Calorimetric Determination of Thermodynamic Parameters for the Dissociations of Acids in Dipolar Aprotic Solvents

Kosuke Izutsu,* Toshio Nakamura, Katsumi Takizawa, and Akihiko Takeda
Department of Chemistry, Faculty of Science, Shinshu University, Asahi, Matsumoto 390
(Received August 9, 1984)

A calorimetric method has been investigated for the determination of the thermodynamic parameters of acid dissociations in dipolar aprotic solvents. For the dissociations of monoprotonated bases BH^+ (B: aniline, pyridine, triethylamine, tributylamine, triethanolamine, 1,3-diphenylguanidine and 1,1,3,3-tetramethylguanidine) in *N,N*-dimethylformamide, dimethyl sulfoxide (DMSO), acetonitrile and propylene carbonate, the solutions of the bases were titrated with small volumes of a "strong acid," trifluoromethanesulfonic acid. In each solvent, there was an approximately linear relation of unit slope between ΔH°_{298} and ΔG°_{298}, showing that the difference in pK_a between different BH^+'s can mainly be attributed to the difference in the enthalpy term. As for the solvent effect on pK_a, however, the entropy term seems to play an important role. A preliminary study has shown that the calorimetric method is also applicable to the dissociations of HX-type weak acids (benzoic and salicylic acids in DMSO, for example), if the dissociation equilibria are not complicated by such reactions as homoconjugation.

Acid-base equilibria in dipolar aprotic solvents have been extensively studied, and fairly abundant data for acid-dissociation constants are available.[1] But the data concerning the thermodynamic parameters of acid dissociations are quite limited, and, in most cases, have been obtained from the effect of temperature on the dissociation constants. To our knowledge, no thermodynamic parameters of acid dissociation in dipolar aprotic solvents have been obtained calorimetrically.

In the present study, we used a calorimetric method to obtain thermodynamic parameters for acid dissociations in dipolar aprotic solvents. The main dissociations investigated were for monoprotonated bases BH^+ (Eq. (1)):

$$BH^+_{solv} \longrightarrow B_{solv} + H^+_{solv}. \quad (1)$$

The reactions which occur when a large amount (100 ml) of a base (B) solution is titrated with small amounts (10—60 μl to keep the heat of dilution negligibly small) of a strong acid (HA) can be considered to consist of the following three steps:

$$HA \longrightarrow (HA)_{solv}, \quad (2)$$

$$(HA)_{solv} \longrightarrow H^+_{solv} + A^-_{solv}, \quad (3)$$

$$H^+_{solv} + B_{solv} \longrightarrow BH^+_{solv}. \quad (4)$$

If we express the heat generated by reactions (2) and (3) by ΔH_1 (kJ mol^{-1}) and that by reactions (2), (3) and (4) by ΔH_T, the heat generated by reaction (4) is equal to $(\Delta H_T - \Delta H_1)$. Thus, the standard enthalpy ΔH°_{298} for the reaction (1) should also be equal to $(\Delta H_T - \Delta H_1)$. Here, ΔH_1 can be obtained by titrating the pure solvent with the "strong acid" HA. In the present study, we used trifluoromethanesulfonic acid as HA. It is one of the strongest acids and a pure, water-free product can be obtained easily. In *N,N*-dimethylformamide (DMF) and dimethyl sulfoxide(DMSO), it actually behaved as a strong acid and reliable values of ΔH_1 could be obtained. In acetonitrile(AN) and propylene carbonate (PC), however, the dissociation of the acid was not complete and only approximate ΔH_1-values could be obtained as will be described later. We also have studied preliminarily on the determination of thermodynamic parameters for the dissociations of HX-type weak acids.

Experimental

Apparatus and Reagents. A multi-purpose calorimeter, model MPC-11, of the Tokyo Riko Co. was used for calorimetric measurements. The cell assembly is shown in Fig. 1. Trifluoromethanesulfonic acid was added with a Gilmont ultra precision 250 μl-microburet S3100A (0.01 μl/div).

DMF, DMSO, and AN were the reagent grade products of Wako Chemicals Co., and PC was a synthetic grade Merck product. They were purified by the methods recommended in Ref. 2). Trifluoromethanesulfonic acid (Wako reagent grade) was purified by a distillation with a semimicro distilling apparatus. All the amines tested were Wako analytical grades. Tributylamine and triethanolamine were distilled under reduced pressures, and other amines were purified by the

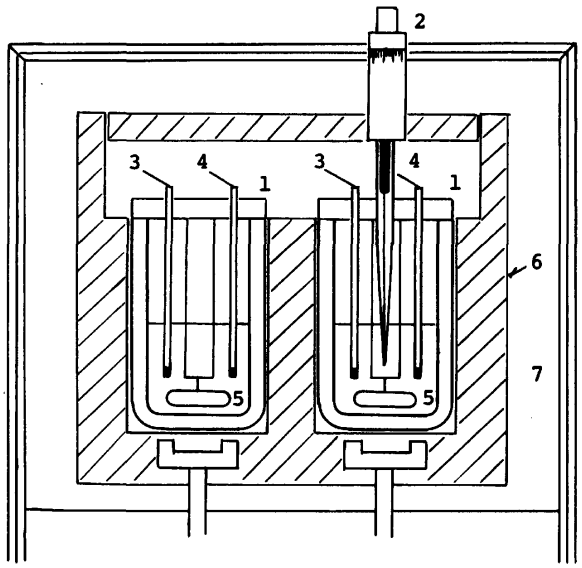

Fig. 1. Cell assembly for calorimetric measurements. 1: Dual cells, 2: microburet, 3: thermistor, 4: heater for calibration, 5: magnetic stirrer, 6: aluminum thermostat bath and 7, air thermostat bath.

methods described in a previous report.[3] Benzoic and salicylic acids (Wako reagent grades) were used as received.

Procedure for Monoprotonated Bases. To the cell was added 100 ml of the solution containing an appropriate amount of the base to be tested (in the case of ΔH_T measurement) or 100 ml of the pure solvent (in the case of ΔH_1 measurement). The cell and the microburet containing trifluoromethanesulfonic acid were set to the calorimeter as shown in Fig. 1 and kept for 2—3 h until they reached a uniform temperature of 25 °C (298 K). The amounts of the bases taken were 100 μl (0.0124 M, 1M=1 mol dm^{-3}) for pyridine, 100 μl (0.0109 M) for aniline, 200 μl (0.0143 M) for triethylamine, 250 μl (0.0105 M) for tributylamine, 200 μl (0.0150 M) for triethanolamine, 150 μl (0.0117 M) for 1,1,3,3-tetramethylguanidine and 211 mg (0.0100 M) for 1,3-diphenylguanidine. The solution in the cell was titrated with six aliquots of the acid, 10.0 μl (1.13×10^{-3} M) each, and, from the temperature changes, the heats corresponding to ΔH_1 and ΔH_T were obtained. The factor to convert temperature change to heat was determined for each solution with an accuracy of ±0.2% by using a built-in heater (accuracy: ±0.1%). During the titrations, the solutions were stirred with a magnetic stirrer at 280 rpm.

Results and Discussion

Thermodynamic Parameters for the Dissociations of Monoprotonated Bases. Measurements of ΔH_1: As described above, trifluoromethanesulfonic acid was added to 100 ml of the pure solvent six times in an aliquot of 10.0 μl (1.13×10^{-3} M) each. For DMF and DMSO, the heat generated each time was almost constant as line 1 in Fig. 2. ΔH_1, obtained from the average of these values, was 112.3±0.3$_2$ kJ mol^{-1} for DMF (n=4, where n is the number of similar measurements) and 102.9±0.3$_1$ kJ mol^{-1} for DMSO (n=6). In PC and AN, the determination of ΔH_1 encountered difficulties due to the incomplete dissociation of the acid. The heat generated by the addition of the acid decreased gradually with the increase of the acid concentration (line 2, Fig. 2). Because the decrease was approximately linear against the amounts of the acid added, we assumed that the value obtained by an extrapolation to zero concentration nearly corresponded to ΔH_1. It was 85.$_4$± 0.9 kJ mol^{-1} for PC (n=5) and 75.$_9$±0.6 kJ mol^{-1} for AN (n=6).

Measurements of ΔH_T: Trifluoromethanesulfonic acid was added to the solution of the base to be tested. The heat generated by each addition of the acid was almost constant (lines 1′ and 2′, Fig. 2) and ΔH_T was obtained as the average of the values. In Table 1 the results of ΔH_T are summarized. Most of the ΔH°_{298} values were obtained by the relation $\Delta H^\circ_{298}=(\Delta H_T-\Delta H_1)$. In DMF and DMSO, however, pK_a for aniline and pyridine were not large enough for the reaction (4) to be quantitative. In those cases, ΔH°_{298} were obtained from $(\Delta H_T-\Delta H_1)$ by correcting for the incompleteness of the reaction.

Thermodynamic Parameters: Thermodynamic parameters for the dissociations of monoprotonated bases are shown in Table 2. The values of ΔG°_{298} were calculated by the relation $\Delta G^\circ_{298}=-RT\ln K_a$. For most of the p$K_a$ we referred to the literature values[3-9], but we determined some of them in this work from the half-neutralization points of the potentiometric titra-

Tributylamine	18.0$_9$[h]	103.2	(78.9)	(24.3)
Triethylamine	18.4$_6$[h]	105.3	(78.9)	(26.4)

a) Ref. 4. b) Ref. 5. c) This work. d) Ref. 6. e) Ref. 7. f) Ref. 8. g) Ref. 3. h) Ref. 9. In the calculation of $\Delta G°_{298}$, the pK_a value without parentheses was used. The values of $\Delta H°_{298}$ and $-T\Delta S°_{298}$ in parentheses are somewhat approximate due to the reasons as described in text.

tions of the bases with trifluoromethanesulfonic acid (use of a glass pH-electrode). The pK_a of pyridine/pyridinium ion system was used as the reference.

In Figs. 3 and 4, the values of $\Delta H°_{298}$ and $-T\Delta S°_{298}$ were plotted against $\Delta G°_{298}$. For each solvent, there is an approximately linear relation of unit slope between $\Delta H°_{298}$ and $\Delta G°_{298}$ (though fairly big deviations are observed for 1,3-diphenylguanidine in PC and AN). Thus, for each solvent, the difference in pK_a values between different monoprotonated bases may mainly be attributed to the difference in the enthalpy term. As for the changes in pK_a with solvents (solvent effect on pK_a), however, the results in the figures show that the entropy term also takes a considerable part, though the reason for this has not been elucidated yet.

Thermodynamic Parameters for the Dissociation of Weak Acid HX. In dipolar aprotic solvents, the dissociation equilibria of weak acids of the type HX often become complicated due to such reactions as dimerization and homoconjugation. In the absence of such complicating reactions and when the acid HX is weak enough, the thermodynamic parameters for the dissociation (Eq. (5)) can be obtained by either of the following methods:

$$(HX)_{solv} \longrightarrow H^+_{solv} + X^-_{solv}. \quad (5)$$

i) The solution of R_4NX (tetraalkylammonium salt of X^-) is titrated by a strong acid HA. The thermodynamic parameters should be obtained by the same principle as in the above.

ii) The solution of the weak acid HX is titrated with an appropriate base B. Then, the reactions which occur can be expressed by:

$$B \longrightarrow B_{solv}, \quad (6)$$

$$(HX)_{solv} \longrightarrow H^+_{solv} + X^-_{solv}, \quad (7)$$

$$H^+_{solv} + B_{solv} \longrightarrow BH^+_{solv}. \quad (8)$$

The enthalpy for reaction (8) is known from the above work and that for reaction (6) can easily be determined. Thus, the enthalpy for reaction (7) should be obtained.

iii) The solution of a base B is titrated with the weak acid HX. The reactions which occur can be expressed by $HX \rightarrow (HX)_{solv}$ and Eqs. (7) and (8). Because

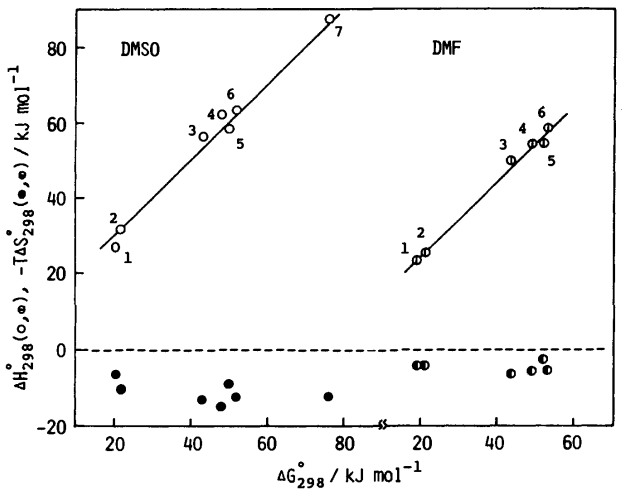

Fig. 3. Relations of ΔH°_{298} and $-T\Delta S^\circ_{298}$ *vs.* ΔG°_{298} in DMSO and DMF.
B: 1 pyridine, 2 aniline, 3 triethanolamine, 4 tributylamine, 5 1,3-diphenylguanidine, 6 triethylamine, and 7 1,1,3,3-tetramethylguanidine.

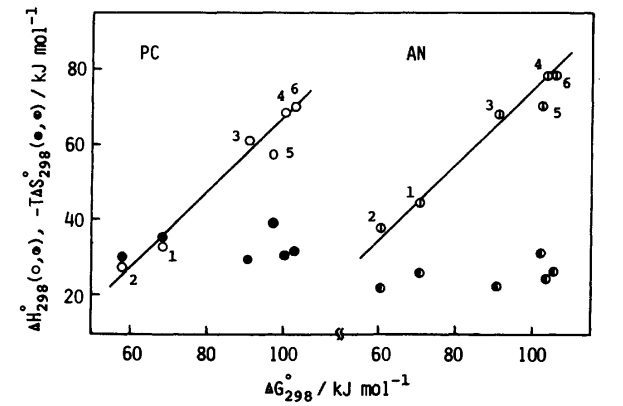

Fig. 4. Relations of ΔH°_{298} and $-T\Delta S^\circ_{298}$ *vs.* ΔG°_{298} in PC and AN (see the caption of Fig. 3).

the enthalpy for reaction (8) is known, that for reaction (7) can be obtained, if the enthalpy for HX→ $(HX)_{solv}$ is obtained separately.

In the present study, method ii) was employed for salicylic and benzoic acids in DMSO. For salicylic acid (pK_a=6.6, ΔG°_{298}=37.7 kJ mol^{-1} [10]), its solution in the cell was titrated with triethylamine ($pK_a(BH^+)$=9.0) and also with tetramethylguanidine (pK_a (BH^+)=13.2[5]). The titration with triethylamine gave ΔH°_{298} of 19.9 kJ mol^{-1} and that with tetramethylguanidine 20.3 kJ mol^{-1}.[11] The average of the two values, 20.1 kJ mol^{-1}, is somewhat larger (but probably more reliable) than 17.1 kJ mol^{-1} which we calculated using literature data of the changes of pK_a with temperature.[10] For benzoic acid (pK_a=10.6, ΔG°_{298}=60.5 kJ mol^{-1} [10]), the titration with tetramethylguanidine gave ΔH°_{298} of 35.6 kJ mol^{-1}[12] which is in good agreement with 35 kJ mol^{-1} obtained from the temperature effect on pK_a.[10]

In the above examples for HX-type weak acids, fair agreements were obtained between calorimetric results and the results from the temperature effect on pK_a. Usually, however, it is rather difficult in dipolar aprotic solvents to determine with enough precisions the temperature effect on pK_a. The calorimetric method as employed in the present work seems to be easier and give more reliable results for dissociations of both BH^+- and HX-type weak acids, if there is a "strong acid" which completely dissociates in the relevant solvents.

This work was partially supported by a Grant-in-Aid for Scientific Research from the Ministry of Education (No. 57470029).

11) ΔH° for reactions (6), (7), and (8) was $-34.1\pm0.2_5$ kJ mol^{-1} (n=3) with triethylamine and $-65.8\pm0.2_0$ kJ mol^{-1} (n=3) with tetramethylguanidine, while ΔH° for reaction (6) was 9.7 kJ mol^{-1} for triethylamine and 1.7 kJ mol^{-1} for tetramethylguanidine.

12) ΔH° of $-50.5\pm0.1_7$ kJ mol^{-1} (n=4) was obtained for reactions (6), (7), and (8) by extrapolation to the tetramethylguanidine concentration of zero.

^{59}Co Quadrupole Effects on the ^{1}H, ^{31}P, and ^{59}Co NMR Spectra of $HFeCo_3(CO)_9[P(OCH_3)_3]_3$ and the ^{1}H NMR Spectra of Other Derivatives

Taro SAITO* and Satoshi SAWADA
Department of Chemistry, Faculty of Engineering Science, Osaka University, Toyonaka, Osaka 560
(Received August 23, 1984)

The ^{1}H NMR spectra of $HMCo_3(CO)_{12}$ (M=Fe or Ru) and $HFeCo_3(CO)_{12-x}[P(OR)_3]_x$ (x=1—3, R=CH_3; x=3, R=C_2H_5 or C_6H_5) showed very broad signals centered near δ=−21 at 27 °C. The band widths were generally smaller for the compounds of larger molecular volume, at lower temperatures and with higher viscosity of the solvent. These data were interpreted in terms of the quadrupole effects of ^{59}Co nuclei to which the hydride proton was μ_3-bonded. Supporting evidence was obtained from the ^{31}P and ^{59}Co NMR spectra and the relaxation time T_1 of $HFeCo_3(CO)_9[P(OCH_3)_3]_3$.

In a previous paper[1] we reported the protonation of the coordinated dinitrogen by a highly acidic cluster hydride $HFeCo_3(CO)_{12}$ (**1**) (Fig. 1).[2] There was a long controversy over the position of the hydride ligand in this cluster[3-7] because ^{1}H NMR spectra did not show the signal for the proton[3,8] and no X-ray data were published. The problem seems to have been settled when the X-ray[8] and neutron[9] diffraction studies of a trimethyl phosphite-substituted derivative $HFeCo_3(CO)_9[P(OCH_3)_3]_3$ indicated unequivocally that the hydride existed on the Co_3 face. Although it seemed probable that the hydride ligand in the unsubstituted cluster **1** was also located on the Co_3 face from the X-ray crystallographic study of $Ph_3PAuFeCo_3(CO)_{12}$,[10] direct evidence was still not enough when the present study started.

During our study on the reaction of $Ni[P(OC_2H_5)_3]_4$ with **1**,[11] we found an unexpected high-field signal in the ^{1}H NMR spectra of a product which was later proved to be due to the hydride in $HFeCo_3(CO)_{11}[P(OC_2H_5)_3]$. The detection of the hydride signals is significant because (i) face-bridged μ_3-hydride cluster compounds[8,12-16] are interesting with respect to the dissociative adsorption of hydrogen molecules on metal surfaces.[9,17] and (ii) the information will be useful for the cobalt hydride cluster compounds showing very broad NMR signals difficult to detect. Thus, we have measured the NMR spectra of **1** and its derivatives and interpreted them.

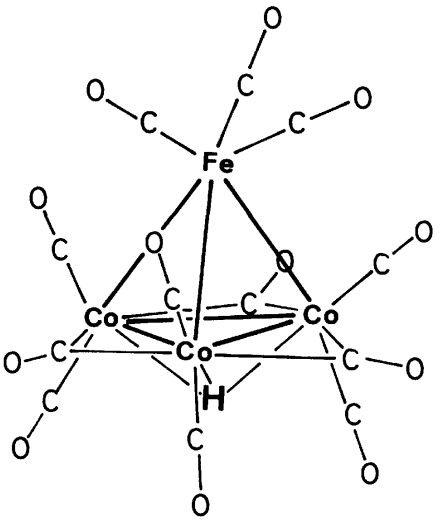

Fig. 1. Postulated structure of $HFeCo_3(CO)_{12}$.

Experimental

Hydridometalcarbonyl cluster compounds **1**—**7** (Table 1) were prepared by methods described in the literature with some modifications.[6,8,18] The compounds obtained after chromatography gave satisfactory elemental analyses and the absence of paramagnetic impurities was checked by the sharpness of the phosphite bands in the ^{1}H NMR spectra.

^{1}H NMR spectra were measured using a JEOL FX-100 FT NMR spectrometer at 100 MHz in the temperature range of +70—−60 °C. Chloroform-*d* solutions were used for the phosphite-substituted cluster compounds, but because of the low solubilities of the unsubstituted clusters $HMCo_3(CO)_{12}$

(M=Fe or Ru) in chloroform, they were dissolved in $Fe(CO)_5$ mixed with toluene-d_8 (5 vol%) for the measurements. $Fe(CO)_5$ did not affect the chemical shifts or line-widths of the spectra as compared with those recorded for saturated chloroform-*d* solutions which required many accumulations ($>10^4$ times) for the unsubstituted derivatives. Several hundred times accumulations were enough for the phosphite-substituted compounds. The relaxation times T_1 were obtained by the inversion recovery method. The effect of the sample viscosity on the line-width was tested for $HFeCo_3(CO)_9[P(OCH_3)_3]_3$ (**4**) in a chloroform-*d*/polyfluorinated hydrocarbon (Daifloil) (1:1) solvent which was about 3.5 times as viscous as pure chloroform-*d* indicated by a Ubbelohde viscosimeter at 27°C.

^{31}P NMR spectra were recorded at 40.7 MHz with JEOL FX-100 FT NMR spectrometer. Chloroform-*d* solutions with external standard (3% aq H_3PO_4) were used for the measurements.

^{59}Co NMR spectra were recorded at 63.8 MHz with JEOL GX-270 FT NMR spectrometer at the laboratory of JEOL. The compouds **2**—**4** were dissolved in chloroform-*d* and **1** was dissolved in $Fe(CO)_5$ mixed with toluene-d_8 (5 vol%) and external standard ($[Co(NH_3)_6]Cl_3$ or $[Co(en)_3]Cl_3$) was used for the measurements. The relaxation times T_1 were obtained by the inversion recovery method.

Results

Figures 2—4 illustrate variable temperature ^1H NMR spectra of **1**, **7**, and **4**, respectively. The spectra of **2**, **3**, **5**, or **6** are similar to those of **4** except chemical shifts and line-widths and the values are listed in Table 1. Variable temperature ^{31}P and ^{59}Co NMR spectra of **4** are shown in Figs. 5 and 6, respectively.

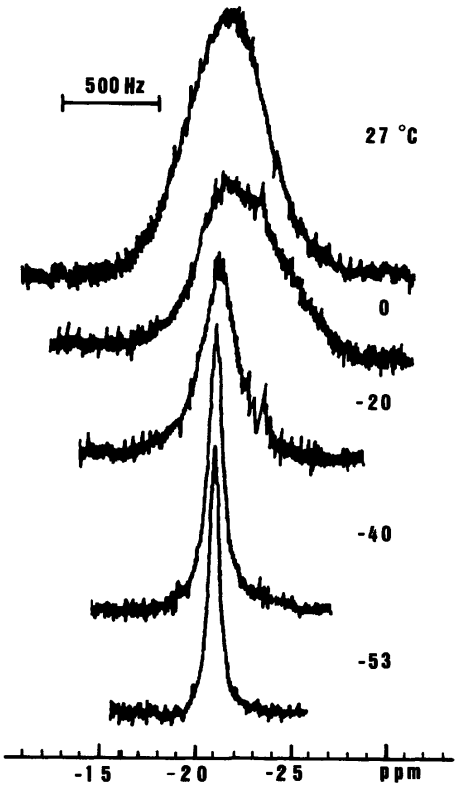

Fig. 2. Variable temperature ^1H NMR spectra of $HFeCO_3(CO)_{12}$ (**1**).

Fig. 3. Variable temperature ^1H NMR spectra of $HRuCo_3(CO)_{12}$ (**7**).

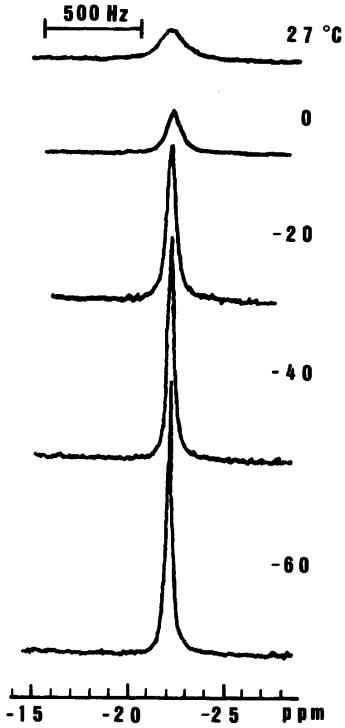

Fig. 4. Variable temperature ^1H NMR spectra of $HFeCo_3(CO)_9[P(OCH_3)_3]_3$ (**4**).

The ^1H NMR spectra indicated that the line-widths at half-signal height ($w_{h/2}$) were very broad and no couplings with ^{59}Co or ^{31}P nuclei were observed. The line-widths became narrower as the temperatures were lowered but the chemical shifts were invariable and no splittings of the major peaks resulted. A much sharper band of minor intensity (<1/20) appeared overlapped

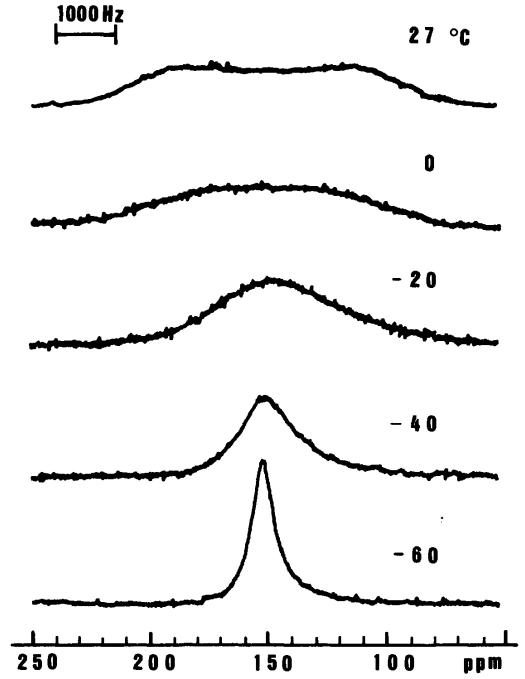

Fig. 5. Variable temperature ^{31}P NMR spectra of $HFeCo_3(CO)_9[P(OCH_3)_3]_3$ (**4**).

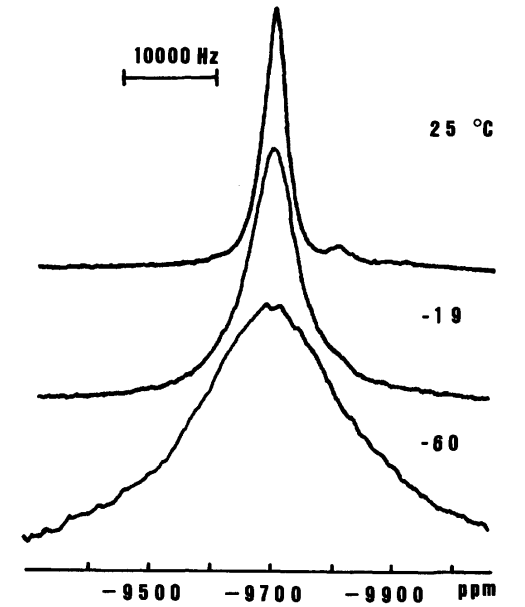

Fig. 6. Variable temperature ^{59}Co NMR spectra of $HFeCo_3(CO)_9[P(OCH_3)_3]_3$ (**4**). Chemical shifts were measured from $[Co(en)_3]Cl_3$ external standard.

on the major broad band and the signal intensities were temperature dependent.

The line-widths of a viscous solution of **4** in chloroform-*d*/Daifloil was 74 Hz as compared with 137 Hz of the pure chloroform-d_1 solution at 27 °C.

The ^{31}P NMR spectrum of **4** was a very broad saddle shaped doublet at 27 °C and became broad singlets at lower temperatures. The chemical shift (135.2 ppm) from the external H_3PO_4 standard did not change upon cooling the sample.

The chemical shifts and the line-widths of the ^{59}Co NMR spectra of **1**, **2**, **3**, and **4** at 27 °C are given in Table 2. The spectra of **1** and **4** are singlets and those of **2** and **3** are doublets, the higher field bands being assigned to the cobalt atoms coordinated with trimethyl phosphite.

Table 2. Chemical shifts and half-height widths of ^{59}Co NMR spectra of $HFeCo_3(CO)_{12-x}[P(OCH_3)_3]_x$

Compound		/ppm[a]	$W_{h/2}$/Hz
$HFeCo_3(CO)_{12}$	**1**	−3856	674
$HFeCo_3(CO)_{11}[P(OCH_3)_3]$	**2**	−3849 (1)[c]	1304
		−3913 (2)[c]	2065
$HFeCo_3(CO)_{10}[P(OCH_3)_3]_2$	**3**	−3836	b)
		−3863	
$HFeCo_3(CO)_9[P(OCH_3)_3]_3$	**4**	−3901	2609

a) Measured from $[Co(NH_3)_6]Cl_3$ external standard at 27 °C. b) Not resolved. c) Intensity ratio.

The relaxation times T_1 of the ^1H resonance of **4** were 207, 72, and 25 ms at 27, −20, and −60 °C, respectively. The T_1 for the ^{59}Co resonance of the same compound were 0.140, and 0.053 ms at 25, and −19 °C, respectively.

Discussion

The broad high-field signals in the ^1H NMR spectra of $HFeCo_3(CO)_{12-x}[P(OR)_3]_x$ show the calculated intensities relative to the phosphite protons and can be assigned to a single hydride proton. The signals for the unsubstituted $HMCo_3(CO)_{12}$(M=Fe or Ru) are also assignable to the hydride proton judging from the similarity of the chemical shifts and line shapes. The chemical shift values around $\delta=-21$ indicate that the hydrogens are bonded to transition metals and not to an oxygen atom of carbonyl groups.[19-21] Up-field shifts of about 0.3 ppm was observed by exchange of each carbonyl group on cobalt by a trimethyl phosphite, showing electron-donating influence of the latter ligand on the hydride proton. The proton chemical shift of the Co_3 face-bridged hydrides in $(\eta\text{-}C_5H_5)_4Co_4H_4$ was reported to be at $\delta=-23.06$[24] which is near the values of the present cluster hydrides. Thus it seems more likely that the hydride proton is bound to cobalt rather than to iron or ruthenium. The failure to detect the signals in the past[3,8] may be ascribable to the very broad nature of the resonance line due to the effect of the ^{59}Co quadrupole.[22,23]

The hydride spectra of cobalt hydride complexes generally do not show splittings due to scalar couplings of the proton with cobalt. For example, $HCo(CO)_2[P(OC_6H_5)_3]_2$[25] or $HCo[P(OC_2H_5)_3]_4$[26] show sharp resonance lines having splittings due to the coupling only with ^{31}P nuclei and $HCo(PF_3)_4$[22] shows a broad singlet with the width of about 180 Hz at room temperature. These spectral features are caused by the quadrupole of cobalt nuclei ($I=7/2$) which have the very short relaxation time T_1 except for the complexes with cubic symmetry around cobalt.[27]

The relaxation time T_1 of cobalt is expressed as follows:

$$\frac{1}{T_1}=\frac{3}{40}\frac{(2I+3)}{I^2(2I-1)}\left(\frac{e^2qQ}{\hbar}\right)^2\tau_c \quad (I=7/2), \qquad (1)$$

$$\tau_c = \frac{4\pi\eta' a^3}{3kT}, \quad (2)$$

where e^2qQ/h is electric quadrupole coupling constant, τ_c correlation time of molecular reorientation, η' viscosity, a molecular radius, k Boltzman's constant and T absolute temperature.[28,29] The spectral shapes of NMR spectra of the nuclei (I=1/2) coupled with quadrupolar nuclei have been analyzed by Pople[30] and Suzuki and Kubo.[31] Yamasaki[32] has extended it to ^{59}Co (I=7/2) and calculated the simulation spectra which are dependent on a parameter $\eta=2\pi JT_1$ where T_1 is relaxation time of cobalt and J is scalar coupling constant. Where η is small, the splittings due to the scalar couplings are not observed and the spectra broaden. However, when η is much smaller, the resonance of the nuclei (I=1/2) is out of the influence of cobalt and becomes sharper.

The T_1 of ^{59}Co is reciprocally proportional to τ_c and becomes smaller when the viscosity and molecular volume increase and the temperature decreases. As the viscosity of the solvent increases at lower temperatures, the effect of lowering the temperature on the T_1 is most pronounced. A typical example of the temperature effect was illustrated in the variable temperature ^{1}H, ^{31}P, and ^{59}Co NMR spectra of **4**. The T_1 of ^{59}Co decreased when the temperature was lowered and the spectra broadened (Fig. 6). On the other hand, ^{1}H and ^{31}P spectra became sharper at lower temperatures (Figs. 4 and 5). The line shapes of ^{31}P (I=1/2) spectra correspond to those of the simulation curves[32] at *ca.* η=0.5 for the spectrum at 27°C and *ca.* 0.2 for that at −20°C. The ^{1}H spectra are already singlets at 27°C and the line widths decrease at lower temperatures. Since the trimethyl phosphite ligands are bound to cobalt,[8,9] the line broadening mechanism for the ^{31}P nuclei is likely the same as that for the hydride. Namely, both the ^{1}H and ^{31}P spectra broaden because of the quadrupolar effect of ^{59}Co nuclei and sharpen at lower temperatures where the T_1 of ^{59}Co becomes much smaller.

The influence of viscosity upon the T_1 was evident from the comparison of the spectra in chloroform and in Daifloil. The increase of molecular volume by the phosphite exchange was also reflected in the decrease of line-widths (Table 1). For instance, by the approximation of regarding the cluster compounds as spheres, the molecular volume of **6** is calculated to be about twice that of **4**, and corresponding decrease of the line-widths was observed (Table 1).

The scrambling of carbonyl groups in $HFeCo_3(CO)_{12}$ and its derivatives was studied by ^{13}C and ^{17}O NMR spectroscopies.[33,34] It was shown that the scrambling was rather slow at lower temperatures, especially for the phosphite-substituted hydrides which have larger energy barrier for the fluxionality. As most of the ^{1}H NMR spectra of the present study were recorded below 27°C, the chemical shifts and line-widths are probably not influenced significantly by the carbonyl scrambling. The possibility that the sharpening of the spectra at lower temperatures may have been caused by hydride fluxionality can be ruled out because there were no chemical shifts and splittings of the signals which must have been shown in the temperature dependent spectra of the fluxional hydride. However a minor fraction of the hydride may be bound to iron or ruthenium,[7] since we observed a weak and sharp line overlapped on the broad main peak.

Conclusion

The present study has shown that the ^{1}H NMR spectra of the mixed carbonyl hydride complexes $HMCo_3(CO)_{12-x}[P(OR)_3]_x$ (M=Fe or Ru, x=0—3) have resonances in the normal region as transition metal hydrides but the line widths are murh broader than ordinary hydride complexes. We consider that the line broadening is caused by intermediate length of the relaxation time T_1 of cobalt, namely the T_1 is too short to show the ^{1}H-^{59}Co scalar couplings but too long to decouple the interaction completely. The T_1 could be remarkably reduced by lowering the temperature of the measurements, by raising the viscosity of the solvents or by increasing the molecular volume. When the T_1 became short enough in these ways, the hydride resonance was effectively "decoupled" and showed much narrower lines. As the spectral changes of the hydride resonance upon lowering temperature are similar to the behavior of ^{31}P NMR spectra of **4** in which trimethyl phosphites are coordinated to each cobalt,[8,9] the hydride proton must be bonded also to cobalt. It is reasonable to assume that the hydride is bonded to the Co_3 face in solution just as in the solid state.[8,9] The similarity of the ^{1}H NMR spectra of other derivatives including **1** or **7** suggests that the hydride ligands in these complexes are bonded also to the Co_3 face.

We wish to thank Mr. Yoshio Terawaki for the measurements of ^{1}H and ^{31}P NMR spectra and JEOL for the ^{59}Co NMR spectra. We thank also Professors Hiizu Iwamura, Yoji Arata and Akira Yamasaki for helpful suggestions and discussions.

Synthesis of Hg(II) Complexes of Cysteine-Containing Oligopeptides

Norikazu UEYAMA, Michio NAKATA, and Akira NAKAMURA*
Department of Macromolecular Science, Faculty of Science, Osaka University, Toyonaka, Osaka 560
(Received September 17, 1984)

Tetrapeptides, Z-Cys-Ala-Ala-Cys-OMe (Z=benzyloxycarbonyl), Z-Cys-Val-Val-Cys-OMe, and Z-Cys-Gly-Pro-Cys-OMe, having Cys-X-Y-Cys sequences were synthesized by using an acetamidomethyl (Acm) protecting group. The Hg(II) complexes of these peptides, Hg_2Cl_2(Z-Cys-Ala-Ala-Cys-OMe) **1**.[1] Hg(Z-Cys-Ala-Ala-Cys-OMe) **2**, Hg_2Cl_2(Z-Cys-Gly-Pro-Cys-OMe) **3**, Hg(Z-Cys-Val-Val-Cys-OMe) **4**, and Hg_2Cl_2(Z-Cys-Ala-Cys-OMe) **5** were synthesized by the reaction of the S(Acm) protecting peptides and $HgCl_2$ in *N,N*-dimethylformamide. Two Raman bands due to Cl-Hg-S of **1**, **3**, or **5** were observed at 314, 281, or 276 cm^{-1} in solid, whereas a single band due to S-Hg-S was found at 326 cm^{-1} for **2** or 327 cm^{-1} for **4**, in solid.

The tetrapeptide sequences of -Cys-X-Y-Cys- (X, Y=amino acid residues) serving as a macro-ring chelate with the cysteinyl thiolate coordinations are frequently found for metal binding sites of many of metal thiolate proteins: for example, Fe proteins; Cys(6)-Thr-Val-Cys(9) and Cys(39)-Pro-Leu-Cys(42) for *Clostridium pasteurianum* rubredoxin,[2] Cys(44)-Ser-Ser-Cys-(47) for *Spirulina plantesis* ferredoxin,[3] Cys(8)-Ile-Ala-Cys(11)- Gly-Ala-Cys(14) and Cys(35)-Ile-Asp-Cys(38)-Gly-Ala-Cys(41) for *Peptococcus aerogenes* ferredoxin:[4] Zn proteins; Cys(97)-Gly-Lys-Cys(100)-Arg-Val-Cys-(103) for horse liver alcohol dehydrogenase (E-chain),[5] Cys(137)-Lys-Tyr-Cys(140) for *Escherichia coli* aspartate carbamoyltransferase:[6] metallothioneins: Cys(21)-Lys-Gln-Cys(24), Cys(26)-Ala-Ser-Cys(29), and Cys(41)-Ala-Lys-Cys(44) for equine renal metallothionein 1B.[7] In such cases, conformational restriction due to the steric effects of the chelating tetrapeptides caused by side chains of the two amino acid residues, X and Y, interposed between the two cysteine residues definitively plays crucial roles on the stabilities of the chelate rings, the determination of geometries around a metal ion, and the revelation of enzymatic activities.

In order to elucidate the side chain conformational effects discussed above, we have been studying various metal complexes such as Pd(II)[8,9], Fe(III),[10] Co(II),[11] and Mo(IV, V)[12] of cysteine-containing tetrapeptide (Z-Cys-X-Y-Cys-OMe) in the relevance to the metal thiolate proteins. We were also interested in the formation of Hg(II) complexes of Z-Cys-Val-Val-Cys-OMe possessing more bulky side chains, Z-Cys-Gly-Pro-Cys-OMe having a restricted conformation with a Gly-Pro sequence,[13] and tripeptide, Z-Cys-Ala-Cys-OMe which contains only one amino acid residue between two cysteinyl residues. In biological systems with mercury, Hg(II) complexation with cysteine thiolate is involved in toxicity[14] and detoxicity. For example, mercuric reductase contains two active thiols which are proposed to bind Hg(II) ion to give RS-Hg-SR.[15] In this paper we describe detailed procedures for the syntheses of the cysteine-containing oligopeptides, Z-Cys-X-Y-Cys-OMe (X, Y=Ala; X, Y=Val; X=Gly and Y=Pro) and Z-Cys-Ala-Cys-OMe, and for the syntheses of Hg(II) complexes of the cysteine-containing peptides. We synthesized two types of Hg(II)/Cys-containing peptide complexes such as RS-Hg-SR and RS-Hg-Cl. The bulkiness and hydrophobicity around Cys residue may control the formation of either RS-Hg-SR or RS-Hg-Cl species.

Experimental

Materials. Glycine, L-alanine, L-valine, L-proline, L-cysteine hydrochloride, benzyloxycarbonyl chloride (Z-Cl), anhydrous hydrogen bromide in acetic acid (25%), DCC, and *N*-hydroxysuccinimide (HOSu) were purchased from Protein Research Foundation. Isobutyl chloroformate was purchased from Merck-Schuchardt and used without further purification. 2-(*t*-Butoxycarbonylthio)-4,6-dimethylpyrimidine (*t*-Boc-S) was obtained from Mitsubishi Chemical Industries Co., Ltd. Tetrahydrofuran (THF) and dioxane were distilled after refluxing over sodium. Acetonitrile was refluxed over calcium hydride and distilled. Purification of *N,N*-dimethylformamide (DMF) and triethylamine were purified by distillation. All other reagents used were of commercial grade.

Peptide Syntheses. Benzyloxycarbonyl derivatives of L-alanine, L-valine, and L-proline were prepared by the same procedures with Z-Cl cited in the literature.[16] *t*-Butoxycarbonyl derivative of L-alanine was prepared according to the literature method using *t*-Boc-S.[17] Glycine methyl ester hydrochloride was also prepared by the analogous method to a literature using thionyl chloride.[18] HCl·H-Cys(Acm)-OH was prepared by the modified method to a literature.[19]

1. Synthesis of Z-Cys(Acm)-Ala-Ala-Cys(Acm)-OMe Z-Cys(Acm)-OH. Benzyloxycarbonyl chloride (100 cm^3, 0.5 mol) and 4M NaOH solution (375 cm^3 (1 M=1 mol dm^{-3})) were added alternately to a solution of HCl·H-Cys(Acm)-OH (114.4 g, 0.5 mol) in 4 M NaOH solution (250 cm^3) over about 1.5 h period in an ice-cooled bath, and stirred for 3 h at room temperature. The product was obtained as an oil, which was crystallized on standing the chloroform solution, and recrystallized from ethyl acetate–ether: yield, 70 g (44%); mp 106—107 °C (dec); $[\alpha]_D$ −40.7° (*c* 0.905, methanol). Anal. Calcd for $C_{14}H_{18}N_2O_5S$: C, 51.52; H, 5.56; N, 8.58. Found: C, 51.50; H, 5.63; N, 8.40.

Z-Ala-Cys-(Acm)-OMe. A solution of Z-Ala-OH (45.0 g, 0.20 mol) and triethylamine (28.8 cm^3, 0.20 mol) in THF (200 cm^3) was cooled to −15 °C. To this solution was added iso-Boc-Cl (26.0 cm^3, 0.20 mol) with stirring at −15 °C. After 15 min, a solution of HCl·H-Cys(Acm)-OMe (60.0 g, 0.20 mol) and triethylamine (28.0 cm^3, 0.20 mol) in DMF (50 cm^3) was added with stirring at −15 °C. The reaction mixture was stirred for 1 h with cooling and then overnight at room temperature. The solution was concentrated under

reduced pressure. About 500 cm³ of water was added to the residue and the resulting white solid was collected on a glass filter, and washed sequentially with water, 4% $NaHCO_3$ aqueous solution, water, 2% HCl aqueous solution, and water. The product was dried over P_2O_5 *in vacuo*: yield, 50 g (61%); mp 143—145 °C (dec); $[\alpha]_D$ −21.7° (*c* 1.07, DMF). Anal. Calcd for $C_{18}H_{25}N_3O_6S$: C, 52.54; H, 6.12; N, 10.21. Found: C, 52.53; H, 6.12; N, 10.15.

Z-Ala-Ala-Cys(Acm)-OMe. To Z-Ala-Cys(Acm)-OMe (25 g, 0.06 mol) was added 25% HBr solution in acetic acid (50 cm³) at 0 °C. The solution was allowed to stand for 1.5 h with stirring at room temperature. Ether was added to this solution to precipitate HBr·H-Ala-Cys(Acm)-OMe. The supernatant was decanted off and the residue was washed with ether several times. The dipeptide hydrobromide salt obtained was dried over KOH *in vacuo*. To a solution of Z-Ala-OH (13.5 g, 0.06 mol) and triethylamine (8.3 cm³, 0.06 mol) in THF (200 cm³) was added iso-Boc-Cl (7.7 cm³, 0.06 mol) at −15 °C. After 15 min, a solution of HBr·H-Ala-Cys(Acm)-OMe and triethylamine (8.3 cm³, 0.06 mol) in DMF (30 cm³) was added with stirring at −15 °C. Following treatments were same as the syntheses of Z-Ala-Cys(Acm)-OMe: yield 10.5 g (36%); mp 183—186 °C (dec); $[\alpha]_D$ −32.9° (*c* 1.07, DMF). Anal. Calcd for $C_{21}H_{30}N_4O_7S$: C, 52.27; H, 6.27; N, 11.61. Found: C, 52.26; H, 6.32; N, 11.61.

Z-Cys(Acm)-Ala-Ala-Cys(Acm)-OMe. In order to remove the Z-group, Z-Ala-Ala-Cys(Acm)-OMe (2.3 g, 5 mmol) was treated with about 40 cm³ of 25% HBr/acetic acid. The resulting tripeptide hydrobromide salt, HBr·H-Ala-Ala-Cys(Acm)-OMe, was dried over KOH *in vacuo*. To a solution of Z-Cys(Acm)-OH (1.5 g, 5 mmol) and triethylamine (0.7 cm³, 5 mmol) in THF (100 cm³) was added iso-Boc-Cl (0.6 cm³, 5 mmol) at −15 °C. After 15 min, a solution of HBr·H-Ala-Ala-Cys(Acm)-OMe and triethylamine (0.7 cm³, 5 mmol) in DMF (20 cm³) was added with stirring at −15 °C. The reaction mixture was stirred for 1 h with cooling and stood overnight at room temperature. Subsequent work-up was done in the same manner as described for Z-Ala-Cys(Acm)-OMe: yield 1.2 g (36%); mp 210—213 °C (dec); $[\alpha]_D$ −33.6° (*c* 0.667, DMF). Anal. Calcd for $C_{27}H_{40}N_6O_9S_2$: C, 49.38; H, 6.14; N, 12.80. Found: C, 49.17; H, 6.15; N, 12.09.

t-Boc-Ala-Cys(Acm)-OMe. To a solution of *t*-Boc-Ala-OH (34.1 g, 0.18 mol) and triethylamine (24.8 cm³, 0.18 mol) in THF (200 cm³) was added iso-Boc-Cl (23.1 cm³, 0.18 mol) with stirring at −15 °C. After 15 min, an ice-cooled solution of HCl·H-Cys(Acm)-OMe (43.7 g, 0.18 mol) and triethylamine (24.8 cm³, 0.18 mol) in DMF (40 cm³) and chloroform (100 cm³) was added to the mixed anhydride solution with stirring at −15 °C. The reaction mixture was stirred for 1 h at 15 °C and overnight at room temperature. After evaporation of the solvent under reduced pressure, the addition of about 500 ml of saturated NaCl aqueous solution to the residue caused the separation of an oily material, which was extracted with ethyl acetate. The organic layer was washed sequentially with sat. NaCl aq, 4% $NaHCO_3$ aq solution saturated with NaCl, sat. NaCl aq, 10% citric acid aq solution saturated with NaCl, and sat. NaCl aq solution and dried over anhydrous Na_2SO_4. After the desiccant was filtered off, the solvent was removed under reduced pressure and ether was added to the residue to result in crystallization. The product was collected on a glass filter, washed with ether, and dried over silica gel *in vacuo*: yield, 32 g (47%); mp 85—86 °C (dec); $[\alpha]_D$ −48.7° (*c* 0.371, DMF). Anal. Calcd for $C_{15}H_{27}N_3O_6S$: C, 47.73; H, 7.21; N, 11.13. Found: C, 47.79; H, 7.20; N, 10.16.

t-Boc-Ala-Ala-Cys(Acm)-OMe. Hydrogen chloride gas was introduced into an ice-cooled solution of *t*-Boc-Ala-Cys(Acm)-OMe (20.4 g, 0.054 mol) in dioxane (150 cm³) for about 20 min to result in a white precipitate of HCl·H-Ala-Cys(Acm)-OMe. The reaction mixture was allowed to stand for about 30 min. After an addition of ether, the supernatant was decanted off. The dipeptide hydrochloride salt was washed with ether thoroughly and dried over KOH *in vacuo*. To a solution of *t*-Boc-Ala-OH (10.2 g, 0.054 mol) and triethylamine (7.5 cm³, 0.054 mol) with stirring at −15 °C for about 15 min. To this solution, an ice-cooled solution of the HCl·H-Ala-Cys(Acm)-OMe prepared previously and triethylamine (7.5 cm³, 0.054 mol) in DMF (10 cm³) and chloroform (100 cm³) was added with stirring under the continuous cooling. The reaction mixture was stirred at −15 °C for 1 h and at room temperature overnight. The solvent was removed under reduced pressure and about 500 cm³ of sat. NaCl aq solution was added to the residue. An oily material which was separated on the addition of the NaCl solution was extracted with ethyl acetate. Subsequent procedures were the same as described for *t*-Boc-Ala-Cys(Acm)-OMe: yield 4.2 g (17%); mp 144—145 °C (dec); $[\alpha]_D$ −34.1° (*c* 0.113, DMF). Anal. Calcd. for $C_{18}H_{32}N_4O_7S$: C, 48.20; H, 7.19; N, 12.49. Found: C, 47.23; H, 7.08; N, 12.07.

Z-Cys(Acm)-Ala-Ala-Cys(Acm)-OMe. Isobutyl chloroformate (0.9 cm³, 7 mmol) was added to a solution of Z-Cys(Acm)-OH (2.2 g, 7 mmol) and triethylamine (1.0 cm³, 7 mmol) in THF (10 cm³) with stirring at −15 °C. After 15 min, a solution of HCl·H-Ala-Ala-Cys(Acm)-OMe, which was prepared by a treatment of *t*-Boc-Ala-Ala-Cys(Acm)-OMe (3.1 g, 7 mmol) with HCl gas in dioxane (30 cm³), and triethylamine (1.0 cm³, 7 mmol) in a mixed solvent of DMF (5 cm³) and chloroform (10 cm³) was added to the above mixed anhydride solution at −15 °C with stirring. Subsequent treatments were the same as described for Z-Ala-Ala-Cys-(Acm)-OMe: yield 2.9 g (23%); mp 205—208 °C (dec); $[\alpha]_D$ −30.7° (*c* 0.200, DMF). Anal. Calcd for $C_{27}H_{40}N_6O_9S_2$: C, 49.38; H, 6.14; N, 12.80. Found: C, 48.88; H, 6.07; N, 12.41.

2. Synthesis of Z-Cys(Acm)-Ala-Cys(Acm)-OMe. Dipeptide, Z-Ala-Cys(Acm)-OMe (3.8 g, 9 mmol), was treated with 25% HBr/acetic acid (40 cm³) to result in formation of HBr·H-Ala-Cys(Acm)-OMe. A DMF solution (30 cm³) of the free-base dipeptide prepared from the hydrogen bromide salt and triethylamine (1.3 cm³, 9 mmol) was added to a THF solution (100 cm³) of a mixed anhydride prepared from Z-Cys(Acm)-OH (3.0 g, 9 mmol), triethylamine (1.3 cm³, 9 mmol), and iso-Boc-Cl (1.2 cm³, 9 mmol) at −15 °C. Usual work-up as described for the synthesis of Z-Cys(Acm)-Ala-Ala-Cys(Acm)-OMe gave a tripeptide, Z-Cys(Acm)-Ala-Cys(Acm)-OMe: yield 1.0 g (19%); mp 209—212 °C (dec); $[\alpha]_D$ −34.8° (*c* 1.07, DMF). Anal. Calcd for $C_{24}H_{35}N_5O_8S_2$: C, 49.22; H, 6.02; N, 11.96. Found: C, 48.43; H, 5.92; N, 11.43.

iso-Butyl chloroformate (1.0 cm³, 8 mmol) was added to a solution of Z-Cys(Acm)-OH (2.6 g, 8 mmol) and triethylamine (1.1 cm³, 8 mmol) in THF (80 cm³) with stirring at −15 °C. After 15 min, a solution of HCl·H-Ala-Cys(Acm)-OMe, which was prepared by a HCl treatment of *t*-Boc-Ala-Cys(Acm)-OMe (3.0 g, 8 mmol) in dioxane (50 cm³) and triethylamine (1.1 cm³, 8 mmol) in DMF (10 cm³) and chloroform (20 cm³), was added to the mixed anhydride solu-

tion at −15°C with stirring. After the same treatments as described above, Z-Cys(Acm)-Ala-Cys(Acm)-OMe was obtained: yield 4.0 g (85%); mp 211—212°C (dec); $[\alpha]_D$ −30.6° (*c* 0.197, DMF). Anal. Calcd for $C_{24}H_{35}N_5O_8S_2$: C, 49.22; H, 6.02; N, 11.96. Found: C, 48.12; H, 5.86; N, 11.44.

3. Synthesis of Z-Cys(Acm)-Val-Val-Cys(Acm)-OMe. *Z-Val-Cys(Acm)-OMe*: The peptide was prepared from Z-Val-OH and H-Cys(Acm)-OMe by the same procedure as mentioned for Z-Ala-Cys(Acm)-OMe. The crude materials were recrystallized from methanol. Yield 45%; mp 164—166°C; $[\alpha]_D$ −27.0° (*c* 0.97, DMF). Anal. Calcd for $C_{20}H_{29}N_3O_6S$: C, 54.65; H, 6.65; N, 9.56. Found: C, 54.58; H, 6.71; N, 9.53.

Z-Val-Val-Cys(Acm)-OMe: The peptide was prepared from Z-Val-OH and H-Val-Cys(Acm)-OMe by the same method mentioned above. The crude product was recrystallized from methanol. Yield 81%; mp 231—236°C (dec); $[\alpha]_D$ −25.2° (*c* 0.95, DMF). Anal. Calcd for $C_{25}H_{38}N_4O_7S$: C, 55.74; H, 7.11; N, 10.40. Found: C, 55.36; H, 7.09; N, 10.04.

Z-Cys(Acm)-Val-Val-Cys(Acm)-OMe: The peptide was synthesized from Z-Cys(Acm)-OH and H-Val-Val-Cys(Acm)-OMe by the same procedure for Z-Cys(Acm)-Ala-Ala-Cys(Acm)-OMe. The crude product was washed with ether and dried over P_2O_5 *in vacuo* and recrystallized from methanol. Yield 31%; mp 221—224°C (dec); $[\alpha]_D$ −29.3° (*c* 0.98, DMF). Anal. Calcd for $C_{31}H_{48}N_6O_9S_2$: C, 52.22; H, 6.80; N, 11.79. Found: C, 51.45; H, 6.73; N, 11.21.

4. Synthesis of Z-Cys(Acm)-Gly-Pro-Cys(Acm)-OMe. Z-Cys(Acm)-Gly-OMe was prepared from Z-Cys(Acm)-OH and H-Gly-OMe with the mixed anhydride method mentioned above. Z-Cys(Acm)-Gly-OH was obtained by hydrolysis with NaOH in methanol/dioxane. Z-Pro-Cys(Acm)-OMe was prepared from Z-Pro-OH and H-Cys(Acm)-OMe by the same procedure for Z-Ala-Cys(Acm)-OMe. Synthesis of HBr·H-Pro-Cys(Acm)-OMe was done by to the same method described for HBr·H-Ala-Cys(Acm)-OMe.

To the reaction mixture containing 2.5 g of Z-Cys(Acm)-Gly-OH, HBr·H-Pro-Cys(Acm)-OMe, and 1.1 cm³ of triethylamine in 20 cm³ of DMF was added 0.8 g of HOSu and, then, 1.5 g of DCC at 0°C. The reaction mixture was stirred for 1 h with cooling and overnight at room temperature. The solution was concentrated under reduced pressure. The residue was dissolved in chloroform and remaining *N,N'*-dicyclohexylurea was filtered off. The filtrate was washed sequentially with water, 2% HCl aq, water, 4% $NaHCO_3$ aq, and water, and dried over anhydrous Na_2SO_4. After removal of the solvent, Z-Cys(Acm)-Gly-Pro-Cys(Acm)-OMe was obtained as a white solid. Yield, 3.3 g (63%); mp 104°C; $[\alpha]_D$ −93.6° (*c* 0.50, methanol). Anal. Calcd for $C_{28}H_{40}O_9N_6S_2$: C, 50.25; H, 6.03; N, 9.58. Found: C, 50.10; H, 6.07; N, 9.46.

5. Syntheses of Hg(II)/Cys-containing Peptide Complexes. *HgCl(Z-Ala-cys-OMe).* A solution containing 100 mg of Z-Ala-Cys(Acm)-OMe and 65 mg of $HgCl_2$ in 3 cm³ of Me_2SO was stirred for several hours. A quick addition of 30 ml of water to the Me_2SO solution with cooling resulted in precipitation of a white powder, which was collected on a glass filter, washed with sat. NaCl aq and water, and dried over P_2O_5 *in vacuo*. Yield, 110 mg.

In order to secure a complete removal of Acm-group, it is preferable to use two equiv of $HgCl_2$ for an equiv of Acm-group. Mp 91—96°C. Anal. Calcd for $C_{15}H_{10}N_2SHgCl$: C, 31.31; H, 3.33; N, 4.87. Found: C, 31.23; H, 3.40; N, 4.97.

Hg_2Cl_2(Z-cys-Ala-Ala-cys-OMe) 1. To a solution of Z-Cys(Acm)-Ala-Ala-Cys(Acm)-OMe (200 mg, 0.3 mmol) in 10 cm³ of DMF was added 500 mg (1.0 mmol) of $HgCl_2$ during stirring at room temperature. After 5 h, 5 cm³ of NaCl-saturated water and 5 cm³ of methanol were added. Another addition of water (25 cm³) resulted in precipitation of white solids, which were collected with filtration, washed with 10% NaCl aq solution and with two portions of methanol, and dried over P_2O_5 *in vacuo*. Yield 190 mg. Anal. Calcd for $C_{21}H_{28}N_4O_7S_2Hg_2Cl_2$: C, 25.53; H, 2.87; N, 5.72. Found: C, 24.38; H, 2.92; N, 5.51.

Hg(Z-cys-Ala-Ala-cys-OMe) 2. The complex was synthesized from $Hg(OCOCH_3)_2$ (320 mg, 1.0 mmol) and Z-Cys(Acm)-Ala-Ala-Cys(Acm)-OMe (200 mg, 0.3 mmol) in DMF (10 cm³) by almost the same procedure employed for the synthesis of **1**. Anal. Calcd for $C_{21}H_{28}N_4O_7S_2Hg$: C, 35.23; H, 3.96; N, 7.90. Found: C, 37.11; H, 4.12; N, 7.95.

Hg_2Cl_2(Z-cys-Gly-Pro-cys-OMe) 3. The complex was synthesized by the same method described above. Yield 85%. Anal. Calcd for $C_{22}H_{28}N_4O_7S_2Hg_2Cl_2$: C, 26.50; H, 2.83; N, 5.65. Found: C, 24.13; H, 2.88; N, 5.26.

Hg(Z-Cys-Val-Val-Cys-OMe) 4. To a solution of Z-Cys(Acm)-Val-Val-Cys(Acm)-OMe (300 mg, 0.4 mmol) in 20 cm³ of DMF, 300 mg (1.1 mmol) of $HgCl_2$ was added at room temperature. White solids precipitated gradually. After 8 h, the precipitate was collected with filtration, washed with DMF, NaCl-saturated aq solution, and two portions of methanol. The product was dried over P_2O_5 *in vacuo*. Yield 76%. Anal. Calcd for $C_{25}H_{36}N_4O_7S_2Hg$: C, 39.02; H, 4.72; N, 7.32. Found: C, 42.00; H, 5.28; N, 8.03.

Hg_2Cl_2(Z-cys-Ala-cys-OMe) 5. The complex was synthesized by the same method as described for **4**. Anal. Calcd for $C_{18}H_{23}O_6N_3S_2Hg_2Cl_2$: C, 23.66; H, 2.54; N, 4.62. Found: C, 24.61; H, 2.72; N, 4.11.

Physical Measurements. Raman spectra of Hg(II)/Cys-containing peptide complexes in solid were taken on a Jasco R-800 spectrometer with exciting lines at 488.0 and 514.5 nm. Optical rotations were measured with an automatic polarimeter JASCO model DIP-4. Measurements of ^{1}H-NMR spectra were carried out on a Varian XL-100 spectrometer at 100 MHz at *ca.* 30°C. Purities of the synthetic peptides were checked by high-performance liquid chromatography on a WATERS model 6000 A and U6K equipped with WATERS μBondapak C18 column and detected at 254 nm with a Shimadzu spectrophotomeric detector SPD-1. An eluent system used was methanol/H_2O (2/1). The products were also characterized by ^{1}H-NMR spectra. Melting points were uncorrected.

Results and Discussion

Peptide Syntheses. The Acm-group has some distinctive advantages as the protecting group for cysteine thiolates especially in the construction of metallothiolate protein model complexes. It is cleaved in milder conditions than required for benzyl or *p*-methoxybenzyl derivative. Substitution of the Acm-group with Hg(II) ion and the subsequent removal of the Hg(II) ion with H_2S gas readily give SH-free peptides. Undesirable reducing reagents, such as 2-mercaptoethanol or dithiothreitol, are unnecessary

for the construction of metal complexes, *e.g.* iron-sulfur protein model complexes. An active site of metalloproteins has been known to be surrounded by hydrophobic environments particularly when they function as electron mediators.[20] Therefore, an investigation on the Hg(II)/Cys-containing peptide complexes should be carried out in various organic solvents because hydrophobic amino acid residues are involved.

In order to ensure the coordination of the cysteine thiolate to metal ion founds in metalloproteins, terminal amino and carboxyl groups must be protected by Z- or -OMe since Hg(II) readily coordinates to organic function groups such as COO^- and NH_2 groups as established by the X-ray analysis of $[MeHg]_2[SCMe_2CH(NH_2)CO_2]$.[21]

Reaction of Cys(Acm) Group with Hg^{2+}. Veber *et al.* reported that the Acm-group was deprotected in an aqueous solution at pH 4.0 by excess mercury(II) acetate.[22] A reaction between the (S-Acm)-peptide and $HgCl_2$ was performed in dimethyl sulfoxide (Me_2SO) because of insolubility of our fully protected peptides in water. An addition of water, which is crucial for the cleavage of the S-Acm bond with $HgCl_2$, resulted in precipitation of (S-Hg^{II}Cl)-peptide. Figure 1 shows the ^1H NMR of a mixture of Z-Ala-Cys(Acm)-OMe and $HgCl_2$ in Me_2SO. The spectrum (a) is ^1H-NMR spectrum of Z-Ala-Cys(Acm)-OMe in Me_2SO-d_6 showing cysteinyl C_β methylene protons and acetyl-(Acm) signals at 2.95 and 1.84 ppm, respectively. An

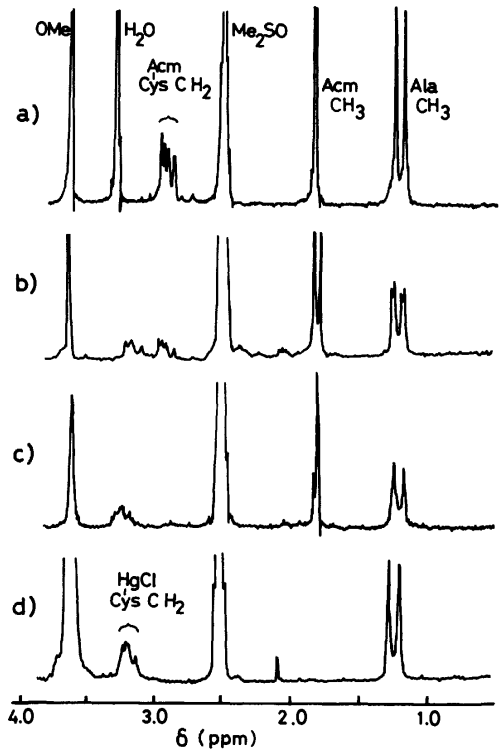

Fig. 1. a): H-NMR spectra of Z-Ala-Cys(Acm)-OMe (30 mg) in Me_2SO-d_6 (0.5 cm^3), b): (a) plus $HgCl_2$ (27 mg) in Me_2SO-d_6, c): (b) plus D_2O (0.2 cm^3), d): HgCl(Z-Ala-cys-OMe) (33 mg) in Me_2SO-d_6.

addition of $HgCl_2$ to the Z-Ala-Cys(Acm)-OMe solution resulted in an appearance of new signals at 3.17 and 1.80 ppm as shown in spectrum (b). The results suggests a direct interaction between the Hg(II) ion and the S atom. A subsequent addition of D_2O to the reaction mixture containing Z-Ala-Cys(Acm)-OMe and $HgCl_2$ gave spectrum (c) with disappearance of signals of the cysteine C_β methylene at 2.95 ppm and Acm acetyl at 1.84 ppm. The signal at 3.26 ppm coincided with cysteine C_β methylene signals of HgCl-(Z-Ala-cys-OMe) at 3.20 ppm represented by spectrum (d). These facts indicate that the addition of water forces the quantitative cleavage of the S-Acm bond by Hg(II) ion.

Two types of Hg(II) complexes were synthesized from the reaction between $HgCl_2$ and Cys-containing peptides. In the case of Z-Cys(Acm)-Val-Val-Cys(Acm)-OMe and Z-Cys(Acm)-Ala-Cys(Acm)-OMe in DMF, **4** and **5** having polymeric structures are obtainable without the addition of water. On the other hand, **1** and **3** were obtained with the addition of water to a DMF solution of $HgCl_2$ and the corresponding peptides. Such a mixed solvent system provides acidic conditions by the hydrolysis of $HgCl_2$ with the addition of water. The results indicate that under the acidic conditions the formation of HgCl(SR) (SR=Cys-containing peptide) predominates, whereas under neutral conditions, where competition of the formation between HgCl(SR) and $Hg(SR)_2$ occurs depending upon solubility. Actually, **2** was synthesized from the corresponding peptide and $Hg(OCOCH_3)_2$ in a weakly acidic aq DMF. The similar two types of the Hg(II)/cysteine complexes has been found to be formed in an aqueous solution by Hay and Porter.[23]

Raman Spectra of Hg(II)/Cys-containing Peptide Complexes. The two types of the complexes, *i.e.* Hg_2Cl_2(peptide)$_2$ and Hg(peptide)$_2$ was examined by their Raman spectra. Figure 2 shows the Raman spectra of Hg_2Cl_2(Z-cys-Ala-Ala-cys-OMe), Hg(Z-cys-Ala-Ala-cys-OMe), Hg_2Cl_2(Z-cys-Gly-Pro- cys-OMe), Hg(Z-cys-Val-Val-cys-OMe), and Hg_2Cl_2(Z-cys-Ala-cys-OMe) in solid state. The intensities of strong bands in the region of 280—320 cm^{-1} were proportional to that of a band at 1003 cm^{-1} due to phenyl of Z group.

The Hg_2Cl_2(peptide) complexes exhibited two strong bands at 281 and 314 cm^{-1}, whereas Hg(peptide) type provided only one strong band at 313—327 cm^{-1}. One strong Raman band is expected for linear S-Hg-S bonding ($D_{\infty h}$ symmetry). Two Raman bands should be observed for linear S-Hg-Cl structure ($C_{\infty v}$ symmetry). Therefore, a strong band at 327 cm^{-1} for Hg(Z-cys-Ala-Ala-cys-OMe) or Hg(Z-cys-Val-Val-cys-OMe) is assignable to ν(Hg-S). The ν(Hg-Cl) band of $HgCl_2$ was observed at 312 cm^{-1} in solid state, although ν(Hg-Cl) was reported to be observed at 348 cm^{-1} in inert gas matrices.[24] Tentatively two bands at 318 and 281 cm^{-1} for Hg_2Cl_2(Z-cys-Ala-Ala-cys-

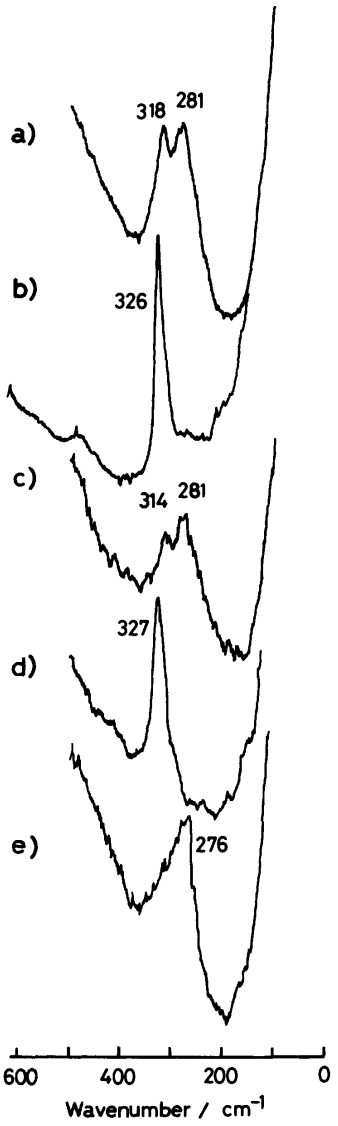

Fig. 2. Raman spectra of a): Hg_2Cl_2(Z-cys-Ala-Ala-cys-OMe), b): Hg(Z-cys-Ala-Ala-cys-OMe), c): Hg_2Cl_2(Z-cys-Gly-Pro-cys-OMe), d): Hg(Z-cys-Val-Val-cys-OMe), and e): Hg_2Cl_2(Z-cys-Ala-cys-OMe) in solid.

OMe) and at 314 and 281 cm^{-1} for Hg_2Cl_2(Z-cys-Gly-Pro-cys-OMe) are assigned to ν(Hg-S) and ν(Hg-Cl) by considering their masses. Two Raman bands have been observed at 349 and 325 cm^{-1} for PhHg(H_2-cys-OH)[25] and MeHg(H_2-cys-OH),[26] respectively.

It is interesting that one ν(Hg-S) band of Hg_2Cl_2-(Z-cys-Ala-cys-OMe) was observed at 276 cm^{-1}. The low frequency seemed unusual because the other S-Hg-Cl type complexes exhibit a band at 281 cm^{-1}. Similar low frequency bands were reported by Carty *et al.* for 3-coordinated Hg(II) in $[HgCl_2]_2[SCMe_2CH(NH_3)COOH]\cdot 2H_2O$.[27] The shift of ν(Hg-S) of Hg_2Cl_2(Z-cys-Ala-cys-OMe) may be attributed to the S-Hg-Cl bond weaken by the steric hindrance of two crowded Hg-S(cys) groups.

As described above, the Raman spectroscopy may be utilized as an important diagnostic tool for the characterization of cysteine-containing peptides. The present results will contribute to the investigation of Hg(II)-binding thiol sites surrounded by hydrophobic environments in proteins or burried in membrane. Reductive elimination of metallic mercury from Hg(Z-cys-X-Y-cys-OMe) complexes is important for a model reaction of mercuric reductase proposed to contain RS-Hg-SR in the active site. Further investigation on this point is in progress.

Synthesis of DMSO-$SbCl_5$ (1:1) Complex and Its Oxidizing Action toward Alcohols

Jiro YAMAMOTO,* Satoshi ITO, Takashi TSUBOI, Toshiaki TSUBOI, and Kumiko TSUKIHARA
Department of Industrial Chemistry, Faculty of Engineering, Tottori University, Koyama-cho, Tottori-shi 680
(Received May 21, 1984)

From an equimolar mixture of DMSO and $SbCl_5$ in carbon tetrachloride, a DMSO-$SbCl_5$(1:1) complex (**1**) was formed as a white precipitate in a quantitative yield. The structure of **1** was determined by X-ray crystallographic analysis. Butyraldehydes, para-substituted benzaldehydes and benzils were obtained by the oxidation of butylalcohols, para-substituted benzylalcohols and benzoins using **1** as an oxidizing agent.

In a series of investigations of synthetic reactions using $SbCl_5$ complexes with organic compounds having an oxygen atom, a new compound **1** was synthesized from DMSO and $SbCl_5$ and used as an oxidizing agent toward some alcohols. Benzils were formed in high yield on the oxidation of the corresponding benzoins by **1**. It was found that an oxygen and two chlorine atoms of **1** were used as the real reagents on the oxidation of benzoins.

Experimental

Synthesis of DMSO-$SbCl_5$ (1:1) Complex 1. A white precipitate was deposited immediately from the solution prepared by mixing 1.1 g (14 mmol) DMSO and 4.7 g (14 mmol) $SbCl_5$ in carbon tetrachloride (10 ml and 20 ml respectively) under cooling. The mixture was allowed to stand overnight. The products were collected by filtration, throughly washed with carbon tetrachloride followed by petroleum ether. The yield was 5.2 g (98.7%); mp 153 °C. IR (KBr) 1420, 1400, 1320, 1035, 980, 875, 500, and 300 cm^{-1}. UV ($CHCl_3$) 278 nm (ε 800). Found: C, 6.23%, H, 1.64%. Calcd for C_2H_5SO-$SbCl_5$: C, 6.37%; H, 1.60%.

Crystal Structure Analysis of the DMSO-$SbCl_5$ (1:1) Complex 1. The thin plate crystals grown from a benzene solution of **1** were orthorhobic, a=23.418(8) Å, b=13.517(5) Å, c=10.529 Å, $\alpha=\beta=\gamma=90°$, and space group Iba2. Intensity data were collected on a Rigaku four circle diffractometer with a Zr-filtered Mo-$K\alpha$ radiation, λ=0.7107 Å. A crystal was sealed in a glass capillary containing mother liquid to avoid deterioration of crystallinity during the intensity data collection. A total of 1588 non-zero unique intensity data up to 2θ=54° were measured by the θ—2θ scan technique.

The Patterson function followed by a minimum function, and successive Fourier and difference Fourier methods showed a disordered DMSO-$SbCl_5$ (1:1) complex together with a solvent molecule of benzene in an asymmetric unit. The initial structure was refined to an R-factor of 0.13, $R=\sum||F_o|-|F_c||/\sum|F_o|$, by the least squares method with an isotropic temperature factor for all the non-hydrogen atoms of the complex and the benzene molecule. Further refinement with an anisotropic temperature factor for the non-hydrogen atoms of **1** gave no appreciable improvement in the crystal structure. The reasons for the failure of the refinement may be because the intensity data have systematic errors from X-ray absorption by the crystal, the capillary and the mother liquid, and the benzene molecule loosely packed in the crystal. As a difference Fourier synthesis did not give any reasonable residual density, the structual analysis of the crystal was terminated at this stage. The atomic scattering factors were taken from the International Table for X-ray crystallography.[1] All the caluculations were carried out at the Computer Center of Tottori University. The final positional and thermal parameters with their estimated standard deviations are listed in Table 1.

Preparation of 2,2'-Dinitrobenzoin 5d. Crude **5d** was prepared by mixing both EtOH solution of *o*-nitrobenzaldehyde and KCN aqueous solution. Pure **5d** was obtained by crystallization with acetone-water (1:1) solution, mp 164—165 °C(lit,[2] 168—169 °C). *p*-Toluoin was also prepared in the same way, mp 86—87 °C (lit,[3] 88—89 °C). The commercially available benzoins, butyl alcohols and benzyl alcohols were used as received.

Oxidation of Benzoin 5a with DMSO-$SbCl_5$ (1:1) Complex 1. A mixture of **5a** (1.0 g, 4.7 mmol) and **1** (1.8 g, 4.7 mmol) was kept in nitromethane (5 ml) for 5 h at 40 °C. The reaction mixture was poured into ice-water and filtered. The filtrate was extracted with ether and the solution was dried with Na_2SO_4. After evaporation, the residue was separated by column chromatography (benzene-silicagel) to give benzil (**2**) (0.96 g, 96.8%). Dimethyl sulfide (**3**) was detected in the reaction mixture by gas chromatography (Injection: 170 °C, Column: 70 °C, N_2: 60 ml/min., Silicon SE 30). The reaction products were identified by comparison of their melting points and IR spectra with those of authentic samples.

Results and Discussion

The compound **1** immediately crystallized from an equimolar solution of DMSO and $SbCl_5$ in carbon

tetrachloride in quantitative yield. The crystals **1** having a sharp mp were presumed to be DMSO-$SbCl_5$ (1:1), from the results of elemental analysis.

An X-ray crystallogrophic structure determination for **1** was undertaken. The structure **1** with bond lengths and their estimated standard deviations and the atomic numbering scheme are given in Fig. 1. The central metal atom exhibits a distorted octahedral coordination with five chlorine atoms and an oxygen atom of DMSO. The bond angles are listed in Table 2. The DMSO molecule is statistically disordered in the crystal. Two pairs of disordered positions were assigned for an oxygen and a sulfur atom. Each methyl carbon atom, however, was located at a single site. Consequently the methyl sites are shared with two disordered molecules. The bond distances of Sb-Cl for Cl(1), Cl(2), Cl(3), and Cl(5), 2.33 Å to 2.37 Å, are in good accord with those of $SbCl_5$-$PO(CH_3)_3$, 2.32 Å to 2.37 Å.[4] The Sb-Cl (5) bond is significantly shorter than the other Sb-Cl bonds. The bond angles for the two disordered oxygen, antimony and five chlorine atoms depart considerably from those of a regular octahedral structure. This distortion prevents the sulfur atom of DMSO from making abnormal short contacts with chlorine atoms.

The oxidation of benzyl alcohol (**4a**) and its derivatives (methyl (**4b**), nitro (**4c**), and chloro (**4d**) in para-position) with equimolar **1** gave the corresponding benzaldehydes in moderate yields. The yield of benzaldehydes somewhat increased at reflux temperature in the cases of **4b**, **4c**, and **4d**. When air was conducted into the reaction mixture of **4a** and **1**, the yield of benzaldehyde (**5**) also increased (Table 3). The oxidation of butyl (**6a**), isobutyl (**6b**) and *s*-butyl alcohol (**6c**) with **1** also proceeded at room temperature to give butyraldehyde, isobutyraldehyde and ethyl methyl ketone respectively in moderate yields. When the reaction of the butyl alcohols (**6a**, **6b**, and **6c**) with **1** was carried out at 80 °C under air stream, the yield of carbonyl compounds increased. In the absence of **1**, the yield of **5** was only 2.5% even under aeration and refluxing conditions. Under similar conditions, butyl alcohols (**6a**, **6b**, and **6c**) were not oxidized at all.

In the oxidation of benzoin (**7a**), *p*-toluoin (**7b**), *p*-anisoin (**7c**), 2,2′-dinitrobenzoin (**7d**) and furoin (**8**) with **1**,the corresponding benzils or furil were formed in high yields at room temperature (Table 4). When the reactions of **7a** and **7b** with 1 were carried out at elevated temperature, the yields of the corresponding benzils were further improved. A 98.7% yield of **2** was also obtained at a low molar ratio (**7a**/1=0.5)

a) Nitromethane was used as a solvent in most runs. b) DMSO was used as a solvent. c) A mixed solvent (30 ml benzene and 5 ml nitromethane) was used. d) In parenthesis, the yield of benzils studied by Dyke and Pritchard[5] are given.

(Table 4). In the oxidation of **7b** and **7c** with **1**, the yield of the corresponding benzils was low in comparison with **7a** and **7d** under the same conditions (Table 4). It seems to depend on the electron donating character of the methyl and methoxy groups.

The complexes of $SbCl_5$ with trimethylamine oxide, pyridine *N*-oxide[5] and *N,N*-dimethylbenzylamine oxide[6] were used in the oxidation of both **7a** and **8**. Dyke and Pritchard[7] also carried out the oxidation of **7a**, **7c**, and **8** using a DMSO-acetic acid medium. But **1** is a better reagent to give benzils from the corresponding benzoins in comparison with the reagents described above.[5-7] In the reaction of **4a**, **5a**, or **7a** with $SbCl_5$, the corresponding carbonyl compounds were not detected under the present mild conditions.

Increasing the ratio of **1** to **7a** resulted in increasing yields of both **2** and concomitant **3**, as shown in Fig. 2. It is evident that an oxygen atom in **1** is consumed in the oxidation of **7a**. In order to estimate the amount of chlorine which was consumed in the reaction of **7a** with **1** (10 h at 40 °C), the hydrogen chloride generated was transfered into aqueous silver nitrate solution by bubbling nitrogen gas through the reaction mixture. The oxidation of **7a** with **1** under these conditions should proceed essentially to completion (Table 4). The precipitated silver chloride corresponded to 88.6% of the expected value based on the assumption that two of the chlorine atoms in **1** are consumed as the oxidizing agent. Therefore, the present reaction may be shown by the following stoichiometry [Equation (a)].

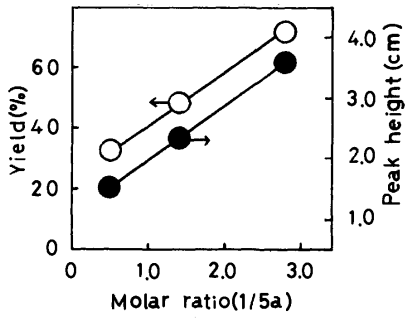

Fig. 2. The oxidation of benzoin **5a** with DMSO-$SbCl_5$ (1:1) complex **1**.
Reaction conditions: Benzoin 1.0 g (4.7 mmol) in nitromethane (10 ml) at 50 °C for 2 h.
○: Benzil, ●: $(CH_3)_2S$

$$2C_6H_5\text{-}\underset{\underset{O}{\|}}{C}\text{-}\underset{\underset{OH}{|}}{CH}\text{-}C_6H_5 + DMSO\text{-}SbCl_5 \longrightarrow$$

$$2C_6H_5\text{-}\underset{\underset{O}{\|}}{C}\text{-}\underset{\underset{O}{\|}}{C}\text{-}C_6H_5 + (CH_3)_2S + SbCl_3 + 2HCl + H_2O \quad (a)$$

When **7a** was allowed to stand with an equimolar combination of DMSO and $SbCl_3$ in nitromethane for 24 h at room temperature, the compound **2** was obtained in a 48% yield with **3**, but no hydrogen chloride was generated. Thus, the reaction of benzoins with **1** seems to proceed in the following two steps. When **1** was mixed with **7a** in nitromethane, hydrogen chloride generated immediately. Therefore, two chlorine atoms in **1** first react with **7a** to form **2** [Equation (b)] and subsequently another molecule of **7a** was also oxidized to **2** by the interaction of both DMSO and $SbCl_3$ [Equation (c)].

$$2C_6H_5\text{-}\underset{\underset{O}{\|}}{C}\text{-}\underset{\underset{OH}{|}}{CH}\text{-}C_6H_5 + DMSO\text{-}SbCl_5 \longrightarrow$$

$$2C_6H_5\text{-}\underset{\underset{O}{\|}}{C}\text{-}\underset{\underset{O}{\|}}{C}\text{-}C_6H_5 + DMSO + SbCl_3 + 2HCl \quad (b)$$

$$2C_6H_5\text{-}\underset{\underset{O}{\|}}{C}\text{-}\underset{\underset{OH}{|}}{CH}\text{-}C_6H_5 + DMSO + SbCl_3 \longrightarrow$$

$$2C_6H_5\text{-}\underset{\underset{O}{\|}}{C}\text{-}\underset{\underset{O}{\|}}{C}\text{-}C_6H_5 + (CH_3)_2S + SbCl_3 + H_2O \quad (c)$$

S_H2 Reactions of Triethylgermyl Radical with Thiosulfonic *S*-Esters and Selenosulfonic *Se*-Ester

Michio KOBAYASHI,* Masanori KOBAYASHI, and Masato YOSHIDA
Department of Chemistry, Faculty of Science, Tokyo Metropolitan University, Setagaya-ku, Tokyo 158
(Received June 25, 1984)

The triethylgermyl radical was found to react with thiosulfonic *S*-esters to generate sulfonyl radicals. The S_H2 character of this new reaction was confirmed by a C-13 CIDNP study and products analysis. Selenosulfonic *Se*-ester reacts with germyl radical in a similar way.

Aryl areneselenosulfonates (**1**) are known to suffer a Se–S cleavage by attack of carbon radicals.[1] On the contrary, arenethiosulfonates (**2**), sulfur analogs of selenosulfonic *Se*-ester, are thermally highly stable and are not cleaved by the attack of carbon radicals. For instance, when *S*-*p*-tolyl *p*-toluenethiosulfonate (**2a**) was refluxed in benzene in the presence of phenylazotriphenylmethane (PAT) or azobisisobutyronitrile (AIBN), almost no decomposition of **2a** was observed.

We have found that thiosulfonic *S*-esters are easily attacked by germyl radical more nucleophilic than carbon radical, at the S–S bond. Although many investigations of the reaction of germyl radicals with olefins and organic halides have been reported,[2] very little is known about the reactivity of the germyl radical with sulfur bonding. We have established the S_H2 character[3] of this new reaction and the results will be described in this paper.

Results and Discussion

When solutions of thiosulfonic *S*-esters $ArSO_2SAr'$ (**2**) are treated with 2 molar amounts of triethylgermane (**3**) in benzene in the presence of 0.2 molar equivalent of azobisisobutyronitrile for 17 h, thiosulfonic *S*-esters are decomposed completely and germyl esters of arenesulfonic acid (**4**) and thiogermane (**5**) are obtained in high yields.

$$2Et_3GeH + ArSO_2SAr' \xrightarrow{AIBN} ArSO_3GeEt_3 + Ar'SGeEt_3$$

(**3**) (**2**) (**4**) (**5**)

	Yield/%	Yield/%
a: Ar = Ar′ = *p*-Tol		
b: Ar = Ar′ = Ph	**4a** 96	**5a** 92
	4b 82	**5b** 82

Each product was identified by comparing its spectroscopic properties with those of the authentic samples prepared according to the literature.

Since thiosulfonic *S*-esters were found not to react with triethylgermane in the absence of AIBN, the above reaction was considered to be initiated by hydrogen abstraction from germane by a α-cyanoisopropyl radical and followed by radical chain reactions. The fact that germyl sulfonate (**4**), not germyl sulfinate (**6**), was isolated as the main product indicated the involvement of atmospheric oxygen. Therefore, the reaction of thiosulfonic *S*-esters with triethylgermane was carried out under deoxygenated conditions in the presence of AIBN. Under these conditions, the reactions proceeded only halfway and a part of **2** was recovered unchanged. No germyl sulfonate (**4**) but germyl sulfinate (**6**) and sulfone (**7**) were obtained as reaction products along with thiogermane (**5**).

$$ArSO_2SAr' + Et_3GeH \longrightarrow \underset{\underset{\text{(6a)}}{\overset{\|}{O}}}{ArSOGeEt_3} + Ar'SGeEt_3 \text{ (5a),(5b)} + \underset{\underset{\text{(7a)}}{CN}}{ArSO_2CMe_2}$$

Substrate	AIBN/2	Recovered (**2**)/%
2a	0.2	65
2c	1.0	24

Products (Yield/mol%)

6a (9), **5a** (24), **7a** (9)

6a (10), **5b** (68), **7a** (37)

These findings suggest that the sulfonyl radical can not abstract a hydrogen atom from triethylgermane and combine with germyl radical and α-cyanoisopropyl radical to form **6** and **7** respectively. Assuming this inactivity of sulfonyl radical as hydrogen abstractor, it was possible to explain why the reaction was stopped halfway in the absence of oxygen.

The above reaction may be expressed in the following reaction sequences.

$$AIBN \longrightarrow 2Me_2\dot{C}CN$$

$$Me_2\dot{C}CN + Et_3GeH \longrightarrow Et_3Ge\cdot + Me_2CHCN \quad (1)$$

$$Et_3Ge\cdot + ArSO_2SAr' \longrightarrow Et_3GeSAr' + ArSO_2\cdot \quad (2)$$

$$ArSO_2\cdot + Et_3Ge\cdot \longrightarrow \underset{\overset{\|}{O}}{ArSOGeEt_3} \quad (3)$$

$$ArSO_2\cdot + Me_2\dot{C}CN \longrightarrow \underset{\underset{CN}{|}}{ArSO_2CMe_2} \quad (4)$$

In the presence of atmospheric oxygen, the sulfonyl radical combines with oxygen to form a sulfonylperoxyl radical which can abstract a hydrogen atom from germane to regenerate germyl radical and thus start chain reaction.

$$ArSO_2\cdot + O_2 \longrightarrow ArSO_2OO\cdot \quad (5)$$

$$ArSO_2OO\cdot + Et_3GeH \longrightarrow ArSO_2OOH + Et_3Ge\cdot \quad (6)$$

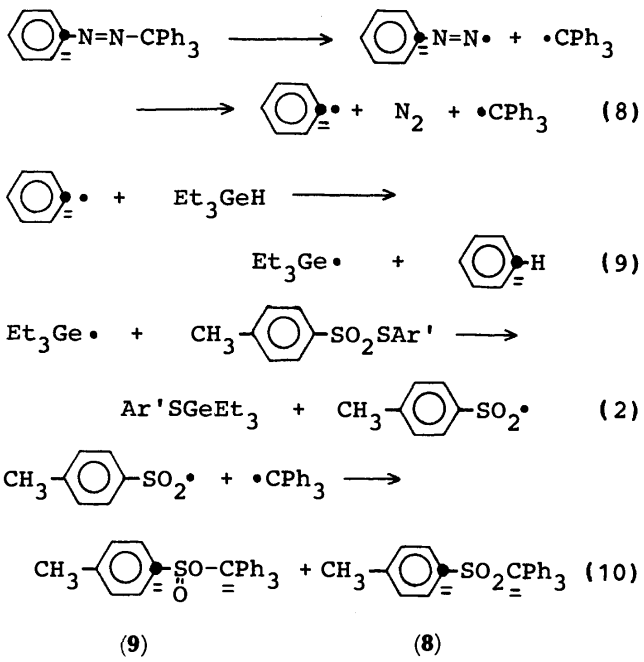
$$ArSO_2OOH + Et_3GeH \longrightarrow ArSO_2OGeEt_3 + H_2O \quad (7)$$

Reaction (Eq. 2) is an S_H2 type reaction. To establish the S_H2 character for such a reaction shown below;

$$R\cdot + X\text{-}Y \longrightarrow RX + Y\cdot$$

it is essential to certify the formation of RX in high yield and also to verify that the expelled fragment Y is ejected from the solvent cage as a free radical unaccompanied by any radical partner.

We have confirmed the generation of free sulfonyl radicals in the reaction (Eq. 2) by C-13 CIDNP. When a sample tube containing a solution of **2a** and equimolecular PAT in nitrobenzene was inserted into the NMR probe previously heated at 90°C, the CIDNP signals shown in Fig. 1a were observed. These signals were attributed to the phenyl carbon atom C_1 in the starting material PAT and also to the phenyl carbon atom C_1 in *o*- and *p*-nitrobiphenyl which were formed by the attack of the phenyl radical generated from PAT on the solvent nitrobenzene; same signals could also be observed in the decomposition of PAT alone in nitrobenzene. All the thiosulfonic *S*-ester (**2a**) was recovered unchanged after the complete consumption of PAT. On the other hand, when the reaction of **2a** and PAT was carried out in the presence of an equimolecular amount of triethylgermane at 90°C, new CIDNP signals due to benzene (emission), *p*-tolyl triphenylmethyl sulfone (**8**), triphenylmethyl *p*-toluenesulfinate (**9**) were observed as shown in Fig. 1b. The latter reaction may be explained by the following reaction scheme.



(= denotes the nuclear polarized carbon atoms)

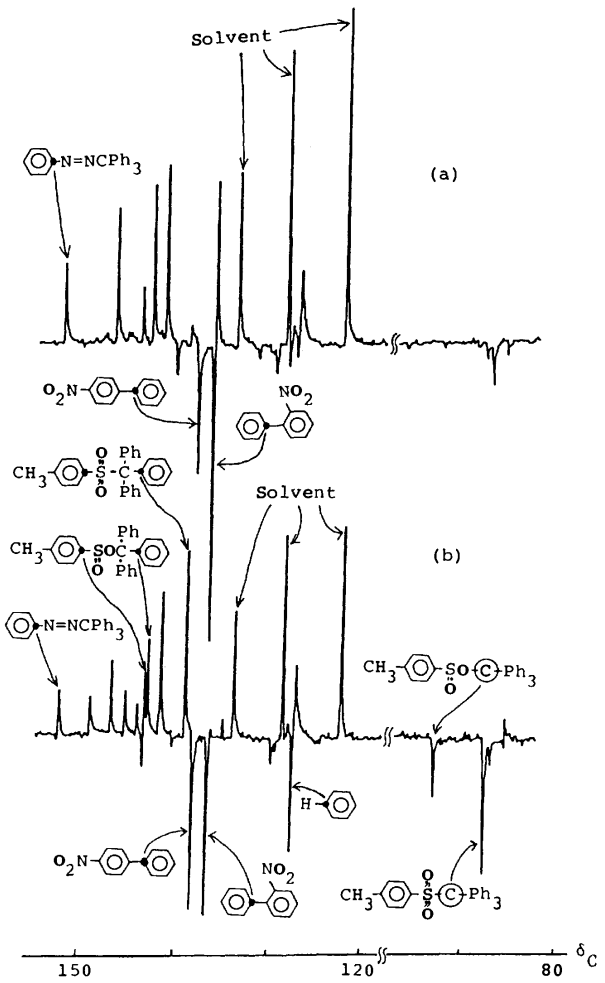


Fig. 1. ^{13}C-CIDNP spectra in the reaction of PAT and *p*-TolSO$_2$STol-*p* (a), and PAT, Et$_3$GeH, and *p*-TolSSO$_2$Tol-*p* (b) at 90°C in PhNO$_2$.

Since the nuclear spin of C_1 in the phenyl radical which diffused out of the solvent cage was polarized in β state, the benzene molecule formed by hydrogen abstraction from **3** should exhibit an emission signal. The germyl radical generated in this reaction (Eq. 9) attacked the sulfur atom of **2** to form thiogerman (**5**) and expelled a sulfonyl radical. The latter radical came diffused out of the solvent cage and reacted with a triphenylmethyl radical to form a new radical pair. Spin selection occurred during this encounter of the radical pair to result in nuclear β polarization at the tertiary carbon atom of the triphenylmethyl radical which had a smaller *g* value than the sulfonyl radical, thus causing an emission signal from the quarternary carbon atoms of **8** and **9**.

Se-Phenyl *p*-tolueneselenosulfonate (**1a**) is known to be decomposed easily by attack of carbon radicals on the selenium atom.[1] Reaction of **1a** with triethylgermane was also investigated.

Reaction between triethylgermane (**3**) and **1a** was found to proceed in the air without addition of any radical initiator, but in the presence of AIBN, the reaction was completed in a much shorter period. After the reaction, the triethylgermyl ester of *p*-toluenesulfonic acid (**4a**) and diphenyl diselenide (**10**) were obtained in almost quantitative yields.

$$Et_3GeH + p\text{-}TolSO_2SePh \xrightarrow[air]{AIBN} Et_3GeO\text{-}SO_2Tol\text{-}p + PhSeSePh$$
(**1a**) (**4a**) 93% (**10**) 98%

When the reaction was carried out under deoxygenated conditions, triethylgermyl sulfinate (**6a**), sulfone (**7**), and diselenide (**10**) were obtained.

$$Et_3GeH + (\mathbf{1a}) \xrightarrow[\text{In degassed tube}]{\text{AIBN (0.2 mol)}} Et_3Ge\text{-}O\text{-}S\text{-}Tol\text{-}p \quad (\mathbf{6a})\ 35\%$$
$$+ PhSeSePh + p\text{-}TolSO_2CMe_2 + (\mathbf{1a})\text{recovered}$$
$$\text{CN}$$
(**10**) 58% (**7**) 31% 23%

The reaction of the germyl radical with selenosulfonic *Se*-ester was considered to proceed similarly to the reaction of germyl radical and thiosulfonic *S*-ester:

$$Et_3Ge\cdot + (\mathbf{1a}) \longrightarrow Et_3GeSePh + p\text{-}TolSO_2\cdot \qquad (11)$$

The fate of the sulfonyl radical expelled was the same as in the case of thiosulfonic *S*-ester. Instead of phenylselenogermane (**11**), diphenyl diselenide (**10**) was isolated in high yield. In a separate experiment, it was confirmed that phenylselenogermane (**11**) reacted with selenosulfonic *Se*-ester (**1a**) to give **4a** and **10** in almost quantitative yields under atmospheric conditions (Eq. 12).

$$Et_3GeSePh + (\mathbf{1a}) \xrightarrow[O_2]{} p\text{-}TolSO_2OGeEt_3 + PhSeSePh \qquad (12)$$

Experimental

Materials. *Triethyl(p-tolylthio)germane (**5a**)*: To a solution of bromotriethylgermane (0.0209 mol) and *p*-toluenethiol (0.0209 mol) in 30 ml of benzene was added a solution of pyridine (0.0229 mol) in benzene (10 ml) at room temperature and stirred for 1.5 h. The precipitated pyridinium bromide was removed and the filtrate was washed with water, dried over anhydrous magnesium sulfate, and evaporated. The residue was purified by redistillation; yield 85%. Bp 121—122 °C/2 mmHg (1 mmHg=133.322 pa). Mass, *m/z* 284 (M^+); ^{1}H-NMR, 0.91—1.10 (m, 15H), 2.25 (s, 3H), 6.99, 7.26 (ABq, 4H, *J*=8.4 Hz); ^{13}C-NMR, 7.6, 8.6, 21.0, 129.3, 129.8, 134.9, 136.0.

*Triethyl(phenylthio)germane (**5b**)*: This was prepared from bromotriethylgermane and benzenethiol in a similar way to **5a**; yield 66%. Bp 105—107 °C/2 mmHg (lit,[4] 112—113 °C/1 mmHg). Mass, *m/z* 270 (M^+); ^{1}H-NMR, 0.90—1.07 (m, 15H), 7.05—7.47 (m, 5H); ^{13}C-NMR, 7.7, 8.6, 126.2, 128.4, 133.3, 134.9.

*Triethyl(phenylseleno)germane (**11**)*: To a solution of bromotriethylgermane (0.0299 mol) and equimolar benzeneselenol in 20 ml of benzene was added pyridine (0.0328 mol) in 10 ml of benzene under nitrogen stream at room temperature, and stirred for 1.5 h. After similar workup of the reaction mixture as for **5a**, **11** was obtained in 87% yield. Bp 130—132 °C/2 mmHg. Mass, *m/z* 316 (M^+); ^{1}H-NMR, 1.03 (s, 15H), 7.00—7.60 (m, 5H); ^{13}C-NMR, 8.1, 9.0, 125.7, 126.5, 128.5, 136.6.

Triethylgermyl p-*Toluenesulfonate (**4a**)*: A solution of triethylgermane (2.04 mmol) and *p*-toluenesulfonic acid (2.04 mmol) in toluene was refluxed for 24 h. After the evaporation of the solvent, the residue was purified by recrystallization from ethanol. Mp 69.5—70.0 °C. ^{1}H-NMR, 1.05—1.30 (m, 15H), 2.29 (s, 3H), 7.09, 7.56 (ABq, 4H, *J*=7.8 Hz); ^{13}C-NMR, 7.4, 9.1, 21.5, 126.5, 129.3, 137.9, 142.6; IR, (CCl_4), 1330, 1172 cm^{-1} (SO_2), 915 cm^{-1} (Ge-O).

*Triethylgermyl Benzenesulfonate (**4b**)*: This was prepared in a similar way to **4a**. Bp 185 °C/5 mmHg (lit,[5] 160 °C/1.3 mmHg. ^{1}H-NMR, 1.00—1.28 (m, 15H), 7.00—7.90 (m, 5H); ^{13}C-NMR, 7.3, 9.2, 126.4, 128.7, 132.2, 140.6; IR, (CCl_4), 1325, 1175 cm^{-1} (SO_2), 925 cm^{-1} (Ge-O).

Triethylgermyl p-*Toluenesulfinate (**6a**)*: This was prepared according to the literature.[6] ^{1}H-NMR, 1.08 (s, 15H), 2.31 (s, 3H), 7.22, 7.52 (ABq, 4H, *J*=7.8 Hz); ^{13}C-NMR, 7.5, 8.9, 21.4, 124.5, 129.4, 141.3, 148.1; IR, neat, 1120 cm^{-1} (S-O), 838 (Ge-O).

Cyanoisopropyl p-*Tolyl Sulfone (**7**)*: This was purified by recrystallization from methanol. Mp. 114—115 °C. ^{1}H-NMR, 1.67 (s, 6H), 2.43 (s, 3H), 7.36, 7.81 (ABq, 4H, *J*=8.4 Hz); ^{13}C-NMR, 21.1, 21.8, 57.5, 129.9, 130.4, 130.7, 146.5; IR, KBr, 1140, 1162, 1188, 1292, 1308, 1322 cm^{-1} (SO_2), 2240 cm^{-1} (CN); Anal. Found: C, 59.17; H, 5.95; N, 6.35%. Calcd for $C_{11}H_{13}NSO_2$: C, 59.17; H, 5.86; N, 6.27.

Thiosulfonic *S*-esters[7] and trietylgermane[8] were prepared according to the literature.

Reaction Between Triethylgermane and Thiosulfonic S-ester. Reaction in Air: A solution of triethylgermane (**3**) (1.0 mmol), thiosulfonic *S*-ester (**2a**) (0.5 mmol) and AIBN (0.2 mmol) in benzene (10 ml) was refluxed for 17 h. After the evaporation of the solvent under reduced pressure, the products were identified by ^{1}H- and ^{13}C-NMR.

Reaction Under Degassed Conditions: A solution of **2a** (0.622 mmol), **3** (0.622 mmol) and AIBN (0.124 mmol) in benzene (7 ml) was deoxygenated by a freeze-thaw cycle, sealed in an ampoule and heated at 80 °C for 38 h. The products were separated by column chromatography and identified by NMR.

CIDNP Measurement. Carbon 13 CIDNP was observed on JEOL FX-60 FT-NMR spectrometer at 90 °C; Ph-N=N-CPh_3 (C_1 of Ph: 152.1, A), Ph-$C_6H_4NO_2$-*p* (C_1 of Ph: 138.7, E), Ph-$C_6H_4NO_2$-*o* (C_1 of Ph: 137.3, E), *p*-$TolSO_2CPh_3$ (C_1' of Ph: 139.8, A, C_α: 87.3, E), and *p*-Tol(SO)$OCPh_3$ (C_1 of *p*-Tol: 141.0, A, C_α: 92.2, E, C_1' of Ph: 142.5, A).

Liquid Crystal Materials with Sulfur Atoms Incorporated in the Principal Structure III. Trans and Cis Isomers of New Liquid Crystal Material: 2-(*p*-Substituted phenyl)-5-alkyl-1,3-dithianes

Yuichiro HARAMOTO * and Hiroyoshi KAMOGAWA
Department of Applied Chemistry, Yamanashi University, Takeda 4, Kofu 400
(Received August 11, 1984)

Trans and cis isomers of 2,5-disubstituted 1,3-dithianes were synthesized by the acid-catalyzed thioacetalization of *p*-substituted benzaldehydes and dithiols. The results of identifications of trans and cis isomers made by means of ^{13}C-NMR chemical shifts indicate that the isomerism occurred at the 5 position in the 1,3-dithiane ring. Benzaldehydes with electrondonating *p*-substituents produced less cis isomers than that with the cyano group, which seems to indicate the establishment of an equilibrium in the formation reaction between trans and cis isomers. Several electro-optic properties of *trans*- and *cis*-2-(*p*-cyanophenyl)-5-alkyl-1,3-dithianes were determined by using them as a dopant of mixture of liquid crystals. Mixture added with trans isomers was superior to that added with cis isomers in several points.

In recent years, we have synthesized 2,5-disubstituted 1,3-dithianes and 1,3-oxathianes[2,3,4] as novel analogs of the 1,3-dioxanes now in practical uses.[1] These compounds were produced in both trans and cis isomers. Then we analyzed these two isomers by means of ^{13}C-NMR to determine which isomer was trans and at what position the isomerism occurred in the 1,3-dithiane ring.

In addition to this, we compared several physical properties of trans and cis 2-(*p*-cyanophenyl)-5-alkyl-1,3-dithianes by using them as a dopant of liquid crystal mixtures.

Results and Discussion

2,5-Disubstituted 1,3-dithianes were synthesized *via* the following route.

In step **3**→**5**, the ^{1}H-NMR of the product indicated a splitting of the singlet due to the C-2 proton of the 1,3-dithiane ring, which was caused by the presence of two isomers, both trans and cis. In compound R′=CN, separation of trans and cis isomers was successfully carried out either by recrystallizations from hexane or by centrifugal liquid chromatography (CLC).

In compounds R′=OR, or CH_3, separation of trans and cis isomers was done by recrystallizations (5—7 times) from hexane to get pure one isomer. The mother liquors were collected and several recrystallizations were further effected to isolate some of the other isomer. In ^{1}H-NMR, these two isomers have different signal patterns of CH_2–S: isomer A with a broad rugged singlet proton signal at δ=2.5—2.9 and isomer B with a broad quintet signal at δ=2.4—3.5 (Table 1).

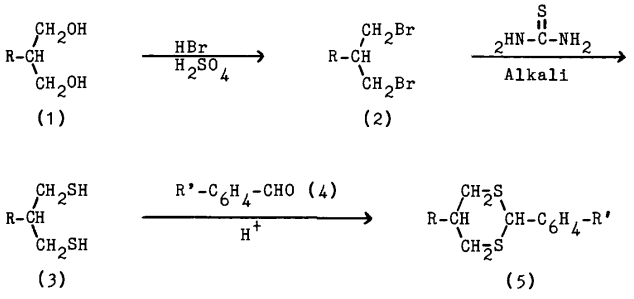

Fig. 1.

The ^{13}C-NMR characteristics of isomeric 2-(*p*-substituted phenyl)-5-alkyl-1,3-dithianes were investigated by means of the ^{1}H-complete decoupling (COM), ^{1}H-off resonance decoupling (OFR), and ^{1}H-selective decoupling (SEL) procedures. As C-2 and C-4, C-6 protons in the 1,3-dithiane ring show peculiar chemical shifts in ^{1}H-NMR, the ^{1}H-selective decoupling method was useful to determine the assignment in ^{13}C-NMR. In compounds R=C_2H_5, R′=CN, the difference in the ^{13}C-NMR chemical shift for the 1,3-dithiane ring carbons between isomers A and B (δ isomer A—δ isomer B) are 0.76 (C2), 1.79 (C4, C6), and 6.39 (C5) (Table 1).

These values indicate that the isomerism occurs at C5 with a large difference ($\Delta\delta$=6.39), and not at C2 ($\Delta\delta$=0.76).

In the ^{13}C-NMR data of 5-alkyl-1,3-dithiane, the C5 signal for 5-equatorial isomer lies at a lower magnetic field than that for 5-axial isomer.[5] Therefore, it is concluded that isomer A is 5-equatorial (trans) and B is 5-axial (cis).

With increasing purity, several trans isomers of this class began to exhibit the monotropic liquid crystal phase under a polarization microscope.[3] As two isomers (cis and trans) are white powder as produced, whereas two raw material compounds (**3**, **4**) are liquid, mixcd isomers are obtained in pure state after about two recrystallizations. At this point the mixture contains about 10% of cis isomer. This mixed isomer did not exhibit any liquid crystal phases. It is generally known that when two different liquid crystalline compounds with the same phase were mixed, the mixture exhibits the liquid crystal phase.[6] Therefore, cis isomer is considered to have no nematic liquid crystalline properties. In addition to this, some separable cis isomers (for example R=C_7H_{15}, R′=OC_2H_5; trans isomer of this compound exhibits the monotropic nematic liquid crystal phase: I 57 N 48 C) also did not exhibit any liquid crystal phases.

This fact supports that the cis isomers generally do not exhibit liquid crystal phases.

a) Determined gas-chromatographically Column: OV 17, 3m; Oven temp 250°C.

The production ratio of cis to trans isomers, as determined by means of gas chromatography (Table 2), seems to depend upon the kind of *p*-substituent (R') of compounds **5**. In step **3**→**5**, benzaldehyde **4** having the electron-donating substituent (R'), such as the alkyl and alkoxyl groups, produced much more C-5 equatorial isomer (trans) than C-5 axial isomer (cis). On the contrary, **4** with the electron-withdrawing substituent, such as the cyano group, produced both isomers in a nearly equal ratio.

This result is explainable as follows. In step **3**→**5**, possible configurations around C-5 and C-2 are as follows: C-5 Eq C-2 Ax, C-5 Eq C-2 Eq, C-5 Ax C-2 Ax, and C-5 Ax C-2 Eq. (Eq: equatorial, Ax: axial) As the C-2 substituent is the steric hindered *p*-substituted phenyl group, C-2 Ax should be converted to the more stable state C-2 Eq through the next equilibration

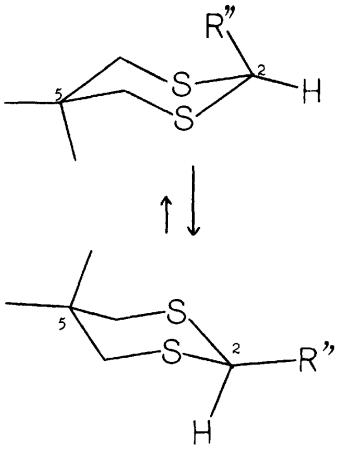

Fig. 2.

(Fig. 2).

Namely, C-5 Eq C-2 Ax and C-5 Ax C-2 Ax are converted to C-5 Ax C-2 Eq and C-5 Eq C-2 Eq, respectively. Therefore, C-2 configuration becomes all Eq. and the ratio of trans (C-5 Eq C-2 Eq) to cis (C-5 Ax C-2 Eq) should become nearly equal to unity. Nevertheless, in the 1,3-dithianes with the *p*-electron-donating phenyl group, trans isomers are produced more than cis isomers. In the 1,3-dithianes with the p-electron-donating phenyl group, the backward reaction of cis to trans may occur more readily owing to the reversible nature of the 1,3-dithiane ring formation and the stabilization of the carbocation at C-2 due to

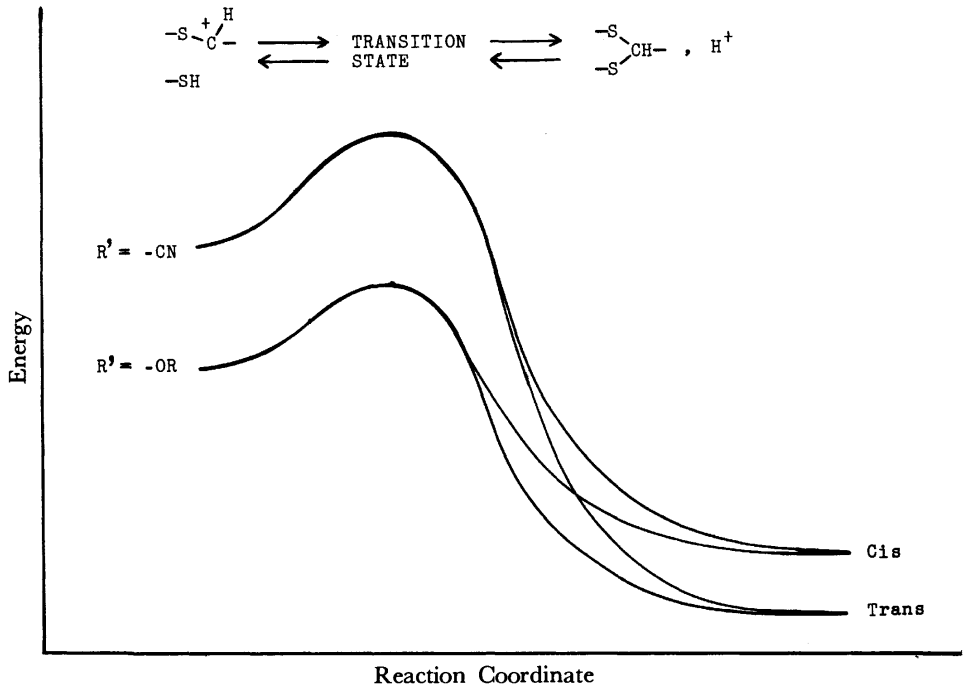

Fig. 3.

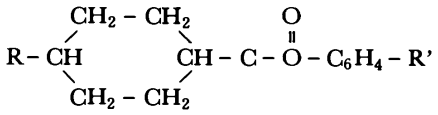
TABLE 3. COMPOSITION OF LIQUID CRYSTAL MIXTURE

	Mixture T (trans) mol/%	Mixture C (cis) mol/%
[a]Base mixture	90	90
R=C_2H_5	5	5
R=n-C_4H_9	5	5

a) Composition of base liquid crystal mixture (Base mixture)

R	R'	mol/%
n-C_3H_7	OC_2H_5	8.8
n-C_3H_7	$OC_4H_9^n$	20.9
n-C_4H_9	OCH_3	17.9
n-C_4H_9	OC_2H_5	17.2
n-C_5H_{11}	OCH_3	18.7
C_2H_5-C_6H_4-COO-C_6H_4-CN		5.5
$C_4H_9^n$-C_6H_4-COO-C_6H_4-CN		5.5
$C_5H_{11}^n$-C_6H_4-C_6H_4-C_6H_4-CN		5.5



the electron -donation by R' (Fig. 3). Thus, this backward reaction (cis to trans) is equilibrium controlled,[7] energetically more favorable trans isomer will be produced in a higher ratio than cis isomer. In 1,3-dithiane with the *p*-cyanophenyl group, the electron-withdrawing substituent (CN) destabilizes the carbcation at C2, so that the activating energy of the backward reaction is too large to make the reaction thermodynamically-controlled.

Several electro-optic properties of *trans*-and *cis*-2-(*p*-cyanophenyl)-5-alkyl-1,3-dithianes by using them as a dopant of a mixture of liquid crystals were given in Table 4. And the compositions of mixture T (trans) and mixture C (cis) were given in Table 3. Threshold

TABLE 4. ELECTRO-OPTIC AND OTHER RELEVANT PROPERTIES

Threshold voltage (Vth)	Mixture T (trans) 1.82 V	Mixture C (cis) 1.69 V
Rising time (T_r)	100 m s	84 m s [c]
Decay time (T_d)	70 m s	89 m s
Birefringence (Δn)	0.103	0.090
Dielectric anisotropy ($\Delta\varepsilon$)	+5.37	+4.56
Steepness factor[a]	1.34	1.36
Temperature dependence[b]	0.35%/°C	0.53%/°C

a) Steepness factor=Vsat/Vth. b) Temperature dependence=$-1/V\text{th}(dV\text{th}/dT)$ Vth: threshold voltage, Vsat: saturated voltage c) Von=4 volt, Voff=0 volt.

voltage (Vth), rising time (T_r), decay time (T_d), birefringence (Δn), dielectric anisotropy ($\Delta\varepsilon$), steepness factor and temperature dependence of Vth were measured in mixture T and mixture C respectively.

Threshold voltage (Vth) of mixture C (cis) is smaller than that of mixture T (trans). Generally, Vth is proportional to the square root of $K/\Delta\varepsilon$.[8] (K: elastic constant). In mixture C, axial alkyl chain should weaken the interactions among liquid crystal molecules, so that K of mixture C seems to be smaller than that of mixture T. But $\Delta\varepsilon$ of mixture T is somewhat larger than that of mixture C. The result obtained for Vth must imply that K had larger influence than $\Delta\varepsilon$.

Rising time (T_r) of mixture T is longer than that of mixture C.

Generally, T_r is proportional to $\eta/(\Delta\varepsilon V^2 - K\pi^2)$.[9] Viscosity ($\eta$) of mixture containing 2 mol% of trans isomers (R=C_2H_5, C_4H_9) is 11 cp (25 °C), and that of cis isomers (R=C_2H_5, C_4H_9) is 13 cp. So η of mixture T is somewhat smaller than that of mixture C. Therefore values of viscosity (η) and $\Delta\varepsilon$ are support reverse result of T_r. But K of mixture C seems to be smaller than that of mixture T as written above. The result obtained for T_r must imply that difference of K had larger influence to T_r than differences of $\Delta\varepsilon$ and η. Since decay time (T_d) is proportional to η/K,[9] it is reasonable that the T_d of mixture T having larger K and smaller η is shorter than that of mixture C. In birefrigence (Δn), the value for mixture C is smaller than that for mixture T, so that mixture C must use a somewhat thick cell to gain a sufficient contrast. The facts that $\Delta\varepsilon$ of mixture T is somewhat larger, steepness factor is also superior, and temperature dependence is smaller, indicate that mixture T is superior to mixture C.

Experimental

IR, ^{1}H-NMR, ^{13}C-NMR, and mass spectra were obtained with a Hitachi 215 spectrophotometer, a JNM-PMX 60 spectrometer, a JNM-FX 90Q FT-NMR spectrometer, and a Hitachi RMU-6 MG spectrometer, respectively. Elemental analyses were carried out with a Perkin-Elmer 250 instrument. Centrifugal liquid chromatography was made with a Hitachi CLC-5 apparatus. Transition temperature and mesomorphic phases were determined by means of both a Mitamura Riken micro melting point apparatus equipped with polarizers and Rigaku Denki D.S.C. CN8059L1, CN8208A2. The viscosity (η) and dielectric anisotropy ($\Delta\varepsilon$), and birefringence (Δn) of liquid crystal mixtures were measured using a Tokyo Keiki E type rotating cone viscometer, a Yokokawa Hewlett Packard 4274A multi frequency LCR meter, and a Hitachi 340 spectrometer, respectively.

The measurement of liquid crystal properties are carried out by using 9.4 μm twisted nematic cells to ensure good guiding of the plane of polarization. Syntheses and detailed analytical data of compounds **1**, **2**, **3**, and **5** were written in a previous paper.[3] ^{1}H-NMR and ^{13}C-NMR data of separable cis and trans isomers are in Table 1.

The authors wish to express their gratitudes to Suwa Seikosha Co., Ltd. for extensive assistances in the measurement of liquid crystal properties.

Charge-transfer Complexes, Gas-liquid Chromatographic and Photochemical Characteristics, and Solvent Adducts of Polyphenylenes and Related Linear Polyphenyls[1)]

Yasuhiro FUJIOKA
Kyoto Pharmaceutical University, Misasagi-nakauchi-cho, Yamashina-ku, Kyoto 607
(Received May 12, 1984)

The absorption spectra of the charge-transfer (CT) complexes formed by two acceptors (tetracyanoethylene and 2,3-dichloro-5,6-dicyano-*p*-benzoquinone) with thirteen macrocyclic polyphenylenes and with thirty-eight linear polyphenyls were measured in dichloromethane. A linear relationship existing between the first transitions of the CT-complexes and those of the uncomplexed donor hydrocarbons made it possible to predict the CT-bands of new polyphenylenes and polyphenyls. By the gas-liquid chromatography using a glass capillary column, forty-nine polyphenyls and polyphenylenes, containing a large number of isomers, were successfully analyzed. The relationship between the retention times and the structure of linear polyphenyls was expressed by means of a simple empirical equation, and the equation was also applicable to the polyphenylenes by adding a correction factor. These equations are extremely useful for the estimation of the retention time and elution order and the structure of unknown polyphenyls and polyphenylenes. The reductive irradiation of *m,m,o,p,o*-pentaphenylene provided the bridged annulene compound. For six polyphenylenes and the related compounds, the criteria for the occurrence of the intramolecular photocoupling reaction were discussed. Among the examined polyphenylenes, *m,o,o,m,o,o*-hexaphenylene and *o,p,p,o,p,p,o,p,p*-nonaphenylene formed the adducts with several solvents.

In the preceding paper[2)] fourteen macrocyclic polyphenylenes have been synthesized to elucidate the relationship between the structures (the number and arrangement of the phenylene rings) and the physical properties such as infrared (IR), ultraviolet (UV), proton magnetic resonance (^{1}H NMR), and mass (MS) spectra on a series of linear and branched polyphenyls.[3)] The polyphenylenes have been characterized by the structure, in which both terminal rings of polyphenyls were linked to each other so that the rotation of pivot bonds was restricted significantly due to their rigid geometry. The results have indicated that the ^{1}H NMR and UV spectral studies provided useful conformational information, and the Hückel molecular orbital (HMO) calculations of the longest-wavelength absorption bands of polyphenylenes also gave additional grounds for their conformation deduced from their spectral data and Dreiding stereomodels.

The present study was undertaken to investigate several chemical behaviors of thirteen polyphenylenes {*m,m,o,p,o*-pentaphenylene (**1**); *m,m,o,m,m,o*- (**2**), *m,o,o,m,o,o*- (**3**), *o,o,p,o,o,p*- (**4**), *m,o,p,m,o,p*-(**5**), *o,p,o,p,o,p*-(**6**), *m,o,p,o,p,o*- (**7**), *m,o,m,o,m,o*- (**8**), *m,m,m,o,m,o*-(**9**), and *m*-hexaphenylene (**10**); *m,o,p,p,o,m,p*- (**11**) and *m,m,m,m,p,o,p*-heptaphenylene (**12**); and *o,p,p,o,p,p,o,p,p*-nonaphenylene (**13**)} as well as those of the closely related linear polyphenyls (**14**—**53**). So far, several studies have been reported on the charge-transfer (CT) complexes of biphenyl and three terphenyls,[4)] on the photodehydrocyclization of several *o*-terphenyl-type compounds,[5)] and further on the gas chromatographic analysis of linear and branched polyphenyls,[6)] but none on those of polyphenylenes. On the gas-liquid chromatography (GLC) of aliphatic or monocyclic compounds, it has been known that the "retention index" by Kováts serves to estimate their structure.[7)] Karger *et al.*[8)] and Ono[9)] have reported the applicability of the Hammet Equation for GLC using the series of isomers of phenols and anilines and of alkyl benzenes, respectively. In a programmed-temperature gas chromatography Solomon has suggested a relationship between elution temperatures and structures of polyphenyls, but their analytical conditions and the complex additive terms are to be improved.[6a)]

The CT-complexes have been formed by the donor hydrocarbons with two acceptors (tetracyanoethylene (TCNE) and 2,3-dichloro-5,6-dicyano-*p*-benzoquinone (DDQ)) in dichloromethane, and the relationship between the longest-wavelength absorption bands of the CT-complexes and those of the uncomplexed donors has been discussed. The gas-liquid chromatographic analysis of the polyphenylenes and polyphenyls has been performed and the relationship between the structures (the number and arrangement of the benzene rings) and the retention time has been formulated. In addition, the intramolecular photocoupling reactions and solvent adduct formations of polyphenylenes have also been discussed.

Results and Discussion

Charge-transfer Complexes. The CT-complexes between the donors (thirteen polyphenylenes (**1**—**13**) and thirty-eight related polyphenyls (**14**—**34**, **36**—**41**, and **43**—**53**)) and two acceptors (TCNE and DDQ) were prepared in dichloromethane[10)] and their absorption spectra were determined. The CT-complexes, which were characterized by the intensely colored solutions (orange to greenish blue), showed generally plural absorption bands for TCNE[12)] and only one band for DDQ. Tables 1 and 2 list the longest-wavelength absorption (first) CT-bands of the polyphenylenes and polyphenyls, respectively, and also the first bands of each uncomplexed hydrocarbon. Now the observed first transition energies (E_{ct}) for the CT-complexes are plotted against the observed first π-π^* transition ener-

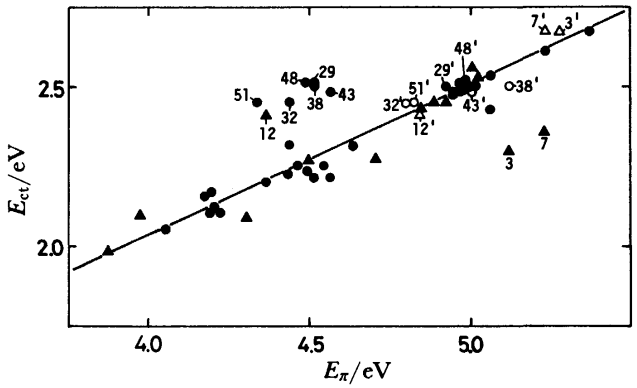

Fig. 1. Plot of the transition energy (E_{ct}) for the first CT-band of TCNE-donor complex *vs.* the energy (E_π) for the first π-π^* transition of the donor; the points are numbered according to the compound number in Tables 1 and 2; ●: Linear polyphenyls, ▲: polyphenylenes.

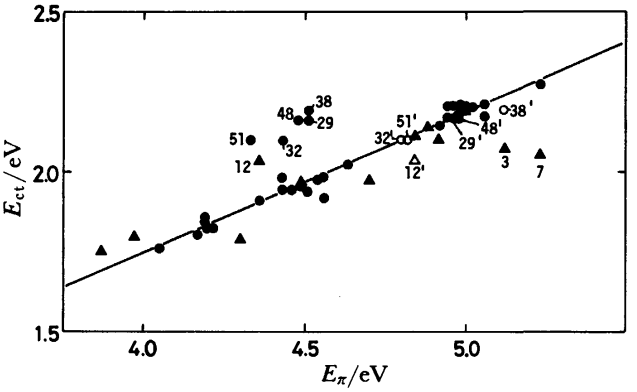

Fig. 2. Plot of the transition energy (E_{ct}) for the first CT-band of DDQ-donor complex *vs.* the energy (E_π) for the first π-π^* transition of the donor; the points are numbered according to the compound No. in Tables 1 and 2; ●: Linear polyphenyls, ▲: polyphenylenes.

gies (E_π) for the donor hydrocarbons (Figs. 1 and 2).

In Fig. 1, all but nine of the points lie approximately on a straight line (slope=0.47).[13] This linear relationship between E_{ct} and E_π is similar to that found previously for the CT-complexes between polycyclic aromatic hydrocarbons and trinitrofluorenone and defined by the following Eq. 1.[14]

$$E_{ct} = (1/2)E_\pi + C, \quad (1)$$

where C is a constant for the acceptor such as TCNE or DDQ.

The deviation of the values for compounds (**12**, **29**, **32**, **38**, **43**, **48**, and **51**) from the straight line is probably due to the obscurity of their real first CT-bands, because their first CT-bands were broad at the longer-wavelength side, and their E_{ct} were correlated to the energies of the second bands for the uncomplexed donors, in which all the first bands were observed as a shoulder or an inflection (the points with primed numbers in Fig. 1). For compounds, **3** and **7**, the deviation cannot be explained, even though the energies of the second CT-bands (465 and 460 nm, respectively) were

correlated to the energies of the second (235 nm) and first (237 nm) bands of the donors.[2]

An analogous correlation was observed between the CT-bands of DDQ-complexes and the first bands of the uncomplexed donors (Fig. 2; the slope of the fitted straight line=0.43).[15]

The foregoing results indicated that the polyphenylenes (containing 5—9 benzene rings) and polyphenyls (containing 2—6 benzene rings) formed the weak CT-complexes with TCNE or DDQ in solution, and an approximately linear relationship with a slope of one-half existed between the first transitions of the CT-complexes and those of the uncomplexed donors. Consequently, these results made it possible to predict the CT-bands of new polyphenylenes and polyphenyls.

Gas-liquid Chromatographic Characteristics. The retention times (t_R) of nine polyphenylenes (**1—9**) and a series of polyphenyls (**14—53**), having high boiling points and a large number of isomers, were determined at 5—15 different column temperatures (70—340 °C) using a glass capillary column (Dexsil 300GC as liquid phase).[16] For comparison the t_R at the same column temperature were calculated using Eq. 2

$$\log t_R = A \times 1/T + B \quad (2)$$

and the least squares method.[17] The log t_R at 250 °C thus determined are shown in Tables 3 and 4.

To investigate the structure-retention time correlation of the polyphenyls and polyphenylenes, the retention indexes (R_I) were firstly obtained as a simple difference between the log t_R of each polyphenyl and biphenyl (**14**) as a standard. Then, the comparison between the R_I-values of three terphenyls (**15—17**) and that of **14** gave the following estimated values for each phenylene unit: *o*- (0.74), *m*- (1.17), and *p*-phenylene (1.23). Further, by introduction of the correction factor

a) Refer to the footnote b) to Table 3.

for the number of the phenylene ring, $(0.96)^{n-1}$ (n: the total number of phenylene rings), following empirical Eq. 3 was obtained.

$$R'_I = (0.96)^{n-1} \times (0.74x+1.17y+1.23z+\alpha), \quad (3)$$

where x, y, and z are the number of *o*-, *m*-, and *p*-phenylene rings constituting each polyphenyl, respectively, and α is the correction factor for the substitution pattern of the phenylene rings. The values are estimated as follows: −0.01, −0.12, and −0.11 for an *o*-, *m*-, and *p*-phenylene rings adjacent to the *o*-phenylene ring, respectively, and +0.11 for a *m*- or *p*-phenylene ring adjacent to the *p*-phenylene ring.

The R'_I-values calculated by Eq. 3 are in good agreement with the experimental R_I-values (Table 3). The results are also confirmed by the approximate linear relation of the log t_R values to the R'_I-values (Fig. 3).[18] Care must be taken in appling indiscriminately a variety of analytical conditions. However, when unknown polyphenyls were bracketed with polyphenyls of known retention indexes, empirical Eq. 3 is useful for the estimation of the retention time, the elution order and the presumption of their structures.

Meanwhile the data of nine polyphenylenes (penta- and hexaphenylenes) are also listed in Table 4, which differ from the linear polyphenyls in not having both terminal rings. Empirical Eq. 4 for the polyphenylenes was derived from Eq. 3 by adding a new correction factor (β=−1.20).

$$R''_I = (0.96)^{n-1} \times (0.74x+1.17y+1.23z+\alpha) + \beta \quad (4)$$

The R''_I-values calculated by Eq. 4 are in fair agreement with R_I- or log t_R-values obtained from the experimental values except for compounds **3**, **4**, and **9** (Table 4 and Fig. 3). These results can be explained by the fact that compounds **1**, **2**, and **5**—**8**, showing a good agreement with experimental values, are nonplanar due to a spacial overcrowded conformation, while other compounds **3**, **4**, and **9** are more planar in the vapor phase.

Furthermore, when the R_I-values of the polyphenylenes were compared with those of the corresponding linear analogues (Table 5), the former gave approximately the same or somewhat larger R_I-values than the latter, except for **4** and **9** which showed clearly larger

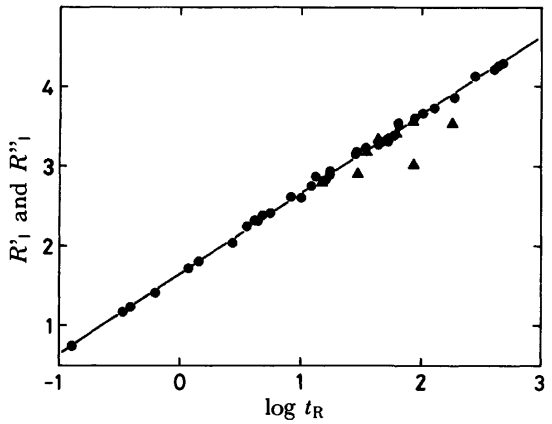

Fig. 3. Plot of the log of the retention time (log t_R) *vs.* the calculated retention index (R'_I and R''_I); ●: Linear polyphenyls, ▲: polyphenylenes.

values. That is to say, by the cyclization of the linear polyphenyls to the macrocyclic analogues the retention times were hardly affected or slightly delayed.

Foregoing results indicated that the relationship between the number and arrangement of benzene rings and the retention times of polyphenyls and polyphenylenes could be expressed by simple empirical equations, respectively. Both equations are very useful for the prediction of the retention time, elution order and the presumption of structures of unknown polyphenylenes and polyphenyls.

Photo-aryl Coupling Reaction. The bridged-annulene formation and photodehydrocyclization were examined by UV irradiation under degassed and oxidative conditions for compounds **1**, **5**, **6**, **9**, and **11**—**13** (except for **12** and **13** under the former conditions). Of these polyphenylenes, **1** and **6** correspond respectively to the di- and tribenzo analogues of the cyclophanes (**54** and **55**), for which the formation of the bridged annulenes (**54a** and **55a**) have been reported by Boekelheide *et al.*[19] (Scheme 1). In these attempts, the reductive coupling of **1** and the oxidative coupling of **1** and **6** gave the desired products, but other coupling reactions examined were unsuccessful.

When the degassed solution of **1** was irradiated, its color became immediately reddish orange (new absorption bands appeared at 372 (sh), 386, 468, and 498 nm) and then reddish orange needles (**1a**)

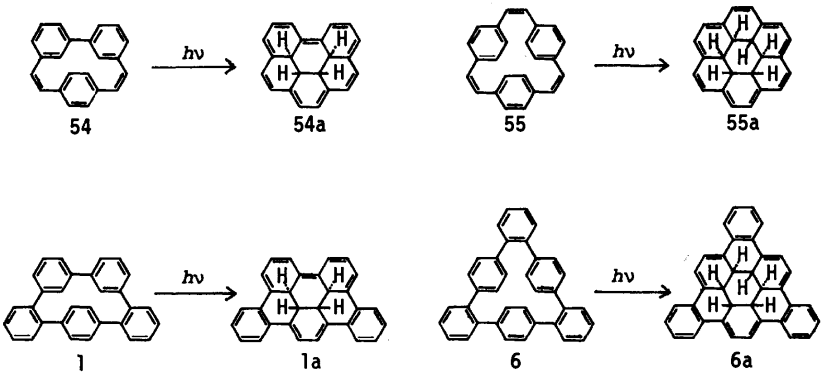
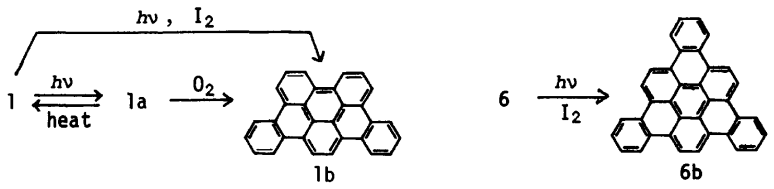


Scheme 1.



Scheme 2.

precipitated on prolonged irradiation.[20] On heating the colored solution or after standing it overnight at room temperature, it returned to the original colorless solution with the disappearance of the crystals. The reversible change was also confirmed by their absorption spectra.[21] On the other hand, in the presence of oxygen the irradiation yielded stable yellow needles (**1b**) *via* a reddish orange solution. The dehydrocyclized compound **1b** was also obtained by the photocoupling in the presence of iodine, and the absorption spectrum (λ_{max}: 228 (sh), 234, 256 (sh), 289, 300, 333, 349, 362, 368, 385, and 397 nm) was clearly distinguishable from those of **1** and **1a**.[22] The foregoing conversions can be reasonably summarized as shown in Scheme 2.

The irradiation of **6** gave dehydrocyclized compound **6b** in the presence of iodine, but not bridged annulene **6a** under the degassed conditions (Scheme 2).[24]

In connection with the photocoupling reactions of stilbene- and *o*-terphenyl-type compounds, the principal reasons for the occurrence of the coupling are summarized as follows: 1) the electron density on the carbon atoms undergoing coupling,[26] 2) the steric factors,[5a,c] 3) the nonexistence of the intermediate dihydro structures,[27] 4) the sum of the free valence numbers in the first excited state ($\sum Fr^*$) obtained for the atoms undergoing coupling and the localization energy (L^*).

The latter is the difference between the π-electron energy in the first excited state of the starting compound and that in the ground state of the intermediate dihydro derivative of the end product.[5c,27,28] Laarhoven *et al.*[5c], and Sato and Morita[28b] have independently carried out the calculation of the $\sum Fr^*$- and L^*-values by the HMO-method, and presented the critical values for the occurrence of the photocoupling: $\sum Fr^* > 1$ and $L^* < 3.45$, and $\sum Fr^* > 0.95$ and $L^* < 3.54$, respectively.

In order to consider the occurrence of the photocoupling reactions, the $\sum Fr^*$- and L^*-values of the polyphenylenes (**1**, **5**, **6**, **9**, **11**, and **12**), as well as those of the closely related compounds (**54**—**62**)[19,29] were calculated by the HMO-method (Table 6).

These values ($\sum Fr^*$ and L^*) indicate that the results of the photocoupling of the polyphenylenes and the related compounds may be explained on the basis of the criteria proposed by Sato and Morita, except for **6**, **9** and **55**. The photocoupling exceptions (**6** and **55**) may be correlated to the structures, in which three *p*-phenylene rings are fixed by three coplanar linkage. Meanwhile the uncoupled exception (**9**) is reasonably explained by the steric hindrance.

The foregoing results have indicated that the reaction indices ($\sum Fr^*$ and L^*) are useful as a measure for the occurrence of the photocoupling of macrocyclic polyphenylenes and cyclophanes with the coupling position on the macroring.

Formation of the Solvent Adducts. As described above, all the investigated aromatics formed the CT-complexes based on the weak affinity between the π-electrons of the donor and acceptor. Rapson *et al.* have previously reported the adduct-formation between *o*-tetraphenylene and a few solvents.[30] In the present study the formation of solvent adducts of the polyphenylenes was examined for several solvents, which is presumably due to the dipole-dipole interaction.

Among seven polyphenylenes (**1**—**6** and **13**) investigated, two compounds (**3** and **13**) formed successfully the adducts with several solvents, except for **3**-*m*-xylene and **13**-aniline. The thermogravimetric data are given in Table 7. The molar ratios of **3**-solvent adducts were 1:1 except for **3**-benzene (1:2), while those of **13**-solvent adducts were 1:2 except for **13**-*p*-xylene and **13**-pyridine (1:1). When some adducts (*e.g.*, **3**-benzene and **13**-*m*-xylene) were allowed to stand overnight in air at room temperature, the transparent

aniline	109	16.9	1.0		0	

a) Temperature at which the maximum weight decrease in the DTG curve is observed. b) Adduct-formation temperature (%, mol): >60°C (0.22, 0.01); >50°C (0.41, 0.02); >40°C (2.54, 0.11); >30°C (15.76, 0.80); <30°C (17.10, 0.90).

crystals became opaque, and after a longer time disintegrated gradually to powder with the release of solvents. However, the adducts such as **3**-*p*-xylene and **13**-benzene were appreciably stable, especially in a tightly stoppered tube. The facts may be correlated to the solvent release temperatures of the adducts. Furthermore, for the **3**-*o*-xylene adduct the experimental results shown in Table 7 (footnote b) were obtained. Thus, **3** and *o*-xylene gave the approximately 1:1 adduct at temperatures under 30°C, but no adduct above 60°C. Consequently the formation of the adduct is obviously related with the solvent release.

The foregoing results suggested that the solvent adduct formation was limited to the particular polyphenylenes. Hence the adduct formation is different from the charge-transfer complex formation, and does not have an obvious correlation with the structures.

Experimental

Instruments. Melting points were determined with a Shimadzu DSC-30M differential scanning calorimeter. The absorption spectra were measured on a Shimadzu UV-240 spectrophotometer, and IR spectra on a Leitz III-G spectrophotometer. The molecular weights were determined with a Hitachi RMU-6MG mass spectrometer. The gas-chromatographic analyses were performed on a Shimadzu GC-7A gas chromatograph equipped with a flame ionization detector. The solvent releases of the adducts were measured by thermogravimetry using a Shimadzu TGA-30M thermogravimeter equipped with a Differentiator TD-30. The HMO calculations were carried out on Hewlett-Packard HP-85 or NEC PC-9801 personal computer.

Materials. The following polyphenylenes used were the authentic samples prepared previously[2]: *m,m,o,p,o*-pentaphenylene (**1**); *m,m,o,m,m,o*- (**2**), *m,o,o,m,o,o*- (**3**), *o,o,p,o,o,p*- (**4**), *m,o,p,m,o,p*- (**5**), *o,p,o,p,o,p*- (**6**), *m,o,p,o,p,o*- (**7**), *m,o,m,o,m,o*- (**8**), *m,m,m,o,m,o*- (**9**), and *m*-hexaphenylene (**10**); *m,o,p,p,o,m,p*- (**11**) and *m,m,m,m,p,o,p*-heptaphenylene (**12**); and *o,p,p,o,p,p,o,p,p*-nonaphenylene (**13**). Commercially available biphenyl (**14**) and terphenyls (**15**—**17**) were purified before use. Quater- to sexiphenyls (**18**—**53**) used were the authentic samples prepared previously.[3a-d,f] Commercially available tetracyanoethylene (TCNE) and 2,3-dichloro-5,6-dicyano-*p*-benzoquinone (DDQ) were purified before use, and dichloromethane (spectral-grade) was used without further purification.

Electronic Spectroscopic Measurements of Charge-transfer Complexes. Solutions of the complexes were prepared by dissolving the donors (0.005—0.05 mmol) in the acceptor-solution (10 ml) of known concentration (TCNE or DDQ; 0.01—0.1 mol/l) in dichloromethane, except for several sparingly soluble donors, for which they were prepared by saturating in the similar acceptor solution. The absorption spectra were measured in a 1- or 10-cm cell for the range 350—900 nm. The most reliable absorption maxima were obtained by the several determinations using the different concentrations of the two components or by the differential spectra with the acceptor absorption in known concentration.

Determination of Retention Times on the Gas-chromatographic Analyses. The retention times of polyphenyls and polyphenylenes were determined for 5 to 15 appropriate column temperatures in the range of 70—340°C and were corrected using methane gas. The samples were used as a benzene solution of approximately the same concentration except for a few less soluble compounds. The logarithm of retention time obtained (log t_R) was plotted against the reciprocal of the column temperature (T^{-1}, absolute temperature). All of the plots showed a linear relation[17] which was employed for the calculation of the t_R at 250°C. Other analytical conditions were as follows. Column: Dexsil 300GC glass-SCOT 10 m×0.3 mmϕ; acuracy of column temperature: ±0.1°C; carrier gas: He; flow rate: 0.70 ml/min; inlet pressure: 0.4 kg/cm^2; sprit ratio: 60:1; make-up gas: 40 ml.

Irradiation of the Degassed m,m,o,p,o-*Pentaphenylene (1) Solution.* A cyclohexane solution of **1** (8.97×10^{-5} mol/l) in a quartz cell (12 mmϕ) was carefully degassed, sealed, and irradiated using a low-pressure mercury lamp (2537 Å). After a short time the colorless solution turned into a reddish orange one, and the absorption spectrum showed an intensity decrease of the characteristic band (at 237 nm) of **1**, with an appearance of the additional bands of **1a** at 372 (sh), 386, 468, and 498 nm. After two minutes irradiation the solution showed no further change. When the irradiated colored solution was heated or allowed to stand overnight at room temperature, the solution turned into the original colorless one showing identical absorption spectrum.

The similar 5 minutes irradiation of **1** in a cyclohexane solution in the presence of air gave a pale yellow solution with the characteristic bands of **1b** at 228 (sh), 234, 256 (sh), 300, 333, 349, 362, 368, 385, and 397 nm, *via* a reddish orange

solution of **1a**.

Irradiation of m,m,o,p,o-*Pentaphenylene (1) in the Presence of Iodine.* A mixture of **1** (114 mg) and iodine (76 mg) in benzene (17 ml) was irradiated in a quartz cell under nitrogen atmosphere using a 500 W high-pressure mercury lamp for 20 h. The recrystallization of the product from xylene gave tribenzo[*b,n,pqr*]perylene (**1b**) as yellow needles; mp 390°C (lit,[31] 380°C); 107 mg (95%). IR: 697 w, 710 vw, 728 vw, 747 vs, 758 vs, 761 sh s, 799 s, 823 m, 833 vw, 838 vw, 857 w, 864 vw, 872 vw, 890 w, 899 cm^{-1} w. UV: $\lambda_{max}(\varepsilon)$ 228 (sh) (80700), 234 (103500), 256 (sh) (23100), 289 (74100), 300 (99500), 333 (15600), 349 (28400), 362 (27900), 368 (34200), 385 (2100), and 397 nm (600). (Found: C, 95.44; H, 4.50%; M^+, 376).

Irradiation of o,p,o,p,o,p-*Hexaphenylene (6) in the Presence of Iodine.* The irradiation of the solution of **6** (137 mg) and iodine (76 mg) in benzene (17 ml) was carried out in the same manner as **1**. The recrystallization of the product from dimethyl sulfoxide gave tribenzo[*a,g,m*]coronene (**6b**) as yellow needles; mp 550°C; 130 mg (96%). IR: 686 w, 747 vs, 753 sh s, 790 w, 811 s, 822 w, 827 m, 833 w, 858 w, 880 cm^{-1} w. UV: λ_{max} 221, 242, 254, 260, 300 (sh), 310, 323, 339, 348, 355, 363 nm. Found: C, 95.89; H, 4.00%; M^+, 450. Calcd for $C_{36}H_{18}$: C, 95.97; H, 4.03%; M^+, 450.

Solvent Adduct Formations of m,o,o,m,o,o-*Hexaphenylene (3) and* o,p,p,o,p,p,o,p,p-*Nonaphenylene (13).* The polyphenylenes, **3** and **13**, were crystallized from the following solvents: benzene, toluene, *o*-, *m*-, and *p*-xylene, pyridine, and aniline. They were crystallized out as solvated forms from each of the solvents, except for **3** from *m*-xylene and **13** from aniline.

3-Benzene: one-to-two adduct, colorless transparent plates. Found: C, 94.13; H, 5.94%. Calcd for $C_{36}H_{24}\cdot 2C_6H_6$: C, 94.07; H, 5.93%.

3-Toluene: one-to-one adduct, colorless transparent cubes. Found: C, 94.15; H, 5.90%. Calcd for $C_{36}H_{24}\cdot C_7H_8$: C, 94.12; H, 5.88%.

3-*o*-Xylene: one-to-one adduct, colorless transparent cubes. Found: C, 94.01; H, 6.08%. Calcd for $C_{36}H_{24}\cdot C_8H_{10}$: C, 93.91; H, 6.09%.

3-*p*-Xylene: one-to-one adduct, colorless transparent plates. Found: C, 93.95; H, 6.15%. Calcd for $C_{36}H_{24}\cdot C_8H_{10}$: C, 93.91; H, 6.09%.

3-Pyridine: one-to-one adduct, colorless transparent plates. Found: C, 92.00; H, 5.55; N, 2.60%. Calcd for $C_{36}H_{24}\cdot C_5H_5N$: C, 91.93; H, 5.46; N, 2.61%.

3-Aniline: one-to-one adduct, colorless plates. Found: C, 91.85; H, 5.61; N, 2.51%. Calcd for $C_{36}H_{24}\cdot C_6H_7N$: C, 91.77; H, 5.68; N, 2.55%.

13-Benzene: one-to-two adduct, colorless transparent cubes. Found: C, 94.33; H, 5.80%. Calcd for $C_{54}H_{36}\cdot 2C_6H_6$: C, 94.25; H, 5.75%.

13-Toluene: one-to-two adduct, colorless transparent cubes. Found: C, 94.00; H, 6.10%. Calcd for $C_{54}H_{36}\cdot 2C_7H_8$: C, 93.97; H, 6.03%.

13-*o*-Xylene: one-to-two adduct, colorless transparent cubes. Found: C, 93.81; H, 6.29%. Calcd for $C_{54}H_{36}\cdot 2C_8H_{10}$: C, 93.71; H, 6.29%.

13-*m*-Xylene: one-to-two adduct, colorless transparent cubes. Found: C, 93.75; H, 6.36%. Calcd for $C_{54}H_{36}\cdot 2C_8H_{10}$: C, 93.71; H, 6.29%.

13-*p*-Xylene: one-to-one adduct, colorless transparent cubes. Found: C, 94.15; H, 5.79%. Calcd for $C_{54}H_{36}\cdot C_8H_{10}$: C, 94.14; H, 5.86%.

13-Pyridine: one-to-one adduct, colorless needles. Found: C, 92.86; H, 5.35; N, 1.85%. Calcd for $C_{54}H_{36}\cdot C_5H_5N$: C, 92.76; H, 5.41; N, 1.83%.

The solvent releases of the adducts were determined under the following conditions: heating rate, 10°C/min; sample size, about 5 mg weighed accurately in a sealed cell with a pinhole; atmosphere, N_2 gas (40 ml/min).

The author wishes to thank Professor Aritsune Kaji of Kyoto University for his valuable discussions and suggestions.

12) In a series of aromatic hydrocarbons including biphenyl and *p*-terphenyl, Lepley and Thompson have indicated a correlation between the energies of second CT-bands for their TCNE-complexes and the penultimate occupied HMO coefficients (in β-unit) for the hydrocarbons (Ref. 4b). However, the absorption spectra of a large majority of the TCNE-complexes examined in the present study

displayed commonly an absorption maximum or a shoulder near 400 nm as the second or the third CT-band. The energies of the CT-bands near 400 nm of polyphenyl- and polyphenylene-TCNE complexes are rather correlated with those of the E-bands near 200 nm of the respective donor hydrocarbons.

13) The line was fitted by the least squares method except the complexes of two groups (correlation coefficient: 0.95).

14) A. R. Lepley, *J. Am. Chem. Soc.*, **84**, 3577 (1962).

15) Correlation coefficient: 0.95.

16) For polyphenyls and polyphenylenes, as well as for the series of alkylbenzenes (Ref. 9), the saturation vapor pressures of substituted components were assumed to be proportional to those of unsubstituted components.

17) Correlation coefficients: lager than 0.999 for all compounds.

18) Correlation coefficient: 0.997.

19) a) R. B. DuVernet, T. Otsubo, J. A. Lawson, and V. Boekelheide, *J. Am. Chem. Soc.*, **97**, 1629 (1975); b) T. Otsubo, R. Gray, and V. Boekelheide, *ibid.*, **100**, 2449 (1978).

20) The crystals were not isolated due to the ready oxidative dehydrogenation.

21) The ^{1}H NMR spectra of **1a** could not be determined due to the poor solubility and the reversibility to **1**.

22) The radical anion (greenish blue) prepared from **1** with sodium in THF under nitrogen atmosphere showed the absorption maxima at 380 (sh), 415, 556, and 590 nm. In the presence of a trace of oxygen, however, the spectrum showed the bands at 363 (sh), 367, 384, 395 (sh), 421, 480, 534 (sh), 555, 676, 740, and 833 nm, and it was actually identical with that of the radical anion prepared from **1b**. This fact suggests that the radical anion undergoes an oxidative dehydrocyclization (*cf.* Ref. 23).

A Comparative Study of Photoinduced Isomerizations between 1-*exo*- and 1-*endo*-Cyano-1a,7b-dihydro-1*H*-cyclopropa[*a*]naphthalenes

Hisako KOBAYASHI, Masahiko KATO,* and Toshio MIWA
Faculty of Science, Osaka City University, Sugimoto-3, Sumiyoshi-ku, Osaka 558
(Received June 30, 1984)

The titled compunds 1-*exo*-Cyano-1a,7b-dihydro-1*H*-cyclopropa[*a*]naphthalenes(**8a**), 1-*endo*-Cyano-1a, 7b-dihydro-1*H*-cyclopropa[*a*]naphthalenes(**8b**), were photolyzed in several solvents. The results were: (1) The isomerization proceeded faster in aprotic nonpolar solvents than in polar ones. (2) The 1-*endo* derivative (**8b**) rearranged faster than the 1-*exo*-isomer (**8a**). (3) **8b** was isomerized through Berson-Willcott rearrangement by the fission of bonds C_1-C_{7b} and C_1-C_{1a}, while **8a** gave 1-cyanomethylnaphthalene (**5b**) as a main product. (4) Examination with an optically active 1-*exo* derivative (**8a**) showed that the *exo-endo* interconversion occured by the simultaneous two centered (30%) and one centered (70%) epimerization.

The photochemical isomerization of 1-substituted 1a,7b-dihydro-1*H*-cyclopropa[*a*]naphthalenes (**1**) had been found to proceed in two directions (Scheme 1):[1-6] The rearrangements by the fission of the C_1-C_{7b} bond (Path a) to give 7-substituted 7*H*-benzocycloheptenes (**2**) and 2-substituted naphthalenes (**3**) and by the fission of the C_1-C_{1a} bond (Path b) to give 5-substituted 5*H*-benzocycloheptenes (**4**) and 1-substituted naphthalenes (**5**), in addition to the secondary photoproducts originating from **2** and **4**. The difference in photochemical reactivities between 1-*endo* and 1-*exo* substituted derivatives of **1** had been studied in methanol with 1-methoxycarbonylmethyl-3-isopropyl-1a,7b-dihydro-1*H*-cyclopropa[a]naphthalene (**6**), which gave the same products in different proportions.[4] The results were in line with the stereochemical course of the re-

arangement established using optically active substrates.[3,5]

It is well known that the substitution with an electron-withdrawing group on the cyclopropane ring will have a strong affect on the bond strengths of the three membered ring under both ground and excited states.[7] Therefore, it was interesting to investigate the difference in photochemical reactivities between *exo* and *endo* isomers of 1-methoxycarbonyl- or 1-cyano-1a,7b-dihydro-1*H*-cyclopropa[*a*]naphthalene and to compare it with the photochemical behavior of *exo* and *endo* isomers of **6**. Swenton *et al.* found that when 1-deuterio-1-*exo*-methoxycarbonyl-1a,7b-dihydro-1*H*-cyclopropa[*a*]naphthalene (**7a**-1-d_1) was irradiated, though the typical products *via* path b were not detected, the deuterium atom on C_1 scrambled into the hydrogens on C_{1a} and C_{7b} of recovered **7a**,[2] which suggested that the rearrangement occurs in two directions. Later on, we reported that the direct irradiation at low temperature of 5-methoxycarbonyl-5*H*-benzocycloheptene (**4a**), which is assumed to be one of the primary photoproducts of the skeletal rearrangement of **7a**, gave exclusively 1-*endo*-methoxycarbonyl-1a,7b-dihydro-1*H*-cyclopropa[*a*]naphthalene(**7b**).[8] Beacause of the thermal instability of **7b** (facile Cope rearrangement),[8] comparison of the reactivities between exo and endo isomers of **7** was difficult.

Recently, the cyano derivatives (**8a** and **8b**) were obtained in stable crystalline forms,[6] therefore, we studied concurrently their photochemistry under direct irradiation in several solvents. The results were different from their isomerization under sensitized irradiation,[6] and also from the results obtained with **6**.[4]

Results

Irradiation of **8b** (*endo*) in benzene for 30 min resulted in a 94.3% recovery of the material. The mixture was composed of **8a** (yield, 2%), **8b** (35%), **9b** (11%),[10] **10b** (15%),[9] 7-cyano-[9] and 1-cyano-2a,7a-dihydro-7*H*-cyclobut[*a*]indene[9] (**11b**, 18%; **12b**, 8%). They were identified by direct comparison with the authentic samples obtained through direct irradiation of **4b**[9] and of 7-cyano-5*H*-benzocycloheptene (**13b**).[10]

The preparative photochemistry of **8a** has also been examined with an optically active isomer (see below) and **5b** was obtained as the main product, which was identical with an authentic sample prepared according

to the known procedure.[11]

In order to uncover the effect of the solvent polarity on the product composition,[9] the rearrangement of **8a** and **8b** was carried out in several solvents. The results are shown in Table 1. It is observed that the rates for disappearance of **8a** and **8b** are faster in aprotic nonpolar solvents than in polar ones. In every solvent, **8b** was consumed somewhat faster than **8a** and,

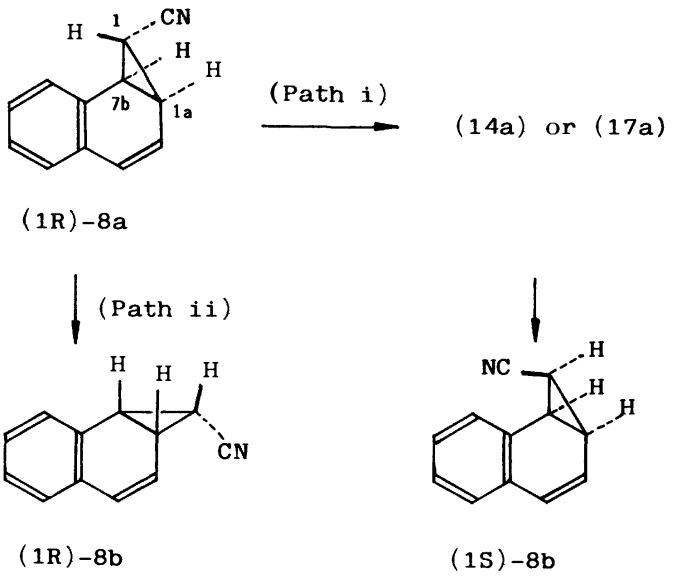
a) The concentrations of **8a** and **8b** were kept constant throughout and their initial concentration was set equal to 100. All figures are normalized to those obtained in benzene. b) Compounds **8a** and **8b** were not distinguishable by GLC because of their thermal interconversion. c) Following product ratios are shown as **A**, **B**, and **C**: **A**=(**9b**+**12b**)/(**4b**+**10b**+**11b**+**5b**); **B**=**5b**/(**4b**+**10b**+**11b**+**5b**); **C**=(**4b**+**10b**+**11b**)/(**9b**+**12b**). d) To calculate the mean values of **A**, **B**, and **C**, the data of 1h-irradiation were omitted, where some of the products were formed in small amounts, hence, the margins of the error in **A**, **B**, and **C** seemed to be large.

although **5b** was not detected in the products from **8b**, it was the main product from **8a**.

Discussion

It was found that, in every solvent studied, **8a** produced **5b** in the largest quantity along with **9b** and **11b**, while **8b** gives mainly **11b** and **10b** (or **9b**). Dissimilar to the results of the direct irradiation of *exo*-**6** and *endo*-**6**,[4] the *exo-endo* interconversions of **8** were found to occur during irradiation, though the rates were very slow. To test the mechanism of the isomerization from **8a** to **8b** under direct irradiation, (+)-(1R)-**8a** ([α]$_D$ +103°) was photolyzed in benzene and the following compounds were isolated: **8b** (6%, [α]$_D$ +259° ±40°), **9b** (13%), and **3b** (19%), in addition to the recovered **8a** (48%, [α]$_D$ +94.2°±2°). This result indicates that the racemization of the starting material was 8.6±0.2% and the retention of optical activity for isomerization of **8a** was 45±7%. Thus, it is estimated that the one-centered epimerization (Scheme 2, Path i) in (1R)-**8a** was contaminated with the two-centered epimerization (Path ii) to an extent of 30%. This result was quite different from that under sensitized irradiation where the very fast one-centered epimerization was observed.[6] Under the sensitized conditions, a triplet biradical species (**14a**) could solely be the convincing intermediate, and hence no racemization of both carbon centers C_{1a} and C_{7b} was observed.

In order to discover if **5b** was formed through a biradical intermediate derived from **8a**, **8a** was irradiated in the presence of tributyltin hydride, a good



Scheme 2.

hydrogen donor,[12] or dideuterium selenide, a trapping agent.[13] In the presence of tributyltin hydride, however, no product other than those produced in the absence of these addenda was observed. In the presence of dideuterium selenide, neither was any deuterium incorporated into **5b**. These observations, in conjunction with the formation of **5b** even in benzene,[14] show that the isomerization of **8a** would occur either through a biradical in a solvent cage with a life-time too short to be trapped with such reagents or through an intramolecular concerted process which leads directly to **5b**. Such a process has been argued by

Lambert and Laarhoven in the photochemical di-π-methane rearrangement.[15]

As mentioned above, **6**, **15**, and **16** were found to rearrange in a concerted manner with inversion of the C-1 configuration in two directions, and a series of the rearrangement products following them has been established (Scheme 1).[3-5] Based on this knowledge, it is apparent that compounds **10b** and **11b** are formed *via* **4b** and compounds **9b** and **12b** *via* **2b**.[16] The process might proceed *via* an excited singlet state of **8a**, which will make bond reorganization follow either path a or path b to give **2b** and **4b**, respectively. It is possible that the rearrangement goes through a transient singlet biradical species such as **14a**.

Zimmerman introduced the K concept for predicting the multiplicity control of the di-π-methane rearrangement of 1,1,2,2-tetraphenyl-5,5-bis(methoxycarbonyl)-1,4-pentadiene and made a number of generalization to estimate the relative magnitude of K for different excited transition states or species.[17] A small K reaction is preferred by the singlet and the large K reaction is preferrd by the triplet species. In the generalization he proposed: "(1) Pericyclic reactions tend to have small *K*'s. (2) Biradical species with electron-withdrawing group on biradical centers have diminished *K*'s." According to his proposal, thus, transient biradical species such as **14** and **17** may possibly be in their singlet excited states if the transformation is not the concerted process. Sensitized irradiation *via* triplet states gave rise to different results.[6]

The schematic bird's eye-view of the movement of the exo-substituent on C-1 is shown in **18a** while that of the endo-substituent on C-1 in **18b**, where the ring carbons of **8** lie in a plane of the paper. The bonds to the substituents, H and CN, attached to C-1 are projected on the plane and are shown with a rod having a blackened circle at the end, which expresses a cyano group. The C-1 atom and the bonds from C-1 to the ring carbons are omitted. As the least-motion process should be energetically more favorable than the other,[18] the excited *endo*-isomer (**8b**) is expected to react toward both sides faster than the excited *exo*-isomer (**8a**). This trend is seen in all solvents, but especially in polar solvents. Thus, from Table 1, it is observed that the rates for the isomerization of **8a** and **8b** in several solvents stand in the decreasing order of: benzene, cyclohexane, acetonitrile, and *t*-butyl alcohol=methanol. This fact suggests that the transition state of this reaction would not be a polar one.

Similarities in the ratios (**A**) of the proportion of path a products (**9b**+**12b**) to that of path b products (**4b**+**10b**+**11b**+**5b**) in aprotic nonpolar solvents are observed on irradiation of **8a** and **8b** (in benzene, 0.50±0.01; in cyclohexane, 0.43±0.01). As compound **5b** is not formed from **8b**, **5b** must be formed from **8a** in compensation for the formations of **4b**, **10b**, and **11b**. The rates of the formation of **5b** are similar in every solvent, except in benzene. The values (**C**) of (**4b**+**10b**+ **11b**)/(**9b**+**12b**) for **8a** may be used as a criterium for how the path b is affected by solvents. The retardation (%) of the reaction through path b compared to that through path a in various solvents is obtained using cyclohexane as a standard: methanol (33%), acetonitrile (27%), *t*-butyl alcohol (12%), benzene (38%), and cyclohexane (0%). In accordance with these data, the molar fraction (**B**) of **5b** in path b products in methanol was found to be the highest (0.74±0.05), and in cyclohexane the lowest (0.52±0.04). The values for the other solvents were approximately the same (0.66± 0.05). These facts may be explained as follows. The solvation of the cyano group in **8a** will not be specifically hindered. In the movement of the *exo*-substituent (**18a**), the molecule seems not to alter any solvation energy along path a, but the movement in path b resulted in the loss of the solvation energy by the interference of the substituent with a hydrogen on C-7. Thus the pathway b (**4b**+**5b**+**10b**+**11b**) will be more or less unfavorable compared to path a (**9b**+ **12b**).[9] In **18b**, though one side facing the 6-membered ring is severly blocked to solvation, the degree of solvation is not much altered along both pathways a and b. The interaction of C_7-H with the solvated cyano group and the loss of solvation energy in **19** will raise the energy barrier for symmetry allowed excited Berson-Willcott rearrangement. The situation for solvation of **5b** would not differ from that of **8a**. Therefore, the molecular portion *via* the 1,2-hydrogen shift to **5b** will increase among the molecules following path b. The 1,2-hydrogen shift may also be the symmetry-allowed [$\sigma 2_a + \sigma 2_a$] in the excited state; the orbitals involved are shown in **20**.

A considerable rate acceleration and anomalies for the photoreaction of **8a** and **8b** were observed in benzene compared with the data in the other solvents studied. Similar phenomena had been observed for the photoreaction of **4b**.[9] The reason for the accleration in benzene is still unclear.

Orbital Symmetry Considerations. In order to obtain knowledge about the polarity signs of the lobes for the frontier orbitals during the Berson-Willcott rearrangement, we calculated some phases of the electronic states during the rearrangement of **1** (R=H) to 1,1a-dihydro-1*H*-cyclopropa[*a*]naphthalene (**21**; R=H) making use of the extended Hückel M. O. calculations.[19] The molecular geometry of norcaradiene was taken from the X-ray crystallographic analysis data of 2,5-dimethyl-7,7-dicyanobicyclo[4.1.0]hepta-2,4-diene[20] with some modifications of the double bond to that of a benzene ring (1.43 Å). In line with the Woodward-Hoffmann rule, the C-1 orbital-lobe of the HOMO at the half way of the rearrangement in 120° mechanism[4] comes near the C-7a orbital-lobe of the same mathematical sign (bonding; allowed), while that of the LUMO comes near the opposite sign of C-7a orbital-lobe (*anti*-bonding; forbidden). On the other hand, the C-1

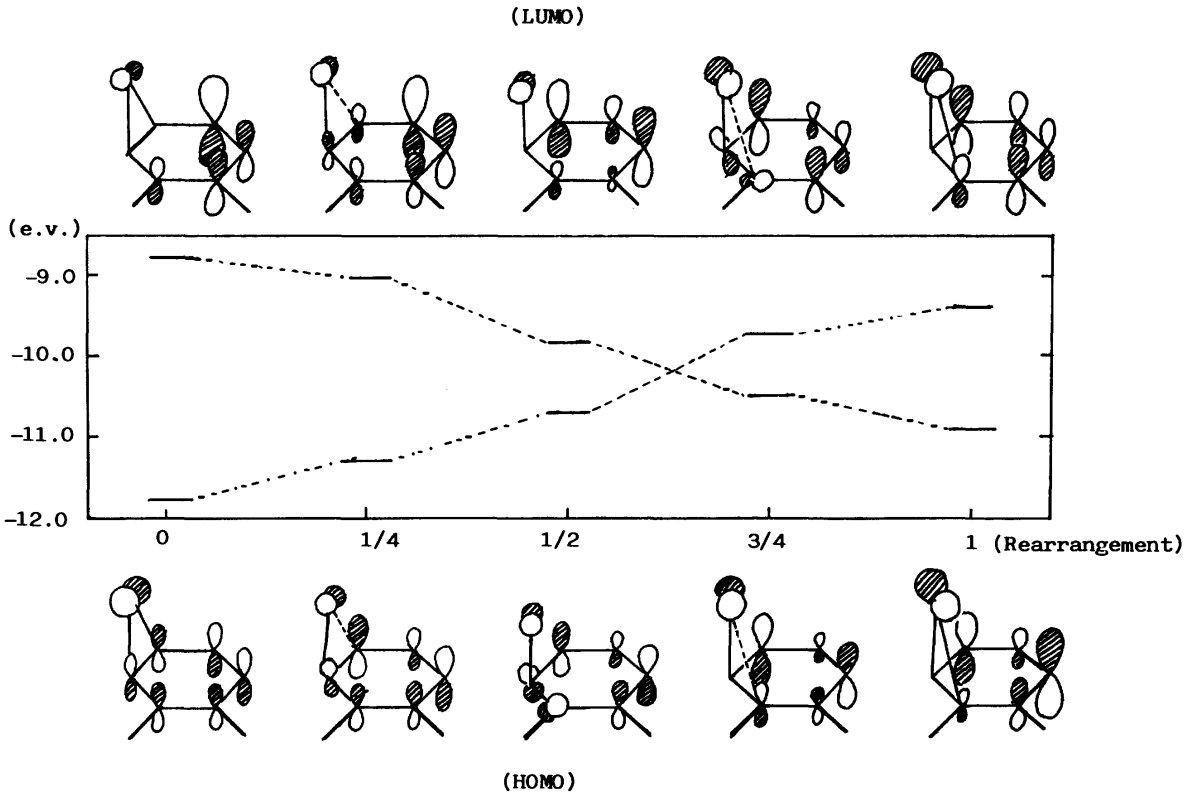


Fig. 1. The schematic orbital-lobes with their polarity signs and the corresponding orbital energy levels of the HOMO and the LUMO during rearrangement of 1 in the 60° mechanism.

orbital-lobe of the LUMO at the half way in 60° mechanism[4] comes near the C-7a orbital-lobe of the same sign (bonding; allowed). The schematic orbital-lobes with their polality signs and the corresponding orbital energy levels of the HOMO and the LUMO during rearrangement in 60° mechanism, calculated at the stages of the start, 1/4, 1/2, 3/4, and the complete rearrangements, are shown in Fig. 1. It is interesting to see that the LUMO (or HOMO) of the starting material is linked continuously with the HOMO (or LUMO) of **21** (R=H) in the polarity sings and their rough sizes of orbitals. The difference in the energy levels between the HOMO and the LUMO becomes smallest near the half way of the rerrangement. Though the calculations are classical, the rearrangement in the 60° mechanism would be photochemically allowed in the excited states, therefore, may proceed in a concerted manner.

Experimental

General Procedure. IR and ^{1}H-NMR were recorded according to the method given in the previous paper.[6,9] A Shimadzu Gas Chromatograph GC-4BM was used for the analytical purposes (Hydrogen ion flame detector). The column used was ϕ3.5 mm×1.0 m column charged with 3% Silicone OV-17 on Chromosorb WAW. For preparative column chromatography under medium pressure, a silica gel column (Merck Kiesegel 60, 230—400 mesh; ϕ8.2×500 mm) equipped with a F.M.I. pump (type RP-SY-1CSC) was used. For irradiation on a preparative scale, a solution charged in a vessel fitted with a Pyrex cooling jacket was purged with dry nitrogen for five min and internally irradiated with an Ushio High Pressure mercury lamp (HPL) (UM-452). The characterization of compounds, **4b**, **8a**, **8b**, **9b**, **10b**, **11b**, and **12b** had been reported previously.[1,2,8,9] In this experiment, the IR and NMR spectra, and the GLC retention times were compared with those of authentic specimens.

Irradiation of Racemic 8b. Racemic **8b** (54.8 mg; 0.33 mmol) dissolved in anhydrous benzene (40 mL) was irradiated internally with a HPL (UM-102) under ice-water cooling for 30 min. After evaporation of the solvent, the residue taken in benzene was filtered through a short column of silica gel (10 g) and the product chromatographed on 23 g of silica gel using 10% ether–hexane as solvent under medium pressure (1.2 atm). The products were **8a** (1.1 mg; 2%), **8b** (19.1 mg; 35%), **10b** (8.4 mg; 15%), **11b** (9.7 mg; 18%), **9b** (6.1 mg; 11%), and **12b** (4.3 mg; 8%). The ^{1}H NMR spectra of **10b** and **11b** were identical with those of the reported ones[9] and those of **9b** and **12b** were identical with the ones obtained by the photolysis of **13b**.[1,2] **9b**: NMR ($CDCl_3$) δ=0.43 (1H, d,d, J=4.4, 6.4 Hz), 2.12 (1H, d,d, J=9.7, 4.4 Hz), 3.9 (1H, bd, 6.4, 9.7 Hz), 6.19 and 6.39 (2H, AB type, J=9.8 Hz), 7.1—7.4 ppm (Ar-H). **12b**: NMR ($CDCl_3$) δ=3.02—3.28 (2H, m), 4.37 (1H, b), 7.02 (1H, bs), 7.1—7.3 ppm (Ar-H). **5b**: NMR ($CDCl_3$) δ=4.13 (2H, s), 7.4—7.65 (4H, m), 7.8—7.95 (3H, m). The GLC retention times (min) for them were also coincident with those of authentic specimens: Column temperature, 150 °C; hydrogen flow rate, 30 mL min^{-1}; retention times: **11b**, 4.3 min; **12b**, 4.6 min; **10b**, 5.8 min; **9b**, 6.2 min; **8**, 9.4 min.

Irradiation of Optically Active 8a. Optically active **8a** ([α]$_D$ +103°; 54.7 mg, 0.33 mmol) dissolved in anhydrous benzene (40 mL) was irradiated as described above. The products were **8a** (26.2 mg; 48%), **8b** (3.0 mg; 6%), **9b** (7.4 mg; 14%), and **5b**[11] (10.5 mg; 19%). The recovered **8a** and **8b** were

further purified by column chromatography under medium pressure (10% ether-hexane as an eluent): **8a** ($[\alpha]_D^{30}$ +94.2° (c=0.12 (CH_3OH)); **8b** ($[\alpha]_D^{31.5}$ +259° (c=0.15 (CH_3OH)).

Irradiation of 8a in the Presence of Tributyltin Hydride. **8a** (116 mg; 0.69 mmol) and hexadecane (24 mg; 0.11 mmol) were dissolved in anhydrous benzene and made up to 100 mL solution. This solution was divided into three portions; 40 mL, 30 mL, and 30 mL. To these solutions, tributyltin hydride (53% in tributyltin chloride) was added in the amounts of 1.51 g (10 mol-equivalent to **8a**), 619 mg (5.5 mol-equivalent), 227 mg (2 mol-equivalent), respectively. They were irradiated independently with a HPL (UM-102) for 30 min. The peak areas of the products analyzed by GLC were as follows: for 10 mol-equivalent of the hydride; **8**:**9b**:**5b**= 58:9:15.5; for 5.5 mol-equivalent; **8**:**9b**:**5b**=61:8.8: 13.0; for 2.0 mol-equivalent; **8**:**9b**:**5b**=59:9:15.3. (The data were obtained by taking the initial amount of **8a** as 100 and normalizing with the peak of hexadecane as constant).

Irradiation of 8a in the Presence of Dideuterium Selenide. To **8a** (56 mg; 0.33 mmol) dissolved in anhydrous benzene (15 mL) was added a solution of dideuterium selenide[21] in anhydrous benzene (1.75 mmol/25 mL) and the mixture was irradiated internally as above for 30 min. After irradiation (no precipitation of selenium was observed), the benzene solution was washed successively with 1 M aq sodium hydroxide (2 mL×2), water, saturated brine, and dried. Separation of the products by column chromatography gave **8b** (7 mg) and a mixture (41 mg) of **8a**, **9b**, and **5b**. Careful examination of ^1H NMR spectrum of the latter on the peak areas at 4.13 and 7.8—7.95 ppm for benzylic and α-protons of **5b**, respectively, shows that the resultant **5b** was not contaminated by more than 5% of the deuterated **5b**.

Comparison of the Photoreaction of 8a and 8b. The solvents used for photolysis were purified as reported earlier.[9] Methanol, t-butyl alcohol, acetonitrile, benzene, and cyclohexane were used as solvents. Each 1.0 mmol dm^{-3} solution of **8a** or **8b** was prepared in an appropriate solvent containing 0.10 mmol dm^{-3} of hexadecane as an internal standard. The photochemical reactions were carried out with the same technique (merry-go-round apparatus) described before.[9] Five tubes containing the same solution (5 mL) to be examined and two containing the benzene solution (5 mL) were photolyzed at the same time with a high pressure mercury lamp (UM-452) through a Pyrex filter under cooling (ice-water). During the irradiation, the test tube was taken out every one hour and each of 10 μL of the solution was examined by GLC with temperature programing (100 °C to 150 °C; 5 °C min^{-1}). The retention times of the products were as follows: Hexadecane, 9.1 min; **11b**, 12.3 min; **12b**, 13.1 min; **4b**, 13.9 min; **10b**, 14.3 min; **9b**, 14.7 min; **8**, 19.0 min; **5b**, 21 min. Each relative area of each peak was normalized to the area of the hexadecane and the data for each solvent were adjusted to the data obtained in benzene. The data in all solvents studied are listed in Table 1. No calibrations were made for each product because the use of a temperature programing technique might make the margin of error significant large. However, it may be said that the margin of error will be within 20% among different compounds and within 5% among the same compounds.

Hydrolysis of Active Esters of Aliphatic Carboxylic Acids with Cyclic Dipeptide Catalysts Consisting of L-Histidine and Different Aliphatic α-Amino Acids

Yoshihiko MASUDA, Masao TANIHARA, Yukio IMANISHI,* and Toshinobu HIGASHIMURA
Department of Polymer Chemistry, Faculty of Engineering, Kyoto University, Yoshida Honmachi, Sakyo-ku, Kyoto 606
(Received July 2, 1984)

The hydrolyses of a series of *p*-nitrophenyl carboxylates with different acyl chains were investigated at 25 °C, pH 7.8 using cyclic dipeptides[*cyclo*(-L- or D-Xyz-His-) consisting of L-histidine (L-His) and an α-amino acid (Xyz) with different aliphatic side chains] as catalysts. Consequently, *cyclo*(-D-Leu-L-His-) and *cyclo*(-D-Val-L-His-) were found to be specifically effective catalysts for the hydrolysis of *p*-nitrophenyl laurate. These trans (D-L-type) cyclic dipeptides were much more efficient catalysts than their diastereomers, and were more reactive than imidazole, despite the fact that the former are less basic than the latter. The conformation of the cyclic peptides in solution was investigated using proton magnetic resonance spectroscopy and the relationship between conformation and catalytic activity was investigated. Consequently, it was found that the hydrophobic interaction between a catalyst and a substrate and the stereochemical fit for the cooperation of functional groups in the intramolecular nucleophilic catalysis are very important in order to attain a highly efficient catalysis. It was also found that the functional groups should have a certain size and flexibility in order to realize an effective stereochemical fit between functional groups of catalysts and substrates.

The specific catalysis of hydrolytic enzymes has been shown to depend upon the intramolecular cooperation of side-chain functional groups which are confined to a specific spatial conformation by the influence of the secondary structure of a polypeptide chain. In order to develop a catalyst with an enzyme-like character, the use of cyclic peptides seemed to be promising.[1] On the basis of this view, we synthesized cyclic dipeptides consisting of leucine and histidine and investigated the catalysis in the hydrolysis of *p*-nitrophenyl carboxylates. A very high catalytic activity of *cyclo*(D-leucyl-L-histidine)[*cyclo*(-D-Leu-L-His-)] in the hydrolysis of *p*-nitrophenyl laurate [$CH_3(CH_2)_{10}COOC_6H_4NO_2$] at 25 °C, pH 7.9 in 20% dioxane/water at the substrate concentration of 3.0×10^{-5} mol dm^{-3} has been reported by us.[2] *Cyclo*(-D-Leu-L-His-) (pK_a=6.00) is less basic than imidazole (pK_a=7.05) and the former was less efficient than the latter as a catalyst for the hydrolysis of *p*-nitrophenyl esters of short-chain carboxylic acids. However, it was specifically reactive for the hydrolysis of $CH_3(CH_2)_{10}COOC_6H_4NO_2$, that is, in the above conditions the second-order rate constant k_{cat} was 34—68 dm^3 mol^{-1} min^{-1} which was several tens of times as large as k_{cat}=1.9 dm^3 mol^{-1} min^{-1} by imidazole. It was considered that the hydrophobic interaction between the catlyst and the substrate should have played an important role in the above reactions.

It should be interesting to confirm if the above explanation is commonly applicable to other combinations of catalysts and substrates. This sort of investigation will be effective to explore a substrate-selective catalysis, that is, an efficient catalysis for a specific substrate, by controlling the structure of the cyclic peptide.

Experimental

Cyclic Dipeptides. *N*-Benzyloxycarbonyl α-amino acid or *N*-*t*-butoxycarbonyl α-amino acid and L-histidine methyl ester were condensed by an active ester method or with dicyclohexylcarbodiimide to obtain a linear dipeptide blocked at both terminals. A benzyloxycarbonyl group and *t*-butoxycarbonyl group were removed by catalytic hydrogenation and HCl/dioxane, respectively. The cyclization was carried out by refluxing in methanol. Cyclic dipeptides were recrystallized from water or a water/acetone mixture. It should be emphasized that ion-exchanging resins were not used to purify the intermediates and the products. Syntheses of *cyclo*(-Gly-L-His-), *cyclo*(-L-Leu-L-His-) and *cyclo*(-D-Leu-L-His-) have been reported previously.[2] *Cyclo*(-L-Ala-L-His-), mp 252—254 °C. Calcd for $C_9H_{12}N_4O_2$: C, 51.92; H, 5.81; N, 26.91%. Found: C, 51.70; H, 5.54; N, 26.96%. *Cyclo*(-D-Ala-L-His-), mp 235—236 °C. Calcd for $C_9H_{12}N_4O_2\cdot H_2O$: C, 47.78; H, 6.24; N, 24.76%. Found: C, 47.71; H, 6.10; N, 24.40%. *Cyclo*(-L-Phe-L-His-), mp 263 °C. Calcd for $C_{15}H_{16}N_4O_2$: C, 63.37; H, 5.67; N, 19.17%. Found: C, 63.07; H, 5.60; N, 20.00%. *Cyclo*(-D-Phe-L-His-), mp 255—257 °C. Found: C, 63.17; H, 5.53; N, 19.76%. *Cyclo*(-L-Val-L-His-), mp 220—224 °C. Calcd for $C_{11}H_{16}N_4O_2$: C, 55.92; H, 6.83; N, 23.71%. Found: C, 55.72; H, 6.89; N, 23.02%. *Cyclo*(-D-Val-L-His-), mp 228—230 °C. Found: C, 55.88; H, 6.68; N, 23.46%. *Cyclo*(-DL-Nle-L-His-), mp 207—213 °C. Calcd for $C_{12}H_{18}N_4O_2\cdot H_2O$: C, 53.72; H, 7.51; N, 20.88%. Found: C, 54.41; H, 7.32; N, 20.77%.

To synthesize *cyclo*(-D-Pip-L-His-) a racemic pipecolic acid-(2-piperidinecarboxylic acid) was optically resolved to obtain (*R*)-pipecolic acid(D-Pip). (+)-Tartaric acid was added to the racemic pipecolic acid to form a (*R*)-pipecolic acid — (+)-tartaric acid complex. To the complex, lead (IV) acetate was added to remove (+)-tartaric acid and to obtain (*R*)-pipecolic acid.[3] (*R*)-Pipecolic acid — (+)-tartaric acid complex, mp 182—185 °C (lit,[3] 182 °C), $[\alpha]_D$ 19.9 (H_2O) (lit,[3] 20.0). (*R*)-pipecolic acid, $[\alpha]_D$ 26.6 (H_2O)(lit,[4] 26±1). (*R*)-*N*-(Benzyloxycarbonyl)pipecolic acid was condensed with methyl L-histidinate using *N*-ethoxycarbonyl-2-ethoxy-1,2-dihydroquinoline to obtain a linear dipeptide blocked at both terminals. The subsequent procedure leading to *cyclo*-(-D-Pip-L-His-) was the same as the above. (*R*)-*N*-(Benzyloxycarbonyl)pipecolic acid, mp 110—113 °C (lit,[4] 112—113 °C); $[\alpha]_D$ 60.0 (AcOH) (lit,[5] 57.2±1). *Cyclo*(-D-Pip-L-His-), mp 185—195 °C. Calcd for $C_{12}H_{16}N_4O_2$: C, 58.05; H, 6.50; N, 22.57%. Found: C, 58.21; H, 6.57; N, 22.34%.

Methyl *N*-methoxycarbonyl-L- or D-leucyl-L-histidinate

(MeOCO-L or D-Leu-L-His-OMe) was used as a reference catalyst for the hydrolysis. They were synthesized in the same way as reported previously.[2]

Substrate. Vaious carboxylic acids were condensed with *p*-nitrophenol using dicyclohexylcarbodiimide, and the active esters were purified by recrystallization from ethanol. All esters were proven to be pure by an elemental analysis. Syntheses and purifications of *p*-nitrophenyl acetate [$CH_3COOC_6H_4NO_2$], 3-phenylpropionate [$Ph(CH_2)_2COOC_6H_4NO_2$] and laurate [$CH_3(CH_2)_{10}COOC_6H_4NO_2$] have been reported previously.[2] *p*-Nitrophenyl 5-phenylvalerate[$Ph(CH_2)_4COOC_6H_4NO_2$], mp 64.5—65.0°C. Calcd for $C_{17}H_{17}NO_4$: C, 68.22; H, 5.72; N, 4.68%. Found: C, 68.07; H, 5.80; N, 4.90%. *p*-Nitrophenyl decanoate [$CH_3(CH_2)_8COOC_6H_4NO_2$], mp 32.5—33°C. Calcd for $C_{16}H_{23}NO_4$: C, 65.51; H, 7.90; N, 4.77%. Found C, 65.75; H, 7.91; N, 4.74%. *p*-Nitrophenyl cyclohexanecarboxylate [$c\text{-}C_6H_{11}COOC_6H_4NO_2$], mp 50°C. Calcd for $C_{13}H_{15}NO_4$: C, 62.64; H, 6.07, N, 5.62%. Found: C, 62.91; H, 6.11; N, 5.56%. *p*-Nitrophenyl pivalate-[$Me_3CCOOC_6H_4NO_2$], mp 98—99°C (lit,[5] 94—95°C).

Hydrolytic Reaction. Hydrolyses were carried out at 25°C, pH 7.8 (KH_2PO_4–NaOH buffer) in 20% dioxane/water mixture. The catalyst concentration with respect to the imidazolyl group was in the range 1.65—11.2×10^{-4} mol dm^{-3}. It was lowered to 5.49×10^{-5} mol dm^{-3} when the effect of the dilution of the catalyst was examined. The substrate concentration was 3.0×10^{-5} mol dm^{-3}. However, the concentration of $CH_3(CH_2)_{10}COOC_6H_4NO_2$ and $CH_3(CH_2)_8COOC_6H_4NO_2$ was 6.0×10^{-6} mol dm^{-3} or 2.0×10^{-6} mol dm^{-3} to avoid association. A mixture of the buffer solution and the aqueous catalyst solution was kept at a constant temperature in an ultraviolet cell and a dioxane solution of substrate, which was kept at the same temperature, was added to start the hydrolytic reaction. By this procedure, an excellent reproducibility of the reaction was obtained even when a slight turbidity was observed in the hydrolysis of $CH_3(CH_2)_{10}COOC_6H_4NO_2$. To determine the reaction rate, a JASCO UVIDEC-1-type spectrophotomer was employed. The concentration of the *p*-nitrophenolate ion liberated in the reaction was determined by the absorbance at 400 nm, and the rate of hydrolysis was calculated. Optical cells having optical path lengths of 1 cm and 5 cm were used when the substrate concentration was 3.0×10^{-5} mol dm^{-3} and 6.0×10^{-6} mol dm^{-3} or 2.0×10^{-6} mol dm^{-3}, respectively. A second-order rate constant k_{cat} was calcutated from the pseudo-first-order rate constant k_1, the rate constant for the spontaneous hydrolysis k_w, and the effective imidazolyl concentration under reaction conditions. With all cyclic dipeptide catalysts the side-chain imidazolyl group of L-histidyl residue is in its neutral form at pH 7.8, so that the effective concentration is the same as the total concentration. On the other hand, with imidazole as a catalyst the fraction of catalytically active imidazole was 0.85 at pH 7.8. The second-order kinetics has been described previously.[2] The catalytic activities were compared in terms of k_{cat}.

Conformational Analysis. The side-chain conformation of cyclic peptides in solution was investigated by 220 MHz and 100 MHz ^1H nuclear magnetic resonance (NMR) spectroscopy. Varian HR-220 and HA-100 spectrometers were used. Dimethyl-d_6-sulfoxide(Me_2SO-d_6) and D_2O (NaOD–KD_2PO_4 buffer, pH 7.8) were used as solvent. Tetramethylsilane (Me_4Si) was used as an internal standard for the Me_2SO-d_6 solution. Sodium 2,2-dimethyl-2-silapentane-5-sulfonate[$Me_3Si(CH_2)_3SO_3Na$] and Me_4Si were used as an internal standard and an external standard for the D_2O solution, respectively.

Results and Discussion

The Hydrolysis of p-*Nitrophenyl Laurate with* Cyclo-*(-*L-*or* D-*Leucyl-*L-*Histidyl).* In a series of experiments to confirm the previous experimental results, we could not reproduce the rapid hydrolysis of $CH_3(CH_2)_{10}COOC_6H_4NO_2$ by *cyclo*(-D-Leu-L-His-) under the same conditions. A trace amount of some long-chain alkylamine, which was contaminated into the *cyclo*-(-D-Leu-L-His-) synthesized in the previous way, might have catalyzed the apparently fast hydrolysis. It has been reported that the hydrolyses of *p*-nitrophenyl esters of long-chain carboxylic acids are greatly accelerated by long-chain alkylamine.[6,7] Since a trace amount of long-chain alkylamine may be concentrated in a cyclic peptide during the purification with anion-exhange resin Amberlite IRA-400 which was used in the previous experiments, cyclic peptide catalysts were resynthesized without using ion-exchangers in the present investigation. The hydrolytic experiments of $CH_3(CH_2)_{10}COOC_6H_4NO_2$ with a pure *cyclo*(-D-Leu-L-His-) and related peptide catalysts were carried out nearly the same conditions as before, and k_{cat} values are shown in Table 1 together with other data. It is remarkable that the k_{cat} value, by pure *cyclo*(-D-Leu-L-His-), is much smaller than that reported previously. We must conclude that k_{cat}=34—68 $dm^3 mol^{-1} min^{-1}$ reported in a previous paper is much larger than the real value. The origin of the error is perhaps some hydrophobic amine contaminated from an ion-exchanger during the synthesis of *cyclo*(-D-Leu-L-His-).

Table 1. Second-order rate constants(k_{cat}, $dm^3 mol^{-1} min^{-1}$) for the hydrolysis of *p*-nitrophenyl laurate[a]

Catalyst	pK_a	$[S]_0^{b)}$=6.0×10^{-6} mol dm^{-3}	$[S]_0^{b)}$=3.0×10^{-5} mol dm^{-3}	
			Present experiment	Previous experiment
None (k_w, min^{-1})	—	0.24×10^{-3}	0.07×10^{-3}	0.20×10^{-3}
Imidazole	7.05	1.6	3.8	1.9
MeOCO-L-Leu-L-His-OMe	6.60	1.3	0.73	≈0
MeOCO-D-Leu-L-His-OMe	6.60	2.7	0.77	0.18
Cyclo(-L-Leu-L-His-)	6.25	0.05	0.08	0.25
Cyclo(-D-Leu-L-His-)	6.00	2.6	1.1	34—68

a) 25°C, pH 7.8, 20% dioxane/water. b) Initial substrate concentration.

However, it was not possible to isolate and identify the hydrophobic amine.

In previous experiments in which the substrate concentration was 3.0×10^{-5} mol dm^{-3}, sometimes the solution was trubid and precipitation occurred during the reaction. In these cases, the first-order plot with respect to the concentration of the reaction product was not linear. In view of several papers,[8,9] $CH_3(CH_2)_{10}COOC_6H_4NO_2$ tends to associate in a 20% dioxane/water solution at a concentration of 3.0×10^{-5} mol dm^{-3} and the association affects the k_{cat} value. A similar situation will be met with $CH_3(CH_2)_8COOC_6H_4NO_2$, too. Therefore, the hydrolyses of $CH_3(CH_2)_{10}COOC_6H_4NO_2$ with pure cyclic dipeptides containing L-histidine were carried out at substrate concentrations of 6.0×10^{-6} mol dm^{-3} and 2.0×10^{-6} mol dm^{-3}, which seemed to be low enough to avoid association. Under these conditions the reaction solution was nearly transparent. In particular, at the substrate concentration of 2×10^{-6} mol dm^{-3}, the reaction solution was perfectly transparent, and a first-order plot on the basis of the absorption due to dissociated *p*-nitrophenolate ion was linear except for the very early stage of the hydrolysis of $CH_3(CH_2)_{10}COOC_6H_4NO_2$. The k_{cat} values were determined from the linear part of first-order plot and are summarized in Table 2. In Table 2 the effect of dilution of catalyst on k_{cat} is also shown.

In Table 2, the catalyst dilution does not induce a definite change in k_{cat}. Therefore, the catalysts should be completely soluble under the conditions employed in the present investigation. An inspection of the experimental data shown in Tables 1 and 2 shows that a substrate dilution from 3.0×10^{-5} mol dm^{-3} to 6.0×10^{-6} mol dm^{-3} increased k_{cat} for $CH_3(CH_2)_{10}COOC_6H_4NO_2$ with peptide catalysts, that the reproducibility of the hydrolyses of $CH_3(CH_2)_{10}COOC_6H_4NO_2$ and $CH_3(CH_2)_8COOC_6H_4NO_2$ at a concentration 6.0×10^{-6} mol dm^{-3} is excellent, and that the further dilution of both substrates from 6.0×10^{-6} mol dm^{-3} to 2.0×10^{-6} mol dm^{-3} increased the k_{cat} values again. Since the aggregation of these hydrophobic substrates in 20% dioxane/water at a concentration of 2.0×10^{-6} mol dm^{-3} is suppressed to the minimum extent as described above, the k_{cat} values obtained at 2.0×10^{-6} mol dm^{-3} are regarded as the true values. It is remarkable that the cyclic peptides, consisting of D-leucyl or D-valyl and L-histidyl residues, have a high catalytic activity toward $CH_3(CH_2)_{10}COOC_6H_4NO_2$ under diluted conditions as compared to imidazole. It should be a marked result because these cyclic peptide catalysts are less basic than imidazole. The binding of hydrophobic substrates by a hydrophobic side chain of leucyl or valyl residue must have increased the reaction rate. In fact, in a mixed solvent containing more dioxane, the k_{cat} of *cyclo*(-D-Leu-L-His-) and *cyclo*(-D-Val-L-His-) was much smaller than that of imidazole as shown in Table 3.

Most interestingly, the catalysis by *cyclo*(-D-Leu-L-His-) or *cyclo*(-D-Val-L-His-) was much stronger than that by *cyclo*(-L-Leu-L-His-) or *cyclo*(-L-Val-L-His-), although both enantiomorphic pairs of catalysts are considered to be equally hydrophobic. The different activities of enantiomorphic catalysts may have been caused by different orientations of side chains in these cyclic dipeptides. In *cyclo*(-L-Leu-L-His-) or *cyclo*(-L-Val-L-His-), the side chains exist at the opposite side of the cyclic dipeptide plane.[10] To realize the hydrophobic binding of a substrate in an aqueous solution and subsequent intramolecular nucleophilic catalysis, *cyclo*(-D-Leu-L-His-) and *cyclo*(-D-Val-L-His-)

TABLE 2. EFFECTS OF DILUTION OF CATALYST AND SUBSTRATE ON THE SECOND-ORDER RATE CONSTANT (k_{cat}, dm^3 mol^{-1} min^{-1}) FOR THE HYDROLYSIS OF HYDROPHOBIC ESTERS WITH HYDROPHOBIC CYCLIC DIPEPTIDE CATALYSTS

must have a suitable orientation of the functional groups and a stereochemical fit with a substrate.

Hydrolysis Catalyzed by Cyclic Dipeptides Carring an Alkyl Side Chain of Different Chain Lengths. The hydrophobicity of cyclic dipeptide catalysts can be controlled by the kind of α-amino acid (Xyz) which is coupled with L-histidine in the cyclic dipeptide. Thus, we can investigate the effect of the nature of cyclic dipeptide catalysts on the hydrolyses of a highly hydrophobic $CH_3(CH_2)_8COOC_6H_4NO_2$ and a less hydrophobic $CH_3COOC_6H_4NO_2$. The experimental results are summarized in Table 4.

The basicities of the side-chain imidazolyl groups of cyclic dipeptides are lower by *ca.* 0.7 pK unit than that of imidazole. The basicities are not seriously affected by the different natures and configurations of the α-amino acid residues which are coupled with L-histidine in the cyclic dipeptides.

For the hydrolysis of $CH_3COOC_6H_4NO_2$, which has the shortest acyl chain among the substrates investigated, imidazole was the most efficient catalyst and none of the cyclic dipeptide catalysts used were found to be more efficient than imidazole. No particular interaction, such as a hydrophobic interaction, seems to operate between $CH_3COOC_6H_4NO_2$ and the cyclic dipeptides. As a consequence, the cyclic dipeptide catalysts, which are less basic and are accompanied by a higher steric hindrance in the nucleophilic reaction, are less efficient than imidazole. It should be pointed out that with all diastereomeric catalysts a D-L-type dipeptide is somewhat more(up to twice) reactive than an L-L-type cyclic dipeptide. As will be described subsequently, this difference must be due to a less steric hindrance in the reaction of an imidazolyl group of the D-L-type cyclic dipeptide.

On the other hand, in the hydrolysis of $CH_3(CH_2)_8COOC_6H_4NO_2$, which has a long acyl chain, cyclic dipeptide catalysts carrying a bulky side chain were found to be relatively reactive. More interestingly, under these conditions *cyclo*(-D-Xyz-L-His-) s were 3—5 times more reactive than their diastereomers. This reactivity difference should be ascribed to a favorable orientation of the side chains of *cyclo*(-D-Xyz-L-His-) in the intramolecular catalysis toward a bound substrate.

Next, the hydrolytic reactions of *p*-nitrophenyl carboxylates having different lengths of an acyl chain with some hydrophobic cyclic dipeptide catalysts were investigated. The experimental results are summarized in Table 5.

The second-order rate constants k_{cat} for the hydrol-

yses with imidazole as a catalyst decreased on going from $CH_3COOC_6H_4NO_2$ to $CH_3(CH_2)_{10}COOC_6H_4NO_2$. The same trend was also observed in a hydrolyses catalyzed by L-L-type cyclic dipeptide catalysts. These experimental findings indicate an increasing steric hindrance against a nucleophilic attack by imidazole or an imidazolyl group as the length of the acyl chain of the substrates increases.

On the other hand, the k_{cat} values for the hydrolyses catalyzed by D-L-type cyclic dipeptides did not decrease markedly as the acyl chain length of the substrates increased. Interestingly, in the hydrolysis of $CH_3(CH_2)_{10}COOC_6H_4NO_2$, *cyclo*(-D-Val-L-His-) and *cyclo*(-D-Leu-L-His-) were more reactive than imidazole. In these experimental results, the important contribution of the hydrophobic binding of $CH_3(CH_2)_{10}COOC_6H_4NO_2$ by the hydrophobic cyclic dipeptides is again indicated.

The reactivity difference between the *cyclo*(-D-Xyz-L-His-)s, where Xyz is Leu, Val, and Phe, and their diastereomers is much larger in the hydrolysis of $CH_3(CH_2)_{10}COOC_6H_4NO_2$ than in the hydrolysis of $CH_3(CH_2)_8COOC_6H_4NO_2$, which is in turn larger than those in the hydrolyses of $CH_3COOC_6H_4NO_2$, $Ph(CH_2)_2COOC_6H_4NO_2$, and $Ph(CH_2)_4COOC_6H_4NO_2$. In other words, the more important the hydrophobic interaction between substrate and cyclic dipeptide, the larger the reactivity difference between the diastereomers of the cyclic dipeptides. *Cyclo*(-D-Xyz-L-His-) is intrinsically more reactive in a nucleophilic reaction toward $CH_3COOC_6H_4NO_2$, $Ph(CH_2)_2COOC_6$-H_4NO_2, and $Ph(CH_2)_4COOC_6H_4NO_2$ because of less steric hindrance than *cyclo*(-L-Xyz-L-His-). In addition to this, the conformation of *cyclo*(-D-Xyz-L-His-) is far more favorable in the intramolecular reaction toward a bound substrate than that of *cyclo*(-L-Xyz-L-His-).

Conformational Analysis of Side-Chain Group of Cyclic Peptide by Nuclear Magnetic Resonance Spectroscopy. An attempt was made to elucidate the hydrolytic activity — conformation relationship of the cyclic peptide catalysts through an analysis of the side-chain conformation of the cyclic peptides by NMR spectroscopy.

^1H NMR spectra of *cyclo*(-Xyz-L-His-) in Me_2SO-d_6 or D_2O solution were obtained, and the chemical shifts (δ^α, δ^β) of H^α and H^β of the two α-amino acid residues and the coupling constants($J^{\alpha\beta}$) between them were determined. These values are summarized in Table 6.

The $J^{\alpha\beta}$ values were substituted into a Karplus-type equation, by which the proportions of conformers existing in three conformational energy minima were calculated with reference to the internal rotation around the C^α-C^β bond. On that basis, the proportion F, which represents the folded conformation with the side chain stacking over the plane of cyclic dipeptide, and the proportion U, which represents the unfolded conformation with the side chain protruding outside the plane of cyclic peptide, were calculated and are shown in Table 7. In the same table, those values that have been determined by NMR spectroscopy with *cyclo*(-L- or D-Leu-L-His-) and *cyclo*(-Gly-L-His-) are also shown.[10]

The backbone conformation of these cyclic dipeptides was not investigated in detail. However, it may be considered, on the basis of the previous conclusion obtained with *cyclo*(-L- or D-Leu-L-His-),[10] that L-L-type cyclic dipeptides take a flagpole-boat conformation and that D-L-type cyclic dipeptides assume a nearly planar conformation. In all the cyclic dipeptides investigated, the fraction with a folded conformation of the side chain of L-histidyl residue was more than 1/3, the statistical value. This tendency is particularly marked for D_2O. The folded conformation is stabilized by an aromatic — amide interaction between an imidazolyl group and the backbone of the cyclic di-

a) The standard substance is Me_4Si in Me_2SO-d_6 and capillary Me_4Si in D_2O. b) The standard substance is $Me_3Si(CH_2)_3SO_3Na$. c) Coupling constant was not determined (see Table 3). d) No C^γ atom is present. e) Two methyl groups are present at the γ position.

peptide. This interaction seemed to be more important in D_2O than in Me_2SO.[11,12] The high-field shift of the H^α signal of a D-Xyz residue of *cyclo*(-D-Xyz-L-His-), as compared with that of L-Xyz residue of *cyclo*-(-L-Xyz-L-His-) (see Table 6), might be due to a magnetic-shielding effect of the imidazolyl group. This indicates a molecular conformation in which H^α of D-Xyz residue protrudes over the plane of the imidazolyl group in the folded conformation of the side chain of the L-histidyl residue. Similarly, in Table 6, the H^β signal of the L-Xyz residue in *cyclo*(-L-Xyz-L-His-) is shifted to a higher magnetic field than the H^β signal of the D-Xyz residue in *cyclo*(-D-Xyz-L-His-). When two H^β atoms are concerned, they are nonequivalent and one of them is more strongly shifted to a high field than the other. These phenomena might have been caused by a magnetic-shielding effect of the imidazolyl group, and again indicate a folded conformation of the side chain of L-histidyl residue in which the H^β of L-Xyz residue protrudes over the plane of imidazolyl group.

These experimental NMR spectroscopy results indicate that in *cyclo*(-D-Xyz-L-His-) two side chains exist on different sides of the almost planar backbone plane of the cyclic dipeptide, and that in *cyclo*(-L-Xyz-L-His-) two side chains exist on the same side of the boat-type plane of the cyclic dipeptide. This conclusion means that the molecular conformation[10] proposed previously for *cyclo*(-L- or D-Leu-L-His-) is commonly available in other cyclic dipeptides. It is, therefore, conceivable to say that a conformation in which an isobutyl side chain of the D-Leu residue exists on the other side of an imidazolylmethyl side chain of the L-His residue with respect to the cyclic dipeptide backbone enables a stereochemical fit in binding a long-chain $CH_3(CH_2)_{10}COOC_6H_4NO_2$ by hydrophobic interaction with the isobutyl group and in the intramolecular nucleophilic attack by the imidazolylmethyl group.

There are two γ-methyl groups in *cyclo*(-L- or D-Val-L-His-), so that a Karplus-type equation is not applicable to this cyclic dipeptide. Therefore, the internal rotation around the C^α-C^β bond cannot be investigated on the basis of the coupling constant. In this cyclic peptide, however, one or two methyl groups are present in an unfolded position in any rotational state. Therefore, with *cyclo*(-D-Val-L-His-) a conformation becomes available in which one or two methyl groups situate fairly close to the backbone of the cyclic dipeptide and on the other side of the imidazolylmethyl group. This sort of arrangement of the functional groups may provide a favorable stereochemical fit with $CH_3(CH_2)_{10}COOC_6H_4NO_2$ for a concerted hydrophobic binding — intramolecular nucleophilic catalysis.

Cyclo(-D-Phe-L-His-) was found not to be so effective for the hydrolysis of *p*-nitrophenyl esters of long-chain carboxylic acids, although the side chain benzyl group of the Phe residue may well be hydrophobic comparable to the isobutyl side chain of the Leu residue and the isopropyl side chain of the Val residue. The reason for the low catalytic activity may exist in the peculiar orientation of the two side chains of *cyclo*(-D-Phe-L-His-). It is desirable to know the conformation of *cyclo*(-D-Phe-L-His-) in an aqueous solution, because the hydrolysis was carried out in a 20% dioxane/water mixture. Unfortunately, for the limited solubility of *cyclo*(-D-Phe-L-His-) in water, only the conformation in Me_2SO was investigated. As shown in Table 6, the NMR chemical shift of the H^α of the Phe residue in *cyclo*(-D-Phe-L-His-) is nearly the same as that in *cyclo*(-L-Phe-L-His-). In other words, the H^α of the Phe residue in *cyclo*(-D-Phe-L-His-) is free from the magnetic-shielding effect of the imidazolyl group of the His residue, which is a significant exception in the *cyclo*(-D-Xyz-L-His-) series. This indicates that the extent of the folded orientation of the imidazolylmethyl side chain of His residue in *cyclo*(-D-Phe-L-

Fig. 1. Molecular conformation of *cyclo*(-D-Phe-L-His-) in Me_2SO-d_6 simulated by computer. Internal rotation angles: amide bond, planar cis; ϕ, −9.3°; ψ, 9.3°: His-χ^1, gauche: Phe-χ^2, 90°. Bond lengths and bond angles were usual values.
a, side view, b, top view.

His-) is less than that of others. As shown in Table 7, the folded conformation of the side-chain benzyl group of *cyclo*(-D-Phe-L-His-) amounts to nearly 60% in Me_2SO. The contribution of the folded conformation will be more important in an aqueous solution than in Me_2SO. Since the amide — aromatic interaction of the cyclic peptide backbone is stronger with a phenyl group than with an imidazolyl group,[11,12] *cyclo*(-D-Phe-L-His-) should have been forced to take the conformation depicted in Fig. 1 in an aqueous solution. Evidence supporting the conformation of Fig. 1 is collected in Table 6. For example, the NMR signal of the H^{α} of His residue in *cyclo*(-D-Phe-L-His-) shifts extensively to the upfield. This means that the benzyl group of the Phe residue situates very near to the H^{α} of the His residue. This type of arrangement of functional groups should lead to a poor stereochemical fit for the hydrophobic binding of *p*-nitrophenyl esters of long-chain carboxylic acids and the intramolecular nucleophilic attack.

Effect of the Nature of Hydrophobic Group on the Intramolecular Cooperation of a Hydrophobic Binding Group and a Nucleophilic Catalytic Group. It has been shown that the orientation of functional groups in the side chains of a cyclic dipeptide consisting of a hydrophobic D-amino acid and L-histidine is suitable to their intramolecular cooperation toward the hydrolysis of hydrophobic nitrophenyl carboxylates.[2] It was also shown above that subtle change in the structure of a hydrophobic side chain delicately influences the intramolecular cooperation, as in *cyclo*(-D-Phe-L-His-). To elucidate this point and to gain more information regarding the design of an efficient catalyst, the effect of the structure of the hydrophobic group in both catalyst and substrate on the reactivity was investigated.

First of all, $Me_3CCOOC_6H_4NO_2$ and *c*-$C_6H_{11}COOC_6H_4NO_2$ were chosen as the *p*-nitrophenyl carboxylates to be tested. They have a hydrophobic acyl chain which is different in structure from those investigated so far. These esters were hydrolyaed with a series of *cyclo*(-L- or D-Xyz-L-His-) and the experimental results are shown in Table 8.

Either $Me_3CCOOC_6H_4NO_2$ or *c*-$C_6H_{11}COOC_6H_4NO_2$ carries a highly hydrophobic acyl chain. However, both were not hydrolyzed efficiently with *cyclo*(-D-Xyz-L-His-) bearing a hydrophobic side chain. According to the examination regarding the molecular model, the acry group of $Me_3CCOOC_6H_4NO_2$ is spheric. Therefore, the arrangement of the acyl group and the ester group of a substrate does not fit with the arrangement of the functional groups of *cyclo*(-D-Xyz-L-His-). Similary, the cyclohexane ring of *c*-$C_6H_{11}COOC_6H_4NO_2$ assumes a rigid conformation, which makes a stereochemical fit between functional groups of the substrate and the catalyst difficult. This situation must have led to the sluggish reaction.

Next, *cyclo*(-D-Pip-L-His-) was synthesized as a cata-

Table 8. Second-order rate constants(k_{cat}, $dm^3 mol^{-1} min^{-1}$) for the hydrolysis of *p*-nitrophenyl pivalate and *p*-nitrophenyl cyclohexanecarboxylate by hydrophobic cyclic dipeptide catalysts *Cyclo*(-Xyz-L-His-)[a]

Substrate	$CH_3COOC_6H_4NO_2$	$Ph(CH_2)_2COOC_6H_4NO_2$	$CH_3(CH_2)_8COOC_6H_4NO_2$	$c\text{-}C_6H_{11}COOC_6H_4NO_2$
Cyclo(-D-Pip-L-His-)	0.9	1.3	0.5	1.8
Imidazole	17.5	14.0	7.4[b]	8.3

a) 25°C, pH 7.8, 20% dioxane/water, $[S]_0=3.0\times10^{-5}$ mol dm^{-3}. b) $[S]_0=6.0\times10^{-6}$ mol dm^{-3}.

lyst having a rigid hydrophobic functional group, and was used in the hydrolyses of *p*-nitrophenyl carboxylates. The experimental results are shown in Table 9.

In the hydrolysis catalyzed by *cyclo*(-D-Pip-L-His-), an efficient catalysis, as has been observed with other hydrophobic cyclic dipeptides [*cyclo*(-D-Xyz-L-His-)], was never observed. According to Bláha *et al.*,[13,14] the backbone of the cyclic dipeptide containing pipecolic acid, *cyclo*(-D-Pip-Gly-), *cyclo*(-D-Pip-L-Leu-), and *cyclo*(-D-Pip-L-Phe), is nearly planar. The piperidine ring of the Pip residue is not so strained as to seriously alter the backbone conformation of the cyclic dipeptide. As estimated from $J^{\alpha\beta}$ of the NMR spectrum of *cyclo*(-D-Pip-L-His-) in Me_2SO-d_6, 70% of the imidazolylmethyl groups take the folded form (*F*) and the rest (30%) the unfolded form (*U*). Therefore, *cyclo*(-D-Pip-L-His-) takes nearly the same conformation of functional groups as other hydrophobic *cyclo*(-D-Xyz-L-His-). The unexpectedly low catalytic activity of *cyclo*(-D-Pip-L-His-) should therefore be due to the insufficient flexibility of the peperidine ring of the Pip residue to inhibit a satisfactory stereochemical fit of functional groups between catalyst and substate.

The above experimental results indicate that cylic dipeptides consisting of a hydrophobic D-amino acid and an L-histidine could be an efficient catalyst for the hydrolysis of hydrophobic *p*-nitrophenyl carboxylates, that the efficient catalysis is based upon a satisfactory stereochemical fit of functional groups between catalyst and substrate, and that the functional group should bear a certain size and a moderate flexibility in order to attain the sterochemical fit.

Disproportionation of Cyclohexadienes Catalyzed by Metallic Nickel

Mutsuji SAKAI,* Toshiya KIMURA, Toshiaki NAKAOKA, Yasumasa SAKAKIBARA, and Norito UCHINO
Department of Polymer Science and Engineering, Kyoto Institute of Technology, Matsugasaki, Sakyo-ku, Kyoto 606
(Received August 10, 1984)

Cyclohexadienes, 1,3-cyclohexadiene (**1**) and 1,4-cyclohexadiene (**2**), disproportionated to benzene (**3**) and cyclohexene (**4**) in the presence of catalytic amounts of metallic nickel prepared from nickel halides and zinc powder in *N,N*-dimethyformamide (DMF) under nitrogen.

In the preceding paper, the authors pointed out that a small amount of benzene was formed in the hydrogenation of 1,4-cyclohexadiene by a $Ni(acac)_2$–$Al_2Et_3Cl_3$–PPh_3 catalyst.[1] Recently, it has been reported that Ziegler catalysts prepared from Co(II) or Ni(II) alkanoates and alkylaluminiums are active for the disproportionation of cyclohexadienes to benzene and cyclohexene.[2] Homogeneous catalysts (Cr,[3] Zr,[4] Ru,[5] Rh,[6] and Ir[7] compounds) are known for the disproportionation of cyclic dienes. In many cases, isomerization took place simultaneously. Catalytic reactions involving disproportionation and dehydrogenation are also noted with heterogeneous metal calalysts (Ni,[8] Rh,[9] and Pd[10] catalysts). We have found that metallic nickel (colloidal state) prepared from anhydrous nickel halides and zinc powder was active for the disproportionation of cyclohexadienes. Compared with other metal catalysts, advantages of the metallic nickel catalyst are negligible isomerization and dehydrogenation, and easy access to the reagents. The utility of metallic nickel for catalytic reactions will be further extended.

$$\text{Cyclohexadiene} \xrightarrow[\text{under } N_2]{NiBr_2\text{–Zn, in DMF}} \underset{(3)}{\text{Benzene}} + \underset{(4)}{\text{Cyclohexene}}$$

(1,3-Cyclohexadiene, **1**; 1,4-Cyclohexadiene, **2**)

Experimental

Materials. Metal halides, metal powders, and alkylaluminium compounds were commercially available and used without further purification. Solvents and dienes were dried and distilled under nitrogen before use. $[NiBr_2(PPh_3)_2]$ was prepared according to the literature.[11]

Procedure. A typical reaction of **1** is as follows. To a 50 cm^3 flask fitted with a septum inlet and a magnetic stirrer were added anhydrous nickel bromide (44 mg, 0.2 mmol) and zinc powder (65 mg, 1.0 mmol) in *N,N*-dimethylformamide (DMF) (15 cm^3). After the atmosphere was replaced with nitrogen the catalyst was allowed to stand overnight at room temperature. The mixture became a black solution containing fine metallic nickel. To the mixture was added **1** (400 mg, 5 mmol) in DMF (5 cm^3), and the mixture was stirred with a magnetic stirrer and kept in a thermostated bath. The reaction was stopped by adding a dilute hydrochloric acid solution and the aqueous mixture was shaken with toluene. The toluene extract was washed with water, dried over anhydrous calcium chloride, and subjected to GLC analysis.

Analysis. The gas chromatographic analyses were performed on a Shimadzu GC-8A instrument with a TC detector and helium carrier gas using a 3 m column of 20% bis(2-cyanoethyl) ether on Celite 545. The amounts of products were determined by the peak areas of chromatogram using *p*-xylene as an internal standard.

Results and Discussion

Cyclohexadienes (**1** and **2**) disproportionated to **3** and **4** by metallic nickel. The results are shown in Table 1. The catalyst prepared from anhydrous nickel chloride or bromide and zinc powder was most effective for the disproportionation reaction. Bis(acetylacetonato)nickel, nickel acetate, nickel sulfate, nickel hydroxide, and cobalt bromide have little activity for the reaction. Zinc powder was more effective as a reductant than magnesium and manganese powders. Three times amounts of zinc powder to nickel bromide were sufficient to reduce nickel(II). When sodium borohydride was used as a reductant, the hydrogenation of **1** took place predominantly to give **4**. Table 2 shows the effect of solvent. DMF, hexamethylphosphoric triamide (HMPA), and methanol were good solvents for the disproportionation. However, little disproportionation reaction occurred in dimethyl sul-

TABLE 1. NICKEL CATALYSTS FOR THE DISPROPORTIONATION OF **1**[a]

foxide (DMSO), acetonitrile, tetrahydrofuran (THF), and toluene. Under a nitrogen atmosphere, the mixture consisting of nickel bromide and zinc powder in DMF turned black after stirring for 5 h at room temperature. Resulting nickel did not precipitate and could not be separated by filtration. The catalyst mixture containing colloidal nickel was used as it was. It was not deteriorated over a long period and stable to water; however, it was air sensitive. An active species for the disproportionation may be metallic nickel since the reaction was retarded significantly by the addition of triphenylphosphine, as shown in Table 3. The disproportionation of **1** was studied in the temperature range from 0 to 100 °C, as shown in Fig. 1. At 100 °C the catalyst was satisfactorily active.[12] Table 4 shows that the 1,3-diene disproportionated faster than the 1,4-diene did. Little isomerization of cyclohexadienes was observed. 1-Methyl-1,4-cyclohexadiene (**5**), 1,3-cyclooctadiene (**6**), and 1,5-cyclooctadiene (**7**) did not react and remained unchanged under similar reaction conditions.

Table 2. Effect of solvent[a)]

a) **1**, 5 mmol; $NiBr_2$, 0.2 mmol; Zn, 1.0 mmol; solvent, 20 cm^3; temp, 60 °C.

In Scheme 1 the most probable mechanism of the disproportionation of **1** is illustrated and metallic nickel is represented as Ni(0) (one atom). Nickel(II) is reduced to nickel(0) by zinc. Nickel(0) is colloidal and so fine that it has large surface area and many reaction sites. The diene **1** is activated by coordination (adsorption) on the active site of nickel(0). The cleavage of allylic C–H bond of **1** by nickel(0) (oxidative addition) gives a nickel hydride intermediate, followed by insertion reaction, β-hydrogen elimination, and reductive elimination to give **3** and **4**. No disproportionation of **4** occurs, probably because of its weak coordination. The diene **2** also disproportionated with nickel(0) under the conditions, but much more

Oxidative Cyclization of 3-(3-Heterocycle-substituted 2-Propenoyl)tropolones

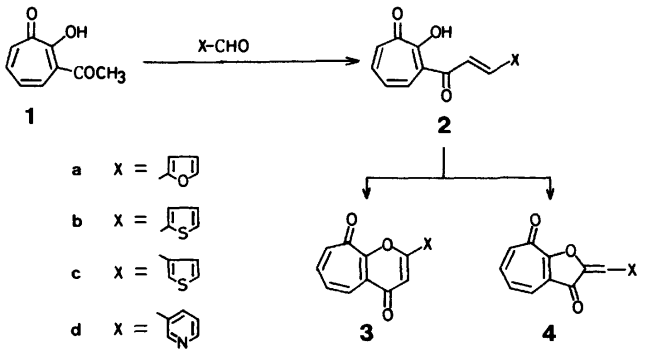
Masaaki HONDA and Kimiaki IMAFUKU*
Department of Chemistry, Faculty of Science, Kumamoto University, Kurokami, Kumamoto 860
(Received August 11, 1984)

3-[3-(2-Furyl)-2-propenoyl]- (**2a**), 3-[3-(2-thienyl)-2-propenoyl]- (**2b**), 3-[3-(3-thienyl)-2-propenoyl]- (**2c**), and 3-[3-(3-pyridyl)-2-propenoyl]tropolone (**2d**) were prepared by the condensation of 3-acetyltropolone with the corresponding heterocyclic aldehydes. The compounds **2a—d** were oxidized with selenium dioxide to afford 2-heterocycle-substituted cyclohepta[*b*]pyran-4,9-diones, while oxidation with both alkaline hydrogen peroxide and 2,3-dichloro-5,6-dicyano-*p*-benzoquinone gave 2-(heterocycle-substituted methylene)-2*H*-cyclohepta-[*b*]furan-3,8-diones.

Previously, we reported that 3-cinnamoyltropolones were oxidized with selenium dioxide,[1] alkaline hydrogen peroxide,[2] and 2,3-dichloro-5,6-dicyano-*p*-benzoquinone (DDQ)[3] to afford flavonoid-like compounds. The present paper deals with the synthesis and oxidative cyclization of 3-(2-propenoyl)tropolones having a five- or six-membered heterocyclic ring at 3-position on the 2-propenoyl group and the effects of the heterocyclic ring on the cyclization.

Results and Discussion

Synthesis. 3-Acetyltropolone (**1**) reacted with heterocyclic aldehydes at room temperature in the presence of potassium hydroxide solution to afford each of 3-(3-heterocycle-substituted 2-propenoyl)tropolones (**2a—d**). Their structures were established by the spectral data and elemental analysis, which are summarized in Table 1.



Scheme 1.

Oxidation with Selenium Dioxide. In flavonoid chemistry, Mahal *et al.* found that 2′-hydroxychalcones were oxidized with selenium dioxide to give flavones.[4] When a solution of 3-(3-heterocycle-substituted 2-propenoyl)tropolones (**2a—c**) in dioxane were refluxed in the presence of selenium dioxide, 2-heterocycle-substituted cyclohepta[*b*]pyran-4,9-diones (**3a—c**) were isolated. Their structures were determined by the spectral data and elemental analysis, which are summarized in Table 2.

The reaction of **2d**, which has a pyridine ring, did not give a desired product but a tarry material. The variation of the reaction conditions, such as molar ratio, solvent, reaction time, *etc.*, did not improve the reaction.

Oxidation with Alkaline Hydrogen Peroxide. It is well known that 2′-hydroxychalcones are oxidized with alkaline hydrogen peroxide to give the corresponding flavonols (Algar-Flynn-Oyamada reaction)[5,6] and that, if a methoxyl group is present at the 6′-position of the chalcones, aurones rather than flavonols are obtained.[7] In troponoid, we found that 3-cinnamoyltropolones were oxidized with alkaline hydrogen peroxide to give 2-arylmethylene-2*H*-cyclohepta[*b*]furan-3,8-diones.[2]

When 3-(3-heterocycle-substituted 2-propenoyl)tropolones (**2a—d**) were oxidized with hydrogen peroxide in the presence of sodium hydroxide, 2-(heterocycle-substituted methylene)-2*H*-cyclohepta[*b*]furan-3,8-diones (**4a—d**) were obtained. Their structures were deterimed by the spectral data and elemental analysis, which are summarized in Table 3.

In the reaction, large excess of hydrogen peroxide or alkali decreased the yields of the products. In addition, the heterocyclic aldehydes were detected in the reaction mixture by the NMR measurements.

Oxidation with DDQ. In dehydrocyclization of 3-cinnamoyltropolones with DDQ, we found that unsubstituted and 3-methoxy-substituted 3-cinnamoyltropolones gave the flavone-like compounds, while the other 2- and/or 4-methoxy-substituted ones gave aurone-like compound.[3] Thus, it was expected that π-rich five-membered heterocycle-substituted 3-(2-propenoyl)tropolones might give the aurone-like products, while π-defficient six-membered heterocycle-substituted 3-(2-propenoyl)tropolones might give the flavone-like products. However, a mixture of the compounds **2a—d** and DDQ in dry benzene was refluxed to afford **4a—d** in all the cases. The difference between the five- and six-membered heterocyclic ring was not observed.

Experimental

The melting points were determined with a Yanagimoto MP-S2 apparatus and are uncorrected. The IR and UV spectra were taken on a JASCO IRA-1 and a Hitachi EPS-3T spectrophotometer, respectively. The NMR spectra were recorded with a Hitachi-Perkin-Elmer R-24 spectrometer (60 MHz). The high-resolution mass spectra were obtained with a JEOL DX-300 apparatus.

*3-(3-Heterocycle-substituted 2-Propenoyl)tropolones (**2a—d**).* Potassium hydroxide solution (5%, 40 ml) was added to a mixture of 3-acetyltropolone (**1**) (1.6 g, 10 mmol) and heterocyclic aldehyde (20 mmol) in 50% aqueous methanol (60 ml). After stirring for 24 h at room temperature, the mixture was diluted with water (100 ml) and acidified with 3 M (1 M=1 mol dm^{-3}) hydrochloric acid to give a precipitate, which was recrystallized from ethanol to afford 3-(3-heterocycle-substituted 2-propenoyl)tropolone (**2a—d**).

Selenium Dioxide Oxidation. A mixture of **2** (**a**, **b**, or **c**) (1.0 mmol) and selenium dioxide (584 mg, 5.0 mmol) in dioxane (10 ml) was refluxed for 36 h. The solvent was evaporated off, and the residue was diluted with ethanol (100 ml) and stirred for 2 h in the presence of Raney nickel (580 mg, 10 mmol). After filtration and removal of the ethanol, the residue was dissolved in chloroform, washed with a saturated sodium hydrogencarbonate solution and water, and dried over sodium sulfate. Evaporation residue was chromatographed on a Wakogel B-10 plate (30×30 cm) with diethyl ether and recrystallized from ethanol–dichloro-

methane to give 2-heterocycle-substituted cyclohepta[*b*]-pyran-4,9-dione (**3a—c**).

Alkaline Hydrogen Peroxide Oxidation. To a suspended solution of **2** (**a**, **b**, **c**, or **d**) (2.0 mmol) in ethanol (40 ml) was added 30% hydrogen peroxide (2 ml) under stirring at 0 °C. After addition of 12% potassium hydroxide solution (10 ml), the stirring was continued for 5 h. The mixture was acidified with 3 M hydrochloric acid and extracted with chloroform. The extract was concentrated and chromatographed on a Wakogel B-10 plate (30×30 cm) with chloroform and recrystallized from benzene to to give 2-(heterocycle-substituted methylene)-2*H*-cyclohepta[*b*]furan-3,8-dione (**4a—d**).

DDQ Oxidation. A mixture of **2** (**a**, **b**, **c**, or **d**) (1.0 mmol) and DDQ (450 mg, 2.0 mmol) in dry benzene (20 ml) was refluxed for 20 h. The reaction mixture was poured into a saturated sodium carbonate solution (100 ml) and extracted with chloroform. The extract was washed with water, dried over sodium sulfate, and brought to dryness by evaporation of the solvent. The residue was recrystallized from benzene to give **4a—d**.

We wish to thank Professor John F. W. McOmie, University of Bristol, England, for his valuable suggestion. We are also grateful to Mr. Hiromichi Matsuura, Wakunaga Pharmaceutical Co., Ltd., Hiroshima, for his kind measurements of the high-resolution mass spectra.

Reaction of Substituted Benzaldehydes with Sodium Hydrogensulfide or Sodium Sulfide in Liquid Ammonia

Yuji TAKIKAWA,* Kazuaki SHIMADA, Tetsuo MINAMI, Ryu SATO,† and Saburo TAKIZAWA
Department of Applied Chemistry, Faculty of Engineering, Iwate University, Morioka, Iwate 020
†*Department of Resource Chemistry, Faculty of Engineering, Iwate University, Morioka, Iwate 020*
(Received August 23, 1984)

Reactions of substituted benzaldehydes with sodium hydrogensulfide in the presence of nitrobenzene, nitrosobenzene, or azobenzene in liquid ammonia produce the corresponding benzyl alcohols and benzamides. On the other hand, reaction of benzaldehyde with sodium sulfide produces benzyl alcohol and benzamide. A reaction mechanism has been proposed which involves benzaldehyde anion radical.

The Cannizzaro reaction has been considered as one of the most fundamental reactions in organic chemistry.[1] A variety of mechanisms for this reaction have been proposed,[2] and the mechanism presently accepted involves a hydride transfer. Radical chain mechanisms have been suggested[3] but discounted mainly because radical initiators or inhibitors have no significant effect on reaction rate.[4] Recently, however, Chung[5] has evidenced a possible involvement of radical intermediates in a Cannizzaro reaction consuming benzaldehyde-α-d in alkaline aqueous dioxane or dioxane alone; a formation of monodeuterated benzyl alcohol-α-d_1 suggests formation of benzaldehyde anion radical, followed by hydrogen atom abstraction from solvent. Ashby *et al.*[6] have studied reaction of benzaldehydes having electron-withdrawing substituents with NaOH in THF/HMPA (9:1) by EPR spectroscopy and obtained evidence for existence of paramagnetic species in solution. In our previous paper,[7] we have reported that reaction of 9-nitroanthracene with NaSH in liquid ammonia gave 10,10′-di-aci-nitro-9,9′,10,10′-tetrahydro-9,9′-bianthryl, di-9-anthryl disulfide, anthracene, and anthraquinone. These products suggest formation of 9-nitroanthracene anion radical by transfer of electron generated from NaSH-liq NH_3 to 9-nitroanthracene. This result urged us to attempt oxidation-reduction reactions *via* single electron-transfer by using NaSH- or Na_2S-liq. NH_3. In this paper, we report results on reaction of substituted benzaldehydes with NaSH or Na_2S in liquid ammonia.

Results and Discussion

Benzaldehyde (**1**) reacts with liquid ammonia in the presence and absence of NaSH to give *N*,*N*′-dibenzylidene-α,α-toluenediamine quantitatively, and no such oxidation-reduction as the well-known Cannizzaro reaction occurs (Runs 1 and 2 in Table 1). However, addition of a small amount of nitrobenzene in this reaction system gave benzyl alcohol and benzamide in 27 and 25% yields, respectively, besides a small amount of *N*-benzylideneaniline (Run 3 in Table 1). On the other hand, reaction of **1** with $Na_2S \cdot 5H_2O$ in liquid ammonia gave benzyl alcohol and benzamide in good yields without formation of *N*,*N*′-dibenzylidene-α,α-toluenediamine (Run 5 in Table 1). Reaction of substituted benzaldehydes with NaSH in the presence of nitrobenzene gave the corresponding benzyl alcohols and benzamides (Runs 6—9 in Table 1). This reaction was also catalyzed by nitrobenzene derivatives such as *m*-dinitrobenzene and 1,3,5-trinitrobenzene (Runs 2—4 in Table 2). On the other hand, no formation of benzyl alcohol or benzamide was effected by addition of either aromatic nitro compounds, such as *p*-dinitrobenzene, 1-nitronaphthalene,[8] and 9-nitroanthracene,[7] which give substitution products in reaction with NaSH in liquid ammonia, or nitro compounds, such as *p*-nitroaniline, *p*-nitrotoluene, and nitromethane, which have high polarographic half-wave potentials (Runs 5—10

in Table 2). Because nitrobenzene was easily reduced by NaSH in liquid ammonia to give aniline, azobenzene, and other reductants,[8] we investigated whether the catalytic behavior for the formation of benzyl alcohol and benzamide was due to the addition of nitrobenzene or its reductant. Nitrobenzene, nitrosobenzene, and azobenzene were found to exhibit the catalytic behavior for the formation of benzyl alcohol as shown in Table 3. Azoxybenzene, phenylhydroxylamine, hydrazobenzene, and aniline did not exhibit the catalytic behavior. Moreover, reactions of nitrobenzene or its reductants with NaSH at 40 °C for 5 h in liquid ammonia were investigated, results obtained being shown in Table 4. Both nitrobenzene and nitrosobenzene, showing the catalytic behavior, reacted with NaSH in liquid ammonia to give azobenzene, whereas azobenzene, after allowed to react with NaSH, resulted in almost complete recovery of itself only with formation of a small amount of hydrazobenzene. Accordingly, azobenzene is one of catalyzers for the formation of benzyl alcohol and benzamide in the reaction of **1** with NaSH in liquid ammonia. However, we can't deny that nitrobenzene and nitrosobenzene themselves act also as catalyzers.

On the other hand, the reaction of **1** with $Na_2S \cdot 5H_2O$ produced benzyl alcohol and benzamide in good yields (Run 5 in Table 1).

This reaction was investigated in such solvents as Et_2NH, Et_3N, MeOH, DMF, and HMPA, results obtained being shown in Table 5. The reaction with NaSH occurred only in such solvents[9,10] as liquid ammonia and HMPA which are favorable for single electron-transfer reaction,[11,12] but the reaction with $Na_2S \cdot 5H_2O$ occurred in various organic solvents.

Attempted reaction of benzophenone with NaSH in the presence of azobenzene in liquid ammonia at 40 °C for 5 h resulted only in recovery of the substrate. An addition of formalin (37%) to this reaction system, however, led to formation of benzhydrol in 27% yield;

reaction with $Na_2S \cdot 5H_2O$ in the presence of formalin (37%) in liquid ammonia under the same conditions yielded benzhydrol in 58% yield. These results suggest that the methylenic hydrogen generated newly in the alcohol is not the hydrogen in H_2O, NH_3, or NaSH but the one in formaldehyde. Consequently, the formation of benzyl alcohol and benzamide in the reaction of substituted benzaldehydes with NaSH or $Na_2S \cdot 5H_2O$ in liquid ammonia is taken to be a result of an intermolecular reaction.

The following facts have been disclosed on the reaction of substituted benzaldehydes with NaSH in liquid ammonia.

1. The reaction with liquid ammonia in the absence and presence of NaSH produces *N,N'*-dibenzylidene-α,α-toluenediamine quantitatively.
2. The reaction proceeds only in the presence of an additive such as nitrobenzene, nitrosobenzene, or azobenzene which are good electron acceptors.
3. No sulfur-containing products are produced.
4. *N,N'*-dibenzylidene-α,α-toluenediamine formed by the reaction of benzaldehyde with ammonia does not react with NaSH in the presence of azobenzene in liquid ammonia.
5. The methylenic hydrogen generated newly comes from the formyl group in benzaldehydes.
6. The reaction proceeds only in liquid ammonia or HMPA.

