if $k_i C_{MMA} > k_q$, the following equation is obtained which agrees with the experimental Eq. 1:

$$R_p = \frac{k_p C_{MMA}}{(2k_t)^{1/2}}\phi^{1/2} I^{1/2} C_{\alpha T}^{1/2}(\varepsilon l)^{1/2}. \quad (19)$$

$\alpha TO_2\cdot$ may be a derivative from the 6-chromanyloxyl radical. The chromanyloxyl radical formed would be stabilized by radical delocalization and the most reactive site of the delocalized radical seems to be the C-5 position.[7] Then the initiation point of polymerization may be the C-5 position. Because the polymerized poly(methyl methacrylate) has an absorption band above 400 nm even after purification, it is thought that the oxidative product of α-tocopherol is present at the end of the produced poly(methyl methacrylate). The molecular weight of the polymer produced in the presence of α-tocopherol as a photoinitiator was investigated; the molecular weight was measured by the viscometric method.[8] The results are shown in Table 2, revealing that the presence of α-tocopherol suppresses the increase in the molecular weight.

Table 2. Molecular weight of the poly(methyl methacrylate) produced with α-tocopherol as initiator[a]

$C_{\alpha T}$ / mol dm^{-3}	$[\eta]_{sp}$[b]	$\bar{M}_v$
none	2.00	10.0×10^5
3.66×10^{-5}	1.78	8.6×10^5

a) Bulk polymerization under aerobic conditions, with irradiation by a mercury lamp (80 mW cm^{-2}). b) Measured at 30 °C in acetone with an Ubelohde viscocimeter.

Table 3. Comparison of various vinyl monomers polymerized with α-tocopherol

Temperature is 30.6 °C and lighe intensity is 80 mW cm^{-2} under aerobic conditions

Monomer	$C_{\alpha T}$ / mol dm^{-3}	Conversion / %h^{-1}
Methyl methacrylate	none	0.7
	4.33×10^{-4}	2.0
Styrene	none	0.6
	5.71×10^{-4}	2.2
Ethyl cinnamate	none	0.005
	7.33×10^{-4}	0.052

The effect of α-tocopherol as an initiator on other vinyl monomers were studied. It has been found that α-tocopherol can initiate styrene as well as MMA but hardly initiate ethyl cinnamate (Table 3).

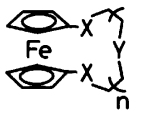
(Received February 16, 1985)

Polyoxa-1,*n*-dithia[*n*](1,1′)ruthenocenophanes were prepared by treatment of 1,1′-ruthenocenedithiol with α, ω-dibromo polyethers. The ruthenocenophanes formed efficiently complexes with soft ions, but not with hard and borderline cations. The ^{1}H- and ^{13}C-NMR spectral data of the silver(I) ion-complexed ruthenocenophanes suggested a partial electron-transfer interaction between the ruthenium atom of the ruthenocene nucleus and the incapsulated silver(I) ion. The crystal structure of the 1:1 complex of 4,7,10,13-tetraoxa-1,16-dithia[16](1,1′)ruthenocenophane with mercury(II) chloride was determined by the X-ray method. The crystals are triclinic, space group $P\bar{1}$, with a=13.722 (3), b=11.678 (4), c=8.179 (2) Å, α=102.69 (3), β=72.82 (2), γ=100.73 (2)°, Z=2, D_x=2.11 g cm^{-3}. The mercury(II) cation and the two chloride ions are situated in the central cavity of the macrocyclic moiety and at the apexes, respectively. The distance between the ruthenium atom of a ruthenocene nucleus and the incapsulated mercury(II) ion is 4.846 (2) Å which is too long for direct metal-metal interaction.

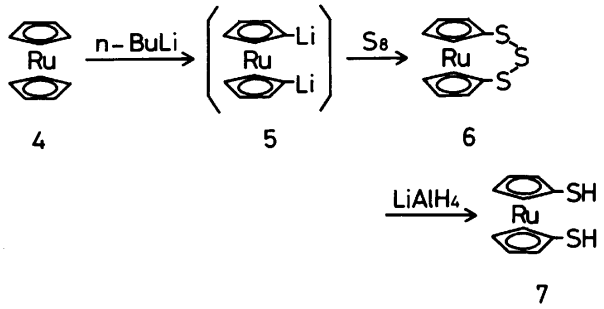
Preparation of a number of crown ethers was first reported by Pedersen twenty years ago.[1] Since that time, a large number and variety of crown, thiacrown and oxathiacrown ethers have been prepared and their complexes with various metal cations and/or organic ammonium cations have been extensively studied.[2] Recently, in order to develop a new functionality, many research groups have attempted to investigate the modified crown ethers.[2] For example, the syntheses of



1 : X=Y=S
2 : X=Y=O
3a: X=S, Y=O
3b: X=O, Y=S

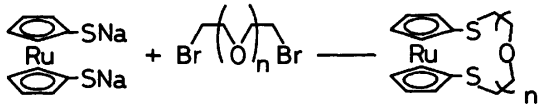
many kinds of macrocyclic compounds containing phosphorus, arsenic, and/or other coordinatable atoms have been reported[2] and in this connection, several research groups[3] have reported new-type crown ethers, thiacrown ethers, and oxathiacrown ethers which contain a ferrocene unit as an integral part of a ring member. Although a number of ferroceno crown ethers have already been reported, a crown ether containing a ruthenocene unit is rare.[4,5] Therefore, we wish to report the syntheses of polyoxa-1,*n*-dithia[*n*](1,1′)-ruthenocenophanes, their ability for forming complexes with various metal cations including transition metals, and the crystal structure of the complex of 4,7,-10,13-tetraoxa-1,16-dithia[16](1,1′)ruthenocenophane with mercury(II) chloride.

Syntheses and Spectral Studies. The reaction of 1,1′-dilithioruthenocene (**5**), which was prepared from ruthenocene (**4**) and butyllithium in the presence of *N,N,N′,N′*-tetramethylethylenediamine (TMEDA), with sulfur gave 1,2,3-trithia[3](1,1′)ruthenocenophane (**6**) in a 43% yield. The ^{1}H-NMR spectrum of **6** showed the cyclopentadienyl (Cp) ring protons as a AA′BX pattern at δ 4.05—4.83, supporting the assigned structure. Reduction of **6** with lithium aluminum hydride in boiling ether afforded a 94% yield of ruthenocene-1,1′-dithiol (**7**) as colorless crystals. The ^{1}H-NMR spectrum of **7** showed the Cp ring protons as A_2B_2 pattern at δ 4.47 (t, 4H, J=3.5 Hz) and 4.66 (t, 4H, J=3.5 Hz), and SH protons as a singlet at 2.25 (s, 2H). Also the IR spectrum of **7** showed C–H absorption bands of the Cp rings at 1485 and 3097 cm^{-1} and S–H absorption band at 2500 cm^{-1}. Disodium ruthenocene-1,1′-dithiolate (**8**), which was prepared from the reaction of **7** with aqueous sodium hydroxide in ethanol, was allowed to react with dihalide (**9a**) in aqueous ethanol using highly diluted conditions to give 4,7,10,13-tetraoxa-1,16-dithia[16](1,1′)ruthenocenophane (**10a**) as pale yellow crystals in a 17% yield. In the same manner, the reaction of **8** with dihalide (**9b**) and (**9c**) also gave 4,7,10-trioxa-1,13-dithia[13](1,1′)ruthenocenophane (**10b**) and 4,7-dioxa-1,10-dithia[10](1,1′)-ruthenocenophane (**10c**) in 48 and 23% yields, respectively. The structures of **10a**—c were confirmed as follows. For example, the molecular formula of **10a** was deduced to be $C_{20}H_{18}O_4S_2Ru$ by elemental analysis and mass spectroscopy (M^+, m/z 498). In the ^{1}H-NMR spectrum of **10a**, the resonance for the methylene protons



4 5 6 7

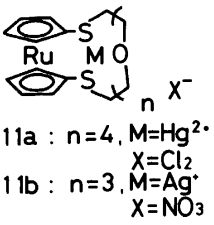
attached to the sulfur atom appeared as a triplet (J= 6.3 Hz, 4H) at δ 2.86, in addition to a singlet (12H, OCH_2CH_2) at δ 3.51 and a triplet (J=6.3 Hz, 4H, OCH_2CH_2S) and a pair of triplets (each 4H, J=1.7 Hz, Cp-H, Cp-H) at δ 4.74 and 4.61. The IR spectrum of **10a** displayed absorptions of the ruthenocene ring and ether linkage at 3090, 1470, and 1102 cm^{-1} respectively, but there was no band arising from the S-H group. The electronic spectra of **10a** (λ_{max} 310 nm in CH_3CN) suggest the presence of a ruthenocene nucleus. The structures of other new ruthenoceno crown ethers (**10b**



8 9a : n=4, b : n=3, c : n=2 10a : n=4, b : n=3, c : n=2

and **10c**) were also determined by a method similar to that described above.

Complexing Ability. The complexing ability of the crown ether with metal cations depends on several factors. These include cavity size of the ligand, cation diameter, spacial distribution of the ring binding sites, the character of the heteroatoms, and other causes.[6] The complexation of polyoxa-1,*n*-dithia[*n*](1,1′)ferrocenophanes (**3a**) with a variety of metal cations has already been reported in the previous paper.[7] The ferrocenophanes (**3a**) showed a highly complexing ability with silver(I) and thallium(I) ions, while little or negligible with alkali metal, calcium, strontium, and lead cations. These results suggest that the character of the heteroatom is the most important factor in the complexation ability. In order to compare the complexing ability of **10** with that of the corresponding ferrocenophanes (**3a**), the extraction ability of **10** with a variety of metal cations was measured by the method described by Pedersen[8] and the results are summarized in Table 1. The complexing ability of **10** was little or negligible for hard cations (K^+, Cs^+, Rb^+, Li^+, Na^+,



11a : n=4, M=Hg^{2+}, X=Cl_2
11b : n=3, M=Ag^+, X=NO_3

Ca^{2+}, Ba^{2+}, and Sr^{2+}) and borderline cations (Cu^{2+}, Co^{2+}, and Ni^{2+}), but excellent for soft cations (Ag^+, Hg^{2+}, and Tl^+). The results of the extraction ability may be explained by the HSAB rule.[9] That is, the successive displacement of an oxygen atom in the macrocyclic ring of the ruthenocenophane by a sulfur atom, which is softer compared with an oxygen atom, increases the affinity to soft ions. The highly complexing ability of **10** with soft ions compared with the corresponding ferrocenophanes (**3a**) suggests some participation of the ruthenium atom of the ruthenocene nucleus in the process of complexation. It is also interesting that the extraction ability of thallium(I) ion showed a remarkable dependence on the cavity size in the macrocycle of **10**.

The ^{1}H-NMR spectrum of **10** in acetonitrile-d_3 was compared with that measured in the presence of an equivalent amount of silver nitrate. The chemical shift of the ligands (**10**) and the difference in the chemical shift between the free ligands and the complexes are shown in Table 2. The change of chemical shifts of the

a) Shift changes are presented in parentheses.

ruthenocenophanes (**10**) on complexation with metal cations seems to be attributable to (i) an electronic field effect caused by a incorporated metal cation, (ii) perturbation of the electron density on the carbon atom through Ag-Ru-ring and/or through Ag-S-ring, and (iii) a factor due to the conformational change on complexation. In the case of the complexes of polyoxa[*n*](1,1′)ferrocenophanes (**2**) with the alkali metal thiocyanates, the differences of the chemical shift between the α- and β-protons of Cp rings depends on the ring size of ligands and the diameter of the incapsulated metal cations.[10] On the contrary, in the ^{1}H-NMR spectrum of the free ligands (**10**) and their silver complexes the chemical shift differences of the α- and β-ring protons were approximately the same, although these signals were remarkably shifted (0.15—0.23 ppm) to down field. If the down field shift is caused by perturbation of the inductive and conjugative effect of the sulfur substituent on coordination to a silver cation through a sulfur atom, the α-protons would be expected to resonate at a lower-field than the β-protons. Therefore, a relatively large down-field shift of the Cp ring protons seems partially to be due to the perturbation of the electron density on the Cp rings by charge transfer from the Ru atom to the Ag(I) ion, although other effects could not be ruled out. In the ^{1}H-NMR spectra of **10**, the methylene protons attached to the sulfur atom showed a large down-field shift (0.21—0.32 ppm), but those attached to the oxygen atom showed a small down-field shift (0.03—0.17 ppm). This finding is in good accord with the HSAB rule,[9] and indicates the presence of a strong coordination of the sulfur atom and a weak coordination of the oxygen atom to the central metal cation. Furthermore, the following finding in the ^{1}H-NMR spectra of **10** is also interesting. The protons of the methylene groups in the free ligands appeared as a triplet (J=*ca.* 6.5 Hz), while the methylene protons in the complexes were shifted to down-field and better resolved as shown in Fig. 1. This result suggests that in the complexes, the silver(I) ion is incapsulated by both sulfur and oxygen atoms in the macrocycle and the complexes takes a more rigid conformation. Similar conclusions were also obtained in the ^{13}C-NMR spectra of the free ligands and their silver complexes of **10** (Table 3). In the spectrum of **10a**, the bridgehead carbon, α-, and β-carbons of the Cp rings and the methylene carbons attached to a sulfur atom showed their resonances at δ 88.1, 77.3, 72.6, and 39.6 ppm, respectively, together with the methylene carbons, which were not rigorously assigned, at δ 71.5, 71.3, and 70.9 ppm. However, when an equimolar amount of silver(I) nitrate were added to an acetonitrile-d_3 solution of **10a**, the ^{13}C-NMR spectrum showed resonances at δ 83.1, 78.7, 74.5, and 40.4 ppm (C_b, C_α, C_β, and CH_2S), together with the resonances of other methylene carbons attached to oxygen atoms at δ 71.2, 71.0, 70.8, and 68.0 ppm. The signal of the bridgehead carbon in **10a** shifted to up-field but those of α- and β-carbons of a ruthenocene nucleus shifted to down-field. These results would be explained by the following effects: (i) The direct electron transfer from the ruthenium atom to the complexed silver(I) ion, (ii) the electron transfer *via* the sulfur atom from the Cp ring to the silver(I) ion, and (iii) a conformational change of the ruthenocenophane on complexation. When silver(I) nitrate was added to a solution of **10a**, the peaks of methylene carbons shifted and became more resolved (four peaks→five peaks). This result is also explained on the basis of the rigid conformation of the macrocycle in the ruthenocenophane (**10a**) as described in the

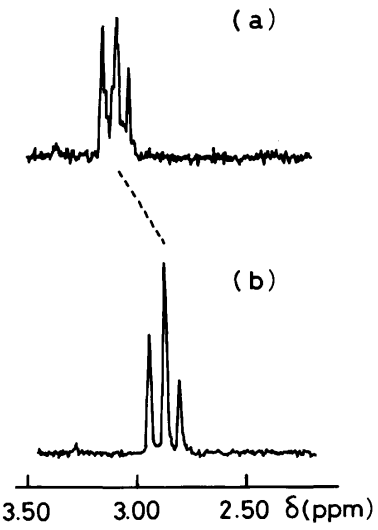

Fig. 1. ^{1}H-NMR Spectra of 10b (b) and the Ag^+ complex of 10b (a).

description of ^{1}H-NMR spectra.

Isolation of Complexes. The 1:1 complexes of **10** with $HgCl_2$ and $AgNO_3$, (**11a**) and (**11b**), respectively, were isolated. In the ^{1}H-NMR spectrum (in CD_3CN) of **11a**, the signals of methylene protons next to a sulfur atom, α-, and β-ring protons of ruthenocene nucleus were shifted down-field only +0.19, +0.03, −0.03 ppm, compared with those of **10a**, respectively. On the other hand, the ^{1}H-NMR spectrum of the complex $Cp_2Ru \cdot HgCl_2$ (**12**) in CD_3CN showed a signal at δ 5.31 corresponding to the Cp-ring protons.[11] The down-field shift of the Cp-ring protons of **12**, compared with those of ruthenocene (**4**), is about +0.7 ppm. Hence, the difference in the chemical shift between the free ligand (**10a**) and the complex (**11a**) seems to be attributable to the inductive and field effects *via* the coordinated sulfur atom by complexation of mercury(II) ion into the crown ether part of the ligand, although a possibility of the weak coordination of the incorporated mercury(II) ion to the Ru atom of ruthenocene nucleus cannot be ruled out. The above explanation was supported by the X-ray crystallographic analysis of **11a** as described below.

Crystal Structure of 11a. The conformation of the complex (**11a**) is illustrated in Fig. 2, which also shows the atom labels used. The positional parameters for non-hydrogen atoms are listed in Table 4. Also, the bond lengths, bond angles and torsion angles are listed in Table 5.

The complex can be divided into two parts: The complexing unit containing dithia-18-crown-6 like moiety which is defined by S(6) to S(21), and the ruthenocene unit. In the complexing unit, the mercury(II) ion and the two chloride ions are situated in the central cavity and at the apexes, respectively. The six heteroatoms (two S and four O atoms) take a slightly distorted half chair form in which O(12) and O(15) deviate by 0.61 and −0.16 Å, respectively, to the side of Cl(1) from the mean plane of the remaining four atoms, S(1), O(9), O(18), and S(21), with a maximum deviation of 0.06 Å at O(9). The mercury(II) ion is situated in the same plane with a deviation of 0.17 Å. The intramolecular atomic distances between the mercury(II) ion and the six heteroatoms are 3.034(6), 3.120(18), 2.888(17), 2.838(17), 3.048(17), 3.330(6) Å with S(6), O(9), O(12), O(15), O(18), and S(21), respectively. These values are longer than the sum of the ionic radius of a mercury(II) ion (1.10 Å) and the van der Waals radius of a sulfur atom (1.85 Å) or O (1.40 Å).[12]

The Cl–Hg–Cl angle is 172.7 (2)° which slightly deviates from the expected 180°. The Hg–Cl bond lengths of 2.327(7) and 2.304(7) Å are in agreement with reported values for the linear Hg–Cl bond.[13] Thus, the mercury(I) ion forms a distorted hexagonal-bipyramidal geometry with the two chloride ions coordinated axially. The organic ligand moiety in present complexing unit has structural similarity compared with that in the complex of $HgCl_2$:1,4-dithia-18-crown-6 (HGDTC).[14] The 13 torsion angles about the chemically corresponding bonds between the both complexes agree well, and the average difference is about 5°. However, in the case of HGDTC the mercury(II) ion interacts with the two sulfur atoms from the outside of the macrocyclic ring because the C–C bridge joining the sulfur atoms directs into the interior of the ring. The Cp rings take an eclipsed conformation to each other and the dihedral angle between the rings is 3.4°. The Ru···C and inter-ring C···C distances of the ruthenocene unit are in the ranges of 2.18(3) to 2.23(3) Å and 3.60(4) to 3.73(4) Å with the average values of 2.21 and 3.67 Å, respectively, and the distances from the Ru atom to the best plane of the Cp rings are 1.84(3) and 1.83(3) Å. These values agree well with those of ruthenocene[15] and [4](1,1′)ruthenocenophane.[16] The distance between the Ru atom of the ruthenocene nucleus and the mercury(II) ion incorporated is 4.846(2) Å which is too long for direct metal–metal interaction, because the sum of the van der Waals radius of the Ru atom and the ionic radius of the Hg^{2+} ion is 3.15 Å[12].

The crystal packings are formed with van der Waals forces; the short intermolecular distances are 3.36(3), 3.49(3), and 3.707(8) Å for C(3)···O(15) (x,1+y,z), Cl(1)···C(16) (−x,−y,1−z), and S(6)···S(6) (1−x,1−y,1−z), respectively.

Experimental

The melting points are uncorrected. The electronic spectra were measured on a Hitachi 340 Spectrometer. The ^{1}H-NMR and ^{13}C-NMR spectra were obtained on a JEOL FX-90Q Spectrometer, TMS being chosen as an internal standard. The mass spectra were taken by using a Hitachi M-80 Spectrometer. The IR spectra were measured on a JASCO DS-701G Diffraction Grating Infrared Spectrophotometer.

Material. All solvents and reagents were used as purchased unless otherwise specified. Ruthenocene, 1,8-dibromo-3,6-dioxaoctane, 1,11-dibromo-3,6,9-trioxaundecane, and 1,14-dibromo-3,6,9,12-tetraoxatetradecane were prepared according to the literatures. Silica gel for thinlayer chromatography utilized Wakogel B-5F.

1,2,3-Trithia[3](1,1′)ruthenocenophane (6). To a mixture

of hexane (3.5 cm³) and TMEDA (3.0 cm³, 0.019 mol) was added a solution of butyllithium (0.024 mol) in hexane (18 cm³) and then a solution of ruthenocene (2.0 g, 8.65 mmol) in hexane (35 cm³) under nitrogen. The mixture was then further stirred for 8 h at room temperature. To the mixture was added 1,2-dimethoxyethane (90 cm³, 0.86 mol) and sulfur (1.72 g, 0.05 mol) and the mixture was then stirred for 12 h at refluxing temperature. After the mixture had been cooled to room temperature, the precipitates were filtered and washed with ether. The filtrate and the washings were combined, washed with 10% aq sodium hydroxide solution and water, and concentrated *in vacuo*. Sublimation of the residue at 130°/1.5 mmHg (1 mmHg=133.322 Pa) gave crude **6**. Recrystallization of the crude material from hexane gave pure **6** as yellow flat plates, mp 183.5—184°C, in 42.7% yield. Found: C, 36.76; H, 2.55%. Calcd for $C_{10}H_8S_3Ru$: C, 36.91; H, 2.48%. MS (70 eV): *m/z* 326 (M^+). ^{1}H-NMR ($CDCl_3$): δ=4.05—4.83 (m, 8H). IR (KBr): 3097 and 1401 cm^{-1}.

Ruthenocene-1,1'-dithiol (7). **6** (1.78 g, 5.47 mmol) was added to ether (107 cm³) containing lithium aluminum hydride (0.05 g, 0.013 mol) under nitrogen. Stirring was continued at refluxing temperature for 3 h, and the mixture was then cooled to ice-water temperature. To the mixture was added dropwise 1.5% aq potassium hydroxide solution (142 cm³) and an aq layer was separated. The aq solution was extracted with three 20 cm³ portions of ether. The aq solution was acidified with concd hydrochloric acid until it became weakly acidic, and then extracted with four 20 cm³ portions of ether. The combined extracts were dried and concentrated to give pure **7** as colorless crystals, mp 116—117°C, in 94% yield. Found: C, 40.54; H, 3.59%. Calcd for $C_{10}H_{10}S_2Ru$: C, 40.66; H, 3.42%. MS (70 eV): *m/z* 296 (M^+). ^{1}H-NMR ($CDCl_3$): δ=2.25 (s, 2H, -SH), 4.47 (t, *J*=3.5 Hz, 4H, Cp-H), and 4.66 (t, *J*=3.5 Hz, Cp-H). IR (KBr): 3097, 2500, and 1419 cm^{-1}.

*General Procedure for Polyoxa-1,*n*-dithia[*n*](1,1')ruthenocenophanes. 4,7-Dioxa-1,10-dithia[10](1,1')ruthenocenophane (10c).* A solution of **7** (1.51 g, 5.12 mmol) in 20% aq sodium hydroxide solution (100 cm³) and a solution of 1,8-dibromo-3,6-dioxaoctane (1.76 g, 6.38 mmol) in 60% ethanol (100 cm³) were added dropwise at the same rate to 60% ethanol (200 cm³) for a period of 3.5 h at refluxing temperature under nitrogen, and then further stirred for 3 h. After the solution had been cooled to room temprerature, 100 cm³ of water was added to the reaction mixture. The solution was extracted with four 30 cm³ portions of ether. The ether extracts were combined, washed with water, and concentrated *in vacuo*. The residual oil was chromatographed by silica gel TLC (using benzene-acetone 10:1 as eluent). The third fraction was eluted with acetone at room temperature, followed by filtration. The evaporation of the solvent gave pale yellow oil which solidified on standing. Recrystallization of the crude material from hexane gave a pure **10c** as yellow needles, mp 101.0—101.5°C, in 23.4%. Found: C, 46.66; H, 5.12%. Calcd for $C_{16}H_{20}O_2S_2Ru$: C, 46.92 ; H, 4.93%. MS (70 eV): *m/z* 410 (M^+). IR (KBr): 3075, 2850, 1410, and 1127 cm^{-1}. UV (MeOH:H_2O=1:1): λ_{max} 320 nm (ε=472).

4,7,10-Trioxa-1,13-dithia[13](1,1')ruthenocenophane (10b). Pale yellow flat plates, 48% yield. Found: C, 47.96; H, 5.48%. Calcd for $C_{18}H_{24}O_3S_2Ru$: C, 47.66; H, 5.68%. MS (70 eV): *m/z* 454 (M^+). IR (KBr): 3090, 2860, 1470, 1416, 1352, 1282, 1115, and 807 cm^{-1}. UV (MeOH:H_2O=1:1): λ_{max} 320 nm (ε=472).

4,7,10,13-Tetraoxa-1,16-dithia[16](1,1')ruthenocenophane (10a). Pale yellow flat plates, mp 46.2—48.0°C, 17% yield. Found: C, 48.48; H, 5.81%. Calcd for $C_{20}H_{28}O_4S_2Ru$: C, 48.26; H, 5.68%. MS (70 eV): *m/z* 498 (M^+). IR (KBr): 3090, 2860, 1480, 1418, 1353, 1286, 1136, and 811 cm^{-1}. UV (MeOH:H_2O=1:1): λ_{max} 320 nm (ε=472).

Complex of 4,7,10,13-Tetraoxa-1,16-dithia[16](1,1')ruthenocenophane (10a) with Mercury(II) Chloride. A solution of **10a** (41 mg, 0.082 mmol) in acetonitrile (1 cm³) was added dropwise to a solution of mercury(II) chloride (22 mg, 0.081 mmol) in acetonitrile (1 cm³). The resulting precipitates were filtered and washed with a small amount of acetonitrile to give a pure 1:1 complex (**11a**), mp 172.0—173.0°C, in 69% yield. Found: C, 31.44; H, 3.75%. Calcd for $C_{20}H_{28}O_2S_2Ru$: C, 31.23; H, 3.68%. IR (KBr): 3090, 2910, 1470, 1411, 1355, 1298, 1102, and 810 cm^{-1}. UV (CH_3CN): λ_{max} 310 nm (ε=455).

Complex of 4,7,10-Trioxa-1,13-dithia[13](1,1')ruthenocenophane (10b) with Silver(I) Nitrate. To a solution of **11b** (30 mg, 0.066 mmol) in acetonitrile was added a solution silver(I) nitrate (11 mg, 0.065 mmol) in acetonitrile (1 cm³). To the mixture was added dropwise 3 cm³ of ether to give colorless precipitates. The precipitates were washed with a small amount of acetonitrile and then ether to give a pure 1:1 complex (**11b**), mp 157.0—157.5°C, in 84% yield. Found: C, 34.51; H, 3.78; N, 2.22%. Calcd for $C_{18}H_{24}NO_5S_2AgRu$: C, 34.67; H, 3.89; N, 2.25%. IR (KBr): 3190, 2920, 2870, 1470, 1450, 1384, 1110, 1025, and 810 cm^{-1}. UV (CH_3CN): λ_{max} 310 nm (ε=403).

Extraction Ability. Extraction ability of the ruthenocenophanes with metal picrate was examined by the method described in the previous paper.[17] The results are summarized in Table 1.

X-Ray Crystal Determination of 11a. A crystal of dimensions 0.5×0.3×0.2 mm obtained from methanol, was used for the intensity measurement. Intensity data were obtained on a Rigaku AFC5 apparatus equipped with a rotating-anode X-ray generator and using a graphite monochrometer (λ(Cu$K\alpha$)=1.5418 Å, $2\theta \geq 128°$) was used. The data were corrected for Lorentz and polarization effects but not for absorption. Among the 3749 unique reflections collected, 3352 were considered to be observed at the 2.0σ (F_o) level.

Crystal Data. $C_{20}H_{28}O_4S_2Cl_2RuHg$, M=769.2. Triclinic, *a*=13.722(3), *b*=11.678(4), *c*=8.179(2) Å, α=102.69(3), β=72.82(2), γ=100.73(2)°, *Z*=2, D_x=2.11 g cm^{-3}, space group $P\bar{1}$.

The structure was solved by the combination of the heavy atom technique and direct methods using MULTAN[18] and refined by block-diagonal least-squares methods. Positions of the hydrogen atoms were estimated from standard geometry. The final refinements with anisotropic temperature factors for the non-hydrogen atoms were reduced the R to 0.089. The anomalous dispersion corrections were applied to the scattering factors of Hg, Ru and Cl.[19]

Thermal parameters for non-hydrogen atoms and observed and calculated structure factors are kept at the Chemical Society of Japan (Document No. 8530).

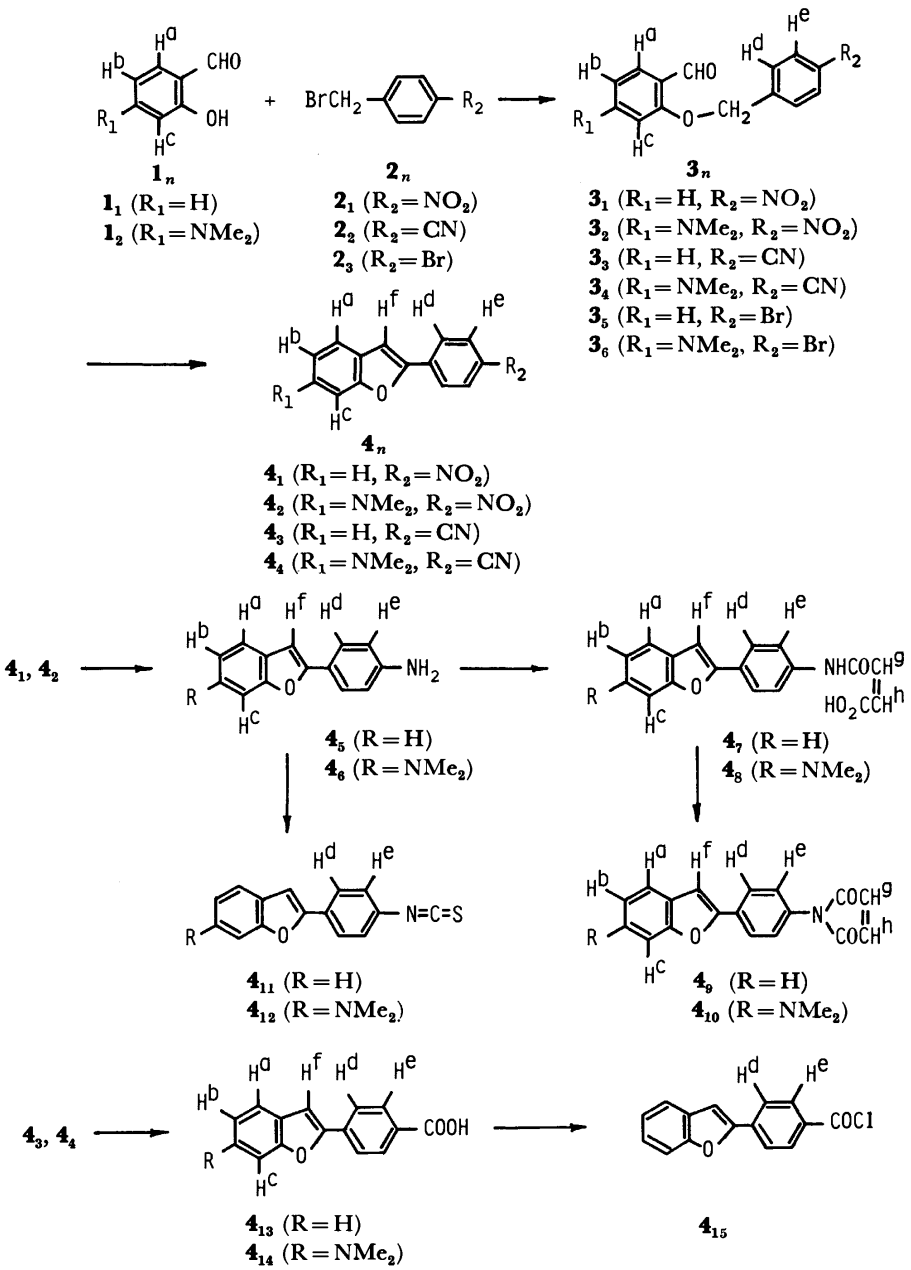
Development and Application of Organic Reagents for Analysis. VI.[1] Synthesis and Fluorescence Spectral Properties of 2-(4-Substituted phenyl)benzofurans

Shuzo AKIYAMA,* Hiroyuki AKIMOTO, Shin'ichi NAKATSUJI, and Kenichiro NAKASHIMA
Faculty of Pharmaceutical Sciences, Nagasaki University, 1-14 Bunkyo-machi, Nagasaki 852
(Received February 21, 1985)

A synthesis of fifteen kinds of 2-(4-substituted phenyl)benzofurans (**4**$_n$) was carried out and their fluorescence spectral properties were investigated concerning their applicability as organic reagents for analyses.

In order to develop sensitive and useful fluorogenic reagents, our attention became directed toward the synthesis of derivatives of 2-phenylbenzofuran which were expected to exhibit strong fluorescence due to the presence of a latent *trans*-stilbene skeletone. The synthesis of 2-(4-substituted phenyl)benzofurans (**4**$_n$) was carried out and their fluorescence spectral properties were investigated in order to determine the applicability of **4**$_n$ as reagents for analyses. As shown Scheme 1, the construction of a benzofuran skeletone



Scheme 1.

of $\mathbf{4}_{1-4}$ was realized by a reaction of salicylaldehydes ($\mathbf{1}_1$ and $\mathbf{1}_2$) with *p*-nitro- and *p*-cyanobenzyl bromides ($\mathbf{2}_1$ and $\mathbf{2}_2$) in the presence of an alkali following cyclization to a furan ring.[2] The nitro compounds ($\mathbf{4}_1$ and $\mathbf{4}_2$) were reduced to corresponding amino compounds ($\mathbf{4}_5$ and $\mathbf{4}_6$). These could be converted to various other compounds ($\mathbf{4}_{7-12}$). In addition, the cyano compounds ($\mathbf{4}_3$ and $\mathbf{4}_4$) were transformed to acids ($\mathbf{4}_{13}$ and $\mathbf{4}_{14}$) and subsequently to the acid chloride ($\mathbf{4}_{15}$).

The electronic absorption and fluorescence spectra of these 2-phenylbenzofuran derivatives were measured and several characteristics were observed.

Results and Discussion

Synthesis of 2-(4-Substituted phenyl)benzofurans ($\mathbf{4}_n$). A synthesis of $\mathbf{4}_n$ was achieved according to Scheme 1. 2-(Benzyloxy)benzaldehydes ($\mathbf{3}_1$, $\mathbf{3}_2$, and $\mathbf{3}_3$) were prepared by the reaction of $\mathbf{1}_n$ with $\mathbf{2}_n$ in the presence of KOH in EtOH (R_2=NO_2) or sodium ethoxide in dimethylformamide(DMF)–EtOH (R_2=CN). 2-(4-Substituted phenyl)benzofurans ($\mathbf{4}_{1-3}$) were obtained from the cyclization of $\mathbf{3}_{1-3}$ in the presence of sodium methoxide in DMF or KOH in DMF.[2] The nitrile ($\mathbf{4}_4$) could be directly synthesized by a reaction of $\mathbf{1}_2$ with $\mathbf{2}_2$ without the isolation of $\mathbf{3}_4$. Cyclizations of the bromides ($\mathbf{3}_5$ and $\mathbf{3}_6$) were unsuccessful under the above conditions.

The nitro compounds ($\mathbf{4}_1$ and $\mathbf{4}_2$) were easily reduced with iron(III) chloride–hydrazine hydrate to yield corresponding amino compounds ($\mathbf{4}_5$ and $\mathbf{4}_6$) in good yields.

From the purpose of the synthesis of the maleimides ($\mathbf{4}_9$ and $\mathbf{4}_{10}$), which could be expected as organic reagents for the selective determination of thiols, $\mathbf{4}_5$ and $\mathbf{4}_6$ were treated with maleic anhydride to give the maleamic acids ($\mathbf{4}_7$ and $\mathbf{4}_8$).[3] The cyclization of $\mathbf{4}_7$ and $\mathbf{4}_8$ in the presence of sodium acetate in acetic anhydride afforded $\mathbf{4}_9$ and $\mathbf{4}_{10}$.

The isothiocyanates ($\mathbf{4}_{11}$ and $\mathbf{4}_{12}$) were obtained by the treatment of $\mathbf{4}_5$ and $\mathbf{4}_6$ with an excess of thiophosgene.[4]

The nitriles ($\mathbf{4}_3$ and $\mathbf{4}_4$) were hydrolyzed with an alkali to give the carboxylic acids ($\mathbf{4}_{13}$ and $\mathbf{4}_{14}$), from which the acid chloride ($\mathbf{4}_{15}$) was derived.

Electronic Absorption Spectral Properties of $\mathbf{4}_n$. The longest wavelength absorption maxima of 2-phenylbenzofurans ($\mathbf{4}_n$) that were observed are given in Table 1. From the data it has become apparent that a dimethylamino substitution in $\mathbf{4}_n$ produces a red shift and a hypsochromic effect.

Fluorescence Spectral Properties. The fluorescence spectra of $\mathbf{4}_n$ were measured and the relative fluorescence intensities were compared with one another (Table 1). Red shifts were observed at the emission maxima (λ_{em}) of the dimethylamino substituted compounds relative to the corresponding unsubstituted ones. The isothiocyanates ($\mathbf{4}_{11}$ and $\mathbf{4}_{12}$) exhibited very little fluorescence and the nitro and *N*-maleimide compounds ($\mathbf{4}_1$, $\mathbf{4}_2$, $\mathbf{4}_9$, and $\mathbf{4}_{10}$) showed almost no fluorescence. These *N*-maleimides ($\mathbf{4}_9$ and $\mathbf{4}_{10}$) when combined with thiols showed strong fluorescence, *e.g.*, the adduct of $\mathbf{4}_9$ with *N*-acetyl-L-cysteine: λ_{ex} 320, λ_{em} 360 nm; the adduct of $\mathbf{4}_{10}$ with *N*-acetyl-L-cysteine: λ_{ex} 346, λ_{em} 470 nm (Fig. 1).[5] The large difference (124 nm) between λ_{ex} and λ_{em} in the latter seems to be an advantageous property as an analytical reagent for practical use. Recently, we have briefly reported on the fluorometric determination of glutathione using $\mathbf{4}_{10}$. This has proved to be useful as a new fluorigenic thiol-selective reagent.[6] Similarly, the isothiocyanates ($\mathbf{4}_{11}$ and $\mathbf{4}_{12}$) reacted with aliphatic amines to afford adducts which emitted strong fluorescence. An application of $\mathbf{4}_{11}$ and $\mathbf{4}_{12}$ to analytical reagents is now in progress.

Table 1. Spectral Data of 2-(4-Substituted Phenyl) Benzofurans

Compound	λ_{max}^{EtOH}	log ε	λ_{em}^{EtOH}	RFI[a]
$\mathbf{4}_1$	357	4.38	—	—
$\mathbf{4}_2$	438	4.34	—	—
$\mathbf{4}_3$	322	4.57	380	100
$\mathbf{4}_4$	392	4.48	512	36
$\mathbf{4}_5$	321	4.56	387	83
$\mathbf{4}_6$	345	4.52	400	71
$\mathbf{4}_9$	310	4.53	—	—
$\mathbf{4}_{10}$	355	4.50	—	—
$\mathbf{4}_{11}$	329	4.73	372	3.2
$\mathbf{4}_{12}$	375	4.59	430	8.5
$\mathbf{4}_{13}$	314	4.54	385	32
$\mathbf{4}_{14}$	366	4.48	465	31

a) Relative fluorescence intensity: the nitrile $\mathbf{4}_3$ is arbitrarily taken as 100 [concentration: 2μM (1 M= 1 mol dm^{-3})].

Experimental

Melting points are uncorrected. The ^{1}H NMR spectra (tetramethylsilane as an internal standard) were recorded on a JEOL FX 90Q spectrometer (chemical shifts given in ppm units). The IR spectra were taken using a JASCO IRA 2 spectrophotometer, the MS using a JEOL JMS-01SG mass spectrometer, and the UV using Hitachi 210 and Shimadzu UV-150 spectrophotometers. The fluorescence spectra were measured with a Shimadzu RF-540 fluorescence spectrophotometer.

4-(Dimethylamino)salicylaldehyde ($\mathbf{1}_2$). Aluminum chloride (18.8 g, 0.14 mol) was added to a solution of *m*-dimethylaminophenol (12.50 g, 0.094 mol) in chloroform (185 ml) and triethyl orthoformate (84 g, 0.57 mol) at room temperature and was mixed for 10 min. After the exothermic reaction had ceased, HCl (10%, 50 ml) was added and stirred to hydrolyze the resulting acetal. The mixture was neutralized with aq sodium hydroxide (10%). The resulting deposit was filtered off through a short column of Celite and washed with $CHCl_3$. The filtrate was combined with a cleaning solution, washed with saturated aq NaCl, dried over $MgSO_4$, and concentrated *in vacuo*. Recrystallization of the product from $CHCl_3$ gave 9.82 g (65%) of $\mathbf{1}_2$, mp 78—79 °C (79—80 °C[7]); ^{1}H NMR ($CDCl_3$): δ=2.81 (s, 6H, NMe_2), 5.8—6.1 (m, 2H, H^a and H^b), 7.13 (s, 1H, H^c), 9.20 (s, 1H, CHO); IR (Nujol): 1640

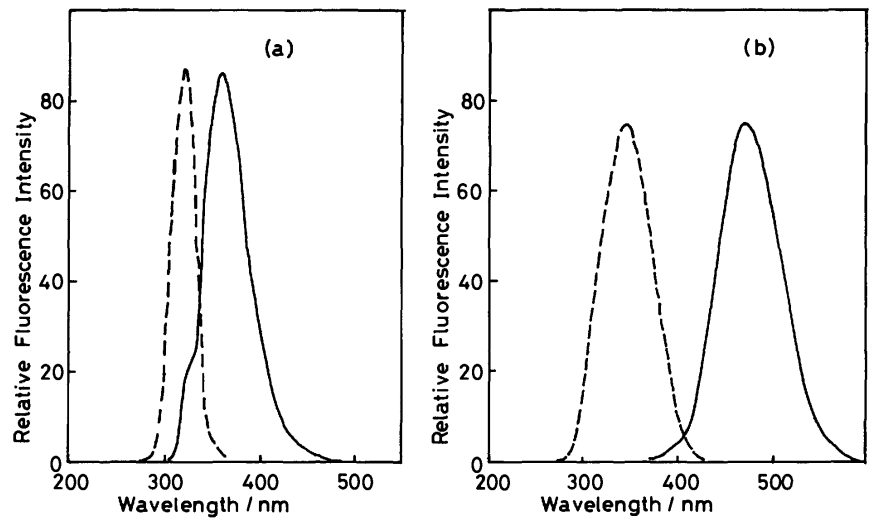


Fig. 1. Fluorescence spectra of the reaction mixtures of $\mathbf{4}_9$ and $\mathbf{4}_{10}$ with *N*-acetyl-L-cysteine (NAC).
(a): adduct of $\mathbf{4}_9$ with NAC; (b): adduct of $\mathbf{4}_{10}$ with NAC.
Procedure: A solution of $\mathbf{4}_9$ or $\mathbf{4}_{10}$ in acetone (0.5 mM 0.5 ml) was mixed with a solution of NAC-0.1 M H_3PO_4 (pH 7.0) (0.5 mM, 10 ml), stood for 1 h at room temperature, and then the fluorescence spectra were measured.

(C=O) cm^{-1}.

4-Dimethylamino-2-(4-nitrobenzyloxy)benzaldehyde ($\mathbf{3}_2$). A solution of KOH (0.40 g, 7 mmol) in EtOH (3 ml) was added to a solution of 4-(dimethylamino)salicylaldehyde ($\mathbf{1}_2$) (1.00 g, 6 mmol) and 4-nitrobenzyl bromide ($\mathbf{2}_1$) in EtOH (12 ml). Then, the mixture was refluxed for 7 h. After the solution had been cooled, the resulting crystals were filtered off, washed with water, and dried *in vacuo*. Then, the crystals were recrystallized from EtOH; 1.02 g, 56%; mp 179—180 °C; ^{1}H NMR ($CDCl_3$): δ=3.06 (s, 6H, NMe_2), 5.27 (s, 2H, CH_2), 6.05 (d, J=3 Hz, 1H, H^c), 6.33 (J=3, 9 Hz, 1H, H^b), 7.44 (d, J=9 Hz, 1H, H^a), 7.64 (d, J=9 Hz, 2H, H^d), 8.25 (d, J=9 Hz, 2H, H^e), 10.23 (s, 1H, CHO); IR (Nujol): 1655 (C=O) cm^{-1}; MS: m/z 300 (M^+). Found: C, 63.91; H, 5.38; N, 9.26%. Calcd for $C_{16}H_{16}N_2O_4$: C, 63.99; H, 5.37; N, 9.33%.

2-(4-Nitrobenzyloxy)benzaldehyde ($\mathbf{3}_1$): Yield, 86%; mp 117 °C (118 °C[8]); ^{1}H NMR ($CDCl_3$): δ=5.28 (s, 2H, CH_2), 6.92—8.32 (m, 8H, aromatic H), 10.52 (s, 1H, CHO); IR (Nujol): 1680 (C=O) cm^{-1}; MS: m/z 257 (M^+). (Found: C, 65.37; H, 4.28; N, 5.60%).

2-(4-Bromobenzyloxy)benzaldehyde ($\mathbf{3}_5$): Yield, 81%; mp 94—94.5 °C; ^{1}H NMR ($CDCl_3$): δ=5.14 (s, 2H, CH_2), 6.95—7.91 (m, 8H, aromatic H), 10.52 (s, 1H, CHO); IR (Nujol): 1685 (C=O) cm^{-1}. Found: C, 57.58; H, 3.79%. Calcd for $C_{14}H_{11}BrO_2$: C, 57.76; H, 3.81%.

4-Dimethylamino-2-(4-bromobenzyloxy)benzaldehyde ($\mathbf{3}_6$): Yield, 36%; mp 126—128 °C; ^{1}H NMR ($CDCl_3$): δ=3.05 (s, 6H, NMe_2), 5.10 (s, 2H, CH_2), 6.04 (d, J=3 Hz, H^c), 6.29 (J=3, 9 Hz, H^b), 7.30 (d, J=9 Hz, 2H, H^e), 7.50 (d, J=9 Hz, 1H, H^a), 7.73 (d, J=9 Hz, 2H, H^d), 10.22 (s, 1H, CHO); IR (Nujol): 1645 (C=O) cm^{-1}. Found: C, 57.40; H, 4.82; N, 4.50%. Calcd for $C_{16}H_{16}BrNO_2$: C, 57.50; H, 4.83; N, 4.19%.

2-(4-Cyanobenzyloxy)benzaldehyde ($\mathbf{3}_3$): Yield, 79%; mp 103—104 °C (105—106 °C[9]); IR (Nujol): 2250 (C≡N), 1685 (C=O) cm^{-1}. (Found: C, 76.01; H, 4.66; N, 6.02%).

6-Dimethylamino-2-(4-nitrophenyl)benzofuran ($\mathbf{4}_2$). A solution of $\mathbf{3}_2$ (0.90 g, 3 mmol) in DMF (6 ml) was added to a solution of sodium methoxide (prepared from Na (69 mg, 3 mmol)) in MeOH (1 ml) and refluxed for 20 min. The crystals ($\mathbf{4}_2$) deposited after adding MeOH (12 ml) to the mixture were filtered off and recrystallized from EtOH: red needles (0.73 g, 86%); mp 209.5—210.5 °C; ^{1}H NMR ($CDCl_3$): δ=3.04 (s, 6H, NMe_2), 6.76 (d, J=9 Hz, 1H, H^b), 6.81 (s, 1H, H^c), 7.10 (s, 1H, H^f), 7.43 (d, J=9 Hz, 1H, H^a), 7.85 (d, J=9 Hz, 2H, H^d), 8.24 (d, J=9 Hz, 2H, H^e); MS: m/z 282 (M^+). Found: C, 67.99; H, 4.97; N, 9.89%. Calcd for $C_{16}H_{14}N_2O_3$: C, 68.08; H, 5.00; N, 9.92%.

2-(4-Nitrophenyl)benzofuran ($\mathbf{4}_1$): Yield, 82% (yellow needles); mp 183.5—184.5 °C (182 °C[8]); ^{1}H NMR ($CDCl_3$): δ= 7.22—8.35 (m, 9H, aromatic H); MS: m/z 239 (M^+). (Found: C, 70.29; H, 3.71; N, 5.85%).

2-(4-Cyanophenyl)benzofuran ($\mathbf{4}_3$): Yield, 72%; mp 143—145 °C (145—146 °C[9]); ^{1}H NMR ($CDCl_3$): δ=7.15—7.97 (m, 5H, aromatic H), 7.69 (d, J=9 Hz, 2H, H^d), 7.93 (d, J=9 Hz, 2H, H^e); IR (Nujol): 2225 (C≡N) cm^{-1}; MS: m/z 219 (M^+). (Found: C, 82.28; H, 4.08; N, 6.44%).

6-Dimethylamino-2-(4-cyanophenyl)benzofuran ($\mathbf{4}_4$). A solution of $\mathbf{1}_2$ (2.00 g, 0.012 mol) in DMF (10 ml) was added to a solution of sodium ethoxide (prepared from Na (0.30 g, 0.013 mol)) in EtOH (8 ml) over a period of 20 min at room temperature. After the mixture had been stirred for 20 min, $\mathbf{2}_1$ (2.62 g, 0.013 mol) in DMF (8 ml) was added. The resulting solution was heated the at 110 °C for 2 h and the EtOH was removed under reduced pressure. The condensed solution was poured into a mixture of ice-cold water (54 g) and MeOH (16 ml) and stirred at 0 °C for 1 h. Deposited crystals were collected, washed with water, and then dried *in vacuo*. Crude $\mathbf{4}_4$ was recrystallized from petroleum benzine (bp 60—80 °C), 1.30 g, 41%: mp 164.5—166 °C; ^{1}H NMR ($CDCl_3$): δ=3.03 (s, 6H, NMe_2), 6.79 (J=3, 9 Hz, 1H, H^b), 6.89 (d, J=3 Hz, 1H, H^c), 7.04 (s, 1H, H^f), 7.42 (d, J=9 Hz, 1H, H^a), 7.63 (d, J=9 Hz, 2H, H^d), 7.83 (d, J=9 Hz, 2H, H^e); IR (Nujol): 2225 (C≡N) cm^{-1}; MS: m/z 262 (M^+). Found: C, 77.86; H, 5.34; N, 10.71%. Calcd for $C_{17}H_{14}N_2O$: C, 77.84; H, 5.38; N, 10.68%.

6-Dimethylamino-2-(4-aminophenyl)benzofuran (4₆). A benzene (20 ml)–MeOH (18 ml) solution of **4₂** (1.00 g, 4 mmol), active carbon (0.08 g) and a catalytic amount of $FeCl_3 \cdot 6H_2O$ was refluxed for 10 min and then hydrazine hydrate (98%) (2.30 g) was added dropwise.[10] The mixture was refluxed for 7 h and filtered off under reduced pressure. A concentrate of the filtrate yielded a crude product which was recrystallized from cyclohexane to afford **4₆** (0.72 g, 81%, orange needles): mp 198.5—200 °C; ^{1}H NMR ($CDCl_3$): δ= 2.98 (s, 6H, NMe_2), 6.68 (s, 1H, H^c), 6.71 (d, J=9 Hz, 2H, H^e), 6.80 (d, J=9 Hz, 1H, H^b), 7.25 (s, 1H, H^f), 7.35 (d, J=9H, 1H, H^a), 7.59 (d, J=9 Hz, 2H, H^d): IR (KBr): 3420, 3340 (NH_2) cm^{-1}; MS: m/z 252 (M^+). Found: C, 76.42; H, 6.34; N, 11.11%. Calcd for $C_{16}H_{16}N_2O$: C, 76.16; H, 6.36; N, 11.10%.

2-(4-Aminophenyl)benzofuran (4₅): Yield, quantitative; mp 150—151 °C (152—154 °C[11]); ^{1}H NMR ($CDCl_3$): δ=3.81 (broad s, 2H, NH_2), 6.67—7.70 (m, 9H, aromatic H); IR (KBr): 3440, 3340 (NH_2) cm^{-1}; MS: m/z 209 (M^+). (Found: C, 80.64; H, 5.31; N, 6.72%).

N-[4-(2-benzofuranyl)phenyl]maleamic Acid (4₇). A mixture of **4₅** (0.50 g, 2.4 mmol) and maleic anhydride (0.23 g, 2.4 mmol) in $CHCl_3$ (5 ml) was stirred for 3 h at room temperature. The deposited crystals were filtered off, washed with a small amount of $CHCl_3$, and then recrystallized from EtOH to afford **4₇** (0.64 g, 86%, orange crystals): mp *ca.* 238.5 °C (dec.); ^{1}H NMR (DMSO-d_6): δ=3.59 (broad s, 1H, NH), 6.31 (d, J=12 Hz, 1H, H^g or H^h), 6.53 (d, J=12 Hz, 1H, H^g or H^h), 7.21—7.95 (m, 9H, aromatic H), 10.52 (s, 1H, COOH); IR (KBr): 1695 (COOH), 1625 (CONH) cm^{-1}; MS: m/z 307 (M^+). Found: C, 70.32; H, 4.21; N, 4.57%. Calcd for $C_{18}H_{13}NO_4$: C, 70.35; H, 4.26; N, 4.56%.

N-[4-(6-Dimethylamino-2-benzofuranyl)phenyl]maleamic Acid (4₈): Yield, 84%; mp 219.5—221 °C; ^{1}H NMR (DMSO-d_6): δ=2.95 (s, 6H, NMe_2), 3.80 (broad s, 1H, NH), 6.32 (d, J=12 Hz, 1H, H^g or H^h), 6.52 (d, J=12 Hz, 1H, H^g or H^h), 6.71—7.45 (m, 4H, H^{a-c} and H^f), 7.76 (s, 4H, $H^{d,e}$), 10.56 (s, 1H, COOH); IR (KBr): 1695 (COOH), 1620 (CONH) cm^{-1}; MS: m/z 350 (M^+). Found: C, 68.56; H, 5.14; N, 7.88%. Calcd for $C_{20}H_{18}N_2O_4$: C, 68.56, H, 5.18; N, 8.00%.

N-[4-(6-Dimethylamino-2-benzofuranyl)phenyl]maleimide (4₁₀): A mixture of **4₈** (1.17 g, 3.3 mmol) and sodium acetate (0.03 g, 0.3 mmol) in acetic anhydride (18 ml) was refluxed and cooled in an ice bath. The deposited crystals of **4₁₀** were collected and washed with water while the filtrate was neutralized with aq NaOH (20%) and extracted with $CHCl_3$ (30 ml×2). The organic phase was washed with saturated aq NaCl, dried over $MgSO_4$, and concentrated *in vacuo* to afford **4₁₀**. The combined products were recrystallized from acetone to give reddish purple crystals (0.51 g, 46%): mp 203—204 °C; ^{1}H NMR ($CDCl_3$): δ=3.01 (s, 6H, NMe_2), 6.84 (s, 2H, $H^{g,h}$), 6.68—7.91 (m, 8H, aromatic H); IR (Nujol): 1710 (C=O) cm^{-1}; MS: m/z 332 (M^+). Found: C, 72.15; H, 4.81; N, 8.28%. Calcd for $C_{20}H_{16}N_2O_3$: C, 72.28; H, 4.85; N, 8.43%.

N-[4-(2-Benzofuranyl)phenyl]maleimide (4₉): Yield, 45%, mp 250.5—251.5 °C; ^{1}H NMR ($CDCl_3$): δ=6.87 (s, 2H, $H^{g,h}$), 7.06 (s, 1H, H^f), 7.45 (d, J=9 Hz, 2H, H^d or H^e), 7.20—7.88 (m, 4H, *o*-disubstituted benzene H), 7.95 (d, J=9 Hz, 2H, H^d or H^e); IR (Nujol): 1710 (C=O) cm^{-1}; MS: m/z 289 (M^+). Found: C, 74.52; H, 3.80; N, 4.81%. Calcd for $C_{18}H_{11}NO_3$: C, 74.43; H, 3.83; N, 4.84%.