Since **1** reacts with ammonia in the absence and presence of NaSH to give *N,N'*-dibenzylidene-α,α-toluenediamine quantitatively, the formation of benzyl alcohol and benzamide is not a simple Cannizzaro-like reaction *via* intermolecular reaction of **1** with hemiaminal, which has been formed from **1** and ammonia.

Another Cannizzaro-like reaction

$$\underset{\mathbf{1}}{PhCHO} + NaSH \xrightarrow[liq.\,NH_3]{} Ph\text{-}\underset{\displaystyle SH}{\overset{\displaystyle O^-}{\overset{|}{C}}}\text{-}H \xrightarrow{1}$$

$$PhCH_2OH + PhCOSH \xrightarrow{NH_3} PhCONH_2 + H_2S$$

is also conceivable. This mechanism, however, is also denied because in this reaction no sulfur-containing products are obtained and because the reaction of thiobenzoic acid with liquid ammonia at 40°C for 5 h gives ammonium thiobenzoate quantitatively.

The other Cannizzaro-like reaction

$$PhN{=}NPh + NH_3 \rightleftharpoons Ph\overset{+}{N}H{=}NPh + NH_2^- \xrightarrow{1}$$

$$Ph\text{-}\underset{\displaystyle NH_2}{\overset{\displaystyle O^-}{\overset{|}{C}}}\text{-}H \xrightarrow{1} PhCH_2OH + PhCONH_2$$

is also conceivable, but, in conflict with this sequence, the reaction of **1** with ammonia in the presence of azobenzene gives *N,N'*-dibenzylidene-α,α-toluenediamine, no benzyl alcohol or benzamide being formed (Run 8 in Table 3). Accordingly, this mechanism is also unlikely.

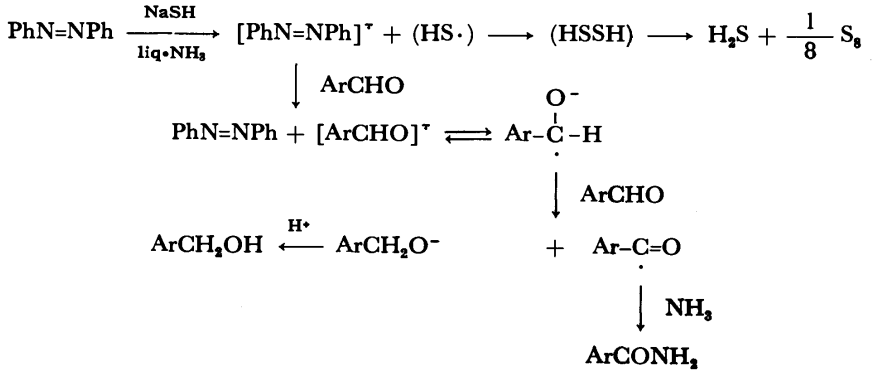
Meanwhile, as described above, the reduction of **1** by hydrazobenzene is also unlikely (Runs 5 and 8 in Table 3).

Since the reactions in question proceed only in the presence of an additive such as nitrobenzene, nitrosobenzene, or azobenzene which are good electron acceptors,[10,11] a reaction mechanism involving single electron-transfer, as shown in Scheme 1, may be considered as one of plausible mechanisms.

The polarographic half-wave potentials (−0.45—0.04 V in H_2O) of nitrobenzene, nitrosobenzene, and azobenzene are lower than those (−1.15—−0.77 V in H_2O) of substituted benzaldehydes and benzophenone. Accordingly, the initiation step is an electron-transfer to azobenzene from NaSH as an electron-donor species in liquid ammonia,[7] and the subsequent electron-transfer to benzaldehyde from azobenzene anion radical generates benzaldehyde anion radical. It then abstracts hydrogen atom from benzaldehyde to form benzyl alcoholate and benzoyl radical. The benzyl alcoholate in turn abstracts proton from solvent to afford benzyl alcohol. Meanwhile, the benzoyl radical reacts with NH_3 to afford benzamide. A solution of NaSH in HMPA at room temperature assumes an intense blue color. This solution liberate gradually H_2S and elemental sulfur according to

$$2\,NaSH \xrightarrow{HMPA} (2\,Na^+ e^-) + (2\,HS\cdot),$$

$$(2\,HS\cdot) \longrightarrow (HSSH) \longrightarrow H_2S + \frac{1}{8} S_8.$$



Scheme 1.

These results also support the single electron-transfer mechanism. We investigated these reactions by EPR spectroscopy in HMPA, but the signals obtained were too broad to allow us to make their assignment.

Experimental

General. The reagents used were commercial reagent-grade materials except 9-Nitroanthracene and were purified by recrystallization or distillation prior to use. 9-Nitroanthracene was prepared and purified according to the literature.[13] IR spectra were recorded on a Hitachi 295 infrared spectrophotometer. ^1H NMR spectra were recorded on a Hitachi R-22 (90 MHz) spectrometer in carbon tetrachloride or deuteriochloroform solution containing tetramethylsilane as an internal standard. Mass spectra were recorded on a Hitachi RMU-6M spectrometer with a direct inlet system operating at 20 eV. GLC analysis was carried out with a Hitachi 063 gas chromatograph. For column chromatography Wakogel C-300 was used. Products obtained were identified by comparing IR, NMR, MS, GLC, and MP data with those of authentic samples.

Reaction of Benzaldehyde (1) with NaSH in the Presence of Nitrobenzene in Liq. NH_3. A solution of **1** 212 mg (2 mmol), NaSH (98%) 114 mg (2 mmol), and nitrobenzene 31 mg (0.25 mmol) in liq. NH_3 (10 ml) in a titanium autoclave under nitrogen atmosphere was stirred at 40 °C for 5 h. After removal of NH_3, CCl_4 was added to the reaction mixture. The yields of benzyl alcohol (27%), and *N*-benzylideneaniline (9%) and *N,N'*-dibenzylidene-*α,α*-toluenediamine (5%) were determined by measuring NMR intensities of methylene and methine groups, respectively, using *p*-nitrotoluene as an internal standard in CCl_4 solution. The aqueous solution of residue was extracted with $CHCl_3$. After removal of $CHCl_3$, the residue was separated by silica-gel column chromatography using $CHCl_3$ as an eluent to give benzamide in 25% yield.

Reaction of Substituted Benzaldehydes with NaSH in the Presence of Various Nitro Compounds in Liq. NH_3. A solution of a substituted benzaldehyde (2 mmol), NaSH (98%) 114 mg (2 mmol), and a nitro compound (0.1—2.0 mmol) in liq. NH_3 (10 ml) in a titanium autoclave under nitrogen atmosphere was stirred at 40 °C for 5 h. The reaction mixture was treated as in the case of the reation with nitrobenzene added. Results obtained are summarized in Tables 1 and 2.

Reaction of Benzaldehyde (1) with NaSH in the Presence of a Reductant of Nitrobenzene in Liq. NH_3. A solution of 212 mg (2 mmol), NaSH (98%) 114 mg (2 mmol), and a reductant (2 mmol) in liq. NH_3 (10 ml) in a titanium autoclave under nitrogen atmosphere was stirred at 40 °C for 5 h. After removal of NH_3, CCl_4 was added to the reaction mixture. The yield of benzyl alcohol was determined by measuring the NMR intensity of the methylene group using *p*-nitrotoluene as an internal standard in CCl_4 solution.

Reaction of Nitrobenzene or its Reductants with NaSH in Liq. NH_3. A solution of nitrobenzene or its reductants (nitrosobenzene, phenylhydroxylamine, azoxybenzene, azobenzene, hydazobenzene, or anilne,) (2 mmol), and NaSH (98%) 114 mg (2 mmol) in liq. NH_3 (10 ml) in a titanium autoclave under nitrogen atmosphere was stirred at 40 °C for 5 h. After removal of NH_3, CCl_4 was added to the reaction mixture, and filtered. After removal of CCl_4, the residue was separated by silica-gel column chromatography using $CHCl_3$ as an eluent to give reductants of nitrobenzene. Results obtained are summarized in Table 4.

Reaction of Benzaldehyde (1) with $Na_2S \cdot 5H_2O$ in Liq. NH_3. A solution of **1** 212 mg (2 mmol) and $Na_2S \cdot 5H_2O$ 336 mg (2 mmol) in liq. NH_3 (10 ml) in a titanium autoclave under nitrogen atmosphere was stirred at 40 °C for 5 h. The reaction mixture was treated similarly to give benzyl alcohol and benzamide in 35 and 37% yield, respectively.

Reaction of Benzophenone with NaSH in the Presence of Azobenzene and Formalin in Liq. NH_3. A solution of benzophenone 364 mg (2 mmol), NaSH (98%) 114 mg (2 mmol), azobenzene 182 mg (1 mmol), and formalin (37%) 162 mg (2 mmol) in liq. NH_3 (10 ml) in a titanium autoclave under nitrogen atmosphere was stirred at 40 °C for 5 h. After removal of NH_3, the reaction mixture was extracted with $CHCl_3$. After removal of $CHCl_3$, the residue was separated by silica-gel column chromatography using $CHCl_3$ as an eluent to give benzhydrol in 27% yield.

Reaction of Benzophenone with $Na_2S \cdot 5H_2O$ in the Presence of Formalin in Liq. NH_3. A solutin of benzophenone 364 mg (2 mmol), $Na_2S \cdot 5H_2O$ 336 mg (2 mmol), and formalin (37%) 405 mg (5 mmol) in liq. NH_3 (10 ml) in a titanium autoclave under nitrogen atmosphere was stirred at 40 °C for 5 h. Similar treatment of the reaction mixture gave benzhydrol in 58% yield.

The Synthesis of the Chloro and Dichloro Derivatives of 2,10-Dihydroxydicyclohepta[*b,d*]furan-3,9-diones

Tomoyuki KUSABA, Akira MORI,† and Hitoshi TAKESHITA*,†

Graduate School of Engineering Sciences, 39, Kyushu University, Kasuga-koen, Kasuga, Fukuoka 816

†*Research Institute of Industrial Science, 86, Kyushu University, Kasuga-koen, Kasuga, Fukuoka 816*

(Received September 3, 1984)

4,8-Dichloro- and 5,7-dichloro-2,10-dihydroxydicyclohepta[*b,d*]furan-3,9-diones were synthesized. Although the latter could be obtained by condensation of 4-chloro-*p*-tropoquinone and its hydroquinone, the former required the hydrolysis of condensate of 3-chloro-*p*-tropoquinone and 7-chloro-5-hydroxy-2-methoxytropone. This mixed condensation led to several unsymmetrically substituted derivatives in improved yields.

In 1968, Norin and Baggaley[1] reported a structural study on a dimeric troponoid constituent from a conifer, *Juniperus utahensis Lemm.*, utahin (**1a**).[2] They suggested its identity with the oxidative condensation product obtained *via* several routes from hinokitiol (4-isopropyltropolone)[3,4] but was reluctant to draw a final conclusion as to its structure. A similar condensate (**1b**) has been obtained from 4-methyltropolone by Haworth *et al.*[5] Recently, we have reported the synthesis of the parent compound, 2,10-dihydroxydicyclohepta[*b,d*]furan-3,9-dione[6] (**2**), from 5-hydroxytropolone (**3**) and *p*-tropoquinone (**4**),[7] as well as the unambiguous synthesis of **1a**.[8]

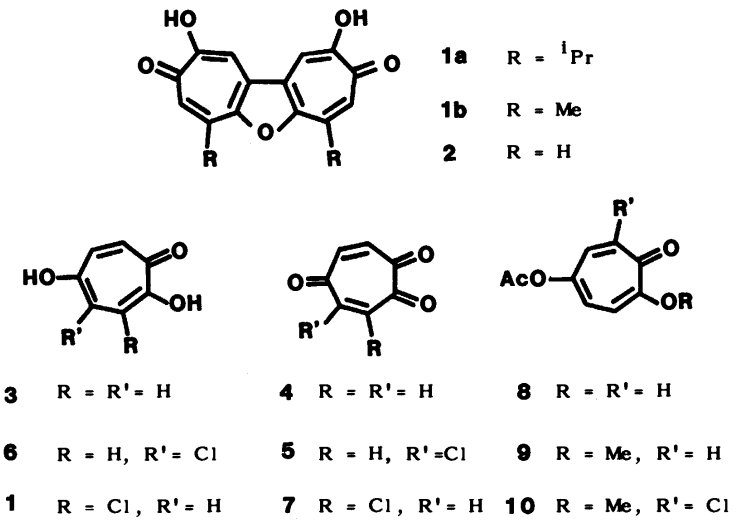
In this paper, we wish to describe the synthesis of 4,8-, 5,7-, and 1,8-dichloro derivatives as well as the controlled mixed condensation of the tropoquinones with 5-hydroxy-2-methoxytropones.

First two chloro-*p*-tropoquinones have been prepared as follows: 4-Chloro-*p*-tropoquinone (**5**) was easily prepared by means of DDQ (2,3-dichloro-5,6-dicycano-*p*-benzoquinone)-oxidation of 4-chloro-5-hydroxytropolone (**6**) which was derived from *p*-tropoquinone (**4**)[9] with hydrochloric acid.[10] On the other hand, 3-chloro-*p*-tropoquinone (**7**) was prepared from 5-acetoxytrpolone (**8**) *via* 5-acetoxy-2-methoxytropone (**9**), 4-acetoxy-2-chloro-7-methoxytropone (**10**), and 3-chloro-5-hydroxytropolone (**11**) by sequential reactions with diazomethane, *N*-chlorosuccinimide (NCS),[11] hydrochloric acid in acetic acid, and the DDQ-dehydrogenation.

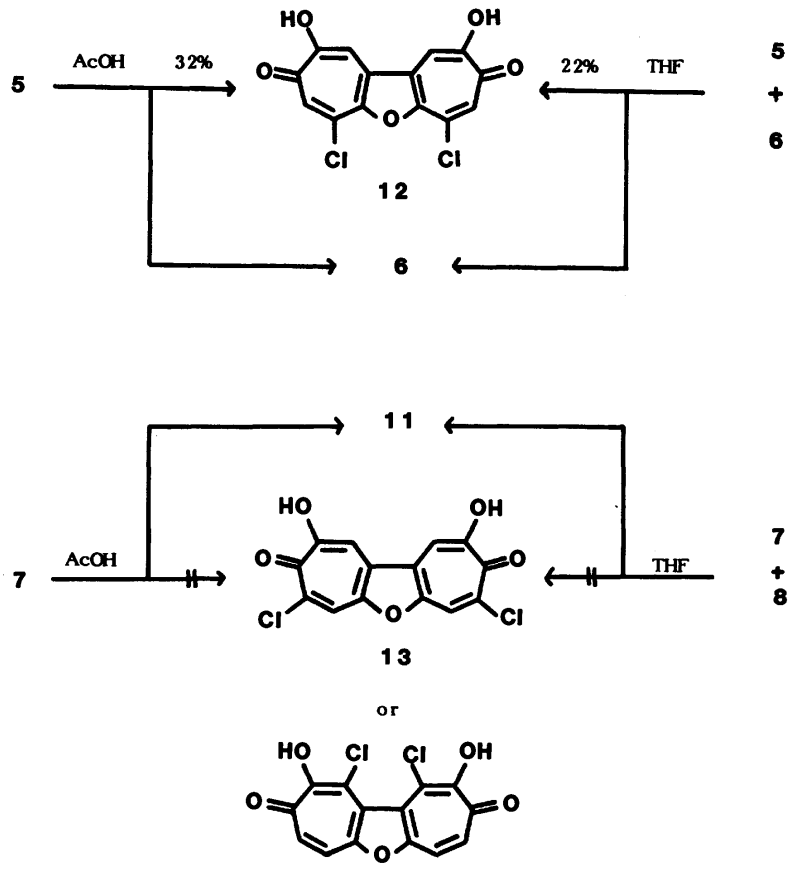
Following our previous methods, preparation of the 5,7-dichloro derivative (**12**) was carried out in two ways; the first was the partial reduction of **5** with acetic acid to yield **12** in 32% yield. The major reaction path in this case was, however, the reduction of **5** to its hydroquinone, **6**. The second was the coupling of **5** and **6** in tetrahydrofuran (THF) to give **12** in 22% yield. Again the reduction of **5** to **6** was the preferred process; this has led us to conclude that THF is also suitable for the reduction of tropoquinones to 5-hydroxytropolones.

Moreover, attempts to prepare 4,8-dichloro derivative (**13**) or 1,8-dichloro derivative (**14**) by the two methods failed; again, the reduction of **7** to **11** was exclusive. Therefore, we have modified the substrate to the 2-methoxytropone derivative based on the following grounds.

Since 3-bromotropolone (**A**) has been known to exist mainly as the tautomeric form of 3-bromo-2-hydroxytropone (**Aa**),[12] the predominant tautomer of 3-chloro-5-hydroxytropolone (**11**) must be a similar 3-chloro-2,5-dihydroxytropone (**11a**). From the view on this bond fixation, the condensation of **11** must be facilitated at C-4 over C-6. On the other hand, a steric hindrance from the adjacent chlorine atom must disfavor the condensation at C-4. Consequently, the attempted



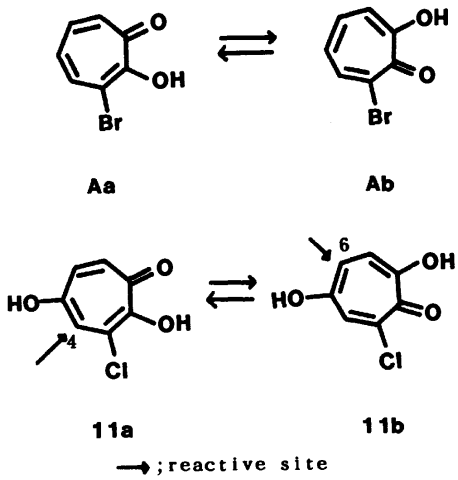
Scheme 1.



Scheme 2.

condensation of **11** with the quinone, **7**, which also possesses an adjacent chlorine atom at the reactive site, C-4, should merely have resulted in the reduction of **7** to **11**.

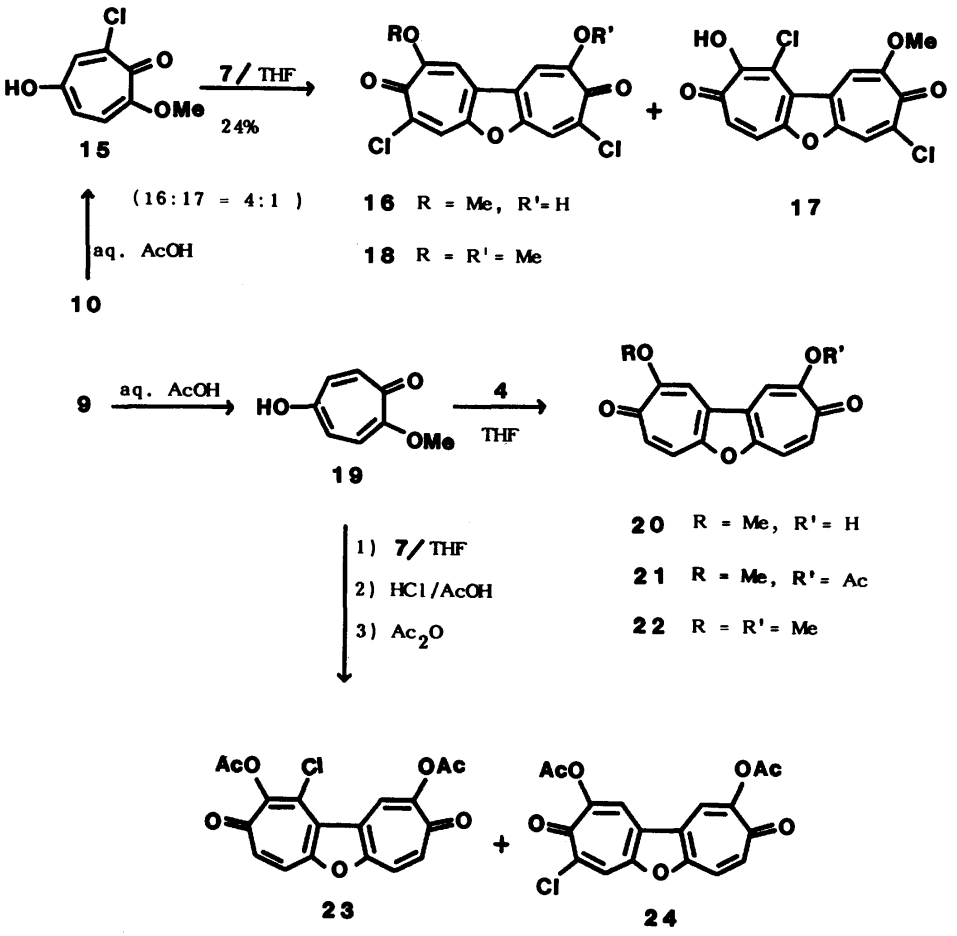
Thus, in view of the bond alternation, the fixed C=C bond system of **11** in the 2-chloro-7-hydroxy form would facilitate the condensation. This can be simply done by making a monomethyl ether. A mild condensation of 2-chloro-4-hydroxy-7-methoxytropone (**15**), which could be prepared from **10** by a 33%-aqueous acetic acid-hydrolysis, with **7** at 15—25 °C furnished two condensates in 24% yield with a 4:1 ratio; they are 4,8-dichloro-2-methoxy derivative (**16**) and 1,8-dichloro-10-methoxy derivative (**17**). From the mixture, the major product, **16**, was isolated after methylation to 4,8-dichloro-2,10-dimethoxy derivative (**18**) by sublimation. The hydrochloric acid-hydrolysis of **18** or **16** in acetic acid afforded **13**. Thus, the use of the 5-hydroxy-2-methoxytropones has not only provided an entry for mixed types of condensates, but also improved the yields for the single species condensates; *e.g.*, when 5-hydroxy-2-methoxytropone (**19**), which could be prepared easily from **9**, was mixed with **4** in THF at 15—25 °C for 15 min, the condensate isolated in 45% yield was the 2-methoxy derivative (**20**). This compound **20** was characterized as 2-acetoxy-10-methoxy derivative (**21**), and 2,10-dimethoxy derivative (**22**).



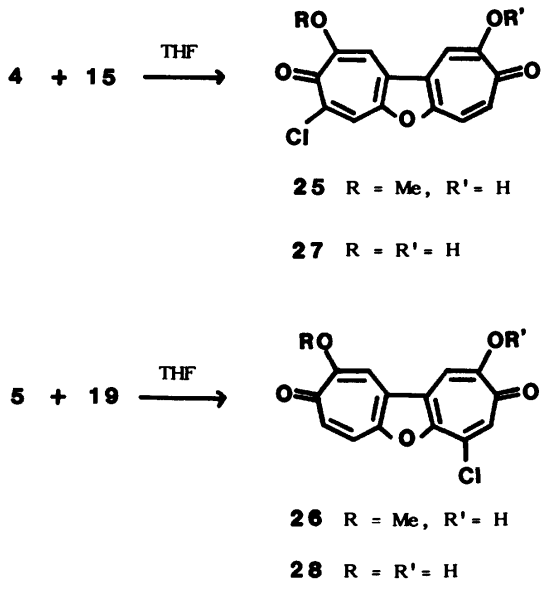
Scheme 3.

Similarly, the condensation products of **7** and **19**, isolated by consecutive treatments with hydrochloric acid in acetic acid and with acetic anhydride, were 2,10-diacetoxy-1-chloro derivative (**23**) and 2,10-diacetoxy-4-chloro derivative (**24**). Further, the condensations of **4** with **15** and **5** with **19** gave 4-chloro-2-methoxy derivative (**25**) and 7-chloro-2-methoxy derivative (**26**) in regiospecific fashion, respectively. The hydrolysis of **25** and **26** yielded 4-chloro (**27**) and 5-chloro (**28**) derivatives.

In conclusion, appropriate combinations of the



Scheme 4.



Scheme 5.

two components, *p*-tropoquinones and 5-hydroxy-2-methoxytropones, are capable of leading to various kinds of the dicyclohepta[*b*,*d*]furandione derivatives in improved yields, some of which are indeed quantitative after subtracting the amounts of recovered troponoids. Various aspects of the chemistry of these condensed furan derivatives are under investigation.

Experimental

Elemental analyses were performed with a Hitachi 026 Model CHN Analyzer by Miss M. Yamaguchi and S. Hirashima, at this Institute. The mps were measured by a Yanagimoto Micro-mp Apparatus, and were uncorrected. The IR spectra were taken either in CCl_4 solutions or as KBr disks with a Jasco Model A 102 spectrometer. The NMR spectra were measured, in $CDCl_3$ solution unless otherwise stated, by a JEOL FX100 Model Spectrometer, and the chemical shifts were expressed in the δ unit from the internal TMS. The mass spectra were measured on a JEOL OlSG Model Apparatus.

Preparation of 4-Chloro-p-tropoquinone (5). To an acetone solution (10 cm^3) of **6**[9] (260 mg), was added an acetone solution (5 cm^3)of DDQ (375 mg) at 15—25 °C. After 10 min, the acetone was removed *in vacuo*, and the residue was washed with benzene. The benzene washings were combined, concentrated, and chromatographed on a silica-gel column with benzene to yield pale yellow needles, mp 91—93 °C (decomp), **5**, 198 mg (77%) [Found: C, 49.32; H, 1.84%. Calcd for $C_7H_3O_3Cl$: C, 49.29; H, 1.78%. MS *m/z*, 170 and 172 (M^+). ^1H NMR δ=6.83 (1H, d, J=13 Hz), 6.97 (1H, d, J=13 Hz), and 7.30 (1H, s). ^{13}C-NMR δ=133.3, 133.7, 137.6, 147.2, 179.6, 182.5, and 183.4. IR ν 3050, 1655, 1630, 1600, 1235, 920, and 855 cm^{-1}].

Preparation of 5-Acetoxytropolone (8). To an AcOH solution (20 cm^3) of **3** (2.50 g), Ac_2O (2 cm^3) was added at 100 °C for 1 h, and the mixture was refluxed for 1.5 h. The reaction mixture was distilled *in vacuo*, and the residue

washed with $CHCl_3$ to recover the insoluble **3**, 1.28 g (51%). From the filtrate, colorless crystals, **8**, 1.60 g (100%), mp 107—108 °C (lit,[13] 110—111 °C) [^{1}H NMR δ=2.29 (3H, s), 7.08 (2H, dd, J=11, 1.5 Hz), 7.16 (2H, dd, J=11, 1.5 Hz), and 8.37 (1H, br. s). ^{13}C NMR δ=20.9, 122.6 (2C), 131.6 (2C), 149.3, 169.4 (2C), and 170.7], were isolated after recrystallizations from EtOAc–hexane (1:2).

Preparation of 5-Acetoxy-2-methoxytropone (9). A $CHCl_3$ solution (10 cm^3) of **8** (1.6 g) was treated with an Et_2O solution of CH_2N_2 at 0 °C to give **9**, 1.6 g (94%), colorless crystals, mp 85—86 °C [Found: C, 61.97;, H, 5.25%. Calcd for $C_{10}H_{10}O_4$: C, 61.85; H, 5.19%. ^{1}H NMR δ=2.29 (3H, s), 3.93 (3H, s), 6.65 (1H, d, J=11 Hz), 6.80 (1H, ddd, J=11, 2, 1 Hz), 7.01 (1H, dd, J=13, 2 Hz), and 7.16 (1H, dd, J=13, 1 Hz). ^{13}C NMR δ=20.8, 56.4, 110.5, 123.6, 133.8, 135.9, 148.9, 164.0, 169.3, and 179.3. MS m/z, 194 (M^+). IR ν 3000, 1760, 1570, 1200, 1145, and 910 cm^{-1}].

Preparation of 4-Acetoxy-2-chloro-7-methoxytropone (10) from 9 and NCS. A benzene solution (30 cm^3) of **9** (1.00 g) and NCS (830 mg) was refluxed for 24 h with stirring. The mixture was heated *in vacuo* to remove the solvent. Pale yellow crystalline residue was washed with benzene, and the washings chromatographed on a silica-gel column; the eluent obtained from EtOAc–hexane (2:1) was **10**, 560 mg (77%), pale yellow needles, mp 112—113 °C [Found: C, 52.53; H, 3.87%. Calcd for $C_{10}H_9O_4Cl$: C, 52.53; H, 3.98%. ^{1}H NMR δ=2.29 (3H, s), 3.94 (3H, s), 6.72 (1H, d, J=11 Hz), 6.86 (1H, dd, J=11, 2 Hz), and 7.67 (1H, d, J=2 Hz). ^{1}H NMR δ=20.8, 56.8, 111.1, 124.3, 133.5, 143.0, 145.9, 162.2 169.2 and 172.5. MS m/z, 228 and 230 (M^+). IR ν 3030, 2950, 1760, 1625, 1610, 1595, 1220, 1160, 1125, and 990 cm^{-1}], and subsequently, the recovered **9**, 380 mg (38%), was obtained.

Preparation of 3-Chloro-5-hydroxytropolone (11). A glacial AcOH solution (5 cm^3) of **10** (210 mg) and conc HCl (1 cm^3) was refluxed for 4 h. The mixture was heated *in vacuo* to remove the solvent, and the residue washed with EtOAc and recrystallized from MeOH–EtOAc to give **11**, colorless needles, mp 221—222 °C (decomp), 149 mg (94%) [Found: C, 48.62; H, 2.92%. Calcd for $C_7H_5O_3Cl$: C, 48.72; H, 2.93%. ^{1}H NMR (CD_3OD) δ=7.00 (1H, dd, J=12, 3 Hz), 7.30 (1H, d, J=12 Hz), and 7.65(1H, d, J=3 Hz). ^{13}C NMR (CD_3OD) δ=123.5, 123.9, 129.7, 140.2, 157.9, 163.6, and 167.8. MS m/z, 172 and 174 (M^+). IR ν 3200—2400, 1585, 970, 960, 930, 850, and 760 cm^{-1}].

Preparation of 3-Chloro-p-tropoquinone (7). Under the similar conditions to those in the preparation of **5** from **6**, **11** (48 mg) was converted to **7**, 38 mg (80%). Recrystallizations from benzene gave pale yellow crystals, mp 73—74 °C (decomp) [Found: C, 49.51; H, 1.75%. ^{1}H NMR δ=6.84 (2H, d, J=1 Hz) and 7.30 (1H, t, J=1 Hz). ^{13}C NMR δ=133.8, 137.2, 138.5, 143.4, 180.2, 184.5, and 184.8. MS m/z, 170 and 172 (M^+). IR ν 3030, 1695, 1660, 1320, 1170, 925, 880, 860, and 850 cm^{-1}].

Formation of 5,7-Dichloro Derivative (12) by Partial Reduction of 5. An AcOH (3 cm^3) solution of **5** (104 mg) was refluxed for 1.5 h with stirring. The solvent was removed *in vacuo*, and the residue washed with MeOH. The residue thus obtained was sublimed on a cold finger to give **12**, yellow needles, mp>300 °C, 8 mg (32%) [Found: C, 51.79; H, 2.08%. Cacld for $C_{14}H_6O_5Cl_2$: C, 51.72; H, 1.86%. ^{1}H NMR (CF_3COOD) δ=8.24 (2H, s) and 8.32 (2H, s). MS m/z, 324 and 326 (M^+). IR ν 3250, 3050, 1620, 1590, 1540, 1510, and 1400 cm^{-1}]. From the MeOH soluble fractions, 79 mg (75%) of **6** was obtained.

Condensation of 5 with 6. To a THF solution (10 cm^3) of **6** (252 mg), a THF solution (5 cm^3) of **5** (249 mg) was added at once. The mixture was kept at 15—25 °C under N_2 atmosphere for 16 h with stirring. After the removal of the solvent *in vacuo*, the residue was washed with a small amount of MeOH. Insoluble solid material was collected by filtration to give **12**, 33 mg (22%). From the MeOH washings, 348 mg (69%) of **6** was obtained.

Attempted Formation of 4,8-Dichloro Derivative (13) or 1,8-Dichloro Derivative (14). *a)*: A THF solution (4 cm^3) of **7** (43 mg) and **11** (43 mg) was kept at room temperature for 2 d. The solvent was removed *in vacuo*, and the residue crystallized from MeOH to give 76 mg (100%) of **11**. No other compound was identified.

b): An AcOH solution (2 cm^3) of **7** (38 mg) was refluxed for 2 h, and the solvent removed *in vacuo*; the pale yellow crystals obtained by recrystallizations from MeOH were **11**, 39 mg (100%).

Preparation of 2-Chloro-4-hydroxy-7-methoxytropone (15). An aqueous AcOH solution (33%, 3 cm^3) of **10** (200 mg) was heated at 100 °C for 10 h with stirring. The mixture was then evaporated *in vacuo* and the residue washed with EtOAc, and recrystallized from MeOH to give **15**, 155 mg (95%), mp 170—173 °C (decomp) [Found: C, 51.37; H, 3.82%. Calcd for $C_8H_7O_3Cl$: C, 51.49; H, 3.79%. ^{1}H NMR (CD_3OD) δ=3.88 (3H, s), 6.77 (1H, dd, J=11, 2.5 Hz), 7.15 (1H, d, J=11 Hz), and 7.85 (1H, d, J=2.5 Hz). ^{13}C NMR (CD_3OD) δ=57.2, 116.3, 118.7, 133.2, 146.2, 157.8, 159.9, and 172.9. MS m/z, 186 and 188 (M^+). IR ν 3050—2500, 1615, 1590, 1540, 1480, 1475, 1450, 1440, 1355, 1250, 1220, 1000, 835, and 755 cm^{-1}].

The Condensation of 7 with 15 to 4,8-Dichloro-10-methoxy Derivative (16) and 1,8-Dichloro-10-methoxy Derivative (17). To a THF suspension (30 cm^3) of **15** (830 mg), a THF solution (20 cm^3) of **7** (1.00 g) was added at once under N_2 atmosphere. The mixture was kept at 15—25 °C for 16 h. The solvent was removed *in vacuo*, and the residue washed with MeOH. The insoluble mass was passed through a Celite column with $CHCl_3$ to yield a 4:1-mixture of **16** and **17**, 380 mg (24%). Droplet-counter-current distribution fractionation of the mixture with $CHCl_3$–AcOH–H_2O (2:2:1) led to a separation of **16**, yellow crystals, mp 274—277 °C (decomp) [Found: C, 53.07; H, 2.33%. Calcd for $C_{15}H_8O_5Cl_2$: C, 53.12; H, 2.38%. MS m/z, 338, 340, and 342 (M^+). ^{1}H NMR δ=4.08 (3H, s), 7.16 (1H, s), 7.75 (1H, s), 8.27 (1H, s), and 8.40 (1H, s). IR ν 3500—3300, 3250, 3040, 1615, 1570, 1510, 900, and 860 cm^{-1}], and **17**, yellow crystals, mp 225—227 °C (decomp) [Found: M. W., 337.9750. Calcd for $C_{15}H_8O_5{}^{35}Cl_2$: M. W., 337.9749. ^{1}H NMR δ=4.04 (3H, s), 7.39 (1H, d, J=12 Hz), 7.85 (1H, d, J=12 Hz), 8.24 (1H, s), and 8.69 (1H, s). IR ν 3150, 1615, 890, and 850 cm^{-1}]. From the MeOH washings, the troponoids, **11** and **15**, 1.4 g (1:1), were recovered.

Methylation of 16 to 18. To a $CHCl_3$ solution (50 cm^3) of **16** (345 mg) was treated with ethereal CH_2N_2 to form precipitates, 223 mg, which were collected and sublimed at 300 °C to obtain 219 mg (55%) of colorless crystals, mp> 300 °C, **18** [Found: C, 54.30; H, 2.90%. Calcd for $C_{16}H_{10}O_5Cl_2$: C, 54.41; H, 2.86%. ^{1}H NMR δ=4.08 (6H, s), 7.12 (2H, s), and 8.25 (2H, s). MS m/z, 352, 354, 356 (M^+). IR ν 3025, 2940, 1615, 1580, and 990 cm^{-1}].

Hydrolysis of 16 to 13. An AcOH solution (4 cm^3) containing conc HCl (1 cm^3) of **16** (41 mg) was heated at 90 °C for 24 h. After evaporation of the mixture, the residue was washed with MeOH and sublimed on a cold finger to yield

yellow needles, **13**, mp>300 °C, 33 mg (85%) [Found: C, 51.90; H, 2.16%. Calcd for $C_{14}H_6O_5Cl_2$: C, 51.72; H, 1.86%. ^{1}H NMR (CF_3COOD) δ=8.38 (2H, s) and 8.75 (2H, s). MS *m/z*, 324, 326, 328 (M^+). IR ν 3250, 3040, 1620, 1590, 1570, 1500, and 1450 cm^{-1}].

Preparation of 5-Hydroxy-2-methoxytropone (19). A 50%-aqueous AcOH solution (10 cm^3) of **9** (600 mg) was heated at 90 °C for 16 h. The mixture was evaporated to dryness, and the residue washed by AcOEt. The crystalline residue was sublimed on a cold finger to yield **19**, pale yellow needles, mp 154—155 °C, 423 mg (91%) [Found: C, 62.99; H, 5.25%. Calcd for $C_8H_8O_3$: C, 63.15; H, 5.30%. ^{1}H NMR (CD_3OD) δ=3.86 (3H, s), 6.74 (1H, dd, J=11, 2 Hz), 7.11 (1H, d, J=11 Hz), and 7.24 (2H, d, J=2 Hz). ^{13}C NMR (CD_3OD) δ=56.6, 116.4, 119.1, 134.1, 138.1, 160.6, 161.9, and 178.5. IR ν 3100—2400, 1595, 1535, 980, 858, 840, and 780 cm^{-1}].

Condensation and Acetylation of 19 with 4 to 2-Acetoxy-10-methoxy Derivative (21). To a THF suspension (10 cm^3) of **19** (210 mg), a THF solution (10 cm^3) of **4** (190 mg) was added at 15—25 °C. After 16 h with stirring, the mixture was heated *in vacuo* to remove the solvent, and, without further purifications, was acetylated by Ac_2O (5 cm^3), and kept at 100 °C until the mixture became homogeneous. After cooling the mixture, the solvent was removed *in vacuo*, and the residual mass washed with EtOAc, and crystallized from $CHCl_3$ to give 275 mg (100%) of **21**, mp 237—239 °C [Found: C, 65.11; H, 3.80%. Calcd for $C_{17}H_{12}O_6$: C, 65.38; H, 3.87%. ^{1}H NMR δ=2.40 (3H, s), 4.01 (3H, s), 6.94 (1H, s), 7.16 (1H, d, J=12 Hz), 7.22 (1H, d, J=12 Hz), 7.54 (1H, d, J=12 Hz), 7.61 (1H, d, J=12 Hz), and 7.68 (1H, s). ^{13}C NMR δ=20.7, 56.6, 102.0, 119.3, 122.5, 123.8, 124.5, 125.4, 134.2, 136.4, 151.5, 153.6, 154.1, 161.3, 168.7, 178.1, and 179.8]. EtOAc-soluble fractions gave a mixture of 2,5-diacetoxytropone and **9**, 209 mg.

Hydrolysis of 21 to 10-Methoxy Derivative (20). A 50%-aqueous AcOH solution (10 cm^3) of **21** (275 mg) was heated at 100 °C with stirring for 16 h. After the solvent was evaporated, the residue was sublimed on a cold finger to give **20**, 220 mg (93%), mp>300 °C [Found: C, 66.54; H, 3.87%. Calcd for $C_{15}H_{10}O_5$: C, 66.67; H, 3.73%. ^{1}H NMR (CF_3COOD) δ=4.63 (3H, s), 8.09 (1H, d, J=12.5 Hz), 8.44 (1H, d, J=12.5 Hz), 8.53 (1H, d, J=11.7 Hz), 8.58 (1H, s), 8.97 (1H, d, J=11.7 Hz), and 9.03 (1H, s). MS *m/z*, 270 (M^+). UV ($CHCl_3$) λ_{max}: 263 nm (ε=29600), 272 (36200), 299 (18000), 321 (15200), 380 (20500), 396 (30800), and 411 (28500). IR ν 3250, 3050, 1610, 1565, 1520, 1460, 1410, 1250, 1200, 1155, 1110, and 980 cm^{-1}].

Methylation of 20 to 2,10-Dimethoxy Derivative (22). A $CHCl_3$ solution (3 cm^3) of **20** (50 mg) was treated with CH_2N_2 in Et_2O at 0—5 °C. Sublimation on a cold finger of the mixture yielded **20**, yellow crystals, mp 227—230 °C, 22 mg (57%) [Found: M. W., 284.0685. Calcd for $C_{16}H_{12}O_5$: M. W., 284.0684. ^{1}H NMR δ=4.08 (6H, s), 7.05 (2H, s), 7.21 (2H, d, J=13 Hz), and 7.62 (2H, d, J=13 Hz). ^{13}C NMR δ=56.5 (2C,) 103.0 (2C), 123.8 (2C), 124.9 (2C), 134.1 (2C), 151.7 (2C), 161.0 (2C), and 179.9 (2C). IR ν 1610, 1560, and 1520 cm^{-1}].

Condensation of 19 with 7 and Subsequent Transformation to 2,10-Diacetoxy-1-chloro Derivative (23) and 2,10-Diacetoxy-4-chloro Derivative (24). To a THF suspension (2 cm^3) of **19** (95 mg), a THF solution (4 cm^3) of **7** (106 mg) was added at 15—25 °C under N_2 atmosphere. The solvent was removed *in vacuo*, the resultant residue washed with MeOH, and the reddish yellow crystalline solid directly hydrolyzed in AcOH (7 cm^3) with conc HCl (1.5 cm^3) at 100 °C for 16 h. After evaporation of the solvent *in vacuo*, the residue, 74 mg, was acetylated with Ac_2O (7 cm^3) at 100 °C for 16 h. After removal of Ac_2O *in vacuo*, the residue was chromatographed on a silica-gel column to give at first, yellow crystals, **24**, mp 225—226 °C, 43 mg (50%) [Found: C, 57.47; H, 3.33%. Calcd for $C_{18}H_{11}O_7Cl$: C, 57.69; H, 2.96%. ^{1}H NMR δ=2.38 (3H, s), 2.40 (3H, s), 7.27 (1H, d, J=13 Hz), 7.60 (1H, s), 7.68 (1H, d, J=13 Hz), 7.69 (1H, s), and 8.30 (1H, s). ^{13}C NMR δ=20.5 (2C), 118.4, 118.8, 122.3, 122.7, 125.2, 137.3, 144.2, 151.6, 152.1, 154.3, 154.7, 168.3 (2C), 171.9, and 178.1. IR ν 3050, 2940, 1765, 1615, 1580, 1540, 1375, 1350, 1190, 1115, 1050, 930, and 855 cm^{-1}], and subsequently, other yellow needles, mp 158—159 °C, **23**, 2 mg (2%) [Found: C, 57.75; H, 3.13%. Calcd for $C_{18}H_{11}O_7Cl$: C, 57.69; H, 2.96%. ^{1}H NMR δ=2.38 (3H, s), 2.43 (3H, s), 7.17 (1H, d, J=12.5 Hz), 7.25 (1H, d, J=12.7 Hz), 7.64 (1H, d, J=12.5 Hz), 7.66 (1H, d, J=12.7 Hz), and 8.76 (1H, s). ^{13}C NMR δ=20.4, 20.6, 121.2, 121.4, 123.6, 125.2, 125.4, 133.1, 135.8, 136.9, 151.6, 152.9, 153.0, 154.7, 167.1, 168.4, 176.1, and 178.1. MS *m/z*, 374 and 376 (M^+). IR ν 3050, 2950, 1770, 1620, 1585, and 1179 cm^{-1}].

From the MeOH soluble fractions of the condensation reaction mixture, **11** and **9**, 98 mg (44%) were obtained.

Condensation of 15 with 4. Formation of 4-Chloro-2-methoxy Derivative (25): To a THF solution (2 cm^3) of **15** (164 mg), a THF solution (4 cm^3) of **4** (120 mg) was added at once under N_2 atmosphere. After stirring for 48 h the solvent was removed, and the residue washed with MeOH. The residue was collected by filtration and washed again with MeOH to give yellow crystals, mp>300 °C, **25**, 113 mg (35%) [Found: C, 59.00: H, 3.13%. Calcd for $C_{15}H_9O_5Cl$: C, 59.13; H, 2.98%. ^{1}H NMR (CF_3COOD) δ=4.44 (3H, s), 8.18 (1H, d, J=12 Hz), 8.38 (1H, s), 8.51 (1H, d, J=12 Hz), 8.87 (1H, s), and 8.95 (1H, s). MS *m/z*, 304 and 306 (M^+). UV ($CHCl_3$) λ_{max}:268 nm (ε=31600), 276 (37600), 299 (20000), 405 (32900), and 422 (32900). IR ν 3300, 3050, 1610, 1570, 1520, 1470, 1405, 1240, 1170, and 980 cm^{-1}].

Hydrolysis of 25 to 27. An AcOH solution (3 cm^3) of **25** (50 mg) and conc HCl (1 cm^3) was heated at 100 °C for 24 h. After removal of solvent *in vacuo*, the residue was sublimed on a cold finger to give yellow crystals, mp>300 °C, **27**, 44 mg (95%) [Found: C, 57.82; H, 2.70%. Calcd for $C_{14}H_7O_5Cl$: C, 57.85; H, 2.43%. ^{1}H NMR (CF_3COOD) δ=8.30 (1H, d, J=11.7 Hz), 8.40 (1H, s), 8.61 (1H, d, J=11.7 Hz), 8.81 (1H, s), and 8.83 (1H, s). UV ($CHCl_3$) λ_{max}:271 nm (ε=33100), 278 (39200), 302 (18100), 330 (13500), 394 (20700), 412 (31600), and 427 (27600). IR ν 3250, 3050, 1630, 1600, 1565, 1550, 1460, 1250, 1170, 1120, 880, 850, and 840 cm^{-1}].

Acetylation of 27 to 24. An Ac_2O solution (3 cm^3) of **27** (26 mg) was heated at 100 °C for 20 h to form yellow crystals, mp 225—226 °C, 28 mg (78%), which was identical with **24**.

Condensation of 19 with 5. To a THF suspension (10 cm^3) of **19** (69 mg), a THF solution (4 cm^3) of **5** (77 mg) was added at 15—25 °C. After 16 h, the mixture was heated *in vacuo* to remove the solvent, the residue was washed with MeOH to recover **19**, 40 mg (57%), and **6**, 42 mg (55%), and the residue sublimed *in vacuo* to give yellow crystals, mp 292—294 °C (decomp), 58 mg (100%), **26** [Found: C, 58.84; H, 2.97%. Calcd for $C_{15}H_9O_5Cl$: C, 59.13; H, 2.98%. ^{1}H NMR (CF_3COOD) δ=4.61 (3H, s), 8.28 (1H, s), 8.52 (1H, d, J=12 Hz), 8.65 (1H, s), 8.96 (1H, s), and 8.99 (1H, d, J=12 Hz). MS *m/z*, 304 and 306 (M^+). IR ν 3250, 3030, 1605, 1570, 1545, and 1510 cm^{-1}].

Hydrolysis of 26 to 5-Chloro Derivative (28). An AcOH

solution (3 cm^3) of **26** (17 mg) and conc HCl(1.5 cm^3) was heated at 100°C for 4 h. Then, the mixture was evaporated *in vacuo*, and the residue trituated with MeOH, and sublimed on a cold finger to give **28**, 15 mg (83%) [Found: C, 57.82; H, 2.70%. Calcd for $C_{14}H_7O_5Cl$: C, 57.85; H, 2.43%. ^1H NMR (CF_3COOD) δ=8.16 (1H, d, J=12 Hz), 8.30 (1H, s), 8.44 (1H, s), 8.54 (1H, d, J=12 Hz), and 8.60 (1H, s). (Received September 11, 1984)

To investigate the photochemical electron transfer from aromatic olefins to copper(II) or iron(III) ions, a series of substituted styrenes (**1**) was irradiated in the presence of copper(II) or iron(III) salts in methanol, which gave dimethoxylated monomers (**2**) and one or more of three types of dimethoxylated dimers [α,α- (**3**), α,β- (**4**), and β,β-dimers (**5**)]. The formation of these products are reasonably attributed to the participation of the cation radicals of the olefins generated by electron transfer from the excited olefins to the metal ions. Substituents on the substrates are found to govern the reaction products.

Recently, much attention has been paid to the photochemical electron-transfer processes from the viewpoint of mechanistic photochemistry, energy storage, photoimaging, preparative chemistry, *etc.*[1] On photochemical electron transfer involving styrenes, investigations were reported for the excitation of organic electron acceptors like 1,4-dicyanobenzene or methyl 4-cyanobenzoate followed by electron transfer to their excited state from ground-state styrenes to give the cation radicals of the olefins.[2—4] On the other hand, few investigation was done for the electron transfer from the excited styrene to an acceptor except a short report by Tsutsumi and Murai that the irradiation of styrene (**1a**) in the presence of copper(II) perchlorate in methanol gave a dimethoxylated monomer **2a** and a dimethoxylated dimer (α,α-dimer **3a**) as isolatable products.[5]

$$\underset{\textbf{1a}}{PhCH{=}CH_2} \xrightarrow[Cu^{2+}/MeOH]{254\ nm} \underset{\textbf{2a}}{PhCH(OMe)CH_2OMe} + \underset{\textbf{3a}\ (\alpha,\alpha\text{-dimer})}{[PhCH(CH_2OMe)\text{-}]_2}$$

To get deeper insight into the electron transfer from the excited organic compounds, particularly aromatic olefins, to metal ions, a series of styrene derivatives **1** were irradiated in the presence of copperr(II) and iron(III) salts. This paper discribes the results of the reaction; 1) the irradiation gives in addition to **2** and **3**, other isomeric dimethoxylated dimers **4** (α,β-dimer) and **5** (β,β-dimer), 2) the reaction products are similar to those of the electrolysis of the styrene **1** with a platinum anode in the same solvent,[6a] 3) the reaction course of the cation radicals of **1** is controlled by the substituents on the α-, β-, and p-carbons of the olefins **1**.

Results

Photochemical Reaction of Substituted Styrenes in the Presence of Metal Ions in Methanol. In a typical run, styrene (**1a**, 28 mmol) was irradiated in the presence of copper(II) perchlorate (56 mmol) in methanol (300 cm^3) under nitrogen stream at room temperature with a 160-W low pressure mercury lamp for 40 h. After the irradiation, 70% of **1a** was consumed and a dimethoxylated monomer **2a** (yield 41% based on **1a** consumed) was obtained in addition to three types of dimethoxylated dimers [α,α- (**3a**, yield 4%), α,β- (**4a**, 0.7%), β,β- (**5a**, 1.5%)] (see Scheme 1). During the irradiation, a small amount of metallic copper was precipitated. The structure of the products was identified from spectral data in comparison with authentic samples obtained from the anodic oxidation of **1a** in methanol with a platinum or a graphite anode.[6] The yields of the reaction products were determined by GLPC analysis.

In control experiments, when **1a** was left standing in methanol with $Cu(ClO_4)_2$ for 25 d under nitrogen atmosphere at room temperature without irradiation, **1a** was completely recovered, and also irradiation of **1a** in the presence of $Cu(ClO_4)_2$ in methanol with bromine lamp (effective longer than 400 nm) through a Pyrex filter under nitrogen atmosphere at room temperature gave only a trace amount of **2a**. Moreover, UV spectra of the mixture of **1** and $Cu(ClO_4)_2$ in methanol did not show any new absorption band.

Other styrene derivatives **1** were likewise irradiated in the presence of $Cu(ClO_4)_2$ in methanol. The results are summarized in Table 1 together with the oxidation potentials of the olefins. The use of iron(III) perchlorate instead of copper(II) perchlorate in the photochemical reaction of **1a—d** in methanol gave **2a** (12%),

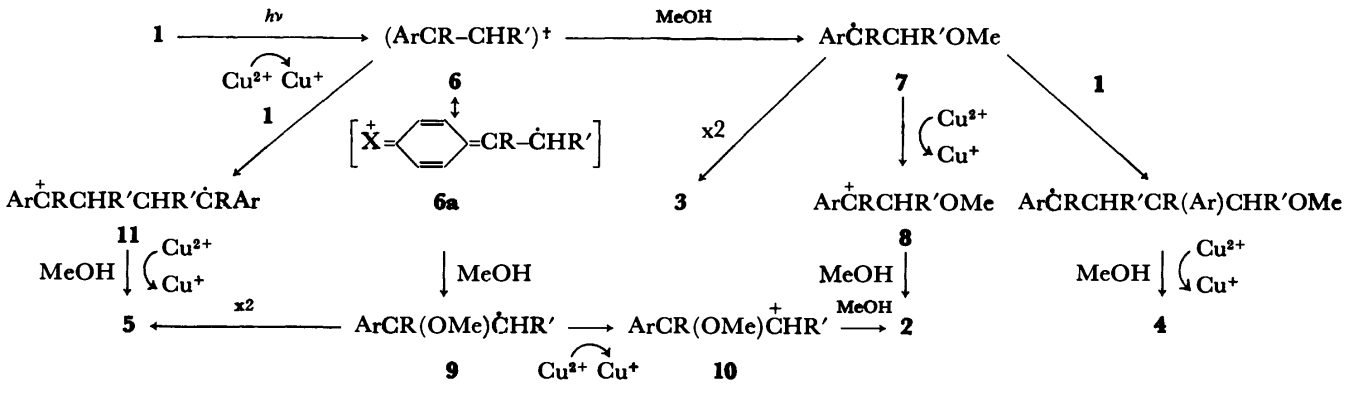
Discussion

Substituent Effect on the Selectivity for Products. As Table 1 shows, **1a**, **1b**, and **1c** with the higher oxidation potentials among **1**'s afforded **2**, α,α-dimer **3**, and β,β-dimer **5**, accompanied by α,β-dimer **4** from **1a**. On the other hand, **1d**, **1f**, and **1g** with the lower oxidation potentials gave no α,α-dimer **3** but exclusively β,β-dimer **5** together with **2**. On the basis of the above selectivity for the production of the dimethoxylated dimers, **1a**, **1b**, and **1c** are now classified as group I olefins, while **1d**, **1f**, and **1g** as group II olefins. **1e** is classified as group I in view that irradiation of **1e** with $Cu(ClO_4)_2$ in methanol gave exclusively α,α-dimer **3e** together with **2e** but no β,β-dimer **5e**, although **1e** has the same oxidation potential as **1f** of group II. As the above results indicate, the selectivity for production of dimethoxylated dimers is governed by the substituent on the α-, β-, or *p*-carbon of **1**; group II olefins with electron-donating groups such as *p*-methyl or *p*-methoxyl group tend to produce β,β-dimer **5** selectively, while group I olefins without electron-donating groups on the aromatic nucleus tend to give α,α-dimer **3** rather than β,β-dimer **5**.

Mechanism. Formation of the various products is satisfactorily understood in terms of a mechanism depicted in Scheme 2.

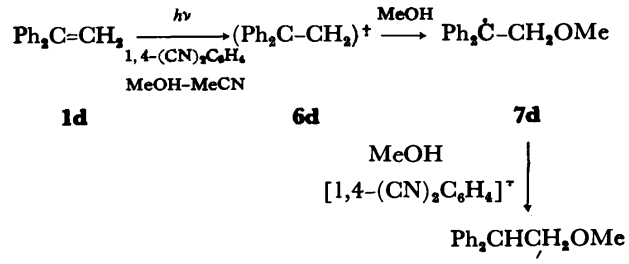
The initial step after the excitation of **1** is certainly the electron transfer from the excited state of **1** to the metal ions to generate the cation radical **6**.

In group I olefins, the production of α,α-dimer **3** seems to be plausible only through dimerization of radical **7**, which results from the addition of methanol to β-carbon of the cation radical **6**. Also, radical **7** will collapse into α,β-dimer **4** through addition to the olefins, or be further oxidized by copper(II) ion into carbocation **8** finally giving rise to **2**. However, in the photochemical reactions of group II olefins, production of neither α,α-dimer **3** nor α,β-dimer **4** suggests that radical **7** does not participate as a reaction intermediate. In cation radicals **6** arising from group II olefins as compared with those arising from group I olefins, the positive charge tends to be more highly distributed on the aromatic ring and concurrently the unpaired electron must have higher density on the terminal carbon. This situation can be schematically expressed by a resonance canonical form (**6a**) and was actually observed in ESR spectrum of the cation radicals of *N*,*N*-dimethylalkenamines generated by electrolysis.[7] Therefore, **6** from group II olefins, owing to their higher spin density on their terminal carbon atoms, will more facilely add to olefins than those from group I olefins finally leading to β,β-dimer **5**, and consequently, due to the less positive charge population on their terminal carbon atoms, will react with methanol on their α-carbon atoms to give radical **9**, which will be further oxidized by copper(II) ion to give carbocations **10** finally affording **2**.[8]



Scheme 2.

For the methanolysis of the cation radical **6**, electron transfer between **1d** and excited electron acceptors like 1,4-dicyanobenzene and 1-cyanonaphthalene in methanol was reported to give anti-Markownikoff adduct of methanol to the olefin through the formation of radical **7d** as an intermediate.[2d] It is noticeable that, in the present reaction of group I olefins, methanolysis of the intermediate cation radical **6** occurs by the same orientation as the above reaction, however, for group II olefins, methanolysis of the cation radical **6** proceeds by a different orientation giving **9**.



The free-energy change (ΔG) for the electron-transfer processes from the excited olefin to metal ions is given by Eq. 1,[9] where $E(D/D^+)$ and $E(A^-/A)$ are the oxidation potential of the donor (D) and the reduction potential of the acceptor (A), respectively, and $e_0^2/\varepsilon\alpha$ is the energy gained by bringing the two ion radicals to the encounter distance (α) in a solvent of dielectric constant ε (methanol, $\varepsilon_{25°}$=32.7) and estimated to be 0.065 eV (1.5 kcal/mol) in methanol. The singlet energies, E_s, of 4-methoxystyrene and styrene are obtained from the fluorescence spectrum or literature,[10] respectively. In Table 2 are listed the calculated values of ΔG for the olefins. The electron-transfer process from the excited olefins to copper(II) ion is shown to be exothermic.

$$\Delta G(\text{kcal/mol}) = 23.06[E(D/D^+) - E(A^-/A) - e_0^2/\varepsilon\alpha] - E_s \quad \text{(kcal/mol)} \quad \text{(Eq. 1)}$$

The proposed mechanism in Scheme 2 requires the second electron transfer from radical **7** or radical **9** to metal ions. The free-energy change of this process cannot be easily estimated because the oxidation potentials of radical **7** and **9** cannot be measured.[11] However, their oxidation potentials seem to lie at more cathodic levels than the reduction potentials of the metal ions. Therefore, the second electron-transfer process seems also exothermic as reported by Kochi *et al.*[12-14]

Table 2. Singlet energies of the olefins and calculated ΔG values, using Eq. 1, for the electron-transfer process involving the singlets of the olefins and copper(II) ion

	Eox/V[a]	Ered/V[b]	*Es* (kcal/mol)	*ΔG* (kcal/mol)

$Cu(ClO_4)_2$	—	−0.88		

a) Oxidation potential. b) Reduction potential. c) Taken from S. L. Murov, "Handbook of Photochemistry," Marcel Dekker, New York (1973), p. 20. d) Obtained from the fluorescence spectrum.

Experimental

The IR spectra were obtained from a Hitachi 260-50 infrared spectrophotometer and a Hitachi 260-10 infrared spectrophotometer. The NMR spectra were recorded on a JEOL JNM-MH-100 spectrometer, a JEOL-FX-100 spectrometer, and a JEOL-FX-90Q spectrometer. The mass spectra were determined with a Hitachi RMU-6MC mass spectrometer. Gas-liquid phase chromatographic analysis was performed on a Hitachi 163 gas chromatograph equipped with a flame ionization detector.

Materials. Styrene, 4-chlorostyrene, α-methylstyrene, 1,1-diphenylethylene, and *trans*-β-methylstyrene were commercial samples from Wako Pure Chemical Industries. 4-Methylstyrene and 4-methoxystyrene were prepared by decarboxylation of the corresponding cinnamic acids as described in the literature.[15] Copper(II) perchlorate and iron(II) perchlorate were purchased from Kanto Chemical.

Preparation of Authentic Samples. Authentic samples of dimethoxylated monomers **2** (except for **2c**) and dimethoxylated dimers (except for **3b**, **3c**, and **3e**) were prepared by anodic oxidation of olefins **1** in methanol.[6]

Preparation of 1,2-Dimethoxy-1-phenylpropane (2e). Metallic sodium (1 g, 43 matom) was dissolved in 100 cm^3 of methanol and then freshly distilled β-methylstyrene (4.5 g, 38 mmol) was added to the mixture. The mixture was subjected to constant-current (1 A) elctrolysis at a platinum plate anode (approximate area 60 cm^2) with a platinum wire as a cathode and SCE as a reference electrode under argon atmosphere at room temperature for 2 h. Because a current was not able to be maintained at 1 A after 2 h, constant-current electrolysis was continued at 0.1 A for 3 h. The electrolysis mixture was diluted with water (300 cm^3) and extracted with dichloromethane (80 cm^3×2). The organic layer was washed with water, dried (Na_2SO_4), and analyzed by GLPC. The products obtained by evaporation of the dichloromethane solution were separated with flash-column chromatography.[16] The structures of the products were determined on the basis of their spectral data and elemental analysis.

PhCH(OMe)CH(Me)OMe (2e), erythro-*form*: Bp 59 °C/4 mm; MS: *m/z* 180 (M^+), 149, 121 (100%), 117, 105, 91; IR (neat): 1100 cm^{-1}, ν_{C-O}; ^{1}H-NMR ($CDCl_3$): δ=1.12 (d, *J*= 8 Hz, 3H, Me), 3.16 (s, 6H, 2MeO), 3.18 (m, 1H, CH), 4.14 (d, *J*=4 Hz, 1H, CH), 7.30 (s, 5H, Ph); ^{13}C-NMR ($CDCl_3$): δ= 139.2 (s), 128.0 (d), 127.4 (d), 86.0 (d), 80.6 (d), 57.1 (q), 57.0 (q), 14.3 (q); Found: C, 73.30; H, 8.92%. Calcd for $C_{11}H_{16}O_2$: C, 73.29; H, 8.94%. *threo*-form: Bp 62 °C/4 mm: MS: *m/z* 180 (M^+). 149, 121 (100%), 117, 105, 91; IR (neat): 1100 cm^{-1}, ν_{C-O}; ^{1}H-NMR ($CDCl_3$): δ=0.92 (d, *J*=7 Hz, 3H, Me), 3.24 (s, 3H, OMe), 3.40 (s, 3H, OMe), 3.50 (m, 1H, CH), 4.08 (d, *J*=7 Hz, 1H, CH), 7.28 (s, 5H, Ph); ^{13}C-NMR ($CDCl_3$): δ=139.1 (s), 128.2 (d), 127.8 (d), 127.6 (d), 87.4 (d), 80.0 (d), 57.3 (q), 57.0 (q), 15.6 (q); Found: C, 73.19; H, 8.86%. Calcd for $C_{11}H_{16}O_2$: C, 73.29; H, 8.94%.

Measurements of the Oxidation Potentials of Styrenes. Cyclic voltammetric data were obtained using a three-electrode cell with a Hokuto HA-201 potentiostat and a Hokuto HB-104 function generator. The working electrode was a platinum wire (1 mm diameter) sealed into glass and a counter electrode was a platinum gauze. A $Ag/AgNO_3$ (0.1 mol/dm^3)

electrode was used as a reference electrode and 0.1 mol/dm^3 tetraethylammonium perchlorate as supporting electrolyte. The current-potential curves were recorded directly from the output of the potentiostat on a Rika Denki RW-11 X-Y recorder. The measured value for **1d** agreed well with the reported value.[17]

Irradiation of Styrenes with Copper(II) Salt in Methanol. A solution of styrenes **1** (5 g, 28—48 mmol) in methanol (300 cm^3) containing copper(II) perchlorate (21—36 g, 56—96 mmol) was irradiated under a nitrogen stream at room temperature with a 160-W low pressure mercury lamp (Riko UVL-160LA) for 49 h. The reaction mixture was diluted with water (500 cm^3) and extracted with dichloromethane (100 cm^3×2). The organic layer was washed with water and dried (Na_2SO_4). After evaporation of the solvent, the residue was subjected to flash-column chromatography[16] on silica gel to give **2**, **3**, **4**, and **5**. The structures of the products (**2**, **3**, **4**, and **5**) were confirmed from their spectral data and elemental analysis, or by comparison of their spectral data with those of authentic samples. The organic layer was analyzed by GLPC to determine the yields of the products (Table 1).

1,2-Dimethoxy-2-phenylpropane (2c): Oil; bp 64°C/3 mm; MS: *m/z* 165, 149, 134 (100%); IR (neat): 1070—1140 cm^{-1}, $\nu_{C\text{-}O}$; ^{1}H-NMR ($CDCl_3$): δ=1.52 (s, 3H, Me), 3.10 (s, 3H, OMe), 3.30 (s, 3H, OMe), 3.40—3.50 (ss, 2H, OCH_2), 7.15—7.50 (m, 5H, aromatic H); ^{13}C-NMR ($CDCl_3$): δ= 142.5 (s), 128.1 (d), 127.2 (d), 126.5 (d), 80.8 (t), 78.9 (s), 59.5 (q), 50.6 (q), 20.1 (q); Found: C, 72.97; H, 9.02%. Molecular Design of Crown Ethers. 3.[1] Extraction of Alkaline Earth and Heavy Metal Picrates with 14- to 17-Crown-5 and 17- to 22-Crown-6

Yoshihisa INOUE,* Mikio OUCHI, and Tadao HAKUSHI
Department of Applied Chemistry, Himeji Institute of Technology, 2167 Shosha, Himeji, Hyogo 671-22
(Received September 13, 1984)

The solvent extraction of alkaline earth and heavy metal picrates with a series of ring-contracted and ring-enlarged crown ethers has been carried out in order to reveal the effects of methylene-chain length upon cation-binding ability. Compared with the parent 3*m*-crown-*m*, the ring-contracted crown ethers and their sila analogues possess limited extractabilities, often as low as those for the corresponding glymes. On the other hand, the ring-enlarged crown ethers, in general, show gradual, but not drastic, decreases in extractability for most cations with increasing methylene-chain length. Interestingly, the extractabilities for Ag^+, Tl^+, and Ba^{2+} do not decrease monotonously with ring expansion; in particular 16-crown-5 is a better extractant for Ag^+ than 15-crown-5 and even than 18-crown-6. These results are accounted for in terms of cavity size, conformation, and molecular symmetry of crown ethers. Effects of cation hydration upon extractability and the limitations of solvent extraction technique are also discussed.

Despite the extensive work on crown ether chemistry, the effect of methylene-chain length between two adjacent oxygen atoms of a crown ether upon its complexation ability has not been explored systematically until very recently. Recent investigations from this laboratory[2-4] have shown that, compared with common, symmetrical 3*m*-crown-*m* ethers (*m*=5,6), the ring-contracted and ring-enlarged (3*m*+*n*)-crown-*m* ethers (*n*=−1 to 4) exhibit drastic changes in cation-binding ability with alkali metal ions, endowing (3*m*+*n*)-crown-*m* characteristic cation-selectivities which are distinctly different from those for 3*m*-crown-*m*. It is interesting and significant that the introduction of extra methylene(s), which lower the crown ether's molecular symmetry, does not simply lead to monotonous decreases in complexation ability for all alkali cations but results in unequal decreases or even in an enhancement of cation-binding ability. 16-Crown-5, for example, possesses higher cation-binding ability and selectivity for Na^+ than 15-crown-5. More recently, Kimura *et al.*[5] have shown that, among 13- to 16-crown-4 derivatives, 14-crown-4 is most selective for Li^+ over any other alkali or alkaline earth metal ions. These selectivity shifts or enhancements caused by changing methylene-chain length between two adjacent oxygen atoms have been attributed to the changes in cavity size and/or conformation of the crown ether ring.[2-4]

In this paper, we report our results on the effects of ring contraction and ring enlargement upon cation-binding abilities for alkaline earth and heavy metal ions assessed by solvent extration studies. The extractabilities for alkali,[3,4] alkaline earth, and heavy metal ions are compared and discussed in terms of cavity size, conformation, and molecular symmetry of the crown ethers and also in terms of cation hydration energy. The limitations of solvent extraction as a method for evaluating complexation ability of crown ethers are also considered.

Results

Solvent extractions from aqueous solutions (3.0×10^{-3} M† in salt) of alkaline earth and heavy metal picrates were performed at 25.0±0.1 °C with dichloromethane solutions (3.0×10^{-3} M in ligand) of a variety of symmetrical and less-symmetrical crown ethers and their acyclic analogues under the same conditions employed earlier for alkali metal picrates.[2-4] The % extractabilities (% *Ex*), defined as % picrate extracted into the organic phase, were measured twice and the average values are shown in Table 1; two independent measurements gave very close % *Ex* values with error of <0.5%. This equimolar condition has been employed,††

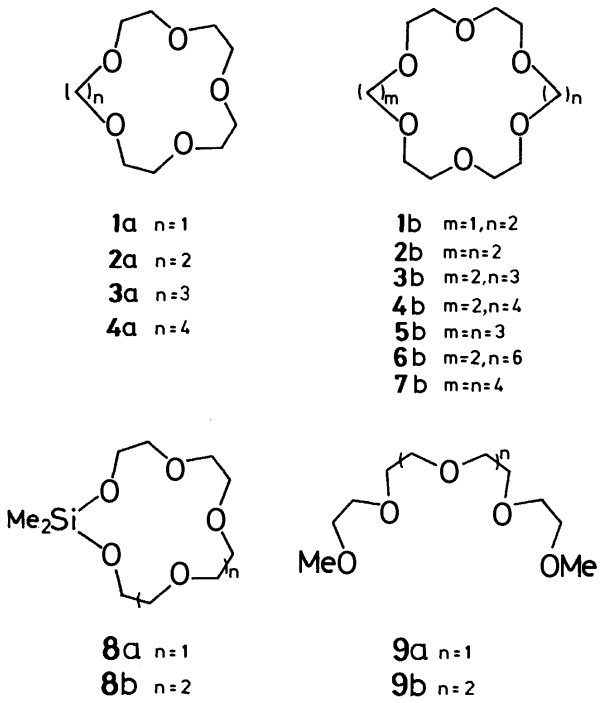

Chart 1.

†1M=1 mol dm^{-3}.

††Added in proof. E. Weber has indicated in a private communication that his group is going to employ the same equimolar condition to assess cation-binding ability of crown ethers. We propose that this condition is adopted widely for the facile assessment and that the results are accumulated for comparison.

a) Unit of K_{ex}: M^{-2} for monovalent and M^{-3} for divalent cations. b) Dichloromethane-water system at 25.0 °C. c) Least-square-means calculation gives a slope of 1.34 in this particular case, indicating the participation of 1:2 sandwitch type complex to some extent; the actual value K_{ex} value must be lower.

since the cation-selectivity sequence judged from the % Ex values coincides with that from the extraction equilibrium constants (K_{ex}).[2,3]

With selected combinations of crown ethers and mono- and divalent cations, the extraction equilibium constants (K_{ex}) and the complex stoichiometeries (n) for n:1 crown ether-cation complexes were also determined. The solvent extraction of a metal picrate MA_m (m=1 or 2) with n molecules of a crown ether (CE) is expressed by the following overall extraction equilibrium,

$$M_{aq}^{m+} + m A_{aq}^{-} + n CE_{org} \overset{K_{ex}}{\rightleftharpoons} [M(CE)_nA_m]_{org}$$

and the equilibrium constant (K_{ex}) is given by Eq. 1.

$$K_{ex} = \frac{D_M}{[A^-]_{aq}^m [CE]_{org}^n} \quad (1)$$

where

$$D_M = \frac{[M(CE)_nA_m]_{org}}{[M^{m+}]_{aq}} \quad (2)$$

Modification of Eq. 1 leads to the following equation.

$$\log(D_M/[A^-]_{aq}^m) = n \log[CE]_{org} + \log K_{ex} \quad (3)$$

Extraction studies were carried out under a variety of conditions to determine extraction equilibrium constant K_{ex} and complex stoichiometry n; [ligand]=0.5—5.0×10^{-3} M and [picrate]=3.0×10^{-3} M. As exemplified in Figure 1, in the most cases the plots of log (D_M/$[A^-]_{aq}^m$) *versus* log $[CE]_{org}$ gave straight lines with a slope (n) of unity, indicating that 15- to 17-crown-5 and 18- to 20-crown-6 form 1:1 crown ether-cation complexes under the conditions employed. The logK_{ex} values are given as intercepts of the straight lines; the results are listed in Table 2.

Discussion

Ring-contracted Crown Ethers 1 and 8. As can be seen from Table 1, all the ring-contracted crown ethers **1** and their sila analogues **8** possess extremely low extractabilities for the alkaline earth and heavy metal ions as compared with the symmetrical ligands 15-crown-5 (**2a**) and 18-crown-6 (**2b**), respectively. The extractabilities may more appropriately be compared with the corresponding glymes **9**. Similarly poor extraction ability has been previously reported in solvent extractions of alkali metal picrates with the same ring-contracted crown ethers **1** and **8**.[4,6] It was shown there that removal of a methylene group from a symmetrical crown ether results in nearly complete loss

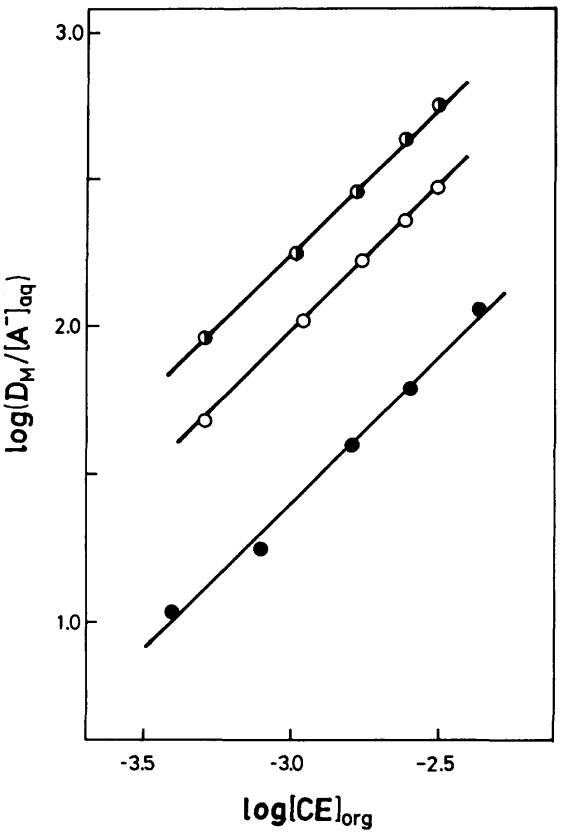

Fig. 1. Plots of $\log(D_M/[A^-]_{aq})$ versus $\log[CE]_{org}$ obtained in extraction experiments on 15- to 17-crown-5 **2a**(○), **3a**(◑), and **4a**(●) with silver picrate.

of complexing ability for most cations examined.

As has already been proposed in the extraction of alkali metal ions, the origin of the drastic reduction in cation-binding ability for alkaline earth and heavy metal ions is probably due not to diminished cavity size but to the conformational disorder induced by the ring contraction, since the removal of a methylene group does not reduce significantly the cavity size of crown ether and the replacement of the O–C–O linkage of **1** by a longer O–Si–O linkage to give **8** does not contribute to raise the extractability. Examinations of CPK space-filling molecular models also support the irregular spatial arrangement of the donor oxygen atoms; one of the five or six donor atoms cannot be accommodated in the plane of the remaining donor atoms, while the cavity sizes are *ca.* 1.7 Å for **1a**, **2a**, or **8a** and 2.5—2.6 Å for **1b**, **2b**, or **8b**. It is clear that, in this situation, one of the formal donor oxygen atoms no longer acts as an effective donor atom; this may be the major reason for the drastic decrease in the extractability of the ring contracted crown ethers **1** and **8**.

Ring-enlarged Crown Ethers **3**—**7**. The introduction of extra methylene (s) at one or two transannular position (s) of the symmetrical 3*m*-crown-*m* gives ring-enlarged crown ethers. In general, these crown ethers of low symmetry, *i.e.* 16- and 17-crown-5 and 19- to 22-crown-6 possess lower % *Ex* or K_{ex} values for the cations examined in this study. This is also the case with the solvent extraction of alkali metal picrates with the same crown ethers.[3] For most cations, the % *Ex* or K_{ex} value decreases gradually or, in some cases, drastically with increasing methylene-chain length, although even the extremely enlarged 17-crown-5 **4a** and 22-crown-6 **6b**, **7b** are still the better ligands than the corresponding glymes **9**. Interestingly, the % *Ex* for Ba^{2+} is relatively insensitive to the ring expansion and therefore the less symmetrical crown ethers **3b**—**7b** exhibit higher Ba^{2+} selectivity than the parent 18-crown-6 **2b**. It is also noted that the highest selectivity for Ba^{2+} is given not by the crown ethers but by acyclic pentaglyme **9b**.

The major reason for the gradual decrease in % *Ex* or K_{ex} is certainly the lower symmetry, or in other words the less-favorable spatial arrangement of donor oxygen atoms, resulting from the ring expansion. In this context, the comparison of % *Ex* for the *asym*- and *sym*-isomers of 20- and 22-crown-6 is interesting. The % *Ex* values for *sym*-isomers **5b** and **7b** are considerably lower than those for *asym*-isomers **4b** and **6b** except for the complexation of Ag^+ with 22-crown-6. It may be concluded that, when the same number of methylene group is introduced into a crown ether, the double extension of methylene-chain length at the transannular positions giving a *sym*-crown ether is much more effective in diminishing cation-binding ability than the single extension giving an *asym*-crown ether. This is probably due to the greater deformation of spatial arrangement of donor atoms induced by the double, rather than single, extension of methylene-chain length.

Some exceptions to the gradation of % *Ex* or K_{ex} are seen at the same time in the extraction of Ag^+, Tl^+, and Ba^{2+}. In spite of the increased methylene-chain length, *asym*-20-crown-6 (cavity size 3.3 Å) exhibits somewhat higher % *Ex* values for Tl^+ (cation diameter 3.00 Å) and Ba^{2+} (2.72 Å) than 19-crown-6 (2.7 Å), although the % *Ex* values are considerably lower than those for the parent 18-crown-6. These irregular increases in % *Ex* may roughly be accounted for in terms of the size-fit concept[7]—relationship between relative sizes of cation and crown cavity; see Table 3 for these quantities.[8] A more remarkable result was obtained in the extraction of Ag^+ with 16-crown-5. In contrast to the monotonous decreases in % *Ex* or K_{ex} for the other cations, 16-crown-5 exhibits fairly higher % *Ex* and K_{ex} values for Ag^+ than the parent 15-crown-5 or even than 18-crown-6, preserving the 1:1 stoichiometry. This may be an exceptional case in which 18-crown-6 does not show the highest cation-binding ability, although Gokel *et al.*[9] have reported that 18-crown-6 shows the highest stability constants (K_s) for Na^+, K^+, NH_4^+, and Ca^{2+} in the homogeneous solution. This preferential extraction of Ag^+ by 16-crown-5 may originate from the "nesting" interaction in the 1:1 complex with Ag^+ as is the case with Na^+. It has been shown previously[2,3] that 16-

crown-5 possesses the highest extractability and selectivity for Na^+ among alkali metal ions, which is explained by the most favorable cavity size and orientation of the donor atoms for 1:1 complexation with Na^+, *i.e.* "nesting" interaction, and by the less-favorable "perching" interaction with the larger cations, K^+, Rb^+, Cs^+. The same situation may be attained in the 1:1 complex of 16-crown-5 with heavy metal ions. Taking into account of the axial development of hybrid orbital of silver ion originating from the d_{z^2}-s mixing,[10] Ag^+ (formal cation diameter 2.30 Å) is considered to be better accommodated in the cavity (1.8 Å) of 16-crown-5 than in the smaller cavity (1.7 Å) of 15-crown-5.

It is concluded that the cation-binding ability of the ring-enlarged crown ethers for monovalent cations is determined by a critical balance between the enlarged cavity size and the reduced molecular symmetry, although the cation selectivity is well accounted for in terms of the size-fit concept. It is also shown that the unfavorable effect of the conformational change induced by ring enlargement may be minimized or cancelled, in particular, with the size-fitted cations like Na^+ and Ag^+, but leads to the drastic decrease of extractability with the mismatched cations. This discriminating effect can be utilized as a tool to enhance the cation selectivity as demonstrated in the complexations of Na^+ and Ag^+ with 16-crown-5 and of Ba^{2+} with 19- to 22-crown-6.

Limitations of Solvent Extraction Technique. The solvent extraction of aqueous metal picrates has been employed as a facile method to assess cation-binding ability of crown ethers. However there may be some ambiguities with the binding ability assessed by this technique, since the extractability (% *Ex*) or extraction equilibrium constant (K_{ex}) would not necessarily be determined only by the cation-binding ability of ligand and the other factor might have a dominant effect.[9] In Table 4, the % *Ex* and K_{ex} values for 15-crown-5 and 18-crown-6 are compared with the corresponding stability constants (K_s) in homogeneous solution determined by the other investigators.[11,12] With monovalent cations, the K_{ex}, or % *Ex*, values parallel exactly the K_s values in methanol, indicating that the cation-binding ability and cation selectivity can be assessed quantitatively by the solvent extraction technique at least for monovalent cations.

Serious discrepancy is however found between the K_{ex} and K_s values for divalent cations. Thus the size-fit concept fails to explain the extractability trend for alkaline earth metal ions. This is most evident with

15- to 17-crown-5. As can be seen from Tables 1, 2, and 4, the K_{ex} or % *Ex* values for Mg^{2+} and Ca^{2+} are quite low for these ligands, although the cation diameters of these divalent cations (Mg^{2+} 1.44Å, Ca^{2+} 2.00Å)[8b] would fit in the cavity of 15-crown-5 (1.7Å), 16-crown-5 (1.8Å), or 17-crown-5 (2.0Å). By contrast, the formally mismatched larger cations, *i.e.* Sr^{2+} and Ba^{2+}, are extracted more efficiently. These results strongly suggest that, in the solvent extraction of divalent cations, the extractability and cation-selectivity cannot be discussed by the size-fit concept alone and the other factor plays a primary role to determine the above quantities.

The major difference between the series of mono- and divalent cations is not the cation diameter but the energy of hydration. As listed in Table 3, the divalent cations possess much higher free energy of hydration ($\Delta G^{\circ}_{H_2O}$) than the monovalent ones; $-\Delta G^{\circ}_{H_2O}$ values are 68—114 kcal/mol* for the monovalent cations, while 314—454 kcal/mol for the divalent ones.[13] This does not immediately mean that the cation of higher hydration energy encounters greater difficulty upon complexation with a ligand, since the higher hydration energy also promises stronger interaction with the donor oxygen atoms of the ligand as well as water molecules. Indeed, judged from the K_s values obtained in homogeneous solutions (Table 4), the cation selectivities among the divalent cations appear to be accounted for in terms of the size-fit concept. The major difficulty for the divalent cations to be extracted into the organic phase may originate from the incomplete dehydration of the cation upon extraction. Iwachido *et al.*[14] have reported that the cation extracted into the organic phase in the form of 1:1 complex with a crown ether is not entirely dehydrated and the number of water molecule coextracted with a cation is much greater for the divalent than monovalent cations; for example, the hydration numbers for M^{n+}-dibenzo-18-crown-6 complex in nitrobenzene are: Na^+ 1.2; K^+–Cs^+ 0.1; Ca^{2+} 5.1; Sr^{2+} 4.9; Ba^{2+} 4.4. Therefore, although the organic phase and the crown ether reported are different from those used in this study, the discrepancy between the K_{ex} and K_s values for divalent cations probably ascribable to the higher barrier for the heavily hydrated complex to be extracted into the organic phase.

In conclusion, it is evident that the solvent extraction technique works well with monovalent cations to give appropriate K_{ex} or % *Ex* trends in accord with the K_s trends, but is inadequate as a metod to assess cation-binding ability and cation selectivity of crown ethers for di- and probably tri-valent cations.

Experimental

Material. *Crown ethers.* The ring-contracted crown ethers **1** were prepared by the method described by Kawakami *et al.*[6] Commercially available 3*m*-crown-*m* **2** (Nisso Co.) and sila crown ethers **8** (Petrarch Systems Inc.) were used without further purification. The ring-enlarged crown ethers **3**—**7** and glymes **9** were synthesized as reported previously.[3]

Metal Picrates. *Alkali metal picrates* were prepared from picric acid and the corresponding metal hydroxide as reported.[2-4]

Silver Picrate. Picric acid (4.1 g, 18 mmol) was dissolved in hot water (100 mL), to which silver oxide (2.0 g, 8.6 mmol) was added slowly and the mixture was stirred for additional 10 min at that temperature.[15] The precipitate formed upon cooling was recrystallized twice from ethanol and then once from water to give 0.6 g (20% yield) of silver picrate.

Thallium picrate was prepared from picric acid (3.4 g, 15 mmol) and thallium oxide (3.0 g, 7.1 mmol) in hot water according to the procedure described above. Recrystallization twice from water gave 2.5 g (81%) of thallium picrate.

Alkaline earth metal picrates were prepared from picric acid (4.6 g, 20 mmol) and the corresponding metal carbonate (10 mmol) in hot water according to the procedure described above.[16] Recrystallization twice from water gave 0.6 g (11%) of magnesium picrate, 0.9 g (15%) of calcium picrate, 0.9 g (14%) of strontium picrate, or 3.0 g (50%) of barium picrate. Magnesium, calcium, and strontium picrates were pentahydrates, and barium picrate was anhydrous salt.

Extraction Studies. The general procedures employed were similar to those described in previous papers.[2-4] The concentration of heavy metal picrate in the organic phase was determined from its absorption at 375 nm in a 1:1 mixture of dichloromethane and acetonitrile. The molar extinction coefficients at 375 nm of silver and thallium picrates are 18800 and 18900 $M^{-1}cm^{-1}$, respectively. The concentration of alkaline earth metal picrate in the organic phase was determined according to the procedure in the literature.[16] After the phase separation, 5 mL of the dichloromethane phase was withdrawn and evaporated to dryness, to which was added 5 mL of acetonitrile. After further dilution, if necessary, with acetonitrile, the picrate concentration in acetonitrile was determined from its absorption at 374 nm. The molar extinction coefficients at 374 nm for magnesium, calcium, strontium, and barium picrates are 29400, 29700, 29500, and 29000 $M^{-1}cm^{-1}$, respectively.

Synthesis and Properties of Gramicidin S Analogs Containing D-Phe-L-Pro-D-Val or L-Phe-L-Pro-D-Val Sequences in Place of D-Phe-L-Pro-L-Val Sequence in the β-Turn Part of the Antibiotic

Makoto TAMAKI,* Tadashige OKITSU, Mie ARAKI, Honami SAKAMOTO, Michiaki TAKIMOTO, and Ichiro MURAMATSU†

(Received September 18, 1984)

In order to investigate the contribution of configurations of amino acid residues around Pro residues in gramicidin S to its activity and conformation, [D-Val$^{1,1'}$]- and [D-Val$^{1,1'}$ L-Phe$^{4,4'}$]-gramicidin S were synthesized by a liquid-phase method. The CD spectra of these analogs and gramicidin S in aqueous solutions differ from each other, indicating that these peptides have different conformations. These analogs have practically no activity against the Gram-positive microorganisms tested, indicating the importance of the presence of the D-Phe-Pro-Val sequence in gramicidin S regarding activity.

Gramicidin S (GS)[1] is an antibiotic cyclodecapeptide isolated from *Bacillus brevis*. Its secondary structure has been established as an antiparallel β-sheet conformation (Fig. 1).[2] This conformation is characteristically featured (with the orientation of side chains) in such a way that the charged Orn side chains are situated on one side of the molecule and the hydrophobic Val and Leu side chains are situated on the other side. The side-chain arrangement is apparently held together by a rigid conformation containing two D-Phe-Pro type II′ β-turns.[2,3] In studies regarding the structure-activity relationship of GS, it has been proposed that this specific conformation is necessary in order to exhibit an antibiotic activity.[4]

Recently, we reported in studies of an antibiotic cyclododecapeptide, gratisin, that the configurations of amino acid residues around Pro residues in synthetic isomers greatly affect their conformation, and that the activity of *cyclo*(-Val-Orn-Leu-D-Phe-Pro-D-Tyr-)$_2$ was similar to that of GS against *Bacillus subtilis* and stronger than that of *cyclo*(-Val-Orn-Leu-D-Phe-Pro-Tyr-)$_2$.[5] In connection with these results, it is of interest to study the relationship between configurations of amino acid residues around Pro residues in GS and its secondary structure or antibiotic activity.

Kawai *et al.*[6] synthesized [L-Ala$^{4,4'}$]-GS, in which D-Phe-Pro-Val sequences in GS were replaced with Ala-Pro-Val sequences, and elucidated the structure-activity relationship.

In the present paper, we wish to describe the synthesis and antibiotic activity of [D-Val$^{1,1'}$]- and [D-Val$^{1,1'}$, L-Phe$^{4,4'}$]-GS (Fig. 2), in which the D-Phe-Pro-Val sequence in GS is replaced, respectively, with D-Phe-Pro-D-Val and Phe-Pro-D-Val. We also wish to discuss the relationship between partial sequences around Pro residues and CD patterns in GS and the analogs.

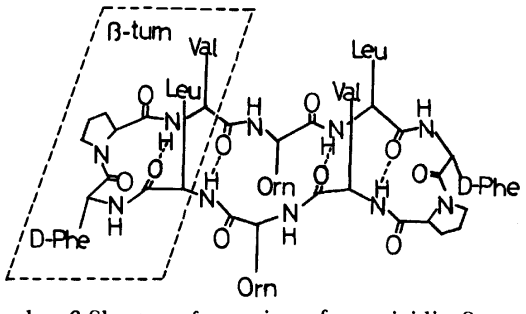

Fig. 1. β-Sheet conformation of gramicidin S.

The synthetic routes of [D-Val$^{1,1'}$]-GS (**7**) and [D-Val$^{1,1'}$, L-Phe$^{4,4'}$]-GS (**13**) are shown in Schemes 1 and 2. In the synthesis of protected [D-Val$^{1,1'}$]-GS (**6**), the Boc-dipeptide ester (**1**) was synthesized with DCC and HOBt, and then converted into the hydrazide (**2**). The Z-tripeptide benzyl ester (**3**) was obtained with DCC and HOBt by stepwise elongation as an oil. The hydrogenolysis of **3** gave the tripeptide (**3′**). The coupling of **2** and **3′** was carried out using an azide method and afforded the Boc-pentapeptide (**4**), which in part was converted into the Boc-pentapeptide succinimido ester (**4′**) with 1-ethyl-3-(3-dimethylaminopropyl)carbodiimide (WSCD) and HOSu. The coupling of **4′** and the pentapeptide derived from **4** afforded the Boc-decapeptide (**5**) which was converted into the decapeptide succinimido ester (**5′**). The cyclodecapeptide (**6**) was derived by the cyclization of **5′** in pyridine at 60°C for 2 h in a 25% yield. In the synthesis of

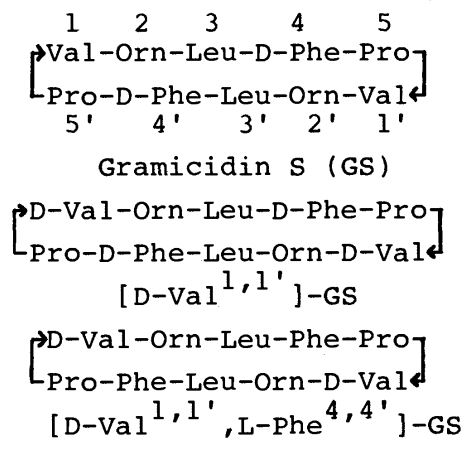

Fig. 2. Primary structures of gramicidin S and its analogs.

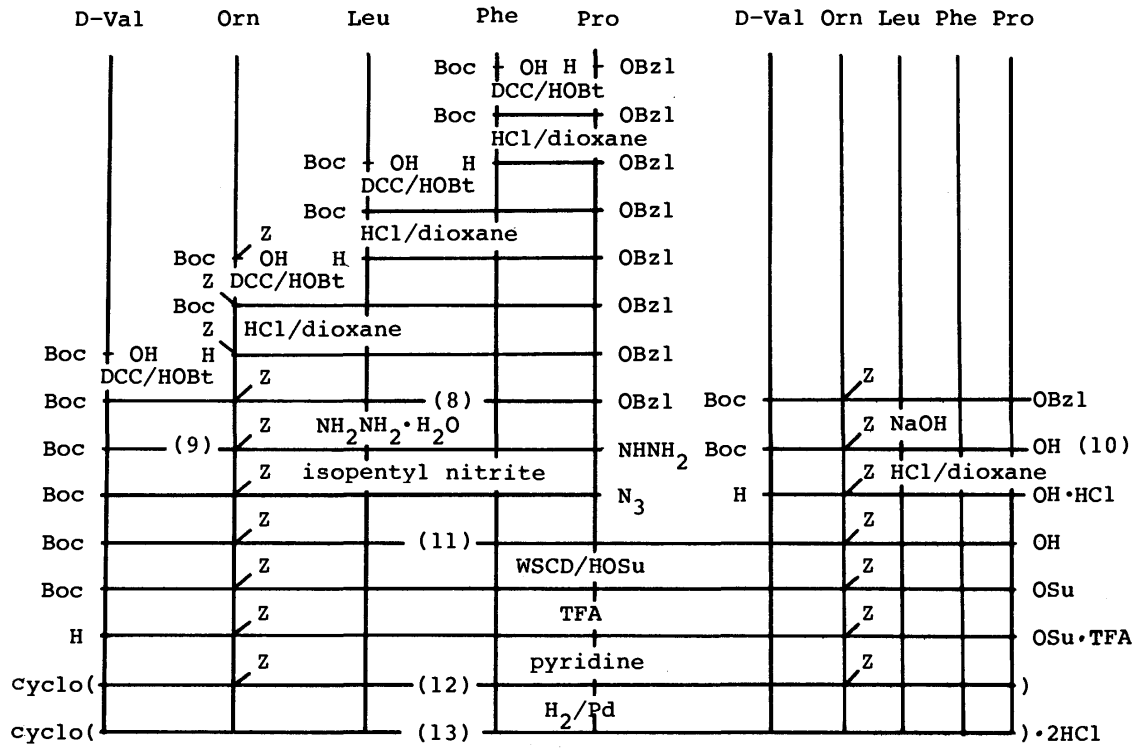

Scheme 2. Synthesis of [D-Val$^{1,1'}$, L-Phe$^{4,4'}$]-GS.

protected [D-Val$^{1,1'}$, L-Phe$^{4,4'}$]-GS (**12**), the Boc-pentapeptide benzyl ester (**8**) was synthesized by stepwise elongation using DCC and HOBt from the Pro benzyl ester. A part of **8** was converted into the hydrazide (**9**), and another part was saponified to obtain the Boc-pentapeptide (**10**). The coupling of **9** and the pentapeptide derived from **10** was carried out using an azide method and afforded the Boc-decapeptide (**11**). The cyclization of **11** was performed using an active ester method in a similar manner as described regarding the synthesis of [D-Val$^{1,1'}$]-GS. The desired peptide was obtained in a 47% yield. The masking groups of **6** and **12** were removed by hydrogenolysis. Their homogeneity was confirmed by thin-layer chromatography, cellulose plate electrophoresis, elemental analysis, amino acid analysis, high-performance liquid chromatography (HPLC) and secondary ion mass spectrometry (SIMS).

The CD spectra of [D-Val$^{1,1'}$]-GS, [D-Val$^{1,1'}$, L-Phe$^{4,4'}$]-GS, and GS in aqueous solutions are shown in Fig. 3. The spectral shapes of these peptides differ from each other, indicating that they have different conforma-

——, GS: ---, [D-Val$^{1,1'}$]-GS: –·–, [D-Val$^{1,1'}$, L-Phe$^{4,4'}$]-GS.

tions in aqueous solutions. Recently, in CD spectroscopic studies of cyclododecapeptide gratisin, we reported that the CD spectra of synthetic isomers could be classified into four groups, and that the isomers belonging to each group possess analogous partial sequences around the Pro residues. That is, L-X-Pro-L-Y, D-X-Pro-L-Y, L-X-Pro-D-Y, and D-X-Pro-D-Y.[5] Each CD spectrum of [D-Val$^{1,1'}$]-GS, [D-Val$^{1,1'}$, L-Phe$^{4,4'}$]-GS and GS showed a similar pattern to that of the gratisin isomer having the corresponding partial sequences around the Pro residues (D-X-Pro-D-Y, L-X-Pro-D-Y and D-X-Pro-L-Y, respectively). The CD pattern of [L-Ala$^{4,4'}$]-GS[6] also resembles that of the gratisin isomer having a L-X-Pro-L-Y partial sequence. It is interesting that the CD spectra of these peptides related with both GS and gratisin are dependent on the particular sequence around the Pro residue, although these peptides have a different number of ring members. The CD spectra of [Pro$^{4,4'}$, Asn$^{5,5'}$]-GS and [Pro$^{4,4'}$, D-Ala$^{5,5'}$]-GS reported by Sato *et al.*[7] also showed a similar sequence dependence, although the Pro residues occupy positons different from 5 and 5′ in GS. Moreover, the CD spectrum of *cyclo*(-Leu-Orn-Leu-Orn- Leu-D-Phe-Pro-)$_2$ synthesized by Ando *et al.*[8] was also similar to that of GS. This may result from the presence of a D-X-Pro-L-Y partial sequence in the peptide. These results indicate that the CD spectra of these peptides in aqueous solutions reflect the partial sequences around the Pro residues, which affect (largely) the conformation of these peptides.

[D-Val$^{1,1'}$]-GS showed antibiotic activity only against *Corynebacterium diphtheriae* at a concentration of 25 μg/ml, and no activity toward the other Gram-positive microorganisms tested. [D-Val$^{1,1'}$, L-Phe$^{4,4'}$]-GS showed no antibiotic activity against all the Gram-positve microorganisms tested. That is, the D-Phe-Pro-Val sequences in GS can not be substituted by Phe-Pro-D-Val or D-Phe-Pro-D-Val sequence without affecting the activity. In gratisin analogs, several isomers containing different sequences in the corresponding part were more or less active.[5] The significant difference between GS and gratisin in this regard may result from the distinction of their rings, in other words, the flexibility of the β-turn parts.

Experimental

All the melting points are uncorrected. The CD spectra were obtained using a JASCO spectropolarimeter (model J-500). The CD spectroscopy of GS and its analogs was carried out with an aqueous solution of their dihydrochlorides. The molecular weights of GS analogs and several intermediary products were determined by secondary ion mass spectrometry (SIMS) using a Hitachi M-80B mass spectrometer and fast atom bomberdment (FAB) mass spectrometry using a JMS D-300 mass spectrometer. Amino acid analyses were carried out using a Hitachi 835 amino acid analyzer, after hydrolysis of the peptides in 6 M HCl (1 M=1 mol dm^{-3}) at 110°C for 24 h. HPLC was performed by an ODS column (φ 4.6×250 mm) using MeOH–5% $NaClO_4$ aq (5:1)[1] as eluting solvent. Thin-layer chromatography was performed on Merck silica-gel F_{254} plates with the following solvent systems (v/v): R_f^1, $CHCl_3$–MeOH (9:1); R_f^2, $CHCl_3$–MeOH–AcOH (95:5:3); R_f^3, *n*-BuOH–AcOH–H_2O (4:1:1); R_f^4, *n*-BuOH–pyridine–AcOH–H_2O (4:1:1:2).

Boc-D-Val-Orn(Z)-OEt (1). DCC (2.9 g, 14 mmol) was added to a solution of Boc-D-Val (3.0 g, 14 mmol), HOBt (2.1 g, 15.5 mmol), Orn(Z)-OEt·TsOH (6.5 g, 14 mmol) and TEA (2 ml, 14 mmol) in $CHCl_3$ (70 ml) at 0°C. This solution was stirred for 3 h at 0°C and overnight at room temperature. After the reaction mixture was concentrated *in vacuo*, AcOEt (20 ml) was added to the residue, and insoluble substance was removed by filtration. The filtrate was then diluted with AcOEt (150 ml). The solution was washed (successively) with 5% citric acid, water, 5% Na_2CO_3 and water, and then dried over sodium sulfate. After removal of the drying agent, the solvent was evaporated *in vacuo*. The product was recrystallized from hot AcOEt; yield, 4.56 g (65%); mp 130—132 °C; $[\alpha]_D^{29}$ −4.0° (*c* 1, DMF); R_f^1 0.88, R_f^2 0.68. Found: C, 61.25; H, 7.98; N, 8.53%. Calcd for $C_{25}H_{39}O_7N_3$: C, 60.83; H, 7.96; N, 8.51%.

Boc-D-Val-Orn(Z)-NHNH$_2$ (2). A solution of **1** (4.0 g, 8.1 mmol) and hydrazine hydrate (5 ml) in DMF (15 ml) was allowed to stand for 24 h at room temperature. The solution was concentrated, and then water was added to the residue. The resulting solid was collected by filtration; yield, 3.5 g (90%); mp 179—180°C; $[\alpha]_D^{29}$ −9.7° (*c* 1, DMF); R_f^1 0.41; R_f^2 0.44. MS (FAB), *m/z* 480 (MH^+). Found: C, 57.65; H, 7.82; N, 14.32%. Calcd for $C_{23}H_{37}O_6N_5$: C, 57.60; H, 7.78; N, 14.60%.

Z-Leu-D-Phe-Pro-OBzl (3). The coupling of Boc-D-Phe (5.4 g, 20 mmol) and Pro-OBzl·HCl (5.15 g, 20 mmol) were performed by the method described in the preparation of **1**. The product was dissolved in 4 M HCl/dioxane

(30 ml) containing anisole (0.5 ml) at 0°C. After stirring for 30 min at room temperature, the solution was concentrated *in vacuo*. The residue was dissolved in $CHCl_3$ (30 ml). The solution was washed by 5% Na_2CO_3 and water under cooling with an ice bath. To this solution were added Z-Leu (5.3 g, 20 mmol), HOBt (2.96 g, 22 mmol) and DCC (5.15 g, 20 mmol). The mixture was treated in a similar way to that described in the preparation of **1**. The crude tripeptide was purified by chromatography on a silica-gel column (2×40 cm) using a solvent system of $CHCl_3$–MeOH (50:1). The fractions containing the desired product were combined and concentrated. The product was obtained as an oil in a yield of 3.18 g (27% calculated from Pro-OBzl as the starting material). R_f^1 0.80, R_f^2 0.65.

Boc-D-Val-Orn(Z)-Leu-D-Phe-Pro-OH (4). Compound **3** (2.64 g, 4.4 mmol) was dissolved in 90% MeOH (30 ml), and then 1 M HCl (4.4 ml) was added to the solution. The mixture was hydrogenated in the presence of Pd black for 10 h. After removal of the catalyst, the filtrate was concentrated *in vacuo*. To a solution of **2** (2.1 g, 4.4 mmol) in DMF (20 ml) were added 9 M HCl/dioxane (1.4 ml, 12.6 mmol) and isopentyl nitrite (0.7 ml, 5.0 mmol) at −40°C. After stirring at −20°C for 15 min, TEA (1.8 ml, 12.6 mmol) was added at −40°C. This mixture was combined with a solution of the total amount of the H-Leu-D-Phe-Pro-OH prepared above and TEA (1.25 ml, 8.8 mmol) in DMF (12 ml). The mixture was stirred at 0°C for 3 d, and concentrated. The residue was dissolved in AcOEt (100 ml). The solution was washed with 5% citric acid, water, 5% Na_2CO_3 and water, and dried. After the removal of the drying agent, the solution was evaporated. The product was recrystallized from MeOH–ether; yield, 3.05 g (84%); mp 191—192°C; $[\alpha]_D^{29}$ −36.7° (*c* 1, DMF); R_f^1 0.37, R_f^2 0.39. MS (FAB), *m/z* 823 (MH^+). Found: C, 62.57; H, 7.81; N, 10.14%. Calcd for $C_{43}H_{62}O_{10}N_6$: C, 62.76; H, 7.59; N, 10.21%.

Boc-[D-Val-Orn(Z)-Leu-D-Phe-Pro-]$_2$-OH (5). To a solution of **4** (1.17 g, 1.4 mmol) in DMF (7 ml) was added HOSu (0.35 g, 3 mmol) and WSCD·HCl (0.52 g, 2.7 mmol) at 0°C, and then the mixture was stirred for 48 h at room temperature. The solution was evaporated, and then water was added to the residue. The resulting solid, Boc-D-Val-Orn(Z)-Leu-D-Phe-Pro-OSu (**4'**), was collected by filtration, and washed with water and dried. Another crop of **4** (1.17 g, 1.4 mmol) was dissolved in 4 M HCl/dioxane (10 ml) containing anisole (0.5 ml) at 0°C. After stirring at room temperature for 30 min, the solution was concentrated *in vacuo*. To a solution of H-D-Val-Orn(Z)-Leu-D-Phe-Pro-OH prepared above and TEA (0.4 ml, 2.8 mmol) in DMF (8 ml) at 0°C was added **4'** derived from **4**. The mixture was left to stand for 2 h at 0°C and overnight at room temperature. The solution was evaporated, and the residue was dissolved into AcOEt (200 ml). The solution was washed with 5% citric acid and water, and was evaporated. The product was recrystallized from MeOH–ether; yield, 1.37 g (64%); mp 146—148°C; $[\alpha]_D^{29}$ −38.3° (*c* 1, DMF); R_f^1 0.32, R_f^2 0.42. Found: C, 62.91; H, 7.67; N, 10.75%. Calcd for $C_{81}H_{114}O_{17}N_{12}\cdot H_2O$: C, 62.93; H, 7.56; N, 10.87%.

cyclo[-D-Val-Orn(Z)-Leu-D-Phe-Pro-]$_2$ (6). Boc-[D-Val-Orn(Z)-Leu-D-Phe-Pro-]$_2$-OH (0.94 g, 0.6 mmol) was converted into the succinimido ester (**5'**) by the method described for **5**. It was dissolved in TFA (10 ml) containing a few drops of anisole at 0°C. The mixture were stirred for 30 min at room temperature and then concentrated. The residue, the trifluoroacetate of the decapeptide active ester, was triturated with ether, collected by filtration and dissolved in DMF (8 ml). The solution was added dropwise into pyridine (400 ml) at 60°C. After stirring for 3 h at 60°C, the solvent was evaporated, and then water was added to the residue. The resulting solid was collected by filtration, washed with water and dried. The product was purified by reprecipitaion from MeOH–ether; yield, 0.21 g (25%); mp 146—148°C; $[\alpha]_D^{29}$ −58.0° (*c* 0.5, DMF); R_f^1 0.73, R_f^2 0.70. Found: C, 63.89; H, 7.56; N, 11.81%. Calcd for $C_{76}H_{104}O_{14}N_{12}\cdot H_2O$: C, 63.93; H, 7.48; N, 11.77%.

cyclo(-D-Val-Orn-Leu-D-Phe-Pro-)$_2$·2HCl (7). **6** (100 mg, 0.07 mmol) was hydrogenated in 90% MeOH (35 ml) containing 1 M HCl (0.14 ml) in the presence of Pd black for 8 h. After removal of the catalyst, the filtrate was concentrated *in vacuo*. The product was purified by gel filtration on a Sephadex LH-20 column (1×150 cm) using MeOH as solvent, and by reprecipitation from MeOH–ether; yield, 40 mg (47%); mp 241—243°C (dec.); $[\alpha]_D^{29}$ −55.1° (*c* 0.2, EtOH); R_f^3 0.55, R_f^4 0.71. Amino acid ratios: Val, 0.93; Orn, 0.90; Leu, 1.05; Phe, 1.07; Pro, 1.07. MS (SIMS), *m/z* 1141 ($C_{60}H_{93}O_{10}N_{12}$; MH^+) Found: C, 55.93; H, 7.68; N, 12.83%. Calcd for $C_{60}H_{92}O_{10}N_{12}\cdot 2HCl\cdot 4H_2O$; C, 56.01; H, 7.99; N, 13.06%.

Boc-D-Val-Orn(Z)-Leu-Phe-Pro-OBzl (8). This product was synthesized with DCC and HOBt by stepwise elongation from Pro-OBzl·HCl (2.57 g, 10 mmol) as described for the preparation of **3**. The product was purified by a silica-gel column (2.2×40 cm) using $CHCl_3$–MeOH (50:1) as a solvent, and the fractions containing the desired product were combined and concentrated. The product was recrystallized from MeOH–ether; yield, 4.6 g (50%); mp 92—96°C; $[\alpha]_D^{29}$ −37.9° (*c* 1, DMF); R_f^1 0.80, R_f^2 0.59. Found: C, 66.08; H, 7.55; N, 9.09%. Calcd for $C_{50}H_{68}O_{10}N_6$: C, 65.77: H, 7.51, N, 9.20%.

Boc-D-Val-Orn(Z)-Leu-Phe-Pro-NHNH$_2$ (9). Compound **8** (1.49 g, 1.63 mmol) was treated with hydrazine hydrate (1.5 ml) as described for the preparation of **2**; yield, 0.95 g (70%); mp 132—135°C; $[\alpha]_D^{29}$ −32.0° (*c* 0.5, DMF); R_f^1 0.55, R_f^2 0.44. Found: C, 60.54; H, 7.75; N, 13.03%. Calcd for $C_{43}H_{64}O_9N_8\cdot H_2O$: C, 60.40; H, 7.77; N, 13.10%.

Boc-D-Val-Orn(Z)-Leu-Phe-Pro-OH (10). In a solution of **8** (1.01 g, 1.1 mmol) in MeOH (24 ml) and dioxane (12 ml), 1 M NaOH (2.3 ml) was added. The solution was stirred for 5 h at room temperature. After the addition of water (10 ml), the solution was evaporated, and then 10% citric acid was added to the residue. The resulting solid was collected by filtration, washed with water and dried. The product recrystallized from MeOH–ether; yield, 0.68 g (75%); mp 134—136°C; $[\alpha]_D^{29}$ −28.6° (*c* 0.5, DMF); R_f^1 0.50, R_f^2 0.44. Found: C, 62.42; H, 7.71: N, 10.48%. Calcd for $C_{43}H_{62}O_{10}N_6$: C, 62.76; H, 7.59; N, 10.21%.

Boc-[D-Val-Orn(Z)-Leu-Phe-Pro-]$_2$-OH (11). This compound was prepared from **9** (0.62 g, 0.73 mmol) and **10** (0.6 g, 0.73 mmol) as described for the preparation of **4**. The product was purified by gel filtration on a Sephadex LH-20 column (2.5×120 cm) using MeOH as solvent, and recrystallization from MeOH–ether; yield, 0.74 g (66%); mp 150—151°C; $[\alpha]_D^{29}$ −37.1° (*c* 0.5, DMF); R_f^1 0.40, R_f^2 0.40. Found: C, 62.86; H, 7.35; N, 10.84%. Calcd for $C_{81}H_{114}O_{17}N_{12}\cdot H_2O$: C, 62.93; H, 7.56; N, 10.87%.

cyclo[-D-Val-Orn(Z)-Leu-Phe-Pro-]$_2$ (12). This compound was prepared from **11** (0.41 g, 0.27 mmol) as described for the preparation of **6**. The product was purified

by silica-gel column chromatography, and recrystallization from MeOH–ether; yield, 179 mg (47%); mp 218—219 °C; $[\alpha]_D^{29}$ −22.0° (*c* 0.5, DMF); R_f^1 0.66, R_f^2 0.41. Found: C, 64.31; H, 7.59; N, 12.23%. Calcd for $C_{76}H_{104}O_{14}N_{12}$: C, 64.75; H, 7.43; N, 11.92%.

cyclo(-D-*Val-Orn-Leu-Phe-Pro-*)$_2$·2HCl (**13**). This compound was prepared from **12** (105 mg, 0.074 mmol) as described for the preparation of **7**; yield, 66 mg (74%); mp 239—241 °C; $[\alpha]_D^{29}$ −31.8° (*c* 0.2, EtOH); R_f^3 0.68, R_f^4 0.65. Amino acid ratios: Val, 0.95; Orn, 1.03; Leu, 1.03; Phe, 1.00; Pro, 1.00. MS(SIMS), *m/z* 1141 ($C_{60}H_{93}O_{10}N_{12}$, MH^+). Found: C, 56.03; H, 7.78; N, 13.08%. Calcd for $C_{60}H_{92}O_{10}N_{12}\cdot 2HCl\cdot 4H_2O$: C, 56.01; H, 7.99; N, 13.06%.

Cellulose Plate Electrophoresis. It was carried out with cellulose (Avicel) plate and with a solvent system of HCOOH–AcOH–MeOH–H_2O (1:3:6:10 v/v, PH 1.4) for 2 h at 500 V/20 cm. Each of analogs revealed a single spot, the mobility being the same as that of GS.

Microbiological Assays. The microorganisms employed were *Stapylococcus aureus* ATCC 6538, *Streptomyces pyogenes* N.Y.5, *Corynebacterium diphtheriae* P.W.8, *Micrococcus pyogenes* ATCC 10240, *Bacillus subtilis* ATCC 6633, *Escherichia coli* NIHJ-JC2 and *Proteus vulgaris* OX 19. The minimum concentration of the compounds necessary for the complete inhibition of growth of these microorganisms was determined by an agar dilution method with 10^6 organisms per milliter.

We are grateful to the staff of the Research Laboratories of Toyo Jozo Co. for elemental analyses, microbiological assays and the measurements of FAB Mass, and also to Professor Makoto Suzuki, Meijo University, for the measurement of SIMS.

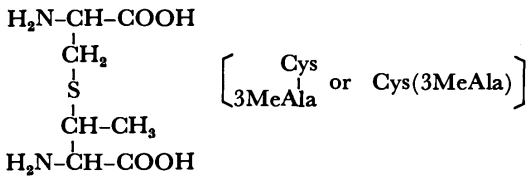
Syntheses of Four Stereoisomers of β-Methyllanthionine.

Tateaki WAKAMIYA, Yoshiaki ODA, Koichi FUKASE, and Tetsuo SHIBA*
Department of Chemistry, Faculty of Science, Osaka University, Toyonaka, Osaka 560
(Received September 27, 1984)

Four stereoisomers of β-methyllanthionine were synthesized by coupling of *N*-benzyloxycarbonyl-3-methyl-D-cysteine with β-chloroalanine. ^{1}H NMR analysis and retention time in amino acid analysis were studied on these compounds.

β-Methyllanthionine is a unique sulfide amino acid which was first found as a constituent of peptide antibiotics subtilin[1] and nisin[2] and also occurred in yeast.[3] Recently, the same amino acid was observed in a new angiotensin converting enzyme inhibitor, ancovenin.[4] The configuration of this amino acid in



β-Methyllanthionine = (3-Methylalanin-3-yl)cysteine

all these biologically active peptides was determined to be of (2*R*)-*S*-[(2*S*,3*S*)-3-methylalanin-3-yl]cysteine.[5] To confirm this result synthetically, we prepared four stereoisomers in which the configuration of α-carbon atom of 3-methylalanine part was fixed in *S* configuration corresponding to D-amino acid. Another four possible compounds of *R* configuration on α-carbon atom of 3-methylalanine moiety were not prepared in this work, since all the physicochemical properties except the opposite sign of specific rotation are obtainable from the corresponding enantiomer with (2*S*)-3-methylalanyl configuration. Although Okawa *et al.* reported the syntheses of two enantiomers of protected *threo*-β-methyllanthionine by addition of *N*-benzyloxycarbonyl-L-cysteine benzyl ester to benzyl *N*-benzyloxycarbonyl-(2*S*,3*S*)- or (2*R*,3*R*)-3-methyl-2-aziridinecarboxylate, other enantiomers and free forms of all diastereoisomers have not yet been known in their physical properties.[6]

The synthesis of β-methyllanthionine in this investigation was attempted by coupling of *N*-benzyloxycarbonyl-3-methylcysteine with β-chloroalanine. For this purpose both *threo*- and *erythro*-3-methyl-D-cysteine were required. The *threo* compound was prepared by our previous method *via* an addition of thiocarboxylic acid to aziridinecarboxylic acid derivative obtained from threonine.[7] On the other hand, the *erythro* compound was obtained by S_N2 substitution of *p*-toluenesulfonyloxy group on β-carbon atom of threonine derivative with thiobenzoic acid[8] as shown in Fig. 1. From the amino acid analysis of the product, we could assure that the reaction proceeded without racemization to form *erythro*-3-methyl-D-cysteine, *i.e.*, (2*S*,3*R*)-3-methylcysteine.

Coupling of each *N*-benzyloxycarbonyl-3-methyl-

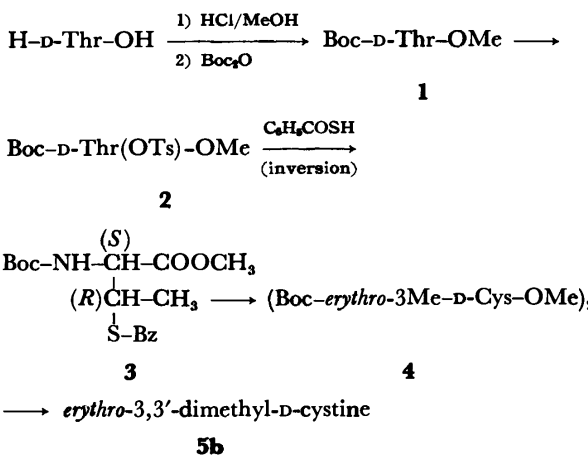


Fig. 1. Preparative scheme of *erythro*-3,3′-dimethyl-D-cystine. Boc=*t*-butoxycarbonyl.

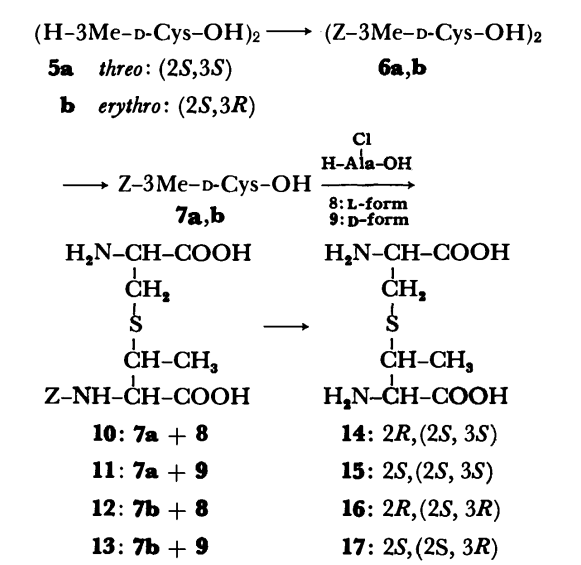

Fig. 2. Preparation of four stereoisomers of β-methyllanthionine.

cysteine (**7a** and **7b**) with L- or D-β-chloroalanine (**8** or **9**) was carried out according to the procedure for the preparation of *meso*-lanthionine by Photaki *et al.*[9] (Fig. 2). Each coupling product, **10**—**13**, was then treated with hydrogen bromide in glacial acetic acid to give corresponding β-methyllanthionine, **14**—**17**, respectively. Physicochemical properties of the compounds **6**—**17** were listed in Table 1. Retention times of final products in amino acid analysis were also given in Table 1. ^{1}H NMR analysis of the compounds **10**—**17** was summarized in Table 2.

TABLE 1. ANALYTICAL DATA OF STEREOISOMERS OF β-METHYLLANTHIONINE AND THE COMPOUNDS RELATED TO THEIR SYNTHESES

Compound	Yield/%	Mp (θ_m/°C, dec)	$[\alpha]_D$/°	Formula	Found (Calcd) (%) C	H	N	S	Retention time in amino acid analysis (min)

Abbreviations; s: singlet, d: doublet, dd: double doublet, t: triplet, m; multiplet.
a) Measured in 2 M DCl. b) Measured in D_2O. c) Three peaks due to A_2B system were observed.

Of four stereoisomers of β-methyllanthionine obtained, (2*R*)-*S*-[(2*S*,3*S*)-3-methylalanin-3-yl]cysteine (**14**) was identical with the natural one from nisin or ancovenin confirming the assumed structure unequivocally. Now, these synthetic compounds will be useful as authentic samples for structural determination of β-methyllanthionine of unknown configuration when found newly in nature.

Experimental

All melting points are uncorrected. The NMR spectra were obtained with Varian XL-100-15 spectrometer and sodium 2,2-dimethyl-2-silapentane-5-sulfonate (DSS) was used as the external standard. Chemical shifts were given by δ value (ppm) from DSS. Specific rotations were measured with a Perkin-Elmer 141 polarimeter. Amino acid analysis was carried out with a Hitachi KLA-5 analyzer.

N-t-Butoxycarbonyl-D-threonine Methyl Ester (1). To a solution of D-threonine methyl ester hydrochloride[7a] (12.8 g, 75.6 mmol) in anhydrous methanol (160 ml) were added dropwise triethylamine (11.5 g, 113 mmol) and di-*t*-butyl dicarbonate (18.1 g, 83.2 mmol) under ice cooling. The reaction mixture was stirred overnight at room temperature and then concentrated *in vacuo*.

Ethyl acetate extract from an oily residue obtained was washed successively with water, saturated sodium chloride solution, 10% citric acid solution, saturated sodium hydrogencarbonate solution, and saturated sodium chloride solution. The extract was dried over magnesium sulfate and concentrated *in vacuo* to give **1** as an oily product: yield 15.0 g (85.2%); $[\alpha]_D^{32}$ +7.7° (c 1.0, $CHCl_3$). Found: C, 50.10; H, 8.17; N, 5.79%. Calcd for $C_{10}H_{19}NO_5 \cdot 0.3H_2O$[10]: C, 50.33; H, 8.28; N, 5.87%.

N-t-Butoxycarbonyl-O-p-toluenesulfonyl-D-threonine Methyl Ester (2). To a solution of **1** (9.70 g, 41.6 mmol) in pyridine (120 ml) was added *p*-toluenesulfonyl chloride (79.4 g, 416 mmol) under cooling in an ice–salt bath. The reaction mixture was stirred for 3 h in the chilled bath and then in an ice bath until the starting material disappeared. The reaction mixture was poured onto crushed ice and extracted with ethyl acetate (1 l×2). The extract was subjected to the general aqueous washing procedure as mentioned above.

Ethyl acetate layer was then dried over magnesium sulfate and concentrated *in vacuo*. An oily residue thus obtained was purified by silica-gel column chromatography. Elution with benzene removed unreacted *p*-toluenesulfonyl chloride. The desired *p*-toluenesulfonate **2** was eluted with ethyl acetate as an oily product: yield 14.9 g (92.5%); $[\alpha]_D^{32}$ −15.5° (*c* 1.39, CH_3OH). Found: C, 52.28; H, 6.62; N, 3.59; S, 8.26%. Calcd for $C_{17}H_{25}NO_7S \cdot 0.2H_2O$[10]: C, 52.22; H, 6.55; N, 3.58; S, 8.20%.

S-Benzoyl-N-t-butoxycarbonyl-erythro-3-methyl-D-cysteine Methyl Ester (3). To a solution of potassium hydroxide (10.5 g, 187 mmol) in methanol (100 ml) was added thiobenzoic acid (25.7 ml, 219 mmol). The mixture was stirred for 5 min at room temperature and then concentrated *in vacuo* to give potassium thiobenzoate which was dried in a vacuum desiccator. To potassium thiobenzoate transferred in a reaction vessel was added the compound **2** (18.4 g, 47.5 mmol) in DMF (61 ml) under nitrogen atmosphere with cooling in an ice bath. The solution was stirred for 64 h at room temperature and the reaction mixture was extracted with ethyl acetate. The extract was washed with saturated sodium chloride, sodium hydrogencarbonate and then sodium chloride solutions. Ethyl acetate layer was dried over magnesium sulfate and concentrated *in vacuo*. An oily residue was column-chromatographed on silica gel (Merck #7734, 7×19 cm). Elution with benzene–ethyl acetate (19:1) gave pure **3** as an oily product: yield 7.59 g (45.2%); $[\alpha]_D^{17}$ −23.7° (*c* 1.65, $CHCl_3$). Found: C, 57.23; H, 6.53; N, 3.94; S, 9.06%. Calcd for $C_{17}H_{23}NO_5S \cdot 0.1H_2O$[10]: C, 57.48; H, 6.58; N, 3.94; S, 9.03%.

N,N'-Bis(t-butoxycarbonyl)-erythro-3,3'-dimethyl-D-cystine Dimethyl Ester (4). Debenzoylation and oxidation of the compound **3** (100 mg, 0.28 mmol) were carried out in a similar manner as described in the previous paper.[7] After usual treatment of the reaction mixture as described in preparation of **3**, crude product was purified by column chromatography on silica gel (Merck #7734, 0.8×17 cm). Pure oily material was obtained by an elution with benzene-ethyl acetate (9:1): yield 60 mg (85%); $[\alpha]_D^{17}$ +52.9° (*c* 1.14, $CHCl_3$). Found: C, 48.56; H, 7.35; N, 5.65; S, 12.60%. Calcd for $C_{20}H_{36}N_2O_8S_2$: C, 48.37; H, 7.31; N, 5.64; S, 12.91%.

erythro-3,3'-Dimethyl-D-cystine (5b). A suspension of **4** (1.57 g, 3.16 mmol) in 6M† HCl (40 ml) was heated for 2 h at 110°C. The hydrolyzate was concentrated *in vacuo* and the residue was dissolved in 50% ethanol (30 ml). The solution was neutralized by an addition of pyridine to give crystalline product which was recrystallized from water and ethanol: yield 722 mg (85.1%); mp 177—183°C (dec); $[\alpha]_D^{19}$ +515° (*c* 1.02, 1 M HCl). Found: C, 35.13; H, 6.15; N, 10.07; S, 23.46%. Calcd for $C_8H_{16}N_2O_4S_2 \cdot 0.3H_2O$[10]: C, 35.10; H, 6.11; N, 10.23; S, 23.42%.

N,N'-Bis(benzyloxycarbonyl)-threo- and erythro-3,3'-dimethyl-D-cystine (6a and 6b). To a solution of the compound **5a**[7] or **5b** (900 mg, 3.36 mmol) in 1 M sodium hydroxide (13 ml) was added benzyloxycarbonyl chloride (1.1 ml, 7.1 mmol) under ice cooling. The solution was stirred for 2 h at 0°C and then extracted with ether. The aqueous layer acidified with 2 M HCl was extracted with ethyl acetate. The ethyl acetate extract was washed with saturated sodium chloride solution, dried over magnesium sulfate, and concentrated *in vacuo*. Each benzyloxycarbonyl derivative **6a** and **6b** was obtained respectively as an oily substance.

N-Benzyloxycarbonyl-threo- and erythro-3-Methyl-D-cysteine (7a and 7b). Disulfide derivative **6a** or **6b** (688 mg, 1.28 mmol) was dissolved in methanol (2.7 ml) and concentrated hydrochloric acid (0.83 ml) was added to the solution under ice cooling. To the solution was added zinc powder by portions and the suspension was stirred in an ice bath until the disulfide disappeared. The reaction mixture was filtered to remove zinc powder and the filtrate was concentrated *in vacuo*. The residue was dissolved in ethyl acetate and the solution was washed with saturated sodium chloride solution. Ethyl acetate layer was dried over magnesium sulfate and concentrated *in vacuo* to obtain mercapto derivative **7a** or **7b** respectively as an oily product.

Coupling of Mercapto Derivative with β-Chloroalanine. Mercapto derivative **7a** or **7b** (679 mg, 2.52 mmol) was dissolved in 4.4 M potassium hydroxide (1.5 ml). To the solution warmed at 50°C were added β-chloroalanine hydrochloride (403 mg, 2.52 mmol)[11] and 2.6 M potassium hydroxide (1.9 ml). The solution was warmed at 50°C for 30 min and at room temperature for 44 h under argon atmosphere. The reaction mixture was acidified and extracted with ether. Aqueous layer was concentrated *in vacuo* and the residue dissolved in a small amount of 2 M ammonium hydroxide was applied to HP-20 column (3×16 cm). Elution with water and 50% methanol gave desired product which was crystallized by trituration with methanol and ether.

Analytical sample was obtained by further column chromatography on Amberlite IRCG-50 (H^+ form) using water as an eluent. Pure material was recrystallized from water.

β-Methyllanthionine (14—17). Each *N*-benzyloxycarbonyl-β-methyllanthionine derivative (**10—13**) (340 mg, 0.96 mmol) obtained above was dissolved in 25% HBr in glacial acetic acid (12 ml). To the solution kept at room temperature for 2 h was added ether to precipitate respective β-methyllanthionine as hydrobromide. A solution of the hydrobromide in a small amount of water was neutralized with pyridine. Addition of methanol and ether to the solution gave a free amino acid (**14—17**) respectively which was recrystallized from water and methanol. The data of physical properties of these products (**14—17**) were shown in Table 1 and 2.

The authors are deeply indebted to Ajinomoto Co. Ltd., for the supply of D-threonine.

Magnetic Properties of Conjugated Systems. Bond Orders and Imaginary Bond-Bond Polarizabilities of "Acyclic" Bonds†

Noriyuki MIZOGUCHI
Department of Physics, Meiji College of Pharmacy, Nozawa, Setagaya-ku, Tokyo 154
(Received June 28, 1984)

Within the London-McWeeny formalism of the π-electron magnetic properties, the contribution of each bond in a conjugated system to the London susceptibility is studied. By using the relations between the bond orders P_{rs} and the imaginary bond-bond polarizabilities $\bar{\pi}_{(rs)(tu)}$ proved in a previous paper, it is shown that two equations, $P_{rs}+\beta\bar{\pi}_{(rs)(rs)}=0$ and $\bar{\pi}_{(rs)(vw)}=0$, hold for the "acyclic" bond r-s in a conjugated system. The equations show that no bonds in acyclic conjugated systems or in acyclic fragments of cyclic systems make any contributions to the London susceptibilities (or to the ring currents) of the systems. On the basis of these equations, the expression for the London susceptibility is simplified. Moreover, we will discuss the relationships between the above equations and some consequences of McWeeny's unitary transformation.

In 1937 London first laid the foundations of the quantum mechanical theory of π-electron magnetic properties using the Hückel molecular orbital method.[1-4] The π-electron contribution to the magnetic susceptibility of a conjugated system is called the London susceptibility.[5] Pople[6] and McWeeny[7] modified London's method to estimate the proton NMR shielding constants.

It is well-known that, within the London formalism, an external, uniform, magnetic field perpendicular to the molecular plane has no effect on noncyclic conjugated systems.[1-4,8] By using graph theory,[9] Aihara[10] reexamined Pople's approach and showed that the London susceptibility of a polycyclic conjugated molecule can be expressed as a sum of the circuit susceptibilities over all the circuits found in the system.[11] Recently, using Coulson's integral formula,[12] we have proved the circuit rule for the magnetic susceptibility, which states that the circuit susceptibility for the $(4n+2)$-membered circuit is diamagnetic, while that for the $(4n)$-membered circuit is paramagnetic.[11]

In McWeeny's perturbation approach,[3,7] the London susceptibility is expressed in terms of the bond order[12] and the imaginary bond-bond polarizability.[7] Recently we[13] ourselves have proved several general relations between bond orders and imaginary bond-bond polarizabilities, which reflect the local topological nature of the bonds considered, *i.e.*, the mode of branching.

As has been mentioned above, the relationship between the magnetic properties and the structure has been extensively studied. However, it has not been known how each bond in acyclic conjugated systems and in acyclic fragments of cyclic systems contributes to the London susceptibilities. In the present paper, by the use of the relations between the bond orders and the imaginary bond-bond polarizabilities we will reexamine the properties of the bond orders and imaginary bond-bond polarizabilities for the bonds in those systems. The physical meanings of the equations obtained will also be discussed. Moreover, we will study the relationships between the equations thus obtained and some consequences of McWeeny's unitary transformation.

London Susceptibility and Relations between Bond Orders and Imaginary Bond-Bond Polarizabilities

Following London,[1-4] the Hückel matrix elements of a planar conjugated hydrocarbon, in the presence of an external, uniform, magnetic field, $\boldsymbol{H}$, perpendicular to the molecular plane, are given by:

$$h_{rr} = \alpha, \tag{1a}$$

$$h_{rs}\begin{cases} = \beta\exp(iw_{rs}) & \text{if atoms } r \text{ and } s \text{ are adjacent,} \\ = 0 & \text{otherwise,} \end{cases} \tag{1b}$$

where α is the Hükel Coulomb integral, where β is the Hückel resonance integral in the absence of the field, which is assumed to be equal for all the bonds in the molecule, and where w_{rs} is given by:

$$w_{rs} = (e/\hbar c)\, S_{rs} H = -\, w_{sr}. \tag{2}$$

In Eq. 2, e, $\hbar$, and c are the usual fundamental constants with these symbols, S_{rs} is the signed area of the triangle formed by an arbitrary origin and the bond r-s, and H is the field strength. With respect to the zero-field atomic orbital, the matrix elements of the perturbation due to the magnetic field are:

$$\Delta_{rs} = h_{rs} - \beta = \beta(iw_{rs} - \frac{1}{2} w_{rs}^2 + \cdots\cdots). \tag{3}$$

In McWeeny's notation[7] the partial London susceptibility for the J-th MO, χ_J, is given by:

$$\chi_J = 2\beta\left(\frac{e}{\hbar c}\right)^2 \left\{\sum_{(rs)} p_{J,rs} S_{rs}^2 + \sum_{(rs)}\sum_{(tu)} \beta\bar{\pi}_{J,(rs)(tu)} S_{rs} S_{tu}\right\}, \tag{4}$$

where the sum runs over all the bonds in the molecule and where $P_{J,rs}$ and $\bar{\pi}_{J,(rs)(tu)}$ are, respectively, the partial Coulson bond order of the bond r-s[14] and the partial imaginary bond-bond polarizability between the bonds r-s and t-u for the J-th MO:[15]

$$P_{J,rs} = C_{rJ}\, C_{sJ}, \tag{5}$$

and:

†This is Part II in a series in which Ref. 13 is Part I.

$$\pi_{J,(rs)(tu)} = \sum_{K(\neq J)} \frac{(C_{rJ}C_{sK} - C_{sJ}C_{rK})(C_{tK}C_{uJ} - C_{uK}C_{tJ})}{(X_J - X_K)\beta} \quad (6)$$

where X_J and C_{rJ} are, respectively, the orbital energy (in units of β) and the coefficient of the r-th AO of the J-th MO in the absence of the magnetic field and where the sum runs over all the unperturbed molecular orbitals except the J-th MO.

We have proved several relations between partial bond orders and partial imaginary bond-bond polarizabilities for each nondegenerate MO for the bonds in the two subgraphs, G1 and G2, shown in Fig. 1:[13]

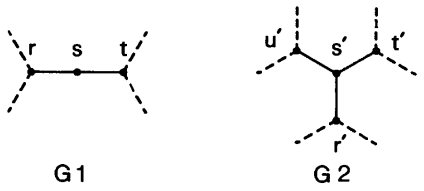

Fig. 1. Subgraphs G1 and G2.

for the bonds in the subgraph G1:

A' $\pi_{J,(vw)(rs)} = \pi_{J,(vw)(st)}$,

B' $P_{J,rs} + \beta\pi_{J,(rs)(rs)} = P_{J,st} + \beta\pi_{J,(st)(st)}$,

C' $P_{J,rs} + \beta\pi_{J,(rs)(rs)} = \beta\pi_{J,(rs)(st)}$,

for the bonds in the subgraph G2:

D' $\pi_{J,(vw)(r's')} = \pi_{J,(vw)(s't')} + \pi_{J,(vw)(s'u')}$,

E' $P_{J,r's'} + \beta\pi_{J,(r's')(r's')} = \beta\pi_{J,(r's')(s't')} + \beta\pi_{J,(r's')(s'u')}$,

where v-w is an arbitrary bond. The partial imaginary bond-bond polarizabilities in the relations A' and D' must be mutual.

Bond Orders and Imaginary Bond-Bond Polarizabilities of "Acyclic" Bonds

A bond (edge) in a molecular graph may be classified into one of two types, an "acyclic" bond or a "cyclic" bond. They are defined as follows: The deletion of a "cyclic" bond from a molecular graph reduces the number of rings in the molecular graph, but the deletion of an "acyclic" bond does not. For example, the bonds 1-7, 2-8, 3-9, 4-10, 5-11, and 6-12 in the [6]-radialene molecular graph G3 shown in Fig. 2 are "acyclic" because the deletion of any one of these bonds does not reduce the number of rings in G3. All the other bonds in G3 are "cyclic." Edge 1-7 in the biphenyl molecular graph G4 in Fig. 2 is "acyclic." Of course, all the bonds in an acyclic system are "acyclic."

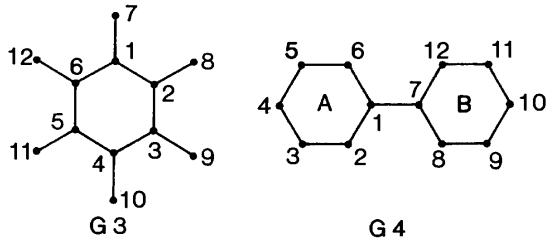

Fig. 2. Molecular graphs G3 and G4.

"Acyclic" and "cyclic" bonds play drastically different roles in the calculations of the magnetic properties of conjugated molecules. For the "acyclic" bond r-s we have the following equations:

$$\pi_{J,(rs)(vw)} = 0, \quad (7)$$

$$\pi_{(rs)(vw)} = 0, \quad (8)$$

$$P_{J,rs} + \beta\pi_{J,(rs)(rs)} = 0, \quad (9)$$

and:

$$P_{rs} + \beta\pi_{(rs)(rs)} = 0, \quad (10)$$

where v-w is an arbitrary bond except in the case of the bond r-s. Here, it should be noted that two quantities, $P_{J,rs}$ and $\pi_{J,(rs)(rs)}$, are not zero for any bonds, and that the (total) self imaginary bond-bond polarizabilities of bonds in an arbitrary closed-shell system are positive:[13]

$$\pi_{(rs)(rs)} > 0. \quad (11)$$

By virtue of the relations A'—E', Eqs. 7—10 will be illustrated for several typical systems. For the sake of simplicity, only Eqs. 7 and 9 will be discussed in detail because Eqs. 8 and 10 can be easily derived from Eqs. 7 and 9 respectively.

A) It will be convenient for the later discussions to prove initially Eqs. 7 and 9 for a terminal "acyclic" bond, a-b, shown in Fig. 3. By substituting the vari-

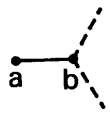

Fig. 3. Terminal "acyclic" bond a—b.

ational constraint for the carbon atom (vertex) a:

$$-X_J C_{aJ} + C_{bJ} = 0, \quad (12)$$

into Eq. 7, and with some manipulations, the partial mutual imaginary bond-bond polarizability between the bond a-b and an arbitrary bond, v-w, is rewritten as follows:

$$\beta\pi_{J,(ab)(vw)} = \sum_{K\neq J} \{C_{aJ}C_{aK}(-C_{vK}C_{wJ} + C_{wK}C_{vJ})\}$$

$$= \sum_{K} \{C_{aJ}C_{aK}(-C_{vK}C_{wJ} + C_{wK}C_{vJ})\}, \quad (13)$$

where the sum $\sum_{K(\neq J)}$ has been replaced by the sum $\sum_{K}$. Since from the orthonomalities of AO's and MO's, we have[16]

$$\sum_{J} C_{rJ}C_{sJ} = \delta_{rs}, \quad (14)$$

the right-hand side of Eq. 13 vanishes. Hence, it follows that

$$\pi_{J,(ab)(vw)} = 0. \quad (15)$$

In a similar way, we can show that

$$\beta\pi_{J,(ab)(ab)} = \sum_{K} \{C_{aJ}C_{aK}(-C_{aK}C_{bJ} + C_{bK}C_{aJ})\}$$

$$= -C_{aJ}C_{bJ}. \quad (16)$$

Thus, we have proved that

$$P_{J,ab} + \beta\pi_{J,(ab)(ab)} = 0. \tag{17}$$

Therefore, it has been shown that Eqs. 7 and 9 are valid for the bond, *a-b*, shown in Fig. 3.

B) Next, two acyclic systems will be discussed. First, let us take linear polyene with N carbon atoms G5 in Fig. 4. We have already shown in the preceding section

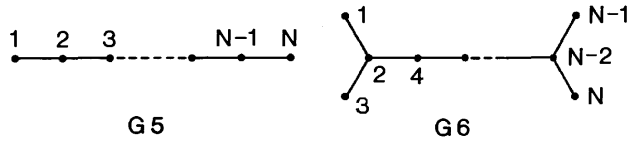

Fig. 4. Molecular graphs G5 and G6.

that Eqs. 7 and 9 hold for the bond, 1-2, in G5 because the bond corresponds to the bond, *a-b*, in Fig. 3. By only applying the relations A′ and B′ and Eqs. 15 and 17 to all the other bonds in G5, we easily obtain:

$$\pi_{J,(j\,j+1)(k\,k+1)} = 0, \tag{18}$$

and:

$$P_{J,j\,j+1} + \beta\pi_{J,(j\,j+1)(j\,j+1)} = 0, \tag{19}$$

where j, k=1, 2,···, N-1 and $j \neq k$.

Second, consider the molecular graph G6 shown in Fig. 4. We have already proved for the terminal bonds, 1-2, 2-3, (N-2)—(N-1), and (N-2)—N, in G6 in the previous section:

$$\pi_{J,(rs)(vw)} = 0, \tag{20}$$

and:

$$P_{J,rs} + \beta\pi_{J,(rs)(rs)} = 0, \tag{21}$$

where r-s stands for one of the bonds 1-2, 2-3, (N-2)—(N-1), and (N-2)—N and where v-w is an arbitrary bond. The application of the relation D′ to the bond 2-4 gives:

$$\pi_{J,(12)(vw)} = \pi_{J,(23)(vw)} + \pi_{J,(24)(vw)}. \tag{22}$$

From Eqs. 20 and 22, it follows that

$$\pi_{J,(24)(vw)} = 0. \tag{23}$$

From the relation E′ we obtain:

$$P_{J,24} + \beta\pi_{J,(24)(24)} = \beta\pi_{J,(24)(12)} + \beta\pi_{J,(24)(32)}. \tag{24}$$

Because of Eq. 20, the two terms on the right-hand side of Eq. 24 vanish, and so:

$$P_{J,24} + \beta\pi_{J,(24)(24)} = 0. \tag{25}$$

Further, by applying the relation A′ and Eq. 23 (and the relation B′ and Eq. 25) to the other bonds in G6, we can easily show that Eq. 7 (and Eq. 9) holds for all the bonds in G6.

C) Acyclic fragments in cyclic systems will be discussed in this section. The molecular graph of the biphenyl G4 in Fig. 2 shows one "acyclic" bond, 1-7. The relation E′ gives:

$$P_{J,12} + \beta\pi_{J,(12)(12)} = \beta\pi_{J,(12)(71)} + \beta\pi_{J,(12)(61)}. \tag{26}$$

From the relation C′ we obtain:

$$P_{J,12} + \beta\pi_{J,(12)(12)} = \beta\pi_{J,(12)(61)}. \tag{27}$$

A comparison of Eq. 26 with Eq. 27 gives:

$$\pi_{J,(12)(71)} = 0. \tag{28}$$

By applying the relation A′ to other bonds in the ring A and by using Eq. 28, we obtain:

$$\pi_{J,(17)(vw)} = 0, \tag{29}$$

where v-w is an arbitrary bond in the ring A of G4. In the same way, one can show that Eq. 29 holds for any bonds in the ring B.

From the relation E′, the following equation is obtained:

$$P_{J,17} + \beta\pi_{J,(17)(17)} = \beta\pi_{J,(17)(21)} + \beta\pi_{J,(17)(61)}. \tag{30}$$

The relation A′ gives:

$$\pi_{J,(17)(12)} = \pi_{J,(17)(61)} = -\pi_{J,(17)(21)}, \tag{31}$$

where we have used the following equation:[13]

$$\pi_{J,(rs)(tu)} = -\pi_{J,(sr)(tu)} = -\pi_{J,(rs)(ut)}. \tag{32}$$

From Eqs. 30 and 31, we obtain:

$$P_{J,17} + \beta\pi_{J,(17)(17)} = 0. \tag{33}$$

Accordingly, it has been shown that Eqs. 7 and 9 hold for the "acyclic" bond, 1-7, in G4.

The last example is the molecular graph with an acyclic fragment, G7, shown in Fig. 5. It seems evident

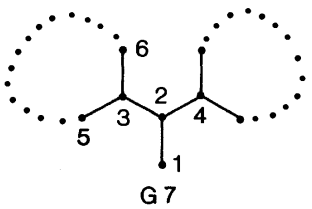

Fig. 5. Molecular graph with acyclic fragment G7.

that Eqs. 7 and 9 are valid for the bond 1-2 in G7. For the bond 2-3, the relation D′ gives:

$$\pi_{J,(23)(vw)} = \pi_{J,(35)(vw)} + \pi_{J,(36)(vw)}, \tag{34}$$

where v-w is an arbitrary bond. From Eq. 32, we obtain:

$$\pi_{J,(36)(vw)} = -\pi_{J,(63)(vw)}, \tag{35}$$

and from the relation A′:

$$\pi_{J,(35)(vw)} = \pi_{J,(63)(vw)}. \tag{36}$$

Equations 35 and 36 show that the right-hand side of Eq. 34 vanishes:

$$\pi_{J,(23)(vw)} = 0. \tag{37}$$

Similarly, it is shown that

$$\pi_{J,(24)(vw)} = 0. \tag{38}$$

From the relation E′, the following equation is obtained:

$$P_{J,23} + \beta\pi_{J,(23)(23)} = \beta\pi_{J,(32)(53)} + \beta\pi_{J,(32)(63)}. \tag{39}$$

Because of Eq. 37, the right-hand side of Eq. 39 vanishes, hence,

$$P_{J,23} + \beta\pi_{J,(23)(23)} = 0. \quad (40)$$

In the same manner, one can show that Eq. 9 is valid for the bond 2-4. Thus, we have shown that Eqs. 7 and 9 are valid for all the "acyclic" bonds in G7.

The above examples make it obvious that Eqs. 7 and 9 hold for any "acyclic" bonds in an arbitrary system. It should be noted that Eqs. 7 and 9 are not valid for degenerate MO's. However, it can easily be shown that Eqs. 8 and 10 hold also for bonds in closed-shell molecules, even with degenerate energy levels, provided that the (total) imaginary bond-bond polarizabilities, not in the form of Eq. 41, but in that of Eq. 42, are used:[13]

$$\bar{\pi}_{(rs)(tu)} = \sum_J \sum_{(K\neq J)} g_J \frac{(C_{rJ}C_{sK} - C_{sJ}C_{rK})(C_{tK}C_{uJ} - C_{uK}C_{tJ})}{(X_J - X_K)\beta}, \quad (41)$$

$$\bar{\pi}_{(rs)(tu)} = 2\sum_J^{\text{occ}} \sum_K^{\text{unocc}} \frac{(C_{rJ}C_{sK} - C_{sJ}C_{rK})(C_{tK}C_{uJ} - C_{uK}C_{tJ})}{(X_J - X_K)\beta}, \quad (42)$$

where g_J is the occupation number of the J-th MO and where $\sum^{\text{occ}}$ and $\sum^{\text{unocc}}$, respectively, run over occupied and unoccupied MO's.

Simplified Expression for London Susceptibility

The London susceptibility has usually been expressed in the form of Eq. 4.[3,7] The first term on the right-hand side of Eq. 4 is a first-order correction of the second term in Δ_{rs} (see Eq. 3), namely, of $-(\beta/2)\,w_{rs}^2$ (second-order with respect to the field strength, H), while the second term is a second-order correction of the first term in Δ_{rs}, namely, of i βw_{rs} (first- order with respect to H). However, a partial bond order and a partial self imaginary bond-bond polarizability always appear in the form of the sum of the two quantities, *i.e.*, in the form of $P_{J,rs}+\beta\bar{\pi}_{J,(rs)(rs)}$ in the relations B′, C′, and E′ and in Eqs. 9 and 10. When we consider the contributions of individual bonds in a molecule to its London susceptibility, it may, therefore, be appropriate to rewrite χ_J in the following form:

$$\chi_J = 2\beta\left(\frac{e}{\hbar c}\right)^2\left[\left\{\sum_{(rs)}(P_{J,rs}+\beta\pi_{J,(rs)(rs)})\right)S_{rs}^2\right\} + \sum_{(rs)\neq(tu)}\sum \beta\pi_{J,(rs)(tu)}S_{rs}S_{tu}\Big]. \quad (43)$$

Then, each term in Eq. 43 may be interpreted as follows: each term in the first sum on the right-hand side of Eq. 43, namely, $P_{J,rs}+\beta\bar{\pi}_{J,(rs)(rs)}$, is associated with the π- electron energy change due to an alternation in the resonance integral of the bond r-s itself, while each term in the second sum, namely, the mutual imaginary bond-bond polarizability $\bar{\pi}_{J,(rs)(tu)}$, is associated with that due to the changes in the resonance integrals of the bonds r-s and t-u.

Now we can clarify the physical meaning of Eqs. 7—10. The equations mean that no "acyclic" bonds make any contributions to the London susceptibility. Therefore, it may be more appropriate to rewrite the expression for χ_J in this simplified form:

$$\chi_J = 2\beta\left(\frac{e}{\hbar c}\right)^2\left[\sum_{(rs)}^{\text{"cyclic"}}\left\{(P_{J,rs}+\beta\pi_{J,(rs)(rs)})S_{rs}^2\right\} + \sum_{(rs)\neq(tu)}^{\text{"cyclic"}}\sum_{(tu)}^{\text{"cyclic"}} \beta\pi_{J,(rs)(tu)}S_{rs}S_{tu}\right], \quad (44)$$

where the sum runs over only all the "cyclic" bonds in the molecule. The above expression reduces the number of bonds which must be calculated. In the case of [6]-radialene, for example, the number is reduced to half. The set of Eqs. 7—10 provides an alternative way of explaining the well-known fact that the London susceptibilities of any acyclic conjugated systems are zero.

It has been pointed out that the magnitude of the London susceptibility is partially quenched if bond alternation occurs.[15,17] We can prove that the equations corresponding to the relations A′—E′ and to Eqs. 7—10 hold for bonds of molecules with bond alternation.[18]

Ring Current and Equations 7—10

The expression for the ring current[2,19,20] can be derived more easily from the expression for the partial London susceptibility in the form of Eq. 44 than from that in the form of Eq. 4 without the use of the "current-density" formalism.[21-23]

Assume, as in the usual way,[2] that the London susceptibility arises from an induced circulation of π-electrons along the framework of carbon atoms in a conjugated molecule (ring current). Further, the induced ring current may formally be considered as a sum of individual "bond currents" associated with each bond in the molecule.[20,23,24] Then, the "bond current" intensity of the bond r-s, J_{rs}, is given by:[20]

$$J_{rs} = (P_{rs} + \beta\pi_{(rs)(rs)})S_{rs} + \sum_{(tu)}\beta\pi_{(rs)(tu)}S_{tu}, \quad (45)$$

where the sum runs over all the bonds except the bond r-s. The above equation shows that the "bond current" of the bond r-s arises from the contributions of two types; one is that due to the first term on the right-hand side of Eq. 45, *i.e.*, $P_{rs}+\beta\bar{\pi}_{(rs)(rs)}$, which is associated with an alternation in the resonance integral of the bond r-s itself, while the other is that due to the mutual imaginary bond-bond polarizability in the second term, $\bar{\pi}_{(rs)(tu)}$, which is associated with a change in the resonance integral of the other bond, t-u.

Equations 7—10 indicate that, if the bond r-s is "acyclic," then the change in the resonance integral, due to the applied field, of the bond r-s (see Eq. 3) has no effect on the induction of the "bond current" of the bond r-s itself or on the induction of the "bond current" of any of the other bonds in the system. As a result, we may reasonably conclude that, when there are no rings

in a system, the (ring) current does not arise. As in the case of Eq. 44, it is sufficient also for Eq. 45 to sum over only the "cyclic" bonds in the molecule.

The "bond current" is entirely equivalent to the concept of the "ring current" as long as the "bond current" is conserved. The set of the relations A'—E' ensures that the "bond current" intensity given by Eq. 45 is conserved.[25] In this connection, it is interesting to notice that the relations A'—E' show that the two quantities, $P_{J,rs}+\beta\bar{\pi}_{J,(rs)(rs)}$ and $\bar{\pi}_{J,(rs)(tu)}$, obey Kirchhoff's law.[13]

The Relationship between Eqs. 7—10 and Some Consequences of McWeeny's Unitary Transformation

McWeeny has shown that, by virtue of a suitable unitary transformation, the sums in Eq. 44 may be reduced to the sums of one bond in each ring.[7] Gayoso and Boucekkine[26] have proposed a further unitary transformation which generalizes that devised by McWeeny. In the present paper, the transformation devised by Gayoso and Boucekkine will be used and called simply "McWeeny's unitary transformation." It seems that it will be significant and interesting to discuss the relationship between Eqs. 7—10 and some consequences of McWeeny's unitary transformation for "acyclic" bonds.

The matrix of the unitary transformation, $\boldsymbol{U}$, is a diagonal matrix, whose elements are given by:

$$U_{11} = 1,\ U_{rr} = (a_{1j}a_{jk}\cdots\cdots a_{tr})^*, \tag{46}$$

where the asterisk stands for the complex conjugate and where

$$a_{rs} = h_{rs}/\beta = \exp(iw_{rs}), \tag{47}$$

and where $(1j)(jk)\cdots(tr)$ is a sequence of edges (bonds) representing the shortest chain between the vertex (atom) labelled 1 and that labelled r in a chosen spanning tree of the original molecular graph. A tree which connects all the vertices of a graph, G, is called a spanning tree of G.[19,27] The bond which must be added to the particular spanning tree in order to reform the original graph, G, is called the "circuit-completing" bond.[7] Let $\bar{\boldsymbol{h}}$ be the transformed matrix of $\boldsymbol{h}$ due to $\boldsymbol{U}$:

$$\bar{\boldsymbol{h}} = \boldsymbol{U}^\dagger \boldsymbol{h}\, \boldsymbol{U}. \tag{48}$$

The non-zero elements, h_{rs}, corresponding to the "circuit-completing" bonds are transformed to the non-zero elements, $\bar{h}_{rs}$, while all the other non-zero elements, h_{rs}, are transformed to β.

Consider biphenyl again. Figure 6 shows a spanning tree, T, whose "circuit-completing" bonds are the bonds 1-6 and 7-8. The matrix elements of biphenyl are transformed as follows:

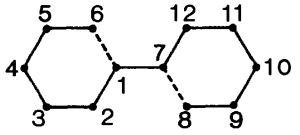

Fig. 6. Spanning tree of the biphenyl molecular graph T.

for the elements corresponding to all bonds except 1-6 and 7-8, for instance:

$$\begin{aligned}\bar{h}_{56} &= U_{55}^* h_{56} U_{66} \\ &= (a_{12}a_{23}a_{34}a_{45})h_{56}(a_{12}a_{23}a_{34}a_{45}a_{56})^* \\ &= \beta, \end{aligned} \tag{49-a}$$

$$\bar{h}_{17} = U_{11}^* h_{17} U_{77} = h_{17}(a_{17})^* = \beta, \tag{49-b}$$

for elements corresponding to the "circuit-completing" bonds 1-6 and 7-8:

$$\begin{aligned}\bar{h}_{16} &= U_{11}^* h_{16} U_{66} = h_{16}(a_{12}a_{23}a_{34}a_{45}a_{56})^* \\ &= \beta\exp\{-i(w_{12}+w_{23}+w_{34}+w_{45}+w_{56}+w_{61})\} \\ &= \beta\exp(-iw_{\mathrm{A}}), \end{aligned} \tag{49-c}$$

$$\bar{h}_{78} = \beta\exp(iw_{\mathrm{B}}). \tag{49-d}$$

In the above equations, we have defined for each ring:

$$w_{\mathrm{R}} = (e/\hbar c)S_{\mathrm{R}}H, \tag{50}$$

where S_{R} is the signed area of a ring, R, of G4. Accordingly, we have certainly found that all the non-zero elements of h_{rs} corresponding to all bonds except the "circuit-completing" bonds are transformed to β. The set of Eqs. 49 shows that all the perturbation due to the applied magnetic field can be thought of as being concentrated in only one bond (edge) of each ring (in this case, the bonds 1-6 and 7-8).[7,19] By virtue of the relations A'—E' we can also perform the "concentration of perturbation."[19]

The elements of $\boldsymbol{U}$ are dependent on the graph of a chosen spanning tree (see Eq. 46), but one can draw many spanning trees for one molecular graph.[19,27] However, the above example shows that, by the unitary transformation, the matrix elements corresponding to any "acyclic" bonds in an arbitrary system are transformed to β, irrespective of the choice of spanning tree. This means that an "acyclic" bond behaves as if the magnetic field was not applied. Therefore, it follows that all the non-zero Hückel Hamiltonian matrix elements of an acyclic system are changed to β. In other words, the Hückel Hamiltonian matrix of an acyclic conjugated system in the presence of the magnetic field is transformed to the field-free Hückel Hamiltonian matrix of the system by the unitary matrix.

Now it may be apparent that the consequences of the unitary transformation correspond to the fact that Eqs. 7—10 hold for "acyclic" bonds. However, it should be noted that there is a difference between Eqs. 7—10 and the consequences of the unitary transformation. Equations 7—10 show that, in the case of acyclic systems, the coefficient of each element of the perturbation matrix, Δ_{rs}, in Eq. 43 is zero, hence, the second-order energy change with respect to the field strength H is zero. On the other hand, the consequences due to the unitary transformation for acyclic systems mean that all the elements of the perturbation matrix, Δ_{rs}, for

the transformed Hamiltonian matrix, $\bar{h}$, are zero, and so the energy change due to the applied field is exactly zero. Of course, in our perturbation approach, the first-order energy change with respect to the field strength, H, vanishes for all arbitrary systems, even with rings.[3)]

However, as has been mentioned in Ref. 11, the term "circuit susceptibility" is more appropriate than "ring susceptibility" in the discussion of the London susceptibility.

Calorimetric Studies of the Interaction between the Lecithin and Copolymers of L-Lysine and L-Leucine

Masayuki NAKAGAKI* and Emiko OKAMURA
Faculty of Pharmaceutical Sciences, Kyoto University, Yoshida-Shimoadachicho, Sakyo-ku, Kyoto 606
(Received June 29, 1984)

The interaction between the dimyristoyl phosphatidylcholine (DMPC) bilayers and aqueous copolymers of L-lysine and L-leucine was investigated by means of differential scanning calorimetry. None of the copolymers had any effects on the transition temperature of DMPC, irrespective of the lysine/leucine ratio, although the pretransition peak disappeared. The transition enthalpy did not appreciably change upon the addition of copolymers if the leucine fraction was small (<0.25), but it remarkably decreased upon the addition of a copolymer with a large leucine content (>0.3). The latter case suggests the penetration of copolymers into the hydrophobic region (hydrocarbon-chain region) of DMPC as a result of the hydrophobic effect of leucine residues. On the contrary, copolymers of a small leucine content can penetrate at most into the polar region of DMPC because of the electric charge derived from lysine residues, indicating the effect of the copolymer composition on the penetrability of a copolymer into lipid layers.

The interaction between proteins or polypeptides and lipid membranes has been studied by means of various kinds of physicochemical techniques. It is considered that calorimetric studies are useful in investigating the effect of these proteins or polypeptides on the state of lipid membranes, particularly on the fluidity of hydrocarbon chains or on the phase transition of these membranes. Many calorimetric studies have thus been carried out of the systems of various lipids and proteins or polypeptides,[1-6] and different effects of proteins on the lipid phase transition have been proposed.[7]

The surface pressures of lecithin monolayers spread on lysine-leucine copolymer solutions were measured, and the penetration of these copolymers into lecithin monolayers was investigated in our previous study.[8] It was found, in that study, that the extent of penetration was dependent on the copolymer composition: The penetration was less when the leucine fraction in the copolymer, X_{Leu}, was smaller than 0.25, while it was remarkable at a X_{Leu} value larger than 0.3. Under our experimental conditions, however, all the copolymers are randomly coiled, and the conformational changes are not induced in the bulk solution.[8] Therefore, some kinds of substantial changes in lipid membranes should be regarded as possible reasons for the above penetration.

In the present study, differential scanning calorimetry (DSC) has been carried out in order to investigate the interaction between these copolymers and lecithin bilayers, and to discuss the characteristic properties of lecithin-copolymer interaction in some detail.

Experimental

Materials. As lecithin, L-α-dimyristoyl phosphatidylcholine (DMPC) from the Sigma Chemical Company was used without further purification. The random copolymers of lysine and leucine were the same as those previously used.[8] These copolymers were dissolved in redistilled water.

Differential Scanning Calorimetry. The differential scanning calorimetry was carried out on a Shimadzu DSC-30 calorimeter. The samples were prepared as follows: A 2—5 mg portion of the lipid was weighed in an aluminium sample pan. A copolymer solution of known concentration (0—20.3 mg/0.1 ml) was then added by capillary. After the lipid and the solution had been mixed with a pin at 30—40 °C and dispersed uniformly, the pan was hermetically sealed. The samples were heated and cooled at a constant rate of 5 °C/min. All scans were repeated for at least three cycles in order to confirm that the observed transition profile was reproducible. The water/lipid ratio was high enough to form multibilayers or lamellar phases of DMPC. Palmitic acid (mp 62.65 °C; enthalpy of melting, 10.0 kcal mol^{-1}) was used to standardize the apparatus for a quantitative heat determination. The peak areas were measured by weighing paper cutouts of the peaks.

Results and Discussion

DSC Curves of DMPC Multilayers in Copolymer Solutions. Figure 1 shows the DSC curves upon the heating of DMPC dispersed in water containing various copolymers. It is known that phospholipids dispersed in excess water form lamellar phases.[9] The heating curve accompanied by the gel-to-liquid crystalline transition of pure DMPC is shown in Fig. 1-(a); it indicates that the main transition is at 24°C, and the pretransition, at 15°C. The calculated value of the calorimetric enthalpy change, ΔH, was 4.6 kcal mol^{-1}. Figures 1-(b)—(f) give the DSC heating curves of DMPC dispersed in aqueous copolymer solutions of various lysine-leucine ratios. The copolymer concentration was 10 mg/0.1 ml. In each case, the pretransition peak disappeared upon the addition of a copolymer. However, the transition temperature (the onset of main transition), T_c, did not change.

Calorimetric Enthalpy Change Accompanied by Phase Transition. The calorimetric enthalpy change, ΔH, accompanied by the gel-to-liquid crystalline transition of DMPC, is calculated from the peak area, and the values are plotted against the polymer residue/lipid ratio in Fig. 2. In the case of polylysine or the copolymers containing a small leucine fraction (<0.25), the ΔH values did not appreciably change compared with the case without copolymers (pure DMPC alone), irrespective of the value of the polymer/lipid ratio. On the other hand, the ΔH values are decreased by the addition of copolymers with large leucine fraction (>0.3). The values of ΔH are decreased with an increase in the polymer/lipid ratio and asymptotically converge, similarly in the case of the lecithin-gramicidin A system previously reported.[10]

The Effect of the Copolymer Composition. The dependencies of the transition temperature (T_c) and the enthalpy change (ΔH) of DMPC on the copolymer composition were established. The results when the polymer residue/lipid ratio is 5 are shown in Fig. 3. A similar tendency was found in the case of other polymer residue/lipid ratios (not shown). As is shown in Fig. 3-(a), the transition temperature was almost constant and was not appreciably different from that of pure DMPC (24°C), irrespective of the copolymer composition. The values of ΔH were, however, dependent on the copolymer composition: (1) if the leucine fraction (X_{Leu}) was smaller than 0.25, the ΔH values were almost constant (4.3—4.8 kcal mol^{-1}) and not appreciably different from that of pure DMPC (4.6 kcal mol^{-1}), irrespective of the composition of the added copolymers, and (2) in the cases of X_{Leu} values larger than 0.34, the ΔH's were decreased remarkably to 2.3—2.5 kcal mol^{-1}.

According to the differential scanning calorimetry studied by Susi *et al.*,[11] T_c is increased and ΔH is

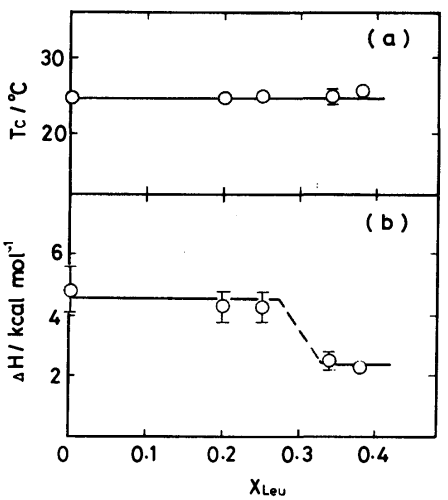

Fig. 3. The dependence of (a) the transition temperature (T_c) and (b) the enthalpy of transition (ΔH) of DMPC, on the leucine fraction of copolymers (X_{Leu}), at the polymer residue/lipid ratio of 5.

decreased in the case of polylysine-DMPC liposomal systems. This seems to contradict our present results. However, this apparent contradiction may be ascribed to the difference in experimental conditions, such as the method of preparation or the polymer/lipid ratio. Under the present conditions, no appreciable effects on T_c and ΔH were observed upon the addition of polylysine except for the disappearance of the pretransition, while the ΔH values were decreased by the addition of copolymers with a large leucine fraction, suggesting the effect of the leucine fraction of the copolymer on the membrane behavior.

The Mechanism of the Interaction between Lecithin and Lysine-Leucine Copolymers. The enthalpy change in the lecithin bilayer membrane accompanied by a phase transition, ΔH, was dependent on the leucine fraction of the copolymer, X_{Leu}, as has been described above. Further, the ΔH values are remarkably decreased around a X_{Leu} value of 0.3, which corresponds to the region with a sharp increase in the surface pressure of a lecithin monolayer upon the addition of copolymers.[8] On the other hand, copolymers had no effects on the transition temperature of the lecithin. It is, therefore, ascertained that the remarkable surface pressure increase of a lecithin monolayer in the presence of copolymers[8] was not due to the conformational change of copolymers.

Papahadjopoulos *et al.* have suggested three categories of protein-lipid interactions according to the correlation in calorimetric studies between the membrane permeability and the monolayer-area expansion.[7] Our results for the lysine-leucine copolymers will be discussed in comparison with their suggestion, and a plausible mechanism for the interaction between lecithin and lysine-leucine copolymers will be considered.

First, the interaction between lecithin and copolymers with a leucine fraction smaller than 0.25 may correspond to the Group 1 interaction in Ref. 7. According to the Papahadjopoulos postulate, no effects on monolayer expansion have been observed at a high value of the initial surface pressure (25 mN m^{-1}). In our results, a small increase in the area per molecule was observed in the low-surface-pressure region, while the extent of the increase becomes smaller at a higher surface pressure. Further, as has been described in Ref. 7, the enthalpy change of the transition, ΔH, of neutral phospholipids such as lecithin did not appreciably change; this also coincides with our present result. According to the results of Papahadjopoulos *et al.*,[7] this interaction is ascribable to the binding of the protein to the surface of lipid bilayers, without any penetration into the hydrocarbon region.

On the other hand, the interaction between lecithin and copolymers of a leucine fraction larger than 0.34 may correspond to the Group 3 interaction in Ref. 7. In this case, the surface pressure of a lipid monolayer increases as has previously been reported in Ref. 8, while the enthalpy change in the transition(ΔH) decreases. The transition temperature (T_c), however, does not change appreciably, These phenomena are attributable to the fact that proteins or polypeptides penetrate deeply into the hydrophobic domain. The deep penetration of proteins or polypeptides enhances the monolayer expansion.[8] By this hydrophobic interaction between lipids and proteins, the number of free lipid molecules decreases, and finally the ΔH value decreases. Since only a few lipid molecules participate in this interaction, and the bilayer is almost unperturbed,[7] no appreciable effects are observed on the transition temperature of a lipid, T_c.

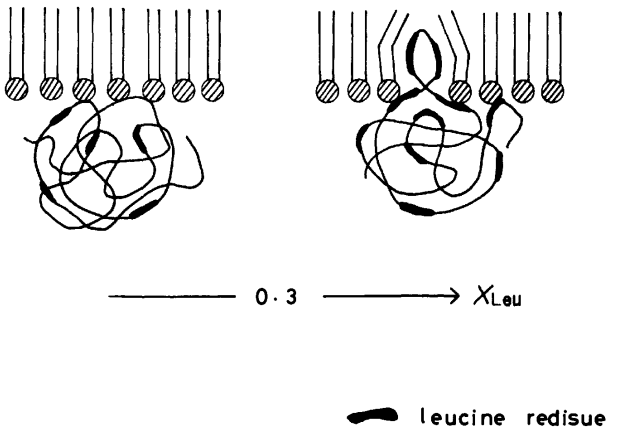

Fig. 4. A schematic model of the possible interaction between lecithin and lysine-leucine copolymers.

In the interaction between lecithin and lysine-leucine copolymers, the copolymers with a leucine fraction,X_{Leu}, smaller than 0.3, at most, interact only with the polar region of the lipid membrane because of the large electric charge derived from the lysine residues of the copolymer. On the other hand, the copolymers with X_{Leu} values larger than 0.3 penetrate into the hydrocarbon region of bilayers because of the hydrophobicity of the leucine residues. Figure 4 shows a schematic model of the possible interaction between lecithin and copolymers.

It has been accepted that the penetration ability of proteins into lipid membranes depends mainly on both the hydrophobicity and the electrostatic character of such proteins and polypeptides. Furthermore, it is of great interest that a change in the amino-acid composition of a copolymer also induces a remarkable increase in the penetration ability into lipid layers.

We are grateful to Professor Dr. J. T. Yang and Dr. Shigeo Kubota for the gift of the lysine-leucine copolymers.

The Electrical Properties of Calcium Sulfide Doped with Lanthanum Sulfide and Zirconium Sulfide

Gin-ya ADACHI,* Nobuhito IMANAKA, Mineo SATO, and Jiro SHIOKAWA
Department of Applied Chemistry, Faculty of Engineering, Osaka University, Yamadaoka, Suita, Osaka 565
(Received July 5, 1984)

Calcium sulfides doped with tri- and tetravalent metal sulfides were prepared. Their electromotive forces (EMF) were measured on a galvanic cell(Fe+FeS| Solid Electrolyte| Cu+Cu_2S) where the solid electrolyte was a material in a CaS-Ln_2S_3-MS_2 system. The cell, using calcium sulfide doped with La_2S_3 and ZrS_2, exhibited an EMF value as high as the one calculated for thermodynamical equilibrium. The CaS-La_2S_3-ZrS_2 solid electrolyte showed, predominantly, an ionic conduction in the sulfur pressure range from 10^{-4} to 10^2 Pa with an activation energy of approximately 56.7 kJ·mol^{-1}, which was lower than for CaS and CaS-La_2S_3.

Galvanic cell techniques, applying CaO-stabilized zirconia[1,2] and calcium fluoride,[3-7], had been investigated to determine the chemical potentials of sulfur at elevated temperatures. When ZrO_2(CaO) was used as the electrolyte, a metal oxide was formed at the interface of the metal sulfide electrode and the electrolyte, according to the following equilibrium equation:

$$MS(s) + 3/2O_2(g) = MO(s) + SO_2(g)$$

It is necessary that the resulting metal oxide is insoluble in the metal sulfide electrode. When CaF_2 was used as the electrolyte, on the other hand, the sulfur chemical potential was first converted to a calcium chemical potential and then to a fluorine chemical potential, where F^- anions were mobile species in the CaF_2 solid electrolyte. Therefore, the electromotive force(EMF) became less accurate because of the double chemical potential conversion.

Recently, calcium sulfide[8-10] has been found to be a Ca^{2+} ionic conductor at elevated temperatures. Otowa *et al.*[9] measured the isotope tracer diffusion coefficients of sulfur and proved that the electric charge carrier in the ionic-conductive calcium sulfide is predominantly the Ca^{2+} ions. Attempts[11-16] have been concentrated on applying calcium sulfide to a solid electrolyte in order to determine the sulfur chemical potentials. However, calcium sulfide holds several disadvantages. One is its lower electrical conductivity. The other is the presence of a region where electronic conduction cannot be ignored. The doping of a tri-, or tetravalent ion into calcium sulfide[12-16] has been carried out in order to improve its electrical properties.

In this study, tri- and tetravalent metal sulfides were doped into calcium sulfide so as to increase the Ca^{2+} ion vacancies and to obtain a larger sulfur pressure independent region. EMF measurements were conducted by constructing a galvanic cell (Fe+FeS and Cu+Cu_2S as electrodes) for the purpose of examing the possibilities of the calcium sulfide doped with metal sulfides as an electrolyte. The sulfur pressure dependency on the electrical conductivity were also investigated on a sample with the most promising properties.

Experimental

Materials. Calcium sulfate dihydrate ($CaSO_4·2H_2O$; impurity, Chloride: max. 0.003%, Nitrate: max. 0.005%, Heavy metals: 0.001%, Copper: 0.0005%, Lead: 0.0005%, Arsenic: 0.0001%, Iron: 0.001%) was purchased from Wako Pure Chemical Indusries Ltd.. Lanthanum (purity: 99.9%) and yttrium (purity: 99.9%) oxides were secured from Shinetsu Chemical Co. Ltd.. Zirconium (purity: 97%), titanium (purity: 99.5%) and neobium (purity: 99.9%), and wolfram (purity 99.9%) metals were bought from Mitsuwa's Pure Chemicals, and Wako Pure Chemical Industries Ltd., respectively. FeS (Practical Grade) and Cu_2S (purity: 99.99%) were purchased from Wako Pure Chemical Industries Ltd. and Mitsuwa's Pure Chemicals, respectively. Pure calcium sulfide was prepared by heating $CaSO_4·2H_2O$ in a carbon boat at 973 K for 2 h and then at 1273 K for 5 h under a flowing gas atmosphere of hydrogen sulfide (purity: 99%). Lanthanum and yttrium chloride were prepared by adding a diluted hydrochloric acid aqueous solution to La_2O_3 and Y_2O_3, respectively. Ln_2S_3 (Ln=La and Y) were obtained by heating $LnCl_3$ (Ln=La and Y) in a carbon boat at 673 K for 2 h in an argon gas flowing atmosphere and then at 1273 K for 5 h in an H_2S gas flow. Metal sulfides (M=Zr, Ti, W, and Nb) were prepared by heating a mixture of the metal and sulfur in an evacuated quartz capsule at 773 K for 2 h and at 1273 K for 5 h. The CaS, Ln_2S_3 (Ln=La and Y), and MS_2 (M=Zr, Ti, W, and Nb) was thoroughly mixed in an agate mortar. The cation ratio in the CaS–Ln_2S_3–MS_2 system was 96:2:2 for Ca^{2+}, Ln^{3+}, and M^{4+}, respectively. The mixture was made into pellets with a pressure of 6.7×10^8 Pa. Sintering of the pellets was performed for 4 h at 1273 K in a flow of hydrogen sulfide gas. The samples were analysed using an X-ray diffraction apparatus (Rigaku's Rotaflex diffractometer with Cu $K\alpha$ radiation). The preparation of the electrodes (Fe+FeS and Cu+Cu_2S) was also conducted by sintering the pellets of the metal and metal sulfide (50:50 by molecular weight) for 3 h at 773 K in an argon gas-flow atmosphere.

Measurements. The apparatus for the EMF measurements (galvanic cell technique) is illustrated in Fig. 1. A good contact between the electrolyte and the electrodes was assured by pushing the quartz rod B to the quartz tube A with springs. The electrical conductivity was also measured with the apparatus shown in Fig. 1. In the conductivity measurements, a gold film was deposited on both surfaces of the sample with Shinku Kiko's vacuum-deposition apparatus (ULVAC, VP-C2A) so as to reduce the resistance between the sample and the platinum plate electrodes. The electrical conductivity was measured with a Hewlett Packard vector impedance meter 4800A (from 5 Hz to 500 kHz). The sulfur pressure was controlled by the regulation of the hy-

drogen and hydrogen sulfide gas-flow volumes by flow meters. A noninductive resistance furnace was used in order to avoid any noise in both the EMF and conductivity measurements.

Results and Discussion

By X-ray diffraction analysis, samples of $CaS-Ln_2S_3$ (Ln=La and Y)-MS_2 (M=Zr, Ti, W, and Nb) were found to form solid solution. The properties of these solutions are summarized in Table 1. The invasion of the Cu^+ ion from the $Cu-Cu_2S$ electrode into the solid electrolyte occurred in samples of $CaS-La_2S_3-MS_2$ (M =Ti, W, and Nb) and $CaS-Y_2S_3-ZrS_2$. When the $CaS-Y_2S_3-TiS_2$ sample was employed as a solid electrolyte, the measured EMF was considerably lower than the calculated EMF at 973 K, which is derived from the Gibbs free energy data of Oishi *et al.*[4] and Brooks.[18] On the other hand, the cell with calcium sulfide doped with La_2S_3 and ZrS_2 exhibited an EMF as high as the calculated value. In addition, the Cu^+ ion invasion from the electrode disappeared. For the $CaS-La_2S_3-ZrS_2$ electrolyte, the average ionic radius of the dopants was 0.102 nm,[17] which is the closest to the ionic radius of Ca^{2+} (0.114 nm)[17] for the three component systems.

A good candidate for a solid electrolyte in the three component systems is considered to be the $CaS-La_2S_3-ZrS_2$ system.

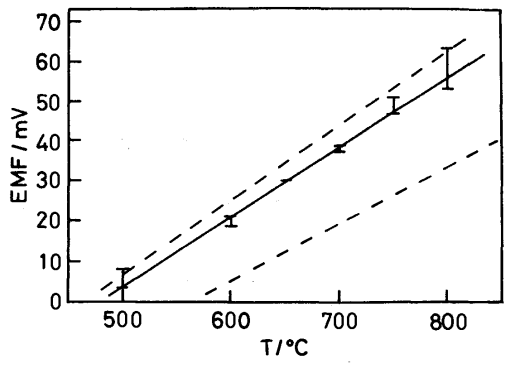

Fig. 2. The temperature dependences of the EMF for $Fe+FeS|CaS$(2 atom% La_2S_3 and 2 atom% ZrS_2)$|Cu+Cu_2S$ cell.
The maximum and minimum EMF (---) are calculated from the Gibbs free energy data of Oishi *et al.*[4] and Brooks,[18] and Alcock and Richardson[19] and Nagamori,[20] respectively.

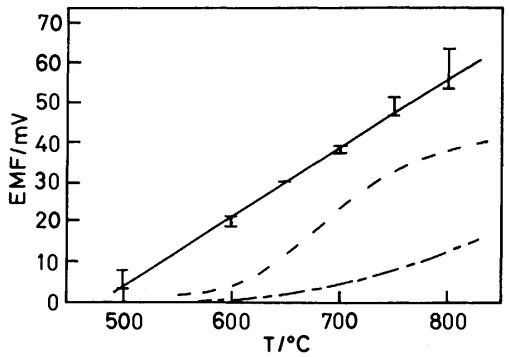

Fig. 3. The temperature dependences of the EMF for Fe+FeS|Solid electrolyte|$Cu+Cu_2S$ cell.
——: CaS(2 atom% La_2S_3 and 2 atom% ZrS_2), ———: CaS(5 atom% La_2S_3), ——: CaS.

The EMF results for the $CaS-La_2S_3-ZrS_2$ electrolyte are presented in Fig. 2. The maximum and minimum EMF were calculated from the Gibbs free energy data of Oishi *et al.*[4] and Brooks,[18] and Alcock and Richardson[19], and Nagamori,[20] respectively. The measured EMF shows itself in well within the calculated EMF range.

A comparison of the EMF results for cells using CaS, $CaS-La_2S_3$,[15] and $CaS-La_2S_3-ZrS_2$ systems is shown in Fig. 3. The calcium sulfide in which La_2S_3 was held in a solid solution, exhibited a higher EMF compared with the calcium sulfide alone. This was attributed to the formation of cation vacancies during doping. In the $CaS-La_2S_3-ZrS_2$ system, the EMF properties were appreciably improved in comparison with both CaS and $CaS-La_2S_3$.

The sulfur pressure dependency of the electrical conductivity is illustrated in Fig. 4. The conductivities are independent of the sulfur pressure variation for all samples measured at 700, 800, and 900 °C. This result indicates that electrical conduction is predominantly ionic in an $CaS-La_2S_3-ZrS_2$ system. In a previous work,[11] it was reported that calcium sulfide exhibits a

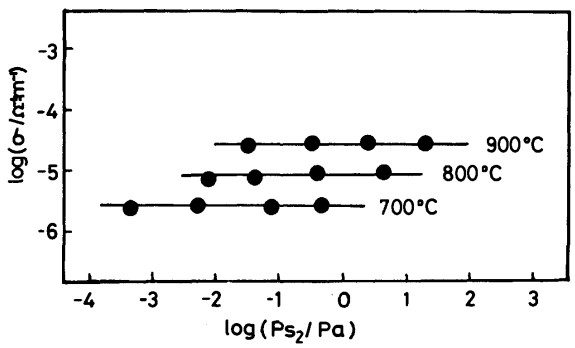

Fig. 4. The variation of the electrical conductivity of CaS(2 atom% La_2S_3 and 2 atom% ZrS_2) with sulfur pressure at 700, 800, and 900°C.

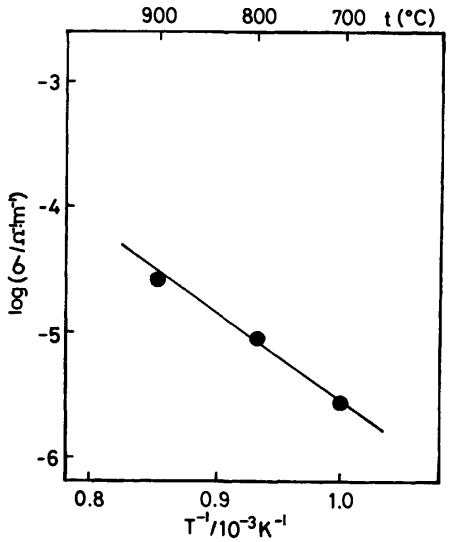

Fig 5. The temperature dependences of the electrical conductivity for CaS(2 atom% La_2S_3 and 2 atom% ZrS_2) under an atmosphere of H_2/H_2S=1.5/1.

P-type conduction at log P_{S_2} higher than approximately −6. In our earier paper,[15] electronic conduction was found to appear in the CaS-La_2S_3 system, at log P_{S_2} lower than about −5.5. By doping La_2S_3 and ZrS_2 simultaneously into CaS, the ionic conduction becomes dominant. The electronic conduction seems to be negligibly small compared with the ionic conduction due to the Ca^{2+} migration.

The temperature dependences of the log σ are shown in Fig. 5. From the slope of the line, the activation energy for the CaS-La_2S_3-ZrS_2 system was calculated to be 56.7 kJ·mol^{-1}. This value is smaller than both 99.6 kJ·mol^{-1} [11] for CaS, and 79.9 kJ·mol^{-1} [15] for CaS-La_2S_3.

The migration of a Ca^{2+} ion from a cation site to a cation vacancy becomes easier after increasing the number of cation vacancies.

In conclusion, the EMF characteristics of CaS with Cu+Cu_2S and Fe+FeS electrodes are remarkably improved by the doping of La_2S_3 and ZrS_2 simultaneously into the host CaS. The conduction mechanism of the CaS-La_2S_3-ZrS_2 solid solution is predominantly ionic. The CaS-La_2S_3-ZrS_2 system has the potential of being utilized as a solid electrolyte for a galvanic cell over a large range of sulfur pressures (10^{-4} to 10^2 Pa).

Solvent Effects on the Monomer-Dimer Equilibrium and Dimerization of the 1-Methyl-2-methoxycarbonylpyridinyl Radical

Hirami SHIMOISHI, Shozo TERO-KUBOTA,† and Yusaku IKEGAMI*
Chemical Research Institute of Non-Aqueous Solutions, Tohoku University, Katahira 2-1-1, Sendai 980
(Received August 2, 1984)

Solvent effects on the hyperfine splitting constants, monomer-dimer equilibrium, and kinetic parameters of the dimerization of the 1-methyl-2-methoxycarbonylpyridinyl radical have been examined in detail, using methylcyclohexane, toluene, 2-methyltetrahydrofuran, acetone, and acetonitrile as the solvents. A comparatively large activation energy for the fast step in the two-step dimerization mechanism suggests strongly that the dimeric intermediate is the 2,2′-dimer of the radical, which subsequently rearranges to the stable 4,4′-dimer.

Equilibrium between the 1-methyl-2-methoxycarbonylpyridinyl radical (R) and the covalently bonded dimer (D) was discussed in our previous papers.[1,2] Since the equilibrium lies largely in favor of D at room temperature, and since D decomposes reversibly to generate R upon irradiation with light in the near-UV region, the dimerization mechanism showing a two-step decay of R in 2-methyltetrahydrofuran (MTHF) was successfully elucidated by kinetic ESR spectroscopy.[3] In this study, however, the structure of the dimeric intermediate (DI) in the two-step decay process of R was left for further investigation, though the π-complex dimer was suggested for it. Concerning the structure of DI, a kinetic study of the dimerization of the 1-alkyl-4-phenylpyridinyl radicals suggests the 4,4′-dimer as DI; it subsequently rearranges to the stable 2,2′-dimer through the [3,3]sigmatropic mechanism.[4] The activation energy for the DI formation was too large (>27 kJ mol^{-1}) for us to suggest the π-complex dimer as DI. Because of the short lifetime of DI, the attempted spectroscopic analysis of DI has been unsuccessful.[3]

We then examined the thermodynamic parameters of the equilibrium and kinetic parameters for the dimerization in various solvents with a view to establishing the magnitude of solvent dependence for these parameters and also whether or not the two-step mechanism can be used in solvents with different polarities. We are also interested in solvent effects on neutral radicals, as have been reported previously for the stable 1-methyl-4-methoxycarbonyl- and 1-methyl-4-acetyl-pyridinyl radicals.[5] The present examination provides valuable information about solvent effects on the equilibrium system formed by a pyridinyl radical with an intermediate stability.

Methylcyclohexane, toluene, MTHF, acetone, and acetonitrile were used as solvents. The Block-Walker reaction field parameters were adopted in discussing the experimental data. This paper will end by proposing the 2,2′-dimer of R as a favorable structure for DI.

Experimental

Materials. The pyridinyl radical R was prepared by the reduction of 1-methyl-2-methoxycarbonylpyridinium iodide with 3% sodium amalgam in degassed acetonitrile, purified by distillation as previously reported,[1] and then dissolved in the desired solvent. Commercial methylcyclohexane (spectral grade) was dried over sodium metal, degassed, and then distilled under a vacuum. The purification of the other solvents has been described in a previous paper.[6]

Concentration of the Species. The addition of 1,1-dimethyl-4,4′-bipyridinium dichloride (methylviologen) to a solution of R and D caused a quantitative electron-transfer reaction, thus generating the methylviologen cation radical. The total concentration of the species was determined from the absorption measurement of the cation radical (ε 13000 at λ_{max} 605 nm). An electronic double-integrator of ESR signals was used to determine the concentration of R. A benzene solution of 2,2-diphenyl-1-picrylhydrazyl was used as the standard sample, and the concentration was determined from its optical absorbance (ε 14150 at 519 nm). The ESR sensitivity-variation in different solvents was calibrated with an internal standard of strong pitch in a capillary tube.

ESR Spectroscopy. A Varian E-109E EPR spectrometer was used for the ESR measurements. The system of kinetic ESR spectroscopy has been described previously.[3]

Results and Discussion

Solvent Effects on the Hyperfine Splitting Constants of R. In a previous paper,[5] an expression for the solvent effects on the hyperfine splitting (hfs) constants of a free radical was derived by obtaining the π-electron spin densities of the radical in solution by means of the perturbation theory; it was demonstrated that, for some neutral radicals, the hfs constants are correlated with the Block and Walker reaction-field parameter of $\theta(\varepsilon_r)=3\varepsilon_r(\ln\varepsilon_r)/(\varepsilon_r\ln\varepsilon_r-\varepsilon_r+1)-6/(\ln\varepsilon_r)-2$, where ε_r is the relative permittivity of the solvent.[7] We then used this parameter to express the solvent dependence of the hfs constants for the present radical. The equilibrium ($2R \rightleftharpoons D$) system showed well-resolved hfs of the ESR spectrum in all solvents, and each spectrum was analyzed with six splitting constants, to which the assignments were given by comparing them with the spin densities calculated by the McLachlan procedure. Plots of the hydrogen and nitrogen hfs constants (a_{obsd}) *vs.* $\theta(\varepsilon_r)$ are shown in Fig. 1. In this figure, the sign of each a_{obsd} value was chosen according to these relations; $a^H_{obsd}=Q^H_{CH}\,\rho_{calcd}$, with $Q^H_{CH}<0$,[8] and $a^N_{obsd}=Q^N\rho^\pi_N+Q^N_{CN}\times\sum\rho^\pi_{CN}$, with $|Q^N|>|Q^N_{CN}|$ and positive Q^N,[9,10] nega-

tive spin densities appearing at the 3 and 5 positions.

The correlation between the values of a_{obsd} and $\theta(\varepsilon_r)$ is good, though the plots for the toluene solvent deviate significantly from the lines obtained by the least-squares method. The deviation is probably due to a specific interaction, such as a charge-transfer mechanism between the radical and the solvent toluene. The variations in the a_{obsd} values with the change in the solvent are small, the largest change being observed at the 6 position from 0.208 mT in methylcyclohexane to 0.256 mT in acetonitrile. Accordingly, the solvent effects on the spin distribution are not very large, not even for the density at the 2 position with the largest spin density in the pyridine ring; therefore, the dimerization mechanism is not influenced by the perturbation in the shape of the singly occupied molecular orbital due to the change in solvent. Therefore, the solvent effects described hereinafter will mainly be ascribed to the stabilization of the energy level by solvation.

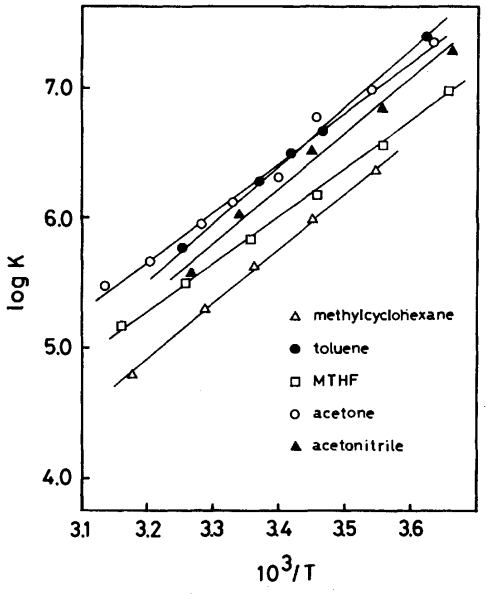

Fig. 2. Monomer-dimer equilibrium constants (K) *vs.* $1/T$.

Solvent Effects on the Monomer-Dimer Equilibrium. The monomer-dimer equilibrium constant is expressed as $K=[D]/[R]^2=([Total]-[R])/2[R]^2$, where [Total] is the total concentration of D and R, which can be determined by titration with 1,1′-dimethyl-4,4′-bipyridinium dichloride. [R] is determined by the use of an electronic double-integrator of ESR signals. The measurements were carried out at temperatures between 3 °C and 45 °C. Plots of log K *vs.* $1/T$ afforded a good straight line for each solvent, as is shown in Fig. 2. The thermodynamic parameters obtained from these linear relationships are listed in Table 1. The equilibrium tends to shift towards the D side with an increase in the solvent polarity. Plots of the free energy change (ΔG) against $\theta(\varepsilon_r)$ gave a linear relationship, with the exception of the value in toluene, as is shown in Fig. 3. The enthalpy change (ΔH) also shows a solvent dependence, the absolute value ($|\Delta H|$) becoming smaller with an increase in the solvent polarity.

Because R has a dipole moment, while that of D is equal to zero or very small, the stabilization of R by solvation with polar solvents would be larger than that of D. The solvation enthalpy, $\Delta\Delta H$, is assumed to be the difference between the dimer-formation enthalpy in a solution (ΔH_{solv}) and that *in vacuo* (ΔH_{vac});[11] therefore, $\Delta\Delta H_{solv}=\Delta H_{solv}-\Delta H_{vac}=\Delta H_{D,solv}-\Delta H_{2R,solv}$, where

Table 1. Thermodynamic parameters for the monomer-dimer equilibrium of R in various solvents

Solvent	ΔH	ΔS	$\Delta G^{a)}$	$K^{a)}$
	kJ mol^{-1}	J K^{-1} mol^{-1}	kJ mol^{-1}	mol^{-1} dm^3
Methyl-cyclohexane	−82.5	−170	−31.8	3.86×10^5
Toluene	−86.7	−172	−35.5	1.66×10^6
MTHF	−69.0	−121±4	−32.9	7.44×10^5
Acetone	−74.1	−129	−35.6	1.89×10^6

a) At 25 °C.

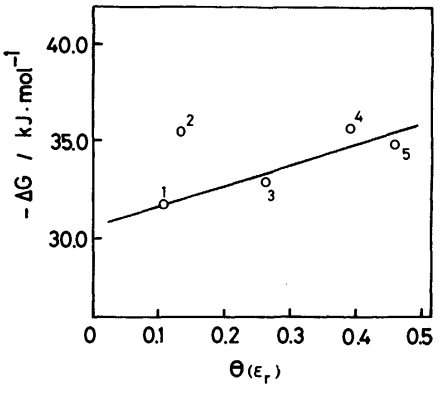

Fig. 3. Free energy change (ΔG) at 25°C *vs.* the Block-Walker's parameters ($\theta(\varepsilon_r)$).

$\Delta H_{D,solv}$ and $\Delta H_{2R,solv}$ are the solvation enthalpies of D and R respectively. As the dipole moment of methylcyclohexane is approximately zero, the enthalpy change in this solvent is assumed to be that under a vacuum. Then, $\Delta H_{vac}=\Delta H_{methylcyclohexane}=-82.5$ kJ mol^{-1}. For the case of the acetone solvent, $\Delta\Delta H_{acetone}$ becomes 8.4 kJ mol^{-1}; this positive value indicates the large stabilization of the R side. In a similar way, the solvation free energy is obtained: $\Delta\Delta G_{acetone}=-3.8$ kJ mol^{-1}; this indicates that D is stabilized by the solvation at this temperature. The difference in signs of $\Delta\Delta G$ and $\Delta\Delta H$ is caused by the entropy term: $\Delta\Delta S_{acetone}=\Delta S_{acetone}-\Delta S_{vac}=41$ JK^{-1} mol$^{-1}=\Delta S_{D,acetone}-\Delta S_{2R,acetone}$. Since $\Delta S_{methylcyclohexane}$ ($\simeq\Delta S_{vac}$) is largely negative (Table 1), the positive $\Delta\Delta S_{acetone}$ value can be explained if there is a stronger orientation of acetone molecules to R than to D. It is thus assumed that the ΔS value of -170 JK^{-1} mol^{-1} in methylcyclohexane is mostly the entropy change for D formation and that, in acetone, the $\Delta\Delta S_{acetone}$ value contributes positively to ΔS, suppressing it to the observed value (-129 JK^{-1} mol^{-1}). Consequently, the importance of the entropy term in polar solvents is established for the present equilibrium system.

Kinetic Parameters of Dimerization. In our previous paper,[3] a kinetic ESR study aimed at the dimerization of R generated by the flash photolysis of D in MTHF was described. Similar examinations for R in methylcyclohexane exhibited the growth-and-decay curves shown in Fig. 4. The following features were recognized in the same manner as in MTHF: (1) a two-step decay of R is observed around -65 °C, as shown in Fig. 4b; (2) the decay of the fast step observed at tempratures below -40 °C is represented as a reversible second- and first-order for the range of -95—-70 °C; (3) the slow step is a first-order decay in the -40—40 °C range, and (4) no change in the hfs pattern is exhibited. The same features were observed in toluene and acetone. In acetonitrile, the measurements were carried out at temperatures above -40 °C, and a first-order decay was observed.

Although the fast step could be treated as a second-order reaction, some deviations were observed because of the influence of the reverse reaction. Therfore, the step was treated as a reversible second- and first-order reaction, k_1 one which can be represented by the following equation:

$$2k_1t=-\frac{1}{2[\bar{R}]}\ln\left|\frac{[R]-[\bar{R}]}{[R]+[\bar{R}]}\Big/\frac{[R]_0-[\bar{R}]}{[R]_0+[\bar{R}]}\right|$$

where [R], [$\bar{R}$], and [R]$_0$ are the concentration, the pre-equilibrium concentration, and the initial concentration of the radical respectively. The plots based on this equation gave good linear relationships, as is shown in Fig. 5a. The Arrhenius plots yielded an activation energy (E_{a1}) of 28.9 kJ mol^{-1} and a frequency factor (A) of 1.5×10^{14} mol^{-1} dm^3 s^{-1}. These values and the rate constant obtained by extrapolation to 25 °C are

a) At 25 °C, b) From Ref. 3.

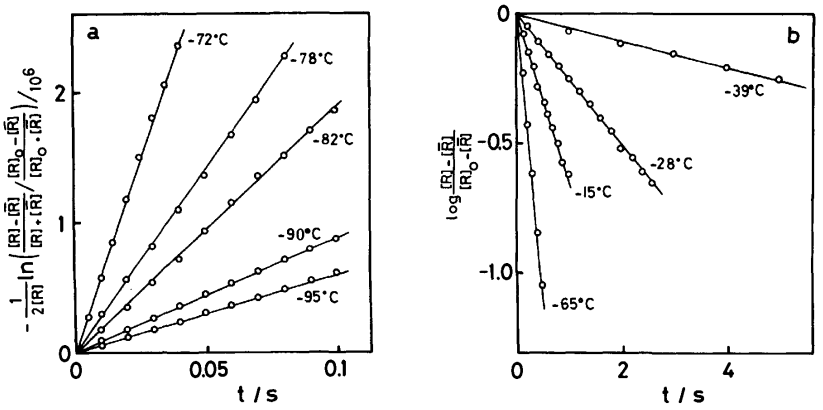

Fig. 5. (a) Reversible second- and first-order plots for the fast step and (b) first-order plots for the slow step in the decay of R in methylcyclohexane.

shown in Table 2, together with those obtained using toluene, MTHF, and acetone as solvents. The rate constant in methylcyclohexane is comparable to that in a diffusion-controlled reaction.[12]

The E_{a1} value of 28.9 kJ mol^{-1} in methylcyclohexane tends to decrease with an increase in the solvent polarity, showing 19.2 kJ mol^{-1} in acetone, while the ΔG value at 25 °C increases and k_1 decreases with an increase in the solvent polarity. The relationship between the ΔG values and the solvent parameters $\theta(\varepsilon_r)$ was poor, though a tendency could be recognized. The activation parameters for the fast step are also indicative of a great influence of the frequency factor upon k_1. The ΔS values, as estimated from the A values, are 4.5, −17.1, −10.7, and −11.5 JK^{-1} mol^{-1} for R in methylcyclohexane, toluene, MTHF, and acetone respectively. It is noteworthy that a positive value is obtained for methylcyclohexane. Since the fast step passes through a transition state in which two radicals are oppositely oriented to each other by the dipole-dipole interaction, the positive ΔS value presumably originates from the strong interaction between two radicals, regardless of the nonpolar solvent molecules. This orientation would be reduced in its strength by solvation to R in polar solvents, resulting in the negative ΔS values, because the solvation corresponds to the reduction of the dipole moment of the radical.

The rate constant, k_2, of the slow step is represented by this equation:

$$k_{obsd} = \frac{k_2}{2}t = -\ln\frac{[R] - [\bar{R}]}{[R]_0 - [\bar{R}]}$$

The good relationships shown in Fig. 5b were obtained for the measurements in methylcyclohexane. The activation parameters obtained from the Arrhenius plots are summarized in Table 2 for the results in five solvents.

The E_{a2} value has a tendency to decrease with an increase in the solvent polarity. The large value for acetonitrile is abnormal. As a long irradiation of the acetonitrile solution caused significant damage to the sample, there may be a specific interaction between the sample and the solvent. The values of ΔG_2 and k_2 show that the reaction becomes slow with an increase in the ΔG_2. Concerning the solvent dependence of ΔG_2, the plots *vs.* $\theta(\varepsilon_r)$ showed a good relationship among the solvents except for a slight deviation for toluene.

Preequilibrium between R and DI. The above results clearly prove that the radicals generated by the photolysis of D rapidly establish a preliminary equilibrium. In the irradiation with a strong, short light pulse, the initial concentrations of R and DI immediately after the irradiation are represented as $[R]_0$ and $[DI]_0$ respectively. At the preequilibrium, these concentrations become $[\bar{R}]$ and $[\overline{DI}]$ respectively. The constant (K_1) can be determined from the following equation:

$$K_1 = \frac{[\overline{DI}]}{[\bar{R}]^2} = \frac{[R]_0 - [\bar{R}]}{2[\bar{R}]^2}$$

since $[DI]_0/([R]_0 - [\bar{R}]) \ll 1$.

The measurements were performed at the shutter speed of 1/15 s, using a UV-29 glass filter at temperatures between −70 °C and −95 °C. Under these conditions, however, accurate values for K_1 could not be obtained. For instance, the measurement in methylcyclohexane gave no fine signal because the formation of DI was very rapid. The reliable results obtained in toluene, MTHF, and acetone were in these ranges: $K_1 = (1.0—2.0) \times 10^7$ mol dm^{-3} (at −75 °C) and $\Delta H_1 = -23—-33$ kJ mol^{-1}.

On the Structure of DI. The above results can enable us to draw a free energy *vs.* reaction coordinate

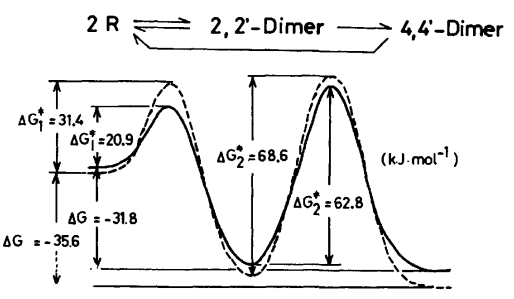

Fig. 6. A free energy at 25 °C *vs.* reaction coordinate diagram for the dimerization of R proceeding *via* DI. ——: in methylcyclohexane. -----: in acetone.

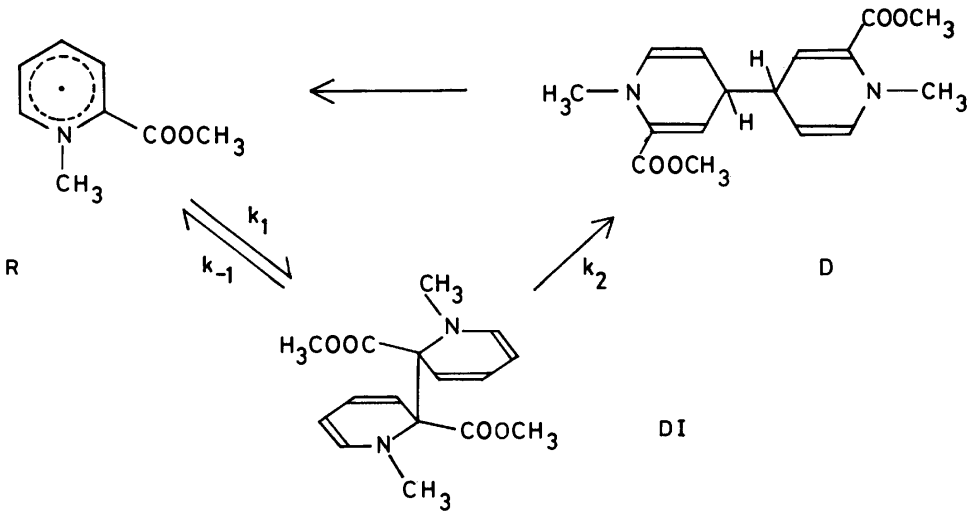

diagram for the present dimerization, as depicted for the methycyclohexane and acetone solvents in Fig. 6.[13] The structure of D reported previously[1] was recently confirmed by NMR measurements at a temperature below 0 °C, the spectrum disclosing that the dimer consists of two diastereoisomers.[14]

Concerning the structure of DI, the previous paper[3] suggested that DI was a singlet π-complex with a sandwich-like structure and expected that a charge-transfer absorption due to the complex would be observed. Further examinations, however, provided no evidence supporting the π-complex structure.

The observation of the two-step decay of R in all five solvents means that the dimerization mechanism does not differ with the solvent, and the relatively large E_{a1} values strongly imply that DI is a σ-bonding dimer rather than a π-complex. The value of 28.9 kJ mol^{-1} in methylcyclohexane is not conceivable for the E_{a1} of π-complex formation. Since free radicals are apt to react at positions with a high spin density, it is simply assumed that the coupling point is the 2 position, where the highest spin density is indicated by the McLachlan calculation.[2] The transformation of the intermediate 2,2′-dimer into the stable 4,4′-dimer can be interpreted as a [3,3]sigmatropic rearrangement, by analogy with the dimerization of the 1-alkyl-4-phenylpyridinyl radicals.[4]

The Spin Exchange of Nitroxide Radicals with Ni^{2+} Ions in SDS Micellar Solutions

Masayuki AIZAWA
Electrotechnical Laboratory, 1-1-4, Umezono, Sakuramura, Niiharigun, Ibaraki 305
(Received August 7, 1984)

The spin-exchange rate of three kinds of hydrophobic nitroxide radicals with paramagnetic ions, Ni^{2+} ions, was measured in an aqueous sodium dodecyl sulfate (SDS) micellar solution at 30 °C. In the presence of SDS micelles, two of the three radicals had their spin-exchange rates accelerated, whereas the rate of the other radical was deaccelerated. These strange results were interpreted on the basis of a different solubilized location of the radicals in SDS micelles. The translational mobility of the Ni^{2+} ions on a micellar surface was estimated from the spin-exchange rate in the accelerated systems.

In preceding studies,[1-3] my coworkers and I investigated the molecular motion of hydrophobic nitroxide radicals solubilized in surfactant micelles by means of the ESR method. The translational mobility of the radicals in micelles[3] was estimated from the magnitude of the spin-exchange rate between the radicals.

The spin-exchange interaction[4] is one of the intermolecular magnetic interaction, occurring upon an intermolecular collision between paramagnetic particles. Due to this fact, the spin-exchange rate is proportional to the rate of intermolecular collisions. One can, therefore, calculate the translational diffusion coefficient from the spin-exchange rate constant if an appropriate model is applied for the diffusion process.

In the present study, the spin-exchange rate of nitroxide radicals with Ni^{2+} ions in micellar solutions was measured in order to investigate how the presence of surfactant micelles affects the collisions between ions and organic molecules in water. If the information on the collisional process in micelles can be obtained, it will be utilized for understanding the mode of ion-binding to the micellar surface and the reaction mechanism of a micellar catalysis.

Experimental

Three kind of nitroxide radicals (Fig. 1) were used as solubilizates. The synthesis of the two of them, 2,2,6,6-tetramethyl-4-benzoyloxy-1-piperidinyloxyl (BzONO, Fig. 1(a)) and 2,2,6,6-tetramethyl-4-myristoyloxy-1-piperidinyloxyl (MyONO, Fig. 1(b)), has been reported elsewhere.[1,3] The other nitroxide radical, 2,2,6,6-tetramethyl-4-(1-naphtoyloxy)-1-piperidinyloxyl (NpONO, Fig. 1(c)), was synthesized by the reaction of the corresponding acid chloride with a nitroxide alcohol, and was purified in a way similar to that described in the literature.[5] The results of an elemental analysis of NpONO was as follows: Found: C, 73.52; H, 7.38; N, 4.26%. Clcd for $C_{20}H_{24}O_3$: C,73.59; H, 7.41; N, 4.29%; mol wt 326.4.

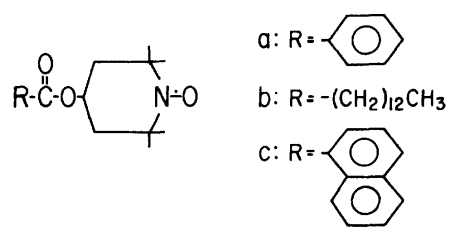

Fig. 1. (a) BzONO, (b) MyONO, and (c) NpONO.

Sodium dodecyl sulfate (SDS) of a specially prepared reagent and nickel nitrate of a guaranteed grade were purchased from Nakarai Chemicals Ltd. The SDS was recrystallized several times from ethanol-water solutions and was further purified by the method of Harrold.[6] The paramagnetic salt was used without further purification.

ESR spectra of the nitroxide radicals solubilized in SDS solutions with various amounts of Ni^{2+} ions were recorded on a JEOL model FE1X spectrometer at 30±0.5 °C.

The concentration of Ni^{2+} ions in sample solutions was determined by chelatometric titration.

Results and Discussion

As is well known, the usual ESR spectrum of nitroxide radicals in solutions consists of three lines owing to the contact interaction between an electron spin (S=1/2) and a ^{14}N nuclear spin (I=1). The three lines correspond to the ^{14}N nuclear spin quantum numbers, M_I=+1, 0, and −1, toward the high-field direction.

In the present study, the three lines broaden their linewidths (in the same manner) with an increase in the concentration of Ni^{2+} ions. I, therefore, will discuss the behavior of the lowest field line (M_I=+1) as a representative line.

In Fig. 2, the peak-to-peak linewidth, $W(+1)$, of the three nitroxide radicals in 5.2wt% SDS solutions are

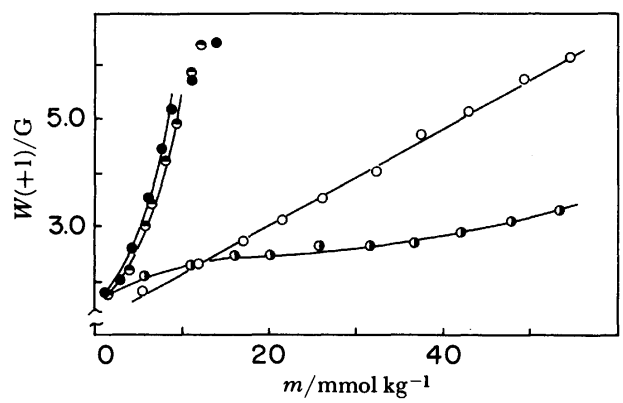

Fig. 2. Plots of the linewidth, $W(+1)$, *vs.* the concentration of Ni^{2+} ion, m, in various systems. ○: (BzONO+Ni^{2+})/water, ◑: (BzONO+Ni^{2+})/SDS, ◓: (NpONO+Ni^{2+})/SDS, and ●: (MyONO+Ni^{2+})/SDS. [SDS]=5.2 wt%.

plotted as a function of the concentration, m, of Ni^{2+} ions. A similar plot of BzONO in water is also shown in the same figure; because of low solubility in water, the spectrum of the other two radicals, NpONO and MyONO, could not be measured.

In the presence of the spin-exchange interaction, $W(+1)$ (that is, the spin-spin relaxation rate, $T_2^{-1}(+1)$) is theoretically described by the spin-exchange rate constant, k_e, and the concentration of the paramagnetic ion, m, in the following expression;

$$W(+1) = (2/\sqrt{3})T_2^{-1}(+1) = (2/\sqrt{3})\{T_{20}^{-1}(+1)+k_e m\} \quad (1)$$

where $T_{20}^{-1}(+1)$ is the spin-spin relaxation rate when no spin-exchange interaction occurs. Thus, it can be predicted that the $W(+1)$ increases linearly with the m.

As can be seen from Fig. 2, the prediction is valid only in the case of BzONO in water. The $W(+1)$-m plots of NpONO and MyONO in the SDS solutions curve upwards steeply, and that of BzONO exhibits little dependence on m.

Most of the SDS molecules in the 5.2wt% SDS solutions dissolve as micelles and the nitroxide radicals are solubilized into micelles. The nonlinear plots in the cases of SDS solutions may be related to this fact.

Comparing these plots with each other, it can be seen that the spin-exchange rates of NpONO and MyONO with paramagnetic ions are accelerated, whereas that of BzONO is deaccelerated in the presence of SDS micelles. The spin-exchange interaction occurs upon collisions between paramagnetic particles. This finding indicates that the SDS micelle affects the collision process between the nitroxide radical and the Ni^{2+} ion.

I will consider why such inverse effects are brought about in the same SDS solutions. There are three possible ways to explain this.

The first possibility is that the retarding effect in the (BzONO+Ni^{2+})/SDS system is an apparent phenomenon caused by the superposition of the signal of BzONO in the bulk solution onto that in the micellar phase. From the solubility value of BzONO into the SDS solution,[7] however, it can be estimated that the more than 99% of the BzONO molecules exist in the micellar phase in the case of the 5.2wt% SDS solution. Thus, the above possibility is implausible.

The second possibility is that the mobility of BzONO in SDS micelles is very low in comparison with the other two radicals. The BzONO molecule, however, has the smallest value of the rotational correlation time, τ_c, in the SDS micelle among the three radicals used (*cf.* Table 1). The values of τ_c were calculated according to a well-known formula.[8] This implies that the BzONO molecule is most mobile in its rotational mode; a similar phenomenon holds also in the translational mode.

The third possibility is that the solubilized location of BzONO in the SDS micelle is not available for an effective collision with paramagnetic ions. It is well known that the isotropic hyperfine splitting constant, a_N is a parameter which reflects the polarity of the microscopic environment where the nitroxide group exists: The value of a_N increases with the polarity.[9] From the a_N values given in Table 1, it can be seen that the BzONO molecule is located in the more polar region of the SDS micelle than is the NpONO or MyONO molecule.

Table 1. The isotropic hyperfine splitting constant, a_N, and the rotational correlation time, τ_c

	[SDS](wt%)	a_N/G	$\tau_c/10^{-10}$ s rad^{-1}
(BzONO+Ni^{2+})/SDS	0	17.0	0.35
	5.2	16.8	0.96
	7.6	16.7	
(NpONO+Ni^{2+})/SDS	0	16.9	
	5.2	16.4	2.4
(MyONO+Ni^{2+})/SDS	1.3	16.6	
	2.6	16.6	
	3.9	16.6	
	5.2	16.6	3.4

Assuming that the SDS micelle is an ordinary spherical micelle with the Stern layer and the diffuse layer being used as the binding regions of the counterions, I think that the nitroxide group of BzONO is in the diffuse layer, whereas that of NpONO or MyONO is near the Stern layer: The nitroxide group of BzONO protrudes from the micellar surface. When Ni^{2+} ions are added to SDS solutions, they will initially become bound to the Stern layer and then, to the diffuse layer with a further increase in their concentration. Consequently, a nitroxide group of BzONO in the diffuse layer cannot collide with the Ni^{2+} ions bound to the Stern layer.

On the basis of the above idea, I can predict that the spin-exchange rate of BzONO increases at higher concentrations of Ni^{2+} ions where the Ni^{2+} ions become bound to the diffuse layer. Figure 3 shows the $W(+1)$-m plots of BzONO for two solutions with different amounts of SDS over a wider range of m. It is

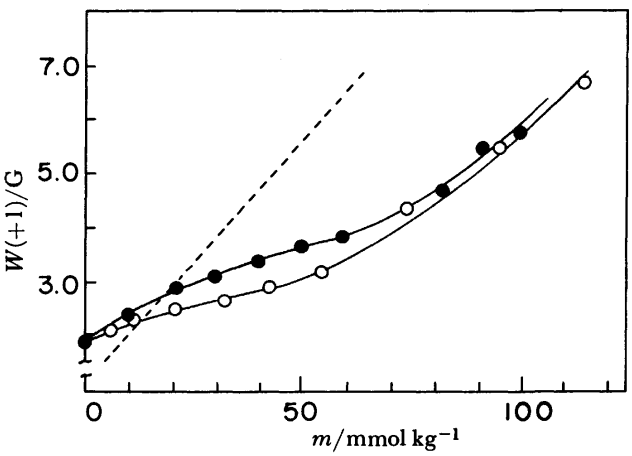

Fig. 3. Plots of $W(+1)$ *vs.* m in (BzONO+Ni^{2+})/SDS systems with the SDS concentrations of 5.2 wt%: (○) and 7.6 wt%: (●). Dashed line is a similar plot of (BzONO+Ni^{2+})/water.

noticeable that $W(+1)$ varies consistently with prediction. The concentration where a sharp increase in $W(+1)$ begins, corresponds to a sufficient content to neutralize about 50% of the negative charges of the micellar dodecyl sulfate ions. This finding coincides with Zayev's results[10] regarding proton NMR relaxation studies on a system similar to the present one. Zayev has discovered two binding areas of the Cu^{2+} ion onto SDS micelles. One is an area of complete binding up to a Cu^{2+} ion content of 50—60% with respect to that equivalent to dodecyl sulfate ions. This area corresponds to the Stern layer. The other is the area of weak binding above the Cu^{2+} ion content; this area corresponds to the diffuse layer.

It is additionally noticeable (in Fig. 3) that until the sharp increase in $W(+1)$ begins, the $W(+1)$ in 7.6wt% SDS solutions is greater than that in 5.2wt% SDS solutions. This fact may imply that the BzONO in a micelle interacts with Ni^{2+} ions bound onto the other micelles.

From the above discussion, it is concluded that the deaccelerating effect of SDS micelles on the spin-exchange rate of BzONO with paramagnetic ions results from the solubilized location of BzONO emerging outside from the micellar surface.

In order to investigate the acceleration in the ($NpONO+Ni^{2+}$)/SDS or ($MyONO+Ni^{2+}$)/SDS system, the $W(+1)$ of MyONO in the solutions with various amounts of SDS was measured as a function of the Ni^{2+} ion concentration. The data obtained are plotted in Fig. 4. In all the solutions, the accelerating effect can be observed (*cf.* the straight dashed line in the figure). A similar plot of MyONO in water will be depicted by a straight line with a smaller slope than of the dashed line.

In this case, the accelerating effect results from the condensation of Ni^{2+} ions on the micellar surface and, moreover, from an appropriate solubilized location of the nitroxide group of MyONO for colliding with the Ni^{2+} ions: Its nitroxide group exists in the Stern layer.

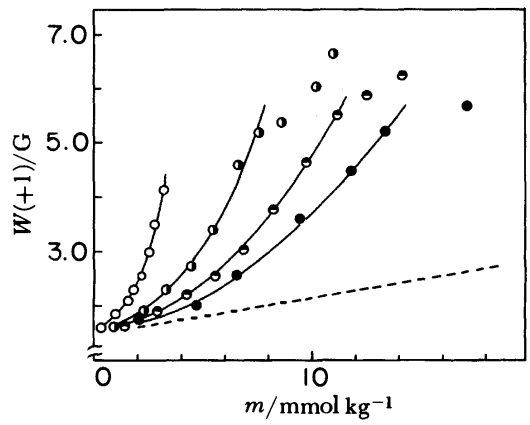

Fig. 4. Plots of $W(+1)$ *vs.* m in ($MyONO+Ni^{2+}$)/SDS systems with the SDS concentrations of 1.3 wt%: (○); 2.6 wt%: (◑); 3.9 wt%: (◓); 5.2 wt%: (●). Dashed line is a similar plot of ($BzONO+Ni^{2+}$)/water.

If the above idea holds, plots of $W(+1)$ against the mole ratio, X_r, of Ni^{2+} ions on the micellar surface in these solutions will be on the same line. The X_r was defined by the following equation;

$$X_r = n(Ni^{2+})/\{n(DS^-) + n(MyONO)\} \quad (2)$$

where $n(Ni^{2+})$ is the number of Ni^{2+} ions bound onto one micelle on the assumption that all Ni^{2+} ions are bound onto micelles, $n(DS^-)$ the number of dodecyl sulfate ion in one micelle, being equal to the aggregation number=62,[11] and n(MyONO) is the number of MyONO solubilized in one micelle, being equal to unity in the present case. I assumed that $n(DS^-)$ and n(MyONO) are approximately constant. Strictly speaking, they will change with an increase in the concentration of Ni^{2+} ions.

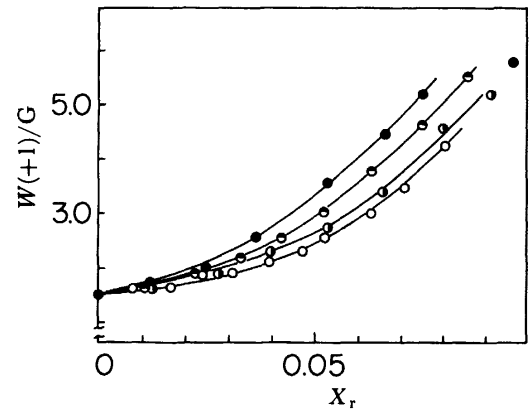

Fig. 5. Plots of the linewidth, $W(+1)$ *vs.* the mole ratio, X_r, of Ni^{2+} ion on the micellar surface in ($MyONO+Ni^{2+}$)/SDS systems with the SDS concentrations of 1.3 wt%: (○); 2.6 wt%: (◑); 3.9 wt%: (◓); 5.2 wt%: (●).

Figure 5 shows the obtained $W(+1)$-X_r plots. They are not on a common line, but on upwardly curved lines (their curvatures become greater with the SDS concentration). This fact indicates that the above assumption regarding $n(DS^-)$ and n(MyONO) is inadequate, and/or that there is an intermicellar interaction which induces the spin-exchange with the Ni^{2+} ions bound to other micellar surfaces.

In the plots, the departure from linearity might be a result of the distribution of the number of bound Ni^{2+} ions per micelle. In previous studies,[2,3] my coworkers and I investigated the spin-exchange between BzONO or MyONO molecules solubilized in SDS micelles. We obtained similar curved lines in plots of $W(+1)$ against the mole fraction of radicals in the SDS micelles. The curved lines could be successfully simulated by considering the distribution of the number of radical molecules per micelle. The non-linear behavior of some observed parameters in several other studies regarding micellar solution[12,13] was interpreted using a similar model.

Consequently, in an estimation of the translational diffusion coefficients of Ni^{2+} ions bound to a SDS micellar surface, I will analyze the $W(+1)$-X_r plots in

consideration of the distribution of Ni^{2+} ions. The analysis is in progress; the results will be described in my next paper. Qualitatively, in comparison with the previous results of the lateral diffusion of MyONO in the SDS micelle,[3] I can presume that the translational mobility of Ni^{2+} ions on the micellar surface are not extremely different from that of MyONO solubilized in the micelle.

I wish to thank Professor H. Uedaira of Hokkaido University for his helpfull discussions.

Fluorescence of RbH and RbD Formed by Irradiating the Mixed Gases Rb+H_2 and Rb+D_2 with Laser Light

Hajime KATÔ,* Yukiko TOYOSAKA, and Tomonari SUZUKI
Department of Chemistry, Faculty of Science, Kobe University, Nada-ku, Kobe 657
(Received August 22, 1984)

When a mixture of ^{85}Rb, $^{85}Rb_2$, and D_2 was irradiated by laser light at 5145 or 4880 Å, small visible particles appeared and the fluorescence spectra were observed. By analyzing these spectra, we determined the rotational constants B_v and the centrifugal distortion constants D_v and H_v for the $X\ ^1\Sigma^+$ and $A\ ^1\Sigma^+$ states of ^{85}RbD. By considering the isotopic dependence of the Dunham coefficients, we determined various molecular constants of ^{85}RbH whose values were in good agreement with the observed fluorescence spectra of ^{85}RbH excited by laser lines at 4762, 4765, and 4880 Å. The process of RbH formation is discussed.

In 1975, Tam, Moe, and Happer reported that micron-size visible particles were produced in a cell filled with cesium and hydrogen upon Ar^+-laser irradiation at 4545 or 4579 Å.[1] The pressure broadening of the 7p→6s doublets at 4555 and 4593 Å allowed a substantial pumping of the Cs atoms from the ground state $6s\ ^2S_{1/2}$ to the $7p\ ^2P_{3/2}$ or $7p\ ^2P_{1/2}$ state

$$Cs(6s) + h\nu \longrightarrow Cs(7p). \quad (1)$$

They suggested that the particles (often called "laser snow") were crystals of cesium hydride salt produced by the following reactions:

a) $$Cs(7p) + H_2 \longrightarrow CsH + H, \quad (2)$$

or

$$Cs(7p) + H_2 \longrightarrow Cs(6s) + H_2(v), \quad (3)$$

$$Cs(6s) + H_2(v) \longrightarrow CsH + H, \quad (4)$$

where $H_2(v)$ represents a vibrationally excited hydrogen molecule.

b) Collisions with other CsH molecules lead to a $(CsH)_2$ molecule, which would further polymerize to form crystals of CsH. Particle formation was also observed when rubidium, mixed with H_2, was irradiated at 4880 or 4765 Å. In this case, the first step in the process was the production of excited Rb_2 ($C\ ^1\Pi_u$) molecules. The process regarding RbH formation is interesting.

There are few previous spectroscopic analyses of RbH. In 1939 Gaydon and Pearse[2] observed the $A\ ^1\Sigma^+ \rightarrow X\ ^1\Sigma^+$ transition of RbH in the 4680 to 6540 Å region in emission. Bartky[3] observed the absorption spectrum of RbD. He showed that the previous vibrational assignment of the $A\ ^1\Sigma^+$ state of RbH had to be changed, and gave revised molecular constants for RbH. Hsieh *et al.*[4] observed the laser-induced fluorescence spectra of RbH excited by an Ar^+ laser line at 4765 Å.

Here, we report the laser-induced fluorescence spectra of RbD excited at 5145 and 4880 Å, and of RbH excited at 4762, 4765, and 4880 Å. Since the vibrational constant ω_e of RbD is about $(\mu^{RbH}/\mu^{RbD})^{1/2}$ times that of RbH (where μ^{RbD} and μ^{RbH} are the reduced masses of RbD and RbH, respectively), we observed the fluorescence lines of RbD by about $(\mu^{RbD}/\mu^{RbH})^{1/2}$ times that of RbH in a given energy region. Hence, we could determine more accurate potential curves for RbD than for RbH. We report on the rotational constants B_v and the centrifugal constants D_v and H_v, which are independent of the method of least squares, for the $X\ ^1\Sigma^+$ and $A\ ^1\Sigma^+$ states of RbD. The potential curves of the $X\ ^1\Sigma^+$ and $A\ ^1\Sigma^+$ states and the Franck-Condon factors of the $A\ ^1\Sigma^+ - X\ ^1\Sigma^+$ transition are calculated. The fluorescence spectra of RbD excited by laser lines at 4880 and 5145 Å are compared with the calculated results. By using the isotopic dependence of diatomic Dunham coefficients, we determined the molecular constants of RbH. By referring to the potential energy curves of H_2, Rb_2, and RbH, we estimated the processes of RbH formation.

Experimental

^{85}Rb metal was obtained by the reduction of $^{85}RbCl$ (Oak Ridge National Laboratory, 99.78% of $^{85}RbCl$ and 0.22% of $^{87}RbCl$). A mixture of 120 mg of $^{85}RbCl$ and 120 mg of Ca metal granules was enclosed in a breakable glass tube of 6 mm o.d. with a slender neck. It was enclosed in an exhaused Pylex glass tube of 10 mm o.d. We broke the neck of the glass tube and heated the contents to 450 °C for 20 min. The heating caused the ^{85}Rb metal to become volatilized. This ^{85}Rb metal was driven into a cooler part of the tube and was sealed off.

The optical cells were constructed from Corning 1720 aluminosilicate glass tube of 13 mm o.d., and were baked for 8 h (1 h=60 min) at 600 °C in a vacuum of 10^{-6} Torr (1 Torr= 133.322 Pa). A mixture of the ^{85}Rb metal and the H_2 or D_2 (500 Torr) in the cell (at temperatures ranging from 300 to 500 °C) was irradiated at various frequencies of an Ar^+ laser. The vapor pressures of Rb and Rb_2 at 400 °C were estimated to be about 14 and 0.24 Torr, respectively. The experimental arrangement to measure the fluorescence spectra was the same as that reported in our previous paper.[5] The monochromator was calibrated using atomic Hg and Kr lines (Oriel, spectral lamps C-13-61 and C-13-12), and the accuracy of the line position measurements was within $\pm 0.3\ cm^{-1}$.

Results and Discussion

When a mixture of ^{85}Rb, $^{85}Rb_2$, and D_2 was irradiated by a multimode 4880 Å Ar^+ laser line, we observed the appearance of small visible particles. The laser power was 1.0 W and the beam diameter was 2 mm. The flu-

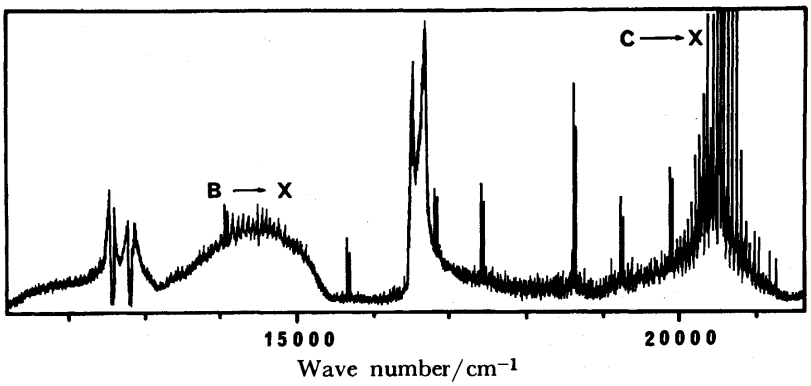

Fig. 1. Fluorescence spectrum of a mixture of ^{85}Rb metal and D_2 irradiated by the 4880 Å Ar^+ laser line. The cell temperature was 400°C. A spectral slit width of 1 cm^{-1} was used. A series of P, R doublet are the resonance fluorescence $A\ ^1\Sigma^+(v'=14,\ J'=4)\rightarrow X\ ^1\Sigma^+(v'',\ J''=3$ and 5) of ^{85}RbD. Rb atomic fluorescence at 12816 cm^{-1} ($5p^2P_{3/2}\rightarrow 5s^2S_{1/2}$) and 12578 cm^{-1} ($5p^2P_{1/2}\rightarrow 5s^2S_{1/2}$) appeared self-reversed due to the large optical density of atomic Rb. All the other bands are the fluorescence of Rb_2 (See Ref. 20).

orescence spectrum (Fig. 1) was observed. The fluorescence of Rb_2, the atomic lines of Rb ($5p\ ^2P_{3\,2}\rightarrow 5s\ ^2S_{1\,2}$) and Rb ($5p\ ^2P_{1\,2}\rightarrow 5s\ ^2S_{1\,2}$), and a series of P and R doublets with a vibrational spacing which can be identified as the fluorescence of RbD were observed. The molecular constants of the $X\ ^1\Sigma^+$ and $A\ ^1\Sigma^+$ states were reported by Bartky.[3] We identified the rotational quantum number J of the P, R doublet to be P ($J''=5$) and R ($J''=3$) from the observed spacing of the doublet. Since the R-branch was observed at the higher frequency side of the laser line, the series of P and R doublets were identified as the resonance fluorescence of ^{85}RbD originating from the excitation $A\ ^1\Sigma^+$ ($v'=14,\ J'=4$)$\leftarrow X\ ^1\Sigma^+$ ($v''=0,\ J''=5$). The vibrational quantum number $v''=0$ was assigned since any anti-Stokes P, R doublet of RbD was not observed, and $v'=14$ was assigned by referring the energy of the laser line and the calculated transition energies.

In the region near each resonance P and R doublet, we observed fluorescence lines from rotational levels of the excited state populated by a collision-induced rotational-energy transfer. A spectrum of the rotationally resolved $v'=14\rightarrow v''=3$ band is shown in Fig. 2. Similar spectra were observed when the cell was irradiated by a 5145 Å Ar^+ laser line, and the assignment of the transition could be achieved in the same way. The observed line positions and the relative intensities of the resonance lines of ^{85}RbD excited at 4880

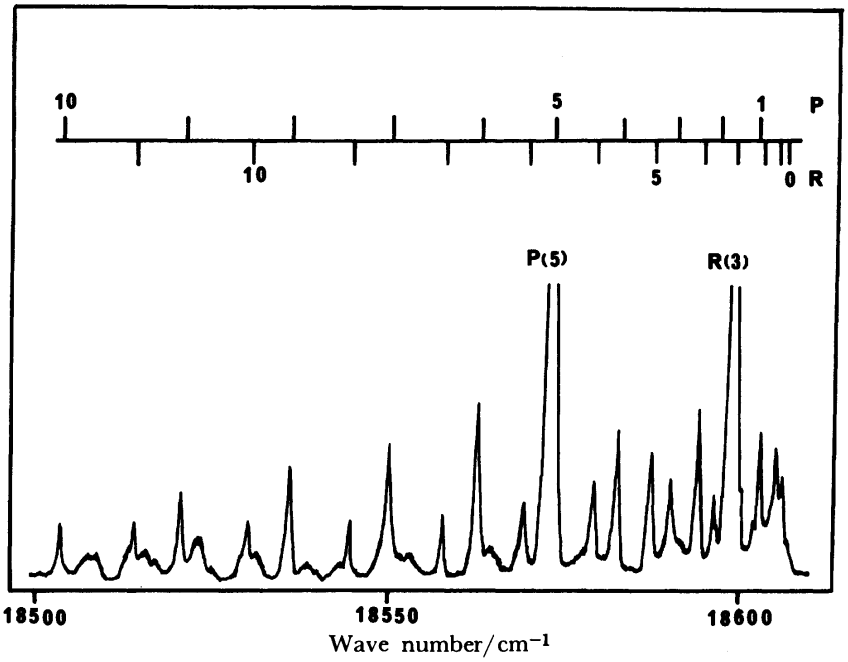

Fig. 2. Fluorescence lines from rotational levels of the excited state in the near region of the resonance fluorescence lines $A\ ^1\Sigma^+(v'=14,\ J'=4)\rightarrow X\ ^1\Sigma^+(v''=3,\ J''=3$ and 5) of ^{85}RbD. Assignments are shown above each line.

and 5145 Å are listed in Table 1.

The line positions $\sigma(v'J'-v''J'')$ of a fluorescence series can be represented by the energy difference between the $(v'J')$ and $(v''J'')$ vibrational-rotational levels of the excited and ground states:

$$\sigma(v'J' - v''J'') = T_{e'} + E_{v'J'} - E_{v''J''}, \quad (5)$$

where

$$E_{vJ} = \sum_{ij} Y_{ij}\left(v+\frac{1}{2}\right)^i J^j(J+1)^j, \quad (6)$$

T_e is the electronic term energy separation, and the Dunham coefficients Y_{ij}[6] are determined to reproduce the observed line positions. The transition energies calculated from the molecular constants reported by Bartky are in good coincidence with the observed

a) Relative intensity as the intensity of a transition to v''=0 is 10.

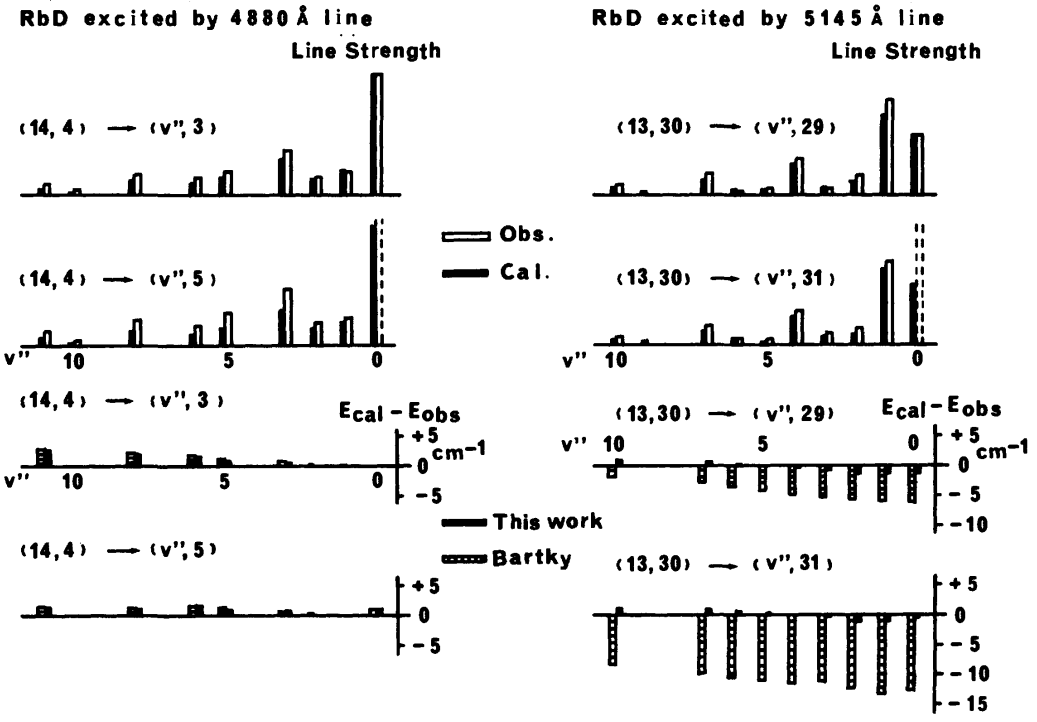

Fig. 3. Comparison between the calculated and observed relative line strengths for fluorescence series $A\ ^1\Sigma^+(v'=14,\ J'=4)\rightarrow X\ ^1\Sigma^+(v'',\ J''=3$ and 5) and $A\ ^1\Sigma^+(v'=13,\ J'=30)\rightarrow X\ ^1\Sigma^+(v'',\ J''=29$ and 31) of ^{85}RbD excited by the 4880 and 5145 Å Ar$^+$ laser lines, respectively (upper 4 figures). Lower 4 figures show the transition energy difference, $E_{cald}-E_{obsd}$ (in units of cm^{-1}), which is the difference of the transition energies between the observed ones and the ones calculated by using molecular constants determined by this work and by Bartky.[3]

energies for the transitions between states of small rotational quantum numbers J, but the coincidence of the transition energies for large J is poor (See Fig. 3). We adopted the vibrational constants reported by Bartky as Y_{io}, and the rest of the Dunham coefficients Y_{ij} ($j \neq 0$) for the $X\ ^1\Sigma^+$ state were determined by a least squares fitting of all the observed transition energies.

The rotation-vibration energy of a diatomic molecule is conventionally expanded in the form[7]

$$E_{vJ} = G(v) + B_vJ(J+1) - D_vJ^2(J+1)^2 + H_vJ^3(J+1)^3 + \cdots, \quad (7)$$

where $G(v)$ is the energy of the rotationless molecule in the vibrational state v, B_v is the corresponding

a) In units of cm^{-1}.

rotational constant, and D_v and H_v are the centrifugal distortion constants. The Dunham coefficients Y_{ij}, which were determined in order to reproduce or extrapolate the measured line positions, depend on the statistical nature of the fitting, and the values are often highly correlated with the number of expanded terms. An accurate vibrational constant $G(v)$ can be obtained by fitting it to the line positions of $J=0$ or small J.

We used a direct approach to separate the effects due to B_v from those due to D_v, H_v, *etc.* as the constants independent of the fitting. In the Rydberg-Klein-Rees (RKR) method[8] the potential curve is derived from the vibrational constant $G(v)$ and the rotational constant B_v. Primitive RKR potential curves of the $X\,^1\Sigma^+$ and $A\,^1\Sigma^+$ states were calculated for the vibrational constant $G(v)$ and the approximate rotational constant

$$B_v = \sum_i Y_{i1}\left(v+\frac{1}{2}\right)^i. \tag{8}$$

Once an approximate potential curve was obtained, the centrifugal distortion constants could be theoretically evaluated as constants independent of the fitting.[9,10] By using a computer program of Hutson,[11] we calculated the centrifugal distortion constants. These theoretical values were used to obtain more reliable rotational constants and an improved RKR curve. This procedure was iterated until it converged. The RKR potential energy curves obtained in this way are listed in Table 2, and the rotational constant B_v and centrifugal distortion constants D_v and H_v for the $X\,^1\Sigma^+$ and $A\,^1\Sigma^+$ states are listed in Table 3.

Once a potential curve was constructed, the vibrational wave functions and the eigenvalues were obtained by solving the radial Schrödinger equation.[12] The line strengths of the emission are proportional to $\nu^4|\langle v'|v''\rangle|^2$, where the electric transition moment is assumed to be constant over the range of vibrations v' and v''. ν is the frequency of a transition and $|\langle v'|v''\rangle|^2$, is the Franck-Condon factor. A comparison of the observed and calculated intensity distributions as well as the transition energy difference, $E_{cald}-E_{obsd}$, are shown in Fig. 3 for the $A\,^1\Sigma^+$ ($v'=14$, $J'=4$)$\rightarrow$ $X\,^1\Sigma^+$ (v'', $J''=3$ and 5) and $A\,^1\Sigma^+$ ($v'=13$, $J'=30$)$\rightarrow$ $X\,^1\Sigma^+$ (v'', $J''=29$ and 31) transitions. This confirms that the present vibrational assignments are correct regarding intensity distribution.

The isotopic dependence of the Dunham coefficients Y_{ij} of a diatomic molecule has been studied.[6,13] Except for very precise data, the Dunham coefficients Y_{ij}^A and Y_{ij}^B of two isotopic molecules (A and B, respectively) are expressed to a very good approximation by[7]

$$Y_{ij}^A/Y_{ij}^B = (\mu^B/\mu^A)^{j+1/2}, \tag{9}$$

where μ^α (α=A, B) is the reduced mass of an isotopic molecule. We expanded the centrifugal constants D_v and H_v in the form of Eq. (8) for the rotational constant B_v as

$$D_v = -\sum_i Y_{i2}(v+1/2)^i, \text{ and } H_v = \sum_i Y_{i3}(v+1/2)^i, \tag{10}$$

TABLE 4. DUNHAM TYPE COEFFICIENTS FOR THE $X\,^1\Sigma^+$ AND $A\,^1\Sigma^+$ STATES OF THE ^{85}RbH MOLECULE. ALL VALUES ARE GIVEN IN cm^{-1}

	Y_{43}=−0.373×10^{-11}

The Dunham-type coefficients Y_{ij} of ^{85}RbD were determined by a least-squares fitting of the values in Table 3. Then, by using Eq. (9), we obtained the Dunham-type coefficients of ^{85}RbH. The results are listed in Table 4.

The transition energies calculated from the constants in Table 4 agreed satisfactorily with the observed series of fluorescence lines of ^{85}RbH excited at 4762, 4765, and 4880 Å. A comparison of the observed and calculated intensity distributions as well as the transition energy difference, $E_{cald}-E_{obsd}$, are shown in Fig. 4 for the observed series of resonance fluorescence of ^{85}RbH excited at 4762 Å. From the figure we see that the molecular constants determined by Hsieh *et al.* are less accurate than the ones determined by Bartky for the transitions with a small rotational quantum number J. The constants reported by Bartky are in good coincidence with the observed values for transitions with a small J. However, for large J agreement was poor, as it was for RbD.

The RKR potential energy curves for the $X\,^1\Sigma^+$ and $A\,^1\Sigma^+$ states of ^{85}RbH were calculated for the molecular constants in Table 4, and the results are listed in Table 5. The molecular constants $\omega_e x_e$ ($=-Y_{20}$) and α_e ($=-Y_{11}$) of the $A\,^1\Sigma^+$ state are abnormally negative, and the potential energy curve approaches its asymptote unusually slowly with increasing internuclear distance. The exceptional potential form of the $A\,^1\Sigma^+$ state of alkali metal hydrides has been explained to be the result of strong mixing between two zero-approximation states of the ionic and covalent character.[14] The dissociation energy D_e of the $X\,^1\Sigma^+$state of RbH was estimated to be 14580±600 cm^{-1}.[15]

Let us now discuss the process of RbH formation. The potential curves of H_2 ($X\,^1\Sigma_g^+$), Rb_2 ($X\,^1\Sigma_g^+$ and $C\,^1\Pi_u$), and RbH ($X\,^1\Sigma^+$ and $A\,^1\Sigma^+$) are schematically shown in Fig. 5. Accurate spectroscopic data of H_2

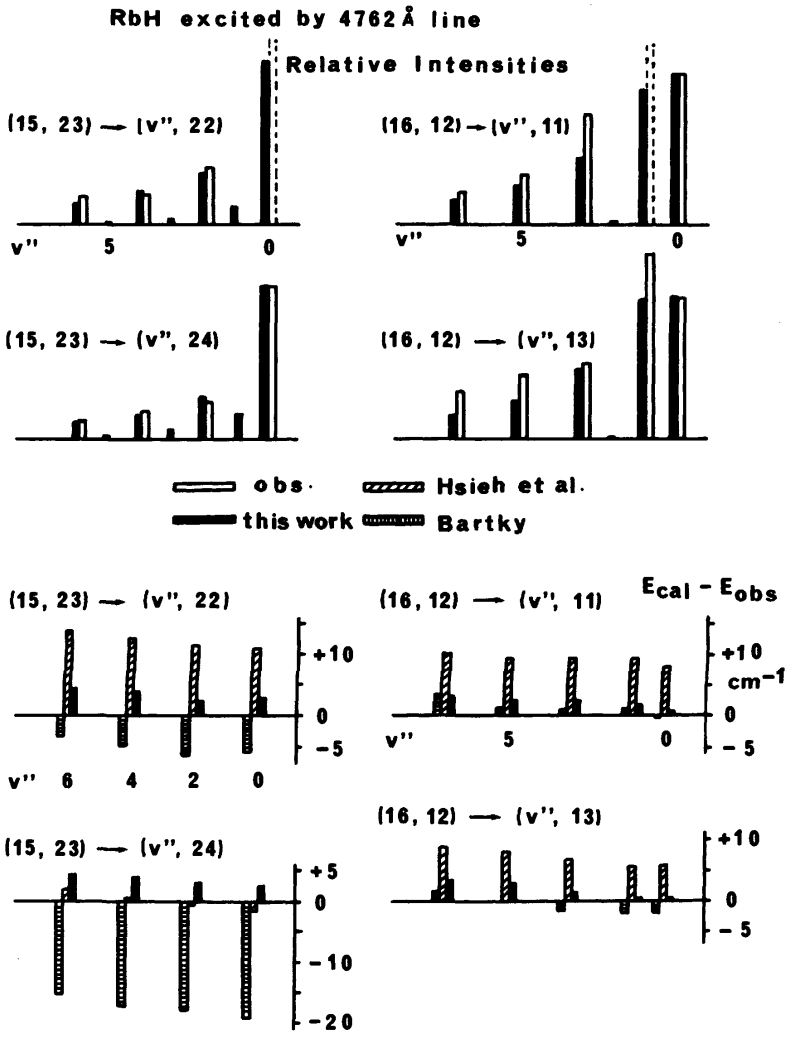

Fig. 4. Comparison between the calculated and observed relative line strengths for the fluorescence series $A\ ^1\Sigma^+(v'=15, J'=23) \rightarrow X\ ^1\Sigma^+(v'', J''=22$ and 24) and $A\ ^1\Sigma^+(v'=16, J'=12) \rightarrow X\ ^1\Sigma^+(v'', J''=11$ and 13) of ^{85}RbH excited by the 4762 Å Ar^+ laser line (upper 4 figures). Lower 4 figures show the transition energy difference, $E_{cald}-E_{obsd}$ (in units of cm^{-1}), which is the difference of transition energies between the observed ones and the ones calculated by using the molecular constants determined by this work, by Bartky,[3] and by Hsieh *et al.*[4]

have been reported for the Lyman bands ($B\ ^1\Sigma_u^+ - X\ ^1\Sigma_g^+$) and the RKR potential curve of the $X\ ^1\Sigma_g^+$ state has been fairly well established.[16-18] The dissociation energy D_e of the $X\ ^1\Sigma_g^+$ state of H_2 has been determined to be $38284\pm15\,cm^{-1}$.[18] The dissociation energy D_e of the $X\ ^1\Sigma_g^+$ state of Rb_2 has been determined to be $3950\pm160\,cm^{-1}$, and energy of the bands of the $C\ ^1\Pi_u - X\ ^1\Sigma_g^+$ transition have been represented by

$$\begin{aligned} E(v',v'') = 20835.1 &+ [36.46(v'+1/2) \\ &- 0.124(v'+1/2)^2] - [56.78(v''+1/2) \\ &- 0.0785(v''+1/2)^2 - 0.00083(v''+1/2)^3] \end{aligned} \quad (11)$$

in units of cm^{-1}.[19] Brom and Broida[20] assigned the excitation of Rb_2 irradiated at 4880 Å as the $X\ ^1\Sigma_g^+$ ($v''=8$) $\rightarrow C\ ^1\Pi_u$ ($v'=3$) transition. Hence, the excited Rb_2 molecule has about $17000\,cm^{-1}$ of excess energy when it is dissociated into two Rb ($5s\ ^2S_{1/2}$) atoms.

The dissociation energies D_0 of H_2 and RbH molecules are 36000 and $14000\,cm^{-1}$, respectively. The excited Rb_2 molecule does not have a potential energy which exceeds the difference between the dissociation energies of H_2 and RbH. Hence, the formation of RbH in the ground state $X\ ^1\Sigma^+$ through the primary reaction

$$Rb_2(C^1\Pi_u) + H_2 \longrightarrow RbH + H + Rb(5^2S) \quad (12)$$

or through two step reaction: vibrational activation

$$Rb_2(C\ ^1\Pi_u) + H_2 \longrightarrow Rb_2(X\ ^1\Sigma_g^+) + H_2(v) \quad (13)$$

followed by

$$H_2(v) + Rb(5^2S) \longrightarrow RbH + H, \quad (14)$$

which is analogous to the one suggested for CsH formation, is impossible from the energy requirements of the reaction.

The spectra for a mixture of ^{85}Rb and H_2 were sim-

a) r_- and r_+ are the classical minimum and maximum internuclear separation, respectively, for a vibrational level v''.

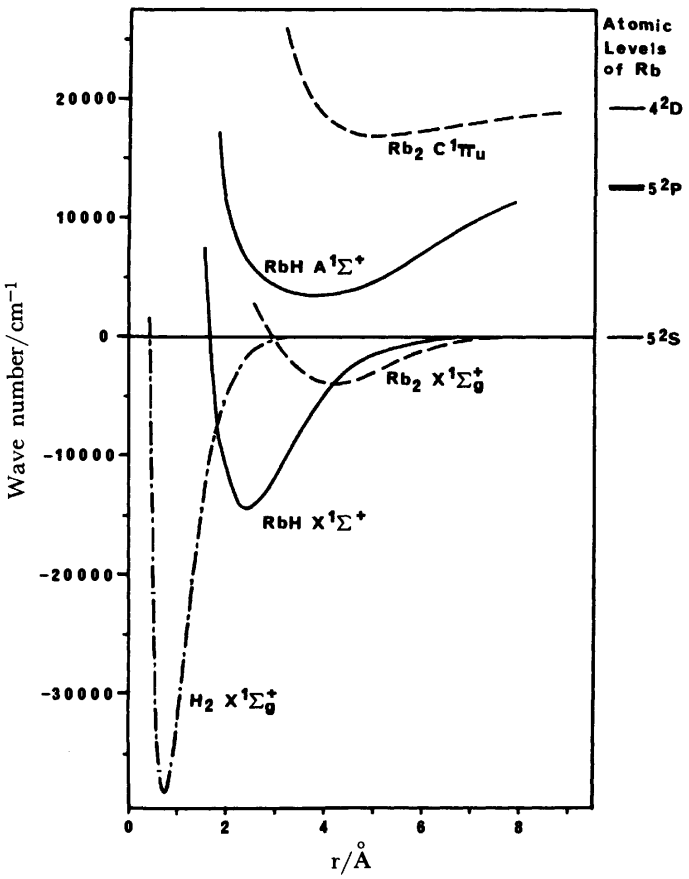

Fig. 5. Potential energy curves of $H_2(X\ ^1\Sigma_g^+$: RKR in Ref. 17), Rb_2 ($X\ ^1\Sigma_g^+$: RKR calculated from molecular constants in Ref. 21, and $C\ ^1\Pi_u$: Morse), and RbH($X\ ^1\Sigma^+$ and $A\ ^1\Sigma^+$: RKR in Table 5).

ilar to those shown in Figs. 1 and 2. We observed the resonance fluorescence of Rb_2, fluorescence of Rb_2 from the energy transferred states, and the atomic lines of Rb(5p $^2P_{1/2}\rightarrow$5s $^2S_{1/2}$) and Rb(5p $^2P_{3/2}\rightarrow$5s $^2S_{1/2}$) in addition to the resonance fluorescence of RbH. The density of H_2, Rb, and Rb_2 in the cell at 400°C are about 10^{19}, 5×10^{17}, and 10^{16} cm^{-3}, respectively. The excited Rb_2 molecule collides mostly with a H_2 molecule, and about once in ten with a Rb atom. The $H_2(v)$ molecule which was vibrationally excited through the reaction (13) collides mostly with a H_2 molecule in the ground state and will lose some of its vibrational energy. The reaction (14) would require vibrational excitation of the H_2 molecule to $v>6$, which will not be possible under our experimental conditions. A reaction with a Rb atom in the excited state 5p $^2P_{3/2}$ or 5p $^2P_{1/2}$ (it requirs $H_2(v>2)$) would be possible. However, this would not be the main process of the RbH formation, since the density of the Rb(5p $^2P_{1/2}$ and 5p $^2P_{3/2}$) atoms are low. Under our experimental conditions we have not observed fluorescence from highly excited Rb atoms, such as Rb(6p) and Rb(4d). This was the same for a cell containing only rubidium. Hence, there is no possibility of the reaction through a multi-photon process. By estimating from the energy requirments of the reaction, the most probable process of RbH formation would be a bimolecular reaction *via* an exciplex [Pb_2*H_2]

$$Rb_2(C\ ^1\Pi_u) + H_2(X\ ^1\Sigma_g^+) \longrightarrow [Rb_2{}^*H_2] \longrightarrow 2RbH(X\ ^1\Sigma^+). \quad (15)$$

However, nothing is known about the possible existence of the transient complex [Rb_2*H_2], and more

work is necessary to clearify this situation.

H. K. thanks the Ministry of Education, Science and Culture for Grant-in-Aid for Scientific Research No. 58490020. A part of the calculations were carried out at the computer center of IMS.

Reaction in the System $N(CH_3)_4$-ZrO_2-P_2O_5-H_2O. Preparation and Characterization of Framework Zirconium Phosphates $(NH_4)_xH_{1-x}Zr_2(PO_4)_3$ and $HZr_2(PO_4)_3$

Tsuyoshi KIJIMA* and Yoshiyuki YAJIMA
National Institute for Research in Inorganic Materials, Sakura-mura, Niihari-gun, Ibaraki 305
(Received July 3, 1984)

The hydrothermal reaction in the system ZrO_2-P_2O_5-H_2O in the presence of tetramethylammonium ions was examined within the temperature range 160—350 °C. This reaction resulted in the formation of framework zirconium phosphates $(NH_4)_xH_{1-x}Zr_2(PO_4)_3 \cdot yH_2O$ ($0.6 \leq x \leq 1$, $y \leq 0.3$) as well as some other phases, including two tetramethylammonium intercalates. The framework phases were rhombohedral with lattice constants of, *e.g.*, $a=8.669$ and $c=24.23$ Å for $x=1.0$. These phases were deammonated at 400—640 °C and converted to the proton-exchanged form $HZr_2(PO_4)_3$. The protons of this phase are easily exchanged by unhydrated Li^+ and Na^+ ions, but not by K^+ and Cs^+, owing to the sieving effect of the bottleneck in the $(Zr_2P_3O_{12})^{-1}$ framework. The acid strength of the proton form is a little weaker than that of α-zirconium phosphate.

Inclusion phenomena have attracted increasing attention in inorganic chemistry. In previous papers concerned with molecular inclusion, we reported the adsorption of amino acids by layered zirconium phosphates[1] and the complexation of copper(II)-montmorillonite with a modified cyclodextrin.[2] Recently, another type of application has been made in preparing several useful micro-porous compounds, such as zeolite ZSM-5[3] and framework aluminophosphates,[4] by a method in which their organic base-including precursors were hydrothermally crystallized prior to the decomposition of the complexing moieties.

Zirconium phosphate, other than with a layered structure, can be obtained with a framework structure. This phase is the end member of the zirconium phosphate silicate $M_{1+x}Zr_2Si_xP_{3-x}O_{12}$ ($0 \leq x \leq 3$, M=univalent cation). It is represented by a composition of $x=2$ and M=Na (NASICON) with a fast Na^+ ion conductivity and has an open three-dimensional skeleton framework with four cavities per formula weight.[5] It is, therefore, of interest to apply the inclusion crystallization method to the NASICON system.

An attempt was, thus, made to examine a hydrothermal reaction in the system ZrO_2-P_2O_5-H_2O in the presence of tetramethylammonium (TMA) ions.

In the present study, we obtained framework zirconium phosphates $(NH_4)_xH_{1-x}Zr_2(PO_4)_3$ and $HZr_2(PO_4)_3$ in addition to two tetramethylammonium intercalates. Alberti has already reported that the proton exchanged form of $MZr_2(PO_4)_3$ is obtained by washing $LiZr_2(PO_4)_3$ with dilute HCl.[6] After the present work was underway, we learned that Ono[7] prepared the ammonium- and the proton-exthanged forms of $MZr_2(PO_4)_3$ by a hydrothermal reaction using the system NH_3-ZrO_2-P_2O_5-H_2O. Clearfield, Roberts and Subramanian[8] also reported the hydrothermal synthesis of these two phases using the amine or ammonium exchanged forms of α-zirconium phosphate as a starting material or the reaction of NH_4Cl with $Zr(NaPO_4)_2$.

Experimental

Hydrothermal experiments were carried out as follows. To a 1:1 mixed aqueous solution of 1 mol dm^{-3} $ZrOCl_2$ and 1 mol dm^{-3} tetramethylammonium bromide, a 1 mol dm^{-3} phosphoric acid solution was added to keep the P/Zr ratio constant at 1.5 or 4. After the pH value of the reaction mixture had been adjusted to 0.8—9 with a 10% tetramethylammonium hydroxide solution, the mixture was sealed in a gold capsule or stainless steel bomb (fitted with a Teflon liner) and kept for 2—10 d at 160, 220, 280, 310, or 350 °C. The resulting solids were centrifuged, washed with distilled water and dried at 40 °C in air. Measurements of X-ray diffraction, TG traces, and infrared (IR) transmission were made using the same instruments and procedures as described elsewhere.[1] A wet analysis of zirconium and phosphorus was conducted by modifying the method of Clearfield, Blessing and Stynes.[9] An analysis of C, H, N loss on ignition was made using a conventional method. Ion exchange experiments were performed by the following procedure: 0.01—0.02 g of solid was contacted with 3 cm^3 of distilled water, followed by the addition of 0.5 cm^3 of a 1.0 mol dm^{-3} MCl solution. After each equilibration at 25 °C, the pH of the supernatant was measured, which enabled us to evaluate the number of protons released to the solution. A qualitative measurement of the acid strength was made in the same manner as previously described.[10]

Results and Discussion

The products resulting from the hydrothermal reactions were characterized primarily by their X-ray diffraction patterns and the results are summarized in Fig. 1. The two phases which give X-ray diffraction profiles similar to those of $NaZr_2(PO_4)_3$ and $KZr_2(PO_4)_3$[5] are denoted as NASICON(I) and NASICON(II), respectively. The numbers for the other phases designate the first interplanar spacing in their respective powder patterns. In the temperature range below 300 °C, the three phases labelled 12.6, 10.5, and 9.9 were obtainable as a single phase and the phases labelled 9.2 and 8.6 coexisted with the NASICON(I) phase. At higher temperature the NASICON(II) phase was obtained as a single phase at pH 1—9 and a mixture of some less crystalline phases, including the NASICON(I) phase, appeared at pH 0.8.

Among the three single phases labelled by numbers,

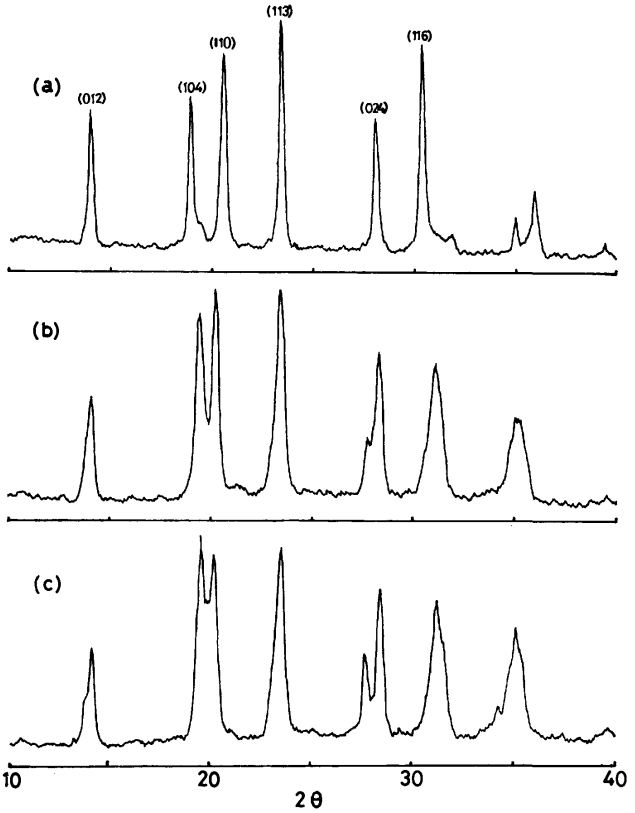

Fig. 2. X-Ray diffraction patterns of (a) sample A, (b) sample A-1, and sample A-2 for Cu$K\alpha$ rays. Main reflections are indexed for sample A.

composition analysis was made on phases 10.5 and 9.9 with high crystallinity. N, C, H analyses of these two phases yielded: N, 1.89; C, 6.23; H, 2.49 and N, 1.83; C, 6.12, H, 2.39 wt% or 1:3.85:18.4 and 1:3.90:18.3 in molar ratio, respectively. Both phases were also found to convert to α-ZrP_2O_7 upon heating to 1000°C. On the basis of the above results, in connection with the TG data, phases 10.5 and 9.9 can be identified as the TMA intercalates of α-zirconium phosphate, with compositions of $ZrH_{1.52}(TMA)_{0.48}(PO_4)_2 \cdot 0.6\ H_2O$ and $ZrH_{1.54}(TMA)_{0.46}(PO_4)_2 \cdot 0.4H_2O$, respectively. These two intercalates expanded their layers by as little as 3.1 or 2.5Å over that of the anhydrous form of α-zirconium phosphate. These values are much less than 6.9Å for the van der Waals diameter of the TMA ion. This is probably because the methyl groups of intercalated TMA ions would dip under the surface of the phosphate layer, due to an ionic attraction with the surface oxygens.

A similar but more detailed characterization was made on the NASICON(II) -type samples obtained. Table 1 lists data concerning the composition and structure of two typical samples prepared under different conditions. Both samples exhibited similar X-ray diffraction patterns, one of which is shown in Fig. 2(a). An organic analysis of sample A (obtained from a phosphorus-rich reaction mixture) yielded: N, 2.23; C, 0.32; H, 0.62 wt% or 1:0.17:3.89 in molar ratio, indicating that the NASICON(II) phase includes NH_4^+ ions, probably produced by the thermal decomposition of the TMA ions. An analysis of the deammonated form of sample A gave: ZrO_2, 51.2; P_2O_5, 44.5 wt% or 1:1.51 in P/Zr ratio. From the above data and the TG traces (described later), the composition of sample A was determined (Table 1). Sample B, obtained from a reaction mixture with a P/Zr ratio of 1.5, yielded solids containing fewer ammonium ions. The observed X-ray diffraction peaks for both samples were indexed on the basis of hexagonal cells with the lattice constants listed in Table 1. It has been noticed that the ammonium-exchanged form of $MZr_2(PO_4)_3$ contracted along the a axis and expanded along the c axis, compared to the Li, Na, or K forms.[5]

Figure 3 shows the TG curves for samples A and B. Upon heating, the ammonium form releases its water at 280—350°C and undergoes deammonation at 400—

640°C to convert to the proton analogue $HZr_2(PO_4)_3$. This conversion was confirmed by an IR observation. During the second weight loss, the NH_4^+ deformation band at 1440 cm^{-1} disappears and the band due to OH stretching appears at 3645 cm^{-1}. The third weight loss at higher temperatures is due to the condensation of the phosphate groups.

Ion-exchange-capacity measurements on samples A and B and their calcined products were made using the procedure described before. In each run, the pH of an equilibrated solution decreased from an initial value of *ca.* 4.5 to 2—3.5 in 24—30 h and remained constant for longer times. The data obtained are summarized in Table 2. The X-ray diffraction profiles of the calcined products were characterized by the shift of the two diffraction peaks corresponding to the (104) and (110) reflections of the ammonium form as well as by the broadening or splitting of the peaks corresponding to its (012) and (124) reflections, as shown in Fig. 2 (b) and (c). For sample A-1, calcined at 600 °C for 1 h, the ion exchange capacities for Li^+ and Na^+ ions are close to 2.14 mmol g^{-1} for the theoretical capacity of $HZr_2(PO_4)_3$, while those for K^+ and Cs^+ are 25—55 times smaller than the theoretical value. The X-ray diffraction and IR patterns of sample A-1 were changed to those for $LiZr_2(PO_4)_3$ or $NaZr_2(PO_4)_3$ after treatment with their corresponding chloride solution, but little affected by using KCl and CsCl solutions. These findings indicate that the protons in $HZr_2(PO_4)_3$ are exchanged by unhydrated Li^+ and Na^+ ions which are 0.74 and 1.02 Å in ionic radius, respectively. Also, protons other than surface protons are unreplaceable by K^+ and Cs^+ ions which are 1.38 and 1.70 Å in ionic radius, respectively. Because of their isomorphous structures, the diameter of a bottleneck formed by three ZrO_6 octahedral edges and three PO_4 tetrahedral edges for $HZr_2(PO_4)_3$ would be close to that for $NaZr_2(PO_4)_3$, *i.e.*, twice the difference of the Na-O distance[11] and O^{2-}-ion radius (or 2.3 Å). This diameter is large enough to allow Li^+ and Na^+ ions to diffuse into the cavity in the $(Zr_2P_3O_{12})^-$ framework, but too small for K^+ and Cs^+ ions. Thus, that the selectivity of $HZr_2(PO_4)_3$ for Li^+ and Na^+ uptakes is much higher than that for the others can be attributed to an ion-sieving effect of the intracrystalline bottleneck. It has also been noticed that the number of protons replaceable by Li^+ and Na^+ ions decreases with an increase in calcination time. However, the number of protons replaceable by K^+ and Cs^+ remains unaltered. One possible explanation for this behavior may be that the condensation of inner HPO_4^{2-} group in $HZr_2(PO_4)_3$ proceeds in preference to that of the surface ones.

α-zirconium phosphate	+	+	−	−	−	Ref. 10

a) +, Acidic color; −, basic color; +*, see text.

The acid strength of $HZr_2(PO_4)_3$ in water as well as in benzene was qualitatively determined using sample A-1. This compound was found to have, qualitatively, the same acid strength of Ho≥3.3 in both liquids. The data obtained are shown in Table 3, along with those for α-zirconium phosphate.[10] For Ho=+3.3, however, the triphosphate solid rapidly became pale red on contact with the indicator, but turned pale gray in 1 h or more. Such fading was not observed for the α-zirconium phosphate. These results indicate that the acid strength of $HZr_2(PO_4)_3$ in a little weaker than that of α-zirconium phosphate.

The authors wish to thank Mr. Y. Ogura and Y. Masuda for the preparation of high pressure bombs, Dr. M. Onoda for helpful advice regarding X-ray analysis, and Dr. F. Okamura and M. Goto for their fruitful

advice and encouragement during this work.

The essence of this article was presented in Abst. No. 4Q32 of the 49th National Meeting of the Chemical Society of Japan, 1984 (received December 10, 1983).

Mössbauer Study of ^{60}Co γ-Ray Irradiated $Fe_xMg_{1-x}(NH_4)_2(SO_4)_2 \cdot 6H_2O$

Nobuhiko SAKAI,* Fumiko SAKAI,† and Hisashi SEKIZAWA

(Received July 19, 1984)

The γ-ray radiolytic oxidation of Fe^{2+} ions in $Fe_xMg_{1-x}(NH_4)_2(SO_4)_2 \cdot 6H_2O$ ($x=1.0$, 0.75, 0.56, 0.35, and 0.075) is studied by Mössbauer spectroscopy. For $x \leqq 0.75$, a part of Fe^{2+} ions remain unoxidized even after heavy irradiation of ^{60}Co γ-rays in contrast to the complete disappearance of Fe^{2+} ions for $x=1.0$. At least three kinds of Fe^{3+} ions are produced, and two of them order magnetically at liquid He temperature. Their saturated relative amount after heavy irradiation depends on the concentration of Fe, and is well explained by the random distribution probability of Fe and Mg ions among the six neighboring metallic sites around the Fe^{2+} ion.

Irradiation of ^{60}Co γ-rays induces oxidation of Fe^{2+} ions in hydrated salts. This phenomenon has been explained by the OH radical mechanism, *i.e.* energetic electrons created by the γ-ray Compton scattering or the photo-electron effect induce OH radicals along their paths from coordination H_2O molecules around Fe^{2+} ions, and these OH radicals oxidize the Fe^{2+} to Fe^{3+} ions.[1-3] A Mössbauer spectroscopic study of the oxidation of Fe^{2+} ions in $FeSO_4 \cdot nH_2O$[1] supported the OH radical mechanism. The oxidation occurs when n is not zero, and the chemical formula of the final radiolytic product was proposed to be $Fe_x(OH)_y(SO_4)_z \cdot nH_2O$,[1] and an accurate formula was later established in the case of $FeSO_4 \cdot 7H_2O$ to be $Fe(OH)(SO_4) \cdot 2H_2O$.[2] Electron and γ-ray irradiation experiments on $Fe(NH_4)_2(SO_4)_2 \cdot 6H_2O$ also indicate radiolysis of the water of crystallization.[4,5] The OH radical mechanism due to the electron capture process of ^{57}Co to ^{57}Fe was also suggested by a Mössbauer experiment on ^{57}Co-doped hydrated salts. However, except for the coordination water, little is known about the effect of the environment around a Fe atom on the oxidation of Fe^{2+} by γ-ray irradiation in a hydrated salt. Even though the water molecules around a Fe^{2+} are necessary to oxidize Fe^{2+} to Fe^{3+} at the primary step of the oxidation process, it is not clear whether their presence itself is sufficient or not for the final stabilization of Fe^{3+} ions in solids.

Besides the studies of the OH radical oxidation, after-effects of Auger ionization following electron capture were studied[6] using several ^{57}Co-labelled Co(III) complexes having no H_2O molecules. In some cases, depending on the structure of neighboring molecules, Fe(II) states were observed in emission spectra, which led to the conclusion that fragmentation of the parent molecules occurred as a consequence of the Auger ionization. Furthermore, emission spectra of ^{57}Co-labelled Co(III) complexes, containing various anions in the second coordination sphere, revealed that the yield of Fe(II) state was strongly affected by the presence of oxalate anions in the second coordination sphere.[7]

In the present study, a mixed crystal system $Fe_xMg_{1-x}(NH_4)_2(SO_4)_2 \cdot 6H_2O$ was prepared to examine the effect of the environment around a Fe^{2+} ion on its oxidation induced by the γ-ray irradiation. Here, the environment around a Fe^{2+} ion is characterized by a local distribution of Mg^{2+} ions which is expected to be stable under γ-ray irradiation.

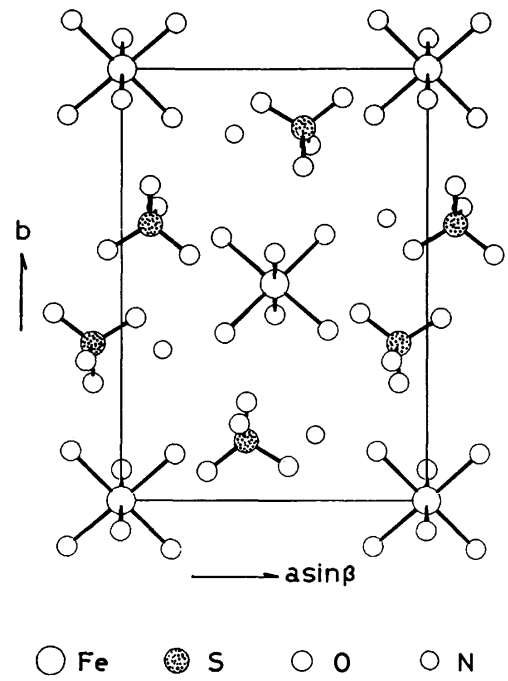

Fig. 1. Crystal structure of $Fe(NH_4)_2(SO_4)_2 \cdot 6H_2O$. The dimensions of the unit cell are $a=9.324$ Å, $b=12.65$ Å, $c=6.24$ Å, and $\beta=106.8°$.[8]

The crystal structure of ammonium magnesium sulfate hexahydrate, $Mg(NH_4)_2(SO_4)_2 \cdot 6H_2O$, is isomorphous to that of $Fe(NH_4)_2(SO_4)_2 \cdot 6H_2O$, and a desired amount of Mg ions can be mixed without changing the monoclinic crystal structure of $Fe(NH_4)_2(SO_4)_2 \cdot 6H_2O$. A unit cell of this crystal is shown in Fig. 1. Each Fe ion in this crystal structure is surrounded by six H_2O, two NH_4, and two SO_4 molecules as first neighbors. Further apart, there are six Fe ions as second neighbors. If only the first neighbors around a Fe^{2+} ion contribute to the stabilization of a Fe^{3+} ion produced by irradiation, the ratio of Fe^{2+} to the induced Fe^{3+} ions should remain constant after the same irradiation dose, independent of a different Mg concentration. Therefore, if the ratio of Fe^{2+} to Fe^{3+} ions is found to change with the concentration of Mg ions, we can say that the stablization of the induced Fe^{3+}

ions are affected by the second neighboring Mg, Fe ions, or other molecules.

Experimental

Mixed crystals of $Fe_xMg_{1-x}(NH_4)_2(SO_4)_2\cdot 6H_2O$ were prepared by dissolving commercially available reagents of x amount of $Fe(NH_4)_2(SO_4)_2\cdot 6H_2O$ and $1-x$ amount of $Mg(NH_4)_2(SO_4)_2\cdot 6H_2O$ into water for x=1.0, 0.8, 0.6, 0.4, and 0.1. Concentrations of Fe in the precipitated mixed crystals from saturated solution at room temperature were determined by chemical analysis to be 0.75, 0.56, 0.35, and 0.075 for x=0.8, 0.6, 0.4, and 0.1, respectively. The observed X-ray diffraction patterns of the mixed crystals were equivalent to that of $Fe(NH_4)_2(SO_4)_2\cdot 6H_2O$. The mixed polycrystals were irradiated by ^{60}Co γ-rays at temperatures below 42°C in loosely sealed glass tubes. The ^{60}Co γ-ray irradiation was accomplished up to 5.23×10^9 rad(H_2O). The dose rate was between 2.80 and 2.93×10^6 rad(H_2O)/h.

After being irradiated with the desired amount of dose, a part of each specimen was separated from the glass tube and mixed with vacuum grease for the Mössbauer spectroscopic analysis. After the heavy irradiation, the specimens were broken to fragile blocks, and the specimen with x=1.0 slightly moistened. Their colors were white or yellow-brown depending on the concentration of Fe ions. After an irradiation of 5.23×10^9 rad(H_2O), $Fe(NH_4)_2(SO_4)_2\cdot 6H_2O$ crystals turned almost totally to blocks of transparent acicular crystals. The dimensions of each crystal were about 0.01 mm in diameter and 0.2 mm in length.

Results

Measurements of the Mössbauer spectra of the irradiated samples were made mainly at room temperature, and partly at liquid N_2 and liquid He temperatures. The Mössbauer spectra were analyzed by a computer processing which includes least squares fitting of Lorentzian curves to the experimental absorption peaks, with a correction for the base-line sag. The same recoilless fraction was assumed for all the Fe ions. The assignments for Fe^{3+} in the following are based on the values of the isomer shifts of the corresponding absorption peaks.

$Fe(NH_4)_2(SO_4)_2\cdot 6H_2O$: The Mössbauer spectra of the irradiated $Fe(NH_4)_2(SO_4)_2\cdot 6H_2O$ specimens measured at room temperature are shown in Fig. 2. The fitted absorption peaks are shown in the figure by the solid curves. Before irradiation, only the quadrupole-split peaks of Fe^{2+} were observed. The Fe^{3+} peaks are successfully analyzed under an assumption of two kinds of quadrupole-split peaks(Fe^{3+} (1) and Fe^{3+} (2)). The Fe^{2+} peaks disappeared completely on heavy irradiation above 3.66×10^9 rad(H_2O), and no changes were observed in the Mössbauer spectra by further irradiation up to 5.23×10^9 rad(H_2O). The Mössbauer spectrum of a sample irradiated to 5.23×10^9 rad(H_2O) was also measured at 4.2 K and shown in Fig. 3a. The peaks of Fe^{3+} radiolytic products in this specimen can be resolved at least into three components, and two of

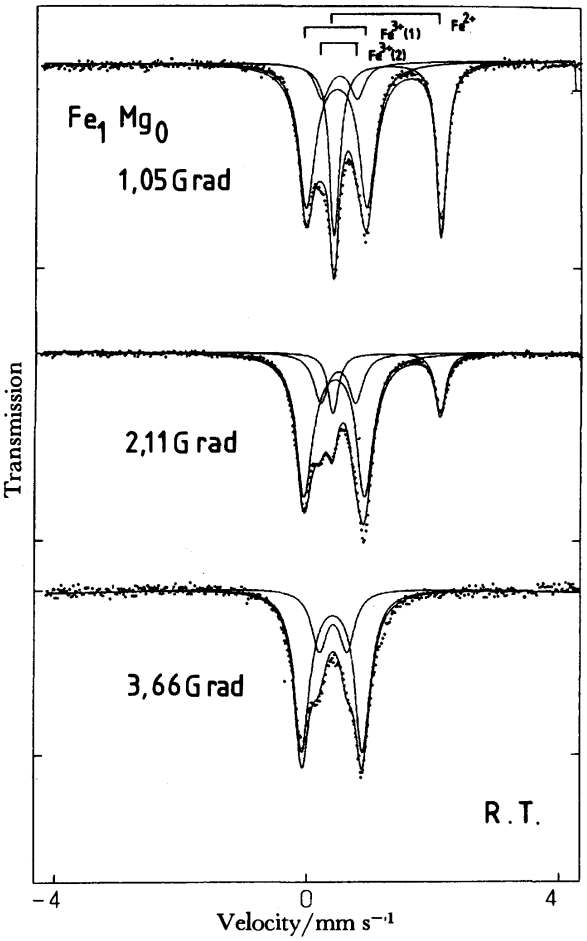

Fig. 2. Mössbauer spectra of $Fe(NH_4)_2(SO_4)_2\cdot 6H_2O$ irradiated by ^{60}Co γ-rays. The solid lines are the calculated absorption peaks.

them are in magnetically ordered states. The major component denoted by Fe^{3+} (1a) evidently corresponds to the recognized acicular small crystals. The minor component denoted by Fe^{3+} (1b) in the figure was not resolved in the room-temperature spectrum, and is considered to be included in the Fe^{3+} (1) component. The values of the hyperfine magnetic fields and other Mössbauer parameters are tabulated in Table 1, together with those at room temperature.

The total amount of Fe^{3+} approaches nearly exponentially to a constant value in relation to the γ-ray dose. From the Fe^{3+}/Fe ratio determined by the computer fitting, the G value (the number of Fe^{3+} ions produced for each 100 eV of energy absorbed) is evaluated to be 2.65±0.35 for the ^{60}Co γ-ray dose below 2.7×10^9 rad(H_2O); the ratio of the atomic number Z to the mass number A for the specimen and that for water were used to estimate the absorbed dose in the specimen.

The effect of humidity on the oxidation was examined in some cases. A specimen in a sealed tube with CaO as desiccant was irradiated. After an irradiation of 1.1×10^9 rad, the remaining Fe^{2+} peak became broad and the amount of Fe^{3+} was markedly higher, *i.e.* Fe^{2+}/Fe was lower in comparison with the irradiation

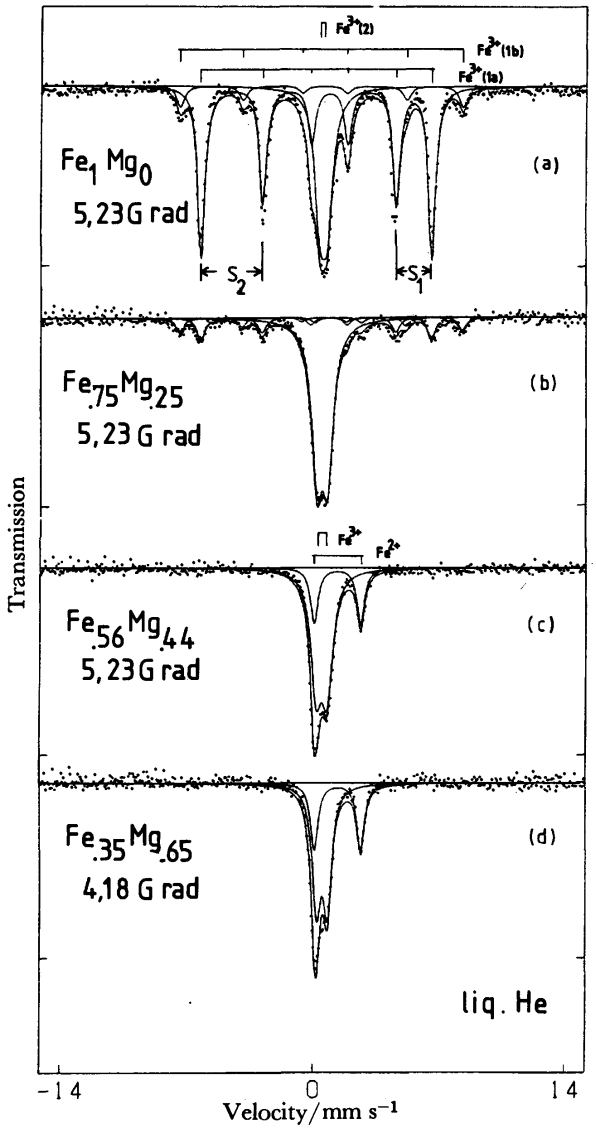

Fig. 3. Mössbauer spectra of γ-ray irradiated $Fe_xMg_{1-x}(NH_4)_2(SO_4)\cdot 6H_2O$ measured at 4.2 K.

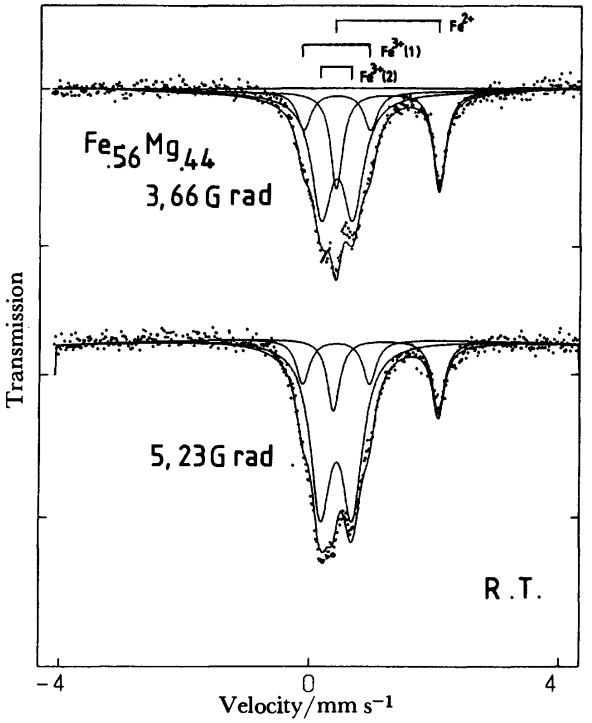

Fig. 4. Mössbauer spectra of γ-ray irradiated $Fe_{0.56}Mg_{0.44}(NH_4)_2(SO_4)_2\cdot 6H_2O$ measured at room temperature.

in air (see Fig. 6). On the contrary, the Fe^{2+}/Fe ratio was higher when a specimen was irradiated together with a small amount of water.

$Fe_xMg_{1-x}(NH_4)_2(SO_4)_2\cdot 6H_2O$: The Mössbauer spectra of the irradiated mixed crystals with $x=0.56$ and $x=0.075$ measured at room temperature are shown in Figs. 4 and 5, respectively. The Fe^{2+} quadrupole splitting of $x=0.075$ is 2% smaller than that of $x=1.0$. All spectra were analyzed by assuming two Fe^{3+} components ($Fe^{3+}(1)$ and $Fe^{3+}(2)$). The best fitted values of the quadrupole splitting and the isomer shift of $Fe^{3+}(2)$ were not the same for all the spectra and distributed to some extent as tabulated in Table 1. In the case of the specimen with $x=0.56$, some of the Fe ions retain the Fe^{2+} state even after the irradiation of 5.32×10^9 rad(H_2O) which was sufficient in the case of $Fe(NH_4)_2(SO_4)_2\cdot 6H_2O$ to change all Fe^{2+} ions to Fe^{3+}. The suppression of the radiolytic oxidation of Fe^{2+} ions is more significant for $x=0.075$ as can be seen in Fig. 5. Almost 85% of Fe ions still remain in the Fe^{2+} state after an irradiation of 2.8×10^9 rad(H_2O). The ratio of the remaining Fe^{2+} to the total Fe *versus* the γ-ray dose is plotted in Fig. 6. It should be noted that the Fe^{2+}/Fe ratios measured at liquid N_2 temperature agreed with those at room temperature within 5%. Then, the assumption that Fe^{2+} and Fe^{3+} ions have the same recoilless fraction is fairly good. It is characteristic that all the curves for the Fe^{2+}/Fe ratios are saturated. The

saturated final value of the Fe^{2+}/Fe ratio is lower for higher concentration of Fe ions.

Figure 3b shows a spectrum of the specimen with $x=0.75$ measured at 4.2 K after an irradiation of 5.23×10^9 rad(H_2O). The $Fe^{3+}(1)$ component having a large quadrupole splitting at room temperature orders magnetically, but the rest of the $Fe^{3+}(2)$ having a smaller splitting does not. The room-temperature Mössbauer spectrum of $x=0.56$ contains a small amount of the $Fe^{3+}(1)$ component. However, no magnetically split peaks were observed at 4.2 K for this specimen (see Fig. 3c). This can be ascribed to the weak intensities of these absorption peaks.

Discussion

The Mössbauer spectra of the mixed crystals $Fe_xMg_{1-x}(NH_4)_2(SO_4)_2 \cdot 6H_2O$ show that the relative amount of the Fe^{3+} radiolytic products to the total Fe varies remarkably with the concentration of Mg ions. The evaluated absorbed dose in each mixed crystal from the Z/A ratio different slightly from one another, but their mutual deviations are only within 2%. Thus the large differences in the saturated ratios of the remaining Fe^{2+} to the total Fe (Fig. 6) can not be explained by these slight differences between the absorbed doses in the mixed crystals.

We notice that there are two kinds of Fe^{3+} ($Fe^{3+}(1)$ and $Fe^{3+}(2)$) in the spectra shown in Figs. 2—4; one of them orders magnetically at 4.2 K and another does not. There is a possibility of another Fe^{3+} component ($Fe^{3+}(3)$) to exist, which has a much smaller quadrupole splitting, in the spectra of $x=0.075$ and 0.35, because its addition is effective in obtaining a better fitted spectrum as shown in Fig. 5; this component does not order magnetically at 4.2 K.

In Fig. 7, the summed saturated ratio of the magnetically ordered components ($Fe^{3+}(1)=Fe^{3+}(1a)+Fe^{3+}(1b)$) to the total Fe, and that of the rest Fe^{3+} ($Fe^{3+}(2,3)$) are plotted separately. We can analyze the behavior of these ratios as follows. Since the ratios depend on the Fe concentration, the spacial statistical average for the distribution of Fe in the mixed crystal seems to be related to these ratios. Assuming a random distribution of Fe and Mg atoms among the simple cubic lattice, we can estimate the probability that we find N or more than N Fe atoms within a sphere with radius

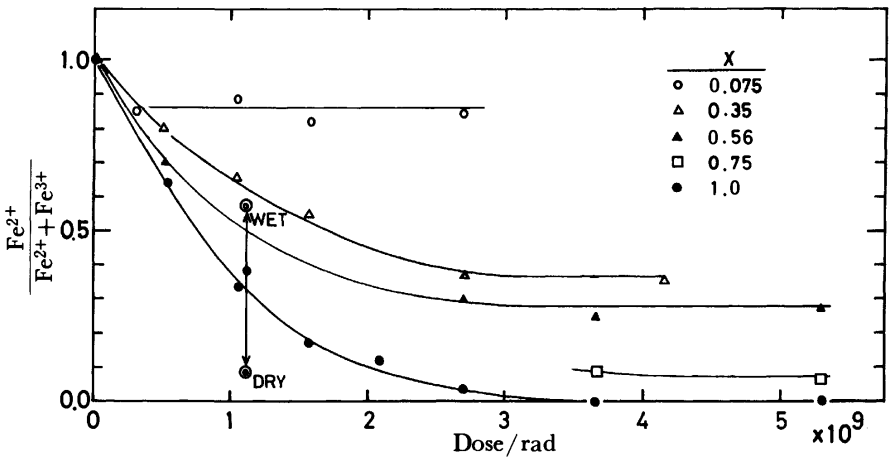

Fig. 6. Fe^{2+}/Fe ratios determined by the calculated Mössbauer absorption intensities. The notations WET and DRY for $x=1.0$ denote the specimens irradiated with water and CaO, respectively.

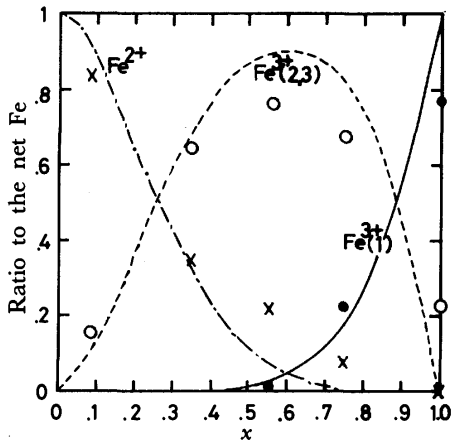

Fig. 7. The ratios of the saturated amount of Fe^{3+} ions induced by γ-ray irradiation and the remaining Fe^{2+} ions. The notations $Fe^{3+}(1)$ and $Fe^{3+}(2,3)$ denote the magnetically ordered component and the rest one, respectively.

R around an Fe atom. Figure 8 shows the concentration dependence of this probability. The unit of the radius is the lattice constant of the simple cubic lattice. The change of the probability becomes steep as the radius increases, that is, as the number of the sites in the sphere increases. The observed ratios shown in Fig. 7 change rather gradually against the Fe concentration. Then the effective local environment, which is considered to be related to the formation of stable Fe^{3+} ions, is best characterized by the probability for R= 1.0. This means that only the neighboring six metallic-ion sites are strongly related to the radiolysis of a Fe atom.

Using the probability for R=1.0, we can interpret the saturated ratios of the remaining Fe^{2+}, $Fe^{3+}(1)$, and $Fe^{3+}(2,3)$. When a Fe^{2+} is initially surrounded by six or five Mg ions ($N<2$), this Fe^{2+} ion cannot be oxidized into a stable Fe^{3+} ion by the ^{60}Co γ-ray irradiation (dot-dashed curve: N=2 curve of Fig. 8(a) being inverted), even though water molecules exist as the nearest neighbors. The ratio of the $Fe^{3+}(2,3)$ components can be explained by the total probability that any number of Fe ions from 2 to 5 initially occupies the neighboring six metallic-ion sites (dashed curve: the vertical distance from the curve 2 to 6 of Fig. 8a). The distributed values of the quadrupole splitting of $Fe^{3+}(2,3)$ component as mentioned in Table 1 reflect the occurrence of the different sites of this component. Furthermore, if the neighboring six metallic ion sites around a Fe^{2+} ion are initially all occupied by Fe ions, this Fe^{2+} ion is oxidized and has a possibility to recrystallize into the new compounds denoted by $Fe^{3+}(1)$. The calculated probability is shown in the figure by a solid curve.

The above proposed interpretation implies that the Fe^{3+} ions are stabilized only when more than one Fe^{3+} states are produced among the neighboring six sites at the same time or within the relaxation time of Fe^{3+} states, and these Fe^{3+} states are probably stabilized by constituting a Fe^{3+} ion cluster. In a low Fe concentration region, these clusters are considered to be created isolatedly, and Fe^{3+} ions ($Fe^{3+}(2,3)$) in the clusters cannot be in a magnetically ordered state, at least above 4.2 K. In a high Fe concentration region, $x>0.5$, a part of the created clusters can segregate new Fe^{3+} compounds (Fe^{3+}(1a,1b)), because the original mixed crystal possesses many paths which connect Fe ions without interruption by Mg ions. According to the percolation theory, the percolation probability of the simple cubic lattice is 0.254 for the site property.[9]

This simple model, however, does not completely explain the observed ratios; fairly large Fe^{2+} ratios above x=0.5, and the existence of the nonmagnetic component at x=1.0. It should be emphasized that the proposed model describes only the initial circumstance around a Fe^{2+} ion, and does not specify the process of recrystallization of the material, which will occur

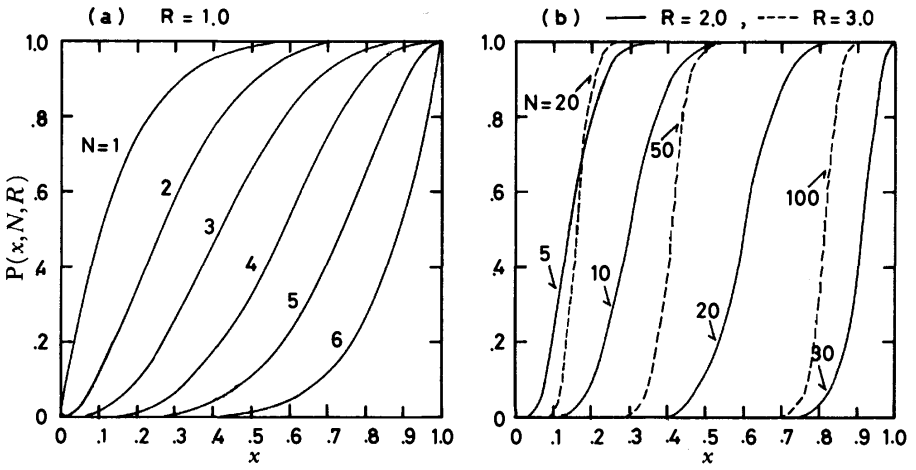

Fig. 8. The probabilities that N or more than N Fe atoms are found in a sphere of radius R. Fe atoms with a concentration of x are assumed to be dispersed at random on the simple cubic lattice sites. (a) R=1.0, and the number of the lattice sites in the sphere, N_s, is 6. (b) solid curves; R=2.0 and N_s=32, dashed curves; R=3.0 and N_s=122.

during irradiation for several months. Therefore, during recrystallization, the model-calculated ratios of Fe^{3+} ions will be modified. As mentioned above, humidity evidently affected the formation of the Fe^{3+} compound. Particularly, when the initial amount of water of crystallization is not the same as the final one, as it probably is in the present case, excess water molecules will play an important role in the recrystallization process, which act to suppress the formation of Fe^{3+} ions. The amount of the remaining Fe^{2+} ions above $x=0.5$, which is larger than the model-calculated value, seems to be due to this excess water. Thus, the final amount of Fe^{3+} ions is the result of at least two competitive processes; the OH radical process which is considered to be an important mechanism at the primary step of the radiolysis, and the following recrystallization process.

The radiolytic chemical reaction which produces Fe^{3+}(1a) component from $Fe(NH_4)_2(SO_4)_2\cdot 6H_2O$ is considered to be

$$Fe(NH_4)_2(SO_4)_2\cdot 6H_2O \rightsquigarrow Fe(NH_4)_2(OH)(SO_4)_2\cdot nH_2O + 1/2H_2 + (5-n)H_2O, \quad (n<5),$$

because i) the radiolytic product did not have an odour of ammonia, and ii) SO_4 molecules are not separated by the γ-ray irradiation in the case of $FeSO_4\cdot 7H_2O$. The measured X-ray diffraction pattern of the radiolytic product from $Fe(NH_4)_2(SO_4)_2\cdot 6H_2O$ could not be found in the X-ray powder diffraction file.[10] To the authors' knowledge, a material having the chemical formula $Fe(NH_4)_2(OH)(SO_4)_2\cdot nH_2O$ is not known.

Conclusion

The ^{60}Co γ-ray irradiation induced the oxidation of Fe^{2+} ions in a mixed salt $Fe_xMg_{1-x}(NH_4)_2(SO_4)_2\cdot 6H_2O$ (x=1.0, 0.75, 0.56, 0.35, and 0.075). At least three kinds of Fe^{3+} states were clearly observed, and the relative saturated amount of the induced Fe^{3+} ions to the total Fe ions in each mixed salt varied remarkably with the concentration of Mg ions. This phenomenon can not be explained only by the presence of the coordination water. The simple six-neighbor metallic site model, which represents the effective initial environment around a Fe^{2+} ion, well explains the characteristic concentration dependence of the saturated amounts of these Fe^{3+} radiolytic products. This result suggests that the initial environment, which includes only the neighboring six metallic ion sites around a Fe^{2+} ion, strongly affects the formation of the final Fe^{3+} products from this mixed hydrated salt. It is interpreted that the induced Fe^{3+} states are only stabilized when more than one Fe^{3+} ions are produced among the neighboring six sites at the same time or within the relaxation time of Fe^{3+} states, and these Fe^{3+} states are probably stabilized by constituting a Fe^{3+} cluster. In a high Fe concentration region, these clusters can segregate new Fe^{3+} compounds. However, to clarify the discrepancy between the model-calculated ratios and the experimental ones, more detailed consideration on the recrystallization process is required.

We are grateful to Dr. T. Okada for his helpful advice on the Mössbauer measurements, and Mr. K. Nakano for his assistance in the operation of the γ-irradiation equipment.

The Distribution of Mercury, Arsenic, and Antimony in Sediments of Kagoshima Bay

Hayao SAKAMOTO
Department of Chemistry, Faculty of Science, Kagoshima University, Koorimoto, Kagoshima 890
(Received September 8, 1984)

Mercury, arsenic, and antimony were determined in marine sediments collected from Kagoshima Bay, and their distribution was investigated. The contents of mercury, arsenic, and antimony in surface sediments were higher than those in the marine sediments of the open ocean. The average contents of mercury, arsenic, and antimony in surface sediments in the northern part of the bay were higher than in the southern part. The high-temperature sediments (about 200 °C) in the vicinity of a sea bottom fumarole, located at a depth of about 200 m in the northern part of the bay, showed abnormal concentrations of mercury, arsenic, and antimony derived from the fumarole gas; the contents of these components decreased sharply with an increase in the distance from the fumarole. A high degree of positive correlation was found among the contents of the three components (mercury, arsenic, and antimony) over the northern part of the bay. In contrast, no such correlation was observed in the southern part of the bay. This is in accord with the fact that volcanic activity is more vigorous in the northern than in the southern part of the bay.

In November, 1973, high pollution with mercury exceeding the "provisional permissible level for mercury contained in fishes and shellfishes (0.4 mg kg^{-1})" was found[1] in some of the *Trichiurus lepturus* caught in the northern part of Kagoshima Bay.

Investigations of other types of fish then followed, and autonomous regulation was extended to include ten other types of fish (*Trachurus japonicus, Nemipterus bathybius, Conger myriaster, etc.*) by August, 1975. Concurrently, extensive studies[2-4] of the mercury pollution of fishes living in Kagoshima Bay, investigation of possible pollution sources,[5-7] and medical checks[8-10] of the local inhabitants have been carried out by the aid of the central and local governments. In spite of these efforts, however, the mechanism of the pollution of fish with mercury is not yet absolutely clear.

Mercury, arsenic, and antimony are elements of special interest in connection with volcanic activity[11,12] because of the volatility they exhibit as elements and in the form of compounds.

This study will concentrate on the volatile components (mercury, arsenic, and antimony) derived from volcanic activity based on the notion that volcanic activity must be related to the marine environment of Kagoshima Bay. The horizontal and vertical distributions of the mercury concentration in sea water of Kagoshima Bay have previously been reported.[13] This paper describes the results of concentrations on mercury, arsenic, antimony in marine sediments collected from Kagoshima Bay.

Experimental

General Circumstances of Kagoshima Bay. Kagoshima Bay is a narrow inner bay (about 75 km long and about 25 km wide)—an arm of the sea penetrating far into the land from south to north.

Its bottom has unique topographic features, as may be seen from the vertical section shown in Fig. 1. Sakurajima Volcano, standing between the central and northern parts of the bay, separates the two sea areas, which communicate

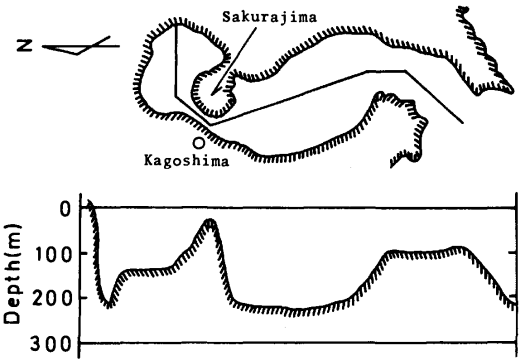

Fig. 1. Vertical section of Kagoshima Bay.

with each other only through Nishi Sakurajima Suidō, a shallow area about 40 m deep. Thus, sea-water exchange between the northern part (140 to 200 m deep) and the open ocean is not easy. The progress of pollution in the whole bay caused by human activities, both connected with daily living and industrial, is also dictated by the sea-water exchange because of the intricate topography of the bay's bottom. Considerable fumarolic activity is observed around Points **A** and **B** in the northern part of Kagoshima Bay (Fig. 2); this activity influence the marine environment in a number of ways. On the other hand, the speed of sediment accumulation in Kagoshima Bay is high due to the emissions from Minamidake of Sakurajima Volcano, which has continued to be active since October, 1955. The effects of the volcano emissions upon the sediments will be reported in a separate paper.

Methods of Collecting and Preserving Sedimentary Samples. A Smith-McIntyre spring-loading grab was used to collect surface sediments, and a Fhleger bottom sampler, equipped with a plastic inner tube 3.3 cm in inside diameter, was employed for the investigation of the vertical distribution. The sediment sample collected was immediately cut at 10 cm intervals; each fragment was enclosed in a polystyrene bottle, refrigerated at the site, and then brought back to our laboratory. Each sample was then suction-filtered with a 0.45 μm Millipore filter, air-dried (taking care to avoid any extraneous contamination), and ground in an agate mortar. The uniform sediment samples thus obtained were preserved for the subsequent determination of mercury, arsenic, and antimony.

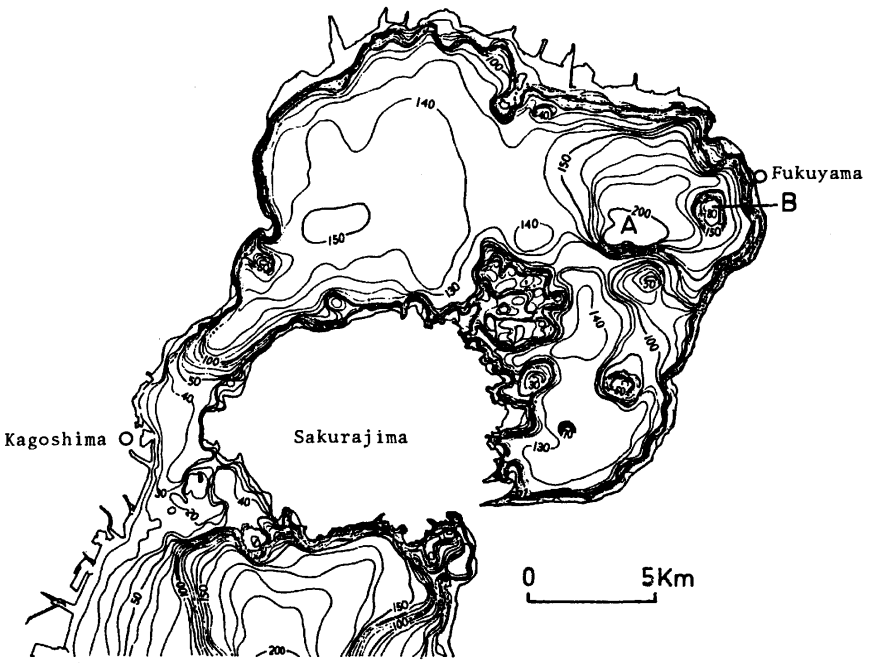

Fig. 2. Topographical map of northern Kagoshima Bay and the locations (A and B) where the submarine fumarolic activities were found.

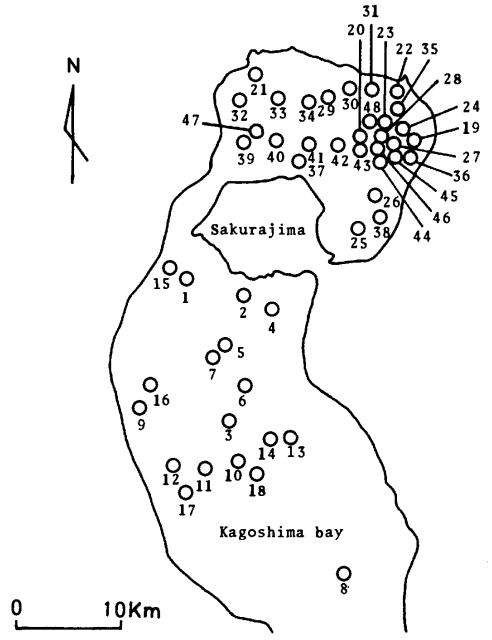

Fig. 3. Sampling stations of marine sediments in Kagoshima Bay.

Sampling Stations in Kagoshima Bay. The sediment sampling stations in Kagoshima Bay are shown in Fig. 2 and Fig. 3; the station numbers are tabulated in Table 1.

Apparatus. The apparatus used included a Rigaku Mercury SP (this apparatus was connected to an Ohkura recorder); a Hitachi spectrophotometer Model 101; an Iwaki-KM (Model V-D) shaker, and a Shimadzu-MAF atomic-absorption spectrophotometer.

Reagents. *Standard Solution of Mercury(II), 1 mg cm^{-3}*: Dissolve 1.354 g of mercuric chloride in 10 cm^3 of 5 mol dm^{-3} sulfuric acid, and dilute to 1000 cm^3 with water.

Standard Solution of Arsenic(III), 1 mg cm^{-3}: Dissolve 1.320 g of diarsenic trioxide in 10 cm^3 of 10 mol dm^{-3} sodium hydroxide, and dilute to 1000 cm^3 with water.

Standard Solution of Antimony(III), 1 mg cm^{-3}: Dissolve 1.874 g of antimony trichloride in water, and dilute to 1000 cm^3 with water.

The acids used (sulfuric acid, nitric acid, hydrochloric acid, hydrofluoric acid, perchloric acid) and potassium permanganate were all analytical-special-reagent-grade for the measurements of the toxic metals.

Procedure for the Determination of Mercury. A sediment sample (0.02 to 0.20 g), homogenized as much as possible under wet or air-dried conditions, was weighed out into a porcelain boat previously ignited to exclude any trace of mercury that might be left adhered, and covered with an addition agent (calcium hydroxide and sodium carbonate, both ignited at 700°C and then mixed in a 1:1 volume ratio). The analytical sample thus prepared was heated in the furnace of a mercury analyzer at about 300°C for three minutes, and then at about 700°C for four minutes to complete the decomposition; the mercury vapor thus evolved was caught in a potassium permanganate solution acidified with sulfuric acid[14] or with a porous gold collector.[15] In the method using a porous gold collector, once the collector heating time is properly set on the timer, the evolution of mercury vapor and its measurement by cold vapor atomic-absorption spectrometry are performed automatically, giving results of a high reproducibility in a short time.

Procedure for the Determination of Arsenic. A sediment sample (0.05 to 0.20 g) was weighed out into a Teflon beaker; 4 cm^3 of perchloric acid (60%), 3 cm^3 of sulfuric acid (96 to 98%), 8 cm^3 of hydrofluoric acid (46%), and 2 cm^3 of potassium permanganate solution (2%) were then added, and the mixture was heated on a hot plate (100°C) to effect decomposition and subsequently evaporated to dryness. After cooling, 3 cm^3 of 12 mol dm^{-3} hydrochloric acid and 6 cm^3 of

redistilled water were added to dissolve the residue, and the solution was transferred into an arsine generator, where the arsenic was separated as arsine (AsH_3) by the addition of arsenic-free zinc and determined by the Ag-DDTC method.[16] The results of this method showed good agreement with those obtained by atomic-absorption spectrometry.[17]

Procedure for the Determination of Antimony. A sediment sample (0.05 to 0.50 g), weighed out into a porcelain crucible, was fused with 2.5 g of potassium pyrosulfate. After cooling to room temperature, 10 cm^3 of 6 mol dm^{-3} hydrochloric acid, 10 cm^3 of 6 mol dm^{-3} sulfuric acid, and 5 cm^3 of redistilled water were added to dissolve the fusion product, the solution was transferred into a separating funnel, and the antimony was determined by the Rhodamine B method.[18]

The contents of mercury, arsenic, and antimony in the marine-sediment samples were measured according to the methods described above. Actual analysis was made on air-dried samples. Separately, part of each sample was heated at 110 °C for 6 h to determine the weight loss; the measurements were then converted to the values on a bone-dry basis.

Results and Discussion

Contents of Mercury, Arsenic, and Antimony in Surface Sediments (0 to 10 cm deep). The analytical results for the contents of mercury, arsenic, and antimony in surface sediments (0 to 10 cm deep) of Kagoshima Bay are shown in Table 1. In the following discussion,

a) A is the area 200 m-deep within *ca.* 100 m from the center of the fumarole group. b) B is the area 78 m-deep within *ca.* 50 m from the center of the fumarole group. c) C is the area excluding A and B. d) $\overline{X_A}$ is the arithmetic mean. e) $\overline{X_G}$ is the geometric mean. f) n is the number of determined samples.

Kagoshima Bay is divided into two sections by the line connecting Kagoshima City and Sakurajima: The southern part (Stn. 1 to 18) and the northern part (Stn. 19 to 48, A and B). The results for the northern part are summarized in Table 2, in which data are separately shown for the 200 m station (A), the 78 m station (B), and the other stations (C). $\overline{X_A}$ represents the arithmetic mean; $\overline{X_G}$ the geometric mean, and n; the number of samples collected. It is apparent from the table that the contents of mercury, arsenic, and antimony at the 200 m station (A) are abnormally high. The data for the 200 m and 78 m stations are those of sediment samples collected in a past survey; (an investigation by the government and Kagoshima prefecture, in which the author paticipated as a member, which was carried out to determine if the mercury derived from volcanic activity is responsible for the mercury pollution of fishes and shellfishes).

These samples were collected by means of a submarine boat (HAKUYO; displacement, 6.6 tons) while visually observing the sea-bottom fumarole. No abnormal values, such as those seen at the 200 m station, were found at the 78 m station. This difference may probably be correlated to the fact that the fumarole gas at the 78 m station is relatively low in temperature and has a composition similar to that of natural gas, while the fumarole gas at the 200 m station is considerably high in temperature (the max. was 215 °C) and contains much hydrogen *etc.*[6] The average values of mercury, arsenic, and antimony in the surface sediments collected from the southern part, in which volcanic activity is milder, are lower than those in the northern part.

Horizontal Distribution of Mercury, Arsenic, and Antimony in Surface Sediments of Kagoshima Bay. Figures 4—6 show the horizontal distribution on mercury, arsenic, and antimony in surface sediments collected at 48 stations over the entire area of Kagoshima Bay.

Higher contents of these compositions are observed in the northern part, particularly in the vicinity of the 200 m-deep fumarole and in the area near the estuary of the river Amori, flowing down from the Kirishima Volcano region. This suggests a close correlation of the mercury, arsenic, and antimony components to volcanic activity.

Sedimentary samples with abnormally high concentrations of mercury, arsenic, and antimony, as collected near the 200 m deep fumarole, have never been found in any ship survey from sea level.

Let us now compare the mercury content in surface sediments collected in Kagoshima Bay with those in other inner bays.

Already reported are 0.12—0.33 mg kg^{-1} for Funka Bay,[19] 0.115—0.794 mg kg^{-1} for Tokyo Bay,[20] 0.190—0.550 mg kg^{-1} for Osaka Bay,[19] and 0.1—0.2 mg kg^{-1} for Tokuyama Bay[21] (20 cm deep). Compared with these values, the range of mercury concentrations observed in the southern and northern parts of Kagoshima Bay are lower (except for the vicinity of the 200 m-deep fumarole); 0.008—0.10$_8$ mg kg^{-1} (geometric mean: 0.033 mg kg^{-1}) and 0.002—0.73$_1$ mg kg^{-1} (geometric mean: 0.087 mg kg^{-1}) respectively.

However, an unusually high concentration range of 0.45$_9$—267 mg kg^{-1} (geometric mean: 4.0$_3$ mg kg^{-1}) is found in the limited area in the vicinity of the 200 m-deep fumarole.

Vertical Distribution of Mercury, Arsenic, and Antimony in Sediments of Kagoshima Bay. Figure 7 shows the vertical distribution of mercury, arsenic, and antimony contained in sediments of the northern (Stn. 48) and southern (Stn. 18) parts of Kagoshima Bay. In this figure, the contents of mercury, arsenic, and antimony (abscissa) are plotted against the depth (ordinate) (10 cm-interval vertical sections from the surface of the sediment to a depth of 100 cm).

In the southern part (Stn. 18), little change is observed in the contents of mercury, arsenic, and antimony with the depth. In the northern part (Stn. 48), on the other hand, the vertical distribution is uneven for mercury and arsenic. This figure also shows higher contents for all of the components in the northern than in the southern part. This tendency is also the case with the other sampling stations.

Relationship between Mercury and Arsenic Contents in Surface Sediments Around the Fumarole in the Northern Part. Figure 8 shows the relationship between the mercury and arsenic contents in the surface sediments collected at the 200 m-deep station around the fumarole in the northern part of Kagoshima Bay. As can be seen from the figure, a fairly high degree of positive correlation exists between the two (correlation coefficient: 0.65).

Relationship between Arsenic and Antimony Contents in Surface Sediments Around the Fumarole in the Northern Part. Figure 9 shows the relationship between the contents of arsenic and antimony in the same samples as have been used to describe the relationship between mercury and arsenic. Here, also, there is a high degree of positive correlation (correlation coefficient: 0.83).

Relationships of Mercury, Arsenic, and Antimony Contents to the Distance from the Fumarole (200 m-Deep

Locations in the Northern Part). Figure 10 shows the relationships between the contents of mercury, arsenic, and antimony in surface sediments and the distance from the fumarole. It is apparent from these figures that abnormal concentrations of mercury, arsenic, and antimony are observed only at hot positions near the fumarole. The contents of these components sharply decrease with the distance between the sampling position and the fumarole, gradually approaching the background level of the open ocean.

the contents of mercury, arsenic, and antimony in the northern than in the southern part. This is in accord with the more vigorous volcanic activity in the former than in the latter part.

It may be considered that factors such as geological circumstances (Kirishima and Sakurajima) and the intricate submarine topography of the northern part.

Conclusion

The horizontal and vertical distributions of the contents of mercury, arsenic, and antimony in the sediments collected from Kagoshima Bay have been studied. The results may be summarized as follows: (1) The distribution of mercury, arsenic, and antimony contents in the surface sediments of Kagoshima Bay revealed high concentrations of these components in a limited area in the northern part. (2) The vertical distribution of these components in sediments of Kagoshima Bay clearly showed higher concentrations in the northern than in the southern part. Little change was observed in the contents with the depth in the sediments of the southern part, but apparent changes with depth were noticed in the sediments of the northern part. (3) A high degree of correlation was found among the three components (mercury, arsenic, and antimony) in surface sediments of the northern part, but no such close correlation existed among those in the southern part. (4) Abnormal concentrations of mercury, arsenic, and antimony were found at a hot position, 200 m deep, near the center of volcanic activity in the northern part, and a sharp decrease in the contents of these components was observed with the increasing distance from the fumarole. This suggests that these components have been deposited as a result of volcanic activity which both took place in the past and are under way at present. (5) It has already been demonstrated[6] that all sediments containing mercury, arsenic, and antimony in markedly high concentrations are also rich in montmorillonite, stibnite, and dolomite.

It may thus be concluded that the abnormally high concentrations of mercury, arsenic, and antimony found in surface sediments at the hot position 200 m deep near the fumarole in the northern part of Kagoshima Bay is derived from natural volcanic activity at the sea bottom and is not caused by human activities.

Studies of the mechanism of mercury concentration in fishes are under way in various fields of research, but a satisfactory explanation has not yet been reached. For a complete elucidation, it would be essential to continue monitoring of water quality, sediments, living things, volcanic activity, and other phenomena in the bay.

The author wishes to express his thanks to Professor Masaakira Kamada of Kagoshima University, Professor Joyo Ossaka of the Tokyo Institute of Technology, Professor Takejiro Ozawa of Saitama University, and Dr. Junichi Hirabayashi of the Tokyo Institute of Technology for their helpful discussions. The author is also indebted to the Environmental Government and Environmental Pollution Control Section of Kagoshima Prefecture and the Institute of Environmental Pollution and Public Health of Kagoshima Prefecture for their practical assistance,

such as in the collection of samples, as well as for their endlessly helpful discussions during this investigation.

Studies of the Complexes of Np(V) with Inorganic Ligands by Solvent Extraction with Thenoyltrifluoroacetone and 1,10-Phenanthroline. I. Carbonato Complexes

Yasushi INOUE* and Osamu TOCHIYAMA

Department of Nuclear Engineering, Faculty of Engineering, Tohoku University, Aramaki-aza-Aoba, Sendai 980

(Received September 11, 1984)

The complex formation of Np(V) in a carbonate medium has been studied in 1 mol dm^{-3} $NaClO_4$ at pH 6.5—8.3 and 25 °C using the solvent-extraction method with thenoyltrifluoroacetone (TTA) and 1,10-phenanthroline. The formation constants of the complexes of Np(V) with CO_3^{2-} were $\log(\beta_1/\text{mol}^{-1}\,\text{dm}^3)=4.14\pm0.01$ and $\log(\beta_2/\text{mol}^{-2}\text{dm}^6)=6.78\pm0.01$, with no indication of the formation of HCO_3^- complexes. Based on these constants, the distribution of chemical species of neptunium are discussed under various conditions encountered in natural water.

The solution chemistry of neptunium has received much attention in recent years since the ^{237}Np in radioactive wastes will have a long-term radiological toxicity in the human environment. Since this element most probably exists as a quinquevalent state in neutral solutions, the study of the complex formations of Np(V) in aqueous solutions is very important for the understanding of the behavior of this element in natural water.

In spite of this importance, quinquevalent neptunium has not been extensively studied due to its reduced reactivity with various ligands as a result of its low ionic potential. However, recent studies[1,2] by means of solvent extraction with thenoyltrifluoroacetone (TTA) and 1,10-phenanthroline (phen) revealed that Np(V) still forms considerably stable complexes with many organic ligands such as hydroxy carboxylic acids, dicarboxylic acids, amino carboxylic acids and some other widely used chelating reagents.

This induced us to study the complex formation of Np(V) with some inorganic anions using the same solvent extraction technique. Among inorganic anions, the carbonate ion deserves special attention because of its pronounced tendency to interact with cations and because of its wide distribution in the environment. Since the formation of carbonato complexes is expected to affect the movement of neptunium in natural water, reliable stability constants are required for estimating the behavior of the element in the environment.

The present paper deals with the determination of the formation constants of Np(V)-carbonato complexes by means of solvent extraction with TTA and phen, and the distribution of chemical species of neptunium in solutions under various conditions are discussed based on the obtained results.

Experimental

Reagents. The ^{239}Np tracer was prepared by milking from ^{243}Am (obtained from the Commissariat a l'Energie Atomique) by the method of Sill,[4] and adjusted to the quinquevalent state by evaporation to dryness and dissolution in water.[5] Thenoyltrifluoroacetone and 2-morpholinoethanesulfonic acid monohydrate (MES) were obtained from Dojindo Laboratories (Kumamoto, Japan) and used without further purification. The solutions of these chemicals were freshly prepared just prior to use.

Procedures. To avoid the possible contamination by any complex-forming substances or by neptunium with a valence state other than quinquevalent (which might be introduced during milking), the following back-extraction procedure was adopted. The ^{239}Np tracer was first extracted into an organic (3-methyl-1-butanol or dichloromethane) solution containing the desired concentrations of TTA and phen. A 4-cm^3 portion of this organic solution containing ^{239}Np was then mechanically shaken for 15 min (140 times/min) at 25±1 °C in a glass tube with the same volume of aqueous solution containig 1 mol dm^{-3} sodium perchlorate, buffer reagents (a proper mixture of 0.1 mol dm^{-3} of MES and 0.1 mol dm^{-3} of tris(hydroxymethyl)aminomethane (THAM)) and a variable concentration of sodium hydrogencarbonate. After phase separation, a 1-cm^3 portion of each phase was pipetted into a counting tube and the γ-activity of each phase was measured with a well-type NaI(Tl) scintillation counter. The remaining part of the aqueous phase was used for the pH measurement.

Calculation of Stability Constants. The distribution ratio D of Np(V) in the presence of the complexing agent (X) can be expressed by:

$$D = D_0/(1+\sum\beta_n[X]^n), \quad (1)$$

where D_0 is the distribution ratio of Np(V) in the absence of the complexing agent, and β_n is the overall formation constant of the Np(V) complex with the ligand X (charges of ions are omitted for simplicity). Equation 1 is equivalent to linear function:

$$y = f(x), \quad (2)$$

where

$$y = 1/D,$$
$$f(x) = 1/D_0 + \sum(\beta_n/D_0)x^n,$$

and

$$x = [X].$$

A set of data (x_i, y_i) was analyzed by the least-squares method to determine the β_n values. Since the counting-time of the γ-activity was set to make the relative statistical errors of the total counts approximately constant, residuals of observed ratios, y, were expected to be proportional to the value of $1/D$ from error propagation rules. Although the observed value of $1/D$ is not error free, this value gives a good basis for an estimate of the weight of the observation. Therefore, the least-squares fitting was carried out to minimize the follow-

ing sum of the weighted squares of the residuals:

$$S = \sum\{y_i - f(x_i)\}^2/y_i^2. \quad (3)$$

This procedure is nearly equivalent to obtain a best fit of the plots of log D against log [X] to Eq. 1.

Results

The distribution ratio of Np(V) in the presence of a complexing agent can be expressed by Eq. 1. In the presence of a polybasic acid as a complexing agent, however, there is a possibility of the formation of different types of complexes; that is, the ligands in different stages of dissociation can react with Np(V). When ligands HL and L (charges omitted) can react with Np(V) in solution, the ratio D_0/D, the reciprocal of which is equivalent to the fraction of neptunium in the form of free ion (NpO_2^+), is given by:

$$D_0/D = 1 + \sum\beta'_n[HL]^n + \sum\beta_n[L]^n, \quad (4)$$

where β'_n and β_n are the overall formation constants of the respective complexes:

$$\beta'_n = [M(HL)_n]/[M][HL]^n, \quad (5)$$

$$\beta_n = [ML_n]/[M][L]^n, \quad (6)$$

where M=NpO_2^+. The concentration of HL and L can be related in terms of the acid dissociation constant:

$$K_a = [H][L]/[HL]. \quad (7)$$

Thus, Eq. 4 becomes:

$$D_0/D = 1 + \sum B'_n[HL]^n = 1 + \sum B_n[L]^n, \quad (8)$$

where

$$B'_n = \beta'_n + \beta_n K_a^n/[H]^n, \quad (9)$$

and

$$B_n = \beta'_n[H]^n/K_a^n + \beta_n. \quad (10)$$

Measurement of D as a function of [HL] or [L] leads to the apparently constant values of B'_n or B_n, provided that the extraction is carried out in a medium buffered at constant pH. Since B'_n or B_n is the function of pH, as expressed by Eq. 9 or 10, a set of B'_n or B_n obtained at various pH discloses the contribution of each series of complex formation to give the constant values, β'_n and β_n.

Six series of experiments were carried out on solutions ranging from pH 6.5 to 8.3 to obtain a distribution ratio at various added concentrations of sodium hydrogencarbonate. In each series of experiments, the distribution ratio was obtained in a medium buffered at constant pH. The pH of the aqueous phase drifted during extraction; the pH after shaking differed from the initial pH by less than 0.4 unit in each series of experiments and the experimental values of D were corrected to those at a constant pH by using experimental extraction curves which were obtained previously.[3] The concentration of a particular species of carbonate, [HCO_3^-] or [CO_3^{2-}], at an equilibrium pH was calculated according to the following relationship:

$$C_L = [H_2CO_3] + [HCO_3^-] + [CO_3^{2-}] = [H_2CO_3](1 + K_1/[H^+] + K_1K_2/[H^+]^2), \quad (11)$$

where

$$K_1 = [H^+][HCO_3^-]/[H_2CO_3] = 10^{-6.02}\ \text{mol dm}^{-3}, \quad (12)$$

$$K_2 = [H^+][CO_3^{2-}]/[HCO_3^-] = 10^{-9.57}\ \text{mol dm}^{-3}, \quad (13)$$

at 25 °C, μ=1.0.[6] In the calculation, the concentration of the undissociated acid in the organic phase was assumed to be negligibly small. To ascertain the validity of this assumption, two kinds of solvents, 3-methyl-1-butanol and dichloromethane, were used as an organic diluent. Plots of log(D/D_0) *vs.* log([HCO_3^-]/mol dm^{-3}) and log([CO_3^{2-}]/mol dm^{-3}) are given in Figs. 1 and 2, respectively. The plots in Figs. 1 and 2 give the values of B'_n and B_n in Eq. 8, respectively, if HL and L denote HCO_3^- and CO_3^{2-}, respectively. Since the plots in Fig. 2 indicate that the B_n values in Eq. 10 are independent of pH, it can be safely concluded that the complex formation of Np(V)

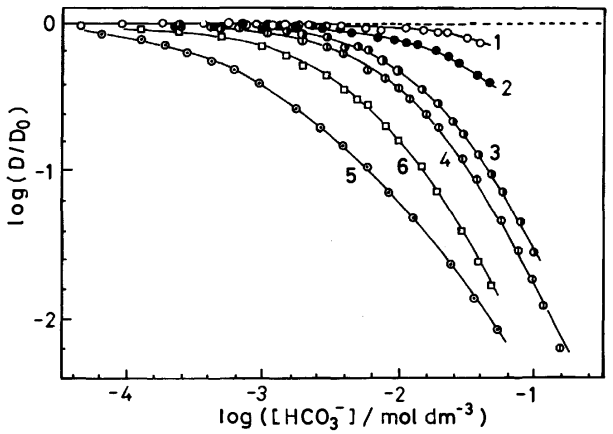

Fig. 1. Plots of log(D/D_0) *vs.* log([HCO_3^-]/mol dm^{-3}). pH: (1) 6.50, (2) 7.00, (3) 7.50, (4) 7.80, (5) 8.30, (6) 8.11. (1)—(5): C_{TTA}=10^{-4} mol dm^{-3}, C_{phen}=10^{-2} mol dm^{-3} in 3-methyl-1-butanol. (6): C_{TTA}=10^{-3} mol dm^{-3}, C_{phen}=10^{-2} mol dm^{-3}, in dichloromethane.

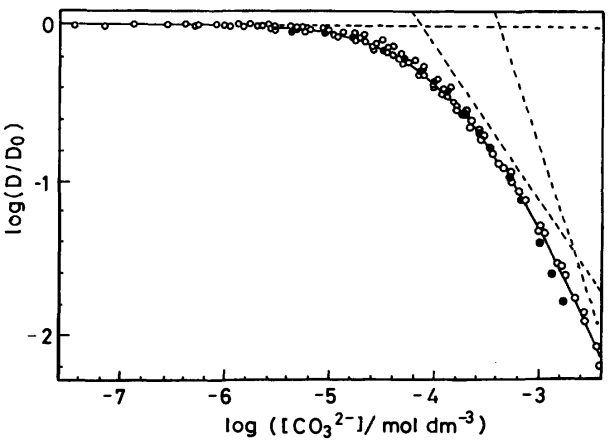

Fig. 2. Plots of log(D/D_0) *vs.* log([CO_3^{2-}]/mol dm^{-3}). ○: pH 6.50—8.30, C_{TTA}=10^{-4} mol dm^{-3}, C_{phen}=10^{-2} mol dm^{-3}, in 3-methyl-1-butanol. ●: pH 8.11, C_{TTA}=10^{-3} mol dm^{-3}, C_{phen}=10^{-2} mol dm^{-3} in dichloromethane.

with HCO_3^- is negligibly small in the pH region investigated, that is, only the carbonate ion CO_3^{2-} participates in the complex formation. We cannot distinguish between MCO_3^- and $M(OH)(HCO_3)^-$; the behavior of these species in the solvent extraction system is identical since the latter merely differs from the former in having an additional H_2O. However, it is quite unreasonable to imagine the formation of $M(OH)(HCO_3)^-$ since even a positively charged NpO_2^+ ion does not form any complexes with an HCO_3^- ion. The formation of mixed hydroxo-carbonato complexes such as $M(OH)(CO_3)^{2-}$, $M(OH)_2(CO_3)^{3-}$, $M(OH)(CO_3)_2^{4-}$, *etc.* can also be eliminated since the formation of these kinds of complexes would give a pH dependence to a family of plots of $\log(D/D_0)$ *vs.* $\log([CO_3^{2-}]/\text{mol dm}^{-3})$. This can be easily understood when we regard $CO_3\cdot nH_2O^{2-}$ as HL and $OH\cdot CO_3\cdot(n-1)H_2O^{3-}$ as L in Eqs. 8—10. Therefore, we can conclude that only carbonate complexes are present in the solution within the pH range studied. A least-squares study of these six series of experiments (113 points) resulted in:

$$\log(\beta_1/\text{mol}^{-1}\text{dm}^3) = 4.14 \pm 0.01,$$
$$\log(\beta_2/\text{mol}^{-2}\text{dm}^6) = 6.78 \pm 0.01.$$

Although higher complexes such as $M(CO_3)_3^{5-}$ cannot be excluded, it was difficult to detect them because the concentration of CO_3^{2-} and pHs greater than those adopted in the present experiment would result in the oxidation of Np(V) to Np(VI), as discussed below.

Discussion

Figure 3 shows the fraction of Np(V) in the form of a particular carbonato complex as a function of carbonate ion concentration at equilibrium, evaluated using the stability constants obtained in the present experiment. NpO_2^+ predominates when the equilibrium carbonate concentration is lower than $10^{-4.5}$ mol dm^{-3}. The equilibrium concentration of various species in distilled water exposed to air can be estimated with the use of Eq. 11 and Henry's law:

$$K_H = [H_2CO_3]/P_{CO_2}, \quad (14)$$

where P_{CO_2} is a partial pressure of carbon dioxide. By substituting $K_H=10^{-1.48}$ mol dm^{-3} atm^{-1},[7] $P_{CO_2}=10^{-3.5}$ atm, $pK_1=6.02$, $pK_2=9.57$, and

$$[H^+] \simeq [HCO_3^-], \quad (15)$$

we obtain:

$$[H_2CO_3] = 10^{-5.0}\ \text{mol dm}^{-3},$$
$$[H^+] = [HCO_3^-] = 10^{-5.5}\ \text{mol dm}^{-3},$$
$$[CO_3^{2-}] = 10^{-9.6}\ \text{mol dm}^{-3},$$

and

$$C_L = 10^{-4.8}\ \text{mol dm}^{-3}.$$

When experiments are carried out which exclude the dissolution of more carbon dioxide than the equilibrium concentration in distilled water exposed to air, Np(V) does not form substantial amount of carbonato complexes since the concentration of the carbonate ion never exceeds $C_L=10^{-4.8}$ mol dm^{-3}. In some natural systems like sea water and inland water, however, the pH is controlled by other coexisting components than dissolved carbon dioxide. Hence, the concentration of carbon dioxide depends on the equilibrium pH controlled by the solutes. At equilibrium, the concentration of the carbonate ion can be expressed as:

$$[CO_3^{2-}] = P_{CO_2}K_HK_1K_2/[H^+]^2. \quad (16)$$

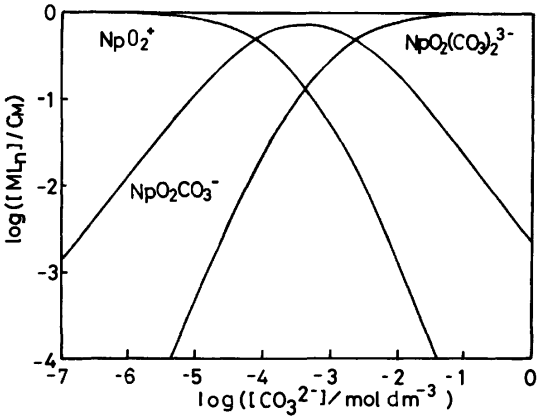

Fig. 3. Logarithmic diagram of the Np(V)–carbonate system.

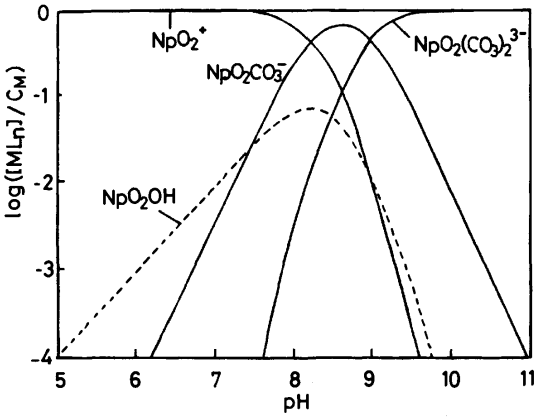

Fig. 4. Logarithmic diagram of the Np(V)–carbonate–hydroxide system at $P_{CO_2}=10^{-3.5}$ atm.

Figure 4 shows the fractional distribution of the chemical species of Np(V) in a solution in equilibrium with an atmosphere of $P_{CO_2}=10^{-3.5}$ atm as a function of pH. In the calculation, hydrolysis constants of Np(V) are taken from the table compiled by Allard *et al.*[8]

$$[MOH]/[M^+][OH^-] = 10^{5.0}\ \text{mol}^{-1}\ \text{dm}^3,$$
$$[M(OH)_2^-]/[M^+][OH^-]^2 = 10^{10}\ \text{mol}^{-2}\ \text{dm}^6.$$

As compared with the diagram in the absence of carbon dioxide,[9] chemical species of Np(V) predominating in a slightly alkaline solution drastically change from hydroxo to carbonato complexes. The precipitation of hydroxides should be markedly suppressed in the presence of an equilibrium amount of carbonate ions.

Diagrams for a tracer neptunium-carbonate-hydroxide system at $P_{CO_2}=10^{-3.5}$ atm were constructed in the

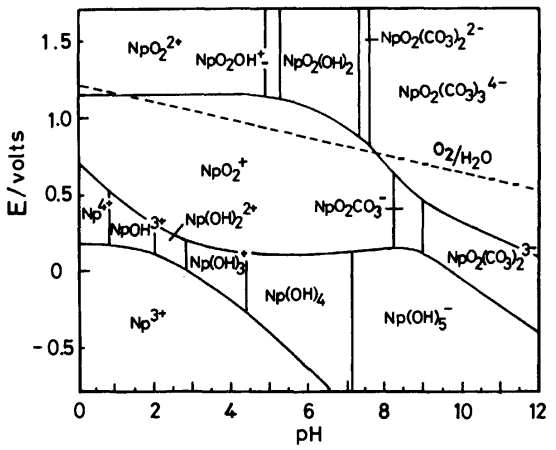

Fig. 5. Potential-pH diagram of tracer neptunium–carbonate–hydroxide system at $P_{CO_2}=10^{-3.5}$ atm.

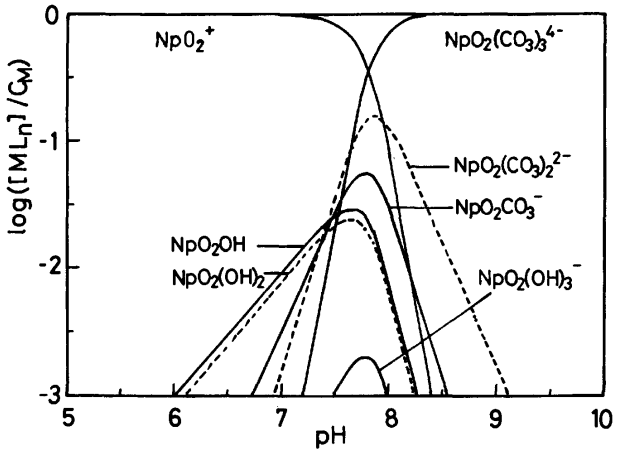

Fig. 6. Logarithmic diagram of tracer neptunium–carbonate–hydroxide system at $P_{CO_2}=10^{-3.5}$ atm and $P_{O_2}=1/5$ atm.

same manner as previously described.[9] They are shown in Figs. 5 and 6 in the form of potential-pH and fraction-pH diagrams. Hydrolysis constants and standard potentials for redox reactions were taken from a table compiled by Allard *et al.*[8] Since reliable data for carbonato complexing of Np(VI) are unavailable,[10] the data for U(VI):[6]

$$\log(\beta_1/\mathrm{mol^{-1}\,dm^3}) = 9.02,$$

$$\log(\beta_2/\mathrm{mol^{-2}\,dm^6}) = 16.22,$$

and

$$\log(\beta_3/\mathrm{mol^{-3}\,dm^9}) = 21.54$$

for

$$\beta_m = [UO_2(CO_3)_m^{2-2m}]/[UO_2^{2+}][CO_3^{2-}]^m,$$

were used as a substitute. Since uranium and neptunium in the same valence state generally have similar formation constants, a small disparity in the constants of U(VI) and Np(VI) will only slightly influence the predictions. The formation of carbonato complexes of Np(III) and Np(IV) are considered negligible as compared with the formation of hydroxo complexes by the analogy of other ter- and quadrivalent actinoids. The fraction-pH diagram was constructed at the potential of the solution in equilibrium with 1/5 atm O_2:

$$E = 1.219 + (RT/F)\ln([H^+]/\mathrm{mol\,dm^{-3}}). \quad (16)$$

This potential is shown by a dashed line in Fig. 5. Figures 5 and 6 clearly indicate that the sexivalent state is stabilized by carbonato complexing in slightly alkaline solutions at $P_{CO_2}=1/5$ atm. Even under reducing conditions, neptunium is not expected to form hydroxides which lead to precipitation but to form soluble carbonato complexes of Np(VI) or Np(V). Since it is not unusual for natural water to experience this kind of condition, the concentration of a carbonate ion must be carefully estimated or analyzed in order to predict the geochemical behavior of neptunium.

Das von einer Schwingungsmühle gemahlte Ammoniumhydrogenamidophosphat ($NH_4HPO_3NH_2$) hat es herausgestellt, daß nach einer Stunde Laufzeit die erste endotherme Spitze in DSC Kurven in zwei Teile geteilt wird. Die Absorption infolge NH und Zwitterions in IR Spektren wird vom Einfuß der Schwingungsmühle verändert. Das Ergebnis unterstützt eine Transformation von $NH_4HPO_3NH_2$ nach einer Zwischenphase, die durch die starke Wasserstoffbindung zwischen NH und POH gebildet worden hat.

Bei thermischer Zersetzungsreaktion vom Ammoniumsalz der Phosphorsäure bilden sich hohe Anteile von Ammoniak und Phosphorsäure. Demzufolge wurde das Ammoniumsalz der Phosphorsäure als flammensicherer und feuerbeständiger Agent für Zellulosematerialien gebraucht. Einige Forschungen[1] wurden über die thermischen Zersetzung der obigen Verbindung ausgeführt, aber der Mechanismus der Zersetzungsreaktion ist noch nicht vollständig erforscht.

In der früheren Abhandlung[2] wurde die thermische Zersetzungsreaktion mit DTA, DSC, und TG erforscht. In der jetzigen Abhandlung wird der Effekt der Mechanochemie auf die thermische Zersetzungsreaktion untersucht und die Veränderung der physikochemischen Eigenschaften von $NH_4HPO_3NH_2$ diskutiert.

Durchführung der Experimente

Materialien. $NH_4HPO_3NH_2$ wurde nach der Methode zusammengesetzt,[3] die in der früheren Abhandlung beschrieben ist. Das Produkt wurde unter 3333 Pa bei Raumtemperatur für zwei Tage getrocknet und mit Daten von IR Spektren[4] und Röntgenbeugungsbildern identifiziert.[5]

Gef.: P, 29,96; N(gesamt), 24,25; N-NH_4, 12,16%. Ber. für $H_7N_2O_3P$: P, 29,16; N(gesamt), 24,56; N-NH_4, 12,28%.

Apparate und Verfahren. Der Ammoniakgehalt wurde mit Lösung der Schwefelsäure nach der Kjeldahl Methode bestimmt. Der Phosphorgehalt wurde mittels Ionenaustauschchromatographie[6] analysiert und mittels Papierchromatographie[7] mit saure und basische Lösungsmitteln getrennt. Die DTA, DSC, und TG Kurven wurden in der Luft mit einer Aufheizgeschwindigkeit von 5 °C/min mit einem Rigaku TG-DTA, TG-DSC Thermoflex aufgenommen. Für DTA und DSC wurde α-Al_2O_3 als Bezugsmittel gebraucht. Die Röntgenbeugungsbilder wurden mit einem Shimadzu-Beugungsmesser (Cu $K\alpha$-Strahlung, Ni-gefiltert) erhalten. Die IR Spektren wurden mittels Präparation von KBr-Preßlingen mit einem Beugungsgitter IR Spektrometer der JASCO aufgenommen. Die Schwingungsmühle wurde nur in der Luft gebraucht. $NH_4HPO_3NH_2$ (3,0 g) und eine Stahlstange (Diameter 0,025 m, Länge 0,045 m) wurden in einen 100-ccm-Stahltoph hineingetan und dann mit der Schwingungsmühle von Laboratoriumgröße (Heiko Seisakusho AG) gemahlen. Der spezifische Oberflächenraum wurde nach der BET Methode geschätzt, die Stickstoff bei 77 K adsorbieren läßt.

Ergebnisse und Diskussion

Thermische Analyse. Abbildungen 1 und 2 zeigen den Effekt der Schwingungsmühle auf DSC und TG von $NH_4HPO_3NH_2$. Die DSC Kurven ergeben drei endotherme Spitzen in der frühen Stufe der Laufzeit der Schwingungsmühle. Die erste Spitze (E_{D_1}), die in zwei Teile geteilt ist, verschiebt sich auf die Seite der Tiefentemperatur mit Laufzeit der Schwingungsmühle. Die zweite Spitze (E_{D_2}), die bei 470—480 K für die untersuchten Verbindungen beobachtet wird, kann von Bildung des Ammoniummetaphosphates abhängig sein. Das wurde mittels Ionenaustauschchromatographie, Papierchromatographie, und Röntgenbeugungsbilder von allen Proben beobachtet, die vor und hinter E_{D_2} in den DSC Kurve herausgenommen wurden. Die Stelle von E_{D_2} verschiebt sich ein wenig auf die Seite der Tiefentemperatur mit zunehmender Laufzeit der Schwingungsmühle und die Spitzenintensität wächst. Die letzte, große, breite Spitze (E_{D_3}) wird im Temperaturgebiet 530—650 K beobachtet, in welchem $NH_4HPO_3NH_2$ zu Metaphosphorsäure zersezt wird. Die TG Kurven in

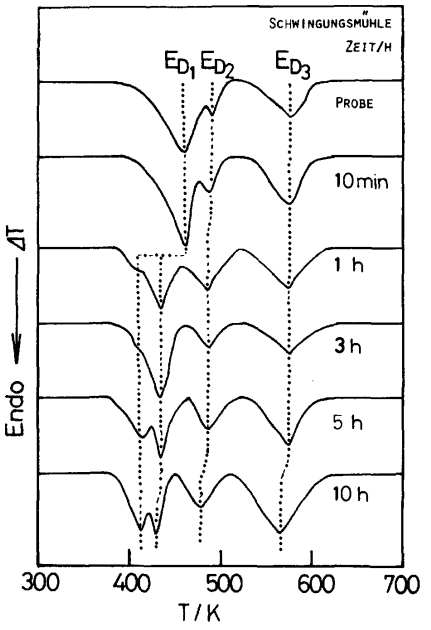

Abb. 1. Variationen von DSC Kurven für $NH_4HPO_3NH_2$ mit Laufzeit der Schwingungsmühr.

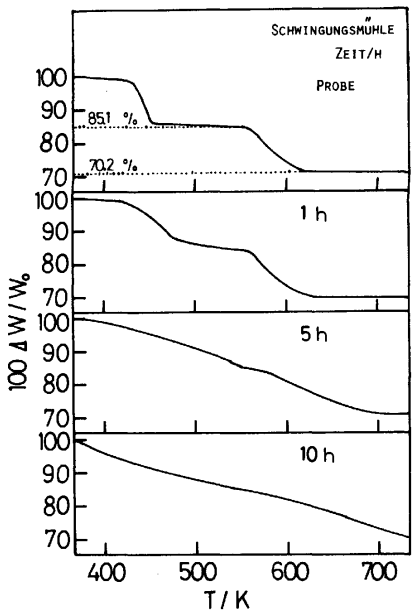

Abb. 2. Variationen von TG Kurven für $NH_4HPO_3NH_2$ mit Laufzeit der Schwingungsmühle.

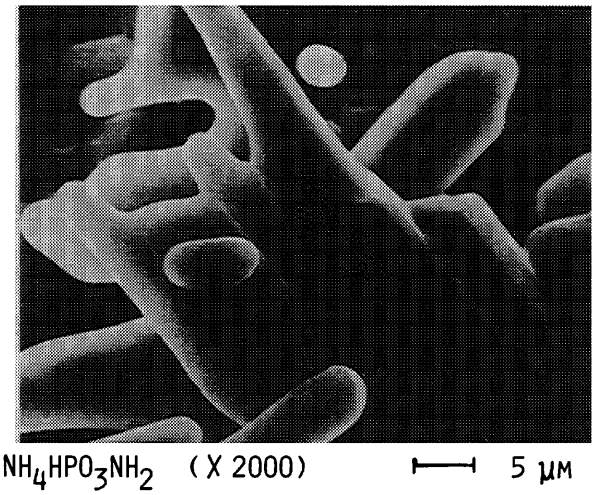
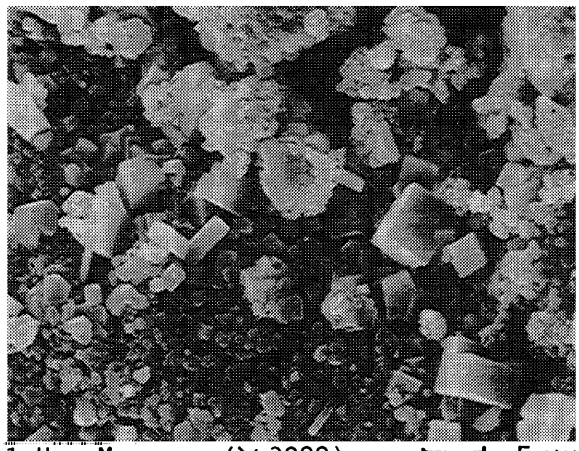
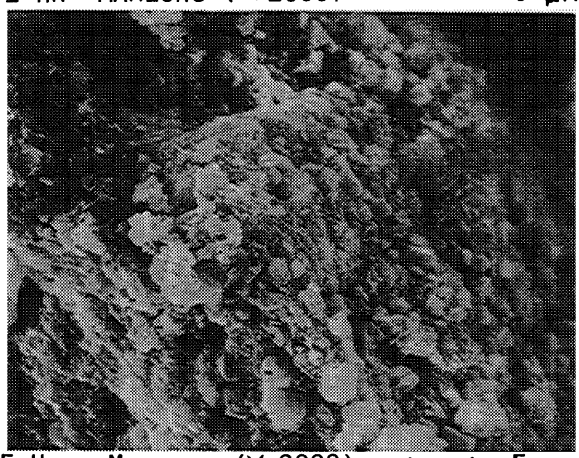
Abb. 2 zeigen, daβ der Prozeβ der Zersetzung von $NH_4HPO_3NH_2$ in zwei Stufen ausgeführt wird. Die Zahlenwerte, die auf der punktierten Linie von TG Kurven (Abb. 2) liegen, zeigen die berechneten Werte der Gewichtverluste, die dem aus der Probe austretendem Ammoniak entsprechen. Es gibt keine deutliche Hochebene in den TG Kurven bei der Verlängerung der Laufzeit der Schwingungsmühle. Aus dieser undeutlichen Hochebene ergibt sich, daβ beides die Transition der Amidogruppe zu Ammoniak und die Auslassung des Ammoniaks vom Zwischenprodukt gleichzeitig im gemahlten Material verlaufen. Diese Arbeit hat es ins klare gebracht, daβ die Stelle der Spitzen von DTA und DSC und die Anfangstemperatur der Zersetzung von $NH_4HPO_3NH_2$ sich auf die Seite der hohen Temperaturen mit zunehmender Aufheizgeschwindigkeit verschieben.

Veränderung in Größe und Form. Die Veränderungen in Größe und Form der Partikel von $NH_4HPO_3NH_2$ mit Laufzeit der Schwingungsmühle werden in Abb.







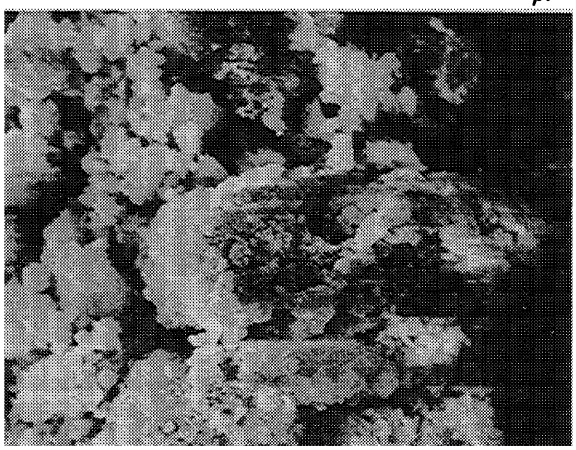


Abb. 3. Elektronenmikrophotographie vom gemahlten $NH_4HPO_3NH_2$ in verschiedenen Abstanden.

3 bei verschiedenen Abständen dargestellt. Die erste brettförmige Partikel wird im gemahlten $NH_4PO_3NH_2$ nach einer Stunde bemerkt. Der Durchmesser der Partikel, die über fünf Stunden gemahlt wurde, nahm um 0,5—2,0 μm ab.

Röntgenbeugungsbild und Spezifischer Oberflächeraum. In den drei größten Intensitätslinien des Röntgenbeugungsbildes von $NH_4HPO_3NH_2$ sind die entsprechenden Abstände (*d*-Werten in Å) 5,72, 4,23, und 4,28. Diese Spitzenintensitäten nehmen mit zunehmender Laufzeit

der Schwingungsmühle bedeutend ab. Die Röntgenbeugungsbilder auf dem Gebiete zwischen 2,98 und 8,85 Å überlappen gegenseitig. Für Bestimmung der Kristallitengröβe nach der Scherrer Methode,[8] wurde die Beugungslinie von 2,23 Å des unentschiedenen Millerschen Indexes ausgewählt, um Überlappung zuvermeiden. Die Halbwertsbreite der Beugungslinie zu 2,23 Å wird mit zunehmender Laufzeit der Schwingungsmühle verbreitert. Das Phänomen wurde bereits nach zehn Minuten Laufzeit der Schwingungsmühle beobachtet. Die Kristallitengröβe nahm von 500 zu 160 Å mit zunehmender Laufzeit der Schwingungsmühle ab. Der nach der BET Methode bestimmte spezifische Oberflächenraum von $NH_4HPO_3NH_2$ ist 2,0 M^2/g und der der über zwei Stunden gemahlten Partikel ist 2,5—3,5 M^2/g; Die Laufzeit der Schwingungsmühle hat nur kleinen Einfluβ. Es ist nach diesem Ergebnis verständlich, daβ die Agglomeration von primären Partikeln mit zunehmender Laufzeit der Schwingungsmühle vergröβert wird.

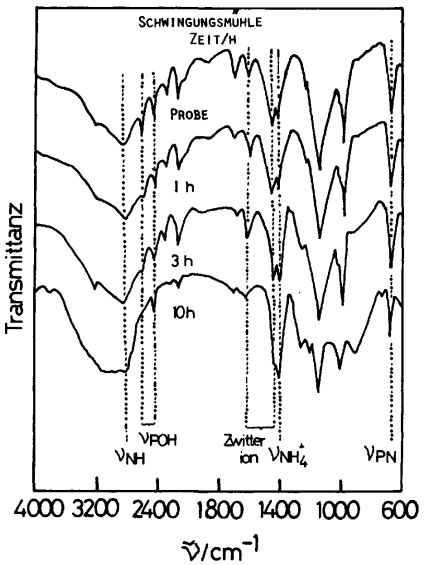

Abb. 4. IR-Spektren vom gemahlten $NH_4HPO_3NH_2$ in verschiedenen Abständen.

IR Spectra. Abbildung 4 zeigt den Effekt der Schwingungsmühle auf IR Spektren von $NH_4HPO_3NH_2$. Auf den Kurven erscheint auch ein freies NH zwischen 3000 und 3600 cm^{-1}. Eine zwischenmolekulare Brücke NH wird zwischen 2810 und 2840 cm^{-1} unter einer Verschiebung durch Wasserstoffbindung auf tiefere Frequenz gesehen. Die Bänder bei 1615 und 1470 cm^{-1}, die aus Bildung des Zwitterions entstehen, erfahren einen Einfluβ im Verhältnis zu der Zeitspanne, in welcher die Mühle in Betrieb gewesen ist. Aus den Veränderungen der IR Spektren von $NH_4HPO_3NH_2$ mit zunehmender Laufzeit der Schwinungsmühle scheint es somit erlaubt zu schlieβen, daβ gemäβ der Betriebszeit der Mühle die Fraktion der starken Wasserstoffbindung zwischen NH und POH zunimmt. Wahrscheinlich hängt diese starke Wasserstoffbindung mit der Transformation von $NH_4HPO_3NH_2$ ins

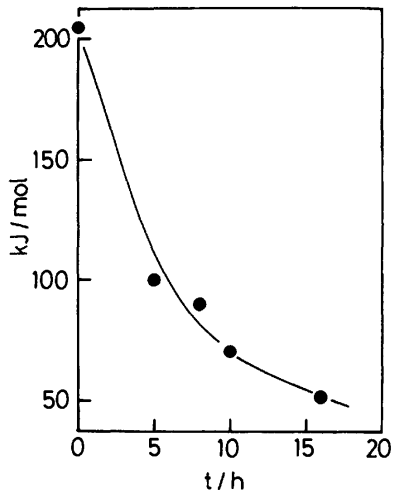

Abb. 5. Variationen von Aktivierungsenergie mit Laufzeit der Schwingungsmühle.

Zwitterion $NH_4PO_3^-NH_3^+$ zusammen.

Kinetik der Thermischen Zersetzung im Festen Zustand. Die Kinetik der thermischen Zersetzung wurde im Temperaturgebiet von 420 bis 470 K untersucht. In Analyse der isothermischen DSC-Kurve, nach Mcghie *et al.*,[9] konnte man annehmen, daβ die Fläche unter der Spitze die Gesamtzersetzungswärme darstellt. Die vollständige Geschwindigkeitsgleichung für die thermische Zersetzung ergibt sich aus der Gleichung

$$k/\mathrm{min}^{-1} = 3.6 \times 10^{22} \exp[(-208.6 \pm 0.2)/RT].$$

Dieser Wert der Aktivierungsenergie stimmte am besten mit E_A=203,5±0,5 kJ/mol überein, die aus DTA Kurven nach der Kissinger Gleichung[10] berechnet wurde. Diese Resultate wurden so bestimmte, daβ beide DTA und DSC die gleiche Aktivierungsenergie haben konnte. Abbildung 5 zeigt den Effekt der Schwingungsmühle auf die Aktivierungsenergie des Desamidierenes von $NH_4HPO_3NH_2$. Die Aktivierungsenergie nimmt mit zunehmender Laufzeit der Schwingungsmühle ab. Aus den obigen Resultaten läβt sich annehmen, daβ die Zunahme des amorphen Zustandes und die Leichtigkeit der Transformation der Amidogruppe zu Ammoniumion von einander abhängig sind.

Theory of Time-resolved Resonance Raman Scattering from Vibrationally Hot Molecules

Yuichi FUJIMURA,* Yukiyoshi OHTSUKI, and Takeshi NAKAJIMA
Department of Chemistry, Faculty of Science, Tohoku University, Sendai 980
(Received April 7, 1984)

A theory of time-resolved resonance Raman scattering (RRS) from molecules is developed. The time-resolved RRS cross section is defined as a product of the time-dependent vibronic energy distribution and the scattering cross section from the single vibronic level. The theory is applied to the time-resolved RRS from vibrationally hot molecules whose vibronic distribution characterized by a canonical distribution with temperature higher than that of the heat bath relaxes to the equilibrium one in the presence of a collisional vibrational relaxation. Analytical expressions for the time-resolved RRS cross section are derived within a displaced harmonic oscillator model. It is shown that in the strong coupling case the intensities of the Stokes and anti-Stokes Raman bands in the rigorous resonance case vary inversely as the time-dependent average vibrational occupation number. Some model calculations are performed to illustrate the time-dependent intensity changes of the Raman bands.

Time-resolved Raman spectroscopy is one of the attractive methods for studying relaxation dynamics taking place in highly non-equilibrium ground or electronically excited states of molecules. There have been a considerable number of experimental results on the application of the time-resolved Raman spectroscopy to vibronically excited molecules, photochemical and biological intermediates and so on.[1,2]

Let us consider vibrationally hot molecules characterized by a canonical distribution with temperature T^0 higher than that of the heat bath T. This distribution relaxes to the equilibrium distribution with T after collisional vibrational relaxations. The vibrational energy distribution in the v vibrational state at time t is given as[3]

$$\rho_v(t) = \{1 - \exp[-u(t)]\}\exp[-vu(t)], \tag{1}$$

where

$$u(t) = \log\left[\frac{\exp[-z(t)]\{1-\exp(\theta-\theta^0)\}-\exp(\theta)\{1-\exp(-\theta^0)\}}{\exp[-z(t)]\{1-\exp(\theta-\theta^0)\}-\{1-\exp(-\theta^0)\}}\right], \tag{2}$$

with $z(t)=\kappa t\{1-\exp(-\theta)\}$, $\theta=\hbar\omega/kT$ and $\theta^0=\hbar\omega/kT^0$ in which κ is the collisional vibrational relaxation constant, and ω is the frequency of the vibrational mode of the molecule. The canonically hot molecules are produced by a shock wave method[4] or by a radiationless transition following an optical excitation[5] *etc.* The collisional vibrational relaxation of the hot molecules in the presence of heat bath molecules has mainly been investigated by using the time-resolved one-photon absorption technique so far.[5] The typical relaxation times are in micro to nanoseconds region, depending on the pressure of the perturber molecules. Application of the time-resolved Raman spectroscopy to the investigation of the relaxation mechanism has not been reported. It is interesting to mention the difference in the band structure between the time-resolved one-photon absorption spectra and the time-resolved Raman spectra to be observed. The former consists of a structureless, broad bands,[5] and on the other hand, the latter should consist of vibrational Stokes and anti-Stokes band structures in a highly non-equilibrium condition. The broad band structure in the absorption spectra originates mainly from electronic relaxations taking place in the optically excited electronic state. Compared with the time-resolved absorption method, the time-resolved Raman scattering method may make a significant contribution to analyzing the relaxation mechanism from the view point of the band structure mentioned above.

In this paper we present an applicability of the time-resolved Raman spectroscopy to analyzing the relaxation mechanism of the canonically hot molecules and show how the collisional vibrational relaxation reflects the time-resolved Raman spectra. For this purpose we derive an expression for the cross section of the time-resolved resonance Raman scattering. To our knowledge, there are few theoretical papers on the time-resolved Raman spectroscopy applied to highly non-equilibrium system so far. Luzzi and Vasconcellos,[6] and Vasconcellos and Luzzi[7] have developed a theoretical study of the time-resolved Raman scattering from a highly photoexcited semiconductor plasma by using the Zubarev non-equilibrium ensemble method. In the next section we use the generating function method to derive the time-resolved resonance Raman scattering cross section. This method has been proved to be a powerful method for deriving the Raman scattering cross section of molecules.[8,9]

Theory

We consider a resonance Raman scattering (RRS) from initial state $a\{v\}$ to final state $a\{v'\}$ *via* resonant state $b\{m\}$ where a and b denote the initial (final) and resonant electronic states, respectively, and { } denote the relevant vibrational states. The time-resolved RRS differential cross section in a solid angle $d\Omega$ per unit scattered photon frequency ω_2, $d^2\sigma(\omega_1,\omega_2,t)/d\Omega d\omega_2$ is defined as

$$\frac{d^2\sigma(\omega_1,\omega_2,t)}{d\Omega d\omega_2} = \sum_v \rho_v(t)\frac{d^2\sigma_v(\omega_1,\omega_2)}{d\Omega d\omega_2}, \tag{3}$$

where ω_1 is the incident photon frequency, $d^2\sigma_v(\omega_1,\omega_2)/d\Omega d\omega_2$ is the RRS differential cross section from single vibronic level (SVL) v, and $\rho_v(t)$ is the population of the initial vibrational state v at time t. In this treatment, it is assumed that the time-dependence of the population can be observed after transient effects have terminated. The single vibronic level RRS cross section is expressed as

$$\frac{d^2\sigma_v(\omega_1,\omega_2)}{d\Omega d\omega_2} = C\omega_1\omega_2^3 \sum_{v'} \frac{\Gamma_{av',av}}{(\omega_{v',v}-\omega_1+\omega_2)^2+\Gamma_{av',av}^2} \times \left| \sum_m \frac{M_{av',bm}(2)M_{bm,av}(1)}{i(\omega_{bm,av}-\omega_1)+\Gamma_{bm,av}} \right|^2, \quad (4)$$

where $C=(2\pi\hbar^2\varepsilon_0c^4)^{-1}$, and $M_{bm,av}$ (1)represents the component of the transition moment along the polarization direction $\hat{e}_1$ between two vibronic states bm and av. $\Gamma_{av',av}$ and $\Gamma_{bm,av}$ are the dephasing constant associated with the initial and final states, and that with the resonant and initial states, respectively.

In order to derive an expression for the time-resolved RRS differential cross section, it is convenient to express Eq. 4 in terms of the generating function,

$$\frac{d^2\sigma_v(\omega_1,\omega_2)}{d\Omega d\omega_2} = \frac{1}{2}C\omega_1\omega_2^3|M_{ab}^0(2)M_{ba}^0(1)|^2\int_0^\infty d\tau\int_0^\infty d\tau'\int_{-\infty}^\infty d\xi \times \exp[i\xi(\omega_1-\omega_2)+i\omega_1(\tau'-\tau) - \Gamma_{ba}(\tau+\tau') - \Gamma_{v'v}|\xi|]G_v(\tau,\tau',\xi), \quad (5)$$

where the generating function for the single vibronic level RRS, $G_v(\tau,\tau',\xi)$ takes the form,

$$G_v(\tau,\tau',\xi) = \langle v|\exp[i\hat{H}_b\tau/\hbar]\exp[-i\hat{H}_a\xi/\hbar]\exp[-i\hat{H}_b\tau'/\hbar] \times \exp[i\hat{H}_a(\xi-\tau+\tau')/\hbar]|v\rangle. \quad (6)$$

In deriving Eq. 5, the vibrational quantum number dependence of the dephasing constants has been omitted, that is, Γ_{ba} and $\Gamma_{v'v}$ should be interpreted as the average electronic and vibrational dephasing constants, respectively, and the Condon approximation has been used, that is, electronic transition moments $M_{ab}^0(2),M_{ba}^0(1)$ are independent of the nuclear coordinates.

In the displaced harmonic oscillator model, in which the Hamiltonians of the initial (final) electronic and the resonant electronic states are given by

$$\hat{H}_a = \frac{\hbar\omega}{2}(\hat{p}^2+q^2) = \hbar\omega(\hat{b}^\dagger\hat{b}+\frac{1}{2}), \quad (7a)$$

and

$$\hat{H}_b = \frac{\hbar\omega}{2}[\hat{p}^2+(q-\Delta)^2]+\varepsilon^0 = \hat{H}_a - \frac{\hbar\omega\Delta}{\sqrt{2}}(\hat{b}+\hat{b}^\dagger) + \frac{\hbar\omega\Delta^2}{2} + \varepsilon^0, \quad (7b)$$

we can derive the generating function, Eq. 6 as

$$G_v(\tau,\tau',\xi) = \exp\left[\frac{i\varepsilon^0(\tau-\tau')}{\hbar} + \frac{\Delta^2}{2}\{\exp(i\omega\tau)-1\} + \frac{\Delta^2}{2}\{\exp(-i\omega\tau')-1\} + \lambda^*(\tau)\lambda(\tau')\exp(-i\omega\xi)\right]L_v(|\alpha(\tau,\tau',\xi)|^2), \quad (8)$$

where ω is the frequency of the harmonic oscillator, Δ is the dimensionless displacement between the equilibrium positions in the initial and resonant states and ε^0 represents the electronic energy gap between the bottoms of the two electronic states. A detailed derivation is given in Appendix A. In Eq. 8, L_v, the Laguerre polynomials, is defined as

$$L_v(|\alpha(\tau,\tau',\xi)|^2) = \sum_{k=0}^{v} \frac{v!(-|\alpha(\tau,\tau',\xi)|^2)^k}{(k!)^2(v-k)!}, \quad (9)$$

with

$$\alpha(\tau,\tau',\xi) = \lambda(\tau) - \lambda(\tau')\exp(-i\omega\xi), \quad (10)$$

and

$$\lambda(\tau) = \frac{\Delta}{\sqrt{2}}\{1-\exp(-i\omega\tau)\}.$$

Substituting Eqs. 1 and 5 with Eq. 8 into Eq. 3, and carrying out summation over v, we obtain

$$\frac{d^2\sigma(\omega_1,\omega_2,t)}{d\Omega d\omega_2} = \frac{1}{2}C\omega_1\omega_2^3|M_{ab}^0(2)M_{ba}^0(1)|^2\int_0^\infty d\tau\int_0^\infty d\tau'\int_{-\infty}^\infty d\xi \times \exp[i\xi(\omega_1-\omega_2)+i\omega_1(\tau'-\tau) - \Gamma_{ba}(\tau+\tau')-\Gamma_{v'v}|\xi|]G(\tau,\tau',\xi), \quad (11)$$

where

$$G(\tau,\tau',\xi) = \exp\left[i\varepsilon^0(\tau-\tau')/\hbar - \{v(t)+1\}\left\{\frac{\Delta}{\sqrt{2}}\lambda^*(\tau) + \frac{\Delta}{\sqrt{2}}\lambda(\tau')-\lambda^*(\tau)\lambda(\tau')\exp(-i\omega\xi)\right\} - v(t)\left\{\frac{\Delta}{\sqrt{2}}\lambda(\tau)+\frac{\Delta}{\sqrt{2}}\lambda^*(\tau') - \lambda(\tau)\lambda^*(\tau')\exp(i\omega\xi)\right\}\right], \quad (12)$$

and $v(t)=\{\exp[u(t)]-1\}^{-1}$, which is the average vibrational occupation number at time t. In deriving Eq. 11 the following formula has been used,

$$\sum_{v=0}^{\infty}\exp[-vu(t)]L_v(|\alpha(\tau,\tau',\xi)|^2) = \frac{\exp[-|\alpha(\tau,\tau',\xi)|^2v(t)]}{1-\exp[-u(t)]}. \quad (13)$$

Equation 12 has the same structure as that of the generating function for the RRS cross section of molecules in the thermal equilibrium.[8] An analytical expression for the time-resolved RRS cross section can easily be derived from Eq. 11 with Eq. 12:

$$\frac{d^2\sigma(\omega_1,\omega_2,t)}{d\Omega d\omega_2} = C\omega_1\omega_2^3|M_{ab}^0(2)M_{ba}^0(1)|^2\exp[-\{2v(t)+1\}\Delta^2] \times \left(\sum_{k=0}^{\infty}\sum_{l=0}^{\infty}\frac{\left[\{v(t)+1\}\frac{\Delta^2}{2}\right]^k\left\{v(t)\frac{\Delta^2}{2}\right\}^l}{k!l!}\right.$$

$$\times \frac{\Gamma_{v'v}}{[\{\omega_1-\omega_2-(k-l)\omega\}^2+\Gamma_{v'v}^2]}\Bigg)$$

$$\times\left|\sum_{p=0}^{k}\sum_{q=0}^{l}\sum_{r=0}^{\infty}\sum_{u=0}^{\infty}\binom{k}{p}\binom{l}{q}(-1)^{r+u}\frac{\left[\{v(t)+1\}\frac{\Delta^2}{2}\right]^r}{r!}\frac{\left\{v(t)\frac{\Delta^2}{2}\right\}^u}{u!}\right.$$

$$\left.\times\frac{1}{[\mathrm{i}\{\omega_1-\varepsilon^0/\hbar-(p-q+r-u)\omega\}+\Gamma_{ba}]}\right|^2. \quad (14)$$

In the case in which the molecular system is characterized by a high temperature, that is, $\{2v(t)+1\}\Delta^2/2 \gg 1$ is satisfied, an approximate expression for the time-resolved RRS can be used. In this case expanding $\exp(\pm i\omega\tau)$ and $\exp(\pm i\omega\tau')$ in Eq. 12 to the second order,[10] substituting the resulting expression into Eq. 11 and carrying out the integration over ξ, we obtain

$$\frac{d^2\sigma(\omega_1,\omega_2,t)}{d\Omega d\omega_2} \simeq C\omega_1\omega_2^3|M_{ab}^0(2)M_{ba}^0(1)|^2$$

$$\times\sum_{k=0}^{\infty}\sum_{l=0}^{\infty}\frac{\{S_{v1}(t)\}^k\{S_v(t)\}^l}{k!l!}\frac{\Gamma_{v'v}|F^{(k+l)}(\omega_1)|^2}{[\{\omega_1-\omega_2-(k-l)\omega\}^2+\Gamma_{v'v}^2]}, \quad (15)$$

where

$$F^{(k+l)}(\omega_1)=\int_0^\infty d\tau(\omega\tau)^{k+l}$$

$$\times\exp\left[i\left(\frac{\varepsilon^0}{\hbar}+\frac{\Delta^2\omega}{2}-\omega_1\right)\tau-\Gamma_{ba}\tau-\frac{S(t)\omega^2\tau^2}{2}\right], \quad (16)$$

$S_{v1}(t)=\{v(t)+1\}\Delta^2/2$, $S_v(t)=v(t)\Delta^2/2$, and $S(t)=S_{v1}(t)+S_v(t)$. Equation 16 can be expressed in terms of the repeated integrals of the error function defined by[11]

$$i^{(n)}\mathrm{erfc}(z)=\frac{2}{\sqrt{\pi}}\int_z^\infty\frac{(x-z)^n}{n!}\exp(-x^2)dx, \quad (17)$$

as

$$F^{(k+l)}(\omega_1)=$$

$$\frac{\sqrt{\pi}}{2}\frac{(k+l)!}{\omega}\left\{\frac{2}{S(t)}\right\}^{(k+l+1)/2}\exp(z^2)i^{(k+l)}\mathrm{erfc}(z), \quad (18)$$

with

$$z=\left\{\Gamma_{ba}-i(\varepsilon^0/\hbar+\frac{\Delta^2}{2}\omega-\omega_1)\right\}^2/[\{2S(t)\}^{1/2}\omega]. \quad (19)$$

In the high temperature case, anti-Stokes bands as well as Stokes bands make a significant contribution to the Raman spectra. Expressions for the time-resolved RRS, Eqs. 14 and 15 consist of the Rayleigh, Stokes, and anti-Stokes components:

$$\frac{d^2\sigma(\omega_1,\omega_2,t)}{d\Omega d\omega_2}=\frac{d^2\sigma^{(R)}(\omega_1,\omega_2,t)}{d\Omega d\omega_2}$$

$$+\sum_{n=1}^{\infty}\left\{\frac{d^2\sigma^{(ST-n)}(\omega_1,\omega_2,t)}{d\Omega d\omega_2}+\frac{d^2\sigma^{(AST-n)}(\omega_1,\omega_2,t)}{d\Omega d\omega_2}\right\}, \quad (20)$$

where the first, second and the last terms represent the Rayleigh scattering, n-th order Stokes and n-th order anti-Stokes cross sections, respectively. For example, the cross sections for the n-th order Stokes and anti-Stokes bands in Eq. 15 can be expressed by putting $n=k-l$ and $n=l-k$ as

$$\frac{d^2\sigma^{(ST-n)}(\omega_1,\omega_2,t)}{d\Omega d\omega}$$

$$=\sum_{l=0}^{\infty}\frac{S_{v1}^{n+l}S_v^l}{(n+l)!l!}|F^{(n+2l)}(\omega_1)|^2\frac{\Gamma_{v'v}}{\{(\omega_1-\omega_2-n\omega)^2+\Gamma_{v'v}^2\}}, \quad (21)$$

and

$$\frac{d^2\sigma^{(AST-n)}(\omega_1,\omega_2,t)}{d\Omega d\omega_2}=\sum_{l=0}^{\infty}\frac{S_{v1}^lS_v^{n+l}}{l!(n+l)!}|F^{(n+2l)}(\omega_1)|^2$$

$$\times\frac{\Gamma_{v'v}}{\{(\omega_1-\omega_2+n\omega)^2+\Gamma_{v'v}^2\}}, \quad (22)$$

respectively where $S_{v1}=S_{v1}(t)$, $S_v=S_v(t)$ and the expression for the Rayleigh scattering band is equivalent to Eqs. 21 or 22 with $n=0$. The cross sections for the n-th order Stokes and anti-Stokes bands in Eq. 14 can be evaluated in the similar way.

Discussion

In the previous section we have derived an expression for the time-resolved RRS from molecules in which the initial distribution is characterized by a canonical distribution with higher temperature than that of the heat bath. One of the merits of carrying out the summation over v in Eq. 3 to derive the expression for the time-resolved RRS differential cross section is spontaneously to bring about concept of time-dependent average occupation numbers $v(t)$. The average occupation number decreases as the molecular system becomes cool because of the collisional vibrational relaxation. Intensities of anti-Stokes bands originate from the nonzero average occupation numbers. In order to demonstrate the time-dependence of the RRS spectra we perform a model calculation of the Raman band intensity. Figure 1 shows the time-resolved RRS spectra of molecules whose initial distribution is characterized by a canonical distribution with temperature $T^0=800$ K at the initial time and relaxes to the equilibrium one with 300 K after collisional vibrational relaxations. The broken and solid lines represent the RRS spectra at $\kappa t=0$ and 2 in a unit of κ, respectively. These Raman bands are calculated by using Eq. 14 under the rigorous resonance condition $\omega_1=\varepsilon^0/\hbar$. The average vibrational occupation numbers $v(t)$ at $\kappa t=0$, and 2 are 3.52 and 1.99, respectively. The parameters used in the calculation are vibrational frequency $\omega=200\,\mathrm{cm}^{-1}$, dimensionless displacement $\Delta=0.5$, the damping constants $\Gamma_{ba}=100\,\mathrm{cm}^{-1}$, and $\Gamma_{v'v}=20\,\mathrm{cm}^{-1}$. We can see the increase in the intensities of the Rayleigh and first-order Stokes Raman bands with the development of time. Higher order Stokes and anti-Stokes Raman bands, on the other hand, decrease in their intensities.

Figure 2 shows time-resolved RRS spectra in the

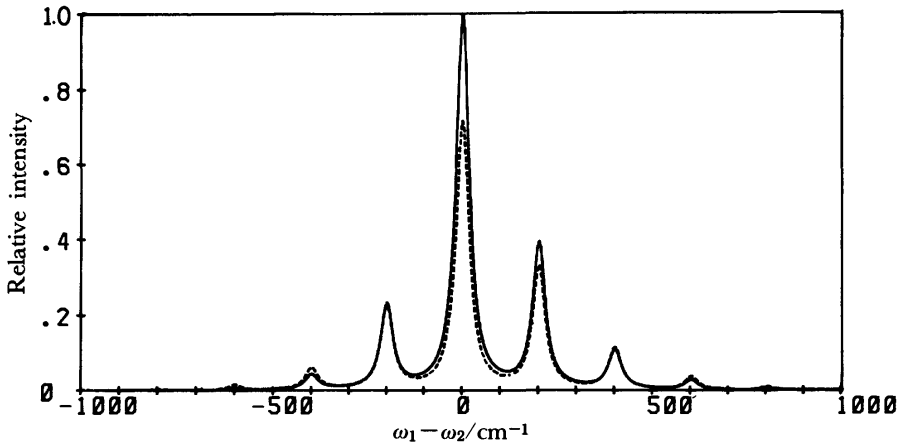

Fig. 1. The calculated time-resolved resonance Raman spectra. The broken and solid lines represent the Raman spectra for $\kappa t=0$ and 1.0 in a unit of κ, respectively. The resonant condition $\omega_1=\varepsilon^0/\hbar$ is assumed. The constants used are $T^0=800\,\mathrm{K}$ and $T=300\,\mathrm{K}$ for the initial and thermal equilibrium temperatures, $\omega=200\,\mathrm{cm}^{-1}$ for the frequency of the displaced harmonic oscillator with dimensionless displacement $\Delta=0.5$, and $\Gamma_{ba}=100\,\mathrm{cm}^{-1}$, and $\Gamma_{v'v}=20\,\mathrm{cm}^{-1}$ for the dephasing constants. The calculation is carried out by using Eq. 14.

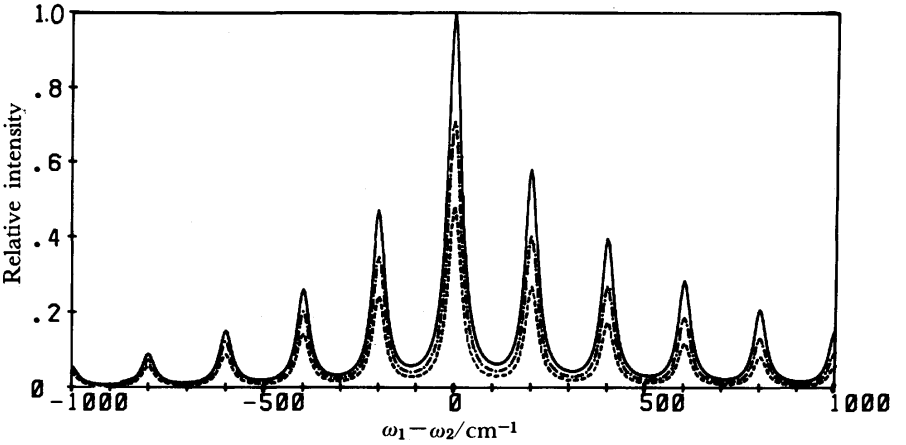

Fig. 2. The calculated time-resolved resonance Raman spectra in a strong coupling case. The broken, dotted broken, and solid lines represent the Raman spectra at $\kappa t=0$, 1.0 and 2.0, respectively. The constants used are $T^0=2000\,\mathrm{K}$ and $T=300\,\mathrm{K}$, $\Delta=2.0$ and the other constants are the same as those in Fig. 1. The resonant condition $\omega_1=\varepsilon^0/\hbar+\Delta^2\omega/2$ is assumed. The calculation is carried out by using Eq. 15. The average occupation numbers $v(t)$ at $\kappa t=0$, 1.0 and 2.0 are 9.51, 6.25 and 4.25, respectively.

strong coupling case. Here $\Delta=2.0$ and $T^0=2000\,\mathrm{K}$ are taken, and the other parameters are the same as those in Fig. 1. The calculation has been carried out by using Eq. 15. It was assumed that $\omega_1=\varepsilon^0/\hbar+\omega\Delta^2/2$ which corresponds to the classical resonance condition. From Fig. 2, we can see that in the strong coupling case n-th order anti-Stokes bands as well as the Stokes bands increase in their intensities with the time development. The average occupation numbers at $\kappa t=0$, 1, and 2 are $v(t)=9.51$, 6.25, and 4.25, respectively. In order to understand this time-dependent behavior we derive an analytical expression for the time-dependent Raman scattering cross section, Eq. 16 in the resonance condition. In the strong coupling case and further in the case in which $\{v(t)+1/2\}^{1/2}\Delta\omega>\Gamma_{ba}$ is satisfied and the damping effects (Γ_{ba}) can be neglected, noting that

$$F^{(p)}(\omega_1=\varepsilon^0/\hbar+\omega\Delta^2/2)=\frac{1}{\omega}\left(\frac{\pi}{2}\right)^{1/2}S^{-1/2}(p-1)!!S^{-p/2}, \tag{23a}$$

for even p, and

$$F^{(p)}(\omega^1=\varepsilon^0/\hbar+\omega\Delta^2/2)=\frac{1}{\omega}S^{-1/2}(p-1)!S^{-p/2}, \tag{23b}$$

for odd p, we can obtain an analytical expression for Stokes band intensity, Eq. 21 as

$$\frac{\mathrm{d}^2\sigma^{(ST-n)}(\omega_1,\omega_2,t)}{\mathrm{d}\Omega\mathrm{d}\omega_2}=S^{-1}\Xi^{(ST-n)}, \tag{24}$$

with

$$\Xi^{(ST-n)} = \frac{1}{\omega^2}\sum_{l=0}^{\infty}\left(\frac{S_{v1}}{S}\right)^{n+l}\left(\frac{S_v}{S}\right)^{l} \times \frac{\{(n+2l-1)!!\}^2}{(n+l)!l!}\frac{\Gamma_{v'v}}{\{(\omega_1-\omega_2-n\omega)^2+\Gamma_{v'v}^2\}}, \quad (25a)$$

for odd n, and with

$$\Xi^{(ST-n)} = \frac{\pi}{2\omega^2}\left[\sum_{l=0}^{\infty}\left(\frac{S_{v1}}{S}\right)^{n+l}\left(\frac{S_v}{S}\right)^{l} \times \frac{\{(n/2+l-1)!!\}^2}{(n+l)!l!}\frac{\Gamma_{v'v}}{\{(\omega_1-\omega_2-n\omega)^2+\Gamma_{v'v}^2\}}\right], \quad (25b)$$

for even n, where $S=S(t)$. Equation 24 indicates that the time-dependence of the Stokes band intensities originates mainly from S^{-1} for high temperatures because $S_{v1}/S_v \sim 1$ and therefore $\Xi^{(ST-n)}$ is independent of time. Similarly, the time-dependence of the anti-Stokes bands originates from S^{-1}:

$$\frac{d^2\sigma^{(ST-n)}(\omega_1,\omega_2,t)}{d\Omega d\omega_2} \propto S^{-1}(t) \propto v(t), \quad (26a)$$

and

$$\frac{d^2\sigma^{(AST-n)}(\omega_1,\omega_2,t)}{d\Omega d\omega_2} \propto S^{-1}(t) \propto v(t). \quad (26b)$$

These expressions explain why the Raman bands in the strong coupling case increase in their intensities with the time development as shown in Fig. 2. It should be noted that Eqs. 26 are valid for the short time domain in which the strong coupling can be defined.

In summary in this paper we have developed a theory of the time-resolved RRS from molecules. The time-resolved RRS cross section is defined as a product of the SVL RRS cross section and its time-dependent population which is derived from the master equation. As an example we have applied the theory to the RRS from molecules whose population distribution is given by a canonical distribution characterized by temperature T^0 higher than that of the heat bath. It is shown that the time-resolved resonance Raman scattering method can be used to clarify the relaxation mechanism of canonically hot molecules. In a subsequent paper other types of the populations relaxation will be taken into account.

Appendix A

Derivation of the generating function for the SVL resonance Raman scattering cross section. In this Appendix we derive the generating function of the cross section for the resonance Raman scattering from single vibronic level v in the displaced harmonic oscillator model. In theory section it is shown that the generating function $G_v(\tau,\tau',\xi)$ takes the form,

$$G_v(\tau,\tau',\xi) = \langle v|\exp[i\hat{H}_b\tau/\hbar]\exp[-i\hat{H}_a\xi/\hbar]\exp[-i\hat{H}_b\tau'/\hbar] \times \exp[i\hat{H}_a(\xi-\tau+\tau')/\hbar]|v\rangle \quad (A.1)$$

Substituting the following expression into Eq. (A. 1)

$$\exp[i\hat{H}_b\tau/\hbar] = \exp[i\varepsilon_a^0\tau/\hbar + \frac{\Delta^2}{2}\{\exp(i\omega\tau)-1\}]\exp[i\hat{H}_a\tau/\hbar] \times \exp[-\lambda(\tau)\hat{b}^\dagger]\exp[\lambda^*(\tau)\hat{b}], \quad (A.2)$$

we obtain

$$G_v(\tau,\tau',\xi) = \exp[i\varepsilon_a^0(\tau-\tau')/\hbar + \frac{\Delta^2}{2}\{\exp(i\omega\tau)-1\} + \frac{\Delta^2}{2}\{\exp(-i\omega\tau')-1\}]\,A_v(\tau,\tau',\xi), \quad (A.3)$$

where

$$A_v(\tau,\tau',\xi) = \langle v|\exp[i\hat{H}_a\tau/\hbar]\exp[-\lambda(\tau)\hat{b}^\dagger]\exp[\lambda^*(\tau)\hat{b}] \times \exp[-i\hat{H}_a\xi/\hbar]\exp[-i\hat{H}_a\tau'/\hbar] \times \exp[-\lambda(-\tau')\hat{b}^\dagger]\exp[\lambda^*(-\tau')\hat{b}] \times \exp[i\hat{H}_a(\xi-\tau+\tau')/\hbar]|v\rangle, \quad (A.4)$$

with $\lambda(\tau)=\Delta/\sqrt{2}\{1-\exp(-i\varepsilon\tau)\}$. Equation A. 2 has been derived by using the Feynman disentangle technique.[9] Applying the Boson operator technique[9] to Eq. A. 4, we can obtain

$$A_v(\tau,\tau',\xi) = \exp[\lambda^*(\tau)\lambda(\tau')\exp(-i\omega\xi)]\langle v| \times \exp[-\alpha(\tau,\tau',\xi)\exp(i\omega\tau)\hat{b}^\dagger] \times \exp[\alpha^*(\tau,\tau',\xi)\exp(-i\omega\tau)\hat{b}]|v\rangle, \quad (A.5)$$

where

$$\alpha(\tau,\tau',\xi) = \lambda(\tau)-\lambda(\tau')\exp(-i\omega\xi). \quad (A.6)$$

Noting that

$$|v\rangle = \frac{1}{\sqrt{v!}}(\hat{b}^\dagger)^v|0\rangle, \quad (A.7)$$

we can rewrite Eq. A. 5 as

$$A_v(\tau,\tau',\xi) = \exp[\lambda^*(\tau)\lambda(\tau')\exp(i\omega\xi)]\frac{1}{v!} \times \langle 0|\hat{b}^v\exp[-\alpha(\tau,\tau',\xi)\exp(-i\omega\tau)\hat{b}^\dagger] \times \exp[\alpha^*(\tau,\tau',\xi)\exp(i\omega\tau)\hat{b}](\hat{b}^\dagger)^v|0\rangle, \quad (A.8)$$

which is expressed as

$$A_v(\tau,\tau',\xi) = \exp[\lambda^*(\tau)\lambda(\tau')\exp(i\omega\xi)]\frac{1}{v!} \times \langle 0|\{b-\alpha(\tau,\tau',\xi)\exp(-i\omega\tau)\}^v \times \{\hat{b}^\dagger+\alpha(\tau,\tau^\dagger,\xi)\exp(i\omega\tau)\}^v|0\rangle = \exp[\lambda^*(\tau)\lambda(\tau')\exp(i\omega\xi)]\frac{1}{v!} \times \sum_{k=0}^{\infty}\frac{(v!)^2\{-|\alpha(\tau,\tau',\xi)|^2\}^{(v-k)}}{(k!)^2(v-k)!}, \quad (A.9)$$

where we have used the relation

$$(\hat{b}^\dagger+\alpha^*)^v|0\rangle = \sum_{k=0}^{v}\frac{v!(\alpha^*)^{v-k}}{(v-k)!\sqrt{k!}}|k\rangle. \quad (A.10)$$

Equation A. 9 can be expressed in terms of the Laguerre polynomials which is defined by

$$L_v(|\alpha|^2) = \sum_{k=0}^{v}\frac{v!(-|\alpha|^2)^k}{(k!)^2(v-k)!}, \quad (A.11)$$

as

$$\Lambda_v(\tau,\tau',\xi) = \exp[\lambda^*(\tau')\lambda(\tau)\exp(i\omega\xi)]L_v(|\alpha(\tau,\tau',\xi)|^2). \tag{A.12}$$

Substituting Eq. A. 12 into Eq. A. 3 we obtain the expression for the generating function:

$$\begin{aligned} G_v(\tau,\tau',\xi) = \exp[&i\varepsilon^0(\tau-\tau')/\hbar \\ &+ \frac{\Delta^2}{2}\{\exp(i\omega\tau)-1\} + \frac{\Delta^2}{2}\{\exp(-i\omega\tau')-1\} \\ &+ \lambda^*(\tau)\lambda(\tau')\exp(-i\omega\xi)]L_v(|\alpha(\tau,\tau',\xi)|^2). \end{aligned} \tag{A.13}$$

Orbital Phase Design of Acyclic Electron Localizing and Delocalizing π-Conjugated Polyions and Related Systems

Satoshi INAGAKI,* Koji IWASE, and Hirofumi KAWATA
Department of Chemistry, Faculty of Engineering, Gifu University, Yanagido, Gifu 501-11
(Received May 1, 1984)

Acyclic localization-delocalization of electrons in π-conjugated hydrocarbon polyions was predicted in terms of the continuity-discontinuity of the phase of the component orbitals. Many pairs of electron-localizing and -delocalizing conjugated polyions were designed as the model systems of which the relative stabilities have not been explored so far.

The concept of localization and delocalization of electrons is fundamental in organic chemistry. Among the prominent examples are the $4n+2$ π electron rule for aromaticity[1] and the stereoselection rule for pericyclic reactions.[2] The frontier orbital theory for chemical reactivity[3] emphasizes the delocalization between the molecules or bonds. The charge transfer force for intermolecular complexation of electron donor and acceptor[4] belongs to this category. An introduction of orbital symmetry or phase arguments[2,3] makes substantial progress in the theory of cyclic localization and delocalization. Chemical reactions *via* cyclic transition state are under control of the frontier orbital phase of the reacting molecules or parts of molecules or under the conservation of orbital symmetry.

Recently, mechanism of cyclic delocalization among more than two molecules, molecular fragments, or bonds was examined to derive the orbital phase continuity conditions for cyclic delocalization:[5] (a) The most electron-donating orbitals out of phase; (b) the most electron-accepting orbitals in phase; (c) the most electron-donating and -accepting orbitals in phase. The most electron-donating orbital is the HOMO of molecular systems, a bonding orbital of a bond, or a non-bonding orbital of lone-pair electrons. The most electron-accepting orbital is the LUMO of molecular systems, an anti-bonding orbital of a bond, or a vacant orbital on cationic centers. Electron-delocalizing systems are here defined as those which meet the three orbital phase requirements simultaneously. Otherwise, conjugate systems are classified into electron-localizing ones. The orbital phase conditions were already shown[5,6] to cover the aromaticity rule and the stereoselection rule.

More recently, cyclic orbital interaction was shown to be contained in acyclic conjugation.[7] The orbital phase conditions for cyclic delocalization are also applicable to estimating the degree of acyclic delocalization. Unfortunately, the related chemical phenomena observed so far are limited. In this paper we attempt to explore some new aspects of acyclic conjugation in view of continuity and discontinuity of orbital phase. π-Conjugated hydrocarbon polyions are employed as the model species.

Orbital Phase Design

Suppose that four orbitals, a, b, c, and d, interact in a cyclic manner in which the orbital sequence is illustrated in **1**. The interaction is hereafter denoted by the cyclic (a, b, c, d) interaction. The orbitals treated here are limited to occupied (p) and vacant (p*) p-orbitals of ionic centers and bonding (π) and anti-bonding (π*) orbitals of a π-bond. The π and π* orbitals can interact with the others at the same or different atomic orbitals. The former one-centered interaction is denoted by the subscript, 1, the latter two-centered interaction by 2. The other subscripts, s (suprafacial) and a (antarafacial), are introduced to specify whether an orbital takes part in cyclic interaction at the same or opposite side of orbital lobes. For a given set of orbitals, there are many possible modes of cyclic interactions which differ from one another in the orbital sequence, the interacting lobe (s or a) or center (1 or 2). Some interactions are those contained in real molecular systems, the others being not. The orbital interactions are subjected to the orbital phase analysis to predict that the associated molecular systems are electron-localizing or -delocalizing.

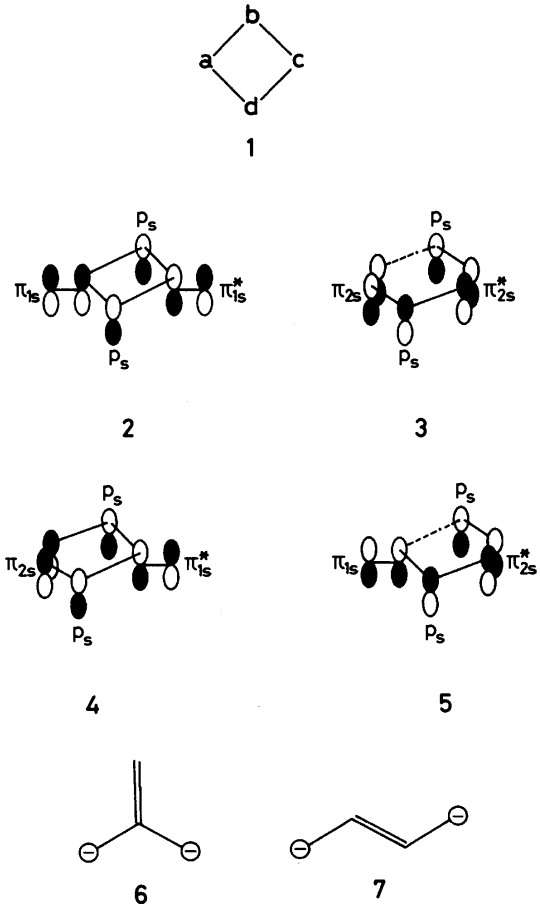
We start with cyclic (π_s, p_s, π^*_s, p_s) interactions. The orbital sequence and the interacting lobes are given there. Whether the π and π* orbitals interact at one or two centers makes a difference. There are four modes of interactions: (π_{1s}, p_s, π^*_{1s}, p_s) (**2**), (π_{2s}, p_s, π^*_{2s}, p_s) (**3**), (π_{2s}, p_s, π^*_{1s}, p_s) (**4**), (π_{1s}, p_s, π^*_{2s}, p_s) (**5**) interactions. When we apply the orbital phase condition, we can classify the cyclic orbital interactions into electron-localizing and -delocalizing ones. The p and π orbitals are electron-donating orbitals, and the π* orbital is an electron-accepting orbital.

In **2** all relations between the neighboring orbitals meet the phase requirements: The electron-donating π and p orbitals out of phase, the donating p and accepting π* orbitals in phase. The interaction is electron-delocalizing. The conditions cannot simultaneously be satisfied in **3**, where the dotted line between the p_s and π_{2s} orbitals in phase indicates that the phase relation is opposite to the requirement. The interaction is electron-localizing. Similarly, the remaining interactions, **4** and **5**, are predicted to be delocalizing and localizing, respectively. The cyclic orbital in-

teractions, **2** and **3**, are associated with real acyclic conjugated species, as previously shown[7] and will be briefly described in the following paragraph: The electron-delocalizing interaction **2** with trimethylenemethane (TMM) dianion (**6**) and the localizing interaction **3** with butadiene (BD) dianion (**7**). There are no actual acyclic systems related to the remaining interactions (**4**, **5**).

Dianions of TMM and BD are considered to be composed of two anionic centers and a double bond. The electron delocalization among the three systems is described in terms of the configuration interactions or the orbital interactions as is schematically represented in Fig. 1a.[7] An electron shifts from an anionic center to the double bond through the interaction of the ground-state configuration, G, with the electron-transferred configuration, T_1. The configuration interaction is approximated to be the interaction of the p-orbital of the anionic center with the π^* orbital of the double bond. An electron hole results from the transfer. The hole can be supplied with an electron from the double bond through the interaction of the transferred configuration with the locally-excited configuration, E. The T_1-E configuration interaction corresponds to the p-π orbital interaction. As a result the G-T_1-E configuration interaction or the π-p-π^* orbital interaction is involved in the above process. There is an analogous process starting with an electron shift from the other anionic lone-pair orbital. The process involves the G-T_2-E configuration interaction or the π-p-π^* orbital interaction, where the p orbital is different from that in the aforementioned process. All interactions are suprafacial. Now we realize that the delocalization involves the cyclic (π_s, p_s, π^*_s, p_s) interaction. In the TMM dianion both anionic centers interact with the same carbon of the double bond. The π and π^* orbitals take part in cyclic interaction at one center (π_{1s},π^*_{1s}) as is shown in **2**. In the BD dianion the anionic centers interact with the different carbons of the double bond. The two-centered interactions at the π and π^* orbitals (π_{2s} and π^*_{2s}) are involved in cyclic interaction (**3**).

We have examined cyclic (π_s,p_s,π^*_s,p_s) interactions which have been found to include the orbital interactions for the dianions of TMM and BD. We replace p_s by p^*_s to examine the corresponding dications. Similar arguments lead to a (π_{1s}, p^*_s, π^*_{1s}, p^*_s) interaction (**8**) and a (π_{2s}, p^*_s, π^*_{2s}, p^*_s) interaction (**9**) in place of **2** and **3**. The interactions are similarly associated with real systems; those corresponding to **4** and **5** being not. The interaction, **8**, is electron-delocalizing, while **9** is electron-localizing. The delocalizing interaction is contained in the TMM dication (**10**), the localizing one in the BD dication (**11**) as is shown in Fig. 1b. An electron shifts from a double bond to a cationic center through the G-T_1 interaction. The configuration interaction is approximated to the π_s-p^*_s interaction. The transferred electron goes back to the π^* orbital through the T_1-E interaction or through the p^*_s-π^*_s orbital interaction. There is another way of electron delocalization *via* the other cationic center



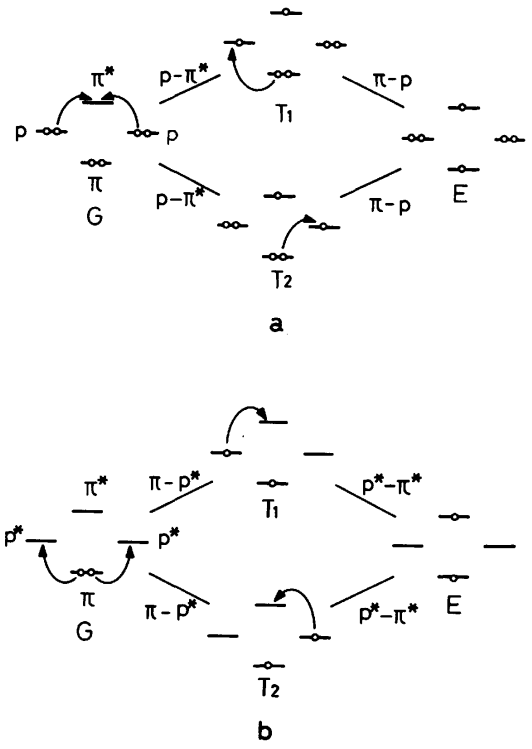


Fig. 1.

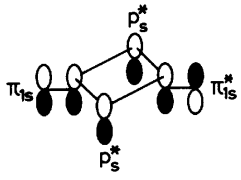
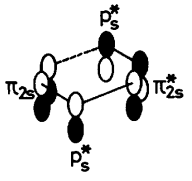
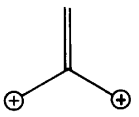


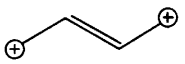
8



9



10



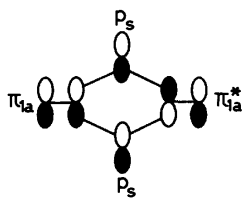
11

through the G-T_2-E interaction or through the π_s-p*$_s$-π^*_s interaction. As a result, the delocalization among two cationic centers and a double bond contains the cyclic (π_s, p*$_s$, π^*_s, p*$_s$) interaction. The delocalizing **8** with one-centered interactions of π and π^* orbitals is associated with the TMM dication, the localizing **9** with the BD dication.

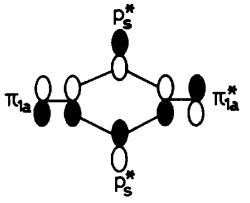
We have described the suprafacial (π_s, p$^{(*)}_s$, π^*_s, p$^{(*)}_s$) interactions and treat here their antarafacial analogues, the (π_a, p$^{(*)}_s$, π^*_a, p$^{(*)}_s$) interactions. The antarafacial counterparts of the suprafacial interactions for the divalent ions of TMM and BD, and these only, are associated with real systems. The electron-delocalizing interaction (**2**) contained in TMM dianion corresponds to the (π_{1a}, p_s, π^*_{1a}, p_s) interaction (**12**). That (**8**) contained in TMM dication corresponds to the (π_{1a}, p*$_s$, π^*_{1a}, p*$_s$) interaction (**13**). These are related to the antarafacial analogues of the TMM divalent ions, where a double bond interacts with two ionic centers at the same carbon (**14** and **15**). Electron-localizing counterparts are the (π_{2a}, p_s, π^*_{2a}, p_s) and (π_{2a}, p*$_s$, π^*_{2a}, p*$_s$) interactions (**16** and **17**). The related systemes are the antarafacial analogues of BD divalent ions (**18** and **19**).

We have described cyclic (π, p$^{(*)}$, π^*, p$^{(*)}$) interactions and found that the orbital interactions (**2**, **3**, **8**, **9**, **12**, **13**, **16**, **17**) are associated with the real molecular systems (**6**, **7**, **10**, **11**, **14**, **15**, **18**, **19**), respectively. Although there are many other possible interactions of four orbitals, none of them are contained in real polyvalent ions. We will here design electron-localizing and -delocalizing species with more electric charges by fusing the cyclic orbital interaction units for the divalent ions singled out above. Charge (positive or negative) does not alter the conclusion with respect to localization and delocalization,[8] as can be seen in the preceding arguments. The following will be confined to polyanions.

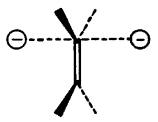
We first fuse the suprafacial interaction units, *i.e.*, the delocalizing interaction, **2**, and the localizing interaction, **3**. The fusion of **2** at one of p_s's gives rise to a delocalizing chain of cyclic orbital interaction (**20**). The related system is polyanion where



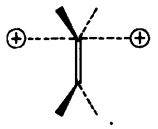
12



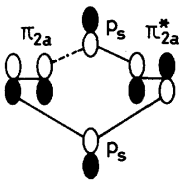
13



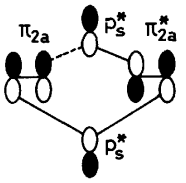
14



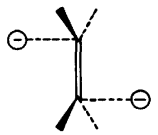
15



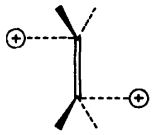
16



17



18



19

each neighboring pair of TMM dianions share one of anionic centers (**21**). The localizing counterpart (**22**) similarly derives from **3**. The cyclic orbital interaction corresponds to the polyanion (**23**) where anionic centers are shared by BD dianions. The two-site fused interactions (**24** and **25**) are those contained in the delocalizing dianion (**26**) and the localizing dianion (**27**).

Secondly, we fuse the antarafacial interaction units, *i.e.*, the delocalizing interaction (**12**) and the localizing interaction (**16**). Similar arguments lead to the delocalizing (**28**) and localizing (**29**) chains of cyclic orbital interactions in case of one-site fusion. These are associated to ions and double bonds stacked alternately (delocalizing **30** and localizing **31**). The two-site fusion gives rise to the delocalizing (**32**) and localizing (**33**) arrays of orbitals, which are those contained in **34** and **35**, respectively.

We have described the cyclic interactions of two p$^{(*)}$'s, π and π^* orbitals, which have been shown to be contained in the divalent ions of TMM and BD (**6**, **7**, **10**, **11**) and their corresponding antarafacial analogues (**14**, **15**, **18**, **19**) and designed electron-localizing and -delocalizing polyions (**21**, **23**, **26**, **27**, **30**, **31**, **34**, **35**) by fusing them at one and two sites. We will next describe cyclic orbital interactions of one p orbital and three of π or π^* orbitals. The real acyclic systems

represented by some interactions, *i.e.*, the (p, π^*, π^*, π) interactions (**36**, **38**) and (p, π^*, π, π) interactions (**37** and **39**), are monovalent ion units, *i.e.*, the conjugated anions, **40** and **41**, as will be shown in the following paragraph. We will then design some dianions by fusing the cyclic orbital interaction units in a different manner.

The mechanism of electron delocalization from the anionic center to the distant double bond through the middle bond in **40** and **41** is shown in Fig. 2a. An electron shifts from the anionic center to the middle bond through the G-T_1 or p-π^* interaction. The transferred electron shifts farther to the terminal bond through the T_1-T_3 or π^*-π^* interaction. The process involves the p-π^*-π^* interaction. There is another path for the distant delocalization. An electron shifts from the middle to terminal bond through the G-T_2 or π-π^*

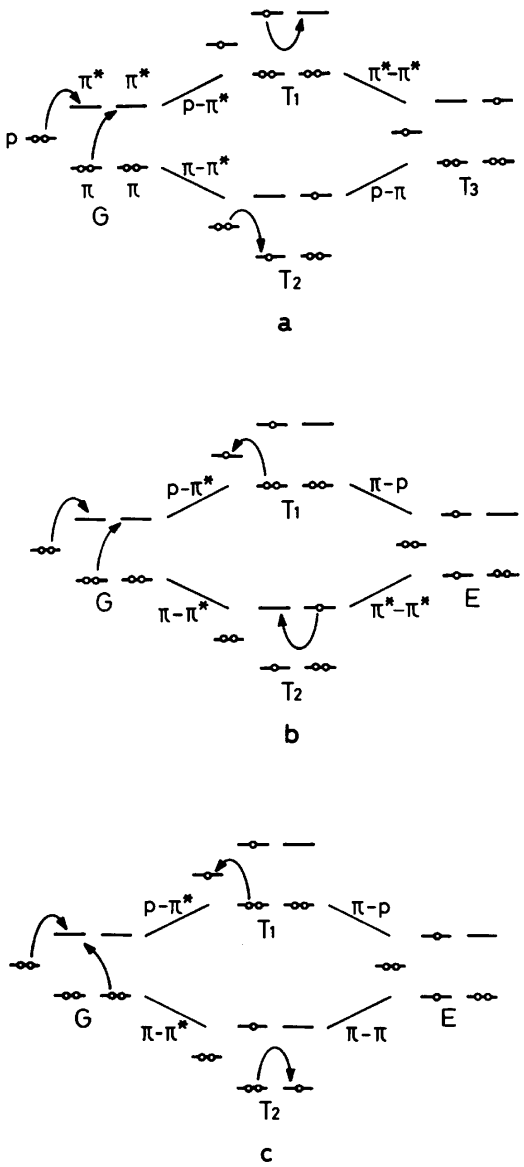

Fig. 2.

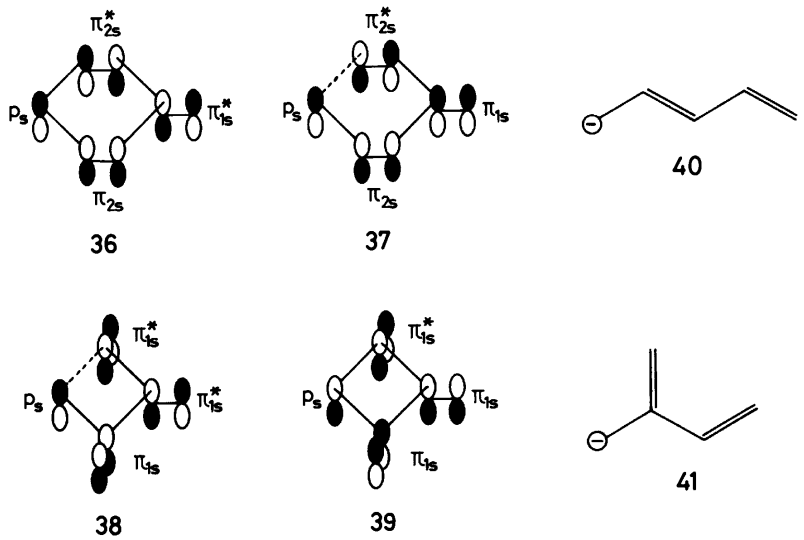
interaction, leaving an electron hole in the middle π bond. The hole then shifts to the anionic center through the T_2-T_3 or p-π interaction. The process involves p-π-π^* interaction. As a result, the distant delocalization *via* the two paths contains the (p_s, π^*_s, π^*_s, π_s) interactions (**36—39**).

The cyclic interactions are identical with that involved in a way of polarization of the middle bond (Fig. 2b). The electron shift from the anionic center to the middle bond leaves an electron hole which moves to the latter. The process involves the G-T_1-E or π_s-p_s-π^*_s interaction. In the other path, an electron first shifts from the middle to terminal bond and then back to the former through the G-T_2-E or π_s-π^*_s-π^*_s interaction. As a result, the polarization involves the same (p_s, π^*_s, π^*_s, π_s) interaction as the distant delocalization. The dual property of the cyclic orbital interaction should be noted for forthcoming arguments.

Another polarization path is shown in the bottom half of Fig. 2 c. The electron shift from the terminal to middle bond leaves an electron hole, which moves to the latter through the G-T_2-E or π_s-π_s-π^*_s interaction. This forms a different cyclic (p_s, π_s, π_s, π^*_s) interaction with the π_s-p_s-π^*_s interaction, which has been shown in the preceding paragraph to be involved in the polarization of the middle bond (The top halves of Fig. 2b and 2c represent the identical process).

We have shown that cyclic orbital interactions of one p orbital and three π and π^* orbitals are contained in the conjugated monoanions. The cyclic orbital interaction with the dual nature—the distant delocalization of the lone-pair electrons and the polarization of middle bond—is favored by phase continuity (**36**) in the anion **40**, and disfavored by phase discontinuity (**38**) in the anion **41**. The cyclic orbital interaction for the polarization only is favored by phase continuity (**39**) in **41**, and disfavored by phase discontinuity (**37**) in **40**.

Now we design cyclic orbital interactions for dianions by fusing the delocalizing interaction units derived



from the monoanions. The interaction (**36**) for the delocalization-polarization in **40** and that (**39**) for the polarization in **41** are combined to share the neighboring pair of π_{2s} and π^*_{1s} in **36** and that of π_{1s} and π^*_{1s} in **39**. The resulting orbital interaction (**42**) is associated with the dianion (**43**) where the diene moieties in the monoanions are superimposed. When the orbital interactions (**36**) for the delocalization-polarization are combined with each other to share the π^*_{1s}-π^*_{2s} pairs, a cyclic interaction (**44**) for the dianion **45** is generated. A combination of the interactions (**39**) for the polarization to share the π_{1s}-π_{1s} pairs leads to a cyclic interaction (**46**) for the dianion (**47**).

Now we predict the relative stabilities of the designed dianions. The cyclic orbital interaction unit (**36**) with the dual nature of delocalization and polarization should contribute to more stabilization than the polarization interaction (**39**). The stability is then expected to increase with the number of the delocalization-polarization interactions involved if there is no extra-stabilization on fusion. In the dianion **45** the cyclic orbital interaction units are both the delocalization-polarization interactions. The dianion **43** contains one, the remaining (**47**) none. The stability then decreases in the order of **45**>**43**>**47**. However, the fusion of orbital interaction units can enhance the effects of each other as significantly as to invert the ordering. A pair of orbitals shared on fusion in **42** is a primary[9] interaction between electron-donating and accepting orbitals. In addition, the cyclic six-orbital (p, π^*, π^*, p, π, π) interaction in **42** satisfies the phase continuity requirements. In contrast, the orbital interactions shared in **44** and **46** are secondary[9] between electron-donating orbitals or between electron-accepting orbitals. The extra-stabilization due to the fusion should be smaller, if any. In addition, the cyclic six-orbital (p, π^*, π^*, p, π, π) interactions do not satisfy the phase continuity requirements.[10] The extra-stabilization on fusion is then expected to be greater in **43**. The stability ordering of **43** and **45** might be inverted.

The conjugate dianions designed in the preceding sections are considered to be vinylogues of TMM and BD dianions. There is a pair of corresponding vinyl-

ogues of the antarafacial analogues (**14** and **18**) of the TMM and BD dianions, where two juxtaposed π-bonds interact with two anionic centers in a different manner as shown in **48** and **49**. The interactions involved are cyclic six-orbital (p_s, π^*_a, π^*_a, p_s, π_a, π_a) interactions, **50** and **51**. The cyclic six-orbital interaction is favored by the phase continuity (**50**) for **48** and disfavored by the phase discontinuity (**51**) for **49**. It follows that **48** is more stable than **49**. The relative stability makes a contrast with the aforementioned stability of the antarafacial analogues (**14**, **18**) of the TMM and BD dianions. We could experimentally examine the prediction by preparing such polycyclic species as **52**—**55**.

Geometry Optimization

The preceding orbital phase arguments have been limited to the localization-delocalization of π electrons, and have not taken into account the effects of σ electrons and inner-shell electrons. It is necessary to examine whether these effects may modify or alter the orbital phase predictions, and to supplement the qualitative arguments by means of numerical values. Molecular geometries of some ions are optimized by *ab initio* molecular orbital calculations with STO-3G basis set. The geometries fully optimized under given symmetry constraints are shown in Fig. 3. The relative energies of the isomers to be compared are listed in Table 1.

The TMM dianion is estimated to be more stable by 22.5 kcal mol^{-1}† than the BD dianion. The relative stability is consistent with the orbital phase prediction[7] and with the experimental observation.[11] The bond lengths also support the preceding arguments. The bond alternation is remarkable in the electron-localizing BD dianion. The small distance (1.35 Å) between the inner carbons suggests a double bond character while the distance between the inner and outer carbons is long (1.47 Å). The carbon–carbon bond length (1.42 Å) in the electron-delocalizing TMM dianion is intermediate between those in the BD dianion.[12] Similar results are obtained for the TMM and BD dications. The energy difference is 18.1 kcal mol^{-1}. The bond lengths are 1.43 Å in the TMM dication, and 1.36 Å and 1.50 Å in the BD dication.

The one-site fusion is found to still retain the delocalization and localization characters of the unit dianions. The fully cross-conjugated C_7H_9 trianion[13] (**21**) is more stable by 7.6 kcal mol^{-1} than the fully linearly conjugated C_7H_9 trianion[14] (**23**). The bond alternation in the linear trianion is similar to that in the BD dianion. The short bond length is 1.35 Å, the long bond lengths being 1.47 Å and 1.48 Å. All the carbon–carbon bond lengths (1.41, 1.43, and 1.47 Å) in the cross trianion range between those in the linear trianion. Noteworthy is that the distance between the fused and central carbons in the TMM dianion unit is close to the larger distance in the linear trianion. The cross trianion tends to shift from the one-site fused pair of TMM dianions to two allyl anions connected with each other at their central carbons by an anionic carbon.

The two-site fusion of the TMM and BD dianion units gives rise to the four and six-membered ring dianions (**26**, **27**). The direct comparison of the thermodynamic stabilities due to π-electron delocalization is hampered by ring strain. The instability of benzene dianion is also a direct result of the Hückel rule. It is more interesting to compare the delocalizing dianion (**26**) with its four-membered ring isomer (**56**). The delocalizing **26** was estimated to be more stable by 29.2 kcal mol^{-1}. The bond lengths range less widely (1.36—1.46 Å). The structure of the 1,3-isomer deviates from formally fused TMM dianions toward a combined system of anionic centers and exocyclic double bonds. The 1,2-isomer tends to obtain a property of linearly-conjugated dianion by lengthning a bond in the ring.

Geometry optimization of C_6H_8 dications shows that the relative stability decreases in the order of **57**>**58**>**59**. The stability of **57** relative to **58** suggests the importance of the extra-stabilization by sharing the primary orbital interaction corresponding to **42** for the dianions. A conspicuous feature in the optimized geometry is a strong tendency toward two allyl cations. The linear dication appreciably alternates

the single and double bonds. The remaining isomer of C_6H_8 dications, **60**, which has an electron-localizing BD dication unit, is the least stable. The geometry suggests that the dication is a combination of a pentadienyl cation and a cationic center. These results are almost the same as those of the dianionic analogues[15] (**43**, **45**, **47**, **61**).

Electron Configuration Analysis for Many System Interaction

The *ab initio* calculations almost completely support the orbital phase predictions on the relative stabilities of the polyions, and give more detailed information of molecular geometries. Here we attempt to look into the relation of these calculated properties with the mechanism of electron delocalization among many bonds, cationic and anionic centers. We are concerned with the delocalization of π-electrons in conjugate polyions, composite systems of double bonds and anionic or cationic centers. The ground-state configuration (G) has two electrons in each bonding orbital of double bonds and in each non-bonding orbital on the anionic centers, and no electron in p-orbitals on the cationic centers. The delocalization is expressed by mixing the electron transferred configurations (T) and locally-excited configurations (E) into G. The ground-state wavefunction is then formulated as

$$W = C_G G + \sum_T C_T T + \sum_E C_E E + \quad (1)$$

In the transferred configuration an electron is shifted from an occupied orbital of a bond or an anionic center to a vacant orbital of another bond or a cationic center. In the locally-excited configuration an electron is promoted from the bonding orbital to the antibonding orbital in a bond.

In general there are many Kekulé structures for a given molecule. A Kekulé structure corresponds to a ground-state configuration. It is meaningful to analyze how electrons delocalize starting from the main Kekulé structure. The electron configuration analysis for many system interaction (ECAMSI)[16] is employed to single out the main Kekulé structure. The wavefunction is subjected to ECAMSI for different ground-state configurations or Kekulé structures. The calculations yield the coefficients of G, T, and E configurations. The main Kekulé structure is one with the biggest C_G.

Some quantities are defined to examine the delocalization in a quantitative manner. The integration of the normalized wavefunction (Eq. 1) all over the space leads to the following equation:

$$1 = C_G^2 + \sum_T C_T^2 + \sum_E C_E^2 + \sum_T 2C_G C_T S(G,T) + \sum_{T_1>T_2} 2C_{T_1} C_{T_2} S(T_1,T_2) + \sum_{T,E} 2C_T C_E S(T,E) + \quad (2)$$

The square terms are the weights of electron configurations. The first cross terms represent the contribution from the G-T configuration interactions. This can be used as a measure of adjacent delocalization through the neighboring occupied and unoccupied orbital interactions. The second cross terms represent the contribution from the T-T configuration interactions. This can be used as a measure of distant delocalization beyond more than one systems through the interactions between the neighboring occupied orbitals and between the neighboring vacant orbitals. The third cross terms represent the contribution from the T-E configuration interactions. This can be used as a measure of polarization of bonds. The coefficients of configurations show the extent of contribution of each configuration to the electronic structure of a molecule. It has been shown that the ratios of coefficients of various configurations to that of the ground state configuration (C/C_G) are more preferable for comparing electronic structures of different molecules.[7b] We discuss the results of configuration analysis on the basis of the coefficient ratios. The GT, TT, and TE terms of interest are defined as follows:

$$GT = \sum_T 2C_G C_T S(G,T)/C_G^2$$
$$TT = \sum_{T_1>T_2} 2C_{T_1} C_{T_2} S(T_1,T_2)/C_G^2$$
$$TE = \sum_{T,E} 2C_T C_E S(T,E)/C_G^2 \quad (3)$$

The main Kekulé structures are confirmed to be such forms as drawn. The results of configuration analysis on the optimized geometries are listed in Table 1. The relative stabilities are completely paralleled with the sums of three terms for the dianions of TMM and BD and for the one-site fused trianions. A difference in the electronic structures comes from the double bond polarization. There is no double bond polarization (C_E=0.0 therefore TE=0.0) in the electron-localizing isomers (**7**, **11**, **23**), as has been predicted by the phase discontinuity of the cyclic orbital interaction. In the delocalizing ones the polarization contributes as significantly as the adjacent delocalization. According to perturbation theory the adjacent delocalization should be similar for the localizing and delocalizing pairs. The increment of the GT term in the delocalizing isomers is considered to be induced by the allowed polarization

The GT and TE terms of the delocalizing two-site fused dianion (**26**) are greater than those of the reference species (**56**), as was predicted. The relative stability can be similarly understood to be also due to the allowed bond polarization and the induced increment of the adjacent delocalization.

The most stable C_6H_8 dianion (**43**) has a greater sum of the three terms than the second (**45**). The magnitude of the GT term in **43** is due to the enhanced mixing of the transferred configuration or primary interaction between the π-π* interaction shared by the fused cyclic orbital interactions as has been described (**42**). The configuration coefficient ratio (0.24) of the transferred

configuration is larger than that (0.17) of the corresponding transferred configuration in **45**. A similarly expected difference in polarization is found in the coefficient ratios. The locally-excited configuration ratio (0.32) for the cross-conjugated double bond in **43** is more than twice greater than that (0.13) in **45**.

There is a limit to the parallelism between the simply predicted or calculated stabilities and the results of configuration analysis. The sum of the three terms for the dianions (**47** and **61**) of lower stabilities are greater than that of more stable **43** or **45**. A possible explanation for the lost parallelism might be related with the "multiplicity" of the main Kekulé structure. The main Kekulé structure is uniquely determined "singlet" for **43** and **45** for which the sum of the three terms of configuration analysis is well correlated to the total energy. There is one more equivalent Kekulé structure for **47** and **61**, which are then expressed by the "doublet" Kekulé structures. The multiplicity arises from the discrepancy in symmetry between Kekulé structures and molecular geometries. Lower symmetry of Kekulé structures might enforce "undesirable" electronic rearrangements to recover the symmetry of electronic structures imposed by molecular geometries. The artificial failure inevitably results in overestimation of GT, TT, and TE terms.

The authors thank Prof. Paul von Ragué Schleyer of Universität Erlangen-Nürnberg for private communication of their results in prior to publication and stimulating criticisms on our manuscript. The *ab initio* molecular orbital calculations were carried out on a HITAC-M200H computer, Institute for Molecular Science, with IMSPACK programs. The other calculations were carried out on a FACOM-M382 computer, Nagoya University Computer Center. This work was supported by Grant-in-Aid for Scientific Research from the Ministry of Education, Science, and Culture.

8) a) The pioneering works by Clark, Schleyer and their collaborators have been encountered with greater difficulties in preparing dications[b] than dianions[c] of TMM, and they have been tempted to throw doubt on the thermodynamic stability of the dications. The TMM dianion with a phenyl group on each methylene was readily prepared at 20°C, whereas a reasonable synthetic route to the corresponding triphenyl TMM dication leads only to ring closure or intramolecular Friedel-Crafts reaction involving the aromatic moiety. This contrast may be attributable to the kinetic cause: Electrophilic aromatic substitutions are familiar while the substrates of nucleophilic ones are limited. The difficulties have been demonstrated by other attempts, but the origins seem unclear. There may be no well-established grounds for claiming that polycations and polyanions have similar stabilities. The similarities, which allow us to exclude a group of counterparts (polycations) from the arguments in the text, are the relative stabilities of the isomeric ions. Meaningful is the comparison of the TMM dication with the BD dication, but not that of the dication with the dianion; b) K. Schötz, T. Clark, H. Schaller, and P. v. R. Schleyer, *J. Org. 9) According to the perturbation theory the interaction between electron-donating and accepting orbitals is contained in the second-order energy terms, whereas those between donating orbitals and between accepting orbitals are contained in higher-order terms.[5]

10) On fusion there appears another cyclic six-orbital interaction, *i.e.*, (p, π^*, π, p, π^*, π) interaction. The orbital phase is continuous. However, the continuity does not promote electron delocalization because the donating and accepting orbitals are excessively alternated along the chain in the orbital cycle. For more details see the continuity and discontinuity of cyclic conjugation.[6]

12) a) Some molecular orbital calculations of more realistic models with coordinated Li atoms have been reported. In the BD "dianion" lithium cations were indicated to bridge the terminal carbons symmetrically and doubly.[b] The most stable structure of TMM "dianion" has a 1,3- and 1,3'-bridged structure (C_2)[c], which was, however, found to be different from the X-ray structure of tribenzylidenemethane di(lithium tetramethylethylene diamine (TMEDA))[c]: one lithium bridges the 1,3 positions of a allyl system while the other bridges the remaining carbons in 1,2-manner. The models for this structure (C_s) and with the highest symmetry (D_{3h}) were calculated to be higher in energy by about 4 kcal mol^{-1}. Anyway, we think that our dianion model is sufficient to compare the relative stabilities of polymetallated hydrocarbon isomers of the same number of carbons and charges but topologically different carbon skeletons; b) P. v. (Received May 24, 1984)

WC, W_2C, and W were comparatively studied for CO hydrogenation to reveal the catalytic role of carbon alloyed with metals. The main products of the reaction were CH_4, CO_2, and H_2O on these catalysts, but the kinetic data obtained for WC catalyst were different from those for W_2C and W catalysts: *i.e.*, the apparent activation energies for CO consumption and for CH_4 formation on WC were found to be about three times larger than those on W_2C or W. Furthermore, the catalytic activity of WC was about 20 times larger than that of W_2C and W. It was suggested that the hydrogenation of CO on WC proceeds *via* direct hydrogenation of adsorbed CO forming a CHO adsorbed species as an intermediate, whereas on W_2C and W catalysts, dissociation of CO occurs in the initial step, followed by further hydrogenation of adsorbed carbon to form CH_4. X-ray photoelectron spectroscopic (XPS) studies on WC and W_2C showed that the WC surface catalytically activated was almost free from graphite carbon and oxygen as poison, but W_2C surface was largely covered with graphite carbon. These distinctive catalytic behavior differences between the carbide catalysts are discussed on the basis of the structure of the active surfaces.

The hydrogenation of carbon monoxide is a current problem in research on heterogeneous catalysis, and has been studied by many investigators on supported and unsupported metal catalysts.[1,2,3] Recently, it has been shown that the transition metal carbides form a new group of catalysts for the hydrogenation of benzene,[4] ethylene,[5,6] and carbon monoxide.[7,8] For the hydrogenation of carbon monoxide, the metal carbides were found to produce higher molecular weight hydrocarbons involving olefins other than methane.[7] A subsequent kinetic study suggested that the adsorbed CO and H atoms form an intermediate of CH_xO type prior to the C-O bond rupture.[8]

From the point of view of catalyst modification by alloying metals with carbon, the states of the carbon species are of importance in understanding the difference in the catalytic properties between metal carbides and the original pure metals. For example, McCarty and Madix found that the carbide-carbon on the Ni(110) plane changes its catalytic properties like those of copper metal for the decomposition of formic acid.[9] Boudart and coworkers reported that W and Mo catalysts modified by C and O atoms exhibit activity and selectivity resembling those of Group VIII transition metals.[10,11] Ross and Stonheart reported that the electrocatalytic activity of tungsten carbide was sensitive to surface composition.[12,13] The unique physical properties such as extremely high melting point, metal-like thermal and electronic conductivities, superconductivity *etc.* of transition metal carbides can be closely related to their electronic structure derived from the coexistence of covalent, metallic and ionic bonds. They have been extensively studied both experimentally and theoretically.[14] However, little effort has been devoted to understanding their chemical reactivity and catalysis. In particular, the question as to how the carbon incorporated in metals affects the catalytic activity still remains open.

In the present study, the hydrogenation of CO was investigated on WC, W_2C, and W in order to reveal the catalytic behavior of the transition metal carbides. Attention was focused on the reaction mechanisms over these catalysts and on the structure of active sites which are responsible for the catalysis. By the use of computer aided analysis of pressure dependencies, a surface intermediate of CHO species was concluded to be formed during the reaction on WC, whereas, it was expected on W_2C and W that CO first dissociates into C and O atoms on the surface, followed by hydrogenation to produce methane. XPS technique was used to examine the surface states of the catalysts.

Experimental

The kinetic measurements of the reaction were carried out using a recirculation reactor, 520 ml in volume, with a liquid nitrogen cold trap for removing the condensable products from the reaction system during the course of the reaction. The reaction products were analyzed using gas chromatography and mass spectrometry. The powdered materials, WC, W_2C, and W (≈300 mesh) of high purity (>99%) were purchased from Fru-uchi Chemicals Co. X-ray diffraction measurement of WC exhibited only the peaks due to monocarbide, but the diffraction peaks of W_2C catalyst showed a slight trace of metallic tungsten. Before the kinetic measurements, WC was catalytically activated by heating *in vacuo* at 700 °C as described elsewhere.[5] W_2C and W were reduced at 600 °C in an atmosphere of hydrogen at 100 Torr (1 Torr=133.322 Pa) until there was no further formation of H_2O, and subsequently evacuated at 700 °C. The material balance of carbon in the reaction system was maintained within ±5%. The BET surface area of WC measured by Kr adsorption was 1.5 $m^2 g^{-1}$, which was almost identical to the area of the other powdered carbide catalysts. XPS spectra were recorded on a Hewlett-Packard 5950A ESCA spectrometer using monochromatic Al $K\alpha$ exciting radiation. The samples pressed into discs were transferred into the preparation chamber of the spectrometer and subjected to *in situ* heat-treatment *in vacuo* or in hydrogen at 700 °C.

Result

Figure 1 shows the variation of product distributions with reaction temperature on WC and W_2C. The main products were CH_4, CO_2, and H_2O on WC catalyst at temperatures above 400 °C, and the formation of hydrocarbons of higher molecular weight became appreciable at lower temperatures even at high values of the H_2/CO ratio. Among the metal carbide catalysts investigated here and elsewhere,[7,8] WC is most liable to produce methane. The distribution of products on W catalyst was almost identical to that on W_2C.

Figure 2 shows the dependence of the initial rates of CO consumption and of CH_4 formation on the reaction temperature during the CO hydrogenation under the initial pressures of H_2 at 100 Torr and CO at 10 Torr. The apparent activation energies for CO consumption and CH_4 formation were respectively 64.4 and 76.1 kJ mol^{-1} on WC, 18.4 and 26.8 kJ mol^{-1} on W_2C, and 20.1 and 25.9 kJ mol^{-1} on W catalysts. It is noted that the two values for W_2C and W catalysts are very close in both processes and the values for WC are about three times larger than for W or W_2C catalyst. The catalytic activity ratio of WC, W_2C, and W per unit weight were 200:1.4:1 at 400 °C. The amounts of CO chemisorbed at 0 °C were determined to be 4×10^{14} and 5×10^{13} mol cm^{-2} on the activated WC and W_2C, respectively. This finding indicates that the WC catalyst is roughly 20 times more active per CO-site than W_2C catalyst.

The pressure dependence of the reaction rates was investigated on WC and W_2C at the reaction temperature of 400 °C, where the main products were CH_4, H_2O, and CO_2. The results are shown in Figs. 3 to 5, and they are summarized in Table 1. The reaction orders of the rates of CO consumption and CH_4 formation are similar to those on the transition metals such as Ni, Pd, Rh, Ru *etc.*[15] However, characteristic features on the carbide catalysts can be seen in the reaction orders for the formation of H_2O and CO_2 on WC; *i.e.*, the order for H_2O formation exceeds unity with respect to H_2 pressure, but is negative with respect to CO pressure. Furthermore, the order for CO_2

TABLE 1. PRESSURE DEPENDENCE OF REACTION RATES ON WC AND W_2C

	r_{CO}		r_{CH_4}		$\bar{r}_{H_2O}$		$\bar{r}_{CO_2}$	
	x	y	x	y	x	y	x	y
WC	0.9	0.3	1.2	0.1	1.5	−0.3	0.6	0.7
W_2C	0.4	—	0.8	—	1.0	—	0.0	—

r (or $\bar{r}$)$=k P_H^x P_{CO}^y$, where r represents the initial rate, and $\bar{r}$ is the average rate estimated from the amount produced in a constant initial period of reaction, 10 min.

formation is positive with respect to H_2 pressure. These characteristics of pressure dependence are in common with those on other metal carbides such as TiC, TaC, and Mo_2C. While, on W_2C, the orders of H_2O and CO_2 with respect to H_2 pressure are 1.0 and nearly zero, respectively.

In a previous XPS study on TaC and WC,[5] the peaks assigned only to the pure state of the respective metal monocarbide were observed when the samples were heated *in vacuo* at temperatures higher than the temperatures required for activation, while the oxidized states of the metals were observed in the lower temperatures. In the present case of WC and W_2C, the characteristic peaks due to the oxides disappeared after the activation treatments were made (Figs. 6 and 7). As shown in Fig. 7(a), the catalytically activated WC exhibited a typical peak only at 283.2 eV which can be attributed to carbide carbon, indicating that the surface was almost free from graphite-like contaminant. However, the superimposed peaks were observed with almost equal intensity at 284.8 and 283.5 eV for the

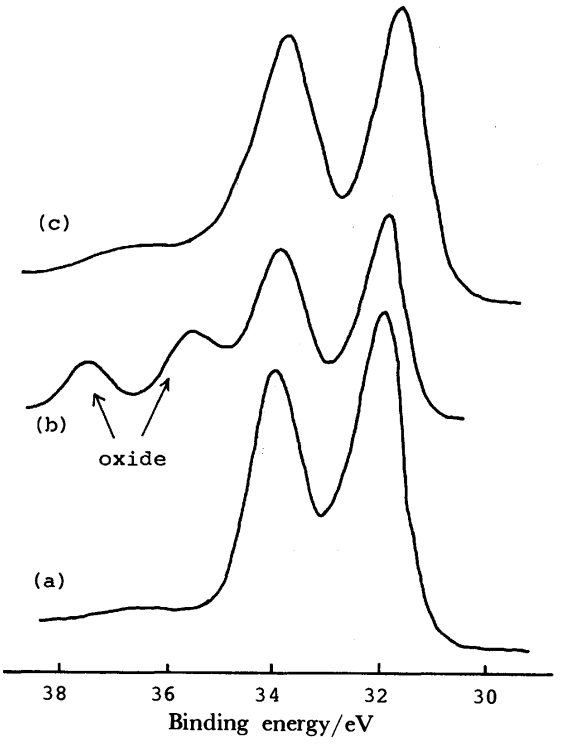

Fig. 6. XPS spectra of W 4f region for WC and W_2C. (a) activated WC, (b) untreated WC, and (c) activated W_2C.

activated W_2C (Fig. 7(c)). The existence of the former peak indicates that the surface of W_2C is largely covered with graphite-like carbon. The C 1s peak of WC was found to shift toward lower binding energy relative to that of graphite carbon by 1.6 eV, suggesting that the electrons are transferred from the W to C atoms. It is of note that the observed shift of W_2C, 1.4 eV was smaller than that of WC.

Discussion

Structure of Active Sites. The present kinetic measurements of CO hydrogenation showed a remarkable difference among the WC, W_2C, and W catalysts. The latter two catalysts exhibited very similar activation energies, specific activities and product distributions. WC, on the contrary, exhibited a marked catalytic activity; the activation energies for CH_4 formation and CO consumption were about three times larger than those on W_2C and W, and the specific activities were larger by about 20 times. This different catalytic behavior among the catalysts may arise from the different states of the active sites distributed on the surfaces. Figure 8 shows the crystal structures of WC and W_2C and the periodic arrangement of constituent atoms for $(10\bar{1}0)$ and (0001) planes. These carbides have similar hexagonal structures: The monocarbide consists of an alternate stacking of W- and C-layers along the c-axis direction, whereas W_2C has a series of a unit consisting of two W-layers and a C-layer.[14] As for the $(10\bar{1}0)$ plane of these carbides, both W and C atoms compose the uppermost layer in contact with each other, whereas either of W- or C-atoms compose the uppermost layer for the (0001) plane. Although there is little knowledge concerning the surface structure of WC, an ISS study on the single crystal faces of TiC by

1: crystal structure, 2: $(10\bar{1}0)$ face, and 3: (0001) face.
○: W atom, and ◐: C atom.

Oshima *et al.*[16] gives some assistance for describing the behavior of the WC surface. It revealed that with the TiC (111) face Ti atoms compose the uppermost layer and the adsorption rate of oxygen on the (111) face is 100 times larger than that on the (100) face.[16] It is of note that the structures of the (0001) and $(10\bar{1}0)$ faces of WC resemble those of the (111) and (001) faces of TiC, respectively. More recently, Aono *et al.* reported that the carbon vacancies on the TiC (100) plane were very active for the adsorption of oxygen.[17] If carbon vacancies are formed on the WC surface during the activation treatments and are responsible for the catalytic reaction, the catalytic behavior of WC is expected to become closer to that of W_2C, which is opposed to the experimental facts obtained here. Furthermore, considering the uptake of CO adsorption, 30—40 percent of the total surface atoms of WC are estimated to be catalytically effective. This suggests that the surface vacancies are less likely to contribute to the hydrogenation of CO.

It is found that the surface of activated WC is free from contaminants such as oxygen and graphite-like carbon. However, a large amount of graphite residues remains on W_2C even after the high temperature treatment *in vacuo*, and the adsorption amount of CO on W_2C is very small in comparison with that on WC. From the previous study on TaC, the surface graphite acts as a strong poison for the catalytic reaction of ethylene hydrogenation. Assuming that the metal atoms are exposed as the uppermost surface layer of WC (0001) and W_2C (0001) faces as in TiC, the (0001) faces are expected to be catalytically more active than the $(10\bar{1}0)$ faces. With WC (0001) surface, the electronic state of the uppermost W atoms should be strongly

modified by the underlying C atoms. This effect is thought to be responsible for the suitable modification of the catalytic properties of surface-exposed W atoms. On the other hand, the nature of the W_2C (0001) surface might be similar to the pure W metal because the second layer also consists of W atoms. Therefore, metallic atoms of the W_2C (0001) surface with high chemical reactivity may strongly bind with contaminants such as graphite carbon or oxygen atoms, resulting in a reduction of the catalytically effective area to only a few per cent of the total surface.

Bradshaw *et al.*[18] performed angle-resolved photoemission measurements of TiC (111) and TiC (100) surfaces. They found that TiC (111) yielded a Ti-terminated (1×1) structure after annealing at 1000°C *in vacuo* and thus the prepared surface readily adsorbed hydrogen molecules, whereas TiC (100) showed no evidence of H_2 adsorption. These findings also suggest that metal-terminated polar surfaces are mainly responsible for the catalytic activities of refractory metal carbides.

Reaction Mechanisms. There is no general agreement of the nature of the reaction intermediates or of the reaction mechanism for CO hydrogenation on metallic catalyst surfaces: Some authors proposed that CO molecules first dissociate into carbon and oxygen atoms. This is followed by hydrogenation of the former adsorbate to produce methane or other higher hydrocarbons and by hydrogenation of the adsorbed oxygen atoms to produce water or by their reaction with CO to produce CO_2 molecules.[2,3,19,20] However, other investigators advocate that the adsorbed CO and H_2 form an oxygen containing surface species, CH_xO (x=1—3), prior to the C-O bond breaking.[1,21,22] In a previous paper,[8] we proposed the latter mechanism for the CO hydrogenation on TaC, TiC, and Mo_2C catalyst mainly for the following reasons:

(i) The adsorbed oxygen atoms on these carbide catalysts are tightly bound to the surfaces and can not be eliminated near the reaction temperatures, regardless of the presence or absence of hydrogen in the gas phase.

(ii) The facts that the reaction order of H_2O formation with respect to the hydrogen pressure exceeds unity and that the formation of CO_2 is enhanced by an increase in H_2 pressure; this suggests the existence of some attractive interaction between chemisorbed CO and H atoms. Thus on WC catalyst, similar reaction mechanism to those proposed previously are likely to contribute to the hydrogenation of CO on WC as follows:

$$CO \overset{K_1}{\rightleftharpoons} CO(a) \tag{1}$$

$$H_2 \overset{K_2}{\rightleftharpoons} 2H(a) \tag{2}$$

$$CO(a) + xH(a) \overset{K_3}{\rightleftharpoons} CH_xO(a) \tag{3}$$

$$CH_xO(a) + 2H(a) \overset{k_4}{\longrightarrow} CH_x(a) + H_2O \tag{4}$$

$$CH_xO(a) + CO(a) \overset{k_5}{\longrightarrow} CH_x(a) + CO_2 \tag{5}$$

$$CH_x(a) + (4-x)H(a) \overset{k_6}{\longrightarrow} CH_4 \tag{6}$$

where (a) denotes an adsorbed state, and K_i or k_i is the equilibrium or rate constant, respectively, of step i.

Assuming that the rate determining step exists in the elimination step of the oxygen atom in the CH_xO species to cause the C-O bond rupture and that all preceding steps are in quasi-equilibrium, the rates of the formation of H_2O and CO_2 are given respectively as

$$R_{H_2O} = \frac{k_4 K_1 (K_2)^{1+x/2} K_3 P_H^{1+x/2} P_{CO}}{(1+\sqrt{K_2 P_H}+K_1 P_{CO})^3} \tag{I}$$

$$R_{CO_2} = \frac{k_5 K_1^2 (K_2)^{x/2} K_3 P_H^{x/2} P_{CO}^2}{(1+\sqrt{K_2 P_H}+K_1 P_{CO})^2}. \tag{II}$$

From these rate expressions, one can estimate possible reaction orders with respect to H_2 and/or CO pressures. Comparing them with the experimental data,

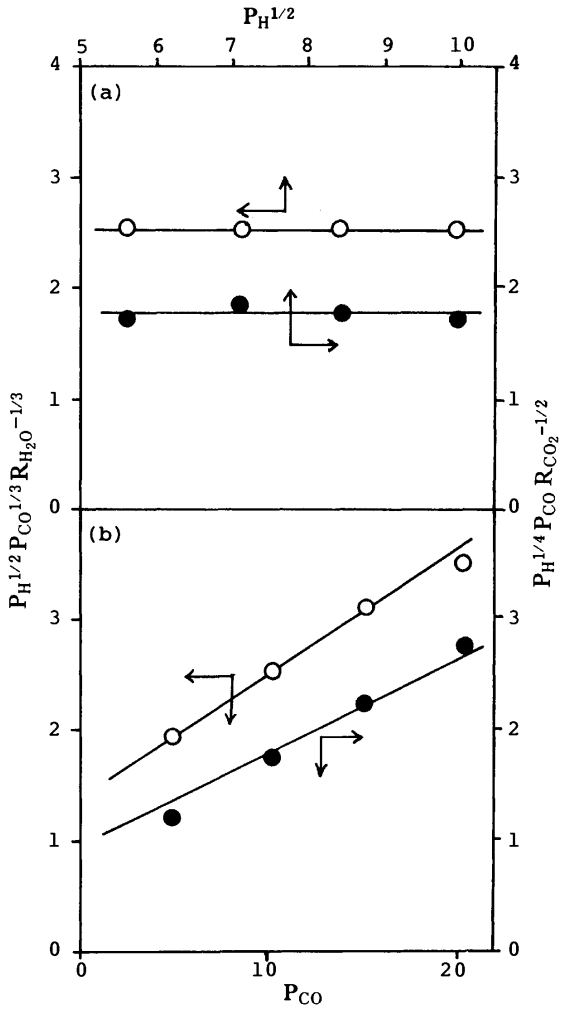

Fig. 9. Least square fitting of pressure dependency by applying the equations (I) and (II) with x=1.
(a) Dependency on H_2 pressure and (b) on CO.
Open and closed circles are the experimental data for the formation of H_2O and CO_2 taken from Fig. 4, respectively.

as described in the previous paper, the value of x can be estimated to be 1 or 2. In order to choose a more restricted value, a least square fitting was achieved between the pressure dependencies given in Fig. 4 and the rate equations of (I) and (II). The best fit was attained when x was unity. Figures. 9(a) and (b) show the results and the optimized values of K_1 and K_2 are known to be 0.082 and 0.0, respectively. By using the value of 2 for the x, an unreasonable negative value for $\sqrt{K_2}$ was obtained.

On the other hand, as described above, the active surface of W_2C behaves like a metallic W surface. Since the dissociation of the C-O bond on a metallic W surface is known to be a non-activated process,[23] it is more likely on W_2C that CO molecules initially dissociate into adsorbed C and O atoms on the surface. Thus, the apparent activation energy of the CO hydrogenation is lower on W_2C and W than on WC. These considerations lead us to a dissociative reaction scheme on W_2C and W catalysts as follows:

$$CO \overset{K_7}{\rightleftharpoons} C(a) + O(a) \quad (7)$$

$$H_2 \overset{K_8}{\rightleftharpoons} 2H(a) \quad (8)$$

$$O(a) + 2H(a) \xrightarrow{k_9} H_2O \quad (9)$$

$$O(a) + CO(a) \xrightarrow{k_{10}} CO_2 \quad (10)$$

$$C(a) + 4H(a) \xrightarrow{k_{11}} CH_4 \quad (11)$$

Provided that the rate-determining step is the elimination of an adsorbed oxygen atom from the surface and that the preceding steps, (7) and (8) are in quasi-equilibrium, the rate equations for the formation of CO_2 and H_2O can be obtained as (III) and (IV).

$$R'_{H_2O} = \frac{k_9 K_7^{1/2} K_8 P_H P_{CO}^{1/2}}{(1+\sqrt{K_7 P_{CO}})^3} \quad (III)$$

$$R'_{CO_2} = \frac{k_{10} k_7^{1/2} P_{CO}^{3/2}}{(1+\sqrt{K_7 P_{CO}})} \quad (IV)$$

Considering the material balance of carbon in the reaction system leads to the rate equation of (V) for the formation of CH_4.

$$R'_{CH_4} = R'_{H_2O} + R'_{CO_2} \quad (V)$$

These rate equations are consistent with the experimental reaction orders shown in Table 1. A marked difference of the rate equations is seen between WC and W_2C; *i.e.*, formation of CO_2 depends on the hydrogen pressure on WC but does not depend on W_2C.

Bell *et al.*[3,19] investigated the reaction pathway involving CO dissociation on Ru catalyst in which they assumed the rate to be controlled in the step of the hydrogenation of the CH_x surface species. The present rate equations are not in accord with their mechanism, because the rate-determining step is different. Since the bonding energy of an oxygen atom to metals is stronger on a W surface (651 kJ mol^{-1}) than on a Ru surface (396 kJ mol^{-1}),[23] thereby the elimination of adsorbed oxygen atom from the surface may control the overall rate of CO hydrogenation on W_2C and W catalysts.

Thermodynamic Analysis of the Potentiometric Titrations of Polypeptides Accompanying the Coil-Beta Conversion

Hiroshi MAEDA
Department of Chemistry, Faculty of Science, Nagoya University Chikusa-ku Nagoya 464
(Received August 14, 1984)

The stability of uncharged β-structure of polypeptides from potentiometric titrations is examined based on thermodynamic considerations with special references to the aggregation and/or precipitation of polypeptides and the irreversible nature of the titration. It is concluded that most of the reported data on various kinds of polypeptides approximately represent the stability of the β-structure. Diverse stabilities exhibited by reported data can be partly ascribed to different extents of the stacking of the pleated sheets.

The stability of the β-structure, an important secondary structure found in proteins, in aqueous media has been studied.[1-15] For an intermolecularly associated β-structure, the free energy of association is derived from the concentration dependence of the conversion.[1] However, all other studies have evaluated the free energy change based on the potentiometric titrations.[2-15]

The interpretations of the potentiometric titrations accompanied by the coil-β conversion are often ambiguous because of slow attainment of equilibrium and/or irreversible behavior. These complex situations originate mainly, not always, from the aggregation and/or precipitation of the polypeptides. Under this situation, the reported values of the free energy change of the conversion are only nominal and apparent. These values are called here tentatively the apparent free energy change, ΔG_{app}, which is defined as follows in the case of poly (weak acid).[16-18]

$$-\Delta G_{app} = 2.303RT\int_{-\infty}^{pH_1}(\alpha_c - \alpha^*)\mathrm{d\,pH}$$
$$= 2.303RT\left[\int_0^1 pH^*d\alpha^* - \int_0^1 pH_c d\alpha_c\right]$$
$$= 2.303RT\int_0^1 (pH^* - pH_c)d\alpha \qquad (1)$$

Here, α_c and α^* (pH_c and pH*) represent, respectively, the degrees of ionization (the values of pH) of the reference solution and the actual solution (including the case with phase separation). The upper limit of the integral, pH_1, corresponds to the pH where α_c coincides with α^*. In the reference solution, random coils are titrated without being converted to the β-structure when protonated. In other words, in the reference solution, only random coils are present at any pH. In the actual solution, the β-structure is formed at low values of pH or at low charge densities. The fraction of random coils at zero ionization is assumed to be negligible in the present study.

Potentiometric titrations accompanying the β-coil conversion have been performed on four different groups of polypeptides; poly(L-tyrosine),[2-7] poly(L-lysine) (PLL)[8,9] poly[*S*-(carboxymethyl)-L-cysteine][10-12] (poly[Cys(CH_2COOH)]) and poly[*S*-(2-carboxyethyl)-L-cysteine] (poly[Cys(CH_2CH_2COOH)]),[12,13] and copolypeptides of L-lysine with L-valine[14] and L-isoleucine.[15] The reported values of ($-\Delta G_{app}$) differ markedly; about 1.25 kJ mol^{-1} for poly(L-tyrosine),[3-7] 590 J mol^{-1} for poly(L-lysine),[8] 3.51 kJ mol^{-1} and 4.60 kJ mol^{-1} for poly[Cys(CH_2COOH)] and poly[Cys(CH_2CH_2-COOH)], respectively[12] and 3.76 kJ mol^{-1} and 2.15 kJ mol^{-1} for poly(L-valine)[14] and poly(L-isoleucine), respectively.[15]

It is pertinent, therefore, to examine whether or not these reported diverse values of ($-\Delta G_{app}$) can be accepted as representing different stabilities of the β-structures formed by different kinds of side chains.

In the present study, the relation between the apparent free energy change (ΔG_{app}) and the stability of the β-structure is analyzed at first when the aggregation or the precipitation of polypeptides occurs. Then, a conventional procedure to evaluate ΔG_{app} from titration data as well as the effect of polypeptide concentration on the stability of the β-structure is examined. Finally, as an example of the usefulness of the present approach, a new interpretation is proposed on the stability of the β-structure of poly(L-lysine) from the titration data.

Theoretical

Relation between the Stability of the β-Structure and ΔG_{app}. In the potentiometric titrations with aggregation of polymers, the thermodynamic analysis has shown that ($-\Delta G_{app}$) consists of essentially two contributions.[19]

$$-\Delta G_{app} = \Delta\mu_p(0)/x + (n_w/n_p)\Delta\mu_w(0)/x \qquad (2)$$

and

$$\Delta\mu_p(0) = \mu_p^c(0) - \mu_p^\beta(0) \qquad (3)$$

Here μ_p and μ_w are the chemical potentials of the polymer component (taken as protonated species) and solvent (water), respectively. Numbers of moles of these components are denoted by n_p and n_w. $\Delta\mu_p(0)$ represents the difference between the chemical potentials of the protonated species of random coil (superscript c) and β-structure (superscript β). The second term of rhs of Eq. 2 represents the solvent contribution.[19,20] When the number of dissociable sites per polymer x is not too small, the solvent contribution is shown to be negligible.[19] In the present study, the second term of Eq. 2 is always neglected. This approximation is valid

for synthetic polypeptides considered in the present study. In the case of proteins, however, the solvent contribution of Eq. 2 can be significant in a certain case.[19] In the case of unimolecular conversion, such as the helix-coil conversion, the concentration dependent terms (cratic terms) of the chemical potential are identical for both conformations. Hence, $\Delta\mu_p(0)$ reduces to the corresponding standard part $\Delta\mu_p^*(0)$. When aggregation occurs, on the other hand, $\Delta\mu_p^*(0)$ can be evaluated from $\Delta\mu_p(0)$ after the correction for the cratic part is made. Further, $\mu_p{}^{\beta*}(0)$ itself can vary with concentration if the "crystallinity" of the β-structure depends on the concentration, as is likely in the case of crystalline polymers. In this sense, the effect of aggregation on ΔG_{app} can be said to be dual, even when the solvent contribution is ignored (which represents also the effect of aggregation).

The effect of phase separation on ΔG_{app} has been developed recently for a simple case where neither conformational change nor aggregation occurs in the solution phase and where the potentiometric equation for the polymers in the precipitated phase is given by Eq. 4.[20]

$$d\mu_p = -2.303\,RT\alpha_b x\,d\,pH \tag{4}$$

The result is given as follows:

$$-\Delta G_{app} = \Delta\mu_p(0)/x - 2.303(RT/C_p{}^t)\int_{-\infty}^{pH_c} C_p(\alpha-\alpha_b)d\,pH. \tag{5}$$

Here, the integration extends over the entire region of precipitation. In this region, the solution (degree of ionization α) and the precipitates (degree of ionization α_b) are in equilibrium with each other. The solubility C_p increases with pH and eventually coincides with the total concentration $C_p{}^t$ in the single solution region ($pH \geq pH_c$). The second term is suggested to be negligible in ordinary cases.[20] Although the effect of aggregation in the solution phase is not taken into account in the derivation of Eq. 5, the effect can be included in the term $\Delta\mu_p(0)/x$ according to the result of the preceding paragraph. Therefore, for the most of the data encountered in the present study, $-\Delta G_{app}$ can be approximated to $\Delta\mu_p(0)/x$, *i.e.*, Eq. 6 holds.

$$-\Delta G_{app} = \Delta\mu_p(0)/x. \tag{6}$$

However, as discussed later, the effect of phase separation could be significant in the case of poly(L-lysine).

It is important to examine the applicability of Eq. 4 to the β-precipitates. As shown experimentaly in a particular example,[21] β-precipitates contain a considerable amount of water, *i.e.*, the β-precipitates most likely consist of a gel which is uniform like a solution. Consequently, Eq. 4 holds for the β-precipitates to a good approximation. Stacked aggregates are also present in a gel constituting crosslinkages. However, as shown later, titration of β-precipitates occurs approximately for those dissociable sites on the surface of the aggregates and those sites inside the stacked aggregates are not titrated. In the course of titration, pleated sheets are peeled off from stacked aggregates. However, this disintegration process does not affect $\mu_p{}^{\beta}$ but the solubility C_p.

Examination of the Procedure of Evaluating ΔG_{app} from Experimental Data. In the present section, the procedure to evaluate ΔG_{app} from titration curves will be examined.

In all the data published up to now, identical values of pK_o were assumed for both random coil and the β-structure. In the case of poly (L-lysine),[8] both β-sheet and random coil limbs are discriminated clearly and they can be reasonably extrapolated to the same point pK_o. In the case of poly[Cys(CH_2COOH)] and its side chain homolog, however, the extrapolation of the β-sheet limb cannot be made unambiguously. In the case of poly(L-tyrosine), the situation is reversed. Extrapolation can be made only from the β-sheet limb and hence pK_o is assumed to be identical with $pK_o{}^{\beta}$. When the stacking of the pleated sheets occurs appreciably, the dissociable sites belonging to adjacent pleated sheets in the interior of the stacked aggregates will have a different value of pK_o, $pK_o{}^{\beta}$, from normal one found in the state of random coils. If $pK_o{}^{\beta}$ is greater than pK_o, $-\Delta G_{app}$ will be greater than reported values in each case discussed above.

In the titration of the stacked aggregates, what is likely to occur is such that titration proceeds with the sites located on the surface of the aggregates and that the sites buried in the interior of the aggregates are not titrated. When the surface charge density of the aggregates increases, the aggregates split into small aggregates or pleated sheets are peeled off one by one from the aggregates, or both. Consequently, there are a number of dissociable sites on the pleated sheets which have normal pK_o at any stage of titration. Under this situation, pK_o remains unchanged, on one hand, irrespective of the degree of ionization α. On the other hand, the distribution of charged and uncharged sites becomes highly deviated from a uniform distribution. The degree of ionization of the surface, α', is much higher than the nominal value α. In Fig. 1, titration curves of hypothetical system are schematically drawn, where a well-defined aggregate species is in equilibrium with unstacked pleated sheet. The titration curve of the aggregate (curve d) differs from that of unstacked pleated sheet (curve c), simply because α and α' are not identical. In other words, an important consequence of the difference between α and α' is included in the titration data themselves when integrated. Also, the question about the term $\log[\alpha/(1-\alpha)]$ does not cause any trouble, as seen below. It is obvious that the quantity pK^* ($=pH^*-\log[\alpha/(1-\alpha)]$) along curve (d) and in the transition region no longer represents the same physical meaning as attached to it in ordinary potentiometric titrations. However, the integral $\int_0^1 (pK^*-pK_c)\,d\alpha$ correctly reduces to the integral

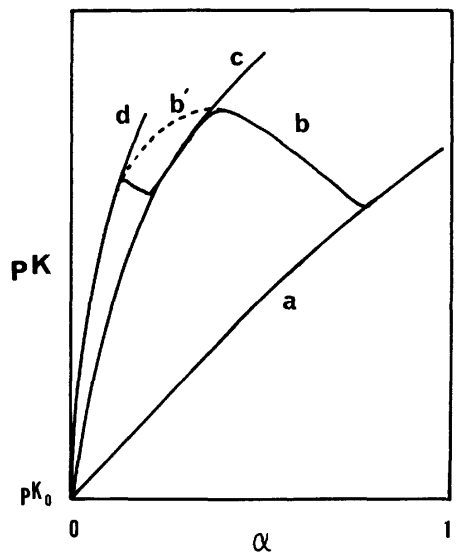

Fig. 1. Schematic titration curves for a hypothetical system where a well-defined stacked aggregate is in equilibrium with unstacked pleated sheet. Titration curves: (a) random coil, (b) actual system (pK^* *vs.* α), (c) single (unstacked) pleated sheet, and (d) stacked aggregate. Dashed curve (b′) represents the titration curve found on poly[Cys(CH_2CH_2COOH)], corresponding to a mixture of various kinds of aggregates.

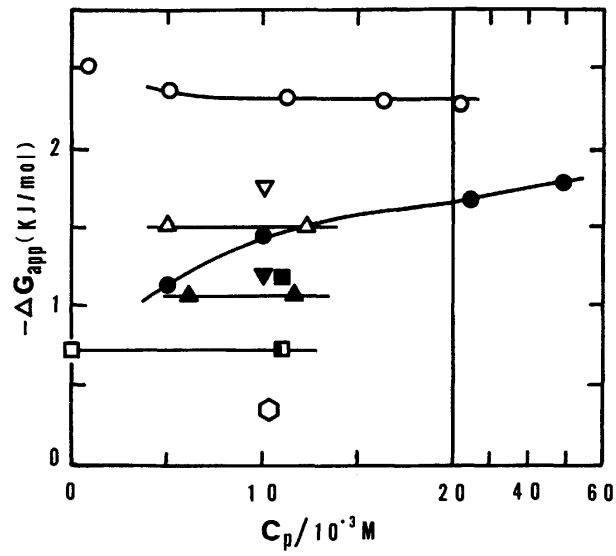

Fig. 2. Dependence of apparent free energy change (ΔG_{app}) on the polypeptide concentration (C_p) at 25°C in the media of ionic strengths 0.1—0.2 M (with a few exceptions). Poly(L-lysine): (○) (DP=670—837).[8] Poly(L-tyrosine): (□) (DP=445),[6] (◧),[5] and (■) (DP=1370).[3,6] Poly[Cys(CH_2COOH)]: (△) (DP=304) and (▲) (DP=50),[11] (▽) (DP=360) and (▼) (DP=62).[12] Poly[Cys(CH_2CH_2COOH)]: (○) (DP=206),[12] and (●) (DP=97).[13]

$\int_0^1$(pH*−pH_c) dα, which is the required quantity in Eq. 1. In this way, the difference between α and α' does not affect the evaluation of ΔG_{app}.

In the titration of poly(L-tyrosine) at high concentrations, titration curves similar to curve (b) in Fig. 1 are reported.[2,4] In the case of poly[Cys(CH_2COOH)], however, a titration curve like curve (b) has never been observed. A distribution about the number of pleated sheets in aggregates is expected and the side-by-side aggregation of pleated sheets is also likely. Under this situation, disintegration of aggregates occurs in diverse ways. As a result of their superposition, the titration curve (b) will be modified as shown by dotted line (b′) in Fig. 1. This kind of titration curve (b′) is observed in poly[Cys(CH_2COOH)] and poly[Cys(CH_2CH_2COOH)]. On the other hand, the titration curves of poly(L-lysine)(PLL) do not show any trace of the stacking as far as this diagnostic tool is concerned. However, fluorescence studies have suggested the stacking of the pleated sheets of PLL.[22-25] Thus, the titration behavior of PLL is different from those of other groups of polypeptide also in this respect.

Effects of Polymer Concentration. Experimentally obtained concentration dependence is summarized in Fig. 2 for the data at 25°C in 0.1—0.2 M (1 M=1 mol dm^{-3}) ionic strength (with a few exceptions). In the case of poly(L-tyrosine) represented by squares, very close values of ($-\Delta G_{app}$) were obtained at 1.1×10^{-2} M[5] and 2×10^{-4} M.[5] In the case of poly[Cys(CH_2COOH)], negligible concentration dependence was found on two samples (DP=304 and 50).[11] For comparison, results on other samples are also shown (DP=360 and 62).[12] In the case of poly[Cys(CH_2CH_2COOH)], the effect of the concentration was extensively examined. Negligible dependence resulted for a high molecular weight sample (DP=206),[12] while a considerable dependence was found on another sample (DP=62).[13] In summary, concentration dependence of the titration curves is negligible except for one example (poly[Cys[CH_2CH_2COOH). DP=62) even when aggregation and/or precipitation occur with increasing concentration. Although extensive study on poly[Cys(CH_2COOH)] and poly(L-tyrosine) in this respect is desirable, we accept the conclusion for the moment and consider its implication.

The chemical potential of the polymer in a random coil can be generally written as follows:

$$\mu_p^c(0) = \mu_p^{c*}(0) + RT\ln a_c = \mu_p^{c*}(0) + RT\ln C_p^t y_p(0). \quad (7)$$

Here a_c and y_p (0) represent the activity and activity coefficient of uncharged random coils, respectively. Generally, explicit expression for $\mu_p^{\beta}(0)$ is not easily obtained, since detailed knowledge on the β-structure is scarcely available. At first, the simplest case is considered where the β-structure can be characterized as forming a pseudophase like detergent micells, as proved to be in the case of poly[Cys(CH_2COOH)] at a concentration range higher than about 1×10^{-3} M.[26] This situation, although simple, is valid for other polypeptides in the same concentration range. In this case, $\mu_p^{\beta}=\mu_p^{\beta*}$ and $\mu_p^{\beta*}(0)$ depends on the concentration only when "crystal structure" varies with the concentration. The chemical potential difference $\Delta\mu_p(0)/x$ is given by Eq. 8 in this case.

$$-\Delta G_{app} = \Delta\mu_p(0)/x = \Delta\mu_p^*(0)/x + (RT/x)\ln C_p^t y_p(0), \quad (8)$$

In this way, $(-\Delta G_{app})$ or $\Delta\mu_p(0)/x$ has to vary with C_p^t through the second term of rhs of Eq. 8, aside from the possible concentration dependence of $\Delta\mu_p^*(0)/x$. However, the second term changes only by $(RT/x)\times 2.303\times 2\simeq 5RT/x$, which amounts to 125 J mol^{-1} for $x=100$ when C_p^t is changed by 100 times. It is now clear that for the high molecular weight samples shown in Fig. 2, the variation of the second term is practically negligible either because x is sufficiently large or because the examined concentration range is not wide enough. Therefore, the apparent inconsistency is solved, which is found between the formal dependence on C_p^t predicted by Eq. 8 and the actually observed independence on C_p^t. Moreover, it is inferred that the "crystal structure" remains constant irrespective of the concentration in these examples. The constant values of thus $(-\Delta G_{app})$ correspond to $\Delta\mu_p^*(0)/x$ under this situation.

$$-\Delta G_{app} = \Delta\mu_p^*(0)/x. \quad (9)$$

However, the values of $(-\Delta G_{app})$ differ considerably for polypeptides of different side chains as well as for different chain lengths, as exhibited in Fig. 2. Different values of the standard chemical potential difference can be partly ascribed to different "crystal structures." For example, the stacking of the pleated sheets is suggested to occur in the case of poly[Cys(CH_2COOH)] under the conditions shown in Fig. 2.[26,27] The extent of the stacking becomes negligible at the concentration range around 1×10^{-4} M[26] or lower.[27] Since the tendency of the stacking of the pleated sheets is stronger in the case of poly[Cys(CH_2CH_2COOH)],[28,29] the observed values of $(-\Delta G_{app})$, which is equivalent to $\Delta\mu_p^*(0)/x$, for these two polypeptides represent the stabilities of the stacked pleated sheets.