4-(6-Dimethylamino-2-benzofuranyl)phenyl Isothiocyanate (4₁₂). A benzene solution of thiophosgene (1 ml) was added to a solution of **4₆** (1.00 g, 4 mmol) in acetone (10 ml). The mixture was refluxed for 1 h and cooled in an ice bath. The crystals which were separated were filtered off and recrystallized from cyclohexane to afford yellow leaflets (0.56 g, 48%). mp 140—140.5 °C; ^{1}H NMR ($CDCl_3$): δ=3.01 (s, 6H, NMe_2), 6.67—7.44 (m, 4H, aromatic H), 7.22 (d, J=9 Hz, 2H, H^d), 7.77 (d, J=9 Hz, 2H, H^e); IR (Nujol): 2070, 2110, 2280 (N=C=S) cm^{-1}; MS: m/z 294 (M^+). Found: C, 69.45; H, 4.79; N, 9.44; S, 10.90%. Calcd for $C_{17}H_{14}N_2OS$: C, 69.39; H, 4.79; N, 9.52; S, 10.89%.

4-(2-Benzofuranyl)phenyl Isothiocyanate (4₁₁): Yield, 45%; mp 127—129.5 °C; ^{1}H NMR ($CDCl_3$): δ=7.26 (d, J=9 Hz, 2H, H^d), 7.01—7.76 (m, 5H, benzofuran ring H), 7.81 (d, J=9 Hz, 2H, H^e); IR (Nujol): 2170, 2150 (N=C=S) cm^{-1}; MS: m/z 251 (M^+). Found: C, 71.82; H, 3.55; N, 5.44; S, 12.86%. Calcd for $C_{15}H_9NOS$: C, 71.69; H, 3.61; N, 5.57; S, 12.76%.

4-(2-Benzofuranyl)benzoic Acid (4₁₃). A solution of **4₃** (0.30 g, 1.3 mmol) and powdered KOH (1.00 g, 18 mmol) in ethylene glycol (25 ml) was refluxed for 6 h, cooled to room temperature, and poured into a mixture of ice-water (50 ml) and concd HCl (0.5 ml). The deposited crystals were filtered off, washed with water, and dried *in vacuo*. Any crude crystals were recrystallized from EtOH to give colorless needles (0.27 g, 83%). mp *ca.* 293 °C (dec) (301—302 °C[12]); ^{1}H NMR (DMSO-d_6): δ=7.19—7.75 (m, 5H, benzofuran ring H), 8.04 (s, 4H, $H^{d,e}$); IR (Nujol): 1680 (C=O) cm^{-1}; MS: m/z 238 (M^+). (Found: C, 75.54; H, 4.14%).

4-(6-Dimethylamino-2-benzofuranyl)benzoic Acid (4₁₄): Yield, 59%; mp *ca.* 157 °C (dec); ^{1}H NMR (DMSO-d_6): δ=3.39 (s, 6H, NMe_2), 6.80 (d, J=9 Hz, 1H, H^b), 6.90 (s, 1H, H^c), 7.39 (s, 1H, H^f), 7.46 (d, J=9 Hz, 1H, H^a), 7.88 (d, J=9 Hz, 2H, H^d), 8.01 (d, J=9 Hz, 2H, H^e); IR (Nujol): 1675 (C=O) cm^{-1}; MS: m/z 281 (M^+). Found: C, 72.43; H, 5.43; N, 4.92%. Calcd for $C_{17}H_{15}NO_3$: C, 72.58; H, 5.37; N, 4.98%.

4-(2-Benzofuranyl)benzoyl Chloride (4₁₅). A mixture of **4₁₃** (1.00 g, 4.2 mmol) and thionyl chloride (25 ml) was refluxed for 15 min and concentrated *in vacuo*. Purification of the residue by recrystallization from cyclohexane gave **4₁₅** as light yellow needles (1.01 g, 94%). mp 159—160 °C; ^{1}H NMR ($CDCl_3$): δ=7.18—7.69 (m, 5H, benzofuran ring H), 7.95 (d, J=9 Hz, 2H, H^d), 8.18 (d, J=9 Hz, 2H, H^e); IR (Nujol): 1760, 1725 (C=O) cm^{-1}; MS: m/z 256 (M^+). Found: C, 70.49; 3.47; Cl, 13.58%. Calcd for $C_{15}H_9ClO_2$: C, 70.19; H, 3.53; Cl, 13.81%.

The present work was partly supported by Grant-in-Aid for Scientific Research (No. 58470031) from the Ministry of Education, Science, and Culture.

Pyrolyse und Eigenschaften von Tris(2,3-epoxypropyl)- und Tris(2,3-epoxy-3-methylpropyl)-1,3,5-triazin-2,4,6(1*H*,3*H*,5*H*)-trion[1)]

Choichiro SHIMASAKI,* Masanori TAKEUCHI, Junichiro TSUTUGUCHI, Koichi SHIMIZU, und Hisato YAMAKAWA

Fakultät für Ingenieurwissenschaften, Universität Toyama, Nakagawasonomachi, Takaoka, Toyama 933

(Eingangsdatum: 5. Januar 1985)

Die Pyrolyse von Tris(2,3-epoxypropyl)-1,3,5-triazin-2,4,6(1*H*,3*H*,5*H*)-trion (**1**) [zwei Razem-Modifikationen: Typus (*R*,*R*,*R*)/(*S*,*S*,*S*) Schmp. 103—104 °C (**1a**); Typus (*R*,*R*,*S*)/(*S*,*S*,*R*) Schmp. 156—157 °C (**1b**)] und Tris(2,3-epoxy-3-methylpropyl)-1,3,5-triazin-2,4,6(1*H*,3*H*,5*H*)-trion (**2**) wurde bei thermischen Analysen untersucht. Der Spaltungsmechanismus durch Elektronenschlag von **1** und **2** wurde massenspektrometrisch untersucht. Die thermische Zersetzungsreaktion verläuft via die Bildung von 5-gliedrige Ringe (Oxazolidinon Ring) und dem Schmelzzustand. Eine kinetische Rechnung der thermischen Zersetungsreaktion auf Grund von DTA Kurven hat gezeigt, daß die Aktivierungsenergien der Zersetzungsreaktionen von **1a**, **1b**, und **2** jeweils 114,170, und 146 kJ mol^{-1} sind. Der Hauptspaltungsmechanismus für der Zersetzung mit dem Elektronenschlag von **1** und **2** besteht aus fünf Spaltungsstilen. Der hochauflösende Massenspektrometrie bestätigte die Zusammensetzung einer großen Anzahl von Spitzen in niederauflösenden Massenstrahlenspektren. Mittels der Kernresonanzspektroskopie läßt sich auch Spinentkopplungen und Lösungsmitteleinflüsse bei **1** und **2** untersuchen.

Einige Forschungen[2)] wurden über die Reaktivität von Tris(2,3-epoxypropyl)-1,3,5-triazin-2,4,6(1*H*,3*H*,-5*H*)-trion (**1**) ausgeführt, das Industriewichtigkeit und Strukturinteresse hat: zwei Razem-Modifikationen **1a** und **1b** wurden ergeben. Obwohl die zwei Strukturen mit IR Spektren[3)] registriert wurden, wurden Untersuchungen über thermische Analysen, wie DTA, nicht ausführlich durchgeführt.

In der jetzigen Abhandlung wurden die thermische Zersetzungsreaktion mit DTA und die Zersetzung mit dem Elektronenschlag zusammengefaßt. Außerdem wurde die Kernmagnetischenresonanzen, die Kopplungskonstanten, und die Lösungsmitteleinflüsse von **1** und Tris(2,3-epoxy-3-methylpropyl)-1,3,5-triazin-2,4,6(1*H*,3*H*,5*H*)-trion (**2**) gemessen.

Durchführung der Experimente

Materialien. **1** wurde von Nissankagaku A. G. erhalten. Es wurde zweimal mit Chloroform rekristallisiert. Die Trennung von **1a** und **1b** von ein ander wurde gleich nach der Methode von Price *et al.*[4)] ausgeführt. **2** wurde aus 2-Chlormethyl-2-methyloxiran und Cyanursäure mit Tetramethylammoniumchlorid als Katalysator, gemäß der Methode von Literatur,[5)] synthetisiert. Die Ergebnisse der physikochemischen Eigenschaften von **1** und **2** sind in Tabelle 1 zusammengestellt.

Apparate und Verfahren. DTA Kurven wurden an der Luft bei verschiedenen Aufheizgeschwindigkeiten mit einem Mitamura-DTA-Apparat aufgenommen. Für DTA und DSC wurde α-Al_2O_3 als Bezugsmittel gebraucht. IR Spektren wurden mittels eines JASCO IRA-I aufgenommen. ^{1}H und ^{13}C NMR-Spektren wurden mit einem JEOL JNM-FX 90 QFT Spektrometer aufgenommen. Als Lösungsmittel wurden deuteriertes Chloroform, Dimethylsulfoxid, und Pyridin, und schweres Wasser verwendet. Tetramethylsilan wurde als innere Standardsubstanz verwendet. Massenspektren wurden durch einen JMS-D300 Massenspektrometer mit direkten Probeinjektionen registriert. Schmelzpunkte wurden durch

Abb. 1. DTA-Kurven von **1a**, **1b**, und **2** in Luft.

einen Mitamura-Mikroschmelzpunkt-Apparat bestimmt und nicht korrigiert. Für Dünnschicht-Chromatographie wurden Platten mit Kiselgel G nach Stahl (Typ 60) von Merck gebraucht. Elementaranalysen wurden bei der Analysen-Zentrale in der Medizinischen-Pharamazeutischen Universität Toyama durchgeführt. Quantitative Analyse von α-Epoxid wurde durch die HCl-Dioxan Methode durchgeführt.[6]

Ergebnisse und Diskussion

Thermische Analyse. Die DTA Kurven von **1a**, **1b**, und **2** sind in Abb. 1 dargestellt. Die DTA Kurven ergeben in allen drei Proben eine endotherme Spitze durch den Schmelzprozeß und jeweils eine exotherme Spitze bei der thermischen Zersetzung. Aber bei der exothermen Spitze von **2** wurde an der Schulter die parallellaufende Spaltbarkeit des Epoxids beobachtet. Aus dem Resultat der IR-Spektren war es zu erwarten, daß die Spaltung des Epoxids von **1a** und **1b** gleichzeit mit der Ringaufspaltung von Triazin vor sich ging. Bevor die exotherme Spitze entstand, ergaben sich keine thermische Zersetzungen für alle drei Proben.

Die Kinetik der thermischen Zersetzung wurde an der exothermen Reaktion untersucht. Am Anfang wurde die Abhängigkeit der Temperatur des DTA-Maximums von der Aufheizgeschwindigkeit bei der thermischen Zersetzung von **1a**, **1b** , und **2** untersucht. Die Ergebnisse, in Abb. 2 dargestellt, zeigen, daß die Temperatur des DTA-Maximums der thermischen Zersetzung auf die höhere Temperaturseite mit steigender Aufheizgeschwindigkeit verschoben wird. Kissinger[7] leitete die einer thermischen Zersetzungsreaktion entsprechende Gleichung ab

$$\frac{\mathrm{d}\ln(\phi/T_m^2)}{\mathrm{d}(1/T_m)} = -E/R, \qquad (1)$$

wo ϕ für Aufheizgeschwindigkeit steht, T_m für Temperatur des DTA-Maximums, E für Aktivierungsenergie, und R für Gaskonstante. Aus Gl. 1 ersieht man, daß bei kleinen Aktivierungsenergien eine starke Verschiebung des Temperaturmaximums der DTA-Kurve zu erwarten ist. In Abb. 3 ist das $\ln(\phi/T_m^2)-1/T_m$ Diagramm zur Berechnung der Aktivierungsenergie dargestellt. In Tabelle 2 sind die aus Neigung berechneten Aktivierungsenergien der Zersetzungsreaktionen bei den 3 Proben registriert. Der Unterschied zwischen **1a** und **1b** ist vom Temperaturmaximum der DTA-Kurve der Zersetzungsreaktionen abhängig, und der Unterschied zwischen **1** und **2** ist von der Seitenkette des Triazinrings abhängig.

Massenspektren. Der Zersetzungsverlauf kann mittels der entsprechenden Massenspektroskopie direkt verglichen werden. Die Abhängigkeit der Massenspektren von den 3 Proben wurden im Gebiet der Ionisierungsspannung 10—75 eV ausgeführt. Die Basisionenspitze von **2** ist m/z 309, Spitze $(M—CH_2O)^+$. Kein Unterschied zwischen den Massenspektren von **1a** und **1b** wurde erkannt. Die Basisionenspitze von [**1**] ist m/z 99, Spitze $(M/3)^+$, und die Spaltung eines einseiti-

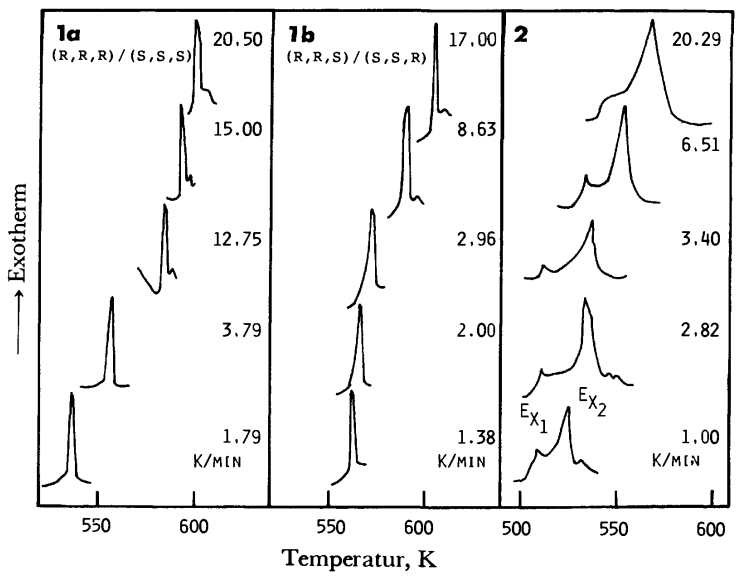

Abb. 2. Abhängigkeit der Temperatur des DTA-Maximums der Aufheizgeschwindigkeit bei der termischen Zersetzung von **1a**, **1b**, und **2**.

TABELLE 2. ZUSAMMENFASSUNG DER KINETISCHEN DATA DER THERMISCHEN ZERSETZUNG VON **1a**, **1b**, UND **2**

Verbindung	$-E/R$[a]	Aktivierungsenergie, E / kJ mol^{-1}	r[b]
1a	5.97	114.4	0.998
1b	8.88	170.1	0.997
2 E_{X_1}	13.17	252.2	0.993
2 E_{X_2}	7.64	146.3	0.998

a) Neigung von gerade Linie. b) Korrelationskoeffizient.

gen Kettenradikals des Triazinrings ist m/z 269, Spitze $(M-28)^+$. Die hochauflösende Massenspektroskopie wurde ausgeführt, um den Spaltungsmechanismus bis in Details zu untersuchen. Die Ergebnisse der Messung sind in Tabelle 3 zusammengestellt.

Aus Tabelle 3 wurde der durch Elektronenschlages erregte Spaltungsmechanismus von **1** und **2** entnommen wie der in Abb. 4 dargestellte. Durch die in Abb. 4 zusammengefaßten Ergebnisse wird erkannt, daß der Hauptspaltungsmechanismus von **1** und **2** aus fünf verschiedenen Spaltungsstilen besteht. Die hierbei auftretenden Spaltungsstile lassen sich in drei Gruppen gliedern:

—Die Spaltung eines einseitigen Kettenradikals des Triazinrings (3 Stile).

—Die Spaltung eines zweiseitigen Kettenradikals des Triazinrings (ein Stil).

—Die Spaltung des Triazinrings; das Ion des Spaltungsprodukts ist gerade $(M/3)^+$.

Bei 1 gab es kein metastabiles Ion (m*), aber bei **2** wurde m* an den Stellen 215.0 und 186.7 erkannt. Diese metastabilen Ionen entsprechen den Prozessen m/z 339→m/z 270 und m/z 309→m/z 240 in Abb. 5. Neben den komplizierteren, bereits aufgeführten Spaltungsmechanismen aus dem Seitenkettenradikal ist die Spitze von $(M/3)^+$—d.h. die Spaltung des Triazinrings—bekannt, die auf Grund ihrer chemischen Zusammensetzung einen wesentlich einfacheren Abbaumechanismus hat. Es gelang uns, mit Hilfe einiger Beispiele, ein Spaltstücksion $(M/3)^+$ aus Isocyanuratderivate (**3**)

zu erhalten, wo die Proben die folgenden waren: R=-H, $-CH_3$, $-CH_2CH_2OH$, $-CH_2CH{=}CH_2$, $-CH_2CH_2CONH_2$, $-CH_2C_6H_5$, $-CH_2CH(OH)CH_2OH$, und -Cl. Alle Proben haben die Spitze von $(M/3)^+$ gegeben.

NMR-spektren. Die ^1H NMR-Spektren von **1** und **2** ergeben eine Reihe interessanter Erscheinungen; das Spektrum des reinen **1** besteht aus einem komplizierten Multiplett mit relativ breiten Banden. In vielen Fällen waren die Bandlagen abhängig vom Lösungsmittel und man kann sich dieses Effektes bedienen, um komplizierte Spektren zu vereinfachen. Daher wurden die ^1H NMR-Spektren von **1** in $CDCl_3$, $(CD_3)_2SO$, und C_5D_5N (deuteriertes Pyridin) gemessen. Wir können die Vereinfachung der Spektren durch C_5D_5N deutlich erkennen. In $CDCl_3$ erschienen die Signale der Epoxidenprotonen H_A und H_B als zwei Quadruplette im Abstand von 2.701 und 2.839 ppm, in $(CD_3)_2SO$ im Abstand von 2.599 und 2.751 ppm, und in C_5D_5N als zwei Singulette im Abstand von 2.708 und 2.743 ppm. Dies ist ein besonders schönes Beispiel der Induktionsverschiebung für **1** in aromatischen Lösungen. Das Spektrum von **1** ist ABX-Typ.

Bei 100 MHz ergab das Spektrum von **1** kompliziertere Signale. Die Spinentkopplungen ließen

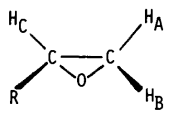
sich auch bei komplizierteren Molekülen anwenden. Darüber hinaus wurden die Signale von **1** bei teilweiser Spinentkopplung gemessen. In Abb. 5 wurden die Spektren von **1** in $CDCl_3$ nach teilweiser Spinentkopplung wiedergegeben. Die Bandgruppen im Spektrum dieser Verbindung wurden so weit voneinander getrennt, daß es möglich war, alle Signale einzeln zu sättigen und die Veränderung bei den übrigen Bändern zu beobachten. Die drei Kopplungskonstanten, J_{AB}, J_{AC}, und J_{BC}, in substituierten Ethylenoxiden (**4**), sind von Reilly und Swalen[8] für eine Reihe von Verbindungen bestimmt worden. Die gefundenen Werte liegen bei J_{AB}=5.8±0.5, J_{AC}=2.2±0.5, und J_{BC}=4.6±0.5.



4

Die Ergebnisse der chemischen Verschiebungen und der Kopplungskonstanten von **1** und **2** sind in Tabelle 4 zusammengestellt. Tabelle 4 zeigt, daß die Werte

TABELLE 5. ^{13}C-CHEMISCHE VERSCHIEBUNGEN IN ppm AUF VERSCHIEDENEN LÖSUNGSMITTELN

Verbindung	δ/ppm C=O	(1)	(2)	(3)	(4)	Lösungsmittel	Konzentration/%
	149.489	46.345	44.734	48.586		$CDCl_3$	20.0
	148.611	46.148	44.978	48.927		C_5D_5N	19.8
	148.952	45.319	43.978	48.488		$(CD_3)_2SO$	19.5
	148.904	52.316	45.831	54.364	19.844	$CDCl_3$	20.6
	149.489	52.365	46.221	54.607	19.844	C_5D_5N	20.2

der Kopplungskonstanten J_{AB}, J_{AC}, und J_{BC}, mit den Werten von Reilly und Swalen übereinstimmen. Bei teilweiser Spinentkopplung übt die Spinentkopplung des Protons A von **1** einen Einfluß auf die Werte der Kopplungskonstante J_{BC} aus; im Proton B beeinflussen J_{CD} und $J_{CD'}$, im Proton C J_{AB} und $J_{DD'}$, und in Protonen D und D' J_{AB}. Die Zuordnung der Spektren wird dadurch erleichtert, daß die Kopplungskonstanten wenig von der Art der Spinentkopplung abhängig sind. Die gefundenen Werte in $CDCl_3$ liegen bei J_{AB}=4.83, J_{AC}=2.42, J_{BC}=4.61, J_{CD}=4.83, $J_{CD'}$=5.27, und $J_{DD'}$= 14.06 Hz.

Die Bandlagen einiger ^{13}C Kernresonanzspektren von **1** und **2** sind in Tabelle 5 angegeben. Die chemische Verschiebung von ^{13}C-Signalen ist nicht von den Lösungsmitteln abhängig.

Die Materialien in der vorliegenden Arbeit wurden von Nissankagaku A.G. angeboten. Für die Bedienung der Apparatur zur Anfertigung der Mass und NMR-Spektren haben sich in dankenswerterweise Fräulein M. Shinoda und Herr K. Yoneyama zur Verfügung gestellt. Herrn Prof. S. Takeuchi danken wir bestens für wertvolle Hinweise.

Reactions of α-Lithiatd 4*H*-1-Benzothiopyran-4-one and 1,2-Dihydrocyclopenta[*b*][1]benzothiopyran-9(3*H*)-one Derivatives

Ichiro HIRAO, Masahiko YAMAGUCHI,* Takashi TERADA, and Koichi HASEBE
Department of Industrial Chemistry, Kyushu Institute of Technology, Sensui-cho, Tobata-ku, Kitakyushu 804
(Received January 14, 1985)

Treatment of 5- and 7-methoxy-2-methyl-4*H*-1-benzothiopyran-4-one with lithium diisopropylamide followed by electrophiles gave 2-substituted 4*H*-1-benzothiopyran-4-ones. Utilizing this reaction, 3-substituted 6- and 8-methoxy-1,2-dihydrocyclopenta[*b*][1]benzothiopyran-9(3*H*)-ones were also synthesized, and several compounds showed potential analgesic and anti-inflammatory activities.

In our previous synthetic studies on heterocyclic compounds directed to the development of biologically active substances, we prepared polycyclic derivatives of 1-alkyl-4-pyridone[1] and 4-pyrone,[2] which have a common 6-membered cyclic structure with nitrogen or oxygen atom at 1-position and a carbonyl group at 4-position. Recently, we found that a sulfur analogue, 1,2-dihydro-8-methoxycyclopenta[*b*][1]benzothiopyran-(3*H*)-one (**8**), possesses analgesic and anti-inflammatory activities. In order to examine the activities of the related compounds, we devised an α-lithiation reaction of this heterocyclic system. The present report describes the reaction of the lithiated 4*H*-1-benzothiopyran-4-ones with electrophiles.

The starting materials, 7- and 5-methoxy-2-methyl-4*H*-1-benzothiopyran-4-one (**3** and **4**) or 8- and 6-methoxy-1,2-dihydrocyclopenta[*b*][1]benzothiopyran-9(3*H*)-one (**8** and **9**), are synthesized from *m*-methoxybenzenethiol (**1**) and ethyl acetoacetate (**2**) or ethyl 2-oxo-1-cyclopentanecarboxylate (**7**), respectively, by the condensation in polyphosphoric acid at 80 °C.[3] Each isomer is separable by chromatography on silica gel. The assignment is based on the NMR spectra. Thus, a triplet with 8 Hz of the coupling constant at δ 7.4 was observed for **4** and **8**, indicating the presence of 1,2,3-trisubstituted aromatic ring, while the other isomers **3** and **9** showed a broad singlet at δ 6.9.

Benzothiopyranones **3**, **4**, **8**, and **9**, thus obtained, were treated with lithium diisopropylamide (LDA) and lithiation ocurred smoothly. The reaction with several alkyl halides and aldehydes gave the corresponding benzothiopyranones **5**, **6**, **10**, and **11** (Scheme 1 and 2). The results are summarized in Tables 1 and

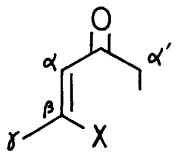
2. In general, the reaction ocurred at C-2 methyl carbon for **3** and **4**, and at 3-position for **8** and **9**. However, a small amount of mixture of other products, presumable compounds formed by alkylation at C-3 carbon, was also detected in methylation and allylation of **3**.

When attentions are paid on β-sulfur substituted α,β-unsaturated carbonyl moiety of these benzothiopyranones, the present process can be classified as the γ-alkylation of enone system. As β-sulfur substituted enones are reported to give α,α-dialkylated products,[4] this synthesis provides a novel example of γ-alkylation. In contrast, carbon-carbon bond formation at γ-position of α,β-unsaturated carbonyl compounds possessing nitrogen[5] or oxygen[6] substituents are well known (Fig. 1).

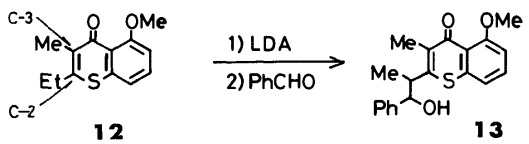


X = RO, RS, R_2N

Fig. 1.

Though the lithiation of **3** was performed at −78 °C in THF-HMPA, lithiated **4** was unstable under these reaction conditions. After the examination of the conditions including bases and solvents, the lithiation was achieved in toluene-HMPA at −78 °C, and addition to aldehydes gave the alcohols **6**. The alkylation, however, was ineffective even in this solvent system.

The lithiated **8** and **9** are treated with electrophiles in THF-HMPA at 0 °C to give 3-substituted 1,2-dihydrocyclopenta[*b*][1]benzothiopyran-9(3*H*)-ones **10** and **11** in good yields. The possibility of the lithiation at 1-position could be excluded for **8** and **9** from the following observations. Thus, 2-ethyl-3-methyl-5-methoxy-4*H*-1-benzothiopyran-4-one (**12**), synthesized from ethyl 2-methyl-3-oxopentanoate, was treated with LDA in toluene-HMPA at −78 °C followed by benzaldehyde, and 2-(2-hydroxy-1-methyl-2-phenylethyl)-3-methyl-5-methoxy-4*H*-1-benzothiopyran-4-one (**13**) was isolated as a mixture of diastereomers. The structure was determined by ^{1}H-NMR. Disappearance of a triplet (δ 1.26) of **12**, and observation of a couple of doublets at δ 1.06 and 1.40 in **13** show that the addition ocurred at the methylene carbon of C-2 ethyl group and not at C-3 methyl carbon (Scheme 3.).



Scheme 3.

Oxygenation of lithiated **8** and **9** was also perfomed by introducing gaseous oxygen at 0 °C followed by the reduction of the resulted peroxide with sodium sulfite[7] to give 6- and 8-methoxy-1,2-dihydro-3-hydroxycyclopenta[*b*][1]benzothiopyran-9(3*H*)-one (**10i** and **11i**). Several attempts to improve the yields, however, were unsuccessful.

Esters **10c** and **11c** were further converted to the corresponding carboxylic acids **10j** and **11j** by treating with lithium hydroxide in refluxing THF-H_2O for 2 h.

Compounds **8**, **10a**, and **10d** showed a potent analgesic activities by the acetic acid induced writhing method. ED_{50}: **8**; 11.5 mg/Kg. **10a**; 5.8 mg/Kg. **10b**; 12.5 mg/Kg. And **8** showed an anti-inflammatory activities against carragenan-induced rat paw edma. ED_{50}: 30 mg/Kg.

Experimental

The melting points are uncorrected. ^{1}H-NMR spectra were obtained with JEOL JNM-FX-60. Chemical shift values are given in ppm relative to internal Me_4Si. IR spectra were performed with Shimadzu IR-408. High resolution mass spectra were taken with JEOL JMS-DX-300. Elemental analyses were performed with Yanagimoto CHN Corder, MT-2 type. Silica gel chromatographies were conducted on Wako gel B5F or C-200 (Wako Pure Chemical Industries LTD.).

7-Methoxy-2-methyl-4H-1-benzothiopyran-4-one (3) and 5-Methoxy-2-methyl-4H-1-benzothiopyran-4-one (4). These compounds were synthesized from *m*-methoxybenzenethiol (**1**) and ethyl acetoacetate (**2**) according to the reported method[3] in 28 and 26% yield, after the separation by silica gel chromatography with ethyl acetate:hexane=1:1 as the eluent. **3**: mp 121 °C (benzene-hexane), lit,[8] mp 118—119.5 °C. ^{1}H-NMR ($CDCl_3$) δ=2.40 (3H, d, J=1 Hz), 3.88 (3H, s), 6.75 (1H, d, J=1 Hz), 6.8—7.1 (2H, m), and 8.39 (1H, dd, J=1, 8 Hz). IR (KBr) 1630, 1600, 1260, and 850 cm^{-1}. Found: C, 63.78 H, 4.99%. Calcd for $C_{11}H_{10}O_2S$: C, 64.06; H, 4.89%. **4**: mp 83 °C (benzene-hexane). ^{1}H-NMR ($CDCl_3$) δ=2.34 (3H, d, J=1 Hz), 3.96 (3H, s), 6.69 (1H, d, J=1 Hz), 6.90 (1H, dd, J=1, 8 Hz), 7.08 (1H, dd, J=1, 8 Hz), and 7.46 (1H, t, J=8 Hz). IR (KBr) 1610, 1260, and 1030 cm^{-1}. Found: C, 64.29; H, 4.99%. Calcd for $C_{11}H_{10}O_2S$: C, 64.06; H, 4.89%.

1,2-Dihydro-8-methoxycyclopenta[b][1]benzothiopyran-9(3H)-one (8), 1,2-Dihydro-6-methoxycyclopenta[b][1]benzothiopyran-9(3H)-one (9). Synthesized from **1** and ethyl 2-oxo-1-cyclopentanecarboxylate (**7**) as above (20 and 20% yield). **8**: mp 137 °C (benzene-hexane). ^{1}H-NMR ($CDCl_3$) δ=1.8—2.4 (2H, m), 2.7—3.2 (4H, m), 3.86 (3H, s), 6.93 (1H, brs), 7.00 (1H, dd, J=2.5, 9 Hz), and 8.43 (1H,dd, J=1, 9 Hz). IR (KBr) 1590, 1240, and 1020 cm^{-1} Found: C, 66.91; H, 5.12%. Calcd for $C_{13}H_{12}O_2S$: C, 67.22, H, 5.29%. **9**: mp 155 °C (benzene-hexane). ^{1}H-NMR ($CDCl_3$) δ=1.8—2.4 (2H, m), 2.7—3.1 (4H, m), 3.95 (3H, s), 6.89 (1H, dd, J=1.5, 8 Hz), 7.08 (1H, dd, J=1.5, 8 Hz), and 7.42 (1H, t, J=8 Hz). IR (KBr) 1605, 1460, 1270, 1040, and 800 cm^{-1}. Found: C, 67.30; H, 5.11%. Calcd for $C_{13}H_{12}O_2S$: C, 67.22, H, 5.21%.

2-Ethyl-3-methyl-7-methoxy-4H-1-benzothiopyran-4-one (12). The compound **12** was synthesized as described above from ethyl 2-methyl-3-oxopentanoate in 16% yield. **12**: mp 110 °C (benzene-hexane). ^{1}H-NMR ($CDCl_3$) δ=1.26 (3H, t, J=7 Hz), 2.17 (3H, s), 2.63 (2H, q, J=7 Hz), 3.94 (3H, s), 6.85 (1H, dd, J=1.5, 8 Hz), 7.12 (1H, dd, J=1.5, 8 Hz), and 7.40 (1H, t, J=8 Hz). IR (KBr) 1610, 1270, 1040, and 800 cm^{-1}. Exact mass

Found: *m/z* 234.0715. Calcd for $C_{13}H_{14}O_2S$: M, 234.0715.

*Reaction of Lithiated **3** with Alkyl Halides and Aldehydes. General Procedure*: Under a nitrogen atmosphere, to a THF (1 ml) solution of diisopropylamine (50 mg, 0.5 mmol) was added butyllithium in hexane (0.32 ml, 0.5 mmol) at −78 °C. After 5 min, **3** (103 mg, 0.5 mmol) in THF (2 ml) and HMPA (1 ml) were added successively. The mixture was stirred for 5 min and an alkyl halide (1.5 mmol) or an aldehyde (0.6 mmol) in THF (2 ml) was added. After 15—30 min at the temperature, the reaction was quenched with saturated aqueous ammoinum chloride, and the products were two times extracted with ethyl acetate. The combined extracts were washed with water and brine, dried over Na_2SO_4. Removal of the solvents *in vacuo*, and chromatography on silica gel (eluent; ethyl acetate:hexane=1:1) gave the product **5**.

*2-Ethyl-7-methoxy-4H-1-benzothiopyran-4-one (**5a**)*: mp 61 °C (ether-hexane). ^{1}H-NMR ($CDCl_3$) δ=1.28 (3H, t, J=7 Hz), 2.61 (2H, q, J=7 Hz), 3.83 (3H, s), 6.72 (1H, s), 6.86 (1H, brs), 6.93 (1H, dd, J=2, 8 Hz), and 8.31 (1H, dd, J=1, 8 Hz). IR (KBr) 1620, 1600, 1260, 1230, 1050, and 1020 cm^{-1}. Found: C, 65.17; H, 5.35%. Calcd for $C_{12}H_{12}O_2S$: C, 65.43; H, 5.49%.

*2-(3-Butenyl)-7-methoxy-4H-1-benzothiopyran-4-one (**5b**)*: mp 65 °C (ether-hexane). ^{1}H-NMR ($CDCl_3$) δ=2.1—2.9 (4H, m), 3.84 (3H, s), 4.8—5.2 (2H, m), 5.5—6.2 (1H, m), 6.74 (1H, s), 6.8—7.1 (2H, m), and 8.35 (1H, dd, J=1, 8 Hz). IR (KBr) 1610, 1600, 1250, and 840 cm^{-1}. Found: C, 68.21; H, 5.76%. Calcd for $C_{14}H_{14}O_2S$: C, 68.26; H, 5.73%.

*2-(2-Ethoxycarbonylethyl)-7-methoxy-4H-1-benzothiopyran-4-one (**5c**)*: mp 126 °C (benzene-hexane). ^{1}H-NMR ($CDCl_3$) δ=1.26 (3H, t, J=7 Hz), 2.3—3.1 (4H, m), 3.87 (3H, s), 4.16 (2H, q, J=7 Hz), 6.78 (1H,s), 6.93 (1H, s), 6.99 (1H, dd, J=2, 8 Hz), and 8.35 (1H, dd, J=2, 8 Hz). IR (KBr) 1725, 1620, 1600, and 1240 cm^{-1}. Found: C, 61.42; H, 5.72%. Calcd for $C_{15}H_{16}O_4S$: C, 61.43; H, 5.52%.

*2-(2-Hydroxy-2-phenylethyl)-7-methoxy-4H-1-benzothiopyran-4-one (**5f**)*: mp 129 °C (benzene-hexane). ^{1}H-NMR ($CDCl_3$) δ=2.94 (2H, d, J=6 Hz), 3.81 (3H, s), 4.33 (1H, brs), 5.04 (1H, t, J=6 Hz), 6.7—7.0 (3H, m), 7.0—7.5 (5H, m), and 8.18 (1H, dd, J=1, 8 Hz). IR (KBr) 3300, 1610, 1600, 1560, 1050, 830, 760, and 710 cm^{-1}. Found: C, 68.70; H, 4.87%. Calcd for $C_{18}H_{16}O_3S$: C, 69.21; H, 5.16%.

*2-[2-Hydroxy-2-(p-methoxyphenyl)ethyl]-7-methoxy-4H-1-benzothiopyran-4-one (**5g**)*: mp 114 °C (benzene-hexane). ^{1}H-NMR ($CDCl_3$) δ=1.84 (1H, brs), 3.00 (2H, d, J=7 Hz), 3.80 (3H, s), 3.88 (3H, s), 5.00 (1H, t, J=7 Hz), 6.79 (1H, s), 6.8—7.1 (4H, m), 7.32 (2H, d, J=8 Hz), and 8.34 (1H, dd, J=1, 8 Hz). IR (KBr) 3400, 1600, 1230, and 835 cm^{-1}. Found: C, 66.55; H, 5.32%. Calcd for $C_{19}H_{18}O_4S$: C, 66.65; H, 5.30%.

*2-[2-Hydroxy-2-(3,4-methylenedioxyphenyl)ethyl]-7-methoxy-4H-1-benzothiopyran-4-one (**5h**)*: mp 162 °C (ethanol-ether-hexane). ^{1}H-NMR ($CDCl_3$) δ=2.97 (2H, d, J=7 Hz), 3.88 (3H, s), 4.58 (1H, brs), 4.97 (1H, t, J=7 Hz), 6.79 (2H, s), 6.8—7.1 (4H, m), 7.32 (2H, d, J=8 Hz), and 8.34 (1H, dd, J=1, 8 Hz). IR (KBr) 3400, 1600, 1230, and 835 cm^{-1}. Found: C, 66.55; H, 5.32%. Calcd for $C_{19}H_{16}O_5S$; C, 66.65; H, 5.30%.

*Reaction of Lithiated **4** with Aldehydes.* The reaction was carried out as described above except that toluene was used as the reaction solvent instead of THF, and ethyl acetate:hexane=3:1 was used for chromatography.

*2-(2-Hydroxy-2-phenylethyl)-5-methoxy-4H-1-benzothiopyran-4-one (**6f**)*: mp 84 °C (benzene-hexane). ^{1}H-NMR ($CDCl_3$) δ=2.87 (2H, d, J=6 Hz), 3.79 (3H, s), 4.55 (1H, brs), 4.98 (1H, t, J=6 Hz), 6.5—6.9 (2H, m), and 6.9—7.5 (7H, m). IR (KBr) 3400, 1600, 1270, and 1040 cm^{-1}. Found: C, 69.28; H, 5.48%. Calcd for $C_{18}H_{16}O_3S$: C, 69.21; H, 5.16%.

*2-[2-Hydroxy-2-(p-methoxyphenyl)ethyl]-5-methoxy-4H-1-benzothiopyran-4-one (**6g**)*: mp 138 °C (benzene-hexane). ^{1}H-NMR ($CDCl_3$) δ=1.73 (1H, brs), 2.94 (2H, d, J=7 Hz), 3.79 (3H, s), 3.93 (3H, s), 4.99 (1H, t, J=7 Hz), 6.71 (1H, s), 6.7—7.0 (1H, m), 6.87 (2H, d, J=7 Hz), 7.18 (1H, dd, J=1.5, 8 Hz), 7.31 (2H, d, J=7 Hz), and 7.44 (1H, t, J=8 Hz). IR (KBr) 3400, 1610, 1260, and 1040 cm^{-1}. Found: C, 66.45; H, 5.41%. Calcd for $C_{19}H_{18}O_3S$: C, 66.65; H, 5.30%.

*Reaction of Lithiated **8** with Electrophiles. General Procedure*: Under a nitrogen atmosphere, diisopropylamine (1 mmol) was suspended in THF (1 ml) at 0 °C. A hexane solution (0.64 ml) of butyllithium (1 mmol) was added and the solution was stirred at 0 °C for 5 min. Then, **8** (232 mg, 1 mmol) was added in one portion followed, after 10 min, by HMPA (2 ml). The mixture was stirred for 10 min. An alkyl halide (3 mmol) or aldehyde (1.1 mmol) in THF (2 ml) was added, and stirring was continued for additional 40—60 min. The reaction was quenched by the addition of saturated aqueous ammonium chloride. The products were extracted twice with ethyl acetate, washed with brine, and dried over Na_2SO_4. The solvents were evaporated *in vacuo*, and the residue was chromatographed on silica gel using ethyl acetate-hexane (1:1) as the eluent.

*1,2-Dihydro-3-methyl-8-methoxycyclopenta[b][1]benzothiopyran-9(3H)-one (**10a**)*: mp 103 °C (benzene-hexane). ^{1}H-NMR ($CDCl_3$) δ=1.31 (3H, d, J=7 Hz), 1.4—2.6 (2H, m), 2.6—3.1 (2H, m), 3.1—3.6 (1H, m), 3.96 (3H, s), 6.90 (1H, dd, J=1.5, 8 Hz), 7.13 (1H, dd, J=1.5, 8 Hz), and 7.44 (1H, t, J=8 Hz). IR (KBr) 1610, 1590, 1450, 1260, and 1040 cm^{-1}.

*1,2-Dihydro-3-ethyl-8-methoxycyclopenta[b][1]benzothiopyran-9(3H)-one (**10d**)*: mp 131 °C (benzene-hexane). ^{1}H-NMR ($CDCl_3$) δ=0.98 (3H, t, J=7 Hz), 1.4—2.5 (4H, m), 2.6—3.4 (3H, m), 3.94 (3H, s), 6.90 (1H, dd, J=1.5, 8 Hz), 7.11 (1H, dd, J=1.5, 8 Hz), and 7.42 (1H, t, J=8 Hz). IR (KBr) 1610, 1590, 1260, and 1040 cm^{-1}. Found: C, 68.92; H, 6.43%. Calcd for $C_{15}H_{16}O_2S$: C, 69.20; H, 6.19%.

*3-Benzyl-1,2-dihydro-8-methoxycyclopenta[b][1]benzothiopyran-9(3H)-one (**10e**)*: mp 131 °C (benzene-hexane). ^{1}H-NMR ($CDCl_3$) δ=1.5—2.3 (2H, m), 2.6—3.1 (5H, m), 3.2—3.8 (1H, m), 3.92 (3H, s), 6.86 (1H, dd, J=1.5, 8 Hz), 7.07 (1H, dd, J=1.5, 8 Hz), 7.23 (5H, s), and 7.39 (1H, t, J=8 Hz). IR (KBr) 1615, 1260, and 1035 cm^{-1}. Found: C, 73.86; H, 5.77%. Calcd for $C_{20}H_{18}O_2S$: C, 74.50; H, 5.63%.

*1,2-Dihydro-3-(α-hydroxybenzyl)-8-methoxycyclopenta[b][1]-benzothiopyran-9(3H)-one (**10f**)*: mp 98—105 °C (benzene-hexane). ^{1}H-NMR ($CDCl_3$) δ=1.4—2.0 (2H, m), 2.4—3.0 (2H, m), 3.5—4.0 (1H, m), 3.86 (3H, s), 4.4—5.0 (2H, m), and 6.6—7.6 (8H, m). IR (KBr) 3400, 1590, 1260, 1040, 760, and 700 cm^{-1}. Found: C, 71.06; H, 5.32%. Calcd for $C_{20}H_{18}O_3S$: C, 70.98; H, 5.36%.

*1,2-Dihydro-3-ethoxycarbonylmethyl-8-methoxycyclopenta[b]-[1]benzothiopyran-9(3H)-one (**10c**)*: mp 97 °C (benzene-hexane). ^{1}H-NMR ($CDCl_3$) δ=1.28 (3H, t, J=7 Hz), 1.4—3.1 (6H, m), 3.3—4.0 (1H, m), 3.94 (3H, s), 4.19 (2H, q, J=7 Hz), 6.89 (1H, dd, J=1.5, 8 Hz), 7.08 (1H, dd, J=1.5, 8 Hz), and 7.41 (1H, t, J=8 Hz). IR (KBr) 1720, 1600, 1260, 1170, 1040, 790, 770, and 690 cm^{-1}. Found: C, 63.63: H, 6.04%. Calcd for $C_{17}H_{18}O_4S$: C, 64.13; H, 5.70%.

*1,2-Dihydro-3-hydroxy-8-methoxycyclopenta[b][1]benzothiopyran-9(3H)-one (**10i**)*: The compound was synthesized by in-

troducing gaseous oxygen to the solution of lithiated **8** for 20 min at 0 °C followed by the reductive treatment with aqueous sodium sulfite. Mp 182 °C (dichloromethane-hexane). ^{1}H-NMR ($CDCl_3$) δ=1.8—3.2 (4H, m), 3.34 (1H, brs), 5.0—5.4 (1H, m), 6.88 (1H, dd, J=1, 8 Hz), 6.97 (1H, dd, J=1, 8 Hz), and 7.40 (1H, t, J=8 Hz). IR (KBr) 3400, 1605, 1585, 1040, and 795 cm^{-1}. Exact mass, Found: m/z 248.0559. Calcd for $C_{13}H_{12}O_3S$: M, 248.0507.

Reaction of Lithiated 9 with Electrophiles. The reaction was carried out as described for **8**.

1,2-Dihydro-3-ethoxycarbonylmethyl-6-methoxycyclopenta[b]-[1]benzothiopyran-9(3H)-one (11c): mp 82 °C (benzene-hexane). ^{1}H-NMR ($CDCl_3$) δ=1.29 (3H, t, J=7 Hz), 1.4—3.1 (6H, m), 3.3—4.0 (1H, m), 3.86 (3H, s), 4.20 (2H, q, J=7 Hz), 6.91 (1H, brs), 6.98 (1H, dd, J=1, 9 Hz), and 8.37 (1H, dd, J=1, 8 Hz). IR (KBr) 1730, 1600, 1025, and 760 cm^{-1}. Found: C, 64.17; H, 5.67%. Calcd for $C_{17}H_{18}O_4S$: C, 64.13; H, 5.70%.

1,2-Dihydro-3-hydroxy-6-methoxycyclopenta[b][1]benzothiopyran-9(3H)-one (11i): mp 184 °C (benzene-hexane). ^{1}H-NMR ($CDCl_3$) δ= 1.6—3.0 (4H, m), 3.37 (1H, brs), 3.89 (3H, s), 5.0—5.2 (1H, m), 7.16 (1H, dd, J=2.5, 9 Hz), 7.39 (1H, d, J=2.5 Hz), and 8.27 (1H, d, J=9 Hz). IR (KBr) 3400, 1590, and 1230 cm^{-1}. Exact mass, Found: m/z 248.0523. Calcd for $C_{13}H_{12}O_3S$: M, 248.0508.

Reaction of Lithiated 12 with Benzaldehyde. The reaction was performed as depicted in the synthesis of 5-methoxy-4*H*-1-benzothiopyran-4-one **6**.

2-(2-Hydroxy-1-methyl-2-phenylethyl)-5-methoxy-3-methyl-4H-1-benzothiopyran-4-one (13): oil. ^{1}H-NMR ($CDCl_3$) δ=1.06 (1.5H, d, J=7 Hz), 1.40 (1.5H, d, J=7 Hz), 1.99 (1.5H, s), 2.23 (1.5H, s), 3.22 (1H, brs), 3.2—3.9 (1H, m), 3.93 (3H, s), 4.81 (0.5H, d, J=6 Hz), 4.94 (0.5H, d, J=4 Hz), and 6.7—7.8 (8H, m). IR (KBr) 3400, 1600, 1265, 1045, 765, and 700 cm^{-1}. Exact mass, Found: m/z 339.1113. Calcd for $C_{20}H_{19}O_3S$: M-1, 339.1055.

Hydrolysis of 10c. A solution of **10c** (760 mg, 2.4 mmol) in THF (10 ml) and 4 M[†] lithium hydroxide (30 ml) was refluxed for 2 h. On cooling, the mixture was acidified with 6 M hydrochloric acid and the products were extracted twice with a mixture of THF and ethyl acetate (1:2). The combined extracts were washed with brine, dried over Na_2SO_4, and concentrated *in vacuo*. The residue was chromatographed on silica gel using ethyl acetate as the eluent to give 3-carboxymethyl-1,2-dihydro-8-methoxycyclopenta[*b*][1]benzothiopyran-9(3*H*)-one (**10j**) (420 mg, 60%): mp 202 °C (dichloromethane-hexane). ^{1}H-NMR (d_6-DMSO) δ=1.4—3.0 (6H, m), 3.4—4.0 (1H, m), 3.85 (3H, s), 5.76 (1H, brs), 6.9—7.3 (2H, m), and 7.50 (1H, t, J=8 Hz). IR (KBr) 3700, 2500, 1720, 1270 and 1030 cm^{-1}. Found: C, 61.60; H, 5.11%. Calcd for $C_{15}H_{14}O_4S$: C, 62.05; H, 4.86%.

Hydrolysis of 11c. The reaction was carried out as described above except that the products were extracted with ethyl acetate, and chromatographed with ethyl acetate-hexane (1:1) to give 3-carboxymethyl-1,2-dihydro-6-methoxy-cyclopenta[*b*][1]benzothiopyran-9(3*H*)-one (**11j**) (58% yield): mp 200 °C (benzene-hexane). ^{1}H-NMR ($CDCl_3$-d_6-DMSO) δ=1.4—2.0 (2H, m), 2.0—3.0 (4H, m), 3.91 (3H, s), 3.5—4.0 (1H, m), 5.39 (1H, brs), 7.0—7.1 (2H, m), and 8.37 (1H, d, J=9 Hz). IR (KBr) 3700, 2400, 1715, 1570, 1540, and 1240 cm^{-1}. Exact mass, Found: 290.0545. Calcd for $C_{15}H_{14}O_4S$: M, 290.0612.

The authors are deeply indebted to Dr. Ryuzo Ueno and his staff of Ueno Pharmaceutical Company, Ltd., for the assay.

[†] 1 M = 1 mol dm^{-3}.

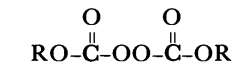
Synthesis and Thermal Decomposition of Di-*t*-Butyl Peroxydicarbonate

Takeshi KOMAI* and Kazuo MATSUYAMA
Chemicals and Explosives Research Laboratory, Nippon Oil & Fats Co., Ltd., Taketoyo, Chita-gun, Aichi 470-23
(Received February 25, 1985)

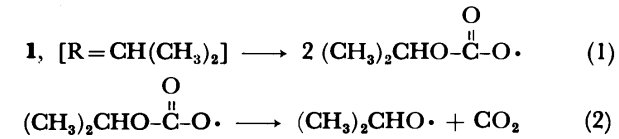
Di-*t*-butyl peroxydicarbonate(DBPD) has been synthesized in a novel route and thermally decomposed at 40—70 °C. The decomposition exhibits first-order kinetics and the values of $\Delta H^{\ddagger}$ and $\Delta S^{\ddagger}$ are 122 kJ mol^{-1} and 46 J K^{-1} mol^{-1}, respectively. 2-Methyl-2-propanol is obtained quantitatively as a decomposition product and the rates are a little dependant on the viscosities of solvents, normal alkanes. The mechanism that involves the initial scission of the O–O bond is discussed and the values of the rates and the activation parameters of DBPD are compared with those of diacetyl peroxide and dibenzoyl peroxide.

Dialkyl peroxydicarbonates (**1**) are useful low-temperature initiators of polymerization for vinyl chloride and other monomers.[1] The decomposition rate of di-



(**1**)

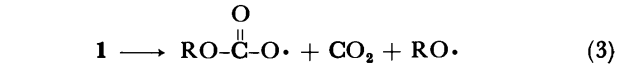
isopropyl peroxydicarbonate in benzene containing styrene at 54 °C is equal to that of dibenzoyl peroxide in the same medium at 82 °C.[2] However, based on the overall activation energy for the decomposition, 118 kJ mol^{-1}, closer to the values (121 to 126 kJ mol^{-1}) reported for dibenzoyl peroxide, Strain and coworkers[3] proposed that the primary rate-determing step was the same for both peroxides, homolytic cleavage of the peroxide bond.



(1)

(2)

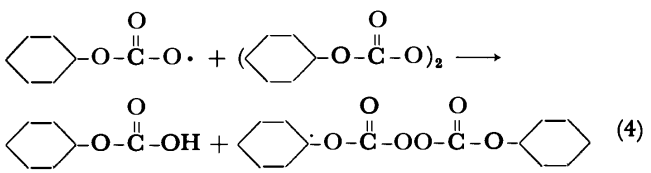
McBay and Tucker[4] examined the thermal decomposition products of peroxydicarbonates in several solvents at 140 °C, and proposed a different decomposition scheme.



(3)

A more recent study[5] of dicyclohexyl peroxydicarbonate (**1**, R=C_6H_{11}) indicated that it was decomposed by the homolytic one-bond fission (Eq. 1) and the decarboxylation of the generated alkoxycarboxyl radical (Eq. 2) was negligible at 50 °C, compared to the reaction with solvent or bimolecular disproportionation.

One of the complexities of the decomposition mechanisms of peroxydicarbonates is that the homolytic decomposition is accompanied with the induced decomposition. For instance, the α-hydrogen atom of dicyclohexyl peroxydicarbonate is abstracted easily by the alkoxycarboxyl radical.[5]

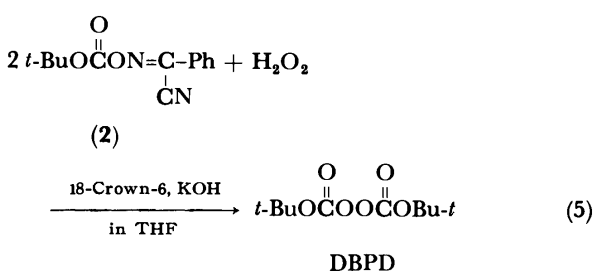


(4)

The amounts of homolytic (Eq. 1) and induced decompositions (Eq. 4) are nearly equal at 0.1 M† in benzene solution.[5] Hence, we have supposed that di-*t*-alkyl peroxydicarbonate (**I**, R=*t*-alkyl) which lacks the α-hydrogen atom in the alkyl group is more suitable for clarifying the homolytic decomposition mechanisms than primary or secondary analogues. For this purpose, we have synthesized di-*t*-butyl peroxydicarbonate (**I**, R=*t*-C_4H_9, DBPD) and measured the decomposition rates and products at 40—70 °C.

Results and Discussion

Synthesis. Di-primary and secondary alkyl peroxydicarbonates have been synthesized by conventional reactions between alkyl chloroformates and hydrogen peroxide in aqueous alkali solution.[6] However, in the case of the synthesis of DBPD the yield is low because *t*-butyl chloroformate is unstable under the reaction conditions.[7] We synthesized DBPD in a novel route from 2-(*t*-butoxycarbonyloxyimino)-2-phenylacetonitrile (Boc ON) (**2**) and hydrogen peroxide in the presence of dicyclohexyl 18-crown-6 (18-Crown-6) equivalent to potassium hydroxide at 2 °C (See Experimental).



(5)

DBPD

This procedure was also applied for the synthesis of di-*t*-butyl peroxymonocarbonate with using *t*-butyl hydroperoxide in place of hydrogen peroxide. In this case, 18-Crown-6 was not necessary.

Kinetics and Products of Decomposition. Decomposition products of DBPD in cumene detected by gas chromatography were 2-methyl-2-propanol, 1,1,2,2-tetramethyl-1,2-diphenyl-ethane and a small amount of *t*-butyl α,α-dimethylbenzyl carbonate. In dodecane and chlorobenzene containing 0.1 M cyclo-

† 1 M=1 mol dm^{-3}.

Table 2. Rate constants for thermal decomposition of DBPD

Solvent	Viscosity[a] cP	Initial concd of DBPD/M	Temp °C	$10^5 k_{obsd}$[b] s^{-1}
Cumene	0.613	0.0203	40	0.722±0.012
Cumene	0.560	0.0203	50	3.12±0.07
Cumene	0.560	0.201	50	3.78±0.12
Cumene	0.490	0.0203	60	11.6±0.3
Cumene	0.440	0.0203	70	49.0±0.4
Hexane	0.235	0.0229	50	3.29±0.03
Decane	0.623	0.0215	50	3.23±0.03
Octadecane	2.29	0.0209	50	3.10±0.07

a) Viscosity of cumene was obtained from *Beilstein III*, **5**, p. 879 and those of *n*-alkanes from Ref. 12. b) Rate constants and their standard deviations were calculated by the method of least squares.

hexane, 2-methyl-2-propanol and unidentified products were obtained. Table 1 summarizes the products data on DBPD decomposition. Thermal decomposition rates were measured by following the disappearance of DBPD by the iodometric titration. The data exhibit first-order kinetics over the temperature range employed (40—70 °C).

Table 2 summarizes the rate constants for the decomposition in cumene and other solvents. When the decomposition is carried out over a ten fold variation in the initial concentration, the rate constant of the reaction increases approximately 20%. This indicates that the data of Table 2 are not pure unimolecular first-order but involving some induced decomposition.