In the case of poly(L-tyrosine), the β-structures at the two concentrations differ considerably. At 1.1×10^{-2} M, the approximation of pseudophase is probably good, based on the results on the molecular weight measurements.[3] Hence, Eq. 9 is expected to hold at this concentration. On the other hand, unimolecular β- structure without aggregation is suggested at 2×10^{-4} M.[6,30] The observed values of $(-\Delta G_{app})$ at this concentration can be also regarded as $\Delta\mu_p^*(0)/x$ because the concentration terms in the chemical potentials cancel out each other just as in the case of the helix-coil transition, when activity coefficients of uncharged polypeptide in the two conformations are approximated to be identical. Similar values of $\Delta\mu_p^*(0)/x$ for both aggregated and unaggregated pleated sheets indicate either that the aggregation at 1.1×10^{-2} M does not involve the stacking of pleated sheets or that the single pleated sheet at 2×10^{-4} M is folded over on itself (self-stacking) as proposed by Auer *et al.*[6,7,30,31] The idea of self-stacking is interesting and it is hoped that the idea will be developed both experimentally and theoretically.

In Eq 9, $(-\Delta G_{app})$ is experimentally obtained and hence independent of the concentration scale employed, while μ_p^{c*} and hence $\Delta\mu_p^*(0)$ depend on it. If the concentration scale is changed from C_p^t to $C_p^{t\prime}=C_p^t\,\xi$, ξ being the conversion factor, $\Delta\mu_p^*(0)/x$ also changes to $[\Delta\mu_p^*(0)/x]'=\Delta\mu_p^*(0)/x+(RT/x)\ln\xi$. The difference $[(RT/x)\ln\xi]$ can be again very small owing to the factor x, unless an extraordinary conversion factor is used such as $\xi=10^x$. Consequently, it can be that $\Delta\mu_p^*(0)/x$ depends, in principle, on the concentration scale but the difference arising from the change of the concentration scale is practically negligible.

Contrary to many examples discussed above, on the other hand, the titration curves are dependent on the polymer concentration for a low molecular weight sample of poly[Cys(CH_2CH_2COOH)],[13] as shown in Fig. 2. Judging from the molecular weight of the used sample, the β-structure is formed by intermolecular association of extended chains to a considerable extent.[26] However, judging from the CD spectra, the fraction of the β-structure is large, very close to the completion, and hence the concentration dependence cannot be ascribed to the effect on the association equilibrium. Therefore, the observed concentration dependence can be understood as representing the situation that the extent of the stacking of the pleated sheets increases with C_p^t.

A New Interpretation of the Titration Data of Poly(L-lysine). As shown in Fig. 2, the stability of the β-structure of PLL is considerably smaller than that of other polypeptide consisting of tyrosine or cysteine derivatives, in spite of a contribution from the hydrophobic interaction which has been suggested for the β-structure of PLL.[8,9,14,15,32] Instead of discussing possible sources for this low stability of β-PLL, a completely different point of view is presented in this section, according to which the stability at 25 °C can be greater than what is given by $(-\Delta G_{app})$.

At 25 °C, an irreversible β-to-coil conversion of PLL takes place when titrated from uncharged to charged states, while a reversible coil-to-helix conversion occurs when titrated from charged to uncharged states. Marked time dependence of pH was reported during the titration from β to coil,[8] showing a slow dissociation of β-aggregates in comparison to helix-coil interconversion. The titration curve does not represent a simple β-to-coil conversion, but it represents a complex conversion from the β-structure to the mixture of the α-helix and random coils: The relative populations of these two states varying with pH. This should be the case, otherwise the titration could be reversible. For the potentiometric titration with separation of phases, Eq. 5 can be rewritten in the case of poly (weak bases) as follows.

$$-\Delta G_{app} = \Delta\mu_p(0)/x - 2.303(RT/C_p^t)\int_{pH_c}^{\infty}(\alpha-\alpha_b)C_p\,d\,pH \quad (10)$$

Here α and α_b represent the degree of ionization or protonation of the solution and the precipitates, respectively. The reason why the second term is negligible in ordinary cases resides in the respect that the solubility varies sharply with pH and hence the integrand remains finite only for a very narrow pH range. The effect of the equilibrium between the helix and random coil is dual. First, it will increase the solubility more than what is expected for the case that only random coils are present. Secondly, the increased solubility will vary gradually with pH, simply because the addition of HCl not only dissociates the β-aggregates but also it converts the α-helices to random coils. The latter process keeps the solubility unchanged. As a result of these two effects, the integrand is expected to remain finite over a wide range of pH. These considerations lead to the interpretation that the second term of Eq. 10 can contribute significantly in the irreversible titration of PLL and hence the term $(-\Delta G_{app})$ underestimates $\Delta\mu_p(0)/x$ considerably. Therefore, it is not unreasonable to expect a value of $\Delta\mu_p(0)/x$ larger than 590 J mol^{-1} $(-\Delta G_{app})$ at 25°C from the titration data of PLL.[8] This consideration predicts that $(-\Delta G_{app})$ increases with temperature (positive ΔH_{app}) even in the case that $\Delta H=0$, simply because both irreversible conversion and phase separation become significant as temperature decreases. A value of 3.64 kJ mol^{-1} was obtained for ΔH_{app} from the temperature dependence of ΔG_{app} including the data corresponding to irreversible titrations.[8] On the other hand, a small temperature dependence (ΔH_{app}=540 J mol^{-1}) was obtained from the titrations accompanying the coil-to-β conversion and limited within soluble range.[9] The present analysis can explain reasonably a large difference between these two values of ΔH_{app}. Conversely, the present point of view based on Eq. 10 is experimentally supported.

Summary

1. Most of the reported values of ΔG_{app} evaluated from the potentiometric titrations accompanying the β-coil conversion, can be approximately accepted as representing $\Delta\mu_p^*(0)/x$, the standard chemical potential difference (per residue) of uncharged polypeptides between the β-structure and random coil state.

2. The values of $\Delta\mu_p^*(0)/x$ vary markedly depending on the kind of side chains.

3. Different values of $\Delta\mu_p^*(0)/x$ are best understood as arising from different extents of "crystallinity" rather than from different extents of the conversion from disordered to the β-conformation. In the case of the β-structure, "crystallinity" corresponds to the extent of the stacking of the pleated sheets.

4. In the case of poly(L-lysine), present analysis suggests that the apparent free energy change $(-\Delta G_{app})$ from irreversible titration with precipitation underestimates the stability of the β-structure.

(Received August 15, 1984)

The ESR spectra of the π-cation radical generated electrochemically from 5,10,15,20-tetraphenylporphyrinatocobalt(II), [Co^{II}(tpp)], have been observed in the presence of various anions and in solvents such as halogenated hydrocarbons, nitriles, ethers, ethanol, and organic acids. From the analyses of these spectra, the π-cation radical has been found to coordinate axially the anion or the solvent according to the order of its coordinating ability; BF_4^-, ClO_4^-, PF_6^-, NO_3^-<nitriles<halogen anions<ethanol<CF_3COO^-, AcO^-, SCN^-, CN^-. The singly-occupied molecular orbital has been assigned to be always $a_{2u}\pi$ orbital regardless of the axial ligands. The spin densities on N and Co much increase due to the axial ligation. It has been further confirmed that the spin polarization mechanism mainly contributes to the appearance of the spin density on Co. These axial-ligand effects are quantitatively explained by a model calculation of the CNDO/2 MO method.

The redox behavior of metalloporphyrins has been widely investigated from biological and biochemical interests and it has been known that most of metalloporphyrins are converted into their π-cation radicals by the oxidation of their porphyrin rings as well as of their central metal ions.[2] Some of natural porphyrins can be oxidized into their π-cation radicals under mild conditions,[3] but such readily oxidizable porphyrins have been rarely found in synthetic ones so far. It has been found that by thermal and light activations 5,10,15,20-tetraphenylporphyrinatocobalt(III) chloride, [Co^{III}(tpp)]Cl, in chlorinated hydrocarbons is converted partially and reversibly into a paramagnetic species, which was identified by ESR as the [Co^{III}(tpp)]$^{2+\cdot}$ π-cation radical coordinating axially two chlorides.[4] From the studies using electrochemical techniques,[1,4b] it has been shown that this radical is also generated by the one-electron oxidation of [Co^{III}(tpp)]Cl or the subsequent two-electron oxidation of [Co^{II}(tpp)] in the same solvents with tetrabutylammonium chloride (TBACl) as a supporting electrolyte. On the other hand, when $TBABF_4$ or $TBAClO_4$ was used, a different paramagnetic species was produced. It was concluded from the ESR observation that the π-cation radical coordinates different anions which perturb its electronic state. These results motivate us to examine in detail the effects of the coexisting anions and solvents on the ESR spectra of the π-cation radical. The ESR spectroscopy is a powerful means for investigating the microscopic structures of the complexes in solutions. Therefore, we have examined the ESR spectra of the π-cation radical using various combinations of anions and solvents.

In this paper, we first describe which anions or solvents are coordinated by the π-cation radical under different conditions and then discuss their effects on the electronic state of the π-cation radical. Secondly, we have made a model calculation of closed-shell CNDO/2 MO method including the cobalt AO in order to fully understand the effect of axial ligation. The results of the calculation will be compared with the experimental results.

It has been known that the electronic states of natural porphyrins are perturbed by their axial ligands, which is related to the bioactivities of the enzymes containing metalloporphyrins.[5] It is hoped that this results will be helpful for understanding their activities.

Experimental

Materials. [Co^{II}(tpp)] and [Co^{III}(tpp)]Cl were prepared by method previously reported.[6] [Co^{III}(tpp)]Br and [Co^{III}(tpp)]$_2(SO_4)$ were prepared in a similar way using HBr and H_2SO_4, respectively, instead of HCl for [Co^{III}(tpp)]Cl preparation.[7] They were identified by elemental analyses and absorption spectra. Dichloromethane (DCM), acetonitrile (ACN), propionitrile (PCN), butyronitrile (BCN), and nitromethane were of spectroscopic grade and dried over Woelm 200 neutral alumina. Tetrahydrofuran (THF), 1,2-dimethoxyethane (DME), and dibromomethane (DBM) were distilled over CaH_2 before use. Ethanol of spectroscopic grade was distilled over magnesium ethoxide immediately prior to use. Trifluoroacetic acid (TFA) and trifluoroacetic anhydride (TFAA) of special grade were used without further purification. $TBABF_4$, $TBAClO_4$, TBACl, and TBABr were commercially obtained. $TBABF_4$ and $TBAClO_4$ of polarographic grade were used without further purification. TBABr was recrystallized once from ethyl acetate–ether (3:1). $TBAPF_6$,[8a] $TBANO_3$,[8b] and TBAF[8c] were prepared according to the methods reported elsewhere. $TBAPF_6$ and $TBANO_3$ recrystallized twice from ethanol–water and benzene, respectively, were confirmed by elemental analyses. TBAF was stored in ether under nitrogen atmosphere. The salts were dried *in vacuo* at room temperature before use except for TBACl which was dried at 90 °C. The preparations of dibenzo-18-crown-6 (DB18C6) complexes with potassium salts were carried out according to the methods given by Pedersen.[9]

Apparatus and Procedures. The ESR spectra were taken with JEOL PE-3X or FE-3X spectrometer equipped with a temperature controller. The Co^{III}(tpp) π-cation radical was generated by electrochemical two-electron oxidation of [Co^{II}(tpp)] otherwise noted, using various electrolytes and

solvents. The best temperature for the ESR measurement depended on the solvent. In most cases, the ESR spectra were measured at temperatures 10 to 20 °C above the melting point of the solvent. The procedure for the ESR measurement combined with electrochemical technique and the method of *g*-value calibration were described previously.[1] Here we only mention the usage of tetrabutylammonium salts and DB18C6·KX complexes (X=CN^-, SCN^-, and AcO^-). Some of the salts used here have been found to function both as the axial ligand source for the cation radical and as the supporting electrolytes. But those salts comprising such an anion as CN^-, SCN^-, or AcO^- could not be used as the supporting electrolyte, since they are very hygroscopic and/or difficult to be purified. Thus on the occasion of introducing such anions into sample solution, DB18C6·KX was added to the solution together with $TBAPF_6$ which acts only as the supporting electrolyte.[10] This method of preparing the sample solution may be generally useful for studying anion effects in nonaqueous solvents in electrolysis. DB18C6 was confirmed to have no effect on the ESR spectra by itself.

Results

The π-cation radical exists in solution as a free ion or a complex with the coexisting anion or the solvent whose effect is reflected sensitively on the ESR spectrum. Table 1 shows the parameters of the π-cation radical. In the following the results are classified into several groups by the electrolyte and solvent, denoted as electrolyte/solvent. The electrolytes should also be recognized as the source of anions coordinated by the π-cation radical.

$TBAPF_6$, $TBABF_4$, $TBAClO_4$, $TBANO_3$/DCM, DBM. It was suggested in the previous paper[1] that the π-cation radical in the system of $TBAClO_4$/DCM or $TBABF_4$/DCM might be complexed with ClO_4 or BF_4. This was deduced from the marked difference between the ESR spectra of these systems and that of TBACl/DCM system in which the π-cation radical was shown to coordinate the chloride. However, there was no direct evidence of BF_4^- or ClO_4^- ligation in the ESR spectra. We have tried to clarify whether or not the π-cation radical coordinates these anions by observing its ESR spectra in the *inert* solvent such as DCM or DBM in the presence of BF_4^-, ClO_4^-, PF_6^-, and NO_3^- (weak-ligand anions).

Table 1. ESR parameters of Co^{III} (tpp) π-cation radical

Solvent	Anion	Axial Ligand	*T* °C	*g* (±0.0002)	ΔH[a] mT	hfcc/mT Co	N	X[b]

a) Total peak-to-peak width including hfcc. b) Axial ligand. c) The π-cation radical was not ligated. d) Previous work.

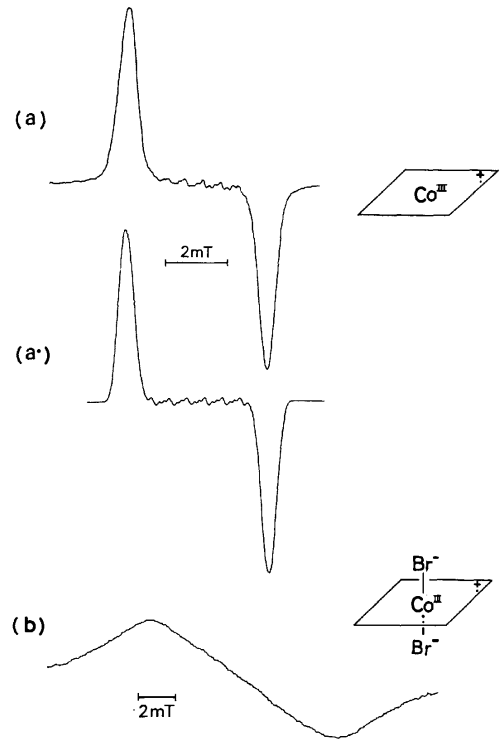

Fig. 1. The ESR spectra of [Co^{III}(tpp)] π-cation radical in the presence of weak-ligand anion and halogen anion: a) $TBABF_4$/DCM at −70°C, a') The computer simulation of a), b) TBABr/DBM at −48°C. The parallelograms in Figs. 1—3 indicate the porphyrin π-system.

The ESR spectra obtained in DCM did not depend on these anions, indicating that the π-cation radical did not coordinate these anions. A typical spectrum is shown in Fig. 1a. Partially resolved hyperfine structures (hfs) due to cobalt and nitrogen nuclei are seen in the spectrum. It is simulated with g=2.0031, a_{Co}= 0.57 mT, a_N=0.18 mT, and linewidth of 0.30 mT.

In DBM the anion dependence of the ESR spectra was not also observed. The hyperfine coupling constants (hfcc) could not be obtained from the ESR spectra because of line-broadening (Fig. 1b). The g-value and the total peak-to-peak width (ΔH_{pp}) were independent of the anions used (see Table 1). The possibility of the ligation of these anions was excluded, but there still remained the possibility of solvent ligation in these systems. The ligation of DBM is expected to cause a large g-value shift owing to the large spin-orbit interaction of bromine. Since the g-value was near that of free spin, it is concluded that the π-cation radical does not coordinate DBM. The g-value in DCM was almost equal to that in DBM and thus the same conclusion is derived for DCM, which is consistent with the inertness of DCM in ligation. The one-electron oxidation of [Co^{III}(tpp)] (1/2)SO_4 in $TBAPF_6$/DCM gave the same ESR spectrum as described above. Therefore, it is also concluded that the π-cation radical does not coordinate SO_4^{2-}.

TBAF, TBACl, TBABr/DCM, DBM. Halogen anions are considered to have moderate coordinating ability and the π-cation radical is expected to coordinate these anions in the inert solvents. TBACl/DCM system has already been examined and Cl hfs was observed.[1] In TBAF/DCM system the ESR spectrum consisted of two components: a central sharp line (ΔH_{pp}=1.5 mT) and a broad line having two peaks on the both sides of the central line. The former was attributed to the H_2tpp radical generated by the loss of the cobalt ion, since there was no splitting due to the cobalt nuclei (I=7/2). The latter showed an additional large splitting due to the fluorine nucleus (2.68 mT), indicating that the π-cation radical coordinates the fluoride.

In TBACl/DBM, the π-cation radical coordinates the chloride as in TBACl/DCM. The ESR spectrum had a similar a_{Co} but was broader than that of in TBACl/DCM. In TBABr/DBM the presence of bromide gave a very broad ESR spectrum of the π-cation radical. The large g-value (2.008) and ΔH_{pp} (10 mT) indicate the ligation of the bromide, but because of the broadness a_{Co} or a_{Br} could not be estimated (Fig. 1b). The one-electron oxidation of [Co^{III}(tpp)] Br in TBABr/DBM gave the same spectrum. TBAF/DBM and TBABr/DCM systems gave no ESR spectra probably because the π-cation radical was unstable in these systems. TBAI was examined in both solvents, but no ESR spectra were observed.

DB18C6·KCN, ·KSCN, ·KOAc+TBAPF$_6$/DCM. Strong ligands such as CN^-, SCN^-, and AcO^- were introduced in the form of DB18C6 potassium complexes mentioned in the previous section. These anions gave considerable changes to the ESR spectra and therefore the π-cation radical is considered to coordinate these anions. The cobalt hfcc's were comparable with that found for the radical complexed with chloride but varied somewhat depending on the anions.

Figure 2a gives the ESR spectrum of the π-cation radical in DB18C6·KCN+$TBAPF_6$/DCM system, which shows well resolved hfs. The spectrum was simulated with one Co (a_{Co}=1.02 mT), four N (a_N=0.26 mT) and eight H (a_H=0.03 mT) nuclei. The nitrogen hfs of the cyanide was not observed. This indicates that the cyanide is bound to the π-cation radical with the carbon, not the nitrogen. On the other hand, the spectrum in DB18C6·KSCN+$TBAPF_6$/DCM system (Fig. 2b) could not be simulated with 1Co, 4N, and 8H. By taking the hfs due to the nitrogen nuclei of the thiocyanate into consideration, the spectrum was well simulated with 1Co (a_{Co}=1.20 mT), 6N (a_N=0.25 mT) and 8H (a_H=0.03 mT), though there was an ambiguity of the a_N value. This result leads to the conclusion that the π-cation radical has N-bound thiocyanate in this system.

The acetate had a peculiar effect on the π-cation radical (Fig. 2c). Though the acetate does not contain a heavy atom, the g-value (2.0072) was much larger than

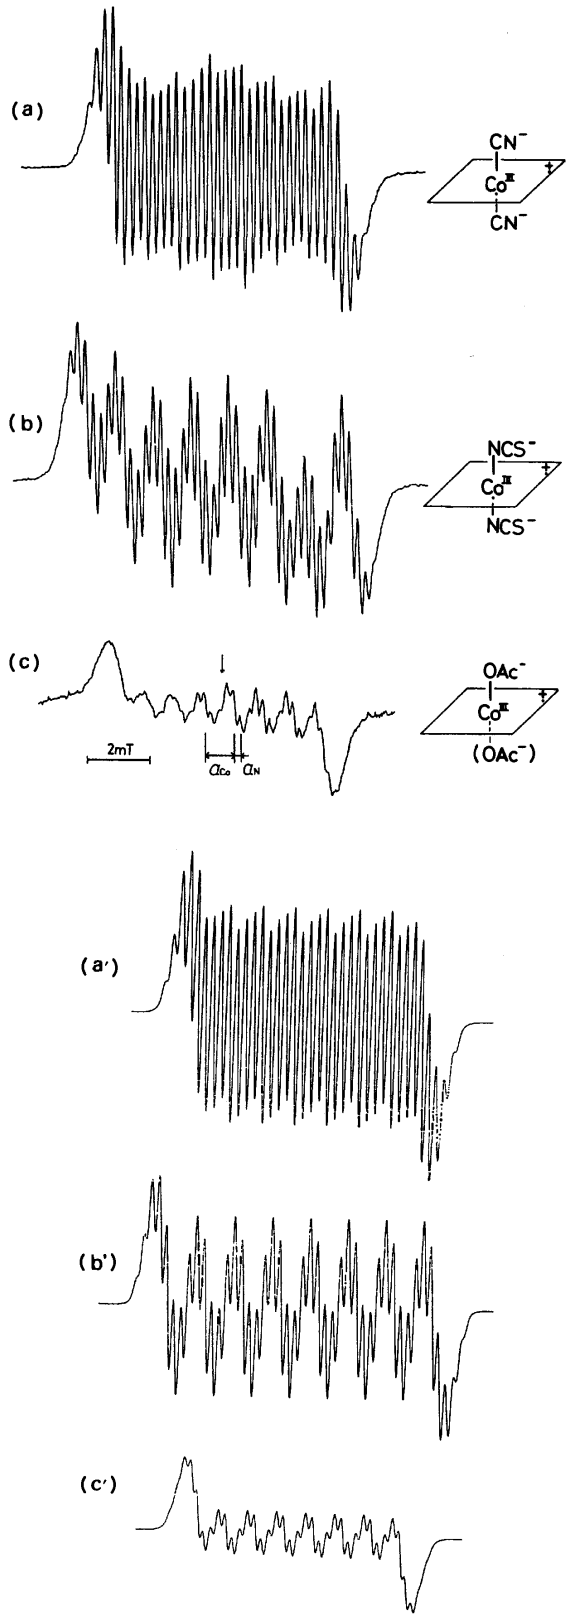

Fig. 2. The ESR spectra of [Co^{III}(tpp)] π-cation radical in the presence of strong ligands: a) DB18C6·KCN+$TBAPF_6$/DCM at −55 °C, b) DB18C6·KSCN+$TBAPF_6$/DCM at −65 °C, c) DB18C6·KOAc+$TBAPF_6$/DCM at −74 °C, a'), b'), c') The computer simulations of a), b), and c), respectively. The linewidths of these spectra depend on Co m_I, but this effect was not considered in these simulations.

that of free spin. It has been said that the assymmetric axial ligation causes a large g-value of the π-cation radical (2.0056) in the case of [Co^{III}(tpp)](py)Cl.[1] It is suggested that five-coordination or the up-and-down axial ligation by different ligands results in the displacement of the cobalt ion and the cobalt d orbital interacts with the singly-occupied a_{2u} π orbital. In the case of the acetate, the π-cation radical is likely to be five coordinate or coordinate two oxygen atoms of the acetate, causing the large g-value shift mentioned above.

The ESR spectrum of DB18C6·KCl+$TBAPF_6$/DCM system was identical with that of TBACl/DCM system. This result shows that the use of DB18C6 does not affect the ESR spectra.

The Effect of Various Solvents in the Presence of Weak-ligand Anions. We also examined in detail the effects of other solvents, using the electrolytes comprised by BF_4^-, ClO_4^-, PF_6^-, and NO_3^-. As in the case of DCM or DBM, the ESR spectra did not depend on the coexisting anions. No hfs in the ESR spectra were observed except for the case of PCN. But the g-value and ΔH_{pp} proved to be a good measure of the ligation state of the π-cation radical. As shown in Table 1, the g-values are different depending on the solvent, and are larger than 2.003, that is, the value in DCM or DBM. Thus it is concluded that the π-cation radical coordinates these solvents in the presence of weak-ligand anions.

Solvent Effects in the Presence of Halogen Anions and Strong-ligating Anions. Since the halogen anions are nucleophiles and so the π-cation radical is subject to undergo reaction with them, the ESR spectra were observed only in a few cases. In TBACl/PCN reported previously,[1] the ESR spectrum was almost the same as in TBACl/DCM, indicating that the chloride also is bound to the π-cation radical and the solvent had only a slight effect. On the other hand, the ESR spectra in EtOH did not change between the halogen anions and weak-ligand anions. This indicates that in EtOH the π-cation radical does not coordinate the halogen anions but EtOH. In both nitriles and EtOH, such anions as CN^-, SCN^-, AcO^- gave almost the same ESR spectra as in DCM, showing that the π-cation radical coordinates these anions.

In the mixed solvent of TFA and TFAA, Co^{II}(tpp) was autoxidized into its π-cation radical. The ESR spectrum was easily observed with a large g-value (2.0050), which might be due to the effect of CF_3COO^- ligation as in the case of AcO^-. The ESR spectrum was not changed by the addition of the weak-ligand anions or the halogen anions. But the addition of SCN^- or CN^- gave the superimposed spectra of three species, the ΔH_{pp} of which were 8 mT, 4 mT, and 1.5 mT. The corresponding species could be assigned as the π-cation radical binding SCN^- or CN^-, that binding CF_3COO^-, and that without the cobalt ion, respectively. Therefore, the coordinating ability of this solvent

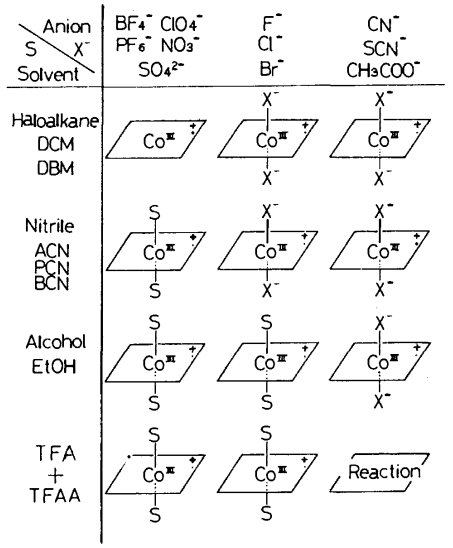

Fig. 3. A diagram for the structure of [Co^{III}(tpp)] π-cation radical in various solvents and in the presence of various anions. X^- and S denote coexisting anion and solvent, respectively.

competes with that of SCN^- or CN^-. Consequently, the order of coordinating ability to the π-cation radical is; BF_4^-, ClO_4^-, PF_6^-, NO_3^-, SO_4^{2-}<nitriles<halogen anions<EtOH<CF_3COO^-, AcO^-, SCN^-, CN^-.

As described in the above sections, the states of axial ligation of the π-cation radical in various solvents and in the presence of various anions are clarified by the change of the ESR spectra. The results are summarized in Fig. 3. The π-cation radical coordinates the anion and solvent according to the order of coordinating ability,well-known as the spectrochemical series.

Discussion

The Axial-ligand Effect on the Electronic State of the π-Cation Radical. As assigned first by the PPP-SCF MO calculation,[12] the singly-occupied molecular orbitals (SOMO) of the two-electron oxidation products of cobalt porphyrins are a_{1u} or a_{2u} π orbital in D_{4h} symmetry, not the 3d orbital of the cobalt ion. This has been confirmed by the fact that their g-values are quite isotropic and near the free-spin value. It has been considered that the a_{1u} and a_{2u} orbitals of metalloporphyrins are nearly degenerate.[13] Indeed, in the case of Co(oep) and Co(etioporphyrin) π-cation radicals, the order of the a_{1u} and a_{2u} π orbitals changes depending on the counter ion: In the presence of weak-ligand anions or F^-, the a_{2u} orbital is the SOMO, while a_{1u} for Br^-.[14] The nature of SOMO can be directly determined by the observation of nitrogen hfs, since the a_{2u} orbital has large spin densities on the nitrogen nuclei, but the a_{1u} has nodes on them. As shown in Table 1, the nitrogen hfs of the order of 0.2 mT was observed regardless of the nature of the ligands. Thus it is concluded that the SOMO is always the a_{2u} orbital different from the oep or etioporphyrin cases. It is noteworthy that the nitrogen hfs is increased by axial ligation.

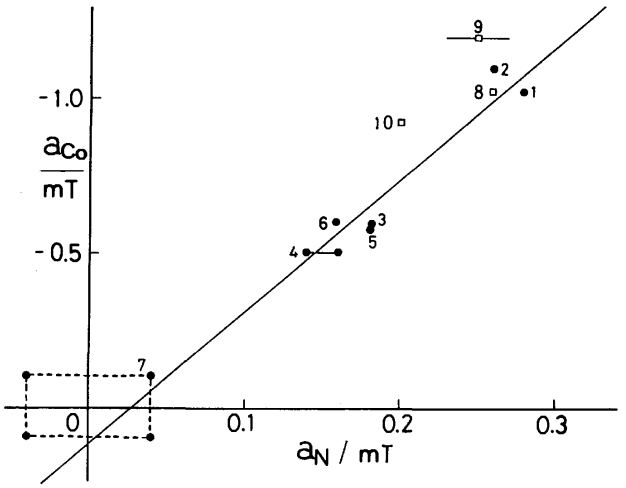

Fig. 4. A correlation between a_{Co} and a_N of some Co(III) porphyrin π-cation radicals; 1: [Co^{III}(tpp)]-Cl_2 (in DCM), 2: [Co^{III}(tpp)]Cl_2 (in PCN), 3: [Co^{III}-(tpp)]$(BF_4)_2$ (in DCM), 4: [Co^{III}(tpp)]$(ClO_4)_2$ (in DCM), 5: [Co^{III}(tpp)]$(ClO_4)_2$ (in BCN), 6: [Co^{III}(pr)$_4$p]-$(ClO_4)_2$ (in BCN), 7: [Co^{III}(oep)]$(ClO_4)_2$ (in DCM), 8: [Co^{III}(tpp)]$(CN)_2$ (in DCM), 9: [Co^{III}(tpp)]$(SCN)_2$ (in DCM), 10: [Co^{III}(tpp)]$(OAc)_2$ (in DCM). This figure is composed by the addition of strong ligand cases (□: 8—10) to Fig. 4. in Ref. 1.

The ESR spectra of the π-cation radical exhibit the ^{59}Co hfs (a_{Co}=0.5—1.2 mT), which indicates that there is a small spin density on the central cobalt ion (at most 0.9%). In D_{4h} symmetry a_{2u} orbital and cobalt s and d orbital cannot overlap with each other. Thus it is necessary to consider a mechanism to interpret the ^{59}Co hfs.

It has been proposed that there is a linear relationship between a_N and ρ_N^π, represented by

$$a_N = Q_{N\text{-}Co}^{Co} \times \rho_N^\pi + \alpha \quad (1)$$

where $Q_{N\text{-}Co}^{Co}$ is a proportionality constant and ρ_N^π is the π-electron spin density on the nitrogen nuclei. The first term represents the contribution from the spin polarization of the σ-electrons in the Co-N bonds by the π-electron spin density on the nitrogen nuclei. The second term means the contribution from the direct overlap between the a_{2u} orbital and the cobalt orbitals. Figure 4 shows a correlation between a_{Co} and a_N listed in Table 1, in addition to those reported previously.[1] The validity of Eq. 1 is further confirmed by the present study. It is seen that α in Eq. 1 is small. Therefore, a_{Co} is mainly produced by the spin polarization mechanism. But when the π-cation coordinates SCN^- or AcO^-, there seems to be a slight deviation from the liner relationship, which is probably caused by the overlap between the p orbital of axial ligands and the a_{2u}.

The CNDO/2 Calculations. In order to explain the observed results, we have made CNDO/2 MO calculations[19] extended to treat metal ions. The parameters used in these calculations are listed in Table 2.

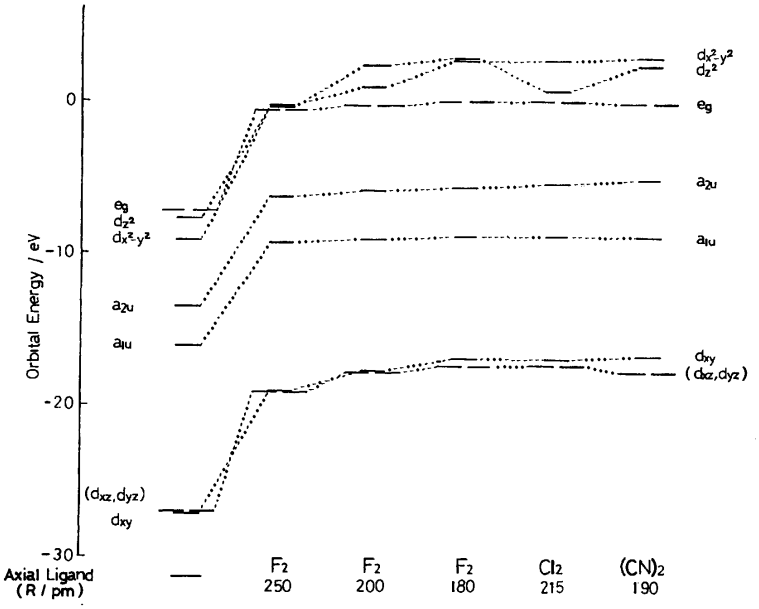

Fig. 5. Molecular orbital energy levels for $[Co^{III}(tmp)]X_2$ (X=F, Cl, CN). R denotes Co–X distance. The d orbitals in this figure denote those orbitals whose electron densities are distributed mainly on the Co 3d orbital (at least 60%). The other orbitals can be characterized as the tmp π orbital.

The geometry of the porphyrin skeleton was obtained from a crystallographic study of $[Co^{II}(tpp)]$ S_4 symmetry.[20] The phenyl groups were replaced with methyl groups for simplifying the calculations. The geometries of the methyl groups were estimated from covalent radii and angles as well as those of hydrogen atoms attached to the pyrrole rings. From the ESR investigations of the π-cation radical of 5,10,15,20-tetraphenylporphyrinatozinc(II), Zn^{II}(tmp), the property of its SOMO has been known to be almost the same as that of Zn^{II}(tpp) π-cation radical.[13,21] Then the tmp skeleton was used instead of the tpp skeleton in our calculations. The axial ligands (F^-, Cl^-, and CN^-) were also placed on both sides of the tmp plane keeping the axial symmetry. The fluoride was placed at the distances of 250, 200, and 180 pm from the cobalt ion. From this one can estimate the effects of axial ligand field on the π-cation radical as a function of distance. The effects of the chloride and cyanide were also examined by taking their distances from the cobalt ion as 215 and 190 pm, respectively, which were obtained from the crystal structure studies (116 pm for C–N distance).[22,23] The order of the ligand field strength is $F^- < Cl^- \ll CN^-$. The π-cation radical free from axial ligation ($[Co^{III}(tpp)]^{2+}\cdot$) was also calculated for comparison.

The calculation was carried out under S_4 symmetry. Figure 5 shows the calculated energy levels. Other results are listed in Table 3. Strictly speaking, the notations of a_{1u}, a_{2u}, and e_g orbitals are only appropriate in D_{4h} symmetry, but they are also used here conventionally. The SOMO is always the a_{2u} π orbital in agreement with the ESR observations mentioned above. The energy difference between the a_N and a_{Co} orbitals is quite large in each case compared with the energy shift due to the axial ligand, which makes the a_{2u} always SOMO. Both orbitals grow slightly more unstable with the strength of the axial ligand field, the extent of which is slightly larger for a_{2u} than for a_{1u}. In Co(oep) and Co(etioporphyrin), both π orbitals are energetically

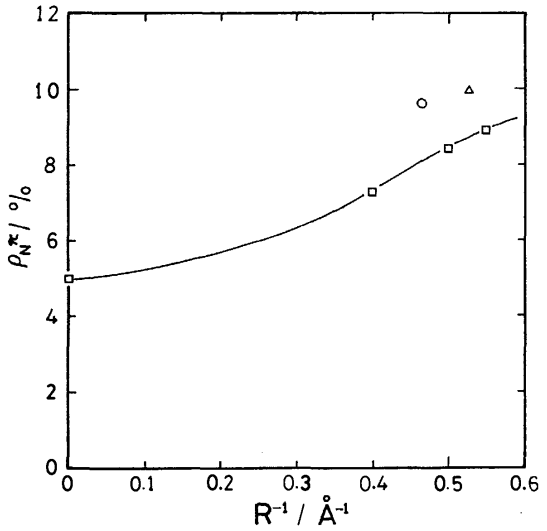

Fig. 6. A correlation between the spin density on the nitrogen nuclei (ρ_N^π) and Co–X distance (R) of $[Co^{III}(tmp)]X_2$ π-cation radical (X: axial ligand); □: $[Co^{III}(tmp)]F_2$, ○: $[Co^{III}(tmp)]Cl_2$, △: $[Co^{III}(tmp)](CN)_2$. The point at $R^{-1}=0$ denotes $[Co^{III}(tmp)]^{2+\cdot}$ π-cation radical free from axial ligation.

very close to each other and so small energy difference shift due to the change of axial ligand field causes the alternation of their SOMO. It is also noted that the energy of Co; $3d_{z^2}$ orbital is strongly affected by the axial ligation, which is consistent with the prediction by the conventional crystal field theory for D_{4h} symmetry.

The spin density on the a_{2u} SOMO is mainly distributed on the nitrogen $2p_z$ orbitals and the carbon $2p_z$ orbitals at the meso positions as expected. Figure 6 shows the relation between the spin density on the nitrogen π orbitals (ρ_N^π) and the distance between the cobalt ion and the axial ligands (R). From the points for $[Co^{III}(tmp)]^{2+\cdot}$ and $[Co^{III}(tmp)]F_2$, one can recognize that ρ_N^π becomes larger as the fluoride approaches the cobalt ion and reaches the value about twice as large as that of $[Co^{III}(tmp)]^{2+\cdot}$. This is in good agreement with the experimentally observed trend that by the axial ligation a_N increased from 0.18 mT for the weak-ligand anions to 0.28 mT for Cl^-. The change from F^- to Cl^- and CN^- gives further small increment for ρ_N^π. Thus it is concluded that the ligand field strength plays the principal role in increasing ρ_N^π.

The a_N's listed in Table 3 are calculated using the McConnell-type equation: $a_N=Q^N_{N(C2H)}\rho_N^\pi$, where $Q^N_{N(C2H)}$ has the value of 2.78 mT, applicable to a nitrogen bonded to two carbon atoms and a proton.[24] The calculated a_N for Cl^- or CN^- is in good agreement with the observed value. The a_N for a weak-ligand anion has the intermediate value between $[Co^{III}(tmp)]^{2+\cdot}$ and $[Co^{III}(tmp)]F_2$ (R=180 pm) and so it is suggested that the weak-ligand anion exists in the vicinity of the cobalt ion, having an electrostatic effect on the a_{2u} SOMO.

The orbitals of the axial ligands directly overlap with a_{2u} SOMO, producing the hfs of the axial ligands. The calculated spin densities on the axial ligands have the value compatible with the observed hfs but the large ambiguity of the Q-value for F or Cl prevents us from making a quantitative discussion.

The cobalt $4p_z$ orbital can mix with the SOMO. The lowering symmetry enables the cobalt $3d_{x^2-y^2}$ and $3d_{xy}$ to mix with the SOMO. In $[Co^{III}(tmp)]^{2+\cdot}$, the spin density on the cobalt $4p_z$ orbital is calculated to be large because of this mixing. However, even in the presence of weak-ligand anions, their electrostatic effects reduce this direct overlap between the cobalt orbitals and the SOMO. In fact, when the π-cation radical coordinates anions, these cobalt orbitals carry only at most 0.4% of spin density and cannot contribute so much to the ^{59}Co hfs. Therefore, as mentioned in the previous part, the ^{59}Co hfs is produced mainly by ρ_N^π through the spin polarization mechanism.

The authors are grateful to Dr. Hisayoshi Kobayashi of Kyoto Prefectural University for supplying them the program of CNDO MO calculation. They also express their thanks to the Data Processing Center of Kyoto University for the use of FACOM M-200 computer.

DNA Sequence and Intramolecular Evolutionary Tree of Calmodulin Gene. Application of Maximum Likelihood Method

Yôichi IIDA

Department of Chemistry, Faculty of Science, Hokkaido University, Sapporo 060

(Received September 19, 1984)

DNA sequences of calmodulin genes taken from chicken and electric eel were examined to investigate the molecular evolution of its protein. One notable feature of the amino acid coding region of the gene is that it can be subdivided into four domains having a similar amino acid sequence. In the present paper, an intramolecular evolutionary tree was constructed with the DNA sequences of the four domains.

Origin and evolution of protein is one of the most important problems in biology and biochemistry. In previous papers,[1-4] we studied the molecular evolution of calmodulin (CaM), one of the calcium-binding proteins. It has four calcium-binding sites, and interacts reversibly with Ca^{2+} to form a calmodulin-Ca^{2+} complex.[5] CaM plays an important role in regulating various enzymatic reactions or cellular processes. It contains 148 amino acids and has a trimethylated lysine at position 115. One notable feature of CaM is that it is widely distributed throughout eukaryotes and that the primary amino acid sequence is highly conservative against evolution. Another interesting feature is that the primary structure of CaM has internal homology, that is, it can be subdivided into four domains having a similar amino acid sequence. It is also found that the amino acid sequence homology is greatest when the first domain (residues 8 to 40) is aligned with the third (residues 81 to 113), and the second domain (residues 44 to 76) is aligned with the fourth (residues 117 to 148). In order to explain this fact, a two-step intragenic duplication model was proposed to the primary amino acid sequence of CaM.[2] In this model, it is assumed that an ancestral one-domain quarter-calmodulin (AQ) underwent an elongation by the first intragenic duplication, which resulted in an ancestral two-domain half-calmodulin (AH). In the period from the birth of AH to the next intragenic duplication (stage 1 in Fig. 4 of Ref. 2), AH underwent evolutionary changes and some replacements of amino acids occurred in it. At the end of stage 1, the second intragenic duplication took place, resulting in an ancestral four-domain calmodulin (AC). In the period from the birth of AC to the present time (stage 2 in Fig. 4 of Ref. 2), AC underwent further evolution and some replacements of amino acids took place.

DNA Sequence of Calmodulin Gene

Previously, using the data on the primary amino acid sequences, we attempted to confirm the above two-step intragenic duplication model.[3] Using the common ancestor method together with the maximum parsimony technique, we constructed an intramolecular evolutionary tree of the four domains of CaM. At that time, however, only the primary amino acid sequences were available for such purposes, and the observed difference of amino acid residues of CaM between the domains was attributed to the difference of nucleotides between the corresponding codons. Referring to "the genetic code," we assumed that the difference of amino acids was given by the least number of nucleotide substitutions of the codons.

Recently, Lagáce *et al.* isolated m RNA of CaM from the electroplax of electric eel (*Electrophorus electricus*), and its cDNA (DNA complementary to m RNA) has been cloned and sequenced.[6] Moreover, Putkey *et al.* isolated the m RNA from chicken brain and determined the primary nucleotide sequence of its cDNA.[7] For the two biological species, the nucleotide sequences of the amino acid coding regions were aligned and compared in Fig. 1 of Ref. 4. Comparison of the corresponding codons revealed that the situation is more complex than has been expected, that is, the difference of the corresponding codons was not always given by the least number of nucleotide substitutions of codons. Corrections for multiple and revertant changes at homologous sites appear to be important to estimate the evolutionary distances between homologous sequences. It is also found that nucleotide substitutions have occurred most frequently at the third positions of codons and that those substitutions are synonymous with respect to the kinds of the amino acid residues. The synonymous nucleotide substitutions have also occurred at the first positions of codons; such mutations are only allowed in the leucine and arginine residues.

In view of these results, we should examine whether the actual DNA sequences of CaM gene may lead to the same intramolecular evolutionary tree as was given previously by the primary amino acid sequences or not. This was done with the cDNA sequences of the chicken and eel CaM genes. In Fig. 1, we show the nucleotide sequences of the four domains of the genes. For each of the biological species, we construct an intramolecular evolutionary tree of the four domains by using "maximum likelihood method."

Intramolecular Evolutionary Tree and Maximum Likelihood Approach

In order to construct an evolutionary tree in terms of DNA sequence data, several approaches are known, such as maximum parsimony method to estimate the

common ancestor sequence and matrix method to estimate pairwise similarity of the sequences.[8] However, most data on DNA sequences involve moderate to large amount of change, such as multiple and revertant changes. In such cases, the maximum parsimony method may fail to construct a correct evolutionary tree, because this method does not take into consideration such probabilistic process of multiple and revertant changes. On the other hand, the matrix method has a difficulty in that it does not make full use of the information available in the original sequences. It has been also pointed out that simple clustering technique based on pairwise similarities can give inconsistent estimates of an evolutionary tree if rates of evolution are sufficiently unequal in different lineages.[9] A third approach invloves method which tries to avoid the above difficulties and to make explicit and efficient use of all of the sequence data by formulating a probabilistic or statistical model of evolution. As such an attempt, Felsenstein proposed an algorithm to evaluate the likelihood of an evolutionary tree.[8] The likelihood of the tree is defined by the product of the probabilities of change in each tree segment, times the prior probability of the ancestral state. The most probable evolutionary tree can be obtained by maximizing such a likelihood value. A computer program was written for the maximum likelihood method.

This method was then applied to our case of CaM genes. We took nucleotide sequence data of the four domains, as shown in Fig. 1. Each domain is composed of 96 nucleotides, which correspond to 32 amino acid residues. For each of the chicken and eel CaM genes, the result computed by the maximum likelihood method shows that the evolutionary tree given by Fig. 2 is the most probable. The maximum likelihood value,

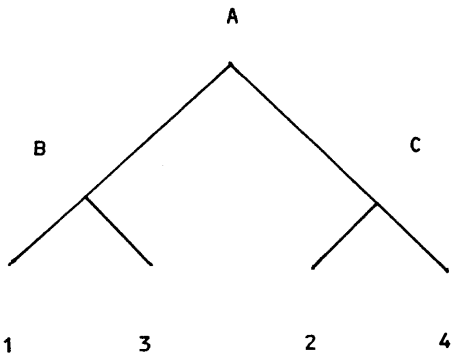

Fig. 2. The intramolecular evolutionary tree of the four domains of the chicken or eel calmodulin (CaM) gene estimated by the maximum likelihood method. This tree shows that the domains 1 and 3 diverged from the common ancestor B, while the domains 2 and 4, from the common ancestor C. B and C had diverged from the common ancestor A.

log likelihood, is calculated as -450.00 in the case of chicken, while it is -477.53 in the case of eel. Figure 2 shows that the domains 1 and 3 came from the common ancestor of B, and the domains 2 and 4, from the common ancestor of C. The common ancestors, B and C, had diverged from the common ancestor A. The evolutionary tree estimated by the cDNA sequence data coincides well with that described previously by the maximum parsimony method together with the amino acid sequence data.[3] Our previous two-step intragenic duplication model is reconfirmed by the present evolutionary tree (for the reason, refer to Ref. 3).

In Table 1, we show data on the optimal branch length, $\hat{p}$, in each tree segment of the evolutionary tree (Fig. 2), together with its 95% confidence limit value. In each of the biological species, the nucleotide sequence of the domain 1 has longer branch length from the

TABLE 1. DATA ON THE OPTIMAL BRANCH LENGTH, $\hat{p}$, IN EACH TREE SEGMENT OF THE EVOLUTIONARY TREE OF THE FOUR DOMAINS, TOGETHER WITH ITS 95% CONFIDENCE LIMIT VALUE

		$\hat{p}$	95% Confidence Limits		$\hat{p}$	95% Confidence Limits	
Domain 1	B	0.4080	(0.2518,	0.5642)	0.4824	(0.3086,	0.6561)
B	Domain 3	0.2247	(0.0591,	0.3904)	0.3047	(0.1103,	0.4991)
B	C	0.3736	(0.2069,	0.5403)	0.3884	(0.1936,	0.5831)
Domain 2	C	0.3539	(0.2034,	0.5044)	0.4627	(0.2958,	0.6296)
C	Domain 4	0.2065	(0.0492,	0.3638)	0.2585	(0.0654,	0.4515)

For the nucleotide sequences of the four domains of chicken or eel calmodulin (CaM) gene, the evolutionary tree is given by Fig. 2.

common ancestor of B than does that of the domain 3. Similarly, the sequence of the domain 2 has longer branch from the common ancestor of C than does that of the domain 4. The distance between any two domains can be calculated by adding the $\hat{p}$ value of each tree path. It is found that distances between domains have appreciably large values of $\hat{p}$, that is, the sum of $\hat{p}$'s is always greater than 1/2. A reason for this is that nucleotides at the third positions of codons have changed considerably.[4] In spite of this, the distance between the domains 1 and 3 or between the domains 2 and 4 is nearest in both of the chicken and eel genes. The $\hat{p}$ data of Table 1 will be valuable for further discussion on the molecular evolution of CaM gene.

We wish to thank Dr. J. Felsenstein for showing us his computer programs.

Solvent Effects on Chemical Reactivities II. Aromatic Substitution Reactions

Takayuki OHMAE
Department of Chemistry, Faculty of Science, Tohoku University, Sendai 980
(Received September 21, 1984)

The propagator method is applied to the study of solvent effects on reactivities of aromatic substitution reactions. We obtain the following set of results: (1) The influence of nonpolar solvent on electrophilic reactions is opposite to that on nucleophilic reactions; (2) the solvent which has the large dielectric constant weakens the directive power of a substituent group; (3) frontier orbitals control solvent effects on the chemical reactivities of aromatic substitution reactions.

Several theories have been proposed to explain experimental results of aromatic substitution reactions.[1-3] Fukui *et al.* have proposed the frontier electron theory.[4,5] Their theory was first introduced in discussing the orientation in electrophilic substitution reactions. Afterward, the theory has been applied not only to electrophilic, but also to radical and nucleophilic substitution reactions as well as addition reactions in conjugated molecules, showing its utility, through a satisfactory agreement of theory with experiment.[6,7]

In a previous work, we have successfully studied solvent effects on selectivities of pericyclic reactions using the propagator method.[8] In this paper, we investigate influences of nonpolar solvent on reactivities of aromatic substitution reactions.

Propagator

The reaction system in question is assumed to be well described by the following hamiltonian in the second quantized representation:[8]

$$\mathbf{H}_0 = \sum_s \alpha_s \mathrm{a}_s^\dagger \mathrm{a}_s + \sum_{s,t} \beta_{st} \mathrm{a}_s \mathrm{a}_t + \sum_q \mathrm{h}\omega \mathrm{b}_q^\dagger \mathrm{b}_q + \sum_q \sum_{s,t} (g_{st}^{q*} \mathrm{b}_q^\dagger + g_{st}^q \mathrm{b}_q) \mathrm{a}_s^\dagger \mathrm{a}_t, \quad (1)$$

where $\mathrm{a}_s^\dagger$ and a_s are respectively the creation and annihilation operators for the π-electron at the s th atom of a solute molecule, $\mathrm{b}_q^\dagger$ and b_q are the creation and annihilation operators for the phonon with mode q, respectively, α_s is the coulomb integral, β_{st} the resonance integral, ω the phonon energy and g_{st}^q the electron-phonon interaction constant. In this model, the solvent is replaced by a phonon gas and solvent-solute interaction by the electron-phonon interaction.[8,9] This model is realistic for nonpolar solvents.

The electron-phonon interaction constant is related with the dielectric constant, ε, of a solvent:

$$g_{st}^q \propto \left(\frac{1}{\varepsilon_\infty} - \frac{1}{\varepsilon}\right)^{1/2}, \quad (2)$$

where ε_∞ is the dielectric constant of the solvent measured at the optical mode.

The propagator, $\mathbf{G}^0(z) \equiv (z-\mathbf{H}_0)^{-1}$, which describes the electronic structure of the solute molecule interacting with solvents, is easily obtained with some approximations:[8,10]

$$\mathbf{G}^0(z) = [(z-\mathbf{h}) - \sum_q \boldsymbol{g}^{q*} n_q (z-\mathbf{h}+\omega)^{-1} \boldsymbol{g}^q - \sum_q \boldsymbol{g}^q (n_q+1)(z-\mathbf{h}-\omega)^{-1} \boldsymbol{g}^{q*}]^{-1}, \quad (3)$$

where

$$\mathbf{h} = \sum_s \alpha_s \mathrm{a}_s^\dagger \mathrm{a}_s + \sum_{s,t} \beta_{st} \mathrm{a}_s^\dagger \mathrm{a}_t. \quad (4)$$

Once the propagator is known we can obtain the eigenvalues and eigenvectors of $\mathbf{H}_0$.

Frontier Electron Density

Let us consider the frontier electron density:

$$f_r^{\mathrm{E}} \equiv \frac{1}{2\pi \mathbf{i}} \int_{\mathrm{H}} \mathrm{d}z \mathbf{G}_{rr}^0(z), \quad (5a)$$

$$f_r^{\mathrm{N}} \equiv \frac{1}{2\pi \mathbf{i}} \int_{\mathrm{L}} \mathrm{d}z \mathbf{G}_{rr}^0(z), \quad (5b)$$

where f_r^{E} and f_r^{N} are respectively the electron density of the highest occupied molecular orbital, HOMO, and the that of the lowest unoccupied molecular orbital, LUMO, and the contours H and L respectively enclose the poles ε_{H} and ε_{L} (see Fig. 1).

It is well known that the chemical reactivity is well correlated with the frontier electron density:[5] 1) in case of reactions with electrophilic reagents, that position having the higher density of HOMO is more susceptible to attack; 2) in case of reactions with nucleophilic reagents, that position having the higer density of LUMO is reactive.

Now, it is well known that the variation of solvent can change the rate and/or the reaction products. In case of aromatic substitution reactions, the variation of solvent changes the isomer ratio of products. In order to study this problem, it is sufficient for us to examine the solvent effects on the frontier electron density.

It is said that the interaction between the solute and the solvent is small, *i.e.*, $|g_{ij}^q| \ll 1$, in the aromatic substitution reaction.[12] Therefore, the propagator in Eq. 3 is well approximated as follows;

$$\mathbf{G}^0(z) \cong (z-\mathbf{h})^{-1} + (z-\mathbf{h})^{-1} \sum_q \boldsymbol{g}^{q*} n_q (z+\omega-\mathbf{h})^{-1} \boldsymbol{g}^q (z-\mathbf{h})^{-1} + (z-\mathbf{h})^{-1} \sum_q \boldsymbol{g}^q (n_q+1)(z-\omega-\mathbf{h})^{-1} \boldsymbol{g}^{q*} (z-\mathbf{h})^{-1}. \quad (6)$$

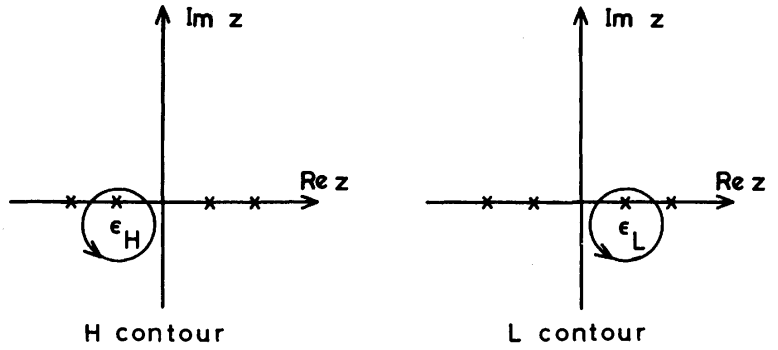

Fig. 1. Contours H and L.
ε_H is the energy of HOMO.
ε_L is the energy of LUMO.

Substituting Eq. 6 into Eqs. 5a and 5b, we obtain the frontier electron density including the solvent effect. For f_r^E,

$$
\begin{aligned}
f_r^E &\equiv \frac{1}{2\pi\mathbf{i}}\int_H dz G^0_{rr}(z) \\
&= \frac{1}{2\pi\mathbf{i}}\int_H dz \langle r|\{(z-\mathbf{h})^{-1} \\
&\quad + (z-\mathbf{h})^{-1}\sum_q \boldsymbol{g}^{q*} n_q (z-\mathbf{h}+\omega)^{-1}\boldsymbol{g}^q (z-\mathbf{h})^{-1} \\
&\quad + (z-\mathbf{h})^{-1}\sum_q \boldsymbol{g}^q (n_q+1)(z-\mathbf{h}-\omega)^{-1}\boldsymbol{g}^{q*}(z-\mathbf{h})^{-1}\}|r\rangle \\
&= f_r^{0E} + \sum_q\sum_{i,j} n_q |\langle r|i\rangle|^2 |g^q_{ij}|^2 \frac{1}{2\pi\mathbf{i}}\int_H dz \frac{1}{(z-\varepsilon_i)^2(z-\varepsilon_j+\omega)} \\
&\quad + \sum_q\sum_{i,j} (n_q+1)|\langle r|i\rangle|^2 |g^q_{ij}|^2 \frac{1}{2\pi\mathbf{i}}\int_H dz \frac{1}{(z-\varepsilon_i)^2(z-\varepsilon_j-\omega)} \\
&\cong f_r^{0E} + \sum_q n_q |\langle r|H\rangle|^2 |g^q_{HL}|^2 \frac{1}{2\pi\mathbf{i}}\int_H dz \frac{1}{(z-\varepsilon_H)^2(z-\varepsilon_L+\omega)} \\
&\quad + \sum_q n_q |\langle r|L\rangle|^2 |g^q_{HL}|^2 \frac{1}{2\pi\mathbf{i}}\int_H dz \frac{1}{(z-\varepsilon_L)^2(z-\varepsilon_H+\omega)} \\
&\quad + \sum_q (n_q+1)|\langle r|H\rangle|^2 |g^q_{HL}|^2 \frac{1}{2\pi\mathbf{i}}\int_H dz \frac{1}{(z-\varepsilon_H)^2(z-\varepsilon_L-\omega)} \\
&\quad + \sum_q (n_q+1)|\langle r|L\rangle|^2 |g^q_{HL}|^2 \frac{1}{2\pi\mathbf{i}}\int_H dz \frac{1}{(z-\varepsilon_L)^2(z-\varepsilon_H-\omega)} \\
&\cong f_r^{0E} + \sum_q (2n_q+)1 |g^q_{HL}|^2 \frac{f_r^{0N}-f_r^{0E}}{(\varepsilon_H-\varepsilon_L)^2}, \qquad (7)
\end{aligned}
$$

where we assume that the electron-phonon interaction constant has a dominant value between HOMO and LUMO. Moreover, we can approximate

$$\frac{1}{2\pi\mathbf{i}}\int_H dz \frac{1}{(z-\varepsilon_L)^2(z-\varepsilon_H+\omega)} \cong \frac{1}{(\varepsilon_H-\varepsilon_L)^2}, \qquad (8)$$

since $|\omega/\varepsilon| \ll 1$. Similarly f_r^N is obtained as

$$f_r^H \cong f_r^{0N} - \sum_q (2n_q+1)|g^q_{HL}|^2 \frac{f_r^{0N}-f_r^{0E}}{(\varepsilon_H-\varepsilon_L)^2} \qquad (9)$$

In Eqs. 7 and 9, f_r^{0E} f_r^{0N} are respectively the usual density of HOMO and LUMO.

It should be noted here that the sign of the second term of Eq. 7 is opposete to that of Eq. 9. This shows that the solvent effect on electrophilic reactions is opposite to that on nucleophilic reactions.

Solvent Effect Index

We define a solvent effect index, τ_r,

$$\tau_r \equiv \frac{f_r^{0N}-f_r^{0E}}{(\varepsilon_H-\varepsilon_L)^2}. \qquad (10)$$

In kindred reactions, the factors in Eqs. 7 and 9 which depend on the phonon mode q can be assumed to be of the same order. So the solvent effects on chemical reactivities are classified by the above index: in case of reactions with electrophilic reagent, that position having the large value of τ_r becomes susceptible to attack; in case of reactions with nucleophilic reagent, that position having the negative value of τ_r becomes more reactive.

The solvent effect indexes of several monosubstituted benzenoids (see Fig. 2) are listed in Table 1. Calcula-

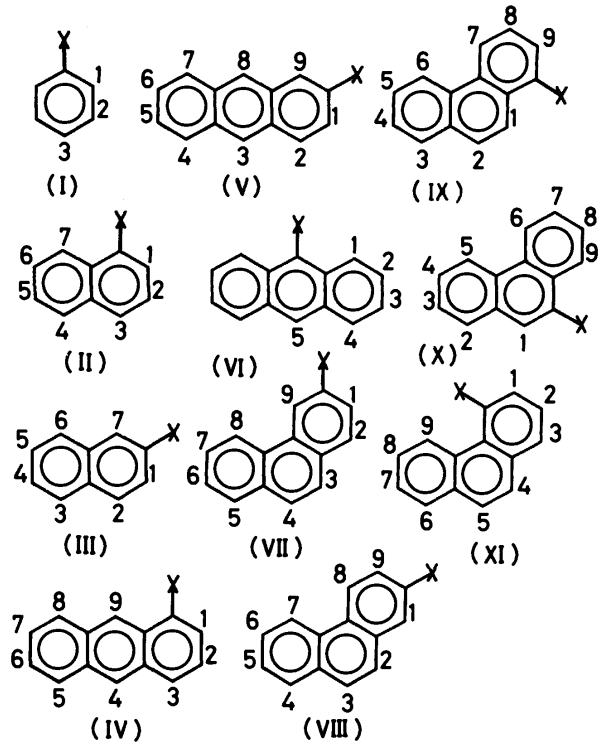

Fig. 2. Monosubstituted benzenoids.

tions are performed within the simple Hückel approximation. The parameters are taken from reference 2.

Table 1 shows the characteristic of the solvent effects on aromatic substitution reactions: 1) Substituent groups have a material effects; for example, at the sites 1 and 2 of molecule I with *ortho-*, *para*-directors, *e.g.*, OH, CH_3, Cl, and OCH_3, electrophilic reactions become favorable: on the contrary at the site 3 of molecule I with a *metha*-director, *e.g.*, NO_2, electrophilic reactions becomes favorable; this fact conclusively shows that solvent effects depend on the nature of the solute molecule only; 2) the stronger the directive power of *ortho-*, *para*-directors, the larger absolute value τ_r.

In conclusion, it should be noted that the solvent which has the large dielectric constant weakens the directive power of a substituent group. If we use the solvent which have the large dielectric constant, we can obtain the reaction products which are minor in the usual reaction conditions. For example, we can obtain the resolcinol using the substitution reaction of the

In-Plane Vibrational Modes of Guanine from an *ab Initio* MO Calculation

Yoshifumi NISHIMURA, Masamichi TSUBOI,* Shigeki KATO,†,†† and Keiji MOROKUMA†
Faculty of Pharmaceutical Sciences, University of Tokyo, Hongo, Bunkyo-ku, Tokyo 113

(Received October 12, 1984)

Harmonic force constants, in-plane vibrational frequencies, and in-plane vibrational modes of guanine have been calculated by an *ab initio* MO method. The force constants were calculated by the use of an energy gradient method with STO-3G basis set, and then they were corrected into "4-31G force constants" by the scaling factors given by us previously for the case of uracil. The corrected set of force constants could reproduce the observed frequencies of guanine, guanine-7, 9-$^{15}N_2$, guanine-1,3,*amino*-$^{15}N_3$ (at positions 1, 3 and amino), guanine-8-*d* (at position 8), guanine-1,9, *amino*-d_4 (at amino and iminos), and guanine-d_5. The calculated vibrational modes could also account for the results of earlier experiments on infrared and Raman spectra of guanine residues in 5'-GMP and other nucleotides.

This is our second paper in a series of *ab initio* MO studies of the internal force field of nucleic acid. The previous one[1] dealt with uracil, and the present paper deals with guanine.

The vibrational spectroscopic studies of the guanine residue have now begun to provide a good insight into the conformation of nucleic acids. This residue has been found to cause many of the Raman lines of DNA and RNA,[2-12] and some of them are found to be useful to diagnose the polynucleotide conformation.[2-3-8,12] The location of a strong guanine Raman line around 650 cm^{-1}, for example, is sensitive to the internal rotation angle around the glycosidic bond and to the pseudo-rotation phase angle of the five-membered ribose ring directly linked to the guanine residue.[2,3] To establish such a spectrum-conformation correlation, it is necessary to clarify the normal mode of vibration for each Raman line of the guanine residue.

For a normal coordinate treatment, it is essential to obtain a reliable set of force constants of the molecule. In the previous paper,[1] we showed that it is practical to calculate the force constants of a big molecule, namely uracil, by the use of an *ab initio* MO method with STO-3G basis set, and it was possible to predict to a significant extent the vibrational modes by the use of "4-31G" force constants which were reached by a correction from the STO-3G force constants. Thus, the calculation could reproduce the observed frequencies, not only of uracil itself, but also of *C*, *C*-dideuterouracil, *N*, *N*-dideuterouracil, perdeuterouracil, and a uracil-$^{15}N_2$ residue.

In this paper, we report a similar study on guanine. Delabar and Majoube[13] reported the experimental frequencies, not only for guanine itself, but also for its three deuterated derivatives and two ^{15}N-substituted derivatives. All the normal frequencies and the corresponding vibrational modes of these guanine derivatives have been calculated in the present study and we can predict satisfactorily the observed frequencies.

Computational Details

The geometry and the harmonic force constants were calculated by the use of IMSPACK program.[14] We optimized the geometry of guanine without any constraint starting from a geometry which had been optimized under the constraint that the molecule is planar. This initial geometry was kindly provided by Mrs. Aida.[15] Our new optimization did not cause any significant change. The internal coordinates adopted here are shown in Fig. 1. Here, the redundancy of the angular coordinates caused by the ring system has been removed by the method of Pulay *et al.*[16]

The vibrational frequencies and the normal modes of vibration were calculated by a program written by us, which is a modified version of NCTB program written by Shimanouchi *et al.*[17] The force constants calculated from the STO-3G basis set were corrected into "4-31G" force constants by the use of the scaling factors, which are given in the previous paper (Table 1 and Eq. (4)) on uracil.[1] These were obtained by a direct comparison of the actually calculated force constants both with the STO-3G and 4-31G basis sets for urea, acrylaldehyde, and formamide. It will be shown below that they are useful for guanine as well as for uracil. Let us also mention here of our trial calculations on imidazole. We have calculated the force constants of imidazole with the STO-3G and the 3-21G basis sets. The STO-3G force constants were then corrected by the use of our scaling factors, and the results were found to be in a good agreement with the 3-21G force constants. The off-diagonal elements of the STO-3G force constant matrix of guanine, smaller than 0.1 mdyn/Å for the stretching-stretching, 0.03 mdyn for the stretching-bending, and 0.01 mdyn·Å for the bending-bending are taken to be zero, so that the number of non-zero force constants turned out to be 171.

Results and Discussion

Equilibrium Geometry. The optimized geometry calculated using the STO-3G basis set is given in Table 1. This should correspond to the geometry of the free guanine molecule, but it showed a good coincidence

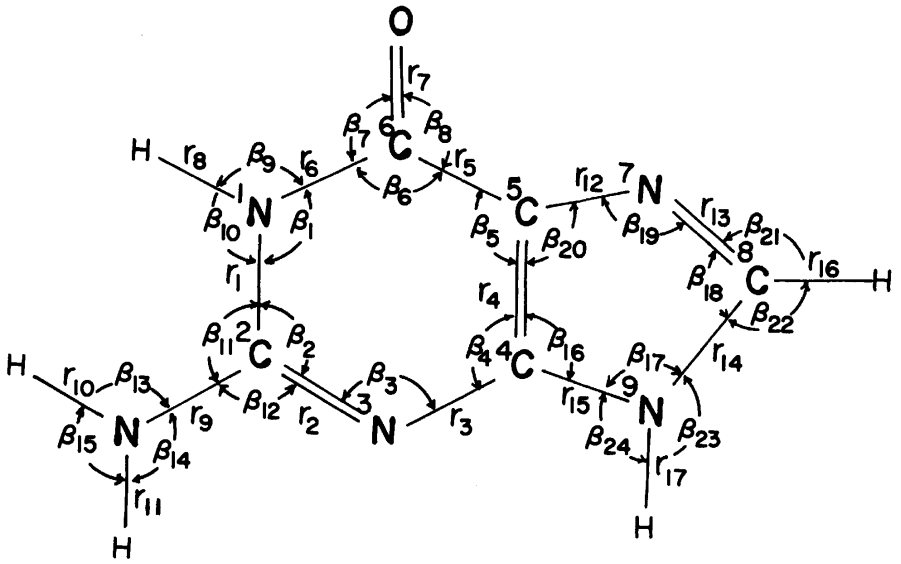

Fig. 1. Internal coordinates of the guanine molecule.

with the averaged values of the bond lengths and bond angles found in the X-ray crystallographical analyses of many guanine derivatives.[18] The averaging may cause a cancelling one another of various effects of intermolecular forces in the crystals to result in an experimental geometry of a guanine molecule, somewhat free from intermolecular force field. It is an interesting finding that the skeletal geometry (involving C, N, and O) of the guanine molecule calculated with the STO-3G basis set reproduced such an experimental geometry.

Force Constants (corrected). The "4-31G" force constants after the correction from the STO-3G force constants, are shown in Tables 2-A—E. In Table 2-A, the diagonal elements of the force constants matrix are shown. The stretching force constants of the ring system varies from 6.427 mdyn/Å for the C_6N_1 to 9.636 mdyn/Å for the N_7C_8 bond, and it is found that the greater force constant corresponds to the shorter bond length. The off-diagonal elements among the

stretching coordinates of the six-membered ring system are nearly equal to the corresponding elements of the uracil molecule[1] as shown in Table 2-B. The off-diagonal elements for the "ortho" positions are

positive, those for the "meta" positions are negative, and those for the "para" positions are positive. Their absolute values are all greater than 0.2 mdyn/Å except for the off-diagonal element between the N_1C_2 stretching and the C_4C_5 stretching coordinates, which is nearly zero. The anomalously small value of this element is considered to be caused by a perturbation by the five-membered ring system, which shares the C_4C_5 bond with the six-membered ring. The off-diagonal elements on the five-membered ring system are nearly equal to those of imidazole molecule (the data are not shown here)[19] except for those involving the C_4C_5 stretching coordinate. It is rather surprising that some of the off-diagonal elements of the stretching coordinates of two bonds located far apart from each other, such as r_1 & r_{14} and r_3 & r_{13}, are as great as 0.2 mdyne/Å as shown in Table 2-B. We could never predict such effectual values of them without the present *ab initio* MO calculation. Also in the calculation, many non-zero off-diagonal elements between the ring stretching and the ring deformation coordinates are found as shown in Table 2-C. The off-diagonal elements among the ring vibrations and the peripheral vibrations are given in Table 2-D and Table 2-E.

Vibrational Frequencies. For the uracil molecule, we showed that the calculated vibrational frequencies using the corrected force constants ("4-31G" force constants) are almost uniformly greater by 8% than the observed fundamental frequencies. Therefore, in our present study on guanine we scaled down the vibrational frequencies by the factor of 0.92. The calculated vibrational frequencies, thus scaled, and the calculated modes are given in Table 3. The calculated frequencies of deuterated guanines are shown in Table 4. In parentheses in these tables, calculated ^{15}N isotope shifts are also given: The first numerical value here indicates the shift (cm^{-1}) for the product in which N_1, N_3, and amino-*N* are substituted by ^{15}N's, namely for pyrimidinic substitution, and the second one the shift for the product, in which N_7 and N_9 are substituted by ^{15}N's, namely for imidazolic substitution.

The largest isotope shift for the pyrimidinic substitution is calculated to be $-24\,cm^{-1}$ for ν_{21} (at 1026 cm^{-1}), and this corresponds to the observed isotope shift ($-26\,cm^{-1}$) for the $1052\,cm^{-1}$ Raman line. For imidazolic substitution, the largest shift is calculated to be $-21\,cm^{-1}$ for ν_{22} ($985\,cm^{-1}$), and this is actually observed ($-20\,cm^{-1}$) for the $950\,cm^{-1}$ line.

In this way, it was attempted to correlate every calculated frequency with an observed frequency by taking an agreement in the isotope effect into account. This attempt was mostly successful except for those in the frequency range higher than $2000\,cm^{-1}$. The difficulty in the higher frequency region is probably caused by the hydrogen bonds. In our calculation, no hydrogen bonding effect was taken into account, whereas the observed frequencies are taken from the solid state guanine whose N_1H and N_9H groups are involved in intermolecular NH···N hydrogen bonds.

The difficulty due to the hydrogen bonds seems to extend into the NH in-plane bending range (1350—1420 cm^{-1}) in a less prominent manner. The amount of couplings of the N_1–H bending modes with some skeletal stretching modes may be sensitive to the diagonal and off-diagonal force constants involving these NH bending coordinates. Therefore only a slightly improper prediction of the force constants may fail in explaining observed ^{15}N-shifts (for $1420\,cm^{-1}$ band, for example). In this frequency region, therefore the calculated vibrational modes should be taken with some reservation, even if the vibrational frequencies predicted for ν_{13}, ν_{14}, and ν_{15} are in good agreement with the observed ones (Table 3).

For the whole other spectral range, however, our present calculation has provided a very good set of vibrational frequencies, which fits the experimental results in a nealy perfect manner.

Vibrational Modes. *I. 4000—2000 cm^{-1}*: In this frequency region, special care must be taken in correlating the calculated and observed vibrations, because many of the infrared and Raman bands here are under severe perturbation by hydrogen bonds. Our present calculation shows that the vibration at 3686 cm^{-1} is the amino antisymmetric stretching and that at $3496\,cm^{-1}$ is the amino symmetric stretching.

In the infrared spectrum on the other hand, 2′,3′-benzylidene-5′-tritylguanosine dissolved in deuteriochloroform shows two bands due to the molecule free from any hydrogen bond at 3515 and $3407\,cm^{-1}$.[20] These two may correspond to the above two. In that solution, however, other bands due to some guanine-guanine association complexes are also found at 3480, 3355, 3305, and $3230\,cm^{-1}$. The vibrational modes of the hydrogen-bonded NH_2 and those of NH are not the subject of our present study.

In the case of C_8–H stretching vibration, the situation is simpler. The calculation shows that the vibration at $3132\,cm^{-1}$ is the C_8–H stretching and that at $2338\,cm^{-1}$ is the C_8–D stretching. On the other hand, a strong Raman line is observed of 5′GMP (guanosine 5′-monophosphate) in D_2O solution at $3125\,cm^{-1}$, and of the C_8-deuterated derivative in H_2O solution at $2325\,cm^{-1}$.[21] The hydrogen bondings at the N–H groups do not seem to affect the C_8–H vibration in the same molecule.

II. 2000—1100 cm^{-1}: A strong infrared band and a medium intensity Raman line around $1700\,cm^{-1}$ of guanine and guanine derivatives have been assigned to the C=O stretching vibration by a number of researchers, and this mode is reproduced in our calculation (ν_6 in Table 3).

In the Raman spectra of guanine, deuterated guanines, and 5′GMP in H_2O and D_2O solutions in the 1620—$1500\,cm^{-1}$ region, there are always three Raman lines, at 1610, 1580, and $1530\,cm^{-1}$.[22-24] These Raman lines are considered to correspond to the ring stretching vibrations, ν_8, ν_9, and ν_{10}, whose vibrational modes are shown in Table 3 as well as in Fig. 2. The calculated vibration ν_7 is the NH_2 scissoring, but this has never been identified in the Raman spectra of guanine and guanine derivatives. The calculated vibrations, ν_9 and ν_{11}, must correspond to the observed Raman lines at $1580\,cm^{-1}$ and $1480\,cm^{-1}$ of 5′GMP in H_2O solution, respectively. Those two Raman scatterings show marked resonance effect with the absorption bands at 278 and/or 253 nm.[25] In these excited states, the geometry of the guanine molecule is supposed to be deformed along these two normal coordinates which are shown in Fig. 2 (ν_9 and ν_{11}).

The Raman line at $1480\,cm^{-1}$ shows a large frequency shift as great as $-23\,cm^{-1}$ upon the C_8–H deuteration,[21] and this was used as a monitor line of the C_8–H deuterium exchange kinetics.[21] In our calculation, this large shifts is well reproduced ($-27\,cm^{-1}$) as shown in Table 5 (k=11). This $1480\,cm^{-1}$ Raman line also shows a marked frequency shift and/or intensity change on the coordination at N_7 of heavy metal ions and on N_7 protonation.[22,24,25] This is also understandable because the calculated normal modes (as shown in Fig. 2) involves a big movement of the N_7 atom, and the

25	619 (−3)	671 (−10)
26	533 (−4)	586 (−2)
27	481 (−2)	501 (−1)

a) From Ref. 21. b) The amount of shift (in cm^{-1}) by the C_8-deuteration is given in each pair of parentheses.

calculated potential energy distribution of C_8N_7 stretching in this vibration is as high as 42%. Therefore, this Raman scattering is naturally sensitive to a perturbation at N_7.

As has already been mentioned, the contribution of the N_1H, N_9H, and NH_2 bending modes in the vibrations in the 1450—1100 cm^{-1} region are not clearly predicted by the present calculation. However, the contribution of the C_8–H deformation mode has been satisfactorily predicted. The calculated vibrations at 1174 cm^{-1} for guanine, at 885 cm^{-1} for guanine-d_1, at 1146 cm^{-1} for guanine-d_4, and at 930 cm^{-1} for guanine-d_5 should involve a great amount of C_8–H or C_8–D in-plane bending mode (see Table 4). These vibrations are correlated with observed IR bands at 1174 cm^{-1}, 926 cm^{-1}, 1168 cm^{-1}, and 897 cm^{-1}, respectively.[13] Thus, the C_8-deuteration effect in *N*-deuterated guanine as well as undeuterated guanine spectra have been clearly reproduced and explained by our calculation.

III. Vibrations with Frequencies below 1100 cm^{-1}: In this frequency region, no complexity coming from the NH bending modes is involved any more. The calculated frequencies and their ^{15}N isotope effects of the ν_{20}, ν_{21}, ν_{22}, ν_{23}, ν_{24}, ν_{25}, and ν_{26} vibrations can be clearly correlated with what were actually observed. The calculated vibrational modes given in Table 3 are considered to be quite useful.

In particular, the ring breathing vibration should be mentioned. Raman spectroscopic studies of nucleic acids have so far showed that a strong and sharp Raman lines at 780, 790, and 725 cm^{-1} of uracil, cytosine, and

adenine, respectively, are assignable to the ring breathing vibrations.[1,22-24] For guanine residues, in 5'GMP for example, no strong Raman line has been found in the frequency region higher than 700 cm^{-1}; instead a much broader and weaker line was observed around 680 cm^{-1}.[22,25] This line has been considered to correspond to some kind of ring breathing vibration perturbed by some ring deformations.[23] However, this Raman line at 650 cm^{-1} is strong enough in the spectrum of solid state guanine.[13] Our present calculation has now predicted that this line is nearly pure ring breathing vibration. Our recent study on guanosine residues indicates that this ring breathing frequency is appreciably affected by the sugar conformation and by the torsion angle around the glycosidic bond connecting the guanine and ribose moieties.[2,3] The broadness and weakness of the 670 cm^{-1} line of 5'GMP in H_2O, therefore, would mean that various conformations are involved in the solution whose frequencies are slightly different from one another.[27] Such a flexibility of the 5'GMP conformation in solution would be removed in the solid state or in a regular-form polynucleotide. On the basis of this argument, a strong, sharp Raman line should be observed if the conformation of 5'GMP is fixed. This is what is actually found as has been detailed elsewhere.[2,3,27]

As shown in Fig. 2, the calculated vibrational mode (ν_{25}) involves a big movement of the N_9 atom and the position-9 hydrogen atom. In the guanosine molecule, this hydrogen is replaced by the sugar, so that the ring breathing vibration should cause a coupling with a vibration in the sugar part. This is a qualitative explanation of the observed dependence of the ring breathing frequency upon the ribose conformation. More detailed description as for how it depends is given in a previous article.[3]

This work was supported by a grant (No. 57060004) from the Ministry of Education, Science, and Culture of Japan. The numerical calculations were carried out at the Computer Center of IMS.

Catalytic Function of Cobalt(III) Complexes with *N,N'*-Disalicylideneethylenediamine on Oxygenation of *t*-Butylphenols

Yūko Aimoto, Wakako Kanda, Sadatoshi Meguro,† Yūji Miyahara, Hisashi Ōkawa,* and Sigeo Kida

Department of Chemistry, Faculty of Science, Kyushu University 33, Hakozaki, Higashiku, Fukuoka 812
†*Department of Forest Products, Faculty of Agriculture, Kyushu University 46-08, Hakozaki, Higashiku, Fukuoka 812*
(Received May 24, 1984)

Catalytic oxygenation of *t*-butylphenols has been examined with the cobalt(III) complexes with *N,N'*-disalicylideneethylenediamine (H_2salen), K[Co(salen)CO_3], Na[Co(salen)$(N_3)_2$], K[Co(salen)$(CN)_2$], [Co(salen)$(py)_2$]PF_6, and [Co(salen)$(NH_3)_2$]PF_6. The CO_3-complex showed a high catalytic activity while the other complexes a low or no catalytic activity. Based on electronic and ESR spectral investigations, it has been shown that the reaction is initiated by the direct oxidation of *t*-butylphenols by the CO_3-complex through a phenolatocobalt(III) intermediate.

Reversible oxygen-carrying functions of cobalt(II) complexes with Schiff base ligands are well known.[1,2] Recently, catalytic oxidations of *t*-butylphenols[3-11] and indoles[12,13] by the use of such cobalt(II) complexes have become of interest as models for biological oxidations, since the catalysis in biological systems is considered to involve the activation of molecular oxygen by metalloenzymes. In the oxygenation of *t*-butylphenols with [Co(salpr)] (salpr^{2-}=bis(3-salicylideneaminopropyl)amine anion), it has been shown that the reaction is initiated by the hydrogen abstraction from the phenol by the superoxocobalt(III) complex [Co(salpr)O_2] initially formed.[9-11] On the other hand, the catalytic function of [Co(salen)](salen^{2-}=*N,N'*-disalicylideneethylenediamine anion) in oxygenations of *t*-butylphenols is less known, though it is generally thought that its oxygen complex takes part in the initiation of the reactions.[3]

It is also shown that [Co(salen)] acts as a good catalyst for oxygen delignification.[14] In the oxidative degradation of guaiacol as a model for the oxygen delignification, the catalytic activity of [Co(salen)] decreases in the order of additives in aqueous solution: $NaHCO_3$>Na_2CO_3>NaOH.[15] Under these conditions [Co(salen)] must be oxidized to a cobalt(III) complex. However, the species formed in alkaline aqueous media have not been characterized as yet.

The objects of this study are (1) to isolate and characterize the cobalt(III) complex derived from [Co(salen)] in aqueous solution containing hydrogencarbonate ion and (2) to examine catalytic activities of this cobalt(III) complex and its related complexes on the oxygenations of *t*-butylphenols, in the hope of obtaining an insight into the catalytic function of [Co(salen)] in the oxygenation reaction.

Experimental

Isolation of the Cobalt(III) Complex Formed in Aqueous Potassium Hydrogencarbonate Solution. [Co(salen)] (5 g) was suspended in a solution of $KHCO_3$ (10 g) in water (300 cm^3). Then chloroform (30 cm^3) was added, and the mixture was stirred for a week at room temperature. The deep green aqueous layer was separated and evaporated to dryness at a temperature lower than 40 °C. The crude product thus obtained was recrystallized from cold water containing potassium hydrogencarbonate (5%) to form green prisms.

Found: C, 43.45; H, 3.81; N, 6.06%. Calcd for $C_{17}H_{14}N_2O_5CoK\cdot 5/2H_2O$: C, 43.50; H, 4.08; N, 5.97%.

Syntheses of Other Cobalt(III) Complexes. Na[Co(salen)$(N_3)_2$]: An aqueous solution of NaN_3 (1 g) was added to a solution of K[Co(salen)CO_3]$\cdot 5/2H_2O$ (hereafter denoted as CO_3-complex, 450 mg) in water (10 cm^3). Soon the $(N_3)_2$-complex separated as brown crystals.

Found: C, 43.34; H, 3.29; N, 25.51%. Calcd for $C_{16}H_{14}N_8O_2CoNa\cdot 1/2H_2O$: C, 43.55; H, 3.43; N, 25.39%.

[Co(salen)N_3]: The $(N_3)_2$-complex (30 mg) was dissolved in water (40 cm^3) to form a reddish brown solution, from which brown crystals separated. They were collected, washed with water, and dried *in vacuo*.

Found: C, 49.75; H, 4.31; N, 17.76%. Calcd for $C_{16}H_{14}N_5O_2Co\cdot H_2O$: C, 49.88; H, 4.19; N, 18.18%.

K[Co(salen)$(CN)_2$]: This complex ($(CN)_2$-complex) was obtained as yellowish orange crystals by the reaction of the CO_3-complex and an excess amount of KCN in water.

Found: C, 51.20; H, 3.49; N, 13.23%. Calcd for $C_{18}H_{14}N_4O_2CoK\cdot 1/2H_2O$: C, 50.82; H, 3.55; N, 13.17%.

[Co(salen)$(py)_2$]PF_6: The CO_3-complex (460 mg) was dissolved in water (15 cm^3) containing pyridine (10 cm^3). To the resulted red solution was added an aqueous solution of KPF_6 to give the $(py)_2$-complex as orange prisms.

Found: C, 49.69; H, 3.85; N, 8.92%. Calcd for $C_{26}H_{24}N_4O_2CoF_6P\cdot 1/2H_2O$: C, 49.70; H, 3.85; N, 8.92%.

[Co(salen)py]PF_6: The $(py)_2$-complex was left standing in a vacuum desiccator over P_2O_5 for a week to give the monopyridine adduct.

Found: C, 45.24; H, 3.58; N, 7.84%. Calcd for $C_{21}H_{19}N_3O_2CoF_6P\cdot 1/2H_2O$: C, 45.18; H, 3.61; N, 7.53%.

[Co(salen)$(NH_3)_2$]PF_6: This complex ($(NH_3)_2$-complex) was obtained in a way similar to that for the $(py)_2$-complex.

Found: C, 37.40; H, 4.07; N, 10.98%. Cacd for $C_{16}H_{20}N_4O_2CoF_6P\cdot 1/2H_2O$: C, 37.44; H, 4.12; N, 10.92%.

Oxygenation Reactions of t-*Butylphenols.* Oxygenation reactions of 2,4,6-tri-*t*-butylphenol and 2,6-di-*t*-butyl-4-methylphenol were examined by the use of the CO_3-, $(N_3)_2$-, $(CN)_2$-, $(py)_2$-, and $(NH_3)_2$-complexes as catalysts. The reactions were carried out by stirring an ethanolic solution containing a substrate and a catalyst for 12 h at room temperature, where the concentration of the substrate was 1×10^{-1} M (1 M=1 mol dm^{-3}) and the [substrate]/[catalyst] ratio was 50. Oxygenation products were separated by preparative thin-

layer chromatography with alumina as an adsorbent or by high-speed liquid chromatography (column; Zorbax-ODS, 15 cm: eluent; acetonitrile–water (4:1)). Identifications of the products were performed by comparing the NMR and IR spectra and melting points of the products with those of authentic samples.

Physical Measurements. Infrared spectra were measured on a Hitachi Infrared Spectrometer Model 215 on KBr disks. Electronic spectra were recorded on a Shimadzu Multipurpose Spectrophotometer Model MPS-5000. ESR spectra (X-band) were recorded on a JES-FE3X Spectrometer. Conductivity measurements were carried out with a Yanagimoto Conductivity Output Model MY-8 in ethanol, the cell constant being determined by the use of tetraethylammonium chloride.

Results and Discussion

The CO_3-complex exhibits the IR bands at 1590 and 1290 cm^{-1}, which are assigned to the vibration of bidentate carbonate group.[16] Absorption spectrum of this complex in water containing excess potassium hydrogencarbonate shows a d-d band at 16.3×10^3 cm^{-1} and an intraligand transition band at 26.6×10^3 cm^{-1} (Fig. 1). The spectrum resembles the spectra of *cis*-β-[Co(salen)(acac)][17] and its homologs.[18–21] All these facts indicate that the CO_3-complex adopts a *cis*-β octahedral configuration with nonplanar $salen^{2-}$ and bidentate carbonate ion (Fig. 2a).

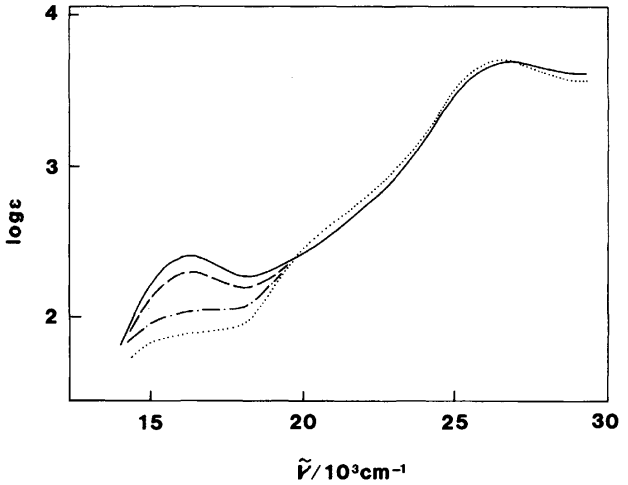

Fig. 1. Absorption spectra of the CO_3-complex: (——) in 10% $KHCO_3$ (1×10^{-3} M), (— —) in 1% $KHCO_3$ (1×10^{-3} M), (— · —) in water (1×10^{-2} M), and (·····) in water (1×10^{-3} M).

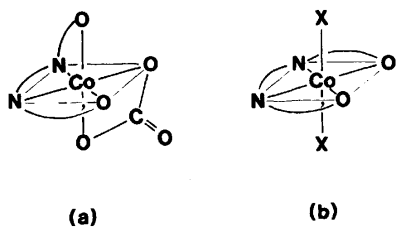

Fig. 2. Schematical representations of (a) *cis*-β-[Co(salen)CO_3]$^-$ and (b) *trans*-[Co(salen)X_2]$^-$ ($^-O\cap N\cap N\cap O^- = N,N'$-disalicylideneethylenediaminate ion).

As is seen in Fig. 1, the 16.3×10^3 cm^{-1} band diminishes its extinction coefficient with lowering of the hydrogencarbonate concentration or diluting the solution with water. This spectral behavior suggests the ligand substitution and/or the configurational change of the complex in aqueous solution. Since the electronic spectrum of a dilute aqueous solution is very similar to that of *trans*-[Co(salen)$(H_2O)_2]^+$,[22] the following equilibrium is supposed for the complex: *cis*-β-[Co(salen)$CO_3]^- + 2H_2O \rightleftharpoons$ *trans*-[Co(salen)$(H_2O)_2]^+ + CO_3^{2-}$. Therefore, we presume that either *cis*-β-[Co(salen)$CO_3]^-$ or *trans*-[Co(salen)$(H_2O)_2]^+$ functions as a catalyst in the oxidative degradation of guaiacol.[15] In oxygen delignification in a dilute sodium hydroxide solution, *trans*-[Co(salen)$(H_2O)_2]^+$ must be the active species. However, this does not rule out the possibility of the catalytic function of *cis*-β-[Co(salen)$CO_3]^-$ in oxygen delignification in the presence of bicarbonate or carbonate ion.

It is also noted in this study that the CO_3-complex can be used as a starting material for the preparation of *trans*-[Co(salen)$X_2]^-$ (X=N_3, CN) and [Co(salen)$B_2]^+$ (B=py, NH_3) (Fig. 2b).

The oxygenation reactions of 2,4,6-tri-*t*-butylphenol and 2,6-di-*t*-butyl-4-methylphenol have been examined by the use of the CO_3-, $(N_3)_2$-, $(CN)_2$-, $(py)_2$-, and $(NH_3)_2$-complexes as catalysts, and the results are given in Table 1. The characterized major products are quinol (**1**), quinone (**2**), and peroxide (**3**) (Fig. 3). In the case with 2,4,6-tri-*t*-butylphenol as the substrate, the CO_3-

a) Reaction condition: [catalyst]=2×10^{-3}M, [substrate]/[catalyst]=50, 12 h in ethanol at room temperature. b) TBP=2, 4, 6-tri-*t*-butylphenol and DBMP=2, 6-di-*t*-butyl-4-methylphenol. c) **1**: quinol, **2**: quinone, and **3**: peroxide (*cf.* Fig. 3).

complex exhibited a high catalytic activity while the $(N_3)_2$-complex a low activity. Other complexes showed practically no catalytic activity. In the case with 2,6-di-*t*-butyl-4-methylphenol, only the CO_3-complex showed a catalytic activity. The main oxygenation product in the former was the peroxide, while the product in the latter was the quinol. It should be noted that the same oxygenation products have been obtained by the use of Co(salen) as the catalyst.[6]

The catalytic activities of the cobalt(III) complexes evidently depend upon the fifth and sixth ligands. For obtaining an insight into the differences in catalytic activities of the complexes, the absorption spectra in ethanol were investigated. The CO_3-complex in ethanol shows bands at 14.2×10^3 and $\approx21\times10^3$ cm^{-1}, attributable to d-d and intraligand transitions respectively (Fig. 4). This spectrum markedly differs from those of *cis*-β-$[Co(salen)CO_3]^-$ and *trans*-$[Co(salen)(H_2O)_2]^+$. Its molar conductivity has been determined to be 34 Ω^{-1} mol^{-1} cm in ethanol, which falls in the range for 1:1 electrolytes.[23] This indicates that carbonate ion is still bonded to the metal in this solvent. It is likely that the complex takes a configuration either of tetragonal pyramid with a unidentate carbonate ion at the apex or of an elongated octahedron with a carbonate ion and a solvent molecule at the apical positions.

The electronic spectra of the $(N_3)_2$-complex are shown in Fig. 4. The spectrum in ethanol differs from that in water containing excess of sodium azide. Further, $[Co(salen)N_3]$ shows the same spectrum as that of the $(N_3)_2$-complex in ethanol. These facts imply that the possible species of the $(N_3)_2$-complex in ethanol is $[Co(salen)N_3]$ or $[Co(salen)N_3(EtOH)]$.

A marked spectral change was also observed for the $(CN)_2$-complex when measured in water containing excess potassium cyanide and in ethanol (Fig. 5). Thus, the complex must have undergone some change in

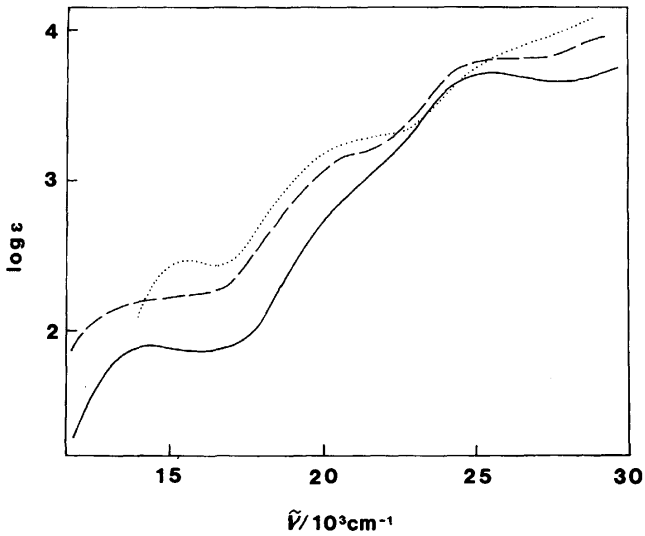

Fig. 4. Absorption spectra of the CO_3-complex in ethanol (——) and the $(N_3)_2$-complex in 2% NaN_3 solution (·····) and in ethanol (— —).

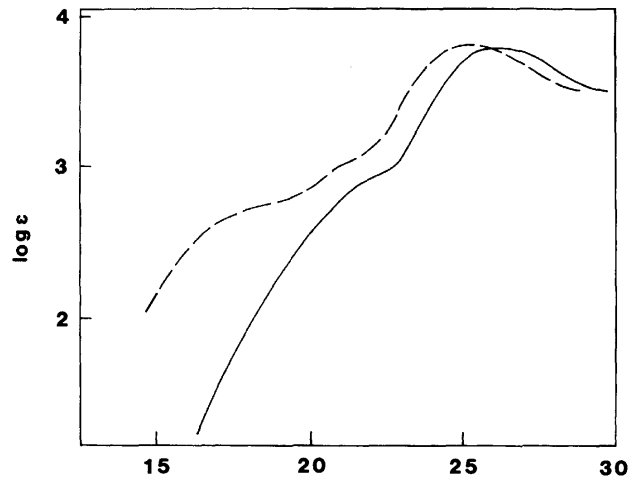

Fig. 5. Absorption spectra of the $(CN)_2$-complex in 2% KCN solution (——) and in ethanol (— —).

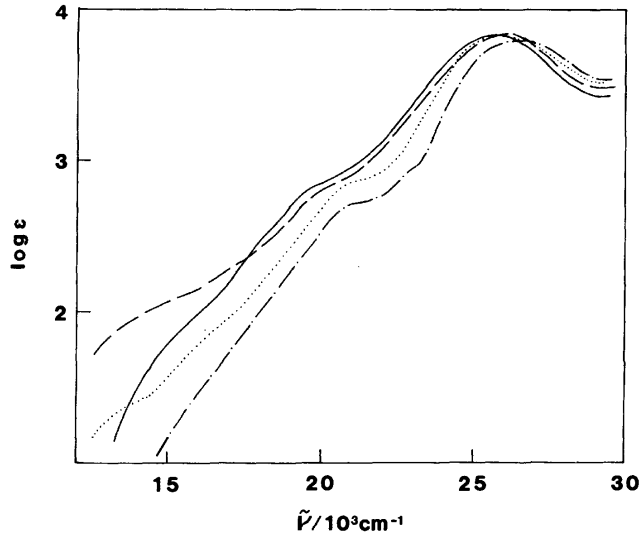

Fig. 6. Absorption spectra of the $(py)_2$-complex in pyridine (——) and in ethanol (— —) and the $(NH_3)_2$-complex in 18% ammonia (— · —) and in ethanol (·····).

ethanol in more or less degree. The spectrum in ethanol is characterized by an absorption at $\approx18\times10^3$ cm^{-1}. A similar absorption band was observed for the five-coordinate [RCo(salen)] (R=alkyl anion) and its homologs.[24-27] We have examined the electronic spectra of the ethanol solutions of the CO_3-complex containing potassium cyanide in various amounts, and found that the extinction coefficient at $\approx18\times10^3$ cm^{-1} becomes maximal when [Co]/[CN]=1. This suggests that [Co(salen)(CN)] or [Co(salen)(CN)(EtOH)] is formed in the solution.

Each spectrum of the $(py)_2$- and $(NH_3)_2$-complexes in ethanol differs from the spectrum in water containing the corresponding base (Fig. 6). Hence, the complex species in ethanol differs from $[Co(salen)B_2]^+$. Since the spectra of the $(py)_2$-complex and $[Co(salen)(py)]PF_6$ are practically the same in ethanol, the species in both solutions are likely to be $[Co(salen)(py)]^+$ or [Co(salen)-

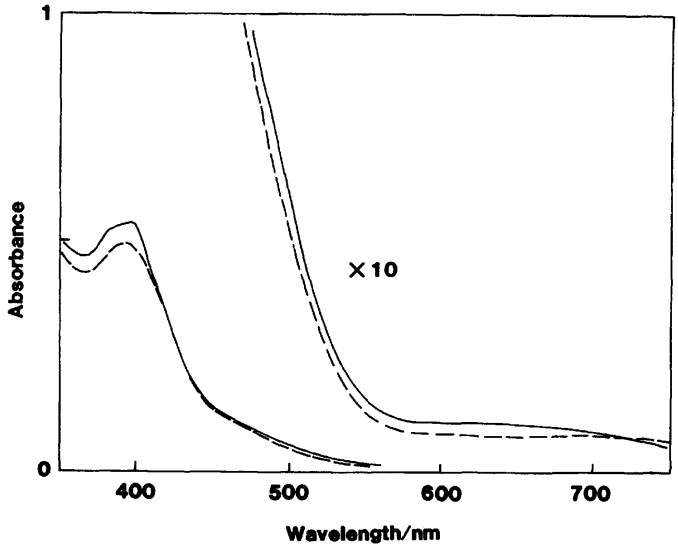

Fig. 7. Electronic spectral change on adding 2,4,6-tri-*t*-butylphenol to an ethanolic solution of the CO_3-complex: (——) CO_3-complex (1×10^{-3} M) and (——) CO_3-complex (1×10^{-3} M)+2,4,6-tri-*t*-butylphenol (1×10^{-2} M).

$(py)(EtOH)]^+$. A similar feature is supposed for the $(NH_3)_2$-complex in ethanol.

Above spectral investigations suggest that all the complexes take an essentially identical configuration; a tetragonal pyramid or an elongated octahedron. Therefore, it is difficult to explain the catalytic activity of the CO_3-complex solely in terms of configurational aspect.

It seems that the high catalytic activity of the CO_3-complex relative to the other complexes is attributable to the high lability of the carbonate ion. In order to verify this, the absorption spectrum of the CO_3-complex in the presence of ten times of 2,4,6-tri-*t*-butylphenol was examined under a nitrogen atmosphere. As seen in Fig. 7, the intensity around 390 nm increased and a new absorption appeared around 630 nm when the substrate was added, suggesting the generation of 2,4,6-tri-*t*-butylphenoxyl radical.[28] Further, this complex/substrate solution exhibited a three-lined ESR signal with a coupling constant of 1.7 gauss near $g\approx2.0$. This signal is very similar to that of 2,4,6-tri-*t*-butylphenoxyl radical,[29] though the hyperfine structures due to the tertiary butyl groups are absent probably because of the presence of the paramagnetic species ([Co(salen)]) in the solution. All these facts indicate that the CO_3-complex oxidizes the phenol to the phenoxyl radical. The preliminary electrochemical investigations have revealed that the Co^{III}/Co^{II} redox potential of the CO_3-complex (−1.2 V *vs.* SCE in ethanol, glassy carbon electrode) is much lower than that of the $(py)_2$-complex.[30,31] This fact suggests that the electron transfer between the CO_3-complex and a *t*-butylphenol is of inner-sphere rather than outer-sphere, through a five-coordinate intermediate with the phenolate group at the apical position. Thus, the mechanism of the catalytic oxygenation with the CO_3-complex may be represented as follows: (1) The substitution of the apical carbonate ion for the phenolate ion to form a phenolatocobalt(III) intermediate, (2) the intramolecular electron transfer to generate Co^{II} (salen) and the phenoxyl radical, and (3) the progression of radical reactions with molecular oxygen (Fig. 8).

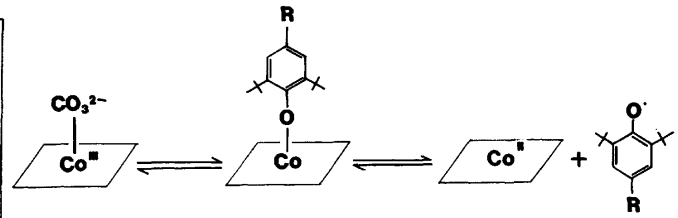

Fig. 8. Catalytic scheme for the oxygenation with the CO_3-complex.

Table 2. Oxygenation of 2,4,6-tri-*t*-butylphenol with [Co(salen)] in the presence of additives[a]

Additive	Conv/%	Products[b]/%		
		1	2	3
none[c]	85	—	24	53
KCN	0			
py	0			

a) Reaction condition: [catalyst]=2×10^{-3} M, [substrate]/[catalyst]=50, [additive]/[catalyst]=10, 12 hrs in ethanol at room temperature. b) *Cf.* Fig. 3. c) Results from Ref. 6, the solvent being methanol.

It is shown that the phenol/phenoxyl redox potential depends upon the substituent on the ring and becomes lower when a more electron donative substituent is introduced into the ring.[32] The ready oxidation of 2,4,6-tri-*t*-butylphenol relative to 2,6-di-*t*-butyl-4-methylphenol is probably due to the generation of the phenoxyl radical in a higher concentration in the former, since the *t*-butyl group is slightly more electron donative than the methyl group. Indeed, the electronic spectrum of the CO_3-complex (in ethanol under nitrogen atmosphere) showed a very little increase around 400 and 630 nm when 2,6-di-*t*-butyl-4-methylphenol (ten times) was added.

The low catalytic activities of the $(N_3)_2$-, $(CN)_2$-, $(py)_2$-, and $(NH_3)_2$-complexes may be due to the difficulties in forming the phenolatocobalt(III) intermediate with these complexes, because of the strong donating abilities of the apical ligands compared with the phenolate ion.

We have further examined the catalytic activity of [Co(salen)] on the oxygenation reactions of *t*-butylphenols in the presence of a donating additive. The results are given in Table 2. Contrary to a high catalytic activity in the absence of an additive,[6] the activity of [Co(salen)] for the oxygenation reaction was almost suppressed on adding cyanide ion or pyridine to the reaction system. This fact again demonstrates that the additives coordinate at the apical position of the air-oxidized Co^{III} (salen) and thence deactivate the catalytic function of [Co(salen)].

Crystal Structure of Nonstoichiometric Tetranuclear Platinum Compound, *cis*-Diammineplatinum α-Pyrrolidone Violet, $[Pt_4(NH_3)_8(C_4H_6NO)_4](PF_6)_2(NO_3)_{2.56}\cdot 5H_2O$

Kazuko MATSUMOTO

Department of Chemistry, School of Science and Technology, Waseda University, Okubo, Shinjuku-ku, Tokyo 160

(Received July 19, 1984)

Nonstoichiometric platinum tetranuclear compound, *cis*-Diammineplatinum α-Pyrrolidone Violet, $[Pt_4(NH_3)_8(C_4H_6NO)_4](PF_6)_2(NO_3)_{2.56}\cdot 5H_2O$, has been synthesized and the crystal structure has been solved with X-ray diffraction analysis. The crystal is triclinic with the space group of $P\bar{1}$ and cell dimensions of a=13.530(8), b=19.242(9), c=10.222(3) Å, α=96.56(9), β=93.82(9), γ=74.64(8)°, V=2547.4 Å^3, and Z=2. The structure have been solved by heavy atom method and the final discrepancy index R_1 was 0.094 and R_2 was 0.090. The cation is structurally identical with those of *cis*-Diammineplatinum α-Pyridone Yellow(PPY), $[Pt_4(NH_3)_8(C_5H_4NO)_4]^{4+}$, *cis*-Diammineplatinum α-Pyridone Blue(PPB), $[Pt_4(NH_3)_8((C_5H_4NO)_4]^{5+}$, and *cis*-Diammineplatinum α-Pyrrolidone Tan(PPT), $[Pt_4(NH_3)_8(C_4H_6NO)_4]^{6+}$, and consists of four platinum atoms linked in a chain with bridging pyrrolidone ligands. Each platinum atom is cis coordinated by two ammine ligands and either two exocyclic oxygen atoms or two deprotonated ring nitrogen atoms of α-pyrrolidone ligands. The Pt-Pt bond distances are 2.848(2), 2.875(2), 2.839(2), and 2.875(2) Å, which are intermediate between those of PPY and PPB, indicating that the average platinum oxidation state is between 2.0 and 2.25. According to the potentiometric oxidative titration of the compound using Ce(IV), the average platinum oxidation state is 2.14 and therefore the compound is considered to consist of 44% of $[Pt_4(NH_3)_8(C_4H_6NO)_4]^{4+}$ and 56% of $[Pt_4(NH_3)_8(C_4H_6NO)_4]^{5+}$.

Although a class of dark blue platinum compounds, so called "Platinum Blues," was first reported as early as 1908[1] and have attracted interest of chemists because of their abnormally deep blue color and paramagnetic nature,[2-4] their structure and formulas have long been unknown, because they are unstable in solution, difficult to synthesize reproducibly and to obtain crystals.

Recently, Barton *et al.* first reported the synthesis of crystalline *cis*-Diammineplatinum α-Pyridone Blue (PPB), $[Pt_4(NH_3)_8(C_5H_4NO)_4](NO_3)_5\cdot H_2O$, and solved the structure by X-ray analysis.[5,6] The compound is a tetranuclear chain cation, whose neighboring platinum atoms are bridged by amide oxygen and deprotonated amide nitrogen atoms. Three of the platinum atoms are formally in the oxidation state of +2, and the remaining one is +3; that is, the average platinum oxidation state is +2.25, although the four platinum atoms are actually rather equivalent and the one unpaired electron is delocalized over the four platinum atoms.[6]

Following the synthesis and structure determination of PPB, several platinum-blue related compounds have been isolated and structurally elucidated. These include *cis*-Diammineplatinum α-Pyridone Yellow (PPY), $[Pt_4(NH_3)_8(C_5H_4NO)_4](NO_3)_4$,[7] *cis*-Diammineplatinum 1-Methylhydantoin Yellow (PHY), $[Pt_4(NH_3)_8(C_4H_5N_2O_2)_4](NO_3)_4\cdot H_2O$,[8] *cis*-Diammineplatinum α-Pyrrolidone Tan (PPT), $[Pt_4(NH_3)_8(C_4H_6NO)_4](NO_3)_6\cdot 2H_2O$,[9,10] and *cis*-Diammineplatinum α-Pyrrolidone Green (PPG), $[Pt_4(NH_3)_8(C_4H_6NO)_4](NO_3)_{5.48}\cdot 3H_2O$.[11] The last compound is nonstoichiometric, being a mixture of diamagnetic hexavalent PPT cation and paramagnetic PPB-corresponding quinquevalent cation. This nonstoichiometry has been confirmed both with single crystal X-ray diffraction analysis and magnetic susceptibility measurement.[11] PPT consists of two Pt(II) and two Pt(III) atoms, whose two unpaired electrons are strongly diamagnetically coupled.[10] PPY and PHY have all their four platinum atoms in the oxidation state of 2+ and are therefore diamagnetic. These compounds reveal that "Platinum Blues" are a class of compounds whose platinum oxidation state can be varied without basic structural change and the color varies according to the platinum oxidation state.

In this paper, another platinum blue related compound, *cis*-Diammineplatinum α-pyrrolidone Violet (PPV), is reported. This compound is nonstoichiometric, being a mixture of PPB-corresponding quinquevalent cation and PPY-corresponding quadrivalent cation. A preliminary report on the structural analysis of the compound has been publlshed previously,[12] Therefore the details of the crystal structure is reported here, together with the result of the potentiometric oxidative titration using Ce(IV), which confirms the average platinum oxidation state of 2.14.

Experimental

Preparation. The preparation procedure of the compound has been already reported in Ref. 12. The results of the elemental analyses are: Found: C, 10.79; H, 3.32; N, 11.70; Pt, 43.4%. Calcd for $[Pt_4(NH_3)_8(C_4H_6NO)_4](PF_6)_2(NO_3)_{2.56}\cdot 5H_2O$: C, 10.72; H, 3.27; N, 11.38; Pt, 43.55%.

Crystal Data. The single crystal of the compound used for intensity measurement was 0.25×0.2×0.1 mm. Preliminary Weissenberg photographs of the crystal showed it is monoclinic. Unit cell parameters were obtained from least-squares fit of 20 reflections in the range of $20°<2\theta<35°$ measured on a Philips PW1100 diffractometer using graphite-monochromated Mo $K\alpha$ radiation. The crystal data are as follows:

$[Pt_4(NH_3)_8(C_4H_6NO)_4](PF_6)_2(NO_3)_{2.56}\cdot 5H_2O$
triclinic $P\bar{1}$
a = 13.530(8)

$b = 19.242(9)$
$c = 10.222(3)$ Å
$\alpha = 96.56(9)$
$\beta = 93.82(9)$
$\gamma = 74.64(8)°$
$v = 2547.4$ Å^3
MW = 1791.9
$Z = 2$
$D_m = 2.40$
$D_x = 2.34$ g cm^{-3}
$\mu = 117.4$ cm^{-1} (for Mo $K\alpha$ radiation)

Data Collection. All the intensities within $3°<2\theta<55°$ were measured on a Philips PW1100 four-cirle diffractometer. The scan mode was ω—2θ, with a scan rate of 2° min^{-1} in 2θ. The scan range was calculated for each reflection according to the formula, $\omega=1.2+0.3\tan\theta$, and stationary-crystal, stationary-counter background measurement was employed. The background measurement time, T_{bck}, was determined according to the formula, T_{bck}=(scan time)/$2(I_{bck}/I_{int})^{1/2}$, where I_{bck} (counts/s) is average value preliminarily measured at both ends and I_{int} (counts/s) is the value of the peak. The measurement was carried out on a crystal sealed in a glass capillary in order to avoid crystal deterioration after long irradiation. Three standard reflections were monitored every two hours, however only random statistical fluctuations were observed throughout the measurement. The data were corrected for the Lorentz-polarization effects and absorption. A total of 8377 reflections with $|F_o|\geq 3\sigma(|F_o|)$ were used for calculation.

Solution and Refinement of the Structure. The coordinates of the four platinum atoms were found from a Patterson map, and a series of block-diagonal least-squares refinements followed by Fourier synthesis revealed all the oxygen, nitrogen, and carbon atoms in the α-pyrrolidonate and ammine ligands. After further refinement of the coordinates with anisotropic temperature factors for all the atoms, a difference synthesis was calculated and all the nitrate and hexafluorophosphate anions and water molecules of crystallization were located. Hydrogen atoms could not be located even with a difference synthesis using the refined coordinates of all the atoms. The structure was finally refined with anisotropic temperature factors for all the atoms to the final discrepancy index of R_1=0.094 and R_2=0.090, where $R_1=\sum||F_o|-|F_c||/\sum|F_o|$ and $R_2=[\sum w_i||F_o|-|F_c||^2/\sum w_i|F_o|^2]^{1/2}$. The weight of each reflection was determined as $w_i=1/\sigma^2(F_o)$. Atomic scattering factors were taken from Ref. 13, and the anomalous dispersion corrections were based on Ref. 14. All the calculations were performed with the local version of

the program UNICS (Sakurai, 1967) and ORTEP (Johnson, 1965).

The final positional and thermal parameters of non-hydrogen atoms are listed in Table 1. The observed and calculated structure factors and anisotropic temperature factors are avilable at the office of this Bulletin (Document No. 8516).

Oxidative Titration. In order to confirm the average platinum oxidation state, oxidative titration using Ce(IV) was carried out. The titration was monitored potentiometrically by using platinum *vs.* AgCl electrodes. The titrant Ce(IV) was prepared by dissolving ammonium cerium(IV) sulfate in 0.36 mol dm^{-3} sulfuric acid to the concentration of 6.1×10^{-3} mol dm^{-3}. About 0.01 g of *cis*-Diammineplatinum α-Pyrrolidone Violet was weighed and dissolved in 40 ml of 0.1 mol dm^{-3} nitric acid. Both the titrand and the titrant were degassed with argon before titration and were also protected from the air by argon flow during the titration.

Description of the Structure and Discussion

Unit cell has two independent platinum tetranuclear cations. The structure of one of them and the atomic-numbering schemes are depicted in Ref. 12. The interatomic distances and bond angles within the cations are listed in Tables 2 and 3, respectively. The cation consists of four platinum atoms linked in a chain with bridging pyrrolidone ligands. Each platinum atom is cis coordinated by two ammine ligands and either two exocyclic oxygen atoms or two deprotonated ring nitrogen atoms of α-pyrrolidone ligands. Each cation has crystallographic center of symmetry at the midpoint of Pt1-Pt1′ and Pt3-Pt3′ bonds, respectively. These central Pt-Pt bondings are achieved by partial metal-metal bonding and probably also by hydrogen bonding between ammine hydrogen atoms and exocyclic oxygen atoms of α-pyrrolidone ligands coordinated to adjacent platinum atoms. The structure of the cation is basically identical with those of PPB, PPY, PHY, PPT, and PPG. The Pt-Pt bond distances are closely related to the average platinum oxidation state in the tetranuclear platinum chain compounds[10] as well as in one-dimensional platium complexes.[15] The Pt-Pt bond length of PPV suggests that the compound consists of platinum atoms with intermediate oxidation state between 2.0 and 2.25.[12] The compound contains 2.56 nitrate anions per cation as concluded later in the discussion of the oxidative titration using Ce(IV). From the X-ray diffraction analysis, two nitrate anions (N1 and N2) have been located with statistical weight of unity, and another two (N3 and N4), with statistical weight of less than unity. The latter two are considered to be distributed in the crystal lattice with a weight of 0.56/2. However, no definite conclusion can be drawn concerning the platinum oxidation state, simply from the number of nitrate anions found in the crystal lattice. The average platinum oxidation state has been confirmed by oxidative titration and the detail is described later in this paper.

a) Bond angle related to terminal Pt–Pt bond. b) Bond angle related to central Pt–Pt bond. c) τ is the tilt angle betewen adjacent platinum coordination planes and ω is the torsion (or twist) angle about the Pt–Pt vector.

Tables 4 and 5 summarizes the geometric features of PPY, PPV, PPB, PPG, and PPT. In PPY, PPV, and PPB the interior Pt–Pt bonds are longer than the terminal ones, while in PPT they are almost equal, and in PPG the relation is reversed. Comparing the difference of the terminal and central Pt–Pt bond lengths in these tetranuclear cations, it seems that the difference of the bond lengths between terminal and central Pt–Pt bonds is specific to the bridging amide ligand and the difference is larger in α-pyridone compounds than α-pyrrolidone ones. The difference is also dependent on the platinum oxidation state and, as the average oxidation state is increased, the difference seems to be decreased. Comparing PPV, PPG, and PPT, the tilt sngle τ shows a slightly decreasing tendency as the platinum oxidation state is increased. This is a result of the shortening of the Pt–Pt bond as the platinum oxidation state is increased. Since the N(ring)···O(exocyclic) bite distance (about 2.3Å) is shorter than the Pt–Pt distance, the tilt angle τ is decreased as the platinum oxidation state is increased and the Pt–Pt bond distance is decreased. Concerning the torsion angles ω about the Pt–Pt vector, there seems to be a distinct difference between α-pyridone compounds and α-pyrrolidone ones. While in PPY and PPB, where the amide ligand is α-pyridone, the angles are about 22°, most of them are decreased to less than 6° in PPG, PPT, and PPV containing α-pyrrolidone. The reason for the remarkably different two ω angles larger than 10° in PPG still remains unexplained even with the present structural analysis of PPV. The small ω values less than 6° signify that the bridging N(ring) and O(exocyclic) in the α-pyrrolidone are almost overlapped when viewed along the Pt–Pt vector for α-pyrrolidone compounds, PPV, PPG, and PPT, while in α-pyridone compounds, PPY and PPB, ω values are about 22°, which suggest that N(ring) and O(exocyclic) are twisted about the Pt–Pt vector. Apart from these tetranuclear compounds, there are several amidate-bridged Pt(II) dimers whose structures have been studied by X-ray diffraction analyses. These include $[Pt_2(NH_3)_4(C_5H_4NO)_2](NO_3)_2 \cdot 2H_2O$ (α-pyridone dimer),[16] $[Pt_2(NH_3)_4(C_6H_7N_2O_2)_2]$ $(NO_3)_2 \cdot H_2O$ (1-methylthymine dimer),[17] $[Pt_2(NH_3)_4(C_5H_5N_2O_2)_2]$-

$(NO_3)_2 \cdot 3H_2O$ (1-methyluracil dimer,[18] $[Pt_2(NH_3)_4(C_5H_6N_3O)_2]$-$(NO_3)_2 \cdot 2H_2O$ (1-methylcytosine dimer).[20] The torsion angles ω in these dimers are all within the range of 13° to 20°, except in 1-methylthymine dimer, where ω is 1.0°. It seems, therefore, the torsion angle is specific to each amide ligand and the effect of platinum oxidation state on ω value is less, compared with that of an amide ligand.

No significant difference was observed in Pt-O, Pt-N, and Pt-NH_3 bond lengths among the six tetranuclear platinum compounds and these values are within the range normally observed in related platinu-(II) ammine complexes.[16-28] The coordination sphere of each platinum atom is almost planar. The shifts of each platinum atom from the least-squares planes are Pt1 0.05Å, Pt2 0.06Å, Pt3 0.04Å, and Pt4 0.02Å. The average P-F distance in PF_6^- anions is 1.57Å with the standard deviation of 0.04Å. All the N-O distances and bond angles within the nitrate anions are within the usual values (average N-O distance, 1.24Å).

Table 6. Possible hydrogen bonding (Å) in the crystal lattice[a)]

a) Roman numerals refer to the symmetry translations as follows: i(−x, −y, −z), ii(1−x, 1−y, 1−z), iii(1+x, y, z), iv(−1+x, y, z), v(1−x, 1−y, −z), vi(−x, 1−y, 1−z), vii(−x, 1−y, −z).

Table 6 summarizes the possible hydrogen bondings in the crystal lattice. The crystal packing is shown in Fig. 1. The axial coordination to platinum atoms at both ends of the chain is important in regard to the relation between the Pt-L_{axial} bond length and platinum oxidation state. Hollis *et al.* reported that axial coordination is favored and the Pt-L_{axial} bond distance is decreased with increasing platinum oxidation state, from a review of amidatebridged dinuclear and tetranuclear compounds of platinum(II) and platinum-(III).[29] In the present compound, only one loose coordination, Pt2-F11 3.15(8)Å, is found as shown in Table 2, and no other significant coordination to platinum atoms at chain ends are observed within 3.5-Å range. This is probably due to the low average platinum oxidationstate of the compound. The bond length 3.15Å of Pt2-F11 is slightly shorter than the axial bond length of 3.32Å for Pt-O(NO_3^-) found in PPB, even if we take into consideration the difference of the ionic radii of O^{2-} (1.40Å) and F^- (1.33Å). It is rather comparable to 3.21Å of Pt-O(NO_3^-) found in PPG. The axial bond length would therefore be determined firstly by average platinum oxidation state, however it is also affected by other forces probably imposed by the crystal packing.

The results of the potentiometric oxidative titration with Ce(IV) in 0.29 mol dm^{-3} and 0.93 mol dm^{-3} HNO_3 are shown in Fig. 2. Both results show that the average platinum oxidation state is 2.14, however, the titration curve is different. While in 0.29 mol dm^{-3} HNO_3 the compound is directly oxidized to Pt(III) state, in 0.93 mol dm^{-3} HNO_3, it is first oxidized to $Pt^{2.5+}$ and secondly to Pt(III), as shown in Fig. 2. From the relation curve

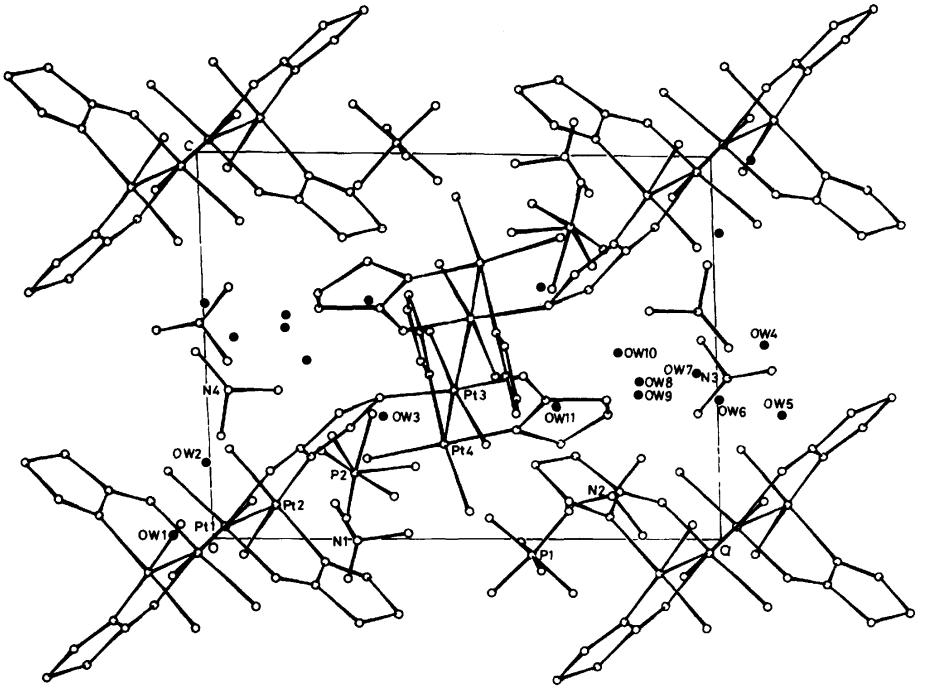

Fig. 1. Crystal structure of $[Pt_4(NH_3)_8(C_4H_6NO)_4](PF_6)_2(NO_3)_{2.56} \cdot 5H_2O$.

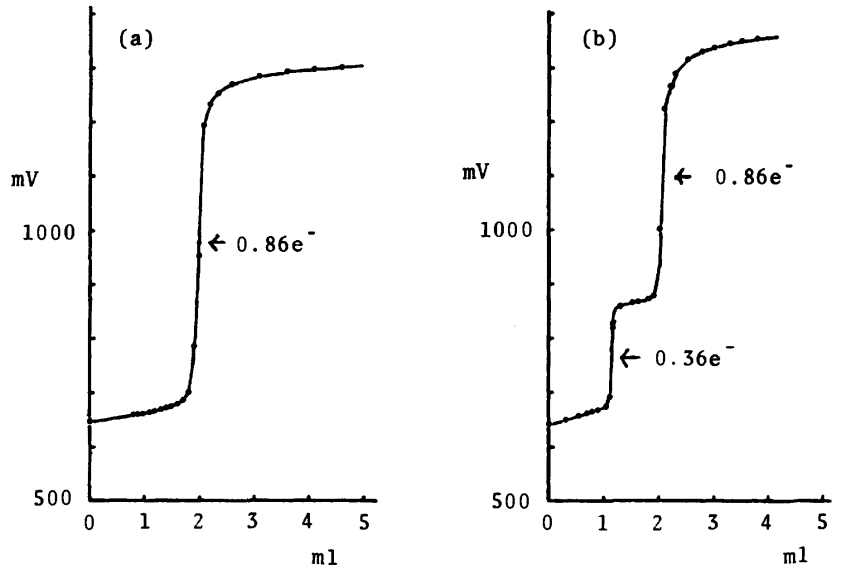

Fig. 2. Potentiometric oxidative titration of PPV with Ce(IV); (a) 0.29 mol dm^{-3} HNO_3 solution, (b) 0.93 mol dm^{-3} HNO_3 solution.
The titrations were monitored by using platinum *vs.* AgCl electrodes.

of Pt–Pt bond distance and average platinum oxidation state,[11] the average platinum oxidation state in the present compound is 2.10 (from the terminal Pt–Pt bond lengths) or 2.25 (from the central Pt–Pt bond lengths). Since the relation still seems to require more data to be recognized as established, we currently adopt the result of oxidative titration and determine the average platinum oxidation state as 2.14. This means that the compound is $[Pt_4(NH_3)_8(C_4H_6NO)_4](PF_6)_2(NO_3)_{2.56}\cdot 5H_2O$, being a mixture of 44% of $[Pt_4(NH_3)_8(C_4H_6NO)_4]^{4+}$ and 56% of $[Pt_4(NH_3)_8(C_4H_6NO)_4]^{5+}$. The fact that the existence ratio of the two cations is nearly 1:1 does not seem to mean any particular inter-cationic or inter-cation and -anion interactions, since there seems no significant interacions between them in the crystal psck-ing. Therefore it seems probable that other crystals with different existence ratio exist. Such possibility is now under investigation.

Reactions of the $[PtCl_2L_2]$ Complexes (L=Sulfide or Tertiary Phosphine) with β-Diketonate Anions

Fumiyo SASAKURA, Kiyoshi ISOBE,* and Shinichi KAWAGUCHI*,†

Department of Chemistry, Faculty of Science, Osaka City University, Sumiyoshiku, Osaka 558

†*Kinki University, Sayamacho, Minamikawachigun, Osaka 589*

(Received August 18, 1984)

cis- and *trans*-$[PtCl_2(Et_2S)_2]$ as well as $[PtCl_2(EtSCH_2CH_2SEt)]$ reacted with thallium(I) β-diketonates, Tl(β-dik), to give complexes containing a central-carbon-bonded β-dik ligand. The reaction of *cis*-$[PtCl_2(PEt_3)_2]$ with Tl(acac) (acac=acetylacetonato) did not give an acetylacetonato complex, but resulted in $[Pt(CO_3)(PEt_3)_2]$, while *trans*-$[PtCl_2(PEt_3)_2]$ yielded [PtCl(acac)(PEt_3)]. $[Pt(PPh_3)_2(H_2O)_2](ClO_4)_2$ derived from *cis*-$[PtCl_2(PPh_3)_2]$ reacted with K(acac) and K(tfac) (tfac=trifluoroacetylacetonato) to afford $[Pt(acac)(PPh_3)_2]ClO_4$ and $[Pt(tfac)(PPh_3)_2]$-ClO_4, respectively. Bases such as Et_3N, K(acac), and K(tfac) removed a proton from the latter complex to give $[Pt(tfac(2-)\text{-}C,O)(PPh_3)_2]$ containing a *C,O*-chelated tfac dianion.

Bis(acetylacetonato)platinum(II) was first prepared by Werner by the reaction of the tetrachloroplatinate(II) with acetylacetone in basic aqueous solution,[1] and the yield reported by Grinberg and Chapurskii[2] was only 35%.[3] The low yield was caused partly by formation of $[Pt(acac)(acac\text{-}C^3)Cl]^-$ as a by-product which contains the central-carbon-bonded acetylacetonate anion (acac-C^3) as a ligand.[4] This complex seems to be produced by the ligand substitution reaction of $[Pt(acac)Cl_2]^-$ with an acac anion and it is worth noting that the [Pt(acac)Cl] moiety prefers the central carbon bonding to the oxygen bonding when it accepts the acac anion as a unidentate ligand.

Recently the reaction between $[Pd(acac)_2]$ and diethylamine to afford $[Pd(acac)(acac\text{-}C^3)(Et_2NH)]$[5] was found by kinetic and equilibrium studies to proceed not directly but *via* $[Pd(acac)(Et_2NH)_2](acac)$.[6] When the diethylamine ligand is replaced by an acac anion, the $[Pd(acac)(Et_2NH)]^+$ moiety also favors the central carbon bonding over the oxygen bonding. On the other hand, *trans*-$[PdCl(C_5H_3(6\text{-}Cl)N\text{-}C^2)(PEt_3)_2]$, which contains the 6-chloro-2-pyridyl group as a carbon-bonded ligand, reacts with thallium(I) β-diketonate such as acetylacetonate, trifluoroacetylacetonate, and hexafluoroacetylacetonate to afford *trans*-$[Pd(\beta\text{-dik-}O)(C_5H_3(6\text{-}Cl)N\text{-}C^2)(PEt_3)_2]$.[7] In this case the $[Pd(C_5H_3(6\text{-}Cl)N\text{-}C^2)(PEt_3)_2]^+$ group prefers oxygen bonding to central carbon bonding of the unidentate β-diketonate ligand.

In recent years very extensive studies have been performed on the reactions of bis(β-diketonato) palladium-(II) and -platinum(II) complexes with various nitrogen bases,[8] tertiary phosphines,[9] and arsines[9b] to convert the *O,O'*-chelated β-diketonate anion to other several types of coordination modes. Factors which favor each of these coordination modes were also investigated. As an extention of these studies, reactions of the $[PtCl_2L_2]$-type complexes containing dialkyl sulfides and tertiary phosphines as L with thallium(I) β-diketonates have been examined, and the results are reported in this paper.[10]

Experimental

Preparation of Complexes. Thallium(I) β-diketonates were prepared by the method analogous to that reported for thallium(I) benzoylacetonate.[11] Potassium acetylacetonate and trifluoroacetylacetonate were obtained by adding acetylacetone or trifluoroacetylacetone to a methanol solution of potassium hydroxide and concentrating the reaction product. Starting complexes, *cis*- and *trans*-$[PtCl_2(SEt_2)_2]$,[12] *cis*- and *trans*-$[PtCl_2(PEt_3)_2]$,[13] *cis*-$[PtCl_2(PPh_3)_2]$,[14] and *trans*-$[PtHCl(PEt_3)_2]$[15] were also prepared according to literatures. 1,2-Bis(ethylthio)ethane, $C_2H_5SCH_2CH_2SC_2H_5$ (S-S), was prepared in the following way similar to that used for 1,2-bis-(methylthio)ethane.[16] Sodium (0.5 g) was dissolved in ethanol and the solution was concentrated to get nearly saturated solution of sodium ethoxide. Ethanethiol (1.5 cm^3) was added to the solution and the mixture was stirred at room temperature for 15 h, when the colorless solution turned to light yellow. 1,2-Dibromoethane (0.83 cm^3) was then added to the solution in small portions. The mixture was heated under reflux for 10 h. After separation of sodium bromide by filtration the solution was refluxed for an additional hour. Water was added to the reaction mixture and the heavy oil layer was separated. The water layer was extracted with diethyl ether. The organic solutions were combined, passed through a column of anhydrous sodium sulfate, and distilled under reduced pressure (bp 37 °C/3 Torr, 1 Torr=133.322 Pa) to obtain colorless liquid (0.7 g).

The following procedures including evaporation of solvents in a rotary evaporator were carried out at room temperature unless otherwise stated.

*(Acetylacetonato)(acetylacetonato-C³)(diethyl sulfide)platinum-(II), [Pt(acac)(acac-C³)(Et₂S)] (**1a**)*: A methanol solution (15 cm^3) of Tl(acac) (0.681 g, 2.25 mmol) was added drop by drop to a methanol solution (15 cm^3) of *cis*-$[PtCl_2(Et_2S)_2]$ (0.500 g, 1.12 mmol) with stirring. Color of the solution changed from yellow to colorless and thallium(I) chloride precipitated. After being stirred for 3 h, the precipitate was filtered off and the filtrate was evaporated to dryness. The residue was treated with dichloromethane and remaining Tl(acac) was separated by filtration. After concentration of the solution, diethyl ether was added to the concentrate to obtain a white precipitate of **1a**. The yield was 0.201 g (37%).

*[Pt(tfac)(tfac-C³)(Et₂S)] (**1b**)*: A mixture of *cis*-$[PtCl_2(Et_2S)_2]$ (0.400 g, 0.90 mmol) and Tl(tfac) (0.640 g, 1.84 mmol) in methanol (30 cm^3) was stirred for 3 h. After separation of TlCl and evaporation of the solvent, the residue was dissolved in dichloromethane and Tl(acac) was filtered off. The yield was 0.186 g (35%).

*[Pt(hfac)(hfac-C³)(Et₂S)] (**1c**)*: The reaction of *cis*-$[PtCl_2(Et_2S)_2]$ with Tl(hfac) in a similar way as above gave **1c** in a 30%

yield. Complexes **1b** and **1c** are readily soluble in diethyl ether, while **1a** is sparingly soluble in the same solvent.

Dichloro[1,2-bis(ethylthio)ethane]platinum(II), [$PtCl_2$(S-S)], was prepared by a method analogous to that exemplified by Cross *et al.*[17] Aqueous solution of an equimolar mixture of $K_2[PtCl_4]$ and the disulfide was stirred for 4 h and then heated under reflux for 1 h. A yellow precipitate was filtered, dried, and recrystallized from hot dichloromethane. The yield was 79%.

[PtCl(acac-C³)(S-S)] (2): A methanol solution (15 cm^3) of Tl(acac) (0.240 g, 0.79 mmol) was added to a suspension of [$PtCl_2$(S-S)] (0.330 g, 0.79 mmol) in methanol (15 cm^3) and the mixture was stirred for 5 h. After separation of TlCl, the solvent was evaporated to dryness. The residue was treated with dichloromethane (10 cm^3) and Tl(acac) was filtered off. The filtrate was again concentrated to dryness and the residue was treated with diethyl ether. A light yellow solid of **2** was purified by reprecipitation from dichloromethane–diethyl ether. The yield was 0.216 g (48%).

[Pt(CO_3)(PEt_3)$_2$] (3): A methanol solution (15 cm^3) of Tl(acac) (0.600 g, 2.00 mmol) was added dropwise to a solution of *cis*-[$PtCl_2(PEt_3)_2$] (0.500 g, 1.00 mmol) in methanol (15 cm^3) through which carbon dioxide was being passed. The mixture was stirred for 5 h under CO_2 bubbling. After separation of TlCl the solvent was evaporated to dryness. The residue was dissolved in a small amount of dichloromethane containing a very small portion of pyridine. Diethyl ether was carefully added until the solution became turbid and the mixture was allowed to stand overnight. White crystals (0.087 g) were obtained in an 18% yield.

[Pt(PPh_3)$_2$(H_2O)$_2$](ClO_4)$_2$ (4): A methanol solution (10 cm^3) of silver perchlorate (0.250 g, 1.19 mmol) was added to a suspension of *cis*-[$PtCl_2(PPh_3)_2$] (0.470 g, 0.60 mmol) in chloroform (10 cm^3). Both solutions were cooled with ice in advance and the mixture was stirred at 0 °C for 5 min. After separation of silver chloride, the filtrate was evaporated to dryness under cooling. A white solid of **4** (0.280 g) was obtained in a 49% yield after purification by reprecipitation from dichloromethane–diethyl ether at room temperature.

[Pt(acac)(PPh_3)$_2$]ClO_4 (5a): A methanol solution (15 cm^3) of K(acac) (0.020 g, 0.13 mmol) was added drop by drop to a suspension of complex **4** (0.100 g, 0.11 mmol) in the same solvent (15 cm^3). After stirring for 24 h, a precipitate of potassium perchlorate was filtered off and the filtrate was evaporated to dryness. The residue was purified by reprecipitation from dichloromethane–diethyl ether and the yield was 0.049 g (49% yield).

[Pt(tfac)(PPh_3)$_2$]ClO_4 (5b): A methanol solution (5 cm^3) of K(tfac) (0.080 g, 0.43 mmol) was added to a dichloromethane solution (30 cm^3) of **4** (0.400 g, 0.43 mmol) and the mixture was stirred for 16 h. After separation of potassium perchlorate, the yellow filtrate was concentrated to dryness. The residue was dissolved in dichloromethane and precipitated K(tfac) was separated by filtration. The filtrate was concentrated to 2—3 cm^3. On addition of diethyl ether to the concentrate a light yellow precipitate appeared, which was purified by reprecipitation from chloroform–hexane. The yield was 0:208 g (50%).

[Pt(acac)(PEt_3)$_2$]PF_6 (6): Acetylacetone (1 cm^3) was added to a methanol solution (15 cm^3) of *trans*-[PtHCl(PEt_3)$_2$] (0.500 g, 1.10 mmol) and to this solution was added dropwise a methanol solution (15 cm^3) of silver hexafluorophosphate (0.270 g, 1.10 mmol). After stirring of the mixture for 24 h, silver chloride was filtered off and the filtrate was concentrated to about one-half volume. Scratching of the flask stimulated crystallization. A white precipitate was recrystallized from dichloromethane–diethyl ether. The yield was 0.236 g (32%).

[Pt(tfac(2—)-C,O)(PPh_3)$_2$] (7): A methanol solution (30 cm^3) containing complex **4** (0.340 g, 0.35 mmol) and K(tfac) (0.140 g, 0.73 mmol) was stirred for 24 h. After separation of potassium perchlorate, the yellow filtrate was evaporated to dryness. The residue was dissolved in a small amount of dichloromethane. Diethyl ether was added carefully to the solution until the upper portion of the solution became turbid and the mixture was allowed to stand overnight. A white crystalline product (0.077 g) was obtained in a 25% yield.

Complex **7** was also derived from **5b** by treating with bases.

(i) Triethylamine (0.036 g, 0.36 mmol) was added drop by drop to a methanol solution (20 cm^3) of complex **5b** (0.222 g, 0.23 mmol) and the mixture was stirred for 19 h. The solution was then evaporated under reduced pressure to leave an oily substance, which was dissolved in a tiny amount of dichloromethane. Diethyl ether was added dropwise to the solution to deposite a white precipitate, which was recrystallized from dichloromethane–diethyl ether. The yield was 0.040 g (20%). When a ten times molar amount of triethylamine was employed the yield of **7** was improved to 36%.

(ii) A methanol solution (15 cm^3) of K(acac) (0.043 g, 0.31 mmol) was added to a solution of **5b** (0.301 g, 0.31 mmol) in the same solvent (15 cm^3) and the mixture was stirred for 24 h. Work-up similar to that starting with **4** gave **7** (0.103 g) in a 38% yield. Employment of an equimolar amount of K(tfac) instead of K(acac) gave a similar yield of **7**.

[PtCl(acac)(PEt_3)] (8): A methanol solution (30 cm^3) containing *trans*-[$PtCl_2(PEt_3)_2$][13] (0.300 g, 0.60 mmol) and Tl(acac) (0.630 g, 2.1 mmol) was stirred for one week. After separation of thallium(I) chloride by filtration, the filtrate was evaporated under reduced pressure to leave an oily substance, which was dissolved in a mixture (15 cm^3) of diethyl ether and petroleum ether (1:2 by volume). Scratching of the flask stimmulated crystallization of the product, which was dissolved in the smallest amount of dichloromethane and passed through a column (40 cm×ϕ1.3 cm) of silica gel. A mixture (60 cm^3) of benzene and petroleum ether (1:2 by volume) was used as the eluant. A light yellow solid (0.18 g) was obtained by evaporation of the eluate. Purity of the product was not good, giving unsatisfactory analysis. The IR and ^1H NMR data in comparison with those for [PtCl(acac)(PMe_2Ph)][18] showed that the product is **8** contaminated with the starting complex.

Measurements. Infrared spectra were measured in Nujol mulls with JASCO IR-E (4000—650 cm^{-1}), Hitachi EPI-L (700—200 cm^{-1}), and JASCO DS 701 G (4000—200 cm^{-1}) spectrophotometers. Electronic spectra were taken on a Hitachi EPS-3T recording spectrophotometer and ^1H NMR spectra on a JNM MH-100 instrument with tetramethylsilane as an internal reference. Molecular weight was determined with a vapor pressure osmometer manufactured by Knauer in West Berlin, West Germany.

Results and Discussion

Characterization of Complexes. Results of elemental analysis and molecular weight determination for

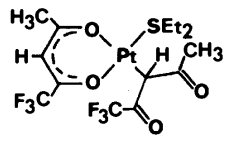
a) Chemical shifts in ppm from internal Me_4Si. Figures in parentheses give the J(Pt-H) values. b) Indiscernible. c) CH_2 bound to platinum in the tfac(2−)-*C,O* ligand, appearing as a doublet of doublets with ^3J(*cis*-P-H)=6.0 Hz and ^3J(*trans*-P-H)=12 Hz flanked by the ^{195}Pt satellites.

the newly prepared complexes are collected in Table 1, and their characteristic IR bands are shown in Table 2. These data are consistent with the proposed structures of these complexes, the IR data for complexes **1a**, **1b**, and **1c** supporting coexistence of chelated and central-carbon-bonded β-diketonate ligands.

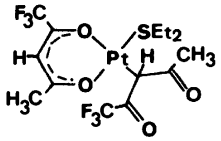
The ^1H NMR signals listed in Table 3 are readily assigned based on the proposed structures. For example, complex **1a** exhibits four methyl signals at 1.32, 1.85, 1.92, and 2.18 ppm. The triplet signal at 1.32 ppm is assigned to the methyl protons of diethyl sulfide. The relative intensity of the δ 2.18 signal corresponds to six protons and it is ascribed to methyl protons of the carbon-bonded acac ligand. The remaining two signals of equal intensity come from two methyl groups of the chelated acac anion. By reference to the case of [Pd(acac)(acac-C^3)L] (L=PPh_3, py, and Et_2NH),[5] the higher-field signal (δ 1.85) is assigined to the methyl group positioned trans to the carbon-bonded acac ligand and the δ 1.92 signal to that cis to the acac-C^3 ligand. Both of two methine signals are flanked by ^{195}Pt satellites and the δ 4.78 signal show-

ing a very strong coupling to Pt is unequivocally assigned to the methine group bound to the metal.

Since the tfac anion forms an unsymmetric chelate ring, the following two geometrical isomers are conceivable for complex **1b**. Three signals at 1.35, 2.08,



cis-(Me, L)-1b



trans-(Me, L)-1b

and 2.32 ppm are assigned similarly to the case of **1a** to methyl protons of Et_2S, chelated tfac, and carbon-bonded tfac, respectively. Each of these signals is accompanied by a minor signal at 1.28, 2.10 or 2.36 ppm indicating contamination with a geometrical isomer as expected. Unfortunately, the corresponding pair of signals are so close to each other as to preclude measurement of the area ratio. Unequivocal assignment of the two sets of signals to these isomers is difficult, but minor signals are tentatively assigned to the *trans*-(Me, L) isomer, since of the two methyl signals at 2.08 and 2.10 ppm from the chelated tfac anion, the minor lower-field one is assigned to the methyl protons positioned cis to the carbon-bonded tfac ligand by reference to the case of **1a**.

It is worth noting that the product from the reaction between *trans*-[$PtCl_2(Et_2S)_2$] and Tl(tfac) gives the same ^1H NMR spectrum as above. During the preparative reactions the platinum(II) complexes seem to undergo geometrical isomerization to yield a thermodynamically favored mixture of isomers. Recently Cattalini and his collaborators studied kinetically the reactions of *cis*- and *trans*-[$PtCl_2(Me_2S)_2$] with pyridine and other nitrogen bases (L) to afford *cis*- and *trans*-[$PtCl_2(Me_2S)L$] and found that the reactions of the cis complex were complicated by its tendency to isomerize to the more stable trans isomer.[19]

Complex **4** was prepared by the reaction of *cis*-[$PtCl_2(PPh_3)_2$] with silver perchlorate in a mixture of chloroform and methanol at 0 °C. Two molecules of water retained per one platinum atom seem to have come from the organic solvents and be coordinated with the metal, perchlorate anions lying in the outer sphere. Hartley and his coworkers[20] prepared the [$Pt(PPh_3)_2L_2$]-(ClO_4)$_2$-type complexes containing various solvent molecule as L and found that anhydrous perchlorate complexes are explosive (**Caution!**). Fortunately complexes **4**, **5a**, and **5b** containing perchlorate in the outer sphere could be handled safely.

The ^1H NMR spectra of complexes **5a**, **5b**, and **6** are simple. Methyl protons of the acac and tfac ligands in **5a** and **5b**, respectively, resonate at much higher field than those in **1a** and **1b** owing to the anisotropic shielding effect of the phenyl rings in the ancillary triphenylphosphine ligands.[5] Thus the chemical shift of methyl protons of acac in **6**, which contains PEt_3 in place of PPh_3 in **5a**, coincides with that for **1a**. The PEt_3 ligands in **3** and **6** exhibit the 2:2:3:2:1 quintet signal in the methyl proton region and another symmetric quintet signal of methylene protons in accordance with the cis arrangement.[21] The IR and ^1H NMR data for complex **7** nearly coincide with those reported by Okeya *et al*,[9b] certifying that the same tfac (2—)-*C*,*O* chelate was obtained from the present reactions.

Synthetic Reactions. The reactions of *cis*-[$PtCl_2(Et_2S)_2$] with twice molar amounts of Tl (β-dik) gave [Pt(β-dik)(β-dik-C^3)(Et_2S)].

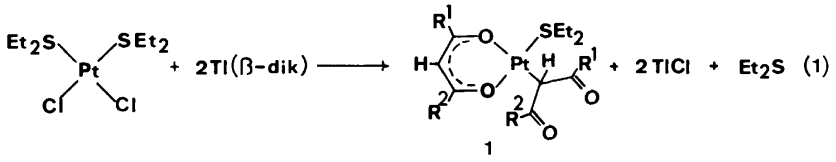
The reaction was almost complete by one hour and a half in either case as evidenced by the quantitative yield of TlCl and absence of the starting complex on the thin layer chromatogram(TLC) of the reaction mixture on silica gel. Although stirring was continued for three hours (Experimental), yields of complexes **1** were not high (30—37%), but products other than **1** could not be detected.

The reactions of *trans*-[$PtCl_2(Et_2S)_2$] with Tl(β-dik) (β-dik=acac, tfac, and hfac) were solwer than those of the cis complex, giving the same products **1a**—**1c**. Thus, the TLC assay showed that the starting complex remained in the reaction mixture even after being stirred for four hours and was exhausted after seven hours. The yield of TlCl also increased slowly with time for several hours.

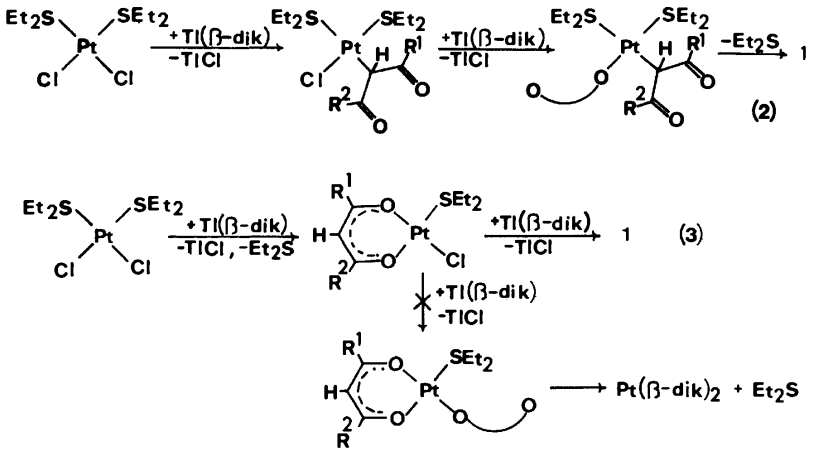
The difference in reactivities of *cis*- and *trans*-[$PtCl_2(Et_2S)_2$] with Tl(β-dik) to give complexes **1** seems to accord with the stronger trans effect of the sulfide than that of chloride, and to suggest that the rate controlling step is displacement of the chloride ligand. (The above-mentioned substitution of Me_2S in [$PtCl_2(Me_2S)_2$] with a neutral ligand proceeds more slowly for the cis isomer than for the trans complex due to the stronger trans effect of the sulfide.[18])

Bis(β-diketonato)platinum(II) complexes react with a number of nitrogen bases[8d] and tertiary phosphines[9b-d] to give various types of complexes, but [Pt(acac)$_2$] does not react with excess Et_2S under various conditions. Converesely the reaction between [$PtCl_2(Et_2S)_2$] and Tl(acac) did not yield [Pt(acac)$_2$] beyond **1a**. Even when [$PtCl_2(Et_2S)_2$] was first treated with silver perchlorate to remove chloride ligands and then forced to react with K(acac), only complex **1a** was produced.

On the other hand, lowering of reaction temperature



1



or decreasing of the amount of Tl(acac) depressed the rate and yield of **1a** but gave no intermediary product. Thus no clue was obtained to find either of the chelated and carbon-bonded β-diketonate ligands of **1** entered first into the coordination sphere.

In the case of $[PtCl_2(S\text{-}S)]$, complex **2** was formed exclusively. No other product was obtained even when excess Tl(acac) up to ten times moles was employed. These results indicate that the $[PtCl(S\text{-}S)]^+$ moiety prefers the central carbon bonding to the oxygen bonding of acac, and that $[PtCl(acac\text{-}C^3)(S\text{-}S)]$ (**2**) is thermodynamically more stable than other conceivable complexes such as $[Pt(acac)(S\text{-}S)]X$ (X=Cl or acac), $[Pt(acac\text{-}C^3)_2(S\text{-}S)]$, and $[Pt(acac\text{-}C^3)(acac\text{-}O)(S\text{-}S)]$.

Production of **2** might suggest that in reaction 1 the β-diketonate carbanion first substitutes a chloride ligand and the second β-diketonate anion replaces the other chloride anion to form an *O*-unidentate linkage and then a sulfide ligand is expelled to close the chelate ring (Eq. 2).

Another alternative mechanism also looks reasonable: A β-dik chelate is first formed and the $[Pt(\beta\text{-dik})(SEt_2)]^+$ moiety favors the carbon bonding of the second β-dik anion over the oxygen bonding which should be stabilized by intramolecular substitution to close the chelate ring (Eq. 3).

It is rather surprizing that complexes **1** and **2** containing a carbon-bonded β-dik ligand were obtained in methanol, since in the following palladium(II) case the carbon bonding of acac is completely disfavored in methanol.[6]

$$[Pd(acac)_2] + 2\,Et_2NH \overset{K_1}{\rightleftharpoons} [Pd(acac)(Et_2NH)_2](acac)$$

$$[Pd(acac)(acac\text{-}C^3)(Et_2NH)] + Et_2NH \overset{K_2}{\rightleftharpoons} [Pd(acac)(Et_2NH)_2](acac)$$

Thus $K_1=32.9\pm1.1\ dm^6\ mol^{-2}$ and $K_2=0.224\pm0.007\ dm^3\ mol^{-1}$ in dichloromethane at 25 °C, but in methanol at 25 °C $K_1=(3.93\pm0.04)\times10^6\ dm^6\ mol^{-2}$ and K_2 was immeasurablly large, no trace of the carbon-bonded acac complex being detected in the equilibrium mixture.[6]

If the latter mechanism (Eq. 3) is the case for the present sulfide complex, the tendency of the $[Pt(acac)(Et_2S)]^+$ moiety to favor the carbon bonding of acac may be very much greater than that of $[Pd(acac)(Et_2NH)]^+$. At the present stage of investigation, it is difficult to conclude which of the two mechanisms is operative.

In contrast with the case of *cis*-$[PtCl_2(Et_2S)_2]$ (Eq. 1), the reaction of *cis*-$[PtCl_2(PEt_3)_2]$ with Tl(acac) did not give any acetylacetonato complex, but resulted in $[Pt(CO_3)(PEt_3)_2]$ (**3**). The observed IR bands included in Table 2 accord with the bidentate coordination of the carbonate ion.[22] When the reaction was carried out under the atmospheric condition, the yield of **3** was as low as a few percent. Addition of water and bubbling of carbon dioxide through the methanol solution improved the yield of **3** to 18%. Conversely the same reaction under nitrogen gave no trace of **3**.

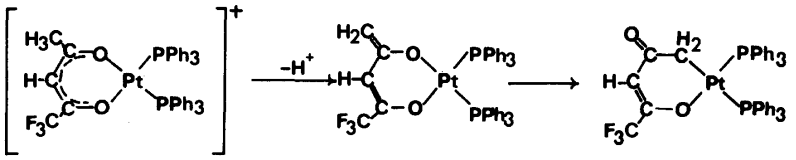
In either case the reaction of Tl(acac) with *cis*-$[PtCl_2(PEt_2)_2]$ to remove the chloride ligands was complete, since the yield of TlCl was almost quantitative and the UV spectrophotometric assay of the filtrate confirmed acetylacetone molecules in a satisfactory yield. Concentration of the solution by evaporation under reduced pressure resulted in a viscous substance, which showed broad IR bands in the 3600—3200 cm^{-1} region and at 1600 cm^{-1} indicative of the aqua or hydroxo ligand.

Thus the reaction sequence to form **3** might be shown by Eq. 4, although the aqua and hydroxo complexes presumed as intermediates have not been isolated.

$$cis\text{-}[PtCl_2(PEt_3)_2] \xrightarrow[-2TlCl]{+2Tl(acac)+2H_2O} cis\text{-}[Pt(H_2O)_2(PEt_3)_2](acac)_2 \xrightarrow[-2acacH]{} cis\text{-}[Pt(OH)_2(PEt_3)_2] \xrightarrow[-H_2O]{+CO_2} [Pt(CO_3)(PEt_3)_2] \quad (4)$$

3

On the other hand, the reaction of *trans*-$[PtCl_2(PEt_3)_2]$ with Tl(acac) was much slower than that of the cis isomer and gave $[PtCl(acac)(PEt_3)]$ instead of the carbonato complex **3**. Such a difference between the two isomers in reactivities and products may be



rationalized based on the strong trans effect of triethylphosphine.

The chloride ligand in *cis*-$[PtCl_2(PEt_3)_2]$ is readily substituted by a carbonyl end of acac anion, which may fail in displacing a PEt_3 ligand to close the chelate ring and be in turn replaced by a water molecule. On the contrary, the chloride ligand in *trans*-$[PtCl_2(PEt_3)_2]$ is less readily substituted by an acac anion, but the dangling carbonyl group of the *O*-unidentate acac ligand may release more easily a PEt_3 ligand which is labilized by the other PEt_3 molecule positioned trans to each other. The bond between the metal and the remaining chloride is strengthened in [PtCl(acac)(PEt_3)] and is not readily cleaved by attack of another acac anion.

When the chloride ligand in *trans*-$[PtHCl(PEt_3)_2]$ was removed by silver hexafluorophosphate in methanol containing acetylacetone, $[Pt(acac)(PEt_3)_2]PF_6$ (**6**) was resulted. Geometrical isomerization probably followed by dihydrogen evolution rather than displacement of a PEt_3 ligand seems to have been induced by acetylacetone.

cis-Dichlorobis(triphenylphosphine)platinum(II) is less reactive than the corresponding triethylphosphine complex and hardly reacts with Tl(β-dik). When the chloride ligands were removed by silver perchlorate, $[Pt(PPh_3)_2(H_2O)_2](ClO_4)_2$ (**4**) was obtained, which is slightly soluble only in haloalkanes such as chloroform and dichloromethane and was characterized by elemental analysis and IR spectra. A very broad and strong band at 1100 cm^{-1} and a band of medium intensity at 625 cm^{-1} suggest that the perchlorate ions lie in the outer sphere.[23] The aqua ligands in **4** can be readily substituted by other ligands. Thus **4** reacted with K(acac) in methanol at room temperature to give $[Pt(acac)(PPh_3)_2]ClO_4$ (**5a**). Similarly the reaction of **4** with an equimolar amount of K(tfac) in a mixture (1:6 by volume) of methanol and dichloromethane gave $[Pt(tfac)(PPh_3)_2]ClO_4$ (**5b**). On the other hand, the reaction of **4** with a twice molar amount of K(tfac) in methanol gave rise to [Pt(tfac(2−)-*C,O*)(PPh_3)$_2$] (**7**).

Complex **7** was previously obtained by Okeya *et al* by the reaction of $[Pt(tfac)_2]$ with PPh_3 and shown to contain a *C,O*-chelated trifluoroacetylacetonate dianion.[9b] More recently similar palladium(II) complexes [Pd(tfac(2−)-*C,O*)LL′] containing triphenylphospine, pyridine and their derivatives as L and L′ were prepared, and the molecular structure of the complex containing triphenylphosphine and 2,6-dimethylpyridine as neutral ligands was confirmed by X-ray analysis.[9e] Complex **7** was inferred to be produced through deprotonation of the chelated tfac ligand by the outer-sphere tfac anion in the presumed intermediate $[Pt(tfac)(PPh_3)_2](tfac)$.[9c] Now the cationic complex was isolated as **5b**, of which reactions with various bases were examined.

Potassium acetylacetonate and trifluoroacetylacetonate as well as triethylamine were successful in abstracting a proton from **5b** to give **7**. On the other hand, pyridine derivatives such as 4-amino-, 4-dimethylamino- and 2,6-dimethylpyridines were proved to be unsuccessful in giving **7**, although they were effective in deprotonating $[Pd(tfac)(PPh_3)_2]^+$ to afford [Pd(tfac-(2−)-*C,O*)(PPh_3)L].[9e] The tfac ligand in **5b** was displaced by pyridines and complexes $[Pt(PPh_3)_2L_2](ClO_4)_2$ containig 4-amino- and 4-dimethylaminopyridines as L were isolated and characterized, the yields being 10 and 29%, respectively. These results suggest that the Pt(II) tfac chelate is more labile than the corresponding Pd(II) chelate against the nucleophilic attack of nitrogen bases. Deprotonation of the chelating tfac monoanion by a base may produce a dienediolate intermediate as was postulated in the case of the Pd(II) complexes.[9e]

We wish to thank Mr. Junichi Gohda for elemental analyses.

Synthesis of 6-Alkylpurine Derivatives by Nickel-complex-catalyzed Coupling Reaction of 6-(Methylthio)purine Derivatives with Grignard Reagents[1)]

Hideyuki SUGIMURA and Hisashi TAKEI*
Department of Life Chemistry, Tokyo Institute of Technology, Nagatsuta, Midoriku, Yokohama 227
(Received July 11, 1984)

6-(Methylthio)purine reacted with RMgX (R=C_6H_5, $CH_3(CH_2)_nCH_2$ (n=2 to 6), $C_6H_5CH_2CH_2$, $(CH_3)_2C{=}CHCH_2CH_2$) in the presence of 5 mol% [$NiCl_2(Ph_2PCH_2CH_2CH_2PPh_2)$] in refluxing THF for 8 h to afford 6-aryl or 6-alkylpurines in 62—74% yields. By applying this reaction to 6-(methylthio)purine nucleoside, 6-(4-methyl-3-pentenyl)-9-β-D-ribofuranosylpurine was synthesized.

In the previous paper,[2)] we reported that heterocyclic thiols or sulfides reacted with Grignard reagents in the presence of a nickel-phosphine complex to give coupling products. This reaction serves as a new and convenient method for the introduction of alkyl and aryl groups to heterocyclic nuclei.

In this report, we describe an application of the method to the synthesis of 6-alkyl and 6-arylpurine derivatives, which correspond to N^6 carbon analogs of cytokinin,[3)] by the coupling reaction of 6-(methylthio)purine (**1**) and 6-(methylthio)purine nucleosides (**3**) with Grignard reagents catalyzed by nickel-phosphine complex.

Henderson and his coworkers[4)] reported the synthesis of 6-(4-methyl-3-pentenyl)purine (**2h**) by the reaction of dianion of 6-methylpurine with 3-methyl-2-butenyl bromide, though the yield was not satisfactory (25%). We tried the coupling reaction of readily available 6-(methylthio)purine (**1**) with 4-methyl-3-pentenylmagnesium bromide in the presence of [$NiCl_2$(dppp)] (dppp=$Ph_2PCH_2CH_2CH_2PPh_2$), and **2h** was obtained in 71% yield.

Then, we also examined the coupling reaction with other alkyl and aryl Grignard reagents and the desired 6-substituted purines were obtained in good yields. The results were summarized in Scheme 1.

Next, we applied this coupling reaction to the synthesis of 6-alkyl-9-β-D-ribofuranosylpurine. Recently, Pichat *et al.*[5)] reported the palladium-catalyzed coupling reaction of Grignard reagents with silylated derivatives of 8-bromopurine nucleosides. The reaction utilizes direct C-alkylation method of purine nucleosides, though the yields of the products were low (10—33%). We examined the coupling reaction of 4-methyl-3-pentenylmagnesium bromide with 9-(2′,3′-*O*-isopropylidene-5′-*O*-monomethoxytrityl or 5′-*O*-*t*-butyldimethylsilyl-β-D-ribofuranosyl)-6-(methylthio)purine (**3a** or **3b**) in the presence of [$NiCl_2$(dppp)] or [$NiCl_2(PPh_3)_2$]. The results were shown in Table 1.

When [$NiCl_2$(dppp)] was used as a catalyst, the yields were unsatisfactory probably because of bulkiness of the sulfides (run 1—3). According to our observation during the study of the nickel catalyzed coupling reac-

tion, $[NiCl_2(PPh_3)_2]$ is more favorable catalyst with bulky sulfides than $[NiCl_2(dppp)]$. Indeed, by using $[NiCl_2(PPh_3)_2]$ in place of $[NiCl_2(dppp)]$, the yields of **4a** and **4b** were improved (run 4 and 5). In these cases, however, 6-unsubstituted purine nucleosides were also obtained as by-products. These by-products, produced by the replacement of methylthio group by hydrogen atom, may be formed by the β-elimination of intermediate nickel complexes.[6]

Deprotection of both **4a** and **4b** was easily performed by a standared manner[7] and 6-(4-methyl-3-pentenyl)-9-β-D-ribofuranosylpurine (**5**) was obtained.

Experimental

Typical Procedure for the Coupling Reaction of 6-(Methylthio)purine (1) with Grignard Reagents. To 166 mg (1 mmol) of **1** and 26 mg (0.05 mmol) of $[NiCl_2(dppp)]$ in 10 ml of anhydrous THF under an argon atmosphere at room temperature was added an ethereal solution of Grignard reagent (2.5 mmol). The solution was stirred for 8 h at refluxing temperature. After cooling, the reaction mixture was quenched with saturated aqueous solution of NH_4Cl, and neutralized with saturated aqueous $NaHCO_3$ solution. The insoluble solid was filtered off through Celite and the Celite was washed with ethanol. The filtrate and the washings were combined and evaporated under reduced pressure. The residue was extracted five times with dichloromethane, the combined extracts were washed and dried over anhydrous $MgSO_4$. The solvent was evaporated and the product was isolated by TLC. All products gave satisfactory elemental analyses. The melting points and NMR spectra of them were summarized in Table 2.

Coupling Reaction of 3a or 3b with 4-Methyl-3-pentenylmagnesium Bromide. To 0.3 mmol of **3a** or **3b**, and 0.05 equiv of a nickel-phosphine complex in 10 ml of anhydrous ether under an argon atmosphere was added an ethereal solution of 4-methyl-3-pentenylmagnesium bromide (1.1 equiv). The mixture was refluxed for 6 h. The reaction mixture was quenched with saturated aqueous solution of NH_4Cl, neutralized with saturated aqueous $NaHCO_3$ solution and

filtered through Celite *in vacuo*. The resulting mixture was separated and the aqueous phase was extracted twice with ether. The combined extracts were washed and dried over anhydrous $MgSO_4$. The solvent was evaporated and the product was isolated by TLC. Resulted **4a** and **4b** were deprotected by a standard manner to yield 6-substituted purine nucleoside **5** in 32—53%. The melting points and spectral data of **3a—b**, **4a—b**, and **5** were summarized in Table 3. The compounds except **3a** and **4a—b** gave satisfactory elemental analyses. **3a** and **4a—b** couldn't be purified completely because they were obtained as foam or syrup. But NMR spectra of them well agreed with the assigned structures.

Chemistry of 1,2-Thiaphosphole 2-Sulfides I. Cycloaddition Reactions of 1,2-Thiaphosphole 2-Sulfides with Some Dienophiles

Hideyuki TANAKA, Shunichi KAMETANI, Takao SAITO, and Shinichi MOTOKI*

Department of Chemistry, Faculty of Science, Science University of Tokyo, Kagurazaka, Shinjuku-ku, Tokyo 162

(Received August 7, 1984)

2,9-Dithia-1-phosphabicyclo[4.3.0]nona-3,7-diene 1-sulfides have been prepared by the reaction of α,β-unsaturated ketones with P_4S_{10} in the presence of NEt_3. 1,2-Thiaphosphole 2-sulfides generated by the thermolysis of the phosphabicyclo compounds underwent cycloaddition reactions with acrylonitrile, styrene, butyl vinyl ether and norbornene to give the [4+2]cycloadducts, respectively.

During the course of the work on the preparation of α,β-unsaturated thione dimers and the cycloaddition reactions of their monomers with various dienophiles,[1] it has been found that attempts to isolate monomeric 1-arylmethylene thiopinacolones **2** resulted in the formation of the unexpected phosphorus(V)-containing compounds **3**.[2] In boiling benzene **3** generated α,β-unsaturated thione monomers **2** and 1,2-thiaphosphole 2-sulfides **4**, both of which could be trapped by acrylonitrile as [4+2]cycloadducts **5** and **6**.[3] To our knowledge, the proposed intermediates **4** are the first representatives of five-membered heterocyclic dienes, S-P(=S)=C-C=C, though analogous π-bonded phosphorus compounds, -(S=)P=C<, have been prepared recently.[4]

In the present paper, we wish to report the detailed study on the cycloaddition reactions of this interesting cyclic heterodienes **4** with a variety of dienophiles leading to P-S-C bridging [4+2]cycloadducts.

Results and Discussion

At first, some additional phosphabicyclo compounds were prepared as starting materials. The results are summarized in Table 1. The yields increased with an increasing electron donating property of the para-substituents of the aromatic rings as in the case of the preparation of the thione dimers.[5] X-Ray difraction analysis was performed for **3a**[6] and the structures of **3b**, **3c**, **9**, and **10** were confirmed by comparison of

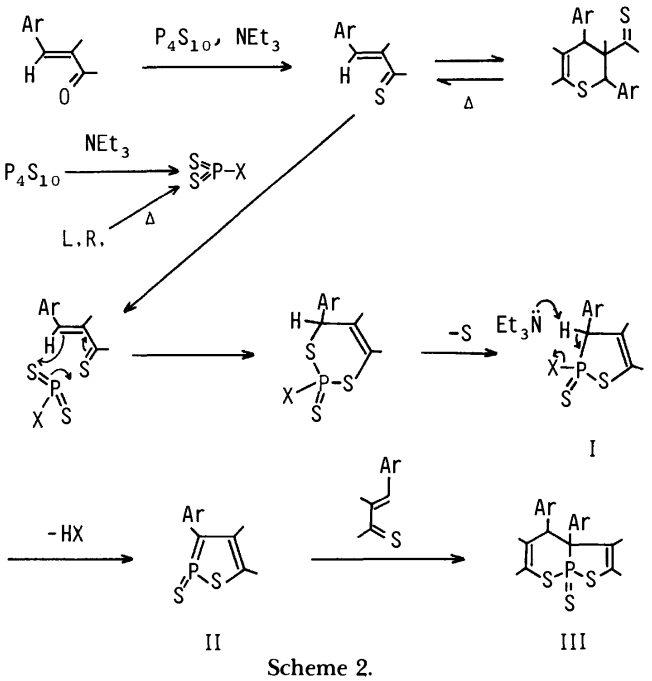
a) Superimposed on Ar–H. b) Chemical shifts of the signals of C-3, C-4, C-7, and C-8 were not assigned.

their NMR spectral data with those of **3a** (Table 2). The signals of the hydrogen atoms attached to the bicyclic skeleton (H-4, H-5, and H-7) and those of the skeletal saturated carbon atoms (C-5 and C-6) showed characteristic H-P and C-P couplings.[7]

Treatment of the thione dimers with P_4S_{10} and NEt_3 in refluxing carbon disulfide also produced the phosphabicyclo compounds. P_4S_{10} is cleaved by liquid NH_3 or NEt_3 to produce diverse complex species containing P, S, and N, *e.g.*, $(NH_4)[PS_2(NH_2)_2]$, $(NH_4)_2[PS_3(NH_2)]$.[8] Therefore it is assumed that the attack of NEt_3 upon P_4S_{10} generates the reactive species, X-(S=)P=S (*e.g.*, X=$Et_3NH^+S^-$), which reacts with α,β-unsaturated thiones to form an intermediate **I** in a similar manner to Lawesson's Reagent (L.R.)[9] (Scheme 2). In the case of L. R. (X=*p*-$CH_3OC_6H_4$), I is actually obtained as a stable compound. But when X is P_4S_{10} fragment as in the present study, it would be an effective leaving group and can be removed readily under suitable reaction conditions. Accordingly it is rationally considered that by action of a base, NEt_3, H-3 proton is eliminated with X to form 1,2-thiaphosphole 2-sulfide **II** which subsequently undergoes cycloaddition reaction as 2π system with the thione monomer (4π) to afford the phosphabicyclo compound **III**.



Scheme 2.

The reaction of **3a** with acrylonitrile in refluxing benzene gave 1,4-cycloadducts **5a**, ***endo*-6a** and a small amount of ***exo*-6a** without the formation of any regioisomers (Table 3). The cycloadduct **5a** was easily identified by comparison with the authentic compounds reported previously[1] and the structure of ***endo***-

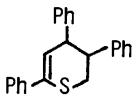
a) Superimposed on $CDCl_3$.

(***endo*-6a**; δ=42.42, ***exo*-6a**; δ=42.40) showed large C-P coupling constants (***endo*-6a**; J_{CP}=42.7 Hz, ***exo*-6a**; J_{CP}=44.0 Hz). This suggests that the methylene carbon is directly bonded to the phosphorus atom.[7] The ^1H NMR spectrum of ***endo*-6a** showed double double doublets of three sets of protons at δ=2.51 (J_{HH}=3.5, 14.0 Hz, J_{HP}=7.5 Hz), 3.07 (J_{HH}=9.5, 14.0 Hz, J_{HP}=14.0 Hz) and 3.64 (J_{HH}=3.5, 9.5 Hz, J_{HP}=4.5 Hz), which are assigned to the H_a, H_b, and H_c by spin decoupling experiments, respectively. The coupling constant value of H_c agreed with those of *exo* proton in 2-substituted norbornene ring system.[10] The ^1H NMR of ***exo*-6a** showed signals of H-5 proton at δ=3.08—3.32 and of H-6 (*gem*-AB) protons at δ=2.70—2.86. The coupling pattern was unambiguously different from that of ***endo*-6a**. *Endo* configuration of cyano group in **6b** and **6c** was determined by comparing their coupling pattern of H_a~H_c with that of ***endo*-6a**. Neither ***exo*-6b** nor ***exo*-6c** was obtained.

Similarly, the thermolysis of **9** or **10** in the presence of acrylonitrile yielded **15** and **16**, or **17** and **18** (Table 3). The reactions proceeded more rapidly than that of **3**. The products **15** and **17** were identfied as [4+2]-cycloadducts of **11** and **12** with acrylonitrile, respectively.[1] The structure and configuration of the adduct **16** were determined by comparing their spectral data with those of **6a** (*endo*, *exo*) as described above. The ^{13}C NMR spectral data of **18** indicated that the cyano group was linked to the carbon atom at 5-position. It is difficult to determine exactly the configuration of cyano group in **18** by ^1H NMR spectra, however, it was presumed to be *exo* because C-P coupling constants of *endo* cyano carbon were 7.3—9.8 Hz in the adducts **6** and **16**, whereas those of the *exo* were 3.7 Hz (Table 4).

With styrene **9** or **10** produced **19**[1] and **20** or **21**[1] and **22**, respectively. Table 3 shows that the orientation of the 1,4-cycloadducts (**20**, **22**) agrees with that of the



19

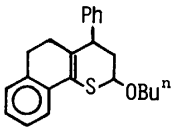
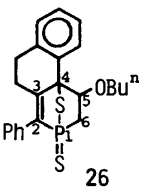
24



25



26

acrylonitrile-adducts (**16**, **18**). The ^1H NMR coupling pattern of **20** agreed with that of the *endo*-adduct **6** or **16**.

The thermolysis of **9** with butyl vinyl ether gave **23**[1] and **24**. In the adduct **24**, the ^{13}C NMR spectral data proved that butoxyl group was linked to the C-5 carbon. The signal of the C-5 carbon showed small coupling constant $^2J_{C(5)P}$(2.4 Hz) as compared with

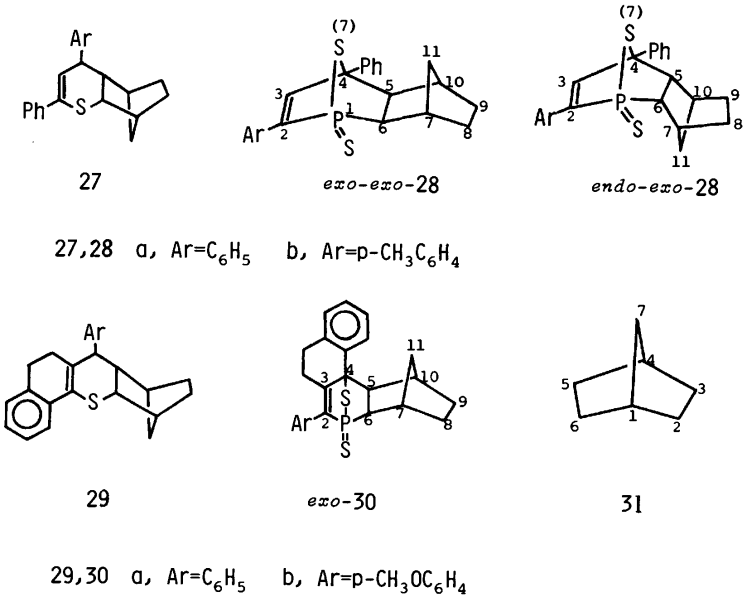


Fig. 1. The configurations of cycloadducts with norbornene. In 2-substituted norbornane, the *exo*-2 group usually shifts the resonance of the C-7 carbon upfield by 1.3—4.4 ppm from the one in norbornane **31** while the *endo*-2 group usually shifts the resonamce of C-6 carbon upfield by 4.9—9.7 ppm from one in **31**[11] (Table 5).

$J_{C(6)P}$ and shifted downfield owing to the butoxyl group (Table 4). Similarly, the reaction of **10** with butyl vinyl ether afforded **25**[1] and **26**. The configurations of **24** and **26** could not be determined.

The reaction of **9** with norbornene gave **27**[1] and **28**. In the case of **9c**, two stereo isomers of **28b** were obtained. In general, the chemical shift of the bridged carbon of *exo* substituted norbornane should shift upfield from that of norbornane **31** due to steric repulsion.[11] One isomer showed the resonance of the C-11 carbon at δ=34.8 shifted upfield by 4.1 ppm from that of **31**. The other isomer had the resonance at δ=30.4 shifted upfield by 8.0 ppm. The chemical shifts of the C-8 and C-9 carbons of both isomers did not change from those of **31** (Table 5). Therefore, both of the isomers would be *exo* with respect to the norbornyl skeleton. On the other hand, the C-2 and C-3 olefinic carbons[11] of the latter isomer resonated upfield by 1.6—3.3 ppm as compared with those of the former, hence the configuration of the latter with respect to 1-phospha-7-thiabicyclo[2.2.1]heptene 1-sulfide ring system would be *endo*; namely the former isomer is ***exo-exo*-28b** and the latter is ***endo-exo*-28b**. The reaction of **10** with norbornene gave **29** and **30**. In the ^{13}C NMR of **30**, the chemical shifts of the C-8 and C-9 carbons did not change, while the C-11 carbon resonated upfield by 6.3 ppm from that of **31**. Therefore, the configuration should be *exo* with respect to norbornyl ring.

As described above, it has been found that 1,2-thiaphosphole 2-sulfides react as cyclic heterodienes readily and regioselectively with acrylonitrile, styrene or butyl vinyl ether.[12] Besides the cycloaddition, other varied reactions can be expected for the 1,2-thiaphosphole 2-sulfides. The reaction with some nucleophiles are now under investigation.

Table 5. ^{13}C NMR Chemical shifts of norbornane **31** and cycloadducts **28b** (J_{CP}/Hz)

Carbons	**31**	*exo-exo*-**28b**		*endo-exo*-**28b**	
	δ	δ	J_{CP}	δ	J_{CP}
C-2	—	146.7	58.6	145.1	52.5
C-3	—	148.7	9.8	145.4	9.8
C-7(C-1)	36.8	39.1		38.5	
C-8(C-2)	30.1	30.7	17.1	32.1	15.9
C-9(C-3)	30.1	30.7		32.9	
C-10(C-4)	36.8	36.6	3.7	36.2	2.4
C-11(C-7)	38.7	34.8		30.7	

Experimental

All the melting points are uncorrected. IR spectra were measured on a Hitachi Model 260-10 spectrometer. ^1H and ^{13}C NMR spectra were recorded on a JEOL JNM-FX 100 spectrometer in $CDCl_3$ solution using Me_4Si as internal standard (^1H; at 100 MHz, ^{13}C; at 25 MHz). ^{13}C NMR spectral data are shown in Tables 2, 4, and 5. ^{31}P NMR spectra were recorded at 40 MHz on a JEOL JNM-FX 100 spectrometer using 85% H_3PO_4 as external standard. Mass spectra were recorded on a Hitachi double focusing mass spectrometer (RMU-7M) operating at an ionizing potential of 70 eV. Elemental analyses of sulfur and phosphorus were performed for some representative compounds. All α,β-unsaturated ketones were prepared by the Aldol condensation of the corresponding ketone with aldehyde.[13] Acrylonitrile, styrene, butyl vinyl ether and norbornene were obtained commercially.

General Procedure for the Preparation of 2,9-Dithia-1-phosphabicyclo[4.3.0]nona-3,7-diene 1-Sulfides. A suspension of α,β-unsaturated ketone (0.04 mol), P_4S_{10} powder (12 g) and NEt_3 (24 cm^3) in dry carbon disulfide (320 cm^3) was gent-

ly refluxed (50—55 °C) under a nitrogen atmosphere (Reaction times are shown in Table 1). The reaction mixture was filtered and the filtrate was evaporated. The residue was chromatographed on silica gel (Wakogel C-200). The solvent was evaporated and the residue was recrystallized from chloroform–ethanol giving the product as colorless crystals.

*3,8-Di-t-butyl-5,6-diphenyl-2,9-dithia-1-phosphabicyclo[4.3.0]-nona-3,7-diene 1-Sulfide (**3a**).* Chromatographed by eluting with benzene–hexane (2:3); ^{1}H NMR ($CDCl_3$) δ=1.22 (s, 9H), 1.27 (s, 9H), 4.76 (dd, 1H, J_{HH}=5.5 Hz, J_{HP}=19.5 Hz), 5.76 (d, 1H, J_{HP}=41.0 Hz), 6.26 (dd, 1H, J_{HH}=5.5 Hz, J_{HP}=5.5 Hz), and 7.00—7.30 (m, 10H); ^{31}P NMR ($CDCl_3$) δ=117.1 (dd, J_{PH}=41.0, 19.5 Hz); MS *m/z* (rel intensity) 470 (M^+; 3), 266 (19), 234 (47), 204 (34), 203 (32), and 147 (100). Found: C, 66.33; H, 6.48; S, 20.46; P, 6.43%. Calcd for $C_{26}H_{31}S_3P$: C, 66.35; H, 6.64; S, 20.43; P, 6.58%.

*3,8-Di-t-butyl-5,6-bis(p-methylphenyl)-2,9-dithia-1-phosphabicyclo[4.3.0]nona-3,7-diene 1-Sulfide (**3b**).* Chromatographed by eluting with benzene–hexane (2:3); ^{1}H NMR ($CDCl_3$) δ=1.21 (s, 9H), 1.27 (s, 9H), 2.23 (s, 3H), 2.29 (s, 3H), 4.72 (dd, 1H, J_{HH}=5.5 Hz, J_{HP}=20.0 Hz), 5.76 (d, 1H, J_{HP}=42.0 Hz), 6.24 (dd, 1H, J_{HH}=5.5 Hz, J_{HP}=5.5 Hz), and 6.90—7.30 (m, 8H); MS *m/z* (rel intensity) 498 (M^+), 280 (8), 248 (65), 218 (22), 203 (41), and 161 (75). Found: C, 67.50; H, 7.12; S, 19.39; P, 6.31%. Calcd for $C_{28}H_{35}S_3P$: C, 67.43; H, 7.07; S, 19.28; P, 6.21%.

*3,8-Di-t-butyl-5,6-bis(p-chlorophenyl)-2,9-dithia-1-phosphabicyclo[4.3.0]nona-3,7-diene 1-Sulfide (**3c**).* Chromatographed by eluting with benzene–hexane (2:3); ^{1}H NMR ($CDCl_3$) δ=1.22 (s, 9H), 1.27 (s, 9H), 4.67 (dd, 1H, J_{HH}=5.5 Hz, J_{HP}=20.0 Hz), 5.66 (d, 1H, J_{HP}=42.0 Hz), 6.17 (dd, 1H, J_{HH}=5.5 Hz, J_{HP}=5.5 Hz), and 6.90—7.30 (m, 8H); MS *m/z* (rel intensity) 538 (M^+), 300 (20), 268 (54), 238 (27), 233 (94), and 181 (100). Found: C, 57.90; H, 5.43; S, 18.16; P, 5.80%. Calcd for $C_{26}H_{29}Cl_2S_3P$: C, 57.88; H, 5.42; S, 17.83; P, 5.74%.

*3,5,6,8-Tetraphenyl-2,9-dithia-1-phosphabicyclo[4.3.0]nona-3,7-diene 1-Sulfide (**9a**).* Chromatographed by eluting with benzene–hexane (1:1); ^{1}H NMR ($CDCl_3$) δ=5.06 (dd, 1H, J_{HH}=5.0 Hz, J_{HP}=18.0 Hz), 6.35 (d, 1H, J_{HP}=42.0 Hz), 6.82 (dd, 1H, J_{HH}=5.0 Hz, J_{HP}=5.5 Hz), and 7.18—7.58 (m, 20H); ^{31}P NMR ($CDCl_3$) δ=116.8; MS *m/z* (rel intensity) 254 (100), 224 (15), 223 (30), and 191 (60). Found: C, 70.61; H, 4.78; S, 19.12; P, 5.56%. Calcd for $C_{30}H_{23}S_3P$: C, 70.56; H, 4.54; S, 18.83; P, 6.07%.

*5,6-Bis(p-methoxyphenyl)-3,8-diphenyl-2,9-dithia-1-phosphabicyclo[4.3.0]nona-3,7-diene 1-Sulfide (**9b**).* Chromatographed by eluting with benzene–hexane (1:1); ^{1}H NMR ($CDCl_3$) δ=3.70 (s, 3H), 3.74 (s, 3H), 4.96 (dd, 1H, J_{HH}=5.0 Hz, J_{HP}=18.0 Hz), 6.30 (d, 1H, J_{HP}=42.0 Hz), and 6.66—7.54 (m, 19H); ^{31}P NMR ($CDCl_3$) δ=116.6; MS *m/z* (rel intensity) 284 (100), 269 (25), 254 (18), and 253 (19). Found: C, 67.18; H, 4.83%. Calcd for $C_{32}H_{27}O_2S_3P$: C, 67.35; H, 4.83%.

*5,6-Bis(p-methylphenyl)-3,8-diphenyl-2,9-dithia-1-phosphabicyclo[4.3.0]nona-3,7-diene 1-Sulfide (**9c**).* Chromatographed by eluting with benzene–hexane (1:1); ^{1}H NMR ($CDCl_3$) δ=2.26 (s, 3H), 2.30 (s, 3H), 5.00 (d, 1H, J_{HH}=6.0 Hz, J_{HP}=20.0 Hz), 6.33 (d, 1H, J_{HP}=42.0 Hz), 6.82 (dd, 1H, J_{HH}=6.0 Hz, J_{HP}=5.5 Hz), and 6.92—7.56 (m, 18H); MS *m/z* (rel intensity) 300, 268 (100), 238 (13), 237 (18), and 205 (29). Found: C, 71.27; H, 5.20%. Calcd for $C_{32}H_{27}S_3P$: C, 71.34; H, 5.05%.

*5,6-Bis(p-chlorophenyl)-3,8-diphenyl-2,9-dithia-1-phosphabicyclo[4.3.0]nona-3,7-diene 1-Sulfide (**9d**).* Chromatographed by eluting with benzene–hexane (1:1); ^{1}H NMR ($CDCl_3$) δ=4.96 (dd, 1H, J_{HH}=6.0 Hz, J_{HP}=20.0 Hz), 6.23 (d, 1H, J_{HP}=42.0 Hz), 6.74 (dd, 1H, J_{HH}=6.0 Hz, J_{HP}=5.5 Hz), and 6.96—7.54 (m, 18H); MS *m/z* (rel intensity) 288 (100), 258 (24), 257 (28), and 225 (36). Found: C, 62.32; H, 3.81%. Calcd for $C_{30}H_{21}Cl_2S_3P$: C, 62.71; H, 3.65%.

*3,8-Bis(p-methoxyphenyl)-5,6-diphenyl-2,9-dithia-1-phosphabicyclo[4.3.0]nona-3,7-diene 1-Sulfide (**9e**).* Chromatographed by eluting with benzene–hexane (1:1); ^{1}H NMR ($CDCl_3$) δ=3.77 (s, 3H), 3.78 (s, 3H), 5.02 (dd, 1H, J_{HH}=5.0 Hz, J_{HP}=18.0 Hz), 6.22 (d, 1H, J_{HP}=42.0 Hz), and 6.66—7.50 (m, 19H); ^{31}P NMR ($CDCl_3$) δ=117.0; MS *m/z* (rel intensity) 284 (100), 253 (25), and 221 (9). Found: C, 67.58, H, 4.97%. Calcd for $C_{32}H_{27}O_2S_3P$: C, 67.35; H, 4.77%.

*3,8-Bis(p-methylphenyl)-5,6-diphenyl-2,9-dithia-1-phosphabicyclo[4.3.0]nona-3,7-diene 1-Sulfide (**9f**).* Chromatographed by eluting with benzene–hexane (1:1); ^{1}H NMR ($CDCl_3$) δ=2.33 (s, 6H), 5.04 (dd, 1H, J_{HH}=5.0 Hz, J_{HP}=18.0 Hz), 6.29 (d, 1H, J_{HP}=42.0 Hz), 6.78 (dd, 1H, J_{HH}=5.0 Hz, J_{HP}=5.5 Hz), and 7.06—7.44 (m, 18H); MS *m/z* (rel intensity) 268 (100), 238 (27), 237 (49), and 205 (29). Found: C, 71.35; H, 5.34%. Calcd for $C_{32}H_{27}S_3P$: C, 71.34; H, 5.05%.

*3,8-Bis(p-chlorophenyl)-5,6-diphenyl-2,9-dithia-1-phosphabicyclo[4.3.0]nona-3,7-diene 1-Sulfide (**9g**).* Chromatographed by eluting with benzene–hexane (1:1); ^{1}H NMR ($CDCl_3$) δ=5.04 (dd, 1H, J_{HH}=5.0 Hz, J_{HP}=18.0 Hz), 6.32 (d, 1H, J_{HP}=42.0 Hz), 6.82 (dd, 1H, J_{HH}=5.0 Hz, J_{HP}=5.5 Hz), and 7.16—7.56 (m, 18H); MS *m/z* (rel intensity) 288 (100), 258 (1), 257 (2), and 225 (29). Found: C, 62.38; H, 3.74%. Calcd for $C_{30}H_{21}Cl_2S_3$ P: C, 62.17; H, 3.65%.

*6b,7-Diphenyl-5,6,6b,7,8,9-hexahydro-14,15-dithia-14a-phosphabenz[4,5]indeno[1,2-b]phenanthrene 14a-Sulfide (**10a**).* Chromatographed by eluting with benzene–hexane (2:3); ^{1}H NMR ($CDCl_3$) δ=1.24—2.98 (m, 8H), 4.28 (d, 1H, J_{HP}=28.0 Hz), and 6.86—7.60 (m, 18H); ^{31}P NMR ($CDCl_3$) δ=123.7; MS *m/z* (rel intensity) 530, 312 (30), 280 (100), 250 (9), and 249 (17). Found: C, 72.70; H, 4.70; S, 17.62; P, 5.12%. Calcd for $C_{34}H_{27}S_3P$: C, 72.44; H, 5.01; S, 17.06; P, 5.49%.

*6b,7-Bis(p-methoxyphenyl)-5,6,6b,7,8,9-hexahydro-14,15-dithia-14a-phosphabenz[4,5]indeno[1,2-b]phenanthrene 14a-Sulfide (**10b**).* Chromatographed by eluting with benzene–hexane (2:3); ^{1}H NMR ($CDCl_3$) δ=1.54—2.74 (m, 8H), 3.75 (s, 6H), 4.89 (d, 1H, J_{HP}=38.0 Hz), and 6.66—7.52 (m, 16H); ^{31}P NMR ($CDCl_3$) δ=109.4; MS *m/z* (rel intensity) 310 (100), 279 (25). Found: C, 69.43; H, 5.32%. Calcd for $C_{36}H_{31}O_2S_3P$: C, 69.32; H, 5.17%.

*6b,7-Bis(p-chlorophenyl)-5,6,6b,7,8,9-hexahydro-14,15-dithia-14a-phosphabenz[4,5]indeno[1,2-b]phenanthrene 14a-Sulfide (**10c**).* Chromatographed by eluting with benzene–hexane (2:3); ^{1}H NMR ($CDCl_3$) δ=1.57—1.84 (m, 8H), 4.30 (d, 1H, J_{HP}=28.0 Hz), and 7.00—7.58 (m, 16H); MS *m/z* (rel intensity) 314 (100), 285 (22), and 283 (22). Found: C, 64.63; H, 3.97%. Calcd for $C_{34}H_{27}Cl_2S_3P$: C, 64.65; H, 3.99%.

General Procedure for the Cycloaddition Reactions of the 2,9-Dithia-1-phosphabicyclo[4.3.0]nona-3,7-diene 1-Sulfides with Dienophiles. A solution of the 2,9-dithia-1-phosphabicyclo[4.3.0]nona-3,7-diene 1-sulfide (2 mmol) and dienophile (6 mmol) in dry benzene (5 cm^3) was refluxed under a nitrogen atmosphere until all the phosphabicyclo compound had been consumed as indicated by TLC. The solvent was evaporated and the residue was chromatographed on silica gel (Wakogel C-200). The solvent was evaporated and the residue was recrystallized from ethanol to give the cycloadduct.

*6-t-Butyl-3-cyano-4-phenyl-3,4-dihydro-2H-thiopyran (**5a**).* Chromatographed by eluting with benzene–ligroin (1:1); IR

(KBr) 2250 cm^{-1} (CN); ^1H NMR ($CDCl_3$) δ= 1.22 (s, 9H), 3.00—3.40 (m, 3H), 3.78 (dd, 1H, J_{HH}=4.8 Hz), 5.66 (d, 1H, J_{HH}=4.8 Hz), and 7.20—7.30 (m, 5H); MS *m/z* (rel intensity) 257 (M^+; 30), 203 (63), and 147 (100). Found: C, 74.68; H, 7.47; N, 5.37; S, 12.74%. Calcd for $C_{16}H_{19}NS$: C, 74.66; H, 7.44; N, 5.44; S, 12.46%.

6-t-Butyl-3-cyano-4-(p-methylphenyl)-3,4-dihydro-2H-thiopyran (**5b**). Chromatographed by eluting with benzene–hexane (2:1); IR (KBr) 2250 cm^{-1} (CN); ^1H NMR ($CDCl_3$) δ=1.21 (s, 9H), 2.34 (s, 3H), 2.90—3.40 (m, 3H), 3.60—3.80 (m, 1H), 5.63 (d, 1H, J_{HH}=5.0 Hz), and 7.00—7.20 (m, 4H); MS *m/z* (rel intensity) 271 (M^+; 29), 218 (22), 203 (100), and 161 (70). Found: C, 75.39; H, 7.85; N, 5.17%. Calcd for $C_{17}H_{21}NS$: C, 75.23; H, 7.80; N, 5.16%.

6-t-Butyl-3-cyano-4-(p-chlorophenyl)-3,4-dihydro-2H-thiopyran (**5c**). Chromatographed by eluting with benzene–hexane (1:1); IR (KBr) 2250 cm^{-1} (CN); ^1H NMR($CDCl_3$) δ=1.22 (s, 9H), 2.98—3.36 (m, 3H), 3.78 (dd, 1H, J_{HH}=4.6 Hz), 5.60 (d, 1H, J_{HH}=4.6 Hz), and 7.06—7.36 (m, 4H); MS *m/z* (rel intensity) 291 (M^+; 25), 238 (41), 203 (40), and 181 (100). Found: C, 65.79; H, 6.02; N, 4.77%. Calcd for $C_{16}H_{18}NClS$: C, 65.85; H, 6.22; N, 4.80%.

*4-t-Butyl-*endo*-5-cyano-2-phenyl-7-thia-1-phosphabicyclo[2.2.1]hept-2-ene 1-Sulfide* (**endo-6a**). IR (KBr) 2250 cm^{-1} (CN); ^1H NMR ($CDCl_3$) δ=1.34 (s, 9H), 2.51 (ddd, 1H, J_{HH}=3.5, 14.0 Hz, J_{HP}=7.5 Hz), 3.07 (ddd, 1H, J_{HH}=9.5, 14.0 Hz, J_{HP}= 14.0 Hz), 3.64 (ddd, 1H, J_{HH}=3.5, 9.5 Hz, J_{HP}=4.5 Hz), and 7.05—7.72 (m, 6H); ^{31}P NMR ($CDCl_3$) δ=−28.9; MS *m/z* (rel intensity) 319 (M^+; 2), 266 (100), 251 (22), 234 (52), 219 (85), and 203 (18). Found: C, 60.18; H, 5.77; N, 4.41; S, 20.02; P, 9.78%. Calcd for $C_{16}H_{18}NS_2P$: C, 60.16; H, 5.68; N, 4.39; S, 20.07; P, 9.70%.

exo-6a: IR (KBr) 2250 cm^{-1} (CN); ^1H NMR ($CDCl_3$) δ=1.39 (s, 9H), 2.70—2.86 (m, 2H), 3.08—3.32 (m, 1H), and 6.72—7.70 (m, 6H); MS *m/z* (rel intensity) 319 (M^+; 2) 266 (100), 251 (22), 234 (29), 219 (22), and 203 (17). Found: C, 60.32; H, 5.60; N, 4.35%. Calcd for $C_{16}H_{18}NS_2P$: C, 60.16; H, 5.68; N, 4.39%.

*4-t-Butyl-*endo*-5-cyano-2-(p-methylphenyl)-7-thia-1-phosphabicyclo[2.2.1]hept-2-ene 1-Sulfide* (**endo-6b**). IR (KBr) 2250 cm^{-1} (CN); ^1H NMR ($CDCl_3$) δ=1.32 (s, 9H), 2.36 (s, 3H), 2.48 (ddd, 1H, J_{HH}=3.0, 13.0 Hz, J_{HP}=7.5 Hz), 3.04 (ddd, 1H, J_{HH}=10.0, 13.0 Hz, J_{HP}=13.0 Hz), 3.60 (ddd, 1H, J_{HH}=3.0, 10.0 Hz, J_{HP}= 4.0 Hz), and 6.92—7.64 (m, 5H); MS *m/z* (rel intensity) 333 (M^+; 2), 280 (100), 265 (21), and 248 (39). Found: C, 61.56; H, 5.97; N, 4.18%. Calcd for $C_{17}H_{20}NS_2P$: C, 61.24; H, 6.05; N, 4.20%.

*4-t-Butyl-*endo*-5-cyano-2-(p-chlorophenyl)-7-thia-1-phosphabicyclo[2.2.1]hept-2-ene 1-Sulfide* (**endo-6c**). IR (KBr) 2250 cm^{-1} (CN); ^1H NMR ($CDCl_3$) δ=1.34 (s, 9H), 2.50 (ddd, 1H, J_{HH}=3.0, 14.0 Hz, J_{HP}=7.5 Hz), 3.08 (ddd, 1H, J_{HH}=10.0, 14.0 Hz, J_{HP}=14.0 Hz), 3.64 (ddd, 1H, J_{HH}=3.0, 10.0 Hz, J_{HP}=4.5 Hz), and 7.04—7.68 (m, 5H); MS *m/z* (rel intensity) 355 (M^+; 1), 302 (44), 287 (11), 270 (23), and 255 (37). Found: C, 54.25; H, 5.00; N, 3.94%. Calcd for $C_{16}H_{17}NClS_2P$: C, 54.31; H, 4.84; N, 3.96%.

exo-5-Cyano-2,4-diphenyl-7-thia-1-phosphabicyclo[2.2.1]hept-2-ene 1-Sulfide (**exo-16a**). Chromatographed by eluting with benzene–ligroin (1:1); IR (KBr) 2250 cm^{-1} (CN); ^1H NMR ($CDCl_3$) δ=2.82—3.04 (m, 2H), 3.54—3.80 (m, 1H), and 6.82—7.68 (m, 11H); ^{31}P NMR ($CDCl_3$) δ=−52.6; MS *m/z* (rel intensity) 286 (15), 254 (100). Found: C, 63.90; H, 4.35; S, 19.35; P, 8.88%. Calcd for $C_{18}H_{14}NS_2P$: C, 63.70; H, 4.16; S, 18.89; P, 9.13%.

exo-5-Cyano-2-(p-methylphenyl)-4-phenyl-7-thia-1-phosphabicyclo[2.2.1]hept-2-ene 1-Sulfide (**exo-16b**). Chromatographed by eluting with benzene–ligroin (1:1); IR (KBr) 2250 cm^{-1} (CN); ^1H NMR ($CDCl_3$) δ=2.36(s, 3H), 2.64—3.12 (m, 2H), 3.50—3.80 (m, 1H), and 7.04—7.60 (m, 10H); MS *m/z* (rel intensity) 353 (M^+; 1), 300 (30), and 268 (100). Found: C, 64.44; H, 4.32%. Calcd for $C_{19}H_{16}NS_2P$: C, 64.57; H, 4.56%.

endo-16b: IR (KBr) 2250 cm^{-1} (CN); ^1H NMR ($CDCl_3$) δ= 2.38 (s, 3H), 2.58 (ddd, 1H, J_{HH}=4.0, 13.0 Hz, J_{HP}=8.0 Hz), 3.12 (ddd, 1H, J_{HH}=9.0, 13.0 Hz, J_{HP}=13.0 Hz), 4.06 (ddd, 1H, J_{HH}=4.0, 10.0 Hz, J_{HP}=3.0 Hz), and 7.12—7.70 (m, 10H); MS *m/z* (rel intensity) 353 (M^+), 300 (24), and 268 (100). Found: C, 64.38; H, 4.28%. Calcd for $C_{19}H_{16}NS_2P$: C, 64.57; H, 4.56%.

exo-10-Cyano-7-phenyl-2,3-benzo-11-thia-8-phosphatricyclo-[6.2.1.$0^{1,6}$]undec-6-ene 8-Sulfide (**exo-18a**). Chromatographed by eluting with benzene–hexane (3:2); IR (KBr) 2250 cm^{-1}(CN); ^1H NMR ($CDCl_3$) δ=2.58—3.52 (m, 7H) and 7.14—7.67 (m, 9H); ^{31}P NMR ($CDCl_3$) δ=−52.1; MS *m/z* (rel intensity) 365 (M^+), 312 (34), and 280 (100). Found: C, 65.75; H, 4.71; S, 17.96; P, 8.28%. Calcd for $C_{20}H_{16}NS_2P$: C, 65.73; H, 4.41; S, 17.55; P, 8.48%.

exo-10-Cyano-7-(p-methoxyphenyl)-2,3-benzo-11-thia-8-phosphatricyclo[6.2.1.$0^{1,6}$]undec-6-ene 8-Sulfide (**exo-18b**). Chromatographed by eluting with benzene–hexane (1:2); IR (KBr) 2250 cm^{-1} (CN); ^1H NMR($CDCl_3$) δ=2.40—3.56 (m, 7H), 3.82 (s, 3H), and 6.80—7.72 (m, 8H); MS *m/z* (rel intensity) 395 (M^+), 342 (3), and 310 (100). Found: C, 63.87; H, 4.89%. Calcd for $C_{21}H_{18}ONS_2P$: C, 63.87; H, 4.58%.

endo-5-Phenyl-2,4-diphenyl-7-thia-1-phosphabicyclo[2.2.1]hept-2-ene 1-Sulfide (**endo-20**). Chromatographed by eluting with benzene–hexane (1:2); ^1H NMR ($CDCl_3$) δ=2.48—4.20 (m, 3H), 6.60—6.76 (m, 1H), and 6.80—7.92 (m, 15H); MS *m/z* (rel intensity) 390 (M^+; 1), 287(2), and 254 (100).

7,10-Diphenyl-2,3-benzo-11-thia-8-phosphatricyclo[6.2.1.$0^{1,6}$]undec-6-ene 8-Sulfide (**22a**). Chromatographed by eluting with benzene; ^1H NMR ($CDCl_3$) δ=1.42—3.80 (m, 6H), 4.42—4.60 (m, 1H), and 6.34—7.79 (m, 14H); ^{31}P NMR ($CDCl_3$) δ= −49.6; MS *m/z* (rel intensity) 416 (M^+), 312 (6), 280 (100), and 249 (10). Found: C, 71.83; H, 5.34; S, 15.47; P, 7.26%. Calcd for $C_{25}H_{21}S_2P$: C, 72.09; H, 5.08; S, 15.39; P, 7.44%.

7-(p-Methoxyphenyl)-10-phenyl-2,3-benzo-11-thia-8-phosphatricyclo[6.2.1.$0^{1,6}$]undec-6-ene 8-Sulfide (**22b**). Chromatographed by eluting with benzene–hexane (1:1); ^1H NMR ($CDCl_3$) δ= 1.40—3.60 (m, 5H), 3.86 (s, 3H), 4.40—4.64 (m, 1H), and 6.75—7.82 (m, 13H); MS *m/z* (rel intensity) 446 (M^+), 342 (6), and 310 (100). Found: C, 69.82; H, 5.41%. Calcd for $C_{26}H_{23}OS_2P$: C, 69.93; H, 5.19%.

5-Butoxy-2,4-diphenyl-7-thia-1-phosphabicyclo[2.2.1]hept-2-ene 1-Sulfide (**24**). Chromatographed by eluting with benzene–hexane (1:1); ^1H NMR ($CDCl_3$) δ=0.60—1.48 (m, 9H), 2.00—2.32 (m, 1H), 2.76—3.00 (m, 1H), 3.12—3.40 (m, 1H), and 7.00—7.76 (m, 11H).

10-Butoxy-7-phenyl-2,3-benzo-11-thia-8-phosphatricyclo[6.2.1.$0^{1,6}$]undec-6-ene 8-Sulfide (**26**). Chromatographed by eluting with benzene–hexane (3:4); ^1H NMR ($CDCl_3$) δ=0.39—1.56 (m, 7H), 2.34—3.00 (m, 7H), 3.12—3.36 (m, 1H), 3.80—4.16 (m, 1H), and 7.00—7.60 (m, 9H); MS *m/z* (rel intensity) 412 (M^+), 378 (1), 346 (1), 312 (13), 280 (100), and 215 (31). Found: C, 66.84; H, 6.20%. Calcd for $C_{23}H_{25}OS_2P$: C, 66.96; H, 6.11%.

8,10-Diphenyl-11-thia-1-phosphatetracyclo[6.2.$1^{3,6}$.$0^{2,7}$]dec-9-ene 1-Sulfide (**exo-exo-28a**). Chromatographed by eluting

with benzene–hexane (3:2); ^{1}H NMR ($CDCl_3$) δ=0.94—3.10 (m, 10H), 7.03—7.67 (m, 11H); ^{31}P NMR ($CDCl_3$) δ=−44.4; MS *m/z*' (rel intensity) 380 (M^+; 2), 286 (100), 254 (8), 223 (10), and 121 (14). Found: C, 69.71; H, 5.82; S, 17.18; P, 7.88%. Calcd for $C_{22}H_{21}S_2P$: C, 69.45; H, 5.56; S, 16.85; P, 8.14%.

10-(p-Methylphenyl)-8-phenyl-11-thia-1-phosphatetracyclo-[6.2.1^{3,6}.0^{2,7}]dec-9-ene 1-Sulfide (**exo-exo-*28b***). Chromatographed by eluting with benzene–hexane (1:2); ^{1}H NMR ($CDCl_3$) δ=0.92—3.07 (m, 10H), 2.36 (s, 3H), and 6.97—7.66 (m, 10H); MS *m/z* (rel intensity) 394 (M^+; 3), 300 (100), and 268 (19). Found: C, 70.33; H, 5.92%. Calcd for $C_{23}H_{23}S_2P$: C, 70.02; H, 5.88%.

endo-exo-*28b*: ^{1}H NMR ($CDCl_3$) δ=0.68—3.40 (m, 10H), 2.36 (s, 3H), and 6.90—7.68 (m, 10H); MS *m/z* (rel intensity) 394 (M^+; 5), 300 (100), and 268 (15). Found: C, 70.30; H, 5.82%. Calcd for $C_{23}H_{23}S_2P$: C, 70.02; H, 5.88%.

9-Phenyl-13,14-benzo-15-thia-8-phosphapentacyclo[6.6.1.1^{3,6}.-0^{1,10}.0^{2,7}]hexadeca-9,13-diene 8-Sulfide (**exo-*30a***). Chromatographed by eluting with benzene; ^{1}H NMR ($CDCl_3$) δ=0.82—3.32 (m, 14H) and 7.16—7.58 (m, 9H); ^{31}P NMR ($CDCl_3$) δ=−41.3; MS *m/z* (rel intensity) 406 (M^+; 3), 312 (100), 280 (9), and 249 (10). Found: C, 70.94; H, 5.75; S, 15.55; P, 7.80%. Calcd for $C_{24}H_{23}S_2P$: C, 70.91; H, 5.70; S, 15.77; P, 7.62%.

9-(p-Methoxyphenyl)-13,14-benzo-15-thia-8-phosphapentacyclo-[6.6.1.1^{3,6}.0^{1,10}.0^{2,7}]hexadeca-9,13-diene 8-Sulfide (**exo-*30b***). Chromatographed by eluting with benzene–hexane (1:1); ^{1}H NMR ($CDCl_3$) δ=1.78—3.32 (m, 14H), 3.80 (s, 3H), and 6.80—7.64 (m, 8H); MS *m/z* (rel intensity) 436 (M^+; 1), 342 (100), and 310 (10). Found: C, 69.01; H, 6.01%. Calcd for $C_{25}H_{25}OS_2P$: C, 68.78; H, 5.77%.

The authors wish to thank Professor Tokiko Uchida for performing the X-ray analysis. The authors also would like to thank Mr. Ryoichi Yamabe for his technical assistance.

A Potent Pyridoxal Model Capable of Promoting Transamination and β-Elimination of Amino Acids

Hiroki KONDO,* Jun-ichi KIKUCHI, Shinji UCHIDA, Tatsuya KITAMIKADO, Eiji KOYANAGI, and Junzo SUNAMOTO

Department of Industrial Chemistry, Faculty of Engineering Nagasaki University, Nagasaki 852

(Received September 3, 1984)

N-Dodecylpyridoxal chloride (**1a**) has been synthesized as a potent pyridoxal 5′-phosphate model. The equilibrium constant for Schiff base formation of **1a** with phenylalanine (21000 M^{-1}) in 3 mM hexadecyltrimethylammonium chloride (CTACl) micelle is over a thousand times larger than that for the *N*-methyl counterpart (**1b**). The Schiff base of **1a** and phenylalanine exists over a broad pH range of 5—11 in two ionic forms, HSB and SB^-, that differ in the protonation state at the azomethine group. These Schiff bases undergo transamination at 30 °C in the absence of a metal ion at considerably different rates; 1.33×10^{-3} and 1.5×10^{-5} s^{-1} for HSB and SB^-, respectively. Likewise, the former species exhibited 11 times higher reactivity in the β-elimination of *O*-phosphonoserine catalyzed by **1a** in 3 mM CTACl at 40 °C. These results indicate unambiguously the importance of a positive charge on the azomethine nitrogen as well as the one residing on the pyridine nitrogen in vitamin B_6 catalysis. The kinetic α-deuterium isotope effect of 5.1 in the transamiantion of phenylalanine with **1a** at pH 7.7 and 30 °C revealed that α-hydrogen abstraction takes place in the transition state.

Pyridoxal 5′-phosphate (PLP)-dependent enzymes play a pivotal role in the metabolism of amino acids.[1,2] Such metabolic reactions comprise transamination, decarboxylation *etc.* It is well known that these reactions can be duplicated in nonenzymatic systems, but rather unphysiological conditions such as high temperature, presence of metal ions[3] and/or high buffer salts[4] are usually needed to promote the reaction. It is, hence, clear that factors responsible for a more efficient catalysis of the coenzyme in enzymatic systems remain to be elucidated. In light of the fact that the PLP catalysis appears to be subject to general acid-base catalysis in the enzyme active site[5,6] as well as in model systems,[4,7] we have envisioned that duplication of this aspect of catalysis would generate a potent pyridoxal model capable of mediating reactions of amino acids under ambient conditions. The present model system consists of a pyridoxal bearing a dodecyl group on the pyridine nitrogen (**1a**) and a hexadecyltrimethylammonium chloride (CTACl) micelle.[8] The positive charge residing on the pyridine ring exerts a strong electron-withdrawing effect on the Schiff base of amino acid, and hydroxide ions concentrated at the cationic micellar surface are expected to serve as a base catalyst.[9] It was found that this system is an excellent catalyst of transamination and β-elimination reactions of ordinary amino acids in the absence of metal ions.

Experimental

Materials. Pyridoxal hydrochloride was obtained from Wako Pure Chemical Ind., Osaka. Pyridoxal methochloride (**1b**) was prepared according to the literature.[10] DL-Phenylalanine and DL-[α-^{2}H]phenylalanine were prepared by the literature method.[11] The deuterium content in the latter was determined as 95.4% by mass spectroscopy.[12] *O*-Phosphonoserine was either prepared[13] or purchased from Sigma. Other L-amino acids, ammonium molybdate and other common chemicals were obtained from Wako. Sodium tetraphenylborate and EDTA were the products of Dojindo, Kumamoto. CTACl was the same as that used previously.[14] Rabbit muscle lactate dehydrogenase and NADH were obtained from Boehringer Mannheim and Kyowa Hakko, Tokyo, respectively.

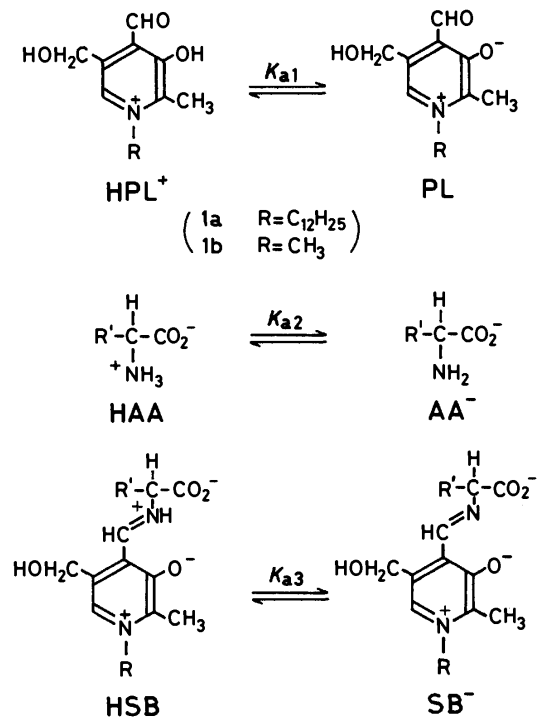
1-Dodecylpyridoxal Chloride (1-dodecyl-4-formyl-3-hydroxy-5-hydroxymethyl-2-methylpyridinium Chloride, 1a). "Pyridoxal inner monomethyl acetal"[10] (1,3-dihydro-1-methoxy-6-methylfuro [3,4-c]pyridin-7-ol, 0.50 g, 3 mmol) was allowed to react with dodecyl iodide (3.0 g, 10 mmol) in 12 ml of refluxing dry MeOH–benzene (5:1 by vol) for 200 h. The solvents were removed *in vacuo* and 100 ml of ether was added to the residue. The precipitate formed was collected by filtration. It was purified by column chromatography twice on a Sephadex LH-20 (Pharmacia) column (1.2×30 cm) with MeOH as eluant. The product was obtained as a light yellow oil in 20% yield.

An aqueous solution (50 ml) of "1-dodecylpyridoxal iodide inner monomethyl acetal" prepared above was mixed with an aqueous suspension of silver chloride, prepared fresh from silver nitrate and potassium chloride. The mixture was stirred at room temperature for 2 h. After removing the solid by filtration, the pH of the filtrate was brought to 2 with hydrochloric acid. Evaporation of the solvent left a very hygroscopic yellow oil. TLC (silica gel) R_f 0.08 (CH_3CN). NMR (DMSO-d_6) δ 0.86 (t, J=5 Hz, 3H), 1.0—2.0 (m, 20H), 2.71 (s, 3H), 4.61 (t, J=7 Hz, 2H), 5.04 (d, J=14 Hz, 1H), 5.18 (d, J=14 Hz, 1H), 6.81 (s, 1H), 8.72 (br s, 1H).

Apparatus. Electronic absorption spectra were taken on a Hitachi 124 or 200 spectrophotometer. Rapid-scanning spectra were determined with a Union Giken RA-401 spectrophotometer furnished with a rapid scanning device RA-415. Fluorescence spectra were recorded on a Hitachi 650-10 fluorescence spectrophotometer. ^{1}H NMR spectra were obtained on a Jeol JNM-MH-100 spectrometer. Mass spectra were determined with a Jeol JMS-DX 300 mass spectrometer in the chemical ionization mode. The pH values of aqueous solutions were read on a Toa pH meter HM-5A fitted with a combination electrode GS-195C.

Equilibria. For determining equilibrium constants for the formation of a Schiff base of **1a** or **1b** with amino acids, a number of aqueous solutions containing $1-3\times10^{-4}$ M† **1a** or **1b** and 0—1 M amino acid at various pH values were prepared

† 1 M=1 mol dm^{-3}.



Scheme 1.

in the absence or presence of 3 mM CTACl.[15] Equilibria of Schiff base formation were attained within 10 min and absorption spectra were determined at 30.0 °C. The pertinent equilibria are depicted in Scheme 1. With **1b**, the two ionic species of Schiff base, HSB and SB^-, were detected spectroscopically over the pH range 7—11. On the other hand, HSB species was hardly visible with **1a** in 3 mM CTACl in the same pH region, though the equilibrium constant for the Schiff base formation is much greater with this system. A pH jump-rapid scanning spectroscopy, however, allowed one to observe HSB species (see below).

The data were analyzed in a way similar to those described previously,[16-18] but with some simplifications where possible. The pH-dependent (K_{pH}, Eq. 1) and independent equilibrium constants (K, Eq. 2) for the Schiff base formation are those defined by Metzler.[15] In a micellar **1a** and phenylalanine system, the Schiff base formation is complete at 10 mM amino acid at pH 9—11 and only a single ionic species each is present for **1a**, phenylalanine and Schiff base in that pH region. Hence, the spectrum determined at pH 11 at the highest amino acid concentration represents the intrinsic spectrum of SB^- whose absorption maximum is located at 393 nm. Furthermore, the K_{pH} values obtained in this pH region are set equal to the pH-independent equilibrium constant K. The intrinsic spectrum of HSB was obtained by a pH jump-rapid scanning technique. To determine the pK_a values of Schiff base and phenylalanine in the micelle, steady state spectral data at pH 4.7, 5.6, 6.0, and 11.0 (16 points) were analyzed by iterative computations until a minimum value of the sum of residual squares U is reached (Eq. 3).[16]

$$K_{pH} = \frac{[SB]_T}{[PL]_T \cdot [AA]_T} \quad (1)$$

$$K = \frac{[SB^-]}{[PL] \cdot [AA^-]} \quad (2)$$

$$U = \sum_{i,j,k} (A^{obs}_{ijk} - A^{cal}_{ijk})^2 \quad (3)$$

$$A^{cal}_{ijk} = \sum_{k,l} \varepsilon_{kl} \cdot C_{ijl} \quad (4)$$

Caluculated absorbance A^{cal}_{ijk} at a given pH i, amino acid concentration j and wavelength k is the sum of contributions of HPL^+, PL, HSB, and SB^- (Scheme 1 and Eq. 4).

Rapid Scanning Spectroscopy. Following two stock solutions were prepared: Solution (A) contained 0.40 mM **1a**, 30 mM phenylalanine and 3 mM CTACl in 10 mM borate buffer, pH 12 and Solution (B) contained 3 mM CTACl and dilute hydrochloric acid. Equal volumes of both solutions were mixed to bring the pH of the resulting solution to ≈4 and an electronic absorption spectrum was recorded at 1 ms intervals (Fig. 1). The absorption band centered at 430 nm disappeared gradually with a half life ≈14 s, finally to make the solution colorless. This phenomenon is explained in terms of rapid protonation to SB^- and subsequent slow dissociation of HSB into its constituents.

Kinetics of Transamination. An aqueous solution (3 ml) of 10 mM phenylalanine, 3 mM CTACl and 0.10 mM EDTA in 10 mM phosphate buffer at a specified pH value was placed in a cuvette and thermally equilibrated at 30.0 °C. A solution of **1a** (30 μl) was injected and the whole mixture was agitated quickly. The concentration of **1a** in the mixture was 0.10 mM. A decrease of the Schiff base absorption was followed continuously at its absorption maximum wavelength. The rate of transamination was determined by Eq. 5.

$$-\frac{d[SB]_T}{dt} = k_{obsd}[SB]_T \quad (5)$$

As the Schiff base formation is not always complete, the rate constant k_{obsd} obtained by Eq. 5, was converted to the specific rate constant of the Schiff base (k) with the aid of Eq. 6, which is derived by a combination of Eqs. 1 and 7 as well as an assumption that the amino acid concentration does not change throughout the reaction, *i.e.*, $[AA]_T \simeq [AA]_0$.

$$k_{obsd} = \frac{k \cdot K_{pH} \cdot [AA]_0}{1 + K_{pH} \cdot [AA]_0} \quad (6)$$

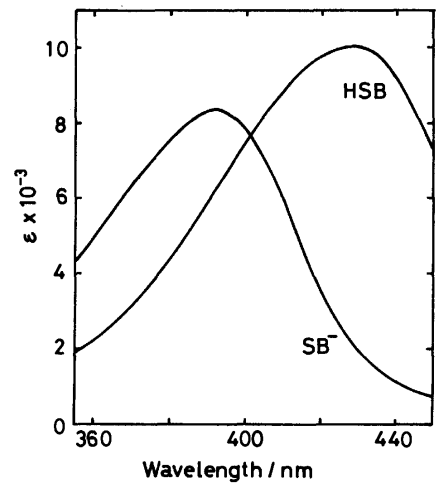


Fig. 1. Electronic absorption spectra of the HSB and SB^- Schiff base of **1a** and phenylalanine in 3 mM CTACl. The trace for HSB was obtained by pH-jump rapid scanning spectroscopy. Details are given under Experimental.

$$\frac{d[PL]_T}{dt} + \frac{d[SB]_T}{dt} + \frac{d[Product]_T}{dt} = 0 \quad (7)$$

β-Elimination of O-Phosphonoserine. Reaction rates were determined by quantitating colorimetrically the inorganic phosphate liberated.[19] A reaction mixture (6 ml) containing 20 mM substrate, 5 mM EDTA and 3 mM CTACl and adjusted to a specified pH value with sodium hydroxide was placed in a constant temperature bath of 40.0 °C. The reaction was started by the addition of 300 μl of **1a** or **1b** solution, the final concentration of the catalyst being 0.50 mM. A 1 ml-aliquot was withdrawn at appropriate time intervals and transferred to a flask containing 1 ml of 3.1 mM sodium tetraphenylborate to precipitate most of the surfactant. A 4 ml-aliquot of molybdate solution, prepared according to Taussky and Shorr,[19] was added and the whole mixture swirled for 1 min. The precipitate was removed by ultrafiltration through a 0.05 μm pore size filter paper (Millipore). The absorbance of the filtrate was read at 720 nm.

Reaction rates (v) were linear with time in the initial stage of the reaction. Combination of a rate equation (Eq. 8) and K_{pH} (Eq. 1) yields Eq. 6′, from which the specific rate constant of the Schiff base (k) is obtained.

$$v = k[SB]_T \quad (8)$$

$$v = \frac{k \cdot K_{pH}[AA]_0 \cdot [PL]_0}{1 + K_{pH} \cdot [AA]_0} \quad (6')$$

Product Analysis. Keto acids produced by transamination of phenylalanine and β-elimination of *O*-phosphonoserine were identified spectroscopically after conversion to their 2,4-dinitrophenylhydrazones. Pyruvic acid was also quantitated by the "coupled assay," in which pyruvic acid is reduced with NADH and lactate dehydrogenase and the remaining NADH is determined by fluorescence spectroscopy.[8] Formation of the pyridoxamine form of **1a** upon transamination with phenylalanine was revealed by an increase in fluorescence intensity at ~438 nm of a reaction mixture.[8] This compound was also confirmed by TLC on silica gel, in which a new ninhydrin-positive fluorescent spot became visible with the progress of reaction.

Results

Schiff Base Formation. The acid dissociation constant (pK_{a1}) of the 3-hydroxyl group of **1a** and **1b** was determined by spectroscopic titrations in water at 30.0 °C as 3.7 or 4.0, respectively. The acid form of either compound possesses an absorption maximum at 296 nm, while the ionized form at 323.5 nm. Whereas the absorption spectrum of **1b** was not affected by SDS or CTACl micelles, the spectrum of **1a** is red-shifted considerably in either micelles. Thus the λ_{max} value of 323.5 nm is shifted to 330.5 and 326 nm in 3 mM CTACl and SDS micelles, respectively. In addition, the pK_{a1} value of **1a** is altered to 2.6 and 4.9 in the CTACl and SDS micelles, respectively. These data indicate that **1a** forms a mixed micelle with the two surfactants.

The equilibrium constant for the Schiff base formation between **1a** or **1b** and amino acid was determined by spectral measurements of solutions that contain varying amounts of amino acid at different pH values.[15] The Schiff base exists over a pH range of 7—11 in two ionic forms, *i.e.*, protonated or ionized with respect to the azomethine group (Scheme 1). The former Schiff base species of **1b** and phenylalanine has a λ_{max} at 416 nm and the latter at 380 nm. The equilibrium constant K defined by Eq. 2 was also determined as 17 M^{-1}. The formation of Schiff base of phenylalanine was enhanced greatly with **1a** in the presence of 3 mM CTACl, but only a single ionic species that has a λ_{max} at 393 nm was discernible in the neutral to alkaline media. This species is likely to be SB^- and the red-shift by 13 nm from that of the corresponding **1b** species is explicable in terms of its location in the micellar phase. The polarity of the micellar environment of the Schiff base was assessed by determining the Schiff base absorption as a function of dioxane concentration in water. As shown in Fig. 2, the λ_{max} shifts to the blue as the dioxane content in the medium is increased. The value of 393 nm in the CTACl micelle corresponds to the polarity of 46% dioxane in water.

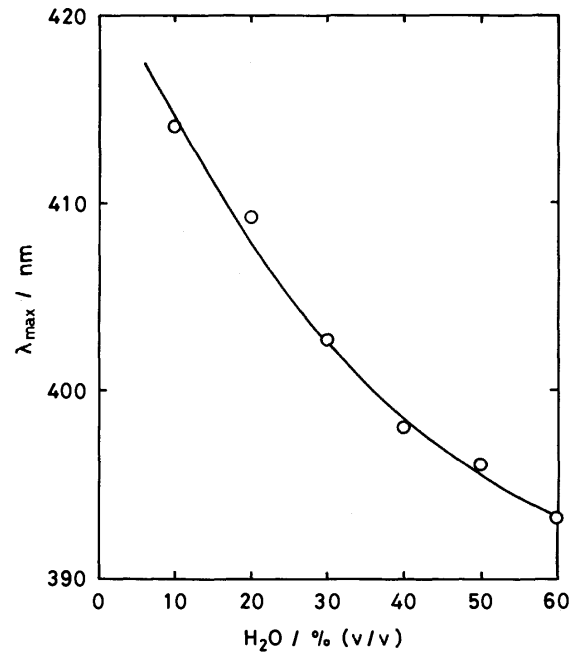

Fig. 2. Relationship of the absorption maximum of SB^- of **1a** and phenylalanine with the water content in dioxane.

The HSB species of the Schiff base of **1a** and phenylalanine in 3 mM CTACl was observed at lower pH values of ≈5. This species possesses an absorption maximum at 430 nm, again shifted to the red by 14 nm from the corresponding Schiff base species of **1b**. Analysis of the spectroscopic data in this pH region yielded the results summarized in Table 1. The equilibrium constant of 21000 M^{-1} is over 1000 times greater than the corresponding value for the **1b** system (17 M^{-1}). Based on the former value, molar distribution of the two Schiff base species of 0.10 mM **1a** and 10 mM phenylalanine is depicted over a broad pH

TABLE 1. EQUILIBRIUM CONSTANTS AND SPECTROSCOPIC DATA FOR THE SCHIFF BASES OF PHENYLALANINE WITH **1a** OR **1b**

Aldehyde	K[a)]/M^{-1}	pK_{a3}[b)]	λ_{max}/nm (ε_{max}/$M^{-1}\cdot cm^{-1}$)	
			HSB	SB^-
1a	21,000	5.0	430(10,000)	393(8,300)
1b	17	8.0	416(8,400)	380(7,900)

a) Defined by Eq. 2. b) For definition see Scheme 1.

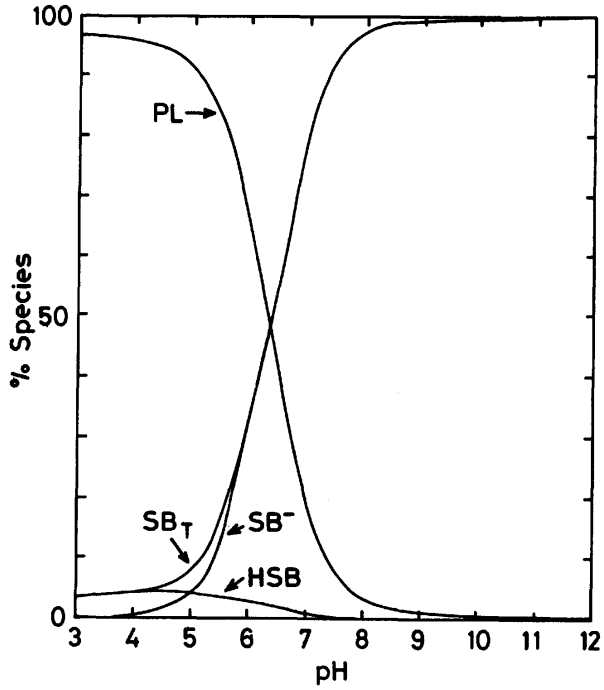

Fig. 3. pH-Distribution profile for HSB and SB^- species of the Schiff base of 0.10 mM **1a** and 10 mM phenylalanine in 3 mM CTACl. The following numerical values are employed: K 21000 M^{-1}; pK_{a1} 2.6; pK_{a2} 8.7; pK_{a3} 5.0.

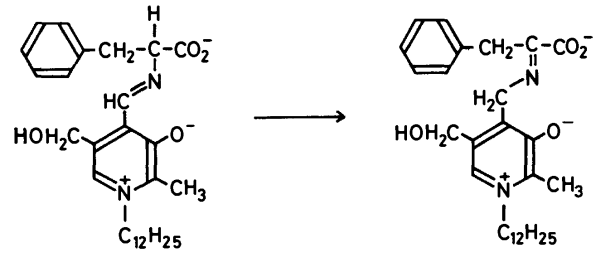
range in the micelle (Fig. 3). The origin of favorable Schiff base formation in this system stems from the hydrophobic interaction of the apolar side chain of amino acid with the micelle. Owing to this interaction a large portion of phenylalanine is partitioned in the micellar phase to form a Schiff base with **1a** residing there. As stated previously,[8] the equilibrium constant is highly dependent on the hydrophobicity of amino acids; the more hydrophobic, the greater is the equilibrium constant. This view is further supported by the fact that equilibrium constants for hydrophilic amino acids such as glutamic acid and *O*-phosphonoserine are comparable with the corresponding values for **1b** or pyridoxal (see below).

One peculiarity encountered in the Schiff base of *O*-phosphonoserine with **1a** in 3 mM CTACl at pH 9 should be worth mentioning. At low amino acid concentrations, the Schiff base formation is observed with a λ_{max} at 387 nm, but further addition of amino acid was not accompanied by a steady build-up of that absorption. Analysis of these spectroscopic data led to a molar extinction coefficient of ≈2000 for SB^- species. The value is quite untenable, as all Schiff bases of pyridoxal and related compounds share a common chromophore which is responsible for the absorption in the visible region with a molar extinction coefficient of 6000—10000.[15-18,20] It is speculated that highly anionic *O*-phosphonoserine may change the micellar structure of CTACl significantly and/or the amino acid may not be partitioned in the micelle to a large extent for some reasons which we are not aware at present. Hence, an extinction coefficient of 7000 was assumed for the SB^- species of *O*-phosphonoserine and this value was used for the evaluation of K_{pH} in the micellar system. The K value for this amino acid is estimated as 7 M^{-1}.

Another point to note is the low pK_a value (5.0) of the Schiff base of **1a** and phenylalanine in the micelle. It is well known that acid dissociation is enhanced at a cationic micellar surface typically by one pH unit (see above), but the change as large as ≈3 pH units cannot be explained by the micellar effect of concentrating hydroxide ions at its surface alone. Since the micellar environment of the Schiff base is less polar (see above), ionization of the iminium proton may be facilitated to generate SB^- species which is electrically neutral with respect to the azomethine group.

Transamination of Phenylalanine. The Schiff base of **1a** formed in 3 mM CTACl micelle undergoes a slow spectral change from 393 to 335 nm.[21] This phenomenon is compatible with transamination of an aldimine into a ketimine, and eventually into its components (Eq. 9). The product analysis supported



(9)

this interpretation. The rate of transamination was determined from the decay of Schiff base absorption at 30.0°C. It should be noted here that as this reaction, like most other nonenzymatic PLP-dependent reactions of amino acids,[3] is accelerated drastically by traces of a metal ion, an appropriate amount of EDTA was supplemented to all reaction solutions to suppress this metal ion effect. The amount of EDTA was decided by the following criteria. The rate obtained in the absence of EDTA was considerably greater than that in its presence because of a metal ion(s) contaminating the reagents used in these experiments, but it was decreased by an incremental addition of the chelator. There is a certain concentration of EDTA beyond which further addition of the reagent brought about no more rate-suppressing effect. At this concentration, addition of 1×10^{-5} M copper(II) or iron(III) ion did not give out any rate acceleration. Hence, the rates

Table 2. Rate constants for the transamination of **1a** with phenylalanine in 3 mM CTACl at 30.0 °C in the presence of 0.10 mM EDTA[a)]

pH	$k_{obsd}\times10^5/s^{-1}$	$k\times10^4/s^{-1}$
4.8	4.07	6.22
5.3	6.63	5.77
5.9	7.10	2.63
8.0	1.39	0.15

a) Rates were determined as described under Experimental and were analyzed with the aid of Eqs. 5 and 6.

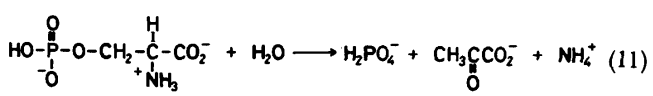
determined in the presence of EDTA represent true rates of the Schiff base, free from metal contamination.

As the Schiff base formation is virtually complete under the present conditions over the pH range 9—11 (Fig. 3), kinetic data were analyzed in terms of a first-order equation with respect to the Schiff base. In cases where the Schiff base formation is incomplete, the determined rate was corrected for with the aid of Eq. 6. The rate constants thus obtained are listed in Table 2. The data were analyzed in terms of different reactivities of the two ionic species of Schiff base involved in the reaction (Eq. 10), where X_{HSB} and X_{SB^-} stand for the

$$k = k_1 \cdot X_{HSB} + k_2 \cdot X_{SB^-} \quad (10)$$

molar fraction of each species. The more acidic species (HSB) has a rate constant $1.33\times10^{-3}\,s^{-1}$ and the other (SB^-) $1.5\times10^{-5}\,s^{-1}$, thus the former is 89 times more reactive. To gain a further insight into the reaction mechanism of this nonenzymatic transamination, kinetic α-deuterium isotope effects of Schiff base have been investigated. The k_H/k_D of 5.1 was obtained for DL-phenylalanine and its α-deuterated counterpart at 30.0 °C and pH 7.7. This value compares with the isotope effect of 9.2 for the transamination of alanine with 4-formyl-3-hydroxy-1-methylpyridinium chloride under similar conditions,[21)] suggesting that α-hydrogen abstraction takes place in the transition state in both reactions.

β-Elimination of O-Phosphonoserine. *O*-Phosphonoserine undergoes β-elimination in the presence of **1b** or **1a**-CTACl (Eq. 11).[11)] The spontaneous reac-



(11)

tion and its CTACl catalysis were negligible under the present reaction conditions, indicating that the β-elimination proceeds via a Schiff base. First, the apparent catalytic efficiency of **1a** and **1b** was compared. The initial rate with **1a** and 3 mM CTACl in the presence of 5 mM EDTA was $6.3\times10^{-8}\,M\cdot s^{-1}$ at pH 9.0 and 40.0 °C, whereas the corresponding value with **1b** was $4.3\times10^{-9}\,M\cdot s^{-1}$, thus the former catalyst being 15 times more effective. The K_{pH} values for **1a** and **1b** at pH 9.0 were 3.8 and 0.5, respectively. Based on these figures, the above rate constants were converted to the specific rate constants of the Schiff base (mainly SB^- species). The numerical values were $1.0\times10^{-3}\,s^{-1}$ for **1a** and $0.9\times10^{-3}\,s^{-1}$ for **1b**, demonstrating that both Schiff bases possess a roughly identical reactivity.

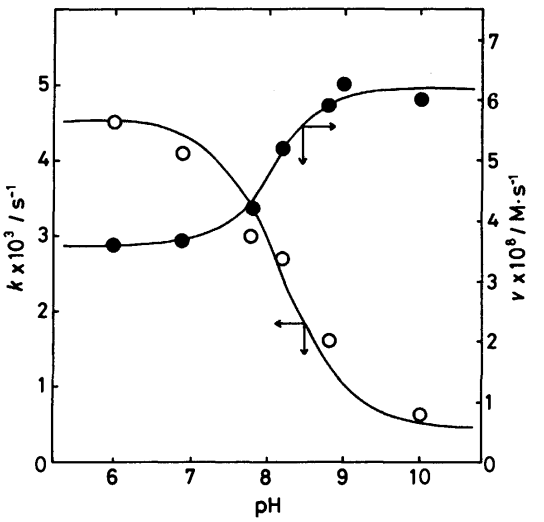


Fig. 4. pH-Rate profiles for the β-elimination of *O*-phosphonoserine in the presence of 0.50 mM **1a** and 5 mM EDTA in 3 mM CTACl at 40.0 °C. Closed circles represent the observed rates and they were converted to the rate constants of the Schiff base with the aid of Eq. 6′ (open circles). The theoretical curve is drawn based on the rate constants 4.6×10^{-3} and $4.2\times10^{-4}\,s^{-1}$ and the acid dissociation constant (pK_{a3}) 8.0.

The pH-dependence of the reaction rates in the presence of **1a** and CTACl is shown with closed circles in Fig. 4. By using the known K_{pH} values, a new pH-rate profile is constructed for the specific rate constant of the Schiff base (open circles and the sigmoid curve connecting them). The sigmoidal curve is interpreted in terms of different reactivities of the two Schiff base species (Eq. 10). The rate constants k_1 and k_2 obtained by this analysis were 4.6×10^{-3} and $4.2\times10^{-4}\,s^{-1}$, respectively. This result of the higher reactivity of HSB is compatible with the following metal ion effect on the elimination. Addition of 0.50 mM copper(II) ion, equimolar to **1a**, brought about a rate increase to $3.0\times10^{-6}\,M\cdot s^{-1}$ at pH 9.0 and 40.0 °C. Supposing that the copper(II) ion forms only a 1:1 Schiff base complex, the specific rate constant of the Cu^{2+}-SB^- species is $7.9\times10^{-2}\,s^{-1}$, 190 times as large as that of SB^-. Since the metal is divalent, it should exert a stronger electron-withdrawing effect, among other effects, than does a proton, thus rendering the α-proton of the Schiff base more labile.

It is also noted that the pK_a of the Schiff base of *O*-phosphonoserine with **1a** (8.0) is much higher than that of phenylalanine, but rather is close to that of phenylalanine and **1b**. This fact and the band location of 387 nm suggest that the Schiff base of *O*-phosphonoserine resides in a micellar domain more polar than that for the Schiff base of phenylalanine.

Discussion

As described above, the present pyridoxal model is

capable of promoting transamination and β-elimination of ordinary amino acids in the absence of metal ions. The reactions are presumed to take place in a mixed micelle of CTACl and **1a**. This view is substantiated by the following observations. The critical micelle concentration of CTACl was estimated as 1.2 mM under the present reaction conditions from an increase in the fluorescence intensity of 8-anilino-1-naphthalenesulfonic acid (ANS). A similar transition in the fluorescence intensity of ANS was found to occur at 0.16 mM CTACl in the presence of 0.10 mM **1a**, suggesting that the latter enhances the micellar aggregation of the former. The notion that **1a** and its Schiff base reside in the apolar micellar phase is supported by the large red-shift of their absorption bands and by the change in their pK_a (see Results). A large proportion of hydrophobic amino acids such as phenylalanine is partitioned in the micelle, thereby enhancing the Schiff base formation with **1a** residing there. This in turn is responsible for the facile transformation of the resulting Schiff base.

In addition to the enhanced Schiff base formation, this system has one more advantage in exploring pyridoxal-dependent reactions. Owing to the *N*-substitution in **1a**, the number of Schiff base species derived therefrom is limited (usually two, if we ignore acid dissociation of an amino acid side chain) over the wide pH range. These two are present in fair amounts under the condition of kinetic experiments, provide distinctly different absorption spectra and their reactivities can be assessed precisely. Based on the kinetic analysis of the transamination of phenylalanine and β-elimination of *O*-phosphonoserine, it is concluded that HSB, protonated at the azomethine group, is more reactive than SB^-.[22] This result is understandable in view of the fact that the primary role of PLP is to play as an electron sink[1-3] and that an electron-withdrawing ability of the Schiff base is greater when it bears more net positive charges. Others, however, dealing with similar data provided an opposite interpretation.[23] The reason for this discrepancy is not known.

This finding may be relevant to the enzymatic PLP catalysis. Absorption bands similar to that for the HSB species of **1a** and amino acid (430 nm) are obtained for some of the PLP-dependent enzymes.[24-26] This band location is characteristic for a Schiff base carrying a proton on the azomethine nitrogen. Whether or not the Schiff base bears a proton on the pyridine nitrogen cannot be decided, as the two forms of the Schiff base provide quite similar spectra.[16] Nonetheless, the fact that the *N*-substituted form is more reactive than the unsubstituted Schiff base[21,22] suggests that enzyme-bound PLP might carry a proton on the nitrogen, which is donated by an acidic group of the active site. This idea is supported by the recent crystallographic data on aspartate aminotransferase, in which the nitrogen of enzyme-bound PLP is hydrogen-bonded by an aspartate residue from the active site.[27,28] It is, hence, tempting to conclude that both the ring and azomethine nitrogen of the Schiff base need be protonated for PLP to perform its function of facilitating an electronic shift from the amino acid portion.

A general base catalysis as well as the general acid catalysis discussed above may be responsible for the high efficiency of the coenzyme in the enzymatic systems. The group involved in this function is the lysine amino moiety that binds PLP in the absence of a substrate.[5,6] A similar mode of base catalysis was observed in nonenzymatic systems also.[4,7] By analogy, hydroxide ions concentrated on the cationic micellar surface are a potential candidate to serve as a base catalyst.[8,9] Whether such a mechanism is working or not in the present system remains to be proven in the future. The fact that the α-deuterium isotope effect obtained in the micellar system is smaller than that for the nonmicellar reaction may provide a clue to solve this problem. At any rate, incorporation of a "powerful" base in our system should enhance the reactivity of the catalyst and further work is being continued along this line in this laboratory.

The authors are grateful to Professor Y. Murakami of Kyushu University for the use of his rapid scanning spectrophotometer. They also thank Dr. K. Sakata of Kyushu Institute of Technology for measuring mass spectra. This work was supported by a Grant-in-Aid for Special Project Research 57102007 from the Ministry of Education, Science and Culture, and by a grant from the Saneyoshi Scholarship Foundation.

Selective Hydrogenation of Cyclooctadienes Using Colloidal Palladium in Poly(*N*-vinyl-2-pyrrolidone)

Hidefumi HIRAI,* Hitoshi CHAWANYA, and Naoki TOSHIMA
Department of Industrial Chemistry, Faculty of Engineering, The University of Tokyo, Hongo, Bunkyo-ku, Tokyo 113
(Received September 10, 1984)

Selective hydrogenation of 1,3-, 1,4-, and 1,5-cyclooctadiene to cyclooctene was carried out at 30 °C under atmospheric hydrogen pressure using colloidal palladium which was prepared by reducing palladium(II) chloride with refluxing methanol in the presence of poly(*N*-vinyl-2-pyrrolidone). The yields of cyclooctene were 99.9% and 97.8% for hydrogenation of 1,3- and 1,5-cyclooctadiene, respectively at the point that an equimolar hydrogen was uptaken by cyclooctadienes. The hydrogenation rate of 1,3- and 1,4-cyclooctadiene (R_1) is expressed as $R_1=k_1[H_2][Pd]$, and that of 1,5-cyclooctadiene (R_2) is expressed as $R_2=k_2[H_2]^{0.7}[Pd]$, where k_1 and k_2 are the rate constants. Alcohols were found to be good solvents for hydrogenation. In particular the fastest rate and the highest selectivity for monoene were observed in methanol among the solvents examined. Effect of bases on the monoene selectivity has also been investigated.

There have been numerous attempts to prepare highly dispersed metal catalysts supported on inorganic materials such as silica, alumina, and active carbon. Dispersion of the metal plays an important role in exhibiting high activity and selectivity of the catalyst.

On the other hand there are relatively little studies on colloidal metals homogeneously dispersed in a liquid phase. Rampino and Nord[1,2] reported that a colloidal dispersion of palladium with an average diameter of 700 Å was prepared by reducing aqueous palladium(II) hydroxide with molecular hydrogen in the presence of poly(vinyl alcohol).

Recently the present authors reported that colloidal noble metals were formed in good reproducibility by reducing the corresponding metal salts with primary or secondary alcohols or ethers in the presence of water-soluble vinyl polymers.[3,4] These colloidal metals were found to have smaller particle sizes (average particle diameters of 10—53 Å), and narrower particle size distributions than those prepared by reduction with molecular hydrogen. During the investigation of catalytic activity of the colloidal dispersions of noble metals, we have found that colloidal palladium prepared by reduction of palladium(II) chloride with methanol in the presence of poly(*N*-vinyl-2-pyrrolidone) catalyzes partial hydrogenation of cyclopentadiene,[5] and methyl esters of unsaturated fatty acid[6] to the corresponding monoenes. In the present paper we describe the selective hydrogenation of three isomers of cyclooctadiene to cyclooctene with the colloidal plladium.[7]

Experimental

Materials. Poly(*N*-vinyl-2-pyrrolidone) K-90 (Tokyo Chemical Industry Co. Ltd.; degree of polymerization, 3200) and palladium(II) chloride ($PdCl_2$) were used without further purification. 1,5-Cyclooctadiene, 1,3-cyclooctadiene, and cyclooctene were distilled under nitrogen before use. 1,4-Cyclooctadiene was prepared from 1,3-cyclooctadiene by bromination followed by reduction according to the literature.[8] All solvents were distilled and stored under nitrogen. Extra pure grade hydrogen (Nippon Oxygen Co. Ltd.; 99.99999% of purity) was passed through a Deoxo column (Nippon Engelhard, Ltd.) before use to remove trace amounts of oxygen. A commercial palladium catalyst used for comparison was 5% palladium on active carbon (Pd-C, Nippon Engelhard, Ltd.; surface area of Pd, 200 m^2/g-Pd).

Preparation of Colloidal Dispersion of Palladium. All manipulations were carried out under nitrogen atmosphere, using the solvents which were deaerated by purging with nitrogen.

Pd-PVP-MeOH/NaOH: Palladium(II) chloride (5.9 mg, 0.033 mmol) was dissolved in methanol (25 cm^3) by stirring the mixture overnight. Poly(*N*-vinyl-2-pyrrolidone) (151 mg, 1.36 mmol of monomeric units) was dissolved in methanol (20 cm^3). The combined mixture of these two solutions was gently heated with a water bath and brought to reflux. After the solution was refluxed for 30 min, a solution of sodium hydroxide (6.6 mg, 0.17 mmol) in methanol (5 cm^3) was added dropwise to the refluxing solution. The solution was refluxed for further 10 min to give a homogeneous dark brown dispersion of colloidal palladium protected by poly(*N*-vinyl-2-pyrrolidone).

Pd-PVP-MeOH/H_2O: A solution of palladium(II) chloride (5.9 mg) in methanol (25 cm^3) was combined with a solution of poly(*N*-vinyl-2-pyrrolidone) (151 mg) in water (25 cm^3). The mixed solution was refluxed over a water bath for 4 h, resulting in dark brown colloidal dispersion of palladium protected by poly(*N*-vinyl-2-pyrrolidone).

Electron Microscopy and Particle Size Determination. The sample film was prepared by evaporating a small amount of the colloidal dispersion of palladium to dryness on a collodion film which was coated with a carbon layer. The electron micrographs were taken at 100 kV at a magnification of 100000. The diameters of 200—900 particles of palladium in an arbitrarily chosen area were measured in an enlarged (4.4×) photograph. The particle size distribution and the number average particle diameter were determined on the basis of these results.

Hydrogenation of Cyclooctadienes. The reaction flask immersed in a thermostated water bath (30 °C) was evacuated and then flushed with hydrogen for 3—4 times. A solvent [(19−x) ml] and a colloidal dispersion of palladium (x ml) was then introduced into the flask and the mixed solution was stirred for 1 h to be saturated with hydrogen. A substrate diluted with a solvent for hydrogenation (1 cm^3) was injected into the reaction flask to start the reaction. Hydrogen uptake under a constant atmospheric pressure was monitored with a gas burette. Initial rates of hydrogenation (in H_2 mol/

Pd mol s) were calculated from the initial rates of hydrogen uptake.

The product was analyzed by GLPC with a flame ionization detector using helium as a carrier gas and a 30 m× 0.28 mmϕ glass capillary column coated with Silicone OV-101 at 55 °C

Kinetic Measurements. Initial rates of hydrogenation of cyclooctadienes with the colloidal palladium (Pd-PVP-MeOH/NaOH) were measured as a function of catalyst concentration, substrate concentration, and hydrogen pressure. Standard conditions are as follows: catalyst concentration=0.01 mmol dm^{-3} (0.1 mmol dm^{-3} for 1,5-cyclooctadiene), substrate concentration=25 mmol dm^{-3}, and hydrogen pressure=728 Torr (1 Torr≈133.322 Pa). Each variable was changed over the following range: catalyst, 0.002—0.01 mmol dm^{-3} (0.02—0.1 mmol dm^{-3} for 1,5-cyclooctadiene); substrate, 5—50 mmol dm^{-3}; hydrogen pressure, 180—728 Torr. The dependence of the rate on hydrogen pressure was measured in mixed gases of hydrogen and nitrogen at 1 atm. The concentration of hydrogen in the solution was determined from the partial pressure of hydrogen using Henry's law.

Under these reaction conditions, the hydrogenation rates were independent of the stirring rates of magnetic stirrers. Thus the reactions were not mass transfer limited.

Results

Preparation of the Colloidal Dispersion of Palladium. Palladium(II) chloride and poly(*N*-vinyl-2-pyrrolidone) were dissolved in methanol to form a yellow solution. After the solution was refluxed for 30 min, a methanol solution of sodium hydroxide was added to the refluxing solution, which caused a color change of the solution to dark brown. Further refluxing for 10 min gave a dark brown homogeneous dispersin of colloidal palladium, abbreviated as Pd-PVP-MeOH/NaOH.

When methanol/water (1/1, v/v) was used as a solvent instead of methanol in the case mentioned above, reduction of palladium ions took place even without addition of sodium hydroxide, resulting in a colloidal dispersion, Pd-PVP-MeOH/H_2O.

Electron micrographs of these colloidal dispersions (Figs. 1 and 2) show formation of well-dispersed palladium particles ranging from 10 to 120 Å in diameter. More than 98% of the particles in the colloidal dispersion, Pd-PVP-MeOH/NaOH, had a diameter below 30 Å, and the average diameter was determined to be 18 Å from the micrograph. In the colloidal dispersion of Pd-PVP-MeOH/H_2O 92% of the particles had a diameter below 30 Å, and the average diameter was determined to be 23 Å.

These colloidal dispersions were so stable that no precipitates of palladium metal appeared and the catalytic activities were unchanged after storing the dispersions under air for a year.

Hydrogenation of Cyclooctadienes. The colloidal palladium, Pd-PVP-MeOH/NaOH, was effective as a catalyst for hydrogenation of 1,3-, 1,4-, and 1,5-cyclooctadiene at 30 °C under atmospheric hydrogen pressure. As shown in Table 1, the hydrogenation rate for

1,3-cyclooctadiene is the fastest among cyclooctadienes and the rate decreases in the order: 1,3-, 1,4-, and 1,5-isomer. For hydrogenation of 1,5-cyclooctadiene the colloidal palladium showed almost the same catalytic activity as that of 5% Pd-C. Typical curves of hydrogen uptake against time are shown in Fig. 3. In hydrogenation of 1,3-cyclooctadiene the rate of hydrogen uptake is very rapid until the amount of hydrogen uptake become equimolar to the charged amount of diene. At this point, however, the rate suddenly decreases

Table 1. Hydrogenation of cyclooctadienes with colloidal palladium[a)]

to 1/570 of the initial rate. The conversion of 1,3-cyclooctadiene was complete at this point and cyclooctene was produced in a 99.9% yield.

In hydrogenation of 1,5-cyclooctadiene (curve b) the change in the rate at an equimolar hydrogen uptake is rather small compared with the case of 1,3-cyclooctadiene (curve a). The yield of cyclooctene is 97.8% in hydrogenation of 1,5-cyclooctadiene. This value is considerably higher than that in the hydrogenation with 5% Pd-C (94.3%).

Initial hydrogenation rate of cyclooctene with colloidal palladium was 1/20 of that of 1,5-cyclooctadiene, and was almost the same as the rate of the second stage (after equimolar hydrogen uptake) in hydrogenation of the diene.

Formation of 1,4-cyclooctadiene in the early stage of hydrogenation of 1,5-cyclooctadiene (shown in Fig. 4) indicates that the hydrogenation is accompanied by isomerization. No other hydrogenated product than cyclooctene is observed at the initial stage of the reaction. Cyclooctane is produced after consumption of most diene.

No isomerization occurred when a methanol solution of 1,5-cyclooctadiene and the colloidal dispersion of palladium was stirred under nitrogen.

1,4-Cyclooctadiene is hydrogenated at 3.3 times the rate of hydrogenation of 1,5-cyclooctadiene (Table 1). While, in hydrogenation of equimolar mixture of 1,4- and 1,5-cyclooctadiene, initial rate of consumption of 1,4-cyclooctadiene is only 1.3 times that of 1,5-cyclooctadiene as shown in Fig. 5.

Kinetics of Hydrogenation of Cyclooctadiene. Initial rates of hydrogenation of 1,3-, 1,4-, and 1,5-

cyclooctadiene were measured as a function of catalyst concentration, substrate concentration, and hydrogen pressure. The rate for 1,3- and 1,4-cyclooctadiene increased linearly with increasing catalyst concentration and hydrogen pressure, and were independent of substrate concentration. Thus, the rate, R, is expressed in the following form:

$$R = k_1[H_2][Pd] \quad (1)$$

where k_1 is a rate constant. The value of k_1 was determined to be 4.86×10^3 and 1.06×10^3 dm^3 mol^{-1} s^{-1} for 1,3- and 1,4-cyclooctadiene, respectively.

The rate of hydrogenation of 1,5-cyclooctadiene increased linearly with increasing catalyst concentration and was independent of substrate concentration. However, dependence on hydrogen pressure deviated from linear relationship. The hydrogenation rate, R, is expressed in the following form:

$$R = k_2[H_2]^{0.7}[Pd] \quad (2)$$

where k_2 is a rate constant.

Effects of Solvents. Hydrogenation of 1,5-cyclooctadiene with colloidal palladium, Pd-PVP-MeOH/NaOH, was carried out using various solvents, as listed in Table 2. For the experiments in solvents without methanol, methanol used for the preparation of the colloid was evaporated under vacuum, and then resulting residues were re-dissolved in the solvent for hydrogenation. Catalytic activity of the colloidal palladium was confirmed not to change by the treatment of evaporation and re-dissolution.

The highest rate of hydrogenation was observed in methanol. In ethanol and 1-propanol the rates were found to be a little lower than that in methanol, but selectivities for formation of monoene were almost the same.

Colloidal palladium protected by poly(N-vinyl-2-pyrrolidone) was insoluble in ethyl acetate and tetrahydrofuran, but it became soluble in the presence of a small amount of methanol. In these mixed solvents hydrogenation rate and selectivity are considerably lower than those in methanol.

Table 2. Effect of solvents on hydrogenation of 1,5-cyclooctadiene[a)]

Solvent (cm^3)	r[b)]	Product composition/%[b)]			
	s^{-1}	1,5-COD	1,4-COD	COE	COA
Methanol(20)[c)]	1.6	0.5	0.4	96.6	2.5

Ethyl acetate(17) /Methanol(3)	0.4	5.7	2.1	89.6	2.6
Tetrahydrofuran(17) /Methanol(3)	0.2	1.3	0.9	94.0	3.8

a) Hydrogenation conditions: temperature 30 °C; total pressure: 1 atm; [Pd]=0.1 mmol dm^{-3}; [COD]=25 mmol dm^{-3}; catalyst, Pd-PVP-MeOH/NaOH. b) Abbreviations: See legend of Table 1. c) The catalyst solution was evaporated and re-dissolved in the hydrogenation solvent.

Effects of Additives. As mentioned above, colloidal palladium, Pd-PVP-MeOH/NaOH, exhibits considerably higher selectivity for formation of monoene than a Pd-C catalyst. Difference in sizes of palladium particles and interaction between palladium and the protective colloid have been considered to play important roles in exhibiting high selectivity of the colloidal palladium.[5,6] In addition, base added in preparation of the colloidal palladium (Pd-PVP-MeOH/NaOH) may have some effect on the selectivity. In order to clarify this effect, hydrogenation of 1,5-cyclooctadiene was carried out in the presence of additives using colloidal palladium, Pd-PVP-MeOH/H_2O, as a catalyst. In Fig. 6 the yield of cyclooctene is plotted against the degree of hydrogenation which is calculated as [(yield of cyclooctene)+(yield of cyclooctane)×2]. In the absence of additives the yield of cyclooctene reaches a maximum value of 95—96%, which is smaller by 2% than one with the base-added colloid (Pd-PVP-MeOH/NaOH).

On addition of sodium hydroxide the yield of cyclooctene over the Pd-PVP-MeOH/H_2O catalyst increased by 0.7% at a degree of hydrogenation of 95—100%. The yield of cyclooctene also increased by addition of triethylamine instead of sodium hydroxide, while it did not change by addition of sodium chloride or hydrochloric acid.

Addition of hydrochloric acid into the solution for hydrogenation with the colloid prepared by addition of base (Pd-PVP-MeOH/NaOH) decreased the yield of cyclooctene from 96.5% to 94.5% at the degree of hydrogenation of 100%.

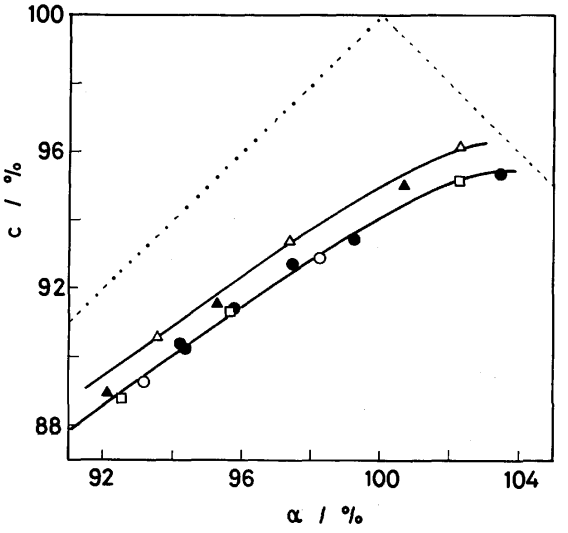

Fig. 6. Effect of additives on the hydrogenation of 1,5-cyclooctadiene with Pd-PVP-MeOH/H_2O. Yield of cyclooctene (c) is plotted as a function of degree of hydrogenation (α). The dotted line shows the yield of cyclooctene at the complete selectivity. [Pd]=0.1 mmol dm^{-3}; [1,5-COD]=25 mmol dm^{-3}. Amount of additives=10 μmol; additives: ●: none, △: NaOH, □: HCl, ▲: Et_3N, ○: NaCl.

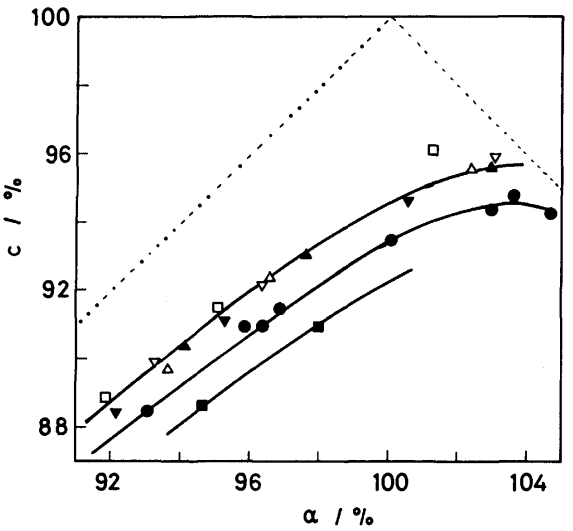

Fig. 7. Effect of additives on the hydrogenation of 1,5-cyclooctadiene with Pd-C catalyst. Yield of cyclooctene (c) is plotted as a function of degree of hydrogenation (α). Pd-C, 4.3 mg; [1,5-COD]=25 mmol dm^{-3}. Additives (amount in μmol): ●: None, △: NaOH(10), ▽: NaOH(20), □: NaOH(40), ▲: KOH(10), ▼: Et_3N(10), ■: HCl(10).

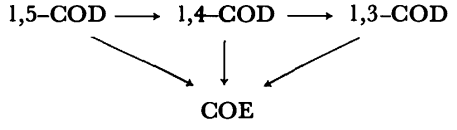
Effects of Additives on the Hydrogenation with Pd-C. Effects of addition of base and acid in the hydrogenation with 5% Pd-C are illustrated in Fig. 7. In the absence of additives the yield of cyclooctene reaches a maximum value of 94—95% at a degree of hydrogenation of 104%. This value in yield is smaller by 3% than that with the base-added colloid and by 1% than that with the water-added colloid.

The yield of cyclooctene increased by 1% on addition of a base such as sodium hydroxide, potassium hydroxide, and triethylamine, but decreased by 1% on addition of hydrochloric acid.

Discussion

Selectivity for the Formation of Cyclooctene. In the first stage of hydrogenation of 1,5-cyclooctadiene with the colloidal palladium, Pd-PVP-MeOH/NaOH, hydrogenation of cyclooctene to cyclooctane was inhibited and cyclooctene was produced in a high yield. However, after most of the diene was consumed, hydrogenation of cyclooctene occurred at an appreciable rate. This fact strongly suggests that adsorption of diene on the catalytic site is much stronger than that of monoene, and thus the adsorption of monoene is completely suppressed in the presence of diene.

Formation of 1,4-cyclooctadiene in hydrogenation of 1,5-cyclooctadiene (Fig. 4) shows that this reaction occurs with accompanying isomerization of nonconjugated dienes to conjugated diene as follows (COD, cyclooctadiene; COE, cyclooctene):



1,3-Cyclooctadiene was not detected in the reaction mixtures, probably because the rate of hydrogenation of 1,3-cyclooctadiene was much higher than that of the isomerization of 1,4-cyclooctadiene to 1,3-cyclooctadiene.

The yield of cyclooctene in hydrogenation of 1,5-cyclooctadiene was 97.8% with the colloidal palladium, and 94.2% with Pd-C. This difference in selectivity is relatively small compared with that in the hydrogenation of cyclopentadiene, in which the yield of cyclopentene is 98.7% with colloidal palladium and 82.6% with Pd-C.[5] Relatively high selectivity for cyclooctene formation in the hydrogenation of 1,5-cyclooctadiene with Pd-C may be explained by the considerably small hydrogenation rate of cyclooctene. Unusually low hydrogenation rate of cyclooctene has also been reported by Jardine *et al.*, and was related to the lower heat of hydrogenation due to the severe transannular interactions in cyclooctane.[8]

In hydrogenation of equimolar mixtures of 1,4- and 1,5-cyclooctadiene, 1,4-cyclooctadiene was consumed 1.3 times as fast as 1,5-cyclooctadiene. These rates of consumption of 1,5- and 1,4-cyclooctadiene were 0.85 and 0.3 times of the rate of the separate hydrogenation, respectively. Large inhibition effect of 1,5-cyclooctadiene in the hydrogenation of 1,4-cyclooctadiene indicates that the adsorption of 1,5-cyclooctadiene on the catalyst is stronger than that of 1,4-cyclooctadiene.

Kinetics of Hydrogenation of Cyclooctadienes. Zero order with respect to substrate and positive order with respect to hydrogen indicate that diene is more strongly adsorbed on the surface of catalysts than hydrogen, and consequently the surface coverage of diene is larger than that of hydrogen.

Dependence of the rate on the hydrogen pressure was the first order in the hydrogenation of 1, 3- and 1, 4-cyclooctadiene, but deviated from the first order in the hydrogenation of 1,5-cyclooctadiene. This divergence from linear relationship can be associated with the extent of accompanying isomerization. As shown in Fig. 4, the yield of 1,4-cyclooctadiene reaches the maximum value of 12% in hydrogenation of 1,5-cyclooctadiene at the hydrogen pressure of 728 Torr. As the hydrogen pressure was decreased from 728 to 371 Torr, the maximum value increased from 12 to 15%. This fact indicates that the proportion of the diene hydrogenated *via* the isomerization to 1,4-isomer increased by decreasing hydrogen pressure.

Effect of Additives. In the hydrogenation with the water-added colloid (Pd-PVP-MeOH/H_2O), selectivity for monoene incrcased by addition of sodium hydroxide and triethylamine. On the other hand, the selectivity decreased by addition of hydrochloric acid in the hydrogenation with the base-added colloid (Pd-PVP-MeOH/NaOH). These results suggest that hydroxide ion have some effects on the selectivity. In accordance with this assumption, addition of sodium

chloride had no effect on the selectivity. Similar effects of addition of bases were also observed with Pd-C. This suggests that bases affect the selectivity not through changes in the state of polymer which protects colloidal palladium, but through direct interactions between palladium metals and hydroxide ions.

McQuillin *et al.* have reported that hydrogenation of 2-butyne-1,4-diol, 2-butene-1,4-diol, and mesityl oxide over Pd-C in ethanol was retarded by the addition of a base such as potassium hydroxide.[9] The effect of base on the monoene selectivity in the present study is also interpreted in terms of inhibition effect of base. As a hydroxide ion is more strongly adsorbed on the catalytic site than monoene, but more weakly is than diene, addition of the ion may inhibit the adsorption of monoene more strongly than that of diene. As a result, monoene selectivity is enhanced with the addition of a base.

By the way discussed above, the base added in preparation contributes to the high selectivity of the base-added colloid (Pd-PVP-MeOH/NaOH). Other factors for the high selectivity may involve the particle size of the palladium particles and the interaction between palladium and the polymer or the support. Thus, in the hydrogenation of cyclopentadiene, the selectivity increased with decreasing size of palladium particles, and with addition of poly(*N*-Vinyl-2-pyrrolidone) to Pd-C and Pd-black.[5]

The difference in activity with solvents (Table 2) is also interpreted by the adsorption of solvent molecules on catalytic sites. On the palladium catalyst, hydrocarbon groups have been reported to be adsorbed more strongly than oxygen atoms.[10] Higher alcohols, ethyl acetate, and tetrahydrofuran act as a kind of inhibitor because of a large portion of hydrocarbon groups in a molecule. Thus, the hydrogenation rate is relatively slow in these solvents. The high hydrogenation rate in methanol can be due to a small hydrocarbon group of methanol and, therefore, a weak inhibiting character of methanol.

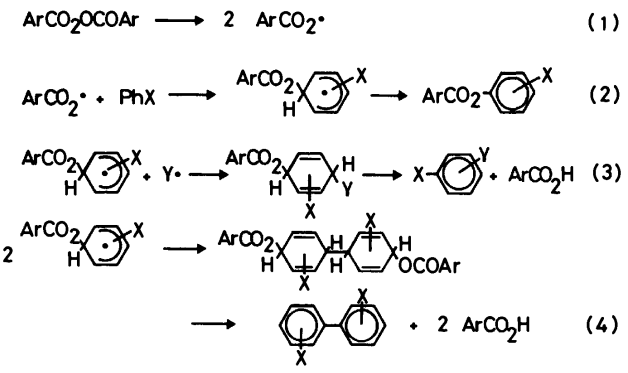
(Received September 25, 1984)

Photolyses of bis(2-thiophenecarbonyl) peroxide (TPO) in benzene and toluene afforded, among free-radical products, biphenyl and dimethylbiphenyls, respectively, which were solely derived from the aromatic solvents. The yields of biphenyls depended upon the rate with which the radical intermediates were generated from the peroxides in sufficiently high concentrations for their dimerization. Photolyses of TPO and dibenzoyl peroxide in 1,3,5-trimethylbenzene afforded also a solvent-derived product, 2,3′,4,5′,6-pentamethyldiphenylmethane. Its formation provides clear evidence for participation of cyclohexadienyl radicals bearing the aroyloxyl group on the methyl-substituted ipso carbon atom.

Aroyloxyl radicals, when generated in aromatic solvents, reversibly add to the solvents to produce aroylcyclohexadienyl radicals,[1,2] which are intercepted by a suitable oxidant to give aryl esters,[3,4] and also undergo recombination with other radicals followed by elimination of arenecarboxylic acid to give arylation products.[5,6] Dimerization of the cyclohexadienyl radicals[7] and subsequent elimination of two moles of the arenecarboxylic acid could be the course leading to biphenyls on decomposition of diaroyl peroxides in aromatic solvents. However, usually in benzene which has been employed as one of "inert" solvents, photochemical and free-radical reactions do not give biphenyl. On photochemical decomposition of bis(2-



thiophenecarbonyl) peroxide (TPO) in aromatic solvents, we have found some remarkable features of the reactions of the aroylcyclohexadienyl radicals; 1) in benzene biphenyl was formed in a noticeable yield, particularly at low temperatures,[8] 2) in toluene among the possible dimethylbiphenyls 2,3′- and 3,3′-dimethyl isomers were formed together with a small amount of 2,2′-dimethyl isomer, and 3) in 1,3,5-trimethylbenzene 2,3′,4,5′,6-pentamethyldiphenylmethane was formed in a considerable yield.[9] In this paper we wish to report some new aspects of reactivities of aroyloxyl radicals with aromatic solvents and the role of ipso intermediates in the reaction.

Results

Photolysis and Thermolysis of Bis(2-thiophenecarbonyl) Peroxide in Benzene. Effects of Light Intensity and Temperature. Bis(2-thiophenecarbonyl) peroxide (TPO, 0.03 mol/dm^3) was irradiated at varying temperatures (5—60 °C) in benzene (3 cm^3) under argon and oxygen atmosphere for five times half-life periods with 313 nm light of varying intensities from a 400 W high pressure mercury lamp through a filter (85 min) or from a 1 kW high pressure mercury lamp directly (20—30 min), or with 337.1 nm laser pulses from a nitrogen laser (80 Hz, 20—30 min). TPO (0.03 mol/dm^3) was also heated in benzene at 80 °C for 2880 min (5 times half-life period) under degassed conditions. The products were determined quantitatively by GLPC except carbon dioxide, which was determined by gravimetry using an Ascarite tube. The results are summarized in Table 1.

TPO (0.03 mol/dm^3) was photolyzed in a mixture (400 cm^3) of varying fractions of benzene and styrene (1:0 to 3:1 by volume) in a nitrogen stream. The carbon dioxide evolved was absorbed with an Ascarite tube and determined by gravimetry. The results are summarized in Table 2 and depicted in Fig. 1.

Spin Trapping of 2-Thiophenecarbonyloxyl Radicals in Photolysis and Thermolysis of TPO. A solution of TPO (0.01 mol/dm^3) containing *N*-benzylidene-*t*-butylamine oxide (0.1 mol/dm^3) was irradiated at room temperature with a 1 kW high pressure mercury lamp or heated at 80 °C for several minutes in the cavity of an ESR spectrometer. The photolysis and thermolysis resulted in the same ESR signals (a_N=1.35 mT) attributable to the 2-thiophenecarbonyloxy spin adduct, *N*-{phenyl(2-thiophenecarbonyloxy)methyl}-*t*-butylaminyloxyl.[10,11]

Trimethylbenzene. Temperature Effects on Product Yields. TPO (0.03 mol/dm^3) was irradiated in 1,3,5-trimethylbenzene (TMB, 3 cm^3) at varying temperatures (20—70 °C) under nitrogen with 313 nm light, and the products were determined by GLPC. The results are summarized in Table 6 and depicted in Fig. 2. Dibenzoyl peroxide (BPO, 0.03 mol/dm^3) was similarly photolyzed in TMB at varying temperatures (5—65 °C), and the results are summarized in Table 7 and depicted in Fig. 2. Thermolyses of TPO and BPO were carried out at 80 °C in TMB under deaerated and aerated conditions. Table 8 lists the results.

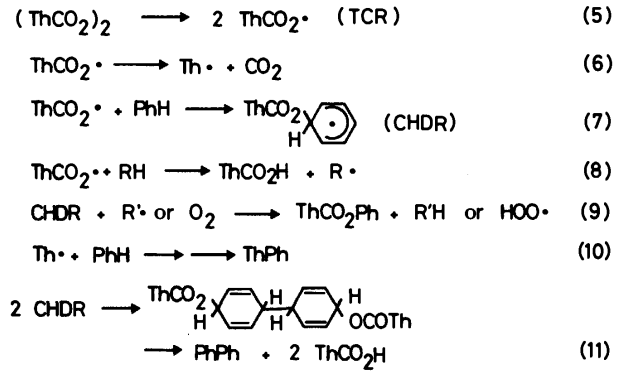
for cyclohexadienyl radicals derived from addition of formyloxyl radicals to toluene, anisole, and 1,3,5-trimethylbenzene by the MINDO/3 method[12] on a FACOM M-200 system. First, the structure of the unsubstituted cyclohexadienyl radical was optimized under C_{2v} constraint.[13] Then, by using this optimized planar ring structure, 6-formyloxycyclohexadienyl and 6-formyloxy-6-methylcyclohexadienyl radicals were optimized. Here, the formyloxyl group was fixed to the conformations for the C–O single bond in which the cyclohexadienyl group and carbonyl oxygen are cis and the carbonyl and *O*-cyclohexadienyl bonds are coplanar, since esters, in general, prefer strongly such a conformation.[14,15] Finally, based on these conformations, the total energies, relative energies, and spin densities of the ipso- and non-ipso-substituted cyclohexadienyl radicals were determined. The results are shown in Figs. 3 and 4. The total energy of the formyloxy-substituted cyclohexadienyl radicals decreases in the order of ipso, ortho, meta, and para isomers. The energy difference between the ipso- and ortho(non-ipso)-substituted cyclohexadienyl radicals is 7.8kcal/mol in the case of 1,3,5-trimethylbenzene, which is the smallest value among the substituted benzenes employed. The difference of energies among the substituted cyclohexadienyl radicals increases in the order of trimethyl-, methyl-, and methoxy-substitution.

Discussion

Mechanism for Formation of Biphenyls. As Table 1 shows, most of the products from the photolysis of TPO in benzene are the same as those from its thermolysis,[16] and their production can be understood in terms of the conventional free-radical pathways.[1,2] The following scheme shows the formation processes of the products except biphenyl; TPO is thermally or photochemically decomposed to give 2-thiophenecarbonyloxyl radicals (TCR) (Eq. 5), which decarboxylate to give 2-thienyl radicals (TR) and carbon dioxide (Eq. 6), add to benzene to give cyclohexadienyl radicals (CHDR) (Eq. 7),[3] or abstract a hydrogen atom to give 2-thiophenecarboxylic acid (TCA)(Eq. 8). CHDRs are oxidized by radicals or oxygen to give phenyl 2-thiophenecarboxylate (Eq. 9). TRs add to benzene to give finally 2-phenylthiophene (Eq. 10).



Scheme 1.

The production of biphenyl is noticeable, since decomposition of various types of radical generators except for phenyl radicals in benzene has never given such a high yield of biphenyl.[1,2] Biphenyl is not produced from phenyl radicals which could be formed from the reaction medium, since chlorobenzene was not detected in the photolysis of TPO in the presence of carbon tetrachloride as a phenyl radical scavenger in contrast with irradiation of benzophenone under similar conditions (Table 3). The formation of biphenyl in the photolysis of TPO in benzene can be reasonably understood by the following scheme; CHDRs generated from addition of TCRs to the solvent benzene undergo dimerization into tetrahydrobiphenyl derivatives[7] followed by elimination of two moles of thiophenecarboxylic acid (Eq. 11). This mechanism is supported by the results of photolyses carried out under oxygen atmosphere which gave phenyl 2-thiophenecarboxylate in a much higher yield than under argon atmosphere at the expense of biphenyl (Table 1).

Efficient production of biphenyl requires that TCRs effectively add to benzene, in competition with decarboxylation, to give CHDRs. This is in contrast with other kinds of aroyloxyl radicals which fail in production of biphenyl in benzene.[1,2] Reluctance of TCR to decarboxylation can be seen in a much lower yield of carbon dioxide (*ca.* 0.3 mol/mol TPO in Table 1) in benzene than from other diaroyl peroxides such as BPO (1.4 mol)[10] and in the efficient formation of the acyloxy spin adduct in the photolysis and thermolysis of TPO in the presence of the nitrone. Although decomposition of other diaroyl peroxides in benzene usually gives only negligible amounts of phenyl arenecarboxylates in the absence of oxidants such as oxygen,[3,17] TPO gives a non-negligible amount of phenyl 2-thiophenecarboxylate (Table 1). This fact can be taken as a piece of evidence for the higher reactivity of TCR towards benzene than other aroyloxyl radicals. The higher reactivity and stability of TCR probably arise from electronic effects of the sulfur atom.[16]

The yield of biphenyl is highly dependent on the photolysis conditions; it is very sensitive to temperature and remarkably reduced with increasing temperature. Since the yield of carbon dioxide was not varied in the temperature range examined, the effect of temperature is not due to acceleration of the decarboxylation rate of TCR. Therefore, the reduction of the yield of biphenyl indicates that TCR is in an addition equilibrium with CHDR and that at higher temperatures than 40 °C CHDR tends to decrease its stationary concentration by dissociating into TCR and benzene rather than undergoing recombination.

According to the above mechanism for biphenyl formation, the yield of biphenyl should be controlled by the stationary concentration of CHDR, and thus by the decomposition rate of the peroxide. In Table 1,

when the apparent half-life period of TPO is decreased from 80 to 25 min by use of higher light intensity, the yield of biphenyl is increased from 0.02 to 0.11 (high pressure mercury lamp) and 0.17 mol (nitrogen laser).

In the presence of styrene as a radical scavenger, carbon dioxide was produced in much higher yield (0.14 mol) in photolysis than in thermolysis (0.01 mol), as shown in Fig 1. This result exhibits the decarboxylation from photoexcited TPO is more efficient than that from vibrationally excited TPO; in the thermolysis carbon dioxide almost results from decarboxylation of out-of-cage TCRs (Eq. 6), while in the photolysis, carbon dioxide results not only from decarboxylation of the out-of-cage TCRs but also from the two-bond fission (O–O and C(α)-C(carbonyl) bonds) of photoexcited TPO in either simultaneous or successive way (Eq. 12) and/or decarboxylation of in-cage TCRs (Eq. 13).[10]

$$(ThCO_2)_2 \longrightarrow ThCO_2\cdot + CO_2 + Th\cdot \quad (12)$$

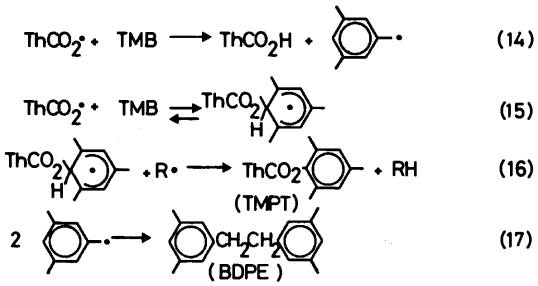
$$(ThCO_2)_2 \longrightarrow (2ThCO_2\cdot)_{cage} \longrightarrow ThCO_2\cdot + CO_2 + Th\cdot \quad (13)$$

Photolysis of TPO in toluene under similar conditions to the above resulted in the formation of dimethylbiphenyls among usual radical reaction products[1,2] (Tables 4 and 5). The isomer ratio of dimethylbiphenyls was high in meta- and ortho-substituted derivatives and very low in para-substituted ones[18] (Table 5). As discussed above on the formation of biphenyl in benzene, dimethylbiphenyls are considered to arise from recombination of cyclohexadienyl radicals formed through addition of TCR to toluene. Temperature effects on the yield of dimethylbiphenyls are consistent with this mechanism. The total yield and isomer ratio of methylphenyl 2-thiophenecarboxylates are 0.1 mol and 63:11:26 for ortho:meta:para isomers, respectively. The isomer ratio is in good agreement with that in the thermolysis of TPO in toluene. In thermolysis oxygen increased the ester yield and gave the isomer ratio which was lower in the ortho and higher in the para ratio. An intermediate isomer ratio (57:16:27) was reported for thermolysis of TPO in acetonitrile containing toluene in the presence of a copper(II) salt.[19]

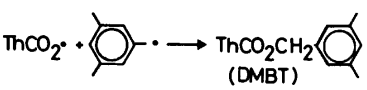
The isomer ratio of dimethylbiphenyls is highly remarkable, since the ratio depends, according to the above mechanism, to the population of isomeric cyclohexadienyl intermediates (for their structures, see Fig. 4). As mentioned above, the photolysis of TPO in toluene under deaerated conditions afforded the isomer ratio of methylphenyl thiophenecarboxylates different from that given by the thermolysis under oxygen. Since the oxidants such as oxygen would scavenge the initially formed cyclohexadienyl intermediates to afford the corresponding esters, their isomer ratios would reflect the population of the isomeric cyclohexadienyl radicals.[20,21] The para-substituted derivatives among dimethylbiphenyls would arise from recombination of the meta or ipso intermediate. Therefore, if the isomer ratio of the esters under oxygen reflects the ratio of the corresponding cyclohexadienyl radicals, the absence of any para-substituted dimethylbiphenyls means that the adjacent positions to the carbon atoms substituted by a thiophenecarbonyloxyl group are almost unreactive in recombination with other acyloxycyclohexadienyl radicals, as previously discussed for photolysis of BPO in toluene.[18] However, since it is expected that the ipso intermediate could undergo recombination at the 3 position with other intermediates to give para-substituted dimethylbiphenyls, the above facts indicate that ipso intermediate would not play an important role in the dimethylbiphenyl formation.

The high ratio of methylphenyl thiophenecarboxylates in the ortho isomer in the decomposition of TPO under the deaerated conditions indicates the contribution of the rearrangement of the ipso intermediate to the ortho one, though the possibility cannot be ruled out that a selectivity in the disproportionation step determined the isomer ratio of the esters.[22]

Intermediacy of ipso Intermediates. Photolysis of TPO in 1,3,5-trimethylbenzene(TMB) at 20 °C afforded thiophenecarboxylate esters, 2,4,6-trimethylphenyl 2-thiophenecarboxylate(TMPT) and 3,5-dimethylphenylmethyl 2-thiophenecarboxylate(DMBT), dimers from the solvent, 1,2-bis(3,5-dimethylphenyl)ethane(BDPE) and 2,3′,4,5′,6-pentamethyldiphenylmethane(PMDM), and 2-thiophenecarboxylic acid (TCA) (Table 6). The formation of TMPT and BDPE can be understood in terms of the usual radical processes (Eqs. 14—17).[1,2] The yield of DMBT is rather

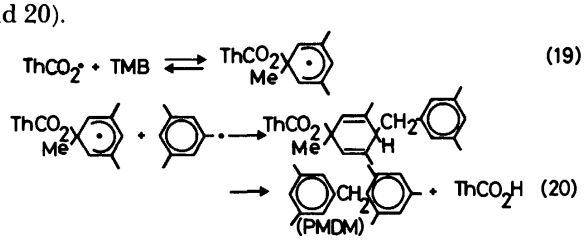


higher compared with that of the corresponding esters from other diaroyl peroxides such as BPO (Table 7). Taking into account the stability of TCR, DMBT is reasonably assumed to be formed through recombination of TCR with 3,5-dimethylphenylmethyl radicals (Eq. 18).

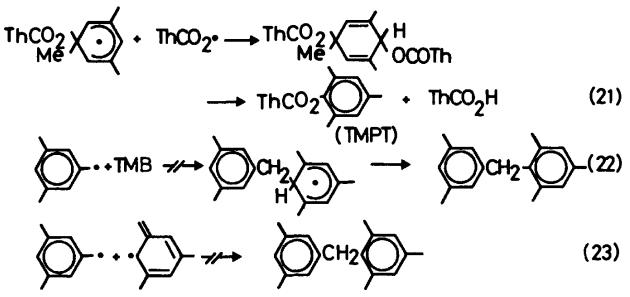


The formation of PMDM is quite unusual since, as the following control experiments show, benzyl-type radicals in general do not facilely add to aromatic rings.[1,2] Therefore, it is reasonably proposed that PMDM is formed through recombination of 3,5-di-

methylphenylmethyl radicals with cyclohexadienyl radicals generated by attack of TCR on the ipso positions of TMB, followed by elimination of TCA (Eqs. 19 and 20).



Attempts were made to eliminate the possibility of addition of benzyl-type radicals to TMB and to confirm contribution of aroyloxyl radicals to PMDM formation. Thus, 3,5-dimethylphenylmethyl radicals were generated in TMB in the absence of any aroyloxyl radicals by the following photochemical and thermal procedures; first, 1,3-bis(3,5-dimethylphenyl)-2-propanone was photolyzed at 10—50 °C to generate the dimethylphenylmethyl radicals through Norrish I cleavage.[23,24] BDPE was produced almost quantitatively and only a slight amount of PMDM was detected on GLPC at all temperatures employed (Table 9). Second, hydrogen atom abstraction by triplet benzophenone was used to generate the benzyl-type radicals.[25] Thus, benzophenone was irradiated in TMB at 25—55 °C to give BDPE and $3,5\text{-}Me_2C_6H_3CH_2CPh_2OH$ but almost none of PMDM (Table 10). Finally, di-*t*-butyl diperoxyoxalate was heated at 35—55 °C in TMB to result in the formation of BDPE (Table 11). In this case *t*-butoxyl radicals abstract a hydrogen atom from a methyl group of the solvent to generate 3,5-dimethylphenylmethyl radicals.[26] These results show that 3,5-dimethylphenylmethyl radicals can neither add to TMB by themselves (Eq. 22) nor recombine at the ring carbons, the potential radical centers of their resonance forms (Eq. 23), but undergo exclusively recombi-



Scheme 2.

nation (dimerization) at their benzyl carbons (Eq. 17).

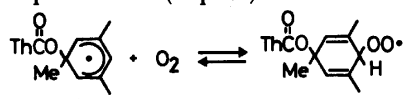
In order to confirm involvement of the aroyloxyl radicals in the formation of PMDM, temperature dependence of product yields in the photolysis of TPO was examined, as summarized in Table 6 and depicted in Fig. 2, since aroyloxyl radicals reversibly add to aromatic solvents. Figure 2 shows that the yield of BDPE increases but those of TMPT and PMDM decrease with increasing temperature. These results are consistent with the above mechanism; at higher temperatures the addition equilibria (Eqs. 15 and 19) tend to be shifted to the side of TCR and TMB, and thus TCR tends to abstract a hydrogen atom from a methyl group of TMB.

As to elimination of ipso substituents, products from homolytic substitution of a methyl group by TCR such as 3,5-dimethylphenyl 2-thiophenecarboxylate were not detected in the photolysis of the peroxides in TMB.

Formation of PMDM and similar temperature effects on the product yields were observed in the photolysis of BPO in TMB (Table 7 and Fig. 2). The product formation can be accounted for by processes similar to those mentioned above except phenyl benzoate, the geminate product,[10] which was not detected in the thermolysis. When the yields of products are compared between the two peroxides at the same temperatures, the yields of BDPE are almost of the same magnitude; however, the yields of PMDM and 2,4,6-trimethylphenyl esters, TMPT and $PhCO_2C_6H_2Me_3$ (TMPB), are higher from TPO than from BPO. The difference in yield is much remarkable in the esters, and this can be understood by the difference in stability between TCR and benzoyloxyl radicals, the latter decarboxylating faster.[27] That TMPT is much higher in yield and suffers more remarkable temperature effects than TMPB (Fig. 2) indicates that TMPT is formed not only through addition of TCR to TMB followed by disproportionation (Eqs. 15,16) but also through recombination of TCR with the ipso intermediate followed by acid elimination (Eq. 21).

Therefore, it is quite reasonable to conclude that the formation of PMDM in photolyses of TPO and BPO provides clear evidence for intermediacy of the ipso intermediates formed by attack of aroyloxyl radicals to TMB.

Thermolysis of the peroxides in TMB shows some intriguing trends. The formation of 2-thienyl 2-thiophenecarboxylate is noticeable, since BPO did not give any corresponding phenyl benzoate. This fact provides another piece of evidence for the stability (slow decarboxylation) of TCR. More remarkable is the increase of the PMDM yield for both peroxides under aerated conditions. Although the cause has not been clarified, it can be tentatively proposed that oxygen will contribute to elongation of a lifetime of the ipso intermediate at high temperature by an addition-elimination equilibrium (Eq. 24).[28,29]



Estimation of Stability of ipso Intermediates from MO Calculations. Open shell restricted SCF-MO MINDO/3 calculations showed that the energy difference between ipso and non-ipso intermediates from TMB (7.8 kcal/mol) is smaller than that from toluene (8.5 kcal/mol) (Fig. 3). This may indicate that the ipso intermediate from TMB is relatively stabilized more

than that from toluene. For anisole as a model compound for diphenyl ether, of which the phenoxyl group has been established to be substituted by benzoyloxyl radicals,[30] the difference of the total energy between the ipso and non-ipso intermediates is much larger (10.0 kcal/mol) than the above two cases. In all three cases, the energy difference among the non-ipso intermediates is small compared with the above values. Similar results have been reported on substituted cyclohexadienyl radicals on the basis of CNDO/2[22] and *ab initio* MO calculations.[31] The relative energies of the isomeric intermediates have been similarly assessed by MINDO/3 calculations based on isodesmic reactions.[32] As discussed above, PMDM is apparently formed from the reaction of 6-aroyloxy-1,3,5-trimethylcyclohexadienyl radicals, of which the model is estimated to be higher in energy than the non-ipso intermediates. Therefore, the stability of substituted cyclohexadienyl radicals seems not to play an important role in the selectivity in the addition step of the aroyloxyl radicals, but to contribute to the ipso →ortho rearrangement as proposed in the case of toluene; the positions of the initial addition of aroyloxyl radicals to aromatic solvents can be predicted by the frontier orbital theory.[22,33]

The calculated spin density predicts that all cyclohexadienyl radicals depicted in Fig. 4 are the most reactive at the 3-position. The isomer ratio of dimethylbiphenyls indicates low reactivity of the 1- and 5-positions as discussed above. Based on the product distributions in toluene and the spin densities, the four cyclohexadienyl intermediates are considered to behave as follows; the ortho and meta intermediates are predominantly responsible for the dimethylbiphenyl formation by recombining at the 3-position, and the para intermediate reacts at the 1- or 5-position because of low reactivity of the 3-position due to the methyl substitution. On the contrary, the ipso intermediate is not responsible for biphenyl formation but rearranges to the ortho one.

Conclusion

The high reactivity of TCR towards aromatic solvents and the high stationary concentration of cyclohexadienyl radical intermediates in photolysis of TPO bring about their bimolecular reactions giving dimeric products of the solvents. Biphenyl and dimethylbiphenyls are formed in noticeable yields in benzene and toluene, respectively, through dimerization of the corresponding cyclohexadienyl radicals followed by acid elimination. In TMB PMDM arises from recombination of the ipso intermediates generated by attack of TCR and benzoyloxyl radicals to TMB with the benzyl-type radicals derived from TMB.

Experimental

Materials. Bis(2-thiophenecarbonyl) peroxide was prepared from 2-thiophenecarbonyl chloride and hydrogen peroxide (30% aqueous solution) in the presence of sodium hydroxide,[16] and dibenzoyl peroxide was commercially obtained. The peroxides were purified by precipitating from dichloromethane–methanol.

Di-*t*-butyl diperoxyoxalate was prepared by adding a pentane solution of *t*-butyl hydroperoxide to a cooled mixture of oxalyl dichloride, pyridine, and pentane, and reprecipitated from pentane.[26]

1,3-Bis(3,5-dimethylphenyl)-2-propanone was prepared by the reaction of 3,5-dimethylphenylmethyl bromide with nonacarbonyldiiron(0) in hexane,[34,35] and purified by recrystallization from petroleum ether.

2,4,6-Trimethylphenyl 2-thiophenecarboxylate was prepared by the reaction of 2,4,6-trimethylphenol and 2-thiophenecarboxylic acid in trifluoroacetic anhydride,[36] and recrystallized from hexane. Mp 89.3—89.8 °C. ^{1}H-NMR ($CDCl_3$): δ=2.12 (s, 6H), 2.24 (s, 3H), 6.79 (s, 2H), 7.06 (m, 1H), 7.50 (d, 1H), 7.86 (d, 1H). IR (KBr): $\nu_{C=O}$ 1720 cm^{-1}. Found: C, 68.13; H, 5.68%. Calcd for $C_{14}H_{14}O_2S$: C, 68.26; H, 5.72%.

3,5-Dimethylphenylmethyl 2-thiophenecarboxylate was prepared by the reaction of sodium 2-thiophenecarboxylate with 3,5-dimethylphenylmethyl bromide in acetic acid.[37] Bp 148.3—149.2 °C/1100 Pa. ^{1}H-NMR ($CDCl_3$): δ=2.32 (s, 6H), 5.29 (s, 2H), 7.0—7.3 (m, 4H), 7.58 (d, 1H), 7.86 (d, 1H). Found: C, 68.42; H, 5.82%. Calcd for $C_{14}H_{14}O_2S$: C, 68.26; H, 5.72%.

3,5-Dimethylphenyl 2-thiophenecarboxylate was prepared by the reaction of 2-thiophenecarbonyl chloride with 3,5-dimethylphenol in a mixture of benzene and pyridine. Mp 39.2—42.3 °C. ^{1}NMR ($CDCl_3$): δ=2.30 (s, 6H), 6.75 (s, 2H), 6.98 (s, 1H), 7.08 (m, 1H), 7.55 (d, 1H), 7.86 (d, 1H). Found: C, 67.21; H, 5.22%. Calcd for $C_{13}H_{12}O_2S$: C, 67.21; H, 5.20%.

2,4,6-Trimethylphenyl benzoate,[38] phenyl,[16] 2-methylphenyl,[16] 3-methylphenyl,[16] 4-methylphenyl,[16] and benzyl 2-thiophenecarboxylate[39] were prepared similarly from 2-thiophenecarbonyl chloride and the corresponding phenols.

2-Thienyl 2-thiophenecarboxylate was prepared by the thermolysis of TPO in the presence of copper(II) chloride in acetonitrile containing thiophene.[16]

2,2′-Dimethyl- and 3,3′-dimethylbiphenyl were prepared by heating 2-iodo- and 3-iodotoluene, respectively, with copper powder (Ullman reaction),[40] and 4,4′-dimethylbiphenyl was commercially obtained.

2,3′-Dimethylbiphenyl was prepared in the following way.[41,42] 3-Methyl-1-(2-methylphenyl)cyclohexanol was prepared by Grignard reaction of 2-bromotoluene with 3-methylcyclohexanone. The cyclohexanol was heated with oxalic anhydride to give a mixture of 3-methyl-1-(2-methylphenyl)cyclohexene and 5-methyl-1-(2-methylphenyl)-cyclohexene. This mixture was refluxed with sulfur in quinoline to afford 2,3′-dimethylbiphenyl.

2,4′-Dimethyl- and 3,4′-dimethylbiphenyl were prepared in a similar way from 4-bromotoluene with 2-methyl- and 3-methylcyclohexanone, respectively.

2,2′,4,4′,6,6′-Hexamethylbiphenyl was prepared by heating 2,4,6-trimethylphenylmagnesium bromide with anhydrous copper(II) chloride.[43]

2-Methyl-, 3-methyl-, and 4-methyldiphenylmethane were prepared from the corresponding methylbenzophenones by modified Wolff-Kishner reaction.[44]

2,3′,4,5′,6-Pentamethyldiphenylmethane was prepared by

Friedel-Clafts reaction of 3,5-dimethylphenylmethyl bromide with 1,3,5-trimethylbenzene in the presence of iron(III) trichloride.[45]

1,2-Bis(3,5-dimethylphenyl)ethane were prepared by heating the corresponding dimethylphenylmethylmagnesium bromide with anhydrous copper(II) chloride.[45]

Benzophenone commercially obtained was recrystallized from methanol and petroleum ether.

Toluene and 1,3,5-trimethylbenzene (special grade, Wako) were purified by distilling over calcium hydride.

Photolyses and Thermolyses of Diacyl Peroxides. A solution (3 cm^3) of a peroxide (0.03 mol/dm^3) in benzene, toluene, or 1,3,5-trimethylbenzene in a Pyrex tube was degassed by the usual freeze-thaw cycles or by bubbling with argon, and irradiated with a 1 kW or a 400 W high pressure mercury lamp using a merry-go-round type Riko Rotary Photochemical Reactor or with a nitrogen laser (Lambda Physik M100B; 337.1 nm, 3.5 mJ/pulse, 80Hz). On irradiation with 254 nm light, a peroxide solution in a quartz tube was deaerated by bubbling with nitrogen, and irradiated with a 160 W low pressure mercury lamp. Irradiation was continued for more than five times the half-life period of the peroxide determined by iodometric analysis or high-performance liquid chromatography (Shimadzu LC2; column, ODS 25cm) under the experimental conditions.

Thermolyses of peroxides were carried out in the following manner. A solution of a peroxide degassed by the usual freeze-thaw cycles or under oxygen in a Pyrex tube was heated in a thermostat for more than five times the half-life period of the peroxide determined under the experimental conditions.

Photolysis of 1,3-Bis(3,5-dimethylphenyl)-2-propanone in 1,3,5-Trimethylbenzene. A solution of 1,3-bis(3,5-dimethylphenyl)-2-propanone in 1,3,5-trimethylbenzene (0.01 mol/dm^3, 3 cm^3) was degassed by the usual freeze-thaw cycles, and irradiated by a 1 kW high pressure mercury lamp for 70 min in a thermostat.

Irradiation of Benzophenone in 1,3,5-Trimethylbenzene. A solution of benzophenone in 1,3,5-trimethylbenzene (0.03 mol/dm^3, 3 cm^3) was degassed and irradiated by a 1 kW high pressure mercury lamp for 3 h in a thermostat.

Thermolysis of Di-t-butyl Diperoxyoxalate in 1,3,5-Trimethylbenzene. A solution of di-*t*-butyl diperoxyoxalate in 1,3,5-trimethylbenzene (0.03 mol/dm^3, 3 cm^3) was degassed and heated in a thermostat for five times the half-life period (1.0 h at 55 °C, 3.5 h at 45 °, and 14.2 h at 35 °) estimated from the reported decomposition rate constants.[26]

Product Analyses. Biaryls, diphenylmethanes, diphenylethanes, and esters were determined quantitatively by GLPC analysis on a Shimadzu GC-4CM PF gas chromatograph equipped with a flame ionzation detector. Acids were determined on a Shimadzu LC2 high-performance liquid chromatograph.

Trapping of Carbon Dioxide in the Presence of Styrene. TPO (0.03 mol/dm^3) in a mixture of varying fractions of benzene and styrene was thermolyzed at 80 °C and photolyzed at room temperature with a 400 W high pressure mercury lamp through a Pyrex wall. The resulting carbon dioxide was absorbed with an Ascarite tube and determined by gravimetry.

Spin Trapping of 2-Thiophenecarbonyloxyl Radicals. A solution of TPO (0.91 mol/dm^3) containing *N*-benzylidene-*t*-butylamine oxide (0.1 mol/dm^3) was heated at 80 °C or irradiated at room temperature with a 1 kW high pressure mercury lamp in the cavity of an ESR spectrometer (JEOL JES-ME-1X) for several minutes.

NAD(P)$^+$-NAD(P)H Models. 53. Proximity Effect of Intramolecular Heteroatom on Reaction Rate

NAD(P)H-model compounds that have a sulfur or oxygen substituent in the molecule have been synthesized and kinetics for the reduction of both substituted and unsubstituted α,α,α-trifluoroacetophenones with these model compounds are studied. Reduction with the heteroatom-containing model compounds proceeds at a slower rate than the reduction with a model without any heteroatom substituents. Furthermore, the dependency of the kinetic isotope effect on the electron-deficiency of the substrate differs. Kinetic parameters reveal that the retardation caused by the heteroatom is due to the loss of entropy in the initial electron-transfer process. The enthalpic term favors the reduction with the heteroatom-containing model.

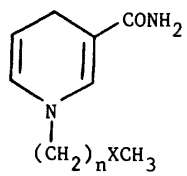
Biomimetic reaction systems for reductions which are catalyzed by NAD(P)H-dependent dehydrogenases have been extensively studied for their reaction mechanisms and applications to organic syntheses.[1] Since the true reductant in this redox system is the 1,4-dihydronicotinamide moiety of NAD(P)H, almost all researches have been concentrated on the chemistry of 1,4-dihydropyridine derivatives. After we found that magnesium ion in dry acetonitrile is a good catalyst in a mimetic system,[2] the requirements for substrates that can be subjected to mimetic reduction have been lessened extensively. However, the enzymic redox system is still much superior to the corresponding mimetic one in the sense that the former system reduces a far wider variety of substrates than the latter. There is no doubt that the difference in the reactivity between enzymic and mimetic systems lies in complex constituents of the enzyme, which supply the essential functional groups for catalysis and, at the same time, construct a favorable environment for the reaction. Therefore, in order to extend the mimetic reaction system, we have to take into account not only the chemical constitution at the reaction center but also environmental effects. There are a lot of positively or negatively polarized groups around the active site of the enzyme, and these groups may assist the transfer of (net) hydride. It is also known that, for some liver alcohol dehydrogenases, a zinc ion is essential for the reaction, and this zinc ion, which is ligated by one molecule of water, is tetrahedrally ligated by cysteinyl sulfurs and histidinyl nitrogens.[3] The zinc ion is supposed to activate substrates as a Lewis acid by ligating onto the carbonyl oxygen of the substrate ketone.[4] However, there is some doubt whether the pentacoordinated zinc ion at the reaction center can retain its catalytic activity as a Lewis acid. At least in a mimetic system, a metal ion with a chelating reagent was not a catalyst.[5]

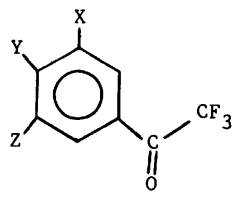
As a trial to introduce some environmental effects into a mimetic reaction system, we synthesized NAD(P)H models that have sulfur or oxygen functional groups as substituents on an alkyl chain at the N_1 position of 1,4-dihydronicotinamide and studied the effects of heteroatoms on the kinetics in the presence or absence of magnesium ion.

It should be mentioned that magnesium ion in the mimetic system is a catalyst for some substrates,[2] but an inhibitor for others.[6] For a third class of substrates, it may be a catalyst or an inhibitor depending on its concentration.[7] Such complex behavior is best interpreted in terms of a multi-step mechanism with the initial electron transfer from the dihydropyridine moiety to the substrate, and of acceleration of this electron-transfer process by magnesium ion.[8]

Results

Six 1-[(ω-methylthio)alkyl]-1,4-dihydronicotinamides (S2NAH, S3NAH, S4NAH, S5NAH, S6NAH, and S8NAH) and one 1-[(ω-methoxy)alkyl]-1,4-dihydronicotinamide (O2NAH) were synthesized as model compounds with a heteroatom in the molecule. Two 1-alkyl-1,4-dihydronicotinamides (PNAH and ONAH) were employed as standards.

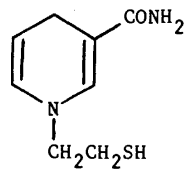




S2NAH: X = S, $n = 2$
S3NAH: X = S, $n = 3$
S4NAH: X = S, $n = 4$
S5NAH: X = S, $n = 5$
S6NAH: X = S, $n = 6$
S8NAH: X = S, $n = 8$
O2NAH: X = O, $n = 2$
PNAH: X = CH_2, $n = 1$
ONAH: X = CH_2, $n = 6$

1a: X = Y = Z = H
1b: X = Z = H, Y = Cl
1c: X = CF_3, Y = Z = H
1d: X = NO_2, Y = Z = H
1e: X = NO_2, Y = Cl, Z = H
1f: X = CF_3, Y = H, Z = NO_2

Substituted and unsubstituted α,α,α-trifluoroacetophenones (**1a—1f**) were prepared as substrates for the reduction. A compound with a free mercapto group (SHNAH) was also prepared, but could not be used in the kinetic studies because of its instability. First-order rate constants were measured by observing the decrease in the intensity at around 350 nm (an absorption characteristic of the dihydropyridine moiety) on a



SHNAH

spectrophotometer. The observed rate constants were corrected for the rate constant for the magnesium ion-catalyzed decomposition of each model compound. The second-order rate constant, k, was calculated by dividing the corrected rate constant by the concentration of the substrate and the results are summarized in Table 1.

Kinetic parameters for some pairs of reactants were calculated from the temperature dependency of the rate constants, and the results are listed in Table 2.

Kinetics were also studied with S2NAH-4-*d*, and the kinetic deuterium isotope effect was calculated using Steffens and Chipman's equation.[9] The values are listed in Table 3. We have confirmed that the accuracy of the value obtained by this procedure is as high as that obtained from the calculation with the dideuterated compound.[8a]

Water in the solvent acetonitrile strongly influences the results in these kinetic studies. Particular attention was paid to this point and the water content of the reaction system was measured before and after each kinetic run and was always less than 0.075% v/v even in the presence of magnesium perchlorate.[10]

Discussion

Hammett plots for the reduction of various substrates with S2NAH and O2NAH in the presence and absence of magnesium ion are illustrated in Fig. 1. In the reductions with S2NAH, a straight line with ρ=2.62 (correlation coefficient r=0.998) is obtained when magnesium ion is absent, but the plot for the reduction in the presence of magnesium ion is composed of two straight lines, one of which has ρ=1.50 (r=0.999) and the other has ρ=0.768 (r=1.000).[11] The corresponding plots for the reduction with O2NAH have essentially the same tendency; ρ=2.55 (r=1.000) for the reduction without magnesium ion, and ρ= 1.59 (r=0.995) and 0.436 (r=0.990) for the reduction with magnesium ion.

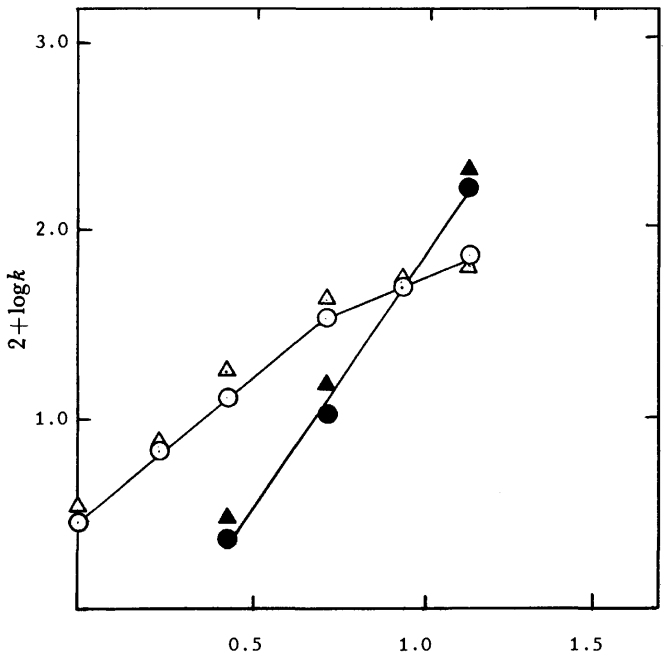

Fig. 1. Hammett plots for the reduction with S2NAH in the presence (○) and absence (●) of magnesium ion and with O2NAH in the presence (△) and absence (▲) of magnesium ion.

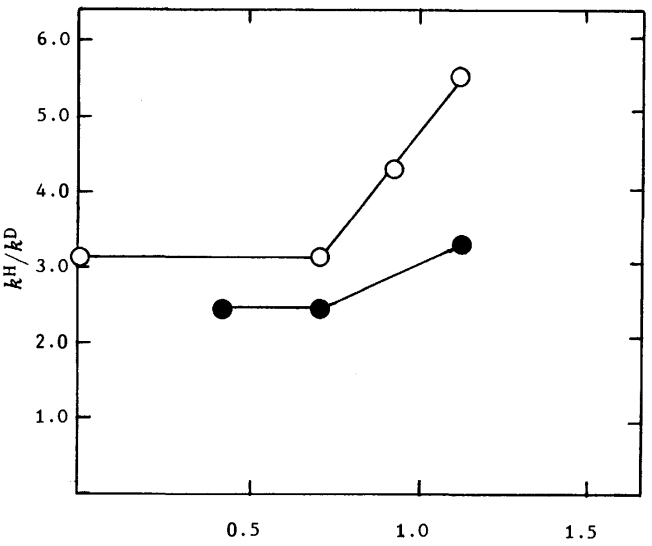

Fig. 2. Plotts of kinetic isotope effects in the reduction with S2NAH against σ-values of substituents in the presence (○) and absence (●) of magnesium ion.

The present results with heteroatom-containing models[12] are a striking contrast to the free energy relationship exerted by PNAH, where the reduction with magnesium ion gave a straight line but that without magnesium ion appeared as a bent line.[8a]

The dependency of kinetic isotope effects on the substituent σ-value for the reduction with S2NAH again differs from that with PNAH. That is, as plotted in Fig. 2, the isotope effect for the former reduction increases, regardless of the presence or absence of magnesium ion, as the electron-deficiency of the substrate becomes large. On the other hand, in the reduction with PNAH, the kinetic isotope effect remained constant when the reduction was run in the presence of magnesium ion, whereas in its absence the value increased to an asymptote.[8a] For each reductant, the σ-value where the slope of the line changes in the plot of the kinetic isotope effect corresponds exactly with the position where the change in slope is seen in the Hammett plot. Thus, it is apparent that the change in slope reveals a change in the rate-determining step, or the reduction is composed of several steps.

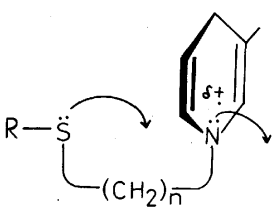
Comparison of activation parameters for the reductions of **1a** (a weakly electron-deficient substrate), **1d** (a moderately electron-deficient substrate), and **1f** (a strongly electron-deficient substrate) with S2NAH in the presence of magnesium ion reveals that the entropy of activation for the reduction of **1f** is much smaller than those for the reductions of **1a** and **1d**. If the reduction proceeded through a one step hydride-transfer mechanism, Hammond's posturation proposes that the transition state for a strongly electron-deficient substrate should resemble the reactant more than the transition state for a less electron-deficient substrate, or the entropy of activation for the reduction of **1f** should be larger than those for the reductions of **1a** and **1d**. On the other hand, if the electron-transfer

step constitutes a major part of the rate-determining step, the stability of the resulting radical ion pair might play an important role in determining the activation parameter, and the entropy of activation may be smaller for **1f** than for **1a** or **1d**. This is a conclusion which comes out of the fact that a strongly electron-deficient substrate in a radical ion pair can keep an electron in its own counterpart more tightly than a less electron-deficient substrate.

Nevertheless, the reduction is accompanied by a certain amount of kinetic isotope effect. Thus, the transition state of the rate-determining step of the reduction seems to be such that the transfer of an electron is accompanied by the loosening of C_4–H bond in the reductant.

Table 1 shows that the reduction with S2NAH or O2NAH is slower than the reduction with PNAH regardless the presence or absence of magnesium ion. The retardation exerted by a heteroatom, however, becomes less important as the number of methylene groups, n, becomes large, and comes to an asymptote after n=6. The asymptotic value is equivalent to the reduction rate with ONAH. Activation parameters for the reduction of **1d** with S2NAH and S8NAH, as listed in Table 3, show that the reduction with the former model is rather preferred by the enthalpic term but the larger contribution of the entropic term results in the retardation of reduction with the former model.

Consequently, the retardation of the reduction caused by the intramolecular heteroatom can be accounted for by a major contribution of the initial process, in which at least a partial positive charge is developed in the reductant without affording a large kinetic deuterium isotope effect (or without dissociating the hydrogen nucleus greatly from the carbon at the 4-position), to the rate-determining step of the reduction. The intermediate must be one which is stabilized, in terms of enthalpy, by the proximity effect of an intramolecular hetero-atom, and the stabilization becomes more important as the electron deficiency of the substrate increases. The structure of the transition state for the initial step is, therefore, best expressed as a one-electron-transfer type of complex between the model compound and a substrate, the cation radical part of which is stabilized by participation by an electron pair on the heteroatom as illustrated in Scheme I. By the participation of an electron pair on the heteroatom, the partial positive charge in the dihydropyridine ring which develops as an electron in this ring is transferred onto the substrate, is stabilized in terms of enthalpy. However, for the electron pair to stabilize the electron-deficient dihydropyridine ring, the side-chain must be kept from free rotation, which causes a decrease in entropy. As the number of spacer methylene groups becomes larger, such participation of a heteroatom becomes less important because the entropic loss becomes too large, and the rate constant for the reduction comes to an asymptotic value. Since the activation energies for the initial electron-transfer process in the reduction with the heteroatom-substituted models are higher than those with PNAH and ONAH, the priority of this process in the rate-determining step of the reduction with a heteroatom-substituted model still remains even with the catalytic assistance of magnesium ion, keeping the kinetic isotope effects for these reductions small.



Scheme 1.

It is noteworthy that an inspection with a CPK-model shows that the sulfur or oxygen atom in S2NAH and O2NAH, respectively, is close to the dihydropyridine ring nitrogen when the dihydropyridine ring and the heteroatom are set at the *syn* position.

Table 1 shows that zinc ion retards the reduction in contrast to the catalytic effect of magnesium ion. However, the retardation diminishes as the alkyl chain becomes longer. The inhibitory effect of zinc ion can be accounted for if zinc ion has a higher efficiency than magnesium ion in stabilizing the charge-transfer ternary complex given by the initial one electron-transfer process.[6c,d] Since zinc ion is softer than magnesium ion as a Lewis acid, the former is better trapped by sulfur than the latter.[13] At the same time, the sulfur atom has a stronger affinity for the zinc ion than for the dihydropyridine ring. When the sulfur atom is set far from the reaction center as in the case of S8NAH, therefore, zinc ion is less involved in the reaction (the interaction between the dihydropyridine ring and the substrate) and the rate increases to the magnitude available without metal ion.

Although, unfortunately, it has been confirmed that intramolecular heteroatoms in the NAD(P)H model compounds decrease the reactivity, the interference is caused by the entropic term. The above conclusion, therefore, proposes that, if the heteroatom in a molecule is fixed at a proper position in the reactant, like atoms in a reaction pocket of an enzyme, there is no entropic interference and the increase in the reaction rate due to enthalpic assistance is expected. Enhanced reactivity caused by the participation of a proximate negative charge has been reported for reduction in micellar system.[14]

Experimental

Melting points were not corrected. UV spectra and VPC were recorded on a Union Giken SM-401 spectrophotometer and Hitachi 633-50 chromatograph, respectively. JEOL JNMFX-100 and Hitachi R-22 spectrometers were employed

for NMR spectroscopy.

Materials. Acetonitrile was refluxed over calcium hydride for several hours, then distilled from the refluxing pot under an argon atmosphere before use. Magnesium and zinc perchlorates were dried over phosphorus pentaoxide for 1 d under reduced pressure at 100 °C. The amount of water in kinetic solutions was determined on VPC (30% bis(2-cyanoethyl) ether, 1 m, 40 °C) before and after the kinetic measurement and was found to be less than 0.075% v/v and 0.094% v/v for the magnesium and zinc perchlorate solutions, respectively.

α,α,α-Trifluoroacetophenone (**1a**), 4-chloro-α,α,α-trifluoroacetophenone (**1b**), 3-trifluoromethyl-α,α,α-trifluoroacetophenone (**1c**), 3-nitro-α,α,α-trifluoroacetophenone (**1d**), 4-chloro-3-nitro-α,α,α-trifluoroacetophenone (**1e**), and 3-nitro-5-trifluoromethyl-α,α,α-trifluoroacetophenone (**1f**) were prepared according to procedures in the literature.[8a]

1-Propyl-1,4-dihydronicotinamide (PNAH) was prepared according to a procedure in the literature.[15] 1-Octyl-1,4-dihydronicotinamide (ONAH) was synthesized similarly. 1-[(2-Methylthio)ethyl]-1,4-dihydronicotinamide (S2NAH), 1-[(3-methylthio)propyl]-1,4-dihydronicotinamide (S3NAH), and 1-[(2-methoxy)ethyl]-1,4-dihydronicotinamide (O2NAH) were prepared in the same manner by the reduction of the corresponding pyridinium salt.[16]

1-[(8-Methylthio)octyl]-1,4-dihydronicotinamide (S8NAH). A solution of nicotinamide (0.48 g) and 10-fold excess of 1,8-dibromooctane in 10 cm³ of acetonitrile was heated at 60 °C for 1 d to obtain 1-(8-bromooctyl)-3-carbamoylpyridinium bromide in 72% yield after recrystallization from acetonitrile. The pyridinium salt was subjected to methylthiolation with sodium methanethiolate in water. The resulting 1-[(8-methylthio)octyl]-3-carbamoylpyridinium bromide (92% yield) was reduced with sodium dithionite to yield yellow crystals of S8NAH in 54% yield after recrystallization from ethanol.

1-[(4-Methylthio)butyl]-1,4-dihydronicotinamide (S4NAH), 1-[(5-methylthio)pentyl]-1,4-dihydronicotinamide (S5NAH), and 1-[(6-methylthio)hexyl]-1,4-dihydronicotinamide (S6NAH) were synthesized similarly.

UV and NMR spectra as well as the results of elemental analyses are listed in Table 4.

2-(Methoxymethylthio)ethanol. A solution of 31.3 g of 2-mercaptoethanol (0.40 mol) in 400 cm³ of ethanol was added to a solution of sodium ethoxide (0.44 mol) in 40 cm³ of ethanol under a nitrogen atmosphere. The mixture was cooled to 0 °C, and to this mixture 35.4 g of chloromethyl methyl ether (0.44 mol) was added dropwise. The reaction mixture was stirred for an hour, then the precipitate was filtered off and the solvent was evaporated from the filtrate. The residue was distilled (bp 58—60 °C/26.6 Pa) to give 35.9 g of 2-(methoxymethylthio)ethanol as an oil (73.5% yield). ^{1}H NMR in $CDCl_3$ (δ from TMS) 2.81 (t, 2H), 3.13 (bs, 1H), 3.42 (s, 3H), 3.78 (t, 2H), and 4.67 (s, 2H).

2-(Methoxymethylthio)-1-chloroethane. Into a stirred mixture of 33.0 g of 2-(methoxymethylthio)-1-ethanol (0.27 mol) and 23.7 g of pyridine (0.30 mol) at 0 °C, 33.7 g of thionyl chloride (0.28 mol) was added dropwise. It took about 1 h. After the reaction, the mixture was warmed to room temperature and organic materials were extracted with ether. The organic layer was washed with water and dried over sodium sulfate, then the solvent was evaporated. The residue was distilled (bp 43 °C/266 Pa) to give 2-(methoxymethylthio)-1-chloroethane in 64% yield (24.2 g). ^{1}H NMR in $CDCl_3$ (δ from TMS) 2.93 (t, 2H), 3.37 (s, 3H), 3.71 (t, 2H), and 4.67 (s, 2H). Found: C, 33.95; H, 6.72%. Calcd for C_4H_9OSCl: C, 34.15; H, 6.46%.

1-[2-(Methoxymethylthio)ethyl]-3-carbamoylpyridinium Chloride. A mixture of 16.9 g of 2-(methoxymethylthio)-1-chloroethane (0.12 mol) and 13.4 g of nicotinamide (0.11 mol) in 12 cm³ of ethanol was refluxed for 20 h. After the reaction, the precipitate was filtered and washed with ether and ethanol to give crude 1-[2-(methoxymethylthio)ethyl]-3-carbamoylpyridinium chloride in 95.6% yield. Recrystallization from methanol–ether gave the pure salt as white crystals in 59.8% yield (based on nicotinamide). ^{1}H NMR DMSO-d_6 (δ from TMS) 3.16 (s, 3H), 3.32 (t, 2H), 4.71 (s, 2H), 4.92 (t, 2H), 8.0—8.4 (m, 2H), 9.05 (s, 2H), and 9.18 (dd, 1H). Found: C, 44.59; H, 5.69; N, 10.25%. Calcd for $C_{10}H_{15}ClO_2S$: C, 45.70; H, 5.77; N, 10.66%.

1-(2-Mercaptoethyl)-3-carbamoylpyridinium Chloride (SHNA$^+$).[17] A solution of 26.3 g of 1-[2-(methoxymethylthio)ethyl]-3-carbamoylpyridinium chloride (0.1 mol) in 400 cm³ of water-acetonitrile (1:1 v/v) was poured into a solution of $HgCl_2$ in 400 cm³ of water-acetonitrile (1:1 v/v) to precipitate white solid. After 24 h, the solid was filtered and washed with acetonitrile and water. Thus obtained mercury-complex of the pyridinium salt was placed in 250 cm³ of water and H_2S gas was bubbled through the water layer for 3 h. The resulted HgS was filtered off, and the filtrate was freeze-dried to give 1-(2-mercaptoethyl)-3-carbamoylpyridinium chloride in 40% yield after recrystallization from methanol-ether mixture. ^{1}H NMR in DMSO-d_6 (δ from TMS) 2.8—3.4 (m, 3H), 4.87 (t, 2H), 7.9—8.4 (m, 2H), 8.92 (s, 2H), 9.18 (dd, 1H), and 9.72 (s, 1H).

1-(2-Mercaptoethyl)-1,4-dihydronicotinamide (SHNAH). A solution of 1.01 g of SHNA$^+$ (5 mmol) in 90 cm³ of water was added to a mixture of CH_2Cl_2 (400 cm³) and buffered aqueous solution of sodium dithionite (21 g of $Na_2S_2O_4$, 37 g of $NaHPO_4 \cdot 2H_2O$, 150 cm³ of 1 mol dm^{-3} aq-NaOH, and 150 cm³ of water; pH=7.5) dropwise with vigorous stirring under an argon atmosphere. After 40 min, the organic layer was separated, and the aqueous layer was extracted with CH_2Cl_2. The combined dichloromethane layer was washed with water and dried over sodium sulfate. The evaporation of the solvent from the dried solution gave 1-(2-mercaptoethyl)-1,4-dihydronicotinamide (SHNAH) as a yellow oil in 68.4% yield (0.63 g). UV in CH_3CN; λ_{max} 354 nm. When this compound was kept in a freezer at −20 °C overnight, an absorption at 303 nm appeared suggesting that the decomposition had begun under such conditions. ^{1}H NMR in $CDCl_3$ (δ from TMS) 1.40 (t, 1H), 2.70 (dt, 2H), 3.0—3.5 (m, 4H), 4.83 (dt, 1H), 5.4—5.9 (m, 3H), and 7.00 (d, 1H).

Kinetic Procedures. A kinetic solution was prepared under an atmosphere of argon and placed in a 1 cm UV cell which had a silicone rubber stopper. The compartment for UV cells was kept within ±0.05 °C of an appropriate temperature through the kinetic run.

As a general procedure, both sample and reference cells were filled with a solution of substrate (and magnesium or zinc perchlorate, when necessary) in acetonitrile to obtain a difference spectrum. Then, an acetonitrile solution of a

a) Numbers in parentheses are calculated values. b) δ from TMS in $CDCl_3$.

model compound was injected into the sample cell with a syringe to start the reaction. An appropriate concentration of the substrate (and the metal ion, when necessary) was chosen to keep at least 80-fold molarity of the substrate (and the metal ion) over the concentration of the reductant. For example, for the run in entry 9 in Table 1, the concentrations were: [**1d**]=6.59×10^{-2} mol dm^{-3}, [Mg(ClO_4)$_2$]=2.58×10^{-2} mol dm^{-3}, and [S8NAH]=3.0×10^{-4} mol dm^{-3}. It was confirmed

that the rates were first-order in the substrate, first-order in the reductant, and zero-order in the metal ion.

The kinetics was followed by observing the decrease in the intensity of absorption at around 400 nm from the reductant. The spectrometer was connected to an NEC PC-8001 computer and the intensity of absorption at appropriate times was monitored over 3 half-lives through the computer. One observed absorption was the average of 80 consecutive measurements. More than 30 points were monitored for a run. The data were automatically subjected to the least-squares treatment to give a pseudo-first order rate constant. The standard deviation and correlation coefficient for each run were better than 1% and 0.9999, respectively. More than 3 runs were averaged to obtain the rate constants listed in Table 1.

One of the authors (A. O.) wishes to thank the Ministry of Education, Japan for a Scientific Research Grant.

(Received September 27, 1984)

Interaction of a highly effective polymeric biocide poly(hexamethylene biguanide hydrochloride)(PHMB) with phospholipid model membranes was investigated spectroscopically by using 8-anilinonaphthalene-1-sulfonate (ANS) as a fluorescent probe. PHMB enhanced the fluorescence intensity and shifted the maximum wavelength of fluorescence of ANS embedded in the negatively-charged liposome composed of egg PC and dicetyl phosphate, while it had only small effect on the neutral liposome composed of egg PC alone. These results were interpreted in terms of preferred binding of PHMB to negatively-charged species. The Benesi-Hildebrand type plots revealed that PHMB was adsorbed to a greater extent onto the negatively-charged membrane than onto the neutral membrane: the dissociation constants for the liposome–ANS complexes derived from the plots gave quantitative evidence for the enhanced binding of PHMB to the negatively-charged membrane. Diaminohexyl biguanide (DAHB), a corresponding monomer to PHMB, was found to have no significant effect on either the neutral nor the negatively-charged liposome, a finding probably related to the fact that DAHB is practically inactive.

Poly(hexamethylene biguanide hydrochloride)(PHMB) is a polymeric biocide which exhibits highly antimicrobial activity against a wide range of microbes such as bacteria, fungi and yeasts.[1] Its mode of action was reported to be similar to that of monobiguanides and bisbiguanides.[2] The sequence of elementary events in the lethal action of those biguanide compounds can be summarized as follows:[3]

1) Adsorption on to the bacterial cell surface;
2) Diffusion through the cell wall;
3) Binding to the cytoplasmic membrane;
4) Disruption of the cytoplasmic membrane;
5) Release of K^+ ions and other cytoplasmic constituents;
6) Precipitation of cell contents and death of the cell.

Among the elementary processes described above, the binding to the cytoplasmic membrane is a very important process, as the disruption of the membrane is considered to be a crucial step in the cidal action. However, the molecular nature of the interaction of the polymeric biocide with the bacterial cytoplasmic membrane has not been fully understood at molecular level.

Fluorescence spectroscopy has been used extensively to study membrane-associated phenomena. Among the common fluorescent probes, 8-anilinonaphthalene-1-sulfonate (ANS) has been one of the most widely used probes in membrane studies.[4] It has been used as a probe for protein studies[5–7] and to study the energized state of mitochondrial membranes.[8]

In the present study, the interaction of PHMB with phospholipid membranes has been investigated by fluorescence spectroscopy with ANS as a probe to obtain insight into the adsorption behavior of the polymeric biocide on to the bacterial membranes.

Experimental

Materials. Egg yolk phosphatidylcholine (egg PC, chromatographically pure) and dihexadecyl phosphate (DCP) were obtained from Sigma and used without further purification. 8-Anilinonaphthalene-1-sulfonate (ANS, magnesium salt) was purchased from BDH (>98% pure) and used as received. PHMB and its corresponding monomer diaminohexyl biguanide (DAHB) were hydrochloride salts, and PHMB was free from contamination by starting materials, DAHB being > 99% pure. (These biguanide compounds are kind gifts from Dr. D. Pemberton of ICI, UK).

Method. Liposomal solutions were prepared by dispersing lipids in Tris-HCl buffer (20 mM Tris, 100 mM KCl, pH 7.4) with the aid of sonication (a MSE probe-type sonicator). The dispersion was then subjected to ultracentrifugation at 100000×g for 40 min (a MSE Prepspin 50). By this procedure, a transparent liposome solution was obtained. Although the preparation method of the liposome solutions was essentially the same in all experiments, two different ways of addition of ANS were employed: i) ANS was incorporated in the liposomal phase by cosonication. That is, lipid films containing ANS were prepared by mixing the lipid solution in chloroform and the ANS solution in ethanol in a flask and by removing the solvents under dry N_2 and subsequent storage in high vacuum. The Tris-HCl buffer was added to the dried lipid film and the lipid was dispersed by sonication. These liposome solutions were used in the experiments concerning Figs. 1, 2, and 3. The effect of PHMB and DAHB was studied by adding some amounts of concentrate of PHMB and DAHB to the liposome solutions. ii) For measurements of fluorescence of ANS at various ANS concentrations (experiments on Benesi-Hildebrand plots, Figs. 4 and 5), liposome solutions which consisted only of lipids were prepared first, and to 4 ml portion of the liposome solution various amounts of ANS concentrate (1.43 mM in

distilled water) were added by means of a microsyringe (up to 50 μl). The resulting solution was mixed vigorously for 30 s and fluorescence spectra were taken. It was confirmed that the fluorescence spectra did not change with time: after 1 h the same spectra were obtained. In the measurements of the ANS fluorescence in the presence of PHMB (Fig. 4, b-d and Fig. 5, b-d), PHMB concentrate was added to the liposome solution by means of a microsyringe with vigorous mixing before the ANS concentrate was added. It must be mentioned here that ANS incorporated in the liposome by cosonication method (i) followed by addition of PHMB gave similar spectra to those observed when ANS was added after PHMB was added to the liposome solution composed of lipids alone.

Emission spectra were recorded on a Perkin-Elmer Hitachi MPF-4 spectrofluorometer and the spectra were uncorrected.

Results

Figure 1 shows the fluorescence spectra of ANS incorporated in egg PC vesicles. As is well known, free ANS emits only very weak fluorescence peaking at around 530 nm in water. In our measurements, the emission spectrum of ANS in buffer alone coincided with the base line at the same sensitivity as used to measure the spectra shown in the figure. Furthermore, addition of 500 μg/ml PHMB to ANS solution (2.2 μM) in buffer alone caused no significant change in spectrum; no detectable emission at the same sensitivity as used for the spectra shown in Fig. 1. This means that increase in the intensity of fluorescence (I_F) observed on addition of PHMB occurs only in the ternary system, egg PC-PHMB-ANS.

Since the first report by Stryer on emission properties of ANS in various solvents,[9] it has been known that both λ_{max} and the fluorescence quantum yield (ϕ_F) are strongly dependent on the polarity of the solvent: with decreasing polarity, λ_{max} shifts to lower wavelengths and ϕ_F increases. Comparison of the fluorescence spectra of ANS embedded in the egg PC liposome and those in various solvents demonstrated that the binding site for ANS in the PC liposome has similar polarity to that of methanol. Similar spectra were observed when ANS molecules were incorporated in negatively-charged liposomes composed of egg PC and DCP (Fig. 2, a), though the intensity was somewhat reduced. These results indicate that the polarity of the binding site for ANS is not so different even when negatively-charged species are present in bilayer. When 210 μg/ml PHMB was added to the egg PC dispersion containing ANS prepared by the method (i), I_F of ANS was slightly increased: Increase of I_F at 460 nm was recognized, though the maximum still remained at 482 nm (Fig. 1, b). Addition of 200 μg/ml DAHB caused no change in I_F and λ_{max}.

Drastic change in spectrum was observed when PHMB was added to egg PC-DCP mixed liposome prepared by the method (i), which was negatively-charged at pH 7.4. Figure 2 shows the fluorescence spectra of ANS embedded in the egg PC-DCP mixed

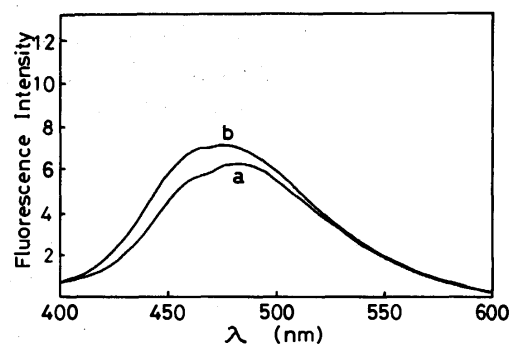

Fig. 1. Fluorescence spectra of ANS embedded in egg PC liposome in the absence and presence of PHMB: a, without PHMB; b, with 210 μg/ml PHMB added. The liposome solution was prepared by dispersing 0.8 mM egg PC in Tris-HCl buffer at pH 7.4; [ANS]= 2.2 μM, λ_{ex}=350 nm.

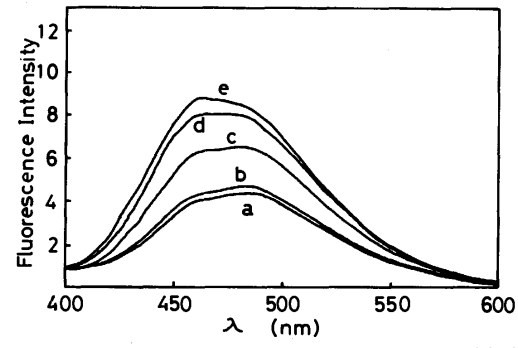

Fig. 2. Fluorescence spectra of ANS embedded in egg PC-DCP liposome in the presence of various concentrations of PHMB: [PHMB]=a, 0; b, 10.1 μg/ml; c, 50.4 μg/ml; d, 111 μg/ml; e, 170 μg/ml, λ_{ex}= 350 nm.
The liposome solution was prepared by dispersing 0.8 mM egg PC and 0.2 mM DCP in Tris-HCl buffer at pH 7.4; [ANS]=2.2 μM.

liposome ([egg PC]=0.8 mM, [DCP]=0.2 mM) in the presence of various concentrations of PHMB (0—170 μg/ml). With increasing concentration of PHMB, I_F increased gradually with gradual change in the shape of the spectrum. At 170 μg/ml of PHMB, λ_{max} is clearly changed to 460 nm. Addition of DAHB to the negatively-charged liposome composed of egg PC-DCP ([DAHB]=500 μg/ml) caused a slight increase of I_F, but to an insignificant extent. In Fig. 3 is depicted the increase of I_F as a function of the concentration of PHMB: the ratio $I_F/(I_F)_0$ at 460 nm was plotted against the concentration of PHMB, where I_F and $(I_F)_0$ are the fluorescence intensities at 460 nm in the presence and absence of PHMB, respectively. It can be readily seen from the figure that the increase of I_F at 460 nm is strongly dependent on the negative surface charge of the liposome. In the case of the neutral egg PC liposome, increase of I_F was very small and practically saturated at 50 μg/ml. On the other hand in the negatively-charged liposome composed of egg PC-DCP ([egg PC]=0.8 mM, [DCP]=0.09 mM) the $I_F/(I_F)_0$ increases with the concentration of PHMB added. Furthermore, much greater increase of I_F was ob-

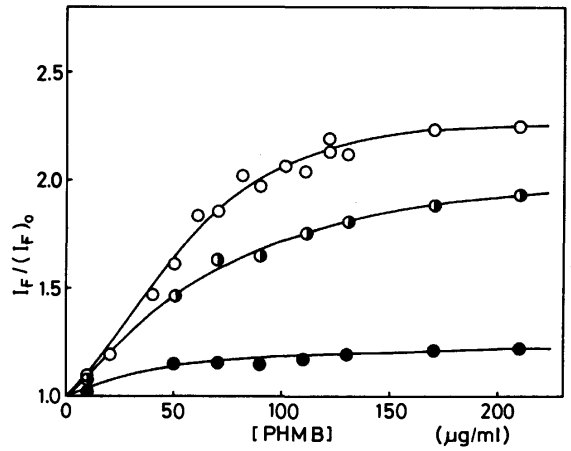

Fig. 3. Effect of PHMB on the fluorescence intensity of ANS embedded in various liposomes: (●), in egg PC liposome ([egg PC]=0.8 mM); (◑), in egg PC-DCP mixed liposome ([egg PC]=0.8 mM, [DCP]=0.09 mM); (○), in egg PC-DCP mixed liposome ([egg PC]=0.8 mM, [DCP]=0.2 mM). [ANS]=2.2 μM.

Table 1. Effect of Mg^{2+} and Ca^{2+} ions on fluorescence intensity of ANS embedded in egg PC liposome and in egg PC-DCP liposome

[ion]		I_F at 485 nm[a]

	49	0.94	0.99
	97	0.93	0.99
	239	0.93	0.97

a) Relative intensity; [ANS]=2.2 μM, λ_{ex}=350 nm. b) [egg PC]=0.8 mM, [DCP]=0.2 mM.

served in the more negatively-charged liposome which contained higher compositional ratio of DCP ([egg PC]=0.8 mM, [DCP]=0.2 mM).

The effects of Mg^{2+} and Ca^{2+} ions on fluorescence intensity of ANS embedded in the egg PC liposome and in the egg PC-DCP liposome were investigated ($MgSO_4$ and $CaSO_4$ were used). As seen in Table 1, unlike PHMB, these divalent cations rather lowered the intensity. These results clearly show that the enhancement of fluorescence intensity observed on adding PHMB is not just a sequence of electrostatic interaction between ANS and positive charges.

In order to investigate adsorption behavior of PHMB onto phospholipid membranes, incorporation of ANS molecules into liposomes without or with PHMB added was studied spectroscopically. In these experiments, addition of ANS was performed by the method (ii) (see Experimental). Higher concentrations of ANS gave rise to increased intensity of fluorescence, but no change in the shape of the spectrum, regardless of the presence of PHMB.

Benesi-Hildebrand type plots have been commonly used to estimate dissociation constants of complexes in many systems.[10,11] This type of plots is applicable to our system since only ANS molecules bound to liposomes contribute to the observed fluorescence intensity.[11]

$$\text{liposome}\cdot\text{ANS} \overset{K_D}{\rightleftarrows} \text{liposome} + \text{ANS}$$

$$\frac{1}{I_F} = \frac{1}{(I_F)_\infty} + \frac{K_D}{(I_F)_\infty}\cdot\frac{1}{[\text{ANS}]} \quad (1)$$

where [ANS] is the initial concentration of ANS (M); I_F, the fluorescence intensity of ANS associated with liposomes; $(I_F)_\infty$, I_F at the infinite concentration of ANS; K_D, the dissociation constant for liposome-ANS complex (M). The concentration of liposomes can be estimated from the concentration of phospholipids employed (1 mM) and the aggregation number of egg PC vesicles reported (N=2335)[12] as 0.4 μM. The concentrations of ANS used for this study were 3.6—18 μM, so that the concentration change in ANS due to association can by neglected. Thus Eq. 1 suffices for the present study. In Fig. 4 are shown $1/I_F$ *vs.* 1/[ANS] plots for the egg PC liposome-ANS system in the presence of various concentrations of PHMB. It is evident from the figure that with increasing concentration of PHMB the slope of the plots is reduced, whilst the intercept remains practically identical. Similar plots for the egg PC-DCP mixed liposome-ANS system are shown in Fig. 5. The same trend with respect to the PHMB concentration may be seen. From these plots, the dissociation constants were calculated and listed in Table 2.

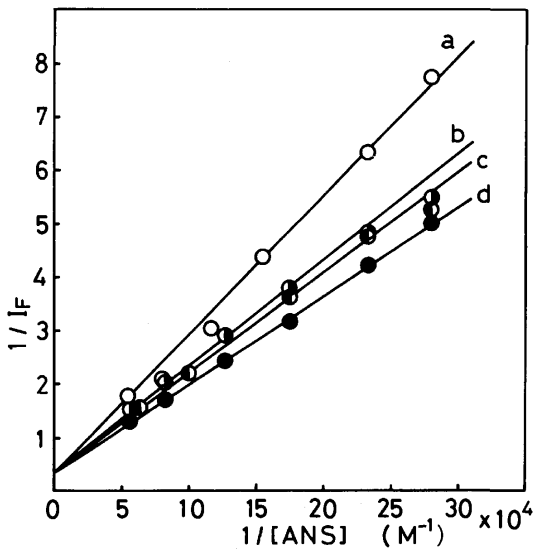

Fig. 4. $1/I_F$ *vs.* 1/[ANS] plots for egg PC-ANS complex in the presence of various concentrations of PHMB:
[PHMB]=a, 0; b, 20.3 μg/ml; c, 50.8 μg/ml; d, 102 μg/ml.
The liposome solution was prepared by dispersing 0.8 mM egg PC in Tris-HCl buffer at pH 7.4.

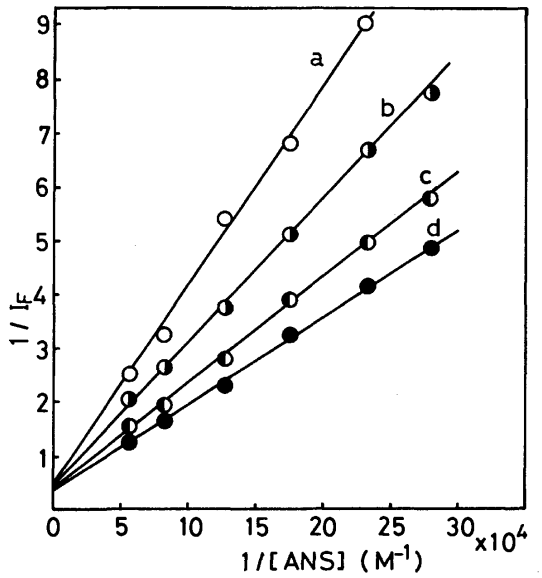

Fig. 5. $1/I_F$ *vs.* 1/[ANS] plots for egg PC-ANS complex in the presence of various concentrations of PHMB:

Discussion

The results obtained in this study clearly indicate that PHMB interacts more strongly with negatively-charged membranes than with a neutral membrane. This is quite reasonable from the fact that biguanides are strong bases (pK_1=10.5—11.5, pK_2=2—3) and are entirely monoprotonated at physiological pH.[13] Thus PHMB acts as a polyelectrolyte (polycation), and on account of the high positive charge density in its vicinity stronger interaction of PHMB with negatively-charged membranes is expected. The large difference between PHMB and DAHB in their interaction with membranes is most probably related to the great difference in their biocidal activity, DAHB being practically inactive.

NMR studies on the egg PC-ANS system have revealed that the amphipathic probe molecules are located at the interface region of the lipid dispersions where they interact with the head-groups of the lipids.[14] In the absence of PHMB, the lower intensity of fluorescence of ANS observed in the egg PC-DCP liposomes than that observed in the egg PC liposomes is evidently attributable to limited incorporation of the ANS molecules into the negatively-charged liposomes due to electrostatic repulsion. The larger K_D value estimated for the egg PC-DCP-ANS complex (at [PHMB]=0) is in support of this view quantitatively. The shift of λ_{max} observed on addition of PHMB to the egg PC-DCP liposomes can by no means be explained by simple increase in incorporation of ANS molecules in the presence of increased amount of PHMB, because the shape of the spectra remains unchanged when the concentration of ANS is varied at the fixed concentration of PHMB. Furthermore, it is evident from the control experiment already mentioned that direct interaction of ANS with PHMB does not contribute to the shift in λ_{max} and the increase in I_F under the experimental conditions employed to measure the spectra. A probable interpretation is as follows. PHMB is adsorbed on to the surface of the membranes where the sulfonato group of ANS is located. Then binding of a biguanide moiety to ANS as a counterion may take place. As a result, a less soluble complex of PHMB-ANS will be formed. This was evidenced by the formation of insoluble PHMB-ANS complex observed when 1% aqueous solutions of PHMB and ANS were mixed. The complex formation between PHMB and ANS will certainly produce less polar microenvironment around the bound ANS molecule in the membrane. The hydrophobic hexamethylene groups which link biguanide moiety in PHMB may contribute to give more hydrophobic environment to the bound ANS molecule. The effect of negatively-charged species (DCP) may be explained by two factors: (1) enhancement of surface adsorption of PHMB by electrostatic attraction and (2) endowment of additional "less polar" nature to the PHMB-ANS complex by participating in the complex as additional counterions of PHMB. These PHMB-ANS complexes are supposed to be solubilized in phospholipid bilayers.

The K_D values for the negatively-charged liposomes provide further support of the above view. The K_D values for the egg PC-DCP-ANS complex decrease with increasing concentration of PHMB added, whilst those for the egg PC-ANS complex remain nearly constant at the concentrations of PHMB higher than 20 μg/ml. These results seem to indicate that the quantity of PHMB adsorbed on to the neutral egg PC liposome is no longer increased above [PHMB]=20 μg/ml, whereas it increases with increasing concentration of PHMB added for the negatively-charged egg PC-DCP liposome. Actually, the lower values of K_D were obtained for the egg PC-DCP liposomes above [PHMB]=50 μg/ml, although below this concentration the K_D values for the negatively-charged liposomes were higher. Thus, the K_D value is a good indicator of adsorption behavior of PHMB onto the phospholipid bilayers. These results are consistent with preliminary results on electrophoretic mobility of the liposomes in

the presence of PHMB: The egg PC-DCP dispersion gave negative value of mobility and the addition of PHMB brought about reversal of the surface charge, giving positive values of mobility.[15]

In conclusion, our work has demonstrated that adsorption of PHMB takes place to a greater extent on to a negatively-charged membrane than on to a neutral membrane. This indicates that the adsorption site for PHMB is mainly negatively-charged species. In bacterial cytoplasmic membranes, there have been found many negatively-charged species such as membrane-bound proteins and acidic phospholipids.[16] Thus our work has provided reason for believing that the target sites for PHMB interaction are these negatively-charged species in intact bacterial membranes.

The BBGKY Equation in the Interaction Site Model for Polyatomic Molecular Fluids

Lloyd Lieh-shen LEE

School of Chemical Engineering and Materials Science, The University of Oklahoma, Norman, Oklahoma 73019, U.S.A.

(Received December 5, 1983)

We extend the atom-atom interaction site model to a fluid of polyatomic molecules in an external field by deriving the first Born-Bogoliubov-Green-Kirkwood-Yvon(BBGKY) hierarchy for a nonuniform system. It is shown that the intramolecular structure contributes to the density gradient as well as the intermolecular correlations. By invoking the mechanical equilibrium conditions for microscopic forces we also obtain new expression for the gradient of the pressure tensor in inhomogeneous fluids. The BBGKY equation provides a consistency check on any theories of the interaction site variety. An examination of the so-called RISM theory[1] of uniform fluids shows that the latter is inconsistent with respect to the BBGKY condition.

The interaction site model (ISM) for structured molecules in a uniform medium has been widely studied in literature.[1-17] It has been applied to the hard polyatomics, soft polyatomics[2-17] and to simulate real molecules (*e.g.* CO_2,[6] benzene[15,18] and water[7,11]). One of the popular theories is the so-called reference interaction site model[1] (RISM), based on certain approximation to the site-site direct correlation function (ss-dcf). Recently some inconsistencies inherent in RISM have been discovered[19-24] and modifications to it have been proposed.[23,24] It is desirable to have an alternative theoretical framework to RISM where exact relations are used. Here we present the formal results, the BBGKY hierarchy, for a nonuniform system using the ISM potential model. Applications will be postponed to a future study.

In section 2 we shall define the singlet (one-body) and pair (two-body) correlation functions in a grand canonical ensemble for polyatomic molecules (PM) in an external field. This picture may, say, correspond to the adsorption of structured molecules near a potential surface (the adsorbent phase). The first memeber of the Born-Bogoliubov-Green-Kirkwood-Yvon hierarchy is then derived. This equation is exact. We can interpret the results as specifying the linear momentum balance at the microscopic level.[25] From the equivalence of the mechanical equilibrium conditions with the BBGKY equation[26] we are able to express the pressure tensor in a nonuniform fluid in terms of the site-site correlation functions. This new expression can be contrasted with other known expressions of the pressure tensor.[27-30] Since the BBGKY equation is exact, any ISM theories concerning the correlation functions must satisfy this equation. Thus we have a consistency condition based on the BBGKY. We analyze the conventional RISM[1] theory in light of our new theoretical framework and discover that the Ornstein-Zernike-like equation given for the ss-dcf in the RISM is not exact. Its corrected form is one involving the incorporation of a Q factor (Section 5), whose form is explicitly given here.

The Grand Canonical Ensemble

In this section we give an explicit definition of the distribution function in a grand canonical ensemble. These explicit definitions will be found to be useful in the derivation of the BBGKY hierarchy.

For the simplicity in notation, we consider first a fluid of heteronuclear diatomics under the influence of an external potential, $U(.)$. There are N_a atoms of type a, and N_b, ($N_b=N_a$), atoms of type b. We distinguish the pair interaction, u $(\alpha_i\gamma_j)$, between atom α_i in molecule i and atom γ_j in a different molecule j (*i.e.* intermolecular potential) and the pair interaction, $\bar{u}$ (a_ib_j), between atom a and atom b of the same molecule i(*i.e.* intramolecular potential). We shall be brief in our descriptions.[31,32] Let V_N, ($N=N_a+N_b$), be the sum of the atom-atom potential energies,

$$V_N = \sum_{i<j}\sum_{\alpha,\gamma} u(\alpha_i\gamma_i) + \sum_k u(a_kb_k) \tag{2.1}$$

and W_N be the sum of the one-body energies,

$$W_N = \sum_k \sum_\alpha U(\alpha_k) \tag{2.2}$$

The grand canonical partition function, $\Xi[U]$, is given by

$$\Xi[U] \equiv \sum_{\underset{\sim}{N}\geq\underset{\sim}{0}} \frac{z_a^{N_a} z_b^{N_b}}{N_a!N_b!} \int_\Gamma d\{N_a\}d\{N_b\} \exp(-\beta V_N - \beta W_N), \tag{2.3}$$

where z_α is the activity of species α (α=a,b), β is the reciprocal temperature, $(kT)^{-1}$, k=the Boltzmann constant, $\{N_a\}$ is the set of position vectors, $\{a_1,a_2,..,a_{N_a}\}$, where a_i represents the distance vector, $\mathbf{r}_i^a$; and $d\{N_a\}$, the product of the differentials $da_1da_2\cdots$ Γ is the phase space appropriate for the diatomics (we exclude the regions of phase space where chemical decomposition of the diatomics takes place). The singlet density, $\rho_a^{(1)}$ $(a_1; U)$, and the pair densities, $\rho_{ab}^{(2)}$ $(a_1b_2; U)$, and $\bar{\rho}_{ab}$ $(a_1b_1; U)$ are defined as,

$$\rho_a^{(1)}(a_1;U) \equiv \frac{1}{\Xi[U]} \sum_{\underset{\sim}{N}>\underset{\sim}{1}} \frac{z_a^{N_a} z_b^{N_b}}{(N_a-1)!\,N_b!} \times \int_\Gamma d\{N_a-1\}d\{N_b-1\} \exp(-\beta V_N - \beta W_N), \tag{2.4}$$

$$\rho_{ab}^{(2)}(a_1b_2;U) \equiv \frac{1}{\Xi[U]} \sum_{\underset{\sim}{N}\geq\underset{\sim}{2}} \frac{z_a^{N_a} z_b^{N_b}}{(N_a-1)!\,N_b(N_b-2)!} \times \int_\Gamma d\{N_a-1\}d\{N_b-1\} \exp(-\beta V_N - \beta W_N) \tag{2.5}$$

and

$$\bar{\rho}^{(2)}_{ab}(a_1b_1;U) \equiv \frac{1}{\Xi[U]} \sum_{N\geq 2} \frac{z_a^{N_a} z_b^{N_b}}{(N_a-1)!\,N_b!} \times \int_\Gamma d\{N_a-1\} d\{N_b-1\} \exp(-\beta V_N - \beta W_N), \quad (2.6)$$

where the argument, $;U$, inside the functions denotes the nonuniformity (when $U=0$, we have the homogeneous case). The overbar, $\bar{}$, denotes the intramolecular quantities. We have not specified the nature of the inhomogeneity, U. It should assume the form appropriate for the problem at hand. For example, in planar adsorption U has the form of Lennard-Jones 10-4 or 9-3 interaction,[33] or of the Boltzmann averaged form.[34] For electrified walls, the Coulombic forces should be added. However, our equations are general. With these definitions at our disposal, we can proceed to the derivation of the BBGKY equation.

The BBGKY Equation

With the definition of the singlet density in (2.4), it is possible to derive the first equation in the BBGKY hierarcy for the ISM. The procedure follows the same line as in the monatomic (MA) case.[35-37] In order to avoid tedious notation we propose the following abbreviations:

$$e^{a}(\alpha_1) = \exp[-\beta U(\alpha_1)] \quad (3.1)$$

$$e^{+a}(\alpha_1) = \exp[+\beta U(\alpha_1)] \quad (3.2)$$

$$E^{ar}(\alpha_1\gamma_j) = \exp[-\beta v(\alpha_1\gamma_j)] \quad (3.3)$$

also,

$$\hat{S}_{(a_1)}(\cdots) \int db_1 da_2 db_2 \cdots da_{N_a} db_{N_b}(\cdots) \quad (3.4)$$

and

$$f^{N_a-1}_{N_b N_b-2} = \frac{z_a^{N_a} z_b^{N_b}}{(N_a-1)!N_b(N_b-2)!} \quad (3.5)$$

where v is the pair potential, which becomes $\bar{u}$ for intramolecular interaction or u for intermolecular interaction. Thus Eq. (2.4) can be written as

$$\rho^{(1)}_a(a_1;U) = \frac{1}{\Xi[U]} \sum f^{N_a-1}_{N_b} \hat{S}_{(a_1)} E^{ab}(a_1b_1) E^{ae}(a_1\varepsilon_2)\cdots e^{a}(a_1)\cdots \quad (3.6)$$

where we have exhibited three typical Boltzmann factors. Denoting the gradient operator with respect to $\mathbf{r}^1_a$ as ∇_1, we differentiate both sides of (3.6)

$$\nabla_1\rho^{(1)}_a(a_1;U) = \Xi[U]^{-1} \sum f^{N_a-1}_{N_b} \hat{S}_{(a_1)} \times \begin{bmatrix} -\nabla_1\beta\bar{u}(a_1b_1)E^{ab}(a_1b_1)\cdots \\ -\sum_\varepsilon (N_\varepsilon-1)\nabla_1\beta u(a_1\varepsilon_2)E^{ae}(a_1\varepsilon_2)\cdots \\ -\nabla_1\beta U(a_1)e^{a}(a_1)\cdots \end{bmatrix} \quad (3.7)$$

Applying the definitions of the singlet and pair densities, we obtain

$$\nabla_1\rho^{(1)}_a(a_1;U) = -\int db_1 \nabla_1\beta\bar{u}(a_1b_1)\cdot\bar{\rho}^{(2)}_{ab}(a_1b_1;U) - \sum_\varepsilon \int d\varepsilon_2 \nabla_1\beta u(a_1\varepsilon_2)\cdot\rho^{(2)}_{a\varepsilon}(a_1\varepsilon_2;U) - \nabla_1\beta U(a_1)\cdot\rho^{(1)}_a(a_1;U) \quad (3.8)$$

(BBGKY: Diatomics)

This is the first member of the BBGKY equation for heteronuclear diatomic molecules immersed in an external field. We observe the appearance of the intramolecular pair density, $\bar{\rho}^{(2)}$, as well as the usual intermolecular one, $\rho^{(2)}$. Higher members of the hierarchy can be similarly derived. Equation (3.8) similar to the monatomic case is not closed. In order to solve for the densities, a closure relation is needed. However, the relation given is exact. Any theory concerning the correlation functions must satisfy (3.8) in order to be consistent. In fact, the first member of the BBGKY hierarchy is known to express the force equilibrium among the molecules. The consistency check is then a check on the mechanical equilibrium.

The Pressure Tensor

From a microscopic linear momentum balance, one can show[25-27,38] that the mechanical equilibrium condition in a nonuniform fluid is given by

$$\sum_\nu \nabla_\nu P^{\mu\nu}(q) = -\sum \rho^{(1)}_a(q)\nabla_\mu U(q) \quad (4.1)$$

$$\mu,\nu = x, y, z$$

where $P^{\mu\nu}$ is the pressure tensor and U is the external potential. For structured molecules with non-central forces, $P^{\mu\nu}$ may be asymmetrical.[28-30] The well-known equivalence of the first BBGKY hierarchy and the mechanical equilibrium condition requires[26]

$$\sum_\nu \nabla_\nu\cdot\beta P^{\mu\nu}(q) = \sum_\alpha \nabla_\mu \rho^{(1)}_a(q;U) + \sum_\alpha\sum_\varepsilon \int d\varepsilon_1 \nabla_\mu\beta\bar{u}(q\varepsilon_1)\cdot\bar{\rho}^{(2)}_{a\varepsilon}(q\varepsilon_1;U)(1-\delta_{a\varepsilon}) + \sum_\alpha\sum_\varepsilon \int d\varepsilon_2 \nabla_\mu\beta u(q\varepsilon_2)\cdot\rho^{(2)}_{a\varepsilon}(q\varepsilon_2;U) \quad (4.2)$$

We obtain a microscopic description of the pressure tensor (*via* its gradient) in terms of the site-site correlation functions and the inter- and intramolecular potentials. (N.B. the factor $(1-\delta_{a\varepsilon})$, is to remove the one-atom autocorrelation, $\bar{\rho}^{(2)}_{aa}$.) It is obvious to see that the first term on the righthand side (RHS) is the kinetic contribution (ideal gas term), while the second term is the interaction contribution due to the internal forces, $\nabla\bar{u}(\alpha_i\gamma_j)$; and the third term due to the usual intermolecular forces, $\nabla u(\alpha_i\gamma_j)$. The pressure tensor $P^{\mu\nu}$ is known[25-27] to be not uniquely defined. Its gradient, ∇P, however, is well behaved,[26] *i.e.* the microscopic $P^{\mu\nu}$ is defined modulo a divergenceless quantity.[28] Since our system is nonuniform ($U\neq 0$), the pressure tensor is asymmetric (the singlet density is anisotropic in the orientation space and the angular velocity in general lacks local orientational rigidity.[28-30]) Even though we are in an atomic picture,[39] the intramolecular contribution (the second term) shall contribute to the asymmetry and to the so-called body torque.[26,29] In the limit $\bar{\rho}^{(2)}=0$, we recover the familiar pressure tensor expression as given by Irving and Kirkwood,[25] Bearman and Kirkwood,[40] and Davis and Scriven.[41]

Analyses of the RISM

We have mentioned in Sect. 3 that any theory on the site-site functions should satisfy the consistency conditions posed by (3.8). We now check the RISM. The original theory[1] on the site-site direct correlation function (ss-dcf), $c^{(2)}_{\alpha\gamma}(\alpha_i\gamma_j)$, $(i\neq j)$, can be written *via* a matrix form,

$$[\omega^{-1}\delta/\rho^{(1)}-c^{(2)}]_{\alpha\xi}[\delta\rho^{(1)}\omega+F^{(2)}]_{\xi\gamma}=\delta_{\alpha\gamma}\delta_D \tag{5.1}$$

(as we shall see shortly, this is not the exact Ornstein-Zernike (OZ) relation. Actually, it is an approximate form of the OZ relation). In (5.1), δ is the unit matrix (or the Kronecker delta, $\delta_{\alpha\gamma}$), $\delta_D(qr)$, is the Dirac delta function; ω is the intramolecular structure used in RISM[1] and is related to our intramolecular pair density, $\bar{\rho}^{(2)}$, *via*

$$\sum_\xi \rho^{(1)}_\alpha(\alpha)\delta_{\alpha\xi}\omega(\xi\gamma)=\rho^{(1)}_\alpha(\alpha)\delta_D(\alpha\gamma)\delta_{\alpha\gamma}+\bar{\rho}^{(2)}_{\alpha\gamma}(\alpha\gamma)(1-\delta_{\alpha\gamma}) \tag{5.2}$$

and $F^{(2)}$ is the truncated (Ursell) pair correlation function,

$$F^{(2)}(\alpha_i\gamma_j)=-\rho^{(1)}_\alpha(\alpha_j)\rho^{(1)}_\gamma(\gamma_j)+\rho^{(2)}_{\alpha\gamma}(\alpha_i\gamma_j), \tag{5.3}$$

In Eq. (5.1) the matrix multiplication conventions have been used (*i.e.* summation over repeated indices and integration over repeated arguments).

As was shown by Lebowitz and Percus[42-44] the basis of OZ is the matrix inverse properties of the two functional derivatives,

$$\frac{\delta(-\beta U)}{\delta\rho^{(1)}}\,\frac{\delta\rho^{(1)}}{\delta(-\beta U)}=\delta\delta_D \tag{5.4}$$

With the definition (2.4) for the singlet density, it is easy to show[45] that the derivative $\delta\rho^{(1)}/\delta(-\beta U)$ is

$$\frac{\delta\rho^{(1)}_\alpha(\alpha)}{\delta(-\beta U(\gamma))}=\sum_\xi \rho^{(1)}_\alpha(\alpha)\delta_{\alpha\xi}\omega(\xi\gamma)+F^{(2)}_{\alpha\gamma}(\alpha\gamma) \tag{5.5}$$

(Here we have suppressed the inhomogeneity, $;U$). Thus (5.5) accounts for the second factor on the LHS of (5.1). The first factor of (5.1) must correspond to the functional derivative $\delta(-\beta U)/\delta\rho^{(1)}$ in order to satisfy the exact mathematical condition (5.4). To estimate this so-called "compressibility" derivative,[46,47] we notice that Eq. (3.8) can be rearranged to give,

$$\begin{aligned}\nabla_1[-\beta U(a_1)] &= \nabla_1 \ln \rho^{(1)}_a(a_1)\\ &+\int db_1\nabla_1\beta u(a_1b_1)\bar{\rho}^{(2)}_{ab}(a_1b_1)/\rho^{(1)}_a(a_1)\\ &+\sum\int d\varepsilon_2\nabla_1\beta u(a_1\varepsilon_2)\rho^{(2)}_{a\varepsilon}(a_1\varepsilon_2)/\rho^{(1)}_a(a_1)\end{aligned} \tag{5.6}$$

Assuming the interchangeability of the two differential operators, ∇_1 and $\delta(.)/\delta\rho^{(1)}$ (see *e.g.* Percus[48]), we can functionally differentiate (5.6) to get,

$$\begin{aligned}\nabla_1\frac{\delta(-\beta U)}{\delta\rho^{(1)}} &= \nabla_1\frac{\delta\ln\rho^{(1)}}{\delta\rho^{(1)}}+\int db_1\nabla_1\beta\bar{u}\frac{\delta}{\delta\rho^{(1)}}\left(\frac{\bar{\rho}^{(2)}}{\rho^{(1)}}\right)\\ &+\sum_\xi\int d\xi_2\nabla_1\beta u\frac{\delta}{\delta\rho^{(1)}}\left(\frac{\rho^{(2)}}{\rho^{(1)}}\right)\end{aligned} \tag{5.7}$$

In comparison with the MA case, it is natural[49] to identify the ss-dcf which is the correlation function between atoms in different molecules as the last term on the RHS $\nabla_1 c^{(2)}_{\alpha\gamma}$ of (5.7):

$$\nabla_1 c^{(2)}_{\alpha\gamma}=-\sum_\xi\int d\xi_2\nabla_1\beta u\frac{\delta}{\delta\rho^{(1)}_\gamma}\left(\frac{\rho^{(2)}_{\alpha\xi}}{\rho^{(1)}_\alpha}\right) \tag{5.8}$$

The first term on the RHS (Eq. (5.7)) is due to the ideal gas (kinetic) contribution (see Eq. (4.2)); while the second term is due to contribution from intramolecular forces. We shall call this term $\mathcal{Q}$, *i.e.*

$$\nabla_1\mathcal{Q}\equiv\nabla_1\frac{\delta\ln\rho^{(1)}}{\delta\rho^{(1)}}+\int db_1\nabla_1\beta u\frac{\delta}{\delta\rho^{(1)}}\left(\frac{\bar{\rho}^{(2)}}{\rho^{(1)}}\right) \tag{5.9}$$

Comparing (5.7) with (5.4) and (5.1) shows that if the RISM assumption (5.1) were correct, the quantity $\mathcal{Q}$ in (5.9) should be given by

$$\mathcal{Q}\overset{?}{=}\omega^{-1}\left(\frac{\delta}{\rho^{(1)}}\right) \tag{5.10}$$

modulo a divergenceless quantity. The question mark on the " ? " sign is to question the equality of the two sides. A check of the cluster expansions[23,24] for ω shows that this equality does not hold beyond the first density term; *i.e.* the quantity in (5.9) is not the same as was assumed in RISM to be $\omega^{-1}(\delta/\rho^{(1)})$:

$$\begin{aligned}\omega^{-1}\left(\frac{\delta}{\rho^{(1)}}\right)&=\Delta^{-1}\begin{pmatrix}\frac{\delta_D}{\rho^{(1)}_a} & -\frac{\bar{\rho}^{(2)}_{ab}}{\rho^{(1)}_a\rho^{(1)}_b}\\ -\frac{\bar{\rho}^{(2)}_{ba}}{\rho^{(1)}_b\rho^{(1)}_a} & \frac{\delta_D}{\rho^{(1)}_b}\end{pmatrix}\\ &=\begin{pmatrix}\frac{\delta_D}{\rho^{(1)}_a}+\frac{\bar{\rho}^{(2)}_{ab}*\bar{\rho}^{(2)}_{ba}}{\rho^{(1)}_a\rho^{(1)}_a\rho^{(1)}_b}+\cdots & -\frac{\bar{\rho}^{(2)}_{ab}}{\rho^{(1)}_a\rho^{(1)}_b}-\cdots\\ -\frac{\bar{\rho}^{(2)}_{ba}}{\rho^{(1)}_b\rho^{(1)}_a}-\cdots & \frac{\delta_D}{\rho^{(1)}_b}+\frac{\rho^{(2)}_{ba}*\rho^{(2)}_{ab}}{\rho^{(1)}_b\rho^{(1)}_b\rho^{(1)}_a}+\cdots\end{pmatrix}\end{aligned} \tag{5.11}$$

where Δ is the normalization factor. Therefore the RISM assumption (5.1) does not satisfy the BBGKY condition. (There was an additional assumption on the ss-dcf in RISM,[50] which we shall not comment here.) We conclude that the relation (5.1) is not a true Ornstein-Zernike relation (we base our definition of OZ on Eq. (5.4)). And the conventional RISM theory is not an exact theory in more ways[19-24] than one.

Discussions

From explicit definitions of the correlation functions in the interaction site model we have derived for the first time the BBGKY equation in a nonuniform system. We specialize to the case of the heteronuclear diatomics. Higher polyatomics can be easily treated along analogous lines. Since the BBGKY equation is equivalent to the mechanical equilibrium condition, we are able to express the pressure tensor in terms of both intra- and inter-molecular correlation functions. These connections confirm that the gradients of the density and the external potential are related to microscopic force balances. Therefore any equations relating the many-body distribution functions using the ISM approach much satisfy this microscopic force balance condition. We examined the reference interaction site model and found that its proposed Ornstein-Zernike-

like equation is not consistent with the general form of the BBGKY equation.

In the monatomic case, other types of hierarchy were given for the gradient of the singlet density, *e.g.*

$$\nabla_1\rho^{(1)} = \rho^{(1)}\nabla_1(-\beta U) + \rho^{(1)}\int \mathrm{d}2\, c^{(2)}\nabla_2\rho^{(1)} \qquad (6.1)$$

as given by Lovett *et al.*[51] (See also[44,52,53]). Their implications in the polyatomic case shall also be investigated in the future.

In the MA Henderson[38] has derived the following pressure gradient relation based on the potential distribution theorem of Widom,[54]

$$\sum_\nu \nabla\beta P^{\mu\nu} = \rho^{(1)}\nabla \ln \rho^{(1)} - \rho^{(1)}\nabla c^{(1)}, \quad \text{(MA)} \qquad (6.2)$$

where $c^{(1)}$ is the one-body direct correlation function. Since the two-body dcf, $c^{(2)}$, can be obtained from $c^{(1)}$ *via* the functional differentiation[55]

$$c^{(2)}(\mathrm{r}, \mathrm{r}') = \frac{\delta c^{(1)}(\mathrm{r})}{\delta\rho^{(1)}(\mathrm{r}')}\,, \quad \text{(MA)} \qquad (6.3)$$

we could differentiate (6.2) with respect to $(\delta/\delta\rho^{(1)})$ (after interchanging the order with the gradient ∇)[48] to obtain

$$\nabla c^{(1)} = -\sum_\nu \nabla\frac{\delta}{\delta\rho^{(1)}}\left(\frac{\beta P_c^{\mu\nu}}{\rho^{(1)}}\right), \quad \text{(MA)} \qquad (6.4)$$

where $P_c^{\mu\nu}$ is the configurational part of the pressure tensor. Equation (6.4) bears striking resemblance to our Eq. (5.8) after the substitution of (4.2). In this respect the monatomics exhibit similar behavior as our diatomic case. (In fact our diatomic equations should reduce to the MA case when the intramolecular potential is set equal to the intermolecular one; or when $\bar{\rho}^{(2)}=0$). In fact Eq. (6.4) lends support to our identification (5.8). The potential distribution theorem has played an important role in the computer simulations of the chemical potential in MA.[56-62] Its extension to polyatomics is under investigation.

Thermal Investigations of 1,4-Butanediamine Complexes of Nickel(II) in the Solid Phase

Goutam De and Nirmalendu Ray Chaudhuri*

Department of Inorganic Chemistry, Indian Association for the Cultivation of Science, Calcutta 700032, India

(Received December 8, 1983)

$[NiL_3]Cl_2 \cdot H_2O$, $[NiL_2(H_2O)_2]Br_2$, and $[NiL_2(NCS)_2]$ (L= 1,4-butanediamine) have been synthesized and their thermal investigations have been carried out. $[Ni_2L_3Cl_4]$, $[NiLCl_2]$, $[Ni_4L_3Br_8]$, and $[NiL(NCS)_2]$ have been synthesized pyrolytically in solid phase by temperature arrest technique from their corresponding parent diamine complexes. All the parent tris and bis(diamine)complexes possess O_h geometry. $[NiLCl_2]$ possesses T_d geometry, whereas, $[NiL(NCS)_2]$ possesses O_h though 1,4-butanediamine is chelated in both of these mono-(diamine) complexes. Thiocyanate is found to be bridged in $[NiL(NCS)_2]$. The probable mechanistic paths of decomposition of these diamine complexes have been propsoed.

Chelating and bridging bidentate character of 1,4-butanediamine (L) in metal complexes are well documented in literature.[1-3] Metal complex having unidentate diamine is also known.[4] Synthesis of $[NiL_3]^{2+}$ is not yet reported. But tris chelate complexes like $[CoL_3]^{3+}$ are known, where L attains seven-membered chelate rings and possesses chair conformations.[5,6] Recently, some 1,4-butanediamine complexes are being used for the preparation of macrocyclic complexes.[7]

We have recently reported a series of thermal investigations of metal 1,2-ethanediamine and 1,3-propanediamine complexes in the solid phase.[8-12] In these investigations we synthesized a good number of novel metal diamine complexes. Besides these, thermally induced structural and conformational changes in nickel(II) diamine complexes were observed by us.[13]

The purpose of this paper is to report the thermochemical studies of nickel diamine complexes having seven-membered chelate rings and to compare their decomposition patterns with those of five and six-membered chelate complexes.

Experimental

The metal salts used were all of A.R. grade purity. 1,4-Butanediamine was supplied from Fluka AG, Switzerland.

Preparation: $[NiL_3]Cl_2 \cdot H_2O$ (**1**), $[NiL_2(H_2O)_2]Br_2$ (**2**), and $[NiL_2(NCS)_2]$ (**3**).

1,4-Butanediamine (L) (3—4 mmol) was added to the ethanolic solution of nickel salt (1 mmol) dropwise with stirring. On mixing immediate separation of complex took place. The resulting heterogeneous mixture was stirred for ≈10 h and the desired complexes were collected by filtration, washed thoroughly with ethanol and dried over fused $CaCl_2$ desiccator.

$[Ni_2L_3Cl_4]$ (**1A**): This was synthesized by keeping the complex (**1**) at ≈185 °C in a nitrogen atmosphere. The thermolysis was stopped when no more diamine was lost as evident by getting a constant weight.

$[NiLCl_2]$ (**1B**): This was synthesized following the method adopted for the synthesis of complex (**1A**) from complex (**1**) at ≈245 °C.

$[NiL_2Br_2]$ (**2A**): This was synthesized by heating the complex (**2**) upto ≈135 °C.

$[Ni_4L_3Br_8]$ (**2B**): This was synthesized from complex (**2**) at ≈260 °C by the similar procedure to that adopted for the synthesis of complex (**1A**).

$[NiL(NCS)_2]$ (**3A**): This was also synthesized from complex (**3**) at ≈235 °C by the similar procedure to that adopted for the synthesis of complex (**1A**).

Molar conductance data of these complexes could not be taken since these complexes decompose in water and are insoluble in all the available solvents.

Analytical, spectral band maxima and magnetic data are shown in Table 1.

The apparatus employed for carrying out thermal analysis is the same as reported earlier.[8,9] Table 2 lists the thermal

data.

Infrared spectra in KBr (4000—400 cm^{-1}) and in polythene discs (400—250 cm^{-1}, in some cases) were recorded using a Beckman IR-20A and Perkin-Elmer 597 IR spectrophotometers respectively and the corresponding data were given in Table 3.

Results

$[NiL_3]Cl_2 \cdot H_2O$ (**1**) becomes anhydrous at 85 °C (Fig. 1, Table 2) showing an endothermic peak at 80 °C. The blue-colored anhydrous species starts decomposition at 135 °C and transforms to $[Ni_2L_3Cl_4]$ at 205 °C through the formation of nonisolable intermediate, $[NiL_2Cl_2]$. The derived $[Ni_2L_3Cl_4]$ on further heating results $[NiLCl_2]$ at 245 °C. The unis(diamine) species is stable upto 285 °C and then decomposes to $NiCl_2$ through the formation of nonisolable intermediate, $[Ni_2LCl_4]$ at 315 °C. DTA curve shows three endotherms for the elimination of first two moles of diamine and three exotherms for the elimination of residual diamine.

$[NiL_2(H_2O)_2]Br_2$ (**2**) starts deaquation (Fig. 2, Table 2) at 75 °C and becomes deaquated completely at 130 °C showing two overlapping endotherms in the DTA profile. The deaquated species starts deamination at 155 °C and transforms to $[Ni_4L_3Br_8]$ at 260 °C, through the formation of nonisolable intermediates. The derived $[Ni_4L_3Br_8]$ starts decomposition at 275 °C and transforms to $NiBr_2$ at 345 °C. The corresponding DTA curve shows three endotherms for elimination of 1.25 mole of diamine and four exotherms overlapping to each other for the elimination of residual diamine.

$[NiL_2(NCS)_2]$ starts deamination (Fig. 2, Table 2) at 175 °C and generates thermally stable $[NiL(NCS)_2]$ at 230 °C. Unis(diamine) species starts decomposition at 280 °C and transforms to $Ni(SCN)_2$ at 340 °C. The DTA curve shows initially an endotherm followed by an exotherm for the elimination of first molecule of diamine. It shows two overlapping exotherms for the elimination of last molecule of diamine.

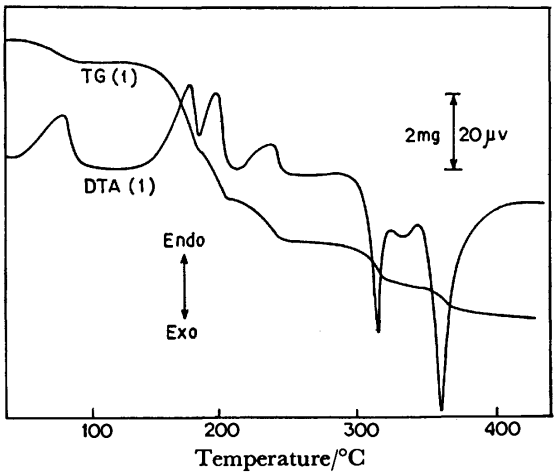

Fig. 1. Thermal curves of $[NiL_3]Cl_2 \cdot H_2O$ (**1**) sample mass, 11.60 mg.

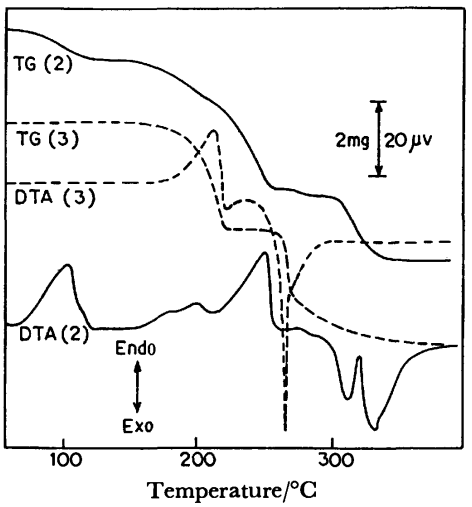

Fig. 2. Thermal curves of $[NiL_2(H_2O)_2]Br_2$ (**2**) (——), sample mass 12.86 mg and $[NiL_2(NCS)_2]$ (**3**) (- - -), sample mass 11.50 mg.

Discussion

Possession of bands at 3300, 3245, 3220, and 3140 cm^{-1} due to $\nu(NH_2)$ and at 2945, 2940, 2860, and 2850 cm^{-1} due to $\nu(CH_2)$ in IR spectrum (Table 3) of $[NiL_3]Cl_2 \cdot H_2O$ (**1**) is well consistent with chela-

vs=very strong, s=strong, ms=medium strong, m=meduim, br=broad, w=weak, vw=very weak, sh=shoulder. a): Compound gives bands at 3240 ms and 3360 ms for ν(OH) and at 1630 sh for δ(HOH). b): Compound gives bands at 3400 sh and 3370 sh for ν(OH) and at 1655 ms and 1645 sh for δ(HOH).

tion character of the ligand.[8-13] Literature shows less number of IR bands due to $\nu(NH_2)$ and $\nu(CH_2)$ for the complexes, where diamine acts as bridging bidentate ligand.[2] Morever, the IR spectrum of complex (**1**) is quite similar to the IR spectrum of $[Ni(tn)_3]Cl_2 \cdot 2H_2O$ (tn=1,3-propanediamine),[9] which also indicates the chelation character of the ligand in the complex.

We are not able to isolate the bis(diamine) species from complex (**1**) by temperature arrest technique owing to its thermal instability. So it is very difficult to suggest the actual configuration of the bis species. But the isolation of *cis* bis(diamine) complexes from $[M(en)_3]Cl_3$ [M=Co(III) and Cr(III)],[14,15] $[Ni(en)_3]Cl_2$ and $[Ni(tn)_3]Cl_2$[9] hint the formation of *cis* bis-(diamine) species here. Decomposition of $[NiL_3]Cl_2$ is different from the corresponding tris chelate complexes of 1,2-ethanediamine and 1,3-propanediamine as it generates $[Ni_2L_3Cl_4]$ (**1A**) upon heating. The IR spectrum (Table 3) of complex (**1A**) shows some additional bands in the regions of stretching (ν), bending (δ), wagging (ρ_w), twisting (τ) vibrations of NH_2 and CH_2 and stretching vibrations of skeleton ν(C–N) and ν(C–C) along with the other bands responsible for chelation character of diamine in comparison to the IR spectrum of complex (**1**). This observation suggests the chelating as well as bridging character of the ligand in complex (**1A**). Two probable structures are suggested (Structures 1* and 1; Scheme 1) for the complex (**1A**). It is rather difficult to say which structure actually displays here. Spectral and magnetic data of the complex cannot distinguish the structures clearly. However, electronic spectral band positions (Fig. 3) in 800—300 nm and their relative intensity difference may suggest the formation of *tbp* geometry.[16] If O_h geometry would be considered for the complex (**1A**), the relative intensity of $\nu_2[^3A_2 \rightarrow {}^3T_1(F)]$ and $\nu_3[^3A_2 \rightarrow {}^3T_1(P)]$ bands in mull spectra would not differ much.[8,9,13]

Scheme 1 clarifies that formation of $[NiLCl_2]$ (**1B**) occurs either from complex (**1A**)(O_h) or from complex (**1A**)(*tbp*). Both the cases seem to be feasible. But if we have octahedrally symmetrical $[Ni_2L_3Cl_4]$, then cleavage of bridging chlorine as well as ligand elimination (Scheme 1) would occur simultaneously during heating, which is rather complicated path. On the contrary, if the complex (**1A**) possesses *tbp* geometry then only ligand elimination would occur for affording $[NiLCl_2]$. In this context single endothermic DTA

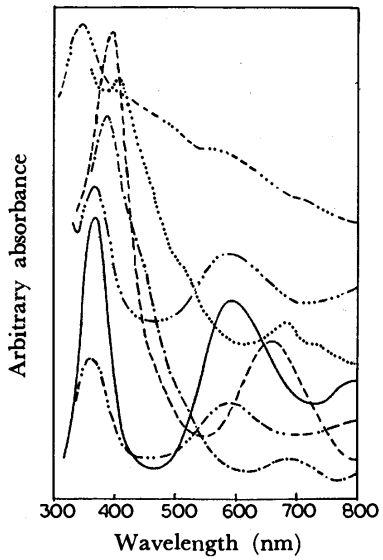

Fig. 3. Electronic mull spectra of $[NiL_3]Cl_2 \cdot H_2O$(**1**) (——), $[Ni_2L_3Cl_4]$ (**1A**) (- - -), $[NiLCl_2]$ (**1B**) (-·-·-), $[NiL_2(H_2O)_2]Br_2$ (**2**) (- ·· - ·· - ·· -), $[Ni_4L_3Br_8]$ (**2B**) (·····). $[NiL_2(NCS)_2]$ (**3**) (-·····-) and $[NiL(NCS)_2]$ (**3A**) (- - ····· - -).

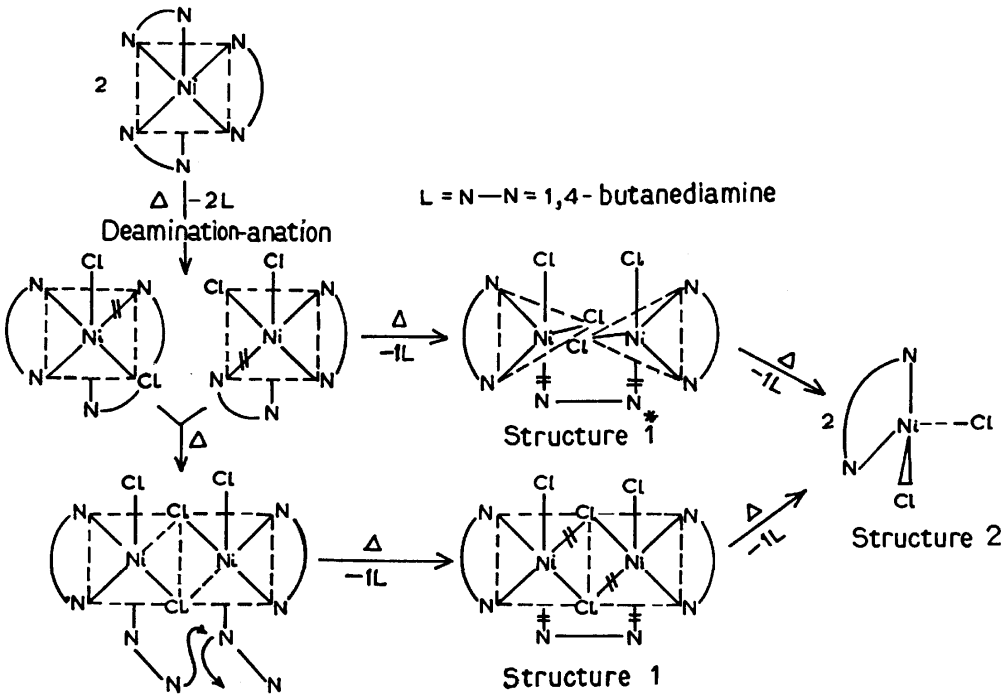


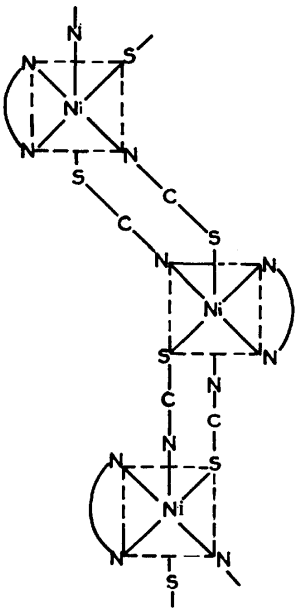
Scheme 1.

peak (Fig. 1) for the solid state reaction of $[Ni_2L_3Cl_4] \rightarrow [NiLCl_2]$ probably corroborates the *tbp* geometry in $[Ni_2L_3Cl_4]$.

The IR spectrum of $[NiLCl_2]$ suggests that the ligand is chelated here. Band appearing at 345 and 336 cm^{-1} in IR spectrum (Table 3) is well significant for terminally coordinated Cl atom in T_d geometry.[17] Higher magnetic moment (Table 1) of $[NiLCl_2]$ in comparison to other complexes is due to greater orbital contribution for loss of symmetry. The electronic spectra in mull (Fig. 3) display the characteristic band of the T_d Ni^{II} system (Structure 2, Scheme 1) at $\approx$670 nm which is tentatively assignable to the $^3T_1 \rightarrow {}^3T_1(P)$ transition (ν_3).[18,19]

In addition to the fundamental modes, we observe other modes of vibration of water molecule $\rho_r(H_2O)$ at $\approx$700 cm^{-1} and ν(MO) at $\approx$395 cm^{-1} in IR spectrum of $[NiL_2(H_2O)_2]Br_2$ (2).[20] The bands responsible for $\rho_r(H_2O)$ and ν (MO)are found to be absent in the anhydrous species. The diaquabis(1,4-butanediamine)nickel(II) bromide and dibromobis(1,4-butanediamine)-nickel(II) complexes are undoubtedly *cis* as is evident from IR assignments[21,22] in comparison to the *trans*-$[NiL_2(NCS)_2]$ (**3**). Complex (**2**) after deaquation-anation decomposes less stoichiometrically than that of its chloro analogue (*vide supra*) and generates isolable as well as nonisolable intermediates. This is probably due to anion effect. Complex (**2B**) possesses some additional bands (Table 3) in comparison to the IR spectrum of complex (**1B**) which might be due to the possession of chelating as well as bridging behavior of the diamine. Higher magnetic moment (than that of an O_h complex) and electronic spectrum of complex (**2B**) (Fig. 3) suggest that nickel(II) is probably tetracoordinated having T_d geometry.

Appearance of ν(CN) at 2095 cm^{-1} and ν(CS) at 770 cm^{-1} in the IR spectrum[23-26] (Table 3) of $[NiL_2(NCS)_2]$(**3**) clearly indicates that the compound (**3**) is actually *trans*-diisothiocyanatobis-(1,4butanediamine)-nickel(II). The IR spectrum of complex (**3**) supports the chelation character of diamine. Complex (**3**) generates $[NiL(NCS)_2]$ (**3A**) at 230 °C in single step as observed from its TG curve (Fig. 2) and corresponding DTA profile gives an endotherm followed by an exotherm. The exothermic peak may be due to some rearrangement taking place in complex (**3A**) after its formation. It is interesting to note that isolation of $[Ni(NCS)_2(en)]$ and $[Ni(NCS)_2(tn)]$ was not possible by us from their corresponding bis(diamine) complexes. Similar IR data of $[NiL(NCS)_2]$ (**3A**) with those of $[NiLCl_2]$ and $[NiL_2(NCS)_2]$ indicate that the ligand is also chelated in complex (**3A**). Magnetic moment (Table 1) of the complex (**3A**) suggests that nickel(II) is octahedrally surrounded. Although electronic spectra in mull (Table 1, Fig. 3) are not well resolved due to its dark color, the band maxima are well consistent for pseudooctahedral coordination of nickel(II) ion. ν(CN) of complex (**3A**) exhibits two intense bands at 2130 and 2120 cm^{-1} and three prominent shoulders at 2160, 2080, and 2060 cm^{-1} (Table 3). These data indicate the bridging character of thiocyanato group in the complex.[27,28] The spectroscopic and magnetic data suggest that all thiocyanato groups are bridged having



Structure 3

pseudooctahedral chromophore in complex (**3A**). Structures of $[M(NCS)_2(bipy)]$[M=Co(II) and Mn(II)] have been reported earlier by Dockum *et al.*[28] This observation suggests the probable structure of complex (**3A**) as depicted above. The occurrence of the geometrical difference in $[NiLX_2](X=Cl^-$ and $NCS^-)$ is probably due to more bridging ability of thiocyanato group although examples of similar type chloro-bridged complexes are known.[28]

Thermal studies on en and tn complexes of nickel(II) reported by us and the present investigation reflect that thermal decomposition is very much dependent on the chain length of diamine.

Studies on Mixed-Ligand Complexes of Cadmium with 2,2′-Bipyridyl and Some Dicarboxylic Acids in Dioxane Medium

Rajani KUMARI, Chandra Pal Singh CHANDEL,* and Chand Mal GUPTA

Department of Chemistry, University of Rajasthan, Jaipur-302004, India

(Received January 5, 1984)

The mixed-ligand complexes of cadmium with 2,2′-bipyridyl and dicarboxylic acids (tartaric, succinic, maleic, malonic, and malic) were studied polarographically in the 50% dioxane medium. The stability constants of simple systems were calculated by Deford and Hume[1] method, and the values of stability constants of mixed-ligand complexes have been determined by the method of Schaap and McMasters.[2] The overall stability constants have been evaluated with the help of Leden's[3] graphical extrapolation method and the values of β_{11}, β_{12}, and β_{21} are (5.24, 5.80, and 8.19) for Cd-bpy-tartarate system (5.62, 6.15, and 8.34) for Cd-bpy-succinate system (5.48, 6.10, and 8.32) for Cd-bpy-maleate system (5.57, 6.15, and 8.37) for Cd-bpy-malonate system, and (5.57, 6.15, and 8.34) for Cd-bpy-malate system.

Polarography has been widely used in complex chemistry. Recently, a large number of mixed-ligand complexes have been studied by this technique. The mixed-ligand complexes of Cd have been studied in our laboratory.[4,6] The present communication is a part of our programme. The metal complexes of 2,2′-bipyridyl have been studied by many workers.[7,8] The spectrochemical studies of bipyridyl with cadmium and other metals have been reported in the literature.[9] The mixed-ligand complexes of 2,2′-bipyridyl with malonate, amino acids, and copper have been carried out by potentiometry[10] and by electrode process.[11] But the literature is quite silent about the polarographic studies of mixed-ligand complexes of cadmium with 2,2′-bipyridyl and dicarboxylates. Hence the present investigations have been undertaken to study their stability constants polarographically.

Theoretical

For a complexation reaction

$$M + iX + jY \rightleftharpoons MX_iY_j, \quad (1)$$

where i, j are stoichiometry numbers, X and Y are two different ligands and charges have been ignored for simplicity.

The overall stability constants β_{ij} for the above reaction is given by

$$\beta_{ij} = \frac{MX_iY_j}{M[X]^i[Y]^j}. \quad (2)$$

According to Schaap and McMasters mixed-ligand complex formation should be preferred over simple complexes whenever the concentration of the ligands involved are such that the products of the formation constants for the simple complexes and the concentration of the ligand raised to the appropriate power are approximately equal, *i.e.*

$$\beta_{MX_i}[X]^i = \beta_{MY_j}[Y]^j = \cdots. \quad (3)$$

$F_0[X]$ function of the Deford and Hume method may be extended to give a new function.

$$F_{00}[X, Y] = \text{antilog}\left[\frac{0.4343\,nF}{RT}E\tfrac{1}{2} + \log\frac{I_M}{I_C}\right], \quad (4)$$

where n, F, R, and T have the same meaning as in the Nernst equation, I_M and I_C are the diffusion current constants of the uncomplexed and complexed metal ion respectively.

This expression can be written in the form (assuming three bidentate ligands)

$$\begin{aligned} F_{00}[X, Y] = {} & \{\beta_{00} + \beta_{01}[Y] + \beta_{02}[Y]^2 + \beta_{03}[Y]^3\}[X]^0 \\ & + \{\beta_{10} + \beta_{11}[Y] + \beta_{12}[Y]^2\}[X] \\ & + \{\beta_{20} + \beta_{21}[Y]\}[X]^2 \\ & + \{\beta_{30}\}[X]^3 \end{aligned} \quad (5)$$

or

$$F_{00}[X, Y] = A + B[X] + C[X]^2 + D[X]^3. \quad (6)$$

Where for a given value of [Y], A, B, C, and D are constant having values defined in equation (5).

The concentration of one ligand is kept constant while that of the other is varied. In practice [Y] is kept constant and [X] is varied. The other functions were

$$F_{10}[X, Y] = \frac{F_{00} - A}{[X]} = B + C[X] + D[X]^2,$$

$$F_{20}[X, Y] = \frac{F_{10} - B}{[X]} = C + D[X],$$

and

$$F_{30}[X, Y] = \frac{F_{20} - C}{[X]} = D.$$

With the help of two values of B at two concentrations the overall stability constants β_{11}, β_{12}, and β_{21} may be calculated.

Experimental

The DME used in recording polarographic waves manually, had the following characteristics, $m = 1.96$ mg s^{-1}, $t = 4.05$ sec drop^{-1}, $h_{corr} = 40$ cm (at 303 ± 1 K in 0.1 M $NaClO_4$ in open circuit (1 M = 1 mol dm^{-3})).

The chemicals used were of AnalaR grade. 2,2′-bipyridyl and dicarboxylic acids were used as complexing agents. Potassium nitrate was used as supporting electrolyte to maintain the ionic strenght constant at 1.5 M. The presence of 0.004 % gelatin in final solution sufficed to suppress the maxima observed. All the investigations were carried out at constant temperature of 303 ± 1 K and in the 50% dioxane medium. The experimental technique was the same as described earlier.[12]

Results

The pK values, calculated by the method of Albert and Sergeant[13] and the values of stability constants of simple systems are tabulated in Table 1. All the systems were studied by keeping the concentration of weaker ligands (dicarboxylic acids) constant while varying that of bipyridyl. In all the systems a single well-defined wave was found. The plots of $-E_{de}$ *vs.* log $(i/(i_d-i))$ were linear with a slope of 30 ± 2 mV showing that two electron reduction is reversible. The reduction is diffusion-controlled as evident by the direct proportionality of the diffusion current to the square root of the effective height of mercury column.

The overall stability constants β_{11}, β_{12}, and β_{21} as calculated by the method of Schaap and McMasters are tabulated in Table 2, and are summarised in Schemes (1—5), where the numerical values indicate the logarithms of the equilibrium constants, The values of F_{ij} function for all the systems are not given in the paper to avoid the length of the paper.

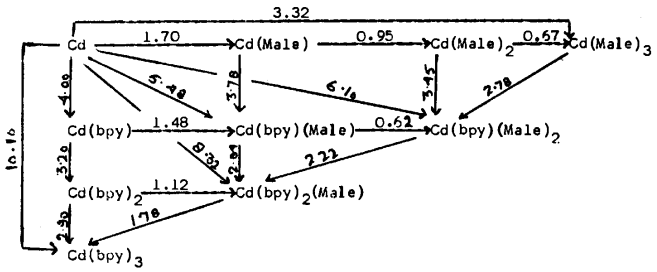
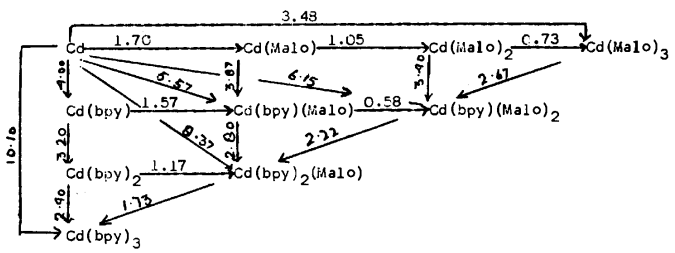
Discussion

By considering the schemes (1—5), the formation of β_{11}, β_{12}, and β_{21} may be explained in a good manner. The tendency to add dicarboxylate to Cd(dicarboxylate), Cd(Bipyridyl) can be compared. The log K values are (0.80, 1.24), (1.42, 1.62), (0.95, 1.48), (1.05, 1.57), and (0.90, 1.57) for Cd-bpy-tartrate, Cd-bpy-succinate, Cd-bpy-maleate, Cd-bpy-malonate, and Cd-bpy-malate systems respectively. The largest part of the difference in log K must be attributed to entropy and electrostatic effect which would favour the formation of a charged complex. The addition of bipyridyl to Cd(dicarboxylate) and Cd(bpy) can also be confirmed, the mixed-ligand complex formation. The log K values are (3.84, 3.20), (4.14, 3.20), (3.78, 3.20), (3.87, 3.20), and (3.67, 3.20) for the Cd-bpy-tartrate, Cd-bpy-succinate, Cd-bpy-maleate, Cd-bpy-malonate, and Cd-bpy-malate systems respectively.

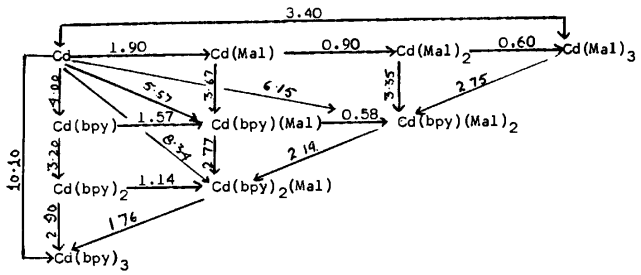
For the addition of dicarboxylate as a second ligand to [Cd(bpy)dicarboxylate)][Cd(dicarboxylate)$_2$] and [Cd(bpy)$_2$]. The log K values are (0.56, 0.74, and 0.99), (0.53, 0.50, and 1.14), (0.62, 0.67, and 1.12),



Scheme 3. Cd-bpy-Maleate system.



Scheme 4. Cd-bpy-Malonate system.



Scheme 5. Cd-bpy-Malate system.

Table 3. Values of stability constants of mixed-ligand of Cd(II) with 2,2'-bipyridyl and dicarboxylic acids by watters and dewitt equations

Systems	Log β_{11}	Log β_{12}	Log β_{21}
Cd-bpy-Tart.	5.12	5.80	8.19
Cd-bpy-Succ.	5.28	6.11	8.34
Cd-bpy-Male.	5.25	6.06	8.32
Cd-bpy-Malo.	5.30	6.16	8.37
Cd-qpy-Mal.	5.28	6.11	8.34

(0.58, 0.73, and 1.17), and (0.58, 0.60, and 1.14) for the Cd-bpy-tartrate, Cd-bpy-succinate, Cd-bpy-maleate, Cd-bpy-malonate, and Cd-bpy-malate systems respectively.

The higher log K values in the addition of dicarboxylate ion to $[Cd(bpy)_2]$ suggest that the addition or the substitution of dicarboxylate occurs easier to $[Cd(bpy)_2]$ than that to [Cd(dicarboxylate)(bpy)] or to [Cd(dicarboxylate)].

The log K values for the addition of bpy as a second ligand to [Cd(bpy)(dicarboxylate)], $[Cd(dicarboxylate)_2]$, and $[Cd(bpy)_2]$ are (2.95, 3.60, and 2.90), (2.72, 3.25, and 2.90), (2.84, 3.45, and 2.90), (2.80, 3.40, and 2.90), and (2.77, 3.55, and 2.90) respectively.

The higher log K values for the addition of bipyridyl to [Cd(dicarboxylate)] suggest that the formation of mixed-ligand complexes is favoured in the presence of weaker ligand.

According to Watters and Dewitt equations, the formation of mixed-ligand complexes may be speculated on the basis of thermodynamical considerations. The values of stability constants calculated on these equations are given in Table 3.

By comparing these values with the observed ones, it may be suggested that MX_2Y complexes are formed in an equilibrium state thermodynamically.

If we assume the following equilibria:

$$[2Cd(bpy)(dicarboxylate)] \rightleftharpoons [Cd(bpy)_2] + [Cd(dicarboxylate)_2]$$

then thermodynamically the value of log K^D is expected to be -0.60 but the observed values were -1.08, -1.14, -1.11, -1.19, and -1.14 for the Cd–bpy–tartrate, Cd–bpy–succinate, Cd–bpy–maleate, Cd–bpy–malonate, and Cd–bpy–malate systems respectively.

If we assume that the two equilibria of the disproportionation reactions, cited below should occur in dioxane medium,

$$[3Cd(bpy)(dicarboxylate)_2] \rightleftharpoons [Cd(bpy)_3] + [2Cd(dicarboxylate)_3]$$

and

$$[3Cd(bpy)_2(dicarboxylate)] \rightleftharpoons [2Cd(bpy)_3] + [Cd(dicarboxylate)_3],$$

then, the values of the disproportionation constant are calculated to be (1.42, 1.55, 1.56, 1.39, and 1.55) and (1.43, 1.42, 1.44, 1.43, and 1.42) respectively for both the equilibria of the corresponding Cd–bpy–dicarboxylate systems.

These results suggest that these mixed ligand complexes may exist more stably than those with a single ligand in an equilibrium state of 50% dioxane medium thermodynamically.

Preparation, Properties, and Analytical Applications of Crystalline Tin(IV) Tungstoselenate

Syed Ashfaq Nabi† and Zia Mahmood Siddiqi*
Department of Chemistry, Aligarh Muslim University, Aligarh 202001, India
(Received January 5, 1984)

Synthesis of tin(IV) tungstoselenate has been done under a variety of conditions. The effects of mixing ratio of reagents and the pH of the mixture on the properties of the material have been studied. The crystalline sample of tin(IV) tungstoselenate has been chosen for detailed studies, such as chemical and thermal stabilities, chemical composition, pH-titrations, IR and X-ray analyses. On the basis of above studies a tentative formula has been proposed for tin(IV) tungstoselenate. The adsorption behaviour of metal ions in different concentrations of perchloric acid has been studied. On the basis of K_d values few analytically important separations of metal ions have been achieved on small columns of tin(IV) tungstoselenate.

It has been observed that double salts often exhibit much better ion-exchange properties than simple salts.[1-5] Most of the ion-exchange studies reported in the area of synthetic inorganic ion-exchangers are based on amorphous products. Zirconium phosphate is probably the most widely studied crystalline ion-exchange material.[6-12] Recently, synthesis and ion-exchange properties of crystalline tin(IV) selenophosphate have been reported by Nabi *et al.*[13] Crystalline inorganic ion-exchanger shows superiority over amorphous products in many respects. Amorphous materials are restricted in their application as they undergo extensive hydrolysis even in weakly alkaline or neutral solutions. Moreover, the crystalline products are rigid in their structure and reversible in nature. Synthesis of crystalline inorganic ion-exchangers is also important in order to understand the mechanism of exchange.

The present paper deals with the synthesis, ion-exchange properties, and analytical applications of tin(IV) tungstoselenate as a new inorganic ion-exchanger.

Experimental

Reagents. Tin(IV) chloride (Baker analyzed, U.S.A.), sodium selenite (BDH), and sodium tungstate (BDH) were used for the synthesis of tin(IV) tungstoselenate. All other chemicals were of analytical reagent grade.

Apparatus. EC Spectrophotometer GS 866D for spectrophotometry, Elico LI-10 pH-meter for pH measurements, Perkin Elmer model 137 spectrophotometer for IR studies, X-ray diffractometer PW 1140/90 for X-ray analysis and stanton thermobalance type H_4 for TGA, were used. A temperature controlled shaker 'SICO' was used for shaking purposes.

Synthesis. Tin(IV) tungstoselenate samples were prepared by adding an aqueous mixture which was 0.05 mol dm^{-3} in sodium selenite and 0.05 mol dm^{-3} in sodium tungstate to 0.05 mol dm^{-3} aqueous solution of tin(IV) chloride in varying volume ratios and at different pH values as indicated in Tables 1 and 2. The pH of the mixture was adjusted by adding either an acid or a base and was then kept for one day at room temperature. The white product was filtered, washed several times with demineralized water to remove excess reagents and then dried at 40 °C. The particles of 50—100 mesh size were obtained when the product was immersed in demineralized water. The material was converted to H^+ form by treating it with 1 mol dm^{-3} nitric acid for 24 h at 25±2 °C. The excess acid was removed after several washings with demineralized water. The material was finally dried at 40 °C in an oven. Tables 1 and 2 describe the conditions of synthesis and few properties of the ion-exchange material.

Ion-exchange Capacity. Ion-exchange capacities for some uni and bivalent cations are reported in Table 3. A 0.5 g exchanger in the hydrogen form was taken in the column. The hydrogen ions were then eluted by applying 1 mol dm^{-3} solutions (pH=6) of cations. The hydrogen ions in the effluent were determined after titrating against standard sodium hydroxide solution.

Chemical Stability. A 0.5 g of the material (sample SSW_4 in Table 1) was shaken with 50 cm^3 of the solvent of interest for 6 h at room temperature. Tin(IV), selenium, and tungsten in the aqueous phase were determined spectrophotometrically using hematoxylin,[14] potassium iodide[15] and potassium thiocynate[16] as colouring reagents, respectively. The results are given in Table 4.

Thermal Stability. The thermogravimetric analysis of the ion-exchanger in the hydrogen form was performed at a heating rate of 10 °C/min. The thermogram of the material is shown in Fig. 1. The effect of heating on the ion-exchange capacity of the material was also examined. The ion-exchange capacity for potassium ions is given in Table 5. The material in the hydrogen form was heated at the desired temperature for 1 h in a muffle furnace.

Chemical Composition. A 0.5 g of the sample was dissolved in hot concentrated hydrochloric acid. The solution was cooled and diluted. Tin[14] and selenium[15] were then estimated spectrophotometrically. Tungsten content was determined by gravimetric analysis.[17]

pH-Titrations. Topp and Peppers' method[18] was used for pH titrations using NaCl-NaOH system. For this purpose 0.5 g of the exchange material was treated with 50 cm^3 of the solution. Figure 2 represents the pH-titration curve of tin(IV) tungstoselenate.

IR Analysis. The infrared spectra of crystalline sample (SSW_4) dried at different temperatures were obtained by potassium bromide disc method (Fig. 3).

X-Ray Analysis. For X-ray diffraction analysis, manganese filtered Fe-$K\alpha$ radiation was used. The sample SSW_4 (dried at 40 °C) in the hydrogen form was used. Table 6 and Fig. 4 show the X-ray results.

Distribution Coefficients. Distribution coefficients for various metal ions in perchloric acid medium were determined by a published method.[19] The ion-exchange material (50—100 mesh size) was equilibrated with cation solutions at 25±1 °C. The ionic strength of Ce(IV) and Th(IV) ion solutions was 0.0041 and 0.0175 respectively whereas the

ionic strength of other ion solutions lie between 0.0006 to 0.006. The results are given in Table 7. The metal ions in the solution after and before treatment with the exchanger were determined by EDTA titrations.

Quantitative Separations. Important separations of metal ions were achieved on the columns of tin(IV) tungstoselenate. The elution curves for each set of separations are shown in Figs. 5a—5c. For each separation, 1.5 g of the exchanger (50—100 mesh size) in the hydrogen form was taken in a column of i.d. 0.6 cm with glass wool support. The mixture of the metal ions solution was adsorbed on the exchanger beads. The exchange bed was washed with demineralized water. The all metal ions loaded were eluted with suitable reagent and collected in 10 cm^3 fractions at the flow rate

of 15 drops/min. The metal ions were then titrated against 0.002 mol dm^{-3} EDTA solution.

Discussion

It is apparent from Table 1 that the mixing ratio of reagents in the preparation of tin(IV) tungstoselenate is found to affect the ion-exchange capacity to some extent. The capacity is found higher for those samples which have been prepared with higher concentrations of either selenite or tungstate in the reaction mixtures. Table 2 shows the effect of pH on the mixing solutions. Between 0—2 pH the capacity remains almost constant but it reduces to 0.77 meq/g when the sample is prepared at pH 3. However, it has been observed that the capacity significantly increased (1.8 meq/g) when the preparation of tin(IV) tungstoselenate is done in highly acidic medium (negative pH).

Table 5. Effect of drying temperature on the ion-exchange capacity (Meq/g) of different material

Temperature/°C	Tin(IV) selenite[20]	Tin(IV) tungstate[21]	Tin(IV) tungstoselenate
40	0.75	0.57	0.88
100	0.75	0.13	0.62
200	0.75	0.10	0.58
300	0.75	0.10	0.48
400	0.75	0.10	0.45
500	0.70	0.10	0.34
600	0.20	0.10	0.22
700	—	0.10	0.20
800	—	—	0.00

The tin(IV) tungstoselenate sample (SSW_4) has been found to possess an ion-exchange capacity higher than tin(IV) selenite[20] and tin(IV) tungstate.[21]

It is interesting to note that tin(IV) tungstoselenate (SSW_4), prepared by mixing tin(IV) chloride sodium selenite and sodium tungstate in the ratio of 4 : 1 : 1 at pH=0, shows the crystalline character. Therefore, this sample has been chosen for detailed studies.

The data in Table 3 show that ion-exchange capacities for alkaline earths are higher than for alkali metals as expected. This is in accordance with the size of the hydrated radii of the metal. In the case of alkali metals, the capacity increases with the decrease in size of the hydrated radius of the ions. However, the capacity for alkaline earth metals remains almost constant as there is little difference in the size of hydrated radii of these metals.

Tin(IV) tungstoselenate is highly stable in water and appreciable concentrations of sulfuric acid, nitric acid,

oxalic acid, perchloric acid, and low concentrations of hydrochloric acid and sodium hydroxide. A comparison of the chemical stability of tin(IV) based ion-exchangers shows that tin(IV) tungstoeslenate is more stable than tin(IV) selenite and tin(IV) tungstate (Table 4). The order of chemical stability of various ion-exchangers are as follows: Tin(IV) tungstoeslenate >tin(IV) tungstoarsenate[22]>tin(IV) molybdoarsenate.[3]

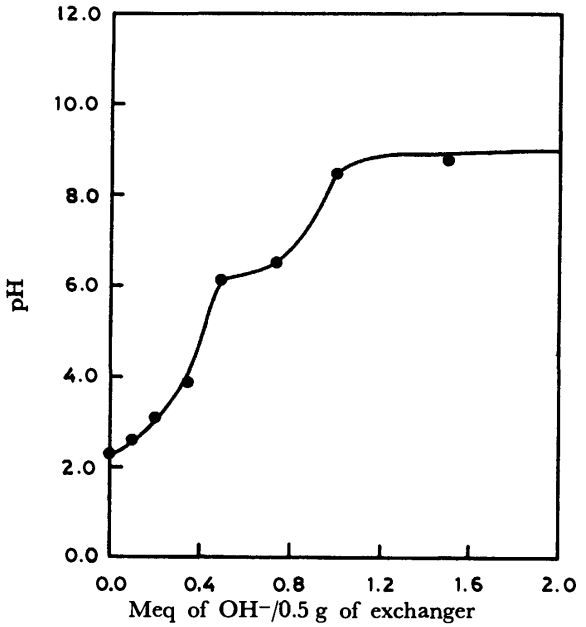

Fig. 2. pH Titration curve of tin(IV)tungstoselenate.

The ion-exchange capacity is also affected by drying temperatures of the material. The data in Table 5 indicate that tin(IV) tungstoselenate is thermally more stable than tin(IV) tungstate. Tin(IV) tungstoselenate shows considerable ion-exchange capacity (0.34 meq/g) even when the drying temperature is raised to 500 °C and can thus safely used as an ion-exchanger. On the other hand tin(IV) tungstate loses its ion-exchange capacity almost completely when a drying temperature is 100 °C.

The thermogram of tin(IV) tungstoselenate (Fig. 1) may be interpreted as follows. The material experiences a continuous loss in weight (11%) upto 200 °C which can be attributed to the loss of external water

Table 6. X-ray data of tin(IV) tungstoselenate (sample SSW_4)

molecules. The weight loss in the region 200—350 °C may be due to the removal of water molecules due to condensation of OH groups and is accompanied by loss of selenium by vaporization. No prominent weight loss is found in the small temperature range 350 °C to 400 °C which probably indicates the gradual loss of selenium by vaporization. This conclusion is also supported by the exchange capacity data at these temperatures. As the temperature is raised beyond 400 °C, decomposition of the material starts which continues upto 800 °C. The loss in weight in this region may be referred to the loss of water molecules by the condensation of the other type of OH groups and loss of tungsten. This is in good agreement of the capacity data at 400—600 °C. The capacity reduces gradually after 600 °C and vanishes completely at 800 °C. The weight becomes constant after 800 °C due to the formation of stable oxides of metals.

Ce^{4+}	3800±64	3665±66	2742±50	909±5

The molar composition of tin(IV) tungstoselenate shows that tin(IV) selenium and tungsten are present in the ratio of 7 : 1 : 18. The pH-titration curve shows bifunctional character of tin(IV) tungstoselenate (Fig. 2) whereas tin(IV) tungstate and tin(IV) selenite are found to be mono and bifunctional respectively.[20,21]

The IR spectra of tin(IV) tungstoselenate dried up to 600 °C resemble each other and show three absorption peaks (Fig. 3). A strong and broad peak in the region 3600—3200 cm^{-1} represents the interstitial water, free water, and OH groups. Another sharp peak in the region 1700—1500 cm^{-1} with a maximum at 1620 cm^{-1} is characteristic of interstitial water. The third peak in the region 1100—250 cm^{-1} may be due to metaloxygen bonds. There is no difference in the IR spectra between hydrogen form and patassium form of the sample dried at 40 °C.

The X-ray diffraction pattern suggests that tin(IV)

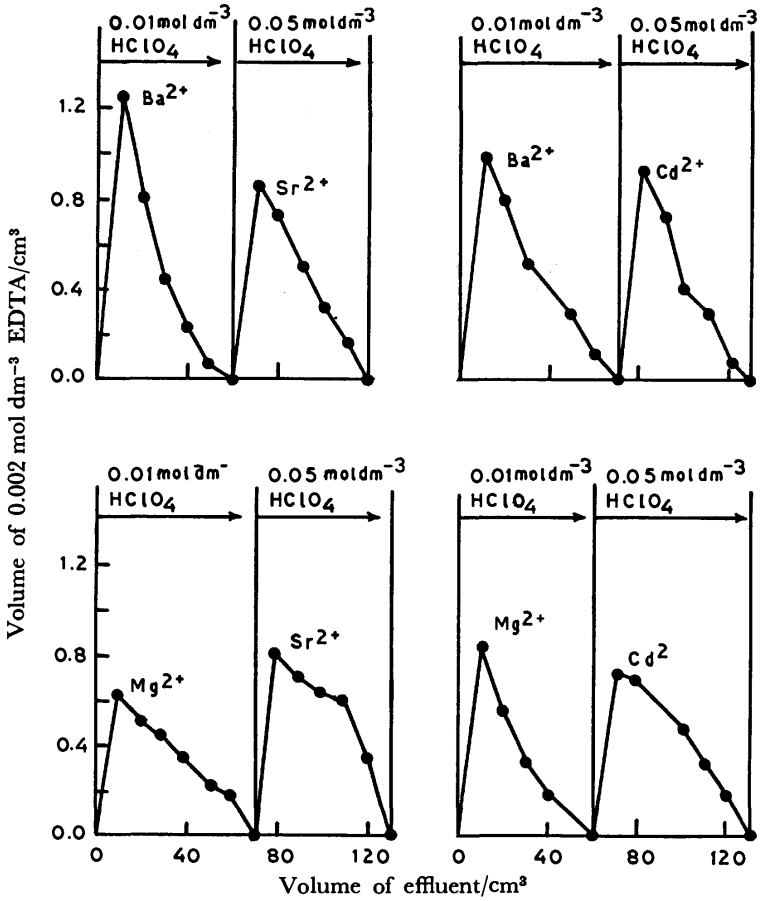

Fig. 5A Separations of Ba^{2+}–Sr^{2+}, Ba^{2+}–Cd^{2+}, Mg^{2+}–Sr^{2+}, and Mg^{2+}–Cd^{2+}.

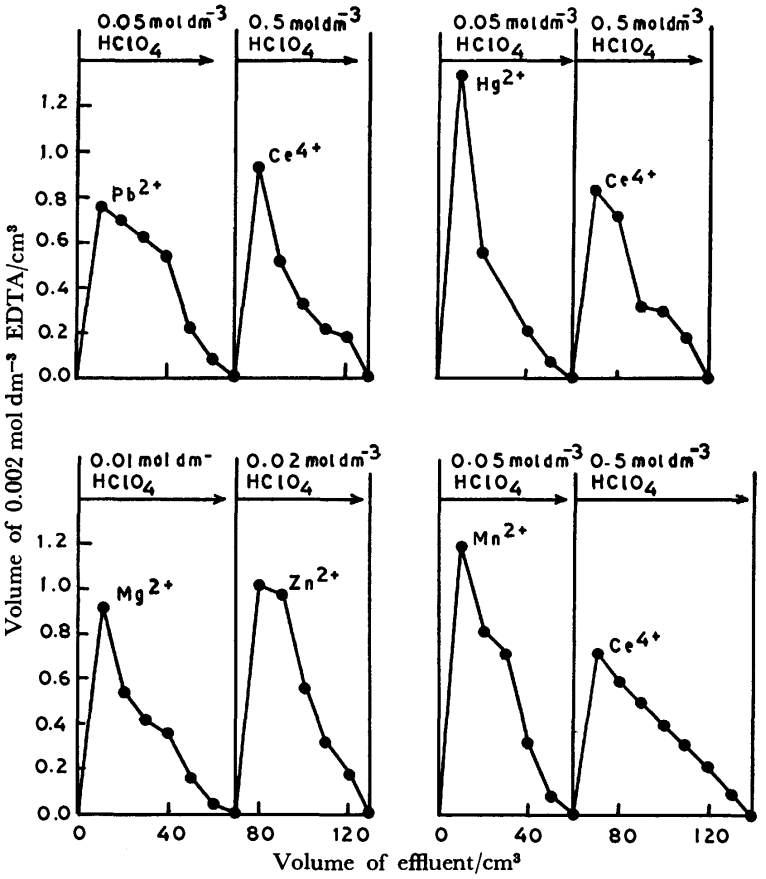

Fig. 5B Separations of Pd^{2+}–Ce^{4+}, Hg^{2+}–Ce^{4+}, Mn^{2+}–Ce^{4+}, and Mg^{2+}–Zn^{2+}.

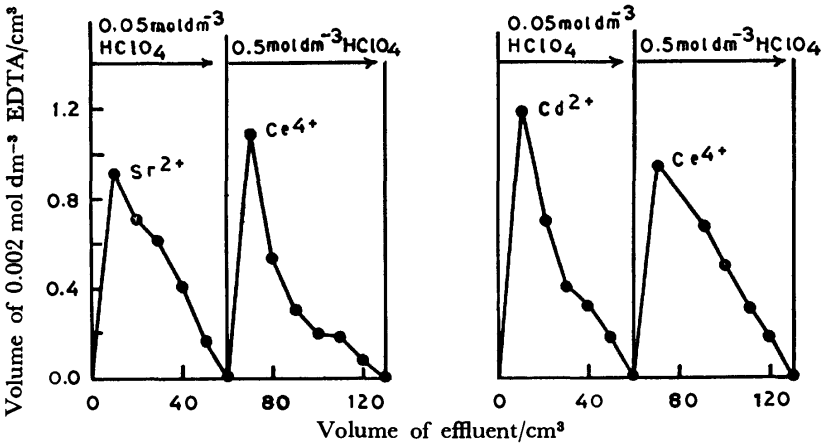

Fig. 5C Separations of Sr^{2+}–Ce^{4+} and Cd^{2+}–Ce^{4+}.

tungstoselenate (sample SSW_4) is crystalline in character. The *d*-values and other results of tin(IV) tungstoselenate are given in Table 6 and Fig. 4.

On the basis of chemical composition, pH-titration, thermogravimetric and IR studies, the following tentative formula may be assigned to tin(IV) tungstoselenate.

$$[(SnO_2)_7 \cdot HSeO_3(HWO_4)_{18}] \quad (1)$$

If all the external water molecules are lost upto 200 °C, the percentage weight loss is 11%. The number of water molecules then calculated by the method of Alberti *et al.*[23] The number of external water molecules per molecule of the exchanger is found to be 45. The formula therefore can be rewritten as

$$[(SnO_2)_7 \cdot HSeO_3(HWO_4)_{18}] \cdot 45H_2O \quad (2)$$

The molecule contains nineteen replaceable hydrogen atoms according to the above formula. If it is assumed that only $7H^+$ ions are exchanged at pH=6, then the ion-exchange capacity calculated from formula 2 is 0.91 meq/g which is very close to the experimental value (1.0 meq/g from pH-titration curve). When the pH of the mixture is increased upto 8.5, the capacity as indicated by pH-titration curve becomes 2.4 meq/g and supports the theoretical ion-exchange

capacity of the material (2.5 meq/g) when all the replaceable hydrogen ions are taken into consideration.

The data in Table 7 show that K_d values for metal ions decrease in general with the increase in the concentration of perchloric acid. K_d values of Th(IV), and Ce(IV) are exceptionally high in all concentrations of perchloric acid, whereas negligible adsorption of almost all metal ions occurs in 0.5 mol dm^{-3} $HClO_4$. The behavior of barium(II) is quite different from other alkaline earth metals and therefore can be selectively separated from a mixture of these metal ions on tin(IV) tungstoselenate.

On the basis of differential selectivity of metal ions in various concentrations of perchloric acid, a number of important separations have been achieved quantitatively using tin(IV) tungstoselenate columns. The elution curves of metal ions separated from one another are shown in Figs. 5A-5C.

The authors are thankful to Prof. W. Rahman, Chairman, for providing research facilities and to C.S.I.R. New Delhi for financial assistance.

The Unusually Strong Effect of a 4-Cyano Group upon Electronic Spectra and Dissociation Constants of 3-Substituted 7-Hydroxycoumarins

Otto S. Wolfbeis,* Ernst Koller, and Petra Hochmuth
Institut für Organische Chemie, Karl-Franzens-Universität, A-8010 Graz, Austria
(Received March 12, 1984)

Synthesis, absorption and fluorescence spectra as well as pK_a values of 7-hydroxycoumarins with electron-withdrawing substituents in positions 3 are described. Introduction of a 4-cyano group is achieved by oxidative cyanation of coumarins using potassium cyanide and elemental bromine. 7-Hydroxycoumarins without a 4-cyano group are useful indicators for measuring physiological pH values due to their intense fluorescences, longwave absorptions and emissions, as well as pK_a values of around 7. The presence of a 4-cyano group gives rise to a dramatic longwave shift in absorption (30—40 nm in methanol) and emission (55—80 nm). In water solution, the fluorescence maxima are at around 570—600 nm, with excitation maxima between 410 and 510 nm, depending on whether the phenol or phenolate species is excited. For all coumarins under investigation, fluorescence is from the anion form even in the pH 2—7 range. This phenomenon is interpreted in terms of excited state dissociation according to the Förster model. The interpretation is corroborated by calculations of the excited state pK_a values, which show them to be lower by 4.5—6.4 units than those of the ground state.

7-Hydroxycoumarins such as 4-methylumbelliferone (4-MU) play an important role in measuring physiological pH values by fluorimetry.[1-6] In addition, esters, ethers and glycosides of 4-MU are frequently used- and commercially available-enzyme substrates for use in clinical chemistry and enzymology. The formation of fluorescent 4-MU from practically nonfluorescent ethers and esters is a measure for the enzyme activity.[7,8]

However, 4-MU has two decisive disadvantages: (a) Its pK_a value of 7.8 is relatively high, so that under physiological pH conditions only partial dissociation to the highly fluorescent anion (fluorescence maximum 450 nm) takes place;[9] (b) its fluorescence is maximally excited between 330 and 360 nm, a spectral region where background fluorescence from biological matter such as serum or intracellular liquids is fairly high, mostly due to the presence of reduced nicotinamide adenine dinucleotide.

By introducing an electron-withdrawing substituent in position 3, we hoped to shift the excitation and emission maxima to longer wavelengths, and simultaneously to lower the pK_a values. The bathochromic effect of certain substituents in position 3 is known in the chemistry of optical brighteners derived from 7-aminocoumarins.[10]

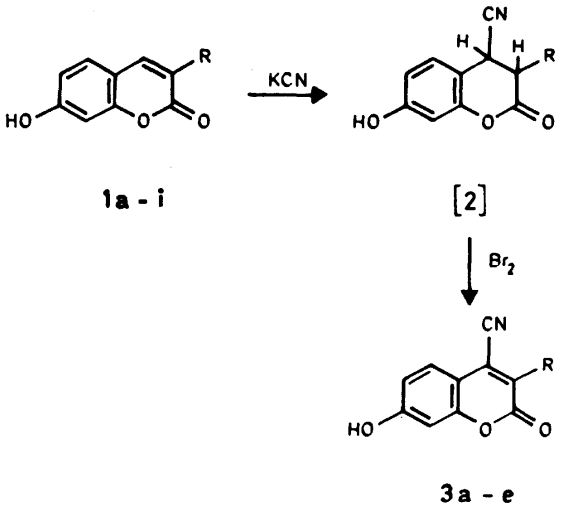
The emission maxima of 3-substituted umbelliferones in alkaline solutions have been reported by Sherman and Robins, and fluorescence intensity was correlated with Hammett σ-constants.[11] More recently, we have reported on the photodissociation of related umbelliferones.[12] Their properties as laser dyes have also been described.[13] The effect of substituents in position 3 on spectra and pK_a values of umbelliferones has not been studied so far.

Results and Discussion

Syntheses. 7-Hydroxycoumarins with a substituent in position 3 (**1a**—**i**) can be prepared according to one of the numerous methods decribed in the literature including patents.[10,14] We found the procedure of condensing 2,4-dihydroxybenzaldehyde with an appropriate CH_2-acidic ester or acid such as ethyl 2-benzoxazolylacetate in the presence of pyridine (as a solvent) and aniline (as a catalyst, 1 mol-equiv), most suitable.[15]

Introduction of a 4-cyano group into umbelliferones was accomplished by addition of potassium cyanide to a suspension of the coumarin in *N,N*-dimethylformamide (DMF) and subsequent dehydrogenation with elemental bromine. We assume that leuko-dyes of general structure **2** are reaction intermediates, which are then oxidized to the respective cyanocoumarins **3a**—**e**.

Oxidative cyanations of dyes with activated double bonds have been described by various authors.[16-20] Oxidizing agents such as ferric ion.[16,19] lead tetra-



1, 3	R

f	2-Furyl
g	2-Thienyl
h	COOH
i	Phenyl

acetate,[17,18,21] bromine,[21] peroxides, and other oxidizing agents[19] have been proposed.

It should be noted that, for unknown reasons, we failed to prepare the 4-cyano derivatives of compounds **1f**—**i**. **3c** was synthesized by oxidative cyanation of the potassium phenolate **1c**, since when employing the free 7-hydroxy compound no reaction took place. **3e** could be prepared in low yield only, possibly due to competitive bromination of the imidazolyl NH.

The structures of the cyanoumbelliferones were confirmed by correct analytical and spectral data. The IR spectra are characterized by carbonyl bands in the 1710—1750 cm^{-1} range, and the lack of an intense band of the cyano group. If at all observable, the band consists of a very weak signal at around 2240 cm^{-1}.

The ^{1}H-NMR spectra are of little significance, since most of the protons come to lie in δ=6.7—8.1 range, except for the methyl group present in **3e**. The protons of the 7-hydroxy groups show no sharp signal in pure dimethyl sulfoxide. However, in the presence of traces of water a signal can be observed at around δ=11.2.

The mass spectra consist of strong signals for the molecular ion (M^+) and fragments resulting from the elimination of CN (M^+-26), HCN (M^+-27), and CO (M^+-28). In each case, the molecular ion peak is the 100 % (base) peak.

The dyes are fairly stable in neutral and acidic aqueous solutions, albeit much less than the respective cyanounsubstituted coumarins. They suffer, however, considerable decomposition at pH values above 8. The 4-cyano group is not stable under sulfonation conditions (*e.g.*, oleum). Therefore, sulfonato groups have to be introduced prior to cyanation.

Electronic Spectra. The spectra of 7-hydroxycoumarins **1a**—**i** in water-free organic solvents consist of an intense absorption band in the 365—390 nm range, and an emission maximum between 450 and 470 nm (Table 1), except for compounds **1h** and **1i**, which absorb distinctly shorter (*ca.* 340 nm).

In aqueous solution both the absorption and fluorescence spectra are highly pH-dependent in the near neutral pH range, a fact that prevents the use of 7-hydroxycoumarins as optical brighteners.[10] The absorption and fluorescence data of aqueous pH 4 and pH 9 solutions are summarized in Table 1. While the fluorescence maxima do not change significantly

Table 1. Longest-wave absorption and fluorescence maxima of 7-hydroxycoumarins **1** and **3** in various solvents[a]

with pH between pH 4 and 9, the relative intensities are around two times higher in alkaline solutions than in acidic solution.

The presence of a 4-cyano group results in a considerable bathochromic shift in both absorption and emission. All cyanocoumarins are orange-red (absorption maxima 405—430 nm) and exhibit bright green fluorescence in organic solvents. The maxima suffer a longwave shift with increasing solvent polarity. The molar absorbances are somewhat lower than those of compounds **1**. The spectra of 4-cyanoumbelliferones in alkaline solutions are far red-shifted in both absorption and emission, when compared with the respective phenol species. In addition, they exhibit large Stokes shifts of 80—90 nm, which, however, in terms of wavenumbers is about the same as for coumarins **1a—i** (3000—4500 cm^{-1}).

pH Effects. The pK_a values of selected umbelliferones were determined by spectrophotometry and are listed in Table 2. As can be seen, the values are temperature dependent and decrease by 0.012—0.016 units per °C increase in temperature. Coumarins possessing a 4-cyano group display distinctly increased acidities (0.6—0.8 units lower).

It is noted that fluorescence of 7-hydroxycoumarins **1** and **3** is almost invariably from the anion form in the pH 4—9 range, despite of photoexciting the undissociated* species in acidic solutions. According to Förster,[22] this can be interpreted in terms of photodissociation due to a decrease in pK_a in the first excited singlet state (S_1-state).

We have calculated the pK_a values of the S_1-state with the help of the following equation,[22-24]

$$pK_a(S_1) = pK_a(S_0) - \frac{N \cdot h}{2.303RT}(\nu'_{BH} - \nu'_B)$$

wherein ν'_{BH} and ν'_B are the wavenumbers of the O–O transition of phenol and phenolate, respectively. The mean of the wavenumbers of absorption and fluorescence was taken as O–O transition.[23]

The results are given in Table 2. They show all coumarins to become stronger acids by 4.5—6.4 pK_a units, a fact that can explain the appearance of anion fluorescence even in weakly acidic solutions: When photoexciting a coumarin such as compound **1a** in pH 4 solution, it will dissociate during the lifetime of the S_1-state by virtue of its $pK_a(S_1)$ of 1.74 (Table 2).

It is, however, noted that shortwave shoulders are in most cases observed in the fluorescence emission bands of coumarins **1** and **3** in pH 4 solutions. These shoulders are attributed to emissions from the neutral species, occurring prior to the S_1-state dissociation step.

Concluding Remarks. We have presented here a series of fluorescent compounds with interesting spectral properties. Their pK_a values between 6 and 7 may render them useful longwave excitable and fluorescing indicators for measuring physiological pH values. Owing to their lower pK_a values, cyanocoumarins **3** are more suitable to measure pH's of weakly acidic bioliquids such as urine, whereas coumarins **1** are more useful to measure near-neutral pH's (such as in blood).

Esters of coumarins **1** and **3** with carboxylic, phosphoric and sulfuric acids, respectively, as well as ethers and glycosides are useful enzyme substrates for direct and continuous kinetic determination of hydrolyses.[25] These results will be reported elsewhere.

Experimental

Melting points are uncorrected. Spectra were recorded on the following instruments: Perkin Elmer Lambda 5 (UV/VIS); Aminco SPF 500 (fluorescence); Perkin Elmer 421 (IR); Varian A60 A (^{1}H-nmr); Varian-Mat 111 (mass spectra). Elemental analyses were performed on a Carlo-

Erba 1106 C,H,N-analyzer. pH values were measured with a pH electrode (Metrohm, Switz.) that was calibrated against pH 7 and pH 4 standard buffers.

General Procedure for the Preparation of 4-Cyano-7-hydroxycoumarins ***3a—e***. 2.6 g (0.04 Mol) potassium cyanide, dissolved in 6 ml water, are added at room temperature to a suspension of 0.02 mol of the respective 7-hydroxycoumarin (**1a—e**) in 50 ml *N,N*-dimethylformamide. Note that **1c** should be employed as its potassium phenoxide salt. The mixture is stirred for 1 h at 40 °C. After filtration, 1 ml (0.02 mol) elemental bromine is added dropwise to the filtrate at 0 °C. The mixture is then stirred for 1 h at this temperature. The resulting precipitate is collected, washed with water and methanol and purified by double recrystallization from the solvent given in Table 3. Physicochemical and spectral data of the new compounds are given in Table 3. All compounds gave C,H, and N-analyses in agreement (deviation maximally ±0.3 %) with calculated values.

Financial support by the "Fonds zur Förderung der wiss. Forschung" (Projekt P5014) is gratefully acknowledged. We also thank Dr. H. Harnisch (Bayer AG, Leverkusen) for generous gifts of chemicals.

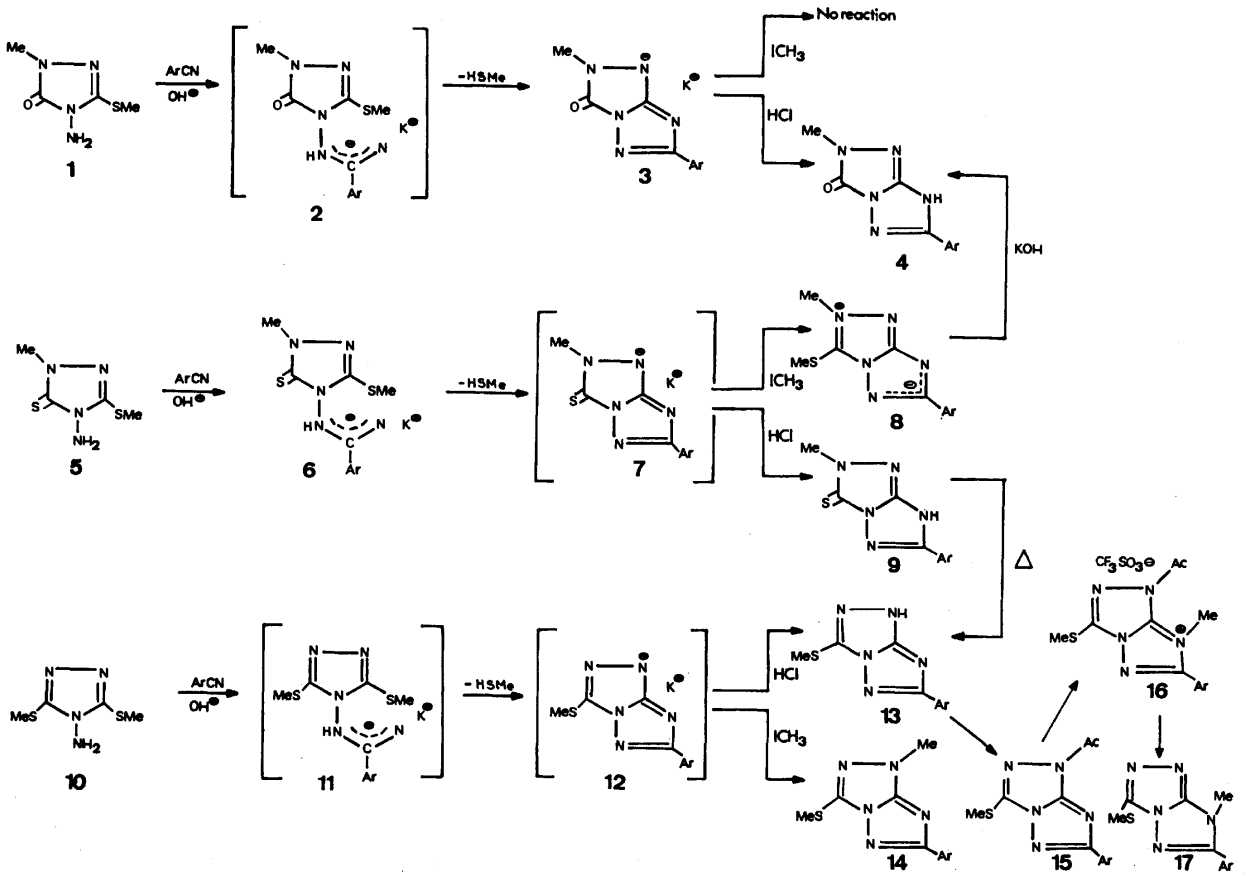
(Received January 13, 1984)

The synthesis, structure, and reactivity of several 1,2,4-triazolo[4,3-*b*][1,2,4]triazole derivatives have been studied. Structures have been established throughout a careful carbon-13 NMR study, and for the most unusual one (inner salt of 2-methyl-3-methylthio-6-phenyl-7*H*-1,2,4-triazolo[4,3-*b*][1,2,4]triazolium hydroxide) by X-ray crystallography: the space group is P21/c, the cell constants are $a=12.6939(5)$, $b=16.0936(6)$, $c=12.0239(5)$ and $\beta=107.247(3)°$ and $Z=8$. The *S*-methyl group is directed towards the fusion of the five-membered rings at +/−syn conformations. The azapentalene moieties have the first atoms of the substituents on its plane and the 6-phenyl rings make an angle of −26.7 and −4.3° with it, in the two independent molecules respectively.

Continuing our interest in azapentalene derivatives[1] we have directed our attention to the 1,2,4-triazolo-[4,3-*b*][1,2,4]triazole ring. We have already obtained some results in these series,[2-4] but we want to present here a coherent view on the synthesis and reactivity of functional (oxo and thioxo) derivatives. Scheme 1 contains all the compounds and reactions studied.

The reaction of arenecarbonitriles in basic medium with 4-amino-3-methylthio-4*H*-1,2,4-triazole derivatives, **1**, **5**, and **10**, yields 6-aryl-1,2,4-triazolo[4,3-*b*]-[1,2,4]triazoles. The potassium salts lead by acidification the neutral molecules **4**, **9**, and **13**. In the first case, the cyclized form **3** was isolated and identified. In the second one, the intermediate amidine salt **6** was obtained. Thus, even in the third case, where the unstability of salts **11** and **12** prevents their isolation,



Scheme 1.

we have supposed the same mechanism. The first step is a nucleophilic addition of the *N*-amino group on the cyano group leading to the amidines **2**, **6**, and **11**. The cyclization step involves the departure of the methylthio group at position 3 with concomitant formation of the triazolotriazoles **3**, **7**, and **12**. These compounds carry at position 6 an aryl group and at position 3 an oxo **3**, thioxo **7** or methylthio group **12**. The tautomerism of the corresponding neutral molecules, **4**, **9**, and **13**, will be discussed later.

Compound **3** did not react with methyl iodide. The potassium salt **6** leads to a new mesoionic ring system **8**. The structure of this compound was established by radiocrystallography (see later). Nitrogens N_1, N_5, and N_7 could also have reacted with methyl iodide, but no *N*,*N*'-dimethyl derivative has been isolated. The high reactivity of the sulfur atom in mercaptotriazoles[5] could explain the formation of **8**, but having carried out the reaction on salt **6** it cannot be excluded that the *S*-methylation precedes the cyclization step. The methylation of salt **12** prepared either from **10** or from **13**, can yield three different *N*-methyl derivatives, but only 1-methyl-3-methylthio-6-aryl-1*H*-1,2,4-triazolo-[4,3-*b*][1,2,4]triazole **14** was actually isolated. The N_1 nitrogen atom is also the most reactive in the parent compound.[2] An isomer of **13** can be obtained using Olofson and Kendall's method.[6] The reaction of the azolide **15** with methyl trifluoromethanesulfonate yields the 7-methyl isomer **17** through the quaternary salt

16. In the case of the parent compound **18** a similar reaction yielded also the 7-methyl derivative **20**.[2]

Hydrolysis of the mesoionic compound **8** results in the formation of **4**. On heating compound **9** rearranges to compound **13** (this rearrangement takes place when the ^{13}C NMR spectrum of **9** is recorded at 80 °C to increase its solubility). The rearrangement **9** → **13** is another example of the well known *N* to *S* migration of alkyl groups in *N*-methylazolethiones.[7,8]

Determination of the Structure of Different Compounds

Carbon-13 NMR spectroscopy was used as the sole tool for establishing the different structures. However, due to its importance and unusual formula the structure of **8a** was determined by X-ray crystallography.

Table 1 presents the crystal data. Unit cell parameters were obtained from a least-squares refinement of 52 reflexions as measured on a Philips PW 1100 diffractometer with Cu $K\alpha$ radiation, up to 45° in θ. The intensities of 4347 reflexions with $\theta \leqslant 65°$ were measured with Cu $K\alpha$ radiation graphite monochromated and $\omega/2\theta$ scans. No deterioration of the sample was observed. Data were corrected for Lorentz and polarization factors but not for absorption. 3560 reflexions with $I \geqslant 2\sigma(I)$ were used in the analysis.

The structure was determined by direct methods[9] and refined by full matrix least-squares[10] anisotropically for all non-hydrogen atoms, leading to a final *R*-factor of 0.054 (R_w=0.058, with an empirical weighting scheme so as to give no trends in <w. Δ^2F>). All scattering factors were taken for neutral atoms.[11]

Final atomic parameters are given in Table 2.[12] There are two crystallographically independent molecules, **8a′** and **8a″**, in the unit cell, with bond lengths and angles as specified in Table 3.

Since the X-ray structures of aromatic azapentalenes are so scarce,[1] those of **8a′** and **8a″** deserve some comments, other than the fact that the mesoionic structure is established without ambiguity. The 1,2,4-triazolo-[4,3-*b*][1,2,4]triazole ring is planar in agreement with its aromatic nature. In order to make easy the discussion carbon C_{7a} has been numbered C_8 and substituents heavy atoms from C_9 to C_{17} (for the second molecule we have used dashed numbers) as represented in Fig. 1.

From the relationship between bond lengths and bond orders, it can be deduced that a canonical form, as the represented below, describes accurately the electronic structure of **8a**. Atoms C_9, S_{10}, and C_{12} lie on the plane of the azapentalene ring. The *S*-methyl group is directed towards N_5 and the dihedral angles 11–10–3–4 (11′–10′–3′–4′) are 58.9(3)° for **8a′** and −74.8(4)° for **8a″**. The 6-phenyl ring is planar. Bond distances and angles in this ring range in 1.367

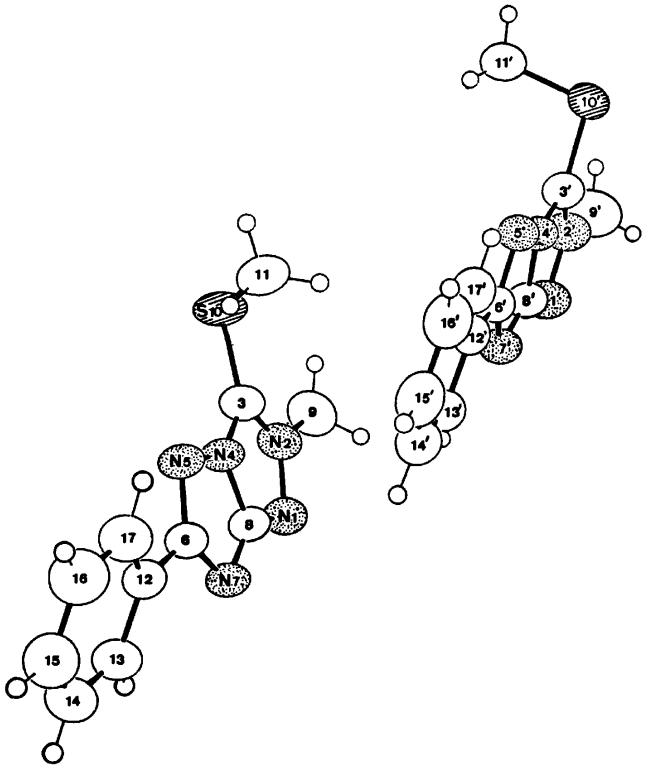

Fig. 1. Ortep drawing of the two molecules with atomic numbering.

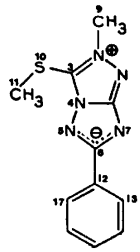
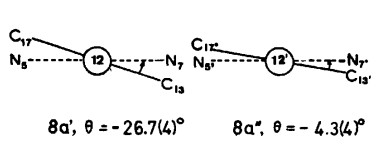
(7)—1.404(4) Å and 118.5(3)—121.7(3)°. The dihedral angles about the 6—12 (6′—12′) bonds are −26.7 (4)° and −4.3(4)°.

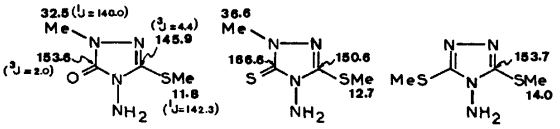




8a′, θ = −26.7(4)° 8a″, θ = −4.3(4)°

These small angles are expected[13] for a situation where hydrogen atoms on $C_{13(13')}$ and $C_{17(17')}$ are opposed to the lone pairs of $N_{5(5')}$ and $N_{7(7')}$.

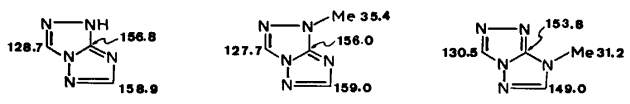
To discuss the ^{13}C NMR results it is useful to divide the compounds of Scheme 1 into two classes: the 1,2,4-triazole derivatives **1**, **5** and **10** (solvent: DMSO-d_6) and the bicyclic compounds **3**, **4**, **8**, **9**, **13**, **14**, **15**, and **17**. The salts **16** have been isolated (see experimental part) but not studied due to its fragility. However, the position of the acetyl group, on N_1 and that of the methyl group, on N_7, follows from the structures of **15** and **17**. Salts **6**, 1,2,4-triazole derivatives, cyclize when dissolved in D_2O with release of methanethiol, so the ^{13}C spectrum obtained correspond to salt **7** and will be discussed together with the bicyclic compounds.



1 5 10

Compound **10** due to its symmetry shows a unique signal for carbons C_3 and C_5. The assignment of carbons C_3 (δ=150.6) and C_5 (δ=166.6) in compund **5** was straightforward from literature data.[14,15] The most difficult case was that of compound **1**, but the assignment was made unambiguous by selective proton decoupling. Irradiation of the SMe signal (δ=2.37, solvent DMSO-d_6) transforms the δ=145.9 quartet into a singlet.

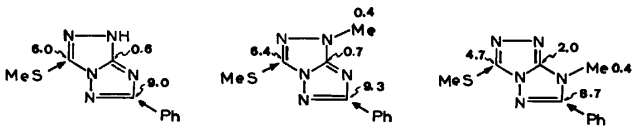
The only ^{13}C NMR spectra of 1,2,4-triazolo[4,3-*b*]-[1,2,4]triazoles so far described are those of the parent compounds **18**, **19**, and **20**.[16,17]



18 19 20

The assignment problems concern exclusively the quaternary carbons C_3, C_6, C_{7a}, C_1', and C_4' (X≠H). The benzene-ring carbons (C_1' and C_4') have been assigned through the known[18] effects of the X-substituent (Table 4). The carbon bearing the phenyl group (C_6) appears as a triplet in the coupled spectra due to a $^3J_{CCCH}$ coupling with protons 2′ and 6′. Methylbenzenes[19] and methylpyridines[20] show similar couplings for the methyl carbon atom. Carbons C_3 and C_{7a} were assigned by internal comparison between the different derivatives of Table 4.

The effect of SMe and phenyl substituents (see below) are almost negligible on C_{7a} and internally consistent on carbons C_3 and C_6:



13a-18 14b-19 17a-20

In benzene derivatives[21] the effect of an SMe group on the *ipso* carbon is +9.7 ppm and that of a phenyl group +13.0 ppm. On carbon C_2 of benzoxazoles, the phenyl produces an SCS of +8.4 ppm.[22] Thus the values obtained in the triazolotriazole series are quite normal, taking into account that we have neglected the long-range effects.

The chemical shifts of *N*-CH_3 groups in compounds **14** and **17** are characteristic of their positions N_1 and N_7 (compare with **19** and **20**[16]). Moreover, the carbons C_2' and C_3' in compound **17a** have identical chemical shifts (a similar situation is observed in ^1H NMR, see experimental part). This corresponds[23] to a hindered phenyl group. Only a methyl substituent on a neighbor nitrogen atom could produce such an effect. The acetyl derivative **15** displays a spectrum close to that of **14**, which proves the 1-acetyl-substituted structure.

Finally, concerning the annular tautomerism of **13**, the similitude of chemical shifts with **14** and the large differences with **17** (see, especially, C_6 and C_1') favor the tautomer *N*(H)1. On the other side, compounds **4** and **9** seem to be *N*(H)7 tautomers (carbons C_6 and C_1' appear as in **17**). Obviously, these conclusions concern exclusively DMSO solutions.

Experimental

All melting points were determined with a Kofler hot-stage microscope and are uncorrected. Spectral characterization was performed with the following instruments: IR, Nicolet FT-5DX, ^1H-NMR (80 MHz), Varian FT-80, ^{13}C-NMR (20 MHz), Bruker WP80SY. Mass spectra (70 eV) were obtained with a Hewlett-Packard 5993 C instrument. Combustion analyses were performed with a Perkin-Elmer 240 °C instrument.

Materials. All the reagents, except those listed below were obtained from commercial sources and were used without purification. The 4-amino-1-methyl-3-methylthio-1*H*-1,2,4-triazole-5(4*H*)-thione **5**,[24] 4-amino-1-methyl-3,5-bis(methylthio)-1,2,4-triazolium iodide,[24] 6-aryl-3-methylthio-1*H*-1,2,4-triazolo[4,3-*b*][1,2,4]triazoles **13**,[3] and 6-aryl-1-methyl-3-methylthio-1*H*-1,2,4-triazolo[4,3-*b*][1,2,4]triazoles **14**[3] were prepared according to the methods described in the literature.

The previously unreported 3-methylthio-6-(*p*-nitrophenyl)-1*H*-1,2,4-triazolo[4,3-*b*][1,2,4]triazole **13h** was prepared from **10** and 4-nitrobenzonitrile. Yield, 41%; white needles, mp 280—282 °C; IR (Nujol) 3080, 1630, 1520, 1220, 980, 870, 840, 720 cm^{-1}.

*4-Amino-1-methyl-3-methylthio-1*H*-1,2,4-triazol-5(4*H*)-one* **1**. A solution of 4-amino-1-methyl-3,5-bis(methylthio)-1,2,4-triazolium iodide (6.36 g, 20 mmol) and sodium methoxide (1.35 g, 25 mmol) in methanol (200 ml), was heated under reflux for 10 h. The reaction mixture was filtered, concen-

a) Solvent: D_2O-dioxane; b) Solvent: DMSO-d_6; c) Not observed; d) Benzylic coupling (triplet, ^3J=3.5 Hz); e) N-CH_3 coupling (quartet, ^1J=142 Hz); f) S-CH_3 coupling (quartet, ^1J=144 Hz); g) Complex multiplet; h) At 80 °C; i) CO-CH_3 coupling (quartet, ^1J=133 Hz).

trated to one third of volume and cooled to 0 °C. The precipitated solid was filtered, dried, and recrystallized from methanol to give 4-amino-1-methyl-3-methylthio-1*H*-1,2,4-triazol-5(4*H*)-one **1** (2.78 g, 87%) as white needles, mp 175—176 °C.

IR (Nujol) 3320, 3210, 1720, 1650, 1560, 1420, 1270, 990, 970, 950, 890, 730 cm^{-1}. ^1H-NMR (DMSO-d_6) δ=5.29 (2H, s, NH_2), 3.30 (3H, s, N-CH_3), 2.37 (3H, s, S-CH_3).

Found: C, 29.91; H, 4.99; N, 34.82; S, 19.87%. Calcd for $C_4H_8N_4OS$: C, 29.99; H, 5.03; N, 34.97; S, 20.01%

General Procedure for the Preparation of Triazolotriazole Salts **3**. To a solution of 4-amino-1-methyl-3-methylthio-1*H*-1,2,4-triazol-5(4*H*)-one **1** (3.5 g, 21.8 mmol) in *t*-butyl alcohol (80 ml), equimolar amounts of potassium *t*-butoxide (2.44 g, 21.8 mmol) and the appropriate aromatic nitrile were added. The reaction mixture was heated under reflux with stirring for 6 h. After cooling, the precipitated solid was separated and recrystallized from ethanol to give the corresponding triazolotriazole salt **3** as crystalline solid in high yield (Table 5).

By this procedure, the following salts **3** were prepared:

3a as colorless prisms. IR(Nujol) 1680, 1600, 1460, 1440, 1280, 1180, 1120, 850, 830, 750 cm^{-1}.

3b as colorless prisms. IR(Nujol) 1680, 1600, 1460, 1440, 1380, 1280, 1120, 1070, 1030, 860, 780, 750, 710, 690 cm^{-1}.

3c as colorless prisms. IR(Nujol) 1680, 1600, 1520, 1460, 1430, 1380, 1200, 1125, 845, 810, 765, 740 cm^{-1}.

3d as colorless prisms. IR(Nujol) 1680, 1600, 1460, 1440,

*General Procedure for the Preparation of 6-Aryl-2-methyl-7*H*-1,2,4-triazolo[4,3-*b*][1,2,4]triazol-3(2*H*)-ones* **4**. To a well stirred solution of triazolotriazole salt **3** (10 mmol) in water (80 ml), 1 M† hydrochloric acid was added dropwise until pH=5. The precipitated solid was collected by filtration, dried, and recrystallized from ethanol to give pure 6-aryl-2-methyl-7*H*-1,2,4-triazolo[4,3-*b*][1,2,4]triazol-3(2*H*)-one **4** as crystalline solid in high yield (Table 6).

By this procedure, the following compounds **4** were prepared:

4a as colorless prisms. IR(Nujol) 3070, 1695, 1650, 1500, 970, 840, 780, 730, 680 cm^{-1}. ^{1}H-NMR (DMSO-d_6/D_2O) δ=7.9—7.6 (5H, m), 3.40 (3H, s), MS *m/z* (%), 215 (M^+, 100), 103 (82).

4b as colorless prisms. IR (Nujol) 3080, 1710, 1650, 970, 835, 730, 680, 640 cm^{-1}. ^{1}H-NMR (DMSO-d_6/D_2O) δ=7.60 (2H, d), 7.15 (2H, d), 3.38 (3H, s), 2.33 (3H, s). MS *m/z* (%), 229 (M^+, 100), 117 (91).

4c as colorless needles. IR (Nujol) 3090, 1710, 1660, 1500, 1470, 1100, 970, 835, 730, 700, 660 cm^{-1}. ^{1}H-NMR (DMSO-d_6/D_2O) δ=7.90 (2H, d), 7.20 (2H, d), 3.39 (3H, s). MS *m/z* (%), 249 (M^+, 100), 251 (M^++2, 31), 137 (85), 139 (25).

4d as colorless prisms. IR (Nujol) 3080, 1705, 1660, 1620, 1590, 1505, 1260, 1185, 1030, 965, 835, 735, 710, 660, 650, 630 cm^{-1}. ^{1}H-NMR (DMSO-d_6/D_2O) δ=7.88 (2H, d), 7.10 (2H, d), 3.85 (3H, s), 3.39 (3H, s). MS *m/z* (%), 245 (M^+, 100), 133 (80).

4e as colorless prisms. IR (Nujol) 3100, 1710, 1660, 1500, 970, 830, 770, 710, 680, 660 cm^{-1}. ^{1}H-NMR (DMSO-d_6/D_2O) δ=7.5—7.2 (4H, m). 3,39 (3H, s), 2.39 (3H, s). MS *m/z* (%) 229 (M^+, 100), 117 (90).

4f as colourless prisms. IR (Nujol) 3070, 1710, 1660, 1500, 1340, 970, 830, 730, 710, 680, 670 cm^{-1}. ^{1}H-NMR (DMSO-d_6/D_2O) δ=7.5—7.2 (3H, m), 3.40 (3H, s), 2.48 (3H, s), 2.34 (3H, s). MS *m/z* (%), 243 (M^+, 100), 131 (82).

General Procedure for the Preparation of Amidine Salts **6**. To a well-stirred solution of 4-amino-1-methyl-3-methylthio-1*H*-1,2,4-triazole-5(4*H*)-thione **5** (3.52 g, 20 mmol) in *t*-butyl alcohol (100 ml), equimolar amounts of potassium *t*-butoxide (2.24 g, 20 mmol) and the appropriate aromatic nitrile, were added. The reaction mixture was heated under reflux for 3 h. After cooling, the precipitated solid was separated by filtration and recrystallized from ethanol to give the cor-

† 1 M=1 mol dm^{-3}.

responding amidine salt **6**, as crystalline solid in moderated yields (Table 5).

By the above procedure, the following salts **6** were obtained:

6a as colorless prisms. IR (Nujol) 3180, 1590, 1580, 1460, 1200, 1120, 1010, 835, 750, 705 cm^{-1}.

6b as colorless prisms. IR (Nujol) 3210, 1590, 1460, 1330, 1130, 1010, 830, 755 cm^{-1}.

6c as colorless prisms. IR (Nujol) 3210, 1595, 1450, 1400, 1280, 1130, 1110, 1020, 1000, 840, 760 cm^{-1}.

6d as colorless prisms. IR (Nujol) 3200, 1590, 1580, 1460, 1255, 1175, 1030, 1000, 855, 760 cm^{-1}.

6e as colorless prisms. IR (Nujol) 3200, 1590, 1450, 1325, 1190, 1120, 1000, 830, 745, 720 cm^{-1}.

6f as colorless prisms. IR (Nujol) 3180, 1590, 1580, 1450, 1190, 1120, 1010, 835, 735, 720 cm^{-1}.

*General Procedure for the Preparation of Inner Salt of 6-Aryl-2-methyl-3-methylthio-7*H*-1,2,4-triazolo[4,3-*b*][1,2,4]triazolium Hydroxides* **8**. To a well-stirred solution of amidine salt **6** (10 mmol) in water (100 ml), methyl iodide (13 mmol) and enough ethanol (about 20 ml) were added to give a clear solution. The resulting solution was kept at room temperature for 24 h. The solvent was partially removed under reduced pressure and the separated solid was filtered, dried and recrystallized from ethanol to give pure **8** as crystalline solid in good yield (Table 7).

By this procedure the following mesoionic compounds **8** were prepared:

8a as white prisms. IR (Nujol) 1590, 1580, 1410, 1350, 1280, 1080, 990, 790, 755, 715 cm^{-1}. ^{1}H-NMR ($CDCl_3$) δ=8.3—7.4 (5H, m), 4.00 (3H, s), 2.75 (3H, s). MS *m/z* (%) 245 (M^+, 38), 212 (25), 129 (44), 103 (34), 77 (100).

8b as white prisms. IR (Nujol) 1585, 1460, 1400, 1330, 1180, 1105, 1030, 980, 830, 755, 730 cm^{-1}. ^{1}H-NMR ($CDCl_3$) δ=7.70 (2H, d), 7.40 (2H. d), 4.05 (3H, s), 2.75 (3H, s), 2.40 (3H, s). MS *m/z* (%) 259 (M^+, 26), 226 (79), 185 (30), 143 (51), 117 (43), 81 (76), 69 (100).

8c as white prisms. IR (Nujol) 1580, 1570, 1470, 1420, 1320, 1020, 990, 840, 760, 730 cm^{-1}. ^{1}H-NMR ($CDCl_3$) δ=7.80 (2H, d), 7.60 (2H, d), 4.00 (3H, s), 2.70 (3H, s). MS *m/z* (%) 281 (M^++2, 6), 279 (M^+, 18), 248 (5), 246 (15), 165 (8), 163 (8), 139 (10), 137 (30), 70 (100).

8d as white prisms. IR (Nujol) 1610, 1590, 1430, 1405, 1350, 1310, 1250, 1180, 1020, 850, 740, 680 cm^{-1}. ^{1}H-NMR ($CDCl_3$) δ=7.90 (2H, d), 7.20 (2H, d), 3.95 (3H, s), 3.80 (3H, s), 2.70 (3H, s). MS *m/z* (%) 275 (M^+, 31), 270 (12), 244 (5), 242 (8), 159 (21), 133 (13), 69 (100).

8e as white needles. IR (Nujol) 1590, 1460, 1330, 1260, 1190, 1025, 990, 820, 750, 735 cm^{-1}. ^{1}H-NMR ($CDCl_3$) δ=8.1—7.3 (4H, m), 4.00 (3H, s), 2.70 (3H, s), 2.65 (3H, s). MS *m/z* (%) 259 (M^+, 43), 226 (12), 143 (72), 117 (25), 69 (100).

8f as white needles. IR (Nujol) 1585, 1560, 1455, 1420, 1325, 1200, 1020, 980, 830, 760 cm^{-1}. ^{1}H-NMR ($CDCl_3$) δ=8.0—7.1 (3H, m), 4.00 (3H, s), 2.75 (3H, s), 2.65 (3H, s), 2.40 (3H, s). MS *m/z* (%) 273 (M^+, 70), 258 (43), 157 (33), 131 (30), 69 (100).

*General Procedure for the Preparation of 6-Aryl-2-methyl-7*H*-1,2,4-triazolo[4,3-b][1,2,4]triazole-3(2*H*)-thiones* **9**. To a well-stirred solution of amidine salt **6** (10 mmol) in water (100 ml), 1 M hydrochloric acid was added dropwise until pH=5. The precipitated solid was collected by filtration, dried, and recrystallized from ethanol to give pure **9** as crystalline solid in high yield (Table 6).

By the above procedure, the following compounds **9** were prepared:

9a as white prisms. IR (Nujol) 3080, 1655, 1605, 1465, 1430, 1380, 1120, 960, 830, 780, 690 cm^{-1}. ^{1}H-NMR (DMSO-d_6/D_2O) δ=7.9—7.3 (5H, m), 3.83 (3H, s). MS *m/z* (%) 231 (M^+, 55), 198 (11), 172 (42), 103 (100), 77 (21).

9b as white needles. IR (Nujol) 3080, 1650, 1610, 1460, 1320, 1200, 1125, 960, 830, 825, 730 cm^{-1}. ^{1}H-NMR (DMSO-d_6/D_2O) δ=7.70 (2H, d), 7.30 (2H, d), 3.80 (3H, s), 2.40 (3H, s). MS *m/z* (%) 245 (M^+, 61), 212 (8), 186 (32), 117 (100), 70 (48).

9c as white needles. IR (Nujol) 3080, 1655, 1605, 1470, 1400, 1100, 960, 840, 830, 730 cm^{-1}. ^{1}H-NMR (DMSO-d_6/D_2O)) δ=7.90 (2H, d), 7.60 (2H, d), 3.80 (3H, s). MS *m/z* (%) 267 (M^++2, 32), 265 (M^+, 100), 234 (4), 232 (12), 208 (21), 206 (63), 139 (10), 137 (30).

9d as white needles. IR (Nujol) 3070, 1650, 1605, 1490, 1460, 1250, 1175, 1025, 950, 850, 845, 810, 735 cm^{-1}. ^{1}H-NMR (DMSO-d_6/D_2O) δ=7.70 (2H, d), 7.30 (2H, d), 3.85 (3H, s), 3.75 (3H, s). MS *m/z* (%) 261 (M^+, 100), 228 (8), 202 (56), 133 (42).

9e as white prisms. IR (Nujol) 3080, 1650, 1460, 1310, 1120, 1050, 950, 825, 770, 720 cm^{-1}. ^{1}H-NMR (DMSO-d_6/D_2O) δ=8.1—7.3 (4H, m), 3.82 (3H, s), 2.65 (3H, s). MS *m/z* (%) 245 (M^+, 100), 212 (7), 186 (34), 158 (25), 143 (11), 117 (44).

9f as white prisms. IR (Nujol) 3080, 1650, 1610, 1460, 1370, 1300, 1200, 1120, 955, 830, 735, 720 cm^{-1}. ^{1}H-NMR (DMSO-d_6/D_2O) δ=8.0—7.1 (3H, m), 3.80 (3H, s), 2.65 (3H, s), 2.40 (3H, s). MS *m/z* (%) 259 (M^+, 100), 226 (13), 200 (28), 172 (36), 131 (76), 116 (62).