Using the method of Nozaki and Bartlett[8] an attempt was made to separate the induced decomposition (k_i) and the unimolecular decomposition (k_d) by the following equation.

$$-\frac{d[DBPD]}{dt} = k_d[DBPD] + k_I[DBPD]^{3/2} \quad (6)$$

The values of k_d=2.77×10^{-5} s^{-1} and k_i=3.47×10^{-5} M$^{-1/2}$ s^{-1} are obtained. In the decomposition of dicyclohexyl peroxydicarbonate (**I**, R=C$_6$H$_{11}$) in benzene at the same temperaure (50 °C), the values of k_d=3.9×10^{-5} s^{-1} and k_i=1.39×10^{-4} M$^{-1/2}$ s^{-1} were reported.[5] For the decomposition of dibenzoyl peroxide the values of k_d=3.3×10^{-5} s^{-1} and k_i=4.3×10^{-5} M$^{-1/2}$ s^{-1} were reported in both benzene and toluene at 80 °C.[8] From these results it can be understood that the ratio of the induced decomposition of DBPD to the unimolecular one is similar to that of dibenzoyl peroxide, but its value is 1/3-fold of that of dicyclohexyl peroxydicarbonate.

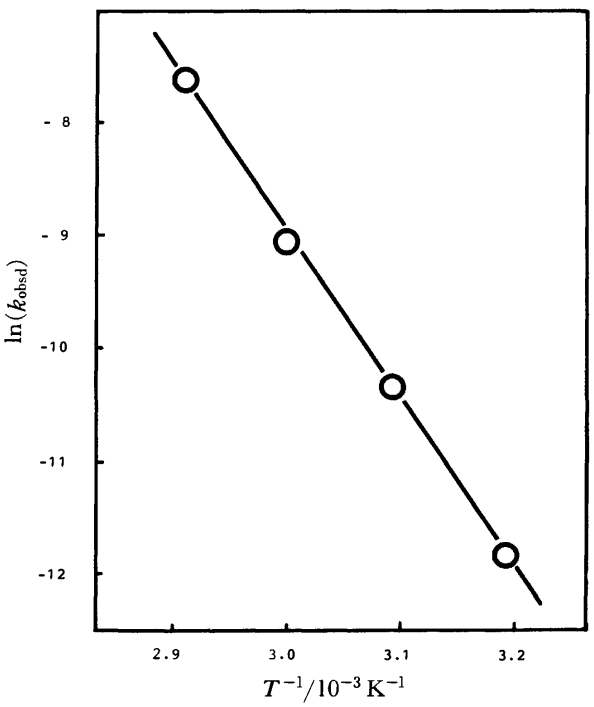

Fig. 1. Arrhenius plot for decomposition of 0.0203 M DBPD in cumene.

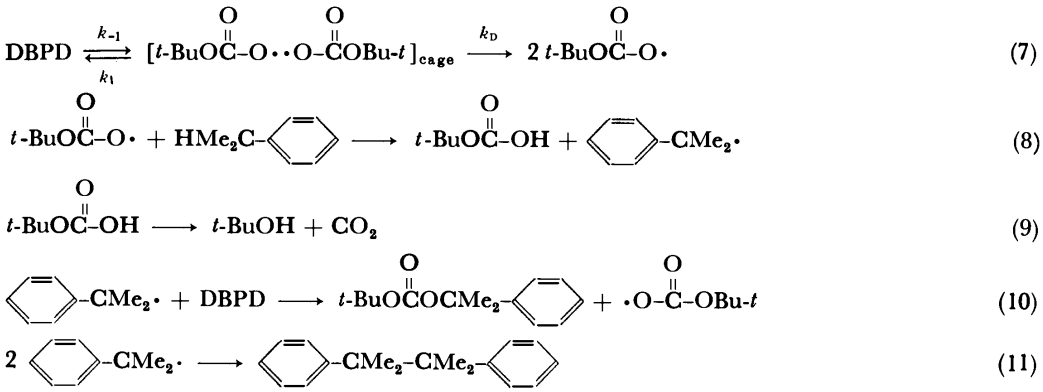
Figure 1 shows an Arrhenius plot for the decomposition of DBPD of 0.0203 M in cumene in the range of 40—70 °C. Table 3 indicates the relative rate at 50 °C and the activation parameters of the DBPD together with those of dibenzoyl peroxide and diacetyl peroxide.

The formation of above-mentioned products and the observed kinetic data can be understood in terms of the reactions in Scheme 1.

TABLE 3. RELATIVE RATES AND ACTIVATION PARAMETERS WITH DECOMPOSITION OF DBPD, DIACETYL AND DIBENZOYL PEROXIDE

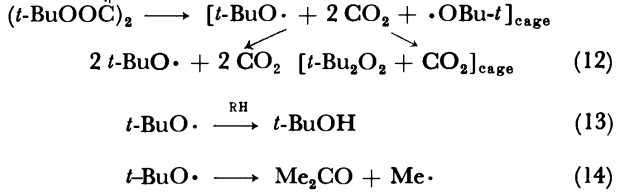
Peroxide	Solvent	Relative rate at 50°C	Activation parameter ΔH^*/kJ mol^{-1}	ΔS^*/JK^{-1} mol^{-1}
DBPD	Cumene	43	122	46
Diacetyl[a]	Toluene	1.8	130	44
Dibenzoyl[b]	Acetophenone	1.0	126	19

a) See Ref. 9. b) See Ref. 10.



Scheme 1.

Niki and Kamiya decomposed di-*t*-butyl diperoxyoxalate in a cumene–benzene mixture at 45 °C and obtained 5.8% of di-*t*-butyl peroxide as the cage product, 4.4% of acetone and 90.8% of 2-methyl-2-propanol.[11]



In the case of DBPD decomposition 2-methyl-2-propanol was nearly quantitaively obtained, but acetone, β-scission product of *t*-butoxyl radical (Eq. 14) was not detected (Table 1). Furthermore, di-*t*-butyl peroxide, as the cage product of two *t*-butoxyl radicals (Eq. 12) and di-*t*-butyl peroxymonocarbonate, that of *t*-butoxyl and *t*-butoxycarboxyl radicals, also were not detected. These results show that *t*-butoxyl radical is not present under the experimental conditions. Accordingly DBPD decomposes with one-bond homolysis, and the decarboxylation of the resulting *t*-butoxycarboxyl radical does not compete with hydrogen abstraction from cumene. This agrees with Van Sickle's results.[5]

The solvent viscosity dependence of the observed rate is one of the methods of separating the concerted and stepwise mechanisms for the peroxide decomposition. The relationship[12] between the observed rate constant (k_{obsd}) and the solvent viscosity (η) is written as

$$\frac{1}{k_{obsd}} = \frac{1}{k_1} + \frac{k_{-1}}{k_1 A_D}\left(\frac{\eta}{A_v}\right)^{\alpha} \qquad (15)$$

TABLE 4. CAGE RETURN OF PEROXIDES

Peroxide	Temperature °C	f_r
DBPD[a]	50	0.04
Diacetyl[b]	80	0.28
Dibenzoyl[c]	80	0.02

a) In decane. b) In octane (See Ref. 13). c) In 2,2,4-trimethylpentane (See Ref. 13).

where k_1 is the rate constant for bond homolysis; k_{-1} is the rate constant for cage return; A_D and A_v are Arrhenius preexponential factors for solute diffusion and self-diffusive flow of solvent, respectively, and α is a proportionality constant between the activation energies for the above-mentioned diffusion and flow ($E_D=\alpha E_v$), set equal to 0.5 for the calculation. The fraction (f_r) of geminate radicals which combine to reform the parent peroxydicarbonate is defined as

$$f_r = \frac{k_{-1}}{k_{-1}+k_D} = 1 - \frac{k_{obsd}}{k_1} \qquad (16)$$

The value of the rate constant for bond homolysis (k_1) of DBPD is estimated to be 3.37×10^{-5} s^{-1} from the intercept of a plot of $1/k_{obsd}$ *vs.* $(\eta/A_v)^{0.5}$ using the values in Table 2 and Ref. 12. The value of f_r in decane can be calculated from Eq. 16. The obtained data are presented in Table 4 with those of dibenzoyl and diacetyl peroxides.[13] The values of $f_r>0.1$ have been expected for the peroxides which decompose with one-bond fission. The value of $f_r=0.04$ for DBPD may suggest its two-bond concerted fission. However, dibenzoyl peroxide which decomposes with one-bond fission also has very low f_r value (Table 4). Pryor[13] proposed that a

larger activation barrier exists for the combination of benzoyloxyl radicals than for acetoxyl radicals. In the case of DBPD, the resonance structures can be written for geminate pair.

$$[2\ t\text{-BuOCO}_2\cdot] \longleftrightarrow [t\text{-BuOCO}_2^-,\ t\text{-BuOCO}_2^+] \longleftrightarrow [t\text{-BuOCO}_2^-,\ Me_3C^+O\text{-}C(=O)\text{-}O]$$

We believe that the solvent viscosity effect test is not a sure method for distinguishing between one-bond and concerted two-bond fission.

The decomposition rate of DBPD is 43 and 24 fold faster than those of dibenzoyl and diacetyl peroxides at 50 °C, respectively (Table 3). However, the activation enthalpies of these three peroxides are almost the same values (*ca.* 125 kJ mol^{-1}), which support the above-mentioned one-bond fission of DBPD (Eq. 7). Hammett's σ_p values of alkoxycarbony,[14] benzoyl and acetyl groups are 0.310, 0.459, and 0.509, respectively. Those of methoxyl, phenyl and methyl groups are −0.37, −0.01, and −0.170, respectively.[15] The alkoxycarbonyl or methoxyl group is the most electron-donating substituent, respectively, in the above-mentioned two sequences, but the difference of electron-donating ability among the substituents in each sequence is small. We suppose that the faster decomposition rate of DBPD than those of diacetyl and dibenzoyl peroxides arises not only from the simply electrostatic repulsion between the peroxyl oxygen atoms, but also from the structural factor of *t*-butoxycarboxyl group.[16]

t-Butyl α,α-dimethylbenzyl carbonate is produced by radical induced decomposition of DBPD (Eq. 10). It is clear from the effects of initial peroxide concentration on the rate and product (Table 1 and 2). But its amount is small. On the other hand, the yield of a radical coupling product, 1,1,2,2-tetramethyl-1,2-di-phenylethane (Eq. 11) is *ca.* 50%. Thus, di-primary or secondary alkyl peroxydicarbonates accept two types of induced decompositions, one is the attack to the peroxyl bond and the other is the abstraction of the α-hydrogen atom on the alkoxyl group.

Experimental

IR and NMR spectra were recorded on a JASCO A-3 and a JEOL JNM-MH-100 spectrometer, respectively. GC analysis was carried out by a Shimadzu GC-6A gas chromatograph using two columns: PEG 20 M, 5% on Shimalite AW-DMCS, 2 m; Silicon GE SE-30, 5% on Shimalite W, 0.5 m. GC-MS spectra were recorded on a JEOL JMS-D300 mass spectrometer.

Materials. 2-(*t*-Butoxycarbonyloxyimino)-2-phenylacetonitrile (Boc-ON) was obtained from Protein Research Foundation. Potassium hydroxide, THF, acetone, 2-methyl-2-propanol, cyclohexane, petroleum ether and dicyclohexyl-18-crown-6 (18-Crown-6) were the products of Wako Pure Chemical Ind. Co. Di-*t*-butyl peroxide was the product of Nippon Oil & Fats Co., Ltd. Cumene, chlorobenzene, cyclohexane, hexane, decane and octadecane, pure grade, obtained commercially, were stirred for several hours with concentrated sulfuric acid, washed with 10% sodium hydrogencarbonate and distilled water, dried with drying agents and distilled through a 24-in Vigreux column. The sample of 1,1,2,2-tetramethyl-1,2-diphenylethane was prepared by the literature method.[17] Purities of these materials were checked by melting point, IR, NMR, and/or GC analysis.

Di-t-Butyl Peroxydicarbonate. To a solution of dicyclohexyl-18-crown-6 (18-Crown-6)(81.9 g, 0.22 mol) in THF (200 cm^3) was added the fine powder of potassium hydroxide (14.5 g, 0.22 mol). After being stirred at room temperature till the powder was dispersed completely, 50% hydrogen peroxide (27.2 g, 0.40 mol) in THF (200 cm^3) was added dropwise to the mixture at 5 °C. Then the mixture was added dropwise at 2 °C for 15 min to Boc-ON (50.8 g, 0.20 mol) in THF (200 cm^3) and the reaction mixture was stirred again at 20 °C for 5 h. After petroleum ether (400 cm^3) was added to the reaction mixture the precipitate formed was filtered. The filtrate was washed four times with water (100 cm^3) and dried over anhydrous Na_2SO_4, and then the solvent was evaporated. The oily residue was crystallized twice from ether by cooling in Dry Ice-acetone to give di-*t*-butyl peroxydicarbonate (DBPD) as white crystals in 8.4% yield. On titration for active oxygen, the purity of the product was shown to be 98.4%. mp 32—34 °C (lit,[7] mp 28—30 °C); IR (CCl_4): 1820 (C=O) and 1795 cm^{-1} (C=O); ^{1}H NMR ($CDCl_3$): δ=1.58 (1H, s, *t*-CH_3). Found: C, 50.57; H, 7.98% Calcd for $C_{10}H_{18}O_6$: C, 51.27; H, 7.75%.

Di-t-Butyl Peroxymonocarbonate. To a suspension of the fine powder of potasium hydroxide (13.2 g, 0.20 mol) in THF (120 cm^3) there was added 80.5% *t*-butyl hydroperoxide (44.8 g, 0.40 mol), and stirred at room temperature till the powder was dispersed completely. Then to the mixture there was added dropwise Boc-ON (24.6 g, 0.10 mol) in THF (100 cm^3) at 30 °C for 1 h and stirred at 35 °C for 6 h. After petroleum ether (200 cm^3) was added to the reaction mixture, the precipitate formed was filtered. The filtrate was washed with 5% NaOH (50 cm^3) and water (50 cm^3), respectively twice, and dried over anhydrous Na_2SO_4, and the solvent was evaporated. The crude product was distilled through a short Vigreux column at 48—50 °C under decreased pressure of 0.9 mmHg (1 mmHg=133.322 Pa) (lit,[18] bp 46—47 °C at 0.47 mmHg) to give di-*t*-butyl peroxymonocarbonate (DBPM); IR (Neat): 1785 (C=O) and 1760 cm^{-1} (C=O); ^{1}H NMR (CCl_4): δ=1.46 (1H, s, *t*-CH_3) and (1H, s, Peroxyl *t*-CH_3). Found: C, 62.59; H, 6.93% Calcd for $C_9H_{18}O_4$: C, 62.84; H, 6.71%.

Kinetic Procedure. A weighed sample of DBPD was dissolved in a known volume of the solvent. Samples (generally 4 cm^3) of solution were pipetted into test tubes. The solutions were exhaustively evacuated, and the tubes were sealed in an atmosphere of nitrogen. The evacuation procedure consisted of cooling in a Dry Ice-acetone bath, evacuation on an oil pump and warming to 10 °C. This was repeated three times before sealing. The tubes were completely immersed in an oil thermostat regulated to ±0.05 °C. At successive time intervals, tubes were removed from the constant temperature bath and immersed in a Dry Ice-acetone bath. Then the concetration of DBPD in the solution was measured by iodometry titration. The reaction were followed up to 75—80% decomposition and exhibited first-order kinetics. The titration procedure involved the use of a

mixture (20:2) of isopropyl alcohol and acetic acid as the solvent, and saturated potassium iodide as the source of iodine. After boiling of 3 min for liberation of iodine, the iodine was titrated to a starch end point with 0.01 N thiosulfate for the dilute solution and 0.1 N thiosulfate for the concentrated solution. The values for the observed first-order rate constants and their standard deviations were calculated from the first-order rate equation using the method of least squares. The values for the activation parameters and their standard deviations were calculated from absolute rate equation of Eyring using the method of least squares.

Decomposition Products. DBPD in solutions was decomposed completely at 40 °C for 130 h and at 50 °C for 40 h and the solutions were analyzed by gas chromatography and mass spectrometer. Effluent peaks were identified by comparing retension times with those of authentic samples and by GC-MS spectra; product, *m/z* (rel. intensity); 2-methyl-2-propanol, 49 (100), 41 (17), and 31 (25); *t*-butyl α,α-dimethylbenzyl carbonate, 236 (M^+, 10), 180 (57), 162 (20), 119 (100) and 57 (65); 1,1,2,2-tetramethyl-1,2-diphenylethane, 238 (M^+, 4), 119 (100) and 91 (22). Cyclohexane and decane were added as internal standards, and the response factors were determined for the identified products with the column of PEG 20 M. The factor of *t*-butyl α,α-dimethylbenzyl carbonate was estimated by comparing its peak with that of 1,1,2,2-tetramethyl-1,2-diphenylethane taking into account the difference of the molecular weight. Di-*t*-butyl peroxide and DBPM were not detected from the gas chromatograph using the columns of PEG 20 M (DBPM was decomposed through the measurement.) and Silicone GE-SE-30 (DBPM was not decomposed through the measurement.) in comparision with the authentic samples.

Synthesis and Molecular Structure of the 2:1-Cycloadduct of 1-Methoxy-2-benzopyrylium-4-olate with Acenaphthylene

Jiro Toyoda, Toshikazu Ibata,* Hatsue Tamura, Kazuhide Ogawa, Tsuyoshi Nishino,† and Matsuji Takebayashi†

Institute of Chemistry, College of General Education, Osaka University, Toyonaka, Osaka 560

†*Department of Chemistry, Faculty of Science and Technology, Kinki University, Higashi-osaka, Osaka 577*

(Received March 5, 1985)

The $Cu(acac)_2$-catalyzed decomposition of *o*-methoxycarbonyl-α-diazoacetophenone in the presence of acenaphthylene gave a 2:1-cycloadduct of the corresponding carbonyl ylide, 1-methoxy-2-benzopyrylium-4-olate, with acenaphthylene along with *exo*- and *endo*-1:1-adducts. The molecular structure of the 2:1-adduct was determined by means of X-ray analysis. The colorless crystals of the adduct are triclinic with the space group $P\bar{1}$, and with the unit-cell dimensions of $a=12.104(2)$, $b=12.477(3)$, $c=9.112(2)$ Å, $\alpha=102.98(3)$, $\beta=110.16(2)$, $\gamma=70.65(1)°$, and $Z=2$. The structure was determined by direct methods and refined by block-diagonal least-squares methods. All hydrogen atoms were revealed by a difference-Fourier synthesis, and further least-squares refinement gave the final R value of 0.057 for 3681 observed reflections. The configurations of methine protons obtained by X-ray methods are compatible with the NMR coupling pattern of the adduct.

1,3-Dipolar cycloadditions of carbonyl ylide with acetylenic, ethylenic, and carbonyl compounds have been studied extensively from the theoretical and synthetic interests.[1] The authors have reported that 1-methoxy-2-benzopyrylium-4-olate (**3**) gave 1,3-dipolar cycloadducts with carbonyl compounds in the $Cu(acac)_2$-catalyzed decomposition of *o*-methoxycarbonyl-α-diazoacetophenone (**1**).[2] In the previous study of this series, the yields of *exo*- and *endo*-1:1-adducts (**4a** and **4b**) of (**3**) with acenaphthylene were reported to be not so high.[3] This may be attributed to the competitive reactions of the 1:1-adducts (**4**) and acenaphthylene toward the carbonyl ylide intermediate (**3**). In order to investigate the possibility of the reaction of the 1:1-adducts with (**3**), the decomposition of *o*-methoxycarbonyl-α-diazoacetophenone (**1**) was reexamined in the presence of acenaphthylene giving the expected 2:1-adduct (**5**), of which the structure was determined by X-ray analysis.

Experimental

The ^1H NMR and ^{13}C NMR spectra of the 2:1-adduct were measured on a Brucker NMR spectrometer, model MA 360 in $CDCl_3$, using TMS as an internal standard.

The Cu(acac)₂-catalyzed Decomposition of (1) in the Presence of Acenaphthylene. A benzene solution of **1** (6 mmol) was added drop by drop into a benzene solution of acenaphthylene (6 mmol) and $Cu(acac)_2$ (0.6 mmol) at 80 °C under stirring in N_2 atmosphere. The reaction products were isolated by column chromatography on silica gel using benzene as an eluent. Colorless crystals (**5b**; 1.56 mol, 26%) were obtained besides the *exo*- (**4a**; 16%) and *endo*-1:1-adducts (**4b**; 25%): (**5b**); colorless crystals; mp 165—166 °C; IR (KBr) 1709 cm^{-1} (C=O); ^1H NMR ($CDCl_3$) $\delta=3.50$ (s, 3H, OCH_3), 4.04 (dd, 1H, Ha, $J_{a,b}=6.7$, $J_{a,4}=1.3$ Hz), 4.05 (s, 3H, OCH_3), 4.39 (dd, 1H, Hb, $J_{a,b}=6.7$, $J_{b,c}=1.3$ Hz), 4.67 (d, 1H, Hc, $J_{b,c}=1.3$ Hz), 5.19 (s, 1H, Hd), 6.28 (d, 1H, H_{17}, $J_{17,18}=7.8$ Hz), 6.95 (t, 1H, H_{18}, $J_{17,18}=J_{18,19}=7.8$ Hz), and 7.1—8.0 (m, 11H, Ar); ^{13}C NMR ($CDCl_3$) 48.56 (d, C_2), 50.27 (q, C_{22}), 53.65 (q, C_{32}), 61.52 (d, C_{13}), 80.83 (s, C_{15}), 86.90 (d, C_{14}), 88.20 (d, C_{23}), 107.63 (s, C_1), 119.82 (s, C_{31}), 191.44 (s, C_{24}), and 21 signals in the region of $\delta=118.69$—145.68. Found: C, 76.21; H, 4.87%. Calcd for $C_{32}H_{24}O_6$: C, 76.18; H, 4.80%.

X-Ray Crystal Analysis of 5. The crystal data of **5** are listed in Table 1 along with the experimental details. The X-ray intensity data were measured on a Rigaku four-circle diffractometer with Ni-filtered Cu $K\alpha$ radiation. The number of nonzero reflections used in the structural determination were 3681.

The space group $P\bar{1}$ was confirmed by a statistical distribution of E values and a successful refinement of the structure.

Using 300 reflections with $|E|\geq 1.78$, the crystal structure was determined by direct methods with the MULTAN 78 program.[6] The E-map computed with the phase set of the highest combined figure of merit (2.708) revealed the positions of all the non-hydrogen atoms. The isotropic refinement, followed by anisotropic refinement reduced R to 0.094. The hydrogen atoms were located on a difference map and their positional parameters were refined together with isotropic thermal parameters, while the other atoms were refined anisotropically by block-diagonal least-squares. The final R value was 0.057. The function minimized was

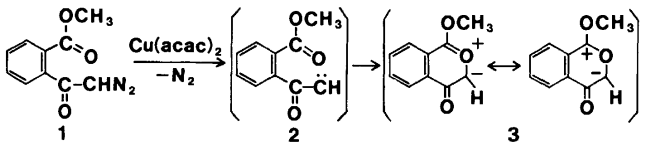
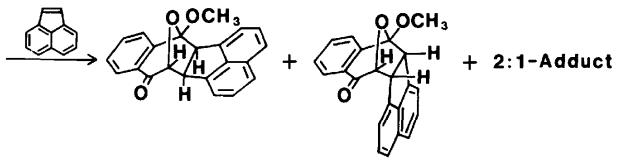
$\sum w(|F_o|-|F_c|)^2$ with the following weighting scheme: $w=1/(\sigma(F_o)^2+0.0063|F_o|+0.0006|F_o|^2)$. All the atomic scattering factors were taken from the "International Tables for X-ray Crystallography." The computations were carried out on an ACOS-S900 computer at the Crystallographic Research Center, Institute for Protein Research Laboratory, Osaka University using "The Universal Crystallographic Computing System-Osaka." Table 2 lists the final atomic and thermal parameters with their estimated standard deviations. The table of the best planes is deposited as Document No. 8534 at the Office of the Editor of Bull. Chem. Soc. Jpn. The bond distances and angles are given in Figs. 3 and 4. The atom numbering is also shown in these figures.

Results and Discussion

Reaction of o-Methoxycarbonyl-α-diazoacetophenone (1) with Acenaphthylene. The ^{1}H NMR spectrum of the 2:1-adduct (**5b**) has signals of four nonaromatic methine protons Ha, Hb, Hc, and Hd at δ 4.04 (dd), 4.39 (dt), 4.67 (d), and 5.19 (s), respectively.

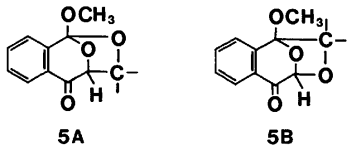
The coupling patterns of protons Ha, Hb, and Hc are quite similar to those of methine protons of *exo*-1:1-adduct (**4a**).[3] This means that each pair of protons Ha–Hb and Hb–Hc locates on adjacent carbons in a similar stereochemistry observed in **4a** and that Hd is on a carbon having no vicinal proton. Therefore the 2:1-adduct is assumed to be the 1,3-dipolar cycloadduct of **3** on carbonyl group of *exo*-1:1-adduct (**4a**). This assumption was confirmed by the fact that the yield of **5b** decreased to 3% with the increase of the yields of **4a** and **4b** (25 and 34%, respectively) when 10 molar excess





4a + 3 ⟶ 5

Scheme 1.



Scheme 2.

of acenaphthylene was used. The finding that the decomposition of **1** in the presence of **4a** gave the same 2:1-adduct (**5**) along with the dimers of **3**[4] is also consistent with the above consideration. On the other hand, the reaction of **3** with *endo*-1:1-adduct (**4b**) in a similar procedure did not give the 2:1-adduct but gave dimers of **3**. This indicates the poor 1,3-dipolarophilicity of the *endo*-1:1-adduct toward **3** in comparison with the reactivity of the *exo*-1:1-adduct (**4a**).

The reaction site of the 1:1-adduct (**4a**) in this reaction is assumed to be carbonyl group.[2,5] The CPK model of **4a** and **4b** reveals that the *endo*-adduct (**4b**) does not allow the approach of the carbonyl ylide (**3**) to the carbonyl group of **4b** due to the structural crowdedness caused by adjacent *o*-phenylene and acenaphthenylene groups.

In general, two regio-isomers (**5A** and **5B**) are possible in the cycloaddition of the carbonyl ylide (**3**) with carbonyl compounds. Of these, **5A** agrees with the ^{13}C NMR spectrum which shows a signal of quartanary carbon (C_{31}) of orthocarboxylate, at very low field (119.82 ppm). Four stereoisomers (**5a—d**) and their enantiomers are feasible in the **5A**-type adducts as is shown in Fig. 1. The stereoisomers **5a**, **5b**, **5c**, and **5d** are described as *RRR*, *RRS*, *RSR*, and *RSS*, respectively in *R–S* description, depending upon the stereochemistry at C_{14}, C_{15}, and C_{23}. The isomers **5a** (*RRR*) and **5b** (*RRS*) have the same stereochemistry at both C_{14} and C_{15}, but different at C_{23}. The **5c** (*RSR*) and **5d** (*RSS*) are also in the same relationship. The isomers **5a** (*RRR*) and **5c** (*RSR*) have the same

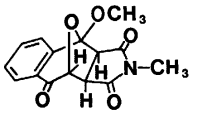
stereochemistry at C_{14} and C_{23}, but different at C_{15}. In these isomers the stereochemistry at C_{31} is prescribed by that at C_{23}. Therefore, there is no need to describe the stereochemistry at C_{31}.

Molecular Structure. The molecular structure of **5** determined by the X-ray analysis is given in Figs. 2—4. The results indicate that **5** has the *RRS*-structure (**5b**), which is one of the four possible structures deduced from the NMR data. The CPK-model inspection shows that the approach of **3** to the carbonyl group of the *exo*-1:1-adduct (**4a**) in the manner to give **5b** is that of the most favorable in stereochemistry. The present compound has two benzene-fused bicyclo[3.2.1]-ring systems, 8-oxabicyclo[3.2.1]-2-octene and 7,8-dioxabicyclo[3.2.1]octa-2-ene-4-one, which are combined in spiro form. Their corresponding dihedral angles are similar to each other as shown in the deposited Table. This conformation is also similar to that of the *exo*-adduct (**6**) between **3** and *N*-methylmaleimide.[7] The bond distances and angles of the 2:1-adduct (**5b**) except the C(2)-C(13) bond distance are comparable to those of **6**. The C(2)-C(13)



6

bond distance, 1.571 Å, in the acenaphthene ring of **5b**, is considerably longer than the corresponding one (1.545 Å) of the acenaphthene-chloranile molecular complex,[8] while the bond distance is comparable to the corresponding ones (1.567, 1.562 Å) of the *cis*-dimer of acenaphthylene.[9] Two of the intramolecular distances (O···H) between the bridged oxygen atoms and the methyl-hydrogen atoms are shorter than the van der Waals distance as shown in Table 3.

Table 3. Intramolecular distances between the bridged oxygens and the methyl hydrogens

O(2)···H(221)	3.24(3) Å
O(2)···H(222)	3.47(3)
O(2)···H(223)	2.36(4)
O(4)···H(321)	3.44(3)
O(4)···H(322)	3.66(3)
O(4)···H(323)	2.54(3)

Coupling Constant. In general, coupling constants of the vicinal protons depend mainly on the dihedral angles and an equation was proposed by Karplus to express the relationship between them.[10] The torsion angles Ha-C(2)-C(13)-Hb and Hb-C(13)-C(14)-Hc were found to be 3.8° and −97.6°, respectively, according to the present X-ray crystal structure determination. The substitution of these torsion angles in the Williamson-Johnson's equation[11] gave calculated values of coupling constants, $J_{a,b}$=10.0 Hz and $J_{b,c}$=−0.11 Hz, which are fairly in accord with the observed values $J_{a,b}$=6.7 Hz and $J_{b,c}$=1.3 Hz.

The coupling between ^{13}C and H separating by three bonds has recently been reported to be useful for the

determination of conformation of rigid cyclic systems[12] and an equation (Eq. 1) to calculate the $J(^{13}C, H)$ using the value of the dihedral angles has been reported by Wasylishen and Schaefer.[13]

$$^{3}J(^{13}C,H) = 4.26 - 1.00\cos\theta + 3.56\cos 2\theta \quad (1)$$

The coupling constants $^{3}J(^{13}C_{14}\text{-Hd})$=4.83 Hz and $^{3}J(^{13}C_{23}\text{-Hc})$=3.60 Hz calculated by application of the torsion angles, $C_{10}\text{-}C_{15}\text{-}C_{23}\text{-Hd}$=33.4° and $C_{23}\text{-}C_{15}\text{-}C_{14}\text{-Hc}$=43.0°, to the equation 1 are consistent with the observed values, $^{3}J(^{13}C_{14}\text{-Hd})$=4.96 Hz and $^{3}J(^{13}C_{23}\text{-Hc})$=2.76 Hz. This also supports the structure of the 2:1-adduct (**5b**).

Anisotropic Effect of Benzene Ring. The ^{1}H NMR spectrum of the 2:1-adduct (**5b**) has a doublet signal of an aromatic proton (H_{17}) at a little higher field (δ 6.28) than the signals of the usual aromatic protons. The high field shift may be attributed to the anisotropic effect of ring current of benzene. The X-ray study indicates that the aromatic hydrogen, H_{17}, locates close to the benzene ring ($C_{25}\text{-}C_{30}$); the perpendicular drawn from the H_{17} to the plane of the benzene ring ($C_{25}\text{-}C_{30}$) has a length of 2.60 Å, and the distance from the foot of the perpendicular to the center of the benzene ring is 1.96 Å.[7] The estimation of the ring current effect according to the Johnson-Bovey's ring current effect map[14] indicates that the high field shift of H_{17} is δ 0.56 ppm. This may assign the signal at δ 6.28 to H_{17}.

The authors indebt to Dr. Masami Sawada and Mr. Yoshio Takai of ISIR of Osaka University for their fruitful discussion and measurement of NMR spectra.

Vacuum UV Photolyses of Some Bichromophoric Alkenes Possessing Hydroxyl or Methoxycarbonyl Group

Yoshihisa INOUE,* Kazuyoshi GOAN, and Tadao HAKUSHI
Department of Applied Chemistry, Himeji Institute of Technology, 2167 Shosha, Himeji, Hyogo 671-22
(Received April 8, 1985)

The direct photolyses at 185 nm of some naturally occurring and related bichromophoric alkenes possessing hydroxyl or methoxycarbonyl group at an allylic, homoallylic, or remote position gave the geometrical isomers as the major photoproducts detectable on gas chromatography. The isomerization yield was highly sensitive to the functional group introduced and its position; allylic alkenols gave poor yields, while both functionalization at a remote position and esterification of the hydroxyl group improve the photoisomerization yield.

The vacuum UV light has recently been used extensively in the investigation of the photochemistry of simple unsaturated compounds like alkenes and alkynes in solution phase.[1,2] With simple alkenes, a wide variety of novel singlet photobehavior *via* π,π^*, π, R(3s), and π,σ^* excited states has been reported to occur upon direct excitation in the vacuum UV, although the cis-trans photoisomerization, where accessible, is the dominant process in most cases.[1,2] On the other hand, much less effort has been done in order to reveal the effects of an additional functional group upon the fundamental photobehavior of simple alkenes, except for the works by Srinivasan[3] and by us.[4] The investigations on the photochemistry of bichromophoric alkenes not only afford insights into the nature of the excited double bond but also extend the scope and limitations of the vacuum UV photochemistry.

In this paper we report our results on the direct photolyses at 185 nm of bichromophoric alkenes possessing a hydroxyl or methoxycarbonyl group at an allylic, homoallylic, or remote position.[5] The bichromophoric alkenes examined in the present work are *trans*-2-buten-1-ol(**1t**), *cis*-3-hexen-1-ol or "leaf alcohol"[6] (**2c**), geraniol (**3t**), nerol (**3c**), methyl oleate (**4c**), methyl elaidate (**4t**), *cis*-3-hexenyl acetate (**5c**), and neryl acetate (**6c**). Most of these are naturally occurring products or their immediate derivatives, and, therefore, the present work will shed light on this relatively unexplored region of photochemistry/natural product chemistry.

Another purpose of this paper is to test the suitability of water as a solvent for the vacuum UV photolysis by using water-soluble alkenols. The solvent available in the vacuum UV has long been restricted to the nonpolar, aprotic saturated hydrocarbons and even an alcohol such as methanol as a polar, protic solvent cannot be used due to the extinction coefficient of several handreds in this wavelength region,[7] whereas water is almost transparent at 185 nm.[7]

Results and Discussion

Photoisomerization. The direct irradiations of the bichromophoric alkenes **1—6** were performed at 185 nm in pentane and/or in water under a nitrogen atmosphere to give the geometrical isomers as the major photoproducts detected by GC analysis and the other valence isomers were not detected in significant yields. The isomerization yield varied drastically depending upon the functional group introduced and its position and also upon the solvent used. The isomerization yields at low and moderate conversions are listed in Table 1.

The direct photolyses of the allylic alcohols **1t**, **3t**, and **3c** in pentane afforded the corresponding geometrical isomers only in poor yields below 40%, while the homoallylic alcohol **2c** gave somewhat improved yield. The irradiation of **1t** or **2c** in water resulted merely in a similarly low or much reduced yield. From the mechanistic point of view, it is noted that no valence isomers other than cis-trans isomer were produced in significant yields and that the prolonged irradiations of **2c** in water led to the accumulated deposition of white precipitate, which was not characterized chemically due to the limited sample availability but is inferred to be water-insoluble polymeric

TABLE 1. DIRECT cis-trans PHOTOISOMERIZATION AT 185 NM OF SOME BICHROMOPHORIC ALKENES

Alkene (10 mM)	Solvent	Irradiation time/min	Conversion /%	Isomerization yield/%[a]
1t	Pentane	10	26	16
		20	36	20

		20	21	25

a) Chemical yield based on alkene consumed. b) Water-insoluble polymeric product was produced as white precipitate.

product. Above results suggest that the major process which occurred upon photolysis of the alkenols **1**—**3** is not the geometrical photoisomerization but the polymerization initiated probably by some radicals generated by the high-energy radiation in the vacuum UV. However, since analogous radical process which competes well with the cis-trans isomeization has not been reported in the photochemistry of simple acyclic alkenes,[1,2] this unexpected photobehavior must originate from the special electronic feature of the alkenols. The presence of oxygen atom at a weakly interactable, especially β, position may change the excitation profile of the alkenes significantly. The $\pi_{C=C} \rightarrow \sigma^*_{\pi CH_2}$ charge-transfer excitation is tentatively proposed as an electronic transition responsible for the radical formation,[3,8-10] since, in both semiempirical and *ab initio* calculations, the π atomic orbital ($\sigma_{\pi CH_2}$) of allylic CH_2 group has shown to mix readily with the π molecular orbital ($\pi_{C=C}$) of C=C bond. In particular, an oxygen atom β to C=C bond may lower the level of the σ^*_π orbital through further participation of its lone-pair electrons to the above mixing. The resulting electronic configuration with a reduced C-H bond order may facilitate the fission of the allylic C-H bond, giving rise to hydrogen and allylic radicals. The introduction of a hydroxyl group into an allylic position of alkene reduces the bond dissociation energy of the allylic C-H bond by 30—40 kJ mol^{-1}.[11] This may also facilitate the allylic bond fission in conjunction with the stabilization of the resulting allylic radical by the electron-donating hydroxyl group. The reason for much reduced isomerization yield upon photolysis

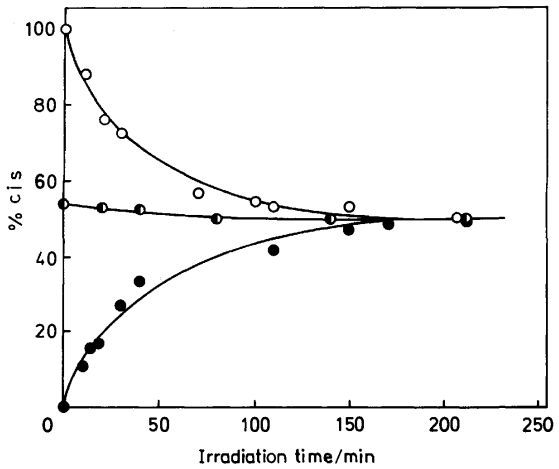

Fig. 1. Percent of the *cis*-isomer (**4c**) in **4** recovered on direct photolysis of **4** at 185 nm in pentane; initial composition: (○) 100% **4c**; (○) 54% **4c**; 46% **4t**; (●) 100% **4t**.

of **2c** in water is not necessarily clear, but the nucleophilic trapping by water of π, 3s Rydberg excited state of alkene may consume the alkene affording addition products, *i.e.* diols,[12] as has been shown by Kropp *et al.* in the direct photolyses of tri- and tetrasubstituted alkenes at >200 nm,[1] and the possibility is not regorously ruled out that the use of a highly polar solvent may change the population of the excited states generated, which leads to different distribution of products.

In sharp contrast to the alkenols, methyl oleate **4c** and methyl elaidate **4t**, possessing a methoxycarbonyl group at a remote position, interconverted mutually in excellent yields upon direct irradiation, as is the case with simple alkenes.[1,2] Although the major reason for the facile isomerization in this particular case is probably the functionalization at a remote position in **4**, it is also expected that the methyoxycarbonyl group may improve the isomerization yield. Indeed *cis*-hexenyl acetate **5c** prepared by esterification of hexenol **2c** gave the trans-isomer **5t** in fairly improved yield as compared with **2c**. However this method is no longer applicable for the allylic alcohol. Neryl acetate **6c** isomerized photochemically only in low yields which are comparable with those for nerol **3c** itself. Thus the attempt to improve the photoisomerization yield by esterification is successful only for the alkenols possessing a hydroxyl group at a homoallylic or more remote position.

Photostationary State. Since the mutural photoisomerization between oleate **4c** and elaidate **4t** was highly efficient, the irradiation at 185 nm was prolonged up to 3 h in order to obtain the *cis/trans* ratio at the photostationary state, $(c/t)_{pss}$. As can be seen from Fig. 1, the prolonged irradiation of any given compositions of **4c** and **4t** afforded the identical ultimate value of 50% cis or $(c/t)_{pss}$ of 1.0. Since the reported molar extinction coefficients of **4c** and **4t** at

Table 2. Photostationary state *cis/trans* ratios on direct photoisomerizations at 185, 214, and 229 nm of methyl oleate **4c** and methyl elaidate **4t** in pentane

Excitation wavelength, nm	$(c/t)_{pss}$
185	1.0
214	1.2
229	0.43

185 nm are 12800 and 11600 $M^{-1}cm^{-1}$, respectively,[13] the decay ratio from the excited singlet (^1p) to **4c** an **4t**, k_{dc}/k_{dt}, is calculated, from the equation $(c/t)_{pss}=(\varepsilon_t/\varepsilon_c)(k_{dc}/k_{dt})$,[14] to be 1.1, which is reasonable for an acyclic alkene.

Similar prolonged irradiation of pentane solutions of a given mixture of **4** was run at 214 and 229 nm by using zinc and cadmium lamps, respectively. The photostationary states were attained at both wavelengths affording the $(c/t)_{pss}$ ratios listed in Table 2. The present $(c/t)_{pss}$ values obtained in the direct excitations of **4** at 185 and 214 nm are much higher than those reported for the semiconductor photosensitization, $(c/t)_{pss}=0.20—0.44$,[15,16] and for the triplet photosensitization, $(c/t)_{pss}=0.21—0.74$,[16] of the same compound, and therefore the direct photoisomerization merits synthetic application.

Experimental

General. Infrared spectra were obtained on a Jasco A-100 spectrometer. Mass spectra were recorded at 70 eV using a Hitachi RMU-6E instrument. ^1H NMR spectra were obtained on a Jeol JMX-60 sepctrometer in chloroform-*d* solution containing 1% tetramethylsilane as an internal standard. Gas chromatographic analyses of the photolyzates from **1**, **2**, **3**, **5**, and **6** were performed on a Yanaco G-180 or G-1800 instrument equipped with a System Instruments Chromatocorder 11 using columns of 20% PEG-20M (1.5 m) at 100 °C, 20% PEG-20M (1.5 m) at 120 °C, 20% PEG-20M (1.5 m) at 180 °C, 10% DEGS (3 m) at 120 °C, and 10% APL (65 cm) at 100 °C, respectively; the internal standards employed for pentane (water) solutions were cyclooctane (*t*-butyl alcohol), cyclooctane (*t*-butyl alcohol), dodecane, dodecane, and undecane, respectively. Liquid chromatographic analyses of the photolyzates from **4** were run on a Yanaco L-4000W instrument equipped with a Yanaco M-315 UV monitor, operated at 205 nm, and a Waters Data Module M730 using a 25 cm column of ODS-T with a water/methanol (2/98) eluent at a flow rate of 1.0 mL min^{-1}; the internal standard added after irradiation was *trans*-2-octene. Under the above conditions, the cis-trans isomers of **1—6** and the internal standard were seprated satisfactorily in each case.

Materials. Commercially available *trans*-2-buten-1-ol (**1t**), *cis*-3-hexen-1-ol (**2c**), geraniol (**3t**), and nerol (**3c**) (all from Tokyo Kasei) were fractionally distilled prior to use. Methyl oleate (**4c**) and methyl elaidate (**4t**) (both from Tokyo Kasei) were used without further purification.

cis-3-Hexenyl acetate (**5c**) and neryl acetate (**6c**) were prepared from the corresponding alcohols **2c** and **3c**. To a stirred mixture of **2c** or **3c** (0.07 mol) and *N,N*-dimethylaniline (0.07 mol) in dry ether (100 mL) was added dropwise acetyl choride (0.07 mol), and the mixture was heated to reflux for 2 h. The subsequent workup and fractional distillation gave the product **5c** or **6c** in 90—95% yield. **5c**: bp 105 °C/130 Torr†; MS *m/z* 142 (M^+); IR (neat) 3020, 2960, 2875, 1745, 1660, 1240, 1040 cm^{-1}; ^1H NMR δ=4.9—5.6 (m, 2H), 3.93 (t, 2H), 1.8—2.6 (m, 4H), 1.98 (s, 3H), 0.95 (t, 3H). **6c**: bp 115 °C/13 Torr; MS *m/z* 196 (M^+); IR (neat) 3025, 2970, 2930, 2850, 1740, 1675, 1235, 1030, 960, 830 cm^{-1}; ^1H NMR δ=4.8—5.5 (m, 2H), 4.47 (d, 2H), 2.0—2.2 (m, 7H), 1.67 (m, 9H).

Photolysis. A pentane or aqueous solution containing an alkene **1—6** (10 mM)†† and an internal standard (2—3 mM) was charged in a Suprasil tubing (1 cm o.d.) and bubbled with nitrogen gas for 10 min at 0 °C. The solution was irradiated at room temperature by using a 30-W mercury resonance lamp made of Suprasil (Eikosha), the light path being flushed with nitrogen gas; the effective radiation in the present case is the 185 nm resonance line, since another intense resonance line at 254 nm is not absorbed by the alkenes **1—6**. The photolyses at 214 and 229 nm were conducted by using 16-W zinc and cadmium resonance lamps (Philips), respectively.

Identification. The photoproducts from **1t**, **2c**, **3**, **4**, **5c**, and **6c** were identified by the comparison of GC retention time of the product with that of the authentic specimen obtained commercially or prepared independently, using a couple of columns of different polarity. The authentic specimens of *trans*-3-hexen-1-ol (**2t**)(Nakarai), **3c**, **3t**, **4c**, **4t**, and geranyl acetate (**6t**)(Nakarai) were commercially available. *trans*-3-Hexenyl acetate (**5t**) was prepared from the corresponding alcohol **2t** according to the esterification procedure mentioned above. The pure specimen of *cis*-2-buten-1-ol (**1c**) was isolated from the photolyzate of **1t**. Preparative-scale irradiation of a pentane solution of **1t** (50 mM) were performed for 5 h with continuous bubbling of nitrogen gas and stirring in an immersion-well reactor (130 mL) using the same lamp. The solvent was distilled fractionally and the residue obtained was trap-to-trap distilled. The trap-distillate was subjected to preparative gas chromatography to give the pure product of **1c**. **1c**: IR (neat) 3350, 3030, 2930, 2880, 1660, 1035, 980, 900 cm^{-1}; ^1H NMR δ=5.57 (m, 2H), 4.17 (d, 2H), 2.5 (br, 1H), 1.67 (d, 3H). **5t**: IR (neat) 3030, 2960, 2930, 2870, 1740, 1660, 1240, 1040, 965, 900 cm^{-1}; ^1H NMR δ=5.2—5.5 (m, 2H), 3.99 (t, 2H), 1.8—2.5 (m, 4H), 2.00 (s, 3H), 0.95 (t, 3H).

Generous support of this work by a grant from the Shorai Foundation for the Promotion of Science and Technology (Grant No. 005) is gratefuly acknowledged.

5) Since typical absorption coefficients for simple alcohols and carboxylic esters are much smaller (by factors of 20—100) than those for simple alkenes (Ref. 8), more than 95% of the incident light is absorbed by the olefinic chromophore and the photoreaction is initiated by the excitation of a π electron. Indeed, no specific difference is seen between simple and bichromophoric alkenes at least above 205 nm, where only a tail of the major absorption band around 185 nm is observed.

(Received April 10, 1985)

The structures of a 1:2 molecular complex(I) of 1,1,6,6-tetrakis(2,4-dimethylphenyl)-2,4-hexadiyne-1,6-diol with ethanol, a 1:1 complex(II) of 1,1-bis(2,4-dimethylphenyl)-2-butyn-1-ol with ethanol, and a 1:1 complex (III) of 9-hydroxy-9-(1-propynyl)fluorene with methanol have been determined by X-ray crystallography. The crystal data are: I, $C_{42}H_{50}O_4$, $P\bar{1}$, a=8.249(3), b=9.522(5), c=14.803(8)Å, α=100.95(4), β=110.82(4), γ=113.08(3)°, Z=1, and R_f=0.105 for 1834 observed Mo $K\alpha$ data; II, $C_{22}H_{28}O_2$, $P\bar{1}$, a=8.142(2), b=11.281(3), c=12.262(4)Å, α=102.76(2), β=97.08(2), γ=111.19(2)°, Z=2, and R_f=0.073 for 2104 data; III, $C_{17}H_{16}O_2$, $P2_1/a$, a=8.641(5), b=10.883(5), c=30.63(2)Å, β=92.88(4)°, Z=8, R_f=0.154 for 1885 data. The crystal structures of I and II are closely related and both feature planar hydrogen-bonded $(OH)_4$ rings centered at centrosymmetric sites. In III, the fluorene and methanol molecules belong to two independent sets, and the molecular components in each set are alternately linked by hydrogen bonds to form infinite zigzag chains parallel to the a axis.

Previously, we reported that 1,1,4,4-tetraphenyl-2-butyne-1,4-diol (**1**) and 1,1,6,6-tetraphenyl-2,4-hexadiyne-1,6-diol (**2a**) form 1:1 and 1:2 crystalline inclusion compounds with various guest molecules, which show the presence of strong hydrogen bonds *via* their IR spectra.[1,2] X-Ray single-crystal analysis of the complexes **1**·$(CH_3)_2CO$[2] and **2a**·$(CH_3)_2CO$[3] disclosed that the acetone moiety is included in a channel and surrounded by phenyl groups, being bound to the anti-oriented OH groups of the host through hydrogen bonding.

If surrounding of the guest species by phenyl rings is important for the stabilization of the complex, an effective host molecule might be derived by employing a more bulky aromatic substituent. Proceeding along this line of reasoning, we subsequently found that 1,1,6,6-tetrakis(2,4-dimethylphenyl)-2,4-hexadiyne-1,6-diol (**2b**) forms a stable 1:2 complex (I) with ethanol, even though **2a** fails to do so. The complexation Phenomenon is potentially useful for the isolation of ethanol from aqueous solution. However, complex I turned out to be too stable for the extraction of ethanol by the usual method, and it appeared that the 2,4-dimethylphenyl group might hinder the escape of ethanol molecules from the channels in the crystalline complex.

We then designed 1,1-diphenyl-2-propyn-1-ol (**3a**), 1,1-bis(2,4-dimethylphenyl)-2-propyn-1-ol (**3b**), and 1,1-bis(2,4-dimethylphenyl)-2-butyn-1-ol (**3c**) as potentially useful host molecules which would include ethanol more loosely than **2b** because one side of the molecular skeleton is opened. Actually, we did find that ethanol can easily be removed from its complexes with **3b** and **3c** by evaporation, even though **3a** does not include ethanol. Another variation in the design of related host systems is achieved by making the two aromatic rings coplanar, as in 9-(1-propynyl)-9-fluorenol (**4**), which has been shown to be an effective reagent for extracting ethanol from its aqueous solution.[4]

In order to test the above hypotheses and as part of our continuing studies on the synthesis and structural characterization of inclusion compounds, we have determined the crystal structures of I, a 1:1 complex (II) of **3c** with ethanol, and a 1:1 complex (III) of **4** with methanol, which are reported in the present paper. The analogous ethanol adduct turned out to be too unstable for X-ray analysis.

Experimental

1,1-Bis(2,4-dimethylphenyl)-2-propyn-1-ol (3b). A solution of Na (49 g) in liquid NH_3 (1.5 l) was stirred at −33 °C for 3 h in the presence of a catalytic amount of $Fe(NO_3)_3 \cdot 9H_2O$. The resulting $NaNH_2$ suspension was cooled to *ca.* −60 °C and acetylene gas bubbled through it for 2 h, and then a solution of 2,2′,4,4′-tetramethylbenzophenone (380 g) in THF (500 ml) was added and stirred for 2 h. The residue left after the evaporation of NH_3 was decomposed with dil HCl and extracted with ether. The ether solution

was washed with water and dried over Na_2SO_4. Evaporation of the solvent gave crude **3b**, recrystallization of which from benzene resulted in pure **3b** (350 g, 87%) as colorless needles, mp 61—63 °C, NMR ($CDCl_3$), 6.9—7.8 (6H, m, Ar), 2.83 (1H, s, =CH), 2.57 (1H, s, OH), 2.30 (6H, s, Me), and 2.02 (6H, s, Me). Found: C, 86.11; H, 7.48%. Calcd for $C_{19}H_{20}O$: C, 86.32; H, 7.63%.

Recrystallization of **3b** in ethanol gave a 1:1 complex which melted at 40—48 °C. NMR ($CDCl_3$) 6.9—7.8 (6H, m, Ar), 3.68 (2H, q, J=6.8 Hz, CH_2), 2.83 (1H, s, CH), 2.30 (6H, s, Me), 2.02 (6H, s, Me), and 1.21 (3H, t, J=6.8 Hz, Me). Found: C, 81.15; H, 8.37%, Calcd for $C_{21}H_{26}O_2$: C, 81.25; H, 8.44%.

1,1-Bis(2,4-dimethylphenyl)-2-butyn-1-ol (3c). To a $NaNH_2$ suspension prepared from Na (49 g) and liquid NH_3 (1.5 l), 1,2-dichloropropane (80 g) was added and stirred for 1 h. To this solution, 2,2′4,4′-tetramethylbenzophenone (140 g) dissolved in THF (200 ml) was added and stirred for 2 h. The residue left after the evaporation of NH_3 was decomposed with dil HCl and extracted with ether. The ether solution was washed with water and dried over Na_2SO_4. Evaporation of the solvent gave crude **3c** as an oil, crystallization of which from ethanol yielded a 1:1 complex (140 g, 76%), II, colorless prisms, mp 64—65 °C. NMR ($CDCl_3$) 6.8—7.7 (6H, m, Ar), 3.68 (2H, q, J=6.8 Hz, CH_2), 2.27 (6H, s, Me), 1.98 (6H, s, Me), 1.82 (3H, s, Me), and 1.21 (3H, t, J=6.8 Hz, Me). Found: C, 85.89; H, 5.70%. Calcd for $C_{22}H_{28}O_2$: C, 86.12; H, 5.68%.

1,1,6,6-Tetrakis(2,4-dimethylphenyl)-2,4-hexadiyne-1,6-diol (2b). A solution of **3b** (100 g) and CuCl (10 g) in acetone (500 ml) containing pyridine (50 ml) was stirred under O_2 atmosphere for 12 h. When 3 M† HCl (500 ml) was added to the reaction mixture, **2b** crystallized out. Recrystallization from benzene gave pure **2b** as colorless prisms (90 g, 90%), mp 192—193 °C. NMR ($CDCl_3$) 6.90—7.73 (12H, m, Ar), 2.29 (12H, s, Me), and 1.98 (12H, s, Me,). Found: C, 86.47; H, 7.44%. Calcd for $C_{38}H_{38}O_2$: C, 86.65; H, 7.27%.

Recrystallization of **2b** from ethanol resulted in a 1:2 complex, **I**, which does not have a clear mp. NMR ($CDCl_3$) 6.90—7.73 (12H, m, Ar), 3.68 (4H, q, J=6.8 Hz, CH_2), 2.29 (12H, s, Me), 1.98 (12H, s, Me), and 1.21 (6H, t, J=6.8 Hz, Me). Found: C, 81.39; H, 7.87%. Calcd for $C_{42}H_{50}O_4$: *c*, 81.51; H, 8.14%.

X-Ray Data Collection. All three complexes turned milky upon exposure to air, and each selected crystal was therefore enclosed in an alcohol atmosphere inside a 0.5 mm Lindemann glass capillary. Determination of the crystal class and orientation matrix was performed on a Nicolet R3m four-circle diffractometer according to established procedures[5] using graphite-monochromatized Mo $K\alpha$ radiation (λ=0.71069 Å). Accurate unit-cell parameters were derived from a least-squares fit of the angular settings for 25 reflections in the range 14°<2θ<18°. Reflection intensities were recorded at an ambient laboratory temperature of 22 °C, and three standards monitored every 50 data measurements showed only random fluctuations within ±2% of their mean values. The crystal data and processing parameters for I—III are sumarized in Table 1.

Structure Determination and Refinement

The raw intensities were processed with the learnt-profile procedure,[6] and redundant and equivalent reflections were averaged to yield a set of structure amplitudes following corrections for Lorentz and polarization factors. No absorption correction was applied. For each complex the statistical distributions of the normalized structure factors strongly favoured a

† 1 M=1 mol dm^{-3}.

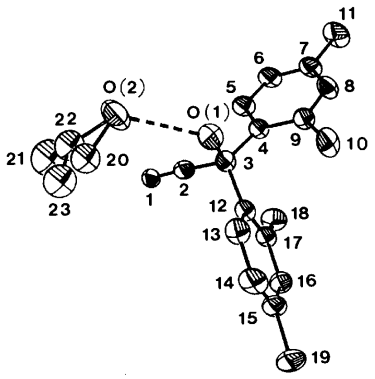

Fig. 1. Perspective view and atom labelling of the asymmetric unit in I. Both orientations of the disordered ethyl group are shown, and the broken line represents an O(1)···O(2) hydrogen bond.

centrosymmetric space group, and structure solution was achieved by direct phase determination based on negative quartets.[7]

In complex I, the 1,1,6,6-tetrakis(2,4-dimethylphenyl)-2,4-hexadiyne-1,6-diol molecule is situated at a center of symmetry, and the carbon atoms of the ethanol molecule exhibit two-fold orientational disorder as illustrated in Fig. 1. The disordered atoms C(20)–C(23) were assigned half weight and isotropic temperature factors, whereas the remaining non-hydrogen atoms were varied anisotropically. The aromatic H atoms were generated geometrically (C–H bond length fixed at 0.96Å) and allowed to ride on their respective parent C atoms.

In complex II the methyl group of the ethanol moiety is two-fold disordered and was accordingly represented by two isotropic "half-carbon" atoms. Anisotropic thermal parameters were assigned to all other non-hydrogen atoms. The aromatic H atoms were treated with the riding model, and the methyl groups were handled as rigid groups in including the contribution of the hydrogen atoms with isotropic temperature factors.

In complex III, there exist two sets of crystallographically independent molecules in the unit cell. In view of the unfavourable data-to-parameter ratio in this structure, all non-hydrogen atoms were refined isotropically except those belonging to the 1-propynyl and hydroxyl groups and the methanol molecules. To further reduce the number of variables, the benzene rings of the fluorene moiety were treated as regular hexagons of edge 1.395Å. The aromatic H atoms were assigned isotropic temperature factors and allowed to ride on their respective parent C atoms.

Computations were performed on a Data General Corporation Nova 3/12 minicomputer using the SHELXTL program package.[8] Analytic expressions of atomic scattering factors were employed, and anomalous dispersion corrections were incorporated.[9] Blocked-cascade least-squares refinement[10] converged to the R indices and parameters listed in Table 1.

Results and Discussion

Perspective views, each with atom labelling, of the asymmetric units in complexes I, II, and III are shown in Figs. 1, 2, and 3, respectively. The final atomic parameters are listed in Tables 2—4. The dimensions of the **3c** host molecule in II closely match the corresponding values for one-half of molecule **2b** in I, and those for the two independent **4** molecules in III are in satisfactory agreement (Table 5).

In the crystal structure of I (Fig. 4), the hexadiynediol molecule **2b** occupies a centrosymmetric site at the center of the unit cell, and its hydroxyl groups are linked by hydrogen bonds to neighboring ethanol molecules, generating a layer structure which features $(OH)_4$ rings centered at a second set of centrosymmetric sites at (0,0,1/2). The dimensions of the planar, hydrogen-bonded $(OH)_4$ ring are: O(1)···O(2)=2.723(8)Å, O(1)···O(2)′=2.669(7)Å, and O(2)···O(1)···O(2)′=84.2(2)°, where the primed superscript denotes the symmetry

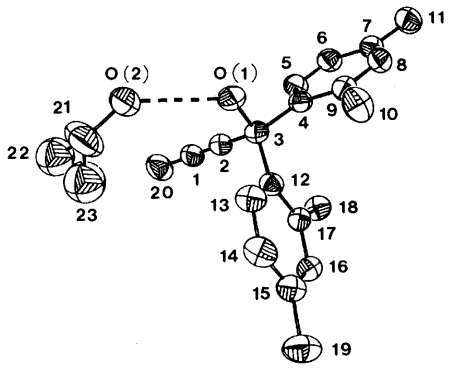

Fig. 2. Perspective view and atom labelling of the two molecular components in II. Both orientations of the disordered methyl group are shown, and the O(1)···O(2) hydrogen bond is represented by a broken line.

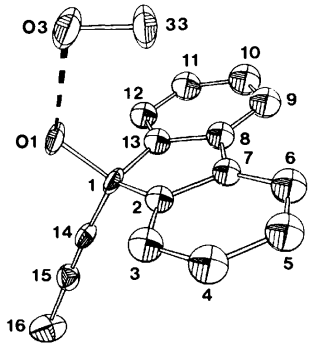

Fig. 3. Perspective view and atom labelling of one set (Type A) of molecular components in III, the O(1)···O(3) hydrogen bond being shown as a broken line. Atom labels for the other fluorene and methanol molecules (Type B) in the asymmetric unit are derived by incrementing the numbering of the corresponding oxygen and methanol carbon atoms by 1, and that of the remaining carbon atoms by 16.

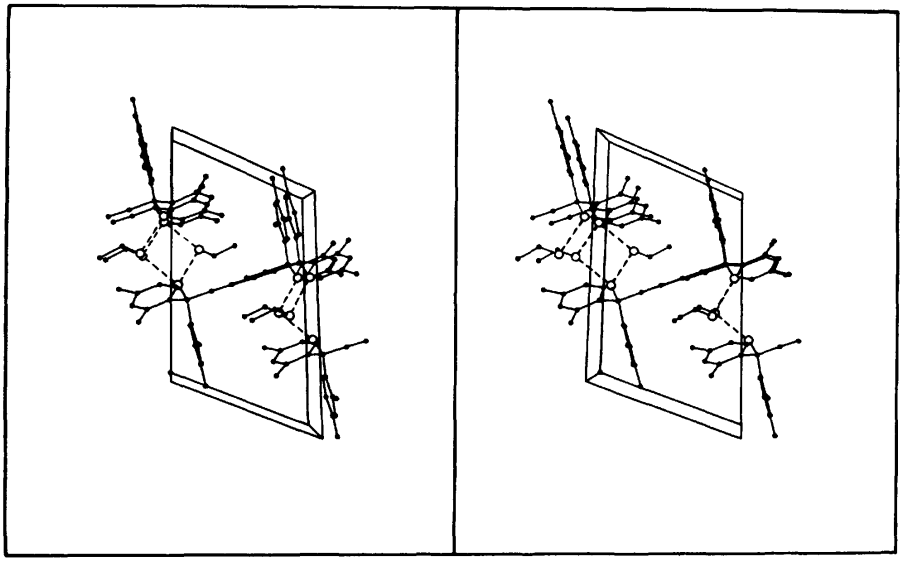

Fig. 4. Stereo view of the crystal structure of the 1:2 adduct (I) of 1,1,6,6-tetrakis(2,4-dimethylphenyl)-2,4-hexadiyne-1,6-diol (**2b**) with ethanol. The origin of the unit cell lies at the lower left corner, with a pointing towards the reader, b slantwise from left to right, and c upwards. The disordered ethyl group is shown in one of its two orientations, and hydrogen bonds are represented by broken lines.

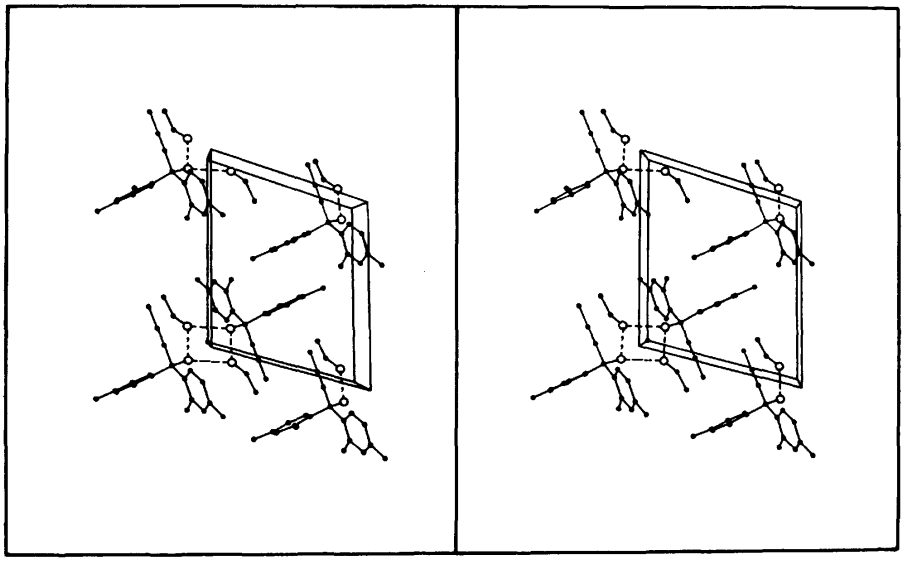

Fig. 5. Stereo view of the crystal structure of the 1:1 adduct (II) of 1,1-bis(2,4-dimethylphenyl)-2-butyn-1-ol (**3c**) with ethanol. The origin of the unit cell lies at the lower left corner, with a pointing towards the reader, b slantwise from left to right, and c upwards. The disordered methyl group of the ethanol molecule is shown in one of its two half-populated sites, and hydrogen bonds are represented by broken lines.

transformation ($-x$, $-y$, $1-z$). In the crystal lattice, van der Waals' contacts between the hydrophobic groups occur mainly across the (001) set of planes, midway between which are located the $(OH)_4$ rings and acetylenic functions.

In the crystal structure of II (Fig. 5), two butynol (**3c**) and two enthanol molecules are likewise alternately linked into a planar, hydrogen-bonded $(OH)_4$ ring centered at (1/2, 0, 0), with dimensions O(1)···O(2)= 2.700(5) Å, O(1)···O(2)′=2.686(4) Å, and O(2)···O(1)···O(2)′=91.9(1)°, where the primed superscript indicates the transformation ($1-x$, $-y$, $-z$). The crystal lattice thus comprises a packing of clearly discernible "dimeric" $(butynol\text{-}ethanol)_2$ aggregates.

The salient features common to the crystal structures of I and II are the effective utilization of crystallographic inversion centers and the occurrence of hydrogen-bonded $(OH)_4$ rings, which have been found

previously in related complexes such as the 1:1 adduct of 9,10-diphenyl-9,10-dihydro-r-9,t-10-anthracenediol (**5**) with 1,4-butanediol.[12] In both structures the environment around the ethyl carbon atoms of the ethanol molecule is relatively spacious, especially in I, allowing for the equal population of two energetically similar orientations. Interestingly, two neighboring CH_3–C≡C– groups in II are related by inversion and play the same role as a –C≡C–C≡C– fragment in I (see Figs. 4 and 5), and the structural relationship is analogous to that between the crystalline adducts **5**·2CH_3OH[13] and **5**·$HO(CH_2)_4OH$,[12] in which a pair of oppositely oriented methanol molecules are topologically equivalent to a 1,4-butanediol species.

Figure 6 illustrates the crystal structure of III, which

*Values matching those in molecule A are displayed. To obtain the atom numbers for O and C atoms in molecule B, add 1 and 16, respectively, to those shown in Fig. 3.

contains two independent sets of fluorene (**4**) and methanol molecules; the molecular species in each set are linked by hydrogen bonds to form infinite zigzag chains parallel to the a axis. The measured parameters of the two independent systems of hydrogen-bonded chains are: O(1)···O(3)=2.76(1)Å, O(1)···O(3)^{i}=2.70(1)Å, O(3)···O(1)···O(3)^{i}=124.0(4)°, O(1)···O(3)···O(1)^{ii}=119.5(4)°, O(4)···O(2)···O(4)^{iii}=122.9(4)°, and O(2)···O(4)···O(2)^{iv}=122.6(4)°, where the superscripts i, ii, iii, and iv denote the symmetry transformations ($^{1}/_{2}+x$, $^{1}/_{2}-y$, z), ($-^{1}/_{2}+x$, $1^{1}/_{2}-y$, z), ($^{1}/_{2}+x$, $^{1}/_{2}-y$, z) and ($-^{1}/_{2}+x$, $^{1}/_{2}-y$, z) respectively. With reference to Figs. 3 and 6, it is noted that the hydrogen-bonded chains generated from Type A fluorene [O(1)-C(16)] and methanol molecules [O(3)-C(33)] lie close to the planes z=1/8 and 5/8, whereas similar chains belonging to the other system are in the proximity of the planes z= 3/8 and 7/8. The van der Waals' contacts between hydrophobic groups thus occur mainly accross the (004) set of planes.

Elucidation of the crystal structures of the complexes I, II, and III in the present study provides a rationale for the formation of analogous alcohol adducts by the relevant host species **2b**, **3c**, and **4**. In each instance the alkyl group of the alcohol guest component is accommodated in a spacious void, so that its substitution by a more bulky alcohol would not be expected to significantly affect the overall pattern of molecular packing and hydrogen bonding.

Studies of the Formation of Complexes of Np(V) with Inorganic Ligands by Means of Solvent Extraction with 2-Thenoyltrifluoroacetone and 1,10-Phenanthroline. II. Fluoro, Sulfato, and Phosphato Complexes

Yasushi INOUE* and Osamu TOCHIYAMA
Department of Nuclear Engineering, Faculty of Engineering, Tohoku University, Aramaki-aza-aoba, Sendai 980
(Received December 6, 1984)

The formation constants of the complexes of Np(V) with fluoride, sulfate, and phosphate have been determined in 1 mol dm^{-3} $NaClO_4$ at 25 °C by means of the solvent-extraction method using 2-thenoyltrifluoroacetone and 1,10-phenanthroline. Extractions at various pH values revealed that $H_2PO_4^-$ and HPO_4^{2-} participate in the complex formation of Np(V).

The study of the complex formation of quinquevalent uranides (U, Np, Pu, and Am) with a variety of ligands in aqueous solutions is important for understanding both the systematics and the nuclear chemical applications of these elements. Among uranides, neptunium is the only element which has a quinquevalent state which is stable enough to permit a study of complex formation in aqueous solutions.[1] Recent compilations[2-5] indicate a general lack of reliable data on the complex formation of Np(V), especially with inorganic ligands.

Previously,[6-8] the formation constants of the complexes of Np(V) with some organic ligands and the carbonate ion have been determined by means of the solvent-extraction method using 2-thenoyltrifluoroacetone (TTA) and methyltrioctylammonium[9] or TTA and 1,10-phenanthroline(phen).[10] Inorganic anions, such as fluoride, chloride, nitrate, sulfate, and phosphate, are also important ligands in both natural and artificial systems. The present authors aimed to determine the formation constants of Np(V) complexes with these ligands by means of solvent extraction with TTA and phen. Among these anions, however, chloride and nitrate cannot be studied since they are expected to form only very weak complexes with Np(V). The complex formation of Np(V) with only fluoride, sulfate, and phosphate has, therefore, been investigated.

Experimental

The neptunium-239 tracer was prepared by milking from ^{243}Am by the method of Sill;[11] it was then adjusted to the quinquevalent state by evaporation to dryness and dissolution in water.[12] To avoid any possible contamination by any complex-forming substances or by neptunium with a valence state other than quinquevalent (which might be introduced during milking), the following back-extraction procedure was adopted. The ^{239}Np tracer was first extracted into an organic (3-methyl-1-butanol or dichloromethane) solution containing the desired concentrations of TTA and phen. A 4-cm^3 portion of this organic solution containing ^{239}Np was then mechanically shaken for 15 min (140 times/min) at 25±1 °C in a glass tube with the same volume of an aqueous solution containing 1 mol dm^{-3} sodium perchlorate, buffer reagents (a proper mixture of 0.1 mol dm^{-3} of 2-morpholinoethanesulfonic acid monohydrate(MES) and 0.1 mol dm^{-3} of tris(hydroxymethyl)aminomethane (THAM)), and a variable concentration of a complex-forming reagent. After phase separation, a 1-cm^3 portion of each phase was pipetted into a counting tube and the γ-activity of each phase was measured with a well-type NaI(Tl) scintillation counter. The remaining part of the aqueous phase was used for the pH measurement. The reagents and apparatus used in the experiments were those previously described.[8]

Results

The distribution ratio of Np(V) in the absence of complexing agents, D_0, can be represented by:[10]

$$D_0 = K_{ex}[HT]_o[phen]_o^m/[H^+], \quad (1)$$

where HT and phen denote the neutral forms of TTA and phen; K_{ex}, the extraction constant; m, the number of molecules of phen in the extracted species, and o, the organic phase. The concentration of HT in the organic phase, $[HT]_o$, is related to the total added concentration of TTA (C_{TTA}) by means of the following equations:

$$\begin{aligned} C_{TTA} &= [HT]_o + [HT] + [T^-] \\ &= [HT]_o(1+1/K_{DR} + K_a/K_{DR}[H^+]), \end{aligned} \quad (2)$$

where:

$$K_a = [H^+][T^-]/[HT] = 10^{-6.46}(\mu=0.1, 25°C),^{12} \quad (3)$$

and

$$K_{DR} = [HT]_o/[HT], \quad (4)$$

for 3-methyl-1-butanol;

$$K_{DR} = 10^{1.63}(\mu=1.0, 20°C),^{13}$$

and for dichloromethane;

$$K_{DR} = 10^{1.81}(\mu=0.1, 25°C).^{13}$$

The concentration of phen in the organic phase, $[phen]_o$, can be assumed to be equal to the total added concentration of phen, C_{phen}, under the conditions adopted in the experiment.

Under some experimental conditions, the effect of complexation with the TTA anion must be taken into consideration. The corrected distribution ratio, D_0', which is obtained experimentally in the absence of

complexing agents other than the TTA anion, can be expressed by the following equation:

$$D_0' = D_0/a, \tag{5}$$

$$a = 1 + \sum\beta_n^T[T^-]^n, \tag{6}$$

where β_n^T is the overall formation constant of the neptunium complex with the TTA anion. Equations 2—4 can be used for the estimation of $[T^-]$. The values of log β_1^T=2.89 and log β_2^T=5.48[14] were used for the calculation. As will be discussed later, uncertainties in the values of K_a, K_{DR}, and β_n^T give systematic errors to the calculation of the formation constants of Np(V) complexes through the conditional constant a in Eq. 6. Therefore, the total concentration of TTA was taken to be as low as was practicable in order to give values of a close to 1 (the largest value of a used in this study was 1.24). The complex formation of Np(V) with MES, THAM, or phen can be ignored under the conditions adopted in this experiment, because the change in the total concentration of MES plus THAM from 0.05 to 0.2 mol dm^{-3} has no effect on the distribution ratio of Np(V).

The distribution ratio of Np(V) in the presence of fluoride or sulfate can be expressed by:

$$D = D_0/(a+\sum\beta_n[L]^n), \tag{7}$$

where [L] is the concentration of F^- or SO_4^{2-} and where β_n is the overall formation constant of the complex of Np(V) with the ligand L (the charges of the ions are omitted for the sake of simplicity):

$$\beta_n = [ML_n]/[M][L]^n, \tag{8}$$

where M=NpO_2^+.

By substituting Eq. 5 into Eq. 7, we obtain:

$$1/D = 1/D_0' + \sum(\beta_n/D_0'a)[L]^n. \tag{9}$$

By using this equation, the β_n values can be obtained, together with D_0', from the analysis of the $1/D$ *vs.* [L] plots.

Figures 1 and 2 show the plots of log D *vs.* log ([L]/mol dm^{-3}) for fluoride and sulfate respectively. In each series of experiments, the distribution ratios were obtained in a medium buffered at a constant pH. Since the pH of the aqueous phase before and after shaking changed only slightly, the pH's of the aqueous phase at equilibrium (after shaking) differed from each other by less than 0.1 unit in each series. Because log D_0 changes with the pH according to Eqs. 1 and 2, the experimental values of D were corrected to those at a constant pH using the extraction curves which were obtained experimentally.[10] Although the value of a in Eqs. 5 and 6 may also change with the pH because of the change in $[T^-]$, the value of a was assumed to be constant in each series of experiments, since the experimental conditions were such that $\sum\beta_n^T[T^-]^n<1$. As the degree of dissociation of HF and HSO_4^- is fairly large in solutions within the pH range studied (pK_a=2.96 for HF and pK_a=1.10 for HSO_4^-),[4] the concentrations of F^- and SO_4^{2-} were taken as equal to the added concentrations of NaF and Na_2SO_4 respectively. The distribution of any species containing fluoride or sulfate in the organic phase was neglected.

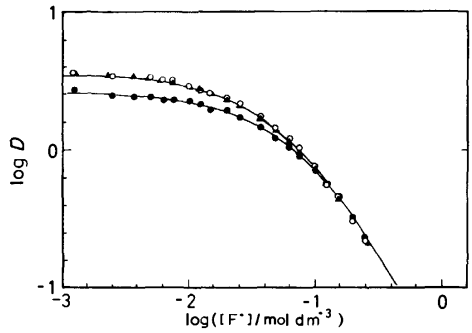

Fig. 1. Plots of log D *vs.* log([F^-]/mol dm^{-3}). Conditions: (○): No. 1, (▲): No. 2, (●): No. 3 in Table 1.

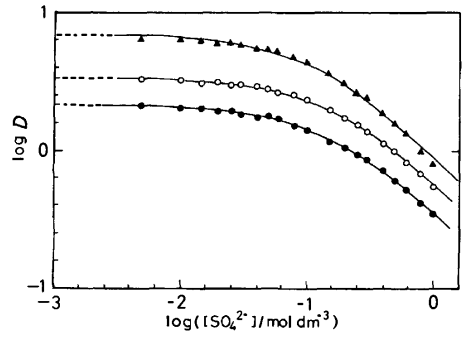

Fig. 2. Plots of log D *vs.* log([SO_4^{2-}]/mol dm^{-3}). Conditions: (○): No. 4, (▲): No. 5, (●): No. 6 in Table 1.

To check the validity of the assumptions mentioned above, different kinds of organic diluents, 3-methyl-1-butanol and dichloromethane, and different pHs were adopted in different series of experiments.

The plots in Figs. 1 and 2 were analyzed to obtain the best fit to Eq. 9 as follows:

Equation 9 is equivalent to a linear function:

$$y = f(x), \tag{10}$$

where:

$$y = 1/D, \tag{11}$$

$$f(x) = 1/D_0' + \sum(\beta_n/D_0'a)x^n, \tag{12}$$

and:

$$x = [L]. \tag{13}$$

A set of data (x_i, y_i) (19—20 points) was analyzed by the

least-squares method to determine the β_n and D_0' values. Since the counting-time of the γ-activity was set to make the relative statistical errors of the total counts approximately constant (0.01—0.02), the residuals of the observed ratios, y, were expected to be proportional to the value of $1/D$, judging from error-propagation rules. Although the observed values of $1/D$ are not error-free, these values give a good basis for estimating the weight of the observation. Therefore, the least-squares fitting was carried out to minimize the following sum of the weighted squares of the residuals:

$$S = \sum\{y_i - f(x_i)\}^2/y_i^2. \quad (14)$$

The results of the analyses are shown in Table 1. Two series of experiments (Nos. 1 and 2) were carried out to check the reproducibility of the experiment, while others were carried out under different conditions in order to check if the unknown factors govern the distribution behavior of Np(V). Although the differences in β_n values were slightly larger than the standard deviations obtained from each series of experiments, the results agreed well with each other and enabled us to analyze the data altogether. Since Eq. 9 can be rearranged to:

$$aD_0'/D - (a-1) = 1 + \sum\beta_n[\mathrm{L}]^n, \quad (15)$$

the least-squares study was carried out between:

$$y = Y \equiv aD_0'/D - (a-1), \quad (16)$$

$$f(x) = 1 + \sum\beta_n x^n, \quad (17)$$

and:

$$x = [\mathrm{L}]. \quad (18)$$

The plots of log Y *vs.* log([L]/mol dm^{-3}) are shown in Figs. 3 and 4. The solid lines show the best fit of the data to Eq. 15, while the dashed lines show the contribution of each species of Np(V). The formation constants thus obtained are listed in Table 1.

In the presence of phoshate as a complexing agent, there is a possibility of the formation of different types of complexes, and the $1/D$ ratio can be expressed as:[8]

$$1/D = 1/D_0' + \sum(\beta_n'/D_0'a)[\mathrm{H_2L}]^n + \sum(\beta_n/D_0'a)[\mathrm{HL}]^n, \quad (19)$$

where H_2L and HL denote $H_2PO_4^-$ and HPO_4^{2-} respectively. The overall formation constants and dissociation constants are given by these equations:

$$\beta_n' = [\mathrm{M(H_2L)}_n]/[\mathrm{M}][\mathrm{H_2L}]^n, \quad (20)$$

$$\beta_n = [\mathrm{M(HL)}_n]/[\mathrm{M}][\mathrm{HL}]^n, \quad (21)$$

$$K_i = [\mathrm{H}][\mathrm{H}_{3-i}\mathrm{L}]/[\mathrm{H}_{4-i}\mathrm{L}], \quad (22)$$

1,2,4,5: C_{TTA}=1×10^{-4} mol dm^{-3}, C_{phen}=1×10^{-2} mol dm^{-3} in 3-methyl-1-butanol.
3,6: C_{TTA}=1×10^{-3} mol dm^{-3}, C_{phen}=1×10^{-2} mol dm^{-3} in dichloromethane.

where pK_1=1.70, pK_2=6.46, and pK_3=10.79.[4] Equation 19 may then be written as:

$$1/D = 1/D_0' + \sum(B_n'/D_0'a)[\mathrm{H_2L}]^n, \quad (23)$$

where:

$$B_n' = \beta_n' + \beta_n K_2^n/[\mathrm{H}]^n, \quad (24)$$

or:

$$1/D = 1/D'_0 + \sum(B_n/D'_0 a)[\mathrm{HL}]^n, \quad (25)$$

where:

$$B_n = \beta'_n[\mathrm{H}]^n/K_2^n + \beta_n. \quad (26)$$

Nine series of experiments were carried out to obtain the plot of log D *vs.* log([$H_2PO_4^-$]/mol dm^{-3}) or the plot of log D *vs.* log([HPO_4^{2-}]/mol dm^{-3}). The pH of the aqueous phase after shaking changed from the initial pH by less than 0.2 unit in each series of experiments; the experimental values of D were corrected to those at a constant pH using the experimental extraction curves which were obtained experimentally. The concentration of a particular species of phosphate was calculated at the pH of interest according to the following relationship:

$$C_L = [H_3PO_4] + [H_2PO_4^-] + [HPO_4^{2-}] + [PO_4^{3-}]$$
$$= [H_3PO_4](1 + K_1/[H^+] + K_1K_2/[H^+]^2 + K_1K_2K_3/[H^+]^3). \quad (27)$$

Some of the plots of log Y (Eq. 16) *vs.* log([HPO_4^{2-}]/mol dm^{-3}) are shown in Fig. 5 as illustrations. The values of B'_n and B_n obtained at various pH's are shown in Table 2, together with the experimental conditions used. Each series of experiments comprised 18 to 20 points of the data-set, and the standard deviations of the values of B'_n and B_n were less than 0.02. Since values of B'_n and B_n show the dependence on the pH in the opposite way, it can be concluded that both, and only, $H_2PO_4^-$ and HPO_4^{2-} ions form considerably stable complexes with Np(V). As the value of B'_n or B_n is a function of the pH, as is expressed by Eq. 24 or 26, a set of B'_n or B_n can be treated by the same least-squares method as explained before to determine the values of β'_n and β_n. Figure 6 shows the results of the least-squares fitting of the values of B_n to Eq. 26; the values of β'_n and β_n thus obtained are listed in Table 3. The fairly large standard deviations of the values can be ascribed to the rather restricted pH range studied, since a pH value than 4.5 is too high to allow the formation of a considerable amount of complexes of Np(V) with the $H_2PO_4^-$ ion. Moreover, uncertainties may be brought about in the observed values since the fraction of Np(V) in a particular chemical form is a quite complex function of both the total concentration of phosphate (C_L) and the pH. the presence of C_L=0.1 mol dm^{-3}, for instance, the fraction of Np(V) in the form of a particular phosphate complex changes as a function of the pH, as is shown in Fig. 7, which was constructed by using the formation constants obtained in the present study.

Discussion

Table 3 lists the formation constants obtained in this study, together with the values reported by other workers.

Rao *et al.*[15] have studied the complexing of Np(V) with F^-, SO_4^{2-}, and some other inorganic anions by the solvent-extraction method using 3,7-dinonylnaphthalenesulfonic acid (DNNS) as the extractant. Their values are smaller than the present values. Figures 3 and 4 show their extraction curves, which have been constructed by the present authors from the table in the original paper. Although they stated that the pH was maintained around 5 in their experiment, there was no description of the pH at equilibrium after the extraction. Since they used a stock solution of Np(V) in $HClO_4$ without any buffer, the aqueous phase might possibly be more acidic than expected. This may lead to the overestimation of $[F^-]$ by neglecting the association into HF. Since the distribution ratios of Np(V) were small even in the absence of the ligands (D=0.219 in the presence of 0.4 mol dm^{-3} DNNS), the range of the distribution ratio they measured was too narrow to obtain reliable formation constants (the percentages of the extraction of Np(V) varied within the small range from 18% to 11%).

Halperin and Oliver[16] repeated the experiment on the sulfate complexing of Np(V) by the same method and under conditions almost equal to those adopted by Rao *et al.*[15] Although they used the same technique, they obtained a considerably smaller value than that reported by Rao *et al.*; the discrepancy is outside the limits of experimental error. We suspect that the starting solution of Np(V) might have contained chemical species other than NpO_2^+, such as peroxide, since Halperin and Oliver used H_2O_2 as a reductant. If such kinds of species are not extractable into the organic phase, this will give systematic errors and lead to a lower formation constant. Hydrogen peroxide has been found to cause unusual behavior in neptunium when used as a redox reagent.[12,17]

Moskvin and Poznyakov[18] studied the complexing of Np(V) with SO_4^{2-}, SO_3^{2-}, HCO_3^-, HPO_4^{2-}, *etc.* by means of coprecipitation with iron(III) hydroxide at pH 8.5. As for the sulfate complex, they have reported a larger value than the present one, though the discrepancy is within the limits of experimental error. The main difficulty in their coprecipitation method is that the distribution ratio of Np(V) in the absence of complexing agents is too high to obtain reliable data, since the distribution ratio was determined from the difference in the activities of the centrifugate and a control (original) solution. The percentage of the adsorption is reported to around 95% and cannot be

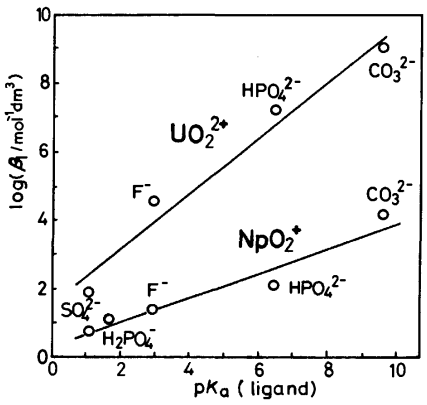

Fig. 8. Correlation between 1:1 chelate formation constants of UO_2^{2+} or NpO_2^+ and pK_a.

controlled, in contrast to the case with the solvent-extraction system adopted in this report.

The failure by Al-Niaimi *et al.*[19] to observe fluoride and sulfate complexing can be ascribed to the low fluoride and sulfate concentrations they used.

As for the formation constants of phosphate complexes, despite the large standard deviations in the present study, they may be considered to be more reliable than those listed in Table 3.

Moskvin *et al.*[18,20] obtained their values in a still more limited pH region (at pH 4.8—6.7 in Ref. 20 and at pH 8.5 in Ref. 18). Their formation constants for the complexes of Np(V) with $H_2PO_4^-$ and HPO_4^{2-} are not very different from the present values. However, if we accept the reported formation constant of the Np(V)-PO_4^{3-} complex, the main species of Np(V) at pH 8.5 should be $NpO_2PO_4^{2-}$, and the formation constants of Np(V)-HPO_4^{2-} complexes cannot be obtained at this pH.

Rees and Daniel[21] have determined the formation constant of the Np(V)-HPO_4^{2-} complex. They measured the distribution of Np(V) between the aqueous phase and a cation-exchange resin at pH 7.5. In their calculation, the concentration of HPO_4^{2-} was assumed to be equal to the total phosphate concentration at this pH. The agreement with the present value is reasonable, since Np(V) forms only a one-to-one complex with HPO_4^{2-} under the conditions they adopted (pH 7.5, $C_L=10^{-3}$—10^{-2} mol dm^{-3}).

In Fig. 8, the formation constants of the Np(V)-complexes with inorganic anions (including CO_3^{2-} by Ref. 8) obtained in the present study are compared with those of the UO_2^{2+}-complexes,[4,22] because UO_2^{2+} is also a dioxo cation of similar type. The good correlation of the stabilities of the Np(V)-complexes with the pK_a values of the ligands implies that all these complexes are formed by the interaction of a hard acid and a hard base.

In conclusion, since the present experiment was conducted to ensure the formation of various chemical species by covering a fairly wide range of ligand concentrations and pH's, the resultant formation constants can be used reliably to estimate the behavior of Np(V) in widely different natural or artificial systems.

The Bound Ligand Effect in the Complexation Kinetics of Some Anionogallium(III) Complexes

Shinkichi YAMADA* and Motoharu TANAKA†

Laboratory of Analytical Chemistry, Faculty of Engineering, Shizuoka University, Johoku, Hamamatsu 432

†*Laboratory of Analytical Chemistry, Faculty of Science, Nagoya University, Chikusa-ku, Nagoya 464*

(Received February 4, 1985)

The formation rate of some anionogallium(III) complexes (GaA) with 4,5-dihydroxy-1,3-benzenedisulfonate (H_2L^{2-}) in the presence of thiocyanate ion has been studied spectrophotometrically by a stopped-flow technique. The rate law is expressed as $d[GaL^-]/dt = k_{Ga}[Ga^{3+}][H_2L^{2-}] + k_{GaOH}[GaOH^{2+}][H_2L^{2-}] + k_{Ga(OH)_2}[Ga(OH)_2^+][H_2L^{2-}] + k_{GaNCS}[GaNCS^{2+}][H_2L^{2-}]$, with $k_{Ga} = 10^{1.23}$ $M^{-1}s^{-1}$ (M=mol dm^{-3}), $k_{GaOH} = 10^{3.36}$ $M^{-1}s^{-1}$, $k_{Ga(OH)_2} = 10^{4.37}$ $M^{-1}s^{-1}$, and $k_{GaNCS} = 10^{3.90}$ $M^{-1}s^{-1}$ at 25 °C and I=0.50M. The enhanced reactivity of GaA as compared to that of Ga^{3+} is attributable to the labilizing effect of the bound ligand A on the rate of loss of coordinated water molecules at GaA. Together with the additional formation rate constants of monoisothiocyanato- and monooxalatogallium(III) with 2-hydroxy-2,4,6-cycloheptatrien-1-one, this labilizing effect is quantitatively discussed in terms of the electron-donating ability of the ligand.

From the mechanistic consideration on the formation constants of metal complexes,[1,2] it has been shown that, taking into account the statistical factor arising from the number of water molecules available for exchange, the water exchange rate constant at MA ($k_{MA}^{-H_2O}$) is expressed as

$$\log (k_{MA}^{-H_2O}/\text{number of } H_2O \text{ in MA}) = \log (k_M^{-H_2O}/\text{number of } H_2O \text{ in M}) + \gamma E(A) \quad (1)$$

where E(A) refers to the electron donor constant[3] of the ligand A and γ is a constant characteristic of the metal ion M.

In the preceding paper,[4] we have studied the kinetics and mechanism of the complex formation of monohydroxo-, monoacetato-, monothiocyanato-, monoazido-, and monofluorozinc(II) complexes with 1,10-phenanthroline and found that the labilizing effect of the bound ligand on the rate of loss of coordinated water molecules is quantitatively described by Eq. 1. Recently, we have shown[5] that Eq. 1 can predict the bound ligand effect of the multidentate-ligand complexes of nickel(II). In the system, the value of the effective E(A) for a multidentate ligand is given by the summation of E(X) of each donor atom X involved in A which is corrected for the effect of vicinal functions. This effective E(A) value is particularly useful in the estimation of the γ parameter for a hard metal ion such as gallium(III): The number of bound ligands suitable for kinetic measurements is limited due to their small formation constants with gallium(III) ion in acidic medium.

To understand how the rate of loss of coordinated water molecules at GaA is labilized by the presence of the coordinated ligand A, we have studied the complexation kinetics described as

$$GaA + H_2L^{2-} \xrightarrow{k_{GaA}} GaAL(\text{and/or } GaL^- + A) + 2H^+, \quad (2)$$

$$GaA + HL \xrightarrow{k_{GaA}} GaAL(\text{and/or } GaL^{2+} + A) + H^+, \quad (3)$$

where A is a bound ligand such as hydroxide, thiocyanate or oxalate. H_2L^{2-} and HL refer to tiron (4,5-dihydroxy-1,3-benzenedisulfonate) and tropolone (2-hydroxy-2,4,6-cycloheptatrien-1-one), respectively. With these two entering ligands, we have already described the thermodynamic and kinetic results on the complexation reaction of the gallium(III) ion and provided definite mechanistic information on the reaction of this cation, on the basis of values of activation volume obtained by a high-pressure stopped-flow technique.[6]

Experimental

The solutions of gallium(III) perchlorate, tropolone, tiron, and sodium thiocyanate were prepared as described elsewhere.[4,6] Sodium oxalate of primary standard quality (Wako-junyaku) was used without further purification. All experiments were carried out in a room thermostated at 25.0±0.5 °C. Temperature of the reaction solution was controlled to within ±0.1 °C. Ionic strength was maintained at 0.50 M with sodium perchlorate. Reaction rates were followed by a stopped-flow spectrophotometer equipped with a data processor. The changes in absorbance at 305 nm and 313 nm, wavelength of the maximum absorption of the 1:1 Ga(III)-tiron and Ga(III)-tropolone complexes respectively, were accumulated to obtain high S/N curves. Other experimental details are described elsewhere.[4,6]

Results

Reaction of Gallium(III) Ion with Tiron. Gallium(III) ion forms a 1:1 complex with tiron in acidic solution where the concentration of gallium(III) is in large excess over that of the ligand:[6]

$$Ga' + H_2L^{2-} \underset{k_{r(H)}}{\overset{k_{f(H)}}{\rightleftharpoons}} GaL^- + 2H^+ \quad (4)$$

where $k_{f(H)}$ is a second-order conditional rate constant involving the concentration of hydrogen ion for the formation of the complex and $k_{r(H)}$ is a pseudo-first-order conditional rate constant involving the concentration of hydrogen ion for the dissociation of the com-

plex. Then the kinetic equation for this reaction is described by

$$d[GaL^-]/dt = k_{f(H)}[Ga'][H_2L^{2-}] - k_{r(H)}[GaL^-] = k_{f(H)}C_L[Ga'] - k_{o(H)}[GaL^-] \quad (5)$$

where [Ga'] denotes the total concentration of gallium(III) not combined with the ligand L^{4-} (aqua and hydroxo gallium ions), and $C_L=[H_2L^{2-}]+[GaL^-]$ and $k_{o(H)}=k_{f(H)}[Ga']+k_{r(H)}$.

Integration of Eq. 5 gives

$$\ln \frac{k_{f(H)}C_L[Ga']}{k_{f(H)}C_L[Ga'] - k_{o(H)}[GaL^-]} = \ln \frac{A_\infty - A_0}{A_\infty - A_t} = k_{o(H)}t,$$

where A_0, A_t, and A_∞ are the absorbances at 305 nm for reaction systems at reaction time 0, t, and ∞, respectively. The rate plot of $\ln\{(A_\infty-A_0)/(A_\infty-A_t)\}$ *vs.* t was linear for over 90% of the reaction. The conditional rate constant involving the concentration of hydrogen ion $k_{o(H)}$ determined from the slope of this plot is correlated with $k_{f(H)}$ and $k_{r(H)}$ by the following relations:

$$k_{o(H)} = k_{f(H)}[Ga'] + k_{r(H)}$$

$$k_{f(H)}/k_{r(H)} = K_{GaL}{}^{H_2L}/(\alpha_{Ga(OH)}[H^+]^2)$$

where $K_{GaL}{}^{H_2L}=[GaL^-][H^+]^2[Ga^{3+}]^{-1}[H_2L^{2-}]^{-1}$ and $\alpha_{Ga(OH)}=1+K_{GaOH}[H^+]^{-1}+K_{GaOH}K_{Ga(OH)_2}[H^+]^{-2}$. Employing the values of $K_{GaL}{}^{H_2L}$ and $K_{GaOH}=[GaOH^{2+}][H^+][Ga^{3+}]^{-1}$ previously determined[6] and $K_{Ga(OH)_2}=[Ga(OH)_2{}^+][H^+][GaOH^{2+}]^{-1}$ reported,[7] the values of $k_{f(H)}$ and $k_{r(H)}$ were calculated as in Table 1.

a) $C_{Ga}=1.12\times10^{-2}$ M, $C_{H_2L}=1.08\times10^{-4}$ M, I=0.50 M, 25 °C.

The increase of the conditional rate constant $k_{f(H)}$ with decreasing concentration of hydrogen ion is attributable to the hydrolyzed species of gallium(III).[8] Thus

$$d[GaL^-]/dt = \{k_{Ga}[Ga^{3+}] + k_{GaOH}[GaOH^{2+}] + k_{Ga(OH)_2}[Ga(OH)_2{}^+]\} \times [H_2L^{2-}] - k_{r(H)}[GaL^-] \quad (6)$$

and

$$k_{f(H)}\alpha_{Ga(OH)} = k_{Ga} + k_{GaOH}K_{GaOH}[H^+]^{-1} + k_{Ga(OH)_2}K_{GaOH}K_{Ga(OH)_2}[H^+]^{-2}.$$

The values of the rate constants for these three reaction paths were determined from the plot of $k_{f(H)}\alpha_{Ga(OH)}$ *vs.* $[H^+]^{-1}$ as shown in Fig. 1 and they are given in Table 2.

The conditional rate constant for the dissociation of the complex, $k_{r(H)}$, is found to be correlated with the concentration of hydrogen ion as

$$k_{r(H)} = 10^{-1.29} + 10^{1.75}[H^+].$$

Reaction of Isothiocyanatogallium(III) with Tiron. Under the conditions where only $GaNCS^{2+}$ is responsible for the reaction of the gallium(III)–thiocyanate complex, the complexation reaction of gallium(III) complexes with tiron is considered to proceed as in Scheme 1.

With the total concentration of thiocyanate ion much

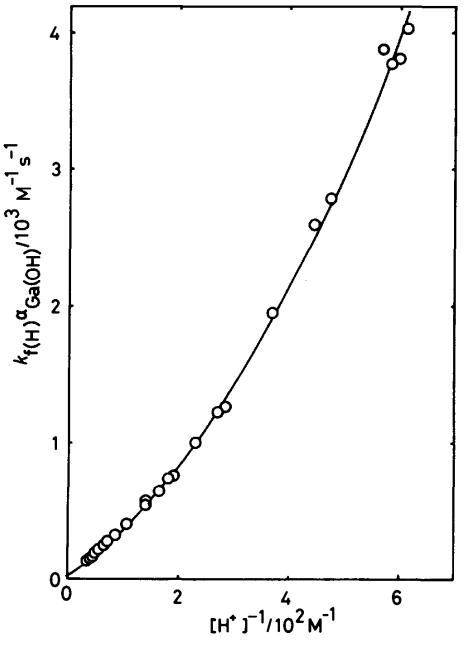

Fig. 1. Plot of $k_{f(H)}\alpha_{Ga(OH)}$ *vs.* $[H^+]^{-1}$.
The solid line is the curve calculated with the values obtained by a least-squares procedure.

$$

Scheme 1.

higher than that of tiron (see Fig. 2), $GaNCS^{2+}$ would be certainly in equilibrium with aquagallium(III) during the reaction. The formation of a small amount of a mixed-ligand complex such as $[Ga(NCS)L]^{2-}$ may be anticipated. However, the coordination of tiron being quantitative at $-\log[H^+]=2.3$ (see Table 1), the kinetic equation for this reaction scheme is described as

$$
\begin{aligned}
d[GaL^-]/dt &= k_{f(H,SCN)}[Ga'][H_2L^{2-}] \\
&= \{k_{Ga}[Ga^{3+}] + k_{GaOH}[GaOH^{2+}] \\
&\quad + k_{Ga(OH)_2}[Ga(OH)_2^+] \\
&\quad + k_{GaNCS}[GaNCS^{2+}]\}[H_2L^{2-}] \qquad (7)
\end{aligned}
$$

where,

$$
k_{f(H,SCN)} = \frac{k_{f(H)}\alpha_{Ga(OH)} + k_{GaNCS}K_{GaNCS}[SCN^-]}{\alpha_{Ga(OH)} + K_{GaNCS}[SCN^-]}
$$

and $K_{GaNCS}=[GaNCS^{2+}][Ga^{3+}]^{-1}[SCN^-]^{-1}$ is the formation constant of the inner-sphere complex of isothiocyanatogallium(III).

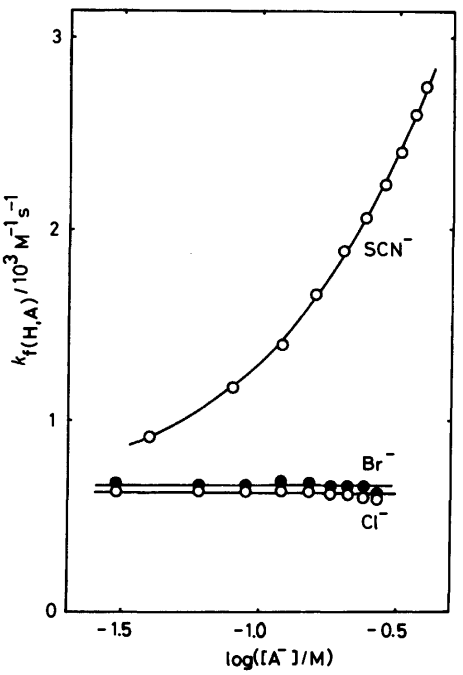

Fig. 2. Plot of $k_{f(H,A)}$ *vs.* $\log[A^-]$.
Conditions: $C_{Ga}=1.12\times10^{-2}$ M, $C_L=1.08\times10^{-4}$ M, and $-\log[H^+]=2.32\pm0.02$ for $A^-=SCN^-$; $C_{Ga}=1.12\times10^{-2}$ M, $C_L=1.01\times10^{-4}$ M, and $-\log[H^+]=2.28\pm0.01$ for $A^-=Cl^-$; $C_{Ga}=1.12\times10^{-2}$ M, $C_L=1.11\times10^{-2}$ M, and $-\log[H^+]=2.28\pm0.01$ for $A^-=Br^-$; all at 25 °C and $I=0.50$ M.

The increase of $k_{f(H,SCN)}$ at constant pH with increasing concentration of SCN^- is attributable to the enhanced reactivity of $GaNCS^{2+}$. From the plot of $k_{f(H,SCN)}$ *vs.* log[SCN^-] (Fig. 2), the k_{GaNCS} value was determined by a least-squares procedure to be $k_{GaNCS}=10^{3.90}$ $M^{-1}s^{-1}$ with $K_{GaNCS}=10^{0.11}$ M^{-1} at 25 °C and I=0.50 M.

In the presence of chloride and bromide, the conditional formation rate constants $k_{f(H,Cl)}$ and $k_{f(H,Br)}$ did not change with increasing total concentration of A up to 0.27 M as shown in Fig. 2. This is most probably due to the small formation constant K_{GaA} for these complexes.[9,10]

Reaction of Isothiocyanatogallium(III) with Tropolone. Gallium(III) ion quantitatively forms the 1:1 complex with tropolone (HL) in acidic solution (−log[H^+]= 0.6—1.3) where the concentration of gallium(III) ion is in large excess over that of the ligand. Under such conditions, the complexation reaction and the kinetic equation for the formation of the (tropolonato)gallium(III) (GaL^{2+}) is expressed as[6]

$$Ga' + HL' \xrightarrow{k_{f(H)}} GaL^{2+} + H^+ \quad (8)$$

$$\begin{aligned} d[GaL^{2+}]/dt &= k_{f(H)}[Ga'][HL'] \\ &= k_{f(H)}\alpha_{Ga(OH)}\alpha_{HL(H)}[Ga^{3+}][HL] \\ &= \{k_{Ga}[Ga^{3+}] + k_{GaOH}[GaOH^{2+}]\}[HL]. \end{aligned} \quad (9)$$

where [Ga′]=[Ga^{3+}]+[$GaOH^{2+}$] and [HL′]=[HL]+ [H_2L^+] =(1+K_{H_2L}[H^+])[HL]=$\alpha_{HL(H)}$[HL].

As in the reaction with tiron, the conditional rate constant $k_{f(H,SCN)}$ increased with increasing concentration of thiocyanate ion. At −log[H^+]=1.25, the values of $k_{f(H,SCN)}$ obtained at various thiocyanate concentrations (C_{SCN}=0.04—0.40 M) were analyzed with the following equation

$$k_{f(H,SCN)}\alpha_{HL(H)} = \frac{k_{f(H)}\alpha_{HL(H)}\alpha_{Ga(OH)} + k_{GaNCS}K_{GaNCS}[SCN^-]}{\alpha_{Ga(OH)} + K_{GaNCS}[SCN^-]}$$

and the k_{GaNCS} value was determined to be $10^{3.12}$ M^{-1} s^{-1} with $K_{GaNCS}=10^{0.47}$ M^{-1} at 25 °C and I=0.50 M. The k_{GaNCS} value obtained with tiron as an entering ligand is higher than this value. This may be due to the partial formation of [Ga(NCS)(OH)]$^+$ at higher pH where kinetics with tiron was carried out.

Reaction of Oxalatogallium(III) with Tropolone. Under the conditions where only $Ga(ox)^+$ is present as the gallium(III)–oxalate complex, the reaction of the gallium(III) complex with tropolone can be expressed as[6]

$$Ga' + HL' \xrightarrow{k_{f(H,ox)}} Ga(ox)L(\text{and/or } GaL^{2+} + ox^{2-}) + H^+ \quad (10)$$

and the kinetic equation is described as

$$d[Ga(ox)L]/dt = k_{f(H,ox)}[Ga'][HL'] \quad (11)$$

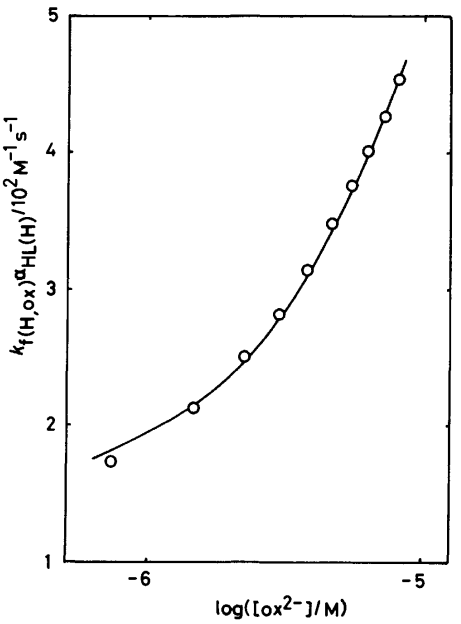

Fig. 3. Plot of $k_{f(H,ox)}$ *vs.* log[ox^{2-}].
Conditions: $C_{Ga}=2.81\times10^{-2}$ M, $C_L=1.03\times10^{-4}$ M, $C_{ox}=1.00\times10^{-3}$—1.00×10^{-2} M, −log[H^+]=1.056± 0.002, at 25 °C and I=0.50 M.

where [Ga′]=[Ga^{3+}]+[$GaOH^{2+}$]+[$Ga(ox)^+$]. Then we obtain

$$k_{f(H,ox)}\alpha_{HL(H)} = \frac{k_{f(H)}\alpha_{HL(H)}\alpha_{Ga(OH)} + k_{Ga(ox)}K_{Ga(ox)}[ox^{2-}]}{\alpha_{Ga(OH)} + K_{Ga(ox)}[ox^{2-}]}$$

where $K_{Ga(ox)}$=[$Ga(ox)^+$][Ga^{3+}]$^{-1}$[ox^{2-}]$^{-1}$ is the formation constant for the inner-sphere complex of monooxalatogallium(III).

At constant pH, the values of $k_{f(H,ox)}$ obtained at various oxalate concentrations were analyzed as a function of [ox^{2-}] by a least-squares procedure.[11] The solid line in Fig. 3 was calculated with $K_{Ga(ox)}=10^{4.44}$ M^{-1} and $k_{Ga(ox)}=10^{3.27}$ $M^{-1}s^{-1}$ at 25 °C and I=0.50 M. The value of $k_{f(H)}\alpha_{HL(H)}\alpha_{Ga(OH)}$ obtained (1.50×10^2 M^{-1} s^{-1}) compares favorably with the value calculated (1.59×10^2 $M^{-1}s^{-1}$) from the relation of $k_{f(H)}\alpha_{HL(H)}\alpha_{Ga(OH)}$= $k_{Ga}+k_{GaOH}K_{GaOH}$[H^+]$^{-1}$ and the values of k_{Ga}, k_{GaOH}, and k_{GaOH} previously determined.[6]

Discussion

On the basis of the values of activation volume, we have shown[6] that the complexation of gallium(III) is accommodated within the framework of a dissociative-interchange mechanism.[12] For the complexation reactions dissociatively activated, the values of k_M/K_{os} and k_{MA}/K_{os} (apart from a statistical factor which is not far from unity,[13] where K_{os} is the formation constant of an outer-sphere complex) are not very different from the values of $k_M{}^{-H_2O}$ and $k_{MA}{}^{-H_2O}$, respectively.[14,15] We calculated rate constants, $k_{Ga}{}^{-H_2O}$ and $k_{GaA}{}^{-H_2O}$, for our system and others. The results are summarized in Table 2 in which are also given the second-order rate

TABLE 3. BOUND LIGAND EFFECTS OF GaA COMPLEXES

A	E(A)	R(A)[a]
H_2O	0.00	0.00
OH^-	1.65	2.07±0.26

SCN^-	1.83	2.19±0.57
ox^{2-}	1.70	1.86

a) $R(A)=\log(k_{GaA}{}^{-H_2O}/\text{number of } H_2O \text{ in GaA})-\log(k_{Ga}{}^{-H_2O}/6)$.

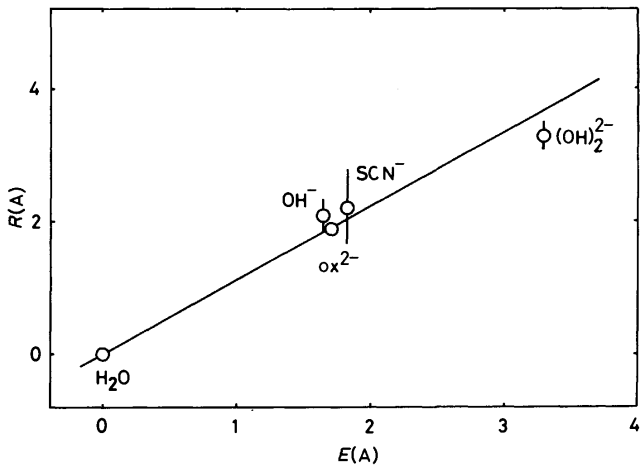

Fig. 4. Plot of R(A) *vs.* E(A).
$R(A)=\log(k_{GaA}{}^{-H_2O}/\text{number of } H_2O \text{ in GaA})-\log(k_{Ga}{}^{-H_2O}/6)$.

constants for complexation reactions. K_{os} were calculated from the Fuoss equation[16] with the distance of closest approach=5 Å, assuming that a negatively charged group removed from the eventual coordination site is unimportant in the calculation of K_{os} values.[17]

With the water exchange rate constant calculated, the bound ligand effect of GaA on the water exchange rate can be estimated by the difference between $\log(k_{GaA}{}^{-H_2O}/\text{number of } H_2O \text{ in GaA})$ and $\log(k_{Ga}{}^{-H_2O}/6)$, which is shown in Table 3 under the heading of R (A). In this Table, the values of E (A) for the monodentate ligands are taken from Ref. 3 and the value for oxalate is the effective E(A) which is given by $E(ox^{2-})=2E(OAc^-)-2\Delta E_{OO}$.[5] Since the donor-donor interaction between hydroxo ligands coordinated to gallium(III) may be anticipated to be small, the value of E ($2OH^-$) is assumed to be $2E$ (OH^-).

The positive values of R(A) indicate that the coordinated ligands do have the expected libilizing effect on the water exchange rate at GaA. If this labilizing effect is attributable to the electron donation from the ligand to the gallium(III) ion, the bound ligand effect could be quantitatively predicted by Eq. 1. Then the plot of R(A) *vs.* E(A) should yield a straight line with an intercept of zero. The value of γ for gallium(III) was estimated from the slope of Fig. 4 to be 1.1. As stated previously,[4,22] a hard metal ion[23] such as Ga(III) has higher γ value than less hard metal ions such as Co(II) (γ=0.47), Ni(II) (γ=0.40), and Zn(II) (γ=0.30). This implies that the harder the metal ion, the more sensitive is the water exchange rate to the electron-donating ability of the ligand already attached.