Basic Hydrolysis of Compounds **8**. A solution of inner salt of 6-aryl-2-methyl-3-methylthio-7*H*-1,2,4-triazolo[4,3-*b*]-[1,2,4]triazolium hydroxide **8** (5 mmol) in 10 % methanolic potassium hydroxide (75 ml) was heated under reflux until evolution of methanethiol was ceased (about 5 h). Then, the solvent was removed under reduced pressure and the residual material was dissolved in water (60 ml). The resulting solution was acidified by dropwise addition of 1 M hydrochloric acid until pH=5. The precipitated solid was collected by filtration, dried and crystallized from ethanol to give 6-aryl-2-methyl-7*H*-1,2,4-triazolo[4,3-*b*][1,2,4]triazol-

3(2*H*)-one **4** in almost quantitative yield.

*General Procedure for the Preparation of 1-Acetyl-6-aryl-3-methylthio-1,2,4-triazolo[4,3-*b*][1,2,4]triazoles* **15**. A solution of 6-aryl-3-methylthio-1*H*-1,2,4-triazolo[4,3-*b*][1,2,4]-triazole **13** (20 mmol) in acetic anhydride (100 ml) was heated under reflux for 1 h with stirring. After cooling, the precipitated solid was collected by filtration, dried under vacuum at 100 °C, and crystallized from ethanol to give pure **15** as crystalline solid in high yield (Table 4).

By this procedure the following compounds **15** were obtained:

15a as white plates. IR (Nujol) 1750, 1570, 1490, 1420, 1310, 1130, 990, 790, 740, 710, 680 cm^{-1}. ^{1}H-NMR ($CDCl_3$/CF_3CO_2H) δ=8.1—7.5 (5H, m), 2.90 (3H, s), 2.75 (3H, s).

15b as white needles. IR (Nujol) 1740, 1585, 1570, 1490, 1430, 1420, 1320, 1205, 1125, 835, 760, 745 cm^{-1}. ^{1}H-NMR ($CDCl_3$/CF_3CO_2H) δ=7.90 (2H, d), 7.50 (2H, d), 2.90 (3H, s), 2.75 (3H, s), 2.40 (3H, s).

15c as white needles. IR (Nujol) 1745, 1570, 1420, 1320, 1210, 1125, 1020, 910, 850, 745 cm^{-1}. ^{1}H-NMR ($CDCl_3$/CF_3CO_2H) δ=7.90 (2H, d), 7.60 (2H, d), 2.95 (3H, s), 2.75 (3H, s).

15e as white needles. IR (Nujol) 1730, 1585, 1570, 1480, 1410, 1380, 1325, 1125, 900, 760, 730 cm^{-1}. ^{1}H-NMR ($CDCl_3$/CF_3CO_2H) δ=8.1—7.4 (4H, m), 2.90 (3H, s), 2.75 (3H, s), 2.65 (3H, s).

15f as white needles. IR (Nujol) 1740, 1570, 1495, 1420, 1320, 1210, 1130, 990, 910, 840, 760, 730 cm^{-1}. ^{1}H-NMR ($CDCl_3$/CF_3CO_2H) δ=7.9—7.1 (3H, m), 2.90 (3H, s), 2.75 (3H, s), 2.65 (3H, s), 2.40 (3H, s).

15g as white needles. IR (Nujol) 1730, 1585, 1570, 1485, 1410, 1380, 1330, 1205, 1125, 1045, 900, 735, 710 cm^{-1}. ^{1}H-NMR ($CDCl_3$/CF_3CO_2H) δ=8.1—7.4 (4H, m), 2.95 (3H, s), 2.75 (3H, s).

15h as white plates. IR (Nujol) 1745, 1575, 1520, 1420, 1350, 1310, 1130, 990, 870, 860, 740, 720 cm^{-1}. ^{1}H-NMR ($CDCl_3$/CF_3CO_2H) δ=7.90 (2H, d), 7.60 (2H, d), 2.90 (3H, s), 2.75 (3H, s).

General Procedure for the Preparation of 1-Acetyl-6-aryl-7-methyl-3-methylthio-7H-1,2,4-triazolo[4,3-b][1,2,4]triazol-7-ium Trifluoromethanesulfonates **16**. To a solution of 1-acetyl-6-aryl-3-methylthio-1*H*-1,2,4-triazolo[4,3-*b*][1,2,4]triazole **15** (10 mmol) in dry dichloromethane (75 ml), methyl trifluoromethanesulfonate (12 mmol) was added dropwise. The reaction mixture was stirred at room temperature for 24 h. Occasionally the trifluoromethanesulfonate salt **16** precipitated in the course of the reaction. If not, the solvent was removed under reduced pressure and the residual material was crystallized from dichloromethane-diethyl ether to give the pure **16** as crystalline solid in high yield (Table 8).

By this procedure the following compounds **16** were prepared:

16a as colorless prisms. IR (Nujol) 1755, 1640, 1530, 1460, 1370, 1300, 1230, 1210, 1160, 1130, 1030, 950, 780, 730, 710, 640 cm^{-1}. ^{1}H-NMR ($CDCl_3$) δ=7.8—7.5 (5 H, m), 4.15 (3H, s), 2.85 (3H, s), 2.75 (3H, s).

16b as colorless prisms. IR (Nujol) 1770, 1620, 1520, 1310, 1270, 1230, 1160, 1030, 980, 840, 770, 740, 640 cm^{-1}. ^{1}H-NMR ($CDCl_3$) δ=8.0 (2H, d), 7.5 (2H, d), 4.15 (3H, s), 2.90 (3H, s), 2.75 (3H, s), 2.40 (3H, s).

16c as colorless prisms. IR (Nujol) 1765, 1610, 1540, 1360, 1270, 1230, 1160, 1030, 1010, 965, 910, 840, 730, 640 cm^{-1}. ^{1}H-NMR ($CDCl_3$) δ=7.90 (2H, d), 7.60 (2H, d), 4.10 (3H, s), 2.90 (3H, s), 2.75 (3H, s).

16e as colorless prisms. IR (Nujol) 1765, 1615, 1550, 1370, 1310, 1270, 1240, 1230, 1160, 1030, 970, 910, 770, 760, 740, 640 cm^{-1}. ^{1}H-NMR ($CDCl_3$) δ=8.2—7.4 (4H, m), 4.15 (3H, s), 2.85 (3H, s), 2.75 (3H, s), 2.65 (3H, s).

16f as colorless prisms. IR (Nujol) 1770, 1620, 1520, 1420, 1310, 1270, 1230, 1180, 1160, 1030, 970, 830, 780, 760, 720, 640 cm^{-1}. ^{1}H-NMR ($CDCl_3$) δ=7.9—7.0 (3H, m), 4.15 (3H, s), 2.90 (3H, s), 2.75 (3H, s), 2.65 (3H, s),

Table 8. 3-Methylthio-6-arylthio-6-aryl-1,2,4-triazolo[4,3-*b*][1,2,4]triazole derivatives **15**, **16**, and **17**

2.40 (3H, s).

16g as colorless prisms. IR (Nujol) 1770, 1620, 1530, 1370, 1310, 1270, 1230, 1160, 1030, 970, 910, 780, 760, 730, 640 cm^{-1}. ^1H-NMR ($CDCl_3$) δ=8.2—7.4 (4H, m), 4.10 (3H, s), 2.90 (3H, s), 2.75 (3H, s).

16h as white needles. IR (Nujol) 1770, 1620, 1550, 1520, 1360, 1320, 1270, 1160, 1040, 975, 910, 870, 860, 730, 640 cm^{-1}. ^1H-NMR ($CDCl_3$) δ=7.90 (2H, d), 7.70 (2H, d), 4.10 (3H, s), 2.85 (3H, s), 2.75 (3H, s).

General Procedure for the Preparation of 6-Aryl-7-methyl-3-methylthio-7H-1,2,4-triazolo[4,3-b][1,2,4]triazoles **17**. To a solution of 1-acetyl-6-aryl-7-methyl-3-methylthio-1*H*-1,2,4-triazolo[4,3-*b*][1,2,4]triazol-7-ium trifluoromethanesulfonate **16** (10 mmol) in water (250 ml), ethanol was added until a clear solution was obtained at 70 °C. Then a saturated aqueous solution of sodium carbonate was added dropwise with stirring, until pH=9. After cooling to 0 °C, the precipitated solid was collected by filtration, dried, and recrystallized from chloroform-hexane to give the pure **17** as crystalline solid in high yield (Table 8).

By the above procedure, the following compounds **17** were obtained:

17a as white prisms. IR (Nujol) 1590, 1470, 1330, 1320, 1170, 1045, 1020, 955, 785, 720, 710 cm^{-1}. ^1H-NMR (DMSO-d_6) δ=7.7—7.2 (5H, m), 3.80 (3H, s), 2.75 (3H, s); ($CDCl_3$) δ=7.60 (5H, s), 3.75 (3H, s), 2.65 (3H, s). The fact that the phenyl appears as a singlet is characteristic of a phenyl out-of-plane (For another example in the azapentalene series, see Ref. 25).

17b as white needles. IR (Nujol) 1590, 1480, 1460, 1270, 1175, 1070, 990, 970, 840, 730 cm^{-1}. ^1H-NMR (DMSO-d_6) δ=7.90 (2H, d), 7.65 (2H, d), 3.80 (3H, s), 2.70 (3H, s), 2.50 (3H, s).

17c as white needles. IR (Nujol) 1590, 1495, 1320, 1180, 1170, 1090, 1000, 945, 835, 720 cm^{-1}. ^1H-NMR (DMSO-d_6) δ=8.00 (2H, d), 7.80 (2H, d), 3.80 (3H, s), 2.70 (3H, s).

17e as white prisms. IR (Nujol) 1590, 1490, 1370, 1320, 1170, 1050, 1030, 950, 785, 740, 730 cm^{-1}. ^1H-NMR (DMSO-d_6) δ=7.8—7.4 (4H, m), 3.65 (3H, s), 2.70 (3H, s), 2.35 (3H, s).

17f as white prisms. IR (Nujol) 1590, 1500, 1370, 1320, 1180, 1140, 1060, 1000, 970, 840, 745, 735, 730 cm^{-1}. ^1H-NMR (DMSO-d_6) δ=7.9—7.3 (3H, m), 3.60 (3H, s), 2.75 (3H, s), 2.45 (3H, s), 2.35 (3H, s).

17g as white prisms. IR (Nujol) 1600, 1500, 1430, 1370, 1320, 1180, 1095, 1040, 970, 780, 745, 720 cm^{-1}. ^1H-NMR (DMSO-d_6) δ=8.0—7.6 (4H, m), 3.70 (3H, s), 2.75 (3H, s).

17h as yellow plates. IR (Nujol) 1590, 1540, 1530, 1470, 1350, 1170, 1060, 950, 860, 760, 720, 710 cm^{-1}. ^1H-NMR (DMSO-d_6) δ=7.90 (2H, d), 7.65 (2H, d), 3.80 (3H, s), 2.70 (3H, s).

We thank Mrs. M. D. Casado, Mrs. M. L. Jimeno, and Mrs. M. Plaza for recording the ^{13}C NMR spectra.

(Received June 22, 1984)

Synopsis. The conformation of the title compound was determined by X-ray crystal analysis. The seven-membered lactam ring is in a quasi-chair conformation with the amide chromophore being approximately coplanar.

We proposed a sign rule (Ogura's sign rule)[1] regarding the relationship between the absolute configuration of the seven-membered lactams and the signs of the n→π* c.d. The Cotton effect of the amide chromophore, indicating that seven-membered lactam rings are classified into two types (A and B) as shown in Fig. 1. The former exibits a positive Cotton effect and the latter a negative one.

Recently, Klyne[2] reported that 7-membered lactam rings connected with a second adjacent ring at the 3,4- or 6,7 positions of the lactam ring showed abnormal CD, and Ogura rule failed to predict the signs of the Cotton effect of several of them. From the results of an X-ray analysis of 2-aza-*A*-homo-5α-cholestan-1-one[3] and ε-caprolactam[4] and on the basis of a study of Dreiding Models, they proposed the hyposesis that the lactam ring A has a positive sign of the C-NH-CO-C torsion angle corresponding to a Cotton effect of the same sign.

We carried out an X-ray analysis of the optical active monocyclic (−)-menthone lactam which obviously has the lactam ring in the conformation depicted in Type B,[5] to confirm the coplanarity of the amide chromophore on which Ogura rule is based. We also wanted to make it clear that (−)-menthone lactam really has a negative C-NH-CO-C torsion angle predicted from the Klyne's hypothesis.

Experimental

A crystal with the dimensions of 0.3×0.4×0.2 mm was used for the structure determination. The density of the crystal was measured by the flotation method using a carbon tetrachloride-light petroleum solution. The cell dimensions and the diffraction intensities were measured on a Rigaku four-circle diffractometer, using graphite monochromated Cu $K\alpha$ radiation at 23°C. Crystal data: $C_{10}H_{19}ON$, orthorhombic, space group $P2_12_12_1$, a=8.837(1), b=40.176(1), c=6.028(1) Å, Z=8. D_c=1.051 g cm^{-3}. 1121 independent reflections within the range of $2\theta<140°$ were collected by the use of the 2θ–ω scan mode with a scanning rate 4° (2θ)min^{-1}. A total 861 independent reflections with $|F_o|>3\sigma(|F_o|)$ were obtained and corrected for Lorentz and polarization factors but not for absorption factors. The structure was solved by a direct method using MULTAN.[6] The E-map of the phase set with the highest figure of merit showed the skeletons of the molecules.

The structure, thus obtained, was refined by a full-matrix least-squares method with anisotropic temperature factors. After all the hydrogen atoms except those of the methyl group had been located in the difference Fourier map, several cycles of least-squares refinement were carried out including these hydrogen atoms. The atomic scattering factors for C, O, and N were given by Cromer and Mann,[7] and that for H by Stewart *et al.*[8] The final R value was 9.5%, where $R=\sum||F_o|-|F_c||/\sum|F_o|$.

independent two molecules I and II are listed in Table 1. The complete table of observed and calculated structure factors, thermal parameters and the atomic coordinates of hydrogen atoms are kept as Document No. 8509 at the Office of the Editor of the Bulletin of the Chemical Society of Japan. A perspective drawing of the molecular structure of (−)-menthone lactam is shown in Fig. 2. The bond angles and bond lengths are listed in Table 2, and torsion angles are in Table 3.

The conformation of the lactam ring of (−)-menthone lactam is a quasi-chair with the amide chromophore being approximately coplanar (Table 3). (−)-Menthone lactam belongs to type B, as shown in Fig. 2, and the mean value of the C-NH-CO-C torsion angle is +2°, whose sign is opposite to that of ε-caprolactam (−4.2°). The conformations of the two independent molecules are almost identical except the isopropyl groups. Although the C-NH-CO-C torsion angles in (−)-menthone lactam have the positive sign which is opposite to that predicted by Klyne's hypothesis, this can not be discussed in detail because the values of the torsion angles have large standard deviations.

The authors are grateful to the Ministry of Education, Science, and Culture for a financial support by a Grant-in-Aid (No. 58570883).

Synopsis. The change of the C ls peak shape in an X-ray photoelectron spectrum was studied for sodium-doped polyacetylene. The C ls peak due to negatively-charged carbon atoms was found to appear on the low-binding-energy side of a peak due to neutral carbon atoms. An electron, which is transferred to a polyacetylene chain from the sodium atom, has been determined to reside over several carbon atoms.

Previously, we studied bromine-doped polyacetylene by X-ray photoelectron spectroscopy[1] and found that the shape of the C ls peak varied markedly with the bromine content. The observed change of the peak shape suggested that the peak was composed of two components, mutually separated by 1.7—2.0 eV, and that the intensity of the higher-binding-energy component increased while that of the lower-binding-energy component decreased on increasing the bromine content. We attributed the former characteristic to the carbon atoms in the metallic domain where carbon atoms are positively charged as the result of a charge transfer to bromine to form a Br_3^- ion, and the other component to the carbon atoms in the low conductive (or undoped) domain. However, the intensity of the higher-binding-energy component continues to increase even when the bromine content exceeds the value where the conductivity shows a steep decrease because of the progress of the addition and/or substitution reaction of bromine with the polyacetylene chain.[1,2] Thus, in a heavily-doped case the higher-binding-energy component might contain a large contribution from carbon atoms which form a bond with bromine. Furthermore, a recent EXAFS study of the bromine-doped polyacetylene revealed that the C-Br bond is formed even in a lightly-doped polyacetylene.[2] Thus, there remains the question whether the higher-binding-energy component of the C ls peak is actually due to the positively-charged carbon atoms in the metallic domain.

Salaneck *et al.* studied AsF_5- and I_2-doped polyacetylene by XPS.[3,4] They also observed two components in their C ls peaks. However, they attributed a shoulder which appeared on the higher-binding-energy side of the peak upon doping with AsF_5 (or I_2), to the conduction-electron-plasmon shake-up. The main, rather sharp component on the lower-binding energy side moves to the higher-binding energies, relative to undoped polyacetylene. They concluded that all the carbon atoms in polyacetylene were uniformly charged and that the average charge per carbon atom depends on the amount of the dopant.

In the case of the sodium-doped polyacetylene where carriers are different from those in the bromine-doped polyacetylene, doped sodium atoms will change to sodium ions giving an electron to the polyacetylene chain, and none of the addition or substitution reaction can occur between sodium and polyacetylene. According to the interpretation proposed by Salaneck *et al.*, the main, rather sharp C ls peak would shift to the lower binding energy and a shoulder due to the conduction-electron-plasmon shake-up would appear on the higher-binding-energy side of the main peak. The chemical shift of the main peak may depend on the amount of the dopant. On the other hand, if we consider the presence of the doped and undoped domains in the sodium-doped polyacetylene, the component due to the negatively-charged carbon atoms in the doped domain would appear on the lower-binding-energy side of the component due to the carbon atoms of the undoped domain. The intensity of the former component would increase and the latter would decrease with the increase of sodium content.

Since the sodium-doped polyacetylene is extremely sensitive to air, we have to prepare specimens under an ultra-high vaccum condition and immediately carry out all XPS measurements without exposing the doped polyacetylene film to air. The present experiment was done by use of a VG ESCA LAB 5. A polyacetylene film, prepared by a previously described method,[5] was introduced into the sample chamber of the apparatus by keeping the film in a nitrogen atmosphere. The polyacetylene film, thus introduced into the apparatus, did not show any detectable O ls peak. Then, the film was exposed to a sodium vapor in a sample-preparation chamber, a sodium-metal dispenser by S.A.E.S. Getters S.p.A. being used as the sodium source. The C ls and Na ls peaks were measured immediately after the deposition of sodium onto the film. The same procedure was repeated in order to study the effect of an increase of the amount of the doped sodium, which means that we measured the sodium-doped polyacetylene with various dopant contents. The Na ls/C ls intensity ratio and the approximate Na/C atomic ratio derived from the intensity ratio, and the C ls peak width (f.w.h.m.) with the repetition of sodium deposition are summarized in Table 1. The Na/C atomic ratio derived from the intensity ratio might be smaller since sodium is only on the surface of the polyacetylene film. The shape of the C ls peak of the undoped polyacetylene and those of two sodium-doped polyacetylenes (after 4th and 7th depositions which correspond to $(CHNa_{0.045})_x$ and $(CHNa_{0.075})_x$, respectively) are shown in Fig. 1(a). The shape of the C ls peak varied markedly upon increasing the sodium content. The f.w.h.m. of the C ls peak increased to 2.8 eV by doping sodium from 1.5 eV of the undoped polyacetylene. However, the total intensity of the C ls

Table 1. XPS Results of sodium-doped polyacetylene

5	0.45	0.055	2.5
6	0.50	0.065	2.7
7	0.60	0.075	2.8

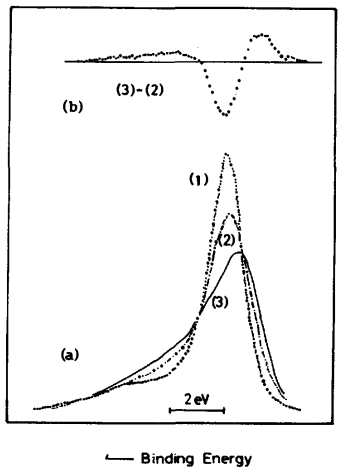

Fig. 1. (a): The C 1s peaks of (1) polyacetylene, (2) Na-doped polyacetylene (4th deposition) and (3) Na-doped polyacetylene (7th deposition).
(b): Difference spectrum of the C 1s peaks of (2) and (3).

peak was found to remain constant. We took the difference between the spectra of the doped samples which have different amounts of sodium in order to see the effect of the increase of the amount of the doped sodium. One of the difference spectrums (Fig. 1(b)) indicates that there are at least two main components in the C ls peak of the sodium-doped polyacetylene. Upon doping sodium, a lower-binding-energy peak (or shoulder) begins to appear and its intensity increases with the sodium content keeping the binding energy constant. The higher-binding-energy peak which corresponds to neutral carbon atoms decreases in intensity. That is, a part of the neutral carbon atoms changes their state upon the sodium doping. Therefore, we attribute the former to the negatively-charged carbon atoms and the latter to the neutral carbon atoms. The chemical shift between the two main components is about 1.2 eV, from which we can estimate the average negative charge per carbon atom to be about −0.2 e. This means that an electron transferred from a sodium atom spreads over at least five carbon atoms. The difference spectrum also shows that the lower-binding-energy peak has a tail on the higher-binding-energy side. This might be attributable to the conduction-electron-plasmon shake-up as suggested by Salaneck *et al.*[3,4] Including this component, there are three components in the C ls peak of the sodium-doped polyacetylene, which cannot be explained by the interpretation proposed by Salaneck *et al.* The difference between the binding energies of the higher-binding-energy component in the C1s level and the Na ls level stays almost constant while increasing of the sodium content. This means that the sodium is in the same state, that is, in the form of Na^+ irrespective of the sodium content.

In conclusion, the XPS data of the sodium-doped polyacetylene suggest that the charge transfer from sodium to polyacetylene results in the formation of negatively-charged carbon atoms and an electron transferred from a sodium atom spreads over several (possibly more than five) carbon atoms of the polyacetylene chain. Based on these facts, we conclude that in the bromine-doped polyacetylene, the higher-binding-energy component is mainly due to the positively-charged carbon atoms, at least in the lightly-doped regions. However, the small contribution of the conduction-electron-plasmon shake-up to this component cannot be excluded.

Application of Laser Flash Photolysis to Determine Association Constants between Zn-TPPS$_3$ and Viologens

Ichiro OKURA,* Shigetoshi AONO, Mikio HOSHINO,† and Akira YAMADA†
Department of Chemical Engineering, Tokyo Institute of Technology, Meguro-ku, Tokyo 152

(Received July 30, 1984)

Synopsis. The association behavior between zinc 5,10,15,20-tetraphenylporphyrintrisulfonate (Zn-TPPS$_3$) and viologens was investigated from the T-T absorption band of the triplet Zn-TPPS$_3$ by laser-flash photolysis. The association constants of Zn-TPPS$_3$ with methylviologen and propylviologen-3,3′-sulfonate (PVS) were 1.7×10^4 and 7.3×10^2 mol^{-1}·dm^3, respectively.

Water-soluble zinc meso-tetraphenylporphyrintrisulfonate (Zn-TPPS$_3$) has been found to be a suitable photosensitizer in the photoinduced hydrogen evolution system, consisting of a photosensitizer, an electron donor, an electron acceptor, and a catalyst.[1] Zn-TPPS$_3$, however, has been reported to form a complex with viologen and it has been clarified that the complex does not take part in the photoreduction of viologen, and that only the uncomplexed Zn-TPPS$_3$ plays an important role in the reaction.[2] The determination of the association constant between Zn-TPPS$_3$ and viologen provides suitable reaction conditions. As it is difficult to determine the association constant from the visible spectra (the visible spectra of the complex is very similar to that of Zn-TPPS$_3$) a laser-flash photolysis was applied to determine the association constant in this study.

Experimental

Methylviologen was purchased from Tokyo Kasei Kogyo Co., and PVS was prepared according to the literature.[3] The sample solution, which consisted of Zn-TPPS$_3$ and viologen (if included), was deaerated by repeated freeze-pump-thaw cycles. Conventional laser photolysis was carried out using a Nd-YAG Laser, Model HY-500 from JK Lasers Ltd., equipped with second, third, and fourth harmonic generators. The second harmonic (532 nm), of *ca.* 100 mJ cm^{-2} and a flash duration of 20 ns was used to excite the sample solutions throughout this study. The analyzing light beams from a xenon lamp (Ushio UXL-150 D, 150 W) were intensified by a factor of *ca.* 20 during the detection of the transient spectra. Transient spectra having a lifetime longer than 200 μs were measured without intensification of the analyzing light. The light, after passing through a sample cell, was focused onto the entrance slit of a monochromator (Model MC-20 N from Ritsu Appl. Opt. Co.). The output from a Hamamatsu photomultiplier (R 758) attached to the exit slit of the monochromator was displayed on a Tektronix oscilloscope, Model 7904.

Results and Discussion

Figure 1-(a) shows an oscilloscopic photograph monitored at 470 nm (the peak wavelength of the T-T absorption band due to the triplet Zn-TPPS$_3$) after a laser flash. In the presence of methylviologen, the decay rate of the transient spectrum measured at 470 nm increased, as shown in Fig. 1-(b) and 1-(c). The methylviologen cation radical (MV^+, λ_{max}=605 nm) initially increased and then decreased as shown in Fig. 1-(e) and 1-(f). The absorbance of the triplet spectrum at 470 nm measured immediately after the laser flash decreased with an increase in methylviologen concentration (Fig. 1-(a), 1-(b), and 1-(c)), and the T-T absorption was not detected at concentrations higher than 5.01×10^{-3} mol·dm^{-3}. As a consequence of the decrease in the absorbance at 470 nm, the concentration of MV^+ formed after the laser flash decreased, and MV^+ formation was not observed in the absence of T-T absorption as shown in Fig. 1-(g). These results can be expressed by the following reaction scheme, suggesting the 1:1 complex (PQ) formation between Zn-TPPS$_3$ (P) and MV^{2+} (Q).

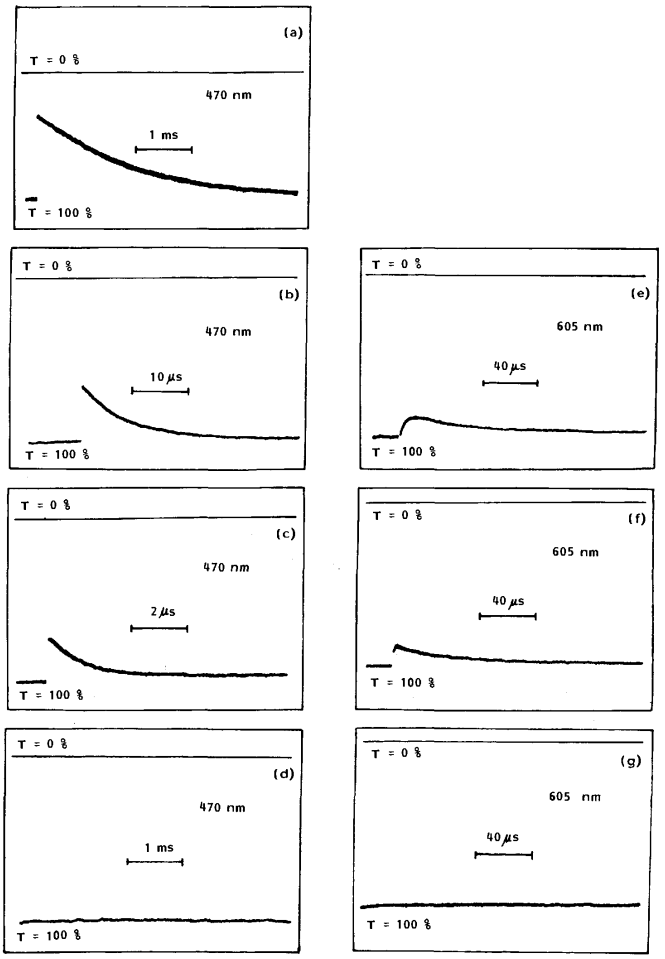

Fig. 1. Oscilloscopic photographs obtained from laser flash photolysis of aqueous solutions of (a) Zn-TPPS$_3$, (b)—(g) Zn-TPPS$_3$+MV^{2+}. Zn-TPPS$_3$: 3.03×10^{-5} mol·dm^{-3}; concentration of viologens, (a): 0, (b), (e): 1.21×10^{-5} (c), (f): 5.01×10^{-5}, (d), (g): 5.01×10^{-3} mol·dm^{-3}.

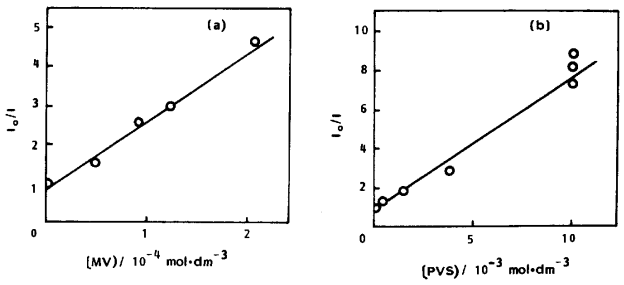

Fig. 2. Relation between I_0/I and the concentration of methylviologen or PVS.

$$P + Q \overset{K}{\rightleftharpoons} PQ$$

$$P \xrightarrow{h\nu} {}^3P^*$$

$${}^3P^* + Q \longrightarrow P^+ + Q^-$$

$$P^+ + Q^- \longrightarrow P + Q$$

$$PQ \xrightarrow{h\nu} PQ^* \xrightarrow{\text{fast}} PQ$$

where K is the association constant.

According to such a reaction scheme, the concentration of PQ increases with the increase of the Q concentration. The absorbance of the T-T absorption at 470 nm is considered to be proportional to the concentration of uncomplexed Zn-$TPPS_3$ on the assumption that the photoexcited complex (PQ*) may convert to PQ very rapidly. We, therefore, obtain,

$$I_0/I = 1 + K[Q]$$

where I_0 and I are the absorbance at 470 nm measured immediately after the laser flash in the absence and in the presence of methylviologen, respectively. This equation is the same as that reported previously[4] in the case of the static quenching of fluorescence.

As shown in Fig. 2-(a), the fairly linear relationship between I_0/I and [Q] indicates that the above proposed scheme is adequate. From the slope of the straight line, the K value was obtained as 1.7×10^4 mol^{-1}·dm^3. For propylviologen-3,3′-sulfonate(PVS), a similar linear relationship was also obtained (Fig. 2-(b)), and the K value was 7.3×10^2 mol^{-1}·dm^3. The difference in the K values between PVS and methylviologen is explained by the difference of electrostatic force between Zn-$TPPS_3$ and viologens or the redox potentials of each viologen.

The difference between the redox potential of methyl-viologen (−0.44 eV *vs* NHE) and that of PVS (−0.41 eV *vs* NHE) is so small that the larger K value of methylviologen compared with PVS may be mainly due to an electrostatic effect. Since the positively charged methylviologen is more favorable to associate with the negatively charged Zn-$TPPS_3$, the larger K value detected for methylviologen (compared with PVS) is plausible.

Triphenylmethyl-substituted Arylthioaminyl Radicals. An ESR Study of *N*-(Arylthio)triphenylmethylaminyls[1)]

Yozo MIURA,* Mamoru ISOGAI, and Masayoshi KINOSHITA
Department of Applied Chemistry, Faculty of Engineering, Osaka City University, Sumiyoshi-ku, Osaka 558
(Received August 1, 1984)

Synopsis. The title radicals have been studied by ESR spectroscopy. The radicals are fairly long-lived in solution and satellite lines due to the ^{33}S atom at natural abundance could be observed in their ESR spectra.

Since the triphenylmethyl group is one of the most bulky groups, triphenylmethyl-substituted free radicals are expected to be sterically protected from reactions by which the free radicals will be destroyed.[2)] Therefore, this steric protection may make the free radicals more long-lived. From this viewpoint triphenylmethyl-substituted arylthioaminyls, **2**, are of considerable interest and the present work was initiated with the hope of isolating them. Thioaminyl radicals (RN̈SR′) are essentially long-lived in solution,[3)] but the thioaminyl radicals stable enough to be isolated as the free radical substance are rare.[4)] The results of an ESR study of **2**, however, showed that **2** were not as stable as we had expected. Interestingly, however, in their ESR spectra satellite lines due to the ^{33}S atom at natural abundance could be observed for any **2** radical. Herein we report the $a_{^{33}S}$ values for **2** and discuss their electronic structures and plausible conformations on the basis of their ESR parameters.

$Ph_3CNHSAr$ $Ph_3CN̈SAr$ t-$BuN̈SAr$
1 **2** **3**

Radicals **2** were generated in benzene from **1** by either of the two methods described in the Experimental section. A typical ESR spectrum is illustrated in Fig. 1 and the ESR parameters are listed in Table 1. The ESR spectra obtained were very clean and the signals due to impurity radicals were either very weak or absent. These clean ESR spectra are in contrast to those of *N*-(arylthio)-*t*-butylaminyl radicals (**3**)[5)] in which an impurity radical, *t*-BuN̈OBu-*t*, was simultaneously recorded with comparable intensity.[6)] This difference may be explained in terms of the steric protection by the bulky triphenylmethyl group from the reactions by which impurity radicals will be produced.

Radicals **2** were fairly long-lived in solution. For instance, the steady-state radical concentrations obtained by method **a** were $\approx 10^{-4}$ mol dm^{-3}, and on interruption of UV-irradiation, the radicals persisted for a long period (≈10 h at room temperature), although they were not stable enough to be isolated.

As can be seen from Fig. 1, the ESR spectra of **2** showed relatively narrow lines and gave well resolved splittings due to the phenylthio aromatic protons. This contrasts with the broad and poorly resolved ESR spectra of **3**.[5)] Interestingly, this line narrowing permitted us clearly to observe the satellite lines due to the ^{33}S atom at natural abundance for any **2** radical, on recording at high gain. The measured intensities heights of the satellite lines correspond to ≈0.12% of the parent peak (theoretical 0.19%). The results are listed in Table 1.

The large a_N and large $a_{^{33}S}$ values for **2** strongly suggest that in **2** the unpaired electron resides mainly

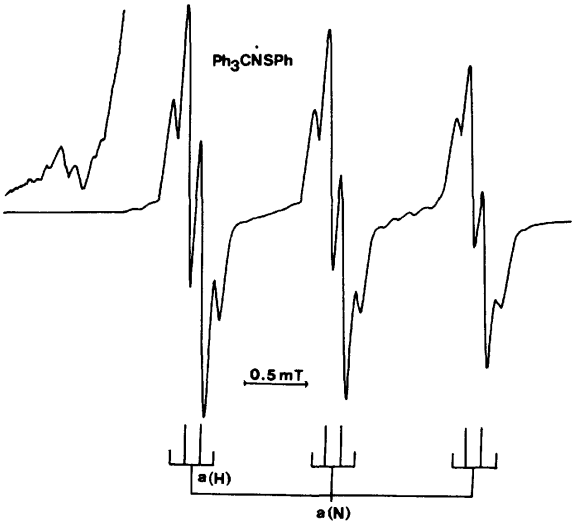

Fig. 1. ESR spectrum of **2a** recorded during photolysis of a solution of **1a** in 1:9 (v/v) di-*t*-butyl peroxide–benzene at 20°C. The left wing is shown under high amplification (100 times) and the satellite lines due to the ^{33}S atom can be clearly seen.

on the nitrogen and sulfur. Furthermore, their ESR parameters (except those for **2d**) are similar to those for **3** (a_N=1.170—1.189 mT, g=2.0068—2.0072).[5] Therefore, it is likely that **2** adopt a similar conformation to that of **3** which we believe to be planar.[3]

To discuss the spin density distribution in **2** in more detail, the spin density on each atom was calculated by both the standard Hückel MO method and the McLachlan perturbation treatment,[7] assuming the radicals to be planar. The parameters used are as follows: $\alpha_N=\alpha+0.6\beta$, $\alpha_S=\alpha+\beta$, $\beta_{NS}=0.7\beta$, $\beta_{CS}=0.7\beta$, $\lambda=0.7$.[3] The spin densities on the nitrogen, sulfur and ortho and para carbons of the phenylthio benzene ring calculated by the Hückel MO method are 0.554, 0.325, 0.04, and 0.04, respectively.[8] Then, the a_N, $a_{33}S$, and a_H values derived from these values by use of the simple McConnell relationship $a_x=Q_x\rho_x{}^\pi$, where Q_N=2.2, Q_{33S}=2.3, and Q_H=−2.7 mT,[3] become 1.22, 0.75, and 0.11 mT, respectively. It is seen from Table 1 that these values are in good agreement with the experimental ones.

The ESR parameters (a_N, a_{33S}, and g) for **2d** are unusually increased compared with those for the other radicals. We believed that these unusual increases in the ESR parameters could be accounted for by assuming that **2d** adopted a twisted conformation in which the phenylthio benzene ring did not lie in the nodal plane of the nitrogen $2p_z$ (and sulfur $3p_z$) orbital. In this assumed conformation the unpaired electron will be poorly delocalized over the phenylthio benzene ring.[9] To confirm this assumption, *N*-(*t*-butylthio)-triphenylmethylaminyl radical (**4**) was generated. If this assumption is correct, the ESR parameters for **2d** should come close to those for **4**. As can be seen from Table 1, the parameters for both radicals are very similar to each other. Consequently, it is concluded that the unusual increases in the ESR parameters for **2d** are attributable to the twisted conformation of **2d**.

Experimental

IR and ^{1}H NMR measurements have been described in a previous paper.[3] Di-*t*-butyl diperoxyoxalate,[10] triphenylmethylamine,[13] and alkane- and benzenesulfenyl chlorides[3,11,12] were prepared by the previously reported methods.

General Procedure for Preparation of N-(Arylthio)triphenylmethylamines (1). A benzenesulfenyl chloride (7.60 mmol) in 30 cm^3 of dry diethyl ether (ether) was added to a stirred solution of triphenylmethylamine (5.78 mmol) and triethylamine (3 cm^3) in dry ether (150 cm^3) at 0 °C. After being stirred for 1 h at 0 °C and for an additional 4 h at room temperature, the reaction mixture was filtered, evaporated, and the residue chromatographed on alumina (Merck art 1097, colum size 4×11 cm). Elution with hexane gave the diaryl disulfide and subsequent elution with 1:3 (v/v) benzene–hexane gave product **1** which was recrystallized from the appropriate solvent.

N-(Phenylthio)triphenylmethylamine (1a). Colorless prisms (from hexane); mp 116—118 °C; yield 67%; IR (KBr) 3300 cm^{-1} (NH); NMR ($CDCl_3$) δ=4.29 (s, 1H, NH, exchanged by D_2O) and 6.93—7.37 (m, 20H, aromatic). Anal. ($C_{25}H_{21}NS$) C, H, N.

N-(4-Chlorophenylthio)triphenylmethylamine (1b). Colorless prisms (from hexane–benzene); mp 151—153 °C; yield 46%; IR (KBr) 3280 cm^{-1} (NH); NMR ($CDCl_3$) δ=4.37 (s, 1H, NH, exchanged by D_2O) and 7.04—7.38 (m, 19H, aromatic). Anal. ($C_{25}H_{20}ClNS$) C, H, N.

N-(3,5-Dichlorophenylthio)triphenylmethylamine (1c). Colorless prisms (from hexane); mp 120—122 °C; yield 67%; IR (KBr) 3320 cm^{-1} (NH); NMR ($CDCl_3$) δ=4.38 (s, 1H, NH, exchanged by D_2O) and 6.87—7.34 (m, 18H, aromatic). Anal. ($C_{25}H_{19}Cl_2NS$) C, H, N.

N-(2,4,6-Trimethylphenylthio)triphenylmethylamine (1d). Colorless needles (from ethanol-benzene); mp 144—145 °C; yield 36%; IR (KBr) 3280 cm^{-1} (NH); NMR ($CDCl_3$) δ=2.21 (s, 6H, *o*-CH_3), 2.23 (s, 3H, *p*-CH_3), 3.85 (s, 1H, NH, exchanged by D_2O), and 6.78—7.35 (m, 17H, aromatic). Anal. ($C_{28}H_{27}NS$) C, H, N.

Although an attempt was made to prepare *N*-(*t*-butylthio)-triphenylmethylamine (**1e**) by the reaction of triphenylmethylamine with 2-methyl-2-propanesulfenyl chloride, it could not be isolated from the reaction mixture. For ESR measurements the concentrate of the reaction mixture was used.

ESR Measurements. Radicals **2** were produced by either of the following two methods: (a) photolysis of a solution of **1** (20 mg) in 1:9 (v/v) di-*t*-butyl peroxide—benzene (0.4 cm^3) with a high-pressure mercury lamp and (b) reaction of **1** (25 mg) with di-*t*-butyl diperoxyoxalate (8 mg) in benzene (0.4 cm^3).

ESR spectra were recorded with a JEOL JES-ME-3X spectrometer. Hyperfine splitting constants and g values were determined by comparison with those (a_N=1.309 mT, g=2.0057) for Fremy's salt in K_2CO_3 aqueous solution.

Effect of Choline Derivatives on the Critical Micelle Concentrations of Anionic and Cationic Surfactants

Masayuki NAKAGAKI and Shoko YOKOYAMA*
Faculty of Pharmaceutical Sciences, Kyoto University, Yoshida-Shimoadachi-cho, Sakyo-ku, Kyoto 606
(Received August 10, 1984)

Synopsis. The decrease of the critical micelle concentration (cmc) of sodium dodecyl sulfate (SDS) was larger, while the decrease of that of dodecyltrimethylammonium chloride (DTAC) was smaller in the presence of choline derivatives than in the presence of NaCl at the same molar concentration.

A large number of studies have been reported on the effect of various electrolytes[1-10] and alcohols[8-15] on the micellization of ionic surfactants. The association of ionic surfactant in aqueous solution is governed by two opposing forces. The hydrophobic force between the hydrophobic tails attracts the surfactant molecules or ions to the micelle core from the aqueous bulk solution. The ionic head groups, on the other hand, favour the aqueous bulk phase, because the electrostatic repulsive force between the head groups prevents the surfactant molecule to associate. In this connection, the decrease of the critical micelle concentration (cmc) by addition of inorganic salts and alcohols may be discussed. The effect of the inorganic electrolytes is explained in terms of the shielding of the electrostatic repulsion by the counterions, while the effect of alcohol is explained from the reduction of the free energy of mixing and the reduction of the surface charge density by the alcohols entering in the palisade layer of the micelle.

Moreover, it has been found that the mixed micelle composed of anionic and cationic surfactants is not formed.[16] Therefore, the effect on the micellization of the salts which have a short hydrophobic part and a polar part of the opposite sign may be interesting.

From these points of view, we studied the critical micelle concentration of anionic and cationic surfactants in aqueous solutions of choline chloride and its esters ($HOCH_2CH_2N^+(CH_3)_3\cdot Cl^-$, $CH_3COOCH_2CH_2N^+(CH_3)_3\cdot Cl^-$, $CH_2COOCH_2CH_2N^+(CH_3)_3\cdot Cl^-$ / $CH_2COOCH_2CH_2N^+(CH_3)_3\cdot Cl^-$), by the measurements of the surface tension.

Experimental

Materials. Sodium dodecyl sulfate (SDS) supplied from Nihon Emulsion Co., Ltd., Japan was extracted with petroleum benzine in a Soxlet apparatus for at least 20 h, recrystallized twice from ethanol, and dried under vacuum for a day and night. Dodecyltrimethylammonium chloride (DTAC) purchased from Nakarai Chemicals, Ltd. was extracted with petroleum ether in a Soxlet apparatus for at least 20 h, recrystallized twice from aceton, and dried under vacuum for a day and night. Choline chloride (Ch), acetylcholine chloride (Ach) and succinylcholine chloride (Sch) purchased from Nakarai Chemicals, Ltd. were of a guaranteed reagent grade and were used without further purification. All solutes were dissolved in deionized and redistilled water.

Surface Tension Measurements. The surface tension was measured by Du Nouy tensiometer. The platinum ring with diameter 23 mm was heated by oxidizing flame before use. All glass apparatus were preserved in chromate-sulfuric acid mixture and linsed well with distilled water before use. Temperature of the thermostat was maintained at 25±0.2 °C. For the calculation of the surface tension of aqueous solutions, the value of 71.96 m N·m^{-1} was used as the surface tension of pure water at 25 °C. The experimental determination of the surface tension was precise to ±0.1 m N·m^{-1}. cmc was obtained from the break point in the curve of surface tension, γ, as a function of logarithm of the concentration of SDS or DTAC, at various values of the concentration of choline derivatives.

Results and Discussion

cmc of SDS in the presence of choline chloride and its derivatives, *i.e.* Ch, Ach and Sch is shown in Fig. 1 together with the data of inorganic salts and normal alkanols quoted from the references.[13,17] cmc of DTAC in the presence of choline derivatives is shown in Fig. 2 together with the data of NaCl quoted from the reference.[17] The measured values of cmc of SDS and DTAC in the absence of additives (8.1 m mol·dm^{-3},

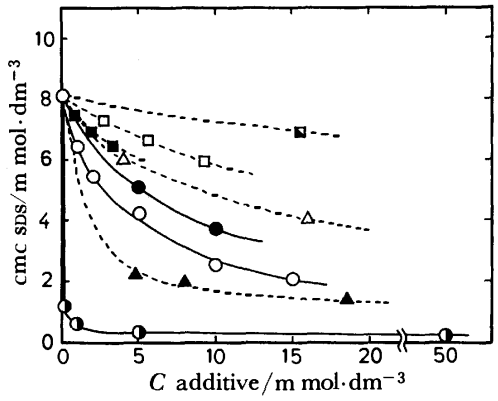

Fig. 1. Effect of Additives on the cmc of SDS at 25 °C.
●: Ch, ○: Ach, ◑: Sch, △: NaCl, ▲: $MgCl_2$,[17] ◪: 1-pentanol, □: 1-hexanol, ■: 1-heptanol,[13] ——: measured results by us, -----: reference results.

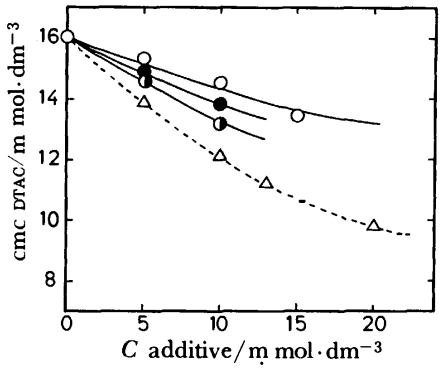

Fig. 2. Effect of Additives on the cmc of DTAC at 25 °C.
The symbols are same as Fig. 1.

16.0 m mol·dm^{-3}) and the values in the presence of NaCl of 5 m mol·dm^{-3} (6 m mol·dm^{-3}, 14 m mol·dm^{-3}) are consistent well with the values from the reference,[17] so the values obtained by us are considered to be adequate.

cmc of SDS and DTAC decreased with increase of the concentration of choline derivatives. The effectiveness of choline derivatives is larger than that of NaCl on the cmc of SDS, while the effectiveness of choline derivatives is smaller than that of NaCl on the cmc of DTAC. Furthermore, in the case of SDS, the order of effectiveness to decrease the cmc is Sch>Ach>Ch>NaCl, while in the case of DTAC, the order is NaCl>Sch>Ch>Ach. These results are considered to be due to the followings: (1) In the case of SDS, the electric charge of micelle has opposite sign to that of choline derivatives: The choline derivatives, as organic ions, may have specific interaction rather than the simple electrostatic effect of shielding by the counterions. In addition, choline derivatives lead to the reduction of the free energy of mixing by entering in the micelle. The difference of effectiveness is explained from the distribution of choline derivatives to micelle from bulk phase and the deepness of penetration, due to the hydrophobic property (Sch is more hydrophobic because Sch has the structure that two molecules of Ach have condensed). Regarding the distribution of choline derivatives between micellar and bulk phases, we have measured the distribution of Ach by means of ultrafiltration and it has been found that Ach enter indeed in the micelle. According to the result, the distribution ratio of Ach of 5 m mol·dm^{-3} in the micellar phase is 30—40% in the presence of SDS or DTAC of 30 m mol·dm^{-3}. The results of ultrafiltration will be reported in detail in a later paper. (2) In the case of DTAC, the electric charge of micelle has same sign to that of choline derivatives: The choline derivatives decrease the cmc by the shielding effect of the electrostatic repulsion by chloride ions as the effect of NaCl, while the choline derivatives entered in the micelle prevent the surfactant molecule to associate by the electrostatic repulsive force between the head groups. Therefore, the effectiveness of the choline derivatives is smaller than that of NaCl. The reason that Sch is more effective than Ch or Ach is considered mainly to be due to the counterion effect because that Sch has the structure composed of two Ach. It can, therefore, be concluded that the facts that the order of the effectiveness to decrease the cmc is Sch>Ach>Ch>NaCl for SDS, and NaCl>Sch>Ch>Ach for DTAC, are explained by the electrostatic effect and the distribution of choline derivatives between micellar and bulk phases.

NMR Spectra of Benzenes Containing Trifluoromethyl Groups

Kensuke TAKAHASHI,* Akihiro YOSHINO, Kenzo HOSOKAWA,† and Hiroshige MURAMATSU†
Nagoya Institute of Technology, Gokiso-cho, Showa-ku, Nagoya 466
†*Government Industrial Research Institute, Nagoya, Hirate-machi, Kita-ku, Nagoya 462*
(Received August 20, 1984)

Synopsis. The ^{1}H, ^{13}C, and ^{19}F NMR spectra of the nine title compounds were measured. The substituent effect of a trifluoromethyl group were generally additive for the ^{1}H, ^{13}C, and ^{19}F chemical shifts. The assignment of the ^{13}C signals was assisted by the observed coupling constants between the carbon and the fluorine, which were about 275, 35, and 6 Hz for the ^{1}J, ^{2}J, and ^{3}J values of these compounds.

The NMR spectral data of the title compounds have not yet been systematically reported except for the ^{19}F NMR data.[1] The aim of this study was to obtain the NMR parameters of the title compounds. The values of the coupling constants between the carbon and fluorine, ^{1}J, ^{2}J, and ^{3}J, were also helpful for the assignment of the ^{13}C signal.

Experimental

The ^{1}H and ^{19}F NMR spectra were observed with a frequency-swept Hitachi R-20B spectrometer, whose center frequencies were 60 and 56.46 MHz, respectively. The ^{13}C NMR spectra were measured using a Varian XL-200 spectrometer with a frequency of 50.3 MHz. The chemical shifts were determined in a chloroform-*d* solution using a small amount of TMS and C_6F_6 as internal references.

The benzenes containing trifluoromethyl group were prepared by the fluorination of the corresponding benzene carboxylic acids by sulfur tetrafluoride in the presence of anhydrous hydrogen fluoride.[2] The compounds studied in this article are summarized (with their reference numbers) in Table 1.

Results and Discussion

Chemical Shifts. The values of the chemical shifts for ^{1}H, ^{19}F, and ^{13}C nuclei are given in Tables 2 and 3.

The ^{1}H chemical shifts fall within a range of 7.45—8.34 ppm with respect to TMS. Therefore, the hydrogen atoms in the present compounds are less shielded than those of benzene (7.31 ppm in the $CDCl_3$ solution). The substituent chemical shift (SCS) values of the trifluoromethyl group (S_o, S_m, and S_p) were evalu-

a) The values in parentheses are the coupling constants between the carbon and the fluorine in Hz. b) Signals are not confirmed yet.

ated from a comparison of the chemical shifts of **1** with that of benzene. They are 0.30, 0.14, and 0.21 ppm, respectively. An ortho-effect, which is an interaction effect of two adjacent substituents, was also taken into consideration. Thus, S_{abc} is used to express the ortho-effect of the a- and b-positioned substituents to the c-positioned nucleus. Then S_{123} and S_{124} can be estimated to be 0.09 and 0.01 ppm from a comparison of the observed chemical shifts of 1,2-disubstituted compounds (**2**) with its calculated ones based on the additivity. The S_{123}, which is 0.09 ppm, gives an appreciable effect to the chemical shifts while the S_{124} can be neglected. By using these SCS values, the chemical shifts of the tri- and tetra-substituted compounds can be evaluated from the additivity rule to obtain values which are in agreement with the experimental ones within 0.1 ppm. The ^{1}H NMR spectrum of **1** was previously analyzed by Kostelnik *et al.*[3] The chemical shifts of **1** in a $CDCl_3$ solution were evaluated by visual fittings of the observed spectrum to the simulated one where the calculation was performed by changing the chemical-shift values and keeping the spin couplings constant.

The ^{19}F chemical shifts of the trifluoromethyl group were similarly treated. The SCS values (S_o, S_m, and S_p) of the ^{19}F chemical shifts of the substituent CF_3 groups are 3.32, −0.31, and −0.54 ppm, respectively. These were derived from a comparison of the chemical shifts of disubstituted compounds (**2**, **3**, and **4**) with that of **1**. Typical examples of the calculated chemical shifts are given for **7** as follows:

$$\delta(\text{F-1}) = 99.25 + S_o + S_p = 102.03 \text{ (Exp. 102.22)}$$

$$\delta(\text{F-2}) = 99.25 + S_o + S_m = 102.26 \text{ (Exp. 102.24)}$$

$$\delta(\text{F-4}) = 99.25 + S_m + S_p = 98.40 \text{ (Exp. 98.42)}$$

The SCS values of the ^{13}C chemical shifts of the trifluoromethyl group were obtained from the ^{13}C chemical shifts of **1** as compared with that of benzene (128.33 ppm in $CDCl_3$). The values are 2.95, −2.76, 0.83, and 3.84 ppm, respectively, for the ipso-, ortho-, meta-, and para-carbons. The observed ^{13}C chemical shifts for tri- and tetrasubstituted compounds are consistent with the calculated ones, which were derived by using the above-mentioned SCS values, within 2 ppm with two exceptions. The large deviations are found to be 4 and 2 ppm for the C_3 of **9** and the C_3 of **2**. When an ortho-effect of S_{123}, which is assumed to be 2.0 ppm, is introduced, the observed ^{13}C chemical shifts become consistent with the calculated ones within 1 ppm.

Coupling Constants. The observed values of the coupling constants between the carbon and fluorine were about 275, 35, and 6 Hz for the ^1J, ^2J, and ^3J (Table 3). The values for **1** were previously reported.[4] These values were useful for the assignment of the ^{13}C signals of the compounds studied. However, the splitting of the ^{13}C signals was disadvantageous for finding the signals. Several signals of **2** and **7** have not yet been confirmed.

The long-range coupling constants between the hydrogen and fluorine are generally small and change in magnitude from compound to compound. An example of the ^{1}H spectra is given in Fig. 1 for **2**.

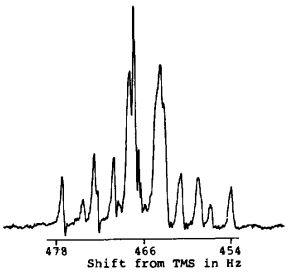

Fig. 1. An observed ^{1}H NMR spectrum of **2** at 60 MHz.

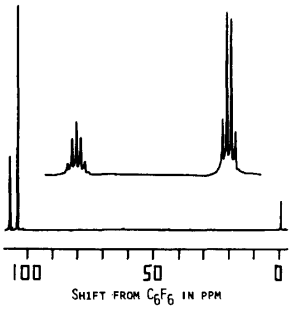

Fig. 2. An observed ^{19}F[^{1}H] NMR spectrum of **8** at 188.22 MHz with an expanded one.

This was analyzed as an AA'BB' spin system. The analysis shows that the chemical shift between the H_3 and the H_4 is 10.1 Hz at 60 MHz and the J_{34}, J_{35}, J_{36}, and J_{45} values are 8.0, 1.3, 0.5, and 7.6 Hz, respectively. The upfield spectrum is broader than the other half by about 0.2 Hz, as shown in Fig. 1. The origin of the broadening is considered to be the couplings between the hydrogens and fluorines. Therefore it is concluded that $|^5J_{HF}| > |^4J_{HF}|$. This is consistent with the analyzed values of **1**.[3] However, $|^4J_{HH}| > |^5J_{HH}|$ has been found in a similar system of toluene.[6] The ^{1}H signal of **6** appeared as a sextet whose splitting was about 0.7 Hz. The situation is also the same with the ^{1}H signals of **5**. The splitting of about 0.7 Hz is consistent with the couplings reported for **1** and **5**.[3,5]

The fluorine-fluorine couplings may be observed for the compounds (**6**, **7**, and **8**), which have unequivalent CF_3 groups. The line breadth of the ^{19}F signal of **6** is about 1.1 Hz. Therefore, the ^6J(F-F) is smaller than 1 Hz. On the other hand, the ^5J(F-F) observed for **8** is about 16 Hz. This is shown in the ^{19}F[^{1}H] spectrum as given in Fig. 2 and consistent with the reported values.[1]

The Electrochemical Behavior of BR_2-linked Bis(glyoximato)nickel(II) Complexes in a Nonaqueous Solvent

Makoto AIHARA,* Yumiko NISHI, Hiroko OMATSU, and Yasuomi NONAKA†

Laboratory of Inorganic Chemistry, Faculty of Home Life Science, Fukuoka Women's University, Higashi-ku, Fukuoka 813

†*Fukuoka Jogakuin Junior College, Minami-ku, Fukuoka 816*

(Received July 4, 1984)

Synopsis. Nickel(II) complexes with dioximers replaced by BF_2 and $B(C_2H_5)_2$ groups for bridging by the hydrogen atom were investigated by electrochemical methods. The nickel(II) complexes exhibited two distinct one-electron reduction waves in *N,N*-dimethylformamide. It was found that the electron-withdrawing effect of the replaced group is exerted on the electronic states of the nickel(II) complexes.

The nickel(II) complexes of BF_2- or $B(Et)_2$- linked dioximers (Fig. 1) were synthesized and characterized by Schrauzer[1] and Gagné.[2] Schrauzer concluded that these substituents exert no effect on the ligand field around the nickel(II) ion. One of the present authors (Y. N.) reported on the effects of BF_2- and $B(Et)_2$-substitution for bridging by the hydrogen atom in the Co(II), Ni(II), and Cu(II) complexes with some oximate ligands.[3] The BF_2-substitution caused a red-shift of the d-d band, increased the $g_{//}$-value for copper(II) complexes, and caused a positive shift of the polarographic half-wave potential of nickel(II) complexes. These results suggested that the electrochemical method is useful in investigating the electronic state of the nickel(II) complexes.

The present report deals with the electrochemical behavior of nickel(II) complexes with BF_2- or $B(Et)_2$-substituted macrocyclic ligands, as is shown in Fig. 1.

Fig. 1. Structures and abbreviations of the complexes in this study.

Experimental

Synthesis of the Complexes. The complexes were prepared according to the method reported previously.[3]

Electrochemical Measurements. All the measurements were carried out in an 0.1 M tetraethylammonium perchlorate (TEAP) solution (1 M=1 mol dm^{-3}) of *N,N*-dimethylformamide (DMF) at 25±0.1 °C. A Fuso Model 312 polarograph and a DME (or HMDE) were employed for the polarographic and cyclic voltammetric measurements, respectively. The reference electrode was an SCE with a salt bridge.[4] Controlled-potential electrolysis was performed at a mercury pool under stirring. The other apparatus was the same as that described previously.[4]

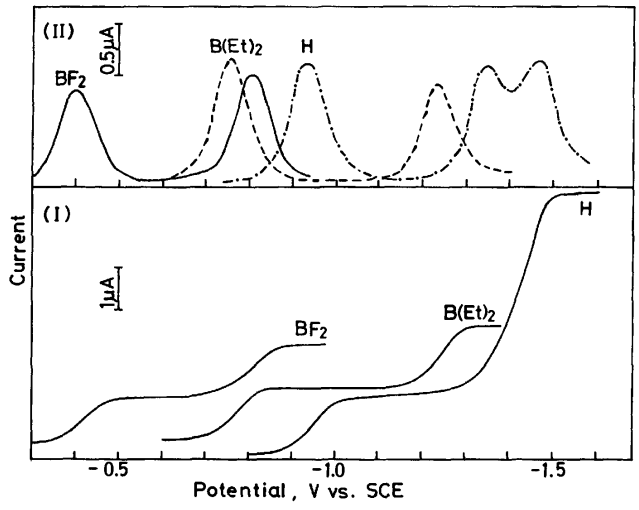

Fig. 2. Current-sampled dc polarograms(I) and differential pulse polarograms(II) of 0.5 mM Ni(dpgX)$_2$ in DMF.

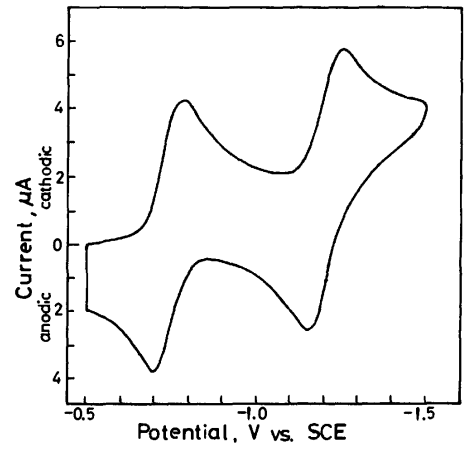

Fig. 3. Cyclic voltammogram of 0.5 mM Ni{dpgB(Et)$_2$}$_2$ in DMF at HMDE, scan rate 200 mV/sec.

Results and Discussion

Some typical current-sampled dc polarograms for the $Ni(dpgX)_2$ complexes in DMF are shown in Fig. 2. For $Ni(dmgX)_2$, the same current-sampled dc polarograms were obtained in DMF. Each complex gives a two-stepped reduction wave. The heights of the first and second waves were almost the same except in the $Ni(dmgH)_2$ and $Ni(dpgH)_2$ systems. The height of the second wave for these two systems was larger than that of the first wave. On the other hand, the second wave for the $Ni(tnomX)^+$ system split into two waves.

These systems were investigated by means of normal pulse polarography. Each system exhibited electrochemical behavior much like the current-sampled dc polarography. The relationship of the current (i, μA) of the normal pulse polarogram and the sampling time

					−1.146	0.40	50	

a) Measured at the concentration of the 0.3 mM Ni(II) complex.

(t, s) was determined. There exists an obvious linear relationship between i and $t^{-1/2}$. These facts indicate that each electrode reaction is diffusion-controlled.

Some typical differential pulse polarograms of $Ni(dpgX)_2$ in DMF are shown in Fig. 2. Two main peaks were observed on each differential pulse polarogram, and their shapes were found to be symmetrical. The differential pulse polarograms for $Ni(dmgH)_2$ and $Ni(dpgH)_2$ indicate that the second wave of the current-sampled dc polarogram contains two-reduction waves. Each second wave of the current-sampled dc polarogram was three times or more larger than the first wave. Therefore, the reduction at the second wave was assumed to correspond to the electron transfer to the metal and ligand in the complex.

A typical cyclic voltammogram of the $Ni\{dpgB(Et)_2\}_2$ in DMF is shown in Fig. 3. Two peaks were observed on the cathodic branch, and two peaks, on the anodic branch, suggesting reversible processes.

The results of constant potential electrolysis showed the consumption of one electron for each step to be as is summarized in Table 1.

The electrode reactions for the $Ni(dmgX)_2$ and $Ni(dpgX)_2$ systems were assumed to be as follows.

$$Ni^{II}L + e \rightleftharpoons Ni^{I}L \quad (1)$$

$$Ni^{I}L + e \rightleftharpoons Ni^{0}L \quad (2)$$

where L denotes $(dmgX)_2$ and $(dpgX)_2$.

For $Ni(tnomX)^+$, the same electrode reaction was assumed for the first wave, but the reciprocal slope of each wave was 37—50 mV. These values were assumed to suggest Ni-Ni metal intramolecular interaction. The same behavior has been observed in polynuclear metal complexes.[5]

A comparison of the half-wave potentials for the $Ni(dmgX)_2$, $Ni(dpgX)_2$, and $Ni(tnomX)^+$ systems is shown in Fig. 4. The order of the half-wave potentials is; BF_2>$B(Et)_2$>H. The Ni(II) complex with the BF_2-substituted group is more easily reduced compared with the other complexes; this is because of the electron-withdrawing effect of the BF_2 group. The electron-withdrawing effect of the BF_2 group in these complexes was observed, although Schrauzer suggested that the effect of BF_2 groups on the nickel(II) ion could not be observed in a spectrophotometric study.

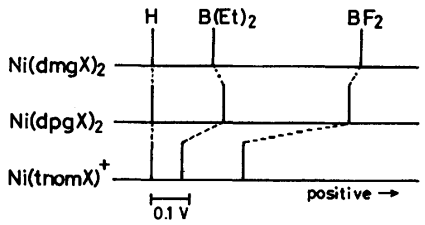

Fig. 4. Comparison of the half-wave potentials of each first wave as a criterion of that of Ni(II) complexes with hydrogen bridging.

The reduction potentials of $Ni(dpgX)_2$ are more positive than those of $Ni(dmgX)_2$. This fact may correspond to the weak electron-donating effect of the phenyl group.

On the other hand, the effect of a substituted group on the $Ni(tnomX)^+$ system is weak compared with those for $Ni(dmgX)_2$ and $Ni(dpgX)_2$. This is because of the structure of $Ni(tnomX)^+$, which has a closed ring and only one substituted group. However, the effect of Ni-Ni metal interaction on the half-wave potential should also be considered. This will be a subject for further study.

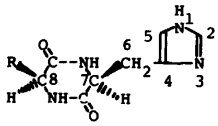
Stability Constants of Complex Formations between Divalent Metal Ions and Cyclic Dipeptides: Cyclo(glycyl-L-histidyl) and Cyclo(L-methionyl-L-histidyl)

Yoshitane KOJIMA,* Noriaki ISHIO, and Tetsushi YAMASHITA
Department of Chemistry, Faculty of Science, Osaka City University, Sugimoto, Sumiyoshi-ku, Osaka 558
(Received July 5, 1984)

Synopsis. The values($\log K_1$ and $\log K_2$) of the complex formations between divalent metal ions and two cyclic dipeptides of this title were determined by Bjerrum's method. It is apparent from ^{1}H NMR data that metal ions link exclusively to the nitrogen atom of the imidazolyl group of cyclo(L-methionyl-L-histidyl).

The authors[1] have studied some metal complexes with cyclic dipeptides as model compounds for metallo-proteins and -enzymes, in which the metal ions link exclusively to the functional groups of the side chains of the peptides.

This paper reports the values of the stability constants of the complex formations between divalent metal ions and cyclic dipeptides with an imidazolyl group[cyclo(glycyl-L-histidyl)=CGH and cyclo(L-methionyl-L-histidyl)=CMH].



CGH; R = H

CMH; R = $CH_2CH_2SCH_3$

9 10 11

Experimental

Materials. CGH and CMH were prepared according to methods reported earlier.[1a] All metal salts obtained commercially were used without further purification.

Measurements. ^{1}H NMR data were obtained in D_2O at 45 °C with sodium 3-trimethylsilyl-1-propanesulfonate as an internal reference using a JEOL PS-100. In the measurements of the stability constants of the complex formations, the titrated solution contained 0.24—1.27 mmol of a cyclic dipeptide, 0.10—0.27 mmol of $Ni(NO_3)_2$, $CuSO_4$ or $ZnSO_4$, and 0.40—1.50 mmol of HCl in 0.50 dm^3, the ionic strength being adjusted to 0.2 mol dm^{-3} with KNO_3. The solution was titrated with a 0.943 mol dm^{-3} NaOH aqueous solution at 25 °C under a nitrogen atmosphere using a Hitachi-Horiba F-5 pH meter. The acid dissociation constants(K_a) used in calculations were determined by titration to be $10^{-6.25}$ and $10^{-6.31}$ for CGH and CMH, respectively. The free-ligand concentration(L) and the average coordination number($\bar{n}$) were calculated from the titer and the hydrogen-ion concentration on the assumption that 1:1 and 1:2 complexes formed. The stability constants, $K_1=[ML]/([M][L])$ and $K_2=[ML_2]/([ML][L])$, were obtained by linear fittings according to the following equation: $Y=K_1K_2X-K_1$, where X is $(2-\bar{n})[L]/(\bar{n}-1)$ and Y is $\bar{n}/\{(\bar{n}-1)[L]\}$.

Results and Discussion

Figure 1 shows that the ^{1}H NMR signals of imidazole-2 and -4 protons are equally broadened in CMH:Cu^{2+} (5000:1) and in CMH:Ni^{2+} (1000:1) systems, respectively, suggesting the coordination of the imidazolyl group to metal ions. The amide protons of the diketopiperazine (DKP) ring are replaced by deuterium in D_2O. Figure 1 also shows no broading or

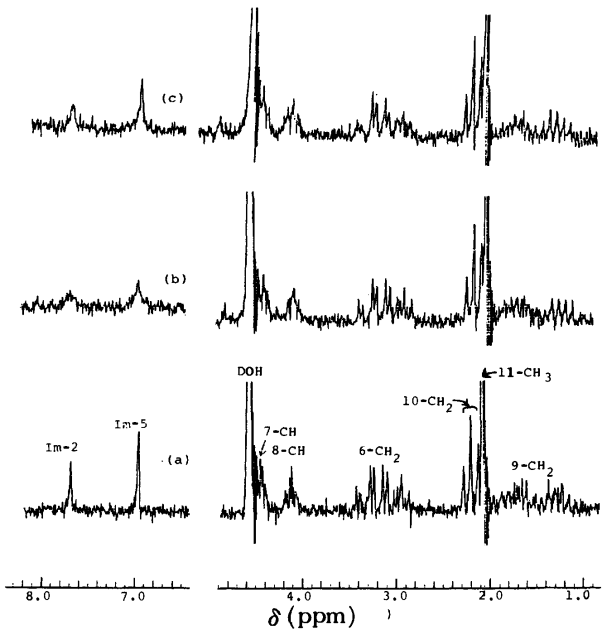


Fig. 1. ^{1}H NMR spectra of D_2O solution of the ligand (CMH) in the absence and presence of Ni^{2+} or Cu^{2+} at 45 °C. Ligand concentration = 0.052 mol dm^{-3}. (a) ligand alone, (b) ligand:Cu^{2+} = 5000:1, (c) ligand: Ni^{2+} = 1000:1. Im; imidazole.

shift of the methylene and methyl protons (C_{10} and C_{11}) adjacent to the sulfur atom and the methine protons (C_7 and C_8), though one of the methine protons (C_7) is partially overlapped by the signal of DOH. These observation suggest that both the sulfur atom[2] of the methionyl residue and the amide groups of DKP do not link with these metal ions. A similar tendency was also observed in the cyclo(L-histidyl-L-histidyl)-Cu^{2+}system reported earlier.[1b] An earlier report of X-ray analysis of a Zn^{2+} complex with CMH indicates that four 1-N atoms of each imidazole of four CMH's coordinate to Zn^{2+} ion.[1c] In the ^{1}H NMR measurement of this complex, a distinct down-field shift [δ (Zn^{2+} complex ion) $-\delta$ (free ligand)=0.33(ppm)] is observed only for the imidazole-2 proton of CMH. Thus, these metal ions(Ni^{2+}, Cu^{2+}, and Zn^{2+}) appear to interact exclusively with the imidazolyl group of CMH.

The stability constants between a divalent metal ion and monodentate ligands (CGH and CMH) were obtained by Bjerrum's method. Figure 2 shows a typical example of an *X-Y* plot. As shown in Table 1, the obtained values of $\log K_1$ and $\log K_2$ seem to be in the order of the Irving-Williams series. Table 1 also shows that the *K* values for CMH are comparable to those for CGH having no functional group except an imidazolyl one. These results suggest that the coordination mode of CMH for metal ions is similar to that of CGH. Table 2 indicates that the *K* values for divalent metal ions and

	1:3.1	2.49	2.20
Cu	1:2.4	3.37	3.19
	1:3.2	3.40	3.28
	1:3.6	3.29	3.20
Zn	1:2.0	2.50	1.48
	1:4.2	2.43	2.31

*M_t and L_t are total concentrations of each metal ion and each ligand, respectively.

cyclic dipeptides (CGH and CMH) are proportional to the strength of the basicities of ligands as compared with those for imidazole and pyridine.

In order to consider higher coordination numbers for metal ions, attempts to obtain the values of K_3 were carried out by successive approximations. However, the values were not successfully obtained because of the relatively small values of $\bar{n}$, as shown in Fig. 3. The values from K_1 to K_4 were also determined by Scatchard's method.[3] The values of logK_1 and logK_2 are shown as follows in order to make a comparison with those obtained by Bjerrum's method: CGH (Ni, 2.47, 1.33; Cu, 3.53, 2.99) and CMH (Ni, 2.38, 1.73; Cu, 3.50, 2.91; Zn, 2.34, 2.24). The stability constants between the Zn^{2+} ion and CGH were not obtained because of bad linearity. The values of logK_1 are in good agreement with those calculated using Bjerrum's method.

The Magnetic Properties of the Ammonium Chloride Adducts of Copper(II) Chloroacetates

Shuji EMORI,* Nobuyuki HARAMAKI, and Yoneichiro MUTO
Department of Chemistry, Faculty of Science and Engineering, Saga University, Honjo-machi, Saga 840
(Received July 25, 1984)

Sinopsis. Various ammonium chloride adducts of copper(II) chloroacetate and copper(II) dichloroacetate were prepared. The variable-temperature magnetic susceptibilities of the dimethylammonium chloride adducts obey the Bleaney-Bowers equation, indicating the existence of the copper(II) acetate type of dinuclear moiety in their crystals. The effect of the counter cations on their magnetic moments was discussed.

A large number of dinuclear copper(II) carboxylate adducts, $[Cu(RCOO)_2 \cdot L]_2$, have been studied to elucidate the factors influencing the magnetic properties in these compounds. In particular, the effects of the carboxylate substituent R and of the axial ligand L upon the strength of the spin-exchange interaction or singlet-triplet separation($-2J$) have been extensively investigated.[1] However, both the variation of surrounding ions around the dinuclear molecule and the crystal packing must also affect the magnetic properties. Goodgame *et al.* reported the preparation and magnetic properties of some dinuclear anionic copper(II) acetate complexes, $\{(CH_3)_4N\}_2[Cu(CH_3COO)_2X]_2$ (X= NCS, NO_2, or Br).[2,3] Because the counter cation can be easily replaced, these anionic dinuclear copper(II) compounds are appropriate to examine the effect of the surrounding ions but only insufficient data have been available. Here, we report the preparation and magnetic properties of the various ammonium chloride adducts of copper(II) chloroacetate and copper(II) dichloroacetate.

The compound with the stoichiometry of $Cu(ClCH_2COO)_2 \cdot n$ACl, where n=2 for A=NH_4 and n=1 for A=$(CH_3)_2NH_2$ and CH_3NH_3, was precipitated in green crystals when an excess of ACl was added to a hot aqueous solution of copper(II) chloroacetate with a small amount of chloroacetic acid, and then the mixture was allowed to stand for a few minutes. The dichloroacetate compond $Cu(Cl_2CHCOO)_2 \cdot n$ACl, where n=5/7 for A=$(CH_3)_2NH_2$ and n=3/2 for A=$(CH_3)_3NH$, was also obtained in a similar way.

The magnetic moments of these compounds (Table 1) were evaluated from their susceptibilities observed at room temperature and the relevant Pascal constants.[4] They are low and practically the same as that of copper(II) acetate monohydrate (1.40 BM at 21 °C).[5] The temperature dependence of the magnetic susceptibilities of the dimethylammonium chloride adducts of copper(II) chloroacetate and copper(II) dichloroacetate over the temperature range of 77—300 K (Fig. 1) was also found to correspond well with the known behavior of copper(II) acetate monohydrate. A reasonably good agreement was found between the experimental results and a theoretical curve calculated from the usual expression[6] for the susceptibility of the copper(II) ions in the copper(II) acetate dimer (Bleaney-Bowers equation), using the following parameters: g=2.19 and $2J$=−278 cm^{-1} for the chloroacetate compound and g=2.21 and $2J$=−271 cm^1 for the dichloroacetate compound, respectively, and $N\alpha$=60×10^{-6} emu/mol (1 emu/mol=4π×10^{-6} m^3/mol). The result obtained is consistent with the assumption that all have the familiar bridged dimeric copper(II) acetate monohydrate structure. Although the chloride ion has a tendency to displace the bridging carboxylate, the anionic dinuclear copper(II) carboxylate is constructed by the axial coordination of a chloride ion with the exception of the dimethylammonium chloride adduct of copper(II) dichloroacetate and the tetramethylammonium chloride adduct of copper(II) chloroacetate. Garner and Senior[7] reported that the reaction of molybdenum(II) trifluoroacetate with tetraethylammonium halides resulted in the formation of the hemi- and mono-adducts, $\{(C_2H_5)_4N\}$, $[Mo_2(CF_3COO)_4X]$, and $\{(C_2H_5)_4N\}_2[Mo(CF_3COO)_2X]_2$, and suggested that the adducts are more stable than the neutral molecule, presumably due in large measure to the lattice energy of these salts. This is also the case for copper(II) carboxylate, and the $(NH_4)_2ZnCl_4$ adduct of copper(II) chloroacetate (1.41 BM at 28 °C) can be isolated easily.[8] From the Table 1 and the magnetic data of the corresponding acetate adducts,[9] the following trends in the magnetic properties can be seen. First, the magnetic moments in the series of the same ammonium chloride adducts increase as the acid strength of the parent carboxylic acids become stronger, which is attributed to the fact that the stronger carboxlylic acid has a tendency to elongate the bridging Cu-O-C-O-Cu length.[1] The IR spectra, assigned by a comparison with the spectra of the corresponding pyridine adducts, show absorption bands characteristic of Cu-Cl stretching vibrations, except for the dimethylammonium chloride adduct of copper(II)

TABLE 1. ANALYTICAL DATA AND EFFECTIVE MAGNETIC MOMENTS AT 27 °C

Compound	Cu(%)		Cl(%)		μ_{eff}(BM)
	Calcd	Found	Calcd	Found	
$Cu(ClCH_2COO)_2 \cdot 2NH_4Cl$	17.88	18.09	19.84	19.69	1.42
$Cu(ClCH_2COO)_2 \cdot CH_3NH_3Cl$	19.98	20.06	11.15	11.22	1.43

$Cu(Cl_2CHCOO)_2 \cdot 3/2(CH_3)_3NHCl$	13.73	13.74	11.49	11.35	1.50

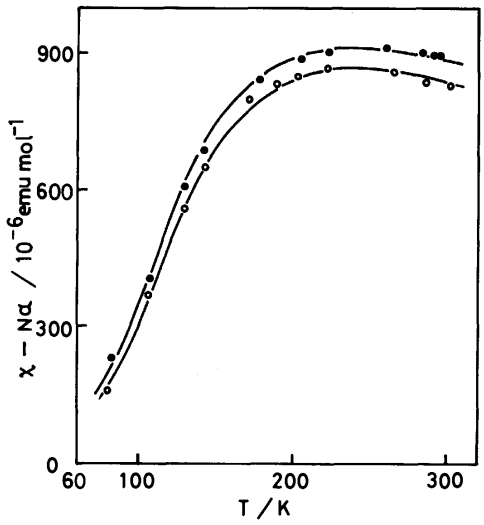

Fig. 1. Magnetic susceptibilities of the dimethylammonium chloride adducts of copper(II) chloroacetate (white circles) and copper(II) dichloroacetate (black circles). The solid curve represents the Bleaney-Bowers equation.

dichloroacetate which shows the complicated spectrum in the region of 276—317 cm^{-1} in agreement with its complicated stoichiometry. The observation of a band shift for the Cu-Cl stretching to the higher frequency, from 232—234 cm^{-1} of the acetates to 260—264 cm^{-1} of the chloroacetates suggests the stronger axial coordination in the chloroacetates. This is consistent with the fact that there is a movement of the copper atom out of the basal plane of its square pyramidal coordination polyhedron when the acid strength increases.[1,10] Secondly, since the difference in the magnetic moments between the chloride adducts (1.38—1.41 BM at 17 °C for the acetates and 1.41—1.43 BM at 27 °C for the chloroacetates, respectively) and the hydrates (1.40 BM at 21 °C for the acetate[5] and 1.45 BM at 24 °C for the chloracetate[11]) is very small, it was difficult to evaluate the effect of the axial ligands. Thirdly, even for the same carboxylate compounds, there are slight differences in the observed magnetic moments of the chloride adducts (1.39—1.41 BM for the ammonium chloride adducts and 1.38 BM for the potassium chloride adduct of copper(II) acetate[9]). This fact suggests that the hydrogen bonds to the bridging carboxylate and the cation affect the magnetic property in addition to the packing effect. The amount of the scattering seems to increase as the parent carboxylic acids become stronger.

Stereoisomers of *trans*-Dichlorocobalt(III) Complex with 1,7-Bis[(*S*)-2-pyrrolidinyl]-2,6-diazaheptane

Masahiko SABURI,* Shusei OBATA, Motowo YAMAGUCHI, and Sadao YOSHIKAWA*

Department of Synthetic Chemistry, Faculty of Engineering, The University of Tokyo, Hongo, Bunkyo-ku, Tokyo 113

(Received August 29, 1984)

Synopsis. The complex *trans*-[$CoCl_2$(SS-pyht)]$^+$ (SS-pyht=1,7-bis[(*S*)-2-pyrrolidinyl]-2,6-diazaheptane), prepared *via* the HCl treatment of *Λ*-*β*-[$CoCO_3$(SS-pyht)]$^+$, was found to take the (*R*,*R*) configuration with regard to the secondary nitrogen centers involving the central chelate. The isomer ratio of two diastereomers (trans(*R*,*S*) and trans(*R*,*R*)) was estimated at the equilibrium in methanol; (*R*,*S*)/(*R*,*R*)= 10.4±2.6.

The *trans*-dichlorocobalt(III) complex of 1,7-bis[(*S*)-2-pyrrolidinyl]-2,6-diazaheptane (SS-pyht), an optically active 2,3,2-tet derivatives having the pyrrolidine rings at the both side arms, was first reported by Jun and Liu[1] (2,3,2-tet=3,7-diazanonane-1,9-diamine). They supposed that the *trans*-[$CoCl_2$(SS-pyht)]$^+$ produced by the standard air-oxidation method takes the (*R*,*R*)[2] configuration with respect to the secondary nitrogen centers connecting the central six-membered chelate and the five membered chelates (Fig. 1a).[1] However, the true structure of the complex ion determined by an X-ray crystallographic study[3] was found to assume the trans(*R*,*S*) configuration (Fig. 1b).

In our previous report,[4] an alternative method, *i.e.*, the treatment of [$CoCO_3$(SS-pyht)]$^+$ with hydrochloric acid, was applied for preparing *trans*-[$CoCl_2$(SS-pyht)]-ClO_4. This Note describes that the above mentioned dichloro complex adopts the trans(*R*,*R*) configuration, as is expected from the observations that the HCl treatment of *β*-carbonatocobalt(III) with 2,3,2-tet[5] or its chiral derivatives[6] yields trans-dichloro complex having the C_2 symmetry (trans(*R*,*R*) and/or (*S*,*S*)).

Experimental

Materials. The ligand, 1,7-bis[(*S*)-2-pyrrolidinyl]-2,6-diazaheptane (SS-pyht), was synthesized by the reported method.[1,4] The complex *trans*(*R*,*S*)-[$CoCl_2$(SS-pyht)]ClO_4 was obtained by the air-oxidation method.[1] The *trans*(*R*,*R*)-[$CoCl_2$(SS-pyht)]ClO_4 was prepared by the reported method *via* the carbonato complex.[4]

Measurements. Visible absorption and circular dichroism (CD) spectra were obtained on a Shimadzu UV-210 spectrophotometer and JASCO J-500 spectropolarimeter, respectively. ^{13}C NMR spectra at 100 MHz were obtained on a JEOL GX-400 spectrometer in the standard manner, employing methanol-*d* as a solvent and tetramethylsilane as an external reference.

Results and Discussion

It has been demonstrated that ^{13}C NMR spectrometry is a convenient tool to determine the molecular symmetry of cobalt(III) complexes with polyamine ligand(s) which has no probe signal appropriate for ^1H NMR spectral examination.[6,7,8] As for the *trans*-[$CoCl_2$(SS-pyht)]$^+$ ion, the (*R*,*S*) isomer, which has no symmetry element (Fig. 1b), is expected to show, in principle, thirteen resonances on the spectrum, while the (*R*,*R*) isomer with the C_2 symmetry (Fig. 1a), should exhibit maximally seven resonances.

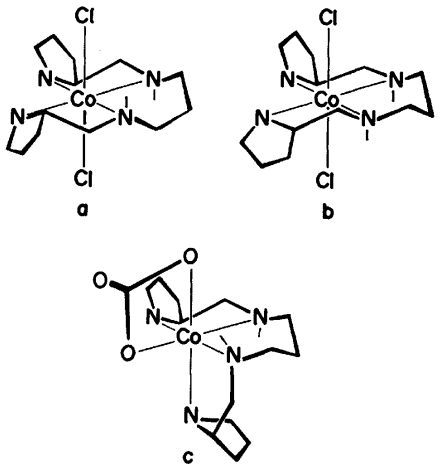

Fig. 1. Structures of *trans*(*R*,*R*)-[$CoCl_2$(SS-pyht)]$^+$ ion, (a), *trans*(*R*,*S*)-[$CoCl_2$(SS-pyht)]$^+$ ion, (b), and *Λ*-*β*-[$CoCO_3$(SS-pyht)]$^+$ ion, (c).

shown. d) The values in parentheses are the relative intensities of resonances.

The *trans*(*R*,*S*)-[$CoCl_2$(SS-pyht)]$^+$ ion, the structure of which has been clarified by the X-ray analysis study,[3] exhibits, in fact, thirteen resonances in the ^{13}C NMR spectrum (see Table). The ligand SS-pyht has thirteen carbon atoms so that the above spectral feature is in accord with that the tetramine in this complex ion adopts a rigid conformation without symmetry, which is anticipated for the trans(*R*,*S*) configuration. The carbon resonances can be classified into four subgroups as in Table, though it is difficult to assign every reso-

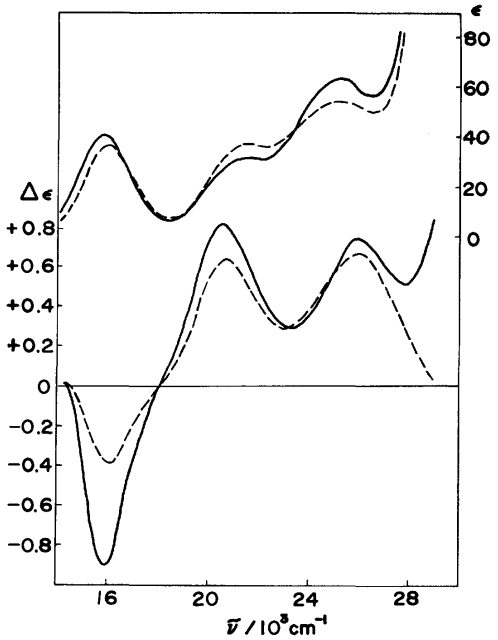

Fig. 2. Visible absorption and CD spectra of *trans*-[$CoCl_2$-(SS-pyht)]$^+$ ion; trans(*R*,*S*) isomer, (——), and trans(*R*,*R*) isomer (----).

nance to the individual carbon of SS-pyht.

We have prepared the *trans*-dichlorocobalt(III) complex of SS-pyht *via* the carbonato complex.[4] The carbonato complex [$CoCO_3$(SS-pyht)]$^+$, which was produced *in situ* by a reaction of SS-pyht with $[Co(CO_3)_3]^{3-}$, showed a dominant positive CD peak in the $^1A_{1g}\rightarrow {}^1T_{1g}(O_h)$ transition region. It has been indicated that the oxalato complex [$Co(C_2O_4)$(SS-pyht)]$^+$ adopts specifically the *Λ*-*β*(*R*,*R*) configuration,[3] and that the CD curve of this complex exhibits a positive Cotton effect in the $^1A_{1g}\rightarrow {}^1T_{1g}(O_h)$ transition. Thus, it is probable that the carbonato complex of SS-pyht also assumes the *Λ*-*β*(*R*,*R*) configuration (Fig. 1c).

The transformation from *Λ*-*β*(*R*,*R*)-[$CoCO_3$(SS-pyht)]$^+$ to trans-dichloro complex in acidic medium should proceed with retention of the configuration with regards to the secondary N centers at the central chelate ring. Thus, it was expected that the *trans*-[$CoCl_2$(SS-pyht)]ClO_4 obtained via the carbonato complex has the (*R*,*R*) configuration with C_2 symmetry (Fig. 1a). The ^{13}C NMR spectrum of the present complex actually showed seven resonances (Table), demonstrating that the complex ion has the C_2 symmetry and, therefore, is assigned to the trans(*R*,*R*) geometry. Thus, *trans*-[$CoCl_2$(SS-pyht)]$^+$ produced by two independent methods clearly differs from each other.

The CD curve of *trans*(*R*,*S*)- and *trans*(*R*,*R*)-[$CoCl_2$(SS-pyht)]$^+$, measured in methanol solution, were apparently dissimilar to each other as shown in Fig. 2. Further, it was noticed that the CD curve of trans(*R*,*S*) isomer obtained here is not identical with that reported by Jun and Liu,[1] though the complex employed are considered to have the same structure. The reason for such difference is uncertain.

It has been shown[9] that both of *trans*(*R*,*S*)- and *trans*(*R*,*R*)-[$CoCl_2$(2,10-Me_2-2,3,2-tet)]$^+$ (2,10-Me_2-2,3,2-tet=(2*S*,10*S*)-2,10-diamino-4,8-diazaundecane) give rise to an equilibrium mixture of these diastereomers by the base treatment in methanol solution, and that the isomer ratio at the equilibrium is readily determined by CD measurements when both of the chiral diastereomers are available. Thus, the CD changes of *trans*(*R*,*S*)-and *trans*(*R*,*R*)-[$CoCl_2$(SS-pyht)]ClO_4 were followed in basic methanol solution, in a similar manner to that employed for the 2,10-Me_2-2,3,2-tet complexes.[9] The curve of the trans(*R*,*R*) isomer changed remarkably, while that of the trans(*R*,*S*) varied slightly. After 2 h standing, however, the CD curves of two diastereomers became identical with each other within experimental error. The wavenumbers and intensities of the CD intersections for the two species (at 23200 and 24900 cm^{-1}) did not change during the base treatment, indicating that any isomer other than the trans(*R*,*R*) and (*R*,*S*) was not formed during the above conversion. It was determined, therefore, that the equilibrium mixture contains only two diastereomers of *trans*-[$CoCl_2$(SS-pyht)]$^+$.

Based on the CD intensities (at 625 and 351 nm) before and after the base treatment, the isomer ratio at the equilibrium is estimated to be (*R*,*S*)/(*R*,*R*)=10.4±2.6, which corresponds to $-\Delta G$=5.85±0.71 kJ·mol^{-1} (or 1.40±0.17 kcal·mol^{-1}) at 300 K. The energy difference between the diastereomers obtained here is large enough for the more stable (*R*,*S*) isomer to occupy more than 90% of the equilibrium mixture, and is the largest one observed so far between the possible diastereomers of trans-dichloro complexes with chiral 2,3,2-tet derivatives.[6,9]

The preference of the (*R*,*S*) isomer over the (*R*,*R*) has been postulated for *trans*-[$CoCl_2$(2,3,2-tet)]$^+$ ion, supposing a significant conformation energy difference between the chair and skew conformation of the central six-membered chelate ring adopted, respectively, by the (*R*,*S*) and (*R*,*R*) isomer, though the exact value has not been determined yet.[5] In line with this assumption, the (*R*,*S*) isomer is more stable than the (*R*,*R*) isomer for most trans-dichloro complexes with chiral 2,3,2-tet derivatives in spite of the destabilizing factors caused by the axially oriented substituent involved in the (*R*,*S*) isomers.[6] The present observation on the SS-pyht complex also supports a general tendency that metal complexes with six-membered chelate ring in the chair conformation is more favourable than those with the chelate in the skew conformation.

Synthesis of 1-Phenylsulfonylcyclopropanecarboxylic Acid Derivatives

Masahiko TAKAHASHI,* Hideo SUZUKI, and Yoshimi KATA
Department of Industrial Chemistry, Faculty of Engineering, Ibaraki University, Hitachi, Ibaraki 316
(Received May 17, 1984)

Synopsis. Ethyl phenylsulfonylacetate was treated with 1,2-dibromoethane in the presence of benzyltriethylammonium chloride and alkali to give 1-phenylsulfonylcyclopropanecarboxylic acid, from which the carbonyl chloride, ester, carboxamide, 1,2-diacylhydrazine, carbonyl azide, carbamate, isocyanate, and γ-butyrolactone derivatives were prepared.

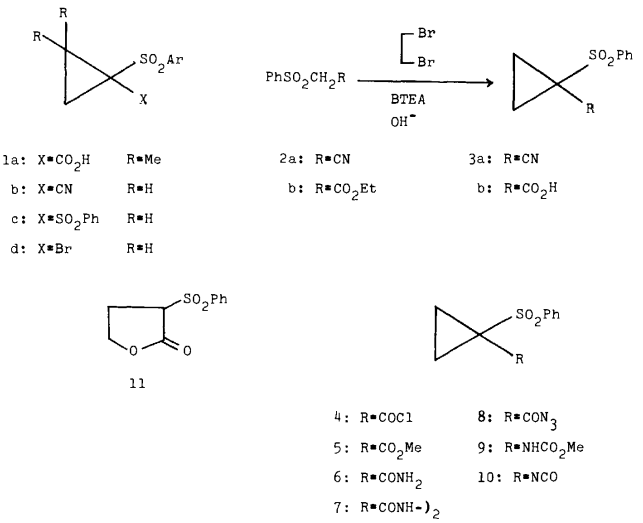
Cyclopropanes which are activated by geminal electron-withdrawing substituents have great potential in organic synthesis.[1] However, the synthesis and reactions of cyclopropanes that have a sulfonyl group[2] as one of the geminal activating groups are limited. Preparative approaches to these cyclopropanes include; (a) carboxylation of lithiated sulfonylcyclopropanes to **1a**;[3] (b) oxidation of arylthiocyclopropanes to the corresponding arylsulfonylcyclopropanes **1b**[4] and **1c**, which has been developed as a synthon for a propyrene 1,3-dipole;[5] (c) direct cyclopropanation of aryl bromomethyl sulfone with 1,2-dibromoethane in the presence of phase-transfer catalyst and alkali to yield **1d**.[6]

In connection with our studies on the synthesis of heterocycles using cyclopropanes[7] we became interested in the reactions of this relatively unknown class of cyclopropanes because of the possibility of their intramolecular cyclization to heterocycles, and therefore we prepared some derivatives of 1-phenylsulfonylcyclopropanecarboxylic acids.

Phenylsulfonylacetonitrile (**2a**) and -acetate (**2b**) undergo Knoevenagel condensation.[2,8] These acidic sulfones **2a** and **2b** were subjected to direct cyclopropanation in a similar manner as for **1d**[6] and other active methylene compounds.[9] Although cyclopropanecarbonitrile (**3a**) was obtained from **2a** in the presence of a catalytic amount of benzyltriethylammonium chloride (BTEA) in a 71% yield, only phenylsulfonylacetic acid was produced from **2b** under the same reaction conditions. Cyclopropanation of **2b**, however, was accomplished by the use of an equimolar quantity of BTEA to yield **3b** in a 67% yield. Treatment of **3b** with thionyl chloride gave the carbonyl chloride **4** (77%), from which the methyl ester **5** (97%), carboxamide **6** (84%), 1,2-diacylhydrazine **7** (71%), and carbonyl azide **8** (79%) were prepared in the usual manner. Heating of **8** in methanol gave the methyl carbamate **9** (92%), indicating the presence of the intermediary isocyanate **10** in the course of the Curtius rearrangement. Isolation of **10** was attempted by heating **8** in toluene but only crude **10** (73%) was obtained. The structure of **10** was ascertained by conversion to **9** on refluxing a methanolic solution of **10**. Attempts to prepare cyclopropylamine from **6** or **9** were unsuccesful.

Cyclopropanecarboxylic acids were reported to rearrange to γ-butyrolactones thermally[10] or in the presence of acids.[11] Heating of **3b** in polyphosphoric acid at 160°C for 10h gave 3-phenylsulfonyltetrahydro-2-furanone (**11**) in a 45% yields.

The structures of the products are evident on the basis of the analytical and spectral data. In particular, the NMR spectra of **3**—**10** showed the characteristic absorptions of A_2B_2 system at *ca.* δ 1.1—2.2 due to the adjacent methylene groups of the cyclopropane rings.



Experimental

Melting points were determined on a Yanagimoto micro-melting point apparatus and are uncorrected. ^{1}H-NMR, IR, and mass spectra were measured with a JEOL JMX-60, a JASCO A-102, and a JEOL JMS-DX300 spectrometer, respectively. Microanalysis was performed with a Shimadzu UM-3B microanalyser.

1-Phenylsulfonylcyclopropanecarbonitrile (3a). A mixture of phenylsulfonylacetonitrile[8] (4.35 g, 24 mmol), 1,2-dibromoethane (9.02 g, 48 mmol), and BTEA (270 mg, 1.2 mmol) in 50% aqueous NaOH (120 cm^3) was stirred with cooling in a water bath for 1 h. The mixture was diluted with water until all the precipitates were dissolved, and extracted with ether. The ethereal solution was dried over $MgSO_4$, and evaporated. The residue was recrystallized from AcOEt to give **3a** (3.51 g, 71%), mp 80—81 °C (lit,[4] mp 88 °C). IR (KBr): 2230 (CN), 1570, 1440, 1415 cm^{-1}. NMR ($CDCl_3$): δ=1.73 (m, 2H), 1.93 (m, 2H), 7.48—8.07 (m, 5H). Found: C, 57.97; H, 4.38%. Calcd for $C_{10}H_9O_2SN$: C, 58.25; H, 4.33%.

1-Phenylsulfonylcyclopropanecarboxylic Acid (3b). A mixture of ethyl phenylsulfonylacetate (**2b**)[8] (2.28 g, 10 mmol), 1,2-dibromoethane (3.76 g, 20 mmol), and BTEA (3.28 g, 10 mmol) in 50% aqueous NaOH (20 cm^3) was stirred in a water bath for 1 h. The mixture was diluted with water until all the precipitates were dissolved, and washed with ether. The aqueous layer was acidified with conc. HCl, and extracted with ether. The ethereal solution was dried over $MgSO_4$ and evaporated. The residue was recrystallized from AcOEt to give **3b** (1.53 g, 67%), mp 144—145 °C. IR (KBr): 3230 (OH), 1720 (CO), 1575, 1475, 1420, 1410 cm^{-1}. NMR ($CDCl_3$): δ=1.77 (m, 2H), 2.00 (m, 2H), 7.60—8.02 (m, 5H), 10.10 (s, 1H). Found: C, 53.06; H, 4.55%. Calcd for $C_{10}H_{10}O_4S$: C, 53.09; H, 4.45%.

1-Phenylsulfonylcyclopropanecarbonyl Chloride (4). Mp

62—63°C (AcOEt). IR (KBr): 3075, 1755 (CO), 1575, 1475, 1445, 1410 cm^{-1}. NMR ($CDCl_3$): δ=2.10 (m, 2H), 2.22 (m, 2H), 7.51—8.07 (m, 5H). Found: C, 49.34; H, 3.67%. Calcd for $C_{10}H_9ClSO_3$: C, 49.09; H, 3.71%.

Methyl 1-Phenylsulfonylcyclopropanecarboxylate (5). Mp 76—77°C (AcOEt). IR (KBr); 1710 (CO), 1575, 1440, 1310 cm^{-1}. NMR ($CDCl_3$): δ=1.58—1.80 (m, 2H), 1.95—2.14 (m, 2H), 3.63 (s, 3H), 7.50—8.06 (m, 5H). Found: C, 54.87; H, 5.06%. Calcd for $C_{11}H_{12}SO_4$: C, 54.99; H, 5.03%.

1-Phenylsulfonylcyclopropanecarboxamide (6). Mp 138 -140°C (MeOH). IR (KBr): 3400, 3170 (NH), 1665 (CO), 1605, 1440 cm^{-1}. NMR ($CDCl_3$): δ=1.75 (s, 2H), 1.80 (s, 2H), 6.15 (br s, 2H), 7.50—7.95 (m, 5H). Found: C, 53.68; H, 4.92%. Calcd for $C_{10}H_{11}O_3NS$: C, 53.33; H, 4.92%.

1,2-Bis[1-(phenylsulfonyl)cyclopropylcarbonyl]hydrazine (7). Mp 147—148°C (AcOEt). IR (KBr): 3250 (NH), 1730 (CO), 1580, 1480, 1445 cm^{-1}. NMR ($CDCl_3$): δ=1.58—1.80 (m, 2H), 1.97—2.18 (m, 2H), 7.50—8.03 (m, 10H), 10.20 (s, 2H). Found: C, 53.29; H, 4.64%. Calcd for $C_{20}H_{20}N_2O_6S_2$: C, 53.56; H, 4.49%.

1-Phenylsulfonylcyclopropanecarbonyl Azide (8). Mp 70—72°C. IR (KBr): 2150 (N_3), 1685 (CO), 1580, 1475, 1445, 1415 cm^{-1}. NMR ($CDCl_3$): δ=1.58—1.80 (m, 2H), 1.98—2.22 (m, 2H), 7.47—8.05 (m, 5H). Found: C, 48.11; H, 3.55%. Calcd for $C_{10}H_9O_3N_3S$: C, 47.81; H, 3.61%.

Methyl 1-(Phenylsulfonyl)cyclopropylcarbamate (9). Mp 108—111°C (AcOEt). IR (KBr): 3180 (NH), 1750 (CO), 1610, 1580, 1510, 1445, 1425 cm^{-1}. NMR ($CDCl_3$): δ=1.27—1.58 (m, 2H), 1.73—2.05 (m, 2H), 3.38 (s, 3H), 5.83 (br s, 1H), 7.53—7.98 (m, 5H). MS: *m/z* 255 (M^+). Found: C, 51.88; H, 5.12%. Calcd for $C_{11}H_{13}O_4NS$: C, 51.76; H, 5.13%.

1-Phenylsulfonylcyclopropyl Isocyanate (10). Mp 50—60°C (further purification was difficult). IR (KBr): 2250 (NCO), 1440, 1315, 1305, 1140 cm^{-1}. NMR ($CDCl_3$): δ=1.12—1.45 (m, 2H), 1.60—1.93 (m, 2H), 7.40—7.92 (m, 5H).

3-Phenylsulfonyltetrahydro-2-furanone (11). A mixture of **3b** (226 mg, 1.0 mmol) and polyphosphoric acid (2 cm^3) was heated at 160°C for 10 h. The mixture was poured into water and the precipitates were collected by filtration. Recrystallization from AcOEt-petroleum ether gave **11** (101 mg, 45%), mp 116—118°C. IR (KBr): 2920, 1750 (CO), 1575, 1475, 1440 cm^{-1}. NMR ($CDCl_3$): δ=2.45—3.20 (m, 2H), 3.98—4.55 (m, 3H), 7.53—8.02 (m, 5H). MS: *m/z* 226 (M^+). Found: C, 52.87; H, 4.47%. Calcd for $C_{10}H_{10}O_4S$: C, 53.10; H, 4.46%.

(Received August 22, 1984)

Synopsis. *trans,trans*-2,2′-Spirobiindan-1,1′-diol (**1**) was resolved as its (−)-ω-camphanic ester and the absolute rotation of the glycol **1** was determined. Two crown ethers and the acyclic analog were derived from (+)-**1**. Two crown ethers incorporating (+)-*cis,trans*-2,2′-spirobiindan-1,1′-diol were also prepared. Their chiral recognition properties in transport of methyl (±)-phenylglycinate hydrochloride and abilities to extract alkali metal picrates were investigated.

In the preceding paper,[1] we reported the preparation of optically active crown ethers incorporating *trans*-2,5-bis(hydroxymethyl)tetrahydrofuran as the chiral center. Our continuing interest in chiral macrocyclic polyether prompted us to incorporate 2,2′-spirobiindan-1,1′-diol with known absolute configuration into crown ether, and in this paper we report the preparation of some optically active crown ethers composed of the glycol as well as their chiral recognition properties and complexation properties.

Among three possible diastereomers of 2,2′-spirobiindan-1,1′-diol, *trans,trans*-glycol (C_2 symmetry) **1** and *cis,trans*-glycol (C_1 symmetry) **2** were isolated in optically active forms.[2-4] There is, however, no report of the determination of the absolute rotation of *trans,trans*-glycol **1**. Reduction of (±)-diketone **3** with LiAlH(OBu′)$_3$ gave (±)-**1** in 95% yield. Treatment of (±)-**1** with 1 equiv of (−)-ω-camphanic acid chloride gave half ester **4** which was recrystallized from acetone to afford (−)-**4**, $[\alpha]_D$ −144°. Reduction of (−)-**4** with $LiAlH_4$ gave (−)-**1** whose ^1H NMR spectrum was in agreement with the reported ^1H NMR spectral data for *trans,trans*-2,2′-spirobiindan-1,1′-diol (**1**).[3] Jones oxidation of (−)-**1**, $[\alpha]_D$ −15.2°, to (2*R*)-(−)-diketone 3,[4] $[\alpha]_D$ −147°, permitted to assign the (1*S*,1*S*′,2*R*) configuration to (−)-**1**. The enantiomeric excess of (−)-**3**, $[\alpha]_D$ −147°, was determined to be >98% by means of HPLC with a chiral column.[5] The antipode; (+)-**1** was also prepared from (+)-**2** as follows. (+)-*cis,trans*-glycol **2**, $[\alpha]_D$ +13.5°, prepared *via* (−)-**5**,[3] was oxidized with Jones reagent to give (2*S*)-(+)-**3**, $[\alpha]_D$ +150°, from which (+)-**1**, $[\alpha]_D$ +15.0°, was prepared by LiAlH(OBu′)$_3$ reduction.

Condensation of (+)-**1** with pentaethylene glycol ditosylate in THF-NaH gave crown ether **6** in 69% yield. Crown ether **7** was obtained in 35% yield by condensation of (+)-**1** with tetraethylene glycol ditosylate. Similarly crown ethers **8** and **9** were derived from (+)-**2**. Acyclic polyether **10** was obtained in 63% yield by condensation of (+)-**1** with diethylene glycol monomethyl ether tosylate. Table 1 lists the chiral recognition behaviour of crown ethers and acyclic polyether with methyl (±)-phenylglycinate hydrochloride. The cationbinding ability of polyethers was assessed by solvent extraction of aqueous solution of alkali metal picrates with $CHCl_3$ solution containing polyethers

Table 1. Differential transport of methyl (±)-phenylglycinate hydrochloride

Host	Time/h	Transport/%	Configuration of dominant enantiomer	Optical purity/%
(+)−**6**	2	5.9	S	5.9
(+)−**7**	22	5.5	R	5.4
(+)−**8**	4	5.5	R	13.0
(−)−**9**	70	4.7	R	4.0
(+)−**10**	90	4.9	S	8.0

Table 2. Extraction of alkali metal picrates

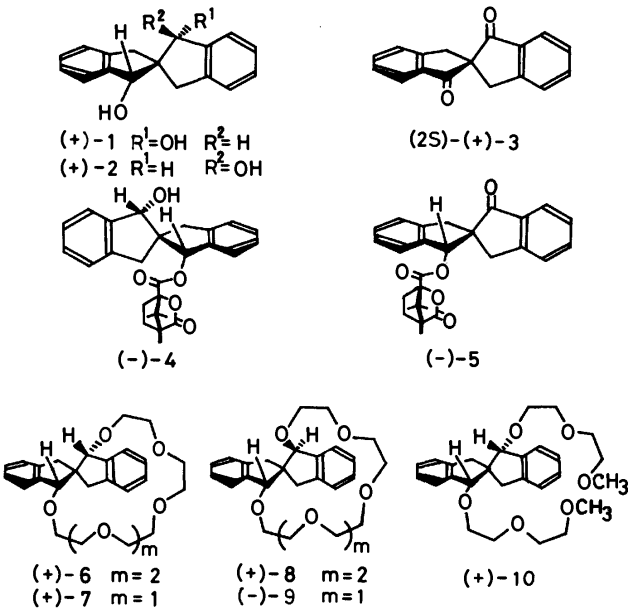
	Li^+	Na^+	K^+	Rb^+	Cs^+
6	1	1	26	11	2
7	1	4	0	0	0
8	0	0	1	0	0
9	0	1	1	0	0
10	0	0	0	0	0
18-crown-6	3	6	66	59	33

a) Defined as % picrate extracted into the organic phase.

6—**10**. The results are given in Table 2.

A number of features in these Tables deserve comment. (1) Crown ethers containing six oxygens carried the amino ester salt more rapidly than did crown ethers containing five oxygens. (2) Crown ethers incorporating *trans,trans*-glycol moiety transported the amino ester salt more rapidly than did crown ethers composed of *cis,trans*-glycol moiety. (3) The enantiomer selectivity of acyclic polyether **10** is comparable to that of crown ethers. (4) Crown ether containing six oxygens as well



as *trans,trans*-glycol moiety showed fairly high relative selectivity for K^+ and Rb^+.

2,2′-Spirobiindan-1,1′-diols are conformationally rigid, so that complexation properties of the crown ethers incorporating these units are extremely depend on the length of polyether bridge as well as the configuration at C 1 and C 1′ of the glycol moiety.

Experimental

*(+)-*cis,trans*-2,2′-Spirobiindan-1,1′-diol (2).* This compound was prepared by Dynessen's method;[3] $[\alpha]_D^{26}$ +13.5° (*c* 0.511, THF) (lit,[3] $[\alpha]_D$ +10.9° (THF)); mp 152—154°C; Anal. ($C_{17}H_{16}O_2$) C, H.

*(±)-*trans,trans*-2,2′-Spirobiindan-1,1′-diol (1).* A solution of (±)-**3**[3] (8.13 g, 32.8 mmol) in dry THF (180 mL) was added to a solution of $LiAlH(OBu^t)_3$ (25.7 g, 98.2 mmol) in dry THF (260 mL). The mixture was refluxed for 13 h and cooled in an ice-bath. To the chilled reaction mixture was added water (80 mL), and an inorganic solid was filtered off. After filtrate was concentrated, the residue was dissolved in $CHCl_3$, washed with water, and dried. The solvent was removed to give a solid which was recrystallized from ethanol to give (±)-**1** (7.85 g, 95% yield); mp 220—222°C; Found: C, 80.89; H, 6.36%. Calcd for $C_{17}H_{16}O_2$: C, 80.92; H, 6.39%.

Optical Resolution of (±)-1. (±)-*trans,trans*-Glycol **1** (10.1 g, 39.8 mmol) was treated with (−)-ω-camphanic acid chloride (17.1 g, 39.8 mmol) by the similar procedure reported for the preparation of the ester **5**.[3] The product was recrystallized from acetone to give (−)-**4** (2.12 g); $[\alpha]_D^{25}$ −144° (*c* 0.292, $CHCl_3$); mp 158—160°C; Found: C, 75.11; H, 6.55%. Calcd for $C_{27}H_{28}O_5$: C, 74.98; H, 6.53%.

The (−)-ester **4** (2.06 g, 4.76 mmol) was refluxed with $LiAlH_4$ (2.71 g, 71.4 mmol) in dry THF (120 mL) for 8 h. After a usual workup, the product was recrystallized from acetone to give (−)-**1** (636 mg, 53% yield); $[\alpha]_D^{25}$ −15.2° (*c* 0.309, THF); mp 234—236°C; Found: C, 80.96; H, 6.40%. Calcd for $C_{17}H_{16}O_2$: C, 80.92; H, 6.39%.

(+)-2,2′-Spirobiindan-1,1′-dione (3). Oxidation of (+)-**2**, $[\alpha]_D$ +13.5° (252 mg, 1.00 mmol) with 8N Jones reagent was carried out according to literature[3] to give (+)-**3** (220 mg, 89% yield); $[\alpha]_D^{28}$ +150° (*c* 0.290, $CHCl_3$). Recrystallization from ethanol furnished colorless needles; $[\alpha]_D^{28}$+149° (*c* 0.363, $CHCl_3$) (lit,[3] $[\alpha]_D$ +151.86° ($CHCl_3$)); mp 218—219°C; Anal. ($C_{17}H_{12}O_2$) C, H.

(−)-2,2′-Spirobiindan-1,1′-dione (3). Oxidation of (−)-**1**, $[\alpha]_D$ −15.2°, (100 mg, 0.396 mmol) with 8N Jones reagent gave (−)-**3** (74 mg, 75% yield); $[\alpha]_D^{24}$ −147° (*c* 0.339, $CHCl_3$); mp 219—220°C; Found: C, 82.18; H, 4.85%. Calcd for $C_{17}H_{12}O_2$: C, 82.24; H, 4.87%.

*(+)-*trans,trans*-2,2′-Spirobiindan-1,1′-diol (1).* (+)-Diketone **3**, $[\alpha]_D$ +150°, (808 mg, 3.26 mmol) was reduced with $LiAlH(OBu^t)_3$ (3.31 g, 13.0 mmol) in dry THF (75 mL) by the same manner as described for (±)-**1** to give (+)-**1** (756 mg, 92% yield); $[\alpha]_D^{26}$ +15.0° (*c* 0.353, THF); mp 233—234°C; Found: C, 80.88; H, 6.37%. Calcd for $C_{17}H_{16}O_2$: C, 80.92; H, 6.39%.

(+)-(1S,5R,22R)-3,4:23,24-Dibenzo-6,9,12,15,18,21-hexaoxatricyclo[20.3.0.0^{1,5}]pentacosa-3,23-diene (6). To a boiling suspension of NaH (150 mg, 6.25 mmol) in dry THF (40 mL) was added a solution of (+)-**1** (528 mg, 2.00 mmol) and pentaethylene glycol ditosylate (1.15 g, 2.22 mmol) in dry THF (70 mL) dropwise over an 8 h period under N_2. The reaction mixture was refluxed for further 16 h under N_2, cooled in an ice-bath, and quenched with water (2 mL). After a usual workup, the crude product was chromatographed on alumina (benzene eluent) to give a solid which was recrystallized from hexane to furnish (+)-**6** (625 mg, 69% yield); $[\alpha]_D^{27}$ +45.3° (*c* 0.371, $CHCl_3$); mp 101—102°C; Found: C, 71.20; H, 7.51%. Calcd for $C_{27}H_{34}O_6$: C, 71.34 H, 7.54%.

(+)-(1S,5R,19R)-3,4:20,21-Dibenzo-6,9,12,15,18-pentaoxatricyclo[17.3.0.0^{1,5}]docosa-3,20-diene (7). A procedure similar to that for **6** using (+)-**1** (510 mg, 2.02 mmol) and tetraethylene glycol ditosylate (1.02 g, 2.03 mmol) gave (+)-**7** (274 mg, 35% yield) as colorless crystals from hexane; $[\alpha]_D^{25}$ +81.3° (*c* 0.200, $CHCl_3$); mp 106°C; Found: C, 73.15; H, 7.44%. Calcd for $C_{25}H_{30}O_5$: C, 73.14; H, 7.37%.

(+)-(1S,5S,22R)-3,4:23,24-Dibenzo-6,9,12,15,18,21-hexaoxatricyclo[20.3.0.0^{1,5}]pentacosa-3,23-diene (8). Condensation of (+)-**2** (816 mg, 3.11 mmol) with pentaethylene glycol ditosylate (1.78 g, 3.44 mmol) was carried out by the same procedure as described for **6**. The product was chromatographed on alumina (benzene eluent) to give (+)-**8** (465 mg, 33% yield) as a colorless oil; $[\alpha]_D^{27}$ +2.77° (*c* 0.433, $CHCl_3$); Found: C, 71.19; H, 7.48%. Calcd for $C_{27}H_{34}O_6$: C, 71.34; H, 7.54%.

(−)-(1S,5S,19R)-3,4:20,21-Dibenzo-6,9,12,15,18-pentaoxatricyclo[17.3.0.0^{1,5}]docosa-3,20-diene (9). A procedure similar to that for **6** using (+)-**2** (680 mg, 2.69 mmol) and tetraethylene glycol ditosylate (1.36 g, 2.70 mmol) gave (−)-**9** (270 mg, 24% yield); $[\alpha]_D^{27}$ −23.0° (0.390, $CHCl_3$); mp 86—87°C; Found: C, 73.09; H, 7.41%. Calcd for $C_{25}H_{30}O_5$: C, 73.14; H, 7.37%.

(+)-(1R,1′R,2S)-1,1′-Bis(5-methoxy-3-oxapentyloxy)-2,2′-spirobiindan (10). After a mixture of (+)-**1** (400 mg, 1.58 mmol), NaH (150 mg, 6.25 mmol), and DMF (30 mL) was stirred at 30°C for 2 h, to the mixture was added a solution of Methyl Carbitol tosylate (960 mg, 3.49 mmol) in DMF (20 mL). The mixture was stirred at 45°C for 24 h under N_2 and quenched with water (1 mL). Workup followed by chromatography on alumina (hexane–benzene 1:1 eluent) gave (+)-**10** (440 mg, 61% yield) as a colorless oil; $[\alpha]_D^{25}$ +46.8° (*c* 0.948, $CHCl_3$); Found: C, 71.30; H, 7.89%. Calcd for $C_{27}H_{36}O_6$: C, 71.02; H, 7.95%.

Enantiomer Differential Transport. Enantiomer differential transport was carried out in a conventional apparatus which consisted of an outer cylindrical glass vessel (24.5 mm inner diameter) and a central glass tube (15.5 mm inner diameter). The 0.005 M $CHCl_3$ solution of the host separated the inner aqueous phase (0.1 M HCl (1 M=1 mol dm^{-3})) and the outer aqueous phase (0.08 M HCl) which contained $LiPF_6$ (0.4 M) and methyl (±)-phenylglycinate hydrochloride (0.04 M). The $CHCl_3$ layer was stirred at 20°C, and transport was followed by monitoring the absorbance at 261 nm and $[\theta]_{261}$ of the inner aqueous phase.

Extraction Procedure. Aqeous solution (5 mL) of metal picrate (2.4×10^{-4} M) and a $CHCl_3$ solution (5 mL) containing the host (2.4×10^{-4} M) were placed in a screw-cap glass tube (30 mL) and the tube was shaken for 30 min at room temperature. Extraction of picrate was followed by monitoring the absorbance at 357 nm of the aqueous phase.

A Practical Synthesis of *N*-Bromo Imides by Use of Sodium Bromite

Shoji KAJIGAESHI,* Takashi NAKAGAWA, Shizuo FUJISAKI, and Akiko NISHIDA
Department of Industrial Chemistry, Faculty of Engineering Yamaguchi University, Tokiwadai, Ube 755
(Received August 27, 1984)

Synopsis. *N*-Bromo imides can be readily prepared under mild conditions by a reaction of imides with sodium bromite in the presence of hydrobromic acid in fairly good yields. The scope and limitation are also presented.

A new reagent, sodium bromite ($NaBrO_2$), has recently been noted in organic synthesis.[1-3] Durig the course of our investigation on the synthetic utilities of sodium bromite,[4] we found that the reaction of imides (**1**) with sodium bromite in the presence of hydrobromic acid under mild conditions gave *N*-bromo imides (**2**) in fairly good yields.

In general, *N*-bromo imides **2**, *e.g.*, familiar *N*-bromosuccinimide, have been prepared by the treatment of a corresponding **1** in an aqueous medium with bromine in the presence of a strong base, or with alkali hypobromite prepared separately by treatment of bromine with a strong base.[5] The derivatives **2** have been also prepared by the reaction of **1** with bromine in water by sodium bromate and sulfuric acid.[6] In our method, sodium bromite (which is available in stable crystals under an ordinary atmosphere and, hence, can be handle much more easily compared with the toxic liquid bromine) was used in place of bromine. *N*-bromo imides **2** such as *N*-bromosuccinimide[5] (**2a**), *N*-bromophthalimide[7] (**2b**), *N*-bromo-α-methylsuccinimide[6] (**2c**), *N*-bromoglutarimide[6] (**2d**), and 1,3-dibromohydantoin[6] (**2e**) were synthesized from the corresponding imides, succinimide (**1a**), phthalimide (**1b**), α-methylsuccnimide (**1c**), glutarimide (**1d**), and hydantoin (**1e**), respectively. *N*-bromo-ε-caprolactam (**3a**) was also prepared from ε-caprolactam.

When hydrobromic acid was added to an ice-cold aqueous solutuion of sodium bromite and imide under stirring, the desired **2** precipitated readily as white crystals. In the cases of syntheses of **2b**, **2c**, and **2d**, aqueous sodium hydroxide was used in order to dissolve the corresponding imides, **1b**, **1c**, and **1d**. These methods (using sodium bromite and hydrobromic acid) showed that one mole of sodium bromite was able to brominate 2 moles of **1** into **2**.

Our method could not be applied to imides which were insoluble in water or alkaline solution (*e.g.*, 1,8-naphthalimide). It was not applicable, furthermore, to imides having other active group in the molecule (*e.g.*, maleinimide) or chain imides (*e.g.*, diacetamide), because other reactions also proceeded under the conditions.

The reaction scheme for the synthesis of **2** may be presented in the following equations. That is, it can be

$$NaBrO_2 + HBr \rightleftharpoons HBrO_2 + NaBr, \quad (1)$$

$$HBrO_2 + HBr \rightleftharpoons 2HBrO, \quad (2)$$

$$2\text{>NH} + 2HBrO \rightleftharpoons 2\text{>N-Br} + 2H_2O, \quad (3)$$

overall:

$$2\text{>NH} + NaBrO_2 + 2HBr \longrightarrow 2\text{>N-Br} + NaBr + 2H_2O, \quad (4)$$

presumed that bromous acid ($HBrO_2$) produced by the reaction of sodium bromite with hydrobromic acid (Eq. 1) reacts with excess hydrobromic acid to give hypobromous acid (Eq. 2) and the subsequent reaction of **1** with the hypobromous acid give *N*-bromo imide (Eq. 3). We now postulate that a major active brominating species is the hypobromous acid derived from sodium bromite and hydrobromic acid as shown in equation 1 and 2. The overall reaction equation is shown is equation 4. Acutually, the experimental results described above concord stoichiometrically with equation 4.

Since further excess hydrobromic acid reacts with hypobromous acid to form free bromine, we can recognize the end point of *N*-bromination by a red coloration due to bromine formed in the reaction mixture. This is one of the merits of our method.

$$HBrO + HBr \rightleftharpoons Br_2 + H_2O \quad (5)$$

Experimental

N-Bromosuccinimide (NBS) (2a). A solution of 94.7% sodium bromite[9] (0.95 g, 6.7 mmol) in water (2 ml) was added to a solution of **1a** (1 g, 10.1 mmol) in water (5 ml). To the cold (0—5 °C) solution was added (dropwise, slowly) 47% hydrobromic acid (1.3 ml, 11.2 mmol) under stirring,[10] and then the reaction mixture was further stirred for 10 min at

0 °C. The precipitate obtained was filtered, washed with cold water and dried at room temperature to give **2a** as white crystals. Weight 1.54 g (86% of theoretical amount). Analysis by iodometric titration[11] showed 44.8% active bromine, as compared with the theoretical value for $C_4H_4BrNO_2$ of 44.9%. Mp 175—178 °C (from water) (lit,[5] mp 173—175 °C). MS: *m/z* 177, 179 (M^+).

N-Bromophthalimide (2b). A solution of 94.7% sodium bromite (0.63 g, 4.4 mmol) in water (5 ml) was added to an aqueous solution of **1b** (1 g, 6.8 mmol) and sodium hydroxide (0.3 g, 7.5 mmol) in water (15 ml). To the ice-cold solution was added (dropwise, slowly) 47% hydrobromic acid (1.8 ml, 15.5 mmol) under stirring,[10] and then the reaction mixture was further stirred for 10 min at 0 °C. The obtained precipitate was filtered, washed with cold water and dried to give **2b** as white crystals. Weight 1.25 g (81% of theoretical amount). Analysis showed 33.6% active bromine, as compared with the theoretical value for $C_8H_4BrNO_2$ of 35.4%. Mp 227—229 °C (from water). MS: *m/z* 225, 227 (M^+).

N-Bromo-α-methylsuccinimide (2c). Compound **2c** could be obtained from **1c** (0.5 g, 4.4 mmol) in the same manner as that of **2b**. Weight 0.38 g (45% of theoretical amount). Analysis showed 38.4% active bromine, as compared with the theoretical value for $C_5H_6BrNO_2$ of 41.4%. Mp 154—157 °C. MS: *m/z* 191, 193 (M^+).

N-Bromoglutarimide (2d). Compound **2d** could be obtained from **1d** (0.6 g, 5.3 mmol) in the same manner as that of **2b**. Weight 0.31 g (30% of theoretical amount). Analysis showed 37.9% active bromine, as compared with the theoretical value for $C_5H_6BrNO_2$ of 41.6%. Mp 149—151 °C. MS: *m/z* 191, 193 (M^+).

1,3-Dibromohydantoin (2e). A 47% hydrobromic acid (1.5 ml, 12.9 mmol) was added to a solution of **1e** (0.5 g, 5.0 mmol) in water (5 ml). To the ice-cold solution was added (dropwise, slowly) a solution of 94.7% sodium bromite (1 g, 7.0 mmol) in water (2 ml) under stirring,[10] and then the reaction mixture was further stirred for 1 h at 0 °C. The precipitate obtained was filtered, washed with cold water and dried to give **2e** as white crystals. Weight 0.9 g (70% of theoretical amount). Analysis showed 59.4% active bromine, as compared with the theoretical value for $C_3H_2Br_2N_2O_2$ of 62.0%. Mp 135—136 °C. MS: *m/z* 256, 258, 260 (M^+).

N-Bromo-ε-caprolactam (3a). Compound **3a** could be obtained from ε-caprolactam (2 g, 17.7 mmol) in the same manner as that of **2a**. Weight 2.7 g (80% of theoretical amount). Analysis showed 39.5% active bromine, as compared with the theoretical value for $C_6H_{10}BrNO$ of 41.6%. Mp 60—63 °C (lit,[8] mp 64—66 °C). MS: *m/z* 191, 193 (M^+).

9) Commercial sodium bromite is now available from Kanto Kagaku Co. Ltd.
10) During the treatment, the mixture was instantaneously colored red owing to bromine formed (see Eq. 5) and soon decolorized. Whereupon a white precipitate was gradually deposited. The hydrobromic acid addition was done until the red color did not disappear. Thus, the amount of hydrobromic acid was employed as noted in the text.

Synthesis of β-Alkylimino α-Cyano Dithiocarboxylic Acids, 3-Alkyl-1,3-thiazine-2,6-dithiones, and Related Compounds

Tatsuo YAMAMOTO, Shigeo HIRASAWA, and Motomu MURAOKA*

Department of Chemistry, Faculty of Science, Josai University, 1-1, Keyaki-Dai, Sakado, Saitama 350-02

(Received August 29, 1984)

Synopsis. The title compounds **2** and **5** were synthesized by the reaction of β-alkylimino nitriles with carbon disulfide.

β-Alkylimino dithiocarboxylic acids have been reported to be unstable except 2-(alkylimino)cyclopentanecarbodithioic acids.[1] No stable acyclic β-alkylimino dithiocarboxylic acids[2] and 2- and 4-(dithiocarboxymethylene)dihydropyridines[3] at room temperature are known. We have previously reported the first examples of stable acyclic imino dithiocarboxylic acids, α-cyano β-imino dithiocarboxylic acids.[4] 2-(Alkylimino)cyclopentanecarbodithioic acids have been prepared by the reaction of 2-iminocyclopentanecarbodithioic acid and alkylamines.[5] This method, however, could not be applied to the synthesis of β-alkylimino α-cyano dithiocarboxylic acids from the imino cyano dithiocarboxylic acids.

Our present finding is that β-alkylimino nitriles[6] react with carbon disulfide in the presence of a base to give β-alkylimino dithiocarboxylic acids (**2**). In some cases, 3-alkyl-2*H*-1,3-thiazine-2,6(3*H*)-dithiones (**5**) were produced.

Compounds **2a—g** were obtained as major product when β-alkylimino nitriles (**1a—g**) were treated with carbon disulfide in the presence of sodium 1,1-dimethylpropoxide in benzene. In some cases, the imino acids were accompanied by a small amount of 4-cyano-3*H*-1,2-dithiole-3-thiones (**3a—c**). 3-Methylimino-3-(*m*-tolyl)-propanenitrile gave 3,5-dicyano-2,6-di(*m*-tolyl)-1-methyl-4(1*H*)-pyridinethione (**4**) in addition to compounds **2e** and **3b**. We have reported that the same type of *N*-unsubstituted 4(1*H*)-pyridinethiones are synthesized by the reaction of 5-cyano-2*H*-1,3-thiazine-2,6(3*H*)-dithiones with β-imino nitriles.[7]

When these reactions were performed in *N*,*N*-dimethylformamide, 3*H*-1,2-dithiole-3-thiones (**3a—c**) were formed as a major product instead of the β-alkylimino dithiocarboxylic acids (**2c—g**). Furthermore, 3-(alkylimino)butanenitriles (**1a—b**) produced 3-alkyl-5-cyano-4-methyl-2*H*-1,3-thiazine-2,6(3*H*)-dithiones (**5a—b**) in addition to **2**. In the ^{13}C NMR spectrum of compound **5b** in dimethyl-d_6 sulfoxide, two quartets at δ 11.86 and 23.62 ppm were observed. Compound **5b** was easily methylated with methyl iodide to form 5-cyano-3,4-dihydro-3-ethyl-4-methylene-6-methylthio-2*H*-1,3-thiazine-2-thione (**6**). In the ^1H NMR spectrum of compound **6**, a pair of dublets appeared at δ 4.98 and 5.17 ppm suggesting the existence of a terminal methylene. From these facts, an alternative structure; 4-alkylimino-3-cyanothiane-2,6-dithiones for compounds **5** was eliminated.

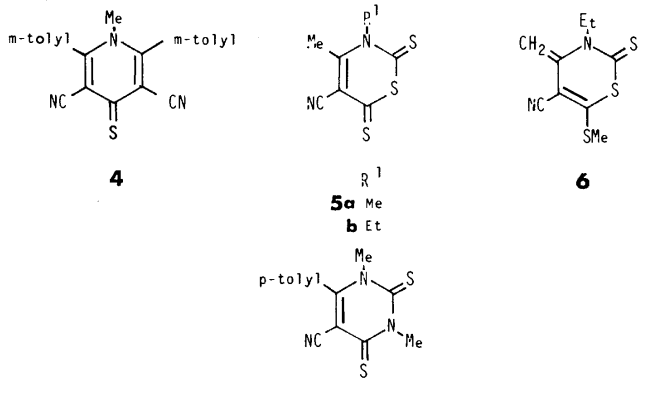
Scheme 1.



Block 1

Occasionally, 1,3-dimethyl-5-cyano-4-(*p*-tolyl)-2,6(1*H*,3*H*)-pyrimidinedithione (**7**) was obtained in very low yield besides compounds **2f** and **3c**.

Experimental

Measurements. NMR spectra were recorded with a Jeol JNM-GX-270 spectrometer. Infrared spectra were measured on Nippon Bunko IR-A-302 spectrophotometer. Mass spectra were determined with a Hitachi LKB-9000 mass spectrometer. Electronic spectra were measured with a Hitachi 557 Double Wavelength Double Beam Spectrophotometer.

2-Cyano-3-(methylimino)butanedithioic Acid (2a). A mixture of 3-(methylimino)butanenitrile (0.80 g, 8.32 mmol), sodium 1,1-dimethylpropoxide (1.40 g, 12.7 mmol), carbon disulfide (1.00 g, 13.1 mmol), and dry benzene (20 ml) was shaken at room temperature for 3 h. Water (40 ml) was added to the mixture and the aqueous layer was washed with ether. Ether (100 ml) and 2M-hydrochloric acid (10 ml (1 M=1 mol dm^{-3})) were added to the aqueous layer and extracted several times with ether. A small quantity of methanol containing piperidine was added to the combined ethereal extracts. Resulting solid was collected, dissolved in hydrochloric acid in acetone (*ca.* 0.5 M, 30 ml), and to this was added water. The yellow crystals separated were recrystallized. ν_{max}(KBr) 2850 s, 2510 s, 2200 s, 1630 vs, 1500 s, and 1270 s cm^{-1}; δ (CD_3COCD_3) 13.62 vb (s, 1H, NH or SH), 5.95 (s, 1H, NH or SH), 3.25 (d, 1.5H, *J*=3.1 Hz, $NHCH_3$), 3.23 (d, 1.5H, *J*=3.1 Hz, $NHCH_3$), and 2.48 ppm (s, 3H, CH_3). (Found: C, 42.01; H, 4.73; N, 16.20; S, 37.07. $C_6H_8N_2S_2$ requires C, 41.79; H, 4.68; N, 16.25; S, 37.22%). Other *β-alkylimino dithiocarboxylic acids (2b—g)* were prepared in the same way.

4-Cyano-5-aryl-3H-1,2-dithiole-3-thiones (3a—c). A mixture of 3-alkylimino-3-arylpropanenitrile (5 mmol), carbon disulfide (12 mmol), and *N*,*N*-dimethylformamide (5 ml) was added dropwise to a mixture of sodium 1,1-dimethylpropoxide (15 mmol) and *N*,*N*-dimethylformamide (15 ml) at 0 °C.

The mixture was kept standing at room temperature for 4 h. Water was added to the mixture and the solid which separated was collected.

3,5-Dicyano-2,6-di(m-tolyl)-1-methylpyridine-4(1H)-thione (4). A mixture of 3-methylimino-3-(*m*-tolyl)propanenitrile (2.00 g, 11.6 mmol), sodium 1,1-dimethylpropoxide (2.00 g, 18.2 mmol), carbon disulfide (1.40 g, 18.4 mmol), and benzene (50 ml) was mechanically shaken at room temperature for 3 h and water (50 ml) was added to this. The solids from both layers were collected and recrystallized. ν_{max} (KBr) 2240 w, 1575 vs, 1480 m, 1260 s, and 1080 m cm^{-1}; δ (DMSO-d_6) 7.42 (m, 8H, C_6H_4), 2.99 (s, 3H, NCH_3), and 2.40 ppm (s, 6H, $C_6H_4C\underline{H}_3$); *m/z* 355 (M^+, 98%), 354 (M^+—1, 100%), and 340 (M^+—CH_3, 48%). (Found: C, 74.40; H, 4.62; N, 11.86; S, 9.17. $C_{22}H_{17}N_3S$ requires C, 74.35; H, 4.62; N, 11.86; S, 9.02%).

5-Cyano-3,4-dimethyl-2H-1,3-thiazine-2,6(3H)-dithione (5a). To a mixture of 3-(methylimino)butanenitrile (2.00 g, 20.8 mmol), sodium 1,1-dimethylpropoxide (6.88 g, 62.4 mmol), and *N,N*-dimethyl formamide (20 ml), was added dropwise carbon disulfide (4.75 g, 62.4 mmol) at −15 °C and the mixture was kept standing at −20 °C for 40 h. Ether (150 ml) and 1M-hydrochloric acid (30 ml) were added to the reaction mixture. The brown crystals insoluble in both layers were collected. ν_{max} (KBr) 2230 m, 1535 s, 1420 s, 1365 s, 1265 s, 1225 s, and 1085 s cm^{-1}; δ (C_5D_5N) 3.88 (s, 3H, NCH_3) and 2.75 ppm (s, 3H, CH_3). (Found: C, 39.01; H, 3.03; N, 13.00; S, 44.91. $C_7H_6N_2S_3$ requires C, 39.22; H, 2.82; N, 13.07; S, 44.91%).

5-Cyano-3-ethyl-4-methyl-2H-1,3-thiazine-2,6(3H)-dithione (5b) was Prepared Similarly. ν_{max} (KBr) 2980 w, 2900 w, 2220 m, 1530 s, 1525 s, 1405 s, 1300 s, 1240 s, 1200 s, and 1100 s cm^{-1}, ^{1}H NMR δ (DMSO-d_6) 4.60 (q, 2H, J=6.6 Hz, $NC\underline{H}_2CH_3$), 2.80 (s, 3H, CH_3), and 1.35 ppm (t, 3H, J=6.6 Hz, $NCH_2C\underline{H}_3$); ^{13}C NMR (DMSO-d_6) 201.70 (s), 191.96 (t, J=6.1 Hz), 158.62 (s), 114.91 (s), 110.96 (s), 47.98 (t, J=143.4 Hz), 23.63 (q, J=131.2 Hz), and 11.86 ppm (q, J=128.2 Hz); *m/z* 228 (M^+, 100%), 195 (M^+—SH, 13%), 141 (M^+—C_2H_5NCS, 4%), and 70 ($CH_3C{\equiv}N^+$—C_2H_5, 33%). (Found: C, 42.28; H, 3.38; N, 12.39; S, 42.38. $C_8H_8N_2S_3$ requires C, 42.08; H, 3.53; N, 12.27; S, 42.12%).

5-Cyano-3,4-dihydro-3-ethyl-4-methylene-6-methylthio-2H-1,3-thiazine-2-thione (6). Triethylammonium salt of **5b** was methylated by treating with methyl iodide in methanol. Water was added to this mixture and resulting solids were collected. ν_{max} (KBr) 2980 w, 2950 w, 2220 m, 1600 s, 1530 m, 1460 m, 1420 m, 1390 s, and 1375 s cm^{-1}; δ ($CDCl_3$) 5.17 (d, 1H, J=3.7 Hz, $=CH_2$), 4.98 (d, 1H, J=3.7 Hz, $=CH_2$), 4.48 (q, 2H, J=7.1 Hz, $NC\underline{H}_2CH_3$), 2.56 (s, 3H, SCH_3), and 1.38 ppm (t, 3H, J=7.1 Hz, $NCH_2C\underline{H}_3$); *m/z* 242 (M^+, 100%), 213 (M^+—C_2H_5, 82%), 195 (M^+—SCH_3, 32%), 155 (M^+—C_2H_5NCS, 26%), and 108 ($CH_2{=}C{=}C(CN)C{\equiv}S^+$, 31%). (Found: C, 44.87; H, 4.38; N, 11.72; S, 39.48. $C_9H_{10}N_2S_3$ requires C, 44.59; H, 4.16; N, 11.56; S, 39.69%).

1,3-Dimethyl-5-cyano-4-(p-tolyl)-2,4(1H,3H)-pyrimidinedithione (7). This compound was isolated on recrystallization of **3c** from the filtrate. ν_{max} (KBr) 2890 w, 2220 m, 1600 w, 1560 s, 1505 s, 1460 s, 1420 m, 1405 s, 1330 s, 1305 s, and 1275 s cm^{-1}; *m/z* 287 (M^+, 100%) and 132 ($C_7H_7C{\equiv}N^+$—CH_3, 24%). (Found: C, 58.66; H, 4.51; N, 14.33; S, 22.10. $C_{14}H_{13}N_3S_2$ requires C, 58.50; H, 4.59; N, 14.62; S, 22.32%).

Solubilization of Alkyl *p*-Hydroxybenzoates in Hexa(oxyethylene) Dodecyl Ether Micelle

Ayako GOTO,* Fumio ENDO, and Takeo HIGASHINO
Shizuoka College of Pharmacy, 2-2-1, Oshika, Shizuoka 422
(Received May 25, 1984)

Synopsis. An experimental study was made on the effect of the alkyl-chain length of alkyl *p*-hydroxybenzoates on their solubilization in nonionic micelle. The location of alkyl *p*-hydroxybenzoate in micelle and the change in micelle structure are discussed on the basis of the experimental result.

Two subjects should be considered to elucidate the solubilization mechanism:[1] One is concerned with the variation of the overall distribution coefficient with the concentration of solubilizate in a micelle and with thermodynamic interpretation of its behavior; the other is concerned with the location of solubilizate in a micelle. The latter subject has been investigated spectrophotometrically by a number of workers, but few papers have been published in which the latter is considered in connection with the former. We[2,3] have reported on the concentration dependence for methyl and ethyl *p*-hydroxybenzoates in nonionic surfactant micelles and explained this dependence on the basis of the regular solution theory.

In the present work we have inferred the location of alkyl *p*-hydroxybenzoate in hexa(oxyethylene) dodecyl ether ($C_{12}E_6$) micelle and discussed the inference in terms of the nonideality of distribution and the change in micelle structure.

Experimental

Hexa(oxyethyelene) dodecyl ether[2] ($C_{12}E_6$) and alkyl *p*-hydroxybenzoates (alkyl=methyl, ethyl, propyl, and butyl) were of reagent grade. Gel filtration was carried out at 20°C in the same way as previously described.[2] The concentration of alkyl *p*-hydroxybenzoates was determined spectrophotometrically[2,3] and that of $C_{12}E_6$ was measured by gas chromatography.[4] Distribution coefficient (K), mole fraction in micelle phase (X_s^m) and that in aqueous phase (X_s^w), cmc, interchange energy (ω), free energy change of solubilization (ΔG), elution volume of micelle (V_m), and cloud point were evaluated in the same way as reported in our previous paper.[2] UV spectra of *p*-hydroxybenzoates in water and aqueous $C_{12}E_6$ solution were measured with a Hitachi EPS-3T spectrophotometer.

Results and Discussion

The apparent distribution coefficients of propyl and butyl *p*-hydroxybenzoates (K_a), X_s^m/X_s^w were measured at 20°C. Figure 1 shows a plot of K_a values of propyl and butyl esters against X_s^m. The values at $X_s^m=0$ corresponds to the K value.[2] ΔG values for alkyl esters obtained from K values are given in Table 1. They are linearly related with the carbon number of the alkyl group of *p*-hydroxybenzoates, and the slope of the straight line corresponds to the increment of -2.6×10^3 J/mol of ΔG per methylene unit. This value is equal to the reported values for alcohols (-2.6×10^3 J/mol) in sodium dodecyl sulfate (SDS) micelle[5] and *p*-hydroxybenzoates (-2.6×10^3 J/mol) in SDS micelle.[6] It may also be concluded that the alkyl moiety of *p*-hydroxybenzoate is incorporated in the hydrocarbon core of micelle. We[3] reported that the solubilization of ethyl *p*-hydroxybenzoate in $C_{12}E_6$ micelle results from both the enthalpy and entropy effects and that the latter effect might be due to a hydrophobic interaction, which is also compatible with the above conclusion.

A red shift was observed with UV maxima of *p*-hydroxybenzoates in $C_{12}E_6$ micelle; methyl, ethyl, propyl, and butyl esters have UV maxima at 257.9, 258.1, 258.4, and 258.9 nm in 2.0% $C_{12}E_6$ solution, respectively, whereas they all have UV maxima at 256 nm in water. The change of spectra in the nonionic surfactant micelle might be due to the following factors:[7] i) specific interactions such as hydrogen bonding; ii) change in polarity of the environment. Therefore, the above red shift suggests an increase in polarity of the environment and/or specific interactions between $C_{12}E_6$ and *p*-hydroxybenzoate. Nemethy and Ray[8] reported that phenol molecules are located in a polar environment of nonionic surfactant micelle and/or are hydrogen-bonded. Muller and Metcalf[9] described that chloroxyrenol is hydrogen-bonded in poly(oxyethylene) dodecyl ether micelle. Therefore, the hydrogen bond between the phenolic hydrogen of alkyl esters and the etheric oxygen of $C_{12}E_6$ may occupy an important position in the specific interactions. This interaction has also been proved in terms of interchange energy (ω), which is

TABLE 1. FREE ENERGY CHANGE OF SOLUBILIZATION OF ALKYL *p*-HYDROXYBENZOATES IN $C_{12}E_6$ MICELLE (ΔG) AND INTERCHANGE ENERGY (w)

p-Hydroxybenzoate	ΔG/J/mol	w/J/mol
Methyl ester[4]	-2.07×10^4	-3700 ± 400
Ethyl ester[5]	-2.26×10^4	-3400 ± 500
Propyl ester	-2.49×10^4	-2800 ± 700
Butyl ester	-2.85×10^4	-3300 ± 500

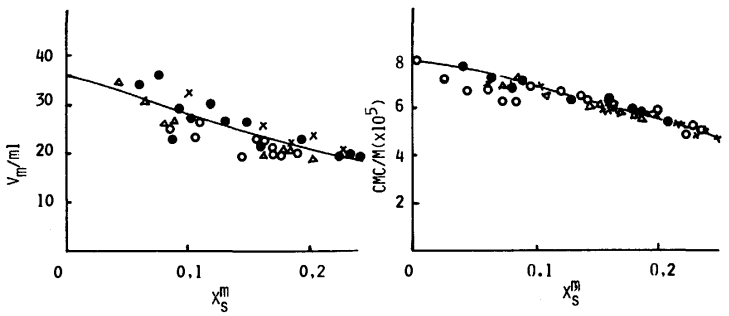

Fig. 2. Variation of the Elution Volumes of the $C_{12}E_6$ Micelles (V_m) and the cmc's of $C_{12}E_6$ Solutions in the Presence of Alkyl *p*-Hydroxybenzoates with Mole Fraction of Alkyl *p*-Hydroxybenzoates, X_s^m.
(●): Methyl ester,[2] (○): ethyl ester, (×): propyl ester, (△): butyl ester.

calculated on the basis of the regular solution theory.[2] These values (ω) are negative as shown in Table 1, corresponding to the ω value of methyl ester in hepta (oxyethylene) dodecyl ether ($C_{12}E_7$) obtained by molar volume measurements.[10] This suggests that $C_{12}E_6$ and alkyl ester in a mixed micelle become thermodynamically stable by mutual attraction. From the above results, it is concluded that solubilized esters are most likely to be located in the area spreading from the inside of hydrocarbon core to the poly(oxyethylene) mantle of micelle. Furthermore, it may also be concluded that the hydrophobic interaction and the specific interaction in a micelle reflect directly the distribution coefficient and that the nonideality of distribution is due mainly to the specific interaction.

Figure 2 shows plots of the retention volume of micelle which is a measure of the hydrated size of micelle[12] and of the cmc against X_s^m. The cmc and retention volume decrease with X_s^m and the pattern of the decrease depends little on the length of the alkyl chain of *p*-hydroxybenzoate. Therefore, Fig. 2 implies that the mixed micelle becomes thermodynamically stable[2,11] by enlarging its size and indicates that the manners of change in cmc and retention volume are nearly the same, suggesting that such a change in micellar structure is due mainly to the specific interaction, *i.e.* the hydrogen bonding between *p*-hydroxybenzoate and $C_{12}E_6$ in the mixed micelle.

Figure 3 shows a plot of cloud points against the concentration of esters added. The longer alkyl chain of *p*-hydroxybenzoates is able to depress the cloud point more deeply because of its denser distribution into the micelle phase. Kuriyama[14] has suggested that increase in micellar weight with increasing temperature is a dominant factor for the cloud formation. Therefore, the depression of cloud point by the ester added is related closely with the increase in micelle size, as shown in Fig. 2a; this effect would result from both the specific interaction favoring the retention of ester in the oxyethylene region of micelle and the structured water supported by the ester in this environment.[13]

Sintered Iron (III) Oxide Photoanode Doped with Molybdenum

Shigero OISHI,* Keiko TAJIME, and Akeri HOSAKA
Sagami Chemical Research Center, Nishi-Ohnuma 4-4-1, Sagamihara, Kanagawa 229
(Received July 21, 1984)

Synopsis. Sintered iron(III) oxide electrodes which contained about 0.01 atomic% of molybdenum showed considerable improvement in generating anodic photocurrent, particularly, in a cathodic potential region. 0.01 Atomic% doping level was found to be attained by sintering at 1200 °C for 12 h using 0.2 atomic% of MoO_2 or 1.0 atomic% of MoO_3.

The photoelectrochemistry of sintered iron(III) oxide has received considerable attention in recent years, because of prospects of an efficient and low-cost photoanode in the direct photoassisted electrolysis of water using visible light.[1-8] In order to make iron(III) oxide conductive by increasing negative carriers, doping with group IVB elements has been intensively investigated, and among them silicon doped iron(III) oxide has appeared to have good properties in producing photocurrent and stability against photodissolution.[2] We report here the photoelectrochemical behavior of sintered iron(III) oxide doped with molybdenum.

Experimental

Electrodes were prepared from α-Fe_2O_3 (99.999%, Alfa Co.) by mixing with 0.02—2 atomic% of MoO_2 (99%, Mitsuwa Co.) or MoO_3 (99.999%, Aldrich Co.), pressing into pellets, sintering at 1150—1300 °C for 6—24 h in air, followed by quenching to room temperature. Dimensions of the pellets were 1.1 cm (diameter)×0.1 cm (thickness). New surfaces were obtained by polishing with emery, washed with water using ultrasonic wave, and etched with concentrated hydrochloric acid. A copper lead was attached to the back surface by ultrasonic soldering. Resistances measured across the thickness were 3—50 Ω. The electrodes were mounted into appropriate glass holders with epoxy resin.

Current-potential curves were obtained with a potentiostat HA-104 (Hokuto Denko Co.) and a regular three-electrode arrangement, in which a platinum wire as a counter electrode and a saturated calomel electrode(SCE) as a reference electrode were used. Iron(III) oxide electrodes were illuminated with a 1 kW xenon lamp through a Pyrex optical system, and a series of interference filter was employed for the measurement of spectral response.

The concentrations of molybdenum in sintered iron(III) oxide were photometrically determined by the use of 3,4-toluenedithiol.[9]

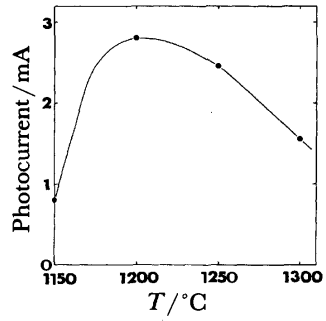

Fig. 1. The dependence of anodic photocurrent upon sintering temperature measured at 0.1 V (*vs.* SCE) in pH 10 borate buffer (0.1 M). Iron(III) oxide pellets containing 0.2 atomic% of MoO_2 were sintered for 6 h.

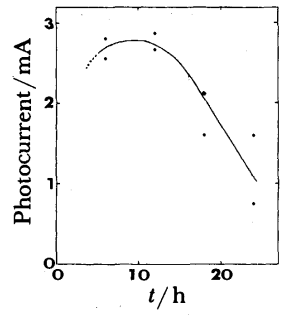

Fig. 2. The dependence of anodic photocurrent upon sintering time measured at the same conditions as Fig. 1. Iron(III) oxide pellets containing 0.2 atomic% of MoO_2 were sintered at 1200 °C.

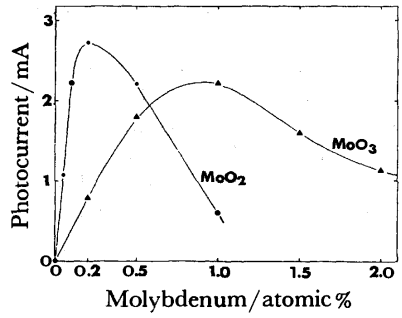

Fig. 3. The dependence of anodic photocurrent upon the amounts of dopants used, measured at the same conditions as Fig. 1. Sintering was conducted at 1200 °C for 6 h.

Results and Discussion

An alumina mortar was used for mixing ferric oxide with dopants because it was found that the use of an agate mortar, the chemical compornent of which is none other than silica, brought about contamination with silicon which concealed any effects caused by other dopants.

Figures 1, 2, and 3 show the dependencies of photocurrent upon sintering temperature, sintering time, and amounts of dopants, respectively. Sintering at 1200 °C for 12 h gave the best result. At these conditions, the concentration of molybdenum at the boundary of each grain of iron(III) oxide may be most suitable for the flow of photocurrent. In the case of electrode sintered at a higher temperature and/or for a longer time, where dopant may diffuse into the grains of iron(III) oxide, photocurrent was rather small. Attempts to know the actual concentration of molybdenum at the electrode surface by means of fluorescence X-ray analysis and ESCA were unsuccessful because of low concentration. Chemical analysis for molybdenum, however, revealed that iron(III) oxide pellets sintered at 1200 °C for 12 h contained

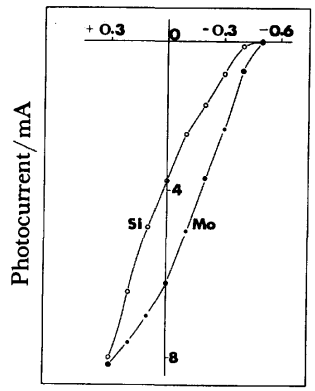

Fig. 4. Photocurrent-electrode potential curves for 0.01 atomic% of molybdenum and 2 atomic% of silicon doped iron(III) oxide electrode, measured in pH 10 borate buffer (0.1 M).

about 1/20 and 1/100 of the original amount of molybdenum when MoO_2 and MoO_3 were used as dopants, respectively. Therefore, in Fig. 3, the best results for anodic photocurrent generation are considered to be obtained at around 0.01 atomic% of doping level based on the actual concentration of molybdenum. The decrease in concentration of molybdenum is due to the oxidation of MoO_2 to volatile MoO_3.[10] Then, it can be concluded that the optimum conditions for sintering are corresponding to those in which 0.01 atomic% of doping level was attained when the sintering of iron(III) oxide was completed.

The surface of the effective electrode was revealed to be porous by means of a scanning electron microscope; one hole (around 20 μm in diameter) per $4\times10^3\,\mu m^2$. Similar microstructure of electrode surface could be observed even in the case of electrodes not containing molybdenum, but they were not effective. The presence of molybdenum is essential for producing photocurrent.

A typical polarization curve for 0.01 atomic% Mo doped iron(III) oxide is shown in Fig. 4. A considerable improvement in the cathodic potential region can be noticed as compared with the case of the best 2% Si doped iron(III) oxide electrode[2] which we could prepare. This advance is important considering the reduction at the counter electrode in the electrolysis cell.

Visible light up to around 570 nm were effective in generating photocurrent and this is in accord with the fact that a band gap of iron(III) oxide is 2.2 eV.[1]

Photodissolution of the electrode was inspected by means of bathophenanthroline photometry using hydroxylamine as a reducing agent of iron(III) to iron(II) ion. The electrode is so stable against photodisolution that detectable amount of iron(II) ion was not found in 10 cm^3 of anolyte(1 mol/dm^3 aq NaOH) when 42 coulomb of photocurrent flowed at 0.3 V (*vs.* SCE).

The electrode is also stable in generating photocurrent, indeed, about 4 mA of steady photocurrent was flowing for 6 h in a two-electrode system divided by agar-agar using a platinum wire as a counter electrode, where 1 mol/dm^3 aqueous sodium hydroxide 0.5 mol/dm^3 sulfuric acid were used as an anolyte and a catholyte, respectively. Moreover, in this case, oxygen and hydrogen could be collected in 92% current efficiency.

The authors thank the Agency of Industrial Science and Technology of MITI under the Sunshine Project contract for support of this work.

(Received July 31, 1984)

Synopsis. D-Glucurono-6,3-lactone derivatives are converted to butenolide or dihydro-2*H*-pyran derivatives by treatment with triethylamine.

Because of the effect of the carbonyl group, uronic acid and aldonolactone derivatives readily underwent β-elimination reactions to yield unsaturated compounds.[1,2,3] D-Glucurono-6,3-lactone (**1**) derivatives were also susceptible to elimination reaction to give unsaturated compounds.[4,5] We wish to report herein the formation of butenolide or dihydro-2*H*-pyran derivatives by elimination reactions of 2,4,5-tri-*O*-acetyl-*aldehydo*-D-glucurono-6,3-lactone diacetyl acylal (**2**), *aldehydo*-D-glucurono-6,3-lactone ethylene dithioacetal (**3**),[6] or 2,4,5-tri-*O*-acetyl-*aldehydo*-D-glucurono-6,3-lactone ethylene dithioacetal (**4**) by treatment with triethylamine.

Acetolysis of methyl β-D-glucofuranosidurono-6,3-lactone with $BF_3 \cdot OEt_2$ in acetic anhydride afforded crystalline **2** in 55% yield. The compound **2** was also obtained from **1** or 1,2,5-tri-*O*-acetyl-β-D-glucurono-6,3-lactone in lower yields, 39% and 27%, respectively. The compound **2** was isolated from the mixture of **2** and 1,2,5-tri-*O*-acetyl-D-glucurono-6,3-lactone by crystallization from ethyl acetate–petroleum ether (1:4). Other acidic catalysts such as H_2SO_4, $AlCl_3$, H_3PO_4, and CF_3COOH did not afford **2**. Treatment of **2** with triethylamine afforded 3-acetoxy-5-(2,2-diacetoxyethylidene)-2(5*H*)-furanone (**5**). The results obtained with various solvents are summerized in Table 1, acetic anhydride was found to be the most suitable solvent and **5** was obtained in 91% yield.

Upon treatment of **4** with acetic anhydride-triethylamine, 3-acetoxy-5-[1-acetoxy-2-(1,3-dithiolan-2-yl) ethyl]-2(5*H*)-furanone (**6**) was obtained as a main product, together with 3-acetoxy-5-[2-(1,3-dithiolan-2-yl) ethylidene]-2(5*H*)-furanone (**7**), in 69% and 11% yields, respectively. This reaction also occurred smoothly in ethyl acetate, and **6** and **7** were also obtained in 74% and 16% yields, respectively.

On the other hand, when **3** was treated with acetic anhydride-triethylamine, the 6,3-lactone linkage rearranged to a 6,2-lactone linkage along with acetylation and elimination reactions. In this reaction, 3,5-diacetoxy-6-(1,3-dithiolan-2-yl)-5,6-dihydro-2*H*-pyran-2-one (**8**) was obtained in 83% yield, but the butenolide derivatives, **6** and **7**, and α-pyrone derivative were not obtained.

TABLE 1. CONVERSION OF **2** INTO **5** BY TREATMENT WITH TRIETHYLAMINE

Solvent	Temp/°C	Time/h	Yield/%
CH_3CN	0	4	3
CH_3CN–Ac_2O	0	2	76
DMF	0	22	0
DMF–Ac_2O	0	3	65
EtOAc	60	2	0
EtOAc–Ac_2O	60	1	50
Ac_2O	0	24	91

The dithioacetal derivatives, **3** and **4**, tend mainly to give monounsaturated product, while **2** gave the conjugated unsaturated compound.

The product **5** and **7** were a mixture of *E* and *Z* isomers. The structures of the two isomers were easily determined by ^{1}H-NMR studies, since the olefinic hydrogen in the *E* isomer is considerably deshielded by virtue of its *cis* relationship to the butenolide oxygene.[7] In the ^{1}H-NMR spectrum of **8**, the value for $J_{5,6}$ (2.4 Hz) indicated the *cis* relationship for the two protons, H-5 and H-6,[8] and the other physical data are consistent with the proposed structure for **8**. Moreover, in the pharmacological screening tests of **5**, antihypertension and bradycardia activities were observed.

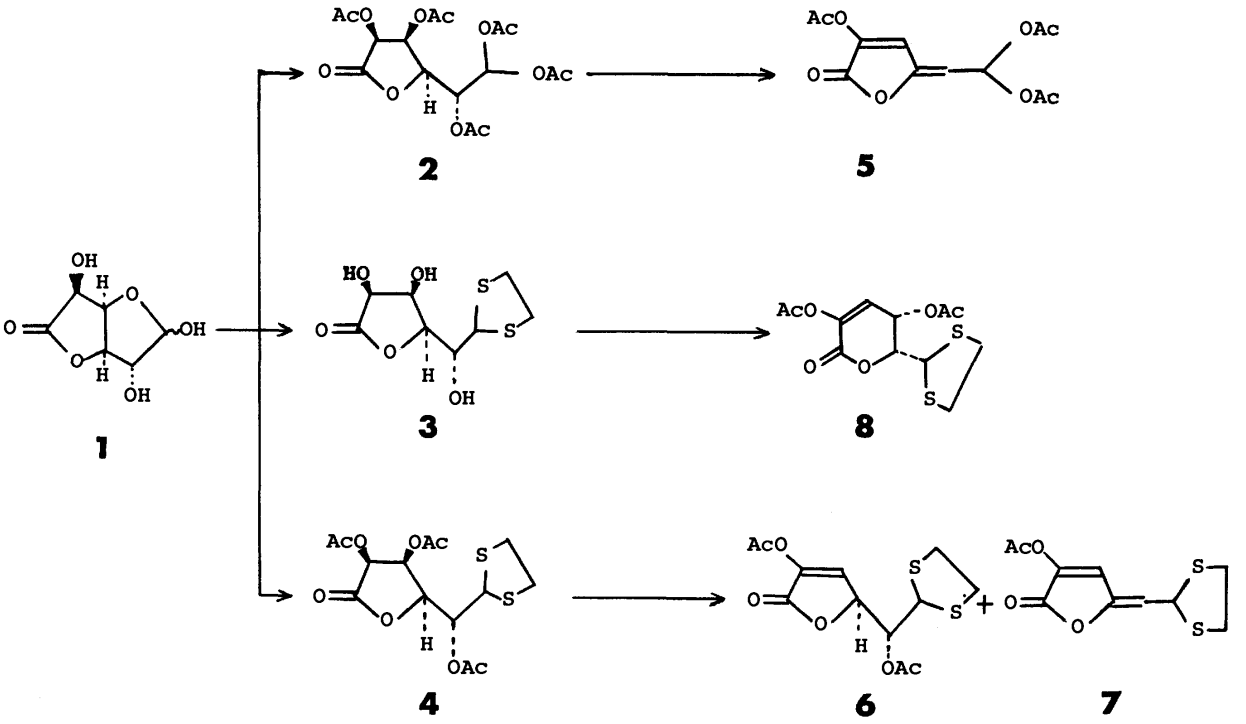
Experimental

Melting points are uncorrected. The infrared spectra and ^{1}H-NMR spectra were recorded on a JASCO A-102 spectrometer and a JNM PMX-60 spectrometer, respectively, under standard conditions.

2,4,5-Tri-O-acetyl-aldehydo-D-*glucurono-6,3-lactone Diacetyl Acylal (2).* To a mixture of acetic anhydride (12 ml) and $BF_3 \cdot OEt_2$ (2 ml) was added methyl β-D-glucofuranosidurono-6,3-lactone[9] (0.3 g). After heating the mixture at 60 °C for 16 h, the reagents were distilled off under reduced pressure. The residue was extracted with ethyl acetate–water and the organic layer was washed with 5% $NaHCO_3$ aq and water, dried and evaporated under reduced pressure. The residue was extracted with 15 ml of ethyl acetate–petroleum ether (1:4) and the insoluble material was **2** (0.25 g, 55%). It was recrystallized from acetone–petroleum ether: mp 202—203 °C. ^{1}H-NMR (DMSO-d_6) δ=2.10 (6H, s), 2.30 (9H, s), 5.00 (1H, dd, J=3.0, 7.8 Hz), 5.44 (1H, dd, J=3.2, 7.8 Hz), 5.63 (1H, dd, J=3.0, 4.9 Hz), 5.95 (1H, d, J=4.9 Hz), 6.63 (1H, d, J=3.2 Hz). IR 1805, 1770, 1750 cm^{-1}. Found: C, 47.51; H, 5.11%. Calcd for $C_{16}H_{20}O_{12}$: C, 47.52; H, 5.00%.

3-Acetoxy-5-(2,2-diacetoxyethylidene)-2(5H)-furanone (5). To a solution of **2** (0.3 g) in acetic anhydride (15 ml) triethylamine (0.5 ml) was added at 0 °C. After stirring for 24 h at 0 °C, the mixture was extracted with benzene-water. The benzene layer was washed with HCl aq and water, dried and evaporated under reduced pressure. The products were separated by column chromatography on silica gel (Wako gel C-200) with ethyl acetate–petroleum ether (2:3). The first moving compound was (*E*)-**5** (0.073 g, 34%) which was recrystallized from carbon tetrachloride–petroleum ether: mp 68 °C. The second moving compound was (*Z*)-**5** (0.12 g, 57%) as oil. (*E*)-**5**; ^{1}H-NMR ($CDCl_3$) δ= 2.13 (6H, s), 2.35 (3H, s), 5.75 (1H, d, J=7.6 Hz), 7.43 (1H, d), 7.77 (1H, s). IR 1780, 1760, 1740, 1680, 1615 cm^{-1}. Found: C, 50.64; H, 4.06%. Calcd for $C_{12}H_{12}O_8$: C, 50.71; H, 4.26%. (*Z*)-**5**; ^{1}H-NMR ($CDCl_3$) δ=2.13 (6H, s), 2.37 (3H, s), 5.47 (1H, d, J=8.0 Hz), 7.40 (1H, s), 7.65 (1H, d). IR 1790, 1760, 1680, 1615 cm^{-1}.

3-Acetoxy-5-[1-acetoxy-2-(1,3-dithiolan-2-yl)ethyl]-2(5H)-furanone (6) and 3-Acetoxy-5-[2-(1,3-dithiolan-2-yl)ethylidene]-2(5H)-



furanone (7). To a solution of **4** (0.150 g) in ethyl acetate (4 ml) triethylamine (0.4 ml) was added. After stirring for 19 h at room temperature, the solution was extracted with ethyl acetate–water. The organic layer was washed with HCl aq and water, dried and evaporated under reduced pressure. The products were separated by column chromatography on silica gel with benzene–ethanol (40:1.5). The first moving compound was **7** (0.016 g, 16%). The second moving compound was **6** (0.093 g, 74%) which was recrystallized from carbon tetrachloride–petroleum ether: mp 168—170 °C. **6**; ^{1}H-NMR ($CDCl_3$) δ=2.05 (3H, s), 2.28 (3H, s), 3.24 (4H, s), 4.83—5.00 (2H, m), 5.50—5.60 (1H, m), 7.00 (1H, d, J=2.0 Hz). IR 1775, 1750, 1650 cm^{-1}. Found: C, 44.97; H, 4.53%. Calcd for $C_{12}H_{14}O_6S_2$: C, 45.27; H, 4.43%. (*E*)-**7**; ^{1}H-NMR ($CDCl_3$) δ=2.33 (3H, s), 3.35 (4H, s), 5.30 (1H, d, J=11.0 Hz), 5.84 (1H, d), 7.69 (1H, s). (*Z*)-**7**; ^{1}H-NMR ($CDCl_3$) δ=2.33 (3H, s), 3.35 (4H, s), 5.37 (1H, d, J=10.4 Hz), 5.71 (1H, d), 7.28 (1H, s).

3,5-Diacetoxy-6-(1,3-dithiolan-2-yl)-5,6-dihydro-2H-pyran-2-one (8). To a solution of **3** (0.200 g) in acetic anhydride (3 ml) triethylamine (0.3 ml) was added. After stirring for 1 h at room temperature, the reagent were distilled off under reduced pressure. The residue was extracted with benzene–water and the organic layer washed with 5% $NaHCO_3$ aq and water, dried and evaporated under reduced pressure. The product was separated by column chromatography on silica gel with benzene–ethanol (40:1.5). Obtained **8** was recrystallized from carbon tetrachloride–petroleum ether (0.210 g, 83%): mp 91—92 °C. ^{1}H-NMR ($CDCl_3$) δ= 2.11 (3H, s), 2.35 (3H, s), 3.23 (4H, s), 4.42 (1H, dd, J=2.4, 10.0 Hz), 4.77 (1H, d, J=10.0 Hz), 5.58 (1H, dd, J=2.4, 6.4 Hz), 6.63 (1H, d, J= 6.4 Hz). IR 1770, 1660 cm^{-1}. Found: C, 45.10; H, 4.62%. Calcd for $C_{12}H_{14}O_6S_2$: C, 45.27; H, 4.43%.

††*Faculty of Pharmaceutical Science, Tokushima Bunri University, Yamashiro cho, Tokushima 770*
(Received September 6, 1984)

Synopsis. The isolation and structural elucidation of 13-hydroxyneocembrene from soft corals were carried out.

In the previous paper, some of us (Hiroshima group) have reported the characterization of a hydroxyneocembrene (**1**), named mayol, from a soft coral, *Sinularia mayi*.[2)] The structural elucidation of **1** was based on the spectral coincidence with the authentic *dl-cis*-1-hydroxyneocembrene synthesized by Tohoku group.[3)] The absolute configuration of the natural mayol, $[\alpha]_D$ +138.5° ($CHCl_3$) however, has remained unsolved because of limited amounts of the material.

In order to determine the absolute configuration, optical resolution of the synthetic *dl*-compound was performed by converting to *l*-camphanates followed by separation with high pressure liquid chromatography-(HPLC). Subsequent chemical transformation of the resultant enantiomers having $[\alpha]_D$ +156° and −156°, respectively, led to the conclusion that mayol has 1*S*,14*R* absolute stereochemistry although the value of optical rotation of the mayol is somewhat less than that of the resolved compound.[4)] For the sake of clarification of the difference of the specific rotation, the natural mayol was converted into the corresponding *l*-camphanate and subjected to HPLC analysis. It was soon made clear that the natural specimen was contaminated with minute amounts of an isomeric hydroxyneocembrene (**2**). It was found later that mayol and the isomeric hydroxyneocembrene could be separated by the repeated column chromatographies of the crude extracts. This paper concerns with the characterization of the isomeric compound.

The isomeric compound (**2**) has a molecular formula of $C_{20}H_{32}O$ (M^+ 288.2428, Calcd. MW=288.2451) having $[\alpha]_D$ −30.3° (*c* 0.93, $CHCl_3$). The gross structure was deduced from ^{1}H- and ^{13}C-NMR spectra, which were indicative of the existence of three CH=CMe- and an isopropenyl groups in addition to a secondary hydroxyl group. Oxidation of **2** with Collins' reagent afforded the corresponding ketone (**3**) having the carbonyl absorption at 1705 cm^{-1} in the IR spectrum, exhibiting that the carbonyl moiety is *not* conjugated with the double bond. This deduction was supported by the observation of only end absorption in its UV spectrum. Wolff-Kishner reduction of **3** gave a hydrocarbon, the mass fragmentation of which was completely identical with the authentic *dl*-neocembrene (**4**).[5)]

The evidence described so far demonstrates the isomeric alcohol (**2**) is 13-hydroxyneocembrene. Recently Faulkner and his co-worker reported the isolation of 2,3-epoxy derivative (**5**) of 13-hydroxyneocembrene from a marine organism.[6)]

Determination of the relative stereochemistry of the 13-hydroxyneocembrene (**2**) by the synthetic study will be the future subject. It should be noticed that the naturally occurring mayol is not enantiomerically mixed with the corresponding antipode as suspected previously.[4)]

4 X = H_2

Experimental

Measurements. NMR spectra were recorded with Varian EM-390 (90 MHz) and Varian XL-200 (200 MHz) spectrometers. Mass spectra were determined with a JEOL DX-300 spectrometer.

Isolation of Mayol (1) and 13-Hydroxyneocembrene (2). Crude MeOH extracts (30 g) from *Lobophytum denticulatum* Tixie-Durivault collected at coral reef of Miyako of Okinawa was eluted through a SiO_2 column with hexane–EtOAc (10:1) and the resultant fractions containing hydroxyneocembrenes (**1** and **2**) were developed on preparative TLC of 10% $AgNO_3$–SiO_2 with the same solvents. Repetition of TLC gave mayol (**1**) (37 mg) and the isomeric alcohol (**2**) (16 mg), respectively. **2** has the following physical data. IR(neat) 3400, 3070, 1660, 1640, 1050, and 890 cm^{-1}; ^{1}H-NMR ($CDCl_3$) δ= 1.54 (3H, t, 1.1 Hz), 1.58 (3H, s), 1.64 (3H, d, 0.9 Hz), 1.79 (3H, q, 0.7 Hz), 3.88 (1H, bt, 6 Hz), 4.83 (1H, bs), 4.92 (1H, bs), and 4.7—5.2 (3H, m); ^{13}C-NMR ($CDCl_3$) δ=14.9 (q), 15.3 (q), 16.7 (q), 22.8 (q), 24.2 (t), 24.8 (t), 24.9 (t), 38.7 (t), 39.9 (t), 43.9 (t), 49.9 (d), 71.6 (d), 111.6 (t), 125.4 (d), 125.9 (d), 127.2 (d), 131.1 (s), 132.9 (s), 134.0 (s), and 147.6 (s).

Purification of 13-Hydroxyneocembrene (2) by the Formation of l*-Camphanate.* To a solution of *l*-camphanyl chloride (22 mg) in pyridine (0.6 ml) was added a benzene solution (1 ml) of 13 mg of the crude mayol with $[\alpha]_D$ +138.5° (a mixture of mayol (**1**) and 13-hydroxyneocembrene (**2**)) at 0 °C. The resulting reaction mixture was stirred at 0 °C for 2 h and then at rt for an additional 1 h. The mixture was diluted with ether (20 ml) and sequentially washed with dil $CuSO_4$ and brine, and then dried over Na_2SO_4 and filtered. The filtrate was evaporated *in vacuo* to give a viscous oil. Repeated HPLC (Lichrosorb SI 100) of the oil with hexane–ether (20:1) provided *l*-camphanates of mayol (9 mg) and of 13-hyroxyneocembrene (5 mg).

l-Camphanate of **2** $[\alpha]_D$ −33.8° (*c* 0.83, $CHCl_3$); ^{1}H-NMR ($CDCl_3$) δ= 0.95 (3H, s), 1.05 (3H, s), 1.10 (3H, s), 1.49 (3H, s), 1.56 (3H, s), 1.64 (3H, s), 1.74 (3H, s), 4.73 (1H, s), 4.85 (1H, m), and 4.8—6.0 (4H, m). The *l*-camphanate of **2** (4 mg) was dissolved in 2M KOH–MeOH (2 ml (1 M=1 mol dm^{-3})). The solution was stirred at rt for 17 h, poured into water, and extracted with ether. The combined organic layers were sequentially washed with 1M HCl, sat $NaHCO_3$, and brine, dried over Na_2SO_4, and then filtered. The filtrate was evaporated *in vacuo* to afford a crude product. The crude

product was passed through a SiO_2 column eluted with hexane–EtOAc (10:1) to give pure 13-hydroxyneocembrene (1.8 mg).

Oxidation of 13-Hydroxyneocembrene (2). To a stirred solution of Collins' reagent (11 mg, 0.04 mmol) in CH_2Cl_2 (1 ml) was added a solution of the alcohol (**2**) (1.2 mg, 0.004 mmol) in CH_2Cl_2 (0.1 ml) at room temperature. The resultant mixture was stirred for 5 min and then diluted with EtOAc (3 ml). The EtOAc layer was passed through a short SiO_2 column and the solvent was evaporated to give a light brown oil. Filtration through a SiO_2 column with hexane–EtOAc (30:1) afforded a colorless oil (**3**)(0.6 mg). The ketone (**3**) has the following physical data. M^+ 286; $[\alpha]_D$ +482.4° (*c* 0.09, $CHCl_3$); IR(CCl_4) 3010, 1705, 1645, and 905 cm^{-1}, ^{1}H-NMR ($CDCl_3$) δ=1.57 (6H, s), 1.66 (3H, s), 1.69 (3H, s), 2.63 (1H, ddd, 11.0, 11.0, 7.0 Hz), 2.71 (1H, bd, 13 Hz), 3.23 (1H, d, 13 Hz), 3.30 (1H, bd, 11 Hz), 4.86 (2H, bs), and 4.8—5.2 (3H, m).

Wolff-Kishner Reduction of the Ketone (3). The ketone (**3**) (0.6 mg) was dissolved into a mixture of 80% hydrazine hydrate (18 µl), NaOH (18 mg) and diethylene glycol (0.3 ml) and gradually heated to 190°C and kept for 3 h at 190°C. After cooling, the reaction mixture was diluted with ether, washed successively with 0.5 M HCl, sat. $NaHCO_3$ and then brine and dried over Na_2SO_4. The ether solution was evaporated and the residue was passed through a SiO_2 column with hexane to afford a hydrocarbon (**4**)) (*dl*-neocembrene) (0.1 mg). M^+ 272 (30%) and *m/z* at 121 (62), 107 (66), 93 (92), 81 (80), 68 (100), and 67 (58). The fragmentation pattern was identical with that of *dl*-neocembrene (**4**).

Valence Isomerization between Water-soluble Norbornadiene and Quadricyclane Derivative

Kazuhiro MARUYAMA,* Hitoshi TAMIAKI, and Tetsuya YANAI
Department of Chemistry, Faculty of Science, Kyoto University, Kyoto 606
(Received September 11, 1984)

Synopsis. Photoisomerization of 3-(arylcarbamoyl)-norbornadiene-2-carboxylic acid **1** to the corresponding quadricyclane derivative **2** in an aqueous alkaline solution was clean and dependent upon the *p*-substituent of the aryl group. The exothermically reversal reaction of **2** to **1** was also clean but independent upon the substituent.

Valence isomerization between norbornadiene and quadricyclane has attracted much attention from solar energy storage.[1] This system has inherently an inevitable problem: norbornadiene cannot absorb sunlight. To overcome the great disadvantage, we have proposed introduction of substituents to norbornadiene.[2] Moreover, we first used water, safe and inexpensive, as the reacting media.[3] Usually, organic solvent had been used in similar systems. In this paper, we describe the effect of the substituents of aryl group in valence isomerization between 3-(arylcarbamoyl)norbornadiene-2-carboxylic acid **1** and 3-(arylcarbamoyl)quadricyclane-2-carboxylic acid **2** in water.

Results and Discussion

Norbornadiene-2,3-dicarboxylic anhydride and *p*-substituted aniline gave norbornadiene derivative **1** in a high yield.[2] The norbornadiene derivative **1** was highly soluble in an aqueous alkaline solution because of the carboxyl group. In an aqueous alkaline solution **1** has absorption band in longer wavelength than 400 nm and absorbs sunlight (Fig. 1). When an aqueous sodium carbonate solution of norbornadiene derivatives **1a—d** was irradiated by light of 366 or 334 nm, the corresponding quadricyclane derivatives **2a—d** were quantitatively formed even in the presence of air (Table 1). The photoisomerization by light of longer wavelength than 300 nm including sunlight was so clean that isosbestic points were observed in UV spectral changes. On irradiating light of 313 nm **1a, b** photoisomerized to **2a, b** quantitatively, but **1c, d** didn't (Table 1). This reaction is photochromic,[4] so **2** isomerizes again to **1** by light which is able to be absorbed by **2**. Under the conditions, **2c, d** isomerized to **1c, d** to attain a photostationary state. These facts may be rationalized by taking into consideration that introduction of a substituent into phenyl group to make **1** absorb light of the longer wavelength affects **2** concomitantly to absorb light of longer wavelength. Similarly, the quantum yield of the photoisomerization decreased with increasing the absorption edge of **1**. Therefore, bathochromic shift of absorption band of **1** induces decrease of both the chemical and the quantum yield of the photoisomerization. Wavelength dependency of the quantum yield is given in Table 1.

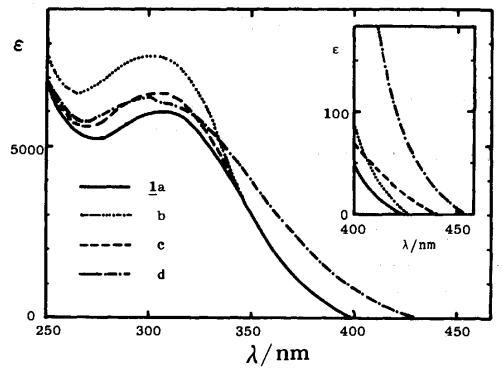

Fig. 1. Ultraviolet and visible spectra of 1 in 0.1 M Na_2CO aq (1 M = 1 mol dm^{-3}).

The isomerized **2** was so stable in a boiling aqueous sodium carbonate solution that none of **1** and other products could be produced under the conditions. However, addition of a catalytic amount of cobalt 5,10,15,20-tetrakis(*p*-carboxyphenyl)porphyrin (Co-TPPC) in the solution at room temperature induced a sudden isomerization of **2** to **1** quantitatively under release of heat. The exothermically catalytic reaction was of pseudo-first order. The rate constant was about 7 $M^{-1}s^{-1}$ and independent upon varieties of *p*-sub-

stituents of **2**. The heat of molar storage was about 60 kJ mol^{-1} and also independent upon the structure of **2a—d**. These facts may be explained as followings; a substituent introduced into phenyl group is so far from the reaction center, double bonds of **1** and so banana bonds of **2**.

From the viewpoint of the conversion efficiency in solar energy,[5] introduction of a substituent is effective little, but in view of utilizing light of longer wavelength of sun, the introduction is of some improvement. This water-soluble solar energy storage system may be promising for actual use by the following two points: i) this system can utilize the light of 450 nm; ii) this system is so clean in both photo- and catalytic reaction.

Experimental

Apparatus. All melting points were measured with a Yanagimoto micro melting point appratus and uncorrected. Ultraviolet and visible spectra were measured with a Shimadzu UV-200 spectrometer. Infrared spectra were measured with a JASCO IRA-1 spectrometer. ^{1}H NMR spectra were recorded on a JEOL JMN-PS-100 spectrometer. Mass spectra were recorded with a JEOL JMS-DX-300 spectrometer. Elemental analyses were performed at the Microanal ysis Center of Kyoto University.

Materials. Compound **1** was prepared from norbornadiene-2,3-dicarboxylic anhydride and *p*-substituted aniline, and the isomerized **2** was prepared by photoreaction of **1** in a similar manner reported previously.[2] Co-TPPC was synthesized according to the literature,[7] and purified by recrystallization from methanol and chloroform.

Measurements. *Quantum Yield*: An apparatus and actinometer as described previously were used.[2] A Na_2CO_3–H_2O solution of **1** was irradiated at an each wavelength and absorbance of **1** at the wavelength was measured at an appropriate time interval. According to the method described by Kaupp and Prinzbach,[6] the quantum yield was determined.

Rate Constant: After a Na_2CO_3–D_2O solution of Co-TPPC was added to a Na_2CO_3–D_2O solution of **2** in a NMR sample tube, signals of **1** and **2** were integrated at an appropriate time interval. According to the method described previously,[2] the second order rate constant in the pseudo-first order reaction was determined.

Isomerization Heat: A Na_2CO_3–H_2O solution of Co-TPPC was added to a Na_2CO_3–H_2O solution of **2** in a test tube. Heat release in the solution was measured by using a corrected copper-constantan thermocouple. After correction of the heat of mixing and the radiative heat, the isomerization heat was determined.

Synthesis of Lariat Ferrocenocrown Ethers and Their Alkali Metal Complexes

Sadatoshi AKABORI,* Yoichi HABATA, and Masaru SATO†
Department of Chemistry, Faculty of Science, Toho University, Funabashi, Chiba 274
†*Chemical Analysis Center, Saitama University, Urawa, Saitama 338*
(Received August 7, 1984)

Synopsis. Lariat ferrocenocrown ethers were synthesized by the reaction of disodium salt of 1,1′-dihydroxyferrocene with *N*-substituted bis(2-chloroethyl)amines and/or by the reaction of bis(2-chloroethoxy)ferrocene with disodium salts of *N*-substituted bis(2-hydroxyethyl)amines. Crystalline 1:1 complexes of *N*-(2-methoxyethyl)-4-aza-1,7-dioxa-[7]ferrocenophane with $LiClO_4$ and $NaClO_4$ were also isolated.

Recently, the syntheses of highly functionalized crown ethers have been described,[1] and in this connection several research groups[2] reported the syntheses and physicochemical properties of ferrocenocrown ethers. We have previously reported on both syntheses and extractability for metal cations of polythia-,[3] polyoxa-,[4] and oxathia[*n*]ferrocenophanes.[5] It was found that these compounds showed high extractability for Tl^+ and Ag^+ and low extractability for alkali and alkaline earth metal cations. However, little is known concerning oxaaza[*n*]ferrocenophanes and lariat ferrocenocrown ethers. We now wish to report on the syntheses of lariat ferrocenocrown ethers and their metal complexes.

The reaction of potassium salt of **1** with **2** gave mononuclear ferrocenocrown ether **4** and its dimer **6** in 20 and 2% yields, respectively, while the reaction of **1** and **3** gave only **5** in the range from 9 to 20% yields. The reaction of **7** with **8** in the presence of NaH and 18-crown-6 as a phase-transfer catalyst[6] gave only **11** in 5% yield, while the reaction of **7** with **9** gave the cyclized products **10** and **12** in 4 and 10% yield, respectively.

The extractability of **4** and **5** for alkali metal picrates was measured by the method described in the previous paper.[4a] All of the lariat ferrocenocrown ethers showed little extractability. However, it was found that the selectivity for alkali metal cations of **4a** increased more than that of other ferrocenocrown ethers. The extractability of **4a** toward alkali metal cations was in the following order: K^+ (3%)>Rb^+=Cs^+(2%)>Na^+(0.6%)>Li^+(0.8). Also, the extractability of the crown ethers depends on the length and kind of the side arm. Compounds **5a** and **5b**, which contained an alkyl group as a side arm, showed a lower extractability compared with **4a**, which is explained in terms of the steric hindrance of a too lengthy side arm.

In contrast with the low extractability, the complex of alkali metal perchlorate with **4a**, and **4b** was isolated quantitatively. These complexes showed a higher melting point than the corresponding ligand and were confirmed by elemental analyses to be a 1:1 complex. Compound **4a** also gave a 1:1 complex with sodium

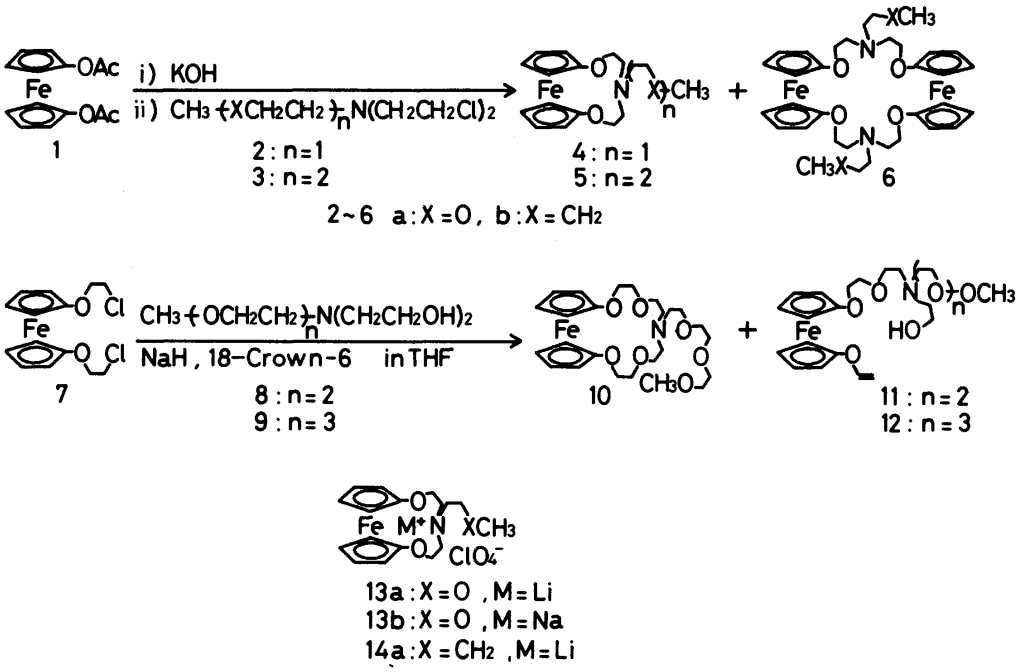
a) The mass spectra were taken on a Hitachi M-80 mass spectrometer(70eV). b) NMR spectra were recorded with tetramethylsilane as internal standard on a JEOL-FX-90Q spectrometer. c) Measured in $CDCl_3$.



perchlorate, while **4b** gave no crystalline complex. As shown in the ^{1}H-NMR spectral data in Table 1, there was only a little difference in the chemical shift between the ligand and the corresponding complex. The signals of the α- and β-protons of the ferrocene ring and the methylene protons in the complexes shifted down field as compared with those in the free ligand. A similar trend was observed on the addition of alkali metal perchlorate to a solution of ligand in acetonitrile-d_3. The tendency for this down-field shift observed here was also similar to that shown in the ^{1}H-NMR data of the polyoxa[n]ferrocenophanes and these alkali metal thiocyanate complexes.[4b]

Experimental

Reaction of 1 with 2a. **1** (2.24 mmol) was added to potassium hydroxide (12.3 mmol) in water (10 cm^3) under nitrogen, and the mixture was stirred under reflux. After 1 h, a solution of **2a** (2.69 mmol) in 60% ethanol (70 cm^3) was added at one time and the mixture was then stirred for 5 h at reflux temperature. After the usual work-up, the reaction mixture was chromatographed on silica-gel TLC (hexane–acetone). The first band gave red oil which was crystallized from hexane to give **4a** in 26% yield. Found: C, 58.90; H, 6.91; N, 4.25%. Calcd for $C_{17}H_{23}O_3NFe$: C, 59.15; H, 6.72; N, 4.06%. The second band gave **6a** as red crystals (from hexane) in 2% yield. Found: C, 58.91; H, 6.99; N, 3.60%. Calcd for $C_{34}H_{46}O_6N_2Fe_2$: C, 59.15; H, 6.72; N, 3.47%.

Similarly, reaction of **1** (6.08 mmol) with **2b** (7.24 mmol) gave **4b** and **6b** in 20 and 3% yields, respectively. **4b** Found: C, 63.25; H, 7.30; N, 4.23%. Calcd for $C_{18}H_{26}O_2NFe$: C, 62.99; H, 7.34; N, 4.07%. **6b**, Found: C, 62.81; H, 7.63; N, 4.15%. Calcd for $C_{36}H_{50}O_4N_2Fe_2$: C, 62.99; H, 7.34; N, 4.08%.

Similarly, reaction of **1** (5.23 mmol) with **3a** (6.5 mmol) gave **5a** in 20% yield. Found: C, 58.60; H, 7.12; N, 3.85%. Calcd for $C_{19}H_{27}O_4NFe$: C, 58.61; H, 7.00; N, 3.60%.

Similarly, reaction of **1** (5.0 mmol) with **3b** (5.3 mmol) gave **5b** in 14% yield. Found: C, 65.51; H, 8.34; N, 3.69%. Calcd for $C_{21}H_{31}O_2NFe$: C, 65.44; H, 8.12; H, 3.64%.

Reaction of 7 with 9. A solution of **9** (3.46 mmol) in the presence of sodium hydride (16.2 mmol) and 18-crown-6 (3.7 mmol) in THF (150 cm^3) was stirred under reflux for 10 h and then a solution of **7** (3.19 mmol) in THF (50 cm^3) was added to the mixture all at one time. After 48 h, the mixture was chromatographed on silica-gel TLC (hexane:acetone=1:1). The first band gave **10** as red oil in 4% yield. Found: C, 57.51; H, 7.72; N, 2.85%. Calcd for $C_{25}H_{39}NO_7Fe$: C, 57.57; H, 7.55; N, 2.69%. The second band gave **12** as red oil in 10% yield. Found: C, 57.82; H, 7.41; N, 2.75%. Calcd for $C_{25}H_{39}NO_7Fe$: C, 57.57; H, 7.55; N, 2.69%.

Similarly, reaction of **7** (2.91 mmol) with **8** (3.29 mmol) gave **11** as red oil in 5% yield. Found C, 58.10; H, 7.65; N, 3.18%. Calcd for $C_{23}H_{35}NO_6Fe$: C, 57.86; H, 7.40; N, 2.93%.

General Procedure for the Alkali Metal Perchlorate Complex. A solution of **4a** or **4b** (0.1 mmol) in acetonitrile (2 cm^3) was added to an acetonitrile solution (2 cm^3) containing alkali metal perchlorate (0.1 mmol). The mixture was heated for a few minutes, and allowed to stand in an ice bath. After the precipitates had been completed, the complex was filtered and then washed with a small portion of acetonitrile. **13a**: Found: C, 45.22; H, 5.16; N, 3.11%. Calcd for $C_{17}H_{23}NO_7FeLiCl$: C, 45.21; H, 5.14; N, 3.10%. **13b**. Found: C, 43.60; H, 4.99; N, 3.05%. Calcd for $C_{17}H_{23}NO_7FeNaCl$: C, 43.65; H, 4.97; N, 3.00%. **14a**. Found: C, 48.03; H, 5.67; N, 3.13%. Calcd for $C_{18}H_{25}NO_6FeLiCl$: C, 48.07; H, 5.62; N, 3.12%.

Synthesis of Pyrazolo[3,4-*d*]thiazoles†

S. V. THIRUVIKRAMAN and S. SESHADRI*

Dyes Research Laboratory, Department of Chemical Technology, Matunga, Bombay 400019, India

(Received November 29, 1983)

Synopsis. Several 5-substituted 1-phenylpyrazolo-[3,4-*d*]thiazole derivatives have been synthesized by reaction of 5-amino-3-methyl-1-phenylpyrazole-4-thiol with different reagents.

There is little information in the literature about pyrazolothiazoles although a good deal of work has been carried out on various other fused pyrazoles. This paper reports a convenient approach to the synthesis of pyrazolo[3,4-*d*]thiazoles.

Thiocyanation of 5-amino-3-methyl-1-phenylpyrazole (**1**) gave rise to the 4-thiocyanato derivative (**2**). The thiocyanato compound was readily hydrolyzed by acid to the amino thiol (**3**). This amino thiol proved to be an excellent precursor for the synthesis of pyrazolo-[3,4-*d*]thiazoles.

Reaction of the amino thiol (**3**) with acetic anhydride gave 3,5-dimethyl-1-phenylpyrazolo[3,4-*d*]thiazole(**4**). The structure of this product (**4a**) was established by its elemental analysis, mass spectrum (*m/z* at 229) and its NMR spectrum. The compound exhibited fluorescence in UV light. It was hoped that the introduction of an aromatic ring at the 5-position of the pyrazolothiazole would shift the fluorescence into the visible region.

Reaction of the amino thiol (**3**) with benzoic acid in polyphosphoric acid at high temperature gave rise to the 5-phenyl derivative (**5a**) as shown by its elemental analysis and mass spectrum (*m/z* at 291). However, this compound also exhibited fluorescence only in UV.

The amino thiol was therefore reacted with cinnamic acid in polyphosphoric acid and the expected 5-styryl derivative (**5b**) was obtained as shown by elemental analysis and infrared spectrum (absence of -NH and amide carbonyl peaks). The 5-styryl derivative (**5b**) showed pale green fluorescence in daylight.

The amino thiol (**3**) was reacted with ethyl cyanoacetate to give 5-cyanomethyl-3-methyl-1-phenylpyrazolo[3,4-*d*]thiazole (**4b**). The structure of this product was established by elemental analysis and infrared spectrum. (Chart I).

We have earlier[1] shown that *o*-cyanoarylamidines (**6**) readily cyclize with ammonium acetate to yield 4-aminoquinazoline derivative (**7**). It was therefore anticipated that a similar heterocyclization could be achieved by reacting the *o*-thiocyanato amidine (**8**) to yield the aminothiadiazepine derivative (**10**). Accordingly the 5-amino-4-thiocyanatopyrazole (**2**) was reacted with the Vilsmeier reagent (DMF/$POCl_3$) which gave the expected amidine (**8**). Hydrolysis of the amidine (**8**) under mild acidic or alkaline conditions gave mercapto amidine (**9**). Hydrolysis of the mercapto amidine with stronger acid or alkali gave rise to the amino thiol (**3**). Reaction of the thiocyanato amidine with ammonium acetate did not proceed as anticipated but gave rise to the mercapto amidine (**9**) identified by mixed mp and TLC comparison with the authentic sample. (Chart II).

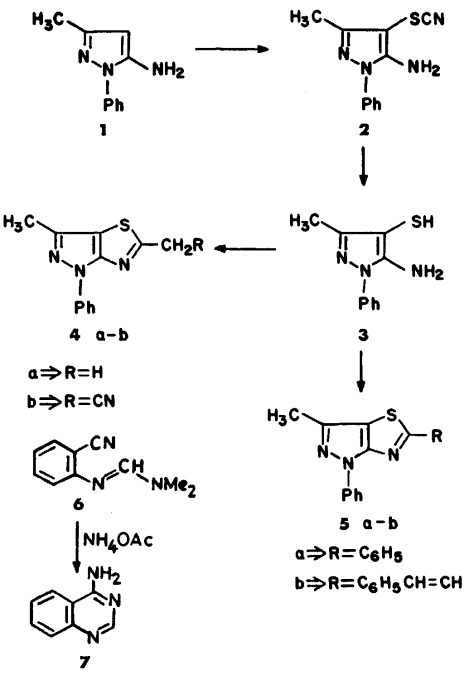

Chart I

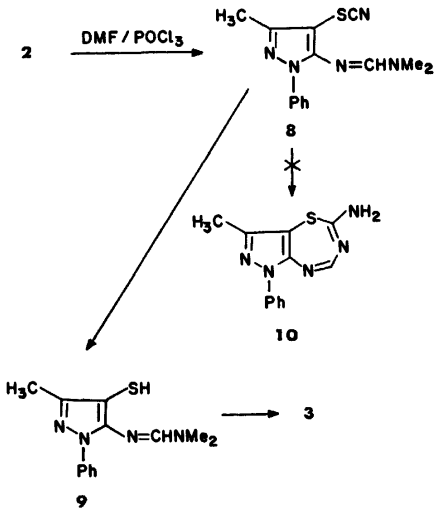

Chart II

Experimental

All melting points are uncorrected. The infrared spectra (in Nujol) were recorded on Perkin Elmer 395 spectrophotometer and ^{1}H-NMR spectra on a Varian EM-360 spectrometer. The mass spectra were recorded on Varian MAT II RS with Varian 100 e data system.

† Abstracted in part from the Ph. D. Thesis of S. V. Thiruvikraman, University of Bombay, 1981.

5-Amino-3-methyl-1-phenyl-4-thiocyanatopyrazole (2). A mixture of aminopyrazole (**1**) (0.01 mol) and potassium thiocyanate(0.03 mol) in MeOH(10 ml) was cooled to 0 °C. Under stirring Br_2(0.01 mol) in MeOH(2 ml) was added dropwise maintaining the temperature below 5 °C. The mixture was stirred for 3 h at 0—5 °C. It was then poured into ice-cold water and neutralized with Na_2CO_3 to pH 9. The yellowish brown thiocyanato compound (**2**) that separated was filtered, washed with water, and dried. The thiocyanato compound (**2**) was obtained in 89% yield and was crystallized from ethanol: mp 115 °C. Found: C, 57.4; H, 4.0, N, 24.0, S, 14.3%. Calcd for $C_{11}H_{10}N_4S$: C, 57.4; H, 4.3; N, 24.3, S, 13.9%; IR: 3300 (NH_2) and 2300 cm^{-1} (SCN).

5-Amino-3-methyl-1-phenylpyrazole-4-thiol (3). A solution of thiocyanato compound (**2**) in dilute HCl (10 ml, 10%) was stirred at room temperature for 4—5 h. The reaction mixture was neutralized with Na_2CO_3 to pH 9 and the yellowish brown compound (**3**) that separated in quantitative yield was crystallized from aqueous ethanol: mp 178 °C. Found: N, 20.4; S, 15.7%; M^+, 205. Calcd for $C_{10}H_{11}N_3S$: N, 20.5; S, 15.6%; M, 205. IR: 3300 cm^{-1} (NH_2).

3,5-Dimethyl-1-phenylpyrazole[3,4-d]thiazole (4a). A mixture of mercaptopyrazole (**3**) and Ac_2O (5 ml) was refluxed for 3 h. After pouring the reaction mixture into ice water the product (**4a**) separated in 85% yield was crystallized from ethanol: mp 148 °C. Found: N, 18.5; S, 14.0%; M^+, 229. Calcd for $C_{12}H_{11}N_3S$: N, 18.3, S, 13.9%; M, 229; ^1H NMR (TFA) $\delta=2.2$ (3H, d, 3-CH_3), 3.0(3H, d, 5-CH_3), 7.4 (5H, s, aromatic).

General Procedure for the Preparation of 5-Aryl-3-methyl-1-phenylpyrazolo[3,4-d]thiazole (5). To polyphosphoric acid (P_2O_5 7 g, H_3PO_4 3 ml) at room temperature, a mixture of 5-aminopyrazole-4-thiol (**3**) (0.005 mol) and aromatic acid (0.005 mol) was added. The reaction mixture was heated to 180 °C and maintained for 1 h. After the usual work up, the product that separated was filtered and washed with water. Thus, the 5-phenyl derivative (**5a**) was obtained in 75% yield and was crystallized from ethanol, mp 152 °C. Found: N, 14.6; S, 11.3; M^+, 291. Calcd for $C_{17}H_{13}N_3S$: N, 14.4; S, 11.0%; M, 291. Also the 5-styryl derivative (**5b**) was obtained in 80% yield and was crystallized from ethanol; mp 200 °C; Found: N, 13.5; S, 9.9%. Calcd for $C_{19}H_{15}N_3S$: N, 13.2, S, 10.1%.

5-Cyanomethyl-3-methyl-1-phenylpyrazolo[3,4-d]thiazole (4b). A mixture of 5-aminopyrazole-4-thiol (**3**) (0.005 mol) and ethyl cyanoacetate (0.005 mol) was heated in an oil bath at 150 °C for 30 minutes. The mixture was cooled, dumped into water, neutralized to pH 6 and filtered. The product was purified by passing through a short column of alumina. It was further crystallized from aqueous ethanol to give **4b** in 72% yield; mp 125 °C. Found, N, 22.1; S, 12.5%. Calcd for $C_{13}H_{10}N_4S$: N, 22.1; S, 12.5%. IR 2240 cm^{-1}(CN) and absence of NH and amide carbonyl peaks.

Vilsmeier Reaction on 5-Amino-4-thiocyanatopyrazole (2). To the Vilsmeier reagent from DMF (7 ml) and $POCl_3$(0.02 mol) at 0—5 °C, 5-amino-4-thiocyanatopyrazole(0.01 mol) was added. After half hour the temperature was raised to 70 °C and maintained for 3 h. After pouring the reaction mixture into ice water, the pH was adjusted to 9 with Na_2CO_3. The oil separated was extracted in C_6H_6 and solvent removed to obtain **8** in 80% yield. Found, N, 24.8; S, 11.2%; M^+, 260. Calcd for $C_{14}H_{15}N_5S$: N, 24.5; S, 11.2%; M^+, 260. IR 2250 cm^{-1}(SCN).

Hydrolysis of Thiocyanatoamidine (8). A mixture of thiocyanatoamidine (**8**) (1 g) and HCl (10 ml, 10%) or NaOH (10 ml, 10%) was stirred overnight. The solution was cooled and neutralized to pH 8—9, when an oil separated. The benzene extract of the oil when eluted with C_6H_6 over a neutral alumina column afforded **9** in 80% yield, crystallized as yellow crystals from ethanol; mp 110 °C. Found: N, 21.4; S, 12.4%. Calcd for $C_{13}H_{16}N_4S$: N, 21.5; S, 12.3%, IR: absence of SCN peak at 2250 cm^{-1} and presence of a weak band at 2500 cm^{-1} for SH function.

We are thankful to Dr. K Nagarajan of Ciba-Geigy Research Centre, Bombay for the mass spectra and to the Microanalytical Section for the analysis, one of us (S. V. T.) is grateful to the U. G. C., New Delhi for the award of a Junior Research Fellowship.

Kinetic and Mechanism of the Electrochemical Reduction of Fluoranthene in *N,N*-Dimethylformamide

Refat Abdel-Hamid

Department of Chemistry, Faculty of Science, Sohag, Egypt

(Received Januray 9, 1984)

Synopsis. Detailed mechanism of electrochemical reduction of fluoranthene has been studied by cyclic voltammetric method in *N,N*-dimethylformamide solution using 0.1 mol dm^{-3} tetraethylammonium perchlorate as a supporting electrolyte. It was found that fluoranthene undergoes a reversible diffusion-controlled one electron-transfer wave followed by an irreversible one-electron one. The reaction in the presence of proton donor such as phenol was also studied. The results reveal that the kinetics of the reaction is first-order in anion radical, zero-order in fluoranthene and first-order with respect to phenol. The overall reaction is of the ECE_h type. It is concluded that the mechanism of the electrochemical reduction of fluoranthene consists of (a) heterogeneous electron transfer to form an anion radical, (b) proton transfer reaction, (c) homogeneous electron transfer in which the neutral radical formed in (b) is reduced to the carbanion and finally (d) the rapid protonation of the carbanion.

Generally, the electrochemical reduction of aromatic hydrocarbons in aprotic solvents involves two one-electron successive steps yielding the anion radical and the dianion respectively.[1,2] Thus the typical cyclic voltammetry reduction pattern of aromatic hydrocarbons in aprotic solvents displays a one-electron reversible wave followed by a one-electron irreversible wave. In the presence of a proton donor such as phenol, a proton transfer reaction following the initial electron transfer step is common to the electrochemical reduction of these compounds. Although the electrochemical behaviour of aromatic hydrocarbons have been the subject of a large number of investigators,[3,4] very few studies have been done on the electrochemical reduction of fluoranthene. The only previous study includes fluoranthene as one of a series of investigated compounds,[5] detailed measurements were not reported.

The objective of the present study was detail electrochemical investigation of fluoranthene in *N,N*-dimethylformamide. Moreover, the study was extended to include the effect of proton-donor concentration on the reduction process. The kinetics and mechanism of the electrode process were proposed and discussed.

Experimental

A Princeton Applied Research Model 303 mercury-drop electrode system in (small) hanging-drop mode linked to a microprocessor-controlled polarograph with 16-bit DAC and three-channel Servoger 460 recorder was used for cyclic voltammetric measurements. The electrode area was 1.06×10^{-2} cm^2. The reference electrode was $Ag/AgNO_3$ (0.01 M) in 0.1 mol dm^{-3} tetraethylammonium perchlorate, TEAP, in *N,N*-dimethylformamide. The solutions were deoxygenated by passing pure nitrogen. The cell and referenced potentials were recorded simultaneously with current.

A. R. grade *N,N*-dimethylformamide was purified and dried using the method discribed previously[6] and stored over Linde type 4A Molecular Sieve under nitrogen atmosphere. Polarographic grade TEAP was dried under vacuum for at least 24 h and used as a supporting electrolyte. Fluoranthene (BDH) and phenol (BDH) were used.

Stock solutions of fluoranthene, 10^{-2} M, and phenol, 1.0 M, were prepared by dissolving the appropriate weights of each in appropriate volume of 0.1 M TEAP/DMF solution. Lower concentrations required were prepared by accurate dilution.

Results and Discussion

Cyclic voltammetric results of 5.0×10^{-4} M fluoranthene in a *N,N*-dimethylformamide solution containing 0.1 M TEAP for scan rates, v, of 14 to 308 mV s^{-1}, show two well-defined waves. A typical cyclic voltammogram is shown in Fig. 1 for fluoranthene. The peak current, i_p, of both waves varies systematically with varying scan rate. The ratio of the cathodic to the anodic currents, i_{pc}/i_{pa}, for the first wave amounts to 1.05 ± 0.05 through the scan rate range used (*c.f.* Table 1). It was found that the peak current for the first wave correlates with the square root of the scan rate, $v^{1/2}$, (correlation coefficient=0.998). The slopes of the straight line graph obtained on plotting i_p against $v^{1/2}$ amounts to 2.51 ± 0.01 μA s$^{1/2}$ V$^{-1/2}$ for 0.5 mM fluoranthene from which the diffusion coefficient, D, of 3.09×10^{-6} cm^2 s^{-1} is evaluated.[7] Furthermore, it is found that the potential separation, $E_{pa}-E_{pc}$, amounts to 59.6 ± 2.3 mV (where E_{pa} and E_{pc} are the anodic and cathodic peak potentials respectively) and the shape of the cyclic voltammetric wave as measured by its width $E_p-E_{p/2}$, is 56.00 ± 0.05 mV. These values are only slightly different than the theoritical values (59.1 and 56.5 mV at 25 °C for $n=1$ respectively[8]). This is probably due to a small uncompensated resistance. It is worthy to mention that the peak potential, E_p, receives no change on varying the scan rate. These facts reveal that the first wave is a reversible one electron transfer diffusion-controlled wave.

On the other hand, from the cyclic voltammograms covering the complete polarographic waves, one observes that for

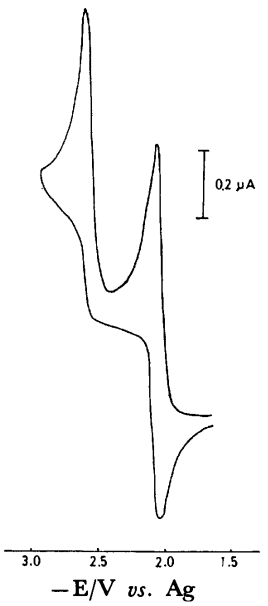

Fig. 1. Cyclic voltammogram of 5.0×10^{-4} M fluoranthene in TEAP/DMF solution at a sweep rate of 77 mV s^{-1} at HMDE.

Table 1. Cyclic voltammetric data for 5 mM fluoranthene in *N*,*N*-dimethylformamide containing 0.1 M tetraethylammonium pherchlorate solutions at 25 °C

Sweep. rate mV s^{-1}	First wave		Second wave	
	$E_p-E_{p/2}$ mV	i_{pc}/i_{pa}	i_{pc} uA	$-E_p$ mV
14	58	1.00	0.50	2612
20	58	0.98	0.46	2620
39	64	1.07	0.76	2626
77	60	1.05	1.05	2633
154	62	1.08	1.39	2640
308	62	1.12	1.90	2658

the second electrode process the anodic counterpart of the cathodic peak is lacking. This behaviour suggests that the second electron transfer is electrochemically unidirectional *i.e.* totally irreversible or is coupled to an irreversible chemical follow-up reaction. Moreover, the cathodic peak current is proportional to the square root of the scan rate (correlation coefficient=0.999) which is consistent with diffusion as the rate-limiting step.

In order to establish that the charge-transfer reaction in the cathodic reduction of fluoranthene is intrinsically slow *i.e.* the electrochemical process is totally irreversible, one can apply relation (1) between the peak potential, E_p, and the peak current, i_p, in a totally irreversible wave.[8]

$$E_p = \frac{(\ln 10)RT}{Bn_bF} \log i_p + \text{constant}. \quad (1)$$

The value of the transfer coefficient, B, obtained assuming that $n_b=1$ (0.38) bears out the total irreversibility of the second wave.

All the above results reveal that fluoranthene, *F*, undergoes a reversible one electron transfer, $E_p=2.088\pm0.003$ V, to form anion radical, $F^{\cdot-}$, followed by an irreversible second wave at higher negative potentials. The anion radicals are reasonably stable during the time of the experiments.

On the addition of proton donor, phenol, the first wave does not increase in peak current or change in the peak potential, while for the second one a change in both the peak current and the peak potential is observed.

The dependence of the peak potential, E_p on the voltage scan rate, v, during the voltammetric reduction of fluoranthene for the second wave is given by the following equation,[9]

$$dE_p/d \log v = [\ln 10/(b+1)]RT/F, \quad (2)$$

where b is the reaction order in *B*, the primary product of electron transfer reaction (3),

$$A + e \rightleftharpoons B, \quad (3)$$

the other notations are conventional. The $dE_p/d \log v$ value of fluoranthene in TEAP/DMF solutions in the presence of 50.0 mM phenol as a proton donor is measured using the linear least-square fit method of E_p *versus* $\log v$. The theoretical value of $b=1$ corresponding to the protonation reaction (4) with phenol in excess is 29.6 at 25 °C.

$$F^{\cdot-} + PhOH \longrightarrow F\cdot\text{-}H + PhO^- \quad (4)$$

It was found that value of $dE_p/d\log v$ closes to the theoretical value (30.7±3.1 mV/decade). Accordingly, one can conclude that, the reaction is first-order with respect to the primary product of the electron transfer reaction.

The dependence of E_p on the concentration of fluoranthene, C_A, is tested using equation 5, where a and i are the reaction order in A, substrate, and the products formed whice further participate in the process.[9]

$$dE_p/d \log C_A = [(a+b+i-1)/(b+1)] \ln 10(RT/F). \quad (5)$$

For the reaction (3), $a=0$, $b=1$, $i=0$, and $dE_p/d \log C_A$ is also zero. The data obtained for different concentrations of fluoranthene (5.0×10^{-4}—2.0×10^{-4} M), reveal that both a and i are zero and $dE_p/d \log C_A$ is zero as well.

It was found that E_p of the second wave depends on the concentration of the proton donor. This dependence is given by equation 6, where x is the reaction order in X(phenol) for the protonation reaction (4).

$$dE_p/d \log C_x = [(X \ln 10)/(b+1)]RT/F. \quad (6)$$

It is expected that x equals 1 and $dE_p/d \log C_x$ equals 29.6 mV/decade at 25 °C. The experimental value obtained for $dE_p/d \log C_x$ amounts to 28.4±4.3 mV/decade scan rate of 154 mV s^{-1}. This indicates that the apparent reaction order in phenol closes unity.

The rate law for the electrochemical reduction of fluoranthene on the basis of the above facts can be written as follows:

$$\text{Rate} = K_{odsd}[F^{\cdot-}][PhOH]. \quad (7)$$

The rate in equation (7) is equivalent to the following rate.[10]

$$\text{Rate} = K_{obsd}[F^{\cdot-}]^2[PhOH]/[F]. \quad (8)$$

The results obtained are consistent with the ECE_h mechanism proposed previously for the voltammetric reduction of aromatic hydrocarbons.[10] Accordingly, the electrochemical reduction reaction of fluoranthene in DMF proceeds *via* the following steps. (a) A heterogeneous reversible one electron transfer step (9) followed by (b) protonation reaction of $F^{\cdot-}$ radical anion by phenol (10), then followed by a homogeneous electron transfer (11) and finally rapid protonation of the resulting carbanion (12). The electroreduction scheme can be represented as

$$F + e \rightleftharpoons F^{\cdot-} \quad (9)$$

$$F^{\cdot-} + PhOH \longrightarrow F\cdot\text{-}H + PhO^- \quad (10)$$

$$F\cdot\text{-}H + F^{\cdot-} \rightleftharpoons F\text{-}H^- + F \quad (11)$$

$$F\text{-}H^- + PhOH \longrightarrow F\text{-}H_2 + PhO^- \quad (12)$$

This work has been performed at The University of Leeds, England. The author wishes to thank Dr. N. Taylor for the provision of facilities.

The Fast and Selective Reduction of Organic Halides by Lithium Hydrotri-s-butylborate

Sunggak KIM* and Kyu Yang YI

Department of Chemistry, Korea Advanced Institute of Science and Technology, Seoul 131, Korea

(Received January 17, 1984)

Synopsis. Lithium hydrotri-*s*-butylborate is shown to be a powerful reducing agent in its reducing abilities toward organic halides and discriminates structurally different organic halides due to the bulkiness of the reagent. Essentially complete utilization of the hydride of the reagent for the reduction of organic halides is also of synthetic significance.

The reductive dehalogenation of organic halides, one of the most fundamental reactions in organic chemistry, is often accomplished by various hydrido complex reducing agents.[1] Among many hydrido complex reducing agents for this purpose, lithium hydrotriethylborate has enjoyed its role as a source of an exceptionally powerful nucleophilic hydride in displacement reaction with organic halides after its discovery in 1973 by Brown.[2]

Although lithium hydrotri-*s*-butylborate, belonging to hydrotrialkylborates along with lithium hydrotriethylborate, has been widely used in the stereoselective reduction of cyclic and bicyclic ketones,[3] the reactivity of lithium hydrotri-*s*-butylborate toward organic halides has not been investigated. Furthermore, it was our purpose to explore the possibility of utilizing the bulkiness of the reagent for selective reduction of a variety of structurally different organic halides.

Results and Discussion

Reductions were usually carried out in tetrahydrofuran at 25 °C under nitrogen using equimolar amounts of the reagent and the substrate and reaction mixtures were maintained at 0.25 M (1 M=1 mol dm^{-3}) in the substrate and 0.25 M in the reagent unless specified. The rate of reduction was followed by GLC at appropriate intervals of time and the yield was determined by GLC using an internal standard.

First, the reactivity of lithium hydrotri-*s*-butylborate toward 1-chlorooctane was examined in order to compare with that of lithium hydrotriethylborate. Employment of 2 molar equiv of each reagent allowed complete reduction of 1-chlorooctane into octane in 4 h, indicating that the reactivity achieved with lithium hydrotri-*s*-butylborate is comparable to lithium hydrotriethylborate.[2]

It has been known that the reaction of alkyl halides with equimolar amounts of lithium hydrotriethylborate proceeds rapidly up to 50%, with further reaction being sluggish probably due to the formation of lithium hydrotriethylborate-triethylborane complex during the reduction.[4] Thus, 2 molar equiv of lithium hydrotriethylborate are required for every molar equiv of alkyl halide for the complete reduction. This phenomenon has been observed with other hydride reducing agents such as sodium borohydride[5] and lithium hydrotrimethoxyaluminate.[6] Since it is expected that the bulkiness of lithium hydrotri-*s*-butylborate would prevent the formation of lithium hydrotri-*s*-butylborate-tri-*s*-butylborane complex, the reagent was reacted with equimolar amounts of 1-chlorooctane. Indeed, the reaction proceeded smoothly, yielding octane in 78, 85, and 94% yield in 2, 4, and 8 h, respectively.

Encouraged by these results, we examined various alkyl halides with equimolar amounts of lithium hydrotri-*s*-butylborate in tetrahydrofuran at 25 °C in order to establish its effectiveness in reduction of organic halides. Simple primary alkyl halides such as 1-iodododecane and 1-bromododecane were almost instantly reduced to dodecane, whereas 1-bromooctane was generally inert toward the reagent at −78 °C and only 5% of 1-bromooctane was reduced to octane in 4 h. Thus, the reagent may be valuable for selective reduction of other readily reducible functional groups such as ketones and esters at −78 °C without simultaneous reduction on alkyl halides including relatively reactive primary alkyl bromides. Simple primary benzylic and allylic halides were rapidly and quantitatively reduced to the corresponding hydrocarbons, whereas secondary benzylic halides required longer reaction times as shown in Table 1. The simple secondary alkyl bromide like 2-bromooctane was reduced at a reasonable rate at 25 °C, whereas 2-chlorooctane was generally inert to the reagent. More sterically hindered cycloalkyl bromides such as cyclohexyl bromide and *exo*-2-bromonorbornane were extremely resistant to reduction. The analysis revealed 11% reduction of cyclohexyl bromide and the inertness of *exo*-2-bromonorbornane at 25 °C in 24 h. Unlike lithium hydrotriethylborate,[2] the low reactivity toward sterically hindered cycloalkyl bromides is attributed to the bulkiness of the reagent. The reduction of tertiary alkyl bromides did not occur and resulted predominantly in elimination in the case of 3-bromo-3-ethylheptane. Furthermore, the reagent was inert toward aryl halide like 1-bromonaphthalene at 25 °C in 24 h.

Since essentially complete utilization of the hydride of the reagent toward relatively reactive organic halides and the low reactivity toward sterically hindered organic halides have been observed in the reduction of organic halides, it is expected that employment of a stoichiometric amount of the reagent may permit selective reduction of structurally different organic halides. For selective reductions, equimolar amounts of two different organic halides were allowed to compete for a limited quantity of the reagent (1 molar equiv) at 25 °C and the results were determined by GLC analysis. 1-Bromododecane was selectively reduced to dodecane (98%) in the presence of 1-chlorooctane (1% reduction) for 5 min, whereas 1-bromododecane was selectively reduced to dodecane (96%) in the presence of 2-bromooctane (4% reduction) under the same reaction

Table 1. Reduction of organic halides with $Li[BH(s\text{-}Bu)_3]$ in THF at 25 °C[a]

Substrate	Time	Product	Yield/%[b]
1-Iodododecane	2 min	Dodecane	100
1-Bromododecane	2 min	Dodecane	99
Benzyl bromide	2 min	Toluene	100
Cinnamyl bromide	2 min	β-Methylstyrene	99
Benzyl chloride	10 min	Toluene	98
α-Methylbenzyl bromide	30 min	Ethylbenzene	99
Benzhydryl bromide	1 h	Diphenylmethane	97
1-Chlorooctane	8 h	Octane	94
1-Chlorododecane	8 h	Dodecane	90
2-Bromooctane	24 h	Octane	56
Cyclohexyl bromide	24 h	Cyclohexane	11
2-Chlorooctane	24 h	Octane	2
3-Bromo-3-ethylheptane	24 h	3-Ethylheptane	0[c]
1-Bromoadamantane	24 h	Adamantane	0
exo-2-Bromonorbornane	24 h	Norbornane	0 (5)[d]
1-Bromonaphthalene	24 h	Napthalene	0

a) The solutions were 0.25 M in the substrate and 0.25 M in the reagent. b) The yields were determined by GLC using internal standards. c) Elimination products (60%) were observed. d) The reduction was carried out at 65 °C for 24 h.

conditions. Similarly, benzyl bromide was selectively reduced to toluene (98%) without simultaneous attack on α-methylbenzyl bromide (2% reduction) at 25 °C for 5 min. However, the selectivity was somewhat decreased in the reduction of organic halides containing two bromo substituents in a molecule. 1,2-Dibromononane was reduced to a 84 : 10 mixture of 2-bromononane and nonane along with 5% of the unreacted original halide at 25 °C in 30 min.

Experimental

Lithium hydrotri-*s*-butylborate in THF was purchased from Aldrich Chemical Co. The hydride concentration (0.90 M) was determined by removing a known aliquot with a hypodermic syringe, hydrolyzing with a THF–water–glycerol mixture (1 : 1 : 1) at room temperature and measuring the hydrogen evolved. Tetrahydrofuran was distilled from sodium benzophenone under nitrogen. All glasswares were dried in a drying oven and cooled under nitrogen. All reduction experiments were carried out under nitrogen, and hypodermic syringes were used to transfer the solutions.

GLC analysis was performed on a Varian 2800 gas chromatograph with an FID detector. All analyses were carried out on 7 ft × 0.125 in† or 4 ft × 0.125 in 5% SE-30 on Chromosorb W columns.

Since the reactions performed are all similar in many respects, typical reactions will be described as specific examples.

Reduction of 1-Chlorooctane with Equimolar Amounts of Li[BH(s-Bu)$_3$] in THF. A 25 ml oven-dried flask with a magnetic stirring bar and a rubber septum under a balloon-filled atmosphere of nitrogen was immersed in a water bath at 25 °C. Then a solution of lithium hydrotri-*s*-butylborate (2.2 ml of a 0.90 M solution, 2.0 mmol) in THF was injected into the reaction flask by a hypodermic syringe, followed by the addition of a solution of decane (2.0 mmol) in THF (2.8 ml) as an internal standard. Finally, a solution of 1-chlorododecane (2.0 mmol) in THF (3 ml) was added and the reaction mixture was stirred at 25 °C. After 30 min, the reaction mixture was withdrawn with a syringe, quenched with water, extracted with ether, and analyzed by GLC. Analysis revealed the presence of 49% of octane. Similarly, aliquots were removed after 1, 2, 4, and 8 h and analyzed by GLC. Analysis revealed the presence of octane in 61, 78, 85, and 94 %, respectively.

Selective Reduction of 1-Bromododecane in the Presence of 2-Bromooctane with Li[BH(s-Bu)$_3$] in THF. A 25 ml oven-dried flask with a magnetic stirring bar and a rubber septum under a balloon-filled atmosphere of nitrogen was immersed in a water bath at 25 °C. Then a solution of 1-bromododecane (2.0 mmol) in THF (2.8 ml) was injected, followed by the addition of a solution of 2-bromooctane (2.0 mmol) and decane (2.0 mmol) in THF (2.8 ml). A solution of lithium hydrotri-*s*-butylborate (2.2 ml of a 0.90 M solution, 2.0 mmol) in THF was slowly added to the reaction flask for 1 min and the reaction mixture was stirred for an additional 4 min at 25 °C. The reaction mixture was quenched with water, extracted with ether, and analyzed by GLC. Analysis revealed the presence of 96% dodecane and 4% octane along with 4% 1-bromododecane and 95% 2-bromooctane.

Synthesis of 4-(1,5,9-Trimethyl-1-vinyl-4,8-decadienyl)catechol Dimethyl Ether

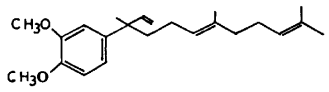
Ramesh Chander ANAND* and Harish RANJAN

Department of Chemistry, Indian Institute of Technology, Hauz Khas, New Delhi 110016, India

(Received January 23, 1984)

Synposis. Synthesis of 4-(1,5,9-trimethyl-1-vinyl-4,8-decadienyl)catechol dimethyl ether has been described utilizing Wittig reaction for the introduction of vinylic substituent at the quaternary carbon.

4-(1,5,9-Trimethyl-1-vinyl-4,8-decadienyl)catechol (**I**), a C_{21} terpenoid with novel structure has recently been isolated[1] from the hexane extracts of the roots and leaves of *Potomorphe umbellata (L)* Miq (Piperaceae*) by Kijjoa and coworkers. It has been assigned constitution (**I**) on the basis of spectroscopic studies.



(I) R=H
(Ia) R=CH3

In the present paper we wish to report a synthesis of 4-(1,5,9-trimetyl-1-vinyl-4,8-decadienyl)catechol dimethyl ether and thus corroborate the structure assigned to (**I**).

4-(1,5,9-Trimethyl-1-vinyl-4,8-decadienyl) catechol dimethyl ether (**Ia**) could be synthesized using 2-(3,4-dimethoxyphenyl)ethanenitrile (**II**) as the suitable starting compound and Wittig reaction for the introduction of vinylic substituent at the quaternary carbon-1. The scheme of the synthesis is given below: 2-(3,4-Dimethoxyphenyl)ethanenitrile (**II**) was subjected to alkylation with 9-bromo-2,6-dimethyl-2,6-nonadiene[2] in the presence of NaH-DME. The quaternary carbon could conveniently be generated by methylation of alkylated nitrile (**III**) with CH_3I in NaH-HMPA mixture. Grignard reaction of CH_3MgI on nitrile (**IV**) followed by acid hydrolysis of the crude product afforded a complex mixture as indicated by TLC. IR also did not show any significant absorption in the carbonyl region. However, nitrile(**IV**) could be converted into vinyl group through multi-step sequence of reactions (**IV**→**Ia**).

Alkaline hydrolysis of 2-(3,4-dimethoxyphenyl)-2,6,10-trimethyl-5,9-undecadienenitrile (**IV**) furnished the acid (**V**) which was esterified with CH_3I in NaH-DMF. LAH reduction of the ester (**VI**) gave the corresponding alcohol. Pyridinechlorochromate oxidation of the alcohol (**VII**) generated the aldehyde (**VIII**) which on submission to methylenetriphenylphosphorane resulted in the formation of 4-(1,5,9-trimethyl-1-vinyl-4,8-decadienyl)catechol dimethyl ether. IR and NMR of this product is in good agreement with the data reported by Kijjoa and coworkers'.

Experimental

Boiling points are uncorrected. IR spectra were recorded on Pye Unicam SP 1200 or Perkin-Elmer IR spectrophotometer. Thin liquid films were used in NaCl or KBr optics. NMR spectra were recorded in CCl_4 or $CDCl_3$ at 60 MHz Varian A60D, 90 MHz Perkin Elmer spectrometer or 100 MHz JNM-FX 100 FT-NMR spectrometer (JEOL). TMS was used as internal standard. Anhydrous Na_2SO_4 was used as drying agent. DMSO and HMPA were dried over CaH_2 and DME was dried over LAH.

2-(3,4-Dimethoxyphenyl)ethanenitrile (II). To a suspension of $SOCl_2$ (8 ml) and powdered $CaCl_2$ (0.5 g) at 35 °C was added 3,4-dimethoxybenzyl alcohol (15.0 g, 0.083 mol) in benzene (15 ml) in 1 h whereupon ether (25 ml) and $CaCO_3$ (1 g) were added. After stirring for overnight, the excess reagent was decomposed by cold water (120 ml) and then worked up in the usual manner. The solvent was distilled off and the residue was refluxed with a mixture of benzene (20 ml), NaCN (8.5 g) and water (40 ml) for 6 h. The solvent was washed with water and dried. The solvent was distilled off and the residual oil was fractionated *in vacuo* to afford nitrile (**II**, 7.7 g) in 52.7 % yield, bp 131—132 °C/2 mm, R_f 0.59 (C_6H_6 : EtOAc 9 : 1). IR: ν_{max} 2255, 1520, 1460, 1385, 1162, 1148, 1030, 810, 768, 745 cm^{-1}. NMR: δ=3.6(2H, s), 3.84 (6H, s), 6.76 (3H, s). Found: C, 68.12; H, 6.74; N, 8.1 $C_{10}H_{11}O_2N$ requires C, 67.78; H, 6.26; N, 7.9%.

* Also known as pariparoba or Caapeba and used in Brazil as popular medicine for the treatment of liver diseases or epilepsy.

0.011 mol) dissolved in DME (5 ml) was added to a stirred suspension of NaH (50 %, 0.625, 0.013 mol) in DME (8 ml) under N_2. After stirring for 1 h, a solution of 9-bromo-2,6-dimethyl-2,6-nonadiene (2.77 g, 0.012 mol) in DME (6 ml) was added to the reaction mixture. It was stirred overnight at room temperature and then heated at 50 ° for 5h. After cooling, it was poured into ice cold water (120 ml). The reaction mixture was extracted with ether (3×40 ml). The combined organic extracts were washed with brine and dried. The solvent was evaporated and the residue chromatographed on silica gel (120 g). The desired product (**III**, 1.4 g) was obtained from the elute with benzene in 40 % yield. R_f 0.76 (C_6H_6–EtOAc 9 : 1). IR: ν_{max} 2245, 1622, 1605, 1530, 1460, 1428, 1272, 1248, 1150, 1032, 850, 810, 765, 640 cm^{-1}. NMR: δ=1.56(6H, s), 1.68(3H, s), 1.8—2.16(8H, m), 3.64(1H, t, J=7 Hz), 3.84(6H, s), 5.08—5.16(2H, m), 6.76(3H, br). Found: C, 77.40; H, 9.20; N, 3.99. $C_{21}H_{29}O_2N$ requires C, 77.02; H, 8.93; N, 4.28%.

2-(3,4-Dimethoxyphenyl)-2,6,10-trimethyl-5,9-undecadienenitrile (IV). To a stirred and cooled solution of NaH(50%, 0.145 g, 3.0 mmol) in HMPA(6 ml) under N_2 atmosphere was added alkylated nitrile (**III**, 0.8 g, 2.4 mmol) dissolved in HMPA (8 ml) dropwise. It was stirred at room temperature for 1 h followed by dropwise addition of a solution of CH_3I (0.710 g, 5.0 mmol) in HMPA (4 ml) at room temperature. After stirring overnight, it was warmed to 60 °C for 2 h. Ice cold water (50 ml) was added to the reaction mixture and extracted with ether (4×25 ml). The combined ether extracts were washed with water (3×25 ml) and dried. The solvent was distilled and residual oil chromatographed on silica gel (60 g). The desired product was obtained with petroleum ether–benzene (2 : 8) as a light yellow oil (**IV**, 0.630 g) in 77% yield; R_f 0.78 (C_6H_6–EtOAc 9 : 1). IR: ν_{max} 2248, 1612, 1530, 1460, 1428, 1398, 1272, 1250, 1155, 1032, 850, 820, 730 cm^{-1}. NMR: δ=1.49(3H, s), 1.56(6H, s), 1.6—2.12(11H, m), 3.86(6H, s), 5.02—5.16(2H, m), 6.78—6.86(3H, m). Found: C, 77.82; H, 9.20; N, 4.33. $C_{22}H_{31}O_2N$ requires C, 77.37; H, 9.15; N, 4.1%.

Reaction of 2-(3,4-Dimethoxyphenyl)-2,6,10-trimethyl-5,9-undecadienenitrile (IV) with Methylmagnesium Iodide. Methylmagnesium iodide was prepared from Mg(0.1 g, 4.2 mmol) and CH_3I(0.596 g, 4.2 mmol) in ether (30 ml). To this chilled solution was added nitrile (**IV**, 0.5 g, 1.4 mmol) in ether (8 ml) with stirring. The resulting mixture was allowed to stir at room temperature overnight and then refluxed for 6 h. The reaction mixture was cooled and acidified with HCl (10%, 25 ml). After working up in the usual manner, it was dried and solvent removed. TLC of the residual oil showed it to be a complex mixture difficult to separate and IR did not show any significant absorption in carbonyl region.