Stereoselective Interaction of Chiral Metal Complexes in Solution as Studied by Chromatography. I. Modes of Chiral Discrimination and Optical Resolution of Anion Complexes

Katsuhiko MIYOSHI, Yukio SAKAMOTO, Atsuko OHGUNI, and Hayami YONEDA*
Department of Chemistry, Faculty of Science, Hiroshima University, Higashi-senda-machi, Naka-ku, Hiroshima 730
(Received March 1, 1985)

Chromatographic resolution of some anion complexes, $[Co(ox)_2(en)]^-$, C_1- and C_2-*cis*(*N*)-$[Co(ox)(gly)_2]^-$, $[Co(ox)_2(gly)]^{2-}$, and $[Co(ox)_2(acac)]^{2-}$ (ox=oxalate ion, en=ethylenediamine, gly=glycinate ion, and acac=acetylacetonate ion), was attempted on an ion-exchange column using as chiral selectors several optically active cation complexes such as $[Co(en)_3]^{3+}$, $[Co(sep)]^{3+}$, $[Co(pn)_3]^{3+}$, $[Co(chxn)_3]^{3+}$, $[Co(acac)(en)_2]^{2+}$, and $[Co(gly)(en)_2]^{2+}$ (sep=1,3,6,8,10,13,16,19-octaazabicyclo[6.6.6]icosane, pn=propylenediamine, and chxn=*trans*-1,2-cyclohexanediamine). The elution orders and degrees of optical resolution attained were interpreted on the basis that chiral discrimination is effected along either the C_3 (or pseudo C_3) axis or the C_2 (or pseudo C_2) axis of the respective complexes; the cation complex faces the anion complex with its N–H protons hydrogen-bonded to the coordinated oxygen atoms of the anion complex along the (pseudo) C_3 or C_2 axis. Plausible association models were proposed, which indicate that homochiral (*i.e.*, *Δ*-*Δ* or *Λ*-*Λ*) and heterochiral (*i.e.*, *Δ*-*Λ* or *Λ*-*Δ*) combinations are favored when the cation complex directs its C_3 and C_2 axes to the anion complex, respectively, regardless of which axis (C_3 or C_2) of the anion complex is directed to the cation complex. Most of the experimental data are consistently explained within the framework of the association models proposed.

Several attempts have been made to resolve metal complex anions into optical isomers by chromatography.[1] However, only few examples are known in which optically active metal complex cations are utilized as chiral selectors, and thus the mechanism of chiral discrimination between complex cation and anion in solution has not yet been elucidated clearly. For example, Tatehata *et al.*[2] have succeeded in complete resolution of $[Co(ox)_2(gly)]^{2-}$ (ox=oxalate dianion and gly=glycinate anion) on the DEAE-Sephadex A-25 column with *Λ*-$[Co(en)_3]^{3+}$ cation (en=ethylenediamine) employed as an eluent, the *Δ* anion complex being eluted faster. They proposed an association model for a favorable pair, *Λ*-$[Co(en)_3]^{3+}$-*Δ*-$[Co(ox)_2(gly)]^{2-}$, in which *Λ*-$[Co(en)_3]^{3+}$ faces the anion complex along its C_3 axis (C_3 access) with its three N–H protons triply hydrogen-bonded to the three oxygen atoms of different chelate rings of $[Co(ox)_2(gly)]^{2-}$. This model well explains fairly strong association between the two complex ions (association constant K_A=480 $mol^{-1}dm^3$ at μ=0.01),[2] but it is not clearly demonstrated why the *Δ* anion complex associates more favorably with *Λ*-$[Co(en)_3]^{3+}$ than the antipode does. Furthermore, this model fails to account for the fact that the reversed elution order is obtained for $[Co(ox)_2(gly)]^{2-}$ when the eluent used is *Λ*-$[Co(d\text{-chxn})_3]^{3+}$ (*d*-chxn=(1*S*,2*S*)-1,2-cyclohexanediamine) which can also direct the C_3 axis like *Λ*-$[Co(en)_3]^{3+}$ to the anion complex, as seen later in Table 1.

Subsequently, Sakaguchi *et al.*[3] attempted to elucidate the discrimination mechanism more generally by employing as chiral selectors various cation complexes which had some structural characteristics restricting their possible interaction modes. A similar allowance was made for the selection of anion complexes to be examined. Some of the results they obtained are listed in Table 1. Based on these elution orders (*i.e.*, favorable pairs), they assumed that favorable pairs are formed between those chiral cation and anion complexes which have the same handedness of chelate rings when viewed along the axis that each complex directs to the counterpart complex upon association. However, it is not easily accepted that the overlapping of chelate rings rather than the interionic hydrogen bonding takes a major part in chiral discrimination between these amine complexes and oxalato or amino acidato complexes. In fact, the mechanism they proposed leads to a somewhat strange assertion that $[Co(en)_3]^{3+}$ always "uses" its C_2 axis to recognize the chirality of the anion complexes. In addition, the elution orders of $[Co(ox)_2(en)]^-$ obtained with *Δ*-$[Co(sep)]^{3+}$ (sep=1,3,6,8,10,13,16,19-octaazabicyclo[6.6.6]icosane) and *Δ*-$[Co(l\text{-chxn})_3]^{3+}$ (*l*-chxn=(1*R*,2*R*)-1,2-cyclohexanediamine) are opposite to those predicted by their proposal.

TABLE 1. ENANTIOMERS OF SOME ANION COMPLEXES WHICH FORM FAVORABLE PAIRS WITH Δ CATION COMPLEXES

edta=ethylenediaminetetraacetate ion and mal=malonate ion.
a) Erroneously determined in Ref. 3 and thus corrected here.

As presented above, no satisfactory explanation has been so far afforded for the elution orders (or favorable pairs formed between chiral complex cations and anions) determined by chromatography. It is a main purpose of the present study to elucidate the detailed mechanism by which chiral discrimination is effected

between these complex cations and anions bearing a hydrogen-bonding ability.

Experimental

Preparation of Metal Complexes. Appropriate salts of *Δ* isomers of $[Co(en)_3]^{3+}$, $[Co(sep)]^{3+}$, $[Co(sen)]^{3+}$ (sen=1,1,1-tris(((2-aminoethyl)amino)methyl)ethane), $[Co(l\text{-chxn})_3]^{3+}$, $[Co(l\text{-pn})_3]^{3+}$, (*l*-pn=(*R*)-propylenediamine), $[Co(gly)(en)_2]^{2+}$, $[Co(acac)(en)_2]^{2+}$, and *cis*-$[Co(NO_2)_2(en)_2]^+$ were available from the previous works[3,4] and/or were prepared by well-established methods. $[Co(sar)(en)_2]^{2+}$[5] (sar=sarcosinate anion), $[Co(\beta\text{-ala})(en)_2]^{2+}$[6] ($\beta$-ala=$\beta$-alaninate anion), and $[Co(N,N'\text{-Me}_2\text{-en})(en)_2]^{3+}$[7] ($N,N'$-Me$_2$-en=$N,N'$-dimethylethylenediamine) were also prepared as racemates of appropriate salts by the literature methods. Racemic $[Co(gly)(N,N'\text{-Me}_2\text{-en})(en)]^{2+}$ and $[Co(\beta\text{-ala})(N,N'\text{-Me}_2\text{-en})(en)]^{2+}$ were newly prepared as perchlorate salts by allowing $[Co(Cl)(gly)(OH_2)(en)]Cl$[8] and $[Co(Cl)_2(\beta\text{-ala})(en)]$,[9] respectively, to react with an equivalent amount of N,N'-Me$_2$-en in dimethyl sulfoxide at 60 °C for 5 h. The precipitates which formed upon addition of acetone were purified and converted to perchlorate salts by ion-exchange chromatography. Found: C, 19.73; H, 5.09; N, 14.31%. Calcd for $[Co(gly)(N,N'\text{-Me}_2\text{-en})(en)](ClO_4)_2=C_8H_{24}N_5O_{10}Cl_2Co$: C, 20.01; H, 5.04; N, 14.59%. Found: C, 21.60; H, 5.24; N, 13.93%. Calcd for $[Co(\beta\text{-ala})(N,N'\text{-Me}_2\text{-en})(en)](ClO_4)_2=C_9H_{26}N_5O_{10}Cl_2Co$: C, 21.87; H, 5.30; N, 14.17%.

Following anion complexes were also available from the previous work[3] and/or were prepared as described in the literature; $[Co(ox)_2(en)]^-$, $[Co(ox)_2(gly)]^{2-}$,[10] $[Co(ox)_2(acac)]^{2-}$,[10] and C_1- and C_2-*cis*(*N*)-$[Co(ox)(gly)_2]^-$.[11] They were found all chromatographically pure. The first two complexes were resolved by conventional methods.[10,12]

The absolute configuration has been assigned to most of the above complexes; the *Δ* isomers have a negative main CD component at the first d-d transition region except for $[Co(sep)]^{3+}$[13] and $[Co(sen)]^{3+}$,[14] the *Δ* isomers of which have a positive component.

Chromatographic Experiments. Two types of experiments were carried out in essentially the same manner as in the previous work[3] to determine the enantiomers of anion complexes which associate favorably with various types of *Δ* cation complexes.

Type (a) Experiment: The SP-Sephadex C-25 resin saturated with a *Δ* complex cation was packed in a glass column (12 mm i.d. ×170 mm). At the end of the column was placed a small amount of the resin (Na^+ form) to adsorb the complex cation eluted slightly during the chromatographic run. A racemic complex anion (0.3 cm^3 in 30 mmol dm^{-3}) was loaded on the top of the column and was eluted with 30% aqueous ethanol solution. The elution rate was regulated at 0.3 cm min^{-1} with a peristaltic pump. The eluate was fractionally collected, and absorption and circular dichroism spectra of each fraction (2 cm^3) were recorded on a Shimadzu UV-240 spectrophotometer and a Jasco J-40CS spectropolarimeter, respectively at ambient temperatures. The elution curves were obtained in this way when necessary, but the degree of resolution was generally so low that only the elution orders were determined for the most cases. Care was taken to ensure that the elution order was determined by the chirality of the complex cation in the resin, but not of the resin matrix.[15] It is the late-eluted enantiomer that interacts favorably with the *Δ* cation complex in the resin. Similar experiments were carried out for some racemic cation complexes on the QAE-Sephadex A-25 column saturated with an optically active $[Co(ox)_2(en)]^-$ or $[Co(ox)_2(gly)]^{2-}$ ion.

Type (b) Experiment: The same procedures as before[3,16] were applied to measure the retention volumes of some anion complexes. A racemic anion complex (20 μl in 0.1 mol dm^{-3}) was loaded with a syringe on the top of the IEX-520-SIL (anion-exchange resin) column and was eluted with an aqueous solution containing a *Δ* cation complex as a chloride salt in 10 mmol dm^{-3}. The column size was 4 mm i.d. ×150 mm and the elution rate was regulated at 0.5 cm^3 min^{-1} with a Jasco BIP-1 pump for HPLC. The eluate was guided to a flow cell to detect the anion complex at an appropriate wavelength with a Shimadzu UV-140 spectrophotometer. The retention volumes thus recorded were found to be reproducible to within at least ±0.1 cm^3. When necessary, two enantiomers of the anion complex were chromatographed separately to estimate respective retention volumes V_R.

Results and Discussion

In Table 2 are summarized enantiomers of anion

Table 2. Enantiomers of anion complexes which form favorable pairs with *Δ* cation complexes

	C_2^-		C_3^-	$C_2^-+C_3^-$	
	$[Co(ox)_2(en)]^-$	C_2-*cis*(*N*)-$[Co(ox)(gly)_2]^-$	C_1-*cis*(*N*)-$[Co(ox)(gly)_2]^-$	$[Co(ox)_2(gly)]^{2-}$	$[Co(ox)_2(acac)]^{2-}$

Δ-$[Co(sen)]^{3+}$	*Λ*	*Λ*	*Λ*	*Λ*	*Λ*

a) Also reported in Ref. 3. b) Erroneously determined in Ref. 3. c) Also reported in Ref. 17. d) Also reported in Ref. 19. e) Very low resolution attained. f) Also reported in Ref. 18. g) Ref. 2.

complexes which are eluted later in the type (a) experiment with *Δ* cation complexes employed as chiral selectors. Thus, it is these enantiomers that form favorable pairs with the *Δ* cation complexes. Some of the favorable pairs listed in Table 2 have been already reported by Tatehata *et al.*[17,18] and Sakaguchi *et al.*[3] Most of their results are reproduced by our present study, but those for $[Co(ox)_2(en)]^-$ obtained with *Δ*-$[Co(sep)]^{3+}$ and *Δ*-$[Co(l\text{-chxn})_3]^{3+}$ are at variance with the present results. Then, the elution order was determined repeatedly for $[Co(ox)_2(en)]^-$ with a longer column, leading to the conclusion that the two elution orders (or favorable pairs) were erroneously determined by Sakaguchi *et al.*

Structural Characteristics of Complexes. The cation complexes used as chiral selectors in the present study are *Δ*-$[Co(en)_3]^{3+}$, *Δ*-$[Co(sep)]^{3+}$, *Δ*-$[Co(sen)]^{3+}$, *Δ*-$[Co(l\text{-chxn})_3]^{3+}$, *Δ*-$[Co(l\text{-pn})_3]^{3+}$ (a mixture of *fac*-lel_3 and *mer*-lel_3 isomers), *Δ*-$[Co(acac)(en)_2]^{2+}$, *Δ*-$[Co(gly)(en)_2]^{2+}$, and *Δ*-*cis*-$[Co(NO_2)_2(en)_2]^+$. It is likely that interionic hydrogen bonds play a major role in association of these amine complex cations with complex anions such as $[Co(ox)_2(en)]^-$, $[Co(ox)_2(gly)]^{2-}$, and $[Co(ox)_2(acac)]^{2-}$. If inter-chelate repulsion is taken into account, hydrogen bonds are intimately formed between amino protons of the cation complex and coordinated oxygen atoms of the anion complex along either the (pseudo) C_3 or the (pseudo) C_2 axis of the respective complexes. That is, we assume that chiral discrimination between these complex cations and anions is effected along either the C_3 or the C_2 axis.

$[Co(sep)]^{3+}$ is covalently capped along both sides of the C_3 axis.[13] Thus, this complex can form hydrogen bonds to the anion complex only along its C_2 axis. Then, we say that $[Co(sep)]^{3+}$ belongs to the C_2^+ group complex and "uses" the C_2 axis only in association with the anion complex (C_2^+ access). $[Co(acac)(en)_2]^{2+}$ and *cis*-$[Co(NO_2)_2(en)_2]^+$ are also classified as the C_2^+ group, since they are expected to approach the anion complex along their C_2 axis from the side of their en rings so as to avoid the electrostatic repulsion between the negatively charged acac or NO_2 groups and the negative charge on the complex anion. On the other hand, $[Co(l\text{-chxn})_3]^{3+}$ and $[Co(l\text{-pn})_3]^{3+}$ are regarded as the C_3^+ group complex, since they are expected to direct the (pseudo) C_3 axis to the anion complex (C_3^+ access) owing to the presence of chxn or CH_3 groups on the chelate rings which will block the C_2^+ access. It is easily accepted that both C_2^+ and C_3^+ accesses are possible for $[Co(en)_3]^{3+}$ and $[Co(gly)(en)_2]^{2+}$, which thus belong to the $(C_2^+ + C_3^+)$ group. $[Co(sen)]^{3+}$ is also regarded as the $(C_2^+ + C_3^+)$ group complex, since it is capped covalently along one side of the C_3 axis, but the other side is available for hydrogen bonds to the anion complex.[14]

The anion complexes are also classified into three groups on the basis of the axis which they "use" in association with the cation complexes. For these anion complexes, charge localization on chelate rings is taken into account to determine the site and the direction of ion association.[3] Thus, $[Co(ox)_2(en)]^-$ and C_2-*cis(N)*-$[Co(ox)(gly)_2]^-$ belong to the C_2^- group complex, while C_1-*cis(N)*-$[Co(ox)(gly)_2]^-$ belongs to the C_3^- group, since three oxygen atoms are disposed triangularly along the pseudo C_3 axis in the last complex. $[Co(ox)_2(gly)]^{2-}$ as well as $[Co(ox)_2(acac)]^{2-}$ is, on the other hand, regarded as the $(C_2^- + C_3^-)$ group if the coordinated oxygen atoms of the acac ligand are available for the hydrogen-bonding interaction with amine complex cations.

Analysis of Favorable Pairs. As is evident in Tables 1 and 2, a typical C_2^+ group cation, *Δ*-$[Co(sep)]^{3+}$ forms favorable pairs always with the Λ anion complexes, whereas a typical C_3^+ group cation, *Δ*-$[Co(l\text{-chxn})_3]^{3+}$ does always with the *Δ* anion complexes. In other words, homochiral (*i.e.*, *Δ*-*Δ* or *Λ*-*Λ*) and heterochiral (*i.e.*, *Δ*-*Λ* or *Λ*-*Δ*) combinations are favored when the cation complex "uses" the C_3 and C_2 axes, respectively, regardless of which axis (C_3 or C_2) of the anion complex is directed to the cation complex. In fact, both *Δ*-$[Co(acac)(en)_2]^{2+}$ and *Δ*-*cis*-$[Co(NO_2)_2(en)_2]^+$ which belong to the C_2^+ group form favorable pairs with the Λ anion complexes.[19] *Δ*-$[Co(l\text{-pn})_3]^{3+}$ which has been tentatively classified as the C_3^+ group, however, favors unexpectedly a heterochiral combination (*Δ*-*Λ*) with the C_2^- group anions such as $[Co(ox)_2(en)]^-$ and C_2-*cis(N)*-$[Co(ox)(gly)_2]^-$. This is probably because the C_2^+ access of $[Co(l\text{-pn})_3]^{3+}$ can not be fully blocked by the CH_3 groups on the pn chelates.

For the $(C_2^+ + C_3^+)$ group cations, a heterochiral (*Δ*-*Λ*) combination is certainly favored in the interaction with the C_3^- and $(C_2^- + C_3^-)$ group anions, but the favorable pairs with the C_2^- group anions are not amenable to generalization. It should be noted here

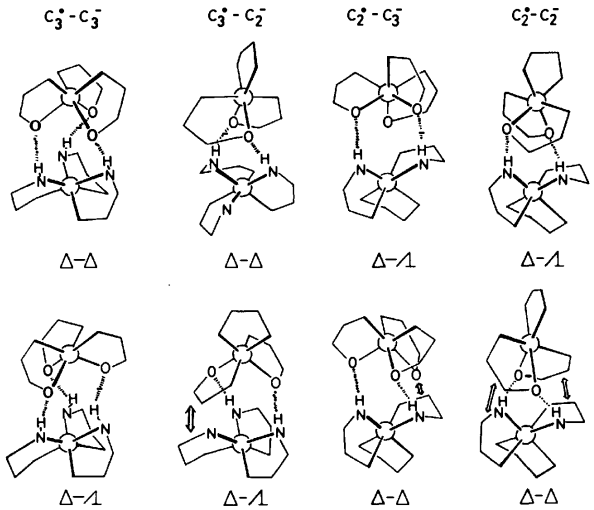

Fig. 1. Association models of $C_n^+ - C_m^-$ interaction modes between *Δ* cation complex and *Δ* or *Λ* anion complex. Favorable pairs are shown at the upper part.

that the degrees of resolution attained with Δ-$[Co(en)_3]^{3+}$ and Δ-$[Co(gly)(en)_2]^{2+}$ are very low, particularly for the C_2^- group anions. This implies that the (C_2^++C_3^+) group cations use both of the C_2 and C_3 axes in association with the anion complexes; they favor a heterochiral combination in the C_2^+ access, while they favor a homochiral one in the C_3^+ access, overall discrimination efficiency being thereby low. By contrast, $[Co(sen)]^{3+}$ always favors a heterochiral combination, though it has been classified above as the (C_2^++C_3^+) group cation.

Association Models. We now propose association models which explain consistently all the experimental data given in Table 2. In constructing the models, two acceptable assumptions were made; hydrogen-bonding interaction prevails between complex cation and anion, and these hydrogen bonds are formed intimately along either the (pseudo) C_3 or the (pseudo) C_2 axis of the respective complexes. All the possible interaction modes (C_3^+—C_3^-, C_3^+—C_2^-, C_2^+—C_3^-, and C_2^+—C_2^-) are depicted in Fig. 1, where C_n^+—C_m^- refers to the interaction in which complex cation and anion "use" the C_n and C_m axes, respectively on association. Each complex is assumed here to have five-membered bidentate chelates such as en, gly, or ox. Favorable pairs are drawn at the upper part, and the anion complex is located above the Δ cation complex in each pair where interionic hydrogen bonds are shown by dotted lines.

In the C_2^+—C_3^- and C_2^+—C_2^- interaction modes, favorable pairs are heterochiral (Δ-Λ or Λ-Δ), since inter-chelate repulsion is anticipated for the homochiral pair, as indicated by arrows. On the other hand, a favorable pair is homochiral (Δ-Δ or Λ-Λ) in the C_3^+—C_2^- mode because of the presence of similar interchelate repulsion in the heterochiral pair. In the C_3^+—C_3^- mode, such repulsion is not anticipated for either pair. However, the strength of the interionic hydrogen bond may be different between the two diastereomeric pairs; it depends greatly on the spacial disposition of the interacting atoms (H and O). A close examination of the two pairs in the C_3^+—C_3^- mode reveals that lone pair electrons on the O atoms of the anion complex are more favorably disposed in the homochiral pair for the hydrogen bonding with axial N-H protons of the cation complex than in the heterochiral pair, when the cation complex assumes the lel_3 conformation. Thus, a favorable pair is also homochiral in the C_3^+—C_3^- mode.

Tatehata *et al.*[2] supposed, on the contrary, that a favorable pair was heterochiral in the C_3^+—C_3^- mode, since they assumed that both $[Co(en)_3]^{3+}$ and $[Co(ox)_2(gly)]^{2-}$ use the (pseudo) C_3 axis in association. If so, favorable pairs formed with Δ-$[Co(l\text{-chxn})_3]^{3+}$ could not be accounted for, as discussed in Introduction. It should be pointed out here that discrimination efficiency may be very low in the C_3^+—C_3^- mode for conformationally labile complexes such as $[Co(en)_3]^{3+}$ and $[Co(gly)(en)_2]^{2+}$, since only a small difference in the strength of the interionic hydrogen bond is expected between the two diastereomeric pairs if the cation complex is conformationally labile.

In this way, the association models proposed here demonstrate that homochiral and heterochiral combinations are favored when the cation complex "uses" the C_3 and C_2 axes, respectively, in conformity with the experimental data listed in Table 2.

Now, if the above generalization is accepted as valid, favorable pairs formed with the (C_2^++C_3^+) group cations are analyzed in more detail. For $[Co(en)_3]^{3+}$, for example, all of the four modes, C_3^+—C_3^-, C_3^+—C_2^-, C_2^+—C_3^-, and C_2^+—C_2^- are possible in the interaction with the (C_3^-+C_2^-) group anions such as $[Co(ox)_2(gly)]^{2-}$ or $[Co(ox)_2(acac)]^{2-}$. The former two modes favor a homochiral combination, while the latter two favor a heterochiral one. The C_3^+—C_3^- mode is likely to contribute appreciably to the overall interaction between $[Co(en)_3]^{3+}$ and $[Co(ox)_2(gly)]^{2-}$ or $[Co(ox)_2(acac)]^{2-}$, but discrimination efficiency of this mode is low owing to the conformational lability of $[Co(en)_3]^{3+}$. Thus, the resulting favorable pair is eventually determined by the C_2^+ access which favors a heterochiral combination; the contribution due to the C_2^+—C_3^- and C_2^+—C_2^- modes surpasses that due to the C_3^+—C_3^- and C_3^+—C_2^- modes. Similarly, the C_2^+—C_3^- mode predominates over the C_3^+—C_3^- mode in the discriminating interaction of $[Co(en)_3]^{3+}$ with the C_3^- group anion like C_1-*cis(N)*-$[Co(ox)(gly)_2]^-$.

With the C_2^- group complex anion, the C_3^+—C_2^- and C_2^+—C_2^- modes contribute to chiral discrimination. It is not obvious in Fig. 1 which mode contributes more effectively. As a result, overall discrimination efficiency should be extremely low; the former mode barely predominates over the latter, a homochiral pair being eventually favored slightly over a heterochiral pair. The results obtained for $[Co(gly)(en)_2]^{2+}$ are analyzed similarly, though the C_2^+—C_2^- mode seems to predominate accidentally over the C_3^+—C_2^- mode in the interaction with C_2-*cis(N)*-$[Co(ox)(gly)_2]^-$ (C_2^-).

$[Co(sen)]^{3+}$ which also belongs to the (C_2^++C_3^+) group, however, always favors a heterochiral combination. This suggests that $[Co(sen)]^{3+}$ uses the C_2 axis more frequently than the C_3 axis,[4] probably because this complex is covalently capped along one side of the C_3 axis, while both of the two sides are available for hydrogen bonding in $[Co(en)_3]^{3+}$ which behaves as a typical (C_2^++C_3^+) group cation. In short, $[Co(sen)]^{3+}$ behaves as if it were a prototype of the C_2^+ group cation.

Effect of N-*Methylation on Chiral Discrimination.* In order to account for the favorable pairs formed with $[Co(en)_3]^{3+}$ or $[Co(gly)(en)_2]^{2+}$, we have made an assumption that both of the C_3^+ and C_2^+ accesses are

Table 3. Enantiomers of complex cations which form favorable pairs with Λ-$[Co(ox)_2(en)]^-$ and Λ-$[Co(ox)_2(gly)]^{2-}$

a) Isomers having CH_3 group(s) parallel to the pseudo C_3 axis. b) Very low resolution. c) *R* and *S* in the parentheses donote the configurations around the N atoms coordinated to Co(III).

involved in the interaction of these cation complexes. Then, if either of the two accesses is prohibited, say, by *N*-methylation of amino groups of the en or gly ligand, the discrimination mechanism would be drastically affected. With this expectation in mind, *N*-methyl derivatives of $[Co(en)_3]^{3+}$, $[Co(gly)(en)_2]^{2+}$, and $[Co(\beta\text{-ala})(en)_2]^{2+}$ were chromatographed on the QAE-Sephadex column saturated with Λ-$[Co(ox)_2(en)]^-$ or Λ-$[Co(ox)_2(gly)]^{2-}$ ion. The late-eluted enantiomers, *i.e.*, those forming favorable pairs with these Λ anion complexes are listed in Table 3.

With Λ-$[Co(ox)_2(en)]^-$ ion (C_2^-), both of the C_3^+—C_2^- and C_2^+—C_2^- modes are possible for $[Co(en)_3]^{3+}$, $[Co(gly)(en)_2]^{2+}$, and $[Co(\beta\text{-ala})(en)_2]^{2+}$. Since the former mode barely predominates over the latter, favorable pairs are homochiral, and the degrees of resolution are very low, as discussed earlier. For $[Co(N,N'\text{-}Me_2\text{-}en)(en)_2]^{3+}$ and $[Co(sar)(en)_2]^{2+}$ which have CH_3 group (s) parallel to the pseudo C_3 axis,[20] favorable pairs with $[Co(ox)_2(en)]^-$ are still homochiral, suggesting that the C_3^+ access is not prohibited in these *N*-methylated complexes. In other words, only two NH_2 groups are involved in the C_3^+—C_2^- mode (see Fig. 1), and the amino group of gly or β-ala is not effectively utilized in the C_3^+—C_2^- mode.

On the contrary, $[Co(gly)(N,N'\text{-}Me_2\text{-}en)(en)]^{2+}$ and $[Co(\beta\text{-ala})(N,N'\text{-}Me_2\text{-}en)(en)]^{2+}$ favor a heterochiral combination with $[Co(ox)_2(en)]^-$ and discrimination efficiency exhibited is not so low. This indicates that the CH_3 group located parallel to the pseudo C_3 axis renders the C_3^+ access impossible in these complexes, provided that the CH_3 group is present on the amino group of en but not of gly or β-ala. Thus, favorable pairs of the two cation complexes with $[Co(ox)_2(en)]^-$ are governed by the C_2^+—C_2^- mode which survives and favors a heterochiral combination, and thus the degree of resolution attained should not be so low.

With Λ-$[Co(ox)_2(gly)]^{2-}$ ($C_2^-+C_3^-$), all of the four modes are possible for $[Co(en)_3]^{3+}$, $[Co(gly)(en)_2]^{2+}$, and $[Co(\beta\text{-ala})(en)_2]^{2+}$. Since the contribution of the C_3^+—C_3^- mode to chiral discrimination is negligible for these conformationally labile complexes, favorable pairs are governed by the C_2^+ access which favors a heterochiral combination. Then, even if the C_3^+—C_3^- and C_3^+—C_2^- modes are prohibited by *N*-methylation favorable pairs remain heterochiral. Instead, discrimination efficiency should be improved. In fact, the degree of resolution is found to be higher for $[Co(gly)(N,N'\text{-}Me_2\text{-}en)(en)]^{2+}$ and $[Co(\beta\text{-ala})(N,N'\text{-}Me_2\text{-}en)(en)]^{2+}$ than for $[Co(gly)(en)_2]^{2+}$ and $[Co(\beta$-

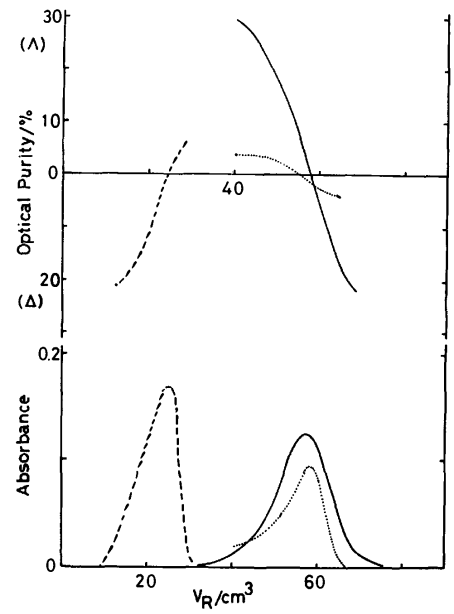

Fig. 2. Elution curves and plots of optical purity obtained for $[Co(ox)_2(en)]^-$ with Δ-$[Co(sep)]^{3+}$ (---), Δ-$[Co(l\text{-}chxn)_3]^{3+}$ (——), and Δ-$[Co(en)_3]^{3+}$ (···) employed as chiral selectors.

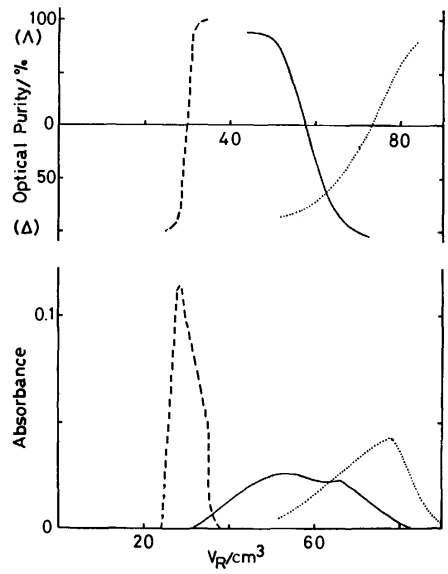

Fig. 3. Elution curves and plots of optical purity obtained for C_1-*cis*(*N*)-$[Co(ox)(gly)_2]^-$ with Δ-$[Co(sep)]^{3+}$ (---), Δ-$[Co(l\text{-}chxn)_3]^{3+}$ (——), and Δ-$[Co(en)_3]^{3+}$ (····) employed as chiral selectors.

ala)$(en)_2]^{2+}$, respectively. In this way, our assumption that both of the C_3^+ and C_2^+ accesses are involved in the (C_2^++C_3^+) group cation complexes, is verified experimentally.

Elution Curves. In Figs. 2 and 3 are shown the elution curves of $[Co(ox)_2(en)]^-$ (C_2^-) and C_1-*cis(N)*-$[Co(ox)(gly)_2]^-$ (C_3^-), respectively, obtained by the type (a) experiment with Δ-$[Co(sep)]^{3+}$ (C_2^+), Δ-$[Co(l\text{-}chxn)_3]^{3+}$ (C_3^+), and Δ-$[Co(en)_3]^{3+}$ (C_2^++C_3^+) ions as chiral selectors. Also plotted is the optical purity of each fraction of the eluate as a function of a retention volume V_R. It is seen that fairly good resolution is attained for both anion complexes with Δ-$[Co(sep)]^{3+}$ and Δ-$[Co(l\text{-}chxn)_3]^{3+}$, for which only the C_2^+ and C_3^+ accesses are possible, respectively. A comparison between Figs. 2 and 3 indicates that better resolution is attained for C_1-*cis(N)*-$[Co(ox)(gly)_2]^-$ (C_3^-) than for $[Co(ox)_2(en)]^-$ (C_2^-) with both cation complexes. This observation suggests that the C_2^+—C_3^- mode contributes more effectively to chiral discrimination than the C_2^+—C_2^- mode, and the C_3^+—C_3^- mode does than the C_3^+—C_2^- mode, provided that the C_3^+—C_3^- mode is of conformationally rigid complexes.

On the other hand, $[Co(en)_3]^{3+}$ certainly serves as a moderately good chiral selector for C_1-*cis(N)*-$[Co(ox)(gly)_2]^-$ (C_3^-), but it hardly discriminates the chirality of $[Co(ox)_2(en)]^-$ (C_2^-); the C_3^+—C_3^- mode is negligible as compared with the C_2^+—C_3^- mode for the former C_3^- complex, while the C_3^+—C_2^- and C_2^+—C_2^- modes contribute almost equally but oppositely to chiral discrimination for the latter C_2^- complex. Similarly, $[Co(en)_3]^{3+}$ is expected not to serve as a good selector for another C_2^- anion complex, C_2-*cis(N)*-$[Co(ox)(gly)_2]^-$.[18] The finding that the degree of resolution attained for C_1-*cis(N)*-$[Co(ox)(gly)_2]^-$ (C_3^-) with $[Co(en)_3]^{3+}$ is comparable to that attained with $[Co(sep)]^{3+}$ or $[Co(l\text{-}chxn)_3]^{3+}$, is consistent with the above assertion that discrimination efficiency is comparatively high in the C_2^+—C_3^- mode. If the C_3^+—C_2^- mode as well as the C_3^+—C_3^- mode of conformationally labile $[Co(en)_3]^{3+}$ is not effective, as mentioned above, $[Co(en)_3]^{3+}$ is expected to serve as a moderately effective selector for the (C_2^-+C_3^-) and particularly for the C_3^- group anions; the contribution of the C_2^+ access overwhelmingly surpasses that of the C_3^+ access in the discriminating interaction of conformationally labile $[Co(en)_3]^{3+}$ with these anion complexes. In fact, Tatehata *et al.*[18] have found that several anion complexes which we can classify as the C_3^- or (C_2^-+C_3^-) group anions, are completely resolved by usual ion-exchange chromatography with $[Co(en)_3]^{3+}$ employed as an eluent, though on a somewhat longer column.

In Figs. 4 and 5 are shown similar elution curves obtained by the type (a) experiment with Δ-$[Co(gly)(en)_2]^{2+}$(C_2^++C_3^+) and Δ-$[Co(acac)(en)_2]^{2+}$ (C_2^+) cations as chiral selectors. It is confirmed that $[Co(gly)(en)_2]^{2+}$ discriminates the chirality of $[Co(ox)_2(en)]^-$ (C_2^-) to a much lesser extent than $[Co(acac)(en)_2]^{2+}$ which uses the C_2 axis only and thus is expected to serve as a good selector. In fact, even $[Co(en)_3]^{3+}$ is less effective than $[Co(acac)(en)_2]^{2+}$ (Fig. 2). On the other hand, when the anion complex uses the C_3 axis only like C_1-*cis(N)*-$[Co(ox)(gly)_2]^-$ (C_3^-), the degree of resolution attained with $[Co(gly)(en)_2]^{2+}$ is almost comparable to that obtained with $[Co(acac)(en)_2]^{2+}$. This is again because the C_2^+—C_3^- mode is effective, but the C_3^+—C_3^- mode of conformationally labile $[Co(gly)(en)_2]^{2+}$ does not contribute appreciably

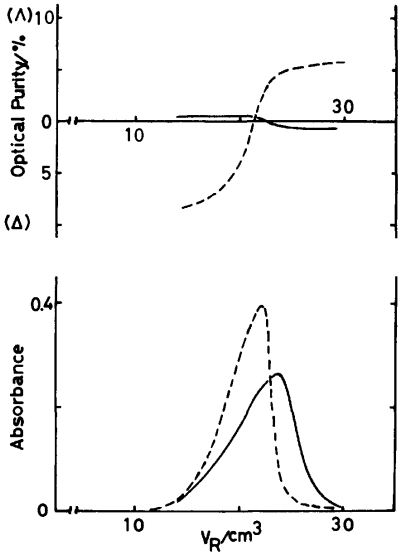

Fig. 4. Elution curves and plots of optical purity obtained for $[Co(ox)_2(en)]^-$ with Δ-$[Co(acac)(en)_2]^{2+}$ (---) and Δ-$[Co(gly)(en)_2]^{2+}$ (——) employed as chiral selectors.

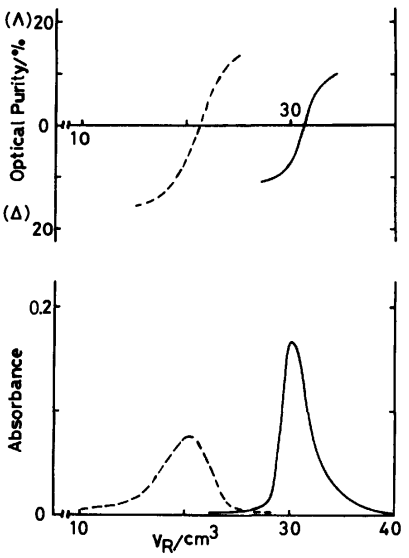

Fig. 5. Elution curves and plots of optical purity obtained for C_1-*cis(N)*-$[Co(ox)(gly)_2]^-$ with Δ-$[Co(acac)(en)_2]^{2+}$ (----) and Δ-$[Co(gly)(en)_2]^{2+}$ (——) employed as chiral selectors.

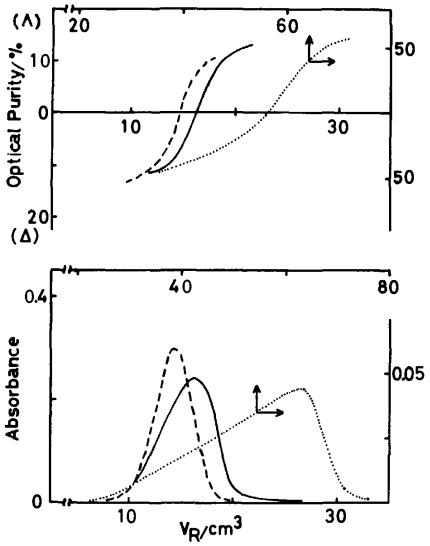

Fig. 6. Elution curves and plots of optical purity obtained for $[Co(ox)_2(gly)]^{2-}$ with Δ-$[Co(acac)(en)_2]^{2+}$ (----), Δ-$[Co(gly)(en)_2]^{2+}$ (——), and Δ-$[Co(en)_3]^{3+}$ (····) employed as chiral selectors.

to chiral discrimination, as discussed above. It is notable that $[Co(gly)(en)_2]^{2+}$ gives a greater retention volume V_R to C_1-*cis(N)*-$[Co(ox)(gly)_2]^-$ (C_3^-) than does $[Co(acac)(en)_2]^{2+}$ (C_2^+). This suggests that the C_3^+—C_3^- mode of $[Co(gly)(en)_2]^{2+}$ contributes appreciably to the overall interaction with the C_3^- anion complex.

Figure 6 shows the elution curves of $[Co(ox)_2(gly)]^{2-}$ obtained similarly with Δ-$[Co(en)_3]^{3+}$, Δ-$[Co(gly)(en)_2]^{2+}$, and Δ-$[Co(acac)(en)_2]^{2+}$ employed as a chiral selector. It is evident there that $[Co(gly)(en)_2]^{2+}$ is as effective as $[Co(acac)(en)_2]^{2+}$ in chiral discrimination of a typical (C_2^-+C_3^-) group anion, $[Co(ox)_2(gly)]^{2-}$, as expected. It is probably the difference in electric charge on the selectors that is responsible for generally lower optical resolution attained with $[Co(gly)(en)_2]^{2+}$ and $[Co(acac)(en)_2]^{2+}$ than with $[Co(en)_3]^{3+}$. The retention volumes V_R of $[Co(ox)_2(gly)]^{2-}$ obtained with these bivalent complexes are actually much smaller than that obtained with $[Co(en)_3]^{3+}$. By the same reason, univalent *cis*-$[Co(NO_2)_2(en)_2]^+$ does not serve as a good selector, though it uses the C_2 axis exclusively.

It is worthy of note here that some experimental results relevant to our present study have been reported. Miyoshi *et al.*[21] have found that Λ-*cis*-$[Co(X)(Y)(en)_2]^{n+}$-type complexes (X and/or Y=anion ligand) displace the chiral equilibrium of $[Cr(ox)_3]^{3-}$ in favor of its Δ enantiomer in dioxane-water mixtures. They have claimed that this phenomenon is successfully utilized to assign the absolute configuration to *cis*-$[M(X)(Y)(diamine)_2]^{n+}$-type complexes. Since these complexes are prototypes of the C_2^+ group cations, they should always favor a heterochiral combination, as is actually the case. Another experimental result to be noted is that the Δ enantiomer is enriched when

Table 4. Retention volumes V_R and separation factors α of $[Co(ox)_2(gly)]^{2-}$ obtained by HPLC

eluent	V_R/cm³		α
	Λ	Δ	
Δ-$[Co(sep)]Cl_3$	19.2	24.0	1.25
Δ-$[Co(l\text{-}chxn)_3]Cl_3$	15.2	11.9	1.28
Δ-$[Co(en)_3]Cl_3$	13.7[a]	14.3[a]	1.04

a) Determined by eluting resolved enantiomers separately.

a racemic mixture of tris(2,6-pyridinedicarboxylato)-terbium(III) is mixed with Λ-$[Cr(en)_3]^{3+}$ in dioxane-water mixtures.[22] Since the lanthanoid complex has an approximate D_3 symmetry and is regarded as the (C_2^-+C_3^-) group anion, all of the four interaction modes are possible. However, the contribution of the C_3^+—C_3^- mode is expected to be small because of the conformational lability of $[Cr(en)_3]^{3+}$. Consequently, the favorable pair should be heterochiral, as explained repeatedly.

Optical Resolution by HPLC. The above-mentioned discussions lead us to conclude that highly charged cation complexes which use the C_3 axis only and are conformationally rigid or which use the C_2 axis only, can recognize the chirality of anion complexes effectively, while those which use the two axes simultaneously do not in general serve as a good selector. However, the type (a) experiment is inherently not suitable for the practical resolution of anion complexes, since so-called ion-exclusion effect due to the negatively charged functional groups in the resin tends to diminish the chance of the anion complex to interact with the chiral cationic selector adsorbed in the resin.[23] In fact, very small retention volumes are obtained for all the anion complexes in the type (a) experiments. Then, we attempted to resolve $[Co(ox)_2(gly)]^{2-}$ by usual ion-exchange chromatography (type (b) experiment) with three cation complexes, Δ-$[Co(sep)]^{3+}$ (C_2^+), Δ-$[Co(l\text{-}chxn)_3]^{3+}$ (C_3^+), and Δ-$[Co(en)_3]^{3+}$ (C_2^++C_3^+) used as a chiral eluent. The retention volumes V_R and separation factors α obtained are given in Table 4.

The V_R values tell us that $[Co(en)_3]^{3+}$ and $[Co(chxn)_3]^{3+}$ which can use the C_3 axis bear a greater elution ability for $[Co(ox)_2(gly)]^{2-}$ than does $[Co(sep)]^{3+}$ which uses the C_2 axis only. That is, the C_3^+ access contributes to the overall interaction with the anion complex to a greater extent than the C_2^+ access. This seems to hold also for the interaction with C_1-*cis(N)*-$[Co(ox)(gly)_2]^-$ (Fig. 3) and $[Co(ox)_2(en)]^-$ (Fig. 2). On the other hand, a much higher α value is obtained with Δ-$[Co(sep)]^{3+}$ (α=1.25) which uses the C_2 axis only and with Δ-$[Co(l\text{-}chxn)_3]^{3+}$ (α=1.28) which uses the C_3 axis only than with Δ-$[Co(en)_3]^{3+}$ (α=1.04) which uses both of the C_3 and C_2 axes. This observation is in perfect agreement with what is predicted by our association models shown in Fig. 1. Tatehata *et*

al.,[2] nevertheless, succeeded in complete resolution of $[Co(ox)_2(gly)]^{2-}$ with chiral $[Co(en)_3]^{3+}$ employed as an eluent on a very long column (1300 mm long) of the DEAE-Sephadex A-25 resin and the α value is estimated to be *ca.* 1.08 from the elution curves. Therefore, if optically active $[Co(sep)]^{3+}$ or $[Co(chxn)_3]^{3+}$ is used in place of $[Co(en)_3]^{3+}$, much more efficient resolution of this anion complex should be achieved.

†*Department of Applied Molecular Science, Institute for Molecular Science, Myodaiji, Okazaki 444*
(Received March 28, 1985)

Nine new cobalt(III) complexes of the types, [Co(acac)(L)(edpp)]$^{2+}$ (L=ethylenediamine(en), (1*R*,2*R*)-1,2-cyclohexanediamine(*RR*-chxn), 2,2′-bipyridyl(bpy)), [Co(acac)(L′)(empp)]$^{2+}$ (L′=en, bpy), and structurally related [Co(acac)(bpy)(en)]$^{2+}$ were prepared and resolved into optical isomers, where acac, edpp, and empp denote an acetylacetonate ion, (2-aminoethyl)diphenylphosphine, and (2-aminoethyl)methylphenylphosphine, respectively. The molecular structure of (+)$^{CD}_{531}$-[Co(acac)(*RR*-chxn)(edpp)](ClO_4)$_2$ was determined by single-crystal X-ray analysis. Crystal data; monoclinic, $P2_1$, a=19.562(3)Å, b=16.882(1)Å, c=9.696(1)Å, β=91.22(1)°, V=3201.3(6)Å^3, Z=4. Three nitrogen donor atoms in the complex ion are arranged in the facial mannar (*fac*(*N*)) and the absolute configuration of the complex ion is *Λ*. The structures of other complexes were assigned by comparing the ^{1}H NMR and circular dichroism spectra with those of the *fac*(*N*)-*Λ*-[Co(acac)(*RR*-chxn)(edpp)]$^{2+}$ complex. The complexes containing a 1,2-diamine yielded selectively the *fac*(*N*) isomer, whereas those containing bpy the *mer*(*N*) isomer.

In our recent studies on cobalt(III)–tertiary phosphine complexes, we have often observed stereoselective formation of a particular geometrical isomer.[1–7] This seems to arise from the steric effect of bulky substituents on a phosphorus donor atom and/or the strong trans effect of a phosphine ligand. In this paper, we have extended the study to cobalt(III) phosphine complexes of the type, [Co(acac)(L)(L′)]$^{2+}$ (L= en, *RR*-chxn, bpy; L′=edpp, empp), where one of the two acac ligands in [Co(acac)$_2$(L′)]$^+$ [6,8] is replaced by the typical chelate ligand with nitrogen donor atoms L. The abbreviations used here are as follows; acac=acetylacetonate ion, en=ethylenediamine, *RR*-chxn=(1*R*,2*R*)-1,2-cyclohexanediamine, bpy=2,2′-bipyridyl, edpp=(2-aminoethyl)diphenylphosphine, empp=(2-aminoethyl)methylphenylphosphine.

Experimental

Phosphine ligands, edpp[9] and empp,[8]* were prepared according to the reported methods and handled under a nitrogen atmosphere until they formed cobalt(III) complexes. Absorption, circular dichroism (CD), and ^{1}H NMR spectra were recorded on a Hitachi 323 spectrophotometer, a Jasco J-40CS spectropolarimeter, and a Jeol JNM-PMX 60 spectrometer, respectively.

Preparation of the Complexes. fac(N)-*[Co(acac)(en)(edpp)]Br$_2$·2H$_2$O*: To a methanol solution (160 cm^3) of [Co(acac)(en)$_2$]Br$_2$[11] (2.5 g, 5.7 mmol) were added edpp (1.17 g, 5.1 mmol) in methanol (10 cm^3) and active charcoal (*ca.* 0.2 g). The solution was stirred at room temperature overnight and then filtered. The filtrate was diluted with water (2 dm^3, pH *ca.* 4 with HCl) and mixed with diethyl ether (500 cm^3) to extract free edpp into the ethereal layer. The aqueous layer was applied on a column (2.5×120 cm) of SP-Sephadex C-25. By elution with 0.2 mol dm^{-3} NaCl, three red bands containing [Co(acac)(en)$_2$]$^{2+}$, [Co(acac)(en)(edpp)]$^{2+}$, and [Co(acac)(edpp)$_2$]$^{2+}$ developed in this order. The second eluate containing [Co(acac)(en)(edpp)]$^{2+}$ was collected and concentrated to *ca.* 200 cm^3 under reduced pressure at 45 °C and mixed with an aqueous solution (30 cm^3) of NaB(C_6H_5)$_4$ (1 g) to give a red precipitate. The precipitate was filtered, washed with water, and then dissolved in a mixture of methanol (500 cm^3) and water (500 cm^3). The solution was applied on a column (2.5×10 cm) of Dowex 1×8 (Br^- form). The eluate was evaporated to dryness under reduced pressure, and the residue was crystallized from water. Yield: 420 mg (13%). Found: C, 39.07; H, 5.55; N, 6.85%. Calcd for $C_{21}H_{35}N_3O_4PBr_2Co$: C, 39.21; H, 5.48; N, 6.53%. The complex is soluble in water and methanol.

fac(N)-*Λ*-*[Co(acac)(RR-chxn)(edpp)](ClO_4)$_2$* *and* fac(N)-*Δ*-*[Co(acac)(RR-chxn)(edpp)](PF_6)$_2$·1.5H$_2$O*: A mixture of [Co(acac)$_3$][12] (5.0 g, 14 mmol), *RR*-chxn (3.2 g, 28 mmol), and active charcoal (*ca.* 0.2 g) in methanol (350 cm^3) was stirred at 25 °C overnight, and filtered. The filtrate was diluted with water (2 dm^3) and applied on a column (5×10 cm) of SP-Sephadex C-25. After red-violet [Co(acac)$_2$(*RR*-chxn)]$^+$ had been eluted from the column with 0.05 mol dm^{-3} NaCl, red [Co(acac)(*RR*-chxn)$_2$]$^{2+}$ was eluted with 0.2 mol dm^{-3} NaCl. The eluate was concentrated to *ca.* 150 cm^3 under reduced pressure at 45 °C. On addition of $NaClO_4$ (5 g) in water (50 cm^3) the concentrate gave a precipitate of a mixture of *Δ*- and *Λ*-[Co(acac)(*RR*-chxn)$_2$](ClO_4)$_2$, which was filtered, washed with a small amount of water, and air-dried. Yield: 5.4 g. A mixture of [Co(acac)(*RR*-chxn)$_2$](ClO_4)$_2$ (0.90 g, 1.5 mmol), edpp (0.35 g, 1.5 mmol), and active charcoal (*ca.* 0.1 g) in methanol (100 cm^3) was stirred overnight at room temperature. The resulting solution was filtered and subjected to column chromatography in the same way as for the en complex. By elution with 0.2 mol dm^{-3} NaCl, the starting complex, and the *Λ*-(FI) and *Δ*-(FII) isomers of the

*The notation of the absolute configurations, *R* and *S*, for the chiral phosphorus atom of a free ligand is reversed upon coordination to the cobalt(III) ion.[10] In this paper, we use the same notation for a coordinationg phosphine ligand as that when it is free.

desired complex were eluted separately in this order. The eluate containing FI was diluted ten times with water, applied again on a column (1×10 cm) of SP-Sephadex C-25, and the adsorbed complex was eluted with 1 mol dm^{-3} $NaClO_4$. The eluate was saturated with $NaClO_4$, and the complex was extracted with chloroform. The chloroform was separated and evaporated to dryness. The residue was crystallized from a mixture of methanol and water (1:1). Yield (FI, *Λ*-isomer): 94 mg (9%). Found: C, 42.55; H, 5.21; N, 5.62%. Calcd for $C_{25}H_{37}N_3O_{10}PCl_2Co$: C, 42.87; H, 5.32; N, 6.00%.

The formation of the other isomer (FII(*Δ*)) was poor (*ca.* 1/3 of the *Λ*-isomer), so that the procedure was repeated several times. The combined eluate containing FII was concentrated to a small volume and mixed with excess $NaPF_6$ to yield a red precipitate, which was recrystallized from a mixture of methanol and water (1:1). Found: C, 36.49; H, 4.52; N, 5.32%. Calcd for $C_{25}H_{40}N_3O_{3.5}P_3F_{12}Co$: C, 36.69; H, 4.93; N, 5.13%. Both complexes FI and FII are soluble in water and methanol.

fac(N)-*Δ*(R),*Λ*(S)-*[Co(acac)(en)(empp)]*$Br_2 \cdot 2H_2O$ *and* fac(N)-*Δ*(S),*Λ*(R)-*[Co(acac)(en)(empp)]*$Br_2 \cdot 1.5H_2O$: These complexes were prepared from $[Co(acac)(en)_2]Br_2$ (0.48 g, 1.05 mmol) and rac-empp (0.18 g, 1.07 mmol) by a method analogous to that for $[Co(acac)(en)(edpp)]^{2+}$. By elution with 0.1 mol dm^{-3} Na_2SO_4, the starting complex, and the *Δ(R),Λ(S)*-(FI) and *Δ(S),Λ(R)*-(FII) isomers of the desired complex were eluted separately in this order. Each eluate containing the empp complex was evaporated to dryness under reduced pressure, and the complex was extracted with ethanol. The extract was applied on a column (1×5 cm) of Dowex 1×8 (Br^- form), and the effluent was evaporated to dryness. The residue was dissolved again in methanol (5 cm^3) and then mixed with diethyl ether (3 cm^3). The solution was stored in a refrigerator, yielding crystals of the complex. Yield: FI (*fac(N)-Δ(R),Λ(S)* isomer), 24 mg (4%); FII (*fac(N)-Δ(S),Λ(R)* isomer), 35 mg (6%). Found for FI: C, 33.26; H, 5.30; N, 7.22%. Calcd for $C_{16}H_{33}N_3O_4PBr_2Co$: C, 33.07; H, 5.72; N, 7.23%. Found for FII: C, 33.88; H, 5.40; N, 7.30%. Cacld for $C_{16}H_{32}N_3O_{3.5}PBr_2Co$: C, 33.59; H, 5.64; N, 7.34%. The complexes are soluble in water and methanol.

mer(N)-*[Co(acac)(bpy)(edpp)]*$(PF_6)_2$: An *N,N*-dimethylformamide solution (100 cm^3) containing $[Co(acac)(bpy)_2](ClO_4)_2$[13] (440 mg, 0.66 mmol) and edpp (153 mg, 0.67 mmol) was stirred at room temperature overnight. The resulting solution was diluted with 5% aqueous acetic acid (3 dm^3), and the free edpp ligand was extracted with diethyl ether (500 cm^3). The aqueous layer was applied on a column (2.5×50 cm) of SP-Sephadex C-25. By elution with 0.2 mol dm^{-3} NaCl, three reddish brown bands containing $[Co(acac)(bpy)_2]^{2+}$, $[Co(acac)(bpy)(edpp)]^{2+}$, and $[Co(acac)(edpp)_2]^{2+}$ were eluted successively. The eluate of the second band was collected and evaporated to *ca.* 50 cm^3 under reduced pressure. On addition of $NaPF_6$ the concentrate gave a reddish brown precipitate, which was filtered and recrystallized from acetone (5 cm^3) by adding water (3 cm^3). Yield: 80 mg (15%). Found: C, 41.96; H, 3.69; N, 5.19%. Calcd for $C_{29}H_{31}N_3O_2P_3F_{12}Co$: C, 41.79; H, 3.75; N, 5.19%. The complex is soluble in methanol and acetone, but hardly in water.

mer(N)-*Δ*(R),*Λ*(S)-*[Co(acac)(bpy)(empp)]*$(PF_6)_2$ *and* mer(N)-*Δ*(S),*Λ*(R)-*[Co(acac)(bpy)(empp)]*$(PF_6)_2 \cdot 1.5H_2O$: These complexes were prepared by a method similar to that for $[Co(acac)(bpy)(edpp)]^{2+}$ using $[Co(acac)(bpy)_2](ClO_4)_2$ (612 mg, 0.91 mmol) and empp (153 mg, 0.92 mmol). By SP-Sephadex C-25 column chromatography, the eluate containing a mixture of *Δ(R),Λ(S)*- and *Δ(S),Λ(R)*-isomers of *mer(N)*-$[Co(acac)(bpy)(empp)]^{2+}$ was obtained from the second band, the small first and large third bands containing $[Co(acac)(bpy)_2]^{2+}$ and $[Co(acac)(empp)_2]^{2+}$, respectively. The second eluate was diluted with water (1 dm^3) and applied again on a column (2×15 cm) of SE-Toyopearl.[14] The adsorbed band was separated into two (FI and FII in the elution order) by elution with 0.3 mol dm^{-3} NaBr. Each eluate was concentrated to *ca.* 50 cm^3 under reduced pressure, and then mixed with NH_4PF_6 (20 mg) to yield an orange precipitate, which was recrystallized from methanol and water (1:1). Yield: FI(*mer(N)-Δ(R), Λ(S)* isomer) 40 mg (6%). FII (*mer(N)-Δ(S), Λ(R)* isomer) 20 mg (3%). Found for FI: 37.28; H, 3.71; N, 5.43%. Calcd for $C_{24}H_{29}N_3O_2P_3F_{12}Co$: C, 37.37; H, 3.79; N, 5.45%. Found for FII: C, 35.91; H, 3.64; N, 5.32%. Calcd for $C_{24}H_{32}N_3O_{3.5}P_3F_{12}Co$: C, 36.11; H, 4.04; N, 5.26%. These complexes are soluble in water and common organic solvents such as alcohols, acetone, and chloroform.