2-(3,4-Dimethoxyphenyl)-2,6,10-trimethyl-5,9-undecadienoic Acid (V). To a mixture or NaOH (1.5 g) in aqueous ethanol (60%, 8 ml) was added alkylated nitrile (**IV**, 0.6 g, 1.7 mmol). The reaction mixture was heated to reflux for 26 h with stirring. After cooling the reaction mixture was poured into ice cold water (75 ml) and unreacted nitrile was extracted with ether (3×50 ml). Aqueous phase was acidified with dil HCl (20%, 30 ml) to pH ≈2. It was saturated with NaCl and extracted with ether (5×20 ml). The combined organic phase was washed with brine (3×25 ml) and dried. The solvent was evaporated and the residual oil was chromatographed on silica gel (50 g). The pure acid (**V**, 0.530 g) was procured through benzene–ethyl acetate (8 : 2) as the eluent in 86.6% yield; R_f 0.36 (C_6H_6–EtOAc 9 : 1). IR: ν_{max}. 3520—3080, 1710, 1630, 1598, 1520, 1462, 1452, 1278, 1140, 1030, 830, 742 cm^{-1}. NMR: δ=1.34(3H, s), 1.56(6H, s), 1.62(3H, s), 1.8—2.1(6H, m), 2.64(2H, m), 3.82(6H, s), 4.98—5.0(2H, m), 6.74—6.84(3H, m), 10.79 (1H, s). Found: C, 73.40; H, 8.88. $C_{22}H_{33}O_4$ requires C, 73.30; H, 8.95%.

Methyl 2-(3,4-Dimethoxyphenyl)-2,6,10-trimethyl-5,9-undecadienoate (VI). To a stirred suspension of NaH (50%, 0.067 g, 1.4 mmol) in DMF (4 ml) was added acid (**V**, 0.450 g, 1.2 mmol) in DMF (3 ml). After 30 min, a solution of CH_3I (0.340 g, 2.4 mmol) in DMF (4 ml) was added to the resulting solution. The reaction mixture was quenched by adding it to ice cold water(60 ml). It was extracted with ether (3×50 ml) and the organic layer was washed with brine (2×30 ml) and dried. The solvent was removed and oil left behind was purified by PLC in benzene–hexane (9 : 1) to give the ester (**VI**, 0.452 g) in 96.7% yield; R_f 0.6 (C_6H_6–EtOAc 9 : 1). IR: ν_{max} 1738, 1598, 1525, 1460, 1280, 1145, 1105, 1030, 820, 805 cm^{-1}. NMR: δ=1.29(3H, s), 1.56(6H, s), 1.64(3H, s), 1.66—1.88(6H, m), 2.56(2H, br), 3.6(3H, s), 3.78(6H, s), 4.96(2H, m), 6.64(3H, m). Found: C, 74.20; H, 9.00. $C_{23}H_{34}O_4$ requires C, 73.46; H, 9.15%.

2-(3,4-Dimethoxyphenyl)-2,6,10-trimethyl-5,9-undecadien-1-ol (VII). A solution of ester (**VI**, 0.4 g, 1.0 mmol) in ether (8 ml) was added dropwise at room temperature to a slurry of LAH (0.152 g, 4.0 mmol) in ether (15 ml). After refluxing for 6 h, it was decomposed with NaOH (2%, 20 ml), and worked up in the usual way. The solvent was evaporated and the residual oil was purified by PLC in benzene–ethyl acetate (9 : 1) to get the pure alcohol (**VII**, 0.28 g) in 80.9% yield; R_f 0.39 (C_6H_6–EtOAc 9 : 1). IR: ν_{max} 3560—3240, 1615, 1525, 1480—1460, 1422, 1270, 1165, 1038, 840, 790, 770 cm^{-1}. NMR: δ=1.28(3H, s), 1.56(6H, s), 1.64(3H, s), ≈1.94(6H, br), 2.28(2H, m), ≈3.6(2H, br), 3.8(6H, s), 4.96(2H, m), 6.64(3H, m). Found: C, 76.34; H, 9.40. $C_{22}H_{34}O_3$ requires C, 76.26; H, 9.89%.

2-(3,4-Dimethoxyphenyl)-2,6,10-trimethyl-5,9-undecadienal (VIII). PCC oxidation of alcohol (**VIII**, 0.2 g, 0.57 mmol) was carried out using PCC(0.170 g), fused NaOAc (0.015 g) in CH_2Cl_2 (30 ml) to afford the aldehyde (**VIII**, 0.172 g) in 87.7% yield; R_f 0.42(C_6H_6–EtOAc 9 : 1). IR: ν_{max} 2728, 1735, 1630, 1525, 1460, 1278, 1268, 1032, 828, 805 cm^{-1}.

3-(3,4-Dimethoxyphenyl)-3,7,11-trimethyl-1,6,10-dodecatriene (Ia). Reaction of aldehyde (**VIII**) with methylenetriphenylphosphorane was carried with NaH (50%, 0.052 g, 1.1 mmol) in DMSO (2.2 ml), methyltriphenylphosphonium iodide (0.458 g, 1.2 mmol) in DMSO(4.2 ml) under N_2 atmosphere. To this solution was added aldehyde (**VIII**, 0.160 g, 0.46 mmol) in DMSO (4 ml) at 10 °C. It was worked up in the usual manner and then chromatographed over silica gel (75 g). The desired product was obtained in petroleum ether–benzene (8 : 2). This was followed by PLC in benzene–hexane (6 : 4) to afford 4-(1,5,9-trimethyl-1-vinyl-4,8-decadienyl)catechol dimethyl ether (**Ia**, 0.066 g) in 42% yield; R_f 0.71 (C_6H_6–EtOAc 9.5 : 0.5). IR: ν_{max} 3110, 1600, 1518, 1447, 1378, 1280, 1128, 1020, 920, 850, 800, 760, 660 cm^{-1}. NMR: δ=1.3 (3H, s, CH_2=CH–C–C$\underline{H}_3$), 1.58[6H, s, –CH=C(C$\underline{H}_3$)$_2$], 1.67 (3H, s, C$\underline{H}_3$–C=CH–), 1.7—2.35 [8H, m, –(C$\underline{H}_2$)$_2$–CH=C(C$\underline{H}_2$)$_2$=C(CH$_3$)$_2$], 3.86 (6H, s, 2× aromatic OCH$_3$), 5.08 [4H, br, –CH=C$\underline{H}_2$ plus –C=C$\underline{H}$–plus–C$\underline{H}$=C(CH$_3$)$_2$], 5.92 (1H, br, –C$\underline{H}$=CH$_2$), 6.72 (3H, m, aromatic protons). Found: C, 81.10; H, 10.24. $C_{23}H_{34}O_2$ requires C, 80.65; H, 10.01%.

Synthesis and Characterization of Hydrazone and Azine Derivatives of Bis(cyclopentadienyl)titanium(IV)

Brij KHERA, Anand Kumar SHARMA, and Narender Kumar KAUSHIK*
Department of Chemistry, University of Delhi, Delhi-110007, India
(Received January 25, 1984)

Synopsis. Pentacoordinated hydrazone and azine derivatives of bis(cyclopentadienyl)titanium(IV) of the type $[(OC_6H_4CR:NNHR')TiCl(Cp)_2]$ and $[(OC_6H_4CR'':NN:CR''C_6H_4O)Ti(Cp)_2]$, where R=H or CH_3, R'=H, C_6H_5 or $C_6H_3(NO_2)_2$ and R''=H or CH_3, have been prepared. The products were characterized by chemical analyses, electrical conductance, IR, ^1H NMR, and electronic spectral studies.

Some hydrazone complexes and a few azine complexes of titanium have been studied.[1-4] However, no systematic study on their organometallic derivatives is available. In view of the versatile chelating ability, widespread applications and lack of data involving organometallic derivatives of titanium, it has been considered of interest to study the reactions of Cp_2TiCl_2 with the title ligands.

Experimental

Physical Measurements. Conductance measurements were made in DMSO on a Systronic Digital Direct Reading Conductivity Meter Type 304. Solid state IR spectra were recorded in KBr pellets in the 4000—200 cm^{-1} region on a Perkin-Elmer 621 grating spectrophotometer. ^1H NMR spectra were recorded in deuterated chloroform on a JEOL JNM-FX 200 Fourier Transform NMR spectrometer. Chemical shifts are expressed relative to an internal reference of TMS (1% by volume). The electronic spectra of these complexes were run on a Perkin-Elmer 4000 Å instrument.

Preparation of the Ligands. Hydrazones of salicylaldehyde and 2'-hydroxyacetophenone were prepared by the gradual addition of salicylaldehyde/2'-hydroxyacetophenone to the ethanolic solution of hydrazine hydrate, phenylhydrazine or 2,4-dinitrophenylhydrazine in equimolar ratio. Due to insoluble nature of 2,4-dinitrophenylhydrazine in ethanol, a minimum quantity of sulfuric acid was added into its ethanolic suspension to make its homogeneous solution. The mixture was stirred under reflux for half an hour and then cooled in an ice bath. The precipitate so obtained was filtered, washed with ethanol and recrystallized from hot ethanol or glacial acetic acid in case of 2,4-dinitrophenylhydrazone derivatives.

Azines were synthesized by the condensation reaction of salicylaldehyde or 2'-hydroxyacetophenone with hydrazine hydrate in 2 : 1 molar ratio in ethanol and the products were isolated in a similar manner as described for the hydrazones.

Preparation of Complexes. To a stirred solution of bis(cyclopentadienyl)titanium(IV)dichloride, $(Cp)_2TiCl_2$ (8 mmole) in 30 ml tetrahydrofuran, a solution containing 8 mmole of appropriate hydrazone or azine in 30 ml tetrahydrofuran was added slowly and the reaction mixture was refluxed for 10—12 h. It was then filtered and the volume of the filtrate was reduced to *ca.* 20 ml by evaporating the solvent under reduced pressure. The crystals of the product were precipitated by adding 80 ml petroleum ether (60—80 °C) to the concentrated filtrate. These were filtered, washed with petroleum ether and dried under vacuum. Recrystallized from dichloromethane by adding excess of petroleum ether.

Results and Discussion

The reactions involved in the preparation of hydrazone and azine derivatives of bis(cyclopentadienyl)-titanium(IV) may be represented according to equations 1 and 2, respectively as shown below:

$$(Cp)_2TiCl_2 + (HO)C_6H_4CR:NNHR' \xrightarrow[68\,°C]{THF} [(OC_6H_4CR:NNHR')TiCl(Cp)_2] + HCl \quad (1)$$

$$(Cp)_2TiCl_2 + (HO)C_6H_4CR'':NN:CR''C_6H_4(OH) \xrightarrow[68\,°C]{THF} [(OC_6H_4CR'':NN:CR''C_6H_4O)Ti(Cp)_2] + 2HCl \quad (2)$$

where R=H or CH_3, R'=H, C_6H_5 or $C_6H_3(NO_2)_2$ and R''=H or CH_3.

Table 1 lists the analytical data and physical characteristics of the complexes. The satisfactory elemental analyses support the stoichiometry assigned to these complexes. These are moderately soluble in chloroform, dichloromethane, acetone, THF and DMSO. Electrical conductance measurements in DMSO show these complexes to be non-electrolytes.

Infrared Spectra. Absorption bands indicating the presence of cyclopentadienyl groups are found at ca. 3100 cm^{-1} ν(C–H), 1450 cm^{-1} ν(C–C), 1025 cm^{-1} ν(C–H) in plane and 810 cm^{-1} ν(C–C) out of plane.[5] Apart from this, the band at 445 cm^{-1} may be assigned to ν(Ti–C_5H_5) vibrations.[6]

A strong band (due to the azomethine, >C=N– group)[7,8] at *ca.* 1630 cm^{-1} in the spectra of free hydrazone ligands is shifted to lower wave numbers (*ca.* 1600 cm^{-1}) in the complexes studied, showing the coordination of azomethine nitrogen to the metal.[9,10] The N–N frequency found at ≈940 cm^{-1} in the free ligands is shifted to higher value (≈970 cm^{-1}).

A high intensity band at *ca.* 1265 cm^{-1} in the free hydrazone ligands may be assigned to the phenolic C–O stretching.[7,8] In the complexes this band appears at ≈1290 cm^{-1}, indicating bonding of the hydrazone ligand through oxygen. Furthermore, ν(OH) band in the 3450—3390 cm^{-1} region disappears in the hydrazone complexes.

The coordination of methine nitrogen and bonding of the phenolic oxygen to the metal is supported by the appearance of two new absorption bands in the spectra of hydrazone derivatives at *ca.* 530—550 cm^{-1} and 430—470 cm^{-1}, which may be assigned to ν(Ti←N) and ν(Ti–O) vibrations,[2] respectively. Band at *ca.* 380 cm^{-1} is the characteristic of ν(Ti–Cl) vibration.[11]

TABLE 1. ANALYTICAL DATA AND PHYSICAL CHARACTERISTICS OF $[(OC_6H_4CR:NNHR')TiCl(Cp)_2]$ AND $[(OC_6H_4CR'':NN:CR''C_6H_4O)Ti(Cp)_2]$

R, R′ or R″	Yield/%	Colour	Decomp temp °C	Found (Calcd) %				
				C	H	Ti	N	Cl

R=H, R′=C_6H_5	60	Yellowish brown	152—155	65.19 (65.03)	4.74 (4.95)	11.07 (11.29)	6.51 (6.60)	8.13 (8.36)
R=H, R′=$C_6H_3(NO_2)_2$	78	Red	144—145	53.82 (53.65)	3.84 (3.69)	9.04 (9.31)	10.95 (10.89)	6.73 (6.90)
R=CH_3, R′=H	70	Pinkish red	186—187	59.46 (59.60)	5.00 (5.24)	13.09 (13.22)	7.59 (7.73)	9.64 (9.79)
R=CH_3, R′=C_6H_5	68	Yellowish brown	178—181	65.48 (65.69)	5.42 (5.25)	10.62 (10.93)	6.32 (6.39)	8.16 (8.10)
R=CH_3, R′=$C_6H_3(NO_2)_2$	73	Orange	168—170	54.74 (54.50)	4.13 (3.97)	8.61 (9.06)	10.46 (10.60)	6.81 (6.72)
R″=H	68	Light brown	156—157	69.12 (69.25)	4.67 (4.81)	11.20 (11.52)	6.70 (6.73)	—
R″=CH_3	65	Yellowish brown	142—143	70.07 (70.29)	5.30 (5.41)	10.67 (10.79)	6.16 (6.31)	—

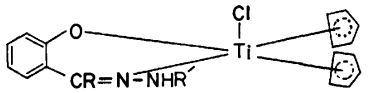
As expected, the spectra of the azine complexes do not show ν(OH), ν(NH), and ν(Ti-Cl) vibrations. The splitting and lowering of the ν(C=N) vibration suggests the coordination of one of the methine nitrogens and hence the formation of two dissimilar rings. The ν(C-O) phenolic shifts to a higher frequency and ν(Ti←N) and ν(Ti-O) vibrations appear as a result of complex formation.

Proton Magnetic Resonance Spectra. All the hydrazone compounds give four different resonance signals corresponding to (i) C_5H_5 ring protons, which appear as a sharp singlet at *ca.* δ=6.40, (ii) the -CR=N- group proton(s), appearing at *ca.* δ=8.60 (R=H); δ=3.00 (R=CH_3), show a downfield shift as compared to the corresponding free hydrazone ligands *ca.* δ=8.40 (R=H), δ=2.75 (R=CH_3), indicating deshielding as a result of coordination through the nitrogen to titanium, (iii) aromatic protons, which appear as a multiplet at ca. δ=6.70—7.80, also show a downfield shift as compared to the corresponding signals in the free ligands (observed at *ca.* δ=6.60—7.50), further supporting the coordination of nitrogen of the azomethine group to the metal, (iv) the -NH- and $-NH_2$ protons (*ca.* δ=4.85 and δ=4.30, respectively) appear at the same positions as observed for the free hydrazone ligands.

The ^{1}H NMR spectra of the azine complexes show three different resonance signals corresponding to (i) C_5H_5 ring protons, (ii) -CR″=N- group proton(s), (iii) aromatic protons, and are quite similar to the ^{1}H NMR spectra of the hydrazone complexes.

Electronic Spectra. The electronic spectra of the complexes in chloroform exhibit a single band in the region 403—412 nm in accordance to the electronic configuration (n-1)d°, ns° of titanium.[11]

Based on analytical data, general behaviour and physicochemical studies, structure I and II may be proposed to the hydrazone and azine derivatives under investigation, respectively.



R=H or CH_3; R′=H, C_6H_5 or $C_6H_3(NO_2)_2$

Hydrogenation of Carbon Monoxide on CO Reducing Catalyst and Solid Acid (III). The Effect of the Pore Size and Acid Properties of Zeolite on the Product Distribution

Hitoshi SAIMA,* Kaoru FUJIMOTO, and Hiro-o TOMINAGA
Department of Synthetic Chemistry, Faculty of Engineering, University of Tokyo, Hongo, Bunkyo-ku, Tokyo 113
(Received June 7, 1984)

Synthesis gas reactions over hybrid catalysts composed of Pd/SiO_2 and zeolites and methanol conversion on the same zeolites were studied. The selectivities to aromatic hydrocarbons were about 30% for the methanol conversions over ZSM-5, de-aluminated mordenite, and de-aluminated Y type zeolite (DAY), which possess strong acid sites. When ZSM-5 or mordenites were combined with Pd/SiO_2 and subjected to synthesis gas conversion, the selectivities to aromatic hydrocarbons were between 10% and 30%. However, the synthesis gas reaction over the hybrid catalyst composed of Pd/SiO_2 and DAY, gave few aromatic hydrocarbons, but aliphatic paraffins with 2 to 6 carbon atoms. Over large pore zeolites like DAY, the diffusion of olefins is so quick that most of the olefins come out of pores to be hydrogenated to paraffins on the Pd/SiO_2 catalyst. In contrast, because of the slow diffusion of olefins in the medium size pores of ZSM-5 or mordenite, olefins stay in the pores for long enough to form aromatic hydrocarbons on the strong acid sites before being hydrogenated.

It has been reported that synthesis gas is converted over a mixture of Zn-Cr oxides or Zr oxide and ZSM-5 at a temperature of 427 °C and a pressure of 83 atm to produce gaseous and liquid hydrocarbons rich in aromatics.[1]

Such synthesis gas reactions over hybrid catalysts composed of methanol synthesis catalysts and zeolites can mitigate the thermodynamic constraint of methanol formation because of the successive conversion, *in situ*, of the methanol to hydrocarbons over the zeolites. When a Cu-Zn-Al methanol synthesis catalyst was used in combination with H-ZSM-5 or H-Y at 10—20 atom and 250—380 °C, aliphatic hydrocarbons with 3 to 6 carbon atoms were obtained with a high selectivity, but few aromatic hydrocarbons were formed.[2] In the case of reactions over a hybrid catalyst composed of Pd/SiO_2 and ZSM-5, polymethylbenzenes were obtained with a high selectivity.[2-3] Similar studies of hydrocarbon synthesis from synthesis gas over several hydrid catalysts containing Cu-Zn-Pd and Zn-Cr catalysts have also been reported.[4-5]

This study attempted to clarify the charateristic feature of various zeolites as components of the hydrid catalysts containing Pd/SiO_2 from the standpoint of the direct synthesis of aromatic hydrocarbons from synthesis gas and to elucidate the effects of the zeolite catalyst on the product distributions.

Experimental

Catalyst Preparation and the Synthesis Reaction. A Pd/SiO_2 catalyst (Pd 4wt%) was prepared by impregnating a commercially available silica gel (Fuji Davison ID; specific surface area: 270 m^2; pore volume: 1.1cc/g; mean pore diameter: 140 Å) with palladium chloride from its acidic aqueous solution by a dry up method. Then the catalyst precursor was dried in an air oven at 120 °C for 20 h and reduced in flowing hydrogen at 400 °C for 4 h.

Na-ZSM-5 type zeolite was synthesized according to the method described in the literature.[6] H-ZSM-5 was prepared from Na-ZSM-5 by ion-exchanging with hydrochloric acid (1 M=1 mol dm^{-3}) at 70 °C for a week, followed by drying at 120 °C for 20 h and calcining at 500 °C for 3 h. The crystallinity of ZSM-5 was measured by X-ray diffractometry, which showed that it was high enough to use in this study. The other zeolites were commercially available substances. H-M(A) (Zeolon 100H mordenite from Norton Co.), H-M(B) (Zeolon 900H mordenite from Norton Co.), RE-Y (Linde type SK-500) and Linde type Aw-500 were activated by calcining at 400 °C for 3 h. H-Y, H-L, and H-X were prepared from Linde type SK-40, Linde type SK-45, and Na-X respectively by treating them 5 times with an aqueous NH_4Cl solution, followed by drying at 120 °C for 20 h and by calcining at 450 °C for 3 h. The DAY (de-aluminated Y type zeolite) was supplied by Shokubai Kasei, Inc. The DAM (de-aluminated mordenite) was prepared from Zeolon 100H (mordenite) by treating it with an aqueous hydrochloric acid solution (8 M) for 24 h. The physical and acidic characters of zeolites are listed in Table 1.

The hybrid catalyst was prepared and activated as follows: Portions of Pd/SiO_2 and zeolite of equal weights were mixed physically and then crushed to powder under an 80 mesh. Then they were pressed into a disk and finally crushed to granules with 20—40 mesh. About 2.0 g of the hybrid catalyst was placed in a tublar reactor (6 mm in inner diameter) and was activated in flowing hydrogen at 400 °C for 2 h. Then the synthesis gas reaction was conducted.

A pressurized flow type-reaction apparatus was used for the synthesis gas reaction. The apparatus was equipped with an electronic temperature controller, a furnace, a tublar reactor, a flow regulator-controller and a back-pressure regulator. All products were withdrawn from the reactor in the gaseous state and were and analyzed gas chromatographically.

For the methanol conversion experiment, zeolites were pressed into disks and crushed to granules with 20—40 mesh. H-M(B), RE-Y, and Aw-500 extrudates were crushed to granules with 20-40 mesh. About 1.0 g portion of

zeolite granules were placed in the tublar reactor and activated in the same way as that of the hybrid catalyst. The methanol reactions were conducted, using the same apparatus as that used for the synthesis gas reaction, by passing through a gaseous mixture of methanol vapor and hydrogen or nitrogen.

Determination of the Acidic Features of Zeolites. About a 200 mg protion of zeolite was put in a glass cell and then evacuated at 500 °C for 2 h. Then the first isotherm of ammonia adsorption was measured at room temperature. After evacuating for 1 h at room temperature, the second isotherm was determined. The difference between the two isotherms, which is defined as the ammount of ammonia chemisorbed, was defined as the "acidity" of the zeolite.

The temperature programmed desorption (TPD) of ammonia on zeolites was measured by heating the sample at the rate of 7.6 °C/min. The desorbed ammonia was measured with a mass spectrometer. (Anelva TE-150). A site which liberated ammonia above 300 °C was defined as a strong acid site.

Results

Acidic Features of the Zeolites. Figures 1,2,3, and 4 show the TPD spectra of ammonia for various zeolites, where θ is the coverage and T is the desorption temperature. It should be noted that the vertical axes $(-d\theta/dT)$ of the Figures indicate the fraction of desorbed ammonia at each temperature, therefore, the integration of each spectrum for all the temperature range is unity. The acidities of the various zeolites, as measured by means of the ammonia chemisorption, are shown in Table 1. As has previously been reported,[2] the spectrum of H-ZSM-5 has two peaks; one is at around 100 °C, and the other is at around 350 °C. The spectrum of H-M(A), similarly to H-ZSM-5, has a low temperature peak at around 100 °C and a high temperature peak at around 350 °C. In the case of DAM, the acidity is apparently smaller than that of the parent mordenite (Table 1), and both the peaks of TPD were shifted to temperatures higher by about 100 °C. These facts indicate that the acid strength of mordenite was promoted by the extraction of aluminium. Although the acidity of H-Y is large, its TPD spectrum shows only one peak, at around 100 °C, indicating that the amount of strong acid sites is quite small. RE-Y, which contains a rare earth metal ion, exhibits a spectrum

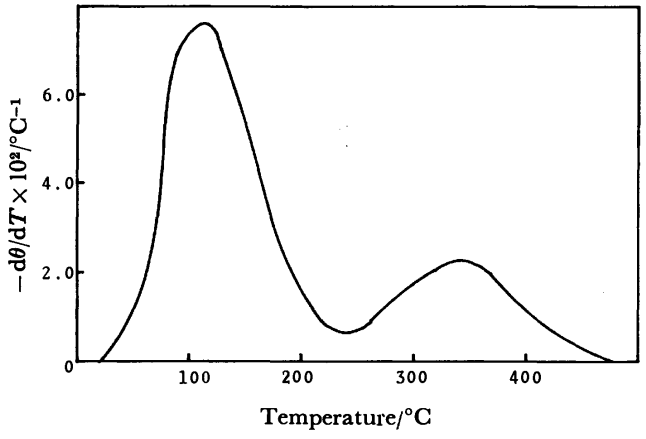

Fig. 1. TPD Profiles of NH_3 from H-ZSM-5.

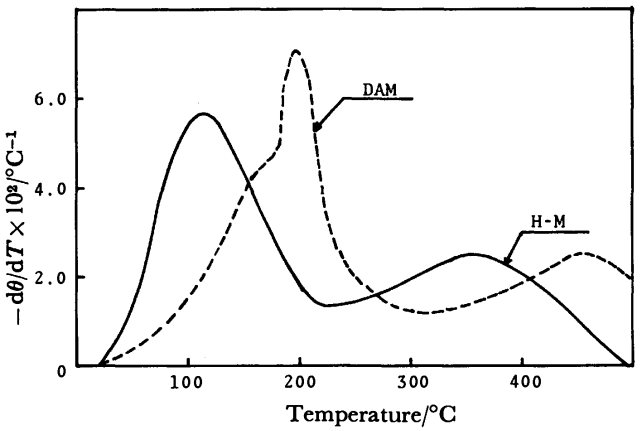

Fig. 2. TPD Profiles of NH_3 from Mordenites.

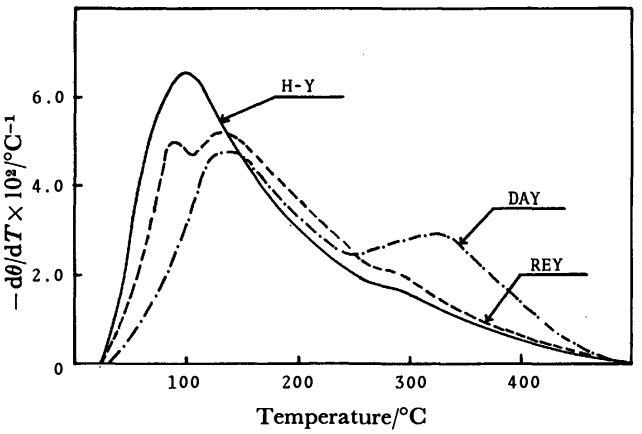

Fig. 3. TPD Profiles of NH_3 from Y Type Zeolites.

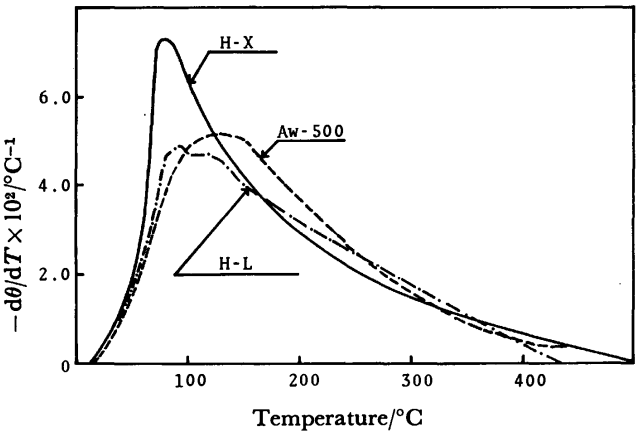

Fig. 4. TPD Profiles of NH_3 from Various Zeolites.

Table 1. Physical and acidic characteristics of zeolites used

Zeolite	Acidity (mmol/g)	Content of aluminium (mmol/g)	SiO_2/Al_2O_3 molar ratio	Fraction of strong acid sites (%)	Pore size (Å)[a]

similar to that of H-Y. DAY, whose acidity is smaller than that of H-Y, as is demonstrated in Table 1 shows a TPD spectrum with two peaks; one is at around 130 °C, and the other is at around 330 °C. It indicates that strong acid sites were generated by extracting aluminium. The TPD spectra of Aw-500, H-X, and H-L exhibit single peaks at around 100 °C.

Reaction of Methanol. Products from methanol conversion over the zeolites, which were measured at 3—4 h after the start of the reaction, are shown in Table 2 and they may be summarized as follows:

(1) Every zeolites tested except H-M(B) and H-Y gave aromatic hydrocarbons with selectivities of around 30% (carbon base).

(2) The C_2 and C_3 hydrocarbons were composed of both olefins and paraffins.

(3) De-aluminated zeolites (DAY and DAM) gave aliphatic hydrocarbons with a higher molecular weight and aromatic hydrocarbon with a higher selectivity, compared with their parent zeolites.

(4) All zeolites gave C_4 paraffins rich in iso-butane.

(5) While the major aromatic hydrocarbons obtained with H-ZSM-5 were di- or trimethylbenzenes, the main aromatics formed over DAM and DAY were C_{11} aromatics and C_{12} aromatics (mostly pentamethylbenzene and hexamethylbenzene respectively).

(6) Every zeolite tested except H-ZSM-5 lost its activity within a few hours.

TABLE 3. CONVERSION OF CO OVER Pd/SiO_2 CATALYSTS

Temperature °C	Yield[a]			
	MeOH	H.C.	CO_2	DME
250	2.3	0.02	—	—
280	4.8	0.1	—	—
300	4.2	0.2	—	—
330	1.8	0.6	0.6	0.17
350	0.8	1.1	1.0	0.23
370	0.7	1.2	1.4	0.33

a) Yield in mol% of carbon monoxide fed, 21 atm, W/F=5 g-cat·h/mol, $H_2/CO=2$,

(7) The excess hydrogen in the product hydrocarbon (H/C>2) indicates that a large amount of carbonaceous material (coke) was deposited on all the zeolites except ZSM-5 during the reaction.

(8) The facts that over DAY, which possesses a fairly large amount of strong acid sites, aromatic hydrocarbons were formed whereas H-Y, which possesses few strong acid sites, gave no aromatic hydrocarbons, are consistent with the suggestion that aromatic hydrocarbons are formed on the strong acid sites.[8]

Methanol Synthesis with Pd/SiO_2. The methanol synthesis activity of the Pd/SiO_2 used in this study is shown in Table 3. The maximum methanol yield was obtained at around 300 °C. Above 300 °C, the yield of methanol decreased markedly with increase in the temperature, presumably because of the thermodynamical limitation. The yields of oxygenates (methanol plus dimethyl ether) and hydrocarbons (90% methane, and the rest, ethane) were about 1.0% and 1.1% respectively at 350 °C, where the synthesis gas reactions were mostly studied.

Synthesis Gas Conversion over the Hybrid Catalysts. The results of synthesis gas conversion with the hybrid catalysts composed of the Pd/SiO_2 and various zeolites are shown in Table 4. The data were examined with particular attention paid to (1) the catalytic activity, (2) the carbon number distribution

of product hydrocarbon, (3) the selectivity to aromatic hydrocarbons, and (4) the content of olefin and branched products in aliphatic hydrocarbons.

The yields of hydrocarbons on the hybrid catalysts were in the range of 3—15%, much higher than those of methanol on the Pd/SiO_2 catalyst alone. For each hybrid catalyst, the main product was hydrocarbon. Small amounts of oxygenates, mainly methanol and dimethyl ether, were also formed when H-L and H-X were combined with the Pd/SiO_2 catalyst.

The selectivities of aromatic hydrocarbons lie between 0—30%, depending on the zeolites used. These results will be discussed later. There are two peaks in the carbon number distribution of the product hydrocarbons; one is at C_2 or C_3 (aliphatic hydrocarbons), while the other is at C_{10} or C_{11} (aromatic hydrocarbons). For the catalysts which contain Y type zeolite as one component, the products were mostly aliphatic hydrocarbons with 1 to 4 carbon atoms. It is worthwhile to note that the conversion of synthesis gas on the hybrid catalysts composed of DAY and Pd/SiO_2 gave few aromatic hydrocarbons, whereas the conversion of methanol on DAY gave hexamethylbenzene with fairly high selectivities.

The data of the olefin contents of C_2 and C_3 hydrocarbons shown in Table 4 indicate clearly that the formation of olefins is quite small on the hybrid catalysts. However, methanol is converted into olefins at a fairly high selectivity on the zeolites, as is exemplified in Table 2. The low selectivity of olefins in the case of synthesis gas conversion is attributed to the hydrogenation of olefins on the Pd/SiO_2 catalyst, as has already been indicated by the present authors.[3]

The *iso*-C_4/*n*-C_4 ratio, representing the degree of chain branching of aliphatic hydrocarbons, lies between 0 and 1.1, and it depends strongly on the zeolite employed.

Discussion

Formation of Lower Paraffins. A comparison of the data in Tables 2 and 4 shows that the selectivities to lower paraffins in the synthesis gas reaction over hybrid catalysts are higher than those of methanol conversion over zeolite catalysts. As has already been mentioned,[3] the products of the synthesis gas reaction over the hybrid catalysts are seriously influenced by the hydrogenation of olefins on the Pd/SiO_2 catalyst along the path shown in Fig. 5. Lower olefins, which are the key intermediates from methanol to aromatic hydrocarbons, are hydrogenated over the Pd/SiO_2 catalyst to inert paraffins, which are stable under the present reaction conditions. Thus, the selectivities to lower paraffins are higher for the synthesis gas reaction than for the methanol conversion on zeolites alone.

Formation of Branched Chain Paraffins. It is apparent from the data shown in Tables 2 and 4 that the *iso*-C_4/*n*-C_4 ratios in the products of synthesis gas reaction are smaller than those of methanol conversion. The low value of the *iso*-C_4/*n*-C_4 ratio in the products of synthesis gas reactions are also attributable to the hydrogenation of olefins on the Pd/SiO_2 catalyst. Most paraffins are formed through the hydrogenation of olefins on the Pd/SiO_2 catalyst, as has been described above. Since the skeletal isomerization of olefins can be assumed to be very fast over a zeolite catalyst, the composition of olefins should be at equilibrium. Therefore, the formations of linear and branched paraffins are on the same level if the hydrogenation reactivities of both olefins are on the same level, because the *iso*-C_4H_8/*n*-C_4H_8 ratio is not high at the equilibrium state.

In contrast, paraffins are thought to be formed, during the methanol conversion on zeolite, by hydrogen transfer,[8] that is, carbonium ions on the zeolite pick up hydride ions from other hydrocarbons during the formation of aromatics or coke. Because of the higher stability of the tertiary carbonium ion, its concentration would be higher than that of the secondary carbonium ion; thus, the formation of branched hydrocarbon would be predominant. The models of both reaction paths are shown in Fig. 6.

The ratios of *n*-C_4 to *iso*-C_4 in the products from synthesis gas *vs.* the pore diameter of zeolites or the super-cage size of faujasites (H-X, H-Y, and DAY) shown in Fig. 7 indicate that the selectivity to *iso*-C_4 is higher for the zeolite with larger pores. This fact is interpreted in terms of the shape selectivity of zeolites. That is, the formation of bulky *iso*-C_4 (5.6 Å)[9] is hard in small pore zeolite such as Aw-500, whose pore diameter is about 4 Å. It should also be noted that the ratios of *iso*-C_4 to *n*-C_4 in the C_4 paraffins obtained over the catalysts containing DAM or DAY are lower than those for the catalysts containing their parent zeolites, which possess a larger acidity.

Formation of Aromatic Hydrocarbons. Figure 8 shows how the selectivity of aromatic hydrocarbons correlates to the fraction of strong acid sites and the pore diameter of zeolite. It clearly shows that aromatic hydrocarbons are formed only with the hydrid catalysts containing the zeolites whose fractions of strong acid

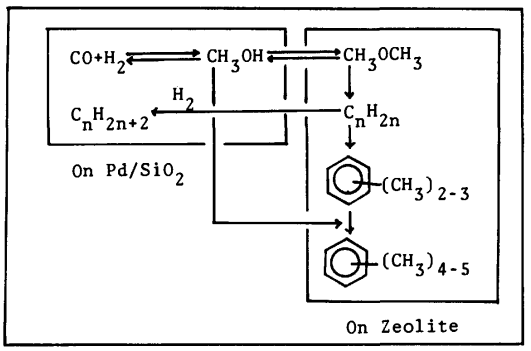

Fig. 5. Reaction Scheme on Hybrid Catalysts.

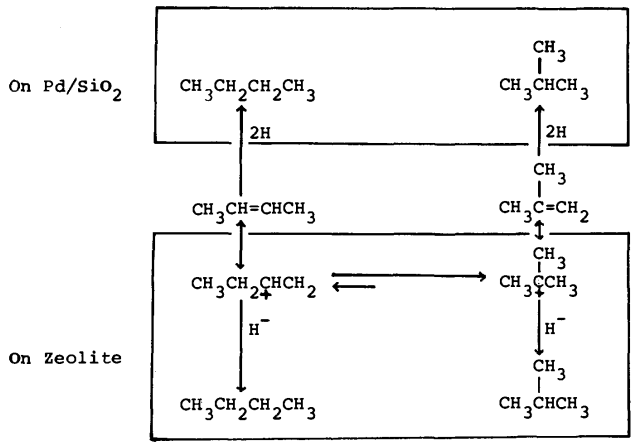

Fig. 6. Chain Branching.

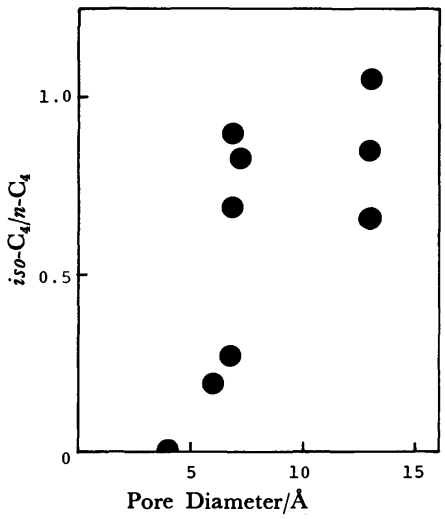

Fig. 7. A Ratio of *n*-C_4 to *iso*-C_4 *vs.* Pore Diameter.

site are higher than 20% and whose pore diameter lie between 6 and 7 Å. It should be noted that there is no relationship between the amount of strong acid sites and the selectivity to aromatic hydrocarbons. For example, the amounts of strong acid site of H-ZSM-5 and H-Y are 0.45 and 0.47 mmol/g respectively. On the hybrid catalyst containing H-ZSM-5, synthesis gas gave aromatic hydrocarbons with a high selectivity, while no aromatic hydrocarbons were formed on the H-Y containing catalyst. The hydrid catalyst containing H-M(A), whose amount of strong acid site is 1.22 mmol/g, gave aromatic hydrocarbons with a selectivity of around 10%, while the hybrid catalyst containing DAM, whose amount of strong acid sites is 0.57 mmol/g, gave aromatic hydrocarbons with a selectivity of around 20%.

Again, the formation of aromatic hydrocarbons is strongly related to the fraction of strong acid sites (Figure 8). This fact is interpreted as follows: The methanol formed on the Pd/SiO_2 is converted to olefins on both weak and strong acid sites.[10] Some of the olefins formed are converted to aromatic hydrocarbons

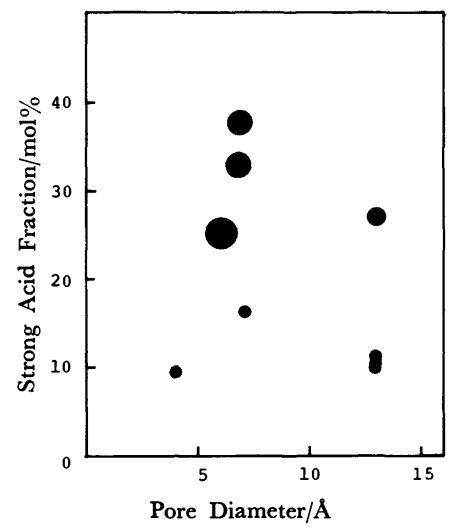

Fig. 8. Strong Acid Fraction and Selectivity to Aromatic Hydrocarbons *vs.* Pore Diameter.
●: Selectivity to Aromatics was more than 20%.
●: Selectivity to Aromatics was between 10% and 30%.
● : Selectivity to Aromatics was between 0% and 10%.
● : Selectivity to Aromatics was 0%.

on the acid site, while others are hydrogenated to the inert paraffins by means of hydrogen transfer on both weak and strong acid sites or by catalytic hydrogenation on the Pd/SiO_2. Consequently, the product distribution is controlled by the relative rate of aromatization and hydrogenation. Therefore, the fraction of strong acid sites (or the ratio of the amount of strong acid sites to that of weak acid site) is an important factor in determining the selectivity to aromatic hydrocarbons.

It is also shown the selectivity to aromatic hydrocarbons is strongly related to the pore diameter of the zeolite contained in the hybrid catalysts. It is strange that DAY gives few aromatic hydrocarbons when it is combined with Pd/SiO_2 and subjected to synthesis gas reaction although it has enough strong acid sites to produce aromatic hydrocarbons from methanol, as is shown in Table 2. This is also interpreted in terms of the diffusion of olefins from the zeolite pores to the Pd/SiO_2 and the successive hydrogenation to inert paraffins on it.

As is shown in Fig. 9, olefins formed from methanol on the zeolite can not be converted into aromatic hydrocarbons on a small pore zeolite like Aw-500, as is demonstrated in Table 4, where it is hard for even *iso*-C_4 to be formed. Thus, olefins are hydrogenated to inert paraffins on the palladium catalyst without being converted to aromatic hydrocarbons. In the case of the hybrid catalysts containing large pore zeolites, like DAY, which have the ability to form aromatic hydrocarbons, the diffusion of olefins is so quick that most of them come out of the pores before being converted into

aromatics, and they reach the palladium catalyst, where they are easily hydrogenated to paraffins. By contrast, in the case of zeolite with medium size pores (6—7 Å), like ZSM-5 or mordenites, olefins stay in the pores for long enough to be converted into aromatic hydrocarbons over the strong acid sites before being hydrogenated to paraffins, because of the slow diffusion of olefins in the pores. Although H-L has a medium size pore (7.1 Å), the fraction of strong acid sites is not enough to form aromatic hydrocarbons. Therefore, olefins formed in the pore will slowly diffuse to the Pd/SiO_2 catalyst without being converted into aromatic hydrocarbons and then hydrogenated to inert paraffins.

The product distribution obtained by methanol conversion on ZSM-5 and DAM and by synthesis gas conversion on the hybrid catalysts containing ZSM-5 and DAM are compared in Fig. 10. It is apparent that, over both catalysts, the aliphatic hydrocarbons formed from synthesis gas are lower in molecular weight than those obtained by methanol conversion and that aromatic hydrocarbons are more highly methylated in the synthesis gas conversion. These characteristics can be attributed to the hydrogenation of lower olefins and to the successive methylation of product methylbenzenes, which have previously been indicated by the present authors.[3]

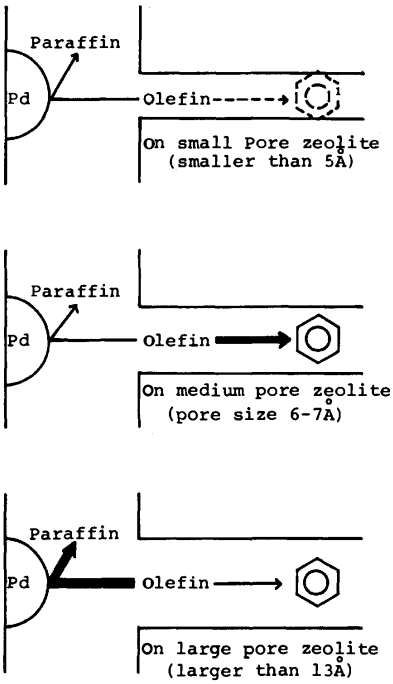

Fig. 9. Effect of Pore Diameter on Formation of Aromatic Hydrocarbons.

Conclusion

The conversion of synthesis gas over hybrid catalysts composed of Pd/SiO_2 and zeolites gave the following conclusions:

(1) The main hydrocarbons formed are C_1—C_3 paraffins and polymethylbenzenes,

(2) The ratio of linear to branched paraffins in the product hydrocarbon is higher for zeolites with larger pores and larger acidities,

(3) The extraction of aluminium in zeolites is effective for increasing strong acid sites, which is essential for the formation of aromatic hydrocarbons,

(4) Aromatic hydrocarbons are formed over the zeolites whose strong acid fraction is higher than 20% of the total acid sites and whose pore size lies between 6 and 7 Å.

The Conformations of (Z)-2,3,4,7,8,9-Hexahydrooxonin and (Z)-Cyclononene. X-Ray Structure Determinations of Isolaurallene and Neolaurallene, and Force-Field Calculations

Akio FURUSAKI,* Shin-ichiro KATSURAGI, Katsunao SUEHIRO, and Takeshi MATSUMOTO
Department of Chemistry, Faculty of Science, Hokkaido University, Kita-ku, Sapporo 060
(Received August 6, 1984)

The molecular structures of isolaurallene and neolaurallene, diastereomeric nonterpenoids ($C_{15}H_{20}O_2Br_2$) from the red algae *Laurencia*, have been determined by X-ray crystallographic analysis. The crystal data are as follows: isolaurallene, orthorhombic, space group $P2_12_12_1$, a=10.393(2), b=27.824(4), c=5.397(1) Å, Z=4, D_c=1.669 g cm^{-3}; neolaurallene, monoclinic, space group $P2_1$, a=13.338(7), b=4.929(1), c=12.435(5) Å, β=98.22(4)°, Z=2, D_c=1.609 g cm^{-3}. The structures were solved by the heavy-atom method, and refined by the block-diagonal least-squares method; the final R-values were 0.076 and 0.069 respectively. The (Z)-2,3,4,7,8,9-hexahydrooxonin rings in the two substances possess essentially the same conformation. The MM2 force-field calculations have shown that this conformation is almost identical to the most stable one of the 11 minimum-energy conformations found for (Z)-2,3,4,7,8,9-hexahydrooxonin. For comparison, the conformations of (Z)-cyclononene have also been examined by the force-field calculations. Of its 10 minimum-energy conformations obtained, the asymmetric one which Favini *et al.* already studied has the lowest energy.

In the force-field calculations for (Z)-cyclononene (**2**), Favini *et al.* considered six conformations, *i.e.*, the chair-chair (CC), boat-chair (BC), chair-boat (CB), boat-boat (BB), twist chair-chair (TCC), and asymmetric (AS) conformation.[1] Since (Z)-2,3,4,7,8,9-hexahydrooxonin (**1**) can have the same molecular symmetry (C_S or C_2) as **2**, it may have conformations similar to those of **2**. We have recently carried out X-ray crystal structure analyses of two natural products, isolaurallene (**3**)[2] and neolaurallene (**4**),[3] and have found that the conformations of the nine-membered ether rings in **3** and **4** resemble each other, and that they differ essentially from any of the six conformations considered by Favini *et al.* It is of great interest to compare the stability of this new asymmetric (NAS) conformation with those of the other conformations. Thereupon, we have performed empirical force-field calculations for **1** and **2**. The present paper describes the X-ray structure determinations and molecular geometries of **3** and **4**, and discusses the results of the force-field calculations.

Experimental

X-Ray Structure Determination of Isolaurallene (3). Colorless, needle-like crystals of **3** were kindly provided by Prof. E. Kurosawa. A single crystal cut into a cube with an edge of *ca.* 0.3 mm was used for the X-ray measurement. The crystal data were as follows: $C_{15}H_{20}O_2Br_2$, mol wt 392.13, orthorhombic, space group $P2_12_12_1$, a=10.393(2), b=27.824(4), c=5.397(1) Å, Z=4, D_c=1.669 g cm^{-3}, μ(Mo $K\alpha$)=51.4 cm^{-1}. The unit-cell dimensions and reflection intensities were obtained on a Rigaku four-circle diffractometer at the Ultra High Intensity X-Ray Diffraction Laboratory of Nagoya University, using graphite-monochromated Mo $K\alpha$ radiation (λ=0.71073 Å). The θ–2θ scanning mode was employed at a θ scan rate of 6° min^{-1}; the background was measured for 5 s at each end of the scan range. Three standard reflections, measured at intervals of every 200 reflections, showed no significant decrease in intensity during the course of data collection. The intensities were corrected for the Lorentz and polarization factors, but not for the absorption or the extinction effect. In the range of 2θ values up to 50°, 1091 unique structure factors above the $3\sigma(F)$ level were selected for the structure determination.

The structure was elucidated by the heavy-atom method, and refined by the block-diagonal least-squares method with anisotropic temperature factors. The absolute configuration was determined by Hamilton's method;[4] the R-factor ratio for the two enantiomeric structures, 1.045, excluded one of them at the 99.5% confidence level. After all the hydrogen atoms had been located in a difference Fourier map, further

least-squares refinements were carried out including the hydrogen atoms with the same fixed isotropic temperature factors of 4.5 Å^2. For these refinements, the following weighting scheme was used:

$$w = 1/\{\sigma(F)^2 \exp(c_1X^2+c_2Y^2+c_3XY+c_4X+c_5Y)\},$$

where $X=|F_o|$ and $Y=\sin\theta/\lambda$. The c_1, c_2, c_3, c_4, and c_5 coefficients were evaluated from the $(\Delta F)^2$ distribution; $c_1=0.237\times10^{-5}$, $c_2=-10.3$, $c_3=-0.877\times10^{-3}$, $c_4=0.142\times10^{-2}$, and $c_5=5.69$. The final R-value was 0.076. The atomic parameters thus obtained are listed in Table 1.[5] The bond distances and angles and the ring torsion angles are given in Table 2 and Fig. 1(a) respectively.

a) $B_{eq}=8\pi^2(u_1^2+u_2^2+u_3^2)/3$, where u_i is the root-mean-square deviation in the i-th principal axis of the thermal ellipsoid.

The calculations for the X-ray study were performed using our own programs. The atomic scattering factors and anomalous-dispersion corrections were taken from the International Tables.[6]

X-Ray Structure Determination of Neolaurallene (4). Colorless, needle-like crystals of **4** were also supplied by Prof. E. Kurosawa. The sample used for the X-ray experiment had dimensions of *ca.* 0.3×0.4×0.5 mm^3. The crystal data were as follows: $C_{15}H_{20}O_2Br_2$, mol wt 392.13, monoclinic, space group $P2_1$, $a=13.338(7)$, $b=4.929(1)$, $c=12.435(5)$ Å, $\beta=98.22(4)°$, $Z=2$, $D_c=1.609$ g cm^{-3}, μ(Mo $K\alpha$)=49.5 cm^{-1}. The cell dimensions and diffraction intensities were measured on a Rigaku four-circle diffractometer at the High Brilliance X-Ray Laboratory of Hokkaido University, using graphite monochromated Mo $K\alpha$ radiation (λ= 0.71073 Å). The $\theta-2\theta$ scan teachnique was applied at a θ scan speed of 4° min^{-1}; the background was counted for 10 s at each end of the scan range. The intensities of three standard reflections, measured at intervals of every 100 reflections, decreased rapidly during the course of data collection; the final-intensity/initial-intensity ratios were *ca.* 0.56—0.68. The intensities were corrected for this damage to the sample as well as for the Lorentz and polarization factors, but not for the absorption or the extinction effect.

The e.s.d.'s given in parentheses refer to the last decimal position.

In the range of 2θ values up to 50°, 1002 independent structure factors above the $3\sigma(F)$ level were selected for the structure determination.

The structure was solved by the heavy-atom method. After the structure had been well refined by the block-diagonal least-squares method with anisotropic temperature factors, the absolute configuration was assigned by Bijvoet's method.[7] Twenty sets of hkl, $\bar{h}k\bar{l}$, $h\bar{k}l$, and $\bar{h}\bar{k}\bar{l}$ reflections having large values of $||F_c(hkl)|-|F_c(\bar{h}\bar{k}\bar{l})||/\sigma(F)$[8] were selected for this purpose. The signs of the corresponding observed and calculated values of $\{|F(hkl)|+|F(\bar{h}k\bar{l})|-|F(h\bar{k}l)|-|F(\bar{h}\bar{k}\bar{l})|\}/2$ were in agreement with each other for all the 20 sets of reflections. The absolute configuration thus determined was supported also by the R-factor ratio for the two enantiomeric structures, 1.010.[4] Since a difference Fourier map revealed all the hydrogen atoms, further least-squares refinements were performed including the hydrogen atoms with the same fixed isotropic temperature factors of 5.7 Å^2. A weighting scheme similar to that for **3** was used; $c_1=-0.107\times10^{-2}$, $c_2=32.3$, $c_3=-0.144$, $c_4=0.160$, and $c_5=-29.4$. In this manner, the R-value reached 0.069. The final atomic parameters are listed in Table 3.[5] The bond distances and angles and the ring torsion angles are given in Table 4 and Fig. 1(b), respectively.

Force-Field Calculations. The force-field calculations were performed using the MM2 program.[9] In the force-field calculations for **2**, Favini *et al.* assumed the C_S or C_2 symmetry for the whole or part of the molecule.[1] Since, however, there appeared to be no valid reason for having such symmetry, in our MM2 calculations, no symmetry was assumed for either **1** or **2**. As a result, it was found for **1** and **2** that, although the symmetric CB and BC conformations correspond to energy minima, the symmetric CC, BB, and TCC conformations correspond to energy maxima, and that, in order to reach energy minima, they must be considerably deformed. With respect to the plane which divides the molecule into two equal parts, the arrangements of the signs of the ring torsion angles in the CB, BC, CC, and BB minimum-energy conformations keep antisymmetric, while those in the AS, NAS, and TCC minimum-energy conformations are neither symmetric nor antisymmetric. Therefore, in this paper, the former four are still referred to as conformations CB, BC, CC, and BB, respectively, and the latter three are called conformations AS1, AS2, and AS3, respectively. In the course of the examination of the interconversions among the conformers of **1**, four additional minimum-energy conformations (AS4, AS5, AS6, and AS7) were obtained. As for **2**, a total of 10 minimum-energy conformations were found. Each of these conformations had the same arrangement of the signs of the ring torsion angles as the corresponding conformation of **1**. The AS6 conformation of **2** was found not to correspond to an energy minimum. When this conformation was optimized, it changed into a new minimum-energy conformation. However, because of the extremely-high strain energy (213

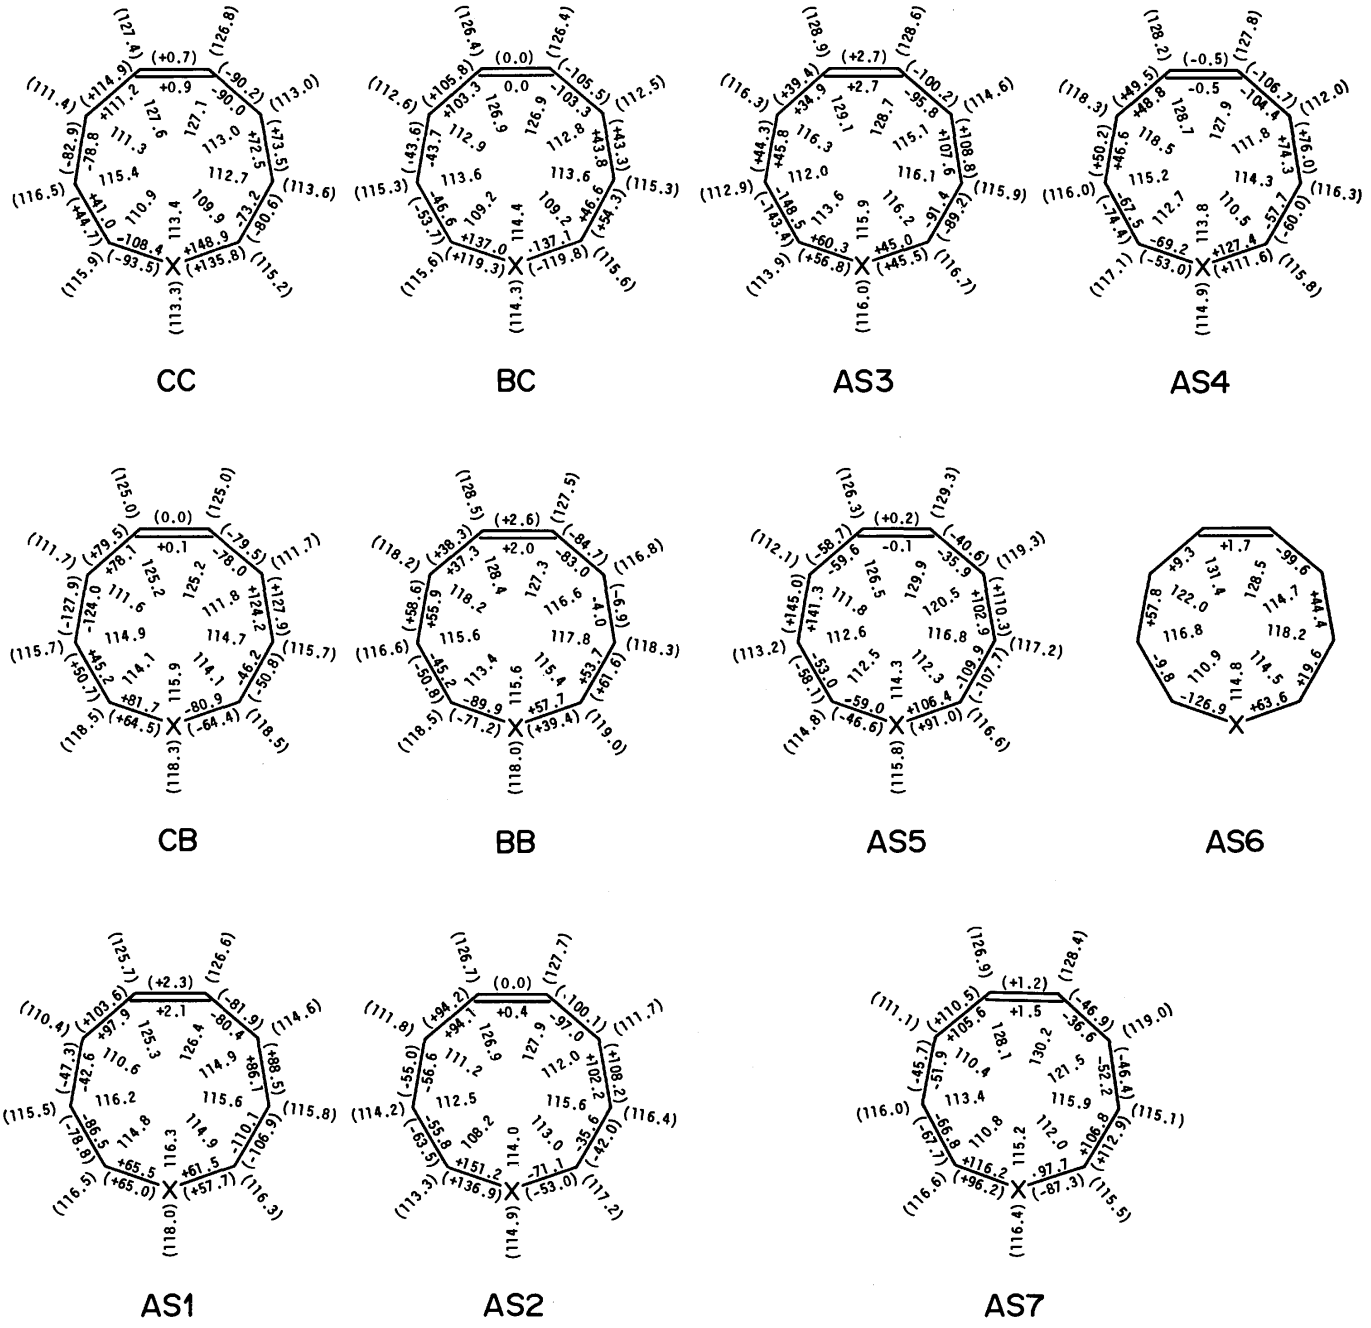

Fig. 2. The bond angles and ring torsion angles (ϕ/°) in (*Z*)-2,3,4,7,8,9-hexahydrooxonin (**1**, X=O) and (*Z*)-cyclononene (**2**, X=CH_2). The values for **2** are given in parentheses.

kJ mol^{-1} relative to AS1), this new conformation was not reckoned among minimum-energy conformations of **2**. The bond angles and ring torsion angles in the 11 different conformations are shown in Fig. 2.

Such interconversions among the conformers of **1** as could be accomplished by a change of one ring torsion angle were studied by the MM2 calculations. Each time the torsion angle used as a conversion parameter was changed by 5°, the strain energy of the molecule was minimized under the condition that this torsion angle should be fixed at the given value. From the energy profile thus obtained, the energy barrier to the conversion was estimated. The reversibility of the conversion was judged according to whether or not the energy change was continuous throughout the conversion. The results are summarized in Fig. 3.

Results and Discussion

(Z)-2,3,4,7,8,9-Hexahydrooxonin (1). The present study has revealed that there are at least 11 minimum-energy conformations of **1** (see Fig. 2). As can be seen from Table 5, the AS2 conformation is the most stable, and has a lower energy than the next most

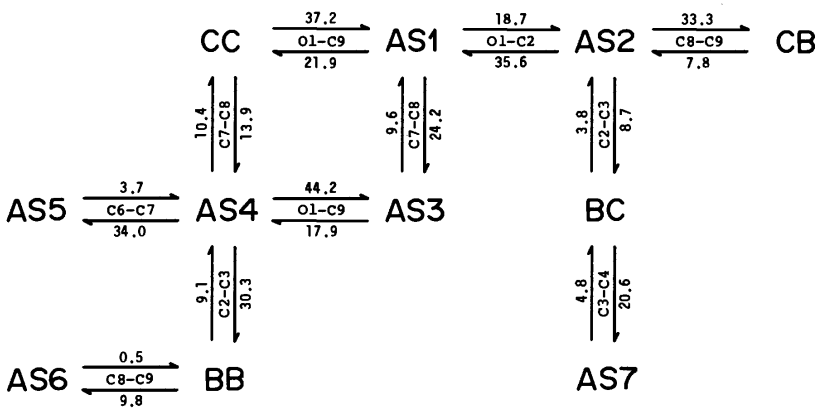

Fig. 3. The interconversions among the conformers of (Z)-2,3,4,7,8,9-hexahydrooxonin (**1**). The energy barriers (ΔE/(kJ mol^{-1})), together with the central bonds of the torsion angles used as conversion parameters, are shown.

stable CC conformation by 1.6 kJ mol^{-1}. The conformational interconversions for **1**, which can be accomplished by driving one ring torsion angle, are shown in Fig. 3. In addition to these reversible conversions, there are many irreversible conversions, *e.g.*, the AS5 →AS6→CC conversion caused by the rotation about the C8-C9 bond, the AS6→AS4 conversion caused by the rotation about the O1-C2, C2-C3, or C3-C4 bond, and the AS7→AS5*[10] conversion caused by the rotation about the C8-C9 bond. These irreversible conversions probably proceed reversibly, if they are performed by driving two or more ring torsion angles simultaneously. Accordingly, Fig. 3 should be considered to show only a part of the possible interconversions for **1**. The calculated energy barriers to the conversions shown in Fig. 3 are 44.2 kJ mol^{-1} or below, which suggests that, at room temperature, the conformations of **1** may change into one another directly or *via* one or more other conformations.

It is interesting to notice that the CB→AS2→BC transformation is accompanied by a remarkable change in torsional strain. Because of the eclipsed bond arrangements around the C7-C8 and C3-C4 bonds, the symmetric CB conformer has great torsional strains (11.6 kJ mol^{-1}) around these bonds (see Fig. 4). The changes from the CB to the AS2 conformer and from the AS2 to the BC conformer remarkably relieve these great torsional strains, respectively. However, the latter change results in an increase in the total strain energy. This is due mainly to the occurrence of great torsional strains around the O1-C2 and O1-C9 bonds.

*Isolaurallene (**3**) and Neolaurallene (**4**).* The conformations of the nine-membered rings in both **3** and **4** are substantially the same as the most stable AS2 conformation of **1** (see Figs. 1 and 2); the maximum torsion-angle deviations (28 and 15°) are observed for the junctures with the oxolane rings respectively. The diastereomeric compounds, **3** and **4**, have the same absolute configuration at each of

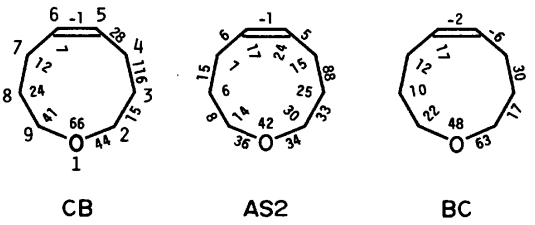

Fig. 4. The distributions of the torsional strain and bond-bending energies ($10 \times E$/(kJ mol^{-1})) in the CB, AS2, and BC conformers of (Z)-2,3,4,7,8,9-hexahydrooxonin (**1**). The torsional energy ($E_t(i-j)$) and bending energy ($E_b(i)$), defined by the following equations, are shown for each bond and each atom respectively: $E_t(i-j) = \sum_{x,y} E_t(x-i-j-y)$; $E_b(i) = \sum_{x,y} E_b(x-i-y)$.

the carbon atoms to which the ethyl group or the bromine atom is attached, while they have different absolute configurations at each of the bridgehead carbon atoms. This stereochemical difference results in a striking contrast between **3** and **4** in regard to the positions of the substituents on the nine-membered ring having the asymmetric AS2 conformation. That is, in **3**, the oxolane ring is fused at the 2- and 3-positions, and the remaining substituents are placed at the 8- and 9-positions; the reverse is the case in **4**.

Since the calculated energy difference between the AS2 and CC conformations of **1** is only 1.6 kJ mol^{-1}, in order to explain why neither **3** nor **4** adopts the CC conformation, it is necessary to examine the steric effects of the substituents in some detail. In the CC conformation of **1**, the axial hydrogen atoms at the 2- and 9-positions are very close to each other, the distance being 2.17 Å (see Fig. 5). Therefore, the replacement of one of these hydrogen atoms by an alkyl group will make the CC conformation unstable. If the nine-membered ring in **4** takes the CC conformation, one of the ethyl and methylene groups attached

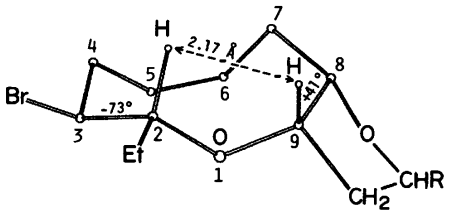

Fig. 5. The most probable arrangement of the substituents in the isolaurallene (**3**) molecule having the CC conformation.

to the C2 or C9 atom must necessarily be axial because of their trans configuration, which explains why **4** does not favor the CC conformation.

The explanation for **3** is not so easy as that for **4**. When **3** has the CC conformation, both of the ethyl and methylene groups bonded to the C2 or C9 atom will occupy the equatorial positions because of their cis configuration (see Fig. 5). If the cis fusion of the five- and nine-membered rings occurs at the C2 and C3 (or C8 and C9) atoms, the C-C2-C3-O (or O-C8-C9-C) torsion angle in the former ring should have almost the same value as the O1-C2-C3-C4 (or C7-C8-C9-O1) torsion angle. Since the magnitude of the C7-C8-C9-O1 torsion angle (41°) is much more suitable to the requirement of the oxolane ring than that of the O1-C2-C3-C4 torsion angle (−73°), it seems to be more reasonable to choose the C8-C9 bond as the junction of the two rings than to take the C2-C3 bond. In the former case, the ethyl group and the bromine atom are placed at the C2 and C3 atoms respectively. If it is assumed that the projections of the Et-C2-O1 and Br-C3-C4 bond angles along the C2-C3 bond are 120°, the Et-C2-C3-Br torsion angle is estimated to be about 47°. This value is somewhat smaller than the corresponding torsion angle (64°) in the AS2 conformation of **1** and the Et-C9-C8-Br torsion angle (66°) found actually in **3**, which would make the CC conformation of **3** more or less unstable. In the above explanation, the conformation of the oxolane ring in **3** has not been taken into consideration; for oxolane is known to be highly flexible.[11]

(Z)-Cyclononene (2). Although Favini *et al.* examined only six conformations of **2**, *i.e.*, the CC, BC, CB, BB, TCC, and AS conformations, the present study has shown that there are at least 10 minimum-energy conformations of **2** (see Fig. 2), and that the symmetric CC, BB, and TCC conformations correspond not to energy minima but to energy maxima. For the reason which has been mentioned in the preceding section, the minimum-energy conformations obtained by distorting the CC, BB, and TCC forms have been named CC, BB, and AS3 respectively, while the AS conformation has been renamed AS1. Table 5 indicates that the most stable conformation of **2** is AS1; this agrees with the result of Favini *et al.* The stability of the AS1 conformation is supported by the fact that the conformation found in the

Table 5. The relative steric energies of the conformers of (*Z*)-2,3,4,7,8,9-hexahydrooxonin (**1**) and (*Z*)-cyclononene (**2**)

Conformer	*E*/(kJ mol^{-1})	
	1	**2**
CC	1.6	0.6
BC	4.9	4.4

AS6	35.6	
AS7	20.7	9.8

caprylolactam hydrochloride crystal resembles it closely.[12] However, the energy differences among the four most stable conformations of **2** are less than 4 kJ mol^{-1}; especially that between the AS1 and CC conformations is only 0.6 kJ mol^{-1}. This computational result suggests that substituted derivatives of **2** may have not the AS1 but the CC, AS2, or AS4 conformation according to the positions occupied by the substituents.

The absence of the AS6 minimum-energy conformation of **2** is explained as follows. In the AS6 conformation of **1**, the O1 atom is situated near the C4, C5, C6, and C7 atoms, the distances being 2.89, 2.92, 2.85, and 2.75 Å respectively. Therefore, when the O1 atom is replaced by a methylene group (-CH_2-), one of the hydrogen atoms in this methylene group must be very close to some of those four carbon atoms. This severe steric hindrance probably makes the AS6 conformation of **2** to be so labile as to be incapable of existing as a stable minimum-energy conformation.

We would like to thank Professor Etsuro Kurosawa of this university for providing us with the samples, and Dr. Chuji Katayama of Nagoya University for measuring the X-ray diffraction intensities of isolaurallene. The calculations for the present study were done on HITAC M-200H and M-280H computers at the Hokkaido University Computing Center.

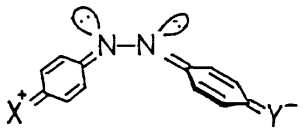
The Thermal *Cis*-to-*trans* Isomerization of *N,N'*-Diacylindigos. Kinetic Pressure, Solvent, and Substituent Effects

Yoshimi SUEISHI,* Kazuo OHTANI, and Norio NISHIMURA
Department of Chemistry, School of Science, Okayama University, Okayama 700
(Received August 13, 1984)

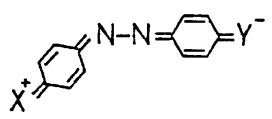
The kinetics of the thermal *cis*-to-*trans* isomerization of *N,N'*-diacylindigos(DAI) in various solvents and under high pressures has been studied. *N,N'*-Dibenzoylindigos(DBI) isomerize about 10 times slower than molecules not having a benzene ring in the acyl groups. The values of the activation volumes were about 8.0 $cm^3\ mol^{-1}$ for the former and about 3.0 $cm^3\ mol^{-1}$ for the latter. It was suggested that the thermal isomerization proceeds *via* the biradical mechanism. The positive values of the activation volume have been interpreted in terms of the increase in the intrinsic volume upon activation. The differences in the isomerization rates and the activation parameters between DBI and the others have been ascribed to an additional interaction between the two phenyl rings in the acyl groups in the *cis*-ground state.

Recently, reaction mechanisms have been actively discussed for the thermal *cis*-to-*trans* isomerization of push-pull azobenzenes. Whitten *et al.*[1] reported that the rate of the thermal isomerization of 4-dialkylamino-4'-nitroazobenzenes is extremely sensitive to solvent polarity and that thermal isomerization proceeds *via* a dipolar rotational transition state (I).



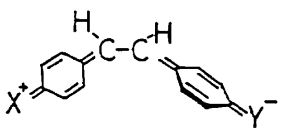
I

Asano *et al.*[2] studied the kinetic-pressure effects for the thermal isomerization of 4-dimethylamino-4'-nitroazobenzene and advocated that the mechanism changes from inversion in hexane to rotation in benzene and polar solvents. They suggested a dipolar transition state (I) in benzene and polar solvents. According to our view, the substituent, solvent, and pressure effects are in favor of the inversion mechanism and a remarkable polarity change will occur on going from the *cis* to the inversion transition state (II).[3]

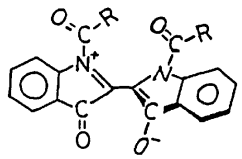


II

The thermal isomerizations of *N,N'*-diacylindigos (DAI) and push-pull stilbenes invariably proceed by the rotation mechanism around the carbon-carbon double bond. In analogy with the case of push-pull azobenzenes, charge-separated transition states (III and IV) are plausible for these compounds. However, according to Calvin and Alter,[4] push-pull stilbenes

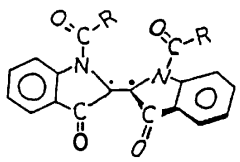


III



IV

thermally isomerize *via* a triplet state at 200—300 °C. Since push-pull stilbenes gradually decompose at high temperature, it is difficult to examine the solvent, substituent, and pressure effects. On the other hand, the thermal *cis*-to-*trans* isomerization of DAI readily takes place at room temperature.[5] For the thermal isomerization of DAI, two routes are possible: the isomerization *via* a double bond breaking to produce either homopolar or dipolar transient species, as indicated by IV and V.



V

In connection with the recent interest regarding the mechanism of the *cis*-to-*trans* isomerization of push-pull azobenzenes, we have undertaken the investigation of the thermal isomerization of DAI in order to clarify which of these routes is more consistent with experimental observations.

Experimental

Reagents. *N,N'*-Diacetylindigo (**1**), *N,N'*-dipropionylindigo (**2**), and *N,N'*-diisobutyrylindigo (**3**) were prepared by the method reported by Blanc and Ross.[6] **1** and **2** were recrystallized from a hexane-chloroform mixture and **3** was recrystallized from hexane. **1**: mp 254—256 °C (lit,[7]

256—257 °C), **2**: mp 211—212 °C (lit,[7] 211—213 °C), **3**: mp 230—231 °C (lit,[7] 229—230 °C). *N,N'*-Distearoylindigo(**4**) was prepared by the method reported by Omote *et al.*[5] and recrystallized from petroleum ether: mp 107.5—108 °C (lit,[5] 101—102 °C). *N,N'*-Bis(cyclohexylcarbonyl)indigo (**5**), *N,N'*-dibenzoylindigo (**6**), *N,N'*-bis(p-methylbenzoyl)indigo (**7**), *N,N'*-bis(p-chlorobenzoyl)indigo (**8**), and *N,N'*-di-2-naphthoylindigo (**9**) were prepared by the method reported by Posner.[8] **5** was recrystallized from a hexane-chloroform mixture: mp 244.5—245.5 °C. **6** and **9** were recrystallized from an acetone-water mixture and **7** and **8** were recrystallized from a hexane-chloroform mixture. **6**: mp 261—262 °C (lit,[7] 256—257 °C), **7**: mp 293—294 °C, **8**: mp 271—272 °C, **9**: mp 251—252 °C.

^{1}H NMR spectra were recorded on a Hitachi R-600 High Resolution NMR spectrometer (60 MHz) with TMS as an internal standard, and IR spectra on a JASCO IRA-I spectrophotometer. **4**: IR (nujol) 1680, 1670, 1600 cm^{-1} (lit,[5] IR (KBr) 1690, 1670, 1600 cm^{-1}); ^{1}H NMR ($CDCl_3$) δ=0.73—2.02 (m, 66H), 2.60—3.09 (m, 4H), 7.00—8.37 (m, 8H). Found: C, 78.32; H, 10.01; N, 3.51%. Calcd for $C_{52}H_{78}N_2O_4$: C, 78.54; H, 9.88; N, 3.52%. **5**: IR (nujol) 1710, 1680, 1600 cm^{-1}; ^{1}H NMR ($CDCl_3$) δ=0.35—2.30 (m, 20H), 2.70—3.34 (m, 2H), 7.00—8.37 (m, 8H). Found: C, 74.79; H, 6.30; N, 5.78%. Calcd for $C_{30}H_{30}N_2O_4$: C, 74.67; H, 6.27; N, 5.81%. **6**: IR (nujol) 1700, 1660, 1590 cm^{-1} (lit,[5] IR (KBr) 1700, 1660, 1590 cm^{-1}); ^{1}H NMR ($CDCl_3$) δ=6.95—8.10(m, 18H). Found: C, 79.80; H, 3.77; N, 4.78%. Calcd for $C_{38}H_{22}N_2O_4$: C, 79.99, H, 3.89; N, 4.91%.

Solvents. Acetonitrile, acetone, and toluene of the reagent grade were purified by drying over calcium chloride, calcium sulfate, and sodium wire, respectively, and distillation.

Apparatus and Procedure. The high-pressure technique and the procedure for kinetic measurements were the same as those described elsewhere.[3] A solution containing an appropriate concentration of DAI (10^{-4} mol/l) in a pressure vessel was irradiated with a 650-W tungsten projection lamp through a filter of potassium dichromate solution to produce the *cis*-isomer. Then, the absorption maximum (λ_{max}=*ca.* 570 nm) of the *trans*-isomer was monitored by means of a Hitachi 100—50 spectrophotometer and the absorbance was recorded.

Results and Discussion

The thermal isomerization of DAI was carried out at various temperatures. It was found that the rate follows first-order kinetics. The rate constants are listed in Table 1, together with the activation pa-

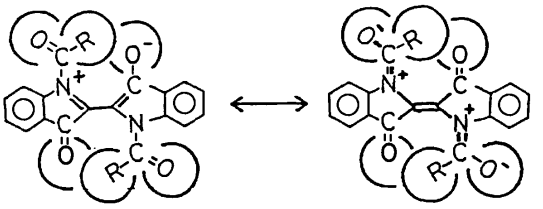
rameters. Figure 1 shows the relationship between the activation energy and entropy. It may be seen that the activation energy tends to increase with an increase in the activation entropy as a whole. From the figure, we notice the following point: the plots for **6—9** shift upward compared with the others. According to Leffler,[9] a linear enthalpy-entropy relationship suggests the simple interaction mechanism. If the activation enthalpy-entropy plots are scattered, more than two interactions must be operating. Shinkai and co-workers[2] showed that the activation enthalpy-entropy plots for the isomerization of azobenzenes give parallel straight lines and accounted the root of the parallel straight lines as the change in mechanism. In opposition to this idea, we have explained[3] that the shift is not due to a mechanism change but, rather, to the extra free-energy change. We consider that the same is true in the present case (see below).

DAI has electron-donating and -attracting groups. Therefore, there are two possible routes for the thermal isomerization (see IV and V). If a reaction starts from a nonpolar state and proceeds *via* a polar transition state (*e.g.*, IV), the reaction rate will be substantially accelerated in polar solvents. However, it was not the case (Table 1). We reported that the wavelengths(λ^{trans}_{max}) at the maximum absorption of the *trans*-isomer of push-pull azobenbenes are sensitive to the solvent polarity and are closely related to the rate of isomerization.[3] In the case of DAI, we observed that the absorption band shifts to a shorter wavelength as the solvent polarity increases (for example, **1** in Table 1). It appears, therefore, that the *trans*-ground state is somewhat more polar than the excited one. However, as far as our data are concerned, no correlation between λ^{trans}_{max} and the rate constant seems to exist. *Trans*-DAI is twisted around the central C=C double bond and the C-N bond of the acyl group and the extent of the twist may depend on the bulkiness of substituents (R). Since the twist causes a reduction in the resonance contribution (VI), the polarity of the *trans*-ground state will be diminished by the introduction of bulky substituents. Since the *trans*-ground state



VI

may be more polar than the excited one, as described above, the decrease in the polarity of the ground state due to the bulkiness of substituent gives rise to a longer wavelength shift. This is in accord with the experimental observations (Table 1). On the other hand, *cis*-DAI is originally extremely twisted around the C=C double bond, and this might be responsible for the small substituent effect on the rate. However, it is of great interest to note that the rate constants for the isomerization of **6—9** are about 10 times smaller than those of **1—5**. A plausible reason will be given later.

Pressure Effects. Table 2 shows the pressure effects on the thermal isomerization in some solvents. The reactions are slightly retarded by external pressures. By using the data in Table 2, the activation volumes ($\Delta V^{\neq}$) at p=1 atm were estimated according to Eq 2.

$$\ln k = a + bp \tag{1}$$

$$\Delta V^{\neq} = -RT\left(\frac{\partial \ln k}{\partial p}\right)_{T,p=1} = -bRT \tag{2}$$

The activation volume ($\Delta V^{\neq}$) is usually divided into two terms:

$$\Delta V^{\neq} = \Delta V^{\neq}_{i} + \Delta V^{\neq}_{el} \tag{3}$$

where $\Delta V^{\neq}_{i}$ is the difference in the intrinsic volume of reacting molecules between the initial and the transition state and $\Delta V^{\neq}_{el}$ due to solvation or electrostriction. The values of the activation volume decrease slightly with an increase in the solvent polarity: from $\Delta V^{\neq}$(acetonitrile)=3.6 cm^3 mol^{-1} to $\Delta V^{\neq}$(toluene)=1.9 cm^3 mol^{-1} in **1**, from $\Delta V^{\neq}$(acetonitrile)=3.3 cm^3 mol^{-1} to $\Delta V^{\neq}$(toluene)=−0.6 cm^3 mol^{-1} in **5** (Table 2). The above solvent dependency indicates that the transition state is slightly more polar than the *cis*-state. In the transition state, the crowded-

ness between the two acyl groups would be relaxed compared to the *cis*-ground state. Then, a resonance contribution, such as

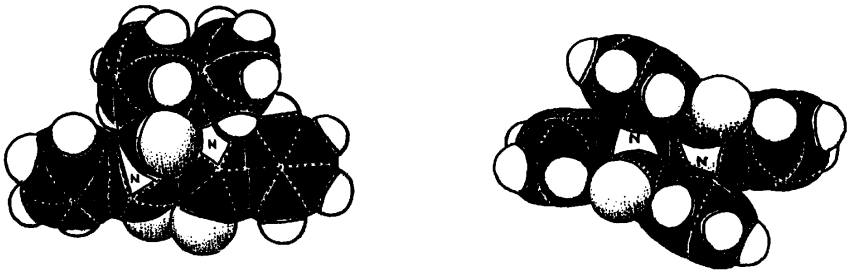
a) 1 kg cm^{-2} = 0.9807 bar. b) at 60 °C.

becomes greater in the transition state than in the *cis*-state. This accounts for the above observations. The volume of activation is, as a whole, small and positive. The positive values of activation volume may be explained in terms of the increase in the intrinsic volume. Since the bond character of the central carbon-carbon bond varies from the C=C double bond to the C-C single bond in the activation process, the bond length must become longer. On the assumption that the central C-C distance increment is 0.21 Å (difference in the distance between the C-C single bond and the C=C double bond) and the thickness of the molecule 3.4 Å, the increase in the van der Waals volume ($\Delta V_W^{\ddagger}$) is calculated to be about 1.5 cm^3 mol^{-1}. Hitherto, the intrinsic volume change upon activation has often been ascribed to the van der Waals volume change. Very recently, however, Yoshimura *et al.*[10] pointed out that there is a large gap between $\Delta V^{\ddagger}$ and $\Delta V_W^{\ddagger}$, and between ΔV and ΔV_W for 1,3-dipolar cycloaddition reactions. Indeed, the molar volumes of normal alkanes of short chain are about twice of their van der Waals volumes. Therefore, $\Delta V^{\ddagger}$ may be $\approx$3 cm^3 mol^{-1}, which agrees with the experimental values. Alternatively, the change in the void volume[11] around the van der Waals volume might be responsible for the gap between $\Delta V^{\ddagger}$ and $\Delta V_W^{\ddagger}$.

It is noted that in **1—5** and **6—9**, significant differences between the activation volumes as well as the rate constants were observed. Cristol and Lewis[12] showed the significant differences of ultraviolet spectra in janusene which has face-to-face rings close enough to interact. Ingraham[13] suggested that if two benzene rings are brought face-to-face (3 Å apart), the VB and LCAO methods predict that there is 4 kcal more resonance energy than for two infinitely separated benzene rings. On the other hand, Cram and Goldstein[14] reported that in the solvolysis of [9]paracyclophanyl tosylate, the interaction between the phenyl ring and a carbonium ion takes place. In the case of *cis*-DBI, the molecular structure has not been established yet. As plausible models, the following conformations may be proposed (Fig. 2). Then, the interactions just described must exist for each conformation: (a) The interaction between the two phenyl rings in the acyl groups which are held face-to-face and (b) the interaction between the phenyl ring in the acyl group and >N- group are important. It is difficult to decide which of the two conformations is more favorable. As far as $\Delta V^{\ddagger}$ is concerned, the face-to-face conformation appears more plausible. It appears that the volume change on going from conformation (b) to the activated state may be similar to those observed for **1—5** since the situation around the benzene rings in solution to the surrounding solvent molecules will not change between (b) and activated complex. Meanwhile, in the face-to-face conformation, the independent mo-



(a) (b)

Fig. 2. Plausible geometical models of *cis-N,N'*-dibenzoylindigo: (a) phenyl-phenyl interaction and (b) phenyl- >N- interaction.

tion of the two benzene rings will be partly restricted, resulting in a smaller exclusion of solvent molecules. This may be responsible for the values of $\Delta V^{\neq}$ for **6—9** compared with those for **1—5**. We tentatively consider that the *cis*-isomer of **6—9** is stabilized by the additional interaction, which is responsible for the significant differences in the rates (Table 1) and the $\Delta V^{\neq}$-values (Table 2), and the upward shift of the activation energy-entropy relationship (Fig. 1).

The Spectrophotometric Determination of Phosphorus with *o*-Hydroxyhydroquinonephthalein and Iron(III)†

Yoshikazu FUJITA, Itsuo MORI,* Shoko KITANO, Hiroshi KAWABE, and Yozo KOSHIYAMA

Osaka College of Pharmacy, 2-10-65, Kawai Matsubara, Osaka 580

(Received August 27, 1984)

On this basis of the coloration formed with *o*-hydroxyhydroquinonephthalein, an anionic dye, and iron (III) in aqueous media, trace amounts of phosphorus(as orthophosphate ion) was determined. A sample solution containing posphorus and the reagent blank in an amber-colored test tube with a stopper were heated at 40 °C for 20 min in the presence of poly(oxyethylene)sorbitan monolaurate, a nonionic surfactant, as a dispersion agent. Beer's law was obeyed over the range of ≈1 μg/10 cm³ of phosphorus, and the apparent molar absorptivity of the complex was 2.5×10^5 dm³ mol^{-1} cm^{-1} at 610 nm. The present method was applied to the determination of total phosphorus in water — a sample solution containing small amounts of metal ions —, and the recovery percentage was satisfactory, about 95%. Other compounds containing phosphorus such as 5′-adenosine triphosphate could also be determined without a preliminary treatment.

Recently, various sensitive spectrophotometric methods for the determination of phosphorus have been reported.[1-19] Most of these methods are based upon the formation of heteropoly acids such as molybdophosphate ion, or the ionic-association complex formation with cationic dyes such as Crystal Violet,[4-7] Ethyl Violet(EV),[8,9] Malachite Green(MG),[10-14] Methylene Blue,[15] Safranin T[16,17] and Rhodamine B.[18,19] However, little work has been done on the determination of phosphorus by using an anionic dye, though an indirect method[20,21] has been studied by utilizing the coloration between molybdenum(VI) freed from heteropolyacid and Pyrocatechol Violet (PV).

Meanwhile, we noticed that the addition of micro amounts of phosphorus (as orthophosphate ion) to the reaction mixture between iron(III) and *o*-hydroxyhydroquinonephthalein(Qnph), an anionic dye, produced a different spectrum than that of the Qnph-iron(III) complex solution in a weakly basic medium.

In this paper, optimum conditions for a new spectrophotometric determination of micro amounts of phosphorus using Qnph and iron(III) were studied, and phosphorus as well as compounds containing phosphorus in water was determined.

Experimental

Reagents and Materials. A standard solution (1.0×10^{-2} mol dm^{-3}) of phosphorus was prepared by dissolving a proper quantity of potassium dihydrogenphosphate (Merck) in water, which was dried at 110 °C to a constant weight. The working solution (5.0×10^{-5} mol dm^{-3}) was made by diluting this stock solution as required. A Qnph solution (1.0×10^{-3} mol dm^{-3}) in methanol was prepared by dissolving Qnph synthesized by the published procedure.[22] An iron(III) solution (5.0×10^{-4} mol dm^{-3}) was prepared by dissolving a proper quantity of iron(III) ammonium sulfate in 5 cm³ of 1.0% sulfuric acid and diluting the mixture to 100 cm³ with water. A 5.0% poly(oxyethylene)sorbitan monolaurate (Nihon Yushi Co. Ltd., LT-221) solution was prepared by dissolving it with water. A solution (1.0×10^{-1} mol dm^{-3}) of sodium tetraborate(borax) was prepared as a buffer solution. All the other reagents and materials were of an analytical grade and were used without further purification. Doubly distilled water was used.

Apparatus. A Shimadzu Model UV-240 recording spectrophotometer with 1.0-cm quartz cells was used for the absorption spectrum and absorbance measurements. A Hitachi-Horiba Model F-7 AD glass electrode pH meter was used for the pH measurements.

Standard Procedure for the Determination of Phosphorus. To a solution containing up to 1 μg phosphorus in a 10 cm³ volumetric flask were added 1.0 cm³ of a 5.0% LT-221 solution, 0.5 cm³ of a 5.0×10^{-4} mol dm^{-3} iron(III) solution, 4.0 cm³ of a 1.0×10^{-1} mol dm^{-3} borax solution, and 0.5 cm³ of a 1.0×10^{-3} mol dm^{-3} Qnph solution. The mixture was diluted to 10 cm³ with water, and the solution was transferred to an amber-colored test tube with a stopper, kept at 40 °C for 20 min and then cooled to room temperature. The absorbance of the Qnph-iron(III)-phosphorus solution (Solution A) was measured at 610 nm against the Qnph-iron(III) solution(Solution B).

Results and Discussion

Color Reaction and Absorption Spectra. The addition of the phosphorus solution to Solution B exhibited an extreme increase in absorbance, and its absorbance at around 610 nm was proportional to the concentration of phosphorus. The reproducibility of color development of Solutions A and B without a surfactant was unfavorable. The use of a nonionic surfactant such as LT-221 was effective as a dispersion agent.

The effect of dyes in this reaction system was examined by measuring the difference of absorbance between a dye-iron(III)-phosphorus solution and a dye-iron(III) solution. The use of xanthene dyes such

† Application of Xanthene Derivatives for Analytical Chemistry. Part 45. Part 44: Y. Fujita, I. Mori, S. Kitano, and Y. Kamada, *Bunseki Kagaku*, 33, E445 (1984).

as Qnph, phenylfluorone(Phfl), Pyrogallol Red(PR) and gallein(Gall) enhanced the absorbance of the dye-iron(III) solution. The reaction sensitivity among Qnph, Phfl, PR, and Gall decreased in the sequence: Qnph≧Phfl ≫ PR and Gall. As for other dyes such as Xylenol Orange, Chromazurol S, PV, and 1-(2-pyridylazo)-2-naphthol, no difference of absorption spectra between the dye-iron(III)-phosphorus solution and the dye-iron(III) solution was observed under the standard conditions.

The effect of metal ions was also examined. Iron(III) or iron(II) ion was effective among the various metal ions tested: iron(III), iron(II), copper(II), aluminum (III), cerium(III), manganese(II), thorium(IV), molybdenum(VI), vanadium(V), cobalt(II), *etc.* Iron(III) was fairly superior to iron(II) in terms of sensitivity.

On the basis of these results, Qnph and iron(III) were chosen for the purpose of fundamental investigations on the determination of phosphorus.

The absorption spectra of Solution A, Solution B and Qnph solution under the standard conditions are shown in Fig. 1.

Effect of pH. The effect of pH on the color development was investigated with a solution containing 0.62 μg/10 cm^3 phosphorus. The maximum and nearly constant absorbance was observed at pH 9.0—9.6. A borax buffer was most effective in terms of sensitivity among the various buffer solutions, such as borax, ammonia-ammonium chloride and carbonate-hydrogencarbonate solutions. In addition, the color reaction between Qnph and various metal ions in borax solution was limited than that in the other buffer solutions, and the influence of other metal ions was relatively small. The constant absorbance was observed upon the addition of more than 3.0 cm^3 of 1.0×10^{-1} mol dm^{-3} borax in the final volume of 10 cm^3. Accordingly, 4.0 cm^3 of 1.0×10^{-1} mol dm^{-3} borax solution (pH 9.3) was used as the buffer solution.

Phosphorus: 3.0×10^{-6} mol dm^{-3}; iron(III): 2.5×10^{-5} mol dm^{-3}; Qnph: 5.0×10^{-5} mol dm^{-3}; LT-221: 1.0 cm^3 of 5.0% LT-221 solution/10ml; borax: 4.0×10^{-2} mol dm^{-3}; Reference: water; curve I: Qnph-iron (III)-phosphorus solution; curve II: Qnph-iron(III) solution; curve III : Qnph solution.

Effect of Surfactants. Among various surfactants tested, LT-221, a nonionic surfactant, was best as a dispersion agent; the maximum and constant absorbance of Solution A against Solution B was observed upon the addition of more than 0.5 cm^3 of a 5.0% LT-221 solution to the final volume of 10 cm^3. The results are given in Table 1.

Effects of Qnph and Iron(III) Concentrations. The effects of the amounts of Qnph and iron(III) were examined by varying the molar ratio of iron(III) to Qnph, the amount of phosphorus being kept constant. As is shown in Fig, 2, the maximum and constant absorbance at 610 nm was observed upon the addition of a 0.4—0.6 cm^3 of 5.0×10^{-4} mol dm^{-3} iron(III) solution in the final volume of 10 cm^3. By the way, the molar ratio of iron(III) to Qnph in the reaction system was found to be 1:2 by the molar-ratio method in the presence of phosphorus. Accordingly, all further work was carried out with 2.5×10^{-5} mol dm^{-3} iron (III) and 5.0×10^{-5} mol dm^{-3} Qnph in the final volume.

Temperature and Stability. The absorbance of Solution A at 610 nm against Solution B was

Table 1. Effect of surfactants

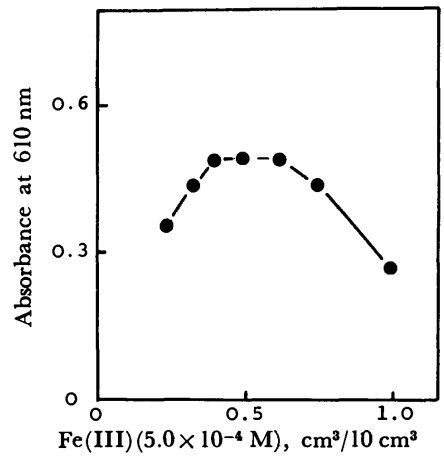

Fig. 2. Effect of iron(III) concentration.
Phosphorus: 2.0×10^{-6} mol dm^{-3}(0.62 μg/10 cm^3); Qnph: 5.0×10^{-5} mol dm^{-3}; LT-221: 1.0 cm^3 of 5.0% LT-221 solution/10 cm^3; borax: 4.0×10^{-2} mol dm^{-3}; Reference: Solution B.

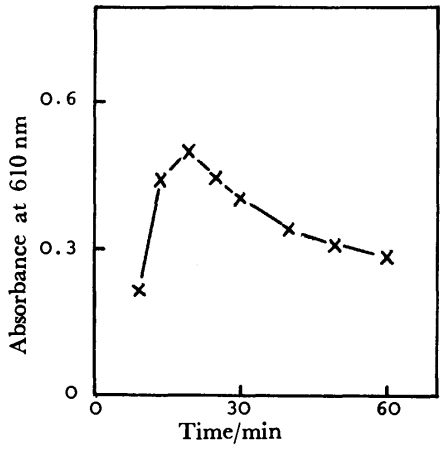

Fig. 3. Relationship between absorbance and heating time at 40 °C.
Phosphorus: 2.0×10^{-6} mol dm^{-3}; iron(III): 2.5×10^{-5} mol dm^{-3}; Qnph: 5.0×10^{-5} mol dm^{-3}; LT-221: 1.0 cm^3 of 5.0% LT-221 solution/10cm^3; borax: 4.0×10^{-2} mol dm^{-3}; Reference: Solution B.

unconstant instantaneously at room temperature (15—25 °C), and more than 6 h was required to obtain a nearly constant absorbance. The effect of the temperature was examined by heating the mixed solution for 10—60 min at various temperatures (35 °C, 40 °C, 45 °C, or 50 °C); the favorable result was obtained by heating the solution at 40 °C for 20 min and then cooling it to room temperature. The relationship between absorbance and heating time at 40 °C is shown in Fig. 3.

On the other hand, Solutions A and B were found to be fairly unstable and lacked reproducibility in diffused light. The reason was probably that Qnph in borax solution easily decomposed by light. The disadvantage is conveniently improved by the use of an amber-colored test tube.

From the results described above, the absorbance of Solution A at 610 nm against Solution B was almost constant for at least 3 h at room temperature under the standard conditions.

Calibration Curve and Repeatability. The calibration curve for phosphorus was constructed according to the standard procedure. Beer's law held in the concentration range of ≈1 μg of phosphorus in the final volume of 10 cm^3. The apparent molar absorptivity at 610 nm was estimated to be 2.5×10^5 dm^3 mol^{-1} cm^{-1}, and the Sandell sensitivity was calculated to be 0.00013 μg cm^{-2} for phosphorus. The coefficient of variation (n=8) was 2.5% for 0.62 μg of phosphorus.

Effects of Foreign Ions. The effects of foreign ions on the determination of phosphorus were examined. Among metal ions tested, small amounts of vanadium(V), zirconium(IV) and copper(II) interfered, but iron(III), aluminum(III) and arsenic(V) did not interfere in equimolar amounts with respect to phosphorus. Divalent heavy metal ions such as manganese(II), cobalt(II), zinc(II) and lead(II) did not interfere in the 5- to 10-fold excess over phosphorus, and other metal ions such as magnesium(II) and calcium(II) did not interfere in the 100-fold excess. Among various anions tested, the presence of small amounts of organic acids such as tartrate and citrate ions, and large amounts of oxalate, thiocyanate, thiosulfate and cyanide ions interfered. Other anions such as nitrate, chloride, and sulfate ions scarcely affected the determination of phosphorus. However, when strong electrolytes were present more than 5000-fold molar excess of phosphorus, it was necessary to measure the difference of absorbance between Solutions A and B containing the same ingredients. The results are summarized in Table 2.

The Composition of the Complex. The molar ratio of iron(III) to Qnph in the presence of phosphorus was estimated by the molar-ratio and continuous-variation methods. The results indicated that the molar ratio of iron(III) to Qnph was 1:2. The result obtained by the continuous-variation method is shown in Fig. 4. The phosphorus-to-iron(III) ratio obtained by the molar-ratio method was 1:2, as is shown in Fig. 5. From the results, the ternary complex formed in this reaction system is expressed as [phosphorus 1: iron(III) 2: Qnph 4].

Application for the Determination of Phosphorus in Water. The present method was applied to the determination of phosphorus in water (effluent of treated waste water and rain water). On the other hand, orthophosphate ion and total phosphorus in the same samples were determined according to the JIS method.[23] The experimental results for total phosphorus were in good agreement with the JIS method.[23] Recovery of phosphorus added to the

samples was satisfactory, about 95%. The results are given in Table 3.

Application to Other Compounds Containing Phosphorus. By using the standard procedure for the determination of phosphorus, other compounds containing phosphorus were measured without a preliminary treatment. Approximate apparent molar absorptivities of these compounds were calculated from the absorbance of Qnph–iron(III)-compounds containing phosphorus solutions at 610 nm against Solution B. The results are given in Table 4.

Conclusion

The fundamental conditions for the determination of phosphorus based on the ternary complex-formation with Qnph, an anionic dye, and iron(III) were discussed, and a new spectrophotometric method for micro amounts of phosphorus has been established. This method is applicable in the concentration range of ≈1 μg phosphorus in the final volume of 10 cm³. The apparent molar absorptivity in this procedure was estimated to be 2.5×10^5 dm³ mol⁻¹ cm⁻¹ for phosphorus. In sensitivity, this method is comparable to the EV-extraction method[9] or MG-extraction method.[13] The present method is aplicable to the determination of total phosphorus in samples containing micro amounts of metal ions, and an application to the determination of organic compounds containing phosphorus without a suitable preliminary treatment may also be feasible.

Though further investigation is necessary, the method proposed here gives an important suggestion for determining phosphorus by using an anionic dye.

Absorption Spectra of Tetrahedral Co(III) and Co(II) Complexes in Heteropolytungstates

Kazuo KOJIMA and Jiro MATSUDA*
Department of Chemistry, Faculty of Science and Engineering, Ritsumeikan University, Kita-ku, Kyoto 603
(Received September 1, 1984)

The absorption spectra of Co(III) and Co(II) in the single crystals of the Keggin-structure compounds, $K_5[Co^{III}W_{12}O_{40}]\cdot nH_2O$ and $K_6[Co^{II}W_{12}O_{40}]\cdot mH_2O$, have been measured at 77 K. The spectra of these complexes in aqueous solutions have also been observed. All the spectra have been interpreted using crystal-field theory by assuming that a Co(III) or Co(II) ion is in T_d symmetry. The parameters, D_q, B, and C/B can be evaluated as 780 cm^{-1}, 630 cm^{-1}, and 4.7 respectively for the Co(III) complex, and 460 cm^{-1}, 650 cm^{-1}, and 4.5 respectively for the Co(II) complex.

A few reports have been published on the absorption spectra of high-spin Co(III) complexes in the tetrahedral ligand fields; Co(III) both in garnets[1] and in xNa_2O-SiO_2 glasses ($x \geq 1.5$),[2] and 12-tungstocobaltate(III) $[Co^{III}W_{12}O_{40}]^{5-}$.[3-5] Only the solution spectra have been measured for the last complex.

We report the absorption spectra of $K_5[Co^{III}W_{12}O_{40}]\cdot nH_2O$ in single crystals at 77 K as well as in aqueous solution at room temperature. These spectra are interpreted on the basis of the crystal-field theory.

On the other hand, 12-tungstocobaltate(II) $[Co^{II}W_{12}O_{40}]^{6-}$ contains Co(II) complex with tetrahedral arrangement of oxygen atoms and the spectra of this anion have been reported only in solutions.[3,4,6,7]

The absorption spectra of $K_6[Co^{II}W_{12}O_{40}]\cdot mH_2O$ in single crystals as well as in aqueous solution are also discussed.

Experimental

$K_5[Co^{III}W_{12}O_{40}]\cdot nH_2O$ and $K_6[Co^{II}W_{12}O_{40}]\cdot mH_2O$ were prepared by the method in the literature.[8] Single crystals of both compounds were grown by slow evaporation of each aqueous solution. The shapes of crystals are hexagonal prisms. Co(III) complex prisms (light yellow) tend to grow more elongate along the hexagonal principal axis than Co(II) complex prisms (emerald green). Co(III) complex prisms are easy to break by polishing. X-Ray powder diffraction data for Co(III) compounds agree with Yanonni's data.[9]

Single-crystal spectra were measured at 77 K using a Shimadzu model MPS-50L spectrophotometer equipped with simple glass Dewars. A Nalumi RM-21 type grating monochromater with a Hamamatsu R-376 photomultiplier was also used to measure the strong band for the Co(II) complex in the visible region. Polished specimens of 0.30—0.70 mm thickness were immersed in liquid nitrogen. Filters of POLAROID HN-42T (visible region) and HR-INFRARED (near-infrared region) were used to measure preliminary polarized spectra. Spectra of aqueous solutions of 3.50×10^{-5} mol dm^{-3} were recorded both on a Hitachi 340 spectrophotometer (ultraviolet to near-infrared region) and on a Shimadzu UV-260 spectrophotometer (ultraviolet region) using 1-cm optical length quartz cells.

Energy matrices including the electrostatic[10] and crystal-field contributions were diagonalized using a HITAC M-160H computer.

Results and Discussion

Spectra of Co(III) and Co(II) Complexes in Aqueous Solutions. The absorption spectra of $K_5[Co^{III}W_{12}O_{40}]\cdot nH_2O$ and $K_6[Co^{II}W_{12}O_{40}]\cdot mH_2O$ in aqueous solutions agree well with the previous data,[3-7] except that very strong bands around 50000 cm^{-1} and shoulders around 45450 cm^{-1} are observed (Fig. 1 and Tables 1 and 2). These bands and shoulders are probably attributed to the transitions within $W_{12}O_{40}$ skeletons, because a similar band and shoulder are observed in the spectrum of aqueous solution of sodium metatungstate $Na_6[H_2W_{12}O_{40}]\cdot 29H_2O$ prepared by the method of Ref. 11 which has the Keggin-structure isopolyanion $[H_2W_{12}O_{40}]^{6-}$. The band for the Co(III) complex is shifted to lower wavenumbers than that of the Co(II) complex, likewise a 38000-cm^{-1} band in Fig. 1 due to the transition within the same skeleton.[3-5,7] It is interesting that these transition energies are

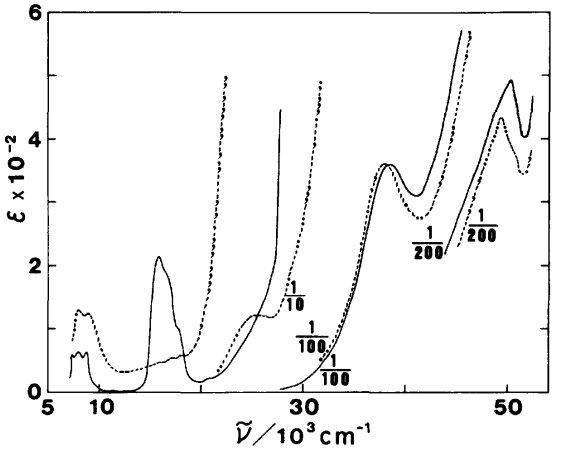

Fig. 1. Aqueous solution spectra of $K_5[Co^{III}W_{12}O_{40}]\cdot nH_2O$ (- - - -) and $K_6[Co^{II}W_{12}O_{40}]\cdot mH_2O$ (——). Fractional numbers show reduced scale for ε.

a) Calculated higher energy levels are omitted. b) Calculation has been carried out with the parameters $D_q=460$ cm^{-1}, $B=650$ cm^{-1}, and $C/B=4.5$. c) Unpolarized spectrum. d) Shoulder. e) Charge-transfer transition within $W_{12}O_{40}$ skeleton. f) Charge-transfer transition between a ligand oxygen atom and a central Co(II) ion. g) These transitions are probably masked. h) $^4A_2\rightarrow{}^2A_2$. i) $\rightarrow{}^2E$. j) $\rightarrow{}^2T_2$. k) $\rightarrow{}^2T_1$. l) $\rightarrow{}^2A_1$. m) $\rightarrow{}^4T_1(^4P)$. n) $\rightarrow{}^4T_1(^4F)$. o) $\rightarrow{}^4T_2(^4F)$. p) Vibrational peaks due to water.

affected by the oxidation state of cobalt ion in spite of the transitions within $W_{12}O_{40}$ skeletons.[5] Weak absorptions at 17120 cm^{-1} and 15380 cm^{-1} for the Co(III) complex are due to spin-forbidden d-d transitions and become well resolved in the single-crystal spectra described below.

Spectra of $K_5[Co^{III}W_{12}O_{40}]\cdot nH_2O$ in Single Crystals.[12] On the assumption that CoO_4 has T_d symmetry (it is known to be distorted[9]), the calculation of transition energies shown in Fig. 2 and Table 1 has been carried out in terms of the following estimations: (1) A band in the near-infrared region is assigned to the $^5E\rightarrow{}^5T_2$ transition, which determines the D_q value directly. (2) C/B is fitted in the vicinity of the value of 4.8.[10,15,16] (3) B is fitted in order to explain the spectra in the 13000—20000 cm^{-1} region(Figs. 2 and 3). From (1), (2), and (3), we evaluate the parameters D_q, B, and C/B as 780 cm^{-1}, 630 cm^{-1}, and 4.7 respectively. Simmons[4] has estimated the values of D_q and B as about 800 cm^{-1} and about 600 cm^{-1} respectively. Wood and Remeika[1] have reported the D_q values of 710 cm^{-1} (calculated) and 830 cm^{-1} (observed). The B value of 630 cm^{-1} is rather small compared with the value of

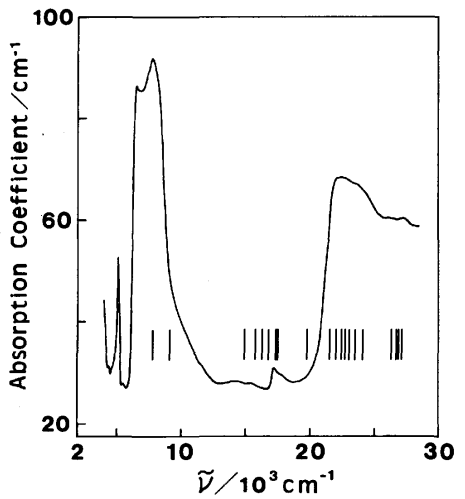

Fig. 2. Single-crystal spectrum of $K_5[Co^{III}W_{12}O_{40}]\cdot nH_2O$ at 77 K together with the calculated energy level positions (vertical lines). Details are shown in Table 1.

1053 cm^{-1} for the free Co(III) ion, which indicates the presence of a strong nephelauxetic effect. With this B

value, the bands in the visible region seem to be assigned fairly well (Fig. 2). A relatively intense band near 17500 cm^{-1} may be due to the $^5E \rightarrow {}^3A_2, \rightarrow {}^3A_1$, and $\rightarrow {}^1E$ transitions. In Fig. 3, anisotropy is observed in the 17500-, 15270-, and 14180-cm^{-1} band.

The $^5E \rightarrow {}^5T_2$ band in the solution spectrum apparently shifts to blue by about 1500 cm^{-1} compared with that of the single-crystal spectrum. It is not clear whether two peaks of this band in the former correspond directly to two peaks of the similar band in the latter, unless the single-crystal spectra are measured at higher temperatures.

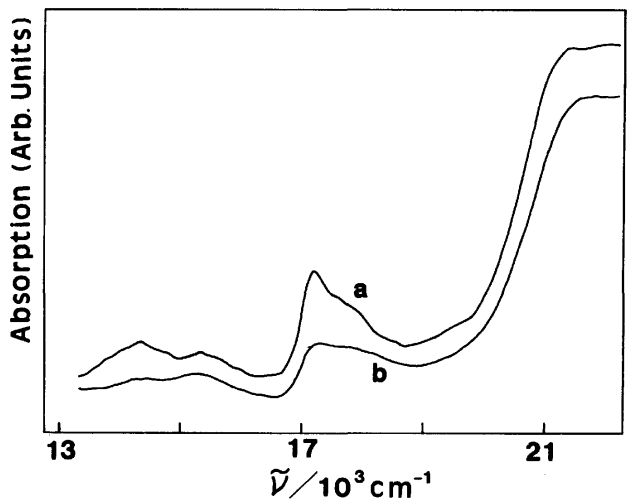

Fig. 3. Polarized single-crystal spectra of $K_5[Co^{III}W_{12}O_{40}]\cdot nH_2O$ in the visible region at 77 K. Electric vector $\boldsymbol{E}$ is perpendicular (a) and parallel (b) to the hexagonal principal axis.

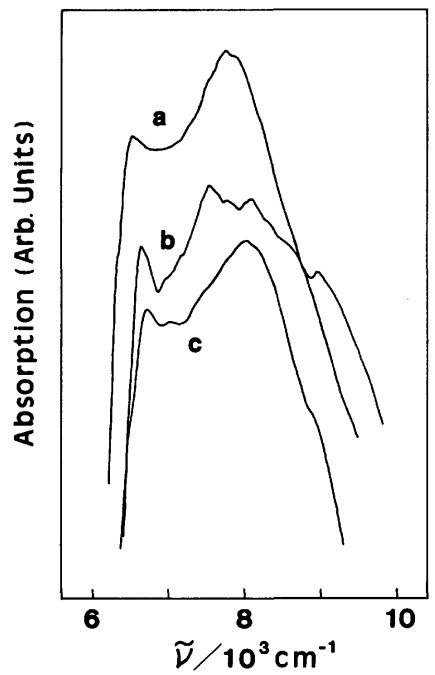

Fig. 4. Polarized single-crystal spectra of $K_5[Co^{III}W_{12}O_{40}]\cdot nH_2O$ in the $^5E \rightarrow {}^5T_2$ transition region at 77 K. The curve a is unpolarized and $\boldsymbol{E}$ is perpendicular (b) and parallel (c) to the hexagonal principal axis. The curves b and c have been shifted expediently upwards along the ordinate.

In the polarized spectra of Fig. 4, four to five peaks are observed and show anisotropy. It is of interest that the spectrum with $\boldsymbol{E}$ parallel to the hexagonal principal axis is similar to the unpolarized spectrum, unlike the $^4A_2 \rightarrow {}^4T_1$ (^4F) band for the Co(II) complex described below. Unfortunately, it is not possible to discuss the details of the reason for the splitting of this band, though the contribution of the distortion probably due to the Jahn-Teller effect[4] may be greater than that of the spin-orbit coupling. If it is possible to find out the reason for this splitting, both the D_q value and the energy of the $^5E \rightarrow {}^3T_1$ spin-forbidden transition expected to be at 9070 cm^{-1} will be confirmed.

A band around 23000 cm^{-1} in Fig. 2 is rather resolved and considerably lower both in intensity and in energy than a corresponding 25510-cm^{-1} band in the solution spectrum. These findings are of interest, though as to the intensity of the 23000-cm^{-1} band there remains some uncertainty arising from the fact that the samples are too fragile to be polished down thin specimens enough for optical measurement. Simmons[4] has proposed that this band may be due to a charge-transfer transition from a ligand oxygen atom to a central Co(III) ion, together with possibilities of other interpretations. On the other hand, the band has been assigned to a reciprocal charge-transfer transition by Dietzel and Coenen.[2] Although a number of spin-forbidden transitions are expected near this band, a charge-transfer transition between a ligand oxygen atom and a central Co(III) ion perhaps contributes mainly to this band.

Three bands at 5480 cm^{-1}, 5080 cm^{-1}, and 4400 cm^{-1} are attributed to the vibrational bands of water by referring to the previous data.[17-20]

Spectra of $K_6[Co^{II}W_{12}O_{40}]\cdot mH_2O$ in Single Crystals.[12] The transition energies calculated with the parameters D_q, B, and C/B of which values are 460 cm^{-1}, 650 cm^{-1}, and 4.5 respectively, explain the observed spectra fairly well (Fig. 5 and Table 2). The D_q value of 460 cm^{-1} is relatively large in comparison with other Co(II) tetrahedral complexes, but it agrees with that of Co(II) in yttrium gallium garnet[1] and is comparable with that of $Co(NCS)_4^{2-}$ [3,21] or $Co(NO_3)_4^{2-}$.[22] Simmons[4] has estimated the D_q and B values as 484 cm^{-1} and 672 cm^{-1} respectively. Nomiya *et al.*[7] has determined it to be 410 cm^{-1}. Likewise for the Co(III) complex, the B value of 650 cm^{-1} is rather small compared with the value of 971 cm^{-1} for the free Co(II) ion. The C/B value of 4.5 is typical for Co(II) tetrahedral complexes.

The $^4A_2 \rightarrow {}^4T_2$ transition is expected to be at 4600 cm^{-1}, but is not observed because of its low intensity[23] and of masking effect by the vibrational bands

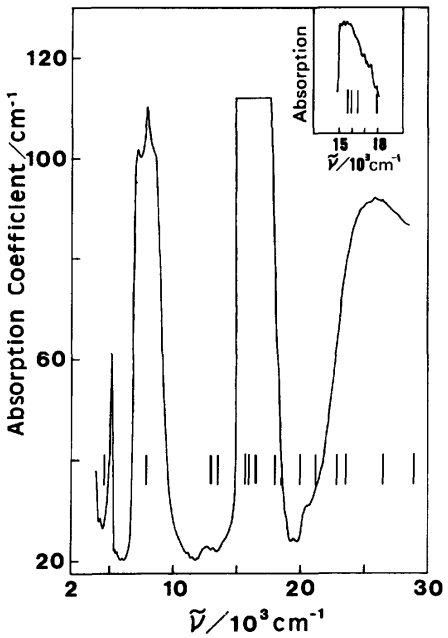

Fig. 5. Single-crystal spectrum of $K_6[Co^{II}W_{12}O_{40}]\cdot mH_2O$ at 77 K together with the calculated energy level positions (vertical lines). Details are shown in Table 2. The inset is the spectrum measured using the grating monochromater.

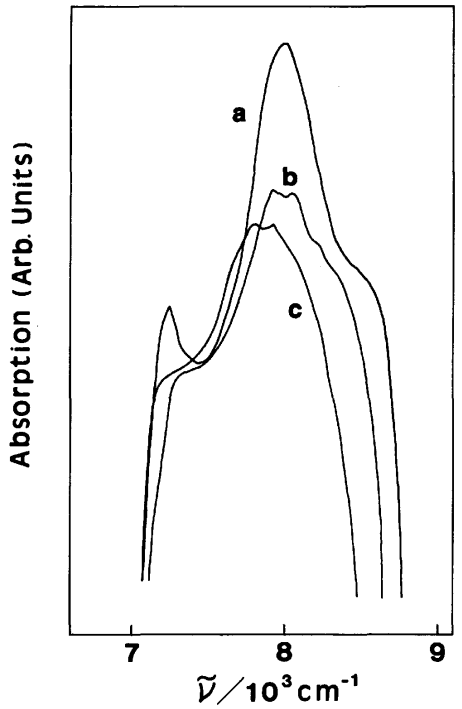

Fig. 6. Polarized single-crystal spectra of $K_6[Co^{II}W_{12}O_{40}]\cdot mH_2O$ in the $^4A_2\rightarrow{}^4T_1(^4F)$ transition region at 77 K. The curve a is unpolarized and $\boldsymbol{E}$ is perpendicular (b) and parallel (c) to the hexagonal principal axis. The curves b and c have been shifted expediently upwards along the ordinate.

due to water at 5560 cm^{-1}, 5160 cm^{-1}, and 4270 cm^{-1}.

The $^4A_2\rightarrow{}^4T_1(^4F)$ band splits into three to four peaks which show slight anisotropy (Figs. 5 and 6 and Table 2). The magnitude of the splitting by about 1340 cm^{-1} is predominantly due to the spin-orbit coupling in the excited state. The first-order value for this splitting is given by 6λ. Therefore, $|\lambda|$ is 223 cm^{-1} for this complex, the value of which is even larger than the free ion value of 178 cm^{-1}.[4,23] When the B value is decreased from the free ion value, $|\lambda|$ is also expected to be decreased. The reason for the above contradiction is probably that $|\lambda|$ is overestimated since it is evaluated primarily on the assumption that the splitting of the $^4T_1(^4F)$ band is entirely due to the spin-orbit coupling.

The $^4A_2\rightarrow{}^4T_1(^4P)$ band is too strong to be fully resolved.

A 26000-cm^{-1} band which perhaps corresponds to a 25910-cm^{-1} shoulder in the solution spectrum may be attributed to a charge-transfer transition between a ligand oxygen atom and a central Co(II) ion. This band is observed in higher wavenumbers than that of the Co(III) complex described above. The similar bands have been reported for the spectra of Co(II) in yttrium gallium garnet (26316 cm^{-1})[24] and of Ni(II) both in yttrium gallium garnet (23255 cm^{-1}) and in ZnO (22935 cm^{-1}).[25]

The authors wish to express their sincere thanks to Mr. S. Okuyama and Mr. E. Sakai for their cooperation in the experiment.

(Received September 6, 1984)

Crystal structures of the two isomeric Co(III) complexes with sexidentate ligands, $(NH_2CH_2CH_2)_2NC^*H(CH_3)CH_2C^*H(CH_3)N(CH_2CH_2NH_2)_2$ (hereafter abbreviated as *R,R*- and *R,S*-tptn) and of the Co(III) complex with a sexidentate ligand, $(NH_2CH_2CH_2)_2NCH_2CH_2CH_2N(CH_2CH_2NH_2)_2$ (abbreviated as ttn) were determined by an X-ray diffraction method. The crystal data and the final *R* factors are: (**1**) [Co(*R,R*-tptn)]$(ClO_4)_3\cdot H_2O$, tetragonal, $P4_22_12$, a=12.800(1), c=15.312(1) Å, V=2509(1) Å^3, Z=4, R=0.053 for 1627 observed unique reflections, (**2**) [Co(*R,S*-tptn)]$Cl_3\cdot 3H_2O$, monoclinic, $P2_1/a$, a=16.778(6), b=14.296(2), c=9.478(4) Å, β=110.99(3)°, V=2123(1) Å^3, Z=4, R=0.045 for 3583 reflections and (**3**) [Co(ttn)]$Br_3\cdot H_2O$, trigonal, $P\bar{3}c1$, a=14.436(4), c=15.718(9) Å, V=2837(2) Å^3, Z=6, R=0.096 for 1183 reflections. The equatorial preference of the methyl groups in the central six-membered chelate ring formed by Co and 2,4-pentanediamine moiety of *R,R*- and *R,S*-tptn has been recognized. In (**1**) the six-membered chelate ring adopts a twist boat form as in (**3**) with the two C-CH_3 bonds in equatorial positions. In (**2**) the six-membered chelate ring takes a largely flattened chair form with the two C-CH_3 bonds again in equatorial positions. The effect of an elongation of the Co-N bond distance on the energy of the first absorption band was discussed.

New sexidentate ligands, *R,R*- and *R,S*-tptn and their Co(III) complexes were synthesized and characterized.[1] $[Co(R,R\text{-tptn})]^{3+}$ gives the first absorption band at 20.8×10^3 cm^{-1}, whereas $[Co(R,S\text{-tptn})]^{3+}$ shows the first absorption maximum at 20.0×10^3 cm^{-1}, indicating that the ligand field exerted by the *R,S*-tptn is weaker than that by the *R,R*-tptn. A simple molecular model indicates that both isomers act as a sexidentate ligand to give metal complexes analogous to those of 1,3-propanediamine-*N,N,N',N'*-tetraacetic acid (trdta) as shown in Fig. 1. The central six-membered chelate ring in (—)$_{546}$-*ΔΔΔ*-[Co(trdta)]$^-$ takes a skew boat form.[2] The central six-membered chelate ring of $[Co(R,R\text{-tptn})]^{3+}$ is expected to adopt a skew boat form with the two C-CH_3 bonds in equatorial positions. In this connection, the absolute configuration must be skew chelate pairs *ΔΔΔ*. If the central six-membered chelate ring of $[Co(R,S\text{-tptn})]^{3+}$ takes a skew boat form, one of the two C-CH_3 bonds will be equatorial and the other axial as shown in Fig. 1. Both of the methyl groups can be in equatorial positions if the central chelate ring takes a chair form with a distorted CoN_6 octahedron. In any case, the *R,S*-complex would be much deformed owing to the nonbonded interactions. Such a strained structure may be reflected in the absorption spectrum. In order to see how the distortion of the CoN_6 chromophore affects the absorption spectra, two complexes (**1**) and (**2**) were subjected to X-ray crystal structure analysis. In addition to this, the structure of (**3**), which has no C-CH_3 bonds in the central six-membered chelate ring, was determined in order to compare the conformation with (**1**) and (**2**).

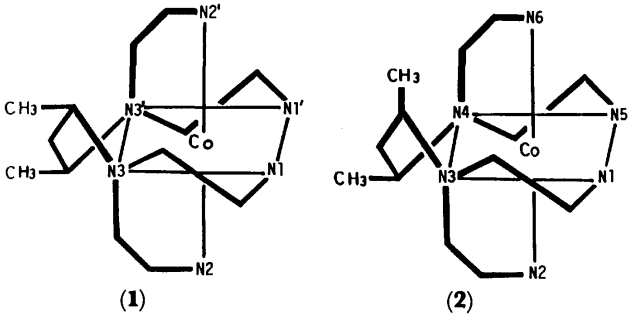

Fig. 1. Coordination of *R,R*- and *R,S*-tptn. The central six-membered chelate ring is assumed to take a skew boat form.

Experimental

Crystals of (**1**), (**2**), and (**3**) grown from aqueous solutions were kindly provided by Professor J. Fujita of Nagoya University. Experimental conditions and refinement informations are listed in Table 1. The preliminary determination of the lattice parameters and the space group of (**1**) and (**2**) was made with a Weissenberg camera. Intensities were measured using graphite monochromatized Mo *Kα* radiation (λ=0.70926 Å) on an automated Rigaku four-circle diffractometer AFC-5. The θ—2θ scan technique was employed at a scan rate of 4° min^{-1} in θ.

The usual corrections were made for Lorentz and polarization factors. The structures of (**1**) and (**2**) were solved by the heavy atom method. Positions of Co and Cl atoms were determined from the Patterson function and the other non-hydrogen atoms were located by Fourier syntheses. All the hydrogen atoms except those of the water molecule in (**1**) were found on the difference synthesis. The Laue group and systematic absences showed that the space group of (**3**) is

P3cl or P$\bar{3}$cl. Assuming the non-centrosymmetry, the structure was solved by direct methods.[3] The possible positions of the Br and Co atoms obtained from the E map were confirmed by the Patterson function. All the non-hydrogen atoms of the sexidentate ligand were found on the Fourier synthesis. A projection of the crystal structure at this stage of the refinement suggested that the Co lies on a twofold axis perpendicular to c. It is a special position **6f** of the space group P$\bar{3}$cl. Accordingly, the space group was determined to be P$\bar{3}$cl. The general position of P$\bar{3}$cl is twelvefold and there are six formula units in a unit cell. Hence, there are 18 Br atoms in the unit cell, sixteen of which were allocated on a set of general positions **12g** and a set of special positions **4d**. It was found that the remaining two Br atoms are disordered. The difference synthesis can be most conveniently accounted for if the Br atoms are distributed randomly on the sets of special positions **2b** and **4c**, and two sets of general positions **12g** (See Table 2). The population parameters of these Br atoms were estimated by the trial and error method in such a way that each isotropic thermal parameter took nearly equal value. Positions of the hydrogen atoms in (**3**) could not be deduced from the difference synthesis so that they were obtained by calculation and not refined.

Anisotropic thermal parameters were introduced for all the non-hydrogen atoms except for the disordered Br atoms of (**3**). The function, $\Sigma w||F_o|-|F_c||^2$ was minimized by block-diagonal least squares. Complex neutral-atom scattering factors were used.[4] The calculations were carried out on a FACOM M180 computer at Keio University with the Universal Crystallographic Computation Program System UNICS III.[5] The final atomic parameters are listed in Table 2.[6]

The absolute structure of (**1**) was determined with reference to the known absolute configuration of *R,R*-tptn prepared from (*R,R*)-2,4-diaminopentane.[7]

Results and Discussion

Perspective drawings of complexes (**1**), (**2**), and (**3**) and projections of the central six-membered chelate rings of these complexes along the twofold axis or along the pseudo twofold axis are presented in Fig. 2. The bond lengths and bond angles within the com-

* Population parameters of Br atoms in disorder are as follows.

Atom	Wyckoff notation of the position	Population parameter	Number of atoms in a unit cell
Br(3)	2b	0.04	0.48
Br(4)	4c	0.025	0.30
Br(5)	12g	0.065	0.78
Br(6)	12g	0.0367	0.44
			Σ 2.00

plex ions are listed in Table 3. The absolute configuration of the complex (**1**) is *ΔΔΛ* as expected. The complex has a crystallographic twofold axis through the Co and C(7) atoms. The central six-membered chelate ring takes a skew boat form with the two methyl groups in equatorial positions. The C(6)–C(5) bond axis is inclined by 6.5(5)° with respect to the coordination plane formed by Co, N(3), and N(3′) atoms, from which the C(6) is shifted by 0.67(1) Å. There are two optical isomers *ΔΔΛ* and *ΔΔΔ* in a unit cell of (**2**) and (**3**). Figure 2 depicts a *ΔΔΛ* isomer for the convenience of comparison with (**1**). The geometry of the complexes (**1**) and (**3**) is essentially identical. The difference of 0.039 Å in Co–N(1) bond lengths of (**1**) and (**3**) is not significant because of the large e.s.d. of the structural data of (**3**).

The central six-membered chelate ring of (**2**) is distorted unsymmetrically, exhibiting a largely flattened chair form with the two C–CH_3 bonds in equatorial positions. The Co, N(3), N(4), and C(6) are practically on one plane, from which the C(7) and C(8) atoms are shifted on opposite sides by 0.28(1) and 0.53(1) Å, respectively. The Co–N bond lengths in (**2**) are in the order Co-tertiary N>Co-apical primary N>Co-primary N atom which is in the trans position to the tertiary N atom. The Co–N(4) bond length of 2.021(3) Å agrees with the Co-tertiary N bond lengths of (**1**) and (**3**) [2.017(4) and 2.018(13) Å]. The Co-tertiary N bond lengths of (**2**) differ from each other, Co–N(3) being longer by 0.021(3) Å than Co–N(4). It

suggests a distortion of the CoN_6 octahedron. N(3)-Co-N(4) angle of 101.0(1)° in (**2**) is larger by 4.8 (2)° than N(3)-Co-N(3′) angle in (**1**). Edge-on view of the five-membered chelate rings are shown in Fig. 3. They adopt an envelope conformation except B ring of (**2**). N(1)-Co-N(3) angle of the chelate ring B, 81.6(1)° and N(2)-Co-N(3) angle of the ring E, 83.7(1)° are smaller than the corresponding angles in the chelate rings C and D by 3.9(1) and 1.0(1)°, respectively.

In Fig. 3 the tertiary N atoms are hatched. The conformations of the apical chelate rings D and E of

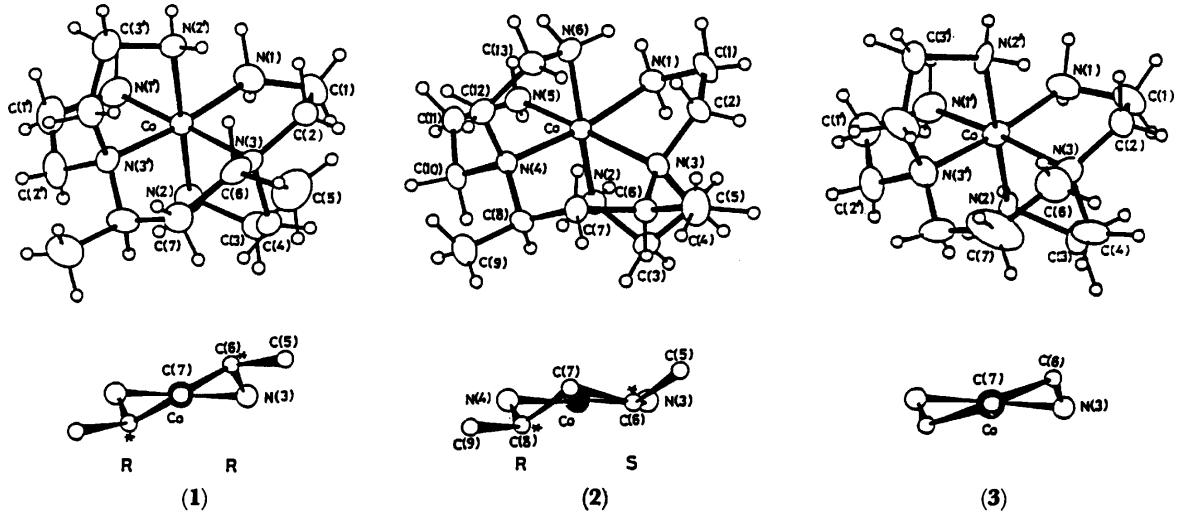

Fig. 2. Molecular structures of (**1**), (**2**), and (**3**). Projections of the central six-membered chelate rings along the midpoint of two tertiary N atoms to the Co are also shown.

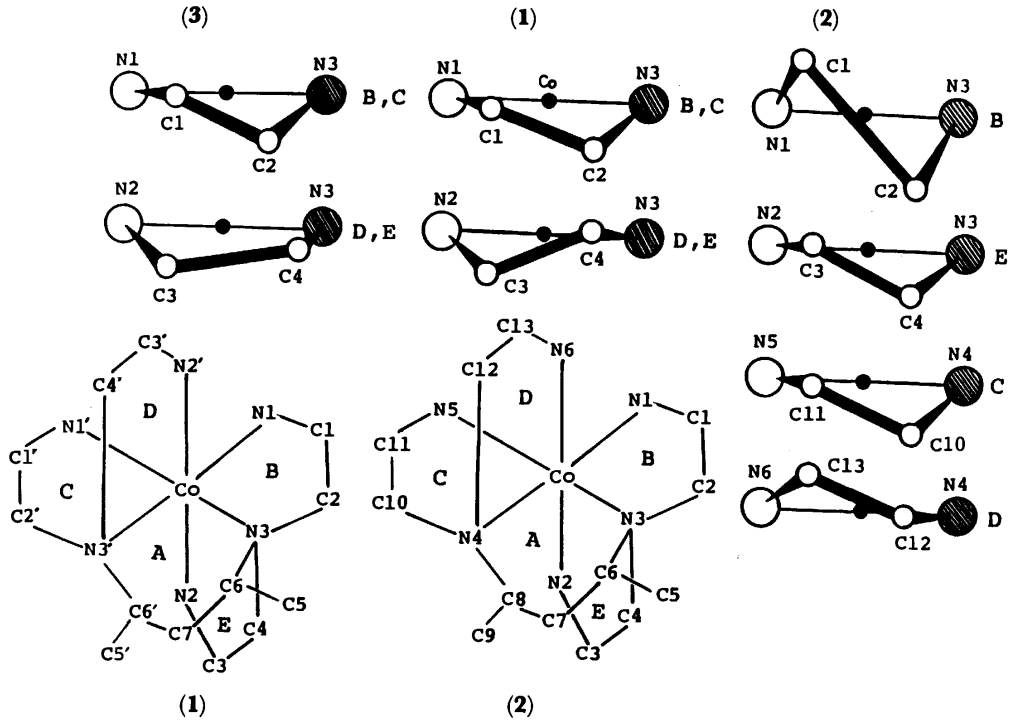

Fig. 3. Edge-on views of the five-membered chelate rings. The shaded circles stand for the tertiary N atoms, the black circles for the Co atoms.

(**1**) and (**2**) differ from each other. The simple molecular model indicates that the ring D in (1) avoids a short contact between H(C6) and one of the H atoms bonded to C(3′), and that the conformation of the ring E in (**2**) is the result of the flattened chair form of the central chelate ring, A. Table 4 lists the hydrogen bonds. The ring D in (**2**) takes a conformation which can form two hydrogen bonds, O(1)···H(N6)1-N(6) and Cl(3)···H(N6)2-N(6) in the crystal. Co-N(3)-C(6) angle of (**2**) is 120.5(2)°. It nearly equals to the mean Co-N-C angle of 122.2(2)° in $[Co(tn)_3]^{3+}$ (tn=1,3-propanediamine), which takes the C_3-chair$_3$ conformation.[8] The N-Co-N angle in the ring E of (**1**) and (**3**) agrees with that of 85.4(1)° in *lel*$_3$-$[Co(en)_3]^{3+}$ (en=1,2-ethanediamine),[9] and smaller by *ca.* 1° than that in the ring B.

The octahedral splitting parameter $10D_q$ can be easily shown to be proportional to r^{-5}, where r is the Co-N distance, if simple electrostatic model is assumed for the ligand field as a crude approximation.[10] In Fig. 4, the energy of the first absorption maxima of some Co(III) complexes with CoN_6 chromophore are plotted against the inverse fifth power of the average Co-N bond distances. A positive correlation is observed. It

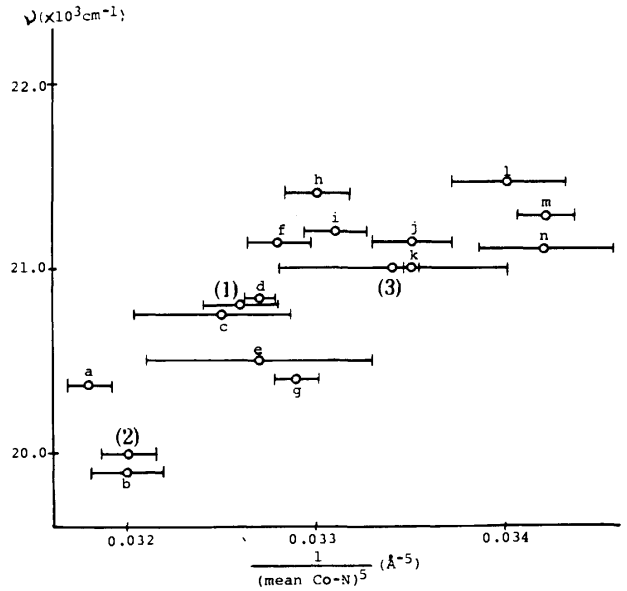

Fig. 4. Plot of the energy of the first absorption band against the inverse fifth power of the mean Co–N bond length of $Co(III)N_6$ complexes: a) $(+)_{589}$-*fac*-$[Co(R,S\text{-ptn})_3]^{3+}$,[11] b) $(+)_{589}$-$[Co(tmd)_3]^{3+}$,[12] c) $(-)_{546}$-$[Co(R,R\text{-ptn})_3]^{3+}$,[13] d) $(+)_{470}$-*cis*-$[Co(NH_3)_2(R,R\text{-ptn})_2]^{3+}$,[14] e) $(+)_{589}$-$[Co(ten)]^{3+}$,[15] f) $(+)_{589}$-(*ob*$_3$)-$[Co(chxn)_3]^{3+}$,[16] g) $(-)_{589}$-$[Co(tn)_3]^{3+}$,[8] h) $(+)_{589}$-(*lel*$_3$)-$[Co(en)_3]^{3+}$,[9] i) $(+)_{589}$-$[Co(linpen)]^{3+}$,[17] j) $(-)_{589}$-(*lel*$_2$ob)-$[Co(chxn)_3]^{3+}$,[18] k) $[Co(NH_3)_6]^{3+}$,[19] l) $(+)_{589}$-*mer*-$[Co(dien)_2]^{3+}$,[20] m) $(+)_{589}$-$[Co(en)_2(3,3'\text{-dmbpy})]^{3+}$,[21] n) $(-)_{589}$-$[Co(R,R\text{-chxn})_2(3,3'\text{-dmbpy})]^{3+}$,[22]. Error bars show ±(e.s.d.)/2.

was shown that the Co–N bond elongation in (**2**) which is caused by the nonbonded interactions is an important factor for the lower energy of the first absorption band than that of (**1**).

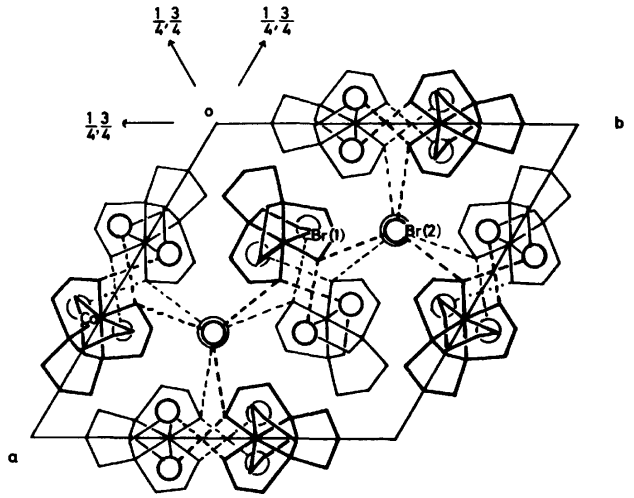

Fig. 5. A projection of the crystal structure of (**3**) along *c*. The broken lines indicate the hydrogen bonds.

A remark will be given on the disorder of the bromide ions in (**3**). The complex ions $[Co(ttn)]^{3+}$ and bromide ions Br(2) are held together by N-H···Br hydrogen bonds to form layers approximately perpendicular to *c* as shown in Fig. 5. These layers are stacked parallel to form a three-dimensional framework by attraction of Br(1) anions between the layers to the complex cations. There exists a hollow around the origin, in which the disordered bromide ions lie. The shortest interatomic distance involving Br(3) atom is 3.38 Å for Br(3)···H(C4)1 ($-y$, $1-x$, $-1/2+z$), longer than 3.05 Å, the sum of the van der Waals radius of Br and H atoms.[23]

The authors are grateful to Professor Junnosuke Fujita, Nagoya University for supplying the crystal specimen.

Studies on the $G(Fe^{3+}\rightarrow Fe^{2+})$-value in the Radiolysis Caused by $^{6}Li(n,\alpha)T$ Reaction in Lithium Tris(oxalato)ferrate(III)

Junko Akashi, Tomoko Kojima, Yoshio Uchida, and Hirotoshi Sano*
Department of Chemistry, Faculty of Science, Tokyo Metropolitan University, Fukasawa, Setagaya, Tokyo 158
(Received October 13, 1984)

The *G*-values for the reduction of iron(III) to iron(II) state caused by $^{6}Li(n,\alpha)T$ reaction in $Li_3[Fe(C_2O_4)_3]\cdot 4.5H_2O$ and in anhydrated $Li_3[Fe(C_2O_4)_3]$ were determined by taking into account the saturation of the effect of increasing neutron fluence. The contribution of the fast neutrons and γ-rays in a nuclear reactor to the reduction was estimated by using a cadmium tube, and by using the results estimated in the ^{60}Co γ-ray irradiation, respectively. The $G(Fe^{3+}\rightarrow Fe^{2+})$-value in the radiolysis caused by $^{6}Li(n,\alpha)T$ reacation in $Li_3[Fe(C_2O_4)_3]\cdot 4.5H_2O$ is larger than that in the γ-ray radiolysis, and is also larger than the *G*-value for anhydrated $Li_3[Fe(C_2O_4)_3]$, suggesting that the radiolysis of the water of crystallization contributes to the reduction of the iron(III) species.

It has been pointed out elsewhere that the chemical effects of EC decay in several ^{57}Co-doped coordination compounds are considered to be caused by a nucleogenic local radiolysis in the compound.[1] In our previous papers,[2,3] the reduction of the iron(III) species to the iron(II) species in lithium tris(oxalato)-ferrate(III) by thermal-neutron irradiation was studied by means of Mössbauer spectroscopy. The reducing effets were attributed to a radiolytic process caused by the $^{6}Li(n,\alpha)T$ reaction.

The present paper describes the details of the effects of the $^{6}Li(n,\alpha)T$ reaction on the hydrated and anhydrated lithium tris(oxalato)ferrate(III), including an estimation of the *G*-values for reductions in those systems which are important for a better understanding of the processes caused by the $^{6}Li(n,\alpha)T$ reaction in connection to the chemical effects in the blanket materials in a fusion reactor. In order to estimate the *G*-value, the dependence of the areal intensity ratio of iron(III) to iron(II) in the Mössbauer spectra were studied on the irradiation time and on the thermal-neutron fluence rate. The effects of the fast neutrons and γ-rays concomitant in the reactor on the reduction were also determined.

Experimental

Hydrated lithium tris(oxalato)ferrate(III), $Li_3[Fe(C_2O_4)_3]\cdot 4.5H_2O$, sodium tris(oxalato)ferrate(III), $Na_3[Fe(C_2O_4)_3]\cdot 5H_2O$ and potassium tris(oxalato)ferrate(III), $K_3[Fe(C_2O_4)_3]\cdot 3H_2O$ were synthesized in the conventional ways.

The particle size of the samples was furnished to 200—300 mesh throughout the present work. Anhydrated $Li_3[Fe(C_2O_4)_3]$ was prepared by heating the $Li_3[Fe(C_2O_4)_3]\cdot 4.5H_2O$ at 400 K for 10-30 min in air.

Each 100 mg of the sample heat-sealed under nitrogen in a polyethylene envelope was irradiated either within or without a 0.5-mm thick cadmium tube in a 100-kW TRIGA MarkII reactor at the Institute for Atomic Energy, Rikkyo University.

The irradiated samples were kept in liquid nitrogen until the Mössbauer spectroscopic measurements were carried out. Mössbauer spectra were recorded with a constant-acceleration type spectrometer at 80 K. Isomer-shift values were reported with respect to metallic iron foil.

γ-Ray irradiations were carried out using a ^{60}Co-source, at the Institute of Physical and Chemical Researches, at a dose rate of 9,780 rad min^{-1} (H_2O).

Results and discussion

The Mössbauer spectrum of a sample irradiated at a thermal-neutron fluence rate of 5×10^{11} n s^{-1} cm^{-2} and at a fast-neutron fluence rate of 4.5×10^{10} n s^{-1} cm^{-2} for 2 h within the cadmium tube, which absorbs neutrons with the energy of less than 0.4 eV, is shown in Fig. 1 (b). The spectra of the sample irradiated at the same fluence rates of thermal and fast neutrons for 4 h within the cadmium tube are compared in Fig. 1 (c). A distinctive change is not found in the irradiated sample compared with the spectrum of the non-irradiated sample (Fig. 1 (a)), except for a small peak component ascribed to iron(II) species as found in Fig. 1 (c). In the spectrum shown in Fig. 1 (c), the areal intensity ratio of iron(II) to the total iron species is estimated to be less than 0.09. As shown in Fig. 1 (d), the ratio in the spectrum of the neutron-irradiated $Li_3[Fe(C_2O_4)_3]\cdot 4.5H_2O$ in the same irradiation conditions as in the case of Fig. 1(c) is estimated to be 0.67. The ratio is much larger without the cadmium tube than that obtained within the tube as found in Fig. 1(c), suggesting that the reduction of iron(III) to iron(II) observed in the neutron-irradiated $Li_3[Fe(C_2O_4)_3]\cdot 4.5H_2O$ is mainly attributed to the effect of thermal neutrons. Figures 2 (a) and (b) show the Mössbauer spectra of $Li_3[Fe(C_2O_4)_3]\cdot 4.5H_2O$ subjected to γ-rays of the total dose of 4×10^{7} rad and 1.0×10^{8} rad, respectively, at a dose rate of 9,780 rad min^{-1} (H_2O). Although the total dose in the reactor for the experiment of Fig. 2 (a) is estimated to be about 7 times larger than that in the irradiation conditions used for Fig. 1 (c), it is still not as remarkable a

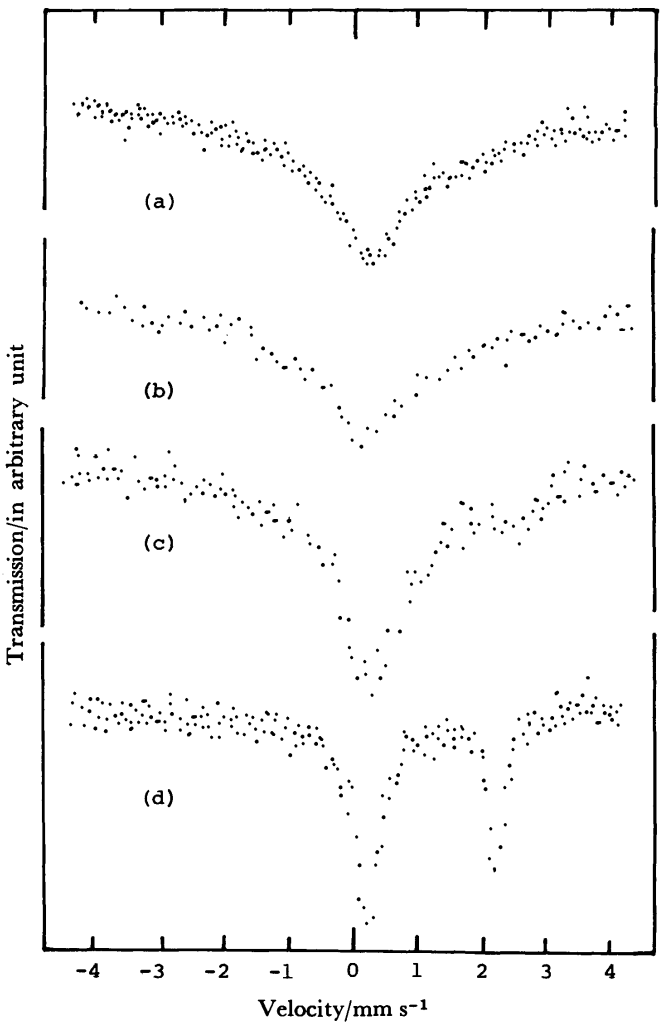

Fig. 1. Mössbauer spectra at 80 K of (a) unirradiated, (b) neutron-irradiated within a cadmium tube, (2 h), (c) neutron-irradiated within a cadmium tube, (4 h), and (d) neutron-irradiated without a cadmium tube, (4 h), $Li_3[Fe(C_2O_4)_3]\cdot 4.5H_2O$. (thermal neutron fluence rate: 5×10^{11} n s^{-1} cm^{-2} fast neutron fluence rate: 4.5×10^{10} n s^{-1} cm^{-2}).

reduction in Fig. 2 (a) as is found in Fig. 1 (c). Based on the linear dependence of the areal-intensity ratio of the iron(II) species to the total iron species in the spectra on the γ-ray irradiation time, the G-value for the reduction of iron(III) in $Li_3[Fe(C_2O_4)_3]\cdot 4.5H_2O$ caused by the γ-ray irradiation is estimated to be 8.4.

The $G(Fe^{3+}\rightarrow Fe^{2+})$-value for γ-ray-irradiated potassium, sodium and ammonium salts obtained in a similar way are listed in Table 1, together with that of the lithium salt for the sake of comparison. The value for the lithium salt is a little smaller than those for the potassium, sodium and ammonium salts.

As in the case of Fig. 1 (d), the neutron-irradiated potassium and sodium tris(oxalato)ferrate(III) at the same neutron irradiation condition also show little contribution of the iron(II) species as found in

Table 1. G-values for reduction of tris(oxalato)-ferrate(III) crystals by ^{60}Co γ-ray irradiations

Compound	$G(Fe^{3+}\rightarrow Fe^{2+})$
$Li_3[Fe(C_2O_4)_3]\cdot 4.5H_2O$	8.4
$Na_3[Fe(C_2O_4)_3]\cdot 5H_2O$	10.1
$K_3[Fe(C_2O_4)_3]\cdot 3H_2O$	15.1
$(NH_4)_3[Fe(C_2O_4)_3]\cdot 2H_2O$	16.1
$Li_3[Fe(C_2O_4)_3]$	7.3

Table 2. Areal intensity ratios of iron(III) species to total iron species in several irradiation conditions in lithium tris(oxalato)ferrate(III)

Fluence rate / n s^{-1} cm^{-2}	Irradiation time / h				
	0.5	1	2	4	6
5×10^{11}	0.82	0.64	0.44 0.45*	0.34	—
1.2×10^{12}	—	—	0.32 0.33*	0.05	0.01

* Irradiated at 200 K, others at an ambient temperature in a reactor.

Fig. 3, which is similar to the result found in ammonium salt reported in the previous result.[2] The results indicate that the G-value is negligibly small for the reduction caused by γ-rays in the lithium tris(oxalato)ferrate(III) during irradiation in the reactor for 4 h at the same neutron fluence rate as in the case of Fig. 1 (d).

The areal-intensity ratios of the iron(III) to the total iron species in several neutron-irradiation conditions for $Li_3[Fe(C_2O_4)_3]\cdot 4.5H_2O$ are listed in Table 2.

The ratio in the neutron-irradiated $Li_3[Fe(C_2O_4)_3]\cdot 4.5H_2O$ at an ambient temperature in the reactor is similar to that in the sample irradiated at 200 K (as cited in Table 2), indicating that the restoration of the iron(III) species through the thermal annealing during and after the $^6Li(n,\alpha)T$ reaction is negligibly small in the system. The ratios for neutron-irradiated $Li_3[Fe(C_2O_4)_3]\cdot 4.5H_2O$ decrease linearly neither with increased irradiation time nor with total neutron-fluence, which can be explained by assuming the presence of a saturation process in the reduction, *i.e.*, the iron(II) species produced by the $^6Li(n,\alpha)T$ reaction is practically not affected by the thermal-neutron irradiation. By simply applying the first-order reaction rate, the number of iron(III) atoms affected by the $^6Li(n,\alpha)T$ reaction is expected to follow the equations,

$$dN/d(nt) = -kN, \quad N=N_0\exp(-knt)$$

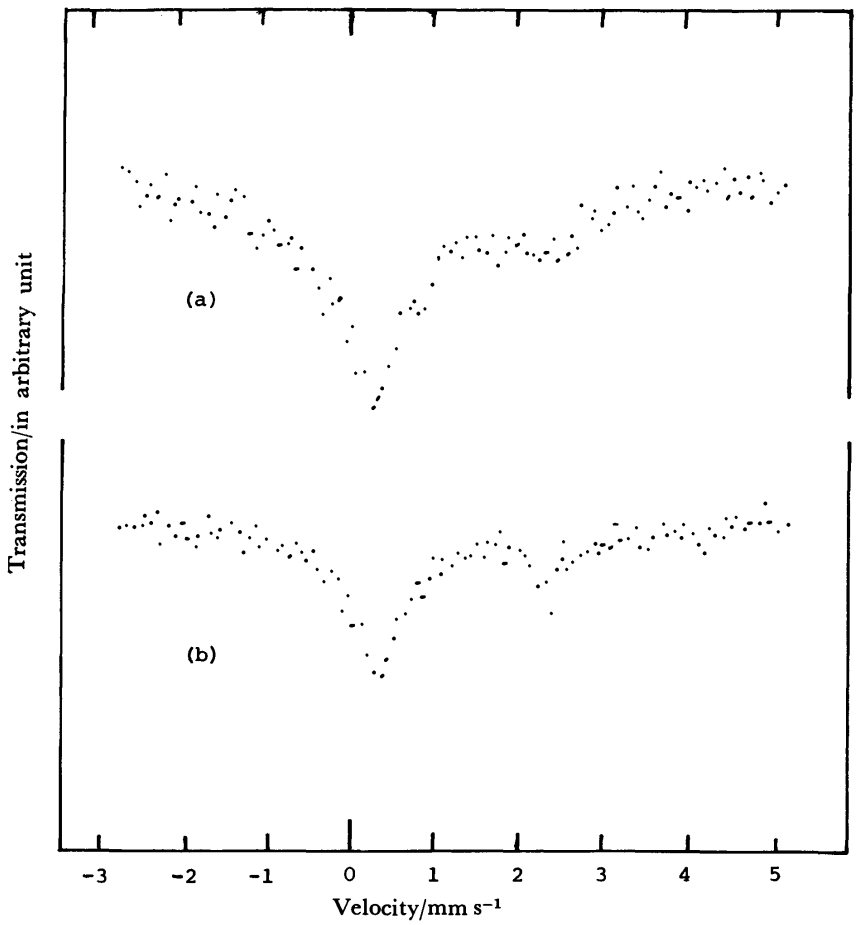

Fig. 2. Mössbauer spectra at 80 K of (a) γ-irradiated (4×10^7 rad) and (b) γ-irradiated (1.0×10^8 rad) $Li_3[Fe(C_2O_4)_3] \cdot 4.5H_2O$.

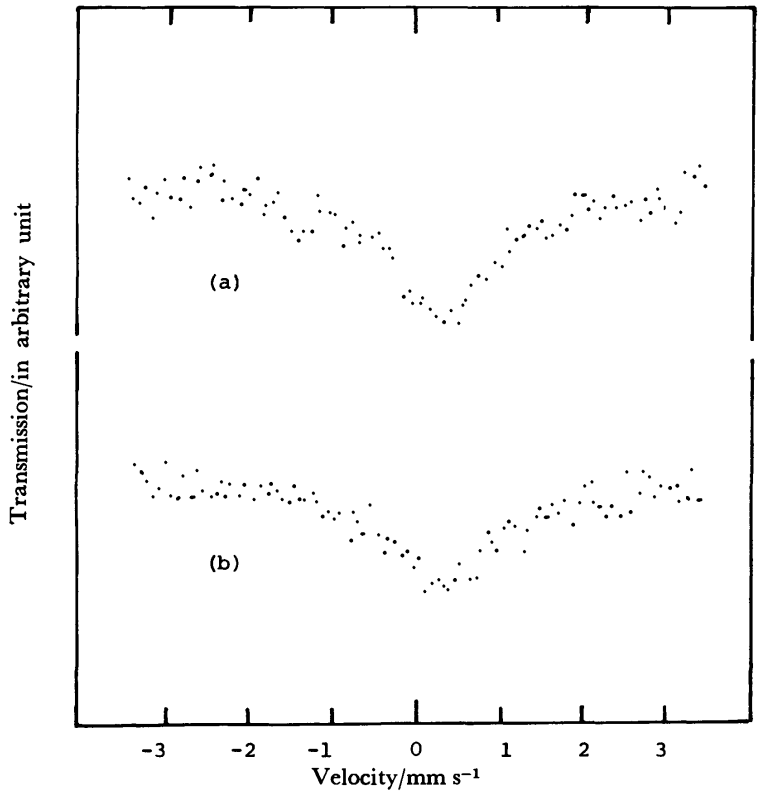

Fig. 3. Mössbauer spectra at 80 K of neutron-irradiated (5×10^{11} n s^{-1} cm^{-2}, 4 h) (a) $Na_3[Fe(C_2O_4)_3] \cdot 5H_2O$ and (b) $K_3[Fe(C_2O_4)_3] \cdot 3H_2O$.

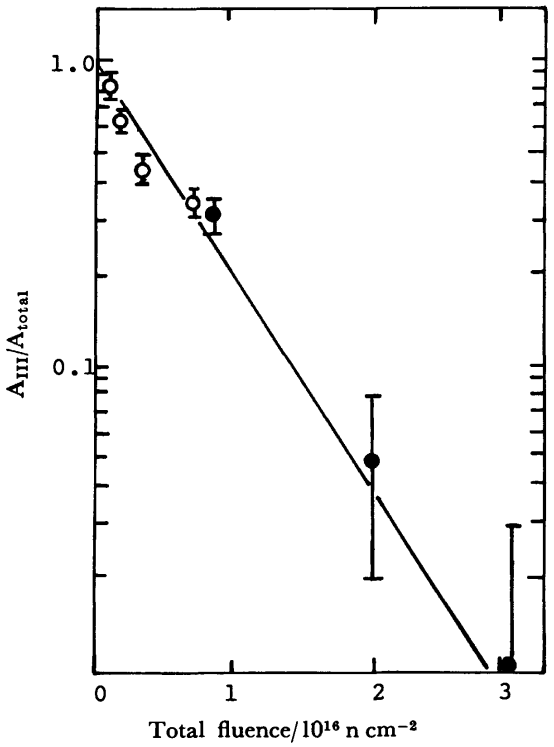

Fig. 4. Areal intensity ratio of Fe(III) to total iron species against thermal neutron fluence in Mössbauer spectra of $Li_3[Fe(C_2O_4)_3]\cdot 4.5H_2O$.

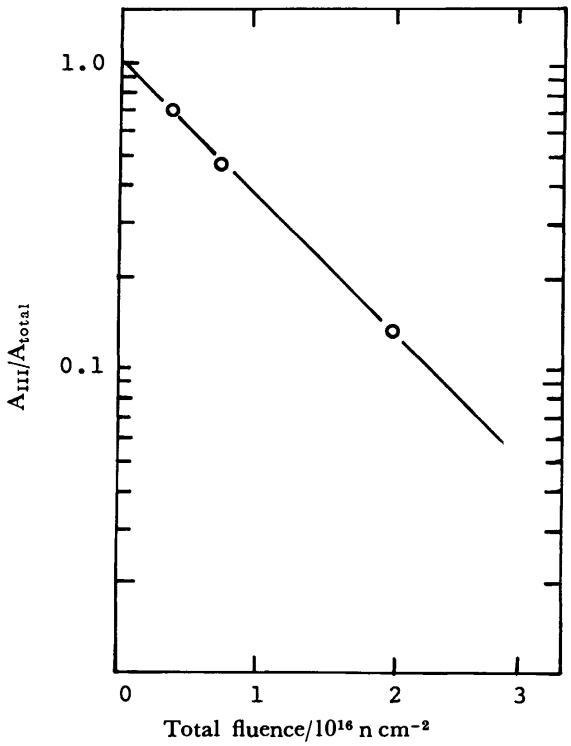

Fig. 5. Areal intensity ratio of Fe(III) to total iron species against thermal neutron fluence in Mössbauer spectra of $Li_3[Fe(C_2O_4)_3]$.

where N: the number of the iron(III) species.
n: thermal neutron fluence rate.
t: irradiation time.
k: rate constant.
N_0: initial number of the iron(III) species.

As a plot of the logarithm of the ratio of the iron(III) species to the total iron species gives practically a straight line against the increased neutron fluence, as shown in Fig. 4. The hypothetical equation seems to be useful to interpret the experimental results. The overall $G(Fe^{3+}\rightarrow Fe^{2+})$-value for the reduction in $Li_3[Fe(C_2O_4)_3]\cdot 4.5H_2O$ caused by the $^6Li(n,\alpha)T$ reaction is estimated to be 18.2 from the gradient of the line in Fig. 4. The G-value for the reduction of an anhydrated compound caused by the $^6Li(n,\alpha)T$ reaction is estimated to be 10.1 based on a similar plot, as shown in Fig. 5.

The G-value corresponds to about half of that obtained for the hydrated one, even after the small increases in the concentrations of iron and lithium compared with those in the hydrated compound. The results imply that the hydrated compound should more easily be subjected to the reduction caused by the $^6Li(n,\alpha)T$ reaction than the anhydrated one, and that the radiolytic products of water of crystallization should play an important role in the reduction of iron(III) to iron(II).

The small deviations of the experimental points from the line found in Fig. 4, may be ascribed to the possible decrease of water of crystallization in the sample during the irradiation at the accumulated fluence values. The G-value for the reduction caused by the $^6Li(n,\alpha)T$ reaction is estimated to be 19.9 from the line component derived from the data in the lower fluence region. These obtained G-values are summerized in Table 3.

Table 3. G-values for the reduction of the iron caused by the $^6Li(n,\alpha)T$ reaction in lithium tris(oxalato)ferrate(III)s

Compound	$G(Fe^{3+}\rightarrow Fe^{2+})$	
$Li_3[Fe(C_2O_4)_3]\cdot 4.5H_2O$	19.9	estimated from areal intensity of the Mössbauer spectrum in early stage of irradiation
	18.2	estimated from log plot as shown in Fig. 4
$Li_3[Fe(C_2O_4)_3]$	10.1	estimated from log plot as shown in Fig. 5

The $G(Fe^{3+}\rightarrow Fe^{2+})$-value for the hydrated lithium tris(oxalato)ferrate(III) in the $^6Li(n,\alpha)T$ reaction is about 2 times larger than that in the γ-ray-radiolysis using a ^{60}Co source, as shown in Tables 1 and 3. The difference should be attributed to the high values of

the linear energy transfer (LET) of alpha and tritium particles emitted by the $^{6}Li(n,\alpha)T$ reaction. The results reveal that a higher density of electrons and excited species, such as radicals or ions, produced by the high-energy particles is more effective in causing the reduction of the iron(III) to the iron(II) species in lithium tris(oxalato)ferrate(III).

The Selective *N*-Monoalkylation of Amides with Alkyl Halides in the Presence of Alumina and KOH

Kazuaki SUKATA*
Nihon Tokushu Kagaku Kogyo Co., Ltd., 3-36, Tohda-cho, Moriguchi, Osaka 570
(Received July 27, 1984)

The effects of alumina impregnated with KOH (KOH/Al_2O_3) and a mixture of alumina and powdered KOH ($KOH+Al_2O_3$) have been examined using the alkylation of benzamide under various conditions. In each case, alkylation occurs exclusively in the pores of the alumina, the extent depending upon the alumina-pore size. For both yield and selectivity for *N*-monoalkylation, $KOH+Al_2O_3$ is superior to KOH/Al_2O_3. Dioxane is the best of the solvents employed. It is proposed that, in dioxane, an enolate-like species, $PhC(O^-K^+)=NR'$, exists as stable ion-pair aggregates, which are the true reactants in the pore. This method, using KOH/Al_2O_3 or $KOH+Al_2O_3$, has been applied to *N*-alkylation of the other amides, giving the *N*-monoalkylated products in substantial yields with extremely high selectivities. 2-Phenylacetamide is regioselectively *N*-monoalkylated in high yields. This regioselectivity is explained in terms of steric hindrance.

It has recently been reported that amides are *N*-monoalkylated in substantial yields under phase-transfer catalytic conditions.[1] In the case of propanamide, which also has a weakly acidic N-H bond, however, the yields are considerably lower than those of benzamide (**1**). When highly-reactive benzyl chloride is employed as an alkylating agent, substantial quantities of *N,N*-dibenzylated products are obtained. More recently, Watanable *et al.* have reported the *N*-alkylation of amides with alcohols using ruthenium compounds as catalysts.[2] In this process, however, the yields and the selectivities for *N*-monoalkylation were low, with only a few exceptions.

In recent years, many studies have been reported on selective organic synthesis using inorganic solids.[3] Recently, the present author has himself reported the selective monoalkylation of phenylacetonitrile (PAN) using alumina impregnated with KOH or NaOH (KOH/Al_2O_3 or $NaOH/Al_2O_3$).[4a] It was shown that the reaction of the carbanion with alkyl halide occurs in the pores of the alumina and that the selectivity can be explained in terms of steric hindrance.

It has now been found that amides are selectively *N*-monoalkylated with alkyl halides in the presence of alumina and KOH.

Results and Discussion

The *N*-alkylation of **1** with alkyl halides (**5**) was carried out under various conditions using KOH/Al_2O_3 or a mixture of alumina and powdered KOH.

N-Alkylation of 1 Using KOH/Al_2O_3. In order to ascertain the effects of solvents, the *N*-alkylation of **1** with ethyl bromide was carried out using M-90-N alumina (Merck, Type 90, activity I, neutral, 70—230 mesh) impregnated with KOH (KOH/M-90-N) in several solvents. Table 1 shows the results. In the case of PAN, the order of the selectivities for monoalkylation has been found to be benzene>dioxane>THF>acetonitrile.[4a] In the case of **1**, however, the order of the selectivities for *N*-monoalkylation was dioxane≫benzene>THF>1,2-dimethoxyethane (DME)≈

Table 1. *N*-Ethylation of **1** using KOH/Al_2O_3 in several solvents[a]

Solvent	Time / h	Yield[b] / %	Selectivity Mono/% ; Di/%
Benzene	8	36	91 ; 9
	2[c]	45	84 ; 16
Dioxane	8	49	98.5 ; 1.5
THF	8	49	80 ; 20
DME	8	48	58 ; 42
Acetonitrile	2	52	58 ; 42
DMSO[d]	6	41	62 ; 38

a) Unless otherwise noted, the reactions were carried out with **1** (10 mmol), ethyl bromide (12 mmol), KOH (50 mmol)/Al_2O_3 (M-90-N, 10 g), and hexadecane (0.3 g) as the internal standard in a solvent (20 ml) at 60 °C. b) Mono+Di; determined by GLC. c) The reaction was carried out with **1** (10 mmol), ethyl bromide (12 mmol), finely powdered KOH (50 mmol), hexadecane (0.3 g) as the internal standard, and *n*-$Bu_4N^+Br^-$ (2 mmol) at 60 °C. d) No catalyst was used.

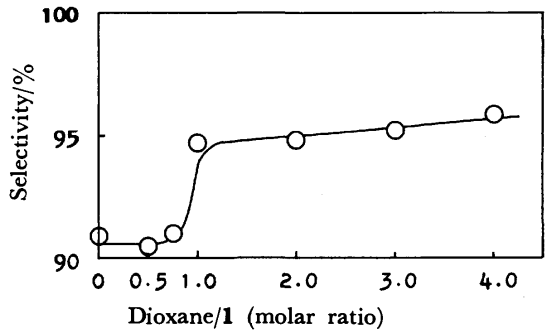

Fig. 1. The influence of the relative amount of dioxane to **1** on the selectivity for *N*-monoalkylation. The reactions were carried out with **1** (10 mmol), ethyl bromide (12 mmol), KOH (50 mmol)/M-90-N (10 g), and dioxane (0, 5, 7.5, 10, 20, 30, 40 mmol) in benzene (20 mL) at 60 °C for 8 h.

acetonitrile. An almost exclusive *N*-monoalkylation was achieved in dioxane.

In order to ascertain the specific solvent effect of dioxane, the influence of the amount of dioxane relative to that of **1** on the selectivity for *N*-monoalkylation was examined using alkylation with KOH/M-90-N and ethyl bromide in benzene (Fig. 1). At the dioxane/**1** molar ratio of *ca.* 1.0, a clear change in the selectivity was observed.

In order to establish the effect of the support pore size, the *N*-ethylation of **1** was carried out using several supports in benzene or in dioxane. Table 2 shows the results. The supports used were M-90-N, M-60-B alumina (Merck, Type 60, activity I, basic, 70—230 mesh), W-200-N alumina (Woelm, Type 200, neutral, activity super I), and Molecular Sieve 13X (MS-13X). The average pore diameters of M-90-N, M-60-B, and MS-13X are 90, 60, and 10 Å, respectively. The average pore diameter of W-200-N appears to be *ca.* 60 Å, based upon its specific surface area, which is *ca.* 200 m^2/g.[5] In the case of MS-13X, almost all of the **1** used was recovered. This resembles the alkylation of PAN.[4a] The pore diameter of MS-13X is too small for the reaction. The selectivities found in dioxane were much larger than those found in benzene in all cases examined.

Apparent differences were observed in the selectivity for *N*-monoalkylation, depending upon the kind of alumina (Table 2). The yield of *N,N*-dialkylation obviously increased with the increase in the average pore diameter. This fact, and the fact that almost no **1** is observed in the organic phase during the reaction, indicate that the *N*-alkylation occurs predominantly in the pore. Jackman *et al.* have recently shown that lithium enolates exist as tetramers or dimers in ether solvents[6] and that ion-pair aggregates are the true reactants in the methylation of lithiobutyrophenone in weakly polar aprotic solvents.[7] Similarly, an enolate-like species

Table 2. *N*-Ethylation of **1** using several supports in benzene or dioxane[a]

Solvent	Support	Yield[b] %	Selectivity Mono/% ; Di/%
Benzene	M-90-N	36	91 9
	M-60-B	42	99 1
	W-200-N	36	96 4
	MS-13X (powder)[c]	≪1	— —
	MS-13X (60—80 mesh)[c]	≪1	— —
Dioxane	M-90-N	49	98.5 1.5

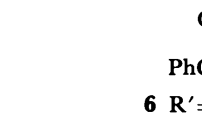
	MS-13X (powder)[c]	≪1	— —
	MS-13X (60—80 mesh)[c]	≪1	— —

a) Unless otherwise noted, the reactions were carried out with **1** (10 mmol), ethyl bromide (12 mmol), KOH (50 mmol)/support (10 g), and hexadecane (0.3 g) as the internal standard in a solvent (20 ml) at 60 °C for 8 h. b) Mono+Di; determined by GLC. c) KOH (50 mmol)/MS-13X (15 g) and a solvent (30 ml) were used.

(**6**) is also considered to exist as ion pairs or ion-pair aggregates and only in dioxane as stable ion-pair aggregates in the pore:



6 R′=H, Et

The clear change at the dioxane/**1** molar ratio of *ca.* 1.0 (Fig. 1) provides strong evidence for the strong interaction between dioxane and **6** of the 1:1 molar ratio, which is very compatible with the molar ratio of the solvent to solute in the structures of the tetramer and the dimer shown by Jackman *et al.*[6] This fact and the above results strongly suggest that ion-pair aggregates of **6**, a tetramer and/or a dimer, are the ture reactants in dioxane, resulting in a large steric hindrance, even in the pore of alumina, which has a relatively large pore diameter. When R′ is hydrogen in **6**, the steric hindrance to the reaction of **6** with **5** is very small.

N-Alkylation of 1 Using Nonimpregnated Alumina and Powdered KOH. Alumina and KOH were ground in a mortar. Hereafter, KOH+Al_2O_3 will represent the mixture of alumina and KOH prepared by this method. The *N*-ethylation of **1** using KOH+Al_2O_3 was carried out in several solvents. Table 3 shows the results. KOH+Al_2O_3 gave better

TABLE 3. *N*-ETHYLATION OF **1** USING KOH+Al_2O_3 IN SEVERAL SOLVENTS[a]

Solvent	Time h	Yield[b] %	Selectivity Mono/% ; Di/%
Benzene	8	36	99 1
Dioxane	8	63	≫99 ≈0.2
	8	62[c]	≫99 ≈0.1
THF	8	55	86 14
DME	6	59	75 25
Acetonitrile	2	47	80 20

a) All the reactions were carried out with **1** (10 mmol), ethyl bromide (12 mmol), KOH (50 mmol)+Al_2O_3 (M-90-N, 10 g), and hexadecane (0.3 g) in a solvent (20 ml) at 60 °C. b) Mono+Di; determined by GLC. c) Al_2O_3 (M-60-B, 10 g).

yields than KOH/Al_2O_3 in a solvent except benzene and acetonitrile, and better selectivities than KOH/Al_2O_3 for *N*-monoalkylation in all solvents. These findings are quite in contrast to the results of the alkylation of PAN, in which KOH/Al_2O_3[4a] is superior to KOH+Al_2O_3[4b] in both yield and selectivity for monoalkylation. This fact indicates that the *N*-alkylation of **1** occurs in the pores of alumina even when KOH+Al_2O_3 is employed. The difference in selectivity between KOH/Al_2O_3 and KOH+Al_2O_3 can be interpreted as follows. For KOH/Al_2O_3, KOH is present in the pores. Therefore, KOH/Al_2O_3 must deprotonate the *N*-alkylated product formed in the pores more rapidly than KOH+Al_2O_3, thus lowering the selectivity. The difference in the yield can be interpreted as follows. Since alumina was ground together with KOH in the case of KOH+Al_2O_3, the particle size of the alumina in KOH+Al_2O_3 must be smaller than the particle size in KOH/Al_2O_3. Therefore, the increase in the yield may be thought to be due to the increase in the surface area of alumina. However, as is shown in Table 4, only slight changes in yield and selectivity for *N*-monoalkylation were observed when twice as much KOH and alumina were used as in the standard. Furthermore, for both KOH/Al_2O_3 and KOH+Al_2O_3, almost no **1** was observed in the organic phase during the reaction. These facts indicate that **1** is uniformly adsorbed on both active and inactive sites. To examine the influence of pulverization of alumina, alkylation of **1** with ethyl bromide was carried out using virgin alumina or alumina ground separately from KOH. In the cases of both M-90-N and M-60-B, the results were quite similar to those obtained by using alumina ground together with KOH. These results indicate that, since KOH/Al_2O_3 contains KOH in its pores, KOH/Al_2O_3 more strongly adsorbs **1** in its pores.

Table 4 summarizes the results of the *N*-alkylation of **1** with various alkylhalides using KOH+Al_2O_3 in dioxane. Alkyl bromide was better than alkyl iodide in both yield and selectivity for *N*-monoalkylation. This finding contrasts with the results of the alkylation of PAN using KOH/Al_2O_3,[4a] where alkyl iodide was better than alkyl bromide. This indicates that the *N*-alkylation of **1** is more sterically retarded than the alkylation of PAN. This fact supports the idea that the ion-pair aggregates of **6** are the true reactants in dioxane. Alkyl iodide gave *N,N*-dialkylated products in higher yields than did alkyl bromide. *N,N*-Dialkylation should occur predominantly in the bulk organic phase and/or on the surface of KOH. The influence of the molecular size of the alkylating agents on the yield was more significant when M-60-B was employed than when M-90-N was used. This result seems surprising since the pore sizes of both M-90-M and M-60-B are much larger than the molecular sizes of **1** and **5**. However, this result can well be understood if the ion-pair aggregates of **6** are the true reactants. This result indicates that the yield and the selectivity for *N*-monoalkylation are intrinsically dependent upon the pore size.

For both KOH/Al_2O_3 and KOH+Al_2O_3, the reaction was very clean; GLC showed that the only products were *N*-mono- and *N,N*-dialkylated **1**. Almost all of the **1** was adsorbed on the alumina. Consequently, *N*-monoalkylated products were isolated in a highly pure state by filtering the solid material and removing the solvent. The unreacted **1** adsorbed on alumina was recovered in an 85—90% yield by adding a small amount of water to the alumina and by then extracting with benzene. Because of this recovery, the yields of *N*-monoalkylation were 89—92% (Table 4).

This method, using KOH/Al_2O_3 or KOH+Al_2O_3, was also utilized in the *N*-alkylation of other amides. Table 5 summarizes the results. In general, the *N*-monoalkylated products were obtained in good yields with extremely high selectivities. However, the use of highly reactive allyl bromide or benzyl bromide as an alkylating agent lowered the selectivity for *N*-monoalkylation. For selectivity in *N*-monoalkylation, KOH+Al_2O_3 and M-60-B were better than KOH/Al_2O_3 and M-90-N, respectively. Butanamide (**3**), bearing a bulkier alkyl group, gave more preferentially *N*-monoalkylated products than acetamide (**2**). For 2-phenylacetamide (**4**), the C-H bond at the α-position is also acidic, so the *C*-alkylation at the α-position is thought to accompany the *N*-alkylation.

$$\underset{\mathbf{4}}{PhCH_2\text{-}\overset{O}{\overset{\|}{C}}\text{-}NH_2} \xrightarrow{R'X} PhCH_2\text{-}\overset{O}{\overset{\|}{C}}\text{-}NHR' + PhCH(R')\text{-}\overset{O}{\overset{\|}{C}}\text{-}NH_2$$

In fact, the components of the products were more complicated than in the cases of the other amides. GLC showed the presence of several components

a) All the reactions were carried out with amide (10 mmol), alkyl bromide (12 mmol), and dioxane (20 ml) for 8 h. b) A: KOH/Al_2O_3, B: $KOH+Al_2O_3$. c) Isolated yield. Unless otherwise noted, the purities were >97%. The values in parentheses are the yields determined by GLC. d) Purities were >96%.

other than *N*-monoalkylated products. In particular, when highly reactive allyl bromide or benzyl bromide was employed, GLC showed the presence of substantial quantities of several products, including the *N*-monoalkylated one.

For comparison, a solid-liquid phase-transfer alkylation of **4** was carried out using powdered KOH and tetrabutylammonium bromide (*n*-$Bu_4N^+Br^-$). Table 6 shows the results. These results indicate that the acidity of the C-H bond is similar to that of the N-H bond.[8] The regioselectivity for the alkylation of **4** using $KOH+Al_2O_3$ or KOH/Al_2O_3 must be explained

TABLE 6. ALKYLATION OF 4 USING SOLID-LIQUID PHASE-TRANSFER METHOD[a)]

Alkyl bromide	Temp °C	Time h	Yield[b)] %	Selectivity for N-monoalkylation/%
C_2H_5Br	60	2.5	35	85
$CH_2=CHCH_2Br$	40	1.5	18	47
$PhCH_2Br$	30	1.5	21	49

a) All the reactions were carried out with **4** (10 mmol), powdered KOH (50 mmol), alkyl bromide (12 mmol), and n-$Bu_4N^+Br^-$ (5 mmol) in benzene (20 ml). An almost complete conversion of **4** was observed. b) Isolated yields.

in terms of the steric hindrance as follows. Since the reaction occurs in the pore, the steric hindrance preventing the *C*-alkylation at the internal position is much larger than that preventing the *N*-alkylation at the terminal position, so the *N*-alkylation occurs predominantly.

In conclusion, amides are selectively *N*-monoalkylated by using KOH+Al_2O_3 or KOH/Al_2O_3. Even 2-phenylacetamide (**4**) is regioselectively *N*-monoalkylated in good yields. In dioxane, the enolate-like species **6** exists as stable ion-pair aggregates, which are the true reactants in the pores.

Experimental

Materials. Unless otherwise noted, reagents were obtained commercially. Benzamide (**1**), acetamide (**2**), butanamide (**3**), 2-phenylacetamide (**4**) (reagent grade, Tokyo Kasei Kogyo Co.), alumina (Merck 90 neutral, 70—230 mesh, activity I, Catalog No. 1077; Merck 60 basic, 70—230 mesh, activity I, Catalog No. 1067; Woelm 200 neutral, activity super I), Molecular Sieve 13X (for gas chromatography, 60—80 mesh), and 85% KOH were used as obtained. Alkyl halide (**5**), benzene, dioxane, THF, DME, and acetonitrile were dried with Molecular Sieve 4A. KOH/Al_2O_3 was prepared by the method previously reported.[4a)] KOH+Al_2O_3 was prepared by the method similar to that reported by Regen where reagent and alumina were ground together in a mortar.[9)] The authentic samples of *N*-ethyl- (**1a**), *N*-propyl- (**1b**), *N*-butyl- (**1c**), *N,N*-diethyl-, *N,N*-dipropyl-, and *N,N*-dibutylbenzamide were prepared by the literature method.[1)]

Typical Procedure Using KOH/Al_2O_3. N-Alkylation of Benzamide (1): A mixture of KOH/Al_2O_3 obtained from 85% KOH (3.3 g, 50 mmol) and alumina (10 g), **1** (10 mmol), **5** (12 mmol), hexadecane (0.3 g) as an internal standard, and a solvent (20 ml) was vigorously stirred at 60 °C for 8 h. After the mixture had been cooled to room temperature, water (5 ml) was added to it with vigorous stirring. The yields of *N*-mono- and *N,N*-dialkylation were determined by GLC analysis of the organic phase. When acetonitrile was employed as a solvent, hexadecane (0.3 g) as an internal standard in benzene (10 ml) was added after the reaction had finished.

N-Allyl-2-phenylacetamide (4d): A mixture of 85% KOH (3.3 g, 50 mmol)/M-60-B (10 g), **4** (1.35 g, 10 mmol), allyl bromide (1.45 g, 12 mmol), and dioxane (20 ml) was vigorously stirred at 40 °C for 8 h. GLC showed that the selectivity was 82%. The solid material was filtered off and washed with benzene (30 ml×2). Removing the solvent under reduced pressure gave 1.5 g of the crude product. Recrystallization from benzene–hexane gave 1.0 g (57% yield, 98% purity) of **4d**, mp 59—61 °C. Further recrystallization gave pure **4d** having mp 60—61 °C; IR (KBr) 3230, 1625, 1555 cm^{-1}. Found: C, 75.05; H, 7.62; N, 8.10%. Calcd for $C_{11}H_{13}NO$: C, 75.43; H, 7.43; N, 8.00%.

N-Ethyl-2-phenylacetamide (4a): A mixture of 85% KOH (3.3 g, 50 mmol)/M-60-B (10 g), **4** (1.35 g, 10 mmol), ethyl bromide (1.3 g, 12 mmol), and dioxane (20 ml) was vigorously stirred at 60 °C for 8 h. GLC showed that the selectivity was 97.5%. The same treatment as **4d** gave 1.25 g (77% yield, 97% purity) of **4a**, mp 60—68 °C. Recrystallization from ether–hexane gave 1.15 g (71% yield) of pure **4a**, mp 69—70 °C (lit,[10)] mp 69.5 °C); IR (KBr) 3290, 1635, 1555 cm^{-1}.

N-Butyl-2-phenylacetamide (4c): A mixture of 85% KOH (3.3 g, 50 mmol)/M-60-B (10 g), **4** (1.35 g, 10 mmol), butyl bromide (1.7 g, 12 mmol), and dioxane (20 ml) was vigorously stirred at 60 °C for 8 h. The same treatment as **4a** gave 1.25 g, (66% yield, 99% purity) of **4b**, mp 53—55 °C. Recrystallization from ether–hexane gave 1.15 g (60% yield) of **4b**, mp 55—56 °C (lit,[11)] mp 55—56 °C); Ir (KBr) 3250, 1630, 1560 cm^{-1}.

Typical Procedure Using KOH+Al_2O_3. N-Alkylation of 1: Alumina (10 g) and 85% KOH (3.3 g, 50 mmol)were ground together in a mortar. To this solid material was added a mixture of **1** (10 mmol), **5** (12 mmol), hexadecane (0.3 g) as an internal standard, and a solvent (20 ml). The mixture was vigorously stirred at 60 °C for 8 h. The reaction mixture was treated and GLC analyzed by the same method as described in the case of KOH/Al_2O_3.

N-Allylbutanamide (3d): A mixture of 85% KOH (3.3 g, 50 mmol)+M-90-N (10 g), **3** (0.87 g, 10 mmol), allyl bromide (1.45 g, 12 mmol), and dioxane (20 ml) was vigorously stirred at 40 °C for 8 h. The solid material was filtered off and washed with benzene (30 ml×2). After removal of the solvent, distillation gave 0.9 g (71% yield, 97% purity) of **3d**, bp 80—87 °C/1 mmHg (1 mmHg=133.322Pa). Purification by column chromatography (W-200-N, benzene and benzene-THF) gave pure **3d** having bp 88—89 °C/1 mmHg; IR (neat) 3280, 1640, 1545 cm^{-1}. Found: C, 65.68; H, 10.31; N, 10.87%. Calcd for $C_7H_{13}NO$: C, 66.14; H, 10.24; N, 11.02%.

N-Benzylbutanamide (3e): The alkylation of **3** with benzyl bromide (2.0 g, 12 mmol) similar to that with allyl bromide was performed using M-60-B. GLC showed that the selectivity was 97.1%. After the same treatment as **3d**, recrystallization from ether–hexane gave 1.4 g (79% yield) of **3e**, mp 49.5—50.5 °C; IR (KBr) 3290, 1630, 1550 cm^{-1}. Found: C, 74.34; H, 8.55; N, 7.90%. Calcd for $C_{11}H_{15}NO$: C, 74.58; H, 8.47; N, 7.91%.

N-Allylbenzamide (1d): The alkylation of **1** using 85% KOH (3.3 g, 50 mmol)+M-60-B (10 g) with allyl bromide (1.45 g, 12 mmol) similat to that of **3** with allyl bromide was performed. The solid meterial was filtered off and washed with benzene (30 ml×2). After removal of the solvent, column chromatography (W-200-N, benzene and benzene-THF)

gave 0.9 g (56% yield) of **1d** having bp 113—114 °C/0.2 mmHg (lit,[12] bp 173—174 °C/14 mmHg); IR (neat) 3300, 1640, 1535 cm^{-1}.

N-Ethylacetamide (2a): Bp 69—70 °C/2 mmHg (lit,[13] bp 140—141 °C/91 mmHg); IR (neat) 3280, 1645, 1555 cm^{-1}.

N-Butylacetamide (2c): Bp 89—90 °C/1.3 mmHg (lit,[13] bp 121—122 °C/13 mmHg); IR (neat) 3270, 1650, 1550 cm^{-1}.

N-Ethylbutanamide (3a): Bp 80—81 °C/1.2 mmHg (lit,[14] bp 101—102 °C/7 mmHg); IR (neat) 3280, 1640, 1540 cm^{-1}.

N-Butylbutanamide (3c): Bp 104—105 °C/1.2 mmHg (lit,[15] bp 138—140 °C/13 mmHg); IR (neat) 3280, 1640, 1545 cm^{-1}.

N-Benzyl-2-phenylacetamide (4e): Mp 119—120 °C (lit,[10] mp 119 °C); IR (KBr), 3280, 1635, 1545 cm^{-1}.

N-Benzylbenzamide (1e): Mp 105—106 °C (lit,[16] mp 106 °C); IR (KBr) 3280, 1640, 1550 cm^{-1}.

I wish to thank Nihon Tokushu Kagaku Kogyo Co., Ltd. for permission to publish this article, and also Dr. Nobuaki Wada for useful suggestions and discussions during this work.

Isomerization of Allylic Alcohols Catalyzed by Vanadium or Molybdenum Complexes[1)]

Seijiro MATSUBARA, Takashi OKAZOE, Koichiro OSHIMA, Kazuhiko TAKAI,* and Hitosi NOZAKI

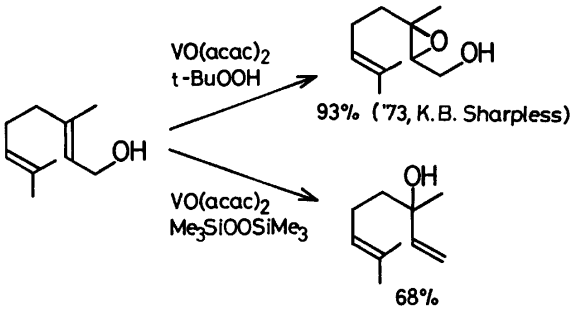
Department of Industrial Chemistry, Faculty of Engineering, Kyoto University, Yoshida, Kyoto 606

(Received October 3, 1984)

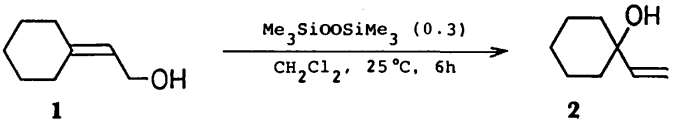
Isomerization of primary allylic alcohols proceeds in dichloromethane at 25 °C in the presence of the catalyst prepared *in situ* from $VO(acac)_2$ or $MoO_2(acac)_2$, and $Me_3SiOOSiMe_3$ to give tertiary isomers in good yields. The catalysts are also effective for the rearrangements of *sec.*→*tert.* allylic alcohols. The isomerization of an allenyl allylic alcohol, 6-methyl-1,2,5-heptatrien-4-ol, gives either (*E*)-2-methyl-3,5,6-heptatrien-2-ol or (*E*)-6-methyl-3,5-heptadien-2-one selectively depending on the reaction conditions.

Allylic transposition reactions have been widely studied.[2)] Treatment of allylic tertiary acetates (or alcohols) with acetic anhydride produces their primary isomers.[3)] Palladium(II) complex is an effective catalyst for the isomerization of allylic tertiary acetates to primary ones.[4,5)] Rearrangements in the opposite sense (*primary*→*tertiary*) are encountered in solvolysis reactions, which are complicated by accompanying elimination, cyclization, and skeletal rearrangement.[6)] Here we wish to report the catalysts which are prepared from $VO(acac)_2$ or $MoO_2(acac)_2$ and $Me_3SiOOSiMe_3$ and are effective in (1) allylic isomerization of primary or secondary alcohols to tertiary ones and (2) regioselective isomerization of 6-methyl-1,2,5-heptatrien-4-ol into either (*E*)-2-methyl-3,5,6-heptatrien-2-ol or (*E*)-6-methyl-3,5-heptadien-2-one. Both reactions proceed in an aprotic solvent under mild conditions.

(1) Isomerization of Primary Allylic Alcohols to Tertiary Ones. Most recently, much attention has been paid on the synthetic utility of bis(trimethylsilyl) peroxide,[7,8)] which is an equivalent of 100% H_2O_2. The peroxide easily prepared from 30% H_2O_2[7)] possesses high solubility in organic solvents and thermal stability. The enhanced nucleophilicity of the oxygen by trimethylsilyl group has effectively been used for the oxidation reaction such as Baeyer-Villiger reaction[8a)] or pyridinium dichromate-catalyzed oxidation of alcohols into carbonyl compounds.[8b)] In further study of this unique reagent in combination with several transition metal catalysts, we have found that the $VO(acac)_2$ or $MoO_2(acac)_2$ catalyst activated with $Me_3SiOOSiMe_3$ effectively induces the title isomerization which is in sharp contrast to the well-known Sharpless' epoxidation of allylic alcohols (Scheme 1).[9)]



Scheme 1.



1 2

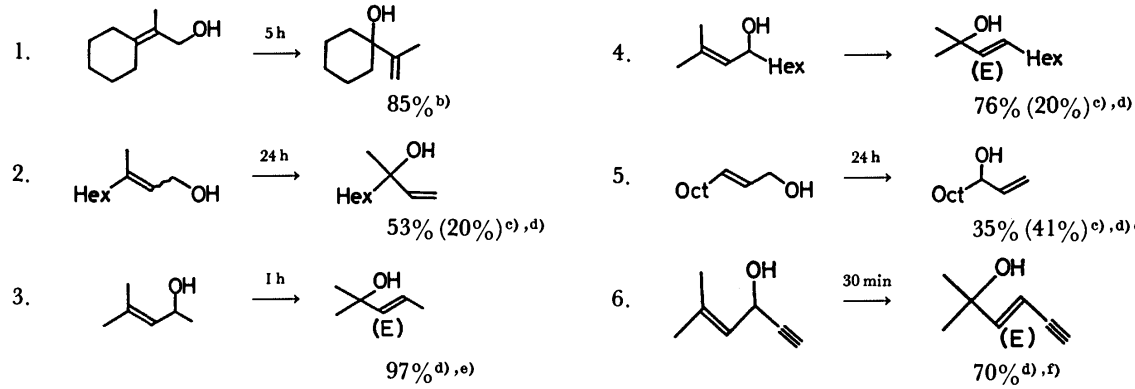
$VO(acac)_2$	(0.1)	GLPC yield	92%	(recovery 2%)
$MoO_2(acac)_2$	(0.1)		76%	(3%)
[$MoO_2(acac)_2$	(0.1) only		35%	(<2%)]

Scheme 2.

No allylic rearrangement occurs in the absence of $Me_3SiOOSiMe_3$ as far as we utilize $VO(acac)_2$ system. Meanwhile, $MoO_2(acac)_2$ catalyst has proved to be effective to bring about the isomerization with or without the peroxide, although several undesired side reactions are accompanied in the latter case. In general, $VO(acac)_2$-$Me_3SiOOSiMe_3$ system gave better yeilds of tertiary alcohol than $MoO_2(acac)_2$ one. For instance, treatment of 2-cyclohexylideneethanol (**1**) with $VO(acac)_2$-$Me_3SiOOSiMe_3$ provided the tertiary alcohol **2** in 92% GLPC yield (2% recovery of **1**), whereas $MoO_2(acac)_2$ system gave **2** in 76% or 35% yield with or without $Me_3SiOOSiMe_3$ respectively (Scheme 2).

The results of allylic isomerization with $VO(acac)_2$-$Me_3SiOOSiMe_3$ are summarized in Table 1. A general procedure is as follows. $Me_3SiOOSiMe_3$ (30 mol%) was added to a solution of $VO(acac)_2$ (10 mol%) in CH_2Cl_2 at 25 °C. The blue color of the solution turned immediately to purple. A solution of a primary alcohol in CH_2Cl_2 was added and the whole was stirred at 25 °C for 6 h. The product was purified by preparative thin-layer chromatography on silica gel. Rearrangement of primary allylic alcohols proceeded very smoothly to give tertiary ones in good yields. In contrast, isomerization of a primary into a secondary alcohol gave less satisfactory results (run 5). The resulting double bond exhibited *E* configuration in runs 3, 4,

TABLE 1. ALLYLIC ISOMERIZATION CATALYZED BY $VO(acac)_2$-$Me_3SiOOSiMe_3$ SYSTEM[a]



a) The substrate (2.0 mmol) was treated at 25 °C with a catalyst prepared from $Me_3SiOOSiMe_3$ (0.6 mmol) and $VO(acac)_2$ (0.2 mmol) in CH_2Cl_2. b) See Ref. 10. c) Recoveries of the unchanged materials are shown in parentheses. d) See experimental section. e) GLPC yield. f) The isomerization of this substrate was also performed in 76% yield with the $MoO_2(acac)_2$ (5 mol%) without $Me_3SiOOSiMe_3$. The reaction was complete within 10 min.

TABLE 2. ISOMERIZATION OF GERANIOL, NEROL, AND LINALOOL WITH $VO(acac)_2$–$Me_3SiOOSiMe_3$ SYSTEM[a]

	Time	Products (%)[b]			
	h	Geraniol	Nerol	Linalool	α-terpineol
geraniol	7	(10)	8	68	2
(geranyl chloride)[c]		10	0	81	7
nerol	7	11	(11)	70	3
(neryl chloride)[c]		0	2	20	72
linalool	12	8	5	(60)	2

a) Reactions were performed on 2.0 mmol scale at 25 °C in CH_2Cl_2. The catalyst was prepared by $Me_3SiOOSiMe_3$ (0.6 mmol) and $VO(acac)_2$ (0.2 mmol) in CH_2Cl_2. b) GLPC yields (10% PFG 20 M, 3% $AgNO_3$, 1.5 m, 110 °C) of these terpene alcohols were determined with hexadecane as the internal standard. c) The results of the solvolysis reaction (H_2O/acetone=95/5) of geranyl chloride or neryl chloride are cited from the literature of C. A. Bunton *et al.* (Ref. 11).

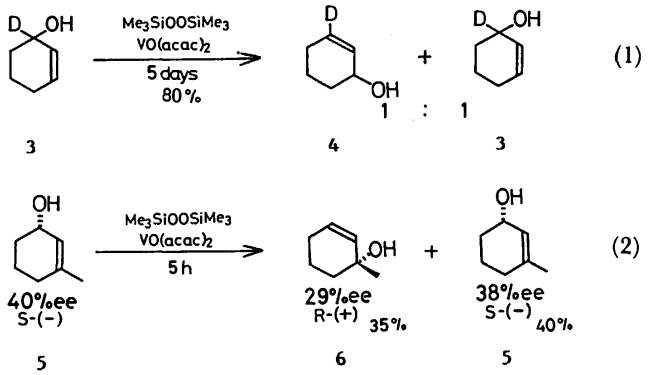
and 6.

Table 2 is concerned with the reaction of geraniol, nerol, and linalool with $VO(acac)_2$–$Me_3SiOOSiMe_3$ system. The isomer distributions of these terpene alcohols were nearly identical irrespective of the starting alcohols in the present reaction. On the other hand, the solvolysis of neryl chloride is recorded to give α-terpineol as the main product, while linalool is produced from geranyl chloride under the S_N1 conditions.[11]

Following reactions in Scheme 3 gave us some information about the mechanism of this isomerization reaction. The equilibrium between a starting allylic alcohol and the rearranged one has been examined with 1-deuterio-2-cyclohexen-1-ol (**3**). An equimolar mixture of 3-deuterio and 1-deuterio compounds was produced (Eq. 1).[12]

Treatment of (*S*)-(−)-3-methyl-2-cyclohexen-1-ol[13] (**5**, 40% e.e.) with this $VO(acac)_2$-$Me_3SiOOSiMe_3$ catalyst gave (*R*)-(+)-1-methyl-2-cyclohexen-1-ol[14] in 35% yield (**6**, 29% e.e.) and the unchanged starting material in 40% recovery as shown in Eq. 2. The hydroxyl group of the substrate **5**, therefore, resides mainly on the same side of the olefinic double bond. This suggests that the isomerization does not proceed *via* a free allylic cation.[15] The conclusion is consonant with the observed production of a trace amount of cyclized α-terpineol from nerol (Table 2).[16]

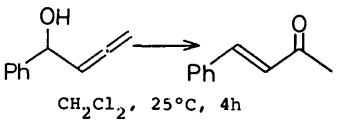
(2) Regioselective Isomerization of 6-Methyl-1,2,5-heptatrien-4-ol. The rearrangement of allenic alcohols proceeds as smoothly as allylic ones. For



Scheme 3.

instance, (*E*)-4-phenyl-3-buten-2-one was produced from 1-phenyl-2,3-butadien-1-ol in good yields (Scheme 4) with Mo or V catalysis. Addition of $Me_3SiOOSiMe_3$ was essential for $VO(acac)_2$ catalysis, but $MoO_2(acac)_2$ turned out to be effective without $Me_3SiOOSiMe_3$. The application of this rearrangement technique to 6-methyl-1,2,5-heptatrien-4-ol (**7**) led to regioselective formation of either (*E*)-2-methyl-3,5,6-heptatrien-2-ol (**8**) and (*E*)-6-methyl-3,5-heptadien-2-one (**9**) depending on conditions (Table 3,4).

Treatment of **7** with 5 mol% of $MoO_2(acac)_2$ in dichloromethane at 25 °C for 10 min provided the enone **9** in 90% yield. The reaction temperature strongly affected the product distributions. The reaction at −78 °C gave tertiary alcohol **8** as a sole product and no trace of **9** was detected in the reaction mixture. The addition of $Me_3SiOOSiMe_3$ to $MoO_2(acac)_2$ did not alter the results dramatically. Following assumptions explain the observations. (1)

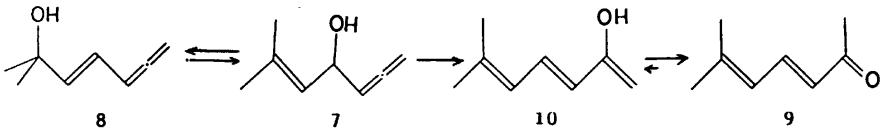


$MoO_2(acac)_2$ (0.1)	75%
$MoO_2(acac)_2$ (0.1)-$Me_3SiOOSiMe_3$ (0.3)	83%
$VO(acac)_2$ (0.1)	0%
$VO(acac)_2$ (0.1)-$Me_3SiOOSiMe_3$ (0.3)	81%

Scheme 4.

An equilibrium of Scheme 5 exists between the two alcohols **7** and **8** in the presence of the $MoO_2(acac)_2$ catalyst. (2) At lower temperature, the kinetically favored tertiary alcohol **8** is produced. (3) At 25 °C, the isomerization to the kinetically less favored trienol **10** competes with the rearrangement of **7** to **8** and the thermodynamically more stable enone **9** is produced exclusively from the tautomerization of **10**.

As shown in Table 4, $VO(acac)_2$ was less effective in



Scheme 5.

the isomerization of **7**. The presence of Me_3SiOO-$SiMe_3$ was essential to obtain a reasonable reaction rate. The catalyzed rearrangement provided a mixture of **8** and **9** in a 4:1 ratio (run 3). Increasing the amount of $Me_3SiOOSiMe_3$ improved the selectivity of the reaction slightly. The ratio of **8**/**9** was 11/1 with 5 mol% of $VO(acac)_2$ and 15 mol% of $Me_3SiOOSiMe_3$ (run 4).[19]

Experimental

The IR spectra were determined on a Shimadzu IR-27-G spectrometer, the mass spectra on a Hitachi M-80 machine, and the NMR spectra on a Varian EM-360 spectrometer. The chemical shifts are given in δ, with tetramethylsilane as an internal standard. The analyses were carried out by the staff at the Elemental Analyses Center of Kyoto University. Dichloromethane was dried on P_2O_5 and distilled. All the experiments were carried out under an argon atmosphere. Purification of products were performed by preparative thin-layer chromatography (TLC) or column chromatography on silica gel (Wakogel C-100). Analytical GLPC was performed with a Yanagimoto GCG-550-F and a Shimadzu GC-4CPT. Preparative GLPC was performed with a JEOL-JGC-20K apparatus.

Bis(trimethylsilyl) Peroxide: The following procedure is a modification of the method described by P. G. Cookson *et al.* too much briefly.[7] Hydrogen peroxide (30%, 11.3 g, 100 mmol) was added in less than 1 min to a stirred solution of 1,4-diazabicyclo[2.2.2]octane (DABCO, 5.6 g, 50 mmol) in diethyl ether (80 ml) at 0 °C and the resulting mixture was stirred for 15 min. Precipitated white solid was filtered through a glass filter, and dried *in vacuo* at room temperature for 5 h. This is the DABCO-hydrogen peroxide complex and is easily decomposed by a catalytical amount of metals. Danger of explosion should be taken care. This DABCO-hydrogen peroxide complex (5.9 g, 33 mmol), DABCO (3.7 g, 33 mmol), and dichloromethane (50 ml) were placed in a flame-dried flask. Chlorotrimethylsilane (12.0 g, 0.111 mol, neat) was added dropwise at 0 °C within 15 min to the solution. After being stirred for 5 h at room temperature, the resulting mixture was filtered to remove DABCO-HCl salt, and the filtrate was concentrated at room temperature under 100 Torr (1 Torr=133.322 Pa). The residue was diluted with pentane, filtered to remove the salt, and the solution concentrated at room temperature under 100 Torr. Distillation of the crude product under reduced pressure provided $Me_3SiOOSiMe_3$ in 32% yield (5.6 g, 32 mmol) as a colorless liquid, bp 40—41 °C/28 Torr: IR (neat): 2960 (s), 1250 (s), 920 (w), 840 (s), 730 (s).[20]

1-Ethenylcyclohexanol (**2**): A dichloromethane solution (5 ml) of $Me_3SiOOSiMe_3$ (0.11 g, 0.60 mmol) was added at 25 °C under an argon atmosphere to a stirred solution of $VO(acac)_2$ (53 mg, 0.20 mmol) in dichloromethane (4 ml). The blue color of the reaction mixture turned to purple immediately and the resulting mixture was stirred at 25 °C for 10 min. A solution of 2-cyclohexylideneethanol (**1**, 0.25 g, 2.0 mmol) in dichloromethane (8 ml) was added at the same temperature and the whole was stirred for an additional 6 h. The mixture was poured into brine (20 ml) and extracted with ether (2×20 ml). The separated organic layers were dried (Na_2SO_4) and concentrated. Purification by preparative thin-layer chromatography (hexane–ethyl acetate, 2:1) on silica gel gave 1-ethenylcyclohexanol (**2**) in 80% yield (0.20 g) as a colorless liquid.[21] GLPC yield 92% of **2** (10% PEG 20 M, 3% $AgNO_3$, 1.5 m, 110 °C) was determined with hexadecane as the internal standard: Bp. 70 °C (bath temp, 10 Torr); IR (neat): 3400, 1642, 1455, 960, 915 cm^{-1}; NMR (CCl_4): δ=1.00—1.80 (m, 11H), 4.88 (dd, J=10.5, 1.5 Hz, 1H), 5.12 (dd, J=17.6, 1.5 Hz, 1H), 5.87 (dd, J=17.6, 10.5 Hz, 1H); MS *m/z* (%): 126 (M^+, 6), 93 (11), 83 (100), 70 (68), 67 (21), 55 (56).

3-Methyl-1-nonen-3-ol:[22] Bp 45 °C (bath temp, 1 Torr); IR (neat): 3400, 3100, 1645, 1400, 970, 915 cm^{-1}; NMR (CCl_4): δ=0.87 (t, J=6 Hz, 3H), 1.00—1.70 (m, 10H), 1.20 (s, 3H), 1.95—2.20 (m, 1H), 4.92 (dd, J=10.5, 1.5 Hz, 1H), 5.07 (dd, J=17.5, 1.5 Hz, 1H), 5.79 (dd, J=17.5, 10.5 Hz, 1H); MS *m/z* (%): 156 (M^+, 0.3), 141 (11), 129 (8), 96 (6), 81 (10), 71 (100), 58 (16).

(E)-2-Methyl-3-penten-2-ol:[23] This compound was produced from 4-methyl-3-penten-2-ol as described above. GLPC analysis (10% PEG 20 M, 3% $AgNO_3$, 1.5 m, 45 °C) of the crude product showed a single peak having a retention time at 4.8 min ((*E*)-isomer). (*Z*)-Isomer (T_r=5.2 min), which was prepared from (*Z*)-1-bromo-1-propene and acetone, was not detected in the reaction mixture. GLPC yield 97% of (*E*)-2-methyl-3-penten-2-ol was determined with dodecane as the internal standard: Bp 70 °C (bath temp, 100 Torr); IR (neat): 3400, 3050, 1675, 970 cm^{-1}; NMR (CCl_4): δ=1.21 (s, 6H), 1.50—1.70 (m, 1H), 1.63 (d, J=5.5 Hz, 3H), 5.40—5.60 (m, 2H); MS *m/z* (%): 100 (M^+, 19), 85 (100), 67 (68), 59 (36), 43 (90).

(E)-2-Methyl-3-decen-2-ol: This compound was produced from 2-methyl-2-decen-4-ol as described above. GLPC analysis (20% PEG 6000, 1.2 m, 122 °C) of the crude product showed a single peak having a retention time at 18.5 min ((*E*)-isomer). (*Z*)-Isomer (T_r=17.2 min) was not detected. Bp 112 °C (bath temp, 2 Torr); IR (neat): 3400, 3050, 1150, 970, 910 cm^{-1}; NMR (CCl_4): δ=0.87 (t, J=6 Hz, 3H), 1.00—1.53 (m, 9H), 1.22 (s, 6H), 1.75—2.15 (m, 2H), 5.40—5.55 (m, 2H); MS *m/z* (%): 170 (M^+, 2), 155 (25), 95 (32), 85 (77), 71 (100), 68 (52); Found: C, 77.52; H, 13.02%. Calcd for $C_{11}H_{22}O$: C, 77.58; H, 13.02%.

1-Undecen-3-ol:[24] This compound was produced from (*E*)-2-undecen-1-ol as described above. GLPC yield 35% of 1-undecen-3-ol (10% PEG 20M, 3% $AgNO_3$, 1.5 m, 116 °C) was determined with hexadecane as the internal standard.

(E)-2-Methyl-3-hexen-5-yn-2-ol:[25] Bp 44 °C (bath temp, 9 Torr); IR (neat): 3250, 2070, 1605, 1140, 955 cm^{-1}; NMR (CCl_4): δ=1.30 (s, 6H), 2.00—2.35 (m, 1H), 2.68 (d, J=2.8 Hz, 1H), 5.60 (dd, J=15.6, 2.8 Hz, 1H), 6.24 (d, J=15.6 Hz, 1H); MS *m/z* (%): 110 (M^+, 1.7), 109 (12), 95 (100), 77 (10), 67 (24), 43 (54).

(S)-(−)-3-Methyl-2-cyclohexen-1-ol (**5**):[13] This compound was prepared by asymmetric reduction of 3-methyl-2-cyclohexen-1-one according to the reported procedure[26]: $[\alpha]_D^{25}$=−35.1° (c=1.86, $CHCl_3$). Enantiomeric excess (40% e.e.) of this alcohol was determined by NMR with $Eu(hfc)_3$ shift reagent.[13]

(R)-(+)-1-Methyl-2-cyclohexen-1-ol (**6**):[14] Treatment of (*S*)-(−)-3-methyl-2-cyclohexen-1-ol (**5**, 40% e.e.) with $VO(acac)_2$–$Me_3SiOOSiMe_3$ catalyst as described above gave a mixture of **5** (35% yield) and **6** (40% recovery). Yields were determined by GLPC (10% PEG 20 M, 3% $AgNO_3$, 1.5 m,

110 °C) with hexadecane as the internal standard. Purification by preparative GLPC (20% PEG 6000, 1 m, 110 °C) gave pure **5** (38% e.e.) and **6** [29% e.e., $[\alpha]_D^{25}=+15.5°$ (c=1.65, $CHCl_3$)]. Enantiomeric excess of these alcohols were determined by NMR with Eu(hfc)$_3$ shift reagent.[13]

The authentic sample of **6** [$[\alpha]_D^{25}=17.3°$ (c=2.0, $CHCl_3$)] was prepared from **5** (40% e.e.) according to the literature about stereoselective 1,3-transposition of allylic alcohols.[27] **6**: Bp 90 °C (bath temp, 50 Torr); IR (neat): 3400, 3050, 1180, 1125, 1020, 855 cm^{-1}; NMR (CCl_4): δ=1.20 (s, 3H), 1.50—2.10 (m, 7H), 5.35—5.75 (m, 2H); MS m/z (%): 112 (M^+, 9.9), 97 (100), 84 (45), 79 (43), 69 (85), 55 (32).

1-Phenyl-2,3-butadien-1-ol:[28] This compound was prepared from benzaldehyde and propargyl alcohol according to the literature.[29] Bp 72 °C (bath temp, 10 Torr); IR (neat): 3250, 1942, 1020, 846 cm^{-1}; NMR (CCl_4): δ=1.78 (bs, 1H), 4.70 (d, J=2 Hz, 1H), 4.77 (d, J=2 Hz, 1H), 5.07 (dt, J=6, 2 Hz, 1H), 5.15—5.40 (m, 1H), 6.87—7.53 (m, 5H); MS m/z (%): 146 (M^+, 2.3), 145 (10), 128 (8), 107 (100), 79 (55), 77 (23).

6-Methyl-1,2,5-heptatrien-4-ol (**7**):[30] The title compound was prepared from 3-methyl-2-butanal and propargyl alcohol according to the reported procedure:[29] Bp 47 °C (bath temp, 9 Torr); IR (neat): 3250, 1940, 1010, 840 cm^{-1}; NMR (CCl_4): δ=1.67 (s, 3H), 1,72 (s, 3H), 2.20—2.50 (m, 1H), 4.50—4.90 (m, 3H), 4.97—5.30 (m, 2H); MS m/z (%): 124 (M^+, 2), 109 (43), 91 (21), 85 (100), 81 (12), 79 (10), 67 (10), 55 (11).

(E)-2-Methyl-3,5,6-heptatrien-2-ol (**8**): A dichloromethane solution (7 ml) of 6-methyl-1,2,5-heptatrien-4-ol (**7**, 0.25 g, 2.0 mmol) was added to a solution of MoO_2(acac)$_2$ (33 mg, 0.10 mmol) in dichloromethane (4 ml) at −78 °C under an argon atmosphere. After being stirred at the same temperature for 10 min, the resulting mixture was poured into brine (20 ml) and extracted with ether (2×20 ml). The separated organic layers were dried and concentrated. Purification by preparative thin-layer chromatography (hexane–ethyl acetate, 5:1) on silica gel gave (*E*)-2-methyl-3,5,6-heptatrien-2-ol (**8**) in 94% yield (0.23 g) as a colorless liquid: Bp 70 °C (bath temp, 7 Torr); IR (neat): 3300, 1925, 1620, 1140, 965, 842; NMR (CCl_4): δ=1.30 (s, 6H), 2.15 (bs, 1H), 4.72—4.90 (m, 2H), 5.15—6.05 (m, 3H); MS m/z (%): 124 (M^+, 9.0), 109 (86), 91 (43), 85 (27), 81 (41), 65 (16), 59 (11), 55 (13), 53 (13), 43 (100); Found: C, 77.09; H, 9.98%. Calcd for $C_8H_{12}O$: C, 77.38; H, 9.74%.

(E)-6-Methyl-3,5-heptadien-2-one (**9**):[31] Treatment of 6-methyl-1,2,5-heptatrien-4-ol (**7**, 0.25 g, 2.0 mmol) with MoO_2(acac)$_2$ (33 mg, 0.10 mmol) in dichloromethane at 25 °C for 10 min as described above gave (*E*)-6-methyl-3,5-heptadien-2-one (**9**) in 90% yield (0.22 g): Bp 45 °C (bath temp, 10 Torr); IR (neat): 1654, 1620, 1580, 1260, 984, 960 cm^{-1}; NMR (CCl_4): δ=1.90 (s, 6H), 2.16 (s, 3H), 5.88 (d, J=12 Hz, 1H), 5.90 (d, J=15 Hz, 1H), 7.23 (dd, J=15, 12 Hz, 1H); MS m/z (%): 124 (M^+, 12), 109 (100), 81 (39), 79 (16), 53 (12), 43 (22).

Financial support by the Ministry of Education, Science and Culture, Japanese Government (Grant-in Aid for Special Project Research 58110005) is acknowledged.

16) A [3,3] sigmatropic rearrangement of inorganic ester such as vanadate or molybdate is considered to be one of the reasonable mechanisms. Actually, it has been reported that heating of a tertiary allylic alcohol with O=V(OR)$_3$[17a] or O=W(OR)$_4$·L[17b] at 160—200 °C gave a mixture of its primary isomer and the starting alcohol via [3,3] sigmatropic rearrangement. In our new method, the rearrangement took place in an opposite direction (primary→tertiary) under much milder conditions. These differences could be ascribed to the presence of Me_3SiOO- group attached on vanadium atom[18] in the [3,3] sigmatropic rearrangement (Scheme 6).

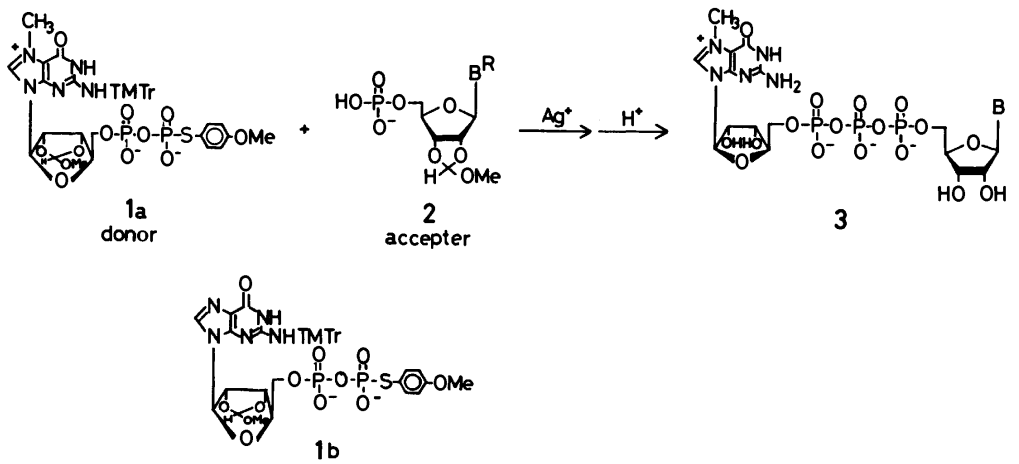
(Received October 4, 1984)

The fully-protected pAUG (**15**) and pAUGACC (**21**) were synthesized by the phosphotriester approach where the phenylthio group was employed as the internal and 5'-terminal phosphate-protecting groups. The partially unblocked oligomers (**32**) and (**33**), obtained by alkaline treatment of (**15**) and (**21**), were condensed with a capping reagent (**1a**) in the presence of imidazole by activation with silver nitrate to afford the capped trimer and hexamer protected with the acid-labile protecting groups, *i.e.*, 4,4,'4"-trimethoxytrityl (TMTr), 4-monomethoxytrityl (MMTr), tetrahydropyran-2-yl (THP), and methoxymethylene (mM) groups. The protected capped oligomers were unblocked by a dilute HCl solution to afford $m^7G^{5'}pppAUG$ and $m^7G^{5'}pppAUGACC$, which were purified by HPLC and characterized by enzyme assays.

Chemical synthesis of capped oligoribonucleotides, $m^7G^{5'}pppNupNupNu\cdots$[1] is one of the intriguing subjects in nucleic acid chemistry, since construction of the unique cap structure will be realized by exploration of new techniques. Previously, we have reported capping reactions utilizing the arylthio group as an activatable pyrophosphate protecting group.[2-6] These studies indicate that, because of the inherent insolubility of 7-methylguanosine derivatives in organic solvents, a capping agent should be protected with sufficiently lipophilic groups so that the capping reaction proceeds homogeneously to obtain reproducible results. Therefore, we recently reported a new capping agent (**1a**) that reacted with nucleotides in the presence of silver nitrate giving rise to the cap structure with high reproducibility.[4] This silver ion-catalyzed reaction required the use of an excess amount (2 equiv) of acceptor nucleotides (**2**) to obtain $m^7G^{5'}pppNu$ (**3**) in good yields (45—60%). This is because the reaction in the reverse ratio of **1** to **2** resulted in a very complicated mixture from which **3** was isolated only in a poor yield (<5%). Similar experiences have been encountered also in the synthesis of unmethylated cap structures, $G^{5'}pppNu$, from **1b** and **2**. The silver ion-mediated reaction can hardly be applied to the synthesis of capped oligoribonucleotides, because the excess use of oligomer components is undesirable. The above complicated reaction may be rationalized by the generation of an highly active metapyrophosphate intermediate (**4**), which can react again with the product so that the P(O)-O-P(O) bond was degraded. In the case of the reaction using the excess acceptor nucleotide, **4** might be trapped mainly with the excess **2** and a little with the product **3** to give a simpler result.

Therefore, we have studied a more generally applicable method for the capping reaction. A reaction of **1b** with **2** (B=Cy, R=DMTr) was chosen to search for suitable conditions that enabled us to use excess amounts of **1b**. Consequently, it was found that coaddition of imidazole dramatically effected the silver ion-catalyzed reaction. When the reaction was carried out in the presence of 30 fold excess imidazole by using 1.7 equiv of **1b** to **2**, TLC exhibited a major spot corresponding to the protected $G^{5'}pppC$ and much less by-products. The workup gave a 61%



Scheme 1.

yield of G[5']pppC. This result is explained in terms of the *in situ* formation of the phosphorimidazolide (**5**)[7] capable of reacting gradually with the acceptor nucleotide and not with the product.

The protecting groups used for **2** have been reported in the previous paper.[4]

Since we could find the practical procedure for the construction of the cap structure, the fully-protected oligoribonucleotides of pApUpG and pApUpGpApCpC were synthesized by our phosphotriester method using the phenylthio group as the phosphate-protecting group. These synthetic strategies are shown in Scheme 3. All the nucleoside and nucleotide units (**6**—**11**) employed are illustrated in Scheme 4.

For the preparation of the uridine unit (**6**), an alternative to the previous route was employed. The new method involves introduction of the anisoyl group into the uracil ring[8] at an earier stage. This approach enabled us to extract the diol (**25**) easily with CH_2Cl_2, while the previous method required bothersome ion-exchange chromatography for removal of excess triethylammonium fluoride used in the conversion of the cyclic silyl ether (**28**) to 3'-*O*-(tetrahydropyran-2-yl)uridine (**29**). The uridine unit **6** was obtained *via* the six-step reaction in an overall yield of 45% from uridine. The 3'-terminal cytidine unit (**10**) was synthesized by benzoylation of the common intermediate (**30**) followed by detritylation of the resulting product (**31**). The 3'-terminal guanosine unit (**11**) was prepared by a new procedure for the methoxymethylenation catalyzed by trimethylsilyl chloride.[9]

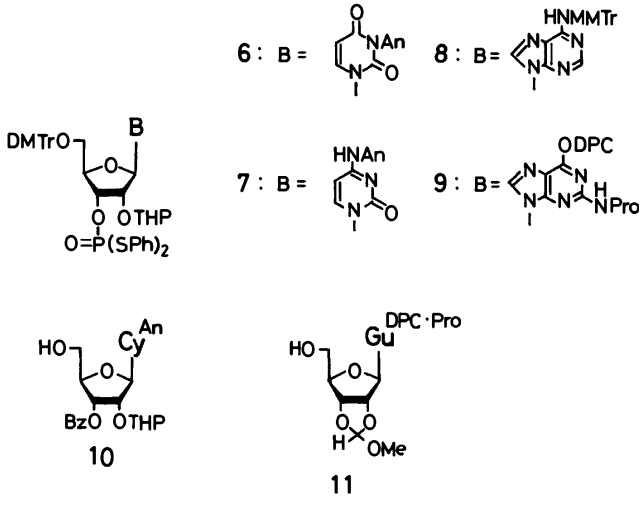
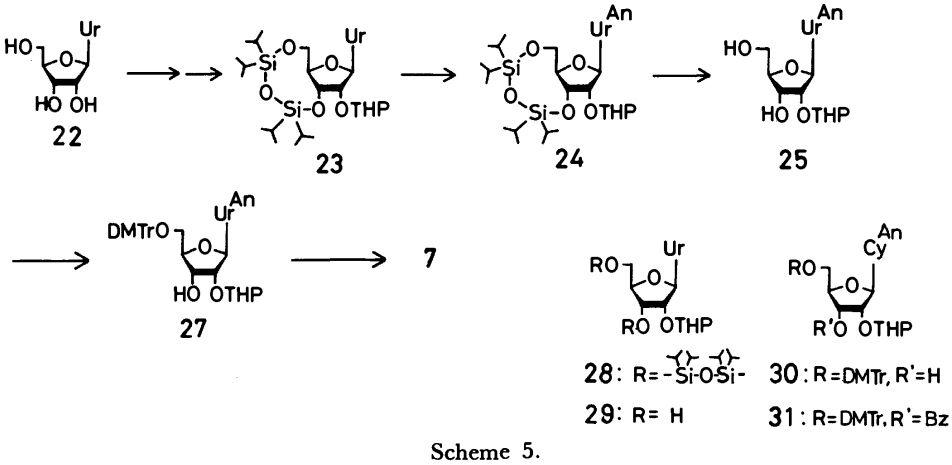
Strategy for the synthesis of the fully protected pAUG (15) and pAUGACC (21): The line (—) means fully protected oligonucleotide chains.

Scheme 3.



Scheme 4.



Scheme 5.

The conditions employed for the fragment condensations of oligomers were essentially the same as those reported previously.[10,11] For the construction of the triphosphate bridge, the 5′-terminal hydroxyls of compounds **14** and **20** obtained from **13** and **19** were phosphorylated with cyclohexylammonium *S,S*-diphenyl phosphorodithioate (**PSS**)[12] in the presence of mesitylene-1,3-disulfonyl dichloride (**MDS**)[13] to afford compounds (**15**) and (**21**), respectively. The phosphorylations proceeded smoothly without any side reactions. Since the cap structure was extremely labile to basic media, all the phenylthio- and acyl-protecting groups were removed by the successive treatments with 0.2 M NaOH (1 M=1 mol dm^{-3}), concentrated aqueous ammonia, and silver acetate prior to the capping reactions. This partial deprotection gave the oligomers (**32**) and (**33**) having the 2′-*O*-tetrahydropyran-2-yl and adenosine N^6-MMTr groups. The former is preserved to avoid side reactions associated with the internal phosphate groups upon the capping reaction. The latter serves as the marker for monitoring the reaction on TLC. Before the capping reactions, the roughly purified trimer **32** and hexamer **33** were treated with 0.01 M HCl to obtain the unprotected trimer pApUpG and hexamer pApUpGpApCpC, respectively. Isolation of the two oligomers was performed by HPLC as shown in Figs. 1 and 2. The yields of pApUpG and pApUpGpApCpC were 20 and 10% yields, respectively. Since these oligomers were prepared as the references in the capping reactions, no attempts to increase the yields have not been made. The enzyme treatments of the trimer and hexamer using venom phosphodiesterase resulted in mixtures of the parent 5′-mononucleotides in the correct ratios as shown in Fig. 3. Next, we examined the triphosphate bridge formation between the oligomer **32** or **33** and the unmethylated precursor (**1b**) of the capping agent **1a**. In these reactions, 5 equiv of **1b**, 20 equiv of imidazole, and 30 equiv of silver nitrate were employed. After the reactions were completed, the remaining acid-labile protecting groups were removed by treatment with 0.01 M HCl. The reaction mixtures were chromatographed on Whatman 3 MM papers and then separated by HPLC. The HPLC elution patterns are shown in Figs. 4 and 5. In the case of G^5′pppApUpG, a main peak, which appeared after pApUpG, was collected and analyzed with venom phosphodiesterase. The enzyme analysis suggested that the main peak was the desired product of G^5′pppApUpG (see Fig. 6A). This capped trimer was isolated in an overall yield of 9% from **15**. Since pApUpG was obtained in 20% yield from **15** by a similar unblocking procedure, it was estimated that the triphosphate bond formation was attained to a degree of *ca.* 45%. This means that the phos-

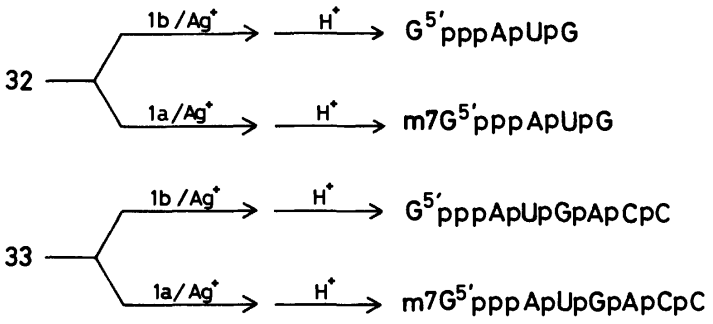

Scheme 7.

phorylation itself proceeded successfully.

In the case of the hexamer, several peaks eluted after pApUpGpApCpC were similarly collected and analyzed. As a consequence, an eminent peak was found to be composed of pA, pC, pG, and pU in the expected ratio and thereby it was determined as G5'-pppApUpGpApCpC. The isolated yield of G5'-ppppApUpGpApCpC was 5% on the basis of the fully protected hexamer **21**. The other peaks of 38 min and 48 min were derived from pG and did not contain the other nucleotides.

Finally, we tried to synthesize the capped oligoribonucleotides, m7G5'pppApUpG and m7G5'-pppApUpGpApCpC, by using G5'pppApUpG and G5'pppApUpGpApCpC as the references for HPLC analysis. In a similar manner, the capping reactions were carried out. The HPLC patterns obtained after the acid treatment are shown in Figs. 7 and 8. We expected that the capped oligomers would appear at positions near or a little behind the starting oligomers owing to the positive charge of the m7G residue. In order to detect the m7G residue, the mixtures were analyzed simultaneously by a HPLC apparatus equipped with a fluorescene detector. The detector was set up by use of the ex and em values of 279 nm and 393 nm, respectively. This double check technique has proved to be very useful for detection of the capped oligomers. On the basis of our expectation mentioned above, some prominent peaks with both UV and fluorescence were collected (Figs. 7 and 8) and characterized by enzyme assay with venom phosphodiesterase (Fig. 9). Consequently, the peaks at 27 min (Fig. 7A) and 35 min (Fig. 8A) were finally identified as the capped oligomers, m7G5'-pppApUpG and m7G5'pppApUpGpApCpC, which were isolated in 8 and 5% overall yields from the fully protected oligomers **15** and **21**, respectively. In these cases, the capping reactions were estimated to proceed to a degree of 40—50%. The enzyme assays of the capped trimer and hexamer with venom phosphodiesterase exhibited the peaks corresponding to pm7G, pA, pU, pG, and pC in the ratios of approximately 1:1:1:1:0 and 1:2:1:1:2, respectively as shown in Fig. 9. Gel electrophoresis of the isolated capped oligomers also showed the expected mobilities as shown in Fig. 10. The structures of the capped oligomers were also more clearly confirmed by digestion with nuclease P_1, which gave m7G5'-pppA and the other nucleotide monomers in the correct ratios as shown in Fig. 11. The cap structure, m7G5'pppA, formed by these enzyme degradations was completely consistent with an authentic sample by comparison with their retention times.

In these reactions the HPLC patterns detected with fluorescence were not so complicated, showing 6—7 eminent peaks. Since the two peaks were assigned as pm7G and ppm7G, the other three or four peaks contained both pm7G and oligomers. Compared with the simple fluorescence HPLC patterns, the UV HPLC patterns were very complicated. Since the UV HPLC patterns obtained in the case of G5'pppApUpG and G5'pppApUpGpApCpC were also complicated, the main reason for the relatively low isolated yields of the capped oligoribonucleotides might be ascribed to the deprotection procedure used for the preparation of **32** and **33**, where the alkaline treatment was used because of its easy post-treatment. Nevertheless sufficient amounts of the capped oligomers for biological studies were successfully obtained. We are now studing improved procedures.

Experimental

^{1}H NMR spectra were recorded at 100 MHz on a JEOL UNM PS-100 spectrometer using tetramethylsilane as an internal standard. UV spectra were obtained on a Hitachi 124 spectrophotometer. Paper chromatography was performed by use of a descending technique with Whatman 3MM papers or Toyo Roshi No. 50 papers using the following solvent system: 2-propanol–concentrated aqueous ammonia–water (Solvent I, 6:1:3, v/v/v). Column chromatography was performed with silica gel C-200 purchased from Wako Co. Ltd., and a minipump for a goldfish basin was conveniently used to gain a medium pressure for rapid chromatographic separation. Thin-layer chromatography was performed on precoated TLC plates Silica Gel 60F-254 (Merck). The R_f values of the protected nucleoside derivatives were measured after development with CH_2Cl_2–MeOH (20:1, v/v) unless otherwise noted. HPLC was performed on a JASCO TRI ROTAR Type II apparatus equipped with a GP-A30 solvent programer, a UVIDEC

100-II UV detecter, a FP-110 fluorescence spectrofluorometer, a RC-225 recorder, and a Ohkura Model R 7005 digital integrator. Analysis and purification of unprotected oligoribonucleotides were performed on a Whatman Partisil 10 SAX column (3.9×250 mm) using the following solvent systems: System A: a linear gradient (0—99%) starting with buffer A (0.005 M KH_2PO_4, pH 4.1) and applying buffer B (0.1 M KH_2PO_4, 1.0 M KCl, pH 4.5) at a flow rate of 2.0 mL/min for 32 min; System B: a linear gradient (0—99%) starting with buffer C (0.005 M KH_2PO_4, 20% CH_3CN, pH 4.1) and applying buffer D (0.5 M KH_2PO_4, 20% CH_3CN, pH 4.5) at a flow rate of 1.5 mL/min for 32 min. Pyridine was distilled two times from *p*-toluenesulfonyl chloride and from calcium hydride and then stored over molecular sieves (3A). DMF was distilled and stored over molecular sieves (3A). Ribonucleosides, 1,1,3,3-tetraisopropyl-1,3-dichlorodisiloxane, and DMTrCl were purchased from Yoshitomi Seiyaku Co. Ltd. Diphenylcarbamoyl chloride and the other reagents were purchased from Tokyo Kasei Co. Ltd. Venom phosphodiesterase was purchased from Boehringer Co. Ltd. and nuclease P_1 from Yamasa Shoyu Co. Ltd. Elemental analyses were performed by the Microanalytical Laboratory, Tokyo Institute of Technology, at Nagatsuta.