[Co(acac)(bpy)(en)]$(PF_6)_2$: An aqueous solution containing $[Co(CO_3)_3]^{3-}$ was prepared from $KHCO_3$ (10 g, 100 mmol) and $CoCl_2 \cdot 6H_2O$ (3.5 g, 15 mmol) according to a literature method.[15] The solution was diluted with water (400 cm^3) and then mixed with a solution of bpy (1.8 g, 12 mmol) in methanol (50 cm^3). The solution was stirred at room temperature for 2 h, and then en·H_2CO_3[15] (1.7 g, 14 mmol) was added with stirring. After 30 min the solution was stirred at 50 °C for 30 min. The resulting red solution was diluted 100 times with water and applied on a column (5×15 cm) of SP-Sephadex C-25. By elution with 0.03 mol dm^{-3} NaCl, red fractions containing complexes with the +1 charge were collected and concentrated to *ca.* 100 cm^3 under reduced pressure. On addition of $NaBF_4$ (13 g) the concentrate yielded a light brown precipitate of $[Co(CO_3)(bpy)_2]BF_4$, which was filtered off. The filtrate was mixed with additional $NaBF_4$ (5 g), and the mixture was kept at 0 °C for a while, yielding a red precipitate of $[Co(CO_3)(bpy)(en)]BF_4$ (5.8 g). The precipitate was filtered and washed with a small amount of cold water. To an aqueous solution (50 cm^3) of $[Co(CO_3)(bpy)(en)]BF_4$ (0.8 g, 1.9 mmol) were added acetylacetone (0.5 cm^3) and acetic acid (0.3 cm^3). The mixture was stirred at 50 °C for 3 h and then filtered. The filtrate was diluted with water (1 dm^3) and applied on a column (2×50 cm) of SP-Sephadex C-25. The desired red complex was eluted from the column with 0.2 mol dm^{-3} NaCl. The eluate was concentrated to *ca.* 50 cm^3 under reduced pressure. The concentrate was mixed with NH_4PF_6 (50 mg) to yield a red precipitate, which was recrystallized from methanol and water (3:1). Yield: 165 mg (13%). Found: C, 30.70; H, 3.30; N, 8.47%. Calcd for $C_{19}H_{23}N_4O_2P_2F_{12}Co$: C, 30.74; H, 3.49; N, 8.43%. The complex is soluble in methanol, but hardly in water.

Optical Resolution of the Complexes. Optical resolution of the complexes was carried out by an SP-Sephadex C-25 column-chromatographic method using a column (2.5×120 cm) and 0.2 mol dm^{-3} $Na_2[Sb_2(d\text{-tartrate})_2]$ as an eluent.[16] For $[Co(acac)(bpy)(en)]^{2+}$ and isomers FI and FII of $[Co(acac)(bpy)(empp)]^{2+}$, the resolution was complete, while it was incomplete for $[Co(acac)(en)(edpp)]^{2+}$, $[Co(acac)(bpy)(edpp)]^{2+}$, and isomer FII of $[Co(acac)(en)(empp)]^{2+}$. However, the first several fractions of the band containing each of these three complexes showed a con-

stant $\Delta\varepsilon/\varepsilon$ value, and were subjected to CD measurements. No resolution was achieved for isomer FI of [Co(acac)(en)(empp)]$^{2+}$.

The eluate containing the resolved complex was diluted 20 times with water and applied on a column (0.7×5 cm) of SP-Sephadex C-25. After the column had been washed with water, the adsorbed complex was eluted with 1 mol dm^{-3} NaCl, and the effluent was used for CD measurements. The complex concentration in the effluent was determined by measuring the optical density of the first absorption band.

X-Ray Analysis. X-Ray analysis of $(+)^{CD}_{531}$-[Co(acac)(*RR*-chxn)(edpp)](ClO$_4$)$_2$ (FI) was performed. Crystal Data: monoclinic, $P2_1$, a=19.562(3) Å, b=16.882(1) Å, c=9.696(1) Å, β=91.22(1)°, V=3201.3(6) Å^3, Z=4, D_m=1.45 g cm^{-3}, D_c=1.45 g cm^{-3}, μ(Mo $K\alpha$)=0.832 mm^{-1}. A specimen with dimensions 0.50×0.45×0.45 mm^3 was used for the X-ray work. Diffraction data were collected on a Rigaku AFC-5 diffractometer with graphite monochromatized Mo $K\alpha$ radiation. Within the range $2\theta<60°$, 5053 independent reflections with $|F_o|\geq 3\sigma(|F_o|)$ were obtained. In order to determine the absolute configuration, intensity data for Bijvoet pair reflections were also collected up to 2θ=35°. The intensity data were corrected for Lorentz-polarization effects, and for absorption.

The calculations of the structure analysis were performed on a HITAC M-180 computer at the Computer Center of the Institute for Molecular Science with the Universal Crystallographic Computation Program System UNICS III.[17] The structure was solved by the direct method (MULTAN). The positions of all the hydrogen atoms were identified in subsequent difference-Fourier maps. The structure was refined by a block-diagonal least-squares method with anisotropic thermal parameters for non-hydrogen atoms and isotropic for hydrogens. The weighting scheme, $w=[\sigma^2_{count}+(0.015|F_o|)^2]^{-1}$, was employed. At the final stage, refinements were carried out on two enantiomeric models, $\Lambda(R,R)$ and $\Lambda(S,S)$, using 6577 intensities including the Bijvoet pair reflections. The R and R_w values were reduced to 0.052 and 0.065, respectively, for the $\Lambda(R,R)$ configuration, whereas the values were 0.060 and 0.074 for the $\Lambda(S,S)$ model, respectively. Thus application of the R-factor ratio test[18] showed that the $\Lambda(S,S)$ model can be rejected at the 99.5% confidence level. This result is consistent with the fact that *RR*-chxn was used for the preparation of the complex.

Table 1 lists the atomic parameters for non-hydrogen atoms. Complete lists of observed and calculated structure factors, hydrogen atomic parameters, and thermal parameters for non-hydrogen atoms are preserved by the Chemical Society of Japan (Document No. 8539).

Results and Discussion

In general, it is difficult to prepare octahedral complexes comprising of three different kinds of bidentate ligands in good yield.[16,19] The [Co(acac)(en)(edpp)]$^{2+}$ complex was obtained in a 13% yield by reaction of [Co(acac)(en)$_2$]$^{2+}$ with edpp in methanol in the presence of active charcoal. The complex was also obtained by a similar reaction between [Co(acac)$_2$(en)]$^+$ and edpp in a yield of less than 10%. However, no desired complex was formed by reaction of

$[Co(acac)_2(edpp)]^+$ and en. Other edpp and empp complexes were prepared by methods analogous to that for $[Co(acac)(en)(edpp)]^{2+}$ from $[Co(acac)(diamine\ or\ bpy)_2]^{2+}$ and the phosphine ligand. The $[Co(acac)(bpy)_2]^{2+}$ complex reacted with the phosphine ligand in the absence of active charcoal to give [Co(acac)(bpy)(phosphine)]$^{2+}$, while the corresponding bis(diamine) complexes did not react under the same conditions.

There are two possible geometrical isomers, *fac(N)* and *mer(N)*, for $[Co(acac)(N\text{-}N)(N\text{-}P)]^{2+}$, where N-N and N-P represent diamine or bpy and aminoalkylphosphine chelate ligands, respectively (Fig. 1). Each of the geometrical isomers has a pair of enantiomers, *Δ* and *Λ*, when all the chelate ligands are achiral, and can have a pair of diastereomers, *Δ(R)(Λ(S))* and *Λ(R)(Δ(S))*, when a chiral ligand is contained. Both [Co(acac)(en)(edpp)]$^{2+}$ and [Co(acac)(bpy)(edpp)]$^{2+}$ formed only one of the two possible geometrical isomers as evidenced by column chromatography. The same isomer of [Co(acac)(en)(edpp)]$^{2+}$ was also yielded selectively by the reaction of edpp with $[Co(acac)_2(en)]^+$ in place of $[Co(acac)(en)_2]^{2+}$. Each of [Co(acac)(*RR*-chxn)(edpp)]$^{2+}$, [Co(acac)(en)(empp)]$^{2+}$, and [Co(acac)(bpy)(empp)]$^{2+}$ yielded two isomers. However, the isomers were a pair of diastereomers with the same geometrical configuration, *fac(N)* or *mer(N)*. (*vide infra*) Thus the [Co(acac)(N-N)(N-P)]$^{2+}$-type complex forms selectively only one of two possible geometrical isomers.

In order to assign geometrical structures of the complexes, a crystal of $(+)_{531}^{CD}$-[Co(acac)(*RR*-chxn)(edpp)]$(ClO_4)_2$ (FI) was subjected to X-ray analysis. There are two crystallographically independent but chemically equivalent complex ions (**1** and **2**). Figure 2 shows a stereoview of complex **1** and the numbering scheme of the atoms. The complex ion has three nitrogen donor atoms arranged in a facial manner and is assigned as the *fac(N)* isomer shown in Fig. 1. The absolute configuration of the complex ion is *Λ*. The selected bond distances and angles for complex **1** are listed in Table 2. The Co(1)-P distance of 2.224(3) Å (Co(2)-P: 2.234(3) Å) is slightly shorter than those found in *trans(Cl,Cl),cis(P,P)*-$[CoCl_2(edpp)_2][CoCl_4]$ (2.255(3) Å)[4], *trans(NCS,NCS),cis(P,P)*$[Co(NCS)_2(edpp)_2]Br\cdot 3H_2O\cdot(CH_3)_2CO$ (2.270 Å)[20], and *cis(NCS,NCS), trans-*

(*P*,*P*)-[Co(NCS)$_2$(edpp)$_2$]Br · CH$_3$OH (2.269Å).[20] The Co(1)-N(2) distance is longer by *ca.* 0.05Å than the mean of Co(1)-N(1) and Co(1)-N(3) distances, indicating trans influence of the P donor atom. Elongations of Co-N bonds due to trans influence of a phosphine ligand have been observed in the above trans-dianiono complexes, and *fac*-[Co{NH$_2$CH$_2$CH$_2$P(CH$_3$)$_2$}$_3$]$^{3+}$[7] and related complexes.[1,3,21] Bond angles around P deviate fairly largely from the tetrahedral angle. In particular, the widening of Co(1)-P(1)-C(14) (120.5(4)Å) is noticeable. This widening may be caused by the steric interaction between the phenyl group containing C(14) and the hydrogen atom(s) on N(1) of *RR*-chxn. The other phenyl group is disposed over the acac ring. (Fig. 3) The angle between the best planes of chelate Co-acac and phenyl rings is 25.6(3)°. The maximum deviations from the best planes of Co-acac and phenyl rings are 0.152Å and 0.04Å, respectively. The distance from C(20) to the best plane of the Co-acac ring is 3.062(8)Å. As shown later, such a stacking structure of the phenyl and acac rings causes a high-field shift of the methine proton signal of acac in ^{1}H NMR spectra. The chelate ring formed by *RR*-chxn takes a typical λ gauche conformation, whereas that formed by edpp an envelope conformation.

Table 3 lists ^{1}H NMR data of the complexes. The *fac(N)*-*Λ*-[Co(acac)(*RR*-chxn)(edpp)]$^{2+}$ isomer (FI) whose structure has been determined shows the methine proton signal of acac at a remarkably high field (5.00 ppm). The high-field shift is attributable to the shielding effect of the phenyl ring disposed over the acac ring.[8] The [Co(acac)(en)$_2$]$^{2+}$ and [Co(acac)$_2$(edmp)]$^+$ (edmp=NH$_2$CH$_2$CH$_2$P(CH$_3$)$_2$) complexes give the corresponding signals at 5.78 ppm,[22] and 5.34 and 5.51 ppm,[8] respectively. The other isomer FII of [Co(acac)(*RR*-chxn)(edpp)]$^{2+}$ also exhibits the methine proton signal at a high field (5.16 ppm) and can be assigned to the same *fac(N)* isomer (*Δ*-isomer). Thus [Co(acac)(*RR*-chxn)(edpp)]$^{2+}$ yields selectively the *fac(N)* geometrical isomer. In the corresponding *mer(N)* isomer, one of the two phenyl groups on P is to be placed above the puckered *RR*-chxn ring. Molecular models show that the *mer(N)* structure brings about a large steric interaction between the phenyl group and the axial hydrogen atoms on nitrogen and carbon atoms of *RR*-chxn. The interaction will render the *mer(N)* isomer unstable.

The methine protons of [Co(acac)(en)(edpp)]$^{2+}$ and isomer FII of [Co(acac)(en)(empp)]$^{2+}$ resonate at a high field, and both complexes are assigned as the *fac(N)* isomer. For *fac(N)*-[Co(acac)(en)(empp)]$^{2+}$, two racemic pairs of diastereomers, *Δ*(*R*),*Λ*(*S*) and *Δ*(*S*),*Λ*(*R*), are possible. (Fig. 4) The former and the latter diastereomers have the phenyl and the methyl groups of empp, respectively over the acac ring. Thus isomer FII of [Co(acac)(en)(empp)]$^{2+}$ is assigned to the racemic pair of *fac(N)*-*Δ*(*R*),*Λ*(*S*) from a high-field shift of the methine proton signal. The other isomer FI of [Co(acac)(en)(empp)]$^{2+}$ shows the methine proton signal at a low field (5.81 ppm), but exhibits the

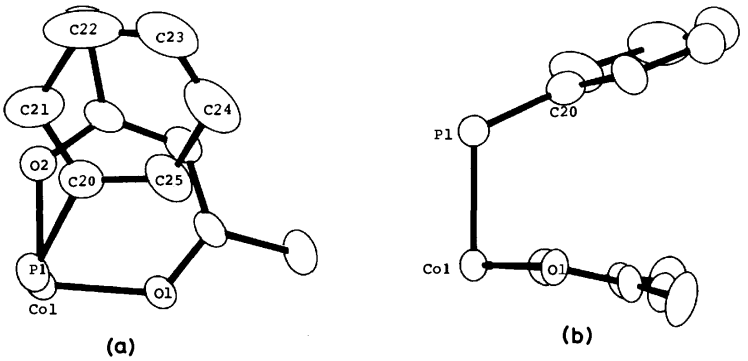

Fig. 3. A stucking structure of the Co-acac and phenyl rings of complex **1**.

TABLE 3. ^{1}H NMR AND ABSORPTION SPECTRAL DATA

Complex	^{1}H NMR[a] (acac)				Absorption[b]	Assignment

[Co(acac)(bpy)(empp)]$^{2+}$(FI)	2.16	2.43	6.03	D_2O	21.5(2.62)	*mer(N)-Δ(R),Λ(S)*
[Co(acac)(bpy)(empp)]$^{2+}$(FII)	2.06	2.21	6.19	D_2O	21.5(2.64)	*mer(N)-Δ(S),Λ(R)*
[Co(acac)(bpy)(en)]$^{2+}$	1.92	2.47	5.83	CD_3OD	19.9(2.23)	

a) δ/ppm from TMS. b) First absorption band peak, $\tilde{\nu}/10^3$cm^{-1}(log ε), solvent: CH_3OH for the bpy complexes and H_2O for the other complexes.

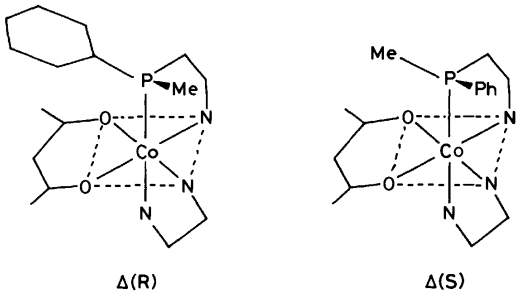

Fig. 4. Diastereomers of *fac(N)*-[Co(acac)(en)(empp)]$^{2+}$.

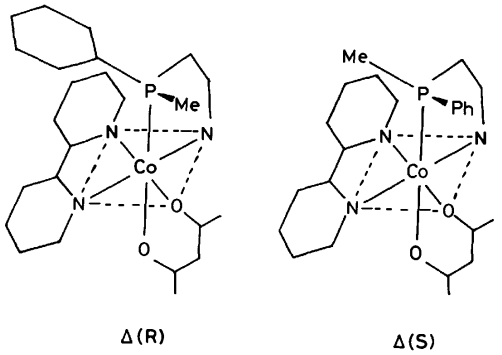

Fig. 5. Diastereomers of *mer(N)*-[Co(acac)(bpy)(empp)]$^{2+}$.

P-CH_3 proton signal at a remarkably high field (1.77 ppm) compared with that of the isomer FII (2.17 ppm). The high-field shift will be attributable to the shielding effect of the pseudo aromatic acac ring. Thus isomer FI can be assigned as the racemic pair of *fac(N)-Δ(S),Λ(R)*. The assignment is supported by absorption spectra of these two isomers. The first absorption band of isomer FI is at a higher energy and smaller in intensity (20800 cm^{-1}, log ε=2.63) than that of isomer FII (20600 cm^{-1}, log ε=2.79), although the spectral patterns are very similar. A similar spectral relation has been observed between the two analogous diastereomers, *Δ(R),Λ(S)* (19700 cm^{-1}, log ε=2.40) and *Δ(S),Λ(R)* (19500 cm^{-1}, log ε=2.62) of [Co(acac)$_2$(empp)]$^+$,[8] the first absorption band of the isomer having the phenyl group disposed over the acac ring being more intense and at lower energy than that of the other isomer. Thus [Co(acac)(en)(empp)]$^{2+}$ also forms selectively the *fac(N)* geometrical isomer (*Δ(R),Λ(S)* (FII), *Δ(S),Λ(R)* (FI)).

All of the bpy complexes, [Co(acac)(bpy)(edpp)]$^{2+}$ and isomers FI and FII of [Co(acac)(bpy)(empp)]$^{2+}$ exhibits the methine proton signal of acac at a low field (5.99—6.19 ppm). The results suggest that the complexes are the *mer(N)* geometrical isomer. When [Co(acac)(bpy)(empp)]$^{2+}$ has the *mer(N)* structure, two racemic pairs of the diastereomers, *Δ(R),Λ(S)* and *Δ(S),Λ(R)* have the phenyl and the methyl groups of empp, respectively over the aromatic bpy ring (Fig. 5). In ^{1}H NMR spectra, isomer FII gives the P-CH_3 proton signal at a remarkably high field (1.20 ppm) compared with that of isomer FI (2.02 ppm). The high-field shift is attributable to the aromatic bpy ring and is more remarkable than that observed for the P-CH_3 protons in *fac(N)*-[Co(acac)(en)(empp)]$^{2+}$ (1.77 and 2.17 ppm), in which the P-CH_3 group is shielded by the pseudo aromatic acac ring. Thus isomer FII of [Co(acac)(bpy)(empp)]$^{2+}$ can be assigned as the racemic pair of *mer(N)-Δ(S),Λ(R)*. As described above, neither P-CH_3 nor acac-CH_3 proton signal of isomer FI shows a high-field shift, and thus the isomer is assigned as the racemic pair of *mer(N)-Δ(R),Λ(S)*. When the bpy complexes take a *fac(N)* structure, a steric interaction arises between the substituent on P and H on C(3) of bpy. The selective formation of the *mer(N)*-bpy complexes, in contrast to the corresponding *fac(N)*-diamine complexes, will be attributable to this steric interaction in the *fac(N)* structure.

Figure 6 shows absorption and CD spectra of isomers FI and FII of [Co(acac)(*RR*-chxn)(edpp)]$^{2+}$. While the absorption spectra are similar, the CD spectra are nearly enantiomeric to each other. Since isomer FI has been determined to have the *Λ* configuration by X-ray analysis, isomer FII is assigned as the *Δ* isomer. The configurational effect(*Λ*) curve estimated by 1/2[$\Delta\varepsilon(\Lambda)-\Delta\varepsilon(\Delta)$][23] is very similar to the CD spectrum of [Co(acac)(en)(edpp)]$^{2+}$ which was obtained

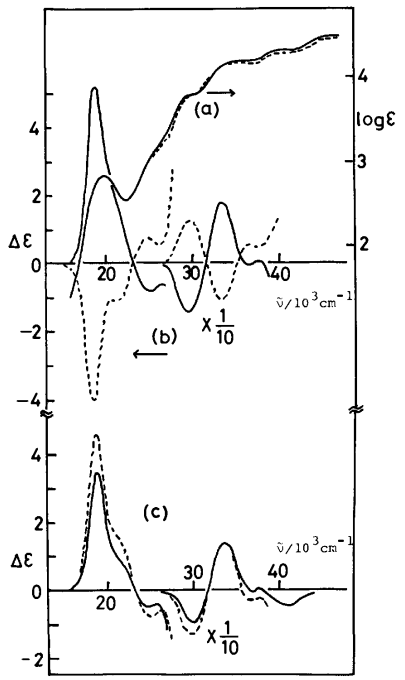

Fig. 6. Absorption (a) and CD (b) spectra of FI (——) and FII (----) isomers of [Co(acac)(*RR*-chxn)(edpp)]$^{2+}$, and the configurational effect (*Λ*) curve estimated by 1/2[Δε(*Λ*)−Δε(*Δ*)] (----) and the CD spectrum of [Co(acac)(en)(edpp)]$^{2+}$ (——) in (c).

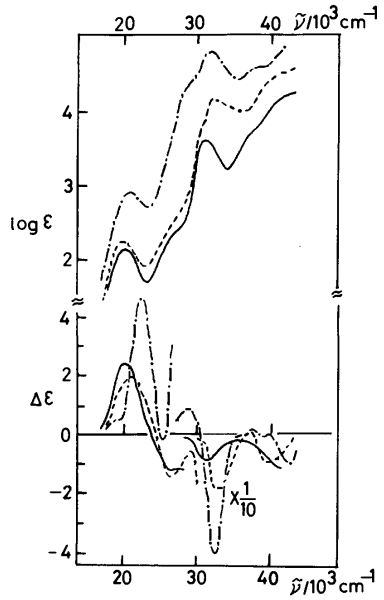

Fig. 7. Absorption and CD spectra of *Λ*-[Co(acac)(en)$_2$]$^{2+}$ (——), [Co(acac)(bpy)(en)]$^{2+}$ (----), and [Co(acac)(bpy)(edpp)]$^{2+}$ (-·-·-).

from the first fraction in SP-Sephadex C-25 column chromatography (see Experimental) (Fig. 6(c)). Thus the en complex given in Fig. 6(c) is assigned to have the *Λ* configuration. In Fig. 7 are compared the absorption and CD spectra of *Λ*-[Co(acac)(en)$_2$]$^{2+}$[24] with those of [Co(acac)(bpy)(en)]$^{2+}$ and [Co(acac)(bpy)(edpp)]$^{2+}$, both bpy complexes being the faster-moving enantiomer in similar SP-Sephadex C-25 column chromatography. Although the absorption intensity and CD strength of the edpp complex are larger than those of the other complexes over nearly the whole spectral region, the spectral patterns are similar among the three complexes. Thus [Co(acac)(bpy)(en)]$^{2+}$ and [Co(acac)(bpy)(edpp)]$^{2+}$ given in Fig. 7 will have the same absolute configuration as *Λ*-[Co(acac)(en)$_2$]$^{2+}$.

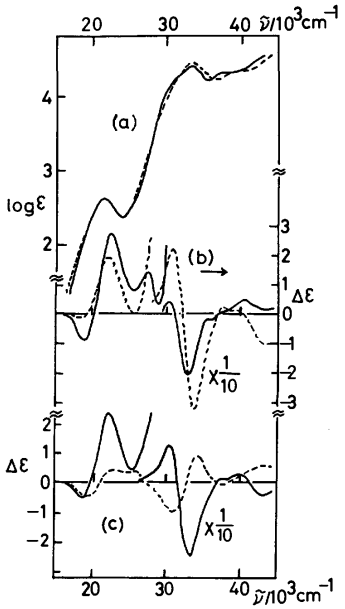

Fig. 8. Absorption (a) and CD (b) spectra of FI (——) and FII (----) isomers of [Co(acac)(bpy)(empp)]$^{2+}$, and the configurational (——) and vicinal (----) effect curves estimated by 1/2[Δε(FI)+Δε(FII)] and 1/2[Δε(FI)−Δε(FII)], respectively, in (c).

Figure 8 shows absorption and CD spectra of isomers FI and FII of [Co(acac)(bpy)(empp)]$^{2+}$. Both isomers were resolved by SP-Sephadex C-25 column chromatography, and the optically active isomers given in Fig. 8 are those eluted faster in chromatography (see Experimental). Both CD spectral patterns (Fig. 8(b)) are similar, and the isomers will have the same absolute configuration for the arrangement of the chelate rings around Co(III). In Fig. 8(c) are given the configurational and vicinal effect curves estimated by 1/2[Δε(FI)+Δε(FII)] and 1/2[Δε(FI)−Δε(FII)], respectively. The configurational effect curve is similar to the CD spectrum of *Λ*-[Co(acac)(bpy)(edpp)]$^{2+}$ in Fig. 7, indicating the same *Λ* configuration for both optical isomers of FI and FII. Since isomers FI and FII of [Co(acac)(bpy)(empp)]$^{2+}$ have been assigned to racemic pairs, *Δ*(*R*),*Λ*(*S*) and *Δ*(*S*),*Λ*(*R*), respectively, on the basis of the ^{1}H NMR spectra, the optical isomers given in Fig. 8 are assigned to have the *Λ*(*S*)(FI) and *Λ*(*R*)(FII) configurations. Accordingly, the vicinal effect curve should be of the (*S*)-empp ligand. The curve is fairly different from those of an analogous (*S*)-$NH_2CH_2CH_2P(C_4H_9)(C_6H_5)$ (ebpp) ligand estimated from CD spectra of [Co(acac)$_2$(ebpp)]$^{+}$[8] and [Co(en)$_2$(ebpp)]$^{3+}$.[7] In order to relate the absolute configura-

tion of chiral phosphorus donor atoms to CD spectra, more CD data of chiral phosphine complexes will be needed.

Mössbauer, Raman, and DTA Studies on the Structure of BaF_2–ZrF_4–FeF_2 Glasses

Tetsuaki NISHIDA,* Toshiaki NONAKA, and Yoshimasa TAKASHIMA
Department of Chemistry, Faculty of Science, Kyushu University 33, Hakozaki, Higashiku, Fukuoka 812
(Received April 1, 1985)

Structural studies on the ternary BaF_2–ZrF_4–FeF_2 glasses have been performed to elucidate the local structure of the ZrF_4-based glasses which are known to be excellent in the optical transparency and the electric conductivity due to F^- ion. Mössbauer and Raman measurements reveal that iron (Fe^{2+} and Fe^{3+}) plays a structural role similar to that of Ba^{2+} ion surrounded by eight fluorine atoms at the interstitial site of one- or two-dimensional zigzag chains composed of ZrF_6 octahedra. Raman and DTA measurements reveal that the increase in the fraction of BaF_2 causes an increase in the coordination number of Zr from 6 to 7. Mössbauer measurements of $25BaF_2 \cdot 65ZrF_4 \cdot 10FeF_2$ glass at lower temperatures lead to a conclusion that the glass undergoes a phase transition at 225±5K, of which structural change is easily reflected in the isomer shift, quadrupole splitting, and the absorption area. This is supported by the DTA measurement of the same sample at lower temperatures, *i.e.*, the DTA curve consists of two exothermic peaks and a wide endothermic peak observed at about 220—230 K and 180—210 K, respectively.

Zirconium tetrafluoride (ZrF_4)-based glasses discovered by Poulain *et al.*[1] have recently been paid much attention owing to the excellent optical transparency ranging from near UV to middle IR[2–5] and to the relatively high fluoride ion conductivity.[6] The former property makes the ZrF_4-based glasses good candidates for optical waveguide materials and laser windows. Another feature of the glasses lies in the chemical resistancy to fluoridating agents such as HF and F_2.[4] In contrast to the relatively well-studied physical properties of these glasses, the structure has not been well understood. The structure of BaF_2–ZrF_4 glass system was studied by Almeida and Mackenzie[7] by means of IR and Raman spectroscopy. They obtained a conclusion that the structure consists of a two-dimensional zigzag chain in which each zirconium atom is surrounded by six fluorine atoms in octahedral symmetry when the BaF_2 content is not high. The coordination number of Zr has also been reported to be seven when the BaF_2 content is about 50 mol%. A similar conclusion was also obtained by Almeida and Mackenzie in a series of BaF_2–ZrF_2Cl_2 glasses.[8] X-Ray scattering studies of the BaF_2–ZrF_4 glass system was first performed by Coupé *et al.*,[9] and they obtained a conclusion that the glasses consist of three-dimensional network and that the coordination number of Zr is seven or eight. The present study was carried out to know the structure of BaF_2–ZrF_4–FeF_2 glasses by means of Raman spectroscopy, DTA, and Mössbauer spectroscopy which has been used for the structural studies of several glasses, such as borate,[10–12] borosilicate,[13,14] phosphate,[15,16] borophosphate,[17] germanate,[18] and zinc chloride[19] glasses.

Experimental

A series of ZrF_4-based glasses were prepared by fusing individual batches (1.0 g) of BaF_2 (99.9%), ZrF_4 (99.9%), FeF_2 (99.5%), and NH_4F (99.5%) in platinum crucibles at 900 °C for 3—5 min in an electric muffle furnace. Transparent and brown glasses were prepared by quenching the melts in the platinum crucibles with ice-cold water. Mössbauer measurements were performed by a constant acceleration method at various temperatures lower than room temperature using a source of ^{57}Co (10 mCi) diffused into a palladium foil. Metallic iron enriched with ^{57}Fe was used to calibrate the velocity of spectrometer and also as a reference for isomer shift. All the Mössbauer spectra were fitted to Lorenzian lineshapes by the least-squares method. Raman measurements were performed in the 90° scattering configuration at room temperature using a 514.5 nm Ar^+ laser line

(100 mW). Slits were opened to 250 μm. Raman spectra were recorded in the HH (||) configuration where the scattered light was analyzed for the vector parallel to that of the incident radiation. DTA measurements of the glasses were performed with a heating rate of 5 °C min^{-1} ranging from −118 °C to 700 °C, and Al_2O_3 powder was used as a reference.

Results and Discussion

The composition region where glass samples were tried to prepare is shown in Fig. 1, in which open circles and closed circles refer to the formation of glass and crystalline sample, respectively and half-closed circles refer to glass ceramic. The glass-forming region of BaF_2–ZrF_4–FeF_2 system is denoted to lie within the area surrounded by a solid line. This is also expressed as 42 mol%≥BaF_2≥22 mol%, 77 mol%≥ZrF_4≥52 mol%, and 15 mol%≥FeF_2≥0. Figure 1 also demonstrates that the glass-forming region of binary BaF_2–ZrF_4 glasses lies in 58—77 mol% ZrF_4, which is relatively well consistent with those reported by Almeida and Mackenzie (52—74 mol%),[7] Poulain *et al.* (60—70 mol%),[20] and Mitachi (58—69 mol%).[21] Mössbauer spectrum of $25BaF_2 \cdot 65ZrF_4 \cdot 10FeF_2$ glass measured at room temperature is shown in Fig. 2, from which we can estimate that most iron species are present as high-spin Fe^{2+} because the isomer shift is larger than 1.0 mm s^{-1}. Figure 2 also indicates that the spectrum contains a weak absorption due to Fe^{3+} of which isomer shift is *ca.* 0.4 mm s^{-1}. Mössbauer parameters for a few ZrF_4-based glasses are shown in Table 1 together with the results of DTA measurements. The errors are estimated to be ±0.01—0.02 mm s^{-1} for the isomer shift, ±0.02 mm s^{-1} or more for the quadrupole splitting and the linewidth, and ±0.5% for the absorption area. The errors are also estimated to be ±1 °C for the glass transition (T_g) and the crystallization (T_c) temperature. Large isomer shift values for Fe^{2+} suggest that each Fe^{2+} ion is surrounded by at least six fluorine atoms and that the chemical bond between iron and fluorine is extremely ionic,[22] because the isomer shift exceeds 1.3 mm s^{-1}. Isomer shift for Fe^{3+} suggests that each Fe^{3+} ion is also surrounded by at least six fluorine atoms. Quadrupole splitting and linewidth are typical of those for the absorption due to Fe^{2+} and Fe^{3+} in glasses. It seems that there is no systematic change in the Mössbauer parameters when the composition is changed. On the other hand, absorption area for the Fe^{2+} shows a distinct decrease with increasing BaF_2 content. This may be due to the increased oxidation atmosphere caused by the addition of BaF_2 into ZrF_4 matrix. (It is generally known that an increase in the basicity of glass matrix brought about by the increased alkali content, *i.e.*, BaF_2 content in the present study, results in an increase in the oxidation state of the transition metal ions in glasses. The present result is well consistent with this idea, and is also supported by the Mössbauer results recently reported by Kawamoto *et al.*[23]) It is also seen from Table 1 that T_g and T_c increase continuously with increasing BaF_2 content. The increase in T_g is also observed in binary BaF_2–ZrF_4 glasses,[7] in which a little higher (5—12 °C) T_g values are reported than those obtained in the present study. Glass transition temperature therefore seems to be reduced by the addition of FeF_2 into the BaF_2–ZrF_4 glasses. Considering that a very similar change in T_g has been observed in germanate glasses with a change in the coordination number of Ge(IV) from 4 to 6,[18] the continuous increases in T_g and T_c observed with the increasing fraction of BaF_2 (Table 1) are ascribed to a successive increase in the coordination number of Zr(IV). The change in the coordination number of Ge(IV) from 4 to 6 in the germanate glasses has also been confirmed by a continuous increase in a parameter of intermolecular force constant, θ^2M, obtained from the temperature dependence of the Mössbauer absorption area.[18] Low temperature measurements of the Mössbauer spectra were then carried out to obtain a structural information on BaF_2–ZrF_4–FeF_2 glasses. The parameter of intermolecular force constant (θ^2M) is known to be expressed by

$$\theta^2M = \frac{3E^2}{kc^2}\left(-\frac{\mathrm{d}\ln f}{\mathrm{d}T}\right)^{-1}, \quad (1)$$

where E and f are Mössbauer transition energy (14.4 keV in the case of ^{57}Fe) and recoil-free fraction, respectively. In the Eq. 1, k is Boltzmann constant and c is the velocity of light. The θ^2M value, in which θ is so-called Debye temperature and M is the mass of Mössbauer nucleus, can therefore be obtained from the slope of the

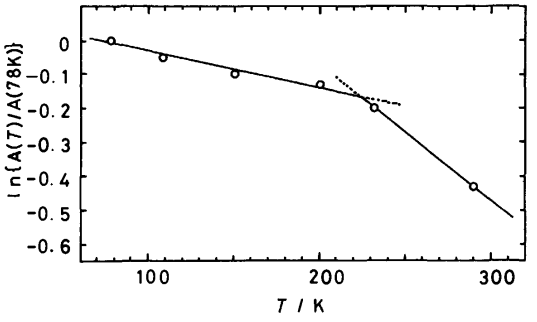

Fig. 3. Change in the absorption area (Fe^{2+} plus Fe^{3+}) with temperature.

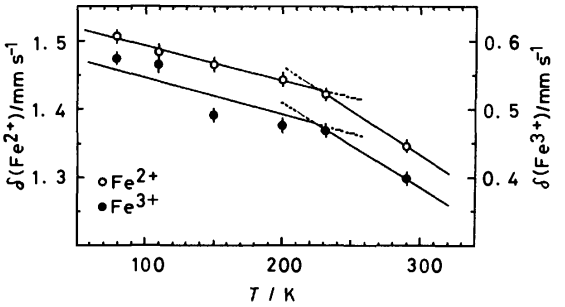

Fig. 4. Change in the isomer shifts of Fe^{2+} and Fe^{3+} with the temperature.

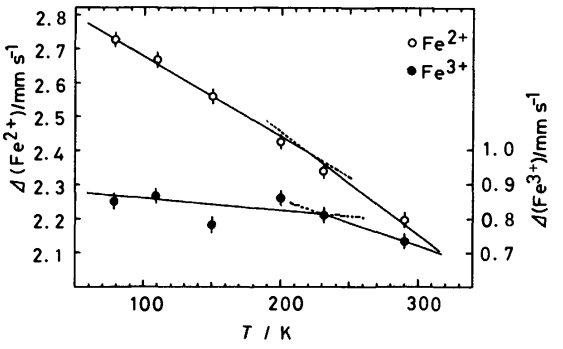

Fig. 5. Change in the quadrupole splittings of Fe^{2+} and Fe^{3+} with the temperature.

absorption area (A) *vs.* temperature (T) plot, because $d\ln f/dT$ can be approximated by $d\ln A/dT$ when a very thin sample is used. The results of the Mössbauer measurements at lower temperatures are shown in Figs. 3—5. The change in the absorption area with temperature is shown in Fig. 3, in which each absorption area is normalized by the area at 78 K. (Total absorption area for Fe^{2+} and Fe^{3+} is plotted in Fig. 3, because the separate plot for Fe^{2+} and Fe^{3+} also gives the same result as Fig. 3) It is obvious from Fig. 3 that the absorption area *vs.* temperature plot gives two straight lines with different slopes, and that the straight lines cross with each other at 224 K. The θ^2M values obtained by dividing $3E^2/kc^2$, *i.e.*, 7.76×10^3 in the present study, with the slope of the individual straight line are 6.9×10^6 and 1.9×10^6 in the temperature ranges of 78—224

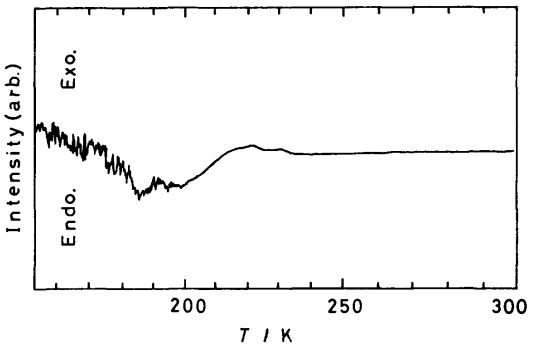

Fig. 6. DTA curve for the $25BaF_2\cdot65ZrF_4\cdot10FeF_2$ glass measured at 155—300 K.

K and 224—290 K, respectively. The drastic change in the θ^2M from 6.9×10^6 to 1.9×10^6 suggests that the intermolecular force between two Zr–F polyhedra is considerably weakened at 224 K, and that iron is present at relatively unstable environment in a sense of lattice dynamics. This leads to a tentative conclusion that iron is present at an interstitial site of Zr–F polyhedra rather than a substitutional site of Zr which is generally considered to be rigid. Large θ^2M value (6.9×10^6) obtained in the temperature range of 78—224 K also supports the conclusion, suggesting that the nature of the chemical bond between iron and fluorine is essentially ionic because the θ^2M values for the ionic compounds are known to be larger than those for the covalent ones ($1—3\times10^6$).[18] The θ^2M value therefore seems to correspond to the intermolecular force between two zigzag chains composed of ZrF_6 octahedra.[7]

The drastic change in the θ^2M observed at 224 K also suggests that the $25BaF_2\cdot65ZrF_4\cdot10FeF_2$ glass undergoes a drastic change in the vibrational mode for some reason such as phase transition. Isomer shifts and quadrupole splittings for Fe^{2+} and Fe^{3+} at lower temperatures are shown in Figs. 4 and 5, and to our surprise these parameters also show distinct changes around 224 K, *i.e.*, at 225 K (isomer shift) and 220—230 K (quadrupole splitting). These Mössbauer results shown in Figs. 4 and 5 lead to a conclusion that a kind of structural change certainly occurs at 225±5 K in the $25BaF_2\cdot65ZrF_4\cdot10FeF_2$ glass, because the plots of isomer shift and quadrupole splitting *vs.* temperature are generally known to give rise to continuous curves similar to straight lines. DTA measurements at lower temperatures were then performed to confirm the structural change. Figure 6 demonstrates a DTA curve for the $25BaF_2\cdot65ZrF_4\cdot10FeF_2$ glass. It is obvious from Fig. 6 that an endothermic reaction occurs at 180—210 K, followed by an exothermic reaction observed around 220—230 K. The DTA curve suggests that a structural change (phase transition) certainly occurs around 225 K, and that the structural change spreads in such a wide region as can be detected by DTA method. It is therefore considered that a reorientation of

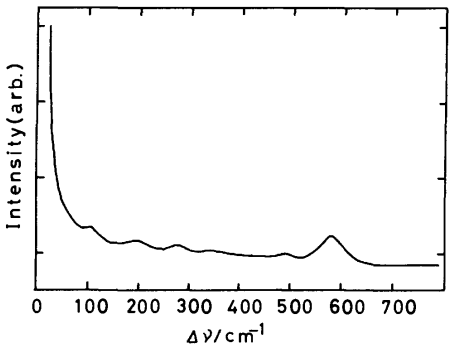

Fig. 7. Raman spectrum for the $30BaF_2 \cdot 60ZrF_4 \cdot 10FeF_2$ glass measured at room temperature.

several ions and atoms, similar to the crystallization at higher temperatures, occurs around 220—230 K.

Almeida and Mackenzie[7] revealed a mutual relationship between Raman peak position and the coordination number of Zr in binary BaF_2–ZrF_4 glasses by comparing each vibrational mode in glasses to that in the corresponding crystalline compounds. Polarized Raman spectrum of $30BaF_2 \cdot 60ZrF_4 \cdot 10FeF_2$ glass measured at room temperature is shown in Fig. 7. According to Almeida and Mackenzie,[7] a distinct peak observed around 580 cm^{-1} is assigned to the symmetric stretching vibrational mode (ν^s) due to four Zr-nonbridging fluorine (-F^-) bands in a ZrF_6 octahedron which constitutes one- or two-dimensional zigzag chain. A weak peak observed around 490 cm^{-1} has been assigned to a symmetric stretching vibration of bridging fluorine atom with which two ZrF_6 octahedra are linked together.[7] In the present study, the symmetric stretching vibrational mode (ν^s) due to the Zr-F^- band is observed at peak positions of 586, 580, and 572 cm^{-1} in $25BaF_2 \cdot 65ZrF_4 \cdot 10FeF_2$, $30BaF_2 \cdot 60ZrF_4 \cdot 10FeF_2$, and $35BaF_2 \cdot 55ZrF_4 \cdot 10FeF_2$ glasses, respectively. This continuous peak shift to the lower frequency region is ascribed to a gradual change in the coordination number of Zr from 6 to 7, because the peak position of the symmetric stretching vibrational mode (ν^s) for the Zr-F^- band is reported to be inversely correlated with the coordination number of Zr and because the peak is observed in the region of 570—600 cm^{-1} in the case of six-coordinated Zr.[7] Almeida and Mackenzie[7] also proved that the increasing fraction of BaF_2 causes a structural change from sheetlike (two-dimensional) zigzag chain to one-dimensional chainlike structure. We can therefore conjecture a structural role of FeF_2 in ZrF_4-based glasses by comparing the peak position of the symmetric stretching vibrational mode for the Zr-F^-band in the binary BaF_2–ZrF_4 glasses[7] with that in the ternary BaF_2–ZrF_4–FeF_2 glasses prepared in the present study. The Raman peaks due to the stretching vibrational mode (ν^s) have been observed at 598 and 580 cm^{-1} in the binary $25BaF_2 \cdot 75ZrF_4$ and $35BaF_2 \cdot 65ZrF_4$ glasses, respectively.[7] Comparison of these results with the peak position of $25BaF_2 \cdot 65ZrF_4 \cdot 10FeF_2$ glass (586 cm^{-1}) prepared in the present study leads to a conclusion that Fe^{2+} plays a structural role similar to that of Ba^{2+}, because the peak position of $25BaF_2 \cdot 65ZrF_4 \cdot 10FeF_2$ glass is almost identical with that of $35BaF_2 \cdot 65ZrF_4$ glass. A little increased peak position of $25BaF_2 \cdot 65ZrF_4 \cdot 10FeF_2$ glass compared to that of $35BaF_2 \cdot 65ZrF_4$ glass *i.e.*, 6 cm^{-1}, is ascribed to the displacement of Ba^{2+} with other metal ions of smaller ionic radii as is also found in the case of SrF_2–ZrF_4 glass.[7] Comparison of the peak position for the $30BaF_2 \cdot 60ZrF_4 \cdot 10FeF_2$ glass (580 cm^{-1}) with that of $40BaF_2 \cdot 60ZrF_4$ glass (577 cm^{-1}) also leads to the same conclusion as in the case of $25BaF_2 \cdot 65ZrF_4 \cdot 10FeF_2$ glass. This is also the case for the $35BaF_2 \cdot 55ZrF_4 \cdot 10FeF_2$ glass in which the corresponding peak (ν^s) is observed at 572 cm^{-1}. This peak position is intermediate between those of $40BaF_2 \cdot 60ZrF_4$ glass (577 cm^{-1}) and $50BaF_2$ $50ZrF_4$ glass (565 cm^{-1}). Coordination number of barium ion has already been reported to be in the range of 8—12 in several barium compounds,[9] and Ba^{2+} is known to be surrounded by eight fluorine atoms in BaF_2.[24] A barium ion is therefore assumed to be surrounded by eight fluorine atoms in one- or two-dimensional zigzag chains composed of ZrF_6 octahedra. The present results obtained from Raman and Mössbauer measurements therefore indicate that Fe^{2+} and Fe^{3+} ions are also surrounded by eight fluorine atoms. As for the coordination number of transition metal higher than six, some review articles[25–27] have been published, in which coordination number 8 is also observed in several metal compounds.

Peak intensity for the Zr-F^- stretching vibrational mode (ν^s) is also considered to give a useful information on the structural change based on the compositional change. In the present study, however, the peak intensity shows a maximum in the $30BaF_2 \cdot 60ZrF_2 \cdot 10FeF_2$ glass, contrary to our general expectation that the peak intensity will increase with increasing fraction of BaF_2. This can be attributed to the change in the coordination number of Zr from 6 to 7, and the fraction of nonbridging fluorine atoms (-F^-) will at least increase in the compositional region in which the coordination number of the central zirconium atom is invariable. Further experiments will be necessary to obtain a more detailed information on the fraction of nonbridging fluorine atoms in ZrF_4-based glasses.

The authors are very grateful to Drs. Toshirou Yagi and Akira Sakai of Kyushu University for their kind help in the Raman measurement and the useful discussion on the results. The present paper is partially supported by a Grant-in-Aid for Scientific Research No. 59740298 from the Ministry of Education, Science and Culture.

The Prediction of Preferred Orientation Planes in X-Ray Powder Diffractometry

Yoshito TAKAKI,* Hiroshi YAMAGUCHI,† and Kazuaki NAKATA
Department of Physics, Osaka Kyoiku University, Tennoji-ku, Osaka 543
†*Department of Earth Science (Mineralogy), Osaka Kyoiku University, Tennoji-ku, Osaka 543*
(Received November 21, 1984)

A method for predicting possible preferred orientation planes in organic and inorganic powders of known crystal structures is presented. The usefulness of this method is demonstrated by applying it to the powders of benzamide, the α-form of 2-pyrazinecarboxamide, benzoic acid, olivine, and the high-temperature form of Li_3PO_4. It should be noted that the existence of preferred orientation axes found in the powders of benzoic acid and Li_3PO_4 can be well explained in terms of zone axes, each formed by two sets of cleavage planes.

A treatment of preferred orientations in X-ray powder diffractometry using an orientation-distribution function for preferentially oriented particles has previously been developed by Uda and Sasa.[1-3] Recently, we extended the above method to include oriented plate-like and needle-like particles in the powder.[4-6]

By using this method, Nakata *et al.*[6] have closely examined the preferred orientations in coarse and fine powders of benzamide and the α-form of 2-pyrazinecarboxamide and have found that the occurrence of preferred orientation planes can be well explained in terms of the layer structure, the layers being linked with each other by weak van der Waals forces. In the above study, the preferred orientation planes for the two substances were found by comparing the observed X-ray powder intensities with those from randomly oriented particles (calculated intensities).

The preferred orientation planes can be easily predicted if one takes into account the well-known fact that cleavages causing preferred orientation effects on X-ray intensities are inherently dependent upon the anisotropic character of the crystal structure and on the strength of bonds between atoms or molecules. From this point of view, we wish here to present a method for predicting possible preferred orientation planes for organic and inorganic powders, the crystal structures of which are known.

Procedure

Prediction of Preferred Orientation Planes for Organic Powders. Organic (molecular) crystals are characterized by the presence of van der Waals bonding as a fundamental type of bonding. Further, strong hydrogen bonds play an important role in the formation of characteristic types of structure in chain structures and in layer structures. Cleavages may then occur along the planes parallel to the chain or to the layer if they are linked by weak van der Waals forces only. Therefore, preferred orientation planes can be predicted by the following procedure:

1) Since cleavages are usually parallel to the planes with simple Miller indices, in our computer calculation (the program is written in N_{88}-BASIC), they are examined for planes (hkl) having interplaner spacings (d-values) larger than 3.0 Å.

2) In a crystal, a plane parallel to (hkl) is represented by:

$$hx + ky + lz = p, \quad (1)$$

where x, y, and z are the fractional coordinates referred to the crystal axes, and where p is a constant.

By varying the value of p, we obtain possible cleavage planes (hkl) from a requirement that the cleavage does not break covalent bonds (molecules) and hydrogen bonds.

3) For each of the possible cleavage planes obtained above, a lattice spacing[7] at right angles to the cleavage plane (D-value, see Fig. 1) is calculated. In this calculation, non-hydrogen-bonded H atoms are omitted since the strength of bonds from an H atom to other atoms is considered to be weak; thus, these bonds do not exert any serious effect on the cleavage. The D-value is used as an indication of the weakness of bonds linking layers of molecules across the cleavage plane.

4) By examining the D values, possible preferred orientation planes are selected.

Prediction of Preferred Orientation Planes for Inorganic Powders. In inorganic crystals, the ionic bond is a fundamental type of bonding linking atoms across a cleavage plane. Therefore, like the lattice spacing, the number of ionic bonds per unit area[8] can also be used as an indication of the weakness of the bonds. In this paper, however, the large D-values are mainly used for selecting preferred orientation planes, since a weak bond is usually accompanied by a large lattice spacing.[7] The following is a procedure for predicting possible preferred orientation planes in inorganic powders:

1) Cleavages are examined for the planes (hkl) with d-values larger than 3.3 Å.

2) Possible cleavage planes are obtained from a requirement that the cleavage does not break covalent bonds.

3) For these cleavage planes, lattice spacings (D-

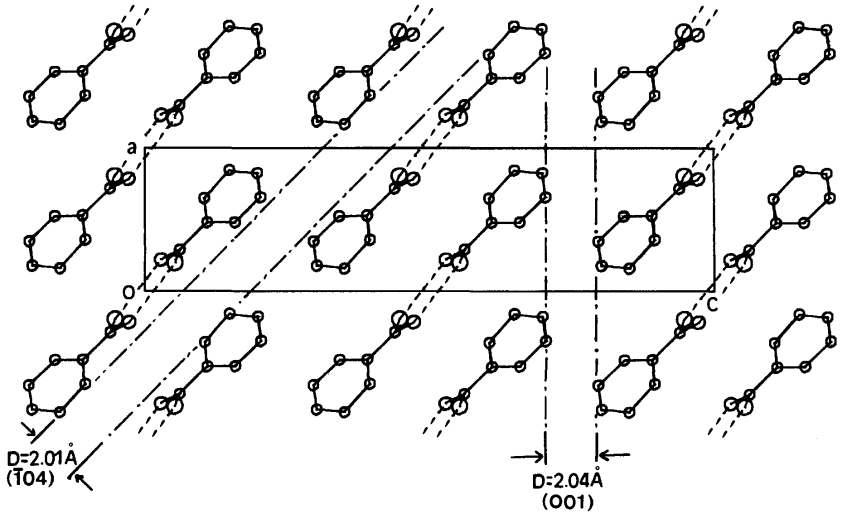

Fig. 1. The crystal structure of benzamide[9] projected along the b axis, showing the cleavages parallel to (001) and ($\bar{1}$04) and their lattice spacings (D-values).

values) are calculated (H atoms are omitted from the calculation).

4) The number of bonds (N) across each cleavage plane in a unit cell is calculated. Within a unit cell, the area of the cleavage plane (S) parallel to (hkl) is also calculated.

5) By examining the values of D (and N/S) and confirming the presence or absence of the sheet of water molecules if the crystal is a hydrate, possible preferred orientation planes are selected.

Prediction of Preferred Orientation Axes. If the crystals obtained from crystal growth are shaped like needles, we must examine the needle axis as a possible preferred orientation axis.[5,6]

In some cases, a zone axis formed by two good cleavage planes coincides with a preferred orientation axis, especially when the zone axis is the needle axis of the crystal, as in the benzoic acid powder. The preferred orientation axis should be examined when the preferred orientations in the powder sample cannot be explained from the cleavage planes predicted by the above procedure.

Application

Benzamide. Crystals[9] are monoclinic, with a=5.607, b=5.046, c=22.053 Å, β=90.66°, and space group $P2_1/c$. Four molecules are contained in a unit cell.

Two possible preferred orientation planes and their D-values, as obtained by the above method, are listed in Table 1. Nakata *et al.*[6] found preferred orientation planes of (001) and ($\bar{1}$04) and explained the occurrence of these planes in terms of the layer structure (Fig. 1). One can see that these two preferred orientation planes are the same as the planes listed in Table 1, and that the two D-values are both larger than 2Å, indicating that the forces linking layers are very weak.

Table 1. Possible preferred orientation planes for benzamide, the α-form of 2-pyrazinecarboxamide and benzoic acid

	hkl	d/Å	D/Å
Benzamide	001	22.05	2.04
	$\bar{1}$04	3.95	2.01
α-Form of 2-pyrazine-carboxamide	100	22.65	1.76
Benzoic acid	$\bar{1}$02	5.16	2.44
	001	21.79	2.33
	100*	5.46	0.44

* The next most possible preferred orientation plane.

α-Form of 2-Pyrazinecarboxamide. The crystals[10] are monoclinic, with a=23.07, b=6.73, c=3.73 Å, and β=101.0° and with the space group $P2_1/a$. Four molecules are contained in a unit cell.

One possible preferred orientation plane (100) was predicted by the present method (Table 1). It is identical with that found by Nakata *et al.*[6] They found also the c preferred orientation axis, which had been predicted from the needle axis.

Benzoic Acid. The crystals[11] are monoclinic, with a=5.510, b=5.157, c=21.973 Å, and β=97.41° and with space group $P2_1/c$. Four molecules are contained in a unit cell.

The three possible preferred orientation planes obtained are listed in Table 1. After the D-values had been examined, the $\bar{1}$02 and 001 planes were selected as the most probable preferred orientation planes. Nakata[12] examined preferred orientations in fine powders and found a great many preferentially oriented needle-like particles with the b axis as the preferred orientation axis and a very small number of plate-like particles with (001) as the preferred orientation plane. The b preferred orientation axis could thus be pre-

TABLE 2. POSSIBLE PREFERRED ORIENTATION PLANES FOR OLIVINE AND THE HIGH-TEMPERATURE FORM OF Li_3PO_4

	hkl	*d*/Å	*D*/Å	*S*/Å^2	*N*	*N*/*S*

dicted as the zone axis formed by the $\bar{1}02$ and 001 cleavage planes.

Olivine. The crystals of forsterite[13] are orthorhombic, with a=4.756, b=10.195, and c=5.981 Å and with space group Pbnm. Four formula units are contained in a unit cell.

One possible preferred orientation plane, along with the values of *D*, *N*, *S*, and *N*/*S*, is listed in Table 2. Yamaguchi *et al.*[14] found that the preferred orientations in powders of olivine from Kaimon-dake can be explained mostly from the 010 preferred orientation plane, in agreement with the prediction of Table 2. Note that the small value of *D*, 0.56 Å, for the plane (010) may support the fact that the cleavage parallel to (010) is imperfect.[13]

High-temperature form of Li_3PO_4. The crystals[15] are orthorhombic, with a=6.12, b=10.53, and c=4.93 Å and with space group Pmnb. Four formula units are contained in a unit cell.

Six possible preferred orientation planes were obtained (Table 2). By examining the *D*-values, the (010) and (120) planes were selected as the most highly probable preferred orientation planes. From a close examination of fine powder samples, Yamaguchi[16] found that the preferred orientations can be explained mainly in terms of the 010 preferred orientation plane and, to some extent, the c preferred orinetation axis. The c preferred orientation axis could also be predicted as a zone axis formed by the 010 and 120 cleavage planes.

The Electric Properties of VO_2 Thin Films Doped with Other Metal Oxides under Water Vapor

Yoshiya KERA,* Tadashi OONISHI, Hisateru IMORI, and Shigeharu KIDA
Department of Applied Chemistry, Faculty of Science and Engineering, Kinki University, Higashiosaka, Osaka 577
(Received February 14, 1985)

The electric property of a pure VO_2 thin films, prepared from a vanadium naphthenate by thermal decomposition, was examined preliminarily under various inorganic gas atmospheres, H_2O, H_2, O_2, N_2O, and NO_2, at 20—200 °C. Only in the case of the H_2O adsorption, did the conductivity-temperature curve change reversibly; in the other cases it changed irreversibly. With respect to the VO_2 films doped with Na_2O, ZrO_2, Cr_2O_3, and TiO_2, similarly, the conductivities changed reversibly with the water vapor adsorbed; the extent and the manner of these changes differed rather greatly depending upon the kind of metal oxides doped. In the Zr–VO_2 film, which had a large conductivity (σ) and its gap ($\Delta\sigma$) at the transition point (T_t=60 °C) relative to the pure VO_2 film, the electric property was almost unaffected by water-vapor adsorption. In the cases of the Cr- and Ti–VO_2 films, with quite small σ and $\Delta\sigma$ values relative to the pure VO_2 film, on the contrary, the ln σ—$1/T$ curves decreased parallelly to less than about one-half of that under a vacuum throughout the temperature range. With the Na–VO_2 film, the σ—$1/T$ curve measured under water vapor gradually nears that under a vaccum with the elevation of the temperature to 200 °C. From the comparisons of the effects of the electric properties of these doped films on the water vapor adsorbed, the structural features of the films, especially the contact states in the boundary layer, were deduced favorably. Furthermore, a possibility of the application to a switching element working at about 60 °C was suggested for the Zr–VO_2 film, and that to a fume sensor working at a temperature less than 200 °C, for the Cr- and Ti–VO_2 films.

Many solid-state physisists and chemists have been interested in vanadium oxide compounds because these compounds show a metal-semiconductor transition.[1-9] We have previously proposed a more convenient method for the preparation of a VO_2 thin film[10] by improving the Sekiya-Matsushita method.[11] Furthermore, we prepared VO_2 thin films doped with various metal oxides and compared their electric properties. The conductivity and also the extent of the conductivity gap, which was observed at the transition point in the pure VO_2 film, were largely affected by the metal-oxide additions. Based on the conductivity changes, the structural features, especially in the grain boundary of these VO_2 films, were discussed.[10]

In the present paper, the electric properties of the VO_2 films doped and undoped with other metal oxides under various atmospheres, especially under water vapor, will be examined in detail in order to obtain further information about the structures and the contact states of the particles in the grain boundary. In fact, the conductivity-temperature curve was considerably affected by the water vapor adsorbed physically, depending upon the kinds of metal oxides doped. The structural features of these doped VO_2 films will be discussed favorably based on these findings, and finally a possibility of their application to a solid state sensor will be suggested.

Experimental

1) Materials and Procedures. Vanadium naphthenate (containing *ca.* 3 wt% of vanadium(IV) ion; Harima Kasei Co., Ltd.) was dissolved in 1-butanol to prepare 10 wt% of the solution. A thin film of vanadium oxide (VO_2 thin film) was formed on a Pyrex glass plate by the following procedures. The glass plate was cut in the size of 11×24 mm^2; on both ends there had previously been deposited gold film (7 mm in width) as an electrode in order to keep a good ohmic contact during the conductivity measurements. Three droplets of the vanadium naphthenate solution were placed on the plate, after which it was dried at 20 °C in air for 1 h. The plate was then inserted into a furnace kept at 600 °C for 20 min to decompose the vanadium naphthenate and then rapidly taken out into the air for cooling. A nitrogen gas stream, bubbled in water kept exactly at 21.5 °C, was introduced into the funace during the decomposition.[10]

Upon the preparation of the VO_2 thin films containing other metal oxides, such as Na_2O, TiO_2, Cr_2O_3, and ZrO_2, these oxides ($NaOCH_3$ in the case of Na_2O), weighed exactly, were added to a 10 wt% 1-butanol solution of vanadium naphthenate and then ground well with an agate mortar in order to dissolve them fully. Then, the solution containing the metal oxides was dropped onto the glass plate with the gold electrodes and subsequently decomposed by the procedures used in the case of the pure VO_2 thin film. The concentrations of these metal oxides added to vanadium oxide were in the range of 40—60 atom%; [(M)/(V)]×100.

2) Measurements. The electric conductivity was measured by the usual two-probe method under various gas atmospheres and under an evacuation below 10^{-3} mmHg†. The pressure measurement was carried out by the use of a mercury manometer at a relatively high pressure and by the use of a Pirani gauge, Shimazu Model PM-12, at lower pressures. In the measurements of the conductivity, the temperature was elevated from 20 to 200 °C at the constant speed of 4.5 °C/min by the use of a programable controller, Yokogawa Model PC-182. The relationship between the conductivity and the temperature was determined exactly by means of an automatic measurement system; both the potential difference between the ends of the VO_2 thin film and the thermoelectric power generated in the AC-thermocouple attached to the film were amplified simulteneously by means of microvoltmeters, Ookura Denki Model AM-2002, and then introduced, at intervals of 1 °C, into a microcomputer, Sharp Model Mz-80K2E, *via* a 12-bit A/D-convertor, Hoowa

† 1 mmHg≈133.322 Pa.

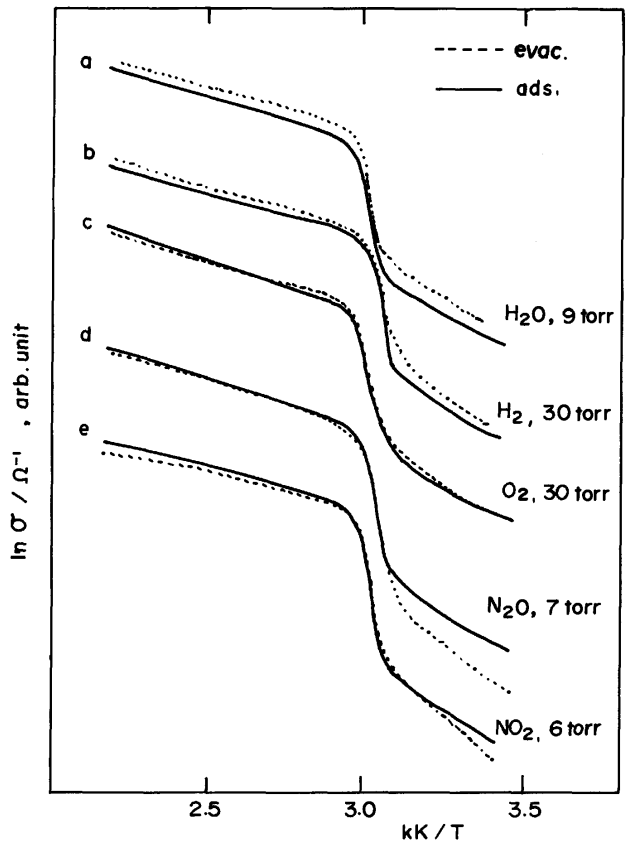

Fig. 1. The $\ln\sigma - 1/T$ curves for the pure-VO_2 thin film measured under various inorganic gas atmospheres; the blank curves are given to each curve with dotted lines, which have been measured under the vacuum before the each measurement. The measurements were repeated alternatively by the use of the same film in the sequence of a→e.

Sangiyo Model ADL-1224.

Results and Discussion

1) Conductivity Changes of Pure VO_2 Thin Film under Various Gas Atmospheres at 20—200°C. The temperature dependence of the conductivity (σ) for the pure VO_2 thin film measured under various inorganic gas atmospheres in the range of 20—200°C are summarized in Fig. 1, in which the ln σ values are plotted against $1/T$. In Curve a, the dotted and full lines denote the curve measured under the vacuum at 10^{-3} torr and under water vapor (p=9 Torr[†]) respectively. After the measurement of Curve a, the σ values for Curve b were measured repeatedly under a H_2 atmosphere (p=30 Torr). Similarly, the σ values under O_2 (p=30 Torr), N_2O (p=7 Torr), and NO_2 (p= 7 Torr) were successively measured, as is shown by Curve c, d, and e respectively. By comparing these σ values with the corresponding values under the vacuum, it is known that the σ decreases with the water-vapor adsorption at all temperatures. The σ decreases just a little under H_2 at all temperatures, but, on the contrary, it rather increases under N_2O at temperatures lower than the transition point (T_t). Under O_2 and NO_2, however, the σ does not change remarkably.

[†] 1 Torr≈133.322 Pa.

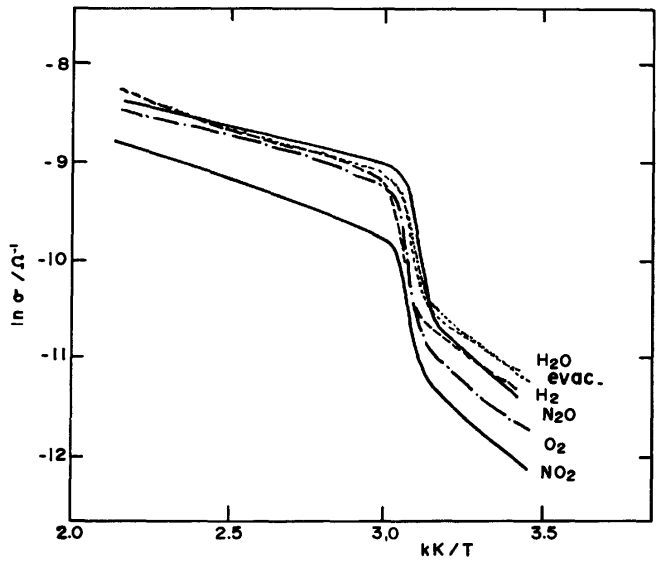

Fig. 2. The comparisons of the blank curves given in Fig. 1: "evac." indicates the curve for the pure-VO_2 film measured at the very initial under the vacuum, and "H_2O" that measured under the vacuum after the experiment under water vapor. "O_2", "N_2O", and "NO_2" also indicate the same meanings. They were successively measured in the order of "evac.", "H_2O", "O_2", "N_2O", and "NO_2", as mentioned in Fig. 1.

TABLE 1. THE CONDUCTIVITIES (σ_h AND σ_l) JUST ABOVE AND BELOW T_t AND THE ACTIVATION ENERGIES (E_h AND E_l) AT THE TEMPERATURES ABOVE AND BELOW T_t, ESTIMATED FROM THE LN$\sigma - 1/T$ CURVES UNDER THE VACUUM AFTER THE INORGANIC GAS ADSORPTIONS, *i.e.*, FROM THE Evac. CURVES IN Fig. 2

Samples	$\sigma_h/10^{-4}\Omega^{-1}$	E_h/eV	$\sigma_l/10^{-4}\Omega^{-1}$	E_l/eV
"Evac."	1.04	0.074	0.34	0.18
"H_2O"	1.04	0.082	0.31	0.21
"H_2"	1.04	0.084	0.28	0.18
"O_2"	0.97	0.068	0.22	0.23
"N_2O"	1.15	0.056	0.27	0.23
"NO_2"	0.54	0.084	0.15	0.24

The $\sigma - 1/T$ curves, a—e, of Fig. 1 are summarized in Fig. 2, where "Evac." indicates the ln $\sigma - 1/T$ curve measured first of all under the vacuum and "H_2" the curve measured also under the vacuum after measurement under water vapor. Similarly, "H_2", "O_2", and "N_2O" have similar meanings. The curve for "NO_2" was measured similarly under the vacuum after the measurement of Curve e in Fig. 1. The electric conductivities just above and below the transition point, σ_h and σ_l, were evaluated approximately by extrapolating linearly the curves above and below T_t in Fig. 2 to the transition point, and the activation energies for the conductions above and below T_t, E_h, and E_l, from the inclination of the corresponding curves. These values are summarized in Table 1. The conduc-

tivity of the pure VO_2 thin film is known to be recovered almost to the initial value by evacuation after measurement under water vapor, but not after those under the other gases, H_2, O_2, N_2O, and NO_2. Therefore, only in the case of the H_2O molecule, a physical adsorption onto the interface among the VO_2 particles (or in the grain boundary) is suggested. Furthermore, the water molecules adsorbed physically could be deduced to affect only the mobility in the grain boundary, because of the parallel change in the $\sigma-1/T$.

The σ was affected just a little under the atmospheres of H_2 and O_2, but in both cases it decreased irreversibly after the measurements under these gases, especially rather largely at temperatures lower than T_t. A series of vanadium oxides, which are generally shown by the formulae; V_nO_{2n+1} and V_nO_{2n-1}, have been reported[12] in which the electric conductivities vary greatly with the n.[9] Therefore, the boundary layer of the pure VO_2 film is expected to be composed of various vanadium oxide compounds, unlike as in the n: *e.g.*, one compound in the grain boundary is mainly affected by the O_2 adsorption, and the other compounds in the other part, by the H_2 adsorption, so as to make the σ values decrease similarly. Under the atmosphere of N_2O, which easily releases oxygen atoms near 200 °C, the grain boundary might be oxidized by it so that the σ is increased irreversibly. In the case of NO_2, we can not explain the irreversible decrease in the σ.

2) Dependence upon Water Vapor of the Electric Property of the VO_2 Thin Films Doped with Other Metal Oxides. The electric property of the pure VO_2 thin film under water vapor are shown again in Fig. 3 as the ln $\sigma-1/T$ curves, a—c. Curve a indicates the curve measured under the vacuum and Curve c, that measured in the air after the film has stood for a long time in a desiccator which had not been kept in a good state. Curve b and c were changed reversibly to Curve a after the evacuation, so their deviation from Curve a can be expected to be caused by water vapor adsorbed physically onto the boundary layer.

With respect to a Na-VO_2 thin film (Na: 40 atm%), the conductivity was measured under the vacuum and also under water vapor, as is shown by the ln $\sigma-1/T$ curves, a and b respectively, in Fig. 4. Curve c indicates the curve measured in the air after the Na-VO_2 film has stood for 2 d in the air. Curves b and c are changed reversibly to Curve a by the evacuation after the measurement. Therefore, the deviations of Curves b and c from Curve a seem to be caused by water vapor adsorbed weakly (or condensed) onto the boundary layer. The extents of the deviations tend to decrease with the elevation of the temperature, nearing zero with the elevation up to near 200 °C in Fig. 4. This finding may suggest that the film is composed of various sizes of particles of the Na-V-O compounds; that the water molecules, which condense into micro-pores formed by the contact of the particles with so many varied types, are desorbed step-by-step with the elevation of the

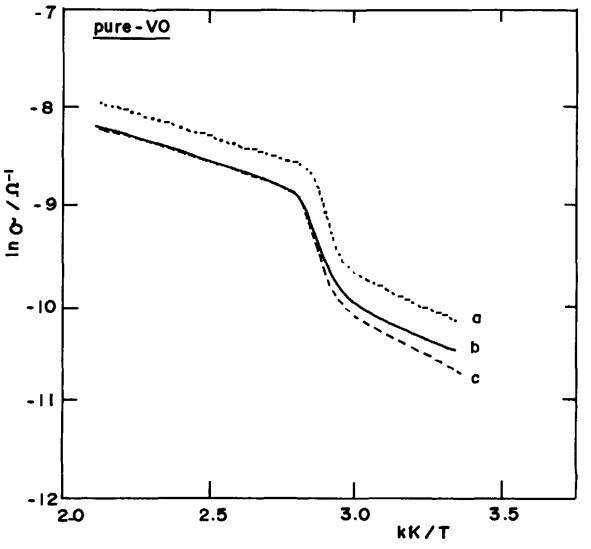

Fig. 3. Changes in the ln $\sigma-1/T$ curve for the pure-VO_2 thin film with water vapor adsorbed physically; a: blank, b: under H_2O (saturated at 20 °C). Curve c indicates the curve measured under the air after keeping it for a long time in a desiccator being not so good in the preservation.

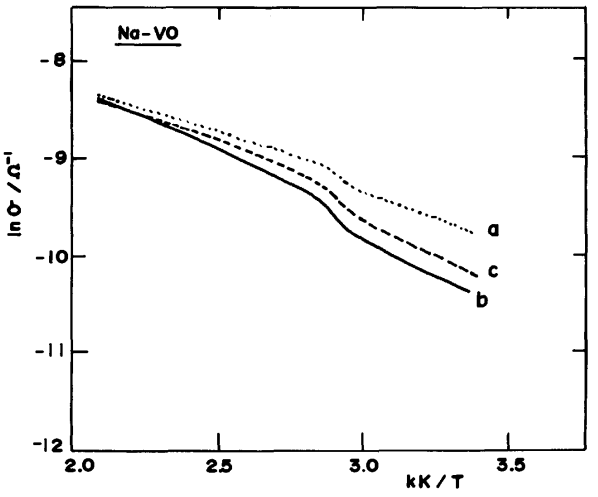

Fig. 4. Changes in the ln $\sigma-1/T$ curve for the Na-VO_2 thin film (Na: 40 atom%) with water vapor adsorbed physically; a: under vacuum, b: under H_2O (saturated at 20 °C). Curve c indicates the curve measured under the air after standing it in the air for 2 d.

temperature, and, further, that the σ-difference varies in proportion to the quantity of the water molecules remaining in the layer.

With respect to a Cr-VO_2 (Cr: 60 atom%) and a Ti-VO_2 (Ti: 40 atm%) thin film, the ln $\sigma-1/T$ curves are shown in Figs. 5 and 6 respectively. From a comparison of Curves a and b, it can be seen that both the Cr- and Ti-VO_2 films are affected considerably by water vapor adsorbed over all the temperature range, 20—200 °C. Curve c in Figs. 5 and 6 indicates the curves measured under the air after the films have been kept in the desiccator for a long time. In

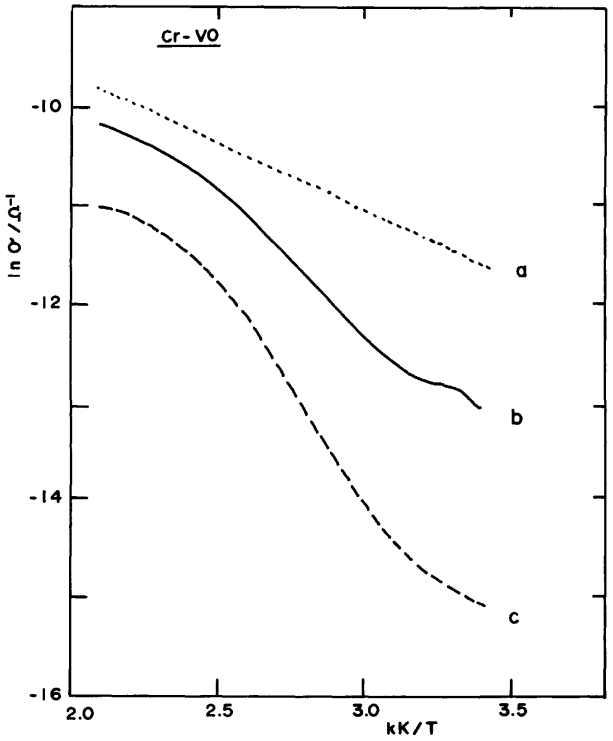

Fig. 5. Change in the $\ln\sigma - 1/T$ curve for the Cr-VO_2 thin film (Cr: 60 atom%) with water vapor adsorbed physically; a: under vacuum, b: under H_2O vapor (saturated at 20 °C). Curve c indicates the curve measured under the air after keeping it for a long time in a desiccator being not so good in the preservation.

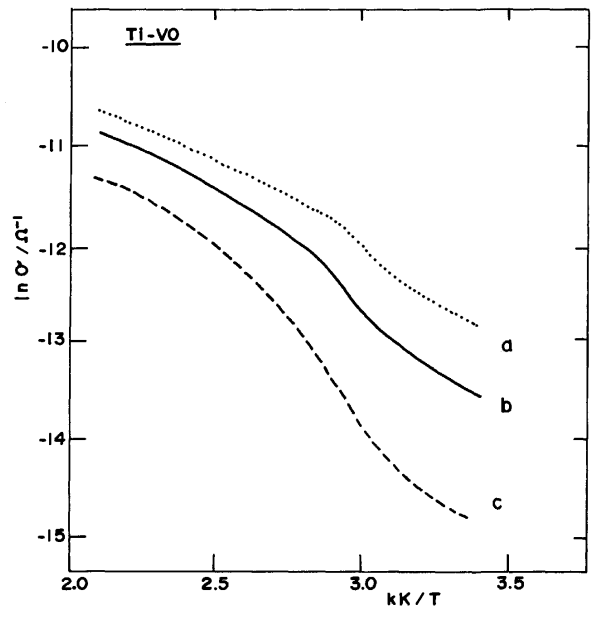

Fig. 6. Changes in the $\ln\sigma - 1/T$ curve for the Ti-VO_2 thin film (Ti: 40 atom%) with water vapor adsorbed physically; a: under vacuum, b: under H_2O vapor (saturated at 20 °C). Curve c indicates the curve measured under the air after keeping it for a long time in a desiccator being not so good in the preservation.

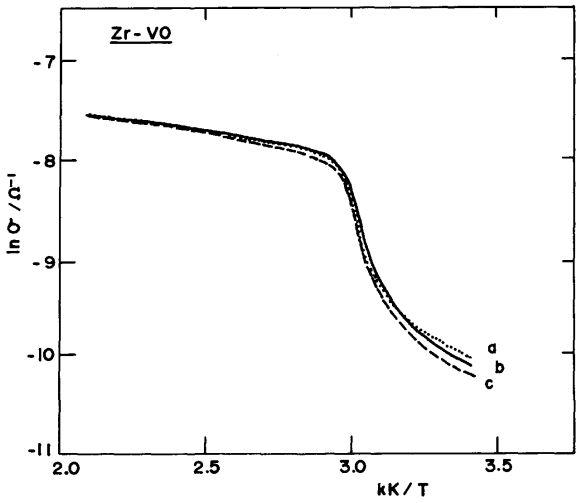

Fig. 7. Change in the $\ln\sigma - 1/T$ curve for the Zr-VO_2 thin film (Zr: 60 atom%) with water vapor adsorbed physically; a: under vacuum, b: under H_2O vapor (saturated at 20 °C). Curve c indicates the curve measured under the air after keeping it for a long time in the desiccator being not so good in the preservation.

both cases, Curves b and c were also changed reversibly to Curve a by evacuation. In the Cr- and Ti-VO_2 it was suggested previously that amorphous (or very small crystalline) Cr_2O_3 and TiO_2 particles, mixed with some vanadium oxides, were formed at the grain boundary and, further, that the apparent conductivities are controlled by that of the grain parts.[10] We can understand easily from such suggestions that the σ values of those films are affected rather greatly by the water vapor adsorbed physically.

With respect to a Zr-VO_2 thin film (Zr: 60 atom%), the conductivity was measured under the vacuum and water vapor, as is shown by the $\ln\sigma - 1/T$ curves, a and b, respectively in Fig. 7. In this case, the σ value was almost entirely unaffected by water vapor; also, when it was left standing for a long time in the desiccator it was not preserved in a so good state (*cf.* Curve b and c respectively). Curves b and c were also changed reversibly to Curve a. The formation of a grown (or crystallized) ZrO_2 particle mixed with vanadium oxide at the grain boundary was shown previously by X-ray diffraction; further, it was suggested that the electric properties of the VO_2 particles themselves appeared more strongly, because the conductivity in the grain boundary was high relative to the inner bulk of the VO_2 particles.[10] On the basis of the suggestion that the conductivity is mainly controlled by the bulk of the VO_2 particles rather than by the grain parts in the Zr-VO_2 film, it can be understood why the conductivity is almost unaffected by the water vapor adsorbed.

For these doped VO_2 films, the conductivities, σ_h and σ_l and the apparent activation energies, E_h and E_l, were estimated similarly from the $\ln\sigma - 1/T$ curves in Figs. 3—7, as is shown in Table 2. The data for the Cr-

TABLE 2. DEPENDENCE UPON WATER VAPOR OF THE ELECTRIC CONDUCTIVITIES OF THE VO_2 THIN FILMS DOPED WITH VARIOUS METAL OXIDES

Samples	$\sigma_h/10^{-4}\Omega^{-1}$	E_h/eV	$\sigma_l/10^{-4}\Omega^{-1}$	E_l/eV
Pure-VO_2				
Evac.	1.57	0.089	0.66	0.113
H_2O	1.37	0.089	0.54	0.118
Na-VO_2				
Evac.	1.09	0.083	0.94	0.092
H_2O	0.80	0.119	0.64	0.138
Zr-VO_2				
Evac.	3.42	0.036	0.79	0.152
H_2O	3.67	0.034	0.79	0.178
Ti-O_2

H_2O	0.049	0.148	0.030	0.160

VO_2 film have been omitted from the table because the transition point could not be seen clearly on the film, but a large effect of adsorbed water vapor can be qualitatively found in Fig. 5. The ratio of the $\sigma(H_2O)$ value to the σ(Evac.) value is about 0.85 in both σ_h and σ_l for the pure VO_2 film, while the ratios between the values about 1.0 and 0.6 for the Zr- and Ti-VO_2 films respectively. Thus, the effect of water-vapor adsorption on the conductivity clearly tends to decrease upon the addition of ZrO_2, while, on the contrary, it is considerably extended by the addition of TiO_2.

These results may be summarized as follows. The changes in the electric properties with various gases, especially with the water-vapor adsorption, were confirmed to be related not only to the chemical properties of the compounds existing in the grain boundary, but also to the states of the contact between the particles. In other words, the states of the VO_2 particles grown and their contact states at the grain boundary, by which the electric property is apparently controlled, could be favorably varied by selecting the kind of metal oxide and its contents.

The Zr-VO_2 thin film may be applied to a switching element working near 60 °C, because of its stability in relation to water vapor in the air; on the other hand, the Cr- and Ti-VO_2 thin films may be applied to a fume sensor working at temperatures from 20—200 °C because of their showing rather large changes of the water vapor adsorbed reversibly, although further studies will be needed to increase the sensitivity. In the case of the Na-VO_2 film, the σ value changed delicately with the temperature under water vapor, so we can not make any suggestions about its application, although considering the structural features of the grain boundary of the VO_2 thin films gives important information.

The Crystal and Molecular Structure of *N*-Ethylcarbazole†

Toshihiko KIMURA,†† Yasushi KAI, Noritake YASUOKA,††† and Nobutami KASAI*
Department of Applied Chemistry, Faculty of Engineering, Osaka University, Yamadaoka, Suita, Osaka 565
(Received February 27, 1985)

N-Ethylcarbazole crystallizes in the orthorhombic system, space group Pbca with fairly large unit cell dimensions of a=7.971(1), b=24.615(3), c=56.587(5) Å, D_m=1.17 g cm^{-3}, D_c=1.168 g cm^{-3} for Z=40. The structure was solved by the direct method and refined anisotropically by the least-squares procedure, R=0.062 for 5134 non-zero reflections. Five crystallographically independent molecules are not different from each other, the carbazole group is planar, and the ethyl group attached to the nitrogen atom is almost perpendicular to the carbazole ring. In the crystal, each carbazole ring makes a similar angle with the a axis [52 to 55°].

Recently, intrinsic and extrinsic photoconductivities of *N*-ethylcarbazole has been extensively studied by H. Mikawa and his co-workers[1] in conncetion with those of poly(*N*-vinylcarbazole).[2] In order to obtain a basic information to elucidate the correlation between the structure and photoconductivity, the crystal structure analysis of *N*-ethylcarbazole has been carried out.

Experimental

A large single crystal, grown from melt in a Bridgeman furnace,[3] was supplied by H. Mikawa and his co-workers of this university. A crystal with approximate dimensions of 0.3×0.35×0.31 mm was cut out and coated with collodion in order to prevent sublimation during the X-ray experiment.

The crystal was mounted on a Rigaku automated, four-circle diffractometer. Nickel-filtered Cu $K\alpha$ radiation was used. Unit-cell dimensions were determined by the least-squares fit of 2θ values of 22 high angle reflections.

Crystal Data: $C_{14}H_{13}N$, M=195.27, orthorhombic, space group Pbca (No. 61), a=7.791 (1), b=24.615 (3), c=56.587 (5) Å, V=11104 (2) Å^3, D_m=1.17 g cm^{-3} (by flotation in an aqueous solution of $ZnCl_2$), D_c=1.168 g cm^{-3} for Z=40, μ (Cu $K\alpha$)= 5.80 cm^{-1}.

Integrated intensities were measured on the diffractometer by the θ—2θ scan technique. The 2θ scan rate and scan width were 4° min^{-1} and $\Delta 2\theta$=(2.0+0.7 tanθ)°, respectively. Backgrounds were measured for 7.5 s before and after the scan of each peak. Intensities of five standard reflections were measured after every 52 reflections, $|F|$ values of which changed about 3 to 5% with time. Their changes could be expressed approximately by a fifth order equation, the coefficients of which were determined from the intensity changes of three stronger reflections, 080, 0,0,16, and 600, and the observed $|F|$ values were corrected with time. A total of 6993 independent (5215 non-zero) reflections was collected up to 2θ=110°. Usual Lorentz and polarization corrections were made but absorption and extinction corrections were ignored.

Solution of the Structure and Refinement

The crystal data show that the corresponding space group is Pbca and 40 molecules are contained per unit cell. The asymmetric unit consists of 5 independent molecules.

The structure could be established by the direct method using *MULTAN* program.[4] Of the 32 choices of the starting sets, only one gave the figure of merit larger than 0.8. The $|E|$ map was then computed using the phases based on this starting set. 54 peaks out of 75 high peaks in the $|E|$ map revealed non-hydrogen atoms of three independent molecules out of five and also parts of the ethyl and carbazole moieties of the other molecules. The successive Fourier synthesis could locate all of the remaining non-hydrogen atoms.

The structure was refined anisotropically by the block-diagonal least-squares procedure (*HBLS* V).[5] The function minimized was $\sum w(\Delta F)^2$, where w=1. Hydrogen atoms except those of the methyl groups were located on a difference Fourier map, which were refined isotropically. In the final cycle of the refinement the R index decreased to 0.062 for 5134 non-zero reflections. Final atomic coordinates with equivalent temperature factors[6] are listed in Table 1.††††

Atomic scattering factors for non-hydrogen atoms were taken from International Tables for X-Ray Crystallography, Vol. IV,[7] and those of hydrogen atoms from Stewart and co-workers.[8]

All the Computations were carried out mainly on a NEAC 2200-700 computer at the Computation Center and at the final stage on an ACOS 850 computer at the Crystallographic Research Center, Institute for Protein Research, Osaka University.

Results and Discussion

Molecular Structure. Since five independent molecules do not differ significantly from each other, only the structure of the molecule 1 is depicted in Fig. 1, with the numbering scheme of atoms. Bond lengths and bond angles in five molecules are given in Table 2.†††††

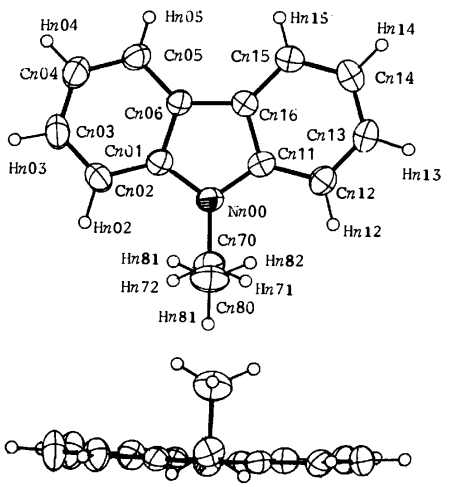

Fig. 1. Molecular structure of *N*-ethylcarbazole (*ORTEP* drawing).[11]
Non-hydrogen atoms are drawn as thermal ellipsoids with 30% probability level and hydrogen atoms as spheres with $B=1.0$ Å^2.
(a) Plan. (b) Side view.

The carbazole moiety is approximately planar (Fig. 1(b)), and no significant difference has been observed between chemically-equivalent bond lengths and bond angles. Average values of bond lengths and bond angles are compared in Table 3 with those of carbazole[9] and *N*-vinylcarbazole.[10] All of the corresponding lengths and angles in the three compounds show accordances within the limit of errors.

In each of the present *N*-ethylcarbazole molecule, the C(*n*01)-N(*n*00)-C(*n*70) angle [av. 125.3°] is equal to the corresponding C(*n*11)-N(*n*00)-C(*n*70) angle [av. 124.5°] and the N(*n*00)-C(*n*01)-C(*n*02) [av. 129.7°] equal to the N(*n*00)-C(*n*11)-C(*n*12) [av. 129.8°]. The ethyl group attached to the nitrogen atom is almost perpendicular to the carbazole plane [av. 87.8°]. On the other hand, in *N*-vinylcarbazole the ethylenic bond planes in two independent molecules make angles of 14.0 and 2.6° with the carbazole planes. The C(01)-N-C(70) angle [128.6(7) or 130.6(7)°] is, therefore, much larger than the C(11)-N-C(70) angle[122.9(7) or

121.2(7)°].[10] The carbazole molecule has crystallographic mirror symmetry about the plane, vertical to the C(06)-C(16), which includes the N and H atoms.[9]

Crystal Structure. Figure 2 shows the crystal structure of *N*-ethylcarbazole projected along the a axis. Carbazole rings of the five independent molecules make similar angles with the a axis, the angles ranging from 36.1 to 38.3°. It is remarkable that no pair of neighboring molecules, in which the π-electron clouds of the carbazole rings overlaps, is found. All the molecules contact with each other by the van der Waals force (Table 4). The closest intermolecular distance between non-hydrogen atoms is observed between molecules directly related by the glide plane [C(405)(x, y, z)···C(480)(1+x, y, z)=3.445(8) Å]. In

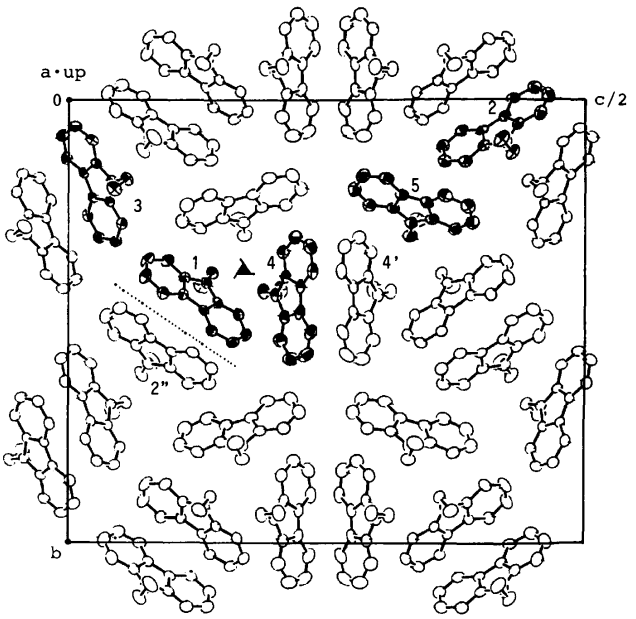

Fig. 2. Crystal structure of *N*-ethylcarbazole (*ORTEP* drawing).[11]
Non-hydrogen atoms are drawn as thermal ellipsoids with 30% probability level. Hydrogen atoms are omitted for clarity. Atoms belong to the five molecules in an asymmetric unit are drawn as ellipsoids with principal and enveloping ellipses whereas others only with enveloping ellipses.
Local pseudo symmetries are also given.

the packing of molecules the following pseudo-symmetries can be locally observed besides the crystallographic symmetry operations: 1) a local pseudo a-glide plane, expressed by a broken line in Fig. 2, between the molecules 1 (x, y, z) and 2'' (−x, 0.5+y, 0.5−z) and 2) a local pseudo three-fold screw axis parallel to the a axis among the molecules 4 (x, y, z), 1 (x, y, z), and 5 (0.5+x, y, 0.5−z).

The authors wish to express their deep thanks to Professor Hiroshi Mikawa and his co-workers of Osaka University for the supply of crystals and helpful discussions. Thanks are also due to Miss Nobuko Kanehisa who helped the authors at the final stage of the computations and *ORTEP* drawings.

Crystal Structures of Complexes between Hexacyanobutadiene and Tetramethyltetrathiafulvalene and Tetramethylthiotetrathiafulvalene

(Received March 6, 1985)

Hexacyanobutadiene(HCBD) forms two kinds of molecular complexes with tetramethyltetrathiafulvalene (TMTTF) one kind with tetramethylthiotetrathiafulvalene(TTMTTF). The crystal structures of these complexes and neutral TTMTTF are determined by X-ray analyses. $(TMTTF)_2$·HCBD is composed of 2:1 donor and acceptor, and TMTTF exists as a dimer cation stacked along the c axis. HCBD anions are included in the cavity of the dimer stack directing their molecular planes parallel to the stacking axis. TMTTF·HCBD is composed of 1:1 donor and acceptor, and has segregated cation and anion stacks with the interplanar spacing of 3.61 Å in TMTTF and 3.43 Å in HCBD columns. TTMTTF·HCBD is shown to have a regular segregated column with a partial charge transfer. Neutral TTMTTF has a non-planar conformation. The C=C and C–S bond lengths of the donors in free and complexed states are correlated with the degree of the charge transfer in these four complexes, and linear relationships are found between these two quantities.

Hexacyanobutadiene (HCBD) is one of the strongest electron acceptors[1,2] and is expected to give charge-transfer complexes.[3] A weak or medium electron donor may form a nominally neutral, weak complex or a segregated mixed valence complex, and a good electron donor may crystallize as an ionic complex. Single crystals of HCBD complexes with tetramethyltetrathiafulvalene (TMTTF) and tetramethylthiotetrathiafulvalene (TTMTTF) were prepared and two complexes of TMTTF·HCBD were obtained; one is 2:1 and the other is 1:1 donor to acceptor ratio. TTMTTF·HCBD formed a crystal of 1:1 ratio.[4]

The crystal structures of these three complexes and that of free TTMTTF were analyzed and the molecular structures of the donors are discussed based on the structural data and the electronic structures of the complexes. This information will be used for the interpretation of the physical properties of these complexes in the succeeding paper.[5]

Experimental

Preparation of HCBD Complexes. HCBD was prepared by the method of Webster.[1] The product was identified by mass and infrared spectra. Molecular complexes of HCBD with TMTTF and TTMTTF were obtained by mixing hot acetonitrile solutions of the donor and the acceptor in the same flask. Complex crystals were grown in the refrigerator for overnight. Two complexes of TMTTF·HCBD were obtained; $(TMTTF)_2$·HCBD crystal is a hexagonal prism of dark green color with the (100), (001), and (20$\bar{1}$) faces and

it is composed of two donor and one acceptor molecules. TMTTF·HCBD is a one to one complex and the crystal is a thin plate showing golden luster with the (010) face. TTMTTF·HCBD is a complex of 1:1 donor to acceptor ratio. The crystal is a black rod elongated along the b axis with the (100) and (001) faces. TTMTTF is a crystal of an orange color.

Crystal Structure Analysis. The X-ray diffraction data were collected by use of an automated four-circle diffractometer, Rigaku AFC-5, set on a rotating anode X-ray generator, Rigaku RU-200, with a graphite monochromated Cu radiation (Cu $K\alpha$=1.5418 Å). Composition of the complexes and crystallographic data are listed in Table 1 together with experimental results. Crystal structures were solved by the Monte-Carlo direct method[6] using MULTAN 78 program system[7] and were refined on F^2 by the full-matrix least-squares program with the analytical absorption correction.[8] Atomic scattering factors were taken from International Tables for X-ray Crystallography.[9] ORTEP[10] was used for drawing of the molecular and crystal structures. Anisotropic temperature factors were used for the refinement of the non-H atoms. All H atoms were located from difference Fourier maps and were refined with the isotropic temperature factors equivalent to that of the bonded carbon atoms.

* The B_{eq} of hydrogen atoms were assumed to be the same with the values for the attached C atoms.

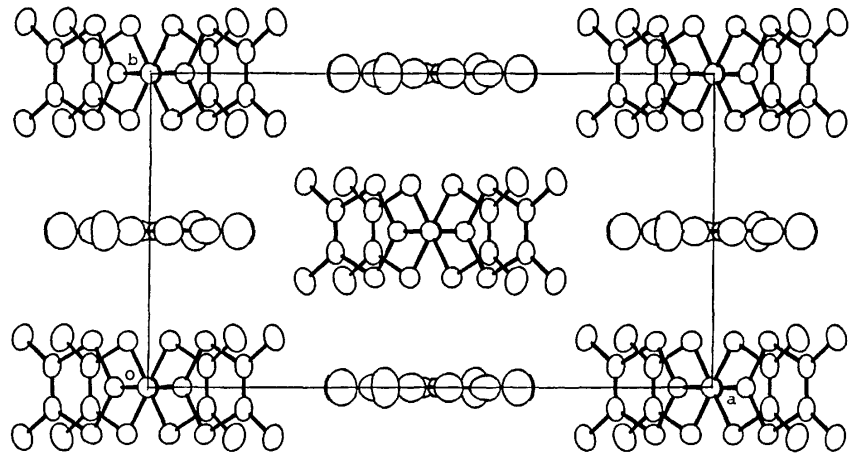

Fig. 1. Crystal structure of $(TMTTF)_2 \cdot HCBD$ projected along the c axis.

The final atomic parameters are listed in Table 2. All computations were carried out at the Computation Center of Nagoya University. The complete F_o—F_c data and the anisotropic temperature parameters are deposited as Document No. 8535 at the Office of the Editor of Bull. Chem. Soc. Jpn.

Results and Discussion

Crystal Structure. $(TMTTF)_2 \cdot HCBD$: Crystal of $(TMTTF)_2 \cdot HCBD$ is composed of two donor and one acceptor molecules. The TMTTF molecules form a dimer, and the stacking axis is parallel to the c axis as shown in Fig. 1. HCBD molecules are included in the channels surrounded by the TMTTF columns and they are lined up without face to face stacking. A crystallographic two-fold axis penetrates the center of HCBD molecule and the molecules are disordered with a pseudo D_{2h} symmetry. The molecular plane of HCBD, which lies on a crystallographic mirror plane, is perpendicular to the plane of TMTTF molecule. The other mirror plane bisects the TMTTF molecule through the long axis.

In most donor-acceptor complexes having a segregated column, the stacking of both donor and acceptor molecules occur along the same direction; however, the present crystal shows different arrangement. It is conceivable that a large polarizability of HCBD parallel to the molecular plane may stabilize the charge resonance interaction in the dimer column of TMTTF. In the literature there are several examples in which the aromatic ring planes are arranged in the crystal parallel to the stacking axis of organic radicals.[11] From the bond length of the central C=C bond of TMTTF and the band position of the electronic spectra,[5] it is suggested that an oxidation occurs by transferring an electron in the ground state from one of the TMTTF dimer to the HCBD molecule. Accordingly the crystal is composed of $(TMTTF_2)^+ \cdot (HCBD)^-$. The interplanar spacing in the dimer is 3.53 Å and that between the dimer is 3.69 Å.

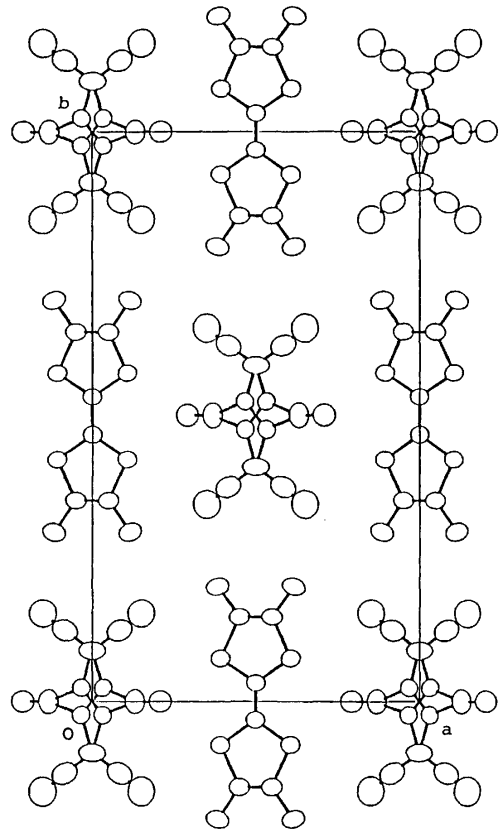

Fig. 2. Crystal structure of TMTTF·HCBD projected along the c axis.

TMTTF·HCBD: The crystal composition is one donor and the one acceptor. They are stacked in segregated columns extending along the c axis (Fig. 2). A mirror plane parallel to the (010) bisects the central C–C bonds of TMTTF and HCBD. A crystallographic two-fold axis penetrates the center of these molecules. The HCBD molecule is disordered in the positions of carbon atoms of the central C–C bond. As will be discussed in the next section, the charge transfer from TMTTF to HCBD seems to be complete, therefore this crystal has segregated columns com-

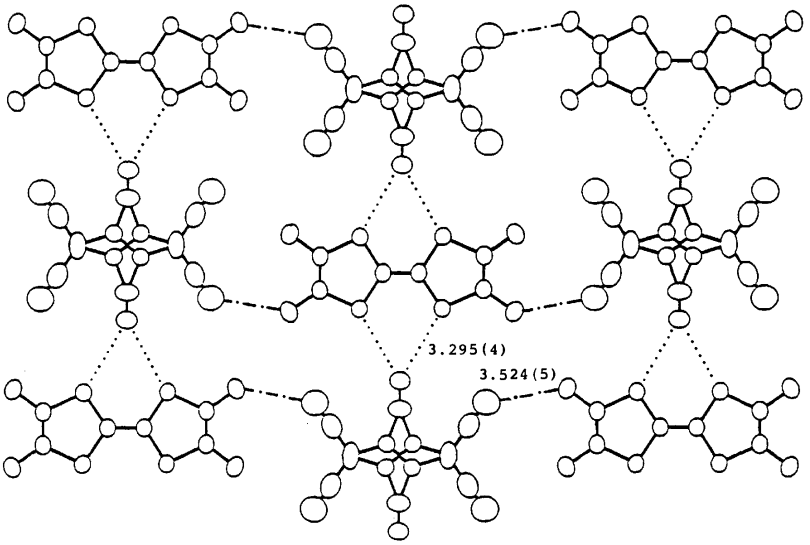

Fig. 3. The network of TMTTF and HCBD molecules projected onto the (101) plane. Close intermolecular distances are illustrated.

posed of ionic constituents. Such a structure of DA complex is known in the case of HMTTF·TCNQF$_4$.[12] The interplanar distance is 3.61 Å in the TMTTF cation column, which is a mean value of the inter- and intra-dimer distances in (TMTTF)$_2$·HCBD. The corresponding distance for HCBD anion is 3.43 Å. The Coulomb force between the charges of the same sign is repulsive for close contact of the same molecules; however, the covalent or the charge resonance interaction will favour a short interplanar distance. The actual molecular packing is determined by a balance of these repulsive and attractive interactions. The inter-column interaction between HCBD and TMTTF molecules is evident in the composite diagram of the (101) plane (Fig. 3). The closest contact is that between S···N with the distance of 3.295 (4) Å, which is shorter than the van der Waals distance of 3.35 Å, and two-dimensional network is formed.

TTMTTF·HCBD: The complex is made of the donor and the acceptor with 1:1 ratio, and they form segregated stacks along the b axis as shown in Fig. 4. Both the donor and the acceptor are stacked in one-dimensional regular lattice, and the spacing between the planes of adjacent TTMTTF molecules is 3.63 Å. The degree of the charge transfer from the donor to the acceptor is a partial one as will be discussed in the next section from the bond lengths. It is inferred that both the donor and the acceptor columns are in mixed valence state. The centers of the molecules are coincident with a center of symmetry of the crystal. The central carbon atoms in HCBD are disordered around the inversion center. There are several close distances between TTMTTF and HCBD in different columns, and they are S···S 3.510(1) Å where the van der Waals distance is 3.70 Å. In the polarized reflection spectra, there is some indication of the inter-column interaction.[5]

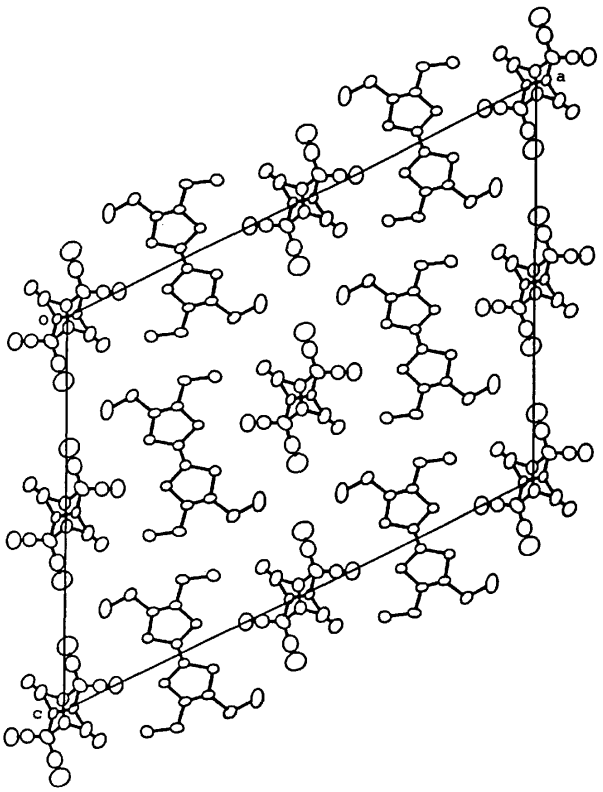

Fig. 4. Crystal structure of TTMTTF·HCBD projected onto the (010) plane.

TTMTTF: The arrangement of the molecules is projected onto the (010) plane as shown in Fig. 5. There are close contacts between S atoms of methylthio groups arranged along [10$\bar{1}$] ranging about 3.54—3.57 Å.

Molecular Structure. ORTEP drawings and important bond lengths are shown for the donor molecules in different crystals in Figs. 6—10. Several papers have been published in which the bond lengths

of TTF analogues are discussed with reference to charges in the molecule.[11] We take the bond lengths of TTF[13] and TTMTTF and their salts TTF perchlorate,[14] and TTMTTF·AsF_6[15] as standards of the neutral and ionic species and draw the correlation diagram between the bond length and the degree of charge transfer as shown in Figs. 11 and 12. The results

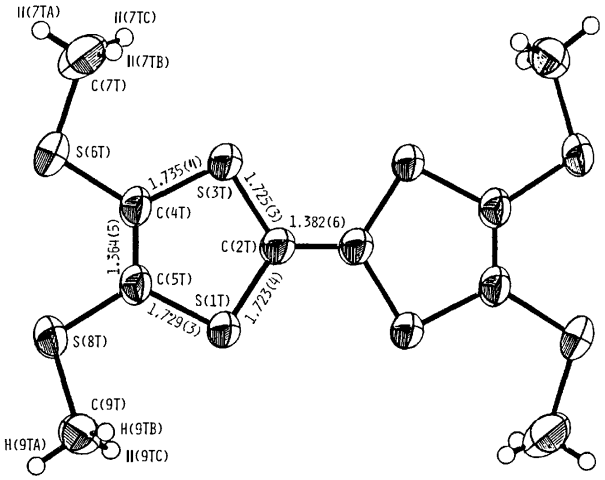

Fig. 8. Molecular structure of TTMTTF in (TTMTTF)·HCBD crystal.

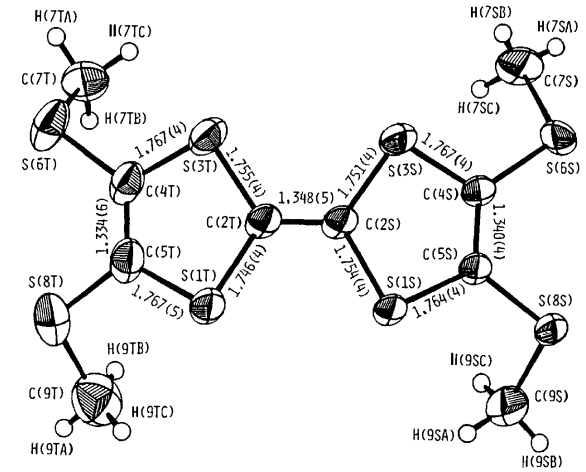

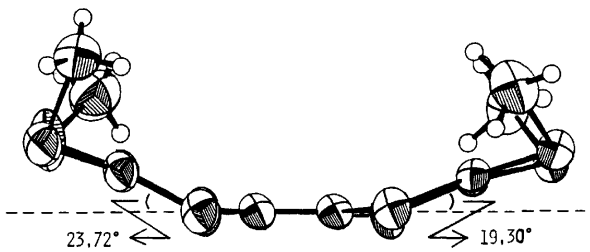

Fig. 9. Molecular structure of neutral TTMTTF (a) and the side view (b).

of the present crystal analysis clearly show that the charges of TMTTF in TMTTF·HCBD is one (ρ=1.0) and that of in $(TMTTF)_2$·HCBD is a half (ρ=0.5) and the value in TTMTTF·HCBD is ρ=0.4—0.6. The standard deviations of the present results are rather small as compared to the published data. We quote here the values for the crystals in which the ρ value is well established by chemical stoichiometry and by other means. They are TTF·TCNQ[16] $(TMTTF)_2$·Br,[17] $(TMTTF)_2$·BF_4 (at 100 K),[18] $(TMTTF)_2$·SCN,[19] HMTTF·TCNQ.[20] The strain caused by substituent groups or benzene ring fusion might be significant in

changing the central C=C bond distance in dibenzotetrathiafulvalene series. In spite of this, the correlation between the bond lengths and the charge density seems to be useful for assessment of the electronic structure of the TTF type donors when the accuracy of structural analysis is sufficiently high.

The molecular structure of HCBD in the crystal of TMTTF·HCBD is illustrated in Fig. 10. However, the precise structure of HCBD is difficult to ascertain because the molecule is disordered in all complexes. It is remarkable that all C–C bond lengths in butadiene skelton are longer than normal values, presumably because all cyano groups will take electrons from the central carbon bonds.

The free TTMTTF molecule has a bent structure (Fig. 9b), in which all methylthio groups and the attached carbon atoms are displaced significantly from the central ring plane. The tilt angles are about 20° in both ends. The terminal C–S–C bonds are strongly bent, and the bond angles are in the range of 101—104°. It is of interest that the molecule is planar in the partial ionic column of TTMTTF·HCBD complex, because the planar conformation will be favoured by the charge resonance interaction.