N^4-Anisoyl-2'-O-(tetrahydropyran-2-yl)-3'-O-benzoylcytidine (10). Compound **31** (2.19 g, 2.58 mmol) was dissolved in CH_2Cl_2 (15 mL) and 2% trifluoroacetic acid in CH_2Cl_2 (15 ml) was added at −20 °C. After the mixture was stirred at −20 °C for 55 min, an additional amount of trifluoroacetic acid (150 μL) was added. After 2 min, pyridine was added, and then extraction was performed with CH_2Cl_2–water. The organic extract was dried over Na_2SO_4, filtered, and evaporated to dryness. The residue was chromatographed on a silica gel column to give **10** (1.02 g, 74%): R_f 0.29; ^1H NMR (d^6-DMSO): δ=1.20—1.88 (6, br, CH_2 of THP), 3.51 (2, m, CH_2-O of THP), 3.85 (3, s, CH_3-O of An), 4.02 (2, br, 5'-H), 4.50 (1, br, 4'-H), 4.72—5.12 (2, br, 2',3'-H), 5.65 (1, m, O-CH-O of THP), 5.80 (1, m, 1'-H), 6.18 (1, m, 5-H), 6.94 (2, d, J=5 Hz, ArH), 7.28—7.64 (4, m, 6-H and ArH), 7.91 (2, d, J=5 Hz, ArH), 8.07 (2, d, J=5 Hz, ArH). Anal. Calcd for $C_{29}H_{31}N_3O_9 \cdot C_6H_{14}$: C, 64.50; H, 6.96; N, 6.45. Found: C, 64.69; H, 7.23; N, 6.13.

General Procedure for the Condensation of Oligoribonucleotide Building Blocks. A fully-protected oligomer used as a diester component was treated with a 4 M pyridine solution of pyridinium phosphinate (20—30 equiv to the oligomer) and triethylamine (20—30 equiv to the oligomer), until the oligomer had been converted to a base-line material on TLC. Then, the mixture was quenched with pyridine–water (1:1, v/v) and extracted three times mith hexane–ether (1:1, v/v) to remove thiophenol. The aqueous layer was extracted three times with CH_2Cl_2. The combined CH_2Cl_2 extracts were washed with 0.2 M triethylammonium hydrogencarbonate (TEAB, pH 7.5) and water and then dried over Na_2SO_4. After the solution was filtered and evaporated, the residue was used as the diester component for the coupling reaction.

Removal of the DMTr group from oligomers was performed with 1% trifluoroacetic acid in CH_2Cl_2 at −10 °C for the times listed in Table 1. The workup was done in the same manner as described in the synthesis of **10**.

Condensation was carried out by mixing the two components, a diester and a hydroxyl components, followed by repeated coevaporations with dry pyridine, dissolving in dry pyridine (20 mL/1 mmol of the latter), and addition of **MDS** and 3-nitro-1,2,4-triazole or *N*-methylimidazole. After the condensation was complete, the mixture was quenched with pyridine–water (1:1, v/v) and extracted several times with CH_2Cl_2. The combined CH_2Cl_2 extracts were washed with 0.1 M TEAB (pH 7.5) and water. Then the usual workup followed by chromatography gave the coupling product as listed in Table 1.

5'-Phosphorylation of 14 and 20. Cyclohexylammonium *S,S*-diphenyl phosphorodithioate was coevaporated three times with dry pyridine and finally dissolved in dry pyridine (3 mL/0.1 mmol of **PSS**). **MDS** was added and the mixture was stirred for 30 min. Then the solution was added to **14** or **20** predried by repeated coevaporations with dry pyridine. The mixture was stirred for the time listed in Table 2. After the reactions was complete, the usual workup gave **15** or **21**.

Full Deprotection of 15. The trimer **15** (12.3 mg, 5 mol) was treated with 0.4 M NaOH–pyridine (1:3, v/v, 2 mL) at room temperature for 40 min. Then, the solution was passed through Dowex 50 W×2 (pyridinium form, 5 mL) and the resin was washed with pyridine–water (1:1, v/v, 50 mL). The eluent was evaporated under reduced pressure and the residue was treated with concentrated aqueous ammonia–pyridine (5:1, v/v, 18 mL) at room temperature for 12 h. Then, the solvent and ammonia were removed by evaporation and the residue was dissolved in pyridine–water (2:1, v/v, 0.5 mL). To the solution was added silver acetate (41.7 mg, 0.15 mmol). The mixture was stirred in the dark for 12 h. Then, the solution was diluted with pyridine–water (1:1, v/v, 20 mL) and hydrogen sulfide gas was bubbled into the solution at 0 °C for several minutes. The precipitate of silver sulfide was removed by centrifugation and the supernatant was concentrated to a gum. The gum was coevapo-

rated three times with methanol–toluene to remove the last traces of pyridine. The residue was dissolved in 0.02 M HCl–dioxane (1:1, v/v, 10 mL). The solution was adjusted exactly to pH 2.0 by addition of 0.1 M HCl. The resulting solution was stirred vigorously at room temperature for 48 h.

Then, concentrated aqueous ammonia (100 μL) was added and the mixture was concentrated to a gum. The gummy residue was partitioned between water (10 mL) and ether (10 mL). The ether was removed and the aqueous layer was further washed with ether (2×10 mL). The aqueous solution was concentrated to a small volume. HPLC analysis of this mixture exhibited a main peak at 19 min as seen in Fig. 1A. This peak was collected and the solvent was removed. The residue was diluted with water so as to decrease the salt concentration to less than 0.1 M, and applied to a column on DEAE-Sephadex A-25 (1×5 cm). Elution with water was performed and then elution with 1 M TEAB buffer (pH 7.5) gave fractions containing the product. Most of TEAB was removed under reduced pressure by coevaporations with water and finally the product was desalted by paper chromatography on Toyo Roshi No 51A developed with 95% ethanol. A band at the origin was eluted with water and the solution was filtered and concentrated to give pApUpG (38.0 OD, 20%): HPLC 20 min (A): UV (H_2O) λ_{max} 255 nm, λ_{min} 277 nm.

Synthesis of G⁵'pppApUpG. The fully protected trimer **15** (5 μmol) was partially deprotected as described in full deprotection of **15**. A mixture of compound **1b** (26.2 mg, 25 μmol) and imidazole (35 mg, 0.5 mmol) was rendered anhydrous by repeated coevaporations with dry pyridine and finally dissolved in dry pyridine (0.5 mL). Silver nitrate (132 mg, 0.75 mmol) was added and the solution was stirred in the dark for 3 h. Then, it was coevaporated with dry DMF (3×5 mL), dissolved in dry DMF (0.3 mL), and finally added to crude **32**, obtained from **15** after treatment with silver acetate, which had been coevaporated with dry pyridine (3×5 mL) and then DMF (3×5 mL). The resulting mixture was stirred in the dark for 48 h. Then pyridine–water (2:1, v/v, 10 mL) was added. Hydrogen sulfide gas was bubbled with stirring into the solution at 0 °C until a clear supernatant had been obtained. The supernatant was concentrated to dryness and coevaporated with methanol–toluene (1:1, v/v 3×5 mL). The residue was dissolved in a solution of 0.02 M HCL–dioxane (1:1, v/v, 10 mL) adjusted exactly to pH 2.0 by 0.1 M HCl. After being stirred for 45 h, the solution was quenched with concentrated aqueous ammonia (0.1 mL) and concentrated to a small volume. The concentrate was chromatographed on Whatman 3 MM paper with Solvent I to give crude G⁵'pppApUpG with R_f 0.09. The crude product was further purified by HPLC as shown in Fig. 4. A peak at 35 min was collected and pooled. The combined fractions were desalted by DEAE-Sephadex A-25 as described in the synthesis of pApUpG to give G⁵'-pppApUpG (25 OD, 10%): HPLC 34 min (System B); UV (H_2O): λ_{max} 255 nm, λ_{min} 232 nm.

Full Deprotection of 21. The same procedure as described in the case of **15** was employed.

The residue, obtained after the acid treatment for removal of the acid-labile protecting groups, was dissoved in water (10 ml) and washed with ether (3×10 mL). The aqueous solution was concentrated, and the residue was applied to Watman 3 MM papers and developed with Solvent I. A band at the origin was cut and eluted with water. The eluent was filtered and concentrated to a small volume. The solution was separated by HPLC. A peak at 30 min (System B) was collected and pooled. The combined fractions were evaporated under reduced pressure and diluted with water. The solution was applied to a column of DEAE-Sephadex A-25 (1×5 cm) and the column was washed with water and then eluted with 1 M TEAB. The eluent was coevaporated repeatedly with water and finally desalted by paper chromatography using Toyo Roshi developed with 95% ethanol. A UV absorbing material at the origin was eluted with water. The eluent was evaporated to give pApUpGpApCpC (22.5 OD, 10%): R_f 0.1 (Solvent I); HPLC 30 min (System B); UV (H_2O) λ_{max} 257 nm, λ_{min} 238 nm.

Synthesis of G⁵'pppApUpGpApCpC. This compound was synthesized from **33** (5 μmol) and **1b** (25 μmol) in the same manner as described in the above experiment: Purification after the acid treatment for removal of the THP, MMTr, and TMTr groups was performed as follows: The residue, obtained by evaporation after quenching of the acid solution used for removed of the acid-labile protecting groups, was dissolved in water (10 mL) and washed with ether (10 mL). The aqueous solution was filtered and separated by preparative HPLC as shown in Fig. 5. A peak at 40 min pooled and desalted by DEAE-Sephadex A-25 as described before to give G⁵'pppApUpGpApCpC (16.7 OD, 5%): R_f 0.14 (Solvent I); HPLC 40 min (System B); UV (H_2O) λ_{max} 258 nm, λ_{min} 230 nm.

Preparation of 1a from 1b. Compound **1b** (30 mg, 25 μmol) was coevaporated with dry DMF (2×5 mL) and finally dissolved in dry DMF (1.25 mL). To the solution was added methyl iodide (19 μL, 0.3 mmol). The mixture was stirred for 16 h and then evaporated under reduced pressure. The residue was coevaporated with dry pyridine (2×5 mL) and then used without further purification in the capping reactions.

Synthesis of m⁷G⁵'pppApUpG. This compound was synthesized from **1a** (5 μmol) and **32** (25 μmol) in the same manner as described in the synthesis of G⁵'pppApUpG. Purification was performed in the same manner as described in the synthesis of pApUpG: R_f 0.14 (Solvent I); HPLC 27 min (System B); UV (H_2O) λ_{max} 230 nm, λ_{min} 230 nm.

Synthesis of m⁷G⁵'pppApUpGpApCpC. This compound was synthesized from **1a** and **33** in the same manner as described in the synthesis of G⁵'pppApUpGpApCpC. Purification was performed in the same manner as described in the synthesis of pApUpG (13 OD, 5%): HPLC 33 min (System B); UV (H_2O) λ_{max} 257 nm, λ_{min} 233 nm.

Enzyme Assay. Treatment with venom phosphodiesterase. A substrate (10 OD) was incubated with venom phosphodiesterase in a mixture of 0.05 M Tris-HCl buffer (pH 8.0, 200 μL) and 1 M $MgCl_2$ (10 μL) at 37 °C for 3 h. When a less amount of substrate than 10 OD was used, the amounts of the enzyme and reagents were decreased to the same degree.

Treatment with Nuclease P_1. A substrate (0.05 OD) was incubated with nuclease P_1 (1 μL) in 0.05 M acetate buffer (pH 5.4, 9 μL) at 37 °C for 30—60 min. The mixture was analyzed by HPLC as described in the text.

We express our appreciation to Professor Kinichiro Miura for helpful discussions throughout our programs. Technical assistance was provided by Dr.

A. Kume, Mr. J. Matsuzaki, Miss K. Kohno, Mr. H. Tanimura, and is gratfully acknowledged. We also thank Mrs. C. Sugimura for typewriting this manuscript. This work was supported by the Grant-in-Aid for Scientific Research from the Ministry of Education, Science and Culture.

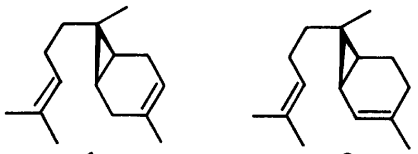
Rearrangement Approaches to Cyclic Skeletons. II. Structural Revision and Total Synthesis of (±)-Isosesquicarene, a [3—6] Fused-Ring Sesquiterpene[1)]

Tadao UYEHARA,* Jun-ichi YAMADA, Tadahiro KATO, and Ferdinand BOHLMANN†
Department of Chemistry, Faculty of Science, Tohoku University, Aramaki-Aoba, Sendai 980
†*Institut fur Organische Chemie, Technische Universtat Berlin, Strasse des 17. Juni 135, D-1000 Berlin 12, West Germany*
(Received October 22, 1984)

The *exo*-7-(4-methyl-3-pentenyl) derivative of 3-carene (**1a**), the original structure reported for (±)-isosesquicarene, was synthesized starting from tropone, and it was found that **1a** is not identical with natural isosesquicarene. The structure of isosesquicarene was reinterpreted as *endo*-7-(4-methyl-3-pentenyl) derivative of 3-carene (**1b**). The first total synthesis of (±)-isosesquicarene, **1b**, has been accomplished on the basis of the photochemical transformation of 4-methylbicyclo[3.2.2]nona-3,6-dien-2-one into the 7-*exo*-methylbicyclo-[4.1.0]hept-2-ene.

The structure proposed for isosesquicarene, a sesquiterpenic hydrocarbon isolated from *Haplopappus tenuisectus* (Greene) Blake, is the 3-carene derivative (**1a**)[3)] which is very similar to that of sesquicarene (**2**).[4)] In connection with the stereoselective synthesis of **2** from tropone,[2)] we attempted a total synthesis of (±)-isosesquicarene, and found that **1a** is not the correct structure of isosesquicarene. In this paper we detail i) a stereoselective synthesis of **1a**, ii) proposal of the probable structure (**1b**) for isosesquicarene, and iii) the first total synthesis of (±)-isosesquicarene, **1b**.



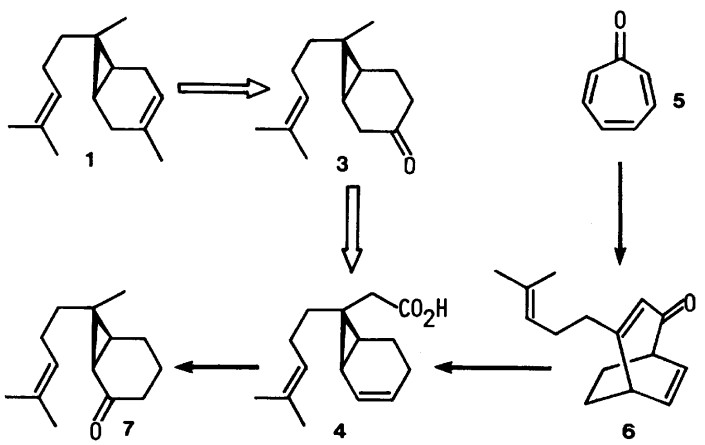
1a **2**

Results and Discussion

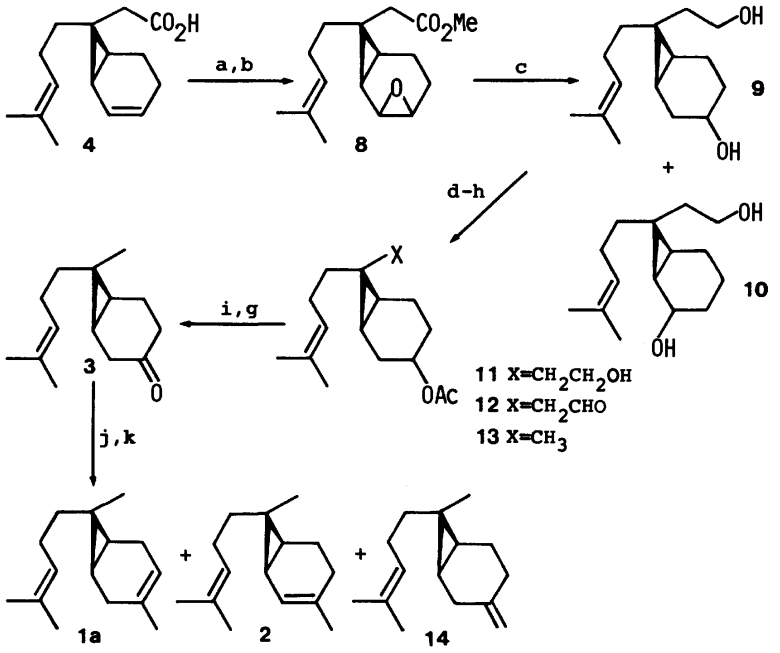
Synthesis of the Original Structure Reported for Isosesquicarene. Scheme 1 shows our synthetic plan along with the background.[2)] The ketone (**3**), a presumable precursor of **1a**, would be derived from the bicyclic acid (**4**) in a manner similar to the conversion of **4** into ketone **7** which is a key synthetic intermediate for sesquicarene (**2**). A practical synthetic route to **4** from tropone (**5**) has already been established *via* photochemical transformation of **6** into the acid.

The iodo lactone, derived from **4**,[2)] was transformed into the epoxide (**8**) in 95% yield from **4** by treating with sodium methoxide in methanol, as shown in Scheme 2. The stereochemistry of the epoxide followed from its ^{1}H-NMR spectra which showed $J_{1,2}$=3.6 Hz.[5)] A regioselective opening of the oxirane ring of **8** was done by heating with $LiAlH_4$ in tetrahydrofuran (THF) to give diols **9** and **10** in 76 and 19% yields, respectively. The minor product was identical with the diol obtained from the iodo lactone by treating with $LiAlH_4$.[2)] A better level of stereocontrol was obtained with diisobutylaluminium hydride (DIBAH) at 0 °C but the yield of **9** was not superior to the $LiAlH_4$ reduction; 67%, **9** and 8%, **10**.

In order to prepare an aldehyde suitable for one-



Scheme 1.



Scheme 2. Synthesis of 3,*endo*-7-Dimethyl-*exo*-7-(4-methyl-3-pentenyl)bicyclo[4.1.0]hept-3-ene (**1a**).[a)]

a) (a): I_2, $NaHCO_3$, ether, H_2O, (b): MeONa, MeOH, (c): $LiAlH_4$, THF, (d): TBDMS-Cl, DMAP, $N(CH_2CH_3)_3$, (e): Ac_2O, Py, (f): AcOH, THF, H_2O, (g): CrO_3–2Py, (h): $RhCl(PPh_3)_3$, PhCN, (i): $LiAlH_4$, ether, (j): MeLi, (k): $POCl_3$, DMAP, Py.

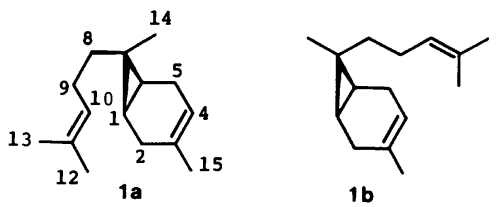
carbon removal from the *endo*-side chain as carbon monoxide using Wilkinson's complex,[6)] the major diol (**9**) was converted into monoacetate **11** in 78% yield. Oxidation of **11** by Collins reagent gave aldehyde **12** in 82% yield. Decarbonylation of **12** by heating with just one equivalent of Wilkinson's complex in benzonitrile at 145 °C for 8 min afforded the acetate (**13**) in 84% yield. Reduction of **13** with $LiAlH_4$ followed by oxidation with Collins reagent produced the desired ketone, **3**, in 91% yield.

Treatment of **3** with an excess of methyllitium at −78 °C gave a mixture of the tertiary alcohols in 73% yield and 22% of unchanged **3**. Dehydration of the alcohols with phosphoryl chloride, pyridine and 4-dimethylaminopyridine (DMAP) produced a 81% yield of three hydrocarbons in a ratio of 63:31:6. The second major product was identical with (±)-sesquicarene (**2**). The specimen of the minor product (**14**) was prepared from **3** by treatment with methylenetriphenylphosphorane in dimethyl sulfoxide (DMSO).

The spectral characteristics of the major product support that its structure is **1a**. However, the NMR spectral data of hydrocarbon **1a** are significantly different from those reported for natural isosesquicarene.

A Structural Revision of Isosesquicarene. It is interesting that both the ^{1}H-NMR data of **1a** and natural isosesquicarene can be arranged in the same tabular form, as shown in Table 1. The assignments of the spectrum of **1a** were performed easily starting from the largest coupling of the H_4 to one of the vicinal methylene protons. Table 1 suggests that both the compounds are the 3-carene derivatives possessing a homoprenyl side chain. A large difference between the chemical shifts of their cyclopropyl methyl protons, H_{14}, indicates that the lower-field resonance of isosesquicarene is not affected largely by the anisotropy effect of the C_3–C_4 double bond.

Thus we propose the C_7-stereoisomer of the original structure, **1b**, as the revised stereostructure of isosesquicarene. The following studies are in order to confirm our proposal.



Total Synthesis of (±)-Isosesquicarene (1b). The synthesis was initiated with ketone **15** as shown in Scheme 3. The ketone has already been prepared form bicyclo[3.2.2]nona-3,6-dien-2-one.[2)] The photochemical conversion of **15** into **16** in a good yield was performed by irradiation of a methanolic solution using a high-pressure mercury lamp through a Pyrex

filter. The fact that ^{1}H-NMR of **16** shows the resonance due to the cyclopropyl methyl protons at δ=1.13 prompted us to forward the scheme.

In order to elongate the endo-side chain, **16** was reduced by $LiAlH_4$ to the alcohol, which was tosylated. Treating of the tosylate with sodium cyanide in DMSO gave nitrile **17** in 84% yield (from **16**). The silyl ether (**19**) was derived from **17** in 70% yield *via* the aldehyde (**18**) by sequential treatment with (i) DIBAH, (ii) aqueous ammonium chloride solution, (iii) $LiAlH_4$, and (iv) *t*-butyldimethylchlorosilane, triethylamine, and DMAP.

Table 1. Proton NMR data of compound **1a** and isosesquicarene (in $CDCl_3$)

	Compound **1a**			Isosesquicarene[a]	
H	δ	mult	J, Hz (coupled to)[b]	δ	mult[c]
1	0.72	dd	9.3(6), 7.2(2α)	0.66	dd
2α	2.18	bdd	18.2(2β), 7.2(1)	2.34	bdd
2β	1.81	m		2.03	m
4	5.27	bs		5.25	bs

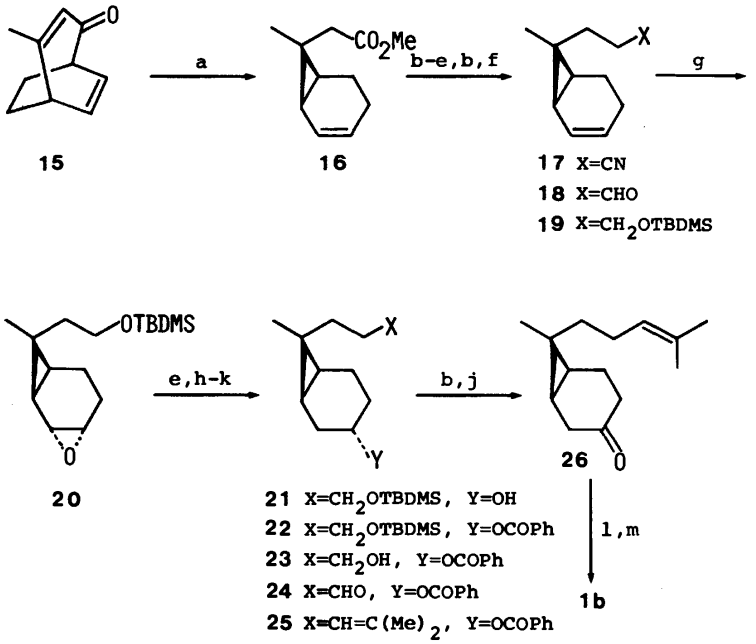
14	0.75	s		1.02	
15	1.64	bs		1.59	bs

a) Ref. 3. b) Distinguished coupling are listed. c) $J_{5\alpha,5\beta}$=19 Hz, $J_{4,5\alpha}$=3 Hz, $J_{5\alpha,6}$=8 Hz, $J_{1,2\alpha}$=8 Hz, $J_{1,6}$=8 Hz, and $J_{9,10}$=7 Hz. d) This work.

Epoxidation of **19** with *m*-chloroperoxybenzoic acid yielded only **20**. The stereostructure of **20** was estimated on the basis of its ^{1}H-NMR spectra ($J_{1,2}$<1 Hz).[5] Treatment of **20** with DIBAH gave only the regioselective C-O cleavage product (**21**), which was converted into the benzoate (**22**) in 71% yield from **19**. This regioselective ring opening is with the assistance of the bonding between the reagent and the epoxide oxygen and due to participation of the cyclopropane to tolerate positive charge at the C_2 in the transition state. ^{1}H-NMR spectra of **22** showed the signals due to the C_3-H at δ=4.91 (b, $W_{1/2}$= 13 Hz). This half-hight width is clearly different from those of **12** and **13**: C_3-H of **12**, $W_{1/2}$=19.5 Hz; C_3-H of **13**, $W_{1/2}$=21 Hz. Thus, the 3-proton of **22** should be a pseudoequatrial one and the benzoyloxyl group should be α-configuration as illustrated. Now it is clear that the epoxidation of **19** proceeded at its less-hindered side.

After removal of the silyl group of **22**, the alcohol (**23**) was transformed into the unstable aldehyde (**24**). Immediately after isolation, **24** was treated with isopropylidenetriphenylphosphorane in ether at −30 °C to give **25** in 68% yield from **23**.



Scheme 3. Synthesis of (±)-isosesquicarene.[a]

a) (a): *hv*, MeOH, (b): $LiAlH_4$, (c): TsCl, Py, (d): NaCN, DMSO, (e): DIBAH, $PhCH_3$, (f): TBDMS-Cl, DMAP, $N(CH_2CH_3)_3$, (g): MCPBA, $NaHCO_3$, (h): $(PhCO)_2O$, DMAP, $N(CH_2CH_3)_3$, (i): AcOH, THF, H_2O, (j): CrO_3-2Py, (k): Ph_3P=CMe_2, (l): MeLi, (m): $POCl_3$, DMAP, Py.

We have examined several routes to shorten the synthetic steps but have not yet found more effective ones because of instability of the aldehydes like **24**.

Reduction of **25** with $LiAlH_4$ followed by Collins oxidation gave ketone **26** in 76% yield. Treatment of **26** with methyllithium at −95 °C yielded a mixture of tertiary alcohols in 74% yield. Dehydration of the alcohols gave a mixture of three hydrocarbons in 74% yield. The major product (**1b**) was purified by repeated preparative VPC. Thus obtained was identical spectroscopically with natural isosesquicarene.

*The stereostructure of isosesquicarene is 3,*exo*-7-dimethyl-*endo*-7-(4-methyl-3-pentenyl)bicyclo[4.1.0]hept-3-ene.*

Experimental

General. Melting and boiling points are uncorrected. IR spectra (in CCl_4, unless otherwise mentioned) were recorded on a Hitachi Model 215 spectrometer. NMR spectra (in CCl_4, unless otherwise noted) were obtained on JEOL JNM-PMX60, Varian EM-390 90 MHz, and Varian XL-200 NMR spectrometers, using tetramethylsilane as an internal standard. The mass spectral studies were conducted using a Hitachi M-52 spectrometer and a JEOL DX-300 mass spectrometer. Photochemical reactions were carried out in an immersion well through a Pyrex filter using a Ushio 300 W high pressure mercury lamp, under an inert atmosphere. THF and ether were distilled from benzophenone ketyl under argon, immediately prior to use. Dichloromethane was distilled from P_2O_5 and stored on 4A molecular sieves. Pyridine (from BaO), triethylamine, methanol (from $Mg(OCH_3)_2$), and DMSO (from BaO) were purified by distillation. Collins reagent,[7] and Wilkinson's complex[8] were prepared by using literature procedures. All reactions were monitored by analytical TLC using E. Merck precoated silica gel $60F_{254}$ plates. Column chromatography was carried out with E. Merck silica gel 60 (70—230 mesh ASTM, twenty to fifty times (w/w)). A Warters silica cartridge "Sep-Pack" was used for small scale rapid chromatography. Analytical VPC was performed on a Hitachi 663-50 gas chromatograph, outfitted with a 3 m×3 mm stainless-steel column packed with 10% FFAP on 60/80 Uniport B, and preparative VPC on a Varian Aerograph model 920 gas chromatograph with TC detector, outfitted a with 10 ft×3/8 in. aluminium column containg 10% FFAP on 60/80 Uniport B.

Preparation of Methyl endo*-2,3-Epoxy-*exo*-7-(4-methyl-3-pentenyl)bicyclo[4.1.0]heptane-*endo*-7-acetate (8).* To a solution of 262.4 mg (1.12 mmol) of **4** in 7 ml of saturated aqueous $NaHCO_3$ was added a solution of 285 mg (1.12 mmol) of iodine in 10 ml of ether over a period of 20 min at room temperature in the dark. After 1 h of stirring, the mixture was diluted with water, and extracted with several portions of ether. The extracts were combined, washed with 5% aqueous $Na_2S_2O_3$ and saturated brine, and then dried over $MgSO_4$. Evaporation of the solvent without heating from outside gave 443.3 mg of a pale yellow oil, which was supplied directly to the following reaction. To a solution of the oil in 5 ml of methanol was added a solution of sodium methoxide in methanol, prepared from 60 mg of sodium and 1.2 ml of methanol, at 0 °C. After 2 h standing at 0 °C, the mixture was diluted with water, and extracted with two portions of ether. The extracts were combined, washed with two portions of water and with saturated brine, and then dried over $MgSO_4$. Removal of the solvent gave 297.5 mg of yellow oil, which was purified by column chromatography (5:1 hexane, ethyl acetate) to yield 280.7 mg (95%) of **8**: bp 100—105 °C/2 Torr; IR 1740 (s), 1190 (m), and 1165 (m) cm^{-1}; NMR δ=5.00 (1H, tm, J=7.2 Hz), 3.62 (3H, s), 3.25 (1H, dd, J=3.6 and 3.6 Hz), 2.83 (1H, dd, J=3.6 and 2.7 Hz), 2.68 (2H, s), 1.66 (3H, bs), 1.60 (3H, bs), and 0.79 (1H, dd, J= 9.0 and 3.6 Hz); MS, m/z (rel intensity) 264 (M^+, 13) and 167 (100). Found: C, 72.67; H, 9.38%. Calcd for $C_{16}H_{24}O_3$: C, 72.69; H, 9.15%.

Reduction of Epoxide 8. Preparation of endo*-7-(2-Hydroxyethyl)-*exo*-7-(4-methyl-3-pentenyl)bicyclo[4.1.0]heptan-3-ol (9).* To a mixture of 146 mg (3.85 mmol) of $LiAlH_4$ and 5 ml of dry THF was added a solution of 398.5 mg of **8** in 30 ml of dry THF at 0 °C. The reaction mixture was heated under reflux for 1.5 h. After cooling to 0 °C, the resulting suspension was treated by successive dropwise addition of a few ml of ethyl acetate, 0.15 ml of water, 0.15 ml of 15% aqueous NaOH, and 0.45 ml of water, and then allowed to warm to room temperature with stirring. The THF solution was filtered, and the filtrate was concentrated *in vacuo* to afford 389.1 mg of a colorless oil. Separation of the products by column chromatography (1:1 hexane, ethyl acetate) gave 287.7 mg (76%) of **9** and 72 mg (19%) of **10**.[2] **9**: IR 3340 (m) and 1055 (s) cm^{-1}; NMR δ=5.00 (1H, tm, J=6.9 Hz), 4.05 (2H, bs), 1.67 (3H, s), and 1.61 (3H, s). The diacetate of **9**: C, 71.07; H, 9.51%. Calcd for $C_{19}H_{30}O_4$: C, 70.77; H, 9.38%.

Transformation of Diol 9 into endo*-7-(2-Hydroxyethyl)-*exo*-7-(4-methyl-3-pentenyl)bicyclo[4.1.0]hept-3-yl Acetate (11).* In order to protect the primary hydroxyl group selectively, a solution of 220 mg (1.2 equiv) of *t*-butyldimethylchlorosilane in 10 ml of CH_2Cl_2 was added to a solution of 287.7 mg (1.21 mmol) of **9**, 137.8 mg (0.19 ml, 1.1 equiv) of triethylamine, and a small amount of DMAP in 9 ml of CH_2Cl_2. After standing for 21 h at room temperature, the solution was washed with saturated aqueous NH_4Cl, dried over $MgSO_4$, and concentrated *in vacuo*. Chromatography (15:1 hexane, ethyl acetate) of the residue gave 341.8 mg (80%) of the monosilyl ether of **9**: IR 3620 (w), 3350 (w), 1090 (s), and 1050 (m) cm^{-1}; NMR δ=4.97 (1H, tm, J= 6.9 Hz), 3.67 (2H, m), 3.47 (1H, m), 1.64 (3H, bs), 1.58 (3H, bs), 0.90 (6H, s), and 0.05 (9H, s).

To protect the secondary hydroxyl group, 2 ml of acetic anhydride was added to a solution of 603.2 mg (1.71 mmol) of the monosilyl ether in 3 ml of dry pyridine. After standing overnight at room temperature, evaporation of the solvent *in vacuo* gave 670.5 mg of the residue, which was chromatographed (10:1 hexane, ethyl acetate) to afford 665.6 mg (98%) of the acetate: IR 1730 (s) and 1030 (m) cm^{-1}. Found: C, 70.01; H, 10.62%. Calcd for $C_{23}H_{42}O_3Si$: C, 70.00; H, 10.73%.

In order to remove the silyl group,[9] 665.6 mg (1.68 mmol) of the acetate was treated with a mixture of 3.4 ml of THF, 3.4 ml of water, and 10.2 ml of acetic acid for 7 h at room temperature. The solution was diluted with ether, washed successively with water (four times), saturated $NaHCO_3$ and brine solutions, dried over $MgSO_4$, and concentrated *in vacuo*. Chromatography (3:1 hexane, ethyl acetate) of the

residue gave 467 mg (99%) of **11**: IR 1730 (s) and 1030 (s) cm^{-1}; NMR δ=4.97 (1H, tm, J=6.9 Hz), 4.56 (1H, m, $W_{1/2}$=21.3 Hz), 3.67 (2H, m), 1.93 (3H, s), 1.65 (3H, bs), and 1.59 (3H, bs).

Preparation of endo-*7-(2-Oxoethyl)*-exo-*7-(4-methyl-3-pentenyl)bicyclo[4.1.0]hept-3-yl Acetate (12).* To a solution of 3.20 g (12.4 mmol) of Collins reagent in 40 ml of dry CH_2Cl_2 was added a solution of 578.2 mg (2.06 mmol) of the hydroxy acetate in 24 ml of CH_2Cl_2. After 6 min stirring at room temperature, the solution was decanted, and the black residue was washed with several portions of ether. The organic layers were combined, washed successively with 5% aqueous NaOH, 5% HCl, saturated $NaHCO_3$ and brine solution, dried over $MgSO_4$, and evaporated. Column chromatography (3:1 hexane, ethyl acetate) of the residue (553.1 mg) gave 529.7 mg (92%) of the unstable aldehyde, **12**: IR 2710 (w), 1730 (s), and 1245 (s) cm^{-1}; NMR δ=9.70 (1H, t, J=2.3 Hz), 4.97 (1H, tm, J=6.9 Hz), 4.58 (1H, m, $W_{1/2}$=19.5 Hz), 2.29 (2H, d, J=2.3 Hz), 1.91 (3H, s), 1.63 (3H, bs), and 1.56 (3H, s); MS, m/z (rel intensity) 218 (M^+−60, 98), 200 (74), 131 (74), and 82 (100).

Decarbonylation of 12. Preparation of endo-*7-Methyl*-exo-*7-(4-methyl-3-pentenyl)bicyclo[4.1.0]hept-3-yl Acetate (13).* A flask containing of a mixture of 155.3 mg (0.56 mmol) of **12**, 514.3 mg (0.56 mmol) of Wilkinson's complex and 2 ml of benzonitrile, prepared under argon, was immersed in a preheated oil bath at 145 °C for 8 min with stirring. The bulk of benzonitrile was removed by Kugelrohr distillation (100 °C/3 Torr), and the residue was rinsed with ethanol, filtered, and washed with ethanol. After evaporation of the solvent, chromatography (10:1 hexane, ethyl acetate) of the residue (343.3 mg) gave 117.3 mg (84%) of **13**: bp 55—60 °C/0.5 Torr (1 Torr=133.322 Pa); IR 1730 (s) and 1250 (s) cm^{-1}; NMR δ=4.98 (1H, tm, J=6.9 Hz), 4.52 (1H, m, $W_{1/2}$=21 Hz), 1.93 (3H, s), 1.65 (3H, s), 1.58 (3H, s), and 1.00 (3H, s); MS, m/z (rel intensity) 190 (M^+−60, 100), 108 (66), and 105 (51). Found: C, 76.95; H, 10.46%. Calcd for $C_{16}H_{26}O_2$: C, 76.75; H, 10.47%.

Preparation of endo-*7-Methyl*-exo-*7-(4-methyl-3-pentenyl)bicyclo[4.1.0]heptan-3-one (3).* To a suspension of 50 mg (1.32 mmol) of $LiAlH_4$ in 2 ml of dry ether was added a solution of 208.6 mg (0.83 mmol) of **13** in 10 ml of ether at 0 °C. After 20 min stirring, to the reaction mixture were added successively 0.05 ml of water, 0.05 ml of 15% aqueous NaOH, and 0.15 ml of water. After stirring until a granular precipitate was formed, $MgSO_4$ was added to the mixture and filtered. Concentration of the filtrate gave 176.3 mg of an oil. Chromatography (5:1 hexane, ethyl acetate) of the oil gave 164.7 mg (95%) of the alcohol: IR 3620 (w), 3330 (m), and 1055 (s) cm^{-1}; NMR δ=4.98 (1H, tm, J=6.9 Hz), 3.43 (1H, m, $W_{1/2}$=22.8 Hz), 1.65 (3H, bs), 1.59 (3H, bs), 1.53 (1H, s), and 0.98 (3H, s).

The alcohol (164.7 mg, 0.79 mmol) was treated with 1.14 g (4.75 mmol) of Collins reagents in 10 ml of dry CH_2Cl_2 at room temperature for 5 min. A workup similar to that employed for the synthesis of **12** gave 165.4 mg of the crude product. Chromatography on silica gel (10:1 hexane, ethyl acetate) gave 143.2 mg (96%) of pure **3**: IR 1710 (s) cm^{-1}; NMR δ=4.95 (1H, tm, J=6.9 Hz), 1.62 (3H, bs), 1.56 (3H, bs), and 0.88 (3H, s); MS, m/z (rel intensity) 206 (M^+, 11) and 82 (100). Found: C, 81.55; H, 10.89%. Calcd for $C_{14}H_{22}O$: C, 81.50; H, 10.75%.

*Preparation of 3,*endo-*7-Dimethyl*-exo-*7-(4-methyl-3-pentenyl)bicyclo[4.1.0]hept-3-ene (1a).* To a solution of 144.7 mg (0.70 mmol) of **3** in 1.5 ml of ether was added dropwise a methyllithium solution, prepared from 500 mg of methyl iodide (3.53 mmol) and 70 mg (10.1 mmol) of lithium in 3 ml of ether at 0 °C by 10 min of sonication,[10] at −78 °C. After 1 h stirring followed by addition of methanol, the mixture was diluted with ether and washed with saturated brine. The etherial solution was dried over $MgSO_4$, and concentrated. Chromatography (15:1 hexane, ethyl acetate) of the residue gave 113.2 mg (73%) of a mixture of the alcohols and 32.5 mg (22%) of **3**.

Three drops of $POCl_3$ were added to a solution of 31.0 mg (0.14 mmol) of the mixture of the alcohols and a small amount of DMAP in 2 ml of pyridine at 0 °C. After 1.5 h stirring at 0 °C, the mixture was diluted with pentane, washed successively with 5% HCl, saturated $NaHCO_3$ and NaCl solutions, and then dried over Na_2SO_4. Concentration of the solution followed by purification using a silica cartridge (pentane) gave 23.1 mg of a colorless oil. The product was shown by analytical VPC and NMR to consist of 63% **1a**, 31% **2**, and 6% **14**. Preparative VPC (10% FFAP, 150 °C) afforded **1a**: IR 2980 (s), 2920 (s), 2830 (s), 1450 (m), and 1380 (m) cm^{-1}; MS, m/z (rel intensity) 204 (M^+, 14), 161 (16), 119 (70), and 93 (100). Found: m/z 204.18590. Calcd for $C_{15}H_{24}$: M, 204.18776.

Preparation of endo-*7-Methyl-3-methylene*-exo-*7-(4-methyl-3-pentenyl)bicyclo[4.1.0]heptane (14).* Methylenetriphenylphosphorane was generated by a typical method[11] from 760 mg (2.13 mmol) of methyltriphenylphosphonium bromide in DMSO. The ylide solution was added to a solution of 76 mg (0.37 mmol) of **3** in 2 ml of DMSO at 35 °C. After 3 h standing at room temperature, the mixture was chilled by ice-water, diluted with water, and extracted with three potions of pentane. The extracts were combined washed with two portions of water and with saturated brine, and then dried over Na_2SO_4. Concentration of the solution followed by purification using a silica cartridge (pentane) gave 68.3 mg (90%) of colorless oil. **14**: IR 3085 (m), 1654 (m), and 888 (s) cm^{-1}; NMR ($CDCl_3$) δ=5.05 (1H, tm, J=6.9 Hz), 4.59 (2H, b, $W_{1/2}$=3.5 Hz), 1.68 (3H, bs), 1.62 (3H, bs), and 0.92 (3H, s); MS, m/z (rel intensity) 204 (M^+, 28), 189 (35), 161 (100), and 122 (86). Found: m/z 204.18822. Calcd for $C_{15}H_{24}$: M, 204.18776.

Photochemical Transformation of 15 into Methyl exo-*7-Methylbicyclo[4.1.0]hept-2-ene*-endo-*7-acetate (16).* A solution of 1.14 g (7.69 mmol) of **15** in 750 ml of methanol was irradiated by a 300 W Hg-lamp for 1.5 h. Evaporation of the solvent gave 1.24 g of a yellow oil. Column chromatography of the crude oil (10:1 hexane, ethyl acetate) gave 1.11 g (80%) of pure **16**: IR 1735 (s) cm^{-1}; NMR δ=5.80 (1H, dm, J=10.2 Hz), 5.60 (1H, dm, J=10.2 Hz), 3.60 (3H, s), 2.20 (2H, s), 2.2—1.4 (4H, m), 1.13 (3H, s), and 1.04 (2H, m); MS, m/z (rel intensity) 180 (M^+, 13), 106 (100), and 91 (94). Found: C, 73.40; H, 8.97%. Calcd for $C_{11}H_{16}O_2$: C, 73.30; 8.95%.

Preparation of exo-*7-Methylbicyclo[4.1.0]hept-2-ene*-endo-*7-propanenitrile (17).* Ester **16** (1.641 g, 9.88 mmol) was reduced by lithium aluminium hydride (570 mg, 15.0 mmol) in ether (120 ml) at 0 °C. A similar workup to that employed for the reduction of **13** gave the corresponding alcohol (1.677 g). To a solution of the crude alcohol in pyridine (10 ml) was added a solution of tosyl chloride (2.75 g,

14.4 mmol) in pyridine (3 ml) at 0 °C. After 2 h stirring at 0 °C, the mixture was diluted with water (50 ml), and extracted with three portions of ether. The combined extracts were washed successively with 5% HCl, saturated $NaHCO_3$ and NaCl solutions, dried over $MgSO_4$, and then concentrated. To a solution of the tosylate (2.784 g) in DMSO (20 ml) was added sodium cyanide (730 mg, 14.9 mmol), and the mixture was heated at 90 °C for 2 h under a nitrogen atmosphere. After dilution with water, the solution was extracted with three portions of CH_2Cl_2. The extracts were combined, washed with three portions of water, dried over $MgSO_4$, and concentrated *in vacuo*. Chromatography (20:1 hexane, ethyl acetate) of the residue gave pure **17** (1.327 g, 84%). **17**: bp 75 °C/15 Torr; IR 2260 (w) and 1455 (s) cm^{-1}; NMR δ=5.82 (1H, dm, J=10.5 Hz), 5.65 (1H, dm, J=10.5 Hz), 2.27 (2H, m), 1.64 (2H, m), 1.11 (3H, s), and 1.06 (3H, s); MS, m/z (rel intensity) 161 (M^+, 13), 119 (100), 107 (37), and 79 (30). Found: C, 82.24; H, 9.60; N, 8.84%. Calcd for $C_{11}H_{15}N$: C, 81.94; H, 9.38; N, 8.69%.

Preparation of exo-*7-Methylbicyclo[4.1.0]hept-2-ene*-endo-*7-propanal (18).* To a solution of 914.6 mg (5.67 mmol) of **17** in 57 ml of toluene was added 3.9 ml of a solution of DIBAH in hexane (1.76 M, 6.86 mmol (1 M=1 mol dm^{-3})) at 0 °C under an argon atmosphere. After 2 h stirring at room temperature, the mixture was cooled by ice-water. Careful addition of 50 ml of saturated aqueous NH_4Cl followed by stirring at room temperature for 30 min gave a suspension, which was filtered through a sintered-glass disk and washed with several portions of ether. The filtrates were combined, washed successively with water, saturated $NaHCO_3$ and NaCl solutions, dried over Na_2SO_4, and concentrated *in vacuo*. Column chromatography (15:1 hexane, ethyl acetate) of the residue (937.0 mg) gave 790.6 mg (85%) of **18**: IR 2815 (m) and 1725 (s) cm^{-1}; NMR δ=9.62 (1H, t, J=1.5 Hz), 5.73 (1H, dm, J=10.1 Hz), 5.62 (1H, dm, J=10.2 Hz), 2.37 (2H, m), 1.57 (2H, m), and 1.05 (3H, s). The 2,4-DNP derivative of **18**: mp 119.5—121.0 °C. Found: C, 59.44; H, 5.92; N, 16.03%. Calcd for $C_{17}H_{20}N_4O_4$: C, 59.29; H, 5.85; N, 16.27%.

Preparation of exo-*7-Methyl*-endo-*7-[3-(t-butyldimethylsiloxy)propyl]bicyclo[4.1.0]hept-2-ene (19).* To a suspension of 240 mg (6.32 mmol) of $LiAlH_4$ in 30 ml of ether was added a solution of 1.03 g (6.25 mmol) of **18** in 20 ml of ether at 0 °C. After stirring for 30 min, a similar workup to that employed for the reduction of **13** gave the corresponding alcohol. To a solution of the alcohol, 0.96 ml (6.88 mmol) of triethylamine, and a small amount of DMAP in 30 ml of dry CH_2Cl_2 was added a solution of 1.13 g (7.50 mmol) of *t*-butyldimethylchlorosilane in 30 ml of dry CH_2Cl_2 under argon. After standing for 17 h at room temperature, the solution was washed with saturated NH_4Cl solution, dried over $MgSO_4$, and evaporated. Chromatography (15:1 hexane, ethyl acetate) of the residue (1.78 g) gave 1.44 g (82%) of **19**: IR 1100 (s) and 840 (m) cm^{-1}; NMR δ=5.81 (1H, dm, J=10.5 Hz), 5.62 (1H, dm, J=10.5 Hz), 3.57 (2H, t, J=6.0 Hz), 1.10 (3H, s), 0.93 (9H, s), and 0.05 (6H, s); MS, m/z (rel intensity) 263 (16), 223 (100), and 147 (69). Found: C, 72.53; H, 11.31%. Calcd for $C_{17}H_{32}OSi$: C, 72.79; H, 11.50%.

Preparation of 2,3-Epoxy-exo-*7-methyl*-endo-*7-[3-(t-butyldimethylsiloxy)propyl]bicyclo[4.1.0]heptane (20).* To a mixture of a solution of 564.8 mg (2.01 mmol) of **19** in 9 ml of CH_2Cl_2 and 339.8 mg (4.04 mmol) of $NaHCO_3$ was added a solution of 415.9 mg (2.40 mmol) of *m*-chloroperoxybenzoic acid in 9 ml of CH_2Cl_2 at 0 °C under an argon atmosphere. After 2 h stirring at 0 °C, the mixture was diluted with water, and extracted with ether. The etherial solution was washed successively with two portions of saturated aqueous $NaHCO_3$, water, and saturated brine, dried over $MgSO_4$, and then concentrated to give 667.3 mg of an oil. An analytical sample of the epoxide (**20**) was purified by column chromatography (10:1 hexane, ethyl acetate). **20**: IR 1265 (m) and 1100 (s) cm^{-1}; NMR δ=3.80—3.61 (2H, m), 3.36—3.13 (2H, m), 1.07 (3H, s), 0.93 (9H, s), and 0.08 (6H, s); MS, m/z (rel intensity) 296 (M^+, 3), 130 (87), and 104 (100).

Preparation of exo-*7-Methyl*-endo-*7-[3-(t-butyldimethylsiloxy)propyl]bicyclo[4.1.0]hept-3-yl Benzoate (22).* A 1.76 M solution of DIBAH in hexane (2.46 ml) was added to a solution of 667.3 mg of the crude epoxide (**20**) in 20 ml of toluene at 0 °C under an argon atmosphere. After 1.5 h stirring at room temperature, the mixture was cooled by ice-water. After addition of 20 ml of saturated aqueous NH_4Cl, the mixture was stirred for 30 min at room temperature. A similar workup to that employed for the synthesis of **18** afforded 661.5 mg of a colorless oil. An analytical sample of the alcohol (**21**) was purified by column chromatography (15:1 hexane, ethyl acetate). **21**: IR 3620 (w), 3450 (w), 1110 (s), and 1095 (s) cm^{-1}; NMR δ=3.68 (1H, m), 3.63 (2H, t, J=6.0 Hz), 1.01 (3H, s), 0.94 (9H, s), 0.72 (2H, m), and 0.08 (6H, s).

Benzoic anhydride (1.20 g, 5.30 mmol) was added to a solution of 661.5 mg of the crude alcohol and a small amount of DMAP in 5 ml of triethylamine under argon. After standing for 24 h at room temperature, the solution was diluted with ether. Aqueous workup followed by chromatography (25:1 hexane, ethyl acetate) gave 573.4 mg (71%) of **22**: IR 1720 (s) and 1115 (s) cm^{-1}; NMR δ=8.5—7.83 (2H, m), 7.55—7.16 (2H, m), 4.91 (1H, m, $W_{1/2}$=13 Hz), 3.61 (2H, t, J=6.0 Hz), 1.00 (3H, s), 0.89 (9H, s), and 0.04 (6H, s). Found: C, 71.83; H, 9.51%. Calcd for $C_{24}H_{38}O_3Si$: C, 71.59; H, 9.51%.

Preparation of exo-*7-Methyl*-endo-*7-(4-methyl-3-pentenyl)bicyclo[4.1.0]heptan-3-yl Benzoate (25).* In order to remove the silyl group, 176.3 mg (0.438 mmol) of **22** was treated with a mixture of 0.88 ml of THF, 0.88 ml of water, and 2.64 ml of acetic acid[9] for 17.5 h at room temperature. A similar workup to that employed for the synthesis of **11** gave 185.4 mg of an oil. Purification by chromatography (3:1 hexane, ethyl acetate) gave 113.8 mg (90%) of the hydroxy benzoate (**23**): IR 3630 (w), 3540 (w), 1715 (s), and 1280 (s) cm^{-1}; NMR δ=8.05—7.83 (2H, m), 7.54—7.18 (3H, m), 4.93 (1H, m, $W_{1/2}$=12 Hz), 3.62 (2H, t, J=6.0 Hz), and 1.00 (3H, bs).

To a solution of 1.75 g (6.8 mmol) of Collins reagent in 20 ml of dry CH_2Cl_2 was added a solution of 324.6 mg (1.13 mmol) of **23** in 15 ml of CH_2Cl_2. The resulting mixture was stirred for 6 min at room temperature. A similar workup to that employed for the synthesis of **12** gave 272.8 mg of an oil. An analytical sample of the aldehyde (**24**) was purified by column chromatography (5:1 hexane, ethyl acetate). **24**: IR 2720 (w), 1720 (s), and 1280 (s) cm^{-1}; NMR δ=9.73 (1H, t, J=1.5 Hz), 8.02—7.82 (2H, m), 7.55—7.18 (3H, m), 4.92 (1H, m, $W_{1/2}$=13.8 Hz), 2.51 (2H, m), and 1.00 (3H, s); MS, m/z (rel intensity) 286 (M^+, 3) and 146 (100).

Isopropylidenetriphenylphosphorane[12] was generated from 1.46 g (3.38 mmol) of isopropyltriphenylphosphonium iodide and 2.1 ml of a 1.5 M solution of *n*-BuLi (hexane) in 35 ml of ether at 0 °C for 1 h under argon. To the ylide solution was added a solution of 272.8 mg of freshly pre-

pared **24** in 2 ml of ether at −30 °C, and the mixture was stirred for 15 min. The solution was diluted with wet ether, and well stirred at room temperature. After removal of the precipitate by filtration, the filtrates were combined, washed with water and saturated NaCl solution, and then dried over $MgSO_4$. Concentration of the solution followed by chromatography gave 239.2 mg (68%) of **25**: IR 1720 (s) and 715 (s) cm^{-1}; NMR δ=8.10—7.82 (2H, m), 7.55—7.12 (3H, m), 5.25—4.77 (2H, m), 1.70 (3H, bs), 1.65 (3H, bs), and 1.03 (3H, s). Found: C, 80.52; H, 9.07%. Calcd for $C_{21}H_{28}O_2$: C, 80.73; H, 9.03%.

Preparation of exo-*7-Methyl*-endo-*7-(4-methyl-3-pentenyl)bicyclo[4.1.0]heptan-3-one (26).* To a suspension of 20.0 mg (0.527 mmol) of $LiAlH_4$ in 2 ml of dry ether was added a solution of 80.0 mg (0.256 mmol) of 25 in 2.5 ml of ether at 0 °C. After 20 min stirring, a similar workup to that employed for the reduction of **13** gave 76.6 mg of an oil. Chromatography (5:1 hexane, ethyl acetate) of the oil gave 50.8 mg (95%) of the alcohol: IR 3625 (w), 3400 (w), and 1050 (m) cm^{-1}; NMR δ=5.05 (1H, tm, J=6.9 Hz), 3.53 (1H, m, $W_{1/2}$=13.5 Hz), 1.68 (3H, bs), 1.62 (3H, bs), and 0.98 (3H, s).

The alcohol (50.8 mg, 0.243 mmol) was treated with 380 mg (1.46 mmol) of Collins reagents in 3.6 ml of dry CH_2Cl_2 at room temperature for 5 min. A similar workup to that employed for the synthesis of **12** gave 42.3 mg of the crude product. Chromatography on silica gel (20:1 hexane, ethyl acetate) gave 37.4 mg (71%) of pure **26**: IR 1710 (s) cm^{-1}; NMR δ=5.05 (1H, tm, J=6.9 Hz), 1.67 (3H, bs), 1.61 (3H, bs), and 1.04 (3H, s); MS, m/z (rel intensity) 206 (M^+, 100) and 82 (84). Found: C, 81.20; H, 10.45%. Calcd for $C_{14}H_{22}O$: C, 81.50; H, 10.75%.

*Preparation of (±)-Isosesquicarene,3,*exo-*7-Dimethyl*-endo-*7-(4-methyl-3-pentenyl)bicyclo[4.1.0]hept-3-ene (1b).* To a solution of 140.0 mg (0.68 mmol) of **26** in 5 ml of ether was added dropwise a methyllithium solution (2.5 equiv) at −95 °C, and the mixture was allowed to warm to room temperature slowly. After addition of methanol–water at 0 °C, the mixture was diluted with ether, washed with saturated brine, dried over $MgSO_4$, and concentrated. Chromatography (20:1 hexane, ethyl acetate) of the residue gave 111.2 mg (74%) of a mixture of the alcohols.

Phosphoryl chloride (0.07 ml) was added to a solution of 130 mg (0.58 mmol) of a mixture of the alcohols and a small amount of DMAP in 5.8 ml of pyridine at 0 °C. After stirring 1 h at 0 °C and 30 min at room temperature, the mixture was diluted with pentane, washed successively with 5% HCl, saturated $NaHCO_3$ and NaCl solutions, dried over $MgSO_4$, and concentrated. Purification using a silica cartridge (pentane) gave 85.7 mg (74%) of a colorless oil. The product was shown by analytical VPC and NMR to consist of 63% **1b** and 28 and 9% of the isomers. Preparative VPC (10% FFAP, 150 °C) afforded pure **1b**: MS, m/z (rel intensity) 204 (M^+, 12), 133 (14), 119 (78), and 93 (100). Found: m/z 204.18840. Calcd for $C_{15}H_{24}$: M, 204.18776.

We are grateful to Mr. Toshiro Yokoyama of Government Industrial Research Institute, Tohoku, at Sendai, for the measurements of the high-resolution mass spectra. We thank Foundation for the Promotion of Research on Medical Resources for partial support of this work.

Digital Derivative Spectrophotometric Determination of Micro Amounts of Iron with 1,10-Phenanthroline

Tetsuo KATSUYAMA* and Junichi SHIDA†

(Received February 16, 1984)

Digital first-order derivative spectrophotometry was applied to the determination of iron with 1,10-phenanthroline. Under the recommended conditions, a linear relationship was confirmed between the first-derivative value and the iron concentration. The present method gives accurate results for iron, ranging from 1.6×10^{-7} to 8×10^{-5} mol dm^{-3} (8.9 μg dm^{-3}—4.5 mg dm^{-3}). The relative standard deviations for the determination of 4.8×10^{-5}, 4.8×10^{-6}, and 4.8×10^{-7} mol dm^{-3} of iron(III) were 0.37, 0.38, and 0.93%, respectively. The effects of 63 diverse ions were examined. The present method was applied to the determination of iron in practical samples, *i.e.*, river water, waste water and sea water.

There are many reagents used in the spectrophotometric determination of iron.[1-4] Among these, 1,10-phenanthroline (phen) is the most widely used. A standard procedure is usually established and the effects of diverse ions are carefully examined.[5-7] The above-mentioned reagent is not highly sensitive.

Derivative spectrophotometry, which uses a derivative spectrum, is effective for increasing sensitivity.[8-13] In the work reported in this paper derivative spectrophotometry was introduced to make the determination more sensitive.

The methods for obtaining a derivative spectrum are divided into two groups, *i.e.*, optical and electrical. The optical group includes the dual-wavelength and wavelengh-modulation methods. The electrical group includes a shift-memory method, an analogue-differentiation method, and a digital-differentiation method.[14] These methods have their individual advantages and disadvantages. In analytical applications, the digital-differentiation method (using a computer) is of interest for several reasons. (1) Absorption-spectrum data are at first stored in the main memory of the computer. Thus, it is easy to calculate a derivative spectrum from the stored data. The *S/N* ratio of the derivative spectrum can be much improved by the use of smoothing treatments. (2) An exact derivative spectrum is derived (a distorted spectrum is obtained in the case of analogue method). (3) A calibration curve (derivative value *vs.* concentration) is linear and passes through the origin even if the wavelength interval for the differentiation becomes large. (4) After a measurement of the absorption spectrum, the final results of the analysis may be obtained automatically, since all calculations are performed by the computer. Thus, in this study the digital-differentiation method was adopted.

The present method can be applied to iron existing at one-hundredth of the concentration which can be determined by ordinary spectrophotometry with phen.

Experimental

Reagents. A 1×10^{-2} M (1 M=1 mol dm^{-3}) iron(III) solution was prepared by dissolving guaranteed reagent-grade iron(III) nitrate in dilute nitric acid. The solution was standardized by edta titration using Variamine Blue B as an indicator. This solution was diluted with 0.02 M nitric acid, as required.

A 2×10^{-3} M phen solution was prepared by dissolving a weighed amount of the reagent in 0.01-M nitric acid.

The other reagents used were of a guaranteed reagent grade.

Apparatus. The absorption spectra and their derivative spectra were measured with a Hitachi 228 double-beam spectrophotometer system. This system is composed of a photometer part and a personal computer equipped with a CRT (display part) and a mini-floppy disk. With this system, the derivative spectrum is obtained as follows. The absorption spectrum measured with the photometer part (spectrum data are stored in the computer memory) is differentiated on the personal computer from one to four times (corresponding to first to fourth derivative spectrum, respectively). The derivative-spectrum data are also stored in computer memory. Then, the derivative spectrum is displayed on a CRT and on the chart of the printer of the photometer part.

In the present system, the output signals from the photometer are fed to the personal computer through an 8-bit AD converter. After the absorption-spectrum data are stored in the main memory of the computer, a most appropriate derivative spectrum can be easily calculated from the data; *e.g.*, when the ordinate of the spectrum are not suitable, the calculation is done again while changing the scale of the ordinate. The length of the time at which the derivative spectrum is calculated and shown on the CRT and the peak-to-trough value of the spectrum is recorded on the printer, was 45 s. in the present conditions (485—600 nm). Thus, the present method can be used over a wide iron-concentration range (without altering the concentration) since the scale of the ordinate of the derivative spectrum can be easily changed.

The flow chart of the present computer program is shown in Fig. 1.

Standard Procedure. A sample solution containing from 8 nmol to 4 μmol of iron is placed in a 50-cm³ volumetric flask. Then, 5 cm³ of 0.5 M hydroxylamine hydrochloride, 8 cm³ of 2×10^{-3} M phen, 5 cm³ of 0.2 M acetic acid, and 5 cm³ of 0.2 M sodium acetate are successively added to the flask. Next, water is added up to the mark of the flask; the final pH is 4.4. The flask is kept for about thirty minutes in a water bath held (thermostatically) at 25 °C. The absorption spectrum of the solution is measured in a 10-mm cell against a reagent blank as the reference. Then, the first-order derivative spectrum is calculated at around 540 nm using wavelength intervals ($\Delta\lambda$) of 10 nm. The vertical distance from the base line to a trough of the spectrum, which is written on a chart, is then determined.

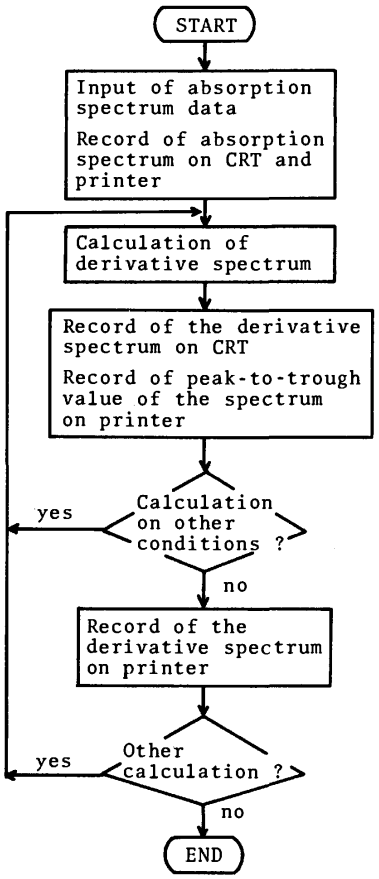

Fig. 1. Flow chart of the computer program for the derivative spectrum.

Results and Discussion

Derivative Spectrum. After the absorption spectrum of the Fe^{II}-phen complex solution was measured, the derivative spectra (first, second, third, and fourth order) were calculated from the measured absorption spectrum by use of the personal computer. Figure 2 shows a measured absorption spectrum and its first- and second-order derivative spectra (third- and fourth-order spectra are omitted). The value of the vertical distance between a peak and a trough of the derivative spectrum was greatest for a first-order derivative spectrum.

The value of the vertical distance from the base line to a trough (or a peak) of the derivative spectrum depended upon the value of $\Delta\lambda$, which can be selected between 1 to 10 nm in this program; the greater the value of $\Delta\lambda$, the longer the vertical distance (Fig. 3). Thus, in order to make the determination more sensitive, first-order derivative spectrophotometry was adopted and the value of $\Delta\lambda$ was set to 10 nm.

Reaction Time. In the color reaction, if the iron content is low, the time for a maximum color development may be long. In order to ascertain this point, the reaction time for the solution prepared by the above stated procedure was measured. When the

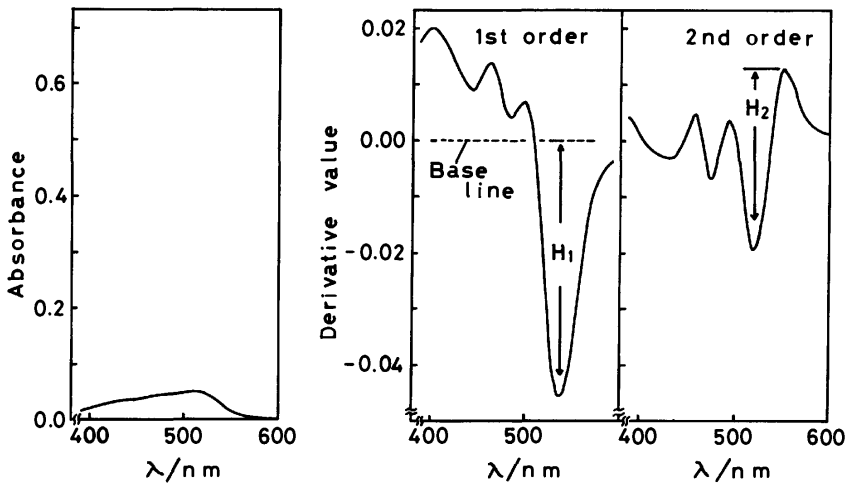

Fig. 2. Absorption spectrum and derivative spectra of Fe^{II}-phen complex solution.
Fe: 4.3×10^{-6} M, phen: 3.2×10^{-4} M, pH: 4.4, $\Delta\lambda$: 10 nm.
H_1 denotes the vertical distance from the base line to a trough of the first-order derivative spectrum and H_2 is the vertical distance between a peak and a trough of the second-order derivative spectrum.

iron content was 2 μmol, 0.2 μmol, and 0.02 μmol per 50 cm^3, the vertical distance from the base line to a trough of the first-order derivative spectrum did not vary for more than about twenty minutes at 25 °C, in respective cases. Thus, in this study, the standing time of the colored solution was set at thirty minutes for a temperature of 25 °C.

Calibration Curves. The first-order derivative spectrum of the Fe^{II}-phen complex solution at around 540 nm was recorded on a chart of the printer of the photometer by the stated standard procedure. The vertical distance from the base-line to a trough (*i.e.*, derivative value) was measured. The first-order derivative value *vs.* the iron concentration gave a straight line passing through the origin as shown in Fig. 4, where the recorder sensitivity was set so that the values of the derivatives, 1.0 in A, 0.1 in B, and 0.01 in C, gave a signal of 15 cm on the chart (full scale: 15 cm). The relative standard deviations of the first-order derivative values were 0.37, 0.38, and 0.93% for 4.8×10^{-5}, 4.8×10^{-6}, and 4.8×10^{-7} M of iron(III), respectively (11 measurements).

Effect of Diverse Ions. The effects of the 63 diverse ions were examined. The experiments were run as follows: a sample solution containing 0.202 or 0.0204 μmol of iron(III) was placed in a 50-cm^3 volumetric flask and then the ion in question was added to the flask; next, the stated standard procedure was applied.

In this study it was decided that the diverse ion concentrations for 500 times the concentration of iron should be sufficient to test for interference; *i.e.*, when this amount did not interfere, a furfher test was not undertaken. Diverse ions were added in the form of nitrate and sodium salt except for the following: K^+, Na^+, NH_4^+, Hg^{2+}, Sn^{2+}, As^{3+}, Sb^{3+}, Ce^{4+}, Sn^{4+}, Zr^{4+}, CN^-, IO_3^-, SCN^-, CrO_4^{2-}, $Cr_2O_7^{2-}$, $Mo_7O_{24}^{6-}$, and tartrate, which were added as KCl, NaCl, NH_4Cl, $HgCl_2$, $SnCl_2$, As_2O_3, $SbCl_3$, $CeSO_4$, $SnCl_4$, $ZrO(NO_3)_2$, KCN, KIO_3, NH_4SCN, K_2CrO_4, $K_2Cr_2O_7$, $(NH_4)_6Mo_7O_{24}$, and potassium sodium tartrate, respectively.

The results are summarized in Tables 1 and 2, from which it can be seen that in the determination of 4.04×10^{-6} M iron (Table 1) silver, mercury, molybdenum, and tungsten interfere with the determination when present at a concentration of 5 times that of iron, and that in the case of 4.08×10^{-7} M iron (Table 2), only mercury(II) ion interferes when present at a concentration of 5 times that of iron.

Determination of Iron in Practical Samples. Iron Ion in River Water: The water sample was collected at the Matsukawa river in Aioicho, Yonezawa, Yamagata (at August, 1983). It was instantly drawn through a membranefilter (pore size 0.45 μm), then, the determination of the iron ion of the filtrate was carried out using the stated standard procedure. The results are shown in Table 3.

Iron in Waste Water: Waste water included the following: (No. 1) water exhausted from the Faculty of Engineering, Yamagata University, and (No. 2) that from T electric company in Yonezawa, Yamagata. To these samples, concentrated hydrochloric acid was added (to become 0.1 M) to keep the iron ions from being adsorbed by the vessel.

Pretreatment of the waste water was done as follows. 100 cm^3 of the sample and 5 cm^3 of concen-

20.00	17.2	34.9	17.7	8.9×10^{-7} (50 ppb)

trated nitric acid was added to a 250-cm³ porcelain dish. The solution was concentrated to about 10 cm³ on a boiling-water bath. Then, 5 cm³ of concentrated nitric acid and 10 cm³ of concentrated perchloric acid were added. The solution was then heated on a hot plate until white fumes of pherchloric acid were produced. After this, the solution was cooled to room temperature, was transfered to a 100-cm³ volumetric flask and water was added up to the mark of the flask.

The determination of the iron was performed by the standard procedure, using 5 cm³ of the prepared solution. In the determination, however, 4 cm³ of 2-M sodium acetate was added in order to adjust the pH to 4.4. The analyses were run three times, starting from the pretreatment of the waste water. The results are shown in Table 4.

Iron in Sea Water: Sea water was collected at Ishinomaki bay. The collection was done at a place 200-m from the beach in Nobiru, Naruse, Miyagi. The sea water was placed in a polyethylene vessel and concentrated hydrochloric acid was added (to become 0.03 M).

4 cm³ of concentrated hydrochloric acid was added to 500 cm³ of the sea water. Then, the sea water was concentrated to about 80 cm³ on a boiling-water bath (using porcelain dish). Infrared heating was used simultaneously. After cooling, the solution was transfered to a 100-cm³ volumetric flask and then water was added up to the mark of the flask. The determination of iron was carried out by the standard procedure, using 20 cm³ of the prepared solution. In the determination, 11 cm³ of 2-M sodium acetate was added as a buffering agent. The results are shown in Table 5.

The waste water and the sea water were also ana-

lyzed for iron by atomic-absorption spectrometry (Tables 4 and 5).[15] The results agreed with those in the present method.

Characteristics of the Present Method. The base line of the absorption spectrum sometimes moved from the zero line. However, the shift of the base line of the first-order derivative spectrum from the zero line was not seen; thus, the calibration curves passed through the origin even in the case of a low iron-ion concentration as shown in Fig. 4.

In ordinary spectrophotometry, a variation of the zero point influences the results. In the present method, the results were not influenced by the deviation of the base line of the absorption spectrum. This is considered to be attributed to the fact that a determination by the derivative method does not depend directly on the absorbance (of the absorption spectrum) but mainly on the shape of the spectrum. Consequently, a derivative value may be magnified without error.

The iron ion of $1.6—8\times10^{-7}$ M (0.009—0.045 mg dm^{-3}) could be determined by the present method; this concentration level is one-hundredth of the concentration $1.6—8\times10^{-5}$ M (0.9—4.5 mg dm^{-3}) which is presented to the ordinary spectrophotometry with phen. The procedures of the present method are not complicated; thus the ppb level of an iron ion (10—50 μg dm^{-3}) can be easily determined by the present method. The concentration of iron ions in ordinary spectrophotometry when using a highly sensitive reagent, *e.g.*, 4,7-diphenyl-1,10-phenanthroline (ε of iron(II) complex: 22400 l mol^{-1} cm^{-1} at 533), 2,4,6-tris(2-pyridyl)-*s*-triazine (ε of iron(II) complex: 22600 l mol^{-1} cm^{-1} at 593) is more than about 0.1 mg dm^{-3};[4] thus, the present method can be said to be very sensitive.

The Synthesis and X-Ray Structure of (L- or D-Alanine-*N*-acetato)(L-histidinato)chromium(III)

Mitsunobu SATO,[1] Masao KOSAKA, and Masatoshi WATABE*
Kogakuin University, Hachioji, Tokyo 192
(Received April 12, 1984)

The (L-alanine-*N*-acetato)(L-histidinato)chromium(III) monohydrate complex, $C_{11}H_{14}N_4O_6Cr$, has been synthesized and its crystal structure has been determined from three dimensional X-ray-diffractometer data. The crystals are orthorhombic, of the space group $P2_12_12_1$, with 4 molecules in a cell with these dimensions: a= 11.052(1), b=13.959(3), and c=9.616(2) Å. Block-diagonal least-squares refinements using 1318 independent nonzero reflections have yielded a conventional R factor of 0.033. The structure consists of monomeric [Cr(L-alama)(L-his)] units and water molecules. The L-alama ligand coordinates to the metal as of dianion, with Cr-O(acetyl), Cr-N, and Cr-O(alanine) bond lengths of 1.960(3), 2.078(5), and 1.946(4) Å respectively. The histidinate monoanion coordinates through Cr-N(amino), Cr-N(imidazole), and Cr-O bonds 2.062(4), 2.036(5), and 1.957(4) Å long respectively. The geometry at chromium is a distorted octahedron, with *cis* bond angles in the range from 80.1(2) to 99.3(2)°. Among the six possible isomers of the [Cr(L-alama)(L-his)] complex, only one isomer was prepared and crystallized; its geometry was R-L-*trans*(*O*)*cis*(*N*).

Chromium has been shown to be an essential trace element, and the hypothetical chromium(III) complex occurring in brewers yeast has been found to have outstanding biological activity.[2] Efforts to purify this factor have led to the detection of chromium, nicotinic acid, glycine, glutamic acid, and cysteine in the purified fraction.[3] Several chromium(III) complexes containing amino carboxylate have been studied.[4-6] In these reports, the monomeric tris(aminocarboxylato)complexes have been reported to have only a facial configuration. While Israily claimed the preparation of the purple meridional isomer of [Cr(gly)$_3$] (gly=glycinate ion), Gillard *et al.* showed this complex to be a dinuclear complex, [Cr(OH)$_2$(gly)$_2$]$_2$ 6H$_2$O.[5] Oki *et al.* reported a number of facial and dihydroxo-bridged dimeric (amino carboxylato)chromium(III) complexes, but their attempt at the preparation of meridional tris(amino carboxylato)chromium(III) was unsuccessful.[6] We ourselves reported the preparation of a mixed (tridentate-aminocarboxylato)chromium(III) complex[7] in the form of the [Cr(L- or D-asp)(L-his)] complex, where asp=aspartate ion and his=histidinate ion. These isomers were tentatively assigned meridional and facial structures by using the resemblance of the CD spectra and high-speed liquid chromatograms of [Cr(L- or D-asp)(L-his)] to those of [Co(L- or D-asp)(L-his)]. However, some ambiguity remains in this structural assignment because of the lack of X-ray crystallographic data. Attempts to grow crystals suitable for X-ray structural analysis were unsuccessful for the [Cr(L- or D-asp)(L-his)] complexes. This report will deal with the preparation and the assignment of [Cr(L- or D-alama)(L-his)], where alama=alanine-*N*-acetate dianion, which belongs to the same [Cr(N)$_3$(O)$_3$] type as that of [Cr(L- or D-asp)(L-his)]. As is shown in Fig. 1, this complex has six possible isomers for each L- or D-alama series because of two factors: the (S) or (R) chirality concerning the asymmetric imino nitrogen atom of alama, which occurs after coordination,[8] and the distribution of coordinated atoms (two meridional isomers and one facial isomer).

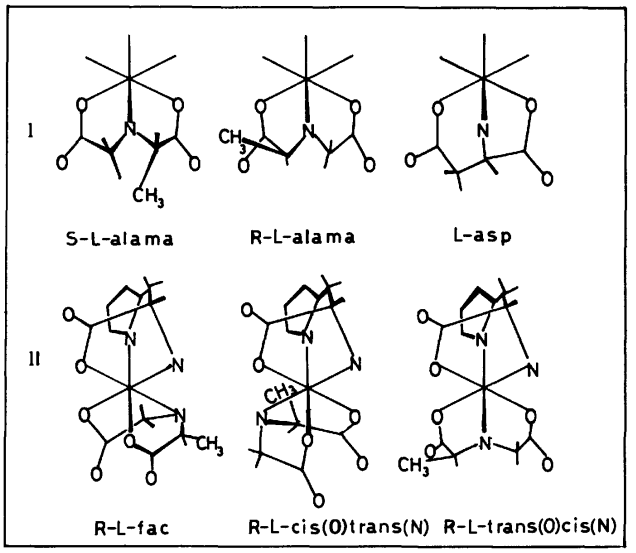

Fig. 1. I; (S) and (R) chirality of L-alama, and L-asp coordinated. II; Three possible R-type geometrical isomers of [Cr(L-alama)(L-his)]. Those of S-type are abbriviated.

Experimental

Isomers of [Cr(L- or D-alama)(L-his)]. To a concentrated ammonia solution (7 cm^3) we added $K_2Cr_2(SO_4)_4 \cdot 24H_2O$ (10 g, 0.01 mol). The precipitate was centrifuged and then suspended in 50 cm^3 of water. To this suspension we then added L-histidine (0.01 mol) and L-alanine-*N*-acetic acid (0.01 mol). After the suspension had been stirred and heated (*ca.* 80 °C) for 1 h, it was centrifuged and cooled to room temperature. One fourth of this solution was placed in a column (5×50 cm) of SP-Sephadex A-25, a strong-anion exchange resin, which was on the chloride form. The complexes in the column were eluted with water slowly. Three

bands descended; the last one contained the neutral species, which was, after having been concentrated and crystallized under room temperature, named *L*. The complex containing D-alanine-*N*-acetate was prepared in a similar way but using D-alanine-*N*-acetic acid instead of L-alanine-*N*-acetic acid; it was named *D*. Anal. Calcd for $[CrC_{11}H_{14}N_4O_6]\cdot H_2O$: C, 35.78; H, 4.64; N, 15.17%, Found (*L*): C, 35.44; H, 4.69; N, 15.24%, Found (*D*): C, 35.32; H, 4.55; N, 14.90%.

Measurements. The visible and ultraviolet absorption spectra were measured with a JASCO UVIDEC-505 spectrometer in an aqueous solution.

Data Collection. The specimens are well-developed orange-yellow prismatic crystals. A crystal with approximate dimensions of 0.20×0.23×0.33 mm was mounted on a Rigaku four-circle automatic diffractometer, AFC-6B, with its elongated axis roughly parallel to the machine axis. Automatic centering and the indexing of 23 low-angle reflections gave the preliminary conditions for data collection. Peak refinement, by which the precise cell parameters was obtained, was performed by the least-squares treatment of the 2θ values of 25 reflections measured with graphite-monochromated Mo $K\alpha_1$ radiation (λ=0.70926 Å). At this point it was clear that the crystal had an orthorhombic symmetry, with a=11.052(1) Å, b=13.959(3) Å, c=9.616(2) Å, and Z=4. Additionally, subsequent measurements of several reflections in order to examine the systematic absences suggested that the crystal belongs to the $P2_12_12_1$ space group. This result was confirmed after the data collection. With Z=4 and the molecular weight of this complex, the calculated density is 1.65 g cm^{-3}, compared with the measured density of 1.64 g cm^{-3} obtained by flotation in a 1,2-dibromoethane-carbontetrachloride mixture. The ω (2θ<30°) and 2θ–ω (2θ>30°) scan methods were employed with a scanning rate of 1°/min. A unique data set (*hkl*) was first collected in the range of $5<2\theta<55$. In order to examine the absolute configuration of the ligands, the Bijvoet-pair data set (*hkl*), with 2θ values between 17° and 27°, was then collected under the same conditions. Three standard reflections were monitored every 50 reflections; they showed only a 1—2% random variation in intensity, for which no correction was made. A total of 1472 reflections was measured, and the standard Lorentz and polarization corrections were applied. The final data set, consisting of 1472 reflections, indicated the systematic extentions of (*h*00) for *h* odd, (0*k*0) for *k* odd, and (00*l*) for *l* odd. Since the compound is optically active, the space group of the crystal was defined as $P2_12_12_1$. Of the 1472 reflections collected, 1318 had $F_o>10[\sigma(F_o)]$ and were used in the subsequent analysis. No absorption correction was made, since the μ value (7.9 cm^{-1}) was low.

Solution and Refinement of the Structure. The structure was solved by a standard heavy-atom method and refined by the block-diagonal least-squares method by the use of the Rigaku RASA SAP-2 system. An unsharpened three-dimensional Patterson function revealed the position of the chromium atom. The positions of the remaining nonhydrogen atoms were determined by successive structure-factor and electron-density-map calculations. Isotropic refinement reduced R=0.135 and R'=0.163, where $R=\Sigma||F_o|-|F_c||/|F_o|$ and $R'=(\Sigma(|F_o|-|F_c|)^2/|F_o|^2)^{1/2}$. The absolute configuration of the ligands in the complex ion was taken to be the *L* isomer. Next, the effects of the anomalous dispersion were introduced into F_c, the values of f' and f'' for Cr, O, N, and C being taken from Ref. 9. The anisotropic refinement of all the nonhydrogen atoms was performed, allowing the hydrogen atoms to vibrate isotropically. The final agreement factors, R and R', are 0.033 and 0.040 respectively. A final difference Fourier synthesis showed no significant electron density with a peak higher than 0.2 e Å.$^{-3}$ In this case, the absorption-edge technique was not sufficient to confirm the absolute configuration of the ligands; rather, the Hamilton test described above was useful.[11] The final positional parameters, along with their standard deviations, are listed in Table 1. Compilations of the anisotropic thermal parameters and of the observed and calculated structure factors are available.

Results and Discussion

Description of the Molecular Structure. The geometry of the complex is shown in Fig. 2. The coordination around the chromium(III) center is approximately octahedral, the ligand binding as the histidinate monoanion and the L-alanine-*N*-acetate dianion. The geometry of this complex was determined to be R-L-*trans*(*O*)*cis*(*N*), where R means that the chirality of the asymmetric nitrogen atom of alama is R, where L means that this complex contains L-alama, and where *trans*(*O*)*cis*(*N*) means that the coordinated oxygen atom of L-his and that of the $-CH_2COO-$ of L-alama are trans to each other (as is shown in Fig. 1, the $-CH_2COO-$ ring of L-alama corresponds to the amino acid moiety of L-asp), and the nitrogen atom of $NH_2CH(COO^-)R$ of L-his and that of L-alama are *cis* to each other. Each conformation of the four chelate rings is also presented in Fig. 3. References to chromium(III) complexes with histidine are scant, consisting of one preliminary report,[12] and one doctoral dissertation by Grouhi-Witte.[13] The histidinate ion coordinates to metal through the imidazole [N(1)] and amine [N(3)] nitrogen atoms and through a carboxyl oxygen atom [O(1)] with bond lengths of 2.036(5), 2.062(4), and 1.957(4) Å respectively. It is noted that the bond lengths of the Cr–N(amino) and Cr–O of this complex are comparable to those of [Cr(gly)$_3$] (2.068 Å for Cr–N(amino), 1.965 Å for Cr–O)[14] and that the bond lengths of Cr–N(imidazole) (2.036(5) Å) and Cr–N(amino) (2.062(4) Å) of the histidinate ligand in the present complex are longer than the corresponding bond lengths of [Co(L-his)(L-pen)],[15] where pen represents the penicilaminate ion, 1.933(3) and 1.925(3) Å respectively. The bond angles subtended the histidinate ligand at chromium N(3)–Cr–O(1)= 80.1(2)°, N(1)–Cr–N(3)=87.2(2)° and O(1)–Cr–N(1)= 89.5(2)°; the smallest angle corresponds to the smallest five-membered ring. The N(3)–Cr–O(1) bond angle, 80.1(2)°, is comparable to that of [Cr(gly)$_3$], which has an average value of 81.8°.[14] The L-alama ion, which is deprotonated at the two carboxyl ends, is coordinated to the metal through the oxygen

of L-alama and the water O(7) atom, the O-O distance being 2.90 Å. In the same manner, the O(6) atom of L-alama is also linked to the water O(7) atom at a distance of 2.74 Å. The N(3) atom of the L-histidine residue is associated with the O(1) and O(2) atoms of the other molecule by an N-H···O hydrogen bond at distances of 2.92 and 2.95 Å respectively. The O(4) atom of L-alama is linked to the N(2) atom of the neighboring imidazole ring and the coordinated N(4) atom in the same manner, the O-N distances being 2.85 and 2.90 Å respectively. These interactions probably assist in the formation of the stable crystal structure.

Absorption Spectra. The absorption spectra of [Cr(L- or D-alama)(L-his)] are shown in Fig. 5, along with the spectra of [Cr(L- or D-asp)(L-his)]. As for [Cr(L-alama)(L-his)], the two major peaks in the visible region are identified as $^4A_{2g} \rightarrow {}^4T_{2g}(F)$ for the 580-nm transition and $^4A_{2g} \rightarrow {}^4T_{1g}$ for the 370-nm transition. For the whole series of $[Co(O)_n(N)_{6-n}]^{3-n}$ complexes, the predicted shifts of the first and second absorption bands have been discussed by Matsuoka *et al.*[16] Their discussion is also applicable to $[Cr(O)_3(N)_3]$. The first absorption band of the third eluate isomer of [Cr(L-asp)(L-his)] and the third eluate isomer of [Co(D-asp)(L-his)] showed no splitting or only a small splitting as was predicted by the above discussion that the first absorption band of a facial isomer should not have three components. Compared with these fac isomers, the L- and D-isomers of [Cr(L- or D-alama)(L-his)], along with the first eluate isomer of [Co(L-asp)(L-his)], and the first eluate isomer of the [Co(D-asp)(L-his)] isomer, have a broad peak because of their splitting into three components. The UV spectra of the L- or D-isomers of [Cr(L- or D-alama)-(L-his)] are found to be more similar to those of the first eluate mer isomers than to those of the fac isomers of [Cr(L- or D-asp)(L-his)] by inspecting the width and peak maxma of the first-absorption band region.

Distribution of the Isomers. Though three geometrical isomers, *cis*(*N*), *trans*(*N*)(*a*), and *trans*(*N*)(*b*) (Fig. 6), are possible in the bis(iminodiacetato)chromate(III) complex, only the *cis*(*N*) isomer has been prepared.[17] Both the *cis*(*N*) and the *trans*(*N*)(*a*) isomers of $[Cr(ida)_2]^-$ seem to have no steric hindrance between two ligands. In the tris(glycinato)chromium-(III) complex, two geometrical isomers, mer and

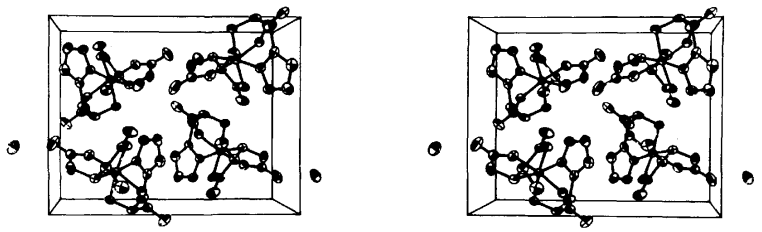

Fig. 4. Stereoscopic illustration of the unit cell contents.

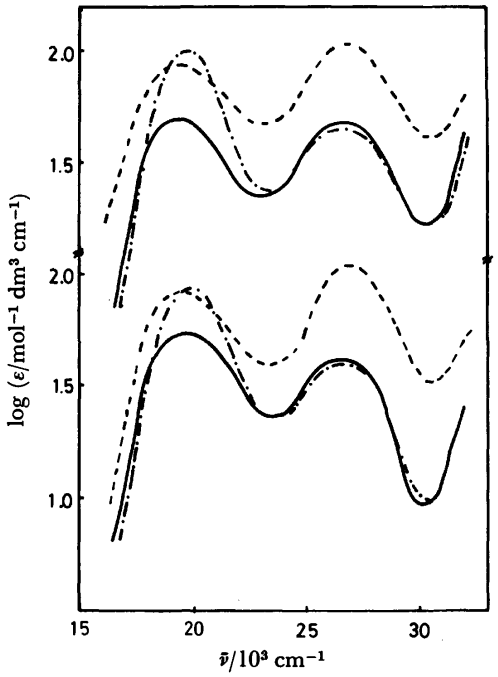

Fig. 5. Visible absorption spectra of [Cr(L- or D-alama)(L-his)] and [Cr(L- or D-asp)(L-his)]. Upper, *L* isomer (----) of [Cr(L-alama)(L-his)]. The first (——) and the third eluates (—·—·) of [Co(L-alama)(L-his)]. Lower, *D* isomer (----) of [Cr(D-alama)(L-his)]. The first (——) and the third eluates (—·—·) of [Co(D-asp)(L-his)].

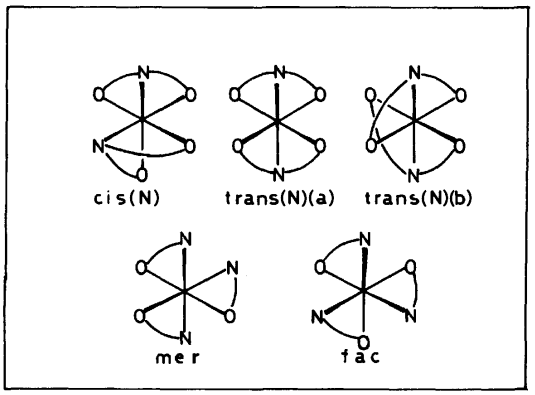

Fig. 6. Geometrical isomers of $[Cr(ida)_2]^-$ (upper) and $[Cr(gly)_3]$ (lower).

fac (Fig. 6), are possible, but only the fac isomer has been prepared. We have previously reported that, in the cobalt(III) complex having both L- or D-aspartate and L-histidinate ions the *trans*(*N*) isomers are less stable than the other isomers.[18] This suggests that the two nitrogen atoms of a five-membered chelate ring avoid the *trans* position around the chromium(III) and cobalt(III) ions. While the two isomers (one mer and one fac isomers) of [Co(L- or D-asp)(L-his)] were prepared in nearly equal amounts, only one mer isomer of [Cr(L- or D-alama)(L-his)] was prepared for each L- or D-series. This stereoselectivity is interesting because it shows the difference in coordination power between asp and alama ligands. When an asp ligand coordinates to a metal ion, it has a rigid skeleton composed of five- and six-membered chelate rings. On the other hand, an alama has two forms in chirality around the coordinated nitrogen atom ((R) and (S) configurations), in which the (R) form has less steric repulsion between methyl protons and methylene protons than does the (S) form, so that the (R) configuration may be preferable to the (S) configuration. Beside the above steric hindrance, a coordinated alama has two five-membered chelate rings which can move around the Cr–N axis. In both the R-L-*cis*(*O*)*trans*(*N*) and R-L-*fac* isomers, the methyl group of alama strikes the imidazole 2-proton or amino protons of the coordinated L-his, while the R-L-*trans*(*O*)*cis*(*N*) isomer has no such repulsion. The steric flexibility seems to be larger in the chromium(III) complex than in the cobalt(III) complex, since we could prepare both a meridional and a facial isomers of the [Co(L- or D-alama)(L-his)] complexes for each L- or D-series.[19]

Solvent Extraction of Mercury(II) from Hydrochloric Acid with 1,2-Bis(hexylthio)ethane

Yoshinari BABA,* Yutaka IKEDA, and Katsutoshi INOUE
Department of Industrial Chemistry, Saga University, Honjo-machi, Saga 840
(Received August 6, 1984)

Solvent extraction of mercury(II) from hydrochloric acid with 1,2-bis(hexylthio)ethane (=BHTE=$\bar{S}$) in 1,2-dichloroethane has been studied at 30 °C. Mercury(II) was found to be extracted into pure 1,2-dichloroethane without extractants, which is due to the physical partition of the neutral species, $HgCl_2$. The partition coefficient, K_D, was evaluated as K_D=0.314. It was clarified that the extraction mechanism with BHTE can be explained in terms of solvation by BHTE and that 1:1 metal: the ligand complex is formed in the organic phase as follows.

$$\bar{S} + HgCl_2 \rightleftharpoons \overline{HgCl_2 \cdot S} \qquad K_e$$

The extraction equilibrium constant, K_e, was evaluated as K_e=1.61×10³ dm³ mol⁻¹.

Solvent extraction of metal ions is one of the effective, energy-saving and nonpolluting processes for hydrometallurgy and/or the treatment of the wastewater containing heavy metals. The most important factor in the solvent-extraction processes is the extractants selective to the specified metal ions to be recovered.

So far, a number of commercial extractants have been developed and used extensively in hydrometallurgy. The majority of them are those of the O or N atom donating ligand type. Those possessing sulfur as a donor atom are relatively few. These are interesting extractants since they have a high selectivity to special metals which are classified as "soft acids" such as copper(I), silver, mercury, gold and platinum-group metals through a so-called soft-soft interaction. Among the sulfur-possessing extractants, there have been many studies of those possessing one sulfur atom such as dialkyl sulfides and dialkyl sulfoxides acting as neutral monodentate ligands.[1-3,5] However, relatively few studies have been carried out on those possessing more than two sulfur atoms acting as polydentate ligands except for *O,O*-dialkyl hydrogenphosphorodithioate.[4]

Some Soviet investigators[6-8] studied the extraction properties of bis(alkylthio)alkanes, the bidentate neutral extractants possessing two sulfur atoms, and found that these are very selective to silver, mercury, gold, palladium and platinum although their works were merely qualitative. Ohki *et al.*[9] have conducted an investigation of the extraction of copper(I), silver(I), and gold(III) by 1,2-bis(hexylthio)ethane. They found that copper and silver are extracted as 1:2 metal:reagent complexes in the extraction from perchlorate media though a 1:1 complex becomes predominant in the region where the reagent concentration is not sufficient for silver. The same was also suggested by Artyukhin *et al.*[8] for palladium extraction from hydrochloric acid.

The present authors have conducted a quantitative investigation on the distribution equilibrium in the extraction of mercury(II) from hydrochloric acid with 1,2-bis(hexylthio)ethane in 1,2-dichloroethane in this paper to clarify the composition of the extracted species and to evaluate the extraction equilibrium constant.

Experimental

Reagents. 1,2-Bis(hexylthio)ethane (BHTE) was synthesized from 1-hexanethiol and 1,2-dibromoethane using a conventional method according to the following reaction.

$$2n\text{-}C_6H_{13}SH + CH_2BrCH_2Br + 2KOH \longrightarrow (n\text{-}C_6H_{13}S\text{-}CH_2\text{-})_2 + 2KBr + 2H_2O$$

The product was purified by vacuum distillation (bp 169—170 °C/5 mmHg (1 mmHg=133.322 Pa)). The identification of this product was carried out using IR and NMR spectra. The purity was verified to be about 97% by gas chromatography. The purified product was diluted using GR-grade 1,2-dichloroethane, the most polar diluent, to a required concentration in order to increase the solubility of the complex to be formed in the organic phase. The initial mercury concentration in the hydrochloric acids was adjusted to 0.005 mol dm⁻³.

Measurements of Extraction Equilibrium. Prior to the measurement of the extraction equilibrium, preliminary experiments were carried out in order to examine the contact time required for the attainment of equilibrium in this system

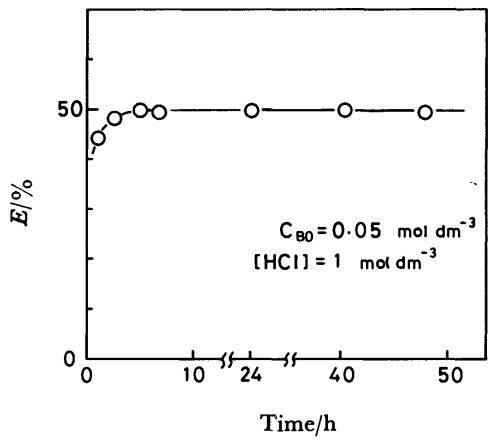

Fig. 1. Relation between the extent of extraction of mercury (II) and the contact time.

and to assure the stability of the extractant and the complex extracted into the organic phase. Figure 1 shows a typical example of the relation between the extent of extraction of mercury and the contact time. From this result, it is obvious that the extraction equilibration is attained within 5—6 h and that the extractant and the extracted complex in the organic phase are stable, at least, for 48 h. Consequently, the contact time in this system was determined as 24 h, also taking account of the convenience of the experimental operation.

Equal volumes (30 cm^3) of the aqueous and organic phases were shaken in a stoppered glass flask for 24 h at 30±0.1 °C. After equilibration, the two phases were separated and analyzed for mercury content in both phases. The mercury concentration in the aqueous phase was determined by titration with EDTA in the presence of an excess of Mg-EDTA using eriochrome black T(BT) as an indicator. That in the organic phase was determined by atomic absorption spectrochemical analysis using a Nippon Jarrell-Ash model AA-782 spectrophotometer after stripping with a 1 mol dm^{-3} aqueous ammonium thiocyanate solution.

Results and Discussion

Extraction of Mercury with Pure Diluent. First of all, mercury was found to be extracted into pure 1,2-dichloroethane without extractants as shown in Fig. 2. The extraction mechanism of mercury from a hydrochloric acid solution is considered to be caused by the physical partition of the neutral species, $HgCl_2$, as follows.

$$HgCl_2 \rightleftharpoons \overline{HgCl_2} \quad (1)$$

$$K_D = \frac{[\overline{HgCl_2}]}{[HgCl_2]} \quad (2)$$

In this case, the distribution ratio of mercury, D, is expressed as follows.

$$D = \frac{[\overline{HgCl_2}]}{C_{Hg\ aq.}} = \alpha_2 \cdot K_D \quad (3)$$

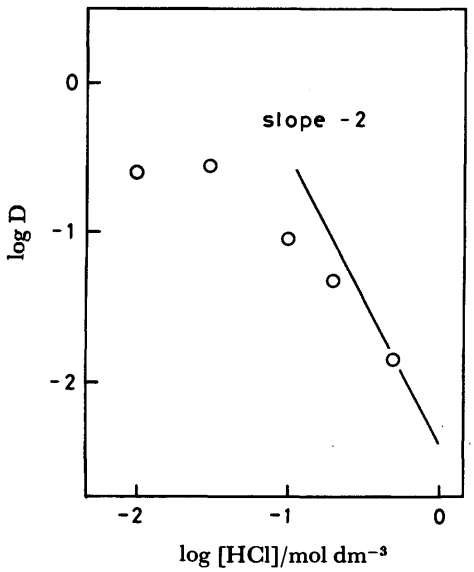

Fig. 2. Equilibrium distribution of mercury (II) from hydrochloric acid solutions with 1,2-dichloroethane.

where

$$\alpha_2 = \frac{\beta_2[Cl^-]^2}{1+\sum_1^4 \beta_i[Cl^-]^i} \quad * \quad (4)$$

The logarithm of Eq. 3 gives the following equation.

$$\log D = \log \alpha_2 + \log K_D \quad (5)$$

Figure 3 shows log-log plots of D against α_2 on the basis of Eq. 5, where the values reported by Hepler[10] were used as the stability constants of chloro complexes, β_i. The plotted points in Fig. 3 lie on a straight line of slope 1 as expected from Eq. 5. From the intercept of the straight line with the ordinate in Fig. 3, K_D was evaluated as K_D=0.314.

Extraction of Mercury from Aqueous Hydrochloric Acid Solutions with BHTE in 1,2-Dichloroethane.

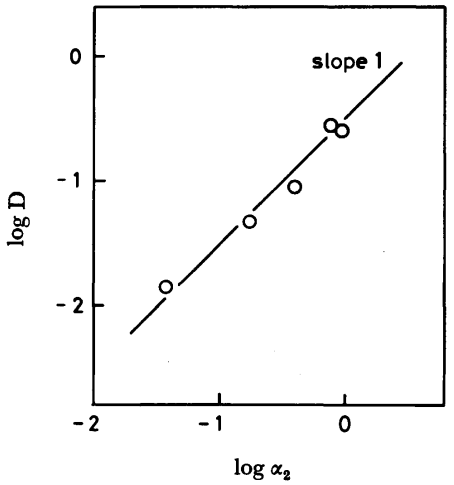

Fig. 3. Relation between logD and logα_2 for extraction of mercury(II) with 1,2-dichloroethane.

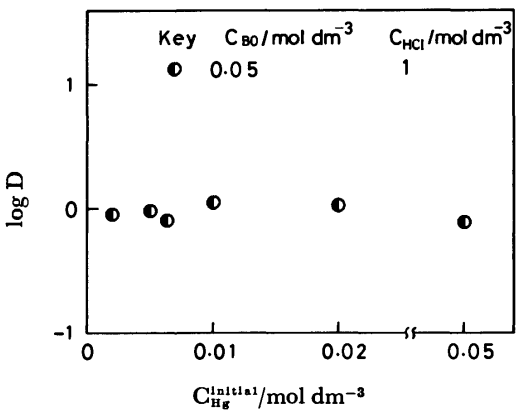

Fig. 4. Effect of the initial mercury concentration in the aqueous phase on the distribution ratio of mercury (II).

* The dimerization constant (K_d) of mercury(II) chloride in aqueous solution was reported as K_d=0.3 at 25 °C by Linhart (*J. Chem. Soc.*, **37**, 258 (1915)). This value is so small as to neglect the dimerization of mercury(II) chloride in hydrochloric acid compared with monomeric chloride complexes.

In order to investigate the species of mercury existing in both phases, the effect of the concentration of mercury on the distribution of mercury was examined. The distribution ratio was found to be independent of the mercury-ion concentration in the aqueous phase over the concentration range (2×10^{-3}—5×10^{-2} mol dm^{-3}) examined as shown in Fig. 4. This indicates that only monomeric complexes are formed in the organic phase. Figure 5 shows the effect of a hydrochloric acid concentration in the aqueous phase on the distribution ratio of mercury, where the difference between the total concentration of mercury in the organic phase and concentration of mercury extracted only by the diluent was used for the calculation of the distribution ratio. As is evident from Fig. 5, the distribution ratio decreases with an increase in the hydrochloric acid concentration. Mercury is considered to be extracted from aqueous chloride solutions according to the reaction described by

$$HgCl_2 + \bar{S} \rightleftharpoons \overline{HgCl_2 \cdot S} \qquad K_e \qquad (6)$$

$$K_e = \frac{[\overline{HgCl_2 \cdot S}]}{[HgCl_2][\bar{S}]} \qquad (7)$$

where $\bar{S}$ denotes the extractant in 1,2-dichloroethane.

In the region of a lower loading ratio of mercury, the concentration of the unreacted extractant, $[\bar{S}]$, is nearly equal to its initial concentration, C_{B0}, and is constant. Moreover, in the region of higher chloride ion concentration ($[Cl^-]>1$ mol dm^{-3}), the concentration of neutral species of mercury in the aqueous phase, $[HgCl_2]$, can be approximated as follows.

$$[HgCl_2] = \alpha_2 \cdot C_{Hg\ aq.} \simeq (\beta_2/\beta_4[Cl^-]^2) \cdot C_{Hg\ aq.} \qquad (8)$$

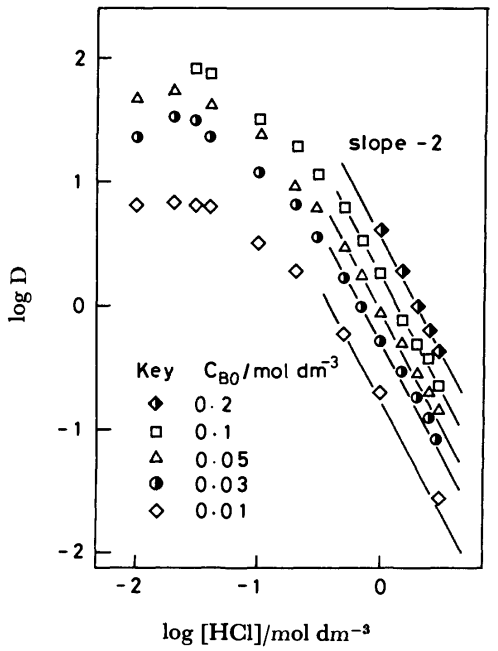

Fig. 5. Equilibrium distribution of mercury (II) from hydrochloric acid solutions with BHTE in 1,2-dichloroethane.

Therefore, the distribution ratio is approximately expressed by Eq. 9 in this region from Eqs. 7 and 8.

$$\log D = -2\log[Cl^-] + a \qquad (9)$$

where

$$a = \log(\beta_2/\beta_4) + \log C_{B0} + \log K_e \qquad (10)$$

In Fig. 5, plotted points lie on straight lines of slope −2 in the higher concentration range of hydrochloric acid as expected from Eq. 9. The values of a, defined by Eq. 10, were evaluated from the intercepts of these lines with the ordinate for each value of C_{B0} and plotted against log C_{B0} as shown in Fig. 6. As is evident from Fig. 6, the plotted points lie on a straight line of

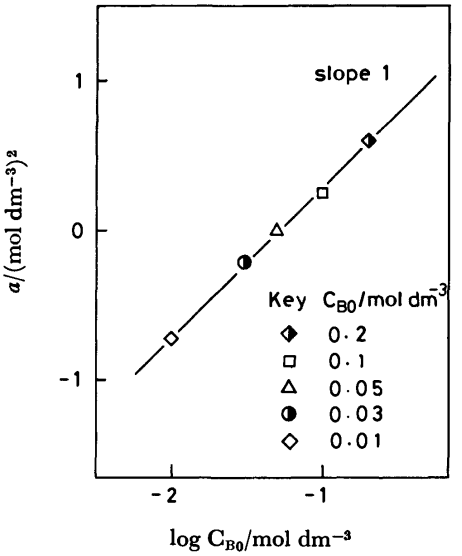

Fig. 6. Relation between a and log C_{B0}.

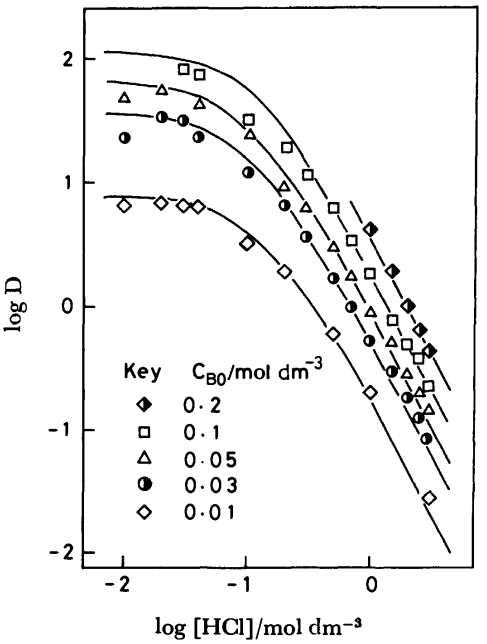

Fig. 7. Equilibrium distribution of mercury(II) from hydrochloric acid solutions with BHTE in 1,2-dichloroethane. The solid lines are the calculated results.

slope 1 as expected from Eq. 10. The extraction equilibrium constant, K_e, was evaluated from the value of the intercept of the straight line with the ordinate in Fig. 6 as $K_e=1.61\times10^3$ dm^3 mol^{-1}.

Meanwhile, in the region of the higher loading ratio of mercury to the extractant, the mass balance of the extractant gives the concentration of the unreacted extractant, [$\bar{S}$], as follows.

$$[\bar{S}] = \frac{C_{BO}}{1+K_e[HgCl_2]} = \frac{C_{BO}}{1+K_e\alpha_2 C_{Hg\ aq.}} \quad (11)$$

Substitution of Eq. 11 for Eq. 7 gives the following equation.

$$\log D = \log \alpha_2 + \log K_e + \log C_{BO} - \log(1+K_e\alpha_2 C_{Hg\ aq.}) \quad (12)$$

The solid lines in Fig. 7 are the calculated results obtained on the basis of Eq. 12 using the value of $K_e=1.61\times10^3$ dm^3 mol^{-1}. The calculated results agree satisfactorily with the experimental ones.

Infrared Spectrum of the BHTE-$HgCl_2$ Complex. The low-frequency infrared spectrum of the crystalline BHTE-$HgCl_2$ complex was measured in order to identify the bond between the metal and the reagent or that between the metal and chlorine. The crystalline complex was prepared as follows. The complex of white slime was precipitated by a dropwise addition of $HgCl_2$ in 0.01 mol dm^{-3} hydrochloric acid to BHTE dissolved in ethanol under intense agitation. It was purified by recrystallizing three times from aqueous ethanol solution to obtain the crystalline complex.

As a result, a single sharp band is observed at 273 cm^{-1} ascribable to the Hg-Cl group, on which Coats *et al.*[11] observed ν(Hg-Cl) at 288 s and 249 m cm^{-1} for the $(CH_3CH_2S\text{-}CH_2\text{-})_2HgCl_2$ complex. Therefore, also taking account of the experimental results on the effect of mercury concentration on the distribution ratio mentioned earlier, the complex extracted into the organic phase is considered to be $(n\text{-}C_6H_{13}S\text{-}CH_2\text{-})_2HgCl_2$.

Conclusion

Solvent extraction of mercury(II) with 1,2-bis(hexylthio)ethane(=BHTE) in 1,2-dichloroethane from hydrochloric acid was studied at 30 °C. It was concluded that mercury(II) can be extracted with 1,2-dichloroethane itself by the physical partition of $HgCl_2$ and that it is extracted with BHTE according to the following extraction reaction.

$$\overline{(n\text{-}C_6H_{13}S\text{-}CH_2\text{-})_2} + HgCl_2 \rightleftharpoons \overline{(n\text{-}C_6H_{13}S\text{-}CH_2\text{-})_2HgCl_2}$$

The authors are indebted to Professor M. Takagi of Kyushu University for his instruction in the synthesis of 1,2-bis(hexylthio)ethane.

The present work was supported by a Grant-in-Aid for Scientific Research from the Ministry of Education, Science, and Culture of Japan.

Preparation of $LaNi_5$ Films and Effects of Hydrogen Absorption on Electrical Resistivities of the Films

Gin-ya ADACHI,* Hiroki SAKAGUCHI, Ken-ichi NIKI, Hiroshi NAGAI, and Jiro SHIOKAWA

Department of Applied Chemistry, Faculty of Engineering, Osaka University, Yamadaoka, Suita, Osaka 565

(Received August 28, 1984)

Thin films of $LaNi_5$ have been prepared by means of a flash evaporation-deposition technique. Electric resistivity measurements on these films were carried out in an atmosphere of hydrogen. The films formed on quartz substrates were amorphous. Resistivities initially increased and then decreased during the absorption of hydrogen. During the desorption process, the reverse phenomenon was observed. The effect of the thickness of the films on the electric properties, during the hydrogen absorption-desorption process, was also studied. Sample pulverization could be avoidable by using films of less than 10 μm in thickness. The hydrogen contents of the films were determined by the quartz-crystal mass-monitoring (QCMM) method.

Technical applications of hydrogen absorption in intermetallic compounds have been eagerly pursued in some aspects,[1-8] such as energy storage, heat pumping and hydrogen purification. The $LaNi_5$ hydrides have been the most throughly investigated of all the hydrides of interest,[9-16] and the structure and phase relations have been well established.

A serious drawback regarding the practical use of $LaNi_5$ is the fact that the material pulverizes during hydrogen charging. The volume increase associated with the formation of the hydrides leads to stresses in the hydride envelope on the unhydrided core material.[9] This stress causes cracks which pulverize the hydride.[17] For $LaNi_5$ subjected to several charging-decharging cycles, the particle diameter was measured to be about 10^2 μm, though there was a broad distribution in size.[18,19]

An amorphous alloy which is prepared by rapid cooling is known to have a considerable resistance to a stress since a strain can be relaxed by the free volume existing in an alloy. The amorphous alloy is, therefore, a promising material for hydrogen storage.

A thin film of an alloy is sometimes amorphous[20] and is worth being investigated for possible applications. The preparation of a thin film of an alloy or an intermetallic compound is difficult owing to the difference in the vapour pressures of component metals. Nevertheless, the following methods have been proposed for the preparation of a thin film of an alloy: (1) ion sputtering;[21] (2) ion plating;[22] (3) vacuum vapour deposition at a temperature sufficiently high that component metals can be vaporized quickly and completely (flash evaporation-deposition).

We prepared some thin films of $LaNi_5$ by the third method and measured their electric properties under several atmospheres of hydrogen. This article is a full account of our preliminary papers.[23,24]

Experimental

Preparation of Films. $LaNi_5$ (La 32.16, Ni 67.84 wt%) powder was supplied by Santoku Metal Industry Co. Ltd., Kobe. Substrates were quartz plates, porous sintered glass discs (pore sizes; 3, 8, 50, and 100 μm) and porous sintered stainless steel discs (SUS304, pore sizes; 0.5 and 1 μm, Shoketsu Kinzoku, Tokyo). Samples for electric measurements were deposited on quartz plates. The substrates (except for a porous sintered stainless-steel discs) were first soaked in a $HCl-HNO_3$ mixed solution for 1 d and were then washed with a neutral detergent and rinsed with deionized water. The plate was cleaned with an ultrasonic washing machine filled with deionized water before drying in a desiccator. The porous sintered stainless-steel discs were first washed with acetone and next with methanol. The discs were then treated in an ultrasonic washing machine. The vacuum-deposition procedure was as follows. The $LaNi_5$ powder was placed on a tungsten boat which was preheated to a temperature of 2.3×10^3 K. Both components of $LaNi_5$ evaporated immediately (at this temperature) and were deposited onto a substrate which was placed just above the tungsten boat. The alloy powder was supplied by a conveyor belt equipped with a hopper. The vacuum during deposition was *ca.* 10^{-3} Pa. After deposition, pure helium gas was allowed into the chamber to prevent the formation of an oxide on the films. The thicknesses of the obtained films were determined by the direct observation of the cross sections of the samples using a Hitachi Scanning Electron Microscope S-405. The composition of the film bulk was determined with a Rigaku X-ray Energy Spectrometer equipped with an Si(Li) detector. The XPS measurement was carried out with a Shimazu Electron Spectrometer ESCA 650B mounted with a Mg target.

Measurements of Properties. Electric-resistivity measurements were performed under a hydrogen atmosphere. A sample with attached leads and a thermocouple were installed in a reactor which was made of 316 stainless steel (Fig. 1). The reactor was connected to a high-pressure manifold with connections to a pressure gauge, a vacuum pump and a high-pressure hydrogen gas cylinder. The resistivity of the film was measured by the four-probe technique.[25,26] The voltage drop across the film for a constant current was recorded as a function of time. Then hydrogen gas was quickly admitted to the vacuum reactor. The resulting changes in voltage drop due to absorption were monitored on a recorder.

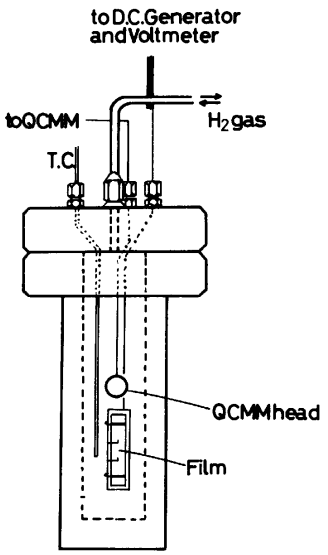

Fig. 1. The apparatus used for the electrical resistivity measurements and the QCMM frequency measurements.

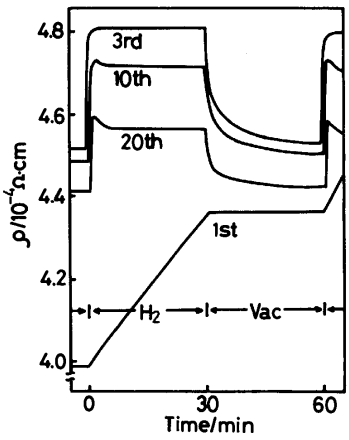

Fig. 2. Variation of resistivities as a function of time for thicker $LaNi_5$ film (thickness *ca.* 0.63 μm) in the activation process (at 313 K for lst and 2nd cycle, at 363 K for other cycle. H_2 2.5×10^6 Pa).

A QCMM apparatus (NICHIDEN ANELVA EVM 32B) was used to determine the quantity of hydrogen absorbed in the films. The apparatus and procedure were as follows. Flash vacuum evaporation was also used to form an $LaNi_5$ film. A crystal monitor head with a quartz disk was placed 0.2 m above a tungsten filament to recieve the metal vapor. The vessel for setting the $LaNi_5$ deposited QCMM head was the same one that was used to measure the electrical resistivity. All the QCMM measurements were done at 333 K. After the vacuum system had reached thermal equilibrium, hydrogen was then introduced into the vessel. The change in the frequency of the quartz was recorded as a function of pressure change.

Results and Discussion

Characterization of Deposited $LaNi_5$ Films: Obtained films were amorphous, at least as determined from X-ray diffraction results. Faint dots were observed in some electron-diffraction patterns. These dots, however, did not originally seem to be due to the presence of any crystalline phase, but due to the oxidation of the film or crystallization by the electron beam in the electron microscope.[27]

The chemical composition of the films (determined by the X-ray fluorescence method) was the same as the original $LaNi_5$ supplied in the hopper. X-ray photoelectron spectroscopy revealed that the La $3d_{2/3}$ peak was split into two components (1.367×10^{-6} and 1.372×10^{-6} J) because of the oxide.[28-33] However, the peak at 1.372×10^{-6} J disappeared after bombardment with argon ions for 30 min. Therefore, the oxide was considered to have formed only on the top surfaces of the films.

The homogeneity of the chemical composition for the whole surface of the films was confirmed by EPMA (Electron Probe Micro Analysis).

The density of the film was 4.44 g/cm³. This was estimated from the weight, area, and thickness of a film (1.33 μm thick). This value is considerably smaller than the bulk value, *i.e.* 8.28 g/cm³.[34]

Stability of the Films during Hydrogen Absorption-desorption Cycles: Intermetallic compounds, such as $LaNi_5$, are brittle materials and break up into fine particles because of their volumetric expansion during hydrogen absorption. The thin films obtained, however, do not form powders even after 150 cycles of the absorption-desorption of hydrogen. This is because that the films are amorphous, *i.e.* hydrogen enters the film just like a hand put into water.

Electric Resistivities: Figures 2, 3, and 4 show the variation in electric resistivity as a function of the time that hydrogen pressure was applied to $LaNi_5$ films of various thicknesses during the activation process.

The resistivity change in a thicker film (*ca.* 0.63 μm thick) is shown in Fig. 2. In the first cycle, the resistivity for the film keeps rising when hydrogen gas is allowed into the system. After the evacuation of the system, the resistivity maintains a constant value. In the third cycle, the resistivity of the film increases immediately and then attains a constant value during the absorption process. During the desorption process, the resistivity decreases rapidly at first and then gradually. During the tenth cycle the variation in the resistivity was almost the same as that during the third cycle. The corresponding increase and decrease was, however, quicker than that for the third cycle. After the first sudden increase, the resistivity decreased slightly. This behaviour suggests that the following steps take place during hydrogen absorption. Hydrogen molecules are adsorbed on the surface of the film and then dissociate into atoms. The dissociated hydrogen atoms reach the underlying $LaNi_5$ by diffusion in

monatomic form along the La_2O_3–Ni interface.[35] The hydrogen atoms take on the conduction electrons of $LaNi_5$ and become the hydrogen anions. This reaction is represented by the formula $H+e^- \rightarrow H^-$. The number of electrons in the conduction band of the $LaNi_5$ decreases and, consequently, the resistivity of the $LaNi_5$ film increases. The second step (the formation of a highly conductive hydride) then, occurs. For a thicker film, the resistivity is maintained at a constant value since the formation of the hydrogen anion is balanced by the formation of the highly conductive hydride. In the hydrogen-desorption process, the dissolved hydrogen anions are removed as hydrogen molecules, releasing their electrons to the conduction band of the metal. Since the number of electrons in the conduction band of the $LaNi_5$ increases, the resistivity of the film decreases. Subsequently, hydrogen which has formed the highly conductive metal hydride, slowly desorbs. The decrease in the resistivity of the film becomes slow.

Figure 3 illustrates the change in resistivity of a thinner film (*ca.* 0.20 μm thick). The behavior during the first cycle is similar to that of the third cycle for a thicker film. As the cycle is repeated, the rate of decrease in the resistivity (which occurs after the increase when hydrogen is first admitted into the system) becomes faster. This is because the quantity of the highly conductive hydride increases. When the system is evacuated (as seen from the results of the 10th cycle in the thicker film) there occurs a sudden decrease in the resistivity because of the removal of the residual hydrogen anions in the film. Then, the resistivity gradually increases due to the decomposition of the highly conductive hydride.

Figure 4 displays the resistivity change in the thinnest film (*ca.* 3.8×10^{-2} μm thick). During the 10th cycle, there was no increase caused by introduction of hydrogen into the system because all of the dissolved hydrogen anions formed highly conductive hydride. As mentioned above, the resistivity change differs depending on the thickness of the film. The thickness of the highly conductive hydride layer seems to be almost the same even though the film thickness is different. For the thicker film, the thickness of the H^- dissolved slightly conductive $LaNi_5$ layer was quite large and the effect of this layer was predominant rather than that of the highly conductive hydride layer. For the thinner film, the effect of the highly conductive hydride was forcible and the electric resistivity fell immediately.

Figure 5 shows the effect of temperature on the electric resistivity of an $LaNi_5$ film (0.3 μm thick) during a hydrogen-desorption process. The rate of released hydrogen which is formed the highly conductive hydride increases with a rise in temperature.

Hydrogen Pressure Dependence on Resistivities: Figure 6 illustrates the pressure dependence of the saturated electric resistivity for hydrogen absorption in the film. The saturated resistivity reaches a constant value at about 1.2×10^6 Pa. Regarding the effect of the temperature on the electric resistivity and the hydro-

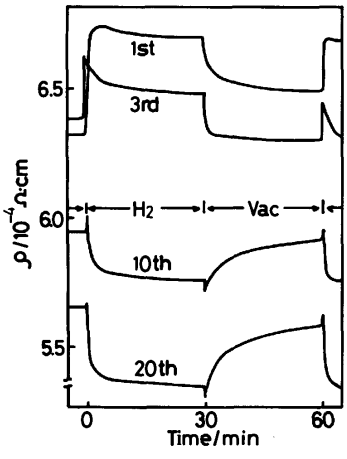

Fig. 3. Variation of resistivities as a function of time for thinner $LaNi_5$ film (thickness *ca.* 0.20 μm) in the activation process (at 313 K for lst and 2nd cycle, at 363 K for other cycle. H_2 2.5×10^6 Pa).

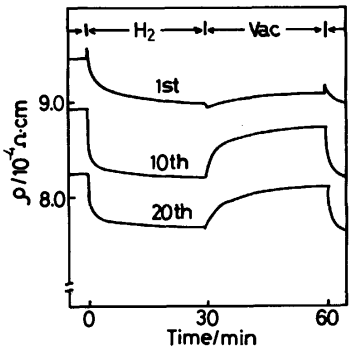

Fig. 4. Variation of resistivities as a function of time for thinnest $LaNi_5$ film (thickness *ca.* 3.8×10^{-2} μm) in the activation process (at 313 K for 1st and 2nd cycle, at 363 K for other cycle. H_2 2.5×10^6 Pa).

gen pressure dependence on resistivities, some typical results since the behavior of the resistivity is unrelated to the film thickness.

Activation Energy for Hydrogen Absorption: The time dependence of the resistivities for the initial stages of absorption is shown in Fig. 7. The reaction-rate constants are obtained from the slopes of straight lines in the figure.[36] Figure 8 gives an Arrhenius plot of the rate constants for the hydrogen absorption of the film. An activation energy for the absorption, E_a, is evaluated from the slope, being 69.1 kJ mol^{-1}. The E_a is related to the reaction which is the formation of a hydrogen anion. This reaction is independent of the film thickness.

Hydrogen Concentration in the Films: Figure 9 gives

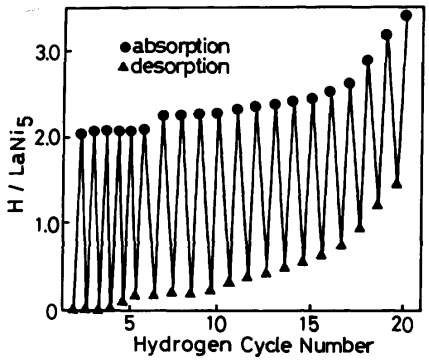

Fig. 9. Hydrogen concentration in an $LaNi_5$ film (thickness *ca.* 1.8 μm) in the hydrogen absorption-desorption cycle (in H_2 2.5×10^6 Pa—Vacuum cycle at 333 K).

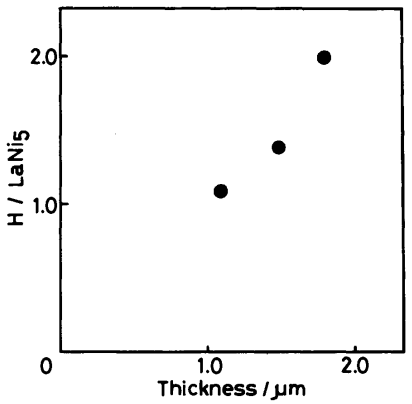

Fig. 10. Hydrogen concentration *vs.* $LaNi_5$ film thickness (in H_2 2.5×10^6 Pa—Vacuum cycle at 333 K).

the hydrogen concentration in $LaNi_5$ films measured by the QCMM method[37] while repeating the hydrogen absorption-desorption cycle. The amounts of hydrogen taken up by the $LaNi_5$ film (*ca.* 1.8 μm thick) is about 2.0 H/$LaNi_5$. It is recognized that the amount of the hydride which is not desorbed from the film increases as the cycle repeats. This agrees with the measurements of the electrical resistivity. The amounts of hydrogen for other films are 1.1 and 1.4 for films of 1.1 and 1.5 μm thickness, respectively. The hydrogen content in their films is dependent on the film thickness and, as indicated in Fig. 10, the hydrogen concentration decreases with a decrease in film thickness. The hydrogen content for thinner films is at present under investigation. For a bulk sample, it is known that the amount of hydrogen taken up by $LaNi_5$ is about 7.[9] The smallness of hydrogen uptake by the films compared with the bulk is due to the amorphous state of the film structure and to the existence of a surface oxide as a dead layer for hydrogen absorption.

Figure 11 shows a pressure-composition isotherm for the $LaNi_5$ film (*ca.* 1.5 μm thick) at 333 K. The hydrogen concentration increases with an increase in

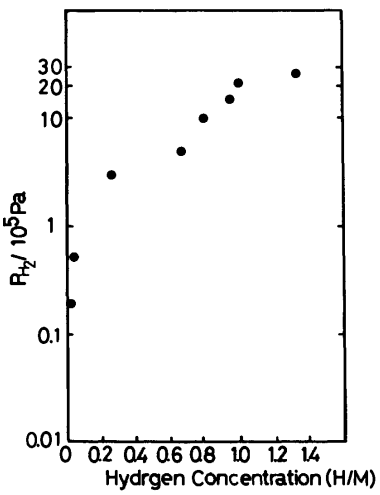

Fig. 11. Pressure-Concentration isotherm for an $LaNi_5$ film (thickness *ca.* 1.5 μm) at 333 K.

pressure. A pressure plateau (usually observed in a bulk sample) is absent. A result for an ZrNi amorphous alloy[38] is analogous to our result. It can be assumed that the absence of a pressure plateau is one of the features of an amorphous alloy.

(Received May 31, 1984)

UV photoelectron spectra were measured for polypropylene (PP), poly(vinyl fluoride) (PVF), 1,2-polybutadiene (1,2-PBD), poly(vinyl chloride) (PVC), and poly(vinyl alcohol) (PVA). Their threshold ionization energies were found to be 8.5, 9.2, 7.5, 8.8, and 8.0 eV (1 eV≅0.1602 aJ), respectively. The evolution of their electronic structures (from those of small related molecules) were analyzed, mainly, by using the photoelectron spectra of these small compounds (including the new data of 1,2-propanediol). The data of previously measured polyethylene (PE) and polystyrene (PS) were analyzed together. With the results, the polymers were classified into three groups according to the increasing order of localization of the positive hole in the cationic state: (1) PE, PP, and PVF, (2) 1,2-PBD, PVC, and PVA, and (3) PS as a representative of aromatic-pendant polymers.

Ultraviolet photoelectron spectroscopy (UPS) has been developed as a powerful tool in studying the electronic structure of organic solids.[1-4] In particular, an important quantity obtainable by UPS is the threshold ionization potential of a solid, which gives the location of the top of a valence band. Together with the energy of the bottom of a conduction band, it gives a basic picture of the electronic structure of a solid. However, so far studies of organic polymers by UPS have been concentrated on polymers with aromatic groups,[5,6] polyethylene (PE) and its model compounds,[7] and some conducting polymers.[8] There seems to be no report on vinyl polymers with pendants other than aromatic rings, except for a relevant report by Vilesov *et al.*[9] on the photon-energy dependence of the photoemission quantum yield. Pireaux *et al.*[10] reported an X-ray photoelectron spectroscopy (XPS) study of vinyl polymers, but the low intensity and the broadness of the spectral features prevented a detailed study of the valence bands.

In this work, we report a UPS study regarding a series of vinyl polymers $\{CH_2CHX\}_n$ with non-aromatic pendant X, *i.e.*, polypropylene (PP, X:CH_3), poly(vinyl fluoride) (PVF, X:F), 1,2-polybutadiene (1,2-PBD, X:$CH{=}CH_2$), poly(vinyl chloride) (PVC, X:Cl), and poly(vinyl alcohol) (PVA, X:OH).

Our aims are (1) to obtain reliable experimental data regarding threshold ionization energy, and (2) to interpret the observed threshold energies (and other spectral features) in terms of intramolecular and intermolecular factors. The results of previously measured polyethylene (PE, X:H)[7a] and polystyrene (PS, X:C_6H_5)[5a] were also analyzed.

For aim (2), the electronic structure of an isolated single polymer chain is used as the base of interpretation. The intermolecular contribution can be deduced by comparing it with the observed solid state results. Unfortunately, however, the gaseous state of a polymer is not realizable, and theoretical calculations are not quantitatively reliable, either. In order to overcome this difficulty, we estimated the electronic structure of an isolated chain from the gas-phase photoelectron spectra of related small molecules by analyzing the pendant-chain and also pendant-pendant interaction. Since no information in the literature was available for 1,3-propanediol, which is related to PVA, we measured its gas-phase photoelectron spectrum. Theoretical band calculations for an isolated polymer chain[10-13] and solid XPS results[10] also helped in the interpretation for some polymers.

This method of analysis shows how the electronic structures of polymer solids evolve from those of small units. The results indicate various patterns of evolution, depending on the polymers. In particular, the degree of delocalization of the positive hole in the cationic state ranges from almost complete localization in a pendant to extensive delocalization over the principal chain. Although rather rough approximations are involved in the present treatment, we believe it gives a general viewpoint for analyzing the electronic structures of polymers.

Experimental

Standard samples of PP (isotactic), PVF, PVC, and PVA were available from Scientific Polymer Products Inc. (catalog Nos. 130, 022c, 038c, and 002, respectively). Low-crystallinity 1,2-PBD was provided by Japan Synthetic Rubber Company. PP was twice reprecipitated from a decalin solution with cyclohexane as a poor solvent; PVF twice from *N,N*-dimethyl formamide (DMF) with methanol; PVC three times from tetrahydrofuran (THF) with methanol; and 1,2-PBD once from a benzene solution with methanol. PVA was used without further purification.

† On leave from the Institute of Chemistry, Academia Sinica, Beijing, China.

The UPS spectrometer consists of a light source and a retarding-potential-type electron energy analyzer, which was reported previously.[14] Two kinds of light sources were used. One was hydrogen discharge lamp attached to a 0.5 m Seya-Namioka-type monochromator and the other was a rare-gas resonance lamp capable of He I (21.2 eV), Ne I (16.8 eV), and Ar I (11.7 eV) emissions. The same ionization energies were obtained by both two light sources.

Since these polymers are insulators, we had to use thin film samples to avoid charging. The films were prepared by putting a few drops of a hot solution (≈0.2 wt%) of a polymer on a Cu-disk (12 mm diameter) substrate, followed by the rotation of the substrate. The rotation spreaded the solution, and the solvent vaporized, leaving a thin film.[15] The temperatures of the solution and the substrate were kept at 60—70 °C except for the case of 1,2-PBD, where the film was prepared at room temperature. The solvents used for PP, PVF, 1,2-PBD, PVC, and PVA were decalin, DMF, benzene, DMF, and redistilled water, respectively.

In this sample preparation procedure, we paid close attention to the suppression of the emission from the substrate, because the threshold energy of the substrate was inferred to be smaller than those of polymers. This requires both a good uniformity of the film and a sufficient average thickness. We found that the uniformity significantly depends on the adhesive property of the solution to the substrate. For example, PVC films of poor (net-like) quality were obtained from THF solution even if a large amount of solution was used, while a uniform film was obtained by using DMF and heating the substrate and the solution. After choosing appropriate solvents, we increased the amount of deposited polymer sample until there was no further change in the spectrum. The concentration and procedures described above gave satisfactory films for getting an intrinsic spectra of the polymers without charging, although we had to use very weak light for some specimens in order to avoid charging. The nominal average thickness of a film was ≈2 μm, but the polymers tended to accumulate at the periphery of a substrate surface when the solvent vaporized away. Therefore, the real average thichness on a substrate surface should be smaller. The absence of charging was verified by the sharpness of the cut off at the low-kinetic-energy side of the spectra.

The He I gas-phase photoelectron spectrum of 1,3-propanediol was measured on the photoelectron spectrometer which was reported previously.[16]

Results and Discussion

Threshold Ionization Energies. In Figs. 1—5, the photoelectron spectra of the polymers are shown. The abscissa represents the solid ionization energy I_s, which is related to the kinetic energy of a photoelectron by $I_s=h\nu-E_k$, where $h\nu$ is the photon energy. The values of the threshold ionization energy are given by $I_s^{th}=h\nu-E_k^{max}$, where E_k^{max} is the maximum kinetic energy of photoelectrons. They are listed in Table 1. These values are the averages of at least six times measurements for each compound. The standard deviation was less than 0.2 eV. Table 1 also lists our previous data for high-density PE[7a] and PS,[5a] the

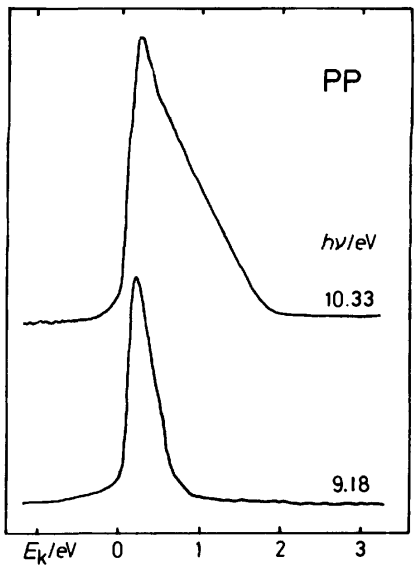

Fig. 1. Photoelectron spectra of polypropylene. The photon energy of the exciting light is shown at the side of each curve.

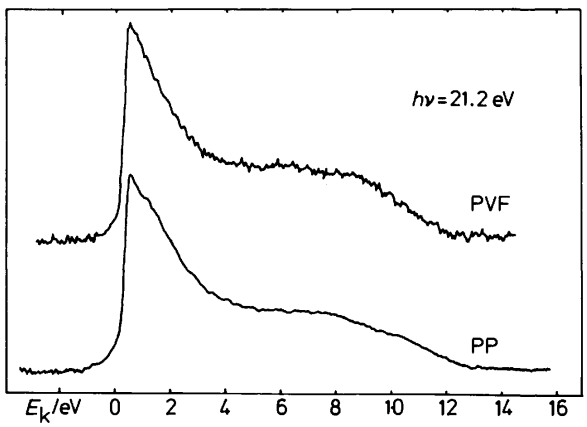

Fig. 2. Photoelectron spectra of poly(vinyl fluoride) and polypropylene by He I (21.2 eV) light source.

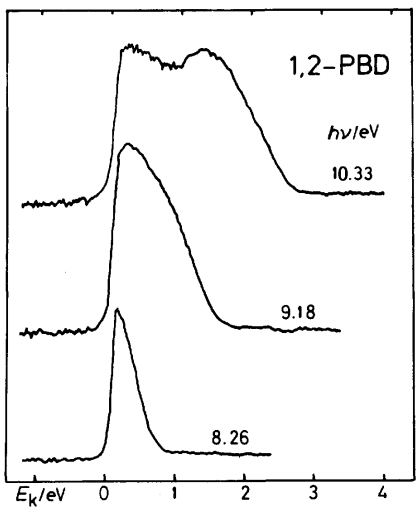

Fig. 3. Photoelectron spectra of 1,2-polybutadiene. The photon energy of the exciting light is shown at the side of each curve.

assignment of the character of the HOMO (discussed below), the threshold (adiabatic) ionization energies of the corresponding "unit" compounds CH_3CH_2X in the gas phase I_g^a(unit),[16-18] and the difference $\Delta I = I_g^a$(unit) $-I_s^{th}$. (Pireaux *et al.*[10] used $CH_2=CHX$ for the unit compound, but this is inadequate since the character of the highest occupied orbital can change from the π orbital in $CH_2=CHX$ to σ or lone pair orbitals in the polymer, as shown below).

Vilesov *et al.*[9] reported the I_s^{th} values of PVA, PVC, poly(*N*-vinylcarbazole) (PVCz), and PS to be 6.0, 6.0, 5.8, and 7.0 eV, respectively. The values for PVA and PVC are much lower than the present results, while those for PVCz and PS are in good agreement with our results (5.85 eV[5d] and 6.95 eV[5a] obtained with the present instrument). Since the preparation of uniform films was more difficult for PVA and PVC than for polymers with aromatic pendants, we may conclude that the data by Vilesov *et al.* are questionable for PVA and PVC.

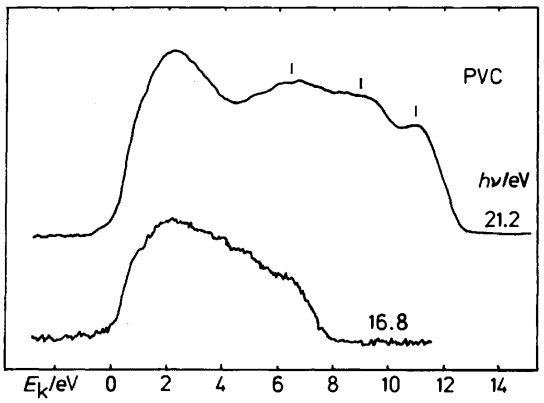

Fig. 4. Photoelectron spectra of poly(vinyl chloride) by He I (21.2 eV) and Ne I (16.8 eV) light sources.

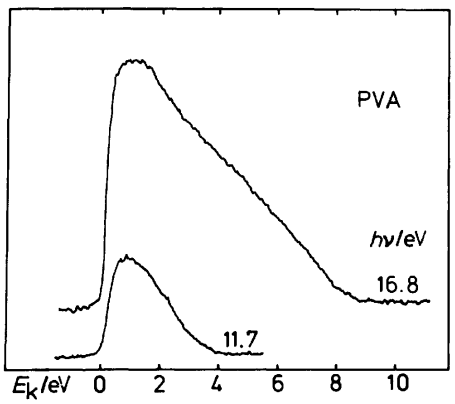

Fig. 5. Photoelectron spectra of poly(vinyl alcohol) by Ne I (16.8 eV) and Ar I (11.7 eV) light sources.

Pireaux *et al.* reported XPS data on the location of the top of the valence band for some of these polymers,[10] but threshold energies derived from their data with estimated work functions ($E_1+\phi$ in Table 6 of Ref. 10) are 0.5—2 eV larger than the present directly-measured values.

Method of Analysis. It is known that for molecular solids, a solid photoelectron spectrum resembles the gas-phase spectrum of the compound if a shift is made in the ionization-energy scale.[19] The similarity indicates the preservation of the electronic structure of a molecule in a solid, and that the photoemission from a molecular solid can be regarded as the ionization of a molecule in the solid. The shift can be attributed to the stabilization of the molecular cation by the polarization of the surrounding molecules; hence, it is called the polarization energy P.[1,4c] According to an analysis of the contribution of molecules in the bulk and at the surface, we already noted that the bulk polarization energy can be evaluated as the difference of the threshold energies of the gas and solid phases rather than the difference in the peak energies.[4c]

In the case of a polymer solid, each chain corresponds to a molecule in the above discussion. Thus, the discussion regarding a photoelectron spectrum of a polymer solid can be divided into that of (1) the electronic structure of an isolated chain and (2) the polarization energy. The character of the occupied orbitals and their relative energy difference is determined by the former factor, while both factors affect the absolute energy scale.

Figure. 6 illustrates our way of interpreting the observed thresholds and spectral features. At first we

TABLE 1. THE THRESHOLD IONIZATION ENERGIES OF VINYL POLYMERS (I_s^{th}) AND THE GAS PHASE THRESHOLD IONIZATION ENERGIES OF THEIR "UNIT" COMPOUNDS (I_g^a)

Compound	I_s^{th}/eV	Assignment	Unit compound	I_g^a (unit)/eV	ΔI/eV[g]
PE	8.5[a]	backbone	CH_3CH_3	11.7[c]	3.2
PP	8.5	backbone	$CH_3CH_2CH_3$	11.1[c]	2.6

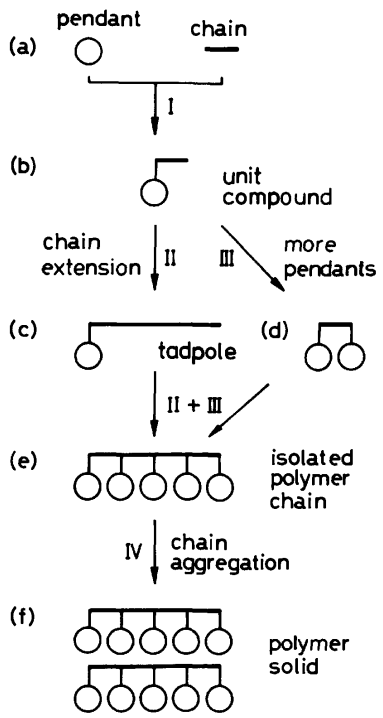

Fig. 6. Schematic representation of the evolution of the electronic structure of a vinyl polymer solid from those of small units.

estimate the electronic structure of an isolated polymer chain (e) from data for small related molecules, by analyzing the effects of the following steps.

(I) The combination of a pendant with a short alkane C_2H_6 to form a unit compound CH_3CH_2X, which is the repeating unit of a vinyl polymer.

(II) The extension of an alkyl chain to form a "tadpole" compound $CH_3(CH_2)_\infty X$.

(III) The attachment of other pendants to the chain to form an isolated polymer chain.

The remaining difference between the estimated structure of an isolated chain and the observed results for a polymer solid (f) is ascribed to the effect of

(IV) aggregation of chains to form a polymer solid.

Steps (I) and (II) jointly correspond to the interaction of a pendant and the principal (backbone) chain, (III) to the interaction among pendants through space or through the principal chain, and (IV) to the interaction among chains. For small compounds from (a) to (d) in Fig. 6, gas-phase UPS spectra are available. Further, additional information on the isolated polymer chain (e) and polymer solid (f) are available from theoretical band calculations[10-13] and XPS spectra,[10] respectively.

In this analysis, we distinguish the ionization energies for the onset and peak of a band in a photoelectron spectrum. In the gas phase, the peak energy for the ionization from a MO corresponds to ionization without a change in the molecular geometry, while the onset corresponds to the ionization to a relaxed molecular geometry.[20] When we assume Koopmans' theorem, the former corresponds to the orbital energy of the MO.[20] Thus, peak energies are more suitable for discussing the evolution of the electronic structure of a molecule. However, bands originating from different MO's often overlap and no clear peak can be observed, as in some of the compounds studied here. In such cases, we can still discuss the change in the electronic structure using onset energies, assuming that the onset-peak energy separation changes little among similar molecules. In the solid spectrum, on the other hand, the physical meaning of the peak energy is ambiguous owing to various mechanisms of peak broadening.[4b,c] Further, no clear peak can be observed for some of the polymers studied here. Fortunately, however, the polarization energy is obtained as the difference between the thresholds of gas and solid states, as described above. Thus, we don't need the peak energies in order to evaluate the intermolecular effects.

Taking account of such a situation, we will mainly use the onset energies in the following analysis, but will also use peak energies when they are available and useful. We denote the threshold (adiabatic) ionization energies of a tadpole compound and a polymer chain as I_g^a(tadpole) and I_g^a(polymer), respectively. As materials for discussion, Table 2 lists the data[21] for small alkanes with corresponding pendants, *i.e.* the ionization energies of the highest occupied orbitals among (1) orbitals localized on the pendant (I_1), and (2) orbitals delocalized over the chain (I_2).

Electronic Structure of an Isolated Chain. A difficulty in the analysis of step (I) for the small pendants studied here is the choice of a compound embodying the "pendant" X. For larger pendants such as aromatic ones, the attchment of an H atom to X has little effect on the electronic structure of the molecular orbitals, and HX is a natural choice. For small X, however, an H atom strongly affects the electronic structure of HX. Therefore, we will not discuss process (I) in detail and will start from CH_3CH_2X, although we also list the threshold ionization energies of HX[21] in Table 2. This difficulty is the reason why we listed I_g^a(unit)'s in Table 1.

The effect of chain extension (II) can be estimated by examining the dependence of the ionization energies on the carbon number n. As shown in Fig. 7, the ionization potentials of normal alkanes form a good linear relation with $1/n$. The decrease of I_2 with n is due to the delocalization of the highest σ orbital. Also the first vertical ionization energies of alkyl alcohols from C_2H_5OH ($1/n$=0.5) to n-$C_8H_{15}OH$ ($1/n$=0.125)[21i] are also linear with $1/n$ within 0.03 eV. This corresponds to a change of the inductive effect to the O_{2p} lone pair orbital. These empirical relations suggest that we can estimate the threshold ionization energy of a tadpole compound by extrapolation to $1/n$=0 with a probable error of ≈0.1 eV. Such plots are shown by

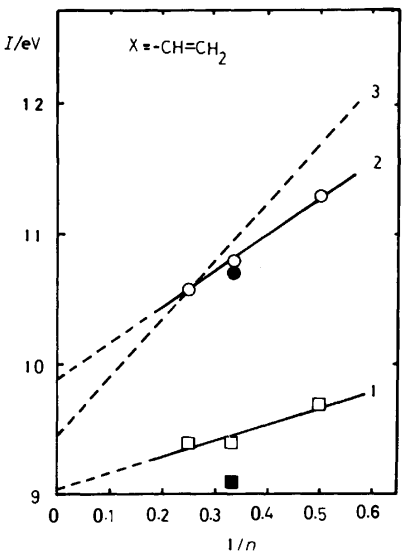

Fig. 8. Dependence of onset ionization energy I of monovinyl-substituted n-alkanes on the reciprocal of the chain carbon number n. 1: onset of π ionization (I_1, □), 2: onset of principal chain ionization (I_2, ○), and 3: I of unsubstituted alkanes from Fig. 7 as a reference. Values of I_1 (■) and I_2 (●) of 1,3-disubstituted propane are also shown.

real lines 1 in Figs. 7—10 for X=CH_3, -CH=CH_2, -Cl, and -OH, respectively. The plot for X=F was impossible owing to a lack of data. By assuming a linear relation between I_2 and $1/n$ also, we see that there will be no crossover between I_1 and I_2 in a tadpole compound, with X=Cl being a case that is a little ambiguous.

The further introduction of pendants will affect the electronic structure through (1) the inductive effect and (2) the interaction among pendants. The details of these effects depend on the polymers, so we will now discuss each polymer.

Polyethylene (PE) and Polypropylene (PP): There are

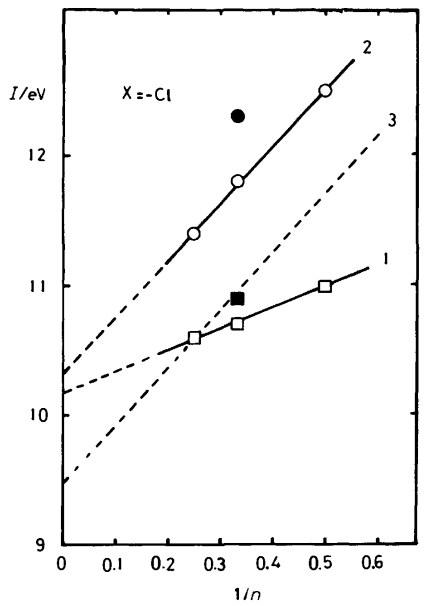

Fig. 9. Dependence of onset ionization potential I of monochloro-substituted normal alkane on the reciprocal of the chain carbon number n. 1: Cl_{3p} ionization (I_1, □), 2: principal chain ionization (I_2, ○), 3: I of unsubstituted alkanes as a reference. Values of I_1 (■) and I_2 (●) of 1,3-disubstituted propane are also shown.

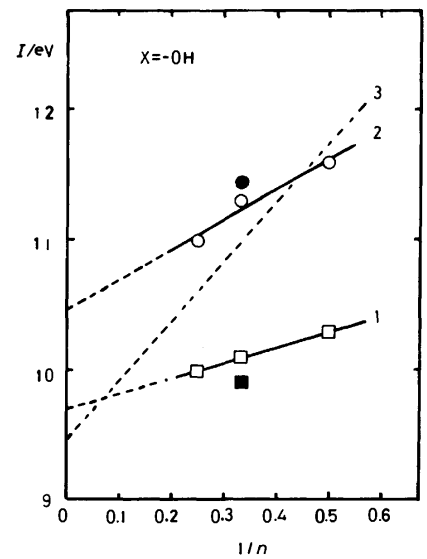

Fig. 10. Dependence of onset ionization potential I of monohydroxy-substituted normal alkanes on the reciprocal of the chain carbon number n. 1: O_{2p} ionization (I_1, □), 2: principal chain or C-O bond ionization (I_2, ○), 3: I of unsubstituted n-alkanes (----) as a reference. Values of I_1 (■) and I_2 (●) 1,3-disubstituted propane are also shown.

only σ-electrons in these polymers, and orbitals are delocalized over the principal chain.

Table 3 lists the I_2's of methyl-substituted alkanes. The values of monomethyl-substituted alkanes are also shown in Fig. 7 (○). The latter are lower than those of unsubstituted compounds (⊙), but the difference decreases with the increase in n and becomes almost zero for $n\rightarrow\infty$. Although the introduction of a second CH_3 group lowers the I_2 for $n=3$ (●) a little, band calculations of isolated chains of PE and PP give a negligible difference between the orbital energies of the HOMOs.[13] Such an insensitivity to the CH_3 substitution can be understood when we consider that (1) the attachment of a CH_3 group does not affect the range of delocalization of the HOMO on the whole chain, and (2) the CH_3 group has almost no inductive effect to alkyl chain.

Therefore, we can expect the I_g^a(polymer) of PP to be the same as I_g^a(tadpole). The latter can be estimated to be 9.6 eV from the extrapolation in Fig. 7 to $1/n=0$. A similar extrapolation for PE gives I_g^a(polymer)=9.4 eV, which is indeed similar to that of PP.

Poly(vinyl fluoride) (PVF): Band calculations[10-12] and XPS[10] show that F_{2p} orbitals have higher ionization potentials than σ orbitals derived from atomic orbitals of carbon and hydrogen. This tendency has already been seen for compounds listed in Table 2. The increase in the length of the alkyl chain seems not to change this situation because of the large difference between I_1 and I_2. Thus, we can expect that the highest occupied orbital is a delocalized one over the principal chain as in the case of PE and PP. The ionization potential of fluoroalkanes in Table 2 are higher than those of corresponding alkanes due to the inductive effect of the fluorine atom. Thus, we expect a higher I_g^a(polymer) of PVF than those of PE or PP. Unfortunately, the data of small related compounds are not sufficient for making a quantitative estimation of I_g^a(polymer).

1,2-Polybutadiene (1,2-PBD): For this polymer, there is a double bond in the side chain with π electrons localized in it. It determines the value of I_1. The right-hand peak in the spectrum for $h\nu$=10.33 eV (Fig. 3) should correspond to this orbital, since such a distinct peak does not appear in the spectra of PE.[7a]

The effect of introducing more than one vinyl group can be seen in CH_2=$CH(CH_2)_3CH$=CH_2 (■, ● in Fig. 8) in which the number of carbon atoms between the pendants is the same as in the polymer. As seen from the vertical ionization energies listed in Table 4, the interaction of the two vinyl groups results in a splitting of 0.4 eV between the π ionization energies of CH_2=$CH(CH_2)_3CH$=CH_2, while their centroid does not shift from the π ionization energy of $CH_3(CH_2)_2CH$=CH_2. This means that the inductive effect of the vinyl group is small, and only the π-π interaction is important. The change of I_2 by the inductive effect is also very small. As a result, I_1 is more decreased than I_2 and the I_g^a(polymer) is determined by the π orbitals.

The effect of π-π interaction in an isolated infinite polymer chain can be evaluated by a simple theory of a one-dimensional chain with only the nearest-neighbor

TABLE 4. VERTICAL IONIZATION ENERGIES OF $CH_3CH_2CH_2X$ AND $XCH_2CH_2CH_2X$ (IN eV)

X	CH_3CH_2CHX I_0	$XCH_2CH_2CH_2X$ I_I	I_{II}	Splitting $I_{II}-I_I$	Shift $(I_I+I_{II})/2-I_0$

interaction β among the units. According to this formalism, the splitting for a dimer is 2β and the energy spread for an infinite chain is 4β, which is symmetric with respect to the energy of one unit.[23] Therefore, the lowest ionization potential in the infinite chain should be lower than that of one unit by the amount of the splitting in the dimer. Assuming the same amount of decrease in the threshold ionization energy as that in the peak energy, we can expect that the value of I_g^a (polymer) is 0.4 eV smaller than I_g^a(tadpole), which can be estimated to be 9.1 eV from the extrapolation in Fig. 8. This gives I_g^a(polymer)=8.7 eV.

Poly(vinyl chloride) (PVC): The values of I_1 are determined by the two Cl_{3p} lone pairs. In the He I spectrum, three features at E_k=11.0, 9.0, and 6.5 eV (I_s=10.2, 12.2, and 14.7 eV) can be clearly seen. These features were also observed in the reported XPS spectrum,[10] with a good agreement of intervals. They should be due to the Cl atoms.

The effect of multiple Cl-substitution can be examined as in the case of 1,2-PBD using the ionization potentials in Table 4. Similar to 1,2-PBD, the introduction of the second Cl atom in $CH_3CH_2CH_2Cl$ gives a splitting of 0.4 eV in the Cl_{3p} lone-pair bands. Unlike 1,2-PBD, however, the large inductive effect of the Cl atoms raises the centroid of these bands by 0.5 eV from that of $CH_3CH_2CH_2Cl$. As a net result of these conflicting effects, I_1 is even increased by 0.3 eV (■ in Fig. 9). On the other hand, I_2(●) experiences only an inductive effect, and is significantly increased (≈0.5 eV).

With the simple theory described for 1,2-PBD, the interaction among the lone pairs in an infinite PVC chain will lower the Cl_{3p} ionization energy by 0.4 eV relative to that of $CH_3(CH_2)_\infty Cl$. The inductive effect will not change the centroid of the Cl 3p levels significantly from that in $Cl(CH_2)_3Cl$ by further Cl-introduction, judging from the small change of ionization energy from CH_2ClCH_2Cl (11.41 eV)[16] to $CHCl_2CH_2Cl$ (11.48 eV)[16] and CCl_3CH_2Cl (11.45 eV).[16] With these conflicting effects, we expect that I_1 will change only a little (≈0.1 eV increase) from $CH_3(CH_2)_\infty Cl$ to $\{CH_2CHCl\}_n$. The value of I_2 will be increased by an inductive effect. With these values and the extrapolation of the lines in Fig. 9 to $1/n=0$, we see that the HOMO of the polymer is derived from the Cl_{3p} lone-pair orbitals with I_g^a(polymer)≃I_g^a(tadpole)= 10.3 eV. The peak at I_s=10.2 eV in Fig. 4 should correspond to this. This assignment agrees with that from XPS.[10] For deeper levels, contributions from lone pairs, C-Cl bonds, and alkyl chains overlap and form peaks of I_s=12.2 eV and 14.7 eV. Since these peaks do not appear in the spectrum of PE, we will tentatively follow the assignments by Pireaux *et al.*[10] to lone pair and C-Cl bonds, respectively.

Poly(vinyl alcohol) (PVA): There are two O_{2p} lone pairs per oxygen atom, which determine the value of I_1.

The way of discussing the effect of the multiple introduction of OH groups is the same as those for 1,2-PBD and PVC, but we must pay attention to the effect of possible hydrogen bonding.[24] Such hydrogen bonding should lead to a larger interaction than the usual van der Waals interaction. As for the intramolecular hydrogen bond, the data of $HO(CH_2)_3OH$ in Table 4 indeed gives a large splitting of 0.6_6 eV for orbitals. The inductive effect of the new OH group is small (0.1 eV increase) for both the mean ionization energy of such a split pair and I_2 (Table 4). With a similar discussion as for 1,2-PBD and PVC, we can estimate a decrease of I_1 by 0.6 eV from $CH_3(CH_2)_\infty OH$ to $\{CH_2CHOH\}_n$.

In the case of an intermolecular hydrogen bond, the inductive effect by the OH groups in the same chain will remain small, but the intramolecular O_{2p}-O_{2p} interaction should be smaller than for the case of an intramolecular hydrogen bond. Instead, the intermolecular interaction of OH groups should cause a lowering of the ionization potential comparable to that from methanol (10.96 eV) to methanol dimer (10.42 eV).[25] Although this is not an intramolecular effect, the total difference between I_g^a (tadpole) and I_s^h should be similar to that in the case of an intramolecular hydrogen bond.

In any case, the ordering of I_1 and I_2 in a polymer chain is not changed from that in $CH_3(CH_2)_\infty OH$ estimated by the extrapolation in Fig. 10, and O_{2p} lone pairs will form the HOMO. Pireaux *et al.*[10] made the same assignment from XPS. The estimated value of I_g^a (tadpole)=9.7 eV gives I_g^a (polymer)=9.1 eV for a polymer chain with intramolecular hydrogen bonds.

Polystyrene (PS): As seen above, the highest occupied states of 1,2-PBD, PVC, and PVA are rather localized on a pendant group, in contrast to the case of PP and PVF where the highest occupied orbital is delocalized over the principal chain. A hole in the cationic state of

aromatic-pendant vinyl polymers is also known to be localized in a pendant group.[5] Therefore it is interesting to compare the present results described above with those of aromatic-pendant polymers.

We will examine polystyrene (PS) as a typical example. In PS, the highest occupied orbital gives a much smaller ionization energy (I_1) than that of the principal chain (I_2), as in most other aromatic-pendant polymers. Further, I_1 does not depend on the length of alkyl chain as shown in Fig. 11. Similar insensitivity to the size of alkyl group can be also seen in the small difference between *N*-ethylcarbazole and *N*-isopropylcarbozole.[26] Such an independence of the chain length is different from the tendency observed for the polymers studied above. This small interaction should be a result of the large difference in energy between π and σ orbitals and the small difference in electronegativity between the chain and the pendant. Another difference is an almost negligible interaction between the aromatic rings as seen in the small difference of I_1 values for ethylbenzene and bibenzyl in Table 2.

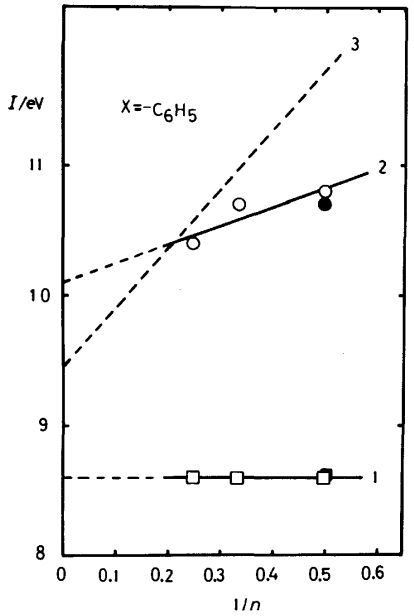

Fig. 11. Dependence of onset ionization potential I of monophenyl-substituted normal alkanes on the reciprocal of the chain carbon number n. 1: π ionization (I_1, □), 2: σ ionization (I_2, ○), 3: I of unsubstituted *n*-alkanes as a reference. Values of I_1 (■) and I_2 (●) of 1,2-disubstituted ethane are also shown.

The value of I_s^{th} is thus determined almost solely by a pendant phenyl group. In this sense, the picture of the ionization of one chromophore is more adequate in the aromatic-pendant polymers than in the other polymers studied here. As a result, both I_g^a(tadpole) and I_g^a(polymer) are expected to be the same as the threshold of ethylbenzene (8.6 eV).

Polarization Energies. Table 5 lists the estimated values of I_g^a(tadpole), I_g^a(polymer), and the polarization energy as the difference I_g^a(polymer)$-I_s^{th}$. It also lists the refractive indices n_D[29] as a guide for the polarizability. Possible errors of P is ±0.3 eV for PE, PP, and PS, while those for 1,2-PBD, PVC, and PVA should be larger (say, ±0.5 eV), mainly due to the uncertainty about the conformational dependence of the pendant-pendant interaction. Thus, we cannot discuss the latter group in detail. We only note that the value of the latter group are within the range covered by those of the former group.

On the average, these values are comparable or a little smaller than the common value of 1.7 eV for aromatic hydrocarbons,[4c] while aliphatic hydrocarbons have similar values. (Although PS has a P=1.7 eV, it is still smaller than the value 2.1 eV for benzene solid[27]). A possible factor contributing to such a trend is the polarizability of the molecules. The refractive indices in Table 5 are comparable to those of aliphatic solids,[27] but smaller than those of aromatic hydrocarbons. (*e,g*, n_D of anthracene for the three optical axes are 1.550, 1.775, and 2.04[30]).

Further, we also note two differences of polymer solids from molecular solids. (1) For some polymers, the positive charge is delocalized in a long chain in contrast to the localization in a molecule. At present there is no satisfactory theoretical method of estimating P for such a case. This situation may contribute to the small P of PE and PP. (2) Even for a localized positive charge, considerable part of the medium surrounding the charge may belong to the same molecule. Thus, the polarization effect from other molecules will be smaller than for molecular

Table 5. Estimated values I_g^a(tadpole), I_g^a(polymer) and P

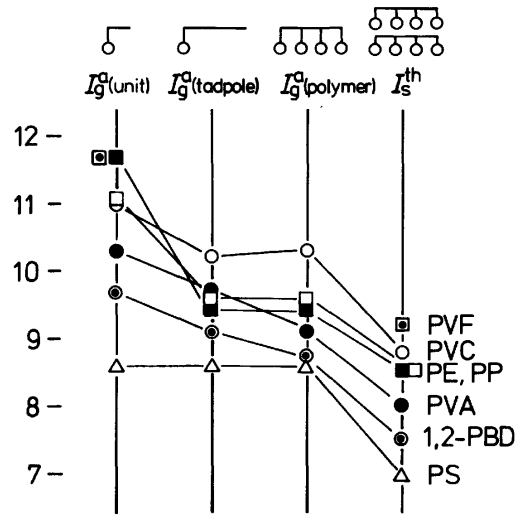

Fig. 12. Change of threshold ionization energy (in eV) from unit compounds to polymer solids.

solids. This may contribute to make the *P* of PS smaller than for benzene.

Summary of the Evolution of the Electronic Structure. Fugure 12 summarizes the change of threshold ionization energy from the unit compounds to polymer solids. As stated above, the estimated values might not be very accurate, in particular for 1,2-PBD, PVC, and PVA. Nevertheless, Fig. 12 clearly shows how a change of thresholds depends on the class of polymers.

For polymers with the HOMO delocalized over the principal chain, an extention of the chain length decreases the threshold energy effectively by delocalization, as seen in PE and PP. Although we could not make a quantitative examination, compounds related to PVF should also follow this trend. This delocalization is the reason for the larger values of ΔI for PE, PP, and PVF in Table 1 than the other polymers. The introduction of methyl groups into a polymer chain in PP does not affect the thresholds, but we can expect some inductive effect by pendants with a very different electronegativity from carbon, (*e.g.* X=F). Such an inductive effect should be the main reason of the much larger I_s^{th} of PVF than that of PE and PP. Similar large I_s^{th}'s were also found for other fluoropolymers.[31] As seen in Table 5, the polarization energies of these polymers are a little smaller than those of other polymers. It may be partly due to the extended distribution of the positive charge over the chain.

In polymers with aromatic pendants, represented by PS, neither a chain extension beyond CH_3CH_2X nor a pendant-pendant interaction affects the threshold. This fact comes from the well-localized nature of the hole, and makes ΔI smaller than those of the other polymers in Table 1, although the polarization energy is a little larger than for the other polymers.

Other polymers with small nonaromatic pendants (1,2-PBD, PVC, and PVA) show an intermediate behavior between the two classes of compounds described above. A chain extension causes a small decrease in the threshold energy, owing to the inductive effect of the alkyl chain. The introduction of many pendants also results in some change, but its magnitude and sign depend on a balance between the pendant-pendant interaction and the inductive effect.

The above discussion shows that an analysis of the change of ionization energy at the transition from a unit compound to a polymer solid is a fairly complex task. Even the inversion of the order of the threshold energies happens among different polymers. Such a situation is much more complex than for the case of simple molecular solids, where the polarization energy is the only origin of a lowering of the threshold energy from a free molecule. However, as shown above, if the analysis is properly made, it gives a deep insight into the electronic structure of polymers.

We also note that a group of polymers with an intermediate delocalization is new in UPS studies regarding polymers. The polymers so far studied could be classified into two extreme cases where the HOMO is either well delocalized (PE and fully conjugated polymers such as polyacetylene and $(SN)_x$)[8] or well localized (vinyl polymers with aromatic pendants[5] and poly(*p*-phenylene-ethylene,[6] where benzene rings are in the principal chain). The present study shows that the degree of delocalization of the cationic state covers a wide range from almost complete localization to extensive delocalization.

The authors express their sincere thanks to Dr. Y. Achiba for the measurement of the photoelectron spectrum of 1,3-propanediol, and to Dr. N. Sato, Prof. J. Delhalle, and Prof. K. Ishii for helpful discussion. Chen Shang Xian is indebted to Yamada Science Foundation for financial support.

(Received June 4, 1984)

The catalytic activity of a copper(II) salt of polymolybdophosphoric acid ($Cu_{1.1}H_{0.8}PA$) for the reduction of NO with the supporting active carbon into N_2 and N_2O was studied at 400 °C using a fixed bed flow reactor. A considerable activity was observable at a stationary state where the spill-over of oxygen left on the active site of the acid to the carbon surface appeared to be rate-determining. The activity of the salt was much higher than for component oxides produced through its decomposition at higher temperatures. This suggested that the active site was characteristic to the salt (very probably the reduced site in the salt). The reaction mechanism in terms of the reaction paths, the N_2O/N_2 selectivity, and the roles of the supporting active carbon are discussed based on kinetic investigations.

A more efficient removal of the air pollutant, NO_x, has been explored in order to achieve a better environment at less cost.[1] The reduction of NO_x with the carbons (Eq. 1)

$$2NO + C \longrightarrow N_2 + CO_2 \quad (1)$$

can represent such a reaction and should be studied more since active carbon is an inexpensive reductant. Okuhara and Tanaka[2] and Inui *et al.*[3] have reported on the reactivities of several kinds of active carbons with NO catalyzed by alkali metal salts and complex oxides supported on them.

The present authors have reported on the reduction of NO_x on copper(II) salt of polymolybdophosphoric acid (CuHPA) which gain some reduced sites during preparation.[4] If the site oxidized by NO is properly reduced by transferring the left oxygen to the support where it is converted or liberated, the catalytic reduction of NO proceeds on the CuHPA. The soluble CuHPA can be easily recovered and regenerated when the support is greatly consumed.

In this study, the reduction of NO with some kinds of active carbon catalyzed by CuHPA was examined. The carbon can enlarge the effective surface area of CuHPA. The redox interaction of HPA with active carbon has been reported by Izumi *et al.*[5] and Baba and Ono.[6] The generation or activation of reduced sites by the carbon support can be expected through a catalyst-support interaction. The reactivity of the active carbon for such a reaction may attract other interests since the spill-over is one of the most important mechanisms regarding catalyst-support cooperation, which is a guide-line for the preparation of a better catalyst.

Experimental

Catalysts. 12-Molybdophosphoric acid ($H_3Mo_{12}PO_{40}$) was purchased from Nippon Inorganic Color and Chemical Co. The copper(II) salt in the form of $Cu_{1.1}H_{0.8}PA$ (CuHPA) was prepared using its corresponding metal carbonate according to a method described in the literature.[7] CuHPA was supported on to several kinds of active carbons (listed in Table 1 with some of their properties) from its methanol solution. The loading of the $Cu_{1.1}HPA$ was 10—33.3 wt%. Granules of 28—40 mesh (prepared by molding and crushing) were used for the catalytic reaction.

Reaction Procedure. The Reaction of NO or N_2O was carried out in a fixed bed flow reactor (8 mmϕ, Pyrex glass tube). The reactant gas contained 1.0% (1.01 kPa) of NO or 2.7% (2.74 kPA) of N_2O (Seitetsu Kagaku Co.). The catalyst weight and the total flow rate were 1.5—2.5 g and 100 $cm^3\,min^{-1}$, respectively. The gas composition was analyzed by a gas chromatograph using columns packed with Porapak (1 m) and Molecular Sieves 13X(2 m). The partial pressure of NO was varied from 1.0 (1.01 kPa) to 10 vol% (10.1 kPa) to observe the rate dependence on its pressure using a flow reactor under the conditions of the differential reactor.

Results

Reduction of NO over CuHPA/DA. The reactivity of NO with DA catalyzed by CuHPA (loading 33 wt%) is illustrated in Fig. 1, where the reaction temperature and the amount of carbon used were 400 °C, and 2 g, respectively. NO was reduced into N_2 and N_2O, producing carbon dioxide. Without CuHPA, the reaction rate was very slow, the conversion of NO being as low as 1.4% at the same temperature. The catalytic role of CuHPA is, thus, definite. NO of 1.2×10^{-2} mole was reduced by 3.4×10^{-4} mole of CuHPA within 20 h. The conversion of NO was initially as high as 65% and decreased, gradually, and leveled off at 17% at 6 h on stream.

The conversion after the initial 5 h was much larger than that observed with CuHPA on silica gel, indicating the favorable role of the active carbon. Carbon dioxide produced at this stage was less than expected from the conversion of NO (roughly 3/5), while the production of carbon dioxide at a steady state maintained the oxygen balance.

The yields of N_2 and N_2O at a steady state are compared to the contact time in Fig. 2. Both yields increased monotonously with an increasing contact time. However, a contact time greater than 4.7×10^{-2} min gave more N_2 at the expense of N_2O, suggesting a contribution from the consecutive reaction to the major competitive formation of N_2 and N_2O as described by Eq. 2.

(2)

The reactivity of DA catalyzed by CuHPA at several reaction temperatures is summarized in Table 2, where the reactivity is described by the stationary conversion observed with the flow reactor. The reactivity increased with an increasing temperature (from 300 to 400 °C), the activation energies for N_2 and N_2O formations being calculated to be 1.23 and 1.83 kJ mol^{-1}, respectively. Although the selectivity of N_2 formation

a) CuHPA/DA(loading: 33 wt%) 2 g, react. temp: 400 °C, feed: NO 1.0% in He carrier, 100 $cm^3 \cdot min^{-1}$, b) after the reaction at 500 °C for 28 h, c) CuHPA/DA (loading: 33 wt%) 0.5 g, react. temp: 300 °C, feed: NO 5%(H_2 5%) in He carrier, 100 $cm^3 \cdot min^{-1}$.

increased rather sharply with a rising reaction temperature, more N_2O was always produced than N_2 at these temperatures. Even if the consecutive conversion of N_2O was taken into account at a high conversion, the higher temperature appears favorable for the formation of N_2. It is very interesting that the reaction temperature of 450 °C provided a smaller conversion than that observed at 400 °C. More N_2 was produced at this temperature in spite of the smaller conversion than that at 400 °C. A higher temperature (500 °C) allow a high conversion (68%) almost exclusively into N_2. After a reaction at 500 °C for 28 h (where 22% of the carbon was consumed), the conversion became as low 3% at 400 °C. The level of the conversion was much lower than that of the same carbon at the same temperature without experiencing 500 °C. It was also noted that slightly more N_2 was produced in spite of the very low conversion. A significant change in the catalyst nature is suggested.

The reactivities of NO at different partial pressures is illustrated in Fig. 3. The reaction rates into N_2 and N_2O are plotted separately. In order to eliminate the

a) CuHPA/DA: 2 g, react. temp: 400 °C, feed: 100 $cm^3 \cdot min^{-1}$ (He carrier).

influence of a consecutive contribution, the conversions were kept below 10%. Both reaction orders in NO to produce N_2 and N_2O were *ca.* 0.5.

The stationary rate of NO reduction was proportional to the amount of supported CuHPA until the loading was 33.3% (Table 3). However, the ratio of N_2/N_2O produced decreased with the increasing loading in spite of the increased conversion where a more consecutive conversion of NO may take place. The catalyst density may influence the relative contribution of competitive reaction path which lead to N_2 and N_2O respectively.

The Reactivity of N_2O. The reactivity of N_2O against DA catalyzed by CuHPA (loading: 33.3%) is summarized in Table 4, where N_2O (2.7%) and N_2O-NO (2.2 and 1.0%, respectively) were examined. N_2O was very reactive at 400 °C, allowing its complete conversion into N_2 under similar conditions of NO reduction where the conversion of NO was 17%. The reactivity of N_2O appeared to be very much suppressed when NO was present (Table 4), while the reactivity of NO was almost unchanged by the presence of N_2O to provide an 18% conversion (NO base). To balance the N_2 produced, the conversion of N_2O was calculated to be only 2.3%.

The Reactivities of Several Kinds of Active Carbons Catalyzed by CuHPA. The conversions of several active carbons with and without the catalyst CuHPA are summarized in Table 1, where the loading and the reaction temperature were fixed at 33% and 400 °C, respectively. The reactivities of the active carbons without the catalyst were very low, the conversion being around 1.4% except for an active PAN-fiber. The conversion, when catalyzed, varied from 7.6 to 21%, carbon black showing the highest reactivity. The selectivity was also variable with the carbons, commercial active carbons of DA and SAC showing smaller selectivity for N_2 production than other carbons. The high reactivity and selectivity (to N_2) of active PAN-carbon-fiber without the catalyst needs to be noted. Details on its reactivity will be reported later.

IR Spectrum of CuHPA on DA. The IR spctra of CuHPA on DA before and after the reaction are illustrated in Fig. 4. By supporting on DA, the IR spectrum of CuHPA was slightly changed. Although the bands around 880 and 800 cm^{-1} somewhat shifted, other major bands were unchanged. The broadening

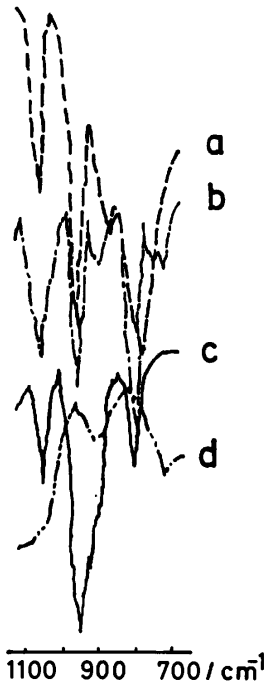

Fig. 4. IR spectra of catalysts after the reaction at several temperature.
a: CuHPA, b: CuHPA/DA, c: CuHPA/DA after the reaction at 400 °C, d: CuHPA/DA after the reaction at 500°C.

of these adsorption bands was observable after the reaction at 400 °C, but still major peaks were unchanged. In contrast, the reaction at 500 °C completely changed the spectrum and the sharp bands observable in the region became very broad or disappeared. The decomposition of CuHPA into component oxides is strongly suggested. The decomposition of CuHPA may take place between 400 and 450 °C.

Discussion

The catalytic activity of CuHPA in the reduction of NO with active carbon is comparable to those for mixed oxides[8] of copper and iron but much less than that for noble metals[3] supported on active carbon. The former catalyst has been reported to be very active for the NO-NH_3 reaction. An interesting observation is that the activity of CuHPA was much larger than that of its decomposed component oxides produced by heating to above 450 °C. Certain sites characteristic to the heteropoly acid appear to be active in this reaction.

In a previous study,[4] the acid supported on silica gel was reported to reduce NO to a limited extent (3.49×10^{-4} mole NO/mole acid within 20 h). Some reduced sites are induced in the acid during the preparation as ESR suggested. Such a reduced site may also be the active site for the present catalysis. NO is reduced by the site into N_2O and N_2, leaving oxygen. Oxygen, thus produced, may spillover to the carbon to produce carbon dioxide and to regenerate the reduced site in the acid. The high conversion during the initial 7—8 h may be partly due to the reduced sites induced prior to the catalysis, and partly due to the active portions of the carbon probably located in the vicinity of CuHPA. Because some portions of the former sites were irreversibly oxidized by NO, a smaller amount of CO_2 was produced than expected from the amount of consumed NO. The conversion decreased, corresponding to the decreasing number of the sites, to the stationary one, which is determined by the regeneration of the active site through the spill-over mechanism. It may be noted that the product from active carbon was only CO_2. Furusawa *et al.*[9] reported that CO_2 was formed by the reaction of NO with active carbon below 579 °C. The oxidation of active carbon may proceed *via* the formation of an oxygen-containing functionarity to form CO_2.[10,11]

The activity in the present reaction is much smaller than that of the reduction with hydrogen in spite of the similar mechanism.[4] This suggests that the rate of the oxygen spill-over onto the active carbon was inferior to that of the reductive regeneration of the active site. It is noted that similar product distributions were obtained in both reactions on the same support.

The reduction of NO on CuHPA supported on the active carbon proceeds into N_2O and N_2 through both competitive and consecutive paths as described in the Results. In spite of the high reactivity, N_2O remained in the product, suggesting its weaker adsorption to the active site. It can be easily converted into N_2 simply to extend the contact time.

The selectivity in the competitive paths is worth being discussed. The reaction kinetics suggest the dissociative adsorption of NO as the common intermediate for both N_2O and N_2, although the former product may require another NO molecule. Thus, the selectivity is determined by the respective rates of coupling of dissociatively adsorbed nitrogen with another nitrogen (to N_2) and NO (to N_2O), respectively. The superior formation of N_2 on the catalyst of low CuHPA loading even at the lower conversion may suggest the favorable geometry of active site for the N_2 formation. It has been reported that several reduced sites are produced in a unit cell of the heteropoly acid.[12]

The roles of active carbon are the support for the catalyst as well as the reductant. Through these two roles, the carbon influences the activity and selectivity of the present reaction. The reactivity of active carbon may be most influential on a stationary conversion, however the initial conversion, which is due to the reduced sites of CuHPA being induced during the catalyst preparation, is much higher on the active carbon than that on silica gel, suggesting a role of the

support in their generation. The redox interaction may attract for the study.[5,6,13] At present, the factors influencing the spill-over are difficult to discuss.

The selectivity is different among the used active carbons, high N_2 formation being noted on the PAN-ACF and the carbon black in spite of their similar conversions to those of the active carbons. Although the removal of N_2O is much easier than NO because of its thermodynamical unstability, such carbons may provide the better catalysts for the conversion of NO to N_2. The support may influence the geometry of the active sites in the supported CuHPA through a magnetic interaction.

Spirolactone of Xanthene. II.[1] Synthesis and Molecular Structure of 2′,5,7′-Trichlorospiro[benzofuran-3(2*H*),9′-[9*H*]xanthen]-2-one

Michio KIMURA
Niigata College of Pharmacy, 5829 Kamishin'ei-cho, Niigata, 950-21
(Received July 12, 1984)

The title compound has been synthesized by the novel condensation reaction of *p*-chlorophenol with oxalic and sulfuric acids; its crystal and molecular structures have been determined by the single crystal X-ray diffraction method. The space group is $C2/c$. There are eight molecules of the title compound in the unit cell of dimensions a=21.316(9), b=17.267(4), c=9.158(6) Å, and β=94.05(5)°. The structure was solved by the direct method and refined by the block-diagonal least-squares method to a value of 0.088 for R using 1993 independent observed reflections with $F_o > 3\sigma(F_o)$. The molecule possesses three phenyl rings fused to spirolactone and the dihedral angles between the phenyl rings are 73.60°, 83.60°, and 22.81°.

In a previous communication,[1] it has been reported that, in the studies of the reactivity of xanthene, the reaction of 1-naphthol with oxalic and sulfuric acids accompanying the loss of four molecules of water gave a novel spirolactone (**1**) of dibenzo[*c*,*h*]xanthene in excellent yield (70—75%), and the molecular structure of **1** has been established by the single crystal X-ray diffraction method (Cu $K\alpha$ radiation) as shown in Fig. 1. In order to increase the examples of this novel reaction and to get some information about the reaction mechanism, further studies concerning the synthesis of derivatives were performed by utilizing substituted phenols in place of 1-naphthol. Reaction of *p*-chlorophenol with oxalic and sulfuric acids gave the corresponding novel spirolactone (**3**), whose molecular structure could not be well established on the basis of chemical and spectroscopic data described in the experimental section. Accordingly, the X-ray analysis of **3** has been undertaken in order to elucidate the correct structure. The established molecular structure for **3** resembles the well known fluoran (**5**),[2] except for the lactone moiety, which is formed by the reaction of phenols with phthalic anhydride in the presence of dehydrating agents as in Scheme 1 (fluorescein if R is OH in **5**).

Experimental

*Preparation of 2′,5,7′-Trichlorospiro[benzofuran-3(2*H*),9′-[9*H*]xanthen]-2-one (3).* To a mixture of *p*-chlorophenol (11.0 g) and oxalic acid (8.0 g), conc. sulfuric acid (8.0 g) was added cautiously, and the resulting mixture was heated gently for 4 h at 140—145 °C in an oil bath. After cooling,

Collection and Reduction of Crystallographic Data. The crystal selected for the measurement of the lattice parameters and intensity data was a cleaved fragment which had approximate dimensions of 0.20×0.15×0.25 mm. A preliminary examination of the crystal carried out on a Rigaku AFC diffractometer showed it to be monoclinic. Systematic absences of $h+k=2n+1$ for hkl and $l=2n+1$ for $h0l$ showed the space group to be ***Cc*** or ***C2/c***. The correct space group was later confirmed to be ***C2/c*** by the successful refinement of the structure. The unit cell parameters at room temperature were refined by the least-squares method using the Bragg angles (Cu $K\alpha$ λ=1.54178 Å) of thirty reflections ($20°<2\theta<35°$). The unit cell dimensions and other data are summarized in Table 1. Intensity data were collected at room temperature on the Rigaku AFC diffractometer utilizing nickel-filtered Cu $K\alpha$ radiation. The $2\theta-\omega$ scans were employed with a scan speed of $4°min^{-1}$ in 2θ and scan range which was varied by $1.2°+0.15°\tan\theta$. Background counts were taken at both ends of the scan with a displacement of 3.0° from the $K\alpha$ peak; the time of each measurement was one-third of the scan time. A total of 2823 unique reflections was measured in the range of $0°<2\theta<120°$. The intensities of three standard reflections were measured after every 57 reflections; three intensities dropped by an average of a few percent over the period of data collection, but no correction factor was applied because the decrease was not considered significant. Lorentz and polarization corrections were applied to convert intensities to structure amplitudes, but no absorption corrections were applied. Standard deviations in the structure amplitudes, $\sigma(F_o)$, were derived from counting statistics.

Solution and Refinement of the Structure. The structure was solved by the direct method using MULTAN[3] to calculate phases for the 300 reflections with $|E_o|>1.60$. The *E*-map computed from the phases with the largest combined figure of merit (2.59) revealed all the non-hydrogen atoms. The 1993 observed reflections for which $|F_o|$ were greater than $3\sigma(F_o)$ were used for the block-diagonal least-squares refinement of the structure. The function minimized was $\Sigma w(|F_o|-|F_c|)^2$, where w is the unit weight for $0<|F_o|\leq 20$ and $w=(20/|F_o|)^{-2}$ for $|F_o|>20$. An initial refinement using individual isotropic temperature factors for the non-hydrogen atoms led to a conventional $R=(\Sigma||F_o|-|F_c||)/\Sigma|F_o|$ of 0.143. After the successive refinement with the anisotropic temperature factors for all the non-hydrogens, all the hydrogen atoms were readily located from the difference Fourier map. In the further refinement positional and isotropic thermal parameters for the hydrogen atoms were included. The refinement, after 6 cycles of block-diagonal least-squares calculation, converged to an *R* of 0.088 and a weighted $R_w=(\Sigma w(|F_o|-|F_c|)^2/\Sigma w|F_o|^2)^{1/2}$ of 0.088. An extinction parameter was refined because extinction effects were considered significant. The refinement was completed when the largest shift in any parameters among the non-hydrogen atoms was less than 0.01% of standard deviations, while the largest shift for the hydrogen atoms was 0.09%. The final positional and thermal parameters† are given in Table 2. The largest peak in the final difference map, 0.2 eÅ^{-3}, was located near the chlorine atoms. The atomic scattering factors for Cl, O, and C were those of Cromer and Weber[4] and for H, the

scattering factors of Stewart, Davidson, and Simpson[5] were used. Computations were performed by the crystallographic program system UNICS.[6]

Discussion

The molecular structure and the labeling sequence of **3** is presented in the ORTEP drawing of Fig. 2. The molecule of **3** has a T-like shape with the benzofuranone moiety nearly perpendicular to the xanthene plane. The gross molecular conformation and the configuration around the spiro-carbon atom (C1) of **3** are similar to the corresponding part of **1**. The bond distances and angles of **3** are presented in Table 3. The average C-C bond lengths in the benzene rings A, C, and E are 1.376, 1.391, and 1.392 Å, respectively, which are normal compared with the values usually found for the C-C distances in aromatic rings (1.395 Å). In Fig. 3 the geometry of the important parts of **3** and of fluorescein are compared. In fluorescein,[2] the bond length (1.525 Å) between the spiro-carbon and oxygen atoms (corresponding to C1-C16 in **3**) is exceptionally long and indicates weakness in the bond which is consistent with the behaviour of fluorescein in solution, where the ready cleavage of that bond yields the fluorescent zwitterion isomer (as shown in Scheme 1). On the other hand, the distance of C1-C23 in **3** (1.482 Å) is typical of C-C sp^2—sp^3 bond, and does not show comparable weakness of the bond. In comparison with related compounds with three fused rings, two C-O bond distances (C7-O8=1.411 and C9-O8=1.389 Å) in

ring D of **3** are comparable with 1.382 and 1.369 Å of 4-azaphenoxathiin,[6] 1.401 and 1.386 Å of phenoxathiin,[7] and 1.378 and 1.377 Å of fluorescein[2] within the experimental errors.

In Table 4 the best least-squares planes are given together with the displacement of the atoms from the best planes. The lactone ring B is coplanar with ring A, and its orientation is almost perpendicular to the xanthene ring, which is similar to that observed in **1**.[1] The dihedral angles between rings A—C, rings A—E, and rings C—E are 73.6°, 83.6°, and 22.81°, respectively, which may be compared with those of **1** (81.4°, 86.9°, and 5.9° in order).[1] The great difference in the butterfly angles of the xanthene rings in **1** and **3** (22.81° and 5.9°) seems to be caused by electron-withdrawing effects of the chlorine atoms and the lesser steric hindrance of the phenyl ring of **3** in comparison with the bulky naphthalene ring of **1**.

fluorescein[2]

Fig. 3. The selected bond lengths and angles around the spiro carbon atom of **3** and fluorescein. The standard deviations are described in Table 3.

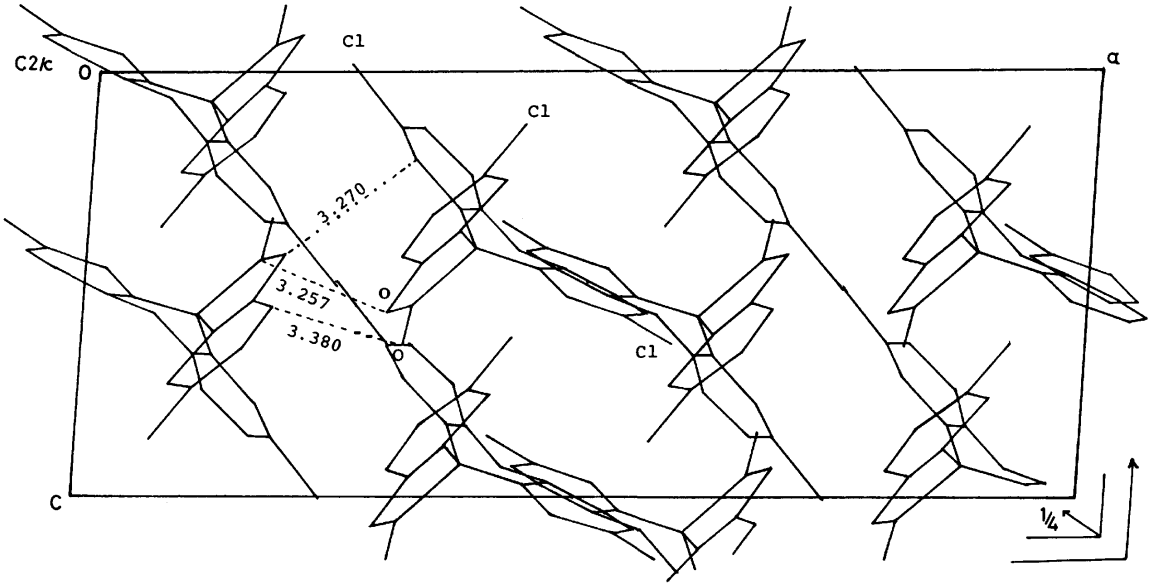

Fig. 4. Projection of the structure along the b-axis.

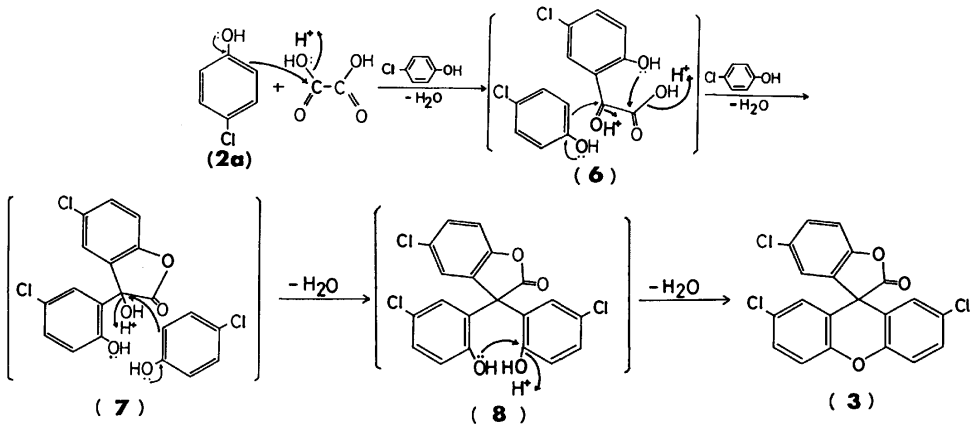

Scheme 2.

On the other hand, the corresponding value of 9.4° for fluorescein is comparable with that of **1** (5.9°). The projection of the crystal structure along the b-axis is shown in Fig. 4, and the shortest intermolecular distances are given in Table 5. There are no unusually close contacts of atoms in the unit cell, and all the intermolecular van der Waals distances are larger than 3.26 Å.

As the molecular structure of **3** has been elucidated by the X-ray diffraction method, a plausible reaction mechanism leading to the formation of **3** could be infered as shown in Scheme 2. The initial step probably involves a Friedel-Crafts type reaction between phenols (**2a**) and oxalic acid to form the oxalophenols (**6**). Subsequently, the nucleophilic attack of another phenols (**2a**) to the protonated carbonyl carbon atom of **7** forms the intermediates (**8**) with three phenol rings connected by the lactone moiety. Further, the intermediates (**8**) proceed by the intramolecular cyclization to the xanthene ring accompanying the loss of one molecule of water to reach **3**. Thus the reaction mechanism to form **3** seems to be based on the nucleophilic approach of the electron localized ortho-position of phenols to the carbonyl carbon atom, which results in the loss of four molecules of water.

Identification of the Adsorbate Formed on a Platinum Electrode from Methanol

Hiroshi MATSUI,* Takeo HISANO, and Toshio TERAZAWA
Department of Applied Chemistry, Faculty of Engineering, The University of Tokushima, Minami-josanjima-cho, Tokushima 770
(Received August 3, 1984)

The kind of carbon-containing adsorbate formed on a platinum electrode from methanol in an acid medium was identified by an electrochemical method. Certain improvements were made in view of the harmful effects of the following factors on the Q^F value, the quantity of electricity required to form adsorbate. The factors: a) The amounts of dissolved oxygen in both solution and electrode itself; b) the concurrent oxidation of the adsorbate in the adsorption process; and c) the presence of by-products of the methanol oxidation, formaldehyde and formic acid. By appropriate procedures, these effects could be minimized or corrected. The ratio Q^F/Q^{ox}, where Q^{ox} was an electric quantity required to oxidize completely that amount of adsorbate corresponding to the Q^F, was found to be 1.8—2.0 when the potential was 0.30—0.54 V, and the methanol concentration 0.005—1 mol dm^{-3}. It was thus concluded that the adsorbate was almost exclusively CO_{ad}.

Different conclusions have been reported about the kind of carbon-containing adsorbate (M_{ad}) formed on a Pt electrode from methanol in acid media. The adsorbates proposed are COH_{ad},[1-7] CO_{ad},[8] a mixture of COH_{ad} and $COOH_{ad}$,[9] *etc.*,[10-11] but most investigators[12] seem to support the conclusion that COH_{ad} is, at least, the dominant species. Most of these conclusions were drawn from electrochemical data, such as the quantities of electricity participating in the formation (Q^F) and subsequent oxidation (Q^{ox}) of the adsorbate. More recently, B. Beden *et al.*[13,14] have identified CO_{ad} as the adsorbate by means of their newly developed technique[14,15] capable of observing *in situ* the vibrational IR spectra of an adsorbate on a Pt electrode. They claimed that there was no spectroscopic evidence for COH_{ad} under their experimental conditions.

Although such spectra would directly indicate the molecular structure of an adsorbate, the traditional electrochemical procedures seem to have an advantage of permitting wider experimental conditions.

The disagreement among investigators about the kind of adsorbate could have resulted from some small but decisive differences in their experimental electrochemical methods. D. Pletcher *et al.*,[16] for example, emphasized recently that the pretreatment of a Pt electrode surface crucially determined the experimental data about the methanol oxidation.

The present paper describes the disturbing effects of the following factors on the value of Q^F. a) Dissolved oxygen present in solution and inside the Pt electrode itself. b) Oxidation of the adsorbate accompanying the adsorption. c) Formaldehyde or formic acid, a possible by-product in the methanol oxidation. By using appropriate procedures in which these disturbing effects on Q^F were minimized or corrected, an electrochemical identification of the adsorbate in question was carried out. It was concluded that the adsorbate was almost exclusively CO_{ad} when the electrode potential was 0.30—0.54 V, the methanol concentration 0.005—1 mol dm^{-3}, and the temperature 0 °C.

Experimental

Test Electrodes. Q^F values were determined by the graphical integration of current-time curves for the M_{ad} formation process, and Q^{ox} values by the anodic pulse method of Breiter *et al.*[17,18] immediately after the adsorption process.

Generally, a large surface area is suitable for measuring small current densities in M_{ad} formation, but a very large pulse current is required to oxidize the M_{ad}. In order to facilitate the measurements of Q^F and Q^{ox} at a single electrode, one of the three test electrodes with roughness factors of about 1, 6, and 44 was used depending on the methanol concentration ranges of 2—1, 0.5—0.3, and below 0.2 mol dm^{-3}, respectively.

To prepare these roughened electrodes, platinum wires of 99.99% purity and 3×10^{-5} m^2 geometrical surface area each were platinized, then heat-treated at 300 or 500 °C in a hydrogen stream. The heat-treatment was necessary in order a) to remove oxygen in the metal itself; b) to prevent the coated Pt black from falling off; and c) to smooth the sharp regions of the Pt-black so that the distribution of currents might not become too uneven.

Electrolysis Cell. The cell consisted of three compartments. The first had a test electrode, around which a spiral platinum wire was concentrically placed as a counter electrode. This pair of electrodes was used to measure Q^{ox} by the pulse method. In the second compartment connected to the first by a narrow glass tube, another counter electrode was placed to keep the test electrode at a desired potential in co-operation with a potentiostat. The narrow tube served to suppress the migration of products formed at the counter electrode toward the test electrode. A palladium-hydrogen reference electrode[19] was in the third compartment connected to the first by way of a Teflon stopcock, which was closed during the deoxygenation of the solution in the other compartments under reduced pressure.

All the potentials described here were referred to a reversible hydrogen electrode in the same solutions.

Potential-pulse Sequence. A potential sequence used for the measurement of Q^F and Q^{ox} is shown in Fig. 1,

differing mainly in the pretreatment of the electrode from those used by Bagotzky[3,20] and Biegler.[8,11]

Effects of dissolved oxygen were serious as shown in Fig. 2, where the electrode had a roughness factor of about 44. In the normal experiments, the solutions were deoxygenated under reduced pressure for 1 min and subsequently by nitrogen-gas bubbling for 30 min through fritted-glass disks (Step A in Fig. 1). Most of the dissolved oxygen remaining in the vicinity of the test electrode was removed during Step B, in which the potential was kept at 0.06 V for 5 min. By this procedure the current for oxygen reduction in the base solution, 0.5 mol dm^{-3} sulfuric acid, was confirmed to have diminished to about 10^{-4} A m^{-2} with a roughened electrode. For a smooth electrode, the effect of oxygen was difficult to minimize to this extent as is indicated in Curve 4 of Fig. 2. Consequently, the electrode was used only when the observed current for M_{ad} formation was larger than the residual reduction current of the dissolved oxygen remaining. In other words, it was used only when the methanol

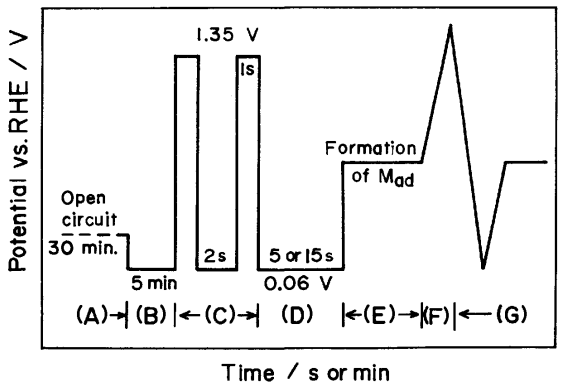

Fig. 1. Potential sequence for measurements of Q^F and Q^{ox}, A) Deoxygenation under reduced pressure and sudsequent N_2 bubbling, B) Reduction of remaining oxygen, C) Cleaning of electrode surface, D) Reduction of surface oxides and removal of oxidation products, E) M_{ad} formation and Q^F measurement, F) Q^{ox} measurement, G) for next run.

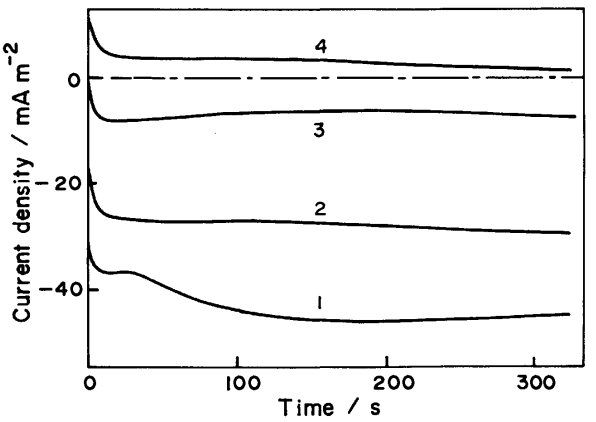

Fig. 2. Current decay on roughened electrode at 0.30 V in 0.03 mol dm^{-3} CH_3OH+0.5 mol dm^{-3} H_2SO_4 solution containing dissolved oxygen, Solution was saturated with air, oxygen was removed by degassing under reduced pressure and subsequent N_2 bubbling for: 1) 0; 2) 5; 3) 7; 4) 30 min.

concentration was higher than 1 mol dm^{-3}. The test electrode underwent final cleaning-up at Step C and D. At 1.35 V, platinum oxides were formed, and most of the M_{ad} were removed by oxidation; at 0.06 V the platinum oxides were reduced without evolution of free hydrogen. The double rectangular pulses in Step C served to remove M_{ad} completely and to prevent the formation of a deep layer of surface oxides. A small amount of by-products, which might be formed at 1.35 V and at high concentrations of methanol, were allowed to diffuse away during Step D (0.06 V), the duration of which was 5 or 15 s. The longer duration was favorable for the complete disappearance of a non-steady current produced in the transit from C into D Steps. The shorter one, however, was superior at methanol concentrations above 0.3 mol dm^{-3}, because the amount of M_{ad} formed even at this low potential became perceptible at longer times. To diminish such concomitant events, all the measurements were made at a low temperature of 0 °C.

The potential sequence was generated by means of a LB-75 M Wenking potentiostat and a handmade pulse generator. In the measurement of Q^F, the currents at Step E were stored in a HR-1200 transient converter (Kawasaki Electronics), which had a decimal 12-bit resolution, and recorded on a WX-4401 XY recorder (Watanabe Instruments Corp.,).

All the current densities described are for a unit true area of electrode surface, determined by the conventional hydrogen deposition method. In the measurement of Q^{ox} (Step F), the scan rates were 263, 99.4, and 27.6 V/s in the methanol concentration ranges of 2—1, 0.5—0.3, and below 0.2 mol dm^{-3}, respectively. Under these conditions, the observed currents were almost exclusively due to the oxidation of M_{ad}.

Results and Discussion

As most investigators[1-5,8,11] approve, the formation of an experimentally perceptible adsorbate from methanol in acid solution and the oxidation of the adsorbate may well be written as

$$M_{ad} \text{ formation: } CH_3OH = M_{ad} + n_1H^+ + n_1e \quad (1)$$

$$M_{ad} \text{ oxidation: } M_{ad} + H_2O = CO_2 + n_2H^+ + n_2e \quad (2)$$

M_{ad} denotes a carbon-containing adsorbate, n_1 and n_2 are the number of participating electrons. It should be noted that the equations do not necessarily represent the only path for methanol oxidation. According to the Eqns., $n_1+n_2=6$. If M_{ad} is, *e.g.*, CO_{ad} or COH_{ad}, n_2 should be 2 or 3, respectively. The ratio $n_1/n_2=Q^F/Q^{ox}$, where Q^F is a quantity of electricity required to form an amount of M_{ad}, and Q^{ox} is that required to oxidize this amount of M_{ad} to carbon dioxide.

Determination of Q^F *by Experimental* i-t *and* Q^{ox}-t *Relationships.* It is no doubt a prerequisite for obtaining a correct value of Q^F by integration of an experimental *i-t* relationship in the adsorption process that the *i* is solely due to the adsorption. As the criterion, previous investigators[3,8,11] employed either of the following theoretical *i-t* relationships:

$$i = k_1/t \quad (3)$$

$$1/i = 1/i_0 + k_2 t \quad (4)$$

where k_1 and k_2 are constants. Equation 3 was derived by Bagotzky *et al*,[3,8,11] by using the next relation.

$$\theta_M = a + b \ln t \quad (5)$$

where a and b are constants, and θ_M is a surface coverage with M_{ad}. They assumed that θ_M was in direct proportion to the number of M_{ad} species. The assumption, however, is not always correct, because every M_{ad} might not always occupy the same number of sites on the electrode surface; the details of which will be reported later. Thus, we prefer to use Q^{ox} instead of θ_M,

$$Q^{ox} = a' + b' \log t \quad (6)$$

where a' and b' are constants. When the values of Q^{ox}/Q_H^0 are within the range about 0.1 to 0.9, Eq. 6 is valid as shown in Fig. 3. Instead of Q^{ox}, Q^{ox}/Q_H^0 is used for convenience of comparison with other data, Q_H^0 being a quantity of electricity required fully to cover the surface with a monolayer of adsorbed hydrogen atoms. According to Eq. 6 or 5, Q^{ox} approaches minus infinity as t approaches zero, while it is required for the derivation of Eq. 4 that Q^{ox} approaches zero. It thus appears that Eq. 3 is preferable to Eq. 4.

Figure 4 shows typical *i-t* relations observed for the adsorption process under the same conditions as in Fig. 3. A linear part with a slope of −0.99 is seen in any curve obtained at a potential within the limits of 0.30—0.48 V, *e.g.*, the latter parts of curves 4 and 5, indicating the validity of Eq. 3. On the other hand, the former parts of the curves at low potentials show considerable deviations from that linear relation, and the lower the potential, the larger becomes the deviation. Although it might be ascribed to a change in the kinetics of adsorbate formation, the nature of the currents remains unknown. However the contributions of the currents to the value of Q^{ox} were so small that treating them as genuine adsorption currents brought no serious errors in obtaining the Q^F—Q^{ox} relationship (Fig. 6).

At potentials above 0.48 V, appreciable and stationary currents were observed even after 30 min from the start of adsorption. If adsorption on a electrode surface is completed, the adsorption current should fall to zero. Consequently, these stationary currents might be considered to be due to both the stationary oxidation of the adsorbate and, in some cases, the formation of by-products. Thus, the net adsorption currents at every moment were estimated by subtracting the stationary current still flowing at 30 min after the start of adsorption from the observed current.

Effects of Formaldehyde and Formic Acid on Q^F *and* Q^{ox}. Breiter *et al.*[21,22,23] reported that appreciable amounts of formaldehyde and formic acid were formed during the oxidation of methanol in acid so-

lution in which the concentration of methanol was relatively high. The effects of these substances on the *i-t* curves for M_{ad} formation process were significant even in their very low concentrations. Figure 5 shows how the presence of formaldehyde increases both the currents and the slopes of the log *i*—log *t* curves. The resulting Q^F were obviously larger than those in the absence of the aldehyde. Its presence, on the other hand, had only a small effect on the values of Q^{ox}, thus resulting in an increase in the Q^F/Q^{ox} values. The effects of formic acid were similar to those of formaldehyde. These contaminants originally present in methanol reagent can readily be removed. However there is no way of removing the substances that are unavoidably formed during the pretreatment for cleaning the electrode surface by potential pulses. Consequently, it seems best to design a pulse sequence which produces only as small amounts of these substances as possible. Such is the case with the sequence described in the experimental section. In addition, it was confirmed that[23] regardless of the potential the formation of these by-products only became perceptible, when the methanol concentration was above about 1 mol dm^{-3}. Their formation at a constant potential should be accompanied by a stationary current. Therefore, the background-current correction to obtain the net adsorption current would also eliminate that stationary current so long as the amount of by -products are not too large.

Q^F-Q^{ox} *Relationship.* Figure 6 shows the typical Q^F-Q^{ox} relations for the adsorption process under the same conditions as those in Figs. 3 and 4. There is a straight line relationship with a slope, Q^F/Q^{ox}, close to 2. In spite of the background-current corrections, upward deviations from linearity took place when the potential was above 0.48 V, while at the same time the Q^{ox} value was large. The cause of such deviation remains unknown. Figure 7 shows the variation in the slope of the linear part with potential. Within the potential range of 0.30—0.54 V, the slope varied only slightly, the average being 1.84. Biegler *et al.*[11] had reported that the slope depended on the potential. The virtual invariance of the slope value can be largely attributed to the current correction, which Biegler *et al.* did not made. The effects of methanol concentration on the slope value are illustrated in Fig. 8. In this instance the potential was 0.42 V, at which no background current was observed. The slope varied only slightly over a wide range of methanol concentration, 0.005—1 mol dm^{-3} the average being 1.89. Higher potentials resulted in slightly larger slopes. Lower potentials also led to slightly smaller values, and moreover narrowed the methanol-concentration range in which the slope remained practically constant.

As described above, the slope is almost constant over the considerably wide ranges of M_{ad}-formation time, potential, and methanol concentration. This fact indicates that only one kind of M_{ad} species is formed. As the M_{ad}, CH_3O_{ad}, CH_2O_{ad}, COH_{ad}, CO_{ad}, or $COOH_{ad}$ is to be expected from Eqs. 1 and 2, if the slope is 1/5, 1/2, 1, 2, and 5, respectively. Because the slope is close to 2, it is concluded that the adsorbate should almost exclusively be CO_{ad}, at least, under those conditions which have hitherto been specified. A slight deviation of the

A Relation between Oxidation State of Sulfur and Acidic Property of Iron Oxide Containing Sulfur

Yoshinori NAGASE, Tuo JIN, Hideshi HATTORI, Tsutomu YAMAGUCHI, and Kozo TANABE*

Department of Chemistry, Faculty of Science, Hokkaido University, Sapporo 060

(Received August 13, 1984)

Five kinds of iron oxide catalysts promoted with sulfur were prepared by impregnating $Fe(OH)_3$ with $(NH_4)_2SO_4$ and by treating Fe_2O_3 and $Fe(OH)_3$ with H_2S and SO_2. Changes in acidic properties of the catalysts with changes in oxidation states of sulfur were investigated by test reactions such as isomerization of cyclopropane and dehydration of 2-propanol over the oxidized or reduced catalysts. It has been found that the generation of acidic properties of the catalysts was independent of the kinds of the starting sulfur compounds, but dependent on the oxidation states of the sulfur. The sulfur in the highest oxidation state was responsible for the strongly acidic property of the catalyst.

It has been reported recently that the iron oxide catalyst promoted with SO_4^{2-} ion exhibited high catalytic activities for the isomerization of cyclopropane and the dehydration of 2-butanol.[1] It was also found that this type of catalyst was quite effective for a coal liquefaction under a high hydrogen pressure and at a high temperature.[2] High catalytic activities in the former reactions were attributed to the enhanced acidic properties of the promoted catalysts, which originated from a strongly electrophilic nature of S=O bonds of sulfur species bound on the surface.[1] In the latter reaction, however, the Fe_2O_3–SO_4^{2-} catalyst is considered to be reduced with hydrogen to lose the high acidic property as well as the catalytic activity. Therefore, it is necessary to examine the influence of the oxidation state of sulfur on the acidic property of Fe_2O_3 containing sulfur. This report deals with whether H_2S and SO_2, besides SO_4^{2-}, as sulfur sources are effective for enhancing the acidic property and how such a property changes when the oxidation state of sulfur is controlled.

Experimental

Catalyst Preparation. Iron oxide and hydroxide were prepared by the hydrolysis of $Fe(NO_3)_3$ with aqeous ammonia. The sulfur promoted catalysts were prepared by adsorbing inorganic sulfur compounds on iron hydroxide or oxide, followed by calcination, reduction, and oxidation. The Fe_2O_3 (A)–SO_4^{2-} catalyst was prepared by immersing $Fe(OH)_3$ in an aqueous solution of $(NH_4)_2SO_4$, followed by drying at 110 °C and calcining at 500 °C. The amount of sulfur loaded was adjusted to about 2 wt% as SO_3. The Fe_2O_3 (A)–H_2S and Fe_2O_3 (A)–SO_2 catalysts were obtained by treating $Fe(OH)_3$ with 1200 Pa of H_2S and SO_2. The Fe_2O_3 (B)–H_2S and Fe_2O_3 (B)–SO_2 catalysts were obtained by treating Fe_2O_3 instead of $Fe(OH)_3$ similarly as above. Treating temperature is denoted as Fe_2O_3 (A)–H_2S-400 (Fe_2O_3 (A) treated with H_2S at 400 °C). When the catalyst was oxidized with O_2 at 500 °C, it is denoted as Fe_2O_3 (A)–H_2S-400–O_2-500. Catalyst nomenclature is illustrated in Table 1. Prior to the reaction, some of the catalysts treated with H_2S and SO_2 were oxidized with O_2 at 400 to 500 °C for 10 min and evacuated at 500 °C, and some of the Fe_2O_3 (A)–SO_4^{2-} catalysts were reduced with hydrogen at 350—500 °C.

Table 1. Catalysts treated with sulfur compounds by different methods

Catalyst nomenclature	Source of sulfur	Supporting method	Temperature of gas treatment/°C
Fe_2O_3	None	—	Untreated[a]
Fe_2O_3(A)-SO_4^{2-}	$(NH_4)_2SO_4$	Impregnation	Untreated[a]
Fe_2O_3(A)-SO_4^{2-}-H_2-350	$(NH_4)_2SO_4$	Impregnation	350 with H_2
Fe_2O_3(A)-SO_4^{2-}-H_2-400	$(NH_4)_2SO_4$	Impregnation	400 with H_2
Fe_2O_3(A)-SO_4^{2-}-H_2-500	$(NH_4)_2SO_4$	Impregnation	500 with H_2
Fe_2O_3(A)-H_2S-400	H_2S	Gas treatment	400 with H_2S
Fe_2O_3(A)-H_2S-400-O_2-500	H_2S	Gas treatment	400 with H_2S and 500 with O_2
Fe_2O_3(B)-H_2S-400	H_2S	Gas treatment	400 with H_2S
Fe_2O_3(B)-H_2S-400-O_2-500	H_2S	Gas treatment	400 with H_2S and 500 with O_2
Fe_2O_3(A)-SO_2-400	SO_2	Gas treatment	400 with SO_2
Fe_2O_3(A)-SO_2-400-O_2-500	SO_2	Gas treatment	400 with SO_2 and 500 with O_2
Fe_2O_3(B)-SO_2-400	SO_2	Gas treatment	400 with SO_2
Fe_2O_3(B)-SO_2-400-O_2-500	SO_2	Gas treatment	400 with SO_2 and 500 with O_2

a) Untreated with any gas, but calcined in air at 500 °C.

The Fe_2O_3 (B)-SO_4^{2-} was prepared by the hydrolysis of iron alum with urea as described in our previous paper.[1] The amount of sulfur loaded was 6 wt% as SO_3. The Fe_2O_3 (B)-SO_4^{2-} catalyst was used for 2-propanol dehydration. For a series of the experiments, the catalyst was evacuated at 500 °C, reduced with a stream of hydrogen at different temperatures, and then evacuated again at the same temperature of reduction. In the case of the catalyst reduced below 200 °C, the final evacuation was performed at 200 °C. For the other series of experiments, the catalysts were treated as in the cases of the first series of experiments and then oxidized with flowing air at 500 °C for 1 h, followed by evacuation at 500 °C.

Measurement of Surface Area. Specific surface area was determined by the BET method using nitrogen.

Measurement of Sulfur Content. The atomic ratios of S/Fe in the catalysts reduced at different temperatures were determined by X-ray fluorescent spectroscopy on the basis of the samples of known S/Fe ratios.

Reaction Procedure. Isomerization of cyclopropane was carried out at 150 °C by use of 0.2 g of catalyst in a closed recirculation apparatus of 800 ml capacity which was equipped with a sampling manifold. A 6,670 Pa of cyclopropane was used. The reaction of 2-propanol was carried out at 200 °C in a closed recirculation apparatus of 266 ml capacity, 4,000 Pa of 2-propanol being passed through 0.2 g of a Fe_2O_3-SO_4^{2-} catalyst. The product was only propene.

Results and Discussion

Isomerization of Cyclopropane. Isomerization of cyclopropane to yield propene is known to be one of the best reactions for examining acidic properties of solid acid catalysts.[3,4] The rates of the isomerization over the Fe_2O_3 catalysts treated with $(NH_4)_2SO_4$, H_2S or SO_2 and then with H_2 or O_2 are summarized in Table 2. The Fe_2O_3 catalyst was inactive, but became active when treated with $(NH_4)_2SO_4$ in accordance with our previous work.[1] However, the activity of Fe_2O_3 (A)-SO_4^{2-} decreased on reduction with H_2 at 400 °C and lost the activity completely when reduced with H_2 at 500 °C. Thus, the oxidized state of SO_4^{2-} is considered to be essential for the generation of acidity of the catalyst.

Table 2. Catalytic activities for isomerization of cyclopropane

Catalyst	Rate of reaction 10^{-5} mol min^{-1} g^{-1}
Fe_2O_3	0
Fe_2O_3(A)-SO_4^{2-}	30
Fe_2O_3(A)-SO_4^{2-}-H_2-350	34
Fe_2O_3(A)-SO_4^{2-}-H_2-400	15
Fe_2O_3(A)-SO_4^{2-}-H_2-500	0
Fe_2O_3(A)-H_2S-400	0
Fe_2O_3(A)-H_2S-400-O_2-500	30
Fe_2O_3(B)-H_2S-400	0
Fe_2O_3(B)-H_2S-400-O_2-500	28
Fe_2O_3(A)-H_2S-500	0
Fe_2O_3(A)-H_2S-500-O_2-500	7
Fe_2O_3(B)-H_2S-500	0
Fe_2O_3(B)-H_2S-500-O_2-500	6
Fe_2O_3(A)-SO_2-400	0
Fe_2O_3(A)-SO_2-400-O_2-500	44
Fe_2O_3(B)-SO_2-400	0
Fe_2O_3(B)-SO_2-400-O_2-500	35
Fe_2O_3(A)-SO_2-500	0
Fe_2O_3(A)-SO_2-500-O_2-500	32
Fe_2O_3(B)-SO_2-500	0
Fe_2O_3(B)-SO_2-500-O_2-500	32

In the case of Fe_2O_3 treated with H_2S or SO_2 at 400 °C, no catalytic activity was observed. However, the Fe_2O_3-H_2S and Fe_2O_3-SO_2 catalysts exhibited almost the same activity as that of Fe_2O_3-SO_4^{2-} when oxidized with O_2. The difference between Fe_2O_3-H_2S and Fe_2O_3-SO_2 was that Fe_2O_3 treated with H_2S at 500 °C followed by oxidation with O_2 showed a low activity ($6—7\times10^{-5}$ mol min^{-1} g^{-1}), whereas Fe_2O_3 treated with SO_2 at 500 °C followed by oxidation with O_2 showed almost the same activity (32×10^{-5} mol min^{-1} g^{-1}) as that of Fe_2O_3 (A)-SO_4^{2-}. Thus, the temperature of treatment with H_2S is important to generate the activity after the oxidation in the case of H_2S-treated catalysts.

The data of Table 2 clearly indicate that the introduction of any kinds of sulfur compounds causes the enhancement of the activity for the acid-catalyzed reaction, provided that the sulfur-treated catalysts are oxidized, whatever the source of sulfur is. Since the high catalytic activities of Fe_2O_3-SO_4^{2-} for the acid type reactions were attributed to strong acid sites created by the electron-attracting property of S=O bonds of a sulfur species like $>S\lesssim^{O}_{O}$ on the surface,[1] H_2S and SO_2 are considered to be converted into the sulfur species by oxidation. In other words, the highest oxidation state of sulfur (S^{6+} in the $>S\lesssim^{O}_{O}$) is necessary to show high catalytic activity.

Dehydration of 2-Propanol. An iron oxide catalyst containing SO_4^{2-} ions was highly active for the dehydration of 2-butanol.[1] The dependency of the catalytic activity on the temperature of H_2 treatment was examined over the catalyst, Fe_2O_3 (B)-SO_4^{2-}, prepared by a urea method by use of the dehydration of 2-propanol as a test reaction. As shown by open circles in Fig. 1, when the catalyst was reduced with flowing H_2 below 100 °C, no detectable change in the activity was observed. The activity, however, abruptly decreased with increase in the reduction temperature from 100 to 150 °C. By raising the temperature from 150 °C to 400 °C, the catalytic activity decreased gradually to zero. The activities of the catalysts reoxidized at 500 °C are also shown by solid circles in Fig. 1. Recovery of the activity by oxidation was observed for all the catalysts. The extent of recovery varied

Δ; Fe_2O_3 (B)-SO_4^{2-} evacuated at 500 °C for 2 h.

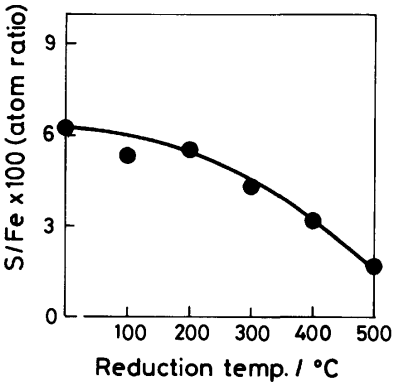

Fig. 2. Variation of S/Fe ratio in Fe_2O_3 (B)-SO_4^{2-} with reduction temperature.

with the reduction temperatures. A catalyst reduced at 200 °C recovered the original activity after the reoxidation and a catalyst reduced at 300 °C recovered about 80% of its original activity. The catalysts reduced above 400 °C, however, restored the activity to a small extent. Recovery by the oxidation indicates that the active sites are related with a higher oxidation state of sulfur.

State of Sulfur. It is pointed out that the activity loss by reduction at lower temperatures may arise from the removal of surface oxygens. An X-ray diffraction analysis revealed that the reduction of Fe_2O_3 took place to yield Fe_3O_4 phase around 250 °C.[5] Therefore, below 300 °C, the reduction may occur *via* a removal of the oxygens bridged to both S and Fe. Such a removal of the oxygens will result in the loss of the catalytic activity in the low temperature range and the lost activity is easily restored by reoxidation in agreement with the case of the isomerization of cyclopropane.

Figure 2 shows the change in the sulfur contents measured by X-ray fluorescent spectroscopy with reduction temperature. The amount of sulfur gradually decreased with an increase in the reduction temperature. Loss of sulfur by raising the reduction temperature from 300 to 400 °C was not significant as compared with a large decrease in the activity. Thus, the marked decrease in catalytic activity observed when reduction temperature was raised from 300 to 400 °C can not be attributed to the removal of the sulfur.

Changes in the surface area by reduction and reoxidation at various temperatures are also shown in Fig. 1. Although this changes are not coincide with the changes in the catalytic activities, poor recovery of the activity for the catalyst reduced at 400 °C is considered to be partly due to a decrease in surface area.

XPS results indicated the reversible change between S^{2-} and S^{6+} states by reduction and reoxidation above 400 °C.[6] This suggests that catalytically inactive iron sulfide is formed by reduction and it is changed to catalytically active sulfate complex by reoxidation. Thus, another reason for the poor recovery is considered to be due to the decrease in the number of sulfur species on the surface by its migration to the bulk on reduction above 400 °C.

Studies on Salt Hydrates for Latent Heat Storage. VII. The Relation between Activation Process of Crystal Nucleation Catalysts for Sodium Acetate Trihydrate and Their Deactivation Temperatures

Takahiro WADA* and Hiroshi YONENO
Central Research Laboratory, Matsushita Electric Industrial Co. Ltd., 1006 Kadoma, Osaka 571
(Received August 31, 1984)

Influences of preheating temperature were studied on crystallization of $CH_3CO_2Na \cdot 3H_2O$ from its melts containing a small amount of $Na_4P_2O_7$ or Na_2HPO_4 as a crystal nucleation catalyst. The relation between the activation process of these nucleation catalysts and their deactivation temperatures was investigated in detail. Aging of nucleation catalyst which was preceded by forced crystallization of $CH_3CO_2Na \cdot 3H_2O$ from its melt containing the catalyst, largely affects the catalyst's deactivation temperature. Whenever $Na_4P_2O_7$ or Na_2HPO_4 was used as a nucleation catalyst, the deactivation temperature was raised by lengthening aging time at a constant aging temperature. When the catalysts were aged for 4 d at 20 °C, the aging effect on them was almost saturated. At lower temperatures, longer aging times were required for saturation of the effect. The results obtained are discussed with a modified adsorption model, which takes into account commensurate-incommensurate phase transition of solid adsorbate.

Sodium acetate trihydrate ($CH_3CO_2Na \cdot 3H_2O$) has attracted attention as a useful heat storage material because of its large latent heat of fusion (264 J/g).[1,2] Pure $CH_3CO_2Na \cdot 3H_2O$ melt supercools to a considerably lower temperature than its melting point (58.4 °C).[3,4] Its practical application has been impaired by this supercooling phenomenon.[5] Wada and Yamamoto[6] first found that addition of $Na_4P_2O_7 \cdot 10H_2O$ is very effective for preventing this supercooling. Afterward, Kimura[7] reported that addition of a mixture of Na_2HPO_4 and anhydrous CH_3CO_2Na also is effective for prevention of the supercooling.

Recently, Wada *et al.*[8,9] studied the influence of preheating on the crystallization of $CH_3CO_2Na \cdot 3H_2O$ from aqueous solutions containing a nucleation catalyst ($Na_4P_2O_7$[10] or Na_2HPO_4[11]). They found that these nucleation catalysts were deactivated at an elevated temperature above the melting point of $CH_3CO_2Na \cdot 3H_2O$ and that temperatures at which the catalysts began to get deactivated were raised with increasing CH_3CO_2Na concentration in the solution. They explained these results on the basis of the crystalline adsorption model proposed by Richards.[12] This model is illustrated in Fig. 1. Adsorbed crystalline layers (crystalline adsorbate) are retained on the nucleation catalyst (adsorbent) surface under such condition as preclude the existence of bulk crystals.

In our previous studies[8,9] the deactivation temperature of nucleation catalysts sometimes varied widely, and the reason for this variation has not yet been understood. In order to elucidate the cause of the variation, we investigated in detail the relation between the activation process of a nucleation catalyst and its deactivation temperature. This paper reports that aging of a nucleation catalyst preceded by forced crystallization of $CH_3CO_2Na \cdot 3H_2O$ from a melt containing the catalyst, largely affects its deactivation temperature. The results obtained are discussed with a modified adsorption model, which takes into account commensurate-incommensurate phase transition of solid adsorbate.

Experimental

$CH_3CO_2Na \cdot 3H_2O$, $Na_4P_2O_7$, and Na_2HPO_4 were guaranteed grade reagents from Wako Pure Chemical Industries Ltd. Eight grams of $CH_3CO_2Na \cdot 3H_2O$ and 0.16 g of nucleation catalyst were placed in a container, about 3 mm in thickness, made of four-layered laminate film: Polyethylene terephthalate (12 μm)/nylon (15 μm)/aluminium film (9 μm)/polyethylene (70 μm). The sample temperature was measured by a chromel-alumel thermocouple attached to the outer wall of the container. The container was placed between plate heaters.

Experimental runs were performed according to the temperature program shown in Fig. 2. Eight containers, each containing 8 g of $CH_3CO_2Na \cdot 3H_2O$ and 0.16 g of nucleation catallyst, were heated at 95 °C for 1 h (D→E) in order to deactivate the nucleation catalyst completely. Then, they were cooled to room temperature (E→F), and the supercooled melts were seeded (F); this is forced crystallization of $CH_3CO_2Na \cdot 3H_2O$. Immediately, the temperature was raised to the freezing point (F→G→H). Then they were cooled to the aging temperature in a thermostat (H→I) and kept there for the aging time (I→J). After that, the containers were heated to a predetermined temperature (J→M), kept there for 1 h (M→N), and then cooled to 40 °C at a rate of 30 °C/h (N→R). In this cooling process, crystallization of $CH_3CO_2Na \cdot 3H_2O$ was detected by a sudden rise in the temperature of the sample (O→P→Q). This process was repeated with the preheating temperature raised stepwise. In some of the eight containers preheated at a certain temperature, $CH_3CO_2Na \cdot 3H_2O$ failed to crystallize on cooling to 40 °C. The nucleation catalyst in such containers must have been deactivated or degraded to lose nucleation ability. The percentage of the containers with

such deactivated nucleation catalysts was plotted against the difference ($\Delta\theta$) between the preheating temperature (θ) and the melting point of $CH_3CO_2Na \cdot 3H_2O$ (58.4 °C), the results being shown in Figs. 3—6.

Results

$Na_4P_2O_7$ as a Nucleation Catalyst. It is clear from Fig. 3 that the nucleation catalyst which was aged for 0.5 h at 20 °C began to get deactivated at 69 °C, higher by about 10 °C than the melting point of $CH_3CO_2Na \cdot 3H_2O$, and that all of the catalysts were deactivated at about 80 °C. The nucleation catalysts which were aged for 4, 20, and 96 h began to get deactivated at 74, 84, and 86 °C, and all of them were deactivated at 86, 92, and 93 °C, respectively. It is understood from Fig. 3 that the deactivation temperature of nucleation catalyst is raised with lengthening aging time at a constant aging temperature. The deactivation behavior of the nucleation catalyst aged for 500 h at 20 °C, which is not shown in Fig. 3, is almost the same as that of the nucleation catalyst aged for 96 h at 20 °C. It is evident that the aging effect at 20 °C is almost saturated within 96 h.

It can be seen from Fig. 4 that the nucleation catalyst aged for 96 h at −20 °C began to get deactivated at 76 °C and that all of them were deactivated at about 83 °C. The deactivation temperature of the nucleation catalyst aged for 96 h at −20 °C is about 10 °C lower than that of the nucleation catalyst aged for 96 h at 20 °C. With the 8 samples which

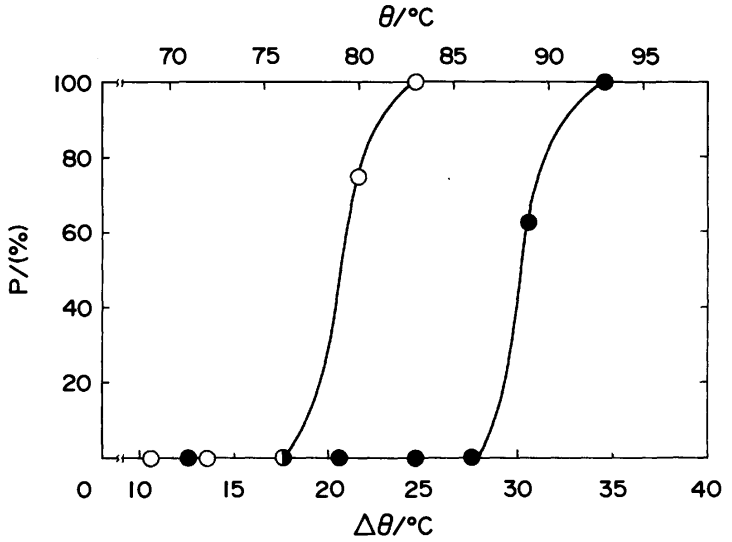

Fig. 4. The influence of preheating temperature on the crystallization of $CH_3CO_2Na \cdot 3H_2O$ from the melts containing a smal amount of $Na_4P_2O_7$, which were aged for 96 h. ○: θ_A(aging temperature) $=-20$ °C, ●: $\theta_A=20$ °C.

were aged for 96 h in liquid N_2, the cooling to 40 °C preceded by the preheating at 65 °C for 1 h caused no $CH_3CO_2Na \cdot 3H_2O$ to crystallize. It is evident that at lower temperatures, longer aging times are required for the full aging effect on nucleation catalyst.

Na_2HPO_4 as a Nucleation Catalyst. It is clear from Fig. 5 that the nucleation catalyst aged for 0.5 h at 20 °C began to get deactivated at 81 °C and that all of them were deactivated at about 88 °C. The nucleation catalyst aged for 20 h or 96 h began to get deactivated at 84 or 86 °C and all of them were deactivated at 89 or 91 °C, respectively. It is understood from Fig. 5 that the deactivation temperature of nucleation catalyst is a little raised with lengthening aging time. The deactivation behavior of the nucleation catalyst aged for 500 h at 20 °C, which is not shown in Fig. 5, is almost the same as that of the nucleation catalyst aged for 96 h at 20 °C. These phenomena are similar to those observed with $Na_4P_2O_7$ as a nucleation catalyst. The time required for saturation of the aging effect is much shorter than in the case of $Na_4P_2O_7$.