This research was supported by the grant in aids of special research project on properties of molecular assemblies (No. 59112003) from the Ministry of Education, Science and Culture.

(Received March 19, 1985)

Experimental results of the polarized reflection spectra and the calculated absorption spectra of 3,4:3′,4′-bis(tetramethylene)-2,2′,5,5′-tetrathiafulvalene (OMTTF)–TCNQ and OMTTF–1,4-dihydro-1,4-bis(dicyanomethylene)triptycene(DBTCNQ) crystals are discussed by developing approximate theoretical models, based on the CT mechanism. The electronic structures conform well that, OMTTF–TCNQ is a neutral crystal whereas, OMTTF–DBTCNQ is ionic. Furthermore, the temperature dependent spin susceptibilities imply the former as diamagnetic and the latter as a regular Heisenberg antiferromagnet.

Recently many scientists show keen interests in the field of highly conducting charge-transfer (CT) complexes. In this regard, complexes of TCNQ as the acceptor and TTF as the donor are the most widely investigated. In this class of complexes, the donor (D) and the acceptor (A) form segregated columns of their own in a mixed valence state[1] ($DD^+DD^+\cdots$ and $AA^-AA^-\cdots$). They are characterized by metallic conductivity ($\sigma\sim10^2$—10^3 $ohm^{-1}cm^{-1}$) and an intense reflectance in the infrared region. Discovery of such high conductivities in the quasi-one-dimensional materials stimulated people greatly to design, synthesize and subsequently to investigate into the CT complexes of the new derivatives of TTF and TCNQ. Many attempts were successful[2] although lots of the crystals were found to belong to another category. Here, the complexes are of the simplest stoichiometry (1:1) and they form mixed stacks of alternating donors and acceptors either in the neutral (···DADADA···) or in the ionic ($\cdots D^+A^-D^+A^-\cdots$) forms and consequently exhibit insulating to semiconductive behavior ($\sigma\sim10^{-9}$—10^{-3} $ohm^{-1}cm^{-1}$). The overlap between D and A hybridizes these states so that the solids in this class are only nominally neutral (**N**) or nominally ionic (**I**) in their ground states.[3]

In this paper we shall report on the electronic spectra and electronic structures of two such mixed stack complex crystals with OMTTF as the common donor. Figure 1 shows their molecular structures. The first crystal is the OMTTF–TCNQ[4] which has been suggested to be neutral from the structural analysis.[5] The second one is a new complex[6] between OMTTF and DBTCNQ.[7] The polarized reflection spectra and hence the calculated absorption spectra by Kramers-Kronig transformation[8] are presented and theoretical interpretations are made with a special emphasis on the CT bands. It has been found that OMTTF–DBTCNQ is an ionic complex,[6] accordingly the ESR measuerments are performed to find its spin susceptibility. The results of the optical and magnetic studies are interpreted in terms of the CT mechanism based on the calculations of the interactions between the MOs of the donor and the acceptor.

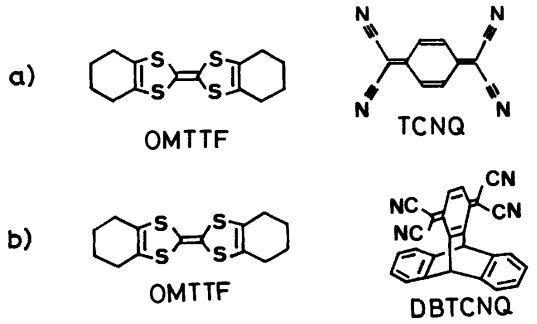

Fig. 1. Molecular structures of (a) OMTTF–TCNQ and (b) OMTTF–DBTCNQ.

Experimental

The crystals of OMTTF–TCNQ and OMTTF–DBTCNQ were of needle shape and lustering surfaces. In the structural analysis,[5] OMTTF–TCNQ crystal is reported as triclinic, $P\bar{1}$. In one of our previous papers,[1] we have reported the cell constants in a different way: $a'=b$, $b'=c$, $c'=a$, $\alpha'=\beta$, $\beta'=\gamma$, and $\gamma'=\alpha$, the dashed parameters being of our previous paper. OMTTF–DBTCNQ on the other hand, is monoclinic, C2/c.[6] The lattice parameters are: $a=18.535$ Å, $b=14.417$ Å, $c=14.906$ Å, $\beta=98.890°$, $Z=4$ and there exists one distorted C_6H_6 (solvent) per molecular complex. The oscillation/Weissenberg photographs were used to select suitable crytal faces for the spectral measurements.

Optical Spectra. The polarized reflection spectra on the (100) plane of OMTTF–TCNQ single crystal have been observed in the range of 3000—35000 cm^{-1} by a reflection spectrophotometer designed in our laboratory. Similar measurements on the (010) plane of OMTTF–DBTCNQ were performed in the range of 5000—25000 cm^{-1}. For both the crystals spectral measurements, one parallel to the needle axis and the other perpendicular to it, were made. Corresponding absorption spectra were then calculated by the Kramers-Kronig transformation.[8] The crystal oscillator strength along the α-axis was evaluated as:

$$f^{\alpha} = 4.32 \times 10^{-9}\int n_{\alpha}(\nu)\varepsilon_{\alpha}(\nu)d\nu \qquad (1)^{9,10}$$

where, ν is the wave number, n_α and ε_α are the α-components of the refractive index and the molar extinction coefficient, respectively.

ESR Measurements. The ESR absorptions were observed by a Varian-E 112 X-band spectrophotometer at 100 KHz field modulation. Measurements were made at the field strength of 3248 Gauss and care was taken with the microwave power so as to prevent saturation effect, if any, of the ESR signal especially at low temperatures. At least 20 single crystals of OMTTF-DBTCNQ and 3 of OMTTF-TCNQ were used due to their size factors. In the crystal setting of both the crystals, the needle axes were kept approximately perpendicular to the magnetic field direction. The absolute intensities of the ESR absorptions were obtained by integration of the derivative curves. Temperature dependent ESR were observed in the range of 1.6—293 K with an accuracy of ±1 K. The spin susceptibility was calculated by comparing the measured intensity with that observed for DPPH and then with spin susceptibility of the latter.[11]

Results and Discussion

Electronic Spectra. *a) OMTTF-TCNQ Crystal:* The polarized reflection spectra parallel and perpendicular to the crystal c-axis as observed on the (100) plane are shown in Fig. 2. In this spectra, there are two low energy bands and two other humps in the //c component. The corresponding absorptions calculated by the K-K transformation[8] are represented by Fig. 3. In the //c spectra, the lowest absorption arises near 5000 cm^{-1} and the second one which is very sharp, in the region of 17200 cm^{-1}. There are also a number of feeble absorptions but all in the high energy side. The $\perp$c component, on the other hand, shows almost no absorption over a wide range of the observed spectra. Therefore, a comparative study between these two spectra reveals that, both the bands of 5000 and 17200 cm^{-1} are absolutely polarized along the c-axis of the crystal. At this stage, a close look into the crystal packings as depicted in Figs. 4 (a) and 4 (b) will provide an important clue to characterize them: The molecular components, OMTTF and TCNQ, stack alternately along the c-axis with the average molecular planes almost perpendicular to it (interplanar distance, 3.53 Å). Therefore, it would be appropriate to suggest these two as the CT bands where OMTTF donates its electrons to the TCNQ molecule: the first absorption is due to the first charge transfer, CT_1 and the second one is due to the second charge transfer, CT_2. In the photoelectron spectra, TMTTF showed closely situated two levels at 6.40 eV (b_{1u}) and 7.99 eV (a_{1u}) which are about 12800 cm^{-1} (1.59 eV) apart.[13] Therefore, in OMTTF-TCNQ, if the CT band from the HOMO is found at 5000 cm^{-1}, the CT_2 band appearing at 17200 cm^{-1} may be assigned to the transition from the second HOMO of OMTTF, because, energy separation (12200 cm^{-1}) between these two bands is close to the difference in energy of the first and second HOMOs in the TMTTF molecule.

In order to estimate the CT state energy, secular

TABLE 1. VALUES OF IONIZATION POTENTIAL(I_P), ELECTRON AFFINITY(E_A), COULOMB(C)/MADELUNG(M) ENERGY, POLARIZATION ENERGY(P), CT CONFIGURATION ENERGY(Δ) AND THE CALCULATED MIXING COEFFICIENTS a AND b OF THE CRYSTALS

Complex	Transition type	I_P (eV)	E_A (eV)	C/M (eV)	P (eV)	Δ (eV)	a	b
OMTTF-TCNQ	CT_1	6.5	2.80	2.96	0.2	0.54	0.995	0.103
	CT_2	8.0	2.80	2.95	0.2	2.05	0.981	0.196
OMTTF-DBTCNQ	back CT	6.5	2.85	3.84	0.7	0.89	0.130	0.992

equation of the following form may be solved. Considering the ground configuration at the zero level and the CT configuration energy to be denoted as Δ, the equation follows:

$$\begin{vmatrix} \Delta - E & 2t_{Ak,DI} \\ 2t_{Ak,DI} & -E \end{vmatrix} = 0 \qquad (2)$$

In this equation, Δ may be defind as:

$$\Delta = I_p - E_A - C - P \qquad (3)$$

where, I_P is the ionization potential, E_A the electron affinity, C the Coulomb potential in the DA pair and P is the polarization energy (positive) of the crystal. Again, $t_{Ak,DI}$ is the transfer integral and may be related to the overlap integral, $S_{Ak,DI}$, approximately as:

$$t_{Ak,DI} = KS_{Ak,DI}\left(\frac{W_{Ak}+W_{DI}}{2}\right) \qquad (4)^{1,12)}$$

where, W_{Ak} and W_{DI} are the respective MO energies and K is a semiempirical constant lying in the range of 1.0—2.0.

For the crystal of OMTTF-TCNQ ionization energies that are yet to explore, were approximated to be 6.5 eV (I_p^1) and 8.0 eV (I_p^2) with reference to those of TMTTF.[13,14] From the MO calculations by Pariser-Parr-Pople method, the two transitions in this crystal may be considered as: CT_1:$D_7 \rightarrow A_9$ and CT_2:$D_6 \rightarrow A_9$, subscript denoting the number of MO counted from the bottom in the concerned molecule. The associated orbital overlaps ($S_{A9,D7}$ and $S_{A9,D6}$) are 0.00367 and 0.02315 so that, transfer integrals may be estimated as t_1=−0.0290 and t_2=−0.2125 eV provided K=1.7 in Eq. 4. Moreover, considering Ohno-Klopman's approximations Coulomb energies as calculated are 2.96 eV (CT_1) and 2.95 eV (CT_2). Now, if we assume that the polarization energy (unknown yet) be as small as 0.2 eV, Δ in Eq. 3 may be estimated as 0.54 eV (Δ_1) and 2.05 eV (Δ_2). Therefore, solving the respective secular equations our theoretical CT transition energies obtained are 0.55 and 2.22 eV which are fairly comparable to the observed values of 0.62 and 2.13 eV, respectively. To estimate approximately the contribution of these CT states to the crystal ground state, mixing coefficients a and b in the wave function,

$$\Psi_G = a\Psi_0 + b\Psi_1 \qquad (5)^{15)}$$

were calculated and are shown in Table 1. Respective magnitudes of a and b thus suggest that, in the ground state crystal of OMTTF-TCNQ is mostly neutral and, in its CT interaction, contribution of the CT_2 is more than that of the CT_1. The observed and the calculated degrees of charge transfer, oscillator strengths and the stabilization energy as displayed in Table 3 are in reasonable agreement. The larger value of the degree of charge transfer of CT_2 than that of CT_1 indicates that the former configuration is quite significant in the CT interaction. Following the theoretical calculations, CT stabilization energy in the ground state is found to be 2.02 kcal mol^{-1}† of which ≈93% (1.88 kcal mol^{-1}) is accounted as the contribution of the CT_2 configuration. The large f_2 of the CT_2 transition may be attributed as due to the allowed character of the transition from the second HOMO(D_6) of OMTTF to the LUMO(A_9) of TCNQ. In contrary, CT_1 transition seems to be of forbidden type as can be decided by the difference in the symmetry of the HOMO and the LUMO, because, the transfer integral between the molecular orbitals of different symmetry will be negligibly small. Nevertheless, both the CT_1 and CT_2 configurations stabilize the crystal ground state only to a certain extent, so that the crystal as a whole is almost neutral in its ground state.

b) OMTTF-DBTCNQ Crystal: Presence of two benzene rings in the DBTCNQ molecule creates a novelty in the crystal of OMTTF-DBTCNQ. One would notice interestingly that, in the crystalline state OMTTF and DBTCNQ form linear stacks in an alternating fashion along the c-axis (average interplanar distance ≈3.60 Å) in a pattern such that the molecular planes of OMTTF and TCNQ moiety of DBTCNQ are almost parallel (Figs. 5 (a) and 5 (b)). As compared with the mode of overlapping in OMTTF-TCNQ crystal, there is a lateral shift of TCNQ moiety along its short axis. By comparing its powder spectra with those of $K^+DBTCNQ^-\cdot 2H_2O$ and $OMTTF^+BF_4^-$, Nakasuji *et al.*[6] suggested that OMTTF-DBTCNQ is an ionic complex. In this paper polarized electronic spectra will conform the assignments of the spectra and the ionic ground state.

The observed reflection spectra polarized parallel and perpendicular to the crystal c-axis are shown in Fig. 6 and the corresponding absorption spectra in Fig. 7. In the absorption spectra, the ⊥ c component

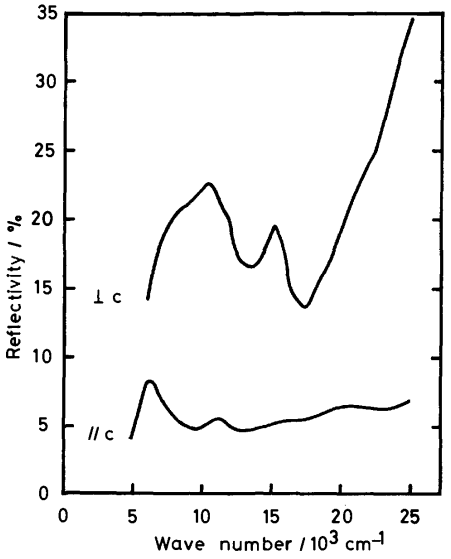

Fig. 6. Reflection spectra of OMTTF-DBTCNQ on the (010) plane.

shows its first absorption in the region of 11800 cm^{-1} which may be suggested as due to the first local excitation (LE_1) in the TCNQ moiety of DBTCNQ, since in solution the first excitation in $TCNQ^-$ has been observed[16] near 12000—13000 cm^{-1}. At the similar energy region (≈11800 cm^{-1}) there is a small absorption also in the //c spectra which may be interpreted

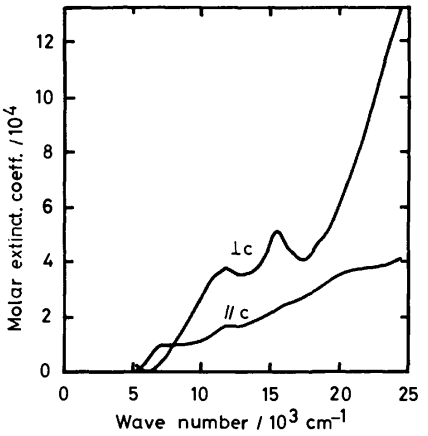

Fig. 7. Calculated absorption spectra of OMTTF-DBTCNQ crystal on the (010) plane.

as the perpendicular component of the former absorption. This is justified because, the molecular planes of OMTTF and TCNQ moiety are not exactly perpendicular to the c-axis, rather inclined to it (roughly by 10—15°). The next absorption at around 15400 cm^{-1} in the ⊥ c spectra may be interpreted as due to a local excitation in $OMTTF^+$ since an absorption at 17000 cm^{-1} of this cation radical has been observed in its powder spectra[6] and also one of the local excitations in TTF^+ has been found near 18000 cm^{-1}.[17] Ultimately, the lowest absorption of 7200 cm^{-1} in the //c component indicates its unique polarization in a direction which is close to the stacking axis. Therefore, it is typical of the CT band and the ionicity in the complex strongly suggests it to be associated with the "back charge transfer" where, an electron transfer occurs from the HOMO of the $TCNQ^-$ moiety to the LUMO of the $OMTTF^+$ radical.

Using the P-P-P method we have performed MO calculations of OMTTF-DBTCNQ also which referred to $\phi_9 \rightarrow \theta_7$ as the CT transition. Here, ϕ and θ are the HOMO and LUMO of DBTCNQ anion and OMTTF cation respectively and the subscripts denote the numbers of MOs in the ions. In addition, considering Ohno-Klopman's approximations, overlap integral calculated was 0.00721 so that the transfer integral may be estimated as t=—0.0573 eV at the value of K=1.7.

In the case of ionic crystals, we like to prefer back CT configuration energy, Δ', to be defind as:

$$\Delta' = M + P + E_A - I_P \qquad (6)$$

Here, M represents the negative of the crystal Madelung energy and the other parameters have the similar significances as in Eq. 3. From the very difference in the redox potentials of TCNQ and DBTCNQ of 0.18 and 0.23 V, respectively, electron affinity of the latter may be assumed to be increased by only 0.05 eV from that of TCNQ, *i.e.*, E_A(DBTCNQ)=2.85 eV. To have an estimation of the crystal Coulomb energy we have computed Madelung energy of OMTTF-DBTCNQ by the

Ewald method[18] following Metzger's expressions.[19] The computation program written here was tested with NaCl, $TMPD^+$-$TCNQ^-$ and $TMPD^+$-ClO_4^- and all of them have shown good coincidence with those calculated by Metzger.[19,20] For the OMTTF-DBTCNQ crystal, detailed charge distributions at different atom positions were calculated by the P-P-P method and they are represented in Table 2. Two runs, at η=15.00 and η=20.00, were made with this charge distribution model and the results are shown in Table 2. Thus the estimated Madelung energy of magnitude of 3.846±0.002 eV may merely be as enough as to ionize a DA pair since, $I_P - E_A \simeq 3.65$ eV is our guess about this complex. Therefore, to find an approximate fit to the observed spectra we have considered $\Delta' \simeq 0.89$ eV which needed obviously a polarization energy of 0.7 eV. This amount is larger than that of the neutral crystal of OMTTF-TCNQ and also seems to be reasonable because, polarization energies of TTF and its methyl-substituted derivatives lie in the range of 0.9—1.4 eV and that of TCNQ is 2.1 eV.[14]

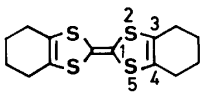
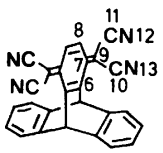
a) For numbering, see below.





The large value of b (Table 1) of the OMTTF-DBTCNQ crystal suggests a highly ionic ground state. Our calculated degree of charge transfer and oscillator strength (based on an ionic complex) are comparable with the observed data (Table 3) and all of them suggest an ionic ground state of the OMTTF-DBTCNQ crystal with an additional stabilization (ΔE=0.33 kcal mol^{-1}) due to the back charge transfer.

Spin Susceptibility: In the ESR measurements, crystal of OMTTF-TCNQ showed only a feeble room temperature absorption with an approximate g of 2.0015. Moreover, in the range of 2.8—300 K no phase transition was found to occur. The observed spin susceptibility was of the order of 10^{-8} emu mol^{-1} most of which may be due to the contamination of crystals with certain paramagnetic impurities.

The ionic crystal, on the other hand, exhibited a single line absorption in the range of 1.6—293 K except a little distortion at 1.6 K. This is because, at low temperatues, ESR intensity shows a small Curie-like upturn which is characteristic of the extrinsic Curie-impurities commonly found in organic salts. However, g value of this crystal was found to be 2.066 at room temperature and increased only by 0.3% at 4.2 K.

The spin susceptibility of OMTTF-DBTCNQ was calculated from the observed intensity and it was corrected by subtracting the contribution of Curie-impurity which showed the Curie constant, C= 7.82×10^{-3} emu K mol^{-1}. The resulting temperature dependence is shown by solid circles as in Fig. 8. A finite spin value near T=0 and presence of a rounded maximum in the temperature dependent spin susceptibility lead to suggest that, OMTTF-DBTCNQ is a typical example of the regular Heisenberg antiferromagnet.[21] An approximate Hamiltonian for such a one-dimensional Heisenberg regular chain is given by:

$$H = \sum_{i=1}^{N} J \boldsymbol{S}_i \cdot \boldsymbol{S}_{i+1} \qquad (7)^{22}$$

where, J represents equal interaction with both the neighbors along the chain and $\boldsymbol{S}_i$ is the spin vector of the ith radical. For a regular Heisenberg antiferro-

magnet Soos[23] has expressed the exchange energy as:

$$J = 2|t|^2/\Delta E_{CT} \quad (8)$$

provided, $\Delta E_{CT} \gg t$. Here, t is Mulliken's CT integral and ΔE_{CT} the energy of CT transition. Our observed spin susceptibility fits moderately well to the Bonner-Fisher model[24] which is calculated for $J=0.005$ eV by using the formulation of Torrance *et al.*;[25] solid line in Fig. 8 represents the calculated values. This value of J is comparable, at least in order, to the expected value of 0.007 eV which may be obtained from equation (8) using our estimated values of t and CT transition energy.

Thus, from so far we have investigated, we find a quite good correlation between the magnetic behaviors and the electronic structures of the two crystals. The OMTTF-TCNQ with two CT transitions and a nearly diamagnetic behavior identifies itself as an almost neutral crystal and probably it has a high energy triplet above its singlet ground state. On the other hand, OMTTF-DBTCNQ is characterized by a single CT transition due to the back charge transfer and magnetically behaves as a simple regular Heisenberg antiferromagnet with a small exchange interaction between the ion radicals along its infinite chain. These facts suggest that OMTTF-DBTCNQ is a highly ionic crystal and the ionicity in the ground state approaches almost to unity. In particular, this OMTTF-DBTCNQ is the third CT crystal as reported yet,[26] with a nearly fully ionic ground state and it follows regular Heisenberg antiferromagnetism strictly over a wide range of temperature.

The authors thank the Instrument Center, Institute for Molecular Science, Okazaki, for the use of a Varian spectrophotometer. This research was supported by the grant in aids of special research project on properties of molecular assemblies (No. 59112003) from the Ministry of Education, Science and Culture.

NMR Study of Molecules in Anisotropic Systems. II.† 1a,2a,3e,4e,5e,6e- and 1e,2e,3e,4e,5e,6e-Hexachlorocyclohexanes Dissolved in Nematic Liquid Crystals

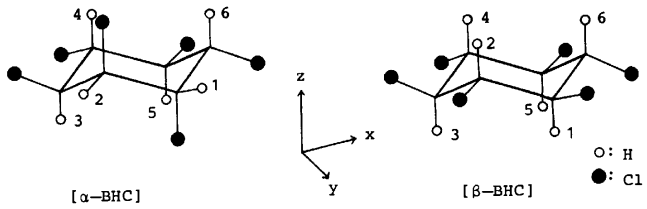
Hideaki FUJIWARA,* Naoto SHIMIZU, Tatsuya TAKAGI, and Yoshio SASAKI
Faculty of Pharmaceutical Sciences, Osaka University, 1-6 Yamada-oka, Suita, Osaka 565
(Received April 20, 1985)

NMR spectra of the titled compounds (α- and β-BHC) have been measured in nematic solvents and analyzed. Vibrational corrections were important for the full interpretation of the observed direct couplings. The order parameters showed that the BHC molecules orient most preferably with their six-membered rings parallel to the optic axis of the nematic solvents. Molecular structure of α-BHC derived from the direct couplings corresponds well with those determined by the X-ray method on a crystal and calculated by the MNDO MO method. For β-BHC, however, discrepancies are found with the crystallographic structure, suggesting molecular deformations in the crystal state. Principal axes have been determined for the order matrix and compared with those for the moment of inertia. The difference between the two principal axis systems in α-BHC is interpreted as due to a steric repulsive effect between the two axial chlorine atoms and the solvent molecules.

NMR spectroscopy of molecules dissolved in anisotropic systems, such as liquid crystals, provides unique informations of direct spin-spin couplings and anisotropies in chemical shifts.[1,2] The direct couplings can give accurate structures of molecules in mobile state, *e.g.*, the r_α structures of benzene determined from NMR spectroscopy in ZLI1167 and from electron diffraction in gas phase agree well with each other.[3] The accurate determination also makes it possible to examine experimentally environmental effects on molecular structure, *i.e.*, the effect of solvent[4] as well as that of the phase under investigation[5] which may be gas, liquid (liquid crystal), or solid. A nematic solvent ZLI1167 is reported[4] as an ideal solvent for benzene derivatives which gives rise to negligible distortion on the molecular structure, whereas it has a weak basic character as revealed with some organotin compounds.[6] Anisotropic environment may also induce a specific molecular deformation of anisotropic nature, which is considered responsible to the observation of dipolar or quadrupolar coupling constants even for molecules with high symmetry such as T_d or O_h.[7] All these properties of the solvents originate from solute-solvent molecular interactions and are of wide interests in view of the similar situations met by molecules dissolved in membrane systems with biological importance.

In the present study, benzene hexachloride (BHC) molecules are taken up which have a flexible framework compared to the rigid benzene ring, and their molecular structures and preferred orientations determined by the NMR spectroscopy. The results are discussed by comparing the principal axes of the moment of inertia and those of the order matrix and by comparing molecular structures derived from several physicochemical methods. The isomers treated here are 1a,2a,3e,4e,5e,6e- and 1e,2e,3e,4e,5e,6e-hexachlorocyclohexane, *i.e.*, α- and β-BHC, respectively.

†See Ref 16 for I.



Experimental

α- and β-BHC (City Chemical Co., USA) were recrystallized several times from ethanol. Nematic solvents ZLI1167 and ZLI1132 (Merck) were used without any special purification. NMR spectra were recorded on a Hitachi R-900M FT spectrometer operating at 90 MHz and at 34.1 °C. Concentrations of the samples were 1 wt% for α-BHC in ZLI1167, and less than 1 wt% (saturated) for β-BHC in ZLI1167 and in ZLI1132. A data point of 16k was used in all measurements and the spectral width and the number of fid's accumulated were 2700 Hz and 3500 for α-BHC, 3150 Hz and 4400 for β-BHC in ZLI1167, and 4950 Hz and 4500 for β-BHC in ZLI1132. Typical line widths were 6 Hz for α-BHC, and 8 Hz (in ZLI1167) and 15 Hz (in ZLI1132) for β-BHC. The sample tube was not rotated when ZLI1132 was used as a solvent.

Spectral analysis was carried out by a computer program LAOCN3 modified to apply to the oriented system.[8] The observed direct couplings were corrected for harmonic vibrations by the program VIBR[9] and processed to the program SHAPE[10] to derive the order and the structural parameters. Principal axes of the moment of inertia were calculated by the program XYZ.[11] All these calculations were achieved with an ACOS System 1000 computer at the Computation Center in Osaka University. Diagonalization of the order matrix was done by a Basic program on a NEC personal computer.

Results and Discussion

Spectral Analysis Leading to the Order and the Structural Parameters. α-BHC belongs to the C_2 point group and gives AA'BB'CC' spin spectra in oriented state, including three chemical shifts and nine

direct couplings as independent variables besides the indirect couplings which are usually substituted by those determined in isotropic media. The spectral pattern observed in ZLI1167 (Fig. 1) is characteristic and the spectral analysis is not laboring. Iteration was made on 96 lines in a final step and rms error between the observed and the simulated frequencies was 0.3 Hz. The results are summarized in Table 1. Order and structural parameters were calculated from the direct couplings (D_{ij}) by the use of SHAPE and they are listed in Table 2, where rms error between the observed and the recalculated D_{ij} values is zero since nine unknown parameters (three order parameters and six structural parameters) are determined from nine experimental data.

β-BHC has the C_{3v} symmetry and gives AA'A''-A'''A''''A''''' spectra in nematic solvents, including one chemical shift and three direct couplings as independent variables. The spectra observed in ZLI1167 (Fig. 2) and ZLI1132 resemble each other and are analyzed easily (Table 3). Iterations were made on 62 lines (in ZLI1167) and 43 lines (in ZLI1132), and rms errors were 0.3 Hz (in ZLI1167) and 0.5 Hz (in ZLI1132). Calculations of the order and the structural parameters from experimental D_{ij} values are summarized in Table 4. Since only one order parameter and one structural parameters are variable independently against three data of D_{ij}, the system is overdetermined. Least squares fits, however, resulted in only partial agreement between the experimental and the recalculated D_{ij}'s, and the rms errors remained large in both nematic solvents used here, *i.e.*, 0.99 Hz in ZLI1167

and 1.56 Hz in ZLI1132 (Table 4).

Corrections for Harmonic Vibrations. It was unexpected that the D_{ij} values observed for the simplest β-BHC were not reproduced well in the above calculation. Model calculations were attempted assuming anisotropic molecular deformations, *e.g.*, C_{2h} symmetry, under the uniaxial orienting system, but they all resulted in unrealistic (very large) deformations. This is the case for both of the nematic solvents used, one of which (ZLI1132) orients parallel to and another (ZLI1167) perpendicular to the external magnetic field. Therefore, corrections for vibrations are considered necessary before invoking to a special molecular deformation. Although such corrections are very small and frequently negligible for the H-H direct couplings, they are known to become important in some cases for a full analysis of the direct couplings, *e.g.*, in cyclopropane[12)] D_{15} is reduced by 1.2 Hz after such correction. Valence force constants which are necessary for the vibrations are not available for BHC itself. Therefore, necessary date are cited from a general valence force field for secondary chlorides[13)] after a dimensional modification to mdyn/Å.††[14)] Calculations of the vibrational corrections are included also in Tables 3 and 4. Rms errors between the experimental and the recalculated D_{ij} values are reduced in great deal and are virtually zero for both of the nematic solvents, supporting successful corrections (Table 4). Vibrational corrections are also applied to α-BHC (Table 1), for which structural parameters change slightly after the correction but not the rms error since the number of unknown parameters equals to that of the experimental data (Table 2).

††dyn=10^{-5}N.

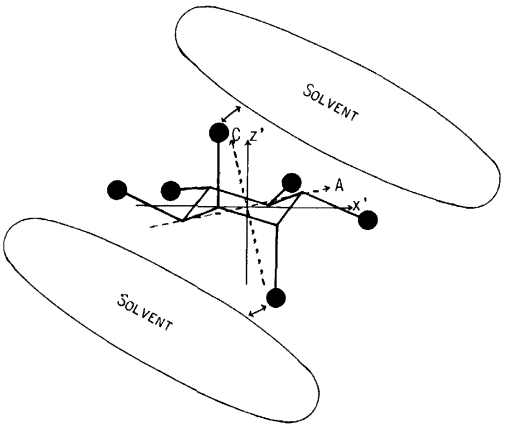

Fig. 3. Principal axis systems for the order matrix (solid line) and for the moment of inertia (dashed line) in α-BHC.
Only Cl atoms are depicted (●).

Orientational Probability from the Order Matrix. As seen from the sign of the order parameters, BHC molecules are most easily oriented like that the *z* axis directs perpendicular to the external magnetic field in ZLI1167 but parallel to it in ZLI1132. When orientation is expressed relative to the optic axis of the nematic solvent, all order parameters need be multiplied by -2 in ZLI1167 which itself orients perpendicular to the external field. Therefore, most probable orientation of the BHC molecules is that their *z* axis is perpendicular to the optic axis in both nematic solvents.

For α-BHC, an off-diagonal element S_{xz} remains non-zero. This S_{xz} is, however, able to be reduced to zero by an appropriate redefinition (rotation) of the cartesian coordinates, *i.e.*, by a diagonalization of the order matrix.[15)] In case of α-BHC such an appropriate rotation is the one that makes $S_{x'z'}=\sum_{pq}\mathrm{COS}\theta_p\mathrm{COS}\theta_q S_{pq}$ ($p,q=x, y, z$) equal zero where θ means the angle between the new (x',y',z') and the old (x,y,z) axes. The new axes are found to be close to the old ones, resulting $S_{x'x'}=-0.08582$ and $S_{z'z'}=0.09799$ for the principal values. Principal axes are also defined with the moment of inertia. They are depicted in Fig. 3 by dashed lines (*A* and *C* axes), *B* axis coinciding with *y* axis which is the molecular C_2 axis. In case of β-BHC, principal axes of the order matrix agree with those of the moment of inertia because of its C_{3v} symmetry. For δ-BHC, where only one chlorine atom is located at an axial position and others are at equatorials, these two

axis systems have been found virtually coincident in a multiple quantum NMR study.[16] In case of α-BHC, two axial chlorine atoms make the *C* axis depart from the *z* axis. But the *z'* axis was not found to deviate considerably from the *z* axis. This is probably because there exists a steric stress effect between the axial chlorine atoms and the solvent molecules, which prevents the *C* axis from being directed perpendicular to the solvent molecules (Fig. 3). A difference of 11° was observed between the two axis systems as shown in Fig. 3.

Solution Structure of the BHC Molecules. Molecular structures are calculated from the observed direct couplings. The direct couplings have been corrected for harmonic vibrations, and hence r_α structure is derived. The results are compared with those determined from other physicochemical methods in Tables 5 and 6, where distance ratios are listed which are derived accurately in the NMR method. In these Tables, NMR means solution structure oriented in nematic phase, X-ray means crystallographic structure, and MNDO means the optimized structure according to the MNDO MO calculation[17] which is listed in place of the unavailable gas-phase structure. These structures corresponds well to each other, supporting reliability of the NMR method adopted here. It is rather difficult to find any dependency of the structure on the phase of investigation in case of α-BHC, but for β-BHC proton distances are seen to be relatively elongated along the *z* axis in crystal state. Such deformation is expected to come from molecular interactions characteristic in crystal states which will be well reflected to the framework of protons located at an outermost sphere of the molecule.

Studies of "Manganese Cycle" for Gasification of Solid Carbon Resources. I. Formation and Hydrolysis of Manganese Carbides and Their Repetition

Hiroyasu IWAHARA,* Hiroyuki UCHIDA, and Satoshi MIZOGUCHI
Department of Environmental Chemistry and Technology, Faculty of Engineering, Tottori University, Koyama-cho, Tottori 680
(Received March 16, 1985)

A new carbide method based on "Manganese Cycle" was studied in order to produce new fuel gas. This process consists of four steps; (i) carbide production from Mn_2O_3 and solid carbon sources, (ii) fuel gas production by means of hydrolysis of the carbide, (iii) spontaneous oxidation of $Mn(OH)_2$ with air to Mn_2O_3, and (iv) regeneration of the carbide from Mn_2O_3 and new carbon sources. In this process, manganese is used as a recyclable medium for gas production, and hydrogen and hydrocarbons (C_1–C_5) are obtained by hydrolysis. Carbon monoxide generated during the formation of the carbide is also utilizable. The addition of Li_2CO_3 was effective for the carbide reproduction.

Recently, much thought has been given to the development of new energy sources replaceable for fossil fuels. And also, many investigators have studied the effective utilization of coal or the other solid carbon sources, which have been wasted or poorly utilized. Production of salt-like carbides and their hydrolysis to obtain hydrocarbons is one of the prospective methods for the gasification of solid carbon sources. Although carbide technology for acetylene production was one of important chemical industries, very high temperature (>2000 °C) is necessary to produce calcium carbide and, nowadays, the technology is unprofitable for the production of organic raw materials. It is desirable to research other salt-like carbides which can be prepared at much lower temperatures.

Tamers[1,2] has proposed the process for total synthesis of benzene by using lithium carbide as the intermediator. His process consists of four steps; (1) production of Li_2C_2 (at 1000 °C), (2) hydrolysis of Li_2C_2 to produce C_2H_2, (3) regeneration of Li from its hydroxide or oxide, and (4) conversion of C_2H_2 to benzene.

Manganese carbides may be another candidate for such a recyclable fuel production medium. Mn_3C is produced at about 1000 °C and hydrolyzed at room temperature to evolve hydrogen and methane ($Mn_3C+6H_2O \rightarrow 3Mn(OH)_2+H_2+CH_4$).[3] The formation and stability of the manganese carbides have been studied by many workers.[4–10] Recently, Christopher[11] has proposed that iron-manganese carbides can be used to produce liquid hydrocarbons by the hydrolysis at high temperature. In his process, since iron(III) chrolide was used to promote the formation of iron-manganese carbide, the latter may be difficult to recycle. And the necessity of the repeated quenching process of the carbides (Mn_3C+Fe_3C) makes the process complicated.

We propose "Manganese Cycle" to produce new fuel gas. As shown in Fig. 1, this process consists of four steps:

(i) Carbide production from Mn (or oxides) and solid carbon sources.

$$x\,Mn + y\,C \longrightarrow Mn_xC_y \qquad (1)$$

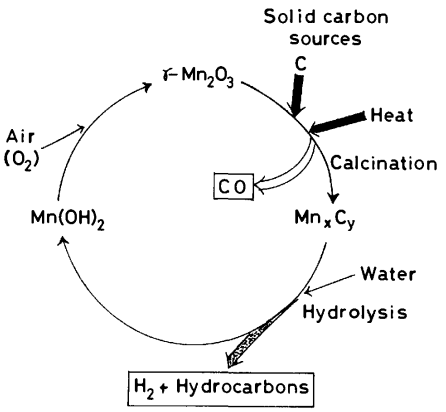

Fig. 1. Schematic illustration of "Manganese Cycle" for gasification of solid carbon resources.

or

$$x\,MnO_z + (y+xz)C \longrightarrow Mn_xC_y + xz\,CO \qquad (2)$$

(ii) Fuel gas production by means of the hydrolysis of the carbide.

$$Mn_xC_y + H_2O \longrightarrow H_2 + \text{hydrocarbons} + x\,Mn(OH)_2 \qquad (3)$$

(iii) Spontaneous oxidation of $Mn(OH)_2$ to Mn_2O_3.

(iv) Regeneration of the carbides from Mn_2O_3 and new carbon sources (the same process as Eq. 2).

Consequently, we can obtain hydrogen and hydrocarbons with hydrolysis of the carbides and, in addition, carbon monoxide during the production of the carbides. Since the manganese source can be recycled, we have only to charge the solid carbon sources and water to this process.

In the present study, we investigated this new carbide method with respect to the formation of manganese carbides, their hydrolysis for gas production and the recycle of manganese in the process.

Experimental

As the starting materials, manganese powder (purity 99.00—99.98%) and graphite powder were used. They were

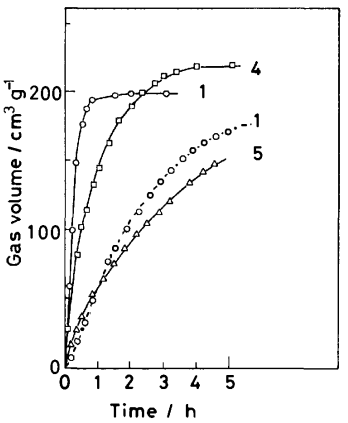

Fig. 3. The volume of evolved gas during hydrolysis. ---: Hydrolyzed at 50 °C, ---: hydrolyzed at 18 °C. (The volume of the gas is converted to a dry basis at 25 °C, and at 101.3 kPa, and the sample No. in the figure is same as in Table 1)

mixed and pressure molded at 400 kg cm^{-2} into the cylindrical form (dia; 14 mm). Test specimens were set in a ceramic tube and calcined at 500—1000 °C in vacuum (0.4—2.0 Torr†) for 3—15 h. After the calcination, specimens were cooled by removing the ceramic tube from the furnace. The carbides thus obtained were identified by X-ray powder diffraction (Fe-$K\alpha$) and subjected to hydrolysis test.

The hydrolysis experiment was carried out by using a gas burette. Since $Mn(OH)_2$, the precipitate by hydrolysis, absorbs oxygen to form γ-Mn_2O_3, the gas burette was purged with dry nitrogen gas before the hydrolysis. The evolved gas was analyzed by gas chromatography (Yanagimoto, Rapid Gas Analyzer G-1001).

Results and Discussion

Formation of Carbides and Their Hydrolysis. The calcined products obtained by the above described method were the mixtures of carbides and carbon, the composition of which depended on the firing temperature and the ratio of the starting materials. Typical examples of the products are shown in Table 1. We obtained different kinds of carbide including Mn_5C_2, Mn_7C_3, $Mn_{15}C_4$, Mn_3C, and $Mn_{23}C_6$ by changing the ratio of Mn to C(Mn/C=1.5—3.0) in the starting material and the calcining temperature (500—1000 °C). Figure 2 shows the currently accepted manganese-carbon phase diagram.[7] Our results exhibited almost mixed phase probably due to insufficient equilibrium time and a rather slow cooling rate.

Some workers have reported the hydrolysis of Mn_3C[3,8], Mn_5C_2,[8] and Mn_7C_3.[10] However, the volume and the composition of the evolved gas were not so clear for some carbides. The volume of evolved gas during hydrolysis of our products (cm^3 per 1 g of the product, at 25 °C and 1 atm†) is also shown in Table 1. Figure 3 shows the increase in the gas volume with time. These carbides could be hydrolyzed more rapidly at 50 °C than at room temperature. While the decomposition of the carbides containing $Mn_{15}C_4$ (calcined at 1000 °C) were rather slow, the hydrolysis of Mn_5C_2 and Mn_7C_3 took place very easily at 50 °C. A hard and dense sinter was observed in the case of No. 5 product. The maximum gas volume evolved was about 220 $cm^3 g^{-1}$ for the product mainly composed of Mn_5C_2. After the hydrolysis, gray precipitate, whose X-ray diffraction gave a broad and weak lines corresponding to $Mn(OH)_2$, was observed in all cases. This precipitate changed gradually dark brown colored γ-Mn_2O_3 on exposure to air.

Compositions of the Gas Evolved. The composition of the product gases was analyzed by gas chromatography and results are shown in Table 2. The calcined product mainly composed of Mn_5C_2 (No. 4 in Table 1) evolved hydrogen, methane, ethane, propane and a small amount of ethylene. On the other hand, much more varieties of hydrocarbons could be detected

†1 Torr=133.322 Pa.

†1 atm=101.3 KPa.

TABLE 2. COMPOSITION OF THE GAS EVOLVED BY HYDROLYSIS AT 50 °C

Carbide	Composition/%[a]										
	H_2	CH_4	C_2H_4	C_2H_6	C_3H_6	C_3H_8	i-C_4H_{10}	n-C_4H_{10}	x	y	Mn/C[b]
No. 1(Mn_7C_3 rich)	48.13	37.43	0.21	9.52	0.22	2.91	0.08	0.24	1.659	0.675	2.46
No. 4(Mn_5C_2 rich)	51.48	36.89	0.10	7.57	—	0.93	—	—	1.519	0.550	2.76

a) Residual gas (1—3%) is air. b) Ratio of Mn to C in the caribide calculated assuming Eq. 4.

in the case of No. 1 product mainly composed of Mn_7C_3. In this experiment, trace amount of C_5-hydrocarbons were sometimes detected. Such composition for our No. 1 product was in good agreement with that for Mn_7C_3 reported Hajek *et al.*[10]

Kor[8] has reported the composition of the evolved gas from the hydrolysis of Mn_5C_2 at 20 °C. His analysis by mass spectrometry found hydrogen, methane, ethane, and propane. And he has also reported that the ratio of Mn to C (Mn/C) calculated from the composition of the product is 2.4 or 2.7 for Mn_5C_2. Then we calculated the ratio of Mn to C by a similar way. The reaction equation of the hydrolysis of the carbide, Mn_xC_y, can be written as Eq. 4 assuming that the precipitate is only composed of $Mn(OH)_2$.[8]

$$\begin{aligned} Mn_xC_y + a\,H_2O \longrightarrow\ & x\,Mn(OH)_2 + p\,H_2 \\ & + q\,CH_4 + r\,C_2H_4 + s\,C_2H_6 + t\,C_3H_6 \\ & + u\,C_3H_8 + v\,C_4H_8 + w\,C_4H_{10} \end{aligned} \quad (4)$$

The values of x and y were calculated from the gas composition and results are shown in Table 2. Mn/C was 2.76 for the carbide mainly composed of Mn_5C_2 (No. 4 in Table 1). This value was larger than the stoichiometric ratio (2.5) for Mn_5C_2. However, a similar result was shown by Kor[8] (Mn/C=2.7) and our gas composition was also coincident with his report. This may be ascribed to the existence of Mn_3C or to the existence of the high valency state Mn in the precipitate. Mn/C was 2.46 for the No. 1 carbide mainly composed of Mn_7C_3. Since Mn_5C_2 phase could be also observed in this specimen, the value of Mn/C may become somewhat higher than the stoichiometric ratio (2.33) for Mn_7C_3.

Furthermore, by substituting the values of x, y, p, q, $\cdots$, v, and w into Eq. 4, the theoretical gas volume evolved from 1 g of the produced carbide can be calculated. For example, from the values of p=0.4813, q=0.3743, $\cdots$, w=0.0024 for the No. 1 product in Table 2, the amount of gas was 0.9874 mole ($p+q+\cdots+w$) per one mole of Mn_xC_y (x=1.659, y=0.675). Therefore, the theoretical gas volume is calculated to be 243 $cm^3\,g^{-1}$ (at 25 °C) for the No. 1 product. The volume of gas obtained in our experiment (197.8 $cm^3\,g^{-1}$) was lower than this value and the yield may be 81%. In the literature,[10] the experimentally observed volume for Mn_7C_3 hydrolyzed at 80 °C was 208 $cm^3\,g^{-1}$ and their predicted value was 213 $cm^3\,g^{-1}$. Our yield might be somewhat higher than 81% if we took account of the liquid phase products, which we did not analyze in the experiment. The analysis of the liquid product is in progress.

Recycle of Manganese. After the hydrolysis, the precipitate was filtrated and γ-Mn_2O_3 thus obtained was subjected to the second production of the carbide. The mixture of γ-Mn_2O_3 and graphite in a stoichiometric composition corresponding to Mn_3C was calcined at 1000 °C in vacuum. Unfortunately, only very small amounts of the carbides were formed in this procedure and the gas volume evolved by the hydrolysis was only 9.8 $cm^3\,g^{-1}$ for 50 h firing specimen. The X-ray diffraction patterns of calcined exhibited only MnO and graphite(unreacted starting material). The reduction of MnO with carbon has been studied by many workers.[12–16] According to Ikeda and Terayama,[16] the reduction of MnO with graphite into Mn_7C_3 began at about 1050 °C in argon atmosphere and the addition of Fe_2O_3 lowered the reduction temperature. If one can find more effective additives for the reduction of MnO, the yield of the carbides may be increased. We added firstly the alkaline carbonates to the specimen. γ-Mn_2O_3 (prepared from $MnCl_2$ and KOH), graphite and alkaline carbonate were mixed and pelletized with hydrostatic pressure of 2×10^3 kg cm^{-2}. In these experiments, the compositions of starting materials were decided by assuming that following reactions took place to form $(Mn_3C)_x(M_2C_2)_y$.

$$3/2Mn_2O_3 + 11/2C \longrightarrow Mn_3C + 9/2\,CO \quad (5)$$

$$M_2CO_3 + 4C \longrightarrow M_2C_2 + 3CO\ (M=K, Na, Li) \quad (6)$$

The specimens were calcined at 1000 °C in vacuum.

Typical results are shown in Table 3. The addition of Na_2CO_3 and K_2CO_3 did not promote the production of the carbide. However, Li_2CO_3 was very effective promoter for carbide formation. For example, when Li/Mn=0.35 (No. 11 in Table 3), the main product after 12 h calcination at 1000 °C was Mn_7C_3 and the volume of gas evolved by hydrolysis at 50 °C was 193 $cm^3\,g^{-1}$, which was close to that obtained for the carbide made from metallic Mn and graphite. Li_2C_2 could not be detected in the products by X-ray diffraction. The composition of product gas was similar to that shown in Table 2. Since neither the appearance of acetylene nor the increase in C_2-hydrocarbon could be detected in this gas, it was considered that the product might not contain Li_2C_2 and that the gas was evolved by hydrolysis of Mn_7C_3.

Effect of Li_2CO_3 on Carbide Formation. In order

Table 3. Formation of manganese carbide from γ-Mn_2O_3 with and without additives

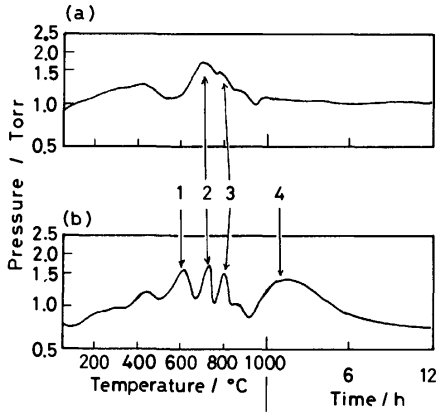

Fig. 4. Change in the total pressure during calcination.*
(a) Mn_2O_3+C ($(Mn_2O_3)_3C_{11}$), (b) Mn_2O_3+Li_2CO_3+C ($(Mn_2O_3)_{1.05}(Li_2CO_3)_{0.30}C_{5.05}$).
* Specimen is heated up to 1000 °C at the heating rate of 200 °C h^{-1} and kept at 1000 °C for 12 h.

to obtain an information about the effect of Li_2CO_3 on the production of Mn_7C_3, the variation of pressure during the calcination was monitored by a vacuum meter (ULVAC, GP-1S). The specimen in the ceramic tube was heated up to 1000 °C at the heating rate of 200 °C h^{-1} and then kept at 1000 °C for 12 h. Since the ceramic tube was evacuated with a vacuum pump at a constant pumping speed, the evolution of gas(CO) could be detected as the increase in the pressure.

Figure 4 shows the change in the total pressure during the calcination with and without addition of Li_2CO_3. In the heating process, appreciable pressure peaks were observed in the temperature range between 600 and 900 °C (peaks 2, 3) in both cases. The peaks 2 and 3 correspond probably to the following reaction steps (Eqs. 7 and 8) since γ-Mn_2O_3 can be reduced to MnO by graphite at these temperatures without Li_2CO_3.[17]

$$Mn_2O_3 + 1/3C \longrightarrow 2/3Mn_3O_4 + 1/3CO \text{ (peak 2)} \quad (7)$$

$$2/3Mn_3O_4 + 2/3C \longrightarrow 2MnO + 2/3CO \text{ (peak 3)} \quad (8)$$

$$Mn_2O_3 + C \longrightarrow 2MnO + CO \quad (9)$$

When Li_2CO_3 was added to the sample ((b) in Fig. 4), additional increases in the pressure were observed at 600 °C (peak 1) and at 1000 °C (peak 4). The peak 1 may be ascribed to the evolution of CO[18] because Li_2CO_3 is easily decomposed to Li_2O at 600 °C in vacuum.

$$Li_2CO_3 + C \longrightarrow Li_2O + 2CO \quad (10)$$

Since the formation of Mn_7C_3 was confirmed after this calcination, the peak 4 should correspond to a reduction step of MnO into Mn_7C_3 which was catalyzed by lithium or Li-compounds ($7MnO+10C \xrightarrow{(Li)} Mn_7C_3+7CO$). Li_2C_2 or metallic lithium should be an effective reducing agent against MnO. Although Li_2C_2 was not detected in the product, appreciable amount of metallic lithium was observed in the ceramic tube after the calcination. Therefore following reaction steps including Li as an intermediator may be possible at peak 4.

$$Li_2O + C \longrightarrow 2Li + CO \quad (11)$$
(1000 °C, under vacuum[2])

$$MnO + 2Li \longrightarrow Mn + Li_2O \quad (12)$$

$$7Mn + 3C \longrightarrow Mn_7C_3 \quad (13)$$

Other posssible reaction steps including Li_2C_2 as an intermediator may be also followed by Eq. 11.

$$2Li + 2C \longrightarrow Li_2C_2\ (950\ °C^{2)}) \quad (14)$$

$$2MnO + Li_2C_2 \longrightarrow 2Mn + 2Li + 2CO \quad (15)$$

$$7Mn + 3C \longrightarrow Mn_7C_3 \quad (16)$$

Anyway, it can be said that lithium is a good catalyzer for reducing MnO to Mn_7C_3, and that "Manganese-Cycle" proposed by us is one of promising methods for the production of hydrogen and hydrocarbons. Carbon monoxide gas during the production of the carbides could be also utilizable. The detailed studies are in progress.

Conclusion

A new carbide method based on "Manganese-Cycle" was studied. In this process, the fuel gas containing hydrogen and hydrocarbons (C_1–C_5) was obtained by the hydrolysis of manganese carbides. And carbon monoxide could also be obtained during the production of the carbides. γ-Mn_2O_3, by-product of the hydrolysis, was

recycled as the manganese source effectively by adding Li_2CO_3 in order to promote the carbide formation.

We would like to thank the staffs of the Laboratory in Tottori Gas Co. for their cooperation in analyzing the gas.

NMR Studies of Picolyl-type Carbanions. VIII.[1,2] Anions Produced by Reactions of Alkyl-substituted Pyridines with Butyllithium

Kazuyori KONISHI,* Hiroshi MATSUMOTO,† Katsuhiro SAITO,† and Kensuke TAKAHASHI†

The Industrial Technology Center of Mie Prefecture, Takajaya-komori-cho, Tsu 514

†*Nagoya Institute of Technology, Gokiso-cho, Showa-ku, Nagoya 466*

(Received December 27, 1984)

The ^{1}H and ^{13}C NMR spectra have been observed for the anions, produced from methyl-, ethyl-, and isopropylpyridines, in tetrahydrofuran (THF). Two kinds of anions are formed concomitantly by lithium-proton exchange and addition of butyllithium from 2-ethyl-, 2-isopropyl-, 4-methyl-, and 4-ethylpyridines. The former reaction tends to occur at the substituent bonded to the position adjacent to nitrogen, and the latter one occurs at the position adjacent to nitrogen without substituent. In the anions formed by the exchange from 2- and 4-ethylpyridines, a specific ring proton is coupled to the α-carbon, and, further, the *ortho*- or *meta*-protons (or -carbons) in the latter anion are nonequivalent respectively at room temperature. The α-carbons in these anions are virtually sp^2-hybridized.

It has recently been reported that two kinds of anions are produced by exchange and addition reactions of methyl-substituted quinolines with and without a 2-methyl group, with butyllithium, respectively, and that the former anions are picolyl-type carbanions, but the latter ones are ionic species having two of three basic characteristics on picolyl-type carbanions.[3] We now take up methyl-, ethyl-, and isopropylpyridines having at least two reaction sites (*i.e.*, the 2- and 6-positions) adjacent to nitrogen in a molecule, and present here some observations of the anions prepared from them.

Experimental

The starting materials, except for 2-, 3-, and 4-isopropylpyridines, used in this study were commercially available. 2- and 4-Isopropylpyridines were prepared by heating pyridine (10.60 g, 134 mmol) and 2-iodopropane (23.21 g, 137 mmol) at 200—240 °C for 16 h in an autoclave. A crude mixture (2.716 g) was obtained after removal of the recovered starting materials by distillation (101 kPa). A part of the mixture (1.267 g) was separated with thin-layer chromatography on silica gel using benzene–ether as a developing solvent to give 2-isopropylpyridine (R_f=0.71, 375 mg, 5%) and 4-isopropylpyridine (R_f=0.54, 515 mg, 7%). The structure of each pyridine derivative was confirmed by comparison of its physical properties with those of the authentic samples.[4,5] 3-Isopropylpyridine was prepared from 3-isopropenylpyridine by the method reported by Brown *et al.*[4] These starting materials were used after dried over calcium hydride and vacuum distilled.

The preparation of the anions was carried out *in vacuo*. About 1—3 mmol of a starting material was reacted with the equimolecular amount of butyllithium in hexane at 0—5 °C. After the completion of the reaction, all the volatile materials were trapped out and dried THF was introduced into the system. By solvent exchange, the solution became red or red-brown. The solution was then transferred into a NMR sample tube, and the tube was sealed off. The ^{1}H NMR spectra were measured at 200, 60, and 60 MHz on an Varian XL-200, Hitachi R-20B, and R-24B spectrometers respectively, and the ^{13}C spectra were measured at 50.3 MHz on a Varian XL-200. The proton and carbon chemical shifts were eval-

Results and Discussion

Typical ^1H NMR spectra of the anions produced from 2-, 3-, and 4-isopropylpyridines are shown in Figs. 1(a)—(c) respectively, and a typical ^{13}C spectrum of the anions produced from 2-ethylpyridine is shown in Fig. 2. The ^1H and ^{13}C NMR chemical-shift data are given in Tables 1 and 2 respectively.
